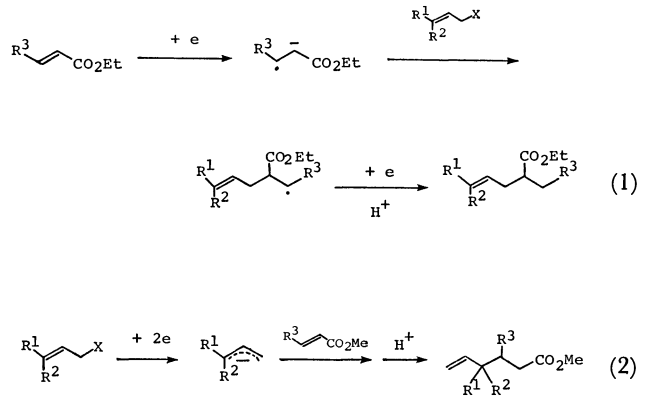
bined to the two different α,β-unsaturated esters **2** and **6** at different sites. These regioselectivities can be interpreted by assuming the involvement of two different mechanisms. The reaction pathway of each electrochemical addition may be determined by whether a more readily reducible species in the electrolysis is α,β-unsaturated esters or allyl halides. Linear sweep voltammetry showed that allyl halides **4** and **8a** are reduced at about −2.5 and −1.1 V *vs.* Hg, while α,β-unsaturated esters **2** and **6** are reduced at −1.7 and −2.7 V *vs.* Hg, respectively (Fig. 1).

Therefore, in the electrochemical reaction of **4** with **2**, a preferential one-electron reduction of **2** generates an anion radical which reacts with the carbon atom of **4** carrying chlorine in an S_N2 fashion to give an intermediary radical species. A further reduction of the radical followed by a protonation of the resulting carbanion would give the observed addition product **5** [Scheme 4, (1)].

In the reaction of either **4** with **6** or **8** with **2**, however, a two-electron reduction of allyl halides **4** or



4: $R^1=R^2=CH_3$, X=Cl
8: $R^1=CO_2Me$, $R^2=H$, X=Br, I
2: $R^3=CO_2Et$
6: $R^3=CH_3$

Scheme 4.

8 may take place to generate allylic carbanions which then add to α,β-unsaturated esters to afford the observed addition products **7** or **9** [Scheme 4, (2)].

The aforementioned explanations are further supported by the results of ordinary chemical reactions. Several carbanions such as 2-substituted allyllithium,[9] dienolate anions derived from α,β-unsaturated acids,[10,11] or α-phenylsulfonyl carbanions[12] always undergo nucleophilic substitution on **4** at the less heavily substituted carbon terminus. On the other hand, the addition reactions of allylic carbanions derived from 3,3-dimethylallyl compounds to carbonyl group,[13] acyl halide,[14] acetal,[15] or α,β-unsaturated carbonyl compounds[16] take place at the more heavily substituted carbon terminus of **4** exclusively. Moreover, lithium dienolates derived from α,β-unsaturated esters undergo alkylation reactions at the α carbon of the ester almost exclusively.[10]

The formation of the addition product such as **5** having an allylic unit attached at a less heavily substituted carbon in the present electrochemical reaction is worth noting, since allylic organometallics always gave the addition products having the allyl groups at a more highly substituted carbon terminus.[16]

Experimental

All the products were isolated and purified by distillation and by preparative GLPC with a JEOL JGC-20K instrument. IR spectra were obtained with a Hitachi EPI-22 spectrometer, and NMR spectra in CCl_4 were measured with a Hitachi R-22 high-resolution spectrometer (90 MHz) using TMS as an internal reference. Mass spectra were obtained with a Hitachi RM-50GC mass spectrometer. Quantitative GLPC analyses were carried out with a Hitachi 063 instrument by an internal standard method.

Materials. *N,N*-Dimethylformamide (DMF) was shaken with phosphorus pentaoxide and then stirred overnight with potassium hydroxide. It was distilled under a reduced pressure of nitrogen atmosphere and then distilled over picric acid. The allyl halides used were washed with sodium thiosulfate solution, dried over calcium chloride, and then distilled.

1-Chloro-3-methyl-2-butene (**4**) was prepared from isoprene by the described procedure.[17] Dry hydrogen chloride (183 g) was added to isoprene (344 g) over a period of 2.5 h at −40 °C, and the resulting mixture was refluxed for 1 h. Distillation of the reaction mixture gave **4** (228 g, 43%): bp 107—109 °C; NMR δ 1.74 (3H), 1.78 (3H), 4.02 (2H), 5.44 (1H).

Methyl 4-bromo-2-butenoate (**8a**) was prepared from methyl crotonate by the described procedure.[18] To methyl crotonate (24 g) in carbon tetrachloride (100 ml) was added *N*-bromosuccinimide (25 g) and benzoyl peroxide (0.2 g) and the mixture was refluxed for 7 h. The usual work up and a distillation of the reaction mixture gave **8a**: bp 88—89° C/15 mmHg†† (lit,[18] 83—85 °C/13 mmHg); NMR δ 3.70 (3H, s), 3.98 (2H, m), 5.99 (1H, m), 6.96 (1H, m); MS *m/e* 180 (M^++2), 178 (M^+).

Methyl 4-iodo-2-butenoate (**8b**) was prepared from **8a** and sodium iodide by a literature procedure;[19] bp 108 °C/19 mmHg; MS *m/e* 266 (M^+).

General Procedure of Electrolysis. For most of the preparative electrolysis, a normal undivided cell (2.8 cm dia.) equipped with a magnetic stirrer, a reflux condenser, and a serum cap for introduction of nitrogen gas was used. Electrolysis was carried out under nitrogen atmosphere at a constant current using two platinum plate electrodes (2×2 cm^2). Amounts of the substrates in each electrolysis are shown in Tables 1 and 2. After electrolysis, the reaction mixture was dissolved in diethyl ether and the solution was washed with sodium thiosulfate solution and water, and dried over magnesium sulfate. The usual work up of the solution gave a product mixture which was subjected to distillation and preparative GLPC with a JEOL-20K instrument to give pure products.

Some physical properties of the products are recorded below.

*Ethyl 3-(Ethoxycarbonyl)-5-hexenoate (**3**)*: Bp 101—103 °C/18 mmHg; n_D^{24} 1.4330; IR (neat) 3090, 1735, 1645, and 925 cm^{-1}; NMR δ 1.24 (6H, t, $CO_2CH_2C\underline{H}_3$), 2.5 (5H, m, C-2H, C-3H, and C-4H), 4.10 (2H, q, $CO_2C\underline{H}_2CH_3$), 4.13 (2H, q, $CO_2C\underline{H}_2CH_3$), 5.05 (2H, m, C-6H), and 5.7 (1H, m, C-5H); MS *m/e* (rel intensity) 169 ($M^+-OC_2H_5$, 46), 140 (56), 123 (40), 95 (44), 67 (100), and 41 (42). Found: C, 61.29; H, 8.34%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%.

*Ethyl 3-(Ethoxycarbonyl)-6-methyl-5-heptenoate (**5**)*: Bp 118—119 °C/19 mmHg; n_D^{24} 1.4422; IR (neat) 3050, 1730, and 855 cm^{-1}; NMR δ 1.24 (6H, t, $CO_2CH_2C\underline{H}_3$), 1.61 (3H, s, $-C\underline{H}_3$), 1.70 (3H, s, $-C\underline{H}_3$), 2.5 (5H, m, C-2H, C-3H, and C-4H), 4.10 (2H, q, $CO_2C\underline{H}_2CH_3$), 4.12 (2H, q, $CO_2C\underline{H}_2CH_3$), and 5.07 (1H, m, C-5H); MS *m/e* (rel intensity) 242 (M^+, 12), 197 ($M^+-OC_2H_5$, 38), 168 (97), and 95 (78). Found: C, 64.13; H, 9.06%. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%.

*Methyl 3,4,4-Trimethyl-5-hexenoate (**7**)*: Bp 117—120 °C/48 mmHg; IR (neat) 3090 and 1745 cm^{-1}; NMR δ 0.88 (3H, d, C-3-$C\underline{H}_3$), 0.97 and 0.99 (each 3H, s, $-C(C\underline{H}_3)_2$), 2.0 (3H, m, $-C\underline{H}C\underline{H}_2CO_2$), 3.62 (3H, s, $CO_2C\underline{H}_3$), 4.9 (2H, m, $C\underline{H}_2$=CH), and 5.80 (1H, m, =C$\underline{H}$); NMR (CCl_4, 40 mol% of Eu(DPM)$_3$ added) δ 1.79 and 1.84 (each 3H, s, $C(C\underline{H}_3)_2$), 3.41 (3H, d, C-3-$C\underline{H}_3$), 5.3—5.7 (2H, m, $C\underline{H}_2$=CH), 6.3—6.7 (1H, m, $-C\underline{H}$), 6.57—6.9 (1H, m, =C$\underline{H}$), 7.02 (1H, dd, J=10 Hz, J=15 Hz, $-C\underline{H}_2CO_2$), 7.54 (1H, dd, J=4 Hz, J=15 Hz, $-C\underline{H}_2CO_2$); MS *m/e* (rel intensity) 170 (M^+, 3), 96 (59), and 69 (100). Found: C, 70.33; H, 10.37%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66%.

*Ethyl 3-(Ethoxycarbonyl)-4-(methoxycarbonyl)-5-hexenoate (**9**)*: Bp 67 °C/1 mmHg; n_D^{21} 1.4492; IR (neat) 3090, 1740,

†† 1 mmHg≈133.322 Pa.

1640, 935, and 860 cm^{-1}; NMR δ 1.26 (6H, t, $CO_2CH_2C\underline{H}_3$), 2.5 (2H, m, C-2H), 3.2 (2H, m, C-3H and C-4H), 3.70 (3H, s, $CO_2C\underline{H}_3$), 4.12 (4H, q, $CO_2C\underline{H}_2CH_3$), 5.2 (2H, m, C-6H), and 5.8 (1H, m, C-5H); MS *m/e* (rel intensity) 241 (M^+-OCH_3, 21), 240 (47), 227 ($M^+-OC_2H_5$, 82), 226 (44), 167 (56), 166 (53), 99 (68), 67 (65), and 29 (100). Found: C, 57.36; H, 7.37%. Calcd for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

*Ethyl 3-(Ethoxycarbonyl)-4-(methoxycarbonyl)-4-hexenoate (**10**)*: NMR δ 1.28 (6H, t, $CO_2CH_2C\underline{H}_3$), 1.97 (3H, d, J=7.5 Hz, C-6-$C\underline{H}_3$), 2.8 (3H, m, C-2H and C-3H), 3.78 (3H, s, $CO_2C\underline{H}_3$), 4.19 (4H, q, two $CO_2C\underline{H}_2CH_3$), and 7.07 (1H, q, J=7.5 Hz, C-5H). MS *m/e* 227 ($M^+-OC_2H_5$).

*Methyl Ethyl 5-(Ethoxycarbonyl)-2-heptene-1,7-dioate (**11**)*: NMR δ 1.24 and 1.26 (each 3H, s, $CO_2CH_2C\underline{H}_3$), 2.7 (5H, m, C-4H, C-5H, and C-6H), 3.71 (3H, s, $CO_2C\underline{H}_3$), 4.13 and 4.17 (each 2H, q, $CO_2C\underline{H}_2CH_3$), 5.85 (1H, d, J=16 Hz, C-2H), and 6.85 (1H, dt, J=16 Hz, J=8 Hz, C-3H). MS *m/e* 227 ($M^+-OC_2H_5$).

Voltammetry. Voltammetry was carried out with a Yanaco V8 potentionstat at a sweep rate of 0.023 V s^{-1} using a platinum disc electrode (1 mm dia.) in DMF containing 0.2 M Et_4NOTs. A potential was measured in V *vs.* Hg pool.

The Rhodium Complex-catalyzed Synthesis of Quinolines from Aminoarenes and Aliphatic Aldehydes

Yoshihisa WATANABE,* Sang Chul SHIM,** and Take-aki MITSUDO
Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto 606
(Received February 25, 1981)

A variety of aminoarenes react with aliphatic aldehydes in the presence of a catalytic amount of a rhodium complex and an excess amount of the corresponding nitroarenes at 180 °C to give 2-alkyl- and 2,3-dialkyl-substituted quinolines in excellent yields. Among the rhodium complexes examined, $[Rh(norbornadiene)Cl]_2$ exhibits the highest activity as a catalyst. Thus, 2-methyl-, 2-ethyl-3-methyl-, 2-propyl-3-ethyl-, and 2-butyl-3-propylquinoline derivatives are readily obtained from aminoarenes and ethanal, propanal, butanal, and pentanal respectively.

The Skraup and related syntheses are well known as methods for the preparation of quinolines from aminoarenes and carbonyl compounds.[1] These methods, however, have some disadvatages; the uncontrolled violence of the reaction and the use of a large amount of acid. Quinolines can be prepared from aminoarenes and olefins using transition-metal complexes as catalyst precursors.[2,3] Rhodium trichloride catalyzes the reaction between aniline and ethylene to give 2-methylquinoline in poor yields.[2] Octacarbonyldicobalt catalyzes the reaction between *N*-benzylideneaniline and ethyl vinyl ether in tetrahydrofuran under nitrogen to give 2-phenylquinoline in moderate yields.[3] More recently, we found that rhodium complexes such as μ,μ'-dichlorobis(norbornadiene)dirhodium(I) are active as catalysts for *N*-heterocyclization, the preparation of quinolines from aminoarenes and aliphatic aldehydes in a non-acidic medium.[4] This is a novel method for the preparation of 2-alkyl- and 2,3-dialkyl-substituted quinolines, applicable in a large-scale reaction. Here, a detailed study on the rhodium-catalyzed synthesis of quinolines will be described.

Results and Discussion

Aniline reacts with aliphatic aldehydes having two α-hydrogens in the presence of a catalytic amount of μ,μ'-dichlorobis(norbornadiene)dirhodium(I) and an excess amount of nitrobenzene as an oxidizing agent at 180 °C to give alkyl-substituted quinolines in moderate to excellent yields. The results are summarized in Table 1. This provides a convenient method for the synthesis of quinolines.

The combination of aniline with ethanal, propanal, butanal, and pentanal gives 2-methyl-, 2-ethyl-3-methyl-, 2-propyl-3-ethyl-, and 2-butyl-3-propylquinoline, respectively. 2-Methylquinoline was identified by comparing its IR and ^{1}H NMR spectra with those of the authentic sample. None of the ^{1}H NMR spectra (60 MHz in $CDCl_3$, with Me_4Si as the internal standard) of these products exhibited the peak at δ 8.8 ppm characteristic of the 2-H of the quinoline nucleus.[5] The ^{1}H NMR (60 MHz) spectrum of the product from aniline–propanal showed a typical pattern of the methyl and ethyl groups, while the ^{13}C NMR (25.05 MHz) spectrum showed three peaks, at 12.5(CH_3), 18.7(CH_3), and 29.1(CH_2) ppm, in the aliphatic carbon region, assignable to the 2-ethyl(12.5 and 29.1 ppm) and 3-methyl(18.7 ppm) groups. Accordingly, this is concluded to be 2-ethyl-3-methylquinoline.

Alkyl groups of 2,3-disubstituted quinolines produced from butanal and pentanal can be readily identified by means of the ^{1}H NMR (60 and 220 MHz) and ^{13}C NMR spectra. The products from aniline–butanal and –pentanal were assigned to 2-propyl(14.4, 22.5, and 37.5 ppm)-3-ethyl(14.4 and 25.0 ppm)quinoline and 2-butyl(14.0, 23.0, 31.7, and 35.4 ppm)-3-propyl-(14.0, 23.5, and 34.3 ppm)quinoline respectively.

The mass spectra of these products exhibited the corresponding molecular ions, and the elemental analysis gave satisfactory results.

The reaction of ethanal gave a considerable amount of a tarry material which appears to reduce the yield of 2-methylquinoline. An attempt of reduce the for-

Table 1. Rhodium-catalyzed synthesis of substituted quinolines from aniline and aldehydes

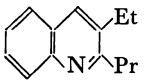
Under argon at 180 °C for 4 h. Molar ratio: Aniline (41 mmol)/aldehyde/nitrobenzene = 1.0/2.5/1.5. Rhodium complex: 0.03 mmol$[Rh(NBD)Cl]_2$. Solvent: Ethanol or benzene(20 ml).
a) Determined by GLC. Based on the amount of aniline used. The figures in parentheses show isolated yields. b) Benzene used as solvent. c) At 150 °C. d) Without solvent. e) Acetic acid(4.1 mmol) was added. f) Acetic acid (8.2 mmol) was added.

**Present address: Department of Industrial Chemistry, Kyung-park National University, Taegu, Korea.

mation of this tarry material was unsuccessful. The reaction at a low temperature (150 °C) or without a solvent gave 2-methylquinoline in poor yields. 2-Butenal gave only a trace of 2-methylquinoline, but a large amount of the tarry material. Paraldehyde [$(CH_3CHO)_3$] and metaldehyde [$(CH_3CHO)_4$] showed no reactivity for this reaction under the conditions used.

On the other hand, propanal, butanal, and pentanal give the corresponding 2,3-disubstituted quinolines in fairly good yields without the formation of any tarry material. The reaction between aniline and butanal was examined in some detail in order to determine the optimum conditions for the preparation of the quinoline; the results are summarized in Table 2. *N*-Butylaniline was formed as a by-product in 5—31% yields. The presence of excess amount of nitrobenzene reduced the formation of *N*-butylaniline. A hydrogen transfer should take place for the formation of the quinoline nucleus.

$$PhNH_2 + 2CH_3CH_2CH_2CHO \xrightarrow[PhNO_2]{[Rh]}$$



$$+ 2H_2O + 2H$$

The nitrobenzene appears to act as an oxidizing agent and to be partially reduced to aniline through the reaction. *N*-Butylaniline appears to be derived *via* *N*-butylideneaniline by hydrogenation. The reaction without nitrobenzene also gave a mixture of *N*-butylaniline and the quinoline, but in poor yields. When the aniline/butanal/nitrobenzene molar ratio is fixed at 1.0/2.2/0.33, the catalytic activity is highest with μ,μ'-dichlorobis(norbornadiene)dirhodium(I), followed by chlorotris(triphenylphosphine)rhodium(I) and hydridocarbonyltris(triphenylphosphine)rhodium(I).

The catalytic activity also depends on the amounts of the rhodium complex used. With μ,μ'-dichlorobis-(norbornadiene)dirhodium(I), the quinoline yield is highest (119%) when the rhodium catalyst of 0.03 mmol (20 mg) is used. The turn-over of the catalyst is calculated to amount to 1600, based on the yield (119%), and the product selectivity is estimated to be more than 95%, based on the butanal used. Higher (200 °C) or lower (160 °C) temperatures gave poorer yields of the quinoline.

Accordingly, the optimum conditions for the preparation of the quinoline are those of Exp. 3 in Table 2. This procedure is applicable for a variety of aniline derivatives combined with ethanal, propanal, and butanal. The reaction between aminoarenes and aldehydes was carried out in the presence of the corresponding nitroarenes as the oxidizing agent. The aminoarene/aldehyde/nitroarene molar ratio was fixed at 1.0/2.5/1.5 in the reaction. The results for *o*- and *p*-substituted anilines including methyl, methoxy, and chloro groups as substituents are summarized in Table 3.

p-Methyl-, *p*-methoxy-, and *p*-chloroaniline- reacted smoothly with ethanal, propanal, and butanal to give

28	*o*-Cl	Propanal	2-Ethyl-3-methyl-8-chloroquinoline	11
29	*o*-Cl	Ethanal	8-Chloro-2-methyl-quinoline	Trace

a) Under argon at 180 °C for 4 h. Solvent, ethanol (20 ml). $[Rh(NBD)Cl]_2$; 0.03 mmol(20 mg). Molar ratio: Aminoarene(41 mmol)/aldehyde/nitroarene = 1.0/2.5/1.5. b) Isolated yield based on the amount of aminoarene used.

2,6- or 2,3,6-substituted quinolines in fairly good yields. The reaction of ethanal has an inclination to give poorer yields because of the formation of the tarry material.

o-Methyl- and *o*-methoxyaniline also showed a moderate reactivity to give 2,3,8-substituted quinolines in good yields when combined with propanal and butanal. *o*-Chloroaniline, however, gave the product in poor yields, indicating that the chloro group located at the ortho position has an inhibitory effect on the reaction. The combination of *o*-chloroaniline with ethanal failed to give 8-chloro-2-methylquinoline almost entirely.

The results for *m*-methyl-, *m*-methoxy-, and *m*-chloroaniline are summarized in Table 4. These aminoarenes reacted with ethanal, propanal, and butanal to give 2,7-di-, 2,3,5-, and 2,3,7-trisusbtituted quinolines in fairly good yields. From *m*-substituted aminoarenes, two isomeric products are expected to be formed.

The products isolated from *m*-methoxyaniline–ethanal, –propanal, and –butanal were proved by GLC to be pure. Their ^{1}H and ^{13}C NMR spectra in the aliphatic region exhibited typical patterns of alkyl groups characteristic of 2-methyl, 2-ethyl-3-methyl, and 2-propyl-3-ethyl groups respectively. The ^{1}H NMR (220 MHz) spectra of the products from propanal and butanal in the aromatic region showed two singlets and two doublets, assignable to the isomeric 7-substituted quinoline, 2,3,7-substituted ones. The spectrum of the ring hydrogens of the 5-isomers, 2,3,5-substituted ones, should have a different pattern; one singlet, two doublets, and one doublet of doublet. Accordingly, the products from propanal and butanal are identified as 2-ethyl-3-methyl-7-methoxyquinoline and 2-propyl-3-ethyl-7-methoxyquinoline respectively. The ^{1}H NMR (220 MHz) spectrum of the product from ethanal exhibited one singlet and four doublets in the aromatic region, asssignable to the 7-isomer.

TABLE 4. SYNTHESIS OF QUINOLINE DERIVATIVES FROM *m*-SUBSTITUTED ANILINES AND ALDEHYDES[a]

Exptl No.	Aniline	Aldehyde	Yield[b] %	Distribution of products[c] 5-Isomer	7-Isomer
30	*m*-MeO	Butanal	44	0	100
31	*m*-MeO	Propanal	45	0	100
32	*m*-MeO	Ethanal	26	0	100
33	*m*-Me	Butanal	68	10	90
34	*m*-Me	Propanal	62	16	84
35	*m*-Me	Ethanal	38	15	85
36	*m*-Cl	Butanal	61	18	82
37	*m*-Cl	Propanal	55	17	83
38	*m*-Cl	Ethanal	20	18	82

a) Under argon at 180 °C for 4 h. Solvent, ethanol (20 ml). Rhodium complex; $[Rh(NBD)Cl]_2$, 0.03 mmol(20 mg). Molar ratio; *m*-Aminoarene(41 mmol)/aldehyde/*m*-nitroarene=1.0/2.5/1.5. b) Isolated yield based on the amount of *m*-aminoarene used. c) Determined by GLC. 5-Isomer, 2, 5- or 2, 3, 5-substituted quinolines; 7-isomer, 2, 7- or 2, 3, 7-substituted quinolines.

The 5-isomer from ethanal should have a different pattern; four doublets and one doublet of doublet. Thus, the product from ethanal is identified as 2-methyl-7-methoxyquinoline.

The reaction of *m*-toluidine and *m*-chloroaniline with ethanal, propanal, and butanal appeared to give mixtures of 5- and 7-isomers respectively. The distribution of the two isomers was determined by GLC analysis. The 7-isomers appear to predominate.

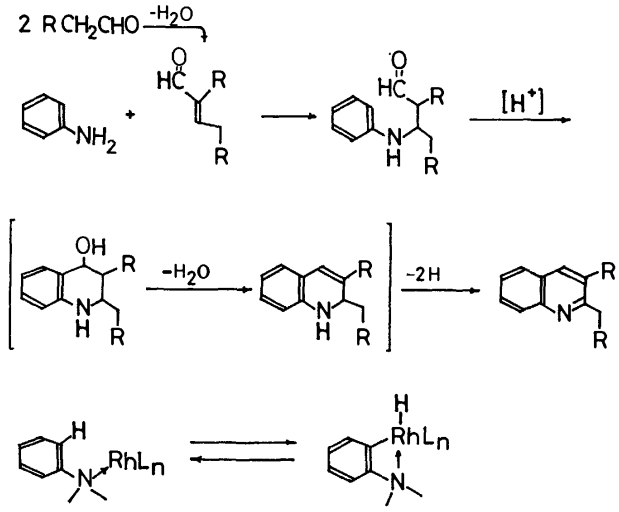
The ^{1}H and ^{13}C NMR spectra of the products from *m*-toluidine–butanal exhibited the typical pattern of the 7-isomer, assigned to 2-propyl-3-methyl-7-methylquinoline. The ^{13}C NMR spectrum clearly showed another pair of peaks with small intensities, assignable to the three alkyl groups (methyl, ethyl, and propyl) in the aliphatic carbon region and the quinoline ring in the aromatic region; nine peaks, five singlets and four doublets by off-resonance decoupling, were observed in the aromatic region. Therefore, the other product is believed to be the 5-isomer, 2-propyl-3-ethyl-5-methylquinoline.

The corresponding 5- and 7-isomers from *m*-toluidine and *m*-chloroaniline, combined with ethanal, propanal or butanal, were similarly analyzed by the spectroscopic method. The fact that the 7-isomers predominate in this procedure is consistent with the finding of the Skraup synthesis, the acid-catalyzed synthesis of quinoline.[6]

The results obtained here clearly demonstrate that the novel *N*-heterocyclization method catalyzed by rhodium complexes in a non-acidic medium is applicable to a veriety of combination of aminoarenes and aldehydes, giving 2-alkyl- and 2,3-dialkyl-substituted quinolines in good to excellent yields.

The Skraup synthesis is generally accepted to follow the following reaction sequence: the self-aldol condensation of aldehyde; the addition of an amine to the condensate, α,β-unsaturated aldehyde; ring closure by dehydration to form 1,2-dihydroquinoline, and the oxidation of the 1,2-dihydroquinoline. Acids such as concentrated sulfuric acid used as catalysts may participate in the ring-closure process of this sequence.

The mechanism of the rhodium-catalyzed synthesis



Scheme 1.

of quinolines is not yet clear, but the rhodium catalyst also seems to participate in the ring-closure process. Aminoarene reacts with the rhodium catalyst to form an *N*-coordinated complex in which the ortho hydrogen in a phenyl ring of aminoarene can be activated. The *N*-coordinated complex may be transformed into an ortho metallated complex by the intramolecular oxidative addition of the activated C–H bond, for it is the key intermediate for the ring-closure reaction. This consideration may be supported by the fact that triphenylphosphine complexes of iridium[7] and iron[8] give hydridometal complexes, ortho metallated complexes, by intramolecular oxidative addition and the fact that X-ray structures of triphenylphosphine complexes of ruthenium[9] and rhodium[10] reveal a short separation between metal and ortho hydrogen in a phenyl ring of the ligand. Aldehydes with two α-hydrogen atoms have a great tendency to aldol condensation under the conditions used, 180 °C in the presence of a base, suggesting that the formation of α,β-unsaturated aldehydes is also one of the key steps in the reaction. The nitroarenes used may be supposed to act as oxidizing agents in the final step, the oxidation of 1,2-dihydroquinolines.

Experimental

μ,μ′-Dichlorobis(norbornadiene)dirhodium(I), $[Rh(NBD)Cl]_2$, was prepared according to the method in the literature.[11] The ethanal, propanal, butanal, nitroarenes, aminoarenes, and other compounds employed in this study were all commercial products. The aldehydes, nitroarenes, and aminoarenes were distilled before use. The benzene and ethanol used were dried by the usual methods.

Analytical Procedure. The melting points and boiling points are uncorrected. The melting points were taken on a Yanagimoto capillary melting-point apparatus. The infrared spectra were measured on a Hitachi model 215 grating spectrophotometer. The ^1H NMR spectra were obtained at 60 MHz with a JEOL LNM-60 NMR or at 220 MHz with a Varian model HR-220 NMR spectrometer. The ^{13}C NMR spectra were determined at 25.05 MHz with a JEOL pulsed Fourier Transform spectrometer, model FX-100. Samples were dissolved in $CDCl_3$, and the chemical-shift values were expressed in δ ppm relative to Me_4Si as an internal standard. The mass spectra were recorded on a JMS O1SG mass spectrometer. The elemental analyses were performed at the Microanalytical Center of Kyoto University.

Reaction Procedure. A stainless steel autoclave (100 ml) equipped with a magnetic stirrer was used in the reaction. Ethanol (20 ml) and $[Rh(NBD)Cl]_2$ (20 mg, 0.03 mmol) were put into the autoclave. After the air in the autoclave had been replaced with argon, 88—100 mmol of aldehyde, 41 mmol of aminoarene, and 60 mmol of nitroarene were put into it, and then the remainder of the air was replaced with argon. The autoclave was kept at 180 °C by electrical heating for 4 h, and then the heating was turned off. The GLC analysis of the reaction products was made using a column (0.3 cmϕ × 3 m) packed with 10% Versamid on Neopak 60—80 mesh. After the solvents had been distilled off, the reaction products were subjected to fractional distillation. 2-Methylquinoline and 2-methyl-6-methoxyquinoline were identified by comparing their IR and ^1H NMR spectra with those of authentic samples (Aldrich). The other products were identified by means of the IR, ^1H NMR, ^{13}C NMR and MS spectra and by elemental analysis. Although the products could not be isolated in an analytically pure form in Exps. 13, 24, 32, 34, and 36, the corresponding quinoline derivatives were identified on the basis of their spectral data.

2-Ethyl-3-methylquinoline (Exptl 10): Yield, 59%; Yellow oil, bp 84—85 °C/0.35 Torr; ^1H NMR (60 MHz) ($CDCl_3$): δ (ppm) 1.32 (t, 3H, CH_3), 2.25 (s, 3H, CH_3), 2.86 (q, 2H, CH_2), 7.34—8.09 (m, 5H, Ar). ^{13}C NMR (25.05 MHz) ($CDCl_3$): δ (ppm) 12.5 (q, CH_3), 18.7 (q, CH_3), 29.1 (t, CH_2), 125.3 (d), 126.6 (d), 127.1 (s), 128.0 (d), 128.5 (d), 129.0(s), 135.2(d), 146.6(s), 162.5(s), MS (*m/e*): 171 (rel intensity 87, M^+), 170(100), 143(43), 115(44). Found: C, 84.28; H, 7.92; N, 8.13%. Calcd for $C_{12}H_{13}N$: C, 84.17; H, 7.65; N, 8.18%.

2-Propyl-3-ethylquinoline (Exptl 11): Yield, 82%; Yellow oil, 92 °C/0.3 Torr; ^1H NMR (220 MHz) ($CDCl_3$): δ (ppm) 1.05 (t, 3H, CH_3), 1.25 (t, 3H, CH_3), 1.82 (sex, 2H, CH_2), 2.73 (q, 2H, CH_2), 2.93 (t, 2H, CH_2), 7.36 (t, 1H), 7.57 (t, 1H), 7.66 (d, 1H), 7.77 (s, 1H), 8.07 (d, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 14.2 (q, CH_3), 14.4 (q, CH_3), 22.5 (t, CH_2), 25.0 (t, CH_2), 37.5 (t, CH_2), 125.3 (d), 126.8 (d), 127.3 (d), 128.1 (s), 128.5 (s), 128.8 (s), 133.1 (s), 135.1 (s). Found: C, 83.78; H, 8.87; N, 6.86%. Calcd for $C_{14}H_{17}N$: C, 84.37; H, 8.60; N, 7.03%.

2-Butyl-3-propylquinoline (Exptl 12): Yield, 45%; Yellow oil, 115 °C/0.35 Torr; ^1H NMR (220 MHz) ($CDCl_3$): δ (ppm) 0.94 (t, 3H, CH_3), 0.95 (t, 3H, CH_3), 1.46 (sex, 2H, CH_2), 1.77 (qt, 2H, CH_2), 2.64 (t, 2H, CH_2), 2.95 (t, 2H, CH_2), 7.68 (s, 1H), 7.59 (d, 1H), 7.34 (t, 1H), 7.52 (t, 1H), 8.05 (d, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 14.0 (q, $2CH_3$), 23.0 (t, CH_2), 23.5 (t, CH_2), 31.7 (t, CH_2), 34.3 (t, CH_2), 35.4 (t, CH_2), 125.5(d), 126.8(d), 127.2(s), 128.3(d, d), 133.7(s), 134.8(d), 146.3(s), 161.9(s). MS (*m/e*): 227 (rel intensity 13, M^+), 212 (23), 198 (27), 185 (69), 170 (85), 157 (100). Found: C, 84.55; H, 9.58; N, 5.99%. Calcd for $C_{16}H_{21}N$: C, 84.53; H, 9.31; N, 6.16%.

2-Propyl-3-ethyl-6-methoxyquinoline (Exptl 13): Yield, 65%; Yellow oil, bp 118 °C/0.3 Torr; ^1H NMR (220 MHz) ($CDCl_3$): δ (ppm) 1.02 (t, 3H, CH_3), 1.27 (t, 3H, CH_3), 1.77 (sex, 2H, CH_2), 2.73 (q, 2H, CH_2), 2.91 (t, 2H, CH_2), 3.66 (s, 3H, $-OCH_3$), 6.98 (s, 1H), 7.03 (d, 1H), 7.73 (s, 1H), 7.95 (d, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 14.3 (q, $2CH_3$), 23.0 (t, CH_2), 25.0 (t, CH_2), 37.2 (t, CH_2), 55.4 (q, $-OCH_3$), 104.7(d), 113.9(s), 114.7(d), 121.0(d), 128.2 (s), 129.2(d), 133.3(d), 135.6(s), 157.2(s).

2-Ethyl-3-methyl-6-methoxyquinoline (Exptl 14): Yield, 70%; Yellow oil, bp 98 °C/0.3 Torr; ^1H NMR (60 MHz) ($CDCl_3$): δ(ppm) 1.33 (t, 3H, CH_3), 2.30 (s, 3H, CH_3), 2.87 (q, 2H, CH_2), 3.73 (s, 3H, $-OCH_3$), 6.80—8.00 (m, 4H, Ar). Found: C, 77.02; H, 7.88; N, 7.16%. Calcd for $C_{13}H_{15}NO$: C, 77.58; H, 7.51; N, 6.96%.

6-Methoxy-2-methylquinoline (Exptl 15): Yield, 34%; Yellow oil or yellow crystalline, bp 96 °C/0.4 Torr or mp 63—64 °C; ^1H NMR (60 MHz) ($CDCl_3$): δ(ppm) 2.67 (s, 3H, CH_3), 3.73 (s, 3H, $-OCH_3$), 6.67—7.93 (m, 5H, Ar). ^{13}C NMR ($CDCl_3$): δ(ppm) 24.8 (q, CH_3), 55.4 (q, $-OCH_3$), 105.1(d), 121.7(d), 122.0(d), 127.2(s), 129.8(d), 134.8(d), 143.7(s), 155.9(s), 156.9(s). (Received March 2, 1981)

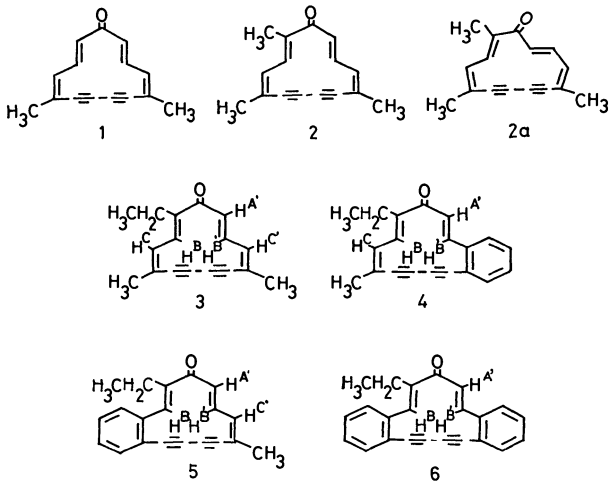
2-Ethyl-5,10-dimethyl-, 13-ethyl-10-methyl-4,5-benzo-, 2-ethyl-10-methyl-4,5-benzo-, and 2-ethyl-4,5:10,11-dibenzo-6,8-bisdehydro[13]annulenone were synthesized. Influence of α-ethyl substitution upon the skeleton of the bisdehydro[13]annulenone ring system is discussed on the basis of ^{1}H NMR and UV spectra of these annulenones and their corresponding α-methyl-substituted derivatives.

In a previous paper[1] the synthesis of the paratropic 5,10-dimethyl- **1** and 2,5,10-trimethyl-6,8-bisdehydro-[13]annulenone **2** was reported and it was shown that α-methyl-unsubstituted annulenone **1** exists in the conformation indicated and, in contrast, the extra α-methyl group of trimethylbisdehydro[13]annulenone **2** causes a change of conformation due to rotation of the opposite double bond, **2** existing in the conformation of **2a** at −60 °C. The benzo-annelated derivatives of **1** and **2** were also prepared and it was shown that the extra α-methyl substituent and fused benzene ring(s) exert a considerable influence on the development of paratropic character and conformational mobility in the bisdehydro[13]annulenone system, as compared with that in the case of α-methyl-unsubstituted compounds.[2]



In view of these results, we investigated effects of different steric bulks of α-alkyl groups on the molecular skeleton of the bisdehydro[13]annulenone ring system. It required the preparation of 3-alkyl-2-alkanones of types **9** and **11** (R=alkyl, R′=H). In practice, we could obtain only 3-ethyl-2-alkanones **9b** and **11b** by acid-catalyzed aldol condensation from aldehydes **7** and **10** (Scheme 1). Thus we could prepare α-ethyl-substituted bisdehydro[13]annulenones **3**—**6**.

Results and Discussion

Synthesis. It is known that reaction of 2-butanone **8a**, an unsymmetrical aliphatic ketone, with aldehydes shows regioselectivity, depending on conditions used; base-catalyzed aldol condensation of 2-butanone **8a** favors C_1 of ketone as the position of attack, in contrast to C_3 favored by acid-catalyzed reaction.[3] In practice, reaction of 3-methyl-2-penten-4-ynal **7**[4] or *o*-ethynylbenzaldehyde **10**[5] with **8a** yielded **9a**[1] or **11a**[2] under acidic conditions but **9f**[1] or **11f** under basic conditions, respectively.

We examined aldol condensations of aldehydes **7** and **10** with 2-pentanone **8b** and its branched isomers **8c** and **8d**, as illustrated in Scheme 1. The results obtained demonstrate that only 2-pentanone **8b** shows regioselectivity for aldehydes **7** and **10**, as 2-butanone **8a** does. Under acidic conditions (acetic acid–sulfuric acid) **8b** yielded C_3-products, while both 4-methyl-**8c** and 4,4-dimethyl-2-pentanone **8d** yielded C_1-products. On the other hand, under basic conditions (sodium hydroxide in aqueous ethanol) all of **8b**—**d** gave C_1-products usually in higher yields than under

acidic conditions.

Thus, we could prepare only 3-ethyl-2-alkanones **9b** and **11b**. For ketones such as **9c—d** and **11c—d**, attempts were tried in vain to make them condense with aldehyde **7** or **10** to get their corresponding acyclic ketones. Starting with ketones **9b** and **11b**, syntheses of α-ethyl-substituted [13]annulenones **3—6** were carried out according to the previously reported procedure,[1,2] outlined in Scheme 2.

Ketone **9b** was condensed with (*Z*)-3-methyl-2-penten-4-ynal **7**[4] in the presence of ethanolic sodium ethoxide in ether to give the acyclic ketone **12** in 77% yield. Oxidative coupling of **12** with anhydrous copper(II) acetate in pyridine and ether at 50 °C[6] afforded annulenone **3** in 32% yield. Condensation of **9b** with *o*-ethynylbenzaldehyde **10**,[5] allowed to proceed similarly to that of **9b** with **7**, gave the acyclic ketone **13** in 47% yield. Oxidation of **13**, as with **12**, gave the monobenzannulenone **4** in 44% yield. Similarly, condensation of ketone **11b** with **7** gave ketone **14** in 28% yield, which was oxidized to give another monobenzannulenone **5** in 37% yield. Reaction of **11b** and **10** afforded ketone **15** in 47% yield. Oxidation of **15** gave dibenzannulenone **6** in 46% yield. The structures of these new compounds were established on the basis of their spectral properties and results of elemental analysis.

Treatment of annulenones **3—6** with trifluoroacetic acid or trifluoroacetic acid-*d* gave their corresponding protonated or deuteronated carbonyl species **3′—6′**, respectively; **3′—5′** were dark red and **6′** was yellow. Quenching of **3′—6′** with aqueous sodium hydrogencarbonate resulted in regeneration of **3—6**, respectively.

Properties. Electronic absorption maxima (in ether) of annulenones **3—6** are given in Table 1. As expected, the spectra are similar to one another, the medium bands exhibiting an appreciable bathochromic shift with increasing number of fused benzene rings, as observed for some benzo-annelated annulenes.[6] In contrast, the longest wavelength bands of these annulenones exhibit absorption shift toward longer wavelengths in the sequence of **3>4≃5>6**, demonstrating the sequence for the degree of extended conjugation of π-electron systems in the bisdehydro-[13]annulenone ring. Electronic absorption maxima of annulenones **3—6** in trifluoroacetic acid are given in Table 2, and it is evident that protonation with this acid causes a bathochromic shift of their main maxima.

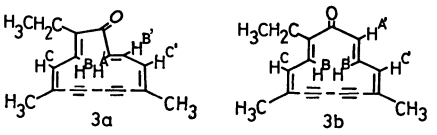
a) All the spectra showed tailing to ≈700 nm.

^{1}H NMR chemical shifts of the protons of annulenones **3**—**6** and those of their corresponding acyclic ketones at 90 MHz are listed in Table 3, together with data for the deuteronated species **3′**—**6′**, obtained through dissolution in trifluoroacetic acid-*d*. Individual assignments were made on the basis of multiplicity, coupling constants (see Experimental), and data of closely related compounds.[1,2)] Variable-temperature ^{1}H NMR spectra of **3**—**6** were taken at 100 MHz over the range −60 to 60 °C, chemical shifts being summarized in Table 4. As indicated in Fig. 1, the spectra of ethyldimethyl-6,8-bisdehydro-[13]annulenone **3** are temperature-dependent. At 35 °C (and above), the $H^{A'}$, $H^{B'}$, and $H^{C'}$ bands of **3** are unresolved multiplets. On cooling, the bands become resolved, and the expected first-order pattern is observed at −30 °C. Further cooling results in increased separation of the $H^{A'}$ and the $H^{B'}$ bands. These observations are similar to those for the spectra of the corresponding α-methyl derivative **2**[1)] and indicate that the ethyldimethylbisdehydro[13]annulenone **3** exists as conformer **3a** and not **3b**. A marked



difference observed in variable-temperature ^{1}H NMR spectra between **2** and **3** is that a spectrum of complete first-order pattern for the structure of **3a** is attained at −30 °C, whereas for the structure of **2a** it is attained at −60 °C. This result reveals that the introduction of the extra ethyl group into **1** to give **3** is more effective than that of the extra methyl group into **1** to give **2**, causing a conformational change on the other *trans* double bond in this bisdehydro[13]-annulenone ring system. On the other hand, the spectra of annulenones **4**—**6** were found essentially temperature-independent (Table 4), revealing that the conformations indicated for **4**—**6** will remain unchanged over the range −60 to 60 °C; similar temperature independence has been obtained for their corresponding α-methyl derivatives.[2)]

If we judge the tropicity of these annulenones from differences in chemical shift among various protons for the cyclic ketone (annulenone) and its corresponding acyclic model (upfield shift for the outer protons and downfield shift for the inner) (Table 3), annulenone **3** is taken to be a paratropic molecule, while **4**—**6** to be atropic ones. It has been observed that the paratropicity of the α-unsubstituted bisdehydro-[13]annulenone series decreases with increasing number of fused benzene rings.[7)] However, an examination of the data shown in Table 3 reveals that α-ethyl-substituted series (**3**—**6**) does not show such a trend.

Table 3. ^{1}H NMR chemical shifts of **3**—**6**, **12**—**15** (in $CDCl_3$), and **3′**—**6′** (in CF_3COOD) at 90 MHz, determined at 35 °C (τ Value; Internal standard, Me_4Si)

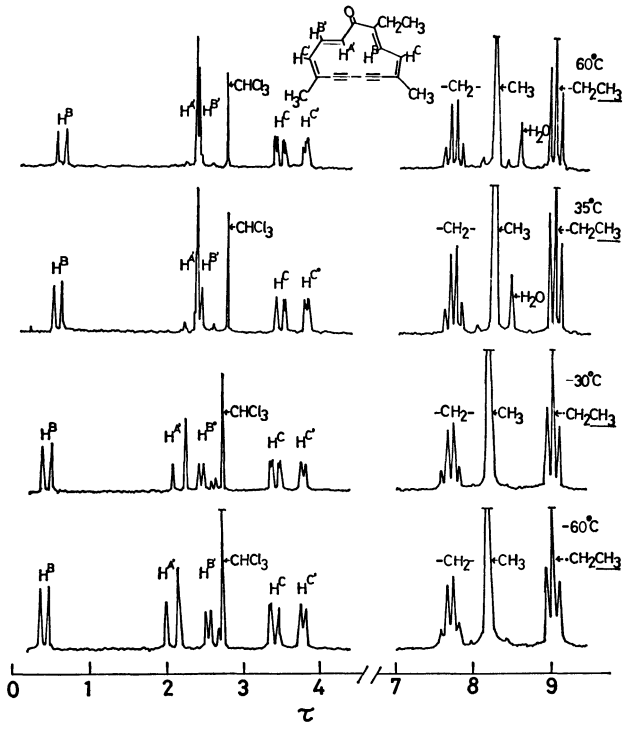

Fig. 1. The ^{1}H NMR FT spectra of **3** in $CDCl_3$ at 100 MHz (Internal standard, TMS).

Because it has been pointed out that annelation of an aromatic ring with an antiaromatic system exerts rather a minor effect on the paratropicity of the $4n\pi$ electron system,[8] and that the patatropicity of $4n$ moiety in the annelated [$4n$]annulene is quite sensitive to even a minor change in conformation,[9] the abovementioned trend observed in the series of α-ethyl-substituted bisdehydro[13]annulenone (**3**—**6**) should be ascribed to small change in the conformation of the [13]annulenone ring due to ethyl substitution at α-position and benzo-annelation, although the local anisotropic effect of the diacetylene unit can not be excluded.

In conclusion, the results obtained from this study indicate that the change of α-substituent from methyl to ethyl group causes both paratropic nature and conformational stability to decrease in the bisdehydro-[13]annulenone ring system.

Experimental

Deoxygenated ether was used to minimize oxidation of the compounds used for aldol condensation, and was freed from peroxide by passage through a short column of basic alumina (Woelm Act. I) followed by flushing with nitrogen immediately before use. Melting points were uncorrected. Mass spectra were recorded by the direct insertion technique with a JEOL JMS-200 spectrometer operating at 75 eV. IR spectra were taken on a Hitachi EPI-S2 spectrophotometer; only those absorptions characteristic of the carbonyl group are given in cm^{-1} for compounds **9** and **11**. UV spectra were measured on a Hitachi 124 instrument in ethanol solution, unless otherwise specified, and recorded in nm. ε-Values are given in parentheses, shoulders being denoted by sh. ^{1}H NMR spectra were recorded on a Varian EM-390 (90 MHz) or a JEOL FX-100 (100 MHz) spectrometer, and the data taken with a Varian EM-390 instrument are specified in this section by τ-value in $CDCl_3$ solution, TMS being used as an internal standard, unless otherwise stated. The coupling constants (J) are given in Hz. Alumina (Act. II—III) was used for column chromatography.

*3-Ethyl-6-methyl-3,5-octadien-7-yn-2-one (**9b**).* A solution of aldehyde **7**[4] (3.00 g, 32 mmol) in acetic acid (16 ml) was added dropwise during 2 h to a stirred solution of 2-pentanone **8b** (10.0 g, 16 mmol) and concentrated sulfuric acid (2.8 ml) in acetic acid (110 ml) at ambient temperature. The solution was stirred for a further 4.5 h, and then was cautiously poured into saturated aqueous potassium carbonate (200 ml). The mixture was diluted with water, and extracted with benzene. The extracts were washed with saturated aqueous sodium chloride solution, and dried over sodium sulfate. The residue obtained after removal of the solvent was chromatographed on alumina (80 g) with 5% ether in hexane. The early fractions gave ketone **9b** (2.08 g, 40%) as a light yellow oil; MS, *m/e*, 162 (M^+, 70%) and 119 (100); mol wt 162.2; IR (neat) 1660 cm^{-1}; UV_{max} 304 nm (51600); NMR τ=2.47 (d, 11, 1H, H^B), 3.27 (d, 11, 1H, H^C), 6.33 (s, 1H, $-C\equiv CH$), 7.57 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.60 (s, 3H, CH_3), 7.90 (s, 3H, CH_3), and 9.02 (t, 8, 3H, $-CH_2C\underline{H}_3$).

Found: C, 79.86; H, 8.40%. Calcd for $C_{11}H_{14}O$: C,

81.44; H, 8.70%. Attempts to improve the elemental analysis failed.

*2,8-Dimethyl-5,7-decadien-9-yn-4-one (**9c**)*: Yield 12% (acidic conditions) and 23% (basic conditions); light yellow oil; MS, *m/e*, 176 (M^+, 13%) and 119 (100); mol wt 176.2; IR (neat) 1680 and 1660 cm^{-1}; UV_{max} 305 nm (33500); NMR τ=2.40 (dd, 15.5, 11, 1H, H^B), 3.56 (d, 11, 1H, H^C), 3.80 (d, 15.5, 1H, H^A), 6.43 (s, 1H, $-C\equiv CH$), 7.53 (d, 7, 2H, $-C\underline{H}_2CH-$), 7.76 (m, 1H, $-CH_2C\underline{H}-$), 7.95 (s, 3H, CH_3), and 9.03 (d, 7, 6H, $-CH(C\underline{H}_3)_2$). Found: C, 81.94; H, 8.95%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

*2,2,8-Trimethyl-5,7-decadien-9-yn-4-one (**9d**)*: Yield 18% (acidic conditions) and 25% (basic conditions); light yellow oil; MS, *m/e*, 190 (M^+, 16%) and 134 (100); mol wt 190.2; IR (neat) 1675, 1660, and 1650 cm^{-1}; UV_{max} 304 nm (39700); NMR τ=2.42 (dd, 16, 12, 1H, H^B), 3.55 (d, 12, 1H, H^C), 3.80 (d, 16, 1H, H^A), 6.42 (s, 1H, $-C\equiv CH$), 7.52 (s, 2H, $-C\underline{H}_2-$), 7.95 (s, 3H, CH_3), and 8.95 (s, 9H, $-C(C\underline{H}_3)_3$). Found: C, 79.78; H, 9.15%. Calcd for $C_{13}H_{18}O$: C, 82.06; H, 9.54%. Attempts to improve the elemental analysis faield.

Ketones **9c** and **9d** were prepared by reaction of **8c** and **8d** with **7**, respectively, in a manner similar to that described above for the preparation of **9b**. Compounds **9c** and **9d** were also prepared by the reaction, under basic conditions, described below for the preparation of **9e**, and the yields under both acidic and basic conditions are given below.

*8-Methyl-5,7-decadien-9-yn-4-one (**9e**)*. A solution of 2.6% aqueous sodium hydroxide (7.0 ml) was added to an ice-cooled stirred solution of aldehyde **7** (1.0 g, 11 mmol) and **8b** (2.8 g, 33 mmol) in ethanol (6 ml). The solution was stirred for a further 2 h at 3 °C, and aqueous sulfuric acid (2 M, 10 ml) was then added. The solution was diluted with water and extracted with benzene. The extracts were washed with aqueous sodium hydrogencarbonate and sodium chloride solution, and dried over sodium sulfate. The residue obtained after removal of the solvent was chromatographed on alumina (70 g). The fractions eluted with 5% ether in hexane afforded ketone **9e** (425 mg, 35%) as a light yellow oil: MS, *m/e*, 162 (M^+, 17%) and 129 (100); mol wt 162.2; IR (neat) 1685 and 1660 cm^{-1}; UV_{max} 301 nm (27000); NMR τ=2.37 (dd, 16, 11, 1H, H^B), 3.54 (d, 11, 1H, H^C), 3.79 (d, 16, 1H, H^A), 6.37 (s, 1H, $-C\equiv CH$), 7.42 (t, 8, 2H, $-C\underline{H}_2CH_2-$), 7.97 (s, 3H, CH_3), 8.34 (m, 8, 2H, $-CH_2C\underline{H}_2-$), and 9.05 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 81.24; H, 8.44%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

Reactions of **8b—d** with aldehyde **10**[5] were carried out similarly to those with aldehyde **7** under both acidic and basic conditions.

*3-Ethyl-4-(o-ethynylphenyl)-3-buten-2-one (**11b**)*. Yield 29%; yellow oil; MS, *m/e*, 198 (M^+, 23%) and 155 (100); mol wt 198.2; IR (neat) 1665 cm^{-1}; UV_{max} 227 sh (25100), 239 (31700), and 281 nm (19600); NMR τ=2.17 (s, 1H, H^B), 2.33—2.80 (m, 4H, ArH), 6.52 (s, 1H, $-C\equiv CH$), 7.52 (s, 3H, CH_3), 7.53 (q, 7, 2H, $-C\underline{H}_2CH_3$), and 8.90 (t, 7, 3H, $-CH_2C\underline{H}_3$). Found: C, 84.71; H, 7.15%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

*6-(o-Ethynylphenyl)-2-methyl-5-hexen-4-one (**11c**)*. Yield 17% (acidic conditions) and 67% (basic conditions); yellow oil MS, *m/e*, 212 (M^+, 15%) and 155 (100); mol wt 212.2; IR (neat) 1680, 1670, and 1660 cm^{-1}; UV_{max} 228 (31900), 242 (40900), 247 sh (39700), and 293 nm (37100): NMR τ= 1.92 (d, 16, 1H, H^B), 2.29—2.70 (m, 4H, ArH), 3.23 (d, 16, 1H, H^A), 6.45 (s, 1H, $-C\equiv CH$), 7.44 (d, 7, 2H, $-C\underline{H}_2-$), 7.52—7.99 (m, 1H, $-CH\langle$), and 9.02 (d, 7, 6H, $-CH-(C\underline{H}_3)_2$). Found: C, 84.68; H, 7.35%. Calcd for $C_{15}H_{16}O$: C, 84.87; H, 7.60%.

*2,2-Dimethyl-6-(o-ethynylphenyl)-5-hexen-4-one (**11d**)*. Yield 34% (acidic conditions) and 71% (basic conditions); yellow oil; MS, *m/e*, 226 (M^+, 6%) and 155 (100); mol wt 226.3; IR (neat) 1680 and 1650 cm^{-1}; UV_{max} 229 (22400), 243 (27900), 248 (27400), and 294 nm (26100); NMR τ=1.88 (d, 16, 1H, H^B), 2.23—2.68 (m, 4H, ArH), 3.18 (d, 16, 1H, H^A), 6.50 (s, 1H, $-C\equiv CH$), 7.40 (s, 2H, $-C\underline{H}_2-$), and 8.90 (d, 9H, $-C(C\underline{H}_3)_3$). Found: C, 84.84; H, 7.95%. Calcd for $C_{16}H_{18}O$: C, 84.91; H, 8.02%.

*6-(o-Ethynylphenyl)-5-hexen-4-one (**11e**)*. Yield 37%; light yellow cubes from hexane–benzene; mp 64—65.5 °C; MS, *m/e*, 198 (M^+, 14%) and 155 (100); mol wt 198.2; IR (KBr disk) 1675 cm^{-1}; UV_{max} 228 (14200), 242 (19800), 247 sh (19000), and 292 nm (18100); NMR τ=1.90 (d, 16, 1H, H^B), 2.35—2.80 (m, 4H, ArH), 3.22 (d, 16, 1H, H^A), 6.49 (s, 1H, $-C\equiv CH$), 7.33 (t, 7, 2H, $-C\underline{H}_2CH_2-$), 8.28 (m, 7, 2H, $-CH_2C\underline{H}_2-$), and 9.01 (t, 7, 3H, CH_3). Found: C, 84.99; H, 7.00%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

*5-(o-Ethynylphenyl)-4-penten-3-one (**11f**)*. Yield 38%; light yellow oil; MS, *m/e*, 184 (M^+, 14%) and 155 (100); mol wt 184.2; IR (neat) 1685 and 1665 cm^{-1}; UV_{max} 229 (16300), 243 (22400), 249 (21500), 261 (8340), and 290 nm (18500); NMR τ=1.89 (d, 16, 1H, H^B), 2.2—2.7 (m, 4H, ArH), 3.20 (d, 16, 1H, H^A), 6.43 (s, 1H, $-C\equiv CH$), 7.25 (q, 8, 2H, $-C\underline{H}_2-$), and 8.80 (t, 8, 3H, CH_3). Found: C, 83.60; H, 6.39%. Calcd for $C_{13}H_{12}O$: C, 84.75; H, 6.57%. Attempts to improve the elemental analysis failed.

*6-Ethyl-3,11-dimethyl-3,5,8,10-tridecatetraene-1,12-diyn-7-one **12***. To a mixture of aldehyde **7**[4] (1.30 g, 14 mmol) and ketone **9b** (562 mg, 3.4 mmol) in deoxygenated ether (20 ml) was added a 20% methanolic potassium hydroxide solution (1.7 ml) with stirring at 0 °C. The mixture was then stirred for 6 h at the same temperature. Neutralization with acetic acid (4.6 ml) followed by pouring into water (200 ml) and extraction with benzene gave an organic extract which was worked up as usual. The residue obtained by evaporation of the solvent was chromatographed on alumina (100 g). The initial fractions gave the unchanged ketone **9b** (164 mg). The following fractions eluted with hexane–ether (4:1) afforded ketone **12** (626 mg, 77%) as a solid. Recrystallization from hexane–benzene afforded yellow needles; mp 74.5—75 °C, MS, *m/e*, 238 (M^+, 10%) and 165 (100); mol wt 238.3; IR (KBr disk) 3250 ($-C\equiv CH$), 2100 ($-C\equiv C-$), 1645 (C=O), 1605, 1590, 1580 (C=C), and 980 cm^{-1} (*trans* C=C); UV_{max} (ether) 251 (19200), 256 (19300), 269 sh (17200), 293 (15300), 324 sh (27500), 336 (29800), and 354 nm sh (20900); NMR τ=2.23 (dd, 15, 11, 1H, $H^{B'}$), 2.52 (d, 11, 1H, H^B), 3.13 (d, 15, 1H, $H^{A'}$), 3.27 (d, 11, 1H, H^C or $H^{C'}$), 3.49 (d, 11, 1H, H^C or $H^{C'}$), 6.46 (s, 1H, $-C\equiv CH$), 6.52 (s, 1H, $-C\equiv CH$), 7.49 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.92 (s, 3H, CH_3), 7.97 (s, 3H, CH_3), and 8.98 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 85.39; H, 7.63%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

*2-Ethyl-5,10-dimethyl-6,8-bisdehydro[13]annulenone (**3**)*. A solution of ketone **12** (825 mg, 3.5 mmol) in pyridine (48 ml) and dry ether (18 ml) was added dropwise during 3.5 h to a stirred solution of anhydrous copper(II) acetate (4.40 g) in pyridine (100 ml) and dry ether (35 ml) at 49—53 °C (bath). The solution was stirred at the same temperature for a further 1.5 h and then cooled. After addition of benzene (200 ml), the mixture was filtered through a Hyflo Super-Cel. The precipitates were washed with benzene (100 ml × 3) and the filtrate was poured into water. The organic layer was separated and the aqueous layer was extracted with benzene. The combined organic extracts were washed successively with 7% hydrochloric acid,

aqueous sodium hydrogencarbonate, and water, and dried over sodium sulfate. The dark red liquid obtained after removal of the solvent was chromatographed on alumina (80 g). The fractions eluted with hexane–ether (9:1) afforded annulenone **3** (257 mg, 32%), which formed red plates from hexane; mp 49—50 °C, MS, *m/e*, 236 (M^+, 28%) and 178 (100); mol wt 236.3; IR (KBr disk) 2150 (–C≡C–), 1650 (C=O), 1620 (C=C), and 985 cm^{-1} (*trans* C=C); UV, see Tables 1 and 2; NMR (−25 °C) τ=0.38 (d, 10, 1H, H^B), 2.10 (d, 16, 1H, $H^{A'}$), 2.50 (dd, 16, 6, 1H, $H^{B'}$), 3.37 (d, 10, 1H, H^C), 3.73 (d, 6, 1H, $H^{C'}$), 7.69 (q, 8, 2H, $-C\underline{H}_2CH_3$), 8.17 (s, 6H, CH_3), and 9.00 (t, 8, 3H, $-CH_2C\underline{H}_3$), and see Figure 1; NMR (CF_3COOD) τ=−0.37 (d, 10.5, 1H, H^B), 1.67—2.13 (m, 2H, $H^{A'}$ and $H^{B'}$), 3.45 (dd, 10.5, 1.5, H^C), 3.79 (dd, 6, 1.5, 1H, $H^{C'}$), 7.65 (q, 8, 2H, $-C\underline{H}_2CH_3$), 8.20 (broad s, 6H, CH_3), and 8.95 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 86.30; H, 6.76%. Calcd for $C_{17}H_{16}O$: C, 86.40; H, 6.83%.

*4-Ethyl-1-(o-ethynylphenyl)-7-methyl-1,4,6-nonatrien-8-yn-3-one (**13**).* A solution of *o*-ethynylbenzaldehyde **10**[5] (1.40 g, 10.6 mmol) in deoxygenated ether (20 ml) was added dropwise during 30 min with ice-bath cooling to a stirred solution of ketone **9b** (1.20 g, 7.3 mmol) in deoxygenated ether (35 ml) containing ethanolic sodium ethoxide (2.1 ml) [from sodium (760 mg) and absolute ethanol (50 ml)]. After stirring for a further 6 h at the same temperature, the reaction was quenched by addition of aqueous oxalic acid. The mixture was poured into water (100 ml) and extracted with benzene. After working up as usual, the red liquid obtained was chromatographed on alumina (100 g). The early fractions gave the recovered aldehyde **10** (285 mg). The following fractions eluted with hexane–ether (17:3) gave ketone **13** (1.18 g, 47%) as a solid. Recrystallization from hexane–benzene afforded light yellow needles: mp 114—115 °C; MS, *m/e*, 274 (M^+, 15%) and 245 (100); mol wt 274.3; IR (KBr disk) 3250 (–C≡CH), 2150 (–C≡C–), 1645 (C=O), 1590 (C=C), 990, and 980 cm^{-1} (*trans* C=C); UV_{max} (ether) 230 (21600), 252 (22100), 259 sh (20600), 309 sh (17200), 327 (19700), and 352 nm sh (13600); NMR τ=1.88 (d, 16, 1H, $H^{B'}$), 2.25—2.75 (m, 6H, $H^{A'}$, H^B, and ArH), 3.23 (d, 11, 1H, H^C), 6.42 (s, 1H, –C≡CH), 6.51 (s, 1H, –C≡CH), 7.43 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.93 (s, 3H, CH_3), and 8.92 (t, 8, $-CH_2C\underline{H}_3$). Found: C, 87.38; H, 6.45%. Calcd for $C_{20}H_{18}O$: C, 87.56; H, 6.61%.

*13-Ethyl-10-methyl-4,5-benzo-6,8-bisdehydro[13]annulenone (**4**).* A solution of ketone **13** (1.1 g, 4 mmol) in pyridine–dry ether (3:1, 84 ml) was added dropwise during 3 h to a stirred solution of anhydrous copper(II) acetate (5.0 g) in pyridine–dry ether (3:1, 180 ml) at 45—50 °C (bath). The solution was stirred for a further 30 min at the same temperature and then cooled. After working up as in the preparation of **3**, the red liquid obtained was chromatographed on alumina (100 g). The fractions eluted with hexane–ether (17:3) gave monobenzannulenone **4** (481 mg, 44%). Recrystallization from hexane–benzene afforded yellow needles; mp 119—120 °C; MS, *m/e*, 272 (M^+, 20%) and 229 (100); mol wt 272.3; IR (KBr disk) 2150 (–C≡C–), 1650 (C=O), 1600 (C=C), and 980 cm^{-1} (*trans* C=C); UV, see Tables 1 and 2, NMR τ=0.95 (d, 11, 1H, H^B), 2.12 (d, 16.5 1H, $H^{B'}$), 2.50 (d, 16.5, 1H, $H^{A'}$), 2.6—2.8 (m, 4H, ArH), 3.24 (dd, 11, 1, 1H, H^C), 7.57 (q, 8, 2H, $-C\underline{H}_2CH_3$), 8.10 (d, 1, 3H, CH_3), and 8.94 (t, 8, 3H, $-CH_2C\underline{H}_3$); NMR (CF_3COOD) τ=0.18 (d, 11, 1H, H^B), 1.93 (d, 16.5, 1H, $H^{B'}$), 2.18 (d, 16.5, 1H, $H^{A'}$), 2.6—2.9 (m, 4H, ArH), 3.25 (d, 11, 1H, H^C), 7.54 (q, 8, 2H, $-C\underline{H}_2CH_3$), 8.10 (s, 3H, CH_3), and 8.90 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 88.40; H, 5.67%. Calcd for $C_{20}H_{16}O$: C, 88.20; H, 5.92%.

*2-Ethyl-1-(o-ethynylphenyl)-7-methyl-1,4,6-nonatrien-8-yn-3-one (**14**).* Potassium hydroxide–ethanol (5.0 ml; 10% W/V) was added to a solution of ketone **11b** (2.40 g, 12.1 mmol) in dry tetrahydrofuran (35 ml), and a solution of aldehyde **7** (2.3 g, 24 mmol) in dry tetrahydrofuran (17 ml) was then added dropwise during 40 min with stirring at 9—10 °C. After stirring for a further 3 h at the same temperature, the reaction was quenched by addition of acetic acid (7 ml). The resulting solution was poured into water (150 ml) and extracted with benzene. The usual working up afforded a red liquid which was chromatographed on alumina (120 g). The early fractions gave the recovered ketone **11b** (586 mg). The following fractions, eluted with hexane–ether (9:1), gave ketone **14** (885 mg, 28%) as a partly crystallized liquid. Crystallization from hexane–benzene afforded yellow cubes: mp 90—92 °C; MS, *m/e*, 274 (M^+, 5%) and 217 (100); mol wt 274.3; IR (KBr disk) 3300, 3250 (–C≡CH), 2100 (–C≡C–), 1650 (C=O), 1595 (C=C), and 980 cm^{-1} (*trans* C=C); UV_{max} (ether) 226 (21000), 244 (18000), and 315 nm (22200); NMR τ=2.17 (dd, 15, 11, 1H, $H^{B'}$), 2.30 (s, 1H, H^B), *ca.* 2.4—2.8 (m, 4H, ArH), 3.13 (d, 15, 1H, $H^{A'}$), 3.45 (d, 11, 1H, $H^{C'}$) 6.50 (s, 1H, –C≡CH), 6.60 (s, 1H, –C≡CH), 7.42 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.93 (s, 3H, CH_3), and 8.92 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 87.59; H, 6.40%. Calcd for $C_{20}H_{18}O$: 87.56; H, 6.61%.

*2-Ethyl-10-methyl-4,5-benzo-6,8-bisdehydro[13]annulenone (**5**).* A solution of ketone **14** (737 mg, 2.7 mmol) in pyridine–dry ether (3:1, 56 ml) was added dropwise during 2.5 h to a stirred solution of anhydrous copper(II) acetate (3.4 g) in pyridine–dry ether (3:1, 120 ml) at 45—50 °C (bath). The solution was stirred at the same temperature for a further 45 min and then cooled. After working up as in the preparation of **3**, the red liquid obtained was chromatographed on alumina (100 g). The fractions eluted with hexane–ether (9:1), gave benzannulenone **5** (269 mg, 37%). Recrystallization from hexane–benzene afforded yellow cubes: mp 101—102 °C; MS, *m/e*, 272 (M^+, 100%); mol wt 272.3; IR (KBr disk) 2150 (–C≡C–), 1625 (C=O), 1595 (C=C), and 970 cm^{-1} (*trans* C=C); UV, see Tables 1 and 2; NMR τ=1.98 (dd, 16, 9, 1H, $H^{B'}$), 2.17 (s, 1H, H^B), 2.5—2.8 (m, 4H, ArH), 2.87 (d, 16, 1H, $H^{A'}$), 3.40 (d, 9, 1H, $H^{C'}$), 7.52 (q, 8, 2H, $-C\underline{H}_2CH_3$), 8.10 (s, 3H, CH_3), 9.02 (t, 8, 3H, $-CH_2C\underline{H}_3$); NMR (CF_3COOD) τ=1.31 (dd, 16, 11, 1H, $H^{B'}$), 2.28 (s, 1H, H^B), 2.5—2.7 (m, 4H, ArH), 3.12 (d, 16, 1H, $H^{A'}$), 3.25 (d, 11, 1H, $H^{C'}$), 7.47 (q, 8, 2H, $-C\underline{H}_2CH_3$), 8.00 (s, 3H, CH_3), and 8.97 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 88.44; H, 5.76%. Calcd for $C_{20}H_{16}O$: C, 88.20; H, 5.92%.

*2-Ethyl-1,5-bis(o-ethynylphenyl)-1,4-pentadien-3-one (**15**).* A solution of *o*-ethynylbenzaldehyde **10** (2.0 g, 15 mmol) in deoxygenated ether (17 ml) was added dropwise during 30 min with ice-bath cooling to a stirred solution of ketone **11b** (0.86 g, 4 mmol) in deoxygenated ether (43 ml) containing ethanolic sodium ethoxide (24 ml) [from sodium (0.38 g) and absolute ethanol (50 ml)]. After stirring for a further 8 h at the same temperature, the reaction was quenched by addition of aqueous oxalic acid. The mixture was poured into water (100 ml) and extracted with benzene. After usual working up, the semi-solid obtained was chromatographed on alumina (120 g). The early fractions gave the recovered aldehyde **10** (434 mg). The following fractions eluted with hexane–ether (4:1) gave ketone **15** (626 mg, 47%). Recrystallization from hexane–benzene afforded light yellow needles: mp 117—118 °C; MS, *m/e*, 310 (M^+, 13%) and 155 (100); mol wt 310.3; IR (KBr disk) 3250 (–C≡CH), 2150 (–C≡C–), 1655 (C=O), 1600 (C=C), and 980 cm^{-1} (*trans* C=C); UV_{max} (ether) 225

(28800), 245 (25200), 254 sh (20600), and 302 nm (16700); NMR τ=1.78 (d, 16, 1H, $H^{B'}$), 2.18 (s, 1H, H^{B}), *ca.* 2.4—2.8 (m, 9H, $H^{A'}$ and ArH), 6.54 (s, 1H, $-C\equiv CH$), 6.62 (s, 1H, $-C\equiv CH$), 7.38 (q, 8, 2H, $-C\underline{H}_2CH_3$), and 8.87 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 89.18; H, 5.67%. Calcd for $C_{23}H_{18}O$: C, 89.00; H, 5.85%.

2-Ethyl-4,5:10,11-dibenzo-6,8-bisdehydro[13]annulenone (6). A solution of ketone **15** (0.52 g, 1.7 mmol) in pyridine–dry ether (3:1, 36 ml) was added dropwise during 3.5 h to a stirred solution of anhydrous copper(II) acetate (2.2 g) in pyridine–dry ether (3:1, 80 ml) at 45—50 °C. The solution was stirred for a further 30 min at the same temperature and then cooled. After working up as in the preparation of **3**, the brown solid obtained was chromatographed on alumina (90 g). The fractions eluted with hexane–ether (3:2) gave dibenzannulenone **6** (241 mg, 46%). Recrystallization from hexane–benzene afforded yellow needles: mp 154 °C (dec); MS, *m/e*, 308 (M^+, 100%); mol wt 308.3; IR (KBr disk) 2200 (–C≡C–), 1660 (C=O), 1610 (C=C), 995 and 985 cm^{-1} (*trans* C=C); UV, see Tables 1 and 2; NMR τ=1.86 (s, 1H, H^{B}), 1.97 (d, 16, 1H, $H^{B'}$), 2.18 (d, 16, 1H, $H^{A'}$), *ca.* 2.5—2.8 (m, 8H, ArH), 7.40 (q, 8, 2H, $-C\underline{H}_2CH_3$), and 8.90 (t, 8, 3H, $-CH_2C\underline{H}_3$); NMR (CF_3COOD) τ=1.66 (s, 1H, H^{B}), 1.72 (d, 16, 1H, $H^{B'}$), 1.98 (d, 16, 1H, $H^{A'}$), *ca.* 2.4—2.8 (m, 8H, ArH), 7.35 (q, 8, 2H, $-C\underline{H}_2CH_3$), and 8.89 (t, 8, $-CH_2C\underline{H}_3$). Found: C, 89.31; H, 5.00. Calcd for $C_{23}H_{16}O$: C, 89.58; H, 5.23%.

Syntheses and Properties of α-Ethyl-substituted Bisdehydro-[15]annulenones

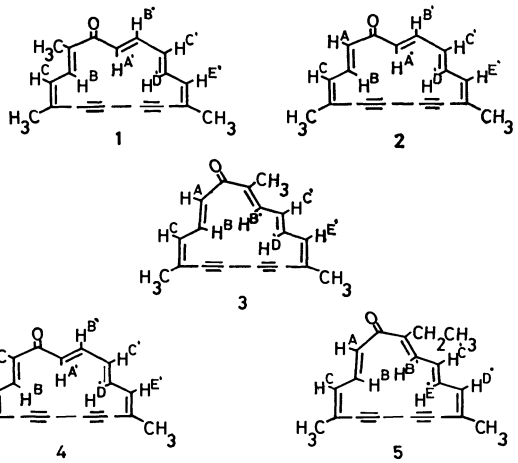
Jūro Ojima* and Yoshiko Murosawa

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received March 2, 1981)

2-Ethyl-5,10-dimethyl- and 15-ethyl-5,10-dimethyl-6,8-bisdehydro[15]annulenone were synthesized. Influence of α-ethyl substitution upon the skeleton of the bisdehydro[15]annulenone ring system is discussed on the basis of ^{1}H NMR and UV spectra of these annulenones and their α-methyl-substituted derivatives.

In a previous paper[1] we reported the synthesis of the diatropic bisdehydro[15]annulenones **1**—**3** and showed that the planarity, *i.e.*, the rigidity of molecular skeleton, of bisdehydro[15]annulenone ring system decreases in the sequence of **1**>**2**>**3**, reflecting the effect of perturbation caused by the introduction of α-methyl substituent. Since 3-ethyl-2-alkanones **6**[2] and **9** were made available, we examined the effect of α-ethyl group on the molecular skeleton of bisdehydro[15]annulenone ring system.



Results and Discussion

Synthesis. Annulenones **4** and **5** were synthesized by a reaction sequence similar to that used for their corresponding α-methyl derivatives.[1] Condensation of ketone **6**,[2] obtained from aldehyde **10**[3] and 2-pentanone, with (2*E*,4*Z*)-5-methyl-2,4-heptadien-6-ynal **7**[4] in the presence of ethanolic sodium ethoxide in ether gave the acyclic ketone **8** in 75% yield. Oxidative coupling of **8** with anhydrous copper(II) acetate in pyridine and dry ether at 50 °C[5] gave annulenone **4** in 38% yield. Acid-catalyzed aldol condensation of **7** with 2-pentanone yielded ketone **9** in 34% yield. Reaction of **9** and **10**, under the same conditions as for **6** and **7**, afforded ketone **11** in 36% yield. Oxidation of **11**, as with **8**, afforded another annulenone **5** in 34% yield. 2-Ethyl-5,10-dimethyl-**4** and 15-ethyl-5,10-dimethyl-6,8-bisdehydro[15]annulenone **5** formed yellow needles (mp 145—146 °C) and orange cubes (mp 97—98 °C), respectively; both **4** and **5** appear to be considerably stable. All the new compounds gave spectral data consistent with the assigned structures and satisfactory results of elemental analysis were obtained except for the unstable acyclic ketone **11**.

Treatment of annulenone **4** or **5** with trifluoroacetic acid or trifluoroacetic acid-*d* gave a red solution indicating formation of the protonated or deuteronated species **4'** or **5'**, respectively. Quenching of **4'** or **5'** with aqueous sodium hydrogencarbonate resulted in regeneration of **4** or **5**, respectively.

Properties. Electronic absorption maxima of these annulenones **4** and **5** as well as related derivatives **1**—**3**[1] are listed in Table 1. As expected, the spectra are similar to one another. However, the main and longest wavelength bands exhibit a small bathochromic shift in the sequence of **4**>**1**>**2** as the α-substituent at C_2-position passes from ethyl *via* methyl to hydrogen, whereas in the spectra of **3** and **5**, the positions of these maxima are in relatively short wavelengths and appear to be independent of alkyl substitution at C_{15}-position, reflecting that the molecular skeletons of **3** and **5** are less planar than those of **1**, **2**, and **4**. The absorption maxima of these annulenones **1**—**5** in tri-

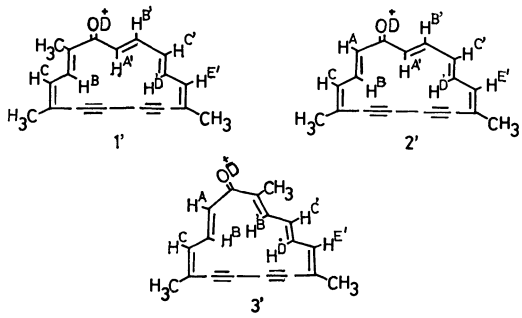
fluoroacetic acid are given in Table 2, and it is evident that protonation of **4** and **5** with this acid causes shift of main maxima to longer wavelengths, similarly to the case of **1**—**3**. The main maxima of these annulenones in trifluoroacetic acid exhibit a bathochromic shift in the order of **4**≃**1**>**2**>**3**≃**5**, suggesting that the positions of main maxima do not depend on alkyl substitution, but on molecular planarity (*vide infra*). Also, the bathochromic shifts (53—63 nm) of the main maxima of **4** and **5** by protonation are much larger than that observed for their corresponding α-ethyl-substituted bisdehydro[13]annulenone (7 nm);[2] similar relations have been observed between [4*n*−2]- and [4*n*]annulenes and dehydroannulenes.[6]

^{1}H NMR chemical shifts of the protons of **4**, **5**, **8**, and **11**, together with those of **1**—**3** reported by us[1] are summarized in Table 3. The individual assignments, some of which are tentative, were made on the basis of multiplicity, coupling constants (Experimental), and data of closely related compounds.[1]

A comparison of the ^{1}H NMR chemical shifts of various protons of annulenones **4** and **5** with those of their corresponding acyclic ketones **8** and **11** indicates that both **4** and **5** are diatropic, as might be expected with 14π-electron systems. This follows from the fact that all the inner protons in **4** and **5** resonate at higher fields than their corresponding protons in **8** and **11**, respectively, whereas essentially all the outer protons (including allylic methylene and methyl protons) in **4** and **5** resonate at lower fields.



^{1}H NMR chemical shifts of the deuteronated species **1**′—**5**′, obtained through dissolution in trifluoroacetic acid-*d*, are also given in Table 3. It is evident that the conformations of **4** and **5** are unchanged. A comparison of the chemical shifts of various protons of **4**′ and **5**′ with those of their corresponding acyclic models **8** and **11**, as with **4** and **5** mentioned above, indicates that the diatropicities of the deuteronated species **4**′ and **5**′ are much more marked than those of annulenones **4** and **5**, respectively.

Variable-temperature ^{1}H NMR spectra of **4** and **5**, recorded over the range of −60 to 60 °C and summarized in Table 4, show that temperature has essentially no effect on spectra of **4** or **5**. Spectra of ethyldimethylbisdehydro[13]annulenone **5**, expected to be more mobile than **4**, are shown in Fig. 1. On cooling, the resonance of the inner (H^B, $H^{B'}$, $H^{D'}$) protons of **5** shifts to a slightly higher field, whereas that of the outer (H^A, H^C, $H^{C'}$, $H^{E'}$) protons (including allylic methylene and methyl protons) to a slightly

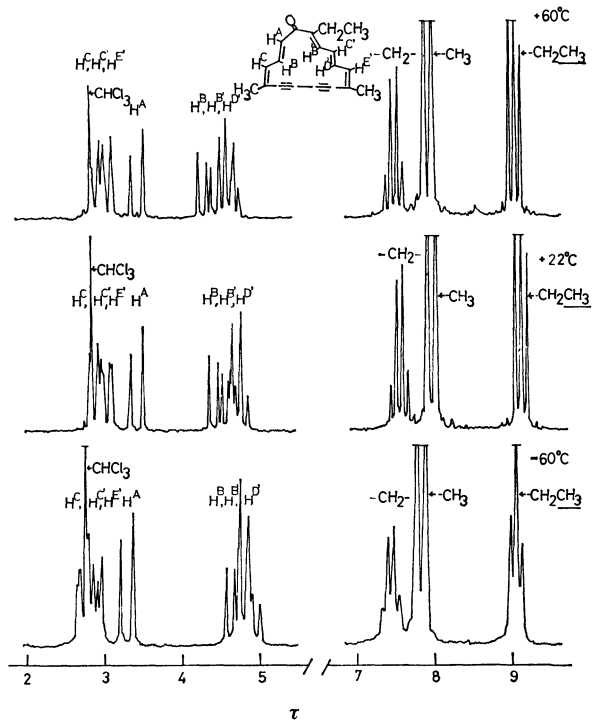


Fig. 1. The ^{1}H NMR FT spectra of **5** in $CDCl_3$ at 100 MHz (internal standard, TMS).

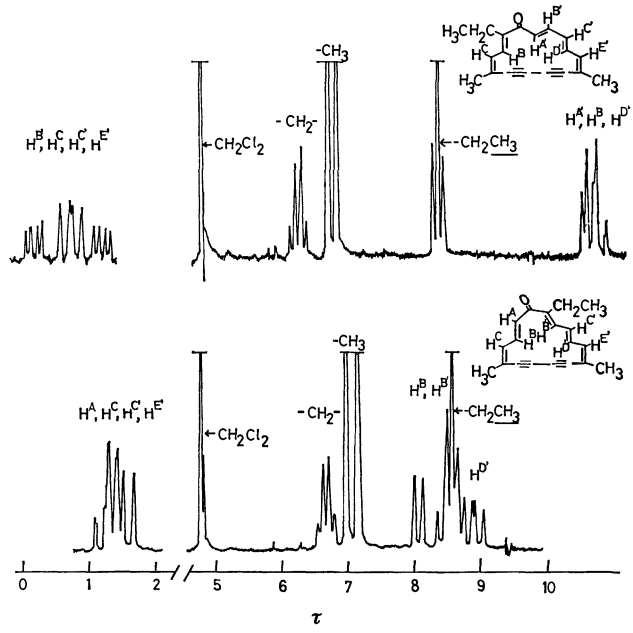

Fig. 2. The 90 MHz ^{1}H NMR spectra of **4** and **5** in CF_3COOD at 35 °C.

lower field. However, the $J_{B,C}$ value (11 Hz), indicating an s-*trans* relationship of the H^B and H^C bonds, does not vary in the range −60—60 °C, excluding any change in conformation due to rotation of the CH^A=CH^B double bond over this temperature range, in contrast to the case of α-ethyl-substituted bisdehydro[13]annulenones.[2] The signals of both the inner and outer protons of **4** exhibit less temperature dependence than those of **5** in the range −60—60 °C (Table 4), reflecting an enhanced rigidity in the mo-

lecular skeleton of **4**. This tendency is manifested very markedly in the spectra of **4** and **5** in trifluoroacetic acid-*d*, illustrated in Fig. 2. It is to be noted that the magnitudes of upfield shifts of the inner protons and of downfield shifts of the outer and methyl protons decrease in the order of **4**>**5**. Also, the chemical shifts of the olefinic and methyl protons of **4**′ are almost the same with those of their corresponding protons of **1**′. Similar relations in chemical shift are seen between **3**′ and **5**′ (Table 3). This fact suggests that the planarity, *i.e.*, the rigidity, of this bisdehydro[15]annulenone ring system decreases in the sequence of **4**≃**1**>**2**>**3**≃**5**. This interpretation, already presented on a different basis, is supported by the fact that their bathochromic shifts in main maxima as well as the longest wavelength bands are in the same sequence in both ether and trifluoroacetic acid (Tables 1 and 2).

Thus, the difference in behavior observed for the bisdehydro[15]annulenone ring system against the α-ethyl and α-methyl substitutions is not so large as that for the corresponding bisdehydro[13]annulenone system,[2] reflecting higher planarity of the molecular skeleton of the former system.

Experimental

Deoxygenated ether was prepared and used as reported.[1,2] Melting points were uncorrected. IR spectra were taken with a Hitachi EPI-S2 spectrophotometer. UV spectra were measured on a Hitachi 124 spectrophotometer and recorded in nm. ε-Values are given in parentheses, shoulders being denoted by sh. Mass spectra were recorded with a JEOL JMS-200 spectrometer operating at 75 eV. ^{1}H NMR spectra were recorded with a Varian EM-390 (90 MHz) or a JEOL FX-100 (100 MHz) spectrometer. Data taken with a Varian EM-390 instrument at 35 °C are specified by τ-value for $CDCl_3$ solution, TMS being used as an internal standard unless otherwise stated. Coupling constants (J) are given in Hz. Merck alumina (Act. II—III) was used for column chromatography. Sodium sulfate was used as drying agent, and solvents were evaporated at the water aspirator pressure.

6-Ethyl-3,13-dimethyl-3,5,8,10,12-pentadecapentaene-1,14-diyn-7-one (8). A solution of aldehyde **7**[4] (1.10 g, 9.3 mmol) in deoxygenated ether (17 ml) was added dropwise during 30 min to a stirred ice-cooled solution of ketone **6**[2] (1.0 g, 6.2 mmol) in deoxygenated ether (47 ml) containing ethanolic sodium ethoxide (6.7 ml) [from sodium (760 mg) and absolute ethanol (50 ml)]. After stirring for 5 h, portions of the ethanolic sodium ethoxide (each 2.0 ml) were added every 2 h. After stirring for a total 8 h, the reaction was quenched by addition of aqueous oxalic acid. The solution was poured into water and extracted with benzene. The benzene extracts were washed successively with aqueous sodium hydrogencarbonate and brine, and then dried. The semi-solid obtained after removal of the solvent was chromatographed on alumina (80 g). The early fractions gave the recovered ketone **6** (188 mg). The later fractions eluted with hexane–ether (4:1) gave ketone **8** (1.23 g, 75%) as a solid. Recrystallization from hexane–benzene afforded orange needles: mp 69—70 °C; MS, *m/e*, 264 (M^+, 74%) and 192 (100); mol wt 264.3; IR (KBr disk) 3300 (–C≡CH), 2100 (–C≡C–), 1640 (C=O), 1610, 1585 (C=C), and 1085 cm^{-1} (*trans* C=C); UV_{max} (ether) 225 sh (10300), 231 (10900), 253 sh (16100), 266 (20500), 277 (20800), 290 (21400), 304 (22800), 340 sh (32000), 356 (36100), and 373 nm sh (29600); NMR τ=2.48 (d, 11, 1H, H^B), 2.57 (dd, 15, 11, 1H, $H^{B'}$ or $H^{C'}$ or $H^{D'}$), 2.87 (dd, 15, 11, 1H, $H^{B'}$ or $H^{C'}$ or $H^{D'}$), 3.12 (d, 15, 1H, $H^{A'}$), 3.26 (d, 11, 1H, H^C or $H^{E'}$), 3.52 (dd, 15, 11, 1H, $H^{B'}$ or $H^{C'}$ or $H^{D'}$), 3.56 (d, 11, 1H, H^C or $H^{E'}$), 6.43 (s, 1H, –C≡CH), 6.53 (s, 1H, –C≡CH), 7.47 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.90 (s, 3H, CH_3), 7.98 (s, 3H, CH_3), and 8.97 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found: C, 86.05; H, 7.43%. Calcd for $C_{19}H_{20}O$: C, 86.32; H, 7.63%.

2-Ethyl-5,10-dimethyl-6,8-bisdehydro[15]annulenone (4). A solution of ketone **8** (1.17 g, 4.4 mmol) in pyridine (79 ml) and dry ether (27 ml) was added dropwise to a stirred solution of anhydrous copper(II) acetate (5.3 g) in pyridine (159 ml) and dry ether (53 ml) during 6 h at 49—52 °C. The solution was stirred for a further 30 min at the same temperature, and then cooled. After addition of benzene (300 ml), the mixture was filtered through a Hyflo Super-Cel. The precipitates formed were washed with benzene (100 ml×3) and the filtrate was poured into water. The organic layer was separated and the aqueous layer was extracted with benzene. The combined organic extracts were washed successively with 7% hydrochloric acid, aqueous sodium hydrogencarbonate, and brine, and then dried. The semi-solid obtained after removal of the solvent was chromatographed on alumina (80 g). The fractions eluted with hexane–ether (7:3) gave annulenone **4** (434 mg, 38%). Recrystallization from hexane–benzene afforded yellow needles: mp 145—146 °C; MS, *m/e*, 262 (M^+, 27%) and 203 (100); mol wt 262.3; IR (KBr disk) 2170 (–C≡C–), 1635 (C=O), 1610 (C=C), and 975 cm^{-1} (*trans* C=C); UV, see Tables 1 and 2; NMR τ=2.36 (dd, 16, 5, 1H, $H^{B'}$ or $H^{C'}$), 2.56 (d, 11, 1H, H^C or $H^{E'}$), 2.73 (d, 11, 1H, H^C or $H^{E'}$), 3.14 (dd, 16, 5, 1H, $H^{B'}$ or $H^{C'}$), 4.47 (d, 16, 1H, $H^{A'}$), 4.50 (d, 11, 1H, H^B), 4.69 (dd, 16, 11, 1H, $H^{D'}$), 7.25 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.70 (s, 3H, CH_3), 7.80 (s, 3H, CH_3), and 8.84 (t, 8, 3H, $-CH_2C\underline{H}_3$); NMR (CF_3COOD, determined with CH_2Cl_2 as an internal standard) τ=0.17 (dd, 15, 7, 1H, $H^{B'}$ or $H^{C'}$), 0.60 (d, 12, 1H, H^C or $H^{E'}$), 0.77 (d, 12, 1H, H^C or $H^{E'}$), 1.20 (dd, 15, 7, 1H, $H^{B'}$ or $H^{C'}$), 6.18 (q, 8, 2H, $-C\underline{H}_2CH_3$), 6.60 (s, 3H, CH_3), 6.73 (s, 3H, CH_3), 8.30 (t, 8, 3H, $-CH_2C\underline{H}_3$), 10.53 (d, 15, 1H, $H^{A'}$), 10.58 (d, 12, 1H, H^B), and 10.67 (dd, 15, 11, 1H, $H^{D'}$), and see Fig. 2. Found: C, 87.15; H, 6.84%. Calcd for $C_{19}H_{18}O$: C, 86.98; H, 6.91%.

3-Ethyl-8-methyl-3,5,7-decatrien-9-yn-2-one (9). A solution of aldehyde **7**[4] (3.0 g, 25 mmol) in acetic acid (13 ml) was added dropwise during 20 min to a stirred solution of 2-pentanone (15.1 g, 0.175 mol) and concentrated sulfuric acid (4.7 ml) in acetic acid (95 ml) at 8—9 °C. The solution was stirred for a further 3 h, and then cautiously poured into saturated aqueous potassium carbonate (200 ml). The mixture was diluted with water, and extracted with benzene. The extracts were washed with saturated aqueous sodium chloride solution, and then dried. The dark red liquid obtained was chromatographed on alumina (80 g). The fractions eluted with hexane–ether (9:1—4:1) gave ketone **9** (1.59 g, 34%) as a yellow liquid: MS, *m/e*, 188 (M^+, 80%) and 159 (100); mol wt 188.2; IR (neat) 3250 (–C≡CH), 2100 (–C≡C–), 1655 (C=O), 1610, 1595 (C=C), and 980 cm^{-1} (*trans* C=C); UV_{max} (ether) 227 (5600), 236 (5710), 310 sh (23700), 331 (32800), and 341 nm sh (32500); NMR τ=2.89 (d, 11, 1H, H^B), 2.95 (dd, 15, 11, 1H, H^D), 3.38 (dd, 15, 11, 1H, H^C), 3.52 (d, 11, 1H, H^E), 6.55 (s, 1H, –C≡CH), 7.56 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.63 (s, 3H, CH_3), 7.98 (s, 3H, CH_3), and 8.01 (t, 8, 3H, $-CH_2C\underline{H}_3$). Found:

C, 82.68; H, 8.29%. Calcd for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

*8-Ethyl-3,13-dimethyl-3,5,8,10,12-pentadecapentaene-1,14-diyn-7-one (**11**).* A solution of ethanolic sodium ethoxide (2.4 ml) [from sodium (760 mg) and absolute ethanol (50 ml)] was added to a solution of ketone **9** (1.0 g, 5.3 mmol) in deoxygenated ether (47 ml), and a solution of aldehyde **10**[3] (1.0 g, 11 mmol) in deoxygenated ether (16 ml) was then added dropwise during 15 min with stirring and ice-bath cooling. After stirring for a further 14.5 h at room temperature, the reaction was quenched by addition of aqueous oxalic acid. The mixture was poured into water, and extracted with benzene. After working up as in the preparation of **8**, the semi-solid obtained after removal of the solvent was chromatographed on alumina (100 g). The early fractions gave the recovered ketone **9** (438 mg). The following fractions eluted with hexane–ether (4:1) gave ketone **11** (498 mg, 36%). Recrystallization from hexane–benzene afforded brown needles: mp 92—93 °C; MS, *m/e*, 264 (M^+, 100%); mol wt 264.3; IR (KBr disk) 3250 (–C≡CH), 2100 (–C≡C–), 1640 (C=O), 1580 (C=C), and 985 cm^{-1} (*trans* C=C); UV_{max} (ether) 233 sh (12600), 250 sh (18500), 260 sh (22400), 275 sh (26600), 287 (29900), 299 (29300), 342 sh (44900), 358 (50100), and 375 nm sh (43800); NMR τ=2.25 (dd, 15, 12, 1H, H^B), 2.85 (d, 12, 1H, $H^{B'}$), 2.93 (dd, 15, 12, 1H, $H^{C'}$), 3.15 (d, 15, 1H, H^A), 3.35 (dd, 15, 12, 1H, $H^{D'}$), 3.50 (d, 12, 2H, H^C and $H^{E'}$), 6.53 (s, 1H, –C≡CH), 6.60 (S, 1H, –C≡CH), 7.47 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.97 (s, 6H, CH_3), and 8.97 (t, 8, $-CH_2C\underline{H}_3$).

Crystals of **11** decomposed rapidly on exposure to diffused light and air at room temperature. Compound **11** gave unsatisfactory results of elemental analysis, which seems attributable to its instability. Found: C, 85.64; H, 7.35%. Calcd for $C_{19}H_{20}O$: C, 86.32; H, 7.63%.

*15-Ethyl-5,10-dimethyl-6,8-bisdehydro[15]annulenone (**5**).* A solution of ketone **11** (370 mg, 1.4 mmol) in pyridine–dry ether (3:1, 32 ml) was added dropwise during 2.5 h to a stirred solution of anhydrous copper(II) acetate (1.8 g) in pyridine–dry ether (3:1, 64 ml) at 48—50 °C. The solution was stirred at 49—51 °C for a further 30 min and then cooled. After working up as in the preparation of **4**, the semi-solid obtained after removal of the solvent was chromatographed on alumina (70 g). The fractions eluted with hexane–ether (3:1—2:3) gave annulenone **5** (124 mg, 34%) as a yellow liquid. Crystallization from hexane–benzene afforded orange cubes: mp 97—98 °C; MS, *m/e*, 262 (M^+, 25%) and 203 (100); mol wt 262.3; IR (KBr disk) 2150, 2100 (–C≡C–), 1620 (C=O), 1590 (C=C), 1000, and 970 cm^{-1} (*trans* C=C); UV, see Tables 1 and 2; NMR τ=2.73 (d, 11, 1H, H^C), 2.82 (dd, 16, 11, 1H, $H^{C'}$), 2.90 (d, 11, 1H, $H^{E'}$), 3.30 (d, 16, 1H, H^A), 4.38 (dd, 16, 11, 1H, H^B), 4.58 (d, 11, 1H, $H^{B'}$), 4.62 (dd, 16, 11, 1H, $H^{D'}$), 7.42 (q, 8, 2H, $-C\underline{H}_2CH_3$), 7.80 (s, 3H, CH_3), 7.92 (s, 3H, CH_3), and 9.00 (t, 8, 3H, $-CH_2C\underline{H}_3$), and see Fig. 1; NMR (CF_3COOD, determined with CH_2Cl_2 as an internal standard) τ=1.23 (dd, 15, 11, 1H, $H^{C'}$), 1.30 (d, 11, 2H, H^C and $H^{E'}$), 1.60 (d, 15, 1H, H^A), 6.60 (q, 8, 2H, $-C\underline{H}_2CH_3$), 6.93 (s, 3H, CH_3), 7.07 (s, 3H, CH_3), 8.02 (d, 11, 1H, $H^{B'}$), 8.46 (dd, 15, 11, 1H, H^B), 8.50 (t, 8, 3H, $-CH_2C\underline{H}_3$), and 8.83 (dd, 15, 11, 1H, $H^{D'}$), and see Fig. 2. Found: C, 87.18; H, 6.82%. Calcd for $C_{19}H_{18}O$: C, 86.98; H, 6.91%.

Reduction by a Model of NAD(P)H. 32. Stereoselective Reduction of Camphoroquinone by a Chiral NAD(P)H Model

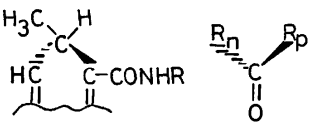
Atsuyoshi Ohno,* Takehiko Goto, Jun-ichi Nakai, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received March 9, 1981)

(+)-, (−)-, and racemic camphoroquinones (CQ) were reduced by each of four NAD(P)H-models such as *N*-(α-methylbenzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2PNPH) in the presence of magnesium ion in acetonitrile with a view to elucidating the intermolecular arrangement in the transition state for asymmetric reduction. Partial rate factors for each attacking mode were calculated. Electronegative substituents in the substrate prefer to facing the carbamoyl group in Me_2PNPH, which is the most important factor determining the stereochemical course of the reduction. 1-Methyl group in CQ has a tendency to interfere with the dihydropyridine moiety in Me_2PNPH approaching the C_2-carbonyl group in CQ. This interference is more important for the selectivity than the intrinsic *exo*/*endo* reactivity difference.

Quite a few organic chemists have tried to design their reactions after the model of biochemical transformations which exhibit too high reactivity and stereospecificity. Dihydropyridine nucleotides, NADH and NADPH, are coenzymes of NAD(P)H-dependent dehydrogenases that reduce carbonyl and other unsaturated compounds stereospecifically in almost all organisms. Hence, for bioorganic chemists, reduction by models of NAD(P)H has been an interesting subject to study. In the course of our study on the biomimetic chemistry of NAD(P)H, we have found that bivalent metal ions such as Mg^{2+} and Zn^{2+} affect reduction of carbonyl compounds by models of NAD(P)H.[1-9] A series of investigations has revealed that the reduction is composed of a three-step electron-proton-electron transfer process and that the bivalent metal ion catalyzes the process of initial electron-transfer.[3,6,9,10]

The bivalent metal ions also control stereospecificity of the reduction.[1,2,11-15] For example, reduction of certain carbonyl compounds with *N*-(α-methyl benzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2PNPH) in the presence of magnesium ion results in an excellent asymmetric induction.[15] The configuration of predominant enantiomer of product alcohol is determined from the configuration of the C_4-position of Me_2PNPH. On an assumption that the carbonyl-oxygen in a substrate points toward the ring-nitrogen of Me_2PNPH, it has been proposed that an electronegative polar group in a substrate faces the electronegative carbamoyl group in Me_2PNPH in the transition state for reduction (**1**) and that the relative



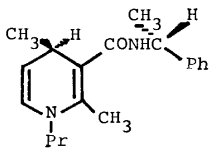
1

R_p: polar substituent
R_n: nonpolar substituent

bulkiness of substituents R_n and R_p plays no important role in determining the configuration of product alcohol.[15] The proposal that two electronegative groups face each other contradicts to a common idea of electronic effect. However, when it gets proved to be correct, it may suggest that the magnesium ion positions itself between the substrate and Me_2PNPH by coordinating two electronegative groups to freeze the intermolecular configuration in the transition state, as an origin of the stereospecificity of the magnesium ion-catalyzed reduction. Thus, it is important, for understanding the role of magnesium ion in the reduction, to get information about the intermolecular arrangement in the transition state for the reduction; for this reason we studied the reduction of 1,7,7-trimethylbicyclo[2.2.1]heptane-2,3-dione (camphoroquinone, CQ) with Me_2PNPH. CQ has two carbonyl groups constrained in a rigid framework, and the oxygen atom in the reacting carbonyl group will be caused to point toward the ring-nitrogen of Me_2PNPH in the transition state because of the large steric effect.

Results

(−)-CQ, (+)-CQ, and (±)-CQ were reduced by (4*R*)-N-[(*R*)-α-methylbenzyl]-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (*RR*-Me_2PNPH), *SS*-Me_2-PNPH, [(*R*)-α-methylbenzyl]-1-propyl-1,4-dihydronicotinamide (*R*-PNPH), 1-propyl-1,4-dihydronicotinamide (PNAH), or 1-benzyl-1,4-dihydronicotinamide (BNAH). All reactions were carried out in dry acetonitrile in the presence of magnesium ion in equivalent amount at room temperature under an argon atmosphere in the dark. The reduction did not proceed without magnesium ion. (−)-CQ afforded a mixture of diastereomeric isomers of four α-keto



RR-Me_2PNPH

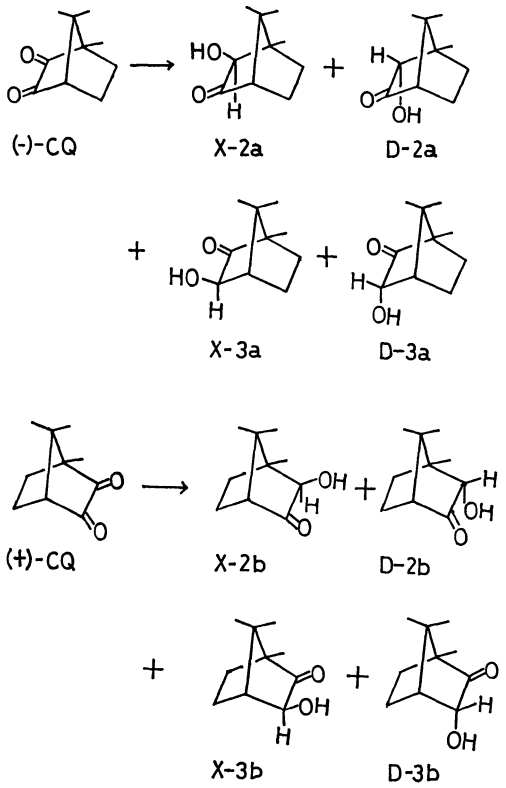
R = $PhCH_2$: BNAH

alcohols: (2*S*)-2-*exo*-hydroxy-1,7,7-trimethylbicyclo-[2.2.1]heptan-3-one (2*S*-*exo*-hydroxyepicamphor, *X*-**2a**), (2*R*)-2-*endo*-hydroxy-1,7,7-trimethylbicyclo[2.2.1]-heptan-3-one (2*R*-*endo*-hydroxyepicamphor, *D*-**2a**), (3*R*)-3-*exo*-hydroxy-1,7,7-trimethylbicyclo[2.2.1]heptan-2-on (3*R*-*exo*-hydroxycamphor, *X*-**3a**), and (3*S*)-*endo*-hydroxy-1,7,7-trimethylbicyclo[2.2.1]heptan-2-one(3*S*-*endo*-hydroxycamphor, *D*-**3a**), whereas (+)-CQ afforded a mixture of their corresponding enantiomeric isomers *X*-**2b**, *D*-**2b**, *X*-**3b**, and *D*-**3b** (Scheme 1).

Structures and relative yields of products were determined on the basis of ^{1}H-NMR spectra.[16] Results for the reductions with BNAH, PNAH, and *R*-PNPH are summarized in Table 1 and those with Me_2PNPH in Table 2. It was confirmed that no isomerization took place between isomeric products.



Scheme 1.

Discussion

CQ has two prochiral carbonyl groups and it is potentially possible that four isomers are to be formed as reduction products. Since these carbonyl groups are frozen to the *Z*-configuration on a rigid hydrocarbon framework which has diastereotopic faces, the ratio of the yields of these isomers reflects the configurational requirement for the carbonyl group in the transition state for the reduction. The results in Table 1 indicate that the *exo*-C_3-attack (see Scheme 2) is the most preferential process in the reduction with such models as have two available hydrogens on the C_4-position, whereas the other modes of attack

appear to have no practical predominance. The chirality of the side chain of *R*-PNPH plays no important role in determining the stereochemistry of the product. The observation reveals that the stereochemistry of the reduction depends on the structural preference of substrate and that no enantiotopic difference for the dihydropyridine ring has any effect. It should be noted that it is the C_1-methyl group that makes the C_3-attack preferential to the C_2-attack. Although not yet given any reasonable explanations, this methyl group plays an important role in determining the intermolecular arrangement in the transition state for the reduction, for which mention will be made later.

Contrary to the above, the stereochemistry of the reduction with Me_2PNPH mainly reflects the configuration of this model compound, the intrinsic reactivity of each position in CQ having only a minor influence. Validity of the product ratios listed in Table 2 is supported by the fact that identical results have been obtained from the following two pairs of reactants essentially the same with each other in composition: (−)-CQ and *RR*-Me_2PNPH *vs.* (+)-CQ and *SS*-Me_2PNPH; and (−)-CQ and *SS*-Me_2PNPH *vs.* (+)-CQ and *RR*-Me_2PNPH. Since the plane of dihydropyridine-ring in Me_2PNPH is not enantiotopic but diastereotopic, these results can be interpreted only on the basis of such an idea that CQ and Me_2PNPH have a preference for the orientation of substituents in the transition state for the reduction.

Before discussing the orientation, it is helpful to evaluate partial rate factors with all the reaction modes for (−)- and (+)-CQ; this evaluation may be effected by solving linear simultaneous equations for eight variables (eight reaction modes) by using the data listed in Table 2. The result is shown in Table 3. First of all, the calculated values predict that the susceptibility of (−)-CQ toward reduction with *SS*-Me_2PNPH will be 66/34 times greater than that of (+)-CQ. This prediction was in excellent agreement with an experimental result that, after the reaction with racemic CQ, the recovered CQ was subjected to a measurement for optical rotation $[\alpha]_D$ and a ratio 61/39 of consumed CQ's was obtained.

The most preferable mode of attack is *exo*-C_3 for (−)-CQ. In this mode the carbamoyl moiety in *SS*-Me_2PNPH will face the electron-rich carbonyl group of the substrate. It is interesting that for (+)-CQ the second preferable mode is not *exo*-C_2 but *endo*-C_3. Although, as already mentioned, CQ has a higher intrinsic reactivity for the *exo*-attack than for the *endo*-attack, the presence of the C_1-methyl group prevents so much the reaction of (+)-CQ from preceding in this mode that even the less realizable *endo*-attack is chosen. Thus, the effect of the methyl group overwhelms the *exo*/*endo* reactivity difference. Alcohol *D*-**2b** is one of the least abundant products. A similar result has been obtained in our laboratory for reductions of a series of 2-pyridyl alkyl ketones.[17]

Table 3. Partial rate factors in the reduction of (−)- and (+)-camphoroquinone with (4*S*)-*N*-[(*S*)-α-methylbenzyl]-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (*SS*-Me_2PNPH)

Obsd[a]		0.61	0.39

a) See text.

Two explanations are feasible for this phenomenon: it is established that magnesium ion will interact with non-reacting electron-rich substituents of substrates.[8] Since the methyl group is an electron-releasing group, the carbonyl-oxygen on C_2 becomes more electron-rich than the one on C_3. Consequently, the carbonyl-oxygen on C_2 becomes the coordinating site, with the carbonyl group on C_3 remaining as the reacting moiety. The other possibility is that the steric effect of 1-methyl group prevents the approach of the dihydropyridine moiety of Me_2PNPH. Although no investigations with CPK-molecular models have predicted such an effect, the orientation of methyl group seems quite important, if this is the case, because none of such effects have been recognized for the *endo*-attack.

For concluding the discussion, we would like to emphasize that the intermolecular arrangement in the transition state for the reduction has proved to be such as shown in **1**, with polar groups facing each other, possibly because the magnesium ion assists their approach by getting into coordination with these groups.

Experimental

Melting points were not corrected. ^{1}H-NMR spectra were recorded on a JNM-FX100 spectrometer. Optical rotation was observed on a Perkin-Elmer 241 polarimeter.

Materials. Racemic camphoroquinone purchased from Aldrich Chemical Co. was recrystallized from hexane: mp 199 °C.

Anhydrous magnesium perchlorate was dried at 80 °C overnight and used immediately. Acetonitrile was distilled three times over phosphorus pentaoxide before use.

(−)- and (+)-Camphoroquinone (CQ). The Evans' procedure[18] with modifications was employed as follows. A mixture of (+)-camphor (10 g, 0.07 mol) and selenium dioxide (15 g, 0.14 mol) in 10 cm^3 of acetic anhydride was heated at 150 °C overnight. After the mixture had been cooled to room temperature, selenium metal was removed from the mixture by filtration and the metal was washed with acetic acid. The combined orange-yellow filtrate was neutralized carefully with a 30% aqueous potassium hydroxide. Yellow crystals appeared, which were filtered and washed with water to yield 10 g (93% yield) of (−)-CQ. The crude (−)-CQ thus obtained was recrystallized several times from hexane: mp 199 °C (lit,[18] mp 199 °C); $[\alpha]_D^{27}$ −108° (c=1.93, benzene) (lit,[16] $[\alpha]_D^{23}$ −122±3° (c=1.825, benzene)).

(+)-CQ was prepared by the same method: mp 199 °C; $[\alpha]_D^{20}$ +105° (c=1.96, benzene).

Models of NAD(P)H. The methods of preparation adopted for BNAH,[19] PNAH,[19] *R*-PNPH,[12] and Me_2PNPH[15] have already been described in literature.

General Procedure. To a mixture of a substrate, a model compound, and magnesium perchlorate, each of 1 mmol, in a flask filled with argon and sealed, 20 cm^3 of dry acetonitrile was added through a syringe. The mixture was allowed to react at room temperature for an appropriate period with stirring in the dark. The reaction was quenched by addition of 10 cm^3 of water and the solution was concentrated *in vacuo* below 30 °C. The organic materials were extracted with chloroform several times and the solvent was evaporated slowly from the extract *in vacuo* below 30 °C. Ample caution was exercised so as not to cause the materials to sublime. The residue was chromatographed on a column of silica gel (Wakogel 200 M) with benzene–ether (4:1 v/v) as eluent, affording unchanged CQ and a mixture of reduction products. The mixture and the recovered CQ were weighed to obtain their yields. An analysis of ^{1}H-NMR spectra of the products in $CDCl_3$ led to the assignment of a mixture of four isomeric α-keto alcohols *X*-**2**, *D*-**2**, *X*-**3**, and *D*-**3**:[16] δ=3.55 s, 1H for *X*-**2**), 3.75 (s, 1H for *X*-**3**), 3.87 (s, 1H for *D*-**2**), and 4.22 (s, 1H for *D*-**3**). Relative yields of these four isomeric products were obtained from the peak areas for each.

Optical rotation observed for the recovered (±)-CQ was $[\alpha]_D^{20}$ +22.4 (c=1.935, benzene), indicating that the mixture was composed of 61% (−)-CQ and 39% (+)-CQ.

Conversion of Physical Unit. The unit used for temperature is correlated with the SI-unit by

$$t/°C = T/K - 273.15.$$

Reduction by a Model of NAD(P)H. 33. Steric and Electronic Effects on Asymmetric Reduction of 2-Acylpyridines

Atsuyoshi Ohno,* Jun-ichi Nakai, Kaoru Nakamura,
Takehiko Goto, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received March 26, 1981)

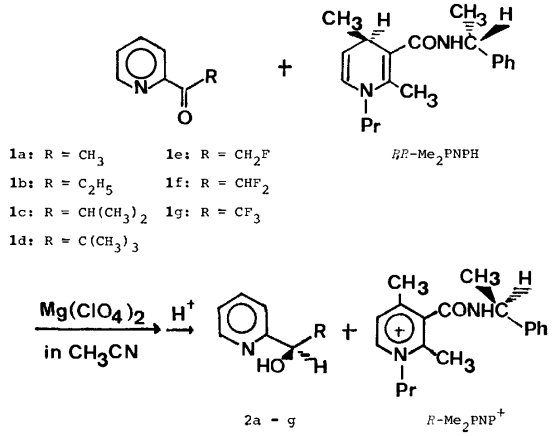
Series of alkyl and fluorinated alkyl 2-pyridinyl ketones have been reduced by a chiral NAD(P)H-model (Me_2PNPH) in the presence of magnesium ion in acetonitrile. Optical yield decreases in the order of substituent: $CH_3 > C_2H_5 > C(CH_3)_3 > CH(CH_3)_2$ and $CH_3 > CH_2F > CHF_2 > CF_3$. The results have been interpreted in terms of conformation of the substrates for alkyl 2-pyridinyl ketones and of electronic competitional effect between two substituents for fluorinated alkyl 2-pyridinyl ketones. Magnesium ion freezes intermolecular arrangement at the transition state of the reduction.

Chiral *N*-(α-methylbenzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2PNPH) reduces certain ketones in the presence of magnesium ion in acetonitrile resulting in excellent chemical and optical yields.[1] Conformation of the product from the reaction reveals that the carbonyl-oxygen in a substrate points toward the ring-nitrogen of Me_2PNPH and the polar (electronegative) substituent in the ketone faces against the (electronegative) carbamoyl group of Me_2PNPH.[2] Relative bulk of substituent on the carbonyl group in a substrate seems to have little influence on intermolecular arrangement at the transition state of the reduction. Namely, the pyridinyl moiety behaves as a polar substituent in the reduction of 2-acetylpyridine, whereas trifluoromethyl group is a polar substituent in the reduction of α,α,α-trifluoroacetophenone. The stereospecificity of the reduction is so excellent that it is interesting to obtain further insight into the factor(s) that is operating to determine the stereochemical course of the reduction. Evidence obtained from the study may provide an information on the mechanism of stereochemical transformation.

In this paper, we wish to report results from the reduction of series of 2-acylpyridines and α-fluorinated 2-acylpyridines.

Results

2-Acylpyridines (**1a—d**) and α-fluorinated 2-acylpyridines (**1e—g**) were reduced to the corresponding alcohol by *RR*-Me_2PNPH in the presence of equivalent amount of magnesium perchlorate in dry acetonitrile at room temperature in the dark. Chemical yields and conversion percentages are listed in Table 1. For the products **2a** and **2b**, enantiomer excess was calculated from their observed optical rotations, whereas those for the other products were calculated from their ^1H- and ^{19}F-NMR spectra by the aid of α-methoxy-α-trifluoromethylphenylacetic acid (MTPA).[3] Absolute configurations of the products were elucidated independently from their signs of optical rotations and CD spectra as well as chemical shifts in NMR spectra of the corresponding MTPA esters. Results are summarized in Table 2.



Complexation constants, *K*, for complexes of 2-acylpyridines and magnesium ion were measured spectrophotometrically,[4] and the results are listed in Table 3.

It has been confirmed that C_4-hydrogen in Me_2PNPH is transferred onto the carbonyl-carbon in a substrate without exchange and that the chirality on the carbamoyl-side chain exerts no influence on the stereochemical course of the reduction in the presence of

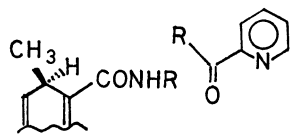
magnesium ion.[1)]

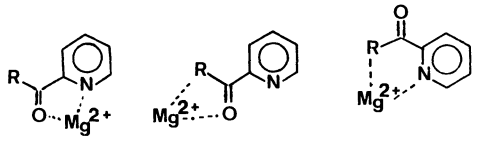
Discussion

α-Fluorinated 2-Acylpyridines. Configurations of alcohols **2a** and **2e—g** reveals that, regardless the number of fluorine atom, the pyridinyl moiety in the ketone faces against carbamoyl group in Me_2PNPH at the transition state of the reduction as depicted by **3**. However, the stereospecificity is largely affected



3

by the number of fluorine-substituent. The result can be accounted for by the difference in electronegativity of substituents on the carbonyl group: as the number of fluorine atom in the substituent R increases, the difference in electron-withdrawing ability between R and pyridinyl group becomes smaller and recognition of polarity-difference becomes difficult. Consequently, magnesium ion can coordinate onto both pyridinyl and fluorinated alkyl groups (See structures **4a—c**).



4a 4b 4c

Note that trifluoromethyl group is the coordination-site in the reduction of α,α,α-trifluoroacetophenone and that complexation constants for **1e**, **1f**, and **1g** are too small to be measured with a reasonable accuracy. The latter evidence indicates that the pyridinyl-nitrogen has no lone-electron pair available for the coordination at least at the ground state of these ketones.

2-Acylpyridines. According to the structure **3**, the substituent R faces against the open-side of Me_2PNPH. Nevertheless, the increase in bulk of R results in the decrease in the stereospecificity of the reduction. The substrate **1c** exerts an abnormal stereospecificity. It is obvious that relative bulk of the substituents cannot account for the result.

Previously we suggested that the change in complexation constant is due to the distortion of dihedral angle between the planes of pyridinyl and acyl groups.[4)] Free 2-acylpyridine in a solution exists with the conformation in which pyridinyl-nitrogen and carbonyl-oxygen sit themselves in the *E*-form.[5)] On the other hand, ^{13}C-NMR, IR, and other spectroscopic studies have revealed that some 2-acylpyridines serve as bidentate ligands that coordinate onto a bivalent metal ion with the nitrogen and oxygen being in the *Z*-form.[6-8)] 2-Acetyl- (**1a**) and 2-propionyl- (**1b**) pyridines are 2-acylpyridines of this kind (Fig. 1a). A large complexation constant suggests that the conformation of the complex is rigid. In these 2-acylpyridines, steric repulsion between the substituent R and pyridinyl-hydrogen on C_3 is negligibly small.

An inspection with a CPK-model, however, suggests that the *t*-butyl group in **1d** is so bulky that the dihedral angle in a stable conformation of complexed **1d** should be about 90° (Fig. 1b). The conformation shown in Fig. 1b′ has extremely high steric strain because of Mg^{2+}–Bu^t repulsion. Small complexation constant for this compound supports the idea that **1d** is no more a bidentate ligand to magnesium ion. Although magnesium ion cannot behave as a fixer

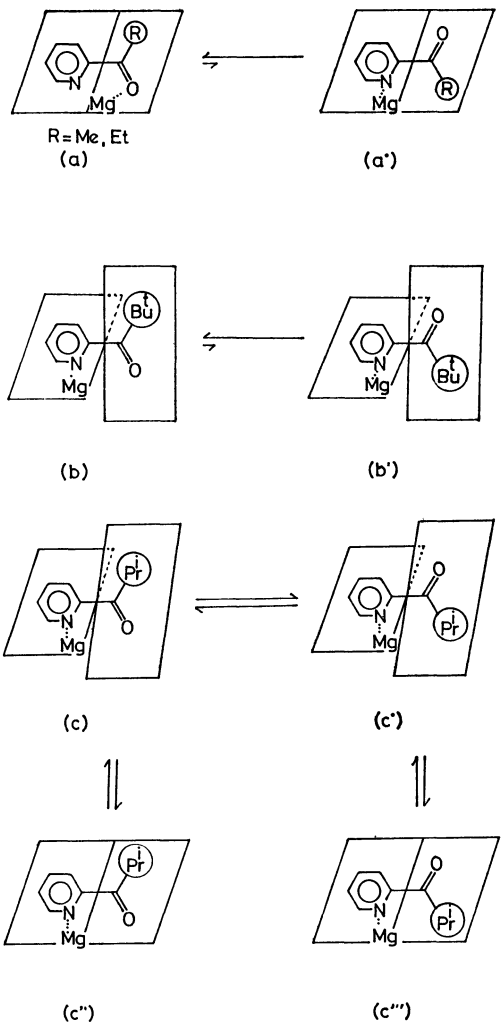


Fig. 1. Conformations of (a) 2-acetyl- and 2-propionylpyridines, (b) 2-pivaloylpyridine, and (c) 2-isobutyrylpyridine in the complex with magnesium ion.

of conformation of **1d**, the steric bulk of *t*-butyl group itself freezes the conformation intrinsically resulting in relatively satisfactory stereospecificity.

The situation is different in **1c**. The steric bulk of 2-propyl group is too large to set two planes coplanar, but it is not large enough to freeze the conformation. Stabilization energy by bidentate coordination onto magnesium ion is not so large as those for **1a** and **1b** but larger than that for **1d**, as seen in the magnitude of complexation constant. Therefore, all four possible rotomers (Fig. 1c) are available as a part of the transition-state complex of the reduction with **1c**, and net result appears non-stereospecific.

Role of Magnesium Ion. The substituent effect on the stereospecificity described above coincide with the idea proposed previously[1,2] that stereospecificity of the reduction is mainly defined by electronic effect. The steric effect has only secondary importance, if any, to define intermolecular arrangement at the transition state of the reduction. However, steric bulk of a substituent in a substrate exerts intrinsic effect on the conformation of the substrate.

Magnesium ion-catalysis for the stereospecificity has an origin in tetradentate sandwich-type coordination to freeze the configuration of transition-state complex (Fig. 2): dihydropyridinyl-nitrogen and carbamoyl-oxygen in Me_2PNPH on one side and pyridinyl-nitrogen or other electronegative substituent and carbonyl-oxygen in a substrate on the other side.[9]

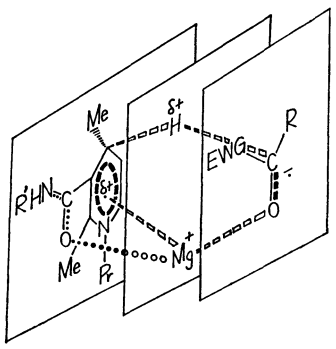

Fig. 2. Schematic illustration of the transition state of the reduction.

Experimental

Instruments. UV, IR, NMR, and mass spectra were recorded on Union Giken SM-401, Hitachi EPI-S2, JEOL JNMFX-100, and JEOL JMSO-1SG or Hewlett Packard 5992B GC/MS spectrometers, respectively. The optical activity was measured on a Perkin-Elmer 241 polarimeter. The CD spectra were obtained with a JASCO J-20 spectropolarimeter. A Yanaco G-1800F and Varian Aerograph Model 920 were used for VPC, and a Yanaco Model L-2000 was used for high-pressure liquid chromatography. Melting and boiling points were not corrected.

Materials. Acetonitrile was distilled three times over phosphorus pentaoxide and stored over 4A molecular sieves under an atmosphere of argon. Anhydrous magnesium perchlorate was dried at 100 °C and stored in a vacuum desiccator over phosphorus pentaoxide. 2-Acetylpyridine (**1a**) (bp 95 °C/34 mmHg) was purchased from Nakarai Chem. Co.

2-Propionylpyridine (**1b**) (bp 96.5—97.5 °C/20 mmHg),

a) δ from TMS in $CDCl_3$. b) δ from CCl_3F in $CDCl_3$.

2-isobutyrylpyridine (**1c**) (bp 99.0—100.0 °C/19 mmHg), and 2-pivaloylpyridine (**1d**) (bp 100.5—101.5 °C/20 mmHg) were prepared from the corresponding alkyl cyanides and 2-pyridinyllithium.[10] 2-(Fluoroacetyl)pyridine (**1e**) (mp 70.0—71.0 °C), 2-(difluoroacetyl)pyridine (**1f**) (purified on a silica-gel column), 2-(trifluoroacetyl)pyridine (**1g**) (mp 84.0—85.0 °C) were synthesized from the corresponding esters and 2-pyridinyllithium.[11] Elemental analyses and spectral data were satisfactory for all materials. Racemic alcohols as authentic samples of the products were obtained by reducing the corresponding ketones with sodium borohydride.[12]

General Procedure for the Reduction. One millimole each of *RR*-Me_2PNPH and magnesium perchlorate were dissolved in 25 ml of anhydrous acetonitrile in a sealed flask. One millimole of the substrate in 5 ml of anhydrous acetonitrile was added by injection by using a syringe, and the mixture was allowed to react at room temperature (about 25 °C) for an appropriate reaction time in the dark in an argon atmosphere. The reaction was stopped by the addition of water, and the product was extracted three times with dichloromethane. The combined dichloromethane solution was dried over sodium sulfate. After evaporation of the solvent at below 30 °C under reduced pressure, the residue was chromatographed on a column of silica gel. The product was further purified by preparative VPC or high-pressure liquid chromatography when neccesary. The purity of the product was confirmed by VPC and by elemental analyses. Columns used for VPC were mainly Silicone DC 200 5% (1 m) and DEGS 10% (1 m). Appropriate mixtures of benzene–ethyl acetate or benzene–ether were employed as the eluents for column chromatography. Thus obtained products were subjected for the measurement of optical rotations or converted into the corresponding MTPA esters for NMR spectroscopy. Optical rotations of the products and NMR chemical shifts of the corresponding esters are summarized in Tables 4 and 5, respectively.

Correlation of Physical Units. Physical units used in this report are correlated with SI-units by the following relationship.

1 M=1 mol dm^{-3}, $t/°C = T/K - 273.15$, p mmHg$=13.5951 \times 980.665 \times 10^{-2} p$ Pa.

Reduction by a Model of NAD(P)H. 34. Substituent Effect on Asymmetric Reduction of Trifluoroacetophenones

Atsuyoshi Ohno,* Jun-ichi Nakai, Kaoru Nakamura,
Takehiko Goto, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received March 26, 1981)

Substituted and unsubstituted α,α,α-trifluoroacetophenones were reduced by a chiral NAD(P)H-model (*RR*-Me_2PNPH). Both electron-releasing and -withdrawing substituents give better optical yields than unsubstitued compound. The result has been interpreted in terms of three-step mechanism which involves initial electron-transfer process.

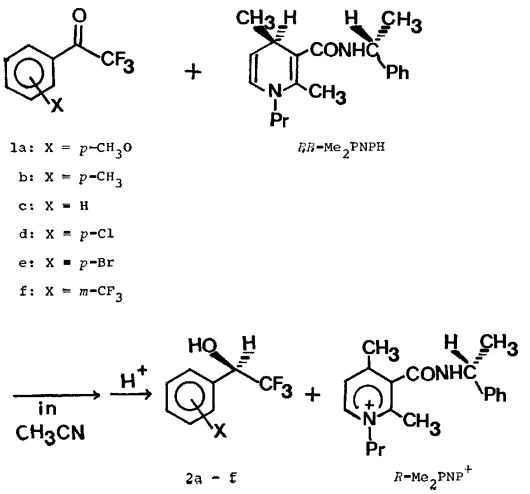
Kinetics, isotope effects, and other evidence have proved that the reduction of certain ketones by 1,4-dihydronicotinamide derivatives proceeds through three-step electron-proton-electron transfer processes.[1] Magnesium ion catalyzes the reduction by assisting the initial electron-transfer process.

On the other hand, it has been demonstrated that the reduction proceeds with excellent stereospecificity when a chiral 1,4-dihydronicotinamide derivative is used as a reductant.[2] Stereospecificity is also catalyzed by magnesium ion. Namely, substituted and unsubstituted α,α,α-trifluoroacetophenones are reduced by a chiral *N*-(α-methylbenzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2PNPH) in more than 90% enantiomer excess in the presence of magnesium ion.[2] Magnesium ion plays a role to freeze the conformation of transition state complex,[3] and electronic substituent effect is more important than the steric effect to difine the stereochemical course.[3,4]

We have been interested in to study whether the reduction of a series of α,α,α-trifluoroacetophenones without magnesium ion results in variation of enantiomer excess due to electronic substituent effect and whether the stereochemical result can be explained by the proposed three-step mechanism without contradiction.

Results

α,α,α-Trifluoroacetophenone and its *p*-methoxy, *p*-methyl, *p*-chloro, *p*-bromo, and *m*-trifluoromethyl derivatives were reduced by *RR*-Me_2PNPH in dry acetonitrile at room temperature in the dark.



The enantiomer excess in the product alcohols (**2**) and their absolute configurations were determined on ^{1}H- and ^{19}F-NMR spectroscopies[5] as well as by VPC (15% BDS, 1 m) after the alcohols were converted into their corresponding α-methoxy-α-trifluoromethylphenylacetic acid (MTPA) esters. Chemical yield, conversion percentage, enantiomer excess, and the configuration of the product are summarized in Table 1. In Fig. 1 logarithms of the isomer ratios are plotted against Hammett σ-values for the substituent.

Discussion

Both electron-releasing and -withdrawing substituents increase the stereospecificity of the reduction. The

result cannot be accounted for by simple steric or electronic substituent effect in a unit reaction.

However, the multi-step mechanism with an initial electron-transfer process explains the variation of stereospecificity. An electron-releasing substituent reduces the electron-affinity of a substrate and the electron-transfer to a substrate of this sort requires high activation energy as shown in Fig. 2a. In this category, only a substrate which has proper intermolecular arrangement can form an electron-transfer complex with Me_2PNPH. Since the intermediate electron-transfer complex is an unstable species, the following proton-transfer step proceeds almost spontaneously. That is, the stereochemistry of the net reduction is defined kinetically in the process of initial electron-transfer.

The selectivity-reactivity relationship[6] predicts that the less the electron-releasing power of a substituent on the substrate, or the less the activation energy for the electron-transfer process, the less the difference in energy between preferred and other conformations (Fig. 2b). Consequently, the reduction becomes less stereospecific.

With a strongly electron-withdrawing substituent on a substrate, on the other hand, the electron-transfer takes place quite rapidly and the intermediate electron-transfer complex becomes more stable than the reactant system (Fig. 2c). The preferential course of reduction in this category is, therefore, controlled by thermodynamic stability of the intermediate. It is noteworthy that the reaction mixture with **1d**, **1e**, or **1f** turned dark green during the reaction and the color disappered at the end of the reaction. The color change suggests the formation of a stable long-living intermediate. Thus, stereochemical course of the reduction is determined by the complex-forming process. When the complex is unstable, stereochemistry is controlled kinetically, whereas when the complex is stable, thermodynamics controls the course. Since magnesium ion catalyzes the electron-transfer process, stereochemistry of the reduction in the presence of magnesium ion is controlled thermodynamically yielding quite high enantiomer excess.[2]

The energy diagrams shown in Fig. 2 are the same as those proposed previously. In conclusion, we would like to emphasize that not only kinetic bihavior but

also stereochemical result can be explained by the three-step reduction mechanism which proposes initial electron-transfer step as the driving force of the reduction.

Experimental

Instruments and general procedure for the reduction were described in a previous paper.[1,3] Melting and boiling points were not corrected.

Materials. Me_2PNPH,[2] acetonitrile,[1,3] and magnesium perchlorate[1,3] were prepared or purified as described before.

p-Methoxy- (**1a**) (bp 114—115 °C/20 mmHg),[7] *p*-methyl- (**1b**) (bp 77.5—78 °C/20 mmHg),[7] unsubstituted (**1c**) (150 °C/760 mmHg),[7] *p*-chloro- (**1d**) (81 °C/20 mmHg),[8] *p*-bromo- (**1e**) (95 °C/4 mmHg),[9] and *m*-trifluoromethyl-α,α,α-trifluoroacetophenone (**1f**) (77 °C/50 mmHg)[1] were synthesized according to the literature procedures.

Configurational Analyses of Products. Optical rotations of the product alcohols are listed in Table 2. Results of VPC-analyses and chemical shifts in ^1H- and ^{19}F-NMR spectra of MTPA esters of the alcohols are summarized in Tables 3 and 4, respectively.

Correlation of Physical Units. Physical units used in this report are correlated with SI-units by the following relationship.

1 M=1 mol dm^{-3}, $t/°C = T/K - 273.15$, p mmHg = $13.5951 \times 980.665 \times 10^{-2}$ p Pa.

Reduction by a Model of NAD(P)H. 35. Spectroscopic Detection of Charge-transfer Intermediate

Atsuyoshi Ohno,* Hiroyuki Yamamoto, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received March 26, 1981)

4,4-Disubstituted 1,4-dihydropyridine derivatives are employed as models of NAD(P)H. Electronic and ESR spectroscopies have proved that these models form charge-transfer complexes with certain substrates, which supports a mechanism of the reduction with 1,4-dihydronicotinamide derivatives to be initiated by initial electron-transfer.

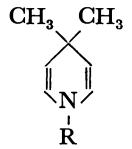
It has been proposed that the reduction of an unsaturated compound with an NAD(P)H-model involves at least one intermediate.[1-3] The nature of the intermediate has been discussed, but direct evidence has scarcely reported.[2,4,5]

Recently, we reported that results from the studies on kinetics and isotope effects for the reduction of a series of substituted and unsubstituted α,α,α-trifluoroacetophenone with 1-propyl-1,4-dihydronicotinamide revealed the importance of initial electron-transfer.[3] Stereochemistry of the reduction with a chiral model compound also supported the proposed mechanism.[6] However, since the intermediate undergoes further reaction spontaneously, it is not easy to detect it. Only when the intermediate becomes thermodynamically more stable than the reactant system, the detection has been succeeded.[2,4,5]

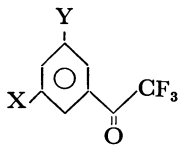
In order to obtain direct evidence for an unstable intermediate, we studied electronic and ESR spectroscopies by the aid of model compounds that have no C_4-hydrogen.

Results

1-Propyl-4,4-dimethyl-1,4-dihydropyridine (**1a**) and 1-phenyl-4,4-dimethyl-1,4-dihydropyridine (**1b**) were employed as reductants.



1a: R=C_3H_7
1b: R=C_6H_5



2a: X=H, Y=Br
2b: X=H, Y=CF_3
2c: X=H, Y=NO_2
2d: X=CF_3, Y=NO_2

Electronic Spectra. To test the formation of a stable charge-transfer (CT) complex with **1a** or **1b**, strongly electron-demanding substrates such as TCNQ, *N*-methylacridinium iodide, and 1,3,5-trinitrobenzene were used for the spectroscopy. Note that these substrates are known to form stable intermediates with an ordinary NAD(P)H-model which has a C_4-hydrogen.[2,3,7,8] When, TCNQ was mixed with **1a** in anhydrous acetonitrile at 50 °C, the solution turned green and exhibited a spectrum with absorption maxima at 746, 764, 825, and 846 nm as shown in Fig. 1. The complexation constant was measured to be 116 M^{-1}. The spectrum is identical to those reported previously.[9,10] 1,3,5-Trinitrobenzene (Fig. 2)[11] and *N*-methylacridinium iodide (Fig. 3)[2] also showed CT-bands when they were mixed with **1b** in acetonitrile.

m-Bromo- (**2a**), *m*-trifluoromethyl- (**2b**), *m*-nitro- (**2c**), and *m*-trifluoromethyl-*m'*-nitro- (**2d**) α,α,α-trifluoroacetophenones were, then, subjected to the spectroscopy. Kinetics and other evidence have predicted that the intermediates formed from these substrates are thermodynamically less stable than their corresponding reactant systems.[3] Yet, their mixtures with **1a** in acetonitrile clearly showed new absorptions with maxima at 367, 369, 371, and 374 nm for **2a**, **2b**, **2c**, and **2d**, respectively, as shown in Fig. 4. The

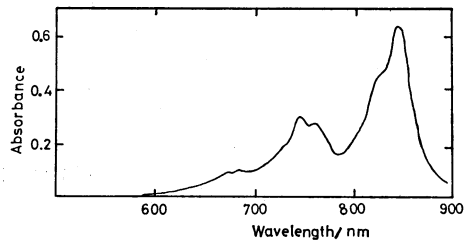


Fig. 1. Electronic spectrum of anion radical of TCNQ.

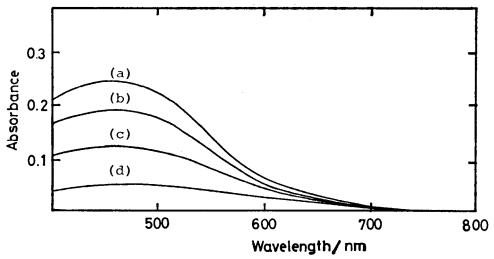

Fig. 2. CT spectra of 1,3,5-trinitrobenzene and 1-phenyl-4,4-dimethyl-1,4-dihydropyridine; (a) [TNB] $=3.56\times10^{-2}$ M, [**1b**] $=3.15\times10^{-2}$ M; (b) [TNB] $=3.67\times10^{-2}$ M, [**1b**] $=2.32\times10^{-2}$ M; (c) [TNB] $=3.79\times10^{-2}$ M, [**1b**] $=1.44\times10^{-2}$ M; (d) [TNB] $=3.91\times10^{-2}$ M, [**1b**] $=0.495\times10^{-2}$ M.

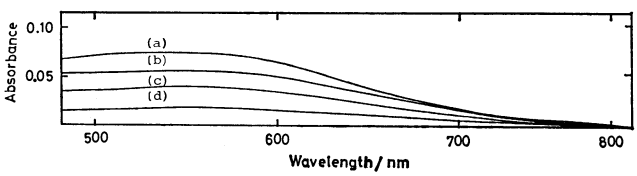

Fig. 3. CT spectra of *N*-methylacridinium iodide and 1-phenyl-4,4-dimethyl-1,4-dihydropyridine; (a) [AI] $=1.20\times10^{-2}$ M, [**1b**] $=6.35\times10^{-2}$ M; (b) [AI] $=1.30\times10^{-2}$ M, [**1b**] $=4.31\times10^{-2}$ M; (c) [AI] $=1.38\times10^{-2}$ M, [**1b**] $=2.74\times10^{-2}$ M; (d) [AI] $=1.47\times10^{-2}$ M, [**1b**] $=0.973\times10^{-2}$ M.

new absorptions satisfied well-known criteria for CT-complexation in solution.[12]

ESR Spectra. A mixture of TCNQ with **1a** in tetrahydrofuran at room temperature (about 25 °C) gave well-resolved ESR signals that were attributable to the signals from anion radical of TCNQ.[10,13] The spectrum is shown in Fig. 5. On the other hand, substrates **2a**—**d** did not give signals under the same condition. However, when magnesium perchlorate was added to the system, broad but distinct signals were recorded. A spectrum from **2d** is shown in Fig. 6 as a representative. The spectrum with $g=2.003$ is characterized by a large width of about 100 G, which indicates that the splitting due to fluorine atoms is involved in the spectrum. The recorded spectrum is identical to that observed from the system of **2d** and sodium metal (Fig. 6b). The signal width is identical to that reported for anion radical of α,α,α-trifluoroacetophenone.[14]

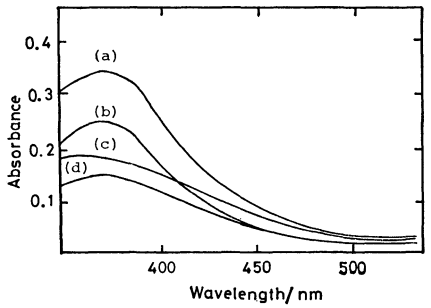

Fig. 4. CT spectra of substituted α,α,α-trifluoroacetophenones and 1-propyl-4,4-dimethyl-1,4-dihydropyridine; (a) [**2d**]$=1.39\times10^{-2}$ M, [**1a**]$=5.58\times10^{-2}$ M; (b) [**2c**]$=1.23\times10^{-2}$ M, [**1a**]$=1.98\times10^{-2}$ M; (c) [**2a**]$=4.57\times10^{-2}$ M, [**1a**]$=6.42\times10^{-2}$ M; (d) [**2b**]$=4.71\times10^{-2}$ M, [**1a**]$=3.84\times10^{-2}$ M.

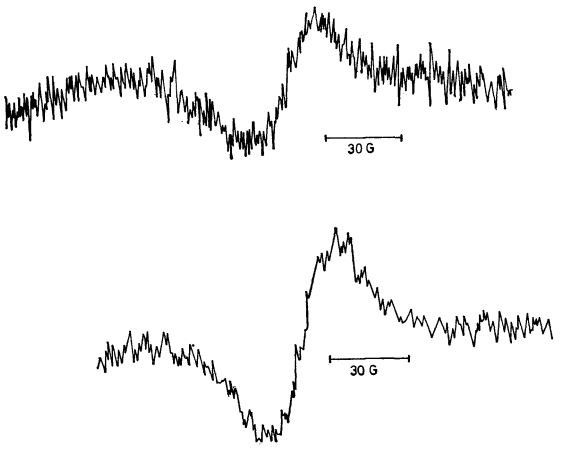

Fig. 6. ESR spectra from mixtures of *m*-trifluoromethyl-*m'*-nitro-α,α,α-trifluoroacetophenone and (a) 1-propyl-4,4-dimethyl-1,4-dihydropyridine and (b) sodium metal.

Discussion

Thus, both electronic and ESR spectroscopies have proved that 1,4-dihydropyridine can transfer an electron onto certain substrate forming a CT-complex. However, there still remains a question whether the detected intermediate is abortive or real. In this connection, it should be noted that the substrates **2a**—**c** are those the reduction of which is catalyzed by magnesium ion.[3] If magnesium ion increased the concentration of abortive CT-complex to exhibit an ESR signal, or if the concentration of reacting substrate were decreased by the addition of magnesium ion, the reduction in the presence of magnesium ion must be slower than that in its absence. The fact that the increase in reduction rate corresponds with the increase in concentration of CT-complex reveals that the CT-complex is not an abortive species but is a real intermediate of the reduction.

In conclusion, we have succeeded to prove that the initial step of the reduction with an NAD(P)H-model is an electron-transfer process.

Experimental

Materials. Acetonitrile was distilled three times on phosphorous pentoxide. Tetrahydrofuran was distilled and dried over sidium, then dried over alloy of potassium and sodium under reduced pressure. TCNQ and 1,3,5-trinitrobenzene were purchased from Nakarai Chem. Co. and purified by recrystallization. *N*-Methylacridinium iodide (mp 87 °C),[12] *m*-bromo-α,α,α-trifluoroacetophenone (bp 78 °C/15 mmHg) (**2a**),[15] *m*-trifluoromethyl-α,α,α-trifluoroacetophenone (bp 150 °C/760 mmHg) (**2b**),[3] *m*-nitro-α,α,α-trifluoroacetophenone (mp 54 °C) (**2c**),[15] and *m*-trifluoromethyl-*m'*-nitro-α,α,α-trifluoroacetophenone (bp 90 °C/8 mm Hg) (**2d**)[3] were prepared according to literature procedures. 1-Propyl-4,4-dimethyl-1,4-dihydropyridine (bp 72 °C/47 mmHg) (**1a**)[16] and 1-phenyl-4,4-dimethyl-1,4-dihydropyridine (mp 36 °C) (**1b**)[17] were also synthesized according to literature procedures. All materials gave satisfactory results from elemental analyses and spectroscopies.

Visible Spectra. Acetonitrile was flushed with dry argon prior to use. A solution of a substrate in acetonitrile was prepared and placed in a cell (1 cm) equipped with a silicone-rubber stopper, then the solution of a model compound in acetonitrile was injected into this solution. Visible spectra was obtained with Union Giken SM-401 spectrometer, the cell-compartment of which was filled with dry argon and kept at 50.0±0.1 °C.

The measurement of association (complexation) constant of TCNQ with **1a** was carried out by the procedure described below. The concentration of **1a** was kept at 2×10^{-4} M and the concentration of TCNQ was changed from 1.58×10^{-3} to 6.32×10^{-3} M. The change in the intensity at 746 nm was measured. The slope of the double reciprocal plot of the intensity and the concentration of TCNQ gave a linear line.

Spectra of the other substrates were obtained with the

Table 1. Concentrations of reagents for the observation of charge-transfer spectra

Substrate	Concn/10^{-2} M	Model	Concn/10^{-2} M
1,3,5-Trinitrobenzene	3.50—3.90	**1b**	0.5—3.2
N-Methyl acridinium iodie	1.25—1.50	**1b**	1.0—6.3
2a	4.40—5.50	**1a**	1.0—8.0
2b	4.40—4.90	**1a**	1.0—8.0
2c	1.21—1.25	**1a**	1.0—3.0
2d	1.39—1.48	**1a**	2.0—5.6

concentrations listed in Table 1.

ESR Spectra. Appropriate amounts of a substrate and **1** were placed in a sample tube and desired amount of the purified dry tetrahydrofuran was brought into the tube in a vacuum. The spectra were obtained on a JEOL-JMS-ME-3X spectrometer at room temperature or below.

Correlation of Physical Units. Physical units used in this report are correlated with SI-unit by the following relationship.

1 M=1 mol dm^{-3}, t/°C=T/K−273.15, p mmHg=13.5951 ×980.665×10^{-2} p Pa.

Intramolecular [2+2]Photocycloaddition of the 3-(3-Butenyloxy)-2-cyclohexenone System

Takashi UMEHARA, Yoshinobu INOUYE,* and Hiroshi KAKISAWA

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305

(Received March 25, 1981)

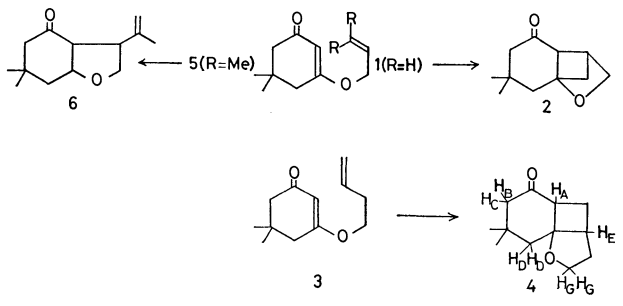
The irradiation of 5,5-dimethyl-3-(4-methyl-3-pentenyloxy)-2-cyclohexenone gave regioselectively, 6,6,10,10-tetramethyl-2-oxatricyclo[5.4.0.0^{1,5}]undecan-8-one, while, that of 5,5-dimethyl-3-[(3-methylcyclohexenyl)methoxy]-2-cyclohexenone afforded, regio- and stereoselectively, 1,5,5-trimethyl-8-oxatetracyclo[8.3.1.0^{2,7}.0^{1,5}]tetradecan-3-one.

Since a successful synthesis of caryophyllene by Corey and his co-workers in 1963,[1] a number of [2+2]-photocycloaddition reactions have been reported as an important step[2] in the synthesis of natural products. Most of them were intermolecular reactions, for example, the addition of an α,β-unsaturated carbonyl moiety of one molecule to a double bond of a second one, but intramolecular approaches have limited to a few cases.[3-5] Nevertheless, the latter are very worthy of investigation because bond formation is expected to be prompted by the closer situation of reaction sites compared to the case of intermolecular reactions and becuase regio- and/or stereoselectivities will be enhanced by a specific and limited arrangement of reaction sites.

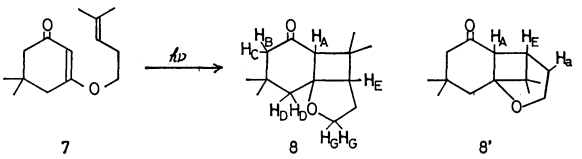
We will here report two intramolecular [2+2]-photocycloadditions of 3-(3-butenyloxy)-2-cyclohexenone derivatives, **7** and **10**. These cyclohexenones can be easily prepared from a β-diketone and a 3-butenyl alcohol derivative or a corresponding halide, as will be described below.

A simple system of 3-alkenyloxy-2-cyclohexenones had been investigated by Tamura and his co-workers.[6] In their work, 5,5-dimethyl-3-allyloxy-2-cyclohexenone-(**1**) changed into a tricyclic compound **2** upon irradiation with a Hg lamp, while 3-(3-butenyloxy)-2-cyclohexenone **3** was reversed in regioselectivity to give another tricyclic compound **4**. The reaction of the dimethyl compound **5** proceeded differently to afford a tetrahydrofuran derivative **6** as a result of a facile ene reaction. Therefore, we initially tried the photoreaction of 5,5-dimethyl-3-(4-methyl-3-pentenyloxy)-2-cyclohexenone(**7**), a dimethyl derivative of **3**, in order to clarify the influence of dimethyl groups on the reaction paths. The dimethyl compound **7** was prepared from dimedone and 5-chloro-2-methyl-2-pentene.[7]

The irradiation of a 1% hexane solution of **7** with an Ushio high-pressure mercury arc lamp gave a single photoadduct as a crystal in a 63% yield. The



mass spectrum shows that the reaction was intramolecular, while the absorption at 1695 cm^{-1} in IR and the four methyl singlets at 0.94, 1.05, 1.05, and 1.08 ppm in NMR spectra clearly indicate that the reaction proceeded by means of [2+2]cycloaddition. Either structure, **8** or **8'**, is possible for the adduct; the NMR spectrum, a broad singlet at 2.35 (H_A), an AB center at 2.03 of J=18 Hz (H_B, H_C), a singlet at 1.90 ($2\times H_D$), and a complex multiplet between 3.60 and 4.20 ($-CH_2-O-$) are consistent with both structures, although, in **8'**, the coupling constant between H_A and H_E is nearly zero, as is to be anticipated from the dihedral angle (90°) of these two protons in the Dreiding models.



The pseudo-contact shift with Eu-FOD was measured; the results are shown in Fig. 1 and in Table 1. The three protons (H_A, H_B, and H_C) adjacent to the carbonyl group are most deshielded, and the magnitudes of the shifts are very close to each other. This shows that the shift reagent nearly comes in contact with the carbonyl oxygen and on the same side with H_A (see **9**). On the other hand, the H_E proton shifts

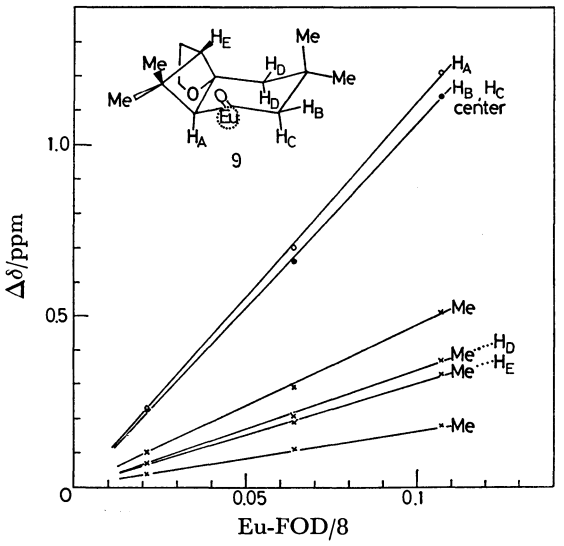


Fig. 1. Pseudocontact shifts of **8** with Eu-FOD in CCl_4.

Table 1. Pseudocontact shifts of **4**, **8**, and **16** with the addition of 0.1 mol equivalent of Eu-FOD in CCl_4

Proton	Δδ Values in ppm		
	4	**8**	**16**

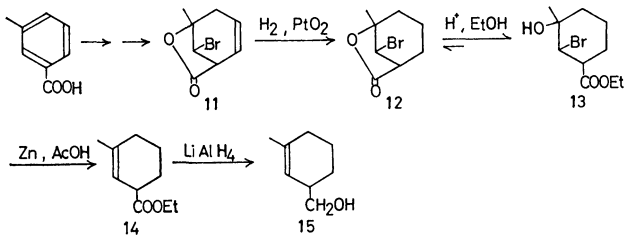
		0.17	

a) Shifts at AB-type center. b) Less precise because of complex multiplets.

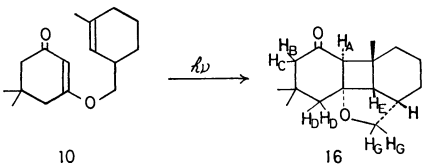
less than H_A and has a magnitude similar to that of H_D. These facts well accord with the structure **8**. In the alternate structure, **8'**, the H_E proton is situated closer to the carbonyl group than H_D; thus, it must have a larger Δδ value. Furthermore, H_E was found to be a double doublet with the coupling constants of 7 and 5 Hz upon the addition of the shift reagent. This is also inconsistent with the structure **8'**, in which the dihedral angle between H_E and the neighbouring axial proton (H_a) is very close to 90°.

Different from the case of **1** *vs.* **5**, the dimethyl group did not exert any influence on the reaction path and regioselectivity in the case of 3-(3-butenyloxy)-2-cyclohexenone **3** *vs.* **7**. This remarkable regioselectivity to give the bicyclo[3.*m*.0]-system has been observed in other cases.[3b,4,8)]

The successful conversion of **7** into **8** led us to investigate the photochemical reaction of 5,5-dimethyl-3-[(3-methyl-2-cyclohexenyl)methoxy]-2-cyclohexenone-(**10**), which has a less flexible olefinic side chain containing one asymmetric carbon atom.



The bromo lactone **11**, prepared[9)] from *m*-toluic acid, was hydrogenated over the Adams catalyst to give a saturated lactone **12**. As the direct reduction of **12** with zinc in acetic acid gave a mixture of an olefinic acid and a debromo lactone, probably produced during the isolation procedure, **12** was initially changed into an ethyl ester **13** and then reduced with Zn–AcOH to afford an unsaturated ester **14**. The ester group in **14** was reduced with lithium aluminum hydride to give an alcohol **15**. The reaction of dimedone with **15** in the presence of *p*-toluenesulfonic acid afforded the enol ketone **10** as an oil.



A similar irradiation of **10** gave a photoadduct in a 47% yield. Its spectroscopic properties well accord with the structure **16**: the carbonyl absorption at 1690 cm^{-1} in the IR spectrum and the three methyl singlets at 0.92, 1.00, and 1.01, the one broad proton singlet at 2.68, an AB-type quartet at 1.98 of J=18 Hz, a two proton singlet at 1.88, and the two triplets at 3.64 (J=9 Hz) and 3.94 (J=9 Hz) in the NMR spectrum. The *cis*-anti-*cis* stereochemical assignment was deduced from the fact that **16** was unchanged upon treatment with lithium diisopropylamide. The predominant formation of one diastereoisomer seems to be characteristic of the intramolecular reaction and is largely due to the steric requirement in the transition state.

Experimental

All the melting points are uncorrected. The IR spectra were taken on a Hitachi 215 grating spectrophotometer. The NMR spectra were obtained with Hitachi H-60 and JEOL MH-100 spectrophotometers, using TMS as the internal standard. The mass spectra were obtained with a Hitachi RMU-6MG mass analyzer. The flash chromatographies were performed using the Wakogel C-300 as the adsorbent.

Irradiation Procedure. A test solution of 170 mg of 5,5-dimethyl-3-(3-butenyloxy)-2-cyclohexenone (**3**) [$\nu(CHCl_3)$: 1640 and 1605 s cm^{-1}], prepared from dimedone and 4-bromo-1-butene in the presence of potassium methoxide, in 20 ml of hexane was irradiated in a Pyrex test tube with an Ushio 450 W high-pressure mercury arc lamp under nitrogen for 30 min. The solvent was then evaporated, and the residue was chromatographed with hexane–ethyl acetate (4:1) to give the known adduct, **4**[6a)] (120 mg, 72%). *m/e*: 194 (M^+) and 124 (base); $\nu(CCl_4)$: 1700, 1065, and 1040 cm^{-1}; δ (CCl_4, 100 MHz): 1.00 (s, 3H), 1.06 (s, 3H), 1.71 (AB center, 2H, J=15 Hz), 2.15 (AB center, 2H), 2.62 (dd, 1H, J=11 and 6 Hz), 1.5—2.0 (m, 2H), 2.0—2.4 (m, 4H), 2.5—2.8 (m, 1H), and 3.7—4.2 (m, 2H).

5,5-Dimethyl-3-(4-methyl-3-pentenyloxy)-2-cyclohexenone (7). A solution of dimedone (2.48 g) in 15 ml of dry HMPA was added, drop by drop, to a solution of potassium methoxide, prepared from 1.02 g of potassium, 5 ml of dry methanol, and 10 ml of HMPA. 5-Chloro-2-methyl-2-pentene[7)] (2.14 g) was added to the mixture, and the whole was heated at 100 °C overnight. Water was added, and the products were taken up in hexane. The solvent was evaporated, and the residue was chromatographed with hexane–ethyl acetate (9:2) to give **7** (741 mg, 19%) as an oil. An analytical sample was prepared by Kugelrohr distillation [bath temp: 70 °C/2 mmHg(1 mmHg=133.322 Pa)]. *m/e*: 222 (M^+) and 83 (base); ν (CCl_4): 1660, 1615, and 1220 cm^{-1}; δ (CCl_4): 1.08 (s, 6H), 1.65 (br. s, 3H), 1.73 (br. s, 3H), 2.08 (s, 2H), 2.23 (s, 2H), 2.37 (q, 2H, J=7 Hz), 3.78 (t, 2H, J=7 Hz), 5.1 (br. t, 1H, J=7 Hz), and 5.18 (s, 1H). Found: C, 75.35; H, 9.96%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

6,6,10,10-Tetramethyl-2-oxatricyclo[5.4.0.0^{1,5}]undecan-8-one (8).

A solution of 573 mg of **7** in 86 ml of hexane was divided into four Pyrex test tubes. The solution was then irradiated under nitrogen for 30 min. The solvent was evaporated, and the residual oil was chromatographed with hexane–ethyl acetate (5:1) to give colorless **8** (361 mg, 63%). Bath temp: 92 °C/2 mmHg; mp 48—49 °C (from pentane); *m/e*: 222 (M^+) and 83 (base); *v* (CCl_4): 1695, 1180, and 1050 cm^{-1}; *δ* (CCl_4, 100 MHz): 0.94 (s, 3H), 1.00 (s, 3H), 1.05 (s, 3H), 1.08 (s, 3H), 1.90 (s, 2H), 2.02 (AB center, 2H, *J*=18 Hz), 1.7—2.4 (m, 3H), 2.34 (s, 1H), and 3.6—4.2 (m, 2H); *δ* (CCl_4, 100 MHz, with the addition of a 0.11 equivalent of Eu-FOD): 1.20 (s, 3H), 1.27 (s, 3H), 1.45 (s, 3H), 1.56 (s, 3H), 1.9—2.2 (m, 2H), 2.27 (s, 2H), 2.48 (dd, 1H, *J*=7 and 5 Hz), 3.17 (AB center, 2H, *J*=18 Hz), 3.56 (s, 1H), and 3.9—4.4 (m, 2H). Found: C, 75.57; H 10.06%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

*8-Bromo-*cis*-5-methyl-6-oxabicyclo[3.2.1]octan-7-one (12).* The known bromo lactone **11**[9] (1.02 g) in 20 ml of ethyl acetate was hydrogenated over the Adams catalyst (109 mg) at a pressure of 1 atm for 80 min. The catalyst was then removed by filtration, and the filtrate was evaporated to give crystals. Recrystallization from pentane gave **12** (0.59 g, 93%); mp 59—60 °C. *v* (CCl_4): 1790s and 1105 cm^{-1}; *δ* (CCl_4): 1.45 (s, 3H), 1.0—2.5 (m, 6H), 2.75 (m, 1H), and 4.37 (d, 1H, *J*=6 Hz). Found: C, 43.97; H, 4.99%. Calcd for $C_8H_{11}O_2Br$: C, 43.86; H, 5.06%.

3-Methyl-2-cyclohexenylmethanol (15). A solution of **12** (13.4 g) in 60 ml of ethanol was refluxed in the presence of a catalytic amount of hydrochloric acid for 2 d. The mixture was passed through a sodium carbonate layer and then evaporated. The residue, after having been made free from a carboxylic acid produced, weighed 12.9 g. The IR spectrum of the residue showed that it was a mixture of **12** ($\nu_{C=O}$ 1790 cm^{-1}) and **14** ($\nu_{C=O}$ 1735 cm^{-1}) in the ratio of 1:3. The mixture was refluxed in 10 ml of acetic acid with 12.8 g of freshly activated (HCl) zinc powder. The solids were removed by filtration and washed with 20 ml of hexane. The filtrate and the washing were combined and then evaporated to give an oil (5.6 g). The oil was dispersed in a 5% sodium hydroxide solution and extracted with ethyl acetate. The extracts were washed with water, dried over Na_2SO_4, and then evaporated to give an ethyl ester **14** (4.4 g) as an oil; *v*(CCl_4): 1730 and 1175 cm^{-1}.

A solution of **14**, without further purification, in 50 ml of dry THF was added, drop by drop, to a cooled solution of lithium aluminum hydride (1.06 g) in 50 ml of dry THF. The mixture was stirred at room temperature for 30 min and then treated successively with 1 ml of water, 1 ml of a 15% sodium hydroxide solution, and 3 ml of water. The granular precipitates were removed by filtration and washed with THF. The filtrate and the washing were combined and then evaporated to give an alcohol **15** (2.5 g, 33% from **12**). Bp 55—63 °C/1 mmHg; *v* (CCl_4): 3400br, 1060, and 1030 cm^{-1}; *δ* (CCl_4): 1.65 (s, 3H), 1.1—2.4 (m, 8H), 2.83 (s, 1H, OH), 3.37 (d, 2H, *J*=6 Hz), and 5.30 (br.s, 1H).

Elemental analysis was performed on its *p*-nitrobenzoate derivative; mp 78—80 °C (from hexane); *v* (KBr): 1715, 1520, 1345, 1285, 1270, and 815 cm^{-1}. Found: C, 65.60; H, 6.14; N, 4.71%. Calcd for $C_{15}H_{17}NO_4$: C, 65.44; H, 6.22; N, 5.08%.

5,5-Dimethyl-3-[(3-methyl-2-cyclohexenyl)methoxy]-2-cyclohexenone (10). A mixture of 200 mg of dimedone, 179 mg of **15**, and 25 mg of *p*-toluenesulfonic acid was heated under refluxing with 40 ml of toluene for 43.5 h, while the water was being removed continuously by means of a water-separator. The mixture was then washed with a 15% sodium hydroxide solution and water until the washing was neutral. After having been dried, the solvent was evaporated to give an oil. The oil was chromatographed with hexane–ethyl acetate (4:1) to give **10** (204 mg, 58%). Bath temp: 60—65 °C/2 mmHg; *m/e*: 248 (M^+) and 108 (base); *v* (CCl_4): 1660, 1616, and 1220 cm^{-1}; *δ* (CCl_4): 1.08 (s, 6H), 1.66 (br.s, 3H), 2.08 (s, 2H), 2.25 (s, 2H), 1.0—2.8 (m, 10H), 3.65 (d, 2H, *J*=6.5 Hz), 5.22 (br.s, 1H), and 5.2—5.5 (m, 1H). Found: C, 77.08; H, 9.77%. Calcd for $C_{16}H_{24}O_2$: C, 77.37; 9.74%.

1,5,5-Trimethyl-8-oxatetracyclo[8.3.1.0^{2,7}.0^{1,5}]tetradecan-3-one (16). A solution of 200 mg of **10** in 22 ml of hexane was irradiated for 6 h. The solvent was then evaporated, and the residue was chromatographed with hexane–ethyl acetate (5:1) to give **16** (93 mg, 47%); mp 76—77 °C (from hexane); *m/e*: 248 (M^+) and 108 (base); *v* (CCl_4): 1690, 1050, and 1045 cm^{-1}; *δ* (CCl_4, 100 MHz); 0.92 (s, 3H), 1.00 (s, 3H), 1.01 (s, 3H), 1.88 (s, 2H), 1.98 (AB center, 2H, *J*=18 Hz), 1.98 (d, 1H, *J*=10 Hz), 2.68 (br.s, 1H), 3.64 (t, 1H, *J*=9 Hz), and 3.94 (t, 1H, *J*=9 Hz). Found: C, 77.28; H, 9.74%. Calcd for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74%.

16 was unchanged even when it was treated with 5 equivalents of lithium diisopropylamide at room temperature overnight.

The present work was partially supported by a Grant-in-Aid for Scientific Reseach (No. 564174) from the Ministry of Education, Science and Culture.

Reactions of Group V Metal Compounds with Sulfur Trioxide

Fumio Ando, Jugo Koketsu,* and Yoshio Ishii
Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai 487
(Received April 11, 1981)

Trialkylphosphines react with equimolar amounts of sulfur trioxide to form the 1:1 adducts $R_3P^{\oplus}$–$SO_3^{\ominus}$. Trialkylarsines and -stibines undergo sulfur trioxide insertion reactions across the metal-carbon bond to give the trisulfonates of the metal $M(OSO_2R)_3$ (M=As, Sb). The reactions of trialkyl phosphites, with sulfur trioxide yield trialkyl phosphates, trialkyl thiophosphates, dialkyl alkylphosphonates, dialkyl sulfates, and polymers which contain phosphorus atoms. The reactions of trialkoxyarsines and -stibines result in the insertion of sulfur trioxide across the metal-oxygen bond to form the alkoxymetal alkylsulfates $(RO)_{3-n}M(OSO_3R)_n$ (M=As, Sb; n=1, 2, 3) depending on the stoichiometric ratios of the reagents used. Pyrolysis of the metal sulfates gives dialkyl sulfates and undistillable residues containing the metals.

In a previous paper,[1] we reported that the reactions of trialkoxyarsines and -stibines with sulfur dioxide gave dialkyl sulfites and metal oxides, whereas trialkyl phosphites were oxidized to the phosphates and the thiophosphates. There are a few reports[2-4] concerning the reaction of sulfur trioxide with tervalent arsenic or antimony halides. Recently, Touzin and Mitacek[5] reported that arsenic(III) fluoride forms the mono-, di-, and tri-SO_3 insertion products $F_{3-n}As(OSO_2F)_n$ depending on the stoichiometric molar ratios. On the other hand, Schmidt and Bipp[6] reported that the 1:1 adducts of triphenyl-, diphenylchloro-, and phenyldichlorophosphines with sulfur trioxide were obtained by the reaction at −78 °C, but phosphine oxides and sulfur dioxide were formed by the reaction at room temperature. Becke-Gogehring and Thielemann[7] reported that triphenyl- and tricyclohexylphosphines, -arsines, and -stibines gave the sulfates $(C_6H_{11})_3AsSO_4$ and $(C_6H_5)_3SbSO_4$ in addition to the corresponding adducts $(C_6H_5)_3P^{\oplus}$–$SO_3^{\ominus}$, $(C_6H_{11})_3P^{\oplus}$–$SO_3^{\ominus}$, and $(C_6H_5)_3As^{\oplus}$–$SO_3^{\ominus}$. However, there has been no report about the insertion reaction of sulfur trioxide across the metal-carbon or metal-oxygen bond of the compounds containing the group V elements. We have investigated the reactions of trialkyl- and trialkoxyphosphines, -arsines, and -stibines with sulfur trioxide.

Results and Discussion

Trialkylphosphines. Trialkylphosphines reacted readily with sulfur trioxide in dichloromethane at −78 °C to give 1:1 adducts of the type $R_3P^{\oplus}$–$SO_3^{\ominus}$ in good yields. The adduct of trialkylphosphine (**1a**)

$$R_3P + SO_3 \longrightarrow R_3P^{\oplus}\text{-}SO_3^{\ominus} \quad (1)$$

is a colorless crystal (mp 35—39 °C); it disproportionated to triethylphosphine oxide and a small amount of triethylphosphine sulfide with evolution of sulfur dioxide on distillation under reduced pressure. The adduct of triisopropylphosphine (**1b**) is a stable crystal and has a very high melting point compared with the others. $Ph_2Bu^nP^{\oplus}$–$SO_3^{\ominus}$ (**1c**) was obtained in 70% yield by the equimolar reaction of butyldiphenylphosphine with sulfur trioxide. The IR spectrum of the adduct (**1c**) shows the symmetric and asymmetric stretching vibrations of the $SO_3^{\ominus}$ group[8] at 1270, 1120, and 1038 cm^{-1}. Assignments of the ^{13}C NMR spectra of the adducts were done according to the literature.[9] Both the large P–C coupling constants observed for the all adducts and the upfield shift of ipso-carbon of the phenyl group of the adduct (**1c**) are characteristic of the phosphonium compounds.[10-12] The 1:1 adduct of triethylphosphine with SO_3 (**1a**) reacted at room temperature with 3 molar excess of triethylphosphine to give 3 mol of triethylphosphine oxide and 1 mol of triethylphosphine sulfide. The

$$\mathbf{1a} + 3Et_3P \longrightarrow 3Et_3PO + Et_3PS \quad (2)$$

phosphonium ion structures of the adducts were also confirmed by their reactions with methyllithium, hydrogen chloride, and acetic acid. The structures of

$$\mathbf{1a} + MeLi \longrightarrow Et_3MePSO_3Li \quad (3)$$

$$\mathbf{1a} + HCl \longrightarrow Et_3ClPSO_3H \quad (4)$$

$$\mathbf{1a} + CH_3COOH \longrightarrow Et_3P(OCOCH_3)SO_3H \quad (5)$$

these reaction products were confirmed by their spectroscopic data and also by elemental analyses.

Trialkylarsines and -stibines. Arsenic or antimony tris(alkanesulfonate) were formed on treatments of trialkylarsines or -stibines with a 3 molar excess of sulfur trioxide. The yields and some spectroscopic data of

$$R_3M + 3SO_3 \longrightarrow M(OSO_2R)_3 \quad (6)$$
$$M=As, Sb$$

these insertion products are shown in Table 1. The reactivity order among the trialkyl derivatives was found to be $R_3Sb > R_3As$. Trialkylarsines and -stibines behave quite differently from triphenylarsine and -stibine[7] and also trialkylphosphines during the reactions with sulfur trioxide. This difference in the chemical behavior might be attributable to the fact that the metal-carbon bond of trialkylarsines and -stibines is weaker than the metal-phenyl or the phosphorus-alkyl bond.[13]

Trialkyl Phosphites. When sulfur trioxide was added to an equimolar amount of trimethyl phosphite at −78 °C, a violent reaction took place to give trimethyl phosphate, trimethyl thiophosphate, dimethyl methylphosphonate, dimethyl sulfate, and polymeric compounds containing phosphorus atoms. The reaction does not obey a simple stoichiometry. Table 2

$$(RO)_3P + nSO_3 \longrightarrow (RO)_3PO + (RO)_3PS + (RO)_2P(O)R + (RO)_2SO_2 + \text{"P-polymers"} \quad (7)$$

shows the effects of the alkyl group of trialkyl phosphite, the molar ratio of the reactants, and the reaction temperature on the distribution of reaction products,

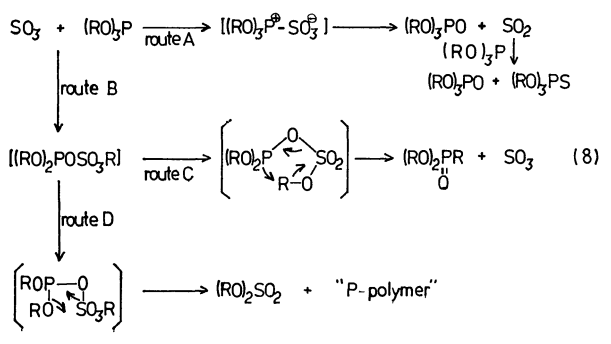
The relative amounts of the products varied depending on the molar ratio of the reactants and the temperature. The selective oxidation of phosphite was observed at low temperature with formation of sulfur dioxide. The formation of sulfates is favored at high temperature and by increasing the amounts of sulfur trioxide. The formation of thiophosphates occured mainly under the reaction conditions where the excess amount of trialkyl phosphite was used. From these results of product distributions, we wish to propose a tentative reaction mechanism as follows:



Trialkyl phosphite is an electron donor which forms a donor-acceptor complex with various electron acceptors. The sulfur atom of sulfur trioxide is the most electrophilic center in the molecule. Therefore, it is reasonable to assume that trialkyl phosphite reacts preferentially with the sulfur atom of sulfur trioxide to give alkoxyphosphonium intermediate (route A), which is not stable because of the electron-withdrawing alkoxyl group on the phosphorus atom. The phosphonium ion decomposed to trialkyl phosphate and sulfur dioxide, which, in turn, reacts with an additional trialkyl phosphite to give trialkyl phosphate and thiophosphate.[1] To explain the formation of dialkyl sulfate and dialkyl alkylphosphonate, we propose a mechanism involving the insertion of sulfur trioxide across the P–O bond of phosphite (route B). The formation of dialkyl alkylphosphonate can be explained by an intramolecular rearrangement of the insertion intermediate with elimination of sulfur trioxide (route C). An analogous mechanism has been reported by Lemper and Tieckman[14] for the rearrangement of diethyl 1-methylallyl phosphite to the phosphonate. Dialkyl sulfate and "P-polymers" might

be formed through the route D. Concerning the formation of dialkyl sulfate and "P-polymers," there might be another mechanism involving the reaction of trialkyl phosphate (formed through route A) with sulfur trioxide as reported by Du Plessis.[15] The reaction of trimethyl phosphate with sulfur trioxide gave dimethyl sulfate and methyl polyphosphates.[15] Trialkyl phosphates whose alkyl substituents were higher than the ethyl group, however, formed stable 1:1 adducts with sulfur trioxide and the corresponding dialkyl sulfates and "P-polymers" were not obtained from the adducts.[16] Therefore, the route D in the reaction mechanism proposed is much more probable than the latter route.

$$(MeO)_3PO + SO_3 \longrightarrow (MeO)_2SO_2 + \text{"P-polymers"} \quad (9)$$

Trialkoxyarsines and -stibines. When sulfur trioxide and trialkoxyarsines were allowed to react at −50 °C in 1:1, 1:2, and 1:3 molar ratios, the corresponding insertion products were obtained almost quantitatively. The insertion products are sensitive to moisture and oxygen, while they are stable at room temperature under an inert atmosphere. Attempts to distill the insertion products under reduced pressure (0.1 mmHg (1 mmHg≈133.322 Pa)) resulted in decomposition giving dialkyl sulfates and white or brown-black residues containing arsenic atoms.

$$As(OR)_3 + nSO_3 \longrightarrow (RO)_{3-n}As(OSO_3R)_n \quad (10)$$
$$n=1,\ 2,\ 3$$

Trialkoxystibines also gave the corresponding insertion products with cleavage of the Sb–O bond. The reactivity of trialkoxystibines toward sulfur trioxide is somewhat greater than that of trialkoxyarsines because of higher polarizability of the metal-oxygen bond of trialkoxystibines than that of trialkoxyarsines. The insertion products were viscous liquids and very sensitive to air and moisture. Attempts to purify these products by distillation or recrystallization were unsuccessful. Pyrolysis under reduced pressure gave dialkyl sulfates along with charred decomposition products containing antimony atoms. The IR, ^1H NMR, and ^{13}C NMR spectra of the arsenic or antimony mono-, bis-, and tris(alkyl sulfates) are given in Table 3 along with the parent metal alkoxide. The IR spectra exhibit symmetric and asymmetric stretching vibrations of SO_2 group at 1220 and 1390 cm^{-1}, respectively. In the ^{13}C NMR spectra, α-methylene carbons shift to low field by the shielding effect of SO_2 group.[17]

$$Sb(OR)_3 + nSO_3 \longrightarrow (RO)_{3-n}Sb(OSO_3R)_n \quad (11)$$
$$n=1,\ 2,\ 3$$

Experimental

All reactions were carried out under an atmosphere of argon or nitrogen. Infrared spectra were recorded on a Shimadzu IR 430 spectrometer. ^1H NMR spectra were recorded on a JEOL C 60 HL spectrometer and ^{13}C NMR spectra on a JEOL JNM-FX 60 FT NMR instrument. Analytical GLC was carried out on a Shimadzu GC 60A apparatus using a 3 m grass column packed with PEG 6000 (10%) with helium as a carrier gas. Dichloromethane was dried over calcium chloride and distilled through a fractionating column.

Reagent. Sulfur trioxide (bp 46 °C) was distilled from sulfuric anhydride (Yotsuhata Chem. Co.) into an ice-cooled flask containing dichloromethane. The concentration of sulfur trioxide was determined by a titration with a standard

solution of sodium hydroxide. Trimethyl phosphite, triethyl phosphite and tributyl phosphite were of commercial material and distilled before use. Tripropyl phosphite (bp 84—87 °C/14 mmHg) and triisopropyl phosphite (bp 63—66 °C/12 mmHg) were prepared by the method described in the literature.[18] Trialkoxyarsines and -stibines[19] were prepared by the reaction of arsenic or antimony trichloride with an appropriate alcohol in the presence of ammonia; $As(OMe)_3$; bp 95—96 °C/35 mmHg, $As(OEt)_3$; bp 59—60 °C/14 mmHg, $Sb(OEt)_3$; bp 49—52 °C/14 mmHg.

Equimolar Reaction of Trialkylphosphine with Sulfur Trioxide. Sulfur trioxide (19.7 mmol in 5 cm³ of dichloromethane) was added to a solution of triethylphosphine (2.31 g, 19.6 mmol) in 10 cm³ of dichloromethane at −78 °C. The mixture was kept for 2 h at −78 °C and then warmed up gradually to room temperature. After removal of the solvent, the product was recrystallized from petroleum ether/chloroform (5/1) to give $Et_3P^{\oplus}-SO_3^{\ominus}$ (3.27 g, 84%), mp 35—39 °C. ^1H NMR ($CDCl_3$): $\delta=1.40$ (dt, 3H, $^3J_{PH}=19.2$ Hz) and 2.49 (dq, 2H, $^2J_{PH}=12.0$ Hz). ^{13}C NMR ($CHCl_3$): $\delta=5.2$ (d, $^2J_{PC}=4.9$ Hz) and 18.2 (d, $^1J_{PC}=64.7$ Hz). ^{31}P NMR ($CHCl_3$): $\delta=-79.5$. IR ($CHCl_3$): $\nu(SO_3^-)$ 1276, 1160, and 1040 cm⁻¹. Found: C, 36.9; H, 7.74; P, 15.0%. Calcd for $C_6H_{15}O_3PS$: C, 36.36; H, 7.63; P, 15.62%. An attempted distillation resulted in a decomposition which gave triethylphosphine oxide (78%) and triethylphosphine sulfide (5%). In a similar way, reaction of triisopropylphosphine (2.05 g, 12.8 mmol) with an equimolar amount of sulfur trioxide gave white crystals, $i\text{-}Pr_3P^{\oplus}-SO_3^{\ominus}$ (2.27 g, 74%), mp 201—203 °C (dec). ^1H NMR ($CDCl_3$): $\delta=1.59$ (dd, 6H, $^3J_{PC}=16.8$ Hz) and 2.87 (m, 1H). ^{13}C NMR ($CHCl_3$): $\delta=17.3$ (d, $^2J_{PC}=2.9$ Hz) and 24.8 (d, $^1J_{PC}=51.9$ Hz). IR (KBr): $\nu(SO_3^-)$ 1238, 1168, and 1020 cm⁻¹. Found: C, 45.3; H, 8.73; P, 13.1%. Calcd for $C_9H_{21}O_3PS$: C, 44.98; H, 8.81; P, 12.89%. Reaction of butyldiphenylphosphine (1.03 g, 4.25 mmol) with an equimolar amount of sulfur trioxide gave $Ph_2BuP^{\oplus}-SO_3^{\ominus}$ (0.96 g, 70%); ^{13}C NMR ($CHCl_3$): $\delta=28.2$ ($^1J_{PC}=70.8$ Hz), 23.2 ($^2J_{PC}=1.2$ Hz), 23.9 ($^3J_{PC}=12.2$ Hz), 13.4 ($^4J_{PC}\approx0$ Hz), 129.8 (ipso, $J_{PC}=100.1$ Hz), 130.92 (ortho, $J_{PC}=9.77$ Hz), 129.06 (meta, $J_{PC}=12.21$ Hz), and 132.7 (para, $J_{PC}=3.1$ Hz). IR (neat): $\nu(SO_3^-)$ 1270, 1120, and 1038 cm⁻¹.

Reactions of $Et_3P^{\oplus}-SO_3^{\ominus}$ with Various Reagent. Triethylphosphine (1.94 g, 16.4 mmol) was added to $Et_3P^{\oplus}-SO_3^{\ominus}$ (1.09 g, 5.47 mmol) in 5 cm³ of dichloromethane at −78 °C. The mixture was warmed up to room temperature and an exothermic reaction took place to give triethylphosphine oxide (1.61 g, 55%) and triethylphosphine sulfide (0.53 g, 16%). The structures of both compounds were confirmed by comparison of the physical properties and spectroscopic data with those of authentic samples.[20] An equimolar reaction of $Et_3P^{\oplus}-SO_3^{\ominus}$ (1.01 g, 5.12 mmol) and methyllithium in ether gave the lithium sulfonate Et_3PMeSO_3Li (0.93 g, 87%), a brown solid, mp>250 °C. ^{13}C NMR ($CHCl_3$): $\delta=6.2$ ($^2J_{PC}=4.6$ Hz, CH_3CH_2), 17.4 ($^1J_{PC}=35.6$ Hz, CH_2), and 19.3 ($J_{PC}=66.7$ Hz, CH_3P). Found: P, 14.1%. Calcd for $C_7H_{18}PSO_3Li$: P, 14.07%. Reaction of $Et_3P^{\oplus}-SO_3^{\ominus}$ (1.84 g, 9.29 mmol) with anhydrous hydrogen chloride in ether gave the sulfonic acid $Et_3P(Cl)SO_3H$ (2.09 g, 96%) as a viscous liquid. ^1H NMR ($CDCl_3$): $\delta=1.28$ (dt, 9H, $^1J_{PH}=19.1$ Hz), 2.23 (dq, 6H, $^2J_{PH}=12.4$ Hz), and 12.44 (s, 1H, SO_3H). ^{13}C NMR ($CHCl_3$): $\delta=5.1$ ($^2J_{PC}=5.5$ Hz) and 17.2 ($^1J_{PC}=62.9$ Hz); IR (neat): $\nu(OH)$ 2240, $\nu(SO_2)$ 1198, 1050, and $\nu(P-C)$ 560 cm⁻¹. Found: P, 13.5%. Calcd for $C_6H_{16}PSO_3Cl$; 13.20%. Reaction of $Et_3P^{\oplus}-SO_3^{\ominus}$ (0.58 g, 2.93 mmol) with acetic acid (0.20 g, 3.33 mmol) gave the corresponding acetate $Et_3P(OCOCH_3)-SO_3H$ (0.69 g, 92%) as a viscous liquid. ^1H NMR ($CDCl_3$): $\delta=1.26$ (dt, 9H, $^2J_{PH}=19.4$ Hz), 2.18 (dq, 6H, $^3J_{PH}=12.6$ Hz), 2.09 (s, 3H, CH_3CO), and 12.41 (s, 1H, SO_3H): ^{13}C NMR ($CHCl_3$): $\delta=5.0$ ($^2J_{PC}=5.1$ Hz), 16.6 ($^1J_{PC}=16.6$ Hz), 20.9 (CH_3CO), and 176.1 (CH_3Co). IR (neat): $\nu(C=O)$ 1724 cm⁻¹. Found: P, 11.6%. Calcd for $C_8H_{19}-O_5PS$: P, 11.99%.

Reaction of Trialkylarsines with Sulfur Trioxide. Sulfur trioxide (20.5 mmol in 10 cm³ of dichloromethane) was added to triisopropylarsine (1.40 g, 6.83 mmol) in 10 cm³ of dichloromethane at −50 °C. After removal of the solvent, arsenic tris(2-propanesulfonate) (2.67 g, 88%) was obtained as a viscous liquid. Found: C, 24.3; H, 4.83%. Calcd for $C_9H_{21}AsO_9S_3$: C, 24.32; H, 4.74%. Reaction of tributylarsine (1.78 g, 7.28 mmol) with 3 molar excess of sulfur trioxide gave arsenic tris(1-butanesulfonate) (3.26 g, 92%). Found: C, 28.9; H, 5.52%. Calcd for $C_{12}H_{27}-AsO_9S_3$: C, 29.63; H, 5.60%.

Reaction of Trialkylstibines with Sulfur Trioxide. Triisopropylstibine (2.06 g, 8.20 mmol) and sulfur trioxide (24.6 mmol) were treated in 20 cm³ of dichloromethane at −50 °C. Antimony tris(2-propanesulfonate) (3.62 g, 90%) was obtained as a viscous liquid. Found: C, 22.4; H, 4.56%. Calcd for $C_9H_{21}O_9S_3Sb$: C, 21.96; H, 4.30%. Tributylstibine (2.08 g, 7.11 mmol) and 3 molar excess of sulfur trioxide gave antimony tris(1-butanesulfonate) (3.18 g, 84%), a viscous liquid. Found: C, 27.4; H, 5.12%. Calcd for $C_{12}H_{27}O_9S_3Sb$: C, 27.03; H, 5.10%.

Reaction of Trialkyl Phosphite with Sulfur Trioxide. A typical reaction is described. When a solution of sulfur trioxide (19.2 mmol in 5 cm³ of dichloromethane) was added to trimethyl phosphite (2.38 g, 19.2 mmol) in 10 cm³ of dichloromethane at −78 °C, a violent reaction took place. After removal of the solvent, the mixture was distilled under reduced pressure to give a fraction (2.57 g) of the bp range of 60—86 °C/12 mmHg. The following substances were isolated from this fraction (1.50 g) by column chromatography on silica gel (changing eluent from cyclohexane to benzene and then to chloroform): trimethyl phosphate (0.33 g), trimethyl thiophosphate (0.06 g), dimethyl methylphosphonate (0.30 g), and dimethyl sulfate (0.82 g). All these compounds were identified by comparing the physical and spectroscopic (IR, ^1H, ^{13}C, and ^{31}P NMR) data with those of the authentic samples.[21] In a similar manner, the reactions of other trialkyl phosphites with sulfur trioxide were performed and the distribution of the reaction products were analyzed by analytical GLC.

Reaction of Triakoxyarsines with Sulfur Trioxide. A solution of sulfur trioxide (17.3 mmol in 5 cm³ of dichloromethane) was added slowly to trimethoxyarsine (2.93 g, 17.4 mmol) in 10 cm³ of dichloromethane at −50 °C. After the solvent was evaporated, dimethoxyarsenic methyl sulfate (3.90 g, 90%) was obtained as a colorless liquid. A distillation of the crude product (2.65 g) under reduced pressure gave pure dimethoxyarsenic methyl sulfate (1.01 g, 39%), bp 96—97 °C/0.22 mmHg; Found: C, 14.3; H, 3.63%. Calcd for $C_3H_9O_6SAs$: C, 14.52; H, 3.66%, along with dimethyl sulfate (0.35 g, 27%) and a residue (1.18 g) containing arsenic atoms. Reaction of trimethoxyarsine (1.65 g, 9.82 mmol) and sulfur trioxide (19.7 mmol) was carried out under similar conditions. The white crystals which formed were washed with hexane. Methoxyarsenic bis(methyl sulfate) (3.03 g, 94%) was obtained, mp 59—63 °C. The distillation of the crude methoxyarsenic bis(methyl sulfate) (1.93 g) gave methoxyarsenic bis(methyl sulfate) (0.54 g, 28%), bp 98—103 °C/0.2 mmHg; Found: C, 10.7;

H, 2.89%. Calcd for $C_3H_9O_9S_2As$: C, 10.98; H, 2.76%, dimethyl sulfate (0.52 g, 38%) and a grayish residue (0.60 g). Reaction of trimethoxyarsine (1.97 g, 11.7 mmol) with sulfur trioxide (35.2 mmol) gave crude arsenic tris(methyl sulfate) (4.49 g, 94%). Distillation of this crude product gave arsenic tris(methyl sulfate) (19%), bp 82—85 °C/0.08 mmHg, Found: C, 8.76; H, 2.28%. Calcd for $C_3H_9O_{12}S_3As$: C, 8.83; H, 2.20%, and dimethyl sulfate (21%). Equimolar reaction of triethoxyarsine (1.65 g, 7.86 mmol) and sulfur trioxide gave diethoxyarsenic ethyl sulfate (2.02 g, 88%). The distillation gave diethoxyarsenic ethyl sulfate (44%), bp 107—110 °C/0.1 mmHg and diethyl sulfate (36%), bp 94—96 °C/18 mmHg; IR (neat): $\nu(SO_2)$ 1385, and 1158 cm^{-1}; ^1H NMR (CCl_4): $\delta=1.43$ (t, 3H), and 4.30 (q, 2H); ^{13}C NMR ($CHCl_3$): $\delta=14.6$, and 69.8. When reaction of triethoxyarsine with sulfur trioxide was carried out in 1:2 and 1:3 molar ratios of the reagents, the corresponding oily insertion products were obtained in 97 and 92% yields, respectively. Attempted distillation of the adducts caused a complete decomposition which afforded diethyl sulfate (54 and 40%, respectively).

Reaction of Triethoxystibine with Sulfur Trioxide. A solution of sulfur trioxide (20.0 mmol in 10 cm^3 of dichloromethane) was added to triethoxystibine (5.12 g, 19.9 mmol) in 10 cm^3 of dichloromethane at −50 °C. In a few minutes, white crystals were formed. The mixture was warmed to room temperature and the crystals were collected by filtration. Recrystallization from benzene/chloroform (9/1) gave diethoxyantimony ethyl sulfate (5.9 g, 88%), mp 76—80 °C. Found: C, 20.5; H, 4.54%. Calcd for $C_6H_{15}O_6SSb$: C, 21.38; H, 4.49%. An attempted distillation of the diethoxyantimony ethyl sulfate (1.23 g, 3.64 mmol) caused the decomposition which gave diethyl sulfate (0.40 g, 2.58 mmol) and a residue (0.82 g). A solution of sulfur trioxide (19.7 mmol in 5 cm^3 of dichloromethane) was added to triethoxystibine (2.55 g, 9.92 mmol) in 10 cm^3 of dichloromethane at −50 °C. After removal of the solvent, the residue was dried under reduced pressure (5 h, at 15—20 °C/0.07 mmHg), leaving a brown viscous liquid (3.96 g) which was used without further purification for ^1H and ^{13}C NMR and IR spectra measurements. These spectra proved the product to be ethoxyantimony bis(ethyl sulfate) (96%). Found: C, 17.8; H, 3.42%. Calcd for $C_6H_{15}O_9S_2Sb$: C, 17.28; H, 3.62%. In a similar way, the reaction of triethoxystibine (3.37 g, 13.1 mmol) and sulfur trioxide (39.4 mmol) in 20 cm^3 of dichloromethane gave antimony tris(ethyl sulfate) (6.03 g, 93%), orange oil. Found: C, 14.5; H, 3.00%. Calcd for $C_6H_{15}O_{12}S_3Sb$: C, 14.49; H, 3.04%. Pyrolysis of the tris (sulfate) (2.00 g, 4.02 mmol) under reduced pressure gave diethyl sulfate (0.53 g, 3.42 mmol) and a charred residue (1.37 g).

Photochemistry of 9-[2-(*N*-Substituted Aminomethyl)-1-naphthyl]-phenanthrenes. Intramolecular Addition of Amines to Excited State of Phenanthrene in Conformationally Rigid System

Akira Sugimoto, Ryozo Sumida, Naoto Tamai, Hiroo Inoue, and Yoshio Otsuji*

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received April 23, 1981)

Irradiation of benzene solutions of 9-[2-(*N*-substituted aminomethyl)-1-naphthyl]phenanthrenes (**3a—d**) gave pyrroline derivatives by the attack of the NH group on the C-9 carbon atom of the phenanthrene ring. The reactions were highly selective in regio- and stereochemical senses, and occurred through exciplexes formed by intramolecular interaction between the amino group and the excited phenanthrene moiety in **3a—d**. Mechanistic features of these photoreactions are discussed on the basis of chemical and photochemical properties of substrates and products.

The photochemical reactions of aromatic hydrocarbons with amines have been studied extensively in recent years. For example, primary and secondary amines undergo the photoaddition to aromatics such as benzene[1] and anthracene[2] mainly at their nitrogen atoms, and tertiary amines generally at their carbon atoms α to the amino groups. Similar photoaddition was observed for naphthalene[3] and stilbene.[4] Substituted aromatics sometimes undergo the photosubstitution by amines.[5] It has been reported that these reactions occur through exciplexes or solvated radical anion-radical cation pairs produced by an intermolecular interaction between the excited aromatics and the ground state of amines. However, since these reactions usually afford several products at the same time, the mechanistic interpretation of the reactions often becomes equivocal.

Intramolecular interactions between excited aromatic hydrocarbons and ground state of amines have also been studied in bichromophoric molecules containing both an aromatic moiety and a tertiary amino group.[6] These studies have mainly manifested photophysical processes such as intramolecular electron-transfer and exciplex formation, but the photochemical properties of these systems have not been much elucidated.

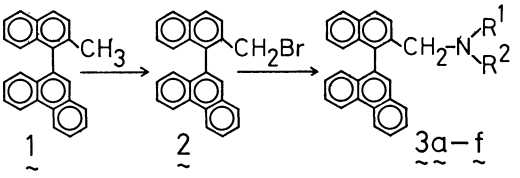
In this study, we synthesized 9-[2-(*N*-substituted aminomethyl)-1-naphthyl]phenanthrenes (**3a—f**) from 9-(2-methyl-1-naphthyl)phenanthrene (**1**), and studied their photochemical behavior. In these compounds (Scheme 1), phenanthrene ring (electron acceptor) and amino group (electron donor) are connected by naphthylmethyl group, whereby the spatial relationship between both groups is rendered relatively rigid for a steric reason: a molecular model shows that in these compounds, the two chromophoric groups can be situated in a neighboring position in their favorable conformations. Consequently, these compounds may serve as a good candidate for the elucidation of photochemical properties in a bichromophoric system.

In this paper we demonstrate that the RN group and hydrogen atom of the amino functions in **3a—d** add respectively to the C-9 and C-10 atoms of the phenanthrene ring in a *cis* mode to form a pyrroline ring system. This reaction is highly selective in regio- and stereochemical senses and occurs through exciplexes formed by intramolecular interaction between the amino groups and the excited phenanthrene moiety.

Results and Discussion

Preparations of the Compounds. The compounds **3a—f** were prepared by the route shown in Scheme 1. The structures of these compounds were secured from their elemental analyses and spectral data (see Experimental).

Preparative Photochemistry and Properties of Products. Irradiation of a degassed benzene solution of **3a** in Pyrex tube with a high-pressure mercury arc gave **4a** as a sole isolable product in high yield. Similar irradiation of **3b—d** gave the corresponding cyclized compounds, **4b—d**, also in high yields (Scheme 2). However, **3e** and **3f** were essentially unreactive under similar conditions, although prolonged irradiation of **3e** afforded a mixture containing at least four compounds. The results are summarized in Table 1. The structures of **4a—d** were established from their elemental analyses, spectral data, and chemical properties. The relevant ^{1}H NMR spectral data are listed in Table 2.



a: $R^1=C_6H_5$, $R^2=H$; **b**: $R^1=CH_3$, $R^2=H$; **c**: $R^1=C_6H_{11}$, $R^2=H$; **d**: $R^1=t\text{-}C_4H_9$, $R^2=H$; **e**: $R^1=C_6H_5$, $R^2=CH_3$; **f**: $R^1=R^2=CH_3$

4b	—	4.20	3.14	3.58	17
4c	—	4.38	3.04	3.68	17
4d	—	4.50	3.37	3.61	18

a) δ Values. Solvent for **3c** and **3f** was CCl_4 and that for others was $CDCl_3$. b) Signals in the region of δ 8.4—8.9 ppm were shown.

The ^{1}H NMR spectrum of **3a** (Fig. 1a) remarkably changed after irradiation. A characteristic multiplet around δ 8.6—8.8 (2H, H-4 and H-5 of phenanthrene ring) shifted to higher field region (δ 6—8, usual aromatic region). A broad singlet at δ 3.80 (1H, NH) and a singlet at δ 4.10 (2H, CH_2NH) of **3a** disappeared and shifted, respectively. Instead, a singlet at δ 5.00 (2H) and an AB quartet (J_{AB}=19 Hz) centered at δ 3.45 (1H) and 3.97 (1H) appeared (Fig. 1b). The singlet at δ 5.00 was assigned to the methylene protons in the pyrroline ring of **4a**. The higher field signals in the AB quartet were assigned to the H_A proton in the cyclohexadiene ring in **4a** and the lower field ones to the H_B proton in the same ring. A downfield shift of H_B proton compared to the H_A proton may be due to a deshielding effect of lone-pair electrons on the adjacent nitrogen atom. Further support for the structure of **4a** was derived from the following observations.

Irradiation of **3a** in D_2O-saturated benzene led to the formation of a monodeuterated compound of **4a** (**4a**-D_B): it must be noticed here that the NH hydrogen in **3a** is replaced by deuterium through a rapid H-D exchange to form **3a**-ND before irradiation. The ^{1}H NMR spectrum of **4a**-D_B (Fig. 1c) showed a singlet at δ 3.45 (1H), which indicates that the H_B atom of **4a** is displaced by deuterium atom in the photoreaction of **3a**-ND (see Scheme 3).

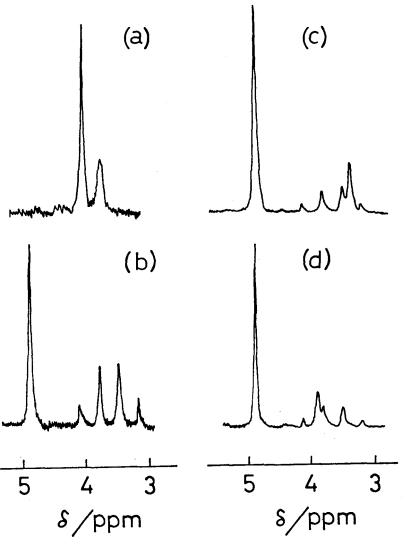

Fig. 1. ^{1}H NMR spectra of **3a** and **4a** in the region of 3—5 ppm.
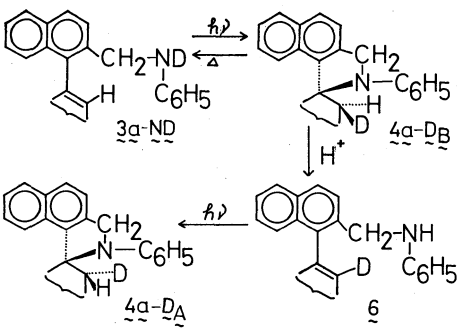
(a): **3a**, (b): **4a**, (c): **4a**-D_B contaminated by **4a**, (d): **4a**-D_A contaminated by **4a**.



Scheme 3.

Compound **4a** was quantitatively converted back into **3a** by heating at its melting point or by treating with sulfuric acid. Compound **3a** thus obtained gave again **4a** in high yield upon irradiation in benzene. However, the compound obtained by heating **4a**-D_B, followed by irradiation in benzene showed the different ^{1}H NMR spectrum from that of the other compound which was obtained by treating **4a**-D_B with sulfuric acid, followed by irradiation in benzene. The ^{1}H NMR spectral examination revealed that the former compound is **4a**-D_B (Fig. 1c) contaminated by a small amount of **4a**. However, the ^{1}H NMR spectrum of the latter compound displayed a singlet at δ 3.93 (1H) (Fig. 1d), indicating that at this time the H_A atom of **4a** is replaced with deuterium atom to give **4a**-D_A.

All of the above observations can be explained in terms of the pathway illustrated in Scheme 3. Irradiation of **3a**-ND causes the addition of the ND function to the C-9 and C-10 carbons of the phenanthrene ring in a *cis*-mode to give **4a**-D_B. Thermolysis of

4a-D_B gives **3a**-ND by *cis*-elimination of the ND function. On the other hand, treatment of **4a**-D_B with acid affords the deuterium-incorporated compound **6** by *trans*-elimination of the N–H bond. Irradiation of **6** results in the formation of **4a**-D_A.

The ^1H NMR spectral data of **4b—d** shown in Table 2 strongly support that they also have the structures given in Scheme 2. The possibility of the structure of **5** for these compound can be neglected.

Spectral Studies. Fluorescence of aromatic hydrocarbons is often quenched by amines. It has been demonstrated that such quenching occurs through exciplexes produced by interaction between the excited aromatics and the ground state of amines, and that the exciplexes thus formed have a high polarity due to electron-transfer from the latter to the former.[7]

Compound **1**, which has no amino group in the molecule, emitted strongly fluorescence upon irradiation in benzene. Its spectral pattern was similar to that of phenanthrene. The fluorescence was efficiently quenched by adding triethylamine into the solution. It is therefore supposed that there exists intermolecular electron-transfer interaction between the amine and the excited phenanthrene moiety in **1**.

Figure 2 shows the fluorescence spectra of **3b**, **e**, **f** in benzene; the fluorescence of **3a** was too weak to be detected. The spectral pattern of these compounds was similar to that of phenanthrene and also of **1**. However, the intensities of the fluorescent lights were appreciably weaker than the intensity of fluorescent light of **1**, and decreased with decreasing ionization potentials of the amino moieties of these compounds.[8] In addition, the intensity of fluorescence of **3b** in benzene decreased by adding acetonitrile into the solution (Fig. 3), whereas that of **1** remained substantially unchanged by the addition of acetonitrile. Furthermore, new broad emissions were observed in benzene in 440 nm region for photochemically unreactive compounds, **3e** and **3f**. The maxima of these new emissions shifted to longer wavelength side by the addition of acetonitrile. Therefore, these emissions are attributable to the formation of exciplexes.

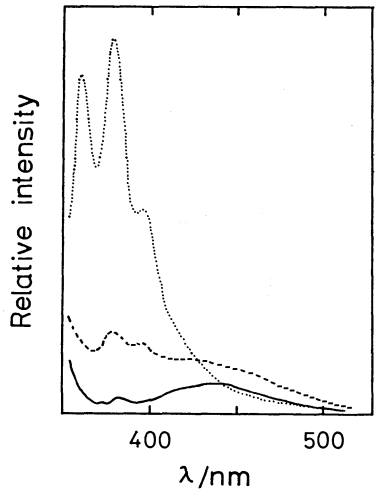


Fig. 2. Fluorescence spectra of **3b**, **3e**, and **3f** in benzene.
·····; **3b**, ——; **3e**, - - - -; **3f**.

These results suggest that intramolecular interaction between the amino groups and the excited phenanthrene ring occurs upon irradiation of **3a—d** and also **3e—f**, and that the interaction has a character of electron-transfer.

Mechanism and Solvent Effect on the Photochemical Reactivity. We now propose a mechanistic pathway shown in Scheme 4 for the photoreaction of **3a—d**.

In an initial stage, intramolecular exciplexes **7** are formed by interaction between the amino groups and the excited phenanthrene moiety. The exciplexes may dissociate to the cation radical-anion radical pairs **8** in polar solvents. The addition of the NH group to the C-9, C-10 bond of phenanthrene ring occurs from **7** or **8** only if the pairs exist in a solvent cage. This reaction takes place almost in a concerted fashion and selectively in a mode of *cis*-addition to form **4a—d**. When **7** have no hydrogen on the nitrogen as in the cases of **3e** and **3f**, the addition reaction does not occur. In these cases, the emissions from exciplexes can be observed.

This mechanistic pathway is consistent with the solvent effect on the photochemical reactivity. The results of Table 1 and Fig. 4 indicate that the yields of **4a—d** decrease with increasing solvent polarity, and the yield depression of **4b** in polar solvent is particularly remarkable.

If **7** and **8** are in a nonpolar solvent, their amino and phenanthryl groups exist in a neighboring position. In such a case, the addition of the amino groups to

—○—: R=CH_3, C_6H_6–CH_3CN, irradiated for 4 h.

the phenanthrene moiety occurs efficiently. On the other hand, they may dissociate in polar solvents to form solvent separated ion pairs which will go back to the component neutral species by back electron-transfer. This assumption accounts for both the stereochemical course of the reaction and the solvent effect on the reactivity. A molecular model shows that in **3a—d**, particularly in **3a**, the amino and phenanthryl groups lie in close proximity in their prefered conformation. The preponderance of the conformation will be multiplied by the attachment of a bulky group on the amino nitrogen. As a result, **3a** reacts smoothly to give **4a** in any solvent.

Experimental

All melting points are uncorrected. IR spectra were obtained on a Hitachi 215 infrared spectrophotometer. ^1H NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz) with tetramethylsilane as an internal standard. Ultraviolet and visiblelight absorption spectra were obtained on a Hitachi EPS-3T spectrometer. Fluorescence spectra were recorded on a Shimadzu RF-501 fluorophotometer.

Materials. *9-(2-Methyl-1-naphthyl)phenanthrene (**1**)*: Grignard reagent, prepared from 1-bromo-2-methylnaphthalene (6.8 g, 30 mmol), magnesium (0.75 g, 30 mmol), and a small amount of iodine in ether–benzene (1:1, v/v), was added over 30 min to a solution of 9-bromophenanthrene (5.5 g, 20 mmol) and dichlorobis(triphenylphosphine)nickel(II) (0.15 g) in anhydrous ether (50 ml). The mixture was refluxed for 5 h and acidified with dil hydrochloric acid. The organic layer was separated, dried ($MgSO_4$), and evaporated. The gummy residue was triturated with a small amount of hexane to give a white solid. The solid was filtered off and recrystallized from ethanol–benzene (2:1, v/v), giving **1** (4.8 g, 70% based on 9-bromophenanthrene): mp 148—150 °C; NMR (CCl_4) δ=2.12 (3H, s, CH_3) and 6.5—8.8 (15H, m, aromatic). Found: C, 94.32; H, 5.58%. Calcd for $C_{25}H_{18}$: C, 94.30; H, 5.70%.

*9-(2-Bromomethyl-1-naphthyl)phenanthrene (**2**)*: A mixture of **1** (3 g, 9.4 mmol), *N*-bromosuccinimide (1.7 g, 9.5 mmol) and benzoyl peroxide (3 mg) in CCl_4 (50 ml) was refluxed for 8 h. After cooling, the deposited solid was filtered off. Evaporation of the filtrate left a gummy substance which solidified upon treatment with a small amount of petroleum ether. The NMR spectrum showed that this solid contains **2** in 90—97% purity. Chromatography of the crude material on silica gel with hexane gave pure compound: mp 123—125 °C; NMR (CCl_4) δ=4.14 and 4.32 (2H, AB-type q, J=10 Hz, CH_2) and 6.8—8.8 (15H, m, aromatic). Found: C, 75.91; H, 4.14%. Calcd for $C_{25}H_{17}Br$: C, 75.57; H, 4.31%.

*9-(2-Anilinomethyl-1-naphthyl)phenanthrene (**3a**)*: A mixture of **2** (3.4 g, 8.5 mmol) and aniline (3.2 g, 34 mmol) in 1,2-dimethoxyethane (60 ml) was stirred for 24 h at room temperature, and the deposited solid was removed by filtration. The filtrate was concentrated under reduced pressure, and the oily residue crystallized immediately upon adding a small amount of methanol. The solid was recrystallized from benzene–hexane (1:1, v/v) to give **3a** (2.41 g, 64%): mp 169—170 °C; IR (KBr) 3400 (NH) and 1320 cm^{-1} (CN); NMR ($CDCl_3$) δ=3.80 (1H, broad s, NH), 4.10 (2H, s, CH_2), 6.2—8.0 (18H, m, aromatic) and 8.6—8.8 (2H, m, aromatic). Found: C, 90.84; H, 5.56; N, 3.47%. Calcd for $C_{31}H_{23}N$: C, 90.92; H, 5.66; N, 3.42%.

*9-(2-Methylaminomethyl-1-naphthyl)phenanthrene (**3b**)*: A solution of **2** (2.5 g, 6.3 mmol) in 1,2-dimethoxyethane (15 ml) was added to a mixture of methylamine hydrochloride (17 g, 0.25 mol) in methanol (80 ml). Solid potassium hydroxide (14 g, 0.25 mol) was then added in 3 g portions with stirring. After stirring for 12 h, the deposited solid was filtered off, and the filtrate was concentrated *in vacuo*. The residue was poured into water and extracted with ether. The extract was concentrated and chromatographed on silica gel with benzene–ether (1:1, v/v) to give **3b** (0.83 g, 38%): mp 65—67 °C; NMR ($CDCl_3$) δ=1.4 (1H, s, NH), 2.12 (3H, s, CH_3), 3.50 (2H, s, CH_2), 7.0—8.0 (13H, m, aromatic), and 8.4—8.8 (2H, m, aromatic). Found: C, 89.63; H, 6.11; N, 3.87%. Calcd for $C_{26}H_{21}N$: C, 89.88; H, 6.09; N, 4.03%.

*9-(2-Cyclohexylaminomethyl-1-naphthyl)phenanthrene (**3c**)*: A mixture of **2** (2.0 g, 5 mmol) and cyclohexylamine (5 ml) in 1,2-dimethoxyethane (20 ml) was stirred for 12 h at room temperature, and the deposited solid was removed by filtration. The filtrate was poured into 100 ml of water, and extracted with benzene. Evaporation of the solvent gave a white solid which was purified by chromatography on silica gel with benzene–ether (1:1, v/v), yielding **3c** (1.43 g, 73%): mp 160.5—161.5 °C; NMR (CCl_4) δ=0.3—2.4 (12H, m, cyclohexyl and NH), 3.50 (2H, s, CH_2), 6.7—8.3 (13H, m, aromatic), and 8.4—8.8 (2H, m, aromatic). Found: C, 89.44; H, 7.25; N, 3.44%. Calcd for $C_{31}H_{29}N$: C, 89.59; H, 7.03; N, 3.37%.

*9-(2-t-Butylaminomethyl-1-naphthyl)phenanthrene (**3d**)*: This compound was prepared by the method similar to that for **3c**. The product was purified by chromatography on silica gel with benzene. The yield of **3d** was 85%: mp 64—70 °C; NMR ($CDCl_3$) δ=0.65 (9H, s, CH_3), 1.0—1.2 (1H, broad s, NH), 3.50 (2H, s, CH_2), 7.0—8.0 (13H, m, aromatic) and 8.5—8.8 (2H, m, aromatic). Found: C, 89.39; H, 6.98; N, 3.55%. Calcd for $C_{29}H_{27}N$: C, 89.42; H, 6.99; N, 3.60%.

*9-[2-(N-Methylanilinomethyl)-1-naphthyl]phenanthrene (**3e**)*: This compound was prepared from **2** and *N*-methylaniline in 1,2-dimethoxyethane by the method applied for the preparation of **3a**: mp 167.5—168.5 °C; NMR ($CDCl_3$) δ= 2.80 (3H, s, CH_3), 4.10 and 4.30 (2H, AB-type q, J=17 Hz, CH_2) and 6.4—8.8 (20H, m, aromatic). Found: C, 90.53; H, 5.90; N, 3.38%. Calcd for $C_{32}H_{25}N$: C, 90.74;

H, 5.95; N, 3.30%.

9-(2-Dimethylaminomethyl-1-naphthyl)phenanthrene (3f): This compound was prepared from dimethylamine hydrochloride and **2** by the method applied for the preparation of **3b**: mp 115—117 °C; NMR (CCl_4) δ=1.97 (6H, s, CH_3), 3.15 (2H, broad s, CH_2), 6.8—7.9 (13H, m, aromatic), and 8.4—8.7 (2H, m, aromatic). Found: C, 89.97; H, 6.36; N, 3.89%. Calcd for $C_{27}H_{23}N$: C, 89.71; H, 6.41; N, 3.88%.

Photoreactions. A general procedure is shown in an example of the photoreaction of **3a**: a solution of **3a** (100 mg, 0.25 mmol) in benzene (10 ml) in a Pyrex tube was degassed by three freeze-pump-thaw cycles under argon and the tube was sealded under reduced pressure. Irradiation was carried out by using a merry-go-round apparatus (Eikosha PIH-300) with a 300 W high-pressure mercury lamp cooled with water. After irradiation, benzene was evaporated under reduced pressure. The residue was dissolved in $CDCl_3$ and its ^1H NMR spectrum was recorded. The yield of the photoproduct **4a** was estimated from the intensities of methylene signals.

Benzene-d_6 solutions of **3a**—**d** (8×10^{-2} M) sealded in NMR measureing tubes were irradiated in a manner similar to that employed for preparative photoreactions. The rates of the photoreactions were measured by following the changes in intensities of signals in the NMR spectra at appropriate time intervals. Yields were estimated on the basis of the relative intensities of methylene signals of each cyclic compound to that of tetramethylsilane used as an internal standard.

Photoproducts. The photoproducts were purified by chromatography on silica gel (**4a** and **4b**) or recrystallization from methanol (**4c** and **4d**). **4a**: mp 105—120 °C (dec); NMR ($CDCl_3$) δ=3.97 and 3.45 (2H, AB-type q, J=19 Hz, CH_2), 5.00 (2H, s, CH_2), and 6.2—8.1 (19H, m, aromatic). Found: C, 90.84; H, 5.65; N, 3.53%. Calcd for $C_{31}H_{23}N$: C, 90.92; H, 5.66; N, 3.42%. **4b**: mp 65—75 °C (dec); NMR ($CDCl_3$) δ=2.05 (3H, s, CH_3), 3.58 and 3.14 (2H, AB-type q, J=17 Hz, CH_2), 4.20 (2H, s, CH_2) and 6.8—8.0 (14H, m, aromatic). Found: C, 90.03; H, 6.40; N, 4.00%. Calcd for $C_{26}H_{21}N$: C, 89.88; H, 6.09; N, 4.03%. **4c**: mp 125—130 °C (dec); NMR ($CDCl_3$) δ=0.5—1.7 (m, cyclohexyl), 3.04 and 3.68 (AB-type q, J=17 Hz, CH_2), 4.38 (s, CH_2) and 6.8—8.0 (m, aromatic). Found: C, 88.97; H, 7.52; N, 3.49%. Calcd for $C_{31}H_{29}N$: C, 89.59; H, 7.03; N, 3.37%. **4d**: mp 100—110 °C (dec); NMR ($CDCl_3$) δ=0.92 (s, CH_3), 3.37 and 3.61 (AB-type q, J=18 Hz, CH_2), 4.50 (s, CH_2), and 6.9—8.0 (m, aromatic). Found: C, 90.06; H, 7.33; N, 3.58%. Calcd for $C_{29}H_{27}N$: C, 89.42; H, 6.99; N, 3.60%.

8) This conclusion was derived from the assumption that the ionization potentials of the amino moieties in these compounds can be estimated from those of the corresponding *N*-substituted methylamines: for example, 8.36 eV for $(CH_3)_2NH$, 8.12 eV for $(CH_3)_3N$, and 7.36 eV for $(CH_3)_2NC_6H_5$ were used as the ionization potentials of the amino moieties in **3b**, **3f**, and **3e**, respectively.

Branched-chain Sugars. XXIII. Stereoselectivities in the Addition of Nucleophiles to Several 4-Uloses[1]

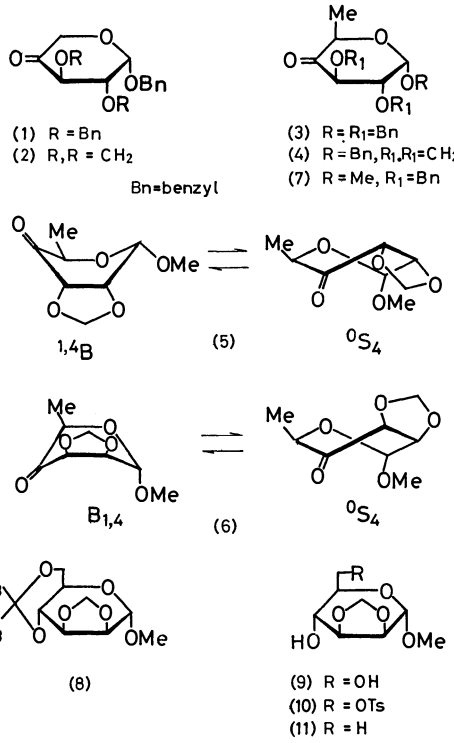
Masafumi MATSUZAWA, Ken-ichi SATO, Toshio YASUMORI, and Juji YOSHIMURA*

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received April 24, 1981)

The stereoselectivities in the 1,2-addition of nucleophiles such as methylmagnesium iodide, vinylmagnesium bromide, and 2-lithio-2-methyl-1,3-dithiane to seven kinds of 4-uloses were examined. The configurations of *C*-vinyl derivatives obtained were determined from the chemical shifts of α-carbons in ^{13}C-NMR spectra.

In the preceding paper of this series[1] benzyl 2,3-di-*O*-benzyl- (**1**) and 2,3-*O*-methylene-β-L-*threo*-pentopyranosid-4-uloses (**2**), benzyl 2,3-di-*O*-benzyl-6-deoxy- (**3**) and 6-deoxy-2,3-*O*-methylene-α-D-*xylo*-hexopyranosid-4-uloses (**4**), and methyl 6-deoxy-2,3-*O*-methylene-α-D-*ribo*-hexopyranosid-4-ulose (**5**) were synthesized as the starting materials for the synthesis of 2,3-*O*-methylene-4-*C*-substituted aldonolactones found in orthosomycins.[2] For this purpose, a two-carbon unit should be stereoselectively introduced into the carbonyl function of **2** and **4**. In this paper, stereoselectivities in the addition of nucleophiles to the above 4-uloses were examined, together with newly synthesized methyl 6-deoxy-2,3-*O*-methylene-α-D-*lyxo*-hexopyranosid-4-ulose (**6**) and known methyl 2,3-di-*O*-benzyl-6-deoxy-α-D-*xylo*-hexopyranosid-4-ulose (**7**).[3]



Results and Discussion

The new 4-ulose **6** was synthesized as follows. Reaction of methyl 4,6-*O*-isopropylidene-α-D-mannopyranoside[4] in *N*,*N*-dimethylformamide with sodium hydride and dibromomethane gave the corresponding 2,3-*O*-methylene derivative (**8**) in 61% yield. Partial hydrolysis of **8** in 70% acetic acid at room temperature for 16 h gave the corresponding *O*-deisopropylidenated product (**9**) in quantitative yield. Monotosylation of **9** gave the 6-*O*-tosylate (**10**) in 63% yield. Reduction of **10** in tetrahydrofuran with lithium aluminium hydride gave the 6-deoxy derivative (**11**) in 78% yield. Oxidation of **11** with dimethyl sulfoxide–trifluoroacetic anhydride[5] gave **6** in 93% yield.

The coupling constants of **5** ($J_{1,2}$=4.2, $J_{2,3}$=8.8, $J_{3,5}$=0.8 Hz) and **6** ($J_{1,2}$=0, $J_{2,3}$=6.4 Hz) indicate that these compounds exist in a boat or a skew-boat conformation, but not in the usual *C*1 conformation. Collins and Whitton[6] suggested the $^{\circ}S_4$ conformation to the 2,3-*O*-isopropylidene analogue ($J_{1,2}$=3.8, $J_{2,3}$=9.0, $J_{3,5}$=1.2 Hz) of **5**, however, the assingment of ^{1,4}B for **5** and the $^{\circ}S_4$ for **6** will be more probable from $J_{2,3}$ values.

As the nucleophiles for 1,2-addition to 4-uloses, methylmagnesium iodide, methyllithium, vinylmagnesium bromide, and 2-lithio-2-methyl-1,3-dithiane were used, and the results were summarized in Table 1.

The configuration of products in these reactions was mainly determined from the chemical shifts of the branching α-carbons in ^{13}C NMR spectra. Application of the fact that equatorially oriented *C*-methyl carbons are deshielded with respect to axially oriented methyl carbons for the configurational assignment of *C*-methylhexopyranosides[7] has been extended to the 1,3-dithian-2-yl,[8] hydroxymethyl,[9] nitromethyl,[10] and benzoylaminomethyl[10] derivatives. As shown in Table 2, this principle was successfully used for the determination of the configuration of 4-*C*-vinyl derivatives, by the comparison of the chemical shifts of methin carbons in the vinyl groups. However, this trend could not be observed in those of methylene carbons in vinyl groups. Miljkovic *et al.* depicted that there are *ca.* 6 ppm difference in the chemical shifts between axial and equatorial *C*-methyl carbons.[7] The smaller differences between **12** and **13**, and **14** and **15** indicate that the conformation of pentopyranosides having an axial substituent tends to deviate from *C*1.

The configurations of epimeric 4-*C*-(2-methyl-1,3-dithian-2-yl) derivatives (**16** and **17**) were determined from the fact that **16** exists in 1*C* ($J_{1,2}$=1.3, $J_{2,3}$=3.0 Hz), whereas **17** in *C*1 ($J_{1,2}$=4.0, $J_{2,3}$=9.2 Hz) conformation. It is known that this bulky group in axial orientation causes a similar inversion of the conformation to that of **16**.[11] The reliability of these assignments was proved by the actual derivation of **15**, **22**, and **28** into naturally occuring branched-chain sugars[12,13] and also by the establishment of a principle for the determination of the chirality of

1-hydroxyethyl groups introduced *via* the corresponding vinyl and ethylidene derivatives.[14]

In the results of **1** (Runs 1—5) shown in Table 1, it is characteristic that the axial attack generally predominates over the equatorial attack, excepting the Grignard reaction in ether at −78 °C. The complementary stereoselectivity between the Grignard and methyllithium reactions at lower temperature was also observed in the cases of methyl 2,3-di-*O*-methyl- and 2,3-di-*O*-mesyl-6-*O*-trityl-α-D-*xylo*-hexopyranosid-4-uloses.[7] The reason for this remarkable fact should be pursued in more detail. The predominancy of the axial attack will be attributed again to changeable conformation of **1**, because the equatorial attacks are predominant in the case of **2** (Runs 6, 7) in which the 2,3-*O*-methylene ring prohibits the inversion of the *C*1 conformation. A similar trend is also observed in the reaction of **7** and **4** (Runs 9, 10) with methylmagnesium iodide, though the equatorial attack is predominant in these hexopyranosides. In the cases of **5** and **6**, the nucleophile exclusively approaches to the carbonyl function from the opposite side of the bulky 2,3-*O*-methylene ring. Similar stereoselec-

a) Data of protons in benzyl groups were omitted. b) $J_{OH,5e}$=3.0 was observed.

tivities were also observed in the reduction of 2,3-*O*-isopropylidene analogue of **5**[6] and 2,3-*O*-isopropylidene analogue of **6**[15] and the Grignard reaction[16] of the enantiomer of the latter. It is obvious that bulkier nucleophiles such as vinylmagnesium bromide and 2-lithio-2-methyl-1,3-dithiane (Runs 7, 8, 11, 12) afford selectively the equatorial attack products, unless otherwise a special steric hindrance is present.

^{1}H NMR parameters of 4-*C*-methyl and 4-*C*-vinyl derivatives thus obtained were shown in Tables 3 and 4, respectively. Among *C*-methyl derivatives, coupling constants ($J_{1,2}$ and $J_{2,3}$) of **29** and **30** indicate that these compounds exist in the usual *allo* and *talo* configurations, respectively. The parameters shown in the both tables will be reasonable for the individual compounds.

Experimental

General Methods. Melting points were determined with a Mel-Temp melting point apparatus and not corrected. Optical rotations were measured at room tem-

perature in 0.5 dm tube with Carl Zeiss LEP-A1 or JASCO DIP-4 polarimeter, using chloroform as a solvent. ^{1}H-NMR spectra were recorded with a JEOL JNM PS-100 spectrometer in deuteriochloroform containing tetramethylsilane as the internal reference. ^{13}C-NMR data (Table 2) were obtained at 30 °C on a JEOL JNM FX-100 spectrometer in the pulse Fourier transform/proton noise decoupled mode at 25.15 MHz in deuteriochloroform. Each spectrum was obtained after 1000 transients with a frequency range of 5000 Hz. The pulse angle of 45° was used, with an acquisition time of 0.8 s and a pulse delay of 0.7 s. Chemical shifts and coupling constants were recorded in δ (ppm) and Hz units. Evaporations were conducted under diminished pressure.

Methyl 4,6-O-Isopropylidene-2,3-O-methylene-α-D-mannopyranoside (8). To a solution of methyl 4,6-*O*-isopropyridene-α-D-mannopyranoside (5.0 g, 21.3 mmol) and sodium hydride (1.5 g, 65 mmol) in *N,N*-dimethylformamide (10 ml, DMF) was added dibromomethane (11.5 g, 65 mmol) at 0 °C. After keeping the mixture at 0—5 °C for 2 h, the solution was poured into cold water, and extracted with ether. The extract was washed with water, dried, and evaporated to give a syrup which was purified on a silica-gel column (benzene–ethyl acetate 5:1) to give a colorless syrup **8** (3.2 g, 60.9%). $[\alpha]_D$ +2.0° (*c* 1.9); NMR: 5.19 and 4.94. (each s, 2H, OCH_2O), 4.97 (s, 1H, H-1), 4.25—3.50 (m, 6H, H-2,3,4,5,6,6'), 3.38 (s, 3H, OMe), 1.50 and 1.42 (each s, 6H, 2×CMe). Found: C, 53.54; H, 7.52%. Calcd for $C_{11}H_{18}O_6$: C, 53.65; H, 7.37%.

Methyl 2,3-O-Methylene-α-D-mannopyranoside (9). Partial hydrolysis of **8** (2.0 g, 8.1 mmol) in 70% acetic acid (20 ml) under reflux for 2 h gave the corresponding *O*-deisopropylidenated product **9** in quantitative yield (1.67 g). Mp 74—75 °C (ethyl acetate), $[\alpha]_D$ +29.6° (*c* 1.1); NMR: 5.17 and 4.98 (each s, 2H, OCH_2O), 4.96 (s, 1H, H-1), 4.21 (dd, 1H, $J_{2,3}$=5.8, $J_{3,4}$=7.0, H-3), 3.89 (d, 1H, H-2), 3.85 (d, 2H, $J_{5,6}$=3.4, H-6 and H-6'), 3.80—3.55 (m, 2H, H-4 and H-5), 3.40 (s, 3H, OMe). Found: C, 46.75; H, 6.90%. Calcd for $C_8H_{14}O_6$: C, 46.60; H, 6.84%.

Methyl 2,3-O-Methylene-6-O-p-tolylsulfonyl-α-D-mannopyranoside (10). To a solution of **9** (1.0 g, 4.85 mmol) in pyridine (10 ml) was added *p*-toluenesulfonyl chloride (1.4 g, 7.4 mmol) in dry benzene (15 ml) at 0 °C with stirring. After standing at 0 °C for 16 h, the solution was poured into ice–water and extracted with chloroform. The extract was processed as usual to give a syrup. The syrup was purified on a silica-gel column (benzene–acetone 8:1) to give a colorless **10** (1.1 g, 62.9%). $[\alpha]_D$ +6.5° (*c* 1.2); NMR: 7.78 and 7.30 (each d, 4H, *J*=8.0, Ph), 5.13 and 4.95 (each s, 2H, OCH_2O), 4.88 (s, 1H, H-1), 4.27 (d, 2H, $J_{5,6}$=3.6, H-6 and H-6'), 4.16 (q, 1H, $J_{2,3}$=5.8, $J_{3,4}$=7.0, H-3), 3.86 (d, 1H, H-2), 3.40—3.76 (m, 2H, H-4 and H-5), 3.55 (s, 3H, OMe), 2.44 (s, 3H, CMe). Found: C, 50.10; H, 5.75; S, 8.65%. Calcd for $C_{15}H_{20}O_8S$: C, 49.99; H, 5.59; S, 8.90%.

Methyl 6-Deoxy-2,3-O-methylene-α-D-mannopyranoside (11). To a solution of **10** (1.0 g, 2.8 mmol) in dimethyl sulfoxide (30 ml, DMSO) was added sodium borohydride (530 mg) and the mixture was kept at 80 °C for 4 h, poured into water (150 ml), and extracted with ether. The etheral extract was treated as usual to give syrupy **11** (410 mg, 77.7%) showing a single component on TLC and NMR. $[\alpha]_D$ +30.8° (*c* 0.9); NMR: 5.14 and 4.96 (each s, 2H, OCH_2O), 4.87 (s, 1H, H-1), 4.11 (dd, 1H, $J_{2,3}$=6.0, $J_{3,4}$=7.0, H-3), 3.87 (d, 1H, H-2), 3.65 (oct, 1H, $J_{4,5}$=9.2, $J_{5,6}$=6.0, H-5), 3.30 (dd, 1H, H-4), 1.29 (d, 3H, H-6), 3.37 (s, 3H, OMe), 2.80 (broad s, 1H, OH). Found: C, 50.47; H, 7.55%. Calcd for $C_8H_{14}O_5$: C, 50.52; H, 7.42%.

Methyl 6-Deoxy-2,3-O-methylene-α-D-lyxo-hexopyranosid-4-ulose (6). To a chilled solution (−78 °C) of DMSO (143 mg, 2 mmol) in dichloromethane (2 ml) was successively added a solution of trifluoroacetic anhydride (318 mg, 1.5 mmol) in dichloromethane (2 ml) with stirring, and after 10 min, a solution of **11** (135 mg, 0.7 mmol) in dichloromethane (4 ml) dropwise. After stirring for 1 h, the reaction mixture was carefully neutralized with triethylamine at −78 °C, and then poured into ice–water. The resulting solution was extracted with chloroform. The usual work-up of the extract gave **6** (125 mg, 93.6%) as a syrup, showing a single component on TLC and NMR. NMR: 5.17 (s, 1H, H-1), 4.98 and 4.88 (each s, 2H, OCH_2O), 4.33 (d, 1H, $J_{2,3}$=6.4, H-2), 4.37 (d, 1H, H-3), 4.24 (q, 1H, $J_{5,6}$=7.0, H-5), 3.47 (s, 3H, OMe), 1.37 (d, 3H, H-6).

This syrup was used for the next reaction, without further purification and measurement of the rotational value, because a small amount of impurities detectable in the NMR spectrum could not be removed.

Reaction of 4-Uloses with Methylmagnesium Iodide. Synthesis of 4-*C*-methyl derivatives is illustrated by the preparation of benzyl 2,3-di-*O*-benzyl-4-*C*-methyl-α-D-xylopyranoside (**12**) and -β-L-arabinopyranoside (**13**). To a chilled solution (−78 °C) of methylmagnesium iodide in ether (2 ml), prepared from magnesium turnings (0.12 g, 4.9 mmol) and methyl iodide (1 g, 7 mmol), was added dropwise a solution of **1** (0.3 g, 0.72 mmol) in ether (1 ml), and the mixture was stirred for 2 h at the same temperature, diluted with ether, and then poured into water. The ether layer was washed with water, dried, and then evaporated to give a syrup. Fractionation of the syrup on a silica-gel column (hexane–ethyl acetate 3:1) gave **12** and **13** as syrups in 27% (84 mg) and 70.6% (220 mg) yield, respectively.

When the reaction was carried out in ether–THF (1:1) at room temperature, **12** and **13** were obtained in 60.5 and 24% yield, respectively. **12**: $[\alpha]_D$ +90.1° (*c* 1.1); **13**: $[\alpha]_D$ +102° (*c* 5.0). Found for **12**: C, 74.23; H, 7.08, and for **13**: C, 74.13; H, 7.18%. Calcd for $C_{27}H_{30}O_5$: C, 74.63; H, 6.96%.

A similar reaction of **2** (0.2 g, 0.8 mmol) with methylmagnesium iodide in ether–THF at room temperature and separation of the epimeric products gave benzyl 4-*C*-methyl-2,3-*O*-methylene-α-D-xylopyranoside (**18**) and -β-L-arabinopyranoside (**19**) in 19% (40 mg) and 53% (112 mg) yield, respectively. Found for **18**: C, 62.86; H, 6.75%, and for **19**: C, 63.02; H, 6.63%. Calcd for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81%.

In a similar way, methyl 2,3-di-*O*-benzyl-6-deoxy-4-*C*-methyl-α-D-glucopyranoside (**23**) and -α-D-galactopyranoside (**24**) were obtained from **7** as syrups in 27 and 59% yield, respectively. **23**: $[\alpha]_D$ +43.9° (*c* 1.1), **24**: $[\alpha]_D$ +81.6° (*c* 1.3). Found for **23**: C, 70.81; H, 7.35%, and for **24**: C, 70.65; H, 7.47%. Calcd for $C_{22}H_{28}O_5$: C, 70.94; H, 7.58%.

The reaction of **5** and **6** with methylmagnesium iodide as above gave selectively one epimer, methyl 6-deoxy-4-*C*-methyl-2,3-*O*-methylene-α-D-allopyranoside (**29**) and -α-D-talopyranoside (**30**), respectively. **29**: syrup, $[\alpha]_D$ +81.7° (*c* 0.8), **30**: mp 105—108 °C, $[\alpha]_D$ +13.3° (*c* 1.3). Found for **29**: C, 52.76; H, 7.95%, and for **30**: C, 52.87; H, 7.99%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%.

Reaction of 4-Uloses with Vinylmagnesium Bromide. Synthesis of 4-*C*-vinyl derivatives is typically presented by the preparation of benzyl 2,3-di-*O*-benzyl-4-*C*-vinyl-α-D-xylopyranoside (**14**) and -β-L-arabinopyranoside (**15**). To a solution of vinylmagnesium bromide, prepared from magnesium turnings (1.2 g, 49 mmol) and vinyl bromide (6 g, 56 mmol),

in THF (5 ml) was added with stirring a solution of **1** (3 g, 7.2 mmol) in THF (5 ml) at room temperature, and the mixture was stirred for 1 h, poured into a saturated aqueous ammonium chloride solution and then extracted with ether. The usual work-up of the extract and separation of the epimeric products on a silica-gel column (hexane–ethyl acetate 15:1) gave **14** and **15** as syrups in 34.4% (1.1 g) and 14% (0.45 g) yield, respectively. **14**: $[\alpha]_D$ +109° (*c* 0.8), **15**: $[\alpha]_D$ +152° (*c* 1.2). Found for **14**: C, 75.59; H, 6.58%, and for **15**: C, 75.31; H, 6.80%. Calcd for $C_{28}H_{30}O_5$: C, 75.31; H, 6.77%.

A similar reaction of **2** (1.1 g, 4.4 mmol) and vinylmagnesium bromide in THF (10 ml), prepared from magnesium turnings (0.8 g, 32.9 mmol) and vinyl bromide (4.0 g, 37.3 mmol), and separation of the epimeric products with a preparative TLC (developed four times with hexane–ethyl acetate 4:1) gave benzyl 2,3-*O*-methylene-4-*C*-vinyl-α-D-xylopyranoside (**20**) and -β-L-arabinopyranoside (**21**) as syrups in 10.5% (129 mg) and 47.8% (585 mg) yield, respectively. **20**: $[\alpha]_D$ +137° (*c* 3.0), **21**: $[\alpha]_D$ +170° (*c* 1.2). Found for **20**: C, 64.87; H, 6.49%, and for **21**: C, 64.24; H, 6.48%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

Reaction of **3** (664 mg, 1.5 mmol) as above gave one epimer, benzyl 2,3-di-*O*-benzyl-6-deoxy-4-*C*-vinyl-α-D-galactopyranoside (**22**) as a syrup in 43.8% (310 mg) yield. $[\alpha]_D$ +141° (*c* 6.0). Found: C, 74.83; H, 6.72%. Calcd for $C_{29}H_{32}O_5$: C, 75.63; H, 7.00%.

A similar reaction of **4** (4 g, 15.1 mmol) in THF with vinylmagnesium bromide and separation of the epimeric products with a lobar column (hexane–ethyl acetate 4:1) gave benzyl 6-deoxy-4-*C*-vinyl-2,3-*O*-methylene-α-D-glucopyranoside (**26**) and -α-D-galactopyranoside (**27**) as syrups in 3.4% (0.15 g) and 51.8% (2.29 g) yield, respectively. **26**: $[\alpha]_D$ +167° (*c* 2.3). **27**: $[\alpha]_D$ +141° (*c* 6.8). Found for **26**: C, 64.96; H, 6.61%, and for **27**: C, 65.98; H, 6.72%. Calcd for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90%.

Reaction of 4-Uloses with 2-Lithio-2-methyl-1,3-dithiane. Synthesis of 4-*C*-[2-methyl-1,3-dithian-2-yl] derivatives is illustrated by the preparation of benzyl 2,3-di-*O*-benzyl-4-*C*-(2-methyl-1,3-dithian-2-yl)-α-D-xylopyranoside (**16**) and -β-L-arabinopyranoside (**17**). To a chilled solution of 2-methyl-1,3-dithiane (1 g, 7.5 mmol) in THF (5 ml) was added dropwise butyllithium (10%, 1.3 ml, 2 mmol) in hexane at −30 °C (Dry Ice–carbon tetrachloride) under argon atmosphere, and the mixture was stirred for 3 h. A solution of **1** (0.3 g, 0.72 mmol) in THF (2 ml) was further added to the mixture at −78 °C, and stirred for 1 h. The reaction mixture was poured into water and extracted with ether. The usual work-up of the extract and separation of the eprimeric products on a silica-gel column (benzene–acetone 16:1) gave **16** and **17** as syrups in 25.2% (0.1 g) and 10.1% (0.04 g) yield, respectively. **16**: $[\alpha]_D$ +82.4° (*c* 3.5), NMR: 7.6—7.3 (m, 15H, 3×Ph), 4.76 (d, 1H, $J_{1,2}$=1.3, H-1), 5.05—4.51 (m, 6H, 3×CH_2Ph), 4.30 (dd, 1H, $J_{2,3}$=3.0, $J_{3,5a}$=1.0, H-3), 4.30 and 3.96 (ABq, 2H, J=11.3 H-5e and H-5a), 3.60 (dd, 1H, H-2), 3.54—1.70 (m, 6H, $SCH_2CH_2CH_2S$), 1.57 (s, 3H, CMe). **17**: $[\alpha]_D$ +82.4° (*c* 3.5); NMR: 7.6—7.3 (m, 15H, 3×Ph), 5.04—4.37 (m, 6H, 3×CH_2Ph), 4.83 (d, 1H, $J_{1,2}$=4.0, H-1), 4.47 (dd, 1H, $J_{2,3}$=9.2, $J_{3,5e}$=1.0, H-3), 4.18 and 3.98 (ABq, 2H, J=12.8, H-5e and H-5a), 3.96 (dd, 1H, H-3), 3.20—1.50 (m, 6H, $SCH_2CH_2CH_2S$), 1.96 (s, 3H, CMe). Found for **16**: C, 67.29; H, 6.34; S, 11.25%, and for **17**: C, 67.41; H, 6.71; S, 11.32%. Calcd for $C_{31}H_{36}O_5S_2$: C, 67.36; H, 6.57; S, 11.60%.

