(Received August 27, 1979)

The reduction of sulfuric acid has been studied for the purpose of the regeneration of activated carbon, which is used as an acceptor of sulfur dioxide from exhaust gas. When activated carbon impregnated with sulfuric acid was heated in a hydrogen atmosphere, sulfuric acid was reduced to sulfur dioxide by carbon in the temperature range from 200 °C to 350 °C. When copper sulfate was added, the sulfuric acid was reduced to sulfur dioxide, mainly by hydrogen, in the temperature range from 190 °C to 270 °C. At 227 °C, for example, the rate of reduction by hydrogen was nine times greater than the rate of reduction by carbon. Copper sulfate was sufficiently effective in an amount of one-fifth of the sulfuric acid in moles, indicating that copper in some form participates in the catalytic reaction.

Activated carbon can be used as an acceptor of sulfur dioxide from exhaust gas emitted by the combustion of fossil fuels. When exhaust gas which contains sulfur dioxide, oxygen, and water vapor is passed through a column of activated carbon, the sulfur dioxide is catalytically oxidized on carbon, according to Eq. 1, to sulfuric acid, which is then accumulated in the micropores of carbon:

$$SO_2 + 1/2O_2 + H_2O \longrightarrow H_2SO_4. \quad (1)$$

The kinetics and mechanism of this reaction have been investigated by several groups of workers.[1-10] Since the rate of the reaction decreases as the amount of sulfuric acid increases, the sulfuric acid must be removed periodically in order to recover the catalytic activity of carbon. Several methods have been proposed for this purpose. One of them is to remove the sulfuric acid as sulfur dioxide by heating it in an inert gas, where the following reaction takes place:[1,2]

$$H_2SO_4 + 1/2C \longrightarrow SO_2 + 1/2CO_2 + H_2O. \quad (2)$$

This method has the advantage that sulfur dioxide is obtained in a concentration high enough to be used directly for a sulfuric acid plant. However, it has the disadvantage of consuming the carbon. Another method is to reduce the sulfuric acid to elemental sulfur by the following two steps:[11,12]

$$H_2SO_4 + 3H_2S \longrightarrow 4S + 4H_2O \quad (3)$$

$$3H_2 + 3S \longrightarrow 3H_2S. \quad (4)$$

Reactions 3 and 4 proceed at 150 °C and 540 °C respectively. In this method, 3 mol of hydrogen are needed per mol of sulfuric acid in the over-all reaction.

Another process has also been investigated, in which a copper-alumina absorbent is used as an acceptor of sulfur dioxide and is regenerated by hydrogen.[13,14] Reactions 5 and 6 occur in the absorption step at 400 °C, and Reaction 7 occurs in the regeneration step at 400 °C. In this process, 2 mol of hydrogen are needed per mol of sulfur dioxide recovered.

$$Cu + 1/2O_2 \longrightarrow CuO \quad (5)$$

$$CuO + SO_2 + 1/2O_2 \longrightarrow CuSO_4 \quad (6)$$

$$CuSO_4 + 2H_2 \longrightarrow Cu + SO_2 + 2H_2O \quad (7)$$

† Present address: Research Laboratories of Osaka Soda Co., Ltd., 9 Otakasu-cho, Amagasaki 660.

The reduction of sulfuric acid by hydrogen (Eq. 8) is even more favorable, because only 1 mol of hydrogen is consumed per mol of sulfur dioxide recovered.

$$H_2SO_4 + H_2 \longrightarrow SO_2 + 2H_2O \quad (8)$$

Although Reactions 2 and 8 are both thermodynamically possible, the second one can be conducted preferentially if an appropriate catalyst is used. The aim of the present work is to test the catalytic effect of copper on this reaction.

It has previously been reported[3,5] that, when Reaction 1 takes place on activated carbon at temperatures from 50 °C to 140 °C, the concentration of sulfuric acid formed is the equilibrium one which depends upon the water-vapor concentration in the gas phase. For example, 73 wt% H_2SO_4 is formed at 100 °C at the water-vapor concentration of 6 vol %. In such an acidic medium and in the presence of oxygen, copper would exist in the form of sulfate. Thus, copper sulfate was used as the catalyst component in this work.

Experimental

Apparatus and Procedure. Granular activated carbon, which had been impregnated with sulfuric acid with or without copper sulfate, was heated in a stream of nitrogen or hydrogen at a constant or linearly increasing temperature, while the evolved gas was analyzed.

The apparatus used is shown in Fig. 1. A Pyrex tube, 23 mm in inner diameter, was used as a reactor; in it an activated carbon sample (13 g) was packed to a length of 9 cm. The reactor was placed in an electric heater. The temperature of the catalyst was controlled so as to increase at the rate of 2 °C/min using a chromel–alumel thermocouple and a temperature-programming unit. In some experiments, the temperature was kept constant. The flow rate of the gas was kept constant at 100 cm^3/min.

Preparation of Samples. Commercially available activated carbon (4 mmϕ × 6 mm, cylindrical, BET surface area 1170 m^3/g), made from coconut shell, was used for all the experiments. The activated carbon was impregnated under reduced pressure with an aqueous sulfuric acid containing 20 g of H_2SO_4 per 100 cm^3, or with a solution containing 20 g of H_2SO_4 and 20 g of $CuSO_4 \cdot 5H_2O$ per 100 cm^3, and then dried at 100 °C for 2 h. These samples contained 0.76 mmol of H_2SO_4 per g of carbon and, if added, 0.15 mmol of $CuSO_4$ per g of carbon. Other samples containing

different amounts of copper sulfate were also prepared.

Analysis of Evolved Gas. The amount of sulfur dioxide evolved was measured as a function of the time, according to the method reported by Kamino *et al.*[2] The outflow gas from the reactor was passed through a 6 wt% hydrogen peroxide solution, and the solution was titrated at appropriate intervals with a standard solution of sodium hydroxide, using a mixed solution of Methyl Red and Methylene Blue as an indicator.††

The total amount of carbon dioxide evolved was determined as follows: after the removal of the sulfur dioxide, the outflow gas was introduced into a 0.025 mol dm^{-3} barium hydroxide solution, in which carbon dioxide was absorbed. The solution was made free from barium carbonate by filtration, and then it was titrated with 0.1 mol dm^{-3} hydrochloric acid. The amount of carbon dioxide absorbed was calculated from the decrease in the concentration of barium hydroxide during each run.

The formation of hydrogen sulfide was checked qualitatively by introducing the outflow gas directly into a silver nitrate solution and looking for a black precipitate of Ag_2S. The formation of elemental sufur was checked by visual inspection, because even a small amount of sulfur could be detected by means of a yellowish-white deposit at the outlet of the reactor. To confirm the results of the above tests, the gravimetric determination of hydrogen sulfide and elemental sulfur was also done by a method described elsewhere.[15]

Results and Discussion

Activated carbon containing 0.76 mmol of H_2SO_4 per g of carbon was heated in a stream of nitrogen or hydrogen under an increasing temperature, while the amount of sulfur dioxide evolved was measured. As is shown by Curves a and b in Fig. 2, which represent the cumulative amount of sulfur dioxide as a function of the increasing temperature, the evolution of sulfur dioxide occurred in the temperature range from 200 °C to 350 °C. This temperature range

†† As the color of this indicator changes from purple to green at pH 5.4, neither carbon dioxide nor hydrogen sulfide, if present, affects the results of titration.

is in good agreement with that reported for Reaction 2 by other workers.[1,2] Curves c and d show similar results for activated carbon containing 0.76 mmol of H_2SO_4 and 0.15 mmol of $CuSO_4$ per g of carbon. In the case of the nitrogen atmosphere (Curve c), the evolution of sulfur dioxide took place in almost the same temperature range as above. In the case of the hydrogen atmosphere (Curve d), the evolution of sulfur dioxide began at 190 °C and was completed at 270 °C. We supposed that Curves a, b, and c correspond to Eq. 2, and Curve d, to Eq. 8. To verify this supposition, the amounts of sulfur dioxide and carbon dioxide evolved were determined in the same runs. The results are shown in Table 1. The mole ratio of CO_2/SO_2 was about 0.5 in the cases in which an activated carbon sample not containing copper sulfate was heated in the hydrogen atmosphere, and in which a sample containing copper sulfate was heated in the nitrogen atmosphere. These results indicate that Reaction 2 took place almost exclusively. On the contrary, the mole ratio of CO_2/SO_2 was much smaller when the sample containing copper sulfate was heated in the hydrogen atmosphere, indicating that Reaction 8 took place predominantly. Hydrogen sulfide and elemental sulfur were not detected in any of the above cases.

The amounts of carbon dioxide and sulfur dioxide

evolved were also measured at constant temperatures, using activated carbon samples which contained copper sulfate. Figure 3 shows the mole ratio of CO_2/SO_2 which was obtained when the sample was heated in the nitrogen or hydrogen atmosphere. In the case of the nitrogen atmosphere, the mole ratio was 0.5, as would be expected from Eq. 2. The mole ratio was much smaller in the case of the hydrogen atmosphere, but increased slightly with an increase in the temperature. This indicates that the rate of Reaction 2 increases more rapidly with an increase in the temperature than that of Reaction 8. Since the reduction of sulfuric acid is considered to proceed only according to Eqs. 2 and 8, of the total amount of sulfuric acid the fraction which is reduced by carbon is simply twice the mole ratio of CO_2/SO_2. At 227 °C, for example, the contribution of Reaction 2 to the total amount of sulfuric acid reduced was 10%, and that of Reaction 8 was 90%.

The rate of reduction of sulfuric acid was also studied at constant temperatures. Figure 4 shows the cumulative amount of sulfur dioxide, which was evolved at constant temperatures, as a function of the time. Figure 5 shows the initial reaction rate, which was determined from the initial slope of the curve in Fig. 4. The rate of the evolution of sulfur dioxide was much higher in the presence of copper sulfate than in its absence at the same temperatures. The Arrhenius plot of the initial reaction rate gives the apparent activation energies of 83 kJ/mol in the absence of copper sulfate and 73 kJ/mol in its presence. These values are regarded as approximately corresponding

to Reactions 2 and 8 respectively, and they indicate that the contribution of Reaction 2 should increase as the temperature increases. This conclusion is consistent with the result that the mole ratio of CO_2/SO_2 increases with an increase in the temperature, as is shown by the solid line in Fig. 3. Judging from the values of the activation energy, the transport processes are not the rate-determining steps in either reaction.

The effect of the amount of copper sulfate was also studied, using activated carbon impregnated with a constant amount of sulfuric acid, but with different amounts of copper sulfate. It may be seen from Fig. 6 that the addition of 0.15 mmol-$CuSO_4$/g-carbon is sufficient for Reaction 8 to occur under these conditions. This amount of copper sulfate is about one-fifth that of the sulfuric acid in moles. Therefore, it is supported that copper in some state has a cataytic effect on Reaction 8.

Concluding Remarks

It was found that sulfuric acid is reduced by hydrogen on activated carbon with copper sulfate at temperatures from 190 °C to 270 °C. A succeeding paper will describe metals other than copper as catalysts, and will discuss the catalytic mechanisms.

(Received September 17, 1979)

The reduction of sulfuric acid, which is formed on the activated carbon catalyst in the course of removing sulfur dioxide from exhaust gas, was investigated. The platinum, palladium, silver, and copper on activated carbon were found to be catalytically active in the reduction of sulfuric acid by hydrogen, while manganese, iron, cobalt, nickel, and zinc were found to be inactive. The copper–carbon catalyst is favorable, because sulfuric acid was reduced selectively to sulfur dioxide on it at temperatures from 190 °C to 270 °C. On the platinum–carbon catalyst, the reduction occurred at a relatively low temperature (140 °C to 200 °C), but hydrogen sulfide and elemental sulfur were formed in addition to sulfur dioxide. It is concluded from thermodynamic calculations that catalytically active metals were in the metallic state on activated carbon under the present reaction conditions. An electrochemical mechanism is proposed for the reaction.

In the course of removing sulfur dioxide from exhaust gas by using the activated carbon catalyst, sulfuric acid is formed and accumulated on the catalyst. As a method for removing the sulfuric acid and regenerating the catalyst, Reaction 1 seems to be suitable,

$$H_2SO_4 + H_2 \longrightarrow SO_2 + 2H_2O \quad (1)$$

because the sulfur dioxide obtained can be used directly for sulfuric acid production. However, other side reactions such as Reactions 2, 3, and 4, may possibly occur. For example, the standard Gibbs energy change, ΔG°, for reactions 1, 2, 3, and 4 at 500 K

$$H_2SO_4 + 1/2C \longrightarrow SO_2 + 1/2CO_2 + H_2O \quad (2)$$

$$H_2SO_4 + 3H_2 \longrightarrow S + 4H_2O \quad (3)$$

$$H_2SO_4 + 4H_2 \longrightarrow H_2S + 4H_2O \quad (4)$$

are −133.0 kJ/mol, −110.8 kJ/mol, −271.5 kJ/mol, and −311.8 kJ/mol respectively.[1] It was reported in a previous paper[2] that, when copper sulfate was added, Reaction 1 took place on activated carbon, with only a small consumption of carbon due to Reaction 2. It was suggested that copper in a certain state exerts a catalytic effect on Reaction 1 selectively. In the present paper, experimental results on several metals other than copper as a catalyst component are described, and a possible mechanism of the catalysis is discussed.

Experimental

Apparatus and Procedure. Granular catalysts were heated in a stream of hydrogen under the condition of a linearly increasing temperature, and the gas thus evolved was analyzed. The apparatus used was described in the previous paper.[2] A Pyrex tube 23 mmϕ in inner diameter was used as the reactor, in which catalyst was packed to a length of *ca.* 9 cm. The amount of catalyst packed in was *ca.* 13 g in the case of activated carbon and *ca.* 15 g or 20 g in the case of activated alumina. The catalyst temperature was controlled so that it increased at the rate of 2 °C/min. The flow rate of hydrogen was held constant at 100 cm³/min. Under these conditions it was easy to follow the amount of sulfur dioxide evolved, and the linearity of the temperature with the time was relatively good.

Preparation of Catalysts. Commercial activated carbon (4 mmϕ × 6 mm cylindrical) made from coconut shell was used for these experiments. The activated carbon was impregnated with aqueous sulfuric acid, together with or after the addition of each metal component, and then dried at 100 °C for 2 h. Manganese, iron, cobalt, nickel, copper, and zinc were added to the carbon by impregnating it with a mixed solution of sulfuric acid and the respective sulfates. Platinum, palladium, and silver were added to the carbon in advance by impregnating it with aqueous solutions of hexachloroplatinic(IV) acid, palladium(II) chloride, and silver nitrate respectively, and by then heating it in a hydrogen atmosphere at 400 °C, where these salts were reduced to metals. The content of the metal or the metal ion was controlled so as to be *ca.* 9 mg/g carbon in all cases. In the case of the copper–carbon catalyst, this amount was sufficient as a catalyst component.[2] The amount of sulfuric acid was *ca.* 0.8 mmol/g carbon. This amount was chosen on the basis of the practical data in a pilot-plant test performed by Kamino *et al.*,[3] where 0.7—1.6 N m³ of sulfur dioxide was adsorbed by 57 kg of activated carbon per hour.

Activated alumina (3 mmϕ spherical) was also used in place of activated carbon. In this case, the metal content was *ca.* 8 mg/g alumina, and the amount of sulfuric acid impregnated was *ca.* 0.7 mmol/g alumina.

Analysis of Gas Evolved. The amount of sulfur dioxide in the outflow gas from the reactor was determined by passing the gas through a hydrogen peroxide solution and by titrating the solution at appropriate intervals with a sodium hydroxide solution.[2] The total amounts of hydrogen sulfide and of elemental sulfur evolved were determined gravimetrically in the other runs, as follows: the outflow gas from the reactor was introduced directly into an acidic solution of silver nitrate, in which silver sulfite, silver sulfide, and elemental sulfur were precipitated. After the filtration of these precipitates, the silver sulfite was removed by washing with an aqueous ammonia solution, and then the elemental sulfur was dissolved in carbon disulfide. The weight of the remaining silver sulfide was measured, from which the amount of hydrogen sulfide evolved was calculated. Since solid sulfur was also deposited at the outlet of the reactor, it was dissolved in carbon disulfide and the solution thus obtained was put together with the former one. After the evapolation of the solvent, the weight of the solid sulfur was measured.

† Present address: Research Laboratories of Osaka Soda Co., Ltd., 9 Otakasu-cho, Amagasaki 660.

Results and Discussion

Activated carbons containing sulfuric acid and various metals or metal sulfates were heated in a stream of hydrogen under the condition of an increasing temperature, while the amount of sulfur dioxide evolved was followed. The results are shown in Fig. 1. When platinum, silver, palladium, or copper was added to activated carbon, the evolution of sulfur dioxide was observed in a lower temperature range than in the case of simple activated cabon. These metals are considered to catalyze Reaction 1. In the cases of platinum–, silver–, and palladium–carbon catalysts, the contribution of Reaction 2 must be smaller, if there is any at all, than in the case of the copper–carbon catalyst, because the rate of this reaction depends upon the temperature, but not upon the presence of metal.[2] When manganese, iron, cobalt, nickel, or zinc was added, the evolution of sulfur dioxide was observed in the same temperature range as in the case of simple activated carbon. In these cases, it was likely that not Reaction 1, but Reaction 2 took place exclusively. A comparison of the total amount of sulfur dioxide evolved was rather difficult because of the poor reproducibility of the initial amount of sulfuric acid impregnated. However, the curve for the platinum–carbon catalyst in Fig. 1 differs apparently from the others, indicating that sulfur dioxide was not the only product. In fact, a yellow deposit was observed at the outlet of the reactor in this case.

In order to see whether carbon in itself plays any role in Reaction 1, similar experiments were carried out by using activated alumina in place of activated carbon. Figure 2 shows the results on copper–alumina and copper–carbon catalysts, as well as on simple activated alumina and activated carbon. The evolution of sulfur dioxide took place on the copper–alumina catalyst in a temperature range *ca.* 100 °C higher than in the case of the copper–carbon catalyst. This fact indicates that carbon also participates in the catalysis in Reaction 1. A similar result was obtained for the platinum–alumina catalyst, where the evolution of sulfur dioxide occurred mainly in the temperature range from 300 °C to 450° C. Incidentally, the total amount of sulfur dioxide evolved was almost the same in Fig. 2, although the initial amount of sulfuric acid on the alumina catalysts was about 1.3 times larger than that on the carbon catalysts.

Since it is possible that sulfuric acid is reduced by hydrogen to elemental sulfur and further to hydrogen sulfide, the amounts of these products were determined in the cases of the platinum–, silver–, and copper–carbon catalysts and the copper–alumina catalyst. As is shown in Table 1, a considerable amount of hydrogen sulfide was formed on the platinum–carbon catalyst, together with a small amount of elemental sulfur. On the silver–carbon catalyst, a small amount of hydrogen sulfide was formed. To the contrary, neither of these products was detected in the case of the copper–carbon catalyst. Considerable amounts

Table 1. The amounts of SO_2, S, and H_2S evolved

Catalyst	Weight of packed catalyst	Evolved gases/mmol		
	g	SO_2	S	H_2S
Platinum–carbon[a]	13	8.5	0.3	3.5
Silver–carbon[a]	13	10.0	0.0	0.2
Copper–carbon[a]	13	10.5	0.0	0.0
Copper–alumina[b]	15	6.0	0.8	4.1

Temperature range: a) Room temperature to 400 °C. b) Room temperature to 500 °C. Heating rate: 2 °C/min.

of hydrogen sulfide and elemental sulfur were formed on the copper–alumina catalyst, which is used in commercial plants of the flue-gas desulfurization process (Shell Process).[4,5] This catalyst seems to be suitable for the purpose of recovering elemental sulfur in combination with the Claus process.

In order to infer the actual state of each metal component under the reaction conditions, the standard Gibbs energy change, ΔG°, for Reaction 5 was calculated from the thermodynamic data.[1]

$$M_{2/n}SO_4 + H_2 \longrightarrow (2/n)M + H_2SO_4 \quad (5)$$

Here, "n" indicates the ionic valence of the metal, M. As is shown in Table 2, the values of ΔG° calculated for silver and copper have a negative sign. This suggests that these metals exist in the metallic state under the present reaction conditions. There is no doubt that platinum and palladium are also in the metallic state, though the necessary data are not available. The other metals in Table 2 have positive values of ΔG°, indicating that these metals exist as sulfates. It is probable that catalytically active metals are in the metallic state, while inactive metals are in the ionic state.

Table 2. The standard Gibbs energy change, ΔG° (kJ/mol), for Reaction 5

$M_{2/n}SO_4$	Temperature/K			
	300	400	500	600
$MnSO_4$	267.4	272.2	276.2	280.2
$FeSO_4$	135.1	141.3	146.6	152.0
$CoSO_4$	70.9	76.5	82.0	88.0
$NiSO_4$	87.4	91.4	95.2	99.5
$CuSO_4$	−29.1	−24.7	−21.2	−17.5
$ZnSO_4$	182.7	188.3	193.2	198.3
Ag_2SO_4	−71.5	−63.1	−55.5	−47.8

It may be noted in Fig. 1 that, when the added metal has a lower hydrogen overvoltage, the evolution of sulfur dioxide takes place in the lower temperature range. Thus, the sequence of hydrogen overvoltage at 25 °C,[6] Pt<Pd<Ag<Cu, agrees substantially with the sequence of the temperature range in which the reaction occurs, Pt<Ag<Pd<Cu.†† Considering that the hydrogen overvoltage is a measure of the electrocatalytic activity of metal in the hydrogen-evolution reaction, and that sulfuric acid is a liquid electrolyte at temperatures below 337 °C, the following electrochemical mechanism is proposed for Reaction 1:

$$H_2 \longrightarrow 2H^+ + 2e^- \quad (6)$$

$$H_2SO_4 + 2H^+ + 2e^- \longrightarrow SO_2 + 2H_2O. \quad (7)$$

Thus, the anodic reaction Eq. 6, proceeds on metal, and the cathodic reaction, Eq. 7, on cabon. Reaction 7 is the reverse of that proposed in the catalytic oxidation of sulfur dioxide on activated carbon.[7,8] When the added metal has a low hydrogen overvoltage, Reaction 6 is catalyzed by the metal: therefore, the total reaction, Eq. 1, can occur at a relatively low temperature. In contrast, alumina has no electric conductivity; therefore, Reaction 7 cannot proceed on alumina. Probably, then the catalytic reduction of sulfuric acid on the copper- or platinum–alumina catalyst occurs by another mechanism.

The standard electromotive force of the hypothetical cell composed of Reactions 6 and 7 is calculated as 0.689 V at 500 K. If the overvoltage for Reaction 6 on the catalyst surface is greater than 0.689 V at 500 K, it is impossible for these reactions to occur at this temperature. This is the case with the simple activated carbon. Thus, one of the present authors has previously investigated the kinetics of Reaction 6 at various electrodes in the eutectic melt of lithium chloride and potassium chloride in relation to the hydrogen–chlorine fuel cell;[9] he found that the overvoltage at the carbon electrode was greater than 0.84 V at 773 K. At the temperature of 500 K, the overvoltage must be much greater. This may be the reason why Reaction 1 does not take place on the simple activated carbon.

It has been reported that sulfur dioxide, hydrogen sulfide, and elemental sulfur were produced in the electrolysis of concentrated sulfuric acid at moderately high temperatures, and that the distribution of the products depended strongly on the temperature.[10,11] Besides, the kinetics and mechanism of the electrode reaction are possibly dependent on the electrode potential. In the catalytic reduction of sulfuric acid in the present work, also, it is probable that the distribution of the products is determined by the reaction temperature and the local potential on the catalyst surface, both of which are dependent on the electrocatalytic activity of the metal added.

Conclusion

It is concluded that the copper–carbon catalyst is the best for the purpose of recovering sulfur dioxide from the reduction of sulfuric acid by hydrogen. This catalyst is not likely to be poisoned by sulfide formation, because copper on carbon may become ionic in the oxidizing atmosphere in the step of sulfuric-acid formation, and then be reduced to metal in the reduction step, cyclically.

†† Palladium seems to be out of order in these two sequences. This may be ascribed either to the specific temperature dependency of its activity, or to the discrepancy of the mechanisms of hydrogen-electrode reaction on it at low and high temperatures.

(Received October 16, 1979)

The polarization spectra of indole, 3-indolebutyric acid, and benzimidazole have been measured and analyzed by means of MO theory taking Σ-Π interaction into consideration. Induced transition moment due to Σ-Π interaction can be assigned to each σ-bond (both direction and magnitude) pictorially. The effect of hetero atom on the electronic absorption spectra can be interpreted reasonably. Agreement between experimental and calculated results is satisfactory.

In previous papers[1,2] the effects of Σ-Π interaction on π-π* transition energy and on the transition moment in a conjugated system were formulated with use of the partitioning technique,[3] Σ-Π interaction being shown to have an important effect upon the excited singlet states. The effect can be neglected for the triplet states, since it arises from the exchange interaction between σ- and π-electrons. The calculated oscillator strength was reduced to almost one-half of the reference one evaluated by the conventional π-electron approximation (P-P-P method). The MO-CI method based on the π-electron approximation usually gives too large transition moments.

Our aim is to elucidate the effect of substituent or hetero atoms in a large conjugated system on the direction and magnitude of the transition moment in view of Σ-Π interaction. The transition moment of π-π* transition is important in weak intermolecular interaction, exciton interaction in the solid state or in enzyme systems, and in optical properties of molecules, such as optical activity, CD and MCD spectra.

A photoabsorbed tryptophan in an enzyme which has indole residue as its functional group interacts with a distant tryptophan in the same enzyme. The origin of such long distance interaction (*ca.* R=30 Å) is thought to be an exciton interaction. Comprehensive studies[4-6] have been made on electronic spectra of indole which is an active part of tryptophan.

We have determined the direction of transition moment of indole, 3-indolebutyric acid, and benzimidazole and compared the result with that of MO-CI calculation taking Σ-Π interaction into consideration. By our method the induced transition moment caused by Σ-Π interaction can be decomposed into individual σ-bonds which are mostly localized. The decomposition of the induced moment will help to clarify the general feature of Σ-Π interaction in a molecule.

Experimental

Materials. Indole, 3-indolebutyric acid, and benzimidazole (guaranteed, Tokyo Kasei Co., Ltd.) were purified by repeated recrystalization from ethanol or a mixed ethanol–water solution. PVA (polyvinyl alcohol) powder (Koso Chemical Co., Ltd., average polymerization degree 1400) was used for preparation of the film. Preparation of the PVA film and details of dichroism were reported.[7]

Measurement. Dichroic spectra of indole and 3-indolebutyric acid in the stretched PVA films were measured with a Simadzu QV-50 spectrophotometer equipped with a Glan-Thompson polarizer available for the region over 220 nm. The dichroic spectra of benzimidazole, whose maximum corresponding to the intense band at 220 nm of indole is at 205 nm, were measured with a Simadzu UV-200S automatic recording spectrophotometer available for the region over 190 nm.

In the dichroism analysis, the stretched ratio Rs indicates the degree of deformation of the PVA structure, the dichroic ratio Rd the ratio of optical densities ($D_{\parallel}/D_{\perp}$) at a given wavelength, and $D_{\parallel}$ and $D_{\perp}$ are the densities for the incident polarized light the electric vector of which is parallel and perpendicular, respectively, to the stretching direction of the film.

Rd can be expressed as a function of Rs and a parameter r, which is defined as the ratio of two components (μ_a and μ_b) of a transition moment of an electronic transition. μ_a and μ_b are the components parallel and perpendicular, respectively, to an orientation axis (OA) peculiar to the molecule.[7] The angle of the transition moment against OA, which will be referred to as the orientation angle, can be obtained using the Rd and Rs values. The apparent orientation angles for the bands are indicated along the Rd curve in Figs. 1 and 2.

Theoretical

A report was given on an improvement of the P-P-P method considering Σ-Π interaction, which was

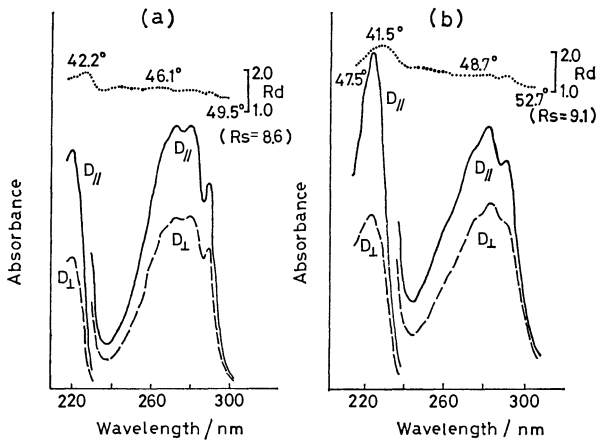

Fig. 1. Dichroic spectra of (a) indole and (b) 3-indolebutyric acid in the stretched PVA film.

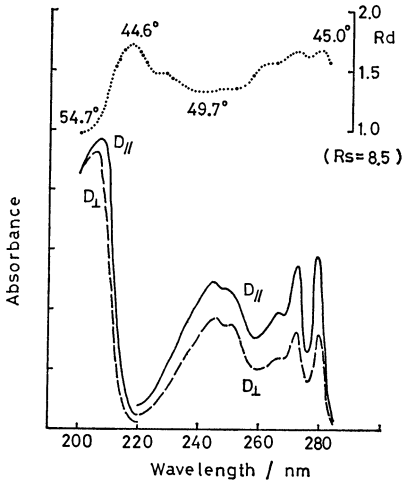

Fig. 2. Dichroic spectra of benzimidazole in the stretched PVA film.

found to be satisfactory for the calculation of electronic spectra of conjugated systems, particularly for the calculation of transition moments.[1]

A physical picture is given of the effect of Σ-Π interaction on the transition moment. The transition moment, $\tilde{\boldsymbol{m}}$, can be expressed by

$$\tilde{\boldsymbol{m}} = \boldsymbol{m}_0 + \Delta\boldsymbol{m} \tag{1}$$

$$\Delta\boldsymbol{m} = \frac{1}{\sqrt{2}\varepsilon}\sum_{i\alpha}\sum_{\mu} C_{i\alpha}d_{i\mu}d_{\alpha\mu}\sum_{\mathrm{AB}}\boldsymbol{r}_{\mathrm{A}}B_{\mathrm{AB}}\gamma_{\mathrm{B}\mu}, \tag{2}$$

where $\boldsymbol{m}_0$ is the transition moment obtained by the conventional P-P-P calculation, $\Delta\boldsymbol{m}$ the correction term due to the Σ-Π interaction, and ε the energy parameter. In Eq. 2, $C_{i\alpha}$ is the variation parameter associated with the configuration, $|{}^{\alpha}_{i}>$, and $d_{i\mu}$ the μ-th AO coefficient of the i-th MO. $\Delta\boldsymbol{m}$ can be decomposed into the individual A–B σ-bond polarization, $\Delta\boldsymbol{m}_{\mathrm{AB}}$, as follows.

$$\Delta\boldsymbol{m} = \sum_{\mathrm{A>B}}\Delta\boldsymbol{m}_{\mathrm{AB}}$$

$$\Delta\boldsymbol{m}_{\mathrm{AB}} = (\boldsymbol{r}_{\mathrm{A}}-\boldsymbol{r}_{\mathrm{B}})B_{\mathrm{AB}}(X_{\mathrm{B}}-X_{\mathrm{A}}), \tag{3}$$

where

$$X_{\mathrm{B}} = \frac{1}{\sqrt{2}\varepsilon}\sum_{i\alpha} C_{i\alpha}d_{i\mu}d_{\alpha\mu}\gamma_{\mathrm{B}\mu} \tag{4}$$

and $\boldsymbol{r}_{\mathrm{A}}$ is the position vector of the atom A. Equation 4 can be rewritten as

$$X_{\mathrm{B}} = \frac{1}{\sqrt{2}\varepsilon}\sum_{\mu} Y_{\mu}\gamma_{\mathrm{B}\mu}, \tag{5}$$

where Y_{μ} is defined by

$$Y_{\mu} = \sum_{i\alpha} C_{i\alpha}d_{i\mu}d_{\alpha\mu}, \tag{6}$$

Y_{μ} represents the component of the transition density (CTD) at μ-th atom. When π-π^* transition takes place, Y_{μ} is produced at μ-th atom, creating an induced charge, X_{B}, on the atom B. In Eq. 3, the vector $(\boldsymbol{r}_{\mathrm{A}}-\boldsymbol{r}_{\mathrm{B}})$ indicates the A-B σ-bond given by the structural formula. $(X_{\mathrm{B}}-X_{\mathrm{A}})$ gives the difference between the induced charge of atom A and that of atom B. B_{AB} plays the role of projection operator whether a σ-bond exists or not between the atoms A and B.

MO-CI calculations have been carried out for indole, 3-methylindole and benzimidazole. As regards their geometry, it is assumed that all molecules consist of regular hexagons and pentagons, in which each C–C and C–N bond length is 1.40 Å. Values for the valence-state ionization potentials, I, and electron affinities, A, of the carbon and nitrogen atoms are taken as follows.

$I(\mathrm{C}) = 11.16\,\mathrm{eV}$ $\quad A(\mathrm{C}) = 0.03\,\mathrm{eV}$

$I(\mathrm{N}^{+1}) = 14.12\,\mathrm{eV}$ $\quad A(\mathrm{N}^{+1}) = 1.78\,\mathrm{eV}$

$I(\mathrm{N}^{+2}) = 26.70\,\mathrm{eV}$ $\quad A(\mathrm{N}^{+2}) = 9.26\,\mathrm{eV}$

The two center core integrals $\beta_{\mu\nu}$ are calculated by the variable β method:[8]

$$\beta_{\mu\nu}(\mathrm{C\text{-}C}) = -1.90 - 0.51\,P_{\mu\nu}\ \mathrm{eV}$$

$$\beta_{\mu\nu}(\mathrm{C\text{-}N}) = -2.09 - 0.53\,P_{\mu\nu}\ \mathrm{eV}.$$

In the CI calculation, all possible singly excited configurations are included.

Results and Discussion

Determination of Orientation Axis. Indole and 3-indolebutyric acid show very similar spectra (Figs. 1(a) and 1(b)). From a comparison of the *R*d curves, we see that the absorption in the range 240—300 nm consists of two bands with different polarizations. Let us denote the bands for the long and short wavelength side by bands (I) and (II). The apparent orientation angles are 49.5° (I) and 46.1° (II) for indole, and 52.7° (I) and 48.7° (II) for 3-indolebutyric acid, both orientation angles increasing with the substituent effect. On the other hand, the apparent angle for a third band (III) at *ca.* 220 nm decreases from 42.2° to 41.5°. Such changes suggest that the orientation axis rotates and approaches the polarization direction of the third band away from those of the first and second transitions. Thus, the polarization direction of bands I and II is on one side of the orientation axis of the molecule and that of band III on the opposite side.

In dichroism analysis, when an absorption band is isolated from the others, the *R*d value for the band should be constant in the band region. However, the value for band III (max. 224 nm) of 3-indolebutyric acid, for example, is not constant but decreases from maximum at 230 nm toward the short wavelength for the band region observed. The decrease in *R*d indicates that band IV penetrates into the band III region. The orientation angle for band III would become smaller than 41.5° if no penetration takes place.

The same situation is considered for band III of indole; the true orientation angle should be less than 42.2°. Since bands I and II overlap each other, their specific orientation angles should be >49.5° and <46.1° for indole and >52.7° and <48.7° for 3-indolebutyric acid, respectively.

Figure 2 shows the dichroic spectra and *R*d curve for benzimidazole. From a comparison of Fig. 2 with Figs. 1(a) and 1(b), we see that bands, I and II (Fig. 2) are isolated from each other and correspond

to bands I and II of indole, respectively, and also band III of benzimidazole corresponds to that of indole. The apparent orientation angles for I(45°) and III(44.6°) of benzimidazole are nearly equal to each other and differ from that of II(49.7°), suggesting that their transition moments are on one side of the orientation axis of the molecule while band II is on the opposite side, in contrast to the case for indole. This indicates that the direction of the transition moment of band I of indole has been moved from one side to the other of the orientation axis by the substituent effect of aza-nitrogen at the 3-position of indole molecule.

The orientation axis of molecule can be determined by a comparison of the experimental orientation angles of band polarizations and the calculated absolute angles of corresponding transition moment.

In the dichroism analysis, the induced orientation axis (OA) of molecule in the stretched PVA substrate is assumed to take a specific direction in the molecular plane. Let us denote the angle between OA and the molecular coordinate axis X by $\theta_{OA}(X)$, where $-90° \leqq \theta_{OA}(X) \leqq 90°$ ($\theta_{OA}(X)$ is defined as positive for anticlockwise direction). If we denote the theoretically calculated angle of the moment of the n-th singlet transition (S_n) against the X-axis by $\theta_n(X)$, and the angle of S_n against OA by $\theta_n(OA)$, we have

$$\theta_n(OA) = 90° \pm (90° - |\theta_n(X) - \theta_{OA}(X)|), \quad (7)$$

where the signs + and − are taken for negative and positive values, respectively. $\theta_n(OA)$ should be compared with the experimental orientation angle $\theta_N(OA)$ of the band number N corresponding to the n-th transition.

We can now determine the absolute angle $\theta_{OA}(X)$ of the orientation axis against the X axis of the molecule in the stretched PVA substrate. The relation between $\theta_n(OA)$ and $\theta_{OA}(X)$ for indole is shown in Fig. 3(a) where the lower limit $\theta_I(OA) > 49.5°$ and upper limits $\theta_{II}(OA) < 46.1°$ and $\theta_{III}(OA) < 42.2°$ are added. For $\theta_{OA}(X)$ satisfactory conditions are as follows: $\theta_I(OA) > 49.5°$ in the range −36.2°—44.8°, $\theta_{II}(OA) > 46.1°$ in the range from 43.5° to −44.3° through 90°, and $\theta_{III}(OA) < 42.2°$ in the range $-38.6° \leqq \theta_{OA}(X) \leqq 45.8°$. The orientation axis (OA) associated with the indole molecule should be restricted to a common direction for which the three conditions are satisfied simultaneously. Such an angle $\theta_{OA}(X)$ (44°±1°) can be found in the range 43.5°—44.8° (Fig. 4(a)).

In the same way, the orientation axis of the 3-indolebutyric acid molecule can be determined to be $\theta_{OA}(X) = 39° \pm 1°$, making use of the calculated result for methyl derivative of indole instead of the 3-(3-carboxypropyl) derivative.

In the case of benzimidazole, the range of angle $\theta_{OA}(X)$ which satisfies the experimental conditions is 5°—29° (Figs. 3(b) and 4(b)). The range is dependent on the experimental data for bands I and IV the orientation angles of which are $\theta_I(OA) \leqq 45°$ and $\theta_{IV}(OA) > 54.7°$, respectively. However, band IV greatly overlaps band III of $\theta_{III}(OA) < 44.6°$ (Fig. 2). If band IV is isolated from band III, it will have

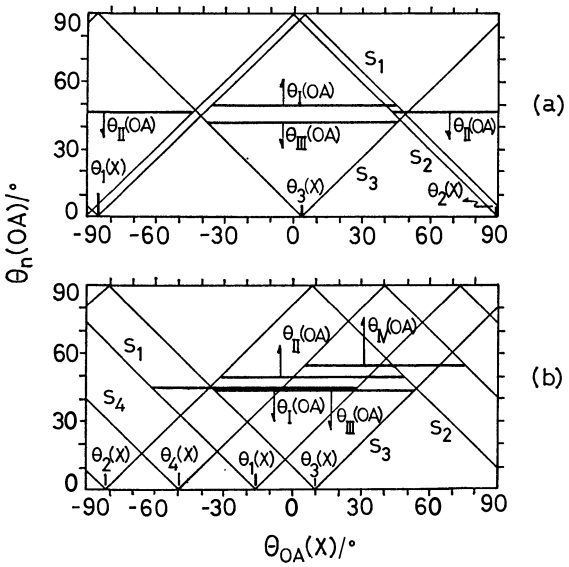

Fig. 3. The angle-relation between the moment of n-th transition (S_n) and the orientation axis (OA) of molecule when the angle of OA to the molecular axis (X) varies in the range −90°—90°.
The abscissa represents the angle of OA to X, $\theta_{OA}(X)$, and the ordinate the angle of the moment of S_n to OA, $\theta_n(OA)$. The horizontal lines indicate the experimental orientation angles (lower or upper limit) of the band number N, $\theta_N(OA)$, which are compared with the theoretical values $\theta_n(OA)$. The allowed angles of $\theta_N(OA)$ are as follows. (a) indole: $\theta_I(OA) > 49.5°$, $\theta_{II}(OA) < 46.1°$, $\theta_{III}(OA) < 42.2°$. (b) benzimidazole: $\theta_I(OA) \leqq 45°$, $\theta_{II}(OA) > 49.7°$, $\theta_{III}(OA) < 44.6°$, $\theta_{IV}(OA) > 54.7°$.

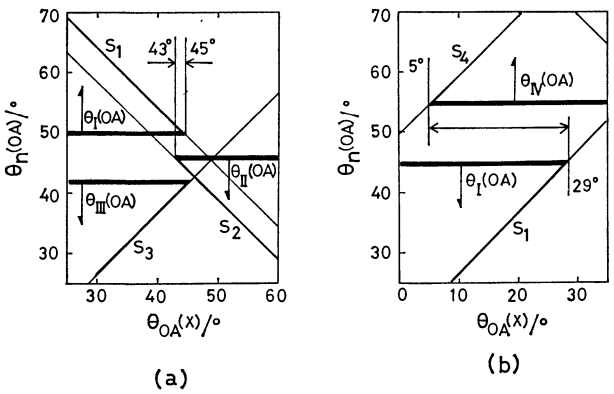

Fig. 4. Angle-relation of $\theta_n(OA)$ and $\theta_{OA}(X)$ of (a) indole and (b) benzimidazole. See the illustration of Fig. 3.

an angle much larger than 54.7°. This will make the lower limit of $\theta_{OA}(X)$ shift from 5° toward 29° (Fig. 4(b)). Since the first peak of band I is considered to be pure electronic transition because of its isolation from band II, the value $\theta_I(OA) = 45°$ would be reliable and the angle of $\theta_{OA}(X)$ may be *ca.* 29°.

The directions of OA of indole, 3-indolebutyric acid and benzimidazole determined experimentally are given in Table 1. $\theta_{OA}(X)$ is the absolute angle of OA against the molecular X(long) axis. The

geometrical relation of OA and the transition moments of S_n are shown in Fig. 5. Agreement between experimental and calculated results is satisfactory. In the case of indole the calculated angles of S_1 and S_2 are 50.3° and 45.6°, respectively. However, the angles observed are 49.5° and 46.1°, respectively, showing that the partial overlapping of the two bands makes the respective transition directions (absolute angles) approach each other (apparent angles). Similarly, the orientation angle of S_3 transition turns toward that of S_4 because of overlapping. The calculated and experimental results agree (Fig. 5).

Substituent Effect on the Electronic Transition Moment. The calculated π-π^* transition energies and oscillator strengths of indole, 3-methylindole, and benzimidazole are summarized in Table 2. Agreement between calculated and experimental results is satisfactory. The calculated transition moments, $\boldsymbol{m}_0$ and $\tilde{\boldsymbol{m}}$, and oscillator strengths, f_0 and f, of these molecules are summarized in Table 3. The directions of $\boldsymbol{m}_0$ and $\Delta\boldsymbol{m}$ are almost opposite each other, f being considerably reduced. It is of interest to study the effect of the methyl group on the transition moment of the methyl substituted systems. The induced σ-polarization of indole and that of 3-methylindole are illustrated in Figs. 6 and 8, respectively. In the case of 3-methylindole, a large induced σ-bond polarization is found

at C–CH_3 σ-bond, but its oscillator strength and the direction of transition moment of the π-π^* excitation are almost the same as those of indole. It is thus concluded that in an alkyl derivative, the induced σ-bond polarization appearing at C–C (alkyl) σ-bond differs at each excited state. However, it has no appreciable effect on the direction of the transition moment of the π-π^* excitation. For determination of the direction of transition moment, the alkyl substituted molecule is often used instead of the parent molecule because of its larger orientation in the adsorption on the PVA film or in crystallization. The theoretical results support the pertinence of such experimental prescription. The induced σ-polarization are shown in Figs. 6—8 where, for the sake of simplicity, the π-π^* transition moments are omitted. The gross features of the induced σ-bond polarizations of each molecule considered resemble each other.

Catalytic Activity of Highly Dispersed Palladium. I. The Mechanism of Cyclohexene Hydrogenation and the Role of ZrO_2 Support

Bu Yong Lee,* Yasunobu Inoue, and Iwao Yasumori

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 19, 1979)

The hydrogenation of cyclohexene vapor on dispersed palladium was studied in the pressure range of 10—40 Torr† at temperatures between 283 and 323 K. Palladium was impregnated on ZrO_2 and α-Al_2O_3 over the wide range of 0.03 to 2.1 wt%, and the percentage exposed was varied from 13 to 96% for Pd/ZrO_2 and from 2 to 15% for Pd/α-Al_2O_3. The hydrogenation activity, V_g, per unit of weight of the Pd dispersed on ZrO_2, exhibited a sharp maximum at 0.05 wt%, but the turn-over frequency, V_s, per exposed atom around this maximum remained almost constant, which shows the reaction to be structure-insensitive. The value of V_s for Pd/ZrO_2 at 301 K was larger than those for Pd/α-Al_2O_3 and Pd bulk metal by one order of magnitude. The ZrO_2 carrier affected the catalytic behavior of palladium; the reaction orders with respect to the hydrogen and cyclohexene pressures changed to 0.73 ± 0.04 and 0.64 ± 0.04 respectively from the corresponding values, 0.97 ± 0.03 and 0.07 ± 0.04 for Pd/α-Al_2O_3 and Pd metal. The deuterium distributions in the reactant and product molecules in the reaction with D_2 suggested that the hydrogenation on Pd/ZrO_2 and Pd/α-Al_2O_3 proceeds *via* the associative mechanism; the slow step is assumed to be the reaction of the surface cyclohexyl radical with the adsorbed hydrogen atom. The poisoning due to preadsorbed CO decreased the catalytic activities of Pd/ZrO_2 and Pd/α-Al_2O_3 almost linearly with the amounts of surface CO and caused a complete deactivation at about a half coverage of the surface Pd atoms, irrespective of the percentage exposed. On the basis of these results, the structure-insensitivity of the cyclohexene hydrogenation on Pd and the carrier effect of ZrO_2 are discussed.

In order to get a fundamental understanding of heterogeneous catalysis by metals, the effect of the surface structure on the activity has been extensively studied using metals dispersed on supports[1] as well as their single crystals.[2] It appears that attention has been forcused on the shapes and size distributions of metal crystallites in connection with their activity, while supports have simply been regarded as inert matrices. Recently, however, it has been pointed out that the peculiar catalytic activity might be induced by the interactions between metal particles and support; this has been known as the "support effect."[3] In this regard, the oxides of Group IV_a metals have exerted noteworthy effects as supports or promotors of the catalytic hydrogenation.

Maxted and Ali[4] reported that palladium metal loaded on ZrO_2, ThO_2, and TiO_2 exhibited not only a higher activity for the liquid-phase hydrogenation of cyclohexene than that of the unsupported metal, but also its maximum in activity at a definite concentration of Pd, depending on the respective supports. Recently, Fujimoto *et al.*[5] showed that the addition of ThO_2 to the silica-supported Pd catalyst markedly increased the activity for the hydrogenation of CO. These positive effects of the oxides are of particular interest, but they have not yet been analyzed in detail.

Since the influence of the oxides on the catalytic behavior of Pd seems to become smaller as the size of metal crystallites increase, distinct evidence of the support effect can be obtained by the use of catalysts in a state of high dispersion or with a large percentage exposed. In the present study, the first one of this series, ZrO_2 was taken as a potentially interesting support on which palladium metal was dispersed over a wide range of surface concentrations and the hydrogenation of cyclohexene was studied. The reaction on α-Al_2O_3-supported and bulk metal palladium was also examined for comparison. Both supported catalysts were characterized by CO chemisorption and X-ray diffraction methods, and the percentage exposed was determined. Although most of the works on cyclohexene hydrogenation over Pd blacks[6] and Pd/Al_2O_3[7] have been carried out in the liquid phase, we studied the reaction in the gas phase because of easier kinetic analysis. The kinetics was supplemented by the results of an examination of the deuterium distributions in the product and reactants in the reaction with D_2.

The relationship between the percentage exposed and the turnover frequency enables us to inspect the effect of the surface structure upon the catalytic behavior, but it is not sufficient for us to evaluate the surface density of active sites. Accordingly, the poisoning due to preadsorbed CO was applied to the present catalyst system in order to evaluate the density and, further, to study the nature of the active sites, which may change through the interaction with carries.

Experimental

Catalysts. Palladium supported on zirconia or α-alumina was prepared by the impregnation method at room temperature. Both supports were washed with 0.1 mol dm^{-3} nitric acid and then rinsed thoroughly with ion-exchanged water. The surface area, as evaluated by the BET method using nitrogen, were 38.5 m^2/g for ZrO_2 and 3.8 m^2/g for α-Al_2O_3. The impregnation of palladium was carried out by adding, drop by drop, an aqueous solution of palladium nitrate, in a concentration of about 13 g/l, to a batch of the supports which were slowly being stirred. The addition was stopped at the incipient wetness of the support, and then the catalysts were dried in air at 393 K for 12 h. The concentration of Pd was thus widely changed, *i.e.*, from 0.03 to 2.1 wt% for Pd/ZrO_2 and from 0.05 to 2.1 wt% for Pd/α-Al_2O_3. Palladium metal powder was prepared by reducing $PdCl_2$ with an aqueous solution of $NaBH_4$.

In order to determine the conditions which provide a

† 1 Torr=133.322 Pa.

catalytic activity as stable and high as possible, the influence of the reduction temperature on the catalytic activity of Pd/ZrO_2 and $Pd/\alpha\text{-}Al_2O_3$ was investigated up to 875 K; reduction at 523 K was found to be a suitable treatment. The catalyst activity was also examined at the same temperature as a function of the reduction time for up to 5 h, but no significant difference was observed after 1 h. Thus, a fresh catalyst was subjected to pretreatment by oxidation with 20 Torr of oxygen at 523 K for 1 h, followed by reduction with 20 Torr of hydrogen at 523 K for 1 h and then evacuation for 1 h at the same temperature. This series of treatments was also employed prior to each kinetic run.

Kinetics of Reaction. The gas-phase hydrogenation of cyclohexene was carried out by using a closed circulation system with a volume of 450 ml. The cyclohexene was degassed, subjected several times to a trap-to-trap distillation, and then transferred to the reaction system. The pressure decrease during the course of the reaction was followed by means of a glass Bourdon gauge. A gas chromatographic analysis verified that cyclohexane was the only product under the present experimental conditions and that the rate of the pressure decrease corresponded exclusively to the rate of cyclohexane formation. The hydrogenation was studied in the pressure range of 10—40 Torr at temperature between 283 and 323 K. The reaction with deutrium was carried out under exactly the same conditions as those used in the hydrogenation. After the reduction, the cyclohexene and cyclohexane were separated gas chromatographically by the use of a 6 m column of Celite-545, with Dinonyl phthalate added, and then analysed by means of a mass-spectrometer, Hitachi RMU-7M, at an ionization voltage of 15 eV. The mass patterns including isotope peak (^{13}C) and the isotope effect on the ionization were corrected.[8] The hydrogen, hydrogen deuteride, and deuterium were analysed by means of gas chromatograph.[9] In order to determine the percentage exposed of palladium atoms, the adsorption of CO was employed at 301 K in a static system with a volume of 150 ml after the catalysts had been treated in the same manner as that employed in the kinetic study. X-Ray diffraction was also applied to the catalysts.