In a similar manner, benzyl 6-deoxy-4-*C*-(2-methyl-1,3-dithian-2-yl)-2,3-*O*-methylene-α-D-galactopyranoside (**28**) was obtained from **4** as a syrup in 35% yield. $[\alpha]_D$ +116° (*c* 8.0), NMR: 7.6—7.3 (m, Ph), 5.77 and 5.67 (ABq, 2H, J=12.0, CH_2Ph), 5.26 (d, 1H, $J_{1,2}$=3.8, H-1), 5.16 and 5.09 (ABq, 2H, J=1.0, OCH_2O), 4.29 (d, 1H, $J_{2,3}$=9.7, H-3), 4.28 (q, 1H, $J_{5,6}$=6.2, H-5), 3.90 (dd, 1H, H-2), 3.22—1.72 (m, 6H, $SCH_2CH_2CH_2S$), 2.00 (s, 3H, CMe), 1.52 (d, 3H, H-6). Found: C, 57.28; H, 6.58; S, 15.88%. Calcd for $C_{19}H_{26}O_5S_2$: C, 57.26; H, 6.58; S, 16.09%.

Reaction of 1 with Methyllithium. To a solution of **1** (0.1 g, 0.24 mmol) in ether (10 ml), a 1 M (1 M=1 mol dm^{-3}) ethereal solution (1 ml) of methyllithium was added with stirring at room temperature. After the reaction mixture was stirred for 1 h, water was added, the ethereal layer was separated, and the aqueous layer was extracted two times with ether (10 ml). The usual work-up of the combined ethereal solution and purification of the product on a preparative TLC (hexane–ethyl acetate 3:1) gave syrupy **12** in 32% (34 mg) yield.

The present work was supported by a Grant-in-Aid for Scientific Research No. 347023 from the Ministry of Education, Science and Culture, Japan. The authors wish to thank Mr. Y. Nakamura for the measurements of the ^{13}C NMR spectra.

Oxidation of Olefins into α-Phenylseleno Carbonyl Compounds. Highly Regioselective *anti*-Markownikoff Type Oxidation of Allylic Alcohol Derivatives[1]

Makoto SHIMIZU, Ryo TAKEDA, and Isao KUWAJIMA*

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 30, 1981)

By using $(C_6H_5Se)_2$–*t*-BuOOH or $(C_6H_5Se)_2$–$(C_6H_5SeO)_2O$ system, oxoselenenylation reactions of C=C bonds have been examined with allylic and homoallylic alcohol derivatives, and substituted cyclohexenes, and allyl *t*-butyldimethylsilyl ethers are found to undergo regioselective conversion into β-siloxy α-phenylseleno carbonyl compounds in high yields.

Regioselective introduction of various functional groups into the carbon atom adjacent to a carbonyl constitutes a major concern in synthetic organic chemistry. For this purpose, α-halo or α-phenylthio substituted carbonyl compounds offer one of the most promising methodologies to distinguish α from α′ carbons to a carbonyl group.

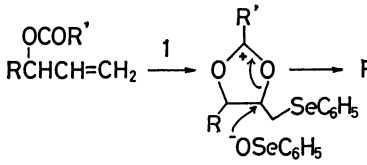
Recent developments in organoselenium chemistry[2] have realized that carbanions stabilized by arylseleno group are capable of attacking various electrophiles[3] and that arylseleno group is readily removed *via syn*-elimination reaction through selenoxides,[2] reduction with Raney nickel or trialkyltin hydride,[4] and so on.

Recently, several methods have been introduced by us[1,5] and others[6] for the direct preparation of α-phenylseleno carbonyl compounds from olefins. However, high regioselectivity in these oxidation reactions has only been achieved with terminal olefins to yield phenylselenomethyl ketones. We have examined steric and electronic effects of substituents for determining regiochemistry in the oxidation of olefins by using a system of diphenyl diselenide and *t*-butyl hydroperoxide, or diphenyl diselenide and benzeneseleninic anhydride.[1]

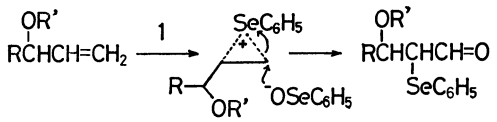
In this paper, we describe oxidation reactions of allylic and homoallylic alcohol derivatives, together with those of substituted cyclohexenes. Although a real reactive species in this reaction has not been confirmed yet,[7] it still appears to be reasonable for us to assume benzeneselenenic anhydride **1** as a plausible one as shown in the following equations.

$$\left.\begin{array}{l} (C_6H_5Se)_2 + t\text{-BuOOH} \longrightarrow \text{“}C_6H_5SeOSeC_6H_5\text{”} \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \mathbf{1} \\ 2(C_6H_5Se)_2 + (C_6H_5SeO)_2O \\ \qquad\qquad \longrightarrow 3\text{“}C_6H_5SeOSeC_6H_5\text{”} \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \mathbf{1} \\ \qquad\qquad\qquad\qquad\qquad\quad OSeC_6H_5 \\ \qquad\qquad\qquad\qquad\qquad\quad | \\ R^1CH{=}CHR^2 \xrightarrow{1} R^1CH\text{-}CHR \\ \qquad\qquad\qquad\qquad\qquad\quad | \\ \qquad\qquad\qquad\qquad\qquad\quad SeC_6H_5 \\ \qquad\qquad \longrightarrow R^1CH\text{-}CO\text{-}R^2 + C_6H_5SeH \\ \qquad\qquad\qquad\qquad\qquad\quad | \\ \qquad\qquad\qquad\qquad\qquad\quad ScC_6H_5 \end{array}\right\} \quad (1)$$

Oxidation of Allylic Alcohol Derivatives. Allylic alcohols are in general easily accessible *via* a number of standard procedures. Neighboring carbonyl group participation (Eq. 2) for allylic esters,[8] and steric



(2)



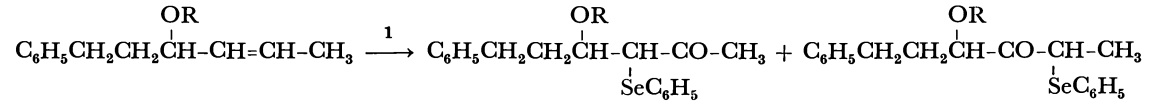
(3)

and electronic effects (Eq. 3) for allylic ethers are considered to play important roles which direct the site of introducing carbonyl functionality in the oxidation of carbon-carbon double bonds. Effects of substituents on oxygen atom were initially surveyed using 1-phenyl-4-hexen-3-ol derivatives. Thus, diphenyl diselenide was oxidized with an equimolar amount of *t*-butyl hydroperoxide in carbon tetrachloride, and *t*-butyl alcohol formed was removed together with the solvent *in vacuo*. The allylic alcohol derivatives were then treated with the resulting solid in refluxing benzene or toluene for an appropriate period and the corresponding oxoselenenylation products **2** and **3** were isolated. The results are listed in Table 1.

Comparison of these results implies that increasing steric conjestion around C=C bonds may enhance regioselectivity to introduce carbonyl functionality onto the remote carbon atoms of the double bonds. Trimethylsilyl ethers did not survive the reaction conditions to result in the formation of complex mixtures; a possible side-reaction may involve generation of the parent allylic alcohols which undergo oxidation under the present reaction conditions.[9] But, *t*-butyldimethylsilyl ether gave a remarkable result; only a single isomer was obtained in excellent yield. Satisfactory regioselectivity was also observed even with benzyl ether. In contrast, an effect based on neighboring group participation shown in Eq. 2 appeared to have little influence on the direction of this reaction.

Based on these results, similar oxidation was examined with a variety of allyl *t*-butyldimethylsilyl ethers. On treating with diphenyl diselenide and benzeneseleninic anhydride, they underwent regiospecific oxoselenenylation reaction to give the corresponding β-*t*-butyldimethylsiloxy α-phenylseleno carbonyl compounds **4**—**8** in excellent yields, without any contamination of their regio-isomers (see Table 2).

Table 1. Regioselectivity on the oxidation of 4-alkoxy-6-phenyl-2-hexene[a)]



2a—d **3a—d**

R	Solvent	Period (h)	Ratio (**2**/**3**)	Yield/%
a) CH_3CO-	Toluene	3.0	67 : 33	71
b) $(CH_3)_3CCO$-	Toluene	10.0	75 : 25	60
c) $C_6H_5CH_2$-	Benzene	6.5	95 : 5	79
d) $(CH_3)_3CSi(CH_3)_2$-	Benzene	4.0	100 : 0	89

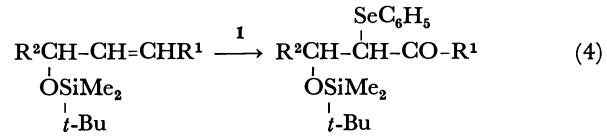
a) Reactions were carried out in a refluxing solvent with olefin: $(C_6H_5Se)_2$: *t*-BuOOH = 1.0 : 4.4 : 4.4.

Table 2. Oxidation of allyl *t*-butyldimethylsilyl ethers[a)]

Olefin	Product	Yield/%
	 (**4**)	87
	 (**5**)	81
	 (**6**)	79
	 (**7**)	74
	 (**8**)	76
	 (**2d**)	89

a) Reactions were carried out in reflxing toluene with olefin: $(C_6H_5Se)_2$:$(C_6H_5SeO)_2O$ = 1.0:1.4:0.7 for terminal olefins and 1.0:2.8:1.4 for internal olefin. b) R = $(CH_3)_3CSi(CH_3)_2$-.

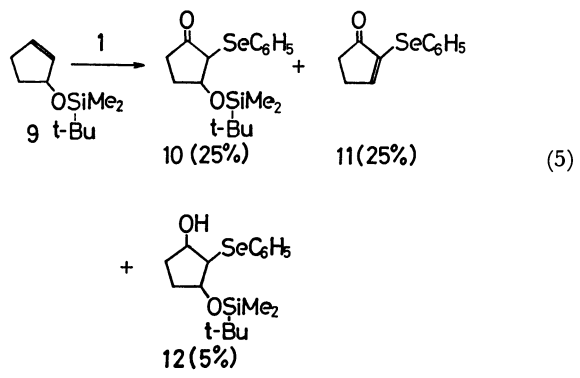
It should be remarkable that the ethers possessing a terminal olefin can be cleanly converted to the corresponding β-siloxy α-phenylseleno aldehydes exclusively, although such type of addition process appears to be disfavored electronically. β-Hydroxy or β-alkoxy aldehydes are usually quite unstable to undergo dehydration, but in these cases the products could be isolated without such kind of decomposition.



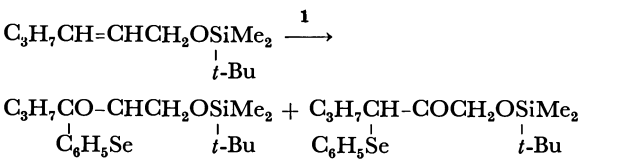
(4)

As the reaction solvent, benzene or toluene is preferable for this transformation. In other low-boiling solvents, a concomitant formation of β-hydroxy selenide was observed. The effect of *t*-butyldimethylsiloxy group was also prominent in the case with cyclohexene derivative, but the oxidation of 3-*t*-butyldimethylsiloxy-1-cyclopentene **9** afforded a mixture of 3-siloxy-2-phenylselenocyclopentanone **10**, 2-phenylseleno-2-cyclopentenone **11**, and 3-siloxy-2-phenylseleno-1-cyclopentanol **12**.

In addition to the bulky *t*-butyldimethylsiloxy group, substituents on the allylic position appear to have a marked influence on the regioselectivity; allyl *t*-butyldimethylsilyl ether derived from primary allylic alcohol did not show good regioselectivity to give a mixture of **13** and **14**.

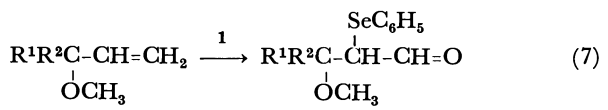


(5)



(6)

Addition of hypohalite to terminal olefins bearing tertiary carbon at their allylic position has been reported to proceed in a highly regioselective manner, and the *anti*-Markownikoff adducts were formed exclusively although the yields were low.[10] In a related system, *anti*-Markownikoff type oxidation was found to take place exclusively with methyl ethers of tertiary allylic alcohols in the present procedure. The results are shown in Table 3. However, in the case with a highly hindered olefin, the reaction did not proceed



(7)

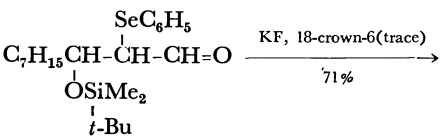
practically under the same conditions to recover the starting olefin.

The aldol type products obtained by the present procedure undergo a facile conversion to the corresponding α-phenylseleno enals on treatment with fluoride anion.[11] The use of other stronger bases such as lithium diisopropylamide (LDA), potassium *t*-butoxide, or tetrabutylammonium hydroxide led to formation of a mixture composed of several products. On the other hand, acidic treatment led to a mixture of α-phenylseleno enal and deselenenylated enal.[12] The products arising from the oxidation of allyl methyl ethers were more easily transformed into α-phenylseleno enals. They readily liberated methanol on treatment with silica gel.

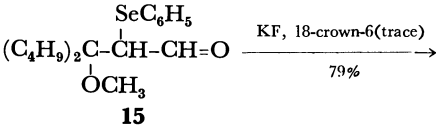
Table 3. Oxidation of *t*-allyl methyl ethers[a]

Allyl methyl ether	Product		Yield/%
		**15**	93
		**16**	86
			trace[b]

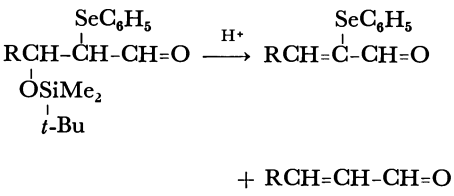
a) Reactions were carried out in refluxing toluene with olefin: $(C_6H_5Se)_2$: $(C_6H_5SeO)_2O$ = 1.0:1.4:0.7. b) Most of the starting material was recovered.



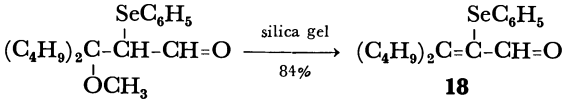
(8)



(9)

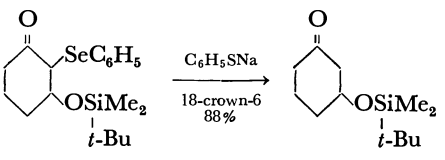


(10)



(11)

In addition, removal of phenylseleno group can also be readily performed. For example, treatment of 2-*t*-butyldimethylsiloxy-3-phenylselenocyclohexanone **8** with an excess amount of benzenethiolate anion in tetrahydrofuran afforded the deselenenylated ketone **19** in 88% yield.[13]



(12)

Considering that the starting materials are easily accessible, this procedure may be employed as a useful alternative for the synthesis of aldols or α,β-unsaturated carbonyl compounds.

(13)

Oxidation of Homoallylic Alcohol Derivatives. As described above, the *t*-butyldimethylsilyl group has worked quite effectively on directing the site of introducing carbonyl functionality in the oxidation of allyl alcohol derivatives. Application of this procedure to homoallylic alcohol analogues has found relatively good regioselectivity.

As typical examples, we have examined the oxidation of 1-phenyl-5-hexen-3-ol, 3-penten-1-ol, and 4-propyl-6-octen-4-ol. The results are listed in Tables 4, 5, and 6.

The results shown in the tables reveal that the effects of homoallylic substituents are not so sufficient to distinguish the remote sp^2 carbon from the other as those of allylic ones. In these cases, the highest ratio of γ-alkoxy α-phenylseleno ketones to their regioisomers is approximately 4:1. From a synthetic point of view, the present method is not so useful for this kind of transformation.

On the other hand, this system offers a convenient route to 4-siloxy-2-cyclopentenone **28**, a useful precursor for the synthesis of prostaglandin derivatives.[14] Thus, oxidation of 4-triphenylsiloxycyclopentene **26** by the present procedure followed by treatment with hydrogen peroxide afforded the cyclopentenone **28** in 65% overall yield.

Oxidation of Cyclohexene Derivatives. In the addition process to cyclohexene derivatives, two major interactions which may direct the site of introduction of anionic species, *e.g.*, $C_6H_5SeO^-$, appear to be involved; one is 1,3-diaxial interaction and the other is 1,2-interaction based on tortional strain. In the case with 3,3-disubstituted cyclohexene, if 1,3-diaxial interaction severely prevents the introduction of $C_6H_5SeO^-$ species to C-1 carbon, oxidation at C-2 may predominate, whereas the attack at C-1 will be a subject of tortional strain. Table 7 lists the results.

The result of the oxidation of spiro compound **29** indicates that 1,2-interaction predominates over 1,3-interaction. Apparently, this interaction was not so prominent for 3-monosubstituted cyclohexene, and the selectivity was greatly decreased with the substrate **31**. Other cases, *e.g.*, 4,4-disubstituted derivatives did not show any preference for regioselectivity of 1,2-electrophilic addition, probably because the steric congestions are almost same for both olefinic carbons and because there is little difference of electronic

Table 7. Oxidation of substituted cyclohexenes[a)]

effects.

Experimental

All reactions were performed under either argon or ultra grade nitrogen atmosphere. NMR spectra were taken on a Hitachi R-24B spectrometer and chemical shifts are recorded in parts per million downfield from internal tetramethylsilane. IR spectra were taken on a Hitachi EPI G-3 or 260-10 spectrometer, and mass spectra on a Hitachi RMU-7M or RMU-6C spectrometer at 70 eV ionizing irradiation. Boiling points were uncorrected.

Diphenyl diselenide, bis(*p*-chlorophenyl) diselenide, and bis(2,4,6-trimethylphenyl) diselenide were prepared by the procedure reported by Sharpless[15)] or Reich.[16)] Benzeneseleninic anhydride was prepared according to the procedure of Woodbridge,[17)] and was stored over P_2O_5.

Oxidation of 4-Alkoxy-6-phenyl-2-hexene with $(C_6H_5Se)_2$-t-BuOOH. Examination of Regioselectivity (General Procedure). To a solution of diphenyl diselenide (1.382 g, 4.4 mmol) in 10 ml of carbon tetrachloride were added molecular sieves 3A (4 g) and a solution of 70% *t*-butyl hydroperoxide (563 mg, 4.4 mmol) in 10 ml of carbon tetrachloride, and the mixture was heated to refluxing for 1 h. Then, *t*-butyl alcohol formed as well as the solvent was removed *in vacuo*, and a solution of 4-alkoxy-6-phenyl-2-hexene (1 mmol) in 5 ml of benzene or toluene was added to the resulting solution. After heated to refluxing for the period indicated in Table 1 followed by usual work-up, the ratio of the regio-isomers was determined on the bases of chromatographycally pure samples.

*4-Acetoxy-6-phenyl-3-phenylseleno-2-hexanone (**2a**).* IR (neat): 1730, 1710 cm^{-1}; NMR (CCl_4): δ 1.80—2.41 (m, 2H), 2.21 (s, 3H), 2.30 (s, 3H), 2.42—3.00 (m, 2H), 3.43—4.00 (m, 1H), 5.01—5.32 (m, 1H), 7.00—7.52 (m, 10H); Found: C, 61.91; H, 5.50%. Calcd for $C_{20}H_{22}O_3Se$: C, 61.71; H, 5.69%.

*4-Acetoxy-6-phenyl-2-phenylseleno-3-hexanone (**3a**).* IR (neat): 1730, 1710 cm^{-1}; NMR (CCl_4): δ 1.83—2.10 (m, 2H), 1.91 (d, J=4.0 Hz, 3H), 2.20 (s, 3H), 2.51—3.00 (m, 2H), 3.35 (q, J=6.0 Hz, 1H), 5.06—5.32 (m, 1H), 7.00—7.52 (m, 10H); Found: C, 61.82; H, 5.63%. Calcd for $C_{20}H_{22}O_3Se$: C, 61.71; H, 5.69%.

*4-Pivaloyloxy-6-phenyl-3-phenylseleno-2-hexanone (**2b**).* IR (neat): 1725, 1710 cm^{-1}; NMR (CCl_4): δ 1.20 (s, 9H), 2.10—2.42 (m, 2H), 2.31 (s, 3H), 2.35—2.62 (m, 2H), 3.60—4.02 (m, 1H), 4.91—5.42 (m, 1H), 6.98—7.62 (m, 10H); Found: C, 64.23; H, 6.50%. Calcd for $C_{23}H_{28}O_3Se$: C, 64.04; H, 6.54%.

*4-Pivaloyloxy-6-phenyl-2-phenylseleno-3-hexanone (**3b**).* IR (neat): 1725, 1705 cm^{-1}; NMR (CCl_4): δ 1.10 (d, J=4.5 Hz, 2H), 1.21 (s, 9H), 1.93—2.42 (m, 2H), 2.43—3.01 (m, 2H), 4.00—4.20 (m, 1H), 4.92—5.45 (m, 1H), 6.88—7.71 (m, 10H); Found: C, 63.90; H, 6.41%. Calcd for $C_{23}H_{28}O_3Se$: C, 64.04; H, 6.54%.

*4-Benzyloxy-6-phenyl-3-phenylseleno-2-hexanone (**2c**).* IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 1.80—2.33 (m, 2H), 2.12 (s, 3H), 2.47—2.83 (m, 2H), 3.57—4.08 (m, 2H), 4.50 (s, 2H), 6.85—7.53 (m, 15H); Found: C, 68.35; H, 6.09%. Calcd for $C_{25}H_{26}O_2Se$: C, 68.64; H, 5.99%.

*3-Benzyloxy-6-phenyl-2-phenylseleno-3-hexanone (**3c**).* IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 1.30 (d, J=6.5 Hz, 3H), 1.76—2.30 (m, 2H), 2.37—2.80 (m, 2H), 4.00—4.37 (m, 2H), 4.50 (s, 2H), 6.90—7.50 (m, 15H). These spectra were identical with those of the authentic samples prepared in the following manner: addition of sodium benzeneselenolate to 4-benzyloxy-6-phenyl-2-hexene oxide followed by oxidation with benzeneseleninic anhydride and diphenyl diselenide.[9)]

*4-t-Butyldimethylsiloxy-6-phenyl-3-phenylseleno-2-hexanone (**2d**).* IR (neat): 1700 cm^{-1}; NMR (CCl_4): δ 0.11 (s, 6H), 0.92 (s, 9H), 2.00—2.60 (m, 2H), 2.30 (s, 3H), 2.70—3.00 (m, 2H), 4.00 (d, J=6.0 Hz, 1H), 4.10—4.42 (m, 1H), 7.00—7.81 (m, 10H); Found: C, 62.25; H, 7.39%. Calcd for $C_{24}H_{34}O_2SeSi$: C, 62.45; H, 7.42%.

Preparation of Allyl t-Butyldimethylsilyl Ethers. Silyl ethers were prepared by silylation of the corresponding alcohols.[18)] They exhibit the following spectroscopic properties.

3-t-Butyldimethylsiloxy-1-decene. IR (neat): 1640, 1460, 1255, 1080, 1010, 995, 925, 840, 780 cm^{-1}; NMR (CCl_4): δ 0.00 (s, 6H), 0.73—1.80 (m, 24H including singlet at 0.82 (9H, *t*-Bu)), 3.73—4.17 (m, 1H), 4.90 (dd, J=8.0 and 3.0 Hz, 1H), 5.00 (dd, J=16 and 3.0 Hz, 1H), 5.70 (ddd, J=16.0, 8.0, and 6.0 Hz, 1H).

3-t-Butyldimethylsiloxy-5-phenyl-1-pentene. IR (neat): 1640, 1600, 1460, 1255, 1090, 1010, 995, 925, 845, 780, 750, 700 cm^{-1}; NMR (CCl_4): δ 0.00 (s, 6H), 0.90 (s, 9H), 1.50—2.00 (m, 2H), 2.43—2.80 (m, 2H), 4.10 (dt, J=5.5 and 5.5 Hz, 1H), 5.00 (dd, J=8.5 and 2.0 Hz, 1H), 5.12 (dd, J=16.0 and 2.0 Hz, 1H), 5.80 (ddd, J=16.0, 8.5, and 5.5 Hz, 1H), 7.07 (s, 5H).

3-t-Butyldimethylsiloxy-3-phenyl-1-propene. IR (neat): 1640, 1600, 1460, 1255, 1130, 1090, 1070, 1010, 990, 940, 925, 870, 840, 780, 700 cm^{-1}; NMR (CCl_4): δ −0.03 (s, 3H), 0.67 (s, 3H), 0.90 (s, 9H), 4.90—5.40 (m, 3H), 5.90 (ddd, J=16.0, 10.0, and 4.0 Hz, 1H), 7.22 (s, 6H).

3-t-Butyldimethylsiloxy-4-methyl-1-pentene. IR (neat): 1690, 1470, 1255, 1080, 1010, 995, 925, 865, 845, 780 cm^{-1}; NMR (CCl_4): δ 0.00 (s, 6H), 0.80 (d, J=6.0 Hz, 6H), 0.83 (s, 9H), 1.65 (ses, J=6.0 Hz, 1H), 3.80 (dd, J=5.0 and 5.0 Hz, 1H), 5.00 (dd, J=8.0 and 2.0 Hz, 1H), 5.03 (dd, J=16.0 and 2.0 Hz, 1H), 5.73 (ddd, J=16.0, 8.0, and 5.0 Hz, 1H).

3-t-Butyldimethylsiloxy-1-cyclohexene. IR (neat): 1250, 1080 cm^{-1}; NMR (CCl_4): δ 0.11 (s, 6H), 0.98 (s, 9H), 1.64—2.21 (m, 6H), 4.08—4.36 (m, 1H), 6.15—6.80 (m, 2H).

4-t-Butyldimethylsiloxy-6-phenyl-2-hexene. IR (neat): 3010, 1250, 1100 cm^{-1}; NMR (CCl_4): δ 0.12 (s, 6H), 0.97 (s, 9H), 1.61—2.10 (m, 3H), 1.89 (d, J=5.0 Hz, 2H), 2.50—2.86 (m, 2H), 3.84—4.30 (m, 1H), 5.43—5.63 (m, 2H), 7.17 (s, 5H).

*3-t-Butyldimethylsiloxy-2-phenylselenodecanal (**4**) (General Pro-*

cedure for the Oxidation of Allyl t-Butyldimethylsiloxy Ethers). To a solution of diphenyl diselenide (874 mg, 2.8 mmol) and benzeneseleninic anhydride (504 mg, 1.4 mmol) in 5 ml of toluene was added a solution of 3-*t*-butyldimethylsiloxy-1-decene (540 mg, 2.0 mmol) in 15 ml of toluene. After stirring for 30 min under refluxing, the reaction mixture was washed with satd aq NaCl and the aqueous layer was extracted with ether. Drying and concentration of the combined extracts followed by purification by silica gel column chromatography afforded the title compound (764 mg, 87%) as an oil and diphenyl diselenide (1.03 g). IR (neat): 1710 cm^{-1}; NMR (CCl_4): δ 0.03 (s, 6H), 0.80—2.00 (m, 15H), 0.83 (s, 9H), 3.23—3.70 (m, 1H), 3.90—4.30 (m, 1H), 6.90—7.77 (m, 5H), 9.23 (d, J=6.0 Hz, C<u>H</u>=O), 9.43 (d, J=4.0 Hz, C<u>H</u>=O); Found: C, 60.11; H, 8.90%. Calcd for $C_{22}H_{38}O_2SeSi$: C, 59.84; H, 8.67%.

3-t-Butyldimethylsiloxy-5-phenyl-2-phenylselenopentanal (5). Bp 110 °C/0.25 mmHg;[19] IR (neat): 1710 cm^{-1}; NMR (CCl_4): δ 0.03 (s, 6H), 0.87 (s, 9H), 1.73—2.33 (m, 2H), 2.33—2.90 (m, 2H), 3.30—3.83 (m, 1H), 3.93—4.40 (m, 1H), 6.70—7.80 (m, 10H), 9.36 (d, J=5.0 Hz, C<u>H</u>=O), 9.43 (d, J=3.0 Hz, C<u>H</u>=O); MS:[20] *m/e* (%) 311 (M^+ −137, 2), 262 (2), 216 (7), 157 (4), 132 (22), 129 (17), 117 (9), 115 (9), 104 (9), 91 (78), 77 (57), 76 (100); Found: C, 62.17; H, 7.37%. Calcd for $C_{23}H_{32}O_2SeSi$: C, 61.73; H, 7.21%.

3-t-Butyldimethylsiloxy-3-phenyl-2-phenylselenopropanal (6). Bp 115—120 °C/0.02 mmHg;[19] IR (neat): 1710 cm^{-1}; NMR (CCl_4): δ −0.02, −0.015, and 0.08 (s, 6H), 0.90 (s, 9H), 3.56—3.83 (m, 1H), 5.07 (d, J=7.0 Hz, C<u>H</u>OSi), 5.22 (d, J=4.0 Hz, C<u>H</u>OSi), 7.00—7.50 (m, 10H), 9.43 (d, J=4.0 Hz, C<u>H</u>=O), 9.50 (d, J=8.0 Hz, C<u>H</u>=O); MS:[20] *m/e* (%) 283 (M^+ −137, 9), 264 (2), 258 (3), 218 (4), 205 (4), 177 (6), 176 (6), 157 (7), 137 (20), 131 (18), 117 (6), 115 (5), 105 (10), 103 (12), 77 (62), 76 (100); Found: C, 60.06; H, 6.57%. Calcd for $C_{21}H_{28}O_2SeSi$: C, 60.13; H, 6.73%.

3-t-Butyldimethylsiloxy-4-methyl-2-phenylselenopentanal (7). Bp 100—105 °C/0.025 mmHg;[19] IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 0.18 (s, 6H), 0.85—1.20 (m, 1H), 1.10 (d, J=2.0 Hz, 6H), 1.00 (s, 9H), 3.57—3.87 (m, 1H), 3.87—4.13 (m, 1H), 6.70—7.53 (m, 5H), 9.30 (d, J=4.0 Hz, C<u>H</u>=O), 9.33 (d, J=4.0 Hz, C<u>H</u>=O); MS:[20] *m/e* (%) 303 (M^+ −83, 8), 249 (M^+ −137, 33), 182 (23), 170 (27), 167 (47), 155 (40), 142 (20), 130 (18), 127 (33), 113 (7), 95 (33), 77 (17), 76 (70), 75 (100); Found: C, 56.39; H, 7.88%. Calcd for $C_{18}H_{30}O_2SeSi$: C, 56.09; H, 7.84%.

3-t-Butyldimethylsiloxy-2-phenylselenocyclohexanone (8). IR (neat): 1710 cm^{-1}; NMR (CCl_4): δ 0.11 (s, 6H), 0.92 (s, 9H), 1.22—2.90 (m, 6H), 3.31—4.50 (m, 2H), 6.98—7.61 (m, 5H); Found: C, 56.09; H, 7.42%. Calcd for $C_{18}H_{28}O_2SeSi$: C, 56.39; H, 7.36%.

Oxidation of 3-t-Butyldimethylsiloxy-1-cyclopentene (9). Diphenyl diselenide (312 mg, 1.0 mmol) was oxidized with 70% *t*-butyl hydroperoxide (141 mg, 1.0 mmol) in refluxing carbon tetrachloride (5 ml) for 1 h. Then all the solvent as well as *t*-butyl alcohol was removed from the reaction mixture, to which was added a solution of 3-*t*-butyldimethylsiloxy-1-cyclopentene (100 mg, 0.5 mmol) in 12 ml of benzene. After heating to refluxing for 2 h, the mixture was washed with satd aq NaCl and the aqueous layer was extracted with ethyl acetate. The combined extracts were dried and concentrated to give an oil, which was purified by preparative TLC to afford 3-*t*-butyldimethylsiloxy-2-phenylselenocyclopentanone **10** (46 mg, 25%), 2-phenylseleno-2-cyclopentenone **11** (30 mg, 25%), and 3-*t*-butyldimethylsiloxy-2-phenylseleno-1-cyclopentanol **12** (9 mg, 5%).

3-t-Butyldimethylsiloxy-2-phenylselenocyclopentanone (10). IR (neat): 1730 cm^{-1}; NMR (CCl_4): δ 0.12 (s, 6H), 0.91 (s, 9H), 1.67—2.30 (m, 4H), 3.42—3.65 (m, 1H), 3.71—4.05 (m, 1H), 7.10—7.71 (m, 5H).

2-Phenylseleno-2-cyclopentenone (11). IR (neat): 1690 cm^{-1}; NMR (CCl_4): δ 2.41—2.87 (m, 4H), 7.01 (t, J=3.0 Hz, 1H), 7.20—7.70 (m, 5H).

3-t-Butyldimethylsiloxy-2-phenylseleno-1-cyclopentanol (12). IR (neat): 3350 cm^{-1}; NMR (CCl_4): δ 0.12 (s, 6H), 0.92 (s, 9H), 2.12—2.70 (m, 5H), 3.10—3.40 (m, 1H), 3.43—3.76 (m, 2H), 7.12—7.62 (m, 5H).

1-t-Butyldimethylsiloxy-2-phenylseleno-3-hexanone (13). IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 0.11 (s, 6H), 0.92 (s, 9H), 1.05—1.82 (m, 5H), 2.34—2.72 (m, 2H), 3.54—4.05 (m, 3H), 7.01—7.52 (m, 5H); Found: C, 56.22; H, 8.01%. Calcd for $C_{18}H_{30}O_2SeSi$: C, 56.08; H, 7.84%.

1-t-Butyldimethylsiloxy-3-phenylseleno-2-hexanone (14). IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 0.19 (s, 6H), 0.93 (s, 9H), 1.05—1.81 (m, 7H), 3.66—3.90 (m, 1H), 4.20 (d, J=7.0 Hz, 2H), 7.00—7.51 (m, 5H); Found: C, 56.18; H, 7.96%. Calcd for $C_{18}H_{30}O_2SeSi$: C, 56.08; H, 7.84%.

3-Butyl-3-methoxy-2-phenylselenoheptanal (15) (General Procedure). To a solution of diphenyl diselenide (874 mg, 2.8 mmol) and benzeneseleninic anhydride (504 mg, 1.4 mmol) in 2 ml of toluene was added a solution of 3-butyl-3-methoxy-1-heptene (368 mg, 2 mmol) in 3 ml of toluene. After stirring for 30 min at refluxing temperature, the reaction mixture was washed with satd aq NaCl and the aqueous layer was extracted with ether. Drying and concentration of the combined extracts followed by purification by silica gel column chromatography (SiO_2 deactivated with 20% of water was used) afforded the title compound (649 mg, 91%) and diphenyl diselenide (960 mg). IR (neat): 1700 cm^{-1}; NMR (CCl_4): δ 0.67—2.00 (m, 18H), 3.20 (s, 3H), 3.50 (d, J=7.0 Hz, 1H), 7.00—7.60 (m, 5H), 9.77 (d, J=7.0 Hz, 1H); Found: C, 61.03; H, 7.98%. Calcd for $C_{18}H_{28}O_2Se$: C, 60.84; H, 7.94%.

2-(1-Methoxycyclohexyl)-2-phenylselenoacetaldehyde (16). Bp 110—115 °C/0.02 mmHg;[19] IR (neat): 1700 cm^{-1}; NMR (CCl_4): δ 1.00—2.20 (m, 10H), 3.17 (s, 3H), 3.62 (d, J=7.0 Hz, 1H), 7.00—7.67 (m, 5H), 9.42 (d, J=7.0 Hz, 1H); MS:[20] *m/e* (%) 312 (M^+, 13), 277 (7), 230 (7), 197 (8), 157 (40), 123 (73), 113 (60), 95 (60), 81 (60), 77 (100), 67 (60); Found: C, 57.87; H, 6.39%. Calcd for $C_{15}H_{20}O_2Se$: C, 57.88; H, 6.48%.

2-Phenylseleno-2-decenal (17). To a suspension of potassium fluoride (102 mg, 1.77 mmol) in 1 ml of benzene were added a solution of 3-*t*-butyldimethylsiloxy-2-phenylselenodecanal (78 mg, 0.177 mmol) in 2 ml of benzene and 18-crown-6 (4.7 mg, 0.018 mmol) in 1 ml of benzene. After stirring for 12 h at room temperature, the reaction mixture was washed with satd aq NaCl and the aqueous layer was extracted with ether. Drying and concentration of the combined extracts followed by purification by silica gel column chromatography (SiO_2 deactivated with 20% water) afforded the title compound (38 mg, 71%) as an oil. Bp 115—118 °C/0.37 mmHg;[19] IR (neat): 1685 cm^{-1}; NMR (CCl_4): δ 0.67—1.80 (m, 13H), 2.26—2.83 (m, 2H), 6.83—7.50 (m, 6H), 9.20 (s, 1H); MS:[20] 310 (M^+, 5), 187 (5), 157 (20), 115 (23), 91 (28), 81 (45), 78 (50), 77 (60), 67 (65), 55 (100).

3-Butyl-2-phenylseleno-2-heptenal (18). To a suspension of silica gel (2 g) in 10 ml of carbon tetrachloride was added a solution of 3-butyl-3-methoxy-2-phenylselenoheptanal (196 mg, 0.55 mmol) in 2 ml of carbon tetrachloride. After stirring for 2 h under refluxing, the reaction mixture was filtered. Concentration followed by purification by silica gel column chromatography (SiO_2 deactivated with 20%

water) gave the title compound (150 mg, 84%). Bp 95—100 °C/0.01 mmHg;[19] IR (neat): 1680 cm^{-1}; NMR (CCl_4): δ 0.50—1.90 (m, 14H), 2.30—2.90 (m, 4H), 7.00—7.33 (m, 5H), 9.53 (s, 1H); MS:[20] *m/e* (%) 324 (M^+, 4), 314 (8), 234 (4), 167 (10), 166 (10), 157 (19), 139 (17), 132 (56), 123 (13), 111 (40), 97 (25), 95 (77), 91 (13), 83 (33), 81 (40), 77 (40), 69 (33), 55 (100); Found: C, 60.56; H, 7.81%. Calcd for $C_{17}H_{24}OSe$: C, 60.84; H, 7.94%.

*3-t-Butyldimethylsiloxycyclohexanone (**19**).* To a solution of sodium hydride (55% in mineral oil, 18 mg, washed twice with hexane) in 1 ml of THF was added a solution of benzenethiol (90 mg, 0.8 mmol) in 1 ml of THF at room temperature, and the mixture was stirred for 5 min. Then a solution of 3-*t*-butyldimethylsiloxy-2-phenylselenocyclohexanone (76 mg, 0.2 mmol) and a trace amount of 18-crown-6 in 2 ml of THF was added to the resulting solution. After allowed to stand for 6 h at room temperature, the mixture was washed with satd aq NaCl, and the aqueous layer was extracted with ether. The combined extracts were dried and concentrated to give an oil, which was purified by silica gel column chromatography to afford the title compound **19** (41 mg, 88%). IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 0.11 (s, 6H), 0.92 (s, 9H), 1.22—2.41 (m, 8H), 3.91—4.20 (m, 1H); Found: C, 63.24; H, 10.37%. Calcd for $C_{12}H_{24}O_2Si$: C, 63.10; H, 10.59%.

1-Phenyl-5-hexen-3-ol was prepared by the reaction of 3-phenylpropanal with allylmagnesium bromide. 3-Penten-1-ol was prepared by treating 1-bromo-3-pentene with aq sodium acetate and then with aq sodium hydroxide. 4-Propyl-6-octen-4-ol was preapared by treating ethyl 3-pentenoate with 2.2 eq of propylmagnesium bromide in ether.

*4-t-Butyldimethylsiloxy-6-phenyl-2-phenylselenohexanal (**20a**).* IR (neat): 1700 cm^{-1}; NMR (CCl_4): δ 0.11 (s, 6H), 0.98 (s, 9H), 1.46—2.33 (m, 4H), 2.51—2.88 (m, 2H), 3.30—3.61 (m, 1H), 4.08—4.30 (m, 1H), 7.02—7.48 (m, 10H), 8.30 (d, J=2.0 Hz, C<u>H</u>=O), 8.80 (d, J=2.0 Hz, C<u>H</u>=O); Found: C, 62.71; H, 7.58%. Calcd for $C_{24}H_{34}O_2SeSi$: C, 62.45; H, 7.42%.

Calcd for $C_{17}H_{27}O_2ClSeSi$: C, 50.30; H, 6.70%.

*5-Methoxy-5-propyl-3-phenylseleno-2-octanone (**24a**).* IR (neat): 1700 cm^{-1}; NMR (CCl_4): δ 0.70—1.61 (m, 16H), 2.13 (s, 3H), 2.92 (s, 3H), 3.57—3.90 (m, 1H), 7.00—7.61 (m, 5H); Found: C, 61.02; H, 8.06%. Calcd for $C_{18}H_{28}O_2Se$: C, 60.84; H, 7.94%.

*5-Methoxy-5-propyl-2-phenylseleno-3-octanone (**25a**).* IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 0.75—1.65 (m, 17H), 1.92 (s, 2H), 2.95 (s, 3H), 3.82—4.10 (m, 1H), 7.02—7.61 (m, 5H); Found: C, 61.13; H, 8.11%. Calcd for $C_{18}H_{28}O_2Se$: C, 60.84; H, 7.94%.

*5-Benzyloxy-3-phenylseleno-5-propyl-2-octanone (**24b**).* IR (neat): 1705 cm^{-1}; NMR (CCl_4): δ 0.73—1.68 (m, 16H), 2.15 (s, 3H), 3.72—4.01 (m, 1H), 4.31 (s, 2H), 7.01—7.58 (m, 10H); Found: C, 67.02; H, 7.68%. Calcd for $C_{24}H_{32}O_2Se$: C, 66.81; H, 7.48%.

*5-Benzyloxy-2-phenylseleno-5-propyl-3-octanone (**25b**).* IR (neat): 1700 cm^{-1}; NMR (CCl_4): δ 0.78—1.72 (m, 17H), 1.85 (s, 2H), 3.72—3.95 (m, 1H), 4.34 (s, 2H), 7.01—7.55 (m, 10H); Found; C, 66.95; H, 7.56%. Calcd for C_{24}-

$H_{32}O_2Se$: C, 66.81; H, 7.48%.

2-Phenylseleno-4-triphenylsiloxycyclopentanone (27). IR (neat): 1740 cm^{-1}; NMR (CCl_4): δ 2.39—2.53 (m, 4H), 3.29—3.60 (m, 1H), 4.54 (t, J=5.0 Hz, 1H), 7.07—7.62 (m, 20H).

4-Triphenylsiloxy-2-cyclopentenone (28). To a solution of 2-phenylseleno-4-triphenylsiloxycyclopentanone (155 mg, 0.3 mmol) and pyridine (0.07 ml, 0.72 mmol) in 1 ml of dichloromethane were added 30% hydrogen peroxide (0.28 ml, 2.6 mmol) and water (0.28 ml) at 0 °C. After stirring at 0 °C for 30 min, the reaction mixture was washed with 7% $NaHCO_3$ and then with 4% HCl. Drying and concentration of the extracts followed by purification with preparative TLC gave the title compound (99 mg, 92%) as an oil. IR (neat): 1680 cm^{-1}; NMR (CCl_4): δ 2.21—2.40 (m, 2H), 3.74—4.00 (m, 1H), 4.83—5.11 (m, 1H), 5.80—6.00 (m, 1H), 7.00—7.66 (m, 15H); Found: C, 77.32; H, 5.40%. Calcd for $C_{23}H_{20}SiO_2$: C, 77.49; H, 5.65%.

Oxidation of Substituted Cyclohexenes. Oxidation of these compounds was performed in a similar manner with that of 4-alkoxy-6-phenyl-2-hexene in refluxing benzene for 3—5 h. The reaction mixtures were treated with benzenethiolate anion as described above, and the resulting deselenenylated products were identified by comparison with the authentic samples. Ratios of the regio-isomers were also determined with the deselenenylated products by GLPC analyses.

Synthesis and Kinetic Investigation of the Atropisomerization of *meso*-Tetra(2-cyanophenyl)porphine

Keiichiro HATANO,* Kazunori ANZAI, Tadashi KUBO, and Shoko TAMAI

Department of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467

(Received May 7, 1981)

Tetra(2-cyanophenyl)porphine (ToCNPP) has been synthesized and isolated into the four respective atropisomers. The rotation of a cyanophenyl ring about the bond to the methine carbon of the porphyrin leads to interconversion reactions among the isomers. The isomerization reactions have been studied kinetically by the separation and quantitative measurement of each isomer on thin layer chromatography plates. The results show that the free energy of activation for the hindered rotation is an average of $\Delta G^* = 110$ kJ/mol at 50 °C. This is the highest barrier ever measured in similar porphyrin atropisomers. The apparent interaction between adjacent cyano groups is observed. The energy of interaction is estimated to be about 2.0 kJ per mole unit of interaction.

Rotational isomerism of some tetraarylporphyrins and their metal derivatives have been investigated by several groups of workers.[1-5] The principal features of the atropisomerism, *i.e.*, tautomerism and statistical distribution of isomers, have been known since the resolution and isomerization of tetra(2-hydroxyphenyl)porphine (ToOHPP) was communicated twelve years ago.[1] Many nuclear magnetic resonance (NMR) studies have also ratified the features.[2-4]

On the other hand, the isolation of a particular $\alpha,\alpha,\alpha,\alpha$ atropisomer of tetra(2-aminophenyl)porphine ($ToNH_2PP$) brought great advances in studies of synthetic models of the hemeproteins, such as the "picket fence" porphyrins.[6-8] We are interested in the steric control of ligand coordination and redox reactions of the central metal ions of metalloporphyrins[9] in connection with the catalytic selectivity and activity of various heme enzymes. Tetra(2-cyanophenyl)porphine (ToCNPP) is expected to be a good and new source for the synthetic models as well as $ToNH_2PP$.

In the course of our study to synthesize and isolate the desired isomer, $\alpha,\alpha,\alpha,\alpha$-isomer, of ToCNPP, we have found a new, but unfavorable for this isomer, effect of the cyano substituents on the atropisomerism. There is a steric repulsion between the CN groups through the space above the porphyrin plane, that disturbs the statistical distribution of isomers, especially, low yields of the $\alpha,\alpha,\alpha,\alpha$-isomer. This is the first report describing the kinetic analysis of the steric interaction as well as the synthesis and rotational isomerization of ToCNPP.

Experimental

Materials. A typical procedure to synthesize ToCNPP is as follows: 2-Cyanobenzaldehyde (10 g, 76 mmol) and pyrrole (5.3 ml, 76 mmol) in a mixture of acetic acid and pyridine (4:1 in volume, total 400 ml) were refluxed for 2 h. After the reaction mixture was cooled down to room temperature, twice the volume of methanol was added and the solution was allowed to stand for at least 2 d. Crystalline products precipitated in the solution were separated by filtration, washed with methanol, and dried in an oven at 50 to 70 °C. It was further purified by chloroform extraction using a Soxhlet extractor. The resulting purple crystals in the solution were collected by filtration (yield: *ca.* 0.4 g, 3%). Found: C, 80.22; H, 3.25; N, 15.11%. Calcd for $C_{48}H_{26}N_8$: C, 80.66; H, 3.67; N, 15.68%. IR (KBr) cm^{-1}: $\nu_{C\equiv N}$ 2230. UV ($CHCl_3$) λ_{max} nm ($\varepsilon \times 10^{-4}$): 419 (37.4), 512 (2.12), 544 (0.72), 587 (1.04), 644 (0.57). Mp >300 °C.

Since ToCNPP is a mixture of four atropisomers, each component was separated by column chromatography using silica gel 100 (70—230 mesh, Merck) and dry chloroform. The chloroform solution of each isomer was evaporated *in vacuo* immediately after elution from the column. Before kinetic experiments, the atropisomers were purified further by preparative thin layer chromatography (TLC) (silica gel 60, 0.5 mm thick, Merck).

All reagents and solvents of reagent grade were used without further purification except chloroform which was washed with water, dried over CaH_2, and distilled.

Measurement of the Isomerization Rates. A chloroform solution of each atropisomer (*ca.* 5 mg/20 ml) in a flask was placed in a water bath kept at 50 or 60 °C. A few microliters of the solution was sampled with a glass capillary at appropriate intervals, and spotted on a TLC plate (silica gel 60, 0.25 mm thick, Merck). The rotational isomerization reaction of an isomer to the additional three components was monitored by measurements of the quantity of respective isomers which were separated with 98:2 chloroform–acetone on a TLC plate. The quantity was measured by spectrometry after the extraction of each isomer from the TLC plate with chloroform. The mole fractions of minor components determined by this method have relatively larger errors than the fraction of major ones. Under the present reaction conditions, no product other than the isomers was detected by TLC even after the reaction for 3 d.

Processing of the Data. The digital integration of the differential rate equations,

$$d[A_i]/dt = \sum_j \sum_l k_j[A_l],$$

where k_j is the first-order rate constant for the j th reaction concerning the A_i species, was performed at small increments of time by a local Fortran program using the Runge-Kutta approximation.[10] An initial set of inputs, *i.e.*, rate constants and concentrations of isomers, was the experimental data obtained by the usual graphic method adapted to the initial stage of the reactions. The rate constants were refined by trial and error to fit the computed values to the experimental values of all isomers for the entire time course of the reaction.

The general structural parameters of the porphyrin skeleton[11] and atomic coordinates of cyano(*meso*-tetraphenylporphinato)manganese(III)[12] in the crystal were tentatively used for calculating the distances between atoms and for drawing.[13] The positions of the CN substituents were determined by assuming that the carbon and nitrogen atoms were on the linear extension from the center of phenyl ring to the ortho carbon with distances of C_{ortho}–C=1.5 Å and

C–N=1.15 Å. All calculations were carried out at the computing center of this university using a NEAC system 700S computer.

Results and Discussion

The Synthesis of ToCNPP. Two solvent systems have been proposed for the general syntheses of *meso*-tetraarylporphyrins in solution[14,15] besides Rothemund's original method and its applications.[16–18] Utilization of propionic acid, as proposed by Adler *et al.*,[14] to make ToCNPP has resulted in a large amount of tarry and black by-products which hamper the purification of the porphyrin in gram-quantities. On the other hand, Treib's procedure,[15] using 1:2 pyridine–acetic acid, for this porphyrin gave no precipitate even though the reaction mixture was allowed to stand for 2 d in a refrigerator.

The precipitation of crystalline products of reasonable purity and high yield from a simple reaction batch is considered to be the most important merit of the preparative procedure. We have determined the optimal conditions for preparing ToCNPP by varing the ratio of pyridine to acetic acid and by following the time course of the formation. The product yields obtained *in situ* by spectrometric methods increase from 4 to 8% by increasing the pyridine ratio from 10 to 33 v/v%. ToCNPP is found to be appreciably soluble in pyridine but much less soluble than the by-products, while ToCNPP is insoluble in acetic acid. Thus, the purest porphyrin products and highest isolated yield of a batch process have been obtained in 20% pyridine as described in Experimental. The total spectrometric yield reaches 7 to 8% level, but the complete isolation of the porphyrin is very difficult. The formation of ToCNPP in the boiling solution seems finished within 30 min and longer reaction time do not improve the yield.

The pyridine–acetic acid solvent system is also found to improve the isolation of crystalline tetra(2-nitrophenyl)- and tetra(2,6-dichlorophenyl)porphines from the single batch compared to the literature methods.[6,19]

Separation and Identification of the Atropisomers. The TLC of the reaction products show three distinct spots with R_f values of 0.47, 0.41, and 0.23 together with several minor spots at 0 to 0.2 when it is developed with 98:2 chloroform–acetone. The three materials extracted from the main spots display identical electronic absorption spectra with characteristic porphyrin maxima[19] and a common IR spectrum with a single C≡N stretching band. Each of the three compounds mutually interconverts in chloroform solution, and a new species at R_f=0.04 on TLC is generated in the interconversion. Thus the four spots on TLC correspond to the four atropisomers of ToCNPP. The distribution of the four isomers, equilibrated at 50 °C for 3 d, is 39 (±4), 24 (±3), 35 (±3), and 2 (±1)%, in the order of decreasing R_f values.

The compound with the smallest R_f value and mole fraction is easily assigned to α,α,α,α-isomer (iv) by consideration of the molecular polarity seen on TLC and the steric hindrance to assembling four cyano groups on the same side of the porphyrin plane. The kinetic studies mentioned below distinguish the α,α,α,β-isomer (iii) from the others as it is the only primary product of the isomerization of every isomer. We have tentatively identified the first and second eluents of chromatography to the α,β,α,β- (i) and α,α,β,β- (ii) isomers, respectively, based on the polarity on TLC. This assignment of the four atropisomers is consistent concerning the order of R_f values on TLC with that of $ToNH_2PP$ reported by Collman *et al.*[6] The crystal structure of ii may be analysed for a definitive assignment elsewhere.

The proton NMR spectra of the isomers have been poorly characterized owing to the complex multiplicity of the phenyl protons and low solubility in NMR solvents at room temperature.

The Kinetic Studies of the Isomerization. Rotation of any one of the four phenyl rings of ToCNPP about the bond to the porphyrin skeleton leads to the stereochemical isomerizations as shown in Fig. 1. Two or more rings can rotate simultaneously, but this can be ignored in the kinetic analysis as a secondary perturbation of small statistical probability. Intramolecular isomerization reactions are generally first-order reactions. The present case is also found to be first-order from the analysis. The designation of the rate constants for the six isomerization reactions is displayed in Fig. 1.

The equilibrium constants defined by $K_m=k_j/k_{j+1}$ are conveniently determined by the distribution of four isomers at 50 °C mentioned above, and the values obtained at 40 and 60 °C are invariant within experimental error. Each of the purified isomers were subjected to the rate determinations.

The refined rate constants are listed in Table 1 and the computer simulations of them are reasonable matches for all experiments at 50 and 60 °C. Two examples are displayed in Figs. 2a) and 2b). The solid lines in the figures are the computer simulations. The rate constants are also consistent with the equilibrium constants obtained experimentally.

The activation energies determined by the Arrhenius equation are found to spread over 84 to 94 kJ/mol for the six reactions, hence, they are averaged into an E_a which is reported in Table 2.

The Rotational and Steric Effects of the Cyano Substituent. The free energy of activation (ΔG^*) is considered to reflect the height of the rotational barrier principally generated by the friction between an ortho substituent and a pyrrole proton of the porphyrin. Our result, a weighted average value $\Delta G^*=110$ kJ/mol given by the Eyring equation at 50 °C, can be compared with the published kinetic data[1–4] for ortho substituted tetraphenylporphyrins. The comparison of ΔG^* should be done at the same temperature. However, since the entropy of activation or the substitute for it is unavailable, we must adapt our data to the extensions of temperatures by assuming that the activation energy (E_a) is employable over the temperature range of 23 to 180 °C. This assumption is plausible because of the intrinsic independence of E_a with temperature. The ΔG^* values of the present isomerization, calculated at appropriate temperatures, are summarized in Table 2, and compared with the bar-

riers reported in literature.[1-4]

The order $CN > CH_3 \approx CH_3O \approx OH$ is seen in the barriers. The cyano substituent on the ortho position of a phenyl ring has a higher rotational barrier, as expected by the bulk of the constituted atoms, than OH or CH_3. Moreover, since the CN group is erected linearly from the phenyl ring while CH_3O is bent at the oxygen atom, the awkwardness of CN passing through the porphyrin plane may contribute some kJ/mol to the activation state as compared with the flexible methoxide. The calculated rate constant for the rotation about one cyanophenyl-porphyrin bond at 23 °C is of the order of 10^{-6} s^{-1}. This value allows direct comparison with the only explicit parameter reported for ToOHPP.[1] That the rate in ToCNPP is about a tenth of that in ToOHPP indicates the reasonable substitution effect for CN.

The abundance ratio of the ToCNPP isomers deviates from the statistical expectation. This is the first reported example of the quantitative measurement for a nonstatistical distribution of porphyrin atropisomers. This can be interpreted as the non-bonded interactions of a CN substituent to CN substituent. The small mole fraction of iv indicates the interaction to be repulsive or maybe electrostatic. With consideration of the statistical ratios, the relative free

Table 2. Activation energy and free energy of activation for a phenyl ring rotation, and energy of steric interaction between neighboring substituent groups at ortho position of the phenyl ring in several porphyrins

energy differences of any one of the isomers can be determined by the relationship $\Delta G^\circ = -RT \ln K$. The energy levels of ii, iii, and iv lie at 3.2, 4.0, and 7.9 kJ/mol above the level of i, respectively, based on the experimental data observed at 50 °C. The repulsive forces are thought to be due to the nitrogen atom of CN, because no such effect is reported for OH, NH_2, or CH_3 substituents. The intramolecular atomic distances of the nitrogen to the adjacent or diagonal nitrogen are interesting parameters to evaluate the long range and weak non-bonded interactions. Supposing that the dihedral angles between the porhyrin plane and all phenyl rings are 90° in molecule iv, the distances are estimated to be 6.1 Å between the adjacent nitrogens and 8.6 Å between the diagonal ones. The latter does not seem to be responsible for the interaction as it must be further than the distance between the adjacent nitrogens of NH_2 in α,α,α,α-ToNH$_2$PP. This static model leads to the conclusion that the energy of an interaction between two nitrogens of CN 6.1 Å apart is 2.0 kJ per mole unit of interaction, since iv has four interactions. This value is also consistent with the interactions in iii. The smaller value seen in ii is perhaps the result of lessened contacts between adjacent cyano phenyl rings resulting from tilting a bit more away from each other, but without making any new closer contacts. However, we do not necessarily predict that the dihedral angles between the porphyrin plane and phenyl planes in the crystal of ii are as small as the smallest angles found in metallotetraphenylporphyrins.[20] There are many examples of intermolecular contacts shorter than 6.1 Å, a result of crystal packing effects. We do, however, claim that the long range (6.1 Å) and appreciable (2.0 kJ/mol·interaction) interaction between the CN groups is observed in the atropisomers of ToCNPP. The unfavorable effect on the isolation of α,α,α,α-isomer may be overcome by the utilization of the intermolecular interaction, *e.g.*, adsorbance,[5] selective crystalization and so on.

We thank Prof. W. R. Scheidt for discussion and editorial assistance.

Asymmetric Synthesis of Axially Dissymmetric 1,1′-Binaphthyls *via* an Intramolecular Ullmann Coupling Reaction of (*R*)- and (*S*)-2,2′-Bis(1-bromo-2-naphthylcarbonyloxy)-1,1′-binaphthyl[1,2]

Sotaro Miyano,* Masayuki Tobita, and Harukichi Hashimoto

(Received May 7, 1981)

An Ullmann reaction of the chiral bifunctional substrate containing two 1-bromo-2-naphthyl moieties, (*S*)-2,2′-bis(1-bromo-2-naphthylcarbonyloxy)-1,1′-binaphthyl, gives an intramolecularly coupled 12-membered cyclic diester in a 36% isolated yield. The intramolecular coupling reaction proceeds with virtually complete diastereoselectivity to induce *S*-chirality into the newly formed bond between the two naphthyl units.

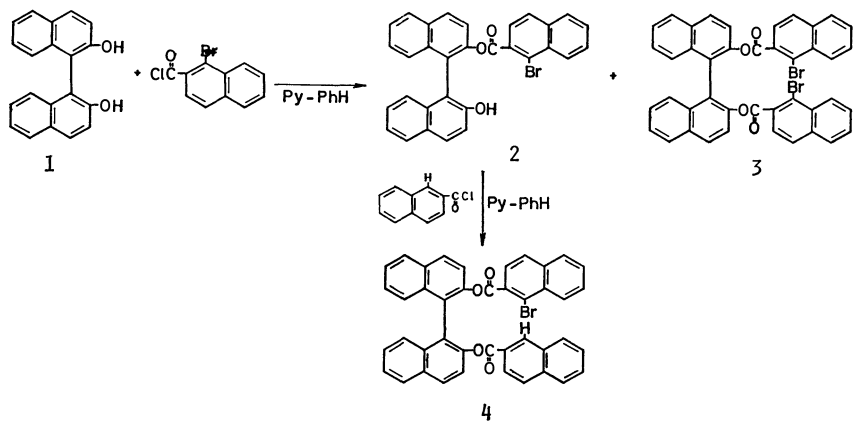
A number of 2,2′-disubstituted 1,1′-binaphthyls have been resolved into atropisomers, and proved to be highly resistant to thermal racemization.[3] The axially dissymmetric binaphthyl structure would be effective for chiral recognition because of its steric bulkiness and structural rigidity.[4,5] Having only the C_2 axis for the element of chirality, and thus minimizing the possibility of complex diastereomeric interactions, the biaryl moiety may also be useful for the elucidation of the mechanism of asymmetric induction. Thus, much attention has recently been centered on asymmetric reactions by the use of axially dissymmetric biaryl derivatives; in some cases a remarkable success has been accomplished.[6,7]

Although there are a number of methods currently available for the synthesis of biaryls,[8] direct routes to their atropisomers are limited:[7a,9] optical resolution of racemates has been adopted in conventional practices for the preparation of the prerequisite atropisomeric binaphthyl skeletons. In 1971, Jacques *et al.*[10] showed that the readily available 1,1′-binaphthyl-2,2′-diol (**1**) can be easily resolved into its antipodes *via* a phosphate ester. We have for some time been trying to utilize the axial dissymmetry of atropisomeric **1** for asymmetric synthesis of other biaryls, and here we wish to describe copper-promoted Ullmann biaryl coupling of 1-bromo-2-naphthoates of **1**.[1]

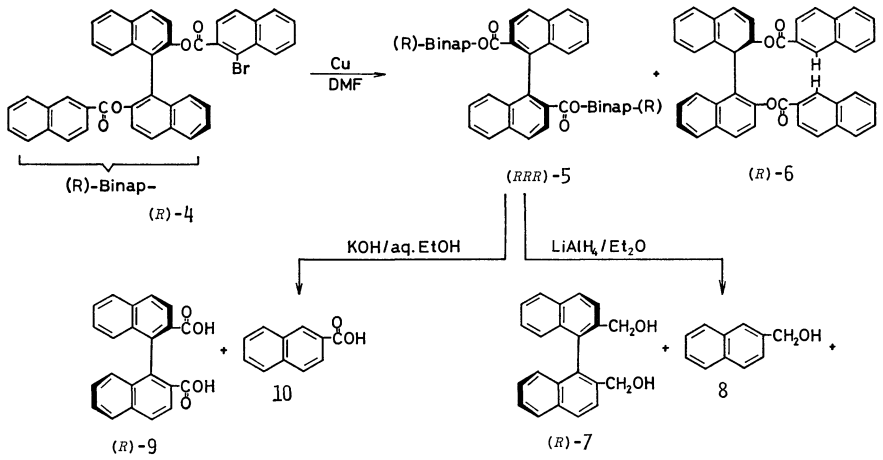
Results and Discussion

The synthesis of 1-bromo-2-naphthoates of **1** (**3** and **4**, and their atropisomers) is outlined in Scheme 1. 1-Bromo-2-naphthoyl chloride, prepared from 1-bromo-2-naphthoic acid[11] by reaction with thionyl chloride, was allowed to react with **1** in pyridine-benzene to give the corresponding monoester **2** and diester **3**. Each ester product was cleanly separated by column chromatography on alumina; benzene eluted the latter only, while ethanol–benzene could be used to liberate the former. The hydroxy ester (**2**) was in turn treated with 2-naphthoyl chloride to yield the mixed diester **4**. Optically active substrates were synthesized by use of (*S*)- and (*R*)-**1**.

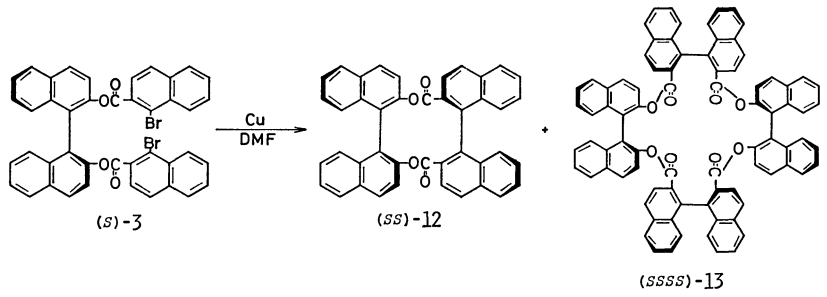
Although the optical yield was poor, the Ullmann coupling reaction of the chiral substrates, (*R*)- and (*S*)-**4**, induced (*R*)- and (*S*)-chirality, respectively, into the newly formed 1,1′-binaphthyl bond, as evidenced as follows: In a typical reaction, (*R*)-**4** was treated with freshly activated copper powder in gently refluxing DMF under nitrogen. Debromination of the substrate ((*R*)-**4**) was completed within 5 h by heating under reflux to give a 15:85 mixture of the reduction ((*R*)-**6**) and the coupled product ((*RRR*)-**5**) in an almost quantitative yield (Scheme 2). Reductive cleavage of the ester linkage of the coupled product ((*RRR*)-**5**) with lithium aluminum hydride (LAH) in boiling ether gave a sample of (*R*)-2,2′-bis(hydroxymethyl)-1,1′-binaphthyl ((*R*)-**7**), which had $[\alpha]_{546}^{23}$ +3.5° (*c* 0.8, acetone). This value corresponds to the optical purity of 4% on the assumption that the enantiomerically pure (*R*)-**7** has the value of $[\alpha]_{546}^{23}$ +86° (*vide infra*). The diol was transformed into (*R*)-α-methoxy-α-trifluoromethylphenylacetic acid ester ((*R*)-MTPA ester);[12] an ^{1}H NMR spectral study of



Scheme 1.



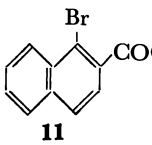
Scheme 2.



Scheme 3.

the ester in the presence of a chiral shift reagent, Eu(fod)$_3$, also showed the % e.e. of the sample to be 4—6%. Any significant racemization of the substrate ((*R*)-**4**) or products ((*RRR*)-**5** and (*R*)-**6**) under the reaction conditions was ruled out by considering the optical purity of the recovered (*R*)-**1**. Alternatively, (*R*)-1,1′-binaphthyl-2,2′-dicarboxylic acid (*R*)-**9** of 3% optical purity[13] was obtained *via* a hydrolytic treatment of a similar Ullmann product with KOH in boiling aq ethanol.

We have previously shown that an Ullmann coupling of *C*-chiral alcohol esters of 1-bromo-2-naphthoic acid induces axial dissymmetry into the 1,1′-binaphthyl bonds, but that the highest optical yield attained is only 13%.[9a] These and above results may imply that intermolecular Ullmann coupling of chiral substrates of type **11** is discouraging for asymmetric synthesis of binaphthyl atropisomers.



(R*: Chiral substituent)

11

On the other hand, we have found that copper-promoted reaction of bifunctional substrates, (*S*)- and (*R*)-**3**, is promising: Ullmann products from these diesters were hydrolyzed by heating under reflux with KOH in aq ethanol to give **9**'s in *ca.* 45% chemical yields. The apparent net optical yield for the joining of two binaphthyl units was estimated to be 30—45% on the basis of optical rotations of the recovered diacids. It seemed that these rather high asymmetric inductions should be attributed to *intramolecular* interactions of the substrates, as the *intermolecular* coupling of atropisomeric **4** scarcely induced axial dissymmetry.

Thus, we tried an attempt to enhance the unimolecular debromination of the diester, (*S*)-**3**. To a well stirred suspension of copper powder in gently refluxing DMF was slowly added a sample of (*S*)-**3** over 1 h period, and then heating was continued for another 5 h. As judged by TLC and HPLC, however, the intended intramolecular Ullmann coupling of (*S*)-**3** to **12** was accompanied by the formation of serious amounts of reduction product ((*S*)-**6**), dimeric ((*SSS*)-**5** and (*SSSS*)-**13**), and other higher oligomeric products (Scheme 3). It should be pointed out here that careful HPLC analysis, including variation of column and eluant, showed only one peak for the intramolecularly coupled product (**12**).[14] A chromatography of the Ullmann product on a silica-gel column using chloroform (1% ethanol) as the eluant gave a 36% isolated yield of the intramolecularly coupled cyclic diester ((*SS*)-**12**) as a white powder. The compound was characterized by elemental analysis, mass, IR, and other spectral studies as well as chemical transformation. Thus, treatment of the cyclic diester with LAH in ether–THF gave only two diols, (*S*)-**7** and (*S*)-**1**, the specific rotations being $[\alpha]_{546}^{23}$ −86.0° (*c* 1.4, acetone) and $[\alpha]_{D}^{24}$ −34.9°

(c 1.03, THF), respectively. These values compare well with literature ones claimed for enantiomerically pure samples; $[\alpha]_{546}^{23}$ −83.0° for (S)-**7**[11] and $[\alpha]_D^{25}$ −33.3° for (S)-**1**.[6,15] Furthermore, within the limits of the NMR detection at 60 MHz, the (R)-MTPA esters of these diols showed, in the presence of $Eu(fod)_3$, no indication of the presence of (R)-diols.

These observations unequivocally indicate that the two 1,1′-binaphthyl axes in the cyclic diester (**12**) have an *SS*-configuration of high enantiomeric purity. This leads to the conclusion that intramolecular Ullmann coupling of (S)-**3** proceeds, though under rather severe reaction conditions, with a virtually complete diastereoselectivity to give cyclic diester of *SS*-configuration ((*SS*)-**12**). An inspection of CPK models of the cyclic diester **12** suggests that two sets of Naph–COO–Naph moieties of (*SS*)-**12** arrange to a double helix-like structure to accommodate the 12-membered cyclic diester as schematically shown in Fig. 1, while those of (*SR*)-counterpart must be bent to a highly strained right angle in order to form the cycle (Fig. 2), thus strongly favoring the *SS*-configuration over *SR*-isomer. In conclusion, the origin of the remarkable diastereoselectivity in the intramolecular coupling may be attributed to the steric requirements of the product cyclic diester, while at present there is no basis for mechanistic conclusions with regard to the Ullmann reaction.

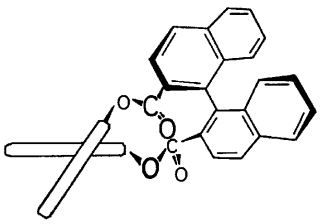


Fig. 1. (*SS*)-**12**.

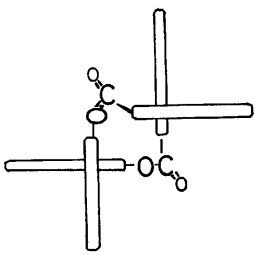

Fig. 2. (*SR*)-**12**.

It is interesting that both of the newly formed 1,1′-binaphthyl bonds in the cyclic dimer ((*SSSS*)-**13**) have also *SS*-chirality of rather high optical purity, though the paucity of the sample has been retarding the elucidation of their accurate structures. Further work along this line is in progress.

Experimental

Measurements. IR spectra were obtained on a Shimadzu IR 430 spectrophotometer. NMR spectra were determined on a Hitachi R-24A instrument using hexamethyldisiloxane as an internal standard in CCl_4 unless otherwise stated. Mass spectra were recorded on a JEOL JMS-D300 double focusing mass spectrometer with direct sample injection. Optical rotations were recorded on a Union PM-101 automatic digital polarimeter in a 1-cm cell at ambient temperature. High performance liquid chromatography (HPLC) was carried out on a JASCO TRIROTAR-III and/or JASCO FAMILIC-100 instrument using columns packed with JASCO SC-01 (ODS), HP-01 (styrene-divinylbenzene), and WC-03 (Carbowax 400) with conventional eluants. Molecular weight was determined in benzene solution with a Hitachi-Perkin-Elmer 115 vapor pressure osmometer. All melting points were corrected.

Materials. Analytical and preparative TLC were carried out on Merck Silica Gel 60H. Solvents for experiments requiring anhydrous conditions were distilled from CaH_2 and stored under nitrogen. 1-Bromo-2-naphthoic acid[11] (mp 188—190 °C), racemic **1**[17] (mp 217—218 °C), and 2-naphthoyl chloride[18] (bp 130—131 °C/400 Pa, mp 51.3—52.3 °C) were prepared according to the reported methods.

1-Bromo-2-naphthoyl Chloride: A mixture of 1-bromo-2-naphthoic acid (5.95 g, 23.7 mmol) and 10 ml† of thionyl chloride was refluxed for 3 h, and the resulting brown-red solution was evaporated to dryness. The residue was dissolved in hot cyclohexane, filtered hot from activated charcoal, and recrystallized to give pale yellow, feather-like crystals: yield, 5.40 g (84.5%); mp 82.5—83.5 °C; IR (KBr) 1780 cm^{-1} (>C=O). Found: C, 49.30; H, 2.10; halogen, 43.07%. Calcd for $C_{11}H_6BrClO$: C, 49.02; H, 2.24; halogen, 42.80%.

Resolution of **1**: The method of Jacques *et al.*[10] and Kyba *et al.*[6] was slightly modified. To a stirred solution of racemic **1** (50 g, 0.175 mol) in CH_2Cl_2 (200 ml) and pyridine (150 ml) was added dropwise 20 ml of $POCl_3$. The mixture was refluxed for 3 h, and then volatiles were evaporated under slightly reduced pressure. The residue was dissolved in a hot Na_2CO_3 (60 g) solution in water (2 l††). An amount of activated charcoal was added, and the mixture was filtered hot. The filtrate was made acidic by addition of 50 ml concd HCl, and the resulting white slurry was stirred overnight at room temperature. The white precipitate was collected and dried in a rotatory evaporator *in vacuo* to give 52.4 g (85.7% yield) of the acid phosphate of **1**. Resolution of the binaphthyl acid phosphate with cinchonine gave, after successive two runs of crystallization from MeOH–H_2O followed by HCl treatment, a 12.0 g sample of (+)-acid (46% yield): $[\alpha]_D^{23}$ +605° and $[\alpha]_{546}^{23}$ +717° (c 1.16, MeOH) (lit,[6] $[\alpha]_{546}^{25}$ +722° (c 0.9, MeOH). The levorotatory acid was recovered from the mother filtrate: 8.3 g (32% yield); $[\alpha]_D^{23}$ −608°; $[\alpha]_{546}^{23}$ −721° (c 0.824, MeOH) (lit,[6] $[\alpha]_{546}^{25}$ −734° (c 0.9, MeOH)). The (+)- and (−)-phosphoric acid were treated with LAH in THF[6] to give (S)-(−)- and (R)-(+)-**1**, respectively.

(S)-1: 8.69 g (88% yield based on the (+)-phosphoric acid); mp 209—210 °C (PhMe); $[\alpha]_D^{23}$ −35.0° (c 1.18, THF).

(R)-1: 5.72 g (84% yield); mp 208—210 °C (PhH); $[\alpha]_D^{23}$ +34.6° (c 0.892, THF).

2-Hydroxy-2′-(1-bromo-2-naphthylcarbonyloxy)-1,1′-binaphthyl (2): To a stirred, water-chilled solution of racemic **1** (1.0 g, 3.49 mmol) in PhH(20 ml)–pyridine(5 ml) was slowly added 0.945 g (3.51 mmol) of 1-bromo-2-naphthoyl chloride. The mixture was stirred overnight at ambient temperature and finally heated under reflux for 3 h. The reaction was quenched with 50 ml of 2 M (1 M=1 mol dm^{-3})

† 1 ml=1 cm^3.

†† 1 l=1 dm^3.

HCl, and extracted with portions of PhH. The combined extracts were washed successively with 2 M HCl, 1 M Na_2CO_3, and then H_2O, and dried over Na_2SO_4. The organic phase was concentrated to a *ca.* 5 ml volume, which was chromatographed on alumina column (Wako-Activated Alumina, 300 mesh). After a small amount of **3** (*vide infra*) was eluted with PhH, 1.32 g of **2** was recovered by use of PhH–EtOH (10:1) eluant (73% yield based on **1**): mp 202—203 °C (PhH); IR (KBr) 3450 (–OH) and 1735 cm^{-1} (>C=O). Found: C, 72.01; H, 3.88; Br, 15.60%. Calcd for $C_{31}H_{19}O_3Br$: C, 71.68; H, 3.69; Br, 15.38%.

Similar reactions of (*S*)- and (*R*)-**1** gave their corresponding atropisomeric **2**.

(S)-**2**: Mp 179—180 °C (PhH); $[\alpha]_D^{22}$ −32.0° (*c* 0.874, acetone); IR (KBr) 3450 (–OH) and 1730 cm^{-1} (>C=O). Found: C, 71.56; H, 3.69; Br, 15.72%.

(R)-**2**: Mp 177—178 °C (PhH); $[\alpha]_D^{23}$ +34.1° (*c* 1.38, acetone).

2,2′-Bis(1-bromo-2-naphthylcarbonyloxy)-1,1′-binaphthyl (**3**): Following the procedure used for the preparation of **2**, a 93% yield of **3** was obtained by the reaction of 2.2 g (8.16 mmol) of 1-bromo-2-naphthoyl chloride and **1** (1.10 g, 3.84 mmol) in PhH(20 ml)–pyridine(5 ml): yield, 2.69 g; mp 226.5—227 °C; IR (KBr) 1745 cm^{-1} (>C=O). Found: C, 67.04; H, 3.34; Br, 21.55%. Calcd for $C_{42}H_{24}O_4Br_2$: C, 67.04; H, 3.21; Br, 21.24%.

(S)-**3**: Mp 180—182 °C; $[\alpha]_D^{22}$ +34.7° (*c* 0.922, acetone); IR (KBr) 1750 cm^{-1} (>C=O). Found: C, 66.81; H, 3.16; Br, 20.84%.

(R)-**3**: Mp 177—180 °C; $[\alpha]_D^{24}$ −33.5° (*c* 1.08, acetone).

2,2′-Bis(2-naphthylcarbonyloxy)-1,1′-binaphthyl (**6**): Mp 211—213 °C; IR (KBr) 1730 cm^{-1} (>C=O). Found: C, 84.73; H, 4.46%. Calcd for $C_{42}H_{26}O_4$: C, 84.83; H, 4.40%.

2-(2-Naphthylcarbonyloxy)-2′-(1-bromo-2-naphthylcarbonyloxy)-1,1′-binaphthyl (**4**): A mixture of 3.71 g (7.14 mmol) of **2** and 1.41 g (7.40 mmol) of 2-naphthoyl chloride in PhH-(40 ml)–pyridine(5 ml) was stirred overnight at ambient temperature and then refluxed for 3 h. The reaction mixture was diluted with 50 ml of PhH, to which was added 100 ml of 2 M HCl. The solid was filtered off and recrystallized from $CHCl_3$ to give 3.86 g (5.73 mmol) of **4**: yield 80.3%; mp 248—249 °C; IR (KBr) 1725 and 1745 cm^{-1} (>C=O). Found: C, 74.66; H, 3.68; Br, 12.12%. Calcd for $C_{42}H_{25}O_4Br$: C, 74.89; H, 3.74; Br, 11.86%.

Optically active **4**'s were soluble in benzene and purified by alumina column chromatography.

(S)-**4**: Vitreous powder; $[\alpha]_D^{24}$ ≈0°; $[\alpha]_{436}^{24}$ +20.3° (*c* 1.03, acetone); IR (KBr) 1730 cm^{-1} (>C=O, broad).

(R)-**4**: Vitreous powder; $[\alpha]_{436}^{24}$ −18.9° (*c* 2.17, acetone).

Ullmann Reaction of (R)-**4**. Just prior to the reaction, 1.0 g of copper powder (200 mesh, Junsei Chemical Co.) was pretreated for activation according to a literature procedure,[19] except that all manipulations were carried out under nitrogen and that the acetone-moist powder was further washed with several portions of PhH. The copper powder and 0.524 g (0.778 mmol) of (*R*)-**4** were charged into a 30 ml round-bottomed flask equipped with a reflux condenser topped with nitrogen inlet. The whole system was evacuated and refilled with nitrogen, and then 10 ml of DMF was added to the flask. The mixture was magnetically stirred and heated to gentle reflux under nitrogen. After 5 h heating, the cooled mixture was diluted with 50 ml of PhH, and solids were filtered off. The filtrate was washed with 2 M HCl and then water, and dried over Na_2SO_4. Evaporation of the solvent *in vacuo* afforded a pale yellow residue, 0.458 g (0.770 mmol, calculated as **6**), which was comprised of a 15:85 mixture of (*R*)-**6** and (*RRR*)-**5**, as judged from the peak areas of UV absorption at 254 nm on HPLC (JASCO SC-01 column, MeCN/H_2O (98/2) eluant). A negative Beilstein test confirmed the absence of the unreacted ester. A preparative TLC of an aliquot of the Ullmann product (0.40 g) using PhH as eluant gave 21 mg of (*R*)-**6** and 0.302 g of (*RRR*)-**5**. The (*RRR*)-**5** melted gradually over a temperature range of 150—160 °C (dec); $[\alpha]_D^{23}$ +91.8° (*c* 1.0, acetone). Found: C, 84.85; H, 4.31%. Calcd for $C_{84}H_{50}O_8$: C, 84.98; H, 4.24%.

The (*RRR*)-**5** (0.25 g) was boiled with 0.2 g of LAH in ether for 3 h. The reaction was worked up as usual, and a preparative TLC with $CHCl_3$/AcOEt (4/1) enabled the recovery of (*R*)-**7** (36 mg, $[\alpha]_{546}^{23}$ +3.5° (*c* 0.8, acetone)), (*R*)-**1** (80 mg, $[\alpha]_D^{23}$ +35.2° (*c* 0.90, THF)), and **8** (26 mg). The diol ((*R*)-**7**) was completely acylated in CCl_4 with excess acid chloride of (*R*)-(+)-MTPA in the presence of excess 4-dimethylaminopyridine to give the diastereomeric pair of di-(*R*)-MTPA ester.[12b] NMR ($CDCl_3$): δ 3.33 (3H, $-OCH_3$), 2H at 4.76 ($-CH_2-$ for (*RR*)-isomer) and 4.82 ($-CH_2-$ for (*SR*)-isomer), 7.25 (10H, –Ph), and 6.7—8.1 (12H, Naphthyl). Addition of $Eu(fod)_3$ caused separation of the $-OCH_3$ signal, where the induced downfield shift for the (*SR*)-ester was larger than that for the (*RR*)-isomer.

Ullmann Reaction of (R)- *and* (S)-**3**. *Procedure A*: The following example is typical. As above, a mixture of (*R*)-**3** (1.00 g, 1.33 mmol) and activated copper powder (prepared from 1.2 g of Cu) in 10 ml of DMF was refluxed for 5 h with vigorous stirring under nitrogen. The organic residue obtained weighed 0.785 g, $[\alpha]_D^{24}$ +70.4° (*c* 0.83, PhH). This sample was refluxed with 2 g of KOH in 95% aq EtOH (20 ml) for 5 h. After the solvent was evaporated, the residue was dissolved in 30 ml of H_2O and made acidic with concd HCl to give a white precipitate. The mixture was extracted with portions of ether. Combined ether extracts were then extracted with 1 M Na_2CO_3; after usual work-up of the aq layer, 2-naphthoic acids ((*R*)-**9**+**10**) were recovered (0.42 g, 92% yield) while diol ((*R*)-**1**) was obtained from the ether layer (0.34 g, 89%, $[\alpha]_D^{24}$ +33.2° (*c* 1.00, THF)). After a TLC (EtOH/28% NH_4OH/H_2O= 16/3/1) of the acid mixture, 0.203 g of diacid ((*R*)-**9**, 44.6% yield based on (*R*)-**3**) and 0.140 g of monoacid (**10**) were obtained.

(R)-**9**: $[\alpha]_D^{24}$ +34.0° (*c* 0.78, 0.1 M NaOH); mp 255—265 °C (dec).

In another run, 0.302 g (0.401 mmol) of (*S*)-**3** was treated with Cu (1 g) in 10 ml of DMF at 120—130 °C for 10 h. The specific rotation of the diacid ((*S*)-**9**) was $[\alpha]_D^{24}$ −49.4° (*c* 0.85, 0.1 M NaOH); the yield was 60 mg.

Procedure B: To a well stirred, gently refluxing suspension of freshly activated copper powder (prepared from 3 g of Cu) in 50 ml of DMF was slowly added (*S*)-**3** (1.54 g, 2.05 mmol) over 1 h period under nitrogen, and heating was continued for another 5 h. The pale yellow organic residue (1.21 g, $[\alpha]_D^{24}$ −196.5° (*c* 1.11, PhH)) was analyzed by HPLC (JASCO SC-01 column, MeCN) to show the presence of, in the order of elution, (*SS*)-**12** (1.00), (*S*)-**6** (0.20), (*SSSS*)-**13** (0.21), (*SSS*)-**5** (0.19), and other higher oligomeric products (in parentheses are shown relative peak areas of UV absorption at 254 nm). A chromatography on a silica-gel column (Wako Gel C-200) using $CHCl_3$ (1% EtOH) as eluant gave 0.437 g of (*SS*)-**12** and 40 mg of (*SSSS*)-**13** as well as trace amounts of (*S*)-**6** and (*SSS*)-**5**.

(SS)-*Tetranaphtho*[*2,1*-b:*1,2*-d:*2,1*-h:*1,2*-j][*1,6*]*dioxacyclododeca-2,4,8,10-tetraene-7,12-dione* ((SS)-**12**): Mp >350 °C; $[\alpha]_D^{23}$ −457.6° (*c* 0.507, PhH); IR (KBr) 1752 cm^{-1} (>C=

O); MS (70 eV), *m/e* (%), 592 (M^+, 27.1), 280 (8.3), 268 (26.6), 252 (4.2), and 239 (4.2). Found: C, 85.41; H, 3.81%. Calcd for $C_{42}H_{24}O_4$: C, 85.12; H, 4.08%.

The cyclic diester ((*SS*)-**12**, 0.332 g, 0.56 mmol) was treated with 0.15 g of LAH in ether(30 ml)–THF(10 ml). After a TLC ($CHCl_3$/AcOEt=4/1), 0.149 g (0.474 mmol) of (*S*)-**7** ($[\alpha]_{546}^{23}$ −86.0° (*c* 1.43, acetone)) and 0.124 g (0.433 mmol) of (*S*)-**1** ($[\alpha]_D^{24}$ −34.9° (*c* 1.03, THF)) were recovered.

(SSSS)-***13***: Mp >400 °C; M.W. 1220 (calibrated with (*SS*)-**12** (M.W.=592)); $[\alpha]_D^{25} \approx 0°$ (*c* 0.304, PhH); $[\alpha]_{436}^{24}$ −291° (*c* 0.134, PhH); IR (KBr) 1745 cm^{-1} (>C=O). Found: C, 84.75; H, 3.63%. Calcd for $C_{84}H_{48}O_8$: C, 85.12; H, 4.08%.

LAH treatment of the cyclic dimer (*ca.* 30 mg) gave a *ca.* 8 mg sample of (*S*)-**7**, the specific rotation of which was estimated to be $[\alpha]_{546}^{23}$ −75—−85° (acetone).

(*S*)-***6***: MS (70 eV), *m/e* (%), 594 (M^+, 22.3), 440 (2.5), 268 (2.7), 156 (8.1), and 155 (56.3).

The (*SSS*)-**5** was inferred from its retention volume on HPLC and IR spectrum.

We are grateful to Professor Shozo Yamaguchi and Dr. Kuninobu Kabuto in our University for helpful suggestions and kind offering of reagents for the preparation of the (*R*)-MTPA esters. This work was partly supported by a Grant-in-Aid for Scientific Research No. 465280 from the Ministry of Education, Science and Culture.

The Biotransformation of Foreign Substrates by Tissue Cultures. I. The Hydroxylation of Linalool and Its Related Compounds with the Suspension Cells of *Nicotiana tabacum*

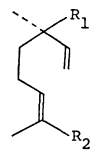
Toshifumi HIRATA, Tadashi AOKI, Yoshio HIRANO, Takashi ITO, and Takayuki SUGA*

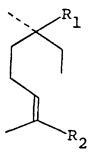
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received May 22, 1981)

It was found that the tissue cultures of *Nicotiana tabacum* "Bright Yellow" possess the ability to transform selectively the *trans*-methyl group in the 3-methyl-2-butenyl group of such foreign substrates as linalool and the related compounds into the hydroxymethyl group. Also, the cultures were found to have the ability to hydrolize the acetoxyl group of their acetates.

In connection with studies on the biosynthetic ability of plant callus tissues,[1] we are considerably interested in their ability to transform foreign substrates. Recently, it has been documented that some plant cell cultures have the ability to transform administered substrates, and such an ability may be used for the transformation of chemical substances.[2-9] However, there have been few systematic studies on their transformation ability and pattern. We, therefore, began investigating the transformation of acyclic monoterpenoid alcohols by the cultured cells of *Nicotiana tabacum* "Bright Yellow." As the acyclic monoterpenoid alcohols, linalool (**1**), linalyl acetate (**2**), dihydrolinalool (**3**), and dihydrolinalyl acetate (**4**) were used. The results have been partly outlined in the preliminary communication.[10] We will here report details of the results.





1: R_1=OH, R_2=CH_3
2: R_1=OAc, R_2=CH_3
5: R_1=OH, R_2=CH_2OH
7: R_1=OH, R_2=CHO
8: R_1=OAc, R_2=CH_2OH
10: R_1=OAc, R_2=CHO

3: R_1=OH, R_2=CH_3
4: R_1=OAc, R_2=CH_3
6: R_1=OH, R_2=CH_2OH
9: R_1=OAc, R_2=CH_2OH

Results and Discussion

Callus tissues induced from the stem of *Nicotiana tabacum* "Bright Yellow" were used in this work. The callus tissues were precultured for 3—4 weeks in Murashige and Skoog's medium[11] prior to the administration of the substrates. A sample of the monoterpenoids was administered to the suspension cells. The suspension cultures were incubated at 25 °C for 7 d under shaking in the dark. After incubation, transformation products were detected by comparing the ether-soluble constituents of both the cultured mass and the culture medium with those of the metabolites of *N. tabacum* suspension cells by means of GLC and TLC. The transformation products were separated by chromatographic methods.

In the biotransformation of linalool (**1**), compound **5** was a major product, as shown in Table 1. The compound (**5**) exhibited the ^{1}H NMR signal at δ 4.00 due to $-C\underline{H}_2OH$, instead of the 8- or 10-methyl signal of **1**. This suggested that the product is a C(8)- or a C(10)-hydroxylated derivative of **1**. The dihydroxy compound (**5**) was selectively hydrogenated with PtO_2 to give a dihydro derivative **6**, which showed a 17% NOE between the hydroxymethyl group (δ 3.94) and the C(6)–H (δ 5.42). The NOE[12] indicated that the hydroxymethyl group is *trans* to the C(1)–C(5) chain portion. This was further supported by the agreement of the observed chemical shift (δ 6.45) of the C(6)–H of the hydroxy aldehyde **7**, with the evaluated shift value (δ 6.40) calculated for the *trans* isomer by fitting Pascual's equation.[13,14] Thus, the product **5** was elucidated to be 8-hydroxylinalool.

When linalyl acetate (**2**) was fed to the tobacco suspension cells, two transformation products, 8-hydroxylinalool (**5**) and 8-hydroxylinalyl acetate (**8**), were found, as shown in Table 1. However, linalool (**1**) resulting from linalyl acetate (**2**) by hydrolysis was not found. Accordingly, the preferential formation of 8-hydroxylinalool (**5**) seems to indicate oc-

TABLE 1. BIOTRANSFORMATION OF LINALOOL (**1**) AND ITS DERIVATIVES (**2**, **3**, AND **4**) BY *Nicotiana tabacum* SUSPENSION CELLS

Substrates	Products	Yield/%[a]
Linalool (**1**)	8-Hydroxylinalool (**5**)	16.5
Linalyl acetate (**2**)	8-Hydroxylinalool (**5**)	14.8
	8-Hydroxylinalyl acetate (**8**)	1.9
Dihydrolinalool (**3**)	8-Hydroxydihydrolinalool (**6**)	14.9
Dihydrolinalyl acetate (**4**)	8-Hydeoxydihydrolinalool (**6**)	15.5
	8-Hydroxydihydrolinalyl acetate (**9**)	2.2

a) The weight percent of the products per the administered substrates.

currence of the hydrolysis of linalyl acetate (**2**) followed by the immediate hydroxylation at C(8) or occurrence of the immediate hydroxylation at C(8) of **2** followed by the hydrolysis of the acetoxyl group. The quite similar results were obtained in the administration of dihydrolinalool (**3**) and dihydrolinalyl acetate (**4**), as shown in Table 1.

We now have established that the suspension cells of *Nicotiana tabacum* "Bright Yellow" have the ability to hydroxylate selectively in the *trans*-methyl group in the 3-methyl-2-butenyl group of linalool (**1**) and its related compounds (**2**—**4**), but not in the *cis*-methyl group. Also, it was found that the cultured cells are capable of hydrolizing the acetoxyl group of the acetates.

Experimental

NOE experiments were carried out on a Hitachi R-22 spectrometer in the frequency-swept and internal-TMS-locked mode. The sample solution was prepared in concentration of 5% (w/v) in CCl_4 and carefully degassed just prior to measurements. GLC analyses were performed on a Shimadzu GC-6A equipped with a FID and a glass column (3 mm×2 m) packed with 2% OV-17 and 10% DEGS on Chromosorb AW-DMCS (80—100 mesh) at 120 °C and 150 °C, respectively, for each case. TLC analyses were carried out with silica gel (Kieselgel GF_{254}; 0.25 mm thick) by using two different solvent systems [(i) EtOAc–hexane (3:7, v/v) and (ii) MeOH–benzene (1:24, v/v)] for each case.

Sample Used. Linalool and its acetate donated from Takasago Perfumery Co. Inc. were purified by column chromatography (silica gel) with a hexane–EtOAc mixture with EtOAc increasing 0 to 15% to give (−)-linalool (**1**) [$[\alpha]_D^{25}$ −19.9° (neat); n_D^{25} 1.4600; d_4^{25} 0.8639; >99.5% pure on GLC] and (−)-linalyl acetate (**2**) [$[\alpha]_D^{25}$ −2.1° (neat); n_D^{25} 1.4550, d_4^{25} 0.8991; >99.5% pure on GLC]. (−)-Dihydrolinalool (**3**) [$[\alpha]_D^{25}$ −2.5° (*c* 1.8, MeOH); n_D^{25} 1.4558; d_4^{25} 0.8601; >99.5% pure on GLC] and (−)-dihydrolinalyl acetate (**4**) [$[\alpha]_D^{25}$ −1.8° (*c* 2.5, MeOH); n_D^{25} 1.4502; d_4^{25} 0.8983; >99.5% pure on GLC] were prepared from **1** and **2**, respectively, by selective hydrogenation with Adams' PtO_2.

Feeding of the Monoterpenoids to the Tobacco Suspension Cells. In this work, we used the callus tissues which were derived from the stem of *Nicotiana tabacum* "Bright Yellow" and then subcultured for about 5 years. Just before use for the transformation, the callus tissues were transplanted to freshly prepared Murashige and Skoog's medium[11] (100 ml per one flask) containing 2 ppm of 2,4-dichlorophenoxyacetic acid and 2% sucrose and then grown with continuous shaking for 3—4 weeks at 25 °C in the dark. To the suspension cells (40—60 g per one flask), the monoterpenoids (20 mg per one flask; total 200 mg) were administered, and then the suspension cultures were incubated at 25 °C for 7 d on a rotary shaker (70 min^{-1}) in the dark.

Isolation of the Products. After incubation as described above, the cells were filtered off and triturated with methanol. The methanol solution, after the removal of the solvent, was extracted with ether. The culture medium filtered from the cells was extracted with ether. These ether soluble fractions were compared by means of GLC and TLC with those of the metabolites of the suspension cells. Transformation products were isolated from the ether soluble fractions by chromatography on a 3% $AgNO_3$–silica-gel plate (1 mm thick) with EtOA–hexane (3:7, v/v) and/or preparative GLC with a glass column (5 mm×2 m) packed with 10% DEGS on Chromosorb AW-DMCS (80—100 mesh) at 150 °C. These products were identified as shown below. The identified products and their quantities are shown in Table 1.

*Identification of the Products. 8-Hydroxylinalool (**5**)*: $[\alpha]_D^{25}$ −12.8° (*c* 1.08, MeOH); IR (Liq.) 3380 (OH) and 1640 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=1.30 (3H, s, C(9)–H_3), 1.68 (3H, bs, C(10)–H_3), 4.00 (2H, s, –C$\underline{H}_2$–OH), and 5.0—6.2 (4H, olefinic H); MS (70 eV), *m/z* (rel intensity) 152 (5, M−H_2O), 137 (7), 119 (9), 71 (51), 67 (37), and 43 (100); direct comparison with a synthetic specimen (co-TLC, co-GLC, IR, ^1H NMR, and MS).

*Derivation of 8-Oxolinalool (**7**) from 8-Hydroxylinalool (**5**)*: A mixture of 8-hydroxylinalool (**5**) (50 mg) and active MnO_2 (40 mg) in CCl_4 (5 cm^3) was stirred at room temp for 12 h. Removal of the solvent from the reaction mixture, after filtration from the inorganic solid, gave an oily product (36 mg). This product was subjected to preparative TLC (silica gel; 1 mm thick) with hexane–EtOAc (4:1, v/v) to give 8-oxolinalool (**7**) (28 mg): IR (Liq.) 2720, 1685 (CHO), and 1640 cm^{-1} (C=C); ^1H NMR (CCl_4) δ=1.33 (3H, s, C(9)–H_3), 1.73 (3H, bs, C(10)–H_3); 6.45 (1H, bt, >C=CH–), and 9.43 (1H, s, CHO); MS (70 eV), *m/z* (rel intensity) 150 (21, M−H_2O), 135 (5), 83 (82), 71 (99), and 43 (100).

*8-Hydroxydihydrolinalool (**6**)*: *m/z* 154 (M−H_2O); IR (Liq.) 3350 (OH) and 1620 cm^{-1} (C=C); ^1H NMR (CCl_4) δ=0.90 (3H, t, *J* 7.5 Hz, C(1)–H_3), 1.19 (3H, s, C(9)–H_3), 1.70 (3H, bs, C(10)–H_3), 3.94 (2H, s, –C$\underline{H}_2$OH), and 5.42 (1H, bt, *J* 7.0 Hz, >C=CH–); direct comparison with a synthetic specimen (co-TLC, co-GLC, MS, IR, and ^1H NMR).

*8-Hydroxylinalyl Acetate (**8**)*: *m/z* 212 (M^+); IR (Liq.) 3500 (OH), 1735 (OAc), 1638 (C=C), and 1250 cm^{-1} (C–O); ^1H NMR ($CDCl_3$) δ=1.55 (3H, s, C(9)–H_3), 1.67 (3H, bs, C(10)–H_3), 2.01 (3H, s, OAc), 4.00 (2H, s, –C$\underline{H}_2$OH), 4.65 (1H, bt, *J* 6.5 Hz, >C=CH–), and 5.0—6.2 (3H, olefinic H). Hydrolysis of **8** with 5% methanolic NaOH gave 8-hydroxylinalool (**5**).

*8-Hydroxydihydrolinalyl Acetate (**9**)*: *m/z* 214 (M^+); IR (Liq.) 3450 (OH) and 1735 cm^{-1} (OAc); ^1H NMR ($CDCl_3$) δ=1.50 (3H, s, C(9)–H_3), 1.69 (3H, bs, C(10)–H_3), 1.95 (3H, s, OAc), 3.99 (2H, s, –C$\underline{H}_2$OH), and 5.0—6.2 (4H, olefinic H). Hydrolysis of **9** with 5% methanolic NaOH gave 8-hydroxydihydrolinalool (**6**).

*Preparation of the Authentic Samples. 8-Hydroxylinalool (**5**)*: Following the reported procedure,[15] linalyl acetate (**2**) (980 mg) was oxidized with SeO_2 (560 mg) in 95% dioxane (5 cm^3) at 70 °C for 30 min. The reaction mixture was subjected to preparative TLC (Si gel; 1 mm thick) with hexane–EtOAc (4:1, v/v) to give 8-oxolinalyl acetate (**10**) (227 mg): IR (Liq.) 2701 and 1686 (CHO), 1734, 1368, and 1246 cm^{-1} (OAc); ^1H NMR (CCl_4) δ=1.54 (3H, s, C(9)–H_3), 1.70 (3H, s, C(10)–H_3), 1.95 (3H, s, OAc), 6.37 (1H, bt, *J* 7.0 Hz, C(6)–H), 9.34 (1H, s, CHO); MS (70 eV), *m/z* (rel intensity) 150 (21, M−AcOH), 135 (14), 121 (18), 107 (17), 71 (45), and 43 (100). Reduction of this oxolinalyl acetate (110 mg) with $LiAlH_4$ (120 mg) in ether under reflux gave dihydroxy compound **5** (56 mg); IR (Liq.) 3400 (OH), 1642, and 922 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=1.29 (3H, s, C(9)–H_3), 1.67 (3H, bs, C(10)–H_3), 4.00 (2H, s, –C$\underline{H}_2$OH), and 5.0—6.2 (4H, olefinic H); MS (70 eV), *m/z* (rel intensity) 152 (3, M−H_2O), 137 (6), 119 (10), 71 (49), 67 (39), and 43 (100).

*8-Hydroxydihydrolinalool (**6**)*: Selective hydrogenation of 8-hydroxylinalool (**5**) (15 mg) on Adams' PtO_2 (5 mg)

in MeOH (3 cm^3) gave **6** (12 mg): IR (Liq) 3350 (OH) and 1620 cm^{-1} (C=C); ^1H NMR (CCl_4) δ=0.90 (3H, t, J 7.5 Hz, C(1)–H_3), 1.19 (3H, s, C(9)–H_3), 1.70 (3H, bs, C(10)–H_3), 3.94 (2H, s, –C$\underline{H}_2$–OH), and 5.42 (1H, bt, J 7.0 Hz, >C=C$\underline{H}$–); MS (70 eV), m/z (rel intensity) 154 (12, M–H_2O), 139 (12), 125 (27), 73 (44), and 43 (100).

The authors wish to express their thanks to Dr. Kunihiko Ojima of Faculty of Agriculture, Tohoku University, for a gift of *Nicotiana tabacum* callus and to the Takasago perfumery Co. Inc., for a gift of sample of linalool and linalyl acetate.

(Received May 28, 1981)

Several linear and branched all-*trans*-multiprenylacetic acids were synthesised, and introduced to the 6 position of the sugar moiety of muramyl dipeptide and its analog, *via* an amino acid as a linking unit. Compared with the saturated stearoyl derivative, all the compounds having a multiprenylacetyl group exhibited more potent adjuvant activity on the induction of delayed-type hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine. The derivatives with larger branched side chains tended to have increased activity.

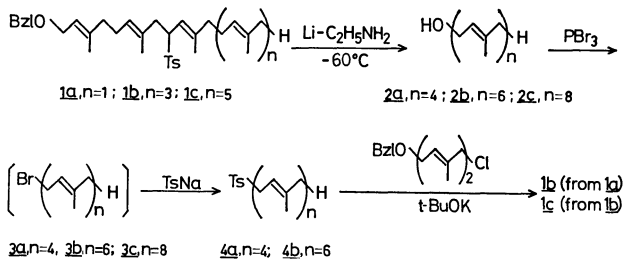
Following the finding that *N*-acetylmuramyl-L-alanyl-D-isoglutamine (MDP) is the effective minimal component of bacterial cell walls eliciting the function of Freund's complete adjuvant,[2)] many studies on the synthesis and evalutation of the activity of MDP and its analogs have been carried out.[3)] During these investigations, several attempts to apply these chemically well-defined compounds to immunotherapy of cancer and infectious disease have been undertaken. Particularly some derivatives with a lipophilic substituent introduced to the 6 position of the carbohydrate moiety of MDP showed interesting results. For example, 6-*O*-mycoloyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine, in which the mycoloyl moiety was of either natural[4)] or synthetic origin,[5)] and 6-*O*-quinonyl-*N*-acetylmuramyl-L-valyl-D-isoglutamine methyl esters[6)] suppressed syngeneic tumor growth (Meth-A fibrosarcoma in BALB/c female mice). Furthermore, 6-*O*-stearoyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine protected the mice from infections.[7)] The potent adjuvant activity of MDP for the induction of delayed-type hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine (ABA–Tyr) in guinea pigs was also retained in these compounds. The results indicate that the lipophilicity of the residues introduced to the MDP molecule plays an important role in potentiating the immunological activity of MDP. The incorporated fatty acid may furnish an affinity for the membranes of macrophages and/or lymphocytes to the molecule: the precise role of the quinone nucleus moiety in the quinonyl MDP derivatives is left to be solved in future.

In order to investigate further the role of the lipophilicity, we tried to introduce a lipophilic unsaturated carboxylic acid to the 6 position of the muramyl moiety of MDP. Thus, nine multiprenylacetic acids (**7**) with different chain lengths were first synthesized. In view of lability of these carboxylic acids to the final hydrogenolytic deprotecting procedure, a coupling of them with amino group of 6-*O*-aminoacyl-*N*-acetylmuramyl dipeptides (**8**)[8)] was attempted under mild conditions to give the desired compounds. The versatility of these compounds (**8**) as intermediates for the synthesis of MDP derivatives has been demonstrated.[8,9)]

In this paper, we describe the synthesis and immunological evaluation of eight new polyprenylacetylamino-acylated MDP derivatives (**9**). The compounds synthesized are presented in Table 3.

Chemistry

Synthesis of Multiprenyl Alcohols (2). All-*trans*-1-benzyloxy-3,7,11,15-tetramethyl-9-(*p*-tolylsulfonyl)-2,6,10,14-hexadecatetraene (**1a**)[10)] served as material for the synthesis of multiprenyl alcohols containing more than four isoprenyl units (**2a**—**c**) as shown in Scheme 1. All-*trans*-3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraen-1-ol (**2a**) was prepared by reductive elimination of the sulfonyl and benzyl group of **1a** with lithium in ethylamine at −60 °C in 95.6% yield.



Scheme 1.

Compound **2a** was then converted to all-*trans*-1-bromo-3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraene (**3a**) by treatment with PBr_3. Without further purification, the bromo compound (**3a**) was allowed to react with sodium *p*-toluenesulfinate dihydrate to give all-*trans*-3,7,11,15-tetramethyl-1-(*p*-tolylsulfonyl)-2,6,10,14-hexadecatetraene (**4a**) in an overall yield of 85%. Compound **4a** was coupled with *trans,trans*-1-benzyloxy-8-chloro-3,7-dimethyl-2,6-octadiene (**5**)[10)] in the presence of *t*-BuOK to give all-*trans*-1-benzyloxy-3,7,11,15,19,23-hexamethyl-9-(*p*-tolylsulfonyl)-2,6,10,14,18,22-tetracosahexaene (**1b**) (89%) which was subjected to reduction with lithium in ethylamine, giving all-*trans*-3,7,11,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaen-1-ol (**2b**) in 82% yield. The multiprenyl chain elongation of **2b** to all-*trans*-3,7,11,15,19,23,27,31-octamethyl-2,6,10,14,18,22,26,30-triacontaoctaen-1-ol (**2c**) was performed by repeating the above mentioned procedure (**2b**→**3b**→**4b**→**1c**→**2c**). Physicochemical properties of the multiprenyl alcohols (**2**) and their intermediates are listed in Table 1.

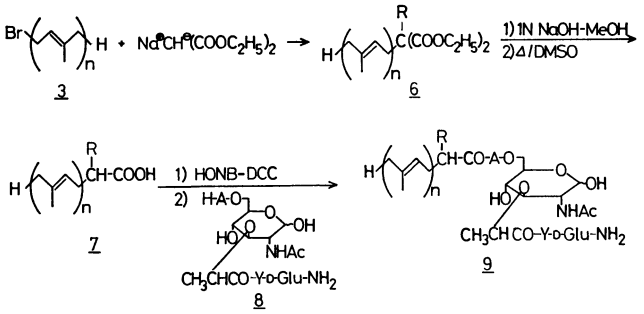
Synthesis of Mutiprenylacetic Acids (7). All-*trans*-5,9,13-trimethyl-4,8,12-tetracosatrienoic acid (**7d**) was synthesized according to the method reported by Fujita *et al.*[11] The eight other multiprenylacetic acids with different chain lengths were synthesized from multiprenyl alcohols (**2**, n=2—8) by the malonic ester method as shown in Scheme 2.



Scheme 2.

Multiprenyl alcohols (**2**) were converted to the corresponding bromides (**3**, n=2—8) by treatment with PBr_3. Using the resulting suitable multiprenyl bromides, diethyl malonate was alkylated in the presence of NaH to give the diethyl, mono- and disubstituted malonate (**6**). The molar ratio of the products of mono- (**6b**) and disubstituted (**6b'**) malonate was 2:1 when one equivalent of **3b**, for example, was allowed to react with diethyl malonate in the presence of one equivalent of NaH in DMF at room temperature for 2 h. The combined yield of **6b** and **6b'** was 82.1% based on **3b**. The reaction conditions that might affect the overall yield as well as the ratio of mono- and disubstituted compounds were not further exaimned since the result obtained was satisfactory for the present study. After the separation of the products by means of silica gel column chromatography with hexane–diisopropyl ether (15:1) as an eluent, each product was hydrolyzed in 1 M KOH (5 equivalent)–MeOH–THF (2:5:1) under reflux. The resulting dicarboxylic acids were subjected to decarboxylation in DMSO at 140—150 °C to give the straight and branched chain multiprenylacetic acids, *i.e.*, all-*trans*-5,9,13,17,21,-25-hexamethyl-4,8,12,16,20,24-hexacosahexaenoic acid (**7b**) and 2-(all-*trans*-3,7,11,15,19,23-hexamethyl-2,6,-10,14,18,22-tetracosahexaenyl)-all-*trans*-5,9,13,17,21,25-hexanethyl-4,8,12,16,22,24-hexacosahexaenoic acid (**7b'**). Physicochemical properties of the multiprenylacetic acids synthesized by this procedure are listed in Table 2 together with those of the intermediates (**6**).

Synthesis of 6-O-Multiprenylacylaminoacyl MDP Derivatives (9). The carboxylic acids prepared above were then converted to *N*-hydroxy-5-norbornene-2,3-

Table 3. Yields and physicochemical properties of MDP derivatives **9**, **10** and **11**

a) These compounds were reported previously.[8] b) Optical rotation was determined when mutarotation was completed (25 h).

dicaboximide (HONB)[12] active ester by dicyclohexylcarbodiimide (DCC) and coupled with 6-*O*-aminoacyl-*N*-acetylmuramyl dipeptide (**8**)[8] to give multiprenylacetyl derivatives of MDP with an amino acid as a linking unit (**9**) (Scheme 2). In this study, 6-*O*-β-alanyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine (**8a**) as an analog of a natural MDP type and 6-*O*-L-leucyl-*N*-acetylmuramyl-α-aminoisobutyryl-D-isoglutamine (**8b**) as an analog of an artificial MDP type with higher activity were used. In this acylation, the carboxylic acids with higher molecular weight gave the lower yields. Particularly the acylation with **7c'** could not be accomplished in spite of many trials. In addition to the steric effect, the large difference in the polarities of the two reactants (**7c'** and **8b**) may prevent access of each component to the reacting point. Stearoyl (**10**) and retinoyl (**11**) residues were introduced to **8a** in a similar manner for comparison of the biological activity. The resulting products were purified by column chromatography on silica gel with AcOEt–pyridine–AcOH–H_2O (80:10:3:5) as a solvent system. Rechromatography using Sephedex LH-20 with EtOH as an eluent gave the pure products listed in Table 3.

Biology

The adjuvant activity of these synthetic MDP analogs for the induction of delayed-typed hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine (ABA–Tyr) in guinea pigs was assayed by a method described earlier.[13] The reslults are shown in Table 4.

All the compounds reported in this paper showed more potent activity than the saturated stearoyl derivative (**10**). Among them, five compounds (**9b**, **9c**, **9b'**, **9d'**, **11**) revealed higher activity than MDP. The high activity of **9e**, in which the carbon number in the side chain is comparable to that of the stearoyl derivative (**10**), showed that the presence of the multiprenyl structure in the carbon chain is favorable for the activity. The activity of **9d'** is higher than **9a**, indicating that the branched structure of the chain is also favorable. The remarkable tendency for the compounds with larger side chains (**9b**, **9c**, and **9b'**) to possess increased activity is interesting although there was no clear-cut relation between the chain length and the activity. The high activity of retinoyl derivative (**11**), in spite of its small carbon number in the chain, suggested that there is some additional immunological function caused by retinoyl moiety as in the case of quinonyl derivatives[9] of MDP.

These results show that the introduction of lipophilic unsaturated carboxylic acids leads to the potentiation of the immunological activity of MDP, thus providing another approach to the development of a new family of immunologically active compounds.

Table 4. Adjuvant activity of MDP derivatives **9**, **10**, and **11** in delayed-type hypersensitivity to ABA-Tyr (100 μg) in guinea pigs

Experimental

Optical rotations were determined with a Perkin-Elmer Model 141 polarimeter. NMR spectra were obtained on Varian EM-360 and EM-390 spectrometers. All chemicals and solvent were reagent grade and used without further purification. The reactions were monitored on TLC with Merck F_{254} silica-gel plates. Evaporation was carried out in a rotary evaporator under reduced pressure at temperatures below 45 °C.

All-trans-*3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraen-1-ol (2a)*. Li (10.9 g, 2 g atom) was dissolved in $EtNH_2$ (300 ml) at −60 °C under N_2. After the solution became blue, a solution of all-*trans*-1-benzyloxy-3,7,11,15-tetramethyl-9-*p*-tolylsulfonyl-2,6,10,14-hexadecatetraene (**1a**) (21 g, 393 mmol) in anhydrous THF (40 ml) was added dropwise for 30 min. The mixture was stirred for 15 min at −60 °C, while blue color was kept. Isoprene (5 ml) and MeOH (100 ml) were carefully added to quench the excess Li. After the careful addition of water (500 ml), the organic solvents were evaporated. The residual aqueous solution was extracted with diisopropyl ether (150 ml×3). The organic layer combined was washed with water, and dried over Na_2SO_4. The solvent was evaporated and the resulting residue was purified by column chromatography (7×15 cm) on SiO_2 using hexane–diisopropyl ether (5:3, and then 1:2) as solvent: 10.9 g (95.6%) (Table 1). NMR ($CDCl_3$): 1.62 (9H, s), 1.70 (6H, s), 1.91—2.18 (12H, m), 4.15 (2H, d), 5.0—5.2 (3H, m), 5.43 (1H, t).

Other Multiprenyl Alcohols (*2b* and *2c*) were prepared from **1b** and **1c** in a similar manner.

All-trans-*3,7,11,15-tetramethyl-1-(*p*-tolylsulfonyl)-2,6,10,14-hexadecatetraene (4a)*. To a solution of **2a** (14.4 g, 49.6 mmol) in absolute THF (70 ml) was added a solution of PBr_3 (5.6 g, 20.7 mmol) in THF (70 ml) dropwise at −7—−10 °C. Then the mixture was stirred at the same temperature for 15 min. The solvent was evaporated and the residue was dissolved in hexane–diisopropyl ether (1:1, 200 ml). The solution was successively washed with 5% $NaHCO_3$ and water, and then dried over Na_2SO_4. The solvent was evaporated to give all-*trans*-1-bromo-3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraene (**3a**). Without further purification, **3a** was dissolved in DMF (150 ml), and sodium *p*-toluenesulfinate tetrahydrate (24.8 g, 99.2 mmol) was added. After stirring for 1 h at room temperature, the mixture was diluted with hexane–diisopropyl ether (1:1, 400 ml), washed with water, and then dried over Na_2SO_4. After evaporation of the solvents, the resulting residue was purified by silica gel chromatography (6×25 cm) using hexane–diisopropyl ether (2:1) as solvent: 18.0 g (84.7%) (Table 1). NMR ($CDCl_3$): 1.36 (3H, d), 1.61 (9H), 1.68

(3H, s), 1.98—2.25 (12H, m), 2.44 (3H, s), 3.78 (2H, d), 5.10 (3H, m), 5.18 (1H, t), 7.31 and 7.74 (4H).

Compound ***4b*** was prepared from 2b in a similar manner.

*All-*trans*-1-benzyloxy-3,7,11,15,19,23-hexamethyl-9-(*p*-tolylsulfonyl)-2,6,10,14,18,22-tetracosahexaene (**1b**).* To a solution of **4a** (17.7 g, 41.3 mmol) and *trans,trans*-1-benzyloxy-8-chloro-3,7-dimethyl-2,6-octadiene (**5**) (13.1 g, 47 mmol) in absolute THF (100 ml)–DMF (12 ml) was added *t*-BuOK (6.96 g, 62 mmol) at −20 °C. After stirring for 20 min at the same temperature, the mixture was diluted with hexane–diisopropyl ether (1:1, 400 ml), and washed with 5% phosphoric acid (400 ml) and water, and then dried over Na_2SO_4. The solvent was evaporated, and the residue was chromatographed on a silica-gel column (5.5×20 cm) with hexane–diisopropyl ether (1:1) as an eluent: 24.6 g (88.9%) (Table 1). NMR ($CDCl_3$): 1.25 (3H, d), 1.55 (3H, s), 1.62 (12H, s), 1.70 (3H, s), 1.85—2.16 (16H, m), 2.44 (3H, s), 2.88 (2H, dd), 3.80 (1H, dd), 4.01 (2H, d), 4.50 (2H, s), 4.90 (1H, d), 4.95—5.24 (4H, m), 5.37 (1H, t), 7.30 and 7.71 (4H, m), 7.33 (5H, s).

Compound ***Ic*** was prepared from **4b** and **5** in a similar manner.

*Ethyl 2-Ethoxycarbonyl-all-*trans*-5,9,13,17,21,25-hexamethyl-4,8,12,16,20,24-hexacosahexaenate (**6b**)* and *Ethyl 2-(All-*trans*-3,7,11,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaenyl)-2-ethoxycarbonyl-all-*trans*-5,9,13,17,21,25-hexamethyl-4,8,12,16,20,24-hexacosahexaenate (**6b′**).* All-*trans*-3,7,11,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaen-1-ol (**2b**) (2.13 g, 5 mmol) was converted to the corresponding bromo-compound (**3b**) in a manner similar to that described in the synthesis of **4a**. To a solution of diethyl malonate (800 mg, 5 mmol) in absolute DMF (10 ml) NaH (240 mg, 5 mmol; 50% suspension in mineral oil) was added under N_2 with stirring. After stirring for 20 min at room temperature, the solution was cooled to −10 °C. A solution of **3b** in absolute THF (10 ml) was added dropwise at −10—−6 °C. After 30 min, the mixture was allowed to react at room temperature and stirring was continued for an additional 2 h. Water (100 ml) was carefully added and the solution was extracted with diisopropyl ether (100 ml). The organic layer was washed with water and dried over Na_2SO_4. The solvent was evaporated and the resulting residue was chromatographed on a silica-gel column (4.2×15 cm) with hexane–diisopropyl ether (15:1) to give pure **6b** and **6b′**: 1.09 g (38.0%) and 1.08 g (44.0%) (Table 2). NMR ($CDCl_3$) for 6b:1.27 (6H, t), 1.64 (21H, s), 1.88—2.19 (20H, m), 2.57 (4H, dd), 3.33 (1H, t), 4.17 (4H, q), 4.92—5.62 (6H, m).

*Other Esters (**6a**, **6a′**, **6c**, **6c′**, **6d**, and **6d′**)* were prepared from the appropriate alcohols and diethyl malonate in a similar manner. Geraniol for the preparation of **6d** and **6d′** was purchased from Wako Pure Chemical Industries, LTD, Osaka.

*2-(All-*trans*-3,7,11,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexenyl)-all-*trans*-5,9,13,17,21,25-hexamethyl-4,8,12,16,20,24-hexacosahexaenoic Acid (**7b′**).* A solution of **6b′** (1.08 g, 1.1 mmol) in 1 M KOH–MeOH–THF (2:5:1, 22 ml) was heated under reflux for 100 h. After cooling to room temperature, 0.5 M HCl (50 ml) was added and the solution was extracted with AcOEt (40 ml). The organic layer was washed with water, dried over Na_2SO_4, and then evaporated. The residue (dicarboxylic acid) was dissolved in DMSO (5 ml) and the solution was heated at 150 °C for 20 min, during which time the evolution of CO_2 was completed. After cooling to room temperature, the mixture was diluted with H_2O (30 ml) and extracted with AcOEt–diisopropyl ether (1:1, 50 ml). The organic layer was washed with water, dried over Na_2SO_4, and evaporated. The resulting residue was chromatographed on a silica-gel column (3.8×6 cm) with hexane–diisopropyl ether (4:1): 720 mg (74.6%). (Table 2). NMR ($CDCl_3$): 1.61 (42H, s), 1.95—2.45 (45H, m), 4.95—5.21 (12H, m).

*Other Multiprenylacetic Acids (**7a**, **7a′**, **7b**, **7c**, **7c′**, **7d**, and **7d′**)* were prepared from the corresponding esters in a similar manner.

*N-Acetyl-6-O-[[2-(all-*trans*-3,7,11,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaenyl)-all-*trans*-5,9,13,17,21,25-hexamethyl-4,8,12,16,20,24-hexacosahexaenoyl]-L-leucyl]muramyl-α-aminoisobutyryl-D-isoglutamine (**9b′**).* To a solution of **7b′** (87.7 mg, 0.1 mmol) and HONB (21.6 mg, 0.12 mmol) in AcOEt–acetonitrile (1:1, 2 ml) was added DCC (24.7 mg, 0.12 mmol) at 0 °C. The mixture was stirred at 0 °C for 1 h and then at room temperature for 3 h. After filtration of precipitates, the solvent was evaporated. The resulting active ester, *N*-acetyl-6-*O*-(L-leucyl)muramyl-α-aminoisobutyryl-D-isoglutamine (**8**)[8] (62 mg, 0.1 mmol) and NEM (26 μl) were dissolved in DMF (1 ml), and the mixture was stirred at 60 °C for 70 h. After evaporation of the solvent, the residue was purified by chromatography on a column of silica gel (2×12 cm) with AcOEt–pyridine–AcOH–water (80:10:3:5), followed by rechromatography on a column of Sephadex LH-20 (1.5×90 cm) with EtOH as an eluent: 20 mg (13.5%) (Table 3).

*Other MDP Derivatives with Acylated Amino Acid (**9**)* listed in Table 3 were prepared from the appropriate carboxylic acids and MDP derivatives with an amino acid in a similar manner.

Biological Assays. Determination of the adjuvant activity on induction of delayed-type hypersensitivity was carried out according to the method described earlier.[13]

We wish to thank Dr. Masao Nishikawa of this division for discussion.

(Received May 29, 1981)

Carbon-14 kinetic isotope effects (k^{12}/k^{14}) were determined for the solvolysis of phenethyl (**1a**) and 2-(*p*-methoxyphenyl)ethyl (**1b**) *p*-nitrobenzenesulfonates in acetic, formic, and trifluoroacetic acids. Phenyl-1 carbon effects were all in the range of 1.02—1.04 except for the acetolysis of **1a** ($k^{12}/k^{14}=1.005$), which has been proved to proceed mainly *via* the aryl unassisted (k_s) pathway. In all other reactions, which proceed mainly *via* the aryl assisted (k_Δ) pathway, the phenyl-1 carbon apparently changes its bonding in the transition states. A large α-carbon effect (1.131) and a small β-carbon effect (1.013) as well as a medium phenyl-1 effect (1.022) were observed for the formolysis of **1b**, whose mechanism is thought to be exclusive k_Δ without troublesome ion-pair return. These observations, together with α- and β-deuterium effects reported already, enabled us to describe the qualitative nature of the bridged transition-state structure of the k_Δ pathway, *i.e.*, advanced C_α–O bond rupture, slight C_α–C_{Ph-1} bond formation, C_α–C_β double bond formation, slight C_β–C_{Ph-1} bond rupture, and breakdown of aromaticity at the phenyl-1 position. These characteristics are very similar to those of the phenonium ion.

After a long debate it has become a generally accepted idea that the solvolyses of all primary and most secondary 2-arylalkyl derivatives proceed through discrete aryl assisted (k_Δ) and/or aryl unassisted (k_s) pathways (Scheme 1).[3] A great deal of attention has been focused on the k_Δ pathway, since it can be regarded as a prototype of intramolecular catalysis, an important phenomenon in enzyme reactions, and also because it leads to the so-called phenonium ion intermediate whose structure has been a subject of discussion.[3] In 1969, we communicated the observation of normal carbon-14 kinetic isotope effects ($k^{12}/k^{14}>1.0$) of labeling at phenyl-1 in the solvolysis of 2-arylethyl *p*-nitrobenzenesulfonates (nosylates, **1**).[2] It was the first definitive evidence for the bonding change of the phenyl-1 carbon in the transition state of the reaction. Details of the study are described in the first half of this paper.

In order to obtain further detailed information concerning the structure of the transition state of the k_Δ pathway, it is desirable to observe kinetic isotope effects of labeling at several different atoms of 2-arylethyl esters. This type of approach is referred to as the successive labeling technique.[4] The first study along these lines has been carried out with 2-methyl-2-phenylpropyl (neophyl) esters (**2**).[5,6]

$ArC(CH_3)_2CH_2OSO_2Ar'$

2

Introduction of two methyl groups on the β-carbon of **1** not only causes the reaction to proceed *via* the k_Δ pathway almost exclusively but also inhibits scrambling of labels at α and β during the course of the reaction of **2**.[7,8] Thus, kinetic isotope effects have been successfully measured for α-^{14}C, α-D_2, β-^{14}C as well as phenyl-1-^{14}C in the solvolysis of **2**,[5,6] and the transition-state structure has been discussed both qualitatively and quantitatively using these data.[6]

In the present study, the successive labeling technique was extended to the parent 2-arylethyl system. The transition-state structure of the k_Δ pathway of 2-arylethyl esters is discussed with the kinetic isotope effects measured for the formolysis of 2-(*p*-methoxyphenyl)-ethyl nosylate (**1b**), and compared with that for the neophyl solvolysis.

Results

Labeling with carbon-14 at the specific carbons of phenethyl nosylate (**1a**) and 2-(*p*-methoxyphenyl)ethyl nosylate (**1b**) was performed by well-established procedures (see Experimental Section). The solvolyses of **1a** and **1b** in acetic, formic, and trifluoroacetic acids were followed by the gravimetric method, in which unreacted nosylates were recovered from the reaction solutions at various fractions of reaction, ranging from 0 to 70 or 80%. The recovery was quantitative for **1a** and almost so for **1b**; in the latter case the recovery factor was used in order to determine the fractions of reaction. The formolysis of **1b** was also followed by the spectrophotometric method. The rate con-

stants obtained by these two methods agreed very well with each other. The linearity of the first-order rate plot for the trifluoroacetolysis of **1a** was rather poor in the absence of sodium trifluoroacetate, but it was much improved when the sodium salt was added to the reaction medium.

Carbon-14 kinetic isotope effects were determined according to the procedures described previously.[6] Calculation of isotope effects was carried out by the linear regression method using

$$\log A_x = \log A_0 - [1-(k^{14}/k^{12})]\log(1-x), \quad (1)$$

where x is the fraction of reaction, and A_0 and A_x are the molar radioactivities of the initial and recovered esters, respectively.[9,10] The results of kinetic isotope effects are summarized together with rate data in Table 1.

Discussion

Phenyl-1 carbon isotope effects were measured in seven cases for different substrates, solvents, and temperatures (Table 1). All the values were in the range of 1.02—1.04 except for the acetolysis of **1a**, for which a very small value close to unity (1.005) was obtained. Dissection of the rate constants (k_t) of the 2-arylalkyl solvolysis into the aryl assisted (Fk_Δ) and aryl unassisted (k_s) components has been carried out by a number of research groups.[3] They found that only the acetolysis of the phenethyl ester among all the systems studied here proceeds mainly *via* the k_s pathway,[11-14] although the dissection was usually studied not for nosylates but for tosylates or brosylates. The fraction of the k_Δ pathway (Fk_Δ/k_t) for the acetolysis of phenethyl tosylate was estimated to be 0.30—0.42 at 115 °C.[11-14] Because no bonding change for the phenyl-1 carbon is expected in the transition state of the k_s pathway, no isotope effect should be observed for this carbon. Thus, our observation of a small isotope effect in the acetolysis of **1a** is well in accord with the dissection studies by the tracer[11-13] or kinetic[14] method.

All the other values of the phenyl-1 carbon-14 isotope effects (1.02—1.04) definitely show that the bonding of the phenyl-1 carbon changes in the transition state of these reactions. Among these values, those for the trifluoroacetolysis (1.03—1.04) were slightly larger than those for the acetolysis or formolysis (1.02—1.03, Table 1). A similar phenomenon was also observed in the solvolysis of **2**; the phenyl-1 carbon-14 effect was 1.035 for the trifluoroacetolysis at 0 °C and 1.023 for the acetolysis at 75 °C.[5] Although the solvent effect on the isotope effects can not be completely neglected, since weaker solvation to the cationic moiety in a less nucleophilic solvent such as trifluoroacetic acid would result in decreased bonding and thus larger isotope effects, most of the difference in these isotope effects is likely to be attributable to the temperature dependence of the isotope effects. Trifluoroacetolysis was always carried out at a lower temperature than acetolysis and formolysis by 55—75 °C, and a definitive normal temperature dependence (a larger isotope effect at a lower temperature) was observed for this phenyl-1 carbon-14 effect in the acetolysis of **2**.[6] As a reported increase of the isotope effect was 0.003 for a decrease in temperature of 15 °C or 0.008 for 35 °C, the observed difference of 0.01 for **1** can be reasonably attributed to a difference in temperature of 55—75 °C.

In order to carry out the successive labeling study in the parent 2-arylethyl system, it is necessary to measure kinetic isotope effects in a solvolysis, in which the reaction not only proceeds exclusively *via* the k_Δ pathway, but is also free from an ion-pair return which is liable to cause scrambling of labels. The formolysis of **1b** is fitted for this purpose. According to the tracer study carried out with carbon-14 by Jenny and Winstein,[15] the formolysis of 2-(*p*-methoxyphenyl)ethyl tosylate proceeds exclusively *via* the k_Δ pathway ($Fk_\Delta/k_t=1.0$) without any ion-pair return ($F=1.00$). The strong ionizing power and the considerable nucleophilicity of formic acid as well as the fairly strong nucleophilicity of the neighboring *p*-methoxyphenyl group may be the reasons for this unique situation. Taking advantage of this, Saunders and Glaser have already studied secondary α- and β-deuterium isotope effects in this formolysis;[16] we

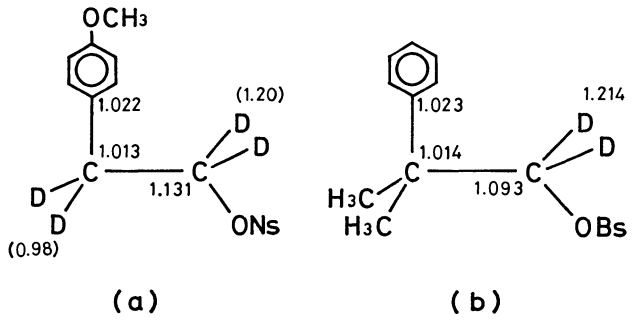

Fig. 1. Carbon-14 and deuterium isotope effects in the solvolysis of (a) 2-(*p*-methoxyphenyl)ethyl nosylate (**1b**) in formic acid at 30 °C, and (b) neophyl brosylate (**2**) in acetic acid at 75 °C. Deuterium effects in (a) are those reported by Saunders *et al.*[16] for the tosylate.

will use their results in our discussion.

Kinetic isotope effects observed in the formolysis of **1b** are summarized in Fig. 1, together with those reported for the acetolysis of **2** for comparison.[5]

It is obvious from Fig. 1 that the isotope effects for various atoms of **1b**, *i.e.*, a large α-^{14}C, medium α-D_2, small β-^{14}C, and medium phenyl-1-^{14}C effects, are almost the same as those for the corresponding atoms of **2**. These observations not only support the results of the dissection studies[7,8,15] that both the formolysis of **1b** and the acetolysis of **2** proceed *via* the k_Δ mechanism, but also indicate that the transition-state structures of both reactions are almost identical. This conclusion confirms the general assumption that neophyl solvolysis can be regarded as a model of the k_Δ process for phenethyl solvolysis.[13,17-19] Thus, the characteristics of the transition-state structure of **1b** can be discussed below in a similar manner to those of **2**[6] by use of the observed data of kinetic isotope effects.

The magnitude of the phenyl-1 carbon-14 effect, 1.022, is within the range (1.02—1.05) observed for the phenyl-1 carbon in a number of phenyl group rearrangements whose mechanisms have been proved to be concerted.[20-23] It is interesting that these medium carbon-14 effects show normal temperature dependence as mentioned above and as observed in the Beckmann rearrangement of acetophenone oxime.[23] When the bonding at the labeled position increases in the transition state, the isotope effect could be small normal, null, or even inverse, and the temperature dependence should be inverse. Thus, the total bonding of the phenyl-1 carbon should decrease, in spite of the hybridization change of this carbon from sp^2 to sp^3. In conclusion, the phenyl-1 carbon changes its bonding in the transition state of the k_Δ solvolysis as a result of C_{Ph-1}–C_α bond formation, breakdown of aromaticity in the benzene ring, and C_{Ph-1}–C_β bond rupture, among which the last two overwhelm the first one.

A large α-carbon-14 isotope effect comparable to those observed in S_N2[24] and a medium α-deuterium effect in contrast to large values for S_N1 and small ones for S_N2 are most characteristic of the k_Δ mechanism.[5,6,25] The importance of symmetry for a carbon isotope effect has been demonstrated in the S_N2 reaction,[26] in which the isotope effect of the central carbon atom becomes maximum when the two partial bonds are equal in strength. The magnitude of an α-deuterium effect is dependent on the vibrational frequencies of the bending motions including the C–H bond, and a larger effect is observed for a looser transition state.[27] Thus, the observed α-effects are compatible with a loose, pseudo-three-centered transition state composed of the phenyl-1 carbon, the α-carbon, and the oxygen of the leaving arenesulfonate.[5,6,25]

The difference between the α-carbon-14 effects for **1b** (1.131) and **2** (1.093), the only apparent difference in Fig. 1, is larger than that expected for the temperature dependence of this effect, since the reported increase in the effect is 0.004 for a decrease of 15 °C in the acetolysis temperature of **2**.[6] The difference in the solvent, formic acid *vs.* acetic acid, wolud not have much influence on the isotope effects. Therefore, the rest of the difference in the α-carbon-14 isotope effects may be attributed to the substituent effect of the phenyl group on the symmetry of the three-centered transition state.[6] The transition-state structure of **1b** may be more symmetric than that of **2** in terms of the breaking C_α–O bond and the forming C_α–C_{Ph-1} bond, resulting in a larger α-carbon isotope effect. Participation by the unsubstituted phenyl group in **2**, which is less nucleophilic than the *p*-methoxyphenyl group in **1b**, may lead to a later transition state with a stronger C_α–C_{Ph-1} bond and a weaker C_α–O bond, giving rise to a smaller isotope effect.[6,26]

A small β-carbon-14 isotope effect, 1.013, is consistent with small but distinct bonding changes at this carbon, which may include C_{Ph-1}–C_β bond rupture and C_α–C_β double bond formation.[28] It is interesting that this change has not been detected by the β-deuterium effect.[16] Quite recently, we observed negative CD_3 effects in the solvolysis of [γ-D_6]-**2** (0.959 per D_6 in acetic acid at 75 °C), which were attributed to the inductive effect by these nonmigrating methyl groups.[1] Nevertheless, the β-carbon-14 isotope effects of **1b** and **2** did not show any appreciable difference. The fact suggests that the inductive effect exerted on the β-carbon by the methyl groups may not greatly alter the structure of the transition state in this solvolytic rearrangement, although the rate of the reaction itself is enhanced to a great extent in the presence of these methyl groups.[29]

All of the above enable us to describe the qualitative nature of the transition-state structure of the k_Δ pathway in the phenethyl solvolysis as follows: (1) C_α–O bond rupture is well advanced, (2) the neighboring phenyl group behaves as an intramolecular nucleophile but C_α–C_{Ph-1} bond formation is not advanced, (3) the aromatic π-electron system of the phenyl group has broken down as a result of the participation, and (4) geometrical changes at C_β are small but may include partial C_β–C_{Ph-1} bond rupture and C_α–C_β double bond formation. Although a bridged ion intermediate does not necessarily follow this bridged transition state of the k_Δ solvolysis, as exemplified in the case of the

neophyl solvolysis, in which the rearranged tertiary cation is believed to be the first intermediate, it is important to point out that the phenonium ion, whose structure was estimated by molecular orbital calculations,[30,31] can be attained with the least structural changes from this transition state.

Experimental

Materials. [*phenyl*-1-^{14}C]Phenethyl alcohol was prepared from [*phenyl*-1-^{14}C]benzoic acid *via* benzoyl chloride, α-diazoacetophenone, and methyl phenylacetate; the last step made use of the Wolff rearrangement in methanol.[32] Esterification of the phenethyl alcohol with *p*-nitrobenzenesulfonyl chloride in pyridine gave [*phenyl*-1-^{14}C]-**1a**. The multistep synthesis of 2-(*p*-methoxy[*phenyl*-1-^{14}C]phenyl)ethyl nosylate ([*phenyl*-1-^{14}C]-**1b**) from [*phenyl*-1-^{14}C]toluene has already been reported.[33] 2-(*p*-Methoxyphenyl)ethyl nosylates labeled with carbon-14 at the α- and β-carbons ([α-^{14}C]- and [β-^{14}C]-**1b**, respectively) were prepared from *p*-methoxybenzyl cyanide (**3**) labeled at the cyanide- and benzyl-carbons, respectively, *via* acid hydrolysis, esterification with methanol, reduction with lithium aluminum hydride, and esterification with *p*-nitrobenzenesulfonyl chloride, successively. One of the precursors, [*cyanide*-^{14}C]-**3**, was synthesized from the reaction of *p*-methoxybenzyl chloride with sodium [^{14}C]cyanide.[34] The other, [*benzyl*-^{14}C]-**3**, was prepared by cyanation of *p*-methoxyphenyl bromide with copper(I) [^{14}C]cyanide[35,36] followed by hydrolysis, esterification, reduction, chlorination, and cyanation.[34] The chemical purity of the labeled compounds was verified by comparison of their physical constants and spectroscopic data with those for the unlabeled compounds. All ^{14}C labeled compounds had molar radioactivities of about 1.3—2.7 mCi/mol. The final arenesulfonates were carefully purified by repeated recrystallization until the molar activities remained constant. Phenethyl nosylate (**1a**): mp 102—103 °C (from hexane–carbon tetrachloride). 2-(*p*-Methoxyphenyl)ethyl nosylate (**1b**): mp 100.0—100.5 °C (from hexane–carbon tetrachloride or hexane–benzene).

Solvolysis Media. Acetic acid was refluxed over 2.0 wt% potassium permanganate, fractionally distilled, and the middle cut was refluxed with 1% pure acetic anhydride followed by fractional distillation (bp 119.1—119.3 °C).[37] Formic acid was purified according to the procedure described by Winstein and Marshall (bp 28.0—29.0 °C/6.60 kPa).[38] Trifluoroacetic acid was distilled through a 1 m, vacuum-jacketed column packed with glass helices. To the middle cut (bp 72.2—72.4 °C) was added 1 wt% freshly distilled trifluoroacetic anhydride.[39] Buffered medium (1.0 dm^3) was prepared by dissolving 0.1 mol of sodium trifluoroacetate in the above trifluoroacetic acid.

Quantitative Recovery of Nosylates ***1a*** *and* ***1b***. About 100 mg of **1a** or **1b** was weighed in a flask and dissolved in 11—30 cm^3 of solvolysis media. Cold distilled water (5 to 20 times the volume of the media used) was added to the solution, and the mixture was left overnight in a refrigerator. Precipitates of **1a** or **1b** were filtered with a weighed glass filtering crucible, washed thoroughly with cold distilled water, dried overnight in an oven at 70 °C (for **1a**) or in a vacuum desiccator over phosphorus pentaoxide (for **1b**), and weighed. The recovery of **1a** was 99.3±0.5% (acetic acid), 99.7±0.3% (formic acid), and 99.1±0.9% (trifluoroacetic acid), and that of **1b** was 97.6±0.1% (acetic acid), 98.4±0.1% (formic acid), and 95.9±1.4% (trifluoroacetic acid).

Kinetic Procedures. Samples of starting material large enough to yield about 100 mg unreacted esters after preselected fractions of reaction, ranging from 0 to 80% completion, were delivered to individual ampoules, dissolved in suitable volumes of the reaction media, and the ampoules were sealed. The reaction was started by placing the ampoules in a constant temperature bath, and quenched by cooling them in an ice bath or a Dry Ice–acetone mixture. After breaking the seal, the contents and the washings of the ampoules (5 cm^3 of the reaction media) were poured into cold water (5 to 20 times the combined volume of the reaction solution and the washing). After standing overnight in a refrigerator, the precipitates (unreacted esters) were filtered with a glass filtering crucible, and then treated as described above. The fractions of reaction were determined from the quantities of the samples used and recovered. For **1b** the recovery factors of 1.025 (acetic acid), 1.016 (formic acid), and 1.043 (trifluoroacetic acid) were used. Data points measured were usually seven.

The rate of formolysis of **1b** was also determined by a spectrophotometric method similar to that used for trifluoroacetolysis by Peterson,[40] in which the increase in the absorbance at 275 nm was followed. The rate constant determined by this method agreed very well with that determined by the gravimetric method (Table 1).

Radioactivity Measurement. The recovered precipitates of unreacted esters were recrystallized repeatedly, usually four times. The purified esters (5—10 mg) were oxidized in a modified Pregl micro combustion furnace,[41] and the ionization current of the radioactive carbon dioxide gas thus generated was measured in an ionization chamber (250 cm^3 capacity, Nuclear-Chicago) with a vibrating-reed electrometer (Nuclear-Chicago Model 6000 Dynacon electrometer system). The rate-of-charge method using a Model T4 interval timer was applied.[41] For the formolysis of [α-^{14}C]- and [β-^{14}C]-**1b**, the ionization current was measured with a Takeda Riken TR-84M vibrating-reed electrometer connected with a digital voltmeter and a computer.[6] It was confirmed that further recrystallization did not change the radioactivities beyond experimental errors.

10) Although the accuracy of radioactivity measurement

has been improved to a great extent in recent years, we still recommend measuring the activities of as many samples as possible, at least five or more, which are recovered from a wide range of the fractions of reaction in order to obtain accurate values of carbon-14 kinetic isotope effects. Unfortunately, it was impossible in some cases of the trifluoroacetolyses in the present study.

Reactions of Ketone Hydrazones and β-Keto Enamines with Disulfur Dichloride. New Synthesis of Thioketones and 5*H*-1,2,3-Dithiazoles

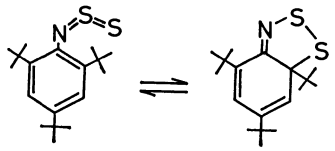
Renji Okazaki,* Kaoru Inoue, and Naoki Inamoto

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 19, 1981)

Ketone hydrazones react with disulfur dichloride in the presence of triethylamine to afford thioketones in good yields. The reaction mechanism involving *N*-thiosulfinylamine ($R_2C{=}N{-}N{=}S{=}S$) and *S*-thioxothioketone ($R_2C{=}S{=}S$) is proposed. The formation of di-*t*-butyl and di-1-adamantyl thioketones even at low temperatures has been interpreted as steric congestion alone being not enough to stabilize the corresponding *S*-thioxothioketones. The reaction of β-ketoenamines with disulfur dichloride gives 5*H*-1,2,3-dithiazoles *via* intramolecular cyclization of intermediary *N*-thiosulfinylamines.

We previously reported an interesting ring-chain tautomerism for *N*-thiosulfinylaniline **1a** which was prepared by reaction of disulfur dichloride with the corresponding aniline;[1] **1a** is in equilibrium with **1b** in solution, while only **1b** exists in the solid state.[2] The conversion of **1a** to **1b** can be regarded as intramolecular 1,3-dipolar cycloaddition of the *N*-thiosulfinyl group[3] or electrocyclization of 1,5-dipole.[4]



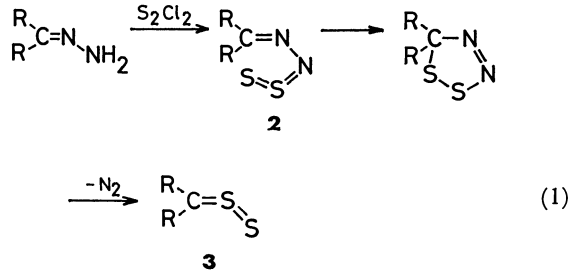
1a **1b**

Such a facile cyclization at the expense of loss of aromaticity observed for **1a** suggests that similar cyclizations are expected to occur also in other systems having X=Y–N=S=S structure.

We report in this paper that the reaction of ketone hydrazones and β-keto enamines with disulfur dichloride indeed proceeds *via* intramolecular cyclization of the *N*-thiosulfinyl group to form thioketones and 5*H*-1,2,3-dithiazoles, respectively.[5]

Results and Discussion

Reactions of Ketone Hydrazones with Disulfur Dichloride. Since a ketone hydrazone is considered to react with disulfur dichloride to give *N*-thiosulfinylamine **2**, which would undergo intramolecular cyclization in view of the tautomerism of **1**, we reasoned that this reaction would provide a route to a hitherto unknown *S*(IV)-thiocumulene, *S*-thioxothioketone **3**.[6]



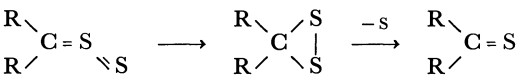
2

3 (1)

The reaction occurred, as expected, smoothly at a low temperature, but the product was not *S*-thioxothioketone but thioketone. For example, simultaneous addition of benzene solutions of di-*t*-butyl ketone hydrazone and disulfur dichloride to a benzene solution of triethylamine at 0 °C afforded di-*t*-butyl thioketone in 96% yield. The formation of di-*t*-butyl thioketone is most probably due to loss of a sulfur atom from the expected thioxothioketone which is unstable at the reaction temperature.

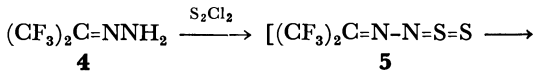
In the hope that the reaction at lower temperatures would enable the isolation of the thioxothioketone, the same reaction was carried out at −85 °C with toluene as solvent, but the product was again di-*t*-butyl thioketone (97%). The reaction using di-1-adamantyl ketone hydrazone in toluene at −90 °C also gave di-1-adamantyl thioketone (pink crystals, 71%). These reactions proceeded very fast, and the color due to the thioketones appeared during the addition of the reagents, suggesting that the thioxothioketone was too unstable to decompose into the thioketone even at such low temperatures.

Decomposition of *S*(IV)-thiocumulenes with loss of sulfur is generally believed[7] to proceed *via* cyclization into a three-membered ring as shown below and, therefore, such a change as from 3-coordinated to 4-coordinated carbon would be less favorable as R group becomes bulkier.

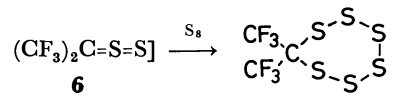


The failure of formation of thioxothioketone having such a bulky group as *t*-butyl or 1-adamantyl suggests that the steric congestion alone is not enough to stabilize the thioxothioketone.

It is known that as the electronegativity of X in thiocumulenes X=S=O or X=S=N–R increases, the S=O bond in the former or the S=N bond in the latter becomes stronger as suggested by shortening of the bond length.[8] If this is the case with the thioxothioketone, then the use of a hydrazone bearing strongly electron-withdrawing substituents is expected to lead to a more stable thiocumulene. To this end, hexafluoroacetone hydrazone (**4**)[9] was allowed to react with disulfur dichloride at −23 °C, but thioxothioketone **6** was not formed, the only characterizable



4 **5**



6 **7**

product being 7,7′-bis(trifluoromethyl)-1,2,3,4,5,6-hexathiacycloheptane (**7**) (3%) along with some sulfur.

A reaction closely related to the above has been reported;[10] *N*,*N*-bis(trimethylsilyl)sulfonamides **8** react with disulfur dichloride to give an eight-membered heterocycle **10**. Since the formation of **10** is explained by the reaction of thiosulfinylamine intermediate **9** with sulfur formed during the reaction,[10] a similar

$$\underset{\mathbf{8}}{R_2N\text{-}SO_2\text{-}N(SiMe_3)_2} \xrightarrow{S_2Cl_2} \underset{\mathbf{9}}{[R_2N\text{-}SO_2\text{-}N{=}S{=}S]} \xrightarrow{S_8} \underset{\mathbf{10}}{R_2NSO_2\text{-}N\langle S_5\rangle}$$

mechanism *via* **5** and **6** is thought to be operative in the formation of **7**.

An attempt to trap **6** by cycloaddition with dibenzoylacetylene was unsuccessful.[3]

Although the reaction of ketone hydrazones with disulfur dichloride did not give expected *S*-thioxothioketones, the formation of thioketones in good yields indicates that the present reaction provides a simple, new method for the synthesis of thioketones from hydrazones and the results using some hydrazones are listed in Table 1.

Table 1. Synthesis of thioketones from hydrazones ($R^1R^2C{=}NNH_2$)[a]

Hydrazones		Yield/% of thioketones	
R^1	R^2	UV	Isolated
t-Bu	*t*-Bu	Quant.	66
1-Ad[b]	1-Ad	71	59
$-Me_2CCH_2CH_2CMe_2-$[c]		Quant.	58
$C_{10}H_{16}$[d]		Quant.	54
$C_{10}H_{16}$[e]		63	
Ph	Ph	54	

a) The reactions were carried out in benzene at 5 °C except for di-1-adamantyl ketone hydrazone, where the reaction was done in toluene at −90 °C. b) 1-Ad denotes 1-adamantyl. c) 2,2,5,5-Tetramethylcyclopentanone hydrazone. d) Fenchone hydrazone. e) Camphor hydrazone.

The yields for sterically hindered thioketones are usually excellent although isolated yields are somewhat diminished. The simultaneous addition of the both substrates has to be done to get a good yield of thioketones. For example, the simultaneous addition method gave thiobenzophenone in 54% yield while the addition of a benzene solution of a hydrazone and triethylamine to disulfur dichloride in benzene formed the thioketone in 8%; the yield was 37% when the reverse addition was used.

The solvent effect of this reaction is remarkable. Although the reactions of di-*t*-butyl ketone hydrazone with disulfur dichloride in benzene and toluene gave di-*t*-butyl thioketone in 96 and 97% respectively as previously described, those in dichloromethane and ether resulted in the yields of 39 and 37% respectively. Thus, the aromatic hydrocarbon is a solvent of choice in the present reaction.

Another preparative method of thioketones from hydrazones, which uses the reaction of phosphoranes with sulfur, has recently been reported,[11] but we believe that the present method is simpler in manipulation and the reaction conditions are milder.

Although the pathway *via* thioxothioketone (Eq. 1) is considered to be a most likely mechanism for the formation of thioketones, other two mechanisms are also conceivable. One is oxidation of a hydrazone with disulfur dichloride to give a diazomethane, followed by the reaction with sulfur (Eq. 2)[12] and the other involves loss of the terminal sulfur from *N*-thiosulfinylamine intermediate to give thionitroso compound **11** followed by cyclization and loss of nitrogen molecule (Eq. 3).

$$R_2C{=}NNH_2 \xrightarrow{S_2Cl_2} R_2C{=}\overset{+}{N}{=}\overset{-}{N} \xrightarrow[-N_2]{S_8} R_2C{=}S \qquad (2)$$

$$R_2C{=}NNH_2 \xrightarrow{S_2Cl_2} \underset{\mathbf{11}}{R_2C{=}N\text{-}N{=}S{=}S} \xrightarrow{-S} R_2C{=}N\text{-}N{=}S$$

$$\longrightarrow \begin{array}{l} R_2C\text{—}N \\ \quad\| \quad\| \\ \quad S\text{—}N \end{array} \xrightarrow{-N_2} R_2C{=}S \qquad (3)$$

The possibility of Eq. 2 was eliminated by the fact that the reaction of diphenyldiazomethane with sulfur in the presence of triethylamine did not give thiobenzophenone under identical conditions. No di-*t*-butyl thioketone was formed by the reaction of di-*t*-butyl ketone hydrazone with sulfur dichloride (SCl_2) in the presence of triethylamine which is expected to yield **11** (R=*t*-Bu), thus ruling out the possibility of Eq. 3.

Reaction of β-Keto Enamines with Disulfur Dichloride. Since β-keto enamines **12** are known to exist as enamine form instead of imine form,[13] the reaction of β-ketoenamines with disulfur dichloride is expected to lead to *N*-thiosulfinylamine **13** or its cyclized form, 5*H*-1,2,3-dithiazole **14** (Eq. 4).

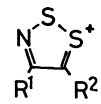
a: $R^1R^2=(CH_2)_4$, $R^3=OEt$
b: $R^1R^2=(CH_2)_3$, $R^3=OEt$
c: $R^1=R^3=Me$, $R^2=H$
d: $R^1=Me$, $R^2=H$, $R^3=OEt$
e: $R^1=R^2=R^3=Me$
f: $R^1=Ph$, $R^2=R^3=Me$
g: $R^1=R^2=Me$, $R^3=OEt$

The reaction indeed proceeded as expected. 1-Amino-2-ethoxycarbonyl-1-cyclohexene (**12a**) was allowed to react with disulfur dichloride to give 6-ethoxycarbonyl-7,8-dithia-9-azabicyclo[4.3.0]non-1(9)-ene (**14a**) in 74% yield. The product was a stable yellow liquid and identified by spectral and analytical data. The electronic spectrum (λ_{max} 380 nm, ε 290) clearly inidicates that the product is not *N*-thiosulfinylamine **13** but 5*H*-1,2,3-dithiazole **14**; the *N*-thio-

sulfinylamine should have a strong absorption in the visible region (*e.g.*, 538 nm (ε 39000) for *p*-(dimethylamino)-*N*-thiosulfinylaniline[3] and 584 nm (ε 1280) for 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline).[1] The mass spectrum showing the fragment of M^+-CO_2Et as a strong base peak is also in keeping with the structure **14**, since cation **15** is a stable 6π-aromatic system and hence is easily formed. The strong peak of M^+-

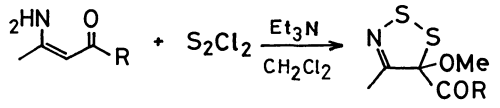


15

COR^3 (*i.e.* **15**) is characteristic of all the products **14 a,c′,d′,e,f** obtained in this study (see Experimental).

Contrary to the successful isolation of **14a**, the reaction of 1-amino-2-ethoxycarbonyl-1-cyclopentene **12b** with disulfur dichloride resulted in black polymeric products. In this case intermediary **13b** is unable to cyclize into **14b** probably because of strain due to two fused five-membered rings and polymerizes *via* intermolecular reaction. Since attempts to prepare 1-amino-2-ethoxycarbonyl-1-cycloheptene, 1-amino-2-ethoxycarbonyl-1-cyclooctene and 1-amino-2-ethoxycarbonyl-1-cyclododecene by the same procedure[13] as used for **12a** and **12b** were unsuccessful, the effect of a ring size on the stability of **14** ($R^1R^2=(CH_2)_n$) could not be studied.

The reaction of 4-amino-3-penten-2-one (**12c**) with disulfur dichloride in the presence of triethylamine at 0 °C in dichloromethane give a trace amount (0.75%) of 5-acetyl-5-methoxy-4-methyl-5*H*-1,2,3-dithiazole (**14c′**) instead of **14c** as a sole isolable product. Since the methoxyl group in **14c′** was thought to come from



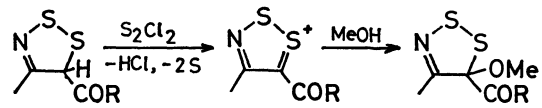
12c: R=Me
12d: R=OEt

14c′: R=Me
14d′: R=OEt

methanol present in dichloromethane as stabilizer, the reaction using an equimolar amount of methanol and two molar equivalents of disulfur dichloride and triethylamine was carried out to give 53% of **14c′**.

A similar reaction of ethyl 3-amino-2-butenoate (**12d**) with disulfur dichloride in the presence of triethylamine and methanol gave 35% of 5-ethoxycarbonyl-5-methoxy-4-methyl-5*H*-1,2,3-dithiazole (**14d′**) (R=OEt). The reaction without methanol under otherwise identical conditions gave no product other than sulfur.

The formation of **14c′,d′** can be explained in terms of oxidation of the hydrogen at 5-position in intermediary **14c,d** by disulfur dichloride followed by reaction of methanol with a resulting dithiazolium ion **15**. The relation of this reaction with the Herz reaction[14]



14c,d **15** **14c′,d′**

TABLE 2. SYNTHESIS OF 5*H*-1,2,3-DITHIAZOLES

Dithiazoles	Yield/%	Bp (°C, mmHg**)	Mp/°C
14a	73	115, 0.5	
14c′	53	136, 5	
14d′	35	100, 6	
14e	83	83, 6	
14f	6.4	110, 6	68—69

** 1 mmHg=133.322 Pa.

has already been discussed.[5b]

In support of the above mechanism, the reaction of 4-amino-3-methyl-3-penten-2-one (**12e**) where there is no hydrogen to be oxidized gave 5-acetyl-4,5-dimethyl-5*H*-1,2,3-dithiazole (**14e**) in 83% yield. A similar reaction also took place with 4-amino-3-methyl-4-phenyl-3-buten-2-one (**12f**) to afford 5-acetyl-5-methyl-4-phenyl-5*H*-1,2,3-dithiazole (**14f**) in 6.4% yield. Although 3-amino-2-methyl-2-butenoate (**12g**) was allowed to react under the same conditions, only polymeric products were obtained for reasons unclear to us yet.

The dithiazoles **14** are thought to be produced by the intramolecular cycloaddition of thiosulfinylamino group to the carbon-carbon double bond of **13**. This is the first synthesis of the compound with a 5*H*-1,2,3-dithiazole ring in the aliphatic system. The 5*H*-1,2,3-dithiazoles synthesized in the present study are summarized in Table 2.

The spectral data indicate that there is no equilibrium between **13** and **14** in the case of these dithiazoles in contrast to the system **1a**⇌**1b**. The visible spectra do not show any absorption due to *N*-thiosulfinyl group (–N=S=S) as mentioned previously. Any peak assignable to the open-chain structure **13** was not observed also in the NMR spectra. However, there still remains a possibility that **14** exists as an equilibrium mixture with **13** to such an extent that it cannot be detected spectroscopically. To check this possibility, the reactions of **14e** with some dipolarofiles (norbornadienes, *N*-phenylmaleimide, 4-phenyl-1,2,4-triazole-3,5-dione, dimethyl acetylenedicarboxylate) were carried out under various conditions,[3] but the cycloadducts were not obtained. These facts seem to suggest that **14** does not dissociate into **13** to an appreciable extent.

Experimental

NMR spectra were recorded at 60 MHz in deuteriochloroform on a Hitachi R-24B or a Hitachi R-24 spectrometer with tetramethylsilane as an internal standard. Mass spectra were measured on a Hitachi RMU-6L mass spectrometer. High resolution mass spectra were obtained with a JOEL D-300 mass spectrometer. Infrared spectra were recorded on a Hitachi EPI-G2 or a Hitachi 260-30 infrared spectrophotometer. Ultraviolet and visible spectra were taken on a Hitachi EPS-3 spectrophotometer or a Hitachi 340 recording spectrophotometer. All melting points were uncorrected. The reactions of hydrazones and enamines with disulfur dichloride were carried out under argon atmosphere.

Materials. Disulfur dichloride was distilled from sul-

fur and active carbon and stored in ampules in a refrigerator. Di-*t*-butyl ketone and di-1-adamantyl ketone hydrazones were prepared by the reported method.[15] The hydrazones of camphor, fenchone, 2,2,5,5-tetramethylcyclopentanone and benzophenone were prepared from the corresponding ketones by the method of Barton.[16] 2,2,5,5-Tetramethylcyclopentanone was prepared by the exaustive methylation of cyclopentanone.[17] Hexafluoroacetone hydrazone[9] was prepared from hexafluoroacetone. β-Ketoenamines were prepared from the corresponding β-diketones by the method of Kloek and Leshinsky,[13] and the new enamines **12 e,f,g** had following properties. **12e**: mp 118 °C; NMR ($CDCl_3$): δ=1.83 (3H, s), 1.95 (3H, s), 2.13 (3H, s), and 6.8—8.0 (2H, broad); IR (KBr): 3250, 3100, 1600, 1500—1420, 1280, 1220, 970, and 650 cm^{-1}; MS: *m/e* (rel intensity) 113 (M^+, 76), 98 (100), 70 (44), 55 (20), and 43 (38). Found: C, 63.54; H, 10.09; N, 12.25%. Calcd for $C_6H_{11}NO$: C, 63.69; H, 9.80; N, 12.38%. **12f**: mp 146.5—147.0 °C; NMR ($CDCl_3$): δ=1.66 (3H, s), 2.08 (3H, s), and 7.12 (s), 6.5—9.0 (broad) (7H in total); IR (KBr): 3250, 3100, 1600, 1500—1420, 1300, 1000, and 700 cm^{-1}; MS: *m/e* (rel intensity) 175 (M^+, 42), 174 (100), 160 (8), 105 (23), 98 (32), and 77 (31). Found: C, 75.28; H, 7.52; N, 7.72%. Calcd for $C_{11}H_{13}NO$: C, 75.40; H, 7.48; N, 7.99%. **12g**: mp 51.0—51.5 °C; NMR ($CDCl_3$): δ=1.23 (3H, t, J=7 Hz), 1.78 (3H, d, J=11 Hz), 4.03 (2H, q, J=7 Hz), and 5.5—7.0 (2H, broad); IR (KBr): 3370, 3120, 1600, 1500, 1270, 1220, 970, and 650 cm^{-1}. Found: C, 58.33; H, 9.16; N, 9.30%. Calcd for $C_7H_{13}NO_2$: C, 58.72; H, 9.15; N, 9.78%.

Reaction of Di-t-butyl Ketone Hydrazone with Disulfur Dichloride. a) In Benzene: To an ice-cold solution of triethylamine (1.06 g, 10.5 mmol) in benzene (20 cm^3) were added simultaneously benzene solutions (10 cm^3 each) of di-*t*-butyl ketone hydrazone (0.78 g, 5 mmol) and disulfur dichloride (0.71 g, 5.25 mmol) at about the same rate using two dropping funnels during 15 min. After stirring for 30 min at room temperature, the reaction mixture was washed with water and dried over anhydrous magnesium sulfate. The yield determined for the solution by the visible spectrum (λ_{max}(ethanol) 536 nm (ε 8.9))[18] was 96%. After removal of the solvent under reduced pressure, the residue was subjected to bulb to bulb distillation (bp 90—116 °C, 18 mmHg**) to give 521 mg (66%) of pure di-*t*-butyl thioketone as pink oil.[16]

b) In Other Solvents: Similar reactions in toluene (−85 °C), ether (−100 °C), dichloromethane (−90 °C) using 3 mmol of the hydrazone afforded the thione in 97, 37, and 39% (estimated by the visible spectra), respectively.

Reaction of Di-t-butyl Ketone Hydrazone with Sulfur Dichloride. To an ice-cold benzene solution (20 cm^3) of triethylamine (1.687 g, 16.7 mmol) were added simultaneously benzene solutions (15 cm^3 each) of di-*t*-butyl ketone hydrazone (1.241 g, 7.95 mmol) and sulfur dichloride (0.86 g, 8.35 mmol). After stirring for 1 h at room temperature, the deep red reaction mixture was washed with water and dried over anhydrous magnesium sulfate. The visible spectrum showed the absence of di-*t*-butyl thioketone. TLC of the reaction mixture also showed that di-*t*-butyl thioketone was not produced in this reaction. Removal of the solvent gave 1.267 g of red oil, 761 mg of which was subjected to bulb to bult distillation to give 251 mg (20%, based on the hydrazone) of di-*t*-butyl thioketone and 43 mg of unidentifiable yellow oil. This suggested that the thione was formed by the thermal decomposition of the reaction mixture.

Reaction of Di-1-adamantyl Ketone Hydrazone with Disulfur Dichloride. The reaction of the hydrazone (330 mg, 1.06 mmol) using the above simultaneous addition method was carried out at −85 °C, and the yield was determined for the reaction solution by the visible spectrum to be 71%. After removal of the solvent under reduced pressure, the residue was purified by TLC (silica gel, hexane) to give 195 mg (59%) of di-1-adamatyl thioketone as pink crystals: mp 184.5—185.0 °C; NMR ($CDCl_3$): δ=1.60—1.80 (18H, m) and 2.00—2.30 (12H, m); IR (KBr): 2950, 1730, 1610, 1440, 1290, 1220, 1140, 1100, 1020, and 720 cm^{-1}; MS *m/e* (rel intensity) 314 (M^+, 13), 179 (17), and 135 (100); UV: λ_{max} (benzene) 548 nm (ε 16.6), λ_{max} (hexane) 548 nm (ε 13.9); Found: C, 80.47; H, 9.35; S, 10.11%. Calcd for $C_{21}H_{30}S$: C, 80.19; H, 9.61; S, 10.19%.

Reaction of Other Hydrazones with Disulfur Dichloride. a) 2,2,5,5-Tetramethylcyclopentanone and Fenchone Hydrazones: The cyclopentanone (155 mg, 1.0 mmol) and fenchone hydrazones were allowed to react with disulfur dichloride in benzene at 5 °C by a method similar to that described for di-*t*-butyl ketone hydrazone (the simultaneous addition method). The yield was determined for the reaction mixture to be quantitative for both the thiones using the literature values of n-π^* absorption.[19,20] After removal of the solvent, the residue was subjected to bulb to bulb distillation to give pure thiones: the cyclopentane thione, 92 mg (58%), bp 116 °C (121 mmHg);[18] thiofenchone, 457 mg (54%), bp 120 °C (10 mmHg).[20]

b) Camphor and Benzophenone Hydrazones: The reactions of the two hydrazones were carried out by the simultaneous addition method in benzene at 5 °C. The reaction mixtures were analyzed for the corresponding thiones by the electronic spectra (n-π^* band), the yields of thiocamphor[19] and thiobenzophenone[20] being 63 and 54%, respectively. The addition of a solution of the benzophenone hydrazone and triethylamine to that of disulfur dichloride and the addition of a solution of disulfur dichloride to that of the hydrazone and triethylamine gave thiobenzophenone in 8 and 37% yields, respectively, as estimated by the electronic spectra.

Reaction of Hexafluoroacetone Hydrazone with Disulfur Dichloride. To a dichloromethane solution (30 cm^3) of triethylamine (5.34 g, 52.9 mmol) cooled with carbon tetrachloride–Dry Ice bath at −23 °C, were added simultaneously dichloromethane solutions (10 cm^3 each) of hexafluoroacetone hydrazone (5 g, 27.8 mmol) and disulfur dichloride (3.75 g, 26.5 mmol) during 1 h. After stirring for 30 min at room temperature, precipitated triethylamine hydrochloride was filtered off, the filtrate was passed through a short column of silica gel, and the solvent was removed under reduced pressure to give 4.12 g of a red-purple oil. Bulb to bult distillation (bp 110 °C, 0.5 mmHg) of the oil gave 1.15 g of a red oil, which was subjected to chromatographic separation (TLC, silica gel, carbon disulfide) to afford 254 mg (2.7%) of **7**: bp 110 °C (0.5 mmHg); IR (neat): 1280—1140, 925, 880, 840, 730, and 700 cm^{-1}; Found: *m/e* 341.8250. Calcd for $C_3F_6S_6$: M, 341.8228. MS: *m/e* (rel intensity) 342 (M^+, 34), 278 (100), 259 (9), 246 (3), 227 (2), 214 (60), and 182 (21).

*Reactions of β-Ketoenamines with Disulfur Dichloride. a) 1-Amino-2-ethoxycarbonyl-1-cyclohexene (**12a**)*: To a solution of **12a** (200 mg, 1.18 mmol) and triethylamine (2.51 mg, 2.49 mmol) in dichloromethane (20 cm^3) was added dropwise a solution of disulfur dichloride (168 mg, 1.24 mmol) in dichloromethane (10 cm^3) at room temperature during 30 min. After additional stirring at room temperature for 1 h, the reaction mixture was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure left 271 mg of orange oil, which

**1 mmHg=133.322 Pa.

was purified by TLC (silica gel, dichloromethane) to give **14a** (203 mg, 74%) as yellow oil: bp 115 °C (0.5 mmHg); NMR ($CDCl_3$): δ=1.25 (t, J=7 Hz) and 1.0—3.1 (m) (11H in total), and 4.16 (2H, q, J=7 Hz); IR (neat): 2950, 1730, 1610, 1440, 1290, 1220, 1140, 1100, 1020, and 720 cm^{-1}; MS: *m/e* (rel intensity) 231 (M^+, 17) and 158 (100); UV: λ_{max} (hexane): 380 (ε 288), 278 (1890), and 234 nm (2010). Found: C, 46.48; H, 5.64; N, 5.92; S, 27.28%. Calcd for $C_9H_{13}O_2NS_2$: C, 46.73; H, 5.66; N, 6.05; S, 27.72%.

*b) 1-Amino-2-ethoxycarbonyl-1-cyclopentene (**12b**)*: To an ice-cold solution of **12b** (298 mg, 1.92 mmol) and triethylamine (427 mg, 4.23 mmol) in dichloromethane (20 cm^3) was added a solution of disulfur dichloride (286 mg, 2.11 mmol) in dichloromethane (10 cm^3) dropwise during 30 min. The color of the solution turned from yellow to black-brown at the end of the addition. Treatment of the reaction mixture gave no identifiable product.

*c) 4-Amino-3-penten-2-one (**12c**)*: The reaction of **12c** (1.043 g, 10.5 mmol) was carried out at 0 °C by the procedure described in *a)*. Chromatographic separation (DCC, silica gel, CCl_4) and Kugel Rohr distillation (bp 60 °C, 5 mmHg) gave 15 mg (0.75%) of **14c′** as yellow oil: NMR ($CDCl_3$): δ=2.05 (3H, s), 2.32 (3H, s), and 3.18 (3H, s); IR (neat): 3450, 3000—2900, 1720, 1430, 1360, 1080, 820 and 740 cm^{-1}; MS: *m/e* (rel intensity) 191 (M^+, 5), 160 (3), and 148 (100); UV: λ_{max}(hexane) 360 (ε 271), 282 (3210), and 244 nm (2710). Found: C, 37.42; H, 4.70; N, 7.49; S, 33.42%. Calcd for $C_6H_9NO_2S_2$: C, 37.68; H, 4.74; N, 7.32; S, 33.52%.

When a dichloromethane solution (10 cm^3) of disulfur dichloride (911 mg, 6.75 mmol) was added to an ice-cold dichloromethane solution (20 cm^3) of **12c** (318 mg, 3.21 mmol), triethylamine (1.36 g, 13.5 mmol), and methanol (0.1 g, 3.21 mmol), 326 mg (53%) of **14c′** was obtained after a similar work up to the above.

*d) Ethyl 3-Amino-2-butenecarboxylate (**12d**)*: A similar reaction with **12d** (372 mg, 2.89 mmol) to that in *c)* in the presence of methanol (92 mg, 2.89 mmol) gave a brown reaction mixture. After washing with water and removal of the solvent, it gave black-brown oil (555 mg), which was subjected to chromatographic separation (DCC, silica gel, dichloromethane–carbon tetrachloride 1:1) to give **14d′** (221 mg, 35%) as brown oil. It was purified by distillation (bp 110 °C, 3 mmHg) to give 194 mg of yellow oil: NMR ($CDCl_3$): δ=1.30 (3H, t, J=7 Hz), 2.15 (3H, s), 3.18 (3H, s), and 4.22 (2H, q, J=7 Hz); IR (neat): 3000—2900, 1740, 1440, 1260, 1100, and 740 cm^{-1}; MS: *m/e* (rel intensity) 221 (M^+, 9), 172 (31), 162 (38), 148 (100), 127 (64), and 126 (81); UV: λ_{max}(hexane) 352 (ε 273), 275 (2930), and 202 nm (3620). Found: C, 38.18; H, 4.85; N, 6.29; S, 29.65%. Calcd for $C_7H_{11}NO_3S_2$: C, 37.99; H, 5.01; N, 6.33; S, 28.98%.

*e) 4-Amino-3-methyl-3-penten-2-one (**12e**)*: The reaction of **12e** (3.56 g, 31.5 mmol) was carried out by the method described in *a)*. After usual work up, purification by Kugel Rohr distillation (bp 83 °C, 6 mmHg) afforded **14e** (4.59 g, 83%) as yellow oil: NMR ($CDCl_3$): δ=1.77 (3H, s), 2.05 (3H, s), and 2.41 (3H, s); IR (neat): 2980, 2930, 1710, 1600, 1430, 1360, 1190, 1090, 960, and 730 cm^{-1}; MS: *m/e* (rel intensity) 175 (M^+, 14), 132 (100), 91 (4), 74 (15), 59 (39), and 43 (68); UV: λ_{max}(hexane) 390 (ε 376), 352 (338), 280 (1530), and 236 nm (1980). Found: C, 41.39; H, 5.26; N, 8.11; S, 36.22%. Calcd for $C_6H_9NOS_2$: C, 41.12; H, 5.18; N, 7.99; S, 36.58%.

*f) 4-Amino-3-methyl-4-phenyl-3-buten-2-one (**12f**)*: The yellow reaction mixture obtained from the reaction of **12f** (300 mg, 1.71 mmol) by the procedure described in *a)* was, after usual work up, subjected to Kugel Rohr distillation to give **14f** (30 mg, 6.4%) as yellow oil which solidified upon standing: bp 110 °C (6 mmHg); mp 68—69 °C; NMR ($CDCl_3$): δ=1.82 (3H, s), 2.37 (3H, s), and 6.9—7.4 (5H, m); IR (KBr): 1705, 1370, 1350, 1200, and 690 cm^{-1}; MS: *m/e* (rel intensity) 237 (M^+, 9), 194 (100), 136 (13), 104 (15), 91 (46), 77 (17), 59 (26), and 43 (32): UV: λ_{max}(hexane) 408 (ε 2340), 348 (2450) 310 (3300), and 246 nm (9120). Found: C, 55.35; H, 4.46; N, 5.69%. Calcd for $C_{11}H_{11}NOS_2$: C, 55.67; H, 4.67; N, 5.70%.

*g) Ethyl 3-Amino-2-methyl-2-butenoate (**12g**)*: The reaction of **12g** (515 mg, 3.60 mmol) by the method described above gave a brown reaction mixture, the usual work up of which afforded no characterizable product.

The authors are grateful to Professor Nobuo Ishikawa of Tokyo Institute of Technology for a generous gift of hexafluoroacetone.

Absolute Intensity Measurement of the ν_4 Band of Fluoroform by the Use of a Tunable Diode-laser Source

Susumu Sofue,† Kentarou Kawaguchi, Eizi Hirota, and Tsunetake Fujiyama*

Institute for Molecular Science, Myodaiji, Okazaki 444

†*Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku Tokyo 158*

(Received May 6, 1981)

The absolute infrared absorption intensities have been measured for the $P_{35}(35)$ and $P_{36}(36)$ lines, which belong to the ν_4 fundamental of fluoroform, by the use of a tunable diode-laser source. The observed intensity, Γ, was 5360+220 $cm^2\ mol^{-1}$. This intensity value was compared with that observed by the conventional method.

The absorption intensities of the vibration spectra of gaseous molecules have been discussed as the intensities integrated over the whole absorption bands. This has been largely due to the fact that the limited resolution of a dispersion-type spectrometer is insufficient to observed individual vibration-rotation lines. Therefore, the experimental method based on the theory of Wilson and Wells[1] has conventionally been employed. In their method, the total pressure in the absorption cell is raised so that the rotational fine structures are completely smeared out, giving the band a smooth contour; this reduces the error resulting from the finite instrumental line-width. The disadvantage of this method is that the observed intensity value can be spoiled by some systematic errors. The two main origins of the systematic errors are:

1) the existence of hot bands originating from the combinations between the vibrational mode in question and the other modes,
and
2) the existence of the accidental coincidence of vibrational-energy levels.

Item 2) can further be divided into two categories: the anharmonic resonance (Fermi resonance) and the Coriolis interaction.

A high-resolution method has an advantage over the conventional method with respect to these problems. In the high-resolution method, it is enough to observe the intensities of several vibration-rotation lines in determining the intensity for the whole band. Since the instrumental line-width can be narrower than a Doppler width, two peaks whose frequency separation is larger than the Doppler width can be observed separately. Usually the molecular constants of the hot bands are slightly different from those of the fundamentals. Therefore, it is possible to detect this slight difference and to observe a spectrum corresponding to a single vibration-rotation transition. As for the problem of resonances, it should be remembered that it is the vibration-rotation levels that really interact with each other. Therefore, even if there are degeneracies with respect to the vibrational levels, only some vibration-rotation levels are considerably perturbed. The other vibration-rotation levels may be too far from their counter levels. Thus, it is possible to estimate the pure intensity for the vibration by observing the resonance-free transitions to these unperturbed vibration-rotation energy levels.

The purpose of this study is to examine the experimental possibility of intensity observation for a vibration spectrum by the use of a tunable diode-laser source spectrometer and to compare the intensity thus observed with that observed by the conventional method. Fluoroform was chosen because we have already determined its molecular constants on the ν_4 fumdamental.[2] The vibrational intensity for the ν_4 fundamental has also been reported as determined by the use of a conventional method.[3]

Experimental

Commercial fluoroform of a 99.95% purity was distilled several times just before the measurement. The sample cell was made of a Pylex tube (30 mm in diameter and 150 cm in length) with CaF_2 windows at its ends. The end planes of the Pylex tubes had been ground by means of a diamond grinder to make an angle of about 88° to the optical axis of the tube, thus avoiding interference. In order to produce the optimum transmittance under an appropriate pressure, it was often necessary to use several sample cells in a series. These cells were connected to a usual glass and grease manifold. The temperature of the sample was believed to be equal to the room temperature.

The measurement of the sample pressure is a critical problem in this kind of work. In the present experiment, a variable-inductance transducer (Tsukasa Sokken, model P90DL channeled to a special carrier amplifier) was connected to the vacuum system. By introducing air into the system, we calibrated the transducer against an MKS Baratron. We could not use the Baraton itself for our pressure measurements because the surface of the diaphragm is corroded by fluoride and so can be damaged by the sample fluoroform. The nonlinearity of the P90DL was estimated to be 4% up to 200 mTorr.†† This figure can serve to indicate the relative accuracy of the instrument as long as the Baratron is accurate. Although the transducer is rather sensitive to the temperature change, we did not use any thermostatting equipment in this work, for the room temperature was controlled well enough. It was recognized that the pressure of the system increased by 2—3% during the intensity measurement; this increase was ascertained to stem from the evaporation of the vacuum grease.

A laser diode, in a closed-cycle refrigerator operating at about 20 K, served as the source of monochromatic radiation. The emitted energy was focused on the entrace slit of a grating monochromator, which served both for the coarse frequency calibration and for the isolation of discrete laser modes. A mechanical vibrating chopper, operating at 400 Hz, was placed immediately before the entrance slit. The laser from the exit slit of the monochromator passed through the sample cells and was focused onto a HgCdTe or PbSnTe detector kept at 77 K. The chopped signal was amplified and fed to a lock-in amplifier, whose reference was obtained from the chopper. The DC signal

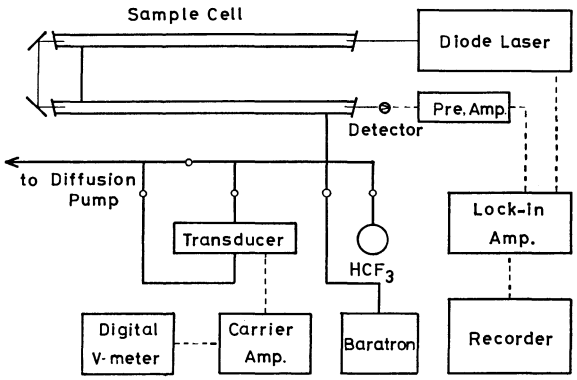

Fig. 1. The block diagram of the experimental arrangement for the intensity measurement.

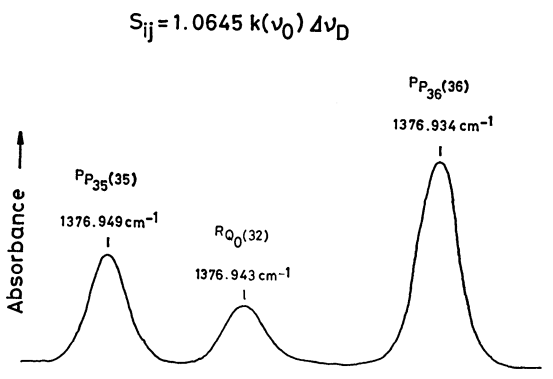

Fig. 2. The spectra for $P_{35}(35)$ and $P_{36}(36)$ of the ν_4 fundamental of fluoroform.

was channeled to an X-T recorder. The signal was strong enough for us to record lines with a high signal-to-noise ratio with a rather short time constant (300 ms) in comparison with the time needed to record an absorption line. Lines were identified in reference to the neighbouring lines. The FWMH (full-width at half maximum) was measured relative to the separation of three line peaks, with the middle one being measured. Figure 1 illustrates the experimental arrangement.

Results and Discussion

Observed Spectra. Figure 2 shows the spectra observed for the $^PP_{35}(35)$ and $^PP_{36}(36)$ lines of fluoroform. The length of the cell was 300 cm, and the pressure was 13.6 mTorr. The observation was made at 293 K. As the accurate frequencies had already been determined for these lines,[2] the FWHM's could be estimated for these two lines. They were 59.7 MHz for $^PP_{35}(35)$ and 63.3 MHz for $^PP_{36}(36)$. It is probable that these two line-shapes are governed by the Doppler broadening, for the calculated Doppler width is 60.5 MHz in this frequency region (HCF_3= 70, T=293 K). This postulation seems reasonable if the following three points are taken into account:

1) the line-width due to the collision broadening is of the order of 0.1 MHz (the pressure-broadening parameter for fluoroform is 18 MHz/Torr[4]),

2) the instrumental line-width can be narrower than 10^{-4} cm^{-1} (3 MHz),

and

3) the synthetic spectra calculated from the precise molecular constants[2] predict no overlapping from other lines with considerable intensities.

Determination of the Line Intensity. The absorption intensity associated with the transition from the energy level, i, to another energy level, j, is defined by this relation:

$$S_{ij} = \int_{-\infty}^{\infty} k(\nu)\mathrm{d}\nu, \tag{1}$$

where $k(\nu)$ is the absorption coefficient which appears in the Lambert-Beer law:

$$I(\nu) = I_0(\nu)\exp(-k(\nu)\chi). \tag{2}$$

In Eq. 2, I_0 and I correspond to the intensities for the incident and transmitted light respectively. χ is a measure of the number per unit of area of the absorbing molecules occurring along the direction of the propagation of the radiation in the sample gas. If the absorbing molecules are at a certain concentration, n, and are contained in a space with a certain length, l, in the direction in which the radiation travels

$$\chi = nl. \tag{3}$$

Knowledge about the dependence of the absorption coefficient on the frequency is needed to estimate S_{ij} from Eq. 1. That is, the explicit expression for the distribution function;

$$k(\nu) = S_{ij}f(\nu-\nu_0), \tag{4}$$

must be known. In the present study, f can be considered to have the form of a Doppler profile under appropriate conditions. Defining $\Delta\nu_D$ as a FWHM of the Doppler limited-absorption line, the following normalized distribution function is obtained:

$$f(\nu-\nu_0) = \frac{(\ln 2/\pi)^{1/2}}{(\Delta\nu_D/2)}\exp[-(\ln 2)\{(\nu-\nu_0)/(\Delta\nu_D/2)\}^2]. \tag{5}$$

By combining Eqs. 4 and 5, one can get this expression:

$$S_{ij} = 1.0645\, k(\nu_0)\Delta\nu_D, \tag{6}$$

which shows that only knowledge about the absorption coefficient at the peak frequency is required to evaluate the line intensity as long as the line shape is approximated by a Doppler profile.

The absolute line intensities estimated from Eq. 6 are summarized in Table 1. In the estimation, we used the theoretically estimated Doppler width, $\Delta\nu_D$= 60.5 MHz, instead of the experimentally observed linewidths, because the experimentally observed linewidths were not accurate enough for the quantitative work; this may be due to the irregularity in the scan rate of the electric current fed to the diode.

Determination of Transition Moment for the ν_4 Fundamental. The absolute line intensity defined by Eq. 1 can have another form in the quantum-mechanical expression. The time-dependent perturbation theory has shown that:

$$S_{ij} = \frac{8\pi}{3hc}(N_j-N_i)\nu_{ij}|\mu_{ij}|, \tag{7}$$

where h is Planck's constant; c, the velocity of light; N_s, the molecular density of the energy level, E_s ($E_j > E_i$); ν_{ij}, the transition frequency, and μ_{ij}, the transition dipole moment. Suppose that the molecules are

	21.7	0.302	0.111	0.113

a) $D(\text{Debye}) = 10^{-18}\ g^{1/2}\ cm^{5/2}\ s^{-1}$.

in thermal equilibrium; that is, the molecules follow the Boltzmann distribution. Then, the density of molecules in the energy level, E_s, can be expressed as;

$$N_s = Ng_s\exp(-E_s/kT)/Z, \tag{8}$$

where N is the total molecular density and g_s, the degree of the degeneracy of the level, s. The estimation of g_s has been discussed in the previous paper.[2] Z is the total partition function, which can be evaluated by computor calculation. In this evaluation, we considered the rotational levels belonging not only to the vibrational ground state, but also to the $v_3=1$ and $v_6=1$ states. As the band origins are: $\nu_3=700$ cm^{-1} and $\nu_6=507$ cm^{-1}, the number of molecules in these energy levels at room temperature cannot be neglected. The vibrational-energy levels higher than 1000 cm^{-1} ($2\nu_6$, ν_2, ν_5, $\nu_3+\nu_6$, ν_4, $2\nu_3$, *etc.*) were neglected because the distribution density is very small. Then, Z can be expressed as the sum of the partition functions for three vibrational levels:

$$Z = Z_0 + Z_3 + Z_6. \tag{9}$$

For example, the explicit formula for Z_0 is:

$$Z_0 = \sum_{J=0}^{\infty}\sum_{J=-J}^{J}(2J+1)g_K g_I\exp(-E_{JK}/kT), \tag{10}$$

where E_{JK} is equal to the $E(J,K)$ of our previous paper,[2] and:

$$\left.\begin{aligned} &g_K = 1 \text{ for } K = 0,\\ &g_K = 2 \text{ for } K \neq 0,\\ &g_I = 2 \text{ for } K = 3n\ (n=1, 2, 3, \cdots), \text{ and}\\ &g_I = 1 \text{ for } K \neq 3n. \end{aligned}\right\} \tag{11}$$

The summation was executed until the term newly added became less than 10^{-10} of the sum theretofore. Z_3 and Z_6 were calculated in the same way, special attention being paid to the symmetry species of the vibration-rotation energy levels ($v_3=1$, A_1; $v_6=1$, E). The result was:

$$Z = 45836 + (3.21\times10^{-2}) \times 45991 + (8.26\times10^{-2})\times 91875 = 54904, \tag{12}$$

where (3.21×10^{-2}) and (8.26×10^{-2}) are the Boltzmann factors for $v_3=1$ and $v_6=1$ respectively. The transition dipole moments thus obtained are shown in Table 1.

On calculating the transition moment from the observed line intensities, we have to pay much attention to the mixing of the energy levels. In the case of the ν_4 fundamental of fluoroform, the possible perturbations are the x-y type Coriolis interaction with $2\nu_3$ and the l-type resonance. Fortunately, for the cases of $^PP_{35}(35)$ and $^PP_{36}(36)$ we do not have to consider the existence of the x-y type Coriolis interaction, because there are no counter levels in the $2\nu_3$ state.[5] The presence of the l-type resonance is not a critical problem for the determination of the transition moment. The degree of the mixing can be calculated exactly, for the eigenvectors can be calculated from the constant q_4.[6] However, there are no interacting pairs for these transitions.[7] In other words, $|0, 1: J, J, -1\rangle$ remains the eigenfunction of the overall Hamiltonian, and J, k, and l are good quantum numbers. The matrix elements of the direction cosine can then, readily be calculated.[8]

Now, the transition moment corresponding to the ν_4 fundamental can be derived. By expanding the components of the electric dipole moment with respect to the normal coordinates, we obtain:

$$\mu_x = (\mu_x)_0 + \sum_k\left(\frac{\partial\mu_x}{\partial Q_k}\right)_{Q_k=0}Q_k + \cdots \tag{13}$$

and by neglecting the terms higher than the quadratic, we can express the matrix element of μ_x by this relation:

$$\langle 0\lvert\mu_x\rvert v_4=1\rangle = \left(\frac{\partial\mu_x}{\partial Q_4}\right)\langle 0\lvert Q_4\rvert v_4=1\rangle. \tag{14}$$

The constant term of Eq. 13 vanishes so long as the anharmonicity is neglected. The numerically estimated values of Eq. 14 are summarized in Table 1.[8]

Comparison with the Results Obtained from the Conventional Method. The observed transition-moment values were converted into the absolute absorption-intensity values in order to compare the present results with the absorption intensities obtained by conventional method.[3] The relation between the absolute intensity, Γ, and the transition moment is:

$$\Gamma = \frac{8\pi^3}{3hc}(N_j - N_i)\left|\left(\frac{\partial\mu_x}{\partial Q_4}\right)\langle 0\lvert Q_4\rvert v_4=1\rangle\right|^2. \tag{15}$$

This equation has the same form as Eq. 7 when Γ is replaced by S_{ij}/ν_{ij}. $|\mu_{ij}|^2$ can be written for a vibrational transition as:

$$|\langle v''\lvert\mu_F\rvert v'\rangle|^2 = |\langle 0\lvert\mu_x\rvert v_4=1\rangle|^2 + |\langle 0\lvert\mu_y\rvert v=1\rangle^2 = 2|\langle 0\lvert\mu_x\rvert v_4=1\rangle|^2. \tag{16}$$

The coefficient of 2 corresponds to the degeneracy of the vibration, which is designated as k in Eq. 15. Again, the vibration-rotation partition functions were considered for the estimation of N_s. In Table 2, the Γ values calculated from Eq. 15 are compared with those obtained by the conventional method. The error for Γ was considered to arise mainly from the errors in the pressure measurement. The direct comparison of these intensity values is not possible because

Table 2. Absolute intensities I/cm^2 mol^{-1}

5360±220	Present result

4960±240	[b]

a) S. Saeki, M. Mizuno, and S. Kondo, *Spectrochim. Acta, Part A*, **32**, 403 (1976). b) The intensity for the ν_4 fundamentaal calculated from the value of a), assuming $T=293$ K.

the intensity values observed by the conventional method contain not only the absolute intensity for the ν_4 fundamental, but also the absolute intensities for such hot bands, like $\nu_6\rightarrow\nu_6+\nu_4$ and $\nu_3\rightarrow\nu_3+\nu_4$, or overtones like $2\nu_3$. For the subtraction of the contributions from these hot band, knowledge about the types of transitions and the intensities of these hot bands is necessary. As the symmetry species of ν_6 is E, the resultant level, $\nu_3+\nu_6$, has the symmetry of A_1+A_2+E. The direct product of the species of these two states:

$$E\times(A_1+A_2+E)=A_1+A_2+3E$$

shows the types of transition. The intensity of the A_1+A_2 type band is supposed to be quite weak, for it is governed by a higher-order derivative of the dipole moment. The $\nu_3\rightarrow\nu_3+\nu_4$ transition belongs to E. In order to discuss the overtone problem, it is necessary to know the magnitude of $|\langle 0|\mu_z|\nu_3=2\rangle|$. However, as we do not see any bands with considerable intensities in the 1400 cm^{-1} region of the survey spectra, $2\nu_3$ is supposed to be quite weak, and so its contribution to I might be negligible. Thus, we can estimate the relative intensities of these hot bands by calculating the Boltzmann factors.

Although Saeki *et al.* do not describe the temperature explicitly in their report,[3] we assumed that their intensity measurement had been carried out at 293 K. Then, the intensity value of Ref. 3 can be corrected for the hot-band effects. The intensity value of 6360 cm^2 mol^{-1} is reduced to:

$$6360\times\frac{1}{1+3\exp\left(-\frac{507}{293\,k}\right)+\exp\left(-\frac{700}{293\,k}\right)}=4960.$$

This intensity value agrees with our present result within the limits of experimental error. This, in turn, suggests that the present experimental procedure is effective enough to observe vibrational intensities with a high accuracy.

Effect of x-y Type Coriolis Interaction on Line Intensity. As the method is established for determining the line-intensities of individual rotation-vibration lines, it is of some interest to see the effects of an x-y type Coriolis interaction on line-intensities. For this purpose, we observed the line-intensities for the $^PP_{J-6}(J)$ series lines, because it has been established in our previous work[2] that the x-y type Coriolis interaction affects the energy levels of this line-series considerably.

A part of the observed results are summarized in Table 3. In can be seen from the table that the effective transition moment, $|\mu_{1j}|$, decreases in magnitude with the increase in J and K values for $v_4=1$. Using the spectral data for the $2\nu_3\leftarrow\nu_3$ band obtained by Graner *et al.*,[9] together with the molecular constants related to the ν_4 band,[2] we can ascertain that the energy level of the $|v_4=1, J, K=J-6>$ state is lower than the of $|v_3=2, J, K=J-5>$ for $J>36$, and *vice versa* for $J<36$. Therefore, the intensity behaviour of Table 3 may be explained by Coriolis coupling with the $2\nu_3$ band, whose intensity is rather weak in comparison with that of ν_4.

Table 3. Line intensites of $^PP_{J-6}(J)$

Line	S/cm^2 atm^{-1}	μ_{1j}/D
$^PP_{24}(30)$	0.277	0.121
$^PP_{27}(33)$	0.237	0.117
$^PP_{30}(36)$	0.191	0.111

D(Debye)$=10^{-18}$ g$^{1/2}$ cm$^{5/2}$ s^{-1}.

If we take a Coriolis interaction and a l-type resonance into account, the wave-function of an excited state may be expressed as:

$$\psi'=a\psi'_+(v_4=1, J, K+1)+b\psi'_0(v_3=2, J, K)+c\psi'_-(v_4=1, J, K-1), \quad (17)$$

where a, b, and c are constants. As the effect of the l-type resonance is negligible in the present case,[2] Eq. 17 can be simplified as:

$$\left.\begin{aligned}\psi'_1&=\cos\beta\psi'_0(v_3=2, J, K)+\sin\beta\psi'_-(v_4=1, J, K-1)\\ \psi'_2&=-\sin\beta\psi'_0(v_3=2, J, K)+\cos\beta\psi'_-(v_4=1, J, K-1)\end{aligned}\right\}, \quad (18)$$

where:

$$\cos2\beta=\frac{\Delta E}{2r},\ \text{and}\ \sin2\beta=\frac{-\xi_{334}}{r}[J(J+1)-K(K-1)]^{1/2}$$

with

$$r=\left[\left(\frac{\Delta E}{2}\right)^2+\xi_{334}^2\{J(J+1)-K(K-1)\}\right]^{1/2},$$

In the above relations, ΔE represents the energy difference between two unperturbed states, $|v_3=2, J, K>$ and $|v_4=1, J, K-1>$. The transition moment corresponding to the transition from the ground state, ψ'', is:

$$\begin{aligned}\langle\psi''|\mu|\psi'_2\rangle&=-\sin\beta\langle\psi''|\mu|\psi'_0\rangle+\cos\beta\langle\psi''|\mu|\psi'_-\rangle\\&=-\sin\beta\cdot M_r\cdot M_k{}^k+\cos\beta\cdot M_s\cdot M_k{}^{k-1}, \quad (19)\end{aligned}$$

where:

$$M_r=\left(\frac{\partial^2\mu_z}{\partial Q_3{}^2}\right)\langle 0|Q_3{}^2|v_3=2\rangle$$

and

$$M_s=\left(\frac{\partial\mu_x}{\partial Q_4}\right)\langle 0|Q_4|v_4=1\rangle$$

and $M_k{}^{k'}$ is a direction cosine matrix element. Thus, the rotation-vibration line-strength is shown to be proportional to this value:

$$\begin{aligned}|\langle\psi''|\mu|\psi'_2\rangle|^2&=\cos^2\beta(M_sM_k{}^{k-1})^2-\sin2\beta M_rM_sM_k{}^kM_k{}^{k-1}\\&\quad+\sin^2\beta(M_rM_k{}^k)^2\\&=(\cos^2\beta-\alpha\sin2\beta+\alpha^2\sin^2\beta)(M_sM_k{}^{k-1})^2, \quad (20)\end{aligned}$$

where:

$$\alpha=\frac{M_rM_k{}^k}{M_sM_k{}^{k-1}}.$$

According to the experimental results of Table 3, the line internsity of the ν_4 band decreases with the decrease in the energy difference between the levels interacting with each other through the Coriolis resonance. Therefore, the second term of Eq. 20 is positive; that is,

$$\alpha \sin 2\beta > 0$$

and, accordingly;[10]

$$\xi_{334} M_\tau M_s > 0. \tag{21}$$

The relation of Eq. 21 has been referred to as an "positive perturbation," following Mills, Smith, and Duncan.[11] As the $v_3=2$ state has not yet been studied with sufficient accuracy, though, the quantitative analysis of line intensities based upon Eq. 20 is left for the future. We can only conclude at this stage that the observed line-intensity values show that the perturbation is positive.

Kinetics and Mechanism of Oxidation of Dimethyl Sulfoxide by Peroxomonosulfate

Thanthoni PANDURENGAN and Pichai MARUTHAMUTHU*

Department of Chemistry, University of Madras, Autonomous post-Graduate Centre, Tiruchirapalli-620020, India

(Received January 23, 1981)

The kinetics of oxidation of dimethyl sulfoxide (DMSO) by peroxomonosulfate (PMS) was carried out in aqueous H_2SO_4 medium (0.1—0.5 M H^+†) and in buffered media, pH=4.6 and 7.0, at temperatures, 10 and 20 °C. The reaction obeys a total second order kinetics, first order each with respect to [PMS] and [DMSO]. The rate was found to be immeasurably fast at pH≥9 and T>20 °C. In strong acid medium, $[H_2SO_4]$=0.1—0.5 M, the reaction was found to follow an inverse first order dependence on $[H^+]$. The rate law for the disappearance of PMS is found to be

$$\text{Rate} = \{k_a + k_b[H^+]^{-1}\}[\text{PMS}][\text{DMSO}]$$

indicating both the acid-independent and inverse acid-dependent reactions occurring concurrently. Dimethyl sulfone was identified as the oxidation product and the reaction stoichiometry, [DMSO]:[PMS] was found to be 1:1. The kinetic and thermodynamic parameters evaluated strongly suggest the nucleophilic substitution mechanism characteristic of peroxides. A comparison is also made with the corresponding reactions of the similar peroxides, H_2O_2, $S_2O_8^{2-}$, $P_2O_8^{4-}$, and $H_2PO_5^-$.

There are many investigations on the oxidation of organic and inorganic compounds by the well-known oxidant, peroxodisulfate,[1,2] $S_2O_8^{2-}$, whereas the corresponding monoperoxo compound, namely peroxomonosulfate, HSO_5^- has received relatively little attention despite the fact that it is known to chemists nearly a century ago.[3] Peroxomonosulfate can be regarded as mono substituted hydrogen peroxide in which one of the hydrogens is replaced by a SO_3 group. Metal ion catalysed[4] and uncatalysed[5] thermal decomposition of peroxomonosulfate (PMS) and oxidation of chloride and halide[6] and nitrite[7] ions have already been carried out by Edwards and coworkers. Recently radiolytic chain decomposition[8] and oxidation of azide, azidopentamminechromiun(III)[9] and tris(2,2′-bipyridine)iron(II)[10] by peroxomonosulfate have been carried out. It has been observed that peroxomonosulfate is a better oxidant than peroxodisulfate in the reaction with halide ions.

It was the intention of the authors to utilize peroxomonosulfate in the oxidation reaction of various substrates to explore the possibility of its synthetic utility. As a part of this goal, dimethyl sulfoxide, which is emerging not only as a solvent but also as a versatile reagent, was chosen as the substrate for the present investigation to find out the ease with which an aprotic solvent is oxidized by peroxomonosulfate. In general, peroxoacids[11,12] are found to be effective oxidants in bringing about the oxidation of sulfides and sulfoxides. In the reactions of sulfides, it is inferred that the nucleophilic attack is made by the sulfur of sulfides on the peroxo oxygen of the oxidant and the reverse was found to be true in the case of sulfoxides. Peroxomonosulfate may resemble either peroxodisulfate (free radical mechanism) or organic peroxides (ionic mechanism) in its reactions. The present investigation focuses attention on (i) the kinetics of the reaction with the concurrent effect of pH and high acidity since the peroxides are prone to acid-catalysis (ii) mechanistic aspects with the kinetic and thermodynamic reasoning and (iii) the comparative behaviour of PMS with those of H_2O_2, $S_2O_8^{2-}$, $P_2O_8^{4-}$, and peroxomonophosphate, $H_2PO_5^-$, in effecting the oxidation of DMSO.

† 1 M=1 mol dm^{-3}.

Experimental

All the chemicals used were of analar grade. Potassium peroxomonosulfate was donated by Du Pont Chemical Co., U.S.A. under the trade name "oxone." It is a triple salt with the composition $2\,KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$. The purity of this salt was estimated by cerimetry using ferroin indicator, as well as by iodometry and was found to be 96% pure. Tests with permanganate showed the absence of free hydrogen peroxide. No attempt was made to further purify this compound because all previous attempts have been reported unsuccessful.[8] From the methods of preparation of this compound, it is assumed that $KHSO_4$ or K_2SO_4 or both might account for the 4% difference between the formula and the analysis results[8]. Other chemicals such as dimethyl sulfoxide (Fluka), KI, $Na_2S_2O_3 \cdot 5H_2O$, NaH_2PO_4, Na_2HPO_4, CH_3COOH, and CH_3COONa (BDH) were all analytical grade samples. Perchloric acid (60%) was from E. Merck and all these chemicals were used as such.

Experiments were carried out in buffered media, pH 4.6 and 7, and in acidic medium provided by 0.1 to 0.5 M H_2SO_4. In buffered media, it was always necessary to use a high concentration of the buffer (0.1 M) since the product, HSO_4^-, is a stronger acid than the oxidant, HSO_5^-. Under the present experimental conditions, no spontaneous self-decomposition of peroxomonosulfate, even up to pH 12, was observed. The kinetics of the reaction was followed by estimating the amount of peroxomonosulfate disappeared by iodometry at different time intervals. The rate constants were obtained using integral method. The stoichiometry of the reaction was determined by taking a known excess concentration of peroxomonosulfate over dimethyl sulfoxide and allowing the reaction to completion at room temperature (30 °C). Different concentrations of DMSO (0.01—0.04 M) and PMS (0.02—0.08 M) were taken and after the reaction was over, the remaining PMS was estimated by iodometry. The stoichiometry of the reaction, [DMSO]:[PMS] in all the concentration range studied, was found to be 1:1. The only product of the reaction was identified to be dimethyl sulfone, a white solid, mp 109 °C;

IR: $\nu_{S=O}$ at 1310 and 1140 cm^{-1}, characteristic of sulfones. The error limits of the kinetic constants were calculated by the method of least squares. Duplicate experiments were carried out to check the reproducibility of the results and it was found that the results were reproducible within the error of ±5%.

Results and Discussion

All the experiments were carried out under pseudo-first-order conditions with [DMSO] at least ten times higher than that of PMS. The experiments could be done only at two different temperatures, 10 and 20 °C, and at higher temperatures, the reaction was found to be immeasurably fast. Plots of log $[PMS]_t$ *versus* time/min (Fig. 1) were found to be linear showing a first-order dependence on [PMS]. The pseudo-first-order rate constants, k'/s^{-1}, evaluated from the slopes of the above plots were found to be independent of the initial concentration of PMS (Fig. 1), further confirming the first-order dependence on [PMS]. The plots of log $[PMS]_t$ *vs.* time at different initial concentrations of DMSO and at a fixed concentration of PMS were found to be linear (Fig. 2) and the pseudo-first-order rate contants, k', evaluated from these plots were found to increase with increase in [DMSO]. Plots of k' *vs.* [DMSO] were found to be linear passing through origin (Fig. 3) showing a first-order dependence with respect to [DMSO] also. From the slopes of the above plots, the second-order rate constants, k_2 ($dm^3\ mol^{-1}\ s^{-1}$), were evaluated. In acid medium (H_2SO_4), the values of k_2 were found to decrease with increase in $[H^+]$ (0.1—0.5 M) and the plot of k_2 *vs.* $[H^+]$ was found to be linear with negative slope showing an inverse first-order dependence on $[H^+]$ and consequently the plot of k_2 $[H^+]$ *vs.* $[H^+]$ was linear with intercept on the ordinate (Fig. 4). The variation of pH from 4.6 to 7 was found to increase the rate (Table 1) and the reaction at pH≥9 was found

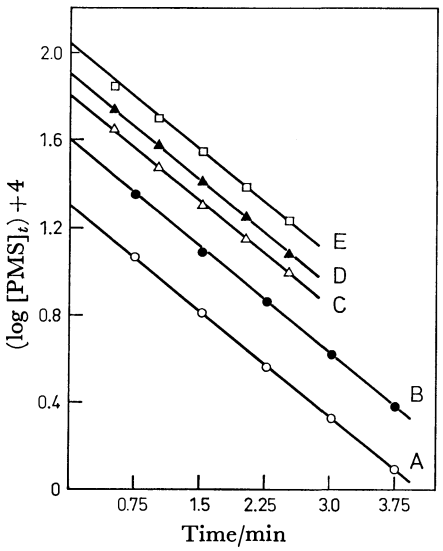

Fig. 1. First-order kinetics in [PMS]. pH=4.6; μ= 0.12 M, T=20 °C; [DMSO]=0.125 M; [PMS]= 2,4,6,8,10×10^{-3} M (A—E).

0.3MH+	10	4.93	40.2	37.7	−146.1	80.8
	20	8.83				

to take place instantaneously and consequently no experiment was done at pH>7. The presence or absence of atmospheric oxygen was found to have no effect on the reaction rate. Added acrylonitrile monomer was found to polymerize in deaerated reaction systems containing (i) acrylonitrile and PMS and (ii) acrylonitrile, PMS, and DMSO when [DMSO]≤[PMS]. However, when the concentration of DMSO was increased to greater than ten times that of PMS, complete suppression of polymerization occurred and consequently no polymer formation was observed. This indicates that at low concentrations of DMSO and in the absence of it, the polymer formed was only due to the direct reaction between PMS and acrylonitrile and not due to the formation of any radical intermediate in the reaction between DMSO and PMS. The absence of any radical intermediate was also confirmed ESR by experiments.[13] DMSO and PMS were mixed in the ESR cavity in a flow system[14] and the ESR measurements were taken. No ESR signal corresponding to any radical species could be seen. Since peroxomonosulfate would give rise to $\cdot OH$ and $\dot{S}O_4^-$ by homolytic scission and $\dot{S}O_4^-$ and OH^- or $\dot{O}H$ and SO_4^{2-} with reducing agents,[10] such very reactive radical species, if they are formed, would have produced radicals such as $\dot{C}H_3$[15] from DMSO. Experiments were also conducted by mixing PMS solution and that of DMSO containing fumaric acid in the flow system and ESR signals were looked for. Since fumaric acid is an efficient spintrapping agent[16–18] for $\dot{O}H$, $\dot{S}O_4^-$, and organic radicals, absence of any ESR signal confirms positively the absence of radicals as the intermediate in the PMS–DMSO system.

Peroxomonosulfuric acid ($HO\text{–}OSO_3H$) has two ionisable protons. Strictly speaking, one is the sulfuric acid proton and the other is the hydrogen peroxide proton. The pK_a value of the sulfuric acid proton lies in a high acidity region and that of hydrogen peroxide proton[4] is 9.4. Since the rate was found to be increased enormously as the pH is increased and decreased as $[H^+]$ was increased and also from the nature of $k_2[H^+]$ *vs.* $[H^+]$ plot leaving intercept on the ordinate (Fig. 4), the following mechanism of oxidation involving acid-independent and inverse acid-dependent paths may be proposed.

$$HO\text{–}O\text{–}SO_3^- \overset{K}{\rightleftharpoons} {}^-O\text{–}O\text{–}SO_3^- + H^+ \quad (1)$$

$$(CH_3)_2SO + HO\text{–}OSO_3^- \xrightarrow{k_a} (CH_3)_2SO_2 + SO_4^{2-} + H^+ \quad (2)$$

$$(CH_3)_2SO + {}^-O\text{–}O\text{–}SO_3^- \xrightarrow{k_b} (CH_3)_2SO_2 + SO_4^{2-} \quad (3)$$

The rate equation for the disappearance of PMS is given as

$$\text{Rate} = \frac{-d[PMS]}{dt} = k_a[DMSO][HSO_5^-] + k_b[DMSO][SO_5^{2-}] \quad (4)$$

$$= k_a[DMSO][HSO_5^-] + \frac{k_bK[DMSO][HSO_5^-]}{[H^+]} \quad (5)$$

$$\frac{\text{Rate}}{[DMSO][PMS]} = k_2 = k_a + k_bK[H^+]^{-1}, \quad (6)$$

where k_2 is the overall second-order rate constant and k_a and k_b are acid-independent and inverse acid-dependent rate constants respectively. Equation 6 may be rearranged into a convenient form,

$$k_2[H^+] = k_a[H^+] + k_b[K]. \quad (7)$$

Using the rate constants at $[H^+]=0.1$—0.5 M, the plot of $k_2[H^+]$ *vs.* $[H^+]$ was drawn (Fig. 4). From the line of best fit, the value of $k_a=7.70\times10^{-2}$ M^{-1} was obtained as the intercept. From the slope of the above plot, k_bK, the value of $k_b=7.37\times10^6$ dm^3 mol^{-1} s^{-1} was obtained using the literature value[4] of $K=3.98\times10^{-10}$. It is seen that k_b is approximately eight orders of magnitude higher than k_a. So, it is not surprising that the reaction between DMSO and PMS is instantaneous at pH>9 where PMS exists as ${}^-O\text{–}O\text{–}SO_3^-$. This also points to the fact that the reaction occurs predominantly with SO_5^{2-} as the active species of PMS. In general, the reactions of peroxide are prone to acid-catalysis. The present investigation is interesting in that an inverse acidity dependence is observed. The higher reactivity of SO_5^{2-} than that of HSO_5^- may be considered to be in favour of a nucleophilic attack by the peroxide.

The foregoing kinetic results, second-order kinetics and inverse acidity dependence, may suggest a nucleophilic substitution mechanism on the sulfur atom in DMSO by PMS as shown below.

$$CH_3SOCH_3 + {}^-O\text{–}O\text{–}SO_3^- \longrightarrow \left[\begin{array}{l} CH_3 \\ \quad\ddot{S}\text{–}O\text{–}OSO_3^- \\ CH_3 \\ \quad O \end{array}\right] \longrightarrow (CH_3)_2SO_2 + SO_4^{2-}. \quad (8)$$

A similar mechanistic behavior involving the nucleophilic attack of peroxide oxygen on the sulfur atom of sulfoxide has been observed in the oxidation of diphenyl sulfoxide by perbenzoic acid.[12] There is also abundant evidence that peroxo anions are strongly

nucleophilic as pointed out in earlier work.[19] The kientic and thermodynamic parameters, for the present investigation, calculated by using standard equations are presented in Table 1. The thermodynamic parameters given are for the overall second-order rate constants, k_2, obtained only at two temperatures, 10 and 20 °C because the reaction was immeasurably fast above 20 °C. Nevertheless the values of activation parameters,

$\Delta H^* = 37.7$ to $47.7\,\mathrm{kJ\,mol^{-1}}$ and

$\Delta S^* = -101.7$ to $-146.1\,\mathrm{J\,deg^{-1}\,mol^{-1}}$

observed by us, are of the same order of magnitude as observed by Edwards[20] for typical nucleophilic second-order reactions,

$\Delta H^* = 37.7$ to $71.2\,\mathrm{kJ\,mol^{-1}}$ and

$\Delta S^* = -41.9$ to $-146.5\,\mathrm{J\,deg^{-1}\,mol^{-1}}$.

Comparison with the oxidation of sulfoxides by other inorganic peroxides:

Oxidations[12,20,21] of sulfides and sulfoxides by hydrogen peroxide and organic peroxoacids, are discussed in terms of nucleophilic reactions. In general, the reactions follow a second order rate law, first order each with respect to [peroxoacid] and [reductant]. In the case of sulfides, the nucleophilic attack on peroxo oxygen is made by sulfur of the sulfide and the reverse was found to be true in the case of sulfoxides.[12] The kinetic and thermodynamic parameters are found to be consistent with the mechanistic reasonings for an S_N2 mechanism.

Peroxodisulfate oxidation of DMSO has not been carried out so far. But from the available data[22,23] on the sulfoxides, such as diethyl and diphenyl sulfoxides, it can be understood that the oxidation rates at low concentrations of sulfoxides follow a total first order kinetics, first order with respect to $[S_2O_8^{2-}]$ and zero order with respect to [sulfoxide] and a total second order, first order each with respect to $[S_2O_8^{2-}]$ and [sulfoxide] at higher concentrations of sulfoxide. From the observation that oxygen does not affect the rate of the diethyl sulfoxide–$S_2O_8^{2-}$ reaction, Howard and Levitt[18,19] suggested that the reactions do not proceed by a free radical mechanism. But it is argued[2] that the increase in the rate of disappearance of peroxodisulfate ion in the presence of sulfoxide and the zero order dependence upon sulfoxide concentration would indicate that a chain reaction is operative.

The kinetics and mechanism of oxidation of dimethyl sulfoxide by peroxodiphosphate[24] was carried out recently. It was found that the reaction was strongly acid-catalysed. The reaction obeys a total first order, first order with respect to the [oxidant] and zero order with respect to [DMSO]. The kinetic data are rationalised by a free radical chain mechanism. Dimethyl sulfone was identified to be the sole product of oxidation, the stoichiometric reaction being

$$(CH_3)_2SO + H_3P_2O_8^- + H_2O \longrightarrow (CH_3)_2SO_2 + 2H_2PO_4^- + H^+. \quad (9)$$

The energy of activation for the reaction is 75.8 kJ mol^{-1} which is lower than the –O–O– bond energy of the peroxide. Comparison of the data on the oxidation of water by peroxodiphosphate indicated that the aprotic solvent, DMSO, was oxidised with more facility than the protic solvent, H_2O.

The kinetics of oxidation of dimethyl sulfoxide by peroxomonophosphate,[25] $H_2PO_5^-$, the phosphorus analog of peroxomonosulfate, was found to follow the similar rate law as in the present investigation except for the acid-dependence. The reaction is found to obey a second order kinetics, first order each with respect to [DMSO] and $[H_2PO_5^-]$. The reaction shows a direct first-order dependence on $[H^+]$ in strong acid (H_2SO_4) medium and the rate decreases with increase in pH in buffered media. This acid-dependence is in sharp contrast to that found in the present investigation wherein an inverse acidity dependence is observed. Comparison of rate constants under similar experimental conditions show that peroxomonosulfate is a more powerful oxidant than peroxomonophosphate and the former oxidant can be used as an analytical reagent to estimate dimethyl sulfoxide at room temperature, provided the estimation is done at alkaline pH.

Effects of Intermolecular Hydrogen-bonding on the Luminescence Properties of Acetophenone. Characterization of Emission States

Suniti Kumar GHOSHAL, Susil Kumar SARKAR, and Gouranga Sundar KASTHA*

Optics Department, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700032, India

(Received May 23, 1980)

The effects of intermolecular hydrogen-bond formation by protic solvents on the absorption and luminescence properties of acetophenone have been investigated. It has been concluded from analysis of the $T \leftarrow S_0$ absorption, phosphorescence excitation spectra and the emission characteristics that the lowest triplet state of acetophenone in its vapor phase and in nonpolar as well as in moderately polar solvents (*e.g.*, ethanol, EPA *etc.*) is of n-π^* character. In rigid polar media, acetophenone exhibits a very weak $^1\pi\text{-}\pi^* \rightarrow S_0$ fluorescence and a weak $^3\pi\text{-}\pi^* \rightarrow S_0$ phosphorescence superposed with the principal ^{3}n-$\pi^* \rightarrow S_0$ emission. A progressive enhancement of both of these emissions with increasing polarity of the solvent has been observed. It is shown that the fluorescence and the dual phosphorescence emissions from acetophenone in rigid polar media arise as a result of decreased efficiencies of the spin-orbit and vibronic coupling interactions due to intermolecular hydrogen-bond formation by the protic solvents.

In spite of extensive spectroscopic[1-18] and photophysical[19-21] studies ambiguity remains concerning the assignment of the lowest triplet state of acetophenone. The phosphorescent state of acetophenone in glassy nonpolar and moderately polar media (*e.g.*, ethanol, EPA) at 77 K has been shown to possess a n-π^* character by several investigators[1-6] and a π-π^* character by others.[7,8] More recently, Mathews and Lytle[9] characterized it as n-π^* and π-π^* type in polar (ethanol, methanol) and nonpolar media, respectively, at 77 K. In the case of pure acetophenone crystal, π-π^* assignment was made of its lowest triplet state on the basis of polarized phosphorescence-excitation spectra[11] and PMDR studies,[12] and n-π^* assignment on the basis of $T \leftarrow S_0$ absorption[10] and the polarization and Zeeman splitting measurement of the $T \leftarrow S_0$ absorption.[13]

As regards the origin of dual phosphorescence emissions in rigid polar media, the phenomenon has been interpreted on the basis of various assumptions.[14,17] Koyanagi *et al.*[6] proposed a model of highly distorted (triple minimum) potential surface in the lowest triplet state of acetophenone in order to explain its dual phosphorescence. A non-interacting density of states model has been postulated to account for the phenomenon. In each case a close proximity of the ^{3}n-π^* states has been assumed as an essential prerequisite for the occurrence of dual phosphorescence emission, but little information is given on the relative positions of the triplet levels in environments pertinent to the problem. The dual phosphorescence is observed in rigid polar media and H-bond acceptor properties of the aromatic ketones[5,22,23] but the possibility that this phenomenon could be associated with the solute–solvent intermolecular H-bonding interaction has not be considered.

Though the fluorescence activation of several aromatic aldehydes, ketones and other carbonyl compounds in protic media is well known[24] no investigation seems to have been made on the possibility of fluorescence activation in the case of acetophenone.

In view of the significance of luminescence properties of aromatic carbonyls in hydrogen bonding media and the conflicting assignment of the lowest triplet state of acetophenone, a detailed investigation on the absorption and emission characteristics of this aromatic ketone has been carried out. This study was carried out in order to obtain information on the relative positions of the n-π^* and π-π^* levels of acetophenone under various conditions, and to examine the effect of intermolecular H-bonding on the photophysical behavior of this phenyl alkyl ketone.

Experimental

Materials. Acetophenone (EGA-Chemie, West Germany) was purified by repeated fractional distillation till no impurity could be detected with a flame ionization detector column (Hewlett-Packard, Model 5730A). Spectrograde ethanol, ether, isopentane, and 3-methylpentane (3-MP) of E. Merck and hexane, pentane, and methylcyclohexane of BDH were further purified by fractional distillation. Freshly prepared and deoxygenated solutions of concentrations 10^{-4}—10^{-5} M were used for recording all the spectra except in the cases of $T \leftarrow S_0$ absorptions where more concentrated solutions (*ca.* 10^{-3} M) were used.

Apparatus: The room temperature (300 K) solution and vapor phase (*ca.* 10^{-2} Torr†) emission spectra and low temperature (77 K) emission, excitation and polarization spectra were recorded on a Perkin Elmer Model MPF 44A fluorescence spectrophotometer. The vapor phase absorption spectra with 10 cm quartz cell at 300 K and 760 Torr and the solution spectra at 300 K and 77 K with a 1 cm quartz cell were obtained with a Shimadzu 210A UV-VIS Absorption spectrophotometer. Photoselection technique was employed for the measurement of the degree of polarization, which was corrected following Azumi and McGlynn.[25] The phosphorescence lifetimes were determined by using Molectron UV-1000 N_2-Laser as the excitation source in conjunction with an EC storage Oscilloscope.

Results

Absorption Characteristics. Figure 1 shows the absorption spectrum of acetophenone in the vapor phase and in protic as well as aprotic solvents at room temperature (300 K). Appreciable solvatochromic effects, such as the hypso- and bathochromic shifts, respec-

† 1 Torr=133.322 Pa.

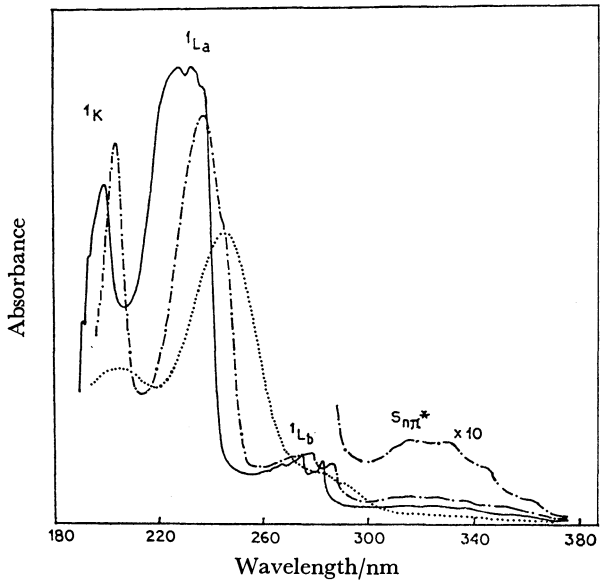

Fig. 1. Singlet-singlet absorption spectra of acetophenone in the vapor phase (——), 3-MP (—·—), and 1% HCl (·····) at 300 K.

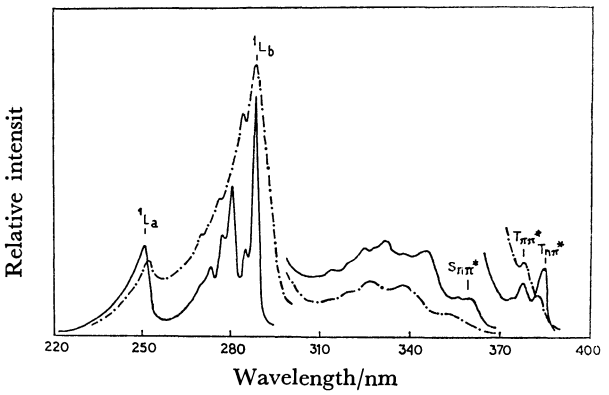

Fig. 2. Phosphorescence excitation spectra of acetophenone in 3-MP (——) and ethanol (—·—) at 77 K.

tively, of the n-π^* and π-π^* bands and noticeable hypochromic effect on both types of bands are evident from a comparison of the spectra. Although in moderately polar and H-bonding media (*e.g.*, ethanol) the higher energy π-π^* bands (^1L_a and ^1K) are relatively less affected, in highly polar and acidic media (*e.g.*, 1% HCl), the red-shifts and hypochromic effect on these bands are substantial but the n-π^* bands are completely obliterated. The results demonstrate the effects of intermolecular H-bonding on the various $\pi^*\leftarrow$n and $\pi^*\leftarrow\pi$ electronic transitions of acetophenone in protic media.

The phosphorescence excitation spectra of acetophenone (Fig. 2) in glassy polar ethanol and nonpolar 3-MP at 77 K provide further data attributable to the effect of solute-solvent H-bonding interaction (Table 1). An appreciable blue shift (*ca.* 464 cm^{-1}) and marked diminution and blurring out of vibrational structure of the ^{1}n-$\pi^*\leftarrow S_0$ bands in the excitation spectra are observed in going from 3-MP to ethanol. The ^{1}n-$\pi^*\leftarrow S_0$ excitation spectra show a significant

lowering (*ca.* 100 cm^{-1}) of the excited state carbonyl stretching frequency of the molecule in ethanol as compared to that in 3-MP glass (Table 2). With increase in the polarity of the medium (*e.g.*, from ethanol to predominantly ethanol–water mixture), further obliteration of the ^{1}n-$\pi^*\leftarrow S_0$ bands takes place. In highly polar and acidic media (1% HCl) these bands are no longer observable in the phosphorescence excitation spectra. The ^1L_a band also shows a similar solvent dependent intensity variation.

Both the vapor and solution phase $T\leftarrow S_0$ absorption spectra of acetophenone (Fig. 3) display two weak but distinct bands. The spectral positions of these bands under different environmental conditions are given in Table 1. From a consideration of the relative changes in absorbance and the solvatochromic shifts exhibited by the bands on passing from the vapor phase to hydrocarbon and to polar solvents, the respective assignments of these bands to $^3\pi$-$\pi^*\leftarrow S_0$ and ^{3}n-$\pi^*\leftarrow S_0$ transitions have been made (Fig. 3). The bands can be clearly discerned in the phosphorescence excitation spectra of acetophenone in polar as well as in nonpolar media at 77 K (Fig. 2). In glassy hydrocarbon (3-MP), the lower energy band (25933 cm^{-1}) has an eminent overlap with the phosphorescence band origin (25815 cm^{-1}), the higher energy one appearing at 26383 cm^{-1}, *i.e.* 450 cm^{-1} towards the higher frequency side of the former. The assignment of these bands to ^{3}n-$\pi^*\rightarrow S_0$ and $^3\pi$-$\pi^*\leftarrow S_0$, respectively on the basis of their characteristic solvatochromic shifts and hypochromic effects are analogous to and conform with those made in the case of absorption.

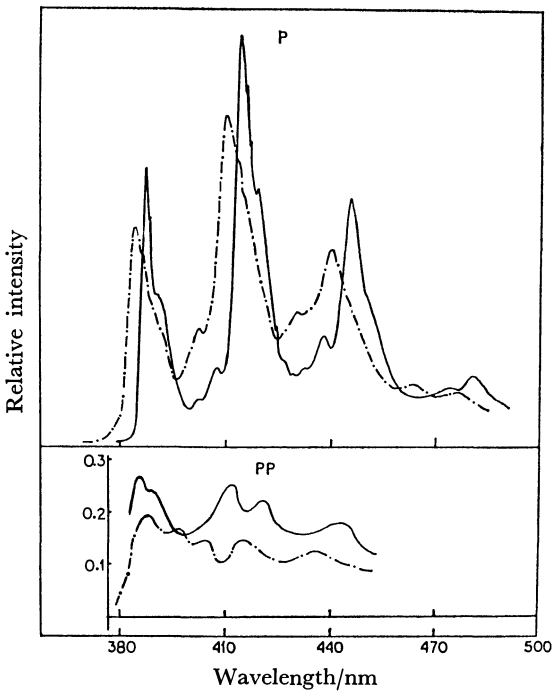

Fig. 4. Phosphorescence (P) and phosphorescence polarization (PP) spectra (with 250 nm excitation) of acetophenone in 3-MP (——) and EPA (—·—) at 77 K.

5:5:2) and nonpolar (3-MP) media under identical conditions. Despite the close resemblance of the two spectra, distinct changes in phosphorescence spectra brought about by the protic solvent are apparent:

(1) The sharp and structured phosphorescence spectrum observed in 3-MP at 77 K appears broadened in EPA glass.

(2) A substantial blue shift (*ca.* 190 cm^{-1}) of the phosphorescence band origin and lowering of carbonyl stretching frequency ($\nu_{C=O}$) occurs with the change of solvent from nonpolar to polar.

(3) A significant diminution in phosphorescence intensity of acetophenone takes place in polar media in comparison with that in glassy hydrocarbon matrices.

(4) Whereas the phosphorescence intensity on the smaller wavelength side of the 0-0 band in glassy hydrocarbon matrices falls steeply, in glassy polar media the band origin is accompanied by a short tail which extends to the higher frequency region beyond the band maximum (384.5 nm). In fact, the phosphorescence spectrum of acetophenone recorded with an expanded scale and higher resolution (Fig. 5) reveals a weak partially resolved blue shoulder at *ca.* 381 nm.

The phosphorescence polarization (PP) curves of acetophenone in glassy hydrocarbon (3-MP) and polar (EPA) media show that in both cases the phosphorescence is strongly positively polarized with respect to ^1L_a excitation, indicating a predominantly in-plane polarization of the phosphorescence emission (Fig. 4). The sharp fall in the value of the degree of polarization (P) in the 3-MP curve around the immediate vicinity of the phosphorescence band origin indicates the presence of some low frequency nontotally symmetric vibronic band in the phosphorescence spectrum. An important distinction between the PP curves in 3-MP

and EPA glass is that the P value is predominantly more positive in aprotic medium than in protic medium. The PP curve in EPA also shows markedly less positive value at 381 nm. A further decrement of the polarization is observed in more polar EWA (ether, water, and ethanol 5:1:4) glass at 77 K.

The phosphorescence decay curves for acetophenone show that while the nature of the decay is nearly exponential in the case of vapor and in hydrocarbon solutions, it is markedly nonexponential (in fact, biexponential) in rigid polar media like ethanol and water at 77 K (Fig. 6). The initial and final slopes of a first order plot from the decay curves of acetophenone in ethanol glass correspond to lifetimes (τ_p) of *ca.* 5 and 70 ms, respectively. The shorter lived component of the phosphorescence emission is, however, found to be contributing mostly (*ca.* 90% of the total intensity) to the phosphorescence intensity. In ethanol–water mixture at 77 K the τ_p values corresponding to the short and long lived components are 6 and 100 ms, respectively, in agreement with the earlier findings.[5]

As the polarity of the solvent is increased there occurs an enhancement in the intensity of the longer lived component of the dual phosphorescence emission until in strongly acidic media it overwhelms the shorter lived one. In this case the phosphorescence lifetime becomes of the order of seconds. This result is similar to that reported by Lamola.[3]

Thus, the predominantly in-plane polarization of the phosphorescence emission, the short lifetime, the solvent shifts and the vibronic structure of the phosphorescence emission provide the conclusive evidence for the n-π^* character of the lowest triplet state of acetophenone in its vapor phase and in nonpolar as well as moderately polar media (*e.g.*, EPA, ethanol) at 77 K. The $T \leftarrow S_0$ absorption spectra of the compound strongly confirm the n-π^* nature of its lowest triplet state in these media.

b) Fluorescence Spectra: In addition to its characteristic strong ^{3}n-$\pi^* \rightarrow S_0$ phosphorescence emission, acetophenone in rigid protic media at 77 K exhibits a very weak $^1\pi$-$\pi^* \rightarrow S_0$ fluorescence with ^1L_a and ^1L_b excitation (Fig. 7). Increase in the polarity or H-bond forming capacity (*e.g.*, ethanol+water, 1% HCl) of the media results in a progressive enhancement of such fluorescence but a gradual decrease in the phosphorescence intensity in the same order. The measured Φ_P/Φ_F values of acetophenone in these polar media are given in Table 2. The data when combined with the reported value of $\Phi_P(\approx 0.6)$ for acetophenone[4] yield an approximate Φ_F value of 1.2×10^{-3} for this molecule in ethanol. Under these conditions, no emission attributable to the ^{1}n-$\pi^* \rightarrow S_0$ fluorescence could be detected.

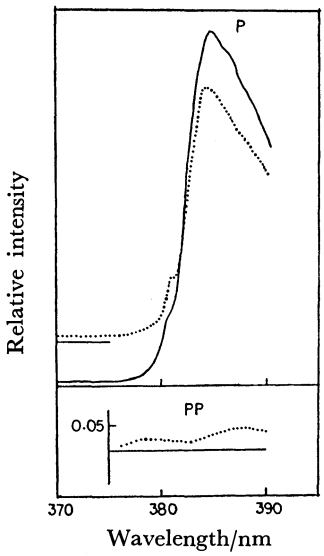

Fig. 5. Part of the phosphorescence (P) spectra (recorded on expanded scale) of acetophenone showing the phosphorescence band origins and the blue shoulder in ethanol (——), EWA (·····) glasses at 77 K and the corresponding phosphorescence polarization (PP) spectrum in EWA.

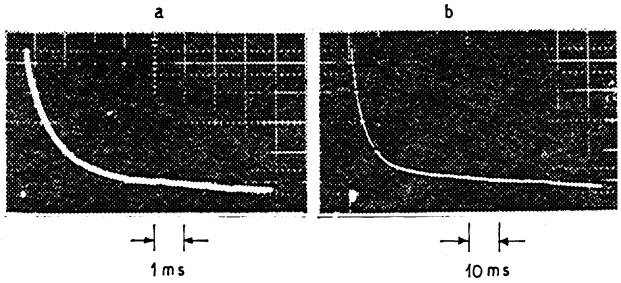

Fig. 6. Phosphorescence decay curves of acetophenone (a) in the vapor phase at 300 K (b) in ethanol at 77 K.

Discussion

Occurrence of the phenomena, *viz.*, blue-shifts of the n-π^* bands, hypochromic effect on the n-π^* and π-π^* (^1L_a) bands, significant lowering of ν_{CO}, fluorescence activation and dual phosphorescence emission from acetophenone in protic media and the progressive enhancement of each with increasing solvent H-bond

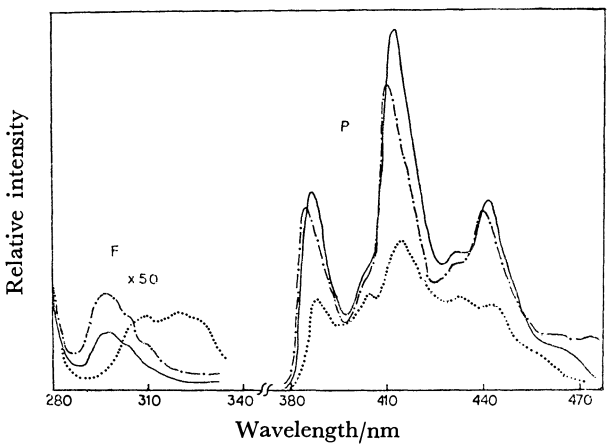

Fig. 7. Fluorescence (F) and phosphorescence (P) spectra of acetophenone in 3-MP (——), predominantly ethanol–water mixture (—·—), and in 1% HCl (·····) at 77 K (Note the broken wavelength scale.).

donor capacity, indicates a close interrelation with intermolecular H-bonding. It might be related to changes in the electronic configuration of the acetophenone molecules caused by solute-solvent interaction, in view of the importance of the electronic structure associated with the carbonyl group, particularly the nonbonding (n) orbital on the oxygen atom, in determining the photophysical behavior of the aromatic ketones and the possible involvement of the oxygen electrons in intermolecular H-bond formation.

The hypsochromic shift of $\pi^*\leftarrow$n transition bands of carbonyls in H-bonding media has now been established.[26,27] It is known by infrared and Raman studies[22,28,29] that the ν_{CO} of carbonyls decreases with increasing H-bonding. Our experimental results are in line with these findings.

Intermolecular H-bonding interaction between the proton acceptor carbonyls and the donor protic molecules affects the electronic configuration of the carbonyl group in several ways. It increases the polarity of the carbonyl group (in the direction C^+–O^-) by increasing the π electron charge on the carbonyl oxygen atom[28,30,31]. As a consequence, the C–O bond strength decreases leading to an increased C–O bond length and smaller ν_{CO}. Since the n electrons on the carbonyl are primarily involved in intermolecular H-bond formation, such solute-solvent interaction is expected to have a pronounced effect on the n orbital of the oxygen atom. The work of Hollas *et al.*[32] indicates that the s character of the n orbital and its extent of delocalization are important in determining the $\pi^*\leftarrow$n transition intensity in aromatic aldehydes and ketones. The marked diminution in the intensity of n-π^* bands of acetophenone observed in going from hydrocarbon to hydroxylic solvents suggests an appreciable decrease in the s character of the sp^2 hybridized[28,33,34] n orbital of the carbonyl oxygen atom.

In aromatic aldehydes and ketones, because of the presence of closely spaced n-π^* and π-π^* electronic states (the n-π^* states being the lower-lying one), the spin-orbit and vibronic interactions between n-π^* and π-π^* excited states are generally very strong. The radiationless deactivation processes, such as internal conversion (IC) and intersystem crossing (ISC) between the pertinent excited states, are very fast and efficient in these types of molecules. This largely accounts for their nonfluorescent nature. The occurrence of π-π^* fluorescence from acetophenone in protic media and the progressive enhancement of such emission with increasing H-bond donor capacity of the solvent thus imply a considerable decrease in the efficiency of ISC or IC, or of both in such media.

The rate or the efficiency of IC between the n-π^* and π-π^* states is dependent to a significant extent on the vibrational overlap integral between the states concerned. Since the magnitude of vibrational overlap integral between n-π^* and π-π^* states decreases as a result of decrease in the charge density of the nonbonding electrons following H-bond formation,[34,35] it is expected that the efficiency of IC between the $^1\pi$-π^* and ^{1}n-π^* states of acetophenone would decrease in protic media.

The magnitude of spin-orbit coupling between the $^1\pi$-π^* and ^{3}n-π^* states of aromatic aldehyde and ketone molecules is largely governed by factors such as the partial π electron density (C_ν^2) and Slater charge (Z_ν) on the carbonyl oxygen atom and the form (hybridization and extent of delocalization) of the n orbital on this atom.[36] It follows that while the π electron density on the carbonyl oxygen atom increases a little, the hybridization factor (γ) undergoes a significant decrement upon H-bond formation. The analysis of Del Bene[37] shows that the increase of π electron charge on the heteroatom due to H-bonding leads to the lowering of the effective nuclear charge (Z_ν) of the atom. Because of the dependence of the spin-orbit interaction matrix element, $|\beta|^2$ (Eq. 8, Ref. 36), on the higher power of Z and the fact that both γ and Z values decrease as a result of H-bonding, it seems that there is an overall decrease in the value of $|\beta|^2$, despite a small increment in the value of C_ν^2. Accordingly, the spin-orbit coupling between the $^1\pi$-π^* and ^{3}n-π^* states of acetophenone should decrease in H-bonding media, and so should the ISC rate between them. It is conceivable, therefore, that because of the decreased efficiencies or rates of $^1\pi$-π^* ⇝ ^{1}n-π^* IC and $^1\pi$-π^* ⇝ ^{3}n-π^* ISC, the $^1\pi$-$\pi^*\rightarrow S_0$ radiative process may become to some extent competitive with these radiationless processes such that some π-π^* fluorescence could be emitted from acetophenone molecules in protic media.

The ^1L_a state of aromatic aldehydes and ketones (*e.g.*, benzaldehyde and acetophenone) which provides the dipole allowed character and in-plane polarization to the lowest triplet state through spin-orbit coupling[1] is known[38] to possess considerable intramolecular charge transfer character. The marked diminution in the ^1L_a band intensity of acetophenone in protic media indicates that the intramolecular charge transfer character of the associated singlet-singlet $\pi^*\leftarrow\pi$ transition is perhaps inhibited as a result of solute-solvent H-bonding interaction. The significant lowering of the P values of phosphorescence emission from acetophenone molecules in H-bonding media, compared to those observed in nonhydrogen bonding media, could be related, at least partly, to the diminished spin-orbit coupling between $^1\pi$-π^* $(^1L)_a$ and ^{3}n-π^* state due to H-bonding. This may be interpreted as evidence in favor of the supposition that the spin-orbit coupling should decrease in H-bonding media.

The simultaneous emission of phosphorescence from both the triplet states (^{3}n-π^* and $^3\pi$-π^*) of acetophenone in protic media suggests that the solvent induced decrease in the efficiency of $^3\pi$-π^* ⇝ ^{3}n-π^* IC process could be at the basis of such phenomenon.

According to Avouris *et al.*,[39] the rate constant of the IC process between two states is given by

$$K_{if}^{ic} = 2\pi/\hbar V_{if}^2 \rho_f(E_i), \qquad (1)$$

where $\rho_f(E_i)$ is the density of closely spaced state 'f' (final) nearly degenerate with the initial state 'i' and V_{if} is the interaction matrix element for the IC process. V_{if} is dependent on the electronic factor β_{ei}^{ic} and vibrational overlap integral.

Intermolecular H-bonding can bring about a dimi-

nution in the overlap integral through the decrease of nonbonding charge density. It can be shown that the magnitude of V_{if} in the triplet manifold would also decrease as a result of intermolecular H-bond formation. We see from Eq. 1 that the density of states, $\rho_f(E_i)$ could also be an important factor contributing to the radiationless transition between the two triplet states. Because of the smaller energy gap between the T_2 (π-π^*)—T_1 (n-π^*) states of acetophenone in protic solvents, the level densities of T_1 near the T_2 origin are expected to be small. Consequently, internal conversion from the low-lying vibrational levels of T_2 to T_1 would be less efficient. As a result of the combined effect of a decrease in both these factors, it is possible that the $T_2 \rightsquigarrow T_1$ IC rate would become sufficiently slow so as to make the $^3\pi$-$\pi^* \rightarrow S_0$ radiative process to some extent competent with the IC process, leading to the observation of dual phosphorescence emission in the case of acetophenone. Several authors previously observed dual phosphorescence emission from other aromatic ketones, *e.g.*, *p*-benzoquinone,[40] indanone,[41] and related molecules in rigid polar media, and attributed the phenomenon to severely prohibited internal conversion from the $^3\pi$-π^* state to a lower lying ^{3}n-π^* state of these molecules.

Thus, the profound influence of the H-bonding solvents on the luminescence spectral properties of acetophenone is seen to arise primarily from the electronic effect of the intermolecular H-bonding interaction. When polarity or H-bond donor capacity of the solvent increases, the ISC and IC processes become progressively less efficient and a trend of progressive enhancement of the π-π^* fluorescence and $^3\pi$-$\pi^* \rightarrow S_0$ phosphorescence is observed. In strongly acidic media protonation of the carbonyl lone pair electrons occurs; the conjugation of the oxygen electrons across the carbonyl group and the intramolecular charge transfer character of the $^1L_a \leftarrow S_0$ transition are strongly affected. In this situation, as the n electrons on the carbonyl oxygen atom no longer remain nonbonding, the $\pi^* \leftarrow$n electronic transition loses its significance and the luminescence characteristics exhibited by the protonated species become more or less normal π-π^* type.

Circular Dichroism of Chromium(III) Complexes. VII. Circular Dichroism in the Spin-forbidden Transitions of *cis*-$[Cr(N)_2(O)_4]$ Type Complexes with Ethylenediaminetetraacetate Analogues

Sumio KAIZAKI* and Hisako MORI

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received January 5, 1981)

Potassium (2*S*,4*S*)-2,4-pentanediaminetetraacetatochromate(III) monohydrate was newly prepared and was found to be formed stereospecifically with a $\Lambda(\Delta\Delta\Lambda)$ absolute configuration as has been revealed for the corresponding Co(III) complex. The circular dichroism spectra in the spin-forbidden transitions of this new complex along with the known analogues, $(-)_{589}$-ethylenediamine-*N*,*N'*-diacetato-*N*,*N'*-dipropionatochromate(III) and $(+)_{589}$-(*S*,*S*)-2,2'-(ethylenediimino)disuccinatochromate(III) complexes, were measured and discussed in comparison with those in the first spin-allowed transitions on the basis of the theoretical relations between the rotational strengths for the spin-forbidden and the spin-allowed transitions in trigonal and tetragonal fields.

In our previous papers of this series,[1-3] circular dichroism(CD) spectra in the spin-forbidden d-d transitions of trigonal and tetragonal Cr(III) complexes have been elucidated in comparison with those in the first spin-allowed d-d transitions by using the theoretical relations between the rotational strengths for the spin-forbidden and the spin-allowed transitions. No CD datum in the spin-forbidden transitions and few CD data in the spin-allowed transitions of chiral Cr(III) complexes with sexidentate ethylenediaminetetraacetate(edta) type ligands have been reported, whereas the CD spectra of several Co(III) complexes with edta analogues have been studied and discussed in relation with their absolute configurations and theories of optical activity.[5-7] The CD spectra in the first band region of such complexes have been dealt with the assumption of C_2 symmetry descending from trigonal(D_3) or tetragonal(D_4) symmetry.[4,5a-c,7a,8] To clarify these CD behavior, it is significant to reveal whether the CD in the spin-forbidden transitions of Cr(III) complexes with edta analogues will be elucidated in terms of the theoretical considerations for the rotational strengths in the d-d transitions on either the trigonal or tetragonal symmetry assumption. In this instance, it is desirable to examine the CD spectra in the spin-forbidden and the spin-allowed transitions of chiral Cr(III) complexes containing edta analogues with four glycinate rings as well as those of the known Cr(III) complexes,[4] $(-)_{589}$-*trans*(O_5)†-ethylenediamine-*N*,*N'*-diacetato-*N*,*N'*-dipropionatochromate(III), $(-)_{589}$-[Cr(eddda)]$^-$, and $(+)_{589}$-*trans*(O_5)†-(*S*,*S*)-2,2'-(ethylenediimino)disuccinatochromate(III), $(+)_{589}$-[Cr(*S*,*S*-edds)]$^-$, both of which have two five-membered and two six-membered N–O chelate rings. Apart from some racemic complexes of the former type,[9] no chiral Cr(III) complexes have yet been known.

This paper reports the preparation and stereospecific formation of a new chiral Cr(III) complex containing (2*S*,4*S*)-2,4-pentanediaminetetraacetate(*S*,*S*-ptnta^{4-}) as one of the closely similar sexidentate ligands to the edta ligand. The CD data in the spin-forbidden transitions as well as in the spin-allowed transitions of this complex are examined together with those in the spin-forbidden transitions of chiral *trans*(O_5) isomers of $(-)_{589}$-[Cr(eddda)]$^-$ and $(+)_{589}$-[Cr(*S*,*S*-edds)]$^-$, of which the CD spectra in the spin-allowed transitions have been previously reported by Radanovic and Douglas.[4] Their CD spectra in the whole region of the d-d transitions are compared with one another and discussed on the basis of both trigonal and tetragonal symmetry assumptions.

† Oxygens of five-membered chelate rings occupy transaxial coordination sites.

Experimental

Preparation of Ligands and Complexes. *1) (2S,4S)-2,4-pentanediaminetetraacetic Acid (S,S-ptntaH$_4$·1.5H$_2$O)*: This ligand was prepared from (2*S*,4*S*)-2,4-pentanediamine by the method for the racemic one.[6] Found: C, 43.27; H, 6.92; N, 7.63%. Calcd for *S*,*S*-ptntaH$_4$·1.5H$_2$O: C, 43.21; H, 6.97; N, 7.75%.

2) $(+)_{589}$-K[Cr(S,S-ptnta)]·H$_2$O: To a solution of 1.0 g of *S*,*S*-ptntaH$_4$·1.5H$_2$O in 15 cm^3 of water was added a solution containing 0.79 g of potassium hydroxide in 10 cm^3 of water. After dissolving 1.2 g of $Cr(NO_3)_3·9H_2O$ in this solution at 70 °C, the mixture was heated at 75—80 °C with stirring for about 16 h. The color of the solution changed gradually from violet to red violet. By adding ethanol to this chilled solution, red powder was obtained. Recrystallization was performed from warm water and ethanol. Found: C, 35.29; H, 4.61; N, 6.36%. Calcd for K[Cr(*S*,*S*-ptnta)]·H$_2$O: C, 35.53; H, 4.59; N, 6.38%.

3) $(-)_{589}$-[Cr(eddda)]$^-$ and $(+)_{589}$-[Cr(S,S-edds)]$^-$: The ligands, ethylenediamine-*N*,*N'*-diacetic-*N*,*N'*-dipropionic acid (edddaH$_4$)[5b] and (*S*,*S*)-2,2'-(ethylenediimino)disuccinic acid (*S*,*S*-eddsH$_4$),[7a] were prepared by the reported methods. $(-)_{589}$-[Cr(eddda)]$^-$ and $(+)_{589}$-[Cr(*S*,*S*-edds)]$^-$ were obtained by the method of Radanovic and Douglas.[4] The absorption and CD spectra along with the infrared spectra confirm that these complexes are *trans*(O_5) isomers which have been previously established.[4,10]

Measurements. Absorption spectra were recorded on a Shimadzu UV-200S spectrophotometer, and CD spectra on a JASCO MOE-1 spectropolarimeter. Infrared spectra were obtained by a JASCO DS-402S spectrophotometer.

Results and Discussion

Stereospecificity of [Cr(S,S-ptnta)]$^-$. The visible absorption spectrum of [Cr(*S*,*S*-ptnta)]$^-$ is quite similar in band position and intensities to that of the trimeth-

ylenediaminetetraacetatochromate(III) complex of the analogous type, [Cr(trdta)]$^-$, as shown in Fig. 1. This fact lends support to sexidentate coordination of an *S,S*-ptnta ligand as in the trdta complex. The CD intensities of the *S,S*-ptnta complex are found to be as large as those of $(-)_{589}$-[Cr(eddda)]$^-$ and $(+)_{589}$-[Cr(*S,S*-edds)]$^-$ as shown in Fig. 1 and Table 1. The CD pattern in the spin-allowed band region

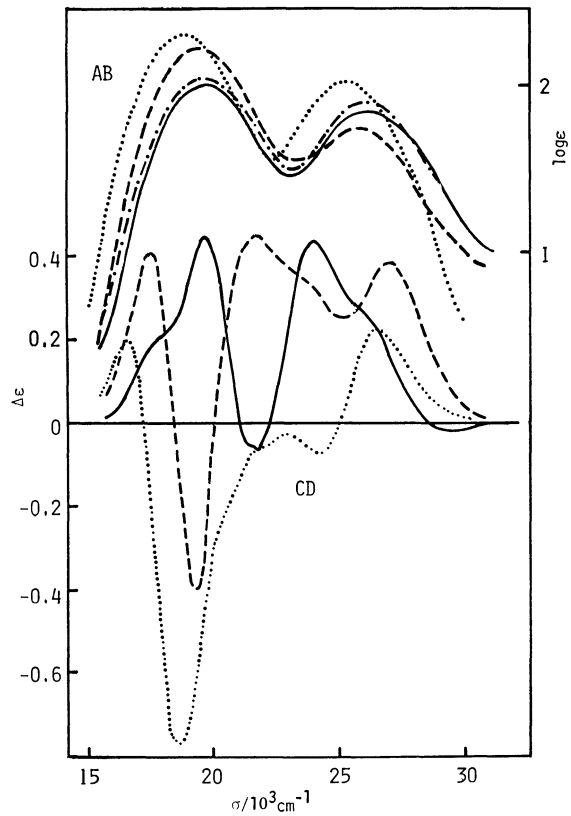

Fig. 1. Absorption and CD curves of $(+)_{589}$-[Cr(*S,S*-ptnta)]$^-$ (——), $(+)_{589}$-[Cr(*S,S*-edds)]$^-$ (– – –), and $(-)_{589}$-[Cr(eddda)]$^-$ (·····), and absorption curve of [Cr(trdta)]$^-$ (—·—) in water.

of the *S,S*-ptnta Cr(III) complex is much different from that of the corresponding Co(III) complex,[6] whereas the CD spectra of $(+)_{589}$-[Cr(*S,S*-edds)]$^-$ and $(-)_{589}$-[Cr(eddda)]$^-$ behave similarly to those of the corresponding chiral *trans*(O_5) isomers of the *S,S*-edds and eddda Co(III) complexes, respectively.[4,5b,7a] As has been revealed for [Co(*R,R*-ptnta)]$^-$,[6] the stereospecific formation of [Cr(*S,S*-ptnta)]$^-$ is expected to take place with a $\Lambda(\Lambda\Delta\Lambda)$ absolute configuration owing to the preference of the equatorial orientation of two methyl groups to the chelate rings.[6] It has been proposed for Co(III) complexes with edta type ligands[5,7] that the CD signs of the lowest frequency component in the first band region are correlated to the absolute configurations; the complexes giving a positive CD component at the lowest frequency side of the first band take a $\Lambda(\Lambda\Delta\Lambda)$ configuration, and *vice versa*. For the *S,S*-ptnta Cr(III) complex, the absolute configuration on the basis of the CD criterion is consistent with that determined in terms of stereospecificity arising from preferential coordination of sexidentate chiral ligands to Cr(III). That is, as in Fig. 1, [Cr(*S,S*-ptnta)]$^-$ with a $\Lambda(\Lambda\Delta\Lambda)$ configuration gives a positive CD component at the lowest frequency side of the first band as has been confirmed for $\Lambda(\Lambda\Delta\Lambda)$-$(-)_{589}$-[Cr(eddda)]$^-$ and $\Lambda(\Lambda\Delta\Lambda)$-$(+)_{589}$-[Cr(*S,S*-edds)]$^-$, of which the absolute configurations have been determined by the X-ray analysis[10] and the stereospecific formation,[4] respectively. Thus, the *S,S*-ptnta Cr(III) complex is formed stereospecifically with a $\Lambda(\Lambda\Delta\Lambda)$ configuration.

CD Spectra in the d-d Transitions. On the assumption of effective C_2 symmetry for the complexes of this type, the lowest-frequency CD component in the first band region is assigned to the $^4B(C_2)$ state, for which the CD signs are considered to be the same as those for the $^4B(C_2)$ state with $^4E(^4T_{2g})$ trigonal parentage or with $^4E(^4T_{2g})$ tetragonal parentage as in the case of the $^1T_{1g} \leftarrow {}^1A_{1g}$ transitions for Co(III) complexes.[4,5b,c,11]

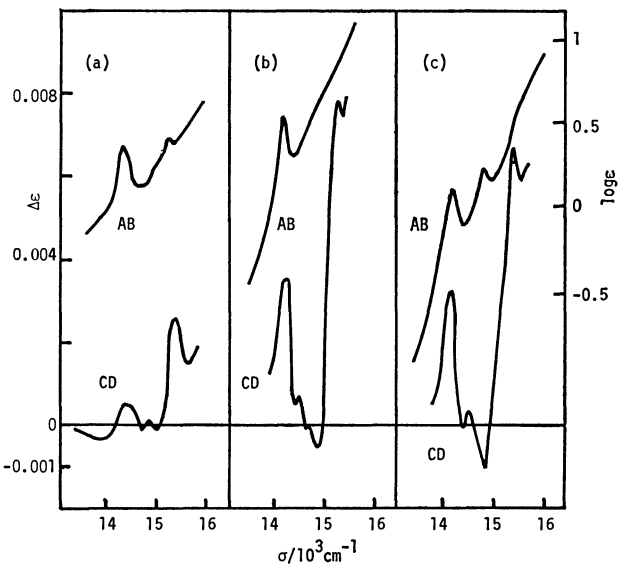

Fig. 2. Absorption (right side ordinate) and CD (left side ordinate) curves in the spin-forbidden transitions of (a) $(+)_{589}$-[Cr(*S*,*S*-ptnta)]$^-$, (b) $(-)_{589}$-[Cr(eddda)]$^-$, and (c) $(+)_{589}$-[Cr(*S*,*S*-edds)]$^-$ in water.

The CD spectra in the spin-forbidden transitions of the present complexes are shown together with the corresponding absorption spectra in Fig. 2. $(+)_{589}$-[Cr(*S*,*S*-edds)]$^-$ and $(-)_{589}$-[Cr(eddda)]$^-$ give a positive CD component near 15300 cm^{-1} and a positive CD one at 14300 cm^{-1} where the lowest-frequency absorption peak is observed. The positions of these two CD peaks coincide with those of the low-temperature absorption bands observed for bis(iminodiacetato)chromate(III) complex.[12] In the region between two strong CD peaks with a positive sign, a weak negative CD component is observed at 14870 cm^{-1} for both the *S*,*S*-edds and $(-)_{589}$-eddda complexes as shown in Fig. 2 and Table 1. Assuming pseudo D_3 symmetry for the complexes, the three CD peaks, (+) near 14300 cm^{-1}, (−) at 14870 cm^{-1}, and (+) near 15300 cm^{-1}, may be assigned to the $^2E(^2E_g)$, $^2A_2(^2T_{1g})$, and $^2E(^2T_{1g})$ states from the lower frequency side as in the case of $(+)_{546}$-[Cr(ox)$_2$(en)]$^-$.[1] The similar CD behavior is observed in the spin-forbidden transitions of the *S*,*S*-ptnta Cr(III) complex, except for the lowest-frequency CD component with a negative sign as shown in Fig. 2. That is, the positive CD peak at 14350 cm^{-1} corresponding to the lowest-frequency absorption peak of the *S*,*S*-ptnta complex and the positive highest-frequency CD peak may be due to the $^2E(^2E_g)$ and $^2E(^2T_{1g})$ states, respectively, as for the *S*,*S*-edds and $(-)_{589}$-eddda complexes. In the region corresponding to the $^2A_2 \leftarrow {}^4A_2$ transition, three weak CD peaks with alternate signs are observed for the *S*,*S*-ptnta complex. In view of these CD behavior, it appears that the correlation between the CD in the spin-forbidden transitions and the absolute configurations for tris-chelate complexes[1] holds also for the present complexes; the complexes giving two $^2E(D_3)$ CD components with a positive sign take a $\Lambda(\Lambda\Lambda\Lambda)$ configuration. From a theoretical point of view,[1] the rotatianal strengths for the $^2E(^2E_g) \leftarrow {}^4A_2$ transition and those for the $^2E(^2T_{1g}) \leftarrow {}^4A_2$ transition in trigonal field are predicted to have the same signs as the net rotational strengths for the $^4T_{2g} \leftarrow {}^4A_{2g}$ transitions and the rotational strengths for the $^4E(^4T_{2g}) \leftarrow {}^4A_2$ transition, respectively. In the case of the *S*,*S*-edds and *S*,*S*-ptnta complexes, such a theoretical relation for the rotational strengths in trigonal field is applicable to CD in the region of the $^2E(^2E_g)$ and $^2E(^2T_{1g}) \leftarrow {}^4A_2$ transitions, because the net CD signs in the first band region and the signs of the $^4B(C_2)$ CD component with ^4E trigonal parentage are positive. The CD of $(-)_{589}$-[Cr(eddda)]$^-$, however, does not follow this relation, since this complex gives a major negative CD band in the first band region, which is presumed to result in the sign inversion of the lowest-frequency CD in the spin-forbidden transitions. Assuming tetragonal symmetry for the complexes, the theoretical relation predicts[2] that the positive highest-frequency CD peak near 15300 cm^{-1} is due to the $^2A_2(^2T_{1g})$ state and the lower frequency one near 14300 cm^{-1} to the $^2A_1(^2E_g)$ or $[^2A_1+{}^2B_1](^2E_g)$ state; the rotational strengths for the $^2A_2$ and $^2A_1 \leftarrow {}^4B_1$ transitions being borrowed from those for the $^4E(^4T_{2g}) \leftarrow {}^4B_1$ transition, and the sum of the rotational strengths for the $^2A_1$ and $^2B_1 \leftarrow {}^4B_1$ transitions from the net one for the $^4T_{2g} \leftarrow {}^4A_{2g}$ transition. The remaining CD peaks may correspond to the $^2E(^2T_{1g})$ state. For $(-)_{589}$-[Cr(eddda)]$^-$, the assignment of the lowest-frequency CD peak to the $[^2A_1+{}^2B_1](^2E_g)$ state is questionable as in the case of the trigonal assumption as mentioned before, because the CD sign of this component is opposite to that of the major component in the first band region. Such a failure of the theoretical relations for the CD in the d-d transitions may be explained by the following approach.

The CD pattern in the spin-forbidden transitions of the *S*,*S*-edds complex is similar as a whole to that of the $(-)_{589}$-eddda complex despite the different CD patterns at the higher frequency side of the first band for these complexes as in Figs. 1 and 2. This fact suggests that the rotational strengths for the spin-forbidden transitions are little affected by those for the higher-frequency components of the $^4T_{2g} \leftarrow {}^4A_{2g}$ transitions but are dominantly borrowed from those for the lowest-frequency $^4B(C_2)^4T_{2g}(O_h) \leftarrow {}^4B(C_2)^4A_{2g}(O_h)$ transition. This intensity borrowing mechanism may be ascribed mainly to the difference in energy intervals between the doublet states and the quartet excited states as has been considered for the elucidation of CD in the spin-forbidden transitions of *trans*-[CrX$_2$(N)$_4$] type complexes.[2] This mechanism is supported by the fact that the CD intensities of the spin-forbidden bands for the present complexes increase in the order of increasing the lower-frequency shift of the lowest-frequency $^4B(C_2)$ CD component as shown in Figs. 1, 2, and Table 1. In such a situation, the contribution to the CD intensities of the spin-forbidden bands from the CD intensity of the negative major spin-allowed band of $(-)_{589}$-[Cr(eddda)]$^-$ is estimated to be only one-half that from the CD intensity of the positive lowest frequency band in the first band region. Therefore, it is probable that the relatively strong CD intensities of two

positive peaks near 14300 and 15300 cm^{-1} are accounted for by the dominant contribution from the CD intensity of the positive lowest frequency $^4B(C_2)$ component. And the minor contribution from the CD intensity of the negative higher-frequency band in the first band region may be responsible for the weakness of the CD peaks near 15000 cm^{-1}. However, the following consideration for the $^2E(^2T_{1g})$ state suggests that the assignment of the negative CD peaks near 15000 cm^{-1} to the electronic transitions is doubtful.

At the lowest frequency side in the spin-forbidden absorption band region for the *S,S*-ptnta complex, a negative CD peak is observed as in Fig. 2. The assignment for this CD component is attempted as follows. On the one hand, this CD peak is assumed to correspond to one of the splitting components of the ^2E_g state which arise from the interplay of the spin-orbit coupling and trigonal field,[13] as in the case of $(+)_{546}$-$[Cr(acac)_2(en)]^+$ and $(-)_{589}$-$[Cr(biguanide)_3]^{3+}$.[1] Then, provided that two positive lower-frequency CD components and a negative higher-frequency one are assigned to the $^4E(D_3)$ and $^4A_2(D_3)$ states, respectively, for the present complex, it may be predicted by the use of Eq. 6 and Table 2 of Ref. 1 that the CD components of the $^2E(^2E_g)$ splitting states, $\bar{E}$ and $2\bar{A}$, have positive and negative sings, respectively, and locate in this order from the lower frequency side. For the *S,S*-ptnta complex, however, this predicted CD pattern is reverse to the observed one. Thus, the lowest-frequency CD peak of this complex may not be assigned to one of the splitting components of the ^2E_g state.

On the other hand, the assumption of the holohedrized tetragonal symmetry for this complex makes alternative assignments possible. In this case, the positive lower-frequency and the negative higher-frequency CD components in the first band region are due to the ^4E and $^4B_2$ states, respectively. From the detailed analyses of the low temperature spin-forbidden absorption and luminescence spectra of $Na[Cr(ida)_2]\cdot 1.5H_2O$ (ida^{2-}=iminodiacetate),[12] it has been revealed that the $^2E(^2T_{1g})$ state is largely shifted to the lower frequency than the $^2A_1$ and $^2B_1(^2E_g)$ states. And this shift is considered to occur owing to the large configurational interaction between the $^2E(^2T_{1g})$ and $^2E(^2T_{2g})$ states as in the case of *trans*-$[CrF_2(en)_2]ClO_4$.[14] The present *S,S*-ptnta complex has the identical chromophore to the bis(iminodiacetato)chromate(III) complex except that two ida^{2-} ligands are joined by a 1,3-dimethyltrimethylene linkage. The doublet states for the *S,S*-ptnta complex are expected to behave similarly to the bis-ida complex as has been revealed from the magnetic circular dichroism measurements of several Cr(III) complexes with edta analogues.[15] Accordingly, the lowest-frequency CD component with a negative sign may be assigned to the $^2E(^2T_{1g})$ state in tetragonal field, though the position of this CD peak is shifted to the higher frequency than that of the absorption and phosphorescence bands.[12] The negative sign of this CD peak is elucidated by taking into account both the configurational interaction between the upper $^2E(^2T_{2g})$ and the lower $^2E(^2T_{1g})$ states and the strong spin-orbit coupling between the $^2E(^2T_{2g})$ state and the nearby $^4B_2(^4T_{2g})$ state, which may give rise to the splitting of the negative CD peaks near 22000 cm^{-1} as shown in Fig. 1. Then, the $^2E(^2T_{1g})\leftarrow{}^4B_1(^4A_{2g})$ transition attains the negative rotational strength by acquiring a piece of the negative rotational strength for the $^4B_2(^4T_{2g})\leftarrow{}^4B_1(^4A_{2g})$ transition to a larger extent than a piece of the positive rotational strength for the $^4E(^4T_{2g})\leftarrow{}^4B_1(^4A_{2g})$ transitions as has been found for the CD of *trans*-$[CrX_2(N)_4]$ type complexes with chiral diamines.[2] Thus, the assignments of these CD components to the electronic transitions suggest that the remaining weak CD peaks are due to the vibronic origin rather than the electronic one.

In conclusion, the CD behavior in the whole region of the spin-forbidden transitions for $(+)_{589}$-$[Cr(S,S\text{-ptnta})]^-$ and related complexes is elucidated on the tetragonal symmetry assumption more consistently than on the trigonal one as summarized in Table 1.

The authors wish to express their thanks to Prof. Yoichi Shimura, Osaka University, for his kind guidance and continuous encouragement throughout this work and also for making the circular dichroism and infrared spectra available for the present work.

Kinetics and Mechanism of Reduction of Hexacyanoferrate(III) by Sodium Tetrahydroborate

Mitra BHATTACHARJEE, Apurba K. BHATTACHARJEE, and Mahendra K. MAHANTI*

Department of Chemistry, North-Eastern Hill University, Shillong 793003 (Meghalaya), India

(Received January 20, 1981)

A kinetic investigation of the reduction of hexacyanoferrate(III) by sodium tetrahydroborate in buffered aqueous solution has been carried out. The rate of the reaction is proportional to the concentration of both, tetrahydroborate and hydrogen ions. The effect of the addition of some inorganic salts has been studied. The temperature has been varied, and the Arrhenius parameters have been evaluated. The rate of hydrolysis of tetrahydroborate has been separately studied. It has been observed that the activation energies for both the reactions—the reduction of hexacyanoferrate(III) and the hydrolysis of tetrahydroborate—are equal. A plausible mechanism for the reduction of hexacyanoferrate(III) has been proposed.

Sodium tetrahydroborate in water or methanol solution was found to be an effective reagent for the conversion of aldehydes and ketones to the corresponding alcohols.[1] The rate of reduction of ketones by sodium tetrahydroborate in isopropyl alcohol as solvent was found to follow second order kinetics.[2] It was though worthwhile to investigate the kinetics of reduction of hexacyanoferrate(III) ions by using this versatile reducing agent, $NaBH_4$, and to propose a mechanism consistent with the observed kinetic data. The decomposition of $NaBH_4$ as a function of time and temperature was separately studied with a view to support the mechanism proposed for this reaction.

Experimental

Materials. Sodium tetrahydroborate (Loba Chemical Co.) was kept under vacuum. The purity of $NaBH_4$ was checked by infrared analysis. Two sharp peaks were obtained at 2290 cm^{-1} and 1120 cm^{-1}, both being characteristic for $NaBH_4$. These have been assigned[3] as follows:

(i) 2290 cm^{-1}: $(B\text{-}H)_{asym}$ stretching

(ii) 1120 cm^{-1}: $B\begin{smallmatrix}/H\\ \backslash H\end{smallmatrix}$ deformation.

The $(B\text{-}H)_{asym}$ stretching mode was further split (2380 cm^{-1} and 2220 cm^{-1}). It has been suggested that the splitting was a consequence of the inability of the tetrahedral anion to rotate freely in the crystal lattice.[4]

All other substances used were of BDH(AR) grade.

Methods. Sodium tetrahydroborate was weighed out accurately and the solution was prepared in sodium hydroxide, whose strength had been determined. Potassium hexacyanoferrate(III) was weighed out accurately and the solution was prepared in sodium hydroxide. The pH of each solution was checked using a pH meter (Toshniwal, digital model). The two solutions were separately thermostated at 25 °C for 3 h. The solutions were then mixed in equal volumes, and the reaction was followed by observing the disappearance of hexacyanoferrate(III). Readings were taken at regular intervals of time, by noting the decrease in optical density at 420 nm,[5] using a spectrophotometer (Systronics, Mk II model). At this wave length, the absorption due to hexacyanoferrate(II) was negligible.[6] The pH of the reaction mixture was checked periodically, during the course of the reaction.

All infrared measurements were carried out using an IR 297 (Perkin-Elmer) spectrophotometer.

Product Analysis. Sodium tetrahydroborate (5×10^{-2} M†) in NaOH (1×10^{-2} M), and potassium hexacyanoferrate(III) (5×10^{-4} M) in NaOH (1×10^{-2} M), were mixed in equal volumes. The mixture was allowed to stand at room temperature for 48 h to ensure the completion of the reaction. The reaction mixture was slowly evaporated in a porcelain dish to near dryness; it was then digested with concentrated HCl and again evaporated to dryness to obtain the residue. The residue was recrystallized from hot water.

A small portion of the recrystallized product was taken in a porcelain dish, mixed with a small amount of concentrated H_2SO_4 to make a paste. About 3 ml of absolute methanol was added. The solution was heated and the vapours ignited. A green-edged flame was obtained, confirming the presence of the borate radical in the residue.

An infrared spectrum of the product sample was taken and compared with the infrared spectrum of a pure boric acid sample. Both the samples were found to be identical. This confirmed that the residue was boric acid.

Results and Discussion

Stoichiometry. The stoichiometry of the reaction was confirmed from colorimetric measurements in the following manner: reaction mixtures containing an excess of hexacyanoferrate(III) were allowed to go to completion, and then analyzed, spectrophotometrically, for the hexacyanoferrate(III) which was left. The results gave a 1:8 ratio according to

$$BH_4^- + 8Fe(CN)_6^{3-} + 2H_2O \longrightarrow BO_2^- + 8Fe(CN)_6^{4-} + 8H^+.$$

Kinetic Results. The rate of disappearance of hexacyanoferrate(III) was first order in each, the tetrahydroborate and hydrogen ions.

Effect of Tetrahydroborate. The rate of the reaction was found to be directly proportional to the concentration of BH_4^- ions. A plot of log k_1 *versus* the concentration of BH_4^- ions was linear, confirming the first order dependence of the reaction on the concentration of BH_4^- ions (Fig. 1).

Effect of Hydrogen Ions. The reaction was studied at varying pH. The rate of the reaction was found to vary as a function of the hydrogen ion concentration. The logarithm of the rate of disappearance of hexacyanoferrate(III) divided by BH_4^- ion concentration was plotted against pH. The plot was

† 1 M = 1 mol dm^{-3}.

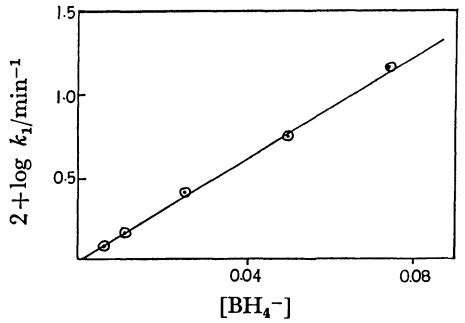

Fig. 1. Plot of logarithm of rate constant (k_1) *versus* the concentration of [BH_4^-].

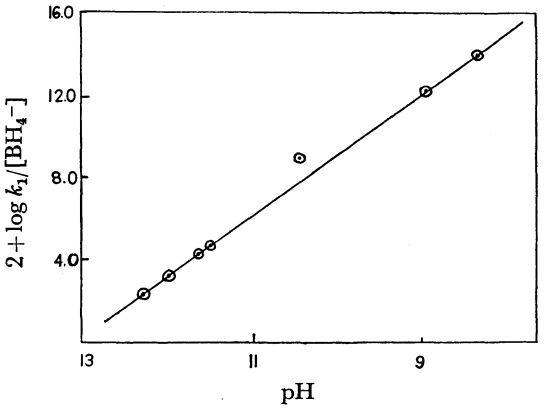

Fig. 2. Plot of logarithm of rate constant (k_1) divided by concentration of [BH_4^-] *versus* pH.

linear, with a slope equal to unity (Fig. 2). This indicated a first order dependence of the reaction on the hydrogen ion concentration.

Effect of Hexacyanoferrate(III). The rate of the reaction was found to be independent of the concentration of hexacyanoferrate(III) ions in the range studied, from 1.0×10^{-4} M to 5.0×10^{-3} M (Table 1).

Effect of Hexacyanoferrate(II). The addition of hexacyanoferrate(II) ion to the reaction mixture resulted in a decrease in the rate of the reaction (Table 2). This decrease in the rate might suggest the possibility of an equilibrium being attained between the hexacyanoferrate(III) and the hexacyanoferrate(II). In the reaction of As(III) with hexacyanoferrate(III) in alkaline medium,[7] added hexacyanoferrate(II) was found to retard the rate of the reaction. In the reaction of mercaptoacetic acid with hexacyanoferrate(III)

12.5	1.07

Hexacyanoferrate(III) = 2.5×10^{-4} M; [BH_4^-] = 8×10^{-3} M; NaOH = 1×10^{-2} M; pH = 11.50; Temp = 25 °C.

in acid medium,[8] a similar retardation was also observed when hexacyanoferrate(II) was added to the reaction mixture.

Effect of Copper(I) Ions. The addition of copper(I) ions to the reaction mixture resulted in a decrease in the rate of the reaction (Table 3).

The choice of copper(I) ions was appropriate, since under the present experimental conditions, there was no possibility of further reduction of the copper(I) ions by the BH_4^- ion. The retardation in the rate of the reaction thus observed may be due to the formation of copper(I) tetrahydroborate ($CuBH_4$), which is stable at −12 °C, but undergoes decomposition at higher temperatures. At 25 °C, the $CuBH_4$ formed would be unstable and would undergo decomposition.

Effect of Added Salts. Potassium, rubidium, and caesium are known to form simple tetrahydroborates, $M(BH_4)_n$, which are stable or decompose only very slowly. The stability of these tetrahydroborates is in the order K<Rb<Cs, and can be related to two factors: (a) the electronegativities of the metal atom of the salts added (K, Rb, Cs), which are much lower than that of boron; and (b) the percentage ionic character. The greater the ionic character, the more stable will be the metal tetrahydroborate.

It is to be expected that the rates would follow the order of stability of these metal tetrahydroborates. This has been observed (Table 4).

Effect of Temperature. The reaction has been studied over the temperature range 25 °C to 55 °C. The rate of the reaction was found to be directly dependent on the temperature, the rate showing an increase with an increase in temperature (Table 5). The plot of log k_1 *versus* the reciprocal of temperature was linear, and the slope was used to calculate the activation energy. The Arrhenius parameters have been calculated and are shown in Table 6. The

Table 4. Effect of added salts

Hexacyanoferrate(III)$=2.5\times10^{-4}$ M; $[BH_4^-]=8\times10^{-3}$ M; NaOH$=1\times10^{-2}$ M; pH$=11.50$; Temp$=25$ °C.

Table 5. Effect of temperature

Temp/°C	$10^2 k_1$/min^{-1}
25	4.54
30	4.97
35	5.55
45	6.58
55	7.37

Hexacyanoferrate(III)$=2.5\times10^{-4}$ M; $[BH_4^-]=8\times10^{-3}$ M; NaOH$=1\times10^{-2}$ M; pH$=11.50$.

Table 6. Arrhenius parameters

Energy of activation (E_a)	$=19.14$ kJ mol^{-1}
Frequency factor (A)	$=1.59$ s^{-1}
Entropy of activation (ΔS)	$=-241.4$ J K^{-1} mol^{-1}
Enthalpy of activation (ΔH)	$=19.14$ kJ mol^{-1}

reaction has a large negative entropy of activation. Qualitatively, this would imply a lowering of the potential energy of the transition state. This would enable the facile formation of the transition state. Moreover, a large negative entropy of activation would correspond to a very low frequency factor; this has been observed for the reaction.

Decomposition of $NaBH_4$ as a Function of Time. It was thought appropriate to study the decomposition of $NaBH_4$, as a function of time. This would enable the determination of the rate of hydrolysis of $NaBH_4$ and would also throw some light on the probable mechanistic pathway of the hydrolytic reaction.

$NaBH_4$ (0.05 M) was prepared in water, and the solution was kept at 25 °C. At definite intervals of time, 5 ml aliquots of this solution were removed, and mixed with 5 ml of a solution of hexacyanoferrate(III) (5.0×10^{-4} M) in NaOH (2.0×10^{-2} M), also maintained at 25 °C. The reaction was followed by measuring the decrease in optical density at 420 nm. The rate constant (k_1) was determined, and the concentration of BH_4^- was calculated from the equation:

$$-\frac{d[Fe(CN)_6^{3-}]}{dt} = k_1[BH_4^-].$$

A plot of log C (concentration of BH_4^- ions) *versus* time was found to be linear, which indicated a first order dependence of the reaction on BH_4^- ion concentration.

The reaction was repeated at different temperatures, and the rate constant at each of these temperatures was calculated. The data are given in Table 7.

A plot of log k_1 *versus* the reciprocal of temperature was linear, and the slope was used to calculate the activation energy. The activation energy for the hydrolysis of $NaBH_4$ was found to be 19.14 kJ mol^{-1}. For the reaction involving the reduction of hexacyanoferrate(III) by $NaBH_4$, the value of the activation energy was also found to be 19.14 kJ mol^{-1} (Table 6).

Table 7. Decomposition of $NaBH_4$ as a function of time and temperature

	90	13.60	3.40

Hexacyanoferrate(III)$=2.5\times10^{-4}$ M; NaOH$=1\times10^{-2}$ M.

Mechanism

Since the rate of the reaction is proportional to the concentrations of both, tetrahydroborate and hydrogen ions, the chemical composition of the activated complex can be written as $H^+BH_4^-$.

The first step of the reaction is:

$$BH_4^- + H^+ \xrightarrow{k_1} H^+BH_4^-. \quad (1)$$

A kinetic scheme consisting of Eq. (1), followed by consecutive steps involving hexacyanoferrate(III) could be used as a basis to explain the experimental results. Each boron intermediate could react with either a hexacyanoferrate(III) ion or with a hydrogen producing species such as water.

The reaction could be represented by the following sequence of steps:

$$BH_4^- + H^+ \longrightarrow H^+BH_4^-,$$
$$H^+BH_4^- + 2Fe(CN)_6^{3-} + H_2O \longrightarrow BH_3OH^- + 2Fe(CN)_6^{4-} + 3H^+,$$
$$BH_3OH^- + 2Fe(CN)_6^{3-} \longrightarrow BH_2OH + 2Fe(CN)_6^{4-} + H^+,$$
$$BH_2OH + Fe(CN)_6^{3-} + H_2O \longrightarrow BH(OH)_2^- + Fe(CN)_6^{4-} + 2H^+,$$
$$BH(OH)_2^- + Fe(CN)_6^{3-} \longrightarrow BH(OH)_2 + Fe(CN)_6^{4-},$$
$$BH(OH)_2 + 2Fe(CN)_6^{3-} \longrightarrow BO_2^- + 2Fe(CN)_6^{4-} + 3H^+.$$

The overall stoichiometric reaction would then be:

$$BH_4^- + 8Fe(CN)_6^{3-} + 2H_2O \longrightarrow BO_2^- + 8Fe(CN)_6^{4-} + 8H^+.$$

The rate law could be expressed as

$$-\frac{d[Fe(CN)_6^{3-}]}{dt} = k_1[BH_4^-][H^+].$$

It has been found that for this reaction, k_1 has the frequency factor of 1.59 s^{-1}, and an activation energy of 19.14 kJ mol^{-1}.

The essential feature of this mechanism is that any given intermediate reacts only with a hydrogen producing species, or else with hexacyanoferrate(III). There is thus no competition for a given intermediate.

Further support of this mechanism is found from the rate measurements of the hydrolysis of BH_4^- ion, in the absence of hexacyanoferrate(III). The mechanism for the hydrolysis may be represented by:

$$BH_4^- + H^+ \longrightarrow H^+BH_4^-$$

followed by hydrogen yielding steps of the type:

(a) $BH_2OH + H_2O \longrightarrow BH(OH)_2 + H_2$,

(b) $2BH_2OH + 2H_2O \longrightarrow 2BH(OH)_2^- + 2H^+ + H_2$,

(c) $BH(OH)_2 + H_2O \longrightarrow H_3BO_3 + H_2$.

This mechanism would predict

$$-\frac{d[BH_4^-]}{dt} = k_1[BH_4^-][H^+].$$

The rate of hydrolysis of $NaBH_4$ was measured and it was found that the rate constant, k_1, corresponds to an activation energy of 19.14 kJ mol^{-1}. This was in agreement with the value determined from the kinetic studies, in the presence of hexacyanoferrate(III).

Intermediate Boron Compounds. The intermediate boron compounds, described in the reaction sequence, could not be isolated. However, there is evidence for the existence of such intermediates from the reaction of diborane with ice and with the "bound water" in silica gel.[9]

These intermediates differ in reducing capacity, and the formulas of the boron intermediates used are primarily intended to show the reducing capacity of the intermediate.

Consider the following steps:

(a) $BH_2OH + Fe(CN)_6^{3-} + H_2O \longrightarrow BH(OH)_2^- + Fe(CN)_6^{4-} + 2H^+$

and

(b) $2BH_2OH + 2H_2O \longrightarrow 2BH(OH)_2^- + 2H^+ + H_2$.

These steps describe a one-electron oxidation by hexacyanoferrate(III) and water respectively, to give the intermediate $BH(OH)_2^-$, which has three equivalents of reducing capacity.

Again, consider the following steps:

(a) $BH_2OH + 2Fe(CN)_6^{3-} + H_2O \longrightarrow BH(OH)_2 + 2Fe(CN)_6^{4-} + 2H^+$

and

(b) $BH_2OH + H_2O \longrightarrow BH(OH)_2 + H_2$.

These steps involve a two-electron oxidation to give $BH(OH)_2$, which has a two-electron reducing capacity

(Received January 5, 1981)

The title compound, serving as intermediate in the chemical and biochemical synthesis of glycopeptides and as a reference substance in the structure elucidation of glycoproteins, was synthesized. 2-Acetamido-4-*O*-allyl-3,6-di-*O*-benzyl-2-deoxy-β-D-glucopyranosyl azide was reduced to the corresponding β-D-glucosylamine and coupled with 1-benzyl *N*-benzyloxycarbonyl-L-aspartate to give 2-acetamido-4-*O*-allyl-3,6-di-*O*-benzyl-*N*-[(*S*)-3-benzyloxycarbonyl-3-benzyloxycarbonylamino)propionyl]-2-deoxy-β-D-glucopyranosylamine. Removal of the allyl group of the latter followed by condensation with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide gave the fully protected *N*-acetyllactosaminyl-L-asparagine. De-blocking of the *O*-acetyl, benzyl, and benzyloxycarbonyl groups gave the title compound.

Carbohydrate chains attached to protein and to lipid moieties are known to be antigenic both at the surface of bacterial and mammalian cells. The role of carbohydrate in antigenic components at the surface of erythrocytes has been well established for the ABO and MN-antigen systems and suggested for I, P, and T-antigen systems.[1] Carbohydrate chains are also components of the cancer cells[2] and transplantation antigens.[3]

In view of these facts and the interest in (a) studying the inhibition of lectins in relation to the structure of receptor sites[4–6] and (b) structural indentification by gas-liquid chromatography combined with mass spectrometry,[7] a research program has been launched for the synthesis of antigenic oligosaccharides,[8] glycopeptides,[9] and isoprenoid sugar phosphates.[10]

The synthesis of *N*-acetyllactosaminyl-L-asparagine has been undertaken as a part of this program and because 2-amino-2-deoxy-4-*O*-β-D-galactopyranosyl-D-glucose (lactosamine) is the determinant group in the antigenic, Type XIV pneumococcus polysaccharide.[11] The synthesized glycopeptide may also be used as a starting material for the synthesis[9,12] and biosynthesis of larger glycopeptides.

Results and Discussion

In synthesizing *N*-acetyl-D-glucosamine-containing glycopeptides[12–17] it has been shown that derivatives of 2-acetamido-2-deoxy-β-D-glucopyranosyl azide[18] were the most convenient starting materials since they are stable, crystalline, and can be transformed, under mild conditions, into β-D-glucopyranosylamine derivatives ready for coupling with amino acids. In addition, β-D-glycosyl azides showed no sign of changing their anomerization throughout reduction and coupling.[17,19,20]

Taking these facts into consideration while designing a synthetic pathway for the title compound, one of three possible approaches may be adopted (a) starting with *N*-acetyllactosamine and going through the α-glycosyl halide, β-glycosyl azide, β-glycosylamine, and finally *N*-acetyllactosaminyl-L-asparagine; (b) Koenigs-Knorr condensation of α-D-galactosyl halide with a suitably protected 2-acetamido-2-deoxy-β-D-glucopyranosyl azide, followed by reduction of the azido group and coupling with aspartic acid; and (c) Koenigs-Knorr condensation of a suitably blocked 2-acetamido-2-deoxy-β-D-glucopyranosylamine-L-aspartic acid derivative with α-D-galactopyranosyl halide. The first approach suffers the disadvantages of the inavailability of *N*-acetyllactosamine, and the possible splitting of the glycosidic linkage during the preparation of the glycosyl halide.[16,17] Executing either of the two other alternatives requires the synthesis of a 2-acetamido-2-deoxy-β-D-glucopyranosyl azide blocked at positions 3 and 6 and having the 4-hydroxyl group available for Koenigs-Knorr condensation.

Previous work[21–23] has shown that the 4-hydroxyl group in 2-acetamido-2-deoxy-D-glucopyranosyl residues is not reactive in the Koenigs-Knorr reaction, and that, when both 4- and 6-hydroxyl groups are free, this reaction occurs exclusively at *O*-6.[22,23] Recourse to open chain intermediates[24] was necessary to prepare (1→4) linked *N*-D-glucosamine-containing oligosaccharides.[8,24–26] Although 2-acetamido-3,6-di-*O*-acetyl-2-deoxy-D-glucopyranosyl derivatives showed no reactivity at the 4-hydroxyl group, benzyl 2-acetamido-3,6-di-*O*-benzyl-2-deoxy-α- and β-D-glucopyranosides[8,27] were successfully condensed to give (1→4) linked oligosaccharides.[8,28] We decided, therefore, to prepare 2-acetamido-3,6-di-*O*-benzyl-2-deoxy-β-D-glucopyranosyl azide (**14**) as a suitable substrate for Koenigs-Knorr condensation with α-D-galactosyl halide to give β-*N*-acetyllactosaminyl azide.

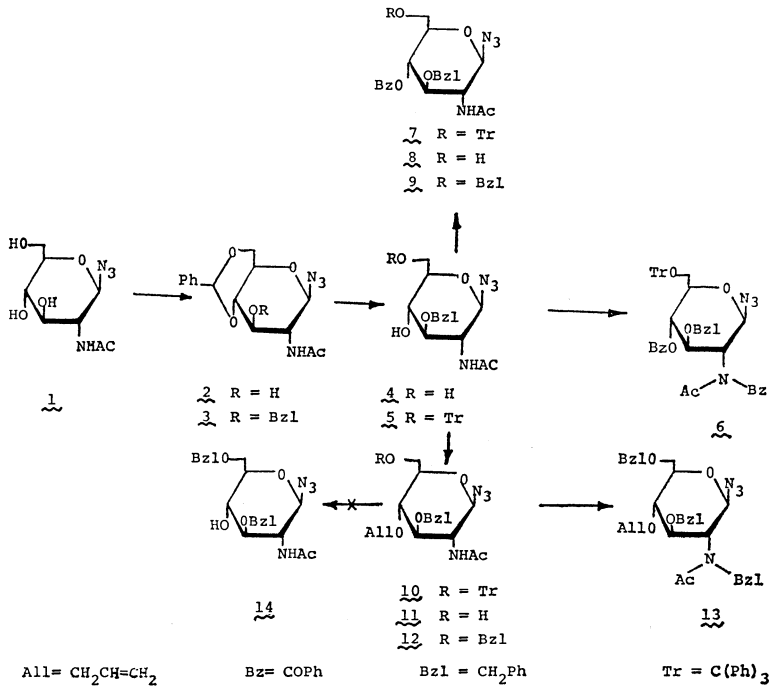
2-Acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranosyl azide[13] (**2**) was prepared by a modified method in which 2-acetamido-2-deoxy-β-D-glucopyranosyl azide[18] (**1**) was treated with benzaldehyde and anhydrous formic acid as a dessicant instead of

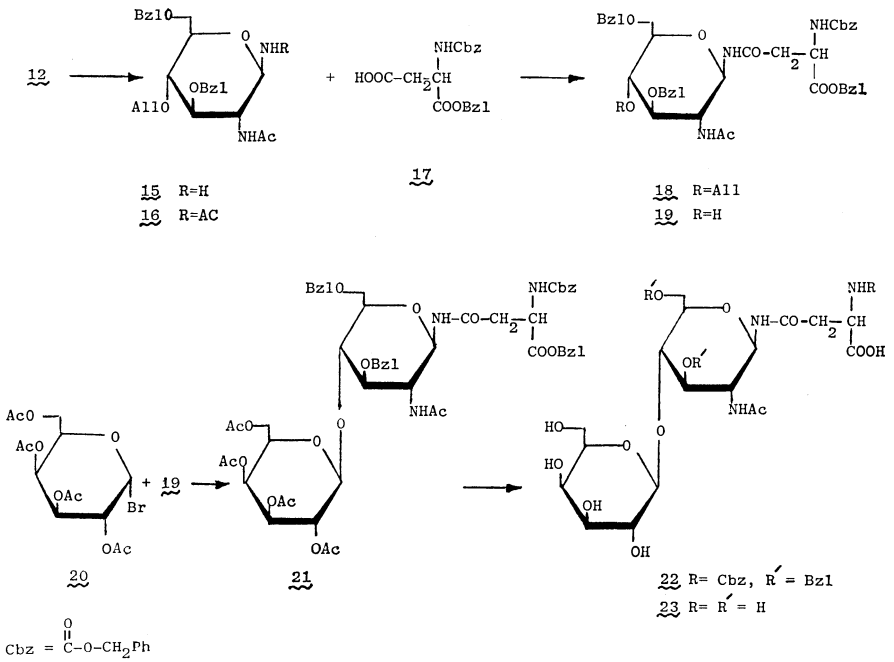
† Present address: Department of Chemistry, Faculty of Science, King Abdul Aziz University, Jeddah, P.O. Box 9028, Saudi Arabia.

the usually used anhydrous zinc chloride. Benzylation of **2** with benzyl bromide in *N,N*-dimethylformamide and in the presence of a mixture of barium hydroxide and barium oxide, gave the 3-*O*-benzyl derivative **3**. Removal of the 4,6-*O*-benzylidene group was achieved by heating with 60% acetic acid to give **4**, which was tritylated to afford **5**. An attempt to prepare 2-acetamido-4-*O*-benzoyl-3-*O*-benzyl-2-deoxy-6-*O*-triphenylmethyl-β-D-glucopyranosyl azide (**7**) by benzoylating **5** with benzoyl chloride in the presence of pyridine at room temperature resulted in *N*- and *O*-benzoylation to give **6**. *O*-Benzylation, however, could be effected when the reaction was performed at −70 °C and in the presence of a limited amount of benzoyl chloride to give **7** in good yield (78%). Detritylation of **7** with hydrochloric acid in aqueous methanol for 4 h at room temperature gave **8**. Attempted conversion of 2-acetamido-4-*O*-benzoyl-3-*O*-benzyl-2-deoxy-β-D-glucopyranosyl azide (**8**) to 2-acetamido-4-*O*-benzoyl-3,6-di-*O*-benzyl-2-deoxy-β-D-glucopyranosyl azide (**9**) by benzylation with benzyl bromide and silver oxide, according to the method described by Sinaÿ[27] for a similar derivative, gave a mixture difficult to separate either by chromatography or fractional crystallization. This result, together with a previous similar one,[8] may be attributed to the partial migration of the 4-*O*-benzoyl group under the slightly alkaline conditions of the reaction.

Consequently, a new route for the synthesis of 2-acetamido-3,6-di-*O*-benzyl-β-D-glucopyranosyl azide (**14**) was contrived with intermediates containing the *O*-allyl protective group[29,30] instead of the benzoyl group. Allylation of **5** with allyl bromide and sodium hydroxide in benzene for 72 h gave 2-acetamido-4-*O*-allyl-3-*O*-benzyl-2-deoxy-6-*O*-triphenylmethyl-β-D-glucopyranosyl azide (**10**) in 77% yield. However, the reaction could be expedited (5 h) and the yield improved (89%) by carrying out the allylation in *N,N*-dimethylformamide. Detritylation of **10** with 60% acetic acid gave 2-acetamido-4-*O*-allyl-3-*O*-benzyl-2-deoxy-β-D-glucopyranosyl azide (**11**). Benzylation of the latter with benzyl bromide in *N,N*-dimethylformamide and in the presence of sodium hydroxide gave the expected *O*-benzylated product **12** in addition to the *O*- and *N*-benzylated product **13** in a 1 : 1.7 ratio. Attempted removal of the 4-*O*-allyl group of **12** by isomerization with tris(triphenylphosphine)-rhodium chloride in the presence of 1,4-diazabicyclo-[2.2.2]octane[8,31,32] followed by splitting of the resulting *O*-1-propenyl group with mercury(II) chloride,[8,33] failed giving a complex mixture of highly polar compounds devoid of the azido group. This may be attributed to the reaction of the azido group with the rhodium triphenylphosphine complex to give glycosylphosphinimines.[34,35] It was necessary, therefore, to reduce the azido group of **12**, and coupling the resulting glycosylamine with L-aspartic acid prior to the removal of the 4-*O*-allyl group.

The commonly used method[12–17] of reducing glycosyl azides by hydrogenation in the presence of Adam's catalyst, would be unsuitable for reducing compound **12** as it would lead to indiscriminate reduction of the azido and allyl groups. Saturation to *O*-propyl groups deprive the *O*-allyl groups their desirable selective removal in the presence of *O*-benzyl groups. Sodium borohydride was attempted as a selective reductant of the azido group without affecting the *O*-allyl function. In methanol, no such reduction took place and compound **12** was recovered unchanged. In *N,N*-dimethylformamide, however, the reduction took place smoothly at room temperatures to give the unstable glycosylamine **15** which showed a positive ninhydrin reaction.[36] The amine **15** was characterized by acetylation into the stable and crystalline 2-acetamido-*N*-acetyl-4-*O*-allyl-3,6-di-*O*-benzyl-2-deoxy-β-D-glucopyranosylamine (**16**).





In order to prevent the formation of bis(glycosylamines),[17,19,37] the unstable amine **15** was used without further purification in the next step. Condensation of **15** with 1-benzyl-*N*-benzyloxycarbonyl-L-aspartate[38,39] (**17**) in the presence of dicyclohexylcarbodiimide gave crystalline 2-acetamido-4-*O*-allyl-3,6-di-*O*-benzyl-*N*-[(*S*)-3-benzyloxycarbonyl-3-(benzyloxycarbonylamino)propionyl]-2-deoxy-B-D-glucopyranosylamine (**18**) in 53% yield. Removal of the 4-*O*-allyl group of **18** using tris(triphenylphosphine)rhodium chloride and mercury(II)chloride gave crystalline **19**.

Koenigs-Knorr condensation of **19** with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide[40] (**20**) in the presence of mercury(II) cyanide gave the fully protected *N*-acetyllactosaminyl-L-asparagine **21**. Assigning the β-D-configuration to the D-galactopyranosyl residue was based on the result of a previous synthesis.[16] Treatment of **21** with lithium hydroxide removed the protective *O*-acetyl groups of the D-galactopyranosyl moiety and the benzyl ester of L-aspartic acid giving **22**. Hydrogenolysis of the *N*-benzyloxycarbonyl and *O*-benzyl groups of **22** gave the title compound **23**.

Experimental

General. Melting points were determined with a Mettler FP2 hot stage equipped with a microscope, and correspond to "corrected" melting points. Optical rotations were determined for solutions in 1-dm, semimicro tubes with a Perkin-Elmer Model 141 polarimeter. Infrared spectra were recorded, for potassium bromide discs or for thin film, with a Perkin-Elmer Model 237 spectrophotometer. Chloroform used was analytical grade and contained about 0.75% ethanol. All solvent mixtures used were v/v. Solvents were dried over molecular sieve (type 5A, Grade 522, 8—12 mesh, Fisher Scientific Co., Fairlawn, N. J.). The cation-exchange resin used was in at least two-fold over the quantity necessary to effect complete ion exchange. Evaporations were performed in a rotary evaporator under diminished pressure, with an outside bath-temperature kept below 40 °C. Solutions (<5 ml) were evaporated under a stream of nitrogen. The microanalyses were performed by Dr. M. Manser, Zurich, Switzerland.

Chromatographic Methods. Column chromatography on silica gel was performed on Silica gel Merck (10—325 mesh, E. Merck A. G., Darmstadt, Germany) used without pretreatment. The ratio of the diameter of the column to its length was 1:8 to 1:12. The volume of the fractions eluted was 2 to 3 ml/g of substance to be chromatographed. The proportion of weight of substance to weight of silica gel was 1:60 to 1:100. Thin-layer chromatography (TLC) was performed on plates precoated with Silica gel G (layer thickness 0.25 mm. Merck), the plates supplied were cut to a length of 6 cm before use, but otherwise they were used without pretreatment. The distance of solvent-travel was 5 cm and the zones were detected by spraying the chromatograms with 1:1:18 *p*-anisaldehyde–sulfuric acid–ethanol[40] following by heating on a hot plate for a few minutes.

2-Acetamido-4,6-O-benzylidene-2-deoxy-β-D-glucopyranosyl Azide (2). A suspension of 2-acetamido-2-deoxy-β-D-glucopyranosyl azide[18] (**1**) (1.88 g) in freshly distilled benzaldehyde (15 ml) was stirred for 5 min at room temperature and then treated with 99% formic acid (20 ml). After stirring for a further 30 min, the reaction mixture was cooled in an ice-bath and gradually neutralized with a saturated aqueous solution of potassium carbonate. The heterogeneous mixture was distilled under reduced pressure and the excess benzaldehyde removed by repeated co-distillation with water. The residue, which remained, was triturated with water, filtered, washed with water, and dried. Crystallization from methanol gave 1.95 g (76%) of **2** as needles, mp and mixed mp[13] 214—216 °C (dec).

2-Acetamido-3-O-benzyl-4,6-O-benzylidene-2-deoxy-β-D-glucopyranosyl Azide (3). A solution of **2** (1.4 g) in dry *N,N*-dimethylformamide (30 ml) was treated with benzyl bromide (1.3 ml), barium oxide (5 g), and barium hydroxide octahydrate (1.3 g) and the mixture was stirred for 2 h at room temperature. Chloroform (50 ml) was added and the mixture was heated under reflux for 2 h while stirring

and then filtered while hot. The inorganic residue was washed with hot chloroform (3×50 ml) and the filtrate and washings were evaporated to dryness. Crystallization of the residue from chloroform–methanol gave 1.45 g (82%) of **3** as needles, mp 224—225 °C (dec); $[\alpha]_D^{30}$ −30° (*c* 2.1, pyridine); ν_{max}^{KBr} 3290 (NH), 2130 (N_3), 1655 (Amide I), 1555 (Amide II), 750, 725, and 690 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol R_f 0.32. Found: C, 62.18; H, 5.71; N, 13.16; O, 18.70%. Calcd for $C_{22}H_{24}N_4O_5$: C, 62.25; H, 5.70; N, 13.20; O, 18.85%.

2-Acetamido-3-O-benzyl-2-deoxy-β-D-glucopyranosyl Azide (4). A suspension of **3** (1.06 g) in 60% acetic acid (50 ml) was heated for 2 h at 90—95 °C. The clear solution was evaporated under diminished pressure and the residue was dried by several co-distillations with toluene. Chromatography of the residue on a column of silica gel with 19:1 chloroform–ethanol gave 655 mg (78%) of **4**, which crystallized from methanol–chloroform–ether; mp 173—174 °C (dec); $[\alpha]_D^{20}$ −29° (*c* 2.24, methanol); ν_{max}^{KBr} 3350 (OH), 3290 (NH), 2130 (N_3), 1645 (Amide I), 1550 (Amide II), 730, and 690 cm^{-1} (Ph); TLC in 4:1 chloroform–ethanol R_f 0.52. Found: C, 53.47; H, 5.99; N, 16.71; O, 23.58%. Calcd for $C_{15}H_{20}N_4O_5$: C, 53.57; H, 5.99; N, 16.66; O, 23.78%.

2-Acetamido-3-O-benzyl-2-deoxy-6-O-triphenylmethyl-β-D-glucopyranosyl Azide (5). A solution of **4** (700 mg) in dry pyridine (30 ml) was treated with chlorotriphenylmethane (1.4 g) for 30 h at room temperature. The mixture was poured onto a mixture of ice (200 g) and potassium carbonate (5 g), and then extracted with chloroform (4×50 ml). The extracts were washed with water (3×50 ml), dried (K_2CO_3) and evaporated. The last traces of pyridine was removed by several additions and evaporations of toluene. The residue was chromatographed on a column of silica gel with 19:1 chloroform–ethanol containing 0.1% of triethylamine, to give 1.16 g (84%) of **5**, which crystallized from dichloromethane–carbon tetrachloride as needles, mp 116—118 °C; $[\alpha]_D^{20}$ −22° (*c* 2.3, chloroform); ν_{max}^{KBr} 3500 (OH), 3280 (NH), 2120 (N_3), 1650 (Amide I), 1550 (Amide II), 740, and 690 cm^{-1} (ph); TLC in 19:1 chloroform–ethanol, R_f 0.32. Found: C, 63.79; H, 5.27; N, 8.62; O, 12.13%. Calcd for $C_{34}H_{34}N_4O_5 \cdot CH_2Cl_2$: C, 63.99; H, 5.37; N, 8.29; O, 11.84%.

2-(N-Acetylbenzamido)-4-O-benzoyl-3-O-benzyl-2-deoxy-6-O-triphenylmethyl-β-D-glucopyranosyl Azide (6). A solution of **5** (800 mg) in dry pyridine (30 ml) was treated with benzyl chloride (2 ml) for 2 h at room temperature. The mixture was poured into an ice-cold solution of sodium hydrogencarbonate and then extracted with chloroform (4×50 ml). The chloroform extracts were washed with water (3×50 ml), and dried (K_2CO_3). Evaporation of the solvent and removal of the residual pyridine by several co-distillations with toluene gave a residue which was chromatographed on a column of silica gel with chloroform. Fractions containing **6** were evaporated and the residue crystallized from dichloromethane–ether–pentane as needles (863 mg; 91%), mp 154—157 °C; $[\alpha]_D^{23}$ −33.4° (*c* 2.3, chloroform); ν_{max}^{KBr} 2120 (N_3), 1725 (O. COPh), 1700 (N. COPh), 1670 (N. $COCH_3$), 745, and 690 cm^{-1} (Ph); TLC in chloroform R_f 0.54. Found: C, 73.23; H, 5.42; N, 7.15; O, 14.20%. Calcd for $C_{48}H_{42}N_4O_7$: C, 73.27; H, 5.38; N, 7.12; O, 14.23%.

2-Acetamido-4-O-benzoyl-3-O-benzyl-2-deoxy-6-O-triphenylmethyl-β-D-glucopyranosyl Azide (7). A solution of **5** (664 mg) in dry pyridine (10 ml) was cooled to −70 °C and treated with a 14% (w/v) solution (1 ml) of benzoyl chloride in dry benzene. The mixture was kept at −20 °C for 16 h and then treated with a few drops of methanol, evaporated, and the residual pyridine removed by repeated addition and distillation of toluene. The syrupy residue which obtained could not be crystallized, and it was, therefore, chromatographed on a column of silica gel with 19:1 chloroform–ethanol to give 532 mg (78%) of **7**. It crystallized from dichloromethane–ether as needles, mp 169—170 °C; $[\alpha]_D^{20}$ +0.5° (*c* 2.8, chloroform); ν_{max}^{KBr} 3280 (NH), 2130 (N_3), 1730 (O. COPh), 1655 (Amide I), 1550 (Amide II), 740, and 680 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol R_f 0.38. Found: C, 72.10; H, 5.54; N, 8.12; O, 14.14%. Calcd for $C_{41}H_{38}N_4O_6$: C, 72.12; H, 5.61; N, 8.20; O, 14.06%.

2-Acetamido-4-O-benzoyl-3-O-benzyl-2-deoxy-β-D-glucopyranosyl Azide (8). A solution of **7** (1.9 g) in methanol (75 ml) was treated with 2 M hydrochloric acid until the mixture becomes just turbid (about 10 ml) and kept for 4 h at room temperature. The mixture was diluted with cold water (200 ml), extracted with chloroform (5×75 ml), and the extracts were washed with water (2×50 ml), saturated sodium hydrogencarbonate solution (2×50 ml), and water (3×50 ml), dried (Na_2SO_4), and evaporated. The residue was chromatographed on a column of silica gel with 9:1 chloroform–ethanol, to give 1.03 g (84%) of **8**, which crystallized from dichloromethane–ether; mp 178—190 °C (dec); $[\alpha]_D^{20}$ −28° (*c* 2.0, chloroform); ν_{max}^{KBr} 3480 (OH), 3280 (NH), 2130 (N_3), 1720 (O. COPh), 1655 (Amide I), 1550 (Amide II), 745, and 700 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol, R_f 0.20, and in 9:1 chloroform–ethanol, R_f 0.40. Found: C, 60.06; H, 5.49; N, 12.76; O, 21.98%. Calcd for $C_{22}H_{24}N_4O_6$: C, 59.99; H, 5.49; N, 12.72; O, 21.79%.

Attempted Synthesis of 2-Acetamido-4-O-benzoyl-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranosyl Azide (9). Compound **8** (500 mg) in anhydrous benzene (30 ml) was treated with benzyl bromide (1.5 ml) and silver oxide (700 mg) and the mixture stirred for 24 h at 60—70 °C in the dark. After cooling to room temperature, the mixture was diluted with dichloromethane (30 ml) and filtered through a celite layer. To the filtrate pyridine (3 ml) was added and the mixture was evaporated and dried by several additions and distillations of toluene. The syrup obtained showed, on TLC, to contain more than four products. Attempted separation of these products by fractional crystallization or by repetitive column chromatography on silica gel using different solvent systems was unsuccessful.

Carrying the reaction at lower temperature (40—50 °C) and for a shorter duration (16 h) led to the same result.

2-Acetamido-4-O-allyl-3-O-benzyl-2-deoxy-6-O-triphenylmethyl-β-D-glucopyranosyl Azide (10). *Method A*: To a solution of **5** (500 mg) in dry benzene (20 ml) allyl bromide (110 mg) and powdered sodium hydroxide (1.25 g) were added and the mixture stirred for 72 h at room temperature. The mixture was filtered on a celite layer and the inorganic residue was washed with benzene (2×50 ml). The filtrate and washings were washed with water (3×50 ml), dried (Na_2SO_4), and evaporated. The residue which obtained was chromatographed on a column of silica gel with 19:1 chloroform–ethanol to give 360 mg (77%) of **10**, which crystallized from dichloromethanol–pentane as needles, mp 190—191 °C; $[\alpha]_D^{20}$ +1.4° (*c* 1.04, chloroform); ν_{max}^{KBr} 3300 (NH), 2130 (N_3), 1650 (Amide I), 1550 (Amide II), 740, and 680 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol R_f 0.44. Found: C, 71.72; H, 6.20; N, 9.05; O, 13.04%. Calcd for $C_{37}H_{38}N_4O_5$: C, 71.82; H, 6.19; N, 9.06; O, 12.93%.

Method B: A solution of **5** (500 mg) in *N*,*N*-dimethylformamide (20 ml) was treated with the same amounts of allyl bromide and sodium hydroxide as described in Method A. After completion of the reaction (5 h), the mixture

was diluted with chloroform (200 ml), washed with water (4×50 ml), and dried (Na_2SO_4). Evaporation of the solvents and chromotography of the residue gave 416 mg (89%) of **10** having the same properties as those just described.

*2-Acetamido-4-O-allyl-3-O-benzyl-2-deoxy-β-D-glucopyranosyl Azide (**11**).* A suspension of **10** (619 mg) in 60% acetic acid (50 ml) was heated for 2 h at 90 °C. The clear solution was evaporated and the residue, which obtained, was dried by several co-distillations with toluene and then chromatographed on a column of silica gel with 19:1 chloroform–ethanol to give 285 mg (79%) of **11**. It crystallized from dichloromethane–ether–pentane as needles, mp 188 °C; $[\alpha]_D^{20}$ −11° (*c* 2, chloroform); ν_{max}^{KBr} 3250 (OH), 3480 (NH), 2140 (N_3), 1650 (Amide I), 1550 (Amide II), 745, and 680 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol R_f 0.21 and in 9:1 chloroform–ethanol R_f 0.43. Found: C, 57.41; H, 6.45; N, 14.89; O, 21.89%. Calcd for $C_{18}H_{24}N_4O_5$: C, 57.44; H, 6.43; N, 14.88; O, 21.25%.

*2-Acetamido-4-O-allyl-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranosyl azide (**12**) and 2-(N-Acetylbenzylamino)-4-O-allyl-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranosyl Azide (**13**).* Benzyl bromide (1.2 ml) and powdered potassium hydroxide (3 g) were added to a solution of compound **11** (600 mg) in a mixture of anhydrous benzene (30 ml) and *N,N*-dimethylformamide (5 ml) and stirred for 3 h at room temperature. The mixture was cooled in an ice-bath, diluted with chloroform (200 ml), washed with ice–water (3×50 ml), 5% citric acid solution (2×50 ml), saturated sodium hydrogencarbonate solution (3×30 ml), and water (3×50 ml), and dried (Na_2SO_4). Evaporation of the solvents gave a syrup which on chromatography on a column of silica gel with 99:1 chloroform–ethanol gave 191 mg (33%) of **13** in the fast-moving fractions as a syrup which could not be crystallized, $[\alpha]_D^{20}$ +2.15° (*c* 1.6, chloroform), ν_{max}^{KBr} 2125 (N_3), 1650 (Amide I), 725, and 680 cm^{-1} (Ph); TLC in 29:1 chloroform–ethanol R_f 0.62. Found: C, 69.06; H, 6.46; N, 10.04; O, 14.60%. Calcd for $C_{32}H_{36}N_4O_5$: C, 69.05; H, 6.52; N, 10.06; O, 14.37%.

From the slow-moving fractions, 365 mg (56%) of **12** were obtained, which crystallized from methanol as needles, mp 159—160 °C; $[\alpha]_D^{20}$ +7.5° (*c* 2.7, chloroform), ν_{max}^{KBr} 3250 (NH), 2125 (N_3), 1645 (Amide I), 1550 (Amide II), 735, and 680 cm^{-1} (Ph); TLC in 29:1 chloroform–ethanol R_f 0.34. Found: C, 64.45; H, 6.52; N, 12.04; O, 17.25%. Calcd for $C_{25}H_{30}N_4O_5$: C, 64.36; H, 6.48; N, 12.01; O, 17.15%.

*Attempted Preparation of 2-Acetamido-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranosyl Azide (**14**).* A solution of **12** (500 mg) and 1,4-diazabicyclo[2.2.2]octane (75 mg; Eastman Kodak Co., Rochester, N. Y. 14650) in 90% methanol (25 ml) was heated to boiling. Tris(triphenylphosphine)rhodium chloride (200 mg; Alpha Products, Ventron Corporation, Danvers, MA 01923) was added, and the mixture was boiled under reflux for 4 h, cooled to room temperature, filtered, and the filtrate, evaporated without being dried. A solution of the residue in chloroform (100 ml) was successively washed with 5% citric acid solution (2×25 ml) and water (2×25 ml), and evaporated without being dried. The residue was dissolved in 90% acetone (25 ml), and the solution was stirred with mercury(II) chloride (500 mg) and yellow mercury(II) oxide (500 mg) for 30 min at room temperature. The mixture was filtered on a celite layer, the inorganic residue was washed with acetone, and the filtrate and washings were evaporated to a syrupy residue (600 mg). TLC of this residue revealed the presence of a complex mixture of highly polar compounds and infrared showed the total loss of the characteristic azido group absorption.

*2-Acetamido-N-acetyl-4-O-allyl-3,4-O-benzyl-2-deoxy-β-D-glucopyranosylamine (**16**).* Attempted reduction of a solution of **12** (117 mg) in methanol (29 ml) with sodium borohydride (100 mg) for 16 h at room temperature or for 6 h at 80 °C was unsuccessful and gave the unchanged azido compound. Therefore, a solution of **12** (117 mg) in *N,N*-dimethylformamide (10 ml) was cooled to 0 °C and treated with sodium borohydride (100 mg) and then allowed to attain room temperature for 6 h. The mixture was treated with a few pieces of Dry Ice, diluted with chloroform (100 ml) and washed with water (5×25 ml), and dried (Na_2SO_4). Evaporation of the solvents gave a residue of 2-acetamido-4-*O*-allyl-3,6-di-*O*-benzyl-2-deoxy-β-D-glucopyranosylamine (**15**) which gave positive test with ninhydrin. The residue was dissolved in methanol (10 ml), treated with acetic anhydride (0.5 ml) for 2 h at room temperature, and evaporated. After several co-distillations with toluene, the substance was chromatographed on a column of silica gel with 19:1 chloroform–ethanol to give 95 mg (79%) of **16**, which crystallized from methanol, mp 214—216 °C; $[\alpha]_D^{20}$ +33° (*c* 1.12, methanol); ν_{max}^{KBr} 3280 (NH), 1650 (Amide I), 1550 (Amide II), 730, 680 cm^{-1} (Ph); TLC in 9:1 chloroform–ethanol R_f 0.53. Found: C, 67.11; H, 7.06; N, 5.69%. Calcd for $C_{27}H_{34}N_2O_6$: C, 67.20; H, 7.10; N, 5.80%.

*2-Acetamido-4-O-allyl-3,6-di-O-benzyl-N[(S)-3-benzyloxycarbonyl-3-(benzyloxycarbonylamino)propionyl]-2-deoxy-β-D-glucopyranosylamine(**18**).* A solution of compound **12** (1.1 g) in *N,N*-dimethylformamide (10 ml) was reduced with sodium borohydride (1 g), as described for the preparation of **15**. Carbon dioxide was bubbled into the solution while maintaining the temperature at 0 °C. The mixture was diluted with chloroform (300 ml), washed with water (6×50 ml), and the solvents were evaporated under reduced pressure with the bath temperature being kept below 30 °C. The residue, without further purification, was dissolved in dichloromethane (30 ml) and treated with 1-benzyl *N*-(benzyloxycarbonyl)-L-asparate[39] (**17**, 1 g) and dicyclohexylcarbondiimide (700 mg), and the mixture was stirred for 16 h at room temperature. The *N,N'*-dicyclohexylurea that had precipitated was filtered off, and the filtrate was evaporated. The residue was chromatographed on a column of silica gel which was first eluted with chloroform to remove the non-carbohydrate compounds, and then with 29:1 chloroform–ethanol to give 975 mg (53%) of **18**. It crystallized from dichloromethane–methanol as needles, mp 216—218 °C; $[\alpha]_D^{20}$ +43° (*c* 1.83, chloroform); ν_{max}^{KBr} 3300 (NH), 1740 (C=O ester), 1650 (Amide I), 1550 (Amide II), 725, and 680 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol R_f 0.33. Found: C, 67.73; H, 6.31; N, 5.34%. Calcd for $C_{44}H_{49}N_3O_{10}$: C, 67.76; H, 6.33; N, 5.39%.

*2-Acetamido-3,6-di-O-benzyl-N-[(S)-3-benzyloxycarbonyl-3-(benzyloxycarbonylamino)propionyl]-2-deoxy-β-D-glucopyranosylamine (**19**).* A boiling solution of **18** (780 mg) and 1,4-diazabicyclo[2.2.2]octane (80 mg) in 95% methanol (60 ml) was treated with tris(triphenylphosphine)rhodium chloride (250 mg) and the mixture was boiled under reflux for 5 h, and then processed as described for the attempted synthesis of **14**. The residue obtained was chromatographed on a column of silica gel with 19:1 chloroform–ethanol to give 503 mg (68%) of **19**, which crystallized from dichloromethane–ether; mp 163—165 °C, $[\alpha]_D^{20}$ +26° (*c* 2.4, chloroform), ν_{max}^{KBr} 3500 (OH), 3300 (NH), 1740 (C=O ester), 1650 (Amide I), 1545 (Amide II), 750, and 690 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol R_f 0.24. Found: C, 66.28; H, 6.27; N, 5.51%. Calcd for $C_{41}H_{45}N_3O_{10}$: C, 66.56; H, 6.13; N, 5.68%.

2-Acetamido-3,6-di-O-benzyl-N-[(S)-3-benzyloxycarbonyl-3-(benzyloxycarbonylamino)propionyl]-2-deoxy-4-O-(2,3,4,6-tetra-O-acetyl-β-D-galactopyranosyl)-β-D-glucopyranosylamine (21). A solution of **19** (740 mg) and mercury(II) cyanide (1.2 g) in 1:1 benzene–1,2-dichloroethane (250 ml) was distilled at atmospheric pressure until 100 ml of the solvents were distilled. The mixture was cooled to room temperature and treated with a solution of 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide[40] **20** (1.5 g) in dry 1,2-dichloroethane (50 ml) during 3 h, while being strirred. The mixture was stirred for a further 48 h, treated with additional amounts of mercury(II) cyanide (1 g) and **20** (1 g), and stirring was continued for a further 24 h. The mixture was diluted with chloroform (300 ml), filtered through a celite layer, and the filtrate was successively washed with water (3×50 ml), a saturated solution of sodium hydrogencarbonate (2×50 ml), a saturated solution of potassium iodide (3×25 ml), and water (3×50 ml), and dried (Na_2SO_4). Evaporation of the solvents gave a residue that was chromatographed on a column of silica gel with 19:1 chloroform–ethanol to give 480 mg (42%) of pure **21**. This could not be crystallized and was obtained as an amorphous powder by precipitation from an ethereal solution by addition of pentane; $[\alpha]_D^{20}$ +29° (*c* 1.1, methanol), ν_{max}^{KBr} 3300 (NH), 1740 (C=O ester), 1665 (Amide I), 1555 (Amide II), 750, and 690 cm^{-1} (Ph); TLC in 19:1 chloroform–ethanol R_f 0.29. Found: C, 57.84; H, 6.26; N, 3.63%. Calcd for $C_{55}H_{61}N_3O_{19}\cdot 4H_2O$: C, 57.79; H, 6.35; N, 3.68%.

2-Acetamido-3,6-di-O-benzyl-N-[N-(benzyloxycarbonyl)-β-L-aspartyl]-2-deoxy-4-O-β-D-galactopyranosyl-β-D-glucopyranosylamine (22). Compound **21** (570 mg) was stirred with a solution of lithium hydroxide (80 mg) in water (30 ml) for 2 h at room temperature. The solution was deionized by passage through Amberlite IRC-50 (H^+) ion-exchange resin, and then evaporated. The residue could not be induced to crystallize and **22** was obtained as an amorphous powder 351 mg (82%) from methanol–ether–pentane; $[\alpha]_D^{20}$ +13° (*c* 2.1, methanol), ν_{max}^{KBr} 3350 (broad, NH and OH), 1720, (COOH), 1650 (Amide I), 1550 (Amide II), 750, and 690 cm^{-1} (Ph); TLC in 8:2 chloroform–ethanol R_f 0.40. Found: C, 55.74; H, 5.80; N, 4.77%. Calcd for $C_{40}H_{49}N_3O_{15}\cdot 2.5\cdot H_2O$: C, 56.07; H, 6.35; N, 4.90%.

2-Acetamido-N-(β-L-aspartyl)-2-deoxy-4-O-β-D-galactopyranosyl-β-D-glucopyranosylamine (23). A solution of **22** (215 mg) in 50% methanol (100 ml) was hydrogenolyzed with hydrogen in the presence of 10% palladium-on-charcoal (100 mg) for 24 h at room temperature and 2 atm. The mixture was filtered on a celite layer and the filtrate was hydrogenolyzed for a second time as just described. Evaporation of the solvents gave a residue (108 mg, 81%) that showed a positive ninhydrin reaction.[36] This residue could not be crystallized and **23** was obtained as a hygroscopic amorphous powder from methanol–acetone–pentane; $[\alpha]_D^{20}$ +6° (*c* 1.1, methanol), ν_{max}^{KBr} 3400 (broad, NH_2 and OH), 1725 (COOH), 1650 (Amid I), and 1550 cm^{-1} (Amide II). Found: C, 40.51; H, 6.59; N, 7.72%. Calcd for $C_{18}H_{31}N_3O_{13}\cdot 2H_2O$: C, 40.53; H, 6.61; N, 7.88%.

Oxidation of Copper in Nitrogen Dioxide

Yoshio TAKASU,* Teruhide TOMO-OKA, and Yoshiharu MATSUDA
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received January 8, 1981)

Synopsis. Thermal microgravimetry, mass spectrometry, and X-ray diffractometry were used to investigate the ability of NO_2 to oxidize copper. NO_2 oxidizes a copper plate with formation of oxide film consisting of Cu_2O (predominant) and CuO. The oxidation obeys a cubic law, and proceeds faster than in oxygen. An oxidation mechanism is presented on the basis of kinetic and structural data.

Although many studies have been made on high temperature oxidation of metals in oxygen, only a few have adopted NO_x as oxidizing agent.[1-3] We previously reported that copper could be oxidized in NO around 973 K but that the oxidation rate was much lower than that in oxygen.[4,5] The present investigation examined corrosive characteristics of nitrogen dioxide NO_2 for oxidation of copper by means of thermal microgravimetry, mass spectrometry, and X-ray diffractometry, mainly with a view elucidating the oxidation mechanism for this system.

Experimental

A poly-crystalline copper plate (99.99%Cu, 0.5 mm in thickness) was annealed *in vacuo* at 1073 K for 2 h, and then cut to the size 10×10 mm^2. After being abraded with an emery paper, the specimen was electropolished in an acid solution (H_2SO_4:H_3PO_4:H_2O=170:540:308 in volume), and rinsed in water and acetone. Highly pure NO_2, NO, and N_2O each in a glass cylinder (Takachiho Chemical Co., Ltd.) were used without further purification. The oxygen and argon were purified by bulb-to-bulb distillation with liquid nitrogen coolant. The oxidation process was followed by a Gulbransen-type microbalance contained in a conventional high-vacuum apparatus which could be evacuated to 2×10^{-5} Torr (1 Torr=133.3 N m^{-2}). Before use for the oxidation experiment, the test specimen was reduced in 20 Torr of hydrogen at 973 K for 1 h. Argon was used to determine the zero point of the microbalance. Oxide species were identified by an X-ray diffraction analysis (Cu $K\alpha$, 0.9 kW), in which the oxide film formed on each specimen was analyzed as it was. A mass spectrometer (JOEL, JMS-D-100) was used to determine the composition of the gas phase. Gas samplers for mass spectrometry were attached to the reaction tube of the microbalance equipment.

Results and Discussion

Figure 1 shows oxidation curves for copper plates placed at 673 K in 10 Torr of each of the corrosive gases NO_2, NO, N_2O, and O_2. Oxidation rate of copper in NO_2 was the highest and that in NO was the lowest. As indicated in Fig. 2, the oxidation of copper in NO_2 obeyed a cubic rate law $(\Delta W)^3=k_c\cdot t$, where ΔW signifies weight gain, k_c the cubic rate constant, and t oxidation time. According to

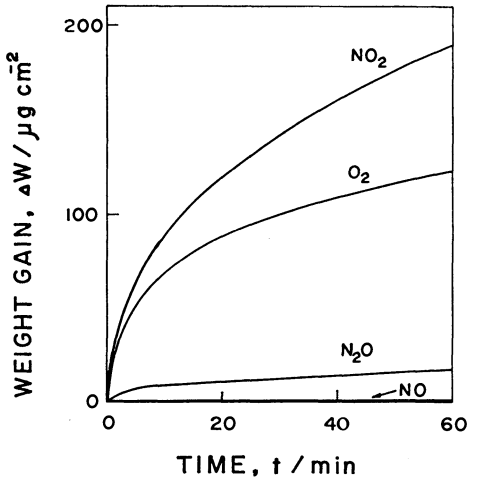

Fig. 1. Oxidation curves of copper plates in 10 Torr of NO_2, NO, N_2O, or O_2 at 673 K.

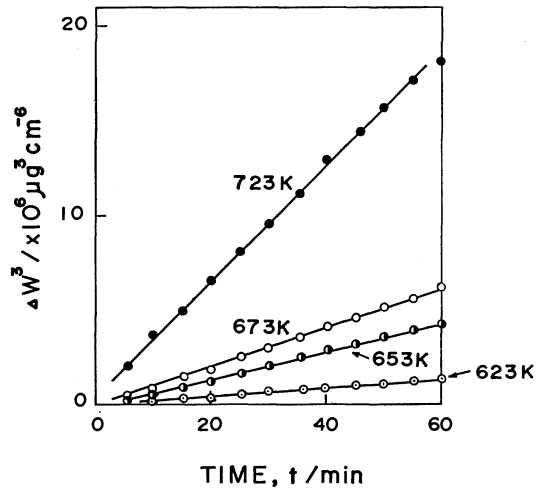

Fig. 2. Cubic plots of the oxidation curves of copper at various temperatures in 10 Torr of NO_2.

the mass spectrometry, the gas phase after a 1 h oxidation of copper at 673 K in 10 Torr of NO_2 consisted of about 97 per cent of NO_2 and a few per cent of NO and N_2O. Since the dissociation of nitrogen dioxide is not negrigible above 753 K, oxidation measurements were performed below 723 K. The oxide film formed in NO_2 was rather coarse and consisted of both Cu_2O (predominant) and CuO, while the one formed in O_2 was dense and consisted only of CuO. In Table 1, the oxidation law, rate constant, apparent activation energy, and kinds of the oxides formed were listed for comparison between oxidation behaviors of copper in NO_2 and O_2. According to

Table 1. Comparison between characteristics of NO_2 and O_2 for the oxidation of copper plates

Gas	Oxidation law	k_c[a] $\mu g^3\ cm^{-6}\ min^{-1}$	E_a[b] kJ mol^{-1}	Oxides
NO_2	Cubic	11×10^4	84	Cu_2O, CuO
O_2	Cubic	3.8×10^4	88	CuO

a) k_c is the rate constant at 673 K. b) E_a is apparent activation energy.

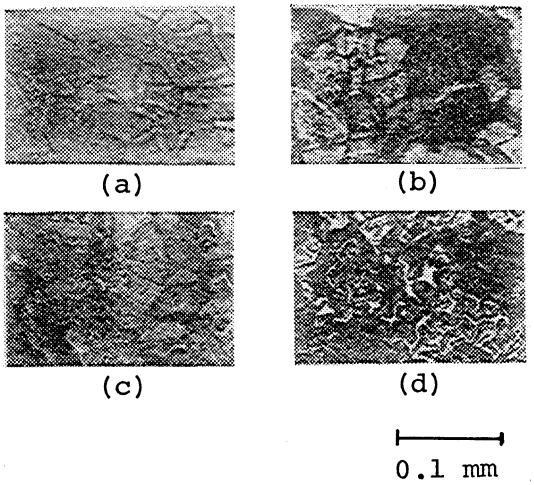

Fig. 3. Optical metallographs of the surfaces of Cu specimens oxidized in 10 Torr of O_2 or NO_2 at 673 K. (a): Non-oxidized(electropolished), (b): oxidized in 10 Torr of O_2 for 1 h, (c) and (d): oxidized in 10 Torr of NO_2 for 5 min and 1 h, respectively.

the Mott theory,[6-8] the rate determining process in the oxidation which obeys cubic rate law is the transfer of ions through the oxide layer under an electronic field formed between the adsorbed layer of gas and the oxide-metal interface. The reason for the higher rate of oxidation of copper in NO_2 than in O_2 is possibly in relation to the formation of a coarse oxide film as shown in Fig. 3. Such a coarse oxide film might result from formation of two different oxides Cu_2O and CuO. On the basis of the above results, the following oxidation mechanism is proposed in which only Cu_2O is considered as metal oxide species because it is predominant in the oxide layer.

Gas-oxide interface

$$NO_2 + e_x^- = NO_2^-, \quad (1)$$

$$2NO_2^- = Cu_2O + 2V^-_{Cu_x^+} + NO + NO_2, \quad (2)$$

$$6NO_2^- = 3Cu_2O + 6V^-_{C_x^+} + N_2O + 4NO_2, \quad (3)$$

In oxide

$$e_0^- \longrightarrow e_x^-, \quad (4)$$

$$V^-_{Cu_x^+} \rightleftarrows V^-_{Cu_0^+}. \quad (5)$$

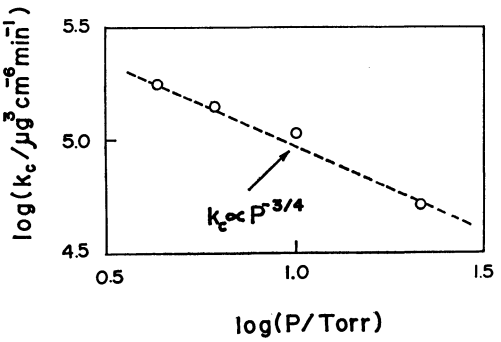

Fig. 4. The relation between the pressure of NO_2 and rate constant for the oxidation of copper at 673 K.

Oxide-metal interface

$$V^-_{Cu_0^+} + Cu = e_0^-, \quad (6)$$

where $V^-_{Cu_x^+}$, $V^-_{Cu_0^+}$, e_x^-, and e_0^- signify the cation vacancy at the gas-oxide interface, that at the oxide-metal interface, the electron at the gas-oxide interface, and the one at the oxide-metal interface, respectively. Considering the theory presented by Mott,[6-8] the cubic rate constant at a constant temperature can be given by $k_c \propto P^n_{NO_2}$, where $n=-1/2$ (in the case of Reaction 2) or $n=-3/2$ (in the case of Reaction 3).[9] The pressure dependence of oxidation constant obtained from this experiment is $-3/4$ as shown in Fig. 4. This value is within the region for the theoretical values given above, suggesting that both Reactions 2 and 3 are occurring in the oxidation process.

One of the authors (Y.T.) gratefully acknowledges the support of this research by a grant from the Itoh Kagaku Shinkokai.

Partial Hydrogenation of Acetylenes on Modified Nickel Boride Catalysts

Yuriko NITTA, Toshinobu IMANAKA, and Shiichiro TERANISHI*

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received January 12, 1981)

Synopsis. Ni–B catalysts modified with a small amount of copper(II) salt have a higher selectivity than palladium and modified Raney nickel catalysts for partial hydrogenation of phenylacetylene, 1-heptyne, 1-ethynylcyclohexene, and propargyl alcohol.

Our previous paper[1] reported that cobalt boride catalyst (Co–B), especially when modified with a small amount of metal salts, are much more effective than nickel boride catalyst (Ni–B) for selective hydrogenation of α,β-unsaturated aldehydes to α,β-unsaturated alcohols; however, for selective hydrogenation of acetylenes to olefins Ni–B is more selective than Co–B. This work investigated modifications of Ni–B by addition of a small amount of metal salts with a view to increasing the selectivity for the partial hydrogenation of acetylenes.

Although palladium has almost completely displaced nickel to be used as catalyst of choice for the partial hydrogenation of acetylenes, the lower price of nickel will make it more useful than palladium if equal or higher selectivity is to be obtained with it.[2] Thus it is worthwhile to study the partial hydrogenation on Ni–B which is very simple to prepare and to use and which is, in activity, equal to or, in some cases, superior to Raney nickel catalyst (R-Ni) for hydrogenation of many kinds of organic functions. With R-Ni, Elsner and Paul[3] reported that deactivation of the catalyst with copper(II) salt in ethanol might provide a selective catalyst for partial hydrogenation of octadecynes, without presenting any information on quantitative compositions of the products.

Experimental

Catalyst. Ni–B and R-Ni were prepared according to the method described previously.[4] Copper boride catalyst (Cu–B) and Co–B were prepared, respectively, with copper(II) chloride and cobalt acetate in a manner similar to that for Ni–B. The copper-modified nickel boride catalyst (Cu-modified Ni–B) was prepared by stirring Ni–B (0.2 g, by the P-1 method[4,5]) in a solution of copper(II) chloride (2—10 mol% of Ni) in 99% ethanol (10 ml) at 30 °C for 10 min. The copper-modified Raney nickel catalyst (Cu-modified R-Ni) was prepared in the same way by using R-Ni (0.2 g) activated at 70 °C. The coprecipitated nickel copper boride catalyst (Ni–Cu–B) was prepared by reducing a mixture of measured amounts of nickel acetate and copper(II) chloride with $NaBH_4$ in water.

Hydrogenation. Acetylenes (0.2 ml) were hydrogenated at 30 °C in ethanol or in cyclohexane (10 ml) under atmospheric pressure of hydrogen. The olefin selectivity of a catalyst was defined as the mol% of olefin in olefin plus paraffin determined by a GLC method at 30% conversion of acetylene. Selectivities of the catalysts were almost independent of the conversion of acetylenes up to 90%.

The other experimental details are the same as those described in our previous paper.[1]

Results and Discussion

Selectivities of boride catalysts in the partial hydrogenation of phenylacetylene fell in the order Cu–B> Ni–B>Co–B, which is considered to be reverse to the order of the strength of adsorption of the acetylene on the catalyst surface as based on the surface *d*-electron density.[1,8] 1-Phenyl-1-propyne, which is supposed to be adsorbed more weakly than phenylacetylene because of the steric hindrance of methyl group, was hydrogenated to the olefin more selectively than phenylacetylene on Ni–B. These facts support the idea, presented in our previous paper[1] concerning the selectivity of Co–B, that the stronger the adsorption bond between the C≡C bond and the metal, the lower the olefin selectivity.

The selectivity of Ni–B was enhanced by the modification with a small amount of copper(II) chloride even to such an extent as exceeds that of Cu–B or polymer-bound Pd complex catalyst (93%),[6] although the hydrogenation rate decreased considerably. In the case of R-Ni, it was necessary to add a larger amount of the copper(II) salt to obtain as high a selectivity as that of Cu–B, probably because of the larger surface area of R-Ni. The selectivity of a coprecipitated nickel copper boride catalyst was lower than those of Ni–B and Cu–B. This fact again shows

Table 1. The olefin selectivity(S) of various catalysts in the hydrogenation of acetylenes

Catalyst	Cu/Ni[a]	Reactant	S/%
Ni–B (P-1)[b]	—	Phenylacetylene	90.0
Ni–B (P-2)[b]	—	Phenylacetylene	91.3
R-Ni	—	Phenylacetylene	88.0
Cu–B	—	Phenylacetylene	92.0
Co–B	—	Phenylacetylene	79.0
Cu-modified Ni–B	0.02	Phenylacetylene	96.3
Cu-modified Ni–B	0.05	Phenylacetylene	97.7
Cu-modified Ni–B	0.10	Phenylacetylene	98.3
Cu-modified R-Ni	0.05	Phenylacetylene	84.1
Cu-modified R-Ni	0.10	Phenylacetylene	83.8
Cu-modified R-Ni	0.20	Phenylacetylene	93.2
Ni–Cu–B	0.10	Phenylacetylene	88.9
Ni–B (P-1)	—	1-Phenyl-1-propyne	92.3
Ni–B (P-1)	—	1-Heptyne	72.5
R-Ni	—	1-Heptyne	78.5
Cu-modified Ni–B	0.05	1-Heptyne	89.7
Cu-modified R-Ni	0.05	1-Heptyne	70.7
Cu-modified Ni–B	0.10	1-Ethynylcyclohexene	94±1
Ni–B (P-1)	—	Propargyl alcohol	68.0
Cu-modified Ni–B	0.10	Propargyl alcohol	80.3

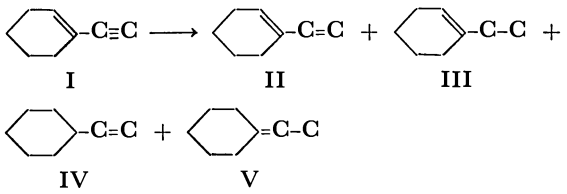
a) Molar ratio of copper(II) salt to nickel salt. b) Prepared in water (P-1) or in 95% ethanol (P-2).

that the coprecipitation method for preparing binary boride catalysts is ineffective for increasing the catalytic selectivity, as already shown for the selective hydrogenation of α,β-unsaturated aldehydes in our previous paper.[1]

The addition of zinc or iron(II) salts instead of copper(II) salts to the Ni–B catalyst raised the selectivity only slightly.

The Cu-modified Ni–B was highly selective also for the partial hydrogenation of 1-heptyne, while Cu–B was almost inactive towards 1-heptyne. XPS studies on Cu-modified Ni–B and R-Ni indicated that the copper(II) ion was deposited as copper metal on the catalyst surface. From these facts, the high selectivity of Cu-modified Ni–B is supposed to be due to the synergetic effect between copper and nickel metals on the catalyst surface, where copper atoms adsorb acetylenes rather weakly but do not adsorb olefins in outer surface or at the top of rugged surface and where nickel atoms activate hydrogen in inner pores or at the bottom of rugged surface.

As an instance of partial hydrogenation of conjugated acetylenes, 1-ethynylcyclohexene was hydrogenated over the Cu-modified Ni–B in cyclohexane. After all reactant I had been exhausted, no further uptake of hydrogen was observed;



I II III

IV V

compositions of the products were as follows: II 94±1%, III+IV *ca.* 3%, and V and the others *ca.* 3%. Ethylcyclohexane was not detected. The yield of II was reported to be 86% at 94% conversion on the Lindler catalyst,[7] and to be 81% at 100% conversion on polymer-bound Pd complex catalyst.[6]

Propargyl alcohol was selectively hydrogenated to allyl alcohol on the Cu-modified Ni–B catalyst in ethanol without being accompanied by hydrogenolysis of the hydroxyl group.

These findings suggest that we can regard Cu-modified Ni–B as superior to the Lindler catalyst for the partial hydrogenation of acetylenes if we take into account both the ease of preparation and separation and the moderate price of nickel.

The authors wish to thank Dr. Yasuaki Okamoto for his valuable discussion and for his assistance in obtaining XPS data.

The Molecular Conformation of 6,14-Di-*O*-acetyl-3-*O*-(2-chlorobenzoyl)-grayanotoxin II as Revealed by X-Ray Methods

Akio FURUSAKI,* Nobuyuki HAMANAKA, and Takeshi MATSUMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

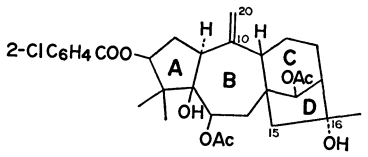
(Received April 18, 1981)

Synopsis. An X-ray crystal analysis has revealed that the six-membered C-ring in the title compound takes a boat conformation, in contrast with that in grayanotoxin II itself.

A series of X-ray crystal analyses[1] revealed that the C-ring conformation of grayanotoxins[2] with the exocyclic double bond, C(10)=C(20), depends largely on the multiplicity of the C(15)–C(16) bond. When this is a single bond, the C-ring prefers a chair conformation. However, the enthalpy difference between the chair and boat conformations of the C-ring is supposed to be small, because the change of the B-ring conformation reduces that energy difference. In this paper, we wish to report an example of grayanoids in which, although the C(15)–C(16) and C(10)–C(20) bonds are single and double bonds respectively, the C-ring adopts a boat conformation.

Experimental

Colorless single crystals of 6,14-di-*O*-acetyl-3-*O*-(2-chlorobenzoyl)grayanotoxin II (**1**) were grown from an acetone-diisopropyl ether solution. The crystal data are as follows: $C_{31}H_{39}O_8Cl$, *M.W.*=575.1, orthorhombic, space group $P2_12_12_1$, a=12.51(1), b=22.12(2), c=10.39(1) Å, Z=4, D_m=1.33 g cm^{-3}, D_c=1.328 g cm^{-3}. The intensities were recorded on multiple Weissenberg photographs taken with Cu $K\alpha$ radiation for the 0th—10th layer around the a axis and for the 0th—8th layer around the c axis, and were measured visually with a calibrated intensity scale. The 2811 independent intensity data thus obtained were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect.



1

Structure Determination

Various attempts were made to solve the structure by the heavy-atom method or the symbolic-addition procedure,[3] but all such attempts were unsuccessful. Thus, the structure analysis was delayed more than 10 years. Since the Monte Carlo direct method was recently developed,[4] it was applied to the present phase determination. The 50 strongest reflections were chosen as the starting set. In order to extend the tentative-phase set derived from random numbers, 12 cycles of the tangent procedure were performed using 542 $|E|$ values above 1.30. Since the 24th phase set showed a low R_K value of 0.339 ($R_K=\Sigma||E_o|-|E_c||/\Sigma|E_o|$), 6 additional cycles of the tangent procedure were carried out using 658 $|E|$ values above 1.20; the R_K value was reduced to 0.249. An E-map based on 641 phases afforded all the 40 non-hydrogen atoms. The structure thus obtained was refined by the block-diagonal-matrix least-squares method with anisotropic temperature factors. The

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the ith principal axis of the thermal ellipsoid.

final R value was 0.123. The final atomic parameters are listed in Table 1. The table of the anisotropic temperature factors and the F_o-F_c table are kept at the Chemical Society of Japan (Document No. 8148).

All the calculations were performed on a HITAC M-200H computer at the Hokkaido University Computing Center, using our own programs. The atomic scattering factors were taken from the International Tables.[5]

Results and Discussion

The molecular framework of **1** and the torsion angles for the grayanane skeleton are shown in Figs. 1 and 2 respectively. The A-ring takes an envelope form; the C(2)–C(3)–C(4)–C(5) part is nearly planar. Since this conformation makes the O(1) atom and the C(18)H_3 group eclipse each other around the C(3)–C(4) bond, it is probably less stable than the envelope form with a planar C(5)–C(1)–C(2)–C(3) or C(1)–C(2)–C(3)–C(4) part. In fact, the present envelope form has not been observed in grayanotoxins I,[1a] II,[1b] XV,[6] XVI,[1c] and XIX.[1e] The B-ring has a chair form with an approximate mirror plane through the C(5) atom, while the C-ring adopts a deformed boat form. Force-field calculations indicate that, in grayanotoxins having the C(15)–C(16) single and C(10)–C(20) double bonds, the molecular conformation with the boat C-ring is less stable than that with the chair C-ring by about 4 kJ mol^{-1}.[7] If this is true, it follows that the occurrence of the present boat C-ring may be due to the molecular-packing effect. The D-ring takes a conformation intermediate between the envelope form with a mirror plane through the C(14) atom and the half-chair form with a two-fold rotation axis through the C(16) atom.

Equilibrium Dissociation Pressure of Hydrogen in Molten LiCl–LiH Mixtures

Kazuhiko Ichikawa* and Kazutaka Kawamura†

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

†*Research Laboratory of Nuclear Reactors, Tokyo Institute of Technology, Tokyo 152*

(Received April 23, 1981)

Synopsis. Pressure-composition-temperature data were collected for the LiCl–LiH system in the respective ranges 0.1—10 mmHg††, 4.5—22.3 mol% LiH, and 550—700 °C by measuring equilibrium hydrogen pressure in a Sieverts' apparatus. The square root of hydrogen pressure *vs.* composition isotherm follows Sieverts' relation for compositions below 10 mol% LiH.

The recent increased interest in physicochemical and thermodynamic properties of solutions containing lithium hydride as one component, such as those of hydrogen isotopes in liquid lithium,[1–4] has been motivated by their use for direct energy conversion devices. The simplest ionic crystal of LiH consisting of Li^+ and H^- has a NaCl-type structure, in which the ionic radius of H^- is as large as 0.2 nm. The molten LiH may be of simple ionic melt like molten lithium halide and may have a high decomposition-pressure of hydrogen at a temperature just above its melting point 686 °C under 1 atm of H_2(g). According to the study[5] on solid-liquid phase equilibrium the LiCl–LiH system has eutectic temperature 496 °C at 34.0 mol% LiH and no formation of solid solutions was observed. In this work we report variation of equilibrium dissociation pressure of hydrogen with concentration and temperature for molten LiCl–LiH binary mixtures.

Experimental

Experiments were carried out in a so-called Sieverts' apparatus[6] which consisted of four main sections designed, respectively, for (a) gas metering, (b) gas equilibration with LiCl–LiH melt, (c) gas pumping, and (d) gas supply. The gas metering section consisted of a mercury manometer (1—760 mmHg) and a McLeod gauge (10^{-4}—1 mmHg). The equilibration section was a fused-silica tube containing a molybdenum crucible filled with sample; the crucible was kept in a long sintered-Al_2O_3 tube because hydrogen is permeable through fused silica at higher temperatures. Before measuring the equilibrium hydrogen pressure, P_{H_2}, the apparatus, with no sample contained, was evacuated up to 10^{-5} mmHg at the high temperature of interest. P_{H_2} was measured as a function of temperature from 550 °C to 700 °C at each of the LiH concentrations, 4.5, 5.3, 7.5, 9.8, 12.3, 20.2, and 22.3 mol%.

Results and Discussion

Figure 1 shows variation of hydrogen pressure with temperature and Fig. 2 shows isothermal plots of the square root of hydrogen pressure *vs.* composition.

Since component LiH in a molten LiCl dissociates into a host of ions Li^+ and H^-, the binary solution has a common cation of Li^+ and the equilibrium

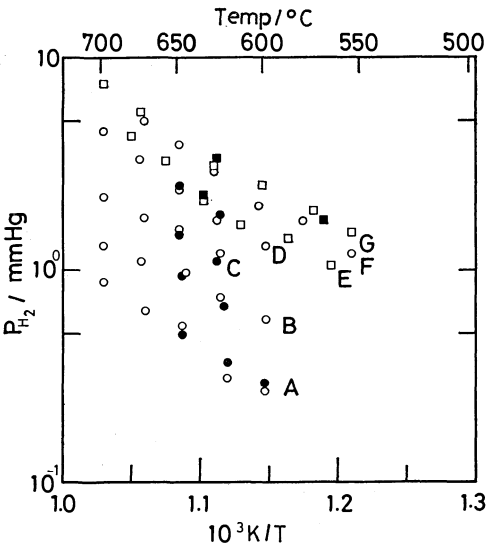

Fig. 1. Temperature dependence of hydrogen pressure for the LiCl–LiH system with each concentration of A: 4.5, B: 5.3, C: 7.5, D: 9.8, E: 12.3, F: 20.2, and G: 22.3 mol% LiH.
The measurements of P_{H_2} with increasing and decreasing temperatures correspond to the open circles or squares and the solid circles or squares, respectively.

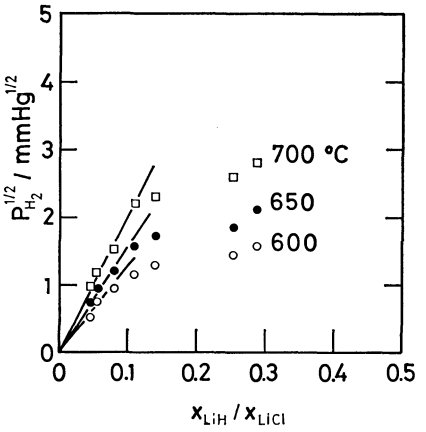

Fig. 2. Isothermal data on the square root of hydrogen pressure *vs.* mole fraction ratio, x_{LiH}/x_{LiCl}, for the LiCl–LiH system.

reaction between the gaseous and liquid phases may be written as

$$\frac{1}{2}H_2(g,\ T,\ P_{H_2}) + Cl^-(soln,\ T,\ P_{Cl_2}) \rightleftharpoons H^-(soln,\ T,\ P_{H_2}) + \frac{1}{2}Cl_2(g,\ T,\ P_{Cl_2}). \quad (1)$$

The equilibrium constant, $K(T)$, for this reaction is given by

†† 1 mmHg=133.322 Pa.

$$K(T) = a_{LiH}P_{Cl_2}^{1/2}/a_{LiCl}P_{H_2}^{1/2}, \quad (2)$$

where a is activity for each component and P is equilibrium pressure of H_2 or Cl_2. Activity coefficient of LiCl, γ_{LiCl}, has been calculated by use of the temperature-composition solid-liquid equilibrium diagram, with no formation of solid solutions, for the LiCl–LiH system.[5] It is equal to *ca.* unity up to 10 mol% LiH around 600 °C, whereas for component LiH at low concentrations γ_{LiH} may be interpreted as being equal to the constant $k(T)$ in Henry's law. The magnitude of $K(T)$, as evaluated with the aid of chemical potentials[7] of pure liquids LiH and LiCl and pure gases H_2 and Cl_2, indicates that the partial pressure of Cl_2 is very low as compared with that of H_2. If we assume that the square root of P_{Cl_2} is proportional to the concentration of chlorine anion or x_{LiCl}, the square root of P_{H_2} in Eq. 2 is given by

$$P_{H_2}^{1/2} = K_{app}(T)\frac{x_{LiH}}{x_{LiCl}}, \quad (3)$$

where $K_{app}(T)$ is apparent Sieverts' constant. The three straight lines shown in Fig. 2 correspond, respectively, to the values of $K_{app}(T)$, $K_{app}(700\,°C) = 20$, $K_{app}(650) = 16$, and $K_{app}(600) = 13$ $mmHg^{1/2}$/(mole fraction ratio, x_{LiH}/x_{LiCl}), though experimental values for the square root of P_{H_2} deviate from Sieverts' law toward the lower values for compositions above 10 mol% LiH. The experimentally determined $K_{app}(T)$ values are equal to *ca.* one third of those for the hydrogen isotope–lithium system.[4] The knowledge of the Sieverts' law constant is of importance to evaluate P_{H_2} for dilute solutions.

Pressure Effects on the Reaction of Hydroxide Ion with Sodium 2-Bromoethanesulfonate

Tsutomu ASANO* and Toshio OKADA

Department of Chemistry, Faculty of Engineering, Oita University, 700 Dannoharu, Oita 870-11

(Received May 21, 1981)

Synopsis. Kinetic effect of pressure on the reaction of hydroxide ion with 2-bromoethanesulfonate was studied. The reaction was moderately accelerated by pressure and the activation volumes suggest that the presence of the negative charge on the sulfonato group does not produce any measurable solvation increase during activation.

Although kinetic effects of pressure have been studied for a variety of organic reactions,[1] little work has been done for reactions between anions or cations. This is rather surprising because activation volume is known to be sensitive to solvational changes, and the approach of two ionic species with the same sign is expected to produce an increase in solvation. For example, when we compare the following two reactions, we would expect more negative activation volume for the latter because of the concentration of the negative charges.

$$A + B^- \longrightarrow [A\cdots B^-]^* \longrightarrow P \quad (1)$$

$$A^- + B^- \longrightarrow [A\cdots B^{2-}]^* \longrightarrow P \quad (2)$$

In fact, this effect of charge concentration on volume change has been observed in the ionization equilibria of some dicarboxylic acids. According to Høiland,[2] and Delben and Crescenzi,[3] the second ionization is accompanied by much larger volume contraction than the first ionization when the two carboxyl groups are located in close spatial proximity to each other (Table 1). Therefore, it is an interesting question whether a similar effect of charge concentration on volume can be observed in kinetic processes.

In this communication, the kinetic effects of pressure on the following elimination reaction[4] is discussed.

TABLE 1. VOLUME CHANGES FOR THE FIRST AND SECOND IONIZATIONS OF SOME DICARBOXYLIC ACID[a,b]

Compound	$\Delta\bar{V}_1^\circ$/mL mol^{-1}	$\Delta\bar{V}_2^\circ$/mL mol^{-1}
Oxalic acid	−6.72	−11.91

Glutaric acid	−13.17	−13.59
cis-1,2-Cyclohexane-dicarboxylic acid	−12.1	−22.9

a) From Refs. 2 and 3. b) At 25 °C in water.

$$BrCH_2CH_2SO_3^- + OH^- \longrightarrow CH_2{=}CHSO_3^- + Br^- + H_2O \quad (3)$$

The second-order rate constants of the reaction at various pressures are given in Table 2 and illustrated in Fig. 1. It is clearly seen in Fig. 1 that the application of pressure causes a moderate increase in the rate constant, and the plot of ln k against pressure is linear in the pressure range studied. The activation volumes of the reaction estimated from the slopes of the plots are given in the last column of Table 2. When we consider the volume change accompanying the approach of an ion toward a neutral substrate, two factors should be taken into account, *i.e.*, volume decrease caused by the partial bond formation between the two species, and volume increase caused by charge delocalization from the attacking ion to the substrate. These factors counterbalance each other, and as a result, moderately negative activation volumes are observed. A case in point is the base-catalyzed hydrolysis of alkyl acetates. The activation volumes for the reaction are in the range of −5.6—7.6 mL mol^{-1}.[5,6] On the other hand, if the substrate is electrically charged as in the present case, a stronger solute-solvent interaction in the transition state is con-

TABLE 2. SECOND-ORDER RATE CONSTANTS AND ACTIVATION VOLUMES FOR THE REACTION OF HYDROXIDE ION WITH 2-BROMOETHANESULFONATE ION

Solvent	T/°C	$k\times10^4$/M^{-1} s^{-1} at Pressure $\times10^{-5}$/Pa					ΔV^*/mL mol^{-1}
		1	245	490	736	981	
H_2O	10	2.22	2.39	2.53	2.72	2.89	−6.3
H_2O	25	11.3	11.8	12.3	13.1	13.9	−5.3
60 wt% MeOH	25	4.32	4.49	4.68	4.80	5.00	−3.6

ceivable and it might result in much larger negative activation volume. However, the activation volumes in water for the present reaction are in the same range as the saponifications, suggesting strongly the absence of solvation reinforcement by the presence of the negative charge on the sulfonato group. The results in aqueous methanol support this argument. If the solvation increase occurs in the activation step, more negative activation volume could be expected in less polar solvents. The experiment shows, however, it is not the case. The value is slightly less negative in aqueous methanol.

The comparison of the present results with the ionization of dicarboxylic acids reveals an interesting point. Since the hydroxide ion attacks a hydrogen atom on the α-carbon which bears the sulfonato group, the distance between the two charge centers in the transition state may be comparable to the one in malonate ion if the delocalization of the negative charge from the hydroxide ion to the substrate is not extensive. Such a transition state formation is expected to be accompanied by solvation increase as in the second ionization of malonic acid, but the activation volumes reported here are not in accordance with this expectation as discussed above. Therefore, it can be safely stated that the extensive negative charge delocalization is realized in the transition state and, probably, the hydration sheath around the sulfonato group remains intact while desolvation occurs around the hydroxide ion.

The present results also indicate that care must be taken when we use reaction volume values in the estimation of activation volumes.

Experimental

Sodium 2-bromoethanesulfonate was prepared as described.[7] The total consumption of hydroxide ion agreed with the theoretical value.

The reactions under pressure were performed by means of a high pressure vessel shown in Fig. 2. The reaction mixture, c, contained in a 50 mL glass syringe was withdrawn through the stainless steel capillary tubing, b, by opening the sampling valve, a, while the pressure of the system was kept constant by sending in pressurizing fluid, hexane. The decrease of the hydroxide ion was followed by titration after quenching the mixture by an excess amount of hydrochloric acid.

Studies of Matrix Effects on ^{57}Co-Labelled Tris(β-diketonato)cobalt(III) by Means of Mössbauer Spectroscopy

Yoichi SAKAI, Kazutoyo ENDO,† and Hirotoshi SANO*,†

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

† *Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158*

(Received September 26, 1980)

Synopsis. The emission Mössbauer spectra at 78 K of ^{57}Co-labelled $Co(dbm)_3$ (dbm=dibenzoylmethanato) dispersed in 2-methyltetrahydrofuran, or of ^{57}Co-labelled $Co(acac)_3$ (acac=acetylacetonato) dispersed in a mixed medium of oxalic acid and polystyrene, give no appreciable magnetic hyperfine structure (hfs), while those of ^{57}Co-labelled $Co(acac)_3$ dispersed in polystyrene and ^{57}Co-labelled crystalline $Co(dbm)_3$ give a magnetic hfs. The results indicate that the local radiolysis of EC-decay involves not only the labelled species itself, but also the neighbouring host matrix.

A number of emission Mössbauer spectroscopic studies of the ^{57}Co-labelled diamagnetic cobalt(III) compounds have shown practically no magnetic hyperfine structure (hfs), although the decayed ^{57}Fe(III)-paramagnetic species are considered to be magnetically diluted in a diamagnetic host.[1-5] The results are indicated in terms of an enhanced spin-spin interaction between the unpaired electrons of the ^{57}Fe and paramagnetic species produced through the EC-decay in the vicinity of ^{57}Fe. In our previous work,[6-7] however, a well-resolved paramagnetic hfs was found in the emission Mössbauer spectra of ^{57}Co-labelled tris(dibenzoylmethanato)cobalt(III), $Co(dbm)_3$, at 4.2 K. The results are explained from the viewpoint of the reduced formation of paramagnetic species (mainly organic radicals) in the vicinity of the decayed ^{57}Fe. It was also reported that the radical formation in the EC-Auger after-effects is small in such compounds that have ligands with a π-conjugated system and that the results are closely related to the radiolytic stability of the labelled compounds.[8]

In the present paper, we examined the emission Mössbauer spectra of the dispersion systems of ^{57}Co-labelled compound in order to get information about the matrix effects in the EC-decay. The dispersion systems of β-diketonates of cobalt(III) used are ^{57}Co-labelled $Co(acac)_3$ dispersed in a mixed medium of oxalic acid and polystyrene, and $Co(dbm)_3$ in 2-methyltetrahydrofuran.

Experimental

Preparation of Source Materials. ^{57}Co-labelled $Co(dbm)_3$ was prepared by following the method described previously.[7] The labelled complex was dissolved in 2-methyltetrahydrofuran, which is known to exist in vitreous structures when it is rapidly cooled. The solution was poured into a cell specially designed for the emission Mössbauer measurement. The cell was set in a cryostat and cooled by immersing it in liquid nitrogen as rapidly as possible.

A 100-mg portion of polystyrene and about 10 mg of $Co(acac)_3$ containing the ^{57}Co-labelled compound were dissolved into tetrahydrofuran, and then a 5-mg portion of oxalic acid was added to the mixture. Oxalic-acid crystals were dissolved on heating, after which the solution was allowed to stand in the air. The homogeneous dispersion of the sample prepared in the cold run was checked by X-ray diffractometry.

Measurement of Mössbauer Spectra. The emission Mössbauer spectra of the source materials at 78 K were measured against an ^{57}Fe-enriched stainless-steel absorber moving in a mode of constant acceleration. Velocity calibration was carried out by normalizing to iron metal.

Results and Discussion

The emission Mössbauer spectra at 78 K of ^{57}Co-labelled $Co(acac)_3$ dispersed in a mixed medium of oxalic acid and polystyrene give practically no magnetic hfs, as is shown in Fig. 1—a; they are similar to those found for pure crystalline ^{57}Co-labelled $Co(acac)_3$.[4] When the results are compared with the emission spectrum of ^{57}Co-labelled $Co(acac)_3$ dispersed in polystyrene,[7] they show that the oxalic acid plays a role in accelerating the rate of relaxation.

The emission Mössbauer spectrum at 78 K of ^{57}Co-labelled $Co(dbm)_3$ dispersed in 2-methyltetrahydrofuran is shown in Fig. 1—b. The magnetic hfs found in pure crystalline ^{57}Co-labelled $Co(dbm)_3$[6-7] decreased drastically in the present system.

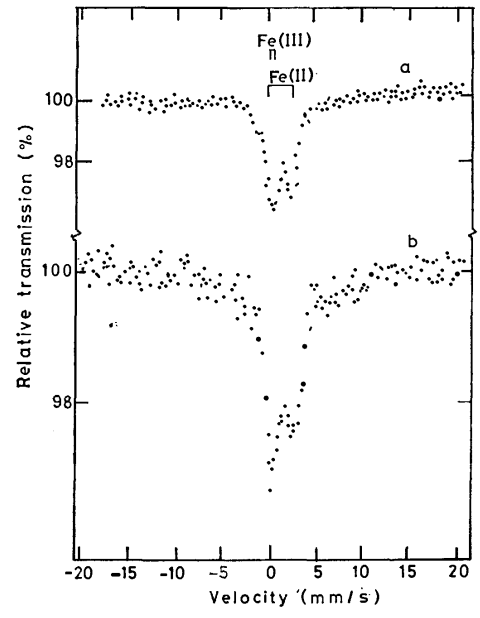

Fig. 1. Emission Mössbauer spectra at 78 K of ^{57}Co-labelled tris(acetylacetonato)cobalt(III) dispersed in a mixed medium of oxalic acid and polystyrene(a), and ^{57}Co-labelled tris(dibenzoylmethanato)cobalt(III) dispersed in 2-methyltetrahydrofuran(b).

We have explained that the appearance or disappearance of magnetic hfs in the emission Mössbauer spectrum of a cobalt(III) compound depends on the radiolytic stability of the source compounds; *i.e.* a compound which is stable against the local radiolysis of EC-decay gives a magnetic hfs.[8] The acceleration of the relaxation rate (or the disappearance of the magnetic hfs) in the present dispersion system can be explained by assuming an enhanced spin-spin interaction due to the increased radiolytic production of paramagnetic radicals in the vicinty of the decayed ^{57}Fe(III). Probably the radiolysis may occur in a dispersion medium as well as in a source compound, and it may be reasonable to conclude, from the results of the present experiment, that the radiation stability of a dispersion medium will contribute to change the rate of relaxation.

Although the relaxation rate is also enhanced by the spin-lattice interaction, this will make a minor contribution since the local heating due to the recoil energy of EC-decay should spread over the surrounding atoms by thermal diffusion in a much shorter time than the lifetime of the Mössbauer nuclear level.

Some Aspects of the Solvent Extraction-spectrophotometric Determination of Copper Dithiocarbamate Complex in Strongly Acidic Media

Takeo TAKADA,* Yukio OKABE,** and Kunio NAKANO
Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171
(Received December 1, 1980)

Synopsis. The time stability of the extracted complexes in isobutyl methyl ketone depends on the pH of the washing solution of the extract and on the stability of the metal complex. The extract is stable to concentrated acid when the organic extract is separated rapidly and washed with water. Copper(II) tetramethylenedithiocarbamate is quantitatively extracted from 1—6 and 1—2 mol dm^{-3} hydrochloric and nitric acid media respectively.

Sodium diethyldithiocarbamate(DDTC) and ammonium tetramethylenedithiocarbamate(Ammonium 1-pyrrolidinecarbodithioate, APCD) have been widely used as extraction and colorimetric reagents for many metal elements. There are a number of publications about the determination of copper(II) with those complexing agents.[1-8] The general principles are based on Sandell and others.[9-10] Many analytical procedures require precise adjustment of pH, usually in the range 2—4, and APCD is often preferred to DDTC when extractions are performed in acidic solution. However, some studies indicate that the pH-range for extraction with APCD is different for copper.[6-8] Moreover, these papers do not provide any information on the optimum range of strongly acidic concentration required for the extraction of copper(II). We have studied the time stability of copper(II)–DDTC and –PCD complexes in isobuthyl methyl ketone(IBMK) with the different acidities of the aqueous phase and the effect of pH of the washing solution on the extract, and we have applied this result to determine trace amounts of copper(II).

Experimental

Reagents. All solutions were prepared by dissolving analytical reagent grade chemicals in doubly distilled water. A 0.01 mol dm^{-3} copper(II) standard solution was prepared by dissolving recrystallized copper(II) sulfate pentahydrate in water, and diluted with water to give an adequate concentration before use. A 1% aqueous solution of DDTC and APCD were prepared. All other solvents were used without further purification.

Recommended General Procedure. The aqueous phase containing standard or sample should be acidified with hydrochloric or nitric acid; then adjust the acidity to the desired value. Add 10 cm^3 of the 1% DDTC or APCD solution, mix and allow to stand for 30 s. Extractions should be done in separatory funnels shaken for 7—10 min with 25 cm^3 of IBMK. After the aqueous phase is withdrawn, the organic phase should then be shaken with 50 cm^3 of water for about 5 min. After separating the two phases, the absorbance of the yellow copper complex in the IBMK phase can be measured at 435 nm against a reagent blank prepared in an identical manner.

** Present address: Denki Kagaku Keiki Co., Ltd. Kichijoji-kita, Musashino 180.

Results and Discussion

Effect of Washing Solution on the Stability of the Extracts. The extraction of metal complex into the organic phase depends upon the hydrogen-ion concentration of the aqueous phase. If the pH is less than some critical value, the amount of the metal ion extracted decreases steeply. Therefore, when the IBMK phase is not separated from the aqueous phase, the decomposition of the metal complex will be faster and will depend on the treatment of the extracts.

Figure 1 show that the time stability of the copper–PCD and –DDTC complexes in IBMK depends on the treatment of the extracts. In this experiment, the aqueous phase was adjusted to acidity 4 mol dm^{-3} with hydrochloric acid. It is seen that the absorbances of both extracts remain almost constant for at least 2 h after washing with water, whereas the use of 4 mol dm^{-3} hydrochloric acid as washing solution causes the very rapid change of the absorbance with time. It was thought that the copper–PCD and –DDTC complexes might be made stable in the IBMK if, after the extraction, the organic phase was washed with neutral water to prevent decomposition of extract by hydrogen ion attack.

IBMK: 25 cm^3, Cu; 8×10^{-4} M.

IBMK were studied over the acidity range 1—8 mol dm^{-3}. The effects of acidity and the degree of extraction are shown in Fig. 2. With DDTC, the extraction is quantitative at acidity 1—3 mol dm^{-3}, but is incomplete at higher acid concentration. With APCD, copper(II) is completely extracted over the acidity range 1—6 mol dm^{-3}, but extraction is incomplete outside this acidity range. The decomposition of copper–PCD complex will be faster in the acidity range more than 6 mol dm^{-3} and will depend on the increase in the acidity of the aqueous phase.

Extraction Behavior in Nitric Acid. With APCD, copper(II) is extracted into IBMK at acidity less than 3 mol dm^{-3}, but the extraction of copper–DDTC complex is incomplete for acidity values. The oxidation decomposition of the dithiocarbamate complex with nitric acid is considered to occur in both the aqueous and organic phases. However, although the extraction range in nitric acid is very narrow compared to that in hydrochloric acid, it is noticeable that the stability of the copper–PCD complex in the organic phase is rather higher than that of the copper–DDTC complex.

Interferences. Synthetic mixtures were prepared with cations commonly found with copper in cadmium metal. No interference was observed in the determination of 5 μg of copper(II) with 1 mg of zinc(II), lead(II), iron(III), and thallium(II), and 10^6 times of cadmium(II).

Determination of Copper in Cadmium Metal. The method has been applied to the determination of a trace amount of copper in cadmium metals as follow: Dissolve 5 g of the sample into 100 cm^3 of 4 mol dm^{-3} nitric acid and rinse the beaker with 5 cm^3 of water. Transfer the solution to a 300 cm^3 separating funnel with 160 cm^3 of water. Add 10 cm^3 of 0.1% APCD solution. Shake the funnel for 8 min with 25 ml of IBMK. The two phases should be allowed to settle for 30 s; the aqueous phase was rapidly separated. The organic phase should then be shaken with 50 cm^3 of water for 5 min. The two phases thus separated. The yellow copper complex in the IBMK phase was measured photometrically at 435 nm against the reagent blank. Amounts of copper in various types of cadmium metals were determined and results were compared with those obtained by the atomic absorption method. The values were in good agreement. A study of the precision at 0.1 ppm level of copper showed the relative standard deviation of 1.3% for five replicates.

The procedure described in this paper is special additional step is unnecessary for stabilization of the extract; it is simple and permits the direct extraction of copper in various metals after decomposition of the metals with concentrated hydrochloric or nitric acid.

The Separation of Aluminium Trichloride and Iron Trichloride by Selective Hydrogen Reduction

Yuichi Shoji, Ryoko Matsuzaki, and Yuzo Saeki*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 12, 1981)

Synopsis. When a gaseous mixture generated by heating a mixture of $AlCl_3$ and $FeCl_3$ (<19 wt%) was introduced, with a hydrogen stream, into a reaction zone held at various temperatures, the iron content in the sublimate decreased markedly above 300 °C; $AlCl_3$ containing less than 10 ppm of iron was obtained at 600 °C.

The production of aluminium *via* the electrolysis of aluminium trichloride($AlCl_3$) or the production of special-grade alumina from $AlCl_3$ requires pure $AlCl_3$. The $AlCl_3$ produced by the chlorination of aluminium-containing materials, however, contains impurities, such as iron, silicon, and titanium chlorides.

The separation of silicon tetrachloride or titanium tetrachloride from $AlCl_3$ presents no special problems because of the sufficient difference in relative volatility and the absence of vapor-phase complexes. The removal of iron trichloride($FeCl_3$) from $AlCl_3$ has been described as being considerably difficult despite the high volatility of pure $AlCl_3$ relative to the pure $FeCl_3$ phase,[1,2] because of the formation of a volatile complex, $AlFeCl_6$, on heating a mixture of $AlCl_3$ and $FeCl_3$.[1,3]

Considering the relative ease of the reduction of Fe(III) to Fe(II), the present authors examined the separation of $FeCl_3$ from $AlCl_3$ by means of selective hydrogen reduction.

Experimental

The $AlCl_3$ used was prepared by the reaction between aluminium (Al: 99.99%) and chlorine at 400 °C.[4] The $FeCl_3$ used was prepared by the reaction between iron (Fe: 99.98%) and chlorine at 500 °C.[5] The hydrogen used was purified up to a dew point below −70 °C by passing it through a membrane of palladium heated at 400 °C.

To examine the $FeCl_3$ content in the sublimate on heating a mixture of $AlCl_3$ and $FeCl_3$ in an argon stream, a mixture of $AlCl_3$ and $FeCl_3$ at a specified ratio in a quartz boat (width: 16 mm, length: 72 mm, depth: 9 mm) was placed in a straight, transparent quartz tube (inner diameter: 24 mm, length: 1000 mm) and heated at 150 °C for 1 h in the middle of a tubular electric furnace (heating length: 300 mm) in an argon stream at a flow-rate of 150 cm^3/min. The temperature of the sample part was controlled within ±2 °C.

For the experiments on the separation of $FeCl_3$ from $AlCl_3$ by means of selective hydrogen reduction, a gaseous mixture generated by heating a mixture of $AlCl_3$ and $FeCl_3$ at 150 °C was introduced, with a hydrogen stream at a flow-rate of 150 cm^3/min, into a reaction zone (inner diameter: 24 mm, length: 280 mm) held at a specified temperature for 1 h.

The total amount of aluminium and iron in the sublimate obtained outside the reaction zone was determined by chelatometric titration,[6] while the amount of iron was determined colorimetrically as 1, 10-phenanthroline complex[7] by using a Shimadzu double-beam spectrophotometer, Model UV-200S. The amount of aluminium was determined by subtracting the amount of iron from the above total amount of aluminium and iron. The chlorine content was determined gravimetrically as AgCl.

Throughout this work, chlorides of aluminium and iron were handled in an argon atmosphere to prevent any contamination by moisture in the air.

Results and Discussion

The $FeCl_3$ content in the sublimate obtained by heating 5.0 g of a mixture of $AlCl_3$ and $FeCl_3$ at a specified ratio in an argon stream was examined. Considering the vapor pressures of $AlCl_3$ and $FeCl_3$, the heating temperature was maintained at 150 °C ($P_{Al_2Cl_6}=11.53\times10^3$ Pa, $P_{Fe_2Cl_6}=1.4$ Pa).[8] The results are shown in Fig. 1.

Jorgensen and Moyle[9] have examined the equilibrium in the $AlCl_3$–$FeCl_3$–Cl_2 system and described that the vapor pressures of Al_2Cl_6, $AlFeCl_6$, and Fe_2Cl_6 at 160—180 °C are not changed by the initial $FeCl_3$ content in the range of 5—50 mol% (6—55 wt%). From the above description, we could well understood that the $FeCl_3$ content in the sublimate was constant on heating a mixture of $AlCl_3$ and $FeCl_3$ with an initial $FeCl_3$ content above 3 wt%. The results shown in Fig. 1 indicate that the clean separation of $FeCl_3$ from $AlCl_3$ is difficult by a repetition of the fractional sublimation.

Next, experiments for separating $FeCl_3$ from $AlCl_3$ by selective hydrogen reduction were carried out. The $FeCl_3$ content in the sublimate obtained by heating 5.0 g of a mixture of $AlCl_3$ and $FeCl_3$ at a specified ratio in a hydrogen stream at 150 °C was examined. The results obtained were the same as those obtained by the heating in an argon stream, shown in Fig. 1.

Then, the gaseous mixture generated by heating 5.0 g of a mixture of 95 wt% $AlCl_3$ and 5 wt% $FeCl_3$ at 150 °C (Fe content in the gaseous mixture: 1.4_6 wt% as $FeCl_3$ or 0.5_0 wt% as Fe) was introduced,

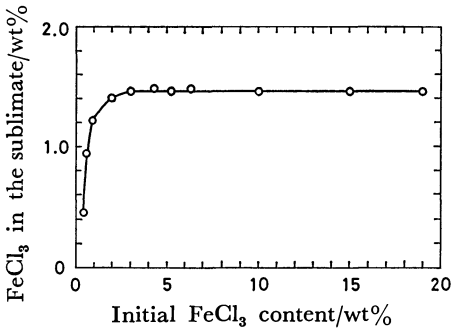

Fig. 1. $FeCl_3$ contents in the sublimates obtained by heating mixtures of $AlCl_3$ and $FeCl_3$ at various ratios in an argon stream.

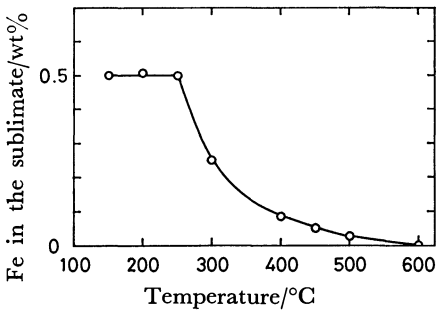

Fig. 2. Fe contents in the sublimates obtained by heating the gaseous mixture, generated by heating a mixture of $AlCl_3$ and $FeCl_3$, in a hydrogen stream at various temperatures.

with a hydrogen stream at a flow-rate of 150 cm^3/min, into a reaction zone held at various temperatures for 1 h. The iron content in the sublimate obtained outside the reaction zone was then examined. The results are shown in Fig. 2.

When the temperature of the reaction zone was below 250 °C, no change in the iron content was observed. Above 300 °C, the iron content decreased markedly, being reduced to 0.002 wt% at 600 °C. At 300—450 °C, it was observed that a colorless powder was deposited in the reaction zone. This colorless powder was identified as iron dichloride($FeCl_2$) by chemical analysis. Above 500 °C, the formation of iron in the form of thin film was observed in addition to $FeCl_2$.

The vapor pressure of $FeCl_2$ is negligible in the temperature range of this experiment.[8] However, it could also be considered that a part of the $FeCl_2$ formed was carried by the hydrogen stream and contaminated the sublimate. Therefore, the sublimate obtained above 400 °C was heated in an argon stream at 150 °C, and the iron content in the sublimate obtained outside the heating zone was examined. From the results, the iron contents were found to be 0.006 wt% at 400 °C, 0.004 wt% at 450 °C, 0.003 wt% at 500 °C, and <0.001 wt% at 600 °C.

From these experimental results, it is revealed that $AlCl_3$ containing less than 10 ppm of iron can be obtained by introducing a gaseous mixture, generated by heating a mixture of $AlCl_3$ and $FeCl_3$, with a hydrogen stream into a reaction zone held at 600 °C.

The Preparation and Properties of Cobalt(III) Phosphine Complexes Containing Nitrite and Acetylacetonate Ions

Satoru HAYAKAWA, Hiroaki NISHIKAWA, Kazuo KASHIWABARA,** and Muraji SHIBATA*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 10, 1981)

Synopsis. Two complexes, $[Co(NO_2)(acac)_2(P)]$-(acac=acetylacetonate ion, P=PBu_3, PBu_2Ph, PMe_2Ph, and $PMePh_2$) and $[Co(NO_2)_2(acac)(PMe_2Ph)_2]$, were prepared by a reaction between $Na[Co(NO_2)_2(acac)_2]$ and phosphines. The geometrical structures were determined on the basis of the ^1H NMR, electronic, and IR spectra. A *cis*(NO_2, P) configuration was assigned to $[Co(NO_2)(acac)_2(P)]$, and a *trans*(P,P) configuration, to $[Co(NO_2)_2(acac)(P)_2]$.

There have been a few cobalt(III) phosphine complexes among the so-called Werner-type complexes.[1] The coordination of phosphine groups to a cobalt(III) ion may be affected by the kinds of other ligands coexisting in the complex. The unidentate phosphine complexes of cobalt(III) thus far prepared have been those with dimethylglyoximate,[2] acetylacetonate,[3] cyanide,[4,5] and halide[6] ions. Other types are, however, required to extend the study of the chemistry of cobalt-(III) phosphine complexes. This note will be concerned with the preparation and properties of cobalt-(III) phosphine complexes containing nitrite and acetylacetonate ions.

Experimental

The phosphines were prepared according to the procedures described previously,[7] and handled under a nitrogen atmosphere until they formed cobalt(III) complexes. The electronic spectra were measured with a Hitachi 139 spectrophotometer, the ^1H NMR spectra, with a JEOL C-60 H spectrometer in $CDCl_3$, using tetramethylsilane as the internal reference, and the IR spectra, with a JASCO DS-301 spectrometer.

Preparation. Nitrobis(acetylacetonato)tributylphosphinecobalt-(III): Tributylphosphine(PBu_3) (4 cm³, 12 mmol) was added to $Na[Co(NO_2)_2(acac)_2]$[8] (4 g, 10 mmol) in a mixture (200 cm³) of benzene and ethanol (4:1), after which the solution was stirred at 50 °C for 5 h. The resulting red-brown solution was evaporated under reduced pressure to dryness. The residue was extracted with a small amount of benzene, which was then chromatographed with a column (ϕ1.5×30 cm) of alumina, using a mixture of benzene and acetone (6:1) as the eluent. Red-brown crystals were obtained by concentrating the first main, red-brown eluate and by adding a proper amount of hexane. Found: C, 52.10; H, 8.54; N, 3.05%. Calcd for $[Co(NO_2)(acac)_2(PBu_3)]$: C, 52.31; H, 8.12; N, 2.77%. The materials remaining at the top of the column were not characterized.

Nitrobis(acetylacetonato)dibutylphenylphosphinecobalt(III): This complex was prepared by means of a reaction between $Na[Co(NO_2)_2(acac)_2]$ and dibutylphenylphosphine(PBu_2Ph) in a mixture of benzene and ethanol (4:1) by a method similar to that used for the PBu_3 complex. Found: C, 54.64; H, 7.15; N, 2.66%. Calcd for $[Co(NO_2)(acac)_2(PBu_2Ph)]$: C, 54.86; H, 7.10; N, 2.67%.

Nitrobis(acetylacetonato)dimethylphenylphosphinecobalt(III): A mixture of $Na[Co(NO_2)_2(acac)_2]$ (3 g, 9 mmol) and dimethylphenylphosphine(PMe_2Ph) (1 cm³, 9 mmol) in benzene (150 cm³) was stirred at room temperature for 48 h. The resulting solution was then subjected to procedures similar to those used for the PBu_3 complex except for the use of a mixture of benzene and acetone (15:1) as the eluent. Found: C, 48.37; H, 5.71; N, 2.96%. Calcd for $[Co(NO_2)(acac)_2(PMe_2Ph)]$: C, 48.99; H, 5.71; N, 3.17%.

Nitrobis(acetylacetonato)methyldiphenylphosphinecobalt(III): A mixture of $Na[Co(NO_2)_2(acac)_2]$ (3 g, 9 mmol) and methyldiphenylphosphine($PMePh_2$) (3 cm³, 15 mmol) in benzene (150 cm³) was stirred at room temperature for 48 h. The subsequent procedures were similar to those used for the PBu_3 complex. Found: C, 54.62; H, 5.57; N, 2.69%. Calcd for $[Co(NO_2)(acac)_2(PMePh_2)]$: C, 54.88; H, 5.41; N, 2.78%.

Dinitroacetylacetonatobis(dimethylphenylphosphine)cobalt(III): A mixture of $Na[Co(NO_2)_2(acac)_2]$ (3 g, 9 mmol) and PMe_2Ph (1.3 cm³, 12 mmol) in ethanol (100 cm³) was stirred at 50 °C for 2 h. The resulting red-brown solution was evaporated under reduced pressure to dryness. The residue was extracted with benzene, which was then chromatographed in a way similar to that used for the PBu_3 complex. The eluate was concentrated under reduced pressure to a small volume and then allowed to stand in a refrigerator to yield red-brown crystals. The presence of $[Co(NO_2)(acac)_2(PMe_2Ph)]$ in the solution was confirmed by the ^1H NMR spectrum. Found: C, 48.16; H, 5.64; N, 4.87%. Calcd for $[Co(NO_2)_2(acac)(PMe_2Ph)_2]$: C, 47.92; H, 5.55; N, 5.32%.

The yields for the above-mentioned complexes were 10—20%.

Results and Discussion

The facile substitution or solvolysis of a nitrite ion in $Na[Co(NO_2)_2(acac)_2]$ has been known and utilized for preparing other bis(acetylacetonato)cobalt(III) derivatives, such as $[Co(NO_2)(acac)_2L]$.[8,9] Tertiary monophosphines can also be expected to react with the dinitro complex in a similar manner. Trialkyl- or alkylarylphosphines react readily with the dinitro complex and yield complexes of the $[Co(NO_2)(acac)_2(P)]$ type, but triphenylphosphine does not yield the corresponding complex.

$[Co(NO_2)_2(acac)(PMe_2Ph)_2]$ was obtained from a reaction mixture of PMe_2Ph and $Na[Co(NO_2)_2(acac)_2]$ in ethanol, $[Co(NO_2)(acac)_2(PMe_2Ph)]$ also being involved in the solution. Free PMe_2Ph and the liberated NO_2^- might attack the $[Co(NO_2)(acac)_2(PMe_2Ph)]$ first formed, thus yielding $[Co(NO_2)_2(acac)(PMe_2Ph)_2]$.

A nitrite ion can coordinate to a metal ion through a nitrogen or oxygen atom. None of the complexes prepared in this study show the N–O stretching in the region of 1000—1100 cm⁻¹, indicating the coordination through the nitrogen atom.

There are two geometrical isomers for the [Co-

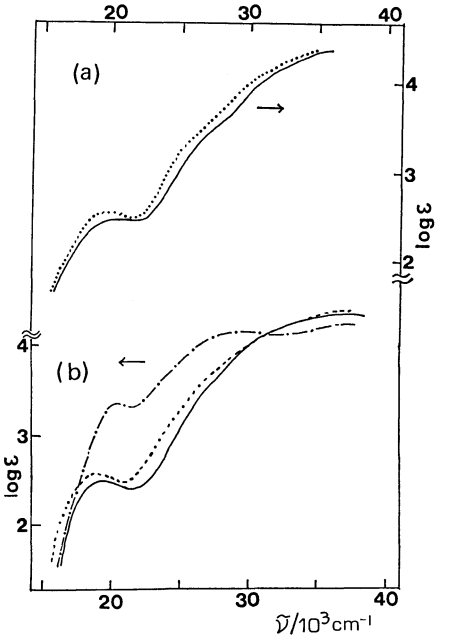

Fig. 1. Absorption spectra in dichloromethane. (a): $[Co(NO_2)(acac)_2(PBu_2Ph)]$ (----), $[Co(NO_2)(acac)_2(PBu_3)]$ (——), (b): $[Co(NO_2)(acac)_2(PMePh_2)]$ (——), $[Co(NO_2)(acac)_2(PMePh)]$ (----), $[Co(NO_2)_2(acac)(PMe_2Ph)_2]$ (—·—·—).

$(NO_2)(acac)_2(P)]$ complex. The ^{1}H NMR spectra can distinguish a *cis* or *trans* configuration. The spectral data are summarized in the table, together with those of the related compounds. All complexes of this type can be assigned to a *cis* configuration on the basis of the number of methyl and methine signals of the coordinated acetylacetonate. One of the methine peaks in each PBu_2Ph, PMe_2Ph, and $PMePh_2$ complex is shielded by a phenyl group on the phosphorus atom and is observed at high magnetic fields, 5.00—5.03 ppm.[10] The absorption spectra exhibit a broad first-absorption band around 20000 cm^{-1} (see Fig. 1). The replacement of the alkyl groups on a phosphorus atom by a phenyl group causes the red shift and increases the intensity of the first absorption band. The ligand-field strength of these phosphines is nearly identical with that of a nitro ligand, or slightly stronger.

There are three geometrical isomers for $[Co(NO_2)_2(acac)(PMe_2Ph)_2]$. The ^{1}H NMR spectrum shows one kind of methyl signal for the acetylacetonato ligand, indicating a *trans*(P,P) or *trans*(N,N) configuration. The remarkable high-field shift of the methine signal strongly suggests a *trans*(P,P) configuration where a phenyl group of the PMe_2Ph molecule is located over the acetylacetonate ring and shields the methine proton, causing it to resonate at a higher magnetic field.[10] The electronic and IR spectra also suggest a *trans*(P,P) configuration. The first absorption band shows a strong intensity (log ε=3.34), which is characteristic of the *trans*(P,P) arrangement of two phosphorus donor atoms.[11] The IR spectrum shows sharp peaks at 821 and 825 cm^{-1} attributable to the NO_2^- bending mode, the presence of two bands suggesting a *cis* configuration of two nitrite ions.[12]

Preparation and Circular Dichroism Spectrum of a (Triazacyclononane)-(tribenzo[*b,f,j*][1,5,9]triazacyclododecene)cobalt(III) Complex

Shuhei Fujinami,* Takao Hosokawa, and Muraji Shibata

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 17, 1981)

Synopsis. A new $[Co(tacn)(tri)]^{3+}$ complex has been prepared and optically resolved (TACN represents 1,4,7-triazacyclononane, and TRI, tribenzo[*b,f,j*][1,5,9]triazacyclo dodecene). From the CD spectral similarity of $(+)^{CD}_{500}$-$[Co(tacn)(tri)]^{3+}$ with $(+)_{546}[Co(tri)_2]^{3+}$, it has been concluded that the metal-centered optical activity of the two tri complexes is derived from a chiral arrangement of (benzene ring)-C=N- moieties.

Cummings and Busch[1] have reported the formation of a macrocyclic terdentate ligand, tribenzo[*b,f,j*]-[1,5,9]triazacyclododecene (abb. as TRI), by the condensation of three molecules of *o*-aminobenzaldehyde in the presence of metal ions. There are two geometrical isomers in a bis(tri)cobalt(III) complex; one is chiral form and the other meso form. The former has been prepared and resolved by Cummings and Busch.[1] The absolute configuration of the $(+)_{546}[Co(tri)_2]^{3+}$ complex has been determined by Wing and Eiss[2] by means of X-ray analysis. The $(+)_{546}$ isomer exhibits a similar CD spectrum to that of the $(+)_{546}$-$[Co(en)_3]^{3+}$ complex in the first absorption band region; the arrangement of the donor atoms in the $(+)_{546}$-$[Co(tri)_2]^{3+}$ isomer also resembles that in the $(+)_{546}$-$[Co(en)_3]^{3+}$ complex to give a left-handed helix about the threefold symmetry axis. On these bases, Wing and Eiss regarded the bis(tri) complex as strong evidence for the metal-centered optical activity arising from the twisted crystal field. On the other hand, Mason and Seal[3] have explained the optical activity of the $[Co(en)_3]^{3+}$ complex in terms of a dynamic coupling model. Therefore, it is necessary to reinvestigate the source of the optical activity in the $[Co(tri)_2]^{3+}$ complex.

In this report, the preparation and optical resolution of a complex containing a symmetric cyclic-terdentate TACN ligand and a dissymmetric TRI ligand, $[Co(tacn)(tri)]^{3+}$, will be reported (TACN represents 1,4,7-triazacyclononane). The CD spectrum of the resolved complex will be compared with that of the $[Co(tri)_2]^{3+}$ complex in order to determine the sources of the metal-centered optical activity.

Experimental

Preparation and Optical Resolution of $[Co(tacn)(tri)]^{3+}$. The $[Co(NO_2)_3(tacn)]$ complex[4] (2.5 g, 7.7 mmol) was suspended in a mixture of ethanol (275 cm^3) and 64% $HClO_4$ (25 cm^3). The whole system was stirred at 60 °C for 3—4 h, whereupon the color of the solution turned from yellow to deep red-brown. After cooling of the resulting solution to room temperature and removal of some precipitated material by filtration, the filtrate was adjusted to pH 3 by a 2 mol/dm^3 ethanolic KOH solution, and then the precipitated $KClO_4$ was filtered off. To the filtrate was added freshly prepared *o*-aminobenzaldehyde[5] (5 g, 41 mmol), and the mixture was refluxed at 80 °C for 8—9 h. The resulting solution was cooled to room temperature, and the precipitated material was filtered and washed with small amounts of ethanol and acetone in turn. The product was dissolved in a large amount of water (*ca.* 2000 cm^3) which had been adjusted to pH 4 by diluted HCl (all adjustments of pH were carried out with diluted HCl, unless otherwise noted). The solution was charged on a column of SP-Sephadex C-25 (2.5×30 cm). The column was rinsed with water (pH 3), and then the adsorbed band was eluted with a 0.3 mol/dm^3 NaCl solution adjusted to pH 3. A yellow band of tervalent cation was collected in a fraction. The effluent was diluted with a large amount of water (*ca.* 2000 cm^3, pH 4), and then poured onto a column of SP-Sephadex C-25 (2×20 cm). The adsorbed band was eluted with a 0.3 mol/dm^3 $NaClO_4$ solution adjusted to pH 3 with diluted $HClO_4$, whereupon one species was eluted and the other remained. The former was identified to be the known $[Co(tacn)_2]^{3+}$ species.[6] The remaining band was then eluted with a 0.3 mol/dm^3 NaCl solution (pH 3). The effluent was concentrated by a rotary evaporator at *ca.* 35 °C, with simultaneous removal of the eluent. To the final filtrate was added small amounts of 64% $HClO_4$ and solid $NaClO_4$, and the whole was kept in a refrigerator for a few days. The yellow crystals which deposited were collected and washed with water (pH 3). The crystals were dried *in vacuo*. The yield was *ca.* 30 mg. Found: C, 40.75; H, 3.80; N, 10.56%. Calcd for $[Co(tacn)(tri)](ClO_4)_3$=$CoC_{27}H_{30}N_6O_{12}Cl_3$: C, 40.39; H, 3.75; N, 11.02%. The product is explosive on heating.

A partial optical resolution was attained by means of a column chromatography (SP-Sephadex C-25, 2 cm×110 cm) by use of a 0.3 mol/dm^3 $Na_2[Sb_2(d\text{-tart})_2]$ solution as eluent.[7] The earlier eluted species was $(+)^{CD}_{500}[Co(tacn)(tri)]^{3+}$ isomer.

Measurements. The absorption and CD spectra were measured with a Hitachi 323 spectrophotometer and a JASCO J-40CS automatic recording spectropolarimeter, respectively.

Results and Discussion

The absorption and CD spectra of the $(+)^{CD}_{500}[Co(tacn)(tri)]^{3+}$ complex are shown in Fig. 1, with those of the related $(+)_{546}[Co(tri)_2]^{3+}$ and $(+)_{546}[Ni(tri)(H_2O)_3]^{2+}$ complexes. The absorption spectrum of the $[Co(tacn)(tri)]^{3+}$ exhibits a shoulder at *ca.* 21000 cm^{-1} ($\log\varepsilon\simeq2.5$), which is assignable to the first absorption band. The band is observed at a frequency higher by 1000 cm^{-1} than the corresponding band for the $[Co(tri)_2]^{3+}$ complex, indicating that the ligand field strength of TRI is weaker than that of TACN. An absorption band observed at 34000 cm^{-1} is assigned intra-ligand transition.[2] Both $(+)^{CD}_{500}[Co(tacn)(tri)]^{3+}$ and $(+)_{546}[Co(tri)_2]^{3+}$ exhibit a positive CD peak at the lowest frequency in the d-d absorption band region, in contrast to $(+)_{546}[Ni(tri)(H_2O)_3]^{2+}$ which shows no apparent CD peak. In the region of 33000—37000 cm^{-1}, the three complexes exhibit one or two intense CD peaks with negative sign. These bands

—·—·—: $(+)_{546}$[Ni(tri)(H$_2$O)$_3$]$^{2+}$.

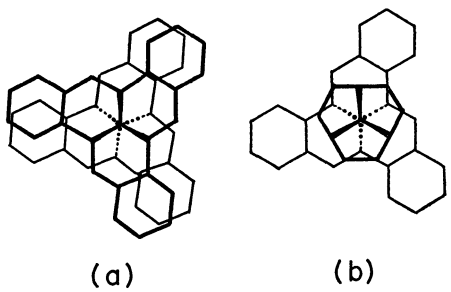

Fig. 2. Absolute configurations.
a): $(+)_{546}$[Co(tri)$_2$]$^{3+}$, b): $(+)^{CD}_{500}$[Co(tacn)(tri)]$^{3+}$.

are considered to be associated with a benzene ring inclining against a –C=N– bond, as is seen in a styrene chromophore.[8] Therefore, it is concluded that these complexes have the same absolute configuration with respect to the TRI ligand, namely, the pitch of the benzene rings has the sense of a left-handed screw.[2] The absolute configuration of $(+)^{CD}_{500}$[Co(tacn)(tri)]$^{3+}$ is predicted as shown in Fig. 2.

According to the X-ray analysis of $(+)_{546}$[Co(tri)$_2$]$^{3+}$,[2] there is a distortion around a threefold axis to give a twisted trigonal prism having the sense of a left-handed screw, due to a strong attractive interaction between two aromatic ligands. Wing and Eiss[2] have considered two sources of the metal-centered optical activity in the $(+)_{546}$[Co(tri)$_2$]$^{3+}$ complex; one is the arrangement of donor atoms distorted from octahedron, and another is structural features inherent in the TRI ligand such as a pitch of the benzene rings or a chiral arrangement of (benzene ring)–C=N– moieties. On the basis of the CD spectrum of $(+)_{546}$[Ni(tri)(H$_2$O)$_3$]$^{2+}$, they have concluded that one TRI ligand is ineffective in generating dissymmetric environment around a metal ion and that the former source is the principal one in $(+)_{546}$[Co(tri)$_2$]$^{3+}$.

On the other hand, the present [Co(tacn)(tri)]$^{3+}$ complex exhibits a clear CD peak in the d-d absorption band region, like $(+)_{546}$[Co(tri)$_2$]$^{3+}$ does. Furthermore, the distortion around the threefold symmetry axis seems to be small in $(+)^{CD}_{500}$[Co(tacn)(tri)]$^{3+}$, on account of a weak interaction between the TACN and TRI ligands, which is considered to be repulsive rather than attractive. Consequently, the crystal field distortion is not regarded as the principal source for the metal-centered optical activity in the $(+)^{CD}_{500}$[Co(tacn)(tri)]$^{3+}$ and $(+)_{546}$[Co(tri)$_2$]$^{3+}$ complexes. It is known[7] that the TACN chelate rings in [Co(tacn)$_2$]$^{3+}$ and [Co(gly)(NH$_3$)(tacn)]$^{2+}$ are flexible and the conformations are not fixed in an aqueous solution. Stereo models suggest that there is no preferential conformation of TACN in the [Co(tacn)(tri)]$^{3+}$ complex. Therefore, the optical activity due to conformations of TACN is considered to be small. It is reasonable to consider that the TRI complexes gain some activity from the chiral sequence of the (benzene ring)–C=N– moieties through the dynamic coupling mechanism.[3] A helical arrangement of the six benzene rings in $(+)_{546}$[Co(tri)$_2$]$^{3+}$ (in a sense of a left-handed helix, Λ) is also ineffective in raising the apparent metal-centered optical activity.

Metal Complexes of Amino Acids. XIV.[1] Carbon-13 NMR of Cobalt(III) Complexes Containing *N*-Substituted Glycines

Tomoharu AMA,* Hiroshi KAWAGUCHI, and Takaji YASUI

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

(Received May 14, 1981)

Synopsis. The down-field shifts of α-carbons in *N*-alkylglycines, which were caused by the chelation to cobalt(III), were larger than those in *C*-alkylglycines. The down-field shifts of *N*-(carboxymethyl)glycine (ida) and *N*-(2-aminoethyl)glycine (enma) in fac complexes were also larger than those of ida and enma in mer complexes, respectively, and those of the *C*-alkylglycines.

In the previous paper,[2] we reported that the chelation of α-amino acids to cobalt(III) ion brigns about down-field changes in ^{13}C NMR chemical shifts of their carboxyl-carbons (C_{oxy}) and α-carbons (C_α). However, references were not made concerning the difference in ^{13}C NMR behavior between α-amino acids containing $-NH_2$ group and those containing –NH–R group. In the present paper, we will describe the difference in the NMR behavor. In addition, we will discuss about the relationship between the coordination forms of the tridentate ligand and the ^{13}C NMR chemical shifts, in connection with the chelation shifts of the α-amino acids containing the –NH–R group.

Experimental

The complexes examined were prepared by the procedures similar to those described in previous papers.[2-7]

^{13}C NMR spectra at 22.5 MHz were recorded on a JEOL FX-90Q spectrometer, in pulsed Fourier transform/proton noise decoupled mode. The field frequency ratio was stabilized by locking to internal D_2O. Peak positions were measured relative to internal dioxane (δ=67.40).

a) $\delta(C_\alpha)$ and $\alpha(C_{oxy})$: Chemical shifts of C_α and C_{oxy} in the free ligand (in acidic D_2O solution). b) $\delta_{ch}(C_\alpha)$ and $\delta_{ch}(C_{oxy})$: Chemical shifts of C_α and C_{oxy} in the chelated ligand. c) $\Delta_{ch}(C_\alpha)$ and $\Delta_{ch}(C_{oxy})$: $\Delta_{ch}(C_\alpha)=\delta_{ch}(C_\alpha)-\delta(C_\alpha)$ and $\Delta_{ch}(C_{oxy})=\delta_{ch}(C_{oxy})-\delta(C_{oxy})$.

Results and Discussion

The chemical shift changes arising from the chelation of amino acids are listed in Table 1, together with the structures and abbreviations of the ligands. The $\Delta_{ch}(C_\alpha)$ and $\Delta_{ch}(C_{oxy})$ values of *C*-alkylglycines ($NH_2CHRCOOH$) are smaller than those of glycine. This result is consistent with those described in the previous papers.[2,3] That is, the $\Delta_{ch}(C_\alpha)$ values of L-val, L-leu, L-ile, L-ser, L-thr, and L-phe were included in the range +3.8—+5.4 ppm, compared with +5.7 ppm of glycine.

On the other hand, the $\Delta_{ch}(C_\alpha)$ values of *N*-alkylglycines ($R-NHCH_2COOH$) are larger than that of glycine, though the $\Delta_{ch}(C_{oxy})$ values of the *N*-alkylglycines are smaller than that of glycine. The $\Delta_{ch}(C_\alpha)$ values of L-pro and L-hyp, which may belong to *N*-alkyl-*C*-alkylglycines, are intermediate between the $\Delta_{ch}(C_\alpha)$ value of the *N*-alkylglycine and that of the *C*-alkylglycine.

N-(Carboxymethyl)glycine (=iminodiacetic acid; ida) and *N*-(2-aminoethyl)glycine (=ethylenediamine-*N*-acetic acid; enma) containing –NH–R groups are able to coordinate to cobalt(III) in both of meridional (*mer*) and facial (*fac*) forms. It is known that the tridentate ida prefers the fac form to the mer form in both $[Co(ida)(NH_3)_3]^+$ and $[Co(ida)_2]^-$ complexes,[4–7] although recently the *mer*-$[Co(ida)_2]^-$ complex was isolated.[9,10] The $\Delta_{ch}(C_\alpha)$ values of the ida taking the fac form are larger than that of glycine. Similarly, the $\Delta_{ch}(C_\alpha)$ values of the enma, taking the fac form in $[Co(enma)(NH_3)_3]^{2+}$ and *trans*(*O*)-$[Co(enma)_2]^+$,[8] are larger than that of glycine. One of the important factors which are responsible for the large $\Delta_{ch}(C_\alpha)$ values will be the –NH–R groups of ida and enma, as is suggested by the present result that the $\Delta_{ch}(C_\alpha)$ values of *N*-alkylglycines are larger than that of glycine.

The chemical shifts of cobalt(III) complexes are affected by the anisotropic effect of cobalt(III) and by the trans influence of the coordinating atoms.[12–15] These effects in *mer*-$[Co(ida)_2]^-$ are equal to those in *s-fac*-$[Co(ida)_2]^-$. However, the $\Delta_{ch}(C_\alpha)$ value of *mer*-$[Co(ida)_2]^-$ is smaller than that of *s-fac*-$[Co(ida)_2]^-$. This difference may result from the difference of the geometrical structures of the ida. Similar result was obtained for the complexes containing diethylene-triamine (dien) by Ha *et al.*[16] They pointed out that the ^{13}C NMR spectral pattern of the *mer* forms of dien is distinguishable from the *fac* forms of dien. The carbons attaching to the central –NH– in the *mer* dien were resonated at lower field than those in the *fac* dien, that is, the Δ_{ch} values of the *mer* dien are smaller than those of the *fac* dien. The $\Delta_{ch}(C_\alpha)$ value of $[Co(glygly)(ida)]^-$, which includes a *mer* ida,[11] is also smaller than the $\Delta_{ch}(C_\alpha)$ values of the complexes including the *fac* ida. Similar result was obtained for the enma complexes. That is, the $\Delta_{ch}(C_\alpha)$ value of enma in *mer*-$[Co(glygly)(enma)]$,[11] is smaller than those of the *fac* enma in the other enma complexes (Table 1).

The differences of the $\Delta_{ch}(C_{oxy})$ values among the ligands examined were not so distinct as those of the $\Delta_{ch}(C_\alpha)$ values.

This work was partially supported by a Grant-in-Aid for Scientific Research No. 554189 from the Ministry of Education, Science and Culture.

The Reductive Coupling of Organic Halide Using Hydrazine and a Palladium Catalyst. II.[1] Homocoupling of 1-Iodoalkanes

Riichiro NAKAJIMA,* Kazuhiro MORITA, and Tadashi HARA
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma, Imadegawa Kamikyo-ku, Kyoto 602
(Received February 5, 1981)

Synopsis. The hydrogenolysis and dimerization of iodoalkanes were catalyzed by Pd in the presence of an appropriate reducing agent. Hydrazine was found to be effective for the coupling of 1-iodoeicosane to give tetracontane, $C_{40}H_{82}$, in a 74% yield. The yield of the coupling product decreased with the decrease of the number of the carbon atoms in the 1-iodoalkanes. Both alkylhydrazines and alkenes were shown not to take part in the reaction as a reaction intermediate.

We reported[1,2] that iodoarenes were converted to the corresponding biaryls in high yields by the use of a catalytic amount of palladium amalgam. No report has been published on the coupling of haloalkanes by the use of a catalytic amount of metal. Stille and Lau[3] reported that the reactive haloalkanes such as 9-bromofluorene were coupled with a stoichiometric amount of a palladium(0) complex. The present study has, therefore, been carried out in order to examine the homocoupling of the inert haloalkanes by the use of a catalytic amount of palladium metal or its salts. The higher iodoalkanes gave the corresponding bialkyls in high yield.

Results and Discussion

As shown in Table 1, 1-iodoalkanes reacted with hydrazine in the presence of catalytic amounts of palladium salt to produce coupling products. The highest yield was obtained in the case of 1-iodoeicosane. Palladium chloride was reduced in the initial stage of the reaction to give the metal, and the palladium metal formed was quantitatively recovered after the reaction. The coupling of iodoalkanes was examined with a catalytic amount of palladium metal in place of its salt to give the corresponding dimers in low yield (Eqs. 1 and 2).

$$2RI + Pd \longrightarrow RR + PdI_2 \quad (1)$$

$$PdI_2 + NH_2NH_2 \longrightarrow Pd + 2HI + N_2 + H_2 \quad (2)$$

To determine the products and the effect of hydrazine on the present reaction, the reaction involving 1-iodotetradecane(**1**) was examined, as shown in Table 2. The reaction products consisted of 1-methoxytetradecane(**2**), 1-tetradecene(**3**), tetradecane(**4**), and octacosane(**5**). The distribution of these products was strongly affected by the presence or absence of palladium and/or hydrazine. The highest yield of the dimer was obtained in the reaction with 85% hydrazine hydrate. In the absence of the catalyst, the methanolysis of iodoalkane occurred, and the hydrogenolysis and dimerization did not. No hydrazine was necessary for the coupling of iodoalkanes, in contrast with that of iodoarenes.[1]

The facts that an alkylhydrazine($RNHNH_2$) was prepared with anhydrous hydrazine and haloalkane[4] and that its decomposition produced the corresponding alkanes (RH and RR)[5] indicate that the reaction *via* alkylhydrazine derivative might be involved in the present system. Several results which exclude this are as follows: (1) The yield of **5** with tetradecylhydrazine (Run 4) was lower than that with hydrazine hydrate (Run 2)[6] and (2) No reaction of hydrazine hydrate with **1** occurred.

Since the reaction with methylhydrazine (Run 3) gave **3** in 46.4% yield, the dimerization of **3** was examined. Its intermediate may be denied from the following results: (1) No octacosene was detected (Run 2), and (2) No reductive coupling of **3** occurred under the experimental conditions in Run 2 except **1**, because **3** was quantitatively recovered.

It is consequently concluded that the coupling of

Table 1. Reductive homocoupling of 1-iodoalkanes using hydrazine and palladium catalyst[a]

Iodoalkane	Coupling product	Yield/%[b]
1-Iodohexane	Dodecane	0.7
1-Iodooctane	Hexadecane	5.4
1-Iododecane	Eicosane	7.9
1-Iodododecane	Tetracosane	14.8
1-Iodotetradecane	Octacosane	33.9
1-Iodotetradecane	Octacosane	44.5[c]
1-Iodohexadecane	Dotriacontane	40.3[d]
1-Iodooctadecane	Hexatriacontane	47.2[d]
1-Iodoeicosane	Tetracontane	55.3[d]
1-Iodoeicosane	Tetracontane	74.2[c,d]

a) A reaction mixture of iodoalkane(25.0 mmol), NaOH (125 mmol), and $PdCl_2$(2.5 mmol) in 16 ml of MeOH containing of 85% $NH_2NH_2 \cdot H_2O$(15 mmol) was refluxed for 6 h. b) Yield determined by GLPC. c) The 1.5-fold amounts of NaOH and 85% $NH_2NH_2 \cdot H_2O$ were used. d) Yield of the crude product.

Table 2. Effect of reducing agent on the reductive homocoupling of 1-iodotetradecane by the use of palladium chloride as catalyst[a]

Run	Reducing agent	Products/%[b]			
		2	**3**	**4**	**5**
1	None	11.0	15.1	59.8	13.3
2	85% $NH_2NH_2 \cdot H_2O$	12.2	19.5	36.4	33.9
3	CH_3NHNH_2	0.0	46.4	48.9	3.3
4	n-$C_{14}H_{29}NHNH_2$	5.1	44.1	99.5	8.0
5	$C_6H_5NHNH_2$	36.3	13.4	50.8	Trace

a) A mixture of **1**(25.0 mmol), $PdCl_2$(2.5 mmol), and NaOH(125 mmol) in 16 ml of MeOH containing the reducing agent(15 mmol) was refluxed for 6 h with stirring. b) Based on the iodoalkane.

1-iodoalkanes with hydrazine may not proceed through the hydrazine derivative and the alkene. Presumably, the hydrogenolysis and dimerization of 1-iodoalkanes proceed *via* an alkylpalladium complex, and the hydrazine used is consumed for reducing the palladium iodide formed.

Experimental

Materials. The reagents used were of commercial grade except of 1-iodooctane,[7] 1-iododecane,[7] 1-iodododecane,[7] 1-iodotetradecane(**1**),[7] 1-iodohexadecane,[7] 1-iodooctadecane[7] (mp 34.2—35.0 °C, lit,[8] 33.7—34.1 °C), 1-iodoeicosane[7] (mp 39.5—40.0 °C, lit,[8] 41.3—41.6 °C). Anhydrous hydrazine[9] was prepared by the methods given in the literature. The purity of all iodoalkanes determined by GLPC was over 98%.

Preparation of Tetradecylhydrazine(a New Compound): A mixture of anhydrous hydrazine (13 g, 0.38 mol), 1-bromotetradecane (21 g, 0.072 mol), and ethanol (15 ml) was refluxed with a magnetic stirrer for 35 h in a flask equipped a reflux condenser with a drying tube. The mixture was cooled until room temperature and then poured into water (50 ml) of 7 g of sodium hydroxide. The solid products and the ether-extractable materials were combined, and distilled under reduced pressure in a nitrogen atmosphere, giving 8.65 g (52%) of the hydrazine: bp 185—188 °C/1.5 kPa; white crystals, mp 40.5—42.0 °C. This melting point agreed closely with the value interpolated from the results of Westphal[4] for dodecylhydrazine (31 °C) and hexadecylhydrazine (57—58 °C). This new hydrazine was identified with maleic acid derivative. The *cis*-2-butenedioic dihydrazide showed: mp 116.5—117.3 °C; Found: C, 69.87; H, 10.60; N, 9.11%. Calcd for $C_{18}H_{32}N_2O_2$: C, 70.09; H, 10.46; N, 9.08%. Since the free hydrazine slowly decomposed in air, it was prepared before every use.

Reductive Coupling of 1-Iodoalkane Using Hydrazine and Palladium Catalyst. A mixture of 1-iodoalkane (25.0 mmol), NaOH (125 or 188 mmol), and $PdCl_2$ (2.5 mmol) in 16 ml of MeOH containing 85% $NH_2NH_2 \cdot H_2O$ (15 or 22.5 mmol) was refluxed for 6 h with stirring. The resulting mixture was filtered, and the residual metal was washed with hexane, and subsequently water. The organic layer was separated from the aqueous layer and evaporated. The yield of dimer was determined by GLPC. The dimers having more than twenty-eight carbon atoms were separated as a residue in the vacuum distillation using the Büchi Kugelrohrofen GRK-50, weighed, and recrystallized from hexane–methanol. Dotriacontane: mp 66.7—67.5 °C (lit,[10] 69.5—70.6 °C); Found: C, 85.38; H, 14.81%. Calcd for $C_{32}H_{66}$: C, 85.24; H, 14.76%. Hexatriacontane: mp 72.5—73.3 °C (lit,[10] 75.2—76.1 °C); Found: C, 85.20; H, 14.91%. Calcd. for $C_{36}H_{74}$: C, 85.29; H, 14.71%. Tetracontane: mp 78.8—79.5 °C (lit,[8] 81.2—81.4 °C); Found: C, 85.20; H, 14.82%. Calcd. for $C_{40}H_{82}$: C, 85.32; H, 14.68%.

Reductive Coupling of 1-Iodotetradecane with Various Reducing Agents. A mixture of **1** (25.0 mmol), $PdCl_2$ (2.5 mmol), and NaOH (125 mmol) in 16 ml of MeOH containing the reducing agent (15 mmol) was stirred for 6 h under reflux. The resulting mixture was filtered, and the residual metal was washed with hexane and then with water. After the organic layer was separated from the aqueous layer, the reaction products were obtained by the evaporation of the solvent, and analyzed by GLPC and GC-MS. Since both **3** and **4** gave an overlapped peak on the column used (SE-30), the peak of **3** was separated from that of **4** by brominating **4** with a bromine–tetrachloromethane solution, followed by the estimation of **4**. Octadecane and eicosane were used as the internal standards.

The present work was partially supported by a Science and Engineering Research Grant-in-Aid from the Science and Engineering Research Institute of Doshisha University.

The Synthesis of New Electron Acceptors, 9,10-Bis[cyano-(ethoxycarbonyl)methylene]-9,10-dihydroanthracene and 10-[Cyano(ethoxycarbonyl)methylene]-9-anthrone

Takashi NOGAMI,* Yasuhiro KANDA, Hidekazu TANAKA, and Hiroshi MIKAWA

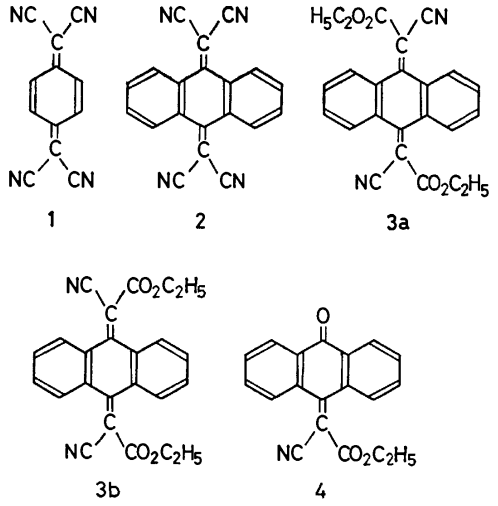
(Received February 6, 1981)

Synopsis. We synthesized two new electron acceptor molecules. Their electron affinities were estimated by measuring the charge-transfer absorption spectra with three donor molecules in a 2-methyltetrahydrofuran solution. The former molecule was estimated to have an electron affinity comparable to 1,3,5-trinitrobenzene, and the latter, to *m*-dinitrobenzene.

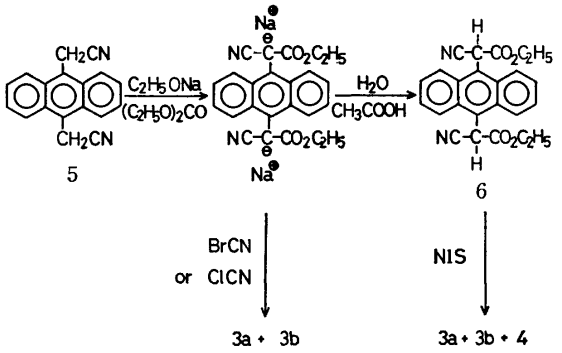
3,6-Bis(dicyanomethylene)-1,4-cyclohexadiene (**1**), often called TCNQ, is known to form highly conductive organic complexes with various donor molecules.[1] The acceptor molecule, 9,10-bis(dicyanomethylene)-9,10-dihydroanthracene (**2**) is also expected to form highly conductive complexes, but it has not yet been synthesized. Although the attempt to prepare



2 was unsuccessful, we could obtain the precursor of **2**, 9,10-bis[cyano(ethoxycarbonyl)methylene]-9,10-dihydroanthracene (**3**), and a by-product, 10-[cyano-(ethoxycarbonyl)methylene]-9-anthrone (**4**). Their electron affinities were estimated by measuring the charge-transfer (CT) absorption bands of the 2-methyltetrahydrofuran (MTHF) solution of these new acceptors and of three donor molecules.

Results and Discussion

Synthesis of the New Acceptors. The synthetic route is illustrated below. 9,10-Bis(cyanomethyl)anthracene (**5**) was synthesized by the procedures described in the literature.[2] The treatment of **5** with sodium ethoxide and diethyl carbonate, followed by hydrolysis, gave 9,10-bis[cyano(ethoxycarbonyl)methyl]anthracene (**6**). The dehydrogenation of **6** with *N*-iodosuccinimide (NIS) gave new electron acceptors, **3a**, **3b**, and **4**. The acceptors, **3a** and **3b**, were also obtained by the reaction of **5** with sodium ethoxide and diethyl carbonate, followed by the reaction with cyanogen chloride or cyanogen bromide.[3]



Measurements of the Charge-transfer Absorption Spectra. The CT-absorption spectra of the new acceptors were measured in a 2-methyltetrahydrofuran (MTHF) solution of **3** and **4** with three donor molecules at room temperature or at 77 K. *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD), *N,N*-dimethyl-*p*-phenylenediamine (DMPD), and *N,N*-dimethylaniline (DMA) were used as the donors. Figure 1 shows the electronic-absorption spectra of these donor molecules with **3**. All these solutions showed a purple color at 77 K, although the color was not seen at room temperature even with the concentrated solution. New absorption bands were observed at the region of wavelengths longer than 400 nm.[4] The plot of the new

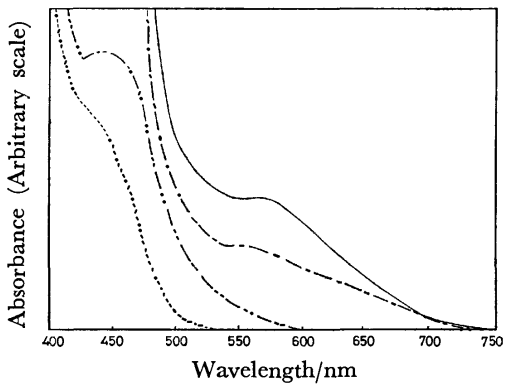


Fig. 1. Charge-transfer absorption spectra of **3** with TMPD, DMPD, and DMA in 2-methyltetrahydrofuran at 77 K.
[**3**] = 1.37×10^{-2} mol/l, [TMPD] = 1.45×10^{-2} mol/l, [DMPD] = 1.38×10^{-2} mol/l, [DMA] = 2.0 mol/l.
——: TMPD–**3**, – – –: DMPD–**3**, ———: DMA–**3**, ——: **3** only.

absorption peak positions ($h\nu_{CT}$) against the ionization potentials (I_p) of the donor molecules[5] gave the linear relation approximated as $h\nu_{CT}=1.1\ I_p-5.3$ in eV units, which is almost identical with that obtained by the use of 1,3,5-trinitrobenzene with various donor molecules.[5] Similarly the electronic-absorption measurements of **4** with the same donor molecules at room temperature gave the linear relation of $h\nu_{CT}=0.9\ I_p-3.3$, almost identical with that obtained by the use of *m*-dinitrobenzene with various donors.[5] Thus, the new absorptions are ascribed to the CT-transition. The electron affinities of **3** and **4** are roughly equal to those of 1,3,5-trinitrobenzene and *m*-dinitrobenzene.[6]

Experimental

Preparations of 9,10-Bis[cyano(ethoxycarbonyl)methylene]-9,10-dihydroanthracene (3) and 10-[Cyano(ethoxycarbonyl)methylene]-9-anthrone (4). 9,10-Bis[cyano(ethoxycarbonyl)methyl]anthracene (6): Sodium metal (0.5 g) was added to ethanol (20 ml), and the unreacted ethanol was distilled out. To the residual sodium ethoxide we then added a mixture of diethyl carbonate (10 g), toluene (3 ml), and **5** (1.5 g). The solution became yellow green. The resultant reaction mixture was stirred under reflux. Since the solvent was distilled out during the reaction, toluene was added from a dropping funnel in order to maintain a roughly constant volume of the reaction medium. After 1.5 h, the reaction mixture was cooled to room temperature and then hydrolysed by adding water (40 ml). Acetic acid (2 ml) was added, the mixtures was extracted three times with dichloromethane (50 ml), and the extract was shaken three times with 50 ml of water. The organic layer was separated and dried overnight over anhydrous magnesium sulfate. After the filtration of the magnesium sulfate, the dichloromethane was completely distilled out, hexane was added, we thus obtained 1.6 g of a brown solid (68%). After treatment with active charcoal, the raw material was recrystallized from diethyl ether to give a yellow powder of **6**: mp 198—205 °C; Found: C, 72.03; H, 5.01; N, 6.81%. Calcd for $C_{24}H_{20}N_2O_4$: C, 71.98; H, 5.03; N, 7.00%; MS: *m/e* 400 (M^+); IR (KBr): 2250 (C≡N), 1730 cm^{-1} (C=O); NMR ($CDCl_3$) $\delta=1.15$ (6H, m, CH_3), 4.20 (4H, m, CH_2), 6.20 (2H, s, tert H), 7.70 (4H, m, ring H), 8.30 (4H, m, ring H).

9,10-Bis[cyano(ethoxycarbonyl)methylene]9,10-dihydroanthracene (3a, 3b) and 10-[Cyano(ethoxycarbonyl)methylene]-9-anthrone (4) Method A: After **5** has been reacted with sodium ethoxide and diethyl carbonate by the procedures described above, BrCN (3.75 g) was stirred in, the mixture was heated gradually up to 55—60 °C for 2 h, and kept overnight at room temperature, and the toluene was distilled out. The addition of cold water, followed by the filtration of the precipitate, gave a raw product (**3**). An additional precipitate was obtained after keeping the filtrate for several days. Purification by means of a liquid chromatograph (Japan Analytical Industry, LC 07), using chloroform as the eluent, gave 1.58 g of **3** (66%) as a pale yellow powder. In the above procedure, ClCN can also be used instead of BrCN. Compound **3**: mp 145—152, 176—182 °C, arising from *cis*- and *trans*-isomers. Found: C, 72.70; H, 4.52; N, 6.96%. Calcd for $C_{24}H_{18}N_2O_4$: C, 72.35; H, 4.55; N, 7.03%. MS: *m/e* 398 (M^+); IR (KBr) 2210 (C≡N), 1720 (C=O), 1580 cm^{-1} (C=C); NMR ($CDCl_3$) $\delta=1.25$ (6H, m, CH_3), 4.30 (4H, m, CH_2), 7.50 (4H, m, ring H), 8.15 (4H, m, ring H).

Method B: The reaction vessel was covered with aluminum foil. Into the acetonitrile (12 ml) solution of *N*-iodosuccinimide (0.6 g) we stirred, drop by drop, an acetonitrile (60 ml) solution of **6** (0.5 g) under a nitrogen atmosphere. The solution was stirred for 3 h at room temperature under the nitrogen atmosphere, 400 ml of chloroform was added, and the solution was shaken four times with 200 ml of an aqueous solution of sodium thiosulfate and potassium hydroxide (both 5%) in the separatory funnel. The organic layer was washed with water until the aqueous layer became neutral. The solution was then dried overnight over calcium chloride, and the solvent was distilled out, we thus obtained a reddish-brown oil. The addition of hexane gave a yellow powder (0.32 g). The raw material was purified by liquid chromatograph, using chloroform as the eluent, to give **3** (0.2 g, 40%) and **4** (0.1 g, 43%). The recrystallization of **4** from a benzene–hexane mixed solvent gave yellow, needle-like crystals. Compound **4**: mp 146—147 °C. Found: C, 75.00; H, 4.06; N, 4.47%. Calcd for $C_{19}H_{13}NO_3$: C, 75.24; H, 4.32; N, 4.62%. MS: *m/e* 303 (M^+). IR (KBr) 2210 (C≡N), 1720, 1690 (C=O), 1580 cm^{-1} (C=C). NMR ($CDCl_3$) $\delta=1.20$ (3H, m, CH_3), 4.20 (2H, m, CH_2), 7.65 (4H, m, ring H), 8.24 (4H, m, ring H).

Electronic-absorption Measurements. The electronic-absorption spectra were measured by means of a Hitachi 340 recording spectrophotometer.

3) Attempts of the separation of **3a** from **3b** by repeated liquid chromatography, using chloroform as the eluent, were unsuccessful. The attempt to convert **3** or **4** to the corresponding acid amide by the reaction of **3** or **4** with aqueous ammonia or liquid ammonia was also unsuccessful.

4) The CT-absorption peak positions of **3** and **4** with three donor molecules (nm): **3**–TMPD 570; **3**–DMPD 550; **3**–DMA 475; **4**–TMPD 490; **4**–DMPD 465; **4**–DMA 430.

5) R. Foster, "Organic Charge-transfer Complexes," Academic Press, London and New York (1969), pp 40—69.

6) The electron affinities of 1,3,5-trinitrobenzene and *m*-dinitrobenzene are 0.7 eV and 0.3 eV respectively (see Ref. 5, p. 387). An irreversible chemical reaction occurred during the measurements of the cyclic voltammetry of **3** and **4**. Thus, we could not obtain their half-wave reduction potentials.

A Convenient Synthesis of 3-(Diethoxymethyl)alkanals

Kazuhiko SAIGO,* Shuji OKAGAWA, and Hiroyuki NOHIRA

Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-ohkubo, Urawa 338

(Received December 12, 1980)

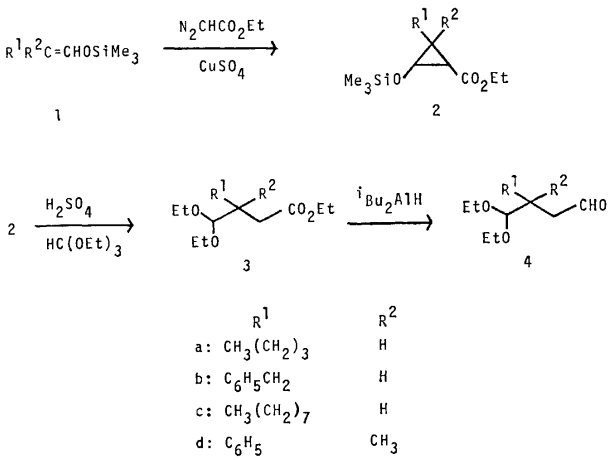
Synopsis. 3-(Diethoxymethyl)alkanals were obtained in moderate yields by the diisobutylaluminium hydride reduction of ethyl 3-(diethoxymethyl)alkanoates, which were simply synthesized in one pot by the copper(II)-catalyzed reaction of ethyl diazoacetate with 1-trimethylsiloxy-1-alkenes, followed by the ring cleavage of the resulting cyclopropanes with concentrated sulfuric acid in the presence of triethyl orthoformate.

1,4-Dicarbonyl compounds are attractive intermediates, and their synthesis is of interest because they can be converted into cyclopentenones, furans, and lactones. Among the many synthetic methods for 1,4-dicarbonyl compounds, the method *via* the cyclopropanation of enol acetates,[1-3] enol ethers,[3-6] or silyl enol ethers[3,7-9] with carbenes generated from 2-diazo carbonyl compounds is the elegant one.

The cyclopropanation was applied to the one pot preparation of ethyl 3-(diethoxymethyl)alkanoates (**3**) based on the consideration that the ring cleavage of the cyclopropanes derived from 1-trimethylsiloxy-1-alkenes and ethyl diazoacetate with an acid in the presence of triethyl orthoformate would result in the one pot synthesis of **3**. When 1-trimethylsiloxy-1-hexene (**1a**) was allowed to react with ethyl diazoacetate (4 equimolar amounts) in cyclohexane in the presence of a catalytic amount of copper(II) sulfate under reflux, distillation under reduced pressure yielded a colorless oil, ethyl 2-butyl-3-(trimethylsiloxy)cyclopropanecarboxylate (**2a**), in 92% yield. Treatment of **2a** in ethanol with concentrated sulfuric acid in the presence of triethyl orthoformate for 24 h at room temperature gave ethyl 3-(diethoxymethyl)heptanoate (**3a**) in 91% yield (83% total yield from **1a**). On the other hand, when the ring cleavage was carried out without isolation of **2a** after the cyclopropanation, similar yield was achieved (78% total yield from **1a**). The reduction of **3a** with diisobutylaluminium hydride (1.5 equimolar amount) in a mixture of cyclohexane and ether (2:3) at −70 °C for 3 h, followed by thin layer chromatographic purification, gave 3-(diethoxymethyl)heptanal (**4a**) in 74% yield.

These results mean that the precursors for 3-substituted furan synthesis, 3-(diethoxymethyl)alkanals (**4**), could be conveniently obtained by the diisobutylaluminium hydride reduction of ethyl 3-(diethoxymethyl)alkanoates (**3**), which were simply synthesized in one pot through two reaction steps; step 1) the cyclopropanation of 1-trimethylsiloxy-1-alkenes (**1**) with ethyl diazoacetate, step 2) the ring cleavage of the resulting cyclopropanes (**2**) with concentrated sulfuric acid in the presence of triethyl orthoformate, as shown in Scheme 1.

Several runs were carried out giving similar ethyl 3-(diethoxymethyl)alkanoates (**3**) or 3-(diethoxymethyl)alkanals (**4**) (Table).



Scheme 1.

TABLE 1. SYNTHESES OF ETHYL 3-(DIETHOXYMETHYL)-ALKANOATES AND 3-(DIETHOXYMETHYL)ALKANALS

3d	**4d**	76	[138[b]]	(0.8)][c]

a) 1 mmHg≈133.3 Pa. b) Bath temperature. c) The products were separated by TLC, and the boiling points were determined by bulb to bulb distillation.

Experimental

Boiling points are uncorrected. The ^{1}H-NMR spectra were recorded in CCl_4 solution at 60 MHz on a Varian A-60 Spectrometer using TMS as an internal standard. The IR spectra were determined on a JASCO IR-2A Spectrometer.

Materials. All silyl enol ethers were synthesized by the similar method described in the literature[10] giving mixtures of (*E*)- and (*Z*)-isomers, and they were used without separation. Ethyl diazoacetate and diisobutylaluminium hydride were prepared by the methods reported, respectively.[11,12]

Synthesis of Ethyl 3-(Diethoxymethyl)alkanoate (3). To a refluxing suspension of 1-trimethylsiloxy-1-alkene (**1**) (10 mmol) and anhydrous $CuSO_4$ (185 mg, 1.2 mmol) in dry cyclohexane (4 ml) was added ethyl diazoacetate (4.57 g, 40 mmol) in dry cyclohexane (19 ml) under argon atmosphere with vigorous stirring in a period of 2.5 h. After refluxing for additional 9.5 h, the reaction mixture was

cooled, and insoluble materials were filtered off and washed with cyclohexane (15 ml×3). The filtrate and the washings were combined and concentrated under reduced pressure. The oily product was dissolved in dry ethanol (5 ml). To the solution were added ethyl orthoformate (1.48 g, 10 mmol) and two drops of concentrated H_2SO_4. After standing for 24 h, H_2SO_4 was neutralized by addition of sodium ethoxide in dry ethanol. The insoluble mass appeared was filtered off and washed with ether (15 ml×3). The filtrate and the washing were combined and concentrated using a rotary evaporator. Distillation of the oil remained gave ethyl 3-(diethoxymethyl)alkanoate (**3**).

3a: IR (neat) 1740, 1180, 1130, and 1075 cm^{-1}; NMR (CCl_4) δ=0.90 (t, 3H, J=5 Hz), 1.03 (t, 3H, J=7 Hz), 1.14 (t, 3H, J=7 Hz), 1.22 (t, 3H, J=7 Hz), 1.1—1.6 (m, 6H), 1.9—2.7 (m, 3H), 3.49 (q, 2H, J=7 Hz), 3.50 (q, 2H, J=7 Hz), 4.06 (q, 2H, J=7 Hz), and 4.26 (d, 1H, J=4 Hz).

Found: C, 69.17; H, 8.94%. Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%.

*Reduction of **3** to 3-(Diethoxymethyl)alkanal (**4**).* To a solution of ethyl 3-(diethoxymethyl)alkanoate (**3**) (1.0 mmol) in a mixture of cyclohexane (10 ml) and ether (15 ml) was added a solution of diisobutylaluminium hydride (1.5 mmol) in cyclohexane (1.5 ml) at −70 °C under argon atmosphere in a period of 10 min. After stirring for additional 3 h at −70 °C, water (0.5 ml) was added to remove excess diisobutylaluminium hydride, and the mixture was warmed to room temperature. To the resulting mixture was added water (10 ml), and the insoluble materials appeared were filtered off. The organic layer was separated, dried with sodium sulfate, and concentrated under reduced pressure. Silica gel thin layer chromatographic purification gave 3-(diethoxymethyl)alkanal (**4**).

4a: IR (neat) 1730, 1115, and 995 cm^{-1}; NMR (CCl_4) δ=0.90 (t, 3H, J=5 Hz), 1.14 (t, 6H, J=7 Hz), 1.2—1.7 (m, 6H), 2.0—2.5 (m, 3H), 3.48 (q, 2H, J=7 Hz), 3.52 (q, 2H, J=7 Hz), 4.23 (d, 1H, J=4 Hz), and 9.43 (t, 1H, J=1 Hz).

Found: C, 66.59; H, 11.34%. Calcd for $C_{12}H_{24}O_3$: C, 66.63; H, 11.18%.

4b: IR (neat) 1730, 1120, 990, 750, and 700 cm^{-1}; NMR (CCl_4) δ=1.13 (t, 3H, J=7 Hz), 1.15 (t, 3H, J=7 Hz), 2.2—2.9 (m, 5H), 3.45 (q, 2H, J=7 Hz), 3.49 (q, 2H, J=7 Hz), 4.22 (d, 1H, J=4 Hz), 7.23 (s, 5H), and 9.56 (t, 1H, J=1 Hz).

Preparation of DL-Alanine by the Reaction of (±)-2-Chloropropionic Acid with Aqueous Ammonia under Pressure[1)]

Yoshiro OGATA* and Morio INAISHI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 23, 1981)

Synopsis. The effects of experimental conditions (molar ratio of reactants, concentration, temperature, and pressure) on the yield of DL-alanine produced by the reaction of (±)-2-chloropropionic acid with aqueous ammonia have been studied. Molar ratio of NH_3: $CH_3CHClCO_2H$ (*ca.* 10:1) much lower than that reported in the literature (68:1) can give a comparable yield (*ca.* 78%) by the reaction under pressure at 70 °C for 5 h, a much shorter time than that reported in the literature (over 96 h). Addition of ammonium carbonate does not increase the yield against the literature.[16)]

There are a number of methods for the chemical synthesis of 2-amino acids, *e.g.*, Strecker reaction with aldehyde–HCN–NH_3,[2-4)] Bücherer method[5)] using hydantoin with the components analogous to the Strecker's, and also ammonolysis of 2-halo acids with aqueous ammonia.[6-16)] The ammonolysis of 2-halo acids uses a large excess of ammonia (*e. g.*, NH_3: halo acid=60:1) at room temperature to avoid by-products, 2,2′-iminodipropionic and 2,2′,2″-nitrilotripropionic acid.

$$CH_3CHClCO_2H + NH_3 \longrightarrow \underset{\text{alanine}}{CH_3CH(NH_2)CO_2H}$$

$$+ \underset{\substack{\text{2,2′-iminodipropionic acid}\\(\text{Im})}}{[CH_3\dot{C}H(CO_2H)]_2NH} + \underset{\text{2,2′,2″-nitrilotripropionic acid}}{[CH_3\dot{C}H(CO_2H)]_3N}$$

However, this large excess of ammonia and a very long reaction time, *e. g.*, 4 d, are inconvenient, whereas the reaction at higher temperature in an open vessel gave a very poor yield because of the volatilization of ammonia. Hence we wished to shorten the reaction time and lower the molar ratio of (NH_3) : (halo acid), and we examined the effects of the molar ratio, reaction time, pressure, and temperature on the yield of DL-alanine produced by the reaction of (±)-2-chloropropionic acid with NH_3.

A few reports[6-16)] are available on this type of synthesis of 2-amino acid, but the reports discussing the effects of reaction conditions in detail are rare [10,16)] The present report is the summary of our data on the effect of several reaction parameters, especially pressure, on the yield of DL-alanine formed by the reaction of (±)-2-chloropropionic acid with aqueous saturated ammonia.

Results and Discussion

Effect of Temperature. A mixture of (±)-2-chloropropionic acid and 14.5 M (1 M=1 mol dm^{-3}) ammonia in a molar ratio of 10:1 was allowed to react in a sealed tube at various temperatures of 0—130 °C for 5 h, and the yield was measured by NMR. The results are shown in Fig. 1.

The optimum temperature was in a range of 50—70 °C; hence the increase of yield with progress of the reaction was recorded at 50, 60, and 70 °C. The results are shown in Fig. 2, which indicates that the optimum temperature is 70 °C, where a 78% yield based on (±)-2-chloropropionic acid is attained in 5 h reaction.

Effect of the Molar Ratio of Reactants. The ammonolysis was conducted with various ratios of $[NH_3]_0/[CH_3CHClCO_2H]_0$: 5/1, 10/1, 20/1, and 30/1.

The reaction with the molar ratio of 5:1 gave an appreciable amount of 2,2′-iminodipropionic acid (Im), while virtually no Im was found in the reaction with the ratio of 10:1. Consequently, we employed the ratio of 10:1 for most of the ammonolysis study. The higher ratio such as 68:1, which had been recommended in the literature[10,11)] gave really somewhat better yields, but the isolation of the product became troublesome due to dilution.

Effect of Initial Concentration of Ammonia. In order

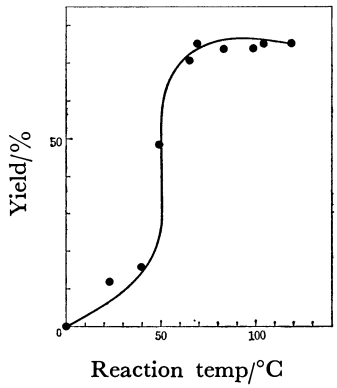

Fig. 1. Effect of the reaction temperature on the yield of DL-alanine formed by the reaction of (±)-2-chloropropionic acid with aqueous ammonia at 0—120 °C for 5 h with $[NH_3]_0$: $[ClCH(CH_3)CO_2H]_0$ =10:1.

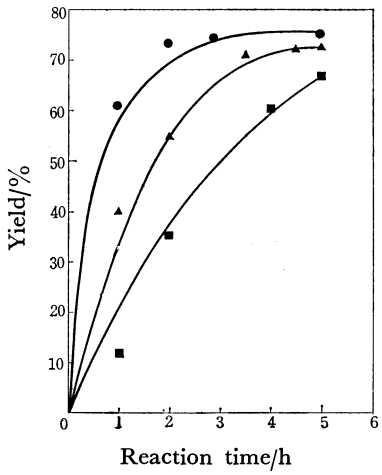

Fig. 2. Conversion curves for the formation of DL-alanine at various temperatures with $[NH_3]_0$:$[CH_3CHClCO_2H]_0$=10:1.
■: 50 °C, ▲: 60 °C, ●: 70 °C.

Table 1. Effect of initial concentration of NH_3 on the yield (%) of DL-alanine at various initial ratios of $[NH_3]_0/[CH_3CHClCO_2H]_0$

$\frac{[NH_3]_0}{[CH_3CHClCO_2H]_0}$	5	10	20	30
$[NH_3]_0=14.5$ M, yield/%	60.5	75.7	84.4	89.7
$[NH_3]_0=22.2$ M, yield/%	66.2	75.1	84.0	89.6

to find the effect of increasing concentration of ammonia, 22.8 M aqueous ammonia was prepared by passing gaseous NH_3 into the ice-cooled aqueous 14.5 M ammonia.

The effect of an increase in initial concentration of ammonia on the yield of DL-alanine at various initial molar ratios of reactants is shown in Table 1. The data in Table 1 show that the supersaturated solution of NH_3 cannot give a higher yield.

Effect of Agitation, Pressure and Addition of Ammonium Carbonate. Since there was no appreciable difference between the reaction in an autoclave and that in a sealed tube, the effect of agitation seems to be small. When the reaction was conducted at over 100 °C in an autoclave (*e. g.*, 130—140 °C at 17—19 atm), the yields of the by-products, Im, and DL-lactic acid, tended to increase.

Addition of ammonium carbonate was reported to give a better yield of DL-alanine,[16] but in our hands its addition reduced the yield to 37% accompanied by a rather high yield of DL-lactic acid.

Isolation of DL-Alanine. The NMR analysis of DL-alanine was checked by its isolation. The isolation was done by evaporation, addition of methanol and filtration. The decrease of alanine yield in the isolation and purification processes was *ca.* 32% in comparison with the yield based on the NMR analysis, whereas the yield of purified alanine which contained *ca.* 0.8 wt% NH_4Cl and no iminodipropionic acid, was 46%. The large loss of alanine in the purification process is due to a high solubility of alanine similar to that of NH_4Cl in aqueous solution. The analogous yield (43—46%) was reported in the reaction of 68 fold excess ammonia with chloropropionic acid carried out at room temperature for 96 h.[10,11] Although a better isolation yield may be obtained for bromopropionic acid due to small solubility of NH_4Br in methanol,[10] we did not attempt to use it because of its high cost.

Experimental

General. NMR spectra were measured on a 60 MHz Hitachi R-24B NMR spectrometer at 25 °C using dimethyl sulfoxide as an internal standard. Melting points were measured by a Yanagimoto micro melting point apparatus and uncorrected.

Materials. (±)-2-Chloropropionic acid (bp: 182.0—182.5 °C) was of guaranteed grade and used without further purification. Aqueous ammonia of 28% (14.5 M) was titrated by standard 0.1 M HCl. DL-Lactic acid with bp 130.0—134.0 °C (25 Torr), and DMSO with bp 81.0—83.5 °C (23 Torr) were of first-grade commercial products. 2,2′-Iminodipropionic acid was prepared according to the literature.[17] D_2O used was 99.8% pure.

Apparatus. Two sorts of apparatus were used for ammonolysis; one is a 1.5 mm thick sealed tube of 150 ml (38 mm × 200 mm) capacity dipped in a polyethylene glycol (PEG) thermostat; the other is a stainless steel autoclave made by Taiatsu Glass Ind. Co., TEM-D 300 type, of 250 ml capacity with a mechanical stirrer, which is dipped in a PEG thermostat.

Typical Procedure. A mixture of (±)-2-chloropropionic acid (0.07 mol, 3.4 g) and 14.5 M aqueous ammonia (50 ml, 0.73 mol) was placed in a sealed tube or an autoclave and heated in a PEG bath. The internal temperature was maintained in a range of ±3 °C.

Thus far, the yield of alanine was measured by isolating it by addition of methanol after completion of the reaction,[8-11] and evaporation of water, but poor solubility of accompanying NH_4Cl in methanol rendered the estimation of the yield rather inaccurate; hence the NMR measurement of the formed DL-alanine solution was employed for estimation of the yield as described below.

Identification and Estimation of Products. Aliquots (each 1 ml) of the reaction mixture were pipetted out, and each sample was added with DMSO as an internal standard, diluted with D_2O, and the NMR peak assigned to methyl proton of DL-alanine (δ: 1.43 d) was measured. The working curve was prepared with an aqueous 14.5 M ammonia solutions of given concentrations of DL-alanine at pH 10—11 containing NH_4Cl (2.0 g). Contaminated DL-lactic acid, (±)-2-chloropropionic acid, and 2,2′-iminodipropionic acid were also characterized and estimated analogously by using their characteristic NMR peaks, δ 1.40, 1.65, and 1.54 d, respectively.

Besides estimation of the yield by NMR analysis DL-alanine was isolated from the reaction mixture. The reaction of (±)-2-chloropropionic acid (0.07 mol) with 14.5 M aqueous ammonia (50 ml, 0.73 mol) was conducted at 70 °C for 5 h in an autoclave. Then the solution was concentrated under a reduced pressure to 10 ml, added with methanol (100 ml), and the product was filtered. The filtered mass weighing 4.6 g (60%) contained 18% NH_4Cl, and it was purified by reprecipitation from water (20 ml) with methanol (100 ml) and then standing the mixture overnight in a refrigerator. The filtered pure DL-alanine (2.9 g) contained 0.8 wt% NH_4Cl, and the yield was 46%.

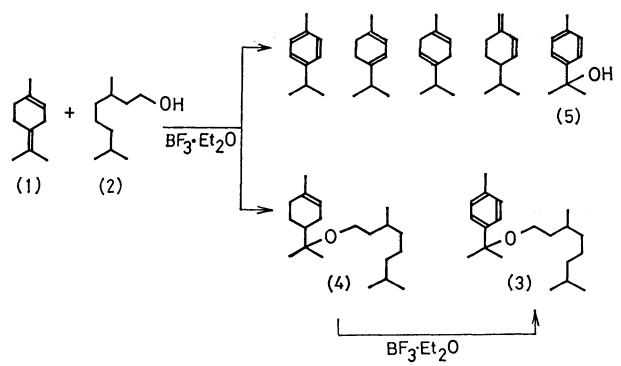
(Received February 16, 1981)

Synopsis. The reaction of terpinolene with tetrahydrogeraniol in the presence of boron trifluoride etherate gave an aromatic ether in addition to the corresponding aliphatic ether, along with *p*-cymene, *p*-cymen-8-ol, and the monoterpene hydrocarbons formed by double-bond migration. The aromatic ether was proved to form upon the treatment of the aliphatic ether with boron trifluoride etherate.

In connection with previous papers on the formation of ethers from monoterpene[1-6] and aliphatic[7,8] alcohols with boron trifluoride etherate, the effect of the same reagent on the addition reaction of tetrahydrogeraniol (**2**) to terpinolene (**1**) was examined.

In a typical experiment, equal portions (1.0 g) of terpinolene and tetrahydrogeraniol were mixed with boron trifluoride etherate (0.05 ml), after which the mixture was allowed to stand at room temperature for 5 days. The reaction mixture was then subjected to elution chromatography on silica gel, followed by preparative-GLC in Carbowax 6000, to give Compounds **3**, **4**, and **5** and also *p*-cymene. The structures of **3**, **4**, and **5** were characterized as 1-methyl-4-[1-(3,7-dimethyloctyloxy)-1-methylethyl]benzene, 1-methyl-4-[1-(3,7-dimethyloctyloxy)-1-methylethyl]-1-cyclohexene, and 1-methyl-4-(1-hydroxy-1-methylethyl)benzene (*p*-cymen-8-ol) respectively on the basis of their spectral data and chemical behavior.

Under mild conditions (Exp. No. 1, Table 1), the aromatic alcohol, **5**, *p*-cymene, and two ethers, **3** and **4**, were obtained as the major products. On the other hand, under vigorous conditions (Exp. No. 2), *p*-cymene was produced as the major product, together with small amounts of **3**, **4**, and **5** and three monoterpene hydrocarbons. Under these conditions, aromatic compounds were obtained as the main components. Furthermore, all the compounds were confirmed by GC/MS analysis. The aromatic ether, **3**, was also prepared albeit in a low yield, by treating the **4** ether with boron trifluoride etherate, as is shown in Table 2 and Scheme 1.



Scheme 1.

The results obtained in this paper are essentially comparable with those of previous works.[1,4-6] However, the formation of the aromatic compounds in considerable amounts is remarkable; this can be interpreted in terms of the participation of oxygen rather than disproportionation. In this connection, the obtaining of *p*-cymen-8-ol (**5**) is interesting; the mechanism of its formation is now under investigation.

Experimental

Apparatus. The IR spectra were taken in a CCl_4 solution, while the ^{1}H-NMR spectra were obtained in a CCl_4 solution, using TMS as the internal reference on a 60 MHz spectrometer. The mass spectra were measured by means of a Hitachi RMS-4 spectrometer under the following operating conditions: 80 eV, ionization-chamber voltage; 80 uA, total emission; 1800 eV, ion-accelerating voltage, and 200 °C, ionization-chamber temperature. The GLC was carried out on an FID-type apparatus in connection with a glass column (3 mm×2 m) packed with OV-1 (2%) on Diasolid L (60—80 mesh) and DEGS (3%) on Shimalite W (60—80 mesh) under a 20 ml/min flow rate of a N_2 carrier.

Materials. Commercial **1** and **2** were used after repeated fractional distillations. Each of them showed a single peak in GLC with OV-1 and DEGS-packed columns, and the IR and ^{1}H-NMR spectra of these materials were coincident with those of authentic ones.

A chemical-grade reagent of $BF_3 \cdot Et_2O$ (BF_3 47%) was used without any purification.

Reaction of 1 with 2 in the Presence of $BF_3 \cdot Et_2O$. To a mixture of **1** (1.0 g) and **2** (1.0 g), 0.05 ml or 0.15 ml of $BF_3 \cdot Et_2O$ was added, drop by drop. The mixture was then allowed to react at room temperature for 5 or 7 d respectively. The reaction mixture was shaken with a saturated aqueous solution of sodium carbonate to neutralize the remaining $BF_3 \cdot Et_2O$, washed with water, dried over anhydrous sodium sulfate, and separated through column chromatography on silica gel with a hexane–ethyl acetate mixture and through preparative-GLC with Carbowax 6000 (*cf.* Table 1).

Characterization of 3. A colorless oil was obtained in a 10% yield. λ_{max}^{EtOH}: 272 nm (220), 264 (260), 256 (250), 251 (280), 217_{sh} (5320), 212 (5580); IR (CCl_4, cm^{-1}): 1511 (aromatic ring), 1385, 1379, 1360 (CH_3–$\underset{|}{C}H$–CH_3, CH_3–$\underset{|}{C}$–CH_3, CH_3–$\underset{|}{C}H$–), 1162, 1075 (C–O–C); ^{1}H-NMR (CCl_4): δ 0.88 (9H, d, J=7 Hz, $C\underline{H}_3$–$\underset{|}{C}H$–$C\underline{H}_3$, $C\underline{H}_3$–$\underset{|}{C}H$–), 1.23 (8H, bs, –$C\underline{H}_2$–×4), 1.53 (6H, s, $(C\underline{H}_3)_2$–$\underset{|}{C}$–O–), 1.66 (2H, bs, –$\underset{|}{C}\underline{H}$–×2), 2.38 (3H, s, $C\underline{H}_3$–Ar), 3.20 (2H, t, J=7 Hz, –O–$C\underline{H}_2$–CH_2–), 7.25 (4H, bs, aromatic proton); Mass (*m/e*): 290 (4%, M^+, $C_{20}H_{34}O$), 135 (15), 133 (58), 112 (30), 110 (22), 105 (21), 91 (21), 81 (19), 71 (49), 70 (35), 69 (50), 57 (67), 43 (base).

Table 1. Reaction conditions and reaction products

Reaction conditions	Experiment No.	1	2
	Terpinolene (g)	1.0	1.0
	Tetrahydrogeraniol (g)	1.0	1.0
	$BF_3 \cdot Et_2O$ (ml)	0.05	0.15
	React. period/d	5	7
	React. temp/°C	20	23
Reaction products (yield/%)[a]	α-Terpinene	7.7	2.0
	β-Phellandrene	3.0	2.8
	γ-Terpinene	1.2	5.6
	p-Cymene	21.8	76.4
	p-Cymen-8-ol (**5**)	37.6	0.6
	Aromatic ether **3**	10.1	8.6
	Aliphatic ether **4**	14.2	1.4
	Others	4.4	2.6

a) The ratios of the components were calculated by means of GLC from their relative peak areas.

Characterization of **4**. A colorless oil was obtained in a 14% yield. IR (CCl_4, cm^{-1}): 1680, 895 (-CH=C-), 1390, 1369 (CH_3-CH-CH_3, CH_3-C-CH_3), 1165, 1142, 1121, 1082 (C-O-C); ^{1}H-NMR ($CDCl_3$): δ 0.85 (9H, d, J=6 Hz, $C\underline{H}_3$-CH-, $C\underline{H}_3$-CH-$C\underline{H}_3$), 1.10 (6H, s, $(C\underline{H}_3)_2$-C-O-), 1.67 (3H, s, $C\underline{H}_3$-C=CH-), 1.93 (4H, bs, -$C\underline{H}_2$-C=C-×2), 3.36 (2H, t, J=7 Hz, -O-$C\underline{H}_2$-CH_2-), 5.46 (1H, bs, $w/2$= 8 Hz, -$C\underline{H}$=C-); Mass (*m/e*): 294 (2%, M^+, $C_{20}H_{38}O$), 199 (8), 141 (5, $C_{10}H_{21}$), 136 (15), 121 (5), 95 (9), 93 (10), 81 (12), 59 (8), 55 (21), 43 (base), 41 (55), 39 (14).

Catalytic Hydrogenation of **4**. Compound **4** (300 mg) was hydrogenated over platinum oxide (30 mg) in acetic acid (7 ml) to take up 1 mol-equivalent of hydrogen, thus giving the dihydro derivative of **4** as a colorless oil in a yield of 80%. IR (CCl_4, cm^{-1}): 1383, 1368 (CH_3-CH-CH_3. CH_3-C-CH_3), 1173, 1151, 1121, 1071 (C-O-C); ^{1}H-NMR ($CDCl_3$): δ 0.85 (12H, d, J=6 Hz, $C\underline{H}_3$-CH-$C\underline{H}_3$, $C\underline{H}_3$-CH-×2), 1.10 (6H, s, $(C\underline{H}_3)_2$-C-O-), 3.34 (2H, t, J=7 Hz, -O-$C\underline{H}_2$-CH_2-).

Preparation of Dihydro **4**. Tetrahydrogeranyl bromide (1.0 g) and sodium dihydro-α-terpineolate (1.0 g) were treated according to the Williamson procedure to give the dihydro derivative of **4** as a colorless oil in a yield of 15%.

Conversion of **4** *into* **3** *by* $BF_3 \cdot Et_2O$. The ether **4** (20 mg), was dissolved in dried ether (1 ml) and mixed with 0.04 ml of $BF_3 \cdot Et_2O$. After the mixture had then been allowed to stand at room temperature for 9 d, a small amount of water was added to the reaction mixture to decompose the excess reagent. The reaction mixture thus reacted was then analyzed by means of gas chromatography on the DEGS separation column to determine the compositions (*cf.* Table 2). Each compound was identified by comparing the retention times with those of authentic samples.

Characterization of **5**. Compound **5** was isolated as a colorless oil in a yield of 38%. λ_{max}^{EtOH}: 272 nm (330), 263 (390), 257 (310), 251 (210), 221_{sh} (6920), 216 (8080), 213 (8020); IR (CCl_4, cm^{-1}): 3599 (-OH), 1511 (aromatic ring), 1380, 1364 (CH_3-C-CH_3), 1168, 1112 (C-O-C); ^{1}H-NMR (CCl_4): δ 1.56 (6H, s, $(C\underline{H}_3)_2$-C-O-), 1.76 (1H, bs, -O$\underline{H}$, disappeared with D_2O), 2.36 (3H, s, $C\underline{H}_3$-Ar), 7.21 7.40 (each 2H, d, J=8 Hz, aromatic proton); Mass (*m/e*): 150 (20%, M^+, $C_{10}H_{14}O$), 135 (base), 133 (16), 91 (24), 43 (21). The spectra were in good agreement with those of 1-methyl-4-(1-hydroxy-1-methylethyl)benzene, the synthesis of which will be described in the following section.

Preparation of **5**. Methyl *p*-methylbenzoate (500 mg) in ether (20 ml) was refluxed with 5% methyllithium in ether (7 ml) for 6 h. The mixture was then treated according to the usual procedure to give 1-methyl-4-(1-hydroxy-1-methylethyl)benzene in a 70% yield.

GC/MS of Reaction Products. GC/MS analyses of reaction products were carried out using a glass column (3 mm× 2 m) packed with 3% OV-1 on Gas Chrom. Q under a 7 °C/min temperature program from 80 to 230 °C; 70 eV, ionization voltage; 3500 eV, ion-accelerating voltage; 290 °C, the ion-source temperature, and 270 °C, the separator temperature. Each compound was gas-chromatographically identical with the respective authentic sample.

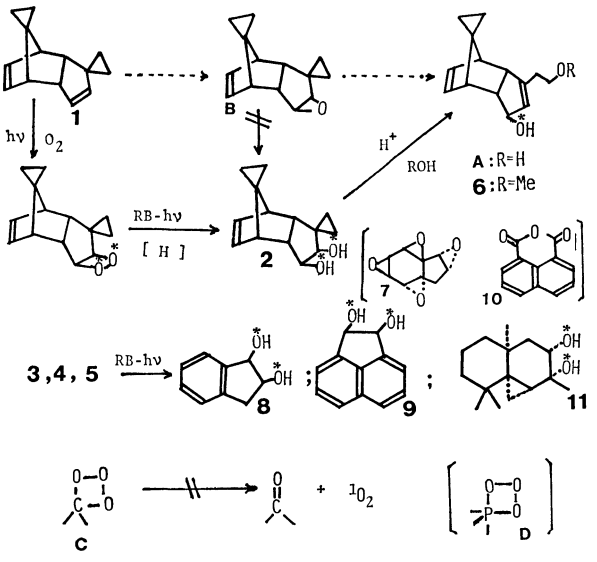
Synthetic Photochemistry. XXIII.[1] The Photoreduction of Dioxetanes to *cis*-1,2-Glycols: ^{18}O-Labelling Experiments

Hitoshi TAKESHITA* and Toshihide HATSUI
Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received March 25, 1981)

Synopsis. The Rose Bengal-sensitized photooxidation of some dioxetane-forming olefins, the Diels-Alder dimer of spiroheptadiene, indene, acenaphthylene, and thujopsene, under an $^{18}O_2$-atmosphere yielded the labelled analogs of the previously characterized *cis*-1,2-glycols. According to the mass-spectral analysis, both oxygens of the glycols were derived from the oxygen molecule.

Recently, we have shown the formation of *cis*-1,2-glycols in the Rose Bengal (RB)-sensitized photooxygenation of certain dioxetane-forming olefins.[2-4] It was deduced that the intermediate dioxetanes were involved in this reductive step. Should this be the case, both the oxygen atoms must come from the molecular oxygen. However, an accompanying formation of a *seco*-cyclopropane glycol (**A**), even in low yields, in the reaction of dispiro[cyclopropane-1,3′-tricyclo[5.2.1.$0^{2,6}$]deca-4′,8′-diene-10′,1″-cyclopropane] (**1**) arises the question that an epoxide (**B**) may be a precursor of both **A** and the *cis*-1,2-glycol (**2**). Consequently, to provide independent evidence, we have carried out ^{18}O-labelling experiments with **1**, indene (**3**),[4,5] a frequently studied dioxetane-forming olefin, and acenaphthylene (**4**),[4] as well as with thujopsene (**5**), a sesquiterpenoid cyclopropane derivative.[3]

Following the previous method,[2] the irradiation of **1** was performed by means of a tungsten lamp with a relatively large amount of RB, *ca.* 1.4 mmol/cm^3, in a mixed solution of methanol and pyridine under a 99%-enriched $^{18}O_2$-atmosphere[6] for 51 h by cooling with running water; the product mixture was then fractionated by silica-gel column chromatography to give the solvolyzed methoxy alcohol (**6**), 3%, and the glycol (**2**), 10%. The mass-spectral determination of **2** revealed an incorporation of two ^{18}O-atoms in the molecule with a more than 62% isotopic purity. Because of the weakness of the intensities of the molecular ions (less than 1% of the total ions), the peaks at *m/e*: 220 ($C_{14}H_{18}O^{18}O$) and 218 ($C_{14}H_{18}O_2$) were obscured under the noise level, and so the given figures (see Experimental) for the intensities of these weak peaks might be higher than the actual isotopic contents. At this stage, it can merely be pointed out that the solvolytic formation from **B** must be a minor path.



Scheme 1.

Next, a similar $^{18}O_2$-photooxygenation was carried out with indene (**3**); when the oxygenation was carried out at −40 °C in methanol, the major product was identified as the tetraepoxide (**7**), which was previously reported to be formed in the oxidation in aprotic solvents.[7] However, when the oxygenation was carried out at *ca.* 15—25 °C, after a work up by silica-gel column chromatography of the reaction mixture,[2,4] the desired *cis*-1,2-indandiol (**8**) was obtained in an 18% yield, together with other, previously identified products.[4,5] The mass-spectral analysis of **8** again confirmed the incorporation of two ^{18}O-atoms, with the relative intensity of *m/e*: 150, 152, and 154 being 2.3:1.7:96.

Although the relative rate of the oxygenation of acenaphthylene (**4**) is known to be very small, we have also carried out an $^{18}O_2$-experiment. The results were entirely the same as those of **8**; the *cis*-1,2-diol (**9**), obtained in a 24% yield, was shown to be $C_{12}H_8$-$^{18}O_2$, the relative intensity of the peaks at *m/e*: 186:188:190 being 8:6:86. The major product in this case was 1,8-naphthalic anhydride (**10**) (58%), whose mass spectrum indicated the incorporation of three ^{18}O-atoms.

As has previously been described, the solvolysis of the epoxy derivatives is known to give not only *trans*-1,2-diols, but, also the *cis*-glycols, **8** and **9**;[4] the present experiments can be employed to evaluate such solvolytic formation of *cis*-1,2-glycols by analyzing the mono-^{18}O-labelled products. The results show that this process is merely a side path; in the cases of **8** and **9**, a mass spectrometry gave estimates of *ca.* 2% and 6%. Consequently, the possible involvement of the epoxides in the sensitized photooxygenative formation of **8** and **9** has been unambiguously eliminated, and in turn, the intermediacy of the dioxetanes for the *cis*-glycol formation has been established.

Finally, the RB-sensitized photooxygenation of **5** was carried out in methanol under a recovered $^{18}O_2$-atmosphere, contaminated with $^{16}O_2$; after a usual work-up using silica gel column chromatography afforded the *cis*-glycol (**11**)[3] in a 15% yield, together with other products characterized previously. The mass-

spectral determination of **11** clarified the incorporation of two ^{18}O-atoms in the molecule; the relative intensity of the molecular ions for 238:240:242 was 54:4:42, where the peak due to the mono-^{18}O-labelled **11** was very weak compared to the peaks of the other isomers, providing firm evidence for eliminating a trioxetane precursor (**C**).[8] Should this be the case, these three peaks should have a ratio of *ca.* 7:4:5 on the basis of the observed ^{16}O:^{18}O ratio of 5:4. At the same time, it may be difficult for any mechanism involving two oxygen molecules to explain these isotope distributions.

Experimental

*RB-Sensitized Photooxidation of **1** with $^{18}O_2$. Isolation of **2** and **6**:* A mixed solution of methanol (20 cm^3) and pyridine (5 cm^3) containing **1** (735 mg) and RB (115 mg) was repeatedly degassed and flushed with nitrogen under reduced pressure at −70 °C, after which 99%-$^{18}O_2$ gas (100 cm^3) was introduced into the reaction vessel by means of a gas buret. The irradiation was performed by means of a 500-W tungsten lamp for 51 h at 15—20 °C with vigorous stirring of the solution by the use of a magnetic bar. The reaction was checked occasionally by the volumetric analysis of O_2-consumption. The mixture was then warmed *in vacuo* to remove the solvent, and the residue was chromatographed on a silica-gel column; together with the recovered **1** (265 mg), the vinyloxirane and the dialdehyde,[9] the glycol **2** (colorless needles, mp 56—57 °C (57 mg, 10%) [Found: *m/e*, 218(4.3), 219(3.7), 220(2.8), 221(1.6), 222(11.6)]), and methoxy alcohol (6)(a colorless oil (18 mg, 3%) [Found: *m/e*, 232(27.8, 233(8.2), 234(100), 235(26.5), 236(7.5)]), were isolated.

*RB-Sensitized Photooxidation of **3**. Formation of **7**:* A methanol solution (20 cm^3) of **3** (735 mg) was similarly irradiated with RB (135 mg) at −40 °C for 10.5 h. The only product consisted of colorless crystals (mp 175—176 °C (lit,[7] 178.5—180.5 °C)), whose NMR spectrum was identical with that of **7** [Found: *m/e*, 188.0567 (10.4, M$^+$, Calcd for $C_9H_8{}^{18}O_4$: 188.0592), 183(4.4), 185(1.7), 186(1.1), 187.0522 (100, M$^+$−1, Calcd for $C_9H_7{}^{18}O_4$: 187.0514, and $C_9H_9O^{18}O_3$ requires 187.0628)].

*RB-Sensitized Oxidation of **3** with $^{18}O_2$. Isolation of **8**:* A methanol solution (20 cm^3) of **3** (500 mg) was irradiated at 15—25 °C by means of a 500-W tungsten lamp in the presence of RB (100 mg) under an $^{18}O_2$-atmosphere for 8.5 h. The reaction mixture was then evaporated *in vacuo* to remove the solvent, and the residue was chromatographed on a silica-gel column; fractions eluted from hexane–ethyl acetate (8:2) contained two methoxy hydroperoxides, homophthalaldehyde and its cyclic acetal,[4] but no further characterization was attempted. From hexane-ethyl acetate (6:4), **8** (colorless crystals, mp 102.5—103 °C, 90 mg (18%) [Found: *m/e*, 154.0766 (M$^+$, Calcd for $C_9H_{10}{}^{18}O_2$: 154.0766)]) was isolated.

*RB-Sensitized Photooxidation of **4** with $^{18}O_2$. Isolation of **9** and **10**:* A methanol solution (12 cm^3) of **4** (430 mg) was irradiated at 15—25 °C by means of a 500-W tungsten lamp in the presence of RB (70 mg) under an $^{18}O_2$ atmosphere for 55 h. The reaction mixture was then evaporated *in vacuo* to remove the solvent, and the residue was chromatographed on a silica-gel column to give, after the elution of the recovered **4** (200 mg), colorless needles (mp 213—214 °C, **9**, 70 mg (24%) [Found: *m/e*, 190.0767 (M$^+$, Calcd for $C_{12}H_{10}{}^{18}O_2$: 190.0766)). The relative intensity of *m/e*: 186: 188:190=8:6:86], and 1,8-naphthalenedicarboxylic anhydride (**10**), mp 268—270 °C, 178 mg (58%) [Found: *m/e*, 204 ($C_{12}H_6{}^{18}O_3$)].

*RB-Sensitized Photooxygenation of **5**. Formation of **11**:* A mixed solution of methanol (8 cm^3) and acetone (6 cm^3) containing **5** (535 mg) and RB (75 mg) was irradiated by means of a 500-W tungsten lamp under an $^{18}O_2$-atmosphere (45%) for 35 h at 20—25 °C. The mixture was then chromatographed on a silica-gel column to give, after the elution of the recovered **5** (238 mg), colorless needles (mp 63—65 °C, **11** (53 mg, 15%) [Found: *m/e*, 242.2009 (M$^+$, Calcd for $C_{15}H_{26}{}^{18}O_2$: 242.2015)). The relative intensities of *m/e*: 240:241:242=54:4:42; *m/e*: 220:222=45:55].

Stereochemistry of Friedel-Crafts Alkylation of Benzene with Optically Active 2-Chlorobutane

(Received April 2, 1981)

Synopsis. The alkylation of benzene with (+)-2-chlorobutane (**1**) by Lewis acid catalyst gave stereospecifically (−)-2-phenylbutane (**2**) with inversion of configuration at low temperature for short reaction times. A lowering of the stereospecificity of the reaction was found to be partly due to the racemization of (+)-**1** and (−)-**2**.

Friedel-Crafts alkylation has long been pointed out to proceed with almost complete racemization when an optically active alkylating reagent was used. For example, Price, Burwell, and Streitwieser reported that the alkylation of benzene with optically active 2-butanol and propan-1,1,1-d_3-2-ol gave almost racemic 2-phenylbutane and 2-phenylpropane-1,1,1-d_3, respectively, and concluded that these alkylations proceeded *via* a free carbonium ion intermediate.[1-3] However, some examples of the highly stereospecific reactions have been reported; the high degree of stereospecificity of the reactions was explained on the basis of the cyclic nature of the alkylating reagents or the formation of the cyclic intermediates.[6]

Recently, Rosenberg reported that the Friedel-Crafts alkylation of benzene with (+)-2-butanol by $AlBr_3$ catalyst gave (−)-2-phenylbutane with 27% inversion of configuration.[4] This is the only example of stereospecific Friedel-Crafts alkylation with such a simple alkylating reagent. On the other hand, Eliel reported that an optically active 2-phenylbutane was readily racemized under the influence of $AlCl_3$ at 0 °C.[5] These results prompted us to investigate the reaction with a simple acyclic reagent, optically active 2-chlorobutane (**1**).

Results and Discussion

Optically pure (*S*)-(+)-**1** was easily prepared from (+)-propylene oxide *via* (−)-2-butanol. The alkylation of benzene with (+)-**1** was carried out using a variety of Lewis acids as the catalyst. These reactions gave 2-phenylbutane (**2**) mainly and few by-products (<1%). The **2** produced was separated and its optical rotation was determined. The results are summarized in Table 1. The alkylations by $AlCl_3$, $FeCl_3$, and $AlCl_3$–CH_3NO_2 catalysts proceeded with inversion of configuration to give (*R*)-(−)-**2**. In the case of $AlBr_3$ catalyst the product was an almost racemic **2**.

In the case of the alkylation by $AlCl_3$ catalyst at −30 °C, the optical yield of the reaction decreased from 24%(50 s) to 14%(100 s) or 12%(120 s) with increasing reaction time. The product given at −10 °C for 20 min was completely racemic. The decrease of the optical yield appears to be due to a great extent to the racemization of (−)-**2** produced, because the alkylation proceeds to completion within 30 s even at −30 °C.

In the presence of $FeCl_3$ the racemization of (−)-**2** scarcely occurred for 60 min at 0 °C (Table 2). On the other hand, the starting (+)-**1** was racemized from $[\alpha]_D$ +27.0° to +6.1° by $FeCl_3$ catalyst in 1,2-dichloroethane for 4 min at 0 °C.

In the preceding paper,[6] we attempted to evaluate the net stereospecificity in the alkylation from the extent of alkylation and the remaining optical activity of the starting material by considering a kinetic model.[7] In the alkylation with (+)-**1** at 0 °C (4 min), **2** was obtained in 70% yield and in 24% optical yield, and the optical activity of the starting chloride was depressed to 22% of the initial value. The rate of alkylation and racemization of the chloride were calculated to be 5.0×10^{-3} s^{-1} and 6.3×10^{-3} s^{-1}, respectively. Therefore, the net stereospecificity in the

a) Mole ratio is (*R*)-2: $FeCl_3$: benzene = 1:0.15:30. A small amount of carbon disulfide was added. b) Measured in benzene (*c* 5.0). c) Measured in benzene (*c* 3.0). d) Calculated from the reported rotation $[\alpha]_D$ −23.6° (neat).[9)]

alkylation step was calculated to be 40%.

Friedel-Crafts reactions of primary halides are thought to proceed in part by a displacement process.[10,11)] Such views are consistent with our stereochemical results about the reaction of 2-chlorobutane. However, the possibility of a carbonium ion character in the alkylating intermediate is not excluded. In addition, the lesser stereospecificity in the alkylations reported in the literature[1–3)] may be attributed in part to the successive racemization of the product and the simultaneous racemization of the starting material, which are caused by raising the reaction temperature and prolonging the reaction time.

Experimental

GLC analysis was carried out on a 2 m column of 10% Carbowax 20 M on Diasolid L with a Shimadzu GC-3BT instrument. Optical rotations were taken with a JASCO DIP-SL polarimeter using 1 or 0.5 cm tubes.

Benzene was washed with concentrated sulfuric acid and water, and distilled after drying on sodium ribbon. Other solvents were dried[12)] and distilled before use. Aluminium chloride was purified by sublimation under nitrogen. Other Lewis acids of commercial GR grade were used without further purification.

*(+)-2-Chlorobutane (**1**).* (+)-Propylene oxide[6)] (20 g, 0.35 mol) was added to an ethereal solution (400 ml) of methyllithium (1.0 mol) at 0 °C. After the addition, the reaction mixture was refluxed for 12 h, decomposed with water (50 ml), and extracted three times with 100 ml of ether. The extracts were fractionally distilled to give 19 g of (−)-2-butanol, $[\alpha]_D$ −11.8°(neat). Dichlorophenylphosphine (12.2 g, 0.0682 mol) and (−)-2-butanol (10 g, 0.137 mol) were mixed at 0 °C, stirred for 1 h, then distilled on a cooled trap *in vacuo*. The distillate was fractionated by a column to yield 4 g of (+)-**1**, bp 68 °C, $[\alpha]_D$ +28.0°(neat), [Lit,[8)] $[\alpha]_D$ +34.8°(neat)].

Alkylation. To a stirred mixture of benzene (13 g, 160 mmol), Lewis acid (0.81 mmol), and carbon disulfide (4 ml), (+)-**1** (500 mg, 5.4 mmol) was added at the prescribed temperature. The resulting mixture was allowed to stand at the above temperature for the prescribed period with stirring, then quenched with ice water (5 ml). The organic layer was separated, washed with water, and dried over anhydrous sodium sulfate. After the removal of solvent, the residue was distilled by fractionating column to give (−)-**2**, bp 68—70 °C/20 mmHg.

*Racemization of (+)-**1** or (−)-**2**.* A stirred mixture of (+)-**1** (500 mg, 5.4 mmol), iron (III) chloride (130 mg, 5.4 mmol), and 1,2-dichloroethane (14 ml) was treated at 0 °C for 4 min. After the usual work-up, the optical rotation of the recovered **1** was measured. Racemization of (−)-**2** was also carried out in a similar manner.

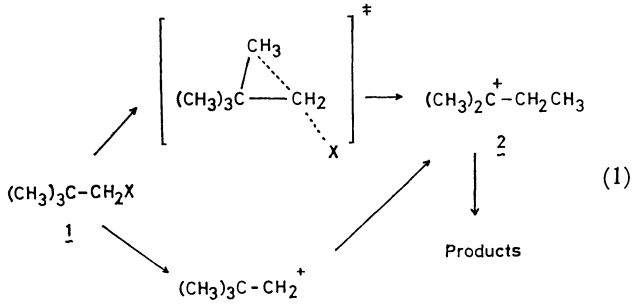
(Received April 17, 1981)

Synopsis. Geometrical optimization of the protonated neopentyl alcohol and the transition state of its heterolysis was carried out using the MINDO/3 SCF-MO method. A cyclic structure was predicted for the transition state. Agreement between the calculated and experimental values for the carbon-14 kinetic isotope effects was excellent.