Material. Zirconia of an extra pure grade was obtained from the Koso Chemical Co., and α-alumina, from the Shimadzu Seisakusho, Ltd. Cyclohexene of an extra pure grade, purchased from Yoneyama Chemical Industries, Ltd., was distilled *in vacuo* and found to be gas chromatographically pure. Hydrogen (99.99% pure) and deuterium (containing less than 0.5% HD) were obtained from Takachiho Kagaku Kogyo and were purified through a molecular-sieve trap cooled to 80 K.

Results

Figure 1 shows the variation in the catalytic activity, V_g, (molecule min^{-1} g Pd^{-1}) of Pd/ZrO_2 and $Pd/\alpha\text{-}Al_2O_3$ for the hydrogenation of cyclohexene with different Pd contents. The Pd/ZrO_2 catalyst was characterized by a marked rise in the activity with an increase in the Pd content and by a maximum at 0.05 wt%, whereas $Pd/\alpha\text{-}Al_2O_3$ shows only a slight increase around 0.2 wt%. A comparison between the highest activities showed that the activity per gram of Pd dispersed on ZrO_2 was about 170 times greater than that of Pd on $\alpha\text{-}Al_2O_3$. Kinetic studies were carried out for most of these catalysts; the results thus obtained are summarized in Tables 1 and 2.

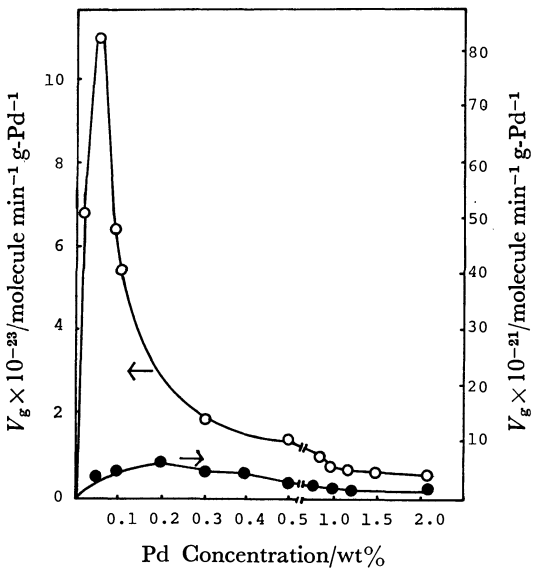

Fig. 1. Change in catalytic activity V_g with Pd content.
Unless otherwise stated, the following conditions were used: P_h=40 Torr, P_e=40 Torr, reaction temp=301 K.
○: Pd/ZrO_2, ●: $Pd/\alpha\text{-}Al_2O_3$.

It should be noted that, for a series of each kind of catalyst, the reactions gave almost the same activation energy and pressure dependence, irrespective of the Pd concentration, but there were significant differences in these kinetic parameters between the reaction on Pd/ZrO_2 and $Pd/\alpha\text{-}Al_2O_3$; the activation energy for the reaction on Pd/ZrO_2 was, on the average, higher by about 13 kJ mol^{-1} than for $Pd/\alpha\text{-}Al_2O_3$ and Pd bulk metal. The reaction orders with respect to the partial pressures of hydrogen and cyclohexene were, respectively, 0.73±0.04 and 0.64±0.04 for Pd/ZrO_2, whereas the corresponding values were 0.97±0.03 and 0.07±0.04 for $Pd/\alpha\text{-}Al_2O_3$ and Pd bulk metal.

The detailed analysis of the reaction was performed by using deuterium as a tracer, and the deuterium distributions in gaseous cyclohexene, cyclohexane, and hydrogen were investigated. The results are summarized in Table 3. Neither hydrogenation nor exchange reaction of cyclohexene with D_2 occurred on either of the supports, ZrO_2 and $\alpha\text{-}Al_2O_3$, under the present experimental conditions. The reaction of cyclohexene with D_2 or with H_2+D_2 on Pd/ZrO_2 and $Pd/\alpha\text{-}Al_2O_3$ demonstrated that considerable amounts of cyclohexene [D_1] and [D_2] were formed at a conversion of from 8 to 10%. Equilibration among H_2, HD, and D_2 in the gas phase proceeded completely in the case of $Pd/\alpha\text{-}Al_2O_3$; the values of K, defined as the P_{HD}^2/P_hP_D radio, were 3.1—4.2(±0.4) in the $C_6H_{10}+D_2$ system and 3.5—3.7(±0.3) in the $C_6H_{10}+H_2+D_2$ system. In the reaction using the Pd/ZrO_2 catalyst, however, although appreciable amounts of HD and H_2 were produced, the equilibrium among them did not hold; the K's were 0.6—0.8 (±0.2) in the $C_6H_{10}+D_2$ system and 1.2—1.3(±0.1) in the $C_6H_{10}+H_2+D_2$ system. As for the product, cyclohexane, a distribution ranging from [D_0] and

$[D_5]$ was observed in the reactions using the respective catalysts, but there was a tendency for Pd/ZrO_2 to provide a higher concentration of cyclohexane $[D_0]$.

Figure 2 shows the isotherms of CO adsorbed at 301 K on 0.05 wt% Pd/ZrO_2 and ZrO_2. Carbon monoxide was introduced up to 60 Torr, and then, after the evacuation at the same temperature for 20 min, the adsorption was repeated under the same conditions. As may be seen from Fig. 2, the amount of CO adsorbed on Pd/ZrO_2 in the second run was much the same as that on the ZrO_2 surface, on which only the reversible adsorption took place. Thus, the difference between the first and second runs gave the amount of irreversible adsorption on the surface of metallic palladium. By assuming that an exposed Pd atom can accommodate one carbon monoxide molecule,[10] the number of Pd atoms exposed was evaluated. Tables 1 and 2 involve the percentage exposed and also the hydrogenation activity per exposed atom, *i.e.*, the turn-over frequency V_s, represented in terms of molecule s^{-1} exposed Pd $atom^{-1}$. It should be noted that the change in V_s was rather small throughout the whole range of Pd loading. The V_s at 0.05 wt% was only twice as large as that at 1.0 wt%. However, the V_s on Pd/ZrO_2 was 20 to 30 times higher than those on Pd/α-Al_2O_3 and Pd bulk metal.

The poisoning effect of CO was examined at 301 K. A known amount of CO was preadsorbed on a bare Pd surface after the pretreatment, after which the catalyst was evacuated for 20 min and the reaction gas was introduced. Figure 3 shows the change in the activity with the increase in the fraction of CO coverage, which was defined as the ratio of the amount of CO adsorbed to that at saturation. In all cases of 0.05, 0.3, and 1.0 wt% Pd/ZrO_2 catalysts as well as of 0.2 wt% Pd/α-Al_2O_3 studied, an almost linear decrease in the activity occurred with the increase in the fraction of the surface occupied by CO, and zero activity was attained at around θ=0.45 when the lines were extrapolated.

Discussion

It is a feature of the cyclohexene hydrogenation on Pd/ZrO_2 that the high activity appears in a narrow range of Pd concentrations, as is shown in Fig. 1. Such a drastic change in the activity contrasts with the results on $Pd/\alpha\text{-}Al_2O_3$. This maximum activity was also observed in the liquid-phase hydrogenation.[4] The measurement of the CO-adsorption on Pd/ZrO_2, however, revealed that the fraction of Pd exposed per unit weight of the metal varied with the amount of Pd loading in a manner parallel to the change in the activity. Accordingly, the turn-over frequency, V_s, was rather constant around the maximum of activity (V_g) and then gradually decreased to about a half of the value with an increase in the Pd content. A similar relation between V_g and V_s was also observed in the case of $Pd/\alpha\text{-}Al_2O_3$, but the value of V_s for $Pd/\alpha\text{-}Al_2O_3$ was smaller by one order of magnitude than that for Pd/ZrO_2, irrespective of the Pd content. The small variation in V_s as well as the similarity in the kinetic parameters over the wide range of percentage exposed suggests that the hydrogenation of cyclohexene is "structure-insensitive" in character and that the sharp maximum in V_g is attributable to the highest density of active sites. The slight fall in V_s with the decrease in the percentage exposed may be due to the decrease in the virtual site density; the steric hindrance between adsorbed cyclohexene molecules may become more distinct on the smooth surfaces of larger particles, or the stoichiometry between the adsorbed CO and the Pd atom may vary with the percentage exposed. From the amount of CO chemisorbed on 0.05 wt% Pd/ZrO_2, the average diameter of Pd particles was calculated to be about 17 Å, provided that the particles are spherical. This estimation indicates that, as a primary effect, the ZrO_2 surface has a high capability of dispersing Pd metal as very fine particles or crystallites which possess a high density of active sites.

Since the surface density of the active site varies in proportion to the percentage exposed of Pd atoms,

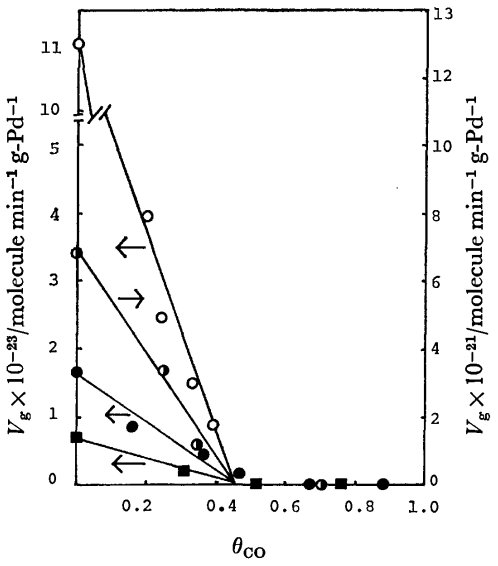

Fig. 3. Poisoning effect of adsorbed CO on cyclohexene hydrogenation.
○: 0.05 wt% Pd/ZrO_2, ●: 0.3 wt% Pd/ZrO_2, ■: 1.0 wt% Pd/ZrO_2, ◑: 0.2 wt% Pd/α-Al_2O_3.

the poisoning due to preadsorbed CO permits us to evaluate the density. As may be seen from Fig. 3, a nearly linear relationship exist between the decline in the activity and θ_{CO}, and the zero activity was brought about at $\theta_{CO}=0.45$ for all the Pd/ZrO_2 and Pd/α-Al_2O_3 catalysts examined. This coincidence of CO coverage where the activity vanishes suggests that the topography of the active sites is similar for Pd particles dispersed on both ZrO_2 and α-Al_2O_3.

There are clear differences in the pressure dependence and activation energy between the reactions on the Pd/ZrO_2 and Pd/α-Al_2O_3 catalysts, but the general features of wide distributions in the reactant and product were rather analogous in both cases and suggest that the hydrogenations proceed via the associative mechanism described by the following pathway;

$$H_2(g) \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} 2H(a) \quad (1)$$

$$C_6H_{10}(g) \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} C_6H_{10}(a) \quad (2)$$

$$C_6H_{10}(a) + H(a) \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} C_6H_{11}(a) \quad (3)$$

$$C_6H_{11}(a) + H(a) \underset{k_4}{\rightarrow} C_6H_{12}(g) \quad (4)$$

were k_i and k_{-i} denote, respectively, the rate constants of the forward and reverse reactions at the ith step. The changes in the fractions of the surface covered with hydrogen atoms, θ_H, cyclohexene, θ_e, and cyclohexyl radicals, θ_y, as functions of the time are described as:

$$\frac{d\theta_h}{dt} = 2k_1P_h\theta_v^2 - 2k_{-1}\theta_h^2 - k_3\theta_h\theta_e + k_{-3}\theta_y\theta_v - k_4\theta_h\theta_y \quad (5)$$

$$\frac{d\theta_e}{dt} = k_2P_e\theta_v - k_{-2}\theta_e - k_3\theta_e\theta_h + k_{-3}\theta_y\theta_v \quad (6)$$

$$\frac{d\theta_y}{dt} = k_3\theta_e\theta_h - k_{-3}\theta_v\theta_y - k_4\theta_y\theta_h, \quad (7)$$

where θ_v denotes the fraction of the vacant surface and is equivalent to $(1-\theta_h-\theta_e-\theta_y)$. The wide deuterium distributions in cyclohexane permit us to assume that Step 3 is in pseudo-equilibrium; thus, the following relationship;

$$K_3\theta_e\theta_h = \theta_y\theta_v \quad (8)$$

is obtained, where $K_3=k_3/k_{-3}$. The employment of the steady-state approximation on the adsorbed hydrogen atoms and cyclohexene molecules, *i.e.*, $d\theta_h/dt=d\theta_e/dt=0$, and the insertion of Eq. 8 into Eqs. 5 and 6 lead to;

$$2k_1P_h\theta_v^2 - 2k_{-1}\theta_h^2 - k_4\theta_y\theta_h = 0 \quad (9)$$

$$k_2P_e\theta_v - k_{-2}\theta_e = 0. \quad (10)$$

Solving the set of Eqs. 8, 9, and 10, we can obtain these expressions for θ_y and θ_h in a steady state;

$$\theta_y = K_2K_3P_e\theta_h \quad (11)$$

and;

$$\theta_h = \frac{\sqrt{2k_1P_h}}{[(1+K_2P_e)\sqrt{2k_{-1}+k_4K_2K_3P_e}+(1+K_2K_3P_e)\sqrt{2k_1P_h}]}, \quad (12)$$

where $K_1=k_1/k_{-1}$. Accordingly, the rate of cyclohexene hydrogenation, V_g, is given by;

$$V_g = k_4\theta_y\theta_h = \frac{2k_1k_4K_2K_3P_hP_e}{[(1+K_2P_e)\sqrt{2k_{-1}+k_4K_2K_3P_e}+(1+K_2K_3P_e)\sqrt{2k_1P_h}]^2}. \quad (13)$$

In order to examine the validity of the derived equation for the observed pressure dependences, Eq. 13 is transformed into;

$$\sqrt{\frac{P_h}{V_g}} = \sqrt{\frac{1}{(2k_1k_4K_2K_3)P_e}}[\sqrt{2k_1P_h}(1+K_2K_3P_e) + (1+K_2P_e)\sqrt{2k_{-1}+k_4K_2K_3P_e}], \quad (14)$$

which provides a linear relationship between $(P_h/V_g)^{1/2}$ and $P_h^{1/2}$ under the condition of a constant P_e. A similar transformation of Eq. 13 with respect to the cyclohexene pressure gives;

$$\sqrt{\frac{P_e}{V_g}} = \sqrt{\frac{1}{(k_4K_1K_2K_3)P_h}}\left[(1+K_2K_3P_e)\sqrt{K_1P_h} + (1+K_2P_e)\sqrt{1+\frac{k_4K_2K_3}{2k_{-1}}P_e}\right], \quad (15)$$

which can not be used for the examination of the pressure dependence. Considering that the desorption of hydrogen is still much faster than the hydrogenation, *i.e.*, $2k_{-1}\theta_h^2 > k_4K_2K_3P_e\theta_h^2$, one can expand the second term in brackets in Eq. 15 as:

$$(1+K_2P_e)\sqrt{1+\frac{k_4K_2K_3P_e}{2k_{-1}}} = \left[1+\left(K_2+\frac{k_4K_2K_3}{4k_{-1}}\right)P_e+\frac{k_4K_2^2K_3}{4k_{-1}}P_e^2+\cdots\right]. \quad (16)$$

Accordingly, Eq. 15 is rewritten in an approximate form:

$$\sqrt{\frac{P_e}{V_g}} = \sqrt{\frac{1}{(k_4K_1K_2K_3)P_h}} \times\left[1+\sqrt{K_1P_h}+\left(1+K_3\sqrt{K_1P_h}+\frac{k_4K_3}{4k_{-1}}\right)K_2P_e\right]. \quad (17)$$

It follows, therefore, that a linear relationship of $(P_e/V_g)^{1/2}$ *vs.* P_e exists under the condition of a constant P_h. As for the hydrogenation on Pd/α-Al_2O_3, in which gaseous hydrogen molecules are in equilibrium with the adsorbed hydrogen atoms, the rate equation was simplified to:

$$V_g = \frac{k_4K_1K_2K_3P_hP_e}{\{1+\sqrt{K_1P_h}+K_2P_e+K_2K_3P_e\sqrt{K_1P_h}\}^2}. \quad (18)$$

It is apparent that this equation provides relationships similar to those described above for the hydrogen- and cyclohexene-pressure dependences. Figure 4 shows good linear plots of the observed values for the above-mentioned relationships, which verifies the validity of Eqs. 13 and 18, and hence the mechanism proposed. The assumption that one of the reactions other than Step 4 is a slow process leads to an unsatisfactory conclusion in explaining the observed pressure dependence and isotope distribution. When Gonzo and Boudart[11] studied the hydrogenation of cyclohexene on γ-alumina-supported Pd in the gas and liquid phases, they observed no appreciable difference in the mechanism of reaction between these systems. They showed that the rate-determining step is the addition of a hydrogen atom to the cyclohexyl species,

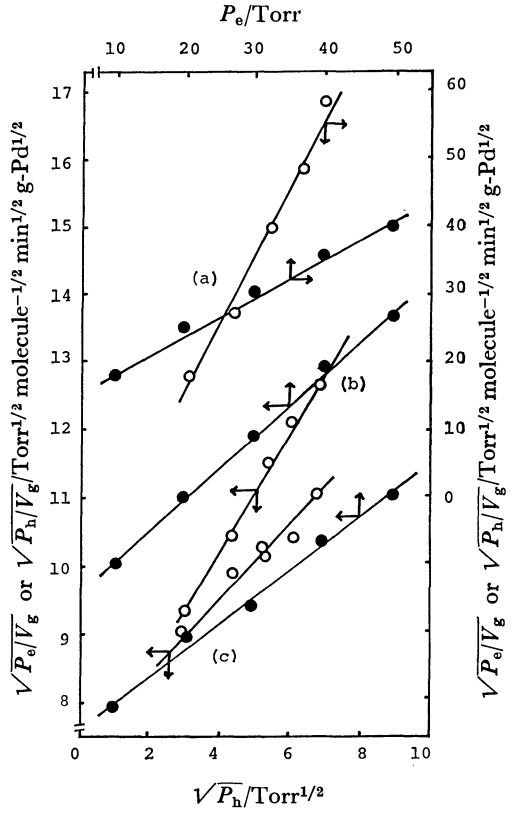

Fig. 4. Plots of $\sqrt{P_h/V_g}$ *vs.* $\sqrt{P_h}$ and $\sqrt{P_e/V_g}$ *vs.* P_e. ○: $\sqrt{P_h/V_g}$ *vs.* $\sqrt{P_h}$ (P_e=40 Torr), ●: $\sqrt{P_e/V_g}$ *vs.* P_e (P_h=40 Torr), reaction temp=301 K. (a): 0.2 wt% Pd/α-Al_2O_3, (b): 1.0 wt% Pd/ZrO_2, (c): 0.08 wt% Pd/ZrO_2.

which accords with the present conclusion. The value of the turn-over frequency, 3.3 s^{-1} at 301 K (P_h=P_e=40 Torr) on 0.05 wt% Pd/ZrO_2 was close to the value, 3.4 s^{-1}, obtained by correcting their data[11] to the present reaction conditions.

These characteristic features of the hydrogenation by Pd/ZrO_2, *viz.*, the high V_s value and the different kinetics as compared to those on Pd/α-Al_2O_3 and Pd bulk metals, are certainly associated with carrier effects caused by ZrO_2. If one assumes the dispersed state of metal to be a spherical particle, the percentages exposed of 96% (0.05 wt% Pd/ZrO_2) and 13% (2.1 wt% Pd/ZrO_2) correspond to particle sizes of about 17 and 140 Å in diameter respectively. As is shown in Table 2, there is evident lack of variation in the kinetic behavior through the whole range of the percentage exposed, while the CO-poisoning results clearly show that almost all the surface atoms exposed are responsible for the catalytic hydrogenation. Thus, these facts lead to two plausible models: a long-range influence caused by the ZrO_2 substrate strongly affects the character of the dispersed metal particles, irrespective of their size, and, alternatively, Pd metal aggregates with a specific morphology are formed on the ZrO_2 surface, thus increasing the fraction of active interface between the metal and the carrier. In a special case, a small fraction of ZrO_2 might be embedded in the crystallites of Pd metal. The latter situation appears to produce noteworthy interaction.

As has been described, the general feature of the Pd/ZrO_2 catalyst was a homogeneous distribution of the active sites over almost the entire surface. However, it was found that the reaction orders with respect to the hydrogen and cyclohexene pressures shifted to 1.0 and 0.1 respectively when the 0.05 wt% Pd/ZrO_2 catalyst was poisoned by adsorbed CO so severely that more than 93% of the catalytic activity was lost. For the reaction on the 0.3 wt% Pd/ZrO_2 catalyst poisoned to the same extent, however, the hydrogen order remained unchanged, though the cyclohexene order was attenuated to 0.35. Although a detailed study will be needed to confirm whether such reaction-order shifts occur gradually with an increase in the amount of adsorbed CO or only in the extreme case of an almost complete deactivation, the almost linear relationships observed in Fig. 3 indicate that the latter is more plausible. The variations in the kinetic behavior are presumably caused by the electronic effect of preadsorbed CO upon the state of palladium-surface atoms rather than by the geometrical blocking of active sites by the CO, so as to put more restriction on the adsorption of hydrogen compared to that of cyclohexene. The finding that the change in the kinetic parameters of the hydrogenation on the catalysts with higher percentages exposed is more prominent gives support to this consideration. It should be noted that the shifts in the kinetic parameters occurred in an opposite direction from those caused by the ZrO_2 substrate. The adsorption of CO on the Pd (111) surface was found to increase the work function by 1.02 eV,[12] indicating an electron transfer from the Pd surface to CO. By taking the present results together with this face into

consideration, we can predict that ZrO_2 works as an electron donor.

In order to confirm this view, it is necessary to examine the effect of added ZrO_2 to Pd upon the catalytic properties, and therefore the analysis of these sytems by X-ray photoelectron spectroscopy seems to be essential. These studies are now in progress by using $Pd+ZrO_2$ dispersed on inactive substrates such as α-Al_2O_3.

The Gibbs Energies, Enthalpies, and Entropies of the Dilution of Aqueous Sodium Chondroitin-4-sulfate and -6-sulfate

Masakatsu YONESE,* Hideya TSUGE, and Hiroshi KISHIMOTO

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-Dori, Mizuho-ku, Nagoya 467

(Received January 29, 1980)

The osmotic coefficients of a solvent, ϕ, in aqueous solutions of sodium chondroitin-4-sulfate (NaChS-A) with a relatively low molecular weight and -6-sulfate (NaChS-C) with various molecular weight were measured by means of vapor-pressure osmometry. The molar Gibbs energes of dilution, $\Delta_{\mathrm{dil}}G$, were determined from the thermodynamic analysis of the ϕ values. The molar entropies of dilution, $\Delta_{\mathrm{dil}}S$, were calculated through the substitution of the molar dilution enthalpies, $\Delta_{\mathrm{dil}}H$, which had been measured previously, into $\Delta_{\mathrm{dil}}G$. These thermodynamic quantities of dilution were discussed by taking Manning's limiting law into consideration. The concentration and temperature dependencies of the observed $\Delta_{\mathrm{dil}}H$ agreed well quantitatively with those of the electrostatic $\Delta_{\mathrm{dil}}H$ calculated by Manning's limiting law, when the distance between the neighboring charges of the polyion, b, was assumed to be 4.8 Å, whereas the observed $\Delta_{\mathrm{dil}}G$ and $\Delta_{\mathrm{dil}}S$ values did not agree quantitatively with the theoretical ones based on electrostatic interactions. From a comparison of the experimental $\Delta_{\mathrm{dil}}S$ values with the theoretical ones, the non-electrostatic dilution entropy was evaluated and discussed.

Chondroitin-4-sulfate and -6-sulfate, whose repeating units are composed of *N*-acetyl-D-galactosamine-4- and -6-sulfates, together with D-glucuronic acids, respectively, are known to be important components of mammalian connective tissues and are expected to interact specifically with the ions in biological environments according to their polyelectrolyte nature. To elucidate their behavior as biopolyelectrolytes, we have previously investigated their physicochemical properties in simple aqueous solutions with various counter-cations, such as osmotic coefficients,[1] partial molar volumes,[2] and the enthalpies of dilution.[3]

This paper concerns the Gibbs energies, enthalpies, and entropies of the dilution of sodium chondroitin-4-sulfate (NaChS-A) with a relatively low molecular weight and -6-sulfate (NaChS-C) with various molecular weights. The Gibbs energies were determined from the thermodynamic analysis of the osmotic coefficients measured by vapor-pressure osmometry. Since the enthalpies had been measured in a preceding work,[3] the entropies of dilution were calculated through the substitution of the enthalpies into the Gibbs energies. These thermodynamic quantities of dilution were discussed by taking Manning's limiting law[4] into consideration.

Experimental

Materials. Sodium chondroitin-4-sulfate (NaChS-A) was obtained commercially from the Seikagaku Kogyo Co., Ltd. (Tokyo, Japan); its average molecular weight $\overline{M}$, was 2.0×10^4. Four kinds of sodium chondroitin-6-sulfate (NaChS-C) with different molecular weights were used, two of them being commercial ones from the Seikagaku Kogyo Co., Ltd. ($\overline{M}=6.5\times10^4$ and 7.3×10^4), and the others having been offered by the Kaken Yakukako Co., Ltd. (Tokyo. Japan) ($\overline{M}=5.7\times10^4$ and 1.1×10^4). Their molecular weights were determined by viscosity measurements.[5,6] Distilled and deionized water was used for the preparation of aqueous ChS salt solutions.

Osmotic Coefficient. The osmotic coefficients were measured by means of vapor-pressure osmometry using an Hitachi-Perkin-Elmer Model 115 Molecular Weight Apparatus.[1] Aqueous sodium chloride solutions were used as reference solutions, and their osmotic coefficients, ϕ', were obtained from the literature.[7] When the solvent vapor pressure of a reference electrolyte solution is equal to that of a polyelectrolyte solution, the osmotic coefficient of the polyelectrolyte, ϕ, is given by

$$\phi = \frac{\nu' m' \phi'}{\nu_{\mathrm{p}} m_{\mathrm{p}}}, \tag{1}$$

where ν' and ν_{p} are the total numbers of cations and anions produced by the dissociation of NaCl and the polyelectrolyte, and where m' and m_{p} are the molalities of NaCl and the polyelectrolyte respectively. The factors of the denominator, ν_{p} and m_{p}, can be written as follows;

$$\nu_{\mathrm{p}} = Z/Z_{\mathrm{g}} + 1 \tag{2}$$

and;

$$m_{\mathrm{p}} = 2m/Z, \tag{3}$$

where Z, Z_{g}, and m are the stoichiometric charge number per polymer, the charge number of a counter ion, and the molality of the polymer on a repeating unit basis (mol kg^{-1}) respectively. Then,

$$\phi = \frac{\nu' m' \phi'}{(Z/Z_{\mathrm{g}}+1)(2m/Z)}. \tag{4}$$

Results and Discussion

The Osmotic Coefficients of NaChS Salts. Figures 1, 2, and 3 show the linear relationships between the ϕ values and polymer concentrations for various ChS samples at 298.15, 310.15, and 323.15 K respectively. They also show that the ϕ values depend on the polymer molecular weights; that is, higher-molecular-weight samples have smaller ϕ values. However, ϕ seems to approach a definite value with the increase in the molecular weight.

The Calculation of the Gibbs Energies, Enthalpies, and Entropies of Dilution. The molar Gibbs energy of dilution per repeating unit containing two ionized groups, $\Delta_{\mathrm{dil}}G$, from the initial concentration, m_{i}, to the final concentration m_{f}, ($m_{\mathrm{i}} \gg m_{\mathrm{f}}$), can be written as follows;

$$\Delta_{\mathrm{dil}}G = 2(1/Z+1/Z_{\mathrm{g}})RT\ln(a_{\pm,\mathrm{f}}/a_{\pm,\mathrm{i}}) \tag{5-a}$$

$$= 2(1/Z+1/Z_{\mathrm{g}})\,RT\ln\left(\frac{2m_{\mathrm{f}}\gamma_{\pm,\mathrm{f}}/Z}{2m_{\mathrm{i}}\gamma_{\pm,\mathrm{i}}/Z}\right), \tag{5-b}$$

Symbols are the same as in Fig. 1.

where $a_\pm$ and $\gamma_\pm$ are the mean activity and the mean activity coefficient of a polyelectrolyte respectively. To obtain $\Delta_{dil}G$ from the relation between m and ϕ, the mean activity coefficients in Eq. 5-b were calculated by means of the Gibbs-Duhem equation:

$$\ln(\gamma_{\pm,f}/\gamma_{\pm,i}) = (\phi_f-\phi_i) + 2\int_{m_f}^{m_i}\frac{1-\phi}{\sqrt{m}}d\sqrt{m}. \quad (6)$$

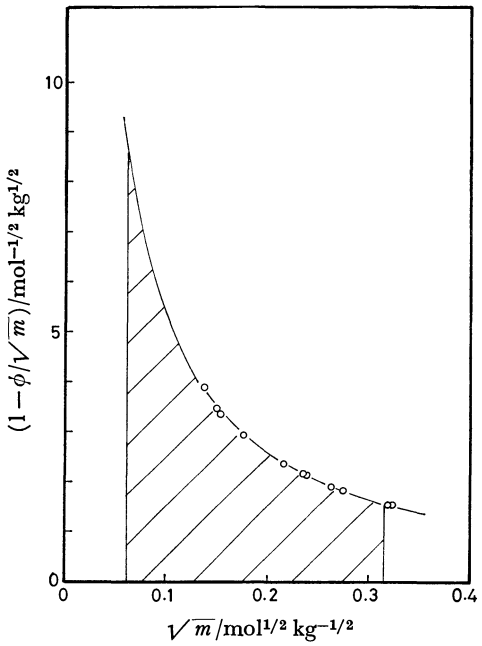

Fig. 4. Graphic integration of Eq. 3 at 310.15 K.
Sample: NaChS-C ($\bar{M}=1.1\times10^4$).

In calculating $\int_{m_f}^{m_i}\frac{1-\phi}{\sqrt{m}}d\sqrt{m}$ by graphic integration, the relations between ϕ values and m were assumed to be linear for the extrapolation of ϕ to the lower-m region. An example of the graph for integration is shown in Fig. 4.

When the experimental results of the molar dilution enthalpies per repeating unit, $\Delta_{dil}H$, in the previous paper[3] are used with the $\Delta_{dil}G$ thus obtained, the molar entropies of dilution, $\Delta_{dil}S$, can be obtained from Eq. 7:

$$\Delta_{dil}S = (-\Delta_{dil}G+\Delta_{dil}H)/T. \quad (7)$$

Table 1 shows $\Delta_{dil}G$, $\Delta_{dil}H$, and $\Delta_{dil}S$ values from $m_i=0.10$ and 0.08 mol kg^{-1} to $m_f=3.85\times10^{-3}$ mol kg^{-1}. These quantities can be divided into non-electrostatic and electrostatic terms, as expressed by Eq. 8.[3,8] The former is the contribution from the dilution of a polyelectrolyte solution in a hypothetical reference state in which all the ions are discharged and is indicated by the superscript "o," while the latter is the contribution from the electrostatic interaction of polyions with counterions and is indicated by the superscript "el."

$$\Delta_{dil}G = \Delta_{dil}G^{el} + \Delta_{dil}G^{o} \quad (8\text{-a})$$

$$\Delta_{dil}H = \Delta_{dil}H^{el} + \Delta_{dil}H^{o}, \quad (8\text{-b})$$

and

$$\Delta_{dil}S = \Delta_{dil}S^{el} + \Delta_{dil}S^{o}. \quad (8\text{-c})$$

According to Manning's limiting law, $\Delta_{dil}G^{el}$, $\Delta_{dil}H^{el}$, and $\Delta_{dil}S^{el}$ per mol of the repeating disaccharide unit can be evaluated as follows in the case of $\xi\geq1.0$:[3]

$$\Delta_{dil}G^{el} = -(RT/\xi)\ln(m_i/m_f) \quad (9\text{-a})$$

$$\Delta_{dil}H^{el} = (RT/\xi)\left(1+\frac{Td\varepsilon}{\varepsilon dT}\right)\ln(m_i/m_f), \quad (9\text{-b})$$

and

The upper values for each sample: $m_i=0.10$ mol kg^{-1}. The lower values for each sample: $m_i=0.08$ mol kg^{-1}. $m_f=3.85\times10^{-3}$ mol kg^{-1}.

$$\Delta_{dil}S^{el} = (2R/\xi)\left(1+\frac{T\mathrm{d}\varepsilon}{2\varepsilon\mathrm{d}T}\right)\ln(m_i/m_f), \qquad (9\text{-c})$$

where R is the gas constant, T is the absolute temperature, ε is the permittivity of the solvent (water), and ξ is the charge density parameter, which is defined by:

$$\xi = e^2/4\pi\varepsilon kTb, \qquad (10)$$

where e is the elementary charge, k is the Boltzmann constant, and b is the distance between the neighboring charges of a polyion.

In a preceding paper,[3] treating the dilution enthalpy of NaChS, we assumed implicitly that the non-electrostatic enthalpy of dilution, $\Delta_{dil}H^{\circ}$, is negligible; then, so as to fit the theoretical values obtained from Eq. 9-b with the experimental $\Delta_{dil}H$ values over as wide range of temperatures and concentrations as possible, we selected $b=4.8$ Å, which was in agreement with the value estimated from the X-ray diffraction measurement of NaChS film. The fit between the experimental $\Delta_{dil}H$ and theoretical $\Delta_{dil}H^{el}$ values at 298.15 K is illustrated in Fig. 5. In this paper, we continued to use 4.8 Å as b for the reason mentioned above and calculated the values of $\Delta_{dil}G^{el}$ and $\Delta_{dil}S^{el}$ from the initial concentration, *i.e.*, 0.10 and 0.08 mol kg^{-1}, to the final concentration of 3.85×10^{-3} mol kg^{-1} at various temperatures, using Eqs. 9-a and -c. The results are tabulated in Table 2, along with the $\Delta_{dil}H^{el}$ values calculated in the preceding paper.

The Evaluation of Non-electrostatic Terms. By substituting the above-mentioned electrostatic quantities, which were evaluated according to Manning's law, and the experimental over-all quantities of dilution into Eqs. 8-a, -b, and -c, we obtained the non-

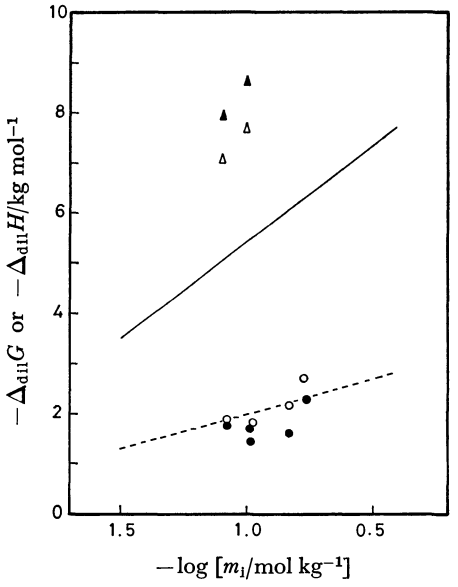

Fig. 5. $\Delta_{dil}G$ and $\Delta_{dil}H$ estimated from the Manning's limiting law for NaChS-C having two different molecular weights at 298.15 K.
△: Observed $\Delta_{dil}G$ ($\bar{M}=5.7\times10^4$), ▲: observed $\Delta_{dil}G$ ($\bar{M}=1.1\times10^4$), ○: observed $\Delta_{dil}H$ ($\bar{M}=5.7\times10^4$), ●: observed $\Delta_{dil}H$ ($\bar{M}=1.1\times10^4$), ——: $\Delta_{dil}G^{el}$ calculated from Eq. 9-a, – – – –: $\Delta_{dil}H^{el}$ calculated from Eq. 9-b.

electrostatic contributions of dilution, $\Delta_{dil}G^{\circ}$ and $\Delta_{dil}S^{\circ}$, shown in the upper and middle sections of Table 3. Also, the values of $\Delta_{dil}S^{\circ}$ can be calculated from $-\Delta_{dil}G^{\circ}/T$ when $\Delta_{dil}H^{\circ}$ is considered to be zero. The values thus calculated, as tabulated in the lower section of Table 3, reflect only the difference in experimental ϕ or $\Delta_{dil}G$ values between samples of different molecular weights, while the values in the middle column involve additionally the differences in the experimental $\Delta_{dil}H$ between different samples.

Next, we will examine the effect of polymer-chain

Table 2. The values of $\Delta_{dil}G^{el}$, $\Delta_{dil}H^{el}$, and $\Delta_{dil}S^{el}$, as calculated from Manning's limiting law

	298.15 K	310.15 K	323.15 K

The upper values for each sample: $m_i=0.10$ mol kg^{-1}. The lower values for each sample: $m_i=0.08$ mol kg^{-1}. $m_f=3.85\times10^{-3}$ mol kg^{-1}. a) Calculated from Eqs. 7 and 8-c. b) Calculated by assuming $\Delta_{dil}H=\Delta_{dil}H^{el}$ or $\Delta_{dil}S^{\circ}=-\Delta_{dil}G^{\circ}/T$.

length on these thermodynamic quantities. As may be seen in Table 1, the polymers with lower molecular weights have larger values of $-\Delta_{dil}G$ and $\Delta_{dil}S$ than the higher-molecular-weight polymers. As compared with the differences in $-\Delta_{dil}G$ and $\Delta_{dil}S$ between samples of different molecular weights seems to be negligible. Therefore, the magnitudes of electrostatic $\Delta_{dil}H^{el}$, $\Delta_{dil}G^{el}$, and $\Delta_{dil}S^{el}$ can be considered to be approximately invariant with the change in the chain length of the polymer. This situation explains the agreements between the corresponding values of $\Delta_{dil}S^{\circ}$ in the middle and lower sections of Table 3. After all, the effects of the chain length on various thermodynamic quantities can be concentrated in $\Delta_{dil}S^{\circ}$. The discussion of $\Delta_{dil}G^{\circ}$ can, then, be reduced to that of $\Delta_{dil}S^{\circ}$. The values of $\Delta_{dil}S^{\circ}$ increase significantly with the decrease in the chain length in Table 3. We cannot explain it clearly in this stage, but can only suggest that the effect of the chain length on $\Delta_{dil}S^{\circ}$ is attributable to the problem of the conformation of ChS. With respect to the value of $\Delta_{dil}S^{\circ}$ of a sufficiently long chain, the discussion is very important because of the comparatively large value of $\Delta_{dil}S^{\circ}$ in $\Delta_{dil}G^{\circ}$. However, in order to elucidate the nature of $\Delta_{dil}S^{\circ}$ more clearly, the structural study of ChS in solution, including that of the solvent, is considered to be necessary.

Studies of the Generation of Excited Singlet Products in the Oxidation of the -CO-CH- Containing Molecules. The Chemiluminescence of Acylcarbazoles

Isao KAMIYA* and Takashi SUGIMOTO

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 19, 1980)

Direct chemiluminescence emissions have been found from the air oxidation of 3-acyl-9-methyl- (**1**), 3,6-diacyl-9-methyl- (**2**), and 9-acylcarbazoles (**3**) due to the generation of an excited singlet state of monocarboxylate ions (from **1** and **2**) and the carbazole anion (from **3**). The relative intensities *vs.* the reaction time for the luminescent reaction of 3-isobutyryl-9-methylcarbazole could be interpreted by a reaction scheme involving consecutive reactions. Using this reaction scheme, the values of the decomposition rate of intermediates at 30, 40, and 50 °C were determined to be 0.19, 0.42, and 0.98 min^{-1} respectively, which were comparable to the values reported for the decomposition rates of isolated dioxetanes giving excited singlet products.

In the course of our studies, we have established the generation of excited triplet carbonyl products from the air oxidation of various simple ketones with a -CO-CH- group, such as 3-methyl-2-butanone and isopropyl phenyl ketone in alkaline aprotic solvents.[1] We further succeeded in observing the direct chemiluminescence (CL) due to the generation of excited singlet products in the air oxidation of such -CO-CH- containing molecules as 9,10-diisobutyrylanthracene and 9,10-dipropionylanthracene.[2] For the luminescent reaction of the -CO-CH- containing molecules (simple ketones and diacylanthracenes), a reaction pathway involving the cleavage of a dioxetane intermediate was discussed as a possible mechanism.

Two different paths have been reported for the thermolysis of isolated dioxetanes. Simple dioxetanes decompose by homolytic cleavage to afford excited products, mainly in triplet states.[3] On the other hand, complex dioxetanes, which give high yields of excited singlet products, decompose by means of the intermolecular electron-transfer mechanism,[4] which is conceptually similar to the CIEEL mechanism.[5]

Thus, it seems likely that the difference in the state of the excited products is due to the different decomposition paths of the dioxetane intermediates: one (produced from simple ketones) gives an excited triplet product, and the other (from diacylanthracenes), an excited singlet product.

In order to test the validity of, and to broaden the scope of, the luminescent reaction mechanism, we have further examined some acylcarbazoles which contain the -CO-CH- group and a fluorescence moiety for the direct CL by air oxidation under the same experimental conditions. In the present paper, we will report the CL emission features observed from the acylcarbazoles and the kinetic evidence for the reaction path involving a dioxetane intermediate in the luminescent reaction of 3-isobutyryl-9-methylcarbazole.

Results and Discussion

3-Acyl-9-methylcarbazoles. When 0.2 cm^3 of a solution of potassium *t*-butoxide (*t*-BuOK) in *t*-butyl alcohol (2×10^{-2} mol dm^{-3}) was added to 2 cm^3 of an aerated solution of 3-isobutyryl-9-methylcarbazole (**1a**) in *N,N*-dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) (1.0×10^{-4} mol dm^{-3}), there appeared a CL emission in the UV region. The CL spectrum measured in a DMF solution had a peak at 370 nm; thus, it was similar to the fluorescence spectrum of the 9-methylcarbazole-3-carboxylate ion (**4**), one of the reaction products, measured in an alkaline DMF solution, as is shown in Fig. 1. Even when the concentration of **1a** was raised to 1.0×10^{-3} mol dm^{-3}, no change in the spectral distribution was observed (*cf*, 3,6-diisobutyryl-9-methylcarbazole below).

9-Methyl-3-propionylcarbazole (**1b**) and 3-acetyl-9-methylcarbazole (**1c**) also exhibited similar CL emissions. However, the carbazole **1b** showed a weaker emission with an intensity one 30th of that from **1a**, and **1c** the weakest (one 1000th). These results indicate that the intensity of the CL emission is much affected by the nature of the C-H bond adjacent to the carbonyl group; it increases in the order of primary<secondary<tertiary. The order of the CL intensity is consistent with those observed in simple ketones and diacylanthracenes. The following reaction scheme, involving the cleavage of a dioxetane intermediate which is produced by the oxygenation of the anion formed by the loss of a proton from the

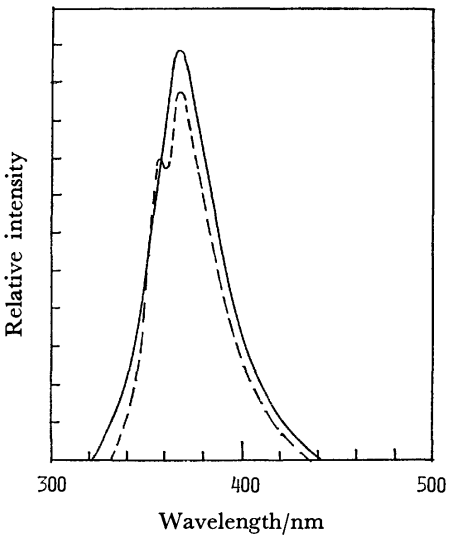

Fig. 1. Chemiluminescence spectrum of **1a** in DMF (solid curve), and fluorescence spectrum of **4** measured in an alkaline DMF solution (broken curve).

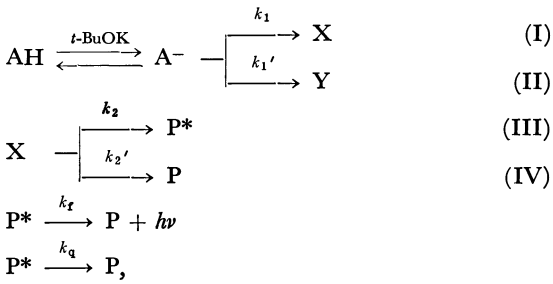
α-carbon atom, seems plausible in explaining the emission feature and the emitting product, **4**.

Recently, an intense CL emission arising from the base-induced oxidation of 3-(alkoxycarbonylamino)-benzofuran-2(3*H*)-ones, which contain a –CO–CH– group, has been reported by Lofthouse *et al.*, who also proposed an analogous reaction scheme involving a dioxetane intermediate for the luminescent reaction.[6]

The change in the concentrations of the reactant, **1a**, and the product, **4**, with the reaction time at 30, 40, and 50 °C in the luminescent DMF system [2 cm^3 of a **1a** solution in DMF (1.0×10^{-4} mol dm^{-3}) + 0.2 cm^3 of a *t*-BuOK solution in *t*-butyl alcohol (2×10^{-2} mol dm^{-3})], as measured by high-performance liquid chromatography, are illustrated in Figs. 2a, 2b, and 2c respectively.[7] Each figure shows that the concentration of **1a**, [**1a**], decreases rapidly to a certain value [**1a**]$_\infty$; thereafter, it is kept almost constant because of the extremely slow decrease, probably due to the consumption of *t*-BuOK and dissolved oxygen. In the rapid decay stage, the plots of log ([**1a**]—[**1a**]$_\infty$) *vs.* the reaction time (t) being almost straight lines, the decomposition of **1a** was found to obey a pseudo-first-order reaction with respect to ([**1a**]—[**1a**]$_\infty$), although a slight deviation arose at the final decay stage. From the slopes of the lines, the apparent rate constants (k) at 30, 40, and 50 °C were determined to be 0.22, 0.26, and 0.43 min^{-1} respectively.

The change in the relative intensities of the CL emission (I_R) with the reaction time, measured under the same experimental conditions, are illustrated by a solid curve in each of figures (2a—2c), where the values of I_R are taken to be normal at the maximum intensity. The figure of the emission curve suggests very strongly that the luminescent reaction arises from the following kinetic scheme involving consecutive reactions:



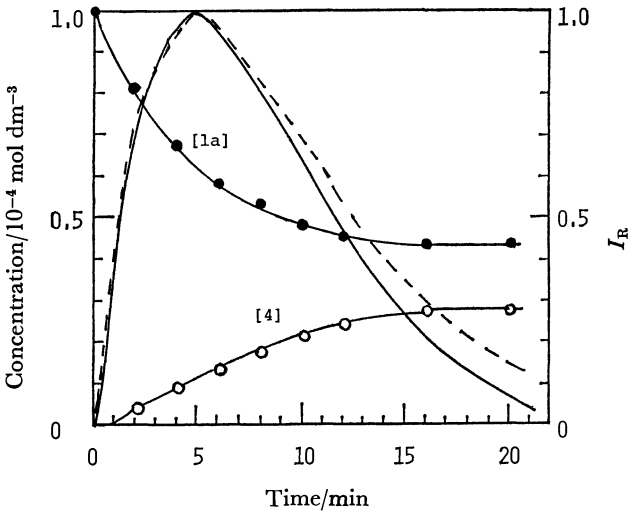


Fig. 2a. Changes in the concentrations of **1a** ([**1a**]) and **4** ([**4**]) with reaction time (t) in DMF at 30 °C, and relative intensities of CL emission (I_R) *vs.* t: observed I_R, solid curve; calculated I_R, broken curve.

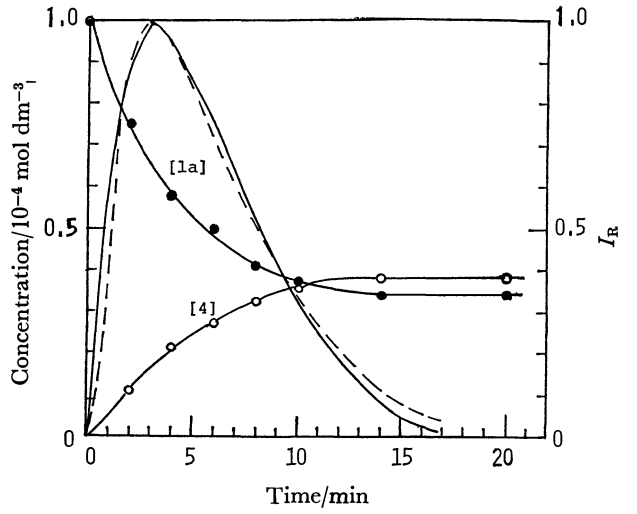

Fig. 2b. Changes in [**1a**] and [**4**], and I_R-t curves in DMF at 40 °C.

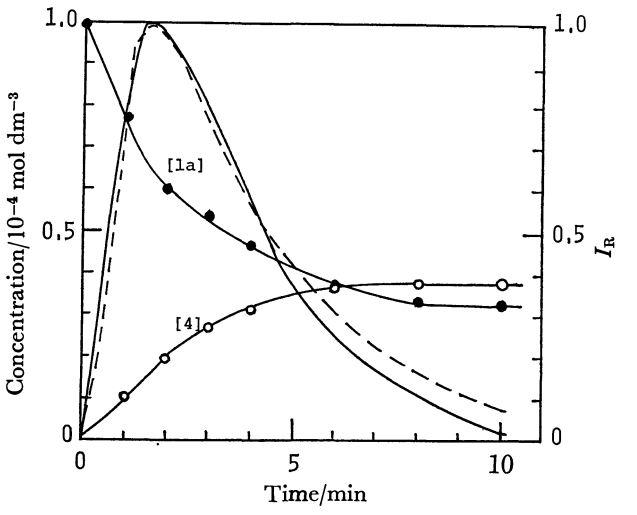

Fig. 2c. Changes in [**1a**] and [**4**], and I_R-t curves in DMF at 50 °C.

where AH=**1a**, X=dioxetane intermediate, Y=other product, and P=**4**.