Neopentyl derivatives **1**, having a fully substituted carbon atom next to the reaction center, usually give rise to substitution and elimination products to be derived from the rearranged *t*-pentyl cation **2** under solvolytic conditions (Eq. 1). The timing of this rearrangement, concerted or stepwise, has long been a subject of controversy. Pieces of evidence for and against methyl participation have been accumulated from kinetic and stereochemical researches.[1,2]



(1)

Recent studies using kinetic isotope effect (KIE) revealed that the three methyl groups are not equivalent in the role in governing the reaction rate, only the migrating methyl group showing a large isotope effect.[3,4] This fact, as well as the KIE data for α and β carbons, tends to support the concerted mechanism.[3,4]

However, methyl participation or bridging is not the only possible explanation for the observed inequality in the KIE for the methyl carbons. Hyperconjugation is also strongly angular-dependent, and the idea that hyperconjugation and bridging may merge has been presented.[5]

In order to gain an additional insight to the mechanism of neopentyl solvolysis, semiempirical SCF-MO calculations were carried out on the heterolysis process of neopentyl alcohol. Kinetic isotope effects were calculated from the molecular vibration frequencies of both the reactant and the transition state, and compared with the experimentally observed values.

Results and Discussion

Calculations were carried out by the MINDO/3 method.[6,7] The local minimum of the protonated neopentyl alcohol $(CH_3)_3CCH_2OH_2^+$ as reactant was determined by the geometrical optimization procedure based on the gradient method.[8] The results are shown in Fig. 1.

In order to determine the transition state geometry, the entire system at given C–O bond lengths was energetically optimized[9] with respect to the remaining degrees of freedom. As the C–O bond was elongated, the methyl group at the *s-trans* position was caused to draw nearer to the α-carbon to form a distorted triangle. The transition state was reached when the C–C distance in question was 1.819 Å, as shown in Fig. 2.

Force constants and molecular vibration frequencies were calculated for the reactant and the transition state. The former has 51 normal frequencies, while the latter has one imaginary ($430i$ cm^{-1}) and 50 normal

α-^{14}C	1.084	1.073
α-D_2	0.982	1.187; 1.190
β-^{14}C	1.011	1.019
γ-^{14}C	1.022	1.037
γ-D_3	1.224	1.123
γ'-^{14}C	1.003	(1.00)[c)]
γ'-D_3	1.007	(0.95)[c)]

a) γ corresponds to the migrating methyl group while γ' to the nonmigrating groups. b) Combined data for the acetolyses of neopentyl *p*-nitrobenzenesulfonate and 2-methyl-2-adamantylmethyl brosylate (Ref. 3). c) Estimated from the data for the above-mentioned two compounds.

frequencies. The reaction-coordinate motion, *i.e.*, the mode of vibration with the imaginary frequency at the transition state, is also shown in Fig. 2. Kinetic isotope effects were calculated from the vibrational frequencies obtained.[10,11] The results are summarized in Table 1 together with the corresponding experimental data.

As can be seen from Table 1, the carbon-14 isotope effects calculated for the various carbon atoms involved agree reasonably well with the experimental data. The results lend strong support to the concept of the concerted mechanism for the neopentyl solvolysis. As for the deuterium isotope effects, however, the agreement between calculated and observed values is found to be rather poor. These contrasting results could best be reconciled by the view that the solvation effect, not considered in the present calculations, would perhaps be more important to those hydrogen atoms which embroider the skeleton carbon atoms and hence are exposed to the solvent environment to a higher extent.

In conclusion, the present calculations support the concerted mechanism for the neopentyl solvolysis, even though there is still some question with respect to the accuracy of MINDO/3 calculations on transition states for ionic reactions.

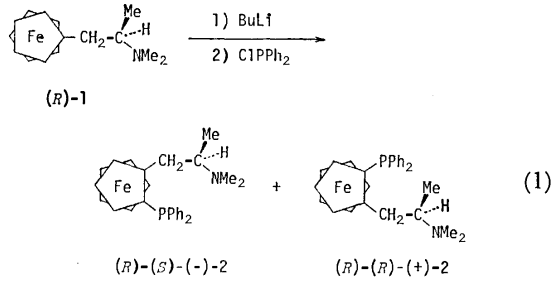
(Received May 25, 1981)

Synopsis. A pair of diastereoisomeric phosphines, (*R*)-*N*,*N*-dimethyl-1-[2-(diphenylphosphino)ferrocenyl]-2-propanamines, have been prepared and used as ligands for nickel-catalyzed asymmetric cross-coupling of 1-phenylethylmagnesium chloride with vinyl bromide to give 3-phenyl-1-butene of 14—15% enantiomeric excess.

We have recently prepared various kinds of chiral ferrocenylphosphines, *e.g.*, (*S*)-*N*,*N*-dimethyl-1-[(*R*)-2-(diphenylphosphino)ferrocenyl]ethylamine [(*S*)-(*R*)-PPFA], starting with *N*,*N*-dimethyl-1-ferrocenylethylamine.[1] Some of them have been found to be effective ligands for several transition metal complex catalyzed asymmetric reactions giving rise to high optical yields.[2] Here we report the preparation of new chiral ferrocenylphosphines from *N*,*N*-dimethyl-1-ferrocenyl-2-propanamine and their use as ligands for nickel-catalyzed asymmetric Grignard cross-coupling.

Results and Discussion

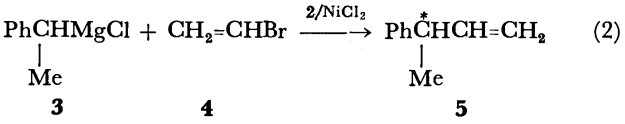
(*R*)-*N*,*N*-Dimethyl-1-ferrocenyl-2-propanamine[3] (**1**) (80% ee) was lithiated with an excess of butyllithium in ether, and the lithiated ferrocene was then treated with chlorodiphenylphosphine. (*R*)-*N*,*N*-Dimethyl-1-[2-(diphenylphosphino)ferrocenyl]-2-propanamines (**2**), which consisted of two diastereomeric isomers in a 1:1 ratio, were obtained in 35% yield (Eq. 1). The



(1)

two isomers were isolated by alumina preparative TLC; the specific rotation of one isomer was $[\alpha]_D^{25}$ +187° and that of the other was $[\alpha]_D^{25}$ −219°. The configurations of ferrocene planar chirality of (+)- and (−)-**2** were estimated empirically[1] to be *R* and *S*, respectively. It should be noted that the lithiation of **1** is not stereoselective while the lithiation of *N*,*N*-dimethyl-1-ferrocenylethylamine has been reported to proceed with high stereoselectivity.[4]

The asymmetry inducing ability of (*R*)-(*R*)- and (*R*)-(*S*)-**2** as chiral ligands was examined in the nickel catalyzed cross-coupling of 1-phenylethylmagnesium chloride (**3**) with vinyl bromide (**4**) (Eq. 2). The



(2)

results are summarized in Table 1, which also contains the results obtained with (*S*)-(*R*)-PPFA ligand.[2a] The catalysts were prepared in situ by mixing nickel chloride and a chiral ligand. The ratio of nickel to ligand did not influence the stereoselectivity, and the catalytically active species is thought to consist of nickel and **2** or PPFA in a one-to-one ratio, not in a one-to-two ratio, regardless of the initial ratio of nickel chloride to the ligand.[2i] The Table contains three significant features. (1) The optical purity of the coupling product, 3-phenyl-1-butene (**5**), obtained here with **2** (14—15% ee) is much lower than that obtained with the PPFA ligand (61% ee). (2) The ferrocene planar chirality in **2** plays a more important role than the carbon central chirality, the diastereomeric isomers (*R*)-(*R*)- and (*R*)-(*S*)-**2** giving **5** with almost the same optical purity and different configurations. (3) The phosphine ligands (*R*)-(*R*)-**2** and (*S*)-(*R*)-PPFA, both of which have the same planar chirality *R*, exhibited opposite stereoselectivity.

The important role of the ferrocene planar chirality causing asymmetric induction is what has been always observed in asymmetric synthesis catalyzed by chiral ferrocenylphosphine-transition metal complexes.[2] The dimethylamino group on the ferrocene side chain has been thought to enhance the stereoselectivity by coordinating to the magnesium atom of the Grignard reagent.[2a] In ferrocenylphosphine **2** the dimethyl-

TABLE 1. ASYMMETRIC CROSS-COUPLING OF **3** WITH **4**[a]

Hayashi, M. Fukushima, M. Konishi, and M. Kumada, *Tetrahedron Lett.*, **21**, 79 (1980). d) **2**:$NiCl_2$=0.8:1.0. e) Corrected for the optical purity of the phosphine ligand (80% ee). f) PPFA:$NiCl_2$=2.0:1.0.

amino group is one methylene farther away from the ferrocene nucleus than in PPFA. This greater distance between the amino group and the chiral ferrocene moiety in **2** must make the stereocontrol by coordination less effective.

Experimental

Optical rotations were measured with a Yanagimoto OR-50 polarimeter. ^{1}H NMR were measured with a JEOL MH-100 spectrometer in chloroform-*d* using tetramethylsilane as an internal standard.

(*R*)-*N*,*N*-Dimethyl-1-ferrocenyl-2-propanamine (**1**) ($[\alpha]_{546}^{20}$ −24.2° (*c* 1.075, ethanol)) was prepared from (*R*)-1-ferrocenyl-2-propanamine ($[\alpha]_{546}^{20}$ −3.29° (*c* 5, ethanol), 80% ee) according to the procedure previously reported,[3] which was obtained by optical resolution of the racemic amine via its tartaric acid salt.[3]

*(*R*)-*N*,*N*-Dimethyl-1-[(*R*)-2-(diphenylphosphino)ferrocenyl]-2-propanamine [(*R*)-(*R*)-**2**] and (*R*)-*N*,*N*-Dimethyl-1-[(*S*)-2-(diphenylphosphino)ferrocenyl]-2-propanamine [(*R*)-(*S*)-**2**].* To a stirred solution of 255 mg (1.1 mmol) of (*R*)-**1** (80% ee) in 2.5 ml of ether was added 3.4 ml of 1.6 M butyllithium (5.4 mmol) in hexane at room temperature under nitrogen. After 5 h stirring at room temperature, 1.3 ml (7.0 mmol) of chlorodiphenylphosphine was added at 0 °C. The reaction mixture was refluxed for 2 h, and then hydrolyzed with saturated aqueous sodium hydrogencarbonate. The resulting organic layer and benzene extracts from the aqueous layer were combined and extracted with 10% phosphoric acid. The aqueous layer was made alkaline with 10% sodium hydroxide, and extracted with ether. The ether solution was dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was purified by preparative TLC on silica gel (R_f 0.3—0.7 with 9:1 ethyl acetate–methanol) to give 160 mg (35% yield) of the product **2** as an orange-red oil. ^{1}H NMR spectrum showed that the product obtained consists of two diastereomeric isomers in one to one ratio. The two isomers were isolated by preparative TLC on alumina (3:5 chloroform–benzene). (*R*)-(*R*)-**2** (42 mg, 9%); R_f 0.7, $[\alpha]_D^{25}$ +187° (*c* 0.82, chloroform), NMR: δ 0.65 (d, 3H, J=7 Hz, CHC$\underline{H}_3$), 2.11 (s, 6H, NC$\underline{H}_3$), 2.33—2.62 (m, 1H, C$\underline{H}$CH$_3$), 2.63—2.82 (m, 2H, C$\underline{H}_2$), 3.75—4.52 (m, 3H, FeC$_5\underline{H}_3$), 3.92 (s, 5H, FeC$_5\underline{H}_5$), 7.13—7.75 (m, 10H, C$_6\underline{H}_5$). (*R*)-(*S*)-**2** (contaminated with 10% of (*R*)-(*R*)-**2**) (40 mg, 9%); R_f 0.6, $[\alpha]_D^{25}$ −219° (*c* 0.78, chloroform), NMR: δ 0.78 (d, 3H, J=7 Hz, CHC$\underline{H}_3$), 2.02 (s, 6H, NC$\underline{H}_3$), 1.94—2.30 (m, 2H, C$\underline{H}_2$), 2.93—3.21 (m, 1H, C$\underline{H}$CH$_3$), 3.65—4.43 (m, 3H, FeC$_5\underline{H}_3$), 3.95 (s, 5H, FeC$_5\underline{H}_5$), 7.08—7.70 (m, 10H, C$_6\underline{H}_5$). Found: C, 71.33; H, 6.58; N, 3.04%. Calcd for $C_{27}H_{31}NPFe$: C, 71.21; H, 6.64; N, 3.08%.

Asymmetric Grignard Cross-coupling. To a 100-ml pressure glass tube containing 13 mg (0.10 mmol) of anhydrous nickel chloride and 36 mg (0.08 mmol) of **2** was added at −78 °C 2.14 g (20 mmol) of vinyl bromide and 27 ml (40 mmol) of 1.5 M 1-phenylethylmagnesium chloride in ether. The glass tube was stoppered and allowed to warm up to 0 °C. The mixture was kept standing at 0 °C for 40 h, and hydrolyzed with 10% hydrochloric acid. After usual work-up, distillation through a short Vigreux column under reduced pressure followed by purification with preparative GLC (Silicone DC-550) gave 3-phenyl-1-butene. The yields and optical rotation data are shown in Table 1.

The present work was partly supported by a Grant-in-Aid for Scientific Research Nos. 510209 and 547080 from the Ministry of Education, Science and Culture.

Fused Heterocycles. IV.[1] Synthesis of 7-(*o*-Hydroxyphenyl)-3,5-dimethyl-7,8-dihydro-6*H*-isoxazolo[4,5-*b*]azepines

Kooturu Malla Reddi, Citineni Janakirama Rao, and Ananthula Krishna Murthy*

Department of Chemistry, University College, Kakatiya University, Warangal 506009, India

(Received December 12, 1980)

Synopsis. Michael addition of acetylacetone to 3-methyl-4-nitro-5-(*o*-hydroxystyryl)isoxazoles gives 4-(*o*-acetoxyphenyl)-5-(3-methyl-4-nitro-5-isoxazolyl)-2-pentanones (**4**). Reductive cyclization of **4** with tin(II) chloride and concentrated hydrochloric acid leads to 7-(*o*-hydroxyphenyl)-3,5-dimethyl-7,8-dihydro-6*H*-isoxazolo[4,5-*b*]azepines. The formation of **4** has been rationalized through ortho effect. NMR and mass spectra of products have been discussed.

Though the formation of isoxazoles fused to a variety of heterocycles[2] has been extensively investigated, the isoxazoloazepines[3] have received very little attention. Furthermore, there is no general method of synthesis of isoxazoloazepines to date. Hence we recently reported the formation of hitherto unknown 3-methyl-5,7-diarylisoxazolo[4,5-*b*]azepines[4] by a facile reductive cyclization of ε-nitro ketones. In continuation of our interest, the report describes the preparation of title compounds.

Condensation of 3,5-dimethyl-4-nitroisoxazole (**1**) with various salicylaldehydes in boiling ethanol in the presence of piperidine gave the regioselective products namely, 3-methyl-4-nitro-5-(*o*-hydroxystyryl)isoxazoles (**2**).[5,6] Michael addition of acetylacetone to **2** has been carried out in boiling triethylamine for 4 h. The products which were insoluble in aq dil. sodium hydroxide and gave no colouration with iron(III) chloride have been identified as 4-(*o*-acetoxyphenyl)-5-(3-methyl-4-nitro-5-isoxazolyl)-2-pentanones (**4**) on the basis of IR (transparent in the hydroxyl region, 1775 cm^{-1} for ester >CO and 1725 cm^{-1} for ketonic >C=O) and NMR spectra (δ 2.35, s, 3H-$OCOCH_3$ and two doublets one each for 2H at 3.50 and 2.85 from two CH_2 groups). The 2-pentanone (**4**) might come through the intermediacy of **3** *via* **3A** and **3B** *i.e.*, due to ortho effect. The mechanism put forth is amply supported by the fact that 3-methyl-4-nitro-5-styrylisoxazoles (with no *o*-hydroxyl in the styryl moiety) and acetylacetone under identical conditions gave the β-diketones (**5**).[7]

The Michael products (**4**) on heating with tin(II) chloride and concd hydrochloric acid for 1.5—3.5 h underwent reductive cyclisation to 7-(*o*-hydroxyphenyl)-3,5-dimethyl-7,8-dihydro-6*H*-isoxazolo[4,5-*b*]azepines (**6**) through the intermediacy of the transient amino ketone. Five isoxazoloazepines thus prepared have been included in the table along with the characterization data. Chemical as well as spectroscopic evidence has been adduced for the occurrence of deacetylation during reduction. The cyclized product is not only soluble in dil. sodium hydroxide but also gives fairly intense colouration with iron(III) chloride. The IR spectrum shows no carbonyl absorption but a hydroxyl function (3300 cm^{-1}). Mass spectrum supports the same as it shows molecular ion at *m/e* 256. NMR spectrum shows only two methyls (δ 2.2, s, 3-CH_3; 1.8, s, 5-CH_3) and a hydroxylic proton at δ 3.8 which was neatly exchanged with D_2O. The four protons of the two methylenes and one methine proton of the azepine ring are not displayed distinctly and show complex splitting pattern in the region δ 2.4—3.5. Probably the chemical shift differences of these three types of protons are very little. The NMR

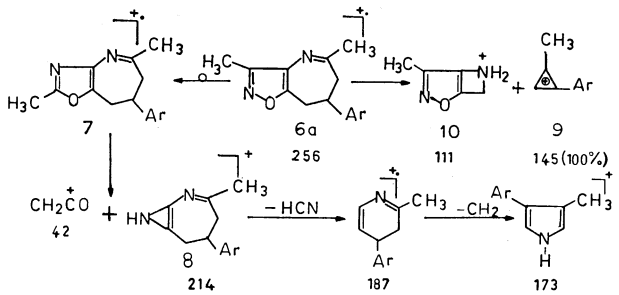

Fig. 2. Mass fragmentation of **6a**. Ar=*o*-OH-C_6H_4-

behaviour of these protons is in keeping with our eariler observation.[4]

In the mass spectrum of **6a**, the signal at *m/e* 214 is due to the ion **8** formed along with ketene by the fragmentation of **7** which comes from the molecular ion. This decomposition of the molecular ion is initiated by the cleavage of the N–O bond, the weakest linkage,[8] followed by ring transformation.[9] The base peak at *m/e* 145 is due to the resonance stabilised cation (**9**) formed together with **10** from the molecular ion.

Experimental

All the melting points are uncorrected. The purity of the compounds was checked by TLC. The IR spectra were recorded on Perkin-Elmer 283 model as KBr discs. ^{1}H NMR spectra were run on 90 MHz Varian EM-390 and 100 MHz JEOL spectrometers using TMS as internal reference and the mass spectra on Varian MAT CH-7 instrument at 70 eV. All the compounds prepared have been included in the table along with the characterization data.

3-Methyl-4-nitro-5-(o-hydroxystyryl)isoxazoles (2). 3,5-Dimethyl-4-nitroisoxazole (2.8 g, 0.02 mol) and salicylaldehydes (2 ml, 0.02 mol) were refluxed in ethanol (30 ml) in presence of traces of piperidine for 1.5 h. The reaction mixture was cooled and the products crystallized from ethanol–acetone.

4-(o-Acetoxyphenyl)-5-(3-methyl-4-nitro-5-isoxazolyl)-2-pentanones (4). 3-Methyl-4-nitro-5-(*o*-hydroxystyryl)isoxazoles (2.4 g, 0.01 mol), acetylacetone (3 ml, 0.03 mol), and triethylamine (35 ml) were refluxed for 3 h. Triethylamine was allowed to evaporate at room temperature. The residue was triturated with pet.ether and finally decomposed in methanol and filtered; colourless crystals from methanol. ^{1}H NMR ($CDCl_3$) of **4a**: δ 7.0—7.4 (m, 4H, Ar–H); 4.05 (m, 1H, >C–H); 3.5 (d, 2H, isoxazole–CH_2); 2.85 (d, 2H, –$COCH_2$–); 2.5 (s, 3H, isoxazole–CH_3); 2.35 (s, 3H, –$OCOCH_3$) and 2.05 (s, 3H, –$COCH_3$).

7-(o-Hydroxyphenyl)-3,5-dimethyl-7,8-dihydro-6H-isoxazolo-[4,5-b]azepines (6). Compound **4** (1.7 g, 0.005 mol), tin(II) chloride (12 g), and concd hydrochloric acid (15 ml) were heated together on water bath. Within a few minutes the reaction mixture became clear solution. After 0.5 h yellow crystalline compound began to separate. The heating is continued for further 2 h, cooled, filtered and washed with water. Recrystallization was effected from methanol. ^{1}H-NMR ($CDCl_3$) of **6a**: δ 6.9—7.2 (m, 4H, Ar–H); 3.8 (s, 1H, Ar–OH); 2.4—3.5 (5H, 6-CH_2–, 8-CH_2–, and >CH); 2.2 (s, 3H, 3-CH_3) and 1.8 (s, 3H, 5-CH_3).

The authors thank Prof. E. V. Sundaram, Head, Department of Chemistry, Kakatiya University for the facilities and Prof. P. Grunanger, University of Pavia, Italy, for helpful discussions. One of the authors (K. M. R) is grateful to the Director of Higher Education, Government of Andhra Pradesh, India, for the permission to carry out research.

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa, 920

(Received July 3, 1980)

An theoretical investigation was made of the vibronic interaction between two electronic levels which are degenerate or nearly degenerate. Within the mean field approximation we derive a simplified effective Hamiltonian to analyze the problem of bond distortion of a molecule; the effective Hamiltonian is diagonalized by a linear canonical transformation of electronic operators. Thermodynamic arguments predict a possibility for appearance of a distorted phase below a characteristic temperature. The distorted phase is realized under a sufficiently strong coupling condition in a non-degenerate case, but under an arbitrarily small coupling condition in a degenerate case. The shift of electronic spectrum, the stabilization energy of the distortion, and thermodynamic quantities are expressed in terms of the parameters associated with the Hamiltonian. Change in electromagnetic properties due to the distortion is discussed. Magnitudes of the bond distortion and energy stabilization in the ground state are numerically estimated for cyclobutadiene, with results in good agreement with literature values.

Let us consider an electronic system with two discrete levels which are degenerate or nearly degenerate and coupled with each other through a vibronic interaction. Such a system can be taken as a prototype model for the variety of molecular distortion phenomena such as the Jahn-Teller or the pseudo Jahn-Teller effect and the bond alternation in conjugated molecules so-called the Peierls transition.[1)]

One attractive point with the present model is that it gives us a simple physical picture for the mechanism of molecular distortion; one can derive analogues with other similar problems in physics, *e.g.*, lattice distortions caused by electron-phonon interactions. It should be noted that there is a marked difference between the two problems, the lattice distortion and the present distortion; the former treats macroscopically large systems whereas the latter considers a single molecule or, at least, an aggregate of independent molecules. In our problem, therefore, we cannot expect any clear-cut transition at a finite temperature but can only anticipate a possible tendency with a large fluctuation towards transition to a new distorted ground state as temperature is lowered. Our finite temperature treatment, presented below, shows that phenomena are characterized by a temperature T_c below which this distortive character is expected to become noticeable. Within our present approximation this characteristic temperature is given by the apparent non-analyticity in free energy and electronic spectrum.

If temperature is much lower than T_c the molecule exists at its ground state where the distorted phase is well defined and stable as compared with the normal undistorted phase, provided the vibronic interaction is sufficiently strong.

To orient ourselves we will recapitulate the theory of bond alternation presented by Longuet-Higgins and Salem[2)] for conjugated molecules of linear polyenes and also present the iterative procedure developed by Nakajima *et al.*[3)] As the first step we tentatively adopt a structure with equal bond lengths and use the Hükel theory. We can thus specify molecular orbitals and orbital energies. From the former we find a set of bond orders, P_{rs}, between the rth and sth atomic sites. Next, we assume the relation of bond order, bond length, R_{rs}, and of bond length, resonance integral, β_{rs}, as

$$R_{rs} = R^0_{rs} + aP_{rs}, \tag{1}$$

$$\beta_{rs} = \beta^0_{rs} \exp(-bR_{rs}), \tag{2}$$

where R^0_{rs} and β^0_{rs} refer to the standarad geometry. Constant a in Eq. 1 is related to the force constant of lattice vibration which is assumed to be harmonic.[2)] Applying the P_{rs} obtained in the first step to Eq. 1, we can get a new set of bond lengths which enables us to estimate new resonance integrals by Eq. 2. We can then proceed to the next step on the eigenvalue problem. Such iterative treatments are repeated until a stable structure has been found. In the present theory, however, we can estimate stabilization energy and stable bond lengths in a single step.

Hamiltonian

The system in question is assumed to be well described by the Hamiltonian in the second quantized representation:

$$H = \sum_i \varepsilon_i a_i^+ a_i + \sum_q \omega_q b_q^+ b_q + \sum_{ijq} g_{ij:q} \phi_q a_i^+ a_j, \tag{3}$$

where a_i^+ and a_i are the creation and annihilation operators for the electron at the ith level, ε_i its energy, ω_q the phonon energy for mode q, $g_{ij:g}$ vibronic interaction constant, and ϕ_q is the phonon operator defined by

$$\phi_q = b_q^+ + b_q. \tag{4}$$

Throughout this article, we will use the unit of $\hbar = k_B = 1$ (k_B is the Boltzmann constant).

As mentioned above, we are considering only two electronic levels and, in order to avoid unnecessary complexity, the relevant phonon mode is also assumed to be single. It is convenient to use the following notations:

$$\varepsilon_1 = -\varepsilon, \ \varepsilon_2 = \varepsilon (\varepsilon > 0), \tag{5}$$

$$C = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}, \ C^+ = (a_1^+, a_2^+), \tag{6}$$

$$\hat{g} = \begin{pmatrix} 0 & g \\ g & 0 \end{pmatrix} = g\sigma_1. \tag{7}$$

Vibronic interaction constant g can be taken as real and we arrive at the model Hamiltonian:

$$H = C^+(-\varepsilon\sigma_3+q\sigma_1\phi)C + \omega b^+b, \tag{8}$$

where the Pauli matrices

$$\sigma_0=\begin{pmatrix}1&0\\0&1\end{pmatrix},\ \sigma_1=\begin{pmatrix}0&1\\1&0\end{pmatrix},\ \sigma_2=\begin{pmatrix}0&-i\\i&0\end{pmatrix},\ \sigma_3=\begin{pmatrix}1&0\\0&-1\end{pmatrix} \tag{9}$$

are used.

We further introduce the effective Hamiltonian, a good approximation to that of Eq. 8:

$$H^{eff} = -\varepsilon C^+\sigma_3 C + g\langle\phi\rangle C^+\sigma_1 C + \omega|\langle b\rangle|^2. \tag{10}$$

This form is based on an expectation that the so-called coherent state impling $\langle\phi\rangle\neq 0$ would be arranged by vibronic interaction.

Canonical Transformation

To diagonalize H^{eff} we will carry out a canonical transformation as follows:

$$\gamma = UC,\ \gamma^+ = C^+U^+, \tag{11}$$

where

$$U=\begin{pmatrix}u&-v\\v&u\end{pmatrix},\ U^+=\begin{pmatrix}u&v\\-v&u\end{pmatrix}, \tag{12}$$

$$u^2 + v^2 = 1. \tag{13}$$

For these equations u and v are real and we have $u>0$. It is obvious that U is unitary ($U^+=U^{-1}$), so we have

$$\begin{aligned} U &= u\sigma_0 - iv\sigma_2, \\ U^+ &= u\sigma_0 + iv\sigma_2. \end{aligned} \tag{14}$$

If we use the inverse transform of Eq. 11, Eq. 10 becomes

$$H^{eff} = \gamma^+(-\varepsilon U\sigma_3U^+ + g\langle\phi\rangle U\sigma_1U^+)\gamma + \omega|\langle b\rangle|^2. \tag{15}$$

Equation 14 readily gives

$$\begin{aligned} U\sigma_3U^+ &= u^2\sigma_3 + 2uv\sigma_1 - v^2\sigma_3, \\ U\sigma_1U^+ &= u^2\sigma_1 - 2uv\sigma_3 - v^2\sigma_1, \end{aligned} \tag{16}$$

so we have

$$H^{eff} = H^d + H^{od}, \tag{17}$$

where H^d and H^{od} are the diagonal and off-diagonal terms, respectively, as defined by

$$\begin{aligned} H^d &= -\gamma^+\{(u^2-v^2)\varepsilon + 2uvg\langle\phi\rangle\}\sigma_3\gamma + \omega|\langle b\rangle|^2, \\ H^{od} &= \gamma^+\{-2uv\varepsilon + (u^2-v^2)g\langle\phi\rangle\}\sigma_1\gamma. \end{aligned} \tag{18}$$

We determine u and v so as to make the off-diagonal term H^{od} vanish:

$$2uv\varepsilon = (u^2-v^2)g\langle\phi\rangle. \tag{19}$$

Combining this with Eq. 13, we get

$$\begin{aligned} u^2 &= \frac{1}{2}(1+\varepsilon/\sqrt{\varepsilon^2+\Delta^2}), \\ v^2 &= \frac{1}{2}(1-\varepsilon/\sqrt{\varepsilon^2+\Delta^2}), \end{aligned} \tag{20}$$

or alternatively,

$$\begin{aligned} u^2-v^2 &= \varepsilon/\sqrt{\varepsilon^2+\Delta^2}, \\ 2uv &= \Delta/\sqrt{\varepsilon^2+\Delta^2}, \end{aligned} \tag{21}$$

where

$$\Delta = g\langle\phi\rangle \quad (>0). \tag{22}$$

As will be explained in a later section, the molecular deformation arises from $\langle\phi\rangle\neq 0$. The positive sign adopted in Eq. 22 corresponds to specifying that we set the coordinate direction so as to make the molecular deformation have positive sign.

Under the condition of Eq. 20 H^d becomes

$$H^d = -\gamma^+\tilde{\varepsilon}\sigma_3\gamma + \omega|\langle b\rangle|^2, \tag{23}$$

where

$$\begin{aligned} \tilde{\varepsilon} &= (u^2-v^2)\varepsilon + 2uvg\langle\phi\rangle \\ &= \sqrt{\varepsilon^2+\Delta^2}. \end{aligned} \tag{24}$$

At this stage, we will look for the solution for a static deformation of molecule which satisfies

$$\langle\dot{\phi}\rangle = 0. \tag{25}$$

To make this explicit, we examine the equation of motion for operators b and b^+. For b we have

$$i\dot{b} = [b, H] = gC^+\sigma_1 C + \omega b. \tag{26}$$

The static condition of Eq. 25 leads to

$$\langle b\rangle = -\langle C^+\sigma_1 C\rangle\omega/g. \tag{27}$$

Since we can obtain entirely the same result for $\langle b^+\rangle$, we conclude that $\langle b\rangle$ and $\langle b^+\rangle$ are real and given by

$$\langle b\rangle = \langle b^+\rangle = \frac{1}{2}\langle\phi\rangle. \tag{28}$$

Therefore, combining this with Eq. 23, we arrive at the result:

$$H^d = -\gamma^+\tilde{\varepsilon}\sigma_3\gamma + \frac{\omega}{4g^2}\Delta. \tag{29}$$

Parameter Δ should be determined self-consistently.

Thermodynamics

Let us study thermodynamic properties of an assembly of molecules on the basis of the approximate Hamiltonian of Eq. 29. The partition function (per molecule) defined by

$$Z \equiv \mathrm{Tr}\exp(-H^d/T) \tag{30}$$

is easily calculated by use of Eq. 29. Using the relation

$$\gamma^+\sigma_3\gamma = \gamma_1^+\gamma_1 - \gamma_2^+\gamma_2, \tag{31}$$

we obtain

$$\begin{aligned} Z &= \exp(-\omega\Delta^2/4g^2T)\mathrm{Tr}\exp(-\tilde{\varepsilon}\gamma_1^+\gamma_1/T) \\ &\quad\times\mathrm{Tr}\exp(\tilde{\varepsilon}\gamma_2^+\gamma_2/T) \\ &= \exp(-\omega\Delta^2/4g^2T)\{\exp(-\tilde{\varepsilon}/2T)+\exp(\tilde{\varepsilon}/2T)\}^2, \end{aligned} \tag{32}$$

for which we have used the fact that the eigenvalue of $\gamma_i^+\gamma_i$ is 0 or 1.

The free energy of this system is given by

$$\begin{aligned} F &\equiv -T\ln Z \\ &= \omega\Delta^2/4g^2 - 2T\ln\{2\cosh(\tilde{\varepsilon}/2T)\}. \end{aligned} \tag{33}$$

Now we minize the free energy with respect to Δ:

$$\frac{\partial F}{\partial\Delta} = \frac{\omega\Delta}{2g^2} - \tanh(\tilde{\varepsilon}/2T)\frac{\partial\tilde{\varepsilon}}{\partial\Delta} = 0. \tag{34}$$

On application of Eq. 24 we get

$$\Delta\left\{\frac{\omega}{2g^2} - \frac{1}{\tilde{\varepsilon}}\tanh(\tilde{\varepsilon}/2T)\right\} = 0. \tag{35}$$

The nontrivial solution for Δ is determined from the relation:

$$\omega\tilde{\varepsilon}/2g^2 = \tanh(\tilde{\varepsilon}/2T). \quad (36)$$

This is the gap equation for Δ and has a solution ($\Delta \neq 0$) if

$$\omega\tilde{\varepsilon}/2g^2 < 1. \quad (37)$$

This is an important relation among the parameters included in the original Hamiltonian. If the two levels are degenerate, the above condition is always satisfied. In the case of non-degenerate levels sufficiently strong vibronic interactions can satisfy Eq. 37.

Characteristic temperature T_c at which Δ vanishes is obtained from Eq. 36 as

$$\omega\varepsilon/2g^2 = \tanh(\varepsilon/2T_c). \quad (38)$$

Now, we will tentatively examine other thermodynamic quantities. The entropy S of this system is estimated as follows:

$$S \equiv -\frac{\partial F}{\partial T} = -\left(\frac{\partial F}{\partial \Delta}\right)_T \frac{\partial \Delta}{\partial T} - \left(\frac{\partial F}{\partial T}\right)_\Delta$$

$$= 2\ln\{2\cosh(\tilde{\varepsilon}/2T)\} - \frac{\tilde{\varepsilon}}{T}\tanh(\tilde{\varepsilon}/2T). \quad (39)$$

In the above derivation, we have made use of Eq. 34. Using the gap equation (36), we get

$$S = 2\ln\{2\cosh(\tilde{\varepsilon}/2T)\} - \omega\tilde{\varepsilon}^2/2g^2T. \quad (40)$$

At the characteristic temperature,

$$S(T_c) = 2\ln\{2\cosh(\varepsilon/2T_c)\} - \frac{\varepsilon}{T_c}\tanh(\varepsilon/2T_c). \quad (41)$$

Since the entropy of the normal phase is given by

$$S_n(T) = 2\ln\{2\cosh(\varepsilon/2T)\} - \frac{\varepsilon}{T}\tanh(\varepsilon/2T), \quad (42)$$

the value of entropy changes continuously from the coherent phase ($\Delta \neq 0$) to the normal phase ($\Delta = 0$), *i.e.*,

$$S(T_c - 0) = S(T_c + 0). \quad (43)$$

On the other hand, heat capacity at constant volume

$$C \equiv T\frac{\partial S}{\partial T} \quad (44)$$

behaves in a different manner, as will be seen in what follows. From Eqs. 36 and 40 we get

$$\frac{\partial S}{\partial T} = -(\omega\tilde{\varepsilon}/2g^2T)\frac{\partial\tilde{\varepsilon}}{\partial T}. \quad (45)$$

We differenciate the gap equation (36) with respect to T and apply some algebraic treatments to have

$$\frac{\partial\tilde{\varepsilon}}{\partial T} = \tilde{\varepsilon}\{1-(\omega\tilde{\varepsilon}/2g^2)^2\}/T\{(\omega T/g^2)+(\omega\tilde{\varepsilon}/2g^2)^2-1\}, \quad (46)$$

which, in conjunction with Eqs. 44 and 45, leads to the formulation of heat capacity:

$$C = (\omega\tilde{\varepsilon}^2/2g^2T)\{1-(\omega\tilde{\varepsilon}/2g^2)^2\}/\{(\omega T/g^2)+(\omega\tilde{\varepsilon}/2g^2)^2-1\}$$

$$= \frac{\tilde{\varepsilon}}{T}\tanh(\tilde{\varepsilon}/2T)\,\mathrm{sech}^2(\tilde{\varepsilon}/2T)/\{(\omega T/g^2)-\mathrm{sech}^2(\tilde{\varepsilon}/2T)\}. \quad (47)$$

The heat capacity of the normal phase is obtained from Eq. 42 as

$$C_n = (\varepsilon^2/2T^2)\,\mathrm{sech}^2(\varepsilon/2T). \quad (48)$$

At the characteristic temperature, the heat capacities of the coherent and normal phases are given by

$$C = (\varepsilon^2/2T_c^2)\{1-(\omega\varepsilon/2g^2)^2\}/\{1+(g^2/\omega T_c)[(\omega\varepsilon/2g^2)^2-1]\}$$

$$C_n = (\varepsilon^2/2T_c^2)\{1-(\omega\varepsilon/2g^2)^2\}, \quad (49)$$

hence

$$\frac{C}{C_n} = 1/\{1+(g^2/\omega T_c)[(\omega\varepsilon/2g^2)^2-1]\} > 1. \quad (50)$$

We want to point out that, as T goes to 0, the heat capacities of these phases behave in accord with

$$C = (\tilde{\varepsilon}^2/2T^2)\exp(-\tilde{\varepsilon}/T),$$

$$C_n = (\varepsilon^2/2T^2)\exp(-\varepsilon/T). \quad (51)$$

It is seen that the former decreases faster than the latter because $\tilde{\varepsilon} > \varepsilon$.

Ground State Properties

At the limit of $T=0$, the gap equation (36) becomes

$$\tilde{\varepsilon} = \sqrt{\varepsilon^2+\Delta^2} = 2g^2/\omega, \quad (52)$$

which gives

$$\Delta^2 = (\varepsilon/s)^2(1-s^2), \quad (53)$$

where s is a dimensionless quantity defined by

$$s = \omega\varepsilon/2g^2 \quad (<1). \quad (54)$$

The ground state energy of the coherent phase is given as a sum of electronic and lattice parts:

$$\tilde{E} = -\tilde{\varepsilon} + \omega\Delta^2/4g^2$$

$$= -\varepsilon(1-s)^2/2s - \varepsilon. \quad (55)$$

Since the energy of the normal phase is $E=-\varepsilon$, the stabilization energy is thus obtained as

$$\delta E \equiv E - \tilde{E} = \varepsilon(1-s)^2/2s$$

$$= 2g^2/\omega\{1-(\omega\varepsilon/2g^2)\}^2. \quad (56)$$

It is seen that, if the inequality (37) holds, we have an energy depression.

The deformation of lattice is expressed as

$$\delta R_\alpha = \sum_q \sqrt{\frac{\hbar}{2M\omega_q}} L_{\alpha q}\langle\phi_q\rangle, \quad (57)$$

where α refers to the site and coordinate indicies and $L_{\alpha q}$ is the transformation matrix from the normal mode q to the real displacement. $L_{\alpha q}$ is calculated by the standard method for actual systems. If we restrict ourselves to treatment of a single mode as we have done so far, we can simplify Eq. 57 to

$$\delta R_\alpha = \sqrt{\frac{\hbar}{2M\omega}} L_{\alpha q}(2g/\omega)\{1-(\omega\varepsilon/2g^2)^2\}^{1/2}, \quad (58)$$

for which Eqs. 23 and 53 are used. The results obtained in this section will be applied to cyclobutadiene later.

Electromagnetic Properties

If the system has an induced dipole moment between levels 1 and 2, the interaction between the radiation field and the electron in our system is described as

$$H_{int} = -\mathbf{E}\cdot\mathbf{d}C^+\sigma_1 C$$

$$= -\mathbf{E}\cdot\mathbf{d}\gamma^+ U\sigma_1 U^+\gamma, \quad (59)$$

where $\mathbf{E}$ is the electric field associated with the applied radiation field and $\mathbf{d}$ is the induced dipole moment in the electronic system. Using Eq. 16, we can rewrite Eq. 59 as

$$H_{\text{int}} = -\mathbf{E}\cdot\mathbf{d}\gamma^{+}\{(u^2-v^2)\sigma_1-2uv\sigma_3\}\gamma, \tag{60}$$

hence we have for the radiative transition probability W_{21}

$$\begin{aligned} W_{21} &\propto (\mathbf{E}\cdot\mathbf{d})^2|\langle\tilde{2}|\gamma^{+}(u^2-v^2)\sigma_1\gamma|\tilde{1}\rangle|^2 \\ &= (\mathbf{E}\cdot\mathbf{d})^2(u^2-v^2)^2 \\ &= (\mathbf{E}\cdot\mathbf{d})^2\frac{\varepsilon^2}{\varepsilon^2+\Delta^2}. \end{aligned} \tag{61}$$

We have an additional information that, even if there is no permanent dipole in the normal phase, there will appear a permanent dipole in the coherent phase, as embodied by

$$\begin{aligned} \mathbf{P} &= -2uv\mathbf{d}\langle\gamma^{+}\sigma_3\gamma\rangle \\ &= -\frac{\mathbf{d}\Delta}{\sqrt{\varepsilon^3+\Delta^2}}\{\exp(2\tilde{\varepsilon}/T)+1\}^{-1}. \end{aligned} \tag{62}$$

It should be pointed out that increasing Δ causes the radiative transition probability to decrease but the permanent dipole to increase.

Illustrative Example. Cyclobutadiene

Cyclobutadiene is a fictious molecule, but has frequently been a subject for theoretical considerations. We will begin with an investigation on the assumption that cyclobutadiene is, in a crude approximation, a square molecule with bonds of equal length, 1.42 Å. This structure has two π electronic levels which are degenerate. The vibrational modes which connect these two levels have symmetries b_{1g} and b_{2g} as shown

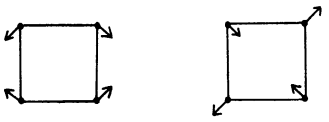

Fig. 1. Normal modes of molecular vibrations.
a: b_{1g} mode, b: b_{2g} mode.

in Fig. 1. Those vibronic coupling constants referring to those modes are designated g_1 and g_2, respectively. These constants are evaluated by the method of Murrel and Pople[4] as

$$\begin{aligned} g_1 &= 0.432/\sqrt{\nu_1}\ \text{eV}, \\ g_2 &= 0.112/\sqrt{\nu_2}\ \text{eV}, \end{aligned} \tag{63}$$

where ν_i is the wave number of the vibration in question in units of 1000 cm^{-1}; we adopt $\nu_i=1.5$, as is usually the case with hydrocarbons having several carbon atoms.

Wave function for the degenerate π levels are written as

$$\begin{aligned} \psi_1 &= \frac{1}{2}(\chi_1+\chi_2-\chi_3-\chi_4), \\ \psi_2 &= \frac{1}{2}(\chi_1-\chi_2-\chi_3+\chi_4), \end{aligned} \tag{64}$$

or alternatively,

$$\begin{aligned} \psi_1 &= \frac{1}{\sqrt{2}}(\chi_1-\chi_3), \\ \psi_2 &= \frac{1}{\sqrt{2}}(\chi_2-\chi_4), \end{aligned} \tag{65}$$

where χ_i is the $2p\pi$ atomic orbital at site i. Equation 64 is suitable for considering the b_{1g} vibrational mode, whereas Eq. 65 is applicable to the b_{2g} mode, so that the coupling matrix $\hat{g}$ is written as Eq. 7.

We can calculate stabilization energies using Eq. 56 with $\varepsilon=0$ (degenerate case) as

$$\begin{aligned} \delta E(b_{1g}) &= 0.831\ \text{eV (rectangle)}, \\ \delta E(b_{2g}) &= 0.107\ \text{eV (diamond)}. \end{aligned} \tag{66}$$

Apparently the former is much higher than the latter, in agreement with the most stable structure of this molecule being a rectangle. The stabilization energy, 0.831 eV, obtained here is very close to that obtained by Liehr, 0.907 eV.[5]

We turn to evaluation of δR_α ($\alpha=l,x$), with our interest restricted in the b_{1g} type distortion. Since $L_{\alpha q}$ has been estimated to be 0.0109 by the standard method,[6] we have from Eq. 58

$$\delta R_\alpha = 0.0325\ \text{Å}, \tag{67}$$

hence the longer and shorter bond distances are evaluated as

$$D_l = 1.485\ \text{Å}, \quad D_s = 1.355\ \text{Å}. \tag{68}$$

For reference, the following values have been obtained by Liehr[5] and by Salem:[7]

$$\begin{aligned} &D_l = 1.54\ \text{Å}, \quad D_s = 1.33\ \text{Å (Liehr)}, \\ &D_l = 1.463\ \text{Å}, \quad D_s = 1.388\ \text{Å (Salem)}. \end{aligned} \tag{69}$$

Similar arguments may be applicable to conjugated chain molecules. In these case, the b_{1g} vibrational mode is expected also to contribute dominantly to the stabilization; however, ε is finite in these case, though we can expect the inequality (37), to be applicable; both the stabilization energy and bond distortion would be smaller than those in the degenerate case discussed in this paper.

Discussion

We have presented the mean field theory for such an electronic system as is composed of two closely-spaced levels and strongly coupled with a phonon mode. Even though we have adopted quite a simple Hamiltonian given by Eq. 8, we have successfully derived some physically interesting results; the appearance of coherent phase and the condition for this phase to be more stable than the normal phase. Expressions for the stabilization energy and associated bond distortion have been derived and their numerical values estimated for cyclobutadiene, with results in good agreement with those obtained by conventional methods.

It should be pointed out that, for usual finite molecules, the characteristic temperature at which the coherent phase appears is so high (over 10000 °C as estimated by Eq. 38) that common molecules should be in the well-established coherent phase with respect to the phonon modes even at room temperature.

As to long chain molecules, there is a leading opinion that the stabilization is caused mostly by electron correlation.[8] We agree to this but want to stress that the electron correlation term, if included in our Hamiltonian, would rise a new problem to us.

Finally, we shoud note that the appearance of non-analyticity of free energy at the finite temperature T_c is to be taken as a shortcoming of our simplest approximation. Nevertheless, we can regard it as an important step of theoretical development, though fluctuating, on the distortion. The thermodynamic properties derived above also must be considered as indicating characteristic features below T_c for the transition towards the distorted ground state. At any rate, a more satisfactory theory is expected which gose over the present framework of approximation.

The problem treated here can also be manipulated by means of Green's function, which will be discussed in the following paper.

Theory of Molecular Deformation Due to the Vibronic Interaction between Two Closely-spaced Electronic Levels. II. Green's Function Treatment

Kiyoshi NISHIKAWA, Minoru KIMURA,† and Shigeyuki AONO*

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa, 920
†Department of Physics, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa, 920

(Received July 3, 1980)

Vibronic interaction between two closely-spaced electronic levels was investigated by use of the temperature Green's function. A Green's function version for the mean field approximation was derived which is capable of reproducing results obtained in the preceding work. The spectrum of phonon in the normal phase was then calculated and the critical (strictly speaking, characteristic, since we are dealing with a finite system) temperature T_c was obtained where the phonon becomes completely soft causing lattice distortion. The fluctuation effect was investigated and the mean field theory was examined for its applicability. When the level spacing is comparable to or larger than the value of the electron-phonon coupling constant, the mean field theory is satisfactory, but when the two levels are nearly degenerate, it is not so good because the problem in question is in the regime involving extremely strong coupling.

In the preceding work (referred to as I hereinafter) we have developed the mean field theory for the title subject. The model considered there is outlined as follows. Let a_i^+ (a_i) be the creation (annihilation) operator of the electron at level i, and $b^+(b)$ the creation (annihilation) operator of phonon. To simplify formulations we introduce the notations

$$C^+ = (a_1^+ \; a_2^+), \; C = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}, \tag{1}$$

$$\phi = b^+ + b. \tag{2}$$

Thus, the Hamiltonian is given by

$$H = -\varepsilon C^+\sigma_3 C + g\phi C^+\sigma_1 C + \omega b^+ b, \tag{3}$$

where

$$\sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \; \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \; \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \; \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \tag{4}$$

are used. Later we will use the following marix for electron-phonon (vibronic) interaction:

$$\hat{g}\tilde{\varepsilon} = \begin{pmatrix} 0 & g \\ g & 0 \end{pmatrix} = g\sigma_1. \tag{5}$$

Within the mean field approximation, operators b^+ and b in Eq. 3 are replaced by their averages. This approximation reduces the Hamiltonian given by Eq. 3 to

$$H^{eff} = -\varepsilon C^+\sigma_3 C + g\langle\phi\rangle C^+\sigma_1 C + \omega|\langle b\rangle|^2. \tag{6}$$

This form is based on an expectation that the so-called coherent state impling $\langle\phi\rangle \neq 0$ will be arranged by the electron-phonon interaction. In I H^{eff} was diagonalized by a linear canonical transformation. The value of $\langle\phi\rangle$ has been determined on the condition that the free energy of our system is optimized with respect to $\langle\phi\rangle$. As a numerical example, the bond distortion and stabilization energy were calculated for cyclobutadiene, in good agreement with those obtained by a current theory.

In this paper, we will present the Green's function theory for the problem. In the first section, we will show that the result obtained in I is derivable on the basis of the simplest approximation on Green's function. In the remaining section, we will investigate the fluctuation effect to examine the validity of the mean field theory.

Phonon Softening

It is known well in the physics of one-dimensional (1-D) conductors[4,5] that the phonon softening induced by electron-phonon interaction causes lattice deformation in these systems. To show that an analogous mechanism is operative in the present problem, we will begin with investigating behaviors of the phonon propagator in the normal state; we will work with the simplest approximation for the polarization part of the phonon propagator as shown in Fig. 1. Analytically it is expressed by

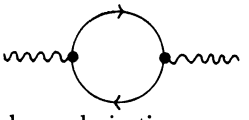

Fig. 1. First order polarization part of the phonon Green's function.

$$\Pi(i\nu_n) = T\sum_{i\omega_n} \mathrm{Tr}\,\hat{g}G^0(i\omega_n)\hat{g}G^0(i\nu_n - i\omega_n), \tag{7}$$

where $G^0(i\omega_n)$ is the Matsubara (temperature) Green's function[2] for a free electron and its expression can be obtained from the first term of Eq. 3 as

$$\begin{aligned} G^0(i\omega_n) &= (i\omega_n\sigma_0 + \varepsilon C^+\sigma_3 C)^{-1} \\ &= \begin{pmatrix} \dfrac{1}{i\omega_n + \varepsilon} & 0 \\ 0 & \dfrac{1}{i\omega_n - \varepsilon} \end{pmatrix} \\ &= \sum_k G_k^0(i\omega_n)\,\sigma_k \end{aligned} \tag{8}$$

with

$$\begin{aligned} G_0^0(i\omega_n) &= \frac{1}{2}\left(\frac{1}{i\omega_n + \varepsilon}\right) + \left(\frac{1}{i\omega_n - \varepsilon}\right) \\ G_3^0(i\omega_n) &= \frac{1}{2}\left(\frac{1}{i\omega_n + \varepsilon} - \frac{1}{i\omega_n - \varepsilon}\right). \end{aligned} \tag{9}$$

If we use Eqs. 5 and 8, Eq. 7 is rewritten as

$$\Pi(i\nu_n) = 2g^2\, T\sum_{i\omega n}\{G_0^0(i\omega_n)\, G_0^0(i\nu_n - i\omega_n) - G_3^0(i\omega_n)G_3^0(i\nu_n - i\omega_n)\}. \quad (10)$$

The frequency sum[3] in Eq. 10 leads to

$$\Pi(i\nu_n) = -g^2\frac{4\varepsilon}{\nu_n^2+4\varepsilon^2}\tanh(\varepsilon/2T). \quad (11)$$

The interacting phonon Green's function is obtained from the Dyson equation

$$D(i\nu_n) = D^0(i\nu_n)/\{1 - D^0(i\nu_n)\Pi(i\nu_n)\}, \quad (12)$$

where the free phonon propagator $D^0(i\nu_n)$ is given by

$$D^0(i\nu_n) = \frac{-2\omega}{\nu_n^2+\omega^2}. \quad (13)$$

Combining Eqs. 11, 13, and 12, we obtain

$$D(i\nu_n) = \frac{-2\omega(\nu_n^2+4\varepsilon^2)}{(\nu_n^2+\omega^2)(\nu_n^2+4\varepsilon^2)-8g^2\,\varepsilon\omega\tanh(\varepsilon/2T)}. \quad (14)$$

In this equation $i\nu_n$ is analytically continued to ν and thus the poles of Eq. 14 are found at

$$(\nu^2)_\pm = \frac{1}{2}(\omega^2+4\varepsilon^2) \pm \left\{\left(\frac{\omega^2+4\varepsilon^2}{2}\right)^2 + 8g^2\varepsilon\omega\tanh(\varepsilon/2T) - 4\varepsilon^2\omega^2\right\}^{1/2}. \quad (15)$$

First, we note that, if coupling constant g is extremely small, Eq. 15 reduces to

$$(\nu^2)_\pm \simeq \begin{cases}\omega^2 & \text{for } \omega > \varepsilon,\\ 4\varepsilon^2\end{cases} \quad (16a)$$

and

$$(\nu^2)_\pm \simeq \begin{cases}4\varepsilon^2 & \text{for } \omega < \varepsilon.\\ \omega^2\end{cases} \quad (16b)$$

They are spectra of independent electron and phonon. Aside from this simplest case, spectrum ν_- in general depends on temperature in a very specific way. In paticular, the behavior of ν_- is quite specific. If g is strong enough, it becomes soft as temperature is lowered. Complete softening of ν_- occurs at the temperature T_c in accordance with

$$\tanh(\varepsilon/2T_c) = (\varepsilon\omega/2g^2). \quad (17)$$

A unique solution is obtainable for T_c if g is so strong as to satisfy the inequality

$$g^2 > \varepsilon\omega/2. \quad (17a)$$

At the temperature T_c we get the spectrum

$$(\nu^2)_\pm = \begin{cases}\omega^2+4\varepsilon^2\\ 0\end{cases} \quad (18)$$

Equation 17 is equal to the relation defining the characteristic temperature for the distortive transition (given by Eq. 38 in I).

The above-demonstrated similarity to the case of 1-D conductor is of significance; however, it is worth while to take notice of the strong coupling condition (17a) applicable to our case, in contrast to the case of 1-D Peierls transition where any weak coupling can lead to the softening.

Electron Propagator

The description in the preceding section is inapplicable to the temperature range below the characteristic temperature T_c. To see how the system behaves at $T \lesssim T_c$, we consider the solution with deformation on the basis of the effective Hamiltonian (6). The propagator for a "free" electron suitable for this case is given by

$$G(i\omega_n) = (i\omega_n\sigma_0 + \varepsilon\sigma_3 - \Delta\sigma_1)^{-1}, \quad (19)$$

where

$$\Delta = g\langle\phi\rangle. \quad (20)$$

A straightforward calculation leads to an alternative form for Eq. 19

$$G(i\omega_n) = \sum_k G_k(i\omega_n)\sigma_k \quad (21)$$

$$G_k(i\omega_n) = \frac{1}{(i\omega_n-\tilde\varepsilon)(i\omega_n+\tilde\varepsilon)} \times \begin{cases} i\omega_n\\ \Delta\\ 0\\ -\varepsilon\end{cases} \text{ for } k = \begin{cases}0\\1\\2\\3\end{cases}, \quad (21a)$$

where

$$\tilde\varepsilon = \sqrt{\varepsilon^2+\Delta^2}. \quad (22)$$

To estimate $\langle\phi\rangle$, we now look for the solution of the static distortion as has been done in I, namely,

$$-\left\langle\frac{\partial}{\partial\tau}b\right\rangle = \langle[b,H]\rangle = 0, \quad (23)$$

which is the average of the Heisenberg equation of motion with respect to the imaginary time τ. Using Eq. 3 to make a calculation on Eq. 23, we obtain

$$\langle b\rangle = -\frac{g}{\omega}\langle C^+\sigma_1 C\rangle. \quad (24)$$

Obviously, for $\langle b^+\rangle$ we are led to entirely the same expression and it follows that

$$\Delta = g\langle\phi\rangle = -\frac{2g^2}{\omega}\langle C^+\sigma_1 C\rangle = \frac{g^2}{\omega}G_1(0^-), \quad (25)$$

where 0^- is negative infinitesimal and

$$G_1(0^-) = T\sum_{i\omega n} G_1(i\omega_n)\exp(i\omega_n 0^-) = T\sum_{i\omega_n}\frac{\Delta}{(i\omega_n-\tilde\varepsilon)(i\omega_n+\tilde\varepsilon)}\exp(i\omega_n 0^-) = (\Delta/2\tilde\varepsilon)\tanh(\tilde\varepsilon/2T). \quad (26)$$

Combining Eqs. 25 and 26, we arrive at the "gap" equation

$$(\tilde\varepsilon\omega/2g^2) = \tanh(\tilde\varepsilon/2T), \quad (27)$$

which is identical with Eq. 36 in I.

Thermodynamics

According to Ref. 6 the difference in free energy between the coherent and normal phases

$$\delta F = F - F_n \quad (28)$$

is given by

$$\delta F = \int_0^g dg\,\langle\phi C^+\sigma_1 C\rangle. \quad (29)$$

In the integrand in Eq. 29 the average $\langle\phi C^+\sigma_1 C\rangle$ is approximated to $\langle\phi\rangle\langle C^+\sigma_1 C\rangle$, which permits Eq. 29 with the aid of Eqs. 25, 26, and 27 to give

$$\delta F = -\int_0^g dg\, 2\langle\phi\rangle\frac{\Delta}{2\tilde\varepsilon}\tanh(\tilde\varepsilon/2T) = -\int_0^g dg\,(\omega\Delta^2/2g^3). \quad (29a)$$

The integration for Eq. 29a can be performed as follows:

$$\begin{aligned}\delta F &= \int_0^{g\omega\Delta^2/2} \mathrm{d}\left(\frac{1}{2g^2}\right) \\ &= \frac{\omega}{2}\int_{\varepsilon}^{\tilde{\varepsilon}} \Delta^2 \frac{\mathrm{d}}{\mathrm{d}\tilde{\varepsilon}}\left(\frac{1}{2g^2}\right)\mathrm{d}\tilde{\varepsilon} \\ &= \frac{\omega}{2}\int_{\varepsilon}^{\tilde{\varepsilon}} \Delta^2 \frac{\mathrm{d}}{\mathrm{d}\tilde{\varepsilon}}\left[\frac{1}{\tilde{\varepsilon}\omega}\tanh\left(\tilde{\varepsilon}/2T\right)\right]\mathrm{d}\tilde{\varepsilon} \\ &= \frac{1}{2}\int_{\varepsilon}^{\tilde{\varepsilon}} (\tilde{\varepsilon}^2-\varepsilon^2)\frac{\mathrm{d}}{\mathrm{d}\tilde{\varepsilon}}\left[\frac{1}{\tilde{\varepsilon}}\tanh\left(\tilde{\varepsilon}/2T\right)\right]\mathrm{d}\tilde{\varepsilon}, \end{aligned} \tag{30}$$

where for the second line the gap equation (27) has been used and for the third line the definition of $\tilde{\varepsilon}$ by Eq. 22 used. Finally, the integration by parts for Eq. 30 gives the free energy difference as

$$\begin{aligned}\delta F = &\frac{1}{2}\left[\frac{\tilde{\varepsilon}^2-\varepsilon^2}{\tilde{\varepsilon}}\tanh\left(\tilde{\varepsilon}/2T\right)\right] \\ &-2T\{\ln[2\cosh\left(\tilde{\varepsilon}/2T\right)] - \ln[2\cosh\left(\varepsilon/2T\right)]\}. \end{aligned} \tag{31}$$

For comparison we evaluate the free energy for the normal state; the partition function for this state is given by

$$\begin{aligned} Z_n &= \mathrm{Tr}\exp(-\varepsilon C^+\sigma_1 C/T) \\ &= \mathrm{Tr}\exp\left(-\varepsilon a_1^+ a_1/T\right)\times \mathrm{Tr}\exp(\varepsilon a_2^+ a_2/T) \\ &= [\exp\left(\varepsilon/2T\right) + \exp(-\varepsilon/2T)]^2 \end{aligned} \tag{32}$$

for which we have made use of the fact that the eigenvalue of $a_i^+ a_i$ is 0 or 1. Therefore, the free energy of the normal state is given by

$$F_n = -T\ln Z_n = -2T\ln[2\cosh\left(\varepsilon/2T\right)], \tag{33}$$

which, combined with Eq. 31, leads to

$$F = (\Delta^2\omega/4g^2) - 2T\ln[2\cosh(\tilde{\varepsilon}/2T)]. \tag{34}$$

Thus, we have obtained the free energy of the distorted state, which is identical with Eq. 33 in I; as far as the above treatment is concerted, the two methods have been shown to be identical.

Fluctuation Effect

Let us examine to what extent the above results are valid by estimating the correction due to fluctuation. To describe the deviation from the mean field quantities, new operator β, β^+, and ψ are defined by

$$b = \langle b\rangle + \beta,\ b^+ = \langle b\rangle + \beta^+, \tag{35}$$

$$\psi = \beta + \beta^+. \tag{36}$$

These definitions allow the Hamiltonian to be rewritten as

$$H = H_0 + H_{\mathrm{int}} + \omega\langle b\rangle\psi + \omega\beta^+\beta + \omega|\langle b\rangle|^2, \tag{37}$$

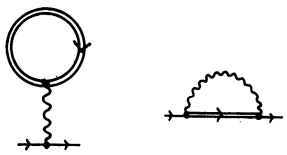
with

$$H_0 = C^+(-\varepsilon\sigma_3 + \Delta\sigma_1)C, \tag{38}$$

$$H_{\mathrm{int}} = C^+ g\psi\sigma_1 C. \tag{39}$$

In what follows, we attempt to estimate the fluctuation effect on electronic spectra within the lowest order of g by considering the self-energy contribution shown in Fig. 2.

Mean field electron propagator G (displayed in solid line in Fig. 2) is obtained from H_0 in Eq. 37. It has already been given by Eq. 21 with Δ to be determined by Eq. 27. Phonon propagator D^0 (displayed in wavy line in Fig. 2) is easily calculated from the third and fourth terms of Eq. 37 and is shown to be identical with Eq. 13.



a b

Fig. 2. First order self-energy terms of the electron propagator.
a: Direct term, b: exchange term.

Using these expressions for propagators, we can express the self-energy parts in Fig. 2 analytically as

$$\Sigma = \Sigma_H + \Sigma_E, \tag{40}$$

where

$$\Sigma_H(\mathrm{i}\omega_n) = Tg^2\sigma_1 D^0(0)\sum_{\mathrm{i}\nu_n}\mathrm{Tr}\sigma_1 G(\mathrm{i}\nu_n) \tag{40a}$$

$$\Sigma_E(\mathrm{i}\omega_n) = -Tg^2\sum_{\mathrm{i}\nu_n}\sigma_1 G(\mathrm{i}\nu_n)D^0(\mathrm{i}\omega_n - \mathrm{i}\nu_n)\sigma_1. \tag{40b}$$

Σ_H is the contribution of Fig. 2a and Σ_E that of Fig. 2b. Following the usual procedure, we evaluate Σ_H as

$$\begin{aligned}\Sigma_H(\mathrm{i}\omega_n) &= (-4g^2/\omega)T\sum_{\mathrm{i}\nu_n}\sigma_1 G_1(\mathrm{i}\nu_n) \\ &= \sigma_1(4g^2/\omega)(\Delta/2\tilde{\varepsilon})\tanh\left(\tilde{\varepsilon}/2T\right) \\ &= \sigma_1\Delta. \end{aligned} \tag{41}$$

In the last step in Eq. 41 we have used the gap equation (27).

The calculation of Σ_E is tedious: First, the algebra of the Pauli matrices yields

$$\Sigma_E = \sigma_0\Sigma_0 + \sigma_1\Sigma_1 - \sigma_3\Sigma_3, \tag{42}$$

where

$$\Sigma_k(\mathrm{i}\omega_n) = -g^2T\sum_{\mathrm{i}\nu_n}G_k(\mathrm{i}\nu_n)D^0(\mathrm{i}\omega_n - \mathrm{i}\nu_n),\quad k = 0, 1, 3. \tag{42a}$$

Each term of this equation will be evaluated separately. The frequency summation of Σ_0 is performed to give

$$\Sigma_0(\mathrm{i}\omega_n) = g^2\left[\frac{\mathrm{i}\omega_n N_1}{(\mathrm{i}\omega_n)^2-(\tilde{\varepsilon}+\omega)^2} + \frac{\mathrm{i}\omega_n N_0}{(\mathrm{i}\omega_n)^2-(\tilde{\varepsilon}-\omega)^2}\right], \tag{43}$$

where

$$\begin{aligned} N_1 &= n(-\tilde{\varepsilon}) + n_b(\omega) \\ N_0 &= 1 - n(-\tilde{\varepsilon}) + n_b(\omega) \end{aligned} \tag{44}$$

and $n(-\tilde{\varepsilon})$ and $n_b(\omega)$ are, respectively, the Fermi and Bose function with corresponding arguments.

We have an approximation

$$(\mathrm{i}\omega_n)^2 - (\tilde{\varepsilon}+\omega)^2 \simeq \tilde{\varepsilon}^2 - (\tilde{\varepsilon}+\omega)^2 \simeq -2\tilde{\varepsilon}\omega \tag{45}$$

considering that $\tilde{\varepsilon}\gg\omega$; this approximation is possibly applicable to the example case discussed in I. Equation 43 can then be reduced to

$$\Sigma_0(\mathrm{i}\omega_n) \simeq \Sigma_0(\pm\tilde{\varepsilon}) = \mp\tilde{\varepsilon}/4. \tag{46}$$

The remaining two terms in Eq. 42 are evaluated in a similar manner as

$$\begin{aligned}\Sigma_1(\mathrm{i}\omega_n) &= -\Delta/4 \\ \Sigma_3(\mathrm{i}\omega_n) &= \varepsilon/4. \end{aligned} \tag{47}$$

Combining Eqs. 41, 46, and 47, we obtain

$$\Sigma(\mathrm{i}\omega_n) \simeq \Sigma(\pm\tilde{\varepsilon}) = \frac{1}{4}\begin{pmatrix}\mp\tilde{\varepsilon}-\varepsilon & 3\Delta \\ 3\Delta & \mp\tilde{\varepsilon}+\varepsilon\end{pmatrix}. \tag{48}$$

Finally, the full electron propagator

$$G(i\omega_n) = [G_0^{-1}(i\omega_n) - \sum(i\omega_n)]^{-1}$$

is given in the form

$$G(i\omega_n) \simeq \begin{pmatrix} i\omega_n \pm \frac{\tilde{\varepsilon}}{4} + \frac{5\varepsilon}{4} & -\frac{7\Delta}{4} \\ -\frac{7\Delta}{4} & i\omega_n \pm \frac{\tilde{\varepsilon}}{4} - \frac{5\varepsilon}{4} \end{pmatrix}^{-1}. \quad (49)$$

The electronic spectrum which involves the contribution from the fluctuation effect is determined from Eq. 49 as

$$\nu = \pm\tilde{\varepsilon}\left(1 + \frac{24}{25}\frac{\Delta^2}{\tilde{\varepsilon}^2}\right)^{1/2}. \quad (50)$$

According to this equation the electronic spectrum is to be corrected by a factor

$$\lambda = \left(1 + \frac{24}{25}\frac{\Delta^2}{\tilde{\varepsilon}^2}\right)^{1/2} - 1. \quad (51)$$

In the case where the two electronic levels are nearly degenerate, *i.e.*, $\varepsilon \simeq 0$, the factor (51) is considerably large since $\lambda \lesssim \sqrt{2} - 1$, whereas if ε is so large that $\tilde{\varepsilon} \gg \Delta$ the correction is small since $\lambda \simeq 0$. The latter inequality implies

$$\varepsilon \simeq 2g^2/\omega, \quad (52)$$

i.e., relatively weak coupling cases. Such cases as involve nearly degenerate levels belong to the extremely strong coupling regime.

Conclusion

We have made use of Green's functions to reproduce the results from the mean field theory presented in I and examined effects of fluctuation on electronic spectra. We are led to conclude that, as seen from Eq. 50, the mean field theory is not necessarily good; if the level spacing is fairly large, *i.e.*, $\varepsilon \simeq g$ or $\varepsilon \simeq \Delta$, the mean field theory is a pretty good approximation, but if the two levels are nearly degenerate, a substantial deviation is inevitable to the mean field theory. For this reason, the numerical estimate for cyclobutadiene (where $\varepsilon \simeq 0$) given in I, though in good agreement with results of other works, must be considered to be only qualitatively reliable.

In order to improve this situation and to reach better understanding of this problem, the perturbation scheme can be hardly suitable because we have no smaller parameters available for the series expansion. In paticular, the vertex renormalization which we have ignored can be expected to be superior to any other corrections. For metals we have the well-known Migdal theorem[7] which has demonstrated that the vertex correction is as small as the order of the small parameter m/M (electron-nucleus mass ratio). We do not think that the theorem is actually applicable to the case of finite systems such as molecules.

Thermal Decomposition Studies of Ammonium Heptamolybdate(6-) Tetrahydrate by Means of High-temperature Oscillating X-Ray Diffraction with a Rotating Anode Type Large Capacity Generator

Kimio Isa* and (the late) Hajime Ishimura

Department of Chemistry, Faculty of Education, Fukui University, Bunkyo 3-9-1, Fukui 910

(Received October 28, 1980)

Ammonium heptamolybdate(6—) tetrahydrate (AHM) was studied by means of high temperature oscillating X-ray diffraction with a large capacity generator of 12 kW. Experimental conditions were determined precisely. It was possible to settle the maximum value of diffracted patterns, and the inherited error was about 1.5%. Thermal decomposition of AHM was studied by means of TG-DTA, but the first decrease of TG could not be explained as a single process of decomposition. Moreover it could also not be explained by means of high-temperature oscillating X-ray diffraction with a standard generator. However, with a large capacity generator, the first decrease of TG could be explained to be a convolution of three steps of decomposition. Moreover, the second and third steps could be explained by observing the microscopic structural change. In a high-temperature oscillating XRD, (heating rate 2 °C/min), a peak temperature of 96 °C was recognized, which had not been reported before. Also from 110 °C to 226 °C, a row of the small peak has been found. Finally, the first stage of decomposition which was thought to be a single step in the experiment of TG-DTA, could be seperated into three steps. Moreover, the onset and offset temperatures of changes of characteristic diffraction intensity are determined. It was proved that high-temperature oscillating X-ray diffraction is a powerful analysing method in thermal analysis.

Thermogravimetry (TG) is defined to be a single step process as illustrated in Fig. 1.[1] We have been studying thermal decomposition of ammonium heptamolybdate-(6—) tetrahydrate ($(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, AHM) in the range of room temperature to 500 °C during several years. We first measured the thermal decomposition of AHM by means of TG under an atmosphere of static air. One of the typical results is shown in Fig. 2.[2] The intermediates (a), (l), and (n) are considered to be plateaus, but the intermediates (j), (k), and (m) are not. The steps (j) and (k) on a TG curve show gentle slopes. We must consider the gentle slopes owing either to some thermal decomposition or to an instrumental effect. From the definition of TG, the stages (j) and (k) contain multistep processes. However, this could be explained partly by DTA (differential thermal analysis). We hope to define elementary processes of this decomposition more precisely by studying the microscopic structure. The experimental methods used were mainly a simultaneous TG-DTA under various atmospheres, and a high-temperature oscillating XRD analysis (XRD: X-ray diffraction). The experimental results of the former have been already published partly.[2] The results of the latter will be discussed in this report.

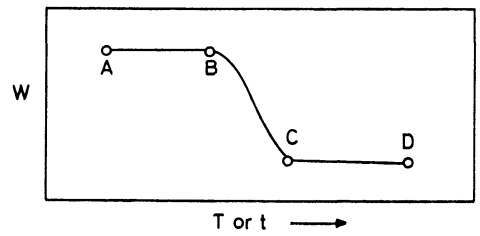

Fig. 1. TG curve of a single step process.
W, *T*, and *t* are weight change, temperature and time, respectively. AB and CD are plateaus.

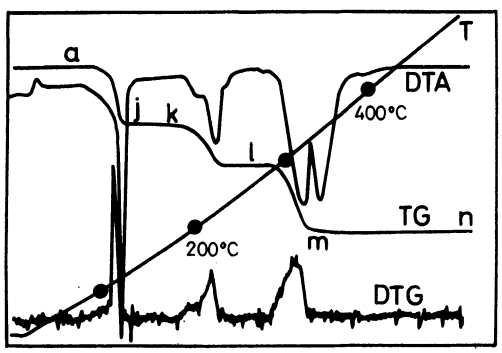

Fig. 2. One of the typical results of TG-DTG-DTA under a static air atmosphere.
Heating rate: 3 °C/min; TG full scale range: 10 mg; DTA full scale range: ±100 μV.

The decomposition of AHM has received considerable attention as it is an isopoly anion reaction. Numerous investigators have studied thermal decompositions of AHM by means of TG, TG-DTA, powder XRD, Ω-tron mass spectrometry, and infrared absorption spectrometry, *etc.* Moreover thermal decomposition of AHM was studied by simultaneous TG-DTG-DTA-HRMS (DTG: differential thermogravimetry, HRMS: high resolution mass spectrometry) under various atmospheres (static, dry air flow, wet air flow, and (NH_3+N_2) mixture gas flow).[2,3] Recently thermal decomposition of AHM was measured by means of DSC (DSC: differential scanning calorimetry) by the authors.[4] Furthermore, by using microscopic structural analysis, we observed a phase transition occurring at 175 °C in addition to those at 110 °C, 210 °C, and 297 °C by means of high-temperature oscillating XRD with a standard X-ray generator. The conditions were: heating rate 2.5 °C/min, ranges of scanning angle, 2θ: 10.5°—13.5°, and voltage and current of the standard X-ray generator 30 kV and 30 mA, respectively. Since the intensity of the X-ray is about 800 cps and the signal-to-noise ratio at a maximum value of diffracted patterns (2θ) is about 10,

the statistical error is about 9.7%. The result of this experiment did not elucidate a gradual decrease of the TG curve. Because of a large statistical error, we could estimate neither the order of the reaction, nor the Arrhenius parameter. Then, using a rotating anode type large capacity generator thermal decomposition of AHM was measured by means of high-temperature oscillating XRD (the maximum voltage and the current are 60 kV and 200 mA, respectively). An X-ray intensity with a brilliance over 6 times as bright as a conventional hermetically-sealed X-ray tube was obtained. As the current can be varied from 10 mA to 200 mA in steps of 5 mA, the maximum peak intensity of the diffracted X-ray can be kept constant, independent of grain size, thickness of the sample, or flatness of the sample surface. In the present experiment it is possible to settle the maximum value of the diffracted pattern at 7200 cps and the inherited error is about 2%. As the maximum value of the diffracted pattern is fixed to be 7200 cps, it will be possible to determine the reaction rate of the thermal decomposition in the case of constant heating.[5]

First we considered the optimum experimental conditions of high temperature oscillating XRD. This is discussed below.

Experimental

Details of the experimental conditions are described below.

X-Ray Tube Output. Patterns of XRD are obtained by JEOL ROTEX JRX-12 using Cu $K\alpha$ radiation. Precise performances are itemized in Table 1.

Table 1. Performances of JEOL ROTEX JRX-12

X-Ray output	12 kW (Cu anode type)

Anode type species	Cu $K\alpha$

High-temperature Sample Holder. The standard sample holder of the goniometer was replaced by a high-temperature sample holder, DX-GOH-V_2(JEOL) in Fig. 3. This is made of a Pt–20%Rh alloy, and the area of the sample setting is 18×12 mm^2, the setting depth being 0.15 mm. It has a low resistance and is heated directly by a large current. Improved temperature measurements have been made using a thin thermocouple wire, Pt–Pt13%Rh, welded to the ribbon sample heater of a high temperature oscillating XRD attachement. The output signal of the thermocouple was read by a digital voltmeter (Takeda Riken Co., TR-6855) *via* a cold junction compensator. Temperature control of the hot stage is done by a controller, ULVAC-RICO PLUG-IN MODULE type THERMAL PROGRAM CONTROLLER, Model HPC-5000 Series. In Fig. 4, a 1 : 13 wounded transformer is connected between the sample holder and the controller. Intensity of diffracted X-ray signal, angle marker signals of oscillating ranges and output reading of the thermocouple are recorded by a Desk Top Recorder D-2R-1S (Ohkura Denki Co.).†

theses in Table 2 are used.

Ranges of Oscillating Angles of Goniometer. The intensity of the diffracted angle, ranging between $2\theta_{low}$ and $2\theta_{high}$, is measured by high temperature oscillating XRD analysis, using limiting switches. At first usual powder XRD patterns are measured from $2\theta=5°$ to $2\theta=50°$. The angle of a maximum value of the diffracted X-ray signal is included in the range between $2\theta_{low}$ and $2\theta_{high}$. Moreover, on heating the sample in steps of 20 °C up to 500 °C, powder patterns of XRD are recorded. The angle of the highest dynamically changing value of the diffracted pattern is included in the range between $2\theta_{low}$ and $2\theta_{high}$ too. In the present case of the thermal decomposition of AHM, an angle of maximum intensity of the diffracted pattern, ($2\theta=9.7°$), is included in the range of the angle. Together with the angle of maximum intensity, more angles of strong intensity are included in the ranges of $2\theta_{low}=9.2°$ and $2\theta_{high}=13.2°$. Consequently the oscillating range of the goniometer is about 4°.

Selection of a Time Constant, τ, of the Electric Circuit. A time constant, τ, of a counting system is chosen below, *i.e.* "τ is smaller than half of the oscillation time of the slit."[6] Concerning the opening angle of the receiving slit, the goniometer scanning rate, its radius and the oscillation of the slit (described below), τ is chosen to be 0.172 s. Opening angle of the receiving slit, goniometer radius, and time width of the slit are found to be 0.0458°, 250 mm, and 0.344 s, respectively.

Conditions of the Experimental Room. In order to get rid of intensity variation due to scattering caused by the air in the path of the X-ray beam, measurements are done under the conditions of constant temperature and moisture. The present experiment is done at the constant temperature of 25 (±0.2) °C.

Heating Rate. The temperature difference, ΔT, between the temperature at an angle $2\theta_{low}$ and that at an angle $2\theta_{high}$ in the course of programmed heating, is defined by

$$\Delta T = \frac{\Delta 2\theta \cdot \mathrm{d}T/\mathrm{d}t}{S}, \qquad (1)$$

where S=scanning speed, $\mathrm{d}T/\mathrm{d}t$=heating or cooling rate, and $\Delta 2\theta=2\theta_{high}-2\theta_{low}$. In a typical experimental condition, ΔT is chosen to be 1 °C, under the conditions, $\Delta 2\theta=4°$, $\mathrm{d}T/\mathrm{d}t=$ 2 °C/min, and $S=8$ °/min.

Response of the Pen Recorder. The response of the pen recorder is 0.6 s for full scale. The half width of a peak is 5 mm and it takes 5 s to describe it. As the response time is shorter than this time, the use of this recorded for high temperature oscillating XRD is satisfactory.

Results and Discussion

Experimental Conditions. Time Constant, τ: As seen from Fig. 5 the best choice of the time constant τ is 0.1 s.

Stability of the Diffracted X-Ray Intensity: In order to examine the stability of the X-ray generator during a measurement, the intensity of the diffracted X-ray signal from the Pt-20%Rh ribbon heater versus experimental time was measured under the same conditions of the actual experiment described below, *i.e.* oscillation angle range from $2\theta_{low}=36.92°$ to $2\theta_{high}=41.17°$ and constant room temperature, during about 250 min. The peak intensity was measured versus experimental time and was averaged for during 250 min. During the first 24 min we observed a small increase of the signal of $2\theta=40.20°$ ($d=2.244$ Å), probably because the current of X-ray tube had not yet reached its stationary value. As the fluctuations of the X-ray intensity were below 1.5%, we may consider the stability of the X-ray source as fairly good.

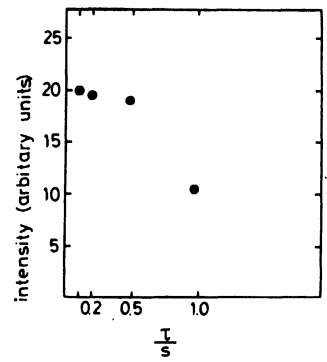

Fig. 5. Plot of intensity of XRD *versus* some time constant (τ).

High-temperature Oscillating XRD of AHM. AHM of Nakarai Co. (GR quality) was used in the form of a powder for the measurements. It was ground and sieved through standard sieves to seperate the fractions of 115—150 mesh, of 150—170 mesh and of 270—325 mesh. Moreover, for reference, a sample of Johnson-Matthey Co. of high purity (specpure chemical batch No. S84208**) was used for the measurements. In particular, in order to compare the experimental results, we mainly used samples of 150—170 mesh.

The intensity ratios of the peaks in the diffracted pattern are changed by the flatness and the thickness of the sample setting. So it is important how a sample is placed on the sample holder by a spatula, and was smoothed by a spoon. The intensity of the diffracted X-ray is about 90% of the full scale intensity (full scale is 2×10^4 cps in one case) of the recorder.

The intensity I of the characteristic X-ray is given by Eq. 2, C, A, V, and V_i are a constant, tube current, tube

$$I = C \cdot A \cdot (V-V_i)^{1.5} \qquad (2)$$

voltage, and exciting voltage, respectively. The intensity of the diffracted X-ray (I) of the diffraction angle, $2\theta=9.7°$ and the tube current are examined under the same experimental conditions as before. With A ranging from 10 mA to 150 mA, the relation (2) was examined experimentally. Considering I as a linear function of A : $I=aA+b$, we found by least squares method $a=0.34$ cps per Ampere and $b=1.85$ cps. Thinking b is small, it is satisfactory to use this X-ray generator for the present experiment under the conditions, mentioned above.

In the present experiment, high temperature oscillating XRD is measured at various heating rates, 0.5, 1, 2, 3, 4, 30, and 50 °C/min, *etc.* ΔT at the various heaintg rates is presented in Table 3. For the comparison with the results of TG-DTA and DSC, the heating in the high-temperature oscillating XRD is chosen to be 2 °C/min.

Experimental conditions: heating rate: 2 °C/min; chart spped: 5 mm/min; $2\theta_{low}$=9.37°; $2\theta_{high}$=13.43°; full scale of diffracted XRD: 1×10^4 cps; scanning speed: 8°/min; time constant: 0.1 s; divergency: 1°; receiving slit: 0.1 mm.

Table 4. Powder XRD patterns of various molybdates and molybdenum oxides in the ASTM X-Ray diffraction data files

ASTM index	Molecular formula	Crystal structure system
11-71	$(NH_4)_6Mo_7O_{24}\cdot 4H_2O$	Monoclinic
18-117	$(NH_4)_4Mo_8O_{26}$	Triclinic
21-0567	MoO_3	Hexagonal
5-0508	MoO_3	Orthorhombic

AHM (150—170 mesh) at the heating rate, 2 °C/min is shown in Fig. 6. Powder XRD patterns have been collected in the ASTM X-ray diffraction data files for the compounds given in Table 4. The XRD intensities for every plane index as a function of temperature are examined precisely. In the following I_0 stand for the maximum peak intensity.

ASTM Index 11-71, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$. The starting material was confirmed to be AHM by means of the standard powder XRD.

d = 9.08 Å, I/I_0 = 100, plane index (040), 2θ = 9.7°.

At about 65 °C this intensity shows a small increase and scattering becomes bigger. At about 84 °C the intensity begins to decrease drastically until about 95 °C and from that temperature it is gradually decreasing and finally at about 157 °C the peak disappears completely.

d = 7.56 Å, I/I_0 = 9, plane index (110), 2θ = 11.7°

This intensity begins to decrease from about 84 °C and disappears at about 100 °C.

d = 7.42 Å, I/I_0 = 9, plane index (110), 2θ = 11.9°

This intensity also begins to decrease from about 84 °C and disappears at about 100 °C.

d = 7.17 Å, I/I_0 = 20, plane index ($1\bar{2}1$), 2θ = 12.3°

This intensity also begins to decrease from about 77 °C and this decrease stops at about 90 °C and then it increases at about 97 °C from that temperature it begins to decrease again and at about 130 °C disappears completely.

The peak intensity of the d value, not described above, corresponding with the diffraction angle 2θ=9.7° begins to appear at about 118 °C. Moreover the peak at the diffraction angle, 2θ=13.4° begins to appear at about 110 °C and it is stable from about 124 °C to about 180 °C. From about 180 °C it begins to decrease and it disappears completely at about 226 °C.

ASTM Index 18-117, $(NH_4)_4Mo_8O_{26}$, Ammonium Octamolybdate(4−).

d = 7.21 Å, I/I_0 = 100, plane index undefined, 2θ = 12.2°.

This intensity begins to appear at about 176 °C and becomes stable at about 233 °C; it begins to decrease at about 266 °C and disappears completely at about 290 °C.

d = 9.21 Å, I/I_0 = 35, plane index undefined 2θ = 9.6°.

This intensity begins to appear at about 175 °C and becomes stable at about 200 °C. Moreover it becomes larger at about 250 °C.

ASTM Index 21-569, Hexagonal MoO_3.

d = 9.12 Å, I/I_0 = 80, plane index (100), 2θ = 9.7°.

The stable state of this peak produced from ammonium octamolybdate(4−) (AOM) is considered to be completed at about 175 °C, but at about 254 °C the peak becomes larger and becomes stable again at about 295 °C. In these temperature ranges, the intensity at the diffraction angle, 2θ=9.7°, of hexagonal MoO_3 is three times larger than that of AOM. It begins to decrease at about 355 °C and it disappears at about 405 °C.

ASTM Index 5-0508, Orthorhombic MoO_3.

d = 6.93 Å, I/I_0 = 34, plane index (020), 2θ = 12.7°.

This peak appears at about 358 °C, and becomes constant at about 426 °C. Its intensity is gradually increasing.

Meanwhile, in order to confirm an appearance temperature of maximum intensity at about 98 °C, we measured some high-temperature oscillating XRD's under the conditions described below. These conditions and the result are shown in Fig. 7.

Next, particular temperature stages of thermal decomposition are analysed by means of standard high

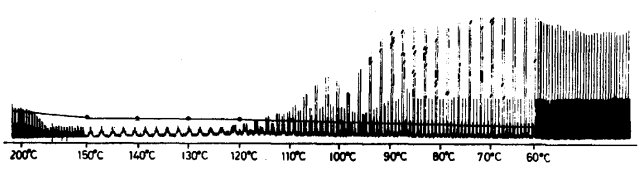

Fig. 7. One of the typical results of high-temperature oscillating XRD of AHM (115—150 mesh). Experimental conditions: heating rate: 2 °C/min; chart speed: 20 mm/min; $2\theta_{low}$=9.19°; $2\theta_{high}$=13.41°; full scale of diffracted XRD: 2×10^4 cps; scanning sped: 8°/min; time constant: 0.1 s; divergency: 1°; receiving slit: 0.1 mm.

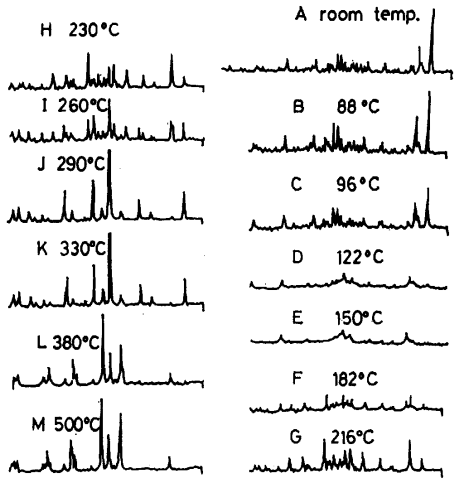

Fig. 8. The standard XRD at several temperatures.

temperature XRD. At the desired temperature, the heating was stopped and after three minutes, the sample was cooled to room temperature, the standard powder XRD's are measured. The results are shown in Fig. 8, A)—M). The patterns of A), H), K), and M) are considered to be AHM, AOM, hexagonal MoO_3 and orthorhombic MoO_3, respectively.

Correspondence with the Results of TG-DTA and High-temperature Oscillating XRD. Thermal decomposition of AHM has been studied by E. Ma[7] and three clear steps were found to be:

$$(NH_4)_6Mo_7O_{24}\cdot 4H_2O \xrightarrow{130^\circ C} (NH_4)_4Mo_5O_{17},$$

$$(NH_4)_4Mo_5O_{17} \xrightarrow{240^\circ C} (NH_4)_4Mo_8O_{26},$$

$$(NH_4)_4Mo_8O_{26} \xrightarrow{360^\circ C} MoO_3.$$

We had already studied thermal decomposition of AHM by means of TG-DTG-DTA and DSC,[2,3],†† but the upper decomposition schemes are not consistent precisely with the present experimental results. The discrepancy can be explained partly by high-temperature oscillating XRD. Before explaining the experimental results, we summarize and XRD measurement method at high temperature step by step.

I. After confirming each reaction stage by means of TG-DTA, the sample of the intermediate product is taken out from a thermobalance and measured by means of standard powder XRD.

II. At constant high temperature stage, high temperature XRD's are measured.[8] In our experiment, using a strong X-ray generator, we are enabled to take only 5 min to measure a standard XRD. It is possible to find an intermediate more easily than in case I. The reaction proceeds further, because the temperature is kept constant during 5 min, so some intermediate may happen to be missed.

III. High temperature oscillating XRD is the best analysis in order not to miss an intermediate of thermal decomposition. This method allows to find the best setting angle ranges of oscillation. Using a large capacity generator, however, the signal-to-noise ratio improve and gains better accuracy than using a standard X-ray generator. At a desired temperature during high-temperature oscillating XRD, a standard XRD is easily measured in a short time. By this improved technique, the structural changes of the precise reaction stages are observed.

Next, in comparison with a high-temperature oscillating XRD, in Fig. 2 we show a typical TG-DTG-DTA result under a static air atmosphere. The temperature of onsets and offsets of TG decrease are shown in Table 5. Also initial, final, and peak top temperatures of DTA and DSC are shown in Table 6.

Table 5. The temperatures of onsets and offsets of TG decrease

Decomposition stage	Onsets temperatures of each stage	Offsets temperatures of each stage
I	92 °C	135 °C
II	185 °C	234 °C
III	277 °C	362 °C

Table 6. The initial, peak top, and final temperatures of DTA and DSC

Decomposition stage	Initial temperature	Peak top temperature	Final temperature
I	92 °C	103 °C, 112 °C[a)]	130 °C
II	165 °C	192 °C, 217 °C[a)] (223 °C, 239 °C)[a)]	236 °C
III	256 °C	263 °C, 305 °C (329 °C)	346 °C

a) indicates the bigger peak when two peaks appear. Temperatures in the parentheses are obtained by DSC.

The results of TG showed a sharp decrease of the first stage at about 92 °C and this decrease ends at about 132°C. From this temperature TG begins to decrease gradually. At about 185 °C the second step of TG begins and at about 277 °C the third step. High-temperature oscillating XRD experiments, however, show a decrease in intensity of the (040)-plane from about 84 °C to 95 °C. This intensity finally disappears completely at about 157 °C. These two tendencies of the intensity curve (rapid and gradual) decreases of high-temperature oscillating XRD are consistent with the decreasing tendency of the first stage of TG.

Concerning the plane $(1\bar{2}1)$, two tendencies, a decreasing intensity at about 77 °C and a peak at about 97 °C, are convolved. We tried to seperate them, but did not succeed until now.

Moreover, we considered the intensity of d=7.21 Å of AHM, the intensity of d=9.21 Å of AOM and the intensity of d=9.12 Å of hexagonal MoO_3 from 176 °C to 258 °C. As the difference of the interplanar spacing,

†† TG-DTG-DTA was measured by means of Rigaku Co. Thermoflex, model 8002 and DSC by means of Daini Seiko Co. DSC, model SSC/560S.

d of the last two cases (*i.e.*, d=9.21 Å and d=9.12 Å) is very small, we could not seperate these two interplanar spacings. There are two possible explanations: one is a co-existance of AOM and hexagonal MoO_3, and the other one is that we simply could not seperate the peaks. In order to consider the possibility of co-existence of AOM and hexagonal MoO_3, we compare with the standard high-temperature XRD's, H) and K), at 230 °C and 310 °C, respectively in Fig. 8. Though the difference of d=9.21 Å in AOM and of d=9.12 Å in hexagonal MoO_3 is recognized slightly, we could not seperate them in a high temperature oscillating XRD. This experiment shows two stable peaks of AOM, d= 7.21 Å and 9.21 Å. At the phase transition of AOM to hexagonal MoO_3, two peaks disappear partly and a new peak, d=9.12 Å of hexagonal MoO_3 appears. In order to confirm these results, we improved the angle resolution of high-temperature oscillating XRD. Under the conditions of D=0.5°, S=0.5°, R=0.05 mm, and $d2\theta/dt$=4°/min, we could not succeed in seperating both peaks. The results also show stable temperature ranges of hexagonal MoO_3 and orthorhombic MoO_3.

The results of TG and DTA may explain the production of MoO_3 only, but whether it is hexagonal or orthorhombic MoO_3 cannot be explained by TG-DTG-DTA alone.

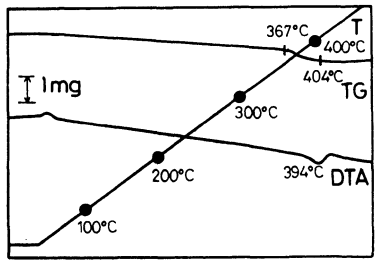

Fig. 9. Results of TG-DTA of a sample removed from the X-ray hot stage at about 330 °C, sample weight: 25.40 mg; TG full scale range: 10 mg; DTA full scale range: ±25 μV; chart speed: 20 cm/h; heating rate: 5 °C/min.

A sample of hexagonal MoO_3 was removed from the hot stage, and was analyzed by means of TG-DTA. The results are shown in Fig. 9 and two different decreasing types of TG are found. In one type the gradual weight loss of TG is about 2.4% from the room temperature to 300 °C. The other type is the rapid weight decrease of about 1.6% from 367 °C to 404 °C. Also the peak temperature of DTA is about 394 °C. The sample may not be simply MoO_3, but may be thought to be either $n\cdot(NH_4)_2O\cdot m\cdot MoO_3$ or $k\cdot H_2O\cdot MoO_3$ (n, m, k are positive integers). For the identification of this substance, a gas analysis is planned by means of simultaneous TG-MS. The weight loss of 2.4% may be due to desorption of water adsorbed by the sample after its removal from the hot stage. We conclude that the intermediate of (K) has hexagonal MoO_3 structure merely.

In X-ray spectroscopy there is always some background signal, and to decide whether or not this can be ignored is an important problem. Moreover, we must consider the accuracy of intensity measurements in high-temperature oscillating XRD. The statistical error depends on the peak intensity. If we define the number of signal intensity and of back ground as N_p and Nb, respectively, the statistical error $\sigma(\%)$ is given by the equation,[9]

$$\sigma(\%) = \frac{1}{\sqrt{Np}} \cdot \frac{\sqrt{1+Nb/Np}}{(1-Nb/Np)} \cdot 100. \qquad (3)$$

In the present experiment, Np and Nb are found to be 7040 cps and 440 cps, respectively, with σ=1.35%. For a standard X-ray tube (30 kV and 30 mA), Np and Nb were 650 cps and 70 cps, respectively, with now σ= 4.62%. Obviously the present experiment has a better accuracy, which enables to analyze a reaction rate and to determine Arrhenius parameters.

Table 7. The results of oscillating high temperature XRD

Decomposition stage	Temperature range of intensity plateaus	Cross point temperature
5 mm/min chart speed		
I_1	room temp—84 °C	89 °C
I_2	96 —100 °C	126 °C
I_3	128 —177 °C	183 °C, 187 °C
II	232 —251 °C	265 °C
III	295 —345 °C	384 °C
20 mm/min chart speed		
I_1	room temp—77 °C	99 °C
I_2	102 —104 °C	126 °C
I_3	129 —174 °C	183 °C, 187 °C

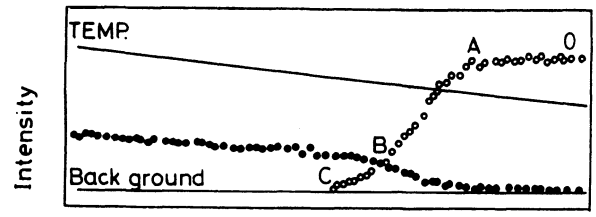

Fig. 10. Model of the result of high-temperature oscillating XRD. In the range OA one structural substance is present. In the range AC a mixture of more structural substances is present.

An appearance, disappearance, and cross point temperatures of the intensity of the diffraction patterns, are shown in Fig. 10. Moreover OA in Fig. 10 is considered to be a range of spacing versus sample temperature under programmed heating. From these measurements we may conclude that in the temperature range OA in Fig. 10, there is only one structural substance, but in the range AC, there is a mixture of structural substances. Finally we could measure points A and C more sharply by this experimental method. Consequently high-temperature oscillating XRD will become one of the most important methods of thermal analysis.

Some other inorganic salts (salts of isopoly acid) will be analyzed by high-temperature oscillation XRD method in future.

Summary

Thermal decomposition of AHM was measures by means of high-temperature oscillating XRD with a rotating anode type large capacity generator. This method enables us to measure microscopical structural changes in the field of thermal analysis. Especially, with improved S/N ratio, it is easy to determine the temperature of a phase transition and a reaction rate constant.

In a high-temperature oscillating XRD of AHM with the heating rate 2 °C/min, a peak temperature of 96 °C was found, which has not been reported before. Also from 110 °C to 226 °C, a series of small peaks was found. Finally, one stage of decomposition which was obtained in TG-DTA experiments, was seperated into three steps. The stability ranges of AOM, hexagonal MoO_3, and orthorhombic MoO_3 were clarified.

The X-ray generator is situated in the Research Institute for Material Science and Engineering, Fukui University. The author wishes to thank Professor Tohgoro Matsuo and Mr. Shigeru Hashiya for convenience of using their X-ray generator. The assistance of Miss Masayo Yoshimen during the early experiments is also acknowledged. The author would like to thank Dr. A. J. H. Boerboom and Dr. G. Harkvoort for critical reading of the manuscript. This work was partly supported by the Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Phosphorescence Spectra of Methyl-substituted 9,10-Anthraquinones in Solutions at 77 K

Akira KUBOYAMA* and Sanae Y. MATSUZAKI

National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305

(Received February 6, 1981)

The phosphorescence spectra and their lifetimes of 9,10-anthraquinone and its 2-methyl and 2,3-dimethyl derivatives in various kinds of glassy solutions at 77 K have been obtained. In the non-hydrocarbon solutions, 2-methylanthraquinone shows, in most cases, a dual phosphorescence, consisting of a $n\pi^*$ phosphorescence and a $\pi\pi^*$ phosphorescence with different lifetimes, while 2,3-dimethylanthraquinone shows a very broad $\pi\pi^*$ phosphorescence spectrum. The quinone-solvent interactions and the relative positions of the close-lying $^3n\pi^*$ and $^3\pi\pi^*$ levels of these quinones are discussed on the basis of the experimental results.

Previously, we have studied the phosphorescence spectra of 9,10-anthraquinone[1,2] (AQ) in various solutions at 77 K. All the phosphorescence spectra observed have been of the $n\pi^*$ type, having a distinct progression of the C–O stretching vibration and a short lifetime around 3 ms. Recently, we have observed the $\pi\pi^*$ phosphorescence spectra of alkylsubstituted 1,4-naphthoquinones[3] in glassy solutions at 77 K, while in 1,4-naphthoquinone only the $n\pi^*$ phosphorescence spectra have been observed in all the solutions. This is thought to be due to the rise of the phosphorescent $n\pi^*$ level and the fall of the low-lying $^3\pi\pi^*$ level of 1,4-naphthoquinone in the alkyl derivatives, resulting from the alkyl-group substitutions and the specific (hydrogen-bond and charge-transfer) and dispersion-force[4] interactions between the quinones and solvents. In this work, the phosphorescence spectra of the methyl-substituted anthraquinones, 2-methyl- and 2,3-dimethyl-AQ's, in various kinds of glassy solutions at 77 K have been studied from this point of view. The phosphorescence spectra of AQ in those solutions have also been studied for the purpose of comparison.

Experimental

Measurements. The phosphorescence spectra and their lifetimes in solutions at 77 K were measured using a phosphoroscope in the manner described in previous papers.[1-3] The solvents used were methylcyclohexane, toluene, ethanol, methanol, and 1-chloro- and 1-bromobutanes. All the solutions were glassy at 77 K. In the toluene solutions, the crystalline state was also formed by slow-cooling.[2] The concentrations of the solutions used always less than 10^{-3} mol dm^{-3}.

Materials. The AQ and the methyl-substituted anthraquinones used were commercially available. The AQ and 2-methyl-AQ were zone-refined (mp 286.6—287.2 °C and 176.6—177.5 °C). The 2,3-dimethyl-AQ was twice recrystallized, from a toluene–cyclohexane (1 : 2) mixture and from acetic acid (mp 207.5—208.8 °C). Spectrograde methylcyclohexane, methanol, and toluene of the Dozin Yakukagaku Co., analytical-grade ethanol of Wako Pure Chemical Industries, and G.R.-grade 1-choro- and 1-bromobutanes of the Tokyo Kasei Kogyo Co. were used.

Results. The phosphorescence spectra obtained are shown in Figs. 1—6, while their observed lifetimes are shown in Table 1.[5] In the methyl-substituted anthraquinones, the phosphorescence spectra depend on the turning-rate of the sector and the excitation-wavelength in some cases, but show no concentration dependence. In AQ, the phosphorescence spectra show none of these dependences. In the captions of Figs. 3—5, the words in parentheses, "slow" and "fast", denote that the turning-rates of the sector are slow and fast respectively. In the captions of Figs. 5 and 6, the wavelengths in parentheses denote the excitation-wavelengths. When the phosphorescence spectra showed sector-turning-rate dependences, two kinds of lifetimes were obtained, the shorter ones of which were obtained with the sector turning relatively fast, and the longer ones of which, with the sector turning as slow as possible.

Discussion

AQ shows only the $n\pi^*$ phosphorescence spectra in the solvents used in this work at 77 K; they show a distinct progression of the C–O stretching vibration and short lifetimes (Figs. 1 and 2 and Table 1).[6] Therefore, AQ may have the T_1 $n\pi^*$ state in these cases.[7] The phosphorescence spectrum of AQ in a toluene crystal is at wavelengths longer by *ca.* 250 cm^{-1} than that in toluene glass, and is situated very close to that in methylcyclohexane. Therefore, the charge-transfer interaction between AQ and toluene in a toluene crystal may be very small. Similar phenomena are also observed in the cases of the methyl-substituted anthraquinones, as will be mentioned later.

The phosphorescence bands of the methyl-substituted anthraquinones in methylcyclohexane (Fig. 1)[13] may reasonably be assigned to the $n\pi^*$ spectrum because of their similarity to that of AQ and their short lifetimes (Table 1). Since the positions of the phosphorescence spectra of the methylsubstituted anthraquinones are very close to that of AQ, the rise in the T_1 $n\pi^*$ levels of the methyl-substituted anthraquinones relative to that of AQ may be very small. As may be seen in Table 1, the lifetime of 2-methyl-AQ is a little longer and a little shorter respectively than those of AQ and 2,3-dimethyl-AQ. This may be due to increases in the mixing[14–16] of the close-lying $^3\pi\pi^*$ state into the T_1 $n\pi^*$ state in these methyl-substituted anthraquinones, accompanied by decreases in the energy separation between these two states resulting from the methyl-group substitutions.

The phosphorescence spectrum of 2-methyl-AQ in toluene glass, obtained with the sector turning fast (Fig. 3), is considerably broader than that of AQ in toluene glass, while the one obtained with the sector turning slow is still broader. In this case, two considerably different lifetimes (17 and 86 ms) are obtained (Table 1). In these spectra, two kinds of phosphorescence spectra, the relatively sharp $n\pi^*$ spectrum and the broad $\pi\pi^*$ spectrum, seem to overlap. The above facts may be explained as follows. As the shorter lifetime (17 ms) is too long as that of the $n\pi^*$ spectrum, it is thought that 2-methyl-AQ in toluene glass has the T_1 $\pi\pi^*$ state and that the energy separation between the T_1 $\pi\pi^*$ state and the close-lying T_2 $n\pi^*$ state is distributed according to the degree of solvation of the quinone molecules.[17] Consequently, the degree of mixing of the T_2 $n\pi^*$ state into the T_1 $\pi\pi^*$ state and the rate of thermal population to the T_2 $n\pi^*$ state in the excited states[18] may take various values. Hence, dual phosphorescences, consisting of the $n\pi^*$ and $\pi\pi^*$ spectra, appear with various figures and lifetimes.

In the toluene glassy solution of 2,3-dimethyl-AQ, the very broad phosphorescence spectrum may be assigned to the $\pi\pi^*$ spectrum because of the absence of the C–O stretching vibrational structure and its long lifetime (100 ms). Previously, in the toluene glassy solution of 2-methyl-1,4-naphthoquinone, a similar, very broad phosphorescence spectrum with a short lifetime (2.0 ms) was observed. The difference in the lifetime between these two quinones is remarkable. Since the intensity of the latter phosphorescence spectrum is considerably weaker than that of the former, the short lifetime of the latter may be mainly due to the existence of some efficient non-radiative dissipative route from the

phosphorescence state.

The above differences in the phosphorescence spectra of 2-methyl- and 2,3-dimethyl-AQ's between the methylcyclohexane and toluene glass solutions may be partly due to the rise in the $^3n\pi^*$ levels resulting from the π-π type charge-transfer interaction between the quinones and toluene, and partly due to the fall in the $^3\pi\pi^*$ levels resulting from the relatively strong dispersion-force interaction between the quinones and toluene.[19] The phosphorescence spectra of the methylsubstituted anthraquinones in toluene crystal may be assigned to the $n\pi^*$ spectra because of their similarity to that of AQ and their short lifetimes, close to those in the methylcyclohexane solution.

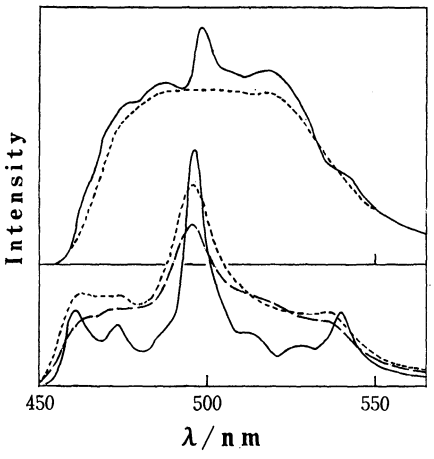

Fig. 4. Phosphorescence spectra of 2-methyl- and 2,3-dimethyl-AQ's in alcohols at 77 K.
(1) Lower curves, 2-methyl-AQ, ——: ethanol, ------: methanol (fast), — —: methanol (slow), (2) Upper curves, 2,3-dimethyl-AQ, ——: ethanol, ------: methanol.

In the methanol solution of 2-methyl-AQ (Fig. 4), a dual phosphorescence similar to that in the toluene solution is observed. As the shorter lifetime (13 ms) is close to that in the toluene solution, the T_1 state of 2-methyl-AQ in methanol is thought to be the $\pi\pi^*$ state, as in the toluene solution. On the other hand, in the ethanol solution of 2-methyl-AQ, the T_1 state may be the $n\pi^*$ state, as its phosphorescence spectrum show a distinct C–O stretching vibrational structure and its lifetime is short.

2,3-Dimethyl-AQ in methanol may have the T_1 $\pi\pi^*$ state because of the similarities of the phosphorescence spectrum and its lifetime to those in the toluene glassy solution. In the phosphorescence spectrum of 2,3-dimethyl-AQ in ethanol, the sharp $n\pi^*$ and broad $\pi\pi^*$ spectra seem to overlap, but the relative weight of the former seems to be far smaller than that of the latter. In view of the above relative weights of the two spectra and the sector-turning-rate independence of the phosphorescence spectrum, it is thought that the $^3\pi\pi^*$ level is lower than the $^3n\pi^*$ level, and that the $n\pi^*$ spectrum appears weakly because of the thermal population in the excited states. The above results indicate that the hydrogen-bond between ethanol and the quinones is,

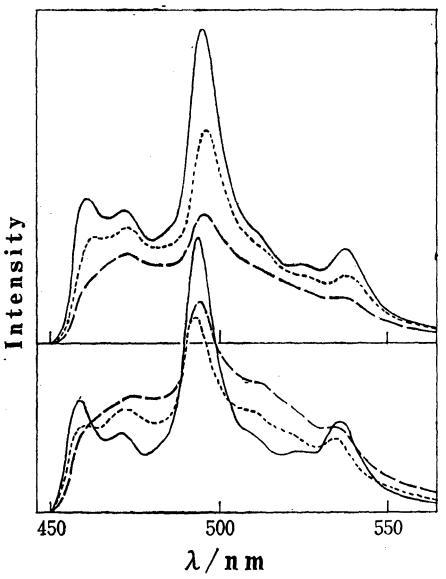

Fig. 5. Phosphorescence spectra of 2-methyl-AQ in 1-chloro and 1-bromobutanes at 77 K.
(1) Lower curves, 1-chlorobutane, ——: (fast, 313 nm), ------: (fast, 365 nm), — —: (slow, 313 nm), (2) upper curves, 1-bromobutane, ——: (fast, 313 nm), ------: (fast, 365 nm), — —: (slow 313 nm).

to some extent, weaker than that between methanol and the quinones.

In the 1-chloro- and 1-bromobutanes solutions of 2-methyl-AQ, dual phosphorescences similar to those in the toluene and methanol solutions are observed (Fig. 5). In these 1-halogenobutane solutions, however, as the shorter lifetimes (7 ms in both solutions) are considerably shorter than those in the toluene and methanol solutions, and are rather close to those in the methylcyclohexane and ethanol solutions, it is thought that differently solvated species which have either the T_1 $n\pi^*$ or the T_1 $\pi\pi^*$ state coexist and that the shorter

TABLE 2. ASSIGNED T_1 STATES OF THE QUINONES[a)]

Solvent	Methylcyclohexane	Toluene	Ethanol	Methanol	1-Chlorobutane	1-Bromobutane
AQ	$n\pi^*$	$n\pi^*$ ($n\pi^*$)	$n\pi^*$	$n\pi^*$	$n\pi^*$	$n\pi^*$
2-Methyl-AQ	$n\pi^*$	$\pi\pi^*$ ($n\pi^*$)	$n\pi^*$	$\pi\pi^*$	$n\pi^*$, $\pi\pi^*$	$n\pi^*$, $\pi\pi^*$
2,3-Dimethyl-AQ	$n\pi^*$	$\pi\pi^*$ ($n\pi^*$)	$\pi\pi^*$	$\pi\pi^*$	$\pi\pi^*$	$\pi\pi^*$

a) The states in parentheses are the ones in toluene crystals.

lifetimes are due to the species which have the T_1 $n\pi^*$ state. In the 1-halogenobutane solutions of 2,3-dimethyl-AQ, in view of their phosphorescence spectra (Fig. 6), it is thought that the $^3\pi\pi^*$ level is lower than the $^3n\pi^*$ level, and that the weak appearances of the sharp $n\pi^*$ spectrum are due to the thermal population in the excited states, as in the ethanol solution.

As may be seen in Fig. 5, with the same turning-rate of the sector the weights of the sharp $n\pi^*$ spectrum relative to the broad $\pi\pi^*$ spectrum are considerably larger in the 313 nm excitation than in the 365 nm excitation. Similar excitation-wavelength dependences are seen in the case of 2,3-dimethyl-AQ in Fig. 6. In a previous work,[3)] a similar phenomenon was also observed in the phosphorescence spectrum of 2-methyl-1,4-naphthoquinone in ethanol at 77 K, where the weight of the sharp $n\pi^*$ spectrum relative to the broad $\pi\pi^*$ spectrum was larger in the 365 nm excitation than in the 313 nm excitation. No definitive explanation of these facts can be obtained at this stage.

In Table 1, the lifetimes corresponding to those of the $\pi\pi^*$ phosphorescence spectra of the methyl-substituted anthraquinones in 1-bromobutane are quite short in comparison with those in the 1-chlorobutane solutions. This may be due to the intermolecular heavy-atom effect[20)] brought about by the bromine atom in 1-bromobutane.

The T_1 states of these quinones in the solutions assigned in this work are shown in Table 2. When the quinone molecules with the T_1 $n\pi^*$ and $\pi\pi^*$ states are thought to coexist, both of the two states are described in Table 2. The results obtained in this work may be useful in studying the photochemistry of these quinones.

4) In general, the dispersion-force interaction between solutes and solvents brings about far larger red-shifts for $\pi\pi^*$ spectra than for $n\pi^*$ spectra, and so under this interaction the $\pi\pi^*$ levels become much lower than the $n\pi^*$ levels.

5) In a previous paper,[1)] the observed lifetime of the phosphorescence spectrum of AQ in a methylcyclohexane–toluene (4 : 1) mixture at 77 K (6.3 ms) is erroneous; the correct value is 3.8 ms.

6) The phosphorescence spectra of AQ in ethanol and 1-chlorobutane are similar to those of 2-methyl-AQ in ethanol (Fig. 4) and of AQ in 1-bromobutane (Fig. 2) respectively.

7) AQ is thought to have two low-energy triplet levels, $n\pi_+^*$ and $n\pi_-^*$, like *p*-benzoquinone.[8,9)] In the text, the $n\pi^*$ triplet level corresponds to the lower one of them, while the higher one is neglected in order to simplify the discussion. According to the CNDO/S-Cl[10)] calculations,[11)] in *p*-quinones the triplet $n\pi_-^*$ level (the $^3B_{1g}$ level in AQ) is lower than the $n\pi_+^*$ level (the ^3A_u level in AQ).[12)]

The Molecular Structures of Thiomethoxymethylbis(triphenylphosphine)-palladium Hexafluorophosphate and Perchlorate at −160 °C

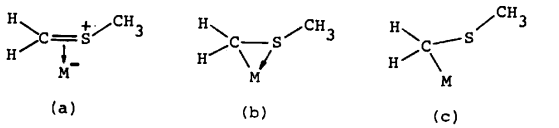
Kunio MIKI,* Yasushi KAI, Noritake YASUOKA,** and Nobutami KASAI*

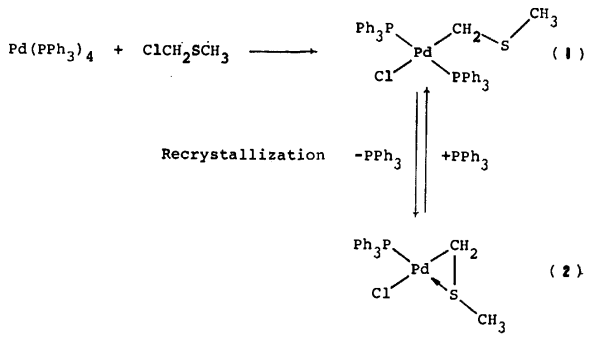
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

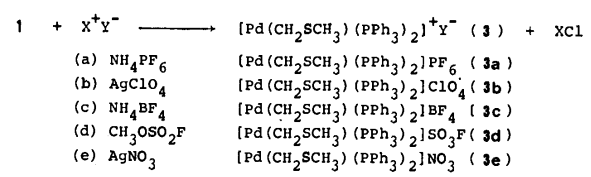
(Received February 12, 1981)

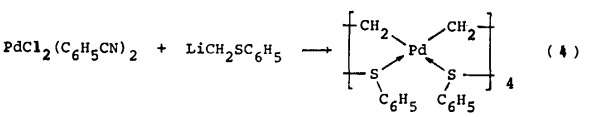
The molecular structures of $[Pd(CH_2SCH_3)(PPh_3)_2]PF_6$(**3a**) and $[Pd(CH_2SCH_3)(PPh_3)_2]ClO_4$(**3b**) at −160°C were determined by means of X-ray diffraction. Crystals of both complexes belong to the monoclinic system: **3a**, $a=11.535(2)$, $b=17.990(4)$, $c=17.754(2)$ Å and $\beta=101.07(1)°$, space group $P2_1/c$ with $Z=4$; **3b**·CH_2Cl_2 solvate, $a=11.496(5)$, $b=20.872(9)$, $c=15.056(6)$ Å and $\beta=94.77(4)°$, space group $P2_1/n$ with $Z=4$. Both structures were solved by the heavy atom method and refined by the least-squares procedure to $R=0.141$ for 3906 reflections and $R=0.102$ for 4595 reflections for **3a** and **3b** respectively. The geometry around the Pd atom in each complex is essentially planar. However, the coordination behavior of the CH_2SCH_3 group in **3a** and in **3b** seems to be different. In **3a**, the CH_2SCH_3 group is bonded to the Pd atom through the Pd–C σ-bond and the donation of the sulfur to the metal atom, forming a Pd–C–S three-membered ring [Pd–CH_2=2.06(4), Pd–S=2.367(8), CH_2–S=1.77(4) and S–CH_3=1.78(4) Å]. On the other hand, the CH_2SCH_3 group in **3b** is coordinated to the metal atom as a methylenemethylsulfonium ion, containing a C=S double bond[Pd–CH_2=2.208(13), Pd–S=2.303(6), CH_2–S=1.678(14) and S–CH_3=1.86(4) Å].

We have hitherto studied the structural chemistry of a series of palladium complexes containing the CH_2SR(R=CH_3, C_6H_5) groups in order to elucidate their coordination behavior, especially that of the sulfur to the metal atom.[1-3] It is interesting that the CH_2SR group is coordinated to the transition metal not only as a monodentate ligand but also as a bidentate one.[4,5] Three types of coordination modes are possible for the thiomethoxymethyl(CH_2SCH_3) group, as shown below:









Scheme 1.

The CH_2SCH_3 group behaves as a π-bonded two-electron ligand in (a), as a bidentate ligand in (b), or as a σ-bonded monodentate ligand in (c).

Recently, a series of novel palladium complexes containing these CH_2SR groups have been prepared by Okawara, Yoshida, and their co-workers.[3,6-8] The outline of the reactions is summarized in Scheme 1.

We have previously carried out structure analyses of Complexes **1**,[1] **2**,[2] and **4**.[3] In Complex **1**,[1] the CH_2SCH_3 group is bound to the Pd atom through the Pd–C σ-bond (type c). On the other hand, in Complex **2**,[2] the CH_2SCH_3 group is coordinated with the type b mode to form a Pd–C–S three-membered ring. The thiophenoxymethyl ($CH_2SC_6H_5$) groups bridge four Pd atoms in Complex **4**,[3] which can be considered as an internuclear modification of type b. These differences in bonding modes may be due to the slight difference of the nucleophilicity of S atom in these complexes.

As a part of this study, we will report here the molecular structures of Complexes **3a** and **3b**, determined by means of X-ray diffraction at −160 °C, in order to reveal the coordination of the CH_2SCH_3 group in these cationic complexes.

Experimental

Several efforts were made for five kinds of complexes, **3a**—**e**, to obtain good single crystals from CH_2Cl_2 solutions. Crystals of $[Pd(CH_2SCH_3)(PPh_3)_2]SO_3F$(**3d**)[7] were too small to use for intensity data collection, and Complex **3e**, $[Pd(CH_2SCH_3)(PPh_3)_2]NO_3$, did not crystallize.[7] Crystals of $[Pd(CH_2SCH_3)(PPh_3)_2]BF_4$(**3c**)[7] were comparatively large, large enough to collect intensities. However, preliminary oscillation and Weissenberg photographs showed many diffuse spots near the normal Bragg reflections, suggesting a disordered structure. If all these diffuse spots can be disregarded, the **3c** crystals can be said to have a *C*-centered monoclinic unit cell with dimensions of $a=18.0$, $b=18.4$, $c=12.3$ Å, and $\beta=107°$.

The crystals of **3a** and **3b** are colorless needles and plates

a) By flotation in carbon tetrachloride/hexane at 25 °C.

respectively. X-Ray structure analyses of these crystals have been performed, although they seemed not too suitable for X-ray diffraction study judging from their size, shape, and/or habits. Preliminary oscillation and Weissenberg photographs taken at room temperature with Cu $K\alpha$ raditaion determined their crystal system and space group. Accurate unit-cell dimensions at −160 and 20 °C were determined by a least-squares fit of the 2θ value of 25 strong reflections measured on a Rigaku diffractometer. The crystal data are summarized in Table 1.

Measurements of the integrated intensities were made at −160 °C on the Rigaku automated, four-circle, single-crystal diffractometer. The crystals used had approximate dimensions of 0.1 mm × 0.1 mm × 0.25 mm and 0.25 mm × 0.3 mm × 0.35 mm for **3a** and **3b** respectively. The low temperature was attained by the gas flow method using liquid nitrogen. The intensity data were collected by the θ-2θ scan technique, using graphite-monochromatized (for **3a**) and Zr-filtered (for **3b**) Mo $K\alpha$ radiation (λ=0.71069 Å). The scan speed was 4° min^{-1}, and the scan width was $\Delta 2\theta=(2.5+0.7\tan\theta)°$. The background intensities were measured for 5 s at both ends of a scan. Totals of 7899 and 7907 reflections with 2θ less than 54° were collected for **3a** and **3b** respectively, 3906 and 4595 reflections of which were considered as observed ($|F_o|>3\sigma(|F_o|)$). The standard reflections (600, 019, and 219 for **3a** and 800, 555, 008 and 0, 10, 0 for **3b**) monitored at regular intervals were constant throughout the data collection. Corrections for Lorentz and polarization factors were carried out in the usual manner, while neither absorption nor extinction correction was made.

Structure Solution and Refinement

Both structures were solved by the heavy atom method. The structures were refined by the block-diagonal least-squares procedure (*HBLS*-V[9]), the function minimized being $\sum w(|F_o|-|F_c|)^2$. The unit weights were employed throughout the refinement. The atomic scattering factors were taken from International Tables for X-Ray Crystallography[10] for non-hydrogen atoms and from those of Stewart *et al.*[11] for hydrogen atoms. The final atomic positional parameters are presented in Table 2.†

*$[Pd(CH_2SCH_3)(PPh_3)_2]PF_6$ (**3a**).* All the non-hydrogen atoms were reasonably located by the Patterson and Fourier syntheses. Several cycles of isotropic refinement reduced the R value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) to 0.17. The temperature factors of the F atoms in the PF_6 anion showed relatively large values (maximum B=11.2 Å^2). Further anisotropic refinement in the usual manner did not go on straightforwardly, some abnormal temperature factors being observed. Therefore, the subsequent refinement was carried out step-by-step using small damping factors for the shifts of the parameters. On a Fourier map, a relatively high peaks, the peak height of which was about 80% of that of the C(1) atom, appeared 1.12 and 2.37 Å distant from the S and Pd atoms respectively. If this peak is identified as a disordered fragment of the S atom, the geometry around the Pd atom is far from the square-planar coordination. Therefore, this peak was ignored and not included in the subsequent refinement. The final R value is 0.141 for 3906 reflections.

*$[Pd(CH_2SCH_3)(PPh_3)_2]ClO_4\cdot 0.25CH_2Cl_2$ (**3b**).* The Fourier synthesis based on the coordinates of the Pd atom, determined from a three-dimensional Patterson map, revealed the locations of all the non-hydrogen atoms in the cation. A few cycles of isotropic refinement reduced the R value to 0.14. A difference Fourier map revealed the location of only the Cl atom of the ClO_4 anion, and its electron density was relatively low and very broad. Subsequent difference Fourier maps could locate only one of the four O atoms in the ClO_4 anion. These Cl and O atoms indicated abnormally large temperature factors in the further refinement. In addition, three other peaks were found on a Fourier map. They were interpreted as those of the solvent CH_2Cl_2 molecule. The calculated density for the formula weight, assuming that one molecule of CH_2Cl_2 is included in an asymmetric unit [1.566 g cm^{-3}], is

† Tables of the complete F_o—F_c data and of the final anisotropic temperature factors are deposited at the Chemical Society of Japan as Document No. 8150.

TABLE 2. FINAL ATOMIC PARAMETERS

Estimated standard deviations are given in parentheses. B_{eq} values are equivalent isotropic temperature factors calculated from anisotropic thermal parameters.[12]

much larger than the observed value of 1.44 g cm^{-3}. These facts suggest a low occupancy of CH_2Cl_2. The occupancy factor for CH_2Cl_2 was then estimated as 0.25, which gives the calculated density of 1.452 g cm^{-3}. The coordinates of the C atom of CH_2Cl_2 were fixed in the further refinement. Several more cycles of refinement were carried out anisotropically for the Pd, S, P, and C atoms in the cation and isotropically for Cl, O, and C in the ClO_4 anion and the CH_2Cl_2 molecule. The final R factor is 0.102 for 4595 reflections.

Results and Discussion

Bond lengths and bond angles in the two complexes are listed in Tables 3 and 4 respectively.

In spite of the low temperature measurements, the precision of neither structure is high enough to make a detailed discussion. This is considered mainly due to the poor quality of the **3a** and **3b** crystals. In both **3a** and **3b** crystals, the PF_6 and ClO_4 anions have rather disordered structures, which may also be connected with the precision of the present structures.

Structures of PF_6 and ClO_4 Anions. In **3a**, six F atoms of the PF_6 anion, especially four out of those, show abnormally low peak heights and a broadening in the electron density distribution. As an example, an electron density map on the plane formed by the P and four F atoms is given in Fig. 1. The ^{19}F NMR studies of **3a** suggested that the PF_6 anions are rapidly reorienting about the octahedral axes[13] at random, or nearly so, even at liquid nitrogen temperature.[14]

The locations of three oxygen atoms in the ClO_4 anion

a) The other O atoms in the ClO_4 anion could not be located. b) The coordinates of the C(S) atom were not refined.

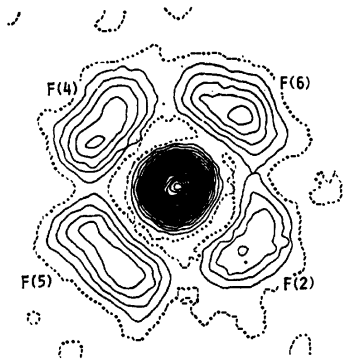

Fig. 1. Electron density distribution on the plane formed by the P(3), F(2), F(4), F(5), and F(6) atoms of the PF_6 anion in $[Pd(CH_2SCH_3)(PPh_3)_2]PF_6$ (**3a**). The contours are drawn at the interval of 1.0 e/Å^3. Zero contours are shown as broken lines while negative contours are omitted.

could not be determined in **3b**, because the electron densities around the central Cl atom are very broad and relatively low except for the O(1) atom. Disordered structures and large thermal motions of the ClO_4 anion have been reported in some complexes.[15]

Structures of $[Pd(CH_2SCH_3)(PPh_3)_2]$ *Cations.* Figure 2 shows *ORTEP* drawings[16] of the cations in these complexes. In Fig. 3, the coordination geometries around the Pd atom in **3a** and **3b** are compared with that of **2**.[2] The geometry around the Pd atom in each complex is essentially square-planar. The equations of the least-squares planes and the deviation of atoms from the planes are presented in Table 5. The planarity of the coordination plane in each complex is not so high, the maximum deviations from the plane being 0.17 and 0.10 Å for **3a** and **3b** respectively, while that in **2** is only 0.04 Å.[2]

Two PPh_3 groups are bonded to the Pd atom in *cis*-coordination. In both complexes, the Pd–P(1) bond lengths are slightly longer than those of the Pd–P(2). This is partly due to the difference in the *trans*-influences of the C and S atoms in the CH_2SCH_3 groups.

In the CH_2SCH_3 group in **3a**, the S–C(1) and S–C(2) bond lengths are close to the S–C single bond length [1.82 Å].[17] The Pd–C(1) bond length is considered to be a normal value for the Pd(II)–C(sp^3) σ-bond. Since these bond lengths, as well as the Pd–S, are comparable to the corresponding ones in **2**,[2] the coordination mode

a) The coordinates of the C(S) atom were not refined.

of the CH_2SCH_3 group to the Pd atom in **3a** is considered to be virtually the same as in **2**. The CH_2SCH_3 group is bonded to the Pd atom by the Pd–C σ-bond, and also by the donation from the S to the Pd atom (the b-type mentioned above).

On the other hand, the coordination mode of the CH_2SCH_3 group to the Pd atom in **3b** is different from those in **2** and **3a**. In **3b**, the S–C(1) bond length is significantly shorter than those in **2** and **3a**, and it is close to the S=C double bond length [1.61 Å][17] rather than the S–C single bond length [1.82 Å].[17] The S–C(2) bond length is considered to be equal to the S–C single bond length. The Pd–C(1) distance is obviously longer than those in **2** and **3a**, and rather near to the Pd–C(olefin) lengths [2.174 and 2.233 Å] in $[Pd(\eta^5\text{-}C_5H_5)(PEt_3)(styrene)]BF_4$.[18] The Pd–S distance, somewhat shorter than those found in **2** and **3a**, is in good agreement with that in $[Pd(CS)_2(PPh_3)_2]$[2.31 Å].[19] These facts imply that the a-type coordination mode, where the CH_2SCH_3 group functions as a methylene-methylsulfonium ion, makes a great contribution to the bonding of the CH_2SCH_3 group.

Perspective views of the coordination mode are shown in Fig. 4. The C(1)–S–C(2) plane is almost perpendicular to the P(1)–Pd–P(2) plane in **3b**. The dihedral angles between these planes are 91.3° in **3b**, whereas

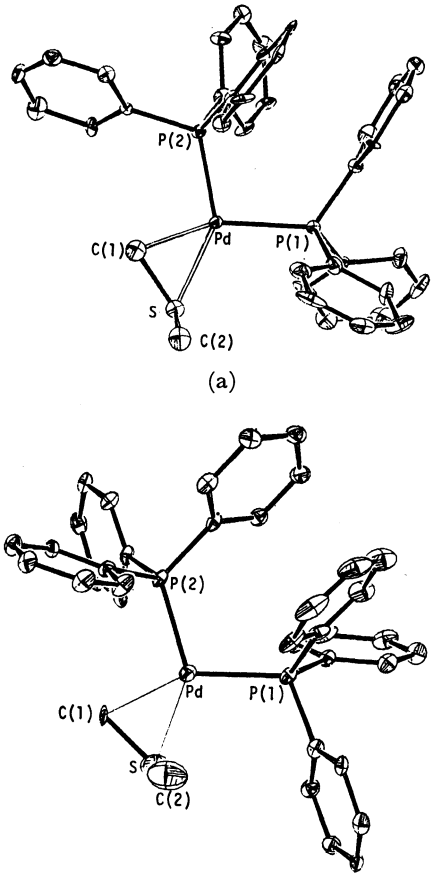

Fig. 2. An *ORTEP* drawing[16] of the $[Pd(CH_2SCH_3)(PPh_3)_2]$ cation. The thermal ellipsoids correspond to 30% probability levels. The atomic numberings for the phenyl groups of the triphenylphosphine groups are omitted. Six carbon atoms of the phenyl group are numbered as C(*n*1)—C(*n*6), where $n=1$—6. The C(11), C(21), and C(31) atoms are attached to the P(1) atom while C(41), C(51) and C(61) to P(2).

a) Not included in the calculation of the plane.

they are 100.0° in **3a** and 100.9° in **2**. As presented in Table 5, the C(1) and S atoms in **3a** are located on the opposite sides of the P(1)–Pd–P(2) plane, 0.13 and −0.20 Å away from it respectively, while in **3b** these two atoms deviate by 0.26 and 0.36 Å on the same side of the P(1)–Pd–P(2) plane.

The resonance structures (d) and (e) presented below are suggested for the bonding of the CH_2SCH_3 group to the Pd atom,[8] which is connected with the stabilization of these complexes, although the main representation of the structure is probably (e). The contribution from (d) in the cationic complexes **3** may play a greater part than in a neutral complex such as **2**. However, the contributions from (d) in **3a** and **3b** seem to differ from each other, which may be due to the counter anions.

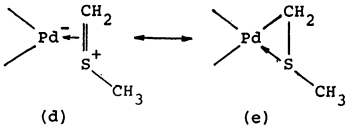

Table 6 shows the contacts between the $[Pd(CH_2SCH_3)(PPh_3)_2]$ cation and the PF_6 or ClO_4 anion in **3a** and **3b**. Both anions are considered to have the

Table 6. Contacts between the $[Pd(CH_2SCH_3)(PPh_3)_2]$ cation and the PF_6 or ClO_4 anion

Distances between the Pd atom (the center of the cation) and the P (for PF_6 in **3a**) or Cl (for ClO_4 in **3b**) atom (the center of the anion) are shown.

Distance (l/Å)	(**3a**)	(**3b**)
	Pd(x,y,z)···P(3)	Pd(x,y,z)···Cl(1)
Nearest	4.759(8)(x,y,z)	5.317(17) (x,y,z)
Second	5 .252(8)($1-x$, $-1/2+y,1/2-z$)	6.288(17) ($-1+x,y,z$)

As shown in Fig. 5, only the above two contacts may exemplify significant interaction between the cation and the anion.

spherical symmetry. The distances between the Pd atom and the central atom of the anions (the P and Cl atoms) are compared with each other in Table 6. The radius of the PF_6 anion (P–F=1.54 Å) is larger than that of the ClO_4 anion (Cl–O=1.42 Å). Nevertheless, the Pd···P(3) distances in **3a** are sigificantly shorter than those of the Pd–Cl(1) in **3b**. These facts imply that **3a** may behave as a stronger ion-pair than **3b**, which is probably connected with the difference in the coordination modes between **3a** and **3b**.

Crystal Structure. The crystal structures of **3a** and **3b**, both projected along the a* axis, are given in Fig. 5. All the intermolecular atomic contacts in **3a** are considered as usual van der Waals distances, the shortest atomic contact being 3.22(4) Å [C(15)(x,y,z)··· F(3)($2-x,-1/2+y,1/2-z$)]. In **3b**, an abnormal short contact [2.82 Å] can be calculated for C(S)(x,y,z)··· C(S)($1-x,-y,-z$) distance. However, we can not discuss it further because of the low occupancy (0.25) of the CH_2Cl_2 molecule.

All the computations were carried out on NEAC 2200-700 and ACOS 800 computers at Computation Center, Osaka University, and on an ACOS 700 computer at Crystallographic Research Center, Institute for Protein Research, Osaka University.

Ultrasonic Absorption in Solutions of Sodium Iodide in Isopropyl Alcohol and Isopropyl Alcohol-Water Mixtures

Tsunemichi Okuwa* and Kozo Ohno†

Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

†*Osaka Electro-communication University, Hatumachi, Neyagawa, Osaka 572*

(Received February 13, 1981)

Ultrasonic relaxational absorption was observed in solutions of NaI in *i*-PrOH. Assuming the excess ultrasonic absorption to be caused by the relaxation of the dissociation equilibrium of NaI in the solutions, the dissociation and recombination rates of NaI, the Arrhenius activation energy, and the enthalpy and volume changes due to dissociation were calculated; these were compared with the values estimated from other methods. An increase of the dissociation constant of NaI was observed with an increase in the concentration of H_2O in *i*-PrOH–H_2O mixtures.

Strong 1-1 electrolytes such as sodium iodide dissociate completely in aqueous solution. Ultrasonic absorptions due to chemical relaxation are not found in such solution. But in isopropyl alcohol, which has a lower dielectric constant than water, NaI would dissociate incompletely and a dissociation equilibrium would exist between the Na^+ ions, the I^- ions, and the undissociated NaI molecules. Then the excess ultrasonic absorption observed in *i*-PrOH would be caused by the relaxation of the reaction.

Experimental

The ultrasonic absorption spectra of NaI solutions in *i*-PrOH–H_2O mixtures were measured by the ultrasonic pulse method from 10 to 90 MHz at 20 °C. The concentrations of NaI were 0.1—0.3 molality (mol/1000 g solvent) and weight percentages of *i*-PrOH in *i*-PrOH–H_2O mixtures were 50, 60, 70, 80, 90, and 100%. The ultrasonic velocity was measured by the interference of the pulse wave and a continuous wave at 5 MHz.

Results and Discussion

The ultrasonic absorption α/f^2 in solutions of NaI in *i*-PrOH is shown in Fig. 1, where α is the absorption coefficient of amplitude and f the frequency. A single relaxation represented by the next equation fits the curves over the frequency range measured:

$$\frac{\alpha}{f^2} = \frac{A}{1+(f/f_{max})^2} + B,$$

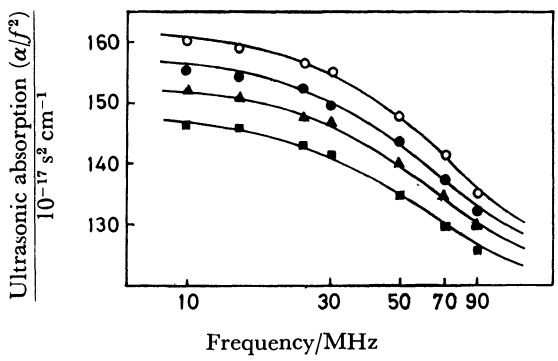

Fig. 1. Ultrasonic absorption in solutions of NaI in Molality of NaI, ■: 0.15, ▲: 0.20, ●: 0.25, ○: 0.30.

where f_{max} is the relaxational frequency, A the relaxational absorption, and B the non-relaxing absorptions due to viscosity, thermal conduction, *etc.* The relaxation parameters are listed in Table 1.

Table 1. The relaxation parameters in solutions of NaI in *i*-PrOH

Temp °C	Concn of NaI (molality)	A 10^{-17} s² cm⁻¹	B 10^{-17} s² cm⁻¹	f_{max} MHz
20	0.15	28.6	118	58.0
	0.20	33.3	120	61.3
	0.25	37.0	120	64.0
	0.30	40.0	122	66.8
25	0.15	27.0	110	64.1
	0.20	31.3	110	67.6
	0.25	34.5	110	70.7
	0.30	38.5	112	73.6
30	0.15	26.3	100	69.8
	0.20	30.3	100	73.0
	0.25	33.3	102	76.0
	0.30	37.0	102	78.4
35	0.15	25.6	90	75.8
	0.20	29.4	90	79.3
	0.25	32.3	92	82.1
	0.30	35.7	92	85.8

Here we assume the relaxation to be caused by the following equilibrium:

$$NaI \underset{k_b}{\overset{k_f}{\rightleftarrows}} Na^+ + I^-.$$

For such an equilibrium the relaxation frequency f_{max} is given by[1]

$$2\pi f_{max} = k_f + k_b \sigma \gamma_\pm^2 C\left(2+\frac{\partial \ln \gamma_\pm^2}{\partial \ln \sigma}\right), \quad (1)$$

where σ is the degree of dissociation, $\gamma_\pm$ means the ionic activity coefficient, k_f and k_b are the rate constants, and C is concentration. The dissociation constant K can be described by[2]

$$K = \frac{k_f}{k_b} = \frac{\sigma^2 C \gamma_\pm^2}{1-\sigma}, \quad (2)$$

$$K^{-1} = \frac{4\pi N}{1000}\left(\frac{e^2}{DkT}\right)Q(b), \quad (3)$$

$$b = \frac{e^2}{a_B DkT},$$

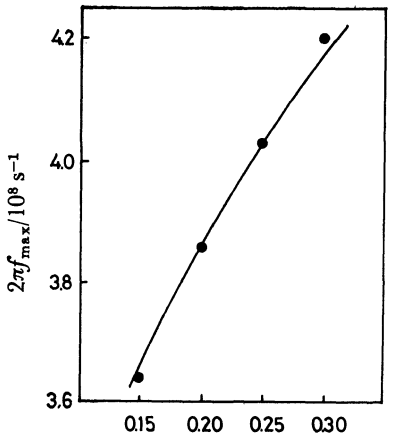

Fig. 2. Relation between f_{max} and concentration of NaI in *i*-PrOH at 20 °C.
●: Experimental value.

a) 1 M=1 mol dm^{-3}.

where a_B is the distance between the centers of the two ions forming the ion pair at their closest distance of approach, k is Boltzmann's constant, D dielectric constant, N Avogadro's constant, T absolute temperature, e the electronic charge, and $Q(b)$ is a function of b. By the method of successive approximation,[3] k_f, k_b, K, and a_B were calculated using Eqs. 1, 2, and 3. In Table 2, the kinetic values derived by this process are listed. The experimental and the calculated values of f_{max} are shown in Fig. 2. As may be seen in Table 2, the apparent Bjerrum distance $a_B \simeq 5.9$ Å is larger than the sum of the ion radii 3 Å and is independent of temperature. This result suggest that a solvated ion pair state exists and that the number of solvation would be invariable over the temperature range measured.

The rate constant k_b is given by Arrhenius as follows:

$$k_b = Pe^{-\Delta E/RT},$$

where P is a constant and ΔE is the activation energy.

When $\log k_b$ values are plotted against $1/T$, the activation energy is obtained from the slope. Using k_b values in Table 2, one obtains $\Delta E \simeq 5.4$ kcal mol^{-1}. This value is of the order of magnitude to be expected for a diffusion controlled process.[1] The rate constant k_b, as due to a diffusion controlled process, is given by[4]

$$k_b = \frac{8NkT}{3000\eta}\left(\frac{-b}{e^{-b}-1}\right) \quad (mol^{-1}\ s^{-1}),$$

where η is solvent viscosity. By substitution of the numerical values[5] at 25 °C, one gets $k_b \simeq 1.7\times10^{10}$ $mol^{-1}\ s^{-1}$. The agreement between the calculated and experimental values is fairly good.

The variation of the dissociation constant with temperature is given by

$$\left(\frac{\partial \ln K}{\partial T}\right) = \frac{\Delta H}{RT^2},$$

where ΔH is the enthalpy change. Taking the K values in Table 2, one gets $\Delta H \simeq -3.1$ kcal mol^{-1}. The energy diagram of NaI in the solution is shown in Fig. 3. The maximum excess ultrasonic absorption per wavelength at the relaxation frequency, μ_{max}, is given by[1,6]

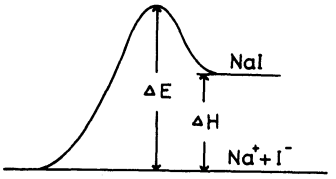

Fig. 3. Energy diagram of NaI in *i*-PrOH.
$\Delta E \simeq 5.4$ kcal mol^{-1}, $\Delta H \simeq 3.1$ kcal mol^{-1}.

$$\mu_{max} = \frac{\beta}{2\beta RTV}\left(\Delta V - \frac{l}{dC_p}\Delta H\right)^2 \frac{1}{\chi}, \quad (4)$$

$$\chi = \left(\frac{1}{n_{Na^+}} + \frac{1}{n_{I^-}} + \frac{1}{n_{NaI}}\right),$$

where ΔV is the volume change for the reaction, l the coefficient of thermal expansion, C_p the heat capacity at constant pressure, d density, V the volume, β the adiabatic compressibility, and n_{Na^+}, n_{I^-}, and n_{NaI}, are the numbers of the moles of the sodium ion, the iodide ion, and the undissociated sodium iodide. The adiabatic compressibility is obtained from the measured values of ultrasonic velocity. The number of the moles of species n_{Na^+}, n_{I^-}, and n_{NaI} are estimated from the degree of dissociation. Solvent parameters are given in Table 3. By substituting these values in Eq. 4, we find $\Delta V \simeq -15$ cm^3/mol. This value is of the same order as the volume change of NaI in *i*-BuOH:[10]

The ultrasonic absorptions α/f^2 in solutions of NaI in *i*-PrOH–H_2O mixtures are shown in Figs. 4, 5, and 6. As may be seen in these figures, the addition of NaI in *i*-PrOH–H_2O mixture causes an increase in the magnitude of the relaxational absorption. This increase is attributed to the relaxation of dissociation equilibrium of NaI in the solution, assuming that the relaxational absorption of *i*-PrOH–H_2O mixture[11-13] is independent of the concentration of NaI. Therefore we assume the relaxational absorption due to dissociation of NaI to be

$$\left(\frac{\alpha}{f^2}\right)_{solution} - \left(\frac{\alpha}{f^2}\right)_{solvent} = \frac{A}{1+(f/f_{max})^2} + B,$$

where $(\alpha/f^2)_{solution}$ is the absorption of the NaI solution in the *i*-PrOH–H_2O mixture and $(\alpha/f^2)_{solvent}$ is the absorption of the *i*-PrOH–H_2O mixture. The relaxation parameters and the kinetic values are listed in Tables 4 and 5. As is seen in Table 5, the dissociation constants

of NaI increase with decreasing the concentration of *i*-PrOH in mixtures. This increase is caused by an increase of dielectric constant in the solution. However, no relaxational absorption due to NaI was observed when the weight percent of *i*-PrOH in *i*-PrOH–H_2O mixtures were lower than 60. Perhaps NaI dissociates completely in such solutions.

Studies on the Electronic Structures of Hydrocarbon Diradicals by the Unrestricted Hartree-Fock Theory

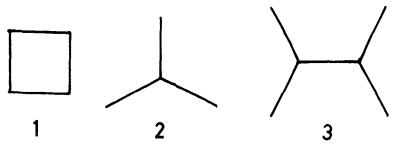
Katsufumi HASHIMOTO* and Hideo FUKUTOME

Department of Physics, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 16, 1981)

Electronic structures of low-lying states of cyclobutadiene, trimethylenemethane (**2**), and tetramethyleneethane (**3**) are studied by the unrestricted Hartree-Fock (UHF) theory. Characteristics of electronic correlations, called dynamical spin polarization effect, in these molecules are well described by corresponding orbitals and spin density structures of low-lying UHF solutions. The spin polarization of σ electrons is found to be relatively small but not negligible for quantitative discussion. The two low-lying singlet states of **2** are described by two UHF solutions with different spin density structures. The fact that the singlet UHF state of **3** lies a little below the triplet UHF state is explained by the difference in the spin polarization of the bonding π electrons between the singlet and triplet states. Two rules are given which predict the spin structure of low-lying UHF states and the spin multiplicity of ground states of hydrocarbon diradicals. These rules are applied to 1,1,2,3,3-pentamethylenepropane and 1,3-dimethylenecyclobutadiene, which confirms their validity.

Recent theoretical studies on cyclobutadiene (**1**) and trimethylenemethane (**2**) have revealed the importance



of correlation effects in determining the spin multiplicity of ground states and the stable geometry of low-lying states of hydrocarbon diradicals. Borden[1] showed that a strong correlation effect in **1** causes a violation of Hunt's rule and makes the ground state singlet. This effect was also shown to make the equilibrium geometry close to a square. These results are in agreement with experiments.[2] As for **2**, Yarcony and Schaefer III[3a] and Borden[3b] pointed out that the correlation of the two nonbonding (NB) electrons much reduces the energy difference in the singlet state between the planar geometry and the geometry with a methylene group orthogonal to the remaining allyl group.

These results indicate that in order to understand electronic properties of hydrocarbon diradicals, it is necessary to clarify correlation effects involved. As pointed out by Borden[1] and Kollmar and Staemmler,[4] the most important correlation effect in diradicals is similar to the spin polarization effect in free radicals. They called it the dynamical spin polarization effect. Therefore, the unrestricted Hartree-Fock (UHF) theory is powerful in analyzing the correlation effect. In this paper, we apply the UHF theory to three diradicals **1**, **2**, and tetramethyleneethane (**3**). We show that the corresponding orbitals and the spin density structure in the UHF theory well describe the dynamical spin polarization effect in low-lying states of the molecules. Concerning **3**, the singlet state is predicted to lie a little below the triplet state. From results for **1**, **2**, and **3**, we derive simple rules to predict the spin multiplicity of ground states and the spin structure of low-lying UHF solutions of hydrocarbon diradicals.

UHF calculations were made with the INDO approximation[5] using the computer program written by Takahashi and Igawa which uses the direct optimization method developed by Igawa and Fukutome[6] and is capable of calculating UHF solutions and their instabilities of any types. We use the notation proposed by Fukutome[7] for the types of UHF solutions and their instabilities.

Analysis of a Simplified Model of Diradicals with Two Electrons in Two NB MOs

Before performing all-valence-electron UHF analyses, we examine in this section UHF solutions for a simple model with two degenerate NB MOs ϕ_A and ϕ_B of different symmetries in a spatial symmetry group. In the model, there are one triplet state (Ψ_T) and three singlet states (Ψ_{S1}, Ψ_{S2}, and Ψ_{S3}) which are represented as

$$\Psi_T = (\phi_A\phi_B - \phi_B\phi_A)/\sqrt{2}\,\Theta_T,$$
$$\Psi_{S1} = (\phi_A\phi_A - \phi_B\phi_B)/\sqrt{2}\,\Theta_S,$$
$$\Psi_{S2} = (\phi_A\phi_A + \phi_B\phi_B)/\sqrt{2}\,\Theta_S,$$
$$\Psi_S{}^3 = (\phi_A\phi_B + \phi_B\phi_A)/\sqrt{2}\,\Theta_S,$$
$$\Theta_T = (\alpha\beta+\beta\alpha)/\sqrt{2},\ \Theta_S = (\alpha\beta-\beta\alpha)/\sqrt{2}.$$

Their energies are given by

$$E_T = 2K + \langle AA|BB\rangle - \langle AB|BA\rangle,$$
$$E_{S1} = 2K + \gamma - \langle AB|BA\rangle,$$
$$E_{S2} = 2K + \gamma + \langle AB|BA\rangle,$$
$$E_{S3} = 2K + \langle AA|BB\rangle + \langle AB|BA\rangle,$$

where

$$\langle AB|A'B'\rangle = e^2\int d1d2\phi_A(1)\phi_B(1)\phi_{A'}(2)\phi_{B'}(2)/r_{12},$$

and we assume that the single particle energies of ϕ_A and ϕ_B are equal to K and that $\langle AA|AA\rangle = \langle BB|BB\rangle = \gamma$. By the relation

$$\gamma > \langle AA|BB\rangle > \langle AB|BA\rangle > 0$$

the energetic order of the states except Ψ_{S3} is determined as

$$E_{S2} > E_{RHF} > E_{S1} > E_T,$$

where RHF means the restricted HF state $|\phi_A\alpha,\phi_A\beta|$ with the energy $E_{RHF} = 2K+\gamma$. The energetic position of Ψ_{S3} depends on the extent of the differential overlap

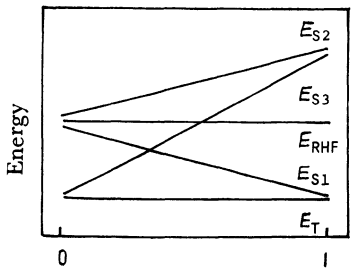


Fig. 1. The correlation diagram of low-lying states of diradicals against the extent of the differential overlap between the two NB MOs.

between ϕ_A and ϕ_B. Let's consider two extreme cases. When the overlap is nearly complete, $\langle AA|BB\rangle$ is nearly equal to γ, so that Ψ_{S3} is higher than the RHF and nearly degenerate with Ψ_{S2}. Ψ_{S1} and Ψ_T also are nearly degenerate. When ϕ_A and ϕ_B are disjoint, $\langle AA|BB\rangle$ is much smaller than γ, so that Ψ_{S3} is lower than the RHF and nearly degenerate with Ψ_T. Ψ_{S1}, Ψ_{S2}, and the RHF are also nearly degenerate. By connecting these extreme cases we obtain dependence of the energetic order of the four states on the overlap of ϕ_A and ϕ_B as shown in Fig. 1. It is found that in the two-electron model the ground state is always the triplet state. In the two extreme cases, however, the singlet state lies close to the triplet state, so that the enegetic order is possible to change in the all-valence-electron model. Figure 1 shows that in the case of the intermediate overlap the two singlet states Ψ_{S1} and Ψ_{S3} may lie below the RHF. In the following, we examine how the two singlet states are described by the UHF theory.

First we obtain the UHF solution emerging from the instability of the RHF. The four instability matrices ($^1ST_\pm$, $^3ST_\pm$)[7] of the RHF are 1×1 dimensional in the model and are given by

$$^1ST_+ = 2(a-b),\quad ^1ST_- = {}^3ST_+ = -2b,$$
$$^3ST_- = -2(a+b),$$
$$a = \langle AB|BA\rangle,\quad b = (\gamma-\langle AA|BB\rangle)/2,\quad a, b > 0.$$

Because the $^3ST_-$ instability matrix has the lowest negative eigenvalue, we consider this instability. The $^3ST_-$ instability of the RHS indicates that there is an axial spin density wave (ASDW) UHF solution (ASDW1) lower in energy than the RHF. The orbitals of ASDW1, which is a real DODS solution, are a spin polarized mixture of ϕ_A and ϕ_B

$$\text{ASDW1} = |\psi_{1+}\alpha, \psi_{1-}\beta|,\ \psi_{1\pm} = \cos\theta\phi_A \pm \sin\theta\phi_B,$$

and the energy is given by

$$E_{ASDW1} = E_{RHF} - (a+b)\sin^2 2\theta.$$

E_{ASDW1} has a minimum at $\theta=45°$, so that we obtain

$$\psi_{1\pm} = (\phi_A \pm \phi_B)/\sqrt{2},$$
$$E_{ASDW1} = 2K + (\gamma+\langle AA|BB\rangle)/2 - \langle AB|BA\rangle.$$

The wave function of ASDW1 is expanded as

$$(\Psi_{S1}-\Psi_T)/\sqrt{2},$$

showing that the singlet component of ASDW1 is Ψ_{S1}.

Next we examine the stability of ASDW1. The four instability matrices ($A_\pm M_\pm$)[7] of ASDW1 are 2×2 dimensional in the model and are given by

$$A_+M_+ = \begin{pmatrix} 2a, & 2b \\ 2b, & 2a \end{pmatrix},\quad A_+M_- = \begin{pmatrix} 2a, & 0 \\ 0, & 2a \end{pmatrix},$$
$$A_-M_\pm = \begin{pmatrix} -b, & -b \\ -b, & -b \end{pmatrix}.$$

The lowest eigenvalue of the A_+M_+ instability matrix is $2(a-b)$ with the eigenvector $\begin{pmatrix} 1 \\ -1 \end{pmatrix}$. Therefore, if $a-b<0$ which is the same condition as $E_{S3}<E_{S1}$, ASDW1 is A_+M_+ unstable, that is, ASDW1 is unstable for a spin unflip excitation and there is another ASDW solution (ASDW2) lower in energy than ASDW1. ASDW2's orbitals are determined by the eigenvector $\begin{pmatrix} 1 \\ -1 \end{pmatrix}$ of the A_+M_+ instability in the following form

$$\text{ASDW2} = |\psi'_{1+}\alpha, \psi'_{1-}\beta|,\ \psi'_{1\pm} = \cos\theta\psi_{1\pm} \pm \sin\theta\psi_{2\pm},$$
$$\psi_{2+} = \psi_{1-} = (\phi_A-\phi_B)/\sqrt{2},$$
$$\psi_{2-} = \psi_{1+} = (\phi_A+\phi_B)/\sqrt{2},$$

and the energy is given by

$$E_{ASDW2} = E_{ASDW1} + (a-b)\sin^2 2\theta.$$

E_{ASDW2} has a minimum at $\theta=45°$, so that we obtain

$$\psi'_{1+} = \phi_A,\ \psi'_{1-} = -\phi_B,\ E_{ASDW2} = 2K + \langle AA|BB\rangle.$$

Cleraly the singlet component of ASDW2 is Ψ_{S3}.

Last we examine the stability of ASDW2. The instability matrices of ASDW2 are

$$A_+M_+ = \begin{pmatrix} 2b, & 2a \\ 2a, & 2b \end{pmatrix},\quad A_+M_- = \begin{pmatrix} 2b, & 0 \\ 0, & 2b \end{pmatrix},$$
$$A_-M_\pm = \begin{pmatrix} -a, & -a \\ -a, & -a \end{pmatrix}.$$

Therefore, if $b-a<0$ which is the same condition as $E_{S1}<E_{S3}$, ASDW2 is A_+M_+ unstable. We can show similarly that the UHF solution arising from this instability is ASDW1.

The above results show that ASDW1 and ASDW2 well describe the two low-lying singlet states (Ψ_{S1} and Ψ_{S3}) which involve strong electronic correlations. The stability relations among the three HF solutions, the RHF, ASDW1, and ASDW2, are summerized in Table 1. We note that in the two-electron model, if $E_{S1}>(<)$ E_{S3}, ASDW1 (ASDW2) is always unstable, but that this is not necessarily the case with all-valence-electron calculations. This situation is also shown by the second scheme in Table 1.

UHF Calculation on Cyclobutadiene

We performed an all-valence-electron UHF calculation on **1** by varying the C–C bond length (R) from

1.61 Å to 1.31 Å. The other geometrical parameters are fixed as shown in Fig. 2a. In the geometries the RHF π orbitals are a bonding (B) π MO (ϕ_1), two nearly degenerate NB π MOs (ϕ_2, ϕ_3), and an antibonding (AB) π MO (ϕ_4):

$$\phi_1 = (\chi_1+\chi_2+\chi_3+\chi_4)/2,\quad \phi_2 = (\chi_1+\chi_2-\chi_3-\chi_4)/2,$$
$$\phi_3 = (\chi_1-\chi_2+\chi_3-\chi_4)/2,\quad \phi_4 = (\chi_1-\chi_2-\chi_3+\chi_4)/2,$$

where χ_i is the π atomic orbital (AO) of the i-th carbon atom in Fig. 2a. The MOs ϕ_1—ϕ_4 are of b_{1u}, b_{2g}, b_{3g}, and a_u symmetries in the D_{2h} point group, respectively. As R is varied, the MOs ϕ_2 and ϕ_3 cross at square geometries, so that there are two RHF ground states with different occupancies of the π MOs: RHF1 = $(\phi_1)^2(\phi_2)^2$ and RHF2 = $(\phi_1)^2(\phi_3)^2$. RHF1 and RHF2 are the RHF ground states in the regions $R>R'$ and $R<R'$, respectively. Near the square geometry they become ^{3}ST- unstable. Because the differential overlap between the two NB MOs is complete, this case corresponds to the last scheme of Table 1 and an ASDW solution, ASDW1, emerges from the instability. ASDW1 connects smoothly RHF1 and RHF2. The correlation diagram of the π MOs and the adiabatic potentials of the RHFs and the UHF solutions are shown in Fig. 3. This shows that ASDW1 is the HF ground state near the square geometry and that the triplet ASDW solution is higher in energy than ASDW1 in contrast to the two-electron model. The equilibrium geometry of the singlet ground state obtained from ASDW1's potential becomes very close to the square one in contrast to the rectangular equilibrium geometries of the RHF's potentials. These features stem from the correlation effect which becomes important as the square geometry is neared.

In order to analyze the electronic correlation in

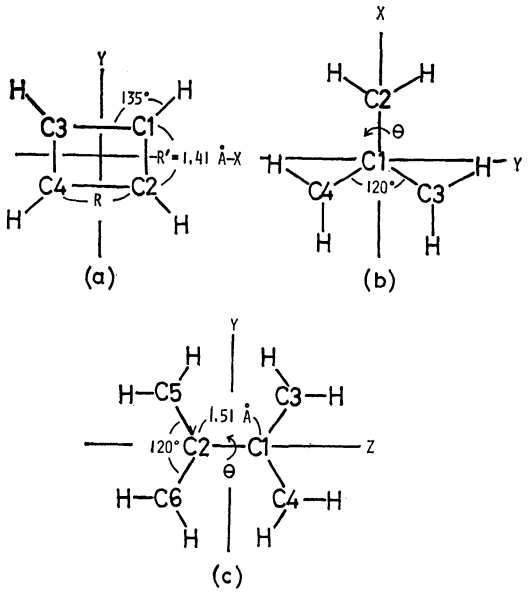

Fig. 2. Geometries used in the calculations for **1**, **2**, and **3**. All the C–H bond lengths are fixed to 1.1 Å, the C–C bond lengths, whose values are not indicated, to 1.41 Å, and all the H–C–H angles to 120°. **1** has the D_{2h} and D_{4h} symmetries at $R\neq R'$ and $R=R'$. respectively. **2** has the D_{3h}, C_{2v}, and C_2 symmetries at $\theta=0°$, 90°, and $\theta\neq 0°$ and 90°, respectively, and **3** has the D_{2h}, D_{2d}, and D_2 symmetries at $\theta=0°$, 90°, and $\theta\neq 0°$ and 90°, respectively.

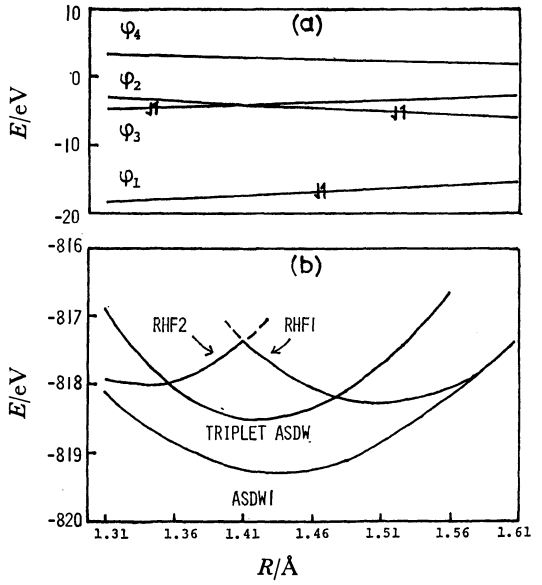

Fig. 3. The correlation diagram of the Hückel type π MOs (a), and the adiabatic potentials of the RHFs, ASDW1 and the triplet ASDW (b) of cyclobutadiene.

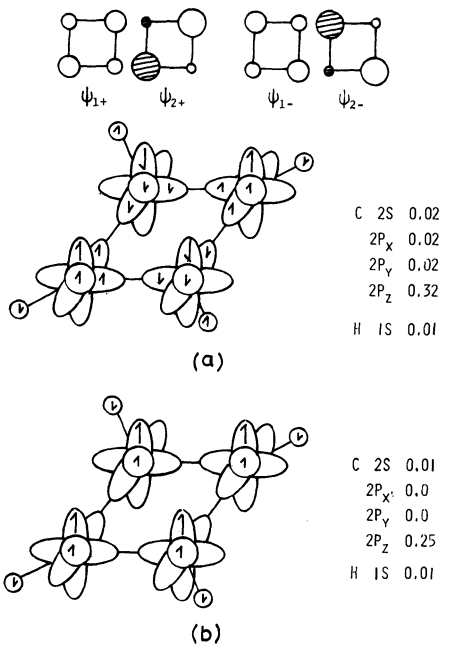

Fig. 4. The π corresponding orbitals and the spin density structure of ASDW1 (a) and the spin density structure of the triplet ASDW (b) of cyclobutadiene. The carbon π AOs with positive MO coefficients are represented by white circles and those with negative MO coefficients by shaded ones. The radii of the circles are proportional to the magnitudes of the MO coefficients. The spin densities with positive and negative z components are represented by up- and downward arrows, respectively. The magnitudes of the spin densities on carbon and hydrogen AOs are the same for all the C–H units except their signs.

ASDW1, we show in Fig. 4 the π corresponding orbitals and the spin density structure of ASDW1 at the equilibrium geometry. The spin density structure of the triplet ASDW is also shown for comparison. The excitations contributing to the $^3ST_-$ instability which produces ASDW1 from the RHF have the B_{1g} symmetry. Therefore, the π excitations $\phi_2 \rightarrow \phi_3$ (or $\phi_3 \rightarrow \phi_2$) and $\phi_1 \rightarrow \phi_4$ contribute to the instability. Consequently, not only the NB π orbitals but also the B π orbitals are spin polarized as follows:

$$\psi_{1\pm} = \cos\theta_1\phi_1 \pm \sin\theta_1\phi_4, \quad \psi_{2\pm} = \cos\theta_2\phi_2 \pm \sin\theta_2\phi_3.$$

The σ orbitals are also spin polarized, but to a smaller extent than the π orbitals, due to the σ excitation with the B_{1g} symmetry.

The triplet ASDW is obtained with the trial wave function

$$\Psi_T^0 = |\text{core}, \phi_1\alpha, \phi_1\beta, \phi_2\alpha, \phi_3\alpha|,$$

where core represents the doubly occupied RHF σ MOs. After the SCF procedure, the π orbitals remain unchanged but the core part is spin polarized with the corresponding orbitals retaining the same symmetries as the original RHF σ orbitals.

The spin polarization of the B π orbital ϕ_1 appears only in the singlet state. Its physical significance is as follows.[1] The splitting of the B π orbital occurs in such a way that $\psi_{1\pm}$ overlaps $\psi_{2\pm}$ more than $\psi_{2\mp}$ as shown in Fig. 4. Such coherent splittings of $\psi_{1\pm}$ and $\psi_{2\pm}$ reduce the Coulomb repulsion between the electrons of opposite spins because they are localized to different regions. The electrons of the same spin localize to the same region but this does not enhance the Coulomb repulsion between them because the Pauli principle prevents their close encounter. In contrast to the singlet state, the spin polarization of the B π electrons is not induced in the triplet state because the spin density of the NB π electrons is uniform in the triplet state. The spin polarization of the B π electrons which operates only in the singlet state makes the singlet ASDW lower in energy than the triplet ASDW.

Next we discuss on the spin polarization of the σ electrons shown in Fig. 4. The spin polarization of the σ electrons is induced in such a way that the σ spin densities on a carbon atom and that on adjacent hydrogen atom are arranged in the same and opposite directions, respectively, compared to that of the π spin density on the carbon atom. This enhances the exchange interaction between the σ electrons and the π electrons on each carbon atom and reduces the Coulomb repulsion between σ electrons. The magnitude of the σ spin polarization is relatively small. However, its effects are not so small as can be neglected in quantitative discussion.

UHF Calculation on Trimethylenemethane

We preformed a UHF calculation on **2** by rotating a methylene group out of the plane of the remaining allyl group. The other geometrical parameters are fixed as shown in Fig. 2b. At the planar geometry, the RHF π MOs are a B π MO (ϕ_1), two degenerate NB π MOs (ϕ_2, ϕ_3), and an AB π MO (ϕ_4):

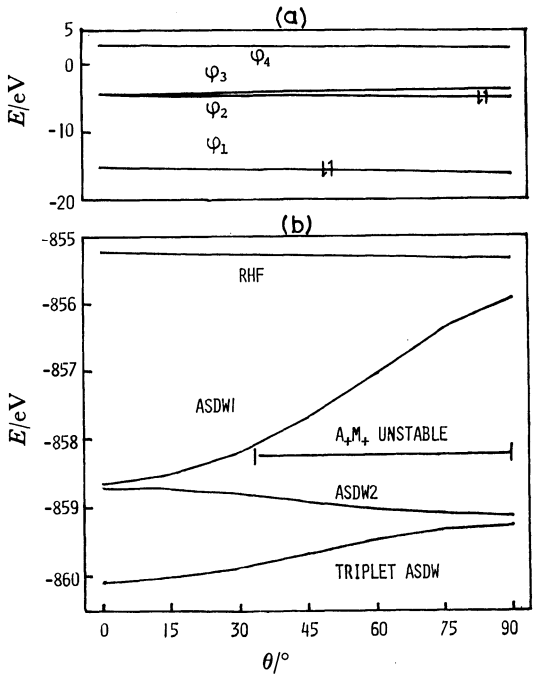

Fig. 5. The correlation diagram of the Hückel type MOs (a) and the adiabatic potentials of the RHF, ASDWs, and the triplet ASDW (b) of trimethylenemethane. The A_+M_+ instability domain of ASDW1 is also indicated. The region out of the domain corresponds to the second scheme in Table 1.

$$\phi_1 = a\chi_1 + b(\chi_2+\chi_3+\chi_4)/\sqrt{3}, \quad \phi_2 = (\chi_3-\chi_4)/\sqrt{2},$$
$$\phi_3 = (2\chi_2-\chi_3-\chi_4)/\sqrt{6},$$
$$\phi_4 = -b\chi_1 + a(\chi_2+\chi_3+\chi_4)/\sqrt{3}, \quad a \approx b \approx 0.7.$$

The MOs ϕ_1 and ϕ_4 belong to the a_2'' (b) symmetry and ϕ_2 and ϕ_3 to the e'' (a and b) symmetry at the planar D_{3h} geometry (nonplanar C_2 geometry). In the process of the internal rotation, the two NB MOs remain nearly degenerate (ϕ_2 lies a little below ϕ_3) as shown in Fig. 5a. The LCAO expression of ϕ_2 is unchanged while the main AO component of ϕ_3 turns out to be the p robe perpendicular to the twisted methylene group. Therefore, in the rotation the differential overlap between the two NB MOs varies from medium to nearly zero. This situation corresponds to the left half side of Fig. 1 and the first and second schemes of Table 1. Therefore, two singlet UHF states exist below the RHF. The UHF adiabatic potentials are shown in Fig. 5b. This calculation shows that the ground state is triplet and that its equilibrium geometry is planar. On the other hand, the lowest singlet UHF state (ASDW2) has the orthogonal equilibrium geometry. These results are in agreement with other calculations[3] and experiments.[8] It should be noted that at the planar geometry the two singlet states which are approximated by ASDW1 and ASDW2 are degenerate and belong to the E' representation of the D_{3h} point group. The calculated energies of ASDW1 and ASDW2 at the planar geometry are not exactly the same. However, the gap is very small and much reduced compared to the value in the RHF calculation of the two state.[3c]

In order to analyze the electronic correlation among

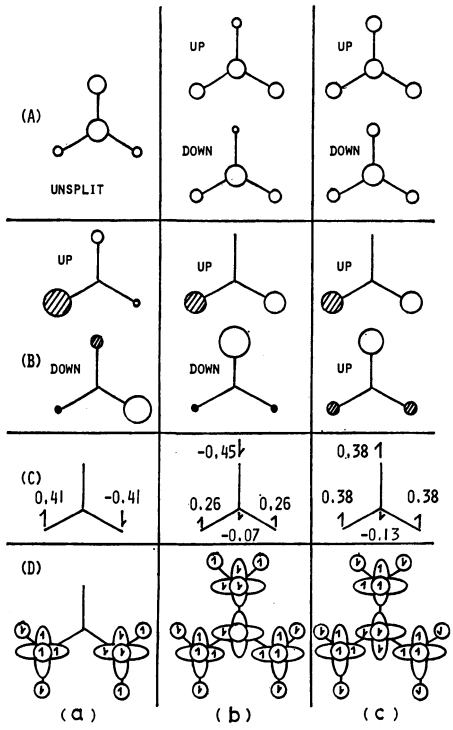

Fig. 6. The corresponding orbitals for the B π electrons (A) and for the NB π electrons (B), and the spin density structure on the π AOs (C) and on the σ AOs (D) of ASDW1 (a), ASDW2 (b), and the triplet ASDW (c) of planar trimethylenemethane. The numerals in (C) are the magnitudes of the spin densities. Those on the σ AOs are either ± 0.01 or ± 0.02.

the three UHF states, we show in Fig. 6 the π corresponding orbitals and the spin density structures of the UHF states at the planar geometry. The $^3ST_-$ instability which connects the RHF with ASDW1 has the B symmetry in the C_2 group. We adopted the C_2 symmetry because the RHF with the occupancy $(\phi_1)^2(\phi_2)^2$ of the π MOs is of symmetry adapted only to the C_2 group. The excitations $\phi_2 \rightarrow \phi_3$ and $\phi_2 \rightarrow \phi_4$ with the B symmetry contribute to the instability. Consequently, the NB orbitals in ASDW1 are spin polarized in the following manner:

$$\psi_{2\pm} = \cos\theta_1\phi_2 \pm \sin\theta_1(\cos\theta_2\phi_3 - \sin\theta_2\phi_4).$$

After the SCF procedure, ϕ_1 also is mixed into $\psi_{2\pm}$ because it has the same symmetry as ϕ_3 and ϕ_4 in the C_2 group.

ASDW2's orbitals are adapted to the C_2 symmetry and not to the D_{3h} one because its trial wave function

$$|\text{core}, \phi_1\alpha, \phi_1\beta, \phi_2\alpha, \phi_3\beta|$$

has the C_2 symmetry and not the D_{3h} one. Therefore, ϕ_1, ϕ_3, and ϕ_4 with the same b symmetry are mixed in ASDW2 after the SCF procedure, but ϕ_2 is unchanged:

$$\psi'_{3-} = \cos\theta_3\phi_3 + \sin\theta_3(\cos\theta_4\phi_4 + \sin\theta_4\phi_1),$$
$$\psi'_{1-} = \cos\theta_{5-}\phi_1 - \sin\theta_{5-}(\cos\theta_{6-}\phi_4 - \sin\theta_{6-}\phi_3),$$
$$\psi'_{1+} = \cos\theta_{5+}\phi_1 - \sin\theta_{5+}(\cos\theta_{6+}\phi_3 - \sin\theta_{6+}\phi_4).$$

The ASDW2's orbitals ψ'_{1-} and ψ'_{3-} have large MO weights on χ_1 and χ_2 AOs and ψ'_{+} does on χ_3 and χ_4 AOs so that electrons with different spins are caused to localize in different regions.

The triplet ASDW's orbitals are adapted to the D_{3h} symmetry because of the D_{3h} adaptation for the trial wave function

$$|\text{core}, \phi_1\alpha, \phi_1\beta, \phi_2\alpha, \phi_3\alpha|.$$

Therefore, only ϕ_1 and ϕ_4 with the same a_2'' symmetry are mixed in the triplet ASDW

$$\psi^t_{1\pm} = \cos\theta_{7\pm}\phi_1 \pm \sin\theta_{7\pm}\phi_4.$$

By the spin polarization of $\psi^t_{1\pm}$ a negative spin density appears on the central carbon atom.

We note that the spin structures of ASDW2 and the triplet ASDW are similar to those of the singlet and triplet GVB wave functions obtained by Davis and Goddard III.[3d] The forms of the orbitals of ASDW1 and ASDW2 are retained in the process of the rotation because the system has the C_2 symmetry throughout the process. The change in the spin polarization effect in the triplet ASDW also is small.

Next, we clarify the difference between ASDW1 and ASDW2. As mentioned above, ASDW2 is adapted to the C_2 symmetry, so that its spin structure is also invariant to the C_2 spatial rotation. The spin structure of ASDW1 is invariant not to the C_2 rotation but to the joint C_2 rotation of space and spin. This difference between the symmetries of the spin structures means that the singlet components of ASDW1 and ASDW2 belong to different C_2 symmetries as shown by Ozaki.[9] In fact, the singlet component of ASDW1 has the A symmetry but that of ASDW2 the B symmetry.

UHF Calculation on Tetramethyleneethane

We performed a UHF calculation on **3** by rotating the two allyl groups around the central C–C bond. The other geometrical parameters are fixed as shown in Fig. 2c. At the planar geometry the RHF π MOs are two B π MOs (ϕ_1, ϕ_2), two nearly degenerate NB π MOs (ϕ_3, ϕ_4), and two AB π MOs (ϕ_5, ϕ_6):

$$\phi_1 = a(\chi_1+\chi_2)/\sqrt{2} + b(\chi_3+\chi_4+\chi_5+\chi_6)/2,$$
$$\phi_2 = a'(\chi_1-\chi_2)/\sqrt{2} + b'(\chi_3+\chi_4-\chi_5-\chi_6)/2,$$
$$\phi_3 = (\chi_3-\chi_4+\chi_5-\chi_6)/2, \quad \phi_4 = (\chi_3-\chi_4-\chi_5+\chi_6)/2,$$
$$\phi_5 = -b(\chi_1+\chi_2)/\sqrt{2} + a(\chi_3+\chi_4+\chi_5+\chi_6)/2,$$
$$\phi_6 = -b'(\chi_1-\chi_2)/\sqrt{2} + a'(\chi_3+\chi_4-\chi_5-\chi_6)/2,$$
$$a \approx b' \approx 0.8, \quad b \approx a' \approx 0.6.$$

The MOs ϕ_1—ϕ_6 are of b_{3u}, b_{2g}, b_{1g}, a_u, b_{3u}, and b_{2g} symmetry in the D_{2h} group, respectively. In the process of the rotation, the two NB MOs remain nearly degenerate and cross at about $\theta = 40°$ as shown in Fig. 7a. The crossing occurs due to the spiroconjugation effect.[10] Therefore, there are two RHF ground states with the occupancies RHF1 $= (\phi_1)^2(\phi_2)^2(\phi_3)^2$ and RHF2 $= (\phi_1)^2(\phi_2)^2(\phi_4)^2$. RHF1 and RHF2 are the RHF ground states in the regions $\theta < 40°$ and $\theta > 40°$, respectively. The differential overlap between the two NB MOs is nearly complete throughout the rotation process, so that this case belongs to the last scheme of Table 1 and there is only a singlet ASDW state (ASDW1) below the RHF. The adiabatic potentials of the RHF and

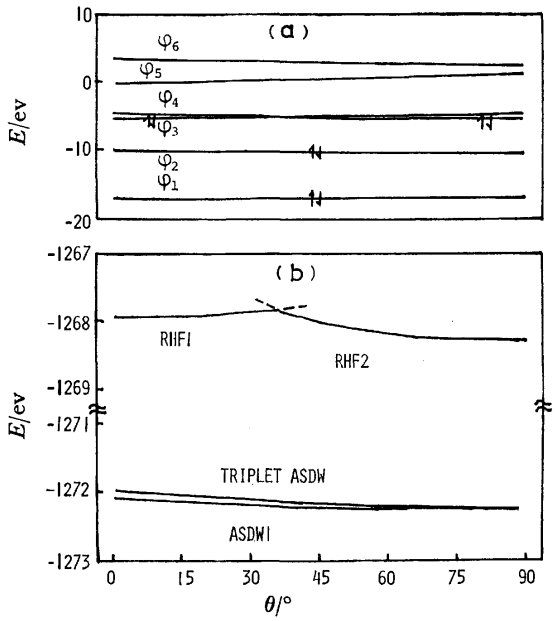

Fig. 7. The correlation diagram of the Hückel type MOs (a) and the adiabatic potentials of the RHFs, ASDW1 and the triplet ASDW (b) of tetramethyleneethane.

UHF states are shown in Fig. 7b. Our calculation, like a previous one,[10] shows a rather small energy change in the rotation. The singlet ASDW1 is found to lie a little below the triplet ASDW everywhere and has a very shallow potential minimum at about $\theta=50°$.

Next we examine the electronic correlation between the singlet and triplet ASDW states at the planar geometry. The $^3ST_-$ instability which connects the RHF and ASDW1 has the B_{1u} symmetry. Therefore, the excitations $\phi_3\rightarrow\phi_4$, $\phi_2\rightarrow\phi_5$, and $\phi_1\rightarrow\phi_6$ with the B_{1u} symmetry contribute to the instability. Consequently, all the orbital pairs are spin polarized as

$$\psi^s_{1\pm}=\cos\theta_1\phi_1\pm\sin\theta_1\phi_6,\quad \psi^s_{2\pm}=\cos\theta_2\phi_2\pm\sin\theta_2\phi_5,$$
$$\psi^s_{3\pm}=\cos\theta_3\phi_3\pm\sin\theta_3\phi_4.$$

The triplet ASDW's orbitals are adapted to the D_{2h} symmetry because its trial wave function

$$|\text{core},\ \phi_1\alpha,\ \phi_1\beta,\ \phi_2\alpha,\ \phi_2\beta,\ \phi_3\alpha,\ \phi_4\alpha|$$

has the B_{1u} symmetry in the D_{2h} group. After the SCF procedure, ϕ_2 and ϕ_6 with the b_{2g} symmetry and ϕ_1 and ϕ_5 with the b_{3u} one are mixed in the triplet ASDW to yield

$$\psi^t_{1\pm}=\cos\theta_{4\pm}\phi_1\pm\sin\theta_{4\pm}\phi_5,\quad \psi^t_{2\pm}=\cos\theta_{5\pm}\phi_2\pm\sin\theta_{5\pm}\phi_6.$$

The difference in the spin polarization of the B π MOs between the singlet and triplet ASDW states is that in the singlet ASDW it is produced by the mixing of the second π LUMO to the second π HOMO and of the third π LUMO to the third π HOMO, while in the triplet ASDW by the mixing of the third π LUMO to the second π HOMO and of the second π LUMO to the third π HOMO as shown in Fig. 8. As a result, the spin polarization of the second π HOMO is larger in the singlet ASDW, while that of the third π HOMO is larger in the triplet ASDW. Because the second π HOMO is spin polarized more easily than the third one, the spin polarization effect in the singlet ASDW

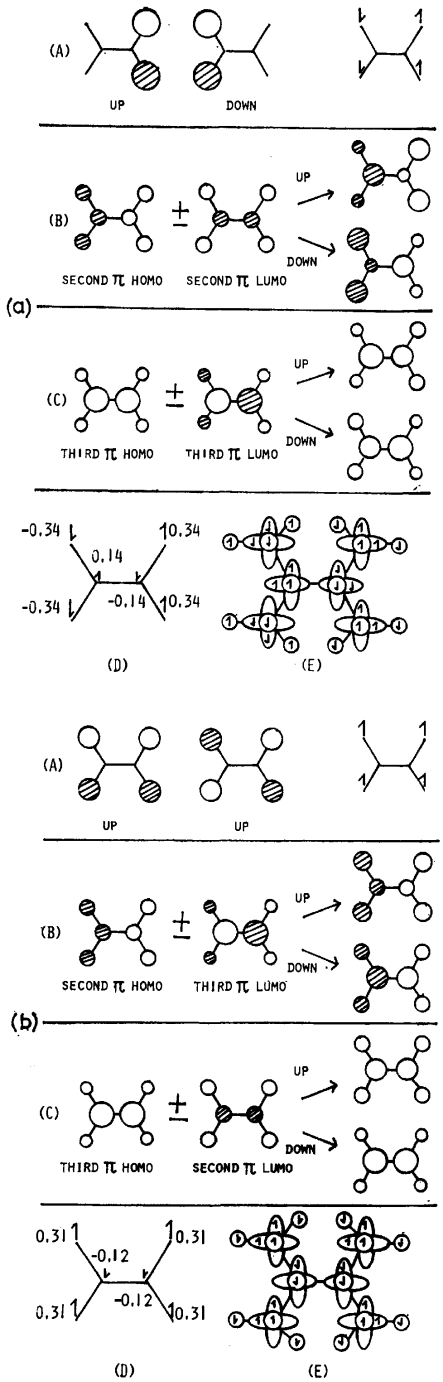

Fig. 8. The corresponding orbitals of the NB π MO (A), second π HOMO (B) and third π HOMO (C) of ASDW1 (a) and the triplet ASDW (b) of tetramethyleneethane. The spin density structures on the π AOs and σ AOs are also shown in (D) and (E), respectively. The numerals in (D) are the magnitudes of the spin densities. Those on the σ AOs are either ±0.01 or ±0.02.

is a little larger than that in the triplet ASDW. This explains why the singlet ASDW lies a little below the triplet ASDW.

The above UHF analysis indicates that the ground state of **3** is singlet and that a triplet state lies close to it. The result is in accord with the *ab initio* CI calcula-

tion by Borden and Davidson.[11] This suggests that the ESR signal of **3** which was observed at the boiling point of nitrogen[12] may be attributed to a thermally accessible triplet state. This prediction can be checked by measurement of the temperature dependence of the ESR signal. However, no such experiments have been carried out and the correctness of our prediction is left to be tested.

Simple Rules to Predict the Spin Multiplicity of the Ground State and the Spin Structure of Low-lying UHF States of Hydrocarbon Diradicals

The above results for **1**, **2**, and **3** show that the UHF theory gives the ground state of correct spin multiplicity. It should be stressed that all the ground states of **1**, **2**, and **3** have alternating spin structures. The results also show that the spin structure of the all-valence-electron UHF calculation is different from that of the two-electron model in such a manner that the weak spin density on an atom adjacent to the atom with large spin density is always antiparallel to the adjacent largest spin density. The preference of the antiparallel spin coupling manifested in the UHF results is consistent with the valence bond picture and seems to have a general validity. By generalizing these results, we can predict the spin multiplicity of the ground state and the spin structure of low-lying UHF states of hydrocarbon diradicals as follows.

Put spins on carbon atoms in alternating directions and if the number of the up and down spins in the alternating spin structure are the same with each other, the ground state is predicted to be singlet, whereas if their difference is two, the ground state is predicted to be triplet. This rule is much simpler than, but as effective as, the one proposed by Borden and Davidson.[11] The main aspect of the spin structure of low-lying UHF states is determined by the two-electron model. The all-valence-electron spin structures are obtained by modifying the directions of the weak atomic spin densities so as to make them antiparallel to the adjacent large spin densities.

To demonstrate the general validity of these rules, we apply them to 1,1,2,3,3-pentamethylenepropane (**4**) and 1,3-dimethylenecyclobutadiene (**5**). First we consider **4**. The two NB MOs (ϕ_A and ϕ_B) obtained with the Hückel Hamiltonian are shown in Fig. 9a. The figure shows that the differential overlap between them is nearly complete, so that there are a singlet ASDW (ASDW1) and a triplet ASDW below the RHF. The spin structures of the NB electrons of the two states are shown in Figs. 9b and 9c. Modifying the weak spin densities so that they are made antiparallel to the adjacent large ones, we obtain Figs. 9b and 9c′. There appear no spin densities on the two central carbons (4 and 5) in Fig. 9b because of the symmetry of the spin structure. The weak spin density on carbon 4 in Fig. 9c′ is made negative so as to be antiparallel to the adjacent one. The alternating spin structure corresponds to the triplet state of Fig. 9c′, so that the ground state is predicted to be triplet. We show in Fig. 9d the UHF results, which confirm our rules.

Next we consider **5**. The overlap between the two NB MOs (ϕ_A and ϕ_B) shown in Fig. 10a is medium, so that there are two singlet ASDWs (ASDW1 and ASDW2) and one triplet ASDW below the RHF. The spin structures of the two NB electrons in the three states are shown in Figs. 10b, 10c, and 10d. Modifying the weak spin densities so that they are made antiparallel

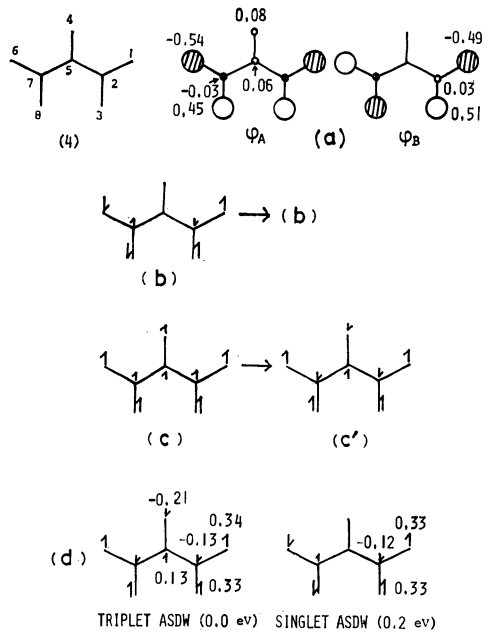

Fig. 9. Two NB MOs (a), the predicted spin structures of ASDW1 (b) and the triplet ASDW (c′), and the result of the all-valence-electron UHF calculation (d) of 1,1,2,3,3-pentamethylenepropane.

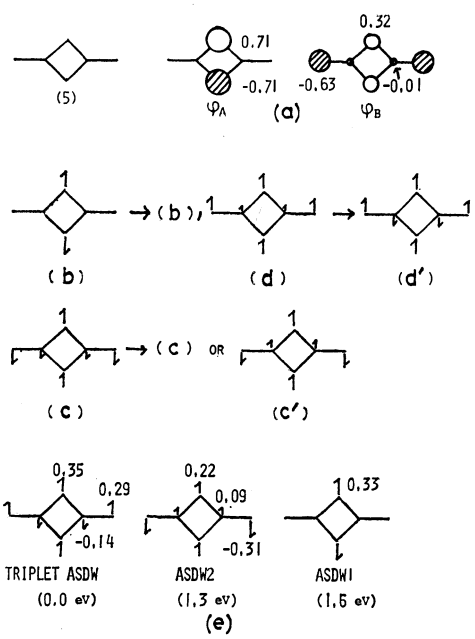

Fig. 10. Two NB MOs (a), the predicted spin structures of ASDW1 (b), ASDW2 (c′) and the triplet ASDW (d′), and the result of the all-valence-electron UHF calculation (e) of 1,3-dimethylenecyclobutadiene.

to the adjacent large ones, we obtain the spin structures shown in the right side of Figs. 10b, 10c, and 10d. The spin structure of Fig. 10b is unchanged because of its symmetry. The spin structure of Fig. 10c is possible to be modified in two different ways, but Fig. 10c' shows the feasible one because the terminal carbon atoms have the largest spin densities. The alternating spin structure corresponds to the triplet state in Fig. 10d', so that the ground state is predicted to be triplet. We show in Fig. 10e the UHF results, which also confirm our rules.

Kinetics and Mechanism of Acylhydrazine Hydrolysis in Sulfuric Acid-Water Mixtures

Mitsuo MASHIMA,* Fujiko IKEDA, Takako DOI, and Sadakatsu NISHIKAWA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received March 23, 1981)

The rates of acid-catalyzed hydrolysis of formylhydrazine, acetylhydrazine, chloroacetylhydrazine, propionylhydrazine, butyrylhydrazine, and octanoylhydrazine in sulfuric acid–water mixtures have been investigated over a wide range of acidities (about 1—18 M H_2SO_4) by means of spectrophotometric methods. First-order kinetics were obtained in all cases, and the pseudo-first-order rate constants showed one of two types of acidity dependences: (i) a rate maximum at intermediate acidities, followed by slow hydrolysis in highly concentrated acids; (ii) a rate maximum at intermediate acidities, followed by a sharp increase in rate at high acidities. This result was treated as a function of the Hammett acidity function, the water activity, and the total concentration of hydrogen ion to yield reaction parameters which are explicable in terms of a change in mechanism at a high acidity from A-2 to A-1. The mechanism change also was deduced from a criterion based on the values of activation entropies.

The rates of acid-catalyzed hydrolysis of amides have been studied systematically, but only a few results[1,2] have been obtained for those of acylhydrazines. Hydrazidinum ion $RCONHNH_3^+$, which is expected to exist in acid solutions,[1,3,4] would have a planar skeleton of O–C–N–N having two π-electrons and two lone-pair electrons. It is of interest to test how this electron system affects the kinetics.

Mechanisms of reaction in strong acid solutions have been recently reviewed in detail by Rochester[5] and Liler.[6] Empirical criteria of acid-catalyzed hydrolysis have been developed in terms of the acidity function, the water activity, the total concentration of hydrogen ions of acid media, and further in terms of the change of hydration number between reactants and transition states. For the hydrolysis containing pre-equilibrium, the value of the dissociation constant of the conjugate acid may also control the rate-determining step. Sulfuric acid-water mixtures are an exceptionally suitable medium to examine the factors affecting the kinetics of acid-catalyzed hydrolysis over a wide range of acid concentrations.

Experimental

Materials and Apparatus. The acylhydrazines were synthesized with methyl or ethyl esters of the corresponding acids and hydrazine hydrates, and purified by recrystallization from ether–ethanol mixtures. Purity was assured by melting point. Sulfuric acid–water mixtures were made by dilution of reagent grade acid with distilled water. The acid solutions were standardized by titration against a standard sodium hydroxide solution, exccpt for highly concentrated acids of which concentrations were determined by measurements of density. Molarities were calculated by calibration on the basis of the literature data of densities.[7]

The ultraviolet solution spectra were measured with a Hitachi EPS-3T Recording Spectrophotometer equipped with a thermostated cell compartment. The temperature in this compartment was controlled within ± 0.1 °C.

Rate Measurements. Reactions were followed by recording the change in absorbance A with time at the absorption maximum. Pseudo-first-order rate constants k were calculated graphically from plots of log $(A-A_\infty)$ *vs.* time (min) or by means of a computer program which gives, by adjustment of A_∞, the first-order rate constant which best fits the observed data. In view of the highly diluted reaction solutions, about 10^{-3} M (1 M = 1 mol dm^{-3}), used for spectrophotometric examination, no attempt was made to isolate reaction products from the reaction solutions. In order to check the A_∞, the absorption spectra of the prepared mock solutions were examined and compared with those of reaction solutions.

Results

Rate Profiles. The rate-acidity dependences of hydrolysis of the acylhydrazines were found to fit into one of two categories. The dependence of formylhydrazine and chloroacetylhydrazine is characterized by an initial rate increase with the acid concentration, passing through a maximum, followed by a rate decrease with further increasing acid concentration. Other acylhydrazines resemble this, except that the final increase occurs steeply at higher acid concentrations. It has been confirmed that the acylhydrazine hydrolysis also shows a rate maximum as amide[8] and ester[9] hydrolysis do, but at relatively high acidities: about 12 M H_2SO_4 for formylhydrazine, in contrast to about 5 M H_2SO_4 for formamide.[8a] The values of rate constants and acid concentrations at the maximum rate have been estimated graphically and collected in Table 2.

An important difference in reaction activities is found between the first two members of the aliphatic series $RCONHNH_2$, and an anomaly is found among the first three members, as pointed out for aliphatic acid amide homologues;[10] acetylhydrazine is less active than propionylhydrazine, but the difference is not very large. It also should be noted that the chlorine-substitution in the acyl group changes the reactivity in the low acidity region very little but does affect the reactivity at the very high acidity region.

Treatment of Rate Data. The pseudo-first-order rate constants, k, of hydrolysis of formylhydrazine and acetylhydrazine at 25 °C have been used in order to test several treatments which are useful for obtaining mechanistic conclusions in terms of the values of acidity function H_0,[11] activity of water a_w,[12] total concentration of hydrogen ion $[H^+]$,[13] and pK_{SH^+} of conjugate acid.[1,3]

One criterion of the reaction mechanism has been presented by Bunnett and Olsen,[14] who have found a

linear correlation of $\log k+H_o$ *vs.* $H_o+\log[H^+]$ and proposed the values of the proportionality slope parameter ϕ as useful to characterize the medium dependence of rate constants. Typical ϕ plots are illustrated in Fig. 1, which shows the following: for formylhydrazine the points below 12 M H_2SO_4 give a good straight line ($\phi=0.95\pm0.01$), and above 13 M H_2SO_4 another straight line ($\phi=1.37\pm0.01$) can be drawn through the remaining points; for acetylhydrazine the similar linearities are obtained below about 10 M H_2SO_4 ($\phi=1.00\pm0.01$) and in the middle region of about 11—14 M H_2SO_4 ($\phi=1.29\pm0.00$), and one more linearity ($\phi=0.09\pm0.00$) is found above about 14 M H_2SO_4. It has been deduced[14,15] that for substrates

protonated on N or O atom the ranges of ϕ values for different modes of water involvement in the rate-determining step are: $-0.34<\phi<0$ for water not involved, $0.18<\phi<0.47$ for water acting as a nucleophile, and $\phi>0.47$ for water acting as a proton transfer agent. Applying this criterion, the ϕ values obtained imply that the hydrolysis of formylhydrazine proceeds by the mechanism (A-2) involving water as a proton transfer agent over all the range of acid concentration studied; acetylhydrazine is hydrolyzed by the same mechanism up to about 14 M H_2SO_4, and above the acid concentration the hydrolysis mechanism changes into the one involving no water (A-1). A mechanistic conclusion similar to that for formylhydrazine is obtained for chloroacetylhydrazine, and a conclusion similar to that for acetylhydrazine is obtained for propionylhydrazine butyrylhydrazine and caprylylhydrazine (refer to the ϕ values in Table 3).

a) The values of H_o, $[H^+]$ and a_w at 25 °C are used for the kinetic data at 55 °C. b) The acid concentration range in which the parameters are calculated is inserted in the parentheses.

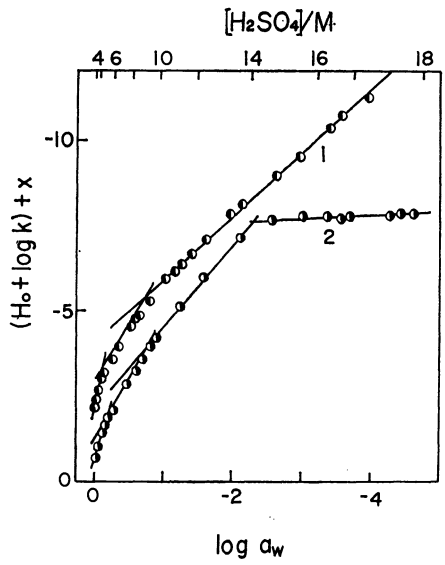

Fig. 2. Plots of $H_o+\log k_{obsd}$ *vs.* $\log a_w$ for the hydrolysis in sulfuric acid at 25 °C; vertical displacement values $x=0$ for formylhydrazine (1) and $x=-2$ for acetylhydrazine (2).

linearly with $\log a_w$ and that the values of the correlation slope parameter w were useful as the criterion of the reaction mechanism. Typical w plots are shown in Fig. 2. The plots should be divided into three (for formylhydrazine) or four (for acetylhydrazine) linear portions. The w values estimated for each portion are collected in Table 3, along with the acid concentration ranges in which the w values are calculated. A complementary parameter w^* was defined by Bunnett[16] as a useful index of the response of the reaction to the catalysis by concentrated acid, *e.g.* sulfuric acids above 4 M. The w^* plots, $\log k-H_o-\log[H^+]$ *vs.* $\log a_w$, are shown in Fig. 3. This clearly indicates that for acetylhydrazine the mechanism change expected from the magnitude of ϕ values takes place, *i.e.* for this compound a curved

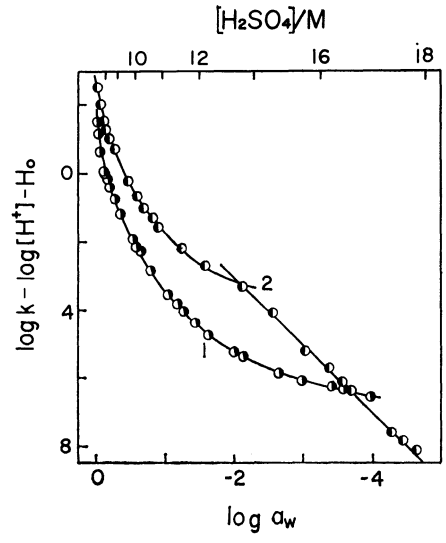

Fig. 3. Plots of $\log k_{obsd}-\log[H^+]-H_o$ *vs.* $\log a_w$ for the hydrolysis of formylhydrazine (1) and acetylhydrazine (2) at 25 °C.

line similar to that for formylhydrazine can be drawn through the points up to about 14 M H_2SO_4, while a good linearity is found beyond 14 M H_2SO_4.

The applicability of the Zucker-Hammett hypothesis[17] was also examined. However, the plot of $\log k$ *vs.* H_o showed no linearity over the range of acid concentration, except for a narrow range of very high acidity, and the plot of $\log k$ *vs.* $\log[H^+]$ also gave a linear portion in a narrow range at low acidities only.

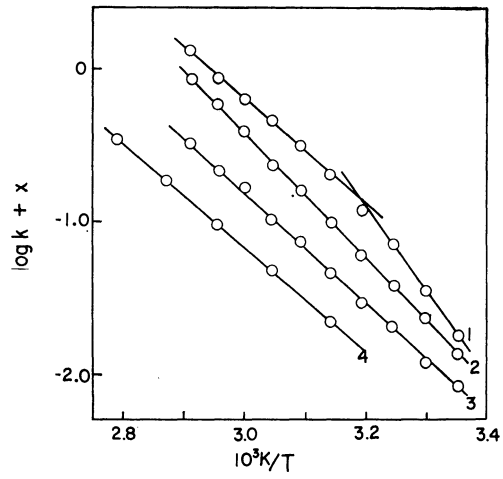

Fig. 4. Arrhenius plots for the hydrolysis of acetylhydrazine; vertical displacement value $x=0$ at 16.7 M H_2SO_4 (1), $x=0.6$ at 11.1 M (2), $x=0.2$ at 8.83 M (3), $x=0.4$ at 2.72 M (4).

Activation Parameters. The rate-temperature dependence was examined at several acid concentrations representative of linear portions in the plots mentioned in the foregoing section. Typical Arrhenius plots, $\log k$ *vs.* $1/T$, are shown in Fig. 4 for the hydrolysis of acetylhydrazine at 2.72, 8.83, 11.1, and 16.7 M H_2SO_4. The plots at high acid concentration for each substrate, except chloroacetylhydrazine, were divided into two linear portions. In these cases the rate constant-temperature dependence can be reasonably treated under the assumption that the activation heat capacities ΔC_p^* vary with temperature.[18] However, our present data do not seem to cover a sufficiently wide temperature range to do the treatment. Therefore, the values of activation parameters were calculated for each linear portion and are collected in Table 4.

After studying the acid-catalyzed hydrolysis of esters, Schaleger and Long[19] have suggested that the typical values of activation entropies are 0 to 42 J K^{-1} mol^{-1} for the A-1 mechanism and -63 to -126 J K^{-1} mol^{-1} for A-2. In fact, for the ethyl acetate hydrolysis[9] the ΔS^* value changed from a negative value (-64.0 J K^{-1} mol^{-1} at 40.2% H_2SO_4) typical of A-2 reactions to a small positive value ($+9.6$ J K^{-1} mol^{-1} at 98.4% H_2SO_4) typical of A-1 reactions; for the amide hydrolysis, which proceeds probably through the A-2 mechanism, the ΔS^* value[20] is -69.5 J K^{-1} mol^{-1} for formamide, -86.6 J K^{-1} mol^{-1} for acetamide, and 88.3 J K^{-1} mol^{-1} for propionamide in 1.00 M HCl.

The mechanistic change of acylhydrazine hydrolysis

a) The linear Arrhenius plots were obtained in the temperature range which is indicated in the parentheses. b) The temperature at which ΔS^* was calculated.

from A-2 to A-1, at a very high acid concentration, was deduced again from the above-mentioned criterion in terms of the ΔS^* values. For each acylhydrazine the larger negative entropies were obtained in the acidity region in which the hydrolysis was expected to go through the A-2 mechanism, and in highly concentrated acids the ΔS^* values were positive or slightly negative, except for chloroacetylhydrazine. Although the ΔS^* values are based on pseudo-first-order rate constants which are dependent on acidity, the observed medium dependence of ΔS^* (see Table 4) would not be expected to lead to such a drastic change, unless a mechanism change was involved. However, for formylhydrazine no indication of the mechanism change from A-2 to A-1 was obtained from the criterion based on the reaction parameters ϕ, w, and w^*, while a relatively small negative value of ΔS^*, probably suitable to the A-1 mechanism, was obtained at a low temperature in 16.5 M H_2SO_4. This inconsistency may be due to the fact that the hydrolysis of formylhydrazine at high acidity is unimolecular (A-1), but is retarded by high activation energies. Even if this is the case, the Arrhenius plots involving two linear portions still need to be interpreted. For all the acylhydrazines with the exception of chloroacetylhydrazine, the values of activation energies and entropies, estimated from the linear portion of Arrhenius plot in higher temperature region and at high acidity, are identical with those obtained at lower acidities. This seems to indicate that change of hydrolysis mechanism occurs; in other words, there are two competing reactions, probably A-1 and A-2, which are predominant at low and high temperature, respectively.

Discussion

In the acidity region in which the hydrolysis proceeds through the A-2 mechanism, formylhydrazine has been observed to undergo hydrolysis about thirty times faster than acetylhydrazine (see Table 1). Acetylhydrazine is hydrolyzed as slow as chloroacetylhydrazine, with a k value of 4.12×10^{-1} min^{-1} at 25 °C in 7.8 M H_2SO_4 (not shown in the table). In spite of such a large rate difference, these three acylhydrazines give nearly equal values of activation energies and of entropies. Therefore, it may be said that the hydrolysis in the low acidity region is not entropy-controlled, nor is it an energy-controlled reaction. The greater stability of acetylhydrazine can not be ascribed to the electron-donating property of methyl group compared with the formyl hydrogen atom, because chloroacetylhydrazine, whose chloromethyl group has no electron-donation power, is as stable as acetylhydrazine. Thus the stability would come from the steric hindrance of the bulky acyl group which prevents it from attacking the water molecule. At high acidity, chloroacetylhydrazine shows no mechanism change from A-2 to A-1; this has been deduced from the criterion based on the reaction parameters and also from that based on activation entropies. The effect of substitution on acylhydrazine hydrolysis ought to be studied more widely. The regions of hydrolysis by the A-1 and A-2 mechanisms are usually separated by a minimum in the rate constant-acid concentration profile curves;[21] this is the case for the hydrolysis of acetylhydrazine, propionylhydrazine, butyrylhydrazine, and caprylylhydrazine.

The magnitude of the parameter used as the criterion of reaction mechanism depends upon how broad a range of acid concentration is covered by the kinetic experiments;[14] our present data, covering a sufficiently wide acidity range for the acylhydrazine hydrolysis, clearly reflect a medium change. The plots based on the linear free relationship[14] give a good linearity which covers all the examined range of acid concentration. However, the plots are divided into two or three linear portions (see Fig. 1 and Table 3). For the first one or two portions, the ϕ values are suitable to the A-2 mechanism, but the value for the higher acidity region is slightly larger than that for the lower acidity region. No acceptable interpretation of the small difference in ϕ values may be deduced from the ϕ plots only.

A striking behavior of the w^* plots, $\log k-H_o-\log[H^+]$ *vs.* $\log a_w$, is worth noting (see Fig. 3): the plot of acetylhydrazine gives a curved line up to an acid concentration which begins to give a linear portion, and so the mechanism change from A-2 to A-1 is expected to be involved; otherwise such a sudden change in curvature is not expected. Moreover, we should pay attention to the curved line portion, because the apparently continuous change of $\log k-H_o-\log[H^+]$

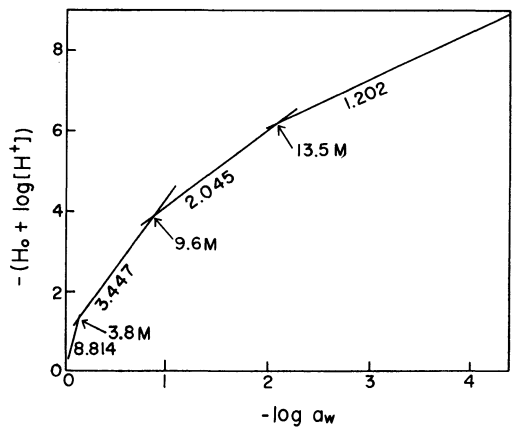

Fig. 5. The plots of $-(H_0+\log[H^+])$ *vs.* $-\log a_w$ for sulfuric acid-water mixtures.

which changing log a_w is considered to come from some affecting factors, which are continuously changed with acid concentration, on the hydrolysis rate. The relation between Hammett's acidity function and water activity has been discussed by several authors.[14,16,22,23] For sulfuric acid-water mixtures in the concentration range examined, the "excess acidity,"[23] $-(H_0+\log[H^+])$, is plotted against $-\log a_w$ by the use of data[11-13] available in Fig. 5. The plot is divided into four linear portions: the initial three portions in slope value and also in the acidity region correspond to the initial three linear portions of the w plots, *i.e.* the local linearlities of the plot of the excess acidity against the water activity are directly reflected on the w plot (compare the slope values and the range of acid concentration inserted in Fig. 5 with those presented in Table 3). Since the correspondence was found for all the acylhydrazines examined, it is not considered to be accidental. This means that the plot of log $k+H_0$ *vs.* $H_0+\log[H^+]$ (the Bunnett-Olsen ϕ plot[14]) gives a straight line with the ϕ value of unity; this is equivalent to the fact that the acidity dependence of rate constants comes from the change of total concentration of hydrogen ions, that is, the linear plot of log k *vs.* log $[H^+]$ with the slope value of unity (the Zucker-Hammett hypothesis[17]) is obtainable. In fact, the ϕ values nearly equal to unity were obtained over the acid concentration range in which the acylhydrazines were hydrolyzed through the A-2 mechanism. However, the ϕ values at lower acidity regions are slightly smaller than those at higher acidity regions; this was found for all the acylhydrazines which gave ϕ values which differed slightly from each other. This seems to imply that the hydration change which occurs with protonation and/or transition of substrate molecules also affects the rate constant-acidity dependence. Finally, we can say that the w^* parameter is greatly sensitive to small deviations from the Zucker-Hammett criteria and that the ϕ parameter will provide a more reliable criterion for the interpretation of the dependences of rate constants and also of reaction mechanisms on changes in acid concentration.

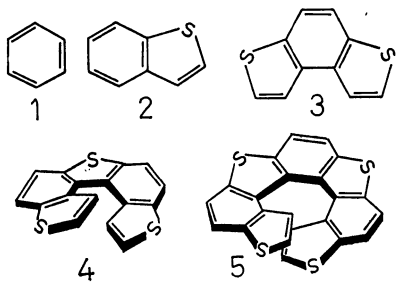
An NMR Study on the Association Stabilities of Thiaheterohelicenes against 7,7,8,8-Tetracyanoquinodimethan. Effect of the Staggered Configuration of Helicene

Hisao TANAKA, Hiroko NAKAGAWA, Koh-ichi YAMADA, and Hiroshi KAWAZURA*
Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02
(Received March 28, 1981)

In order to evaluate the influence of the staggered configuration of helicene on complex formation, a ^{1}H NMR technique was applied to the complexing equilibria of thiaheterohelicene homologs with 7,7,8,8-tetracyanoquinodimethan (TCNQ). Formation constants of the complexes showed irregular changes in the case of [5] and [7]-thiaheterohelicenes in which the staggerings occur. This irregularity could be interpreted on the basis of the observed abnormal decrease of the bonding entropy. The reduced bonding entropy was understood in terms of the incomplete quenching of internal freedom, which was expected from the peculiar orientation of the staggered thiaheterohelicene towards planar TCNQ in the charge-transfer complex.

To understand the molecular staggering due to the helical shape of helicenes, it will be useful to examine the thermodynamic stability of their charge-transfer (CT) complexes with an appropriate π-acceptor. In a series of studies[1-3] on thiaheterohelicenes with alternating thiophene and benzene rings, we have reported[1] that the thiaheterohelicene molecules act as π-donors to give the 1 : 1 CT complexes with a strong π-acceptor, 7,7,8,8-tetracyanoquinodimethan (TCNQ). Formation constants of the complexes, determined preliminarily by a Benesi-Hildebrand (B-H) treatment[4] on the CT-band intensities, were in the order of benzo[1,2-*b* : 4,3-*b'*]dithiophene (**3**)<[7]thiaheterohelicene (**5**)<[5]-thiaheterohelicene (**4**). This order was different from the ordinary trend in which formation constants in the complexes of cata-condensed aromatic donors increase with the number of aromatic rings. The reduced stability in the complex of [7]thiaheterohelicene has been considered to reflect its helical configuration, where two terminal thiophene rings are annularly overlapped.[5] However, it was difficult to inquire further into the thermal stabilities of the complexes, because of a lower degree of the accuracy of the formation constants which were determined by the B-H method on the weak CT absorptions.

A Hanna-Ashbaugh (H-A) treatment[6] on the ^{1}H NMR chemical shifts of interacting molecules was appropriate for the more exact determination of the formation constants and allowed us to estimate the enthalpy and entropy changes on complexation. This paper aims to clarify the steric effect caused by the staggering of helicene. The examination of thermodynamic parameters in the TCNQ complexes of thiaheterohelicene homologs: benzene (**1**), benzo[b]-thiophene (**2**), **3**, **4**, and **5** has led us to appreciate the importance of the entropy factor.



Experimental

Materials. Benzo[1,2-*b*: 4,3-*b'*]dithiophene(**3**), [5]-thiaheterohelicene(**4**), and [7]thiaheterohelicene(**5**) were synthesized[3,7] by photocyclization of the corresponding precursor olefins. Benzene-d_6 (**1**) and benzo[b]thiophene (**2**) were purchased from Merck Co. These compounds were purified as follows. **2** and **3** were column-chromatographed over alumina with hexane as an eluent, then sublimated under vacuum. **4** and **5** were also column-chromatographed over alumina with benzene, followed by recrystallization from benzene.

7,7,8,8-tetracyanoquinodimethan was purchased from Merck Co. and was purified by recrystallization three times from pure acetonitrile. 1,1,2,2-Tetrachloroethane-1,2-d_2 ($C_2D_2Cl_4$) used as an NMR solvent was of the spectroscopic grade (Merck; *Uvasol*).

Preparation and Measurement of NMR Samples. 1.77 mg of TCNQ crystals was dissolved in 3500 mm^3 of $C_2D_2Cl_4$ including a trace of tetramethylsilane (TMS). A 500 mm^3 portion of the solution was taken out with a micropipette (Gilson, Pipetman model P, $\pm$0.5% in error), and was put into each of the six 2000 mm^3-sample tubes containing various amounts (3—40 mg) of thiaheterohelicene which were weighed to a precision of 10^{-3} mg by a microbalance. After complete dissolution, a 400 mm^3 portion from each solution was transfered into a 5 mm-diameter NMR tube.

The ^{1}H NMR spectra of six samples thus prepared and of one sample containing only the TCNQ solution originally prepared were successively measured at a fixed temperature, then similarly measured at other temperatures. The measurements were done in the Fourier transform mode on a JEOL PFT-100 spectrometer operating at 100 MHz with an internal deuterium lock. 4096 or 8192 data points were taken over a 1 kHz spectral width at a tilt angle of 45°, repeated at 2.2 or 4.5 s intervals. The accumulation and data reduction of the NMR spectrum were performed on an EC-100 computer attached to the spectrometer. The error in reading the peak position of TCNQ protons was judged to be $\pm$0.3 Hz. The temperature of a given sample was regulated by a VT-3C variable temperature unit and was read from an Ohkura AM-1001 microvoltmeter connected to a copper–constantan thermocouple whose terminal was set in an NMR tube inside the probe. The temperature was constant within *ca.* 1 °C during each series of measurements.

Results

In the samples prepared, TCNQ was held at the low concentration of 2.5×10^{-3} mol/dm^3 to make sure that the amount of the thiaheterohelicene was in a large excess (10 to 100-fold excess to the amount of TCNQ),[8] which was requisite for an application of the H-A method. The ^{1}H NMR signal of TCNQ protons which was not hidden by the intense signals of thiaheterohelicene protons could be detected by 100—200 times of pattern accumulation. The observed signal moved noticeably to the up-field with an increase of the thiaheterohelicene concentration, as exemplified in the spectra of benzodithiophene (**3**)–TCNQ systems (Fig. 1). The net up-field shift $\Delta(=\delta_0-\delta)$, where δ and δ_0 are the chemical shifts of TCNQ protons in the complexing medium and in the uncomplexed state, respectively, was in close relation to the thiaheterohelicene concentration $[D]$, as shown by the fairly linear plots of Δ^{-1} *vs.* $[D]^{-1}$. This is seen in Figs. 2-A, B, and C for benzodithiophene (**3**)–TCNQ, [5]thiaheterohelicene (**4**)–TCNQ, and [7]thiaheterohelicene (**5**)–TCNQ systems, respectively. It is also seen from the figures that the intercepts of the plots at different temperatures show an excellent focussing.

Thus, the plots in Fig. 2 were analyzed by a least-squares method, using the H-A relation:[6]

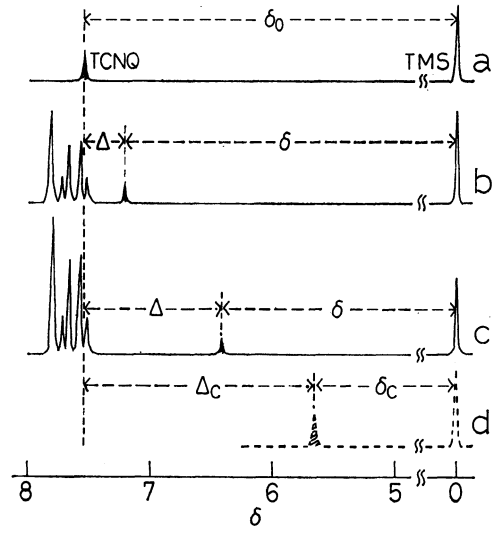


Fig. 1. ^{1}H NMR spectra of the complexing media of benzodithiophene(**3**)–TCNQ at 237 K and the definition of shifts, δ, δ_0, δ_c, Δ, and Δ_c. For $[A]=2.5\times10^{-3}$ mol/dm^3, a): $[D]=0$, b): $[D]=3.92\times10^{-2}$, c): $[D]=2.63\times10^{-1}$ mol/dm^3, d): extrapolated to $[D]=\infty$.

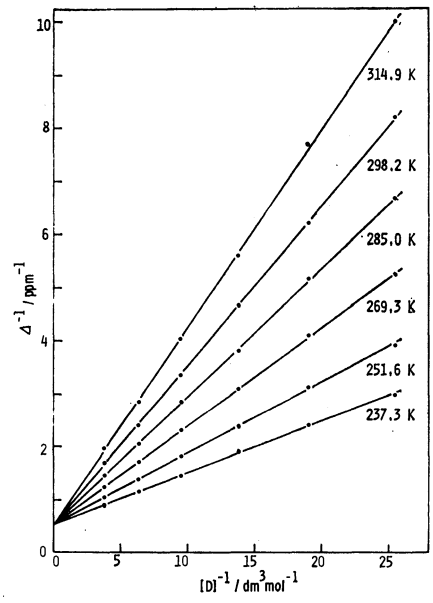

Fig. 2-A. Δ^{-1} *vs.* $[D]^{-1}$ plots for benzodithiophene(**3**)–TCNQ system; $[A]=2.5\times10^{-3}$ mol/dm^3 and $[D]=3.919\times10^{-2}$, 5.252×10^{-2}, 7.228×10^{-2}, 1.055×10^{-1}, 1.576×10^{-1}, and 2.627×10^{-1} mol/dm^3.

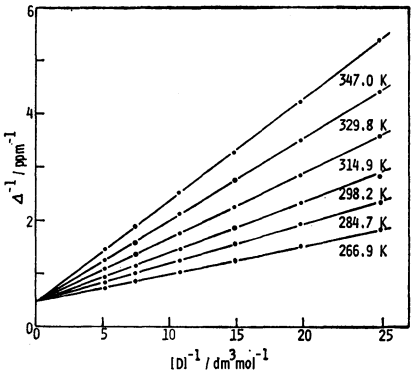

Fig. 2-B. Δ^{-1} *vs.* $[D]^{-1}$ plots for [5] thiaheterohelicene-(**4**)–TCNQ system; $[A]=2.5\times10^{-3}$ mol/dm^3 and $[D]=3.872\times10^{-2}$, 5.046×10^{-2}, 6.742×10^{-2}, 9.309×10^{-2}, 1.384×10^{-1}, and 1.945×10^{-1} mol/dm^3.

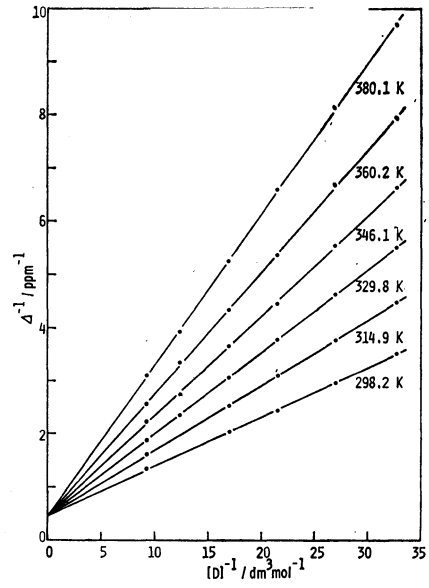

Fig. 2-C. Δ^{-1} *vs.* $[D]^{-1}$ plots for [7]thiaheterohelicene-(**5**)–TCNQ system; $[A]=2.5\times10^{-3}$ mol/dm^3 and $[D]=3.056\times10^{-2}$, 3.720×10^{-2}, 4.644×10^{-2}, 5.909×10^{-2}, 8.076×10^{-2}, and 1.085×10^{-1} mol/dm^3. The ^{1}H NMR signals of TCNQ for $[D]=8.076\times10^{-2}$ mol/dm^3 at 298.2 and 314.9 K were not observed because of overlapping with the donor signals.

a) The averaged probable error; 3.8% of Δ_c. b) 4.5% of K.

$$\Delta^{-1} = (K\cdot\Delta_C)^{-1}\cdot[D]^{-1} + \Delta_C^{-1} \quad (1)$$
$$K = [AD]/[A]\cdot[D] \quad (A+D=AD).$$

Here K is the formation constant for the molecular complex and $\Delta_c(=\delta_0-\delta_c)$ the Δ in the pure complex (Fig. 1). Table 1 lists the K and Δ_c values, together with the standard deviations (SD) of the least-squares calculations, for the TCNQ complexes of **1**—**5** at various temperatures. Those values for benzene-d_6 (**1**)–TCNQ and benzothiophene (**2**)–TCNQ systems were determined only at lower temperatures owing to the smaller up-field shifts of TCNQ protons.

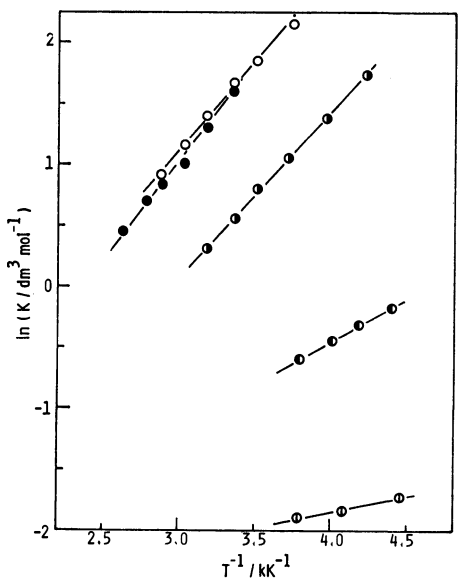

Fig. 3. Plots of ln K *vs.* T^{-1}. ◫): **1**–TCNQ, ◐): **2**–TCNQ, ◑): **3**–TCNQ, ○): **4**–TCNQ, ●): **5**–TCNQ.

Table 2. The enthalpy(ΔH) and entropy change(ΔS) in the complex formation

Complex	ΔH/kJ mol^{-1}	ΔS/J K^{-1} mol^{-1}
1–TCNQ	−2.0±0.8	−23.5±3.2
2–TCNQ	−5.7±0.5	−26.7±2.0
3–TCNQ	−11.2±0.2	−33.1±0.6
4–TCNQ	−11.7±0.5	−25.7±1.6
5–TCNQ	−13.0±0.4	−30.5±1.0

Figure 3 shows the plots of ln K to T^{-1}. The enthalpy (ΔH) and entropy changes (ΔS) collected in Table 2 were determined from the least-squares fitting of the plots to the van't Hoff equation:

$$\ln K = -(\Delta H/R)\cdot T^{-1} + \Delta S/R. \quad (2)$$

Discussion

Δ_c and K for the 1 : 1 Complex. The nice fit of the plots of Δ^{-1} *vs.* $[D]^{-1}$ to the H-A Eq. 1, which is judged from the small SD's in Table 1, allows us to assume[6,9] that only the 1 : 1 molecular complex is formed in the donor-acceptor equilibrium in the concentration range used for the present study. Table 1 also indicates that the intrinsic shifts Δ_c's for the 1 : 1 complex scatter independently of temperature and fall into a small range and that the averages are ordered as follows: 1.70 (**1**–TCNQ)< 1.79 (**2**–TCNQ) < 1.89 (**3**–TCNQ) < 2.12(**4**–TCNQ)<2.25 ppm(**5**–TCNQ). This ordering may be understood on the basis of the idea[10] that the shift Δ_c of TCNQ molecule facing the donor molecule is induced by the long range shielding due to the ring current which is accumulated with an increase of the number of rings of the donor. Thus, the parameter Δ_c exhibits a natural profile of the cata-condensed aromatic donors; however, it does not give a direct indication of the staggered configuration characteristic of helicenes.

On the other hand, an anomaly is observed for the association constants in the complex series: K's in $C_2D_2Cl_4$ at 25 °C are in the order of 0.13(**1**–TCNQ)< 0.41 (**2**–TCNQ) < 1.73 (**3**–TCNQ) < 4.85 (**5**–TCNQ) < 5.28 dm^3/mol(**4**–TCNQ), where the values for **1**–TCNQ[11] and **2**–TCNQ are obtained by extrapolating the van't Hoff plots in Fig. 3 to 298.2 K. We can note again a reduction of the K in **5**–TCNQ like that preliminarily found[1] from the B-H treatment of the CH_2Cl_2 solution. Interestingly, a similar result was also obtained[12] from a high performance liquid chromatography (HPLC) with a column of silica gel bonded with a strong π-acceptor, 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid (TAPA). The elution order of the donors was **1**, **2**, **3**, **5**, and **4** giving the inversion of **4** to **5**, contrary to the absence of inversion in the case which used a column of silica gel only. Evidently, the CT interaction between donor molecule

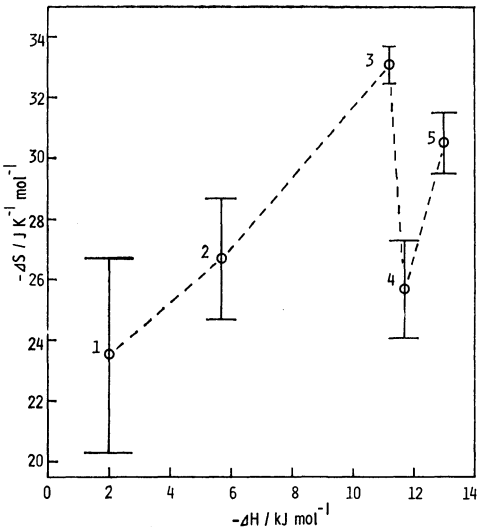

Fig. 4. Plots of $-\Delta S$ *vs.* $-\Delta H$. 1): **1**-TCNQ, 2): **2**-TCNQ, 3): **3**-TCNQ, 4): **4**-TCNQ, 5): **5**-TCNQ.

and fluorenylidene moiety of TAPA may produce this inversion. The inverse order is independent of solvent, detection method, or aromatic acceptor used, and so must be related to the inherently helical configuration of the donor.

ΔH and ΔS in the Complexation. Figure 4 shows the plots of $-\Delta H$ and $-\Delta S$ in the complex series. The enthalpy changes $-\Delta H$'s, *i.e.* bonding energies, tend to increase in the order of **1**, **2**, **3**, **4**, and **5**, although the increments among **3**, **4**, and **5** are smaller than those among **1**, **2**, and **3**. The above order may be interpreted in terms of the electron-donative abilities of the donors, which increase with ring accumulation. In fact, their ionization potentials[1] decrease in the same order as the above. As a result, the enthalpy changes suggest the effect of the staggering of **4** and **5**, but fail to explain the inversion in the K values.

The behavior of the entropy changes $-\Delta S$'s, *i.e.* degrees of bonding restriction, as seen in Fig. 4, is extraordinary: the $-\Delta S$ value reduces abruptly in the complex of **4** and still does not recover, in the complex of **5**, to the value in the complex of **3**. The inversion in the K values corresponds to the abnormal decrease of the $-\Delta S$.

It is known[13] that an increase of bonding energy causes an increase of bonding entropy in consequence of the stronger restriction between complexing species. This correlation may be valid in the case of absence of sterical hindrance, as demonstrated[13] in the iodine–alkylbenzene series. Indeed, the relation of the $-\Delta H$ and $-\Delta S$ among the complexes of planar molecules **1**, **2**, and **3** seems to follow the above general criterion. The abnormal decrease of the bonding entropy $-\Delta S$ in the complex of **4** should be a most direct proof for the existence of the sterical hindrance within the complex and certainly corresponds to the appearance of the staggered configuration in **4**, as revealed[2] by our X-ray structural analysis on the **4**-TCNQ complex. The change from **4** to **5** in Fig. 4 can be explained by the same criterion as in the case of **1**—**3**. This line of reasoning leads us to infer that a contribution of the staggering effect to the $-\Delta S$ approaches a limit against the ring accumulation, in so far as helicene and TCNQ molecules face each other.

Finally, we wish to comment on the decrease of bonding entropy, *i.e.* the gain of additional freedom, brought about by the staggering: the present complexes may be divided into two types with respect to the orientation manner of the donors towards planar TCNQ. In the complexes of planar **1**—**3**, the aromatic planes of donor and TCNQ molecules orient nearly parallel. But in the complexes of staggered **4** and **5**, both planes are much inclined[2] to each other. Hence the intensity distribution in the bonding interaction between aromatic planes is far from uniform. Thus, in the latter case, a possible displacement at the weakly interacting locus where both planes are widely separated may not change so steeply the total stabilization energy. This is a possible explanation for the existence of the additional freedom in the complexes of **4** and **5**, though the details must await an energy calculation of the complex system.

Here it should be noted that the staggering effect was visualized by looking not at the helicenes themselves, but at their molecular complexes. The influence of the staggering on the intramolecular properties; ionization potentials, transition energies,[14] and even spin densities of the radical anions[15] is not so easy to detect.

Redetermination of the Crystal Structure and the Electrical Resistivity of Rb-TCNQ-II

Hayao KOBAYASHI

Department of Chemistry, Faculty of Science, Toho University, Funabashi Chiba 274

(Received March 31, 1981)

The crystal structure of Rb-TCNQ-II was redetermined. The interplanar distance between the neighbouring TCNQ's is 3.25 Å, which is almost equal to those of highly conducting TCNQ salts. The electrical resistivity and the structure of the TCNQ columns suggest that the complete charge transfer in Rb-TCNQ-II makes this crystal low-conducting. The activation energy of the electrical conduction indicates that the dimerization gap appears below the monomer-dimer transition temperature. The temperature dependence of the electrical resistivities of Rb_2TCNQ_3 is also described.

Among the quasi-one-dimensional molecular crystals known at present, alkali metal salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) are of particular interest because of the simplicity of their crystal and electronic structures.[1] The crystal of Rb-TCNQ shows polymorphism. The crystal structure of Rb-TCNQ-II was reported eight years ago.[2] However, the recent studies of the crystal structures and the physical properties of alkali-TCNQ suggest that the reported interplanar distance of the TCNQ's of 3.43 Å in Rb-TCNQ-II is too long. Since the intensity data used in the previous work was not considered to be accurate enough,[3] the structure was redetermined on the basis of the newly collected intensity data.

Experimental

The crystals were prepared by a diffusion process of RbI and TCNQ in acetonitrile. All the crystals examined were twinned. The lattice constants were determined by means of a Rigaku automated four-circle diffractometer. The crystal data are:[4] $Rb^+(C_{12}H_4N_4)^-$, F.W.=289.6, triclinic, a=9.907(2), b=7.180(2), c=3.886(1) Å, α=88.55(2). β=86.86(2), γ=94.41(2)°, U=273.6(1) Å^3, d_c=1.757 g cm^{-3}, Z=1, space group $P\bar{1}$, $F(000)$=141, μ(Mo $K\alpha$)=45.5 cm^{-1}. The intensity data were collected with monochromated Mo $K\alpha$ radiation up to 2θ=60°. The crystal used had approximate dimensions of 0.3×0.23×0.07 mm^3. Of the 1718 accessible reflections, 1240 significant reflections were obtained ($|F_o| > 3\sigma(|F_o|)$).

Starting with the positional parameters previously obtained,[2] the structure was refined by the block-diagonal least-squares method. Since the twin ratio was not known, the scale factors of $|F(hkl)|$ were determined as: $S(l)\sum_{kh}|F_o(hkl)| = \sum_{kh}|F_c(hkl)|$, where $S(l)$ is the scale factor of the l-th layer (l=0, 1, 2, 3, 4, 5) and where $|F_o|$ and $|F_c|$ are the observed and calculated structure amplitudes respectively. The full-matrix least-squares refinement gave the following scale factors: $S(0)=0.846/\sqrt{2}$, $S(l)$=0.998—1.002 (l=1, 2, 3, 4, 5). The final R value was 0.059. The weighting scheme was: $w=1/[a+b|F_o|+c|F_c|^2]$ for $|F_o| \geqq 5.6$ (absolute scale), a=11.20, b=1.00, c=0.033; w=0.1 otherwise. The atomic coordinates are listed in Table 1.†

† List of the observed and calculated structure factors and tables of anisotropic thermal parameters for non-hydrogen atoms and atomic parameters for hydrogen atoms are kept at the Chemical Society of Japan as Document No. 8152.

TABLE 1. THE FINAL ATOMIC COORDINATES

The values for fractional coordinates are multipied by 10^4.

Results and Discussion

Figure 1 shows the crystal structure. The TCNQ's stack along the c axis to form monadic columns. There

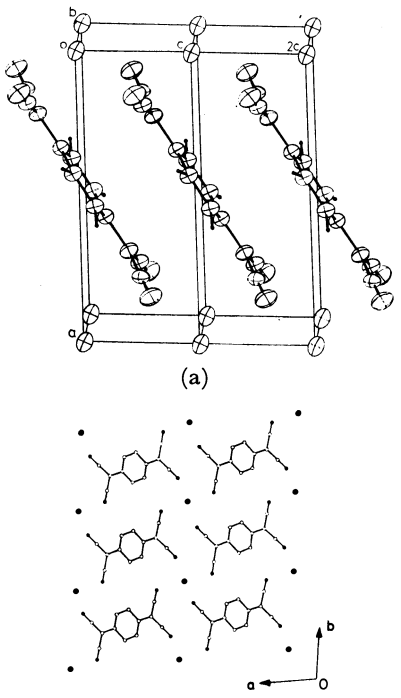

Fig. 1. (a) The crystal structure of Rb-TCNQ-II. (b) The molecular arrangement.

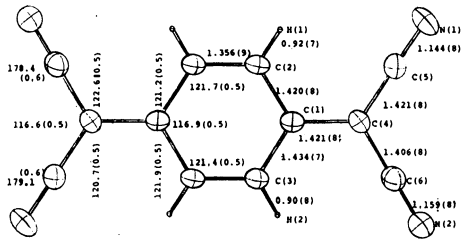

Fig. 2. The bond lengths and the bond angles of TCNQ with the standard deviations in parentheses.

are eight short contacts between Rb and the surrounding nitrogen atoms (≦3.27 Å). The shortest Rb···N distance is 3.052 Å. The bond lengths and the bond angles are shown in Fig. 2. The bond lengths agree well with those of the TCNQ anion[5] but significantly differ from those of neutral TCNQ:[6] the length of the C(1)-C(4) bond is 0.047 Å longer than the corresponding bond length of the neutral TCNQ molecule. The least-squares plane through TCNQ is: $-0.4973(X-0.5a)+0.1828(Y-0.5b)+0.8340Z=0.0$, where X, Y, and Z(Å) are the coordinates referred to the crystal axes a, b, and c respectively. The interplanar distance between adjacent TCNQ's of 3.248 Å is the shortest in alkali-TCNQ salts and almost equal to those of highly conducting salts: Na-TCNQ, 3.39 (80 °C);[7] K-TCNQ, 3.48 (120 °C);[8] NH_4-TCNQ, 3.31;[9] *N*-methylphenazinium-TCNQ (NMP-TCNQ), 3.25;[10] hexamethylenetetrathiafulvalene (2-(5,6-dihydro-4*H*-cyclopenta-1,3-dithiole-2-ylidene)-5,6-dihydro-4*H*-cyclopenta-1,3-dithiole)-TCNQ (HMTTF-TCNQ), 3.25;[11] quinolinium-TCNQ, 3.22;[12] acridinium-TCNQ, 3.26 Å.[13] As described in Ref. 2, the mode of overlap of TCNQ is of the "ring-external bond type" (see Fig. 3), which is found in every highly conductive TCNQ salts.[14]

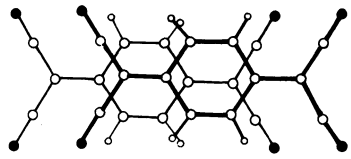

Fig. 3. The ring-external bond type overlapping in Rb-TCNQ-II.

Electrical Resistivities. The d.c. electrical resistivities of Rb-TCNQ-II were measured along the c-axis by the four-probe method (see Fig. 4). The room-temperature resistivity of 50 Ωcm is much smaller than those of the other alkali-TCNQ's,[14] which is consistent with the small intermolecular distance of Rb-TCNQ-II.

Although the structure of the TCNQ columns of Rb-TCNQ-II closely resembles those of NMP-TCNQ and HMTTF-TCNQ, the conductivities of NMP-TCNQ and HMTTF-TCNQ are four orderes of magnitude larger than that of Rb-TCNQ-II. This clearly shows the importance of the intramolecular Coulomb repulsion. Since the ρ of Rb-TCNQ-II is considered to be 1, Rb-TCNQ-II has a Coulomb gap at the Fermi wave number, k_F, where the ρ values of of NMP-TCNQ and HMTTF-TCNQ are 2/3[15] and

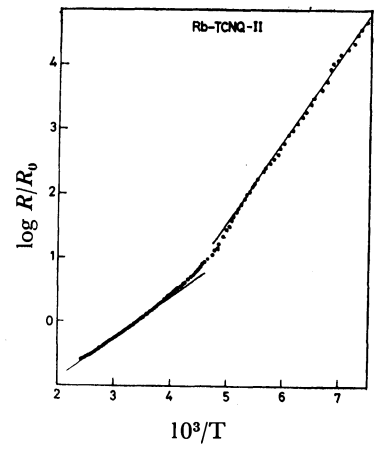

Fig. 4. The temperature dependence of the d.c. electrical resistivity of Rb-TCNQ-II.
The room-temperature resistivity R_0 is 50 Ω cm.