Assuming that competitive decomposing reactions (III and IV) obey the first-order reaction,[8] and recalling the finding that the competitive reactions of I and II also obeyed a pseudo-first-order reaction with respect to ([AH]−[AH]∞), we can write the CL intensity (I) at the initial stage as:

$$I = k_1k_2\Phi_f\{([AH]_0-[AH]_\infty)/(k_d-k)\} \times\{\exp(-kt)-\exp(-k_dt)\}$$
$$= \alpha\beta\Phi_f([AH]_0-[AH]_\infty)\{kk_d/(k_d-k)\} \times\{\exp(-kt)-\exp(-k_dt)\}, \quad (1)$$

where $[AH]_0$ is the initial concentration of **1a**, $k_1+k'_1=k$, $k_2+k'_2=k_d$, $\alpha=k_1/k$, $\beta=k_2/k_d$, and $\Phi_f=k_f/(k_f+k_q)$. Putting t_m as the time required to reach the maximum of $I(I_m)$, we can derive the following equations:

$$k_d\exp(-k_dt_m) = k\exp(-kt_m), \quad (2)$$

and:

$$I_m = \alpha\beta\Phi_f([AH]_0-[AH]_\infty)\{kk_d/(k_d-k)\} \times\{\exp(-kt_m)-\exp(-k_dt_m)\}.$$

Therefore,

$$I_R = I/I_m = \{\exp(-kt)-\exp(-k_dt)\}/ \{\exp(-kt_m)-\exp(-k_dt_m)\}.$$

From the CL emission curves shown in Figs. 2a—2c, t_m being found to be 5.0, 3.0, and 1.5 min at 30, 40, and 50 °C respectively, the values of k_d at these temperatures can be calculated from Eq. 2 to be 0.19, 0.42, and 0.98 min^{-1} using the values of k determined above.

Taking the values of k, k_d, and t_m, we can calculate the values I_R by means of the following numerical equations:

30 °C; $I_R = \{\exp(-0.22t)-\exp(-0.19t)\}/ \{\exp(-0.22\times5)-\exp(-0.19\times5)\}$
$= \{\exp(-0.22t)-\exp(-0.19t)\}/(-0.054)$

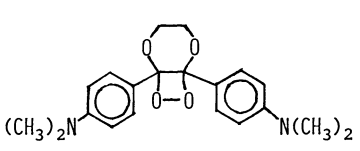
40 °C; $I_R = \{\exp(-0.26t)-\exp(-0.42t)\}/0.174$

50 °C; $I_R = \{\exp(-0.43t)-\exp(-0.98t)\}/0.295$.

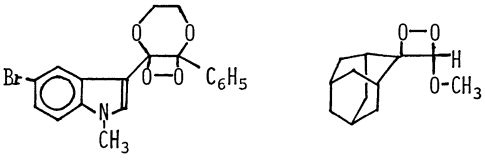
The dotted curves in Figs. 2a—2c illustrate the curves of I_R *vs.* t calculated from the above equations. The curves of I_R thus calculated are in fairly good agreement with those of the observed I_R values (solid curves) at these temperature except at the final stage, where the reactions of I and II obey the first-order reaction no longer.

It should be noted that the values of k_d (for example, 0.42 $min^{-1}=7.0\times10^{-3}$ s^{-1} at 40 °C) are comparable to the values reported for the decomposition rates of isolated dioxetanes (6.5×10^{-3} s^{-1} for the **7** dioxetane in DMF at 25 °C,[9a] 7.6×10^{-3} s^{-1} for **8** in benzene at 65 °C,[9b] 4.6×10^{-3} s^{-1} for **9** in CH_2Cl_2 at 25 °C,[9c] and 2.96×10^{-3} s^{-1} for **10** in decane at 79 °C[9d]).[10]

The activation energy for the decomposition of X (the competitive reactions of II and IV) was estimated to be 68 kJ mol^{-1} from the Arrhenius plot of k_d.



7 8



9 10

Analogous values have been obtained for the decomposition of dioxetanes (82.4 kJ mol^{-1} for **7** and 87.9 kJ (21 kcal) mol^{-1} for **8**[9a,9b]).

Using the value of 1.28×10^{-2} proposed by Lee *et al.*[11] for the efficiency of the CL emission from a standard luminol solution in DMSO (1.26×10^{-6} mol dm^{-3}), the efficiencies of CL from the **1a** solution in DMF [Φ_{CL}=quantity of total light (mol) emitted from 1 dm^3 of the solution/([AH]$_0$−[AH]$_\infty$)] at 30, 40, and 50 °C were determined to be 3.5×10^{-4}, 4.2×10^{-4}, and 5.7×10^{-4} respectively from the ratio of the total light emitted from the luminol solution to the total measured light from the **1a** solution.[12] From Eq. 1, Φ_{CL} can be written as:

$$\Phi_{CL} = \int I dt/([AH]_0-[AH]_\infty) = \alpha\beta\Phi_f.$$

The value of $\alpha=k_1/(k_1+k'_1)$ is given by [**4**]∞ (the final concentration of **4**)/([AH]$_0$−[AH]∞) and was found to be almost unchanged in the temperature range between 30 °C and 50 °C, since the values of [**4**]∞/([**1a**]$_0$−[**1a**]∞) were obtained to be 0.51, 0.58, and 0.57 at 30, 40, and 50 °C respectively. As Φ_f is not so varied with the temperature, the effect of the temperature on Φ_{CL} may be mainly attributed to the temperature dependence of β ($=k_2/(k_2+k'_2)$, which is itself presumably due to the difference in activation energy between the reaction of III (k_2) and the reaction of IV (k_2'),[13] since there has been found a difference in activation energy between a higher-energy path leading to an excited product and a lower-energy path leading to a product in a grand state in the decomposition of dimethyldioxetane.[14]

3,6-Diacylcarbazoles. 3,6-Diisobutyryl-9-methylcarbazole (**2a**) also gave rise to CL emission with an intensity comparable to that from **1a**. Figures 3a and 3b illustrate the changes in the spectral distribution with the reaction time observed when 0.2 cm^3 of *t*-BuOK solution in *t*-butyl alcohol (2×10^{-2} mol dm^{-3}) was added to 2 cm^3 of **2a** solution in DMSO in two different concentrations (1.0×10^{-3} mol dm^{-3} and 1.0×10^{-4} mol dm^{-3}). The figures indicate that the spectrum of the CL emission from **2a** varies during the course of the reaction. In a solution with a high **2a** concentration, the apparent emission was, at the initial stage, composed of one intense peak at 440 nm with a spectral distribution similar to that of the fluorescence of **2a**. During the course of the reaction,

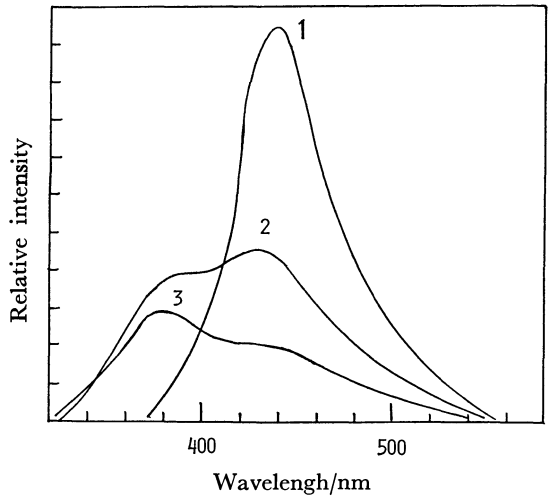


Fig. 3a. Change of CL spectrum of **2a** with reaction time in a DMSO solution of high **2a** concentration (1.0×10^{-3} mol dm^{-3}).
1→2→3.

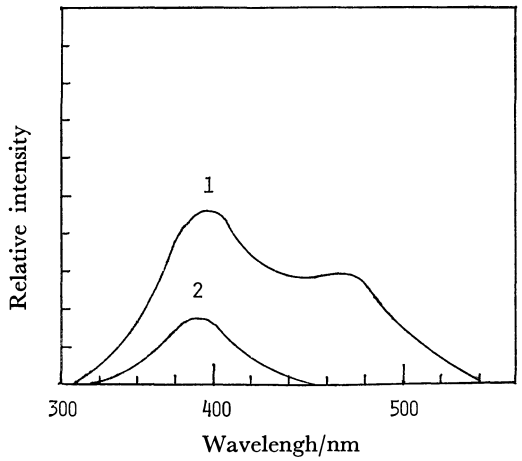

Fig. 3b. Change of CL spectrum of **2a** with reaction time in a DMSO solution of low **2a** concentration (1.0×10^{-4} mol dm^{-3}). 1→2.

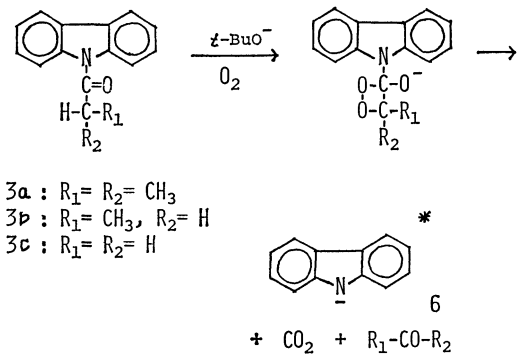
the intensity of the peak gradually decreased with a blue shift, and simultaneously a new peak appeared at about 370 nm. In a solution with a low **2a** concentration, the spectrum had two peaks at the initial stage; these peaks also varied with a blue shift until only one peak, at 370 nm, was observed. Thus, it seems likely that a portion of the excited product emits UV light (370 nm), while the other portion of the excited product transfers energy to unoxidized **2a**, thereby exciting **2a** to emit fluorescence (440 nm).

9-Methyl-3,6-dipropionylcarbazole, whose C–H bond adjacent to the carbonyl group is secondary, showed a much weaker emission than **2a**, and 3,6-diacetyl-9-methylcarbazole, which possesses a primary C–H bond, exhibited a very weak emission. From the finding that the emission from the exctied product showed a peak at 370 nm, it seems likely that excited singlet 3-acyl-9-methylcarbazole-6-carboxylate ions (**5**) are generated from the air oxidation by the same mechanism as that proposed for **1a**. In the reaction systems, **5** may be successively oxidized, since the final product was the 9-methylcarbazole-3,6-dicarboxylate ion, which showed a greenish fluorescence with a peak at 450 nm. However, it seems unlikely that the CL emission arises from the oxidation of **5**, since no emission peak at 450 nm was observed in the luminescent reactions.

3,6-Diisobutyrylcarbazole and the lower homologues gave an oxidation product which showed fluorescence with a peak at 470 nm, but an extremely weak emission was observed from its oxidation. This is probably because the luminescent reaction is debased by competitive processes brought about by the hydrogen atom at the 9-position of the carbazole. A similar debasement has been oberved in the oxidation of 9-isobutyrylanthracene.[2]

9-Acylcarbazoles. 9-Isobutyrylcarbazole (**3a**) and 9-propionylcarbazole (**3b**) exhibited CL emission with intensities one 50th of those from **1a** and **2a**. An extremely weak emission was exhibited by 9-acetylcarbazole (**3c**). The spectrum of the fluorescence from the spent reaction solution in DMSO, as measured with exciting at 340 nm, and the roughly estimated spectral distribution of the CL emission from **3a** (because of low intensity) are illustrated in Fig. 4, together with the fluorescence spectrum of



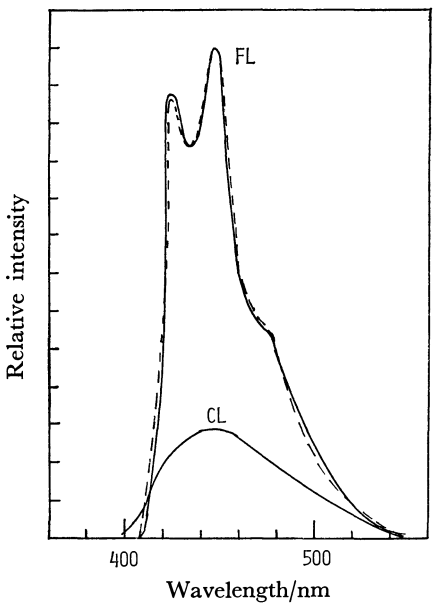


Fig. 4. Spectral distribution of CL emission from **3a** (CL), fluorescence spectrum of the spent reaction solution (FL), and fluorescence spectrum of **6** measured in an alkaline DMSO solution (broken curve).

the carbazole anion (**6**) measured in an alkaline DMSO solution with exciting at 340 nm. The figure shows that the CL spectrum is analogous to the fluorescence of the product, which is very similar to the fluorescence of **6**. Carbazole was isolated, and acetone was also obtained as 2,4-dinitrophenylhydrazone from the oxidation products. These results are interpreted by the reaction scheme shown in the previous page, leading to the generation of an excited-singlet carbazole anion *via* a dioxetane intermediate.

Summarizing the results of the present study, we conclude that excited-singlet products are surely generated in the air oxidation of molecules containing a –CO–CH– group and a fluorescence moiety in alkaline aprotic solvents. The emission features and emitting products generated by oxidation suggest that dioxetanes may be the critical intermediates in giving excited-singlet products. Work is now in progress to search for other –CO–CH– containing molecules which exhibit CL in high yields.

Experimental

The elemental analyses were conducted at the Analytical Section, Meijo University, Nagoya.

*The Preparation of 3-Acyl-9-methylcarbazoles (**1a—c**).* Aluminium chloride (11.0 g) was added, in small portions, into a vigorously stirred solution of 9-methylcarbazole[15] (15.0 g) and isobutyryl chloride (11.0 g) in benzene (300 cm^3) at 5—8 °C over a 30-min period. The mixture was stirred at that temperature for an additional 30 min and then at 25—30 °C for 24 h. Thereafter the mixture was poured onto crushed ice (400 g). The benzene layer, after being separated from the aqueous solution, was participated by water, aqueous sodium hydrogencarbonate, and water as usual. The benzene solution was concentrated to about 50 cm^3 and placed in a silica-gel column (Wako Gel C-100, 5×45 cm). The column was eluted first by a 1:1 mixture of benzene and hexane (1.5 dm^3) to remove the unchanged starting material. The column was then eluted by benzene. The subsequent evaporation of the eluate gave an oily residue, which was crystallized from ethanol to give colorless needles (45% yield) of 3-isobutyryl-9-methylcarbazole (**1a**); mp 64.5—66 °C (from ethanol) (Found: C, 81.56; H, 6.69; N, 5.43%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%).

Similar treatments of 9-methylcarbazole with propionyl chloride or acetyl chloride gave, respectively, 9-methyl-3-propionylcarbazole (**1b**) [25% yield, mp 83.5—84.5 °C (from ethanol) (Found: C, 80.73; H, 6.17; N, 5.75%. Calcd for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90%)] and 3-acetyl-9-methylcarbazole (**1c**) [50% yield, mp 99—100 °C (from methanol) (Found: C, 80.86; H, 5.70; N, 6.09%. Calcd for $C_{15}H_{13}NO$: C, 80.69; H, 5.87; N, 6.27%)].

The Preparation of 3,6-Diacyl-9-methylcarbazoles. 9-Methylcarbazole (20 g) was added, in small portions, to a vigorously stirred mixture of aluminium chloride (60 g) and isobutyryl chloride (40 g) in nitrobenzene (200 cm^3) at 0 °C. The resulting solution was stirred in an ice-bath for 6 h and then at 20—25 °C for 2 d. The solution was subsequently poured onto crushed ice (500 g), and the aqueous layer was discarded. The nitrobenzene solution, after being participated by water, was subjected to steam distillation to remove the solvent. The oily residue was extracted with benzene (2×200 cm^3). The extract was concentrated to about 150 cm^3 and fractionated on a silica-gel column (5×50 cm), eluted by a mixture of ethyl acetate and benzene (1:9). The evaporation of the eluate and subsequent crystallization from acetone gave colorless needles (82% yield) of 3,6-diisobutyryl-9-methylcarbazole (**2a**); mp 128—129.5 °C (from ethanol) (Found: C, 78.60; H, 7.18; N, 4.15%. Calcd for $C_{21}H_{23}NO_2$: C, 78.47; H, 7.21; N, 4.36%).

The replacement of isobutyryl chloride by propionyl or acetyl chloride in the foregoing reaction gave 9-methyl-3,6-dipropionylcarbazole [66% yield, mp 196—197 °C (from ethanol) (Found: C, 77.92; H, 6.52; N, 4.62%. Calcd for $C_{19}H_{19}NO_2$: C, 77.79; H, 6.53; N, 4.77%)] and 3,6-diacetyl-9-methylcarbazole [59% yield, mp 198—199 °C (from ethanol) (Found: C, 75.70; H, 5.61; N, 5.21%. Calcd for $C_{17}H_{15}NO_2$: C, 75.87; H, 5.97; N, 5.53%)] respectively.

The Preparation of 3,6-Diacylcarbazoles. Carbazole (10 g) was added, in small portions, into a vigorously stirred solution of isobutyric anhydride (10 g) and aluminium chloride (15 g) in nitrobenzene (150 cm^3) at 0—5 °C. The resulting dark green solution was stirred at 4—5 °C for 12 h and then added to ice-cold 0.5 mol dm^{-3} hydrochloric acid (300 cm^3). The nitrobenzene solution was separated from the aqueous layer and submitted to steam distillation to remove the solvent. The residual solid was dissolved in ethyl acetate and fractionated on a silica-gel column (4.5×50 cm), eluted by ethyl acetate–benzene (2:3). The evaporation of the eluate and subsequent crystallization from ethyl acetate gave yellow needles (26% yield) of 3,6-diisobutyrylcarbazole; mp 203.5—204 °C (Found: C, 78.14; H, 6.82; N, 4.96%. Calcd for $C_{20}H_{21}NO_2$: C, 78.14; H, 6.89; N, 4.56%).

3,6-Dipropionylcarbazole [36% yield, mp 238—240 °C (from ethyl acetate) (Found: C, 77.19; H, 5.98; N, 4.76%. Calcd for $C_{18}H_{17}NO_2$: C, 77.39; H, 6.13; N, 5.01%)] and 3,6-diacetylcarbazole [11% yield, mp 236—237 °C, dec (from ethyl acetate) (Found: C, 76.57; H, 5.04; N, 5.35%. Calcd for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.22; N, 5.57%)] were similarly synthesized from carbazole and the appropriate acid anhydride.

*The Preparation of 9-Acylcarbazoles (**3a—c**).* A mixture of potassium carbazole (5.0 g), isobutyryl chloride (10 g), and sodium carbonate (5 g) was heated under reflux for 2 h. The mixture was then added to water (50 cm^3), and the product was extracted with ether (2×100 cm^3). The extract, after washing with sodium hydrogencarbonate and water, was evaporated to give an oily residue, which was then fractionated on a silica-gel column (3.4×40 cm), eluated by a 1:1 mixture of hexane and benzene. The eluate was evaporated and subsequently crystallized from methanol to give colorless needles (80% yield) of 9-isobutyrylcarbazole (**3a**); mp 43—44.5 °C (Found: C, 81.01; H, 6.19; N, 6.01%. Calcd for $C_{16}H_{15}NO$: C, 80.98; H, 5.90; N, 6.37%).

9-Propionylcarbazole (**3b**) [85% yield, mp 90.5—91 °C (from methanol) (Found: C, 80.69; H, 5.67; N, 6.27%. Calcd for $C_{15}H_{13}NO$: C, 80.69; H, 5.87; N, 6.27%)] and 9-acetylcarbazole (**3c**) [60% yield, mp 67—68.5 °C (from methanol) (Found: C, 80.14; H, 5.09; N, 6.53%. Calcd for $C_{14}H_{11}NO$: C, 80.36; H, 5.30; N, 6.69%)] were similarly obtained from potassium carbazole and propionyl or acetyl chloride respectively.

*The Isolation of 9-Methylcarbazole-3-carboxylic Acid and 9-Methylcarbazole-3,6-dicarboxylic Acid from the Oxidation Products of the 3-Isobutyryl or 3,6-Diisobutyryl Precursor (**1a** or **2a**).* 3-Isobutyryl-9-methylcarbazole (500 mg) in DMF was added to *t*-BuOK (4.0 g) in DMF (250 cm^3), after which the mixture was stirred under oxygen at 25 °C for 2 h. Water (100

cm^3) was added to the mixture, and the resulting solution was evaporated to dryness under reduced pressure. The residue was dissolved in water (150 cm^3), and a small amount of an insoluble material was removed by extraction with benzene (2×50 cm^3). The solution was brought to boil, adjusted to pH 2—3 with hydrochloric acid, and then chilled. The colorless needles (385 mg, 86% yield) of 9-methylcarbazole-3-carboxylic acid melted at 258—259 °C (from water) (Found: C, 74.59; H, 4.67; N, 6.09%. Calcd for $C_{14}H_{11}NO_2$: C, 74.65; H, 4.92; N, 6.22%).

3,6-Diisobutyryl-9-methylcarbazole, on air oxidation in a way similar to that described above, yielded 9-methylcarbazole-3,6-dicarboxylic acid (95% yield), which did not melt below 300 °C (Found: C, 66.70; H, 4.33; N, 5.23%. Calcd for $C_{15}H_{11}NO_4$: C, 66.91; H, 4.12; N, 5.20%).

Measurements of the CL Intensity and Fluorescence Spectra. A 2-cm^3 aerated solution of the acylcarbazoles in DMF or DMSO was placed in a quartz cell, which was kept at a constant temperature by means of a thermostatically controlled cell holder. The CL intensity was measured immediately after adding 0.2 cm^3 of a solution of *t*-BuOK in *t*-butyl alcohol (2×10^{-2} mol cm^{-3}) into the solution of the reactant on a Hitachi MPF-2A fluorescence spectrophotometer, with the exciting source turned off. The fluorescence spectra were measured on the same apparatus.

Measurements of the Changes in the Concentrations of Reactant and Product in CL Reaction of ***1a*** *by High-performance Liquid Chromatography.* We took 0.2-cm^3 aliquots of the reaction solution out at regular intervals and immediately added them to a solution of phosphoric acid in methanol (2×10^{-3} mol dm^{-3}, 0.2 cm^3) to stop the oxidation. A 25-mm^3 aliquot of the solution was subjected to high-performance liquid chromatography using a JASCO Trirotar on a JASCO SS-10-ODS-A reverse-phase column (4.6×250 mm), using methanol as the elution solvent (1.0 cm^3/min). The eluate containing the unchanged reactant (**1a**) and product (9-methylcarbazole-3-carboxylic acid, **4**) was detected on a JASCO UVIDEC-100-II UV spectrometer at 285 nm, and the retention times and the quantities of **1a** and **4** were determined by calculating the areas of the peaks with a Intelligent 5000 E integrator.

The authors wish to thank Mr. Nobuhiko Honda for his technical assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 354136 from the Ministry of Education, Science and Culture.

12) When light is detected by the signal of an electrophotometer, the total light intensity per unit volume from a chemiluminescent solution is given by $T=G\int S_t dt$, where G is the instrumental factor and where S_t is the magnitude of the signal measured over the emission band at time t and is experimentally determined by the graphical integration of the spectral distribution curve, corrected for the wavelength response of the photomultiplier.

Assuming that the ratio of S_t to the magnitude of the signal at the peak of the emission spectrum ($I(\lambda_m)_t$), $\sigma=S_t/I(\lambda_m)_t$, is kept constant during the reaction, we can write: $T=G\sigma\int I(\lambda_m)_t dt$. $\int I(\lambda_m)_t dt$ is experimentally determined by the graphical integration of the $I(\lambda_m)_t$ *vs.* t-curve. Thus, $\Phi_{CL}=G\sigma\int I(\lambda_m)_t dt/[M]$ for a solution ([M] is the concentration decrement of M), and $\Phi'_{CL}=G\sigma'\int I'(\lambda'_m)_t dt/[M']$ for the other solution, so that:

$$\Phi_{CL}=\Phi'_{CL}\sigma[M']\int I(\lambda_m)_t dt/\sigma'[(M]\int I'(\lambda'_m)_t dt.$$

13) Assuming that $k_2=A\exp(-E_a/RT)$, $k'_2=A'\exp(-E_a'/RT)$ and $A\sim A'$, we can write that $1/\beta-1=\exp(\Delta E_a/RT)$, where $\Delta E_a=E_a-E_a'$ is the difference in activation energy between Reactions III(E_a) and IV(E_a'). If ΔE_a is tentatively taken to be 10 kJ mol^{-1} with reference to the value reported for dimethyldioxetane (13—14 kJ mol^{-1}),[14] the β values are calculated to be 1.8×10^{-2}, 2.1×10^{-2}, and 2.4×10^{-2} at 30, 40, and 50 °C respectively. The ratio of the β values (1.0:1.2:1.3) is roughly agreeable to that the observed Φ_{CL} values (1.0:1.2:1.6).

Spectral Behavior of 3,6-Substituted Aminoacridine Dyes with Emphasis on the Perturbation of the Exonuclear Amino Groups

Kiwamu YAMAOKA,* Sumihare NOJI, and Mamoru YOSHIDA
Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received April 7, 1980)

The optical absorption spectra of several derivatives of Proflavine (PF) and Coriphosphine O (CP) were measured in aqueous solutions at 25 °C. The effect of the perturbation of one or both of the exonuclear amino groups on the spectral behavior was studied in order to explore the relationship between the spectra and the chemical structures of the symmetric 3,6-disubstituted acridine dyes which can bind to various polyelectrolytes, often showing metachromasy. The metachromatic spectra of the complexes between 3,6-diaminoacridine dyes and polyanions were reproduced reasonably well when one of the two amino groups of PF was converted to an acylamino group. A similar result was observed when the amino group of CP was acetylated. In these cases, the spectra show two absorption bands of nearly equal intensity on both sides of the single peak of PF and CP in the visible region. These results are indicative of the close similarity in chemical structures between the monacylamino PF and the PF bound to the electron-rich sites of polyanions.

The symmetric 3,6-diaminoacridine dyes and their derivatives, such as Proflavine (PF), Trypaflavine (TF), and Acridine Orange (AO), show a deceptively simple absorption band in the visible wavelength region. Yet, a recent work has clearly shown that the spectral feature of this band is quite complex, actually consisting of two orthogonally polarized component bands with vibrational structures.[1] The visible spectra of those dyes are all metachromatic, exhibiting large hypo- and hypsochromic changes in solutions in the presence of various polyelectrolytes.[2] Because of this striking metachromatic behavior, the bathochromic change of the spectra has long been ignored, in spite of an early mention of the importance of the long-wavelength absorption component band associated with the dye-polymer complexes.[3] The pure spectra of TF bound to various polymers have indeed shown a long-wavelength band in addition to the short-wavelength band, their intensity being about equal.[4]

In contrast with the above cases, substitution on the 10- and/or 9-position of the acridine nucleus affects the absorption spectrum of acridine itself only slightly.[5] For example, 10-methylacridinium and 9-aminoacridinium both show a visible spectrum in which the short-axis polarized transition (the ^1L_a band) is well separated from the long-axis polarized transition (the ^1L_b band).[1,6,7] These two acridines also bind to some polymers,[8–12] but they show no appreciable metachromatic effect. The bound-dye spectra have revealed that both the short- and long-axis polarized bands shift toward the red slightly with a concomitant decrease in intensity.[11,12] Thus, introduction of amino groups into the 3- and 6-positions of acridine appears to be responsible for the large metachromatic spectra of dye–polymer complexes.

In the course of the study of spin-labeled acridine dyes, attachment of a nitroxide radical to one of the 3,6-amino groups of PF altered the visible spectrum of PF in such a way that the original peak was split into two bands.[13] Interestingly, the spectral profile of this monosubstituted-PF (slPF) resembled the spectra of TF bound to various polyions.[4] This remarkable change of slPF, however, disappeared and a PF-like simple spectrum was restored when both amino groups of PF were coupled with the radicals.[14] These results are suggestive of three possibilities: (1) The nitroxide radical effects the spectral splitting of the mother compound PF. (2) Conjugation of the newly produced acylamino group with the acridine ring perturbs the π-electron system. (3) Lowering of molecular symmetry from a C_{2v} to a less symmetric C_s group increases the separation between the short- and long-axis polarized components of the visible band. The present work was undertaken for the purposes of (1) discriminating these points, and (2) exploring the relation between the spectra of 3,6-substituted diaminoacridine dyes, in which an amino group or groups are perturbed, and the bound-dye spectra of dye-polymer complexes. For this purpose, the absorption spectra of a number of closely related acridine dyes were determined and correlated.

Experimental

Materials. Proflavine (PF), 3,6-diaminoacridinium chloride **1a**, was purified according to Albert.[5] Monoacetylated Proflavine (AcPF), 3-acetamido-6-aminoacridinium chloride **1b**,[15] and diacetylated Proflavine (Ac_2PF), 3,6-diacetamidoacridinium chloride **1c**,[16] were prepared by a standard acetylation procedure. Preparations of monopyrrolidinylated Proflavine (slPF), 6-amino-3-(1-oxy-2,2,5,5-tetramethyl-3-pyrrolidinyl-carbonylamino)acridinium chloride **1d**,[13,17] and dipyrrolidinylated Proflavine (sl_2PF), 3,6-bis(1-oxy-2,2,5,5-tetramethyl-3-pyrrolidinyl-carbonylamino)-acridinium chloride **1e**,[14,17] were described in detail elsewhere. Coriphosphine O (CP), 3-amino-6-dimethylamino-2-methylacridinium chloride **2a**, was purchased from Chroma Gesellschaft, Schmid & Co. and was purified by the silica gel thin layer chromatography, with an eluent system of 1-butanol–acetic acid–water (4:1:5). Acetylated Coriphosphine O (AcCP), 3-acetamido-6-dimethylamino-2-methylacridinium chloride **2b**, was prepared by acetylating CP with an acetic acid–acetic anhydride mixture at 118 °C. Crude AcCP was purified in a manner similar to CP. All chemical structures of dyes **1a** to **2b** are shown in Fig. 1.

Measurements. Absorption spectra were measured on a Hitachi model EPS-3T recording spectrophotometer at 25 °C. Optical titration of each dye was carried out to determine the pK-value, usually at the wavelength of maximum absorption in a concentration range of 5×10^{-5} M (1 M = 1 mol/l) in the presence of 1.0×10^{-2} M Tris buffer. The pH values were controlled by adding either 0.05 M

HCl or 0.05 M NaOH; no precipitate of dye occurred. The molar absorption coefficient ε was expressed in M^{-1} cm^{-1}. The pH was determined with a Hitachi-Horiba F-7 pH meter.

Results and Discussion

Absorption Spectra of Acetylated Proflavines. The absorption spectra of mono- and diacetylated Proflavines, AcPF and Ac$_2$PF, are shown in Fig. 2, together with the spectrum of PF for comparison. In the upper half, the spectra of the protonated forms of these dyes are given. The spectrum of AcPF shows two absorption bands of nearly equal intensity in the visible wavelength region. Each band clearly consists of some subbands, probably the vibrational structure, which are more pronounced in organic solvents. Close examination indicates that these two bands are separated unevenly with respect to the original single peak at 444 nm of PF, *i.e.*, the longer-wavelength band is almost unshifted but the shorter-wavelength band is shifted by 50 nm toward the blue. It is quite interesting to note that a further acetylation of the remaining amino group of AcPF results in a simple spectral profile in the visible wavelength. This spectrum of Ac$_2$PF rather resembles that of PF, although their intensity and peak position differ from each other greatly. The UV spectra of these protonated dyes also vary with the degree of acetylation in such a way that the major peak at 262 nm of PF moves toward the long wavelengths.

In the lower half of Fig. 2, the spectra of the deprotonated (neutral or base) forms are shown. Again the effect of the perturbation of the exonuclear amino groups on the spectra is quite remarkable. Just as the removal of the proton from the 10-position gives rise to the hypo- and hypsochromic changes for PF, a very similar effect appears for the base forms of AcPF and Ac$_2$PF. The visible bands of the base forms are located in the 370—390 nm region regardless of the substituents at the 3- and 6-positions. The spectral behavior of the basic AcPF is most interesting, *i.e.*, the longer-wavelength peak diminishes to be just a shoulder near 410—420 nm, while the shorter-wavelength band remains. The visible and UV spectra of the base forms of PF and Ac$_2$PF are again similar to each other.

The results in Fig. 2 clearly show three points: The nonsymmetric substitution of either the 3- or 6-position of PF by an acetyl group gives rise to a new spectral feature, *i.e.*, the appearance of two absorption maxima. The symmetric substitution of both the 3- and 6-positions of PF reverts to the original feature of the single peak. Finally, the removal of a proton from the 10-position affects the spectral profiles hypso- and hypochromically.

Absorption Spectra of Spin-labeled Proflavines. The absorption spectra of mono- and dipyrrolidinylated Proflavines, slPF and sl$_2$PF, are shown in Fig. 3, together with the spectrum of PF for comparison. These protonated PF derivatives (upper half) behave surprisingly similarly to their acetylated counterparts. The visible spectrum of slPF shows two bands of about equal intensity, *i.e.*, the longer-wavelength band is

at 450 nm, but the shorter-wavelength band is further apart by 60 nm from the peak of PF. The spectrum of sl_2PF, which is obtained by substitution of the remaining amino group of slPF, reverts to the simple spectrum of PF. The UV spectra of slPF and sl_2PF behave just like those of AcPF and Ac_2PF. It should be noted that the free nitroxide radical absorbs light very weakly, showing the maximum absorption at 398 nm (ε=8.6, absorbance=0.18 at 21 mM in aqueous solution). The results in Figs. 2 and 3 exclude the contribution of the radical to the observed spectra of slPF and sl_2PF in the visible wavelength region.

The spectra of the deprotonated forms of PF, slPF, and sl_2PF are shown in the lower half of Fig. 3. The removal of a proton from the 10-position affects each spectrum in the very same way as in the case of the acetylated counterparts. Comparison of the data in Fig. 3 with those in Fig. 2 clearly indicates that the simultaneous substitution of two amino groups on the 3,6-positions by either acetamido or pyrrolidinyl radical groups results in the spectral feature closely related to that of PF itself. This is conceivable in the sense that the substitution at both positions retains the molecular C_{2v} symmetry for all PF, Ac_2PF, and sl_2PF. Yet, it is surprising to see that the conversion of each exonuclear amino group to an acylamino group restores the original band structure.

Absorption Spectra of Coriphosphines. Now, a question arises: Is the appearance of two bands of nearly equal intensity in the visible region due to the perturbation of one of the two exonuclear amino groups ? Alternatively, does the breakdown of molecular symmetry from the C_{2v} to the C_s point group result in two bands instead of one ? The answer is given in Fig. 4, where the absorption spectra of CP and its acetylated derivative, AcCP, are shown. The structure of CP differs from PF in that a methyl group is attached at the 2-position of the acridine nucleus and one of the amino groups is substituted by the dimethylamino group (Fig. 1). Hence, the molecular symmetry of CP is lower than the C_{2v} and may be considered to be C_s. Yet, the absorption spectrum of CP is close to that of PF, showing a single band at 465 nm in the visible region.

The spectrum of AcCP clearly shows two absorption bands at 490 nm and 381 nm, just as the cases of AcPF (Fig. 2) and slPF (Fig. 3). Results in Fig. 4 at once ascertain that the lowering of the symmetry of PF as such does not cause the splitting of the single peak into two peaks of nearly equal intensity. This view is further supported by the acetylation of the amino groups of CP. The base forms of CP and AcCP behave similarly to the deprotonated PF dyes, as is shown in the lower half of Fig. 4. A noticeable difference is that the longer-wavelength peak of AcCP remains as a distinct peak even when the proton is removed from the 10-position, In conclusion, it is most probably the acylation of one, but not both, of two amino groups on the 3,6-positions that results in the new spectral feature, *i.e.*, the development of two bands.

Comparison of Optical Properties of Dyes ***1a—2b.*** Since systematic studies of the effect of the substitution of particular groups on the spectra of the 3,6-disub-

a) The value in the parentheses is the peak or shoulder wavelength in nm. b) This value is taken from Ref. 19.

stituted acridine dyes are few, it is appropriate to compare their spectral properties. The data are summarized in Table 1. In the concentration range covered in this work, the Beer-Lambert law holds for each dye in aqueous and ethanolic solutions. Thus, the possibility that the changes in all spectra result from dye-aggregation can be excluded. The pK-values were determined for dyes **1a—2b** by optical titration. It is clear from Table 1 that conversion of amino groups to acylamino groups decreases the pK-value in the order of unsubstituted>monosubstituted>disubstituted. This is in conformity with other cases,[5] and the electron-donating tendency of an amido group may be responsible for it. The pK-value of 6.25 for AcPF is in good agreement with a previously reported value of 6.2.[18]

The symmetric 3,6-disubstituted Ac_2PF and sl_2PF should belong to the C_{2v} group as PF and, consequently, their apparently simple visible band should contain the long- and short-axis polarized bands.[1] It would be helpful to identify the directions of the polarization of the two clearly visible absorption bands for AcPF and slPF. However, these transition moments are no longer polarized along the short- and long-axes in a molecular plane under symmetry considerations. Individual transition moments may be determined by the film dichroism method.[1]

All dyes examined in this work bind to sodium polyphosphate, exhibiting the hypso- and hypochromic effects. It is worth noting that the pure spectra of TF bound to various polyelectrolytes are very close to the spectra of AcPF and slPF, each of which contains an exonuclear acylamino group. This apparent similarity suggests that one of the two amino groups of PF or TF in the dye-polymer complexes may be electronically affected by the electron-rich polymer sites such as $-COO^-$, $-SO_3^-$, and $-PO_2^-$– by still unclarified reasons. In this connection, the interaction of AcPF and other dyes described in this work with polyions should be studied to obtain the pure spectra of the bound dyes.[19] Molecular orbital calculations capable of taking into account the substitution effect on the exonuclear groups should also be carried out to elucidate these profound spectral changes on a more quantitative and systematic basis.

Conclusion

The absorption spectra of the symmetric 3,6-disubstituted acridine dyes show a single band in the visible wavelength region regardless of the bulkiness of the substituents (PF, Ac_2PF, and sl_2PF). Conversion of an amino group to an acylamino substituent gives rise to the spectrum which shows two bands of nearly equal intensity. This spectrum resembles the pure spectrum of a 3,6-diaminoacridine bound to various polyelectrolytes. The mere decrease of the molecular symmetry from C_{2v} to C_s cannot result in such a drastic spectral change. The π-electron system of the acylamino group at either the 3- or 6-position must interact with the π-electron system of the acridine nucleus by conjugation.

Kinetic Studies on Intramolecular Excimer Formation in Dinaphthylalkanes

Shinzaburo Ito,* Masahide Yamamoto, and Yasunori Nishijima
Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto 606
(Received April 9, 1980)

Various dinaphthylalkanes in which two naphthyl groups are separated by three carbon atoms were prepared, and intramolecular excimer formation was investigated. All rate constants in Förster's kinetics were determined by the steady state and time-resolved fluorescence measurements. A large difference in the association rate constant was observed with variation of molecular structure. The results suggest that intramolecular excimer formation is directly controlled by the rotational relaxation processes of the molecules from their neighboring conformations to the excimer conformation. A large formation rate (7.9×10^8 s^{-1} at 25 °C) was observed for *meso*-2,4-dinaphthylpentane, the rate for the *racemo* isomer being found to be one tenth of that for the *meso* isomer. This indicates that the isotactic sequence in vinyl aromatic polymers plays an important role in the intramolecular excimer formation.

Excimer is an excited dimer existing only in the excited state by the attractive interaction between an excited chromophore and one in the ground state. It turns unstable in the ground state due to the steric hindrance between chromophores. The formation of intermolecular excimers is thus expected to be controlled by the mutual diffusion of chromophores. Verification of the diffusion controlled process has been carried out mainly using pyrene molecule as a chromophore.[1,2]

The formation of intramolecular excimers is considered to be governed by the micro-structures of molecules to which chromophores are attached. It seems that there are two controlling factors for the intramolecular excimer formation: (a) conformational changes of the molecule which corresponds to the mutual diffusion process in the case of intermolecular excimer formation, and (b) the geometrical arrangement of two chromophores in an excimer state which is determined by the micro-structure of the molecule. Concerning (b), Hirayama proposed the $n=3$ rule for the intramolecular excimer formation.[3] The results indicate that the most favorable arrangement of chromophores is a symmetrical parallel sandwich arrangement which can be formed specifically in a compound having a molecular structure in which two aromatic groups along the alkane chain are separated by three carbon atoms.

This paper deals with (a), the relationship between the micro-structures of molecules and their rotational relaxation processes within the lifetime of a chromophore. A naphthalene chromophore seems to have fairly strict arrangements in the excimer state,[4] its emission properties being favorable for detection in spectroscopic analyses. The photophysical characteristics are useful for investigating the rotational relaxation processes. In order to clarify the problem (a), quantitative study on various model compounds by the time-resolved fluorescence method, is necessary. Advance in the time-resolved technique for photoluminescence measurements enables us to determine the rate constants of the kinetic scheme including the intramolecular excimer formation process.[5-9] We have investigated various dinaphthylalkanes satisfying the $n=3$ rule,[3] under photostationary and transient conditions. The individual rate constant of photophysical processes was determined. From the results, the relationship between the molecular structure and its conformational relaxation is discussed. The compounds examined are regarded as the dimeric model compounds of vinyl polymers. Their photophysical behavior provides useful information on the intramolecular excimers in polymer systems.

Experimental

Materials. 1,3-Di(2-naphthyl)propane (1,3-DNPr) was synthesized by the procedure of Chandross and Dempster.[4] The other sample were prepared by as follows.

1,3-Di(2-naphthyl)butane (1,3-DNBu): 1,3-Di(2-naphthyl)-1-propanone, obtained as an intermediate product in the synthesis of 1,3-DNPr, was reacted with methylmagnesium iodide in ether solution. The oily product was purified by a column chromatography on silica gel. 2,4-Di(2-naphthyl)-2-butanol thus obtained was reduced in acetic acid solution by addition of zinc dust and hydrochloric acid. The product was chromatographed on silica gel with hexane–dichloromethane (4:1): mp 65—66 °C; IR (KBr) 3050, 2950, 2930, 2850, 1630, 1600, 1510, 815, 740, and 475 cm^{-1}; NMR (CS_2) $\delta=1.35$ (3H, d, $J=6.5$ Hz), 1.90—2.16 (2H, m), 2.52—2.96 (3H, m), and 7.06—7.74 (14H, m). Found: C, 92.69; H, 7.18%. Calcd for $C_{24}H_{22}$: C, 92.86; H, 7.14%.

1,3-Di(2-naphthyl)pentadecane (1,3-DNPd) and 1,3-di(2-naphthyl)-5-phenylpentane (1,3-DN-5-PhPe) were synthesized by the same method as that for 1,3-DNBu, 1-bromododecane and 1-bromo-2-phenylethane being used for 1,3-DNPd and 1,3-DN-5-PhPe, respectively, instead of methyl iodide. 1,3-DNPd: IR (KBr) 3050, 2930, 2850, 1630, 1600, 1510, 815, 740, and 475 cm^{-1}; NMR (CS_2) $\delta=0.75$—0.95 (3H, m), 1.17 (20H, s), 1.54—1.83 (2H, m), 1.92—2.18 (2H, m), 2.50—2.80 (3H, m), and 7.05—7.76 (14H, m). Found: C, 90.67; H, 9.82%. Calcd for: $C_{35}H_{44}$; C, 90.46; H, 9.54%. 1,3-DN-5-PhPe: IR (KBr) 3050, 2930, 2850, 1630, 1600, 1510, 815, 740, 695, and 475 cm^{-1}; NMR (CS_2) $\delta=1.85$—2.22 (4H, m), 2.30—2.82 (5H, m), and 6.85—7.80 (19H, m). Found: C, 92.87; H, 6.99%; M^+, 400. Calcd for $C_{31}H_{28}$: C, 92.95; H, 7.05%; M, 400.

2,4-Di(2-naphthyl)pentane (2,4-DNPe): 1,3-Di(2-naphthyl)-2-propen-1-one, obtained in the course of the synthesis of 1,3-DNPr, was reacted with methylmagnesium iodide in the presence of a trace amount of cuprous chloride, and the product was extracted with benzene. After benzene had been removed, the residue was recrystallized from carbon tetrachloride to give colorless crystalline 1,3-di(2-naphthyl)-1-butanone: mp 148—150 °C. The ketone was reacted again with methylmagnesium iodide in ether solution. The product, 2,4-dinaphthyl-2-pentanol, was reduced by the same method as that for 1,3-DNBu. The residual oil was purified by a column chromatography on silica gel.

The oily product consists of *meso* and *racemo* isomers (*ca.* 1:2). The isomers were separated by a recycle gel permeation chromatography. After seventy cycles, fractionated samples were used for measurements. The purity of the isomers was found to be 85% for both isomers by the methyl proton resonance in NMR spectra. Emission intensity was corrected by this proportion of isomers. 2,4-DNPe: IR (KBr) 3050, 2950, 2920, 2860, 1630, 1600, 1505, 815, 740, and 475 cm^{-1}; NMR (CS_2) for *meso* isomer, $\delta=1.35$ (3H, d, $J=7$ Hz), 1.7—2.3 (1H, m), 2.5—2.95 (1H, m), and 7.16—7.80 (7H, m), NMR (CS_2) for *racemo* isomer, $\delta=1.24$ (3H, d, $J=6.8$ Hz), 1.96—2.18 (1H, m), 2.42—2.85 (1H, m), and 7.18—7.80 (7H, m). Found: C, 92.53; H, 7.48%; M^+, 324. Calcd for $C_{25}H_{24}$: C, 92.54; H, 7.46%; M, 324.

Measurements. Tetrahydrofuran (THF) was used as a solvent, which was purified by vacuum distillation after preliminary distillation over sodium metal. The concentration of samples was adjusted to *ca.* 10^{-4} mol dm^{-3} at which the intermolecular excimer formation is negligible. The sample solutions were deaerated by freeze-thaw cycles at 10^{-5} mmHg.† Absorption spectra were obtained with a Shimadzu UV-200S spectrophotometer, and fluorescence spectra with a Shimadzu spectrofluorophotometer model RF-502 in which the spectra were corrected for the instrumental response. The quantum yields of emission were determined relative to that of quinine sulfate in 1 mol dm^{-3} sulfuric acid, whose reported quantum yield is 0.51.[7] The decay curves of fluorescence were directly measured using a pulse fluorometer, TRW instrument model 31B or a single photon counting technique (Ortec Inc., 9200 nanosecond fluorescence spectrometer). The monomer and excimer fluorescence were separated by a suitable combination of filters. A quartz dewar equipped with a thermocouple was used for low temperature measurements.

Results and Discussion

Structural formulas of dinaphthylalkanes are summarized in Fig. 1. The alignment of aromatic groups favorable for intramolecular excimer formation can be achieved when two adjacent aromatic groups are separated by three carbon atoms of alkane chain. Hence, effective intramolecular excimer formation can be expected in these compounds. Absorption spectra for these samples are nearly the same and similar to those of 2-ethylnaphthalene (MNEt) corresponding to the monomeric unit. This indicates that there is no specific interaction between naphthyl groups in the ground state, each chromophore behaving like an isolated naphthalene unit. Figure 2 shows the fluorescence spectra of three typical compounds at −20 °C. They consist of two emission bands. The structured shorter wavelength band and the broad longer wavelength band are assigned to the monomer fluorescence and intramolecular excimer fluorescence, respectively. Relative fluorescence intensities of these bands differ considerably with sample. Although the molecular structures of these samples are very much alike as a common dimer unit, they show different efficiency in excimer formation. This can be attributed to the conformational relaxation processes after excitation of chromophores, from identity of the absorption and emission bands on the spectra of these samples.

The ratios of quantum yield (Φ_D) of excimer fluorescence to that of monomer fluorescence (Φ_M) for all samples at various temperatures are given in Table 1. Figure 3 shows the temperature dependence of Φ_M and Φ_D for three typical samples. Below −100 °C, fluorescence spectra of all samples are almost the same as those of MNEt. There is no indication of interaction between the naphthalene groups in the excited state when the molecular motion is suppressed. With rise in temperature, the monomer fluorescence is quenched steadily with increase in the excimer fluorescence. This shows that intramolecular excimer formation is governed by the conformational changes of the molecules. Some remarks are given concerning Table 1. (1) The compounds having alkyl substituents at one side of the dimer unit such as 1,3-DNBu, 1,3-DNPd, and 1,3-DN-5-PhPe, show the same efficiency of excimer formation, the efficiency being independent of the kind of substituent. (2) 1,3-DNPr

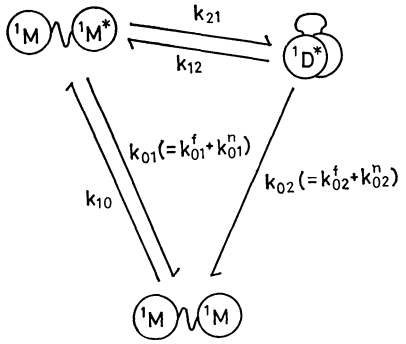

Fig. 5. Photophysical kinetic scheme of the energy dissipation processes. ^{1}M, ^{1}M*, and ^{1}D* represent the ground state of monomer, the excited singlet state of monomer, and the intramolecular excimer, respectively.

shows lower efficiency than that of 1,3-DNBu. (3) The highest efficiency of excimer formation is observed for 2,4-DNPe(*meso*), but its isomer 2,4-DNPe(*rac*) gives the lowest efficiency among the measured compounds. The effect of molecular configuration for intramolecular excimer formation appears typically in these isomers. This large difference in excimer formation for 2,4-DNPe between (*meso*) and (*rac*) is similar to the result of the steady state observation for diphenylpentanes.[10]

The activation energy, E_a, for the excimer formation process can be obtained in the low temperature region by the equation

$$\Phi_D/\Phi_M = K \exp(-E_a/RT),$$

where K is a constant. The plots are shown in Fig. 4. In all samples except for 2,4-DNPe(*rac*), E_a was found to be 4.8—5.3 kcal/mol.†† 2,4-DNPe(*rac*) gives a somewhat larger value of E_a, 5.5 kcal/mol. The activation energy required for intermolecular excimer formation of MNEt in THF was found to be 3.2—3.4 kcal/mol.[11] The larger activation energies of intramolecular excimers indicate methylene chain restriction in the conformational changes. Somewhat larger activation energy for 2,4-DNPe(*rac*) suggests that some other conformational restraints in the excimer formation process are imposed on this compound. Although the activation energies for *meso*- and *rac*-diphenylpentanes were reported by Bokobza *et al.*[10] to be 2.0 and 4.6 kcal/mol, respectively, no such large difference was found for the two isomers of 2,4-DNPe in the present investigation.

The scheme of photophysical kinetics including the intramolecular excimer formation process is given in Fig. 5. However, it is not clear which process causes the difference in the efficiency of excimer formation for these compounds. For the sake of clarification, all the rate constants in the kinetic scheme should be determined by the time-resolved measurements. Rise and decay curves of the excimer emission after excitation by a pulse with a half-width of about 2.5 ns, are

†† 1 cal=4.184 J.

shown in Fig. 6 for three typical samples at 25 °C. On the assumption that the actual lifetime of the monomer emission in the absence of the excimer formation process is equal to the lifetime of MNEt under the same conditions, all the rate constants given in Fig. 5 can be determined by analysis of the transient curves and the quantum yields, Φ_M and Φ_D.