0.72[16] respectively. The importance of the Coulomb gap has been elucidated in a recent paper by Torrance *et al.*;[17] they thoroughly examined the physical properties of two isostructural HMTTF compounds, one metallic and the other insulating.

A change in the slope of the log R/R_0 *vs.* $1/T$ curve suggests a phase transition, which has been established by magnetic measurements (T_c=220 K).[18] X-Ray oscillation photographs taken around the needle axis showed the doubling of the lattice along the c axis below T_c. Therefore, the transition is a monomer-dimer (M-D) transition. It is well-known that the TCNQ columns in TTF-TCNQ and HMTTF-TCNQ exhibit $2k_F$ instability.[19,20] Although no long-range 3-D ordering is observed down to 20 K, a similar lattice modulation has been observed in NMP-TCNQ.[15] The $2k_F$-distortion in the crystals of organic metals arises from Peierls instability. On the other hand, the dimerization in alkali-TCNQ has been considered to be associated with the instability of the spin-Peierls type.[21] The transition temperatures (T_c) of some simple salts of TCNQ are plotted against the interplanar distances(d) in Fig. 5. Since the dimer structure of alkali-TCNQ

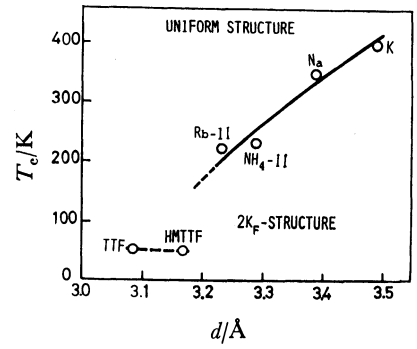

Fig. 5. The relationship between the interplanar distance of TCNQ's (d) and the phase transition temperature (T_c).
The thermal expansion of d was estimated by reference to the temperature dependence of the crystal structure of TTF-TCNQ (A. J. Schultz, C. D. Stuky, R. H. Blessing, and P. Coppens, *J. Am. Chem. Soc.*, **98**, 3197 (1976).

can be regarded as the $2k_F$-structure, the transitions presented in Fig. 5 are "uniform-$2k_F$ transitions." The M-D transition temperatures are almost linearly related to d. The nature of column instability appears to change around d=3.20 Å. Despite the close resemblance of the room-temperature structures of the TCNQ columns, the transition temperatures of Rb–TCNQ-II and HMTTF–TCNQ are quite different from each other.

The activation energies of the conductivities are 0.26 eV below T_c and 0.12 eV above T_c. The increase in the activation energy below T_c indicates the appearance of the dimerization gap. If the energy gap, E_g, is twice as large as the activation energy ($E_g=2E_a$), E_g is 0.24 eV. Since the Coulomb gap U ($\approx$1 eV[22]) is considered to be much larger than 0.24 eV, the conduction cannot be intrinsic.

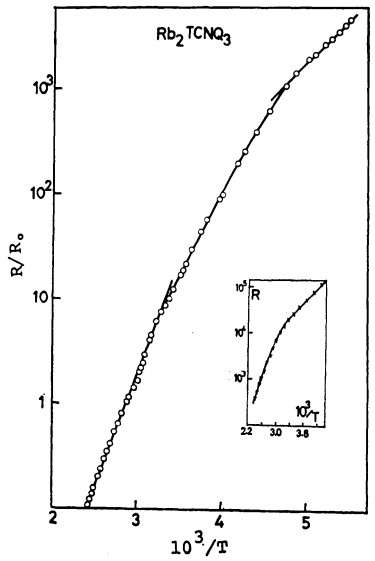

Fig. 6. The electrical resistivity of Rb_2TCNQ_3.
The diagram inserted is the resistivity by Lakhani and Hota (Ref. 23).

Recently, Lakhani and Hota have measured the electrical resistivity of Rb–TCNQ-II (see Fig. 6).[23] Their results are: (1) The room-temperature resistivity is 2×10^4 Ω cm. (2) Below room temperature, the conductivity is extrinsic and is due to the donor levels located 0.18 eV below the conduction band.[24] (3) Above 360 K, the intrinsic hole conduction becomes dominant where the activation energy is 0.44 eV. (4) The conductivity increases with the concentration of the impurity.

Since the room-temperature resistivity and the activation energies are quite different from those obtained by this work, and since their crystals have the form of a truncated pyramid while those used in this work were needle-shaped, the crystals used by Lakhani and Hota appear to be different from Rb–TCNQ-II. Figure 6 shows the resistivities of Rb_2TCNQ_3 measured along the most developed axis of the prismatic crystal ($//\boldsymbol{a}$), which is perpendicular to the TCNQ columns. The room-temperature resistivity is 10^5 Ω cm. E_a is 0.17 eV below 215 K and 0.43 eV above 310 K. Because

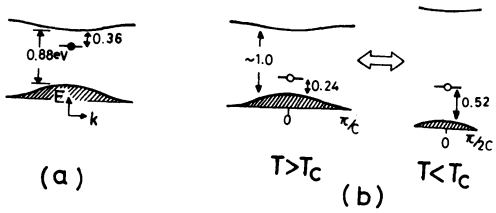

Fig. 7. Schematic representation of the energy-level diagram of Rb–TCNQ.
The intrinsic levels are presented as one-dimensional bands so as to indicate the doubling of the lattice constant at T_c. The band width and the dimerization gaps are assumed to be much smaller than 1 eV.
(a) The energy-level diagram of Rb_2TCNQ_3 based on the two carrier model by Lakhani and Hota (Ref. 23).
(b) The energy-level diagram of Rb–TCNQ-II.

these values agree well with those of Lakhani and Hota, their crystals are considered to be Rb_2TCNQ_3.

Based on the electrical resistivities and thermoelectric powers, Lakhani and Hota have proposed the two-carrier conduction model of Rb–TCNQ which is presented diagramatically in Fig. 7: donor levels are located 0.36 eV below the conduction band, and the band gap is 0.88 eV. Unlike as in the cases of Cs_2TCNQ_3[27] and Rb_2TCNQ_3, the thermoelectric powers of simple salts of alkali–TCNQ are positive ($T<$450 K), which indicates the hole conduction.[28] The activation energy of 0.12 eV ($T>T_c$) suggests that the impurity acceptor levels are located 0.24 eV above the filled band. Below T_c, the dimerization gap appears, which leads a slightly modified model of the energy diagram (see Fig. 7b). The magnitudes of the Coulomb gap and the band-width have been considered to be of the orders of 1 eV and 0.1 eV respectively. However, their precise evaluation will be required for the better understanding of the electrical properties of alkali–TCNQ.

A Study of the Electronic States of Iridium(III) Complexes Containing 1,10-Phenanthroline Ligands. The Contribution of a dd Excited State to the Lowest Triplet State

Yukako OHASHI*

The Institute of Physical and Chemical Research, Hirosawa, Wako 351

(Received April 17, 1981)

To investigate the solvent dependence of the dd contribution to the lowest excited state of *cis*-$[IrCl_2L_2]Cl$ (L=1,10-phenanthroline (phen) and 5,6-dimethyl-1,10-phenanthroline (5,6-Mephen)), the triplet-triplet absorption spectra (15000—25000 cm^{-1}) were measured in *N,N*-dimethylformamide (DMF)–water mixed solvents. From a smaller solvent-dependence of the absorption intensity for $[IrCl_2(5,6\text{-Mephen})_2]Cl$ than for $[IrCl_2(phen)_2]Cl$, the lowest triplet state of the former is considered to have a $\pi\pi^*$ character in 95% v/v DMF–water and 45% v/v DMF–water. However, in pure water a considerable decrease in the triplet-triplet absorbance was observed. Because the molar extinction coefficient of the triplet-triplet absorption of the dd-dd type is 10^{-2} times smaller than that of the $\pi\pi^*$-$\pi\pi^*$ type, the observed decrease in the absorbance is elucidated by the increase in the contribution of the dd state to the lowest triplet state. Using ethanol–methanol (4 : 1, v/v) as a solvent, it was confirmed that the triplet-triplet absorption spectrum shows no change when the solutions are degassed and the temperature is lowered (77 K).

Recently, several studies have been reported on the electronic character of the emitting state of *cis*-$[IrCl_2(phen)_2]Cl$, which is sensitive to the solvents, the temperature, and the methyl substitution of a ligand molecule.[1–5] This characteristic has been interpreted in terms of a change in the character of the lowest triplet state. In this complex, the lowest triplet state of the $d\pi^*$ (metal-to-ligand charge transfer) character and the lowest triplet state of the $\pi\pi^*$ (locally excitation of a ligand) character lie very close to each other. From the studies of the solvent effects on the energies and the lifetimes of the emission in alcoholic solvents at 77 K, Crosby *et al.* concluded that the emittive state is a state of a mixed character of $d\pi^*$ and $\pi\pi^*$, and that the contribution to the lowest triplet state of the two characters is affected by the environment.[1–3] On the other hand, Ballardini *et al.* studied the quantum yield of the photosubstitution reaction of a chloride ion for $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$ by using mixed solvents of DMF and water at room temperature.[6] They reported that the photochemical quantum yields depend on the solvents and the temperature in a very similar way for both complexes. Generally, the ligand substitution takes place through a dd excited state. Therefore, the observed change in the quantum yield reveals the close-lying dd excited state near the lowest triplet state. Recently, Watts *et al.* measured the weak emission of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$ at room temperature and reported the emission from a dd excited state, besides the emission from the $d\pi^*$-$\pi\pi^*$ mixed state previously reported.[5]

We previously measured the triplet-triplet absorption spectra of $[IrCl_2(phen)_2]Cl$ and the related complexes in DMF–water mixed solvents.[7] For these complexes, the relevant solvent effect on the triplet-triplet absorption spectrum was observed, and the changes were interpreted in terms of the decrease in the $d\pi^*$ component in the lowest triplet state with the increase in the solvent polarity. The excited-state absorption spectrum sharply reflects the character of the lowest excited state. Therefore, in the present work we investigated the dd contribution to the lowest triplet state of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$ using excited-state spectroscopy.

Experimental

Materials. *cis*-Dichlorobis(1,10-phenanthroline)iridium(III) chloride trihydrate, $[IrCl_2(phen)_2]Cl\cdot 3H_2O$, and *cis*-dichlorobis(5,6-dimethyl-1,10-phenanthroline)iridium(III) chloride trihydrate, $[IrCl_2(5,6\text{-Mephen})_2]Cl\cdot 3H_2O$, were prepared by following the procedure of Broomhead and Grumley.[8] After the yellow band has been eluted with 0.1 M HCl† from a cellulose cation-exchange column, the emission spectra of the eluted fractions were measured in ethanol–methanol (4 : 1, v/v) at 77 K. The fraction is considered to be pure when the emission decay is exponential and when the lifetimes monitored at 480 nm and 500 nm have the same value, because the by-product has its strong emission at a longer wavelength than that of pure $[IrCl_2(phen)_2]Cl$. Moreover, the emission in 95% v/v DMF–water was measured at 77 K and at room temperature and confirmed to give the same spectrum as a sample B, reported by Ballardini *et al.*[9] The *N,N*-dimethylformamide was of a spectroscopic grade, while the water was distilled four times.

Apparatus. The triplet-triplet absorption spectra were measured at room temperature and at 77 K using a nitrogen laser (Molectron UV24) as an exciting-light source and a pulsed xenon flash as a monitoring-light source.

Results and Discussion

Environmental Effect on the Triplet-Triplet Absorption Spectra. Figures 1 and 2 show the triplet-triplet absorption spectra of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$ at room temperature in the solvents of 95% v/v DMF–water (**1**), 45% v/v DMF–water (**2**), and water (**3**). The concentrations of the six complex solutions were adjusted to take the same optical density for the ground-state absorption at the wavelength of the exciting-light source (337 nm). The concentrations of the complex solutions used are $\approx 10^{-3}$ M. Since

† 1M=1 mol dm^{-3}.

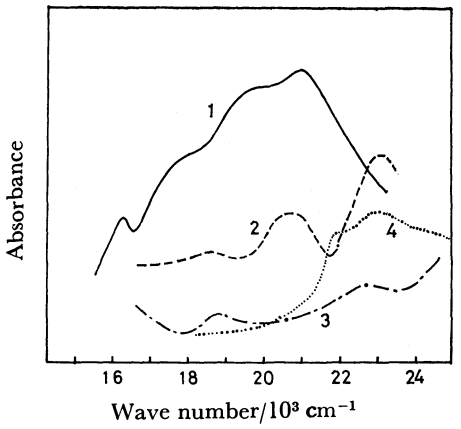

Fig. 1. Triplet-triplet absorption spectra at room temperature of $[IrCl_2(phen)_2]Cl$ in 95% v/v DMF–water (curve 1), in 45% v/v DMF–water (curve 2), in water (curve 3), and of phenathroline molecule in ethanol–methanol (4 : 1, v/v) (curve 4).

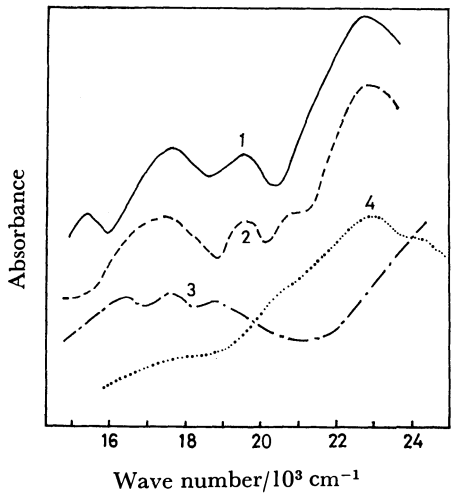

Fig. 2. Triplet-triplet absorption spectra at room temperature of $[IrCl_2(5,6\text{-Mephen})_2]Cl$ in 95% v/v DMF–water (curve 1), in 45% v/v DMF–water (curve 2), in water (curve 3), and of 5,6-dimethyl-1,10-phenanthroline molecule in ethanol–methanol(4 : 1, v/v) (curve4).

the two complexes show no fluorescence and contain a heavy atom (Ir^{3+}), the quantum yields of the intersystem crossing may safely be assumed to be very close to unity. Therefore, the concentrations of the singlet excited molecules populated by the laser radiation are assumed to be equal to that of the lowest triplet state. The absorbances of the six spectra (Curves 1—3 in Figs. 1 and 2) were measured under the same laser condition, so the changes in the absorbances correspond to the changes in the molar extinction coefficient of the triplet state. The absorbances of the free ligands in ethanol–methanol (4 : 1, v/v) are also shown in Figs. 1 and 2. The integrated absorbance of 5,6-Mephen is obtained to be larger by 1.5 times than that of phen.

At room temperature, the decay of the triplet-triplet absorption both of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$ is exponential in 95% v/v DMF–water and in ethanol–methanol (4 : 1, v/v). In 45% v/v DMF–water, it deviates slightly from exponential behavior, but no time-dependence of the triplet-triplet absorption spectrum was observed. In water, the decay is very rapid (τ=25 ns for the non-degassed solutions of both complexes), so that the deviation from the exponential decay is not clear. Since the dearation is not carried out for the DMF–water mixed solvents, the observed lifetimes at room temperature are shorter by 0.6—0.7 times than those of the degassed solutions obtained from the emission measurements.[6] The lifetime of a degassed ethanol–methanol (4 : 1, v/v) of $[IrCl_2(phen)_2]Cl$ is determined from the absorption decay to be 59 ns. After a long radiation of 337 nm light, a dark violet material was produced, even at 77 K, in all the solvents examined. However, the emission and the triplet-triplet absorption spectra of the photoproducts were not found.

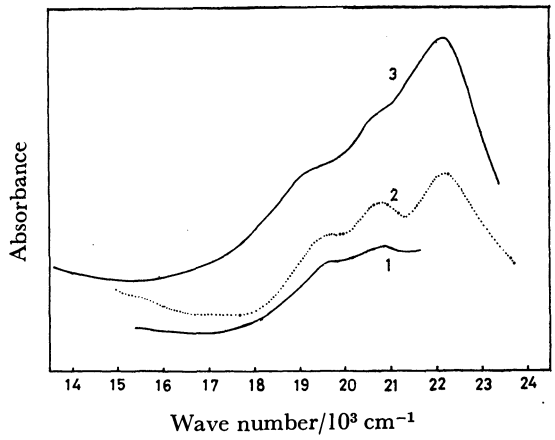

Fig. 3. Triplet-triplet absorption spectra of $[IrCl_2(phen)_2]Cl$ in ethanol–methanol(4 : 1, v/v) at room temperature (curve 1) and at 77 K (curve 2) in a degassed condition. Curve 3 is in a non-degassed ethanol–methanol(4 : 1, v/v) at room temperature. The sample concentrations of curves 1 and 2 are same but the correction of the volume contraction ($\times$0.80) was made for curve 2. The curve 3 is observed in a different concentration.

In order to examine the temperature effect on the triplet-triplet absorption spectrum, the measurements were carried out by using a degassed ethanol–methanol (4 : 1, v/v) solution of $[IrCl_2(phen)_2]Cl$ at 77 K and at room temperature (Fig. 3). The change in the absorption intensity and the spectrum is concluded to be insignificant between 77 K and room temperature after the correction for the volume contraction of the solvent. Over the range of 19500—21500 cm^{-1}, the emission is strong at 77 K, so that the correction was made for the emission contamination; the emission intensity is 1/4 of the decrease in the monitoring light by the absorption at the emission peak. From the comparison of the spectra of the non-degassed solution with that of the degassed solution (Fig. 3), no effect of the dearation on the spectra is observed at room temperature, but the triplet lifetime becomes longer upon dearation: 59 ns and 35 ns for the degassed and

the non-degassed solutions respectively. Therefore, the absorption spectra observed without dearation at room temperature can be assigned to the triplet-triplet transitions.

The Character of the Lowest Triplet State. With respect to $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$, recently two models were proposed for the electronic structure of the low-lying states. Model A assumes the close-lying dd state and the $d\pi^*$ (or $\pi\pi^*$) state to be thermally equilibrated at room temperature, while at a low temperature a barrier is assumed to exist between the two potential minima by virtue of a rigid matrix perturbation; the dd state lies 500 cm^{-1} below the lowest $d\pi^*$ state for $[IrCl_2(phen)_2]Cl$ and 100 cm^{-1} above the lowest $\pi\pi^*$ state for $[IrCl_2(5,6\text{-Mephen})_2]Cl$ in DMF.[5] The dd contribution to the emission is also determined by the use of the excitation and emission polarization spectra.[10] On the other hand, Model B gives a common interpretation for both $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-MePhen})_2]Cl$. It is proposed that a dd state lies close above the emitting state and that the energy separation between the two states decreases with the increase in the solvent polarity.[6,9]

In order to discuss the relation between the above two models and the present environmental effects of the triplet-triplet absorption spectra shown in Figs. 1—3, knowledge of the values of the molar-extinction coefficients of the triplet-triplet transitions (ε_{T-T}) is necessary. With respect to the $\pi\pi^*$-$\pi\pi^*$ transitions in the region of our experiments, the values of ε_{T-T} are evaluated to be in the order of 10^5 l/(mol cm) from the oscillator strengths calculated for free-lignad molecules: 0.2 for 1,10-phenanthroline and 0.4 for 2,2′-bipyridine.[7] The observed ε_{T-T} values for the ligands have not been reported, but the values for molecules with similar electronic structures have been reported:[11] for phenanthrene, ε_{T-T}=21000 l/(mol cm) at 20730 cm^{-1} and 41500 l/(mol cm) at 20410 cm^{-1}, and for biphenyl, ε_{T-T}=35400 l/(mol cm) at 27700 cm^{-1}. From these values, ε_{T-T} of the $\pi\pi^*$-$\pi\pi^*$ transitions are estimated to be of the order of 10^4—10^5 l/(mol cm), assuming the perturbation by the complex formation to be not very large. On the other hand, because the dd-dd transitions are generally weak due to a symmetry-forbidden property, ε_{T-T} is estimated to be of the order of 10—10^2 l/(mol cm), like the ε_G of the ground-to-dd transition, which is 10^2 l/(mol cm) for $[RhCl_2(phen)_2]Cl$[12] and 50 l/(mol cm) for $[IrCl_2(en)_2]Cl$ (en=ethylenediamine).[12] The intensity for the $d\pi^*$-$d\pi^*$ transitions becomes large only when the d orbital for the initial and the final states is common. Since the $d\pi^*$-$d\pi^*$ transition energy can be estimated roughly from the difference in the π^* orbital energies (e_j; j=8—14), the transition energies and the oscillator strengths shown in Table 1 are obtained from the SCF calculation of a free 1,10-phenanthroline. The $d\pi^*$ transition from a d orbital to the antibonding π^* orbital j is described as (d-j). The lowest $d\pi^*$ state, (d-8), degenerates almost to the (d-9) state. Therefore, we assigned the lowest $d\pi^*$ state to $1/\sqrt{2}\{(d\text{-}8)+(d\text{-}9)\}$. Then, the oscillator strengths of the $d\pi^*$-$d\pi^*$ transitions are calculated by means of the following equations:

$$f_j = 1.085 \times 10^{11}\,\sigma_j\,Q_j^2 \quad (\sigma_j \text{ in } cm^{-1} \text{ and } Q_j \text{ in cm})$$

$$Q_j = \int 1/\sqrt{2}\{(d\text{-}8)+(d\text{-}9)\}\,r(d\text{-}j)\,dv$$

$$\sigma_j = e_j - 1/2(e_8 + e_9).$$

From the calculated results, the transitions to be observed in the present measurement are the transitions to (d-11) or (d-12). Therefore, their oscillator strengths are of the same order as those of the $\pi\pi^*$-$\pi\pi^*$ transitions. Judging from the above-mentioned estimation, the ε_{T-T} of the dd-dd transition seems to be smaller by 10^2—10^4 than those of the $d\pi^*$-$d\pi^*$ and the $\pi\pi^*$-$\pi\pi^*$ transitions, so that the increase in the dd component in the lowest tripiet state causes a distinct intensity decrease in the triplet-triplet absorbances.

By the use of Model A, for $[IrCl_2(phen)_2]Cl$ the population ratio of $d\pi^*$ to dd states is estimated as 1/9 at 300 K, based on the reported dd-$d\pi^*$ separation (500 cm^{-1}). However, at 77 K a selective internal conversion is assumed to occur to the lowest $d\pi^*$ state after the excitation to the higher $\pi\pi^*$ state, so that a large increase in the population ratio results.[5] According to this scheme, the triplet-triplet absorbance should show a distinct increase with the temperature decrease. However, as may be seen in Fig. 3, the triplet-triplet absorption spectra at 77 K and at room temperature show no significant change in either the intensity or the peak position in ethanol–methanol (4 : 1, v/v). As far as the triplet-triplet absorption is concerned, the effect of the dd population was not observed at room temperature in this solvent, so that the lowest triplet state can be assigned to a $d\pi^*$ state, as was previously assigned.[2] Since the **1** solvent has a dielectric constant (39) similar to that (26) of the above solvent, and since we observed that the absorption spectra and intensities of the triplet-triplet transitions of the two solvents resembles each other, it is reasonable to make the same assignment for the complex in the **1** solvent.

Mechanism of Solvent Effect for $[IrCl_2(5,6\text{-Mephen})_2]Cl$. In a previous work, the present author suggested that the $\pi\pi^*$ character in the lowest triplet state increases considerably in water for $[IrCl_2(phen)_2]Cl$.[7] As may be seen in Fig. 1, this assignment is confirmed by the resemblance of the triplet-triplet absorption spectra of the complex in water and those of a free 1,10-phenanthroline.

The 5,6-dimethyl substitution of a 1,10-phenanthroline lowers the energy of the lowest $\pi\pi^*$ transition by 1500 cm^{-1} in ethanol–methanol (4 : 1, v/v) at 77 K.

Table 1. Transition energy and oscillator strength of the $d\pi^*$-$d\pi^*$ transition of $[IrCl_2(phen)_2]Cl$

Excited state	Transition energy σ_j/cm^{-1}	Oscillator strength
(d-8)	0	
(d-9)	81	
(d-10)	10500	0.05
(d-11)	13600	0.1
(d-12)	20200	0.1
(d-13)	30200	0.02
(d-14)	40300	0.007

Moreover, the emission energy does not show a solvent dependence, so that the lowest triplet state of $[IrCl_2(5,6\text{-Mephen})_2]Cl$ was assigned to a $\pi\pi^*$ state in alcoholic solvents at 77 K, independent of the solvent polarity.[2] Figure 2 shows that the intensity change of the triplet-triplet transition is small with respect to the spectra for **1** and **2** solvents, in contrast to the spectra of $[IrCl_2(phen)_2]Cl$. Consistent with the expectation from the assignment, the spectra for the two solvents resemble that of a free ligand (Fig. 2). The small intensity difference between the two solvents may be attributed to the change in the $d\pi^*$ component in the lowest triplet state. For this complex also, it has been reported that the lifetime changes from 66.3 μs to 236.1 μs at 77 K, but the emission energy does not change with the increase in the solvent dielectric constant (25—61).[2] Since the extent of the change in the lifetimes is comparable with that of $[IrCl_2(phen)_2]Cl$ (6.95—20.1 μs under the same conditions), the contribution of the $d\pi^*$ state to the emitting state can not be overlooked. Therefore, it is proposed that the lowest triplet state can be assigned to a $\pi\pi^*$ state with a small $d\pi^*$ component.

Considering the solvent dependence of the triplet-triplet absorption spectra,[7] the ground-state absorption spectra,[6] and the low-temperature emission energies[2] of $[IrCl_2(phen)_2]Cl$ and $[IrCl_2(5,6\text{-Mephen})_2]Cl$, the energy of the $d\pi^*$ transition is confirmed to shift to the higher energy side with the increase in the solvent polarity. Therefore, the character of the lowest triplet state should be mainly of the $\pi\pi^*$ character in water, so far as the contribution of the $d\pi^*$ and $\pi\pi^*$ states is concerned. However, as may be seen in Fig. 2, the absorbance in water shows a considerable decrease. This contradiction can be interpreted by means of Model B, which assumes the dd state to lie close above the emitting state and the energy separation to change with the solvent polarity. In the **1** and **2** solvents, the dd-$\pi\pi^*$ energy separation is large, but in water it becomes so small that the thermal distribution to the dd state causes a decrease in the triplet-triplet absorbance. With respect to $[IrCl_2(phen)_2]Cl$, it may be considered that the intensity decrease in water is attributed partially to the increase in the dd component in the lowest triplet state, besides to the increase in the $\pi\pi^*$ component. Since the emission energy of $[IrCl_2(5,6\text{-Mephen})_2]Cl$ is almost independent of the solvent polarity,[2] it may be suggested that the solvent shift of the dd state plays an important role and may be almost comparable to the small energy separation. This conclusion is reasonable because the dd transitions are generally sensitive to the environment, and the energy separation is suggested to be smaller for $[IrCl_2(5,6\text{-Mephen})_2]Cl$ than for $[IrCl_2(phen)_2]Cl$, judging from the work on photosubstitution.[6] For $[IrCl_2(5,6\text{-Mephen})_2]Cl$, Model A does not involve a knowledge of the solvent dependence of the dd-$\pi\pi^*$ energy separation, so the relation to the observed solvent dependence can not be discussed. From the above-mentioned discussion, it may be concluded that, in the polar solvents, the contribution of the dd state to the lowest triplet state can not be disregarded. The relevant evidence showing that the dd state is the lowest at room temperature for $[IrCl_2(phen)_2]Cl$ was not obtained using the technique of the triplet-triplet absorption measurements. However, the fact that the emissions in several solvents deviate from the exponential behavior shows some complicated interaction with the environment.

The formation of a photoproduct is inevitable in the photophysical experiment of the metal complexes. When the lowest excited state is of the $d\pi^*$ or $\pi\pi^*$ character in the complex molecule and of the dd character in the photoproduct, the triplet-triplet absorption measurement is a very adequate method to study the excited states of the complex, for it is not disturbed by the photoproduct.

The author is grateful to Professor Saburo Nagakura of The Institute for Solid State Physics and the Institute of Physical and Chemical Research for his support and valuable suggestions.

The Cadmium-photosensitized Reaction of Saturated Tertiary Amines

Shunzo YAMAMOTO,* Masae YASUNOBU, and Norio NISHIMURA

Department of Chemivtry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received April 18, 1981)

Rate constants for the quenching of the cadmium resonance line at 326.1 nm by triethylamine (TEA), *N*-ethylpiperidine (NEP), and 1-azabicyclo[2.2.2]octane (ABCO) were obtained. Relative rate constants for the formation of an exciplex between an excited cadmium atom and these amines and quantum yields for the emission from the exciplex were also obtained. Contrary to the case of primary amines, in which the electron-donating ability of the nitrogen atom is operative, the exciplex formation in the present case is mainly governed by the magnitude of the steric effect of ethyl groups on the interaction between the nitrogen atom and an excited cadmium atom. Gaseous products were hydrogen, methane, ethane (and/or ethylene), and butane. The quantum yields of these products indicate that the primary photochemical products are methyl and ethyl radicals for TEA and NEP. The amount of products for ABCO was considerably smaller than those for other amines.

In the cadmium-photosensitized reaction of saturated amines, the quenching of the resonance line at 326.1nm and the exciplex emission have been discussed in previous papers in terms of the following reactions:[1)]

$$Cd + h\nu(326.1) \longrightarrow Cd(^3P_1), \quad (1)$$

$$Cd(^3P_1) \longrightarrow Cd + h\nu(326.1), \quad (2)$$

$$Cd(^3P_1) + M \rightleftharpoons Cd(^3P_0) + M, \quad (3), (-3)$$

$$Cd^* + A \longrightarrow \text{quenching}, \quad (4)$$

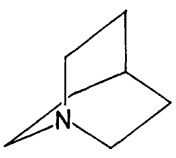
$$Cd^* + A \longrightarrow CdA^*, \quad (5)$$

$$CdA^* \longrightarrow Cd + A + h\nu_e, \quad (6)$$

$$CdA^* + M \longrightarrow Cd + A + M. \quad (7)$$

Here, Cd* represents $Cd(^3P_1)$ and $Cd(^3P_0)$, and CdA* is an exciplex between Cd* and amines. A represents the amine and M stands for a third body. In general, the rate constant for Reaction 5 increases with a decrease in the ionization potential of amines, and for primary amines there is a good correlation between the rate constant and the ionization potential.[2)] The rate constants for secondary and tertiary amines are, however, somewhat smaller than the values predicted from the correlation mentioned above. It has been pointed out that the reactivity of amines is mainly governed by the electron-donating ability of the nitrogen atom, but partly by some other factor which supresses the formation of the exciplex in the cases of secondary and tertiary amines. This additional factor was attributed to the steric effect of the alkyl groups.[3)] It seems to be necessary to examine decomposition processes which compete with the exciplex formation. In the cadmium-photosensitized reaction of amines, however, products have not been yet reported.

In this study, in order to examine the influence of structural properties on the cadmium-photosensitized reaction of amine, we measured the quenching efficiency and the quantum yields for the exciplex emission and for the products of three saturated tertiary amines (TEA, NEP, and ABCO) which are considered to have different steric hindrances around the nitrogen atom.



ABCO

Experimental

The apparatus and the procedure for measuring the emissions (resonance line at 326.1 nm and exciplex emission) were the same as those described previously.[4)] The measurements were done at 220±1 °C.

A Pyrex reaction cell used for measuring the product yields was 20.0 cm long and 2.2 cm in diameter, with a total volume, including access tubing, of about 86 cm^3. It was inserted in an electric furnace kept at 250±1 °C. A hand-made cadmium discharge lamp (filled with *ca.* 2 Torr argon, 1 Torr =133.32 Pa) made of Pyrex was also placed in the same furnace.

Reaction products were analyzed by means of a gas chromatograph using a column of 5 m VZ-7 (Gasukuro Kogyo Co., Ltd.) at 0 °C. In this column, we could not separate ethane from ethylene. The amounts of gases which are noncondensable at 77 K were determined volumetrically by a Toepler pump. The light intensity absorbed by cadmium atoms was estimated by using the *cis-trans* isomerization of *cis*-2-butene as an actinometer.

Cadmium metal used was high-purity grade (99.9999%) manufactured by the Osaka Asahi Metal Co. Ethylamine (EA), Diethylamine (DEA), TEA, piperidine (P), and NEP (G.R. grade) were used after drying over calcium hydride and repeated trap-to-trap distillation. ABCO·HCl was purchased from Pfaltz and Bauer, Inc. The free base was liberated by combining very concentrated ABCO·HCl and NaOH aqueous solutions. This solid amine was filtered and sublimed *in vacuo* through a layer of anhydrous BaO.

Results

In Fig. 1, the emission bands obtained for the cadmium-photosensitized reaction of TEA, NEP, and ABCO are shown. The band for ammonia is also shown for comparison. The quantum yields of the emission for TEA, NEP, and ABCO were determined by comparing the integrated intensities of the emission band with that for ammonia (whose emission quantum yield is known) under the same conditions. The values of quantum yields were found to be almost independent of amine pressure (0.1—1.2 Torr for TEA and NEP, and 0.1—2.0 Torr for ABCO) and argon pressure (50—200 Torr). The average values are listed in Table 1, together with the wavelengths at the peak of the emission bands.

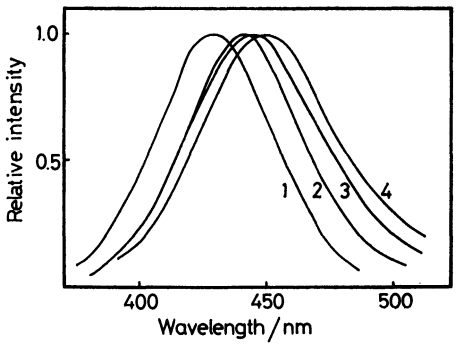


Fig. 1. Emission band contours for NEP (1), TEA (2), and ABCO (3). The curve for NH_3 (4) is derived from Ref. 5.

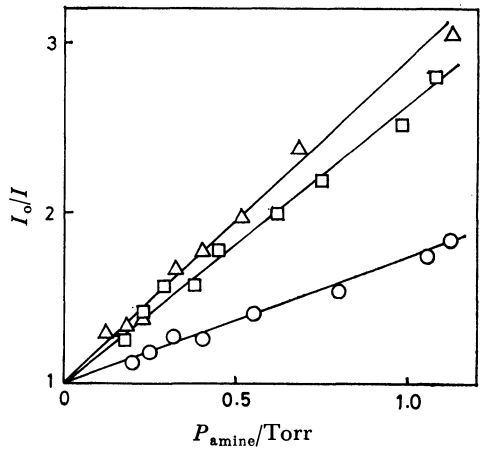

Fig. 2. Stern-Volmer plots for the quenching of the resonance line at 326.1 nm by TEA (□), NEP (△), and ABCO (○).

In order to estimate the efficiency of the quenching of the 326.1 nm resonance line, its emission intensity was measured as a function of the pressure of substrates. The Stern-Volmer plots are shown in Fig. 2, where I_0 and I are the intensities of the resonance line in the absence and in the presence of the substrates, respectively. Half-quenching pressures obtained from the slopes of the straight lines in Fig. 2 are listed in Table 2.

a) Uncertainties in quantum yields, except for hydrogen, are within 5%. b) Pressure of amines was 30 Torr. c) $\phi_d=\phi_{CH_4}+\phi_{C_2H_6}+2\phi_{C_2H_4}$.

The pressure dependence of the intensity at the peak of the emission band (which was expressed on the basis of that at 430 nm for Cd*-NH_3 system) is shown in Fig. 3. The emission intensities were independent of argon pressure.

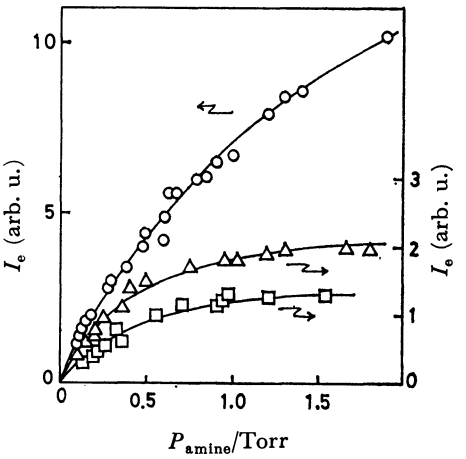

Fig. 3. The intensity at the peak of the emission band from the exciplex as a function of the pressures of TEA (□), NEP (△), and ABCO (○).

Quantum yields of products in the cadmium-photosensitized reaction of saturated amines are summarized in Table 3. In order to check the thermal reaction and the direct photolysis, 30 Torr of the amine was kept in the cell at 250 °C for a few hours in the absence of cadmium under irradiation of the 326.1 nm cadmium resonance line. No decomposition was detected for any amine. The light intensity absorbed by cadmium atoms was estimated to be 0.26×10^{-6} Einstein min^{-1}.

Discussion

In previous papers,[1] the quenching of the resonance line and the exciplex emission were explained according to Reactions 1—7. Because the equilibrium between $Cd(^3P_0)$ and $Cd(^3P_1)$ is easily established under the present experimental conditions,[6] we cannot discriminate the reactions of these two states.

A steady-state treatment leads to the following equation:

$$I_0/I = 1 + k_q[A]/k_2. \quad (8)$$

Here, I_0 and I represent the intensities of the resonance line (defined as $k_2[Cd(^3P_1)]$) in the absence and in the presence of amines respectively; k_q is the composite quenching rate constant: $k_q=k_4+(k_3/k_{-3})k_4'+k_5+(k_3/k_{-3})k_5'$ (k_4 and k_5 are rate constants for Reaction 4 and 5 in the case of $Cd^*=Cd(^3P_1)$ and k_4' and k_5' are those in the case of $Cd^*=Cd(^3P_0)$); $(k_3/k_{-3}=1.68$ at 220 °C). The Stern-Volmer plots in Fig. 1 are expressed by this equation. As was mentioned in previous papers,[1,6] the effective lifetime is almost independent of the pressure of foreign gases in the range we were studying. Therefore, k_2 may be set equal to $1/\tau_0$ (τ_0 is the natural lifetime of $Cd(^3P_1)$ and has been reported to be 2.39×10^{-6} s[7]). From the half-quenching pressure, the values of k_q can be estimated; they are listed in Table 4, together with those for some primary and secondary amines. As is shown in Table 4, the values of k_q for tertiary amines are smaller than those for primary and secondary amines. This tendency has been explained in terms of the steric hindrance of the alkyl groups.[4]

Table 4. The rate constants for the quenching of the resonance line and for the exciplex formation

ABCO	1.6±0.1	13.8	776.6

a) Ref. 4. b) Ref. 8. c) Value for *N*-methylpiperidine.

The steady-state treatment leads to the following equation for the intensity of the exciplex emission:

$$I[A]/I_e = \alpha(k_2/k_5)(1 + k_7[M]/k_6), \quad (9)$$

where I_e is the emission intensity at the peak of the band and I is the intensity of the resonance line at the same pressure of amines; α is the proportional factor between I_e and the total emission intensity. From the pressure dependence of the intensity at the peak of the emission band, relative values of k_5 have been estimated by the method described previously,[3,4] and are listed in Table 4.

In general, the rate constant for the exciplex formation increases with a decrease in I_p values of amines.[2] In the present case, the values of k_5 increase in the order: TEA<NEP<ABCO. This order is not in agreement with the order of the decrease in I_p. TEA is "flexible" in the sense that its ethyl groups hinder the access of the excited cadmium atom to the nitrogen atom. Meanwhile, ABCO is a rigid, bicyclic amine having bridgehead nitrogen atom and is little sterically hindered. Among these amines, if the steric effects overwhelm other factors affecting k_5, the smallest value of k_5 for TEA and the largest value for ABCO could be ascribed to the steric effects.

As mentioned above, the quantum yields of the emission for three tertiary amines are almost independent of amine and argon pressures, indicating that the exciplexes are little quenched by amine and argon. As ABCO has the largest quantum yield of the emission, we assumed that $\phi_e=k_5/k_q$ for ABCO. This indicates that the quantum yield of the emission is determined by the ratio of the rate constant (k_5) for the exciplex formation to the overall quenching rate constant (k_q). We obtained the value of k_5 (1.40×10^{-11} cm^3 molecule^{-1} s^{-1}) for ABCO by the observed values of ϕ_e and k_q. Further, we obtained the values of k_5 for other amines by using the relative values of k_5 shown in Table 4; these values are shown in Table 5. In Table 5, the values of k_5/k_q are also shown. These values are in fair agreement with the experimental values of ϕ_e. This indicates that the above assumption is valid for all these amines. Practically all of the exciplexes formed decay out through the emission process, that is, neither unimolecular decomposition nor a bimolecular quenching of the exciplex occurs.

Table 5. The values of k_5, k_5/k_q, and ϕ_r

ABCO	1.40	0.87	0.87	0.10

a) Ref. 4.

As is shown in Table 3, gaseous products in the cadmium-photosensitized reaction of the saturated amines studied are hydrogen, methane, ethane (and/or ethylene), and butane. It has been reported that in the direct photolysis of TEA,[9] the primary products were hydrogen molecule and methyl and ethyl radicals produced from an excited TEA molecule and that from these radicals methane, ethane, ethylene, propane, and butane were formed. It is reasonable that, in the cadmium-photosensitized reaction of TEA, methyl and ethyl radicals are also precursors of products: methane, ethane, ethylene, and butane are produced *via* processes of hydrogen atom abstraction from amines, disproportionation, and recombination.

In the case of quenching of $Cd(^3P_{0,1})$ by alkane hydrocarbons, it has been pointed out that direct abstraction of a hydrogen atom to form CdH is a major quenching pathway. The quenching cross sections have been explained by assuming an additive cross section for each C–H bond of 1×10^{-5} nm^2, irrespective of type of C–H bond.[10] From the quenching cross section (4×10^{-3} nm^2) and the quantum yield of hydrogen (0.014) in the cadmium-photosensitized reaction of ammonia, the cross section corresponding to an abstraction of hydrogen atom for each N–H bond is similarly calculated to be about 1×10^{-5} nm^2. The quenching cross sections for the abstraction of hydrogen atom from saturated amines can be calculated by using these values. For example, the values for TEA, NEP, and ABCO are about 1.5×10^{-4}, 1.5×10^{-4}, and 1.3×10^{-4}

nm^2, since TEA, NEP, and ABCO have 15, 15, and 13 C–H bonds respectively. From these values and the overall quenching rate constants, the quantum yields of hydrogen (ϕ_{H_2}) for TEA, NEP, and ABCO are estimated to be 0.002, 0.002, and 0.004 respectively. These values are listed in Table 3, together with the values for other amines. The values of ϕ_{H_2} estimated for all amines investigated here are very small. The quantum yield of methane (ϕ_{CH_4}) are calculated by subtracting ϕ_{H_2} from $\phi_{H_2+CH_4}$. For P and ABCO, ϕ_{CH_4} is very small, as expected from molecular structure.

In the cadmium-photosensitized reaction of amines, the primary processes are expressed by the following reactions;

$$Cd^* + A \longrightarrow CdA^*, \quad (5)$$
$$\longrightarrow CdH + R, \quad (10)$$
$$\longrightarrow Cd + CH_3 + A', \quad (11)$$
$$\longrightarrow Cd + C_2H_5 + A'', \quad (12)$$
$$\longrightarrow Cd + \text{biradical}, \quad (13)$$
$$\longrightarrow Cd + A. \quad (14)$$

Reaction 10 indicates a hydrogen atom abstraction by excited cadmium atom from C–H or N–H bond of amines and Reaction 14 indicates a physical quenching process. A′ and A″ in Reactions 11 and 12 indicate the moieties of methyl and ethyl radicals respectively. In the cases of cyclic amines, the formation of biradical must be taken into account (Reaction 13). Reactions 10—14 are included in Reaction 4. In the cases of P and ABCO, Reactions 11 and 12 rarely occur.

The relative values of ϕ_d (defined as $\phi_d=\phi_{CH_4}+\phi_{C_2H_4,C_2H_6}+2\phi_{C_4H_{10}}$; it can be regarded as equal to the sum of initial quantum yields of methyl and ethyl radicals) are 1.00, 2.06, 3.09, and 0.83 for EA, DEA, TEA, and NEP. This ratio is almost the same that of the number of ethyl groups. This suggests that the reasoning that methane, ethane (and/or ethylene) and butane are primarily produced from methyl and ethyl radicals is valid. The values of ϕ_d for tertiary amines decrease in the order; TEA>NEP>ABCO. This decreasing order is in agreement with the increasing order of the emission quantum yield. It is difficult to explain the way by which methyl and ethyl radicals are produced for P and ABCO. In these cases the origin of products remains an open question.

The ratio of recombination to disproportionation of ethyl radicals has been reported to be about 7.4.[11] As is shown in Table 3, however, the ratios of the yields of butane to those of ethane (ethylene) are about 0.15—0.18 for EA, DEA, and TEA. This indicates that ethane is formed exclusively by the abstraction of a hydrogen atom from amines.

The contribution (ϕ_r) of Reactions 14 and/or 13 to the overall quenching processes is estimated by $\phi_r=1-(\phi_e+\phi_d+\phi_{H_2})$. The values of ϕ_r are listed in Table 5. For TEA, as Reaction 13 does not occur, the value of ϕ_r indicates the contribution of the physical quenching process; it is about one-third of the total quenching. On the other hand, in the case of NEP, both Reactions 13 and 14 contribute to the overall quenching processes. If the physical quenching process is almost the same for NEP and TEA, the difference in ϕ_r between NEP and TEA indicates the quantum yield for Reaction 13; it is 0.33. This value is about twice as much as ϕ_d for NEP; the difference is attributed to the number of bonds to be broken. Reaction 13 seems to be responsible for the large difference in ϕ_d between TEA and NEP. The same thing seems to hold between DEA and P. For ABCO, however, the quantum yields for processes other than the exciplex formation are very small. On the other hand, it has a large quantum yield for the emission (the largest value of those reported to date). That is, the quenching by ABCO can be concluded to occur overwhelmingly through the exciplex formation.

Kinetics and Mechanism of 1,4-Cycloaddition between Tetracyanoethylene and Styrenes. II.[1] Effect of Para Substituents

Yasuhiro UOSAKI, Masaru NAKAHARA,* and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received April 24, 1981)

The 1,4-cycloaddition of TCNE to *p*-methyl-, *p*-chloro-, and *p*-bromostyrenes by way of the EDA complex has been studied in chloroform at 25 °C by the spectrophotometric method. The Hammett correlation obtained from the kinetic data provides -5.5 ± 0.2 as the reaction constant ρ. The negative value is large in magnitude relative to other common 1,4-cycloadditions, suggesting some large partial charges in the rate-determining transition state. A linear correlation between the logarithmic forms of the reaction rate and the EDA-complex formation constant is in favor of the reaction scheme where the complex is on the pathway of the cycloaddition.

The 1,4-cycloadduct of tetracyanoethylene (TCNE) with styrene and its derivatives has been discovered in solution by the low-temperature ^{13}C NMR technique combined with a high-pressure quenching method.[2] The effect of α-substituents on the 1,4-cycloaddition has been discussed in detail in a previous paper; a polar transition state is suggested based on the α-substituent effect.[1] The electronic effect of α-substituents is coupled to some extent with the steric hindrance because of the small distance from the reaction sites. For this reason, para substitution is more desirable to see exclusively the electronic effect of substituents on the 1,4-cycloaddition. For this purpose *p*-methyl-, *p*-chloro-, and *p*-bromostyrenes are employed in the present work.

The 1,4-cycloaddition (so-called Diels-Alder reaction) is a typical cycloaddition reaction and of great interest from theoretical and synthetic points of view. A large number of kinetic studies have been done to get insight into the mechanism of this simple and useful reaction, as recently well reviewed.[3] Most of the kinetic data are in favor of the concerted mechanism ((a) in Fig. 1). In the 1,4-cycloaddition studied here, styrenes serve as a diene instead of a dienophile; one unsaturated bond comes from the vinyl group and the other from the phenyl group, and as a result, the aromaticity is lost in the product. The aim of the present investigation is to elucidate the reaction mechanism of this unique 1,4-cycloaddition from the point of view of kinetics.

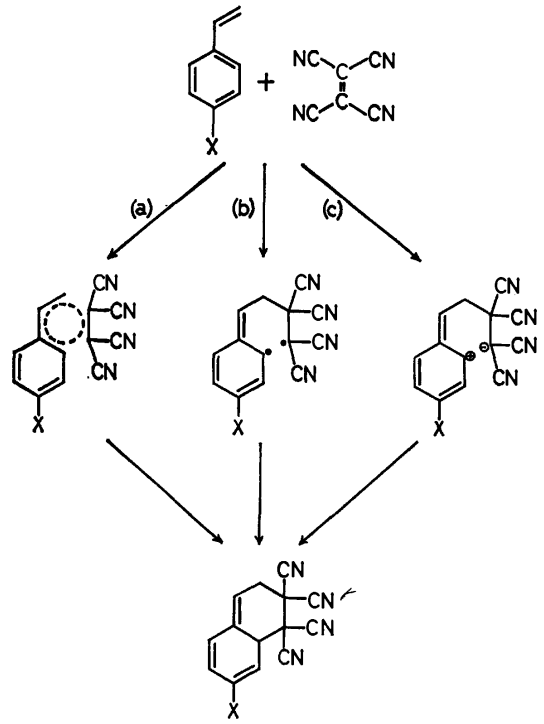

Fig. 1. Conceivable reaction mechanisms for 1,4-cycloaddition of TCNE to para-substituted styrenes (X= CH_3, H, Cl, and Br).

Experimental

p-Methyl-, *p*-chloro-, and *p*-bromostryenes were prepared by dehydrating the corresponding secondary alcohols with $KHSO_4$. The alcohols were synthesized by reducing the para-substituted acetophenones in ethanol with $NaBH_4$. All styrenes were repeatedly distilled at reduced pressure, stored in a refrigerator, and distilled again over CaH_2 before use. TCNE and chloroform were purified by repeated sublimation and distillation, respectively.

The apparatus and experimental procedures in the present work are the same as those described in detail in the previous paper.[1] Temperature was kept constant to ±0.1° C. The concentration of the donor was always much higher than that of the acceptor so as to simplify several equations utilized in the present analysis.

Results

Formation Constant of EDA Complex. When TCNE is mixed with each of the donors in chloroform, the electron-donor-acceptor (EDA) complex is formed instantaneously as a result of the diffusion-controlled reaction and exhibits two absorption maxima due to the first and second charge-transfer transitions in the visible region. All styrenes treated in this work and

a) X denotes the substituent at the para site of styrene (see Fig. 1). b) From Ref. 1. c) From Ref. 5. d) From Eq. 2. e) From Ref. 6.

TCNE have no absorption in this region. Spectroscopic parameters of the complexes are summarized in Table 1 together with some relevant properties of the donors.

The complex formation constant (K_c) and molar absorption coefficient (ε_{max}) of the first charge-transfer band, listed in Table 1, are determined from the Scott equation 1,[4]

$$\frac{[D]_0[A]_0 l}{A_0} = \frac{1}{K_c \varepsilon_{max}} + \frac{[D]_0}{\varepsilon_{max}}, \quad (1)$$

where $[D]_0$ and $[A]_0$ are the initial concentrations of the donor and the acceptor, respectively, l the path length (1 cm) and A_0 the absorbance of the complex before the 1,4-cycloadduct is formed. Figure 2 shows plots of the left-hand side of Eq. 1 against $[D]_0$, the slopes and intercepts of which provide K_c and ε_{max} simultaneously.

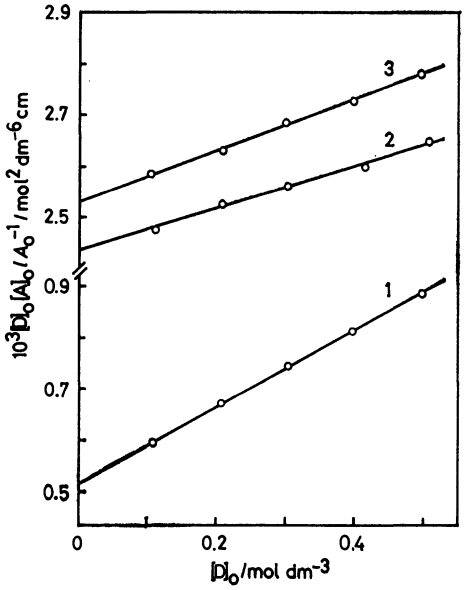

Fig. 2. Plots of $[D]_0[A]_0 l/A_0$ *vs.* $[D]_0$.
1: *p*-Methylstyrene, 2: *p*-bromostyrene, 3: *p*-chlorostyrene.

Since there is no photoelectron spectroscopic investigation on the para-substituted styrenes treated here, the ionization potentials (I_p) of these molecules in Table 1 are estimated by using the relation.

$$h\nu_{CT}/\text{eV} = 0.873(I_p/\text{eV}) - 4.89, \quad (2)$$

which is obtained on the basis of reported ionization potentials of some other styrene derivatives[5] and first charge-transfer transition energies ($h\nu_{CT}$) of their EDA complexes with TCNE.[1]

Reaction Rate of 1,4-Cycloaddition. Since the EDA-complex formation and 1,4-cycloaddition are reversible reactions, the following reaction scheme is assumed:

$$D + A \underset{}{\overset{K_c}{\rightleftharpoons}} \text{EDA Complex} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} P, \quad (3)$$

where k_1 and k_{-1} are the rate constants of the forward and backward reactions, respectively and P denotes the cycloaddition product. The rate equation for the reaction 3 is easily solved and affords the expression

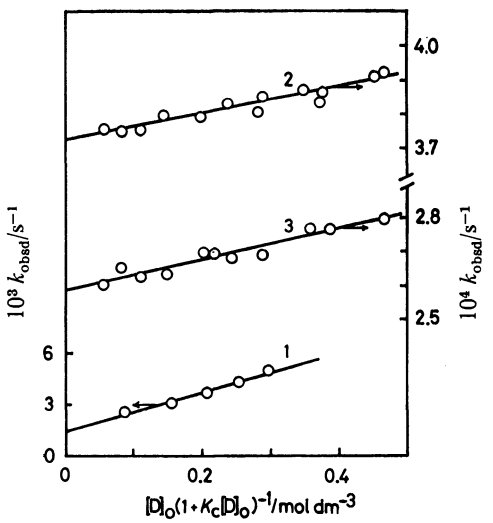

Fig. 3. Plots of k_{obsd} *vs.* $[D]_0/(1+K_c[D])$.
1: *p*-Methylstyrene, 2: *p*-chlorostyrene, 3: *p*-bromostyrene.

for [P] as a function of time (t):[1]

$$[P] = \frac{k_1[EDA]_0\{1-\exp(-k_{obsd}t)\}}{k_{obsd}}, \quad (4)$$

where

$$k_{obsd} = \frac{k_1 K_c [D]_0}{1+K_c[D]_0} + k_{-1}. \quad (5)$$

The pseudo-first-order rate constant, k_{obsd} was determined by the Guggenheim plot. As shown in Fig. 3, plots of k_{obsd} *vs.* $[D]_0/(1+K_c[D]_0)$ are linear, and from these slopes and intercepts we can get the values of k_1K_c and k_{-1}. The overall formation constant for the 1,4-cycloadduct K_p expressed as

$$K_P = \frac{[P]}{[D][A]} \quad (6)$$

$$= \frac{[EDA][P]}{[D][A][EDA]} \quad (7)$$

$$= K_c K_1 \quad (8)$$

$$= K_c k_1/k_{-1} \quad (9)$$

$$= k_f/k_{-1} \quad (10)$$

is given in Table 2 together with $k_f(=K_ck_1)$ and k_{-1}.

Discussion

The Hammett Correlation. The electronic effect of the para substitution (X in Table 1) on the formation of the 1,4-cycloadduct is expressed in terms of the

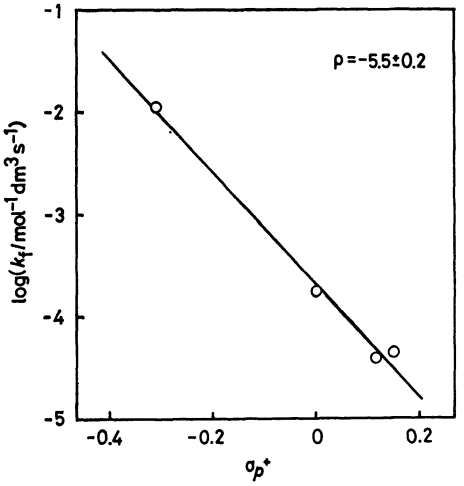

Fig. 4. A Hammett plot of log k_f *vs.* σ_p^+.

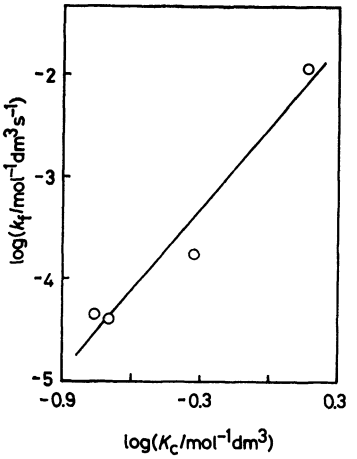

Fig. 5. A Plot of log k_f *vs.* log K_c.

reaction constant ρ, which is determined as -5.5 ± 0.2 from the Hammett plot of log k_f (in Table 2) *vs.* σ_p^+[6] (in Table 1) in Fig. 4. The ρ value obtained here is negative and considerably large in magnitude. Actually, ρ values are in the range of -1.8 to $+2.6$ for many other 1,4-cycloaddition reactions where CC-, NN-, and NO-double and CC-triplet bonds act as dienophiles.[3] The small ρ values found so far are considered to support the concerted mechanism (a) in Fig. 1. A large negative ρ value of -7.1 ± 0.5 has been reported for the 1,2-cycloaddition of TCNE to styrene derivatives having a strong electron-releasing substituent at the para site according to the Yukawa-Tsuno equation.[7] The large negative value for this 1,2-cycloaddition is regarded as an indication of a zwitterionic intermediate which is recognized in a similar 1,2-cycloaddition by various methods.[8] The large negative value found for the present reaction suggests some large partial charges in the rate-determining transition state. The following paper clarifies that the transition state has a dipole moment which is considerable but not so large as in a zwitterion existing in the 1,2-cycloaddition reaction.[9] Thus, the zwitterionic structure (c) in Fig. 1 contributes to the transition state of the 1,4-cycloaddition studied here to some extent. At the present time, however, we can not argue whether this 1,4-cycloaddition proceeds by one step or by two steps, because our attempt to trap any probable polar intermediate by using ice-cold methanol was unsuccessful.[10]

There is a frontier molecular orbital approach to the interpretation of the Hammett correlation.[11] It is not useful, however, in the present reaction because the ionization potential of the donor used as a measure of the HOMO energy (E_{HOMO}) does not correlate with the obtained k_f (see Table 1). In other words, the substituent constants σ_p^+ are not linearly correlated with ($E_{HOMO}-E_{LUMO}$) in the present series of the donors.

A Correlation of the Rate Constant k_f with the Complex Formation Constant K_c. In Fig. 5, the values of log k_f in Table 2 are plotted against log K_c. There exists a linear correlation, the correlation coefficient of which is 0.976. The linear correlation between log k_f and log K_c somehow supports the assumed reaction scheme shown by Eq. 3 because the free energy of the transition state of the 1,4-cycloaddition and the free energy of the complex are not necessarily expected to be linearly correlated in a reaction system where the complex formation is merely a side reaction. Similar correlations are reported in the 1,4-cycloaddition of TCNE to anthracenes[12] and some other kind of reactions.[13] In the former case, a negative activation enthalpy has been found, which is considered to support the scheme shown by Eq. 3 where the complex is on the pathway of the 1,4-cycloaddition reaction.[14] These linear correlations are often taken as evidence for the intermediacy of the EDA complex. The linear correlation found here between log k_f and log K_c suggests that the charge-transfer interaction between the donor and the acceptor is somehow important among interactions in the transition state.

A Theoretical Approach to the Dielectric Relaxation of Alcohol Solutions. II.[1] The Effect of Dilution with Inert Solvents on the Principal Relaxation Times of Primary Alcohols

Ryuichi MINAMI, Koichi ITOH,* Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160

(Received May 8, 1981)

The concentration dependence of the principal relaxation times, τ_P, of primary alcohol/inert solvent solutions are analyzed based on the equation,

$$\tau_p = 2(1+Kx_A)\tau_H,$$

where x_A is the alcohol mole fraction, K the equilibrium constant corresponding to the formation of hydrogen bonded multimers, and τ_H the time constant characterizing the rotational activation process of the terminal OH groups of the multimers. By applying Eyring's absolute rate theory to the activation process, we calculated τ_P as a function of temperature and alcohol concentration. The results reproduce quite well the τ_P values observed for the ethanol/cyclohexane, 1-hexanol/cyclohexane, and 1-propanol/benzene solutions.

In the preceding papers[1,2] we studied the dielectric relaxation processes of pure alcohols and alcohol solutions by assuming the association equilibrium between hydrogen bonded chain multimers. The dipole inversion arising from the cooperative rotation of the OH groups of the multimers was considered to be the main mechanism of the dipole relaxation. To the dipole inversion process we applied the stochastic model of one-dimensional random walk with two absorption walls[3] and found that the relaxation time of an n-mer is given by

$$\tau_n = (1+n)\tau_H. \quad (1)$$

Here τ_H is the reciprocal of the rate constant in which the terminal hydroxyl groups of the n-mer are activated rotationally. The dielectric relaxation observed for liquid alcohols and alcohol solutions was considered to be the sum of the contributions from the dipole relaxation of each n-mer. Using Eq. 1 together with the stoichiometric relationships for the association equilibrium,[4,5] we obtained analytical equations for the dielectric dispersions of pure alcohols and alcohol solutions. It is well known that in a low-frequency region most of alcohols and alcohol solutions show a dielectric dispersion which conforms very well to the simple relaxation pattern of Debye.[6,7] Assuming that the above-mentioned analytical formula under the low frequency limit ($\omega \to 0$) can express the relaxation time corresponding to this dispersion (This has often been called as the principal relaxation time. In this paper we abbreviate it as τ_P.), we obtained τ_P as a function of K, K_b, and x_A, where K is the equilibrium constant of the formation of chain multimers, K_b the constant of the association between the chain-multimers and a solvent with a hydrogen-bonding capacity, and x_A is the mole fraction of alcohols.[1] From the result we successfully estimated the change in the principal relaxation times of primary alcohols due to dilution with solvents having a hydrogen-bond acceptor as well as with inert solvents.[8,9] In the case of alcohol/inert solvent systems we can put $K_b=0$, which leads to the following equation:

$$\tau_p = \frac{\tau_1}{(1+Kx_A)^2} + 2\left\{1 + Kx_A - \frac{1}{(1+Kx_A)^2}\right\}\tau_H, \quad (2)$$

where τ_1 is the dipole relaxation time of alcohol monomers. Under the condition of $Kx_A \gg 1$, the equation can be approximated by

$$\tau_p = 2(1 + Kx_A)\tau_H. \quad (3)$$

In the previous paper[1] we reported that the formula well represents the τ_P *vs.* x_A curves observed for 1-propanol/benzene and 1-butanol/benzene solutions.[8,10] For the cyclohexane solutions of primary alcohols, however, Sagal[11] and Komooka[12] observed a maximum in the τ_P *vs.* x_A curves. As stated previously, in order to explain these results it is necessary to consider the dependence of τ_H in Eq. 3 upon the atmosphere surrounding alcohol molecules or, rather, surrounding the end OH groups of the molecule. In this paper, we studied thermodynamics of the dilution effect of τ_H and discussed the variation of τ_P with x_A in further detail.

Thermodynamic Treatment on τ_P

The mechanism in which the hydroxyl group of one of the two terminal segments of multimers is brought into a rotational transition state can be regarded as a single relaxation process. Therefore, we can apply Eyring's absolute rate theory[13] to this process and get the equation,

$$\tau_H = \frac{h}{k_B T}\exp\left(-\frac{\Delta S^*}{R} + \frac{\Delta H^*}{RT}\right), \quad (4)$$

where h and k_B are the Planck and Boltzmann constants, respectively. ΔS^* the activation entropy, and ΔH^* the activation enthalpy.

As we are interested in the systems where the mole fraction of alcohols, x_A, is larger than 0.5, we can make a further approximation to Eq. 3 as follows:

$$\tau_p = 2Kx_A\tau_H = 2K(1-x_B)\cdot\tau_H(x_B), \quad (5)$$

where x_B ($=1-x_A$) is the mole fraction of an inert solvent B. In the last equation, τ_H is represented as a function of x_B to take the dilution effect on τ_H into consideration. This means that ΔH^* and ΔS^* in Eq. 4 are also a function of x_B. Substitution of Eq. 4 into Eq. 5 yields the following formula for τ_P:

$$\tau_P = \frac{2h(1-x_B)}{k_B T} \times \exp\left\{-\frac{-\Delta S^\circ + \Delta S^*(x_B)}{R} + \frac{-\Delta H^\circ + \Delta H^*(x_B)}{RT}\right\}. \quad (6)$$

In this expression we used the fact that the equilibrium constant K can be expressed as

$$K = \exp\left(\frac{\Delta S^\circ}{R} - \frac{\Delta H^\circ}{RT}\right), \quad (7)$$

where ΔS° and ΔH° are the entropy and enthalpy changes, respectively, due to the hydrogen-bond formation between multimers and a monomer. Equation 6 can be simplified to the equation,

$$\tau_p = \frac{A(x_B)}{T} \exp\left\{\frac{E_a(x_B)}{RT}\right\}, \quad (8)$$

by defining $E_a(x_B)$ and $A(x_B)$ as follows,

$$E_a(x_B) \equiv -\Delta H^\circ + \Delta H^*(x_B), \quad (9)$$

$$A(x_B) \equiv \frac{2h(1-x_B)}{k_B} \exp\left\{\frac{\Delta S^\circ - \Delta S^*(x_B)}{R}\right\}. \quad (10)$$

According to Eq. 8, the plot of $\ln(T\cdot\tau_P)$ against $1/T$ is represented as a straight line with the slope of $E_a(x_B)/R$ and the point of intersection with the vertical axis at $\ln\{A(x_B)\}$.[14,15] On the basis of these results we obtained the values of $E_a(x_B)$ and $A(x_B)$ as functions of x_B for ethanol/cyclohexane,[11] 1-hexanol/cyclohexane,[12] 1-octanol/cyclohexane,[12] and 1-propanol/benzene[16] solutions. Figures 1 and 2 were obtained by plotting $E_a(x_B)$ and $\ln\{A(x_B)/(1-x_B)\}$ against x_B, respectively. Each set of the plots conforms very well to a straight line especially in the region where $x_B<0.5$, indicating that $E_a(x_B)$ and $\ln\{A(x_B)/(1-x_B)\}$ can be approximated by the linear equations,

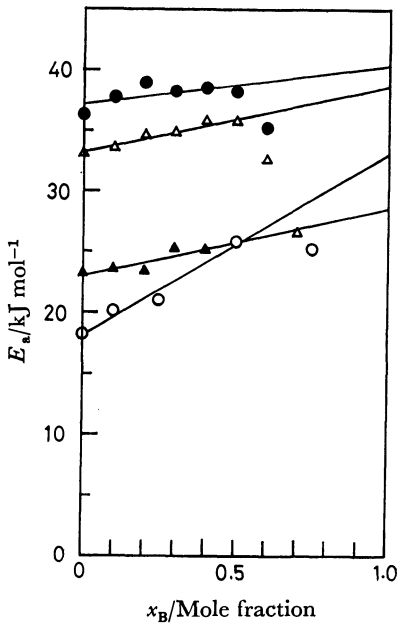

Fig. 1. Variation of E_a with the concentration of inert solvent, x_B, for the ethanol/cyclohexane (○), 1-hexanol/cyclohexane (△), 1-octanol/cyclohexane (●), and 1-propanol/benzene (▲) solutions. The straight lines are drawn to obtain the best fit with the data in the region of $x_B<0.5$ (see text.).

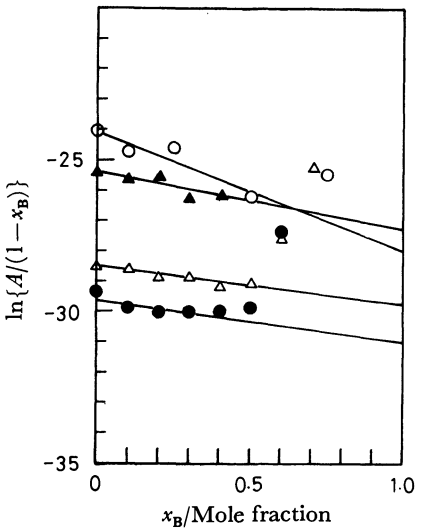

Fig. 2. $\ln\{A/(1-x_B)\}$ *vs.* x_B. The symbols have the same meaning as those in Fig. 1.

$$E_a(x_B) = E_a(0) + \alpha x_B, \quad (11)$$

$$\ln\{A(x_B)/(1-x_B)\} = \ln\{A(0)\} - \beta x_B/R, \quad (12)$$

where α and β are the constants characteristic of the solution in question. Equations 9 and 10 give the followings for pure alcohols ($x_B=0$),

$$E_a(0) = -\Delta H^\circ + \Delta H^*(0), \quad (13)$$

$$A(0) = \frac{2h}{k_B} \exp\left\{\frac{\Delta S^\circ - \Delta S^*(0)}{R}\right\}. \quad (14)$$

Using the above together with Eqs. 11 and 12, we can rewrite Eq. 6 to the following equation, which expresses τ_P explicitly as a function of x_B and T.

$$\tau_p = \frac{(1-x_B)A(0)}{T} \exp\left\{\frac{E_a(0)}{RT} - \left(\frac{\beta}{R} - \frac{\alpha}{RT}\right)x_B\right\} \quad (15)$$

Results and Discussion

Using the least-squares method we determined $E_a(0)$, α, $A(0)$, and β from Figs. 1 and 2. The results are given in Table 1. Inserting the $E_a(0)$, α, $A(0)$ and β values into Eq. 15, we calculated τ_P as a function of x_B and T for each set of the alcohol solutions listed in Table 1. The results are depicted by solid curves in Figs. 3, 4, and 5, where the observed values of τ_P are also included.

Figures 3, 4, and 5 show that the result of calculation for the region of $x_B<0.5$ well reproduces each set of the τ_P *vs.* x_B plots observed at various temperatures. In the region where x_B is larger than 0.5, however, the

results of calculation especially for the ethanol/cyclohexane (Fig. 3), 1-hexanol/cyclohexane (Fig. 4), and 1-octanol/cyclohexane solutions are not in good agreements with the data already reported.[11,12] In this region the approximate equations, (5), (11), and (12), cannot be applied to the systems in question. This is one of the main reasons for the deviation of the theoretical curves from the experimental data. In spite of such a deviation, the theoretical curves in Figs. 3 and 4 clearly predict the observations that the principal dielectric relaxation times of ethanol and 1-hexanol increase on the initial addition of cyclohexane, reach a maximum and then decrease. This result demonstrates the validity of our model proposed to the dielectric relaxation process of alcohol solutions.

From Eq. 3 it can be concluded that the principal relaxation times of alcohol solutions are determined by two factors. The first one is $(1+Kx_A)$, which depends on the distribution of chain lengths of hydrogen-bonded multimers,[17] and the other is τ_H. In the previous paper[1] we assumed that τ_H is constant. Using the thermodynamics of τ_H, which was explained in the preceding section, we can now discuss the dilution and temperature effects of τ_P in further detail.

Equation 9 indicates that the activation energy $E_a(x_B)$ is the sum of ΔH^* (the rotational activation energy of the terminal OH groups of hydrogen-bonded chain multimers) and $-\Delta H^\circ$ (the enthalpy change in the hydrogen-bond formation between chain-multimers and monomers). As the $-\Delta H^\circ$ values are in the region from 16 to 25 kJ/mol,[18] it is clear, from the $E_a(0)$ values listed in Table 1, that $\Delta H^*(0)$ of 1-hexanol and 1-octanol are larger than those of ethanol and 1-propanol; *i.e.*, the larger the hydrocarbon skelton of a primary alcohol is, the larger $\Delta H^*(0)$ becomes. The explanation for this can be given by a mechanism in which a third

alcohol molecule approaches with its oxygen atom oriented favorably to activate the OH group of the terminal molecule hydrogen-bonded to the neighboring one. With the increase in the size of the alcohol molecules the proximate presence of the hydrogen-acceptor atom to the terminal OH group becomes more and more scarce, causing the increase in the value of $\Delta H^*(0)$. In a similar manner we can explain the positive α values for the primary alcohols listed in Table 1. The addition of solvents such as cyclohexane and benzene to primary alcohols is considered to decrease the probability of the approach of an alcohol molecule near the terminal OH group, making it rotational activation more difficult. This will cause the increase in ΔH^* for the primary alcohol solutions.

Based on the activation energies observed for the ethanol/cyclohexane solutions and various pure alcohols, Sagal[11] proposed a mechanism to the dielectric relaxation process of alcohols. In his model the main mechanism of the relaxation is a switching process of hydrogen bonds. The reasoning for the explanation of the dependence of activation energy on the molecular size and shape of alcohols is similar to that given in this paper. Sagal, however, neither gave any explicit model to the structure of liquid alcohols and alcohol solutions, nor specify the OH group to any particular part of the structure. Therefore, although Sagal also noted that the energy necessary to reorient an OH group ($E_a(x_B)$) should be greater than that required to break a hydrogen bond ($-\Delta H^\circ$), he discussed the relationship between these two energies rather ambiguously.

Reactions of Aromatic Radical Anions with Benzhydryl Chloride Studied by Pulse Radiolysis

Setsuo TAKAMUKU,* Hitoshi KIGAWA, Susumu TOKI, Kunihiko TSUMORI, and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received May 8, 1981)

Reactions of the aromatic radical anions with benzhydryl chloride have been investigated by pulse radiolysis. The second-order rate constants were determined for the reactions of benzhydryl chloride with various aromatic radical anions. On the basis of the linear relationship between the free energy and the activation energy, an irreversible electron transfer with an early transition state was elucidated.

Electron transfer reactions (ET) to generate radical-ion intermediates have been of wide-spread interest, especially in the photochemistry connected with solar energy storage. Of particular importance is a system where an endergonic and irreversible ET step is followed by a rapid chemical reaction. In such a system, chemical reactions *via* the radical ions of a substrate can be initiated by a mediator (radical ion) which possesses a lower redox potential than that of the substrate. The system is, thus, of great value for organic synthesis.[1] The interpretation of the kinetics for the system has been carried out by Schuster,[2] based upon the model proposed by Rehm and Weller.[3]

We report herein the measurement of the absolute rate constants for the reactions of aromatic radical anions with benzhydryl chloride and the mechanism of the irreversible ET by a pulse radiolysis technique. The reactions of aromatic radical anions with alkyl and aromatic halides have been investigated by using electrochemical reactions,[4] organometallic compounds,[5] and also pulse radiolysis technique.[6] The currently accepted reaction mechanism includes an initial ET, producing an alkyl radical, and immediately following competitive reactions of the alkyl radical, such as reduction to carbanions, addition to aromatic radical anions, and radical-radical reacaions.[7]

However, we have observed that in the case of intramolecular reactions of biphenyl radical anions with a terminal alkyl chloride which is linked to biphenyl moiety by a methylene chain, an intramolecular S_N2 reaction occurs.[8] Therefore, it seems essential to investigate the initial step of each respective reaction system, to determine whether it is an ET or S_N2 reaction.

Experimental

Materials. Benzhydryl chloride (Tokyo Kasei) was recrystallized twice from the ethanol solution and dried under high vacuum. The white crystal was stored in a refrigerator with silica gel as a drying agent (mp 16 °C). Biphenyl, phenanthrene, *trans*-stilbene, pyrene, and anthracene were purified by recrystallization or sublimation in the usual method. 2-Methyltetrahydrofuran (Wako Pure Chemicals) was distilled over $LiAlH_4$ three times.

Pulse Radiolysis. The L-band linear accelerator at Osaka University was used as the source of electron pulses.[9] The energy was 28 MeV and a 10 ns pulse width was selected for the present experiments. A detector (1P28 photomultiplier) and analyzing light produced by a 450W-Xenon pulse lamp (OPG-450, Osram) were used, and signals were monitored by a storage oscilloscope (Tektronix 7843) and a programmable digitizer (Tektronix 7912AD).

Fresh MTHF solutions were prepared just before irradiation and degassed under high vacuum. The following absorption bands were used in order to monitor the decay rate of the various aromatic radical anions: biphenyl (410 nm), phenanthrene (450 nm), *trans*-stilbene (500 nm), pyrene (495 nm), and anthracene (670 nm).

Results and Discussion

2-Methyltetrahydrofuran (MTHF) solutions of biphenyl containing benzhydryl chloride (BC) were irradiated with a 10 ns electron pulse of a 35 MeV L-band linear accelerator at room temperature. The transient absorption spectra were recorded at various times after the pulse; these are presented in Fig. 1.

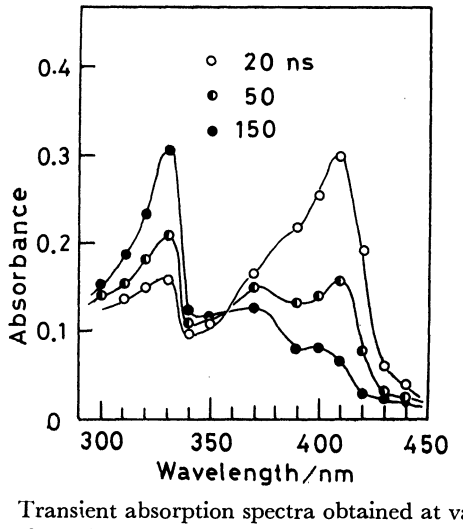

Fig. 1. Transient absorption spectra obtained at various times after a 10 ns pulse irradiation of a MTHF solution of biphenyl (50 mM) and BC (11 mM) mixture. Absorbed dose: 8.8 krad per pulse.

The spectrum observed immediately after the pulse has an absorption maximum at 410 nm, which is assigned to the biphenyl radical anions.[10] The 410-nm band decays according to the pseudo-first-order kinetics with the simultaneous formation of a 330-nm band. This latter band is assigned to a benzhydryl radical, by comparison with the spectrum obtained by the pulse radiolysis of a MTHF solution of BC.[11] The rate of formation of the 330-nm band is fully consistent with

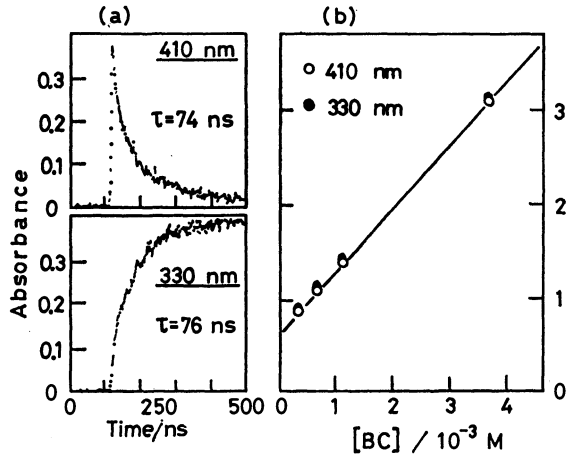

Fig. 2. Kinetic behavior of each band in Fig. 1 (a) The time dependency of transient absorption at 410- and 330-nm bands in Fig. 1. (b) The plot of the pseudo-first-order rate constant obtained from the 330-nm band formation and from the 410-nm band decay *vs.* BC concentration.

the decay rate of the 410-nm band, as shown in Fig. 2a. The plot of the pseudo-first-order rate constant *vs.* the BC concentration is linear; its slope results in the second-order rate constant: $k_S=7.0\times10^9$ M^{-1} s^{-1} (1 M=1 mol dm^{-3}). The two slopes obtained from the 330-nm band formation and the 410-nm band decay are in fair agreement within experimental error (Fig. 2b). Thus, the following equation is supported [M: biphenyl, BC: benzhydryl chloride]:

$$M^{\cdot-} + BC \xrightarrow{k_s} M + Ph_2CH\cdot + Cl^-.$$

In order to clarify the reaction mechanism, the second-order rate constants for the reaction of BC with aromatic radical anions of varying reduction potentials have been determined by a similar method to that described above. The plot of ln k_S as a function of the electrochemical half-wave potentials of the aromatic hydrocarbon (M)[12] yields a linear correlation, except for biphenyl, where the rate constant reaches the diffusion-controlled region, as shown in Fig. 3. The slope of the straight line is −9.45 in the units used here,† which corresponds to $-0.25/RT$.

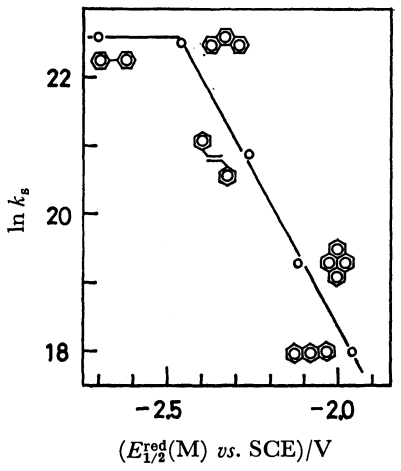

Fig. 3. Dependence of k_s on the reduction potential of various aromatic hydrocarbons.

According to Rehm and Weller,[3] the electron transfer mechanism can be described by the following reaction scheme.

$$M^{\cdot-} + BC \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} (M^{\cdot-}\cdots BC) \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} (M\cdots BC^{\cdot-}) \xrightarrow{k_{30}} M + Ph_2CH\cdot + Cl^-$$

In the present system, it is presumed that the ET step (k_{23}) is endergonic and that, even so, the $BC^{\cdot-}$ radical anion formed undergoes an irreversible bond cleavage at a rate faster than the back ET: thus, $k_{23}\ll k_{21}$ and $k_{32}\ll k_{30}$. Under such a circumstance, the following equation for the rate constant is obtained, applying a steady-state approximation:[2]

$$\ln k_s = \ln K_{12}k_i + \frac{\alpha E^{red}_{1/2}(BC)}{RT} - \frac{\alpha E^{red}_{1/2}(M)}{RT}, \quad (1)$$

where $K'_{12}=k_{12}/k_{21}$ and k_i is the rate constant for the reaction where $\Delta G_{23}=0$ and the activation barrier is $\Delta G_0^{\ddagger}$. $E^{red}_{1/2}$ is the electrochemical half-wave reduction potential of BC and M. The transfer coefficient α is defined as $\Delta G^{\ddagger}=\Delta G_0^{\ddagger}+\alpha\Delta G_{23}$ (see Ref. 2). The present observation appears to be in accord with the relationship expressed in Eq. 1, provided $\alpha=0.25$. If we presume the reversible ET step, the slope of the straight line should be $-1/RT$; this is incompatible with the present results.

Although a simple linear correlation between reactivities and the ionization potentials or the redox potentials of the substrates has been observed in many chemical reactions,[13] there is surprisingly little quantitative information and few discussions on the transfer coefficient. It is, however, worthwhile to mention that a reversible ET system affords a straight line with a slope of $-1/RT$, but a net α value is not obtained in such a system. The idea of the parameter α has been originally proposed by Horiuchi-Polanyi.[14] It is reasonable to accept that α reflects the position of the transition state, along with the reaction coordinate.[15]

Bank and Juckett reported a similar low α value (0.22) for the reaction of aromatic radical anions with alkyl bromides,[5] while $\alpha=0.72$ is calculated from the data presented for the reaction with chlorobenzene by Lund and coworkers.[4] On the basis of these observations, it seems that, when the C–X bond cleavage proceeds very rapidly, α becomes low. Such a low α value indicates an early transition state in which electrons localize mainly upon the aromatic hydrocarbon (M). Thus, it becomes questionable whether a full electron transfer from $M^{\cdot-}$ to BC goes to completion prior to the successive C–Cl bond cleavage in such a labile halide.

A simple estimation suggests that if α is less than one-half, ΔG should be negative.[15] Therefore, our interpretation is that in such a system where α is very low, an irreversible ET proceeds with an early transition state and this, therefore, closely correlates with a rapid C–Cl

† The slope is −9.45 when $E^{red}_{1/2}$ is expressed in V.

bond cleavage; a distinct discrimination between ET (k_{23}) and the successive bond cleavage (k_{30}) steps is difficult. The value of α would be considered as a parameter reflecting the extent of the ET in such a system.

The present work was supported in part by a Grant-in-Aid for Scientific Research No. 55334 from the Ministry of Education, Science and Culture.

(Received May 22, 1981)

The polarization CARS spectra were observed for a few typical Raman lines at various experimental settings. Based upon the observed and calculated spectra, the usefulness and the validity of the polarization CARS method for the study of the overlapped Raman lines observed for a condensed system have been emphasized.

The coherent anti-Stokes Raman scattering (CARS) experiment is a new method of Raman spectroscopy which utilizes the nonlinear optical phenomena induced by the macroscopic third-order nonlinear polarization, $\vec{P}^{(3)}$. This type of spectroscopy has been extensively applied in a wide range of laboratories utilizing the feature of the nonlinear phenomena.[1-5] The polarization CARS is one application of the CARS method, one in which the direction of the polarization of the incident and the scattered light are properly chosen.[6-8]

One of the most important and difficult problems in the field of application spectroscopy lies in the analyses of the spectral lines which are composed of two or more different lines whose resonance frequencies are very close to each other in comparison with their linewidths. For the analyses of the condensed-phase spectra, it is often necessary to resolve an observed line into a number of lines by assuming symmetric lineshape functions, like a Lorentzian or a Gaussian. This method is indeed useful for practical purposes. In many cases, however, the assumption of the lineshape functions is arbitrary in nature and falls short of experimental proof. We started the present work with the belief that we could perform this line-separation into multi-components on a purely experimental basis if we used the polarization CARS method.

In this study, we observe a few typical overlapped Raman lines by the polarization CARS method and ascertain the usefulness and validity of the application of the polarization CARS method for the study of the overlapped Raman lines observed for condensed systems.

Theoretical

Third-order Susceptibility in Liquid. CARS arises from a third-order nonlinear polarization which is induced in the medium at the frequency when $\omega_3 = 2\omega_1 - \omega_2$ by the incident lights, ω_1 and ω_2. This third-order nonlinear polarization at the ω_3 frequency can be expressed as:

$$\vec{P}^{(3)}(\omega_3) = \chi^{(3)}(\omega_3)\vec{E}(\omega_1)\vec{E}(\omega_1)\vec{E}^*(\omega_2), \quad (1)$$

where $\vec{E}(\omega_1)$ and $\vec{E}(\omega_2)$ are the amplitudes of the incident lights and where $\vec{P}^{(3)}(\omega_3)$ is the third-order susceptibility. As the CARS intensity is proportional to $|\vec{P}^{(3)}(\omega_3)|^2$, the CARS spectra are characterized by $\chi^{(3)}(\omega_3)$, which is a fourth-rank tensor. In general, $\chi^{(3)}(\omega_3)$ can be expressed as the sum of two terms:

$$\chi^{(3)}(\omega_3) = \chi^{NR} + \chi^{R}, \quad (2)$$

where χ^{NR} is an electronic or background susceptibility, and χ^{R}, a Raman susceptibility.

It has been established, for a spontaneous Raman scattering, that a totally symmetric Raman line is composed of two parts: an isotropic component and an anisotropic component. The linewidth of an anisotropic component is much broader than that of an isotropic one, because the isotropic linewidth is governed mainly by the reorientational relaxation process.[9] Therefore, it is preferable to write the χ^{R} of Eq. 2 in this form:

$$\chi^{R} = \sum_{r}\left(\frac{\chi^{rI}}{\delta_{rI} - i\Gamma_{rI}} + \frac{\chi^{rA}}{\delta_{rA} - i\Gamma_{rA}}\right), \quad (3)$$

where Γ_{rI} and Γ_{rA} are the linewidths of the isotropic and anisotropic components respectively; $\delta_r = \omega_r - (\omega_1 - \omega_2)$; ω_r is the Raman frequency of the r-th vibrational mode. In the derivation of Eq. 3, we assumed that $\omega_{rI} = \omega_{rA}$.[10]

In an isotropic medium, there are only two independent tensor components, $\chi^{(3)}_{1111}(-\omega_3 : \omega_1, \omega_1, -\omega_2)$ and $\chi^{(3)}_{1221}(-\omega_3 : \omega_1, \omega_1, -\omega_2)$, where 1 and 2 denote two distinguishable Cartesian axes. These tensor components are given by an orientational average of the susceptibilities of individual molecules. According to to Yuratich and Hanna,[11] χ^{rI} and χ^{rA} of Eq. 3 for an electronic non-resonant condition are given by these relations:

$$\chi^{rI}_{1111} = \frac{NL\alpha^2}{12\hbar}, \quad (4)$$

$$\chi^{rI}_{1221} = 0, \quad (5)$$

$$\chi^{rA}_{1221} = \frac{3}{4}\chi^{rA}_{1111} = \frac{NL}{12\hbar}\frac{\gamma_s^2}{15}, \quad (6)$$

where α^2 is the mean value and γ_s^2 is the symmetric part of the anisotropy of an usual Raman tensor. In this discussion we assumed that the antisymmetric part of the anisotropy is negligible. N is the number density of the Raman-active molecules, and L is the local-field correction factor.[1] It is important to add that the following relation holds approximately between the tensor components of χ^{NR}: it is known by the name of the Kleiman relation:

$$\chi^{NR}_{1111} = 3\chi^{NR}_{1221}. \quad (7)$$

Polarization CARS. From the above discussion

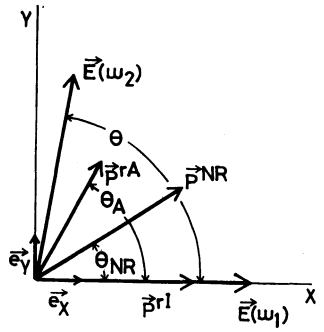

Fig. 1. Polarization directions for polarization CARS experiment.

it can be understood that the polarization, $\vec{P}^{(3)}(\omega_3)$, can be expressed as;

$$\vec{P}^{(3)}(\omega_3) = \vec{P}^{NR} + \sum_r (\vec{P}^{rI} + \vec{P}^{rA}), \tag{8}$$

where the superscripts correspond to those of Eqs. 2 and 3.

We set the experimental conditions as is shown in Fig. 1. One incident light, $\vec{E}(\omega_1)$, is linearly polarized to the X-direction, while the other incident light, $E(\omega_2)$, is polarized on the XY-plane at an angle; θ, with the X-direction. At this experimental setting, the terms of Eq. 8 are expressed by these relations:

$$\vec{P}^{NR} = 3\chi^{NR}_{1111} E_x^2(\omega_1)\{E_X(\omega_2)\vec{e}_X + \frac{1}{3}E_Y(\omega_2)\vec{e}_Y\}, \tag{9}$$

$$\vec{P}^{rI} = \frac{NL\alpha^2 E_x^2(\omega_1)E_X(\omega_2)}{4\hbar(\delta_{rI} - i\Gamma_{rI})}\vec{e}_X, \tag{10}$$

$$\vec{P}^{rA} = \frac{NL\gamma_S^2 E_x^2(\omega_1)}{60\hbar(\delta_{rA} - i\Gamma_{rA})}\left(\frac{4}{3}E_X(\omega_2)\vec{e}_X + E_X(\omega_2)\vec{e}_Y\right), \tag{11}$$

where $\vec{e}_X$ and $\vec{e}_Y$ are unit vectors in the directions of X and Y respectively. If we designate the angles between the X-axis and the vectors, $\vec{P}^{NR}$, $\vec{P}^{rI}$, and $\vec{P}^{rA}$, as θ_{NR}, θ_I, and θ_A respectively (see also Fig. 1), Eqs, 9, 10, and 11 lead to these relations:

$$\tan\theta_{NR} = \frac{E_Y(\omega_2)}{3E_X(\omega_2)} = \frac{1}{3}\tan\theta, \tag{12}$$

$$\tan\theta_I = 0, \tag{13}$$

and

$$\tan\theta_A = \frac{3E_Y(\omega_2)}{4E_X(\omega_2)} = \frac{3}{4}\tan\theta. \tag{14}$$

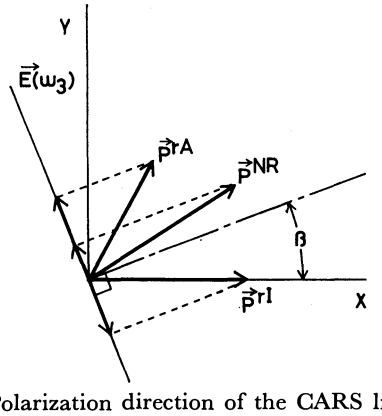

Fig. 2. Polarization direction of the CARS light which passed through the polarization analyzer.

The amplitude of the CARS light, $\vec{E}(\omega_3)$, is proportional to the polarization, $\vec{P}^{(3)}(\omega_3)$, so the observed amplitude, $\vec{E}(\omega_3)$, can have only one polarization state, which is defined by the vector-sum of $\vec{P}^{NR}$, $\vec{P}^{rI}$, and $\vec{P}^{rA}$. In this respect, the CARS light is obviously different from that of the spontaneous Raman scattering. As can be seen from Fig. 2, we can obtain various spectra by setting the polarization direction of the CARS light by putting a polarization analyzer in the path of the CARS light. If we cut off that light whose polarization direction makes an angle; β, with the X-axis, the amplitude, $E(\omega_3)$, which penetrates through the analyzer may be given by this relation:

$$E(\omega_3) \propto \{|\vec{P}^{NR}|\sin(\theta_{NR} - \beta) + \sum_r [|\vec{P}^{rI}|\sin(-\beta) + |\vec{P}^{rA}|\sin(\theta_A - \beta)]\}. \tag{15}$$

Especially, we can obtain "background-free" spectra if we set the experimental condition at $\beta = \theta_{NR}$.

Experimental

Apparatus for Polarization CARS Measurement. A schematic diagram of the polarization CARS spectrometer is shown in Fig. 3. A N_2 laser is oscillated at 337.1 nm with a peak output of 300 kW. The time-width of the N_2 laser is 7 ns, and the repetition rate is 4 Hz. This N_2 laser output is used to pump two dye lasers, 1 and 2, simultaneously. The frequency, ω_1, of the dye laser 1 is fixed at 19200 cm^{-1} (HWHM=0.4 cm^{-1}), while the frequency, ω_2, of the dye laser 2 (HWHM=0.6 cm^{-1}) is tunable. The directions of the polarization of ω_1 and ω_2 are adjusted by the use of two Glan-Laser prism polarizers, GP_1 and GP_2. The two light-beams, ω_1 and ω_2, are adjusted to be parallel with each other before a lens, L_1 (f= 10 cm), and then focused into a sample cell. The phasematching angle is adjusted by sliding a mirror, M_1. The scattered light is selected out by the use of an appropriate aperture. The polarization direction of the CARS light is selected out by means of a Glan-Laser prism polarizer, GP_3. After being passed through a depolarizer, DP, the CARS light is focused into a monochromator (JEOL, Model UI double-monochromator). Finally, the monochromated CARS light is detected by means of a photomultiplier (RCA-1P21) and averaged by the use of a laser photometer (Molectron, LP-20).

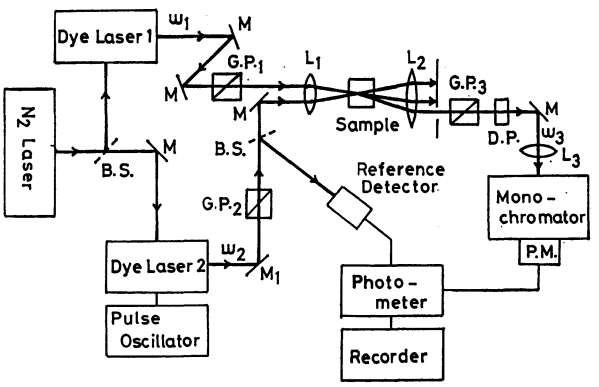

Fig. 3. Schematic representation of the experimental set-up.
BS: Beam splitter, M: mirror, GP: Glan prism, DP: depolarizer, PM: photomultiplier.

A part of the ω_2 is taken out by the use of a beamsplitter, BS, and used for the purpose of the normalization of the CARS light and for the triggering of the photometer. The depolarizer, DP, is used for the cancellation of the polarization characteristics of the monochromator.

Measurement of Ordinary Raman Spectra. The ordinary Raman spectra were recorded by a JEOL, JRS-400T Raman spectrophotometer equipped with an Ar^+-ion laser source (Spectra Physics, Model 164, 488.0 nm). A PL filter (Kenko) was used as a polarizer after being corrected for the polarization characteristics.

Sample. All the chemicals used in the present work were commercially available in a guaranteed grade and were used without further purification. The Raman spectra were observed for pure liquid toluene and chlorobenzene for a binary mixture (1 : 1 in volume) of them. The Raman spectra were also observed for pure liquid styrene.

Results and Discussion

For the purpose of dealing with the CARS lineshapes of Raman modes in liquid, we write the electric field of a CARS light being observed in this form:

$$E(\omega_3)=B\sin(\theta_{NR}-\beta)+\sum_r\left[\frac{R_{rI}\sin(-\beta)}{\delta_r-i\Gamma_{rI}}+\frac{R_{rA}\sin(\theta_A-\beta)}{\delta_r-i\Gamma_{rA}}\right], \quad (16)$$

where:

$$B\propto|\vec{P}^{NR}|=\sqrt{9+\tan^2\theta}\,\chi^{NR}_{1111}E_x^2(\omega_1)E_x(\omega_2), \quad (17)$$

$$R_{rI}\propto\frac{|\vec{P}^{rI}|}{\delta_r-i\Gamma_{rI}}=\frac{NL\alpha^2}{4\hbar}E_x^2(\omega_1)E_x(\omega_2), \quad (18)$$

and

$$R_{rA}\propto\frac{|\vec{P}^{rA}|}{\delta_r-i\Gamma_{rA}}=\sqrt{16+9\tan^2\theta}\times\frac{NL\gamma_s^2}{180\hbar}E_x^2(\omega_1)E_x(\omega_2). \quad (19)$$

Depolarized Raman Lines. A depolarized Raman line has only γ_s^2 in the Raman tensor. Therefore, the polarization CARS spectra expected for this case are represented by this relation:

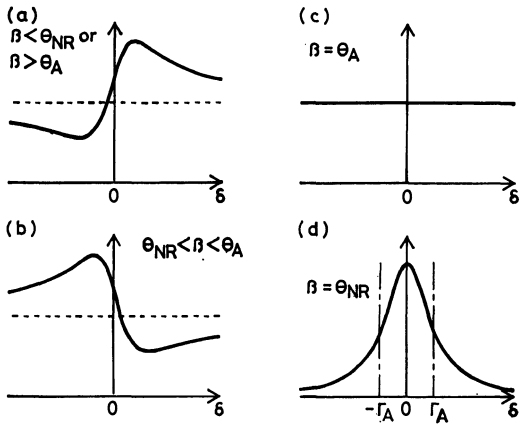

Fig. 4. Typical polarization CARS spectra for an isolated single Raman line.
Remark that (d) corresponds to a "background-free" spectrum.

$$|E(\omega_3)|^2=\left|B\sin(\theta_{NR}-\beta)+\frac{R_A\sin(\theta_A-\beta)}{\delta-i\Gamma_A}\right|^2. \quad (20)$$

The typical spectra expected for this case are illustrated in Fig. 4. It can be seen from the figure that the spectral features change dramatically with the change in β. It must be emphasized that this is the only case in which the Raman line is composed of only one component.

Totally Symmetric Raman Lines. A totally symmetric Raman line is characterized by γ_s^2 and α^2. Therefore, the polarization CARS spectra can be represented by this relation:

$$|E(\omega_3)|^2=\left|B\sin(\theta_{NR}-\beta)+\frac{R_I\sin(-\beta)}{\delta-i\Gamma_I}+\frac{R_A\sin(\theta_A-\beta)}{\delta-i\Gamma_A}\right|^2. \quad (21)$$

It must be emphasized that a totally symmetric Raman line is composed of two components, isotropic and anisotropic, although it seems to be a single line. Thus, Eq. 21 has two Raman-resonant terms, in good contrast to Eq. 20.

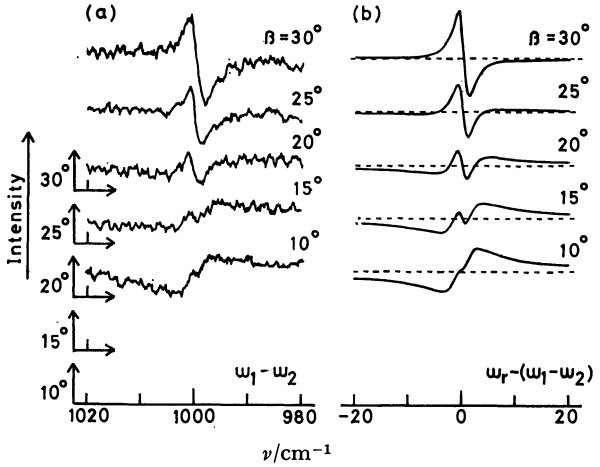

Fig. 5. Polarization CARS spectra for the 1000 cm^{-1} line of pure liquid styrene.
(a): Observed β-dependence, (b): Calculated β-dependence. The dotted lines indicate the background height; $B^2\sin^2(\theta_{NR}-\beta)$.

As an example, we observed the polarization CARS spectra of the 1000 cm^{-1} Raman line of pure liquid styrene for various β-values. Figure 5(a) shows the results for the experimental settings of $\theta=85°$ and $\beta=$ 10, 15, 20, 25, and 30°. The spontaneous Raman spectra of this line, on the other hand, are characterized by these spectral parameters: the polarization degree is 0.05, and the lineshapes are Lorentzian, with $\Gamma_I=$ 1.4 cm^{-1} for the isotropic line and with $\Gamma_A=2.5$ cm^{-1} for the anisotropic line. Using these spectral parameters, the polarization CARS spectra were calculated for this Raman line: the results are illustrated in Fig. 5(b).[12] The good agreement between the observed and the calculated spectra indicates that the physical meaning of the damping factors, Γ_I and Γ_A, which appear in the CARS formulation is essentially the same as that of the half-widths in the spontaneous Raman

scattering formulation.

It can be seen from Fig. 4 that we can clearly identify the existence of the two Raman components, the polarized and depolarized ones, by observing the polarized CARS spectra for various β-values. It is essential that, in the case of a totally symmetric Raman line, a Raman line should be considered to be overlapped lines whose frequencies are equal, but whose linewidths are different from each other.

Two Closely Located Totally Symmetric Raman Lines. In a case where two Raman lines are located very close to each other, we must consider the overlapping of four Raman lines: two isotropic components and two anisotropic components. As a model system, the binary mixture of toluene and chlorobenzene was chosen, because liquid toluene shows a Raman line at $\omega_r=1004$ cm^{-1}, with a depolarization degree of $\rho=0.018$ and with half-widths of $2\Gamma_I=2.1$ cm^{-1} and $2\Gamma_A=4.2$ cm^{-1}, while liquid chlorobenzene shows a Raman line at $\omega_r=1002.8$ cm^{-1}, with a depolarization degree of $\rho=0.025$ and with half-widths of $2\Gamma_I=1.5$ cm^{-1} and $2\Gamma_A=3.8$ cm^{-1}. These two Raman lines are assigned to the C–C stretching vibrations of the benzene rings and have almost equal intensities.

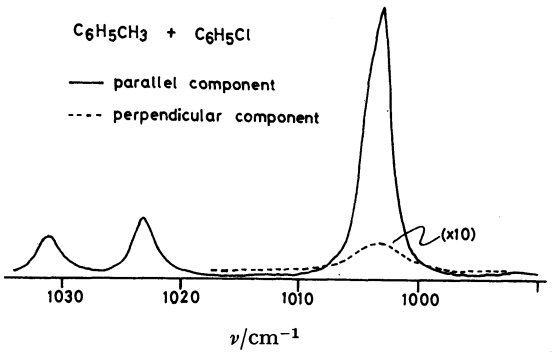

Fig. 6. Observed spontaneous Raman spectra for the binary mixture of toluene and chlorobenzene, (1 : 1 mixture in volume).

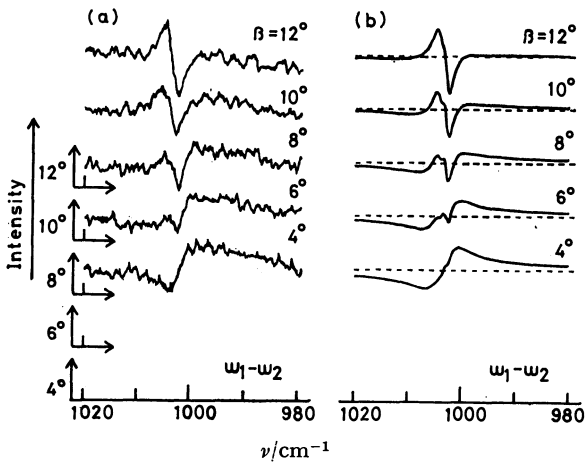

Fig. 7. Polarization CARS spectra for the binary mixture of toluene and chlorobenzene, (1 : 1 mixture in volume).
(a): Observed β-dependence, (b): Calculated β-dependence. The dotted lines indicate the background height, $B^2\sin^2(\theta_{NR}-\beta)$.

Figure 6 shows the Raman spectra observed for the binary solution of toluene and chlorobenzene. In this figure, two Raman lines are overlapped with each other at about 1000 cm^{-1}. It can be seen from the figure that it is almost impossible to separate this line into two Raman lines without knowing accurate spectral information about these individual lines. Figure 7(a) shows the observed polarization CARS spectra for $\theta=85°$ and for $\beta=4$, 6, 8, 10, and 12°. Figure 7(b) shows the results of the simulative calculation of the corresponding spectra on the basis of the above spontaneous Raman data. It can be seen from this figure that the overlapping of two Raman lines can easily be surmised by means of the asymmetric feature of the polarization CARS spectra. That is, the positive and negative peaks are quite different from each other both in shape and area, in good contrast with the spectra given in Fig. 5.[13]

Concluding Discussion. In the preceding paragraphs, the polarization CARS spectra have been discussed for three different cases: (1) a spectrum is composed of only one Raman line and only one component; that is to say, the line corresponds to one vibrational mode and one component: (2) a spectrum is composed of one Raman line which can be assigned to one vibrational mode, but is made from two components, namely, isotropic and anisotropic components, and (3) a spectrum corresponds to two overlapped Raman lines, each of which is made from isotropic and anisotropic components. From the results obtained, we can draw a few important conclusions with respect to the application of the polarization CARS method to the analysis of the overlapped Raman lines.

First, it has been shown that polarization CARS spectra should be analyzed by considering both isotropic and anisotropic scattering processes. It is essential to consider the difference between the isotropic and anisotropic linewidths. Therefore, the separation of the overlapped Raman lines into the individual vibrational lines is not so simple as has been described by Koroteev *et al.*[8] The apparent splittings in the CARS spectra cannot directly be related to the band-overlapping in ordinary Raman spectra.

Secondly, a polarization CARS method can be a useful technique to compare the isotropic and anisotropic components which are related to the same vibrational mode, because we can observe isotropic and anisotropic components separately by using a proper experimental setting. If we set $\beta=\theta_A$ or $\beta=\theta_I$, we can obtain a purely isotropic spectrum or a purely anisotropic spectrum respectively. For other angles, the spectra exhibit rather complicated features, namely, mixtures of isotropic and anisotropic spectra. As we can change the ratio of R_I and R_A properly by changing the θ, this method is extremely useful for the analysis of a Raman line whose depolarization degree is very small.

Thirdly, it has been shown that the polarization CARS spectra are quite sensitive to the change in the spectral parameters of component lines. Although the analyses of polarization CARS spectra themselves are rather complicated and difficult when several Raman modes are overlapped, the simultaneous use of spontaneous Raman and polarization CARS spectra is a very

promising method for the separation of the overlapped Raman lines into their component lines. We can ascertain the validity of the line-separation of overlapped ordinary Raman lines by simulating polarization CARS spectra using the spectral parameters obtained from the line-separation of ordinary Raman spectra. It must be emphasized, however, that this process is purely experimental.

12) The relative magnitude of R_I or R_A to B was determined from the simulation. The final parameters used for the simulation were: $\Gamma_I = 1.4\ cm^{-1}$, $\Gamma_A = 2.5\ cm^{-1}$, $R_I = 1.07B$, $R_A = 0.65B$, and $\omega_r = 1000.0\ cm^{-1}$.

13) The relative magnitudes of R_I and R_A to B were determined from the simulation. The final parameters were: $R_I = 1.03B$ and $R_A = 0.21B$ for toluene, and $R_I = 1.00B$ and $R_A = 0.30B$ for chlorobenzene.

Partition of Carboxylic Acids between Benzene and Aqueous Solution as Considered from the Regular Solution Theory

Yukio Fujii,† and Motoharu Tanaka*

†*Faculty of Engineering, Gifu University, Kagamihara, Gifu 504*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 10, 1981)

The partition of carboxylic acids between benzene and 0.1 mol dm^{-3}(H,Na)ClO_4 aqueous solution has been studied at 25 °C. Carboxylic acids used include acetic, propanoic, butanoic, pentanoic, hexanoic, and decanoic acids. The hydration of monomeric acids in benzene being taken into account, the hydration-corrected partition constant has been calculated. The effect of the chain length on the partition is accounted for with the aid of the newly estimated solubility parameters and empirical binary coefficients. Applicability of the empirical solubility parameter of water (35.89 $J^{1/2}$ $cm^{-3/2}$) has also been discussed.

The distribution behaviors of various organic compounds between two immiscible solvents have been extensively reviewed.[1-3] Milicevic[4] and Koshimura[5] have tried a systematic consideration on the solubility leading to a quantitative prediction of the partition of some organic compounds and metal chelates, respectively.

Of many attempts to introduce basic concepts into a general treatment of partition equilibria, the most successful one is the approach based on the theory of regular solution,[6] although its application to liquid-liquid partition is limited in some cases.[7]

The regular solution theory has been used to interpret the solvent effects on the extraction of organic compounds,[8,9] metal chelates,[10-12] halide complexes,[13,14] and ion pairs.[12,15] The same theory has been found useful in discussing the substituent effects on the partition of pyridine bases.[16]

In the previous papers,[17,18] we have presented the results of the partition of carboxylic acids between benzene and the aqueous solution. In this paper we attempt to interpret the effect of the chain length on the partition of carboxylic acids.

Theoretical

According to Hildebrand and Scatchard's theory of regular solution,[6] the activity of a solute HA, a_{HA}, is given by:

$$RT \ln a_{HA} = RT \ln x_{HA} + V_{HA}\phi_S^2(\delta_S - \delta_{HA})^2, \quad (1)$$

where x_{HA}, V_{HA}, and δ_{HA} denote the mole fraction, molar volume and solibility parameter, respectively, of the solute HA, and ϕ_S and δ_S the volume fraction and solubility parameter of the solvent S, respectively. The pure liquid was chosen as a standard state. The entropy of mixing molecules of the different size being taken into account, the following equation is relevant:

$$RT \ln a_{HA} = RT[\ln \phi_{HA} + \phi_S(1 - V_{HA}V_S^{-1})] + V_{HA}\phi_S^2(\delta_S - \delta_{HA})^2, \quad (2)$$

where the volume fraction of HA, ϕ_{HA}, is related with the molar concentration of HA, $[HA]_S$, as:

$$[HA]_S = 1000\,\phi_{HA}/V_{HA}. \quad (3)$$

Instead of using *the rigid geometric mean assumption* involved in the usual regular solution theory, we include an empirical binary coefficient,[19] $l_{HA,S}$, in Eq. 2. Then, we obtain:

$$RT \ln a_{HA} = RT(\ln [HA]_S - \ln 1000V_{HA}^{-1} + \phi_S(1 - V_{HA}V_S^{-1})) + V_{HA}\phi_S^2[(\delta_S - \delta_{HA})^2 + 2l_{HA,S}\delta_{HA}\delta_S]. \quad (4)$$

When the solute is partitioned between the aqueous and organic phases, *i.e.*, $a_{HA,w}=a_{HA,o}$, and that the concentration of HA is sufficiently low in both phases, *i.e.*, $\phi_w=1$ and $\phi_o=1$, we obtain from Eq. 4 the following expression for the partition constant of HA, $K_{D,HA}$:

$$\log K_{D,HA} = V_{HA}[(\delta_w-\delta_{HA})^2-(\delta_o - \delta_{HA})^2 + 2l_{HA,w}\delta_{HA}\delta_w - 2l_{HA,o}\delta_{HA}\delta_o + RT(V_o^{-1}-V_w^{-1})]/2.303RT, \quad (5)$$

where subscripts w and o denote the aqueous and organic phases, respectively. In Eq. 5 the aqueous solution is considered as a hypothetical regular solution.

Results and Discussion

Hydration and Partition Constants. At low pH, where anionic species may be neglected in the aqueous phase, the conditional partition constant of a monomeric carboxylic acid between the aqueous and organic phases, $K'_{D,HA}$, is written as:

$$HA_w \overset{\beta_{11}}{\rightleftharpoons} HA'_o, \quad K'_{D,HA} = [HA']_o/[HA]_w. \quad (6)$$

Measurement of water solubility[17,18] revealed that the monomeric acids are more or less hydrated in benzene contacted with water:

$$HA_o + H_2O_o \overset{\beta_{11}}{\rightleftharpoons} HA\cdot H_2O_o$$
$$\beta_{11} = [HA\cdot H_2O]_o/[HA]_o[H_2O]_o, \quad (7)$$

where β_{11} denotes the hydration constant. The conditional partition constant, $K'_{D,HA}$, determined from partition data is related with $K'_{D,HA}$, which is corrected for the hydration, as follows:

$$K_{D,HA} = K'_{D,HA}(1 + \beta_{11}[H_2O]_o)^{-1}, \quad (8)$$

where the monomer concentration of water in benzene at 25 °C is taken to be 0.0345 mol dm^{-3}.[18] The values for some aliphatic carboxylic acids are summarized in Table 1.

Evaluation of Solubility Parameters. If the heat of vaporization, ΔH^v/J mol^{-1}, is determined at a certain temperature, say 25 °C, the solubility parameter is given by:

$$\delta_{HA} = (\Delta H^v_{298} - RT)^{1/2}V_{HA}^{-1/2} \quad (9)$$

Table 1. Partition constant and hydration constant of carboxylic acids at 25 °C

Acid	$\log K'_{D,HA}$	$\log \beta_{11}$	$\log K_{D,HA}$ (obsd)	$\log K_{D,HA}$ (calcd)[g]

Chem.*, **31**, 2591 (1969). f) Observed value used for calculation. g) Eq. 5.

where V_{HA}/cm^3 mol^{-1} is the molar volume of the pure liquid acid.

The lower monocarboxylic acids are known to dimerize in gas phase[20] even at pressure as low as 1 mmHg, and hence the heat of vaporization calculated from vapor pressure data only leads to erroneous results. The heat of vaporization from the vapor pressure data should be corrected for the heat of dimerization in the gas phase.[21] The heat of fusion should also be taken into account for the solid acids.[22] The corrected values of vaporization enthalpy in kJ mol^{-1} unit for fatty acids are given in Table 2. It has been shown by a number of workers[22-24] that there is a linear relationship between ΔH^v_{298} of the pure acids of a homologous series and its chain length. For a fatty acids, $CH_3(CH_2)_nCOOH$, we obtain the following best-fitting relation for the heat of vaporization ΔH^v_{298}/kJ mol^{-1} in Table 2:

Table 2. Heat of vaporization, molar volume, and solubility parameter of carboxylic acids at 25 °C

Acid	ΔH^v_{298} / kJ mol^{-1}	V_{HA}[d] / cm^3 mol^{-1}	δ_{HA}[e] / J$^{1/2}$ cm$^{-3/2}$
Acetic acid	51.5±1.7[a]	61.0	28.0
Propanoic acid	55.2±2.1[a]	77.5	26.1
Butanoic acid	58.6±4.2[a]	92.5	24.7
Pentanoic acid	62.3±2.9[b]	110.5	23.8
Hexanoic acid	73.2±2.1[b]	127.0	23.0
Heptanoic acid	72.0±1.7[b]	143.5	22.4
Octanoic acid	82.8±0.8[b]	160.0	21.9
Nonanoic acid	82.4±0.4[c]	176.5	21.5
Decanoic acid	89.5±2.1[c]	193.0	21.2

a) T. Konicek and I. Wadsö, *Acta Chem. Scand.*, **24**, 2612 (1970). b) C. G. Kruif and H. A. J. Oonk, *J. Chem. Thermodyn.*, **11**, 287 (1979). c) D. P. Baccanari, J. A. Novinski, Y. Pan, M. M. Yevitz, and H. A. Swain, *Trans. Faraday Soc.*, **64**, 1201 (1968). d) Calculated according to Eq. 11. e) Calculated according to Eq. 9 by employing calcul ated values of ΔH^v_{298} (Eq. 10) and V_{HA} (Eq. 11).

$$\Delta H^v_{298} = 50.3 + 4.9\,n, \tag{10}$$

where n denotes the number of CH_2 group. The increment in the heat of vaporization per CH_2, 4.9 kJ mol^{-1}, is in good agreement with that of (4.9±0.1) kJ mol^{-1} for normal alkanes, 1-alkenes, 1-alkanols, 1-alkanethiols, 1-chloro-, and 1-bromoalkanes and alkanoates.[23]

For the fatty acids, the molar volumes are proportional to chain length.[24-26] According to Rheineck and Lin,[26] the group contribution to the molar volume in cm^3 mol^{-1} unit is 34.0, 16.5 and 27.0 for methyl, methylene and carboxyl groups, respectively. Then the molar volume V_{HA}/cm^3 mol^{-1} for the fatty acids at 25°C is given by:

$$V_H = 61.0 + 16.5\,n, \tag{11}$$

where 61.0 cm^3 mol^{-1} for acetic acid was used as a standard for convenience.

With values of ΔH^v_{298} and V_{HA} in hand we calculate δ_{HA} of fatty acid by Eq. 9. Calculated δ_{HA} values are tabulated in Table 2.

As solubility parameter of the aqueous solution we used 47.9 J$^{1/2}$ cm$^{-3/2}$ calculated from the heat of vaporization of pure water.[27]

Determination of Binary Coefficients. We assume the additive property of excess enthalpy of mixing, ΔH^E, for functional groups in an organic compound X-$(CH_2)_n$-Y (abbreviated as X-n-Y), X, Y, and CH_2:

$$\Delta H^E_{X\text{-}n\text{-}Y} = \Delta H^E_X + n\Delta H^E_{CH_2} + \Delta H^E_Y. \tag{12}$$

The excess enthalpies of mixing of this compound and X, Y, and CH_2 are given by:

$$\Delta H^E_{X\text{-}n\text{-}Y} = V_{X\text{-}n\text{-}Y}[(\delta_s - \delta_{X\text{-}n\text{-}Y})^2 + 2l_{X\text{-}n\text{-}Y,s}\delta_{X\text{-}n\text{-}Y}\delta_s], \tag{13}$$

$$\Delta H^E_X = V_X[(\delta_s - \delta_X)^2 + 2l_{X,s}\delta_X\delta_s], \tag{14}$$

$$\Delta H^E_Y = V_Y[(\delta_s - \delta_Y)^2 + 2l_{Y,s}\delta_Y\delta_s], \tag{15}$$

$$\Delta H^E_{CH_2} = V_{CH_2}[(\delta_s - \delta_{CH_2})^2 + 2l_{CH_2,s}\,\delta_{CH_2}\delta_s], \tag{16}$$

where the subscript s denotes a solvent with which X-n-Y is mixed.

Substituting Eqs. 13—16 into Eq. 12 and assuming the additivity for the molar volume and the cohesive energy,[26] we obtain

$$\begin{aligned}(l_{X\text{-}n\text{-}Y,s} - 1)\delta_{X\text{-}n\text{-}Y}V_{X\text{-}n\text{-}Y} &= (l_{X,s} - 1)\delta_X V_X + n(l_{CH_2,s} - 1)\delta_{CH_2}V_{CH_2} \\ &\quad + (l_{Y,s} - 1)\delta_Y V_Y \qquad (17)\\ &= (l_{X\text{-}Y,s} - 1)\delta_{X\text{-}Y}V_{X\text{-}Y} + n(l_{CH_2,s} - 1)\delta_{CH_2}V_{CH_2}. \qquad (18)\end{aligned}$$

For an aliphatic carboxylic acid HA, X=CH_3 and Y=COOH. Then we may rewrite Eq. 18 as follows:

$$(l_{HA,s} - 1)\delta_{HA}V_{HA} = (l_{HA^\circ,s} - 1)\delta_{HA^\circ}V_{HA^\circ} + n(l_{CH_2,s} - 1)\delta_{CH_2}V_{CH_2}, \tag{19}$$

where HA° denotes acetic acid. Then the plot of the left hand side of Eq. 19 against n should give rise to a straight line with the intercept of $(l_{HA^\circ,s}-1)\delta_{HA^\circ}V_{HA^\circ}$ and the slope of $(l_{CH_2,s}-1)\delta_{CH_2}V_{CH_2}$.

The binary coefficient $l_{HA,W}$ of hexanoic to nonanoic acids was determined according to the following equation derived from Eq. 4:

$$\log[HA]_w = 3 - \log V_{HA} - 0.434\phi_w(1 - V_{HA}V_w^{-1}) - 0.434V_{HA}\phi_w^2[(\delta_w - \delta_{HA})^2 + 2l_{HA,w}\delta_{HA}\delta_w]/RT, \tag{20}$$

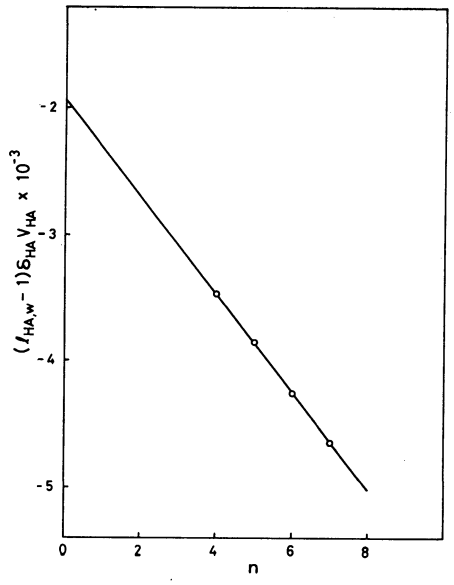

Fig. 1. Correlation between $(l_{HA,w}-1)\delta_{HA}V_{HA}$ and chain length. The line was drawn using the values $l_{CH_2,w}=-0.350$ and $l_{HA\circ,w}=-0.136$.

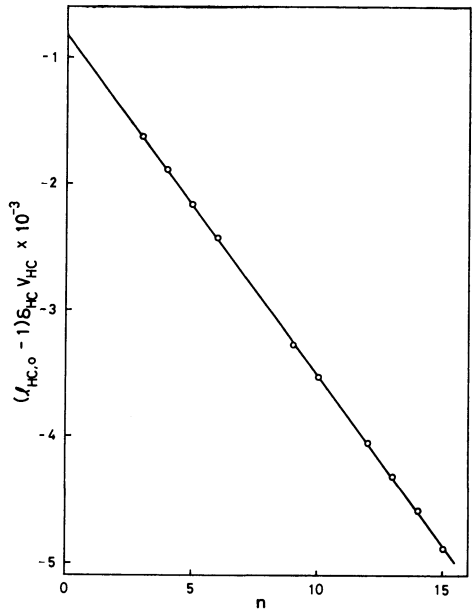

Fig. 2. Correlation between $(l_{HC,o}-1)\delta_{HC}V_{HA}$ and chain length. The line was drawn using the values $l_{CH_2,o}=0.055$ and $(l_{CH_3,o}-1)\delta_{CH_3}V_{CH_3}=-409$.

where $[HA]_w$ is the solubility of monomeric acid in water, corrected for the ionic dissociation. We utilized the solubility of carboxylic acids given by Ralston and Hoerr[28] interpolated to 25 °C.

As predicted from Eq. 19, $(l_{HA,w}-1)\delta_{HA}V_{HA}$ is linearly related with the number of methylene groups in carboxylic acids, n (see Fig. 1). By means of the method of least squares according to Eq. 19, we obtain

$$(l_{HA,w}-1)\delta_{HA}V_{HA}=-1940-386\,n. \quad (21)$$

That is $(l_{HA\circ w}-1)\,\delta_{HA\circ}V_{HA\circ}=-1940$ and $(l_{CH_2,w}-1)\times\delta_{CH_2}V_{CH_2}=-386$ in $J^{1/2}\,cm^{3/2}$ unit. From these equations together with values of $\delta_{HA\circ}V_{HA\circ}$ (Table 2) and $\delta_{CH_2}V_{CH_2}=286$ given by Rheineck and Lin,[26] the following binary coefficients are determined: $l_{HA\circ,w}=-0.136$ and $l_{CH_2,w}=-0.350$.

For hydrocarbons (abbreviated as HC), X=Y=CH_3 in Eq. 17. Then we obtain Eq. 22 for the subscript s=o

$$(l_{HC,o}-1)\delta_{HC}V_{HC}=2(l_{CH_3,o}-1)\delta_{CH_3}V_{CH_3}+n(l_{CH_2,o}-1)\delta_{CH_2}V_{CH_2}. \quad (22)$$

Table 3. Excess enthalpy of equimolar mixture at 298.15 K and derived binary coefficient

System	ΔH^E_{HC}/J mol^{-1}	$l_{HC,o}$
Pentane+Benzene	857[a]	0.028

Heptadecane+Benzene	1289[a]	0.052

a) C. Menduina and M.Diaz-Pena, *Int. DATA Ser., Selec. Data Mixture, Ser. A*, p. 53, 55, 57—62 (1976). b) M. I. Paz-Andrade, *ibid.*, p. 100 (1973). c) J. P. E. Grolier, *ibid.*, p. 223 (1974).

Values of $l_{HC,o}$ for benzene was evaluated from the excess enthalpy of the system $C_6H_6+CH_3(CH_2)_nCH_3$ by means of Eq. 13. The results are tabulated in Table 3. Then the plot of the left hand side of Eq. 22 against n (Fig. 2) gives us the value $(l_{CH_3,o}-1)\,\delta_{CH_3}V_{CH_3}$ from the slope. By means of the method of least squares we obtain $(-270.3\pm1.0)J^{1/2}\,cm^{3/2}$ as $(l_{CH_3,o}-1)\,\delta_{CH_3}V_{CH_3}$ for benzene. $\delta_{CH_3}V_{CH_3}=286$ ($J^{1/2}\,cm^{3/2}$),[26] then we obtain $l_{CH_3,o}=0.055$.

Now according to Eq. 5 together with the known value of the partition constant of acetic acid (Table 1), we can determine the value of $l_{HA\circ,o}=0.034$ for benzene.

With these values of binary coefficients for benzene, we can rewrite Eq. 19 as follows:

$$(l_{HA,o}-1)\delta_{HA}V_{HA}=-1650-270\,n. \quad (23)$$

Values of $l_{HA,w}$ and $l_{HA,o}$ calculated by Eqs. 21 and 23, respectively, are summarized in Table 4.

Partition Constant of Aliphatic Carboxylic Acids. With thus determined values of $l_{HA,w}$ and $l_{HA,o}$ in hand, Eq. 5 enable us to predict the partition constant of aliphatic carboxylic acids. We utilized $\delta_w=47.9\,J^{1/2}$

Table 4. Binary coefficients of carboxylic acids

Acid	$l_{HA,w}\times10$		$l_{HA,o}\times10^2$
	Eq. 21	Solubility[a]	Eq. 23
Acetic acid	−1.36	—	3.4
Propanoic acid	−1.50	—	4.7
Butanoic acid	−1.68	—	5.4
Pentanoic acid	−1.78	—	6.2
Hexanoic acid	−1.93	−1.90	6.3
Heptanoic acid	−2.04	−2.05	6.5
Octanoic acid	−2.15	−2.14	6.5
Nonanoic acid	−2.23	−2.24	6.6
Decanoic acid	−2.29	—	6.7

a) Calculated from the data in Ref. 28.

$cm^{-3/2}$ and $\delta_o = 18.7\ J^{1/2}\,cm^{-3/2}$. Calculated values of the partition constant are listed in Table 1. It is evident that the values calculated by Eq. 5 compare very favorably with the experimental.

It is known that, in a homologous series, the partition constant $\log K_D$ is a linear function of the number of carbon atoms involved. According to Eq. 5, the increment of $\log K_D$ for an added methylene group may be written as:

$$\Delta \log K_D/CH_2 = V_{CH_2}[(\delta_w - \delta_{CH_2})^2 - (\delta_o - \delta_{CH_2})^2 + 2l_{CH_2,w}\delta_{CH_2}\delta_w - 2l_{CH_2,o}\delta_{CH_2}\delta_o + RT(V_o^{-1} - V_w^{-1})]/2.303RT. \quad (24)$$

Here we assume the additivity of molar volume and cohesive energy of functional groups. Now with $V_{CH_2} = 16.5$, $\delta_{CH_2} = 17.44$(Ref. 26), $l_{CH_2,w} = -0.350$ and $l_{CH_2,o} = 0.055$ for benzene, we obtain $\Delta \log K_D/CH_2 = 0.59$ for this solvent from Eq. 24. This value is consistent with the previous findings, *i.e.*, $\Delta \log K_D/CH_2 = 0.56$—$0.64$ for partition of alkanoic acids[3,29] and 1-alkanols[3] between benzene and water. It is worth noting from Eq. 24 that $\Delta \log K_D/CH_2$ depends on the organic solvent used, while it is independent of a polar group of alkyl compounds attached to the terminal. In Table 5 are listed values of $\Delta \log K_D/CH_2$ for several water-organic solvent systems together with $l_{CH_2,o}$, δ_o, and V_o. Interestingly values of $l_{CH_2,o}$ are very near to zero for all solvents as compared to $l_{CH_2,w} = -0.350$.

Table 5. $\Delta \log K_D/CH_2$ values for several organic solvent–water systems

Organic solvent	δ_o [e]	V_o [e]	$l_{CH_2,o} \times 10^2$ [f]	$\Delta \log K_D/CH_2$
Hexane	14.91	131.6	2.1	0.59
Cyclohexane	16.73	108.7	4.5	0.60
Carbon tetrachloride	17.48	97.1	3.9	0.59, 0.60[a]
Benzene	18.73	89.4	5.5	0.57, 0.60[b]
Nitrobenzene	20.45	102.7	4.0	0.56, 0.60[b]

Wakahayashi *et al.*[9] have used the following relationship for the partition constant $K_{B,o}$ of β-diketones and β-diketonates

$$\log K_{D,B} = V_B[(\delta'_w - \delta_B)^2 - (\delta_o - \delta_B)^2 + RT(V_o^{-1} - V_w^{-1})]/2.303RT, \quad (25)$$

where the subscript B denotes a solute partitioned between the aqueous and organic phases. Eq. 25 was successfully used for these systems with the empirical solubility parameter of water $\delta_w' = 35.89\ J^{1/2}\,cm^{-3/2}$.

Table 6. Empirical solubility parameter of water for different solute and solvent

δ_w' is considerably lower than the value obtained from the heat of vaporization $\delta_w = 47.9\ J^{1/2}\,cm^{-3/2}$. Comparison of Eq. 5 with Eq. 25 leads to the following:

$$(\delta'_w - \delta_B)^2 = (\delta_w - \delta_B)^2 + 2l_{B,w}\delta_B\delta_w - 2l_{B,o}\delta_B\delta_o, \quad (26)$$

in which δ'_w is correlated with the binary coefficients $l_{B,w}$ and $l_{B,o}$. From Eq. 26 it is obvious that δ'_w differs from solvent to solvent and from solute to solute. In Table 6 are listed values of δ'_w calculated for different solvents and solutes. If the values of δ'_w are compared for the same solute, they are close to each other for organic solvents of low polarity and limited tendency of hydrogen bonding. From this table may be seen the limit of the use of the empirical δ'_w values in the study of solvent effect on the extraction.

The Crystal and Molecular Structure of *trans*-2,2-Diphenyl-3,4-dichlorothietane

Shigekazu KUMAKURA

Department of Chemistry, Saitama University, 255 Shimo-okubo, Urawa 338

(Received December 8, 1980)

The crystal structure of the title compound has been determined by means of X-ray diffraction. The space group is $P\bar{1}$ with $a=11.665(4)$, $b=8.775(4)$, $c=7.092(2)$ Å, $\alpha=95.73(3)$, $\beta=84.36(3)$, $\gamma=104.90(2)°$, and $Z=2$. The structure was refined to $R=0.048$ for 1770 reflections collected on a four-circle diffractometer. The thietane ring is puckered with dihedral angles, C(2)SC(4)/C(2)C(3)C(4) and SC(2)C(3)/SC(4)C(3), of 150.1° and 149.9° respectively. The conformation of the C–Cl bonds with respect to the thietane skeleton is (3e4e), consistent with that in solution derived from the dipole moments. The average distance of the two C–Cl bonds is 1.781 Å. The C(2)–S, C(4)–S, and C(2)–C(3) bond distances are 1.872(4), 1.811(5), and 1.545(6) Å respectively; agreeing well with the corresponding bond distances observed in the *cis* isomer of the compound; however, the C(3)–C(4) of 1.506(6) Å is much shorter. The bisector of the bond angle formed by the ring substituents at each of the ring atoms is tilted out of the corresponding CCC or CCS planes within the thietane ring so as to increase the staggering of the neighboring substituents. The angle of tilt at C_β is larger than those at the C_α's. The intermolecular S···S contact of 4.080(5) Å is normal in view of the usual van der Waals radii.

Thietane is an example of four-membered ring molecules including a hetero-atom and differs from cyclobutane in the factors governing the geometry of four-membered ring systems. Recently theoretical and experimental investigations[1] on cyclobutane have indicated that the bisector of the methylene group is tilted out of the CCC plane of which the CH_2 group forms an apex and that the tilt of the CH_2 group appears to be an essential feature of bonding in the four-membered ring. Hence, detailed molecular geometries of thietane and its derivatives are required for comparative studies of the four-membered ring systems. The geometry of thietane itself was reported by Karakida and Kuchitsu;[2] however, the angles of tilts exhibited by the methylene groups are still unknown. Thus far, the only paper describing the tilting angle of the methylene group in thietane derivatives explicitly has been a microwave study of thietane 1-oxide by Bevan, Legon, and Millen;[3] the complete data of the molecular structure have not yet been presented. The present paper will describe a crystal-structure analysis of *trans*-2,2-diphenyl-3,4-dichlorothietane (abbreviated hereafter as *trans*-DCTE). The influence of the orientation of the ring substituents on the ring geometry is examined by comparing the molecular structure with that of *cis*-DCTE previously reported,[4] while the tilts of the ring substituents and the deformation of the thietane skeletons will be discussed in terms of the CNDO/2 method.

Experimental

The title compound was synthesised by a cycloaddition of thiobenzophenone to *trans*-dichloroethylene.[5] The crystals grown from a hexane solution are colorless plates. The lattice constants and intensity data were measured on a Philips PW 1100 automatic diffractometer, using Cu $K\alpha$ radiation monochromated by a graphite plate. The ω-2θ scan technique was employed with a scan speed of 4° min^{-1} in ω. The scan-width used was $(1.0+0.35\tan\theta)°$. A total of 1806 non-zero reflections were measured up to $\theta=78°$. 1770 reflections with $|F_o|\geq 3\sigma(|F_o|)$ were used for the analysis. Three standard reflections, monitored every two hours, showed a steady decline in intensity; at the end of data collection, the maximum reduction reached to 29%. The intensity data were put on a common scale by reference to the standard reflections. Lorentz and polarization corrections were applied, but no absorption correction was made ($\mu r\leq 0.5$). The crystal data are listed in Table 1.

Structure Analysis

The Cl and S positions were obtained from a sharpened Patterson map ($B=3.0$ Å^2). The positions of the remaining non-hydrogen atoms were determined by the heavy-atom method. A difference electron-density map computed at the stage of the R value of 0.07 revealed all the H atoms in plausible positions. Subsequent block-diagonal least-squares refinements including isotropic hydrogen atoms gave the final R value of 0.048. The weighting scheme of $w=1$ if $|F_o|\geq 10.0$ and $w=0.3$ otherwise was employed. The atomic scattering factors were taken from *International Tables for X-Ray Crystallography*.[6] The final atomic parameters are listed in Table 2. The atomic parameters for H atoms, the temperature factors for non-hydrogen atoms, and the list of observed and calculated structure factors are kept as Document No. 8149 at the Chemical Society of Japan.

The calculations were carried out on a HITAC 8700/8800 computer at the Computer Center of the

Description and Discussion of the Structure

The molecule is disymmetric, and both enantiomorphs exist in the crystal. A projection of the crystal structure viewed along the a axis is shown in Fig. 1. All the intermolecular contacts observed are normal in view of the usual van der Waals radii. The observed dipole moment of *trans*-DCTE (2.02 D) is close to that of *cis*-DCTE (2.16 D),[7] although their directions in the molecules are different from each other. The closest intermolecular contact of S···S=4.080(5) Å seems to be normal in contrast to the case of *cis*-DCTE (3.32 Å).

The molecular conformation and the atomic-numbering scheme employed are shown in Fig. 2. The conformation observed can be described as (3e4e), based upon the orientations of the Cl substituents with respect to the thietane skeleton; this agrees with that deduced from the dipole-moment study.[7] The two phenyl groups are planar; their orientations are illustrated in Fig. 3.

The bond lengths and angles are listed in Table 3, while the relevant non-bonded distances within the molecule are given in Table 4.

Ring Geometry. The thietane ring is puckered with the (C(2)SC(4)/C(2)C(3)C(4)) puckering angle of 29.9°(θ1) and the (SC(2)C(3)/SC(4)C(3)) puckering angle of 30.1°(θ2). All the inner angles within the thietane ring are much smaller than the values normally exhibited by the sp^3 carbon and the divalent sulfur respectively. The non-bonded S···C(3) and C(2)···C(4) distances are much smaller than the usual van der Waals contacts. The C(2)–S bond length of 1.872(4) Å is significantly longer than the C(4)–S bond length of 1.811(5) Å. The C(3)–C(4) of 1.506(6) Å is much shorter than the C(2)–C(3) (1.545(6) Å). The geometry of the thietane skeleton of *trans*-DCTE is compared with those of *cis*-DCTE, 3-cyano-3,5,7-trimethyl-6-oxo-1-thia-

5,7-diazaspiro[3.5]nonane (CTMTN),[8] 2-(2,6-dimethylphenylimino)-3,3-dimethyl-4,4-diphenylthietane (DDDTE),[9] and thietane itself[2] in Table 5. The puckering angles of *trans*-DCTE are slightly larger than those of *cis*-DCTE. The values of both compounds are larger than the others listed in the table. Significant deviations between the ring geometries of *trans*- and *cis*-DCTE's are found only for the C(3)–C(4) bond distances, the C(2)–S–C(4) angles, and the non-bonded C(2)···C(4) distances. The shortening of the C(3)–C(4) bond (0.074 Å in *trans*-DCTE) brings about a decrease in the C(2)–S–C(4) angle by 2.7° and a contraction of the C(2)···C(4) distance (0.077 Å); it also increases

the puckering angle, $\theta 2$. Newman projections of the ring substituents in *trans*-DCTE are shown in Fig. 4, where those of *cis*-DCTE are superimposed. There are no significant deviations between them, although the *trans* arrangement of the substituted Cl atoms with the Cl(1)···Cl(2) contact of 3.824 Å seems to be stereochemically more favorable than that of the *cis* (3.25 Å). These observations indicate that the shortening of the C(3)–C(4) bond in *trans*-DCTE is a consequence of releasing a steric interaction between the Cl substituents on going from *cis* to *trans*. Furthermore, this C(3)–C(4) bond length is significantly shorter than the usual value for C(sp^3)–C(sp^3). This provides an interesting contrast to the longer bond observed for most cases of the four-membered ring systems, for example, thietane (C–C=1.548(3) Å)[2] and cyclobutane (C–C=1.548(3) Å).[10] A CNDO/2 calculation of the model molecules for *cis*- and *trans*-DCTE's[11] shows that the observed contraction of the C(3)–C(4) bond in the *trans* isomer may be attributed not only to the alleviation of steric hindrance between the Cl substituents, but also to an increased contribution of the 2s AO on C(4) to the C(3)–C(4) bonding. The C(2)–C(3) bond length in *trans*-DCTE is in good agreement with those in *cis*-DCTE, thietane, and CTMTN. The S–C(2) bond lengths in *cis*- and *trans*-DCTE's may be compared with the value in DDDTE, but they are longer than that in thietane. The carbon atoms at the ends of the longer C–S bonds are linked to two phenyl groups. These longer bonds may be a consequence of the lengthening effect due to the two phenyl groups at C_α. The C(4)–S bond length in *trans*-DCTE is in good agreement with those in *cis*-DCTE and CTMTN, but significantly shorter than that in thietane.

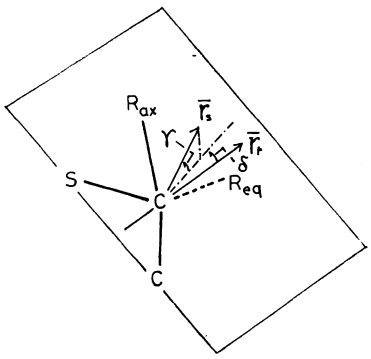

Fig. 5. A definition of the tilting, bending, and twisting angles (γ,δ,χ) exhibited by the ring substitutens. R_{ax} and R_{eq} represent the axial and equatorial substituents, respectively. The vectors, $\bar{r}_s$ and $\bar{r}_r$, are the bisectors of R_{ax}–C–R_{eq} and S–C_α–C_β angles, respectively. The angle, χ, stands for the angle of anticlockwise rotation of the $R_{ax}CR_{eq}$ plane around the vector $\bar{r}_s$.

Orientation of the Ring Substituents. The tilting, bending, and twisting angles (γ,δ,χ) exhibited by the ring substituents are defined as in Fig. 5. Table 6 lists these angles in *cis*- and *trans*-DCTE's and in CTMTN. Their e.s.d.'s are in the range of 0.3°—2°. It is commonly observed for all the compounds that the γ values are positive and that the γ at the C_β is larger than those at the C_α's. Although the puckering angles of *cis*- and *trans*-DCTE's are much larger than those of CTMTN, the γ values at the C_β's in the compounds are approximately equal to each other and agree well with the value of 4° predicted by Pasternak *et al.*[1c] based upon a geometrical model of cyclobutane composed of sp^3 carbons at the puckering angle of 30°. The γ's at the C_α's with the substituents are, however, much smaller than the predicted value. The CNDO/2 energies (E_t) for thietane and the model molecules assumed for *cis*- and *trans*-DCTE's[12] were calculated by varying the tilting angles, γ_1 and γ_2, at C_α and C_β in the range of 0°—6°. The values of γ_1 and γ_2 giving a minimum E_t value for thietane were found to be 1.5° and 3° respectively, while those for the model molecule of *cis*-DCTE were 1° and 5° respectively. The calculated values of these angles approximately agree with those observed for *cis*-DCTE and CTMTN. The tilting of the ring substituents is mainly caused by the resonance energy[13] in the electronic energy calculated; hence, it may be due to the nature of bonding in the thietane ring. On the other hand, the calculated values of γ_1 and γ_2 for the *trans* isomer were about 2°. Both these angles are positive, in accordance with those observed for *trans*-DCTE; however, this relative magnitude does not agree with that observed.

The author is grateful to Professor Yoshihiko Saito, Keiohgijuku University, and Professor Takashi Shimozawa for thier keen interest and valuable discussions. Thanks are also due to Professor Yoichi Iitaka, the University of Tokyo, for the use of the Philips PW 1100 diffractometer.

Spectrophotometric Determination of Formation Constants and Estimation of Molar Absorption Spectra of Individual Components in Chemical Equilibria. Infrared Study of Intermolecular Hydrogen Bonding of 2-Aminopyridine

Hiromu SUGETA

Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received March 27, 1981)

A general method is developed for evaluating formation constants and molar absorption coefficients of constituent species from spectrophotometric data for a multicomponent equilibrium system. The method is applied to analyzing infrared spectra for the intermolecular hydrogen bond system of 2-aminopyridine in carbon tetrachloride solution. 2-Aminopyridine assumes a cyclic dimer structure by dint of an intermolecular hydrogen bonding and the formation constant for the dimerization is 1.4 ± 0.1 mol^{-1} dm^3 at 30 °C.

Spectroscopic methods have widely been used for studying equilibria in solutions. In very complex systems in which numerous equilibria exist, absorption curves of constituent species will overlap each other to give rise to complex envelopes of bands. For such complex systems methods for evaluating equilibrium constants from spectrophotometric data with the nonlinear least-squares method have been discussed by many investigators.[1-5] In their treatments the solution of mass balance equations and Jacobian matrix in the least-squares method were evaluated by numerical computations without resorting to analytical equations.

In this paper a general method for least-squares determination of formation constants and molar absorption coefficients of constituent species from spectrophotometric data is worked out in terms of matrix formulation and programed for electronic computers; a general method for solving mass balance equations for a multicomponent equilibrium system is derived; derivatives of equilibrium concentrations of constituent species with respect to formation constant are given in an analytical form; and a method for recasting the problem of least-squares determination in a simplified form is treated by using methods[6,7] for eliminating linear parameters in nonlinear least-squares adjustment. The method derived is applied to analyzing the intermolecular hydrogen bond system of 2-aminopyridine in carbon tetrachloride solution. Infrared spectra of 2-aminopyridine have been measured by Ramiah and Puranik[8] and Spinner,[9] and a normal coordinate treatment has been carried out by Berezin and Elkin,[10] but no quantitative analyses on intermolecular hydrogen bonding have yet been worked out. Therefore, the present infrared study on the intermolecular hydrogen bond of 2-aminopyridine was undertaken to investigate the molecular structure and formation constant of the hydrogen bond.

Method

Chemical Equilibrium of Multicomponent System. Let us consider the chemical equilibrium of a multicomponent system which consist of reactants X_i $(i=1,\cdots,m)$ and products Y_p $(p=1,\cdots,f)$. Let reaction equation for the system be given by

$$\sum_{i=1}^{m} n_{pi}X_i \rightleftharpoons Y_p \quad (p=1,\cdots,f), \tag{1}$$

where n_{pi} is the stoichiometric coefficient. Denoting the equilibrium concentrations of reactants X_i and products Y_p as $\tilde{\boldsymbol{x}}=[x_1\cdots x_m]$ and $\tilde{\boldsymbol{y}}=[y_1\cdots y_f]$, respectively, the total concentration of reactant X_i as $\tilde{\boldsymbol{x}}^t=[x_1^t\cdots x_m^t]$, and the formation constant of products Y_p as $\tilde{\boldsymbol{K}}=[K_1\cdots K_f]$ where $\sim$ represents the transpose of matrix, we have following equations for ideal solutions:

$$y_p = K_p \prod_{i=1}^{m} x_i^{n_{pi}}, \tag{2a}$$

$$\ln \boldsymbol{y} = \ln \boldsymbol{K} + \boldsymbol{N} \ln \boldsymbol{x}, \tag{2b}$$

$$x_i^t = x_i + \sum_{p=1}^{f} n_{pi} y_p, \tag{3a}$$

$$\boldsymbol{x}_i^t = \boldsymbol{x} + \tilde{\boldsymbol{N}}\boldsymbol{Y}, \tag{3b}$$

where $\ln \boldsymbol{x}$ represents the vector given by

$$\ln \tilde{\boldsymbol{x}} = [\ln x_1 \cdots \ln x_m], \tag{4}$$

and $\boldsymbol{N}$ is the stoichiometric coefficient matrix whose elements are n_{pi}. For a given set of stoichiometry $\boldsymbol{N}$, we can derive the following relations among infinitesimal changes in variables x_i, y_p, K_p, and x_i^t by differentiation of Eqs. 2a—3b:

$$[\boldsymbol{Y}]^{-1}\Delta\boldsymbol{y} = [\boldsymbol{K}]^{-1}\Delta\boldsymbol{K} + \boldsymbol{N}[\boldsymbol{X}]^{-1}\Delta\boldsymbol{x}, \tag{5a}$$

$$\Delta \ln \boldsymbol{y} = \Delta \ln \boldsymbol{K} + \boldsymbol{N}\Delta \ln \boldsymbol{x}, \tag{5b}$$

$$\begin{aligned}\Delta\boldsymbol{x}^t &= \Delta\boldsymbol{x} + \tilde{\boldsymbol{N}}\Delta\boldsymbol{y} \\ &= \tilde{\boldsymbol{N}}[\boldsymbol{Y}][\boldsymbol{K}]^{-1}\Delta\boldsymbol{K} + \{[\boldsymbol{X}] + \tilde{\boldsymbol{N}}[\boldsymbol{Y}]\boldsymbol{N}\}[\boldsymbol{X}]^{-1}\Delta\boldsymbol{x} \\ &= \tilde{\boldsymbol{N}}[\boldsymbol{Y}][\boldsymbol{K}]^{-1}\Delta\boldsymbol{K} + \boldsymbol{H}[\boldsymbol{X}]^{-1}\Delta\boldsymbol{x} \qquad (6a) \\ &= \tilde{\boldsymbol{N}}[\boldsymbol{Y}]\Delta \ln \boldsymbol{K} + \boldsymbol{H}\Delta \ln \boldsymbol{x}, \qquad (6b)\end{aligned}$$

where

$$\boldsymbol{H} = [\boldsymbol{X}] + \tilde{\boldsymbol{N}}[\boldsymbol{Y}]\boldsymbol{N}, \tag{7}$$

and $[\boldsymbol{X}]$, $[\boldsymbol{Y}]$, and $[\boldsymbol{K}]$ are the diagonal matrices whose elements are x_i, y_p, and K_p, respectively, and $\Delta\ln\boldsymbol{x}$ represents the vector given by

$$\Delta \ln \boldsymbol{x} = \begin{bmatrix} \Delta \ln x_1 \\ \Delta \ln x_2 \\ \vdots \\ \Delta \ln x_m \end{bmatrix} = \begin{bmatrix} \Delta x_1/x_1 \\ \Delta x_2/x_2 \\ \vdots \\ \Delta x_m/x_m \end{bmatrix} = [\boldsymbol{X}]^{-1}\Delta\boldsymbol{x}. \tag{8}$$

For a given set of formation constants $(\boldsymbol{K})$ and experimental formal concentrations of reactants $(\boldsymbol{x}^t)$, equilibrium concentrations of reactants $(\boldsymbol{x})$ can be calculated according to the method of Newton-Raphson iteration by making use of the following partial derivatives of total concentration $\boldsymbol{x}^t$ with respect to equilibrium

concentration $\boldsymbol{x}$ which can be derived from Eqs. 6a and 6b under the condition of $\Delta\boldsymbol{K}=0$:

$$(\partial \boldsymbol{x}^t/\partial \boldsymbol{x})_{\Delta \boldsymbol{K}=0} = \boldsymbol{H}[\boldsymbol{X}]^{-1}, \tag{9}$$

$$(\partial \boldsymbol{x}^t/\partial \ln \boldsymbol{x})_{\Delta \boldsymbol{K}=0} = \boldsymbol{H}, \tag{10}$$

where $(\partial \boldsymbol{x}^t/\partial \boldsymbol{x})$ represents the matrix whose i,j elements are $(\partial x_i^t/\partial x_j)$. Partial derivatives of equilibrium concentrations with respect to formation constant for a given set of experimental formal concentrations of the reactants are required for the least-squares determination of formation constants from spectrophotometric data. These derivatives can be derived from Eqs. 5a—6b under the condition of $\Delta \boldsymbol{x}^t=0$ as

$$(\partial \boldsymbol{x}/\partial \boldsymbol{K})_{\Delta \boldsymbol{x}^t=0} = -[\boldsymbol{X}]\boldsymbol{H}^{-1}\tilde{\boldsymbol{N}}[\boldsymbol{Y}][\boldsymbol{K}]^{-1}, \tag{11}$$

$$(\partial \ln \boldsymbol{x}/\partial \ln \boldsymbol{K})_{\Delta \boldsymbol{x}^t=0} = -\boldsymbol{H}^{-1}\tilde{\boldsymbol{N}}[\boldsymbol{Y}], \tag{12}$$

$$(\partial \boldsymbol{y}/\partial \boldsymbol{K})_{\Delta \boldsymbol{x}^t=0} = [\boldsymbol{Y}]\{\boldsymbol{E} - \boldsymbol{N}\boldsymbol{H}^{-1}\tilde{\boldsymbol{N}}[\boldsymbol{Y}]\}[\boldsymbol{K}]^{-1}, \tag{13}$$

$$(\partial \ln \boldsymbol{y}/\partial \ln \boldsymbol{K})_{\Delta \boldsymbol{x}^t=0} = \boldsymbol{E} - \boldsymbol{N}\boldsymbol{H}^{-1}\tilde{\boldsymbol{N}}[\boldsymbol{Y}], \tag{14}$$

where $\boldsymbol{E}$ represents unit matrix.

Least-squares Treatment of Spectrophotometric Data. Suppose a set of absorbance data at λ points in a given wavenumber region for s solutions of different concentrations containing n absorbing components in a chemical equilibrium system. The absorbance per unit path length, $D_{\nu r}$, at wavenumber ν in the rth solution, is expressed by the sum of absorptions of the n components in the system on the assumption of Beer's law:

$$D_{\nu r} = \sum_{i=1}^{n} A_{\nu i}C_{ir}(\boldsymbol{K}) \quad (\nu=1, \cdots, \lambda; r=1, \cdots, s), \tag{15}$$

where $A_{\nu i}$ is the molar absorption coefficient of the ith species at wavenumber ν, and C_{ir} is the concentration of the ith species in the rth solution which is a function of formation constants $\boldsymbol{K}$ and can be calculated by the method as described above. Equation 15 may be written in the matix notation as

$$\boldsymbol{D} = \boldsymbol{A}\boldsymbol{C}(\boldsymbol{K}), \tag{16}$$

where $\boldsymbol{D}$ is a $\lambda \times s$ absorbance matrix, $\boldsymbol{A}$ is a $\lambda \times n$ matrix of molar absorption coefficients, and $\boldsymbol{C}$ is an $n \times s$ concentration matrix. Introducing absorbance vector $\boldsymbol{d}$ and vector $\boldsymbol{a}$ of molar absorption coefficients as defined by

$$\tilde{\boldsymbol{d}} = [\tilde{\boldsymbol{D}}_1\tilde{\boldsymbol{D}}_2 \cdots \tilde{\boldsymbol{D}}_\lambda], \tag{17}$$

$$\tilde{\boldsymbol{a}} = [\tilde{\boldsymbol{A}}_1\tilde{\boldsymbol{A}}_2 \cdots \tilde{\boldsymbol{A}}_\lambda], \tag{18}$$

where $\tilde{\boldsymbol{D}}_\nu$ and $\tilde{\boldsymbol{A}}_\nu$ are row vectors of absorbance and molar absorption coefficients which are the νth rows of matrices $\boldsymbol{D}$ and $\boldsymbol{A}$, respectively,

$$\boldsymbol{D} = \begin{bmatrix} \tilde{\boldsymbol{D}}_1 \\ \vdots \\ \tilde{\boldsymbol{D}}_\lambda \end{bmatrix}, \tag{19}$$

$$\boldsymbol{A} = \begin{bmatrix} \tilde{\boldsymbol{A}}_1 \\ \vdots \\ \tilde{\boldsymbol{A}}_\lambda \end{bmatrix}, \tag{20}$$

Eq. 16 may be written as

$$\tilde{\boldsymbol{D}}_\nu = \tilde{\boldsymbol{A}}_\nu\boldsymbol{C}(\boldsymbol{K}) \quad (\nu = 1, \cdots, \lambda). \tag{21}$$

Now let us consider the problem of determining f formation constants $\boldsymbol{K}$ and $\lambda \times n$ molar absorption coefficients $\boldsymbol{A}$ from $\lambda \times s$ observed absorbances $\boldsymbol{D}^{\text{obsd}}$ by the least-squares method. In Eqs. 16 or 21 absorbances $D_{\nu r}$ are of linear function of molar absorption coefficients $A_{\nu i}$ but of nonlinear function of formation constants K_p. In such cases we can simplify the least-squares treatment into a reduced model by elimination of linear parameters as described in Appendix. For a given set of formation constants $\boldsymbol{K}$, the best least-squares estimate of molar absorption coefficients, $\boldsymbol{A}'(\boldsymbol{K})$, can be given in an explicit form as described in Appendix [Eq. A.6]:

$$\tilde{\boldsymbol{A}}'_\nu = \tilde{\boldsymbol{D}}_\nu^{\text{obsd}}\tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}, \tag{22}$$

$$\boldsymbol{A}' = \boldsymbol{D}^{\text{obsd}}\tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}. \tag{23}$$

Substitution of Eqs. 22 and 23 for Eqs. 21 and 16 gives the observation equations for the reduced model:

$$\tilde{\boldsymbol{D}}'_\nu = \tilde{\boldsymbol{A}}'_\nu\boldsymbol{C} = \tilde{\boldsymbol{D}}_\nu^{\text{obsd}}\tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}\boldsymbol{C}, \tag{24}$$

$$\boldsymbol{D}' = \boldsymbol{A}'\boldsymbol{C} = \boldsymbol{D}^{\text{obsd}}\tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}\boldsymbol{C}, \tag{25}$$

where the prime represents quantities for the reduced model which are functions of $\boldsymbol{K}$ only.

Small changes in absorbance, $\Delta\boldsymbol{D}$, caused by small increments in formation constants, $\Delta\boldsymbol{K}$, are expressed in terms of Jacobian matrix $\boldsymbol{J}'$ for reduced model:

$$\Delta \boldsymbol{D}'_\nu = \boldsymbol{J}'_\nu \Delta \boldsymbol{K}, \tag{26}$$

$$\Delta \boldsymbol{d}' = \boldsymbol{J}' \Delta \boldsymbol{K}, \tag{27}$$

$$\boldsymbol{J}' = \begin{bmatrix} \boldsymbol{J}'_1 \\ \vdots \\ \boldsymbol{J}'_\lambda \end{bmatrix}, \tag{28}$$

$$\boldsymbol{J}'_\nu = [(\partial \boldsymbol{D}'_\nu/\partial K_1) \cdots (\partial \boldsymbol{D}'_\nu/\partial K_f)]. \tag{29}$$

Elements $\partial D'_{\nu r}/\partial K_p$ of Jacobian matrix $\boldsymbol{J}'$ are given according to Eqs. A. 10—A. 12 derived in Appendix:

$$\begin{aligned} \partial \boldsymbol{D}'_\nu/\partial K_p &= (\partial \tilde{\boldsymbol{C}}/\partial K_p)\boldsymbol{A}'_\nu + \tilde{\boldsymbol{C}}(\partial \boldsymbol{A}'_\nu/\partial K_p) \\ &= [\boldsymbol{E} - \tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}\boldsymbol{C}](\partial \tilde{\boldsymbol{C}}/K_p)\boldsymbol{A}'_\nu \\ &\quad + \tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}(\partial \boldsymbol{C}/\partial K_p)(\boldsymbol{D}_\nu^{\text{obsd}} - \boldsymbol{D}'_\nu), \end{aligned} \tag{30}$$

$$\begin{aligned} \partial \boldsymbol{A}'_\nu/\partial K_p &= -(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}\boldsymbol{C}(\partial \tilde{\boldsymbol{C}}/\partial K_p)\boldsymbol{A}'_\nu \\ &\quad + (\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}(\partial \boldsymbol{C}/\partial K_p)(\boldsymbol{D}_\nu^{\text{obsd}} - \boldsymbol{D}'_\nu). \end{aligned} \tag{31}$$

Derivatives $(\partial C_{ir}/\partial K_p)$ can be calculated by the method established in the preceding section (Eqs. 11 and 13). Equations 30 and 31 may be written with reference to Eqs. 19 and 20 as follows:

$$\begin{aligned} \partial \boldsymbol{D}'/\partial K_p &= \boldsymbol{A}'(\partial \boldsymbol{C}/\partial K_p) + (\partial \boldsymbol{A}'/\partial K_p)\boldsymbol{C} \\ &= \boldsymbol{A}'(\partial \boldsymbol{C}/K_p)[\boldsymbol{E} - \tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}\boldsymbol{C}] \\ &\quad + (\boldsymbol{D}^{\text{obsd}} - \boldsymbol{D}')(\partial \tilde{\boldsymbol{C}}/\partial K_p)(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}\boldsymbol{C}, \end{aligned} \tag{32}$$

$$\begin{aligned} \partial \boldsymbol{A}'/\partial K_p &= -\boldsymbol{A}'(\partial \boldsymbol{C}/\partial K_p)\tilde{\boldsymbol{C}}(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1} \\ &\quad + (\boldsymbol{D}^{\text{obsd}} - \boldsymbol{D}')(\partial \tilde{\boldsymbol{C}}/\partial K_p)(\boldsymbol{C}\tilde{\boldsymbol{C}})^{-1}. \end{aligned} \tag{33}$$

Thus, formation constants $\boldsymbol{K}$ can be determined according to the usual procedure based on nonlinear least-squares with reference to observed data $\boldsymbol{D}^{\text{obsd}}$. The normal equations for the reduced model which give correction $\Delta\boldsymbol{K}$ in iteration cycles are given by

$$(\tilde{\boldsymbol{J}}'\boldsymbol{J}')\Delta \boldsymbol{K} = \tilde{\boldsymbol{J}}'(\boldsymbol{d}^{\text{obsd}} - \boldsymbol{d}') \tag{34}$$

$$\tilde{\boldsymbol{J}}'\boldsymbol{J}' = \sum_{\nu=1}^{\lambda} \tilde{\boldsymbol{J}}'_\nu \boldsymbol{J}'_\nu \tag{35}$$

$$\tilde{\boldsymbol{J}}'(\boldsymbol{d}^{\text{obsd}} - \boldsymbol{d}') = \sum_{\nu=1}^{\lambda} \tilde{\boldsymbol{J}}'_\nu (\boldsymbol{D}_\nu^{\text{obsd}} - \boldsymbol{D}'_\nu). \tag{36}$$

Experimental

2-Aminopyridine was recrystallized from carbon tetrachloride and dried. Spectroscopic grade carbon tetrachloride

dried over molecular sieves 3A was used as the solvent. Solutions were prepared in the concentration range of 0.5—0.005 M (1 M = 1 mol dm^{-3}). Infrared spectra were measured with a JASCO A-3 infrared spectrophotometer at 30°C. Absorbances were digitized with an AD converter over the range from 3600 to 3000 cm^{-1}. Absorbance data at 10 cm^{-1} intervals from 3550 to 3360 cm^{-1} and at 20 cm^{-1} intervals from 3360 to 3120 cm^{-1} were used for data analysis.

Results and Discussion

The observed spectra in the NH_2 stretching region of three solutions of 2-aminopyridine in CCl_4 are shown in Fig. 1. In the dilute solution the symmetric (ν_sNH_2)

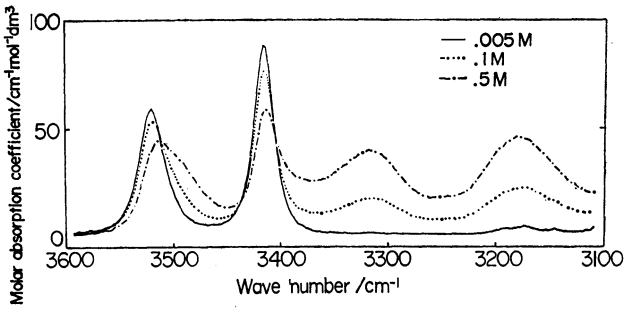

Fig. 1. Infrared spectra of 2-aminopyridine in CCl_4 solution.

and antisymmetric (ν_aNH_2) stretching vibrations of NH_2 group in free species are observed at 3415 and 3520 cm^{-1}, respectively. As the concentration increases both the peaks at 3520 and 3415 cm^{-1} decrease while the broad bands at 3315 and 3170 cm^{-1} grow up and the absorbances at about 3500 and 3390 cm^{-1} increase. These observations suggest that bands due to intermolecular association exist at those wavenumbers.

The concentration dependence of the observed absorbances was analyzed on the basis of the monomer-dimer equilibrium model by the least-squares method as described above. The formation constant for dimerization (K=[dimer]/[monomer]^2) was calculated to be 1.4±0.1 M^{-1} at 30 °C. The calculated molar absorption coefficients for monomer and dimer species are shown in Fig. 2, in which those for dimer species are

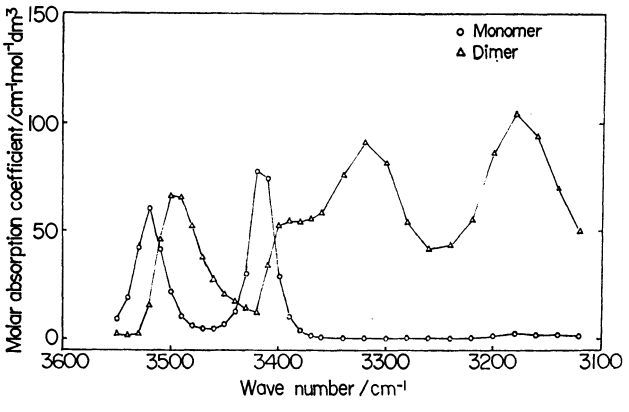

Fig. 2. Molar absorption coefficients for monomer and dimer of 2-aminopyridine.

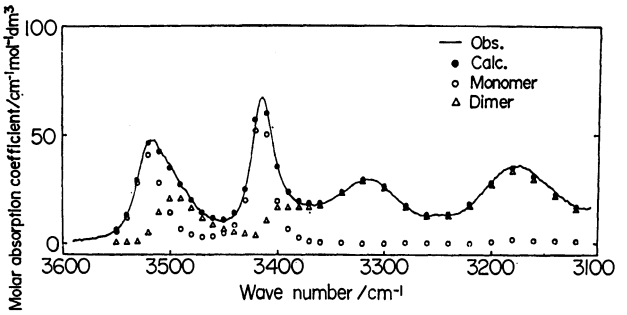

Fig. 3. Observed and calculated spectra for 0.25 M solution.

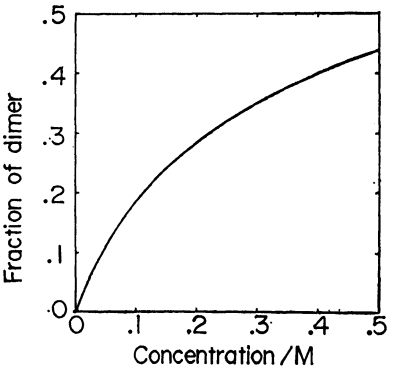

Fig. 4. Concentration dependence of the degree of dimer formation.

given in values per monomer unit. The observed spectra could be reproduced with a root-mean-squares deviation of 0.57 (in the unit of molar absorption). An example of comparison between observed and calculated spectra is shown in Fig. 3, together with contribution from monomer and dimer species for the 0.5 M solution. The concentration dependence of the degree of dimer formation is shown in Fig. 4. It turns out that the fraction of dimer changes from 1.4% at the lowest concentration of 0.005 M to 44% at the highest concentration of 0.5 M. The monomer-trimer model also was applied but the agreement between observed and calculated spectra was poor as compared with the monomer-dimer model. The least-squares treatment on the monomer-dimer-trimer model could give no convergence. Therefore, it can be concluded that dimerization is the predominant association in the concentration range employed.

The calculated molar absorption coefficients in Fig. 2 show that the monomer species has bands at 3520 and 3415 cm^{-1} which are assigned to vibrations ν_aNH_2 and ν_sNH_2, respectively, in the non-hydrogen-bonded species. The calculated dimer spectrum has peaks at 3495, 3320, and 3180 cm^{-1} and a shoulder at about 3390 cm^{-1}. The band at 3495 cm^{-1} can be assigned to the free N–H stretching vibration in the $\overset{\overset{H}{|}}{N}$–H···N hydrogen bond system. The two broad bands at 3320 and 3180 cm^{-1} can be assigned to the Fermi doublet caused by the resonance between the hydrogen-bonded N–H stretching vibration and the overtone of the NH_2

bending vibration at 1630 cm^{-1} in the $\overset{H}{\underset{|}{N}}$–H···N hydrogen bond system, similar resonance beeing observed in the hydrogen bond system of aniline by Wolf and Mathias.[11] The unperturbed hydrogen-bonded N–H stretching fundamental of dimer is estimated to be about 3240 cm^{-1}. The shoulder at 3390 cm^{-1} may be ascribed to the band caused by a Fermi resonance between the hydrogen-bonded N–H stretching fundamental and the overtone of the pyridine ring vibration at 1610 cm^{-1} or the combination tone of the NH_2 bending and ring vibrations.

From the fact that the calculated dimer spectrum has only one non-hydrogen-bonded N–H stretching band it turns out that one proton of NH_2 group is involved in the hydrogen bond while the other proton is free of the hydrogen bonding. It is consequently concluded that 2-aminopyridine in CCl_4 assumes a cyclic dimer structure by dint of an intermolecular hydrogen bond as shown in Fig. 5; it has been observed that 2-aminopyridine assumes the same cyclic dimer structure in the crystalline state.[12]

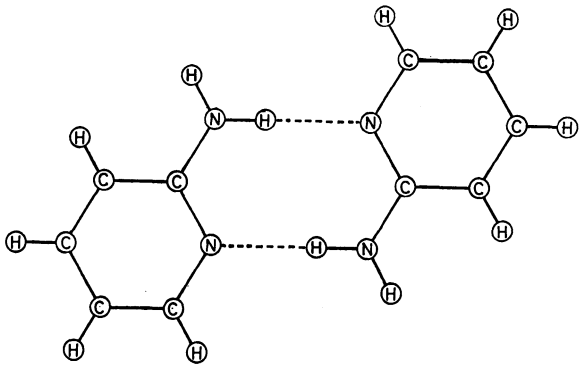

Fig. 5. Intermolecular hydrogen bonding of 2-aminopyridine.

Appendix: Elimination of Linear Parameters in Nonlinear Least-squares Treatment

Consider the problem of a least-squares estimation of the $m+n$ parameters of m nonlinear parameters $\tilde{\boldsymbol{\alpha}}=[\alpha_1\cdots\alpha_m]$ and n linear parameters $\tilde{\boldsymbol{\beta}}=[\beta_1\cdots\beta_n]$ with reference to the t observed values $\tilde{\boldsymbol{Z}}^{obsd}$ associated with the observation equations $\tilde{\boldsymbol{Z}}(\boldsymbol{\alpha},\boldsymbol{\beta})=[Z_1\cdots Z_t]$. Functions Z_q linear in β_k but nonlinear in α_i are generally written as

$$Z_q(\boldsymbol{\alpha},\boldsymbol{\beta}) = \sum_{k=1}^{n} F_{qk}(\boldsymbol{\alpha})\beta_k \quad (q = 1, \cdots, t), \tag{A. 1}$$

where F_{qk} is the nonlinear function of α_i. Eq. A.1 may be written in the matrix notation as

$$\boldsymbol{Z}(\boldsymbol{\alpha},\boldsymbol{\beta}) = \boldsymbol{F}(\boldsymbol{\alpha})\boldsymbol{\beta}. \tag{A. 2}$$

Residual vector $\boldsymbol{\varepsilon}$ and the sum of squared residuals S are given by

$$\boldsymbol{\varepsilon} = \boldsymbol{Z}^{obsd} - \boldsymbol{Z} = \boldsymbol{Z}^{obsd} - \boldsymbol{F}\boldsymbol{\beta}, \tag{A. 3}$$

$$S = \tilde{\boldsymbol{\varepsilon}}\boldsymbol{\varepsilon} = \tilde{\boldsymbol{\beta}}\tilde{\boldsymbol{F}}\boldsymbol{F}\boldsymbol{\beta} - 2\tilde{\boldsymbol{\beta}}\tilde{\boldsymbol{F}}\boldsymbol{Z}^{obsd} + \tilde{\boldsymbol{Z}}^{obsd}\boldsymbol{Z}^{obsd}, \tag{A. 4}$$

where $\sim$ represents the transpose of matrix.

Lawton and Sylvester[6] have pointed out that the $m+n$ dimensional problem with m nonlinear and n linear parameters in a least-squares adjustment could be reduced to an m dimensional problem by elimination of linear parameters. Golub and Pereyra[7] have treated the mathematics and algorism associated with that problem in detail but their derivation requires a familiarity with a somewhat advanced mathematics and is not familiar to chemists. Thus, a rather simple derivation using the elementary algebra will be given in a form appropriate to the present study.

The best least-squares estimate $\boldsymbol{\beta}'(\boldsymbol{\alpha})$ of linear parameters $\boldsymbol{\beta}$ associated with a given set of nonlinear parameters $\boldsymbol{\alpha}$ can be derived from the minimum condition for the sum of squared residuals S:

$$\begin{aligned}(1/2)\partial S/\partial\boldsymbol{\beta} &= (1/2)\partial(\tilde{\boldsymbol{\varepsilon}}\boldsymbol{\varepsilon})\partial/\boldsymbol{\beta} = -\tilde{\boldsymbol{F}}\boldsymbol{\varepsilon}\\ &= \tilde{\boldsymbol{F}}\boldsymbol{F}\boldsymbol{\beta} - \tilde{\boldsymbol{F}}\boldsymbol{Z}^{obsd} = 0,\end{aligned} \tag{A. 5}$$

$$\boldsymbol{\beta} = \boldsymbol{\beta}'(\boldsymbol{\alpha}) = (\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}\tilde{\boldsymbol{F}}\boldsymbol{Z}^{obsd}. \tag{A. 6}$$

Substitution of Eq. A.6 for Eq. A.2 gives reduced observation equations for the reduced model as

$$\boldsymbol{Z}'(\boldsymbol{\alpha}) = \boldsymbol{F}\boldsymbol{\beta}'(\boldsymbol{\alpha}) = \boldsymbol{F}(\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}\tilde{\boldsymbol{F}}\boldsymbol{Z}^{obsd}, \tag{A. 7}$$

where $\boldsymbol{Z}'$ is a function of only nonlinear parameters $\boldsymbol{\alpha}$ and the prime is used for representing quantities for the reduced model. Jacobian matrix $\boldsymbol{J}'$ for the reduced model is defined as

$$J'_{qi} = \partial Z'_q/\partial\alpha_i = \sum_{k=1}^{n}[(\partial F_{qk}/\partial\alpha_i)\beta'_k + F_{qk}(\partial\beta'_k/\partial\alpha_i)], \tag{A. 8}$$

$$\boldsymbol{J}' = \partial\boldsymbol{Z}'/\partial\boldsymbol{\alpha} = [\partial\boldsymbol{Z}'/\partial\alpha_1 \cdots \partial\boldsymbol{Z}'/\partial\alpha_m], \tag{A. 9}$$

$$\partial\boldsymbol{Z}'/\partial\alpha_i = (\partial\boldsymbol{F}/\partial\alpha_i)\boldsymbol{\beta}' + \boldsymbol{F}(\partial\boldsymbol{\beta}'/\partial\alpha_i), \tag{A. 10}$$

where $\partial\boldsymbol{\beta}'/\partial\boldsymbol{\alpha}$ can be derived through differentiation of Eq. A.6:

$$\begin{aligned}\partial\boldsymbol{\beta}'/\partial\alpha_i = &-(\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}[(\partial\tilde{\boldsymbol{F}}/\partial\alpha_i)\boldsymbol{F}\\ &+\tilde{\boldsymbol{F}}(\partial\boldsymbol{F}/\partial\alpha_i)](\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}\tilde{\boldsymbol{F}}\boldsymbol{Z}^{obsd}\\ &+(\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}(\partial\tilde{\boldsymbol{F}}/\partial\alpha_i)\boldsymbol{Z}^{obsd}\\ =&-(\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}\tilde{\boldsymbol{F}}(\partial\boldsymbol{F}/\partial\alpha_i)\boldsymbol{\beta}'\\ &+(\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}(\partial\tilde{\boldsymbol{F}}/\partial\alpha_i)\boldsymbol{\varepsilon}.\end{aligned} \tag{A. 11}$$

Substitution of Eq. A.11 for Eq. A. 10 gives

$$\begin{aligned}\partial\boldsymbol{Z}'/\partial\alpha_i = &[\boldsymbol{E} - \boldsymbol{F}(\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}\tilde{\boldsymbol{F}}](\partial\boldsymbol{F}/\partial\alpha_i)\boldsymbol{\beta}'\\ &+\boldsymbol{F}(\tilde{\boldsymbol{F}}\boldsymbol{F})^{-1}(\partial\tilde{\boldsymbol{F}}/\partial\alpha_i)\boldsymbol{\varepsilon}.\end{aligned} \tag{A. 12}$$

In terms of Jacobian matrix $\boldsymbol{J}'$ given by Eqs. A.9 and A.12 the normal equations for the reduced model are given by

$$(\tilde{\boldsymbol{J}}'\boldsymbol{J}')\Delta\boldsymbol{\alpha} = \tilde{\boldsymbol{J}}'\boldsymbol{\varepsilon}, \tag{A. 13}$$

and

$$\Delta\boldsymbol{\alpha} = (\tilde{\boldsymbol{J}}'\boldsymbol{J}')^{-1}\tilde{\boldsymbol{J}}'\boldsymbol{\varepsilon}. \tag{A. 14}$$

The improved nonlinear parameters $\boldsymbol{\alpha}+\Delta\boldsymbol{\alpha}$ for the next iteration are calculated from Eq. A.14 and the best companion linear parameters $\boldsymbol{\beta}$ are given by Eq. A.6. The method of least-squares with the reudced observation equations given by Eq. A.7 is evidently superior to the one with the original model given by Eq. A.2: The dimension of problem could be reduced to as low as m in the reduced model from $m+n$ in the original model by the elimination of n linear parameters. This reduced dimension could result in a faster convergence, a stabilization of convergence, and a reduction of memories. The initial guess requires only m nonlinear parameters rather than $m+n$ parameters in the original model.

Catalytic Activity of Highly Dispersed Palladium. II. X-Ray Photoelectron Spectroscopic and Thermal Desorption Studies of the Effects of ZrO_2 Added to α-Alumina-supported Palladium

Bu Yong LEE,* Yasunobu INOUE, and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 1, 1981)

The effects of ZrO_2 upon the catalytic properties of α-alumina-supported palladium for the hydrogenation of gaseous cyclohexene were studied by means of detailed kinetic analysis, thermal desorption (TD), and X-ray photoelectron spectroscopy (XPS). The catalysts, with ZrO_2 added in amounts ranging from 0.1 to 45 in Zr/Pd ratio, were characterized by CO chemisorption and X-ray diffraction. The addition of ZrO_2 at the Zr/Pd ratio of 0.5 enhanced the turn-over frequency of the hydrogenation by a factor of 7 and changed the hydrogen order of the reaction from 1.0 to 0.75 and the cyclohexene order from 0 to 0.6. The reaction with D_2 exhibited deuterium-distribution patterns similar to those for the reaction on the ZrO_2-supported Pd catalysts. The hydrogenation pathway on the ZrO_2-added catalyst was described by an associative mechanism in which the slow step was a surface reaction between a cyclohexyl radical and a hydrogen atom. In the thermal desorption spectra, the addition of ZrO_2 caused a broadening of the adsorbed hydrogen peak as well as a shift of the dissolved hydrogen peak toward a lower temperature. The desorption of cyclohexene from Pd/α-Al_2O_3 catalysts underwent a disproportionation to produce benzene around 318 K and cyclohexane at 368 K, whereas the latter peak shifted by 70 K to the lower-temperature side upon the addition of ZrO_2. The XPS study showed that the presence of ZrO_2 provided Pd metal atoms in a negatively-charged state. The support effect was discussed on the basis of the interaction between Pd metal atoms and ZrO_2 oxide.

In recent research in heterogeneous catalysis by supported-metal catalysts, it has been recognized that the catalytic and adsorptive properties of metals loaded depend not only on the characteristics of their geometrical structures, but also on the nature of the underlying supports.[1-5] In the first paper of this series,[6] we have reported that the turn-over frequency of the cyclohexene hydrogenation is larger by one order of magnitude for the ZrO_2-supported Pd catalysts than for the α-alumina-supported Pd and Pd black catalysts. The kinetic behavior of the hydrogenation is also different, and it was proposed that there existed a considerable interaction between the dispersed Pd and ZrO_2 surfaces. For a better understanding of this phenomenon, quantitative information on the interaction between the metal and oxide is needed, and thus it is of interest to employ catalysts in which Pd and ZrO_2 were loaded in different ratios on an inert carrier of α-alumina.

The present study aims at comparing the effect of the ZrO_2 codispersed with Pd to the effects of the ZrO_2 support and at revealing how the catalytic properties vary as a function of the atomic ratio of Zr/Pd. Mechanistic analysis based on the detailed kinetics using D_2 as a tracer was applied to the hydrogenation of gaseous cyclohexene over catalysts with different Zr/Pd ratios. Further, the thermal desorption study was undertaken in order to examine the influence of ZrO_2 upon the adsorbed states of hydrogen and cyclohexene.

In an effort to reveal the change in electronic structures which might be induced through the metal-oxide interaction, X-ray photoelectron spectroscopy (XPS) was employed. The controllable atomic ratio of Zr/Pd in the present system makes this XPS analysis more effective than the previous system of Pd supported on ZrO_2, in which the tail of a large Zr 3d peak interfered with an accurate determination of the Pd 3d levels. The geometric structure of Pd metal in the presence of ZrO_2 was characterized by X-ray diffraction and CO chemisorption methods.

Experimental

The procedure of preparing the catalysts, α-alumina-supported Pd and ZrO_2, and the chemical reagents used were the same as those employed previously[6] except for the use of mixed solutions of palladium and zirconyl nitrates. The concentration of palladium was adjusted to maintain a 2.1 wt% of α-alumina for each of the catalysts, while the atomic ratio of Zr/Pd was increased from 0.1 to 45. Prior to the kinetic run, the catalysts were treated with 20 Torr of oxygen (1 Torr=133.3 Pa) at 523 K, reduced with 20 Torr of hydrogen, and then evacuated at the same temperature. The kinetic behavior of the reaction was examined in the temperature range of 283—323 K, using reactants in the pressure range of 10—40 Torr. The apparatus, procedure, and reactant used have been described elsewhere.[6] The crystallite size and the percentage exposed of the dispersed catalysts were determined by means of the CO chemisorption and X-ray diffraction in manners similar to those employed in the previous study.[6]

The X-ray photoelectron spectra were recorded at room temperature on a Hewlett-Packard 5950A ESCA spectrometer with monochromatized Al $K\alpha$ excitation. Each catalyst sample was pressed in the form of pellets, mounted on a recessed quartz plate, and transferred into the XPS preparation chamber, where it was subjected to "*in situ*" treatment similar to the activation used in the kinetic study except for relatively lower pressures of oxygen and hydrogen (≈5 Torr). The background pressure during photoemission measurement was below 3×10^{-9} Torr. The charging shift was compensated for, or at least minimized, by showering low-energy electron by the use of a flood gun. The binding energies of Al $2s_{1/2}$= 119.1 eV and C 1s=284.8 eV were taken as reference.

The thermal desorption spectra were recorded by using a high-vacuum apparatus pumped at such a high speed that the rate of desorption was proportional to the partial pressure

of the desorbing species.[7] This apparatus was equipped with an ionization gauge to monitor the change in the total pressure, and with a quadrupole mass spectrometer, Mitsubishi MF-T_2M, for the analysis of the desorbed molecules. After being subjected to the pretreatments, the catalyst samples were exposed to different pressures of hydrogen or cyclohexene at various temperatures. The temperature of the catalysts was raised at a rate of 13 K min^{-1} by the use of an outside electric furnace, and was monitored with a Pt-Pt/13%Rh thermocouple which was directly brought into contact with the samples.

Results

Figure 1 shows the variation in the catalytic activity, V_g, as a function of the Zr/Pd ratio. The initial activity, 0.88×10^{21} molecule $min^{-1}g\text{-}Pd^{-1}$, for the 2.1 wt% Pd/α-Al_2O_3 catalyst increased markedly with the addition of ZrO_2 up to a Zr/Pd ratio of 0.5, slowed to a gradual increase, and then reached a stationary value, 4.3×10^{22}, at a ratio of Zr/Pd=45. This activity is in substantial agreement with that for the 2.1 wt% Pd/ZrO_2 catalyst. No catalytic hydrogenation proceeded on the alumina and ZrO_2 under the same conditions. The variations in the pressure and temperature dependence of the hydrogenation rate were systematically examined for the catalysts with different Zr/Pd ratios; the kinetic parameters thus obtained are summarized in Table 1. By the addition of ZrO_2 at a Zr/Pd ratio of 0.5, the reaction order with respect to the hydrogen pressure, P_h, decreased from 1.0 to 0.75, whereas the order with respect to the cyclohexene pressure, P_e, increased from 0 to 0.60. Above this ratio, no significant change was observed, and it should be noted that the values obtained were almost the same as those for the ZrO_2-supported Pd catalysts.[6] There was a similar trend in the variation in the activation energy, E_a, with the addition of the ZrO_2 component.

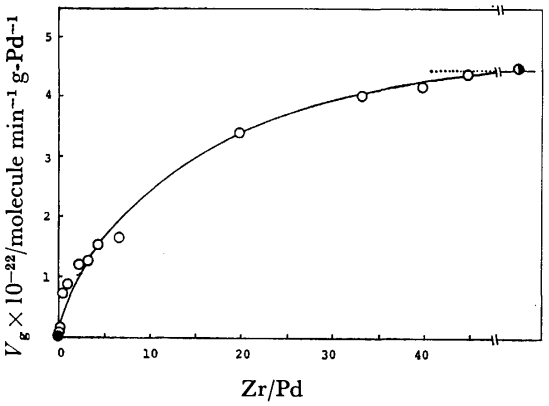

Fig. 1. Variation in catalytic activity, V_g, with Zr/Pd ratio.
P_h=40 Torr, P_e=40 Torr, reaction temperature: 301 K.
●: 2.1 wt% Pd/α-Al_2O_3, ○: ZrO_2-added 2.1 wt% Pd/α-Al_2O_3, ◑: 2.1 wt% Pd/ZrO_2.

Table 1 also shows the results of the characterization of ZrO_2-added Pd catalysts by the CO chemisorption and X-ray line broadening methods, together with the turn-over frequency of the reaction rate, N_t. The percentage exposed, D_{CO}, gradually rose with the increase in the amount of ZrO_2, *e.g.*, by a factor of 1.4 at Zr/Pd=0.5 and of 2.3 at Zr/Pd=2.5, whereas a marked rise in N_t's occurred around the ratio of Zr/Pd=0.3—0.5. Both values converged with those for the 2.1 wt% Pd/ZrO_2 catalyst at Zr/Pd ratios larger than 45.

Table 2 shows the deuterium distributions in the reaction of cyclohexene with D_2 or with an equimolar mixture of H_2+D_2 at 301 K over a catalyst with a Zr/Pd ratio of 0.5. In the case of the former reaction, the cyclohexane product exhibited wide deuterium distributions, ranging from D_0 to D_5, whereas there

also existed exchanged cyclohexene ranging up to D_4. Considerable amounts of HD and H_2 were produced in the gas phase, but the value of K, defined as P_{HD}^2/P_hP_D, remained at 1.3—1.4. The latter reaction with a mixture of H_2 and D_2 gave rise to K=1.4—2.5. These values apparently deviated from that for equilibrium at this reaction temperature, indicating that no equilibrium among H_2, HD, and D_2 in the gas phase was established. It should be noted that the deuterium distributions noted here resembled those obtained for the ZrO_2-supported Pd catalyst rather than those of the α-alumina-supported one.[6] From the above-mentioned variations in N_t, kinetic parameters, and deuterium distribution patterns, one can see that the addition of Zr atoms (as ZrO_2), when its concentration attained about a half of that of Pd atoms, caused an almost complete change in the catalytic properties of the Pd metal.

Figure 2 shows the X-ray photoelectron spectra in the Pd 3d region. Palladium supported on α-alumina gave the peaks due to Pd $3d_{5/2}$ and $3d_{3/2}$ levels at 335.2 and 340.6 eV respectively. As for the ZrO_2-added catalysts, these peaks shifted to 335.0 and 340.5 eV at Zr/Pd=0.5, and to 334.8 and 340.2 eV at Zr/Pd=2.5, whereas little change was observed with the Zr 3d level. Table 3 lists the binding-energy values.

Figure 3 illustrates the thermal desorption spectra of hydrogen. The desorption from α-alumina-supported Pd catalysts provided three peaks, at α(273 K), β_1(363—383 K), and β_2(460 K). The initial adsorption gave rise to the β_2-peak, and further adsorption developed the β_1-peak. With an increase in the amount of hydrogen

of hydrogen adsorbed, whereas the narrower α-peak appeared at 223 K. The TD spectra of hydrogen from the ZrO_2-supported Pd surface were analogous to those for the ZrO_2-added Pd catalyst, except for the appearance of the α-peak at 190 K. Only a small peak of hydrogen was observed around 220 K from α-alumina-supported ZrO_2 without Pd metals.

In order to examine the reactivity of the adsorbed hydrogen, the surface with β-hydrogen was exposed to cyclohexene; as is shown in Fig. 4, the desorption spectra of hydrogen from the $Pd/\alpha\text{-}Al_2O_3$ catalyst resulted in the near disappearance of the β_1-peak, without any significant change in the β_2-peak, whereas those from the ZrO_2-added catalysts lacked the portion on the lower-temperature side of the peak.

The desorption spectra of cyclohexene from the $Pd/\alpha\text{-}Al_2O_3$ surface provided a peak of benzene around 318 K, together with a peak of cyclohexane at 368 K (Fig. 5). In the case of the ZrO_2-added catalyst (Zr/Pd= 0.5), the benzene peak appeared at almost the same temperature, 313 K, while the cyclohexane peak shifted to a temperature lower by 70 K. No peak due to

a): 2.1 wt% $Pd/\alpha\text{-}Al_2O_3$, b): ZrO_2-added 2.1 wt% $Pd/\alpha\text{-}Al_2O_3$ catalyst (Zr/Pd=0.5). Adsorption temperature: 195 K.

cyclohexene was observed in either catalyst. When hydrogen was preadsorbed, followed by the adsorption of cyclohexene, the resulting desorption spectra exhibited only a cyclohexane peak at 320 K for $Pd/\alpha\text{-}Al_2O_3$ and one at 308 K for the ZrO_2-added catalysts.

Discussion

The present study showed remarkable effects of ZrO_2 upon the catalytic activity of Pd dispersed on α-alumina, and also revealed that the characteristic modification is achieved by a concentration of Zr at 0.5 as the Zr/Pd ratio, since the N_t value was increased significantly; also, the kinetic parameters became almost the same as those for the hydrogenation over Pd/ZrO_2 catalysts. The deuterium distributions also exhibited a characteristic pattern similar to those for ZrO_2-supported Pd catalysts, *i.e.*, a wide deuterium exchange in cyclohexane, but less exchange in cyclohexene, as well as a composition of gaseous hydrogen isotopes far from equilibrium. Therefore, we are able to describe the ZrO_2-affected catalytic hydrogenation by the associative mechanism which was employed in the same reaction on the ZrO_2-supported catalysts:[6]

$$H_2(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2H(a), \quad (1)$$

$$C_6H_{10}(g) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C_6H_{10}(a), \quad (2)$$

$$H(a) + C_6H_{10}(a) \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} C_6H_{101}(a), \quad (3)$$

$$H(a) + C_6H_{11}(a) \xrightarrow[k_4]{} C_6H_{12}(g), \quad (4)$$

where k_i and k_{-i} denote, respectively, the rate constants of the forward and reverse reactions at the ith step. The formation of highly-exchanged cyclohexanes allows us

to assume that Step 3 is in pseudo-equilibrium. In addition to this assumption, the employment of the steady-state approximation on the concentrations of hydrogen atom, cyclohexene, and the cyclohexyl intermediate leads to the following rate equation:[6]

$$V_g = \frac{2k_1k_4K_2K_3P_hP_e}{[(1+K_2P_e)\sqrt{2k_{-1}+k_4K_2K_3P_e}+(1+K_2K_3P_e)\sqrt{2k_1P_h}]^2}, \quad (5)$$

where $K_i=k_i/k_{-i}$.

Equation 5 is transformed into:

$$\sqrt{\frac{P_h}{V_g}} = \sqrt{\frac{1}{2k_1k_4K_2K_3P_e}}[\sqrt{2k_1P_h}(1+K_2K_3P_e) + (1+K_2P_e)\times\sqrt{2k_{-1}+k_4K_2K_3P_e}], \quad (6)$$

or;

$$\sqrt{\frac{P_e}{V_g}} = \sqrt{\frac{1}{k_4K_1K_2K_3P_h}}[1+\sqrt{K_1P_h} + (1+K_3\sqrt{K_1P_h}+\frac{k_4K_3}{4k_{-1}})K_2P_e], \quad (7)$$

in an approximate form. Figure 6 shows the plots of the $\sqrt{P_e/V_g}$ term *vs.* P_e, and of the $\sqrt{P_h/V_g}$ term *vs.* $\sqrt{P_h}$, for the catalysts with Zr/Pd=0.5 and 1.0 respectively. The good linear relationships verify the validity of the equation, and hence the mechanism proposed.

By analogy with the previous results on the thermal desorption of hydrogen from Pd powder,[7] Pd wire,[8] and Pd/activated carbon,[9] the β_1 and β_2 peaks from the α-alumina-supported Pd catalysts were associated with the adsorbed hydrogen, whereas the α-peak was assigned to the dissolved hydrogen. Judging from the reactivity with cyclohexene, one can reasonably consider that the β_1-hydrogen species is responsible for the hydrogenation. The shift of this peak toward the lower-temperature side with the amount of hydrogen is indicative of a second-order desorption, and hence of the dissociated state of the hydrogen. This supports the aforementioned reaction mechanism.[6] As to the reactivity and dissociated state, similar situations hold for the β-hydrogen on the ZrO_2-added catalyst. Although the separation between β_1 and β_2 peaks is difficult in this case, it is not unreasonable to assume, by taking the reactivity with cyclohexene into account, that the hydrogen located on the lower-temperature side of the β peak is associated with the β_1-state, as is shown by the dotted line in Fig. 4, and that the remaining peak corresponds to the β_2-state. In this classification, there is a tendency for the β_1 and β_2 hydrogens on the ZrO_2-added catalysts to be desorbed at slightly lower temperatures than those on α-alumina-supported Pd catalysts. An other feature of the ZrO_2 effect was the shift of the α peak due to the dissolved hydrogen to a lower temperature. As is shown in Table 4, the temperature of each peak maximum was lowered with an increase in the Zr/Pd ratio. These results suggest that the dissolved hydrogen became unstable with the addition of ZrO_2, in accordance with a weakening of the adsorption bond of hydrogen. Such unstability is partly ascribable to the increase in D_{CO}, *i.e.*, the crystallite-size effect, but the main reason appears to be the changes in the electronic states of dispersed Pd metals.

Table 4. Variation in the peak temperature of α-hydrogen with the Zr/Pd ratio

	2.1 wt% Pd+ZrO_2/α-Al_2O_3					2.1 wt% Pd/ZrO_2
Zr/Pd ratio	0	0.1	0.3	0.5	2.5	
Peak temperature/K	273	253	238	223	190	190

The present XPS study has revealed that the Pd 3d line shifts to a lower binding energy upon the addition of ZrO_2. Provided the contribution of a relaxation effect to the photoemission process is not significantly changed by the presence of the ZrO_2 component, it follows that this shift reflects an increased electron density around surface Pd metal atoms as a consequence of electron transfer from the oxide to Pd metal atoms. According to the DV Xα-calculation of the electronic state for H–Pd_6 and H–Ni_6 clusters,[10] a hydrogen atom on the Pd cluster is slightly negative, in contrast to largely-negative hydrogen on the Ni cluster, and the formation of a stable hydride phase in the Pd–H system is attributable to covalency in bonding between hydrogen and Pd metal atoms. Therefore, it can reasonably be concluded that the transfer of an electron to the Pd metal observed in the present system makes the adsorbed and dissolved hydrogen unstable.

A possible mechanism of benzene and cyclohexane formation during the thermal desorption of cyclohexene is:

$$C_6H_{10}(a) \longrightarrow C_6H_6 + 4H(a), \quad (8)$$

$$C_6H_{10}(a) + 2H(a) \longrightarrow C_6H_{12}, \quad (9)$$

where Step 9 is regarded as being a combination of Steps 3 and 4. The low-temperature shift of cyclohexane, together with the TD result that the cyclohexene adsorbed on the hydrogen-covered surface was desorbed as cyclohexane at a lower temperature in the presence of ZrO_2, suggests that the total energy level of the adsorbed hydrocarbon species including the cyclohexene and/or the cyclohexyl radical becomes higher in the case of the ZrO_2-added Pd catalyst surface. This view is in line with the fact that the apparent activation energy with reference to the energy level of gaseous reactants became higher for the reaction on the ZrO_2-added Pd catalyst than on the Pd/α-Al_2O_3 catalyst. Thus, it may be concluded that the variations in the reaction orders with ZrO_2 addition are mainly to be contributed to the much weakened adsorption of hydrocarbon species compared to that of hydrogen.

The support effects were also observed for TiO_2, the oxide of Group IV_a metals; nickel deposited on this oxide exhibited a stable and high catalytic activity for the methanation reaction of CO.[11] A recent systematic study using XPS, UPS, LEED, and AES[12] revealed that the nickel atoms at the Ni/TiO_2(110) interface are negatively charged as a result of electron transfer through Ni-O^{2-} interaction, which is responsible for the enhanced backdonation of electrons to the $2\pi^*$ orbital of the adsorbed CO molecule, thereby facilitating the dissociation of CO. The negatively-charged state of platinum was also observed to exist on the $SrTiO_3$(100) surface.[13] The SCF Xα-scattered wave calculation for a Pt atom on the $(TiO_6)^{8-}$ cluster[14] showed that the ability of the Pt atom to chemisorb hydrogen was lost when there was a strong interaction between Pt and Ti atoms, whereas the importance of metal-oxygen interaction and the role of the resulting electronic structure in breaking the hydrogen bond were suggested in the Ru/SiO_2 system.[15]

The present TD spectra of hydrogen showed that the chemisorption of hydrogen was not severely suppressed in the presence of ZrO_2. In our IR study of CO adsorbed on silica-supported Pd surfaces, the absorption bands characteristic of the C–O stretching vibration shifted to a frequency lower by 65 cm^{-1} when ZrO_2 was added at the Zr/Pd ratio of 0.5;[16] this shift is evidently ascribable to the enhanced backdonation to the $2\pi^*$ orbital of CO, which was similar to that observed in the above-mentioned Ni–TiO_2 system. From these findings, therefore, it seems reasonable at present to assume that the interfacial interaction between Pd and ZrO_2 occurs through the Pd–O bond, although we need more essential understanding from the theoretical point of view.

The present ZrO_2-added Pd catalysts allow us to consider two structural models. One is that Pd metal and ZrO_2 oxide particles grow almost independently on the alumina surface and can interact each other through the particle-to-particle interface; this requires a long-range interaction for ZrO_2 to exert its effect. Another model is that the Pd metal is mainly deposited on ZrO_2 oxide over α-Al_2O_3. The latter model is more plausible, since the preferential interaction between Pd and ZrO_2 components can be expected, as is revealed by XPS, and since the catalytic properties of the ZrO_2-added Pd catalysts were substantially the same as those of the ZrO_2-supported Pd catalysts. Furthermore, it seems more reasonable to consider that Pd-metal clusters grow on ZrO_2 with a specific structure so as to increase the interfacial boundary-area with the ZrO_2 component than to assume the long-range interaction of the former model.

In order to verify the validity of these models, we have to await precise analysis, *e.g.*, using the EXAFS technique,[17] which will be able to provide information on the composition and microscopic local structure around each of the atoms in these solid mixtures.

Solid-Liquid and Liquid-Liquid Phase Equilibria in the Symmetrical Tetraalkylammonium Halide-Water Systems

Haruo NAKAYAMA

Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

(Received May 11, 1981)

Solid-liquid and liquid-liquid phase diagrams of the binary R_4NX–water (R=n-C_3H_7—n-C_6H_{13} and i-C_5H_{11}; X=F, Cl, Br, and I) systems were determined in the temperature range between −20 °C and +80 °C. These diagrams showed (1) the formation of a clathrate-like hydrate for four salts $(n\text{-}C_5H_{11})_4NF$, $(n\text{-}C_5H_{11})_4NCl$, $(i\text{-}C_5H_{11})_4NBr$, and $(i\text{-}C_5H_{11})_4NI$; (2) a phase separation into two liquid phases in the systems of $(n\text{-}C_5H_{11})_4NBr$, $(i\text{-}C_5H_{11})_4NBr$, $(n\text{-}C_6H_{13})_4NCl$, and $(n\text{-}C_6H_{13})_4NBr$; (3) that the solubility (in water at a definite temperature) of a series of the salts did not show a systematic change with respect to either the alkyl-chain length or the kind of anion; and (4) that the salt which gave the maximum solubility in water at 25 °C was $(n\text{-}C_5H_{11})_4NCl$ for chloride, $(n\text{-}C_4H_9)_4NBr$ for bromide, and $(C_2H_5)_4NI$ for iodide, respectively. The effect of anions on the solubilities of a series of salts having the same cation was examined. It was found that the ratio m_{Cl}/m_I at 25 °C became as high as 22800 for the tetrapentylammonium salts. Phase diagrams for the bolaform salt $[(n\text{-}C_4H_9)_3N(CH_2)_6N(n\text{-}C_4H_9)_3]X_2$–water systems are also presented.

Though it is well known that the solubilities of symmetrical tetraalkylammonium halides in water are generally high except for iodides, accurate numerical values have been reported only for a limited number of salts[1] and even among the existing data some discrepancies are seen. Our studies on the formation of clathrate hydrates of quaternary ammonium halides[2-4] have found that the solubilities of these salts in water depend sensitively on the temperature, since the phenomena such as the formation of clathrate hydrate and/or the phase separation into two liquids are often observed.

Thus, it would be important to know an accurate phase diagram for the binary mixture of these salts with water before various properties of its aqueous solution are examined. So far as the author knows, no complete phase diagrams for the symmetrical tetraalkylammonium halide–water systems have so far been examined, except for tetrabutylammonium bromide,[5] tetrabutylammonium iodide,[6] and tetrapentylammonium iodide.[6] For the latter two iodides the solubilities in water have been measured at various temperatures (2—43 °C). In this paper we are reporting the complete phase diagrams of the R_4NX (R=n-C_3H_7, n-C_4H_9, n-C_5H_{11}, i-C_5H_{11}, and n-C_6H_{13}; X=F, Cl, Br, and I)–water systems, together with those of the $[(n\text{-}C_4H_9)_3N(CH_2)_6N(n\text{-}C_4H_9)_3]X_2$–water systems.

Experimental

Materials. All the iodides R_4NI (R=n-C_3H_7, n-C_4H_9, n-C_5H_{11}, i-C_5H_{11}, and n-C_6H_{13}) were synthesized by reacting trialkylamines with the corresponding alkyl iodide in ethyl acetate and were purified by recrystallization either from ethyl acetate or ethyl acetate–acetone mixture.[2] These iodides were confirmed by their NMR spectra. Other halides were obtained by neutralizing each hydroxide solution with its corresponding acid HX (X=F, Cl, or Br). The hydroxide solution was prepared by reacting iodide with freshly prepared silver hydroxide in water with vigorous shaking, followed by filtration in a CO_2-free atomsphere.[3] A series of salts $(n\text{-}C_4H_9)_4NX$ and $(i\text{-}C_5H_{11})_4NX$ (X=F, Cl, and Br) was purified by separating out the solids in the form of clathrate hydrates from the above neutralized solutions by cooling. Anhydrous $(n\text{-}C_5H_{11})_4NBr$ was purified by recrystallization from water. Other salts could not be purified either because of high solubility in water or because of two-liquid phase separation. It was observed that three fluorides $(n\text{-}C_4H_9)_4NF$, $(n\text{-}C_5H_{11})_4NF$, and $(n\text{-}C_6H_{13})_4NF$ gradually decomposed when their aqueous solutions were concentrated by evaporation of water. Melting points are summarized in Table 1. Figures in parentheses represent the water content (wt%) of the sample. These salts are somewhat hygroscopic.

Table 1. Melting points (°C) of symmetrical tetraalkylammonium halides R_4NX

R	X		
	Cl	Br	I
n-C_3H_7	143—145 (1.6) [a]	293—295 (0.1)	>290 (0.1)
n-C_4H_9	70—74 (3.5)	99—100 (0.9)	145—147 (0.1)
n-C_5H_{11}	—	99—100 (1.1)	134—135 (0.2)
i-C_5H_{11}	67—68 (1.5)	131—132 (0.7)	146—147 (0.1)
n-C_6H_{13}	—	81—83 (5.3)	103—104 (0.8)

a) Figures in parentheses represent the water content (wt%).

Measurements and Analyses. Phase diagrams for the systems containing all the fluorides and the salts R_4NX having R=n-C_3H_7, n-C_4H_9, i-C_5H_{11} and X=Cl and Br were determined in the following manner. A sample solution (about 1.0—1.5 g) was prepared by weighing out water and a concentrated mother solution; it then was sealed in a small glass ampoule. The concentrations of the mother solutions were determined either by measuring the water content using the Karl Fischer titration method on a MK-AII apparatus (Kyoto Electronics Manufacturing Co.) or by a standard KNCS titration method (the Volhard method).[7]

Each ampoule was gradually cooled until the solid phase appeared and was annealed for at least 24 h at a temperature several degrees lower than the temperature at which the solid phase completely dissolved. After that, the ampoule was slowly warmed (at the rate of about 0.5 °C per hour) with vigorous shaking in a constant temperature bath and the temperature at which the solid phase completely disappeared was accurately determined.

All the phase diagrams of the iodide-water systems were determined by measuring their solubilities in water at various temperatures. In a measuring cell (3 cm diameter and 10 cm high) immersed in a constant temperature bath, the iodide solid was saturated in 10—20 cm^3 of water by vigorous mixing with a magnetic stirrer for 2—10 h. Then a given amount of each saturated solution was withdrawn and was analyzed by the KNCS titration method.

The phase diagrams of $(n\text{-}C_5H_{11})_4NBr$, $(n\text{-}C_6H_{13})_4NCl$, and $(n\text{-}C_6H_{13})_4NBr$ systems, in which a liquid-liquid phase separation occurred, were determined either by an ampoule method or by a solubility measurement. In the former method, the temperature at which the phase separation occurred was measured when an aqueous solution, sealed in an ampoule, was gradually heated. In the latter method, the respective concentrations of the two liquid phases which were in equilibrium with each other at a given temperature were determined by the KNCS titration method.

Results

Tetrapropylammonium Halide–Water Systems. Figure 1 shows the phase diagrams of the tetrapropylammonium halide-water systems. The logarithm of the concentration expressed in mole fraction (X) is plotted against the reciprocal of the absolute temperature. For comparison, the temperature expressed in ordinary Celsius scale is shown on the upper side of the figure. This figure indicates a typical behavior of symmetrical lower quaternary ammonium salts; high solubilities for fluoride, chloride, and bromide and relatively low solubility for iodide. At 25 °C, for example, X's of the chloride and the bromide were 0.255 and 0.162, which correspond to 80.8 and 74.1 wt%, respectively. On the other hand, X was only 0.011 (16.2 wt%) for iodide, though this iodide was the most soluble among the iodides investigated in this study.

In the concentration range between X=0.05 and 0.15, no solid phase appeared, except for the iodide, from the solutions which were kept at −30 °C for two months. Thus, the phase diagrams in this region remain uncertain.

Tetrabutylammonium Halide–Water Systems. The solid-liquid phase diagrams for $(n\text{-}C_4H_9)_4NX$–water systems are shown in Fig. 2 in the same manner as in Fig. 1. The phase diagram for the bromide is in fairly

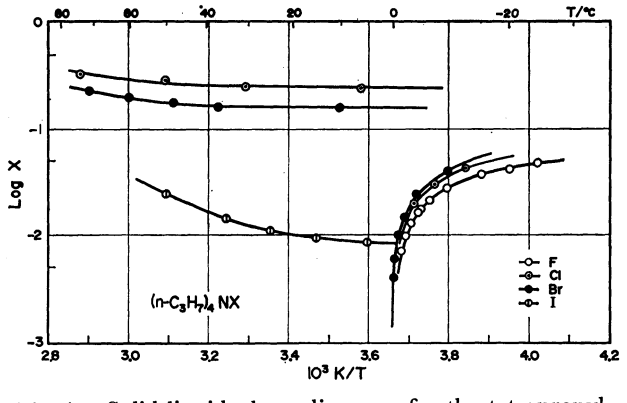

Fig. 1. Solid-liquid phase diagrams for the tetrapropylammonium halide–water systems.

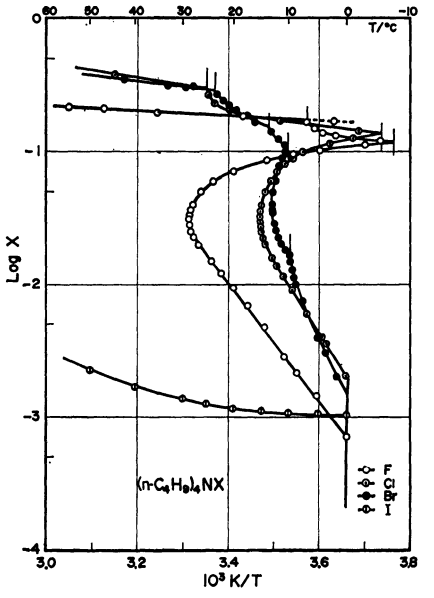

Fig. 2. Solid-liquid phase diagrams for the tetrabutylammonium halide–water systems.

good agreement with the one reported by Diadin *et al.*[5] At temperatures higher than about 30 °C, these phase diagrams also exhibit a similar trend to that in Fig. 1; low solubility for the iodide and high solubilities for the other salts. However, at lower temperatures, the phase diagrams, except for that of iodide, become fairly complicated because of the formation of clathrate-like hydrates[2,5,8,9] and other lower hydrates. The congruent melting point and its composition is 28.3 °C, X=0.032 for the fluoride, 15.0 °C, X=0.032 for the chloride, and 12.9 °C, X=0.040 for the bromide, respectively. These X values correspond to the hydrates $(n\text{-}C_4H_9)_4NF\cdot 30H_2O$, $(n\text{-}C_4H_9)_4NCl\cdot 30H_2O$, and $(n\text{-}C_4H_9)_4NBr\cdot 24H_2O$. For the bromide hydrate two more incongruent melting points were recognized at 9.8 °C (X=0.0168) and at 12.4 °C (X=0.033), although the composition of each hydrate is not known. Diadin *et al.*[5] have reported three incongruent melting points at 9.5, 11.6—11.7, and 12.2 °C and a congruent melting point at 12.36 °C which is slightly different from our result (12.9 °C). A slight discrepancy in a melting point of a clathrate hydrate is often observed.[10,11]

It is interesting to note that the composition of the eutectic points of the clathrate hydrate–ice system are very low (X=0.00075 for the fluoride, 0.0019 for the chloride, and 0.0014 for the bromide). This means that the solubilities of these salts are quite low at temperatures slightly higher than the eutectic point and steeply increase with increasing temperature.

The composition of the other solid phases formed in the concentration ranges of X=0.118—0.168 for the fluoride, X=0.134—0.282 for the chloride, and X=0.106—0.275 for the bromide were not known because the solutions in this concentration ranges, which were highly viscous, were supercooled so easily that ordinary thermal analysis could not be applied. Diadin *et al.*[5] have reported two solid phases $(n\text{-}C_4H_9)_4NBr\cdot 3H_2O$ and $(n\text{-}C_4H_9)_4NBr\cdot 2H_2O$.

The solubility of the iodide is about 10 per cent higher than that reported by Franks and Clarke[6] over the temperature range examined and the minimum in the log X *vs.* T^{-1} curve exists near at 5 °C instead of 12.6 °C.[6]

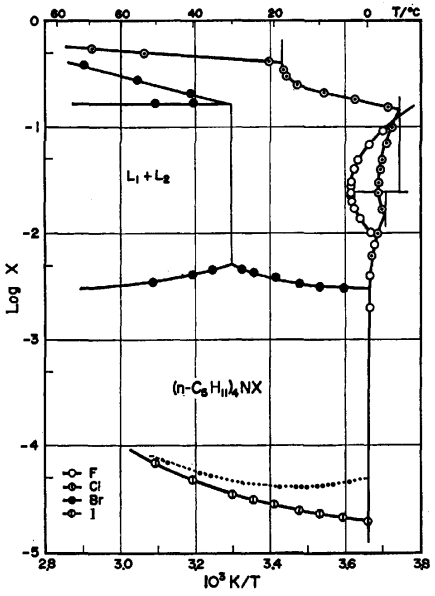

Fig. 3. Solid-liquid and liquid-liquid phase diagrams for the tetrapentylammonium halide-water systems. Dotted line indicates the solubility data for the iodide taken from the Ref. 6.

Tetrapentylammonium Halide–Water Systems. The solid-liquid and liquid-liquid phase diagrams for the $(n\text{-}C_5H_{11})_4NX$–water systems are shown in Fig. 3. For the fluoride and chloride systems, there exist fairly unstable congruent melting points (3.6 °C and −2.3 °C) indicating the formation of clathrate-like hydrates. The peak composition of both hydrates lies around $X=$ 0.025, which corresponds to a hydrate of hydration number 39. The formation of clathrate hydrates of tetrapentylammonium salts has not been reported so far. It is interesting to note that three fairly unstable hydrates can only be formed in the narrowly-limited concentration range of $X\simeq 0.01$—0.1, in striking contrast to the case of tetrabutylammonium (Fig. 2) and tetraisopentylammonium (given later, Fig. 4) salt hydrates.

In the bromide system, phase separation into two liquids occurs above 30.4 °C. The concentration of both phases were, at 50 °C for example, 6.78 wt% in the water-rich phase and 80.92 wt% in the salt-rich phase. Below 30.4 °C the solid phase, which seems to be anhydrous, is in equilibrium with a relatively dilute solution of about 8 wt% or less. This indicates that the solubility of the bromide below 30.4 °C is about a hundredth of that of the chloride.

The solid-liquid equilibrium curve for the iodide is not in agreement with that reported by Franks and Clarke;[6] their curve is shown in Fig. 3 by a dotted line. The observed solubilities were about 1.4 times lower at 25 °C and about 2 times lower at 5 °C than the reported values. Furthermore, our data did not show the existence of a minimum around 16 °C.[6]

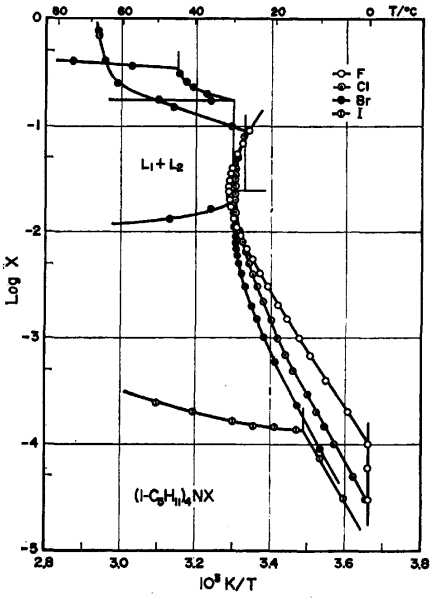

Fig. 4. Solid-liquid and liquid-liquid phase diagrams for the tetraisopentylammonium halide–water systems.

Tetraisopentylammonium Halide–Water Systems. The phase diagrams for the tetraisopentylammonium halide–water systems are given in Fig. 4. The striking feature in this figure is that the formation of clathrate hydrates occurs over a very wide concentration range. In the fluoride system, clathrate hydrate occurs from solutions greater than $X=1\times10^{-4}$ (0.176 wt%), and the solubility of the hydrate steeply increases with increasing temperature. The congruent melting point of the hydrate is 31.5 °C and its X is 0.025, which corresponds to the hydration number of 39. These values are in fairly good agreement with those reported earlier (31.2 °C and about 40).[9] The phase diagrams in the concentrated regions are somewhat uncertain because a solution more concentrated than about $X=0.1$ (66 wt%) gradually decomposes even at room temperature.

The phase diagram of the chloride system exhibits almost the same behavior as that of the fluoride. The formation of clathrate hydrate begins from a solution as low as $X=3\times10^{-5}$ (0.0556 wt%). The melting point and the composition of the hydrate is 29.6 °C and $X=$ 0.025, which corresponds to the same hydration number 39 as that of the fluoride. These values are also in good agreement with those already reported (29.8 °C and hydration number 38.3).[9] The chloride solution was stable even at very high concentrations. The solid phase which appears from the solution greater than $X=0.088$ (eutectic composition at 26.9 °C) seems to be anhydrous.

The phase diagram of the bromide system also indicates the formation of a clathrate hydrate. The clathrate hydrate formation of $(i\text{-}C_5H_{11})_4NBr$ has not been reported so far. However, the congruent melting point and the composition of it could not be determined because of the occurrence of liquid-liquid phase separa-

tion at 30.1 °C. The amount of water in the solid separated from a solution (X=0.005) which had been kept at 10 °C was determined by the Karl Fischer titration method. The mean hydration number was 54.1 for the initial wet sample, and was 36.4 and 0.4 for the solid which had been kept at about 10 °C and allowed to stand in contact with air for 3 h and 48 h, respectively. These results indicate that the solid which is in equilibrium with an aqueous solution at low temperatures has a large amount of water, characteristic of a clathrate hydrate, and the solid kept standing in air gradually loses its water with time owing to an efflorescence. This is a characteristic often found for the clathrate hydrates of quaternary ammonium salts.[2]

The solid phase which appears in the concentration region of X=0.17—0.34 seems to be either a mono hydrate or an anhydrous salt which has a different crystal structure from that of the solid which is stable at temperatures higher than 44.5 °C.

The similarity of the log X *vs.* T^{-1} curve at low temperatures for the iodide system to those of the other systems indicates that iodide also can form a clathrate-like hydrate in the temperature range between an eutectic point (near 0 °C) and an incongruent melting point (13.3 °C). Analogous water analyses for the solid phase separated from its solution phase at 10 °C showed that the mean hydration number was 75.6 for the wet solid sample just after filtration, and 38.9 and 0.18 for the sample which had been kept standing in contact with air for 2 d and 5 d, respectively. These results, just as in the case of the above bromide systems, also suggest that the solid phase which separates out from its solution phase at temperatures lower than 13.3 °C is a clathrate-like hydrate.

The solubility of anhydrous iodide in water is about 4—5 times larger than that of tetrapentylammonium iodide (Fig. 3) at an identical temperature.

Tetrahexylammonium Halide–Water Systems. Phase diagrams for the tetrahexylammonium halide–water systems are shown in Fig. 5. No line indicating the formation of clathrate hydrate is present in this figure. It should be noted that not only in the bromide system but also in the chloride system liquid-liquid phase separation occurs over a wide temperature range. The two liquid phases existed up to at least 100 °C.

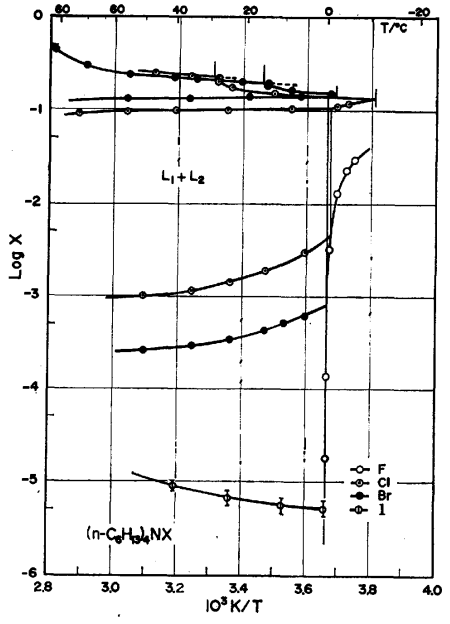

Fig. 5. Solid-liquid and liquid-liquid phase diagrams for the tetrahexylammonium halide–water systems.

In the fluoride system only the ice appeared from the solution of $X<0.03$. From the solutions greater than X=0.03 no solid phase could be formed when cooled at −30 °C for 10 d.

The chloride system shows an eutectic point (at −10.5 °C) between ice and a hydrate, with a hydration number less than 3 and an incongruent melting point at 29.6 °C. The bromide system also has similar points at −1.6 °C and 15.7 °C. The solubility of the iodide was so low that the values obtained would have errors of the order of 10—15 per cent.

Discussion

The Formation of Clathrate Hydrates. Although the formation of clathrate hydrates of $(n\text{-}C_4H_9)_4NX$ (X=F, Cl, and Br)[2,4,8,9,13] and of $(i\text{-}C_5H_{11})_4NX$ (X=F and Cl)[9,12] has already been known, it was newly found in this experiment that other four salts, $(n\text{-}C_5H_{11})_4NF$, $(n\text{-}C_5H_{11})_4NCl$, $(i\text{-}C_5H_{11})_4NBr$, and $(i\text{-}C_5H_{11})_4NI$, could also form a similar type of hydrates.

The two tetrapentylammonium salt hydrates have relatively low melting points (3.6 °C and −2.3 °C), as mentioned earlier. The unstableness of these hydrates may be due to the fact that a pentyl group is somewhat too long[2] to be accomodated stably within a hydrogen-bonded water cage such as a tetrakai- or pentakaidecahedron. Judging from the hydration number of 39, the crystal structure of these hydrates is presumed to resemble that of a tetraisopentylammonium fluoride hydrate[12] (hydration number 39) rather than that of tetrabutylammonium fluoride hydrate[13] (hydration number 30).

Although an accurate hydration number of the $(i\text{-}C_5H_{11})_4NBr$ and of the $(i\text{-}C_5H_{11})_4NI$ hydrates cannot be determined owing to the absence of congruent melting points, it may be assumed to be around 39 taking into consideration: (1) the similarity of log X *vs.* T^{-1} curves at temperatures lower than each incongruent melting point to those of the other fluoride and bromide systems and (2) the above mentioned results of water analyses for the solid separated from its aqueous solution. However, for the bromide hydrate, there is a possibility that some hydrates which have a slightly different hydration number are formed, as in the case of $(n\text{-}C_4H_9)_4NBr$ hydrate, since its log X *vs.* T^{-1} curve becomes almost vertical to the T^{-1} axis at temperatures 29.7—29.9 °C.

The formation of a clathrate hydrate of any other quaternary ammonium iodides has not been reported so far. The fact that $(i\text{-}C_5H_{11})_4NI$ can actually form such a hydrate manifests that the lattice distortion arising from the presence of a large iodide anion can be overcome by the ability of the isopentyl group to stabilize the surrounding hydrogen-bonded water frameworks.[2]

Furthermore, it should be noted that, at temperatures higher than the incongruent point (13.3 °C), the iodide hydrate decomposes into an anhydrous solid and a dilute aqueous solution (around 0.3 wt%). This property would be appropriate to an application of the salt such as the purification of saline water through a cyclic process of the formation and the decomposition of the hydrate.

Solubilities of Tetraalkylammonium Halides in Water. These results clearly show the solubilities of symmetrical tetraalkylammonium halides in water at a definite temperature are affected not only by the type of alkyl chain of the cation and the type of the gegen ion but also by such phenomena as the formation of a clathrate-like hydrate and the separation into two liquid phases. The solubilities of R_4NX in water at 25 °C, which are obtained from the diagrams, are summarized in Table 2, together with the values taken from some recent references.

Table 2. Solubilities of symmetrical tetraalkylammonium halides (R_4NX) in water at 25 °C(in molality)

R	X			
	F	Cl	Br	I
CH_3	—	*ca.* 19.1[1]	6.3±0.2[14]	0.2715[15]
C_2H_5	—	*ca.* 9.5[1]	15.0±0.2[14]	1.75[16]
n-C_3H_7	Extremely high	19.00	10.73 (10.4±0.2[14])	0.6255
n-C_4H_9	12.52 (0.93)[a]	20.53	21.48	0.0679 (0.0622[6])[b]
n-C_5H_{11}	—	40.20	0.2318	0.0018 (0.0025[6])[b]
n-C_6H_{13}	—	0.088[c]	0.019[c]	0.0004

a) Solid phase is a clathrate hydrate. b) At 26 °C. c) Values for water-rich phase in two-liquid phase systems.

For a series of salts having the same alkyl chain, the solubilities decrease with changing X in the order Cl, Br, and I, with the exception of $(C_2H_5)_4NBr$ and $(n\text{-}C_4H_9)_4NBr$. However, the solubilities of a group of salts having the same anion do not show a monotonous change with increasing its alkyl-chain length. Eventually, the alkyl chain which gives the maximum solubility is reduced to *n*-C_5H_{11} for the chloride, *n*-C_4H_9 for the bromide, and C_2H_5 for the iodide.

The approximate values of the solubility ratios for salts with different anions are shown in Table 3. It is interesting to note that, among these figures, relatively high values are seen for tetrabutylammonium salts (except for m_{Cl}/m_{Br}) and tetrapentylammonium salts. The ratio m_{Cl}/m_I for the $(n\text{-}C_5H_{11})_4NX$ salts is exceptionally high, as a result of very high solubility of the chloride and very low solubility of the iodide (Table 2). These high values will give a suitable condition for the separation of one halide anion from another through, for example, the distribution equilibrium between an aqueous phase and an organic phase. It was observed that, when a 0.08 *m* NaI aqueous solution was equilibrated at 25 °C with an equal volume of chloroform after addition of $(n\text{-}C_4H_9)_4NCl$ in amounts equimolar with NaI, 90.4 percent of the I^- ion which had been originally present in the aqueous phase was transferred into the chloroform phase in the form of $(n\text{-}C_4H_9)_4NI$ which is sparingly soluble in water (Table 2) and very soluble in chloroform (67.8 wt% at 25 °C). A more extensive study of the distribution equilibrium is under way and will appear in near future.

Table 3. The solubility ratios (in water at 25 °C) for symmetrical tetraalkylammonium halides (R_4NX) having different anions

R	m_{Cl}/m_{Br}	m_{Cl}/m_I	m_{Br}/m_I
CH_3	3.0	70	23
C_2H_5	0.6	5	8
n-C_3H_7	1.8	30	17
n-C_4H_9	1.0	302	316
n-C_5H_{11}	173	22800	132

Appendix

Phase Diagrams of Bolaform Salt $[(n\text{-}C_4H_9)_3N(CH_2)_6N(n\text{-}C_4H_9)_3]X_2$*-Water Systems.* The formation of clathrate hydrates of this series of salts (except for iodide) has already been reported.[4] The entire phase diagrams of the binary mixture of this type of salts with water have also been determined in this study and are shown in Fig. 6. These diagrams are similar to those of the $(n\text{-}C_4H_9)_4NX$–water systems (Fig. 2).

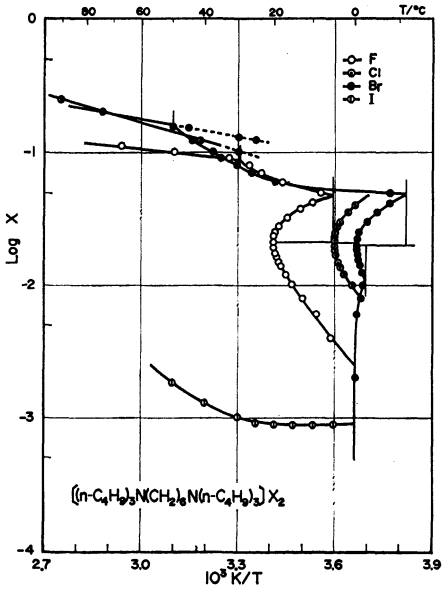

Fig. 6. Solid-liquid phase diagrams for the $[(n\text{-}C_4H_9)_3N(CH_2)_6N(n\text{-}C_4H_9)_3X_2$–water systems.

Electrode reactions of mono-, di- and tri-bridged ferrocenophanes ([3]Fcp, [4]Fcp, [3][3]Fcp, [4][3]Fcp, [4][4]Fcp, [3][3][3]Fcp, [4][4][3]Fcp and [4][4][4]Fcp) in acetonitrile were investigated by direct current polarography, pulse polarography, and cyclic voltammetry. The oxidation of these compounds proceeds reversibly as a one-electron process. The linear relationship between the half-wave potential and the number of methylene groups was obtained for ferrocene and ferrocenophanes other than [3][3]Fcp and [3][3][3]Fcp. The Taft substituent constants of trimethylene and tetramethylene groups were estimated.

Electrochemical properties of ferrocene and substituted ferrocenes have been studied by many authors.[1,2] These studies have revealed that the oxidation of ferrocene and its derivatives proceeds reversibly as a one-electron process in nonaqueous solutions. Their reversible oxidation potentials change in ways dependent on the substituent: the oxidation potential of the derivatives with the electron donating substituents, such as alkyl groups, is lower than that of ferrocene. Such substituent effects have been discussed through the examination of the relation between the oxidation potential and some substituent constant, for example, the Taft substituent constant (σ^*). Thus, Hoh, McEwen, and Kleinberg[3] have reported the following experimental equation:

$$(E_{1/4} \text{ vs. aq SCE})/\text{V} = 0.0978\,\Sigma\sigma^* - 0.1374, \qquad (1)$$

where $E_{1/4}$ is the chronopotentiometric quarter-wave potential in acetonitrile and $\Sigma\sigma^*$ is the summation of Taft substituent constants. This equation is applicable to ferrocene and nineteen mono- and disubstituted ferrocenes.

Fig. 1. Structures and names of ferrocenophanes used in this study. Abbreviation is given in parenthesis.

Recently, many ferrocenophanes have become increasingly important in the organometallic chemistry. However, the electrode reactions and the substituent effects, as mentioned above, still remain open to investigation. Therefore, the electrode reactions of the eight ferrocenophanes shown in Fig. 1 have been investigated by direct current polarography, pulse polarography, and cyclic voltammetry in acetonitrile. The results are reported here. Furthermore, the substituent effects on the oxidation potentials of ferrocenophanes are discussed.

Experimental

Acetonitrile (Wako Chemical Co.) was purified by the method proposed by Coetzee.[4] Ferrocenophanes used in this study were prepared according to the methods given in the literature,[5–9] and identified by the elemental analysis and the measurements of NMR and IR spectra. Tetraethylammonium perchlorate (TEAP) was prepared and dried by the usual method.[10] Ferrocene (Eastman Kodak Co.) and other chemicals were of guaranteed reagent grade and used without further purification.

Direct current (d.c.) polarograms, pulse polarograms, and cyclic voltammograms were recorded with a PAR Model 174A polarographic analyzer equipped with a Rikadenki Model RW-11 x-y recorder and a potential scanner made in this laboratory at Yamagata University. All the measurements were carried out at 25 °C under a dry nitrogen atmosphere by use of a three electrode system consisting of a working electrode (dropping mercury electrode for d.c. and pulse polargraphy, and spherical platinum electrode for cyclic voltammetry), a coiled platinum wire counter electrode, and an aqueous saturated calomel electrode (aq SCE) as a reference electrode. The dropping mercury electrode used had a flow rate of 1.02 mg s^{-1} in acetonitrile at open circuit. Drop time for pulse polarography was controlled to 5 s with the drop timer attached to the Model 174A. The pretreatment of the platinum working electrode (approximately 1 mm in diameter) prior to measurements was to apply a cycling potential (between −0.3 V and 1.1 V *vs.* aq SCE) to the electrode in an aqueous solution of 0.1 mol dm^{-3} sulfuric acid. This electrode was washed with distilled water, dried, and then used in the measurements. For electrolytic contact

of aq SCE, an agar salt bridge with 1 mol dm^{-3} aqueous sodium chloride solution was inserted into one compartment of the electrolytic cell. The half cells in the electrolytic cell were interconnected through a sintered glass disk. All the test solutions contained 0.2 mol dm^{-3} TEAP as a supporting electrolyte.

Results and Discussion

Electrode Reactions of Ferrocenophanes. Ferrocenophanes used here gave one d.c. polarographic oxidation wave in acetonitrile containing 0.2 mol dm^{-3} TEAP as a supporting electrolyte. The limiting current of the wave was found to be diffusion-controlled. The diffusion coefficients at 25 °C calculated from the Ilkovic equation by assuming $n=1$ are given in Table 1. The diffusion coefficient of ferrocene obtained in this study is also given in Table 1. From the result that the values of diffusion coefficients of ferrocenophanes were nearly equal to that of ferrocene, the electrode reaction of each ferrocenophane at the mercury electrode was concluded to be a one-electron process. Table 1 also gives the experimental results for the d.c. polarographic half-wave potential, $E_{1/2}$, and the d.c. polarographic slope, $\Delta E(=E_{3/4}-E_{1/4})$, as conventional criteria of reversibility. The values of ΔE indicate that the oxidation step of ferrocenophanes is a reversible one-electron process.

[4][4][4]Fcp	0.103	55	2.5	1.01

a) Concentration of each compound is 1 mmol dm^{-3}.
b) Diffusion coefficient.

In order to investigate the reversibility of the electrode reactions of the above compounds more exactly, pulse polarograms were obtained by use of the dropping mercury electrode with a drop time of 5 s. Typical pulse polarograms obtained for [4]Fcp, [4][4]Fcp, and [4][4][4]Fcp are shown in Fig. 2. In the case of a reversible oxidation process, the current-potential curve for anodic potential scan coincides with that for cathodic one, and the magnitude of the limiting current ratio for cathodic to anodic scan, $|I_{1c}/I_{1a}|$, closely approximates unity.[11] The values of $|I_{1c}/I_{1a}|$ in last column of Table 1 indicate that the electrode reactions of ferrocenophanes are reversible.

Cyclic voltammograms of these compounds were measured by using a spherical platinum electrode at scan rates of 10 to 500 mV s^{-1}. In the region, −0.2 to 1.0 V *vs.* aq SCE, only one anodic and one cathodic

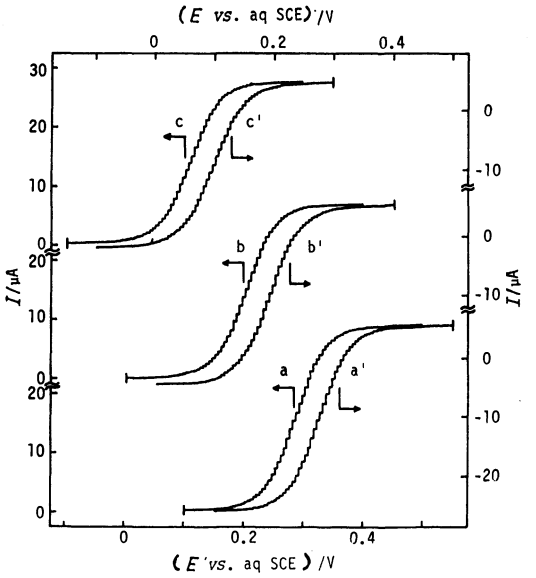

Fig. 2. Pulse polarograms of [4]Fcp (a, a'), [4][4]Fcp (b, b'), and [4][4][4]Fcp (c, c') in acetonitrile containing 0.2 mol dm^{-3} TEAP at 25 °C. Concentration of each compound is 1 mmol dm^{-3}. Curves a, b, and c are by anodic scan, and a', b', and c', cathodic scan.

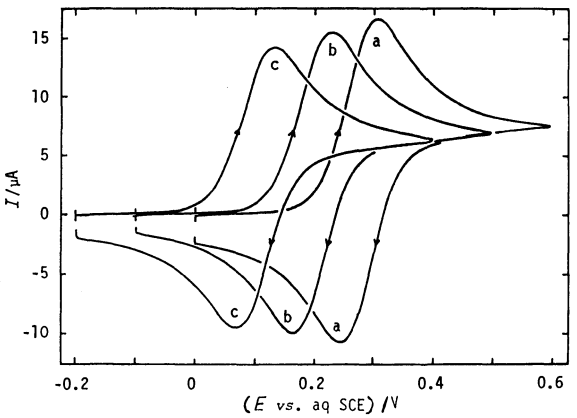

Fig. 3. Cyclic voltammograms of [4]Fcp (a), [4][4]Fcp (b), and [4][4][4]Fcp (c) in acetonitrile containing 0.2 mol dm^{-3} TEAP at 25 °C. Concentration of each compound is 1 mmol dm^{-3}.

current peak were observed. Typical cyclic voltammograms of [4]Fcp, [4][4]Fcp, and [4][4][4]Fcp are shown in Fig. 3. The cyclic voltammetric data at a scan rate of 100 mV s^{-1} for the formal potential, $E_f(=(E_{pa}+E_{pc})/2$, calculated from anodic peak potential, E_{pa}, and cathodic one, E_{pc}), the anodic-cathodic peak separation, $\Delta E_p(=E_{pa}-E_{pc})$, the anodic peak current, I_{pa}, the cathodic peak current, I_{pc}, and the cathodic to anodic peak current ratio, $|I_{pc}/I_{pa}|$, are given in Table 2. The values of I_{pa} of ferrocenophanes almost agree with the value of ferrocene, indicating that the electrode reaction of ferrocenophanes at the platinum electrode is a one-electron oxidation process. In addition, the values of ΔE_p and $|I_{pc}/I_{pa}|$ indicate that the electrode reactions of these compounds are reversible.

From all the results described above, it is concluded

that the electrode reactions of ferrocenophanes used here correspond to a simple reversible one-electron oxidation from the neutral compound to its mono cation in acetonitrile at both mercury and platinum electrodes. As seen in Tables 1 and 2, the values of $E_{1/2}$ and E_f are almost the same. For this reason, the $E_{1/2}$ values are used when the substituent effects on the oxidation potential are discussed below.

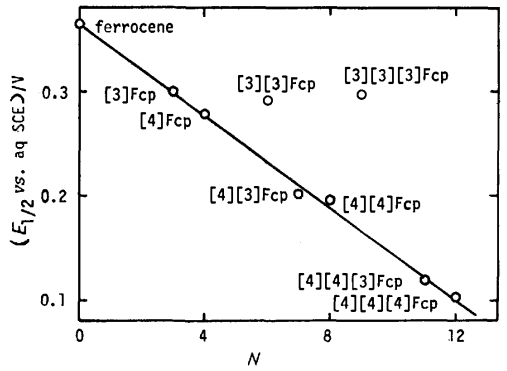

Fig. 4. Half-wave potential, $E_{1/2}$, *vs.* the number of methylene groups, N. Solid line represents Eq. 2.

Substituent Effects on the Oxidation Potential. As seen in Table 1, the $E_{1/2}$ values of ferrocenophanes are lower than the value of ferrocene and generally become more negative with an increase in the number of methylene groups. In Fig. 4, there is shown a plot of the $E_{1/2}$ value *vs.* the number of methylene groups. A linear relationship was observed for ferrocene and ferrocenophanes, except for [3][3]Fcp and [3][3][3]Fcp. The equation of the regression line for this relationship is

$$(E_{1/2}\ vs.\ \text{aq SCE})/\text{V} = -0.0221N + 0.3654 \qquad (2)$$

with a correlation coefficient of −0.9986, where N is the number of methylene groups. This result indicates that the additivity is established between the $E_{1/2}$ value and the number of methylene groups. For example, the $E_{1/2}$ of [4]Fcp is 0.086 V lower than that of ferrocene, and addition of a second tetramethylene group, as in [4][4]Fcp, lowers $E_{1/2}$ by 0.169 V, nearly twice the value found between [4]Fcp and ferrocene. A similar additive effect has been observed in the case of mono- and disubstituted ferrocenes, such as ethylferrocene and 1,1′-diethylferrocene.[12] Therefore, the linear relationship given by Eq. 2 supports the suggestion that the bridge of trimethylene and tetramethylene groups gives rise to few metal-ring distortions in ferrocenophanes, except for [3][3]Fcp and [3][3][3]Fcp. The $E_{1/2}$ values of [3][3]Fcp and [3][3][3]Fcp are more positive than the values expected from Eq. 2. The deviation from this linearity is presumed to be due to steric effects, that is, to metal-ring bond distortions. The distortions in these two compounds can be confirmed by making a molecular model. On the basis of molecular models of [3][3]Fcp and [3][3][3]Fcp, the compression of the metal-ring bond needed to accommodate the bridge was found to be remarkable. Ferrocenophanes except for these two compounds, however, can keep enough distance between ferrocene rings at the normal distance of 332 pm.

The linear relationship between the $E_{1/2}$ and the number of methylene groups suggests that trimethylene and tetramethylene groups have a certain substituent constant. As described above, Eq. 1 is established for many substituted ferrocenes. This equation enables us to estimate the Taft substituent constant, σ^*, of trimethylene and tetramethylene groups. In the case of a reversible electrode reaction, the chronopotentiometric quarter-wave potential, $E_{1/4}$, is equal to the d.c. polarographic half-wave potential, $E_{1/2}$. Furthermore, from the $E_{1/2}$ value of ferrocene obtained in this study, Eq. 1 can be rewritten as follows:

$$(E_{1/2}\ vs.\ \text{aq SCE})/\text{V} = 0.0978\,\Sigma\sigma^* - 0.1142, \qquad (3)$$

where $\Sigma\sigma^*$ is the total of Taft substituent constants. When the $E_{1/2}$ values of 0.300 V for [3]Fcp and 0.279 V for [4]Fcp are substituted for $E_{1/2}$ in Eq. 3, the $\Sigma\sigma^*$ values of [3]Fcp and [4]Fcp are calculated to be 4.24 and 4.02, respectively. Then, the σ^* values of trimethylene and tetramethylene groups (σ^*_3 and σ^*_4) are obtained to be 0.32 and 0.10, respectively (σ^*_3 or $\sigma^*_4 = \Sigma\sigma^* - 8\sigma^*_H$). The $\Sigma\sigma^*$ values of di- and tribridged ferrocenophanes are calculated by using these values of σ^*_3 and σ^*_4: for example, $\Sigma\sigma^*$ value of [4][3]Fcp is 3.36 by the sum of $6\sigma^*_H$, σ^*_3, and σ^*_4. The results of the calculation are given in Table 3. The plot of $E_{1/2}$ *vs.* $\Sigma\sigma^*$ is shown in Fig. 5. The solid line in Fig. 5 represents Eq. 3. In the case of [4][3]Fcp, [4][4]Fcp, [4][4][3]Fcp, and [4][4][4]Fcp, which have the linear relationship between the $E_{1/2}$ and the number of methylene groups and have little metal-ring bond

Table 3. Total Taft substituent constant ($\Sigma\sigma^*$) of ferrocene and ferrocenophanes

Compound	$\Sigma\sigma^*$
Ferrocene	4.90 ($10\sigma^*_H$)
[3]Fcp	4.24 ($8\sigma^*_H+\sigma^*_3$)
[4]Fcp	4.02 ($8\sigma^*_H+\sigma^*_4$)
[3][3]Fcp	3.58 ($6\sigma^*_H+2\sigma^*_3$)
[4][3]Fcp	3.36 ($6\sigma^*_H+\sigma^*_4+\sigma^*_3$)
[4][4]Fcp	3.14 ($6\sigma^*_H+2\sigma^*_4$)
[3][3][3]Fcp	2.92 ($4\sigma^*_H+3\sigma^*_3$)
[4][4][3]Fcp	2.48 ($4\sigma^*_H+2\sigma^*_4+\sigma^*_3$)
[4][4][4]Fcp	2.26 ($4\sigma^*_H+3\sigma^*_4$)

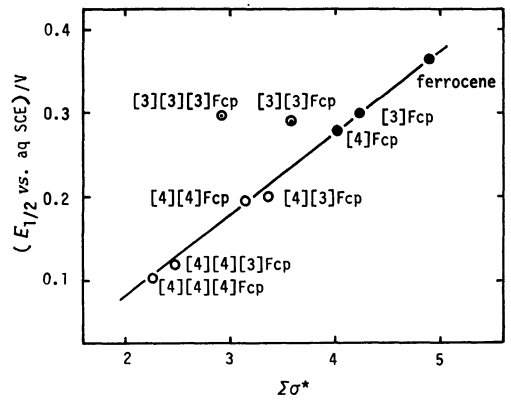

Fig. 5. Half-wave potential, $E_{1/2}$, *vs.* total Taft substituent constant, $\sum\sigma^*$. Solid line represents Eq. 3.

distortions, the points (open circles) are on the solid line. Therefore, the values of σ^*_3 and σ^*_4 obtained by assuming that Eq. 1 or Eq. 3 are valid for [3]Fcp and [4]Fcp seem to be reasonable. If so, the electronic effects of substituents for ferrocenophanes other than [3][3]Fcp and [3][3][3]Fcp are transmitted to the reaction center, *i.e.*, iron atom, through an inductive mechanism.

Since the ferrocenophanes studied here undergo a simple electrode reaction, it is expected that these compounds can be used as a "standard" for electrochemical studies. Application of ferrocenophanes to a reference redox system is now being investigated in many solvents.

The Solvent Extraction of Alkali Metal Picrates by Benzo-15-crown-5

Yasuyuki TAKEDA,* Yoshimasa WADA, and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260
(Received August 14, 1981)

Benzo-15-crown-5 (B15C5) extracted alkali metal picrates (MA) into benzene by forming M(B15C5)A or $M(B15C5)_2A$ complexes and moreover, in the presence of tributyl phosphate (B), B15C5 extracted rubidium and caesium picrates by forming M(B15C5)BA complexes. The extractability sequences of the M(B15C5)A, $M(B15C5)_2A$, and M(B15C5)BA complexes are $Na^+>K^+>Rb^+>Li^+>Cs^+$, $K^+>Rb^+>Cs^+$, and $Rb^+>Cs^+$ respectively. The extraction equilibrium constants for these complexes have been determined at 25 °C, and the synergistic formation constants of the $M(B15C5)_2A$ and M(B15C5)BA complexes in the benzene solution have been calculated. The synergistic effects for the alkali metal ions for the B15C5 system were compared with those for the 15C5 system.

The solvent extractions of alkali metal ions with various crown ethers have been widely studied.[1] In the previous papers,[2,3] it was reported that 15-crown-5 (15C5) extracted alkali metal picrates (MA) into benzene by forming M(15C5)A or $M(15C5)_2A$ complexes and moreover, in the presence of tributyl phosphate (B), 15C5 extracted rubidium and caesium picrates by forming M(15C5)BA complexes.

In this paper, the solvent extraction of alkali metal picrates has been investigated between benzene and water at 25 °C in the presence of benzo-15-crown-5 (B15C5) or both B15C5 and B in order to compare with the case of 15C5. The synergistic formation constants of the $M(B15C5)_2A$ and M(B15C5)BA complexes in the benzene solution have been calculated.

Experimental

Materials. B15C5 and analytical-grade B were obtained from Merck Japan Ltd. and Wako-Pure Chemicals, Ltd. respectively. B15C5 was dissolved in heptane, and filtered while hot. Then it was recrystallized from heptane three times and, before use, dried at 40 °C in a vacuum oven. B was used without further purification. The concentrations of the alkali metal hydroxides and picric acid solutions were determined by means of acid and basic titrations respectively. Analytical-grade benzene was washed twice with distilled water.

Procedure. All the experiments were carried out at 25±0.2 °C. The experimental procedures were the same as those described in the previous papers.[3,4]

The Distribution Coefficient of B15C5. Most of the procedures were similar to those in the previous paper.[5] The average value of the distribution coefficient is 20.

Results

When an aqueous phase of an alkali metal ion (M^+) and a picrate ion (A^-), and a benzene phase of a crown ether (L) or both B and L are equilibrated, the equilibrium constants may be defined by the following equations:

$$K_{ex}(ML_mA) = [ML_mA]_o[H^+]/[M^+][L]_o^m[HA]_o \quad (1)$$

$$K_{ex}(MLBA) = [MLBA]_o[H^+]/[M^+][L]_o[B]_o[HA]_o \quad (2)$$

$$K_{D,L} = [L]_o/[L] \quad (3)$$

$$K_{ML} = [ML^+]/[M^+][L] \quad (4)$$

$$K'_{ex} = [MLA]_o/[ML^+][A^-] \quad (5)$$

$$K_{ex}(HA) = [HA]_o/[H^+][A^-], \quad (6)$$

where the subscript "o" means organic and the lack of a subscript refers to the aqueous phase. Thus, $K_{ex}(MLA)$ can be written as follows:

$$K_{ex}(MLA) = K_{ML}K'_{ex}/K_{D,L}K_{ex}(HA). \quad (7)$$

The $K_{ex}(HA)$ value was spectrophotometrically determined to be 247.

When the benzene phase contains only B15C5, the distribution ratio of the alkali metal may be represented by

$$D = [ML_mA]_o/[M^+]. \quad (8)$$

In the case of $m=1$, Eq. 8 becomes

$$D = K_{ex}(MLA)K_{ex}(HA)[L]_o[A^-]. \quad (9)$$

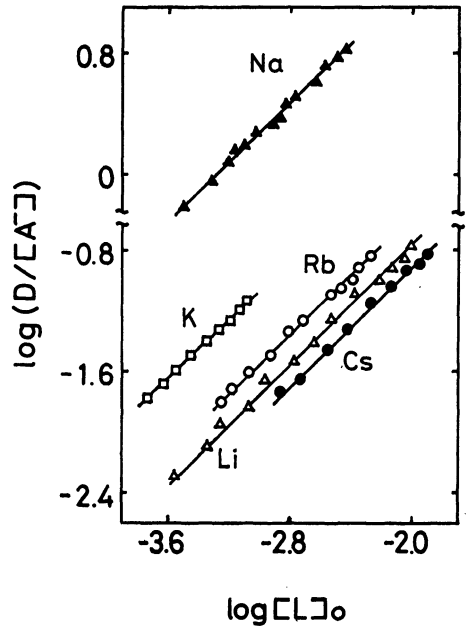

Fig. 1. Plots of $\log(D/[A^-])$ *vs.* $\log[L]_o$ for the MLA system.

The $\log(D/[A^-])$ *vs.* $\log[L]_o$ plot in Fig. 1 shows a linear relationship with a slope of 1 in every case, indicating that B15C5 forms the 1 : 1 complex with the alkali metal ion. The values of $[L]_o$ and $[A^-]$ in Eq. 9 were calculated by means of Eqs. 10 and 11 respectively:

$$[L]_o = ([L]_t - [MLA]_o)/(1 + K_{D,L}^{-1}), \quad (10)$$

$$[A^-] = ([HA]_t - [MLA]_o)/\{1 + (K_{HA} + K_{ex}(HA))[H^+]\}, \quad (11)$$

where the subscript "t" denotes the total concentration and K_{HA} is the association constant of picric acid ($K_{HA}=1.9_5$[6]). In the case of $m=2$, Eq. 8 becomes

$$D = K_{ex}(ML_2A)K_{ex}(HA)[L]_o^2[A^-]. \quad (12)$$

The log $(D/[A^-])$ *vs.* log $[L]_o$ plot in Fig. 2 shows a straight line with a slope of 2 in each case, indicating that B15C5 forms the 2 : 1 complex with the alkali metal ion. The values of $[L]_o$ and $[A^-]$ in Eq. 12 were calculated from Eqs. 13 and 14 respectively:

$$[L]_o = ([L]_t - 2[ML_2A]_o)/(1 + K_{D,L}^{-1}), \quad (13)$$

$$[A^-] = [HA]_t - [ML_2A]_o. \quad (14)$$

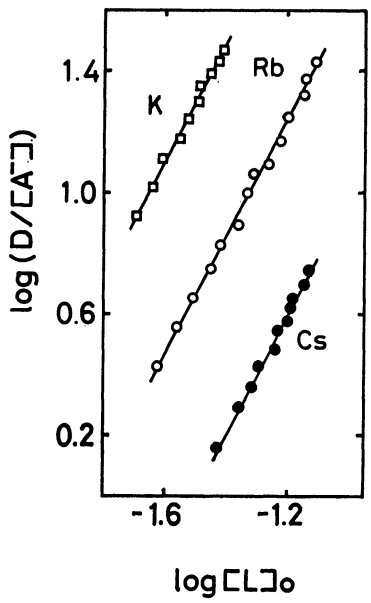

Fig. 2. Plots of $\log(D/[A^-])$ *vs.* $\log[L]_o$ for the ML_2A system.

When the benzene phase contains both B15C5 and B, D may be represented by

$$D = [MLBA]_o/[M^+]. \quad (15)$$

The substitution of Eqs. 2 and 6 into Eq. 15 gives

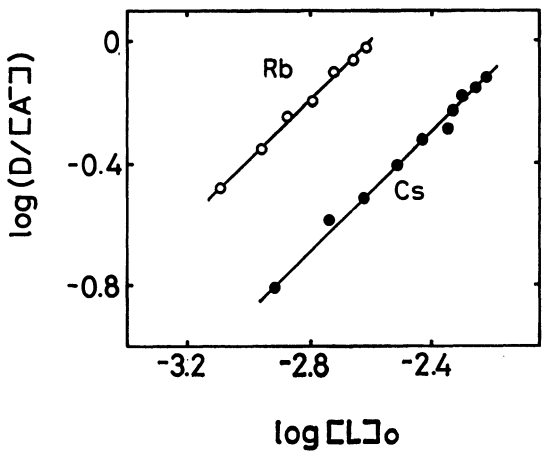

Fig. 3. Plots of $\log(D/[A^-])$ *vs.* $\log[L]_o$ for the MLBA system.

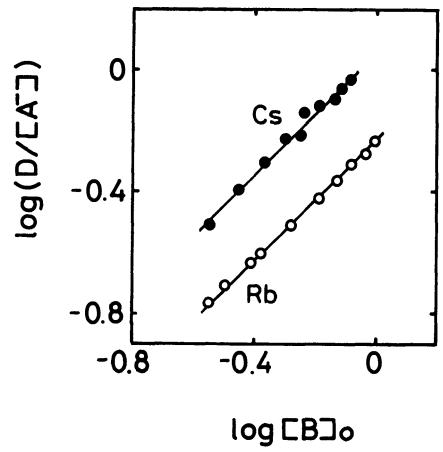

Fig. 4. Plots of $\log(D/[A^-])$ *vs.* $\log[B]_o$ for the MLBA system.

$$D = K_{ex}(MLBA)K_{ex}(HA)[L]_o[B]_o[A^-]. \quad (16)$$

The log $(D/[A^-])$ *vs.* log $[L]_o$ and log $[B]_o$ plots are given in Figs. 3 and 4 respectively. It may be seen from Figs. 3 and 4 that, in each case, the plots of both Rb and Cs have a slope of 1. Thus, the Kex(MLBA) in this work can be described by Eq. 2. The value of $[B]_o$ in Eq. 16 was supposed to be approximately equal to that of $[B]_t$ under the present experimental conditions, and those of $[L]_o$ and $[A^-]$ were calculated from Eqs. 17 and 18 respectively:

$$[L]_o = ([L]_t - [MLBA]_o)/(1 + K_{D,L}^{-1}), \quad (17)$$

$$[A^-] = [HA]_t - [MLBA]_o. \quad (18)$$

The extraction equilibrium constants obtained from these experiments are listed in Table 1, together with those from the literature.

TABLE 1. EXTRACTION EQUILIBRIUM CONSTANTS AT 25 °C

		15C5[2]	B15C5

	Na^+	3.10	4.59
	K^+	1.78	3.23
	Rb^+	1.34	2.74
	Cs^+	1.10	2.38

Discussion

The $K_{D,L}$ value of B15C5, which is more bulky than 15C5, is much larger than that of 15C5.

The logK_{ex}(MLA) series for B15C5 and 15C5 are given by $Na^+>K^+>Rb^+>Li^+>Cs^+$ and $Na^+>K^+>$

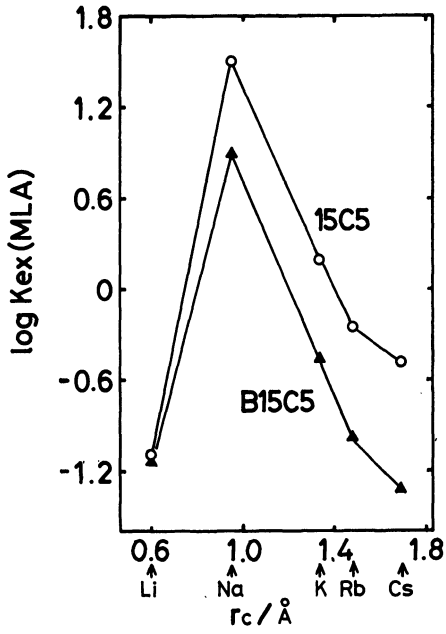

Fig. 5. Plots of log K_{ex}(MLA) *vs.* crystal ionic radii, r_c, of alkali metals for the B15C5 and 15C5 systems.
▲: B15C5, ○: 15C5.

$Rb^+ > Cs^+ > Li^+$ respectively (Table 1). The selectivity tendency of B15C5 (cavity radius: 0.85—1.1 Å[7]) for the alkali metal ions is not much different from that of 15C5 and agrees with the size-fit concept (Fig. 5). A possible explanation for the difference in the sequences of Li^+ and Cs^+ is as follows. The extractability of the crown ether complex with the univalent metal picrate depends on the interaction of the univalent metal ion trapped in the crown ether cavity with water molecules.[8] Since, for the alkali metal ion in the cavity, the interaction of the lithium ion with water molecules seems to be the strongest of all the alkali metal ions, the hindrance for the hydration of the B15C5 complex by the benzo group attached to 15C5 may be much more effective for the case of Li^+ compared to Cs^+. Thus, in the case of B15C5, Li^+ is more extractable than Cs^+. The following data may support the above discussion, though they have been obtained in the nitrobenzene–water system. The numbers of water molecules coextracted with the Li^+–15C5, Li^+–B15C5, Cs^+–15C5, and Cs^+–B15C5 complexes into the nitrobenzene phase are 2.0, 1.4, 0.2, and 0.4 respectively.[9] For the lithium complex, the number of water molecules decreases remarkably on moving from 15C5 to B15C5, while, for the caesium complex, it increases only slightly.

Equation 7 shows that $K_{D,L}$, K_{ML}, and K'_{ex} are important factors which determine the magnitude of K_{ex}(MLA) for the same alkali metal ion and different crown ethers. Although the log ($K_{ML}K'_{ex}$) sequence of B15C5 and 15C5 for the same alkali metal ion is B15C5>15C5, the log K_{ex}(MLA) value of B15C5 for Li^+ is nearly equal to that of 15C5 and that of B15C5 for the other alkali metal ion is smaller than that of 15C5. This is entirely attributed to the much greater $K_{D,L}$ value of B15C5 compared to 15C5 (Table 1). The basicity of the aromatic ether oxygen atom is lower than that of the aliphatic one. Since B15C5 has two aromatic ether oxygen atoms, the B15C5 complex with the same alkali metal ion may be more unstable than the 15C5 complex. The B15C5 complex with the same alkali metal ion may be more extractable than the 15C5 complex because of its larger size compared to 15C5. The log ($K_{ML}K'_{ex}$) value of B15C5 for the same alkali metal ion is larger than that of 15C5 (Table 1). It thus appears that the log ($K_{ML}K'_{ex}$) sequence of B15C5 and 15C5 depends completely on the K'_{ex} sequence. By way of example, in the case of K^+, the log K_{ML} values of B15C5 and 15C5 are 0.38[10] and 0.74,[11] and the log K'_{ex} values are 2.85 and 1.04,[2] respectively.

For the MLA, MLBA, and ML_2A systems, Rb^+ is more extractable than Cs^+, and, for the B15C5–ML_2A system, K^+ is the most extractable (Table 1). In the cases of the MLA, MLBA, and ML_2A systems, the difference in the extractabilities of Rb^+ and Cs^+ increases in going from 15C5 to B15C5.

When MLA undergoes further complex formation with B and L in the organic phase, the equilibria can be described as Eqs. 19 and 20 respectively:

$$MLA_o + B_o \rightleftharpoons MLBA_o,$$

$$K_{MLBA,o} = K_{ex}(MLBA)/K_{ex}(MLA) = [MLBA]_o/[MLA]_o[B]_o, \quad (19)$$

$$MLA_o + L_o \rightleftharpoons ML_2A_o,$$

$$K_{ML_2A,o} = K_{ex}(ML_2A)/K_{ex}(MLA) = [ML_2A]_o/[MLA]_o[L]_o, \quad (20)$$

where $K_{MLBA,o}$ and $K_{ML_2A,o}$ are the formation constants for the MLBA and the ML_2A complexes in a benzene solution respectively; they are summarized in Table 2.

Table 2. Complex-formation constants for synergistic reactions in a benzene solution at 25 °C

		K^+	Rb^+	Cs^+
log $K_{MLBA,o}$	15C5[3]	—	0.81	0.68
	B15C5	—	1.32	1.16
log $K_{ML_2A,o}$	15C5[3]	—	2.40	1.97
	B15C5	2.37	2.17	1.72

The log $K_{ML_2A,o}$ values of B15C5 for K^+ and Rb^+ are approximately identical with those in the literature[10] (K^+: 2.65 and Rb^+: 1.97 in 70 wt% CH_3OH in H_2O, K^+: 2.6 in 80 wt% CH_3OH in H_2O).

It is interesting that, in the benzene solution, both the B15C5 and 15C5 complexes with CsA accept a B molecule, while the 2-thenoyltrifluoroacetone complex with Cs^+ (Cs(TTA)) accepts two B molecules.[12] This may be largely due to that HTTA is a chelating acid, while B15C5 and 15C5 are neutral ligands.

As can be seen from Table 2, for every crown ether system, the smaller the size of the alkali metal ion is, the larger is the complex-formation constant. For the MLBA system, this may reflect the higher charge density of Rb^+ compared to Cs^+. For the ML_2A system, this is presumably attributable to both the charge density of the cation and the accommodation of the cation into the crown ether cavity.

Since B15C5 has two aromatic ether oxygen atoms, the electron density in the B15C5 cavity may be lower than that in the 15C5 cavity. Thus, the apparent charge density of the exposed part of the alkali metal ion trapped in the crown ether cavity seems higher for the case of B15C5 compared to 15C5. Consequently, this may be the reason why, in each case of Rb^+ and Cs^+, the log $K_{MLBA,O}$ value of B15C5 is larger than that of 15C5 (Table 2). In each case of Rb^+ and Cs^+, the log $K_{ML_iA,O}$ value of B15C5 is smaller than that of 15C5. This is probably due to two aromatic ether oxygen atoms of B15C5.

The fact that the crown ether has much more donor oxygen atoms than B may be the reason why, for both B15C5 and 15C5, the log $K_{ML_iA,O}$ value of the same alkali metal ion is larger than the log $K_{MLBA,O}$ value (Table 2).

The Crystal Structure of *cis*-Diammine(orotinato)platinum(II)

Takaaki Solin, Kazuko Matsumoto,* and Keiichiro Fuwa

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 15, 1980)

From the reaction of *cis*-$[Pt(NH_3)_2(H_2O)_2]$ with orotic acid, yellow needle crystals, green needle crystals, and dark-blue microcrystalline crystals were obtained. The results of elemental analyses, the IR absorption spectra, and X-ray Weissenberg photographs showed that the yellow and green needles are identical, whereas the dark-blue microcrystalline compound exhibits slight difference in the elemental analyses and IR spectra. Green needle crystals of *cis*-diammine(orotinato)platinum(II), *cis*-$[Pt(NH_3)_2(C_5H_2N_2O_4)]$, were subjected to X-ray single crystal analysis. The crystals belong to the monoclinic system, with the space group $P2_1/c$, and the cell dimensions are $a=7.468(5)$, $b=7.537(3)$, $c=15.618(9)$ Å, and $\beta=107.90(7)°$, with $Z=4$. The structure was solved by the heavy-atom method and refined to the final R value of 0.0567 for 1918 non-zero reflections. The complex is almost planar, and the platinum atom is coordinated by the orotic acid at N1 and carboxylic oxygen, forming a five-membered chelate ring. The structure of the pyrimidine ring of the orotic acid is compared with free and coordinated uracil and thymine. No definite explanation for the color difference was obtained.

Since the discovery of the antitumor activity of *cis*-diamminedichloroplatinum(II) by Rosenberg *et al.*,[1,2] considerable interest has been focused on this class of square-planar *cis*-diammineplatinum(II) complexes. The mechanism of the antitumor action has been supposed to be the complex formation between *cis*-diammineplatinum(II) compounds and purine or pyrimidine bases of DNA.[3] These bases have several possible coordinating sites, and many investigations have been carried out into the structures of the platinum complexes with purine or pyrimidine bases.[4-16] Among these complexes, the so-called "platinum-pyrimidine blues" are of special interest from the viewpoint of not only the mechanism of the complex formation between *cis*-diammineplatinum and pyrimidines, but also the anomalously deep blue color and the high antitumor activity of the complexes.[17] As for their structures in the solid and solution states, as well as their chemical properties, however, only a little knowledge has thus far been obtained. Although Lippard *et al.* reported the structure of platinum α-pyridon blue,[18,19] there are still a large number of other platinum pyrimidine blues whose formulas and structures are unknown. In the present paper, we wish to report on the crystal structure of the reaction product between *cis*-diammineplatinum and one of the uracil derivatives, orotic acid. We obtained three compounds, yellow needles, green needles and blue microcrystals, from the reaction solution. The green needle crystals were subjected to X-ray diffraction analysis in order to elucidate the structural relations among the three and to discuss whether there are structural changes in the pyrimidine ring of orotic acid due to coordination to a platinum atom.

Experimental

Preparation. The *cis*-diammineplatinum(II) hydrolysis product was prepared from 1 mmol of *cis*-$[Pt(NH_3)_2Cl_2]$ and 2 mmol of $AgNO_3$ in 10 ml of water in the dark. After removing the AgCl by centrifugation and filtration, an equivalent amount of orotic acid in a minimum amount hot water was added; this resulted in the decrease of the pH of the solution to 1—2. On standing at room temperature for 1 d, the solution yielded green needle crystals. If the solution was adjusted to pH 6—7 with NaOH and left to stand for 1 d, it yielded yellow needles. After the filtration of these green or yellow compounds, a small quantity of dark-blue microcrystals precipitated from the filtrate after 2—3 d. Found: Yellow needles; C, 15.35; H, 2.16; N, 14.48; Pt, 50.7%. Green needles; C, 15.38, H, 2.18; N, 14.70; Pt, 49.5%. Dark-blue microcrystals; C, 14.93; H, 2.21; N, 14.27; Pt, 53.0%. Calcd for $[Pt(NH_3)_2(C_5H_2N_2O_4)]$: C, 15.67; H, 2.10; N, 14.62; Pt, 50.91%. Although the results of elemental analyses for yellow and green needles are identical within the limits of experimental error, the platinum content of the dark-blue compound significantly differs from that of the yellow and green needles. Moreover, the IR spectra of the three compounds are very similar to one another; the yellow and green needles give the same spectra, whereas that of the dark-blue compounds shows only a slight difference. The latter has three more absorption peaks, at 545 (w), 660 (w), and 1100 (w) cm^{-1}, than those of yellow and green compounds. These findings suggest that the three compounds have very similar structures. In the present study, the crystal structure of the green compound was investigated by means of X-ray diffraction.

Data Collection. A crystal of 0.15 mm × 0.05 mm × 0.25 mm was used for intensity measurements; the cell dimensions were obtained from twelve 2θ values measured on a diffractometer. The crystal data for *cis*-$[Pt(NH_3)_2(C_5H_2N_2O_4)]$ are: monoclinic $P2_1/c$, $a=7.468$ (5), $b=7.537$ (3), $c=15.618$ (9) Å, $\beta=107.90$ (7)°, $M.W.=383.2$, $Z=4$, $D_x=3.04$ g cm^{-3}, $\mu=176.4$ cm^{-1} for Mo $K\alpha$. The intensity measurements were performed on a Philips four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The ω-2θ scan mode was employed at the scan rate of 1° min^{-1} in 2θ, and the reflections were measured up to 60° in 2θ. Three reference reflections monitored periodically showed no significant intensity loss during the course of the data collection. The data were corrected for Lorentz and polarization effects, and a total of 1918 reflections with $|F_o| \geqq 3\sigma(|F_o|)$ were used for structural analysis.

Solution and Refinement of the Structure. The structure was solved by the heavy-atom method. The platinum atom was located from a three-dimensional Patterson map, while all the remaining non-hydrogen atoms were located from the successive Fourier systheses. Although a difference synthesis was calculated at the final stage of the analysis, the hydrogen atoms were not located. The positional and anisotropic temperature factors were refined by the blockdiagonal least-squares method to the final R factor of 0.0567. All the atomic

scattering factors used were taken from Ref. 20, while the correction of the effect of the anomalous dispersion for platinum was based on Ref. 21. The final atomic coordinates and thermal parameters are given in Table 1.

Results and Discussion

The bond lengths and angles within the molecule are listed in Table 2, while the molecular structure and the numbering scheme are depicted in Fig. 1. Orotic acid coordinates to the platinum atom by chelating with deprotonated N1 and carboxylic O5 atoms to form a five-membered ring. It is of interest where, in uracil or its derivatives, is the coordinating site to platinum atoms and how much the bond lengths and angles within the pyrimidine ring are changed by coordination. Although

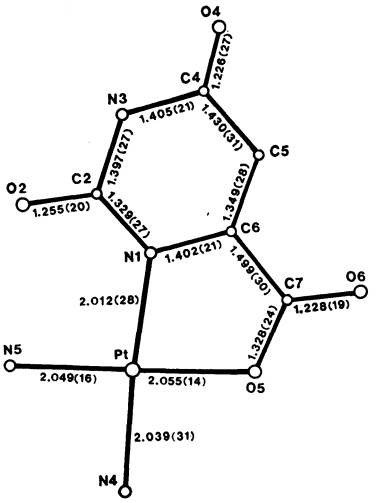

Fig. 1. The molecular structure and the numbering scheme for *cis*-[$Pt(NH_3)_2(C_5H_2N_2O_4)$].

uracil or thymine deprotonates first at the N3 site, and although the pK_a value is 9.5 for both uracil and thymine,[22] most of the platinum complexes so far investigated by X-ray diffraction or NMR show that coordination takes place at N1.[4] One exception is the triammineplatinum uracil complex, [$Pt(NH_3)_3(C_4H_3N_2O_2)$]NO_3, where the platinum atom is considered, on the basis of the NMR spectra, to be coordinated by uracil at N3.[5] In the present complex, the coordination at N1 is much more favored due to the chelate formation.

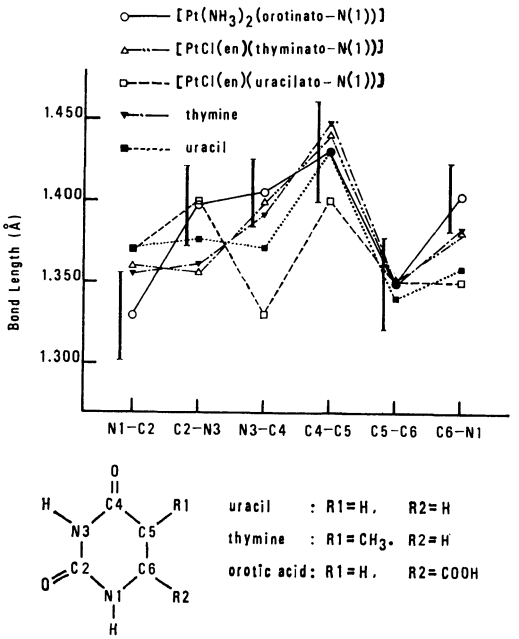

Fig. 2. Comparison of C–C and C–N bond lengths in pyrimidine rings of [$Pt(NH_3)_2$(orotinato-N(1))], [PtCl(en)(thyminato-N(1))], [PtCl(en)(uracilato-N(1))], thymine and uracil. Standard deviations in [$Pt(NH_3)_2$(orotinato-N(1))] are shown with error bars and those of other complexes are in the range one tenth to half of those in [$Pt(NH_3)_2$(orotinato-N(1))].

A comparison of the structures of free and coordinating orotic acid would give valuable information on the change in the electronic structure due to the coordination. However, as no X-ray investigation of free orotic acid has thus far been reported, a comparison with thymine and uracil was carried out. The C–C and C–N bond lengths in thymine,[23] uracil,[24] the platinum thymine complex,[4] the platinum uracil complex,[4] and orotic acid in the present compound are compared in Fig. 2. The corresponding C–C and C–N bond lengths are significantly different from uracil to thymine; these differences were satisfactorily explained by Gerdil[23] in terms of the canonical structures. The C–C and C–N bond lengths of free and coordinating thymine are considered to be identical with each other, whereas the C2–N3, N3–C4, and C4–C5 bond lengths of uracil are slightly different from those of the coordinating uracil. The bond lengths of coordinating orotic acid are different from both uracil and thymine; the N1–C2 distance of orotic acid is significantly shorter than that of uracil or thymine, whereas the C6–N1 distance of orotic acid is longer than that of uracil or thymine. This is explained by the electron flow from the C2–O2 to the N1–C2 bond and from the C6–N1 to the C6–C7 bond, a flow which is aroused by the electrophilic carboxyl group substituted at C6. The comparison of the C=O distances shows that most differences are within the standard deviations and that, therefore, no significant differences are observed. As for the bond angles of the ring nitrogens, C6–N1–C2 (117.5(14)°) is significantly smaller than C2–N3–C4 (124.4(14)°). This fact is consistent with Singh's report[25] that the nitrogen valence angle with an extraannular hydrogen atom is 125±3°, whereas that without any attachment is 116±3°. The coordination of the N1 to the platinum atom does not seem to affect the nitrogen valence angle, since C6–N1–C2 is essentially the same as the valence angle for the nitrogen without any hydrogen attachment. Similarly the two kinds of nitrogen valence angles are also observed in the platinum–uracil complex, (H_5O_2)-$[PtCl(en)(C_4H_3N_2O_2)]Cl$, and the platinum–thymine complex, $[PtCl(en)(C_5H_5N_2O_2)]$.[4]

All the atoms in the molecule are almost coplanar, and the dihedral angle between the best least-squares plane of Pt, N1, N4, N5, and O5, and that of the

pyrimidine ring is 2.81°. The best least-squares planes calculated from all the atoms, the pyrimidine ring and Pt, N1, N4, N5, and O5, are shown in Table 3.

The molecules are hydrogen-bonded to each other; the possible hydrogen bond distances and angles are listed in Table 4 and are shown in Fig. 3. Using the expected coordinates for hydrogen atoms, the donor-hydrogen atom-acceptor angles were calculated. They are between 145.6° and 172.7°, satisfactory for hydrogen-bondings. The only angle which is marked with an asterisk is small; in this case, the hydrogen atom may shift greatly from the donor-acceptor line.

Although the present work has been undertaken in order to elucidate the structural relations among the three complexes, yellow needles, green needles, and dark-blue microcrystals, preliminary Weissenberg photographs show that the yellow and green needles are structurally identical. Since the dark-blue microcrystals are too small for X-ray single-crystal analysis, only the green needle crystals were subjected to X-ray intensity measurement. There is no definite explanation for the color difference at present, but after the X-ray diffraction analysis had been completed, a close microscopic examination of the crystals showed that the yellow and green needles seem to differ only in their habit of crystal growth; that is, they are identical complexes actually, but seem slightly different in color because of the difference in crystal growth. Otherwise, although the results of ESCA showed no difference, a slight difference in the oxidation states of the platinum atoms, which cannot be detected with ESCA, might exist between the yellow and green needles. It has been reported that platinum α-pyridon blue contains platinum atoms of the formal oxidation state, 2.25.[19] The shortest platinum-platinum distance in the present complex is 4.601(1) Å. A comparison of the platinum-platinum distances with those of other complexes, *cis*-diammine-platinum α-pyridon blue: 2.7745(4) and 2.8770(5) Å,[19] and Magnus' green salts: 3.25—3.46 Å,[26] shows that the platinum-platinum distance of the present complex is much longer, and there seems to be no interaction between adjacent platinum atoms.

This work has been suported by a grant for the development of anti-cancer medicines (No. 23665) from the Japanese Ministry of Health and Welfare.

Mössbauer Spectroscopic Study of Potassium Borosilicate Glasses at Low Temperatures

Tetsuaki NISHIDA,* Toshiharu HIRAI, and Yoshimasa TAKASHIMA

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812

(Received January 26, 1981)

The Mössbauer technique at the liquid nitrogen temperature (78 K) was applied to the estimation of non-bridging oxygens in FeO_4, BO_4, and SiO_4 units in potassium borosilicate glasses. Mössbauer spectra consist of a quadrupole doublet and a hyperfine structure due to Fe^{3+} ions with tetrahedral symmetry. The hyperfine structure is attributed to a relaxation effect because magnetic susceptibility measurements revealed the glasses to be paramagnetic in the temperature range 78—295 K. A linear decrease in the absorption area and a similar decrease in the internal magnetic field for the hyperfine structure were observed with an increase in the alkali content of glasses. The decrease is ascribed to a formation of non-bridging oxygen at the site adjacent to iron, because the mean life-time of the internal magnetic field produced by 3d-electrons of iron is considered to decrease with increasing thermal vibration of the iron and neighboring oxygens. Fractions of non-bridging oxygens obtained from the reduction rate of the absorption area of hyperfine structure are in good agreement with earlier results for borate glasses with the same K_2O/B_2O_3 ratios, in the alkali region of 8—20 mol% where the borosilicate glasses are essentially considered to be borate glasses diluted with SiO_2.

NMR studies by Yun and Bray[1] reported on each fraction of BO_3 and BO_4 units in various borate or borosilicate glasses, where the fraction of BO_4 unit proved to increase linearly with the alkali content of glasses in the low alkali region. Mössbauer technique was also applied to studying the structure of borate glasses,[2-7] and a formation of non-bridging oxygen (NBO) was suggested to start at an alkali content of 20 mol%. The fraction of NBO in the oxygens constituting BO_4 or FeO_4 units was also estimated from a Mössbauer study of γ-ray irradiated borate glasses,[6] and from a study at low temperatures.[7] A Mössbauer study of potassium borosilicate glasses[8] suggested the formation of NBO to start at an alkali content of 8 mol% in the case of borosilicate glasses with an SiO_2/B_2O_3 ratio of 2.0. It was also considered that the fraction of NBO in borosilicate glasses is increased as a result of the substitution of B_2O_3 for SiO_2.

The present study was performed to estimate the fraction of NBO in potassium borosilicate glasses by using the Mössbauer technique at low temperatures.

Experimental

Potassium borosilicate glasses denoted by the formula $x\,K_2O\cdot(100-x)(B_2O_3,\ SiO_2)\cdot 0.33\,Fe_2O_3$ were prepared by melting mixtures of weighed quantities of K_2CO_3, H_3BO_3, SiO_2, and Fe_2O_3 of guaranteed reagent grade. As for the iron(III) oxide, an enriched isotopic species $^{57}Fe_2O_3$ (^{57}Fe= 90.24%) was used for the preparation. The value of x was changed from 12 to 40, and the molar ratio of SiO_2 to B_2O_3 was so chosen as to be 2.0. Each mixture in a platinum crucible was melted at 1300 °C for 3 h in an electric muffle furnace. The melt was sometimes stirred to be made homogeneous, and was quenched by steeping the platinum crucible into cold water in a beaker. Amorphous structure of almost colorless and transparent glasses was confirmed by X-ray diffractometry. All the glass samples were preserved in a desiccator to protect them from the atmospheric moisture.

Mössbauer measurements were performed by the constant acceleration method at room (295 K), Dry Ice (196 K), and liquid nitrogen (78 K) temperatures. Cobalt-57 (5 mCi) diffused into a palladium foil was used as the source, and the velocity of the spectrometer was calibrated using a pure iron foil enriched with iron-57. The iron foil was used as a reference for isomer shift values. All the spectra were fitted to Lorenzian line shape by computer calculations.

Results and Discussion

Mössbauer spectra for the potassium borosilicate glass with an alkali content of 12 mol% are shown in Fig. 1. All the Mössbauer spectra at room and Dry Ice temperatures consist of a quadrupole doublet (qd) due to the Fe^{3+} ions with tetrahedral symmetry,[2-12] together with a marked wing shape of base line. Isomer shift values of the quadrupole doublet are consistent with the corresponding values of the borosilicate glasses containing 7 mol% Fe_2O_3.[8] Mössbauer spectra for the borosilicate glasses containing 0.33 mol% Fe_2O_3 can, therefore, be analyzed in the same way as for the borosilicate glasses containing 7 mol% Fe_2O_3, although each of the spectra has a wing shape of base line. This is also the case for the Mössbauer spectra at the liquid nitrogen temperature, *i.e.*, the isomer shift values of the quadrupole doublet are well consistent with the corresponding values of the borosilicate glasses containing 7 mol% Fe_2O_3.

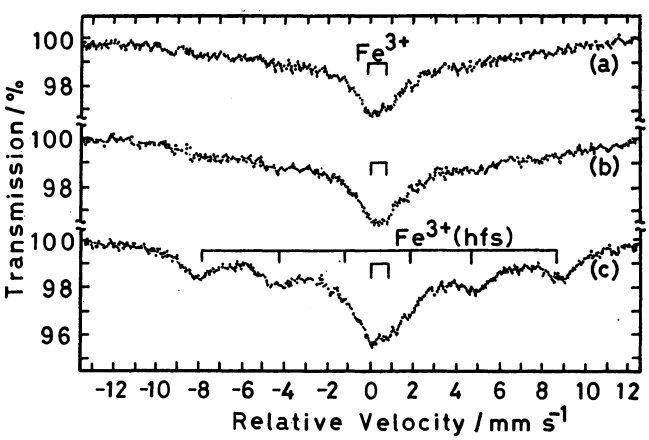

Fig. 1. Mössbauer spectra for the potassium borosilicate glass with an alkali content of 12 mol%.
(a): 295 K, (b): 196 K, (c): 78 K.

Mössbauer spectra at the liquid nitrogen temperature are, therefore, analyzed into a quadrupole doublet and six absorptions of hyperfine structure (hfs). The hfs suggests that the ^{57}Fe nuclei are in the magnetic field and that the mean lifetime of the internal magnetic field is at least of the order of nuclear Larmor precession time. Magnetic susceptibility measurements were then performed to confirm the hfs to be due to a paramagnetic relaxation effect and not due to a magnetic transition or magnetic impurities in the glasses. The data is shown in Fig. 2, which proves the borosilicate glasses to be paramagnetic in the temperature range 78—295 K where the hfs and/or the marked wing shape of base line were observed.

TABLE 1. MÖSSBAUER PARAMETERS FOR THE POTASSIUM BOROSILICATE GLASSES AT 78 K

X[a] mol%	Species	δ[b] mm s^{-1}	Δ[c] mm s^{-1}	Γ[d] mm s^{-1}	A[e] %
12	Fe^{3+}(qd)	0.41	0.89	0.73	32.1
12	Fe^{3+}(hfs)	0.39	−0.14	0.77	67.9
15	Fe^{3+}(qd)	0.38	0.61	0.70	37.4
15	Fe^{3+}(hfs)	0.37	−0.07	0.67	62.6
20	Fe^{3+}(qd)	0.36	0.75	1.03	37.9
20	Fe^{3+}(hfs)	0.33	−0.12	0.96	62.1
25	Fe^{3+}(qd)	0.30	0.68	0.85	39.4
25	Fe^{3+}(hfs)	0.35	−0.07	0.57	60.6
30	Fe^{3+}(qd)	0.30	0.65	0.78	42.0
30	Fe^{3+}(hfs)	0.32	−0.03	0.69	58.0
40	Fe^{3+}(qd)	0.32	0.80	0.86	43.3
40	Fe^{3+}(hfs)	0.34	−0.06	0.64	56.7

a) Alkali content. b) Isomer shift. c) Quadrupole splitting. d) Line width (FWHM). e) Absorption area.

The Mössbauer parameters obtained at the liquid nitrogen temperature are summarized in Table 1. The experimental error including the one from computer calculation is estimated to be ± 0.02 mm s^{-1} or more for the isomer shift, since the spectrum is less sharp than the one for the corresponding borosilicate glass containing 7 mol% Fe_2O_3.[8] In the latter case, the error was estimated to be ± 0.01 mm s^{-1}, and the spectrum consists only of a quadrupole doublet free from the relaxation effect. Errors are also estimated to be ± 0.02 mm s^{-1} for the quadrupole splitting and the line width and ± 0.1% for the absorption area. All the isomer shift values for the Fe^{3+} ions with tetrahedral symmetry are increased because of the decreased second-order Doppler effect at lower temperatures. Table 1 also demonstrates that isomer shift values decrease with increasing alkali content of the glasses, as in the case of borosilicate glasses containing 7 mol% Fe_2O_3[8] measured at room temperature. A continuous decrease in isomer shift with increasing alkali content has already been attributed to a formation of NBO in borate[2-5,7] or borosilicate[8] glasses. The decrease in isomer shift indicates an increased s-electron density at iron nucleus as a result of the formation of NBO at the site adjacent to the iron. The increase in s-electron density can be explained by the increased overlap of the 4s-orbital of iron with the 2*p*-orbital of NBO, followed by the transfer of electron from the NBO to the iron. The electron transfer has also been confirmed by the reduction of Fe^{3+} to Fe^{2+} in borate glasses irradiated with γ-rays.[4,6] The increased s-electron density is also explained by the decreased screening effect of s-electrons by p-electrons, because more electrons (3/4 of which are considered to be p-electron) in the sp^3 hybrid orbital will be attracted to the NBO than to the bridging oxygens. The decrease in isomer shift in borosilicate glasses is thus attributed to a formation of NBO at sites adjacent to iron, boron, and silicon in FeO_4, BO_4, and SiO_4 units, respectively.

The quadrupole splitting values for the quadrupole doublet are also consistent with results for Fe^{3+} ions with tetrahedral symmetry in glasses.[2-12] The negative sign of the quadrupole splitting values for the hfs demonstrates that the direction of the electric field gradient tensor is parallel to the xy plane of the network structure. The very small quadrupole splitting values for the hfs suggest that the direction of the electric field gradient tensor is also the same as that of the internal magnetic field. The small quadrupole splitting may be observed probably because the direction of the internal magnetic field depends upon the relaxation time of 3d-electrons, and therefore upon the measuring temperature. It is, therefore, assumed that the magnitude of the quadrupole splitting for the hfs would become as large as the corresponding value for the quadrupole doublet, at much lower temperatures. All the line width (FWHM) values are also characteristic of the absorptions for irons in glasses,[2-12] and are a little increased because of a relaxation effect.

Figures 3 and 4 show changes of the absorption area and the internal magnetic field for the hfs, respectively. The internal magnetic field was obtained by comparing the distance between the outermost absorptions of the hfs with the corresponding distance of a pure iron foil with an internal magnetic field of 330 kOe at room temperature. It is obvious from Figs. 3 and 4 that there occurs a distinct change of glass structure at the alkali region of 16—18 mol%, because all the glasses were prepared so that the iron content should be equal to each other (0.33 mol%), and because all the spectra were measured at the same temperature (78 K). These results are consistent with the NMR results by Yun and Bray[1] that the borosilicate glasses are essentially

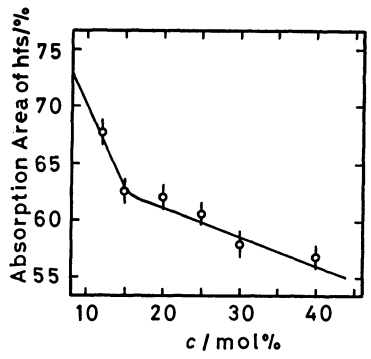

Fig. 3. Mössbauer absorption area of hyperfine structure (hfs) at 78 K plotted against the alkali content of potassium borosilicate glasses.

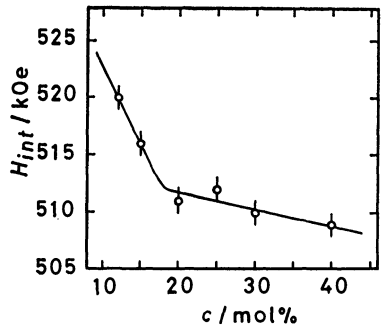

Fig. 4. Internal magnetic field for hyperfine structure (hfs) at 78 K plotted against the alkali content of potassium borosilicate glasses.

considered to be borate glasses diluted with SiO_2 in the alkali region lower than 18 mol%. The additional alkali oxide molecules will therefore be attracted to BO_3 units to form BO_4 units with and without NBO in the alkali region of 8—18 mol%. Formation of BO_4 unit with only bridging oxygens is assumed to occur in the alkali region lower than 8 mol%. In the alkali region higher than 18 mol%, the additional alkali oxide will also be attracted to SiO_4 units to form NBO. The decreasing absorption area of hfs (Fig. 3) can therefore be correlated with the fraction of NBO in FeO_4 units, and also with the fraction in BO_4 and SiO_4 units because all the irons are considered to be present at the substitutional site of boron or silicon. The decrease in the absorption area of hfs is well explained by taking account of the thermal vibration at a certain temperature, *e.g.*, 78 K. The thermal vibration of oxygen is considered to be more frequent in the case of NBO as compared with bridging oxygen, because the former is bonded with only one network former such as iron, boron, or silicon and the latter is bonded with two atoms of network formers.[7] It is, therefore, considered that the thermal vibration of iron is also more frequent in the case of the iron bonded with NBO. Therefore, the internal magnetic field produced by 3d-electrons of iron[7] is considered to be closely correlated with the fraction of NBO in FeO_4 units, because the mean lifetime of the internal magnetic field will be reduced with increasing thermal vibration, *i.e.*, with increasing NBO fraction. The reduction rate of the absorption area for the hfs, therefore, seems to be useful for the estimation of NBO fraction at the site adjacent to iron, because the paramagnetic hfs (relaxation spectrum) is observed as a result of the interaction of the Mössbauer nuclei (^{57}Fe) with the internal magnetic field produced by 3d-electrons of the irons.[7] Fractions of NBO at individual alkali concentrations are summarized in Table 2, where the absorption areas of the hfs at 8 and 10 mol% were obtained by extrapolation of the straight line shown in Fig. 3. The absorption area at the alkali content of 35 mol% was obtained by interpolation of the straight line of Fig. 3. Each of the NBO fractions was obtained by dividing the decreased absorption area by the absorption area at the alkali content of 8 mol% (*i.e.*, 73.0%) where the formation of NBO is considered to start.[8] All the fractions of NBO seem to be reasonable, because the values in the alkali region lower than 20 mol% are consistent, within the experimental error, with earlier results for potassium borate glasses[6,7] having the same K_2O/B_2O_3 ratios as in the borosilicate glasses. The borosilicate glasses are, therefore, considered to be borate glasses diluted with SiO_2 in the alkali region lower than 18 mol%, as described above. The present method seems to be very useful for the estimation of NBO in borate or borosilicate glasses. It is expected that the absorption area for the hfs increases with decreasing iron content of the glasses, and also with a decrease in the measuring temperature. The experimental error for the calculation of absorption area will be reduced with increasing hfs, because the spectral analysis of the innermost peaks is somewhat uncertain in the case of partially relaxed spectra. The fractions of NBO obtained in the present study, however, are considered to be reasonable because each of them was obtained from the relative absorption area of hfs and not from the absolute absorption area of hfs.

Table 2. Estimation of non-bridging oxygens in potassium borosilicate glasses

X[a] / mol %	Absorption area of hfs/%	Fraction[b] of NBO/%
8	73.0	0
10	70.2	3.8±1.9
15	63.0	13.7±1.9
20	61.2	16.1±1.9
25	59.8	18.1±2.0
30	58.6	19.7±2.0
35	57.3	21.5±2.0
40	56.0	23.3±2.0

a) Alkali content. b) Estimated from the decrease in the absorption area of hfs.

The authors are grateful to Dr. Shuji Emori of Saga University for his kind help in the magnetic susceptibility measurements of the glass samples. They are also grateful to Dr. Yusuke Nakayama of Ehime University for his kind suggestions in the computer analyses of the Mössbauer spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 347036 from the Ministry of Education, Science and Culture.

Kinetic Studies of the Electron Transfer Reactions in Iron(II) and Iron(III) Systems. XI. Electron Transfer Reaction between Aquairon(II) and Tris(1,10-phenanthroline)iron(III) in Water Mixed with Methanol, Ethanol, 1-Propanol, and Ethylene Glycol

Goro WADA,* Kumiko TAKAHASHI, and Masako ISOBE
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received January 29, 1981)

The electron transfer reaction $Fe^{2+}_{aq}+Fe(phen)_3^{3+}\rightarrow Fe^{3+}_{aq}+Fe(phen)_3^{2+}$ has been investigated in order to find out the influence of the dielectric nature of media on the reaction rates, by the method of stopped-flow spectrophotometry. As the reaction media, were used aqueous mixtures with various alcohols, such as methanol, ethanol, 1-propanol, and ethylene glycol at their various mole fractions x. The second-order rate constant k grows larger approximately linearly with the increase in x, in a sequence: methanol<ethylene glycol<ethanol<1-propanol. When ln k is plotted against D^{-1} (the reciprocal dielectric constant), all points come together on a single straight line with a positive slope, indifferent to the kinds of the alcohols used. This fact suggests that the reaction proceeds through three successive elementary processes, $Fe^{2+}_{aq}+Fe(phen)_3^{3+}\xrightarrow{i}[Fe(H_2O)_6^{2+}\cdot Fe(phen)_3^{3+}]\xrightarrow{ii}[Fe(H_2O)_6^{3+}\cdot Fe(phen)_3^{2+}]\xrightarrow{iii}Fe^{3+}_{aq}+Fe(phen)_3^{2+}$, in which Process i is the formation of an outer-sphere ion-pair between two reacting ions, Process ii the intramolecular electron transfer in the intermediate complex, and Process iii the separation of the ion-pair into the product ions, the last being the rate-determining step. The reaction scheme is compared with that of the reaction $Fe^{2+}_{aq}+Fe(OH)^{2+}\rightarrow Fe(OH)^{2+}+Fe^{2+}_{aq}$, where the first step of the ion-pair formation is rate-determining.

The electron transfer reactions between iron(II) and iron(III) species in various media have been investigated extensively since the study of Silverman and Dodson.[1] The kinetics of the electron transfer reactions are now roughly divided into two main categories; the inner-sphere and outer-sphere mechanisms, the latter including the hydrogen-atom transfer mechanism. The oxidation reaction of aquairon(II) by tris(1,10-phenanthroline)-iron(III) was first studied by Sutin and Gordon[2,3] by applying a flow method, and was found to proceed *via* the outer-sphere mechanism, with a rate constant $k=3.7\times10^4$ M^{-1} s^{-1} in a 0.5 M perchloric acid media at 25 °C (M=mol dm^{-3}).

In the present study, this reaction was again adopted in order to see which of the two processes, the ionic association process between the two reacting ions or the ionic dissociation process of the associated ion-pair into the two leaving ions, is the rate-determining step in the overall outer-sphere electron transfer. For this purpose, aqueous media mixed with a number of alcohols such as methanol, ethanol, 1-propanol, and ethylene glycol were used with diversely different dielectric constants according to the kinds and the mixing ratios of alcohols. A part of the results have been preliminarily reported elsewhere.[4]

The reaction under consideration is as follows:

$$Fe^{2+}_{aq} + Fe(phen)_3^{3+} = Fe^{3+}_{aq} + Fe(phen)_3^{2+}. \quad (1)$$

Since the standard redox potentials of $Fe^{3+}_{aq}/Fe^{2+}_{aq}$ and $Fe(phen)_3^{3+}/Fe(phen)_3^{2+}$ are 0.76 V and 1.14 V respectively, the equilibrium constant of Reaction 1 is calculated to be $K_a=2.69\times10^6$ at 25 °C. Therefore, the rate of the backward reaction can be ignored in the course of the kinetic measurements. The reaction rate is consequently expressed by an equation

$$v = k[Fe^{2+}_{aq}][Fe(phen)_3^{3+}] \quad (2)$$

with a second-order rate constant k. Under a condition of excess $[Fe^{2+}_{aq}]$ over $[Fe(phen)_3^{3+}]$, the rate can be measured as an apparent pseudo-first-order reaction.

$$v = k'[Fe(phen)_3^{3+}] \quad (3)$$
$$k' = k[Fe^{2+}_{aq}]$$

Experimental

Materials. *$Fe(ClO_4)_2$*: Iron wire of 99.99% purity was dissolved in 3 M perchloric acid and the solution was concentrated under a reduced pressure at 60 °C. The precipitated crystals were washed by ether to remove the occluded acid and dried completely in vaccum.

$[Fe(phen)_3](ClO_4)_3$: Crystals of $[Fe(phen)_3]Cl_2$ were precipitated by adding an appropriate amount of NaCl crystals to a solution containing iron(II) perchlorate and 1,10-phenanthroline with the concentration of the latter slightly excess over the molar ratio 1 : 3. A solution of $[Fe(phen)_3]Cl_2$ in 1 M sulfuric acid was gradually added with PbO_2 powder to oxidize $Fe(phen)_3^{2+}$ ion to $Fe(phen)_3^{3+}$ ion, and after filtering the solution to remove the deposited $PbSO_4$ and the excess PbO_2, crystals of $NaClO_4$ were added to the solution to precipitate the crystals of $[Fe(phen)_3](ClO_4)_3$, which were then filtered out, washed by ether, and dried in a vacuum. The crystals of 1,10-phenanthroline were a commercial reagent and were used without further purification.

Water: Water was purified by double distillation after being deionized through ion-exchange resin.

Alcohols: The alcohols used in the present study were methanol, ethanol, 1-propanol, and ethylene glycol. The first three of the above alcohols were distilled under ordinary atmospheric pressure and the last one under reduced one.

Procedure. Kinetic measurements were carried out by use of a Yanagimoto stopped-flow spectrophotometer Model SPS-1 with a thermostated equipment. The reaction was initiated by mixing two solutions containing Fe^{2+}_{aq} and $Fe(phen)_3^{3+}$ ions respectively. The reaction rate was traced by observing the diminution of transmittance due to the production of $Fe(phen)_3^{2+}$ ion at 510 nm, which was recorded on a memoriscope. The temperature was always kept at

25 °C unless otherwise noted and the ionic strength of the reaction solution was adjusted at 1.0 M with $NaClO_4$.

The apparent pseudo-first-order rate constant k' was evaluated from the slope of a straight line obtained by plotting the values of the left-hand side in the following equation *vs.* reaction time t,

$$\ln([Fe(phen)_3^{3+}]_o - [Fe(phen)_3^{2+}]) = -k't + \ln[Fe(phen)_3^{3+}]_o \quad (4)$$

where $[Fe(phen)_3^{3+}]_o$ is the initial concentration of $Fe(phen)_3^{3+}$ ion at $t=0$. An example of the linearity for a reaction run is shown in Fig. 1. For each mole fraction of alcohols x in water, rate measurements were generally performed about ten times, changing the initial concentrations in ranges of $[Fe^{2+}]_o$ $(0.6—5.0)\times10^{-3}$ M and $[Fe(phen)_3^{3+}]_o$ $(0.5—10.0)\times10^{-5}$ M, the values of k being averaged.

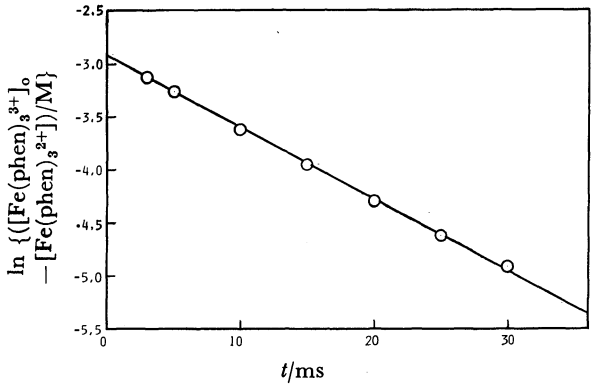

Fig. 1. Plots of $\ln([Fe(phen)_3^{3+}]_o-[Fe(phen)_3^{2+}])$ *vs.* t at $[Fe^{2+}]_o=8.47\times10^{-4}$ M, $[Fe(phen)_3^{3+}]_o=9.28\times10^{-6}$ M, $[HClO_4]=0.05$ M, $\mu=0.1$ M, and 25 °C, in a mixed solvent of water and methanol at $x_{MeOH}=0.225$.

Results and Discussion

Figure 2 shows the variation of k according to the increase in the mole fractions of alcohols. Within the lower mole fractions $x<0.1$, k grows up approximately linearly with the increase in x with steeper slopes in an order, methanol<ethylene glycol<ethanol<1-propanol; namely, it seems that the more the number of the carbon atoms in the monohydric alcohols and the less the number of OH groups in the alcohols with two carbon atoms, the more accelerated is k with the increase in x. In other words, the hydrophobicity of alkyl groups looks like to make the electron transfer reaction occur faster, while the hydrophilicity of OH group shows a trend to behave unfavorably to the reaction.

When the logarithms of k are plotted against the reciprocals of the dielectric constants of the mixed solvents[5] as are depicted in Fig. 3, they come altogether on an approximately single straight line with a positive slope indifferent to the kinds of the alcohols adopted.

$$\frac{d\ln k}{d D^{-1}} > 0 \quad (5)$$

This fact indicates that the reaction is largely controlled by the dielectric constants of the media, although the molecular and structural features of alcohols have been seen to partly affect the reaction rates to some

extent as mentioned above. Thus, the linearity in Fig. 3 can be interpreted by a hypothesis that an electrostatic interaction between the two reacting species plays an important role in the rate-determining step as shown below.

Now, let us consider the mechanism of Reaction 1 as taking place *via* three successive elementary processes.

$$Fe_{aq}^{2+} + Fe(phen)_3^{3+} \rightleftharpoons [Fe(H_2O)_6^{2+}.\ Fe(phen)_3^{3+}] \quad (i)$$

$$[Fe(H_2O)_6^{2+}.\ Fe(phen)_3^{3+}] \rightleftharpoons [Fe(H_2O)_6^{3+}.Fe(phen)_3^{2+}] \quad (ii)$$

$$[Fe(H_2O)_6^{3+}.\ Fe(phen)_3^{2+}] \longrightarrow Fe_{aq}^{3+} + Fe(phen)_3^{2+} \quad (iii)$$

Process i is a step in which an outer-sphere ion-pair formation occurs with a pre-equilibrium constant K_i, Process ii is an intramolecular electron transfer process

with an equilibrium constant K_{ii}, and Process iii is a separation process of the ion-pair into two leaving ions.

When the rate constants of the forward reactions of Processes i, ii, and iii are denoted by k_i, k_{ii}, and k_{iii} and those of the reverse reactions of Processes i and ii by k_i' and k_{ii}' respectively, the apparent second-order rate constant k is expressed by the following relation, derived by virtue of the steady-state method considering both $[Fe(H_2O)_6^{2+}\cdot Fe(phen)_3^{3+}]$ and $[Fe(H_2O)_6^{3+}\cdot Fe(phen)_3^{2+}]$ as reaction intermediates.

$$k = \frac{k_i k_{ii} k_{iii}}{k_i' k_{ii}' + k_i' k_{iii} + k_{ii} k_{iii}} \tag{6}$$

For the three limiting cases, the relation can be simplified as follows:

If $k_{ii}k_{iii} \gg (k_{ii}' + k_{iii})k_i'$

$$k = k_i, \tag{7}$$

if $k_i'k_{iii} \gg k_i'k_{ii}' + k_{ii}k_{iii}$,

$$k = K_i k_{ii}, \tag{8}$$

and if $k_i'k_{ii}' \gg (k_i' + k_{ii})k_{iii}$,

$$k = K_i K_{ii} k_{iii}. \tag{9}$$

Each of these three cases corresponds to that in which Process i, ii, or iii is rate-determining, respectively.

If the overall rate of Reaction 1 were actually controlled by Process i, the dielectric dependence of k_i would be shown by the Scatchard relation,[6,7]

$$\ln k_i = \ln k_i^\circ - \frac{z_A z_B e^2}{kTd_i D}, \tag{10}$$

where D is the dielectric constant of the mixed solvents, k the Boltzmann constant, d_i the internuclear distance between Fe(II) and Fe(III) in the outer-sphere ion-pair formed in Process i, k_i° the imaginary k_i at $D=\infty$, and Z_A and Z_B the numbers of electric charges on the respective reacting ions, *viz.* $Z_A=2$ and $Z_B=3$ in the present case. According to Eq. 10, the linearity of the plot of $\ln k$ *vs.* D^{-1} should have a negative slope, this expectation being against the observed fact shown in Fig. 3. Therefore, the assumption that Process i is the rate-determining step is not probable.

Next, if Process ii were rate-determining, $\ln k$ would vary dependently upon D as follows.

$$\frac{d\ln k}{d\,D^{-1}} = \frac{d\ln K_i}{d\,D^{-1}} + \frac{d\ln k_{ii}}{d\,D^{-1}} \tag{11}$$

Since Process ii is an intramolecular electron transfer, the rate would not be seriously affected by D, and consequently, $d\ln k_{ii}/d\,D^{-1}$ would be approximately equal to zero. But $d\ln K_i/d\,D^{-1}$ would have a negative value with a similar reason to the case in Eq. 10. Therefore, $d\ln k/d\,D^{-1}$ should be negative, this being also contrary to the experimental result.

Finally, the case that Process iii is rate-determining must be considered. By differentiating Eq. 9 with respect to D^{-1}, the following relation is given.

$$\frac{d\ln k}{d\,D^{-1}} = \frac{d\ln K_i}{d\,D^{-1}} + \frac{d\ln K_{ii}}{d\,D^{-1}} + \frac{d\ln k_{iii}}{d\,D^{-1}} \tag{12}$$

Since Processes i and iii are the process of ionic association and ionic separation respectively, the following three relations will be established.

$$\frac{d\ln K_i}{d\,D^{-1}} = -\frac{z_A z_B e^2}{kTd_i} < 0 \tag{13}$$

$$\frac{d\ln K_{ii}}{d\,D^{-1}} \fallingdotseq 0 \tag{14}$$

$$\frac{d\ln k_{iii}}{d\,D^{-1}} = \frac{z_C z_D e^2}{kTd_{iii}} > 0 \tag{15}$$

The symbols appearing in Eq. 15 are similar to those described above, with $Z_C=3$ and $Z_D=2$ in this case. Since $Z_AZ_B=Z_CZ_D=6$, Eq. 12 becomes

$$\frac{d\ln k}{d\,D^{-1}} = \frac{6e^2}{kT}\cdot\frac{d_i - d_{iii}}{d_i d_{iii}} > 0. \tag{16}$$

The bond lengths $d(Fe^{II}\text{–}O)$ and $d(Fe^{III}\text{–}O)$ in aquairon complexes to be taken are 2.21 Å and 2.05 Å respectively,[8] and $d(Fe^{II}\text{–}N)$ in $Fe(phen)_3^{2+}$ ion would be shorter than $d(Fe^{III}\text{–}N)$ in $Fe(phen)_3^{3+}$ ion due to the stronger bonding by back donation in the former complex. Accordingly, $d_i(Fe^{II}\text{–}O,\ Fe^{III}\text{–}N)$ will be larger than $d_{iii}(Fe^{III}\text{–}O,\ Fe^{II}\text{–}N)$, resulting in a positive value in Eq. 16, being consistent with the experimental fact in Fig. 3 and Eq. 5.† This indicates that the absolute value of the electrostatic repulsive energy required to form an ion-pair between ions with the same sign in Process i is smaller than that liberated to dissociate the ion-pair in Process iii. Therefore, it may be reasonably recognized that the rate-determining step of Reaction 1 must be Process iii. Evidence for an initial association, as an example, has been known also in reactions of plastocyanin with some inorganic complexes.[10]

As far as the mole fractions of alcohols are lower than 0.1, the obvious preferential solvation of alcohol molecules would not occur around iron(III) ion[11] and, therefore, the structure of the intermediate ion-pair may be commonly available throughout this range of mole fractions. Since the second-order rate constant for the water exchange in $Fe(H_2O)_6^{3+}$ ion is $k=2.8\times10^2$ $M^{-1}\,s^{-1}$ [12,13] and $Fe(phen)_3^{2+}$ ion is substitution-inert, the intermediate outer-sphere ion-pair is considered to be probable.

A contrasting instance to Reaction 1 has been found in the electron transfer reaction in mixed solvents of water and alcohols at various mole fractions,[14]

$$Fe_{aq}^{2+} + Fe(OH)^{2+} \longrightarrow Fe(OH)^{2+} + Fe_{aq}^{2+} \tag{17}$$

in which case the plot of logarithms of the rate constants shows a good linear relationship with D^{-1} with a negative slope, instead of having a positive slope as in the case of Reaction 1. This fact suggests that the first step must be rate-determining, where the two reacting ions encounter to each other in Reaction 17 with the rate constant $k=k_i$ as a typical instance as is shown in Eq. 7. On this viewpoint, the trend how the dielectric

† According to the numerical calculation from the slope of the straight line in Eq. 16, the values of d_i and d_{iii} can not be strictly decided, but only roughly estimated. Although sets of $d_i=14.0$ Å and $d_{iii}=6.2$ Å, $d_i=12.0$ Å and $d_{iii}=5.7$ Å, $d_i=10.0$ Å and $d_{iii}=5.2$ Å, etc. are numerically derived, any of them may not be probable, as compared with the dimension of the complexes.[9] This discrepancy may mostly be caused by the dielectric saturation phenomenon in the direct vicinity aroud ions.

constants of the reaction media exhibit an influence on the reaction rate looks like to offer a nice tool as a method for distinguishing the rate-determining step among some successive elementary processes in the electron transfer reactions.

The activation enthalpy and the activation entropy of Reaction 1 in a mixed solvent $x_{MeOH}=0.16$ were found to be $\Delta H^*=-0.4\pm0.8$ kJ mol^{-1} and $\Delta S^*=-160$ J K^{-1} mol^{-1} by measuring the reaction rates at 14, 25, 33, and 40 °C. These values are in good accordance with those $\Delta H^*=3.2\pm0.8$ kJ mol^{-1} and $\Delta S^*=-155$ J K^{-1} mol^{-1} measured in pure water by Sutin and Gordon.[2] Cramer and Meyer[15] pointed out that the very small or even slightly negative values of ΔH^* in the oxidation reactions of Fe^{2+}_{aq} by polypyridine complexes of iron(III) and ruthenium(III) suggest the possibility of occurrence of multiple paths in the electron transfer reactions. This idea may also prevail for the reactions in the mixed solvents of alcohols, and may support the reaction mechanism proposed above. They also indicate[15] that the reaction is "non-Marcus" because calculated values for the Fe(II)–Fe(III) polypyridine self-exchange rates are too low approximately by 10^5 [16,17] as expected from the observed rate constant k_{11} for Fe^{2+}_{aq}–Fe^{3+}_{aq} reaction[1,14] and the one k_{12} for the reaction under consideration, according to the Marcus relations which are shown in the followings, the symbols being the same as usual.[18]

$$k_{12} = (k_{11}k_{22}K_{12}f)^{1/2} \tag{18}$$

$$\ln f = \frac{(\ln K_{12})^2}{4\ln(k_{11}k_{22}/z^2)} \tag{19}$$

The reason for the dissatisfaction to the Marcus theory is not only due to the existence of the multiple paths throughout the electron transfer reaction as Cramer and Meyer noticed, but also because of the fact that the reaction Fe^{2+}_{aq}–Fe^{3+}_{aq} does not go through an outer-sphere mechanism in a strictly narrow sense of the word, but through a hydrogen-atom-transfer mechanism.[14] Therefore, k_{11} should not actually satisfy the value expected from the Marcus theory, as a matter of course.

Reactions of Manganese(III) Schiff Base Complexes with Superoxide Ion in Dimethyl Sulfoxide

Takayuki MATSUSHITA* and Toshiyuki SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received February 17, 1981)

The reactions of the chloromanganese(III) complexes of the Schiff bases derived from salicylaldehydes or β-diketones and diamines or monoamines with superoxide ion, O_2^-, in dimethyl sulfoxide were investigated. The complexes were found to react to give either the oxygenated Mn Schiff base complexes or the reduced Mn(II) Schiff base complexes. The difference in the reactivity toward O_2^- was correlated to the polarographic half-wave potentials corresponding to the reduction of Mn(III) to Mn(II) of the complexes. Some oxygenated complexes were isolated and characterized.

Manganese complexes have been of interest in connection with the biological redox processes including catalytic disproportionation of superoxide ion, O_2^-. Examples are the manganese-containing superoxide dismutases (Mn–SOD) and the oxygen evolving photosystem II in green plants.[1] In the Mn–SOD process, a manganese ion may exist in the oxidation state of +III.[2,3] Recently, McAdam *et al.* have reported that the reaction of the Mn–SOD with O_2^- depends on a ratio of O_2^- concentration to the enzyme and that at high ratios (>15) it can not be explained by the simple two-step mechanism proposed for the Cu–SOD. Thus, they have postulated a kinetic model including a form of the enzyme, E_C, as follows:

$$E_A + O_2^- \longrightarrow E_B + O_2$$

$$E_B + O_2^- \xrightarrow{2H^+} E_A + H_2O_2$$

$$E_B + O_2^- \longrightarrow E_C$$

$$E_C \longrightarrow E_A,$$

where E_A represents a native oxidized enzyme, E_B a reduced enzyme, and E_C an enzyme unreactive toward O_2^-.[4]

Howie *et al.* have reported that the reaction of the manganese(II) and -(III) 8-quinolinol complexes with O_2^- in dimethyl sulfoxide (DMSO) can be considered as a redox model for the Mn–SOD.[5] Valentine *et al.* have found that Mn^{III}(tpp)Cl reacts with O_2^- in DMSO to give Mn^{II}(tpp); here tpp denotes tetraphenylporphyrin dianion.[6] Recently, Stein *et al.* have reported that Mn^{III}(cydta)$^-$ and Mn^{III}(edta)$^-$ react with O_2^- in DMSO to give Mn^{II}(cydta)$^{2-}$ and Mn^{II}(edta)$^{2-}$, respectively, where H_4cydta and H_4edta denote 1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetic acid and ethylenediaminetetraacetic acid, respectively.[7]

In this paper we report on the reactions of a series of the chloromanganese(III) Schiff base complexes (Fig. 1) with O_2^- in DMSO.

Experimental

Preparation of Chloromanganese(III) Schiff Base Complexes. All the chloromanganese(III) Schiff base complexes were prepared by the following method, adapted from the literature.[8,9]

Chloro[N,N'-*bis*(*2-benzoyl-1-methylethylidene*)*ethylenediaminato*]-*manganese(III)*, *Mn(bzacen)Cl.* To a dichloromethane (50 cm³)-methanol (50 cm³) solution of *N,N'*-bis(2-benzoyl-1-methylethylidene)ethylenediamine (3.47 g), manganese(III) acetate dihydrate, $Mn(CH_3COO)_3 \cdot 2H_2O$ (2.68 g), was added. The mixture was allowed to stand at 40 °C for 30 min, and then lithium chloride (0.6 g) was added. After having been

a) Measured at room temperature.

stirred for 1 h, the solution was concentrated to *ca.* 20 cm^3 under reduced pressure. Ether (200 cm^3) was then added to precipitate brown solids. They were collected on a glass filter, washed with small volumes of water, 2-propanol, and then ether, and then dried *in vacuo*. They were recrystallized from dichloromethane. The yield was *ca.* 60%. The analytical data and the magnetic moments of some manganese(III) complexes are given in Table 1.

Isolation of Oxygenated Complexes. *[Mn(salen)]$_2O_2$, Complex 1 and [Mn(salen)O]$_n$, Complex 2.* To a DMSO solution of Mn(salen)Cl·H_2O (0.7 g) and 18-crown-6 ether (0.5 g), potassium superoxide, KO_2 (0.15 g) was added in a nitrogen atmosphere at room temperature. After having been stirred for 2 h, the solution was evaporated to remove DMSO under reduced pressure. The reddish brown solids which separated were collected on a glass filter, washed with water, methanol, and then ether, and then dried *in vacuo*. The solids were extracted with dichloromethane (500 cm^3). The dichloromethane solution was evaporated under reduced pressure to give reddish brown needles, complex **1**, which was identified to be [Mn(salen)]$_2O_2$ by the infrared spectrum and the magnetic susceptibilities. On the other hand, the insoluble product in dichloromethane was identified to be [Mn(salen)O]$_n$, complex **2**. The yields of complexes **1** and **2** were 0.21 and 0.43 g, respectively. When the reaction of Mn(salen)Cl·H_2O with KO_2 in DMSO was carried out in the absence of 18-crown-6 ether, the yields of complexes **1** and **2** were 0.03 and 0.50 g, respectively.

The oxygenated manganese complexes, Mn(salchxn)O·H_2O and Mn(5,6-benzosalen)O·H_2O were obtained by the reactions of the corresponding chloromaganese(III) complexes with KO_2 in DMSO and benzene, respectively. These complexes were reddish brown powders and were insoluble in common organic solvents. Therefore, further purification could not be performed. Mn(salchxn)O·H_2O: Found: C, 58.70; H, 4.98; N, 6.98; Mn, 13.23%. Calcd for Mn($C_{20}H_{22}N_2O_4$): C, 58.69; H, 5.42; N, 6.84; Mn, 13.42%. IR: 650 and 618 cm^{-1} (νMn–O). Magnetic moment at room temperature: 1.89 BM. Mn(5,6-Benzosalen)O·H_2O: Found: C, 63.93; H, 3.99; N, 6.23; Mn, 12.25%. Calcd for Mn($C_{24}H_{20}N_2O_4$): C, 63.31; H, 4.43; N, 6.15; Mn, 12.06%. IR: 653 and 603 cm^{-1} (νMn–O). Magnetic moment at room temperature: 2.90 BM.

[Mn(bzacen)O]·$(CH_2Cl_2)_{0.3}$: To a benzene solution (200 cm^3) containing Mn(bzacen)Cl (0.7 g) and 18-crown-6 ether (0.5 g), KO_2 (0.15 g) was added in a nitrogen atmosphere. The solution turned the color from brown to reddish brown gradually on stirring for 2 h. The mixture was filtered and the filtrate was evaporated under reduced pressure. The precipitated solids were collected on a filter, washed with small volumes of water and methanol and then thoroughly with ether, and then dried *in vacuo*. On recrystallization from dichloromethane, reddish brown needles were obtained. The yield was *ca.* 0.2 g. The complex is soluble in dichloromethane and slightly soluble in DMSO. Found: C, 60.07; H, 5.16; N, 6.10; Mn, 12.39%. Calcd for Mn($C_{22}H_{22}N_2O_3$)·(CH_2Cl_2)$_{0.3}$: C, 60.48; H, 5.14; N, 6.33; Mn, 12.40%. IR: 650 cm^{-1} (νMn–O). Magnetic moment at room temperature: 2.55 BM.

The oxygenated complex, Mn(bzacpln)O·$(CH_2Cl_2)_{0.4}$ was obtained in a similar manner. Found: C, 60.45; H, 5.25; N, 6.02; Mn, 11.84%. Calcd for Mn($C_{23}H_{24}N_2O_3$)(CH_2Cl_2)$_{0.4}$: C, 60.40; H, 5.37; N, 6.02; Mn, 11.81%. IR: 644 cm^{-1} (νMn–O). Magnetic moment at room temperature: 1.87 BM.

Reagents. All reagents were of reagent grade. Potassium superoxide, KO_2, was purchased from Alfa products Inc. (Above 96.5%). Dimethyl sulfoxide was distilled twice under reduced pressure prior to use. Benzene was distilled over sodium. Acetonitrile was refluxed over diphosphorus pentaoxide and distilled twice prior to use. Dichloromethane was distilled over calcium chloride.

Preparation of DMSO Solution of KO_2. A DMSO solution of KO_2 (*ca.* 10^{-2} M, 1 M = 1 mol dm^{-3}) was prepared by dissolving KO_2 (18.7 mg) into DMSO (25 cm^3) in the presence of 18-crown-6 ether (0.1 g). The O_2^- concentration of the solution was determined by spectrophotometry.[10]

Measurements. The UV, V, and NIR spectra were recorded on Hitachi EPS-3 and Hitachi 340 recording spectrophotometers. The IR spectra in the 4000—650 and 700—250 cm^{-1} regions were recorded on a Hitachi 215 and on a Hitachi EPI-L grating spectrophotometer, respectively. Polarograms were obtained by using a Yanagimoto p-8 polarograph. A dropping mercury electrode and a mercury pool were used as the working and the reference electrode, respectively; this avoided any effect of water on the reaction systems that would occur if a saturated calomel electrode was used. Tetrabutylammonium perchlorate, $(Bu)_4NClO_4$, was used as the supporting electrolyte and Triton-X 100 as the maximum suppressor. Magnetic susceptibilities were measured by a Gouy method at room temperature. The reactions of the manganese(III) complexes with O_2^- were carried out under nitrogen atmosphere.

Results and Discussion

It is supposed that in the native Mn–SOD the nitrogen and/or oxygen atoms of the amino acid residues of the proteins are coordinated with manganese ions, although the details of coordination structure have not yet been clarified. Recently, the manganese ion in the native Mn–SOD has been found to be in the oxidation state +III.[2,3] The reactions of the manganese(III) Schiff base complexes with O_2^- investigated here afford information in connection with the catalytic disproportionation of O_2^- by the Mn–SOD.

Visible Absorption Spectra. Figure 2 shows the

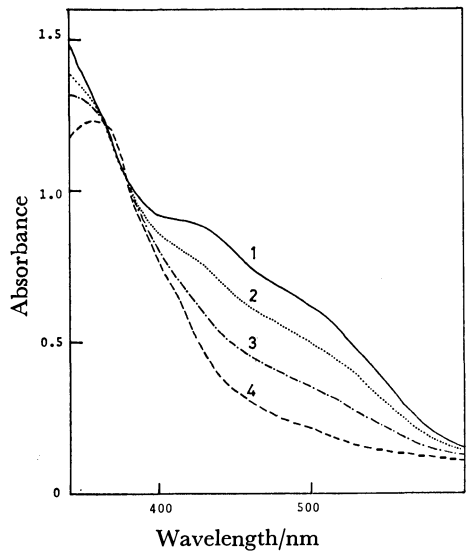

Fig. 3. Spectral changes of a DMSO solution of [Mn(salen)]$_2O_2$, 8×10^{-5} M, caused by the addition of KO_2.
1): No addition, 2): $[KO_2]/[complex]=3$, 3): 6, 4): 10. Cell length: 1 cm.

spectral changes of Mn(salen)Cl·H_2O in the DMSO solution caused by the addition of KO_2 in different molar ratios. The spectra changed remarkably, showing an isosbestic point at 390 nm. And a broad absorption band which appeared for the first time around 480 nm increased in intensity on the addition of KO_2 up to $[KO_2]/[complex]=4$; further amounts of KO_2 caused an decrease in the intensity and the appearance of an absorption band at 364 nm. These spectral changes can be interpreted as follows. The absorption band around 480 nm may be due to the formation of the oxygenated complex. This is supported by the fact that the oxygenated complex, [Mn(salen)]$_2O_2$, obtained by the reaction of Mn^{II}(salen) with molecular oxygen in DMSO is characterized by an intense absorption band in the same region.[11] The spectral changes observed on the further addition of KO_2 are considered to be due to a reaction of the oxygenated complex formed in solution with an excess amount of O_2^- to yield the manganese(II) complex, Mn^{II}(salen). This is confirmed by the facts that the absorption spectrum shown by curve 4 is in agreement with that of Mn^{II}(salen) in DMSO, and that by introducing molecular oxygen (O_2) into this solution it comes to show an absorption curve similar to that of the oxygenated complex, [Mn(salen)]$_2O_2$; this complex again reacts with O_2^-, showing similar spectral changes, as seen in Fig. 3.

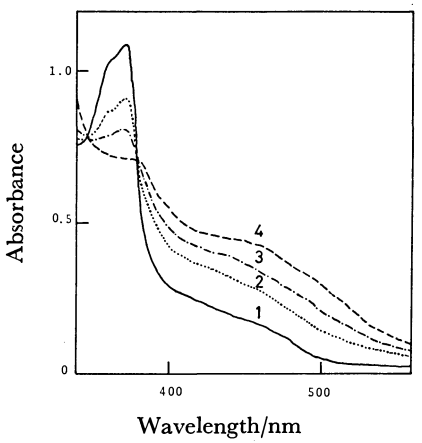

Fig. 4. Spectral changes of a DMSO solution of Mn(acacpln)Cl·$(H_2O)_{0.3}$, 2×10^{-4} M, caused by the addition of KO_2.
1): No addition, 2): $[KO_2]/[complex]=1.5$, 3): 2, 4): 2.5. Cell length: 1 cm.

Figure 4 shows the spectral changes for the complex Mn(acacpln)Cl by the addition of KO_2. These are similar to those observed for the complex Mn(salen)Cl·H_2O. This indicates that the oxygenation of Mn(acacpln)Cl occurs because of the reaction with O_2^-.

Figure 5 shows the spectral changes for the complex Mn(5-NO_2salen)Cl. Unlike the above two complexes, the intensity of the weak absorption band around 500 nm decreases with increasing intensity of a new absorption band at 402 nm. The final absorption curve shown by curve 4 in Fig. 5 is coincident with that of Mn^{II}(5-NO_2salen) in DMSO. This indicates that Mn(5-NO_2salen)Cl is reduced with O_2^- to form the manganese(II) complex. The spectral changes for the complex Mn^{III}(3-MeOsalen)Cl·H_2O are shown in Fig. 6. We previously reported that Mn^{II}(3-MeOsalen)·H_2O was readily oxidized by O_2 in common organic solvents to give the oxidized complex.[11] It is clearly evidenced in Fig. 6 that Mn^{III}(3-MeOsalen)Cl·H_2O is reduced with O_2^- to the manganese(II) complex. Bubbling O_2 into the solution including $[KO_2]/[complex]=3$ and showing absorption curve 4 results in the change of the absorption

to curve 5, which is quite like that observed in the reaction of Mn^{II}(3-MeOsalen)·H_2O with O_2 in DMSO.

Polarograms. The polarograms of the manganese(III) complexes show one cathodic wave around −0.2 V and one- or two-step cathodic waves in the −1.5——2.0 V range. The polarogram of Mn(5-NO_2salen)Cl in DMSO is shown by curve 1 in Fig. 7. The first cathodic wave can be assigned to the reduction of Mn(III) to Mn(II) and the second and third waves may involve the reductions of the coordinated Schiff base ligand.[12,13] An addition of KO_2 to the solution of the complex ($[KO_2]/[complex]=2$) caused a decrease in the height of the first cathodic wave and the appearance of a new cathodic wave at a half-wave potential of −0.6 V. With increasing amounts of KO_2, the wave height of the former decreased and that of the latter increased. The above new cathodic wave can be easily assigned to the

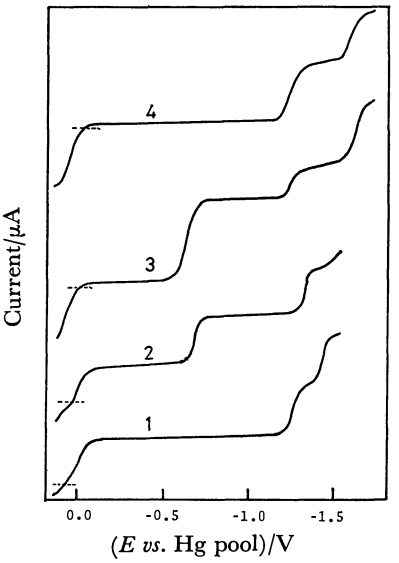

Fig. 7. Changes in polarograms during the reaction of Mn(5-NO_2salen)Cl, 2×10^{-4} M, with KO_2 in DMSO.
1): No addition of KO_2, 2): $[KO_2]/[complex]=2$, 3): 4, 4): after passing N_2 through the solution shown by curve 3.

reduction of free O_2 in the solution, because the half-wave potential is nearly equal to that observed for dissolved O_2 and the wave would disappear readily if nitrogen gas was passed through the solution. The solution obtained after passing nitrogen gas has a polarogram which resembles that of Mn^{II}(5-NO_2salen). These results indicate that Mn(5-NO_2salen)Cl is reduced with O_2^- to yield the manganese(II) complex and O_2, $Mn^{III}L^+ + O_2^- \rightarrow Mn^{II}L + O_2$, where L denotes 5-$NO_2$-salen. This is consistent with the results observed in the absorption spectral changes.

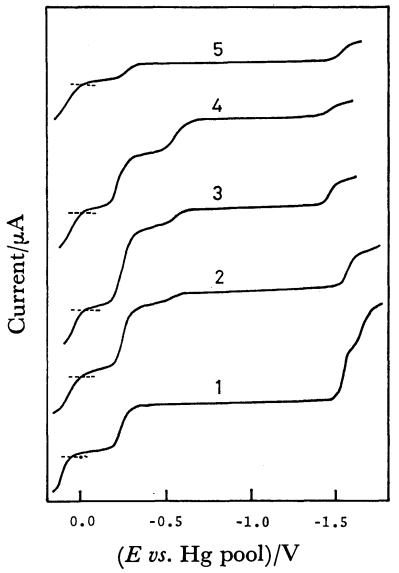

Fig. 8. Changes in polarograms during the reaction of Mn(bzacen)Cl, 2×10^{-4} M, with KO_2 in DMSO.
1): No addition of KO_2, 2): $[KO_2]/[complex]=1$, 3): 2, 4): 4, 5): after passing N_2 through the solution shown by curve 4.

The polarogram of Mn(bzacen)Cl shown in Fig. 8 exhibits three cathodic waves at the half-wave potentials of −0.3, −1.6, and −1.8 V. The first cathodic wave is due to the reduction of Mn(III) to Mn(II). By the addition of KO_2, the cathodic wave due to free O_2 barely appeared in the solution composed with $[KO_2]/[complex]=2$, though the wave height around −0.3 V was observed to increase. Further addition of KO_2 ($[KO_2]/[complex]=4$) caused a decrease in this wave height and an increase in the wave height due to free O_2. The polarogram obtained after passing nitrogen gas through the solution (shown by curve 4 in Fig. 8) exhibits only a small wave height at −0.3 V; this may be due to the residue of the manganese(III) complex. From these polarographic observation, the reaction of Mn(bzacen)Cl with O_2^- can be explained as follows. The increase in the wave height at −0.3 V observed at the molar ratio change from 1 to 2 may be caused by the formation of the oxygenated complex, hence the cathodic wave due to O_2 is slightly observed. At the molar ratio of 4 the oxygenated complex reacts with O_2^- to give the manganese(II) complex and O_2.

Reactivity toward O_2^-. In view of the reactivity toward O_2^- observed in the spectral and polarographic behavior, the chloromanganese(III) Schiff base complexes investigated here can be classified into two types: one involving the complexes which form the oxygenated complex in the solution containing KO_2 in the molar ratio of $[KO_2]/[complex]<2$—3, and the other involving the complexes which are only reduced to the corresponding manganese(II) complexes with the evolution of molecular oxygen. These results are summarized in Table 2, along with the half-wave potentials for the reduction of Mn(III) to Mn(II). The reactivity toward O_2^- is clearly correlated with the reduction potentials of the complexes. That is, the complexes having more negative potentials than that of Mn(salen)Cl·H_2O form the oxygenated complexes, whereas the complexes having more positive potentials than that of Mn(salpln)-Cl are reduced to the manganese(II) complexes.

Table 2. Reduction potentials of manganese(III) complexes and reactivity toward O_2^-

a) Measured in acetonitrile containing 0.1 mol dm^{-3} $(Bu)_4NClO_4$ at 25 °C.

Isolation and Characterization of the Oxygenated Complexes. Several oxygenated manganese complexes were isolated by the reactions of chloromanganese(III) Schiff base complexes with KO_2 in DMSO or benzene. In the case of Mn(salen)Cl·H_2O, two types of the oxygenated complexes, $[Mn(salen)]_2O_2$ and $[Mn(salen)O]_n$, were isolated. The former complex shows an intense broad absorption band around 480 nm. In the IR spectrum the former complex shows a strong band assignable to the Mn–O stretching vibration at 645 cm^{-1}, while the latter, which is insoluble in common organic solvents, shows two strong bands due to the Mn–O stretching vibrations at 665 and 605 cm^{-1}. The effective magnetic moments of $[Mn(salen)]_2O_2$ and $[Mn(salen)O]_n$ were 2.16 and 2.04 BM, respectively. These values are lower than the spin-only one which is expected for a complex with the d^4 or d^3 high-spin configuration; they may be caused by the antiferromagnetic interactions observed for the complexes where the manganese atoms are probably linked by the oxygen atoms: Mn^{III}–O_2–Mn^{III} and $-[Mn^{IV}-O]-_n$.[11]

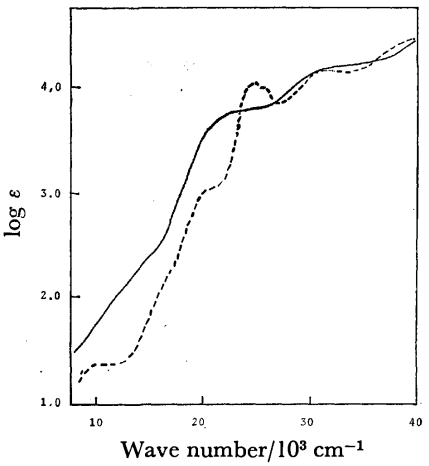

Fig. 9. Electronic spectra.
——: Mn(bzacen)O·$(CH_2Cl_2)_{0.3}$ in dichloromethane,
------: Mn(bzacen)Cl in DMSO.

The other oxygenated manganese complexes obtained in this work also show lower magnetic moments. The IR spectra of the oxygenated complexes, Mn(salchxn)O and Mn(5,6-Benzosalen)O, which are insoluble in common organic solvents, show two strong bands in the 700—600 cm^{-1} region. Therefore, these complexes may have a structure similar to that of $[Mn(salen)O]_n$. On the other hand, the IR spectra of the oxygenated complexes, Mn(bzacen)O and Mn(bzacpln)O, which are soluble in dichloromethane show one strong band in the 700—600 cm^{-1} region. Moreover, the electronic spectrum of Mn(bzacen)O in dichloromethane shows an intense absorption band around 500 nm, as shown in Fig. 9. These results suggest that the oxygenated complexes may have a structure similar to that of

$[Mn(salen)]_2O_2$. Since the manganese(II) complexes with the Schiff bases derived from β-diketones and diamines have not been isolated due to the instabilities, there has been no attempt to prepare their oxygenated complexes by reacting them with O_2.

Among the oxygenated manganese-Schiff base complexes, the compounds with such unitary groups as oxo (Mn=O), μ-oxo (Mn–O–Mn), catena-μ-oxo ($\{Mn–O\}_n$), μ-peroxo (Mn–O–O–Mn), and di-μ-oxo (Mn$\begin{smallmatrix}\diagup O \diagdown \\ \diagdown O \diagup\end{smallmatrix}$Mn) have so far been reported.[1b] However, these structures have been determined only by the elemental analyses and the conventional physicochemical measurements, with the exception of the oxygenated product of Mn^{II}-(salpn)·H_2O. This has been revealed by X-ray structural analysis to be a di-μ-hydroxo structure (Mn$\begin{smallmatrix}\diagup OH \diagdown \\ \diagdown OH \diagup\end{smallmatrix}$Mn), where salpn$H_2$ denotes *N*,*N*′-disalicylidene-1,3-propanediamine.[14]

The reactivity of KO_2 with the present manganese(III) complexes will open a new route for synthesis and will provide a method of characterization for the oxygenated complexes.

Equilibrium and Structure of Deprotonated Bis(glycylglycinato)-copper(II) in Aqueous Solution

Noriyuki NAKASUKA,* Kenya MAKIMURA, and Hiroko KAJIURA†

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 27, 1981)

Potentiometric titration was carried out at 25.0±0.1 °C and at an ionic strength of 1.00 mol dm^{-3} in sodium perchlorate for a system of copper(II)–dipeptide(A)–a second ligand(B) in an aqueous solution to obtain the formation constants of mixed ligand complexes $Cu_pH_qA_rB_s$. A was glycylglycine or glycinamide, and B was ethylamine or 2-aminoethanol. The structure of $CuH_{-1}A_2$ in solution is discussed. It was found that the ligand A acts as a unidentate ligand and the other deprotonated $H_{-1}A$ as a terdentate one for the most part; only about 2% of this complex are in a bidentate-bidentate form.

Glycylglycine, one of the simplest peptides, gives rise to several metal complexes in an aqueous solution, and serves as a model compound for the complexation reactions of polypeptides and even of proteins. Thermodynamic equilibria of copper(II)–glycylglycine complexes have been studied rather extensively,[1-4] and the existence of species such as CuA, CuHA, $CuH_{-1}A$, $CuH_{-2}A$, and $CuH_{-1}A_2$ has been reported (HA represents a glycylglycine molecule). Strandberg *et al.* have elucidated by crystallographic studies the structure of the diaquaglycylglycinatocopper(II) hydrate ($CuH_{-1}A$), in which the peptide NH proton is released; they found that the ligand acts as a terdentate one.[5] For $CuH_{-1}A_2$, however, two possible structures are expected, so it is of interest to discuss the equilibrium data.

Experimental

Reagents. Glycylglycine and glycinamide hydrochloride were used as received (Tokyo Kasei Kogyo Co., G. R.).

Ethylamine hydrochloride and 2-aminoethanol were obtained from Wako Pure Chemical Ind. Ltd. The former was recrystallized from water and dried *in vacuo* at 60 °C, while the latter was vacuum distilled over sodium hydroxide.

Copper(II) perchlorate: Copper(II) carbonate was prepared by mixing copper(II) chloride (Wako Pure Chemical Ind. Ltd., G. R.) with a solution of sodium carbonate. Perchloric acid was added in small excess to the washed copper carbonate and copper perchlorate was then crystallized from the solution.

Sodium perchlorate: Commercial sodium perchlorate (Merck, *pro analysi*) was recrystallized from water. A concentrated solution was analyzed gravimetrically after heating the solution gently in a platinum crucible on a hot plate to dryness. This simple method gives very reproducible and accurate results.

Potentiometry. Measurement of potential was made with a digital pH/mV meter(Orion, model 801) using a glass electrode (Metrohm EA 109) and a reference calomel electrode (Metrohm EA 404), which contained an internal solution of sodium chloride. Each measurement was accurate to 0.2 mV. Titrations were carried out in double-walled glass cell thermostated at 25±0.1 °C under nitrogen presaturated with water vapor. A Metrohm piston burette was used for addition of 1.140 M†† sodium hydroxide solution. The ionic strength of each solution was adjusted to 1.00 M in sodium perchlorate.

Results

Determination of Stability Constants. Complex formation of copper(II) ion (M) with a complexing agent (A) and a second ligand (B) is represented in general by the following expression:

$$pM + qH + rA + sB \rightleftharpoons M_pH_qA_rB_s, \quad (1)$$

where charges are omitted for simplicity. The formation constant β_{pqrs} is defined as follows:

$$\beta_{pqrs} = [M_pH_qA_rB_s]/m^ph^qa^rb^s, \quad (2)$$

where m, h, a, and b refer to the concentrations of the free metal ion, proton, and free A and B ligands, respectively. When B is absent from the system, only β_{par} is defined.

Lefebvre's method (Méthode de la surface potentiométrique)[6] provided compositions of species present as well as approximate values of the corresponding formation constants. These values were further refined by using a least-squares technique with the data $\bar{q}$ (average number of protons bound per mole of constituent A and B)[4] on an electronic computer FACOM 230-75 at the Computation Center of Nagoya University. A Fortran program QPOL (R.-P. Martin, Universite Claude Bernard, Lyon I) was used for this calculation after certain modifications by the present authors. Experimental conditions and the results of calculation are summarized in Tables 1 and 2.

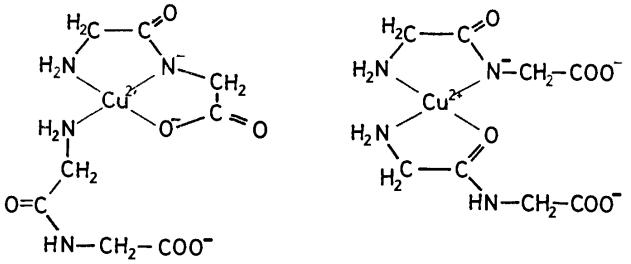
Table 2 shows a remarkable similarity between the protonation constants as well as between the complex formations of CuA for glycylglycine and glycinamide. These similarities indicate that the terminal nitrogen atoms in these ligands have the same basicity.

The values in this work for glycinamide are somewhat larger than those obtained by Dorigatti and Billo;[7] this may be accounted for in terms of different ionic media (0.10 M in $NaClO_4$). The results obtained for glycylglycine are essentially the same as those obtained by Martin *et al.*[4]

Discussion

There are two possible structures for the complex $CuH_{-1}A_2$, as shown in Fig. 1. In the first case, one peptide coordinates to the central ion as a terdentate ligand, while the other works as a unidentate: this is termed type (3,1). This type of crystal structure has already been found for a copper(II)–glycylglycine–imidazole complex.[8]

In the second complex, each ligand coordinates as a bidentate one, although the donor atoms are different.



type(3,1) type(2,2)

Fig. 1. Possible structures for bis(glycylglycinato) copper (II) $CuH_{-1}A_2$.

Therefore this is referred to as type (2,2). The principal point of interest is which predominates in an aqueous solution.

For the first type of complex, a unidentate glycylglycine A may be designated as N, because the donor atom must be the amino nitrogen. Then formation of a complex of type (3,1), $Cu_{-1}AN$, is formulated as follows:

$$CuH_{-1}A + N \overset{K^{N}_{CuH_{-1}AN}}{\rightleftharpoons} CuH_{-1}AN. \quad (3)$$

The formation constant of mixed ligand complexes has been discussed by many authors. Here the formulation of Tanaka[9] is applied, since the interactions between donor atoms are very important in this case.

$$\log K^{N}_{CuH_{-1}AN} = \log K^{N}_{CuN} + \Delta \log K_{os} + \Sigma\delta_{ij}x_i(H_{-1}A)x_j(N), \quad (4)$$

$$\Delta \log K_{os} = \log K_{os}(CuH_{-1}A, N) - \log K_{os}(Cu, N), \quad (5)$$

where K^{N}_{CuN} is the formation constant of CuN, δ_{ij} the effect of the donor atom i in the ligand $H_{-1}A$ on the donor atom j in the ligand N (mainly a repulsion term, $\delta_{NO}=-0.26$ and $\delta_{NN}=-0.35$, and x_i or x_j is the number of the donor atoms i or j in each ligand. K_{os} denotes the formation constant of an outer sphere complex, but with amino acids and their related ligands log K_{os} may be assumed to be negligible.[9]

The data for K^{N}_{CuN} is not available and therefore the formation constant of copper(II)–ammine complex is substituted for it.[10]

$$\log K^{N}_{CuH_{-1}AN} = 4.197 + 0 - 0.97 = 3.24, \quad (6)$$

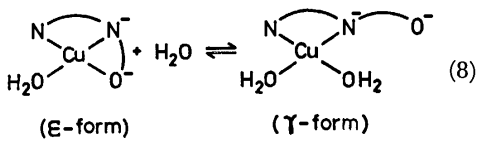
$$\beta_{1\bar{1}2}(3, 1) = \frac{[CuH_{-1}A_2]}{[CuH_{-1}A][N]} \frac{[CuH_{-1}A]\,h}{m\,a} = K^{N}_{CuH_{-1}AN} \cdot \beta_{1\bar{1}1}, \quad (7)$$

$$\log \beta_{1\bar{1}2}(3,^{6}1) = 3.24 + 1.31 = 4.55. \quad (7')$$

The observed value 4.50 for log $\beta_{1\bar{1}2}$ is in good accord with the above value calculated. 2-Aminoethanol and ethylamine act only as a unidentate ligand; the formation constants of their mixed ligand complexes (log $\beta_{1\bar{1}11}$) correspond unambiguously to that of type (3,1). The experimental values of 4.71 (2-aminoethanol) and 4.9 (ethylamine) compare with the theoretical ones. Koltun *et al.* have reported the formation constant of the imidazole complex, from which log $\beta_{1\bar{1}11}$ is calculated to be 4.91 (ionic strength=0.075 M, 25 °C).[2] The terdentate nature in this complex is well established

in a solid state.[8] These findings suggest predominance of the complex of type (3,1) in solution. A similar calculation for type (2,2) is also interesting.

The structure of $CuH_{-1}A$ has been determined by the X-ray method.[5] The majority of the deprotonated ligands may play the role of terdentate ligands also in solution (ε form).



(8)

Nevertheless, there may exist a complex in which the peptide acts as bidentate ligand, though in a very small amount; this type of complex is named γ form. In fact Nakahara *et al.* have prepared dipotassium bis-(glycylglycinato)cuprate(II),[11] whose structure has been determined.[12] The primary coordination around the central ion is approximately square, and two ligands bond to the copper ion through the amino and peptide nitrogen atoms alone, that is, in a γ form.

The thermodynamic constant for the equilibrium between γ and ε is not available, so we consider the complexation reactions of ethylenediamine monoacetic acid (EDMA, potentially terdentate) with copper(II).[13] The equilibrium between γ and ε forms in the EDMA complex is written as follows:

$$R = \frac{[\varepsilon]}{[\gamma]} = \frac{[\mathrm{Cu(edma)}]}{[\mathrm{Cu(edma)'}]} = \frac{[\mathrm{Cu(edma)}]}{m[\mathrm{edma}]} \frac{m[\mathrm{edma}]}{[\mathrm{Cu(edma)'}]}. \quad (9)$$

Cu(edma)' represents a complex in which EDMA is attached to copper(II) ion as a bidentate ligand, with the ethylenediamine nitrogen atoms being donor ones. Thus the formation constant of this complex may be approximated by the Cu–ethylenediamine complex ($\beta_{\mathrm{Cu(en)}}$).[14]

$$R = \beta_{\mathrm{Cu(edma)}}/\beta_{\mathrm{Cu(en)}} = 10^{2.82} \quad (10)$$

This ratio R may be substituted for the equilibrium constant for Reaction 8 of the dipeptide complexes. The validity of this assumption is also confirmed by the following argument on the deprotonation of copper chelates:

$$\mathrm{CuA} \rightleftharpoons \mathrm{CuH_{-1}A'} + \mathrm{H}, \quad (11)$$

where $CuH_{-1}A'$ denotes the deprotonated copper complex of glycylglycine in γ form.

$$K_1 = \frac{[\mathrm{CuH_{-1}A'}]\,h}{[\mathrm{CuA}]} = \frac{[\varepsilon]\,h}{[\mathrm{CuA}]} \frac{[\gamma]}{[\varepsilon]} = \beta_{111}/(\beta_{101}R) = 10^{-7.05}. \quad (12)$$

For glycinamide, corresponding data are not available, but this equilibrium constant K_1, may be approximated by that of the deprotonation of CuA_2 giving rise to $CuH_{-1}A_2$, neglecting some effects resulting from the other ligand A.

$$K_2 = \frac{[\mathrm{CuH_{-1}A_2}]h}{[\mathrm{CuA_2}]} = \beta_{1\bar{1}2}/\beta_{102} = 10^{2.72}\,10^{-10.00} = 10^{-7.28} \fallingdotseq K_1. \quad (13)$$

The equality of K_1 to K_2 justifies experimentally the validity of the R value, because this ratio is used in calculating K_1, while K_2 is derived from the experimental data. Thus the formation constant of the glycylglycine complex of type (2,2) is rewritten as:

$$\beta_{1\bar{1}2}(2,2) = \frac{[\mathrm{CuH_{-1}A_2}]h}{m\,a} = \frac{[\mathrm{CuH_{-1}A'}]}{[\mathrm{CuH_{-1}A}]} \frac{[\mathrm{CuH_{-1}A}]h}{m\,a} \frac{[\mathrm{CuH_{-1}A_2}]}{[\mathrm{CuH_{-1}A'}]\,a} = R^{-1}\beta_{1\bar{1}1}K^{\mathrm{A}}_{\mathrm{CuH_{-1}A'A}}. \quad (14)$$

Application of the formulation from Tanaka[9] gives:

$$\log K^{\mathrm{A}}_{\mathrm{CuH_{-1}A'A}} = \log K^{\mathrm{A}}_{\mathrm{CuA}} + \log K_{\mathrm{os}} + \Sigma\delta_{ij}x_i(\mathrm{H_{-1}A})x_j(\mathrm{A}) = 5.54 + 0 - 1.22 = 4.32. \quad (15)$$

Then we have

$$\log \beta_{1\bar{1}2}(2,2) = -2.82 + 1.31 + 4.32 = 2.81. \quad (16)$$

This calculated value is about two orders of magnitude less than the observed one, while it is in good agreement with the experimental one for glycinamide ($\log \beta_{1\bar{1}2} = 2.72$). Since this amide complex can take only the geometry of type (2,2), as evident from Fig. 2, the agreement is a fair indication of the validity of such an approach.

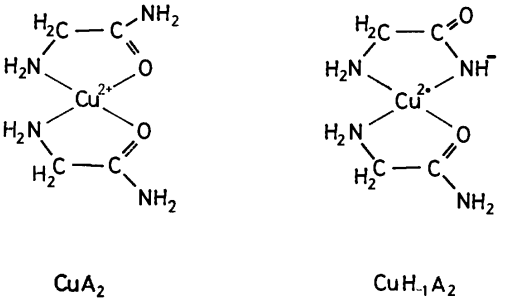


Fig. 2. Structures of bis(glycinamide) copper(II) complexes.

For the mixed ligand complex $CuH_{-1}AB$ which includes glycine as B, a similar calculation shows that $\log \beta_{1\bar{1}1}(3,1) = 4.55$ and that $\log \beta_{1\bar{1}1}(2,2) = 5.35$, while the observed value is 5.255.[4] Thus, glycine and the deprotonated dipeptide both chelate on the basal plane as bidentate ligands, in contrast to the situation in the $CuH_{-1}A_2$ complex. This may result from the much greater ability of glycine to chelate a metal ion compared with the dipeptide interacting with the non-deprotonated CONH group.

On the other hand, glycine is supposed to coordinate with an apical position in its mixed ligand copper(II) complexes with substituted iminodiacetic acids or diethylenetriamine, because its formation constants are considerably greater than those for its esters.[15,16]

For a dipeptide, however, coordination *via* carbonyl oxygen is generally very weak (type (3,1)), and its terminal carboxylate cannot interact with the apical position without considerable strain, according to the Dreiding Stereomodel (type (2,2)). Therefore the apical coordination will be unimportant in the case of

glycylglycinato copper(II) complexes, which probably account for the good agreement between the observed and calculated formation constants as shown above.

In brief, the glycylglycine complex $CuH_{-1}A_2$ of type (3,1) predominates in an aqueous solution, while about 2% of them are still present in the form of type (2,2), since $\beta(2,2)/\beta(3,1) = 1.8 \times 10^{-2}$. This conclusion supports the proposal by Gergely and Nagypál,[17] apart from the question of the apical interaction.

The authors are greatly indebted to Prof. M. Tanaka, Nagoya University, for helpful discussions as well as for continuing encouragement in performing this investigation, and also to Mr. T. Noda, Nagoya University, for technical assistance in improvement of the glassware apparatus.

This research was financially supported in part by a Grant-in-Aid for Scientific Research No. 554184 from the Ministry of Education, Science and Culture.

(Received March 20, 1981)

The complex formation of the Cu(II) ion with ethylenediaminetetraacetic acid (EDTA) and *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid (HEDTA) has been studied potentiometrically and polarographically over the wide pH range from 1 to 11 in aqueous solutions containing 1.0 mol dm^{-1} $NaClO_4$ at 25.0 °C. Both the emf data obtained by potentiometric titrations and the pH-dependence of reversible half-wave potentials were explained in terms of the formation of the following complex species: for the Cu–EDTA complexes, CuL^{2-} ($\log\beta_{101}=17.28\pm0.04$), $CuHL^{-}$ ($\log\beta_{111}=20.15\pm0.04$), CuH_2L ($\log\beta_{121}=22.73\pm0.04$), CuH_3L^{+} ($\log\beta_{131}=24.12\pm0.04$), and $CuH_{-1}L^{3-}$ ($\log\beta_{1-11}=6.83\pm0.05$); for the Cu–HEDTA complexes, CuL^{-} ($\log\beta_{101}=16.30\pm0.05$), CuHL ($\log\beta_{111}=18.76\pm0.04$), CuH_2L^{+} ($\log\beta_{121}=19.85\pm0.04$) and $CuH_{-1}L^{2-}$ ($\log\beta_{1-11}=6.35\pm0.05$), where $\beta_{pqr}=[Cu_pH_qL_r]/[Cu^{2+}]^p[H^+]^q[L]^r$, and where L denotes the unprotonated molecule of EDTA or HEDTA.

The complex-formation reaction of the Cu(II) ion with ethylenediaminetetraacetic acid (EDTA) and *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid (HEDTA) has been studied by a number of workers, and the formation constants of unprotonated and monoprotonated species have been reported.[1,2] The formation constants of the diprotonated Cu(II)–EDTA complex have been reported only by Gorelova *et al.*[3] Interest has also been shown in the problem of determining the protonation schemes of the coordinated ligands and structures of metal complexes by using infrared spectrometry,[4-6] NMR spectrometry[4,7-10] and other methods.[11-14] Nuttall and Stalker[15] have recently proposed, from measurements of the Raman spectra, that protons in protonated Cu(II)–EDTA complexes are located at the oxygen atoms of the ligand carboxyl groups.

In our previous papers[16,17] we have found that a number of protonated complex species of the MH_qL type ($q=1,2,3$ for the EDTA complex and $q=1,2$ for the HEDTA complex) are formed in an acidic solution containing Cd(II) and Pb(II) ions. Therefore, it seemed it would be interesting to see if Cu(II)-complexes with EDTA and HEDTA form a series of protonated species in an acidic solution. The examination of complex-formation equilibria was performed by potentiometric titration measurements, polarographic method, and visible-spectrum measurements over the wide pH range from 1.0 to 11.0.

Symbols

h	Concentration of hydrogen ions at equilibrium.
m	Concentration of metal ions at equilibrium.
H	Analytical excess of hydrogen ions in a test solution.
c_{Cu}	Total concentration of Cu(II) ions.
L	Ethylenediaminetetraacetate anion ($edta^{4-}$) or *N*-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetate anion ($hedta^{3-}$).
c_L	Total concentration of L.
l	Concentration of free L.
$\bar{X}$	Degree of neutralization of H_4L for EDTA or H_3L for HEDTA: $(-H+[H]-[OH])/c_L$.
p	Number of metal atoms bound to the complex.
q	Number of protons bound to the complex; $q<0$ corresponds to the formation of a deprotonated complex.
r	Number of ligands bound to the complex.
β_{pqr}	Equilibrium constant for the reaction: $pM+qH+rL=M_pH_qL_r$.
[ ]	Concentration.
D_{Cu}	Diffusion coefficient of the aqua Cu(II) ion.
D	Average diffusion coefficient of all complex species present.[18]
$(E_{1/2})_{Cu}$	Reversible half-wave potential of the aqua Cu(II) ion.
$(E_{1/2}^r)_{rev}$	Reversible half-wave potential of the Cu(II)–EDTA or –HEDTA system.
R	Gas constant.
T	Thermodynamic temperature.
F	Faraday constant.

All ionic charges are omitted for the sake of convenience.

Experimental

Reagents. *Disodium ethylenediaminetetraacetate* (reagent grade, Dojindo Lab.) was recrystallized twice, dried, and then stored in a desiccator over silica gel. *N-(2-Hydroxyethyl)ethylenediamine-N,N′,N′-triacetic acid* (Dojindo Lab.) was recrystallized from distilled water and dried under a reduced pressure. *Copper(II) perchlorate* was prepared by dissolving $CuCO_3$ in an $HClO_4$ solution and purified by recrystallizing it three times from distilled water. The $CuCO_3$ used was precipitated from a $Cu(NO_3)_2$ solution with Na_2CO_3 and then thoroughly decanted. The stock solution contained a small amount of $HClO_4$ to prevent the hydrolysis of the Cu(II) ion. The concentration of excess $HClO_4$ in the solution was determined from the location of the end point of neutralization by means of a Gran-plot. The concentration of Cu(II) ions in the stock solution was determined by electrogravimetry. *Sodium perchlorate*, *sodium hydroxide*, and *perchloric acid* stock solutions were prepared by the methods described previously.[16] A copper-amalgam was prepared by the electrolysis of a copper sulfate

† Present address: Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184.

†† Present address: Technical Education Center of Tokyo Metropolis, 2-1-45, Horinouchi, Suginami-ku, Tokyo 166.

solution with a Metrohm model E 211 A coulometer. The metal content of the amalgam was about 1 wt%. The oxidation of the amalgam was prevented by preparing and storing it in a nitrogen atmosphere. All the other chemicals were prepared and purified by the methods described previously.[16]

Potentiometric Measurements. The measurements were carried out in a paraffin oil thermostat at (25.00±0.02) °C by using glass and copper-amalgam electrodes. Emf measurements of electrodes were carried out with essentially the same method as has been described previously.[16] The potential of the amalgam electrode became constant after 5—15 min within an accuracy of ±0.02 mV in the pH range of 1.0—2.5 and within an accuracy of ±0.05 mV in that of 2.5—4.0. At pH values above 4.0 the potential was slightly unstable, and it required 1 h to attain a constant value within an accuracy of ±0.1 mV at pH values up to 10.0. The emf of the glass electrode cell became constant after about 5 min and was determined within an accuracy of 0.1 mV over the pH range of 1.0—11.0. The perchlorate concentration was kept constant at 1.0 mol dm^{-3} in all runs. The apparatus and the experimental procedures used for potentiometric titrations have been described previously.[16]

Polarographic Measurements. The polarographic apparatus used was described previously.[18] No buffer was added to the test solution, because the ligands present in a large excess relative to Cu(II) ions have a large buffer capacity in the pH ranges below 3.5 and from 5.5 to 10.5 for both HEDTA and EDTA, and because the polarographic wave-form may be affected by the presence of an acetate buffer in the pH range from 3.5 to 5.5. The hydrogen-ion concentration of the test solution was varied and measured before and after the recording of each polarogram.[16] The difference between the pH values ($-\log h$) obtained before and after recording was less than 0.01 pH unit. No maximum suppressor was added, since no polarographic maximum appeared at pH values above 1. The test solution was deaerated for at least 30 min with argon gas before each measurement.

Spectrophotometric Measurements. The ultraviolet and visible absorption spectra were measured by using a Hitachi Model 200-10 Spectrophotometer at room temperature (25±1 °C).

Results

Determination of the Composition and the Formation Constants of Cu(II)-EDTA and -HEDTA Complexes by Potentiometric Titrations. The titration curves shown in Figs. 1 and 2 result when the experiments were carried out under the conditions where the c_{Cu}/c_L ratio was 1/2, 1/4, 1/6, or 1/8 and where c_{Cu} was changed from 1 to 10 mmol dm^{-3}. Both c_{Cu} and c_L were kept practically constant for each run. The difference in neutralization degree between EDTA or HEDTA solutions with and without Cu(II) ions reveals that protons were released from the ligand by the complex formation, even at pH 1.3.

As has been described previously,[16,17] since any possibility of the formation of polynuclear or polyligand complexes may be disregarded when the solution contains an excess of EDTA and HEDTA ligands relative to the Cu(II) ion, we can use the same procedure for data analysis as that employed for Cd(II)- and Pb(II)-complexes with EDTA and HEDTA.[16,17] We assume that the complex formation proceeds:

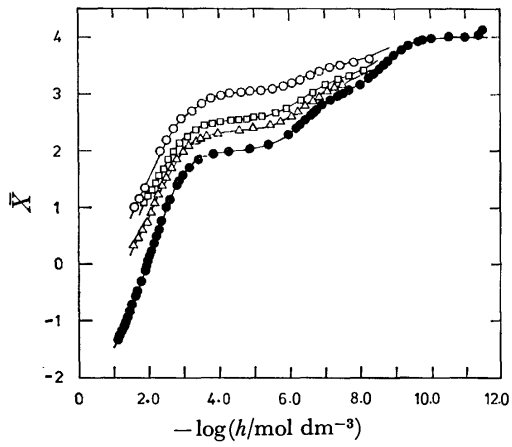

Fig. 1. Degrees of neutralization, $\bar{X}$, of EDTA solutions for the Cu(II)–EDTA system.
●: $c_{Cu}=0.0$ mol dm^{-3}, $c_L=0.02500$ mol dm^{-3}, ○: $c_{Cu}=0.006221$ mol dm^{-3}, $c_L=0.011985$ mol dm^{-3}, □: $c_{Cu}=0.001107$ mol dm^{-3}, $c_L=0.003987$ mol dm^{-3}, △: $c_{Cu}=0.001075$ mol dm^{-3}, $c_L=0.005998$ mol dm^{-3}. Solid lines are the values of $\bar{X}$ calculated by the use of the formation constants given in Table 1.

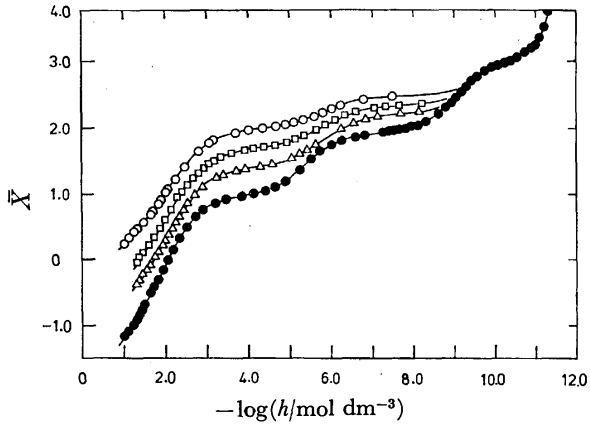

Fig. 2. Degrees of neutralization, $\bar{X}$, of HEDTA solutions for the Cu(II)–HEDTA system.
●: $c_{Cu}=0.0$ mol dm^{-3}, $c_L=0.02500$ mol dm^{-3}, ○: $c_{Cu}=0.01010$ mol dm^{-3}, $c_L=0.02020$ mol dm^{-3}, □: $c_{Cu}=0.004970$ mol dm^{-3}, $c_L=0.02000$ mol dm^{-3}, △: $c_{Cu}=0.002500$ mol dm^{-3}, $c_L=0.02000$ mol dm^{-3}. Solid lines are the values of $\bar{X}$ calculated by the use of the formation constants given in Table 1.

$$Cu^{2+} + qH^+ + L^{z-} = CuH_qL^{(2+q-z)+} \quad (1)$$

from which the following relationships are obtained:

$$c_{Cu} = m + \sum_{q=-1}^{Q}[CuH_qL] \quad (2)$$

$$c_L = l + \sum_{n=1}^{N}[H_nL] + \sum_{q=-1}^{Q}[CuH_qL]. \quad (3)$$

The combination of Eqs. 2 and 3 leads to:

$$l = (c_L - c_{Cu} + m)/(1 + \sum_{n=1}^{N}\beta_{0n1}h^n), \quad (4)$$

where l can be calculated by using the protonation constants of the ligands obtained previously.[16,17] A function, $F_0(h)$, is defined as:

$$F_0(h) = (c_{Cu}-m)/ml = \sum_{q=-1}^{Q}[CuH_qL]/ml = \sum_{q=-1}^{Q}\beta_{1q1}h^q \quad (5)$$

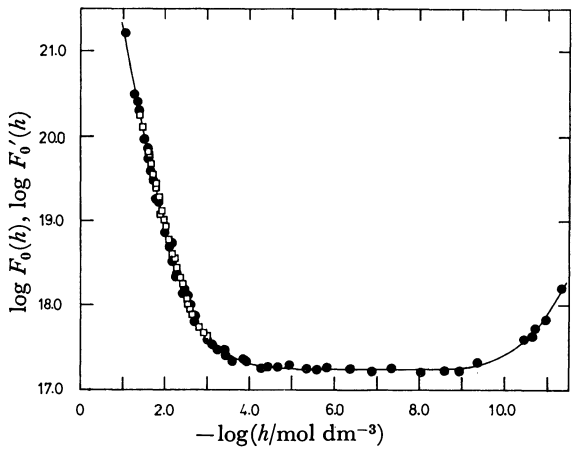

Fig. 3. Plots of log $F_0(h)$ and log $F_0'(h)$ against $-\log h$ for Cu(II)–EDTA system. Solid line is the best fit curve calculated by Eqs. 5 and 9.
□: log $F_0(h)$, ●: log $F_0'(h)$.

The plots of log $F_0(h)$ against $-\log h$ for the EDTA system fall into a single curve regardless of the variations in c_{Cu} and c_L (Fig. 3), and the assumption that no polynuclear and polyligand complexes are formed in an acidic solution is confirmed to be reasonable. The formation constant, β_{1q1}, was calculated from the $F_0(h)$ *vs.* h curve by means of a generalized least-squares method.[16] The method was applied to make the error-squares sum, $\sum\{\log F_0 - \log F_{0,calcd}\}^2$, a minimum for the set of the formation constants over the pH range of 1.0—7.0, where $F_{0,calcd}$ denotes the value of F_0 calculated for a particular set of formation constants. The values of the formation constants of all the complex species present are given in Table 1. In addition to the normal complex, CuL^{2-}, a series of protonated complexes, such as $CuHL^-$, CuH_2L^0, and CuH_3L^+, were detected. No information has yet been published on the formation of the triprotonated species.

Table 1. Formation constants of Cu(II)–EDTA and–HEDTA complexes in 1.0 mol dm^{-3} $NaClO_4$ solution at 25 °C

	Potentiometry	Polarography	Spectrophotometry
Cu(II)–EDTA system			
log β_{1-11}	—	6.83±0.05	5.5±0.1
log β_{101}	17.22±0.10	17.28±0.04	—

log β_{121}	19.86±0.04	19.85±0.04	—

The same analytical method as was used for the EDTA system was used to determine the formation constants for the HEDTA system. Figure 4 demonstrates that the plots of log $F_0(h)$ against $-\log h$ in the HEDTA system give a single curve. From the analysis of the curve, we found that the normal complex, CuL^-,

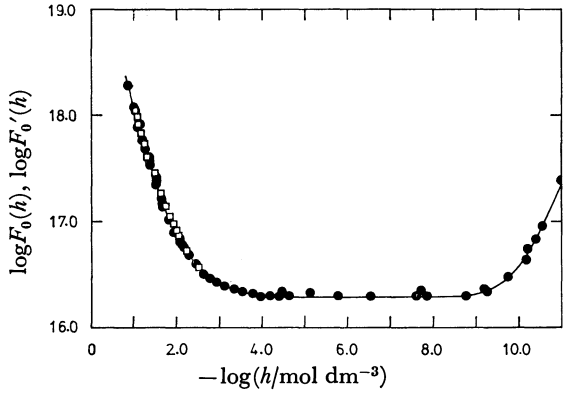

Fig. 4. Plots of log $F_0(h)$ and log $F_0'(h)$ against $-\log h$ for Cu(II)–HEDTA system. Solid line is the best fit curve calculated by Eqs. 5 and 9.
□: log $F_0(h)$, ●: log $F_0'(h)$.

as well as two protonated complexes, CuHL and CuH_2L^+, are formed. The formation constant of the diprotonated species was obtained for the first time in the Cu–HEDTA system. The solid curve in Fig. 4 represents the curve calculated from the final values of the formation constants which are summarized in Table 1.

Above pH 4.0, the emf's of the amalgam electrodes became unstable for both systems, and the values of log $F_0(h)$ in Figs. 3 and 4 were somewhat scattered around the best-fit curve. This may be due to the contamination of amalgam surfaces by a small amount of oxygen dissolved in solution. Thus, we may expect to obtain correct information on complex-formation reactions above pH 4 by means of polarographic measurements.

Determination of the Formation Constants by Polarography. Single well-defined waves with diffusion-controlled limiting currents were observed for the Cu(II)–EDTA and –HEDTA systems in the pH range from 1.0 to

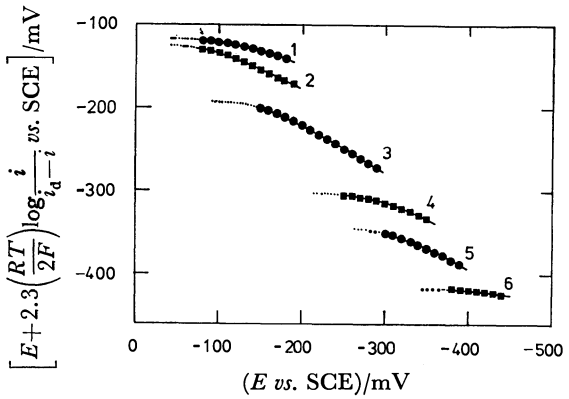

Fig. 5. Typical examples of the plots of $E+2.3\,(RT/2F)\cdot\log[i/(i_d-i)]$ *vs.* E for determination of reversible half-wave potentials. $c_{Cu}=0.00040$ mol dm^{-3}.
●: Cu(II)–EDTA system. $c_L=0.0080$ mol dm^{-3}. Values of $-\log(h/\text{mol dm}^{-3})$: (1) 2.12, (3) 3.73, (5) 6.11.
■: Cu(II)–HEDTA system. $c_L=0.0200$ mol dm^{-3}. Values of $-\log(h/\text{mol dm}^{-3})$: (2) 2.70, (4) 6.05, (6) 10.19.

11.0. The log-plot analysis of the current-potential curves demonstrates that the waves correspond to the quasi-reversible, two-electron reduction. For the quasi-reversible wave we can determine the reversible half-wave potential by using the extrapolation methods.[19,20] Figure 5 shows typical examples of the $[E+2.3(RT/2F)\times \log\{i/(i_d-i)\}]$ *vs.* E plots, where E denotes the potential of the dropping mercury electrode, i the current corresponding to E, and i_d the limiting diffusion current. The reversible half-wave potentials were determined as the limiting constant values of $[E+2.3(RT/2F)\log\{i/(i_d-i)\}]$ at sufficiently positive potentials.[19]

Consider the electrode reaction, symbolically designated by:

$$\left\{\begin{array}{l}\mathrm{CuH_QL^{(2+Q-z)+}}\\ \quad\vdots\\ \quad\downarrow\uparrow\\ \mathrm{CuH_qL^{(2+q-z)+}}\\ \quad\vdots\\ \quad\downarrow\uparrow\\ \mathrm{CuL^{(2-z)+}}\\ \quad\downarrow\uparrow\\ \mathrm{CuH_{-1}L^{(1-z)+}}\end{array}\right\} + 2e(\mathrm{Hg}) \rightleftharpoons$$

$$\mathrm{Cu\,(Hg)} + \left\{\begin{array}{l}\mathrm{H_NL^{(N-z)+}}\\ \quad\vdots\\ \quad\downarrow\uparrow\\ \mathrm{H_nL^{(n-z)+}}\\ \quad\vdots\\ \quad\downarrow\uparrow\\ \mathrm{L^{-z}}\end{array}\right\}. \qquad (6)$$

The reversible half-wave potential can then be expressed by:[18]

$$(E_{1/2})_{\mathrm{rev}} = (E^{\mathrm{r}}_{1/2})_{\mathrm{Cu}} - \frac{RT}{2F}\ln\sqrt{\frac{D}{D_{\mathrm{Cu}}}} - \frac{RT}{2F}\ln[1+(\sum_{q=-1}^{Q}\beta_{1q1}h^q)l]. \qquad (7)$$

Equation 7 can be rewritten as:

$$\left\{\sqrt{\frac{D_{\mathrm{Cu}}}{D}}\exp\left\{\left(\frac{2F}{RT}\right)[(E^{\mathrm{r}}_{1/2})_{\mathrm{Cu}} - (E_{1/2})_{\mathrm{rev}}]\right\} - 1\right\}/l = \sum_{q=-1}^{Q}\beta_{1q1}h^q. \qquad (8)$$

The left-hand side of Eq. 8 is the experimentally accessible quantity and is here written as $F_0'(h)$. Thus,

$$F_0'(h) = \sum_{q=-1}^{Q}\beta_{1q1}h^q, \qquad (9)$$

which is identical to the $F_0(h)$ function defined by Eq. 5.

The plots of $\log F_0'(h)$ against $-\log h$ are shown in Figs. 3 and 4 for the systems of EDTA and HEDTA respectively. In each system, a single curve was obtained for both functions, $F_0(h)$ and $F_0'(h)$, and only small differences between the formation constants determined from these two functions were observed.

In the EDTA system, the triprotonated complex, CuH_3L^+, was also detected by polarography. In the pH range of 4.0—9.5, the values of the $\log F_0'(h)$ function were constant, and we can consider that the Cu(II) ion is present predominantly as the normal complex, CuL^{2-}, in a solution containing an excess EDTA. The values of the $\log F_0'(h)$ function begin to increase above pH 10.0 (Fig. 3), indicating the formation of hydroxo complexes. The $F_0'(h)$ function is proportional to h^{-1} in the range above pH 10.0, and the product $[F_0'(h)-\beta_{101}]\times h$ yields a constant value. This behavior of $F_0'(h)$ can be understood in terms of the formation of only one deprotonated complex, $CuH_{-1}L^{3-}$, which is probably the same as the hydroxo complex $Cu(OH)L^{3-}$, reported previously.[3] The formation constant of the hydroxo complex was determined by the curve-fitting method; it is given in Table 1.

In the HEDTA system, all of the complex species, CuL^-, $CuHL^0$, and CuH_2L^+, being found potentiometrically, were also detected by the polarographic method. Above pH 9.0, the values of the $\log F_0'(h)$ function began to increase, indicating the formation of deprotonated species, $CuH_{-1}L^{2-}$. The formation constants of these four species were determined by the analysis of the $F_0'(h)$ *vs.* h curve; they are given in Table 1.

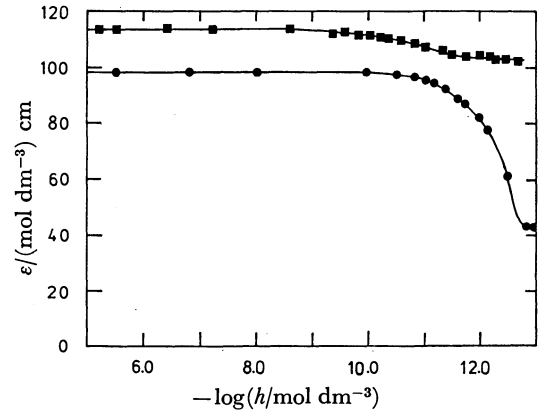

Fig. 6. Variations of the molar absorbances with $-\log h$ at the absorption maxima of Cu(II)–EDTA (●) and Cu(II)–HEDTA (■) solutions.

Spectrophotometric Measurements. In order to obtain further information on the formation of deprotonated species, measurements of the absorption spectra were carried out in the alkaline region. For the EDTA system, the hydroxo complex formation was also observed by spectrophotometry. Figure 6 demonstrates the intensity change in the absorption maximum (at 740 nm) with $-\log h$, from which the formation of the $Cu(OH)L^{3-}$ species was confirmed to be as previously reported by Bhat and Krishnamurthy.[13] On the other hand, the intensity change in the absorption maximum (at 710 nm) with $-\log h$ for the HEDTA system in the pH range of 9.5—12 is not so large (Fig. 6), though two isosbestic points were observed at 600 and 835 nm. This fact proves that two species, the normal complex, CuL^- and only one deprotonated complex, $CuH_{-1}L^{-2}$, are formed in the pH range from 9.5 to 12.

As can be seen from Table 1, the values of the formation constants obtained by spectrophotometry are different from those obtained by polarography. The reason for this discrepancy is not clear at present.

Discussion

The step-by-step protonation constants for protonated complexes of the $CuH_{q-1}L$ type may be defined as $K_H^{CuH_qL} = [CuH_qL]/[CuH_{q-1}L][H] = \beta_{1q1}/\beta_{1(q-1)1}$. The values of log $K_H^{CuH_qL}$ for the EDTA complexes are 2.87, 2.58, and 1.39 for $q=1,2$, and 3 respectively, while those of the HEDTA complexes are 2.46 and 1.09 for $q=1$ and 2 respectively. These values are close to the values of log $K_H^{H_nL}$=log $\{[H_nL]/[H_{n-1}L][H]\}$ with $n=3,4$, and 5 of the corresponding ligands,[17] which are the step-by-step protonation constants for the carboxyl groups of the EDTA and HEDTA ligands. Thus, as has been reported previously[16,17] for the systems of the Cd(II)- and Pd(II)–HEDTA and -EDTA complexes, we may conclude that the protonation of the complexes occurs on the carboxyl groups with the cleavage of Cu(II)–oxygen bonds within the complexes, while the strong Cu(II)–nitrogen bonds remain unaltered.

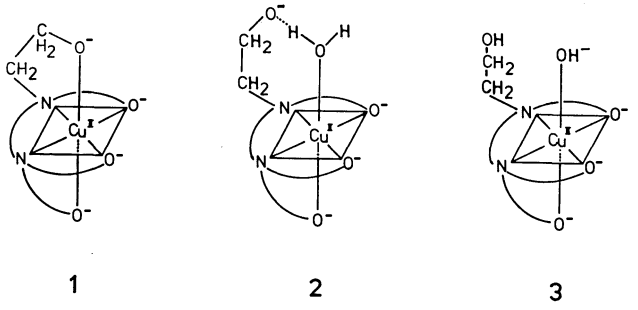

Fig. 7. Possible structures for the deprotonated species of Cu(II)–HEDTA complex.

We define the deprotonation constant of the $CuH_{-1}L$ species as $K_{H_{-1}}^{CuH_{-1}L}=\{[CuH_{-1}L][H]/[CuL]\}$. Then, we obtain log $K_{H_{-1}}^{CuH_{-1}L}=-10.45$ and -9.95 for the EDTA and HEDTA systems respectively. Thus, the values of the deprotonation constant are shown to be almost the same for the EDTA and HEDTA systems. However, Fig. 6 indicates that the intensity changes in the absorption maxima with $-\log h$ in the pH range from 10 to 11.5 are large for the EDTA system, but not for the HEDTA system. The observed result may be attributable to the difference between the deprotonation reaction schemes of the EDTA and HEDTA complexes. The large intensity change in the absorption maximum for the EDTA complex is possibly caused by the deprotonation of the water molecule coordinated to the Cu(II) ion, and the resulting species is a hydroxo complex. On the other hand, three possible reaction schemes for the HEDTA complex may be considered on the basis of the pentadentate coordination of the HEDTA ligand to the Cu(II) ion at the state of the normal complex, as is shown in Fig. 7: (1) the hydroxyethyl group in the ligand releases a proton, and the resulting ethyl alcoholate coordinates to the Cu(II) ion directly; (2) the hydroxyethyl group releases a proton to form a hydrogen bond with the water molecule coordinated to the Cu(II) ion, or (3) the deprotonation occurs from the water molecule coordinated to Cu(II), and the hydroxyethyl group gives no interaction for the hydrolysis reaction. The observed absorption spectra seem to support the reaction scheme (2), since the Cu(II) ion was not subjected to any strong interaction with the deprotonation of the complex.

The degree of neutralization, $\bar{X}$, of H_3hedta exceeds 3.0 at pH values above 11.0, but that of H_4edta remains constant (4.0), although the emf of the glass electrode cell becomes uncertain in such a high pH region. Therefore, it may be considered that the reaction of the hydroxyethyl group of HEDTA to ethylalcolate starts at this pH in the HEDTA solution containing no Cu(II) ion. The adoption of the reaction scheme (2) depicted in Fig. 7 means that the coordination of HEDTA to the Cu(II) ion accelerates the deprotonation of the hydroxyethyl group, since the deprotonation reaction of the Cu(II)–HEDTA complex starts at pH 9.5. The acceleration of the deprotonation process of 2-aminoethanol by its coordination to the metal ion has been reported for the $[Co(NH_2CH_2CH_2NH_2)_2(NH_2CH_2CH_2OH)]^{3+}$ complex.[21]

The authors wish to express their thanks to Drs. H. Ogino and K. Ogino, Tohoku University, for their stimulating discussion on the formation of deprotonated species. The present work was partially supported by a Grand-in-Aid for Scientific Research No. 247065 from the Ministry of Education, Science and Culture.

The Formation of Molybdenum Disulfide by the Reaction between Molybdenum Trioxde and Sulfur Dioxide in the Presence of Carbon

Akimasa YAJIMA, Ryoko MATSUZAKI, Motonori EGUCHI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 27, 1981)

The reaction products obtained by heating a mixture of MoO_3 and carbon in a SO_2 stream at various temperatures were examined. The possible reactions during the above process were also studied. Further, thermodynamical consideration was made of the formation of MoS_2. When a mixture of MoO_3 and carbon was heated in a SO_2 stream, MoO_2 was formed above 400 °C. At 500—550 °C, the formation of a small amount of Mo_4O_{11} was also observed. Above 700 °C, the formation of MoS_2 in addition to MoO_2 was observed, and MoS_2 alone was obtained at 1000 °C. Sulfur was obtained outside the heating zone throughout the temperature range in this experiment. The process of the formation of MoS_2 by the reaction between MoO_3 and SO_2 in the presence of carbon can be represented as follows: The reaction between carbon and SO_2 occurs at first to form sulfur. Above *ca.* 400 °C, the reductions of MoO_3 with carbon and with sulfur occur to form MoO_2. Above *ca.* 700 °C, MoS_2 is formed by the reaction between MoO_2 and sulfur, which are formed by the above reactions.

As sulfidizing agents for synthesizing molybdenum disulfide (MoS_2), hydrogen sulfide and sulfur have been well known. But there has been no report on the chemical process for synthesizing MoS_2 from molybdenum trioxide (MoO_3) using sulfur dioxide (SO_2) as a sulfidizing agent. It is not only interesting from the viewpoint of the synthesis of the sulfide itself, but also important for the development of SO_2 utilization, to obtain knowledge of the above chemical process.

In this work, the reaction products between MoO_3 and SO_2 in the presence of carbon at various temperatures were examined. In order to elucidate the reaction process between MoO_3 and SO_2 in the presence of carbon, the reactions of MoO_3 with carbon and of MoO_3 with gaseous sulfur in a SO_2 stream were examined. Also, the reactions of MoO_2, formed during the reaction process between MoO_3 and SO_2 in the presence of carbon, with carbon and of MoO_2 with gaseous sulfur in a SO_2 stream were examined. Further, thermodynamical consideration was made of the formation of MoS_2.

Experimental

The MoO_3 used was prepared by the thermal decomposition of the guaranteed reagent ammonium paramolybdate at 600 °C. The carbon was prepared by the thermal decomposition of the guaranteed reagent D-glucose. The above materials were used as powders under 150 mesh. Gaseous SO_2 was dried by passing it through concd H_2SO_4 and over P_2O_5.

A mixture of MoO_3 and carbon at a specified ratio in a quartz boat (length: 72 mm, width: 16 mm, depth: 9 mm) was placed in a transparent quartz reaction tube (inner diameter: 28 mm, length: 1000 mm). Gaseous SO_2 was then introduced into the reaction tube. The sample part was positioned in the middle of the tubular electric furnace (heating length: 300 mm) maintained at a specified temperature for 1 h. The temperature of the sample part was controlled within ± 2 °C. After heating, the sample was held at 100 °C for 1 h in an argon stream in order to release the adsorbed SO_2 on unreacted carbon.[1] The reactions of MoO_3 with carbon in an argon stream, of MoO_3 with gaseous sulfur in a SO_2 stream, of MoO_2 with carbon in an argon stream, and of MoO_2 with gaseous sulfur in a SO_2 stream were examined in a similar manner.

The X-ray analysis of the sample was performed with an X-ray powder diffractometer equipped with a proportional counter using Ni filtered Cu radiation. The thermogravimetry (TG) was performed by using a thermal balance with a quartz helix. The sensitivity of the quartz helix used was approximately 72 mm/g, and the heating rate of 2.5 °C/min was employed.

The molybdenum content in the sample was determined gravimetrically as $PbMoO_4$ after the fusion of the sample with a mixture of Na_2CO_3 and K_2CO_3. The sulfur content in the sample was determined gravimetrically as $BaSO_4$ after decomposing the sample with HNO_3 and $KClO_3$.

Results and Discussion

Reaction Products between Molybdenum Trioxide and Sulfur Dioxide in the Presence of Carbon. The TG of MoO_3 (0.3 g) in a SO_2 stream at a flow-rate of 50 cm^3/min was carried out. The heating temperature of the sample was limited to below 700 °C, since MoO_3 vaporized above this temperature. No weight change was observed, and the sample after the heating was found to be unreacted MoO_3 by X-ray analysis.[2] These results indicate that MoO_3 does not react with SO_2.

The reaction between MoO_3 and SO_2 in the presence of carbon was then examined. First, the products obtained by heating a mixture of 2.00 g of MoO_3 and 1.20 g of carbon at various temperatures for 1 h in a SO_2 stream at a flow-rate of 100 cm^3/min were examined. The results are shown in Table 1, together with the weight changes in the samples. The sample in the boat was identified by X-ray analysis.[2-5]

The formation of MoO_2 was observed above 400 °C, and a small amount of Mo_4O_{11} in addition to MoO_2 was also observed at 500—550 °C. The formation of MoS_2 was observed at 700 °C. A small amount of sulfur was obtained outside the heating zone throughout the temperature range in this experiment. The slight increase in the sample weight at 350—400 °C was due to the adsorption of the sulfur formed by the reaction on the unreacted carbon.[1]

In addition to the above observations, it was observed

TABLE 1. PRODUCTS OBTAINED BY HEATING A MIXTURE OF MoO_3 AND CARBON IN A SO_2 STREAM AT VARIOUS TEMPERATURES

Temp °C	Weight change/%	Sample in the boat	Amount of sulfur obtained outside the heating zone/g
350	+0.1	MoO_3	Trace
400	+0.1	$MoO_3>>MoO_2$	Trace
450	−0.1	$MoO_3>>MoO_2$	Trace
500	−4.7	$MoO_2>MoO_3>Mo_4O_{11}$	Trace
550	−7.2	$MoO_2>>MoO_3>Mo_4O_{11}$	Trace
600	−8.8	MoO_2	0.00_5
650	−8.9	MoO_2	0.03
700	−7.8	$MoO_2>>MoS_2$	0.09

that a small amount of unreacted MoO_3 vaporized and deposited outside the heating zone at 700 °C. As seen from Table 1, all the MoO_3 used was converted to non-volatile MoO_2 above 600 °C. The reactions at temperatures above 800 °C were examined by using a mixture of MoO_2 and carbon. When a mixture of 2.00 g of MoO_2 and 1.20 g of carbon was heated in a SO_2 stream (100 cm^3/min) at 800 °C for 1 h, unreacted carbon was not observed in the sample obtained after the heating. This result is considered to be due to the fact that the reaction between carbon and SO_2 proceeds markedly.[1] Based on the results of preliminary experiments on the suitable amount of carbon to be mixed, the products obtained by heating a mixture of 2.00 g of MoO_2 and 5.00 g of carbon in a SO_2 stream (100 cm^3/min) at various temperatures above 800 °C for 1 h were examined. The mixture of MoO_2 and carbon was prepared by adding fresh carbon to a mixture of MoO_2 and carbon, obtained by the reduction of MoO_3 with carbon at 700 °C. The results are shown in Table 2.

TABLE 2. PRODUCTS OBTAINED BY HEATING A MIXTURE OF MoO_2 AND CARBON IN A SO_2 STREAM AT VARIOUS TEMPERATURES

Temp °C	Weight loss/%	Sample in the boat	Amount of sulfur obtained outside the heating zone/g
800	34.3	$MoO_2\approx MoS_2$	3.90
900	54.0	$MoS_2>MoO_2$	4.86
950	57.6	$MoS_2>MoO_2$	5.04
1000	64.2	MoS_2	5.66

Chemical analysis of the sample obtained at 1000 °C showed it to contain 59.8% Mo and 39.9% S. Chemical analysis also proved that sulfur was not adsorbed on the unreacted carbon at 1000 °C. From these results, the sulfur was found to be due to the sulfide formed. The atomic ratio of Mo : S in the sample was calculated to be $1 : 2.0_0$. The results indicated that all the MoO_2 used was sulfidized to MoS_2 at 1000 °C.

Reaction Process between Molybdenum Trioxide and Sulfur Dioxide in the Presence of Carbon. To elucidate the reaction process between MoO_3 and SO_2 in the presence of carbon, the following experiments were carried out under conditions similar to those described above.

Reaction between MoO_3 and Carbon: The products formed by heating a mixture of MoO_3 (2.00 g) and carbon (1.20 g) at various temperatures in an argon stream (100 cm^3/min) for 1 h were examined. The results are shown in Table 3.

TABLE 3. EXPERIMENTAL RESULTS FOR THE REACTION BETWEEN MoO_3 AND CARBON IN AN ARGON STREAM

Temp °C	Weight loss/%	Sample in the boat
350	—	MoO_3
400	0.2	$MoO_3>>MoO_2$
450	0.9	$MoO_3>>MoO_2$
500	5.2	$MoO_2>MoO_3$
600	9.7	$MoO_2>>MoO_3$
700	9.7	MoO_2

These results indicate that the reduction of MoO_3 with carbon to form MoO_2 proceeds above about 400 °C.

Reaction between MoO_3 and Sulfur in a SO_2 Stream: As seen from Table 1, when the mixture of MoO_3 and carbon was heated in a SO_2 stream, sulfur was formed. The reaction between carbon and SO_2 occurs even at 350 °C to form sulfur and this reaction proceeds markedly above about 700 °C, as reported by the present authors.[1] Therefore, the reaction between MoO_3 and gaseous sulfur was examined in a SO_2 stream.

MoO_3 (2.00 g) was heated in a stream of SO_2 (100 cm^3/min) containing a specified amount of gaseous sulfur at various temperatures for 1 h. The amounts of sulfur introduced at various temperatures were controlled so as to be the same as those obtained by heating 1.20 g of carbon in a stream of SO_2 at a flow-rate of 100 cm^3/min for 1 h: the amounts were 0.01 g for the experiments below 550 °C, 0.03 g at 600 °C, 0.09 g at 650 °C, and 0.25 g at 700 °C.[1] The results are shown in Table 4.

These results and the fact that MoO_3 does not react with SO_2 as described before show that the reaction between MoO_3 and gaseous sulfur proceeds above about 400 °C and that MoO_3 was reduced to MoO_2.

TABLE 4. PRODUCTS OBTAINED BY HEATING MoO_3 IN A STREAM OF SO_2 CONTAINING GASEOUS SULFUR

Temp °C	Weight loss/%	Sample in the boat
350	—	MoO_3
400	0.2	$MoO_3>>MoO_2$
450	0.3	$MoO_3>>MoO_2$
500	0.5	$MoO_3>>MoO_2>Mo_9O_{26}$, Mo_4O_{11}
550	0.7	$MoO_3>>MoO_2>Mo_9O_{26}$, Mo_4O_{11}
600	1.0	$MoO_3>MoO_2>Mo_9O_{26}>Mo_4O_{11}$
650	4.2	$MoO_3>MoO_2>Mo_9O_{26}>>Mo_4O_{11}$
700	8.2	$MoO_2>>MoO_3>Mo_9O_{26}$, Mo_4O_{11}

These experimental results showed that the MoO_2 formed by heating a mixture of MoO_3 and carbon in a SO_2 stream (Table 1) was formed by the reductions of MoO_3 with carbon and with sulfur. As seen from Table 1, the formation of a small amount of Mo_4O_{11} in addition to MoO_2 was observed at 500—550 °C. As seen from Table 3, no formation of any intermediate oxide was observed in the reaction between MoO_3 and carbon. As seen from Table 4, however, the formation of intermediate oxides (Mo_4O_{11},[4] Mo_9O_{26}[6]) in addition to MoO_2 was observed during the reaction between MoO_3 and sulfur. It has been reported that on heating a mixture of MoO_3 and a sufficient amount of carbon in an argon stream, no intermediate oxide is formed.[7] These facts suggested that the Mo_4O_{11} formed by heating a mixture of MoO_3 and carbon in a SO_2 stream was due to the reduction of MoO_3 with sulfur.

Formation Reaction of MoS_2 from MoO_2: As mentioned before, when a mixture of MoO_3 and carbon was heated in a SO_2 stream, MoS_2 was formed above about 700 °C. Above this temperature, MoO_3 was reduced to MoO_2. Therefore, the reactions of MoO_2 with carbon in an argon stream and of MoO_2 with gaseous sulfur in a SO_2 stream were examined.

The products formed by heating a mixture of MoO_2 (2.00 g) and carbon (5.00 g) at various temperatures for 1 h in an argon stream (100 cm^3/min) were examined. The results are shown in Table 5.

Table 5. Experimental results for the reaction between MoO_2 and carbon in an argon stream

Temp °C	Weight loss/%	Sample in the boat
700	—	MoO_2
750	0.7	$MoO_2 >> Mo_2C > Mo$
800	2.0	$MoO_2 > Mo_2C > Mo$
900	7.6	$Mo_2C > MoO_2 > Mo$
1000	11.3	$Mo_2C > Mo$

The results indicate that the reaction between MoO_2 and carbon proceeds above about 750 °C to form molybdenum[8] and dimolybdenum carbide (Mo_2C).[9] The Mo_2C was considered to be due to the reaction between the molybdenum formed and the carbon.[7]

The products formed by heating MoO_2 (2.00 g) in a stream of SO_2 (100 cm^3/min) containing a specified amount of gaseous sulfur at various temperatures for 1 h were examined. The MoO_2 used was prepared by the hydrogen reduction of MoO_3 at 600 °C,[10] because the reduction of MoO_3 with carbon gave a mixture of MoO_2 and unreacted carbon, as described in the previous paragraph.

Prior to this experiment, the amounts of sulfur formed by heating 5.00 g of carbon at various temperatures for 1 h in a SO_2 stream at a flow-rate of 100 cm^3/min were examined.[1] Based on the experimental results, the amounts of sulfur introduced at various temperatures were controlled to be 0.43 g for the experiment at 650 °C, 0.81 g at 700 °C, 4.79 g at 800 °C, 5.46 g at 900 °C, and 6.59 g at 1000 °C. The experimental results are shown in Table 6. These results indicate that the

Table 6. Products obtained by heating MoO_2 in a stream of SO_2 containing gaseous sulfur

Temp °C	Weight gain/%	Sample in the boat
650	—	MoO_2
700	4.2	$MoO_2 > MoS_2$
800	10.8	$MoO_2 \approx MoS_2$
900	17.6	$MoS_2 > MoO_2$
1000	22.9	$MoS_2 >> MoO_2$

reaction between MoO_2 and gaseous sulfur proceeds above about 700 °C to form MoS_2.

As shown in Table 5, on heating a mixture of MoO_2 and carbon in an argon stream, MoO_2 was reduced to molybdenum, and Mo_2C was also formed. Thermodynamical consideration was made on the Mo–S–C–O system, in order to discuss whether MoO_2 was converted to MoS_2 *via* molybdenum or without molybdenum formation. The chemical potential diagrams for the Mo–S–C–O system were constructed in a manner similar to that described by Yazawa[11] on the basis of the available thermodynamic data[12] and phase relations.[13] As an example, the digram at 1000 °C is shown in Fig. 1. The broken line shows the oxygen and sulfur potentials in the gas phase formed by the reaction between carbon and SO_2, depending on the carbon content in the gas phase. The activity of carbon is unity at the dot mark. In these calculations, CO, CO_2, O_2, COS, CS_2, SO_2, SO_3, S_2, S_4, S_6, and S_8 were assumed to be gaseous products between carbon and SO_2.

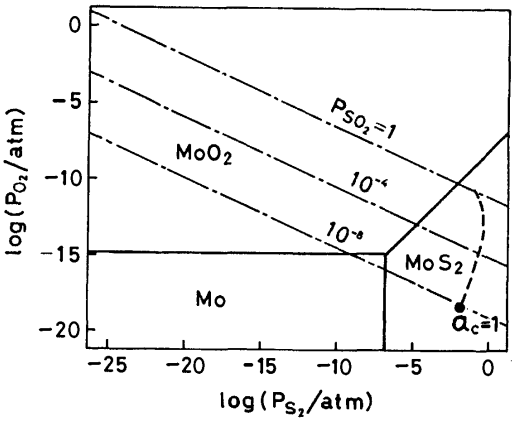

Fig. 1. Chemical potential diagram for the Mo–S–C–O system at 1000 °C.

The results shown in Fig. 1 indicate that MoO_2 is converted to MoS_2 *via* molybdenum under a low pressure of SO_2 below *ca.* 10^{-7} atm, and that MoO_2 is converted to MoS_2 without molybdenum formation under a higher partial pressure of SO_2. Considering the experimental conditions in this work, the results in Fig. 1 show that MoS_2 is formed from MoO_2 without any formation of molybdenum.

The process of formation of MoS_2 by the reaction between MoO_3 and SO_2 in the presence of carbon can be represented as follows: On heating a mixture of MoO_3 and carbon in a SO_2 stream, the reaction between

carbon and SO_2 occurs at first to form sulfur. Above about 400 °C, the reductions of MoO_3 with carbon and with sulfur occur to form MoO_2. Above about 700 °C, MoS_2 is formed by the reaction between MoO_2 and sulfur, which are formed by the above reactions.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 555306 from the Ministry of Education, Science and Culture.

Selective Extraction Spectrophotometric Determination of Iron by Utilizing the Peculiar Absorption of Iron(II)-2-(2-Thiazolylazo)-5-dimethylaminophenol Complex

Kazumasa UEDA,* Yasushi KIYOTA, and Yoshikazu YAMAMOTO

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received April 3, 1981)

Thiazolylazo compounds react with iron(II) to form brownish complexes, which show a characteristic absorption in near-infrared region. These compounds possess the hydroxyl group in the *o*-position next to the azo group. Among them, iron(II)-2-(2-thiazolylazo)-5-dimethylaminophenol complex has the absorption maximum at 760 nm in chloroform; the optimum pH for iron extraction lies between 8.2—10.0. Beer's law holds up to 2.0 $\mu g\ cm^{-3}$ of iron and the molar absorption coefficient is $2.70\times10^4\ dm^3\ mol^{-1}\ cm^{-1}$. The composition and the extraction constant of the complex are estimated to be Fe: TAM=1 : 2 and $\log K_{ex}=-4.20\pm0.04$, respectively. Since the present method utilizes the specific absorption of the iron(II)-TAM complex, the presence of many ions is tolerable, especially of 3d type metals. The method was applied to the determination of traces of iron dissolved in river and sea waters with satisfactory results.

Many azo compounds containing a hetero ring are useful as analytical reagents.[1,2] Above all, thiazolylazo derivatives are especially attractive, because their complexing properties are often specific.[3,4] In previous papers, the authors reported highly selective spectrophotometric methods for the determination of iron with 4-(2-thiazolylazo)resorcinol[5] and 2-(2-thiazolylazo)-4-methylphenol[6] by utilizing the specific absorption of iron(II) complexes in the near-infrared region. The homolog 2-(2-thiazolylazo)-5-dimethylaminophenol (TAM) has been applied for the determination of specific metals, such as uranium,[7] vanadium,[8] niobium,[9] bismuth,[10] yttrium,[11] nickel,[12] titanium,[13] zirconium,[14] and thorium.[15] We investigated the color reaction of TAM with iron(II) and recognized that iron(II)-TAM complex also showed a characteristic absorption at 760 nm. It is rarely the case that a metal complex possesses the absorption maximum in this infrared region. In this research, the fundamental conditions for the selective extraction spectrophotometric determination of traces of iron were investigated. We also prepared eleven (thiazolylazo)phenol and naphthol derivatives in order to elucidate these absorption features and obtained some information about the substituent effect of the chelate ligand and the nature of iron(II) complex.

Experimental

Reagents. Thiazolylazo compounds were synthesized by the diazotization of 2-aminothiazole (or 2-amino-4-methylthiazole and 2-aminobenzothiazole) with nitrous acid and the subsequent coupling with phenols (or naphthols) at 0 °C.[4,16,17] Phenols used were resorcinol, 4-chlororesorcinol, orcinol, *m*-methoxyphenol, *m*-dimethylaminophenol, *p*-methoxyphenol, *p*-chlorophenol, 2,4-dimethylphenol, and pyrocatechol; naphthols were 2-naphthol and 2-naphthol-3,6-disulfonic acid. The products were purified by repeated crystallization with ethanol or re-precipitation with dilute hydrochloric acid and were identified by elementary analyses. TAR, TAM, TAC, and TAN were commercially available and were used without further purification. The standard iron(II) solution was prepared by dissolving ammonium iron(II) sulfate hexahydrate in deionized distilled water. The solution was acidified to pH 1 by sulfuric acid and was standardized by permanganometry. A 0.05% TAM solution was prepared by dissolving the Dotite TAM in ethanol. A fresh 0.1% ascorbic acid solution was prepared every three days. All the other chemicals used were of guaranteed reagent quality.

Apparatus. A sample solution was prepared in a 50 cm^3 graduated centrifuge tube with a glass-stopper; the solution was shaken in an Iwaki-KM type reciprocating shaker. A Kubota K-80 type centrifuge with 5000 min^{-1}. was used for phase separation. A Hitachi-Horiba model M-5 pH meter equipped with a combined glass electrode was used for pH measurements. Absorption spectra and absorbance were measured with a Hitachi 124 recording spectrophotometer and a Hitachi-Perkin Elmer 139 spectrophotometer using 10-mm quartz cells.

Standard Procedure. Transfer the sample solution containing up to 20 μg of iron into a centrifuge tube. Add 1 cm^3 of 0.1% ascorbic acid and 2 cm^3 of 0.05% TAM solutions, and adjust the pH to 9.0 with 5 cm^3 of 1 mol dm^{-3} ammonia buffer solution. Dilute the solution to 20 cm^3 and shake it with 10 cm^3 of chloroform for 5 min. After centrifugal separation, transfer the extract into an absorption cell, and measure the absorbance at 760 nm against the reagent blank.

Results and Discussion

Complexing Properties of Thiazolylazo Compounds with Iron(II). Table 1 shows the complexing properties of (thiazolylazo)phenols and naphthols with iron(II). Thiazolylazo compounds react with iron(II) to form brownish complexes from the weakly acidic to the alkaline region, which have the characteristic absorption maxima beyond 700 nm. The compounds have the phenolic hydroxyl group in the *o*-position next to the azo group; TAPC, possessing this group in the *m*- and *p*-position, shows different absorption features. The bathochromic shift of these absorption maxima is promoted by the resonance effect of the substituent group in the *p*-position to the *o*-hydroxyl group for phenols and of the naphthalene ring for naphthols. TAR, TARCl, and TAM show higher molar absorptivities than TAC, TAMP, and TACl. The difference would come from the inductive and the resonance effects of the substituent in the *m*- and *p*-position to the *o*-hydroxyl group. The derivatives possessing resorcinol

TABLE 1. COMPLEXING PROPERTIES OF THIAZOLYLAZO COMPOUNDS WITH IRON(II)

Systematic name (abbreviation)	λ_{max} / nm	ε / $dm^3\ mol^{-1}\ cm^{-1}$	pH	Solvent
4-(2-Thiazolylazo)resorcinol (TAR)[5]	730	2.90×10^4	8.9—10.3	Water
4-(2-Thiazolylazo)-6-chlororesorcinol (TARCl)	740	2.90×10^4	9.2—10.5	Water
4-(4-Methyl-2-thiazolylazo)resorcinol (MeTAR)	737	2.45×10^4	9.0—10.0	Water
4-(2-Thiazolylazo)orcinol (TAO)	742	2.02×10^4	9.0	Water
2-(2-Thiazolylazo)-5-methoxyphenol (TAMR)	720	1.59×10^4	8.0— 9.0	Water

ring show higher molar absorptivities, but naphthols give lower ones. The effect of the substituent group in the thiazole ring is not so noticeable.

Absorption Spectra. The iron(II) complexes of thiazolylazo compounds usually have two or three absorption maxima. Fig. 1 shows the absorption spectra of 3d type metal–TAM complexes extracted into chloroform. The iron(II) complex has two maxima at 550 nm and 760 nm, while the other 3d type metal complexes have only one maximum near 550 nm. We could not observe any other metal–TAM complex which showed an absorption maximum over 700 nm, hence this maximum at 760 nm is thought to be the characteristic absorption for iron(II). It is not an easy matter to assign these characteristic absorption bands clearly. The configuration of iron(II) complex may differ from those of the other 3d type metal complexes, or thiazole sulfur atom might follow the peculiar behavior on the complexation. But there is some evidence that TAN forms an octahedrally configurated inner complex with iron(II),[18] which is just the same as those of $[Ni^{II}(TAN)_2]$,[19] $[Zn^{II}(TAN)_2]$, and $[Co^{III}(TAN)_2]^+$,[20] and thiazole sulfur atoms never participate in the coordination. The iron(II)–TAN complex also shows the specific absorption at 786 nm in chloroform. Even if iron(II)–TAM complex would take the same configuration as those of the other 3d type metal complexes, its characteristic absorption is thought to be caused by the $t_{2g}\rightarrow\pi^*$ transition of the iron's 3d electrons.[21] As the TAM blank shows no absorption above 650 nm, one might expect the enhancement of the accuracy for the determination of iron.

Effect of pH. The effect of pH on the extraction of iron(II)–TAM complex was examined, as shown in Fig. 2. The extract shows a constant absorbance over the pH range from 8.2 to 10.0. A decrease of the absorbance in the acidic region is attributable to the incomplete formation of the iron(II)–TAM complex, owing to the protonation of the thiazole nitrogen atom.[4]

Choice of Buffering Agent. The iron complex is stable even in relatively higher concentration of ammonia solution, and a constant absorbance is obtained by adding from 2 to 10 cm^3 of 1 mol dm^{-3} ammonia buffer solution. The use of diethylbarbiturate and borax buffer reduces the absorbance, moreover, reproducible absorbances were not obtained. Taking into account the masking effect, 5 cm^3 of 1 mol dm^{-3} ammonia buffer solution was used.

Effect of TAM Concentration. A constant absorbance was obtained by adding from 0.4 to 5.0 cm^3 of 0.05% TAM solution for 15 μg of iron. Though 2 cm^3 of 0.05% TAM solution was used in practice, the amount corresponds 14.5 times excess to that of iron, calculating in molar ratio. If the consumption of TAM is noticeable owing to the coexistence of other metal ions in some sample, further addition of TAM may be allowed, because the absorbance of the reagent blank is negligible.

Effect of Reducing Agent. The iron(III)-TAM complex shows a weak color ($\varepsilon=1.30\times10^3$ at 760 nm); the rate of complexation reaction is slow. But the reaction of iron(II) with TAM is completed almost in a moment, so it is necessary to fix the oxidation number of iron to iron(II). The effect of addition of ascorbic acid and hydroxylamine hydrochloride was examined, but no significant differences were found. In this work, ascorbic acid was used and a constant absorbance was obtained by adding from 1 to 10 cm^3 of 0.1% ascorbic acid. As ascorbic acid forms a 2 : 1 complex with iron(II),[22] it may act as an assistant chelating agent as well as a reducing agent.

Organic Solvent. The chelate was effectively extracted into such hydrocarbons as carbon disulfide ($\varepsilon=2.75\times10^4$, 779 nm), dichloromethane, 1,2-dichloroethane, trichloroethylene, and aromatic hydrocarbons such as benzene (2.72×10^4, 769 nm), toluene, xylene (2.37×10^4, 769 nm), and chlorobenzene. The other ketones and esters show low absorbance, as compared with chloroform, and MIBK destroys the chelate during the extraction. Chloroform was used in practice, because of its fine phase separation and ease of use.

Composition of Iron(II)-TAM Complex. The result obtained by the continuous variation method is shown in Fig. 3; from this it can be confirmed that iron(II) forms a 1 : 2 complex with TAM. As thiazolylazo derivatives generally act as tridentate ligands,[23] this complex will be an inner complex of the six-coordinate octahedral type,[18] and supplementary ligands such as hydroxyl group, ascorbic acid and ammonia would not part icipate in the complex system.

Extraction Equilibrium of Iron(II)-TAM Complex. When $pK_2(8.65)>pH>pK_1(3.13)$,[24] most of the TAM is present in chloroform, and the iron(II) complex formed is also readily extracted into the organic phase. If auxiliary ligands would not participate in the chelate, the following extraction equilibrium can be considered:

$$M + 2HR_{(o)} \rightleftarrows MR_{2(o)}\,2H^+,\quad K_{ex}=\frac{[MR_2]_o[H^+]^2}{[M][HR]_o^2},\quad (1)$$

where M, R, and K_{ex} denote the iron ion, TAM, and the extraction constant, respectively, and the subscript o refers to the organic phase. From Eqs. 1 and 2 can be derived:

$$\log K'_{ex}=\log\frac{[MR_2]_o}{[M][HR]_o^2}=\log K_{ex}+2pH. \quad (2)$$

The value of $\log K'_{ex}$ can be calculated by the measurement of the absorbance. The results are shown in Fig. 4. The plots of $\log K'_{ex}$ against pH show a good linearity, and the slope is 2.0, which indicates that Eqs. 1 and 2 are reasonable. The calculated value of $\log K_{ex}$ is -4.20 ± 0.04. The extractabilities of 3d type metal complexes of TAM were also examined, and the order of the half extraction pH was Cu(4.8)<Ni(5.3)<Fe(5.5)<Co(6.4)<Zn(7.5). Nickel, cobalt, and zinc complexes showed smaller slopes than iron's. These facts indicate that auxiliary ligands may participate in the chelate systems or the rates of the complexation with TAM are slow except iron.

Calibration Curve. A calibration curve was made under the optimum conditions. The curve obeys Beer's law up to 20 μg of iron per 10 cm^3 of chloroform. The optimum concentration range for the accurate determination of iron evaluated by Ringbom's method[25] is 0.3 to 1.2 ppm of iron, corresponding to absorbance values of 0.2 to 0.8 unit. The molar absorption coefficient and Sandell's sensitivity index for $\log I_0/I=0.001$ are 2.70×10^4 $dm^3\,mol^{-1}\,cm^{-1}$ and 2.07×10^{-3}

Kanazawa port	500	0.012(0.015)
Kanaiwa breakwater	500	0.026(0.028)

a) The values obtained by A.A.S. are shown in parentheses.

μg cm^{-2}, respectively, which is more sensitive than the most common reagents,[26] such as 1,10-phenanthroline, 4,7-dihydroxy-1,10-phenanthroline, 2,2′-bipyridine, 2,4,6-tri(2-pyridyl)-1,3,5-triazine, and 1-(2-pyridylazo)-2-naphthol. The variation coefficient of the absorbance for 1.50 ppm of iron is 0.67%; this was determined by ten measurements.

Effect of Diverse Ions. Thiazolylazo dyes generally give similar colored complexes, especially with some of transition metals. That is a disadvantage from the practical viewpoint. As the present method utilizes the specific absorption of iron(II)–TAM complex, the selectivity is significantly elevated. The effect of diverse ions are summarized in Table 2 for cations and in Table 3 for anions, where the tolerance limit is set to ±5% for iron recovery. Iron can be determined in the presence above 20 ppm each of 41 metal ions, where vanadium, bismuth, thorium, uranium, titanium, and zirconium, whose spectrophotometric determinations have already been developed, are tolerable even in large amounts. 3d type metals form colored complexes, but copper can be effectively masked by thiosemicarbazide and nickel, and cobalt by dimethylglyoxime. Since concentrations of these ions in most natural waters are usually low, their interferences are almost negligible. Among the anions tested, acetate, tartrate, thiourea, and citrate can also serve as masking agents.

Determination of Iron in River and Sea Waters. In order to apply the present method to natural waters, we determined iron first in synthetic sea waters.[27] Sea water usually contains 10 ppb order of iron.[28] So known amounts of iron were added to synthetic sea waters as shown in Table 4. The results show that the present method is applicable to sea waters within 3% errors. Table 5 shows the results of determinations in the Sai river from the upper stream to the down stream and in sea waters near river ports. These values agreed well with those obtained by atomic absorption spectrometry. For sea waters, the following procedure is recommended. Take an aliquot of sample solution which is filtered off immediately after sampling. Add 2 cm^3 of concd hydrochloric acid and concentrate the solution to 100 cm^3 on the water bath. Add 1 cm^3 of 0.1% ascorbic acid and 5 cm^3 of 10% sodium acetate solutions, and neutralize by ammonia solution. Transfer the solution into a 200 cm^3 separatory funnel, and determine iron according to the standard procedure. For river waters, filtrates were directly used without preconcentration.

Kinetics of Ligand Substitution Reactions in Trimalonatovanadium(III)

Yasuhisa IKEDA, Sumio SOYA, Hiroshi TOMIYASU, and Hiroshi FUKUTOMI*

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received April 22, 1981)

The kinetics of ligand substitution reactions in trimalonatovanadium(III), $V(mal)_3^{3-}$, with various multidentate ligands, malonate (MAL), ethylenediaminetetraacetate (EDTA), and nitrilotriacetate (NTA) have been studied. The rate constant of the malonate exchange in $V(mal)_3^{3-}$ was obtained from the NMR line-broadening method to be $k_{ex}=50\ s^{-1}$ at 70 °C. The rate of EDTA substitution depends on the entering EDTA species. The values of second order rate constants are $k_{21}=0.04\ M^{-1}\ s^{-1}$ (1 M=1 mol dm^{-3}) for H_2edta as an entering ligand and $k_{22}=0.25\ M^{-1}\ s^{-1}$ for H_3edta at 25 °C. The NTA substitution is reversible under the experimental conditions studied. The apparent rate constants of the forward and backward reactions are $k_3=1.3\times10^{-2}\ M^{-1}\ s^{-1}$ and $k_{-3}=2.0\times10^{-3}\ M^{-1}\ s^{-1}$ at pH 3.5 and 25 °C, respectively. The univalent H_2nta is found to be the only entering ligand.

In spite of numerous investigations on the kinetics of ligand substitutions of various transition metal complexes, sufficient data are not available on vanadium(III) complexes.[1-7] Among vanadium species, ligand substitution reactions have been most extensively studied for oxovanadium(IV)[8-16] and it has been found that the rates depend largely on the properties of entering ligands. Similar substitution processes can be expected for V(III) complexes by considering the electronic configurations of these complexes.

In the present paper, a detailed analysis of the kinetics of ligand substitution reactions for V(III) complexes will be presented for the following reactions.[17]

$$V(mal)_3^{3-} + MAL \rightleftarrows V(mal)_3^{3-} + MAL \quad (1)$$

$$V(mal)_3^{3-} + EDTA \longrightarrow V(edta)^- + 3MAL \quad (2)$$

$$V(mal)_3^{3-} + NTA \rightleftarrows V(nta)(mal)^{2-} + 2MAL \quad (3)$$

Experimental

Vanadium(III) perchlorate solutions were prepared by electrolytic reduction of VO^{2+} in 1.0 M $HClO_4$ at a mercury cathode under an atmosphere of nitrogen. The preparation of VO^{2+} perchlorate was described elsewhere,[11] The concentration of V(III) solutions was determined by titration with standard permanganate. Since V(III) perchlorate is very easily oxidized to VO^{2+}, the preparation of V(III) was carried out just before kinetic experiments. Reagent grade malonic acid (Wako Pure Chemical Ind. Ltd.) was recrystallized twice from distilled water and dried under reduced pressure. Sodium perchlerate was prepared as described earlier.[11] Analytical grade EDTA and NTA were used without further purification. The NMR measurements were carried out on a JEOL JNM-4H-100 spectrometer. The spectrophotometric and kinetic measurements for the EDTA and NTA substitution reactions were made by using a Shimadzu MPS-50 spectrophotometer. The pH was obtained by measurement with a Hitachi-Horiba Model F-7SS pH meter. The ionic strength was kept at 2.5 by the addition of $NaClO_4$ throughout the kinetic experiments.

Results and Discussion

Absorption Spectra of V(III) Complexes. The absorption spectra of various V(III) complexes, $V(H_2O)_6^{3+}$, $V(mal)_3^{3-}$, $V(nta)(mal)^{2-}$, and $V(edta)^-$, are shown in Fig. 1. The main absorption bands, which appear at about 420 and 590 nm for $V(H_2O)_6^{3+}$, are slightly shifted in $V(mal)_3^{3-}$. However, $V(mal)_3^{3-}$ has much larger extinction coefficients than $V(H_2O)_6^{3+}$ in both bands, so that the assignment of the bands to the aqua or malonato complexes can be made from the spectra. The spectra of $V(edta)^-$ and $V(nta)(mal)^{2-}$ are much different from those of $V(H_2O)_6^{3+}$ and $V(mal)_3^{3-}$. Therefore, the rates of ligand substitution between these complex species can be determined from the changes in absorbance.

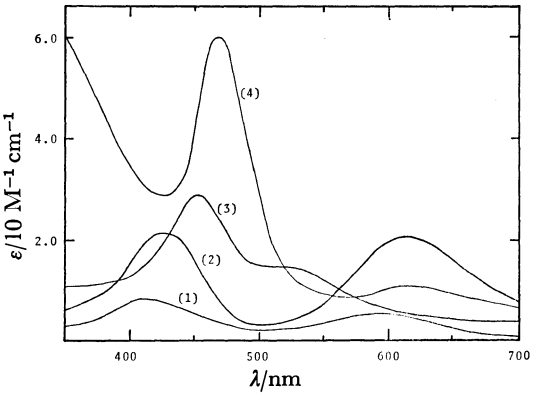

Fig. 1. Absorption spectra of various vanadium(III) complexes: (1): $V(H_2O)_6^{3+}$, (2): $V(mal)_3^{3-}$, (3): V-(edta)$^-$, (4): $V(nta)(mal)^{2-}$.

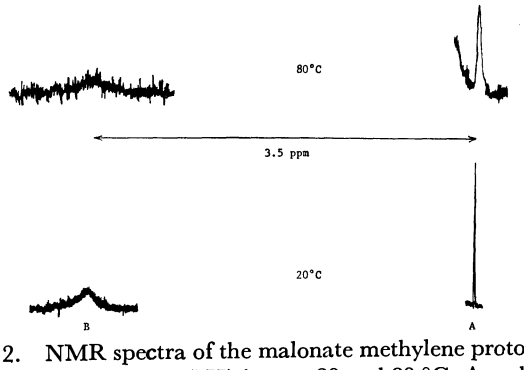

Fig. 2. NMR spectra of the malonate methylene protons in the presence of V(III) ions at 20 and 80 °C: A and B correspond to the methylene protons of bulk malonate and coordinated malonate, respectively.

NMR Measurements in $V(mal)_3^{3-}$ Solutions. The NMR measurements of the methylene protons of malonic acid were made in the presence of V(III) ions and two peaks of the malonate methylene protons were observed as shown in Fig. 2. The downfield and upfield signals are assigned to the coordinated malonate

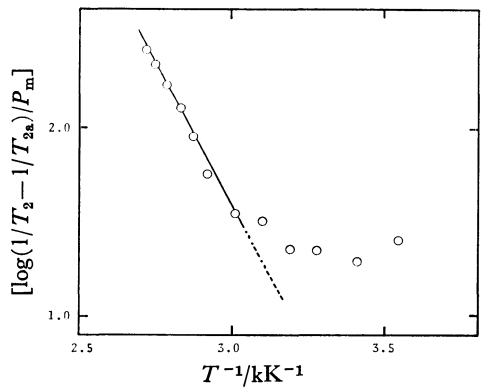

Fig. 3. A plot of $\log((1/T_2-1/T_{2a})/P_m)$ *vs.* $1/T$ for methylene protons of malonic acid in V(III) solution. [V(III)]=0.075 M, $[MAL]_T$=1.0 M, and pH=3.75.

and bulk malonate, respectively. The earlier work on ^{17}O NMR measurements of H_2O in the presence of $V(H_2O)_6^{3+}$ observed a similar splitting of the H_2O signal.[1)]

The signal of the coordinated malonate protons is broad at room temperature because of the direct interaction with the paramagnetic V(III) ion, while that of bulk malonate is very sharp. Figure 2 shows that these malonate signals become broad as the temperature increases above 80 °C. This suggests that the line widths are affected by a chemical exchange between bulk malonate and the coordinated malonate. In order to examine the line broadening in detail, the expression $\log(1/T_2-1/T_{2a})$, where T_2 is the transverse relaxation time of the bulk malonate protons in the presence of V(III) ion and T_{2a} is the transverse relaxation time in the absence of V(III) ion, was plotted against the reciprocal temperature as shown in Fig. 3. The plot gives a straight line with a negative slope. The deviation from the straight line in the region below 50 °C corresponds to the so-called region I.[18,19)] Therefore, it may be concluded that the relaxation process is controlled by a chemical exchange[18)] and the mean life-time of a ligand in the first coordination sphere of V(III) ion, τ_m, is expressed by the equation

$$1/T_2 - 1/T_{2a} = P_m/\tau_m, \quad (4)$$

where P_m is approximated by the Eq. 5 in a dilute solution.

$$P_m = n[\text{complex}]/[\text{total ligand}], \quad (5)$$

where n is the number of coordinated ligands and assumed to be 3 in the present case. The first order rate constants of the malonate exchange in $V(mal)_3^{3-}$, $k_{ex}=1/\tau_m$, are listed in Table 1 for a variety of pH values. Since the NMR measurements were carried out at high temperatures above 70 °C, it was very hard to maintain the V(III) solution and the instrument at constant condition. Consequently, the errors in k_{ex} values are estimated at approximately 20% and it is concluded that k_{ex} does not depend on pH within experimental errors. In the EDTA and NTA substitution reactions, which will be mentioned later, the rates were found to be first order with respect to entering ligands. Although the dependence of the exchange rate on malonate concentrations was not tested, it may be also expected for the malonate exchange that the rate is first order to entering malonate ion, which exists principally in the Hmal or mal form in solution. However, the concentration of Hmal is much larger than that of mal over the pH range studied so that Hmal should play an important role as an entering ligand. In addition, Hmal appears to be more reactive as an entering ligand compared with mal because it is favorable for coming close to the negatively charged complex ion, $V(mal)_3^{3-}$. The values of second order rate constant calculated from the expression, $k_1=k_{ex}/[Hmal]$, are listed in Table 1, which shows that k_1 changes only slightly with pH values. The activation parameters for the malonate exchange obtained from Fig. 3, are summarized in Table 6.

Substitution by EDTA. The substitution of the coordinated malonate by EDTA can be written by Eq. 2. The rate law which consists with the experimental results is expressed by the equation:

$$-d[V(mal)_3^{3-}]/dt = k_2[V(mal)_3^{3-}][EDTA]_T, \quad (6)$$

where $[EDTA]_T$ indicates the total concentartion of EDTA at $t=0$. The rate constant, k_2, was calculated by a least squares method. The values of k_2 obtained at various EDTA concentrations were constant within the experimental errors (Table 2). The pH dependence of k_2 is shown in Table 3 together with the apparent first order rate constant, k_{2f} defined by $k_{2f}=k_2[EDTA]_T$. Since H_3edta and H_2edta are major species in the pH region studied, two substitution processes by H_2edta (k_{21} path) and H_3edta (k_{22} path) are considered leading to the following rate equation:

$$R_2 = k_{21}[V(mal)_3^{3-}][H_2edta] + k_{22}[V(mal)_3^{3-}][H_3edta]. \quad (7)$$

Hence k_{2f} can be given by Eq. 8.

Table 1. Rate constants of the malonate exchange in $V(mal)_3^{3-}$ at 70 °C

pH	k_{ex} / s^{-1}	k_1 / $M^{-1}s^{-1}$
2.89	44	81
2.95	44	77
2.99	40	67
3.40	57	72
3.75	50	56
3.99	50	54

The concentrations of the MAL species were calculated by using the following pK values; $pK_1=5.78$ and $pK_2=2.82$.[22)]

Table 2. Values of second order rate constants of the EDTA substitution reaction at various EDTA concentrations

pH	$[EDTA]_T$ / M	k_2 / $M^{-1}s^{-1}$

[V(III)]=0.0127 M, $[EDTA]_T=2.8\times10^{-2}$ M, $[MAL]_T$ = 1.0 M at 25 °C. The concentrations of EDTA species were calculated by using the following pK values, pK_1= 10.26, pK_2=6.16, pK_3=2.67, pK_4=1.99.[23]

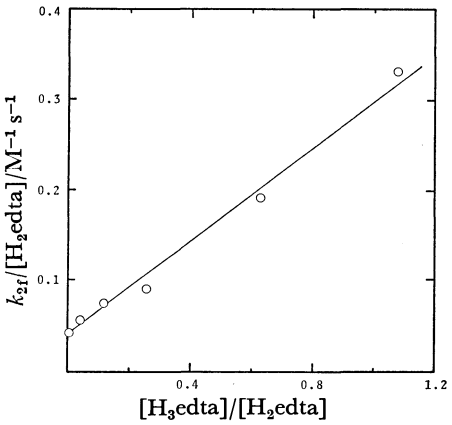

Fig. 4. A plot of $k_{2f}/[H_2edta]$ *vs.* $[H_3edta]/[H_2edta]$ in the substitution reaction of the coordinated malonate by EDTA.

$$k_{2f} = k_{21}[H_2edta] + k_{22}[H_3edta] \quad (8)$$

As shown in Fig. 4, the plot of $k_{2f}/[H_2edta]$ *vs.* $[H_3edta]/[H_2edta]$ is linear and it proves Eq. 8 to be valid. The intercept and the slope of the straight line yield k_{21}=0.04 $M^{-1}\,s^{-1}$ and k_{22}=0.25 $M^{-1}\,s^{-1}$, respectively. The activation parameters obtained from the measurements at temperatures ranging from 20 to 40 °C were summarized in Table 6.

Substitution by NTA. The substitution of the coordinated malonate by NTA can be described by Eq. 3. The V(nta)(mal)$^{2-}$ complex, though its structure is not known, seems to have an octahedral structure. The following explanation will give the stoichiometric evidence for Reaction 3.

Under the experimental conditions studied, Reaction 3 was reversible and the rate equation is

$$-d[V(mal)_3^{3-}]/dt = k_3[V(mal)_3^{3-}][NTA]_T - k_{-3}[V(nta)(mal)^{2-}][MAL]_T. \quad (9)$$

The values of the forward and backward rate constants, k_3 and k_{-3}, were calculated by the least squares method. A typical least squares fit to experimental data is shown in Fig. 5. The results are listed in Table 4 for a variety of $[NTA]_T$ and $[MAL]_T$ values. The pH dependence of the substitution rates is shown in Table 5.

At infinite time, $-d[V(mal)_3^{3-}]/dt=0$, which leads to

$$[V(nta)(mal)^{2-}][MAL]_T/([V(mal)_3^{3-}][NTA]_T) = k_3/k_{-3}. \quad (10)$$

On the other hand, the equilibrium constant, K, of the

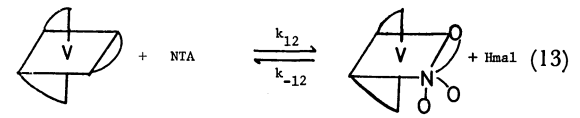
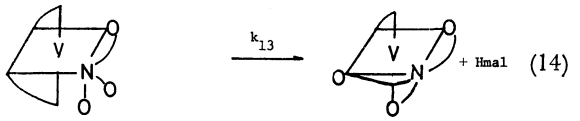
3.77	0.64	1.7	0.93
4.18	0.32	1.9	0.47

[V(III)]=0.00429 M, $[MAL]_T$=0.707 M, $[NTA]_T$=0.146 M, at 25 °C. The concentrations of the NTA species were calculated by using the following pK values; pK_1=9.73, pK_2=2.49, pK_3=1.89.[23]

is obtained from the slope in Fig. 6 to be 1.5×10^2 M. Hence it is confirmed that V(nta)(mal)$^{2-}$ is the most reasonable species for the product of the substitution of the coordinated malonate by NTA.

In comparison with the EDTA substitution reaction, the mechanism seems to be more complicated for the NTA substitution. A plot of k_{3f}/[Hnta] *vs.* [H_2nta]/[Hnta], where k_{3f} is the first order rate constant for Reaction 3, does not give a straight line, while the corresponding plot for the EDTA substitution was linear as shown in Fig. 4. Considering these results, we estimate the following substitution scheme for the NTA substitution. The initial step is a reversible substitution process between V(mal)$_3^{3-}$ (I) and the intermediate complex V(mal)$_2$(NTA) (II), whose charge can not be determined, followed by the chelation of NTA.





where NTA is supposed to be Hnta or H_2nta. In the intermediate complex (II), NTA, which is primarily a quadridentate ligand, coordinates to V(III) as a bidentate. Such a complex is presumed to be unstable compared with the complexes (I) and (III). On the basis of the above assumption, a steady state approximation for the complex (II) leads to the following rate law:

$$R_3 = k_{12}k_{13}[V(mal)_3^{3-}][NTA]/(k_{-12}[Hmal]+k_{13}). \quad (15)$$

The backward rate of Reaction 13 (k_{-12} path) is supposed to be as fast as that of Reaction 1, because both processes are the substitution of bidentate ligands by Hmal. Since the rate constant of the malonate exchange (1) is

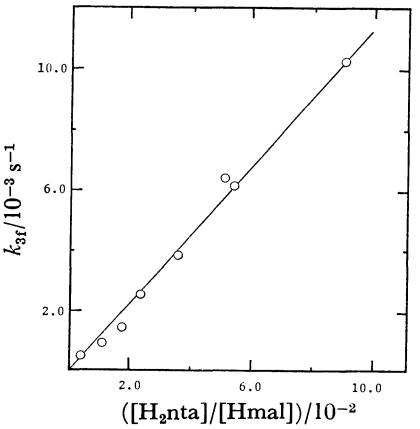


Fig. 7. A plot of k_{3f} *vs.* [H_2nta]/[Hmal] in the substitution reaction of the coordinated malonate by NTA.

Table 6. Activation parameters for the substitution reactions in V(mal)$_3^{3-}$

Reaction	$\Delta H^{\neq}$ / kJ mol^{-1}	$\Delta S^{\neq}$ / J mol^{-1} K^{-1}
Malonate exchange (Reaction 1)	54.8[a]	−50.2[a]
EDTA substitution (Reaction 2)	42.3±1.7	−119±5
NTA substitution (k_3 path in Reaction 3)	67.4±3.8	−44±13

a) The errors in these values are estimated at approximately 20%.

3.5 s^{-1} at 25 °C, which is about hundred times greater than that of the NTA substitution (3), it may be assumed that k_{-12}[Hmal] is relatively larger than k_{13}. If k_{-12}[Hmal]$\gg k_{13}$ is assumed, Eq. 15 becomes

$$R_3 = k_{12}k_{13}[V(mal)_3^{3-}][NTA]/k_{-12}[Hmal], \quad (16)$$

or

$$k_{3f} = k_{12}k_{13}[NTA]/k_{-12}[Hmal]. \quad (17)$$

The plot of k_{3f} as a function of [H_2nta]/[Hmal] is linear (Fig. 7) and this fact supports that the reaction mechanism described above is reasonable. It is also found that only H_2nta of NTA species acts as an entering ligand because the intercept in Fig. 7 is approximately zero. Recently, Tanaka *et al.* reported the existence and reactivity of the protonated species, H_4nta.[20] However, H_4nta will not play the important role, since the concentration of H_4nta (10^{-5}—10^{-7} M) is much lower than those of H_2nta and Hnta in the pH region studied.

The activation parameters were obtained from the measurements at temperatures ranging from 20 to 40 °C. The results were summarized in Table 6.

Conclusion

We conclude that the ligand substitution reactions in V(mal)$_3^{3-}$ proceed *via* an A mechanism.[21] These results are consistent with those of earlier studies.[2,3] Larger negative values of activation entropies as shown in Table 6 may support the A mechanism.

It is of particular interest that univalent anions are markedly reactive as the entering ligand in substitution

reactions compared with other multivalent ions. This is quite reasonable because a mutual repulsion between the univalent anion and trivalent complex anion, $V(mal)_3^{3-}$, is supposed to be much smaller than that between $V(mal)_3^{3-}$ and multivalent anions.

In the earlier study dealing with the malonate exchange in $VO(mal)_2^{2-}$, it was suggested that the reaction would proceed *via* acid catalysis,[12] where the second order rate constants for $VO(mal)_2^{2-}$ and $Hmal^-$ increased more than fivefold when pH changed from 2.30 to 4.05. From the present study, however, we conclude that the acid effect is very small or nearly negligible. In the case of the EDTA substitution reaction, it can not be determined whether the pH dependence of the rate constant is due to the acid catalysis or the concentration dependence of the entering ligand, if only H_2edta is assumed to be active as an entering ligand. However, such an assumption seems unlikely, because H_2edta should be more inactive than H_3edta to $V(mal)_3^{3-}$ owing to the electric repulsion. In fact, the linear relationship between the substitution rate and the hydrogen ion concentration was not obtained in the NTA substitution reaction. As shown in Table 1, the second order rate constant of the malonate exchange in $V(mal)_3^{3-}$ increases slightly with increasing hydrogen ion concentrations. However, it may be hard to conclude whether the exchange rate is slightly accelerated by acid or not, because unlike the malonate exchange reaction in $VO(mal)_2^{2-}$ the pH dependence of the rate constant is too small by considering large experimental errors in NMR measurements.

The authors wish to thank Professor Gilbert Gordon of Miami University for his helpful discussions.

Ternary α-Amino Acid-Palladium(II) Complexes with Ligand-Ligand Hydrogen Bonding

Akira ODANI and Osamu YAMAUCHI*

Faculty of Pharmaceutical Sciences, Kanazawa University, Takaramachi, Kanazawa 920

(Received May 1, 1981)

Histidinate(His)-containing ternary α-amino acid–palladium(II) complexes have been studied by synthetic and spectroscopic methods. The following complexes with imidazolate (im), L- and D-His, L-asparaginate (L-Asn), and L-glutaminate (L-Gln) have been isolated as crystals: $[Pd(im)_2]\cdot 0.5H_2O$; [Pd(L-His)(D-His)]·H_2O; [Pd(L-Asn)-(L-His)]·$2H_2O$; [Pd(L-Gln)(L-His)]·$2H_2O$. The ternary systems involving palladium(II), L-His, and an amino acid L-AA with an OH or a $CONH_2$ group (AA=Asn, Gln, serinate, threoninate, or homoserinate) exhibit absorption maxima at 300—311 nm with ε 310—440 and negative and positive circular dichroism (CD) peaks at 307—328 nm and ≈300 nm, respectively. ^{13}C and ^1H NMR spectra gave the amounts of the *cis* and *trans* isomers of Pd(His)-(AA) in solution and confirmed that Pd(His)(AA) has an N_3O donor set in the coordination plane. Whereas the CD magnitude additivity holds for the ternary systems Pd(L-His)(B) with B=glycinate, L-alaninate, or L-valinate and the systems with L-histidine methyl ester (L-HisOMe) and L-AA, Pd(L-HisOMe)(L-AA), the magnitudes for Pd(L-His)(L-AA) deviate significantly from those estimated on the basis of the additivity. The CD magnitude anomaly as well as the geometrical and rotational isomer populations calculated from the ^1H NMR spectra establishes the existence of the ligand-ligand interaction between the carboxylato group of His and the hydroxyl or amido group of AA in solution.

With the recognition of the importance of non-covalent interactions in biological processes,[1] weak intramolecular interactions between coordinated ligands have recently attracted considerable attention. Intramolecular aromatic ring stacking between 2,2′-bipyridine, 1,10-phenanthroline, or tryptophan and the base moiety of nucleosides or nucleotides in the ternary complexes of copper(II), zinc(II), *etc.* has been detected in solution[2–9] and revealed by X-ray analysis of a crystalline copper(II) complex.[10] Electrostatic ligand-ligand interactions in the ternary α-amino acid–copper-(II) complexes have received substantial experimental support,[11–14] and the recent NMR spectroscopic study provides conclusive evidence for their existence in the corresponding palladium(II) complexes.[15] On the other hand, histidinate(His)-containing ternary amino acid–copper(II) complexes with asparaginate (Asn), glutaminate (Gln), citrullinate, serinate (Ser), homoserinate (Hmser), or threoninate (Thr) (abbreviated as AA hereafter) have been inferred to involve hydrogen bonding between the carboxylato group of His and the polar side group of AA.[16] Preferential crystallization of Cu(L-Asn)(L-His) from the solution containing Cu(II), L-Asn, and DL-His in the ratio of 1 : 1 : 1.5 has led to nearly complete optical resolution of histidine,[16,17] which is in support of the stereoselectivity due to the interaction. The molecular structures of [Cu(L-Asn)(L-His)(H_2O)]·$3H_2O$ and [Cu(L-Asn)(L-His)] disclosed by X-ray analysis[18] exhibit difference in the side chain conformation of L-Asn, indicating the side chain flexibility and its accessibility to the histidine carboxylato group axially coordinated to copper(II). Probably because hydrogen bonds are too weak in aqueous solution to affect the stability constants, however, analysis of the solution equilibria in water[16] and in 20% dioxane–water[19] failed to show any effects of the bonding.

As an extention of the studies on copper(II) complexes, we now carried out synthetic and spectroscopic investigations of the corresponding histidinate- and cysteate-($CySO_3H$)-containing ternary palladium(II) systems in order to obtain convincing information on the ligand-ligand interaction in the ternary systems Pd(His)(AA) in solution.

Experimental

Materials. DL-Histidine methyl ester dihydrochloride was prepared according to the literature.[20] L-1-Methylhistidine, L-histidine methyl ester dihydrochloride, and D- and DL-histidine hydrochloride were purchased from Sigma. All the other amino acids were obtained from Nakarai. Disodium hexachloropalladate(II) and palladium(II) chloride were from Mitsuwa and Kishida, respectively. The deuterated solvents, D_2O, CD_3OD, and DCl in D_2O were obtained from Merck. The chemicals used were of highest grade available.

Syntheses. *[Pd(L-His)(D-His)]·H_2O*: To a solution of palladium(II) chloride (0.36 g, 2.0 mmol) in 2 M HCl (2 ml; 1 M=1 mol dm^{-3}) was added an aqueous solution of DL-histidine hydrochloride (0.84 g, 4.0 mmol), and the pH of the mixture was adjusted at 6—7 with aqueous NaOH. Colorless crystals were collected and recrystallized from water. Found: C, 33.16; H, 4.23; N, 19.97%. Calcd for $C_{12}H_{16}N_6O_4Pd\cdot H_2O$: C, 33.31; H, 4.19; N, 19.42%.

[Pd(im)$_2$]·0.5H_2O: An aqueous solution of imidazole (0.27 g, 4.0 mmol) was added to a solution of palladium(II) chloride (0.36 g, 2.0 mmol) in 2 M HCl (2 ml). The pH of the resulting mixture was adjusted at ≈7 with aqueous NaOH, when almost colorless crystals separated. Found: C, 28.64; H, 2.77; N, 22.15%. Calcd for $C_6H_6N_4Pd\cdot 0.5H_2O$: C, 28.88; H, 2.83; N, 22.45%.

[Pd(L-Gln)(L-His)]·2H_2O: Palladium(II) chloride (0.36 g 2.0 mmol) in 2 M HCl (2 ml) was mixed with aqueous solutions of L-histidine hydrochloride (0.42 g, 2.0 mmol) and L-glutamine (0.59 g, 4.0 mmol), and the pH of the resulting solution was adjusted at 5—6 with aqueous NaOH. The solution was then concentrated *in vacuo* to a small volume at room temperature and kept in a refrigerator for a few days to give yellowish crystals after removal of slightly soluble Pd(L-Gln)$_2$. Found: C, 29.46; H, 4.65; N, 15.85%. Calcd for $C_{11}H_{17}N_5O_5Pd\cdot 2H_2O$: C, 29.91; H, 4.79; N, 15.85%.

[Pd(L-Asn)(L-His)]·2H_2O: The complex was prepared in the manner described for Pd(L-Gln)(L-His). Found: C,

28.62; H, 4.09; N, 16.65%. Calcd for $C_{10}H_{15}N_5O_5Pd \cdot 2H_2O$: C, 28.08; H, 4.48; N, 16.37%.

Instruments. Absorption spectra were recorded in the range 230—430 nm on a Union Giken SM-401 high sensitivity recording spectrophotometer. CD spectra were measured in the range 260—420 nm with a JASCO MOE-1 spectropolarimeter. ^1H NMR spectra at 90 MHz were obtained at 34 °C with a Hitachi R-22 NMR spectrometer equipped with a Hitachi A 1600A signal averaging analyzer internally locked and a Hitachi R-900 Fourier transform NMR spectrometer (90 MHz). ^{13}C NMR spectra at 22.63 MHz were recorded at 34 °C on a Hitachi R-900 Fourier transform spectrometer with D-lock and digital resolution of 0.02 ppm. The probe temperature was measured with a thermocouple.

Spectral Measurements. Absorption and CD Spectra: Absorption and CD spectra were measured at room temperature for the systems involving Pd(II), His, and AA in the ratio of 1 : 1 : 1 at pH 6.5—7.0 at a Pd(II) concentration of 1×10^{-3}—2×10^{-3} M. The samples were prepared from disodium tetrachloropalladate(II) freshly dissolved in water and 0.02 M aqueous solutions of amino acids, the pH values being adjusted with aqueous NaOH (0.05 M) and hydrochloric acid (0.01 M).

NMR Spectra. The samples were prepared in deuterated solvents (pD 5—7) in the manner described above. The palladium(II) concentrations were *ca.* 0.04—0.2 M for ^1H and 0.1—1.0 M for ^{13}C NMR spectral measurements. All carbon chemical shifts were measured relative to dioxane as an internal reference.

Results

Syntheses. Isolation of the crystalline binary copper(II) complex of L-histidine has been a challenge to a number of investigators, and only the *meso* complex, Cu(L-His)(D-His), has been successfully crystallized and analyzed crystallographically.[21] With palladium(II), the corresponding *meso* complex was obtained as crystals, whereas the active complex was obtained as a gelatinous precipitate just as the platinum(II) complex.[22] As regards the ternary complexes, only Pd(L-Asn)(L-His) and Pd(L-Gln)(L-His) were isolated as crystals by using Pd(II), His, and AA in the ratio of 1 : 1 : 2. The ternary complexes with Ser, Thr, and Hmser could not be obtained as analytically pure crystals probably owing to contamination with the binary complexes $Pd(AA)_2$, and are in contrast with the corresponding copper(II) complexes which have been isolated as crystals in previous studies.[16,17]

Spectral Properties. Absorption and CD Spectra: At neutral pH the ternary systems Pd(L-His)(L-AA) exhibit an absorption band centered at 300—311 nm with ε 310—440, whose pattern appears to involve a shoulder and a peak ascribable to $Pd(L\text{-}His)_2$ and $Pd(L\text{-}AA)_2$, respectively (Table 1). The CD spectra of the Pd(L-His)(L-AA) systems have a negative maximum at 307—328 nm with a positive shoulder at $\approx$300 nm and sometimes a weak positive peak at $\approx$380 nm. In the absence of ligand-ligand interactions within complex molecules, the CD magnitude additivity has been shown to hold for the copper(II) and palladium(II) complexes with two amino acids[11,12,15] or a peptide with two or three amino acid residues,[23,24] where the magnitudes, $\Delta\varepsilon_{calcd}$, can be estimated by summing up the experimental magnitude assigned to each molecule or residue of the amino acids constituting the systems. Thus, for ternary palladium(II) systems with amino acids L-A and L-B devoid of interacting side groups, Pd(L-A)(L-B), $\Delta\varepsilon_{calcd}$ given by Eq. 1 corresponds well with the observed value:[15]

$$\Delta\varepsilon_{calcd} = \frac{1}{2}(\Delta\varepsilon_{Pd(L\text{-}A)_2} + \Delta\varepsilon_{Pd(L\text{-}B)_2}), \quad (1)$$

where $\Delta\varepsilon_{Pd(L\text{-}A)_2}$ and $\Delta\varepsilon_{Pd(L\text{-}B)_2}$ refer to the magnitudes exhibited by the binary complexes $Pd(L\text{-}A)_2$ and $Pd(L\text{-}B)_2$, respectively. Because the ligand fields are supposedly different in the histidinate-containing systems from those of the systems with the other amino acids owing to the imidazole ring, we used Eq. 2 for Pd(L-His)(L-AA):

$$\Delta\varepsilon_{calcd} = \Delta\varepsilon_{Pd(DL\text{-}His)(L\text{-}AA)} + \Delta\varepsilon_{Pd(L\text{-}His)(DL\text{-}AA)}. \quad (2)$$

The estimated values given by Eq. 2 are in good agreement with the experimental ones for the systems with glycinate (Gly), L-alaninate (L-Ala), or L-valinate (L-Val) in place of L-AA (Table 1). On the other hand, polar side chains of Ser, Thr, Hmser, Asn, and Gln affect the magnitudes, decreasing the relative magnitudes $\Delta\varepsilon/\Delta\varepsilon_{calcd}$. This is reminiscent of the magnitude anomaly due to the electrostatic ligand-ligand interaction in the ternary copper(II) and palladium(II) systems with an acidic and a protonated basic amino acid and related systems,[11-13,15] and serves as an indication

Table 1. Absorption and CD spectral data for L-His-containing ternary systems

System	pH	Absorption spectrum		CD spectrum		Relative magnitude[a]
		λ_{max} / nm	ε	λ_{max} / nm	$\Delta\varepsilon$	$\Delta\varepsilon/\Delta\varepsilon_{calcd}$
Pd(L-His)(Gly)	7.1	305	310	328	−0.15	1.00
Pd(L-His)(L-Ala)	7.1	311	380	324	−0.10	0.93
Pd(L-His)(L-Val)	7.0	305	420	319	−0.47	0.96
Pd(L-His)(L-Ser)	6.9	305	410	321	−0.11	0.58
Pd(L-His)(L-Thr)	7.1	306	400	315	−0.29	0.90
Pd(L-His)(L-Hmser)	7.1	305	430	323	−0.10	0.64
Pd(L-His)(L-Asn)	6.8	300	400	307	−0.12	0.64
Pd(L-His)(L-Gln)	7.0	305	430	325	−0.15	0.74

a) Calculated according to Eq. 2. The $\Delta\varepsilon$ values were measured at λ_{max} of Pd(L-His)(L-AA).

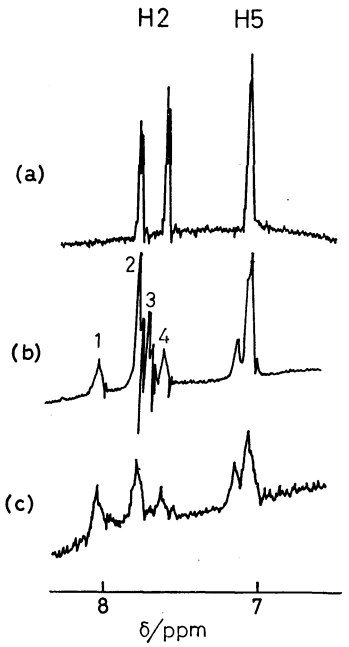

Fig. 1. ^{1}H NMR spectra of the imidazole moiety at pD 5.0 in the systems Pd(L-His)$_2$ (a), Pd(Dmgly)(L-His) (b), and Pd(Gly)(L-His) (c). The numbered signals in (b) correspond to *cis*-Pd(Gly)(L-His) (1), *cis*-Pd(L-His)$_2$ (2), *trans*-Pd(Gly)(L-His) (3), and *trans*-Pd(L-His)$_2$ (4), the geometry referring to the amino groups.

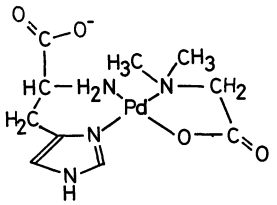

Fig. 2. Preferred coordination structure of Pd(Dmgly)-(L-His).

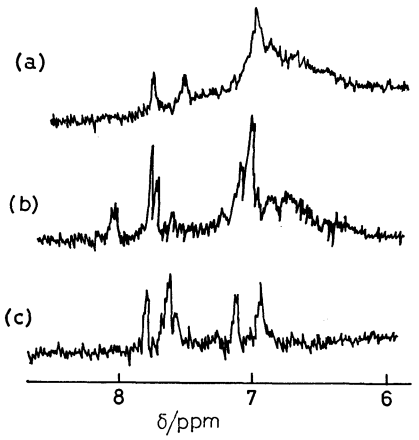

Fig. 3. ^{1}H NMR spectra of the imidazole moiety at pD >7 in the systems 1 : 1.33 Pd(II)-L-His (a), Pd(L-Ala)(L-His) (b), and Pd(L-Ala)(L-1-methylhistidinate) (c).

of side chain interactions between the carboxylato group of L-His and the hydroxyl or amido group of L-AA in the present cases.

NMR Spectra: The signal assignments were made on the basis of the substituent effects, the peak areas, and the chemical shifts observed for the amino acids in the absence of palladium(II).[25] The ^{1}H NMR spectra of Pd(L-His)$_2$ and Pd(Histam)$_2$ (Histam=histamine) show two separate peaks of the C^2 proton of the imidazole nucleus (Fig. 1). The signals exhibit splittings due to coupling with the C^5 proton. Since the imidazolyl groups contained in *cis*-Pt(L-His)$_2$[22] and *cis*-Pd(imH)$_2$Cl$_2$[26] (imH=imidazole) have been reported to give the corresponding peaks at lower fields than those observed for the *trans* forms, the signals at lower fields for Pd(L-His)$_2$ and Pd(Histam)$_2$ are also assigned to the *cis* isomers. In this connection, the spectrum of the ternary system containing *N,N*-dimethylglycinate (Dmgly), Pd(Dmgly)(L-His), shows only the lower field peak of the imidazole moiety in contrast to the two peaks in Pd(Gly)(L-His) (Fig. 1). The difference is probably attributed to the steric repulsion between the C^2 proton and the methyl groups in Pd(Dmgly)(L-His) and may thus point to the structure involving a *cis* arrangement with respect to the amine nitrogens (Fig. 2). Binary complexes of amino acids with the glycinate-like coordination exhibit spectra apparently due to single 1 : 2 species, indicating that the interconversion between geometrical isomers is fast as compared with the NMR time scale. The ternary systems with L-Ala, on the other hand, have four peaks of the C^2 proton, and those which are unaffected by the presence of L-AA can be assigned to *cis*- and *trans*-Pd(L-His)$_2$ involved in the system Pd(L-His)(L-AA) in solution.

At the Pd(II)/L-His ratios of >0.5 at pD 7.0, the binary system gives additional broad peaks at δ 6—8, which are also detected in the spectra of the ternary systems at pD>7 (Fig. 3). Since the ternary system involving L-1-methylhistidinate and L-Ala does not show such broad peaks, they may be associated with the coordination to palladium(II) of the deprotonated pyrrole nitrogen of His, such as is observed with Pd(im)$_2$ where both imidazole nitrogens are coordinated.

The ^{13}C chemical shift differences between free and coordinated amino acids at constant pD, shown in Table 2, reveal that coordination to Pd(II) causes downfield shifts of 11 ppm at the carbonyl carbon of L-Ala and L-Thr and 3 ppm at that of L-His. The imidazole moiety suffers larger irregular shifts indicative of its coordination. The ^{1}H NMR spectral pattern exhibited by the methyl group of L-Ala in Pd(L- or D-His)(L-Ala) corresponds well with that in Pd(Histam)-(L-Ala), while the patterns of all the protons of L-Hmser undergo changes on going from Pd(Histam)(L-Hmser) to Pd(L-His)(L-Hmser) and Pd(D-His)(L-Hmser), suggesting the side chain conformational changes of L-Hmser (Fig. 4). Glutamate involved in place of His in the ternary systems show different patterns of the β- and γ-CH$_2$ groups; Glu in the system Pd(D-Glu)(L-Thr) suffers considerable spectral changes while that in Pd(L-Glu)(L-Thr) shows patterns which are slightly different from those of Pd(L-Glu)$_2$ and Pd(L-Glu)-(L-Ala).

Discussion

Palladium(II)–Amino Acid Bonding Modes. The

TABLE 2. ^{13}C COMPLEX SHIFTS OF BINARY AND TERNARY SYSTEMS[a]

System	Assignment[b]	Complex shifts/ppm									
		L-His[c]						L-Ala or L-Thr			
		C=O	α-C	β-C	C^2	C^4	C^5	C=O	α-C	β-C	CH_3
Pd(L-His)$_2$	*cis*	3.3	−1.1	4.1	2.4	5.2	−3.5

a) In ppm downfield at pD 5.0. Complex shifts are defined as the chemical shift differences between the complexed and free amino acids. b) Complex shifts of the peaks assigned to *cis* and *trans* isomers in the system Pd(L-His)$_2$. c) The carbons C^2, C^4, and C^5 refer to those of the imidazole nucleus.

TABLE 3. ABSORPTION AND CD SPECTRAL DATA FOR L-HisOMe-CONTAINING TERNARY SYSTEMS

System	pH	Absorption spectrum		CD spectrum		Relative magnitude[a] $\Delta\varepsilon/\Delta\varepsilon_{calcd}$
		λ_{max}/nm	ε	λ_{max}/nm	$\Delta\varepsilon$	
Pd(L-HisOMe)(L-Ala)	6.7	304	340	345	−0.042	1.00
Pd(L-HisOMe)(L-Val)	5.0	306	320	324	−0.31	0.98
Pd(L-HisOMe)(L-Ser)	6.9	305	360	343	−0.003	1.0
Pd(L-HisOMe)(L-Thr)	6.7	305	360	371	0.030	1.00
Pd(L-HisOMe)(L-Hmser)	7.0	304	370	339	−0.042	1.00
Pd(L-HisOMe)(L-Gln)	7.0	304	370	336	−0.084	1.04

a) $\Delta\varepsilon_{calcd}=\Delta\varepsilon_{Pd(L\text{-}HisOMe)(DL\text{-}AA)}+\Delta\varepsilon_{Pd(DL\text{-}HisOMe)(L\text{-}AA)}$. The values were measured at λ_{max} of Pd(L-HisOMe)(L-AA).

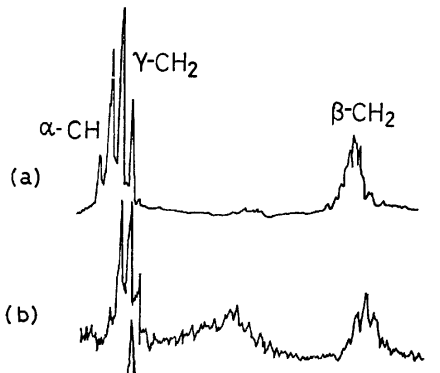

Fig. 4. ^1H NMR signal patterns of homoserinate at pD 7.0 in the systems Pd(Histam)(L-Hmser) (a), Pd(L-His)-(L-Hmser) (b), and Pd(D-His)(L-Hmser) (c).

^{13}C NMR complex shifts found in the Pd(L-His)$_2$ system indicate that His coordinates to palladium(II) through the amine and imidazole nitrogens, while the glycinate-like coordination in Pd(L-AA)$_2$ is confirmed by the absorption and CD spectra[23] as well as the ^{13}C complex shifts (Table 2).[15] The spectral data also show that the ternary complexes, Pd(His)(AA), have an N_3O donor set that corresponds with the set in Cu(L-His)-(L-Thr)[27] and Cu(L-Asn)(L-His)[18] disclosed by X-ray analysis. In solution the geometrical isomers of Pd(His)$_2$ and Pd(Histam)$_2$ exist in approximately the same amounts, and this suggests that the two imidazole rings in the *cis* isomers are slightly distorted from the coordination plane in analogy with the arrangements in *trans*-Pd(Histam)$_2$Cl$_2$[28] and *trans*-Cu(L-His)(D-His),[21] since the steric repulsion between the C^2 protons of the two imidazoles in the *cis* position should otherwise be considerable and tend to favor the *trans* isomers greatly.

Intramolecular Hydrogen Bonding in Ternary Complexes. His-containing Systems: Ligand-ligand interactions between the side chains in ternary copper(II) and palladium(II) complexes have been found to give rise to CD magnitude anomaly in the d-d region due to increased asymmetry.[11-13,15] The L-His-containing ternary palladium(II) complexes with L-AA (AA=Ser, Thr, Hmser, Asn, or Gln) exhibit this anomaly in the $d_{xy}\rightarrow d_{x^2-y^2}$ transition,[15] which is considered to indicate the structural changes in the xy-plane. Direct evidence establishing that the carboxylato group of His is essential for the CD magnitude anomaly is provided by the CD spectra of the systems containing L-histidine methyl ester (L-HisOMe) instead of L-His, Pd(L-HisOMe)-(L-AA), where participation of the carboxylato group in the ligand-ligand interaction is blocked by esterification and as a consequence the relative magnitudes are expectedly close to unity (Table 3). Whereas the signals due to the methyl group of L-Ala in Pd(L-Ala)-(L- or D-His) remain the same as in Pd(L-Ala)(Histam), the presence of the carboxylato group of His in the ternary systems Pd(L-Gln)(L- or D-His) and Pd(L- or D-His)(L-Hmser) affects the ^1H NMR spectral patterns of L-Gln and L-Hmser, respectively. This implies the conformational changes of the amino acid side chains and possibly the effects of the ligand-ligand interaction

Table 4. Fractions of *cis*-isomers in ternary systems[a]

System	Temp °C	$r_{L\text{-His}}$[b]	$r_{L\text{-His}}$[c]	$\frac{r_{L\text{-His}}}{r_{D\text{-His}}}$
1 : 1 : 1 Pd(II)–His–L-Ala	34	0.33	0.35	0.9
1 : 1 : 2 Pd(II)–His–L-Ala	34	0.35	0.34	1.0
1 : 1 : 1 Pd(II)–His–L-Thr	34	0.18	0.13	1.4
1 : 1 : 2 Pd(II)–His–L-Thr	34	0.24	0.16	1.5
1 : 1 : 2 Pd(II)–His–L-Ala	8	0.33	0.32	1.0
1 : 1 : 2 Pd(II)–His–L-Thr	8	0.20	0.16	1.3
1 : 1 : 1 Pd(II)–His–L-Gln	8	0.40	0.24	1.7

a) The fraction is defined as the ratio of the *cis* isomer to the total isomers in the system. b) The fractions for the L-Hi-scontaining systems. c) The fractions for the D-His-containing systems.

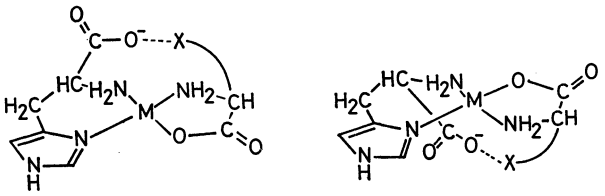

Fig. 5. Geometrical isomers expected from steric requirements for ligand-ligand interactions.

on the species distribution in the ternary systems. That such an interaction is intramolecular rather than intermolecular is reasonably deduced from the fact that the NMR spectral patterns and relative CD magnitudes are indifferent to concentrations of the samples.

The side chain interaction should also affect the distribution of geometrical isomers in the ternary systems as estimated from the peak areas of the C^2 proton signals of the imidazole moiety assigned to each isomer. Table 4 shows that, although the fractions of the *cis* isomers $r_{L\text{-His}}$ and $r_{D\text{-His}}$ in Pd(L-Ala)(L-His) and Pd(L-Ala)(D-His), respectively, are almost identical, those in Pd(L-His)(L-AA) and Pd(D-His)(L-AA) (AA= Thr or Gln) slightly differ from each other, the difference

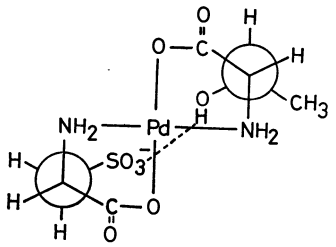

Fig. 6. Conformations of α-amino acids in Pd(L-$CySO_3H$)(L-Thr) with a ligand-ligand interaction.

being more clearly seen from the ratios of *cis* isomer contents in both systems. As shown previously for copper(II) complexes, the intramolecular ligand-ligand interaction requires *cis* arrangements of the NH_2 groups in Pd(L-His)(L-AA) and *trans* arrangements in Pd(D-His)(L-AA) (Fig. 5). In the palladium(II) systems investigated, the *cis* isomer contents in Pd(L-His)(L-AA) are greater than those in Pd(D-His)(L-AA), but the isomers that do not allow the ligand-ligand interaction still predominate, indicating that the stabilization due to the interaction is minimal in aqueous media.

Cysteate-containing Systems: The conformation of a coordinated α-amino acid is represented by the weighted average of three staggered rotational isomers, whose populations can be estimated by using the coupling constants between the protons on the α- and β-carbons and the constants for *trans* and vicinal couplings evaluated for α-amino acids by Pachler[30] and Martin.[31] The ligand-ligand interaction expected between the side chains of L-cysteate, which offers an SO_3^- group instead of the COO^- group of His, and L-Thr in Pd(L-$CySO_3H$)(L-Thr) requires that each amino acid assumes the conformation depicted in Fig. 6. In this connection, we reported in a previous communication[32] that the fractional population of L-$CySO_3H$ assuming the conformation shown in Fig. 6 increases with temperature decrease in 50% CD_3OD, which was taken as evidence for the presence of the hydrogen bond-type ligand-ligand interaction in solution. The abnormal CD magnitude of Pd(L-$CySO_3H$)(L-Thr) in 75% aqueous dioxane as compared with the magnitude of Pd(L-$CySO_3H$)(L-Ala) is also in line with the above conclu-

Table 5. Absorption and CD spectral data for L-$CySO_3H$-containing ternary systems

System	Solvent	pH	Absorption spectrum λ_{max} nm	Absorption spectrum ε	CD spectrum λ_{max} nm	CD spectrum $\Delta\varepsilon$	Relative magnitude[a] $\Delta\varepsilon/\Delta\varepsilon_{calcd}$
Pd(L-$CySO_3H$)(L-Ala)	H_2O	6.6	304	330	344	0.32	0.99
					303	−0.76	0.99
	75% aq dioxane	8.2			347	0.33	0.96
					307	−0.65	0.99
Pd(L-$CySO_3H$)(L-Thr)	H_2O	6.4	319	320	353	0.37	0.94
					311	−1.45	1.00
	75% aq dioxane	7.9			353	0.40	0.87
					309	−1.32	0.96
Pd(L-Ala)(L-Thr)	75% aq dioxane	7.7			353	0.34	1.06
					310	−0.88	1.03

a) $\Delta\varepsilon_{calcd}=1/2(\Delta\varepsilon_{Pd(L\text{-}CySO_3H)_2}+\Delta\varepsilon_{Pd(L\text{-}AA)_2})$. The $\Delta\varepsilon$ values were measured at λ_{max} of Pd(L-$CySO_3H$)(L-AA).

sion (Table 5). The system involving L-lysinate (L-Lys) in place of L-Thr exhibits greater deviation from the CD magnitude additivity and greater increase with temperature decrease of the population of the rotamer of L-$CySO_3H$ shown in Fig. 6,[15] demonstrating that the electrostatic interaction between the ε-NH_3^+ group of L-Lys and the SO_3^- group of L-$CySO_3H$ is more effective than the hydrogen bonding. Involvement of the negatively charged group in the interaction is further supported by the ^1H NMR signal pattern of Glu in Pd(L- or D-Glu)(L-Thr).

Comparison with the Copper(II) Systems. On the basis of synthetic and spectroscopic studies, histidinate-containing ternary copper(II) systems with AA have been inferred to involve an intramolecular hydrogen bond around the central copper(II) ion.[16] Since both copper(II) and palladium(II) form essentially planar complexes with α-amino acids except ornithinate in the same mode of coordination, the present conclusion on the ligand-ligand interaction in the palladium(II) complexes, reached from the CD and NMR studies, most probably holds for the corresponding copper(II) systems and substantiates our previous interpretation[16] of the preferential formation of Cu(L-His)(L-AA) (AA= Asn, Gln, and Thr) in human blood plasma.[33,34] The complex species Cu(L-His)(L-AA) should meet the requirement for copper(II) transport across biological membranes, because hydrogen bonding is more effective in such hydrophobic regions and may have a ligand-discriminating ability. The hydrogen bonded cyclic structure has been elucidated by X-ray analysis for the silver(I) and other metal complexes of an antibiotic monensin,[35] whose ring structures are best suited for the transport.

Interestingly, very recent X-ray structural analysis of [Cu(L-Ala)(L-His)(H_2O)]·$3H_2O$ shows that L-His coordinates to copper(II) through the amino and imidazole nitrogens with the carboxylato group axially bound to a neighboring copper(II).[36] This is in contrast with the modes of coordination found in Cu(L-His)(L-Thr)[27] and Cu(L-Asn)(L-His),[18] where the carboxylato group of His occupies an apical position within the same molecule. The difference in coordination has been attributed to slightly higher basicity of the carboxylato group of L-Ala as compared with that of L-Thr and of L-Asn and resulting lower electronegativity of copper(II).[36] Considering that the difference in the acid dissociation constants ($<$0.3 log unit) does not seem to be large enough to warrant such a structural difference, however, we are inclined to ascribe it to the absence of the intramolecular ligand-ligand interaction in Cu(L-Ala)(L-His).

We are grateful to Professor Yoshio Sasaki, Osaka University, for helpful comments and encouragement. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, to which our thanks are due.

(Received May 11, 1981)

The binary and ternary solubility phase diagrams of the racemic and optically active complexes, $[Co(val)(NH_3)_4]X_2$ and $[Co(leu)(NH_3)_4]X_2$ ($X=(1/2)SO_4^{2-}$, Cl^-, Br^-, and I^-), were determined in water. Spontaneous resolution was found for $[Co(DL\text{-}val)(NH_3)_4]X_2$ ($X=Cl^-$ and Br^-) at 5—55 °C and for $[Co(DL\text{-}leu)(NH_3)_4]SO_4$ at 30—55 °C, the latter of which has been shown to crystallize as both a racemic compound (below 30 °C) and a conglomerate (above 30 °C).

A variety of metal complexes containing racemic amino acid have been prepared, but in most of the cases it remains unknown whether the complex is a racemic mixture (conglomerate) or a racemic compound (double salt between enantiomers), because no solubility isotherm has been reported for the system of such amino acid complexes.

The present paper deals with the binary and ternary solubility diagrams of cobalt(III) complexes, $[Co(L\text{- or }DL\text{-val})(NH_3)_4]X_2$ and $[Co(L\text{- or }DL\text{-leu})(NH_3)_4]X_2$, where val and leu denote a valinate and a leucinate ligand, respectively, and X stands for a univalent anion of Cl^-, Br^-, I^-, or $(1/2)SO_4^{2-}$. The tetraammine type complexes have the only chirality based on that of amino acid.[1] In the case of spontaneous resolution of such a complex, optical resolution of amino acid is realized in each of crystals. Therefore, if an effective recovery route from the metal complex is established, this procedure will be applicable to optical resolution of amino acid. Few reports have been published for the utilization of metal chelate compounds for the optical resolution of racemic amino acids.[2]

Experimental

Materials. *$[Co(L\text{-}val)(NH_3)_4]SO_4\cdot H_2O$*: The complex was prepared from $[Co(H_2O)(NH_3)_5](ClO_4)_3$ and L-valine according to the method of Yasui *et al.*[3] and separated on a column of SP-Sephadex C-25 (Na^+ form) by elution of 0.15 mol dm^{-3} Na_2SO_4. The orange red eluate was evaporated to give the desired crystals, which were recrystallized from water at 50 °C. Found: C, 16.82; H, 6.76; N, 19.75%. Calcd for $[Co(L\text{-val})(NH_3)_4]SO_4\cdot H_2O=C_5H_{24}N_5O_7SCo$: C, 16.81; H, 6.77; N, 19.60%.

$[Co(DL\text{-}val)(NH_3)_4]SO_4\cdot 2H_2O$: This cymplex was prepared by the same procedure as described above except for the use of DL-valine instead of L-valine. Found: C, 16.17; H, 6.83; N, 18.76%. Calcd for $[Co(DL\text{-val})(NH_3)_4]SO_4\cdot 2H_2O=C_5H_{26}N_5O_8SCo$: C, 16.00; H, 6.98; N, 18.66%.

$[Co(L\text{-}val)(NH_3)_4]X_2$ ($X=Cl$, Br, and I): The above sulfate salt of L-valinato complex was converted into the desired salts by ion exchangers (Dowex 50W-X2 for Cl^- or Br^- form; QAE-Sephadex A-25 for I^- form). Found for chloride salt: C, 19.18; H, 7.05; N, 22.27%. Calcd for $[Co(L\text{-val})(NH_3)_4]Cl_2=C_5H_{22}N_5O_2Cl_2Co$: C, 19.12; H, 7.06; N, 22.29%. Found for bromide salt: C, 15.02; H, 5.52; N, 17.35%. Calcd for $[Co(L\text{-val})(NH_3)_4]Br_2=C_5H_{22}N_5O_2Br_2Co$: C, 14.90; H, 5.50; N, 17.37%. Found for iodide salt: C, 12.18; H, 4.48; N, 13.94%. Calcd for $[Co(L\text{-val})(NH_3)_4]I_2=C_5H_{22}N_5O_2I_2Co$: C, 12.08; H, 4.46; N, 14.09%.

$[Co(DL\text{-}val)(NH_3)_4]X_2\cdot nH_2O$ ($X=Cl$, Br, and I): These complexes were prepared by the same method as that for the corresponding L-valinato complexes. Found for chloride salt: C, 19.13; H, 7.01; N, 22.18%. Calcd for $[Co(DL\text{-val})(NH_3)_4]Cl_2=C_5H_{22}N_5O_2Cl_2Co$: C, 19.12; H, 7.06; N, 22.29%. Found for bromide salt: C, 14.82; H, 5.50; N, 17.27%. Calcd for $[Co(DL\text{-val})(NH_3)_4]Br_2=C_5H_{22}N_5O_2Br_2Co$: C, 14.90; H, 5.50; N, 17.37%. Found for iodide salt: C, 11.89; H, 4.65; N, 13.52%. Calcd for $[Co(DL\text{-val})(NH_3)_4]I_2\cdot 0.5H_2O=C_5H_{23}N_5O_{2.5}I_2Co$: C, 11.87; H, 4.58; N, 13.84%.

$[Co(L\text{-}leu)(NH_3)_4]SO_4$ and $[Co(DL\text{-}leu)(NH_3)_4]SO_4\cdot 2H_2O$: These complexes were prepared by the same method as that for $[Co(L\text{-val})(NH_3)_4]SO_4$ with the use of L-leucine or DL-leucine instead of L-valine. Found for L-leucinato complex: C, 20.16; H, 6.82; N, 19.61%. Calcd for $[Co(L\text{-leu})(NH_3)_4]SO_4=C_6H_{24}N_5O_6SCo$: C, 20.40; H, 6.85; N, 19.82%. Found for DL-leucinato complex: C, 17.96; H, 7.20; N, 17.41%. Calcd for $[Co(DL\text{-leu})(NH_3)_4]SO_4\cdot 2H_2O=C_6H_{28}N_5O_8SCo$: C, 18.06; H, 7.34; N, 17.58%.

$[Co(L\text{-}leu)(NH_3)_4]X_2\cdot H_2O$ and $[Co(DL\text{-}leu)(NH_3)_4]X_2\cdot H_2O$ ($X=Cl$, Br, and I): These complexes were prepared from the corresponding sulfate salt by the ion exchangers described above. Found for chloride of L-leucinato complex: C, 20.65; H, 7.44; N, 20.01%. Calcd for $[Co(L\text{-leu})(NH_3)_4]Cl_2\cdot H_2O=C_6H_{26}N_5O_3Cl_2Co$: C, 20.82; H, 7.57; N, 20.23%. Found for bromide of L-leucinato one: C, 16.55; H, 5.98; N, 16.02%. Calcd for $[Co(L\text{-leu})(NH_3)_4]Br_2\cdot H_2O=C_6H_{26}N_5O_3Br_2Co$: C, 16.56; H, 6.02; N, 16.10%. Found for iodide of L-leucinato one: C, 13.63; H, 4.96; N, 13.35%. Calcd for $[Co(L\text{-leu})(NH_3)_4]I_2\cdot H_2O=C_6H_{26}N_5O_3I_2Co$: C, 13.62; H, 4.95; N, 13.24%. Found for chloride of DL-leucinato one: C, 20.89; H, 7.43; N, 19.90%. Calcd for $[Co(DL\text{-leu})(NH_3)_4]Cl_2\cdot H_2O=C_6H_{26}N_5O_3Cl_2Co$: C, 20.82; H, 7.57; N, 20.23%. Found for bromide of DL-leucinato one: C, 16.47; H, 5.95; N, 15.97%. Calcd for $[Co(DL\text{-leu})(NH_3)_4]Br_2\cdot H_2O=C_6H_{26}N_5O_3Br_2Co$: C, 16.56; H, 6.02; N, 16.10%. Found for iodide of DL-leucinato one: C, 13.66; H, 4.96; N, 13.37%. Calcd for $[Co(DL\text{-leu})(NH_3)_4]I_2\cdot H_2O=C_6H_{26}N_5O_3I_2Co$: C, 13.62; H, 4.95; N, 13.24%.

Measurements. Solubility in water was determined according to the previously reported method.[4] The absorption and CD maximum values which were used for the calculations of concentrations of complexes in solutions are summarized in Table 1. The solid phases were identified from elemental analyses, absorption, CD, and infrared spectra. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer, CD with a JASCO MOE-1 spectropolarimeter, and infrared spectra with a JASCO DS-402G spectrophotometer.