The theoretical response functions $I_M(t)$ and $I_D(t)$, for the monomer and excimer fluorescence, are derived by

$$I_M(t) = C_M(e^{-\lambda_1 t} + Ae^{-\lambda_2 t}),$$
$$I_D(t) = C_D(e^{-\lambda_1 t} - e^{-\lambda_2 t}),$$

where C_M, C_D, A, λ_1, and λ_2 are given as functions of the rate constants,[1] and

$$\lambda_{1,2} = [k_{01}+k_{21}+k_{02}+k_{12} \mp \{(k_{01}+k_{21}-k_{02}-k_{12})^2 + 4k_{21}k_{12}\}^{1/2}]/2,$$
$$A = (k_{01}+k_{21}-\lambda_1)/(\lambda_2-k_{01}-k_{21}).$$

The value of A is too large to be estimated accurately from the monomer fluorescence decay curve in the intramolecular excimer systems. On the assumption mentioned above, the rate constants, k_{01}^f and k_{01}^n are determined by measurement of the quantum yield and lifetime of MNEt. The other rate constants, k_{21}, k_{12}, k_{02}^f, and k_{02}^n are then obtained from the observed values, λ_1, λ_2, Φ_M, and Φ_D, by using the following relations,

$$\Phi_M = k_{01}^f(k_{02}+k_{12})/\lambda_1\lambda_2,$$
$$\Phi_D = k_{02}^f k_{21}/\lambda_1\lambda_2,$$

Table 3. Kinetic rate constants at 25 °C

$k_{01}^f/10^7$ s^{-1}	0.49
$k_{01}^n/10^7$ s^{-1}	1.3
$k_{02}^f/10^7$ s^{-1}	0.16—0.22
$k_{02}^n/10^7$ s^{-1}	0.8 —1.2
$k_{12}/10^7$ s^{-1}	2.6 —0.8

$$\lambda_1 + \lambda_2 = k_{01} + k_{21} + k_{02} + k_{12},$$
$$\lambda_1\lambda_2 = (k_{01}+k_{21})(k_{02}+k_{12}) - k_{21}k_{12}.$$

The rate constant k_{21} values measured at various temperatures are given in Table 2, other rate constants at 25 °C for all the samples being summarized in Table 3. There is an appreciable difference in the pseudo-1st order rate constant k_{21} values of the association process among these compounds, although little change is seen in the other rate constants. It is apparent that the marked increase of the excimer formation efficiency observed in the steady state measurements is due to the large values of the association rate constant k_{21}.

The observed compounds seem to have the same geometrical alignment of the naphthyl groups in the excimer state. We might conclude that the rate constant k_{02} does not vary so much with sample. There is no considerable change in the dissociation rate constant k_{12}, although somewhat a larger value is obtained for 2,4-DNPe(*meso*). The value of k_{12} for the intermolecular excimers in concentrated solution of MNEt in THF is given by

$$k_{12} = A\exp(-E_d/RT),$$

where A, E_d, and R are the Arrhenius factor, the activation energy of the dissociation process, and the gas constant, respectively. The values for A and E_d were found to be 4.4×10^{15} s^{-1} and 7.7 kcal/mol, respectively. A much smaller value is obtained for k_{12} in the case of the intramolecular excimer than in the case of the intermolecular excimer. This is due to the binding effect of the methylene chain. The binding energy of the excimer state seems to be the same in the compounds we studied because of a similar molecular structure in the dimer unit. Therefore, it is understandable that there is no appreciable difference in the value of k_{12}. The methyl group of 2,4-DNPe(*rac*) should be situated in an unstable gauche position in the excimer conformation. However, the

unstable energy is too small to affect the dissociation rate constant.

For the association rate constant k_{21}, the compounds 1,3-DNBu, 1,3-DNPd, and 1,3-DN-5-PhPe show the same value. This indicates that the association rates are determined only by the configuration of the common dimer units, and the conformations in the dimer units are not much influenced by the substituent groups of the 3-position for these model compounds. This indicates that the rate of conformational relaxation in the terminal dimer units is not strongly affected by the increase of mass or chain length of these substituent groups. The effect of molecular weight on the rotational relaxation times was reported, *e.g.*, by the measurement of fluorescence depolarization,[12,13] ^{13}C NMR,[14] and ESR.[15] The results indicate that the relaxation time of molecular motions increases with increasing molecular weight. However, no such changes were observed in the case of intramolecular excimer systems. The observed rate constants of intramolecular excimer formation reflect the local segment motions of the end group of the molecule with respect to the molecular coordinate system. It seems that the molecular size of the alkane chain such as pentadecane, is too small to cause changes in the local segment motion and the local environment around the end groups.

Large differences in the association rate constants for 1,3-DNPr, 1,3-DNBu, and 2,4-DNPe(*meso*) and (*rac*) are observed (Table 2). First, let us discuss the results for 2,4-DNPe(*rac*) which gives the smallest value of k_{21}. The rate of intramolecular excimer formation is controlled by the internal rotational motion of the molecule from the equilibrium conformation in the ground state to the excimer one. From the analysis of NMR spectra,[16–18] we know that the preferred conformation for *racemo* dimers is situated at tt, indicating a planar conformation for the alkane chain. In order to reach the excimer conformation from the tt conformation, it is necessary to carry out an unfavorable conformational cange, $g^+ \rightleftarrows g^-$ with respect to the naphthyl groups. This seems to be the cause of the small values of k_{21} and the somewhat larger value of E_a for 2,4-DNPe(*rac*). Secondly, there are considerable differences in 1,3-DNPr, 1,3-DNBu, and 2,4-DNPe(*meso*). These differences are due to the equilibrium distribution of conformations at the ground state, whose distribution determines the initial positions of the naphthalene chromophores immediately after their excitation. Particularly, the population of the neighboring conformation to the excimer conformation seems to play an important role in the excimer formation rate (Fig. 7). The results are interpreted as follows: In 1,3-DNPr where $R_1=R_2=H$, the planar conformation with respect to the naphthyl groups (a) is most stable, the fraction of the neighboring conformation such as (b) not being large. In 1,3-DNBu where $R_1=H$ and $R_2=CH_3$, the neighboring conformation (b) becomes favorable owing to the steric hindrance of the methyl group. In 2,4-DNPe(*meso*) where $R_1=R_2=CH_3$, the conformational distribution seems to be predominantly in the neighboring conformation (b). According to the analysis of NMR

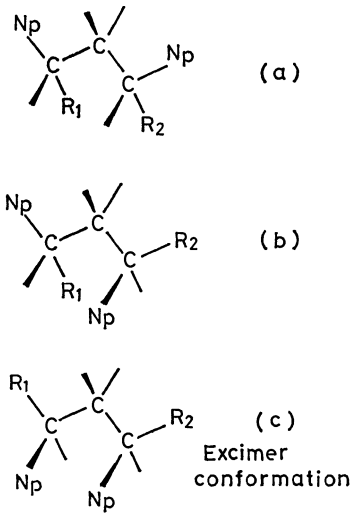

Fig. 7. Stable conformations of (a) 1,3-DNPr, (b) 1,3-DNBu and 2,4-DNPe (*meso*), and (c) the excimer conformation. Np: 2-naphthyl.

spectra for *meso*-diphenylpentane,[16–18] all other conformations have no appreciable fractions. The observed k_{21} values of the three compounds increase in this order. Thus, the association rate constants reflect the population of the neighboring conformation to the excimer state (c), and the rotational motion from this neighboring one to the excimer state.

The compounds we studied can be regarded as model compounds of poly(2-vinylnaphthalene) (PVN), which shows efficient intramolecular excimer formation.[7] 2,4-DNPe(*meso*) is considered to be a model compound of the isotactic sequence in PVN, the large value of k_{21} indicating the important role of isotactic sequence in the intramolecular excimer formation in vinyl aromatic polymers.

The authors wish to thank Dr. Yoshiteru Sakata, Osaka University, for the separation of the isomers of 2,4-DNPe by a recycle gel permeation chromatography. This work was supported by a Grant-in-Aid for Special Project Research on Photophysiology No. 411204 from the Japanese Ministry of Education, Science and Culture.

Molecular Structures of the Reduced 1,2,4-Triazine Derivative and Its Reaction Product with Electron-deficient Acetylene

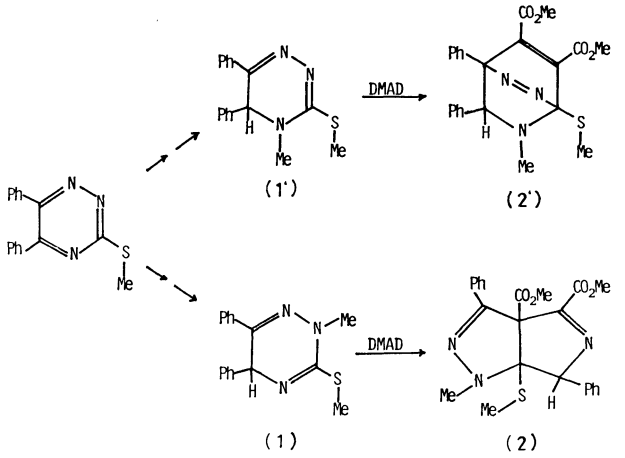
Hiroshi Ayato,* Isao Tanaka, Takashi Yamane, Tamaichi Ashida, Tadashi Sasaki, Katsumaro Minamoto, and Katsuhiko Harada

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 9, 1980)

The molecular structures of 3-methylthio-2-methyl-5,6-diphenyl-2,5-dihydro-1,2,4-triazine (**1**) and its reaction product with dimethyl acetylenedicarboxylate, 5,6-bis(methoxycarbonyl)-2-methyl-1-methylthio-4,8-diphenyl-2,3,7-triazabicyclo[3.3.0]octa-3,6-diene (**2**), were determined by the X-ray method. The former belongs to the triclinic system $P\bar{1}$, with $Z=2$, $a=10.776(2)$, $b=10.203(2)$, $c=8.556(1)$ Å, $\alpha=105.44(2)$, $\beta=104.94(2)$, and $\gamma=60.31(2)°$; the latter belongs to the orthorhombic system $Pca2_1$, with $Z=4$, $a=18.166(2)$, $b=7.444(2)$, and $c=16.080(2)$ Å. Both structures were solved by the direct method. The final R-factors are 0.075 for **1** and 0.048 for **2**. In Compound **1** the dihydrotriazine ring is in the boat form, while in Compound **2** both of the *cis*-fused five-membered rings are in the envelope form.

Unlike the well-studied oxidation reaction of 1,2,4-triazines, the reduction chemistry here is still not completely established. Paudler has suggested that 1,2,4-triazines undergo covalent hydration across the N(4)–C(5) bond,[1] and Neuenhoeffer has shown that they can act as dienes in the Diels-Alder reaction.[2] Therefore, the reduced compound of 3-methylthio-5,6-diphenyl-1,2,4-triazine with $NaBH_4$ would be methylated by methyl iodide to give **1′**, and the reaction of **1′** with dimethyl acetylenedicarboxylate (DMAD) would produce **2′**.[3]



The present X-ray study was attempted in order to confirm the structures of those reaction products; it showed that they were **1** and **2** instead of **1′** and **2′**. The detailed descriptions of their structures will be given in this paper.

Experimental

Compound 1. The intensity data were collected on a Rigaku automated four-circle diffractometer at the Ultra High Intensity X-Ray Diffraction Laboratory of this university, using graphite-monochromatized Mo $K\alpha$ radiation. The ω-2θ scan method with the scan speed of 8°/min (2θ) was applied. A total of 2749 independent reflections up to 50° (2θ) were collected. The crystal used for the experiment had the dimensions of $0.3\times0.3\times0.2$ mm³.

Crystal Data: $C_{17}H_{17}N_3S$, $P\bar{1}$, $a=10.776(2)$, $b=10.203(2)$, $c=8.556(1)$ Å, $\alpha=105.44(2)$, $\beta=104.94(2)$, $\gamma=60.31(2)°$, $V=778.76$ Å³, $Z=2$, $d_{obsd}=1.25$, $d_{calcd}=1.260$ g cm^{-3}, μ(Mo $K\alpha$) = 2.042 cm^{-1}.

Compound 2. The intensity data were collected on a Hilger & Watts four-circle diffractometer at the Faculty of Science, Nagoya University, using Ni-filtered Cu $K\alpha$ radiation. The ω-scan method for $2\theta\leqq80°$ and the ω-2θ scan for $80°\leqq2\theta\leqq114°$ were applied, and 1528 independent reflections were obtained. The crystal dimensions were $0.4\times0.2\times0.4$ mm³.

Crystal Data: $C_{23}H_{23}N_3O_4S$, $Pca2_1$, $a=18.166(2)$, $b=7.444(2)$, $c=16.080(2)$ Å, $V=2174.46$ Å³, $Z=4$, $d_{obsd}=1.33$, $d_{calcd}=1.336$ g cm^{-3}, μ(Cu $K\alpha$) = 15.71 cm^{-1}.

Structure Determination and Refinement

The intensity data of both compounds were corrected for Lorentz and polarization effects, but not for absorption. Both structures were solved by the *MULTAN* program[4] and refined by the block-diagonal least-squares procedure with the *HBLS V* program.[5] All the hydrogen atoms were located on the difference Fourier map. In the refinement, the function minimized was $\Sigma w(|F_o|-|F_c|)^2$, with $w=(\sigma^2(F)+a|F_o|+b|F_o|^2)^{-1}$ for $|F_o|>0$ and $w=c$ for $|F_o|=0$, where $\sigma(F)$ is the standard deviation based on the counting statistics. The thermal parameters of three hydrogen atoms in the *S*-methyl group of **1** were fixed at 8.0 Å² throughout the refinement, but all the others were subjected to the refinement. The final R-factors were 0.075 for **1** and 0.048 for **2**. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[6] All the calculations were carried out on a FACOM 230-75 computer at Nagoya University. The final atomic parameters are given in Tables 1 and 2.[7]

Results and Discussion

Compound 1. The bond lengths and angles are shown in Fig. 1, together with the atom-numbering system. The estimated standard deviations are 0.003—0.005 Å for the bond lengths and 0.2—0.4° for the angles. The equations of the best planes are listed in Table 3. A stereoscopic view of the molecule, as drawn by the *ORTEP II* program,[8] is shown in Fig. 2.

The dihydrotriazine ring is folded at N(2) and C(2) to take a boat form, with the dihedral angle between Plane (I) (N(2), N(1), C(3), C(2), and C(12)) and Plane (II) (N(2), C(1), N(3), C(2), and S) of 146.5°. The phenyl ring bonded to C(2) is in an

axial position with the torsion angle (C(3)–C(2)–C(6)–C(11)) of 14.1°, so that it can avoid close interaction with the C(3)-phenyl group.

The N(1)–C(3) and C(1)–N(3) double-bond lengths are 1.286 Å and 1.269 Å respectively. The N(3)–C(2) bond length is compatible with the single-bond distance, while the N(2)–C(1) bond length of 1.383 Å is significantly shorter and the N(1)–N(2) of 1.394 Å is shorter than the single-bond distance of 1.44 Å.[9] These shortenings and the coplanarity of the C(3)-phenyl group and Plane (I) are due to the delocalization of the π-electrons and lone-pair electrons of N(2). The sp^2 character of the N(2) atom is further evidenced by the planar arrangement of the bonded atoms, as is indicated by the sum of the bond angles, 351.6°. The C(1)–S bond, 1.769 Å, is shorter than the normal

		C(5)[a]	−180	C(11)	−4	C(17)	−9

a) Atoms not included in the best-plane calculations.

C–S single-bond length of 1.81 Å, with a small amount of double-bond character. Consequently, the C(5) atom deviates from Plane (II) by only 0.18 Å, and a short contact, 2.893 Å, occurs between C(5) and N(3). Such a shortening is also observed in 2-(methylthio)benzothiazole,[10] in which the C–S bond length is 1.77 Å.

Compound 2. The bond lengths and angles are shown in Fig. 3, together with the atom-numbering system. The estimated standard deviations are 0.006—0.012 Å for the bond lengths and 0.3—0.8° for the angles. The equations of the best planes are listed in Table 4. A stereoscopic view of the molecule is shown in Fig. 4.

The molecule consists of two central *cis*-fused five-membered rings and six peripheral side groups directly bonded to them. Each of the five-membered rings is in the envelope form. In one five-membered ring, C(1), C(2), N(1), and N(2) are coplanar (Plane (I)), including C(8) of the phenyl group, while in the other ring, C(1), C(5), N(3), and C(4) are coplanar (Plane (II)) with C(22) of the methoxycarbonyl group. These two planes form an angle of 107.7°. The C(3) atom is out of these planes by 0.47 Å and 0.39 Å respectively.

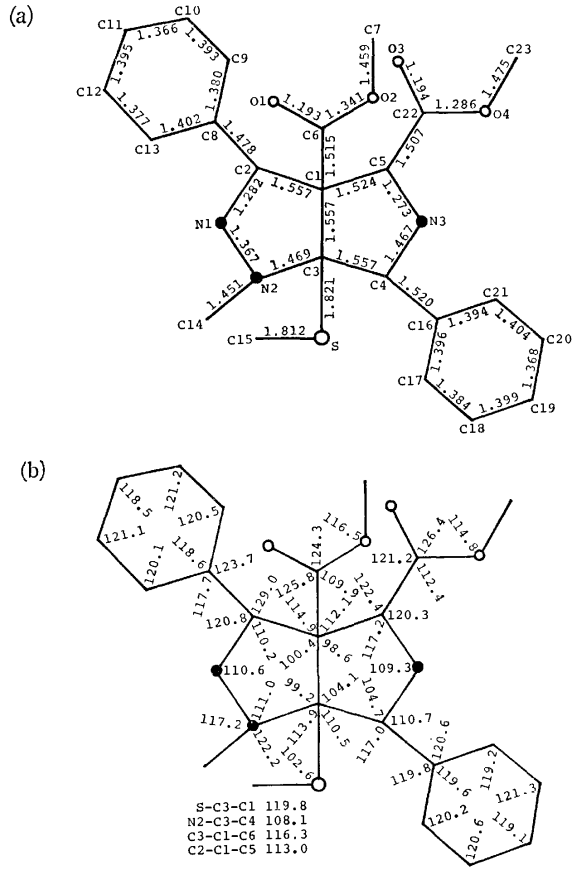

Fig. 3. Bond lengths and angles of **2**. (a) Bond lengths (l/Å), and (b) bond angles (ϕ/°).

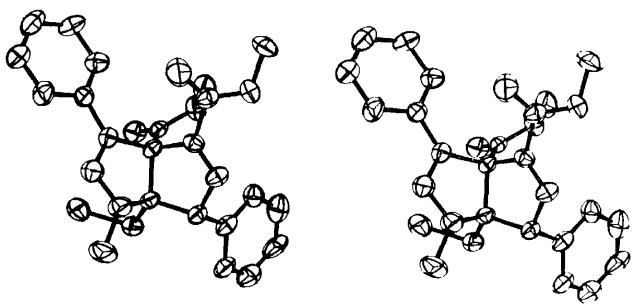

Fig. 4. A stereoscopic view of **2**. The atoms are represented by thermal ellipsoids drawn at the 50% probability level.

Plane(I) and the C(2)-phenyl group are almost coplanar (the dihedral angle is 174.9°), while the dihedral angle between Plane (II) and the C(5)-methoxycarbonyl group is 140.9°, the latter being also roughly planar. As is shown in Fig. 4, three groups, methylthio, C(1)-methoxycarbonyl and C(4)-phenyl, which protrude from the fused ring to the same side, take conformations so as to avoid close interactions among the six peripheral groups.

It may be worth noting the short bond lengths of C(2)–C(8) and N(1)–N(2) compared with the corresponding single ones.[9] These observations and the coplanarity described above suggest that the delocalization of π-electrons occurs between the C(2)-phenyl ring and N(2) *via* C(2) and N(1). The sp^2 character of the N(2) atom is found in this compound as well as in Compound **1**, and the sum of the bond angles around the N(2) atom is 350.4°.

Isobaric Thermogravimetry of the Gas Encapsulation with Molecular Sieves A

Tetsuo TAKAISHI, Yujiro KAMEI,† Atsushi YUSA,† and Tatsuo OHGUSHI*

School of Material Science, Toyohashi University of Technology, Toyohashi 440

† *Komatsu Electronics Metals Co., Hiratsuka 254*

(Received April 22, 1980)

The isobaric gas sorption with (Na,Ca)–A and (K,Ca)–A zeolites was measured gravimetrically in temperature ranges of −160——40 °C for O_2 and N_2, and of room temperature—200 °C for n-C_4H_{10}. The sorption hysteresis, *i.e.*, the gas encapsulation was observed. The maximum point, in the temperature rising branch of the isobar, was located at about −90 °C for N_2 and in the range 120—170 °C for n-C_4H_{10}, and shifted to the lower temperature side with the increasing content of calcium for n-C_4H_{10}. The observed results are explained in terms of an incomplete blocking action of cations on window sites. This incompleteness was amplified by bivalent cations introduced onto other sites than the window sites, and the sieving character of the ion-exchanged zeolite was delicately modified.

The unit cell of zeolite A is a cube with a side-length of about 1.2 nm, at the center of which there exists a nearly spherical cavity accommodating sorbed molecules. This cavity is surrounded by six 8-membered oxygen rings, which costitute windows to the cavity. In commercial molecular sieves 3A and 4A, all of these windows are blocked by K^+ and Na^+, respectively.[1] The molecular sieving characters of these zeolites are primarily determined by the size of the aperture of the *partially-blocked* windows. The effective size of the aperture, however, depends upon temperature. At higher temperatures, a situation is realized that larger molecules, which are not sorbed at lower temperatures, are able to be sorbed. If the temperature is lowered after such molecules being sorbed at higher temperatures, the windows are closed and the sorbed molecules are encapsulated.[2]

Usually the encapsulation process requires high temperature and pressure, in order to ensure a reasonable rate and amount of sorption. However, the encapsulation may be realized at not so much high temperatures and pressures as usual, if the rate of sorption is increased by some means. This is a problem of the present work.

Experimental

The block diagram of measuring system used is shown in Fig. 1(a). A Cahn RG-type electro-balance was used which was drastically improved in the authors' laboratory to be bakable at 180 °C.[3] The pressure of adsorbed gas was measured with a MKS Baratron type-210 diaphragm gauge, and controlled within ±0.5% of the preset value with a Granville-Phillips type-216 automatic pressure controller by adding some manual operations. A main pumping system consisted of a sorption-pump and an ion-spattering pump of a capacity of 50 $l\,s^{-1}$. Apart from gas handling system, the apparatus was free from grease or oil, and a back-ground pressure of 10^{-5} Pa was easily attained in a few hours by a mild baking-out.

The leg of the balance and cryostat are shown in Fig. 1(b). Radiation heating from the upper part of the apparatus and disturbance due to convection were reduced by a copper shield, S, which acted at the same time as a gasket for conflat flange. A sheath IC junction, J, was fixed on the lowest conflat flange by copper wire.

The temperature of the sample was rised or lowered at approximately constant rates, in a similar manner to the

usual thermo-gravimetry. Low temperatures were realized by cooling with cold nitrogen gas supplied from a liquid nitrogen reservoir by electric heating, and controlled within ±0.5 °C of a preset value. Before the sorbate gas was introduced, 10 Pa of He gas was introduced to facilitate the rapid temperature equilibration.

Powdery zeolites of given composition were prepared by a method described in the preceding papers.[4,5] These zeolites were pressed in a form of disc, 13 mm in diameter and about 500 mg in weight. Prior to sorption experiments, zeolite samples were carefully dehydrated, at 390—400 °C for about 100 h, the residual pressure being 10^{-5} Pa or so. This dehydration condition was far better than that in conventional sorption experiments. Sorbate gases, N_2, O_2, and n-C_4H_{10} (supplied from Takachiho Chemical Co.), had nominal purities better than 99.9, 99.8, and 99.7%, respectively, according to mass-spectroscopic analyses and were used after further drying with 13 X zeolite.

Results

(Na, Ca)–A Zeolites. The sorption isobar was measured for n-C_4H_{10} and N_2 with $(Na_{12-2x}Ca_x)$–A zeolite, in which $x=1.93$. According to the preceding paper,[5] this zeolite is classified as 4A in their molecular sieving characters. The temperature was rised or lowered at a constant rate from −155 to −50 °C for N_2 at a constant pressure of 9.3×10^3 Pa,

while for n-C_4H_{10} from room temperature to 200 °C at 8.3×10^3 Pa. The temperature was not rised above 200 °C for fear of cracking and polymerization of n-C_4H_{10}. The form of sorption isobar depended upon the rate of temperature rise. Representative curves for $(Na_{12-2x}Ca_x)$–A are shown in Fig. 2, which shows that the rate of sorption is so low that equilibrium is not attained at 200 °C.

The effect of the composition to the form of the isobar was studied, results being shown in Fig. 3. The peak, in the temperature rising branch, shift to the lower temperature side with the increasing content of calcium. The shift was remarkable for n-C_4H_{10}, but not so for N_2.

(K,Ca)–A Zeolites. The molecular sieving action of $(K_{12-2x}Ca_x)$–A zeolite drastically changes in the neighbourhood of $x=4$.[4] This tendency was further studied in detail by the present method. Sorption isobars for O_2 and N_2 are shown in Fig. 4. Large amounts of N_2 and O_2 were sorbed, virtually without an activation energy, into $(K_{3.58}Ca_{4.21})$–A at −196 °C, so that this zeolite may be classified as 5A. On the other hand, $(K_{4.30}Ca_{3.85})$–A sorbed very small amounts of these gases, being classified as 3A. A diagram in the lower part of Fig. 4 shows that a small amount of sorption took place even at −196 °C without any activation energy, and that some of windows were in the state of "open" against to O_2 and N_2. In the terminology of percolation theory, however, the percolatable fraction of cell is less than 0.03.

As for n-C_4H_{10}, quite different features were observed as shown in Fig. 5; namely, the peak appeared in the isobar with $(K_{4.30}Ca_{3.85})$–A. This means that n-C_4H_{10} was allowed to pass through the window blocked by K^+ at temperatures higher than 100 °C.

Discussion

Let us outline, for a better understanding of the sieving action, the structure of dehydrated zeolite A and cation distribution in it. Figure 6 shows its framework and cation sites. Abbreviations are used as the α-site for the site near the plane of the 8-membered oxygen ring, the β-site for the site near the center of the 6-membered oxygen ring, and the γ-site for the site near the center of the 4-membered oxygen ring. At the center of the unit cell, there exists a large cavity, named the α-cage, which is nearly spherical with a diameter of 1.14 nm and can accomodate visiting gas molecules. The 8-ring constitutes a window to the cavity, and the sieving character of zeolite A is determined by the state of the 8-ring, that is, whether the α-site is unoccupied or occupied by a cation and by what kind of cation. On the other hand, the occupancy factor on the β- and γ-sites does not directly influence the sieving character. The distribution of cations is determined by their affinities to these sites. The γ-site has a very weak affinity for all cations. Na^+ and bi-valent cations like to reside on the β-site than the α-site, while reverse is the case with K^+, Rb^+, and Cs^+.[4-10] Let us express the composition as $(M^{I}_{12-2x}M^{II}_{x})$–A, where M^{I} and M^{II} are uni- and bi-valent cations, respectively. If M^{I} is Na, one open window (unoccupied α-site) per unit cell is produced at $x=2$, while if M^{I} is K, Rb, or Cs, at $x=5$.

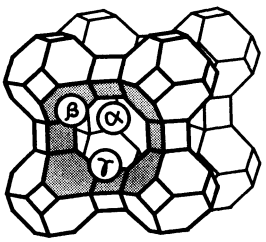

Fig. 6. Structure and cation sites of dehydrated zeolite A.

According to the percolation theory, the sieving character drastically changes in a narrow range of the concentration of the open window arround a critical value say, one per unit cell. The applicability of the theory has quantitatively been proved with (Na,Ca)–A system. In the preceding paper, the percolation theory was applied to sorptions of N_2 at 90 K and *n*-butane at 323 K with (K,Ca)–A system.[4] Then, it was concluded that there exists the third kind of window, named the conditionally-opened window, through which N_2 cannot pass at 90 K but *n*-butane, a larger molecule, can at 323 K. The 6th Ca^{2+} in Ca_6–A occupies the α-site and constitutes a conditionally-opened window.[4] Some fraction, not all, of windows blocked by K^+ also constitute conditionally-opened windows in (K,Ca)–A with a higher Ca-content.[4] This is further proved to be true by the present experiment with $(K_{4.30}Ca_{3.85})$–A.

Let us now present a model for the conditionally-opened window, of which the effective aperture-size markedly increases in a temperature range, 90—400 K. This is done by using the form of the potential surface experienced by the window-blocking cation. Here are taken into consideration potentials due to the framework and exchangeable cations but not that due to co-existing sorbed molecules. In K_{12}–A, the potential $\Phi(0)$ is to have such a sharp valley as shown in Fig. 7(a), the amplitude of thermal oscillation of the blocking K^+ is very small. A large energy may be required to push K^+ ion aside and make a way for a visiting molecule. Hence, the blocked window behaves as a perfectly closed one as far as the present temperature range concerns. In the conditionally-opened window in $(K_{12-2x}Ca_x)$–A, the blocking cation is easily displaced at a moderate temperature, and the potential $\Phi(x)$ is to have a very gentle curvature at its valley, as schematically shown in Fig. 7(b). In the figure, ξ denotes the distance of the shift of the potential minimum from the window plane, η the decrease of the potential at its minimum point, and $\Delta\rho$ the increase in the curvature of the potential surface at its valley. Values for ξ, η, and $\Delta\rho$ depend upon the distribution of cations, especially upon those in the neighborhood of the concerned K^+. If $\Phi(x)$ has a higher symmetry, ξ may be very small or zero. This is the case with Ca_6–A as shown by Firor and Seff.[11] Such a high symmetry is realized only in limitted cases with favourable compositions. With an unfavourable composition, the local configuration of cations arround a given α-site differs from site to site, so that ξ is small for some K^+ while large for others. The value of η influences the stability of the crystal but does not its sieving character which is a main concern in the present work, and is not further discussed. The larger the values for ξ and/or $\Delta\rho$, the smaller the activation energy for the passage of a visiting molecule, as can be seen from Fig. 7(b).

A window with a too large ξ behaves as a pseudo-open window. Its concentration may increase with the increasing x, except at some special values of x where $\Phi(x)$ has a high symmetry. The critical point in the percolation theory must be located at such a composition that the sum of concentrations of the open and pseudo-open windows is 1 p.u.c. This is the reason why the critical point in (K,Ca)–A system is located not at 5 but at 4.2 or so.[4]

There is another conceivable model for the activated sorption process. Breck and Smith proposed the activation of the vibration of breathing mode of the 8-ring.[2] This is unacceptable, since the framework is very rigid and one has never observed a high Debye-Waller factor of the framework. The present model, on the other hand, is in harmony with the structural observation due to Seff and his coworkers; that is, there exist loosely bound and/or displaced M^{I} cation on the α-site in (K,Zn)–A, and (Cs,Ca)–A.[12,13]

There might occur some fear that the residual water molecule influences both of the sieving character and structure. Comparing the present and previous results, one find some discrepancies in the amounts of sorption with samples of the same origine, especially with $(K_{3.58}Ca_{4.21})$–A.[4] This is attributed to the difference in the degree of dehydration. The

Fig. 7. Model for the conditionally-opened window, and the potential experienced by the cation.
(a) Side view of the 8-ring window. Perfectly closed window. (b) Conditionally-opened window. The window aperture is increased with increasing ξ and $\Delta\rho$. $\Phi(x)$: The potential experienced by the window-blocking cation at composition $(M^{I}_{12-2x}M^{II}_{x})$–A, ξ: the distance of the shift of the potential minimum from the window plane, η: the decrease of the potential at the minimum point, $\Delta\rho$: the change in the curvature.

critical point slightly shifts to the lower Ca-content side. On the other hand, the main feature of the curve of composition *vs.* sorption capasity is not so much changed that the applicability of the present model is affected. However, the use of a clean vacuum system is essential to determine the exact value for the critical composition.

Previously, the window size was controlled solely by the kind of cation blocking the window. Now, one can finely control it by changing the form of the potential experienced by the blocking cation, that is, by changing $\Delta\rho$ and ξ values. This indirect method may be named as the cation-loosening one, though this name has a drawback that it does not include the effect of ξ. The cation-loosening can be adopted as an effective mean in tailoring molecular sieve. An example of the success in the tailoring is a highly selective sorption of PH_3 from SiH_4 with (K_4Zn_4)–A, though this was accomplished before the recognition of the method. Other examples of the tailoring are encapsulation of Kr into (K,M^{II})–A and H_2 into (Cs,M^{II})–A. These will be reported in the succeeding papers.[14,15]

The present paper was in part supported by a Grant-in-Aid for Research from the Ministry of Education of the Japanese Government, Contract No. 443001.

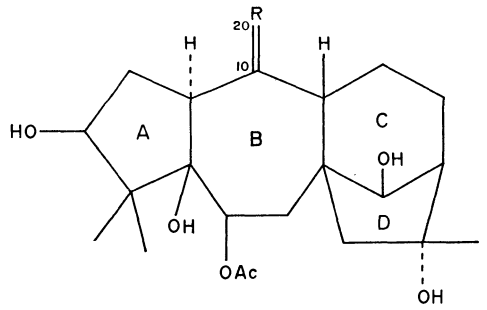
The Crystal and Molecular Structure of Grayanotoxin XVI Hemihydrate

Akio FURUSAKI,* Shinsei GASA, Ryūzō IKEDA, and Takeshi MATSUMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 30, 1980)

The molecular structure of grayanotoxin XVI, $C_{22}H_{34}O_6$, has been confirmed by means of an X-ray crystal analysis of its hemihydrate. The crystals are orthorhombic, with eight formula units in a unit cell with dimensions of $a=17.503$, $b=37.933$, and $c=6.371$ Å; the space group is $P2_12_12_1$. 4180 unique intensity data were collected on a four-circle diffractometer with LiF-monochromated Cu $K\alpha$ radiation. The structure was solved by the Monte Carlo direct method, using the 30 strongest reflections as the starting set, and was refined by the block-diagonal least-squares method. The final R value was 5.5%. The present analysis has revealed that the crystal used comprises about four parts of grayanotoxin XVI (6-*O*-acetylgrayanotoxin II) and one part of 10,20-dihydrograyanotoxin XVI. The molecules of the major component exist in two different conformations: One has the chair B-ring, and the other the twist-chair B-ring. About two-fifths of the molecules of the latter type are replaced at random by the molecules of the minor component.

Grayanotoxin (hereafter G) XVI is one of the physiologically-active diterpenes isolated from *Leucothoe grayana Max.*[1] On the basis of the chemical evidence, the **1** structure was proposed for this toxic substance. The main purposes of the present study were to confirm **1** and to test the effectiveness of the Monte Carlo direct method, a new phase-determining procedure.[2]



1: R = CH_2 2: R = CH_3, H

Experimental

Single crystals of G XVI hemihydrate were obtained as colorless needles from an ethanol–water solution. A sample with dimensions of about $0.1\times0.3\times0.6$ mm^3 was used for the X-ray measurement. The crystal data are summarized in Table 1. The cell dimensions and reflection intensities were measured on a Rigaku four-circle diffractometer using Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) monochromatized with an LiF crystal. The intensity measurement was made by the θ-2θ continuous-scan technique at a 2θ scan rate of 2° min^{-1}; the background was measured for 30 s at each end of the scan range. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or extinction effect. In the range of 2θ values up to 140°, 4180 unique structure factor amplitudes above the $\sigma(F)$ level were selected for the structure determination.

	$b=37.933(11)$ Å
	$c=6.371(3)$ Å
	$V=4230$ Å^3
Z	8
D_x	1.267 g cm^{-3}
μ (Cu $K\alpha$)	7.14 cm^{-1}

Structure Determination

The present structure containing 57 independent non-hydrogen atoms was solved by means of the Monte Carlo direct method.[2] The 30 strongest reflections were chosen as the starting set. In order to extend the tentative-phase set derived from successively-generated random numbers, 12 cycles of the tangent procedure were performed using 932 $|E|$ values above 1.30; during the first 5 cycles, the phases of the starting reflections were kept constant. Since the 261st phase set showed a low R_K value of 34.4% ($R_K=\Sigma||E_o|-k|E_c||/\Sigma|E_o|$),** 8 additional cycles of the tangent procedure were carried out; the R_K value was reduced to 27.6%. An E-map calculated with 864 phases clearly revealed the locations of all the non-hydrogen atoms except one. The computing time required for the phase determination was about 54 min on a FACOM 230-75 computer. This shows that the Monte Carlo direct method is still effective even for structures composed of more than 50 independent non-hydrogen atoms.

The 56 atomic positions obtained from the E-map were refined by the block-diagonal-matrix least-squares method with isotropic temperature factors. A difference Fourier map revealed that the remaining atom, C(A20), was distributed statistically between two positions in the ratio of about 3 to 2. Since close re-examination of the NMR spectrum demonstrated the presence of the dihydrograyanoid **2**, these two atomic positions, named C(A20a) and C(A20b) respectively, were assigned to the methylene carbon atom in **1** and the methyl carbon atom in **2** respectively. The whole structure thus obtained was refined by the least-squares method with anisotropic temperature factors; 0.6 and 0.4 times the atomic scattering factors of carbon were used for the C(A20a) and C(A20b)

** The second lowest of the R_K values for the 261 sets was 37.3%.

atoms respectively. After all hydrogen atoms, except those attached to the randomly-distributed carbon atom, had been located in a second difference Fourier map, further least-squares refinement was repeated including these hydrogen atoms with isotropic temperature factors. The following weighting scheme was used:

$$W=1/\{\sigma(F)^2 \exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients are constants which were determined from the $(\Delta F)^2$ values. In this manner, the R value reached 5.5%. The atomic parameters are listed in Table 2. The tables of the anisotropic temperature factors and of the observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8038).

All the calculations were performed on a FACOM 230-75 computer at the Hokkaido University Computing Center, using our own programs. Random numbers were generated by calling a function RANDOM in the program library of the Computing Center. The atomic scattering factors were taken from the International Tables.[3]

Results and Discussion

Chemical Structure. The skeletons of the two independent G XVI molecules, A and B, are shown in Fig. 1, where each atom is represented as a thermal ellipsoid enclosing a 50% probability. Table 3 gives the bond distances and angles, and Fig. 2 shows the torsion angles in the tetracyclic systems. The C(A10)–C(A20a) and C(A10)–C(A20b) distances are almost equal, lying nearly midway between the accepted distances for C=C and C–C bonds. However, the projected angle of C(A9)–C(A10)–C(A20a) onto the plane normal to the C(A1)–C(A10) bond is significantly different from that of C(A9)–C(A10)–C(A20b) (see Fig. 3). Although these projected angles, 160 and 137°, deviate from their respective standard values of 180 and 120° by about 20°, they indicate that the C(A10)–C(A20a) and C(A10)–C(A20b) bonds are oriented roughly in the directions of the sp^2 and sp^3 hybrid orbitals on the C(A10) atom respectively, the C(A20b) atom being on the β side of the molecule. Since the apparent thermal motion of the C(A10) atom is greater than that of any other atom in the B-ring, the unusual distances and directions of these

a) The hydrogen atoms are denoted by the number of the carbon atom to which they are attached, suffixed by a, b, or c where necessary.

two bonds may be due partly to the disordering of the C(A10) atom.

It is thus concluded that, although about three-fifths of the A molecules correspond to compound **1**, the remaining A molecules correspond to compound **2**.*** Since the B molecules having no disordering correspond to **1**, it follows that the present crystal as a whole contains about one-fifth of **2**. This unexpected contaminant is the first 10,20-dihydrograyanoid to be obtained from *Leucothoe grayana Max.*

Molecular Geometry. As Table 3 shows, all the bond distances are normal except for the randomly-distributed C(A20) atom. There is no great difference between the two crystallographically-independent molecules of G XVI.

The five-membered A-rings in both of the molecules take similar envelope forms; the C(4) atom deviates remarkably from the mean plane for the other four atoms onto the α side of the molecule.† Although this conformation makes the O(1)H and O(2)H hydroxyl groups 1,3-diaxial, it is stabilized by the formation of the intramolecular hydrogen bond, O(2)H···O(1) (see Table 4).

The difference between the A and B molecules can be most clearly seen for the conformations of their central seven-membered B-rings; the B-ring of the former has the twist-chair form with an approximate two-fold rotation axis through the C(A10) atom, while that of the latter adopts the chair form with an approximate mirror plane through the C(B6) atom. According to Hendrickson's calculations,[4] cycloheptane prefers the twist-chair conformation. In Hendrickson's

*** Unless otherwise stated, "A molecules" will mean solely molecules of **1** in the description given below.

† The atomic name, C(i), is used when the description is valid for both of the A and B molecules.

Table 3. The bond distances (l/Å) and angles (ϕ/°), with their standard deviations
The standard deviations given in parentheses refer to the last decimal position.

computed twist-chair form (hereafter HTC), substituents at the 2a, 2'a, 3a, and 3'a positions sustain strong steric repulsions (see Fig. 4(a)). For the O(A2)H and C(A14)H groups situated at the 3a and 3'a positions, however, no unusually-close contacts are observed: for example, O(A2)···H(A7b), 2.66(4) Å; O(A2)···H(A9), 2.87(4) Å; C(A14)···H(A1), 2.89(3) Å; C(A14)···H(A6), 3.08(3) Å; H(A14)···H(A1), 2.23 (5) Å. This relief of the steric hindrance may be explained from the remarkable flattening of the B-ring, due mainly to the conformational transmission[5] at the *trans* A/B- and *cis* B/C-junctions. The magnitudes of the C(A10)-C(A1)-C(A5)-C(A6) and C(A7)-C(A8)-C(A9)-C(A10) torsion angles, 85.0 and 68.8°, are much smaller than the corresponding value for HTC, 97°; hence, the axial nature of the C(A5)-O(A2) and C(A8)-C(A14) bonds is remarkably decreased.

The occurrence of the chair B-ring should be noted in two respects: (1) The chair cycloheptane is less stable than the twist-chair cycloheptane by 2.16 kcal/mol;[4] (2) the bulky C(B14)H group is placed at a very hindered position on the chair B-ring. In Hendrickson's computed chair form of cycloheptane

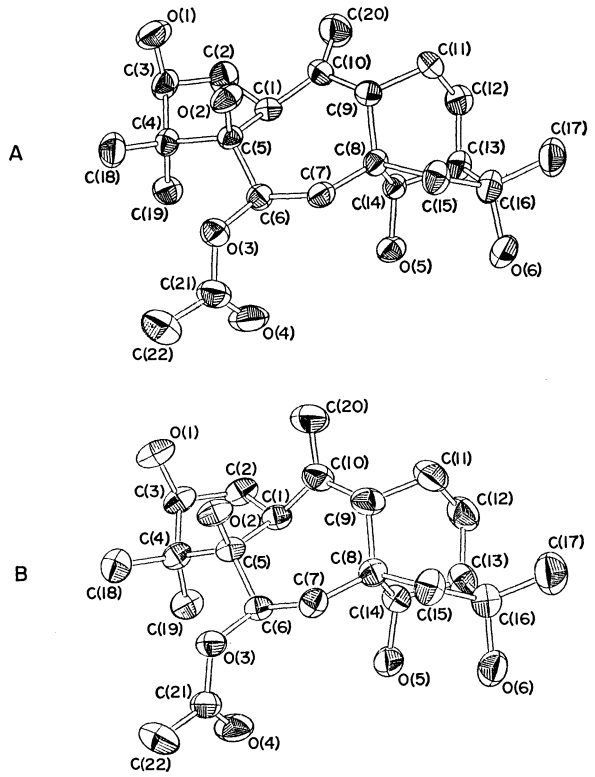

Fig. 1. Perspective views of the A and B molecules. For the sake of clarity, the C(A20b) atom was omitted.

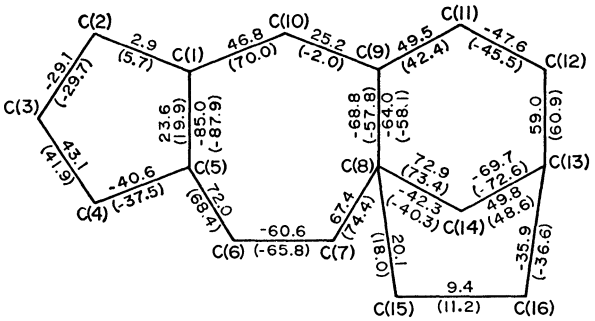

Fig. 2. The torsion angles (ϕ/°) of the A-, B-, C-, and D-rings. Only the torsion angles relevant to atoms which form the same ring are given in the ring. The values for the B molecule are given in parentheses.

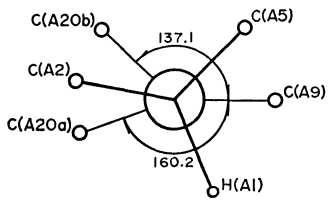

Fig. 3. The projected angles (ϕ/°) onto the plane normal to the C(A1)–C(A10) bond.

(hereafter HC), the 3a-3'a interaction is the severest, and stronger than the 2a-3'a and 2'a-3a interactions in HTC (see Fig. 4(b)). The 3a-3'a repulsion between the C(B14)H group and the H(B1) atom is relieved mainly by the closing of the C(B6)–C(B7)–C(B8)–C(B9) and C(B7)–C(B8)–C(B9)–C(B10) torsion angles. The magnitudes of these torsion angles are

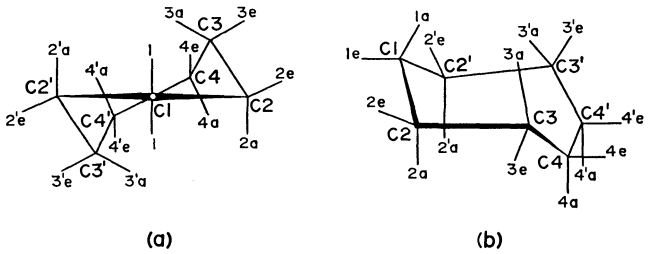

Fig. 4. Hendrickson's (a) twist-chair and (b) chair forms of cycloheptane.

smaller than the corresponding values for HC, 92 and 71°, by about 18 and 13° respectively. Since these torsion angles are opposite in sign, this shows a remarkable decrease in axiality of the C(B8)–C(B14) bond.[6] In spite of such a relief of the 3a-3'a repulsion, the C(B14)H group is still hindered severely: C(B1)···C(B14), 3.344(4) Å; C(B1)···H(B14), 2.82(3) Å; H(B1)···C(B14), 2.66(4) Å; H(B1)···H(B14), 1.98(5) Å.

The exocyclic methylene group in the B molecule, C(B20)H_2, sustains great steric repulsions from the two methylene groups, C(B2)H_2 and C(B11)H_2: H(B20a)···H(B11a), 2.24(7) Å; H(B20b)···H(B2b), 2.12(6) Å. As will be shown by the projected angle of C(B1)–C(B10)–C(B9) onto the plane normal to the C(B10)=C(B20) double bond, 173.1°, these steric repulsions probably push the C(B20)H_2 group away from the C(B1)–C(B10)–C(B9) plane to the β side of the molecule. In the G II molecule having the severe H(20a)···H(11a) interaction of 1.92(5) Å,[7] the C(9)–C(10)–C(20) bond angle is greater than the C(1)–C(10)–C(20). In the B molecule, the relation is reversed: C(B9)–C(B10)–C(B20), 117.9°; C(B1)–C(B10)–C(B20), 120.5°. Further, the C(B2)–C(B1)–C(B10) bond angle is expanded from the corresponding angle in G II, 113.3°, to 117.6°, while the C(B5)–C(B1)–C(B10) bond angle is reduced from 119.5° for G II to 110.9°. These changes in bond angle can be explained on the basis of the strong H(B20b)···H(B2b) repulsion.

The six-membered C-rings in both of the A and B molecules take the chair conformation, but are much deformed by three main causes: (1) the three-bond bridge, C(8)–C(15)–C(16)–C(13); (2) the conformational transmission at the *cis* B/C-junction; (3) the steric repulsion between the C(14)H group and the H(1) atom.

In both the A and the B molecules, the form of the five-membered D-ring is intermediate between the envelope form characterized by the mirror plane through the C(14) atom and the half-chair form characterized by the two-fold rotation axis through the C(15) atom. Although the D-ring is forced to take the envelope form by the existence of the chair C-ring, it is probably deformed by the C(11)H_2···C(17)H_3 repulsion and the O(5)···O(6) hydrogen bonding. In the A molecule, the O(6)H group donates its proton to the O(5)H, while in the B molecule, the latter donates to the former (see Table 4).

Crystal Structure. The crystal structure viewed along the c axis is shown in Fig. 5. There are six kinds of intermolecular hydrogen bonds; the details

O(B5)	O(B6)	2.683(4)	1.89(5)	159(4)
(2) Intermolecular				
O(A1)	O(W)[b]	2.767(4)	1.85(7)	172(7)
O(A5)	O(A2)[c]	2.809(3)	2.04(5)	168(5)
O(B1)	O(A6)[d]	2.866(4)	2.03(5)	166(4)
O(B6)	O(A4)[e]	2.779(4)	2.04(6)	156(6)
O(W)	O(B4)[a]	3.002(5)	2.23(9)	158(8)
O(W)	O(B5)[a]	2.784(4)	1.96(5)	168(5)

The symmetry codes are as follows: a) x, y, z (given in Table 2); b) x, y, $1+z$; c) x, y, $-1+z$; d) $-x$, $1/2+y$, $-1/2-z$; e) $1/2+x$, $1/2-y$, $-z$.

of the hydrogen bonds are given in Table 4. Each water molecule donates its protons to the O(B4) carbonyl and O(B5) hydroxyl oxygen atoms of the same B molecule, and it accepts the proton from the O(A1)H hydroxyl group of the neighboring A molecule. The couples of the A and B molecules connected through such mediation of the water molecule are further held together by the remaining three hydrogen bonds, forming a three-dimensional hydrogen-bonded structure.

The Reactions of NH Radicals with Ethylene and Propene in the Liquid Phase

Takashi KITAMURA, Shigeru TSUNASHIMA,* and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 15, 1980)

The photolysis of hydrogen azide was studied in liquid ethylene, propene, and the mixture with ethane at the temperature of Dry Ice–methanol. The products observed were aziridine (0.18), ammonia (0.16), and nitrogen (1.0) from the ethylene solution and 2-methylaziridine (0.33), allylamine (0.12), ammonia (0.17), and nitrogen (1.0) from the propene solution. The values in parentheses show the yields relative to that of nitrogen. The relative yields were independent of the concentration of hydrogen azide in the range of 0.8—8×10^{-2} mol dm^{-3}. The reaction of NH($a^1\Delta$) radicals with olefin consists of three processes: the addition to double bond, the insertion into the C–H bond, and the deactivation to the $^3\Sigma^-$ state. The branching ratios and the relative rate constants of the reactions of NH($a^1\Delta$) radicals with ethylene, propene, and ethane were estimated.

Since NH is isoelectronic with O and CH_2, it is expected that the reactions of NH will be similar to those of O and CH_2. In spite of many investigations, the reactions of NH are not understood well. The main reason is that most studies failed to detect the NH-containing products. Recently, we found the amine formation in the photolysis of hydrogen azide in liquid ethane, propane, and isobutane at the temperature of Dry Ice–methanol by treating the products with NaOH.[1,2] The amine formation was explained by the insertion reaction of the singlet NH($a^1\Delta$) into the C–H bond of paraffin. If the singlet NH reacts with the olefin like the singlet O or CH_2 reacts with, then the formation of aziridine, the product of NH added to the double bond of ethylene, can be expected.