Table 1. Absorption and CD maximum values used for calculation of solubility[a)]

Complex salt	$\varepsilon(\lambda_{max})$	$\Delta\varepsilon(\lambda_{max})$
$[Co(L\text{-val})(NH_3)_4]SO_4$	83.48 (495)	−0.426 (462)
$[Co(DL\text{-val})(NH_3)_4]SO_4$	83.48 (495)	
$[Co(L\text{-val})(NH_3)_4]Cl_2$	81.98 (495)	−0.418 (462)
$[Co(DL\text{-val})(NH_3)_4]Cl_2$	81.98 (495)	
$[Co(L\text{-val})(NH_3)_4]Br_2$	82.88 (495)	−0.405 (462)
$[Co(DL\text{-val})(NH_3)_4]Br_2$	82.88 (495)	
$[Co(L\text{-val})(NH_3)_4]I_2$	72.91 (495)	−0.366 (462)
$[Co(DL\text{-val})(NH_3)_4]I_2$	72.90 (495)	
$[Co(L\text{-leu})(NH_3)_4]SO_4$	82.30 (492)	−0.326 (459)
$[Co(DL\text{-leu})(NH_3)_4]SO_4$	82.28 (492)	
$[Co(L\text{-leu})(NH_3)_4]Cl_2$	81.33 (492)	−0.329 (459)
$[Co(DL\text{-leu})(NH_3)_4]Cl_2$	81.33 (492)	
$[Co(L\text{-leu})(NH_3)_4]Br_2$	81.95 (492)	−0.319 (459)
$[Co(DL\text{-leu})(NH_3)_4]Br_2$	81.95 (492)	
$[Co(L\text{-leu})(NH_3)_4]I_2$	82.36 (492)	−0.327 (459)
$[Co(DL\text{-leu})(NH_3)_4]I_2$	82.37 (492)	

a) The ε and λ (in parentheses) values are given in the unit of $mol^{-1}\,dm^3\,cm^{-1}$ and nm, respectively.

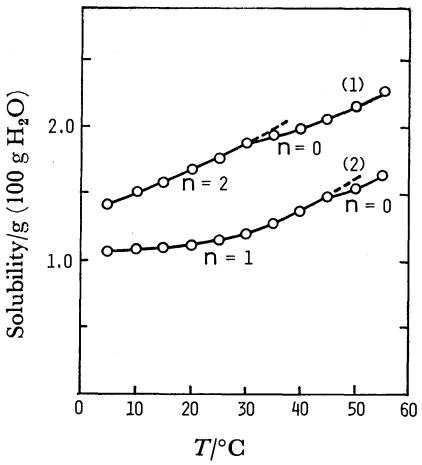

Fig. 1. Solubility curves of $[Co(L\text{-val})(NH_3)_4]SO_4\cdot nH_2O$ (1) and $[Co(DL\text{-val})(NH_3)_4]SO_4\cdot nH_2O$ (2).

Results and Discussion

The binary solubility data are given in Table 2 and Figs. 1, 3, and 5, and the ternary data in Tables 3 and 4 as well as in Figs. 2, 4, and 6—8. In the triangular isotherms the top part (H_2O corner) is enlarged for the sake of convenience and the tie lines are omitted.

The Valinato Complexes. The solubility curves of sulfate salt are shown in Fig. 1. The L-complex shows an inflection at 30 °C, at which the solid phase changes from dihydrate to anhydrate. A similar inflection appears at 45 °C for the DL-complex, corresponding to the transition from monohydrate to anhydrate. Since the solubility of L-complex is larger than that of DL-complex at 5—55 °C, the sulfate salt is not spontaneously resolvable.[5)] The ternary isotherm at 25 °C shows the formation of racemic compound $[Co(L\text{-val})(NH_3)_4][Co(D\text{-val})(NH_3)_4](SO_4)_2\cdot 4H_2O = [Co(DL\text{-val})(NH_3)_4]SO_4\cdot 2H_2O$ (Fig. 2).[4)]

The solubility curves of bromide salt are shown in Fig. 3. The solubility ratio of DL-complex/L-complex is 1.46 at 5 °C and 1.40 at 55 °C. For a spontaneously resolvable 1 : 2 electrolyte, the ratio must be larger than $2^{1/3}=1.26$.[5)] Therefore, the bromide salt is spontaneously resolvable. The ternary solubility isotherm at 25 °C (Fig. 4) shows the only one invariant point. This fact confirms that the two enantiomers form a racemic mixture in the solid state. The racemate of free valine does not form a racemic mixture. This is the first example, in which the complexation of amino acid enabled the spontaneous resolution. The chloride salt shows a similar solubility relationship to the bromide salt, the ratio of DL-complex/L-complex being 1.30 at 5 °C and 1.28 at 55 °C. A crystal, which precipitated out of the racemic solution, showed the same CD

With the iodide salt, the active complex (0.5-hydrate) is more soluble than the anhydrous racemate. No optical rotation was observed for the crystals out of the racemic solution. The result was confirmed by the ternary isotherm at 25 °C which indicates the existence of a racemic compound [Co(L-val)$(NH_3)_4$][Co(D-val)-$(NH_3)_4$]I_4=[Co(DL-val)$(NH_3)_4$]I_2 (Tables 2 and 3).

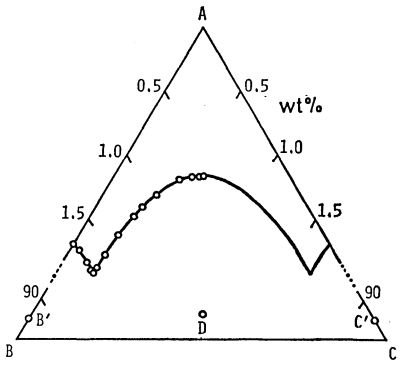

Fig. 2. Solubility isotherm of the system H_2O(A)–[Co(L-val)$(NH_3)_4]SO_4$(B)–[Co(D-val)$(NH_3)_4]SO_4$(C) at 25 °C. The solid phase B′ or C′ is monohydrate of B or C, respectively, and D [Co(DL-val)$(NH_3)_4]SO_4\cdot 2H_2O$.

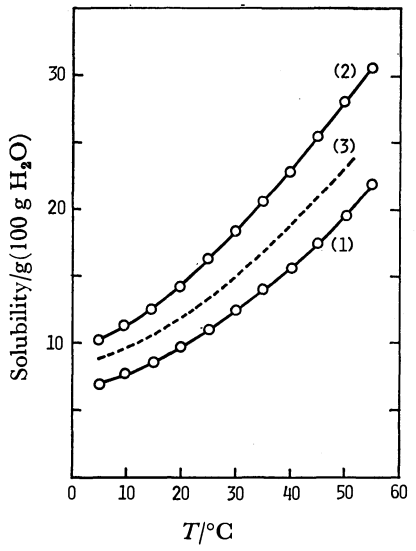

Fig. 3. Solubility curves of [Co(L-val)$(NH_3)_4]Br_2$(1), [Co(DL-val)$(NH_3)_4]Br_2$(2), and calculated curve (3) : (1)$\times \sqrt[3]{2}$.

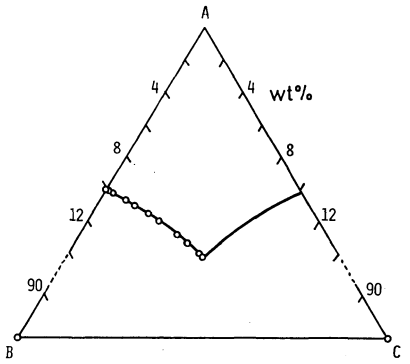

Fig. 4. Solubility isotherm of the system H_2O(A)–[Co(L-val)$(NH_3)_4]Br_2$(B)–[Co(D-val)$(NH_3)_4]Br_2$(C) at 25 °C.

[Co(L-leu)$(NH_3)_4]SO_4$ and [Co(DL-leu)$(NH_3)_4]SO_4$ are shown in Fig. 5. The solubility ratio of DL-complex/L-complex is 2.97 at 5 °C and 4.15 at 55 °C which goes well beyond $2^{1/2}=1.41$ expected for 1 : 1 electrolyte.[5] The racemate shows an inflection at *ca.* 30 °C where the solid phase changes from 2.5-hydrate (below 30 °C)

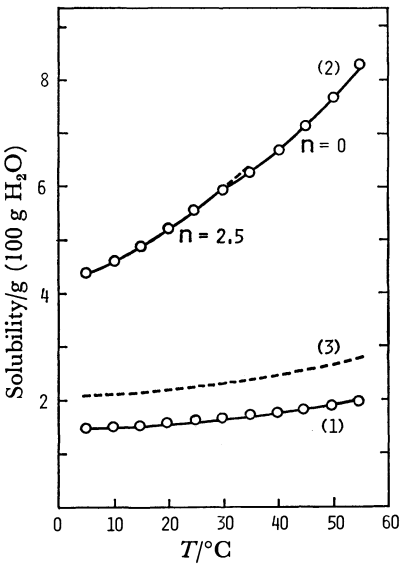

Fig. 5. Solubility curves of [Co(L-leu)$(NH_3)_4]SO_4$(1), [Co(DL-leu)$(NH_3)_4]SO_4\cdot nH_2O$(2), and calculated curve(3) : (1)$\times\sqrt{2}$.

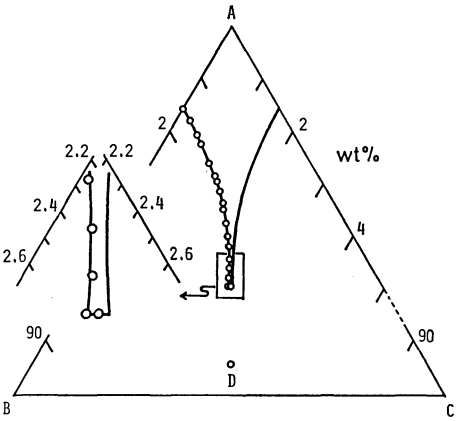

Fig. 6. Solubility isotherm of the system H_2O(A)–[Co(L-leu)$(NH_3)_4]SO_4$(B)–[Co(D-leu)$(NH_3)_4]SO_4$(C) at 20 °C.
The solid phase D is [Co(DL-leu)$(NH_3)_4]SO_4\cdot 2.5H_2O$.

to anhydrate. On the other hand, the anhydrous active complex shows no solid phase change at 5—55 °C. If the racemate forms a racemic mixture, the racemate and the pure enantiomer must have the same composition and crystal structure. Therefore, spontaneous resolution seems to be possible at temperatures higher than 30 °C in this case. The ternary isotherm at 20 °C reveals the formation of racemic compound [Co(L-leu)$(NH_3)_4$]-[Co(D-leu)$(NH_3)_4](SO_4)_2\cdot 5H_2O$= [Co(DL-leu)$(NH_3)_4$]-$SO_4\cdot 2.5H_2O$, though the region for this compound is significantly narrow as compared with those of the pure enantiomers (Fig. 6). The infrared spectra also indicate that the solid crystallized out of racemic solution at 20 °C is different from the optically active complex. As is shown in Fig. 7, the region of the racemic compound disappears at 35 °C and the only invariant point exists in the ternary isotherm. Thus, the racemic sulfate [Co(DL-leu)$(NH_3)_4]SO_4$ crystallizes as both the racemic compound (below 30 °C) and the conglomerate (above 30 °C).

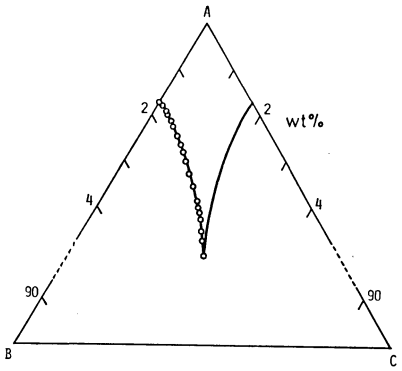

Fig. 7. Solubility isotherm of the system H_2O(A)–[Co(L-leu)$(NH_3)_4$]SO_4(B)–[Co(D-leu)$(NH_3)_4$]SO_4(C) at 35 °C.

The solubility ratio DL-complex/L-complex at temperatures of 5—30 °C goes well beyond $2^{1/2}=1.41$ (Fig. 5), but spontaneous resolution did not occur in this sulfate salt. This fact may be explained in relation to the characteristics of SO_4^{2-} ion, which has been reported to have a strong tendency to associate with various ammine or amine cobalt(III) complexes.[6] The ion-pair formation affects the activity coefficients of the complexes to a great extent and causes the apparent large solubility ratio.

All the halide salts of leucinato complexes are monohydrate regardless of whether it is racemate or active form. The solubility of racemate is lower than that of the corresponding active form, no spontaneous resolution being observed. Figure 8 shows the ternary isotherm of [Co(leu)$(NH_3)_4$]Br_2 at 25 °C. The extremely flat curve of the racemic compound is spread over a wide region and the region of pure enantiomers are much suppressed.

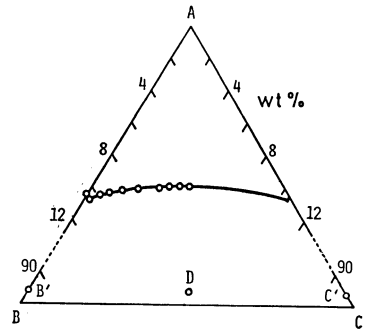

Fig. 8. Solubility isotherm of the system H_2O(A)–[Co(L-leu)$(NH_3)_4$]Br_2(B)–[Co(D-leu)$(NH_3)_4$]Br_2(C) at 20 °C. The solid phase B′ or C′ is monohydrate of B or C, respectively, and D [Co(DL-leu)$(NH_3)_4$]$Br_2\cdot H_2O$.

Multiple Paths for Photo-methylation and -methoxylation of Methyl 2-Pyridinecarboxylate in Methanol

Toru SUGIYAMA, Toshikazu FURIHATA, Kyoko TAKAGI, Michitsugu SATO, Shinya AKIYAMA, Gen P. SATÔ, and Akira SUGIMORI*

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102

(Received September 12, 1980)

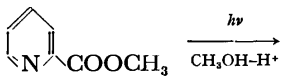
UV-irradiation of methyl 2-pyridinecarboxylate in methanol in the absence of added acid brings about methylation at the 5-position *via* the excitation of C=O of the ester group, while in the presence of added acid the 4-position of the pyridine ring is methylated. In the presence of sulfuric acid methoxylation *via* an excimer is dominant over methylation. In the presence of hydrochloric acid methylation *via* chlorine atoms becomes dominant.

Pyridinecarboxylic acids and their derivatives show a variety of photoreactions. In alcoholic solutions they undergo photochemical decarboxylation, alkylation, hydroxyalkylation, and alkoxylation.[1-4] The features of the photoreactions of the derivatives of pyridinecarboxylic acids are: 1) the photoreactivities are sensitive to the reaction conditions (the nature of the solvents, the concentration of the substrate, the added acids, the concentration of the added acid, and the additives), 2) the same products can be derived from the different excited states, and 3) the simultaneous contribution of several types of excited states.

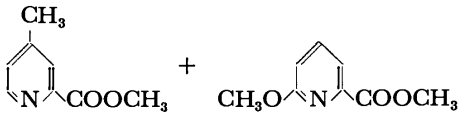
Previously we reported the detailed analyses of the photoreactions of 3-pyridinecarboxylic ester in alcoholic solutions.[2] We report here the analysis of the photoreactions of 2-pyridinecarboxylic ester in alcohol.[5]

Results and Discussion

Similar to 3-pyridinecarboxylic ester, methyl 2-pyridinecarboxylate (**1**) undergoes the substitution of the ring hydrogen by alkyl or alkoxyl group derived from the solvent alcohol upon the UV-irradiation of **1** in the presence of sulfuric or hydrochloric acid.



(1)



(2) (3)

The photo-methylation and -methoxylation of **1** are dependent on the reaction conditions: 1) concentration of the substrate, 2) added acid, and 3) additives.

In Figs. 1 and 2 are shown the dependencies of the photoreactions and the molar absorption coefficient of **1** on the concentration of the added acid at 10^{-3} mol dm^{-3} of **1**. The change in the molar absorption coefficient corresponds to the protonation and the deprotonation of the pyridine derivatives. The dependence of the efficiency of the photoreactions on the acid concentration correlates well with the dependence of the molar absorption coefficient on the acid concentration. This suggests that the photo-methylation and -methoxylation occur effectively, when the substrate is protonated.

In the photoreaction of **1** in methanol in the presence of H_2SO_4, the methoxylation at the 6-position is dominant and the methylation occurs in a low yield (Fig. 1). However, the methylation is promoted by hydrochloric acid, especially at its higher concentrations (Fig. 2). The addition of lithium chloride increases the yield for the methylation as is shown in Table 1. Analogous promotion of the methylation and depression of the methoxylation have been observed in the photoreaction of methyl 3-pyridinecarboxylate, for which a mechanism involving the electron transfer from chloride ion to the substrate has been proposed.[2] In the photoreaction of **1** in the presence of chloride ion, a similar mechanism should operate.

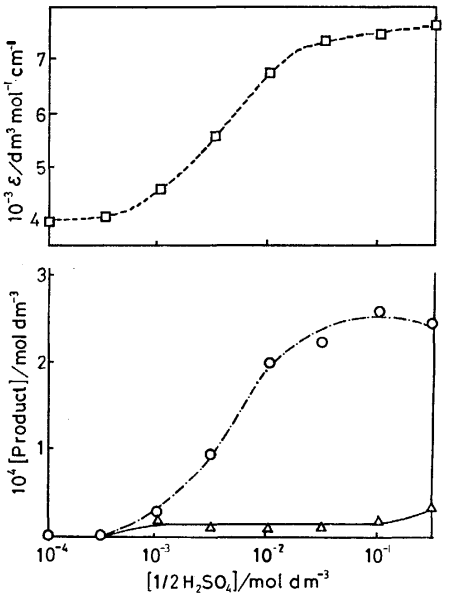


Fig. 1. Dependences of the photoreaction and the molar absorption coefficient of **1** upon the concentration of added H_2SO_4.
[**1**] = 1×10^{-3} mol dm^{-3}, irradiation time, 10 min.
—△—: Yield of **2**, ---○---: yield of **3**, ----□----: molar absorption coefficient.

The most characteristic nature of the photo-methoxylation of **1** is its concentration dependence (Fig. 3). The concentration dependence suggests the participation of a dimer species of the substrate in the photo-methoxylation.

A mechanism involving an excimer can be postulated (Scheme 1). In this Scheme, **A** and **B** represent the products of other processes than the alkoxylation.

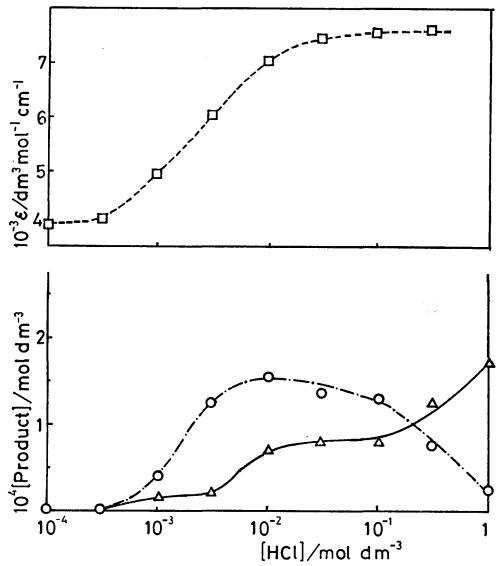

Fig. 2. Dependences of the photoreaction and the molar absorption coefficient of **1** upon the concentration of added HCl.
[**1**]$=1\times10^{-3}$ mol dm^{-3}; irradiation time, 10 min.
—△—: Yield of **2**, ···○···: yield of **3**, ----□----: molar absorption coefficient.

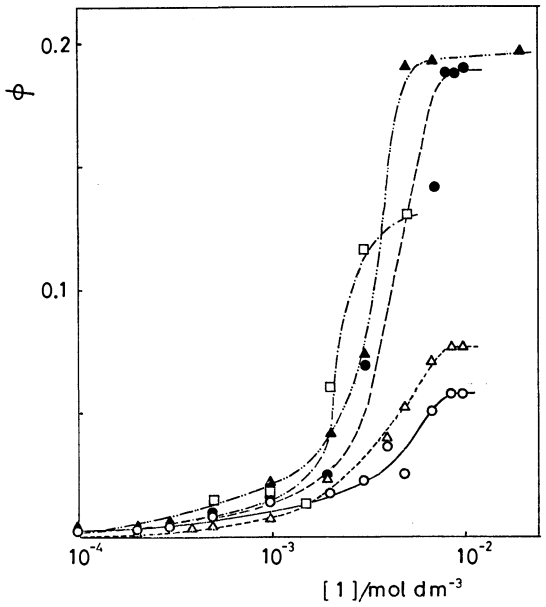

Fig. 3. Dependence of the quantum yield of photomethoxylation on the concentration of **1** at various temperatures.
[H_2SO_4]$=5\times10^{-2}$ mol dm^{-3}.

The mechanism gives the following kinetic relationship:

$$1/\phi_3 = \frac{k_3[CH_3OH]+k_4+k_5}{k_3[CH_3OH]} + \frac{(k_{-1}+k_{-5})(k_{-2}+k_3[CH_3OH]+k_4+k_5)}{k_2k_3[CH_3OH]\,[\mathbf{1}]},$$

where ϕ_3 is the quantum yield of the methoxylation product *via* an excimer. The concentration of methanol

$$\mathbf{1} \underset{k_{-1}}{\overset{h\nu}{\rightleftharpoons}} \mathbf{1}^*$$

$$\mathbf{1}^* + \mathbf{1} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (\mathbf{1}-\mathbf{1})^* \text{ (an excimer)}$$

$$(\mathbf{1}-\mathbf{1})^* + CH_3OH \xrightarrow{k_3} \mathbf{3}$$

$$(\mathbf{1}-\mathbf{1})^* \xrightarrow{k_4} 2\,\mathbf{1}$$

$$(\mathbf{1}-\mathbf{1})^* \xrightarrow{k_5} \mathbf{A}$$

$$\mathbf{1}^* \xrightarrow{k_6} \mathbf{B}$$

3×10^{-3}	1	2	14

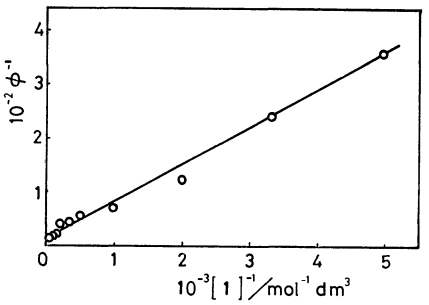

Fig. 4. Relation between the reciprocal of the quantum yields for the photomethoxylation at 40 °C and the reciprocal of the concentration of **1**.

is constant in the experimental conditions.

The plot of $1/\phi_3$ against $1/[\mathbf{1}]$ for the photo-methoxylation at 11 °C resulted in a straight line (Fig. 4) as predicted by the above equation and the mechanism *via* an excimer is thus kinetically supported.[6]

Since **1** is not fluorescent at any concentration even at the liquid nitrogen temperature, no direct evidence for the excimer has been obtained. However, the excimers of quinoline and isoquinoline have been established on the basis of the emission spectra.[7] These facts support the mechanism *via* an excimer.

The effects of additives for the photo-methylation are different from those for the photo-methoxylation. Because the additives absorb the 254 nm light competitively with the substrate, the effects of additives were analyzed by means of an index A, the relative quantum yield calculated on the basis of the light absorbed by the substrate,

$$A = Y/L$$

$$Y = \frac{\text{Yield in the presence of additive}}{\text{Yield in the absence of additive}}$$

$$L=\frac{\varepsilon_1 c_1}{\varepsilon_1 c_1+\varepsilon_Q c_Q}$$
$$=\{\text{Light absorbed by substrate (1)}\}/\{\text{Light absorbed by substrate (1)}+\text{Light absorbed by additive(Q)}\},$$

where ε_1 and ε_Q are the molar absorption coefficients of the substrate and the additive at 254 nm, respectively. Symbols c_1 and c_Q are the concentrations of the substrate and the additive.

$A>1$ means that the additive promotes the reaction and $A<1$ means that the additive inhibits it. A^{-1} corresponds to ϕ_0/ϕ in the Stern-Volmer equation for the quenching experiment.

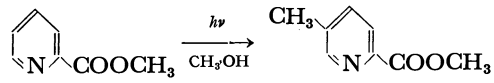
As is shown in Figs. 5 and 6, the methoxylation is inhibited to a smaller extent by benzene and to a larger extent by anthracene. Benzene, which has a high triplet energy value (E_T, 352 kJ mol^{-1}), is an inhibitor, although the effect is small. As reported earlier,[8] acetophenone has no effect on the photo-methoxylation. These facts suggest that the photo-methoxylation does not originate from a triplet state.

The additives may quench either an excited monomer or an excited dimer. The fact that the inhibition by anthracene was observed only for methoxylation and not for methylation suggests that the inhibition occurs not in the process of an excited monomer but in the process of an excited dimer.

The inhibition by benzene and anthracene can be explained by the electron transfer quenching by aromatic hydrocarbons:[9] anthracene with the lower ionization potential (I_p=7.43 eV[10]) causes greater inhibition ($k_q\tau$=300 dm^3 mol^{-1}) than benzene (I_p=9.245 eV,[10] $k_q\tau$=10 dm^3 mol^{-1}) with the higher ionization potential. (Here k_q is the rate constant for bimolecular quenching and τ is the lifetime of an excited species.) The results are similar to those reported by Caldwell *et al.*,[9] who investigated extensively the electron transfer quenching for excimers and exciplexes. Concerning the photo-methoxylation peculiar effects of additives were observed:[8] the photo-methoxylation is promoted specifically by 4-substituted pyridines. The promotion is explained by the exciplex formation between **1** and the 4-substituted pyridine.

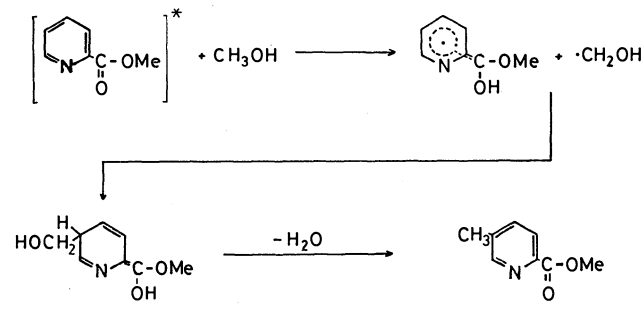
The photo-methylation at the 4-position in the presence of added acid is promoted by benzene. Anthracene has no effect on the reaction. However, a detailed study on the excited state responsible for the formation of **2** could not be done, because methylation is only a very minor reaction.

The UV-irradiation of **1** in methanol in the absence of added acid gives a methylation product. In this case methylation occurs at the 5-position and the efficiency for the methylation at the 5-position is much lower than that at the 4-position in the presence of acid.



(**4**)

With pyridine derivatives photoreactions occur normally at α- and γ-positions.[11] For the unusual alkylation at the β-position, the participation of the ester group should be taken into consideration. The hydrogen abstraction by the excited C=O of the ester group (or the electron transfer followed by proton transfer) has been reported for some aromatic esters.[12] Thus, the following mechanism is conceivable for the photo-methylation at the 5-position.



The effects of additives on the photo-methylation in the absence of added acids (Table 2) suggest that a triplet state is responsible for the methylation at the 5-position: the additives with higher triplet energies, benzene (E_T=352 kJ mol^{-1}) and naphthalene (E_T= 255 kJ mol^{-1}), promote the photo-methylation, anthracene (E_T=178 kJ mol^{-1}) has no effect, and oxygen inhibits the reaction.

Table 2. Effects of additives on the formation of **4** in the absence of added acid
[**1**] = 1×10^{-3} mol dm^{-3}; irradiation time, 20 min.

Additive	[Additive] / mol dm^{-3}	L[a]	Y[a]	A[a]

a) See text for the definition of L, Y and A.

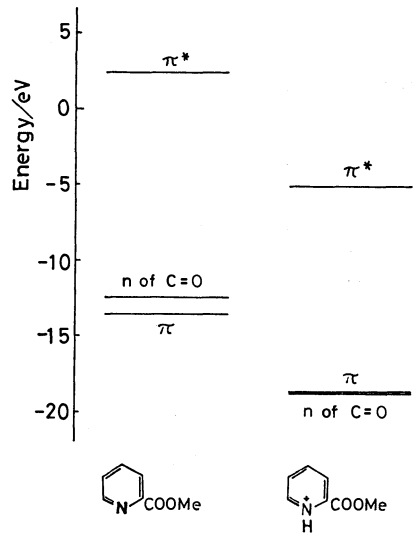

Fig. 7. Electronic state of **1**.

The participation of the n-π^* state of the C=O in the ester group is supported by the consideration of the electronic states calculated by means of CNDO/2.[13] The results are shown in Fig. 7. For the free base form of **1**, the highest occupied orbital is assigned to the non-bonding orbital at C=O. On the other hand, for the pyridinium form π-orbital is the highest occupied orbital. This result can explain that the n-π^* excited state is preferably formed in the irradiation of the free base form of **1**, whereas the π-π^* excited state is populated in the photoreaction of the pyridinium form of **1**.

The photoreactions of methyl 2-pyridinecarboxylate, thus, can be summarized in Scheme 2.

Experimental

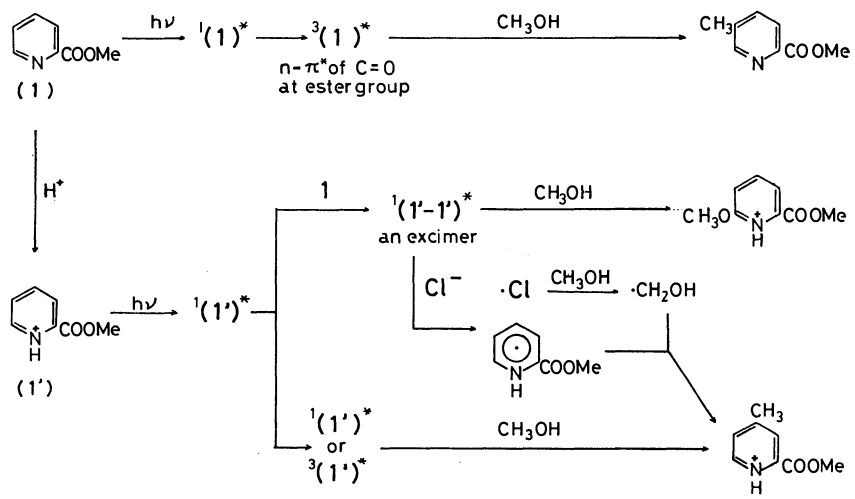
Materials. Commercial methyl 2-pyridinecarboxylate (**1**) (GR grade reagent of Tokyo Kasei Co.) was purified by vacuum distillation; bp 105—108 °C/7 mmHg. (1 mmHg≈ 133.322 Pa.) Anthracene (standard reagent for elementa analysis made by E. Merck Co.) was used for the quenching experiment.

UV-irradiation. The solutions of **1** containing mineral acid, and the additive if necessary, were deaerated by bubbling nitrogen or argon for 40 min before irradiation. The solutions were irradiated with a low pressure mercury lamp in a merry-go-round type irradiation apparatus which was set in a thermostat. Irradiation was carried out at 20 °C except in the experiment for temperature dependence.

Isolation and Identification of Products. After the irradiation the solution was concentrated under reduced pressure and neutralized with sodium hydrogencarbonate when the mineral acid was present. The products were extracted repeatedly with dichloromethane and were separated by means of TLC (plate, GF_{254} (Type 60) of E. Merck Co.; developing solvent, ethyl acetate–dichloromethane 1 : 1 v/v)

Methyl 4-methyl-2-pyridinecarboxylate (**2**), methyl 5-methyl-2-pyridinecarboxylate (**4**), and methyl 6-methoxy-2-pyridinecarboxylate (**3**) were identified by the accordance of their NMR spectra with those reported by Deady *et al.*[14]

Determination of the Yields of Products. The yields of the photoproducts were determined by the UV-spectrophotometric method or by the gas-chromatographic method. For the determination of the quantum yields for the photo-methoxylated product (data for Figs. 3 and 4) the spectrophotometric method was applied using the characteristic absorption of **3** at 287 nm. Actinometry was carried out by using potassium trioxalatoferrate(III). In other cases, the yields of the products were determined by means of GLC (column, 2 m column of PEG 20M (10%) on Celite 545 or 2 m column of Triton OS-15 (15%) on Uniport B; column temperature, 160—170 °C).



Scheme 2.

The authors are grategul to Professor L. W. Deady of La Trobe University in Australia for sending us the spectral data of pyridinecarboxylic acid derivatives.

5) A part of this work has been reported preliminarily: a) T. Sugiyama, T. Furihata, Y. Edamoto, R. Hasegawa, G. P. Satô, and A. Sugimori, *Tetrahedron Lett.*, **1974**, 4339; b) T. Sugiyama, E. Tobita, K. Takagi, M. Sato, Y. Kumagai, G. P. Satô, and A. Sugimori, *Chem. Lett.*, **1980**, 131.

6) The following mechanism *via* the excitation of a dimer formed in the ground state could explain the concentration dependence in Fig. 3 qualitatively.

$$2\,\mathbf{1} \overset{K}{\rightleftharpoons} (\mathbf{1}-\mathbf{1})$$

$$(\mathbf{1}-\mathbf{1}) \xrightarrow{h\nu} (\mathbf{1}-\mathbf{1})^*$$

$$\mathbf{1} \underset{k_{-1}}{\overset{h\nu}{\rightleftharpoons}} \mathbf{1}^*$$

$$(\mathbf{1}-\mathbf{1})^* + CH_3OH \xrightarrow{k_3} \mathbf{3}$$

$$(\mathbf{1}-\mathbf{1})^* \xrightarrow{k_4} 2\,\mathbf{1}$$

$$(\mathbf{1}-\mathbf{1})^* \xrightarrow{k_5} \mathbf{A}$$ (Product of the side reaction from $(\mathbf{1}-\mathbf{1})^*$)

$$\mathbf{1}^* \xrightarrow{k_6} \mathbf{B}$$ (Product of the side reaction from $\mathbf{1}^*$)

This mechanism, however, leads to the following expression for ϕ_3, the quantum yield of **3**:

$$1/\phi_3 = \left(\frac{k_3[CH_3OH]+k_4+k_5}{4K\,k_3[CH_3OH]}\right)\left\{\frac{1}{c}+4K+\left(\frac{1}{c^2}+8K\frac{1}{c}\right)^{1/2}\right\},$$

where $c=[\mathbf{1}]+[(\mathbf{1}-\mathbf{1})]$. This expression is based on the assumption that the molar absorption coefficient of $(\mathbf{1}-\mathbf{1})$ is twice that of **1**. Evidently the above mechanism is not compatible with the observed linear dependence of $1/\phi_3$ on $1/c$ (Fig. 4). The fact that the UV-spectra of **1** at higher concentrations, where photo-methoxylation occurs effectively, are identical with those at much lower concentrations is consitent with the view that $(\mathbf{1}-\mathbf{1})$ plays no important role.

The Interaction between α-Helical Poly-L-lysine and Thyroxine as Measured by Circular Dichroism

Nobuo OKABE,* Mariko OKAMURA, Ryoji TOKUOKA, and Ken-ichi TOMITA
Faculty of Pharmaceutical Sciences, Osaka University, Suita, Osaka 565
(Received October 24, 1980)

The interaction between α-helical poly-L-lysine (poly(L-Lys)) and the thyroid hormone, L-thyroxine (L-T_4), was investigated at pH 11 by means of circular dichroism (CD) measurements in the wavelength region of 200—380 nm. At least four CD bands were induced near 235, 250, 290, and 343 nm. This indicates that these induced Cotton effects occurred as the result of the binding of L-T_4 to poly(L-Lys), probably due to the electrostatic interaction. The wavelengths of the induced CD bands corresponded to those of the UV absorption bands of L-T_4 in the poly(L-Lys) : L-T_4 mixture, although small red-shifts of the CD bands were observed at the shortest and the longest wavelengths (235 nm and 343 nm). These CD bands might be interpreted by the fixed intramolecular orientation around an asymmetric α-carbon atom of the bound L-T_4 or by the intermolecular interaction between the peptide backbone of poly(L-Lys) and the bound L-T_4.

In previous papers,[2-4] the interaction between bovine serum albumin (BSA) or human serum albumin (HSA) and a thyroid hormone, L-thyroxine (L-T_4, Fig. 1), was investigated by means of CD measurements. The negative CD band was induced at the longest UV absorption maximum of L-T_4, suggesting a specific interaction between proteins and L-T_4. However, the binding mechanism has remained obscure. For this reason, as a model study to obtain much information about the binding mechanism of L-T_4 to a protein, the interaction between α-helical poly-L-lysine and L-T_4 was investigated by means of the CD method at pH 11. This synthetic polypeptide was chosen as a suitable model compound for this study because the lysine residue plays an important role in the binding of L-T_4 to human serum albumin;[5] the residue also sometimes appears either at the surface or at the helical region of globular proteins.

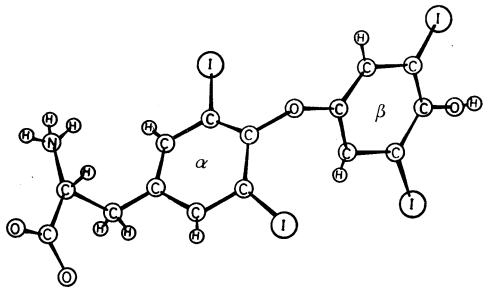

Fig. 1. Perspective drawing of L-T_4 molecule determined by X-ray analysis (Ref. 1). The dihedral angle between the planes of the α-ring and β-ring and the interring C–O–C angle are 79° and 120°±3°, respectively.

Experimental

Materials. Poly-L-lysine HBr (poly(L-Lys)) with a molecular weight of 46500 and a degree of polymerization (DP) of 222 (Lot No. LY-185) was purchased from Miles-Yeda, Ltd., U.S.A., and L-thyroxine sodium salt (L-T_4), from Nakarai Chemicals Co., Kyoto, Japan.

Procedure. Poly(L-Lys) was dissolved in distilled and deionized water, and the pH was adjusted to 11 by adding 1 mol dm^{-3} of NaOH. About 3×10^{-3} mol dm^{-3} of L-T_4 was dissolved in 0.01 mol dm^{-3} of the NaOH solution to serve as a stock solution. To prepared the mixture of poly(L-Lys) and L-T_4, a small amount of L-T_4 was gradually added to 2 cm^3 of the poly(L-Lys) solution under continuous stirring until the appropriate molar ratio was reached. The pH change in the poly(L-Lys) solution upon the addition of L-T_4 was negligible under those experimental conditions. The CD measurements were carried out on a JASCO J-40A spectropolarimeter equipped with a data-processor system, J-DPZ, at the wavelength region of 200—380 nm. CD cells with light-path lengths of 1 and 10 mm were used for the measurement in the wavelength regions of 200—260 nm and 260—380 nm respectively. The optical rotatory dispersion (ORD) measurements were performed with a JASCO J-20 spectropolarimeter. A cell with a light-path length of 2 mm was used in the wavelentgth region of 210—300 nm. The ultraviolet (UV) absorption spectra were obtained with a Hitachi 323 recording spectrophotometer. The pH adjustment was done by means of a Hitachi Horiba D-5 pH meter. The CD ellipticity and the ORD rotation were represented as a unit of degree cm^2 $decimol^{-1}$ on the basis of the concentration of the lysine residues of poly(L-Lys) or L-T_4. All the measurements except one noted in the text were carried out at 22 °C.

Results and Discussion

Figure 2 shows the absorption spectra of L-T_4 in a 30% ethanol aqueous solution at various pH values. The peak around 300 nm (pH 3.2) was shifted to 330 nm with an increase in its height in the alkaline solution (pH 11.7), although a small shoulder remained at 290 nm. The isosbestic points appeared at 285 nm and 308 nm. This peak-height increment at 330 nm is due to the dissociation of the phenolic hydroxyl group of the β-ring of L-T_4 (Fig. 1). The pK value of this group was calculated as 6.32, coincident well with the values of 6.2 and/or 6.7 reported by Steiner[6] and Gemmill[7] respectively. This indicates that the hydroxyl group completely dissociates at pH 11. It is well known that poly(L-Lys) takes a α-helical conformation in the aqueous solution at pH 11. The ε-amino groups of poly(L-Lys) may be not completely uncharged at pH 11, since the pK of these groups is 10.8.[9] This suggests that the negatively charged hydroxyl and carboxyl groups of L-T_4 at pH 11 cause electrostatic interaction with some positively charged ε-amino groups of poly(L-Lys). The binding of L-T_4 to the helical poly(L-Lys) may induce some optical activities to arise from L-T_4, although a

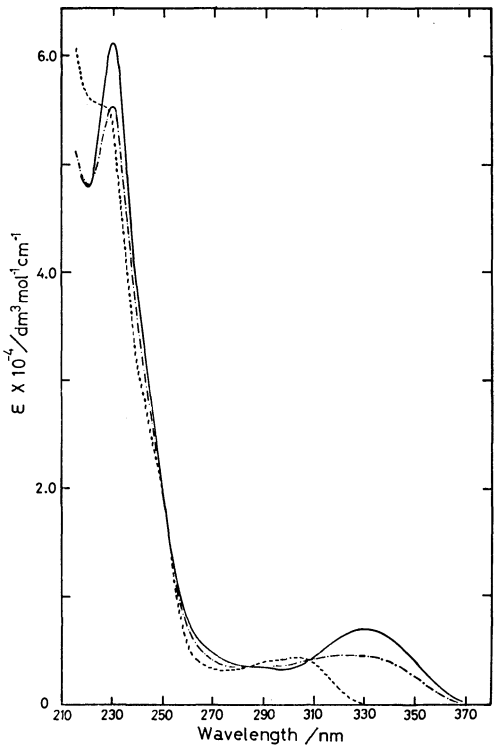

Fig. 2. The ultraviolet absorption spectra of L-T_4 as a function of pH in 30% ethanol aqueous solution. Curves are at pH 11.7 (——); at pH 6.6 (—·—); at pH 3.2 (------). L-T_4 concentration was 4.28×10^{-5} mol dm^{-3}. Temperature was 24 °C.

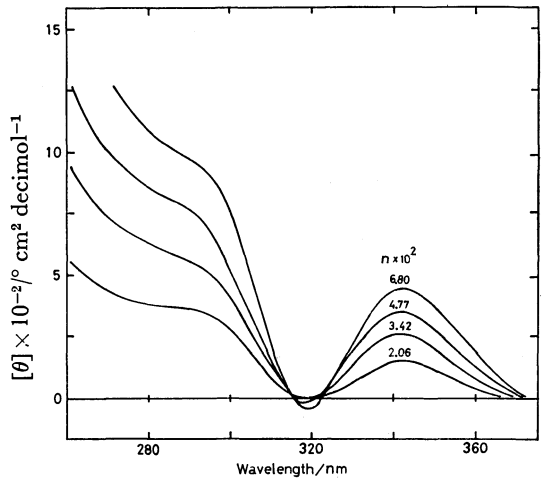

Fig. 3. CD spectra of poly(L-Lys): L-T_4 at pH 11. The ratios of the L-T_4 molecules to lysine residues of poly(L-Lys), n, are cited in the figure. Poly(L-Lys) concentration was kept at 5.31×10^{-6} mol dm^{-3}. The residue ellipticity was calculated on the basis of poly(L-Lys) concentration (DP=222).

free L-T_4 has no detectable optical activity in the wavelength region of 200—400 nm, even at a high concentration of 10^{-4} mol dm^{-3} (these data are not shown here). Therefore, the CD spectra of the poly(L-Lys) : L-T_4 system was measured in the wavelength region of 200—400 nm at pH 11 with a variation in the n ratio, which is defined as the ratio of L-T_4 molecules to the lysine residues of poly(L-Lys).

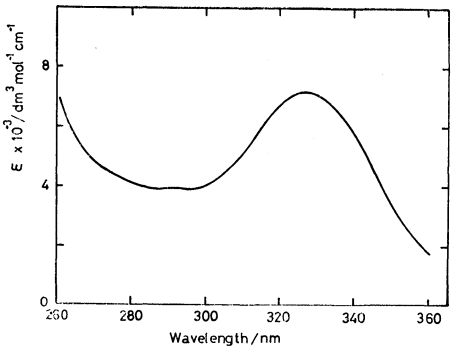

Fig. 4. The ultraviolet absorption spectra of poly(L-Lys): L-T_4 at pH 11.0. The spectra were the same for the ratios of L-T_4 molecules to lysine residues of poly(L-Lys) between 2.58×10^{-2} and 7.75×10^{-2}. Poly(L-Lys) concentration was kept at 5.31×10^{-6} mol dm^{-3}.

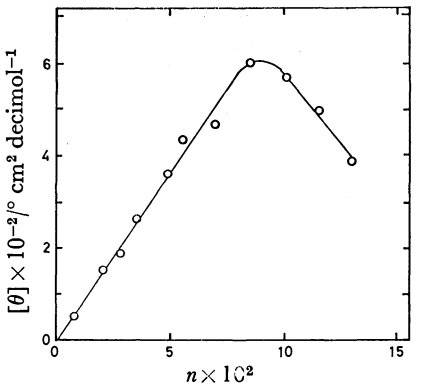

Fig. 5. Plot of the ellipticities of poly(L-Lys): L-T_4 at 343 nm against the ratio of the L-T_4 molecules to lysine residues of poly(L-Lys), n, and pH 11.0. Poly(L-Lys) concentration was kept at 5.31×10^{-6} mol dm^{-3}. The residue ellipticity was calculated on the basis of poly(L-Lys) concentration (DP=222).

The CD spectra and the absorption spectra of the poly(L-Lys) : L-T_4 mixture at various n values in the wavelength region of 260—380 nm are shown in Figs. 3 and 4 respectively. The positive CD bands with a peak near 343 nm and a shoulder around 270—300 nm were induced. The peak near 343 nm showed a red-shift by about 13 nm from the longest absorption maximum at 330 nm. The residue ellipticities at 343 nm are plotted against n in Fig. 5. They increased linearly with the increase in n up to about $n=9\times10^{-2}$, but thereafter they decreased. At n values of over 9×10^{-2} it was impossible to obtain reliable CD data because of the appreciable turbidity in the sample solution due to the aggregation of the poly(L-Lys) : L-T_4 complex. These results suggest the binding of L-T_4 to poly(L-Lys). The aggregation of poly(L-Lys) : L-T_4 might be a result of the neutralization of positively charged ε-amino groups of poly(L-Lys) by the binding of negatively charged hydroxyl and carboxyl groups of L-T_4, followed by an increase in the hydrophobic interaction between poly(L-Lys) : L-T_4 complexes.

The effect of L-T_4 binding on the helical poly(L-Lys) was also investigated by measuring CD and ORD in the far-ultraviolet region, 200—260 nm for CD and 210—

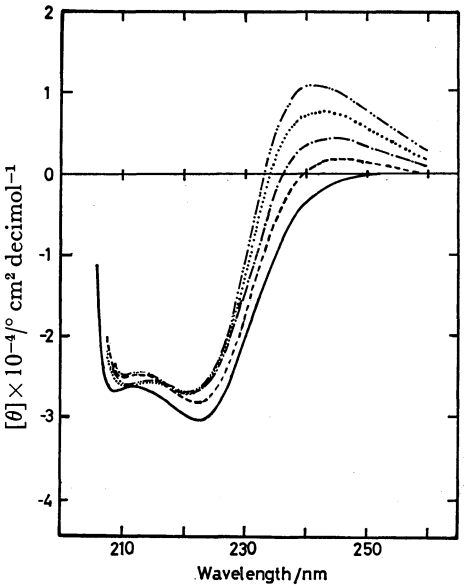

Fig. 6. The far ultraviolet CD spectra of poly(L-Lys): L-T_4 at pH 11.0. The ratios of the L-T_4 molecule to lysine residues of poly (L-Lys) mol are, poly(L-Lys) alone, (——); 2.25×10^{-2}, (------); 4.50×10^{-2}, (—·—); 6.75×10^{-2}, (·····); 9.00×10^{-2}, (-··-). Poly(L-Lys) concentration was kept at 6.13×10^{-6} mol dm^{-3}. The residue ellipticity was calculated on the basis of poly-(L-Lys) concentration (DP=222).

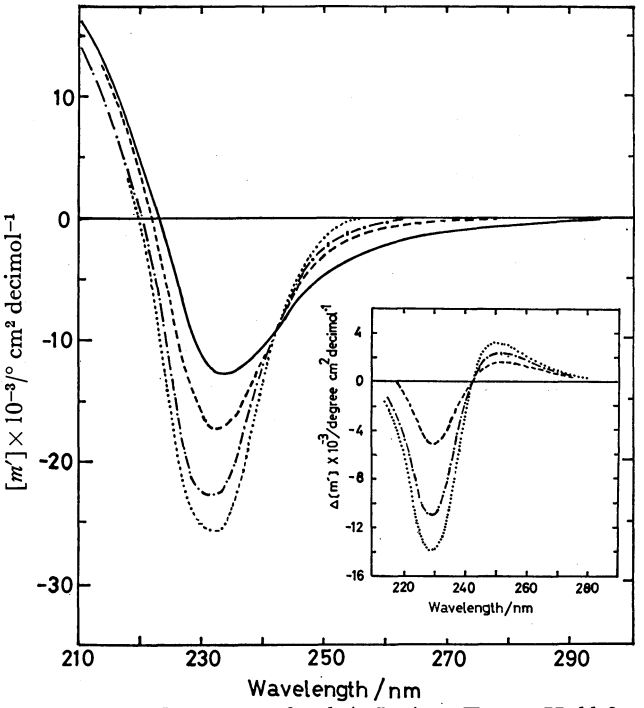

Fig. 7. ORD spectra of poly(L-Lys): L-T_4 at pH 11.0. The ratios of the L-T_4 molecules to lysine residues of poly(L-Lys) are, poly(L-Lys) alone, (——); 2.25×10^{-2}, (----); 4.50×10^{-2}, (-·-); 6.75×10^{-2}, (·····). Poly(L-Lys) concentration was kept at 6.50×10^{-6} mol dm^{-3}. The residue rotation was calculated on the basis of poly(L-Lys) concentration (DP=222). The difference rotation is also shown in the same figure.

300 nm for ORD. Figure 6 shows the CD spectra of poly(L-Lys) in the presence of various amounts of L-T_4. The CD spectrum of a free poly(L-Lys) at pH 11 is characteristic of the α-helical conformation, having the CD maxima both at 208 nm and 222 nm; these maxima are assigned to the π-π^* and n-π^* transitions of the peptide groups respectively, as has been reported by Greenfield and Fasman.[8] The percent helix of poly-(L-Lys) was calculated by means of the equation:[8]

$$\%\ \text{helix} = ([\theta]_{208}-4000)/(33000-4000), \quad (1)$$

where $[\theta]_{208}$ is the residue ellipticities at 208 nm. The helix content of poly(L-Lys) in the absence of L-T_4 was 78%. In the presence of L-T_4, a new CD band appeared at around 240 nm, although the characteristic CD bands at 208 nm and 222 nm still remained. Figure 7 shows the ORD spectra of poly(L-Lys) in the presence of various amounts of L-T_4. The ORD spectrum of a free poly(L-Lys) is characteristic of the α-helical conformation, as has been reported by Davidson *et al.*[10] The negative ORD band of poly(L-Lys) increased at 233 nm, and decreased around 250 nm, in the presence of L-T_4. The difference rotation, $\Delta[m']$, was obtained by subtracting the residue rotation of a free poly(L-Lys) from that of a poly(L-Lys) : L-T_4 mixture according to the following equation and inserted into Fig. 7:

$$\Delta[m'] = [m'](\text{poly(L-Lys)}:\text{L-}T_4) - [m'](\text{poly(L-Lys)}). \quad (2)$$

The difference ORD curves show a positive Cotton effect around 240 nm. These results of both CD and ORD measurements suggest that the Cotton effect observed in the 230—250 nm region was induced by L-T_4 bound to poly(L-Lys). From the data in Fig. 6, the difference ellipticity, $\Delta[\theta]$, was calculated in the same manner as in Eq. 2 by means of the following equation, and $\Delta[\theta]$ at 235 nm was plotted against n in Fig. 8:

$$\Delta[\theta] = [\theta](\text{poly(L-Lys)}:\text{L-}T_4) - [\theta](\text{poly(L-Lys)}). \quad (3)$$

It increased linearly with the increase of n up to about $n=9\times10^{-2}$, as was observed at 343 nm (Fig. 5). This indicates that the induced optical activity at around 235 nm as well as that at 343 nm is attributable to the binding of L-T_4 to poly(L-Lys). In this study, therefore, assuming that no conformational changes in the α-helical poly(L-Lys) were induced by the binding of L-T_4 at low n values, the difference CD spectrum was obtained by using Eq. 3 from the CD spectra measured at the same concentration of poly(L-Lys) at the wavelength region of 200—380 nm, while the difference molar ellipticity for L-T_4 was calculated on the basis of the L-T_4 concentration. The difference CD spectrum at $n=2.25\times10^{-2}$ (Fig. 9(a)) had a large positive peak near 235 nm, a small one at 343 nm, and two shoulders around 250 nm and 290 nm. The UV absorption spectra of the L-T_4 and poly(L-Lys) : L-T_4 mixture were also measured at the same n value ($n=2.25\times10^{-2}$) (Fig. 9(b)). In the case of the poly(L-Lys) : L-T_4 mixture, the UV maximum at 228 nm decreased and a new shoulder appeared near 250 nm, and the small peaks at both 290 nm and 330 nm increased as compared with a free L-T_4. The molar extinction coefficient of 7.25×10^3 at 330 nm for L-T_4 in the poly(L-Lys) : L-T_4 system is slightly larger than the values of 6.27×10^3

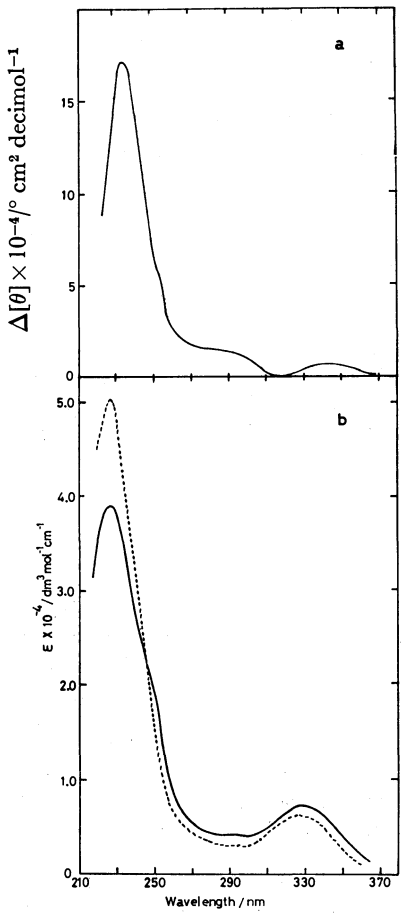

Fig. 9. (a): Difference CD spectrum of poly(L-Lys): L-T_4 obtained by subtracting the CD spectrum of poly(L-Lys) alone from that of poly(L-Lys): L-T_4. The concentration of poly(L-Lys) and L-T_4 were 1.13×10^{-5} mol dm^{-3} and 5.67×10^{-5} mol dm^{-3}, respectively. pH was 11.0. The difference ellipticity was calculated on the basis of L-T_4 concentration.
(b): The ultraviolet absorption spectra of poly(L-Lys): L-T_4, (——) and L-T_4, (……) at pH 11.0. The concentration of poly(L-Lys) and L-T_4 were 1.03×10^{-5} mol dm^{-3} and 5.10×10^{-5} mol dm^{-3}, respectively.

for the free L-T_4 at 325 nm, which is in good agreement with the 6.21×10^3 at 325 nm reported by Gemmill.[7] The induced CD bands appearing in the poly(L-Lys) : L-T_4 complex (Fig. 9(a)) coincided with the corresponding absorption maxima (Fig. 9(b)) except for the small red-shifts at 235 nm and 343 nm.

The induced CD bands observed in this study may be interpreted by the following mechanisms: (1) a certain fixed intramolecular orientation between the carboxyl group and the aromatic ring of L-T_4 occurs upon binding to poly(L-Lys), and (2) intermolecular interaction occurs between the peptide backbone of poly-

(L-Lys) (-C(=O)-N(H)-) and the bound L-T_4. At present, however, it is unclear why the CD maxima at the shortest and the longest wavelengths (235 nm and 343 nm) shifted to wavelengths a little longer from their UV absorption maxima at 230 nm and 330 nm.

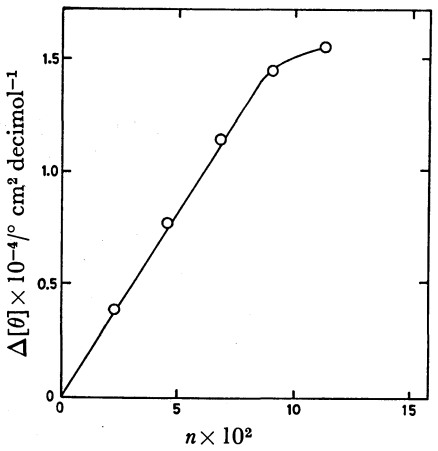

Fig. 8. Plot of the difference ellipticities of poly(L-Lys): L-T_4 at 235 nm against n and pH 11. Poly(L-Lys) concentration was kept at 6.13×10^{-6} mol dm^{-3}. The difference ellipticity was calculated on the basis of poly(L-Lys) concentration (DP=222).

Conclusion

The possibility of the binding of the thyroid hormone, L-T_4, to the α-helical poly(L-Lys) was strongly suggested by the facts that optical activity arising from L-T_4 was newly induced by mixing L-T_4 with α-helical poly-(L-Lys) at pH 11 and that the induced ellipticity increased linearly with an increase in the ratio of L-T_4 molecules to lysine residues of poly(L-Lys). The results of this study suggest that L-T_4 may bind to the helical region of non-specific proteins as well as of specific ones for L-T_4 containing lysine residues in their α-helical regions. The CD peaks observed in this study seem to be usable in investigating the interaction between L-T_4 and specific or non-specific proteins for L-T_4 or other synthetic polypeptides by means of CD measurements.

Bovine Serum Albumin Coordinated Iron-Sulfur Cluster as a Hydrogenase Model†

Ichiro OKURA,* Satoshi NAKAMURA, and Masatoshi KOBAYASHI
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received January 24, 1981)

The bovine serum albumin coordinated Fe_4S_4-cluster, which had hydrogenase activity, was synthesized. Its physical and chemical characteristics were then compared with those of natural hydrogenase. Though the affinities of hydrogenase and the albumin-coordinated Fe_4S_4-cluster for the substrate, methyl viologen, were similar, the hydrogenase activity for hydrogen evolution was 10^5 times greater than the cluster. Two types of Fe_4S_4-clusters, coordinated by the fragments of the cleaved albumin obtained by treatment with cyanogen bromide, were synthesized, and their hydrogenase activities were compared. The activity with the iron–sulfur cluster incorporated in the fragment with MW 40000 was much higher than that of the one incorporated in the fragment with MW 20000. The amino acid arrangement to form the active site was discussed on the analogy of the other iron-sulfur proteins.

The core structures of iron-sulfur proteins have been studied extensively, and the physicochemical investigations have conclusively established that iron-sulfur proteins have at least three fundamental types of central cores: $Fe(S\text{–}Cys)_4$, $Fe_2S_2(S\text{–}Cys)_4$, and $Fe_4S_4(S\text{–}Cys)_4$.[2]

Holm *et al.*[3–11] have reported the synthesis of the tetranuclear cluster complexes $[Fe_4S_4(SR)_4]^{2-}$ and binuclear cluster complexes $[Fe_2S_2(SR)_4]^{2-}$ (R=alkyl or aryl), whose structure and properties demonstrate them to be a close representation of the central cores of iron–sulfur proteins, and have developed the core-extrusion method for the identification of active sites in native iron-sulfur proteins. Rabinowitz *et al.*[12–14] have also applied the method to the preparation and isolation of apoprotein of ferredoxin from *Clostridium pasteurianum*, and have reconstituted ferredoxin by the addition of iron(II) ions, sodium sulfide, and 2-mercaptoethanol. This procedure, which has considerable utility, is now being applied to other iron-sulfur proteins.[15–17]

Recently we found,[18–21] by the extrusion and reconstitution techniques mentioned above, that the hydrogenase from *Desulfovibrio vulgaris* contained two Fe_4S_4-type clusters per enzyme molecule; we also found[18,20] two active sites per enzyme molecule by kinetics and an inhibition method with mercury(II) chloride. The presence of three Fe_4S_4-type clusters has been established in the case of the hydrogenases from *Desulfovibrio gigas*[22] and *Clostridium pasteurianum*,[11] which contain 12 iron atoms and 12 labile sulfur atoms per molecule. Generally, hydrogenase is regarded as an iron-sulfur protein with Fe_4S_4-type clusters. Although the Fe_4S_4-cluster alone does not have the hydrogenase activity,[23] the Fe_4S_4-clusters synthesized in the presence of apo-hydrogenase has the catalytic activity.[21] Therefore, the Fe_4S_4-cluster and also the environment of the Fe_4S_4-cluster within the protein, such as apo-hydrogenae, play important roles in the hydrogenae activity.

In this paper we wish to describe the development of a hydrogen-evolution system which combines the Fe_4S_4-cluster and some protein, and to compare the characteristics of the artificial and natural hydrogenase.

† Part of this paper has been published as a preliminary communication in *J. Mol. Catal.*[1]

Experimental

Materials. The methyl viologen (1,1′-dimethyl-4,4′-bipyridinium dichloride) and trypsin were purchased from the Tokyo Kasei Kogyo Co. and ICN Pharmaceuticals Inc. respectively. The bovine serum albumin, α-chymotrypsinogen-A, and lysozyme were products of the Sigma Chemicals Co. The other chemicals, obtained from the Wako Pure Chemicals Co., were the best commercial grades available. All solutions were degassed and stored under nitrogen. The nitrogen gas was purified by passage through a copper column at 200 °C.

The copolymer of styrene and *p*-vinylphenylmethanethiol was synthesized according to the procedure of Okawara *et al.*[24]

Hydrogenase from the *Desulfovibrio vulgaris* (Miyazaki type, which has kindly been provided by Professor T. Yagi of Shizuoka Univ.) was purified according to the procedure of Yagi *et al.*[25,26]

Measurement of Hydrogenase Activity. The hydrogenase activity was measured under anaerobic conditions. The hydrogenase activities of the iron-sulfur proteins were determined by the rate of hydrogen evolution from reduced methyl viologen at 30 °C and pH 7.0. The evolved hydrogen was analyzed by gas chromatography on a 2 m×0.5 mm active carbon column (Gasukuro Kogyo Co.) with a nitrogen carrier. The reaction mixture (8.5 ml) consisted of 4.0 ml of the iron-sulfur protein solution with the 7.73×10^{-7} M Fe_4S_4-cluster described in "Synthesis of Iron-Sulfur Clusters," 1.96 μmol of methyl viologen, and 5 mg of $Na_2S_2O_4$ in 4.5 ml of a 0.02 M phosphate buffer (pH 7.0).

Synthesis of Iron–Sulfur Clusters. The $[Fe_4S_4(SR)_4]^{2-}$ complexes (R=phenyl or *t*-butyl) were prepared by the procedure of Holm *et al.*[4] The synthesis of other iron-sulfur clusters was carried out under a nitrogen atmosphere as follows. To a stirred solution of thiol or protein with mercapto ligands (4×10^{-5} mol) in 4 ml of H_2O containing 0.01 M iron(II) chloride, 2 ml of aq Na_2S (0.02 M) were added; the mixture thereupon turned dark brown in each case and was incubated at 30 °C for 30 min. The solution was then centrifuged (20000 g×30 min) to remove fine black precipitate, which may be iron(II) sulfate.

Cleavage of Bovine Serum Albumin. Albumin was cleaved according to the method of King and Spencer.[27] To 12.2 ml of a formic acid (75%) solution containing 26.4 μmol of albumin, we added a solution of cyanogen bromide (2.31 mmol) in 36 ml of formic acid, after which the solution was stirred for 20 h at room temperature. Then the solution was

placed in a Sephadex G-75 column (2.2 cm × 140 cm) and eluted with the 0.02 M Tris–HCl buffer (pH 7.0; to compare the hydrogenase activity, this pH value was employed, for this value was suitable for the hydrogenase). The eluted solution was then concentrated by ultrafiltration with an UM-2 Diaflo membrane.

Results and Discussion

Preparation and Properties of Bovine Serum Albumin Coordinated Iron–Sulfur Cluster. The method used for the preparation of the albumin cluster was a modification of those of Suzuki and Kimura[28] and Lovenberg and McCarthy.[29] The preparation was carried out under a nitrogen atmosphere as follows: eighty milligrams of albumin was dissolved in 6 ml of water containing 6.7 mM iron(II) chloride or ammonium iron(II) sulfate. 2-Mercaptoethanol (0.4 ml) was then added, followed by 2 ml of aq Na_2S (0.02 M).

In order to separate the albumin-cluster from the excess reagents, the solution containing the albumin-cluster was placed in a Sephadex G-50 column (5 cm × 23 cm) with 0.02 M Tris–HCl (pH 7.0) containing 0.08 M NaCl as an eluting buffer. The eluting solution was monitored by means of the absorption bands for proteins and iron–sulfur clusters; the results are shown in Fig. 1. Albumin came out at the elution position peak A. As the eluting solution has the absorption band at 420 nm which is attributable to the iron–sulfur clusters, and also a molecular weight corresponding to albumin, the product is not a crude mixture of albumin and the iron–sulfur cluster, but the iron–sulfur clusters incorporated in albumin. The solution was dark brown, and iron(II) sulfide as a by-product may also be incorporated in the protein. Although the eluting solution corresponding to Peak A was centrifuged at 20000 g for 60 min to remove the black precipitate, it was not separated from the protein completely. The iron–sulfur clusters incorporated in albumin were not synthesized by the reaction of the preformed iron–sulfur cluster and albumin. Therefore, the iron(II) sulfide concomitant in the iron-sulfur incorporated in albumin was not avoided by this method. The specific absorption coefficients, 35600 $M^{-1}\,cm^{-1}$ at 280 nm and 14000 $M^{-1}\,cm^{-1}$ at 420 nm,[28] were used to estimate the concentrations of protein and iron–sulfur clusters respectively. The B peak also has ultraviolet and visible absorption bands which seem to be due to an excess of the 2-mercaptoethanol reagent and the synthesized $Fe_4S_4(S\text{–}CH_2CH_2OH)_4$ dianion respectively.

When the solution of the iron–sulfur cluster incorporated in albumin (albumin-cluster; the spectrum is shown in Fig. 2, Curve a) was incubated under a hydrogen atmosphere at 30 °C, the spectrum of the solution changed as is shown in Fig. 2, Curve b. When exposed in air, the spectrum returned to its original shape. A similar spectrum change has been observed[26] in the reduction of hydrogenase from *Desulfovibrio vulgaris* by hydrogen. In this case, however, cytochrome C_3 is needed as an electron-acceptor. When excess 2-mercaptoethanol is added to the albumin-cluster solution for the identification of the core types, the obtained absorption spectrum (λ_{max}=410 nm) of the resulting solution resembled that of the synthesized $Fe_4S_4(S\text{–}CH_2CH_2OH)_4$ dianion, as is shown in Fig. 2, Curve c. From the above results, the iron–sulfur clusters incorporated in albumin seem to be Fe_4S_4-type clusters, but another possibility still remains that the corresponding Fe_2S_2-clusters were rapidly converted to the Fe_4S_4-clusters.

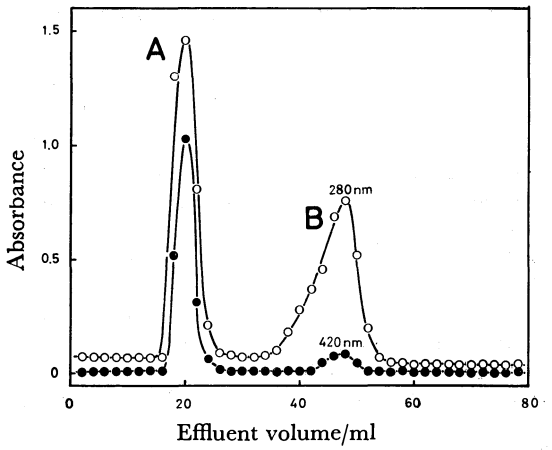

Fig. 1. Elution patterns of the albumin-cluster from a Sephadex G-50 column.

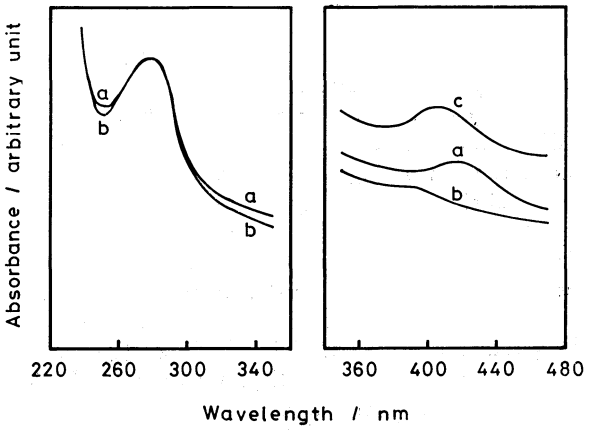

Fig. 2. Absorption spectra of the albumin-cluster.
a: Albumin-cluster, b: Albumin-cluster is incubated under hydrogen for 24 h, c: Mixture of albumin-cluster and 2-mercaptoethanol.

We lack the extinction coefficient data for the spectrum required for a quantitative analysis of the $Fe_4S_4(S\text{–}CH_2CH_2OH)_4$ dianion. However, it is clear that the Fe_4S_4-cluster is the dominant product.

Synthesis of Various Iron–Sulfur Clusters. The method used for the preparation of the iron–sulfur clusters with various mercapto ligands was the same as that used for the albumin-clusters. Though a number of Fe_4S_4 cores are synthesized in the presence of some thiols, SH-containing polymer, and natural proteins containing cysteinyl residues instead of apo-hydrogenase, an estimation has not been made whether each product is a crude mixture of protein and the iron–sulfur cluster or the iron–sulfur cluster incorporated in a compound as a ligand. As is evident from Table 1, no cluster complex but the albumin-coordinated Fe_4S_4-cluster can catalyze the hydrogen-evolution reaction from reduced methyl

Table 1. Catalytic activities of synthesized iron–sulfur clusters

Ligand	Solvent[a)]	Activity (mol-H_2/min/mol-Catal.)
2-Methyl-2-propanethiol	DMF/H_2O	0
Thiophenol	HMPA/H_2O	0
2-Mercaptoethanol	H_2O	0
Dithiothreitol	H_2O	0
Glutathione	H_2O	0
L-Cysteine	H_2O	0
Copolymer of styrene and *p*-vinylphenylmethanethiol	DMSO/H_2O	0
Bovine serum albumin	H_2O	9.62×10^{-3}

viologen, although its activity is lower than that of the actual enzyme, hydrogenase.

Specificity for Electron Carriers and Kinetics. When the albumin-cluster was added to a solution of dithionite-reduced methyl viologen, hydrogen evolved under the same conditions of hydrogenase-activity measurement. Various redox carriers were tested to see if they would replace methyl viologen and mediate the electron transfer to the albumin-cluster from dithionite. The electron-carrier specificities for albumin-cluster and hydrogenases are compared in Table 2. The albumin-cluster was specific for methyl viologen and nicotinamide–adenine dinucleotide.

The time course showed that the amount of hydrogen evolved from reduced methyl viologen increased linearly with the time. It is reasonable to assume that the iron–sulfur cluster in the albumin-cluster (which has not been separated from iron(II) sulfide) has a central role in hydrogen evolution, because it has been confirmed experimentally that iron(II) sulfide has no activity for hydrogen evolution. With a 44-h reaction time, the molar ratio (the turnover number) of the evolved hydrogen for the iron–sulfur cluster was 18.[1)] This means that the albumin-cluster behaves as a catalyst. Though the stability of the albumin cluster was not examined, it seems fairly stable in the long term because it was still intact after a 44-h reaction.

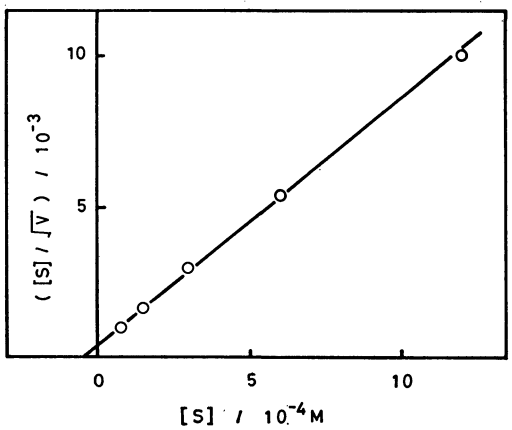

Fig. 3. Relation between $[S]/\sqrt{V}$ and [S].

The initial rate of hydrogen evolution increased with the methyl viologen concentration until it finally reached a constant value. In the case of the hydrogenase, the rate of hydrogen evolution from reduced methyl viologen was expressed as follows:[20,30)]

$$V=\frac{kK^2[S]^2}{(1+K[S])^2},$$

or

$$\frac{[S]}{\sqrt{V}}=\frac{[S]}{\sqrt{k}}+\frac{1}{\sqrt{k}K},$$

where k and K are constants and where [S] is the concentration of methyl viologen. In the case of the albumin-cluster, a good linear relation was also obtained between $[S]/\sqrt{V}$ and [S], as is shown in Fig. 3. Although the $[S]/V$ *vs.* [S] plot on the basis of the first-order kinetic equation:

$$V=\frac{kK[S]}{1+K[S]}$$

was also tried, there were some deviations. The albumin-cluster may also catalyze hydrogen evolution by the same mechanism as that of the hydrogenase. From the slope and the intercept, the equilibrium constant, K, and the rate constant, k, for hydrogen evolution from

Table 2. Electron-carrier specificity in H_2 evolution by the hydrogenase from *Desulfovibrio vulgaris* and the albumin-cluster

Electron carrier	Concentration M	Activity (mol-H_2/min/mol-Catal.)	
		Hydrogenase	Albumin-cluster
Cytochrome C_3	5.94×10^{-7}	245	0
Flavin monoculeotide	2.45×10^{-4}	Trace	0
Nicotinamide–adenine dinucleotide	1.61×10^{-4}	13	4.54×10^{-3}
Coenzyme II	1.72×10^{-4}	0	0
Methyl viologen	2.48×10^{-4}	1770	9.62×10^{-3}
Methylene Blue	1.96×10^{-4}	0	0
Neutral Red	2.03×10^{-4}	47	0
Safranine T	2.07×10^{-4}	40	0
Phenosafranine	1.91×10^{-4}	34	Trace
Potassium hexacyanoferrate(III)	2.01×10^{-4}	0	0

reduced methyl viologen at 30 °C were calculated as follows:

Catalyst	K / M^{-1}	k / min^{-1}
Hydrogenase	8.8×10^{3}	2.3×10^{3}
Albumin-cluster	1.9×10^{4}	1.5×10^{-2}

Judging from the K values, the affinity of the albumin-cluster for methyl viologen seems to be similar to that of the hydrogenase. The k value of hydrogenase, however, was 10^5 times greater than that of the albumin-cluster.

Effect of Mercury(II) Chloride. As has been reported earlier[15,20] some heavy metals, mercury, copper, and silver, strongly inhibit the activity of the hydrogenase, even though their concentrations are low in comparison with that of the hydrogenase. Although the albumin-cluster was inhibited in the presence of mercury(II) chloride, as is shown in Table 3, it was less inhibited than the hydrogenase at the same concentration. Mercury atoms are exchangeable with the iron atoms in the hydrogenase,[20] and the inhibition of the hydrogenase by mercury(II) chloride is a result of the exchange between mercury and iron. Although the inhibition by metal ions is explained by the binding of these ions to the thiolate sulfurs, the inhibition of the albumin-cluster by mercury(II) chloride may be caused by the exchange between mercury and iron, just as in the case of the hydrogenase.

Cleaved Bovine Serum Albumin Coordinated Iron–Sulfur Clusters. Though the Fe_4S_4-cluster of the albumin-cluster combines cysteine residues of albumin, none of the cysteine residues (there are 35 cysteine residues per albumin molecule[31]) participate in the cluster formation, for the concentration of the synthesized clusters is low compared to that of the cysteine residues. To determine the situation needed for the hydrogenase model, the hydrogenase activities were measured with Fe_4S_4-clusters with cleaved albumin as ligands.

The cyanogen bromide cleavage of albumin between two amino acid residues, 183 (Met) and 184 (Arg), gives two peptides with molecular weights of 40000 and 20000.[27] A chromatogram of the formic acid solution containing albumin and cyanogen bromide obtained by means of a Sephadex G-75 column is shown in Fig. 4. Fragment 1 is the original albumin, while Fragments 2 and 3 are examples of cleaved albumin with molecular weights of 40000 and 20000 respectively. The reagents to produce the Fe_4S_4-cluster, iron(II) chloride, 2-mercaptoethanol, and Na_2S, were added to a solution containing the protein corresponding to Fragment 2 or 3, and then the mixture was placed in a Sephadex G-50 column to remove the excess reagents as well as to produce albumin-cluster synthesis. As is shown in Table 4, the activity of the iron-sulfur cluster incorporated in Fragment 2 was much higher than that of the one incorporated in Fragment 3.

Table 3. Inhibition by mercury(II) chloride

Hg^{2+}/Cluster (M/M)	% Activity[a]	
	Hydrogenase	Albumin-cluster
0	100	100
5	82	100
20	42	100
50	0	53
100	—	0

a) Samples were preincubated with $HgCl_2$ for 24 h at 4 °C. Methyl viologen: 2.31×10^{-4} M.

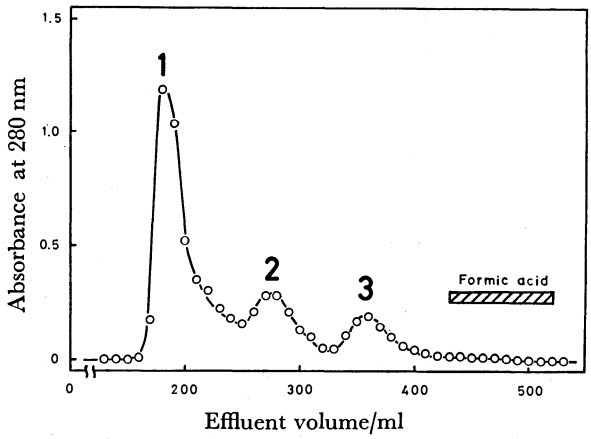

Fig. 4. Separation of cyanogen bromide fragments of albumin on a Sephadex G-75 column.

In albumin, two cysteine residues are adjacent to each other except for the two cysteine residues 276 and 280, where three other amino-acid residues are incorporated between them. This part belongs to Fragment 2 in the cleaved albumin, and there is no other remarkable difference in geometrical arrangement between Fragments 2 and 3. Judging from the chelate structures of other iron–sulfur proteins determined by X-ray diffraction studies,[2] the following two situations in amino acid sequence seem to be required for Fe_4S_4-cluster formation: the existence of four cysteine residues as ligands close to each other, and the presence of two, three, or four other amino acids between the cysteine residues. As Fragment 2 contains the portion of the 263—287 residues which satisfies the situation, the iron-sulfur cluster will be incorporated at this portion of Fragment 2. The concentration of the iron-sulfur cluster is comparable with that of Fragment 2 protein.

Table 4. Hydrogenase activities with some clusters[a]

Protein source	Protein concentration / M	Cluster concentration / M	Activity (mol-H_2/min/mol-cluster)
Albumin whole chain	3.74×10^{-6}	7.73×10^{-7}	7.75×10^{-3}
Fragment 2	1.86×10^{-6}	1.34×10^{-6}	4.84×10^{-3}
Fragment 3	3.42×10^{-6}	2.46×10^{-6}	5.70×10^{-4}

a) See text for reaction conditions.

This means that only one cluster is formed per protein molecule.

After all, not only the proper distance between two cysteine residues which is suitable for the formation of the Fe_4S_4-core in the albumin molecule, but also the proper amino acid residues near the active-site core seem to be required for the hydrogenase activity.

We wish to express our appreciation to Professor Tominaga Keii for his stimulating and helpful discussions.

Application of the Water-gas Shift Reaction. I. Hydrogenation and Hydroformylation Reactions of Olefins with Carbon Monoxide and Water Catalyzed by Rhodium Phosphine Complexes

Tamon OKANO,* Teruyuki KOBAYASHI, Hisatoshi KONISHI, and Jitsuo KIJI*

Department of Environmental Chemistry and Technology, Faculty of Engineering, Tottori University, Tottori 680

(Received February 12, 1981)

The hydrogenation of methyl crotonate with CO and H_2O is efficiently catalyzed by $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ or $[RhCl(C_7H_8)]_2/P(i\text{-}Pr)_3/n\text{-}BuLi$ (C_7H_8=norbornadiene). Both catalyst precursors are shown to form the same active species; *trans*-$Rh(OH)(CO)[P(i\text{-}Pr)_3]_2$. The catalytic activity of the system ($[RhCl(C_7H_8)]_2$/phosphine/*n*-BuLi) increases with increase of the basicity of the phosphine ligands (phosphine=$P(i\text{-}Pr)_3>P(n\text{-}Bu)_3>PPh(i\text{-}Pr)_2>PPh_2(i\text{-}Pr)>PPh_3$). This reaction is also applicable to the hydrogenation of the C=C bond of electron-withdrawing olefins and the C=O bond of ketones and aldehydes. Interestingly, the catalysis for the C=C bond, to which less electron-withdrawing groups are attached, gives dominantly aldehydes due to hydroformylation. The mechanism is also discussed.

The water-gas shift reaction (Eq. 1) attracts our attention from a viewpoint of the use of coal as a hydrogen source. Recently, many studies have been reported on the shift reaction using homogeneous catalysts,[1-4] which are active even at such a low temperature as the boiling point of water. The catalysis generates such a reactive reducing species that hydrogenation[5] and hydroformylation[6,7] of olefins, reduction of nitrobenzenes,[8,9] and α-methylation of ketones[10] and *N*-methylation of amines[11] with formaldehyde have been carried out in homogeneous phase without using molecular hydrogen.

$$CO + H_2O \longrightarrow CO_2 + H_2 \quad (1)$$

To date, metal carbonyls combined with base[1,5,6,8-11] or acid[2] have habitually been used for the shift reaction as well as the organic reactions, while these catalyst systems are perturbed by side reactions such as aldol condensation, hydrolysis, isomerization of double bond, *etc.* One of our authors has reported that homogeneous rhodium phosphine complexes possess high catalytic activities for the shift reaction in an essentially neutral solution.[4] Though few reports have appeared on the catalysis of phosphine complexes for Eq. 1, phosphine complexes are, in general, more active than metal carbonyls in the homogeneous catalytic hydrogenations and hydroformylation reactions.

Aiming at application of the water-gas shift reaction to the organic reactions, we employed the homogeneous rhodium phosphine complexes as the catalyst. The present paper deals with the hydrogenation and the hydroformylation of olefins using carbon monoxide and water in place of molecular hydrogen.

Table 1. Hydrogenation of methylcrotonate with CO and H_2O catalyzed by triphenylphosphine complexes of group VIII[a]

Results and Discussion

Catalytic Activity of Group VIII Metal Complexes. Because it is easily hydrogenated and hydroformylated, methyl crotonate was used as a typical substrate to survey the catalytic activities of different Group VIII metal complexes of triphenylphosphine. The results are shown in Table 1. The catalytic activity increased in the order; Rh>Ru>Co≫Pd. Among them the halide-free rhodium complex, $RhH(CO)(PPh_3)_3$ (**1**), was found to be most active. Methyl butyrate was

formed in a 90% yield. Thus, the halide-free rhodium complexes were used hereafter in the present study to widen the scope of the application of the water-gas shift reaction to the organic reactions.

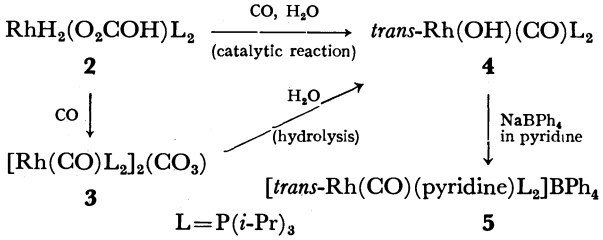
Little is known about the synthetic method for the hydrido rhodium(I) complexes of various phosphines, which are expected as the effective catalyst precursor. Therefore, the effects of the phosphine ligands were examined using a catalyst precursor prepared *in situ* by the reaction of $[RhCl(C_7H_8)]_2$ with *n*-BuLi in the presence of phosphine, which affords the hydrido complex (*vide infra*). The results are summarized in Table 2. By successive replacement of the phenyl groups on the phosphorus of triphenylphosphine by alkyl groups, the catalytic activity for the hydrogenation increased in the order; P(*i*-Pr)$_3$>PPh(*i*-Pr)$_2$>PPh$_2$(*i*-Pr)>PPh$_3$. The replacement by the isopropyl group makes the phosphine more electron-donating and bulky.[12] The activity of the system using P(*n*-Bu)$_3$, which is less bulky than any other ligands examined, was close to that using PPh(*i*-Pr)$_2$. In general, ligand effects may be separated into electronic and steric factors. According to Tolman,[13] the infrared CO stretching frequencies of Ni(CO)$_3$L (L=P(*n*-Bu)$_3$ and PPh(*i*-Pr)$_2$), which reflect the electronic donor-acceptor property of L, are 2060.3 and 2062.4 cm^{-1}, respectively. Both are estimated to be similar in electronic nature. Consequently, the above results suggest that the electronic factor of the auxiliary ligand is more dominant than the steric factor over the greater part of the catalytic activity for the hydrogenation.

In some cases, small amounts of aldehydes were formed by hydroformylation. Their yields increased in the order similar to that of the hydrogenation product, but no appreciable amounts of aldehydes were formed in the case of P(*n*-Bu)$_3$. A plausible interpretation of the fact is described later. From these results, P(*i*-Pr)$_3$ was one of the most effective auxiliary ligands.

Catalyst Precursor. When a THF solution containing $[RhCl(C_7H_8)]_2$, P(*i*-Pr)$_3$, and *n*-BuLi was treated with H_2O and CO_2 (1 atm), a dihydrido hydrogencarbonato complex, $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ (**2**), was obtained. This complex is known to be formed also *via* the oxidative addition of H_2O and CO_2 to $RhH[P(i\text{-}Pr)_3]_3$ or *trans*-$RhH(N_2)[P(i\text{-}Pr)_3]_2$.[14] It has also been reported that *trans*-$RhH(N_2)[PPh(t\text{-}Bu)_2]_2$ is isolated from the reaction mixture of $[RhCl(CH_2{=}CH_2)_2]_2$ with *n*-BuLi in the presence of the phosphine under an atmosphere of nitrogen.[15] These facts indicate that the reaction of $[RhCl(C_7H_8)]_2$ with *n*-BuLi in the presence of phosphine presents a general method to provide the halide-free hydrido phosphine complexes. The dihydrido hydrogencarbonato complex (**2**) is known to react readily with CO to give a carbonyl carbonato complex, $\{Rh(CO)[P(i\text{-}Pr)_3]_2\}_2(CO_3)$ (**3**).[14] Since large amounts of CO, H_2O, and CO_2 are present in the catalytic system, the three catalyst precursors, $[RhCl(C_7H_8)]_2$/P(*i*-Pr)$_3$/*n*-BuLi, **2**, and **3**, shown in Table 3 must form the same active species. The reaction mixture catalyzed by **2** was treated with $NaBPh_4$ in the

$$[RhCl(C_7H_8)]_2 + P(i\text{-}Pr)_3 + n\text{-BuLi} \longrightarrow [\text{rhodium(I) hydride}] \xrightarrow{H_2O,\ CO_2} RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2 \quad \mathbf{2}$$

presence of pyridine to give a cationic complex, {*trans*-Rh(CO)(pyridine)[P(*i*-Pr)$_3$]$_2$}BPh$_4$ (**5**), which is known to be formed by a similar treatment of **3**.[4] This fact suggests that the hydroxo complex, *trans*-Rh(OH)(CO)-[P(*i*-Pr)$_3$]$_2$ (**4**), plays an important role in the catalysis, because **4** in pyridine is known to be in equilibrium with a solvated ion pair complex which produces **5** by an anion exchange with BPh_4^-.[4]



Scheme 1.

Hydrogenation and Hydroformylation of Various Olefins. The reactions of electron-withdrawing and -donating olefins are summarized in Table 4. The hydrogenation of the electron-withdrawing olefins occurred exclusively, except for methyl crotonate. On the contrary, the hydroformylation of styrene occurred in preference to

a) Conditions; $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$=0.1 mmol, substrate=20 mmol, H_2O=50 mmol, P_{CO}=15 atm, THF=6.5 ml, 115 °C, 20 h. b) Based on the substrate used. c) At 150 °C. d) At 165 °C.

hydrogenation. α-Methylstyrene and alkenes gave only the corresponding aldehydes. It is well known that hydrogenation incidental to the hydroformylation with CO and H_2 becomes dominant in the reaction of electron-withdrawing olefins such as α,β-unsaturated aldehydes and ketones,[16] or under conditions of higher H_2/CO ratio.[17] The hydrogen pressure during the reaction of electron-withdrawing olefins is, however, estimated to be very low, because the amount of molecular hydrogen is, at the highest, equal to that of CO_2 produced by the water-gas shift reaction. For example, the yield of CO_2 shown in Table 3 is almost equal to the total yield of organic products. Actually, in the course of the reaction of methyl crotonate (at a 71% conversion), the partial pressure of hydrogen observed was *ca.* 0.09 atm, meaning the H_2/CO ratio to be 0.01. These facts suggest that the hydrogenation of electron-withdrawing olefins occurred at least to a great extent with CO and H_2O as the reducing agent, without intermediate generation of molecular hydrogen. The fitting mechanism is discussed below.

Hydrogenation of carbonyl groups was somewhat difficult. Ketones and aldehydes were reduced only above 150 °C. Namely, α,β-unsaturated carbonyl compounds afforded selectively the corresponding saturated ketones and aldehydes at 115 °C, and at 150 °C the corresponding alcohols were obtained. Nitrobenzene could also be reduced to aniline quantitatively at 165 °C, but the phenyl ring remained unchanged.

Effects of CO and H_2 Pressure. The rate and the product distribution of this reaction strongly depended upon the pressure of CO (Table 3). The maximum conversion of methyl crotonate was attained at 30 atm of the initial CO pressure, and the selectivity to the hydrogenation was decreased with increasing the CO pressure up to 30 atm because of the enhanced rate of the hydroformylation. The insertion of CO into the alkyl-rhodium bond, which is involved in an intermediate, seems to be favored at a moderate pressure. Under higher pressure of CO, however, both the hydrogenation and the hydroformylation were inhibited. The reduced activities are probably ascribed to the decrease in coordinative unsaturated species by the coordination of CO.[18]

To inquire how the addition of molecular hydrogen exerts action on this hydrogenation, methyl crotonate (40 mmol) was reduced in a THF solution containing D_2O (100 mmol) under H_2 (40.6 mmol) and CO (40.6 mmol). After the reaction, the gas phase in the autoclave was a mixture of CO_2 (8.5 mmol), H_2, HD, and D_2 (total 9.3 mmol), and CO (30.2 mmol). Methyl butyrate (38 mmol) was formed. The sum of the amounts of CO_2 formed and H_2 consumed is in good agreement with the yield of methyl butyrate. The result is a consequence of the fact that side reactions are negligible. Therefore, at the highest 21% (CO_2 formed (8.5 mmol)/[H_2 consumed (31.3 mmol)+CO_2 formed]) of the hydrogenation would occur with CO and D_2O rather than H_2 as the reducing agent. However, the

TABLE 5. DEUTERIUM CONTENT OF THE PRODUCTS OF THE HYDROGENATION AND THE HYDROFORMYLATION WITH CO, D_2O, AND H_2[a]

Source of methyl butyrate[c]	Deuterium content (atm-%)[b]	
	α-CH	β-CH
Methyl crotonate CO (15 atm)/D_2O/H_2 (15 atm)	78	41
Methyl crotonate CO(1 atm)/D_2O/H_2 (15 atm)	70	15
Methyl butyrate CO(15 atm)/D_2O/H_2 (15 atm)	<5	<5
Source of β-phenylpropanal[d]	-CHO α-CH	β-CH
α-Methylstyrene CO(15 atm)/D_2O/H_2 (15 atm)	22 6	19

a) Conditions ; $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2 = 0.2$ mmol, $D_2O = 100$ mmol, THF = 6.5 ml, 115 °C. b) The values show deuterium contents out of the hydrogen and deuterium incorporated. c) For 7.5 h. d) For 1 h.

^{1}H-NMR analysis of the formed methyl butyrate showed 59% incorporation of deuterium. Its contents at the 2- and 3-positions were 78 and 41 atom-%,

$$CH_3CH{=}CHCOOCH_3 \xrightarrow{CO,\ D_2O,\ H_2} CH_3{-}CH_{1.59}D_{0.41}{-}CH_{1.22}D_{0.78}{-}COOCH_3$$

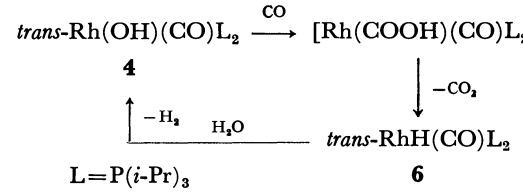
respectively. In a separated experiment, it was confirmed that theH-D exchange reaction of methyl butyrate with D_2O does not occur under these conditions. Another possibility of H-D exchange proceeding through alkylrhodium intermediates (**8a** and **8b**), *i.e.*, a half hydrogenated state, *via* metal hydride addition and elimination[19] (see Scheme 3, **4**⇌**6**⇌**7**⇌**8**) is excluded for the following reason. If this exchange were sufficiently fast, the deuterium contents at the 2- and 3-positions would be closely similar, and would not be effected by the amount of CO (*vide infra*). Therefore, the facts that the amount of deuterium incorporated into methyl butyrate is larger than that of CO_2 formed and that the deuterium content at the 2-position is higher than that at the 3-position rationalize the following assumption; D_2O itself participates in the hydrogenation to a considerable extent without generating D_2 and CO_2, and the hydrogen (deuterium) added to the 2-carbon atom comes dominantly from the water even under a pressure of H_2 (see Cycle B in Scheme 3). The nature of this hydrogenation process is discussed below in more detail.

A similar reaction of methyl crotonate with D_2O and H_2 under a low pressure of CO (1 atm, 2.7 mmol) also gave deuterated methyl butyrate (80% yield), of which deuterium content at the 2- and 3-positions was 70 and 15 atom-%, respectively. Interestingly, lowering CO pressure decreased the deuterium content at the 3-position more markedly than that at the 2-position. The result indicates that the reaction of methyl crotonate with CO–D_2O–H_2 includes the hydrogenations with CO–D_2O (Cycle A) and with D_2O–H_2 (Cycle B), which give methyl butyrate-2,3-d_2 and -2-d, respectively.

The addition of molecular hydrogen extremely accelerated the hydroformylation of α-methylstyrene with CO and D_2O, and a conversion of 68% was reached within 1 h at 115 °C. At the time, the yield of CO_2 was 4.5% based on α-methylstyrene converted. 3-Phenylbutanol, which was formed in a 67% yield, contained 22, 6, and 19 atom-% of deuterium at the 1, 2, and 3-positions, respectively. From the fact that the deuterium contents at the 1- and 3-positions are equal within experimental errors, the incorporated deuterium seems to come from D_2 and HD generated by H-D exchange reactions.[20]

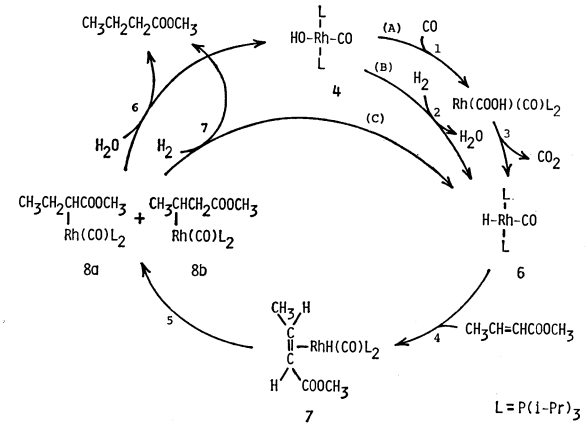
Reaction Mechanism. The hydrogenation with CO and H_2O occurs in two stages; (*i*) formation of a reducing species by a reaction of the catalyst with CO and H_2O, and (*ii*) hydrogenation of olefin with the reducing species. The catalysis in the former stage (*i*) is explained by the same mechanism as the water-gas shift reaction catalyzed by **2**,[4] because both the hydrogenation and the shift reaction were ascertained to contain the hydroxo complex (**4**) as one of the active key intermediates. The precise reaction pathway for the formation of a hydrido complex, *trans*-$RhH(CO)[P(i\text{-}Pr)_3]_2$ (**6**), and molecular hydrogen, in which **4** plays an important role, has been reported elsewhere.[4]

The hydrido complex (**6**) thus formed is a homologue of the active species of $RhH(CO)(PPh_3)_3$ (**1**) which is widely used as catalyst, not only for hydrogenation but also for hydroformylation. Therefore, complex **6** is most



Scheme 2.

suitable for the key intermediate in the latter stage (*ii*). The possible routes for the hydrogenation of methyl crotonate are shown in Scheme 3. In the hydrogenation and the hydroformylation using CO and H_2O, an σ-alkylrhodium intermediate formed by the insertion of olefin into the rhodium hydrido bond of the 16 valence-electron complex (**6**) is most probable. The hydrogenation following Cycles A and B involves the oxidative addition of H_2O followed by the reductive elimination of methyl butyrate to give **4**. The resultant complex is converted into **6** with CO in a similar manner to the water-gas shift reaction (Cycle A, Steps 1 and 3). Cycle C represents the same mechanism as the usual hydrogenation with molecular hydrogen. The mechanism for this hydrogenation with CO and H_2O is well represented by Cycle A from the following reasons. Methyl butyrate and CO_2 are formed in similar yields in the hydrogenation of methyl crotonate (see Table 3); the partial pressure of H_2 is very low during this reaction, therefore there is no appreciable amount of H_2 involved in Steps 2 and 7. Cycle B is not important unless a large amount of H_2 is present, but it is appropriate to illustrate the fact that the amount of deuterium in methyl butyrate formed by the hydrogenation with CO, D_2O, and H_2 is larger than that of CO_2 formed. Undoutedly, all the results indicate that Cycle C is not important.



Scheme 3. Possible mechanisms for the hydrogenation of methyl crotonate with CO and H_2O.

Between the two possible types of σ-alkylrhodium intermediate, the 2-metalated one is predominant in the reaction of electron-withdrawing olefins. This conclusion is based on the following evidence; (*i*) the reaction of methyl crotonate with CO, D_2O, and H_2 gives mainly methyl butyrate-2-*d*, and (*ii*) electron-withdrawing olefins are hydrogenated, whereas electron-donating olefins are hydroformylated. The above view is in accord with the previous reports based on the isomer distribution of the conventional hydroformylation products catalyzed by **1**.[21] The stability of the 2-metalated species is ascribed to the electronic effect of the substituent on the rhodium-bearing carbon atom, because the substituent is able to accept the excess charge on the rhodium induced by the electron-donating trialkylphosphine ligands. Consequently, using more electron-donating phosphines as the ligand, the 2-metalated species is expected to be more dominant. In fact, this expectation is consistent with the observation that the formylation at the 2-position prevails in the reaction of methyl crotonate, using $P(i\text{-}Pr)_3$ as the auxiliary ligand (Table 2).

The more strongly the phosphine is electron-donating, the more the catalytic activities are increased for hydrogenation as well as hydroformylation (Table 2). The enhancement of both rates is explicable in terms of the facilitated oxidative addition reactions of H_2O and H_2 toward the σ-alkyl and acyl intermediates, respectively. Similar ligand effects have been known in various oxidative addition reactions, and are ascribed to the elevated electron density on the metal caused by the donating ligands. For example, the oxidative additions of H_2[22] and H_2O[23] toward rhodium(I) and platinum(0) complexes are accelerated by the coordination of donating phosphines.

It is not clear why the electron-donating and -withdrawing olefins give the respective products selectively, because a number of factors are involved. One plausible explanation is as follows. The modification of the catalyst with donating phosphines causes the activity for the hydroformylation to increase more markedly than that for the hydrogenation (Table 2). The coordination of the donating phosphines increases the electronic density on the rhodium. The equilibrium between alkyl and acyl complexes under the pressure of CO, which has well been established,[18] is displaced to the acyl species by the coordination, because the acyl ligand is capable of accepting the excess charge from the rhodium. This displacement tends to facilitate the hydroformylation. This explanation is supported by the facts that an acyl complex from oxidative addition to $RhCl(CO)(PPh_3)_2$ have not yet been successful and that the addition of acyl bromide to more nucleophilic $RhBr(CO)(PPhEt_2)_2$ was reported to give stable $RhBr_2(CH_3CO)(CO)(PPhEt_2)_2$.[24] Similarly, it is explainable that the electronic property of the substituent of olefins has a large effect on the selectivity. When the substituent is electron-donating, the equilibrium is displaced more markedly to the acyl species than in the case of electron-withdrawing olefins. The α-metalated alkyl complexes formed from electron-withdrawing olefins are considered to be stabilized by its electron-withdrawing group at the α-position, but those from electron-donating olefins are never. This view is also consistent with the observations that the reaction of **1** with $CF_2=CF_2$ gives a stable insertion product, $CHF_2CF_2Rh(CO)(PPh_3)_2$, in which the insertion of CO no longer takes place, and that $CH_2=CH_2$ does not give the corresponding stable alkyl complex but the acyl one.[25]

Exceptional is the function of $P(n\text{-}Bu)_3$, which is strongly electron-donating but less bulky than $P(i\text{-}Pr)_3$. The alkyl ligand of the key intermediate has a larger cone angle than the corresponding acyl ligand.[12] Therefore, the steric repulsion between the alkyl moiety and the bulky triisopropylphosphine, which has displaces the equilibrium, is more evident. When using less bulky $P(n\text{-}Bu)_3$ as the ligand, however, the steric repulsion appears not to be important. Thus, the alkyl intermediate is relatively stable and subjected to hydrolysis to give the hydrogenation product.

Experimental

All reactions and manipulations were carried out under a nitrogen atmosphere. All organic compounds were purified by distillation or recrystallization under a nitrogen atmosphere before use. Literature methods were employed for preparations of $RhH(CO)(PPh_3)_3$,[26] $RhCl(PPh_3)_3$,[27] $RuH_2(PPh_3)_4$,[28] $CoH(N_2)(PPh_3)_3$,[29] $Pd(PPh_3)_4$,[30] $PPh_2(i\text{-}Pr)$,[31] $PPh(i\text{-}Pr)_2$,[32] $P(i\text{-}Pr)_3$,[33] $[RhCl(C_7H_8)]_2$,[34] $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$,[14] and $\{Rh(CO)[P(i\text{-}Pr)_3]_2\}_2(CO_3)$.[14] The ^{1}H-NMR and IR spectra were recorded on a Varian T-60-A spectrometer and a JASCO IRA-1 spectrometer, respectively.

Catalytic Hydrogenation and Hydroformylation. The following procedure is illustrative. To a 65 ml stainless steel autoclave containing a THF solution (6.5 ml) of $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ (**2**) (48.7 mg, 0.1 mmol) were added H_2O (0.9 g, 50 mmol), methyl crotonate (2.0 g, 20 mmol), and CO (15 atm, 40.6 mmol) in that order. After heating at 115 °C for 20 h, the autoclave was cooled to room temperature. The GLC analysis of the gaseous products (on a column, active carbon, 3 m; at 50 °C; carrier gas, H_2) using nitrogen as an internal calibrant showed the presence of CO_2 (19.5 mmol, 98% based on methyl crotonate) and CO (19 mmol). The GLC analysis of the solution (on a column, PEG 20M, 2 m; at 110 °C; carrier gas, H_2) employing naphthalene as an internal standard showed the formation of $CH_3CH_2CH_2COOCH_3$ (1.87 g, 91%), $CH_3CH(CHO)CH_2COOCH_3$ (0.11

g, 4.2%), and $CH_3CH_2CH(CHO)COOCH_3$ (0.1 g, 3.9%).

The other catalytic reaction experiments were carried out according to similar procedures. The amount of H_2 formed was determined by GLC (on a column, molecular sieve 5A, 3 m; at 80 °C; carrier gas, Ar). The catalyst solution from $[RhCl(C_7H_8)]_2$ was prepared in the following manner. A hexane solution of *n*-BuLi (0.15 ml, 0.25 mmol) was slowly added to a mixture of $[RhCl(C_7H_8)]_2$ (23.1 mg, 0.05 mmol) and phosphine (0.2 mmol) in THF (6.5 ml), and the stirring was continued for 30 min. This freshly prepared pale brown solution was used immediately.

Preparation of $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ (2). To a catalyst solution, which was prepared from a mixture of $[RhCl(C_7H_8)]_2$ (46.1 mg, 0.1 mmol), $P(i\text{-}Pr)_3$ (96 mg, 0.6 mmol), and *n*-BuLi (0.6 mmol in 0.36 ml of hexane) in THF (2 ml) with stirring at room temperature for 30 min, was added H_2O (0.25 g, 14 mmol). The resultant brown mixture was stirred under an atmosphere of CO_2 at room temperature for 1 h. The IR spectrum of the concentrated residue showed the formation of a mixture of **2** (ν_{Rh-H} 2140, 2120; $\nu_{C=O}$ 1590 cm^{-1}) and $\{Rh(CO)[P(i\text{-}Pr)_3]_2\}_2(CO_3)$ (**3**) ($\nu_{C\equiv O}$ 1930; $\nu_{C=O}$ 1530 cm^{-1}). The residue was recrystallized from toluene to give colorless crystals of **2** (20 mg, 21%)

Isolation of $\{trans\text{-}Rh(CO)(pyridine)[P(i\text{-}Pr)_3]_2\}BPh_4$ (5) from the Reaction Mixture. A solution from the hydrogenation reaction of methyl crotonate catalyzed by **2** (48.7 mg, 0.1 mmol) was concentrated under reduced pressure, and the oily residue was redissolved in pyridine (5 ml). After addition of $NaBPh_4$ (34.7 mg, 0.1 mmol), the brown solution was stirred at room temperature for 10 min. The mixture was concentrated to dryness, and the solid residue was recrystallized from THF–toluene to give $\{trans\text{-}Rh(CO)(pyridine)[P(i\text{-}Pr)_3]_2\}BPh_4 \cdot 2toluene$ as pale yellow crystals (45 mg, 45%), mp 150 °C dec, $\nu_{C\equiv O}$ 1985 cm^{-1}.

Hydrogenation of Methyl Crotonate with CO, D_2O, and H_2. To a 65 ml autoclave containing a mixture of **2** (97.3 mg, 0.2 mmol, methyl crotonate (4.0 g, 40 mmol), and D_2O (2.0 g,100 mmol) in THF (6.5 ml) were charged CO (15 atm, 40.6 mmol) and H_2 (15 atm, 40.6 mmol), successively. After heating at 115 °C for 7.5 h, the autoclave was cooled to room temperature. The pressure inside the autoclave was 18 atm. The GLC analysis of the gas phase showed the presence of CO_2 (8.5 mmol, 3.1 atm), H_2, HD, and D_2 (total 9.3 mmol, 3.5 atm) and CO (30.1 mmol ,11.3 atm). The GLC analysis of the solution showed the formation of methyl butyrate 3.88 g, 95%). The methyl butyrate was collected into a cold trap under reduced pressure, and purified by distillation. The ^1H-NMR showed the 2-CH_2 (δ 2.2, m), 3-CH_2 (δ 1.62, m), CH_3C (δ 0.95, t), and CH_3O proton signals (δ 3.63, s) in a corrected relative intensity of 1.22 : 1.59 : 3 : 3. The incorporated deuterium contents calculated from these values were 78 and 41% at 2- and 3-positions, respectively.

Hydroformylation of α-Methylstyrene with CO, D_2O, and H_2. In a 65 ml autoclave pressured with CO (15 atm, 40.6 mmol) and H_2 (15 atm, 40.6 mmol), a mixture of **2** (97.3 mg, 0.2 mmol), α-methylstyrene (4.72 g, 40 mmol), and D_2O (2.0 g, 100 mmol) in THF (6.5 ml) was heated at 115 °C for 1 h. The gas phase (2.5 atm) was analyzed by GLC, and shown to contain CO_2 (1.4 mmol, 0.5 atm), H_2, HD, and D_2 (total 0.5 mmol, 0.2 atm), and CO (4.9 mmol, 1.8 atm). The ^1H-NMR spectrum of 3-phenylbutanal purified by preparative GLC showed to contain 22, 6, and 19% of deuterium at the 1-, 2-, and 3-positions, respectively.

The authors wish to express their thanks to Professor Sei Otsuka and Associate Professor Toshikatsu Yoshida of Osaka University for their helpful discussions and suggestions. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 575545 from the Ministry of Education, Science and Culture.

Dimerization of Tryptophan Derivatives in Trifluoroacetic Acid[1)]

Kazunari HASHIZUME and Yasutsugu SHIMONISHI*
Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565
(Received February 23, 1981)

Side-products are formed when Ac–Trp–OMe, Ac–Gly–Trp–OMe, or Ac–Trp–Trp–OMe is stored in trifluoroacetic acid. Two products from each of Ac–Trp–OMe and Ac–Gly–Trp–OMe and one product from Ac–Trp–Trp–OMe are isolated by the column chromatography on silica gel and confirmed for homogeneity by the high-performance liquid chromatography. As confirmed by ^{1}H-NMR and mass spectral analyses, they have dimerized structures through the α-carbon to α′-carbon binding of two indole rings. One of the two products from each of Ac–Trp–OMe and Ac–Gly–Trp–OMe is the *trans*-isomer(s) and the other the *cis*-isomer(s). Only a *trans*-isomer(s) is obtained from Ac–Trp–Trp–OMe.

The acid-labile indole moiety in the tryptophan residue is responsible for several side-reactions under acidic conditions used for peptide synthesis. One type of reactions is an oxidation of the indole ring; Theodolopoulos and Fruton[2)] reported a possible formation of "β-oxindolylalanine" in a treatment of *N*-(benzyloxycarbonyl)tryptophan peptide with hydrogen bromide in acetic acid, however this has not yet been proved. Another type of reactions is a substitution in the indole ring by a cation derived from a protecting group: Concerning this type, Alakhov *et al.*[3)] first pointed out that when *N*-(*t*-butyloxycarbonyl)tryptophan peptide acids or *t*-butyl esters are treated with TFA, a *t*-butyl cation, released from the protecting peptides, is introduced onto the indole ring in the tryptophan residue. Subsequently, this was confirmed by Wünsch *et al.*,[4)] who isolated a side product having been butylated at the NH group of the indole ring in the tryptophan residue. This substitution is reported also to occur at positions 2, 5, and 7 of the indole rings.[4,5)] A third type of reactions is an intra- or intermolecular substitution of the indole ring; Uphaus *et al.*[6)] isolated an α-carboline derivative formed through an intramolecular cyclization in a solution of acetyl-DL-tryptophan in TFA, but in low yield. Recently,[7)] one of the authors and others isolated from a solution of Ac–Trp–OMe in TFA or HF a product having a dimerized structure in which the α-position of one indole ring binds with the α′-position of the other indole ring which is reduced simultaneously to an indoline, as shown in Fig. 1.

In this work, we isolated another product which is also formed when Ac–Trp–OMe is kept in TFA and determined its structure on the basis of ^{1}H-NMR and mass spectra. The spectral analysis suggests that the new product is a steric isomer of the compound previously isolated. We found also that when tryptophan-peptides (Ac–Gly–Trp–OMe and Ac–Trp–Trp–OMe) are stored in TFA under the same conditions as with Ac–Trp–OMe, side-products similar to those from Ac–Trp–OMe in structure are formed.

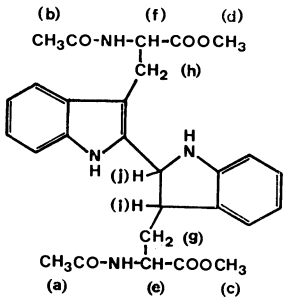

Fig. 1. Dimerized structure of Ac–Trp–OMe.

Results and Discussion

Isolation of Reaction Products. After keeping Ac–Trp–OMe in TFA, we detected two compounds with lower mobility than the starting compound on a TLC plate with a concentration zone (Fig. 2). These compounds gave yellow spots on being stained with the Ehrlich reagent. Previously,[7)] these two compounds could not be separated from each other on a TLC plate with no concentration zone, and only one of them could be isolated on crystallization. In the present work we found that the previously isolated compound corresponds to the compound with the lower R_f value on the TLC plate with a concentration zone, which finding encouraged us to isolate the other compound. For isolation of this compound, a solution of Ac–Trp–OMe in TFA was subjected to a chromatography on a silica-gel

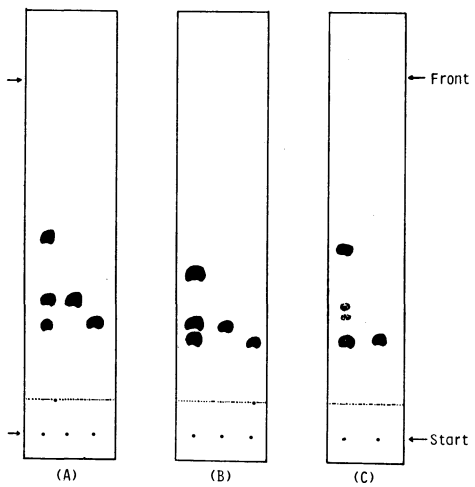

Fig. 2. TLC of products in TFA and isolated materials on silica gel 60 with a concentration zone (Merck Art. 11845). (A) Ac–Trp–OMe (from left, reaction mixture, compounds **1B** and **1A**), (B) Ac–Gly–Trp–OMe (from left, reaction mixture, compounds **2B** and **2A**) and (C) Ac–Trp–Trp–OMe (from left, reaction mixture and compound **3**). Solvent system: (A) and (C), CH_3CN–$CHCl_3$ (2 : 1), (B) CH_3CN–$CHCl_3$–MeOH (60 : 30 : 5). Staining with Ehrlich reagent.

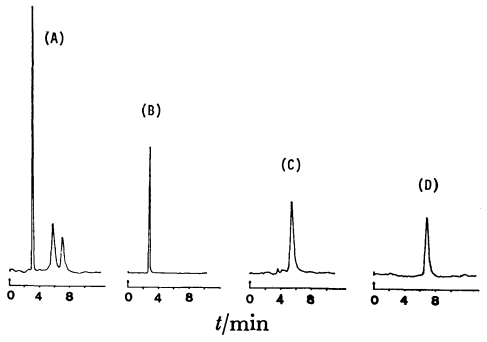

Fig. 3. Elution profiles at 280 nm of reaction mixture of Ac–Trp–OMe in TFA and isolated materials by HPLC on a μ-porasil column (0.39 cm × 30 cm). Solvent: CH_3CN–$CHCl_3$ (2 : 1). Flow rate: 1 ml/min. (A) reaction mixture, (B) starting material (Ac–Trp–OMe), (C) compound **1B**, and (D) compound **1A**.

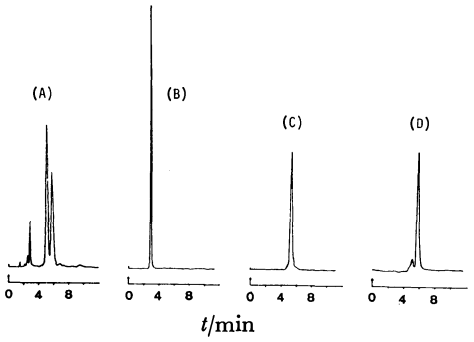

Fig. 4. Elution profiles at 280 nm of reaction mixture of Ac–Gly–Trp–OMe in TFA and isolated materials by HPLC on a μ-porasil column (0.39 cm × 30 cm). Solvent: CH_3CN–$CHCl_3$–MeOH (60 : 30 : 5). Flow rate: 1 ml/min. (A) reaction mixture ,(B) starting material (Ac–Gly–Trp–OMe), (C) compound **2B**, and (D) compound **2A**.

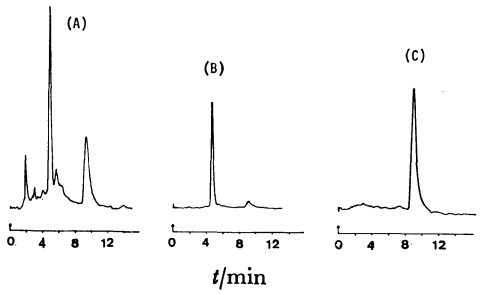

Fig. 5. Elution profiles at 280 nm of a reaction mixture of Ac–Trp–Trp–OMe in TFA and the isolated product by HPLC on a μ-porasil column (0.39 cm × 30 cm) in a solvent mixture of CH_3CN and $CHCl_3$ (2 : 1). Flow rate: 1 ml/min. (A) reaction mixture, (B) starting material (Ac–Trp–Trp–OMe), and (C) compound **3**.

column with a mixture of CH_3CN and $CHCl_3$ (v/v, 2/1). The first compound eluted was the starting compound, and the last compound eluted was identified as the compound previously isolated (denoted as compound **1A**). A compound (denoted as **1B**) eluted between the starting compound and compound **1A** was isolated; the purity of **1B** had been examined by a high-performance liquid chromatography (HPLC) using the same solvent

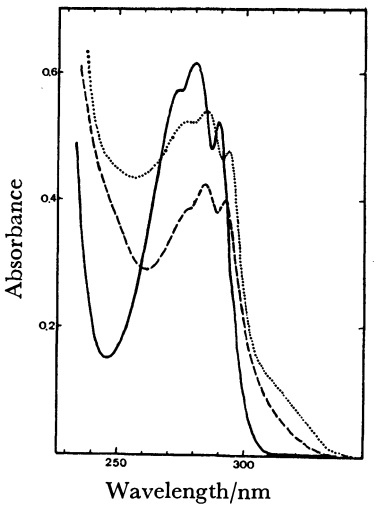

Fig. 6. UV absorption spectra of Ac–Trp–OMe (——), compounds **1A** and **1B** isolated from a solution of Ac–Trp–OMe in TFA (——), and compound **3** isolated from a solution of Ac–Trp–Trp–OMe in TFA (·····) in EtOH.

system as for the preparative chromatography on silica gel to be found homogeneous on HPLC (Fig. 3).

After storage of solutions of tryptophan-peptides (Ac–Gly–Trp–OMe and Ac–Trp–Trp–OMe) in TFA under the same conditions as for Ac–Trp–OMe, TLC indicated presence of new compounds forming yellow spots when stained with the Ehrlich reagent, in addition to the starting compound, as illustrated in Fig. 2. The products from Ac–Gly–Trp–OMe were isolated by chromatography on a silica-gel column using a mixture of CH_3CN, $CHCl_3$, and MeOH (60/30/5) as eluting solvent. Two compounds (denoted as **2A** and **2B**) were eluted separately after the starting compound, and their purities were examined by HPLC (Fig. 4). From a solution of Ac–Trp–Trp–OMe in TFA, we could isolate only one product which was eluted more slowly than the starting peptide from a silica-gel column with a mixture of CH_3CN and $CHCl_3$ (v/v, 2/1) as solvent. Profiles of the reaction mixture and the isolated compound (denoted as compound **3**) on HPLC are shown in Fig. 5.

Structural Determination of Side-products. An elemental analysis showed that compound **1B** has the same composition as the starting compound and also as compound **1A** previously isolated. The mass spectrum of this compound showed a molecular ion at m/z=520, which is twice the m/z value of the starting compound but the same as that of compound **1A**. The UV absorption spectrum also was the same as that of compound **1A**, as shown in Fig. 6. The ^{1}H-NMR spectra of compound **1B** in DMSO-d_6 with and without D_2O suggest the presence of both one indole ring and one indoline ring in the molecule (Fig. 7), as in compound **1A**,[7] although the chemical shifts are slightly different from those of compound **1A**. The chemical shifts were assigned by the decoupling technique described in Ref. 7. These results suggest that compounds **1A** and **1B** are steric isomers associated with the asymmetric α- and β-carbons on the newly formed indoline rings

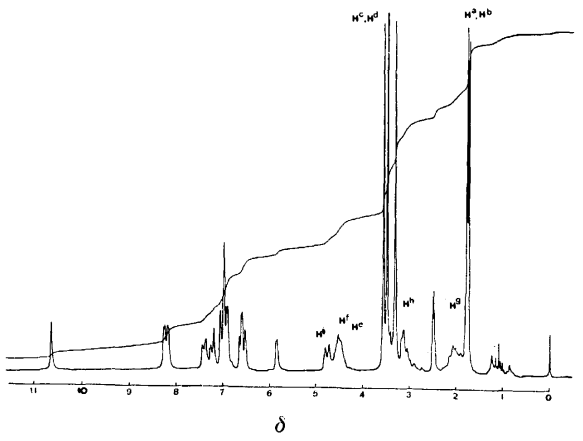

Fig. 7. ^{1}H-NMR spectrum of compound **1B** in DMSO-d_6 at 100 MHz.

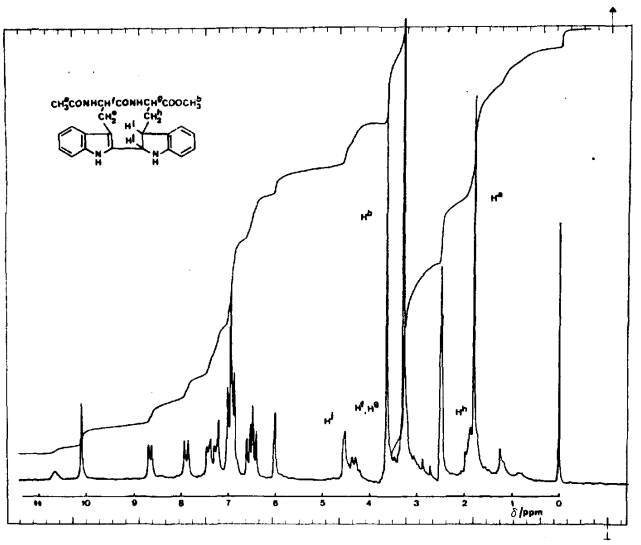

Fig. 8. ^{1}H-NMR spectrum of compound **3** in DMSO-d_6 at 100 MHz.

TABLE 1. COUPLING CONSTANTS (Hz) BETWEEN α-CH AND β-CH IN INDOLINE RINGS

Starting compound	Product	In DMSO-d_6 (+D_2O)	In DMSO-d_6 (+DCl)
Ac-Trp-OMe	**1A**	9.34	8.97
	1B	8.14	8.42
Ac-Gly-Trp-OMe	**2A**	9.33	0.08
	2B	8.79	8.80
Ac-Trp-Trp-OMe	**3**	3.28	3.03
Indoline[8]		J_{trans}=8.43	J_{trans}=6.63
		J_{cis}=8.43	J_{cis}=8.99

because the coupling constant between α-CH (i) and β-CH (j) of the indoline ring in compound **1B** is different from that of compound **1A**, as will be described later.

The two compounds **2A** and **2B** isolated from a solution of Ac-Gly-Trp-OMe in TFA gave analytical values similar to those of the starting peptide, but the molecular ions in their field-desorption mass spectra were at m/z=634, which is twice the value of that of the starting peptide. Their ^{1}H-NMR and UV absorption spectra are similar to those of compounds **1A** and **1B**, respectively, isolated from Ac-Trp-OMe. These results indicate that the compounds isolated from a solution of Ac-Gly-Trp-OMe in TFA have dimerized structures similar to those of the dimerized compounds from Ac-Trp-OMe, and further that they are steric isomers to each other because the coupling constants between α-CH and β-CH on the newly formedinidoline ring are different from each other, similarly to the above-mentioned case with compounds **1A** and **1B**.

The compound isolated from the solution of Ac-Trp-Trp-OMe in TFA was subjected to a field-desorption mass spectrometric analysis and found to have a molecular weight corresponding to m/z=446, the same as that of the starting peptide; an elemental analysis on this compound gave analytical results similar to those on the starting peptide. However, its UV absorption spectrum is different from that of the starting peptide, but similar to those of compounds **1A** and **1B**, as illustrated in Fig. 6. Furthermore, only one NH proton in the indole ring and one NH proton of the indoline ring are observed on the ^{1}H-NMR spectrum, as shown in Fig. 8. These results suggest that in this compound the two indole rings are joined together not intermolecularly but intramolecularly, as shown in Fig. 8.

It is known that protonation of the indoline NH will cause the coupling constant between the α-CH and β-CH of indoline ring increase in the case of *cis*-conformation and to decrease in the case of *trans*-conformation.[8] The coupling constant between α-CH (i) and β-CH (j) in compound **1A** decreased by addition of DCl in DMSO-d_6, while that of compound **1B** increased, as shown in Table 1; such phenomena were observed also in compounds **2A** and **2B**. Also, an addition of DCl to a solution of compound **3** in DMSO-d_6 decreased the coupling constant between α-CH and β-CH of the indoline ring. These facts suggest that compounds **1A**, **2A**, and **3** obtained from Ac-Trp-OMe, Ac-Gly-Trp-OMe, and Ac-Trp-Trp-OMe, respectively, have the *trans*-conformation, while compounds **1B** and **2B** isolated from Ac-Trp-OMe and Ac-Gly-Trp-OMe, respectively, have the *cis*-conformation. These results are summarized in Table 1.

Change in Quantity of Side-products with Time. An HPLC elution profile of a reaction product from Ac-Trp-OMe in TFA is shown in Fig. 3. It is clear that compounds **1A** and **1B** are completely separated not only from the starting compound but also from each other, so that they can be used as a standard for their quantitative determination for a mixture on HPLC. When Ac-Trp-OMe was stored in TFA, besides compounds **1A** and **1B** some fluorescence material, which would not move on a thin layer chromatogram, was formed in too small an amount. Therefore, the amount of the products was calculated by taking the sum of the amounts of the unreacted compound, compounds **1A** and **1B** as 100%. When Ac-Trp-OMe was dissolved in TFA, immediately concentrated under reduced pressure, extracted with ethyl acetate, applied to a column of HPLC, the unreacted compound amounted to 91.4% of the starting reactant, and the percentages of compounds **1A** and **1B** were 2% and 6.6%, respectively, as measured by the method described above.

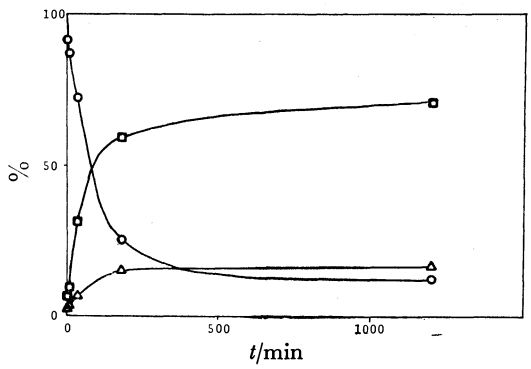

Fig. 9. Relative rate of decrease of Ac-Trp-OMe (—○—) and yields of compounds **1A** (—□—) and **1B** (—△—) in TFA. Values are averages for triplicate measurements.

As illustrated in Fig. 9, a 3-h storage in TFA at 20 °C caused the amount of the reactant to decrease rapidly to less than 25% of the starting reactant. On the other hand, the formation of compound **1A** surprisingly proceeded to more than 60%, but this compound could not be recovered preparatively in a similar yield; the formation of compound **1B** amounted to about 15%. These results suggest either that **1A** will be formed sterically with more advantage or that it is sterically more stable than **1B**. The isolated compounds **1A** and **1B** were stable at room temperature when stored in TFA. Therefore, it seems likely that the dimerized compounds are formed by an irreversible reaction from the starting monomer.

Experimental

All melting points were measured by the capillary method and are given as uncorrected values. TLC was performed on silica gel 60 (Merck Art. 11845) with a concentration zone using the following solvent systems (volume ratios): $CHCl_3$–acetone (2 : 1), $CHCl_3$–CH_3CN (4 : 1), and $CHCl_3$–MeOH–AcOH (95 : 5 : 5). HPLC was performed on a Toyosoda high speed liquid chromatograph HLC-803 and/or a Shimadzu HPLC LC-3A equipped with a data processor, Chromatopac C-R1A. Optical rotations were determined with a Perkin-Elmer Model 241 polarimeter. UV-absorption spectra were measured by using a Hitachi spectrometer type-124, equipped with a recording attachment. ^{1}H-NMR spectra were recorded on a JEOL PFT-100 pulse Fourier transform NMR spectrometer, locked on deuterium and equipped with an FT-1A pulse control system. Chemical shifts were measured relative to an internal reference, tetramethylsilane. Mass spectra were recorded with a second-order double focusing mass spectrometer[9] with a mono field-desorption ion source, equipped with a data processor (JEOL JMA-2000 mass data analysis system).

Ac–Trp–OMe. Ac–Trp–OH (17.4 g) was dissolved in MeOH (300 ml) and mixed with an ethereal solution of diazomethane in an ice–water bath under stirring. The solution was concentrated to dryness under reduced pressure. The residue was recrystallized from ethanol and hexane: wt 14.6 g (79.0%); mp 153—154 °C (lit,[10] 151 °C); $[\alpha]_D^{25}$ +13.2° (*c* 1.0, MeOH) (lit,[10] +13.2°); MS, *m/z*, 260 (M^+); ^{1}H-NMR [DMSO-d_6], CH_3CO δ=1.78 (3H, s), β-CH_2 ≈3.14 (2H, m), OCH_3 3.57 (3H, s), α-CH ≈4.59 (1H, t-d), aromatic CH ≈7.55 (5H, m), amide NH ≈8.32 (1H, d), and indole NH 10.82 (1H, s).

Found: C, 64.87; H, 6.16; N, 10.90%. Calcd for $C_{14}H_{16}O_3N_2$: C, 64.60; H, 6.20; N, 10.76%.

Ac–Gly–Trp–OMe. Z–Gly–Trp–OMe (3.39 g) was dissolved in MeOH (100 ml) and hydrogenated over a palladium–charcoal catalyst under atmospheric pressure. The catalyst was filtered off and the filtrate was concentrated under reduced pressure to a syrupy residue, which was dissolved in DMF (50 ml). The solution was stirred with Ac–ONp (2.8 g) at room temperature for 1 d, and then concentrated to an oil under reduced pressure. The oil was purified on a column (3 cm × 60 cm) of silica gel using a mixture of ethyl acetate and benzene (v/v, 1/1) as elution solvent. Fractions containing the compound were collected and concentrated to a syrup under reduced pressure. The syrupy material was solidified in ethyl acetate and hexane: wt 0.69 g (27%); mp 178 °C; $[\alpha]_D^{24.5}$ +14.0° (*c* 1.0, MeOH); MS, *m/z*, 317 (M^+); ^{1}H-NMR [DMSO-d_6], CH_3CO δ=1.82 (3H, s), β-CH_2 (Trp) ≈3.13 (2H, m), OCH_3 3.55 (3H, s), α-CH_2(Gly) ≈3.70 (2H, d), α-CH(Trp) ≈4.53 (1H, m), aromatic CH ≈7.49 (5H, m), amide NH(Gly) ≈7.99 (1H, t), amide NH(Trp) ≈8.21 (1H, d), and indole NH 10.82 (1H, s).

Found: C, 60.67; H, 5.97; N, 13.37%. Calcd for $C_{16}H_{19}O_4N_3$: C, 60.55; H, 6.04; N, 13.24%.

Ac–Trp–Trp–OMe. Z–Trp–Trp–OMe[11] (4.11 g) was dissolved in MeOH (80 ml) and hydrogenated over a palladium–charcoal catalyst under reduced pressure. The catalyst was filtered off and the filtrate was concentrated to a syrup under reduced pressure. The syrup was dissolved with Ac–ONp (2.8 g) in DMF (50 ml), stirred for a day at room temperature and concentrated to an oil under reduced pressure. The oil was purified on a column (3 cm × 60 cm) of silica gel using a mixture of benzene and ethyl acetate (v/v, 1/1) as eluting solvent. Fractions containing the compound were pooled and concentrated under reduced pressure to a syrupy material, which was triturated in ethyl acetate and hexane: wt 1.21 g (35.5%); mp 78 °C; MS, *m/z*, 466 (M^+); ^{1}H-NMR [DMSO-d_6], CH_3CO δ=1.74 (3H, s), β-CH_2 ≈3.14 (2H × 2, m), OCH_3 3.54 (3H, s), α-CH ≈4.55 (1H × 2, m), aromatic CH ≈7.60 (5H × 2, m), amide NH ≈7.98 (1H, d) and ≈8.36 (1H, d), and indole NH 10.74 (1H, s) and 10.83 (1H, s).

Found: C. 68.01; H, 5.95; N, 12.31%. Calcd for $C_{25}H_{26}O_4N_4$: C, 67.25; H, 5.87; N, 12.55%.

*Compounds **1A** and **1B** from Ac–Trp–OMe.* Ac–Trp–OMe (1.00 g) was dissolved in TFA (10 ml). The solution was kept for 3 h at room temperature in a brown glass vessel to exclude light and then concentrated to dryness under reduced pressure. The residue was dissolved in ethyl acetate, washed with 5% aq $NaHCO_3$ and water and then dried over anhydrous Na_2SO_4. The dried solution was concentrated to a pale yellow solid under reduced pressure. **1A** was crystallized from EtOH and ether and collected to wt *ca.* 280 mg. The filtrate was concentrated to dryness under reduced pressure. The residue was subjected to chromatography in a brown glass column (3 cm × 60 cm) of silica gel 60 suspended in $CHCl_3$, in such a way that the sample was dissolved in $CHCl_3$, charged on the column, washed with a mixture of CH_3CN and $CHCl_3$ (v/v, 1/4) and then eluted with CH_3CN and $CHCl_3$ (v/v, 2/1). Fractions containing compound **1B** were pooled and concentrated to dryness under reduced pressure. The residue was recrystallized from ethyl acetate and hexane: wt *ca.* 50 mg.

*Compound **1A**:* Mp 218 °C; MS, *m/z*, 520 (M^+); ^{1}H-NMR [DMSO-d_6], CH_3CO δ=1.55 (3H, s), and 1.79 (3H, s) β-CH_2

(g) ≈2.16 (2H, m), β-CH_2(h) ≈3.18 (2H, q), OCH_3 3.49 (3H, s) and 3.53 (3H, s), indoline 3-CH(i) concealed under OCH_3, α-CH(e) ≈4.32 (1H, m), α-CH(f) ≈4.60 (1H, m), indoline 2-CH(j) ≈4.73 (1H, d-d), indoline NH 5.97 (1H, d), aromatic CH ≈7.50 (8H, m), amide NH ≈8.23 (1H, d) and ≈8.39 (1H, d), and indole NH 10.88 (1H, s).

Found: C, 64.37; H, 6.15; N, 10.99%. Calcd for $C_{28}H_{32}O_6N_4$: C, 64.60; H, 6.20; N, 10.76%.

Compound ***1B***: Mp 215 °C; MS, *m/z*, 520 (M^+); ^{1}H-NMR (Fig. 7).

Found: C, 64.23; H, 6.23; N, 10.73%. Calcd for $C_{28}H_{32}O_6N_4$: C, 64.60; H, 6.20; N, 10.76%.

Compounds ***2A*** *and* ***2B*** *from Ac–Gly–Trp–OMe.* Ac–Gly–Trp–OMe (1.22 g) was dissolved in TFA (10 ml) and kept under the conditions used for Ac–Trp–OMe. The solution was concentrated to dryness under reduced pressure. The residue was dissolved in CH_2Cl_2, washed with 5% aq $NaHCO_3$ and water and then dried over anhydrous Na_2SO_4. The dried solution was concentrated to a solid under reduced pressure. The solid was dissolved in $CHCl_3$, applied to silica gel 60 in $CHCl_3$ in a brown glass column (3 cm × 60 cm) and washed with a mixture (50 ml) of $CHCl_3$ and CH_3CN (v/v, 2/1). Materials were eluted with a mixture of CH_3CN, $CHCl_3$, and MeOH (v/v/v, 60/30/5). The starting material was eluted first, followed by compounds **2B** and **2A**. Fractions containing compounds **2A** and **2B** were separately pooled and concentrated to dryness under reduced pressure. The residues were collected with ethyl acetate and hexane: wt **2A**, *ca.* 20 mg; **2B**, *ca.* 70 mg.

Compound ***2A***: Mp 152 °C; MS, *m/z*, 634 (M^+); ^{1}H-NMR [DMSO-d_6], CH_3CO δ=1.80 (3H×2, s), β-CH_2(Ind) ≈2.07 (2H, m), β-CH_2(Trp) ≈3.10 (2H, d), OCH_3 3.46 (3H, s) and 3.50 (3H, s), α-CH_2(Gly) ≈3.61 (2H, d) and ≈3.67 (2H, d), indoline 3-CH concealed under OCH_3, α-CH (Ind) ≈4.27 (1H, m), α-CH(Trp) ≈4.60 (1H, m), indoline 2-CH ≈4.77 (1H, d-d), indoline NH 5.91 (1H, s (broad)), aromatic CH ≈7.45 (8H, m), amide NH(Gly) ≈7.76 (1H, t) and ≈7.92 (1H, t), amide NH (Trp and Ind) 8.24 (1H, d) and 8.32 (1H, d), and indole NH 10.80 (1H, s).

Found: C, 60.74; H, 6.27; N, 12.83%. Calcd for $C_{32}H_{38}O_8N_6$: C, 60.55; H, 6.04; N, 13.24%.

Compound ***2B***: Mp 151 °C; MS, *m/z*, 634 (M^+); ^{1}H-NMR [DMSO-d_6], CH_3CO δ=1.80 (3H×2, s), β-CH_2(Ind) ≈2.18 (2H, m), β-CH_2(Trp) concealed under OCH_3, OCH_3 3.27 (3H×2, s), indoline 3-CH concealed under 3.40—3.50, α-CH_2 (Gly) ≈3.66 (2H×2, d), α-CH(Trp and Ind) ≈4.53 (1H×2, m), indoline 2-CH ≈4.86 (1H, d-d), indoline NH 5.92 (1H, s (broad)), aromatic CH ≈7.38 (8H, m), amide NH(Gly) ≈7.85 (1H, t) and ≈7.90 (1H, t), amide NH (Trp and Ind) ≈8.24 (1H, d) and ≈8.31 (1H, d), and indole NH 10.70 (1H, s).

(Received February 28, 1981)

The reaction of ethyl 2-azido-2-alkenoate with organic tervalent phosphorus reagent gave the corresponding 2-phosphoranylideneamino derivative as an stable intermediate. This transformed gradually at room temperature, or immediately on a silica-gel column to give the corresponding 2-phosphinylamino derivative in a good yield. The Arbusov reaction of the intermediate which occurred during the transformation was found to be applicable for the other azido olefins. The formation mechanism and the configurational determination of the new products are discussed.

In connection with the synthesis of α-dehydroamino acid (DHA), which is an important constituent or precursor in the versatile cyclic peptide antibiotics, the development of the synthetic methods for DHA has been of interest and several routes have been investigated by us.[2-6]

So far, no report has been appeared on the synthesis of DHA N-protected with phosphinyl group except for our earlier paper,[7] whereas the diphenylphosphinyl (Dpp) group was utilized recently as an useful N-protecting group for α-amino acid and peptide.[8,9]

In the present paper, we wish to report a preparative route for DHA N-protected with a few kinds of phosphinyl groups by the reaction of ethyl 2-azido-2-alkenoate (**1**) with organic tervalent phosphorus reagents by two steps. Furthermore, the attempt to employ a similar reaction of *t*-butyl 3-azido-2-acetylamino-2-alkenoate (**8**) with triethyl phosphite was successful in giving the corresponding β-N-phosphinyl-DHA derivative.

Results and Discussion

Reaction of 1 with Tervalent Phosphorus Reagent. The reaction of (*Z*)-isomer of **1** (**a**; R=CH_3, **b**; R=C_2H_5, **c**; R=*n*-C_3H_7, **d**; R=*i*-C_3H_7, **e**; R=C_6H_5) with equimolar triphenylphosphine as a typical organic tervalent phosphorus reagent in dry benzene under nitrogen gas at room temperature was readily carried out to give colorless crystals or a syrup, which was identified as ethyl 2-triphenylphosphoranylideneamino-2-alkenoate (**2**), obtained in *ca.* 80% yield. The compound **2** thus obtained was found to be a very stable, even though it was heated for a long time or treated with an acid or a base.

In a similar manner, the reaction of **1** with triethyl phosphite also proceeded smoothly to give a colorless viscous oil, which was identified as 2-triethoxyphosphoranylideneamino-2-alkenoate (**3**), in *ca.* 81% yield. However, the syrupy product **3** isolated purely by the vacuum distillation was found to change gradually into a yellowish solid substance at room temperature during about a month. The colorless crystals obtained in *ca.* 87% yield from **3** were characterized to be ethyl 2-diethoxyphosphinylamino-2-alkenoate (**4**). Interestingly, when the chromatogram of **3** was developed through a silica-gel column using benzene initially and then a mixture of benzene–ethyl acetate (6 : 1 v/v) as the eluent, the compound **3** immediately transformed to give **4** in a fairly good yield. Since the transformation of **3** to **4** was further promoted in the presence of water, it was found that **3** reacted with water to give **4**. As a result, the desired new DHA N-protected with phosphinyl group was first synthesized.

Furthermore, in order to ascertain and generalize the preparative route for the DHA N-protected with phosphinyl group from **1**, a similar reaction of **1** with ethyl diphenylphosphinite was also performed to obtain ethyl 2-ethoxydiphenylphosphoranylideneamino-2-alkenoate (**5**) as a colorless syrup in an almost quantitative yield. Subsequently, the treatment of **5** on a silica-gel column was worked up similarly to give the expected ethyl 2-diphenylphosphinylamino-2-alkenoate (**6**) as colorless needles in *ca.* 74% yield. Furthermore, in order to remove the Dpp N-protecting group, when ethyl 2-diphenylphosphinylamino-2-butenoate (**6a**) was treated with trifluoroacetic acid at room temperature for 2 h, ethyl 2-trifluoroacetylamino-2-butenoate (**7a**) was readily obtained in 75% yield. The structure of **7a** was determined by the independent preparation from ethyl (*Z*)-2-amino-2-butenoate and trifluoroacetic anhydride. Since Breitholle and Stammer[10] reported the removal of N-trifluoroacetyl group in DHA and dehydropeptide (DHP) with amine, the Dpp group was found to be a useful N-protecting group for DHA and DHP, although two-step treatments were required.

In order to confirm the structure and the configuration of **2**—**5**, and **6** thus obtained, the independent preparation of **4** was performed. The reaction of (*Z*)-isomer of ethyl 2-amino-2-alkenoate with diethyl phosphorochloridate by the usual method proceeded to give colorless crystals, whose properties were in complete agreement with **4** prepared from (*Z*)-**1** and triethyl phosphite *via* **3**. As a result, the geometric structure of **4** and **6** could be easily determined to be (*Z*)-isomerism. Accordingly, the configurational structure of **2**, **3**, and **5** was also assigned to be (*Z*)-geometry. On the other hand, the attempt to obtain another independent

preparation of **4** by the direct condensation of α-oxo carboxylic acid ester with diethyl phosphoramidate by the method reported previously[6] was unsuccessful, because of the lability and the decomposition of the phosphoramidate in acidic conditions.

The structure and configuration confirmed above were further supported by the results of the following spectroscopic analyses and by the studies on the formation mechanism.

In the IR spectrum of **2**, **3**, and **5**, the characteristic absorption bands of ester carbonyl, carbon-carbon double bond, and =P–O–CH_2– groups appear at 1722—1700 (strong), 1630—1590 (medium), and 1050—1035 (in **3** and **5**, strong) cm^{-1} regions respectively. On the other hand, in that of **4** and **6**, the stretching absorption bands of NH and >P=O groups newly appear at 3170—3070 (medium) and 1290—1240 (strong) cm^{-1} regions, along with the appearance of ethoxycarbonyl and C=C bands at 1730—1710 and 1660—1625 cm^{-1} regions, respectively.

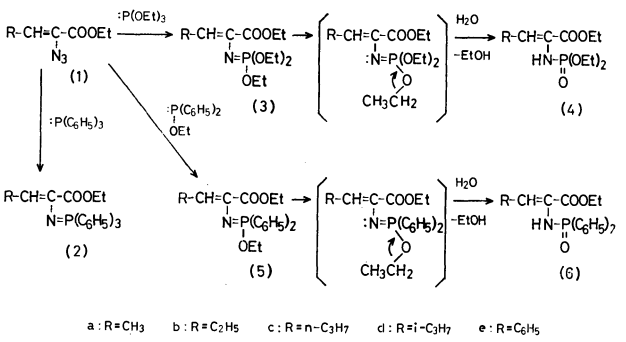
On the other hand, the NMR spectra of **2**—**5**, and **6**, clearly showed the long range coupling between β-olefinic, γ-methylene protons, and phosphorus atoms. As summarized in Tables 1 and 2, the olefinic proton signals of **2**, **3**, and **5** shifted at δ 6.70—5.95 ($J_{3,4}$= 6.8—9.2 Hz), whereas those of **4** and **6** resonated at lower magnetic field (at δ 7.23—6.02) with the comparatively larger coupling constant ($J_{3,4}$=7.0—11.4 Hz). On the other hand, the coupling constants between β-olefinic proton and phosphorus in **4** and **6** were found to be smaller ($J_{3,P}$=1.8—2.6 Hz) than the constants ($J_{3,P}$=2.9—4.5 Hz) in **2**, **3**, and **5**. Similarly, the long range coupling between γ-methylene protons and phosphorus ($J_{4,P}$=2.5—3.0 Hz) was also observed, as listed in Tables 1 and 2. Moreover, in the NMR and IR spectra of **4** and **6**, the appearance of NH groups at δ 5.50—4.70 and at *ca.* 3100 cm^{-1} respectively indicates unambiguously the transformation of the phosphoranylideneamino into the phosphinylamino group.

The above results suggest the following formation mechanism of **4** and **6**: the Arbusov reaction of the intermediates **3** and **5** with water occurred to give **4** and **6** respectively, along with the yielding of ethanol, which could be detected by gas chromatography. This process is illustrated in Scheme 1.

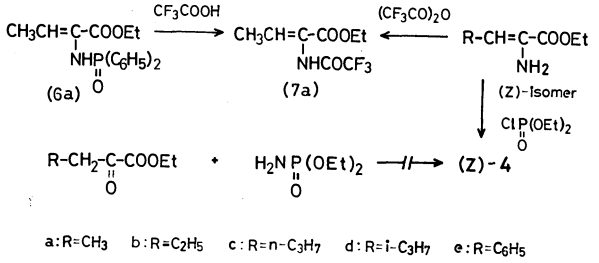
The yields, physical constants, and NMR spectral data of **2**—**5**, and **6** are summarized in Tables 1 and 2.

Reaction of 8 with Triethyl Phosphite. In order to apply extensively to the various azido olefins, β-azido olefin was subjected to the reaction with triethyl phosphite.

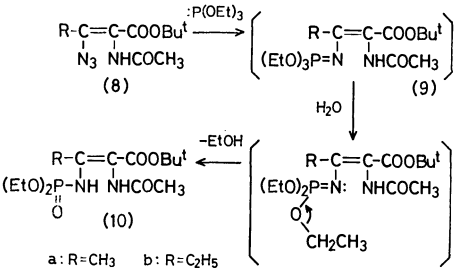
As in the case of **1**, *t*-butyl 2-acetylamino-3-azido-2-alkenoate (**8**: **a**; R=CH_3, **b**; R=C_2H_5), derived by the reaction of *t*-butyl 2-(*N*-bromoacetylamino)-2-alkenoate with sodium azide, with the successive substitution and the subsequent 1,3-shift,[11] was treated with triethyl phosphite to give a pale yellowish syrup in a fairly good yield. Interestingly, the syrupy products thus obtained were found to have a satisfactory elemental analysis for the corresponding β-phosphinylamino derivative (**10**), not the expected β-phosphoranylideneamino derivative (**9**). Furthermore, the above structural identification



Scheme 1.



Scheme 2.



Scheme 3.

was exactly supported by the IR and NMR spectral data as follows. The appearance of the absorption band at 3260—3200 cm^{-1} and that of the chemical shift resonating at δ 6.83—6.70 regions as a broad singlet due to NH and the presence of >P=O at 1260 cm^{-1} as a strong absorption indicates unambiguously the formation of an α,β-unsaturated α,β-diamino derivative, which was identified as *t*-butyl 2-acetylamino-3-diethoxyphosphinylamino-2-alkenoate, obtained in *ca.* 78% yield.

The above results show that the formation mechanism of **10** was the following: the one-pot reaction of **8** with triethyl phosphite took place to give the unstable intermediate **9**, then the following Arbusov reaction with water during the treatment process gave **10**, as is illustrated in Scheme 3.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Laboratory Co. Ltd.), using tetramethylsilane as the internal standard.

Preparation of 2. Into a solution of (*Z*)-**1** (50 mmol) in dry benzene (50 ml) under nitrogen gas we stirred triphenyl-

a) From **3** and **5**. b) From ethyl (*Z*)-2-amino-2-alkenoate and $ClP(O)(OEt)_2$. c) Colorless needles from cyclohexane.

phosphine (50 mmol), portion by portion, under cooling. After the resulting solution had been stirred at room temperature for 1 h, the benzene was evaporated under reduced pressure to give a colorless syrup or a semi-solid residue, in which the latter was crystallized in petroleum ether (20 ml). The collected crystals were recrystallized from cyclohexane to give colorless needles.

Preparation of ***3***. A solution of equimolar (*Z*)-**1** (50 mmol) and triethyl phosphite in dry benzene was worked up similarly to give an oily residue, which was distilled under reduced pressure to give a colorless viscous oil.

Preparation of ***5***. A solution of equimolar (*Z*)-**1** (50 mmol) and ethyl diphenylphosphinite in dry benzene was worked up similarly for 3 h to give a colorless syrup.

Preparation of ***4***. *From* ***3***. *By Standing*: When viscous oil (**3**) was allowed to stand at room temperature for about a month, the oil gradually crystallized to give a yellowish solid substance. The collected solid was recrystallized from hexane or cyclohexane to give colorless needles.

On a Silica-gel Column. The compound **3** (50 mmol) was chromatographed on a silica-gel column using benzene (150 ml) intially and then a mixture of benzene–ethyl acetate (6 : 1 v/v) as the eluent. The fraction solution obtained was evaporated under reduced pressure to give colorless crystals.

From Ethyl (Z)-2-Amino-2-alkenoate and $ClP(O)(EtO)_2$. Into a solution of the enamine (20 mmol) and pyridine (30 mmol) in dry diethyl ether (30 ml) we stirred diethyl phosphorochloridate (25 mmol), drop by drop, at room temperature. After the resulting solution had been stirred at room temperature for 5 h, ether (50 ml) was further added to the reaction solution and then the resultant solution was washed with 1 M HCl†† and with water three times. The ether layer was dried over anhydrous Na_2SO_4 and then concentrated to give a residual product. The residue was purified on a silica-gel column using ehter as the eluent to give colorless needles, which was in agreement with **4** obtained above. Yield *ca.* 80%.

Preparation of ***6***. In a similar manner to that in the case of **4**, compound **5** was chromatographed on a silica-gel column using a mixture of benzene and ethyl acetate (4 : 1 v/v) as the eluent. The fraction obtained was condensed under reduced pressure to give crude residual crystals, which were collected by filtration and then recrystallized from cyclohexane to give **6** as colorless needles.

Preparation of ***7a***. *From* ***6a*** *and* CF_3COOH: A solution of **6a** (10 mmol) in trifluoroacetic acid (5 ml) was stirred at room temperature for 2 h and the reaction solution was concentrated under reduced pressure. The residual oil obtained was distilled to give a colorless oil, bp 67—68 °C/1.5 mmHg,††† yield 75.2%. IR (KBr): 3280 (NH), 1720 (COOEt), 1660 (C=C) cm^{-1}. NMR ($CDCl_3$): δ 8.64bs (NH), 7.07q (3-H, J=7.4 Hz), 1.82 d (4-H, J=7.5 Hz). Found: C, 43.05; H, 4.36; N, 6.11%. Calcd for $C_8H_{10}NO_3F_3$: C, 42.67; H, 4.44; N, 6.22%.

From Ethyl (Z)-2-Amino-2-butenoate and $(CF_3CO)_2O$. Into a solution of the enamine (20 mmol) and pyridine (30 mmol) in dry diethyl ether (20 ml) was added trifluoroacetic anhydride (30 mmol), with stirring, drop by drop under cooling and then the stirring was continued at room temperature for 2 h. After a further addition of ether (20 ml), the resulting solution was washed with water four times and dried ove anhydrous $MgSO_4$. After removal of ether, the residual oil obtained was distilled to give a colorless oil, yield 85.0%.

Preparation of ***10a***. Into a solution of **8a** (4.2 mmol) in dry benzene (10 ml) we stirred triethyl phosphite (4.2 mmol), drop by drop, at 0 °C. After the resulting solution had been stirred at 0 °C for 3 h, the reaction solution was concentrated under reduced pressure to give a residual syrup. The crude syrup obtained was purified on a silica-gel column using a mixture of benzene–acetone (5 : 1 v/v) as the eluent. The fraction was condensed under reduced pressure to give **10a** as a pale yellow syrup, yield 81%. IR (KBr): 3260 (NH), 1700 ($COOBu^t$), 1670 (NHCO, C=C), 1260 (>P=O), 1040 (=P–O–CH_2–) cm^{-1}. NMR ($CDCl_3$): δ 6.70 s (NH), 2.14 s ($COCH_3$), 2.06 s (γ-protons). Found: C, 50.58; H, 8.15; N, 8.16%. Calcd for $C_{14}H_{27}N_2O_5P$: C, 50.30; H, 8.08; N, 8.38%.

Preparation of ***10b***. In a similar manner, the treatment of **8b** with triethyl phosphite was worked up to give **10b** as a pale yellow syrup, yield 74%. IR (KBr): 3200 (NH), 1705 ($COOBu^t$), 1675 (NHCO, C=C), 1260 (>P=O), 1040 (=P–O–CH_2–) cm^{-1}. NMR ($CDCl_3$): δ 6.83 s (NH), 2.78 q (γ-protons, J=8.0 Hz), 2.11 s ($COCH_3$). Found: C, 51.98; H, 8.56; N, 7.91%. Calcd for $C_{15}H_{29}N_2O_5P$: C, 51.72; H, 8.33; N, 8.05%.

†† 1 M=1 mol dm^{-3}. ††† 1 mmHg≈133.3322 Pa.

Synthesis and Properties of *S,S*-Diaryl Thymidine Phosphorodithioates[1)]

Mitsuo SEKINE, Ken HAMAOKI, and Tsujiaki HATA*

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received April 10, 1981)

Appropriately protected or unprotected *S,S*-diphenyl thymidine 3′- or 5′-phosphorodithioates and *S,S*-bis(4-methoxyphenyl) thymidine 3′- or 5′-phosphorodithioates were successfully prepared by the reaction of the thymidine derivatives with cyclohexylammonium *S,S*-diaryl phosphorodithioates in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride (TPS). Stabilities of the thymidylic compounds under acidic or alkaline conditions were described in detail. Several methods for the deprotection of one or both arylthio groups under neutral conditions were also described in connection with the synthesis of oligothymidylates. By the use of the bis(4-methoxyphenylthio)-phosphoryl group, di- and tri-thymidylates were synthesized in high yields.

With the recent remarkable developments of the so-called "phosphotriester method" in oligonucleotide synthesis, the conventional methods for phosphorylation have been reconsidered by introducing new synthetic procedures.[2)] Recently, more considerable attention has been turned to phosphorylating agents which made the phosphotriester products separable by column chromatography on silica gel.[2)]

A few years ago, we described methods for the synthesis of nucleoside *S*-phenyl phosphorothioates by the reaction of nucleotide with a combined reagent of diphenyl disulfide and tributylphosphine[3)] and alternatively by the reaction of nucleoside phosphites with diphenyl disulfide in the presence of a silylating agent *via* highly reactive "nucleoside silyl phosphite" intermediates.[4)] The phenylthio group has been demonstrated as a useful phosphate protecting group in oligonucleotide synthesis.[5)]

In this paper, we wish to report a general method for the synthesis of oligonucleotides by use of *S,S*-diaryl phosphorodithioates as phosphorylating agents for introduction of a 5′-terminal phosphate and promising features of the arylthio groups as "activatable" protecting groups.[6)]

Results and Discussion

In an early work, we showed that *S*-phenyl phosphorodithioate (**1**) could be obtained quantitatively by the reaction of phosphonic acid with diphenyl disulfide in the presence of a trimethylsilylating agent.[4)] However, **1** was too unstable to use as a phosphorylating agent since **1** decomposed rapidly to release benzenethiol in dry pyridine even at room temperature. On the other hand, phosphorothioates of diester-type (*O,S*-phosphorothioates) are known to be rather stable compared with those of monoester-type.[7)] The fact led us to prepare, a new type of compound, *S,S*-diphenyl phosphorodithioate (**2a**) not only to enhance the stability as the phosphorylating agent but also to facilitate the separation of the phosphorylated products by chromatography on silica gel.

By extending the preparative method of **1**, a convenient synthesis of **2a** was performed: When phosphinic acid with further lower oxidation state than phosphonic acid was allowed to react with 2.1 equiv. of diphenyl disulfide in the presence of each 2.1 equiv. of triethylamine and trimethylsilyl chloride in dry tetrahydrofuran (THF) for 20 h at room temperature, **2a** was obtained as the cyclohexylammonium salt in 83% yield. Cyclohexylammonium *S,S*-bis(4-methoxyphenyl) phosphorodithioate (**2b**) was similarly prepared in 85% yield. Both **2a** and **2b** were found to be quite stable compared with **1** under acidic or alkaline conditions such as 80% acetic acid or 0.1 M (1 M=1 mol dm^{-3}) NaOH at room temperature for several weeks.

An improved method for the preparation of **2a** and **2b** in relatively large scale was established in this laboratory.[8)]

The new phosphorylating agents, **2a** and **2b**, were successfully applied to the synthesis of *S,S*-diaryl nucleoside phosphorodithioates (**3**) by condensing **2a** or **2b** with the corresponding nucleosides in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride (TPS). These results are summarized in Table 1. In these reactions, it is noted that all reactions proceeded cleanly without brownish coloration, which was observed often in the case of coupling reactions using TPS in dry pyridine, to give the phosphorylated products in high yields and that the crystalline cyclohexylammonium salt of **2a** could be used without exchange to the pyridinium salt for the phosphorylation by employing two hold TPS. When **2a** was pre-activated by TPS in order to avoid sulfonylation of 5′-hydroxyl groups of nucleosides by TPS, the 2—5% formation of *S,S*-diphenyl phosphorodithiocychlohexylamidate was always accompanied. However, the by-product could be easily separated from *S,S*-diphenyl nucleoside phosphorodithioates since it was

eluted with only dichloromethane by silica-gel column chromatography.

The phenylthio group of **3** was found to be quite stable either in dry or aqueous pyridine and also in 80% acetic acid at room temperature for several days. In addition, when **3a** was refluxed in methanol, ethanol, or 2-propanol for 1 h, **3a** was recovered quantitatively and no transesterification between the dithioester and alcohols was observed. The conditions for the selective removal of one and two phenylthio groups and the relationship with other protecting groups are illustrated in Scheme 3.

When **3c** was treated with 80% acetic acid at room temperature for 6 h, **3f** was isolated in 94% yield. Under these conditions the loss of the phenylthio group was essentially negligible. Whenever **3c** was heated in 80% acetic acid at 100 °C for 1 h, **3f** could be also obtained in 91% yield. In this case, 3% of *S*-phenyl thymidine 3′-phosphorothioate (**4**) was formed by losing one of two phenylthio groups from **3f**. Treatment of **3c** with 0.2 M NaOH–dioxane (1 : 1, v/v) at room temperature for 15 min gave 5′-*O*-monomethoxytrityl-thymidine *S*-phenyl 3′-phosphorothioate (**5**) quantitatively.

Van Boom[9] and Pfleiderer[10] have recently reported that, when dinucleotide derivatives bearing an aryloxy group in internucleotidic phosphate and an unprotected hydroxyl at the 3′- or 5′-position were treated with NaOH to remove one of two phenoxy groups, the 3′–5′ isomerization of phosphoryl group was accompanied to some extent depending upon the conditions. Therefore, in the case of alkaline treatment of **3e** or **3f** which has an unprotected hydroxyl at the 3′-or 5′-position, the above-mentioned problem should be taken into account.

When **3e** was treated with 0.2 M NaOH–dioxane (1 : 1, v/v) at room temperature for 15 min, two new

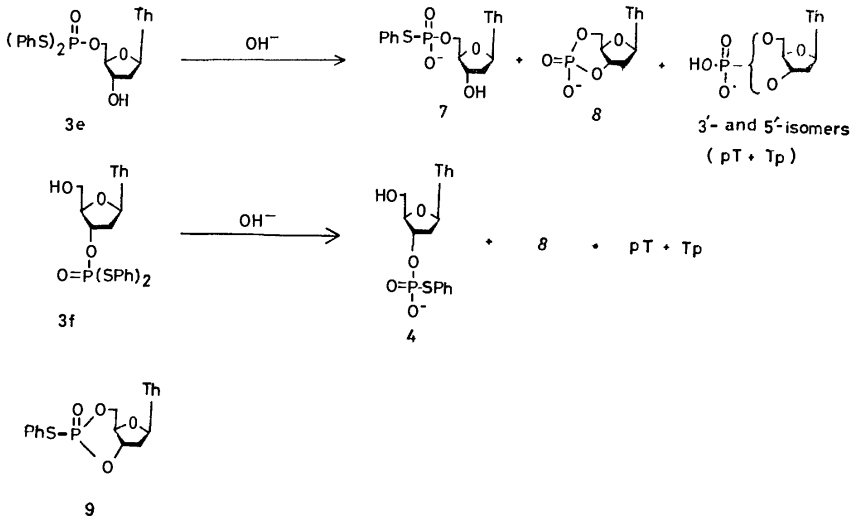
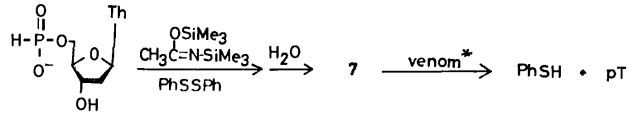


Scheme 4.

spots of R_f 0.53 and 0.20 (Solvent I) were observed other than the major spot which showed the R_f value corresponding to *S*-phenyl thymidine 5'-phosphorothioate (**7**) on TLC. The nucleotidic substance of R_f 0.53 was determined as thymidine 3',5'-cyclic phosphate (**8**) by comparison with the authentic sample. The yield of **8** was estimated to be 12% spectroscopically. The other minor spot was identified with thymidine 3'-or 5'-phosphate formed in 1% yield.

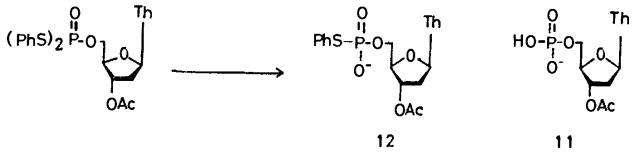
Since it is known that the 3'–5' isomerization of phosphoryl group occurs through a cyclic triester intermediate,[9] if the 3'–5' isomerization occurs during the alkaline treatment of **3e**, thymidine 3',5'-cyclic phosphate derived from thymidine *S*-phenyl 3',5'-cyclic phosphorothioate (**9**) by further alkaline hydrolysis of **9** should be expected as a by-product. Our result indicated that during this alkaline treatment the cyclization reaction along with elimination of one of two phenylthio groups took place at least to the extent of 12%. It is possible that, *S*-phenyl thymidine 3'-phosphorothioate (**4**) might be produced from **9**, if the bond of P–O of **9** at the 5'-position was competitively hydrolyzed with cleavage of the ester bond of P–O at the 3'-position or with cleavage of P–S bond of **9**. Therefore, the nucleotidic material corresponding to **7**, which was estimated to be formed in 87% yield, was further confirmed whether it contained TpSPh (**4**), although it was not separated from PhSpT (**7**) by paper chromatography and electrophoresis.

In a previous paper,[4] we reported that pure PhSpT (**7**) was obtained from thymidine 5'-phosphite by the silylation in the presence of 1.1 equiv. of diphenyl disulfide in quantitative yield. It was found that this pure **7** was completely degraded by snake venom phosphodiesterase in Tris buffer (pH 8). On the other



* *Venom phosphodiesterase*

Scheme 5.



Scheme 6.

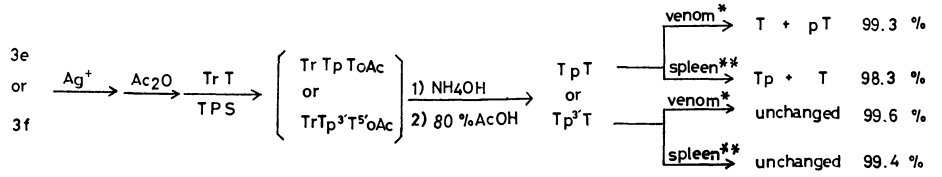
hand, **4** was found to be resistant to the same enzyme. The results are of interest in connection with the report by Nussbaum and Cook that *S*-ethyl thymidine 5'-phosphorothiate (**10**) served as a substrate of snake venom phosphodiesterase.[7]

On the basis of this finding, the nucleotidic substance obtained by alkaline treatment from **3e** was incubated at pH 8 with snake venom phosphodiesterase for 1 h. The nucleotidic substance was degraded in more than 99.3% to give thymidine 5'-phosphate as the sole degraded product. This result indicates that the P–S bond predominantly cleaved on hydrolysis of **9**. Therefore, it is concluded that the 3'–5' isomerization of hydroxy(phenylthio)phosphoryl group is essentially negligible in alkaline treatment of **3e**.

Similarly, treatment of **3f** with 0.2 M NaOH–dioxane (1 : 1, v/v) for 15 min gave a main product of R_f 0.71, **8**, and thymidine 3'- or 5'-phosphate in 76, 21, and 3% yields, respectively. When the product of R_f 0.71 was incubated with snake venom phosphodiesterase, the nucleotidic material remained unchanged and recovered in more than 97%.

This result shows that the 3'–5' isomerization was not observed in the case of **3f**.

Next, complete removal of both phenylthio groups by one-step from **3a** was examined. In spite of facile transformation of S-phenyl nucleoside phosphorothioates to nucleotides by the action of aqueous iodine,[3,4] **3a** was found to be extremely stable toward oxidizing agents such as iodine, sodium periodate, iodosobenzene, hydrogen peroxide, *N*-chlorosuccinimide, and *N*-bromosuccinimide. Removal of both phenylthio groups by use of transition metal salts was examined, since it was expected that sulfur atom has a strong affinity for



*Venom phosphodiesterase **Spleen phosphodiesterase

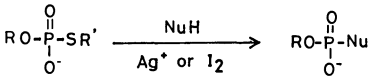
Scheme 7.

the transition metals such as copper, mercury, and silver. Copper(I) chloride, copper(II) chloride, copper-(II) acetylacetonate, copper(II) acetate, mercury(II) acetate, mercury(II) chloride, silver acetate, and silver nitrate were examined. The former three copper salts were not effective. For example, the use of 16 molar equiv. of copper(II) acetylacetonate in pyridine–water (2 : 1, v/v) at room temperature for 24 h gave only 3'-*O*-acetylthymidine *S*-phenyl 5'-phosphorothioate (**12**) in a poor yield. Among the mercury salts, mercury(II) acetate was not effective, but treatment of **3a** with 16 equiv. of mercury(II) chloride at room temperature for 16 h gave **11** quantitatively. On the other hand, two silver salts showed almost the same results as mercury-(II) chloride. From the three effective metal salts, silver acetate was finally chosen as an effective and mild agent for removal of both phenylthio groups. The details of one-step removal of both phenylthio groups from **3a** are summarized in Table 3. This deblocking reaction was carried out at room temperature for 16 h using 16 molar equiv. of silver acetate in pyridine–water (2 : 1, v/v). After the deblocking reaction was completed, the excess of silver acetate, disilver salt of nucleotide, and AgSPh could be converted to the mixture of acetic acid, pyridinium salt of nucleotide, and benzenethiol, respectively, by bubbling hydrogen sulfide with the formation of insoluble silver sulfide which could be easily separated off by centrifugation or filtration. Thus, from **3a**, **3b**, **3c**, and **3d**, the corresponding deblocked nucleotides (**11a**, **11b**, **11c**, and **11d**) were obtained by paper chromatography in 99, 97, 96, and 95 yields, respectively. The use of cation exchange resin (DIAION SK IB, pyridinium form) was also useful for removal of silver ions. In this case, AgSPh was not converted sufficiently to benzenethiol. However, it could be filtered off with the resin.

Table 3. Deprotection of arylthio groups from phosphorylated compounds (**3**)

Phosphorylated compound	Conditions		Product (%)	
	AgOAc (equiv.)	Time h	pT	ArSpT
$(PhS)_2$pT	4	3	46	9
	6	3	55	20
	8	3	55	46
	8	18	97	0
	16	3	80	15
	16	18	100	0
$(PhS)_2$pTOAc	16	18	99 (pTOAc)	0 (PhSpTOAc)
$(4\text{-}CH_3OC_6H_4S)_2$pT	16	18	87	10
	20	18	98	0
MMTrTp$(SPh)_2$	16	18	96 (MMTrTp)	0 (MMTr-TpSPh)

Furthermore, in these silver ion-catalyzed hydrolysis reactions, the 3'–5' isomerization of phosphoryl group was also examined by taking **3e** and **3f**. Each mononucleotidic substance corresponding to pT or Tp obtained by treatment of **3e** or **3f** with silver acetate in aqueous pyridine as described above was acetylated with acetic anhydride in pyridine followed by condensation with 5'-*O*-tritylthymidine in the presence of TPS. Consequently, trityl containing dinucleotide corresponding to TrTpTOAc or TrTp$^{3'}$T$^{5'}$OAc was obtained. The dinucleotide derivatives were deprotected by successive treatment with concentrated ammonium hydroxide and with 80% acetic acid to afford unprotected dinucleotides corresponding to TpT and Tp$^{3'}$T. The dinucleotidic substance (90.1 OD) originally derived from **3e** was degraded by snake venom phosphodiesterase in more than 99.3% to give T (45.4 OD) and pT (47.4 OD) in the ratio of 1.00 : 0.96 and by spleen phosphodiesterase in more than 98.3% to give Tp (42.8 OD) and T (46.2 OD) in the ratio of 1.00 : 1.08. On the other hand, the dinucleotidic substance derived from **3f** was recovered in more than 99.6 and 99.4% yields, respectively, when it was incubated with snake venom phosphodiesterase and with spleen phosphodiesterase under the same conditions. The results indicate clearly that the 3'–5' isomerization of phosphoryl group does not take place during the silver ion-catalyzed hydrolysis in the case of **3e** and **3f**. No isomerization was also suggested from the fact that thymidine 3',5'-cyclic phosphate (**8**) could not be detected.



Scheme 8.

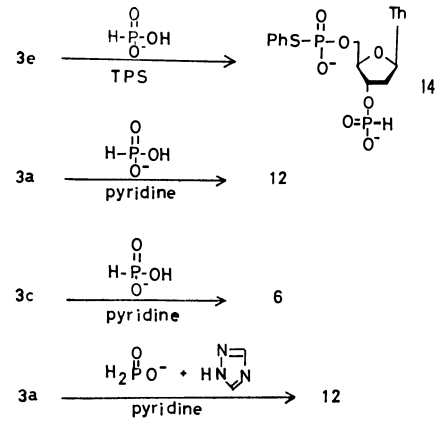
It has been well known that a diester type of phosphorothioates represented as RS–P(O)(OR')O$^-$ can be activated oxidatively on sulfur atom by oxidizing agents such as iodine and sodium metaperiodate to produce a metaphosphate derivative, R'OP(O)=O, which in turn reacts with various nucleophiles to afford the corresponding phosphorylated products. This reaction has been utilized for the synthesis of nucleoside di- and tri-phosphates by Nussbaum.[7] Furthermore, it has recently been reported that unsymmetrical α,γ-dinucleosides triphosphates could be obtained in good

yields by activating the phenylthio group of P¹-*S*-phenyl P²-ribonucleoside 5′-pyrophosphorothioates in the presence of silver salts.[6]

Therefore, conversion of phosphorodithioates to phosphoromonothioates under milder conditions should be required.

In connection with our previous results in oligonucleotide synthesis *via* the phosphotriester method where the phenylthio group was used as an internucleotidic phosphate protecting group,[5] we have found that one of two phenylthio groups can be removed selectively from bis(phenylthio)phosphoryl group under very mild conditions.

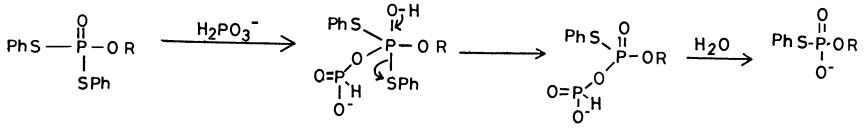
In order to introduce a phosphite group (p_3) into 3′-hydroxyl of **3e** for the preparation of $(PhS)_2pTp_3$ (**13**), **3e** was treated with 4 equiv. of phosphonic acid in the presence of TPS in dry pyridine for 24 h according to the procedure reported early. However, **13** could not be obtained but a product (**14**: $PhSpTp_3$) leaving one of two phenylthio groups was obtained as the main product. The formation of **14** might be explained as a result of elimination of one phenylthio group from the expected compound (**13**) by the catalytic action of phosphonic acid. Consequently, the independent reaction of **3a** with 4 equiv. of phosphonic acid under the same conditions was tested. When **3a** was treated with 4 equiv. of phosphonic acid in dry pyridine at room temperature for 24 h, *S*-phenyl 3′-*O*-acetylthymidine 5′-phosphorothioate (**12**) was obtained quantitatively. The reaction was keenly specific because acetyl group could not be removed at all under the same conditions. It was also found that under the conditions monomethoxytrityl group and trityl group were stable as indicated in the following experiment. When **3c** was treated with 6 equiv. of phosphonic acid in dry pyridine for 20 h, TLC showed a negligible loss of monomethoxytrityl group, and *S*-phenyl 5′-*O*-monomethoxytritylthymidine 3′-phosphorothioate (**5**) was obtained in 86% yield. In comparison with phosphonic acid, phosphates, such as 2,2,2-trichloroethyl phosphate, made only negligible effect on such deblocking reaction.



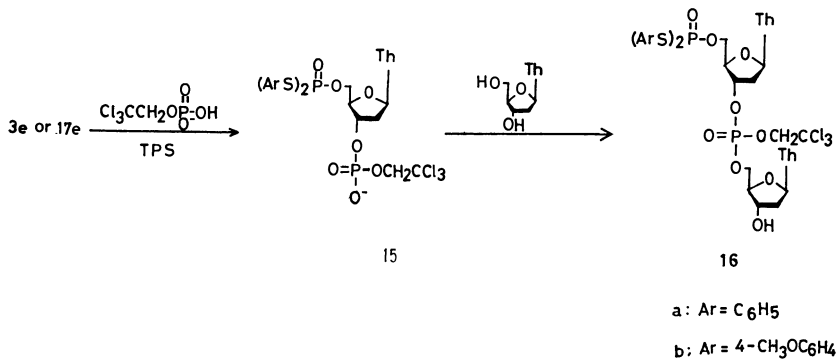
Scheme 9.

In order to extend the catalyst we examined to use phosphinic acid ($pK_a=1.1$)[11] which has a little smaller pK_a value than phosphonic acid ($pK_{a_1}=1.3$).[11] It was found that phosphinic acid is much more soluble in pyridine than phosphonic acid and that the velocity of the deprotection was considerably accelerated for the dearylthioation compared with phosphonic acid: When **3a** was treated with 1.2 equiv. of phosphinic acid in dry pyridine, **3a** disappeared completely after 10 h and **12** was formed in 97% yield along with 3′-*O*-acetylthymidine-5′-phosphate and the corresponding pyrophosphate derivative. Furthermore, an effect of addition of 1,2,4-triazole was tried for the deblocking reaction. The compound, **3a**, was treated with 1.2 equiv. each of phosphinic acid and 1,2,4-triazole at room temperature. The deblocking reaction occured only in 61% yield after 3 h. For the complete deprotection, it took about one day. Although the addition of 1,2,4-triazole reduced the reaction velocity, the deblocking reaction proceeded selectively and gave **12** in quantitative yield without any visible by-products.

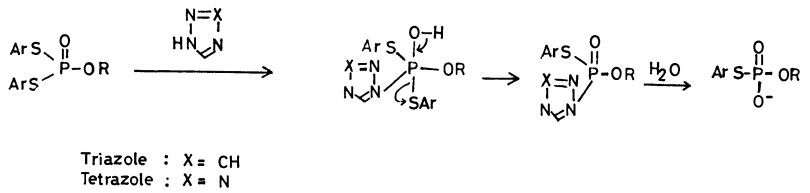
Next, the synthesis of protected dithymidine diphosphate derivatives was examined by using **3e** as the 5′-terminal nucleotide component. Compound **3e** was



Scheme 10.



Scheme 11.



Scheme 12.

phosphorylated with 2,2,2-trichloroethyl phosphate[12] in the presence of TPS and then condensed with thymidine by use of 1-(*p*-nitrobenzenesulfonyl)-1*H*-1,2,4-triazole (NBST).[13] However, the desired dinucleotide (**16a**) was obtained unexpectedly in a lower yield of 44% than expected. In this reaction, a partial dephenylthioation was observed during the second coupling reaction. Such deprotection could be hardly observed during the phosphorylation step using 2,2,2-trichloroethylphosphate and TPS or the condensation step of introducing the bis(phenylthio)phosphoryl group into nucleoside hydroxyls using TPS. The above remarkable difference seemed to be attributed to the kind of condensing agent. The lower yield of **16a** by use of NBST was considered as a result of nucleophilic attack of 1,2,4-triazole to phosphorus of the phosphorodithioate followed by elimination of benzenethiol to give a phosphotriazole intermediate. During the phosphorylation 1,2,4-triazole accumulates up to at least equimolar amount. The phosphotriazole is easily hydrolyzed during work-up of the reaction mixture to form the deblocked product. This catalytic effect of triazole was also confirmed by the following experiment. By treatment of **3a** in the presence of one equiv. of 1,2,4-triazole in dry pyridine at room temperature for 72 h, **12** was formed in 31% yield. In the case of imidazole, **12** was found in 67% yield under the same conditions. On the other hand, tetrazole gave **12** only in 4% yield. Thus, it was concluded that the catalytic effect of these azoles on the undesirable deprotection of the phenylthio group decreases in the following order: imidazole>triazole<tetrazole. The powerful catalytic effect of imidazole might be utilized for the selective removal of the phenylthio group from the bis(phenylthio)phosphoryl group as well as that of phosphonic acid or phosphinic acid described precedingly. In fact, **12** was obtained in 96% yield by treatment with 10 equiv. of imidazole for 28 h. The details of the selective deprotection are summarized in Table 4.

The above results indicate that arenesulfonyl imidazales should not be used condensing agents for phosphorylation of nucleotides having bis(phenylthio)-phosphoryl group. Accordingly, TPS was used for the formation of internucleotidic bond and **16a** was obtained in 92% yield. In this case, the monomethoxytritylation after the condensation was performed so as to remove the by-product of the 3′–3′ isomer.[14]

Since neutral condensing agents such as NBST, 1-(2,4,6-triisopropylbenzenesulfonyl)-1*H*-tetrazole (TPSTe), and 1-(8-quinolinesulfonyl)-1*H*-tetrazole (QSTe) have become apparently more desirable than TPS in several aspects as reported in a number of labolatories,[15–21] our efforts were focused on the exploration of protecting groups more stable towards the above-mentioned azoles. In conclusion, it was found that 4-methoxyphenylthio group having an electron-donating group on benzenethiol was sufficiently stable.

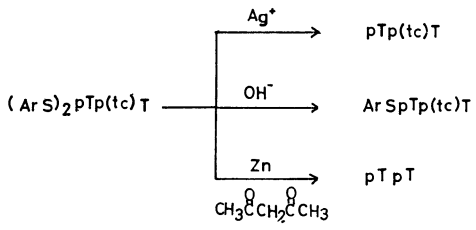
a) The yields of PhSpTOAc and 4-$CH_3OC_6H_4$SpToAc were calculated by using ε values of PhSpT [λ_{max} 267 mm (ε 8.6×10^3)] and 4-$CH_3OC_6H_4$SpT [λ_{max} 267 mm (ε 9.2×10^3)].

The introduction of bis(4-methoxyphenylthio)phosphoryl group into hydroxyls of nucleosides could be readily carried out as well as that of the bis(phenylthio)phosphoryl group as shown in Table 1. The promising feature of 4-methoxyphenylthio group is demonstrated in the following experiment: When 3'-*O*-acetylthymidine *S*,*S*-di(4-methoxyphenyl) 5'-phosphorodithioate (**17a**) was treated with one equiv. of 1,2,4-triazole in pyridine at room temperature for 72 h, only 2% of the corresponding deprotected product (**18**) was formed. Therefore, the deprotection reaction can be suppressed within 1% under the usual conditions using NBST in coupling reactions. In fact, when *S*,*S*-di(4-methoxyphenyl) thymidine 5'-phosphorodithioate (**17a**) was phosphorylated with 2,2,2-trichloroethyl phosphate by use of TPS and successively condensed with thymidine by employing NBST followed by the monomethoxytritylation of the mixture, the corresponding dithymidine diphosphate derivative (**16b**) was obtaind in 90% yield. In a similar manner, the corresponding trithymidylate, (4-$CH_3OC_6H_4S)_2$pTp(tc)Tp(tc)T, was obtained in 82% yield from **16b**.

Removal of Protecting Groups from the Oligomers. Selective removal of one of two phenylthio or two 4-methoxyphenylthio groups from **16a** or **16b** was also carried out by using 0.2 M NaOH–dioxane (1 : 1, v/v) at room temperature for 20 min or by phosphonic acid in pyridine containing a small amount of water at room temperature for 24 h. The product, PhSpTp(tc)T, or 4-$CH_3OC_6H_4$SpTp(tc)T was easily converted to pTp(tc)T by treatment with iodine in aqueous pyridine. This two-step procedure for removal of both arylthio groups is efficient for obtaining pTp(tc)T in high yields. When zinc/acetylacetone in DMF–pyridine[22] was employed for removal of 2,2,2-trichloroethyl group of **16a**, the phenylthio groups were together removed and pTpT was obtained by one-step treatment in 71% yield. It seems to be plausible that the active $ZnCl^+$ formed along with 1,2-dichloroethylene serves as an activating reagent of the phenylthio group to liberate ZnCl(SPh) or $Zn(SPh)_2$. In order to remove 2,2,2-trichloroethyl group selectively, benzenethiol was added as a scavenger of $ZnCl^+$. Contrary to our expectation, pTpT was obtained in 84% yield from **16a**. Under the same conditions, pTpT was obtained in 35% yield from **16b** and the desired product, $(4\text{-}CH_3OC_6H_4S)_2$-pTpT, was obtained in 34% yield.



Scheme 13.

Removal of both phenylthio or both 4-methoxyphenylthio groups from the fully protected dinucleotide (**16a**) or (**16b**) was carried out as follows: Treatment of **16a** or **16b** with 16 equiv. of silver acetate in pyridine–water (2 : 1, v/v) at room temperature for 16 h or 18 h gave the deprotected dinucleotide pTp(tc)T in 98 or 97% yield. The successive treatment of the deprotected dinucleotide with zinc powder in DMF–pyridine (2 : 1, v/v) in the presence of acetylacetone gave pTpT in quantitative yield. On the other hand, treatment of $(4\text{-}CH_3OC_6H_4S)_2$pTp(tc)Tp(tc)T with 20 equiv. of silver acetate in aqueous pyridine followed by zinc/acetylacetone in DMF–pyridine gave pTpTpT in 97% yield.

Experimental

Proton magnetic resonance spectra were recorded at 60 Hz on a Varian A-60 spectrometer. Infrared spectra were obtained on a Hitachi 124 spectrophotometer. Melting points were taken on a Fisher-Johns melting point block. Reagent grade pyridine was distilled by addition of *p*-toluenesulfonyl chloride and stored over calcium hydride for several weeks. Paper chromatography was performed using the descending technique on Toyo Roshi No. 51 or Whatman 3 MM paper. The solvent systems used for paper chromatography were: isopropyl alcohol–concentrated ammonium hydroxide–water (7: 1: 2, v/v) (Solvent I); ethyl alcohol–1 M ammonium acetate (pH 7.5) (7: 3, v/v) (Solvent II); butyl alcohol–water (84: 16, v/v) (Solvent III). Paper electrophoresis was carried out on Toyo Roshi No. 51A (15 cm × 60 cm) impregnated with the solvents described by Markham[23] and 1200 V for 1.5 h (buffer I) or at 1500 V for 1.5 h (buffer II) using an apparatus similar to that described by Markham and Smith;[23] buffer I, 0.05 M potassium phosphate (pH 8.0); buffer II, 0.05 M potassium phosphate (pH 6.0). For separation of appropriately protected nucleotide derivatives of triester-type, silica gel (C-200) purchased from Wako Chemical Co. was used. The eluent was monitored by thin layer chromatography using pre-coated plates of silica-gel 60 F-254 purchased from Merck Chemical Co. The yields of water-soluble nucleotidic products were estimated spectrophotometrically after elution of the bands from paper chromatograms. Absorbances were determined with a Hitachi spectrophotometer by the absorbancy for a blank cut from the paper adjacent to the product spot. Snake venom and calf spleen phosphodiesterases were purchased from Boehringer Mannheim Co.

S,S-*Diphenyl Phosphorodithioate (2a).* Sodium Phosphinate (5.30 g, 50 mmol) was converted to pyridinium salt by passing the aqueous solution through DIAION SK 1B (Mitsubishi Kasei Kogyo Co., pyridinium form). Elution was performed with 500 ml of water. The eluent was evaporated and the residue was dried by repeated coevaporations with pyridine. The resulting white solid was mixed with diphenyl disulfide (22.89 g, 105 mmol) and dissolved in 400 ml of dry tetrahydrofuran (THF). Trimethylsilyl chloride (13.1 ml, 105 mmol) and triethylamine (14.8 ml, 105 mmol, were added dropwise to the THF solution at 0 °C. After the addition the mixture was warmed to room temperature and stirred for 20 h. A precipitate of triethylamine hydrochloride was filtered off and the filtrate was evaporated to dryness. The residue was treated with 2 M hydrochloric acid (200 ml) and extracted with dichloromethane (CH_2Cl_2) (4 × 100 ml). The extracts were combined and evaporated to dryness. The residue was dissolved in chloroform (200 ml) and treated with cyclohexylamine (5.73 ml, 50 mmol). The solvent was removed *in vacuo* to give an oily material which solidified after washing with three 50 ml portions of hexane. The solid was recrystallized from water containing a small ammount of THF to afford 15.8 g (83%) of **2a**: mp 177—

179 °C; IR(KBr) 3040, 2950, 1629, 1580, 1523, 1476, 1388, 1220, 1210, 1052 cm^{-1}; NMR (DMSO-d_6–CD_3OD, 1: 1, v/v) δ 1.00—1.57 (5H, m, protons of cyclohexane ring), 1.57—2.11 (5H, m, protons of cyclohexane ring), 2.86 (1H) m, CH–N), 7.29 (3H, m, ArH), 7.56 (2H, m, ArH).

S,S-*Bis(4-methoxyphenyl)phosphorodithioate.* The title compound (18.8 g, 85%) was prepared according to the same procedure as described above by using bis(4-methoxyphenyl) disulfide (29.2 g, 105 mmol); mp 174—175 °C; IR(KBr) 3050, 2920, 2830, 1588, 1535, 1488, 1450, 1390, 1282, 1238, 1210, 1175, 1050, 1028 cm^{-1}.NMR (DMSO-(DMSO-d_6–CD_3OD, 1: 1, v/v) 1.00—1.64 (m, 5H, protons of cyclohexane ring), 1.64—2.32 (m. 5H, protons of cyclohexane ring), 2.90 (m, 1H, CH–N), 3.82 (s, 6H, OCH_3), 6.89 (d, 4H, J=9.0 Hz, ArH), 7.58 (d, 4H, J=9.0 Hz, ArH).

Found: C, 54.42; H, 6.44; N, 3.12; S, 14.73%. Calcd for $C_{20}H_{28}O_4NS_2P$: C, 54.40; H, 6.39; N, 3.17; S, 14.52%.

Introduction of S,S-*Diaryl Phosphorodithioyl Group into Appropriately Protected Nucleosides. Typical Procedure A) 3'-O-Acethylthymidine* S,S-*Diphenyl 5'-Phosphorodithioate (3a)*: TPS 727 mg (2.4 mmol) was added to **2a** (458 mg, 1.2 mmol) in dry pyridine (2.0 ml) and it was kept at room temperature for 30 min. 3'-O-Acethylthymidine[19] (284 mg, 1 mmol), was added. The mixture was stirred at room temperature for 20 h. The solution was diluted with CH_2Cl_2 (20 ml) and then water (20 ml) was added. The aqueous layer was further treated with CH_2Cl_2 (3×20 ml) and the organic layers were combined and dried over Na_2SO_4. The solution was concentrated *in vacuo* to dryness. The last traces of pyridine was removed by coevaporation with toluene (3× 10 ml). The residue was treated with ethyl acetate (20 ml) whereupon pyridinium salt of 2,4,6,triisopropylbenzenesulfonic acid was separated. The white precipitate was filtered off and washed with cold ethyl acetate (10 ml). The filtrate and washings were combined, dried over Na_2SO_4, and evaporated to a gum. The residue was dissolved in a small amount of benzene and applied to a column on silica gel (20 g). Elution with benzene–ethyl acetate (1: 2, v/v) gave 505 mg (92%) of **3a** as a white foam:

B) S,S-*Diaryl Thymidine 5'-Phosphorodithioates (3d and 17d)*: Compound **2a** (2.1 g, 5.5 mmol) was coevaporated with dry pyridine (3×5 ml) and dissolved in dry pyridine (10 ml). To the solution was added TPS (3.33 g, 11 mmol). The mixture was stirred at room temperature for 1 h and then well pulverized thymidine (1.21 g, 5.0 mmol) was added. After stirring at room temperature for 22 h, the mixture was diluted with chloroform (40 ml) and then water (40 ml) was added. The organic layer was collected and the aqueous layer was further extracted with chloroform (3×10 ml). The organic extracts were combined, dried over Na_2SO_4, evaporated to dryness, and coevaporated with toluene (10 ml). The residue was treated with ethyl acetate (100 ml) and a white precipitate was filtered off. The filtrate was evaporated *in vacuo* and dissolved in dry pyridine after repeated evaporations with dry pyridine (3×5 ml). To the solution was added monomethoxytrityl chloride (577 mg, 2.0 mmol). After stirring at room temperature for 15 h, the mixture was diluted with chloroform (50 ml) and then water (50 ml) was added. The aqueous layer was further extracted with chloroform (2×10 ml) and the organic extracts were combined and dried over Na_2SO_4. The solution was evaporated to dryness *in vacuo*, coevaporated with CH_2Cl_2–toluene (3×5 ml), and the residue chromatographed on silica gel with THF (5: 1, v/v) to afford **3d** (3.34 g, 66%) as a white foam.

Removal of Monomethoxytrityl Group from 3c. S,S-*Diphenyl Thymidine 3'-Phosphorodithioate (3f)*: Compound **3c** (779 mg, 1 mmol) was dissolved in 80% acetic acid (50 ml) and the solution was kept at room temperature for 6 h. The mixture was evaporated to dryness *in vacuo*, and coevaporated with pyridine (5 ml) and then with toluene (3×5 ml). The residue was chromatographed on silica gel with CH_2Cl_2–methanol to give **3e** (477 mg, 94%): UV_{max} (MeOH) 256 nm (ε 14×10^3), UV_{min} (MeOH) 245 nm (ε 13.5×10^3). The data of its elemental analysis and ^{1}H-NMR spectrum are shown in Tables 1 and 2.

Conversion of 3c to 5: To a solution of **3c** (389.5 mg, 0.5 mmol) in dioxane (12 ml) was added 0.2 M NaOH (11 ml) with stirring. The mixture was kept at room temperature for 15 min and then neutralized through a column (1 cm×27 cm) of DIAION SK 1B (NH_4^+ form). The column was washed with dioxane–water (2: 1, v/v, 60 ml), and the eluent and washings were combined and concentrated to *ca.* 20 ml. The aqueous solution was extracted with hexane (3×20 ml) for removal of benzenethiol and then passed through a column (1 cm×27 cm) of DIAION SK 1B (Na^+ form). The column was eluted with dioxane–water (2: 1, v/v, 200 ml) and the eluent was concentrated to *ca.* 20 ml. The solution was extracted with CH_2Cl_2 (3×20 ml) by addition of a few milliliters of saturated sodium chloride. The organic layer was dried over Na_2SO_4, concentrated to 5 ml, and poured into hexane (100 ml). A white precipitate was collected and dried over P_4O_{10} *in vacuo* to give sodium salt (310 mg, 81%) of **5**: UV_{max} (H_2O) 266 nm (ε 10.4×10^3), UV_{min} (H_2O) 255 nm (ε 9.5×10^3), UV_{sh} (H_2O), 232 nm (ε 1.9×10^3).

Found: C, 56.56; H, 5.10; N, 3.52%. Calcd for $C_{36}H_{34}NO_8PSNa\cdot 3H_2O$: C, 56.69; H, 5.29; N, 3.67%.

Conversion of 5 to 4: The sodium salt of **6** (140.7 mg, 0.2 mmol) obtained in the above experiment was treated with 80% acetic acid (10 ml) at room temperature for 6 h. Then water (20 ml) was added and the aqueous solution was extracted with CH_2Cl_2 (3×20 ml). The aqueous solution was evaporated and lyophilized to give a hygroscopic sodium salt (87 mg, 100%) of **4**: UV_{max} (H_2O) 266 nm (ε 9.2×10^3), 245 nm (ε 7.6×10^3), UV_{min} (H_2O) 249 nm (7.6×10^3), 230 nm (ε 6.2×10^3).

Found: C, 40.50; H, 4.41; N, 5.6%. Calcd for $C_{16}H_{18}O_7N_2PSNa\cdot 2H_2O$: C, 40.68; H, 4.70; N, 5.93%.

Alkaline Treatment of 3e and 3f and Enzymatic Assay of the Resulting Diesters: To a solution of **3e** (93 mg, 0.184 mmol) in dioxane (4.4 ml) was added 0.2 M NaOH (4.4 ml) with stirring. After being stirred at room temperature for 15 min, the solution was passed through a column (1 cm×2 cm) of DIAION SK 1B (NH_4^+ form) and the elution was performed with dioxane–water (1: 1, v/v, 60 ml). The eluent was concentrated to *ca.* 10 ml, and extracted with ether (3×10 ml) for removal of benzenethiol. The aqueous solution was concentrated and applied to Whatman 3MM paper developed with Solvent I to afford **7** (R_f 0.72, 87%), **8** (R_f 0.53, 12%), and pT (+Tp) (R_f 0.20, 1%).

A similar treatment of **3f** gave **4** (R_f 0.71, 76%), **8** (R_f 0.47, 21%), and Tp (+pT) (R_f 0.18, 3%).

The ammonium salt (138 OD) of **7**, obtained from **3e** in the above experiment, was incubated with snake venom phosphodiesterase (70 μg) in Tris buffer (pH 8, 1.4 ml) at 37 °C for 1 h. After incubation the mixture was treated with pyridine (1 ml) and chromatographed on Whatman 3MM paper developed with Solvent I to give pT (R_f 0.20, 130 OD) as the sole nucleotidic material.

In a similar manner, the ammonium salt (143 OD) of **4**, obtained by alkaline treatment of **3f**, was incubated under the same conditions. The paper chromatography showed unchanged **4** (138 OD) and Tp (R_f 0.20, 2 OD).

Enzymatic Assay of the Authentic Samples (7 and 4): The ammonium salt (112 OD) of **7**, obtained from thymidine 5′-phosphite, was incubated with snake venom phosphodiesterase (66 μg) in Tris buffer (pH 8.0, 1.32 ml) at 37 °C for 1 h. One tenth of the incubation mixture was treated with pyridine (0.1 ml) and analyzed with paper electrophoresis (pH 8.0), which showed a single band of pT (12.5 OD).

The ammonium salt (76.1 OD) of **4**, obtained by treatment of **5** with 80% acetic acid in the previous experiment, was incubated with snake venom phosphodiesterase (38 μg) in Tris buffer (pH 8, 0.76 ml) at 37 °C. After 1, 6, and 20 h, 0.1 ml aliquots of the incubation mixture were analyzed with paper electrophoresis (pH 8.0), and the bands corresponding to pT were eluted with water, and the yields of pT were spectroscopically calculated to be 1.5% (1 h), 7% (6 h), and 11% (20 h), respectively. These results showed that this enzyme is essentially resistant to TpSPh within 1 h but degrades it gradually to Tp and benzenethiol for prolonged incubation.

One-step Removal of Both Phenylthio Groups from Bis(phenylthio)-phosphoryl Group. Typical Procedure A): To a solution of silver acetate (97 mg, 0.58 mmol) in pyridine–water (2 : 1, v/v, 3 ml) was added **3a** (20.0 mg, 36.5 μmol) and the homogeneous solution was vigorously stirred at room temperature. The solution turned gradually to a suspension. After being stirred for 18 h, the suspension was bubbled with hydrogen sulfide gas until a clear supernatant solution had been obtained. The precipitate was removed by centrifugation (or sometime by filtration) and washed with water (2×5 ml). The supernatant and washings were concentrated to *ca.* 2—3 ml and chromatographed on Whatman 3MM paper developed with solvent II to give a single band of R_f 0.20. Elution of the band with water afforded pTOAc (315 OD, 99%).

B): To a solution of **3c** (77.9 mg. 0.1 mmol) in pyridine (5 ml) was added water (2.5 ml) and then silver acetate (267 mg, 1.6 mmol). The resulting solution was stirred vigorously at room temperature for 18 h and then bubbled with hydrogen sulfide gas at 0 °C until a clear supernatant solution had been obtained. The resulting suspension was evaporated *in vacuo* to remove excess hydrogen sulfide and then diluted with pyridine–water (2 : 1, v/v, 10 ml). The black precipitate was removed by centrifugation, and the supernatant and washings with pyridine–water (2 : 1, v/v, 3×2 ml) were combined, evaporated, and chromatographed on Whatman 3MM paper developed with Solvent I. A band of R_f 0.45 was eluted with water to give MMTrTp (37.1 OD, 96%).

Treatment of 3e and 3f with Silver Acetate in Aqueous Pyridine. In the Case of 3e: To a solution of **3e** (33.9 mg, 0.767 mmol) in pyridine (3.9 ml) was added water (1.9 ml) and then silver acetate (205 mg, 1.23 mmol). The mixture was stirred vigorously at room temperature for 16 h. The resulting suspension was bubbled with hydrogen sulfide gas until a clear supernatant had been obtained. The precipitate of silver sulfide was centrifuged and the supernatant solution was decanted. The precipitate was washed with pyridine–water (2 : 1, v/v, 2×3 ml), and the supernatant and washings were collected and then evaporated to dryness. The residue was dried by repeated evaporations with dry pyridine (4×3 ml) and treated with acetic anhydride (0.22 ml) in dry pyridine (0.77 ml) at room temperature for 12 h. Then ice–water (20 ml) was added and the mixture was extracted with chloroform (3×20 ml). The aqueous layer was evaporated to dryness and a benzene adduct of TrT (35.9 mg, 0.064 mmol) was mixed. The mixture was dried by repeated evaporations with dry pyridine (4×3 ml) and treated with TPS (46.5 mg, 0.15 mmol) in dry pyridine (0.8 ml) at room temperature for 3 h. Then the mixture was quenched with water (20 ml) and extracted with chloroform (3×10 ml). The organic extracts were collected, evaporated to dryness *in vacuo*, and treated with 80% acetic acid (10 ml) at 100 °C for 20 min. After removal of the solvent *in vacuo*, the residue was treated with concd NH_4OH–MeOH (1 : 1, v/v, 20 ml) at room temperature for 10 h. Then the mixture was evaporated to dryness and chromatographed on Whatman 3MM paper developed with Solvent I. A band of R_f 0.43 corresponding to TpT was eluted with water to give a nucleotidic material of 194 OD.

In a similar manner, a nucleotidic material (203 OD) corresponding to Tp$^{3'}$T was obtained from **3f** (40.5 mg, 0.08 mmol) *via* TrTp$^{3'}$T$^{5'}$ OAc.

Enzymatic Assay of the Dithymidine Monophosphate Derivatives Obtained in the Above Experiments. A): TpT (90.1 OD, 4.92 mol) obtained from **3e** was incubated with snake venom phosphodiesterase (50 μg) in 0.1 M Tris buffer (pH 8, 1.0 ml) at 37°C for 12 h. After addition of pyridine (1 ml), the mixture was chromatographed on Whatman 3MM paper developed with Solvent I to give T (45.4 OD, 96.1%) and pT (47.4 OD, 100%).

The same substrate (90.1 OD, 4.92 mol) was incubated with spleen phosphodiesterase (140 μg) in 0.05 M NH_4OAc (1.0 ml) at 37 °C for 8 h. Paper chromatography of the mixture gave T (46.2 OD, 98%) and Tp (42.8 OD, 90%). In the above two enzymatic assays, the band corresponding to the original substrate was eluted with water and its recovery was spectroscopically calculated and estimated to be 0.71% (0.64 OD) and 1.7% (1.5 OD), respectively. B) Tp$^{3'}$T (90.7 OD, 4.96 μmol) obtained from **3f** was incubated with snake venom phosphodiesterase and spleen phosphodiesterase under the same conditions as described in the above enzymatic assays. In both cases, the bands corresponding to the substrate unchanged and pT (or Tp) were cut and eluted with water. The recovery of Tp$^{3'}$T was 100% (91 OD) and 98.6% (87 OD), respectively, after treatment with snake venom and spleen phosphodiesterases. pT and Tp eluted were estimated to be less than 0.3% (0.16 OD) and 0.6% (0.36 OD).

Reaction of 3e with Phosphonic Acid in the Presence of p-Toluenesulfonyltriazole. To a solution of phosphonic acid (0.124 mmol) in pyridine–water (9 : 1, v/v, 1 ml) added **3e** (15.7 mg, 0.02 mmol). The mixture was rendered anhydrous by repeated evaporations with pyridine (5×4 ml) and treated with 1-(*p*-toluenesulfonyl)-1*H*-triazole (27.4 mg, 0.124 mmol) in dry pyridine (0.5 ml) at room temperature for 24 h. Then the mixture was quenched with water (10 ml) and extracted with CH_2Cl_2 (3×10 ml). The organic layer was analyzed by TLC ("Avicel" plate, Funakoshi Co.), which showed no significant spots containing phosphate group indicating that the Hanes-Isherwood test (spray) was negative. TLC of the aqueous layer showed a main product of R_f 0.49 (Solvent I) which was formed almost quantitatively. The spot did not change when concd NH_4OH was added to an aliquot of the aqueous layer. When one third of the aqueous layer was dried by repeated evaporations with dry pyridine (4×1 ml) and treated with 2,2′-dipyridyl disulfide (4.4 mg, 0.02 mmol) in the presence of *N,O*-bis(trimethylsilyl)acetamide (0.1 ml) in dry pyridine (0,2 ml) at room temperature for 2 h, the spot changed to a new one of R_f 0.23 (Solvent I) or 0.39 (Solvent III) corresponding ot PhSpTp. The spot was also converted to a new spot of R_f 0.84 (Solvent I) when one third of the aqueous layer was treated with diphenyl disulfide in place of 2,2′-dipyridyl disulfide. The spot of R_f 0.84 was identical with PhSpTpSPh obtained by treatment of **3d** (29 mg, 0.038 mmol) with 0.2 M NaOH–dioxane (1 : 1, v/v, 8 ml) at room temperature for 15 min. Treatment of PhSpTpSPh

with 20 equiv. of iodine in pyridine–water (2 : 1, v/v) gave pTp of R_f 0.05 (Solvent I). The changes in the above transformations of the product of R_f 0.23 were also followed by paper electrophoresis. The data are shown as follows: PhSpTp$_3$: Rm (pH 8.0, relative to pT) 0.94; PhSpTp: 1.10; PhSpTpSPh: 0.82; pTp: 1.18. These results suggested that the initial product from the reaction of **3e** with phosphonic acid was PhSpTp$_3$.

*Selective Removal of One Phenylthio Group from **3a** by Using Phosphonic acid.* By dissolving phosphonic acid (2.05 g, 25 mmol) in THF using 25 ml measuring flask, 1 M solution of phosphonic acid was prepared. The standard solution of 2.4 ml was taken, evaporated, and dried by repeated evaporations with dry pyridine (3×1 ml). To the pyridinium phosphonate was added **3a** (27.4 mg, 0.05 mmol) in dry pyridine (*ca.* 0.5 ml). The weight of the mixture was 537 mg. Aliquots from the reaction mixture after 0.5, 1, 7, 11, and 21 h were taken out, weighed, and applied to paper electrophoresis (pH 6.0) at 1500 V for 1 h. A band of Rm 0.8 (to pT) was eluted with 0.1 M phosphate buffer (pH 7.0) and the yield was estimated by UV spectrophotometer.

*Conversion of **3c** to **5** by Use of Phosphonic Acid.* The pyridinium salt (2.4 mmol) of phosphonic acid and **3c** (312 mg, 0.4 mmol) were mixed, dried by repeated evaporations using dry pyridine (4×1 ml) and finally dissolved in dry pyridine (4 ml). After being stirred at 30 °C for 15 h, the solution was treated with CH_2Cl_2 (20 ml) and water (20 ml). The aqueous solution was further extracted with CH_2Cl_2 (3×10 ml). The CH_2Cl_2 extracts were combined dried over Na_2SO_4, concentrated to *ca.* 2 ml, and poured into hexane (50 ml). A white precipitate was collected and dried over P_4O_5 *in vacuo* for 12 h to give the free acid of **5** (236 mg, 86%). The product was almost homogeneous on TLC [R_f 0.42 (silica gel plate), Solvent III].

Synthesis of (PhS)$_2$pTp(tc)T. Pyridinium salt (0.6 mmol) of 2,2,2-trichloroethyl phosphate and **3e** (203.1 mg, 0.5 mmol) were mixed, dried by repeated coevaporations with dry pyridine (4×3 ml), and treated with TPS (379 mg, 1.25 mmol) in dry pyridine (2.5 ml) at room temperature for 20 h. Then CH_2Cl_2 (20 ml) and water (20 ml) were added. The aqueous layer was extracted with CH_2Cl_2 (3×10 ml). The CH_2Cl_2 extracts were combined, dried over Na_2SO_4, and evaporated to dryness, and then thymidine (183 mg, 0.75 mmol) was added. The mixture was rendered anhydrous by repeated coevaporations with dry pyridine (4×4 ml), dissolved in dry pyridine (1.0 ml), and finally treated with *p*-nitrobenzenesulfonyl 1,2,4-triazole (153 mg, 0.6 mmol) at room temperature for 24 h. Then CH_2Cl_2 (20 ml) and water (20 ml) were added to the solution. The aqueous layer was further extracted with CH_2Cl_2 (3×10 ml) and the extracts were combined and evaporated to dryness after dryning over Na_2SO_4. The residue was evaporated with toluene (3×4 ml) to remove the last traces of pyridine and chromatographed on silica gel with CH_2Cl_2–methanol to give the title compound (209 mg, 44%): NMR ($CDCl_3$) δ 1.81 (3H, s, C=C–CH_3), 1.90 (3H, C=CH_3), 2.13—2.67 (4H, 2'H), 4.44 (2H, m, 4'H), 4.24—4.70 (5H, m, OH and 5'H), 4.70 (2H, d, J_{P-H}=7 Hz, Cl_3CCH_2–O–P), 5.00—5.47 (2H, m, 3'H), 6.33 (2H, m, 1'H), 7.20—7.73 (12H, m, ArH and)H): UV_{max} (MeOH) 261 nm (ε 21.4×10^3), UV_{min} (MeOH) 241 nm (ε 16.6×10^3).

Found: C, 43.32; H, 3.95; N, 5.87%. Calcd for $C_{34}H_{37}O_{13}N_4S_2P_2Cl_3$: C, 43.35; H, 3.96; N, 5.95%.

Similarly, the use of TPS (303 mg, 1 mmol) in the second coupling reaction gave (PhS)$_2$pTp(tc)T (433 mg, 92%). This compound was further treated with monomethoxytrityl chloride (308 mg, 1 mmol) in dry pyridine (10 ml) for 6 h in order to remove the 3'–3' isomer. After the usual workup, pure (PhS)$_2$pTp(tc)T (400 mg) was obtained by chromatography. For further transformation or deprotection, this purified material was used.

*Treatment of **3a** or **17a** with Imidazole, 1,2,4-Ttriazole, and Tetrazole. General Procedure*: To a solution of **3a** or **17a** in dry pyridine was added an appropriate azole. The reaction conditions and the results are summarized in Table 4. The total weight of the reaction mixture was measured and 10—20 mg aliquots of the mixture after the times described in Table 4 were taken to be analyzed by paper electrophoresis.

*Synthesis of (4-$CH_3OC_6H_4S$)$_2$pT(tc)T (**16b**).* Pyridinium salt (513 mg, 1.2 mmol) of 2,2,2-trichloroethyl phosphate was dried by repeated evaporations with dry pyridine (4×5 ml) and finally dissolved in dry pyridine (5 ml). TPS (727 mg, 2.4 mmol) was added to the mixture and the solution was stirred at room temperature for 21 h. Then CH_2Cl_2 (30 ml) and water (30 ml) were added. The organic layer and further extracts with CH_2Cl_2 (3×10 ml) from the aqueous layer were combined, dried over Na_2SO_4, and concentrated to dryness. The residue was rendered anhydrous by repeated evaporations with dry pyridine (5×4 ml) and treated with NBST (509 mg, 2 mmol) in dry pyridine (1 ml) for 1 h. Then well pulverized thymidine (363 mg, 1.5 mmol) was added to the mixture. The mixture was stirred at room temperature for 26 h. Then CH_2Cl_2 (30 ml) and water (30 ml) were added and the organic layer was collected, and then the aqueous solution was further extracted CH_2Cl_2 (3×10 ml). The organic extracts were combined, dried over Na_2SO_4, and concentrated to dryness. The residue was coevaporated with toluene (4×4 ml), and chromatographed on silica gel with CH_2Cl_2–methanol to afford **16b** (902 mg, 90%). The crude product containing the 3'–3' isomer was further treated with monomethoxytrityl chloride (308 mg, 1 mmol) in pyridine (10 ml) at room temperature for 6 h to remove the 3'–3' isomer and the purified material (798 mg) was used for further transformation and deprotection: NMR($CDCl_3$) δ 1.82 (6H, m, CH_3), 2.00—2.50 (4H, m, 2'H), 3.75 (6H, OCH_3), 4.00—4.27 (2H, m, 4'H), 4.27—4.57 (5H, m, CHOH and 5'H), 4.60 (2H, d, J_{P-H}=7 Hz, Cl_3CCH_2O–P), 4.90—5.32 (1H, m, CH–O–PS), 6.08—6.56 (2H, m, 1'H), 6.85 (4H, d, J=8.4 Hz, ArH), 7.24 (2H, s, C=CH), 7.58 (4H, dd, J=2 Hz, J=8.4 Hz, ArH); UV_{max} (MeOH) 257 nm (ε 35.7×10^3), UV_{min} (MeOH) 225 nm (ε 18.6×10^3).

Found: C, 43.52; H, 4.19; N, 5.61%. Calcd for $C_{36}H_{41}O_{15}N_4Cl_3P_2S_2$: C, 43.15; H, 4.12; N, 5.59%.

*Deprotection of the Fully Protected Dithymidine Diphosphates (**16a**) and (**16b**).* The protected dinuclotide, **16a**, (7.9 mg, 8.4 μmol) was treated with silver acetate (22,4 mg, 0.134 mmol) in pyridine–water (2 : 1, v/v, 0.8 ml) at room temperature for 16 h. Then the mixture was bubbled with hydrogen sulfide gas at 0 °C until a clear supernatant had been obtained, and the suspension was sucked by aspirator for a few minutes for removal of excess hydrogen sulfide. The black precipitate was removed off centrifugation by and washed with pyridine–water (2×2 ml). The supernatant and washings were combined and evaporated to dryness *in vacuo*. The residue was dissolved in DMF–pyridine (2: 1, v/v, 0.8 ml). The analysis of the solution with paper electrophoresis (pH 6.0) showed a single spot of Rm 0.50 (relative to pT) corresponding to pTp(tc)T (151 OD, 98%). To the DMF–pyridine solution was added zinc powder (50 mg) and acetylacetone (0.08 ml) and the mixture was stirred vigorously at room temperature for 8 h. Then water (5 ml) and DIAION SK 1B (NH_4^+ form, 5 ml) were added with stirring. The supernatant was passed through a column (1 cm×5 cm) of DIAION SK 1B (NH_4^+ form) and the resin was washed with concd NH_4OH–water (1 : 1, v/v, 30 ml). The eleuent was evaporated and

chromatographed on Whatman 3MM developed with Solvent II. A band of R_f 0.18 was eluted with water to give pTpT (150 OD, 98%). b) In a similar manner, pTpT (250 OD, 99.5%) was obtained from **16b** (11.27 μmol). In this case, 20 equiv. of silver acetate was used and the time for complete removal of 4-methoxyphenylthio group was 18 h.

Conversion of $(PhS)_2$pTp(tc)T to PhSpTp(tc)T. A): $(PhS)_2$pTp(tc)T (7.3 mg, 7.74 μmol) was treated with 0.2 M NaOH–dioxane (1 : 1 (v/v), 0.2 ml) at room temperature for 20 min. Then DIAION SK 1B (NH_4^+ form, 1 ml) was added to the mixture and the supernatant was analyzed by paper electrophoresis and paper chromatography. The electrophoresis showed a single spot of Rm 0.51 (relative to pT, pH 6.0) corresponding to PhSpTp(tc)T [$UV_{max}(H_2O)$ 266 nm, UV_{min} (H_2O) 236 nm, $UV_{sh}(H_2O)$ 250 nm] which appreared at R_f 0.77 (Solvent I) in paper chromatography.

B): $(PhS)_2$pTp(tc)T (7.3 mg, 7.74 μmol) was mixed with pyridinium salt of phosphonic acid (0.046 mmol) and dissolved in pyridine–water (19 : 1, v/v, 0.2 ml). The solution was kept with stirring at 30 °C for 2 d. Paper chromatography and paper electrophoresis of the solution showed the same product as described in the above experiment the yield was nearly quantitative.

Conversion of PhSpTp(tc)T to pTp(tc)T. PhSpTp(tc)T obtained by alkaline treatment of $(PhS)_2$pTp(tc) was dissolved in pyridine–water (2 : 1, v/v, 1 ml) and iodine (392 mg, 1.55 mmol) was added with continuous stirring. The mixture was stirred at room temperature for 30 min and then 1 M sodium sulfite was added until the color of iodine had disappeared. The clear solution was diluted with pyridine (5 ml) and the resulting salt (mainly Na_2SO_4) was filtered off and washed with pyridine–water (5 : 1, v/v, 5 ml). The filtrate and washings were combined, concentrated, and analyzed with paper chromatography. A single spot of pTp(tc)T (R_f 0.18 (Solvent II), 121 OD, 90%) was obtained.

*Conversion of $(4\text{-}CH_3OC_6H_4S)_2$pTp(tc)T (**16b**) to 4-$CH_3OC_6H_4$SpTp(tc)T.* To a solution of **16b** (5.8 mg, 5.8 μmol) in dioxane (0.2 ml) was added 0.2 M NaOH (0.2 ml). After being stirred at room temperature for 20 min, the solution was passed through a column (1 cm × 1 cm) of DIAION SK 1B (pyridinium form) and the resin was washed with pyridine–water (1 : 1, v/v, 10 ml). The eluent was concentrated to *ca.* 4 ml. The weight of the condensed solution was 3.94 g. One gram of the solution was analyzed with paper electrophoresis to afford three spots of Rm 0.57, 0.85, and 1,22 (relative to pT, pH 6.0). The fast running spot was estimated to be pTpT or TpTp (2.2 OD, 8.4%). The middle spot may be cyclic dithymidine diphosphate derivative, $\overline{|\text{pTpT}|}$ (2.2 OD, 8.2%). The slowest moving spot was 4-$MeOC_6H_4$SpTp(tc)T (22.0 OD, 83%, $UV_{max}(H_2O)$ 264 nm, 241 nm; UV_{min} (H_2O) 252 nm, 231 nm).

*One-step Conversion of **16a** to pTpT.* To a solution of **16a** (9.4 mg, 0.01 mmol) in DMF–pyridine (2 : 1, v/v, 0.7 ml) were added acetylacetone (0.07 ml) and zinc powder (0.5 mmol). The mixture was vigorously stirred at room temperature for 8 h. After being passed through a column (1 cm × 3 cm) of DIAION SK 1B (NH_4^+ form), the mixture was analyzed by paper electrophoresis. Compounds pTpT and $(PhS)_2$pTpT were formed in 61 and 22% yields, respectively. Some alternative conditions for the deprotection with zinc-acetylacetone are summarized in Table 4.

Synthesis of $(4\text{-}CH_3OC_6H_4S)_2$pTp(tc)Tp(tc)T. A mixture of **16b** (501.6 mg, 0.5 mmol) and 2,2,2-trichloroethyl phosphate (126.3 mg, 0.55 mmol) was rendered anhydrous by repeated evaporations with dry pyridine (4 × 3 ml) and finally dissolved in dry pyridine (5 ml). To the solution was added TPS (333.6 mg, 1.1 mmol) and the mixture was stirred at room temperature for 2 d. Then CH_2Cl_2 (20 ml) and water (20 ml) were added. The aqueous solution was extracted with CH_2Cl_2 (3 × 10 ml). The organic extracts were combined and concentrated to dryness. The residue was mixed with well pulverized thymidine (145.3 mg, 0.6 mmol). The mixture was rendered anhydrous by repeated evaporations with dry pyridine (4 × 4 ml) and dissolved in dry pyridine (3.0 ml). It was treated with NBST (280 mg, 1.1 mmol) at room temperature for 2 d. Then CH_2Cl_2 (20 ml) and water (20 ml) were added. The aqueous layer was extracted with CH_2Cl_2 (3 × 10 ml), and the organic extracts were combined and concentrated and dried by repeated coevaporation with dry pyridine (3 × 4 ml). The residue was finally dissolved in dry pyridine (3 ml) and allowed to react with monomethoxytrityl chloride (154 mg, 0.5 mmol) at room temperature for 6 h. Then the mixture was extracted by addition of CH_2Cl_2 (20 ml) and water (20 ml). The aqueous layer was extracted with CH_2Cl_2 (2 × 10 ml) and the organic extracts were combined, dried over Na_2SO_4, and concentrated to dryness. The residue was coevaporated with toluene (3 × 5 ml) and chromatographed on silica gel with CH_2Cl_2–methanol to afford the title compound (593 mg, 82%).

Deprotection of $(4\text{-}CH_3OC_6H_4S)_2$pTp(tc)Tp(tc)T. To a solution of $(4\text{-}CH_3OC_6H_4S)_2$pTp(tc)Tp(tc)T (28.8 mg, 0.02 mmol) in pyridine–water (2 : 1, (v/v), 2.5 ml) was added silver acetate (66.8 mg, 0.4 mmol). The mixture was stirred vigorously at room temperature for 24 h. The resulting suspension was bublled with hydrogen sulfide gas until a clear supernatant had been obtained at 0 °C (*ca.* 5 min). The black precipitate was removed off by centrifugation and washed with pyridine–water (2 : 1, v/v, 2 × 2 ml). The supernatant and washing were combined and evaporated to dryness. The residue was dissolved in DMF–pyridine (1 : 1, v/v, 1 ml). To the solution was added acetylacetone (0.4 ml) and then zinc powder (80 mg). The mixture was stirred at room temperature for 3 h. Then water (4 ml) was added and the solution was passed through a column (1 cm × 5 cm) of DIAION SK 1B (NH_4^+ form). The resin was washed with water (30 ml). The eluent and washings were combined, concentrated to *ca.* 2 ml, and chromatographed on Whatman 3MM paper to afford pTpTpT (470 OD, 97%) which appeared at the position of 9.6 cm from the starting point after development by *i*-PrOH–concd NH_4OH–H_2O (6 : 1 : 3, v/v/v) for 3 d.

Enzymatic Assay of pTpTpT. Compound pTpTpT (85 OD) obtained in the above experiment was incubated with snake venom phosphodiesterase (40 μg) in 0.1 M Tris buffer (pH 8, 1 ml) at 37 °C for 18 h. After addition of pyridine (1 ml) the mixture was analyzed by paper chromatography using Whatman 3MM paper to give pT (91 OD) as a single degradation product.

Synthesis of Macrocyclic [*n.n.n*](1,3,5)Cyclophane Polylactones

Masayuki KANISHI, Jun-ichi KUNIZAKI, Junji INANAGA, and Masaru YAMAGUCHI*
Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812
(Received April 10, 1981)

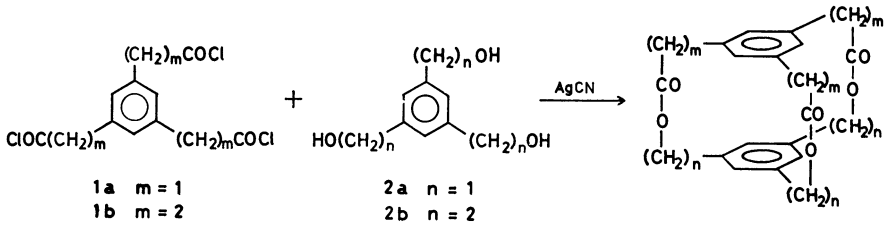
A series of new macrocyclic cyclophane polylactones has been synthesized by one-step condensation of the appropriate tri(acid chloride)s and triols using the silver cyanide-promoted esterification procedure.

A remarkable development of the chemistry of crown ethers and cryptands has promoted the synthesis of various types of macrocyclic diolides or tetraolides.[1] However, they have so far been essentially confined to monocyclic compounds in respect to the macrocyclic polyolide rings and no bicyclic analogues[2] have been reported, probably because of the lack of powerful lactonization methods suitable for this purpose.[3] Most of the hitherto reported polyolides have been prepared by the reaction between di(acid chloride)s and diols[4] in varied yields depending on the ease of cyclization of substrates. However, a simple extension of the method to the synthesis of macrobicyclic analogues from tri(acid chloride)s and triols does not seem to be very promising because of the highly unfavorable entropy factors in the dual cyclizations.

Recently, silver cyanide has been found to promote the esterification reaction between acid chlorides and alcohols to a high extent and several strongly hindered esters have been synthesized by this method.[5] In this report is demonstrated the applicability of the method to the synthesis of macrocyclic cyclophane polylactones (**3a**—**f** and **5**) which seem to be otherwise difficultly accessible by one-step procedure.

Starting Materials. 1,3,5-Benzenetrimethanol (**2a**) was prepared by lithium aluminum hydride reduction of triethyl 1,3,5-benzenetricarboxylate according to the literature.[6] Conversion of **2a** into α,α′,α″-trichloromesitylene by the reported procedure[6] followed by the treatment of the latter with potassium cyanide under the presence of phase-transfer catalyst[7] gave 1,3,5-benzenetriacetonitrile which was then hydrolyzed to give known 1,3,5-benzenetriacetic acid[8] in good overall yield. Conversion of the triacetic acid to the corresponding tri(acid chloride) (**1a**)[6] or to 1,3,5-benzenetriethanol (**2b**)[6] and transformation of α,α′,α″-trichloromesitylene to 1,3,5-benzenetripropionic acid[6] or to 1,3,5-benzenetripropanol (**2c**)[9] were carried out by the reported procedures. 1,3,5-Benzenetripropionyl trichloride (**1b**) was prepared from the corresponding triacid in a similar way to **1a**. Treatment of 1,3,5-benzenetricarbonyl trichloride with mono(tetrahydropyranyl) ether[10] of 2,2′-oxydiethanol gave **4a** which on hydrolysis with 1 mol dm^{-3} hydrochloric acid gave **4b** in 48% yield from the tri(acid chloride). Treatment of **1a** with a large excess of 2,2′-oxydiethanol in dichloromethane gave **4c** in 61% yield.

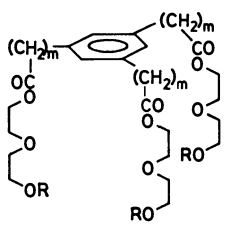
Synthesis of Cyclophanes. Condensations of the tri(acid chlorides)s (**1a** or **1b**) and the triols (**2a**, **2b**, **2c**, or **4c**) were carried out under high-dilution conditions in the presence of silver cyanide in refluxing benzene, xylene, or acetonitrile, giving the cyclophanes (**3a**—**f** and **5**) in 3.6—20.4% yields. They are summarized in Table 1. In an experiment carried out for comparison, reaction of **1b** with **2a** in refluxing pyridine under the similar high-dilution conditions in the absence of silver cyanide gave **3d** in only 3% yield. In experiments with the combination of 1,3,5-benzenetricarbonyl trichloride and **2a** or **4b**, no monomeric products were isolated. Properties of the cyclophanes obtained are listed in



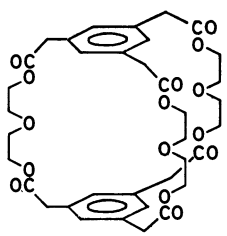
1a m = 1
1b m = 2

2a n = 1
2b n = 2
2c n = 3

3a m = n = 1
3b m = 1, n = 2
3c m = 1, n = 3
3d m = 2, n = 1
3e m = n = 2
3f m = 2, n = 3



4a R = THP, m = 0
4b R = H, m = 0
4c R = H, m = 1



5

Table 1. Isolated yield of cyclophanes

Acid chloride	Alcohol	Solvent[a]	Time of addition/h	Product[b]	Mp/°C	Isolated yield/%
1a	**2a**	Benzene	25	**3a**	>305	6.8
1a	**2b**	Benzene	21	**3b**	244	3.9
1a	**2c**	Xylene	26	**3c**	177.5	3.6
1b	**2a**	Benzene	20	**3d**	267	20.4
1b	**2a**	Pyridine	20	**3d**		3.0[c]
1b	**2b**	Benzene	26	**3e**	220	6.0
1b	**2c**	Acetonitrile	9.5	**3f**	190	6.1
1a	**4c**	Xylene	34	**5**	132	13.6

a) Triols were dissolved in a small amount of acetonitrile and then diluted with the solvent given in the Table. b) Each product gave a distinctive molecular ion peak as a monomer in MS spectrum. c) The experiment was carried out in 1 mmol scale without the addition of silver cyanide.

Table 2. Spectral properties of cyclophanes

Compound	UV/nm (ε)	IR[a]/cm^{-1}	^{1}H NMR			
			Aromatic[b]	$-CH_2-COO-$	$-CH_2-OCO-$	Other protons
3a	268(405)	1732	7.04, 6.83	3.32(s)	4.97(s)	
3b	266(767)	1730	6.79, 6.66	3.40(s)	4.42 (t, J=6.0 Hz)	2.82 (t, J=6.0 Hz)

a) ν_{CO}. b) All singlet. c) The signal was overlapped with the neighboring methylene protons α to the benzene ring. d) The signal indistinguishably overlapped with the methylene protons α to the two benzene rings. e) The signal indistinguishably overlapped with other protons of ethylene bridges.

Table 2.

Aromatic protons of these cyclophanes resonated in NMR spectra at the upper field by *ca.* 0.1—0.3 ppm than those of open chain models (the trimethyl esters or triacetates of the corresponding triacids or triols, respectively), as a trend usually observed in cyclophanes. The C=O stretching vibrations of the cyclophanes with shorter bridges (**3a**, **3b**, and **3d**) appeared at the higher wavenumber positions by *ca.* 10 cm^{-1} than those with longer bridges (**3c**, **3e**, **3f**, and **5**) implying the presence of some strain in the former compounds. However, UV absorptions which appeared at almost the same positions as those of open chain models (266 nm) indicated that the strain, if any, is not appreciable. The UV spectra did not change after the addition of tetracyanoethylene.

Recrystallization of the cyclophanes (**3a—f**) from benzene, ethyl acetate, or acetonitrile did not give any adducts with the solvent molecule.

Though the open chain triol (**4b**) gave a crystalline 1 : 1 adduct with KSCN, the cyclized **5** did not form the isolable adduct. Further examination of **5** on complexation with metal salts such as KSCN, LiSCN, NaSCN, Cs_2CO_3, $MgSO_4$, $AgNO_3$, $CuSO_4$, and NH_4Cl by 2,4,6-trinitrophenol method[11] also gave negative results.

Experimental

Melting points or boiling points were uncorrected. UV spectra (Hitachi 200-10) were recorded in dichloromethane solutions. IR spectra (Hitachi R-215) were obtained in potassium bromide pellets. ^{1}H NMR spectra (Hitachi R-20B) were taken in deuteriochloroform solutions. Mass spectra (Hitachi RMU-6MG) were recorded with a direct-inlet system operating at 70 eV. Solvents were purified and dried by the standard methods.

1,3,5-Benzenetrimethanol (2a). Mp 77 °C (lit,[6] 77 °C), 95%.[12]

1,3,5-Benzenetriacetonitrile. α,α′,α″-Trichloromesitylene[6] (4 g, 18 mmol) was added dropwise to a mixture of potassium cyanide (6 g, 122 mmol) and 18-crown-6 (690 mg, 2.7 mmol)[7] in acetonitrile at room temperature and the mixture was stirred for 6 days. The reaction was followed by TLC. The mixture was filtered and the precipitate was extracted with dichloromethane. The combined filtrate and extract were concentrated and the residue was chromatographed on a silica-gel column from benzene–ethyl acetate (9 : 1). The early fractions contained the practically pure trinitrile (2.8 g, 80%) which was recrystallized from a mixture of benzene and petroleum ether. Mp 123—125 °C. NMR; δ 3.80 (s, 6H), 7.33 (s, 3H): IR; 2220, 1870, 1600, 1420, 1390 cm^{-1}. Found: C, 73.74; H, 4.74; N, 21.46%. Calcd for $C_{12}H_9N_3$: C, 73.83; H, 4.65; N, 21.53%.

1,3,5-Benzenetriacetic Acid. 1,3,5-Benzenetriacetonitrile (1.45 g, 7.46 mmol) was dissolved in a mixture of concentrated sulfuric acid (2.2 ml) and water (2.5 ml) and the solution was refluxed for 5 h. The cooled mixture was diluted with water (5 ml) and extracted with ether. Evaporation of ether gave

a colorless solid which was recrystallized from acetic acid to give 1,3,5-benzenetriacetic acid [1.85 g (98%), mp 208—209 °C (lit,[8] 215—216 °C)].

*1,3,5-Benzenetripropionyl Trichloride (**1b**).* It was prepared from 1,3,5-benzenetripropionic acid (294 mg, 1 mmol) by refluxing with excess thionyl chloride (1 ml) in benzene (1 ml) for 4 h. Colorless needles, mp 59—60 °C (from pentane). NMR; δ 6.94 (s, 3H).

*Tris(tetrahydropyranyloxyethoxyethyl) 1,3,5-Benzenetricarboxylate (**4a**).* Pyridine (16 ml) was added to an ice-cooled solution of 1,3,5-benzenetricarbonyl trichloride (5.2 g) and tetrahydropyranyloxyethoxyethanol (11.7 g)[10] in dry benzene under stirring. After stirring overnight at room temperature, the mixture was filtered and concentrated. Hydrochloric acid (0.1 mol dm^{-3}, 140 ml) was added to the residue and the mixture was extracted with ether. The extract was washed with water, aqueous sodium hydrogencarbonate, and water, and dried over sodium sulfate. Evaporation residue was separated by TLC on silica-gel (acetone–benzene, 1 : 4) giving **4a** as a viscous oil, 11.8 g (83%). IR; 2900, 1720, 1240, 740 cm^{-1}: NMR; δ 8.86 (s, 3H), 4.6 (m, 9H), 3.75 (m, 24H), 1.65 (m, 18H). Found: C, 59.18; H, 7.40%. Calcd for $C_{36}H_{54}O_{15}$: C, 59.48; H, 7.49%.

*Tris(hydroxyethoxyethyl) 1,3,5-Benzenetricarboxylate (**4b**).* **4a** (4 g, 5.5 mmol) was stirred in a mixture of hydrochloric acid (1 mol dm^{-3}, 36 ml) and THF (25 ml) at room temperature for 12 h. Sodium hydrogencarbonate (3.4 g) was added and the mixture was extracted with petroleum ether. The aqueous layer was evaporated and the residue was extracted with dioxane. TLC (silica-gel, dioxane–petroleum ether 5 : 2) of the evaporation residue of the extract gave **4b** as a viscous oil[13] (1.51 g, 58%).[9] NMR; δ 8.88 (s, 3H), 4.85 (m, 6H), 3.75 (m, 18H), 3.14 (s, 3H).

Evaporation of a solution of **4b** (32.4 mg, 0.068 mmol) and KSCN (9 mg, 0.093 mmol) in acetone (1 ml) followed by treatment of the residue with ethyl acetate gave an adduct which melted at 85—86 °C (recrystallized from acetone–ethyl acetate). IR; 3500—3200, 2050, 1720, 1240, 740 cm^{-1}. Found: C, 45.96; H, 5.22; N, 2.49%. Calcd for $C_{21}H_{30}O_{12}\cdot$ KSCN: C, 46.23; H, 5.29; N, 2.45%.

*Tris(hydroxyethoxyethyl) 1,3,5-Benzenetriacetate (**4c**).* A solution of **1b** (140 mg) in dichloromethane (8 ml) was added dropwise to a stirred solution of 2,2′-oxydiethanol (13.3 ml), pyridine (0.17 ml) and dichloromethane (10 ml) under ice-cooling. After stirring overnight, the mixture was refluxed for 5 h. Solvent and excess 2,2′-oxydiethanol were then removed under vacuum as thoroughly as possible. The residue was separated by TLC (Merck, kieselgel 60HF$_{254}$, silanisiert; water–acetonitrile 2 : 1) giving **4c** as a viscous oil[13] (148 mg, 61.3%). NMR; δ 7.15 (s, 3H), 4.3 (m, 6H), 3.65 (m, 24H), 2.5 (s, 3H). The triol did not give an isolable KSCN adduct.

*Cyclophanes (**3a**—**f**, **5**).* Cyclophanes were prepared by essentially the same procedure as exemplified below for **3a**.

A solution of **2a** (168 mg, 1 mmol) in a mixture of acetonitrile (50 ml) and dry benzene (400 ml), and a solution of **1b** (308 mg, 1 mmol) in dry benzene (450 ml) were added dropwise at the same rate to a stirred suspension of silver cyanide (10 g, 75 mmol) in refluxing benzene (100 ml) over a period of 25 h. The mixture was cooled, filtered, and concentrated. The residue was separated by TLC (silica-gel, benzene–ethyl acetate 4 : 1). The residue of the corresponding zone was recrystallized from ethyl acetate to give **3a** (25 mg, 6.8%) as colorless prisms, mp>305 °C. Mass; 366 (M$^+$), 294, 278, 234, 219.

CH-Analyses of these cyclophanes are given in Table 3.

Table 3. CH-analysis of cyclophanes

Compound (Formula)	Found (%)		Calcd (%)	
	C	H	C	H
3a ($C_{21}H_{18}O_6$)	68.62	4.99	68.84	4.98
3b ($C_{24}H_{24}O_6$)	70.33	6.06	70.57	5.92
3c ($C_{27}H_{30}O_6$)	71.73	6.79	71.98	6.71
3d ($C_{24}H_{24}O_6$)	70.32	5.91	70.57	5.92
3e ($C_{27}H_{30}O_6$)	71.90	6.75	71.98	6.71
3f ($C_{30}H_{36}O_6$)	72.95	7.30	73.14	7.37
5 ($C_{36}H_{42}O_{15}$)	60.41	5.97	60.49	5.92

2) Not a few macrobicyclic cryptands with bridgehead nitrogen atoms [A review: J. M. Lehn, *Acc. Chem. Res.*, **11**, 49 (1978)] and bridgehead carbon atoms [for example; A. C. Coxon and J. F. Stoddart, *J. Chem. Soc., Perkin Trans. 1*, **1977**, 767] have been known. Two porphyrin derivatives having macrotricyclic tetraolide structure have been prepared by means of porphyrin-ring-formation reaction [J. Almog, J. E. Baldwin, R. L. Dyer, and M. Peters, *J. Am. Chem. Soc.*, **97**, 226 (1975); N. E. Kagan, D. Mauzerall, and R. B. Merrifield, *J. Am. Chem. Soc.*, **99**, 5484 (1977)]. Various carbopolycylic cyclophanes are also known [for example; A. J. Hubert, *J. Chem. Soc., C*, **1967**, 6, 11; H. E. Högberg, B. Thulin, and O. Wennerström, *Tetrahedron Lett.*, **1977**, 931]. Most of these compounds have been prepared by stepwise cyclizations.