Many investigations in the gas phase failed to detect the aziridine formation.[3-6] Jacox and Milligan photolyzed a mixture of hydrogen azide and ethylene in the Ar matrix at 4 K and detected aziridine by infrared absorption spectroscopy. No kinetic study, however, was given.[7]

The photolysis of hydrogen azide was studied in liquid ethylene and propene at the temperature of Dry Ice–methanol in order to investigate the reactivity of NH radicals to olefin.

Experimental

The experimental methods were essentially the same as those described in the previous papers.[1,2] Hydrogen azide was prepared *in vacuo* by heating a mixture containing sodium azide and an excess amount of stearic acid; it was used after having been dried with phosphorus pentaoxide and degassed at −120 °C. Pure grade ethylene (Yokohama Chemicals Co.), ethane, and propene (Takachiho Shoji Co.) were used after the low temperature distillation. The mixture of hydrogen azide (8—80 μmol) and hydrocarbon (≈10 mmol) was prepared in a quartz tube of 8 mm o.d. and liquefied at the temperature of Dry Ice–methanol. The amount of the solution was about 1 cm^3. The solution was irradiated with a medium pressure mercury lamp (Toshiba H-400P) through a filter (Toshiba UV 27) which cut off the light shorter than 250 nm.

After the irradiation, non-condensable products at the temperature of liquid nitrogen were analyzed with a combination of a Toepler pump, a gas burette, and a CuO furnace at 300 °C. The solvent hydrocarbon was evacuated at a temperature lower than −80 °C. Less volatile products, including unreacted hydrogen azide, were passed through a trap packed with NaOH coated glass wool. The products thus obtained were analyzed with GLC, using a column packed with Amine 220 on NaOH coated Celite 545 (Gasukuro Kogyo Co., 5 m in length) at 40 °C. For the identification of the products, a mass spectrometer was used.

Results

The products observed in the ethylene solution of hydrogen azide were nitrogen, ammonia, and aziridine. Beside these products, small peaks of unidentified products were observed on the gas chromatogram. These peaks were too small to be analyzed. Neither methane nor hydrogen formation was observed. The products observed in the propene solution were nitrogen, ammonia, 2-methylaziridine, and allylamine.

To check the validity of the present analytical method, known amounts of ammonia and aziridine were added to the ethylene solution of hydrogen azide. After having been passed through the NaOH trap, less volatile parts were analyzed with GLC. Figure 1 shows the amounts of aziridine and ammonia recovered as functions of those introduced in the solution. The recovery was almost 100%.

Figures 2 and 3 show the relative yields of the products obtained in the ethylene and propene solutions, respectively, as functions of the concentration of hydrogen azide. The relative yields of the products

were independent of the concentration of hydrogen azide. The yields of aziridine and ammonia were 0.18 ± 0.02 and 0.16 ± 0.02 times that of nitrogen in the case of ethylene. In the case of propene, the yields of 2-methylaziridine, allylamine, and ammonia were 0.33 ± 0.02, 0.12 ± 0.01, and 0.17 ± 0.01 times that of nitrogen.

When the mixture of ethylene and ethane were used as the solvent, the ethylamine formation competed with the aziridine formation. Figure 4 shows the relative yields of the products obtained in the mixture of ethane, ethylene, and hydrogen azide, as functions of the mole fraction of ethylene. In this case, the $[HN_3]/([C_2H_4]+[C_2H_6])$ ratio was kept constant at 2.0×10^{-3}.

When ethylene was added to the propene solution of hydrogen azide, the aziridine formation competed with the formations of 2-methylaziridine and allyl amine, as is shown in Fig. 5. In this case, the $[HN_3]/([C_2H_4]+[C_3H_6])$ ratio was 2.5×10^{-3}.

Discussion

Reaction Mechanism. In previous papers,[1,2] the amine formation in the photolysis of hydrogen azide in liquid paraffin was explained by the insertion of $NH(a^1\Delta)$ into the C–H bond of paraffin. As was shown in Fig. 4, when ethylene was added to the ethane solution of hydrogen azide, the ethylamine formation decreased and the aziridine formation increased. In the case of propene, the allylamine/2-methylaziridine ratio was independent of the concentration of hydrogen azide, as is shown in Fig. 3. These results suggest that aziridine is formed by the addition of the singlet NH to the double bond of olefin. To explain the results obtained, the following reaction mechanism was considered:

$$HN_3 + h\nu \longrightarrow {}^1NH + N_2 \qquad (1)$$

$$^1NH + Ol \longrightarrow \text{aziridine} \qquad k_a \qquad (2)$$

$$\longrightarrow \text{amine} \qquad k_1 \qquad (3)$$

$$\longrightarrow {}^3NH + Ol \qquad k_d \qquad (4)$$

$$^3NH + HN_3 \longrightarrow NH_2 + N_3 \qquad (5)$$

$$NH_2 + HN_3 \longrightarrow NH_3 + N_3 \qquad (6)$$

$$N_3 + Ol \longrightarrow OlN + N_2. \qquad (7)$$

Here, ^1NH and ^3NH represent the NH radicals in the $a^1\Delta$ and $X^3\Sigma^-$ states respectively. Ol means olefin used. In the case of propene, allylamine is a possible insertion product. The insertion into the vinylic C–H bond will give vinylamine, which is known to be an unstable compound at room temperature; therefore, the vinylamine, even if formed, will not be detected.

In the case of paraffin, Reaction 8 was assumed for the reaction of N_3:[1,2]

$$N_3 + N_3 \longrightarrow 3\,N_2. \qquad (8)$$

Since olefin is known as a radical scavenger, Reaction 7 is assumed instead of Reaction 8. The product OlN will give a polymer.[8]

As shown in Figs. 2 and 3 and in the previous papers,[1,2] the relative yield of ammonia in the olefin solution was larger than that in the paraffin solution and was independent of the concentration of hydrogen azide. The following reactions might be considered for the ammonia formation:

$$^1NH + RH \longrightarrow NH_2 + R \qquad (9)$$

$$^3NH + RH \longrightarrow NH_2 + R \qquad (10)$$

$$NH_2 + RH \longrightarrow NH_3 + R. \qquad (11)$$

Here, RH denotes an hydrocarbon molecule. If these reactions are taken into the mechanism, it is necessary to assume that the rate of the abstraction by ^1NH or ^3NH from ethylene is almost the same as that from propene and faster than that from paraffin including isobutane. This assumption is not acceptable, since olefin is known as a radical scavenger and the rate is faster than that of the hydrogen atom abstraction. The rate of the abstraction is known to depend on the strength of the C–H bond included.

Another possible mechanism for the ammonia formation is a molecular hydrogen abstraction from hydrocarbon:

$$^1NH + C_2H_4 \longrightarrow NH_3 + C_2H_2, \quad \Delta H = -200\ \text{kJ mol}^{-1}. \qquad (12)$$

Reaction 12 can successfully explain the concentration dependence of the ammonia formation. If Reaction 12 occurred in the case of ethylene, we should also consider the similar reaction in the case of paraffin:

$$^1NH + C_2H_6 \longrightarrow NH_3 + C_2H_4, \quad \Delta H = -240\ \text{kJ mol}^{-1}. \qquad (13)$$

By the inclusion of Reaction 13 in the mechanism, the concentration dependence of the ammonia formation should have an intercept. This was not the case, as was shown in the previous paper.[2] There is no reason to assume that Reaction 12 is important in the case of olefin while the similar reaction is not important in the case of paraffin. Thus it may be concluded that a reaction such as Reaction 12 is not important.

The remaining sources of ammonia are Reactions 5, 6, and 14:

$$^1NH + HN_3 \longrightarrow NH_2 + N_3. \qquad (14)$$

In fact, Reaction 14 has been considered to be important in the case of paraffin to explain the result that the relative yield of amine decreased with an increase in the concentration of hydrogen azide.[2] In the case of olefin, Reaction 14 should not be important, since the relative yield of aziridine or amine is constant for the change in the concentration of hydrogen azide. Thus, the remaining sources of ammonia are Reactions 5 and 6.

In the case of paraffin, Reaction 15 has been considered to explain the material balance and the concentration dependence of the ammonia formation:

$$NH_2 + NH_2 \longrightarrow N_2H_4. \qquad (15)$$

If Reaction 15 is included in the mechanism, the relative yield of ammonia should linearly increase with an increase in the concentration of hydrogen azide. In the case of olefins, however, this is not the case, as is shown in Figs. 2 and 3. That is, the rate of Reaction 15 is negligibly small in the olefin solution.

As was discussed above, it was necessary to ignore Reactions 14 and 15 to explain the results obtained with the olefin solution. In the case of paraffin, the rate of Reaction 14 has been considered to depend on the solvent.[2] Although the detailed interaction is unknown, the solvent effect seems to be the only way to explain the difference in the hydrogen azide concentration dependence of ammonia formation in paraffin and in olefin solutions.

Cornell *et al.* assumed the reactions of triplet NH with ethylene to explain the formation of HCN, CH_3CN, H_2, and CH_4 in the photolysis of a mixture of hydrogen azide and ethylene in the gas phase at room temperature:[4]

$$^3NH + C_2H_4 \longrightarrow CH_3CN + H_2$$
$$\longrightarrow HCN + H + CH_3. \qquad (16)$$

If Reaction 16 is included in the mechanism, the H_2 and CH_3CN formations should be observed. However, these were not found, as shown in the Results section. An intermediate of Reaction 16 may be a vibrationally excited aziridine in the triplet state, which may be efficiently deactivated to the ground state under the present experimental conditions:

$$^3NH + C_2H_4 \longrightarrow \text{aziridine}. \qquad (17)$$

A similar addition reaction to the double bond of olefin has been considered in the cases of triplet O and CH_2.[9–12] If Reaction 17 is included in the mechanism, the relative yield of ammonia should increase while that of aziridine should decrease with an increase in the concentration of hydrogen azide, because of the competition between Reactions 5 and 17. This is not the case, as shown in Figs. 2 and 3. That is, the addition reaction, if it occurred, should be negligible compared with Reaction 5. In the case of O atoms, the addition rate of the triplet oxygen has been measured to be about two orders of magnitude slower than that of the singlet O atoms at room temperature.[10] In the case of NH radicals, Cornell

et al. estimated the rate of Reaction 16 to be about 10^7 dm^3 mol^{-1} s^{-1} at room temperature.[4] Recently, McDonald *et al.* have determined the rate constant for the reactions of the singlet NH with ethylene to be 2.3×10^{10} dm^3 mol^{-1} s^{-1} at room temperature.[13] That is, the rate of triplet NH is about three orders of magnitude smaller than that of the singlet NH. If Reaction 17 has some activation energy, the rate will become smaller under the present experimental conditions.

Material Balance. From the above reaction mechanism, the following relations are expected to hold between the amounts of the products:
for ethylene;

$$N_2 = \text{aziridine} + 3 \text{ ammonia}, \quad (18)$$

for propene;

$$N_2 = \text{2-methylaziridine} + \text{allylamine} + 3 \text{ ammonia}. \quad (19)$$

Using the values shown in Figs. 2 and 3, the (aziridine+3 ammonia)/N_2 and the (2-methylaziridine+allylamine+3 ammonia)/N_2 ratios can be estimated to be 0.67 ± 0.08 and 0.96 ± 0.04 respectively. In the case of propene, the ratio is close to unity, while the ratio in the case of ethylene is considerably smaller than unity. That is, about 30% of NH-containing products are missing in the case of ethylene. Similar results have been obtained in the case of paraffin, and hydrazine was assumed to be the missing product (Reaction 15). In the case of ethylene, however, the hydrazine formation was ignored, as was discussed in the previous section. It is necessary to consider another mechanism for the missing products. This point will be discussed later.

In the case of paraffin, hydrogen formation has been observed. This was explained by assuming that about 9% of the photodissociation of hydrogen azide leads to the formation of hydrogen atom and N_3:[2]

$$HN_3 + h\nu \longrightarrow H + N_3 \quad (20)$$

$$H + HN_3 \longrightarrow H_2 + N_3. \quad (21)$$

In the presence of an excess amount of olefin, the scavenging of hydrogen atoms by olefin may be more important than Reaction 21. This explains the absence of hydrogen formation in the olefin solution:

$$H + Ol \longrightarrow R, \quad (22)$$

where R denotes a C_2H_5 or C_3H_7 radical. There is a possibility that the reaction of R affects the total yield of nitrogen. The following reactions can be considered for the reactions of alkyl radicals:

$$R + N_3 \longrightarrow RN_3 \quad (23)$$

$$R + R \longrightarrow \text{products} \quad (24)$$

$$R + HN_3 \longrightarrow RH + N_3. \quad (25)$$

If Reaction 23 is important, the nitrogen formation is not affected and Eqs. 18 and 19 still hold. If Reaction 24 is important, Reaction 20 has to be taken into account for the formation of nitrogen. The correction is about 9%. If Reaction 25 is important, the correction of 18% is necessary for the yield of nitrogen. Although it is difficult to decide which reaction is important under the present experimental conditions, the correction of 18% is too large for the case of propene.

Relative Rate Constant. Assuming the above reaction mechanism, the following rate constant ratios can be estimated by using the yields of products shown in Figs. 2 and 3.

$$k_{ae}/k_{de} = \text{aziridine/ammonia} = 1.1\pm0.2 \quad (26)$$

$$k_{ap}/k_{dp} = \text{2-methylaziridine/ammonia} = 1.9\pm0.1 \quad (27)$$

$$k_{ip}/k_{dp} = \text{allylamine/ammonia} = 0.67\pm0.04 \quad (28)$$

$$k_{ap}/k_{ip} = \text{2-methylaziridine/allylamine} = 2.9\pm0.3, \quad (29)$$

where subscripts a, i, and d stand for the addition, insertion, and deactivation reactions of the singlet NH with ethylene (e) or propene (p) respectively.

From the results shown in Fig. 5, the relative rate constant of the reaction of the singlet NH with ethylene to that with propene can also be estimated. Using the steady-state treatment, Eqs. 30, 31, and 32 can be obtained for the relative yields of the products:

$$\text{aziridine}/N_2 = k_{ae}c/k_e X \quad (30)$$

$$\text{2-methylaziridine}/N_2 = k_{ap}c/k_p\ (1-X) \quad (31)$$

$$\text{allylamine}/N_2 = k_{ip}c/k_p\ (1-X), \quad (32)$$

where $X=k_e[C_2H_4]/(k_e[C_2H_4]+k_p[C_3H_6])$. The symbol c means $(N_2-2\,NH_3)/N_2$, which was almost independent of the fraction of ethylene, as is shown in Fig. 5. k_e and k_p are the sum of the rate constants for the addition, insertion, and deactivation of the singlet NH with ethylene and propene respectively.

In order to estimate the k_e/k_p ratio, a weighted mole fraction, X′, is introduced, which is defined as follows:

$$X' = f[C_2H_4]/(f[C_2H_4]+[C_3H_6]), \quad (33)$$

where f is a weighted factor. If $f=k_e/k_p$, then $X=X'$. Assuming a value for f, the values of X' can be calculated for any mole fraction of ethylene. If the f factor is equal to k_e/k_p, the plots of the left-hand-side of Eqs. 30, 31, and 32 against X' should give straight lines for each product. Such plots are made by varying the f factor until good linearities can be obtained for every product. When the f factor was assumed to be 1.6, good linearities could be obtained, as are shown in Fig. 6; that is, $k_e/k_p=1.6$.

A similar relative rate constant for the reaction of the singlet CH_2 with ethylene and propene has been estimated to be 0.77 in the gas phase.[9] For the singlet O, 2.2/6.0=0.37 has been reported.[10] The trend in the reactivity of the singlet NH is in the opposite direction to those of the singlet O and CH_2; the ratio for NH is larger than unity, while those for O and CH_2 are smaller than unity. No proper interpretation can be found for this anomaly at present.

From the slopes of the straight lines in Fig. 6, the k_{ae}/k_e, k_{ap}/k_p, and k_{ip}/k_p ratios can be estimated to be about 0.30, 0.48, and 0.17 respectively. Combining these values with those estimated from Eqs. 26—29, the k_{de}/k_e and k_{dp}/k_p ratios can be estimated to be 0.27 and 0.25 respectively. These values are listed in Table 1. Although the $(k_{ap}+k_{ip}+k_{dp})/k_p$ ratio is close to unity, the $(k_{ae}+k_{de})/k_e$ ratio is only 0.57. That is, some reaction path is missing in the case of ethylene. The extent of the missing reaction cor-

TABLE 1. VALUES OF RELATIVE RATE CONSTANTS

	C_2H_4		C_3H_6	
Addition	[1.00][a]	(0.30)[b]	1.0	(0.48)
Insertion				
Vinyl[c]	1.43	(0.43)	0.21	(0.10)
Allyl	0	0	0.35	(0.17)
Deactivation	0.90	(0.27)	0.52	(0.25)
Total	3.33	(1.00)	2.08	(1.00)

a) The rate of aziridine formation in the ethylene solution is assumed to be unity. b) The values in parenthese show the relative values for each olefin, assuming the total rate to be unity. c) Values estimated on the assumption that the missing reaction is the insertion into the vinylic C–H bond.

responds to the amount of the missing NH-containing products, which was disscussed in the previous section. The missing product might be vinylamine, since this compound is known to be unstable at room temperature.

The following relations can also be obtained by using the steady-state treatment:

$$\text{2-methylaziridine/aziridine} = k_{ap}[C_3H_6]/k_{ae}[C_2H_4] \quad (34)$$

$$\text{allylamine/aziridine} = k_{ip}[C_3H_6]/k_{ae}[C_2H_4]. \quad (35)$$

The k_{ap}/k_{ae} and k_{ip}/k_{ae} ratios were estimated to be 1.0 ± 0.1 and 0.32 ± 0.05 respectively, using the results shown in Fig. 5. The rate of the addition to the double bond of ethylene is almost equal to that of propene. The relative rate constants are summarized in Table 1.

From the results shown in Fig. 4, it is possible to estimate the relative rate of the insertion into the C–H bond of ethane to the addition to the double bond of ethylene.

$$^1NH + C_2H_6 \longrightarrow C_2H_5NH_2 \quad (36)$$

When competition between Reactions 36 and 2 is considered, the following relation can be obtained:

$$\text{ethylamine/aziridine} = k_{36}[C_2H_6]/k_{ae}[C_2H_4]. \quad (37)$$

The k_{36}/k_{ae} ratio is estimated to be 0.82 ± 0.05. Since ethane has 6 C–H bonds, the addition reaction is about $6/0.82=7.3$ times faster than the insertion reaction per C–H bond. This value can be compared with 3 $k_{ap}/k_{ip}=8.6$, *i.e.*, the addition reaction is 8.6 times faster than the insertion into the allylic C–H bond of propene. In the case of the singlet O, DeMore estimated this ratio to be $0.37/0.071=5.2$ in the Ar solution at 87 K.[11] For the singlet CH_2, this ratio was larger than 10, depending on the source of the CH_2.[12] The ratio obtained with the singlet NH is between the ratios obtained with the singlet O and CH_2.

Table 1 shows that the branching ratio for the deactivation (Reaction 4) by ethylene is almost the same as that by propene and slightly larger than that by paraffin.[2] In this article, Reaction 4 followed by Reactions 5 and 6 is assumed to be responsible for the ammonia formation. However, Reaction 9, the hydrogen atom abstraction from hydrocarbon by the singlet NH, is indistinguishable from Reaction 4 only from the kinetics. If Reaction 9 should be considered instead of Reactions 4 and 5, the branching ratio for the deactivation would be that of Reaction 9. In this case, it is necessary to assume that the rate of the abstraction from ethylene is faster than those from propene and from paraffin, as was discussed already.

(Received May 26, 1980)

Lasing wavelengths and fluorescence spectra were measured for a mixed dye system containing various concentrations of Rhodamine 6G (Rh-6G) and 3,3′-diethylthiacarbocyanine iodide (DTC), which have very closely located S_1 levels, in acetone at room temperature. A new way of confirming the occurrence of energy transfer is presented on the basis of the reabsorption effect. It was found that most of the pump power absorbed by Rh-6G is transferred to DTC. A study of the fluorescence decay by a picosecond laser revealed that the energy transfer is essentially governed by the Förster mechanism. The observed fluorescence decay data agree fairly well with the R_0 value of 73.2 Å calculated from the spectral overlap.

Dye lasers have made a great progress over a wide wavelength region ranging from the ultraviolet (UV) to the infrared (IR). Hildebrand[1] and Lin[2] reported near-IR dye laser emission from several polymethine dyes directly pumped by UV nitrogen laser radiation (λ=337.1 nm). However, it is difficult to obtain efficient laser emission in longer wavelength regions (*e.g.*, near-IR), from nitrogen-laser pumped dye solutions, mainly because of very small absorption at 337.1 nm. A means to overcome the difficulty is the excitation of a dye laser through energy transfer processes for some dye mixture systems excited by 337.1-nm radiation of a nitrogen laser.[3-9] The energy transfer process with the use of a proper mixture of dyes can provide a means of extending the wavelength region in which lasing is achieved.

In the dye mixture systems studied so far, the fluorescent levels of donor and acceptor are widely separated (over 1800 cm^{-1}),[3-9] and thus there is little ambiguity in the lasing species. In a system of a donor and acceptor with closely located energy levels, however, it is difficult to identify the lasing species. Investigation of such a system seems to be important in connection with the intermolecular energy transfer in photosynthetic pigments, considering that several forms of chlorophyll with slightly different absorption maxima are operative in the primary energy-transfer process in photosynthesis.[10] In this connection, we have studied the energy transfer mechanism. The intermolecular singlet-singlet electronic energy transfer was found to proceed by at least three mechanisms: the resonance, exchange, and trivial mechanisms.[11] In order to differentiate various mechanisms contributing to energy transfer in dye laser systems, the study of fluorescence decay curve with a picosecond laser seems to be effective.

In this paper, we report the lasing behavior and energy transfer mechanism of the system 3,3′-diethylthiacarbocyanine iodide (DTC) as an acceptor and Rhodamine 6G (Rh-6G) as a donor in acetone at room temperature. The S_1 levels of both dyes are closely located. Some results have been reported.[12]

Experimental

Rh-6G (laser-dye grade; Eastman Kodak Co.), DTC (laser-dye grade; Dojindo Lab.), and acetone (spectrograde or guaranteed grade) were used without further purification.

The nitrogen and dye laser system and the spectrofluorometer were constructed in our laboratory. The nitrogen laser was similar to the one described by Basting *et al.*[13] and Maeda and Miyazoe.[14] The dye solution in a quartz spectrofluorometer cell with a square section 1×1 cm^2 was transversely pumped by 337.1-nm radiation from a pulsed nitrogen laser with an output peak power of *ca.* 500 kW at the nitrogen pressure *ca.* 60 Torr. No mirrors were employed, lasing being conducted between the side walls of the dye cell.

The dye lasing wavelengths and fluorescence spectra were measured with a Nalumi RM-21 500-mm grating monochromator equipped with an EMI 6256S photomultiplier. For the fluorescence spectra, the sample degassed in 9 mm diam. pyrex tubes was excited by an Ushio USH-500D 500-W super-high-pressure mercury arc lamp, Toshiba V-V40 and UV-39 filters being used to select 436-nm light.[15] For the fluorescence decay curves, the sample in a quartz spectrofluorometer cell was pumped with the second harmonic (530 nm) of a Nd^{3+}: YAG laser, the decays being measured with a Hamamatsu C979 streak camera. The donor emission was selected with a Nihon-Shinkukogaku IF-W interference filter (λ_{max}=560 nm). The time-sale of the streak camera was fully calibrated. The width of the exciting pulse was *ca.* 26 ps. The results of three shots on the same sample were averaged. All measurements were made at room temperature. Other experimental details have been reported.[9,16]

Results and Discussion

Spectra. The absorption and fluorescence spectra of Rh-6G and DTC are shown in Fig. 1. The good spectral overlap between the Rh-6G fluorescence and DTC absorption suggests the possibility of energy transfer from Rh-6G to DTC. Since the peak wavelengths of the fluorescence spectra are close to each other for these dyes, the emission in a mixture of the two dyes can not be concluded to originate from the acceptor (DTC).

Confirmation of Energy Transfer by Reabsorption Effect. Since we observed no lasing for DTC by itself, it may follow that the excitation energy is effectively transferred from Rh-6G to DTC when the laser emission in the mixtures originates from DTC. The lasing wavelengths and fluoresence spectra of the Rh-6G-DTC dye mixture system were measured at various donor concentrations for a fixed acceptor concentration. The plot of peak wavelengths (λ_{max}) in the laser emission (L) and fluorescence (F) *versus* donor concentration [D] is shown in Fig. 2, together with the concentration dependence of the λ_{max}-values in L and F of Rh-6G alone in acetone. The λ_{max}-values in L and F of the dye mixture are independent of concentration while those in the Rh-6G only system shift to longer wavelengths with increasing concentration because of the reabsorption effect. This indicates that the emission in the dye mixture originates essentially from DTC.

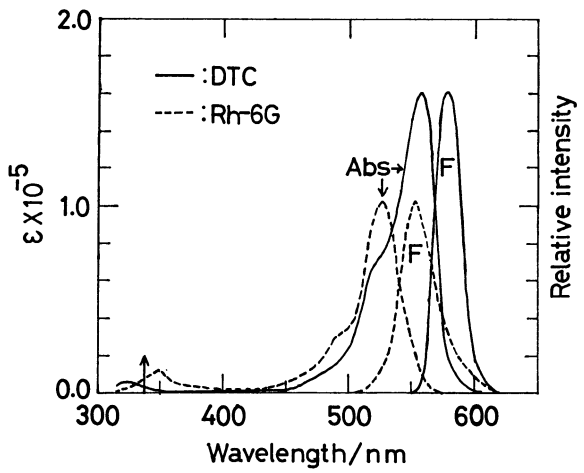

Fig. 1. Absorption (Abs) and fluorescence (F) spectra for the Rh-6G and DTC dyes separately.
Absorption path length: 1 mm. Concentration: Rh-6G, 5×10^{-5} M for Abs and 1×10^{-5} M for F; DTC, 5×10^{-5} M for Abs and 1.5×10^{-5} M for F; in acetone. The arrow on the abscissa refers to the 337.1-nm excitation wavelength.

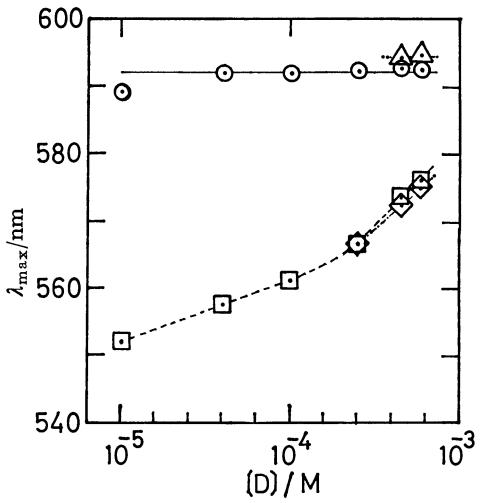

Fig. 2. Plots of the λ_{max}-values in the laser emission (L) and fluorescence (F) *versus* the Rh-6G concentration [D] for a fixed DTC concentration (1.5×10^{-4} M).
▲ and ⊙: L and F of Rh-6G-DTC dye mixture system, respectively; ◈ and ⊡: L and F of Rh-6G alone, respectively. It was not possible to obtain laser action from Rh-6G alone as well as from the mixture in the low concentration range under our experimental conditions.

We measured the λ_{max}-values of L and F in the dye mixture system at various acceptor concentrations for a fixed donor concentration. The results are shown in Fig. 3 together with the concentration dependence of λ_{max} in F of DTC in acetone. The λ_{max}-values in F of both the dye mixture and the DTC-only system agree, showing a shift due to the reabsorption effect as in the case of the Rh-6G. The λ_{max}-values in L of the dye mixture system show a concentration dependence similar to those of F mentioned above. The results show that the laser emission in the dye mixture system originates essentially from DTC at least within the concentration range studied. Most of the excitation energy absorbed by Rh-6G is transferred to DTC as a useful pump power, *viz.*, pumping by excitation transfer is efficient.

We carried out an experiment with dye mixtures containing coumarin 2 as donor and coumarin 1 as acceptor in ethanol at room temperature and at 77 K over a wide range of concentration. The S_1 levels of both dyes are more closely located than the Rh-6G-DTC system. We have confirmed on the basis of the reabsorption effect that in this system the energy transfer from coumarin 2 to coumarin 1 occurs at 77 K.[17]

Fluorescence Decay Behavior. Rh-6G-only and DTC-only System: Fluorescence was monitored at 560 nm and 580 nm for Rh-6G and DTC, respectively. An exponential decay was observed in each case with

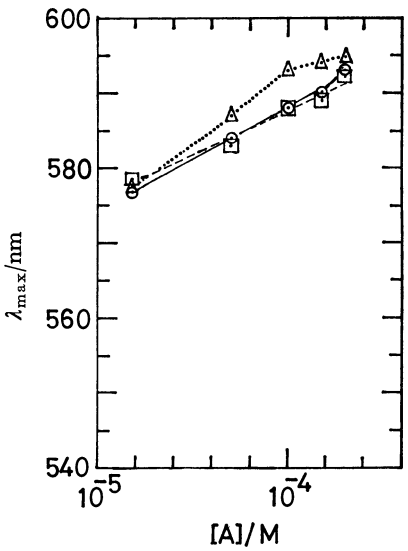

Fig. 3. Plots of the λ_{max}-values in L and F *versus* the DTC concentration [A] for a fixed Rh-6G concentration (5×10^{-4} M).
▲ and ⊙: L and F of Rh-6G-DTC dye mixture system, respectively; ◙: F of DTC alone.

lifetime of 2.6 ns (Rh-6G 1.0×10^{-5} M)[18]† and 130 ps (DTC 2.0×10^{-6} M). The latter is in good agreement with the predicted value of Roth and Craig.[19]

Rh-6G Plus DTC System: Fluorescence was monitored at 560 nm. The λ_{max}-values in F of Rh-6G and DTC are 552 nm (10^{-5} M) and 590 nm (10^{-4} M), respectively. The experimental decay curves indicate that the initial part ($t\lesssim400$ ps) suffered from a serious overlap of the DTC-fluoresence. Since the initial part ($t\lesssim30$ ps) was influenced by the exciting pulse duration, only the later part of the decay was used for the analysis. The following holds for the Förster-type time-dependent fluorescence decay of the donor in the presence of a large number of acceptor molecules:[20,21]

$$I_Q(t) = I_Q(0)\exp\{-t/\tau_D - 2([A]/C_0)(t/\tau_D)^{1/2}\} \quad (1)$$

where $C_0=(7.65/R_0)^3$. R_0, critical transfer distance, is given by the formula

$$R_0^6 = \frac{9000(\ln 10)\phi_D\kappa^2}{128\pi^5 Nn^4}\int f_D(\bar{\nu})\varepsilon_A(\bar{\nu})d\bar{\nu}/\bar{\nu}^4. \quad (2)$$

In these formulas, τ_D is the fluorescence lifetime of the donor in the absence of energy transfer, ϕ_D the fluorescence quantum yield of the donor, N Abogadro's number, n reflactive index of the media, f_D the spectral distribution of the donor fluorescence normalized to one (in units of quanta on a wavenumber scale), and ε_A the molar decadic extinction coefficient of the acceptor. The average value of κ^2, an orientation factor, is 2/3 when the molecules are free to rotate at a rate much greater than that of transfer, and 0.475[22] when the orientation of the donor and acceptor is random but the rate of rotation is much smaller than that of transfer. From Eq. 1 and the fluorescence decay in the absence of the acceptor

$$I_F(t) = I_F(0)\exp(-t/\tau_D), \quad (3)$$

we have the linear relationship:

$$\ln[I_Q(t)/I_F(t)] = \ln[I_Q(0)/I_F(0)] - 2([A]/C_0)\tau_D^{-1/2}t^{1/2}. \quad (4)$$

The values of C_0 and R_0 can be calculated from the spectral overlap of fluorescence band of Rh-6G and absorption band of DTC to be 1.14×10^{-3} M and 73.2 Å, respectively. The value of the orientation factor κ^2 was assumed to be 2/3 in this calculation (*vide infra*). In Fig. 4, $\ln[I_Q(t)/I_F(t)]$ is plotted against $t^{1/2}$, the number of data points being restricted for the sake of clarity. The straight line in the figure has the slope calculated with the values given above. The experimental points representing the later part of decay seem to fit the line although the data points are scattered because of the small intensity of $I_Q(t)$. This suggests that the energy transfer in the present dye laser system takes place essentially through the process of nonradiative resonance transfer of the Förster type. A large R_0 value is due to a large spectral overlap, which is in turn caused by the closely located S_1 levels of the dyes.

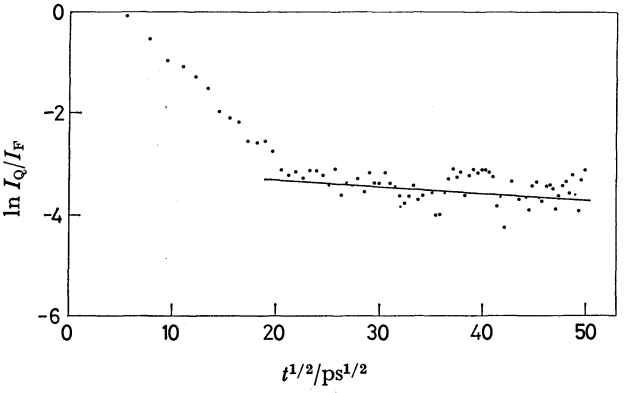

Fig. 4. $\ln[I_Q(t)/I_F(t)]$ plotted as a function of $t^{1/2}$. $I_Q(t)$: Rh-6G 1×10^{-5} M, DTC 9×10^{-5} M, $I_F(t)$: Rh-6G 1×10^{-5} M. The slope of the straight line was calculated with $R_0=73.2$ Å.

The Förster theory assumes that the rate of translational diffusion is small enough to preclude a significant perturbation of the random distribution of distances between D and A during the course of measurement.[11d,11e] On the basis of picosecond-absorption spectroscopic studies Rehm and Eisenthal[23] stated that the Förster theory gives a good description of singlet-singlet energy transfer between Rh-6G (donor) and malachite green (acceptor) in glycerol even up to the earliest time (20 ps). Porter and Tredwell[21] carried out similar studies with a picosecond laser and streak camera system on the same pair in a low viscosity solvent (ethanol), showing that the Förster theory is applicable up to a limiting time resolution of 10 ps. They showed that translational diffusion does not distort the kinetics of the energy transfer system at a viscosity of 1.2 cP.†† The significant changes in the intermolecular distances during energy transfer can be precluded because of the relationship[11c]

$$R_0 \gg [2(D_D+D_A)\tau_D]^{1/2}, \quad (5)$$

where D_D and D_A are the diffusion coefficients of the donor and acceptor, respectively. In our case, the viscosity of the solvent (0.32 cP) is *ca.* 4-fold smaller than in their case; the diffusion coefficient of Rh-6G would be *ca.* 4 times larger, assuming the Stokes-Einstein relation $D=kT/(6\pi\eta b)$.[11b] The coefficient for DTC is unknown. However, the size and charge of the molecule are comparable to those of Rh-6G indicating that the value of the coefficient should be similar. Thus, $[2(D_D+D_A)\tau_D]^{1/2}$ would be *ca.* 45 Å, twice as large as in the case of Porter and Tredwell. Our value of R_0, 73.2 Å is much larger.

Gösele *et al.*[24] reported that an expression formally analogous to Eq. 1 can be obtained for the time-dependent fluorescence intensity even when diffusion governs the fluorescence quenching effects. In the diffusion-governed kinetics, instead of R_0^3, should be used $r_{AD}^2 D^{1/2}\tau_D^{1/2}$ multiplied by a constant with a value close to 2, where r_{AD} is a certain collision distance and D the sum of D_A and D_D (the quantity α in their formulas is replaced by R_0^6/τ_D). According to these authors, the quenching effects are controlled by diffusion and by long-range energy transfer when $Z_0=R_0^3/(2r_{AD}^2 D^{1/2}\tau_D^{1/2})\ll1$ or $Z_0\gg1$, respectively. For the case where the long-range energy transfer is

† 1 M=1 mol dm^{-3} in this paper.

†† 1 cP=10^{-3} kg m^{-1} s^{-1} in SI units.

dominant, we have $R_0 \gg r_{AD}$ and hence $R_0^2 \gg 2^{1/2} r_{AD}^2$. When we multiply the left and right sides of the inequality 5 by R_0^2 and $2^{1/2} r^2{}_{AD}$ respectively, we obtain the relation $Z_0 \gg 1$. Thus, the relation $Z_0 \gg 1$ is equivalent to inequality 5.

Birks[11c] and Birks and Georghiou[25] observed the donor fluorescence decay of phenanthrene in the absence and presence of acridine in six solvents of viscosity η=64.6 cP (cyclohexanol) to 0.4 cP (heptane). Their results were compared with the relations of Förster[20], Yokota and Tanimoto[26], and Voltz *et al.*,[27] the last being developed from diffusion theory and extrapolates to Stern-Volmer kinetics.[11c] A mean value of R_0=25.5 Å was obtained from the spectroscopic data. At η=64.6 cP, where $\sqrt{2D\tau_D} < R_0$, the donor decay follows Förster kinetics. At η<3.7 cP where $\sqrt{2D\tau_D} > 3R_0$, the decay was exponential, following Stern-Volmer kinetics. At intermediate viscosities, where the decay was non-exponential but more rapid than predicted by the Förster relation, the decay agreed with the Yokota-Tanimoto relation within experimental error. The Voltz relation predicted a more rapid decay than that observed.

In our case, R_0 is much larger than $\sqrt{2D\tau_D}$. In the Yokota-Tanimoto relation, the second term in the exponent of Eq. 1 is multiplied by

$$B = [(1+10.87x+15.50x^2)/(1+8.743x)]^{3/4} \quad (6)$$

with $x = D\alpha^{-1/3}t^{2/3} = DR_0^{-2}\tau_D^{1/3}t^{2/3}$. The slope of the $\ln[I_Q(t)/I_F(t)]$ *vs.* $t^{1/2}$ plot is not constant but dependent on $t^{1/2}$ because of the presence of B. For our case with $D = 1\times10^{-5}$ cm^2 s^{-1}, R_0=73.2 Å, and τ_D=2.6 ns, the slope calculated by means of the Yokota-Tanimoto relation increases in absolute value with $t^{1/2}$. The experimental points in Fig. 4 show no such tendency. The slope is constant and time-independent, indicating that the Förster kinetics is applicable, although the viscosity of the solvent is very low. If we compare our results with those of Birks and Georghiou,[25] we find the following: (1) a larger R_0 value, R_0=73.2 Å instead of 25.5 Å, (2) a larger b value, large dye molecules instead of small molecules phenanthrene and acridine and (3) a smaller τ_D value, τ_D=2.6 ns instead of $\tau_D \approx 60$ ns. Each of the effects (1), (2), and (3) diminishes the boundary value of η for diffusion-dominated kinetics, *i.e.*, a value of η which satisfies $\sqrt{2D\tau_D} = 3R_0$. The value becomes smaller by a factor of $(73.2/25.5)^2 \approx 8$ than that of Birks and Georghiou if we take (1) into consideration.

The energy transfer seems to follow the Förster mechanism, although some contribution of diffusion controlled process can not be entirely ruled out.

Bojarski and Dudkiewicz[28] proposed the concentration effects on orientation factor κ^2 by considering the concentration-dependent ratio of rotation time (τ_r) and time of the excitation energy localization $\tau_1 = [\sum_D k_{D^*D} + \sum_A k_{D^*A} + k_F + k_q]^{-1}$, where k_{D^*D} and k_{D^*A} denote the rate constant of long-range nonradiative electronic excitation energy transfer due to the dipole-dipole interaction between an excited donor (D*) and an unexcited donor (D) and that between D* and an acceptor (A), respectively, and k_F and k_q those for emission and internal conversion, respectively. They assumed the value of κ^2 to be a function of $a = \tau_r/\tau_D$ and $\gamma = [A]/C_0$. The deviation of κ^2 from the value of rapid rotation is important when $\gamma \geq 1$ for $a \lesssim 0.1$. For a larger a, it becomes prominent from a smaller γ. They reexamined the data of Porter and Tredwell[21] and concluded that the small systematic change in C_0 can be caused by the change in κ^2. In the case (P. and T.) (τ_r=320 ps. τ_D=4200 ps, a=0.0762) the acceptor concentration is very high (10^{-2}—10^{-3} M), the values of γ being in the range 3.05—0.33. In our case, the value of τ_r should be smaller than that in more viscous ethanol (320 ps). With τ_D=2600 ps, the value of a would be *ca.* 0.1. Since $\gamma = 9\times10^{-5}/1.14\times10^{-3} = 0.079$, the deviation of the value of κ^2 from the value of rapid rotation can be neglected. The value $\kappa^2 = 2/3$ seems to be reasonable.

Concluding Remarks. A new method has been worked out for confirming the occurrence of energy transfer on the basis of the reabsorption effect. Rh-6G, with a high fluorescence quantum yield (0.83 or 0.92)[18] and a good spectral overlap characteristics with DTC, can be used as an efficient donor for lasing of DTC even though DTC has a very low fluorescence quantum yield (0.048).[19] The energy transfer occurs by a nonradiative process of the Förster-type. French *et al.*[10] found that the absorption bands of chloroplasts can be considered as a superposition of bands associated with several chlorophyll forms. A very efficient energy transfer occurs among them, their S_1 levels being very close. The dyes we used have very closely located S_1 levels. A combination of these dyes can be considered as a model system of chloroplasts. Occurrence of resonance energy transfer is possible for these dyes even in dilute solutions (below 10^{-3} M) mainly due to good spectral overlap characteristics, *i.e.*, a large value of R_0. Further experiments on the energy transfer of these dyes in micellar systems are in progress.[29-30]

Thermodynamic Studies of Thallium Halide Formation in Nonaqueous Solvents

Yukio Sasaki,* Masao Takizawa, Kisaburo Umemoto,** and Niro Matsuura**

Tokyo Institute of Polytechnics, Iiyama, Atsugi, Kanagawa 243-02

***Department of Pure and Applied Science, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153*

(Received May 29, 1980)

The differences in the order of stability among halide ions for metal halogeno-complexes in nonaqueous solvents and water are examined by means of the thermodynamic constants for the formation of thallium halides of transfer from water to *N,N*-dimethylformamide (DMF) and propylene carbonate (PC). The thermodynamic constants for the formation of thallium halides were calculated from the solubility products of thallium halides. The differences in the order of stability for thallium halides were found to be dependent mainly on the enthalpy changes for the formation of thallium halides of transfer from water to DMF and PC, while the enthalpy changes of transfer for thallium halides are themselves largely influenced by the enthalpy changes for halide ions of transfer from water to DMF and PC.

In previous papers,[1-4] the formation of metal halogeno-complexes was investigated potentiometrically in dimethyl sulfoxide, *N,N*-dimethylformamide, and propylene carbonate. The order of stability for metal halogeno-complexes (halogeno-cadmium, -lead, -copper and -zinc complexes[5]) among halide ions in nonaqueous solvents was found to be different from that in water. The classification of metals according to their complexation with halide ions is shown in Table 1. The solid line indicates the classification by Ahrland[6] in water, while the broken line indicates the classification obtained by our studies in nonaqueous solvents.[7] The stability of the halogeno-complexes on outside metals of the triangle in Table 1 decreases in the order of $Cl^->Br^->I^-$. However, the stability on inside metals is the reversed order; $I^->Br^->Cl^-$.

The purpose of the present paper is to elucidate the reason for differences in the stability on metal halogeno-complexes in *N,N*-dimethylformamide, propylene carbonate, and water from the thermodynamic constants for the formation of thallium halides.

Experimental

Materials. The purification of *N,N*-dimethylformamide (DMF) and propylene carbonate (PC), the preparation and purification of tetraethylammonium perchlorate, and the preparation of the saturated thallium amalgam have been described elsewhere.[8,9] The tetraethylammonium halides and thallium(I)perchlorate($TlClO_4$) were obtained commercially and were purified by recrystallization with water–ethanol or ethanol–ethyl acetate mixtures. The electrolytes were dried in a vacuum oven for 2 d in the temperature range of 60—70 °C.

Procedure. The solubilities of thallium(I)halides (TlX) were determined by means of potentiometric titration. A solution of 10^{-3} mol dm^{-3} of $TlClO_4$ was titrated with a solution of 5×10^{-2} mol dm^{-3} of TlX. The indicator electrode was a saturated thallium amalgam electrode, while the reference electrode was an aqueous saturated calomel electrode (SCE) equipped with a nonaqueous salt bridge.[9] The experimental device is shown in Fig. 1. The potential of the cell was measured on a Hewlett-Packard Model 34703A ohm meter. Each temperature was controlled to an accuracy of 0.1 °C.

Results and Discussion

The titration curves for Tl^+ with Cl^- in PC at 10, 20, and 25 °C are shown in Fig. 2. One well-defined equivalent point at $C_{Cl^-}/C_{Tl^+}=1$ (mol ratio) was found in each titration curve (Fig. 2). The precipitation

ΔE: potential shift caused by addition of Cl^-, tetraethylammonium perchlorate: 0.1 mol dm^{-3}.

appeared in the range from 10 to 30 °C soon after halide ions were added. This fact shows that the precipitation of TlX occurred as is shown in Eq. 1. In previous papers,[10] it was confirmed that the

$$Tl^+ + X^- = TlX. \quad (1)$$

Nernst equation was obeyed in DMF and PC containing $TlClO_4$ in the range from 1×10^{-4} to 2×10^{-3} mol dm^{-3}. The solubility products of TlX, assuming no complex formation of Tl^+ with Cl^-, and using the activity coefficients of TlX in DMF and PC,[10] were calculated from the titration curves on the basis of the Nernst equation. The order of the solubility products of TlX in DMF and PC is; TlI>TlBr>TlCl. The enthalpy changes ($\Delta H^\circ_{(TlX)}$) for the formation of TlX were obtained graphically from the slope of the log K_{s0} *vs.* $1/T$ plot (Vant Hoff plot, Eq. 2), where the K_{s0}

$$\log K_{s0} = \frac{\Delta H^\circ_{(TlX)}}{2.303R}\frac{1}{T} + \text{const.} \quad (2)$$

are solubility products. Figure 3 shows the plots of log K_{s0} *vs.* $1/T$ in DMF, PC, and water. The solubility products in water were obtained by means of the solubilities quoted from the literature.[11,12] The order of the solubility products in water is the reverse of that DMF and PC, as is shown in Fig. 3. The values of log K_{s0} for TlX in DMF and PC at 25 °C are given in Table 2. The values of log K_{s0} in DMF are in fair agreement with those of the literature.[10,13] However, the log K_{s0} values in PC are not in agreement with those of Salomon.[14] It is presumed that this disagreement arises from the use of the lithium–lithium halides reference electrode, since lithium metal may react with PC.[13]

The free-energy changes ($\Delta G^\circ_{(TlX)}$) for the formation of TlX can be correlated to log K_{s0} with the temperature in Eq. 3, and

$$\Delta G^\circ_{(TlX)} = 2.303RT \log K_{s0} \quad (3)$$

Table 3. Thermodynamic constants for formation of thallium halides in DMF, PC, and water at 25 °C

Solvent	TlX	$\Delta G^\circ_{(TlX)}$ / kJ mol^{-1}	$\Delta H^\circ_{(TlX)}$ / kJ mol^{-1}	$T\Delta S^\circ_{(TlX)}$ / kJ mol^{-1}
DMF	TlCl	−48.98	−30.51	+18.46
	TlBr	−45.33	−29.38	+15.95
	TlI	−39.14	−26.86	+12.28
PC	TlCl	−64.51	−77.33	−12.82
	TlBr	−61.85	−70.40	−8.55
	TlI	−56.98	−46.62	+10.36
Water	TlCl	−21.34	−26.30	−4.97
	TlBr	−31.43	−34.57	−3.13
	TlI	−41.36	−71.05	−29.69

the entropy changes ($T\Delta S^\circ_{(TlX)}$) were calculated from the $\Delta H^\circ_{(TlX)}$ and $\Delta G^\circ_{(TlX)}$. These thermodynamic

constants in DMF and PC were compared with those in water. The thermodynamic constants in DMF, PC, and water at 25 °C are given in Table 3. The thermodynamic constants in water, in the same manner as with DMF and PC, were obtained graphically. In Table 3, the order of the stability of TlX with $\Delta G^\circ_{(TlX)}$ in DMF and PC is found to be TlCl>TlBr>TlI, while it is TlI>TlBr>TlCl in water. Accordingly, the results in DMF and PC do not give support to the classification of the thallium ion obtained by Ahrland.[6] The reason for difference in stability in nonaqueous solvents and water was investigated by means of the thermodynamic constants for the formation of TlX of the transfer from water to DMF and PC. These constants, $\Delta G^\circ_{tr(TlX)}$, $\Delta H^\circ_{tr(TlX)}$ and $T\Delta S^\circ_{tr(TlX)}$, are listed in Table 4. From the values of $\Delta G^\circ_{tr(TlX)}$, it is manifest that TlCl becomes the most stable compound among the TlX compounds. The differences in $\Delta H^\circ_{tr(TlX)}$ and $T\Delta S^\circ_{tr(TlX)}$ between TlCl and TlI are -48.40 and -18.54 kJ mol^{-1} for transfer from water to DMF, and -75.46 and -47.90 kJ mol^{-1} for transfer from water to PC, respectively. Therefore, it was found that the enthalpy changes in transfer from water to DMF and PC contribute much to the free-energy changes of the transfer.

The thermodynamic constants, $\Delta G^\circ_{tr(TlX)}$, $\Delta H^\circ_{tr(TlX)}$ and $T\Delta S^\circ_{tr(TlX)}$, were compared with those of halide ions (X^-) for transfer from water to DMF and PC. These constants, ΔG°_{tr}, ΔH°_{tr}, and $T\Delta S^\circ_{tr}$, with crystal ionic radii of X^-, are given in Table 5. The ΔG°_{tr} were calculated by the use of the medium effects[10,15] in Eq. 4.

$$\Delta G^\circ_{tr} = 2.303RT \log_m \gamma_I \quad (4)$$

Table 4. Thermodynamic constants for formation of thallium halides of transfer from water to DMF and PC at 25 °C

Transfer	TlX	$\Delta G^\circ_{tr(TlX)}$ / kJ mol^{-1}	$\Delta H^\circ_{tr(TlX)}$ / kJ mol^{-1}	$T\Delta S^\circ_{tr(TlX)}$ / kJ mol^{-1}
From water to DMF	TlCl	−27.64	−4.21	+23.43
	TlBr	−13.89	+5.19	+19.08
	TlI	+2.22	+44.19	+41.97
From water to PC	TlCl	−43.18	−51.03	−7.85
	TlBr	−30.41	−35.83	−5.42
	TlI	−15.62	+24.43	+40.05

The ΔH°_{tr} are available in the literature.[16,17] The ΔG°_{tr} shown in Table 5 is the greatest positive value for Cl^-, which has the smallest ionic radius and the most strongly solvated anion in water, DMF and PC[18,19] among the X^- compounds. The fact shows that Cl^- is the most unstable anion for transfer from water to DMF and PC. Therefore, it is considered that the free-energy changes for the formation of TlX, $\Delta G^\circ_{tr(TlX)}$, are greatly influenced by the free-energy changes of X^-, ΔG°_{tr}, for transfer from water to DMF and PC. From a comaprison of ΔH°_{tr} with $T\Delta S^\circ_{tr}$ among the X^-, it can be seen that the values of ΔH°_{tr} contribute much to those of ΔG°_{tr}. Accordingly, it may be concluded that the differences shown in Table 1 in the order of stability for metal halogeno-complexes in DMF, PC, and water depend mainly on the enthalpy changes ($\Delta H^\circ_{tr(TlX)}$) for the formation of TlX, and that the $\Delta H^\circ_{tr(TlX)}$ are greatly influenced by the enthalpy changes (ΔH°_{tr}) of halide ions.

The Crystal Structure of [*N*-(*t*-Pentyloxycarbonyl)-L-prolyl]-L-alanylglycine

Yasuyuki YAMADA, Isao TANAKA,* and Tamaichi ASHIDA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya 464

(Received May 29, 1980)

The crystal structure of the title compound was determined by the X-ray method. The space group is $P2_1$, with $a=18.741(3)$, $b=12.602(1)$, $c=9.553(1)$ Å, $\beta=118.46(2)°$, and $Z=4$. The structure was determined successfully by the vector-space-search method, using a dimer structure of Boc–Pro–Val–Gly–OH as a rigid group. The final R value was 0.075 for 2025 non-zero reflections. Two independent molecules related by a pseudo two-fold axis are linked by β-sheet-type hydrogen bonds. This kind of dimerization commonly occurs in all the Boc–Pro–X–Gly–OH peptides except Boc–Pro–Leu–Gly–OH. The packing similarity of these peptides is discussed.

A series of structure analyses of the [*N*-(*t*-butoxycarbonyl)]-L-prolyl-X-glycine (Boc–Pro–X–Gly–OH, X; any amino acid residue) type oligopeptides have shown that these peptides take either one of two conformations, a folded or an extended one. The folded conformation of Boc–Pro–Leu–Gly–OH[1] is designated as the β-turn structure[2] because of the presence of a 4-1-type intramolecular hydrogen bond. On the other hand, the extended conformation of Boc–Pro–Ile–Gly–OH[3] and Boc–Pro–Val–Gly–OH,[4] both with a branched side chain at the C^β carbon, is characterzied by the formation of β-sheet-type intermolecular hydrogen bonds. These analyses, therefore, seem to illustrate the fact that a slight difference in the side chain results in the complete change of the main-chain folding.

The present study is concerned with the crystal analysis of peptides containing an alanyl residue at the X site. The alanyl residue having only a methyl group as a side chain seems to exert the least steric effect on the main-chain folding. We could expect, therefore, to get some clue as to whether or not the branched structure at the C^β atom has some definite effect on the main-chain folding. Crystals of [*N*-(*t*-butoxycarbonyl)]alanyl peptide, Boc–Pro–Ala–Gly–OH, however, contained four molecules in an asymmetric unit, furthermore, they were twinned. Therefore, we gave up trying to analyze it; as an alternative, [*N*-(*t*-pentyloxycarbonyl)-L-prolyl]-L-alanylglycine (Poc–Pro–Ala–Gly–OH) was studied.

Experimental

The synthesis was performed by first preparing the [*N*-(*t*-butoxycarbonyl)alanyl]glycine benzyl ester (Boc–Ala–Gly–OBzl), followed by the conventional removal of the Boc group and the addition of N-protected proline Poc–Pro–OH, leading to Poc–Pro–Ala–Gly–OBzl. After the removal of the benzyl group by catalytic reduction, the aimed peptide was crystallized from an ethylacetate solution. The crystal data are given in Table 1.

Table 1. Crystal data

Molecular formula	$C_{16}H_{27}O_6N_3$
Molecular weight	357.40
Space group	$P2_1$
Cell constants	$a=18.741(3)$ Å
	$b=12.602(1)$ Å
	$c=9.553(2)$ Å
	$\beta=118.46(2)°$
Density obsd	1.21 g/cm³
calcd	1.20 g/cm³ (for $Z=4$)

A crystal with dimensions of 0.14 mm × 0.07 mm × 0.06 mm was used for the X-ray experiment. A Hilger & Watts four-circle diffractometer equipped with Ni-filtered Cu K_α radiation was used for the data collection. The ω-2θ step scanning mode was adopted. Data were collected up to $2\theta=100°$ for total 2169 reflections, of which 2025 were non-zero. Lorentz and polarization corrections were applied, but no absorption correction was made.

Structure Determination

The direct method was first applied, but did not give reasonable results. The vector-space-search program RICS was next applied on the assumption that the molecule has either a β-turn or an extended conformation.[4] The extended model, 20 atoms of Boc–Pro–Val–Gly–OH excluding the N-terminal and side-chain carbons, seemed to be probable, but the partial structure tangent refinement based on these atomic coordinates did not converge properly. It was further assumed that two independent molecules exist as a dimer, as is observed in Boc–Pro–Ile–Gly–OH[3] and Boc–Pro–Val–Gly–OH.[4] This assumption was quite reasonable in view of the similar packing pattern of the two previously analyzed peptides. The phases calculated from the 40 atoms thus obtained easily led to the whole structure. All the H atoms were located on the difference Fourier map.

The structure was refined by the block-diagonal least-squares program HBLS V.[5] The function minimized was $\Sigma\omega(|F_o|-|F_c|)^2$, where the weights, ω, were unity for all the non-zero reflections and zero for the zero reflections. The final R value was 0.097 for all the reflections and 0.075 for the non-zero reflections. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[6] The final positional parameters are given in Tables 2 and 3.† The isotropic temperature factor, $B=4.4$ Å², was assigned to all the hydrogen atoms.

Discussion

The structure of Poc–Pro–Ala–Gly–OH is charac-

† The F_o and F_c tables and anisotropic temperature factor table are kept as Document No. 8109 at the Chemical Society of Japan.

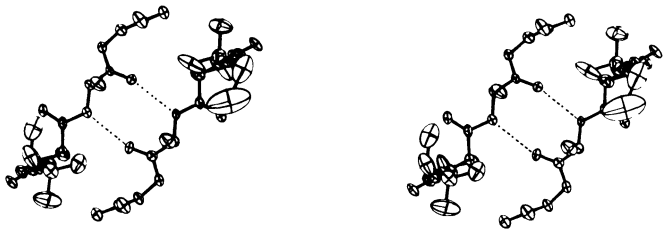

Fig. 1. ORTEP drawing of the dimer structure of Poc–Pro–Ala–Gly–OH *via* β-sheet type hydrogen bonds.

terized by dimer formation with a pair of β-sheet-type hydrogen bonds. The ORTEP drawing[7] of the dimer, viewed along a pseudo-twofold rotation axis, is given in Fig. 1. The bond lengths, bond angles, and torsion angles are shown in Fig. 2. Some abnormal bond lengths in the pentyloxy group may be ascribed to its extremely large thermal motion.

Among the Boc(Poc)–Pro–X–Gly–OH type peptides, those which have Ala, Val, and Ile at the X position crystallize with a similar packing pattern. The crystal-lattice transformation of the alanyl peptide by $a'=a+c$, $b'=b$, and $c'=c$ clearly shows the close relationship between the crystal packings of the alanyl and valyl peptides. Although the space group of the isoleucyl peptide, $P2_12_12$, differs from those of the valyl and alanyl peptides, $P2_1$, the former crystal packing is still close to the latter. That is to say, although the alanyl and valyl peptides are devoid of the twofold axis, there still remains a pseudo-twofold rotation symmetry. The packing similarity is illustrated in Fig. 3, in which dotted lines are drawn in the alanyl and valyl peptide crystals in order to coincide with the unit cell of the isoleucyl peptide.

The similarity of the molecular packing is again obvious in Table 4, which shows the hydrogen-bonding system. No significant difference in the hydrogen-bonding pattern is observed for the two independent molecules (A) and (B); the patterns differ only in the point in which the C-terminal of the molecule interacts with water for the two independent molecules (A) and (B) of Boc–Pro–Val–Gly–OH. Thus, the hydrogen-bonding patterns of three peptides, Boc–Pro–Ile–Gly–OH, Boc–Pro–Val–Gly–OH, and Poc–Pro–Ala–Gly–OH, differ only in the interactions with water molecules, the β-sheet-type hydrogen bonds being completely reserved. The lack of a strict twofold axis in the alanyl and valyl dimer should, therefore,

be attributed to inter-dimer interactions at the C-terminal.

Boc–Pro–Leu–Gly–OH is special in terms of its molecular interaction as well as its molecular conformation. In other words, all three substances besides the leucyl peptide are stabilized by the intermolecular hydrogen bonds, whereas the leucyl peptide is stabilized by the intramolecular one. The dimer structure of the alanyl peptide implies that the C^{β} branched side-chain structure of the valyl and isoleucyl residues is not the only reason for them not to take a β-turn structure, and that the intermolecular interaction emerges as the more important stabilization factor.

No appropriate reason has been given for the uniqueness of the leucyl peptide, but on the basis of these crystal structure analyses, together with other examples, Z–Gly–Pro–Leu–Gly–Pro–OH[8] and Z(*p*-Br)–Gly–Pro–Leu–Gly–OH,[9] we may conclude that there is a stronger tendency for the leucyl residue to be involved in the third site of the β-turn.

Chiral Mesophases of 12-Hydroxyoctadecanoic Acid in Jelly and in the Solid State. II. A New Type of Mesomorphic Solid State

Taro TACHIBANA,* Tomoko MORI, and Kayako HORI
Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received June 18, 1980)

A new type of chiral solid mesophase was obtained by evaporating the solvents from solutions or jellies of chiral 12-hydroxyoctadecanoic acid (12HOA). The mesomorphic solids exhibited some optical properties characteristic of a helicoidal mesophase: (1) spherulitic or Schlieren texture under a polarizing microscope, (2) reflective circular dichroic band, and (3) induced circular dichroic spectra with a single sign due to achiral molecules added to the solid. From the circular dichroic and X-ray studies, it was concluded that the helicoidal mesophase structure exists locally as small domains with a chiral smectic structure within the mesomorphic solids. Microscopic observation revealed that, upon heating, the transition of the mesomorphic solid to the crystalline solid occurred. This process was studied by differential scanning calorimetry. Formation of a variety of helicoidal systems from chiral molecules such as 12HOA and polypeptides was regarded as a phenomenon characteristic of chiral assemblies of amphiphilic molecules.

In the preceding paper,[1] we described a chiral mesomorphic system which occurs in jellies of 12-hydroxyoctadecanoic acid (12HOA) with a solvent such as benzene or carbon tetrachloride. The jellies were shown to be composed of a number of small ordered domains with a supramolecular helicoidal structure such as has been found in the chiral smectic phase. In the course of the investigation, we have found that solids prepared by evaporating the solvents from the jellies showed liquid crystalline textures under a polarizing microscope, and that they exhibited enantiomeric circular dichroism (CD) similar to that observed for the jellies.[2] Further, the solids yielded almost the same X-ray diffraction patterns as those of the crystalline powder. These results indicate that much of the original structure of the jelly is retained in the mesomorphic solid: the solid also is composed of a number of small ordered domains with a chiral structure, which is probably a chiral smectic type.

Mesomorphic solids with a chiral structure were first found for a synthetic polypeptide, poly (γ-benzyl L-glutamate) (PBG), by Samulski and Tobolsky.[3] They reported that it forms stable solid films with a liquid crystalline local structure when the films are made by casting from solutions. This was evidenced from the X-ray study and the swelling experiment. Tachibana and Oda[4] found that solid films prepared from some samples of poly (γ-methyl D(L)-glutamate) (PMG) exhibit iridescent colors due to the selective reflection of circularly polarized light of one sense. Hatano *et al.*[5] observed an induced circular dichroism (ICD) for achiral molecules such as pyrene or acridine orange buried in solids of PMG. All these observations were attributed to the presence of the cholesteric (chiral nematic) phase in the solid films of PBG or PMG. The chiral solid mesophases have been hitherto known only for synthetic polypeptides and other biopolymers,[6] and their mesomorphic behavior was associated with the structure of polymer molecules. However, the chiral solid mesophase of 12HOA is different from that of the above-mentioned polymers in that the former is made up of a low-molecular-weight compound; it is probably a chiral smectic phase. The present paper will deal with the structure and properties of the newly found mesomorphic solid state.

Experimental

Materials. Crystalline samples of chiral 12HOA used were the same ones as in the preceding paper.[1] The solvents used were of reagent grade and further purified by standard methods. The samples of chiral 12HOA in the mesomorphic solid state were (1) apparently amorphous solids obtained by freeze-drying jellies or concentrated solutions, and (2) translucent solid films cast from solutions on quartz plates at room temperature. For freeze-drying, jellies (conc. of 12HOA, 50—100 mmol l^{-1}) were previously frozen at −40 °C in a deep-freezer, and solutions (0.6 mol l^{-1}) in 1-pentanol or 1-hexanol were frozen with liquid nitrogen.

Methods. The apparatus and procedure were essentially the same as those described in the preceding paper.[1] The CD of 12HOA in the solids obtained from jellies and from solutions were measured by a Nujol mull method after the solids had been powdered. The Nujol mull was enclosed between two flat quartz plates in the form of a thin layer. The CD spectra were not modified by varying the content of samples in a Nujol mull. The CD of 12HOA in the solid film state was measured on films formed by evaporation of the solvent from the solution on a quartz plate. The linear dichroism contribution to the observed CD signal was eliminated by rotating the sample around the light beam.[7] Thermal studies were made by the use of a DSC-2 Perkin-Elmer differential scanning calorimeter. The temperature scale was calibrated using the mp of indium supplied by the Perkin-Elmer Corp. The heat of transition was calibrated using the area under the fusion peak of indium and its known enthalpy of fusion (3.26 kJ mol^{-1}). IR spectral change with temperature was recorded on a JASCO IR-G infrared spectrophotometer with a controlled heating apparatus.

Results and Discussion

Formation of Mesomorphic Solids. Chiral 12HOA dissolves readily in cyclohexane, aromatic solvents, and chlorinated solvents such as carbon tetrachloride, chloroform, dichloromethane, and chlorobenzene, and these solutions set into jellies above a certain concentration. The jellies exhibit the optical properties characteristic of the helicoidal mesophase.[1,2] Ap-

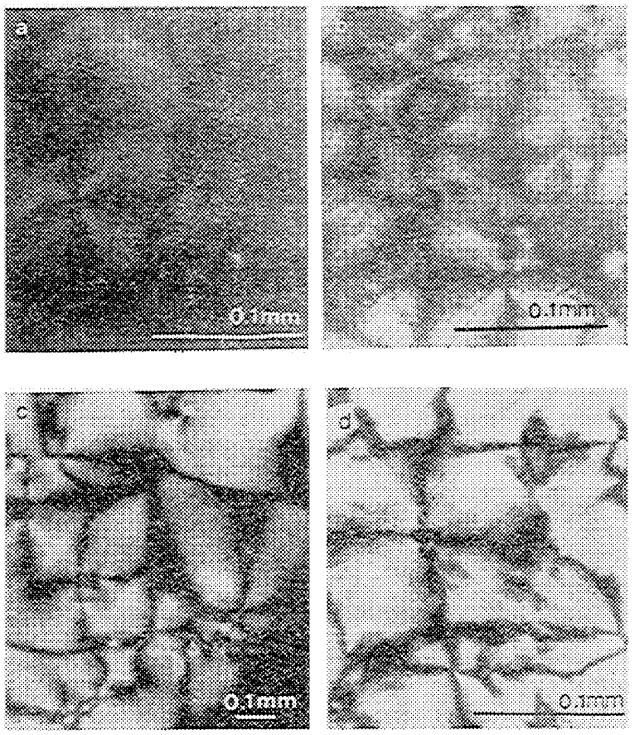

Fig. 1. Typical textures under a polarizing microscope. (a): Spherulitic texture of a CCl_4-jelly (35.2 mmol l^{-1}), (b): spherulitic texture of a solid film made from CCl_4-jelly (35.2 mmol l^{-1}), (c): schlieren texture of a CCl_4-jelly (318 mmol l^{-1}), (d): schlieren texture of a solid film made from CCl_4-jelly (318 mmol l^{-1}).

parently amorphous solids were obtained by freeze-drying the jellies, and solid films were made by casting from the jelly-forming solutions at room temperature. These solids dissolved readily in solvents for the crystalline solid. Visual observation by means of polarizing microscopy showed that these solids displayed, between crossed polarizers, the same spherulitic or Schlieren texture as did the original jellies, irrespective of solvents used, of the supporting material such as quartz, glass, potassium bromide, or calcium fluoride, and of the surface-treatment. The texture was more strikingly observed with the solid films. Figure 1 shows typical examples of the texture. The spherulitic domains in the solid films showed negative birefringence, as did that in the original jellies. These observations demonstrate that the texture in the original jellies was retained, on drying, in the solids, suggesting that the solid formed from the jellies have the same mesomorphic structure as was present in the original jellies.

On the other hand, solutions of chiral 12HOA in normal alcohols with the numbers of carbon atoms from two to seven did not form jellies; but another interesting phenomenon was observed. A drop of each hot concentrated solution of chiral 12HOA in alcohols was placed between two glass plates for microscopic use, allowed to come to room temperature, and continuously observed under a polarizing microscope. At first, there appeared a number of spherulites, but after a short period they were replaced by many needle-like microcrystals. The change from the spherulites to the crystals was faster when the alcohol used was

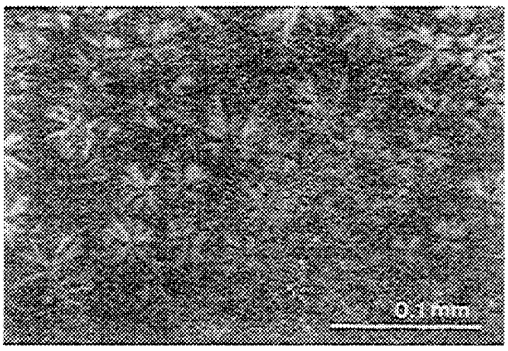

Fig. 2. Spherulites of (*R*)-12HOA in a suspension in 1-hexanol under a polarizing microscope.

shorter in hydrocarbon chain. Therefore, it was difficult to separate the spherulites from the solution by evaporation or filtration. However, it was possible to keep the spherulites stable for some time by mixing the thick suspension of the spherulites with Nujol immediately after occurrence of the spherulites. Figure 2 presents spherulites of (*R*)-12HOA, which were precipitated from 1-hexanol. The spherulites showed birefringence with an optically negative sign, as observed for spherulitic textures in jellies with other solvents such as benzene or carbon tetrachloride. Apparently amorphous solids from alcoholic solutions of chiral 12HOA were obtained by freeze-drying a 1-pentanol or 1-hexanol solution of chiral 12HOA. As will be described later, this solid also is a mesomorphic state.

Circular Dichroism in the Mesomorphic Solids. As described in the preceding paper, jellies of chiral 12HOA with benzene or carbon tetrachloride exhibit a weak but definite CD band in a range of wavelengths in which they absorb no light; the sign is negative for the (*R*)-enantiomer and positive for the (*S*)-enantiomer. The observed CD has been ascribed to the preferential reflection of circularly polarized light of one sense by the jellies in which there are a number of ordered domains with a supramolecular helicoidal structure. Mesomorphic solids of 12HOA prepared by freeze-drying the jellies also were found to exhibit a definite, but broad CD band around 550 nm with negative sign for the (*R*)-enantiomer and positive sign for the (*S*)-enantiomer, while the crystalline powder of chiral 12HOA in Nujol mull showed no CD peak except that due to the molecular absorption ($\approx$200 nm). Figure 3 shows a typical example of the CD spectra of the mesomorphic solids of both enantiomers. Jellies of chiral 12HOA with various solvents exhibited a CD band in a longer wavelength region with an increase in the refractive index of the solvent used. However, mesomorphic solids prepared from the jellies exhibited a CD band in almost the same region of wavelength, 520—580 nm, irrespective of the kind of the solvent used. These data are given in Table 1. From these CD results, it is reasonable to consider that the orginal supramolecular helicoidal structure in jellies (probably a chiral smectic structure) is essentially retained in the mesomorphic solids. Thus, the solids can be regarded as a new type of chiral mesomorphic solid state.

On the other hand, the solid films of chiral 12HOA

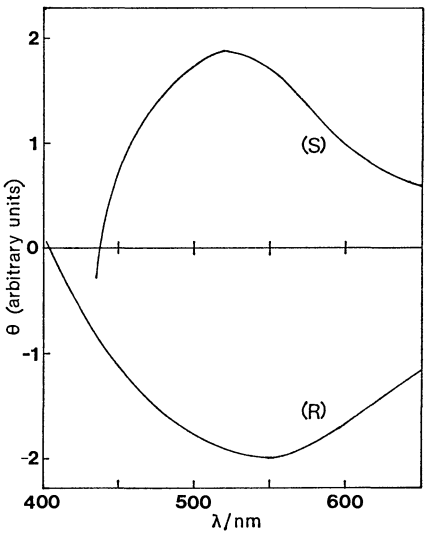

Fig. 3. Enantiomeric CD spectra of the mesomophic solids in Nujol mulls for (*R*)- and (*S*)-12HOA, made from benzene-jellies. The shape of the curve and the location of the peak varied slightly for different samples.

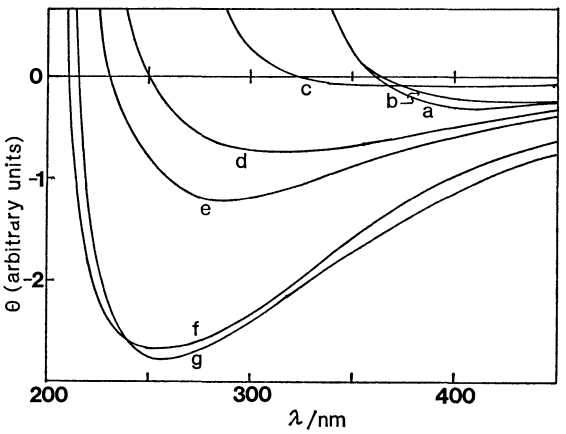

Fig. 4. Changes of CD spectra from a jelly state (128 mmol l^{-1}, with CCl_4) to a solid film state, (a) 5 min, (b) 20 min, (c) 35 min, (d) 40 min, (e) 45 min, (f) 50 min, (g) 80 min after jelly formation.

cast from solutions showed a definite CD band around 250—270 nm with a negative sign for the (*R*)-enantiomer and with a positive sign for the (*S*)-enantiomer, irrespective of the solvents used. Since this result required further investigations, the change of the CD spectrum with drying of the jelly was measured on the films of benzene solution on a quartz plate. The CD change occurred gradually with drying; as the solvent evaporated, the CD increased in its intensity after an initial small decrease and shifted its band maximum from 400 to 250 nm. Figure 4 shows various CD spectra intermediate between the jelly spectrum and the solid film spectrum. This result seemed to be related to a special ordering of the molecules due to some orientational effect at an interface with air or a wall effect of film-supporting plate, but not due to the change of the helical pitch in the supramolecular helicoidal structure, since the CD bands of the solids obtained by freeze-drying locate in a longer wave-

Table 1. The maximal wavelengths of CD of helicoidal mesophase formed from solutions of (*R*)-12HOA in various solvents

	n_D^{20}	λ_{max}/nm		
		Jellies	Solids	
			Freeze-dried	Films
Cyclohexane	1.426	370	520—580	250

Benzene	1.501	480	520—550	260
Chlorobenzene	1.524	530—580	530—590	250

The signs of the CD bands were all negative. Jellies or solids were made with solutions ranging in concentration of (*R*)-12HOA from 50 to 100 mmol l^{-1}. Measurements were all made at room temperature.

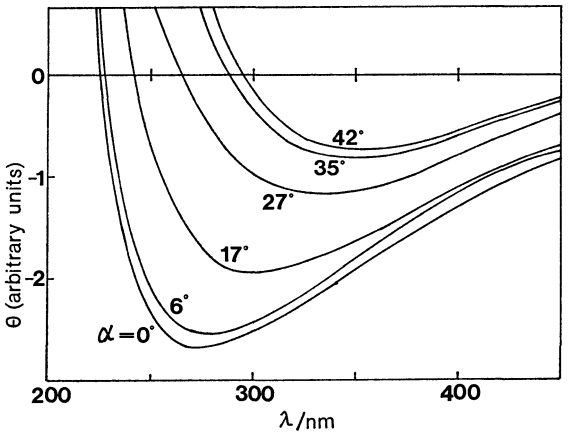

Fig. 5. CD spectra of a solid film for oblique incidence. Here, α denotes the angle between incident beam and normal to the film-supporting plate. Corrections were made for variation of the path length for oblique incidence.

length region than those of the jellies, as shown in Table 1. In order to investigate this possibility, measurements were made on the variation of the CD spectra with the angle, α, between the incident beam and the normal to the film supporting plate. As shown in Fig. 5, the CD spectrum was found to be remarkably dependent on the angle α; the CD intensity decreased and the CD maximum shifted to a longer wavelength side with increasing α. Such a tendency was not observed for the jellies. One can see a striking similarity between the CD spectra in Fig. 4 and those in Fig. 5. This similarity suggests strongly that the CD change shown in Fig. 4 may be explained by the occurrence of an oriented local order in solid films. This deduction was confirmed by the fact that, when the solid films were detached from the quartz plate and crushed to powder, the CD maximum appeared at a wavelength region near to that observed for the amorphous solids obtained by freeze-drying jellies. The details of the alignment in solid films should be examined by using other methods.

Interestingly, both the jellies of (*R*)-12HOA and the solids from them exhibited a CD band with a

negative sign, but suspensions of spherulites of (*R*)-12HOA in alcohols were found to exhibit a positive CD band around 250 nm, regardless of the normal alcohols used. Suspension of (*S*)-12HOA exhibited a negative CD band. Mesomorphic solids from alcohols were obtained by freeze-drying 1-pentanol or 1-hexanol solutions of (*R*)-12HOA, though it was difficult to prepare mesomorphic solid samples by freeze-drying the other alcoholic solutions. The amorphous solids thus obtained exhibited a positive CD band around the same wavelength region as did the suspensions. This CD result indicates that the spherulites in the alcoholic suspensions and the mesomorphic solids from the suspensions have both a supramolecular helicoidal structure, the helical sense of which is opposite to that of a supramolecular helicoidal structure in the mesomorphic solids from the jellies. The chirality of the helicoidal mesophase can be determined by the sign of the reflective CD band; a right-handed (left-handed) helicoidal mesophase reflects right (left) circularly polarized light and transmits left (right) circularly polarized light at the reflective CD band.[8-10] The mesomorphic solids from jellies of (*R*)-12HOA exhibit a negative CD band, and those from alcoholic solutions of (*R*)-12HOA exhibit a positive CD band. This indicates that the circularly polarized light reflected selectively by the solids from jellies is right-handed and that from alcoholic solutions is left-handed. This result leads us to conclude that the screw sense of the supramolecular helicoidal structure in the mesomorphic solids from jellies of (*R*)-12HOA is right-handed and on contrary, that from alcoholic solutions of (*R*)-12HOA is left-handed. Solvent dependence of the chirality of the helicoidal mesophase has already been reported[11] for the cholesteric lyotropic mesophases of polypeptides. The present results show that chiral smectic mesophases of 12HOA also undergo a similar solvent effect.

Induced circular dichroism could be detected for anthracene, which was incorporated into mesomorphic solids from jellies of (*R*)-12HOA. The ICD bands with single negative sign were obtained; these were superimposed on the CD curve of the mesomorphic solids, corresponding to the electronic spectra between 300 and 400 nm. Such ICD characteristics have been reported for jellies of 12HOA,[1,2] and for lyotropic cholesteric liquid crystals of poly(glutamate)[12] and *N*-acyl amino acids,[13] and attributed to a weak interaction between anthracene and the helicoidal systems. The ICD results obtained here also support the assertion that there are helicoidal systems in the mesomorphic solids of 12HOA.

Thermal Behavior. Microscopy with a controlled hot stage showed that, when the solid films were heated, the mesomorphic texture became obscure at about 348 K, followed by the appearance of needle-like microcrystals. Finally the microcrystals melted at 353 K. The microcrystals were stable at room temperature upon cooling and showed no reflective CD bands, indicating the absence of the supramolecular helicoidal structure. This optically observed kinetic behavior was investigated by differential scanning calorimetry (DSC). Figure 6 shows typical thermograms obtained

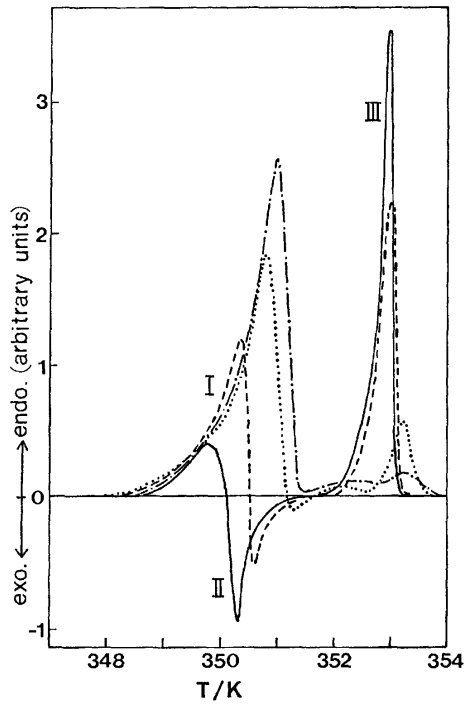

Fig. 6. DSC traces of the mesomorphic solids made from CCl_4-jelly at the various heating rates, ——: 0.31 K min^{-1}, ----: 0.62 K min^{-1}, ·····: 1.25 K min, —·—: 2.5 K min^{-1}.

by heating solid samples made from the carbon tetrachloride-jellies from room temperature to 356 K at four different heating rates. Each DSC trace showed two endothermic peaks, designated as I and III, and one exothermic peak, designated as II. The endothermic peak III occurred at 353 K. The peak III corresponds to the fusion of the needle-like microcrystals observed under a microscope, and occurred very close to the melting point (353.6 K) of the crystalline solids precipitated from solution. The endothermic peak I, which began to appear at 348 K at the appropriate heating rate, indicates a phase transition from the mesomorphic solid to a more disordered solid state. This peak did not recur upon reheating a sample cooled to room temperature from the melt, and the second run showed only the peak at 353 K. This result indicated that the mesomorphic solid state is a monotropic modification which occurs only when it separates out from solution.

It is noticeable that the endothermic peak I was followed by an exothermic peak II within an extremely narrow temperature range. The combination of the DSC result with the microscopic observations would suggest that, upon heating, the mesomorphic solid state transformed into a more disordered solid state at 348 K with an endothermic process (peak I) and that, immediately after the transformation, crystal formation from the disordered solid state occurred with the exothermic process (peak II).

The thermograms for the mesomorphic solids were greatly dependent upon the heating rate, as shown in Fig. 6; those for crystalline samples of 12HOA, however, did not show such dependence. Therefore, the heating rate dependence of DSC traces for the

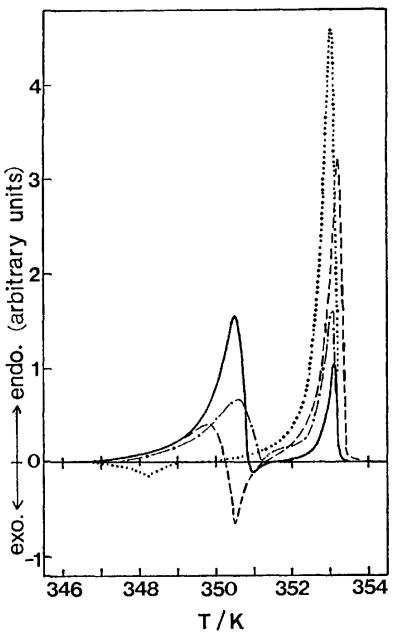

Fig. 10 DSC traces of the mesomorphic solids at a heating rate of 0.31 K min^{-1}.

vary with the solvents used for preparation of the solids. The DSC trace of the solid from the cyclohexane-jelly was missing the endothermic peak I observed for that from the carbon tetrachloride-jelly. The solid from the chlorobenzene-jelly gave a larger endothermic peak I and a smaller endothermic peak III, in comparison with the endothermic peaks I and III, observed for the solid from the carbon tetrachloride-jelly. The DSC curves with an intermediate shape were obtained for the solids from other jellies and alcoholic solutions. In every case, as the heating rate became faster, the endothermic peak I for the transition of the mesophase to a more disordered phase became higher and the endothermic peak III became lower. When the mesomorphic solids are formed by evaporating the solvents from the jellies or the solutions of 12HOA, the degree of organization of the hydrocarbon chains in the smectic domains probably is different, depending on the solvent used. This may explain the difference in the DSC traces and in the CD spectra of the solids prepared by using various solvents.

X-Ray Diffraction Studies. Figure 11 shows the X-ray diffraction patterns of a powdered sample of the mesomorphic solids and of the crystalline solids, together with that of the benzene-jelly. The mesomorphic solids exhibit the patterns which are very similar to those of the powdered crystalline solids, although each peak in the former is broader than that in the latter. These patterns are composed of comparably sharp peaks corresponding to a long spacing of 4.67 nm (shorter than twice the extended length of 12HOA molecule)[1] and peaks corresponding to short spacings (below 0.46 nm) associated with the interchain packing. This result indicates that there is little difference in short-range-order structure between the mesomorphic solid and the crystalline solid and that, consequently, the mesomorphic solids are composed of a number of small domains with a lamellar structure similar to that in the crystalline solid, though the organization of the alkyl chains in the lamellar structure in the former is less ordered than that in the crystalline solid. Since the lamellar mesophase is a separate phase from the crystalline phase, as evidenced by the thermal studies, it is concluded that the mesophase has a smectic structure, which often forms lyotropic liquid crystals of amphiphilic molecules.

The X-ray examination was also done for the solid films formed by air-drying the benzene-jellies on a sample plate. The diffraction patterns were almost the same as those of the mesomorphic solids obtained by freeze-drying the jellies, except that the patterns from the solid films were missing the reflection peak corresponding to a short spacing of 0.46 nm. The 0.46 nm peak was recovered for the powdered sample obtained by crushing the solid films which were detached from the plate. Therefore, this effect is considered to be attributable to the same orientation effect as has been found in the CD study of the solid films.

Concluding Remarks. Helicoidal Order in Micellar and Polymer Systems: In the present series of papers (I and II), it was described that chiral 12HOA can form lyotropic helicoidal mesophase and solid analogues. This acid and its salt have been found to form helically twisted microfibrils,[17,18] Here it would

Table 2. Similarity of mode in molecular association between PMDG and (*R*)-12HOA

State	Aggregated forms	
	PMDG	(*R*)-12HOA
Dil soln	α-Helix	Chiral micelle
Concd soln and amorphous solid	Helicoidal mesophase (chiral nematic)	Helicoidal mesophase (chiral smectic)
Fibrous state	Helically twisted fibrils (right-handed)	Helically twisted fibrils (left-handed)

be useful to call attention to the helicoidal association of polymer molecules of some polypeptides such as PBG or PMG. That is, these polymer molecules can assemble into a variety of helicoidal forms,[3] *i.e.* (1) helicoidal configuration[3] of single molecule (α-helix), (2) helicoidal (chiral nematic) mesophase in solution above a critical concentration, (3) solid films with helicoidal (chiral nematic) local order, and (4) helically twisted microfibrils.[19] Table 2 illustrates the similarities between 12HOA and PMG with regard to the mode of molecular association. Here a micelle of 12HOA corresponds to the α-helix of a PMG molecule, since the former itself also constitutes a chiral system[20] as does the α-helix. Polypeptides are considered to be amphiphilic in nature since they can form stable monomolecular films at an air-water or oil-water interface. Furthermore, it should be pointed out that both polypeptides and 12HOA are capable of forming the inter- or intramolecular hydrogen bonds. Undoubtedly these common properties of both chiral amphiphiles are responsible for the similarities in the formation of helicoidal assemblies. Chiral 12HOA is a small molecule, but these molecules can link with each other to form "a chiral polymer" by intermolecular hydrogen bonding between the hydroxyl groups; as a result, these "polymer molecules" behave like chiral amphiphilic macromolecules such as polypeptides. The polymer-like behavior of chiral 12HOA that forms jellies with solvents, spherulites or microfibrils are well explained by the formation of the hydrogen-bonded polymers.

The similarity between chiral 12HOA and polypeptides led us to infer that there are some other amphiphiles exhibiting a similar behavior. In fact, this has been shown in several reports. Sakamoto *et al.*[13,21] found that optically active *N*-acyl amino acids such as *N*-lauroyl amino acid form cholesteric mesophase in apolar solvents and form chiral aggregates in polar solvents. They ascribed this result to chiral intermolecular hydrogen bonding. Sato and Hatano[22] found that the nonionic surfactant, "Tween 80" (Atlas Powder Co.) induced CD spectra to an achiral dye solubilized into the micellar solutions. They ascribed this result to the formation of a helicoidal mesophase in concentrated aqueous solution of the surfactant. Kunitake *et al.*[23] observed ICD spectra of a hydrophobic azo dye added to synthetic bilayer membranes of chiral dialkylammonium amphiphiles derived from alanine and glutamic acid. This result seems to suggest that the bilayer membranes constitute a chiral mesomorphic system.

The association behavior of bile acids and their salts also is worthy of remark. Several workers[24,25] have reported ICD results for achiral molecules dissolved in aqueous micellar solutions of sodium deoxycholate, suggesting the fomation of chiral micelles. Ramanathan *et al.*[26] observed that deoxycholic acid formed helical microfibrils when its water suspensions were dried on carbon films and that the helical twist was right-handed. The gelation of sodium deoxycholate solutions also has been often investigated, and the role of hydrogen bonding in the molecular association has been discussed.[27,28] These results seem to suggest that the gels of the deoxycholate can form helicoidal mesophases under a suitable condition, but the evidence has not yet been obtained. All the results observed with these chiral amphiphiles indicate that chiral amphiphiles constitute chiral or helicoidal micellar systems throughout the formation of sequences of intermolecular hydrogen bonds.

In general, amphiphilic molecules exhibit a variety of modes of molecular association, such as micelle, mono- and multilayers, bilayer membrane (liposome), smectic phase, and nematic phase. In addition, when amphiphilic molecules have a chiral structure, they are able to take a preferred orientation in the molecular assemblies, leading to occurrence of chiral assemblies. The resulting assemblies have a different structure from that of assemblies of achiral molecules or racemate molecules. This is reflected in the critical micelle concentration of solution[29] or in the compression curve of monolayers at an air-water interface.[30,31]

In a macroscopic scale observable with a microscope, amphiphiles form thin ribbons or microfibrils. This has been investigated most often with soaps and phospholipids. In some cases, these ribbons or fibrils twist helically regardless of whether the amphiphiles are chiral or not. Then, achiral amphiphiles produce both right-handed and left-handed helices in equal numbers, *e.g.* as have been observed for helical microfibrils from calcium tallowate in grease or from alkali-metal soaps. On the other hand, chiral amphiphiles produce a one-handed helix depending on the chirality of the molecule, though the helical sense is influenced by solvent effects.

The morphology of the assemblies of chiral amphiphilic molecules is of biological interest, since helically twisted lamellae or microfibrils are often encountered in biological systems. The present study suggests that these biological materials form helicoidal mesophases. On this connection, it is instructuve to cite a recent review by Bouligand,[6] who collected examples illustrating that biopolymers assemble into cholesteric liquid crystals or into more or less solid analogues, and that certain fibrous and regularly twisted materials can be considered as polymerized cholesterics.

We wish to thank Miss Y. Onishi for her co-operation in the experimental work, Dr. K. Sakamoto of Central Research Laboratories, Ajinomoto Co., Inc., for his valuable comments, Professor M. Hatano of

Tohoku University for valuable information regarding the signs of CD, and Professor M. Nakazaki of Osaka University for the kind advice concerning the definition of the handedness in a helix. We also are indebted to Professor J. Kumanotani of the University of Tokyo, for giving us the opportunity to use a DSC-2 Perkin-Elmer differential scanning calorimeter.

The Electronic Structures of Condensed Materials Studied by Ultraviolet Photoelectron Spectroscopy

Takashi TAKAHASHI and Yoshiya HARADA*

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received June 24, 1980)

The solid phase ultraviolet photoelectron spectra of water, carbon disulfide, benzene, *N*-methylaniline, and pentane condensed on a gold substrate at 77 K were measured. The features of the spectra are similar to those of the corresponding gas phase spectra. The difference between the gas and solid phase *IP*'s, the relaxation shift, is nearly constant for each compound studied except for the case of water, where the $3a_1$ molecular orbital state in solid is affected by the hydrogen bonding. The values of the relaxation shift for water, benzene and carbon disulfide are 1.1—1.3 eV, while those for *N*-methylaniline and pentane are 0.6 and 0.7 eV, respectively. The small values for the latter compounds are due to the fact that the molecules are loosely packed in the solids. The mechanisms of the band broadening for the molecular crystal are discussed in relation to the spectrum of solid carbon disulfide. For *N*-methylaniline the spectra of the gas, liquid and solid phases were compared. To our knowledge, this is the first case in which the electronic structures of all the three phases are studied by ultraviolet photoelectron spectroscopy.

The technique of photoelectron spectroscopy provides direct information about the electronic structures of materials in the gas and solid phases. Therefore, it is of considerable interest to investigate the change in the electronic structure due to the phase change by means of photoelectron spectroscopy.

In this work we measured the ultraviolet photoelectron spectra of water, benzene, carbon disulfide, *N*-methylaniline, and pentane in the solid phase and compared them with the corresponding spectra reported for the gas phase. Since all the compounds are liquids at room temperature, they are condensed easily without contamination during exposure. Water, carbon disulfide, benzene, and pentane were chosen as typical organic or inorganic compounds. *N*-methylaniline was studied, because its He I spectrum has been measured in the liquid state[1] and we can compare the electronic structures of all the three phases of gas, liquid, and solid.

Experimental

The samples of benzene, carbon disulfide, *N*-methylaniline, and pentane were distilled twice under vacuum. For the water sample, distilled water was used.

The measurements of the spectra were carried out using an ultra-high vacuum photoelectron spectrometer, which has a preparation and an analyser chamber.[2] The base pressure of the spectrometer was less than 3×10^{-10} Torr. The He I (21.22 eV), Ne I (16.85 and 16.67 eV) and Ar I (11.83 and 11.62 eV) resonance lines were used as the exciting sources. For the Ne or Ar doublet, the mean value of the energies was used to analyse the spectra. The resolution of the electron energy analyser was approximately 0.15 eV FWHM (full width at half maximum) in the present experiment.

In the preparation chamber the sample vapour was condensed onto a freshly deposited gold film held at 77 K. The vapour was let in the chamber at a point just above the substrate through a variable leak valve and a copper pipe. The pressure was less than 1×10^{-8} Torr during the condensation. To prevent the sample charging effect the exposure was stopped at intervals to monitor adsorbate peaks. The spectra shown in the following section are those which were measured just before the peak shift caused by the charging sets in.

Results and Discussion

Water (H_2O). Figure 1 illustrates the change in the He I spectra showing the condensation of water on a gold film at 77 K. To obtain the ionization potential (*IP*), the kinetic energy, E_K, of the electrons was determined by taking the zero of kinetic energy as the low energy cutoff of each spectrum† and then the relation $IP=h\nu-E_K$ was used. This method gives the work function of gold to be 4.9 eV, which is in good agreement with the value, 4.9—5.1 eV, recommended by Eastman.[3]

In Fig. 1 the features of the spectra at about 11,

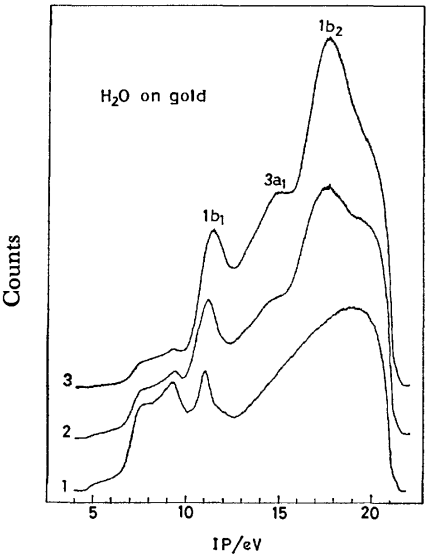

Fig. 1. He I spectra of water condensed on Au at 77 K. (1): Clean gold, (2): H_2O on gold, exposure time, 50 s at 5×10^{-9} Torr, (3): H_2O on gold, exposure time, 100 s at 5×10^{-9} Torr.

† To obtain the cutoff a small shoulder near 0 eV kinetic energy was taken out of consideration, because it is due to stray electrons.

15, and 17.5 eV correspond to the $1b_1$, $3a_1$, and $1b_2$ bands in the spectrum of gas phase water. The large peak between 18 and 21 eV is due to inelastically scattered electrons in the solid film.

As can be seen in Fig. 1, the structures of the spectra between 5 and 10 eV originated from the gold substrate little shift when water molecules are adsorbed. Similar results are observed for all the samples studied and are in contrast with the results observed by Yu *et al.* on a MoS_2 substrate,[4] where the MoS_2 bands gradually shift as coverage increases. They attributed the shift to a dipole between the MoS_2 substrate and the adsorbed molecules. In the case of a metal substrate, the thickness of the electron deficient layer due to the adsorbed gas is much less than the escape depth of photoelectrons. Therefore, the dipole effect may not cause the observable shift of the gold substrate peaks.

In Table 1 the gas phase vertical *IP*'s of water[5] are compared with the solid phase ones. The difference between the gas and solid *IP*'s, the relaxation shift, R ($=IP(\text{gas})-IP(\text{solid})$), mostly corresponds to the polarization energy due to the molecular ion left in the solid after a photoelectron is removed.

TABLE 1. THE VERTICAL IONIZATION POTENTIALS OF GAS AND SOLID WATER TOGETHER WITH THE RELAXATION SHIFTS

Orbital	*IP*(gas)[5] / eV	*IP*(solid) / eV	R[a] / eV
$1b_1$	12.62	11.3	1.3
$3a_1$	14.78	15.0	−0.2
$1b_2$	18.55	17.6	1.0

a) $R=IP(\text{gas})-IP(\text{solid})$.

Atkinson *et al.* have also measured the He I spectrum of water adsorbed on gold and found the structures at 6.3, 10.2 and 12.6 eV below the Fermi level of gold.[6] Adding 4.9 eV for the work function of gold, we have 11.2, 15.1, and 17.5 eV for the ionization potentials of solid water, which are in good agreement with the values obtained in the present experiment (Table 1).

In Table 1 the relaxation shift of the $3a_1$ state is negative. As was pointed out by Campbell *et al.*,[7] on solidification of water, the $3a_1$ molecular orbital state is predominantly affected by the hydrogen bonding because of its orbital geometry, and appears considerably perturbed in the solid state spectrum. Therefore, the negative value of the relaxation shift for the $3a_1$ state may be due to the stabilization of the $3a_1$ orbital caused by the hydrogen bonding and also to the change in the band shape.

Benzene (C_6H_6). Figure 2 shows the He I spectra of benzene condensed on the gold substrate. The characteristic features of the solid spectrum shown in the figure are summarized in Table 2 together with the corresponding features of the gas phase spectrum.[8,9] Since the e_{2g} and $a_{2u}(\pi)$ bands are not well resolved in the gas phase spectrum, they are observed as a single band at 10.7 eV in the solid phase

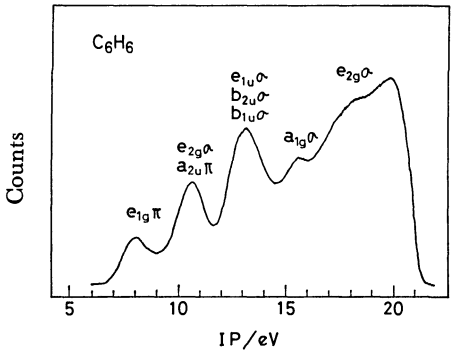

Fig. 2. He I spectrum of benzene condensed on Au at 77 K.

TABLE 2. THE VERTICAL IONIZATION POTENTIALS OF GAS AND SOLID BENZENE TOGETHER WITH THE RELAXATION SHIFTS

Orbital	*IP*(gas)[8,9] / eV		*IP*(solid) / eV	R[a] / eV
$1e_{1g}\pi$	9.24		8.1	1.1
$3e_{2g}$	11.49	11.8[b]	10.7	1.1
$1a_{2u}\pi$	12.3			
$3e_{1u}$	13.8			
$1b_{2u}$	14.7	14.3[b]	13.1	1.2
$2b_{1u}$	15.4			
$3a_{1g}$	16.85		15.5	1.3_5
$2e_{2g}$	19.2		—	—

a) $R=IP(\text{gas})-IP(\text{solid})$. b) Centre of the bands.

spectrum (Fig. 2). Similarly the band at 13.1 eV is correlated to the e_{1u}, b_{2u}, and b_{1u} bands in the spectrum of the gas.

As shown in Table 2, the relaxation shift of solid benzene is 1.1—1.3 eV, which is in good agreement with the corresponding values obtained by Yu *et al.* (1.0 eV)[4] and Grobman and Koch (1.15 eV).[10]

The observed relaxation energies for naphthalene,[10] anthracene[10] and naphthacene[11] are 1.1, 1.2, and 1.0—1.3 eV, respectively. Thus the relaxation energy is essentially constant for the aromatic molecules, benzene to naphthacene. This means that the value of the relaxation energy for polycyclic aromatic crystals depends on the molecular packing, irrespective of the size of the molecules.

Carbon Disulfide (CS_2). Figure 3 shows the He I, Ne I and Ar I spectra of carbon disulfide condensed on the gold substrate. The peak positions in the spectra are the same for the three different excitation sources.

In Table 3 the vertical *IP*'s of solid carbon disulfide obtained from Fig. 3 are compared with those of the gas.[8] The relaxation shift for each band is 1.2—1.3 eV, being nearly constant as in the case of benzene.

It is worthwhile to note that the width of each band in the solid spectra is fairly constant and also does not depend on the excitation energy (Fig. 3). Subtracting the background emission due to the secondary electrons, we obtained the FWHM's (full width at half maximum) of the π_g, π_u, σ_u, and σ_g bands to be 0.8_5, 0.9_5, 0.8_0, and 0.9_0 eV, respectively. On the other hand, the corresponding FWHM's estimated

Table 3. The vertical ionization potentials of gas and solid carbon disulfide together with the relaxation shifts

Orbital	IP(gas)[8]	IP(solid)	R[a]
	eV	eV	eV
π_g	10.10	8.8	1.3
π_u	12.84	11.6	1.2
σ_u	14.48	13.2	1.3
σ_g	16.20	14.9	1.3

a) $R=IP(\text{gas})-IP(\text{solid})$.

from the envelope of the vibrational structure of the gas phase spectrum are very different and are 0.10, 0.27, 0.03, and 0.03 eV, respectively.[8] The small FWHM values for the σ_u and σ_g bands in the gas spectrum are due to the fact that each of these bands consists of the strong 0-0 peak with the very weak vibrational progression.