3) Several mild and fairly rapid esterification methods have recently been developed in connection with the synthesis of natural macrolides [K. C. Nicolaou, *Tetrahedron*, **33**, 683 (1977); T. G. Back, *ibid.*, **33**, 3041 (1977); E. Haslam, *ibid.*, **36**, 2409 (1980)]. However, when sensitive functionalities do not exist in the molecule, the use of acyl halides still remains as one of the most effective carboxylic acid-activation.

4) Recently, activation of the hydroxyl group by dibutyltin oxide has been developed and some macrocyclic tetraolide have been synthesized (A. Shanzer and N. Mayer-Shochet, *J. Chem. Soc., Chem. Commun.*, **1980**, 176; A. Shanzer and E. Barman, *ibid.*, **1980**, 259). Reaction of carboxylates and alkyl halides has also been used for the synthesis of this class of compounds (Ref. 1) and the use of caesium carboxylates has recently been recommended [O. Piepers and R. M. Kellogg, *J. Chem. Soc., Chem. Commun.*, **1978**, 383].

12) As **2a** was very soluble in water, the isolation procedure

was modified as described below. The ethereal reduction mixture was cooled and after the addition of a calculated amount of water, excess Dry Ice was added to the mixture. The mixture was then filtered and the precipitate was washed well with ethanol. The filtrate and the wash were combined and concentrated to a white solid. Sublimation [140 °C (bath temp), 133 Pa] gave **2a** in 95% yield.

13) The removal of a small amount of contaminating water was difficult and the sample gave a low carbon value by *ca.* 1% in CH-analysis.

Restricted Rotation Involving the Tetrahedral Carbon. XL. Barriers to Rotation of 9-(1-Methyl-2-propenyl)triptycenes[1)]

Hiromi KIKUCHI, Shiro HATAKEYAMA, Gaku YAMAMOTO, and Michinori ŌKI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received June 20, 1981)

9-(1-Methyl-2-propenyl)triptycenes were prepared by addition of substituted benzynes to 9-(1-methyl-2-propenyl)anthracene or Dields-Alder addition of *p*-benzoquinone to the anthracene followed by enolization and methylation. The crystals of these compounds were pure or enriched isomers of the possible rotamers but the rotational barriers were too low to obtain every possible isomer in a pure state at room temperature. The barriers to rotation were obtained by both classical and dynamic NMR methods. These values were almost the same when the peri-substituent was either a chloro or a bromo but were definitely lower when the peri-substituent was a methyl or a methoxyl.

Although stable rotamers of 9-*t*-alkyltriptycenes were isolated at room temperature,[2)] the same has not been possible for any organic compound which carries a *s*-alkyl group. We have reported in a previous paper[1)] that triptycenes which carry a *s*-alkyl group give one of the possible rotamers as crystalline materials but due to their low barriers to rotation it is not possible to isolate another. Thus it has become necessary to carry out a series of experiments which reveal the effect of substituents on the rotational barriers in order to search a model which gives a high enough barrier to rotation for isolation of rotamers at room temperature.

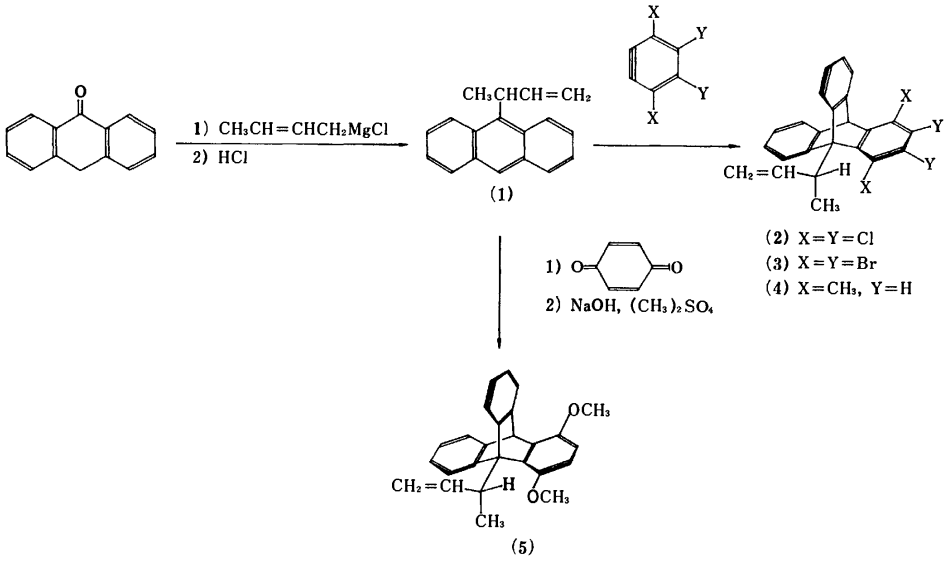
Introduction of a π-system to a tertiary carbon in the 9-position of triptycene definitely lowers the barrier to rotation about the C_9–C_{subst} bond.[3)] However, it is also pointed out that, since the barrier to rotation is the difference in free energies between the ground state and the transition state of rotation, a large substituent is not necessarily raising the barrier to rotation and sometimes it even lowers the barrier.[4,5)] Since it is not known what will be the effect of a π-system on the barrier to rotation in the *s*-alkyl series, we have wished to start the investigation of this series by putting a vinyl group instead of a methyl of an isopropyl group.

The compounds in question were prepared in the following ways. A Grignard reaction of anthrone with *trans*-2-butenylmagnesium chloride afforded 9-(1-methyl-2-propenyl)-9,10-dihydro-9-anthrol which was dehydrated to give 9-(1-methyl-2-propenyl)anthracene (**1**). The anthracene was treated with benzynes to give triptycenes (**2**, **3**, and **4**). Treatment of the anthracene with *p*-benzoquinone followed by enolization and subsequent methylation gave 1,4-dimethoxy-9-(1-methyl-2-propenyl)triptycene (**5**).

This paper presents the results of the investigation and discusses the effects of substituents on the barrier to rotation.

Experimental

9-(1-Methyl-2-propenyl)anthracene (1). A Grignard reagent was prepared by adding 22 g (0.24 mol) of *trans*-1-chloro-2-butene in ether to a mixture of 7 g (0.29 mol) of magnesium and 50 mL of ether during a period of 2 h. Anthrone (38 g or 0.29 mol) was added in small portions to the Grignard solution and the reaction mixture was decomposed with aqueous ammonium chloride. The organic layer was treated in the usual manner to afford 9-(1-methyl-2-propenyl)-9,10-dihydro-9-anthrol. This crude product in chloroform was treated with concentrated hydrochloric acid at room temperature for 1 h. The mixture was washed, dried, and evaporated. The desired product, mp 44—46 °C, was obtained in 27% yield after chromatography on silica gel with the use of hexane as an eluent. Found: C, 93.31; H, 6.73%. Calcd for $C_{18}H_{16}$: C, 93.06; H, 6.94%. ^{1}H NMR ($CDCl_3$,



δ): 1.75 (3H, d, J=7 Hz), 5.00 (1H, m), 5.11 (1H, m), 5.28 (1H, m), 6.41 (1H, m), 8.34 (1H, s), 7.2—8.6 (8H, m).

1,2,3,4-Tetrachloro-9-(1-methyl-2-propenyl)triptycene (2). To a boiling solution of 1.9 g (8 mmol) of 9-(1-methyl-2-propenyl)-anthracene and 1 mL of isopentyl nitrite in 30 mL of dichloromethane, was added 4.1 g (14 mmol) of tetrachloroanthranilic acid[6] in 10 mL of acetone in 30 min. The solution was evoporated and the residue was purified by chromatography on silica gel (hexane). Recrystallization of the product from hexane–acetone afforded 0.9 g (25%) of the desired material, mp 191—196 °C. Found: C, 64.88; H, 3.48%. Calcd for $C_{24}H_{16}Cl_4$: C, 64.60; H, 3.62%. High resolution MS gave M^+ peaks at *m/e* 444.0021, 445.9965, 447.9941, and 449.9940, whereas calculation requires *m/e* 444.0002, 445.9973, 447.9943, and 449.9914. The relative intensities of these peaks were in good agreement with those calculated from the natural abundance of ^{35}Cl and ^{37}Cl. ^1H NMR ($CDCl_3$, δ) of the crystals, immediately after dissolution in chloroform-*d* at room temperature indicated that the crystals contained 3 : 1 *ap* and $\pm sc$ conformations. The intensities of the signals changed as time elapsed and the following signals were observed for the rotamers. *ap*: 1.98 (3H, d, J=6.7 Hz), 4.7—5.7 (3H, m), 5.94 (1H, s), 6.2—6.7 (1H, m), 6.9—7.9 (8H, m). $\pm sc$: 1.85 (3H, d, J=6.7 Hz), 4.7—5.7 (3H, m), 5.94 (1H, s), 6.2—6.7 (1H, m), 6.9—7.9 (8H, m).

1,2,3,4-Tetrabromo-9-(1-methyl-2-propenyl)triptycene (3), mp 235—240 °C, was similarly prepared from **1** and tetrabromoanthranilic acid[7] in 23% yield. Found: C, 46.19; H, 2.59%. Calcd for $C_{24}H_{16}Br_4$: C, 46.20; H, 2.58%. High resolution MS showed M^+ peaks at *m/e* 619.8008, 621.7984, 623.7924, 625.7906, and 627.7876, whereas calculation requires *m/e* 619.7987, 621.7967, 623.7947, 625.7927, and 627.7908. The intensities of the observed peaks agreed well with those calculated from the natural abundance of ^{79}Br and ^{81}Br. ^1H NMR ($CDCl_3$, δ) of the crystals, immediately after dissolution in chloroform-*d* at room temperature, indicated that the crystals contained 3 : 1 *ap* and $\pm sc$ conformations. The intensities of the signals changed as time elapsed and the following signals were observed for the rotamers. *ap*: 1.97 (3H, d, J=6.6 Hz), 4.9—5.7 (3H, m), 6.01 (1H, s), 6.1—6.7 (1H, m), 6.8—7.9 (8H, m). $\pm sc$: 1.83 (3H, d, J=6.6 Hz), 4.9—5.7 (3H, m), 6.01 (1H, s), 6.1—6.7 (1H, m), 6.8—7.9 (8H, m).

1,4-Dimethyl-9-(1-methyl-2-propenyl)triptycene (4), mp 140—141 °C, was prepared from **1** and 3,6-dimethylanthranilic acid[8] as above. The yield was 9%. Found: C, 93.11; H, 7.39%. Calcd for $C_{26}H_{24}$: C, 92.81; H, 7.19%. A ^1H NMR spectrum obtained at −25 °C immediately after dissolving the sample of crystalline **4** in chloroform-*d* at −25 °C indicated that the compound was consisted of pure *sc* forms. However, another ^1H NMR spectrum recorded at room temperature immediately after dissolving the crystals of **4** in chloroform-*d* showed that the equilibrium between the conformers had been already reached. The following data were obtained. $\pm sc$: 1.98 (3H, d, J=6.7 Hz), 2.44 (3H, s), 2.58 (3H, s), 4.26—4.70 (1H, m), 5.07—5.67 (2H, m), 5.53 (1H, s), 6.32—7.84 (11H, m).

1,4-Dimethoxy-9-(1-methyl-2-propenyl)triptycene (5). A mixture of 1 g (4 mmol) of 9-(1-methyl-2-propenyl)anthracene and 0.47 g (4 mmol) of *p*-benzoquinone in 30 mL of toluene was heated under reflux for 4 h. After cooling, crystals were collected and washed with ethanol to give 0.91 g (63%) of the adduct. ^1H NMR ($CDCl_3$, δ): 1.93 (2/3 3H, d, J=7 Hz), 1.70 (1/3 3H, d, J=7 Hz), 2.9—3.4 (2H, m), 3.4—3.8 (1H, m), 4.58 (1H, d, J=2 Hz), 5.1—5.7 (2H, m), 5.98 (2H, s), 6.07—6.57 (1H, m), 6.96—7.85 (8H, m).

To the crude adduct (2.7 mmol) in 50 mL of dioxane was added 0.43 g (10.8 mmol) of sodium hydroxide in 5 mL of water and the mixture was stirred with 0.68 g (5.4 mmol) of dimethyl sulfate for 2 d. The mixture was diluted with water and extracted with benzene. The benzene layer was washed with aqueous ammonium chloride and then with water, and dried over magnesium sulfate. After evaporation, the residue was recrystallized from hexane–ethanol to give a pure product, mp 203—204 °C, in 26% yield. Found: C, 84.99; H, 6.50%. Calcd for $C_{26}H_{24}O_2$: C, 84.75; H, 6.56%. ^1H NMR spectrum ($CDCl_3$, δ) of the crystals, immediately after dissolution in chlorofom-*d* at −25 °C, indicated that the compound was a mixture of 8 : 1 *ap* and $\pm sc$ isomers. The intensities of the signals changed rather rapidly and the equilibrium was attained within 30 min at room temperature. We conclude that the crystals obtained here were consisted of almost pure *ap* forms. The following assignments were made. *ap*: 1.90 (3H, d, J=6.7 Hz), 3.70 (3H, s), 3.76 (3H, s), 4.42—4.83 (1H, m), 4.97—5.65 (2H, m), 5.81 (1H, s), 6.35—7.86 (9H, m), 6.50 (2H, s). $\pm sc$: 1.88 (3H, d, J=6.7 Hz), 3.60 (3H, s), 3.74 (3H, s), 4.42—4.83 (1H, m), 4.97—5.65 (2H, m), 5.81 (1H, s), 6.35—7.86 (9H, m), 6.46 (2H, s).

Measurements of Spectra. The ^1H NMR spectra were obtained on a Hitachi R-20B spectrometer operating at 60 MHz or a Varian EM 390 spectrometer operating at 90 MHz. Both were equipped with a temperature variation accessory. The temperature was read by a thermocouple. High resolution mass spectra were obtained on a JEOL JMS-D300 instrument.

Kinetic Measurements. Samples were dissolved in chloroform-*d* placed in NMR sample tubes at low temperature to make up ca. 25 mg per 0.5 mL solutions. The sample tube was placed in an NMR probe of which temperature was set at a given one and the methyl signals were scanned every 30 s. In practice, the inner signal of the methyl doublet due to the $\pm sc$ form overlapped with the outer signal of that due to the *ap* form. Therefore it was necessary to calibrate the intensities of the signals due to $\pm sc$ and *ap* forms to obtain the populations. This was performed by simulating the spectra by computation. Namely, the intensity ratios of inner and outer signals due to *ap* and $\pm sc$ forms were calculated by the dynamic NMR program by putting the chemical shift difference and the coupling constant. This gave the intensity ratio of the inner signal due to the *ap* form and the outer signal due to the $\pm sc$, 0.92, if the populations were the same. This ratio was used throughout the calculation for calibration.

Dynamic NMR Method. The NMR measurements were carried out with *o*-dichlorobenzene solutions. The spectra of the methyl part were simulated by computation with the use of modified Binsch program.[9] The chemical shift difference drifted according to temperatures. Thus the tendency at lower temperatures was extrapolated to afford the chemical shift difference at a given temperature where the line shape could not afford the exact difference directly. The coupling constant was assumed to be constant throughout the temperature range examined. The chemical shift of the methine proton was determined by searching that which gave the sharpest signal due to the methyl protons on irradiation of the former. T_2 was determined by a trial-and-error method to give the best fit of the calculated spectra with the observed at low temperatures. Populations of the rotamers were taken as constant and those in chloroform-*d* were diverted. This is because both are relatively nonpolar solvents and the population ratios in chloroform-*d* was constant throughout the temperature range. The best rates of exchange were obtained by visual fitting of the calculated spectra with the

observed.

Representative rates (s^{-1}) of isomerization (*ap*→*sc*) and temperature (°C) in parentheses are given below.

2: 10.1 (161.9), 11.7 (167.0), 16.8 (172.4), 20.5 (176.4), 23.0 (178.0).

3: 3.1 (150.9), 7.1 (166.3), 8.8 (169.2), 13.7 (176.0), 15.9 (180.0).

4: 2.7 (125.3), 4.0 (129.5), 5.3 (134.1), 8.1 (140.8), 11.3 (146.2), 13.7 (148.9).

5: 3.2 (127.4), 4.6 (132.9), 9.1 (143.7), 9.4 (146.9).

Coalescence temperatures were obtained with the sample solutions used for the dynamic NMR study. Since the populations of the rotamers were not equal, the determination of the coalescence may involve some errors.[10]

Acquisition of Kinetic Parameters. The rate constants of the isomerization in the classical method were obtained by assuming the first order reversible reactions. They were obtained as follows:

2: 3.72×10^{-5} (20.5), 1.34×10^{-4} (31.1), 2.54×10^{-4} (36.0), 4.38×10^{-4} (42.8), 8.57×10^{-4} (46.8).

3: 6.31×10^{-5} (26.7), 2.73×10^{-4} (35.1), 3.24×10^{-4} (39.1), 6.68×10^{-4} (44.0).

where the unit is s^{-1} and the numericals in parentheses are temperatures in °C. Equilibrium constant ($\pm sc/ap$) of **2** was 0.81 throughout the temperature range examined. Equilibrium constant ($\pm sc/ap$) of **3** was also constant at 0.88 over the temperature range. **4** and **5** gave the equilibrium constants at ambient temperature as 1.52 and 0.72, respectively.

The rate constants, which were obtained by the classical or the dynamic NMR method were put into the Eyring equation to obtain the enthalpy and the entropy of activation.

The rates of isomerization (*ap*→*sc*) and the free energies of activation at the coalescence temperature were obtained by the following equations.[11] The chemical shift difference ($\Delta\delta$) was obtained as described above.

$$k_c = \frac{\pi}{\sqrt{2}}\Delta\delta$$

$$k_c = \frac{k_B}{h}T_c e^{-\frac{\Delta G^{\ddagger}}{RT}}$$

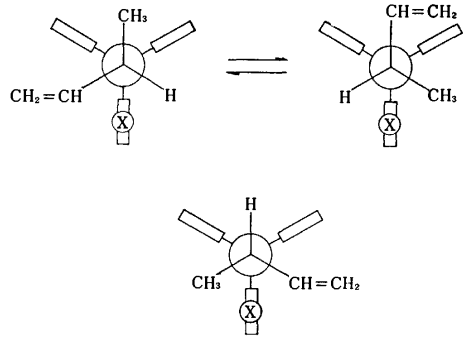
Results and Discussion

Assignment of Conformations. The naming of the conformations of these compounds poses problems again,[12] because it contains a chiral center. Due to the presence of a chiral center, enantiomers of the $-sc$ and *ap* forms shown in the scheme are possible and $+sc$ form may be confused with **6** because it is another $+sc$ conformation. However, in practice, we observe the existence of only two rotational isomers by ^{1}H NMR. Thus we may assume that a conformation (**6** or its enantiomer) in which a methyl and a vinyl group flank the peri-substituent does not exist because of the steric repulsions as were in other cases:[13] we may forget the conformation **6** in the following discussion. From the above grounds, we wish to name the conformation on the left side of the equilibrium equation and its enantiomer as $\pm sc$ for the simplicity of discussion in this paper. Accordingly, the conformation on the right of the equation and its enantiomer are called *ap*.

Assignment of conformations is not an easy task. A distinct difference in ^{1}H NMR spectra is seen with the chemical shifts of methyl signals but the data themselves give no definite information. We wish to assign a conformation which gives rise to a higher field methyl signal to $\pm sc$ and that which gives a lower field methyl signal to *ap* tentatively. It is reasonable if we consider the van der Waals shifts because the methyl flanking the peri-substituent should suffer the steric compression which tends to give the chemical shifts at lower fields. A small difference in chemical shifts of the methyls in compound **5** relative to others lends support to this assignment because a smaller compression should cause a smaller down field shift.

Kinetics by the Classical Method. The rates of rotation in 1,2,3,4-tetrahalo compounds (**2** and **3**) were conveniently measured at about room temperature but those of 1,4-dimethyl (**4**) and 1,4-dimethoxy (**5**) compound were too large to obtain reliable data at ambient temperatures. Thus the classical method for determining the rates of rotation was abandoned for the latter two compounds.

The rate constants of rotation of **2** and **3** given in the Experimental part afforded the following data. **2** gave



(6)

Table 1. Activation parameters for rotation (*ap sc*) of 9-(1-methyl-2-propenyl)triptycenes obtained by dynamic NMR method

Substituent	$\Delta H^{\ddagger}$ kcal mol^{-1}	$\Delta S^{\ddagger}$ e. u.	$\Delta G_c^{\ddagger a)}$ kcal mol^{-1}	$\Delta G_c^{\ddagger b)}$ kcal mol^{-1}	T_c °C	$K^{c)}$ (sc/ap)
1,2,3,4-Cl_4	19.0±2.0	−11.2±4.6	24.0	24.3	176.2	0.81
1,2,3,4-Br_4	21.0±1.2	−7.4±2.7	24.3	24.2	176.0	0.88
1,4-$(CH_3O)_2$	18.5±2.5	−10.7±6.1	22.9	22.7	140.7	0.72
1,4-$(CH_3)_2$	21.5±0.8	−3.2±1.9	22.8	22.3	137.2	1.52

a) Free energies of activation at the coalescence temperature calculated by using $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. b) Free energies of activation at the coalescence temperature calculated by using the temperature and the chemical shift difference. c) The equilibrium constants were independent of temperature in the range of 20—50 °C.

$\Delta H^{\ddagger}$ 21.0±1.4 kcal/mol (1 cal=4.18 J) and $\Delta S^{\ddagger}$ −7.2± 4.5 e. u. (1 e. u.=4.18 J K^{-1} mol^{-1}). Using these values, $\Delta G^{\ddagger}_{298}$ and $\Delta G^{\ddagger}_{449.5}$ were calculated as 23.1 and 24.3 kcal/mol. **3** gave $\Delta H^{\ddagger}$ 24.5±4.6 kcal/mol and $\Delta S^{\ddagger}$ 4.3±15.0 e. u. Using these values, $\Delta G^{\ddagger}_{298}$ and $\Delta G^{\ddagger}_{449.2}$ were obtained as 23.2 and 22.6 kcal/mol respectively.

The results suggest that the barriers to rotation in compounds **2** and **3** are about the same but are definitely larger than those of **4** and **5**. At any rate, the barriers in these compounds are not high enough for the isolation of rotamers at room temperature. Thus attempt at isolating rotamers of these compounds was abandoned, although the crystalline forms of **4** and **5** were almost pure rotamers and those of **2** and **3** showed some enrichment.

Dynamic NMR Studies. Results obtained by the total line shape analyses of ^{1}H NMR spectra together with those of coalescence temperature method are listed in Table 1. The free energies of activation for rotation, calculated by using $\Delta H^{\ddagger}$'s and $\Delta S^{\ddagger}$'s which were obtained by total line shape analyses, agreed reasonably well with those which were calculated by the T_c's and $\Delta\delta$'s. As was pointed out in the Experimental section, the reading of the coalescence temperatures might involve some errors because of the different populations of the two rotamers. Considering these limitations, we conclude the agreement is satisfactory. It is also worthy to note that the free energies of activation for rotation at 298 K (22.3 and 23.2 kcal/mol for **2** and **3** respectively) calculated with the use of $\Delta H^{\ddagger}$'s and $\Delta S^{\ddagger}$'s from the total line shape analyses agree quite closely with those (23.1 and 23.2 kcal/mol for **2** and **3** respectively) obtained from $\Delta H^{\ddagger}$'s and $\Delta S^{\ddagger}$'s from the classical method, although the enthalpies and entropies of activation themselves seemed to differ to some extent.

Among compounds examined here, the tetrahalo derivatives (**2** and **3**) gave the maximum barriers to rotation and 1,4-dimethoxy and 1,4-dimethyl derivatives gave lower barriers. For the 1,4-dimethoxy compound (**5**), it is a reasonable outcome since the effective size of the methoxyl group is much smaller than those of chloro and bromo groups. However, since the van der Waals radius of the methyl group (2.0 Å) is known to be larger than those of the chloro (1.80 Å) and the bromo (1.95 Å) group, the results deserve mention here. The facts that compounds carrying a methyl group in a peri-position of the triptycene skeleton show lower barriers to rotation than those carrying a halogen at the same place have been noted from time to time.[13,14] We have ascribed this phenomenon to the possible gear effect: since a methyl group is a three-toothed gear, its effective size could be smaller than a chloro or a bromo group in a congested state. This postulate was questioned by Mislow *et al.*[15] because, in 1,2,3,4-tetrahalotriptycenes, the buttressing effect is present, whereas it is absent in 1,4-dimethyltriptycenes. However, since we have been able to show that the buttressing effect of the 2-substituent in this system acts to lower the barrier to rotation of a 9-substituent when the latter is tertiary,[5] the buttressing effect does not seem to be a cause for the lower barriers of the 1-methyl compounds, at least, in the 9-*s*-alkyl series.

This is clearly shown when we carefully examine the barriers to rotation of the compounds reported here and 9-(2-methoxy-1-methylethyl)triptycenes reported in a previous paper.[1] In both cases, 1-methoxy compounds show lower barriers to rotation than 1-chloro compounds but the barriers of the latter compounds are almost the same with 1-bromo compounds: this indicates that the barriers to rotation of triptycenes carrying a *s*-alkyl group at the bridgehead become maximum when the peri-substituent is a chloro or a bromo group. A series of 9-isopropyltriptycenes showed the same tendency.[1,13] Being a larger group than a bromo, the methyl group in 1-position may cause a lower barrier as was the case of *t*-alkyltriptycenes. The maximum barrier is achieved in *t*-alkyltriptycenes when the peri-substituent is a fluoro or a methoxyl[4] and we realize that the substituent which gives the maximum barrier to rotation in *s*-alkyl series shifted to a larger size. This must be a reflection of a fact that, being a smaller group than a *t*-alkyl, the *s*-alkyl group in 9-position of triptycene gives less crowdedness in the ground state and the highest barrier is manifested when the peri-substituent is bulkier. Thus the exact cause for the low barrier of the methyl compounds is not yet known. It is obvious that we must take the crowdedness in the ground state into account.

Comparison of the barriers to rotation of the compounds examined here with those of 9-(2-methoxy-1-methylethyl)triptycenes reveals that both exhibit almost the same height if the peri-substituent is the same. Since the van der Waals half-thickness of the π-system (1.70 Å) is known to be smaller than the van der Waals radius (2.0 Å) of the methyl, of the methoxymethyl and the vinyl groups which we compare here, the latter must be smaller in an effective size. We take the results again that they reflect the stabilities of the ground states of the 9-(1-methyl-1-propenyl) series because in the transition state for rotation of this series the free energy is thought to be less increased relative to those of 9-(2-methoxy-1-methylethyl) series.

Conformational Equilibriums. Comparing the conformational equilibrium constants of the compounds examined here, we immediately notice that the stable conformation switches from *ap* to ±*sc* when we go from compounds **2**, **3**, and **5** to compound **4** if our assignment of the conformation is correct. Since we have assigned the conformations by considering the van der Waals shifts of the methyl signals in ^{1}H NMR spectra and have not been able to provide further evidence, we may have to discuss the cause of the switch in conformational equilibriums with great care. However, it is tempting to consider that in these congested systems a weak interaction which is otherwise not detected can be found:[16] there could be a weak attractive interaction, which stabilizes the *ap* conformation in spite of the fact that a methyl group is larger than a π-system, between a methyl group and a group bearing a lone-pair of electrons. Such possibilities are suggested by Zushi *et al.*[17]

Syntheses of Recyclized Macrolide Antibiotics and Related Derivatives from Mycaminosyltylonolide

Akihiro TANAKA, Azuma WATANABE, Reiko KOBAYASHI, Tsutomu TSUCHIYA,* and Sumio UMEZAWA

Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

(Received June 30, 1981)

Mycaminosyltylonolide diethyl acetal was, after reduction of the 9-keto group, hydrolyzed, and the seco-acids obtained were recyclized to give new 16-membered (9*R*)- and (9*S*)-hydroxy macrolide derivatives, in which the 23-hydroxyl group of the starting substance was incorporated into the macrolactone ring. Selective oxidation of the (9*S*)-hydroxy derivative (**15**) with DDQ gave the keto compound (**18**). Removal of the acetal-protecting groups gave a new macrolide (**19**), which is antibacterial. Several other *O*-acetyl derivatives were also prepared and their antibacterial activities were measured. By the ^{1}H- and ^{13}C-NMR spectroscopies of 3,23-di-*O*-acetyl-mycaminosyltylonolide diethyl acetal by varying the temperature, the presence of two rotamers was clarified.

Mycaminosyltylonolide[1] (**1**) easily obtained by acidic hydrolysis of tylosin,[2] a typical 16-membered macrolide antibiotic, has fairly strong antibacterial activity, inspite of the relatively simple structure. Since structurally related demycarosyljosamycin[3] obtained by acidic hydrolysis of josamycin,[4] and demycarosylcarbomycin B,[5] both having mycaminosylmacrolactone structure, have much weaker antibacterial activity, the activity of **1** will partially be ascribable to the structure of the macrolactone portion, tylonolide. In this paper, we describe a new mycaminosylmacrolactone (**19**) obtained by recyclizing the 23-hydroxyl group of the seco-acid of **1** to the carboxylic acid to form a 16-membered lactone.

Synthesis of the new mycaminosylmacrolactone was started from mycaminosyltylonolide diethyl acetal (**2**) prepared from **1**. To protect the C-8 position from epimerization during the synthesis, the carbonyl at C-9 of **2** was reduced with sodium borohydride following the procedure by Masamune *et al.*,[6] to give two 9-hydroxy derivatives. The configurations at C-9 of the faster- (**6**) and the slower-moving derivatives (**7**) were decided from the studies of their ^{1}H-NMR spectra. Since structurally related macrolide, josamycin (leucomycin A_3) (9*R* epimer) and 9-epi-josamycin (9*S* epimer) show, in their ^{1}H-NMR spectra,[7] the coupling constants of $J_{9,10}$ 9.0 and 4.0 Hz, respectively, **6** ($J_{9,10}$ 8.0 Hz) and **7** ($J_{9,10}$ 4.5 Hz) could reasonably be assigned as 9*R*- and 9*S*-isomers. Removal of the acetal protecting groups of **6** and **7** by treatment in acidic aqueous acetonitrile gave the corresponding aldehyde derivatives (**8** and **9**) in high yields. Again the $J_{9,10}$ of **8** and **9** were shown to be 8 and 4 Hz, respectively. The deblocking of the acetal-protecting groups is necessary in order to have antibacterial derivatives.

Ring-opening of the macrolactone portion of the mixture of **6** and **7** to 15-hydroxy carboxylic acids (**10**, **11**) (seco-acids) was performed by treating the mixture with sodium hydroxide in aqueous methanol. The completion of the opening was verified by the lack, in the ^{1}H-NMR spectrum, of the H-15 proton signals near δ 4—5. The structures were also confirmed by the formation of the corresponding esters (**12**, **13**).

Recyclization of **10** and **11** was carried out by applying the double activation method developed by Corey *et al.*[8] Treatment of the mixture (**10**, **11**) with 2,2′-dipyridyl disulfide and triphenylphosphine according to Mukaiyama *et al.*[9] gave intermediary active esters,

which were then diluted (0.003—0.006 M) with toluene and heated (80 °C, 24 h) to give a mixture of recyclized products (**14** and **15**) in 17% yield (after purification). Similar treatment of the acids (**10**, **11**) with bis(4-*t*-butyl-1-isopropyl-2-imidazolyl)disulfide[10] and triphenylphosphine followed by dilution with toluene and heating as described above gave the better yields of **14** (*R*-isomer, 11.7%) and **15** (*S*-isomer, 11.7%), the total yield being 26%. Recyclization by the method of Masamune *et al.*[11] was unsuccessful in this case. The structures of **14** and **15** were proved by the ^{1}H-NMR (250 MHz) studies. The H-14 proton resonance (multiplet, δ 3.19 for **12** and δ 3.29 for **13**), which was clearly discernable from other signals by the presence of coupling with the olefin proton at C-13, could be correlated, by the decoupling method, to the resonance of the CH_2 protons (H-15a,b) at δ 4—4.4 (δ 4.20 and 4.29 for **14**; δ 4.07 and 4.38 for **15**). The low-field resonances of the C-15 methylene protons as compared with those of C-23 methylene protons ($\delta \approx 3.7$) of **1** and **5** indicated that the methylenes of **14** and **15** should be bonded to a carboxyl group. The methylenes in question should originate from the 23-methylenes of **10** and **11**, because all the free hydroxyl groups (at C-3, 15,2′, and 4′) other than that at C-23 are bonded to a methine group, respectively. In the above reaction, formation of condensation products formed by linking the carboxylic acid groups with the secondary hydroxyl groups above-mentioned, or formed by intermolecular condensation should be considered, however, none of them were isolated. The fact that **14** and **15** were not the intermolecular-condensation products was verified from the physicochemical properties of **14**, **15** and other derivatives as described later. It is, therefore, concluded that ring closure occurred principally at the primary hydroxyl groups to form 16-membered lactones. It should be noted that this is the first successful macrolide recyclization of seco-acids bearing a sugar portion.

Deacetalation of **14** gave (9*R*)-9-hydroxy compound (**16**) which is a recyclized congener of bioactive **8**. Deacetalation of **15**, however, failed to give the corresponding (9*S*)-9-hydroxy compound (**17**) owing to the difficulty of isolation of **17** from the reaction mixture.

Selective oxidation at C-9 of **14** and **15** was next performed. Oxidizing agents usually used for macrolides were, for example, active manganese dioxide[6,12] in dichloromethane, aluminium isopropoxide–cyclohexanone in toluene[13] (Oppenauer method), pyridinium chlorochromate in dichloromethane,[14] chromium trioxide in hexamethylphosphoric triamide[15] and acetic anhydride–dimethyl sulfoxide. These reagents, however, when applied to **14** and **15**, gave poor yields of the desired 9-keto derivatives possibly owing to the simultaneously occurring nonselective oxidation of the hydroxyl, dimethylamino, and olefinic groups. One successful case was met, however, when 2,3-dichloro-5,6-dicyano-*p*-benzoquinone[16] (DDQ) was used. This reagent had been reported[17] to convert allylic alcohols to the corresponding unsaturated aldehydes or ketones. Treatment of **15** (9*S* isomer) with DDQ in tetrahydrofuran gave 9-keto compound (**18**) in 47% yield. Use of benzene as solvent, which is usually used in this kind of reaction, was found to be unsuccessful. The structure of **18** was confirmed by the IR, mass, and ^{1}H-NMR spectroscopy. In the ^{1}H-NMR spectrum, no signal assignable to H-9 was observed, and H-10 olefin proton appeared as a doublet indicating again that H-9 was lacked. Similar oxidation of the 9*R* isomer (**14**), however, gave **18** in only 2.5% yield with an unresolved product mainly produced, indicating that the oxidation

(hydrogen abstraction) pathway is highly dependent on the stereo-specificity. Deacetalation of **18** gave **19** which is the recyclized congener of **1**.

Several acetyl derivatives were further prepared in order to confirm the structure of **18** and to test their antibacterial activities. Acetylation of **18** gave 3,21,2′,4′-tetra-*O*-acetyl derivative (**20**), which on treatment with methanol (*vide supra*) gave 3,21-di-*O*-acetyl derivative (**21**). Deacetalation of **21** gave 3,21-di-*O*-acetyl derivative (**22**) of **19**.

Antibacterial spectra of the compounds having the aldehyde free were shown in Table 1. Comparison of the data of **19** and **1**, and **22** and **4** (*vide infra*) shows that the recyclized products have antibacterial activity lower than the mother compounds. It should be noted, however, that the recyclized compounds, except **16**, show stronger activities than that of demycarosyl-josamycin which is closely related to **19**.

Several acetyl derivatives of **1** were also prepared as reference compounds for biological test. Mycaminosyl-tylonolide diethyl acetal (**2**) was treated with acetic anhydride in pyridine to give 3,23,2′,4′-tetra-*O*-acetyl derivative, which, on treatment with methanol,[18] gave 3,23-di-*O*-acetyl derivative (**3**), showing that the 2′- and 4′-*O*-acetyl groups were selectively removed. Acidic hydrolysis of **3** in aqueous acetonitrile gave deacetalated 3,23-di-*O*-acetyl derivative (**4**). Acidic hydrolysis of **3** in slightly stronger conditions gave 3-*O*-acetyl derivative (**5**).

Here we describe the conformational feature of **3** detected by ^{1}H-NMR spectroscopy by varying the temperature (see Fig. 1). At 50 °C in chloroform-*d*, all proton signals appeared as sharp lines, and at lower temperatures, they gradually broadened. Among them, the singlet of 3-*O*-acetyl (δ 2.12) showed rapid broadening; the ratio of the height of the acetyl signal for that of 23-*O*-acetyl (δ 2.03) changed as follows: 0.66 (at 50 °C), 0.42 (44 °C), 0.34 (34 °C), 0.14 (20 °C). At 0 °C the 3-*O*-acetyl signal melted away not to be detectable. At −10 °C, the acetyl peak at δ 2.08 (*ca.* 4.5H in strength) still kept sharp line, but a broadened peak (*ca.* 1.5H) newly appeared at δ 2.26. At −20 °C the latter peak sharpened a little, and at −40 °C all peaks assignable to acetyls appeared as four sharp singlets at δ 2.09 (major), 2.10 (major), 2.12 (minor), and 2.29 (minor, *ca.* 1.2H). The H-3 signals (δ 5.23) also behaved similarly. The sharp multiplet (apparently double triplets of $J_{2b,3}$ 8.5 Hz, $J_{2a,3} \simeq J_{3,4} \simeq 4$ Hz) at 50 °C gradually broadened at lower temperatures, and at 20 °C it became a broadened singlet. At 0 °C it melted away (δ 5.0—5.4). At that temperature, the following signals still kept sharp lines or slightly broadened: methyls of 17, 21, 22, 6′; 23-*O*-acetyl, dimethylamino, $-OCH_2C\underline{H}_3$; methylenes of 16, 23; methines of 15 and 3′. At −10 °C, line-resharpening of all signals began, and H-3 signals were separated into two broadened singlets at δ 5.13 and 5.33 (*ca.* 1 : 1 in strength), which, at lower temperatures, gradually sharpened to become two doublets (J 7.5 and 9 Hz) in the strength of *ca.* 1.2 : 1 (−20 °C), 1.5 : 1 (−40 °C), and 2 : 1 (−55 °C) without substantial change in the shift-values. Other signals separated into two parts were those of H-10 (eminent below −10 °C), -11 (below −20 °C), -13 (below −20 °C), 18-methyl (below −20 °C), and H-1′ (−20 °C). Other signals which showed great broadening at low temperatures were the peaks of H-4 (broadening began at 34 °C, and at 0 °C, melted away), H-10 (broadening began at 20 °C), H-2a and -2b (broadening began both at 10 °C and melted away at 0 °C), 18-methyl (broadening began at 10 °C), and possibly H-7.

Above data can be summarized as follows: 1) line-broadening occurred not at a time, the signals of H-3, 3-*O*-acetyl, H-4, and H-10 being first broadened, then those of 18-methyl, H-2a, and -2b followed, 2) the signals at C-15, 16, 17, 21, 23, 3′, 6′, of $(OCH_2C\underline{H}_3)_2$, 23-*O*-acetyl, and $N(CH_3)_2$ resisted to the broadening, and 3) at low temperatures, the signals of H-3, 10, 11, 13, and 3-*O*-acetyl separated into two parts with varying the strength-ratio with the temperatures.

These data disclosed the conformational feature of **3** dissolved in chloroform-*d*. First, it is concluded, from 3), that **3** will have two rotational isomers on the NMR time scale, and at 55 °C, for example, they show faster interconversion to give a clear spectrum. The situation is typically shown by the fact that the J values relating

Table 2. The ^{13}C-NMR chemical shifts of **1**, **3**, and **4** in $CDCl_3$ (in ppm downfield from TMS)

	1 (at 20 °C)	**3** (at 50 °C)	**4** (at 20 °C)

a) May be interconvertible.

to H-2a, 2b, 3, and 4 is changed at the temperatures above and below 5 °C. The coalescence point is estimated to be near 5 °C, the (high) value being unexpected for the macrolide derivative. From 2) and 3) it is suggested that the origin of the energy barrier for the interconversion between the rotamers might be principally created by the steric crowd of the substituents between C-3—C-8 including 3-*O*-acetyl. The diene portion will come near to the above portion (C-3—C-8) and be influenced by the above rotational changes. The positions remote from the above portion (C-3—C-8) will not much be influenced, keeping always similar spectral environments.

Above conclusions were basically confirmed by the ^{13}C-NMR spectroscopy. The spectra of **3** measured at various temperatures are shown in Fig. 2. Signal assignments (see Table 2) were made on the basis of the comparison of the spectrum with that of tylosin[19] and also by off-resonance method as well as by selective proton decouplings (see Experimental). In the spectrum, the signals of ^{13}C-3, 4, 8, and 10 appeared, even at 50 °C, as low and broadened peaks. At 20 °C, the signals of ^{13}C-18 (slight), 16 (slight), 19, O$\underline{C}$H$_2$CH$_3$, 20, 13, and 9 were additionally broadened. At −40 °C, most of the carbon signals split into doublets of unequal intensities. These results indicate again that **3** has two major rotational isomers.

Experimental

General. Melting points were determined on a Kofler block and are uncorrected. Optical rotations were measured with a Perkin-Elmer 241 polarimeter. Thin-layer chromatography (TLC) was carried out on Wakogel B5 silica gel with detection by spraying with sulfuric acid, followed by slight heating. Column chromatography was performed on Kiesel gel 60, 230—400 mesh (E. Merck). UV spectra were recorded with a Hitachi 200-10 spectrometer, and IR spectra, with a Hitachi 255 grating spectrometer. ^{1}H-NMR spectra were recorded at 90 MHz with a Varian EM-390 spectrometer, or at 250 MHz in the FT mode using a Bruker WM 250 spectrometer at 20 °C unless otherwise stated. ^{13}C-NMR spectra were recorded in the FT mode with a Bruker WM 250 spectrometer operating at 62.9 MHz.

^{1}H-NMR(in CDCl$_3$ at 250 MHz) of **1**: δ 0.95 [3H t, Me(17)], 1.02 [3H d, Me(18)], 1.22 [3H d, Me(21)], 1.27 [3H d, Me(6′)], 1.83 [3H very narrow m; apparently s, Me(22)], 1.96 (1H d, $J_{2a,2b}$ 15 Hz, H-2a), 2.36 (1H t, J 10 Hz, H-3′), 2.50 (6H s, NMe$_2$), 2.53 (1H dd, $J_{2b,3}$ 10 Hz, H-2b), 2.6 (1H m, H-8), 2.9 (H-14), 3.06 (1H t, $J\simeq$9.3 Hz, H-4′), 3.26 (1H m, H-5′), 3.47 (1H dd, $J_{1',2'}$ 7.5 Hz, $J_{2',3'}$ 10.5 Hz, H-2′), 3.73 (1H, H-5), 3.75 (2H d, J 5 Hz, H-23a,b), 3.85 (1H br d, $J\simeq$10 Hz, H-3), 4.25 (1H d, H-1′), 4.95 (1H dt, $J_{14,15}=J_{15,16a}\simeq$9 Hz, $J_{15,16b}$ 2.5 Hz, H-15), 5.92 (1H slightly br, d, $J_{13,14}$ 10 Hz, H-13), 6.30 (1H d, J 15 Hz, H-10), 7.34 (1H d, H-11), 9.70 (1H s, CHO).

Irradiation at δ 1.65 (H-4, 16a, and possibly one of H-7a, 7b) caused the triplet of H-17 and the doublet of H-18 to collapse to a doublet and a singlet, respectively; at the same time, signals both at δ 1.88 (H-16b) and of H-5 to change. Irradiation at δ 2.6 (H-2b, -8) collapsed the doublets of H-2a, -3, and -21 to singlets respectively; the signals near δ 1.5 (H-7a,7b) also changed. Irradiation at δ 2.9 (H-14 and -19?) caused the doublet of H-23, the doublet of H-13, and the double triplets of H-15 to collapse to a singlet, a singlet, and a doublet, respectively.

^{13}C-NMR (in CDCl$_3$ at 20 °C). (s, d, and t cited in the parenthesis are the splitting pattern in the off-resonance). Carbon- 17, 18, 22, 21, 6′, 16(t), 6(d), 7(t), 2(t), 8(d), NMe$_2$, 19(t), 5(d), 1′(d), 10(d), 12(s), 13(d), 11(d), 1(s), 20(d), 9(s) (see Table 2.) were assigned on the bassi of the comparison of the shift-values with those of tylosin[19] as well as by off-resonance method. Carbon-23 can be assigned by the off-resonance method (appeared as a triplet) as well as by the appearance at an up-field shift (62.73 ppm) in comparison to the shift (68.2 ppm) of C-23 of tylosin, the shift being in accord with the removal of the glycoside linkage from tylosin. On H-3′ proton irradiation, C-3′ appeared as a singlet; the splitting spaces of the signals (each doublet) of C-4′, 2′ and 5′, 3 and 15 became wider in this order, which were proportional to the order of the $\Delta\delta$ value of the protons (H-4′, 2′, 5′, 3, and 15) from the δ value of H-3′. This observation assisted the carbon assignments in question. Distinction between C-4 and -14 was performed by the H-14 proton irradiation.

Mycaminosyltylonolide Diethyl Acetal (2). A solution of **1** (825 mg) in dry ethanol (8.3 ml) containing anhydrous *p*-toluenesulfonic acid (360 mg) was kept at room temperature for 20 min. After addition of triethylamine (0.3 ml), the solution was concentrated and the residue was dissolved in chloroform. The solution was washed with saturated aqueous sodium hydrogencarbonate and water, dried over sodium sulfate and concentrated to give a solid. Recrystallization from acetone solution by adding hexane gave needles, 852 mg (92%), mp 193—195 °C, $[\alpha]_D^{25}$ +14° (*c* 1, chloroform); UV λ_{max} (MeOH) 283 nm (log ε 4.40).

Found: C, 62.29; H, 8.95; N, 2.13%. Calcd for $C_{35}H_{61}NO_{11}$: C, 62.57; H, 9.15; N, 2.08%.

3,23-Di-O-acetylmycaminosyltylonolide Diethyl Acetal (3). Treatment of **2** (992 mg) in pyridine (10 ml) with acetic anhydride (2.5 ml) at 50 °C for 2 d gave 3,23,2′,4′-tetra-*O*-acetyl derivative, which gave, on TLC with benzene–acetone (5 : 1), a spot of R_f 0.35. The crude derivative was dissolved in methanol and the solution was kept at 50 °C overnight to give an amorphous solid of **3**, 1.05 g (94%); R_f 0.5 on TLC with chloroform–methanol (7 : 1) (the tetraacetyl intermediate: R_f 0.95), $[\alpha]_D^{25}$ +3° (*c* 1, chloroform).

Found: C, 62.15; H, 8.59; N, 1.88%. Calcd for $C_{39}H_{65}NO_{13}$: C, 61.97; H, 8.64; N, 1.85%.

^{1}H-NMR (in CDCl$_3$ at 250 MHz) (at 50 °C): δ 0.93 [3H t, Me(17)], 1.03 [3H d, Me(18)], 1.15 [3H d, Me(21)], 1.15—1.24 [6H, (OCH$_2$C$\underline{H}_3$)$_2$], 1.31 [3H d, Me(6′)], $\simeq$1.35—1.5 (H-19a), $\simeq$1.37—1.52 (H-7), 1.61 (1H m, H-16a), $\simeq$1.75 (H-4), $\approx$1.8 (H-16b), 1.81 [3H s, Me(22)], $\approx$2.0 (H-6, 19b), 2.03 (3H, s, 23-*O*-Ac), 2.12 (3H s, 3-*O*-Ac), 2.22 (1H dd, $J_{2a,3}$ 3.3 Hz, $J_{2a,2b}$ 15 Hz, H-2a), 2.32 (1H t, H-3′), 2.51 (6H s, NMe$_2$), 2.57 (1H dd, $J_{2b,3}$ 8.5 Hz, H-2b), 2.95—3.07 (3H, H-8, 14, 4′), 3.29 (1H m, H-5′), 3.44—3.55 [(OC$\underline{H}_2$CH$_3$)$_2$], 3.59 (1H dd, H-2′) $\approx$3.67 (H-5); 4.08 (1H dd with the lower-field half being intense, $J_{14,23a}$ 6.5 Hz, $J_{23a,23b}$ 11.5 Hz, H-23a), 4.14 (1H dd with the higher-field half being intense, $J_{14,23b}$ 5 Hz, H-23b), 4.23 (1H d, $J_{1',2'}$ 7.5 Hz, H-1′), 4.54 (1H apparent t, H-20), 4.84 (1H ddd, H-15), 5.25 (1H m, H-3), 5.86 (1H d, $J_{13,14}$ 10 Hz, H-13), 6.17 (1H d, J 15.5 Hz, H-10), 7.25 (1H d, H-11).

Irradiation of 17-methyl collapsed the multiplet of H-16a to double doublets ($J_{15,16a}$ 9.5, $J_{16a,16b}$ 15 Hz), and the signals between δ 1.77—1.86 (H-16b) changed. Irradiation at δ 1.82 (H-16b and 4) caused the triplet of H-17, the multiplet of H-15, the multiplet of H-3 and the doublet of CH$_3$ (18) to collapse to a doublet, double doublets ($J_{14,15}$ and 9.5 Hz), double doublets, and a singlet, respectively; the signals of

H-16a also changed although they were biased by the near-by irradiation. Irradiation at δ 3.0 (H-8, 14, and 4′) collapsed the doublet of Me(21) to a singlet, the multiplet of H-23a, -23b to an AB quartet, the doublet of H-13 to a singlet, and the multiplet of H-15 to double doublets; the signals of H-5′ and -3′ also changed to the form as expected. Irradiation of H-3 caused the signals of H-2a, -2b to collapse to an AB quartet and the signals near δ 1.75 (H-4) to change. Irradiation at δ 3.67 (H-5) caused the signals of H-4 to change. Irradiation at δ 1.95 (H-6, 19b) caused the signals between δ 1.35—1.53 (H-7, 19b) to simplify, and the triplet of H-20 to a doublet. To confirm the signal assignments, the positions of H-15, 20, and 1′ were also irradiated.

At −20 °C: 18-Methyl separated into two incomplete doublets at δ 1.01 and 1.10. H-1′ separated into two, the bigger half being appeared at δ 4.33 (J 7.5 Hz). H-13 gave two doublets (each $J\simeq$10 Hz) at δ 5.88 and 5.97. H-10 gave two doublets (each $J\simeq$15 Hz) at δ 6.03 and 6.34. H-11 gave apparent triplet at δ 7.34.

At −40 °C: 18-Methyl gave two doublets at δ 1.01 (J 6.3 Hz) and 1.12 (J 5 Hz). The bigger signals of H-1′ appeared at δ 4.35 ($\simeq$0.6H d, J 7.5 Hz). H-3 gave two slightly broaened doublets at δ 5.09 ($\simeq$0.6H, $J\simeq$7.5 Hz) and 5.33 ($\simeq$0.4H, $J\simeq$10 Hz). H-13 gave two sharp doublets (J 10 Hz) at δ 5.90 ($\simeq$0.6H) and 5.98 ($\simeq$0.4H). H-10 gave two sharp doublets (J 15.5 Hz) at δ 6.03 ($\simeq$0.4H) and 6.37 ($\simeq$0.6H).

^{13}C-NMR (in $CDCl_3$ at 50 °C). Carbon-17, 18, 22, ($\underline{C}H_3$-CH_2O-)$_2$(q, each), 21, 6′, ($\underline{C}H_3CO_2$–)$_2$, 16(t), NMe_2(q), 14(d), ($CH_3\underline{C}H_2O$–)$_2$ (t, each), 23, 5, 1′, 20(d), 10, 12, 13, 11, 1, ($CH_3\underline{C}O_2$–)$_2$, 9(s) (see Table 2) were assigned on the basis of the comparison of the shift-values with those of **4** as well as by the off-resonance. The carbons ranging between 30—45 ppm (C-2, 4, 6, 7, 8, 14, and 19) could be classified into two groups of methylene (C-2, 7, 19) and methine (C-4, 6, 8, 14) by the method of off-resonance. By the proton irradiation at δ 1.3, C-2(d) could be distinguished from C-7(s) and 19(s). By the H-14(16 and 22) proton irradiation, C-4(s) and C-6 (narrow d) could be distinguished from C-8 and 14. The above assignments were also confirmed by the proton irradiations of H-6 and of 14(8 and 4′). By the latter irradiation, also, assignments of carbons (between 70—76 ppm) of 4′(s), 5′(very narrow d), 2′(narrow d), 3′(d), 15 and 3(wide d, each) were made. The above assignments were substantiated by the observation that the $^1J_{C-H}$ values in question came roughly in the range of similar magnitudes (by gated decoupling method). Carbon-3 was decided by the H-3 proton irradiation.

3,23-Di-O-acetylmycaminosyltylonolide (4). A solution of **3** (100 mg) in a mixture of acetonitrile (2 ml) and 0.1 M aqueous hydrochloric acid (2 ml) was kept at room temperature for 1 h. After addition of sodium hydrogencarbonate (34 mg) and water (4 ml), the reaction mixture was extracted with chloroform. The crude product obtained was purified by chromatography on a short column of silica gel with chloroform–methanol (7 : 1) to give an amorphous solid of **4**, 86 mg (96%), $[\alpha]_D^{25}$ +19° (c 0.7, chloroform).

Found: C, 61.83; H, 8.35; N, 2.32%. Calcd for $C_{35}H_{55}NO_{12}$: C, 61.66; H, 8.13; N, 2.05%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): δ 0.94 [3H t, Me(17)], 1.09 [3H d, Me(18)], 1.23 [3H d, Me(21)], 1.27 [3H d, Me(6′)], 1.83 [3H s, Me(22)], 1.78—1.92 (H-4, 16b), 2.05 (3H s, 23-*O*-Ac), 2.15 (3H s, 3-*O*-Ac), 2.35 (1H t, H-3′), 2.50 (6H s, NMe_2), 2.64 (1H dd, H-2), 2.98—3.1 (H-14), 3.07 (1H t, H-4′), 3.27 (1H dd, H-5′), 3.48 (1H dd, H-2′), 3.57 (1H d, H-5), 4.09 (1H dd, H-23a), 4.16 (1H dd, H-23b), 4.21 (1H d, H-1′), 4.82 (1H ddd, H-15), 5.18 (1H unresolved d, $J\simeq$10 Hz, H-3), 5.90 (1H d, H-13), 6.30 (1H d, H-10), 7.43 (1H d, H-11), 9.65 (1H s, CHO). Above assignments were confirmed by the decoupling method.

^{13}C-NMR (in $CDCl_3$ at 20 °C). Carbon-17, 18, 22, 21, 6′, ($\underline{C}H_3CO_2$–)$_2$ (q, each), 16(t), 6, 7, 2(t), 8(d), NMe_2, 19(t), 23(t), 3(d), 5′, 15, 5, 1′, 10, 12, 13, 11, 1, ($CH_3\underline{C}O_2$–)$_2$ (s, each), 20(d), 9(s) (see Table 2.) were assigned on the basis of the comparison of the shift-values with those of **1** as well as by the off-resonance method. Carbon-15 was confirmed by the H-15 proton irradiation. Distinction between C-4 and -14 was performed by the H-14 proton irradiation. Distinction between C-2′, 3′, and 4′ was performed by the H-4′ proton irradiation, whereupon C-4′ appeared as a singlet, and C-2′ and 3′ as a doublet, respectively, but the peak space of the latter doublet was wider than that of the former one (see the similar statement of ^{13}C-NMR of **3**). Since $^1J_{C2'-H2'}$ and $^1J_{C3'-H3'}$ were observed to be almost equal (by the gated decoupling technique), assignments of C-2′ and 3′ by the above space-method will be resonable.

3-O-Acetylmycaminosyltylonolide (5). An aqueous solution (3.5 ml) of **3** (69 mg) and *p*-toluenesulfonic acid monohydrate (26 mg) was kept at 65 °C for 20 h. After addition of sodium hydrogencarbonate (20 mg), the reaction mixture was extracted with chloroform. The crude product obtained showed, on TLC with chloroform–methanol-28% aqueous ammonia (10 : 1 : 0.1), three spots of R_f 0.4 (slight **3**), 0.3 (major, **5**), and 0.22 (slight, 23-*O*-acetyl derivative?). Silica-gel column chromatography with chloroform–methanol–28% aqueous ammonia (20 : 1 : 0.1) gave an amorphous solid of **5**, 30 mg (51%), $[\alpha]_D^{18}$ +15° (c 1, chloroform).

Found: C, 62.17; H, 8.46; N, 2.18%. Calcd for $C_{33}H_{53}NO_{11}$: C, 61.95; H, 8.35; N, 2.19%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): δ 1.85 [3H s, Me(22)], 2.15 (3H s, 3-*O*-Ac), 2.50 (6H s, NMe_2), 3.66 (1H dd, $J_{14,23a}$ 7 Hz, $J_{23a,23b}$ 11.5 Hz, H-23a), 3.73 (1H dd, $J_{14,23b}$ 5 Hz, H-23b), 4.21 (1H d, H-1′), 4.80 (1H m, H-15), 5.20 (1H unresolved d, $J\simeq$11 Hz, H-3), 5.93 (1H d, H-13), 6.29 (1H d, H-10), 7.41 (1H d, H-11), 9.65 (1H s, CHO).

Irradiation at δ 2.93 (H-14) collapsed the signals of H-23a, 23b to an AB quartet, and the doublet of H-13 to a singlet.

(9R)-9-Deoxo-9-hydroxy- (6) and (9S)-9-Deoxo-9-hydroxymycaminosyltylonolide Diethyl Acetal (7). To an ice-cold solution of **2** (567 mg) in methanol (5.7 ml) was added sodium borohydride (96 mg) and the solution was kept in the cold for 3 h. On TLC with chloroform–methanol–28% aqueous ammonia (12 : 1 : 0.1), the reaction mixture showed spots of R_f 0.37 (**6**), 0.33 (**7**) (the color-intense was equal), and 0.3 (very slight), the spot of **2** (R_f 0.4) being disappeared. After concentration, the residue was extracted with chloroform and the solution was washed with water, dried, and concentrated. Column chromatography of the residue with chloroform–methanol–28% aqueous ammonia (15 : 1 : 0.1) gave amorphous solids of **6** (73 mg, 13%), **7** (86 mg, 15%) and the mixture of the two (383 mg, 67%).

6: $[\alpha]_D$ +38° (c 1, chloroform); UV λ_{max} (MeOH) 237 nm (log ε 4.57).

Found: C, 62.11; H, 9.20; N, 2.08%. Calcd for $C_{35}H_{63}NO_{11}$: C, 62.38; H, 9.42; N, 2.08%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): δ 1.78 [3H s, Me(22)], 2.51 (6H s, NMe_2), 4.28 (1H broadened d; at 50 °C: sharp dd, $J_{8,9}$ 2.5 Hz, $J_{9,10}$ 8.0 Hz, H-9), 4.34 (1H d, H-1′), 4.65 (1H unresolved m; at 50°C, sharp dd, J 4 and 6.5 Hz, H-20), 4.89 (1H dt, H-15), 5.24 (1H d, J 10 Hz, H-13), 5.76 (1H dd, $J_{10,11}$ 15.5 Hz, H-10), 6.15 [1H br ($\simeq$6.0—6.3) s; at 50 °C, sharp d, J 15.5 Hz, H-11].

Irradiation (at 50 °C) of H-10 collapsed the signals of H-9

and H-11 to a small doublet, and a singlet, respectively. Irradiation (at 50 °C) at δ 1.9 (H-8) collapsed the double doublets of H-9 to a doublet (J 8 Hz).

7: $[\alpha]_D^{25}$ +37° (*c* 1, chloroform); UV λ_{max} (MeOH) 237 nm (log ε 4.41).

Found: C, 62.56; H, 9.27; N, 2.16%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): δ 1.78 (3H s, Me(22)), 2.51 (6H s, NMe_2), 4.32 (1H d, H-1′), 4.61 (H-20), 4.90 (H-15), 5.29 (1H d, J 10 Hz, H-13), 5.95 (1H br ($\simeq$5.85—6.1) s; at 50 °C: sharp dd, $J_{9,10}$ 4.5 Hz, $J_{10,11}$ 15.5 Hz, H-10), 6.47 (1H d, H-11). Signals of H-1′, -20, -15, -13, and -11 slightly sharpened at 50 °C.

Irradiation (at 50 °C) of H-10 collapsed the doublet of H-11 to a singlet. Irradiation (at 50 °C) at δ 3.92 (H-9) collapsed the double doublets of H-10 to a doublet.

*9-Deoxo-9(R)-hydroxy- (**8**) and 9-Deoxo-9(S)-hydroxy-mycaminosyltylonolide (**9**).* To a solution of **6** or **8** (40 mg, 0.06 mmol) in acetonitrile (1.2 ml) was added 0.1 M aqueous hydrochloric acid (1.2 ml) and the solution was kept at room temperature for 1 h. After addition of aqueous saturated sodium hydrogencarbonate (1.2 ml), the mixture was extracted with chloroform. The organic solution was washed thoroughly with water, dried over sodium sulfate, and concentrated. The residue was chromatographed on a short column of silica gel with chloroform–methanol–28% aqueous ammonia (10 : 1 : 0.1) to remove the slightly remained starting material to give an amorphous solid of **8** (30.5 mg, 86%) or **9** (31.5 mg, 88%).

8: $[\alpha]_D^{25}$ +44° (*c* 0.5, chloroform). ^{1}H-NMR ($CDCl_3$): δ 4.23 (1H dd, $J_{8,9}$ $\simeq$2 Hz, $J_{9,10}$ 8 Hz, H-9), 4.94 (1H dt, H-15), 5.33 (1H d, $J_{13,14}$ 10 Hz, H-13), 5.78 (1H dd, H-10), 6.25 (1H d, $J_{10,11}$ 16 Hz, H-11), 9.86 (1H s, H-20).

Found: C, 62.28; H, 9.01; N, 2.26%. Calcd for $C_{31}H_{53}NO_{10}$: C, 62.08; H, 8.91; N, 2.34%.

9: $[\alpha]_D^{25}$ +34° (*c* 0.5, chloroform). ^{1}H-NMR ($CDCl_3$): δ 4.95 (1H dt, H-15), 5.37 (1H d, H-13), 5.96 (1H dd, $J_{9,10}$ 4 Hz, $J_{10,11}$ 16 Hz, H-10), 6.57 (1H d, H-11), 9.80 (1H s, H-20).

Found: C, 61.99; H, 8.86; N, 2.24%. Calcd for $C_{31}H_{53}NO_{10}$: C, 62.08; H, 8.91; N, 2.34%.

*Basic Hydrolysis of the Mixture of **6** and **7** (to Give **10** and **11**).* To a solution of a mixture of **6** and **7** (4.95 g) in methanol (92 ml) was added 0.4 M aqueous sodium hydroxide (92 ml) and the mixture was heated at 50 °C for 5 h. Addition of 1 M aqueous hydrochloric acid (37 ml) followed by concentration to $\approx$80 ml gave precipitates of sodium chloride, which was filtered and washed with methanol. The filtrate and the washings combined were concentrated, filtered from sodium chloride further precipitated, and the concentrate was chromatographed on a column of Sephadex LH-20 (pretreated with methanol) with methanol to give a mixture of sodium chloride-free products (**10**, **11**), 4.56 g (91%).

*Esterification of **10** and **11** (to Give **12** and **13**).* To a solution of a mixture of **10** and **11** (142 mg) in dry tetrahydrofuran (1.4 ml) was added bis(4-*t*-butyl-1-isopropyl-2-imidazolyl) disulfide (124 mg) and triphenylphosphine (82 mg) under argon atmosphere and the mixture was kept at room temperature for 5 min. Methanol (14 ml) was added and the solution was kept overnight at room temperature. The products obtained were chromatographed with chloroform–methanol–28% aqueous ammonia (9 : 1 : 0.1) to give a mixture of **12** and **13**, 78.5 mg (53%). The mixture was further chromatographed (8 g of silica gel) in a similar manner to give **11** (R_f 0.32 on TLC with chloroform–methanol–28% aqueous ammonia = 10 : 1 : 0.1), 10.9 mg, and **12** (R_f 0.28), 15.4 mg, and the mixture of the two.

11: $[\alpha]_D^{21}$ −4° (*c* 0.5, chloroform); *m/e* 705 (M^+), 659. Found: C, 61.08; H, 9.41; N, 2.00%. Calcd for $C_{36}H_{67}NO_{12}$: C, 61.25; H, 9.57; N, 1.98%.

^{1}H-NMR ($CDCl_3$): δ 3.72 (3H s, CO_2Me).

12: $[\alpha]_D^{21}$ −10° (*c* 0.5, chloroform): *m/e* 659. Found: C, 61.16; H, 9.34; N, 2.13%.

^{1}H-NMR ($CDCl_3$): δ 3.72 (3H s, CO_2Me).

*Cyclization of **10** and **11** (to Give **14** and **15**).* *Method A*: To a solution of a mixture of **10** and **11** (30.6 mg, 0.044 mmol) in dry tetrahydrofuran (0.6 ml) was added, under argon atmosphere, 2,2′-dipyridyl disulfide (14.6 mg, 0.066 mmol) and triphenylphosphine (17.4 mg, 0.063 mmol) and the mixture was kept at room temperature for 30 min. Concentration gave a residue, which was dissolved in dry toluene (16 ml) and the solution was heated at 80 °C for 24 h. The reaction mixture showed, on TLC, two spots of R_f 0.25 (**14**) and 0.28 (**15**) (with 10 : 1 : 0.1 chloroform–methanol–28% aqueous ammonia) accompanied by tailing zones of R_f 0—0.18 and 0.34—0.45. The solution was concentrated and the residue was dissolved in chloroform. The solution was washed with water, dried over sodium sulfate, and concentrated. The residue was chromatographed on a silica-gel column (6 g) with chloroform–methanol–28% aqueous ammonia (12 : 1 : 0.1) to give a mixture of **14** and **15**, 5.1 mg (17%).

Method B: To a solution of a mixture of **10** and **11** (4.56 g, 6.59 mmol) in dry tetrahydrofuran (90 ml) was added bis-(4-*t*-butyl-1-isopropyl-2-imidazolyl) disulfide (3.91 g, 9.88 mmol) and triphenylphosphine (2.60 g, 9.88 mmol) under arogon atmosphere and the mixture was kept at room temperature for 5 min. The reaction mixture showed, on TLC with 6 : 1 chloroform–methanol, spots of R_f 0.3 (active ester) and 0 (hydrolyzed products of the active esters?). Concentration gave a residue, which was dissolved in toluene (1140 ml) and the solution was heated at 80 °C for 24 h. The TLC pattern of the reaction mixture was substantially the same with that obtained by "Method A". Similar work-up as described in "Method A" gave an amorphous powder, which was chromatographed on a silica-gel column (Wakogel C-200, 450 g) with chloroform–methanol–28% ammonia (10 : 1 : 0.1) to give **14** (0.52 g, 11.7%), **15** (0.52 g, 11.7%), and a mixture of **14** and **15** (0.10 g, 2.3%).

14: $[\alpha]_D^{25}$ −6° (*c* 0.5, chloroform): UV λ_{max} (MeOH) 236 nm (log ε 4.26); IR(KBr): 1640, 1730 cm^{-1}.

Found: C, 62.44; H, 9.19; N, 2.18%. Calcd for $C_{35}H_{63}NO_{11}$: C, 62.38; H, 9.42; N, 2.08%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): 0.96 [3H d, Me(19 or 16)], 0.98 [3H t, Me(23)], 1.13 [3H d, Me(16 or 19)], 1.19 and 1.21 [each 3H t, $OCH_2C\underline{H}_3)_2$], 1.32 [3H d, Me(6′)], 1.78 [3H d, $J\simeq$1 Hz, Me(20)], 2.26 (1H dd, $J_{2a,2b}$ 14 Hz, $J_{2a,3}$ 4 Hz, H-2a), 2.37 (1H dd, $J_{2b,3}$ 7.5 Hz, H-2b), 2.38 (1H t, H-3′), 2.50 (6H s, NMe_2), 3.02 (1H t, H-4′), 3.19 (1H m, H-14), 3.35 (1H dd, H-5′), 4.2 (1H t, $J_{14,15a}=J_{15a,15b}$ 10.5 Hz, H-15a), 4.29 (1H dd, $J_{14,15b}$ 6 Hz, H-15_b), 4.32 (1H d, J 7.5 Hz, H-1′), 4.62 (1H unresolved t, H-18), 5.38 (1H slightly br d, $J_{13,14}$ 10 Hz, H-13), 5.55 (1H dd, $J_{9,10}$ 9 Hz, $J_{10,11}$ 15 Hz, H-10), 6.18 (1H sharp d, H-11).

Irradiation of H-14 caused the signals of H-15a, -15b to collapse to an AB quartet, the doublet of H-13 to a singlet. Irradiation at δ 3.58 (includes H-9) collapsed the signals of H-10 to a doublet. Irradiation at δ 1.45 [includes H-22 and -4(or 8)] collapsed the triplet of Me(23) and the doublet at δ 1.13 to singlets. Irradiation at δ 1.67 (H-8 or 4) collapsed the doublet at δ 0.96 to a singlet. Irradiation of H-5′ collapsed the doublet of Me(6′) and the triplet of H-4′ to a singlet and a doublet, respectively.

15: $[\alpha]_D^{25}$ −4° (*c* 0.5, chloroform); UV λ_{max} (MeOH)

236 nm (log ε 4.23); IR(KBr): 1640, 1730 cm^{-1}.

Found: C, 62.07; H, 9.20; N, 2.07%. Calcd for $C_{35}H_{63}NO_{11}$: C, 62.38; H, 9.42; H, 2.08%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): δ 0.94 [3H d, Me(19 or 16)], 0.98 [3H t, Me(23)], 1.18 [3H d, Me(16 or 19)], 1.18 and 1.19 [each 3H t, $(OCH_2C\underline{H}_3)_2$], 1.31 [3H d, Me(6')], 1.76 [3H d, $J\simeq1$ Hz, Me(20)], 2.21 (1H dd, $J_{2a,2b}$ 14 Hz, $J_{2a,3}$ 4 Hz, H-2a), 2.34 (1H dd, $J_{2b,3}$ 9.5 Hz, H-2b), 2.38 (1H t, H-3'), 2.50 (6H s, NMe_2), 3.01 (1H t, H-4'), 3.29 (1H m, H-14), 3.34 (1H dd, H-5'), 4.07 (1H t, $J_{14,15a}=J_{15a,15b}$ 10.5 Hz, H-15), 4.29 (1H d, H-1'), 4.37 (1H ,H-9), 4.38 (1H dd, $J_{14,15b}$ 6 Hz, H-15b), 4.61 (1H dd, J 4 and 7.5 Hz, H-18), 5.35 (1H slightly br d, $J_{13,14}$ 10 Hz, H-13), 5.67 (1H dd, $J_{9,10}$ 3.5 Hz, $J_{10,11}$ 15.5 Hz, H-10), 6.34 (1H dd, $J_{9,11}\simeq1.5$ Hz, H-11).

Irradiation of H-14 caused the signals of H-15a and -15b to collapse to two doublets, and the doublet of H-13 to a singlet. Irradiation of H-9 collapsed the double doublets of H-10 and those of H-11 to a doublet, respectively, to form an AB quartet.

Deacetalation of ***14*** *(to Give* ***16****).* To a solution of **14** (46.6 mg) in acetonitrile (1.4 ml) was added gradually 0.1 M aqueous hydrochloric acid (1.4 ml) and the mixture was kept at room temperature for 1 h. After addition of aqueous saturated sodium hydrogencarbonate (1.5 ml), the mixture was extracted with chloroform. The chloroform-soluble products were chromatographed with silica gel with chloroform–methanol–28% aqueous ammonia (9 : 1 : 0.1) to give an amorphous solid of **16**, 32.3 mg (78%), $[\alpha]_D^{25}$ −12° (*c* 0.5, chloroform), UV λ_{max} (MeOH) 236 nm (log ε 4.34).

Found: C, 61.83; H, 8.81; N, 2.07%. Calcd for $C_{31}H_{53}NO_{10}$: C, 62.08; H, 8.91; N, 2.34%.

^{1}H-NMR ($CDCl_3$): δ 5.43 (1H d, H-13), 5.50 (1H dd, H-10), 6.21 (1H d, H-11), 9.81 (1H s, –CHO); $J_{9,10}$ 9, $J_{10,11}$ 16, $J_{13,14}$ 10 Hz.

Oxidation of ***15*** *(to Give* ***18****).* To an ice-cold solution of **15** (73.1 mg) in tetrahydrofuran (1.5 ml) was added DDQ (49.3 mg) and the solution was kept at room temperature for 1 h. The solution showed, on TLC with chloroform–methanol–28% aqueous ammonia (10 : 1 : 0.1), spots of R_f 0.4 (**18**), 0.33 (**15**), 0.1 and 0. Concentration gave a residue which was charged on a silica-gel column (7 g) and the column was washed with ethyl acetate (350 ml). DDQ and the reduced compound of DDQ were eluted. The developing solvent was then changed to chloroform–methanol–28% aqueous ammonia (12 : 1 : 0.1) to elute **18** to give a pale-brown solid (59.5 mg). The methanol solution of the solid was decolorized with charcoal and, after evaporation, the residue was chromatographed with chloroform–methanol–28% aqueous ammonia (15 : 1 : 0.1) to give a colorless solid of **18**, 34.4 mg (47%); recrystallization from acetone–hexane gave plates, mp 165—168 °C, $[\alpha]_D^{18}$ +16° (*c* 0.5, chloroform); UV λ_{max} (MeOH) 284 nm (log ε 4.32); IR(KBr): 1590, 1680, 1730 cm^{-1}; *m/e* 671 (M^+).

Found: C, 61.56; H, 9.06; N, 2.01%. Calcd for $C_{35}H_{61}NO_{11}\cdot1/2\ H_2O$: C, 61.74; H, 9.18; N, 2.06%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): δ 1.83 (3H d, $J\simeq1$ Hz, Me(20)], 2.50 (6H s, NMe_2), 4.18 (1H t, H-15a), 4.30 (1H d, H-1'), 4.46 (1H dd, H-15b), 4.66 (1H m, H-18), 5.85 (1H d, H-13), 6.35 (1H d, H-10), 7.17 (1H d, H-11); $J_{10,11}$ 15, $J_{13,14}$ 11, $J_{14,15a}$ 10, $J_{14,15b}$ 6.5, $J_{15a,15b}$ 10 Hz.

Deacetalation of ***18*** *(to Give* ***19****).* Compound **18** was treated similarly as described for **16** to give crude **19** in *ca.* 80% yield (the purity was estimated to be *ca.* 90%). Repeated column-chromatography gave no pure product. On TLC with chloroform–methanol–28% aqueous ammonia (10 : 1 : 0.1), it gave the spots of R_f 0.3 (**19**) and 0.24 (slight).

^{1}H-NMR (in $CDCl_3$ at 250 MHz; peaks for **19** were only cited): δ 4.24 (1H d, H-1'), 4.27 (1H dd, H-15b), 4.48 (1H t, H-15a), 5.88 (1H d, H-13), 6.21 (1H d, H-10), 7.18 (1H d, H-11), 9.80 (1H s, –CHO); $J_{10,11}$ 15.5, $J_{13,14}$ 10.5, $J_{14,15a}$ 10, $J_{14,15b}$ 6, $J_{15a,15b}$ 10 Hz.

*3,21,2',4'-Tetra-*O*-acetyl Derivative (***20***) of* ***18****.* A solution of **18** (82.9 mg) in pyridine (0.8 ml) containing acetic anhydride (0.21 ml) was kept at 50 °C for 2 d. Usual work-up gave amorphous solid of **20**, 92 mg (89%), $[\alpha]_D^{22}$ +65° (*c* 1, chloroform).

Found: C, 61.72; H, 8.12; N, 1.75%. Calcd for $C_{43}H_{69}NO_{15}$: C, 61.48; H, 8.28; N, 1.67%.

^{1}H-NMR ($CDCl_3$): δ 1.90, 2.05, 2.10 and 2.15 (each 3H s, Ac).

*3,21-Di-*O*-acetyl Derivative (***21***) of* ***18****.* A methanol solution (2.0 ml) of **20** (41.6 mg) was kept at 50 °C overnight. Evaporation gave a residue, which was chromatographed on a silica-gel column with chloroform–methanol–28% aqueous ammonia (25 : 1 : 0.1) to give an amorphous solid, 37.2 mg (99%), $[\alpha]_D^{23}$ +61° (*c* 1, chloroform): TLC: R_f 0.32 (*cf.* **17**: R_f 1) (20 : 1 : 0.1 chloroform–methanol–28% aqueous ammonia).

Found: C, 61.68; H, 8.50; N, 1.76%. Calcd for $C_{39}H_{65}NO_{13}$: C, 61.97; H, 8.64; N, 1.85%.

^{1}H-NMR (in $CDCl_3$ at 250 MHz): δ 0.89 (3H t, H-23), 1.10 [3H d, J 7 Hz, Me(16)], 1.11—1.24 [9H, Me(19) and $(OCH_2C\underline{H}_3)_2$], 1.31 [3H d, Me(6')], 1.57 (2H m, H-22), 1.92 [3H very narrow m, Me(20)], 2.04 and 2.11 (each 3H s, 3- and 21-*O*-Ac), 2.37 (1H t, J 10 Hz, H-3'), 2.51 (6H s, NMe_2), 3.04 (1H t, $J\simeq10$ Hz, H-4'), 3.12 (1H m, H-14), 3.30 (1H m, H-5'), 3.55 (1H dd, H-2'), 3.94 (1H dd, $J_{14,15a}$ 5 Hz, $J_{15a,15b}$ 10.5 Hz, H-15a), 4.29 (1H d, $J_{1',2'}$ 7.5 Hz, H-1'), 4.48 (1H t, J 10 Hz, H-15b), 4.59 (1H dd, J 3.7 and 7.5 Hz, H-18), 4.86 (1H br m, H-3), 4.96 (1H m, H-21), 5.77 (1H slightly br d, $J_{13,14}$ 10 Hz, H-13), 6.40 (1H sharp d, $J_{10,11}$ 15.5 Hz, H-10), 7.16 (1H slightly br d, H-11).

Irradiation of H-14 collapsed the doublet of H-13 to a singlet, the quartet of H-15a and the triplet of H-15b to an AB quartet in total, and the multiplet of H-21 to a quartet. Irradiation at δ 1.57 (H-22a,b) collapsed the triplet of H-23 to a singlet.

Deacetalation of ***21*** *(to Give* ***22****).* Treatment of **21** similarly as described for **16** gave an amorphous solid of **22** in 79% yield, $[\alpha]_D^{22}$ +61° (*c* 1, chloroform).

Found: C, 61.67; H, 8.12; N, 1.98%. Calcd for $C_{35}H_{55}NO_{12}$: C, 61.66; H, 8.13; N, 2.05%.

We are grateful to Professor Hamao Umezawa of Institute of Microbial Chemistry for his support and encouragement. We also wish to thank Mr. Saburo Nakada, Department of Applied Chemistry, Keio University, for the microanalysis, and Dr. Masa Hamada of Institute of Microbial Chemistry, for the bioassay. Thanks are also due to Miss Miyako Igarashi of our Institute for her helpful assistance to make the manuscript.

Studies on the Behavior of Natural Surfactant at the Oil-Water Interface. II. Behavior of Natural Surfactant at the Oil-Water Interface

Keizo OGINO,* Hitoshi YAMAUCHI, and Yoshinori UENO

Faculty of Science and Technology, Science University of Tokyo, Yamazaki Noda, Chiba 278

(Received January 20, 1981)

The behavior of natural surfactants was studied at an oil-water interface by measurement of the interfacial tension and the observation of the oil-water interface. Lecithin was used as an oil-soluble substance and sodium cholate was used as a water-soluble substance; *n*-paraffin, corn oil, unsaturated fatty acid and fatty alcohol were used as an oil phase. The reduction of interfacial tension was greatest in a dodecane–sodium cholate solution system, but the minimum interfacial tension was observed in an oleic acid–sodium cholate solution system. Spontaneous emulsification occurred in the oil phase when oleic acid was left in contact with sodium cholate solution. The most remarkable change was found in the system of oleic acid in contact with sodium cholate solution, in which crystal of cholic acid were formed at the interface.

At the oil-water inferface, various interfacial phenomena occur when the oil containing oil-soluble substance is allowed to contact the water containing water-soluble substance. Manabe and Okuyama[1] have reported that there are many natural surfactants, especially in living body.

We have studied the molecular interactions at the interface of oil/water systems with various kinds of additives with respect to the tendency of spontaneous emulsification,[2-4] and the behavior of natural surfactants, lecithin and cholesterol, at the oil-water interface.[5]

In this work, lecithin and sodium cholate were used as oil-soluble and water-soluble natural surfactants, respectively. Lecithin is an important constituent of biological membranes and has been used widely in field such as the food industry as an excellent emulsifier.[6-8] Sodium cholate to be used is one of the bile salts. Bile salts are necessary for absorption of oil-soluble vitamins such as Vitamin A, D, E, and K.[9-11] Further, it is known that cholesterol is solubilized by a lecithin-bile salt micelle.[12]

In the present investigation, the behavior of natural surfactants at the oil-water interface was studied by the measurements of interfacial tension; the interfacial products were observed by a polarizing microscope.

Experimental

Materials. *Natural Surfactants*: Lecithin from soybean, the so-called asolecithin (Associated Concentrates Inc.) of commercial grade containing 95—98% lipid, was used. Sodium cholate (Tokyo Kasei Ind. Ltd.) of reagent grade was used without further purification.

Oil Phase: Dodecane (Nikko petrochemical Co.), Corn oil (Ajinomoto Co.), *cis*-9-octadecenoic acid (oleic acid) and *cis*-9-octadecen-1-ol (oleyl alcohol) (Tokyo Kasei Co.) of a commercial grade were used without purification.

Water Phase: Double distilled and deionized water with an indicated resistivity of 18.0 megohm/cm was used.

Apparatus. The interfacial tension was measured by a Wilhelmy-type surface-tensiometer (Shimadzu Surface Tensiometer ST-1) and interfacial products were observed by a polarizing microscope with crossed nicols (Nippon Kogaku S-PO).

Procedure. Lecithin and sodium cholate were dissolved in oil and water, respectively, and the interfacial tension was measured at various concentrations of the solutes at 30 °C. These measurements were made 30, 50, and 15 min after the contact of oil and water phases in the case of dodecane and *cis*-9-octadecenoic acid, corn oil and *cis*-9-octadecen-1-ol, respectively. It was confirmed that the equilibria at these interfaces were reached after the times mentioned above.

Results and Discussion

The Lowering of Interfacial Tension. Figure 1 shows the effect of concentration of sodium cholate on the interfacial tension at the oil-water interface. As is shown, the interfacial tension decreased with increasing concentration of sodium cholate. In particular, the reduction of interfacial tension was the greatest in dodecane–sodium cholate solution system, but the minimum interfacial tension was observed in *cis*-9-octadecenoic acid–sodium cholate solution system, being about 1.7 dyn†/cm at higher concentration of sodium cholate. The interfacial tension of *cis*-9-octadecenoic acid–sodium cholate solution system was lower than *cis*-9-octadecen-1-ol. This may be due to a stronger

interaction between the carboxyl group of *cis*-9-octadecenoic acid and cholate ions than between *cis*-9-octadecen-1-ol and cholate ions.

Figure 2 shows the effect of the concentration of sodium cholate on the interfacial tension at the oil (containing 2×10^{-3} wt% lecithin)-water interface. As can be seen, the interfacial tension showed similar results to that of Fig. 1 except for dodecane, the interfacial tension of which was considerably lowered by the addition of a low concentration of lecithin. From the results, it was confirmed that lecithin affected most strongly the interfacial tension of dodecane–water.

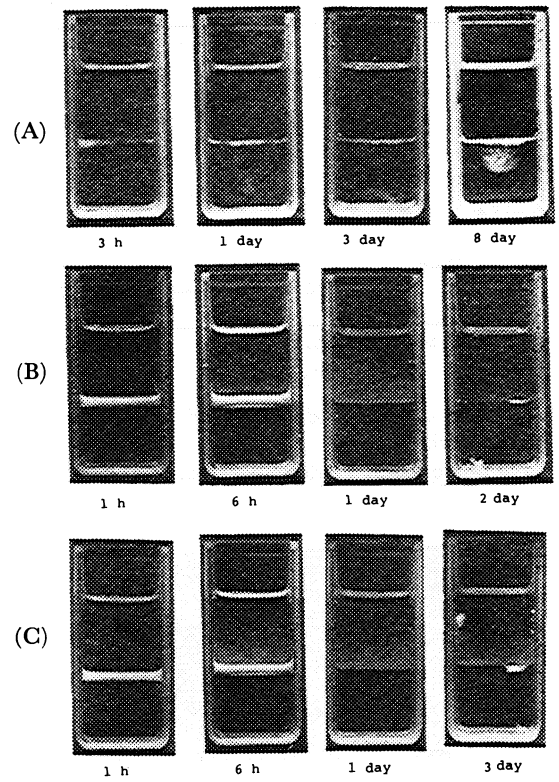

Fig. 5. The progress of spontaneous emulsification with time.
Water phase: sodium cholate 1×10^{-1} mol dm^{-3}.
Oil phase: (A) corn oil+lecithin 5×10^{-2} wt%. (B) *cis*-9-octadecenoic acid. (C) *cis*-9-octadecenoic acid+lecithin 1×10^{-2} wt%.

Figures 3 and 4 show the surface pressure (π)-area (A) curves calculated from Figs. 1 and 2 using the Gibbs equation. It is evident that the area is greatly decreased with increasing cholate ions at low surface pressure. This means that the molecules are tightly packed at higher surface pressure, the compressibility of the film being small.

Spontaneous Emulsification and Interfacial Product. Figure 5 shows the state when oils were left to stand in contact with sodium cholate solution. When corn oil containing lecithin was left in contact with aqueous solution, spontaneous emulsification occurred in the water phase.[5] However, no distinct change was recognized by the use of corn oil without lecithin. Further, the spontaneous emulsification was also observed when corn oil containing lecithin was left in contact with distilled water. From these results, it is found that lecithin affects the spontaneous emulsification when corn oil is used as the oil phase.

On the contrary, spontaneous emulsification occurred in the oil phase and the crystals were deposited at the oil-water interface when *cis*-9-octadecenoic acid was left in contact with sodium cholate solution. A similar change was also observed when *cis*-9-octadecenoic acid containing lecithin was used as the oil phase. However

Oil phase: *cis*-9-octadecenoic acid.
Water phase: sodium cholate 1×10^{-1} mol dm^{-3}.

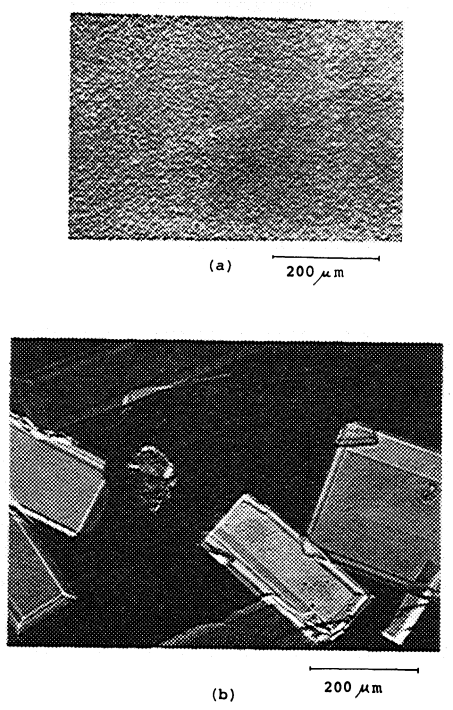

Fig. 7. The products formed at the oil-water interface.
(a) Thin milky film. Oil phase: dodecane+lecithin 1×10^{-2} wt%. Water phase: sodium cholate 1×10^{-1} mol dm^{-3}.
(b) Plate crystals. Oil phase: *cis*-9-octadecenoic acid +lecithin 2×10^{-2} wt%. Water phase: sodium cholate 1×10^{-1} mol dm^{-3}.

both spontaneous emulsification and crystal deposit were not observed when *cis*-9-octadecenoic acid containing lecithin was left in contact with water.[5] From these results, it is found that sodium cholate affects spontaneous emulsification when *cis*-9-octadecenoic acid is used as the oil phase.

Figure 6 shows the change of pH of the aqueous phase with time when *cis*-9-octadecenoic acid was left in contact with sodium cholate solution. It is clear from this figure that the initial pH of the water phase decreased rapidly with time. It seems that sodium ions of the water phase reacted with *cis*-9-octadecenoic acid, hydrogen ions of the water phase increased and some of the cholate ions transferred to the oil phase with the hydrogen ions. The results indicate that spontaneous emulsification or crystal deposit occur in the oil phase. Davies *et al.* showed that the spontaneous emulsification was caused by one or more of the following possibilities:[13,14] i) The instability of the interface due to a non-uniform diffusion of the components of the phases across the interface, which disturbs the interface violently enough to form droplets of the adjacent bulk phase. ii) An accompanying diffusion of oil and an additive into water, which results in a dilution of the additive by the water, leaving oil droplets to form an emulsion. iii) The temporary appearance of a negative interfacial tension which causes an enlargement of the interface area.

Schulman *et al.*[15,16] have shown that spontaneous emulsification occurs when a complex is formed between an oil-soluble substance and a water-soluble surfactant at the oil-water interface. The spontaneous emulsification of oil containing lecithin in contact with sodium cholate solution is attributed to the formation on liquid crystal of lecithin or to the formation of mixed micelle consisting of lecithin and sodium cholate.

Figure 7 shows photographs of the interfacial products. The thin milky film formed at the dodecane-sodium cholate solution interface is shown in Fig. 7-a. The plate crystals deposited at the *cis*-9-octadecenoic acid–sodium cholate solution interface are shown in Fig. 7-b. Crystals were obtained a few days after the oil and water phase came into contact at sodium cholate concentrations above 5×10^{-2} mol dm^{-3}. This crystal was identified to be a single crystal of cholic acid by the measurement of the melting point, IR spectroscopy and X-ray diffraction.

Similar results were obtained when (9*Z*,12*Z*)-9,12-octadecadienoic acid (linoleic acid) was used as the oil phase and were not obtained when *cis*-9-octadecen-1-ol was used. As mentioned above, it seems that the hydrogen ions of *cis*-9-octadecenoic acid, (9*Z*,12*Z*)-9,12-octadecadienoic acid and cholate ion in water affect the formation of this single crystal.

Cyclic Voltammetry of Aromatic Amine *N*-Oxides in Nonaqueous Solvents and the Stability of the Free Radicals Produced[1)]

Hiroshi MIYAZAKI, Yoshio MATSUHISA,† and Tanekazu KUBOTA*,†

Shionogi Research Laboratories, Shionogi and Co., Ltd., 5-12-4, Fukushima-ku, Osaka 553

†*Gifu College of Pharmacy, 6-1, Mitahora-higashi 5-chome, Gifu 502*

(Received January 27, 1981)

Cyclic voltammograms of aromatic amine *N*-oxides were recorded in nonaqueous solvents at various sweep rates less than 10 V/s. The measurement was carried out for both cathodic and anodic sweeps, and the sweep rate for obtaining a good cyclic voltammogram was correlated with the wave height of the a.c. polarogram in the reduction and oxidation processes, respectively. A good correlation was found between the sweep rate and the wave height in both the reduction and oxidation processes. This confirmed that the two values serve as good measures of the stability of the anion or cation free radical produced by the electrode reaction of the aromatic amine *N*-oxides. The data were also examined by comparison with results from an electron spin resonance study. Finally, the temperature effect on the cyclic voltammogram of pyridine *N*-oxide was investigated in detail.

The study of cyclic voltammetry (CV) of aromatic amine *N*-oxides was carried out in nonaqueous solvents to compare the results with those of our previous polarographic and electron spin resonance (ESR) investigations on the same compounds.[2-7)] The results of these CV studies are considered to be good measures of the reversibility of the electrode reaction[8)] and were expected to display good correlation with the previous results mentioned above.

Experimental

The CV measurement was made using a combination of a Yanagimoto Applied Potential Sweep Unit Model PE-21-TB2SS, a Yanagimoto polarograph P8-AP, a Hitachi Synchroscope Model V-104, and a Riken Denshi XY-Recorder Model D-51P to obtain a cyclic voltammogram at a sweep rate of 0.0017—10 V/s. As working electrodes, a PAR Model 9323 hanging mercury drop electrode (HMDE), a hanging mercury electrode (HME), and a platinum disk electrode (PDE: 2 mm in diameter) were used. All the measurements of samples, except for pyridine *N*-oxide (PNO: *vide infra*) were done at 25±0.1 °C by using the so called three-electrode-technique, a saturated calomel electrode (SCE) being employed as a reference electrode except for the low temperature measurement. The solvents used were *N*,*N*-dimethylformamide (DMF) and CH_3CN containing 0.1 mol dm^{-3} tetrapropylammonium perchlorate (TPAP) as the supporting electrolyte.

The cathodic sweep cyclic voltammogram of PNO was measured in the temperature range between 23.5 °C and −40

a) Data in DMF. b) Data in CH_3CN. c) Obtained with DME, and taken from Refs. 2, 3, 4, and 5. d) Obtained with HMDE. e) Taken from Refs. 2, 3, and 6. Here "Yes" means that the ESR spectra due to the anion or cation free radicals were recorded at room temperature. However, the free radicals of several *N*-oxides were obtained only at below 0 °C; in such a case the asterisk is put on "Yes" as superscript. f) Obtained with PDE at 600 r.p.m., and taken from Ref. 5. g) Obtained with PDE. h) The equation, $E_{1/2}=(E_{p,f}+E_{p,b})/2$, was used to determine the half-wave potential. Each value of $E_{p,f}$ and $E_{p,b}$ is for the CV curves at the sweep rate where the backward sweep wave becomes evident. See text for details. i) This is the value corresponding to the $(i_{p,b}/i_{p,f})=0.5$. See text for details.

°C.[10] A platinum wire was employed instead of the SCE, since the SCE can not be used at the lower temperatures.[9] HME was employed as a working electrode, the solvent being DMF containing TPAP. Note here that, since the PNO anion radical is unstable at room temperature (*vide infra*), checking the reversibility of the electrode process at the lower temperature was the most important problem for PNO.

The aromatic amine *N*-oxides used here, listed in Table 1, are the same ones previously studied with polarographic and ESR techniques.[2-7]

Results and Discussion

For the analyses of CV curves, the following methods were applied. The peak current of the backward sweep was measured by the switching potential current (SPC) method reported by Nicholson.[11-12] The value of the half-wave potential $E_{1/2}$ was cyclovoltammetrically determined by the equation $E_{1/2}=(E_{p.f}+E_{p.b})/2$, which is in principle applicable to the reversible redox system.[13] Here, $E_{p.f}$ and $E_{p.b}$ are the forward and the backward peak potentials, respectively. This equation gave $E_{1/2}$ values almost independent of the sweep rate and compatible with those determined polarographically. In the case of the cathodic sweep, generally speaking, the CV curves recorded in DMF with HMDE were almost the same as those obtained with PDE, and the difference is not remarkable. The CV data recorded with HMDE are given in Table 1, which also lists the other experimental results and, as references, our previously reported data. In the cathodic sweep cyclic voltammograms of the *N*-oxides in DMF the backward sweep waves were always observed for all the samples, except for PNO, at room temperature and at a sweep rate less than 10 V/s. Comparison with previous ESR and polarographic studies of the *N*-oxides[2-7], clearly shows that this backward sweep wave is due to the oxidation process of the anion radical produced by the cathodic sweep. The sweep rate to obtain the backward sweep wave would be related to the stability of the anion radical. In the case of PNO, we could not observe the backward sweep wave at room temperature even when the sweep rate is increased to 10 V/s, as shown in Fig. 1a. However, when the voltammogram was recorded at −30 °C and at a moderate sweep rate, the backward sweep wave was clearly observed, as is seen in Fig. 1b.[14] Since our previous study indicated that the ESR spectrum of the PNO anion radical was clearly obtained at about −50 °C by employing the electrochemical technique,[2] the above backward sweep wave must be due to the oxidation process of the PNO anion radical, in agreement with the ESR study.

Next we would consider the anodic sweep cyclic voltammogram in CH_3CN. Only four of the aromatic amine *N*-oxides studied here showed the backward sweep wave under the present experimental conditions (see Table 1). A typical compound, phenazine 5,10-dioxide, shows a clear backward sweep wave even at 0.1 V/s. This agrees with observations by other workers.[15] The cyclic voltammogram of quinoxaline 1,4-dioxide (Fig. 2) showed no clear backward sweep wave at the rate 0.1 V/s, but the curve is obviously observed at 2 V/s. The cation radical of this *N*-oxide

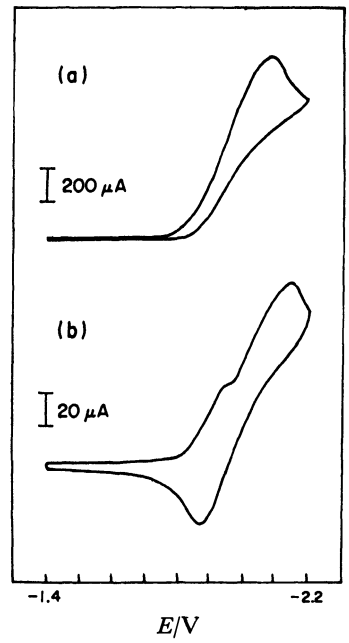

Fig. 1. Cyclic voltammograms of pyridine *N*-oxide (2.51×10^{-3} mol dm^{-3}) in DMF containing 0.1 mol dm^{-3} TPAP. Sweep rate and temperature were, respectively, 10 V/s and 23.5 °C for (a), and 8 V/s and −30 °C for (b). The electrode system was HME and platinum wire, the latter being used instead of SCE (see text).

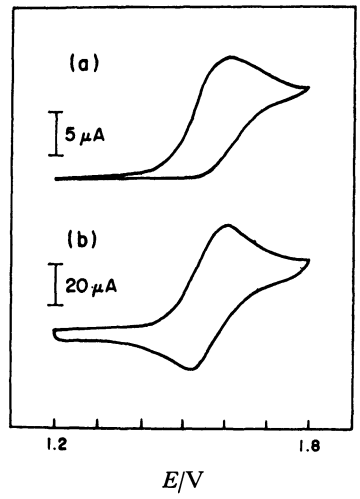

Fig. 2. Cyclic voltammograms of quinoxaline 1,4-dioxide (8.02×10^{-4} mol dm^{-3}) in CH_3CN containing 0.1 mol dm^{-3} TPAP at 25 °C. Sweep rate was 0.1 V/s and 2 V/s for (a) and (b), respectively. Reference electrode was SCE.

is unstable compared with that of phenazine 5,10-dioxide. In the case of pyrazine 1,4-dioxide, the cation radical was more unstable and therefore the backward sweep wave required a higher sweep rate. These observations agreed well with the results derived from our ESR study of cation radicals.[6]

Based on the discussion mentioned hitherto the sweep rate of the cyclic voltammogram should be closely correlated with the life time of the anion or cation free radical produced by the electrode reaction. Alternative-

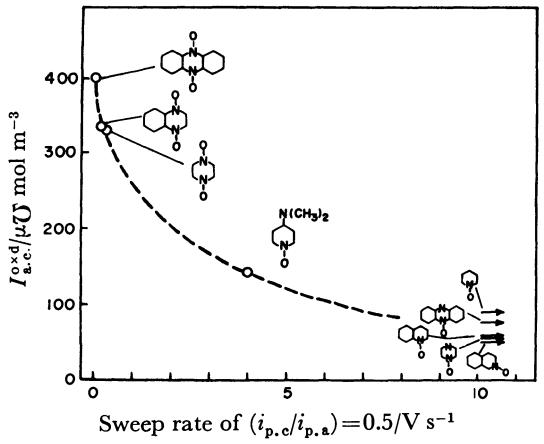

Fig. 3. Relationship between the wave height of the a.c. polarograms and the sweep rate at $(i_{p.c}/i_{p.a})=0.5$ of the cyclic voltammograms in the oxidation process of aromatic amine *N*-oxides in CH_3CN. The backward sweep wave was not observed for the compounds designated by arrows.

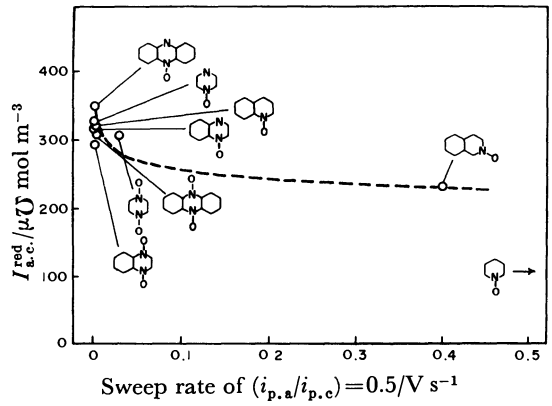

Fig. 4. Relationship between the wave height of the a.c. polarograms and the sweep rate at $(i_{p.a}/i_{p.c})=0.5$ of the cyclic voltammograms on the reduction process of aromatic amine *N*-oxides in DMF. See text on the pyridine *N*-oxide, the backward sweep wave of which was not observed at room temperature.

ly many reports support the fact that the wave height of an a.c. polarogram is a good measure of the reversibility of the electrode reaction.[16] Accordingly, the correlation between the sweep rate of the cyclic voltammograms and the wave height of a.c. polarograms was examined for the *N*-oxides studied. As a sweep rate of the former, the value of $(i_{p.b}/i_{p.f})=0.5$ was conveniently chosen (see Table 1), since the half wave height of a backward sweep against the forward sweep wave height would be considered to be related to the life time of the free radical.[8c] This value was obtained by plotting the $i_{p.b}/i_{p.f}$ value to the sweep rate, where $i_{p.b}$ and $i_{p.f}$ are the peak height of the backward and the forward sweep waves, respectively. The wave heights of a.c. polarograms, reported in our previous papers,[2-5] were obtained under the same experimental conditions and with the same compounds as those employed here. The data are cited in Table 1. In Figs. 3 and 4 the above correlation was illustrated. Figure 3 indicates that the wave height $I^{oxd}_{a.c}$ of the a.c. polarograms for oxidation and the sweep rate value at $(i_{p.c}/i_{p.a})=0.5$ have a good correlation with each other and that the larger the $I^{oxd}_{a.c}$ value and the smaller the sweep rate value, the more stable is the cation radical. The ESR spectra of the cation radicals of the three *N,N'*-dioxides and the 4-(dimethylamino)pyridine 1-oxide shown in Fig. 3 were successfully measured (*vide supra*).[6] As seen in Fig. 4, a correlation of the $I^{red}_{a.c}$ (wave height of a.c. polarogram for reduction) to the sweep rate value at the $(i_{p.a}/i_{p.c})=0.5$ was also obtained, although the relation was somewhat ambiguous compared with the case of Fig. 3. This is due to the high stability of the anion radicals of the *N*-oxides[2-5] as discussed hitherto, so that the $I^{red}_{a.c}$ values are rather large and the sweep rate values defined above are also small. From the results shown in Figs. 3 and 4, we may say that the potential sweep rate for yielding a cyclic voltammogram with a good backward sweep wave is a good measure for checking the reversibility of the electrode reaction of the aromatic amine *N*-oxides in nonaqueous solvents, and that a good correlation exists between the potential sweep rate and the wave height of a.c. polarograms or the stability of the free radicals of the *N*-oxides as studied by the ESR technique.

12) Using ferrocene as the standard (0.1 mol dm^{-3} TPAP/CH_3CN, Pt electrode) we compared the SPC technique with the conventional holding method.[8a,b] The result indicated that the former method is better than the latter, and it always leads to the 1.00 for the value of (backward sweep peak current$=i_{p.b}$)/(forward sweep peak current$=i_{p.f}$) despite of the selection of switching potentials. The value of $(i_{p.b}/i_{p.f})$ is calculated by the equation: $(i_{p.b}/i_{p.f})=(i^{\circ}_{p.b}/i^{\circ}_{p.f})+0.485\times(i^{\circ}_{sp}/i^{\circ}_{p.f})+0.086$. The i°_{sp} is the current at the switching potential. Here superscript zero means the current measured

from the galvanometer zero line, so that $i_{p,f}=i^{\circ}_{p,f}$.

An Optical Absorption Study of Trapped Electrons in γ-Irradiated 3-Methylhexane–2,2,4-Trimethylpentane–2,2-Dimethylbutane Mixture Glasses at 77 K

Toyoaki KIMURA,* Naoyuki OGAWA, and Kenji FUEKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 8, 1981)

An optical absorption study was made on trapped electrons in γ-irradiated 3-methylhexane–2,2,4-trimethylpentane–2,2-dimethylbutane glasses at 77 K. The absorption maximum of trapped electron spectra shifts to longer wavelengths and the trapped electron yield decreases with decreasing 3-methylhexane concentration. The observed spectral shifts were interpreted through a semicontinuum model calculation.

Excess electrons generated by ionizing radiation in polar and nonpolar matrices have been extensively studied by various experimental methods. Studies on electron mobilities in nonpolar hydrocarbon liquids have revealed that electron mobilities range over three orders of magnitude depending on the hydrocarbon liquids,[1] which reflects the strength of interaction between an excess electron and the medium. Measurements of the quasi-free electron state energy V_0 have also shown that the V_0 value differs considerably among hydrocarbons in the liquid state[2,3] as well as in the glassy state.[4] On the basis of the results from these two types of experiment, hydrocarbons can roughly be classified into two types: type I in which electron mobilities are high (>10 cm^2 V^{-1} s^{-1}) and the V_0 values are low, and type II in which electron mobilities are low (<1 cm^2 V^{-1} s^{-1}) and the V_0 values are high. It is well known that excess electrons in the type I hydrocarbons are not localized, whereas those in the type II hydrocarbons are localized. On the other hand, it is known that optical absorption spectra of trapped electrons (e_t^-) in hydrocarbon glasses at 77 K are similar to each other.[5] This may be due to the fact that hydrocarbon matrices studied so far belong to type II. Thus, it is of interest to investigate how the optical absorption spectrum of e_t^- would change if we could choose as matrices the hydrocarbons which do not belong to type II. Values of V_0 of the type I hydrocarbons, 2,2,4-trimethylpentane (224TMP) and 2,2-dimethylbutane (22DMB), and the type II hydrocarbons at 77 and 295 K are listed in the upper, middle and bottom portions in Table 1, respectively. The electron mobilities ($10 \gtrsim \mu_e \gtrsim 1$ cm^2 V^{-1} s^{-1}) and V_0 values in 224TMP and 22DMB lie between those in the type I hydrocarbons and those in the type II hydrocarbons. We have found that a mixture of 224TMP and 22DMB makes a clear glass at 77 K. We report here absorption spectra and yields of e_t^- in the mixed systems of 3-methylhexane(3MHx)–224TMP–22DMB. We used a mixture of 224TMP and 22DMB in 1 : 1 volume ratio (at room temperature), which will be designated as (224TMP–22DMB) in what follows.

TABLE 1. QUASI-FREE ELECTRON STATE ENERGIES IN SOME HYDROCARBONS

	V_0 at 77 K/eV	V_0 at 295 K/eV
Neopentane	0.33[a]	−0.38[c]
224TMP	0.57[a]	−0.17[c]

Experimental

3-Methylhexane (Tokyo Kasei, extra pure) and 2,2,4-trimethylpentane and 2,2-dimethylbutane (Tokyo Kagaku Seiki, standard pure) were degassed and then purified *in vacuo* three times using molecular sieves 13X which were heated at 550 K *in vacuo* for 12 h before use. The hydrocarbons were taken into a volumetric flask *in vacuo*, and vacuum distilled into optical cells. Samples were sealed off a vacuum line. The optical cells were made of Suprasil quartz and the optical path length was ≈2 mm. γ-Irradiation was made with ^{60}Co γ-rays to a dose of 1.0×10^5 rad. Optical absorption spectra were taken on a Hitachi 323 spectrophotometer. γ-Irradiation and optical absorption measurements were carried out at 77 K.

Results and Discussion

Optical Absorption Spectra. No optical absorption was observable for the γ-irradiated (224TMP–22DMB) samples in the wavelength range from 340 to 2000 nm over the dose range from 0.1 to 1.8 M rad. Thus, it is concluded that electrons cannot be stably trapped in the (224TMP–22DMB) glass at 77 K. The optical absorption spectrum of e_t^- in a 3MHx–(224TMP–22DMB) mixture glass has an absorption maximum at a wavelength longer than that in neat 3MHx glass. The e_t^- spectrum in a 0.5 electron fraction (e.f.) 3MHx–

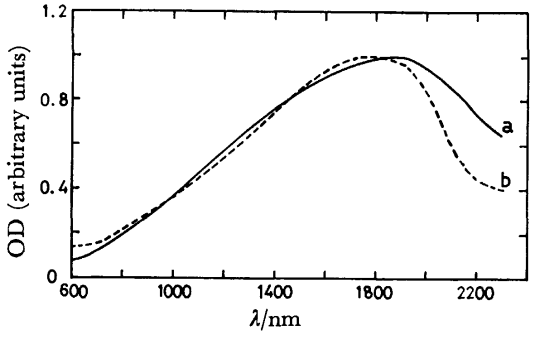

Fig. 1. Optical absorption spectrum of e_t^- in (a) 0.5 e.f. 3MHx–(224TMP–22DMB) and (b) 3MHx.

Table 2. Comparison of the observed wavelengths at the absorption maxima and the calculated wavelengths of the 1s→2p transition in 3MHx–(224TMP–22DMB) systems

[3MHx], e.f.	λ_{max}(obsd)/nm	$\lambda_{1s\rightarrow 2p}$(calcd)/nm
0.2	—	2030
0.4	1950	1780
0.5	1900	1720
0.6	1880	1670
0.8	1800	1570
1.0	1780	1500

(224TMP–22DMB) glass is shown in Fig. 1 together with that in neat 3MHx. Both spectra in Fig. 1 are normalized to the same peak height. It is seen in Fig. 1 that the spectrum in 0.5 e.f. 3MHx–(224TMP–22DMB) system has λ_{max} at 1900 nm (curve a), whereas that in neat 3MHx has λ_{max} at 1780 nm (curve b), and that the half-width of spectrum a is somewhat wider than that of spectrum b. The values of λ_{max} for e_t^- in 3MHx–(224TMP–22DMB) systems are listed in Table 2 as a function of e.f. of 3MHx.

Semicontinuum Model Calculation of the Optical Transition. In the present calculation we assumed four 3MHx molecules in a first solvation layer, which were arranged in such a way that the center of e_t^- and the midpoints of each C–C bond in the main chain of 3MHx lie on a straight line. The medium beyond the first solvation layer was treated as a continuous dielectric medium. The total energy for the ith state is given by Eq. 1,

$$E_t(i) = E_k(i) + E_e^s(i) + E_m^s(i) + E_e^l(i) + E_m^l(i) + E_q(i) + E_v + E_{HH}, \quad (1)$$

where E_K is the kinetic energy of the excess electron; E_e^s and E_m^s are short-range electronic and medium rearrangement energies, respectively; E_e^l and E_m^l are long-range electronic and medium rearrangement energies, respectively; E_q is the short-range repulsive interaction energy between the excess electron and the medium electrons; E_V is the energy required to form a cavity in the medium; and E_{HH} is the repulsive interaction energy between the hydrogen atoms in the different methyl groups nearest to the center of the cavity in which the electron is localized. Detailed expressions for each term in Eq. 1 are given in Ref. 6. The 1s→2p transition energy is then calculated using hydrogenic 1s and 2p wave-functions as Eq. 2. The physical parameters for the mixtures, A_{mix}, were estimated assuming a simple relation, $A_{mix}=\sum_i \chi_i A_i$, where χ_i and A_i are the mole fraction and the physical parameter value for hydrocarbon component i, respectively. The V_0 values for 224TMP and 22DMB were taken from Table 1. The V_0 value for 3MHx at 77 K is not available. Since V_0 values for the type II hydrocarbons at 77 K in Table 1 are close to 1.0 eV although it is somewhat lower for 3MP, we have assumed that V_0 for 3MHx is 1.0 eV at 77 K. Using these V_0 values the short-range repulsive interaction between the excess electron and the medium electrons was incorporated in the calculation. The values of 1s→2p transition energy in wavelength units are listed in Table 2. The calculated $\lambda_{1s\rightarrow 2p}$ is in semiquantitative agreement with the observed λ_{max}. The calculation accounts for a red shift in λ_{max} of e_t^- in 3MHx–(224TMP–22DMB) systems with decreasing concentration of 3MHx. This trend is unchanged even if different molecular arrangements in the first solvation layer are assumed. Such a shift is ascribed to the lower V_0 values for (224TMP–22DMB) compared with that for 3MHx.

$$h\nu_{1s\rightarrow 2p} = E_t(2p) - E_t(1s) \quad (2)$$

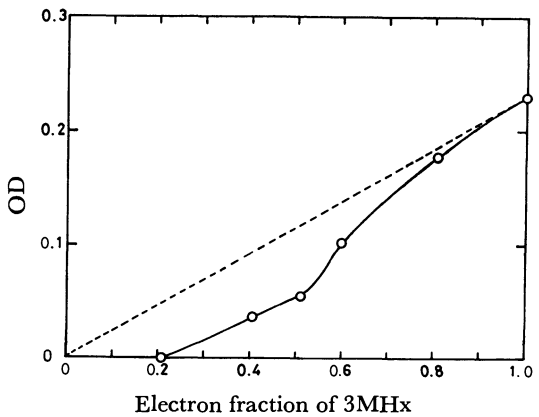

Fig. 2. Optical densities of e_t^- in 3MHx–(224TMP–22DMB) systems *vs.* electron fraction of 3MHx.

The Yield of Trapped Electrons. Trapped electrons in 3MHx decay quite slowly at 77 K. In 3MHx–(224TMP–22DMB)systems the decay rate of e_t^- increases with decreasing 3MHx concentration. Taking the decay into consideration, the optical density of e_t^- immediately after the 10 min γ-irradiation, normalized to the 1 mm optical path length, is shown in Fig. 2 as a function of e.f. of 3MHx. It can be seen from Fig. 2 that the optical densities of e_t^- in 3MHx–(224TMP–22DMB) systems are lower than those expected from a linear relationship (dashed line) between OD of e_t^- and e.f. of 3MHx, especially at lower concentrations, and that e_t^- is not observable for $\lesssim$0.2 e.f. 3MHx. The V_0 value for 0.2 e.f. 3MHx–(224TMP–22DMB) system in which no e_t^- is observable is calculated to be 0.67 eV. Then, we are tempted to say that electrons cannot be trapped in the glassy hydrocarbon matrices whose V_0 is lower than $\approx$0.67 eV.

The viscosity of 3MHx–(224TMP–22DMB) systems probably decreases with decreasing 3MHx concentration, which reflects on the decay rate of e_t^-. Thus, we cannot exclude the possibility that e_t^- has decayed out completely for low 3MHx concentrations before the optical measurements are made. Taking the case of 0.5 e.f. 3MHx–(224TMP–22DMB) system as an example, only 14% correction for the e_t^- decay is required for the observed OD at the shortest time to obtain OD at time zero**, whereas the observed e_t^- yield is about a half of that expected from a simple mixture law. Further, we note that the decay of e_t^- does not occur over an hour in 0.2 e.f. 1-propanol–(224TMP–

** Since the correction for e_t^- decay was made by extrapolation of data points from steady-state experiments, the resulting initial OD or e_t^- yield should not be taken as identical to that obtained by pulse radiolysis measurements.

22DMB) system.[7] These observations indicate that the matrix viscosity alone is insufficient for the interpretation of decrease in the e_t^- yield. The decrease in the e_t^- yield at lower 3MHx concentrations mentioned above may probably be explained in terms of lower V_0 and viscosity of (224TMP–22DMB). It should be pointed out that both lower values of V_0 and viscosity arise from a larger free volume in the medium.[8]

The present work was partially supported by the Nagoya University Computation Center.

Prediction of Adsorption Isotherms of Organic Compounds from Water on Activated Carbons. II.[1] Relative Adsorbabilities of Elements

Ikuo ABE,* Katsumi HAYASHI, and Mutsuo KITAGAWA**
Osaka Municipal Technical Research Institute, Ogimachi, Kita-ku, Osaka 530
***Society for Activated Carbon Research, Ogimachi, Kita-ku, Osaka 530*
(Received April 27, 1981)

Synopsis. In order to predict the adsorbability of organic compounds out of water onto activated carbon, the contribution of individual atoms to the adsorbability is calculated. The contribution of the carbon atom is positive, that of nitrogen and oxygen atoms is negative, and that of the hydrogen atom is very small.

Adsorption onto activated carbon provides a technique for purification of municipal and industrial wastewaters. In the design of such water purification facilities, equilibrium adsorption information is required. To reduce experimental work, it is desirable to predict the adsorbability of organic compounds.

In a previous paper,[2] the partition coefficients (α) of 93 organic compounds between the solution and the adsorbed phases at an infinite dilution have been calculated and correlated with the molecular weight (MW). Further details of the relationship between $\log \alpha$ and MW are illustrated in Fig. 1. For 52 aliphatic monofunctional compounds, a good linear relationship has been obtained, with a high correlation coefficient (r). Furthermore, the standard deviation (s), the t-value in the Student test, and the over-all goodness of fit expressed by means of the F-value indicate that the relationship is statistically significant. The adsorbability of the multifunctional compounds is lower than that of the monofunctional compounds. This result suggests that the adsorbability of oxygen and nitrogen atoms constituting the functional group is lower than that of the carbon atom. The over-all correlation coefficient is low for this reason.

The relationship between adsorbability and molecular weight can be expressed by the following equation:

$$\log \alpha = aMW + b = a(12N_C + 1N_H + 14N_N + 16N_O + \cdots) + b, \quad (1)$$

where N_C, N_H, N_N, and N_O are the number of carbon, hydrogen, nitrogen, and oxygen atoms, respectively, in a molecule, and a and b are constants. Equation 1 assumes that the individual atoms contribute to the adsorbability of the molecule by the relative magnitude of atomic weight.

In order to estimate the exact contribution of the individual atoms to the adsorbability, the a coefficients in Eq. 2 have been calculated by multiple regression analysis. The relative magnitude of these coefficients is a measure of the contribution to the adsorbability.

$$\log \alpha = a_C N_C + a_H N_H + a_N N_N + a_O N_O + \cdots + b. \quad (2)$$

The data of 91 compounds, excluding two halogenated compounds, have been processed by a SHARP PC-7300 computer, and Eq. 3 has been derived. Table 1 shows

Table 1. Squared correlation matrix for independent variables in Eq. 3

	N_C	N_H	N_N	N_O
N_C	1.000			
N_H	0.458	1.000

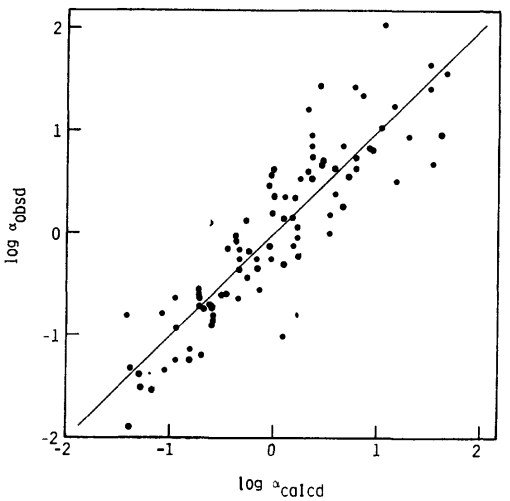

Fig. 2. Relationship between $\log \alpha$ observed and $\log \alpha$ calculated using Eq. 3.
$\log \alpha_{obsd} = 0.9998 \log \alpha_{calcd} - 0.0002$,
$n=91$, $r=0.8803$, $s=0.4090$, $F=306.3$***, $t=17.50$***.

$$\log \alpha = 0.4370N_C - 0.04465N_H - 0.2050N_N - 0.1302N_O - 1.501 \quad (3)$$

(n=91, r=0.8803, s=0.4161, F=74.01***, $t(N_C)$=13.60***, $t(N_H)$=−2.659**, $t(N_N)$=−2.104*, $t(N_O)$=−2.490*)

the squared correlation matrix for degree of collinearity between the variables used in Eq. 3.

A comparison of the coefficients in Eq. 3 yields the following conclusions. The presence of carbon atom in a molecule increases the adsorbability of the molecule. Nitrogen and oxygen atoms decrease the adsorbability. The contribution of hydrogen atom is much smaller than those of the other atoms.

Figure 2 shows the relationship between log α observed and log α calculated using Eq. 3. For the same 91 compounds, the relation between log α and the molecular weight is expressed by Eq. 4:

$$\log \alpha = 0.01639MW - 1.558. \quad (4)$$

(n=91, r=0.6050, s=0.6864, F=51.39***, t=7.169***)

These results indicate that Eq. 3 provide a better approximation than Eq. 4. The adsorbability of many compounds can be predicted from the molecular formula alone.

Metachromatic Absorption Spectra of Spin-labeled Mono- and Diaminoacridine Dyes Bound to Synthetic Polyelectrolytes[1]

Kiwamu YAMAOKA,* Takumi MATSUDA, and Tsuyoshi MURAKAMI
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received April 16, 1981)

Synopsis. Interactions between nitroxide spin-labeled dyes (Acridine Orange, Proflavine, and 9-aminoacridinium chloride) and poly(*p*-styrenesulfonate), polyphosphate, and polyacrylate were studied by measuring visible absorption spectra in aqueous solutions. The bound-dye spectra and equilibrium constants were determined by the principal-component-analysis method. The metachromatic behavior of dye–polymer complexes was clarified.

Previous reports have shown that acridine dyes labeled with stable nitroxides can be utilized in the study of dye–polymer interactions by two independent methods of ESR and optical absorption.[2] Molecular dynamics of spin-labeled dyes bound to various polyelectrolytes were clarified by analyzing ESR signals of spin moieties.[2,3] The characteristics of absorption spectra of newly synthesized spin-labeled and other related dyes were compared to determine the effect of attaching the labels.[4] For full utilization of these dyes as ESR-optical double probes, their spectral behavior should be assessed quantitatively in the presence of various polymers under diverse conditions.

In this Note, the metachromatic behavior of three spin-labeled acridine dyes toward three polyelectrolytes with different charged-groups will be reported. By applying the principal-component-analysis (PCA) method to the measured absorption spectra of each dye–polymer combination, the spectrum and the fraction of the bound-dye species were evaluated, together with the apparent equilibrium constant. For each polyelectrolyte, the bound-dye spectra are similar to those of the corresponding unlabeled or mother dyes, indicating that the metachromatic tendency is well preserved.

Experimental

Materials. Spin-labeled dyes were all described in detail previously: monopyrrolidinylated Proflavine (slPF),[2–4] monopiperidylated Acridine Orange (slAO),[2,3] and a spin-labeled 9-aminoacridinium chloride (slAA).[2,3,5] Their structural formulas are shown in Fig. 1. A 3-acetamido derivative of Proflavine (AcPF), for which R_1=–$NHCOCH_3$,[4] was used as the reference for slPF. Sodium salts of poly(*p*-styrenesulfonate) (NaPSS), polyphosphate (NaPP), and polyacrylate (NaPA) were also described elsewhere.[6,7]

Measurements and the Procedure for Data Analysis. Absorption spectra were measured at 25 °C as before.[4,6] A salt-free dye solution was titrated by the dropwise addition of a salt-free polymer solution in an absorption cell with a Gilson micropipet.[1] The molar absorption coefficients, ε, are defined both for dye–polymer solution and for the bound-dye species in the same manner as before.[6,7] A series of titration spectra for a given dye–polymer system were analyzed by the extended PCA procedure.[6–8]

Results and Discussion

Pure Spectra of Bound-dye Species and Equilibrium Constants.

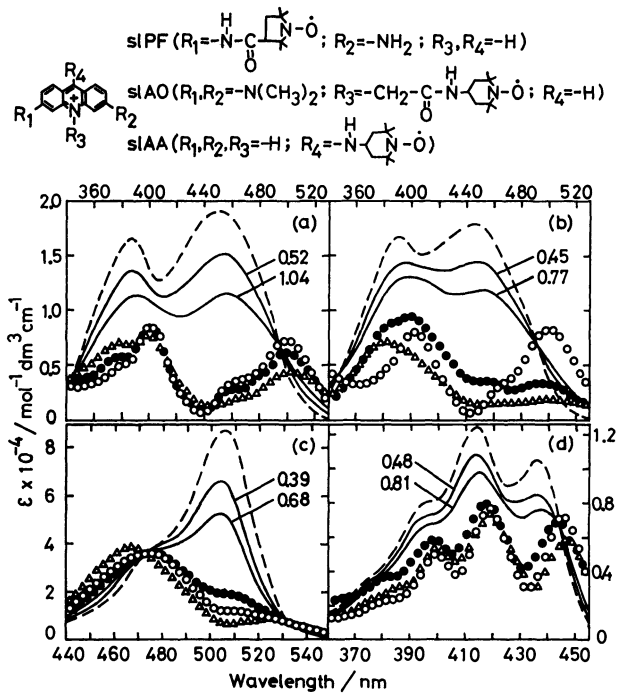

Fig. 1. Structural formulas of dyes and the bound-dye spectra extracted from the series of titration spectra of dye–polymer systems. (a) slPF, (b) AcPF, (c) slAO, and (d) slAA. Polymers bound by each dye are (○) NaPSS, (△) NaPP, and (●) NaPA. Broken lines are the spectra of dyes in the absence of polymers. Solid lines are typical spectra of the respective dye–NaPSS solutions, for which *P*/*D* values are indicated.

Figure 1 shows typical absorption spectra of each of four dyes in the presence and the absence of polyanions. For each dye–polymer system, five to nine titration spectra were measured at a neutral pH over a low *P*/*D* range (0 to 1—2), where *P* and *D* are the concentrations of a polymer in monomer unit and of a dye, respectively.[6] Only a few observed spectra were drawn here, since the details are the same as those reported previously.[6,7] The number of light-absorbing, independent species, *i.e.*, *components*, in each dye–polymer solution was concluded to be two, a free and a bound dye species, by comparing the eigenvalues of the correlation matrix.[6–8] In order to apply the extended PCA procedure to each dye–polymer combination, therefore, use was made of the binding scheme with the apparent equilibrium constant K and the adjustable parameter α: $K=[DP^*]/[D][P]^{\alpha}$. The notations are all the same as before.[6–8] Estimated values of K and α are given in Table 1.

The visible spectra of slPF and AcPF show two absorption bands (Figs. 1a and b) as a result of acylamination, differing from those of PF and Trypaflavine (TF).[2,4] The monosubstituted slPF and AcPF bind

a) Values in parentheses are the initial concentrations of the respective dyes in μmol/dm³. b) $K'=K[\mathrm{P}]^{\alpha-1}$ calculated at $P/D=1$.

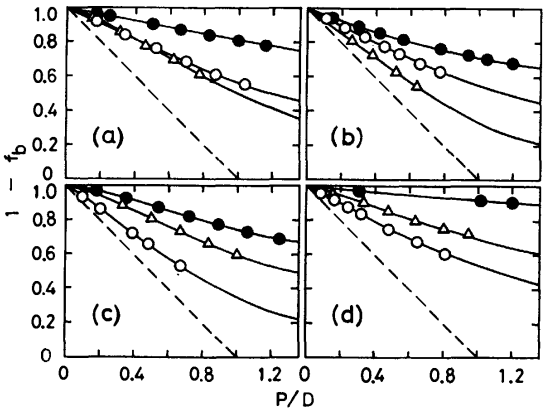

Fig. 2. The P/D dependence of the fraction of free-dye species remaining in the dye–polymer solution, $1-f_b$. (a) slPF, (b) AcPF, (c) slAO, and (d) slAA. The values obtained directly from the t matrix[6–8] are shown by the respective symbols which are the same as in Fig. 1. Solid lines are the binding curves which were calculated with values of K and α in Table 1.[6,7] Dashed lines indicate the relationship: $(1-f_b)=1-(D^b/P)(P/D)$, for which $D^b/P=1$, where D^b is the concentration of a dye species actually bound to the polymer site in solution.

to each of three polyanions, whose functional groups are phosphate, sulfonate, and carboxylate, giving rise to the bound-dye spectra, which resemble each other but differ from those obtained for symmetric TF.[6] Except for the case of AcPF–NaPP, each of the two bands of the bound-slPF or -AcPF spectrum is bathochromic and hypochromic relative to the corresponding band of the spectrum of free slPF or AcPF, showing a possible vibrational structure with energy separations of 1400—1650 cm^{-1};[9] the bound-dye spectra generally show neither hypsochromism nor a new *metachromasy band*, both of which are characteristic of a symmetric 3,6-diaminoacridine dye.[6] The bound-dye spectra of slAO (Fig. 1c) are typically metachromatic, showing the hypochromic effect with new broad bands—one on the longer and the other on the shorter wavelength side of the spectrum of free slAO.[6,10,11] The bound-dye spectra of slAA (Fig. 1d) are associated with a marked hypochromism and a modest bathochromic shift but without any metachromasy band; they are very similar to those of the unlabeled 9-aminoacridinium–polyanion systems reported previously.[7]

Fractions of Bound-dye Species. The fraction of bound-dye species in each solution, f_b, was calculated with values of K and α in Table 1.[6–8] The results are shown in Fig. 2, where the fraction of free-dye species remaining in solution, $1-f_b$, is plotted against P/D. Curvatures of the $(1-f_b)$ *vs.* P/D curves are mostly convex in the initial P/D range, corresponding to values of α larger than unity.[6,7] It is convenient to compare the values of $(1-f_b)$ at $P/D=1$, where equimolar amounts of a dye and a polyanion are present in solution. Spin-labeling lowers the fraction of bound-dye species slightly for slPF but considerably for slAA; the substitution of a label to the amino group may be responsible.[12] Polyacrylate shows a weak affinity toward each spin-labeled dye ($f_b<30\%$ at $P/D=1$) in a way similar to that noted for other dyes;[6,7] this is probably due to the weak acid nature of the side chain.

In conclusion, the spectra of spin-labeled acridine dyes bound to three representative polyanions are very similar to the bound-dye spectra of the corresponding nonlabeled dyes in the low P/D range and, therefore, these labeled dyes can be used for elucidation of metachromasy by the ESR and other magnetic methods.

The Crystal Structure of Dibromobis(iminodiacetamide)palladium(II)

Masao SEKIZAKI

College of Liberal Arts, Kanazawa University, Marunouchi, Kanazawa 920

(Received April 22, 1981)

Synopsis. The crystals are triclinic, $P\bar{1}$. R is 0.047 for 1617 independent non-zero reflections. The complex has a centrosymmetric square-planar coordination, with two imino nitrogen and two bromine atoms in *trans* positions.

Iminodiacetamide, $HN(CH_2CONH_2)_2$ (abbreviation, $idaaH_2$), acts as a terdentate ligand to the copper(II)[1] and nickel(II)[2] atoms through one imino nitrogen and two amide oxygen atoms. However, the molecular structures of these two complexes are different, as is shown in Fig. 1. If some other transition metals are used, complexes with different structures can be expected. With this expectation, the palladium(II) complex has been prepared and its crystal structure has been analysed.

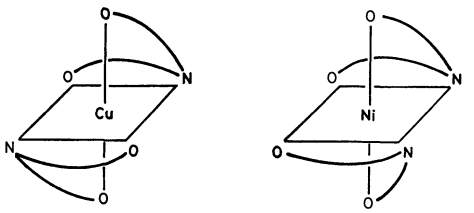

Fig. 1. The structures of $[Cu(idaaH_2)_2]^{2+}$ and $[Ni(idaaH_2)_2]^{2+}$.

Experimental

Preparation of the Complex. Palladium metal powder (0.5 g) was dissolved in an excess amount of a hot conc HBr–HNO_3 mixture (3 : 1 in volume). To this solution, an aqueous solution of 0.2 g of the ligand prepared by a method previously reported[1] was added. The mixture was then kept at pH 2—3 by the use of an HBr or KOH solution, after which it was slowly cooled to room temperature until yellowish-brown plate crystals precipitated.

Measurement of Intensity Data. A crystal with dimensions of 0.1 mm × 0.1 mm × 0.1 mm was selected. The intensities were measured up to $2\theta=60°$ on a Philips PW1100 four-circle diffractometer with Mo $K\alpha$ radiation monochromated by a graphite plate (θ-2θ scan). The 1617 independent reflections with $|F|>3\sigma$ were used with no corrections for absorption and extinction effects ($\mu r=0.3$).

Analytical and Crystal Data. Found: C, 17.92; H, 3.15; N, 15.49%. Calcd for $C_8H_{18}N_6O_4PdBr_2$: C, 18.18; H, 3.43; N, 15.90 %. F. W.=528.50. Triclinic, $a=9.694(2)$, $b=7.434(2)$, $c=6.505(2)$ Å, $\alpha=88.51(4)$, $\beta=101.34(4)$, $\gamma=71.50(2)°$. $U=434(1)$ Å^3. $D_x=2.02$ g/cm^3. $Z=1$. Space group $P\bar{1}$. $\mu=59.3$ cm^{-1} (Mo $K\alpha$ radiation, $\lambda=0.7107$ Å).

Determination and Refinement of the Structure. The structure was determined by means of a heavy-atom method. The block-diagonal least-squares refinement was carried out with the weights of 1.0 for $|F_o|>1.3$ and 0.5 for the others. The positional parameters of all the hydrogen atoms obtained by means of a D-Fourier synthesis were refined with the isotropic temperature factors of 4.0 Å^2. The final R was 0.047. The atomic scattering factors were taken from Ref. 3, together with the anomalous scattering factors, f', of the palladium and bromide ions. A FACOM M-160 computer at the Data Processing Center of Kanazawa University and a FACOM M-200 computer at the Computation Center of Nagoya University were used. The final atomic parameters are listed in Table 1.†

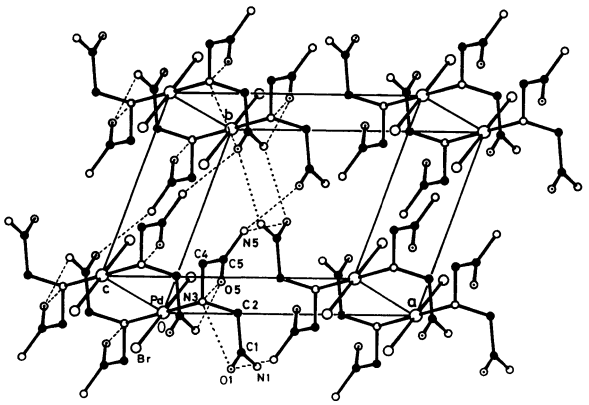

Fig. 3. Crystal structure. Dashed lines exhibit hydrogen bonds.

Description of the Structure

The molecular structure is shown in Fig. 2, along with the bond lengths. The bond angles are listed in Table 2.

The complex is square-planar, with the central atom lying on a center of symmetry of the triclinic unit cell. The bromide ions coordinate in *trans* positions of the square-plane so as to form a non-ionic complex. Each of the iminodiacetamide molecules acts as a unidentate ligand through the imino nitrogen atom; the two amide groups are uncoordinated. This coordination mode of the ligand molecule is different from that for the copper(II)[1] or nickel(II)[2] complex (Fig. 1). Details of the differences will be discussed elsewhere in comparison with other metal–iminodiacetamide complexes.

Table 3. Hydrogen bonds (l/Å)

D —— H···A[a]				D–H	H–A	D–A
N(3)(x,y,z)H	O(1)(	x,	y, z)	0.77	2.47	2.86

N(1)(x,y,z)Ha	O(1)(1−x,	−1−y,	$-z$)	0.96	2.08	2.98
N(1)(x,y,z)Hb	O(5)(	x,	y, −1+z)	0.68	2.24	2.83
N(5)(x,y,z)Ha	O(1)(1−x,	$-y$,	1−z)	0.92	2.06	2.98
N(5)(x,y,z)Hb	O(1)(	x,	1+y, z)	1.49	2.62	3.17
N(5)(x,y,z)Hb	Br (	x,	1+y, z)	1.49	2.08	3.50

a) D, hydrogen donor; A, hydrogen acceptor.

The crystal structure is shown in Fig. 3. The hydrogen bonds are shown in this figure and also in Table 3.

The amide groups turn their oxygen atoms to the palladium atom, and a bifurcated intramolecular hydrogen bond is formed with the imino nitrogen atom, as is shown in Fig. 2 by dashed lines. The two amide nitrogen atoms approach the oxygen atoms of the neighboring molecules to form intermolecular hydrogen bonds in the directions of [1$\bar{1}$0], [100], [010], and [001]. The three-dimensional network is, thus, completed by these N–O-type hydrogen bonds. No contacts shorter than 3.5 Å are, however, observed around the bromine atom.

The author is grateful to Professor Seiji Sugiura of Kanazawa University for the use of the diffractometer.

The Action of Boron Trifiuoride on Aromatic Nitrile Oxides

Shinsaku SHIRAISHI,* Tadashi SHIGEMOTO, Masatoshi MIYAHARA, and Shojiro OGAWA
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received July 14, 1980)

Synopsis. The action of boron trifluoride etherate on stable aromatic nitrile oxides effected the isomerization of nitrile oxides into isocyanates competitively with their dimerization to 1,4,2,5-dioxadiazines and/or (1,2,4-oxadiazol-4-io) oxytrifluoroborates. Quenching the reaction with methanol at an earlier stage of the reaction gave methyl benzohydroximate. The reacion was interpreted in terms of the initial coordination of BF_3 with the nitrile-oxide-oxygen atom.

We found the catalytic isomerization of stable aromatic nitrile oxides (NO, **1**) into isocyanates with some Lewis acids. Morrocchi and his co-workers reported the reaction of 2,4,6-trimethylbenzonitrile oxide (**1b**) with BF_3 forming 3,5-bis-(2,4,6-trimethylphenyl)-1,2,4-oxadiazol-4-io]oxytrifluoroborate (**5b**) and 3,6-bis(2,4,6-trimethylphenyl)-1,4,2,5-dioxadiazine (**4b**),[1] but they did not mention the formation of isocyanate. No catalytic isomerization of nitrile oxides has been reported except that with sulfur dioxide, which has been established to proceed *via* a 1,3-dipolar cycloadduct.[2] Here we report the multiplicity of the action of boron trifluoride on stable nitrile oxides.

Results and Discussion

An equimolar reaction of 2,3,5,6-tetramethylbenzonitrile oxides (**1a**) with $BF_3 \cdot OEt_2$ in refluxing dichloromethane gave 2,3,5,6-tetramethylphenylisocyanate (**2a**) in 55% yield. The treatment of the reaction mixture with methanol improved the recovery of **2a** up to 78% as methyl 2,3,5,6-tetramethylphenylcarbamate (**3a**). Various Lewis acids were also found to effect the isomerization of NO (Table 1), though in unsatisfactory yields because of the formation of a sticky mass. The reaction with $BF_3 \cdot OEt_2$ was rather clean, though, and so a detailed investigation was conducted on it (Table 2). The products varied with the reaction conditions employed. In the reaction in dichloromethane, **3a** was obtained as the sole isolable product, but in benzene, 2,4-bis-(2,3,5,6-tetramethylphenyl)-1,4,2,5-dioxadiazine (**4a**) was obtained along with **3a**. In toluene or xylene, a small amount of [3,5-bis(2,3,5,6-tetramethylphenyl)-1,2,4-oxadiazol-4-io]oxytrifluoroborate (**5a**) was obtained in aditdion to **3a** and **4a**. On the contrary, **5a** was the main product in ether, accompanied by a small amount of **3a**. In diisopropyl ether, the three products were obtained in comparable yields. It is noteworthy that the formation of **5a** was favorable compared with that of **4a** in a more polar solvent and that of **4a** in a less polar one. Table 2 also shows that the molar ratio of BF_3/NO influences on the products composition in the reactions in benzene or ether. Morrocchi *et al.* reported the reaction of **1b** with gaseous BF_3 or $BF_3 \cdot OEt_2$ forming **4b** and **5b**.[1] They suggested that **4b** was formed by the bimolecular cyclization of BF_3 coordinated NO. This speculation seems inconsistent with our experimental

TABLE 1. YIELD OF THE URETHANE IN THE REACTION OF THE NITRILE OXIDE WITH VARIOUS LEWIS ACIDS

Nitrile oxide	Lewis acid	Product	Yield/%

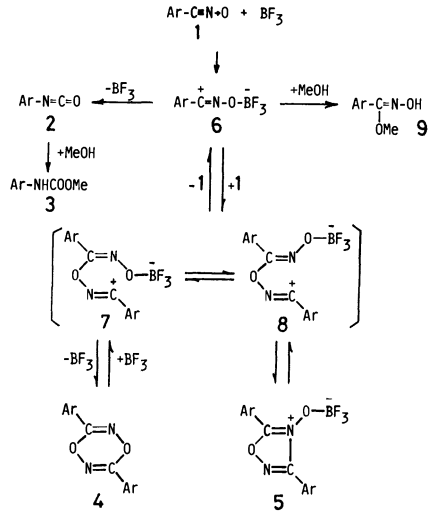
	0.75	9	0	65
	0.50	7	0	57[a]
	0.38	7	0	39[b]
	0.20	0	0	27[c]

a) A small amount of **9a** was also obtained. b) Unreacted **1a** and **9a** were recovered in 19 and 15% yields respec tively. c) **9a** and **1a** were also recovered in 36 and 16% yields respectively.

results. If it were the case, **4a** should be formed favorablly at a higher BF_3/NO ratio, but our result was the opposite as seen in the reactions in benzene. Furthermore, when the reaction was quenched with methanol soon after the addition of $BF_3 \cdot OEt_2$ in the solution of **1b**, methyl 2,4,6-trimethylbenzohydroximate (**9b**) was obtained in a moderate yield in the reaction in either benzene or ether. **9b** was obtained by Grundmann and Frommeld[3] by the methanolysis of **1b** with sulfuric acid. The result implies that the reaction proceeds through the initial coordination of BF_3 with the NO oxygen atom. A subsequent reaction of the free NO with the BF_3-coordinated one (**6**) is considered to afford **4** and **5**. At this stage, two conformers, **7** and **8**, are conceivable for the intermediate; **8** is more stable in polar solvents, and **7** in less polar ones. **7** and **8** may lead to **4** and **5** respectively.

The treatment of **4a** with $BF_3 \cdot OEt_2$ in benzene and subsequently with methanol gave **3a** in 75% yield, but in ether no change was observed. Nor was change observed in diisopropyl ether, where the treatment of **1a** with BF_3 gave **3a** as well **4a** and **5a**. Furthermore, **5a** was confirmed not to be affected by $BF_3 \cdot OEt_2$ in either benzene or ether. This indicates that no interconversion between **2a**, **4a**, and **5a** in the ethereal solvents takes place and that the unimolecular rearrangement fo **6** may be a route to **2** except in benzene, where



1~9 : Ar = a) 2,3,5,6-$(CH_3)_4C_6H$, b) 2,4,6-$(CH_3)_3C_6H_2$

Scheme 1.

a route *via* **4** cannot be definitely ruled out.

The reaction of **1a** with $BF_3 \cdot OEt_2$ in anisole gave *p*-methoxybenz-2,3,5,6-tetramethylanilide (**10a**) in 68% yield. This may be formed by a Friedel-Crafts reaction of the isocyanate formed with anisole.[4]

Experimental

The melting points are uncorrected. The column chromatography was conducted on silica gel (Waco-gel C-200) with chloroform as the eluent. The IR and ^1H NMR were measured in a KBr disk and in $CDCl_3$ respectively.

Materials. The nitrile oxides (**1a**) and (**1b**) were prepared according to Grundmann and Richter's procedure.[5] The Lewis acids were distilled under nitrogen before use. The solvents were purified and dried by usual methods.

Reactions of **1a** *with* $BF_3 \cdot OEt_2$. *In Dichloromethane*: Into a solution of **1a** (351 mg, 2.0 mmol) in dichloromethane (50 ml) $BF_3 \cdot OEt_2$ (250 μl, 2.0 mmol) was added. The solution was then heated to reflux for 2 h. The subsequent evaporation of the solvent gave an oil, which was treated with column chromatography to give 192 mg (55%) of **2a**, mp 24—25 °C. IR(neat): 2200 cm^{-1} (N=C=O). Treating it with methanol at room temperature (r.t.) overnight gave 224 mg (99%) of **3a**: mp 156—157 °C. IR: 3920 (NH), 1720 cm^{-1} (C=O). ^1H-NMR: δ 2.15 (6H, s, Me), 2.26 (6H, s, Me), 3.75 (3H, s, OMe), 6.96 (1H, s, ArH). Found: C, 69.40; H, 8.38, N, 6.89%; M^+, 207.1294. Calcd for $C_{12}H_{17}NO_2$: C, 69.54; H, 8.27; N, 6.76%, M^+, 207.1258.

The addition of methanol (10 ml) to the reaction mixture after the reaction and subsequently letting it stand at r.t. overnight gave **3a** in 78% yield on column chromatography. This methanol treatment was applied to all the working-up steps hereafter for the full recovery of the **2** in the form of **3**.

Reactions with the other Lewis acids and working-up were conducted similarly. The results are summarized in Table **1**.

In Benzene: A solution of **1a** (1.0 mmol) and $BF_3 \cdot OEt_2$ (1.0 mmol) in benzene (20 ml) was allowed to stand at 25 °C for 3 d under nitrogen. After methanol treatment of the reaction mixture without separating a solid precipitate a precipitate was taken by filtration (67 mg). The filtrate was evaporated to give an oil, column chlomatography of which gave 9 mg of the same solid as was separated above from an earlie elute, **4a**; mp 195—198 °C (from methanol). The total yield was 43%. From the later elute, 76 mg (37%) of **3a** were obtained. **4a**: IR: 2860—3000, 1635, 1615, 1590, 1460, 1330, 1025, 820 cm^{-1}. ^1HNMR: δ 2.26 (12H, s, Me), 2.33 (12H, s, Me), 7.06 (2H, s, ArH). Found: C, 75.41; H, 7.74; N, 7.89%; M^+, 350.1954. Calcd for $C_{22}H_{26}N_2O_2$: C, 75.40; H, 7.48; N, 7.99%; M^+, 350.1993.

In Ether: A solution of **1a** (2.0 mmol) and $BF_3 \cdot OEt_2$ (0.40 mmol) in ether (20 ml) was kept at 25 °C for 3 d. The white needles of **5a** which precipitated were collected by filtration, 113 mg (27%); mp 203—205 °C (from benzene–pet. ether). Methanol treatment of the filtrate and working-up with column chromatography gave 55 mg (16%) of **1a** and 150 mg (36%) of **9a** mp 198—200 °C. Neither **3a** nor **4a** was obtained. **5a**: IR: 2840—3000, 1580, 1050, 860 cm^{-1}. ^1H NMR: δ 2.18 (6H, s, Me), 2.20 (6H, s, Me), 2.32 (12H, s, Me), 7.19 (1H, s, ArH), 7.26 (1H, s, ArH). Found: C, 62.95; H, 6.23; N, 6.56%. Calcd for $C_{22}H_{26}BF_3N_2O_2$: C, 63.17; H, 6.27; N, 6.70%. **9a**: IR: 3200—4000 (OH), 1650 cm^{-1}(C=N). ^1H NMR: δ 2.18 (6H, s, Me), 2.23 (6H, s, Me), 3.74 (3H, s, OMe), 7.00 (1H, s, ArH), 7.90 (1H, broad,OH). Found: C, 69.54; H, 8.34; N, 6.83%; M^+, 207.1257. Calcd for $C_{12}H_{17}NO_2$: C, 69.54; H, 8.27; N, 6.76%; M^+, 207.1258.

The reaction in toluene, xylene, or diisopropyl ether was conducted and worked-up in almost the same manner.

In Anisole: The reaction was conducted using 1 mmol each of **1a** and $BF_3 \cdot OEt_2$ in 10 ml of anisole at r.t. for 3 d. Methanol treatment and solvent evaporation gave an oil, the trituration of which with ether and subsequent filtration gave 123 mg of *p*-methoxybenz-2,3,5,6-tetramethylanilide (**10a**). From the filtrate, 16 mg (9%) of **4a** and 71 mg of **10a** were obtained on column chromatography. The total yield of **10a** was 68%. **10a**, mp 225—227 °C (from benzene–pet. ether): IR: 3285 (NH), 2840—3020, 1630 cm^{-1} (C=O). ^1H NMR: δ 2.11 (6H s, Me), 2.21(6H, s,Me), 3.28 (3H,s, OMe), 6.84(1H, s,ArH), 6.92 (2H, d, ArH), 7.35 (1H, broad, NH), 7.83 (2H, d, ArH). Found: C, 75.84, H, 7.40; N, 4.55%; M^+, 283.1581. Calcd for $C_{18}H_{21}NO_2$: C, 76.30, H, 7.47; N, 4.94; M^+, 283.1571.

Quenching with Methanol. Ten minutes after the addition of $BF_3 \cdot OEt_2$ (0.5 mmol) to a solution of **1b** (161 mg, 1.0 mmol) in ether (50 ml), methanol (5 ml) was added to the solution. The mixture was kept standing at r.t. for 3 d. The subsequent solvent evaporation and column chromatography gave 13 mg (8%) of **1b** and 116 mg (60%) of **9b**; mp 140—141 °C (lit,[3] 140—141 °C). A similar reaction in benzene gave 4% of **1b**, 14% of **4b** (mp 171—174 °C (lit,[1] 172—173 °C)), and 54% of **9b**.

A similar reaction of **1a** in ether afforded 74% of **9a** as the sole isolable product.

Reaction of **4a** *with* $BF_3 \cdot OEt_2$. A solution of **4a** (88 mg, 0.25 mmol) and $BF_3 \cdot OEt_2$ (65 μl, 0.50 mmol) in benzene (20 ml) was let stand at 25 °C for 3 d. The subsequent methanol treatment of the solution and evaporation of the solvent gave a solid, which afforded 12 mg (14%) of **4a** and 78 mg (75%) of **3a** on column chromatography. A similar treatment of **4a** in ether or diisopropyl ether only resulted in no change.

Solid Phase Synthesis of Crystalline Protected Penta-L-tryptophan Methyl Esters

Masaaki UEKI,* Shigeru IKEDA, and Takashi HANDA

Department of Applied Chemistry, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 26, 1980)

Synopsis. Solid phase syntheses of protected tryptophan homo-oligomers were accomplished by utilizing dimethylphosphinothioyl(Mpt) group as an N^{α}-amino protecting group which was removed by treatment with triphenylphosphine dihydrochloride. By measurements of the ultraviolet and fluorescence spectra it was ascertained that no modification on the tryptophan indole ring had occurred during these syntheses.

Studies on conformation of tryptophan containing peptides have restriction because of difficulty in synthesizing pure model peptides. The usual synthesis by the use of *t*-butoxycarbonyl (Boc) group as an N^{α}-amino protecting group is not applicable to the synthesis of tryptophan containing peptides without special care because *t*-butylation of the tryptophan indole ring easily occurs during deprotection by trifluoroacetic acid.[1] Occurrence of modification of the indole nucleus can be most conveniently detected by fluorescence spectrum measurement.[2]

Recently we reported that the diphenylphosphinothioyl (Ppt) group was useful for the synthesis of tryptophan containing peptides because Ppt–Cl, a by-product formed in the deprotection step, did not modify the indole ring.[3,4] Lately dimethylphosphinothioyl (Mpt) group was found to be much more easily removable than the Ppt group and especially suitable for solid phase synthesis as shown in the synthesis of Leu^5-enkephalin and its D-Ala^2 analog.[5] In this work solid phase synthesis of tryptophan oligomers by use of Mpt-tryptophan was tried.

The *N*-Mpt group can be removed by the hydrogen chloride reagents used generally in peptide synthesis. As an especially effective reagent for the removal of the Mpt group, hydrogen chloride absorbed in a solution of triphenyl phosphine (TPP) in dichloromethane is recommended. TPP is added; firstly because it can suppress the acidity of HCl through the salt formation with TPP (pK_a 2.3 in 80% ethanol)[6] and secondly because it makes it possible to prepare a storable dichloromethane solution of HCl of practically useful concentration. The effectiveness of the acidity control of HCl by TPP was made clear by comparison of deprotection rates of Boc- and Mpt-di-L-tryptophan methyl esters in the presence or absence of TPP. The results are summerized in Table 1. The rate of removal of the Boc group which needs sufficient proton concentration was markedly lowered by the addition of TPP. On the other hand the removal rate of the Mpt group was affected only slightly.

Table 1. Deprotection rate of R–L-Trp–L-Trp–OCH_3

Reagent	R=Mpt k/h^{-1}	R=Boc k/h^{-1}
0.1 M HCl/CH_2Cl_2	1.90	2.40
0.1 M HCl (0.1 M TPP)/CH_2Cl_2	1.65	0.027

The stability of tryptophan during the course of deprotection of the Mpt group was ascertained by measuring the per cent recovery of tryptophan with an amino acid analyzer. When Mpt-L-tryptophan was deprotected by treating with 0.2 M† HCl (0.2 M TPP)/CH_2Cl_2 a clear colorless solution resulted to give 98% recovery of tryptophan. No ninhydrin-positive spot other than tryptophan was detected by silica gel thin layer chromatography.

Solid phase syntheses of protected penta-L-tryptophan methyl esters were performed on the automatically programmed Beckman model 990 peptide synthesizer.

Table 2. Properties of protected tryptophanhomo-oligomers

Compound	Mp/°C	$[\alpha]_D^{25}$(deg)	Found (Calcd)(%) C	H	N

† 1 M=1 mol dm^{-3}.

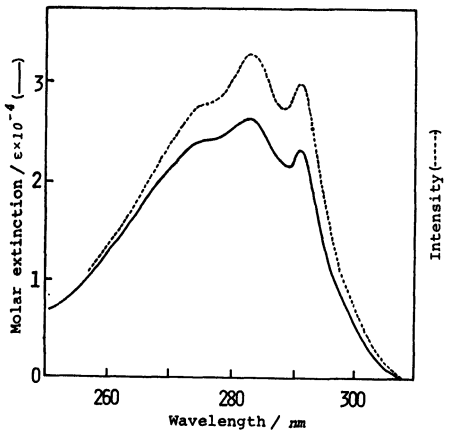

Fig. 1. a) UV spectrum of **1**(——) in methanol. b)Fluorescences excitation spectrum of **1** (emmission at 340 nm) (------) in methanol.

N^{α}-Mpt-penta-L-tryptophan methyl ester (**1**) was separated from the resin support by transesterification.[7] The crude product was purified by gel chromatography on Sephadex LH-20 and recrystallization from ethanol. Pure **1** was obtained in 60% yield as colorless crystals.

In order to know the effect of *N*-terminal group N^{α}-Boc-penta-L-tryptophan methyl ester (**2**) was also synthesized by coupling tetra-L-tryptophan resin with Boc-L-tryptophan. Compound **2** was obtained in 66% yield after the same processes of isolation and purification used in the synthesis of the Mpt derivative. The N^{α}-acetyl (Ac) derivative was obtained in 66% yield by treating unprotected penta-L-tryptophan resin with acetic anhydride and triethylamine.

Among the three types of protected-penta-L-tryptophan methyl esters the Mpt derivative showed the highest solubility in organic solvents such as methanol.

N^{α}-Mpt-tri- and tetra-L-tryptophan methyl esters were synthesized according to the same solid phase procedures. N^{α}-Mpt-mono- and di-L-tryptophan methyl esters were obtained by a liquid phase method. The physical properties and elemental analysis data of all the synthetic peptides are summarized in Table 2.

Chemical purity was checked by high performance liquid chromatography by adopting an ODS support and a linear (0 to 3%) methanol–chloroform gradient for elution. Each peptide appeared as a single peak.

Purity of the peptide **1** was further ascertained by measurements of the ultraviolet and fluorescence spectra. The UV spectrum (Fig. 1a) showed the typical curve of tryptophan with λ_{max} at 283 nm; also the fluorescence excitation spectrum (Fig. 1b) gave the same pattern as the UV spectrum. From these results it was ascertained that no modification on the tryptophan indole ring had occurred during the synthesis. Boc- and Ac-derivatives also showed high purity.

The relationships between the spectroscopic properties and the conformation of these synthetic peptides are now being studied and the results will be published in due course.

Experimental

N^{α}-*Dimethylphosphinothioyl-penta-*L-*Tryptophan Methyl Ester (Mpt-*L-*Trp-*L-*Trp-*L-*Trp-*L-*Trp-*L-*Trp-*L-*Trp-*OCH_3*) (**1**).* Chloromethylated copoly(styrene-1% divinylbenzene) resin (0.96 mmol Cl/g, Wako Pure Chemicals Ind., Ltd.) was esterified with N^{α}-Mpt-L-tryptophan by the caesium salt method.[8] The amino acid content of the resin was obtained as 0.56 mmol/g by Dorman method.[9] One gram of the ester resin was placed in the reaction vessel of the Beckman model 990 peptide synthesizer. Mpt group was removed by treating twice for each 30 min with 0.2 M HCl (0.2 M TPP)/CH_2Cl_2. After neutralization with 10% triethylamine in dichloromethane, couplings were mediated with the oxidation-reduction condensation[10] using tris(*p*-methoxyphenyl)phosphine and 2,2′-dithiodipyridine. After four cycles of these procedures N^{α}-Mpt-penta-L-tryptophan was cleaved from the resin support as its methyl ester by treating it five times with 1 M triethylamine in methanol for each 12 h. All the filtrates and methanol washings were combined and evaporated *in vacuo*. The residue was washed with water and dried to give a slightly yellow solid containing minor impurity when analyzed on silica gel by thin layer chromatography; 0.611 g. The solid was dissolved in a small volume of methanol and applied to a Sephadex LH-20 (1.9 cm × 100 cm) column. Methanol eluate (flow rate-1 ml/min) was monitored by UV spectrophotometry at 254 nm and collected as 5 ml fractions. The fractions containing a single component, when detected on silica gel thin layer chromatography, were combined and evaporated to give colorless crystals of **1**; 0.414 g. An analytically pure sample was obtained by recrystallization from ethanol; 0.354 g (60% calculated from N^{α}-Mpt-L-tryptophan resin).

Abnormal $LiAlH_4$ Reduction of 4,4-Diphenyl-3-cyano-2-methyl-2-pyrrolin-5-one

Sadatoshi AKABORI,* Kazue TAKAHASHI, Michiko OHTOMI, and Yohko SAKAMOTO

Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274

(Received January 29, 1981)

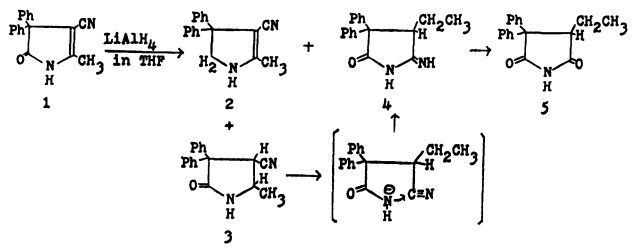
Synopsis. The reduction of 4,4-diphenyl-3-cyano-2-methyl-2-pyrrolin-5-one with lithium aluminum hydride yields three unexpected reduction products, together with the usual product.

We have recently reported[1] that benzoins can be converted into 4,4-diaryl-3-cyano-2-methyl-2-pyrrolin-5-ones in good yields by a reaction with sodio-3-iminobutanenitrile in THF.

We now wish to report our results on the reduction of 4,4-diphenyl-3-cyano-2-methyl-2-pyrrolin-5-one (**1**) with $LiAlH_4$. Thus, **1** was treated with an excess of $LiAlH_4$ under anhydrous conditions, in THF. The expected compound (**2**) was formed in a minute amount; 3,3-diphenyl-4-cyano-5-methyl-2-pyrrolidinone (**3**) was a major product, along with **4** and **5** in about 5 and 3% yields respectively.

The molecular formula of **2** was deduced to be $C_{18}H_{16}N_2$ by means of the mass spectrum (M^+, *m/e* 260) and the elemental analysis. The IR spectrum of **2** displayed a strong NH absorption at 3300 cm^{-1} and C≡N at 2190 cm^{-1}. However, the IR spectrum lacked bands arising from the carbonyl group. Furthermore, in the ^1H NMR spectrum of **2**, the resonance for the methylene group appeared at δ 4.02 (s, 2H) as a sharp singlet, in addition to a singlet (3H, CH_3) at δ 2.00, a broad singlet (1H, NH) at δ 4.45, and a multiplet (10H, aromatic protons) at δ 7.27. All these results can be accommodated in the **2** structure. The molecular formula of **3** was deduced to be $C_{18}H_{16}N_2O$ by means of the mass spectrum (M^+, *m/e* 276) and by elemental analysis. The ^1H NMR spectrum of **3** showed the signal of methyl (δ 1.35, d, J=5 Hz) and two methine (δ 3.75, m, and 4.20, d, J=8 Hz) groups, in addition to a broad singlet (1H, NH) at δ 8.74 and a multiplet (10H, aromatic protons) at δ 7.30, which could be assigned to two phenyl groups. Decoupling experiments revealed that the multiplet observed at δ 3.57 is coupled to a proton at δ 4.20 with J=8 Hz and also to a methyl proton at δ 1.35 with J=5 Hz, showing the presence of the CH_3–CH–CH– moiety. The presence of the carbonyl group was supported by the appearance of the characteristic carbonyl absorption at 1720 cm^{-1} in the IR spectrum. From these facts, the structure of **3** was assigned. The molecular formula of **4** was deduced to be $C_{18}H_{18}N_2O$ by means of the mass spectrum (M^+, *m/e* 278) and by the elemental analysis. The ^1H NMR spectrum of **4** showed the signals of methyl (δ 0.69), methylene (δ 1.52), and methine (δ 4.42) groups, in addition to two NH protons as a broad singlet at δ 6.95 and δ 8.05 and phenyl protons as a multiplet at δ 7.38. Decoupling experiments revealed that the multiplet protons observed at δ 1.52 are coupled to the methyl protons at δ 0.69 with J=7 Hz, and also to a methylene proton at δ 4.42 with J=7 Hz, showing the presence of a $-CHCH_2CH_3$ moiety. Irradiation at δ 1.52 changed the triplet at δ 0.69 into a singlet and the triplet at δ 4.42 into a singlet. Its IR spectrum exhibited absorption bands at 3300 (NH), 1770, and 1700 cm^{-1}. These absorptions suggested the presence of a –CO–NH–C(=NH)– moiety. All these results can be accommodated in the **4** structure. The molecular formula of **5** was also deduced to be $C_{18}H_{17}NO_2$ by means of the mass spectrum (M^+, *m/e* 279) and the elemental analysis. Compound **5** showed IR absorption bands at 3200, 1780, 1715, and 1500 cm^{-1}. These absorptions suggested the presence of a –CO–NH–CO– moiety. From these facts, the structure of **5** was assigned.

It is known[2] that an amide, on reduction with $LiAlH_4$, is converted in a good yield into a corresponding amine. For example, in THF at 65 °C, 5,5-dimethyl-2-pyrrolidinone is reduced to 2,2-dimethylpyrrolidine in a 67—79% yield. However, the similar reaction of **1** failed to give 3,3-diphenyl-4-cyano-5-methyl-2,3-dihydropyrrole (**2**) as a main product. The considerable difficulty in the reduction of the carbonyl group may be explained by the steric hindrance given by the adjacent two phenyl groups. It is interesting to note that $LiAlH_4$ reduces the double bond of **1**,[4] in spite of the fact that it does not reduce ethylenic or acetylenic hydrocarbons.[3] The formation of **4** can be explained by the process initiated by the cleavage of the N–C_5 bond of **3** and the attack of the nitrogen anion[5] on the carbon atom of the cyano group, followed by the addition of a proton at the C=N$^-$ group. Additionally, the hydrolysis of **4** affords **5**. With the proper control of the amount of $LiAlH_4$, *N,N*-disubstituted amide is known[5] to be susceptible to the cleavage of the –CO–NH– bond. However, the formation of an amine and an aldehyde on the reduction of an amide is induced by the addition of the hydride anion to the carbonyl. The present reduction differs from this type of cleavage in that the C–N bond is directly attacked by the hydride. In support of this explanation, two compound, **4** and **5**,[7] were obtained, in 13 and 8% yields respectively, by the reduction of **3** with $LiAlH_4$ in THF.



Experimental

All the melting points are uncorrected. The infrared spectra were measured on a JASCO IRA-2 Diffraction Grating

Infrared Spectrometer. The NMR spectra were determined on a JNM-4H-100 spectrometer instrument, using TMS as the internal reference. The MS spectra were taken by using a JEOL-JMS-OlSG-2 mass spectrometer.

Materials. 4,4-Diphenyl-3-cyano-2-methyl-2-pyrrolin-5-one was prepared according to the procedure described in a previous paper.[1] Lithium aluminum hydride was used without further purification. The solvents were purified by distillation.

*Reduction of **1** with Lithium Aluminum Hydride in THF.* A solution of 2.74 g (10 mmol) of **1** in 150 ml of THF was added, over a period of 2 h, to a stirred suspension of an excess of lithium aluminum hydride (1.52 g, 40 mmol) in 150 ml of THF at reflux under an atmosphere of nitrogen. After careful decomposition with cold water, the solution was concentrated to *ca.* 80 ml. To a solution this obtained we added 10% hydrochloric acid (30 ml). The mixture was allowed to stand overnight to give yellowish solids. The precipitated solids were filtered off and recrystallized from ethyl acetate–hexane to give **3** (78%); mp 224—226 °C. Found: C, 78.11; H, 5.99; N, 10.20%. Calcd for $C_{18}H_{16}N_2O$: C, 78.23; H, 5.86; N, 10.14%. MS 276 (M^+). IR (KBr) 3290 (NH), 2200 (C≡N), 1720 (C=O) cm^{-1}. ^1H NMR (DMSO-d_6) δ 1.35 (d, J=5 Hz, 3H, CH_3), 3.75 (m, 1H, CH), 4.20 (d, J=8 Hz, 1H, CH), 7.30 (m, 10H, aromatic H), 8.74 (bs, 1H, NH). The evaporation of the mother-liquor at room temperature, after the separation of the **3**, gave a solid residue which was fractionally recrystallized from hexane containing a small amount of ethyl acetate to give **2** (3%); mp 115—116 °C. Found: C, 82.69; H, 6.31; N, 10.56%, Calcd for $C_{18}H_{16}N_2$: C, 83.04; H, 6.20; N, 10.74%. MS 260 (M^+). IR(KBr) 3300 (NH), 2190 (C≡N), 1600 cm^{-1}. ^1H NMR($CDCl_3$) δ 2.00 (s, 3H,CH_3), 4.02 (s, 2H, CH_2), 4.45 (s, 1H, NH), 7.27 (s, 10H, aromatic H). The mother-liquors, after isolation of **2**, were evaporated at room temperature to give the crude **5**. The recrystallization of the crude material from ethanol give pure **5** (3%); mp 134—136 °C. Found: C, 77.48; H, 6.13; N, 4.98%, Calcd for $C_{18}H_{17}NO_2$: C, 77.48; H, 6.13; N, 5.01%. MS 279 (M^+). IR (KBr) 3200 (NH), 1780, 1715 cm^{-1}. ^1H NMR (DMSO-d_6) δ 0.92 (t, J=5 Hz, 3H, CH_3), 1.15 (m, 2H, CH_2), 3.65 (t, J=6 Hz, 1H, CH), 7.25 (m, 10H, aromatic H), 9.13 (bs, 1H, NH).

*Isolation of **4** from the Reduction Mixture of **1** with $LiAlH_4$ in THF.* The reduction was carried out in the same manner used the above reaction. After careful decomposition with water, the solution was concentrated to *ca.* 80 ml. The aqueous solution was extracted with ether; the ether extract was washed with water, dried over anhydrous $MgSO_4$, and filtered. After the removal of the solvent and several recrystallizations from ethyl acetate–hexane, we obtained 0.692 g of **3**. The aqueous solution was allowed to stand at room temperature until crystallization occurred. The recrystallization of the filtered solid product from ethanol gave **4** as colorless crystals in 5% yields; mp 289—291 °C. Found: C, 77.52; H, 6.58; N, 10.05%. Calcd for $C_{18}H_{18}N_2O$: C, 77.67; H, 6.58; N, 10.05%. MS 278 (M^+). IR (KBr) 3300 (NH), 1770, 1700 cm^{-1}. ^1H NMR (DMSO-d_6) δ 0.69 (t, J=7 Hz, 3H, CH_3), 1.52 (m, 2H, CH_2), 4.42 (t, J=7 Hz, 1H, CH), 7.38 (bs, 10H, aromatic H), 6.95 (bs, 1H, NH), 8.05 (bs, 1H, NH).

*Reduction of **3** with Lithium Aluminum Hydride in THF.* A solution of 1.38 g (5 mmol) of **3** in 70 ml of THF was stirres, over a period of 2 h, into a suspension of an excess of $LiAlH_4$ (0.76 g, 20 mmol) in 70 ml of THF at reflux under an atmosphere of nitrogen. After careful decomposition with cold water, the volume of the solution was concentrated to *ca.* 35 ml. To the solution thus obtained we added 10% hydrochloric acid (13 ml). The mixture was allowed to stand overnight to give a yellowish, unreacted material as a solid. The solids were filtered off and recrystallized from ethyl acetate–hexane to give pure **3** (0.75 g). The evaporation of the mother-liquor at room temperature, after the separation of the **3**, gave a solid residue which was fractionally recrystallized from ethyl acetate–hexane to give **4** (13%); mp 289—291 °C. The mother-liquors, after the isolation of **4** were evaporated at room temperature to give the crude **5**. The recrystallization of the crude material from ethanol give pure **5** (8%); mp 134—136 °C.

The authors wish to thank Mr Mitsuo Takayama, Department of Pharmacology, Toho University, for the measurements of the mass spectra.

Acid-induced Ring-opening of 2′-Substituted Spiro[anthracene-9(10H), 1′-cyclopropan]-10-ones

Kiyoichi HIRAKAWA* and Hajime SATO

Department of Chemistry, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386

(Received February 6, 1981)

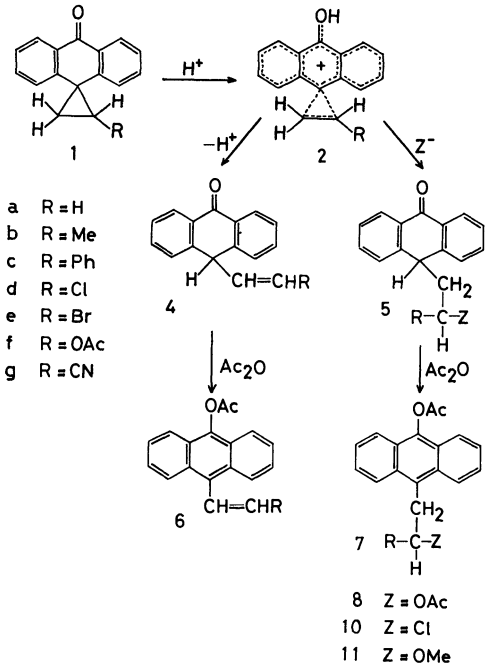
Synopsis. The title compounds (**1**) reacted under acidic conditions to give cyclopropane ring-opened products. In these reactions of **1** bearing methyl-, phenyl-, chloro-, bromo-, and acetoxy-substituents, the cyclopropane ring opened from the more substituted side.

We have previously investigated the reactions of spiro keto compounds.[1,2] In these investigations, it has been found that phenyl-substituted spiro[anthracene-9(10*H*),1′-cyclopropan]-10-ones undergo thermal rearrangement with ring expansion to aceanthrylen-6(2*H*)-ones, whereas a simple cyclopropane-opening, involving the formation of the hydroxy-carbonium ion (*e.g.* **2**) as an intermediate, is observed in the acid-induced reaction. We have further examined the cyclopropane-opening reactions of 2′-substituted spiro[anthracene-9(10*H*),1′-cyclopropan]-10-ones **1** under acidic conditions and their utilization in the preparations of substituted anthracenes.

Results and Discussion

The spiro anthrones **1a**—**c** and **g** were prepared by previously known procedures.[3] The spiro anthrones **1d**—**f** were obtained in 66, 45, and 53% yields, respectively, by irradiation of 10-diazoanthrone (**3**) in the presence of an appropriate olefin.

As was observed in the previous work, the expected products **4** and **5** in the reaction with acidic reagent (HZ) were too unstable to be isolated.[1] Therefore, the acid-induced reactions were carried out in acetic anhydride in the presence of a small amount of mineral acid to convert **4** and **5** to isolable **6** and **7**. Treatment of **1a**, **b**, and **f** with acetic anhydride–sulfuric acid gave **8a** (86%), **b** (81%), and **f** (33%), respectively.[4] The structures of products were assigned as **8** rather than $AcOC_{14}H_8CHRCH_2OAc$, cyclopropane ring-opening from the less substituted side, by their ^1H NMR spectral data: *e.g.* the assignment of **8b** is based on its absorption for methylene and methine hydrogens at δ 3.74 (center, m) and 5.27 (m), respectively; these values are normal compared with those estimated from the absorption which was found in **8a**. The structure $AcOC_{14}H_8CHMeCH_2OAc$ should exhibit methylene absorption near δ 4.12—4.56 (for CH_2CH_2OAc of **8a**), and the observed methine absorption at δ 5.27 is too far downfield to support this claim. The similar acid-induced reactions of 2′-halogenosubstituted spiro anthrones **1d** and **e** afforded 10-acetoxy-9-(formylmethyl)anthracene (**9**) (14—17%) and **8f** (34—35%). The anthracene **9** was identified on the basis of its spectral data and chemical behavior, *i.e.* the reaction of **9** with acetic anhydride in the presence of sulfuric acid led to **8f**. The formation of **9** may be accounted for by the formation of the anthracenes **7d** and **e** followed by elimination of acyl halide.[5] On the other hand, the reaction of **1g** bearing such strongly electron-withdrawing groups as CN gave a complex mixture.



The reactions of **1a**, **b**, **d**, and **e** with acetic anhydride-hydrochloric acid yielded **10a** (78%), **b** (75%), **d** (71%), and **e** (69%), respectively, as the major products, together with **8a** (4%), **b** (5%), **9** (10%), and **9** (9%), respectively, as the minor products. The structural assignments of **10** are based on their ^1H NMR spectral data. The predominant formation of **10** is compatible with the common observation that a chloride ion is more nucleophilic than an acetate ion.[6] Under similar conditions, the spiro anthrones **1c** and **f** afforded a complex product mixture, and **1g** gave no products.

The ring-opening of **1** with hydrochloric acid in methanol were further examined. As mentioned above, the products of the type **5** (Z=Cl or OMe) were too unstable to be isolated, so that they were isolated after acetylation. The reactions of **1a** and **b** gave **10a** (70%) and **b** (65%), respectively. In the similar treatment of **1c**, the anthracene **11c**, which resulted from the solvolysis of **5c** (Z=Cl) in methanol, was obtained in a 69% yield. The similar treatment of **1d**, **e**, and **g** with methanolic hydrochloric acid gave no product.

The spiro anthrone system is intriguing in that the protonation of the carbonyl oxygen may lead to a hydroxy-carbonium ion **2** which is conceivably bridged.[7] The direction of the cyclopropane-opening is consistent with the expectation that the relative stability of the incipient cationic centers will be a controlling factor.

Experimental

Preparations of 2'-Substituted Spiro[anthracene-9(10H),1'-cyclopropan]-10-ones **1**. ***1d***: A solution of 10-diazoanthrone (**3**)[8] (3.30 g, 15 mmol) in benzene (300 ml) was saturated with vinyl chloride, and the resulting mixture was then irradiated at 5 °C with a 100 W high pressure mercury lamp through a Pyrex filter until TLC showed the absence of **3** (*ca.* 12 h). The solvent and unchanged vinyl chloride were removed under reduced pressure; then the residue was chromatographed on silica gel (benzene as eluant). The first eluate gave **1d** as colorless needles (2.52 g, 66%), mp 122—123 °C.

1e: The product from photoreaction of **3** (3.30 g, 15 mmol) with vinyl bromide (32.1 g, 0.3 mol) in benzene (300 ml) under nitrogen was chromatographed to give **1e** as colorless needles (2.02 g, 45%), mp 134—135 °C.

1f: A similar photoreaction of **3** (3.30 g, 15 mmol) and vinyl acetate (28.8 g, 0.3 mol) in benzene (300 ml) gave **1f** as colorless microcrystals (2.21 g, 53%), mp 94—95 °C.

The spectral and analytical data of **1d**—**f** are consistent with the proposed structures.

Reaction of **1** *with Acetic Anhydride–Sulfuric Acid.* A solution of a spiro anthrone **1** (2—3 mmol) in acetic anhydride (30 ml) containing sulfuric acid (0.5 ml) was allowed to stand at room temperature (10 h). After TLC showed the absence of the starting material, the mixture was poured into water. The precipitate was worked up by recrystallization or chromatography. Spectral and analytical data of the products are given below.

8a: Yellow needles (from benzene); mp 157 °C; IR (KBr disc) 1768 and 1750 cm^{-1} (CO); ^1H NMR ($CDCl_3$) δ 2.20 (3H, s), 2.51 (3H, s), 3.58—4.02 (2H, a part of A_2B_2), 4.12—4.56 (2H, a part of A_2B_2), and 7.15—8.95 (8H, m); MS *m/e* 332 (M^+). Found: C, 74.60; H, 5.68%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

8b: Yellow microcrystals (from benzene–hexane); mp 130—131 °C; IR 1778 and 1746 cm^{-1} (CO); ^1H NMR δ 1.13 (3H, d, J=6.5 Hz), 1.93 (3H, s), 2.50 (3H, s), 3.63 and 3.84 (1H each, AB part of ABX, J_{AB}=13.5, J_{AX}=8,2, J_{BX}=5.7 Hz), 5.27 (1H, m), and 7.25—8.58 (8H, m); MS *m/e* 336 (M^+). Found: C, 74.94; H, 6.00%. Calcd for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99%.

8f: Yellow microcrystals (from benzene–hexane); mp 185—186 °C; IR 1760 cm^{-1} (CO); ^1H NMR δ 1.90 (6H, s), 2.62 (3H, s), 4.10 (2H, d, J=6.0 Hz), 7.12 (1H, t, J=6.0 Hz), and 7.40—8.65 (8H, m); MS *m/e* 380 (M^+). Found: C, 69.33; H, 5.38%. Calcd for $C_{22}H_{20}O_6$: C, 69.46; H, 5.30%.

9: Yellow microcrystals (from benzene); mp 198—200 °C; IR 1755 and 1726 cm^{-1} (CO); ^1H NMR δ 2.66 (3H, s), 4.65 2H, d, J=2.1 Hz), 7.35—8.35 (8H, m), and 9.83 (1H, t, J=2.1 Hz); MS *m/e* 278 (M^+). Found: C, 77.51; H, 5.12% Calcd for $C_{18}H_{14}O_3$: C, 77.68; H, 5.07%.

Reactions of **1** *with Acetic Anhydride–Hydrochloric Acid.* The procedure was identical with that described above, except that hydrochloric acid (1 ml) was used instead of sulfuric acid. The products were isolated by chromatography, followed by recrystallization from benzene–hexane. The characterization data of products are given below.

10a: Pale yellow needles; mp 206—207 °C; IR 1765 cm^{-1} (CO); ^1H NMR δ 2.58 (3H, s), 3.52—4.22 (4H, m), and 7.25—8.40 (8H, m); MS *m/e* 300/298 (M^+). Found: C, 72.46; H, 5.10; Cl, 11.76%. Calcd for $C_{18}H_{15}O_2Cl$: C, 72.35; H, 5.06; Cl, 11.87%.

10b: Pale yellow needles; mp 173 °C; IR 1768 cm^{-1} (CO); ^1H NMR δ 1.44 (3H, d, J=6.5 Hz), 2.55 (3H, s), 3.64—4.78 (3H, m), and 7.25—8.42 (8H, m); MS *m/e* 314/312 (M^+). Found: C, 72.85; H, 5.61; Cl, 11.22%. Calcd for $C_{19}H_{17}O_2Cl$: C, 72.96; H, 5.48; Cl, 11.33%.

10d: Pale yellow needles; mp 192—193 °C.

10e: Yellow needles; mp 195—196 °C.

Reactions of **1** *with Methanol–Hydrochloric Acid.* A solution of **1** (2—3 mmol) in methanol containing hydrochloric acid (1 ml) was refluxed under nitrogen for 1 h. The solvent was removed under reduced pressure. After the usual acetylation using acetic anhydride, the products were purified by recrystallization or chromatography.

11c: Yellow needles (from benzene–hexane); mp 160 °C; IR 1755 cm^{-1} (CO); ^1H NMR δ 2.56 (3H, s), 3.06 (3H, s), 3.55—4.65 (3H, m), and 7.15—8.35 (8H, m); MS *m/e* 370 (M^+). Found: C, 81.05; H, 5.95%. Calcd for $C_{25}H_{22}O_3$: C, 81.05; H, 5.99%.

A Short-step Synthesis of 4-Hydroxyproline

Junko HARA, Yoshinobu INOUYE,* and Hiroshi KAKISAWA
Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305

(Received March 23, 1981)

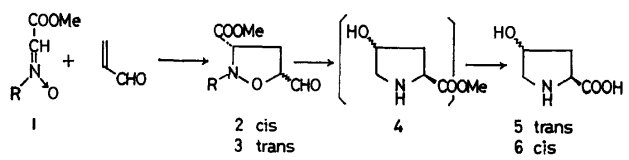
Synopsis. The reaction of *N*-benzyl-, *N*-diphenylmethyl-, or *N*-(1-phenylpropyl)-α-methoxycarbonylmethanimine *N*-oxide newly prepared with acrylaldehyde in benzene, followed by hydrogenolysis over palladium hydroxide and by acid hydrolysis, gave 4-hydroxyprolines.

After Leuchs synthesis[1] of 4-hydroxyprolines *via* a α-bromo-δ-chloro-γ-valerolactone, many procedures have been reported: one was a variant of the Leuchs method involving a α,δ-disubstituted γ-valerolactone intermediate,[2] others was a methods using a 2-amino-4-pentenoic acid derivative,[3] and the rest were along different routes.[4,5] All of these were based on the stepwise introduction of two asymmetric centers; the ratios of allohydroxyproline (**6**) to hydroxyproline (**5**) were near one. The predominant production of **6** was recognized in some cases,[2c,2e,4] but the overall yields were not high due to the rather long reaction sequences.

We wish to report here a new short-step synthesis of 4-hydroxyprolines (**5** and **6**). The method is comprised of 1,3-dipolar cycloaddition of *N*-alkyl-α-methoxycarbonylmethanimine *N*-oxide (**1**)[6] with acrylaldehyde, followed by the cleavage of the N–O bond and recyclization between the nitrogen and the aldehyde group to give a pyrrolidine ring. Two asymmetric centers can be introduced simultaneously at the stage of the cycloaddition.

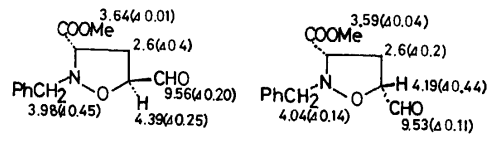
The nitrones [**1**: **a**; *N*-benzyl-, **b**; *N*-diphenylmethyl-, and **c**; *N*-(1-phenylpropyl)-α-methoxycarbonylmethanimine *N*-oxides] were prepared according to the previous procedure.[6] NMR spectra of **1** showed the presence of both *E*- and *Z*-isomers.

The reaction of **1a** (E/Z=1.6) with acrylaldehyde in benzene for 24 h gave a mixture of two isomeric isoxazolidines (**2a** and **3a**; **2a**/**3a**=1.6); the structures were assigned by the comparison of their NMR spectra and pseudocontact shifts (0.057 equiv. of Eu-FOD) with those of the related compound.[6] The mixture thus obtained was subjected to the catalytic hydrogenolysis and the resulted crude ester **4** was hydrolyzed to give a mixture of **6** and **5** (**6**/**5**=1.61) in a 46% yield based on **1a**.



1 — 2 cis, 3 trans — 4 — 5 trans, 6 cis

a: R = $C_6H_5CH_2$ b: R = $(C_6H_5)_2CH$ c: R = $C_6H_5(C_2H_5)CH$



2a 3a

Table 1. The ratio of allo-Hyp(**6**)/Hyp(**5**) and yield in variation of nitrone and reaction type

		Nitrone		
		1a	**1b**	**1c**
Type I	**6**/**5**	1.61	3.66	1.43
	Yield/%	46	56	55
Type II	**6**/**5**	1.87	5.90	1.23
	Yield/%	32	71	65

When **1b** (E/Z=1.1) was used, a mixture of **6** and **5** (**6**/**5**=3.66) was obtained in a 56% yield.

The above results show that the E/Z ratio in $CDCl_3$ had not necessarily reflected on the ratio of **6**/**5**. This led to the finding[7] that nitrones (**1**), though they exist in a *Z*-form in a crystalline state, exhibit a novel *E*-*Z* equilibrium in a solution. Therefore, two types of reactions were performed in order to clarify the synthetic utility of the present method. In type I, the crystalline *Z*-nitrone was added to a solution of acrylaldehyde in benzene, while in type II, acrylaldehyde was added to a equilibrium mixture of *E*- and *Z*-nitrones in benzene.

The results are summarized in Table 1. The **6**/**5** ratio was the highest when **1b** was subjected to the type II condition. Stereoselectivity (**6**/**5**=5.90) and overall yield (71%) for the production of **5** and **6** are superior to hitherto reported procedures.[2-5] On the other hand, the stereoselective production of **5** was not specified in the present method.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi 215 grating spectrophotometer and the NMR spectra were measured with a JEOL MH-100 spectrophotometer, using TMS as the internal standard. The amino acid chromatograms were taken on a Dionex D-500 Mark II analyzer using a column of DC-6A (1.75φ× 480 mm) at 41 °C with an elution buffer Li-A (pH 2.75).

Preparation of Nitrones. Nitrones (**1a**, **1b**, and **1c**) were prepared by condensation of methyl glyoxylate with a corresponding *N*-alkylhydroxylamine.

1a: Mp 90—92 °C (colorless prisms from benzene); ν(KBr): 1727, 1570, 1220, and 1205 sh cm^{-1}; δ ($CDCl_3$, E/Z=1.6): 7.6—7.1 (m, C_6H_5 and =CH), 5.70 (s, N–CH_2– of *E*-form), 4.98 (s, N–CH_2– of *Z*-form), 3.77 (s, $COOCH_3$, *Z*), and 3.78 (s, $COOCH_3$, *E*); E/Z=3.3 (C_6D_6). Found: C, 61.87; H, 5.65; N, 7.18%. Calcd for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.65; N, 7.24%.

1b: Mp 131.5—132.5 °C (colorless needles from benzene); ν (KBr): 1725, 1700, 1550 br, 1215, and 1205 cm^{-1}; δ ($CDCl_3$, E/Z=1.1): 8.2 (s, =CH, *E*), 7.5—7.2 (m), 6.28 (s, N–CH, *Z*), and 3.71 (s, $COOCH_3$, *E*+*Z*); E/Z=1.7 (C_6D_6). Found: C, 71.50; H, 5.52; N, 5.13%. Calcd for $C_{16}H_{15}NO_3$: C, 71.36; H, 5.61; N, 5.20%.

1c: Mp 72.5—74.5 °C (colorless prisms which formed slowly from benzene); ν (KBr): 1730, 1550 br, 1220 sh, 1210,

and 1170 cm^{-1}; δ ($CDCl_3$, E/Z=0.95): 7.7—7.2 (m, C_6H_5 and =CH), 6.86 (dd, J=10 and 6 Hz, N-CH, Z), 4.83 (dd, J=10 and 6 Hz, N-CH, E), 3.84 (s, $COOCH_3$, E), 3.80 (s, $COOCH_3$, Z), 2.7—1.9 (m, $C\underline{H}_2CH_3$, $E+Z$), 0.97 (t, J=7 Hz, $CH_2C\underline{H}_3$, Z), and 0.94 (t, J=7 Hz, $CH_2C\underline{H}_3$, E); E/Z= 1.9 (C_6D_6). Found: C, 65.13; H, 6.78; N, 6.31%. Calcd for $C_{12}H_{15}NO_3$: C, 65.14; H, 6.83; N, 6.33%.

Preparation of **6** *and* **5**. Typical procedures of both types were as follows:

Type I: To a solution of acryladehyde (1.5 mmol) in benzene (4 ml), was added **1a** (0.5 mmol), in one portion. The mixture was stirred at room temperature for 24 h. The removal of benzene and the excess of acryladehyde *in vacuo* at 25 °C gave an oily mixture of **2a** and **3a** (100%, **2a**/**3a**= 1.6). Without further purification, the mixture thus obtained was dissolved in methanol (20 ml) and then hydrogenated over palladium hydroxide (85 mg) under a hydrogen atmos phere (3 atm) for 24 h, After removal of the catalyst, the filtrate was concentrated to give **4** (127 mg), which was subsequently refluxed with 1 mol dm^{-3} HCl (5 ml) for 4.5 h. After decolorizing with activated carbon, the solution was concentrated to give pale yellow crystals (103 mg). The ratio of stereoisomers and the yield from **1a** were determined by amino acid analysis (**6**/**5**=1.61, yield 46%).

Type II: A solution of **1b** (0.26 mmol) in benzene (5 ml) was left at room temperature for 3 h. To the solution was added acrylaldehyde (0.8 mmol) in one portion and the mixture was stirred at room temperature for 24 h. The removal of benzene and excess of acryladehyde *in vacuo* at 25 °C gave a colorless oily mixture of **2b** and **3b** (100%, **2b**/**3b**=4.4). The mixture of **2b** and **3b** (87 mg) was subjected to catalytic hydrogenolysis and acid hydrolysis under similar conditions as in Type I, giving a crystalline mixture of **6** and **5** (**6**/**5**=5.90, yield 71% from **1b**).

In the case of **1a** or **1c**, the solution in benzene was left for 3 h or 2 d, respectively, before the addition of acryladehyde.

We are deeply indebted to Dr. Chikahiko Eguchi, Central Research Laboratories, Ajinomoto Co., Inc., for a gift of allohydroxyproline.

Stereochemical Behavior of 1-Methoxycyclopropyl Radical in Hunsdiecker Reaction[1]

Teiichi Ando,* Takashi Ishihara, Akira Yamashita, and Masahiro Matsumoto

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 23, 1981)

Synopsis. The Hunsdiecker reaction of Ag (*E*)- and (*Z*)-2,2-dichloro-1-methoxy-3-methylcyclopropanecarboxylates with bromine in CCl_4 at 0 and 77 °C occurs with substantial inversion of configuration, suggesting that the 1-methoxycyclopropyl radical is configurationally less stable than the 1-fluorocyclopropyl or the 1-methoxyvinyl radical.

Recent studies[2] have established that the configurational stability, or the energy barrier for inversion, of 1-substituted cyclopropyl radicals is strongly affected by the nature of the 1-substituent; best known is the effect of 1-fluorine stabilizing the pyramidal configuration of the cyclopropyl radical, which is much more powerful than that of 1-chlorine.

As compared with the configurational stability of 1-halo radicals, that of the 1-methoxy radical has only scarcely been investigated, probably because of the difficulty of its generation. In fact, no reports on this subject have appeared so far in the literature except the one by Walborsky *et al.*[2b,c]

The stereochemistry of the Hunsdiecker reaction of Ag salts of some 1-methoxy- and 1-fluorocyclopropanecarboxylic acids has now been examined to learn the effect of the 1-methoxyl substituent on the stereochemical stability of cyclopropyl radicals.

Results and Discussion

The Hunsdiecker reaction of Ag salts of (*Z*)-2,2-dichloro-1-methoxy- (**1a**), (*E*)-2,2-dichloro-1-methoxy- (**2a**), and (*Z*)-2,2-dichloro-1-fluoro-3-methylcyclopropanecarboxylic acids (**1b**) was effected in the presence of bromine in CCl_4, to give the corresponding bromocyclopropane as an isomeric mixture (Scheme and Table 1). The structures of these bromocyclopropanes were determined from their ^1H[3] and/or ^{13}C NMR spectra.[4]

The reaction of methoxy acids **1a** and **2a** occurred with substantial inversion of configuration even at 0 °C. The stereospecificity was completely lost at 77 °C; the isomer ratios of the product are equal irrespective of the stereochemistry of the starting acid. This indicates that isomeric 1-methoxycyclopropyl radicals are configurationally rather unstable, inverting their configuration at a rate comparable to their bromine abstraction at 0 °C and at a rate faster than the latter at 77 °C.

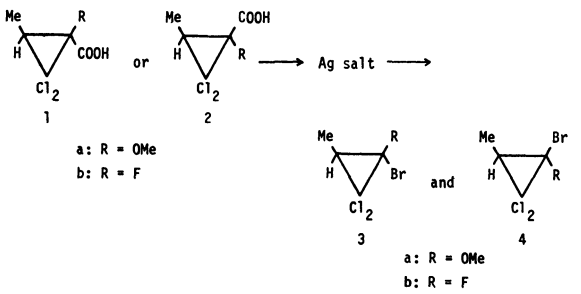

Table 1. Hunsdiecker reaction of acids **1** and **2**

Acid	Temp °C	Time h	Yield %	Isomer ratio retn : invn
1a	0	1.5	54	58 : 42
	0	2.0	76	56 : 44
	77	1.5	53	41 : 59
	77	2.0	59	39 : 61
2a	0	2.0	—	68 : 32
	0	3.0	71	69 : 31
	77	0.5	—	61 : 39
	77	1.0	62	62 : 38
1b	20	1.5	—	90 : 10
	20	2.5	59	91 : 9
	77	2.0	69	81 : 19
	77	3.0	—	82 : 18

In discussing the effect of the 1-methoxyl substituent from the above facts, the presence of two 2-chlorine atoms in this system must be taken into account, because they can more or less destabilize the pyramidal configuration of cyclopropyl radicals. Such an effect of electronegative 2-substituents was suggested theoretically by Dewar *et al.*[6] and demonstrated experimentally in our previous work.[7]

The Hunsdiecker reaction of Ag salt of **1b** was conducted in this connection; the reaction took place with high (but not complete) stereospecificity at room temperature, and the degree of inversion increased at 77 °C (Table 1). Evidently, the configurational stability of the 1-fluorocyclopropyl radical is lowered to such an extent that its inversion of configuration competes with its bromine abstraction, in spite of the presence of 1-fluorine.

These findings, as combined with the extremely high configurational stability of 2-hetero-unsubstituted 1-fluorocyclopropyl radicals observed in the previous work,[2] strongly suggest the existence of the 2-chlorine effect in the 1-methoxy radicals as well as in the 1-fluoro radical.[8] The data in Table 1 also show that the 1-methoxy radical is configurationally less stable than the 1-fluoro radical, *i.e.*, that the 1-methoxyl substituent is less powerful than the 1-fluoro in stabilizing the pyramidal configuration of cyclopropyl radicals.

The behavior of 1-methoxycyclopropyl radicals described herein is in sharp contrast with that of (*E*)- and (*Z*)-1-methoxy-1-propenyl radicals.[9] This difference can be explained in terms of the difference in *s*-character of the odd-electron orbital between the cyclopropyl and the vinyl systems, though the above-cited 2-chlorine effect may play a minor role. It is to be noted that similar differences have been observed between the 1-chlorocyclopropyl[2] and the 1-chlorovinyl radicals.[10]

Experimental[11]

Methyl (E)-2-Methoxy-2-butenoate. Methyl *trans*-2-methylglycidate was treated with *p*-toluenesulfonic acid to form 2-hydroxy-3-(*p*-tolylsulfonyloxy)butanoate (100%), which was then methylated with methyl iodide/Ag_2O (97%). Treatment of the resulting 2-methoxy-3-(*p*-tolylsulfonyloxy)-butanoate with KOH in methanol, followed by acidification, gave an isomeric mixture of (*E*)- and (*Z*)-2-methoxy-2-butenoic acid (*E*/*Z*=85/15). Recrystallization from hexane gave pure (*E*)-acid, mp 44.5—45.5 °C (65%), which was converted to the methyl ester by the usual method (82%), bp 62—63 °C/16 mmHg. IR (film) 1724, 1644, 1207, 1164, 1105, 1026 cm^{-1}; ^1H NMR δ 1.93 (d, J=7.4 Hz, 3H), 3.50 (s, 3H), 3.70 (s, 3H), 5.14 (q, J=7.4 Hz, 1H); MS *m/e* (%) 130 (M^+, 68), 55 (100).

Methyl (Z)-2-Methoxy- and (Z)-2-Fluoro-2-butenoates were prepared according to the method of Owen[12] and of Bergmann *et al.*,[13] respectively. Attempts to prepare the (*E*)-fluoro acid or its ester in our hands were unsuccessful.

*1-Substituted 2,2-Dichloro-3-methylcyclopropanecarboxylic Acids (**1a**, **2a**, and **1b**)* were prepared by addition of dichlorocarbene to the corresponding methyl 2-substituted-2-butenoate followed by hydrolysis. The reaction conditions were similar to those described in our previous paper.[14]

1a: 37% yield; mp 75—76 °C; IR (KBr) 3000, 1708, 1292, 1258, 1040 cm^{-1}; ^1H NMR δ 1.29 (d, J=6.6 Hz, 3H), 2.43 (q, J=6.6 Hz, 1H), 3.76 (s, 3H), 12.24 (s, 1H); ^{13}C NMR δ 7.9 (Me on ring).

Found: C, 36.30; H, 4.11; Cl, 35.47%.

2a: 37% yield; mp 52.5—53.5 °C; IR (KBr) 3030, 1706, 1301, 1158, 1075 cm^{-1}; ^1H NMR δ 1.43 (d, J=6.6 Hz, 3H), 2.03 (q, J=6.6 Hz, 1H), 3.61 (s, 3H), 12.14 (s, 1H); ^{13}C NMR δ 9.7 (Me on ring).

Found: C, 36.29; H, 4.22%. Calcd for $C_6H_8O_3Cl_2$: C, 36.21; H, 4.05; Cl, 35.63%.

1b: 33% yield; mp 42—43 °C; IR (KBr) 3000, 1720, 1250, 1180, 1000 cm^{-1}; ^1H NMR δ 1.37 (d, J=6.6 Hz, 3H), 2.53 (dq, J=6.6 and 7.8 Hz, 1H), 11.16 (s, 1H); ^{13}C NMR δ 7.4 (J_{CF}=6.0 Hz, Me on ring).

Found: C, 31.82; H, 2.57; Cl, 38.04; F, 10.16%. Calcd for $C_5H_5O_2Cl_2F$: C, 32.11; H, 2.70; Cl, 37.92; F. 10.16%.

*Hunsdiecker Reaction of **1a**, **2a**, and **1b**.* To a suspension, which had been maintained at a specified temperature, of Ag salt (5 mmol) in dry CCl_4 (10 ml) was rapidly added 1.2 equiv. of bromine in dry CCl_4 (10 ml). After a specified period, inorganic silver salt was removed by filtration and was washed with a small amount of CCl_4. The filtrate was concentrated below 30 °C. The isomer ratios in the products were measured by GLC before distillation.

3a** and **4a: Bp 78—79 °C/15 mmHg; IR (film) 2960, 1043, 780, 765 cm^{-1}; ^1H NMR **3a**: δ 1.30 (d, J=6.6 Hz, 3H), 2.12 (q, J=6.6 Hz, 1H), 3.54 (s, 3H), **4a**: δ 1.25 (d, J=6.6 Hz, 3H), 1.84 (q, J=6.6 Hz, 1H), 3.54 (s, 3H); ^{13}C NMR **3a**: δ 8.1 (Me on ring), **4a**: δ 13.3 (Me on ring); MS *m/e* (%) 232 (M^+, 1), 199 (100).

3b** and **4b: Bp 52—53 °C/23 mmHg; IR (film) 2940, 1096, 996, 898, 862 cm^{-1}; ^1H NMR **3b**: δ 1.35 (d, J=6.6 Hz, 3H), 2.03 (dq, J=6.6 and 7.2 Hz, 1H), **4b**: δ 1.33 (dd, J=6.6 and 1.6 Hz, 3H), 2.06 (dq, J=6.6 and 19.8 Hz, 1H); ^{13}C NMR **3b**: δ 7.9 (J_{CF}=5.2 Hz, Me on ring), **4b**: δ 12.7 (J_{CF}=0 Hz, Me on ring); MS *m/e* (%) no parent to 220, 141 (100).

The Synthesis of 2,5-Dialkylcyclopentanones from Aliphatic Aldehydes and Formaldehyde

Yoshihisa WATANABE,* Fukashi SAKAMOTO, Sang Chul SHIM, and Take-aki MITSUDO
Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto 606
(Received April 8, 1981)

Synopsis. Aliphatic aldehydes react with formaldehyde in the presence of dimethylamine hydrochloride at 200 °C to form 2,5-dialkylcyclopentanones in moderate yields. Propanal, butanal, and pentanal give 2,5-dimethyl-, 2,5-diethyl-, and 2,5-dipropylcyclopentanone respectively, but ethanal gives only a tarry material.

A large variety of methods are available for building up the cyclopentanone and cyclopentenone ring.[1-9] In the course of our study of the α-methylation of ketones,[10] we have found a novel method for the preparation of cyclopentanone derivatives by treating aliphatic aldehydes with formaldehyde in the presence of a secondary amine hydrochloride. The combination of straight chain aliphatic aldehydes with formaldehyde in the present method represents a unique pathway to the formation of the cyclopentanone ring.

Experimental

Reagent. The propanal and butanal were distilled and dried over Na_2SO_4. The other reagents were commercial products. Formaldehyde(guaranteed reagent 35% Wako Chemicals Co.,) was used.

Reaction Procedure. An autoclave with a 100-ml capacity, made of stainless steel and equipped with a magnetic stirrer, was used in each run. Forty mmol of aliphatic aldehyde, 35% aqueous formaldehyde (40—80 mmol as formaldehyde), 20 ml of a solvent, and 20—40 mmol of dimethylamine hydrochloride were put into it. After the replacement of the argon in the autoclave, it was kept at 200 °C by electrical heating for 4 h. The products, such as 2,5-dimethyl-, 2,5-diethyl-, 2,5-dipropyl-, and 2,5-dipentylcyclopentanone, were isolated by distillation or column chromatography. They were characterized by their IR, ^1H, ^{13}C-NMR, and mass spectra, and by elemental analysis. The 2,5-dimethylcyclopentanone formed was identified by a comparison of its mp, IR, and ^1H and the ^{13}C-NMR spectra of its 2,4-dinitrophenylhydrazone derivative with those of an authentic sample. GLC analysis was made using internal standards: a column (0.3 cmϕ × 3 m) packed with PEG 20M 10%.

2,5-Diethylcyclopentanone (**1b**); bp 71—76 °C/17 Torr (1 Torr = 133.3 Pa). Found as 2,4-dinitrophenylhydrazone, mp 113—115 °C: C, 56.01; H, 6.24; N, 17.48; O, 20.25%. Calcd for $C_{15}H_{20}N_4O_4$: C, 56.24; H, 6.29; N, 17.48; O, 19.98%. 2,5-Dipropylcyclopentanone (**1c**); bp, 89—92 °C/8 Torr. Found as semicarbazone, mp, 168—170 °C: C, 63.69; H, 10.36; N, 18.56%. Calcd for $C_{12}H_{23}N_3O$: C, 63.96; H, 10.29; N, 18.65%. 2,5-Dibutylcyclopentanone (**1d**); bp 86—92 °C/4 Torr. Found as semicarbazone, mp 118—120 °C: C, 65.80; H, 10.72; N, 16.12%. Calcd for $C_{14}H_{27}N_3O$: C, 66.34; H, 10.74; N, 16.31%. 2,4-Dipentylcyclopentanone (**1e**) was chromatographed on silica gel (3 cm × 30 cm), using benzene as an eluent. A light yellow liquid was obtained.[12]

Analytical Procedure. The infrared spectra were measured on a Hitachi model 215 grating spectrophotometer. The ^1H-NMR spectra were obtained at 60 MHz with a JEOL JNM-60, at 100 MHz with a JEOL JNM-100, and at 220 MHz with a Varian model HR-220 NMR spectrometer. The ^{13}C-NMR spectra were obtained at 25.05 MHz with a JEOL pulsed Fourier transform spectrometer model FX-100. Samples were dissolved in $CDCl_3$ and the chemical shift values were expressed in δ-values (ppm) relative to Me_4Si as an internal standard. The mass spectra were recorded on a JMS-O1SG mass spectrometer.

Results and Discussion

Two molecules of aldehydes reacted with one molecule of formaldehyde in the presence of dimethylamine hydrochloride to form 2,5-dialkylcyclopentanones in moderate yields. The results are summarized in the Tables. Each of the C_3—C_7 aldehydes with a straight chain structure, such as propanal, butanal, pentanal, hexanal, and heptanal, gives the corresponding 2,5-

1e	*trans*	1740	224	222.5	49.5	27.7	31.8	30.0	27.1 22.5	14.0
	cis				(48.4)	(26.8)				

dialkylcyclopentanone. Ethanal failed to give cyclopentanone, but provided only a tarry material. The amine salt is necessary for this ring formation (see Run 7).

The ^{13}C-NMR spectra of the products from butanal, pentanal, hexanal, and heptanal exhibited two sets of peaks with different intensities, assignable to *trans*- and *cis*-2,5-dialkylcyclopentanone.[11] The *trans* isomers predominate in **1b**, **1c**, and **1d**, and the *trans* to *cis* mole ratios are estimated to be about 2 : 1 from the height of peaks of ^{13}C-NMR spectra. With **1e**, the *trans* isomer highly predominates, and only a trace of the *cis* isomer is formed.

Though the mechanism of this reaction is not yet clear, the following two condensates are considered to be the reaction intermediates: the 2-alkylpropenal derived by the reaction of the aldehyde with formaldehyde, and an enamine (Eq. 2). 2,5-Dialkylcyclopentanones may be derived from these condensates *via* several steps. This consideration may be supported by the fact that the reaction between 2-ethylpropenal and 1-(1-pyrrolidinyl)-1-butene at 200 °C for 4 h gave 2,5-diethylcyclopentanone in a 13% yield, while 2-alkylpropenals were readily formed under the conditions used.

The Formation of a Propellane by the Oxidation of Biphenylene with Manganese(III) Acetate

Kazu KUROSAWA* and John F. W. McOMIE**

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
***School of Chemistry, The University, Bristol, Cantock's Close, Bristol BS8 1TS, England*

(Received April 24, 1981)

Synopsis. The reaction of biphenylene with manganese (III) acetate gave 2-acetoxybiphenylene, 2-formylbiphenylene, 2-(acetoxymethyl)biphenylene, and 7-oxa-10,11-benzotricyclo[4.3.2.0]undeca-2,4,10-trien-8-one. The reaction pathways are discussed.

Although a number of investigation of the reactions of biphenylene have been reported, the reaction of manganese(III) acetate with this compound was not known. In connection with our previous investigations of the radical reactions of manganese(III) acetate with various aromatic compounds,[1,2] the reaction of biphenylene with manganese(III) acetate was examined. The reaction of biphenylene with manganese(III) acetate in a molar ratio of 1 : 4 in boiling acetic acid containing 8 equivalents of acetic anhydride gave three products, **2**, **3**, and **4** (Table 1, Entry 2). Compounds **2** and **3** were found to be 2-acetoxybiphenylene and 2-formylbiphenylene respectively by studying their ^{1}H-NMR and IR spectra. The ^{1}H-NMR spectrum of Compound **4** in CCl_4 indicated the presence of an acetoxymethyl group [δ=2.00 (3H, s) and δ=4.80 (2H, s)] and seven aromatic protons centered at δ=6.65. The IR spectrum exhibited a carbonyl absorption at 1738 cm^{-1}. When **4** was oxidized with manganese(III) acetate, 2-formylbiphenylene (**3**) was obtained. Therefore, the structure of **4** was proved to be 2-(acetoxymethyl)biphenylene (Scheme 1). When the reaction was conducted in acetic acid containing a large amount of acetic anhydride, it gave **4** and **5** (Entry 3). The yield of **4** was much improved at the expense of the yields of **2** and **3**, and the maximum yield was obtained when the molar ratio was 1 : 4 (Entry 3). The structure of **5** was also elucidated by means of the study of its ^{1}H-NMR spectrum, which showed the presence of an AB system (δ=2.74 and 2.97 with a J value of 18.0 Hz), vinylic protons [δ= 5.8—6.5 (4H, m)], and aromatic protons centered at δ=7.35 (4H, m). Its IR spectrum showed a carbonyl absorption at 1775 cm^{-1} characteristic of five-membered lactone. These spectral properties suggested that the structure is 7-oxa-10,11-benzotricyclo[4.3.2.0]-undeca-2,4,10-trien-8-one. The ^{13}C-NMR of **5** further

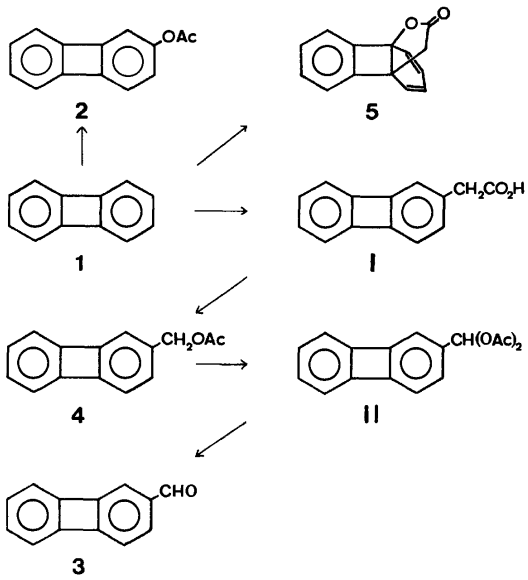
a) Yields are based on the substrate used.



Scheme. 1.

confirmed the structure. The data are shown in the experimental part.

It is well known that there are two reaction mechanisms operative in the manganese(III) acetate oxidation. One is the electron-transfer mechanism, which operates in the oxidation of aromatic compounds having ionization potentials below 8 eV.[3,4] The other is the free-radical mechanism, which operates in the reaction of compounds having higher ionization potentials.[4] Both mechanisms can compete in the reaction of some aromatic compounds under certain reaction conditions.[4] The free-radical mechanism predominates under anhydrous conditions and at high temperatures. It seems reasonable to assume that **2** was derived *via* the electron-transfer mechanism, by analogy to the oxidation of 2-methylnaphthalene, which gave 1-acetoxy-2-methylnaphthalene,[4] whereas the other products were formed *via* the free-radical mechanism. The fact that the acetoxymethyl group in **4** is located at the (2) position is in harmony with the results of the phenylation reaction of biphenylene, where 2-phenylbiphenylene is the major product, together with a minor quantity of 1-phenylbiphenylene.[5] It should be pointed out that there was no precedent for the formation of a lactone from an aromatic substrate in the oxidation by manganese(III) acetate. Interestingly, the lactone is a propellane and a derivative of the ring system (A), but it cannot isomerize to benzocyclooctene (B) (Fig. 1). Several reactions are known in which X-Y reagents add to biphenylene, and the product is nearly always a derivative of (B), as is shown in the reactions of biphenylene with nitric acid and acetic anhydride,[6] and with bromine,[7] and in the reaction of methoxybi-

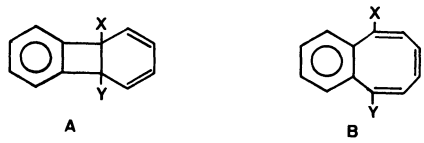


Fig. 1.

phenylene with bromine.[8] The formation of the acetoxymethyl group *via* the carboxymethyl group (I) in the oxidation by manganese(III) acetate has been well established,[4] and the further oxidation of **4** gave 2-(diacetoxymethyl)biphenylene (II), which yielded **3** on hydrolysis during the work-up procedure (Scheme 1).

Experimental

The ^{1}H-NMR spectra were recorded with a Hitachi R-24 NMR spectrometer, with TMS as the internal standard, while the proton-decoupled ^{13}C-FT NMR spectrum was measured at 22.5 MHz on a JEOL FX 90Q spectrometer (pulse width, 24 μs; spectral width 5000 Hz; data points, 8000; acquisition time 920 ms) in a 5-mm tube at 28 °C, using TMS as the internal reference. The IR spectra were taken for the chloroform solution on a JASCO IRA-1 grating spectrometer. The UV spectra were recorded for the methanol solution with a Hitachi EPS-3T spectrophotometer. The melting points were determined on a Yanagimoto micro-melting-point apparatus and were not corrected.

Oxidiation of Biphenylene with Manganese(III) Acetate. A typical procedure for the oxidation of biphenylene with manganese(III) acetate was as follows. A mixture of biphenylene[9] (2 mmol), manganese(III) acetate dihydrate,[3] acetic acid (20 ml), and acetic anhydride was heated under reflux for the time shown in the table until the color of the Mn(III) ion disappeared. Water (150 ml) was then added to the reaction mixture, and the solution was kept at room temperature overnight. The reaction mixture was extracted with benzene twice (30 ml of each portion), and then the benzene was removed *in vacuo*. The resulting semi-solid was separated on TLC, using chloroform as the developing solvent.

2-Acetoxybiphenylene (2): Mp 91—92 °C (light petroleum) (lit,[10] mp 91—92 °C); UV λ_{max} (ε) 245 (27900), 252 (46900), 330 (2980), 335_{sh} (3350), 344 (6270), 347_{sh} (5960), and 365 nm (8500); ^{1}H-NMR ($CDCl_3$) δ=2.23 (3H, s, OAc) and 6.2—6.9 (7H, m, aromatic).

2-Formylbiphenylene (3): Mp 80—81 °C (light petroleum) (lit,[11] mp 78—79 °C); IR 1700, 2720, and 2810 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.5—7.5 (7H, m, aromatic) and 9.61 (1H, s, CHO).

2-(Acetoxymethyl)biphenylene (4): Mp 63—64 °C (EtOH); IR 1738 cm^{-1} (OAc); UV λ_{max} (ε) 245.5 (28300), 254 (55000), 329.5_{sh} (2750), 335_{sh} (2910), 345.5 (5900), 347.5 (5660), 352.5_{sh} (4050), and 365 nm (8900). Found: C, 80.30; H, 5.32%. Calcd for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%.

7-Oxa-10,11-benzotricyclo[4.3.2.0]undeca-2,4,10-trien-8-one (5): Mp 125 °C (CCl_4); IR 1775 cm^{-1} (γ-lactone); UV λ_{max} (ε) 221_{sh} (3960), 228_{sh} (3120), 258_{sh} (1410), 264_{sh} (1860), 269.5 (2130), 276 (2050), and 285_{sh} (723); ^{13}C-NMR δ= 39.709 (–CH_2–), 51.736 (–C–CH_2–), 84.837 (–C–O–), 121.080, 121.242, 121.513, 122.380, 124.059, 128.989, 129.260, 131.373 (four vinylic =CH– and four aromatic =CH–), 146.650 (=C–), 146.975 (=C–), and 175.308 (>C=O). Found: C, 79.86; H, 4.81%. Calcd for $C_{14}H_{10}O_2$: C, 79.98; 4.79%.

Oxidation of 2-(Acetoxymethyl)biphenylene (4) with Manganese(III) Acetate. A mixture of **2** (45 mg), manganese (III) acetate dihydrate (107 mg), acetic acid (2 ml), and acetic anhydride (0.1 ml) was heated under reflux for 20 min. The reaction mixture was diluted with water (20 ml) and then extracted with benzene. After the removal of the benzene *in vacuo*, the resulting mixture was separated on TLC, using benzene as the developing solvent, to give **3** (10 mg, 28%) and also unchanged **4** (15.6 mg, 35%) identical with authentic samples.

Oxidation of 2-(Acetoxymethyl)biphenylene (4) with Manganese(IV) Oxide. A mixture of **2** (45 mg), manganese (IV) oxide (1 g), and anhydrous diethyl ether (50 ml) was stirred at room temperature for 48 h. After the manganese (IV) oxide has been removed by filtration, the ethereal solution was concentrated and the resulting product was purified on TLC, using benzene as the developing solvent, to give **3** (20 mg, 56%).

Synopsis. A water soluble surfactant porphyrin 5,10,15-tris(1-methylpyridinium-4-yl)-20-[4-(octadecyloxy)phenyl]-21*H*, 23*H*-porphine triiodide and its metal complexes have been synthesized and characterized.

Recently, several surfactant porphyrins have been reported in relation to the simulation of the intricate functions of chlorophylls in photosynthetic membranes.[1-3]

We report here the synthesis of 5,10,15-tris(1-methylpyridinium-4-yl)-20-[4-(octadecyloxy)phenyl]-21*H*,-23*H*-porphine triiodide and its metal complexes which are amphiphilic.

Experimental

*Preparation of 5,10,15-Tris(4-pyridyl)-20-[4-(octadecyloxy)-phenyl]-21*H, *23*H*-porphine (Abbreviated as H_2TPyStPP).* A starting compound, *p*-(octadecyloxy)benzaldehyde, was prepared in the following manner according to the literature method.[4] *p*-Hydroxybenzaldehyde (48.8 g, 0.4 mol) and octadecyl iodide (243.2 g, 1.7 mol) in cyclohexane (320 cm³) were heated under reflux for 3 h. The reaction mixture was cooled to room temperature and extracted with diethyl ether (300 cm³). The ether was evaporated and the residue was distilled under high vacuum (250 °C, 0.03 Pa) to give the product (25.6 g, 17.1%).

p-(Octadecyloxy)benzaldehyde (21.2 g, 0.057 mol), 4-pyridinecarbaldehyde (18.2 g, 0.17 mol), and pyrrole (15.2 g, 0.23 mol) in propionic acid (1000 cm³) were heated under reflux for 2 h. Propionic acid was removed by distillation to give a mixture of porphyrins having one to three octadecyloxyphenyl and three to one pyridyl groups. Tetrakis(octadecyloxyphenyl)- and tetrapyridylporphine were not produced. The crude mixture was dissolved in chloroform and chromatographed on alumina columns (Merck 70—230 mesh, grade 2—3, 5 cm×50 cm) with chloroform as an eluent. Mono-, bis-, and tris(octadecyloxyphenyl) porphyrins eluted first and the other by-products tended to be adsorbed on alumina. Similar procedures were repeated three times and the mixture of the three porphyrins was obtained. When the mixture was again chromatographed using half the flow rate of chloroform, three bands were separated and the slowest elute was the solution of the target compound. Chloroform was evaporated to give the mono(octadecyloxyphenyl) porphyrin. Yield 6.5 g (12.8% based on *p*-(octadecyloxyphenyl)benzaldehyde). Found C, 79.21; H, 7.45; N, 10.67%. Calcd for $C_{59}H_{63}N_7 \cdot 1/2H_2O$: C, 79.16; H, 7.21; N, 10.95%. Vis ($CHCl_3$) 418 (ε 369000), 483 (sh), 514 (17500), 550 (6910), 580 (5490), and 646 nm (3100).

Preparation of [Zn(TPyStPP)]. H_2TPyStPP (0.5 g, 0.56 mmol) and $Zn(CH_3COO)_2 \cdot 2H_2O$ (0.25 g, 1.1 mmol) in acetic acid (50 cm³) were heated under reflux for 1 h. Acetic acid was removed by distillation to give a solid product. The zinc porphyrin was isolated by using alumina column (Merck, 70—230 mesh, grade 2—3, 2 cm×30 cm) chromatography with a mixture of chloroform and methanol (8 : 2) as an eluent. Yield 0.48 g (90%). Found: C, 74.77; H, 6.63; N, 10.25%. Calcd for $C_{59}H_{61}N_7OZn$: C, 74.63; H, 6.48; N, 10.33%. Vis (DMSO) 317 (ε 19200), 406 (sh), 428 (512000), 516 (sh), 560 (20600), and 599 nm (7380).

Preparation of [Co(TPyStPP)] and [Mn(OH)(TPyStPP)]. The cobalt and manganese complexes were prepared from H_2TPyStPP and $Co(CH_3COO)_2 \cdot 4H_2O$ or $Mn(CH_3COO)_2 \cdot 4H_2O$ by similar procedures to those for the preparation of the zinc porphyrin. In the case of the cobalt complex, tetrahydrofuran was used as an eluent of the chromatography. [Co(TPyStPP)]: Yield 85%. Found: C, 73.11; H, 6.59; N, 9.51%. Calcd for $C_{59}H_{61}CoN_7O \cdot 3/2H_2O$: C, 73.05;H, 6.65; N, 10.11%. Vis ($CHCl_3$–CH_3OH (1 : 1)) 328 (ε14800), 432 (141000), 546 (8970), and 592 nm (sh).

[*Mn(OH)(TPyStPP)*]: Yield 85%. Found: C, 74.08; H, 6.56; N, 10.00%. Calcd for $C_{59}H_{62}MnN_7O_2$: C, 74.12; H, 6.54; N, 10.25%. Vis (DMSO) 372 (ε 41900), 394 (44000), 463 (143000), 512 (7140), 565 (12200), 600 (8170), and 762 nm (1140).

Preparation of [Mg(TPyStPP)]. The magnesium complex was prepared according to the method of Eschenmoser.[5] The preparation was carried out in nitrogen atmosphere. Magnesium turnings (1.5 g, 62 mmol) and ethyl iodide (5 cm³, 62 mmol) were treated in diethyl ether (80 cm³) to give ethyl Grignard (C_2H_5MgI) reagent. 3,5-Di-*t*-butyl-4-hydroxytoluene (1.5 g, 11 mmol) was treated with the Grignard solution (8 cm³, 5.8 mmol), and H_2TPyStPP (0.5 g, 0.56 mmol) in dichloromethane (40 cm³) was added dropwise to the reaction mixture in 30 min. The solution was kept for 16 h at room temperature and water (500 cm³) was added. After the mixture was well shaken in a separatory funnel, the dichloromethane layer was separated. Dichloromethane was removed and the residue was dried *in vacuo*. The magnesium porphyrin was isolated by alumina column chromatography using $CHCl_3$–CH_2OH (8 : 2) as an eluent. Yield 0.36 g (70% based on H_2TPyStPP). Found: C, 77.54; H, 6.80; N, 10.48%. Calcd for $C_{59}H_{61}N_7MgO \cdot 1/2H_2O$: C, 77.24; H, 6.81; N, 10.69%. Vis (DMF) 314 (ε 21200), 404 (sh), 425 (570000), 520 (sh), and 563 nm (20100).

N-*Methylation of [Mg(TPyStPP)].* [Mg(TPyStPP)] (0.5 g, 0.54 mmol) and methyl iodide (7.8 g, 55 mmol) in mixed solvents of chloroform, methanol, and tetrahydrofuran (1 : 1 : 1) (300 cm³) were heated under reflux in nitrogen atmosphere for 5 h. The solvents were removed by distillation and the solid product was dried *in vacuo*. The *N*-methylated porphyrin was purified by column chromatography using alumina (Merck, 70—230 mesh, grade 4) columns and $CHCl_3$–CH_3OH (8 : 2) as an eluent. Yield 0.73 g (90%). Found: C, 49.72; H, 5.22; N, 6.37%. Calcd for $C_{62}H_{70}I_3MgN_7O \cdot 9H_2O$: C, 49.76; H, 5.93; N, 6.55%. Vis ($CHCl_3$–CH_3OH (1 : 1)) 328 (ε 14800), 432 (141000), 546 (8970), and 592 nm (sh).

N-*Methylation of H_2TPyStPP and [M(TPyStPP)] (M=Zn, Co, and Mn).* The porphyrins were treated with methyl iodide in mixed solvents of chloroform, methanol, and tetrahydrofuran (1 : 1 : 1) in a similar manner to the *N*-methylation of magnesium porphyrin. In the case of the cobalt

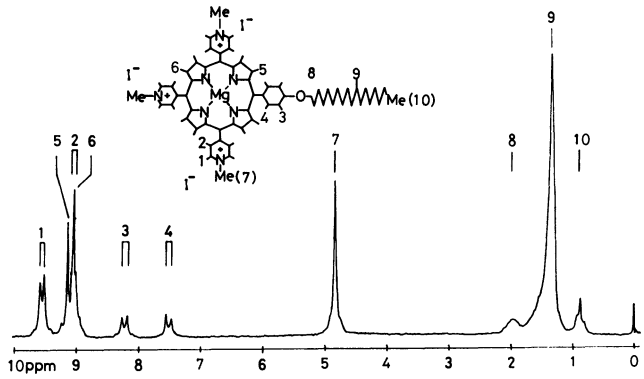

Fig. 1. ^{1}H-NMR Spectrum of 5,10,15-tris(1-methylpyridinium-4-yl)-20-[4-(octadecyloxy)phenyl]porphinatomagnesium(II) triiodide (dimethyl sulfoxide-d_6 solution, TMS internal reference, 100 MHz).

complex, a mixture of chloroform, methanol, and pyridine was used as an eluent.

5,10,15-Tris(1-methylpyridinium-4-yl)-20-[4-(octadecy)loxyphenyl]-21H,23H-porphine Triiodide (Abbreviated as $H_2TMePyStPPI_3$): Yield 50%. Found :C, 56.67; H, 5.66; N, 7.47%. Calcd for $C_{62}H_{72}I_3N_7O$: C, 56.76; H, 5.53; N, 7.18%. Vis (DMSO) 422 (ε 230000), 515 (15000), 552 (6800), 584 (5200), and 645 nm (3100).

[Zn(TMePyStPP)]I_3: Yield 80%. Found: C, 50.60; H, 5.06; N, 6.21%. Calcd for $C_{62}H_{70}I_3N_7OZn\cdot 6H_2O$: C, 50.20; H, 5.57; N, 6.61%. Vis (H_2O) 437 (ε 127000), 568 (16200), and 614 nm (9160).

[Co(TMePyStPP)]I_3: Yield 85%. Found: C, 54.67; H, 5.15; N, 7.19%. Calcd for $C_{62}H_{70}CoI_3N_7O$: C, 54.40; H, 5.15; N, 7.16%. Vis (H_2O) 332 (ε 12700), 439 (58700), 554 (8920), and 610 nm (sh).

[Mn(OH)(TMePyStPP)]I_3: Yield 50%. Found: C, 52.77; H, 5.20; N, 6.73%. Calcd for $C_{62}H_{71}I_3MnN_7O_2\cdot 2H_2O$: C, 52.52; H, 5.33; N, 6.91%. Vis (H_2O) 400 (ε 44700), 464 (111000), 563 (12900), 680 (1920), and 774 nm (1970).

Results and Discussion

All the *N*-methylated porphyrins are soluble in polar organic solvents such as *N,N*-dimethylformamide, dimethyl sulfoxide, tetrahydrofuran, methanol, chloroform, *etc.* They are soluble also in water due to the hydrophilic 1-methylpyridinium-4-yl groups forming presumably normal micelle colloid solutions. In a preliminary experiment to check the colloid formation in water, loss of porphyrins was not observed after passing the solution through a Sephadex G-50 column, indicating that they dissolve in water as high molecular weight aggregates. Because of the water solubility, they can be readily incorporated into pre-formed vesicles of phospholipids by immersing them in aqueous solutions of the porphyrins to give interesting asymmetrical vesicles[6] which are convenient systems for the study of the role of electron mediators in the photo-induced electron transport *via* the lipid membranes.[7–10]

Ring-opening Polymerization of Tetrahydrofuran Initiated by the 2-Norbornyl Cation Generated from *exo*-2-Norbornyl Tosylate in the Presence of Lithium Perchlorate

Ken'ichi TAKEUCHI, Yukari KATO, and Kunio OKAMOTO*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 26, 1981)

Synopsis. *exo*-2-Norbornyl tosylate initiates ring-opening polymerization of THF in the presence of lithium perchlorate. The deuterium scrambling of *exo*-2-norbornyl-*exo*-3-*d* tosylate indicates the S_N1 nature of the initiation mechanism.

The S_N2 type initiation of the ring-opening polymerization of THF has been extensively studied by Saegusa and his coworkers by use of superacid esters as initiator.[1] On the other hand, the mechanism of initiation by carbocation is not straightforward. Some stable carbocations such as triphenylmethyl[2] and tropylium[3] ions initiate the polymerization, but the actual initiator is believed to be a proton which is expelled from the 2-oxacyclopentyl cation, generated by the hydride-abstraction of THF by the stable carbocations.[2] In contrast, acyl[4] and polystyryl[5] cations react with THF to form oxonium ions at the initiation step (Eq. 1).

(1)

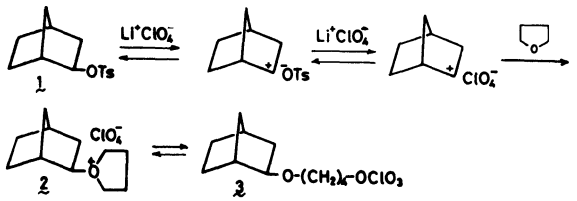
Recently we reported that the ionization of *exo*-2-norbornyl tosylate (**1**) in THF is dramatically promoted by added lithium perchlorate ($LiClO_4$).[6] Although it has been well known that $LiClO_4$ promotes ionization of organic substrates in ethereal solvents,[7-9] the fate of the carbocations produced in such reactions has not necessarily been clarified. Here we report that the 2-norbornyl cation thus generated initiates the polymerization of THF following Eq. 1, providing a clear example of S_N1 type initiation.

Results and Discussion

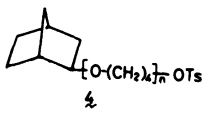
*Time-course and Products in the Reactions of **1** in THF in the Presence of Lithium Perchlorate.* In the absence of $LiClO_4$ the tosylate **1** is stable in THF even heated to 50 °C for 24 h. However, the addition of $LiClO_4$ causes the formation of the species which is easily saponified on titration with aqueous sodium hydroxide.

When the reaction of **1** (0.0981 M, 1 M = 1 mol dm^{-3}) in the presence of $LiClO_4$ (0.2984 M) in THF at 50.0 °C is followed titrimetrically, it obeys first-order kinetics ($k_1 = 2.24 \times 10^{-5}$ s^{-1}) until 20% reaction and then slows down, eventually leveling off at 10 h reaction with liberation of acid in 43% on titration. From the reaction mixture was isolated viscous liquid (46% on THF) which solidified on standing. The ^1H and ^{13}C NMR spectra of the polymers indicated that they were produced from THF *via* ring-opening polymerization and that they contained the *exo*-2-norbornyl and tosyl moieties (see Experimental). Integration of ^{13}C NMR signals for the norbornyl and tetramethylene groups indicated that the average degree of polymerization was *ca.* 60, which approximately agreed with the value calculated from the weight of polymers and the amount of the initiator **1**. A GLPC analysis of the reaction mixture prior to isolation of polymers revealed that none of nortricyclene, norbornene, or norbornane were formed, suggesting that the acid titrated was not a free acid arising from possible elimination reactions. Furthermore, saponification of the polymers in 90% ethanol with added sodium hydroxide indicated that 56% of the initial TsO- group was incorporated in the polymers.

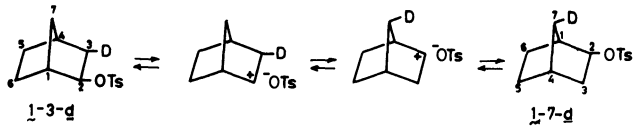
These findings strongly indicate that the initiation occurs following an S_N1 mechanism, *i.e.*, ionization of **1** followed by the attack of THF to the produced 2-norbornyl cation. The *exo*-configuration of the terminal 2-norbornyl group indicates that the attack of THF to the norbornyl cation occurs from *exo* side, which is generally the case in S_N1 solvolyses of **1**.[10,11] Presumably, the



first formed oxonium ion **2** and the propagating oxonium ion are in equilibrium with their corresponding ester forms (*e.g.* **3**),[1b] and these four species are easily hydrolyzed during titration. The results of the NMR analysis and the saponification experiment indicate the formation of terminated species **4**.



*Deuterium Scrambling in the Reclaimed Tosylate **1**.* Further evidence for ionization of **1** in THF containing $LiClO_4$ was obtained by examining *d*-scrambling of *exo*-2-norbornyl-*exo*-3-*d* tosylate (**1**-3-*d*). When **1**-3-*d* (0.100 M) was heated in THF with added $LiClO_4$ (0.307 M) for 38 min at 50.0 °C, the reclaimed tosylate was found to be a mixture of **1**-3-*d* (87%) and **1**-7-*d* (13%) by examining the *d*-contents at the 3- and 7-positions with ^{13}C NMR. This indicates that the Wagner-Meerwein rearrangement occurs through ionization under the reaction conditions, which is also generally observed in S_N1 solvolyses of **1**.[10]



Experimental

Materials. THF was distilled from $LiAlH_4$ just before use. Lithium perchlorate ($LiClO_4 \cdot 3H_2O$) was dehydrated at 160 °C and 4 Torr.† The tosylates **1** and **1**-3-*d* were prepared as described previously.[12]

Polymerization of THF and Analysis of Polymers. A solution of **1** (0.0981 M) and $LiClO_4$ (0.2984 M) in THF (1.000 cm^3) was heated in a sealed tube under nitrogen at 50 °C for 87 h. The viscous solution was worked up in the usual manner to give a pale brown viscous liquid (0.409 g) which solidified on standing: ^1H NMR ($CDCl_3$, 60 MHz) $\delta=1.57$ (br. t, $J=4$ Hz) and 3.40 (br, t, $J=4$ Hz); ^{13}C NMR ($CDCl_3$, 25 MHz) $\delta=24.3$ (C-6), 28.3 (C-5), 34.5 (C-7), 34.8 (C-4), 39.3 (C-3), 40.0 (C-1), and 82.0 (C-2) for the norbornyl group, 26.2 and 70.0 for the tetramethylene groups, and 21.3 (CH_3), 127.5, and 129.5 for the tosyl group. The ^{13}C NMR data for the norbornyl group agree well with those for *exo*-2-(4-phenoxybutoxy)norbornane.[6] Saponification of the polymers (0.4086 g) in 10.00 cm^3 90% ethanol containing NaOH (0.00965 M) at 100 °C in sealed tubes for 1 h showed liberation of acid corresponding to 56% of the original tosylate, which was invariant on prolonged saponification time.

Deuterium Scrambling. A solution containing **1**-3-*d* (1.071 g, 0.1002 M) and $LiClO_4$ (1.633 g, 0.3069 M) in THF (40.0 cm^3) was heated to 50.0 °C for 38 min under nitrogen in a sealed tube, and the unchanged tosylate was recovered in the usual manner (0.160 g). The deuterium distribution was determined by the integration of ^{13}C NMR ($CDCl_3$, 25 MHz) signals as previously reported.[12]

Rate Measurements. The reaction was conducted under nitrogen in sealed tubes. Aliquots were titrated in acetone with 0.01 M NaOH by using Lacmoid as indicator.

† 1 Torr=133.322 Pa.

Synopsis. The nature of the sand separated from Athabasca tar sand (Canada) by solvent extraction was examined. The existence of α-SiO_2 was confirmed by X-ray analysis. By DTA-TG determination, the occurrence of displacive transformation from low quartz to high quartz at 573±1 °C was proved, this coincides with the results obtained by means of X-ray analysis.

The amount of synthetic crude oil extractible from Athabasca tar sand is estimated to be roughly comparable with the total recoverable oil reserves in the Middle East.[2] However, an inorganic matter, sand, constitutes 87—89 wt % of the tar sand.[3] Consequently, if the tar sand is used as a source of petroleum in the near future, the treatment and/or utilization of the sand will be of great importance.

Hereby reported are the results of an examination of the nature of the sand separated from Athabasca tar sand by solvent extraction.

Experimental

Preparation. The procedure and apparatus employed for the extraction were the same as those used previously.[3]

Measurements. The benzene-insoluble residue (sand) was observed under an optical microscope. X-ray fluorescence analysis and X-ray powder diffraction were carried out on the sand. Simultaneous DTA-TG determination was carried out with a sample weight of 61.7 mg at a heating rate of 10 °C min^{-1}.

Results and Discussion

Athabasca tar sand was extracted with hexane and benzene in steps.[3] The yield of the sand (benzene-insoluble matter) was 87.6—88.5 wt.%, which is almost equal to the ash content of tar sand, 87.2 wt.%, as determined by a high-temperature ashing technique (815 °C).

The color of the sand after solvent extraction was brownish white, but it proved to be transparent upon washing with water. The optical micrograph of the sands is shown in Fig. 1. The maximum diameter of sands is 400 μm, while a typical diameter is 100—150 μm.

Temperature/°C
Fig. 3. DTA-TG profile up to 800 °C of the sand.

The X-ray powder diffraction profiles of the sand and the high-temperature ash are shown in Fig. 2. All the peaks in both profiles were identified as those of α-SiO_2.

A DTA-TG profile of the sand up to 800 °C is shown in Fig. 3. The weight decrease up to 800 °C is 0.2 wt.%. An endothermic peak at 573±1 °C was observed, which corresponds to the displacive transformation from low quartz to high quartz. This result coincides with that obtained by X-ray analysis.

X-Ray fluorescence analysis of the sand shows that the principal constituting elements are Si and Al. Zn, Cu, K, Fe, Ni, Ti, Ca, and Cl are present as minor or trace elements. Therefore, the existence of other unknown components such as aluminates can be estimated.

The authors are grateful to Professor D. M. Bodily of the University of Utah for his helpful discussion.