In order to interpret the difference in the bandwidth between the solid and gas phase spectra, it is necessary to know the mechanisms of broadening of the solid state bands. Since, as described above, the bandwidth in the solid spectra little depends on the excitation energy, the width of the upper state in solid (conduction bandwidth) is considered not to make large contribution to the broadening of the bands in contrast to the cases of metals or ordinary semiconductors. For the molecular crystal such as solid carbon disulfide, possible dominant mechanisms of the broadening are:[12] (a) the polarization energy dispersion due to the lattice vibrations in the neutral state, (b) the energy loss of the photoelectrons during their transport to the surface as a result of the excitations of the intramolecular vibrations of neutral molecules, and (c) the difference in the ionization potential between the surface and the bulk. The FWHM of the solid band expected from the mechanism (a) may be a few tenth of a relaxation energy R.†† Therefore, it is possible in the present case that the

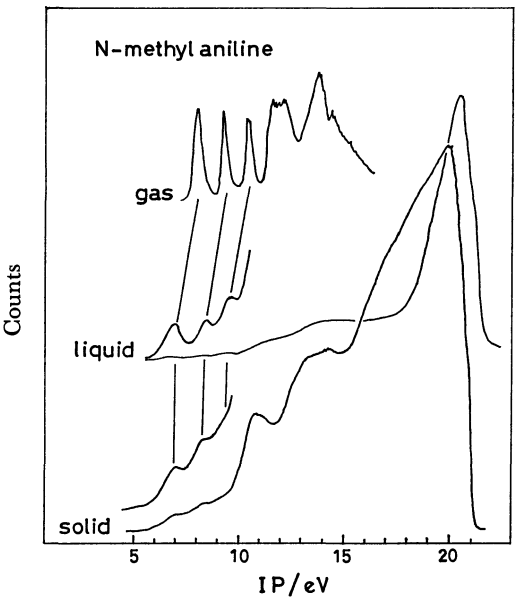

Fig. 4. He I spectra of *N*-methylaniline in the gas,[8] liquid[1] and solid phases.

Table 4. The vartical ionization potentials of gas, liquid, and solid *N*-methylaniline together with the relaxation shifts

π_3	9.05	8.6	8.4	0.4_5	0.6_5
n	10.20	9.8	—	0.4	—
σ	11.5	—	(11.0)	—	(0.5)

a) $R_1=IP(\text{gas})-IP(\text{liquid})$. b) $R=IP(\text{gas})-IP(\text{solid})$.

mechanisms (b) and (c) also contribute to the bandwidth ($\approx$0.9 eV) which amounts to about 70% of the relaxation energy (1.2—1.3 eV). The fact that the FWHM's of the solid phase bands are nearly constatnt irrespective of those of the gas phase bands suggests that the mechanism (b) involving the energy loss due to the intramolecular vibrations makes considerable contribution to the broadening of the solid bands.

N-*Methylaniline* ($C_6H_5NHCH_3$). Figure 4 shows the He I spectrum of *N*-methylaniline condensed on the gold substrate together with the spectra in the gas[8] and liquid[1] phases. To our knowledge, *N*-methylaniline is the first compound whose ultraviolet photoelectron spectrum has been measured in all the three phases of gas, liquid, and solid. As is seen in Fig. 4, the bands are more diffuse in the order of gas, liquid and solid, the order of increasing intermolecular interaction.

Table 4 gives the vertical *IP*'s of *N*-methylaniline in the three phases together with the relaxation shifts, R_1 and R for the liquid and solid phases. In the table we find that the value of R_1 (0.4—0.5 eV) is

†† For example, in the case of solid naphthacene, the estimated FWHM due to the machanism (a) is 0.3 eV, the relaxation energy being *ca.* 1.2 eV.[12]

not much different from that of R ($\approx$0.6 eV). Since the relaxation shift is mostly due to the polarization energy of the neutral molecules surrounding a molecular ion, the small difference between the two sets of values suggests that no large change in the intermolecular distance arises on going from liquid to solid.

Pentane (C_5H_{12}). Figure 5 shows the He I spectrum of pentane condensed on the gold substrate. Since the gas phase spectrum of pentane is diffuse and its band assignment has not been well established, we compared the positions of prominent features of the gas phase spectrum[14] with those of the solid phase one (Table 5).

As is shown in Table 5, the relaxation shift of pentane is 0.7 eV, which is small compared with those of the other samples studied (1.1—1.3 eV), except for the case of *N*-methylaniline (0.6 eV). The molecule of pentane is chain-like and has freedom of rotation about its CC single bonds. When such molecules are solidified, especially at low temperature, they are expected to be loosely packed in solid. This may be the reason why pentane shows a small relaxation shift. In the case of *N*-methylaniline, its large substituent of the benzene ring may hinder a close packing of molecules in solid, also leading to a small relaxation shift.

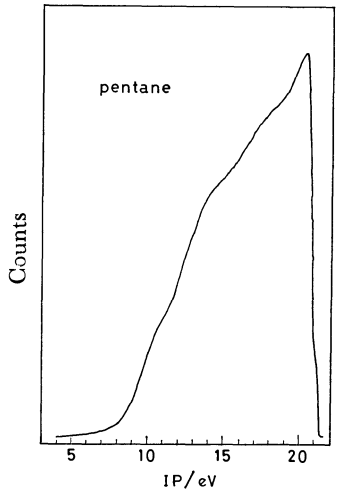

Fig. 5. He I spectrum of pentane condensed on Au at 77 K.

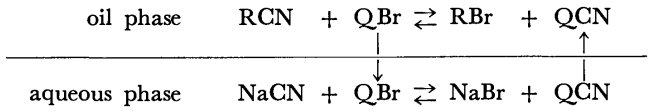
(Received June 25, 1980)

The static and kinetic feature of the reaction of sodium cyanide with 1-bromoalkanes in the presence of various phase transfer catalysts was investigated in the oil/water system by using a layered scintillation method and the mechanism of catalytic action was discussed. From the measurement of equilibrium constants for both reactions of hexadecyltrimethylammonium cyanide with 1-bromooctane and of sodium cyanide with hexadecyltrimethylammonium bromide in organic phase, it was pointed out that the latter reaction was responsible for the advance of overall reaction. It was also found that majority of the phase transfer catalysts exist in the oil phase. It was suggested that an uptake reaction of cyanide ion from the aqueous phase at the interface is essential and that the reaction process does not follow a simple model proposed by Starks *et al.*

It is well known that the presence of a small quantity of phase transfer catalyst such as hexadecyltrimethylammonium bromide remarkably promotes the reaction of 1-bromooctane in the organic phase with sodium cyanide in the aqueous solution, although the reaction does not take place even after two weeks boiling in the absence of the catalyst. The mechanism of this reaction has been considered by Starks *et al.* as follows:[1)]



where QBr denotes quaternary ammonium bromide. It has been postulated that the circulation of the catalyst between the two phases dominates. On the other hand, a few papers against this simple model have also been presented.[2–4)]

In the preceding papers,[5–8)] a new technique using liquid scintillation counter has been devised for the study of the interaction in the oil/water system. This method has been proved to be very useful for the direct measurement of the dynamic and static interaction including the interfacial accumulation as well as the oil-water partitioning of radioactive species.

In this paper, the application of this method to the reaction of various 1-bromoalkanes with sodium cyanide in the presence of the phase transfer catalysts is described from both views of kinetics and statics and the mechanisms of catalytic action is briefly discussed.

Experimental

The procedure for measurement was described elsewhere.[5,6)] The pH of the aqueous solution was adjusted at 9.0 with Menzel's buffer solution. The experiments were carried out at 20±1.5 °C except for the case otherwise described.

Materials. In this study, 1-bromobutane, 1-bromohexane, 1-bromooctane, 1-bromodecane, 1-bromododecane, 1-bromohexadecane, bromobenzene, and 1-bromonaphthalene were used as reagents in organic phase. In these, 1-bromooctane was purified by fractional distillation. Quaternary ammonium bromides used here as the phase transfer catalysts were tetramethylammonium bromide(Me_4NBr), tetraethylammonium bromide(Et_4NBr), tetraprorylammonium bromide(Pr_4NBr), tetrabutylammonium bromide (Bu_4NBr), trimethylvinylammonium bromide(Me_3VNBr), benzyltriethylammonium bromide($BeEt_3NBr$), hexadecyltrimethylammonium bromide(CTAB), ethyldimethylhexadecylammonium bromide($CEtMe_2NBr$), and hexadecylpyridinium bromide(CPydBr). Most of these reagents were commercial ones and were used without further purification unless otherwise stated. Radioactive sodium cyanide-^{14}C obtained from New England Nuclear was used as a nucleophilic agent for the displacement reaction, and it was diluted to a suitable specific activity 9.16 Ci/mol with nonradioactive sodium cyanide of guaranteed grade. Radioactive and nonradioactive hexadecyltrimethylammonium cyanide(CTACN) were prepared from CTAB by using anion exchange resin in the CN form. Radioactive [methyl-^{14}C] hexadecyltrimethylammonium bromide(CTAB-^{14}C) was purchased from The Radiochemical Center, England. 2,5-Diphenyloxazole (PPO) and 1,4-bis-(5-phenyloxazolyl)benzene (POPOP) obtained Packed Instrument Co., Ltd. were used as scintillators.

Procedure. Layered Scintillation Method: The scintillator solution without a reactant (ST) was prepared by dissolving 2 g PPO and 0.125 g POPOP into 1000 cm^3 of a toluene solution containing 10 vol% 1-butanol. The scintillator solution with a reactant(ST(R)) was prepared by dissolving a given amount of bromoalkanes in ST.

First, 10 cm^3 of ST(R) or ST was layered on 10 cm^3 of the aqueous solution of cyanide ion labeled with ^{14}C, and the time course of increase in the amount of radioactive substance entering into the scintillator phase was measured by a liquid scintillation counter, Beckman LS-100.

After the reaction reached equilibrium, 0.5 cm^3 of the aqueous solution and 5 cm^3 of the scintillator solution were taken from each phase. The concentration of the radioactive substance in each phase was determined by the standardization procedure as follows; 0.5 cm^3 of the radioactive aqueous solution was mixed with 5 cm^3 of ST, 5 cm^3 of ST(R) (or ST) and 10 cm^3 of methanol. 5 cm^3 of the scintillator solution was mixed with 0.5 cm^3 of nonradioactive solution of cyanide ion having the same composition as the radioactive one, 5 cm^3 of ST and 10 cm^3 of methanol. Since the quenching efficiencies are the same for these standardized solutions, we can determine the partition coefficient of the total radioactive cyanide from the ratio of the counts of the two standardized solutions. The partition coefficients measured in this study were as follows:

1) $$K_{CN} = \frac{[CN]_o}{[CN]_w} = \frac{[NaCN]_o + [QCN]_o}{[NaCN]_w + [QCN]_w}$$

(Partition coefficient of cyanide ions in the absence of a 1-bromoalkane and in the presence of the catalyst)

2) $K^{R}_{CN} = \dfrac{[CN]_o + [RCN]_o}{[CN]_w}$

$= \dfrac{[NaCN]_o + [QCN]_o + [RCN]_o}{[NaCN]_w + [QCN]_w}$

(Partition coefficient of cyanide ions in the presence of a 1-bromoalkane and catalyst)

3) $K^{R}_{NaCN} = \dfrac{[NaCN]^{R}_{o}}{[NaCN]_w}$

(Partition coefficient of sodium cyanide in the absence of catalyst and in the presence of a 1-bromoalkane)

4) $K_{NaCN} = \dfrac{[NaCN]_o}{[NaCN]_w}$

(Partition coefficient of sodium cyanide in the absence of both the catalyst and a 1-bromoalkane)

5) $K_{QCN} = \dfrac{[QCN]_o}{[QCN]_w}$

(Partition coefficient of CTACN in the absence of a 1-bromoalkane when QCN is used in place of the mixture of NaCN and QBr)

6) $K^{R}_{QCN} = \dfrac{[QCN]_o + [RCN]_o}{[QCN]_w}$

(Partition coefficient of CN in the presence of a 1-bromoalkane when QCN is used in place of the mixture of NaCN and QBr)

7) $K_Q = \dfrac{[Q]_o}{[Q]_w} = \dfrac{[QCN]_o + [QBr]_o}{[QCN]_w + [QBr]_w}$

(Partition coefficient of Q^{+}-^{14}C)

In these equations the subscripts o and w, and superscript R refer to oil and aqueous phase and the reactant, respectively.

Potentiometric Measurement: The concentrations of bromide and sodium ions in the aqueous phase were potentiometrically measured by Horiba N-7 Ion Meter with the aid of the specific ion electrode for bromide and sodium ions of Activion Halstead and Horiba Ltd., respectively. In some instances, the concentration of cyanide ion was also measured with the cyanide ion electrode of Orion Research Inc.. The experimental conditions were the same as those in the layered scintillation method.

Results

Time Courses of Permeation of Hexadecyltrimethylammonium Ions and Cyanide Ions. The time course of the permeation of hexadecyltrimethylammonium ions from aqueous to organic phase without agitation is shown in Fig. 1. This figure indicates that the time courses of hexadecyltrimethylammonium entering into the organic phase of the systems with and without 1-bromooctane are almost the same and reach equilibrium within 2 h.

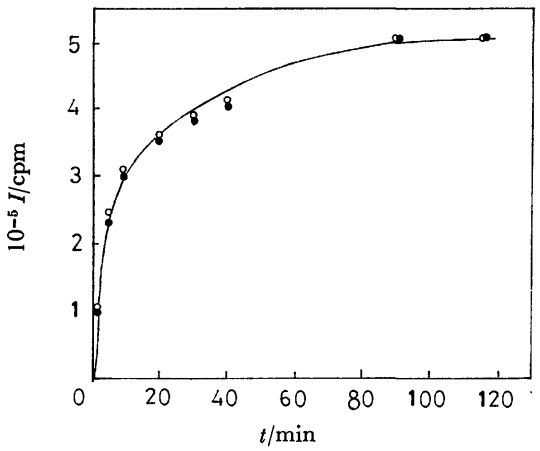


Fig. 1. Time courses of permeations of hexadecyltrimethylammonium ions into scintillator phase. ○: In the absence of 1-bromooctane, ●: in the presence of 115 mM 1-bromooctane. Initial concentration of CTAB is 0.1 mM.

On the other hand, the permeation of cyanide ions is much slower than that of hexadecyltrimethylammonium ions and it takes 20—30 h to reach equilibrium. The time course of increasing counting rate can be expressed by

$$I_\infty - I = I_\infty \exp(-kt) \quad (1)$$

for the system without the displacement reaction of 1-bromoalkane and cyanide ion in the organic phase, while it becomes

$$I_\infty - I = I_{1\infty}\exp(-k_1 t) + I_{2\infty}\exp(-k_2 t) \quad (2)$$

for the system with the displacement reaction, where I denotes the counting rate at a time t, I_∞, $I_{1\infty}$, and $I_{2\infty}$, those at an infinite time and k, k_1, and k_2, the rate constants.

The estimated values of rate constants are summarized in Table 1. In these rate constants, k_1 is thought to be the rate constant for the permeation of cyanide ion into the organic phase, since the value of k_1 is near to that of k for the system without the displacement reaction of 1-bromooctane and cyanide ion. Hence, k_2 may be refered to the rate constant for the displacement reaction in the organic phase. An agitation may cause the increase in k_1.

Partition Coefficients for Various Systems. Table 1 also shows the partition coefficients of cyanide ions

TABLE 1. PARTITION COEFFICIENTS OF CYANIDE IONS AND RATE CONSTANTS

Aqueous phase	NaCN* [a]	NaCN*	NaCN*+CTAB	NaCN*+CTAB	CTACN*	CTACN*
Organic phase	—	$C_8H_{17}Br$	—	$C_8H_{17}Br$	—	$C_8H_{17}Br$
Partition coefficient	0.206 (K_{NaCN})	0.205 (K^{R}_{NaCN})	0.207 (K_{CN})	0.478 (K^{R}_{CN})	0.196 (K_{QCN})	0.568 (K^{R}_{QCN})
Rate constant						
k or k_1/h^{-1}	0.360	0.350	0.358	0.304	0.336	0.308
k_2/h^{-1}	—	—	—	0.162	—	0.0240

a) The asterisk denotes the labeled compound with ^{14}C and initial concentrations of NaCN, CTAB, CTACN, and $C_8H_{17}Br$ are 0.1, 0.1, 0.11, and 115 mM, respectively.

in various systems. The partition coefficients of cyanide ions are small and independent of counter ions since $K_{CN} \simeq K_{NaCN} \simeq K_{QCN}$. It is also found that the direct displacement reaction of NaCN with 1-bromooctane does not take place in the absence of phase transfer catalyst since $K^{R}_{NaCN} = K_{CN}$. The occurrence of displacement reaction is indicated by the result, $K^{R}_{CN} > K_{CN}$, when the phase transfer catalyst CTAB is present. The use of CTACN in the place of the mixture of CTAB and NaCN in the aqueous phase leads to the advance of the displacement reaction in the organic phase to more extent ($K^{R}_{QCN} > K^{R}_{CN}$).

The partition coefficients of hexadecyltrimethylammonium ions, K_Q, are shown in Table 2. Since the partition coefficient of CTA^+ is larger than that of CN^-, it is evident that most of CTA^+ exist in the organic phase. The increase in the concentration of 1-bromooctane leads to the slight decrease of the partition of CTA^+, but in the lower concentration of 1-bromooctane the partition coefficients are the same as that in the absence of 1-bromooctane.

Tables 3 and 4 show the partition coefficients in the systems other than that of 1-bromooctane and CTAB. From these tables, it is found that alkyl bromide with carbon number less than 6 or more than 8, and aryl bromides were not catalyzed by the phase transfer catalysts used in this experiment. Table 3 also indicates that Me_4NBr, Me_3VNBr, $BeEt_3NBr$, and Bu_4NBr are not effective or almost noneffective in the catalytic action. As shown in Table 4, CTAB is effective only in the case of $C_8H_{17}Br$ while $CEtMe_2NBr$ and CPydBr cause the displacement reaction of cyanide with $C_6H_{13}Br$ and $C_8H_{17}Br$ and Et_4NBr, with $C_6H_{13}Br$. The rate constants for these systems are summarized in Table 5. As shown in this table, the time course obey the Eq. 2 except the systems of $C_6H_{13}Br$ with $CEtMe_2NBr$ or Et_4NBr which have smaller partition coefficients than other systems in this table.

Formation Constant. The partition coefficient of cyanide ions increases with the increase in the initial concentration of 1-bromooctane as shown in Fig. 2. Let us define the formation constant of alkanenitrile in the organic phase as

$$K^{o}_{f(RCN)} = \frac{[QBr]_o[RCN]_o}{[QCN]_o[RBr]_o}. \quad (3)$$

Rearranging Eq. 3 we have

$$[RCN]_o = K^{o}_{f(RCN)}[RBr]_o[QCN]_o/[QBr]_o$$
$$= K^{o}_{f(RCN)}([R]_T - [RCN]_o)[QCN]_o/[QBr]_o, \quad (4)$$

where $[R]_T$ is the total concentration of alkyl group.

In the system using CTACN in place of the mixture of NaCN and CTAB, the total concentration of Q, $[Q]_T$, is given as follows:

$$[Q]_T = [QCN]_o(1+K^{-1}_{QCN}) + [QBr]_o(1+K^{-1}_{QBr}). \quad (5)$$

Then,

$$[QBr]_o = \{[Q]_T - [QCN]_o(1+K^{-1}_{QCN})\}/(1+K^{-1}_{QBr})$$
$$= \{[CN]_T - [QCN]_o(1+K^{-1}_{QCN})\}/(1+K^{-1}_{QBr}) \quad (6)$$

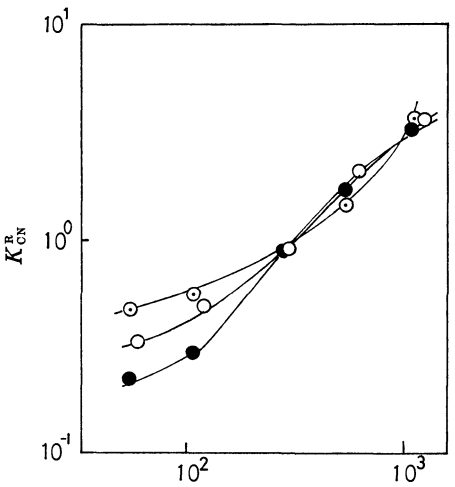

Fig. 2. Plot of partition coefficient *vs.* concentration of 1-bromooctane in the presence of QBr.
○: CTAB, ●: $CEtMe_2NBr$, ⊙: CPydBr. Initial concentrations of NaCN and QBr are all 0.1 mM.

$C_8H_{17}Br$	$CEtMe_2NBr$	0.086	0.0082
$C_6H_{13}Br$	CPydBr	0.120	0.0104
$C_8H_{17}Br$	CpydBr	0.141	0.0097
$C_6H_{13}Br$	Et_4NBr	0.128	—

The experimental conditions are the same as those of Table 4.

where $[CN]_T$ is the total concentration of CN. In obtaining Eq. 6 the initial condition, $[CN]_T=[Q]_T$, is used. On the other hand, we derive from the equations for K_{QCN} and K^R_{QCN}

$$[RCN]_o = \frac{K^R_{QCN}-K_{QCN}}{K_{QCN}}[QCN]_o = \frac{K^R_{QCN}-K_{QCN}}{1+K^R_{QCN}}[CN]_T \tag{7}$$

and hence, from Eqs. 6 and 7, we obtain

$$(1+K^{-1}_{QBr})[QBr]_o = [QCN]_o(K^R_{QCN}-K_{QCN})/K_{QCN}. \tag{8}$$

Combining Eqs. 4, 7, and 8 gives

$$\frac{[R]_T}{[CN]_T}\cdot\frac{1+K^R_{QCN}}{K^R_{QCN}-K_{QCN}} - 1 = \frac{K^R_{QCN}-K_{QCN}}{K^o_{f(RCN)}K_{QCN}(1+K^{-1}_{QBr})}. \tag{9}$$

Figure 3 shows the plots for the system of CTACN and 1-bromooctane according to Eq. 9, from which the values of $K^o_{f(RCN)}$ are found to be 9.34×10^{-4} at 20 °C and 1.46×10^{-1} at 28 °C, and corresponding free energy, ΔG, 17.0 and 0.48 K J/mol, respectively.

We also estimated an equilibrium constant for the formation of QCN in the organic phase defined as

$$K^o_{f(QCN)} = \frac{[NaBr]_o[QCN]_o}{[NaCN]_o[QBr]_o}. \tag{10}$$

This value can be estimated with the aid of following equations by measuring the concentrations of cyanide, bromide and sodium ion in each phase for the system of NaCN and CTAB without RBr

$$[CN]_o = [NaCN]_o + [QCN]_o \tag{11}$$

$$[Br]_o = [NaBr]_o + [QBr]_o \tag{12}$$

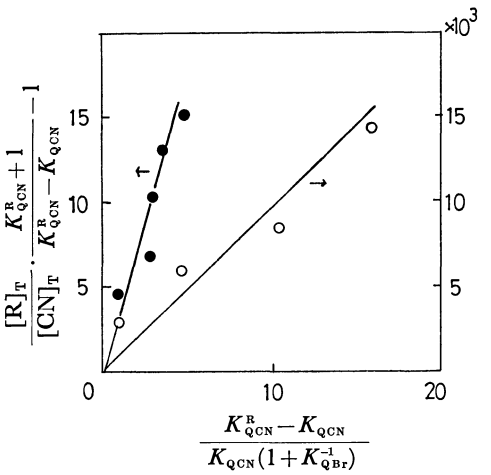

Fig. 3. Plot of Eq. 9 for the system of CTACN and 1-bromooctane.
○: 20 °C, ●: 28 °C. Initial concentration of CTACN is 0.1 mM at 20 °C and 1 mM at 28 °C.

$$[Na]_o = [NaCN]_o + [NaBr]_o \tag{13}$$

and

$$[NaCN]_o(1+K^{-1}_{NaCN}) = [QBr]_o(1+K^{-1}_{QBr}). \tag{14}$$

From the results of potentiometric measurement, the value of $K^o_{f(QCN)}$ for hexadecyltrimethylammonium cyanide was found to be 75 at 28 °C ($\Delta G=-10.8$ K J/mol).

Discussion

Consider the displacement reaction of sodium cyanide with 1-bromooctane occurring in the presence of CTAB. There are four species in the aqueous phase, NaCN, NaBr, QCN, and QBr, which permeate into the organic phase. Majority of CTA^+ ions exists in the organic phase at the equilibrium (Table 3), while the partition coefficient of cyanide ions is small compared to K_Q (Tables 1 and 2). Consequently it is thought that CTA^+ in the aqueous phase permeate into the organic phase mainly in the form of CTAB. Furthermore, as shown in Fig. 1, the permeation rate of CTA^+ into the organic phase is so large that the amount of CTA^+ in the organic phase are saturated rapidly. The mode of permeation does not change even in the presence of 1-bromooctane in the organic phase. On the other hand, the permeation of cyanide ions into the organic phase is much slower than that of CTA^+ and hence we may consider the ionic exchange reaction of CN^- by Br^- at the interface as the counter ion of CTA^+ as was suggested by Makosza *et al.*[2] We have two rate constants for the system with the displacement reaction of 1-bromooctane and CN^- and they are attributed to the permeation of CN^- into the organic phase and the displacement reaction in the organic phase respectively. From these facts, we may conclude that the catalytic action of CTA^+ would proceed rather in the organic phase and not by the circulation between the aqueous and organic phase.

The free energy change for the displacement reaction of 1-bromooctane and CTACN is positive, and hence it is thermodynamically impossible that this reaction

proceed independently. But this reaction may proceed by utilyzing the negative free energy for the displacement reaction between NaCN and CTAB at normal temperature. The free energy change for the overall reaction of NaCN and 1-bromooctane in the presence of CTAB is estimated to be -10.3 kJ/mol at 28 °C, which shows the possibility of the advance of the overall reaction. However, we may consider that the increase in temperature puts forward the displacement reaction of CTACN with 1-bromooctane from the fact that the value of $K^{\circ}_{f(RCN)}$ at 28 °C is larger than that at 20 °C.

The direct reaction of NaCN and 1-bromooctane seems not to advance because of very small reaction rate (Table 1). According to Starks *et al.*, the increase in the ionic radius of cation lowers the activation energy for the displacement reaction.[9] Changing Na^+ to CTA^+ may be essential for the acceleration of displacement reaction.

The authors wish to appreciate to Dr. M. Hayashi for his helpful discussion concerning the result in this work.

Crystal Structures of Mixed Ligand Copper(II) Complexes Containing L-Amino Acids. II. (L-Alaninato)aqua(L-histidinato)-copper(II) Trihydrate

Taizo Ono and Yoshio Sasada*

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received June 30, 1980)

Copper(II) complex containing L-alanine and L-histidine crystallizes from aqueous solution at pH 7.0. Crystals of (L-alaninato)aqua(L-histidinato)copper(II) trihydrate are monoclinic, space group $P2_1$, $a=10.980(4)$, $b=7.362(3)$, $c=9.700(2)$ Å, $\beta=101.45(3)°$, and $Z=2$. There is some disorder for the location of three water molecules of crystallization. Four coordinating atoms in an approximately planar arrangement around copper are the α-amino nitrogen and imidazole δ-nitrogen of L-histidine, and α-amino nitrogen and α-carboxyl oxygen of L-alanine. They take a *cis* conformation with respect to the amino groups. The axial site is occupied with oxygen atom of water, so that the coordination geometry is square-pyramidal. Similarity and difference are discussed in comparison with the coordination mode in copper complexes containing L-histidine and L-asparagine.

Histidine-containing ternary amino acid copper(II) complexes in serum have attracted wide attention in relation to the copper(II) transport in biological systems, and the preferred second amino acids are asparagine, glutamine and threonine.[1,2] In the previous paper,[3] we have reported the crystal structure of (L-asparaginato)(L-histidinato)copper(II) and its hydrate, in which the coordination mode is the same as that of aqua(L-histidinato)(L-threoninato)copper(II) hydrate.[4] It is interesting to examine the structures of the ternary copper complexes of which the second amino acid is thought less cooperative. We have prepared (L-alaninato)aqua(L-histidinato)copper(II) trihydrate and determined the three-dimensional structure by X-ray analysis.

Experimental

1 mmol of L-alanine (0.0891 g) and 1 mmol of L-histidine (0.1552 g) were dissolved with 10 ml of ion-exchanged water. The solution, into which 1 mmol of copper(II) hydroxide (0.0976 g) prepared by the same manner as in the previous paper was added, turned blue by stirring. After removing the precipitate of copper(II) oxide, small amount of methanol was poured. Blue plate crystals of (L-alaninato)aqua(L-histidinato)copper(II) trihydrate were grown by standing the solution for a few days at room temperatures. Elemental analysis. Found: C, 28.95; H, 5.81; N, 15.28%. Calcd for $C_9H_{22}N_4O_8Cu$: C, 28.61; H, 5.87; N, 14.82%.

Crystal data are: Monoclinic, $a=10.980(4)$, $b=7.362(3)$, $c=9.700(3)$ Å, $\beta=101.45(3)°$. $D_m=1.63$ g cm^{-3} (by floatation), $D_x=1.63$ g cm^{-3}, $Z=2$. Systematic absence, $0k0$ for odd k. Space group, $P2_1$ or $P2_1/m$.

Accurate unit cell dimensions were obtained from a least-squares fit to 2θ data of 18 reflexions measured on a Rigaku automated four-circle diffractometer. Intensity data were collected on the diffractometer with graphite monochromated Mo $K\alpha$ radiation at room temperature. A θ-2θ scan technique was employed, and reflexions for $2\theta \leq 55°$ were recorded. A total of 1746 non-zero reflexions out of 1897 were obtained. Intensities were corrected for the Lorentz and polarization factors but not for absorption and secondary extinction.

Structure Determination

Since this crystal contains L-amino acid, the space group $P2_1/m$ was certainly excluded. The x and z coordinates of a copper atom were obtained from the Harker section in the sharpened three-dimensional Patterson map. Its y coordinate was taken arbitrarily as 0.25. The Fourier map phased with the copper atom has shown a pseudo-symmetry due to a mirror plane at $y=0.25$. Most of atoms in the amino acids were near this plane. Four atoms coordinated to the central copper atom were selected to be in accordance with the stereochemistry of the remaining part of the complex. All the non-hydrogen atoms except for three oxygen atoms of water of crystallization were assigned by successive Fourier syntheses. When the R factor was 0.11, the difference Fourier map showed a disorder about these three water molecules in the space along the two-fold screw axis at

0, y, 0.5. Seven sites with appropriate occupancies were given for three oxygen atoms. Later stage of refinement was achieved by the full-matrix least-squares. Contributions from hydrogen atoms were not included. The R factor dropped to 0.078 for observed reflexions. Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[5] The final atomic parameters are listed in Table 1.[6]

Description of the Structure and Discussion

Figure 1 shows the packing of the molecules in the crystal, the hydrogen bonds being indicated by broken lines. Each complex molecule is connected along b through the axial coordination of the carboxyl oxygen of alanine related by the two-fold screw, which is hydrogen-bonded to the coordinated water in the next complex. α-Carboxyl group of histidine forms two hydrogen bonds, O(2) with water O(1′) of the complex at $1-x$, $0.5+y$, $1-z$ and O(1) with N(3) of imidazole of the complex at x, y, $1+z$. Three-dimensional network is constructed by the bridging coordination of alanine and these hydrogen bonds. The network leaves the cavities along 0, y, 0.5, in which three water molecules take randomly some of seven sites. These random water molecules form hydrogen bonds with the cavity wall and with each other,

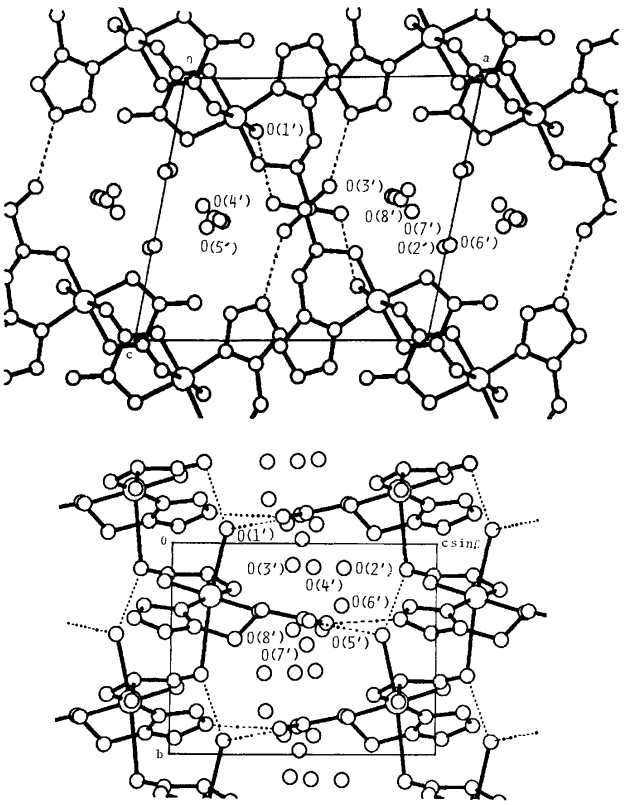

Fig. 1. Crystal structure of (L-alaninato)aqua(L-histidinato)copper(II) trihydrate projected along **b** (upper) and **a** (lower).

although details of the hydrogen bonds of this kind need not be discussed. The possible hydrogen bonds are listed in Table 2. Other than hydrogen bonds, all non-bonded intermolecular distances are normal.

Figure 2 shows the stereo pair of the diagram of the complex. Bond lengths and angles are given in Fig. 3 and Table 3, respectively. L-Alanine molecule coordinates to the central copper through α-amino nitrogen N(11) and α-carboxyl oxygen O(11), while L-histidine links through α-amino nitrogen N(1) and imidazole δ-nitrogen N(2). These four atoms occupy

the corners of the planar coordination square, taking a *cis* conformation with respect to the amino groups. The coordination distances, 2.006(10), 1.966(8), 2.000 (10), and 1.961(9) Å, are in agreement with those in the related complexes.[3,7,8] The axial coordination sites are occupied with a water molecule and a carboxyl oxygen of L-alanine in the neighbouring complex as mentioned above. These oxygen atoms, O(1′) and O(12)[a] where superscript a denotes the neighbouring alanine, are at 2.512(9) and 2.864(9) Å from copper, respectively. It has been reported that the in-plane covalent radius of copper is 1.30 Å and the out-of-plane radius is 1.90 Å.[9] If the covalent radius of oxygen is taken as 0.66 Å, Cu–O length should be 2.56 Å which is very close to the value of Cu–O(1′) in the present complex. On the other hand, Cu–O (12)[a] is considerably longer than the expected value. If the fact that the copper atom is 0.09 Å out of the best plane for the equatorial coordinating atoms toward the axial water molecule is also taken into account, it seems that the present complex is five-coordinated square-pyramidal.

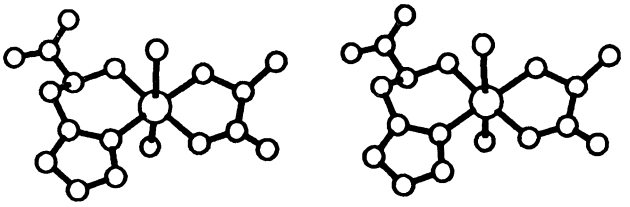

Fig. 2. Stereoview of the structure of (L-alaninato)-aqua(L-histidinato)copper(II).

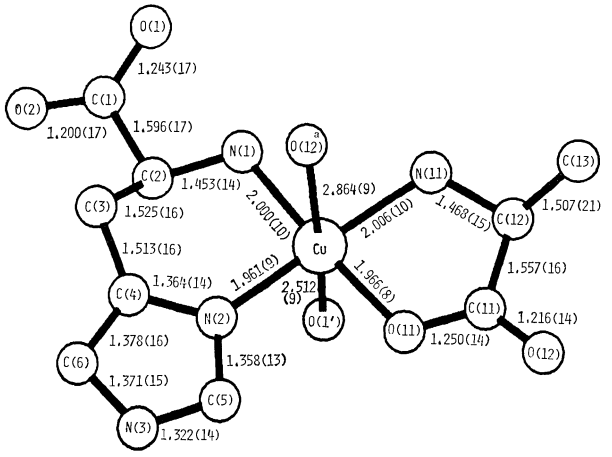

Fig. 3. Bond lengths (*l*/Å) in (L-alaninato)aqua(L-histidinato)copper(II).
Estimated standard deviations in the last digits are in parentheses.

The imidazole ring is planar within the experimental errors, whose mean plane makes a dihedral angle of 4.1(0.4)° with the plane of N(1)–Cu–N(2).

Common feature observed among Cu(ala his), Cu(asn his), its hydrate and Cu(his thr) is a *cis* conformation with respect to the amino groups. In terms of electrostatic repulsion of two carboxyl groups which coordinate to copper at the oblique axial and equatorial positions in the latter three complexes, the *cis* form may be more favourable. In fact, the O···O distances between these carboxyl groups are over 4.0 Å in the observed *cis* form. If the *trans* form were constructed with the same molecular dimensions, short contacts between carboxyl oxygen atoms would be 3.38, 3.25, and 3.15 Å. In the Cu(ala his) complex, however, there is no approach between the carboxyl groups of histidine and alanine. Therefore, the steric hindrance between hydrogen atoms at imidazole moiety and equatorial amino group should be more important. The distances in question were calculated for a hypothetical *trans* form, the smallest being 1.92 and 1.65 Å for Cu(asn his) and its hydrate, respectively.

Table 3. Bond angles (ϕ/°)

C(2)-C(1)-O(2)	117.4(11)	N(11)-C(12)-C(13)	114.7(11)
O(1)-C(1)-O(2)	127.6(13)	Cu-O(11)-C(11)	117.5(7)

a) O(12)[a] denotes O(12) in the complex at the symmetry-related position, $-x$, $0.5+y$, $-z$.

These are of course formidable values. In Cu(ala his), the closest approach is 2.06 Å, which may also enough to exclude the *trans* form. It should be added that the *cis* form of the complexes of Cu(asn his) and Cu(his thr) would be further stabilized by the possible ligand-ligand interaction in the solution proposed by Nakahara *et al.*[10,11]

The principal difference between the present and previously reported mixed-ligand complexes is the coordination mode of histidine. In Cu(asn his), its hydrate and Cu(his thr), L-histidine coordinates to copper as a tridentate ligand, while in Cu(ala his) it behaves as a bidentate ligand, that is to say, α-carboxyl group of L-histidine does not coordinate to copper but extends to form the hydrogen bonds with the neighbouring complexes. Neumann *et al.*[1] has reported that mixed-ligand copper complexes, Cu(asn his), Cu(gln his), and Cu(his thr), are preferably formed in serum. These observations can be related to the higher stability of the chelation of histidine as tridentate ligand. Difference in the coordination mode of histidine might be interpreted by pK_a's of the second amino acids, which are 2.34, 2.02, 2.15 and 2.17 for L-alanine, L-asparagine, L-threonine, and L-glutamine, respectively.[12] L-Alanine has distinctly higher pK_a than those of the remaining three amino acids. The high pK_a means the large electron density of carboxyl oxygen. Therefore, it is suggested that amino acid with higher pK_a donates more electron to copper ion, and the electrostatic interaction of copper with axial carboxyl group is not enough to hold the distorted coordination of α-carboxyl group of histidine.

The authors are grateful to Professor Akitsugu Nakahara and his collaborators of Osaka University for their kind advice and to Dr. Akio Takenaka in our laboratory for his assistance in the final refinement and in drawing the diagrams by the computer graphics. Part of the present work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Study of Cationic Surfactant Ion Selective Poly(vinyl chloride) Membrane Electrode Containing Dibenzo-18-crown-6

Tamaki MAEDA, Makoto IKEDA, Mitsuhiro SHIBAHARA, Takahide HARUTA, and Iwao SATAKE*

Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890

(Received July 15, 1980)

Study was made of the potentiometric selectivities of poly(vinyl chloride) membrane with and without dibenzo-18-crown-6. It was found that these membrane electrodes were highly selective for cationic surfactant ions and showed a Nernstian response to surfactant ion such as 1-dodecylpyridinium ion even in the concentration range as low as 10^{-6} mol/dm^3. The selectivity coefficients of inorganic cations, taken with respect to 1-dodecylpyridinium ion, were of the order of 10^{-5} or less, while that of surfactant ion was found to depend not only on hydrophobic alkyl chain length but also on the type of hydrophilic head group. For cationic surfactants with the same hydrocarbon chain length, the membrane without crown ether exhibited the order of selectivity: 1-alkylpyridinium ion > alkyltrimethylammonium ion > alkylammonium ion. In the case of the membrane with crown ether, the selectivity sequence became alkylammonium ion > 1-alkylpyridinium ion > alkyltrimethylammonium ion. For a homologous series of cationic surfactants, the selectivity coefficient increased regularly with increasing alkyl chain length.

A recent study of a number of surfactant ion selective membrane electrodes[1-18] has revealed the utility of such electrodes in the determination of critical micelle concentration[2-4,7,8,15,17,18] as well as in potentiometric titration[1,2,9-14,16] of ionic surfactant solutions. In addition, the use of surfactant ion electrode made it possible to obtain information regarding the surfactant ion activity in solution of ionic surfactant with[5,6] and without[2-4,7,17] interacting polymers.

With the exception of ionic polymer membrane,[17] all of the surfactant ion sensitive membrane electrodes so far studied are composed of either liquid[1-13] or plastic[14-18] membrane, into which is dissolved an ion exchanger made up of a surfactant ion and an oppositely charged organic ion. An ion association complex between cationic and anionic surfactant ions has widely been used as an ion exchanger.[2-7,14,16,17] These electrodes are found to be highly selective for surfactant ion over inorganic ions.[4,12,13] On the other hand, the presence of an interfering surfactant ion is shown to affect appreciably the electrode response to a particular surfactant ion in such a way that the interference increases regularly with increasing hydrocarbon chain length of the interferent.[4,12,13,17]

So far as we know, however, little is known about the selective behavior of surfactant ion sensitive membrane electrode containing electroneutral carriers. It is well known that macrocyclic polyether such as dibenzo-18-crown-6 serves as an electroneutral carrier of membrane electrode sensitive to alkali metal cations, especially to potassium ion.[19-22] Moreover, crown compounds have been found to form complexes with primary alkylammonium ions in aqueous[23] and methanol[24,25] media. It is thus interesting to study whether the crown compound-based membrane electrode responds selectively to cationic surfactant ions. In this paper is described the selective property of cationic surfactant ion sensitive poly(vinyl chloride) (PVC) membrane electrode with and without dibenzo-18-crown-6.

Experimental

Materials. Dibenzo-18-crown-6 (Nakarai Chemicals Ltd.) was recrystallized twice from benzene and dried *in vacuo*. Alkylammonium chlorides with 10, 12 and 14 carbon atoms were prepared from the corresponding alkylamines (purity > 99%, Nakarai Chemicals Ltd.) according to the method of Kolthoff and Strickes.[26] Alkyltrimethylammonium chlorides with 10, 12, and 16 carbon atoms (Tokyo Kasei Kogyo Co. Ltd.) were recrystallized twice from acetone. 1-dodecylpyridinium chloride (Wako Pure Chemical Industry Co. Ltd.) was purified by repeated recrystallization from acetone, then from isobutyl methyl ketone and finally by extraction with ether for 48 h. Tetraalkylammonium chlorides of guaranteed grade and other chemicals of reagent grade were used without further purifications.

Membrane Potential Measurements. The measurements were made with the membranes consisting of 20% PVC and 80% plasticizer, and of 1% dibenzo-18-crown-6, 20% PVC and 79% plasticizer by weight, (abbreviated hereinafter as carrier-free membrane and crown ether membrane). PVC (reported degree of polymerization is 1100) and bis(2-ethylhexyl) phthalate were dissolved into the least amount of tetrahydrofuran and mixed with a tetrahydrofuran solution of dibenzo-18-crown-6. The solution was poured onto a Petri's dish with a cover and allowed tetrahydrofuran to evaporate gradually at room temperature. A resulting membrane of 0.15 mm thickness was fixed to one end of PVC tube of 10 mm diameter by using a tetrahydrofuran solution of PVC as an adhesive. The preparation of carrier-free membrane is the same as that described above, except that dibenzo-18-crown-6 is omitted.

The electrode assembly is shown schematically in Fig. 1. In order to eliminate the leakage of ammonium ion from agar bridge, a double junction was constructed by inserting a small test tube with a pin-hole at the top into PVC electrode. The electrode was rinsed well with distilled water and stored in air when not in use. The selectivity coefficient was determined with the following cell by using the mixed solution method.[27]

Reference electrode (Ag–AgCl) | 1 mol/dm^3 NH_4NO_3 Agar bridge | Reference solution (DPC, 1×10^{-4} mol/dm^3) | PVC membrane | Sample solution (DPC, C_i; Interferent, C_j) | 1 mol/dm^3 NH_4NO_3 Agar bridge | Reference electrode (Ag–AgCl).

Here, C_i denotes the varying concentrations of 1-dodecylpyridinium chloride (DPC) and C_j the constant concentration of interfering ion, respectively. The electromotive force (EMF) (E) of the cell was measured with an accuracy of

±0.1 mV, by using a Yokogawa Universal Digital Meter model 2502 connected to a voltage follower amplifier (input impedance $\approx10^{13}\,\Omega$). All measurements were conducted at 25 °C. The PVC membrane was renewed after a series of experiments for a given kind of interferent.

Results and Discussion

It has already been found by Higuchi *et al.*[28] that PVC membrane plasticized with *N,N*-dimethyloleamide or dioctyl phthalate shows a Nernstian response to tetraalkylammonium ions. One might, thus, expect that the carrier-free membrane would also response to cationic surfactant ions. Curve (a) in Fig. 2 shows the typical semilogarithmic plots of EMF of the carrier-free membrane electrode *vs.* DPC concentration in the absence of interferent. In the concentration range below the critical micelle concentration (1.7×10^{-2} mol/dm^3), a linear relation with a slope of 59.6 mV per decade change in DPC concentration was found to hold down to 3×10^{-7} mol/dm^3. The observed slope agrees well with an ideal Nernst slope (59.2 mV at 25 °C), suggesting that the membrane is completely permselective to surfactant ion and 1-dodecylpyridinium ion behaves almost ideally in this concentration range. Similar Nernstian response was also obtained for the crown ether membrane, though a linear relation was confined to the range above 2×10^{-6} mol/dm^3. These electrodes are stable and permit the replicate measurements with surfactant solutions. For example, with the crown ether membrane, the observed slope of 59.3 mV/decade was reproducible to ±0.1 mV over a period of 47 d.

The presence of an interfering ion other than 1-dodecylpyridinium ion, particularly of surfactant ion, affects appreciably the membrane potential. A typical example is given in Fig. 2 by curve (b), which shows the change in EMF of the carrier-free membrane electrode with DPC concentration under constant concentration of dodecyltrimethylammonium chloride. Below a certain DPC concentration, the EMF of the cell tends to deviate gradually from a straight line with a Nernst slope and eventually to level off.

According to the common practice in describing the selectivity of membrane electrode, we calculated the selectivity coefficient, K_{ij}^{pot}, from the following equation,

$$E = E_a - \frac{RT}{F}\ln\frac{a_i + K_{ij}^{pot}a_j}{a_i^\circ}, \qquad (1)$$

where subscript i refers to the primary ion to which the membrane is selective, j to the interfering ion and superscript ° to the reference solution, respectively. E_a is the asymmetric potential of overall cell system and other symbols have their usual meanings. As is shown in Fig. 2, the measurements were made by applying the mixed solution method, *i.e.*, E was followed as a function of the primary ion concentration under the conditions where the concentration of the interfering ion was kept constant. For simplicity, the activity coefficients in Eq. 1 were ignored in the following estimation of K_{ij}^{pot}. In order to estimate the most reliable value of selectivity coefficient, we used a slight modification of graphical curve-fitting method devised by Sillén[29] in the determination of equilibrium constants. Denoting $2.303RT/F$ by S and introducing new variables,

$$X = \frac{C_i}{K_{ij}^{pot}C_j} \qquad (2)$$

and

$$Y = -S\log(1+X), \qquad (3)$$

Eq. 1 may be written as

$$E = E_a + Y - S\log\frac{K_{ij}^{pot}C_j}{C_i^\circ} = Y + D_1. \qquad (4)$$

Furthermore, it follows from Eq. 2 that

$$\log C_i = \log X + \log K_{ij}^{pot}C_j = \log X + D_2. \qquad (5)$$

Under our experimental conditions, both D_1 and D_2 are constant. The comparison of Eq. 4 with Eq. 5 leads immediately to the conclusion that the experimental plot of E against log C_i is shifted by constant D_1 in the ordinate and by D_2 in the abscissa from a plot of Y against log X. As is schematically shown in Fig. 3, therefore, the normalizing curve, in which Y is plotted as a function of log X for the given value of S, may easily be superimposable on the experimental plot of E against log C_i by sliding it both along ordinate and abscissa. The curve-fitting should be made so as to give the best fit of experimental data over the concentration range of C_i studied. This can usually be attained without difficulty. Then one may read the value of log X_o which corresponds to $C_i=C_j$. According to Eq. 5, the value of X_o thus determined is equal to the reciprocal of K_{ij}^{pot}.

The estimated values of selectivity coefficients for various interfering ions are summarized in Table 1, where 1-dodecylpyridinium ion is conventionally taken as the primary ion, i. In some cases in which K_{ij}^{pot} defined above is much larger than unity, the determination of it suffers some experimental limitations, since the presence of even the trace amounts of interfering ion affects significantly the electrode response to 1-dodecylpyridinium ion. For instance with 1-hexadecylpyridinium ion and hexadecyltrimethylammonium ion, the presence of these ions as low as 10^{-6} mol/dm^3 was sufficient to interfere the electrode response to 1-dodecylpyridinium ion. In such cases, therefore, we determined K_{ji}^{pot} and converted it to K_{ij}^{pot} on the basis of the relationship, $K_{ij}^{pot}\cdot K_{ji}^{pot}=1$, which is confirmed to hold for surfactant solutions.[17] It should be noted that inorganic cations and tetraalkylammonium ions with shorter alkyl chain length do not affect appreciably the electrode response to 1-dodecylpyridinium ion. An interesting feature of Table 1 is a marked difference in selectivity sequence for surfactant ions with the same alkyl chain length. The carrier-free membrane gives the selectivity sequence as 1-alkylpyridinium ion>alkyltrimethylammonium ion>alkylammonium ion. In the case of the crown ether membrane, however, the selectivity sequence becomes alkylammonium ion>1-alkylpyridinium ion>alkyltrimethylammonium ion. In fact, the selectivity coefficients of the crown ether membrane for alkylammonium ions are greater than those of the carrier-free membrane by a factor of about 100. This result may reasonably be interpreted in terms of the selective interaction of dibenzo-18-crown-6 with primary alkylammonium ion in membrane phase, since dibenzo-18-crown-6 has been found to form complex in methanol only with primary alkylammonium ion among various organic ammonium ions.[24]

Another important aspect of Table 1 is the regular increase in selectivity coefficient for a homologous series of interfering surfactant ions with respect to the hydrocarbon chain length. A similar trend was already noted both for liquid and plastic membrane electrodes containing an ion association complex.[4,12,13,17] On the basis of an assumption that the mobilities of ions of similar size in membrane phase are comparable with each other, Cutler *et al.*[17] attributed the regular change in selectivity coefficient for a homologous series of surfactant ions to the regular change in partition coefficient of surfactant ion between membrane and aqueous phases.

In the presence of an excess plasticizer, which is the case for the present experiment, the selectivity characteristics of PVC membrane will presumably be described by the theory of liquid membrane electrode. Ciani *et al.*[30] derived the following expression for the

selectivity coefficient of liquid membrane with electrically neutral ligand.

$$K_{ij}^{pot} = \frac{u_{jx}^* k_{jx} K_{jx}}{u_{ix}^* k_{ix} K_{ix}} = \frac{u_{jx}^* k_j K_{jx}^*}{u_{ix}^* k_i K_{ix}^*} \quad (6)$$

In Eq. 6, u represents the mobility, k the partition coefficient and K the association constant. The asterisk refers to the membrane phase and subscript ix to the complexed cation formed between cation i and electrically neutral ligand x.

For a homologous series of surfactant ions, it seems reasonable to assume that the association constant of the complexed cation is independent of hydrocarbon chain length. Moreover, the mobilities of complexed cations will probably be comparable with each other so long as the difference in hydrocarbon chain length remains small. In such cases, therefore, the selectivity coefficient will depend only on the partition coefficient of surfactant ion, and Eq. 6 reduces to

$$\frac{K_{ij}^{pot}}{K_{il}^{pot}} \approx \frac{k_j}{k_l}. \quad (7)$$

The same relationship has already been noted for PVC membrane containing an ion association complex.[17] Equation 7 provides a reasonable explanation for the regular change in K_{ij}^{pot} of the crown ether membrane shown in Table 1, since k is the increasing function of hydrocarbon chain length. In order to check the validity of Eq. 7, we made a tentative calculation of the free energy change, w, for transferring one methylene group from an aqueous medium to the membrane phase. Denoting the number of methylene groups of surfactant ion by n, Eq. 7 can be rewritten as

$$\frac{K_{ij}^{pot}}{K_{il}^{pot}} = \exp\frac{w(n_l - n_j)}{RT}. \quad (8)$$

In Table 2 are given the values of w calculated from Eq. 8 with the data for the crown ether membrane. It is worth noting that the values of w are all similar in magnitude regardless of the type of ionic head group and are close to the free energy change of -3400 J mol^{-1} for transferring one methylene group from an aqueous medium to pure long chain aliphatic alcohols.[31] This observation seems to support the validity of the foregoing treatment based on the theory of liquid membrane.

Examination of Table 1 also shed light on factors which determine the selectivity coefficient of the carrier-free membrane. It can immediately be seen that the quotients of the selectivity coefficients of the carrier-free membrane for a homologous series of surfactant ions are comparable to those of the crown ether membrane. This fact implies that Eq. 7 must also hold, at least experimentally, for the carrier-free membrane. Indeed, the substitution of the selectivity coefficients of the carrier-free membrane into Eq. 8 gives w of $-(2900—3300)$ J mol^{-1} which is in good agreement with those in Table 2. So far as a homologous series of surfactant ions is concerned, therefore, the presence of the electroneutral ligand seems to play a minor role in determining the selectivity characteristics of PVC membrane electrode.

Table 2. The calculated values of w from Eq. 8 with the data for the crown ether membrane at 25 °C

Surfactant	n_j	n_l	$-w$/J mol^{-1}
Alkylammonium ion	12	10	3200
	14	12	3000
	14	10	3100

	16	12	2800
	16	10	3000
1-Alkylpyridinium ion	16	12	3200
			av. 3100

These membrane electrodes provide a simple means of determining a cationic surfactant ion activity even in the presence of added salts. Under appropriate conditions, it is also possible to estimate the activity of a particular surfactant ion in mixed surfactant solution. Details of the determination of the surfactant ion activity in micellar solution will be reported in a separate paper.

cm³. The capillary had a capacity of 0.1 cm³ and was graduated to 10^{-3} cm³. The dilatometer was calibrated by using water for which very accurate density data are available at various temperatures.[23] The precision in relative volume change is in the order of 10^{-5}, which is comparable with that in other precision dilatometric studies.[1,7] The purified material was melted and transferred with a syringe to the cell of the dilatometer. The sample in the dilatometer was degassed by repeated melting under vacuum. The whole dilatometer except for the top of the capillary was immersed in a water bath made of glass, so that we could observe color changes accompanying mesomorphic transitions. The well-stirred bath was thermostatted to ±0.01 °C at each temperature. The volume was at first read 15 min after a temperature rise of *ca.* 0.1 °C and every 10 min until it reached a stationary value.

Results

The volume(V/cm³ g^{-1})-temperature(t/°C) relations of COC and CO in the Sm, Ch, and I phases are shown in Figs. 1 and 2, respectively. The volume varies linearly with temperature except in the ranges where transitions and pretransitions occur. The thermal expansivities are 8.34, 8.31, and 7.68×10^{-4} K^{-1} in the Sm, Ch, and I phases of COC, respectively and 10.32, 9.93, and 7.55×10^{-4} K^{-1} in the Sm, Ch, and I phases of CO, respectively. The trend that the lower-temperature phase has a larger expansivity is often found for liquid crystals.

The volume changes in the vicinity of and at the Sm-Ch and Ch-I transitions are complicated by the pretransition anomalies below and above the transition points, as in other cholesteryl esters,[2-4,6-8] while if the nematic(Ne) phase is involved instead of the Ch phase they are usually much less complicated. These anomalies are relatively more pronounced on the side of the Ch phase. A temperature width of 0.5 °C is required for the Sm-Ch transition to be completed and that of 3 to 4 °C for the Ch-I transition. The transition volume ΔV are defined here by the difference between the two straight lines of the related phases and the transition temperatures by a point where $\partial V/\partial t$ has its maximum value. The transition parameters obtained thus are summarized in Table 2. The transition which has a smaller change in the thermal expansivity, has a smaller change in volume in COC, while such a correlation is not found in CO. The present value of $\Delta V_{\text{Sm-Ch}}$(COC)/cm³ mol^{-1}, 0.34[24] is slightly smaller than that given by Lorenz and Stegemeyer,[15] 0.411. The value of $\Delta V_{\text{Sm-Ch}}$(CO)/cm³ mol^{-1}, 0.88 is comparable with that in the literature,[8] 0.92. The value of $\Delta V_{\text{Ch-I}}$(CO), 0.88 cm³ mol^{-1} is larger than that of $\Delta V_{\text{B-I}}$(CO),[8] 0.49 cm³ mol^{-1} because the cholesteric to "blue phase" (B) transition is not included in the latter transition volume.[25] The B phase is regarded here as being included in the pretransition phenomena when the volume change for the Ch-I transition is obtained.

When the volume of COC began rising due to the Sm-Ch transition, the turbidity suddenly increased and was followed by a red or scarlet color. In CO, on the other hand, the change in turbidity was less

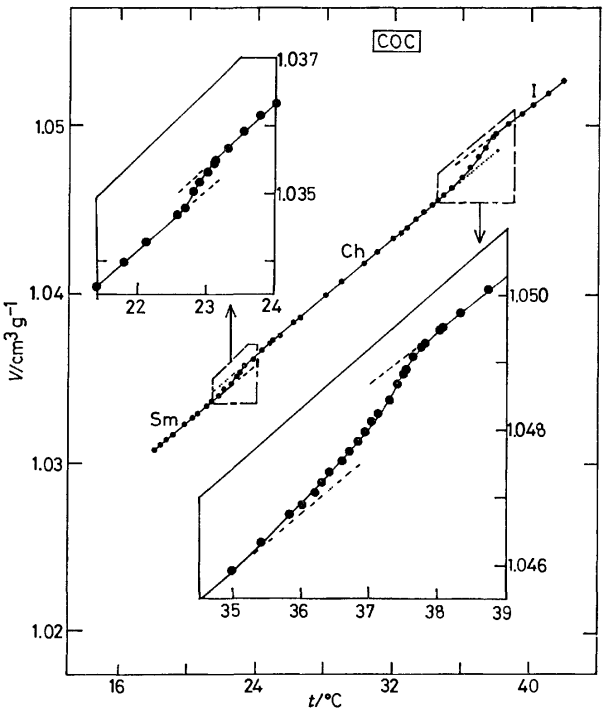

Fig. 1. Volume-temperature relation of COC.

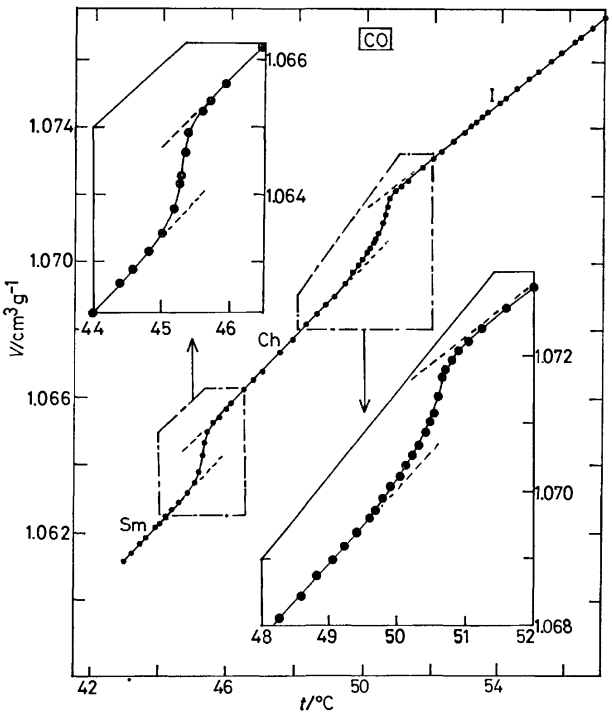

Fig. 2. Volume-temperature relation of CO.

Table 2. Transition parameters for COC and CO

Material	Transition	t_{tr}[a]	ΔV_{tr}[b]
COC	Sm-Ch	22.8	0.34
	Ch-I	37.5	0.66
CO	Sm-Ch	45.4	0.88
	Ch-I	50.7	0.88

a) Transition temperature(°C). b) Transition volume (cm³ mol^{-1}).

drastic and such a color change did not take place. When the volumes of COC and CO began rising due to the Ch-I transition, a blue color appeared together with a sudden increase in transparency; the point is identified with the Ch-B transition and lower by a few °C than the Ch-I transition point. On cooling, however, the blue color survived until 4 to 5 °C below the point found on heating. Thus, the color change had a hysteresis in contrast to the volume change. On heating, the B phase was seen over the pretransition range below the Ch-I transition point.

Discussion

Sm-Ch Transition. Besides the reasons mentioned in the introduction, there are some theoretical reasons why great attention is paid to the order of the Sm-Ch transition. As well known, the thermodynamic criterion for the first-order transition is simply that the first derivatives of the chemical potential with respect to pressure and temperature become discontinuous at a transition point. As seen in Figs. 1 and 2, it is very difficult to find such a discontinuity in the non-linear portion of the V-t relation. The maximum value of $\partial V/\partial t$ is larger in CO than in COC; there is a tendency that the larger the transition volume ΔV the larger the maximum slope $\partial V/\partial t$. The fact that the maximum slope is not infinite but rather small seems to correspond to the finding by Lushington *et al.*[14] that the Sm-Ch peak in the heat capacity-temperature curve is considerably broad and rounded. Thus, it is not easy to decide the transition order solely based on the experimental data; the transition order will be discussed below in view of theory.

Molecular theories based on the mean-field approximation[26-29] indicate that the Sm-Ne transition is allowed to be second order instead of first order for certain values of the potential parameters. McMillan's theory[27] predicts that a second-order transition occurs if the reduced temperature $T_r = T_{Sm\text{-}Ne}/T_{Ne\text{-}I}$ is smaller than $T_r^c = 0.87$; $T_r^c = 0.88$ according to a more refined calculation.[28] The present results in Table 2 give 0.953 and 0.984 as $T_r = T_{Sm\text{-}Ch}/T_{Ch\text{-}I}$ for COC and CO, respectively; similarity in the phase behavior between the Ch and Ne phases is assumed here, as often it is. These values are considerably larger than the critical value of T_r. The difference between T_r and T_r^c is smaller in COC than in CO, corresponding to the relation $\Delta V_{Sm\text{-}Ch}(COC) < \Delta V_{Sm\text{-}Ch}(CO)$. The order of the Sm-Ne transition in CBOOA[30] has been investigated using several different experimental techniques,[31-36] and most of the experimental results[31-34] except some ones[35,36] are in favor of the first-order transition. The reduced temperature for COC, 0.953 is even larger than that for CBOOA, 0.935. Thus, the Sm-Ch transition in COC is more difficult to become second order than at least that in CBOOA is. The comparison of T_r values supports the conclusion that the Sm-Ch transition in COC is weakly first order at atmospheric pressure. Indeed, there is a theory which predicts that the Sm-Ch(Ne) transition is always at least weakly first order.[37]

Ch-I Transition. It is generally accepted that the Ch(Ne)-I transition is first order. The mean-field theories[26-29,38] indicate that the Ne-I transition is always accompanied by a discontinuous change in the long-range orientational order parameter. Since the Ch phase is similar to the Ne phase as mentioned above, the Ch-I transition is also expected to have a discontinuous change in the order parameter. In practice, however, the V-t relations in Figs. 1 and 2 show no clear discontinuity at the Ch-I transition due to the pretransition phenomena, as in the case of the Sm-Ch transition. The volume changes with temperature in the pretransition region of the Ch-I transition are expressed as follows;

$$V = V_{Ch}^n + 8.7\times10^{-4} - 5.9\times10^{-4}(37.56-t)^{1/2} \quad (1)$$

$$V_{Ch}^n = 1.01548 + 8.69\times10^{-4}t \quad (2)$$

for COC and

$$V = V_{Ch}^n + 8.1\times10^{-4} - 6.7\times10^{-4}(50.53-t)^{1/2} \quad (3)$$

$$V_{Ch}^n = 1.01683 + 10.63\times10^{-4}t \quad (4)$$

for CO.[39,40] Here, V_{Ch}^n ($cm^3\,g^{-1}$) denotes the normal volume without the pretransition anomalies, and the constants in Eqs. 1 and 3 are determined by the least-squares fitting of $(V-V_{Ch}^n)^2$ to a function, $a(b-t)$ (a and b, constants). Figure 3 illustrates how Eqs. 1 and 3 fit the experimental data. The anomalous (nonlinear) dependence of the volume on temperature below the transition point can be explained in terms of the Landau-de Gennes theory for the first-order transition.[41,42] The Gibbs free energy G is assumed here to be expanded in powers of a scalar order parameter s as

$$G = G_I + (1/2)As^2 - (1/3)Bs^3 + (1/4)Cs^4, \quad (5)$$

where G_I is the free energy of the isotropic phase.[43] Here, as A is often assumed to have the form $A_1(T-T^*)$ in order to discuss the transition thermodynamics, it is expanded here as

$$A = A_1(T-T^*) + A_2(P-P^*). \quad (6)$$

The coefficients A_1, A_2, B, and C are constants, and T^* and P^* are somewhat below the transition temperature and pressure, respectively. The equilibrium

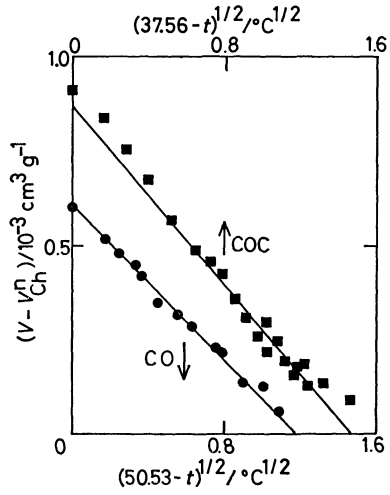

Fig. 3. Fitting of Eqs. 1 and 3 to the pretransition volume data below the Ch-I transition point.

values of s in the Ch phase are obtained as the solutions of the equation $\partial G/\partial s=0$; $s=0$ for the I phase and for the Ch phase

$$A - Bs + Cs^2 = 0. \quad (7)$$

Differentiating Eq. 5 with respect to pressure at constant temperature and taking account of Eqs. 6 and 7, we get

$$V = V_I - A_2B^2/4C^2 + (A_2^2/2C)(P-P^*) + (A_1A_2/2C)(T-T^*) - (A_2B/4^{1/2}A_1^{1/2}C^{5/2}) \times \{[B^2/4A_1C-(A_2/A_1)(P-P^*)]-(T-T^*)\}^{1/2}. \quad (8)$$

If V_I varies linearly with temperature, the equation derived above has the same form as Eqs. 1 and 3 with respect to temperature. If the coefficient B is zero as in the case of the second-order transition, the last term on the right-hand side of Eq. 8 drops, and V becomes a linear function of T. This is not the case, as shown by Eqs. 1 and 3. Thus, the nonlinear behavior of the volume in the pretransition region is explained by the existence of the third term in Eq. 5 which is required for the first-order transition.

43) The Gibbs free energy density G/V is usually expanded to the fourth power of s. Strictly speaking, therefore, some higher powers had better be included in Eq. 5 because V itself is expressed by a power series of s. For example, $V=V_I+2A_2s^2$ in the present approximation, so that some terms of s^5 and s^6 may be added. For simplicity, however, these higher terms are neglected in the present discussion.

(Received February 8, 1980)

Molecular motion in solid $(CH_3NH_3)_2TeX_6$ (X=Cl, Br, and I) was studied by measuring the spin-lattice relaxation time, T_1, of ^1H and ^{35}Cl nuclei in several crystalline phases appearing below room temperature. A deep minimum of the proton T_1 was observed in the low-temperature phase of all the compounds, indicating that the methylammonium ion performs a rapid reorientation as a whole about its three-fold axis. The activation energies, E_a, for the motion of cations are determined to be 7.0, 3.7, and 2.7 kJ/mol for X=Cl, Br, and I respectively. In $(CH_3NH_3)_2TeI_6$, which has the lowest E_a value, the relaxation process associated with the tunneling of the cation is apparent at low temperatures. For all the complexes studied, a shallow T_1 minimum ascribable to the independent rotation of the CH_3 and NH_3 groups in the cation was observed on the high-temperature side of each deep T_1 minimum. The ^{35}Cl T_1 of $(CH_3NH_3)_2TeCl_6$ exhibited a distinct minimum at the lower phase-transition point at 139 K and a discontinuity at the higher one near 230 K. The hindered rotation of the $[TeCl_6]^{2-}$ octahedron occurs in the room-temperature phase, with an E_a value of 48 kJ/mol.

It has been reported that many methylammonium hexahalometallates(IV), $(MA)_2MX_6$ (MA=CH_3NH_3, M=Sn, Pt, Se, Pd, and Pb, and X=Cl, Br, and I), have a rhombohedrally distorted K_2PtCl_6-type structure with the space group $R\bar{3}m$ at room temperature[1] and undergo a structural phase transition at low temperatures.[2,3] Some of them have been studied by means of the halogen nuclear quadrupole resonance (NQR),[2-4] the ^1H nuclear magnetic resonance (NMR),[5] and single-crystal X-ray diffraction in high- and low-temperature phases.[6] It was found that these compounds all have one phase transition similar to one another in nature at temperatures between 103 and 163 K.[3]

On the other hand, methylammonium hexahalotellurates(IV), with crystal structures different from those of the above complexes, also show interesting phase transitions. Kume *et al.* have made halogen NQR and differential thermal analysis (DTA) experiments on $(MA)_2TeX_6$ and found a phase transition at 139 K and an anomaly in the NQR spectra near 230 K for $(MA)_2TeCl_6$, while its hexabromo and hexaiodo analogs gave phase transitions at 158 and 289 K, and at 119 K, respectively.[7] Kitahama and Kiriyama reported the results of their X-ray diffraction study of $(MA)_2TeCl_6$ at various temperatures.[8] According to them, the hexachlorotellurate(IV) has a hexagonal, layered, CdI_2-type structure at room temperature, with the space group $P\bar{3}$ (or $P\bar{3}m1$); the cell constants were $a=7.340$ and $c=7.066$ Å; and $Z=1$. The crystal can be supercooled down to about 105 K without any structural change at both 230 and 139 K. Around 105 K, the crystal is sluggishly transformed to the low-temperature phase (LTP), with an accompanying change in crystal symmetry from $P\bar{3}$ to $R\bar{3}m$. When the temperature is increased from LTP, no structural change was detected by the X-ray study at 139 K,[8] where a clear anomaly was observed by the NQR and DTA measurements.[7] On a further increase in the temperature, the crystal reverts to the room-temperature phase (RTP) near 230 K, even though the DTA study shows no anomaly around this temperature. On the other hand, at room temperature $(MA)_2TeBr_6$ and $(MA)_2TeI_6$ form cubic crystals, presumably belonging to the space group $Fm3m$.[7] In the present investigation, the proton T_1 and the ^{35}Cl NQR T_1 were measured to reveal the nature of the molecular motions in the tellurium complexes. The results thus obtained were compared with those in a similar series of complexes with the rhombohedral structure of the space group $R\bar{3}m$.

Experimental

The proton spin-lattice relaxation time, T_1, was measured at 20 and 60 MHz with a Bruker B-KR 322 s pulsed NMR spectrometer by employing the conventional 180°-*t*-90° pulse sequence. The recovery of nuclear magnetization after the 180° pulse was slightly non-exponential in the vicinity of the temperature of the T_1 minimum. In this case, T_1 value was evaluated from the initial part of the magnetization *vs.* *t* curve. The spin-locking pulse sequence was used for the determination of the rotating-frame spin-lattice relaxation time, $T_{1\rho}$, for $(MA)_2TeI_6$. The NQR T_1 of ^{35}Cl in $(MA)_2TeCl_6$ was determined by the use of a 180°-*t*-90°-*t'*-180° pulse sequence, while its resonance frequency was read directly on a Schomandl ND 100 M frequency synthesizer. A NIC 1074 signal averager was, if necessary, employed in order to increase the signal-to-noise ratio of the ^{35}Cl NQR echo.

The temperature above 77 K was controlled to within ±0.5 K by using an Ohkura EC 61 temperature controller and measured with a copper *vs.* constantan thermocouple. Temperatures below 77 K were obtained by allowing the sample to warm (*ca.* 0.2 K/min) from the temperature of liquid helium and measured with a gold-cobalt *vs.* copper thermocouple.

The samples used were prepared from tellurium dioxide, a methylamine solution, and the corresponding acid of hydrogen halide.[7]

Results and Discussion

Chlorine-35 NQR in $(MA)_2TeCl_6$. The temperature dependence of the ^{35}Cl NQR frequencies,

** Present address: Department of Chemistry, Faculty of Science, Kobe University, 1-1 Rokkodai-cho, Nada-ku, Kobe 657.

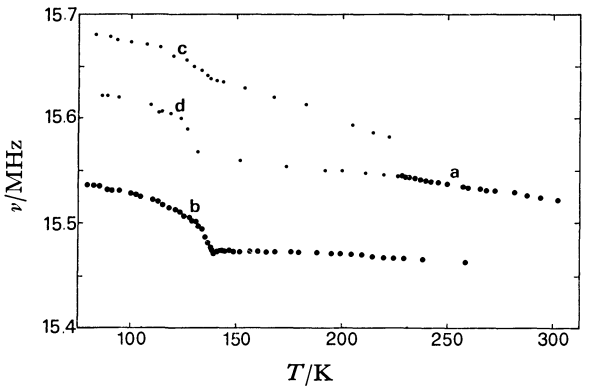

Fig. 1. Temperature dependence of ^{35}Cl NQR frequencies in $(CH_3NH_3)_2TeCl_6$.

as measured by the pulse method, is shown in Fig. 1. The results are in good agreement with those of an earlier work.[7] At room temperature, only a single resonance line, **a**, is observed at 15.52 MHz. When the sample is cooled from room temperature, the **a** line fades out near 230 K. After further cooling down to about 100 K, another line, **b**, is detected, its frequency being 15.54 MHz at 80 K. When the sample is warmed from 80 K, the resonance frequency gradually decreases and gives rise to a small, cusp-shaped anomaly, as in the case of rhombohedral $(MA)_2SnCl_6$, in the vicinity of 139 K.[2,3] On further heating, the **b** line broadens and the **a** line again appears at about 230 K. The former line fades out at about 260 K, while the latter increases in its intensity.

Two additional resonance lines, **c** and **d**, are frequently observed together with the main line, **b**. These extra lines show a temperature dependence similar to that of the **b** line. The intensity of these lines, however, is very weak and varies from sample to sample with the thermal history. Especially, these extra lines are liable to be observed when the sample is cooled from the transition region where both main lines, **a** and **b**, are seen simultaneously in the heating run. Kitahama and Kiriyama observed heavy streaks in the X-ray photographs of LTP with the space group of $R\bar{3}m$, indicating the development of several crystal domains arising from stacking faults in the layered lattice, as well as weak reflections originating from the $P\bar{3}$ phase, which had not been transformed on cooling down to 92 K.[8] The strong NQR line **b** can be attributed to the $R\bar{3}m$ phase, while the weak extra lines may be attributed to some crystal domains associated with the stacking faults and to the unconverted $P\bar{3}$ phase. A similar unusual NQR feature was observed for polytypism found in some compounds with layered structures.[9]

The NQR relaxation time of chlorine-35 in $(MA)_2TeCl_6$ was measured above 80 K. In Fig. 2, the values of T_1 measured on the **a**, **b**, and **c** resonances are identified by different symbols. The T_1 of the **d** resonance could not be measured because of its poor signal intensity and also because of interference from the intense line **b**. The log T_1 *vs.* $1/T$ curve shows an anomalous minimum around the lower

transition temperature (T_{t1}=139 K) and a discontinuous change near 230 K (T_{t2}), where the crystal structure sluggishly changes from $R\bar{3}m$ to $P\bar{3}$ in the heating run.

One can expect the following three processes to interpret the observed relaxation: the usual lattice vibration at low temperatures, the hindered rotation of the $[TeCl_6]^{2-}$ octahedron at high temperatures, and the phase transition around 139 K. The relaxation rate due to the lattice vibration is given by:

$$(T_1)_{vib}^{-1} = aT^2 + b, \quad (1)$$

where a and b are constants.[10] The temperature dependence predicted from this relation is shown in Fig. 2 by the dotted line, which was fitted on the experimental values at 82 and 100.5 K. On the other hand, the T_1 in RTP decreases exponentially with a decrease in the inverse temperature, indicating the occurrence of a hindered rotation of the complex anion. The relaxation due to such hindered rotation is given by $T_1 = C\tau_c$.[11] The correlation time, τ_c, for the rotation is assumed to have this form:

$$\tau_c = \tau_0 \exp(E_a/RT). \quad (2)$$

The constant, C, is 2/3 for the rotation around the C_3-axes of the octahedral anion, which lie on the crystal C_3-axis.[4] The straight line in Fig. 2 is calculated by taking E_a=48 kJ/mol, and $\tau_0 = 1.3 \times 10^{-13}$ s.

The last relaxation process is characterized by the distinct T_1 minimum at T_{t1}. This phenomenon is very similar to those of the halogen NQR T_1 of cubic A_2PtBr_6 ($A=K^+$ and NH_4^+)[12,13] and of rhombohedral $(MA)_2MCl_6$ (M=Sn and Pt).[4] For the former compounds, the T_1 anomaly is interpreted in terms of a softening of the zone-center rotary-lattice mode of the octahedron, which causes a transition from the cubic to the tetragonal phase. A very similar type

of anomalous T_1 change at the transition point was observed in the latter compounds. This anomaly was also explained in terms of a softening of the rotary mode of the complex ion,[4] although no distinct structural change was disclosed on the phase transition.[6] Accordingly, it may be that the T_1 anomaly in the present tellurium complex ion also originates from a softening of the rotary mode of the complex. Quite similary to $(MA)_2SnCl_6$, no structural change was detected at the transition point of the present compound; that is, both LTP and MTP (the middle-temperature phase between T_{t1} and T_{t2}) belong to the same space group, $R\bar{3}m$.[8] One may, therefore, presume that, in the crystals of rhombohedral $(MA)_2MCl_6$, the rotation angle of the octahedral anion at the phase transition is too small to be detected by means of X-ray diffraction.

Proton T_1 *in* $(MA)_2TeCl_6$. The temperature variation of the proton T_1 in $(MA)_2TeCl_6$ gives two different results, depending on the direction of the change in the temperature. Figure 3 shows the results for T_1 as the temperature increases from 4.2 or 77 K. No drastic change was recognized in the log T_1 *vs.* $1/T$ curves at either phase transition point, T_{t1} or T_{t2}, indicating that the motion of the MA^+ ion is almost unaffected by these transitions. By analogy with $(MA)_2SnCl_6$,[5] the deep minimum near $kK/T \approx 15$ is assignable to the reorientation of the MA^+ ion as a whole about its C_3-axis, while the small depression near $kK/T \approx 10$ is assignable to the independent reorientation of the CH_3 and NH_3 groups in the cation. In this system, the spin-lattice relaxation rate for the MA^+ ion is written by:

$$T_1^{-1} = A[\tau_1/(1+\omega_0^2\tau_1^2)+4\tau_1/(1+4\omega_0^2\tau_1^2)] + B[\tau_2/(1+\omega_0^2\tau_2^2)+4\tau_2/(1+4\omega_0^2\tau_2^2)], \quad (3)$$

where $\tau_1 \ll \tau_2$.[5,14] The motional constants, A and B, stand for the contributions to T_1^{-1} from the dipolar interaction modulated *via* the C_3 rotation of the MA^+ ion as a whole, and *via* the independent rotation of the CH_3 and NH_3 groups on the coordinates of the MA^+ ion, respectively. These constants can be determined theoretically from the dimensions of the MA^+ ion[5,14] or experimentally from the T_1 minimum values. The τ_1 symbol is the correlation time for the rotation of the cation as a whole, while τ_2 symbolizes the uncorrelated rotation of the two groups. The preexponential factor, τ_0, and the activation energy, E_a, in the usual Arrhenius relation are determined experimentally.

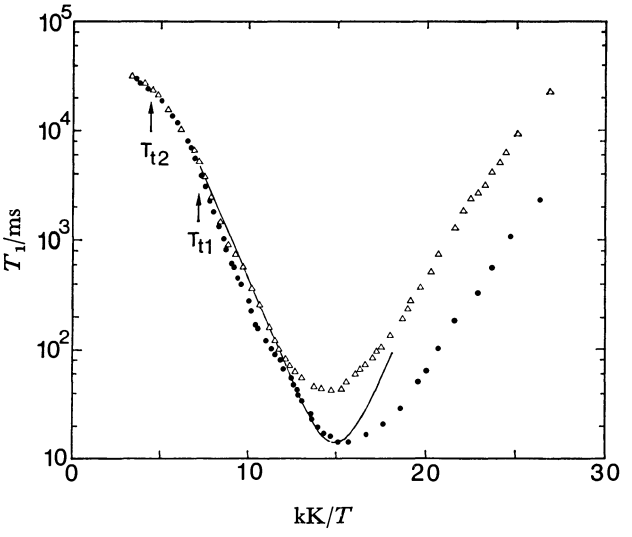

Fig. 3. The spin-lattice relaxation times of protons in $(CH_3NH_3)_2TeCl_6$ measured on heating run from 4.2 or 77 K.
●: 20 MHz, △: 60 MHz.

The experimental points in LTP, however, cannot be fitted to Eq. 3 because the deep T_1 minimum is broad and asymmetric, although all the MA^+ ions are crystallographically equivalent.[8] One possible explanation is that the correlation time is widely distributed because of the stacking faults previously described. The rather long T_1 minimum compared with the theoretical value is consistent with such breadth of the T_1 minimum. Therefore, the activation parameters are evaluated separately from the slopes on the low- and high-temperature sides of the T_1 minimum (Table 1). The T_1 curve simulated by the use of these activation parameters is represented in Fig. 3 by a solid line. The activation energy for the reorientation of the MA^+ ion reflects the intermolecular potential barrier, which is determined partly by the NH···Cl hydrogen bonding and partly by the MA^+···Cl van der Waals force. The E_a values in the Pt, Sn, and Te chloro complexes are 3.6, 4.2, and 6.0 (averaged value) kJ/mol respectively.[5] This order is the same as that of the chlorine ionicity, i, in these complexes, as deduced from ^{35}Cl NQR frequencies, which give i=0.43, 0.66, and 0.67 in that order.[3] This suggests that the former interaction is more effective on the motion of MA^+ ions than the latter one in the present system. The small value of E_a indicates that, in these compounds, the NH···Cl hydrogen bonds are quite weak as compared with that in CH_3NH_3Cl.[15]

When the crystal is cooled down from room temperature, the T_1 behavior is very different from that of the heating process described above. It has been reported that the crystal structure remains unchanged until 105 K on cooling[8] and that the DTA curve shows no heat anomaly in the temperature range of 260—230 K.[7] As can be seen from Fig. 4, the T_1 value at 20 MHz is clearly shortened by about one quarter in the narrow temperature range of 230—222 K. This T_1 anomaly indicates that the motional state of the MA^+ ion abruptly changes at T_{t2}. The T_1 curve between kK/T=4.5—7.5 shows the presence of a new relaxation process superimposed on the rapid reorientations of the CH_3 and NH_3 groups. The long T_1 value of about 4 s observed in this temperature range suggests that the predictable additional motion is, for example, a small-angle tilting of the C_3 axis of the MA^+ ion from its original orientation. This suggestion is supported by the fact that the ^{35}Cl NQR line (**a** in Fig. 1) fades out at 230 K, because such a tilting motion introduces a large fluctuation of the electric-field gradient (EFG) at the chlorine site.[7]

Proton T_1 *in* $(MA)_2TeBr_6$. The temperature

dependence of the proton T_1 at 20 MHz is shown in Fig. 5. The two phase transitions found in the NQR and DTA experiments[7] are marked by discontinuity in the log T_1 *vs.* $1/T$ curve. It is interesting to note that a shallow T_1 minimum near 100 K is clearly observed, because the deep T_1 minimum appears at 44 K, lower by 20 K than that of $(MA)_2TeCl_6$. The T_1 curve in LTP is apparently asymmetric and broad. At the present stage, however, the proton relaxation below 70 K is ascribable to the reorientation of the whole MA^+ ion. The relaxational parameters thus obtained are listed in Table 1. The observed asymmetric T_1 minimum is probably due to the tunneling-assisted relaxation, because of the low rotational barrier of the C_3 reorientation of the cation.[16] As the crystal structures of both LTP and MTP are yet unknown, we cannot, though, rule out the possibility that the presence of two or more nonequivalent MA^+ ions causes the asymmetry of the T_1 curve.

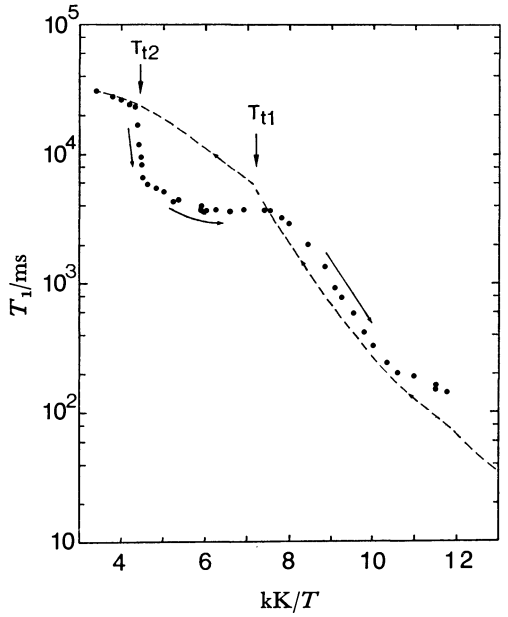

Fig. 4. The spin-lattice relaxation times of protons in $(CH_3NH_3)_2TeCl_6$ measured at 20 MHz on cooling run from room temperature. The broken line shows the data at 20 MHz on heating run.

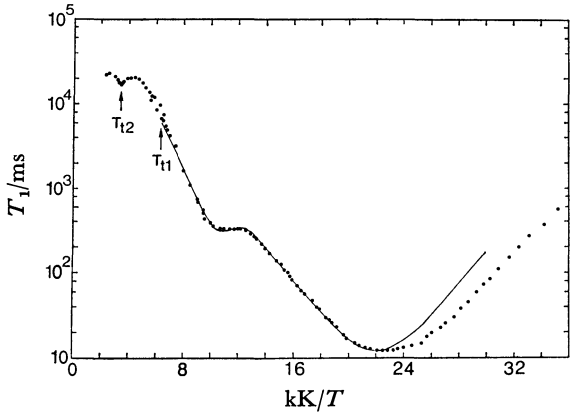

Fig. 5. Temperature dependence of the proton T_1 at 20 MHz in $(CH_3NH_3)_2TeBr_6$.

By using Eq. 3 and assuming that $\omega_0\tau_1 \ll 1$, the data between $kK/T=6$ and 18 were analyzed for the motion specified by τ_2, yielding a T_1 minimum of 430 ms at $kK/T=10.6$ and an activation energy of 9.0 kJ/mol. This process can be assigned to the intergroup dipolar interaction in the cation.[5] The theoretical T_1 minimum due to the independent reorientation is evaluated to be 460 ms, which is in good agreement with the observed value. The E_a value of 9 kJ/mol is reasonable as the internal rotation barrier in the MA^+ ion.[5]

Proton T_1 *and* $T_{1\rho}$ *in* $(MA)_2TeI_6$. The experimental relaxation times for $(MA)_2TeI_6$ are given in Fig. 6, where the log T_1 and log $T_{1\rho}$ are plotted against the inverse temperature, and in Fig. 7, where the log T_1 below 70 K is shown against the temperature. The occurrence of a phase transition was confirmed at 119 K by the discontinuity in both the T_1 and $T_{1\rho}$ curves. There are three temperature regions, characterized by different relaxation processes, for T_1: the linear region of the T_1 curve in RTP, the shallow T_1 minimum in the $kK/T=10$ to 15 region, and the two T_1 minima at very low temperatures. In the series of $(MA)_2MX_6$ (X=Cl and Br), each complex shows a single deep T_1 minimum attributed to the C_3 reorientation of the whole MA^+ ion. The T_1 behavior of $(MA)_2TeI_6$, however, is rather different from that of the foregoing complexes. This is because the T_1 curve in the low temperature rigion yields two T_1 minima, the values of which

Table 1. Motional parameters for $(MA)_2TeX_6$

Compound	A or B[a]/s^{-2}	E_a[b]/kJ mol^{-1}	τ_0/s	Motion
$(MA)_2TeCl_6$	6.2×10^9	7.0 (5.0)	1×10^{-14}	C_3-rotation of MA^+ ion
	—	—	—	independent rot. of CH_3 and NH_3 groups
	—	48	1.3×10^{-13}	hindered rot. of $[TeCl_6]^{-2}$ ion
$(MA)_2TeBr_6$	7.1×10^9	3.7 (3.3)	4×10^{-13}	C_3-rotation of MA^+ ion
	2.1×10^8	9.0	5×10^{-14}	independent rot. of CH_3 and NH_3 groups
$(MA)_2TeI_6$	—	2.7	—	C_3-rotation of MA^+ ion
	2.0×10^8	5.0	3×10^{-12}	independent rot. of CH_3 and NH_3 groups
	—	6.1	—	overall rot. of MA^+ ion

a) The calculated values are $A=10\times10^9$ and $B=1.9\times10^8$ s^{-2} for r(C-H)=1.10, r(N-H)=1.04, r(C-N)=1.47 Å, and all the tetrahedral angles.[4] b) The value in parentheses is estimated from the slope on the low-temperature side of the T_1 minimum.

●: 20 MHz and △: 60 MHz.

are much greater than that expected for the classical C_3 reorientation. The second moment, evaluated from the solid-echo envelope,[17] was 9.5 ± 1.5 G^2 even at 4.2 K. This value is much smaller than the theoretical one of 29.8 G^2 for the MA^+ ion in its stationary state, but close to that for the rapidly reorienting MA^+ ion about its C_3-axis.[5] Additionally, the linear portion of the high-temperature side of the deep T_1 minima gives a very low E_a value of 2.7 kJ/mol. All of these results suggest the existence of tunneling-assisted relaxation in the present system.[18] Considering the transitions among tunneling sublevels in the torsional states of the CH_3 or NH_3 groups, Haupt proposed the following expression of the relaxation rate:[19]

$$T_1^{-1} = AJ(\omega_t \pm n\omega_0) = \frac{A\tau}{1+(\omega_t \pm n\omega_0)^2\tau^2}, \quad (4)$$

where A is a constant, ω_t is the tunnel-splitting frequency, and $n=1$ or 2. If $\omega_t \gg \omega_0$, the relaxation rate due to the intramolecular dipolar coupling associated with $J(\omega_t \pm n\omega_0)$ becomes frequency-independent, while the rate due to the intermolecular one is of the usual BPP type.[20] Therefore, two T_1 minima should be observed, one at $\omega_t\tau=1$ and the other at $\omega_0\tau=0.62$. The T_1 minima in Fig. 7 are frequency-dependent, but to a lesser extent than would be expected from the BPP theory; that is, the ratio, $(T_{1\,\mathrm{min}})^{60\,\mathrm{MHz}}/(T_{1\,\mathrm{min}})^{20\,\mathrm{MHz}}$, which is equal to 3 in the classical dipolar relaxation, is less than 2 in the present case. Although this T_1 behavior can be explained qualitatively in terms of $J(\omega_t \pm n\omega_0)$, it is difficult to deduce the tunneling frequency because two spin systems (CH_3 and NH_3) complicate the problem and because it has not been established that all the MA^+ ions are equivalent in LTP. It is desirable to measure the T_1 and $T_{1\rho}$ of selectively deuterated CH_3ND_3 or CD_3NH_3 salts as well as to determine the crystal structure of LTP.

The activation energy, E_a, for the MA reorientation changes greatly with X in $(MA)_2TeX_6$, as Table 1 shows. The order of the E_a values is the same as that of the electronegativity of halogens in the complex ions. Quite a similar inclination of the E_a value was discussed above for $(MA)_2MCl_6$ with M=Pt, Sn, and Te. Therefore, the differences in the potential barrier among the present tellurium compounds may be determined mostly by the electrostatic interaction between NH_3 groups and halogens in complex ions.

By fitting the experimental points between 110 and 42 K to Eq. 3 ($\omega_0\tau_1 \ll 1$), the shallow T_1 minimum for the motion specified by τ_2 is determined to be 490 ms at 20 MHz. This value is comparable to those of the other MA-compounds and also to the calculated one for the uncorrelated rotation of the MA^+ ion.[5] The E_a value of 5.0 kJ/mol, however, is significantly smaller than those (8—9 kJ/mol) of the others. The difference in E_a seems to be large in contrast with our estimate of a nearly constant energy.[5] Therefore, it may be acceptable to consider that some other relaxation processes, for example, a tunneling or 180° flip of the MA^+ ion, exist in this temperature range in addition to that of the foregoing two motional modes. It may be also plausible to anticipate that the geometry of the MA^+ ion in the present complex is not the same as that in the earlier complexes because of the difference in interionic interactions or packing of the ions in the crystal.

In RTP, the log T_1 value decreases linearly with $1/T$ from room temperature to T_t; the slope of the decrease gives the E_a value of 6.1 kJ/mol. Since the crystal structure is cubic and the proton second moment is only 0.5 G^2 in this phase, this relaxation process is ascribable to the overall reorientation of the dumbbell-like cation.

The observed values of the proton $T_{1\rho}$, on the other hand, behave unusually in RTP. Contrary to the $T_{1\rho}$ expression based on the BPP theory, the $T_{1\rho}$ minimum at the r.f. strength, H_1, of 5 G appeared at a higher temperature than that of the $T_{1\rho}$ at 10 G. Furthermore, on the high-temperature side of both

$T_{1\rho}$ minima, the $T_{1\rho} \propto H_1^2$ relation holds for the six observed $T_{1\rho}$ values in the H_1 range of 2.5—15 G. Such anomalous behavior suggests an intermolecular dipolar relaxation of the second kind between the protons and iodine nuclei.[21] The overall rotation of the MA^+ ion may result in a large fluctuation of the EFG at the site of iodine, in contrast to its C_3 reorientation, which affects the EFG only slightly. This fluctuation shortens the iodine spin-lattice relaxation time $T_1(I)$. Thus, the dipole interaction between the protons and iodine nuclei affects the proton $T_{1\rho}$ through the cross relaxation. This type of relaxation is expressed as follows:[22]

$$T_{1\rho}^{-1} = M_2(\text{H-I})\gamma_H^2 T_1(I)/[1+\omega_1^2 T_1(I)^2], \quad (5)$$

where M_2(H–I) is the proton second moment due to the H–I dipole interaction and where $\omega_1 = \gamma_H H_1$. The value of M_2(H–I) was estimated to be 0.078 G^2 from the $T_{1\rho}$ minimum. Then, the $T_1(I)$ value was obtained by substituting the known parameters into Eq. 5. The results are also included in Fig. 6. It may be noted that the $T_1(I)$ of 50 μs at room temperature shortens with decreasing temperature, while retaining the same slope as that of the proton T_1 above T_t. This finding is strong evidence for the idea that the proton $T_{1\rho}$ is governed by the proton–iodine interaction modulated *via* the overall reorientation of the MA^+ ion. On a lowering of the temperature, the $T_1(I)^{-1}$ becomes large beyond the order of the usual NQR linewidth. This is a reason why the NQR signal fades out below 156 K.[7]

The authors are grateful to Professor Emeritus Ryôiti Kiriyama of Osaka University and Professor Daiyu Nakamura of Nagoya University for their continued interest and encouragement.

Adsorption of *N*-Dodecyl-β-alanine to the Spread Monolayer of Lecithin or Dilaurin

Kazuo Tajima* and Takao Tsutsui

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received May 6, 1980)

The adsorption of *N*-dodecyl-β-alanine (NDA) was studied at the air–solution interface with the spread film of L-α,β-dimyristoyllecithin (DML) or α,α′-dilaurin (DIL). The adsorbed amounts were measured by radiometry using tritium-labelled NDA, combined with surface pressure measurements. Measurements of IR, DSC, and NMR were made in order to determine the bulk properties of amphoteric moieties in the mixture of DML and NDA. For the mixed monolayer of NDA and DML or DIL, the surface composition *vs.* area curves were obtained at various surface pressures. The molecular interaction in monolayer was discussed on the basis of the excess free energy of mixing, which was calculated at various surface pressures and compositions. As a result, the mixing of DIL and NDA in monolayer was ideal at surface pressures less than 5 mN m^{-1}, whereas the mixed monolayer of DML and NDA showed a remarkable condensation in surface molecular area. Such a large condensation at low surface pressure was concluded to be due to the formation of ion pairs between the choline and alanine moieties on the water surface, by referring to the findings obtained by studying the lipid properties in the bulk phase. It was also found that the DML–NDA monolayer near close packing exhibited various types of complicated behavior, depending on the surface compositions. The appreciable differences in the nature of the amphoteric moieties in DML and NDA molecules can explain these findings.

Studies of the monolayer behavior of phospholipids on the surface of surfactant solution are very useful for understanding some of the actions of surfactant on the biomembrane. Nevertheless, few studies on the interaction of membrane lipids with surfactant have been performed, due to some experimental and theoretical restrictions. Studies of mixing in the insoluble lipid films[1] or of binding properties of lipid and metallic ions[2] are more numerous. The thermodynamic approach to analyzing the nature of penetrated films must be based on precise information about the monolayer composition, especially for the penetrated films with the ionic interactions between the polar groups of lipids.[3] Recently, Hendrikx, and Ter-Minassian-Saraga,[4] who studied the adsorption of a cationic surfactant to a lecithin monolayer, found that the mixed monolayer formed a stable two-dimensional micelle on the water surface. The use of ionic surfactant as penetrant, however, would not be convenient for the thermodynamic analysis of the monolayers, because it is almost impossible to distinguish the hydrophobic interaction in the penetrated monolayer with the ionic interaction caused by the surfactant (and/or spread) film ions and their gegen ions.

In the present study, experiments are carried out on the spread monolayer of lecithin and dilaurin into which an ampholytic surfactant is penetrated. By determining the adsorbed amounts by radiometry, attempts are made to elucidate the behavior of the penetrated monolayers as a function of the surface composition or the surface pressure. Further, the work is discussed about the interaction between the polar groups of lecithin and surfactant in monolayer, combined with the observations on their mixtures in the bulk phase.

Experimental

Materials. After the usual purifications, L-α,β-dimyristoylphosphatidyl choline (DML), which had been purchased from Fluka Co., showed a single spot in the TLC analysis. Dilaurin (DIL), *i.e.* glycerol α,α′-dilaurate, was purified by the recrystallization with hexane. *N*-Dodecyl-β-alanine (NDA), *i.e.* 3-(dodecylammonio)propionate, was employed as an ampholytic surfactant. For the radiometry, the alkyl chain in NDA was labelled with tritium.[5] The solution was prepared by using water which was distilled thrice after being refluxed with acidic permanganate solution overnight. Chloroform and hexane were used for the spreading solvent.

Measurements of Surface Properties. Adsorbed amounts of NDA were determined by the radiotracer method. The radioactivity of tritium β-rays at the air–solution interface was detected by a plastic scintillation counter.[6] Equilibrium surface tension was measured by the Wilhelmy plate method. All measurements were made at 30±0.5 °C, above the gel-liquid transition temperature of DML on the water surface.[7] The pH of the solution was at 5.8±0.2 throughout the experiments: at this value NDA[8] and DML[9] in water possess an amphoteric structure.

Preliminary experiments indicated that the surface pressure *vs.* mean molecular area curves which were obtained by the compression method, coincided well with those obtained by the successive additions of spread solution onto the water surface. All the spread monolayers used in present work, then, were formed by the addition method on the solution surfaces at which NDA had already been adsorbed.

Measurements of Bulk Properties. In order to elucidate the polar interaction between DML and NDA in the bulk state, DSC, IR, and NMR measurements were carried out. In the DSC measurements (Rigaku Denki 8056), the lipids were mixed up well in an aluminium DSC pan with chloroform, allowed to stand overnight *in vacuo* to evaporate the solvent, and sealed in nitrogen gas. The measurements were made as a function of mole fraction of NDA. The specimen for the IR measurement (Hitachi EPI G-2) was prepared in the same manner as that used in the DSC analyses. The absorption spectra were taken as functions of the temperature and mole fraction by the Nujol method. The NMR spectra (JEOL FX-100) were also taken for the 0.1 mol dm^{-3} deuteriochloroform solutions of DML, NDA, and their equimolar mixture at 25 °C.

Results and Discussion

Figure 1 shows the relationship between the surface pressure, π, and spread amount, Γ_1, of DML or DIL

monolayer formed on the solution surface of NDA at various concentrations. Figure 2 exhibits the plot of the surface excess, Γ_2, of NDA against the spread amounts of DML or DIL. The subscripts 1 and 2 mean the film-forming substance and surfactant, respectively. In Fig. 2-b, a little hump was observed on the desorption isotherms of NDA at the intermediate region of concentrations, upon spreading small amounts of DML. This means that DML strongly interacts with the adsorbed NDA on the water surface. On the other hand, the isotherms of NDA for the DIL films simply decreased with increasing spread amounts for all concentrations studied. Thermodynamical discussion for these adsorption isotherms will be made elsewhere.

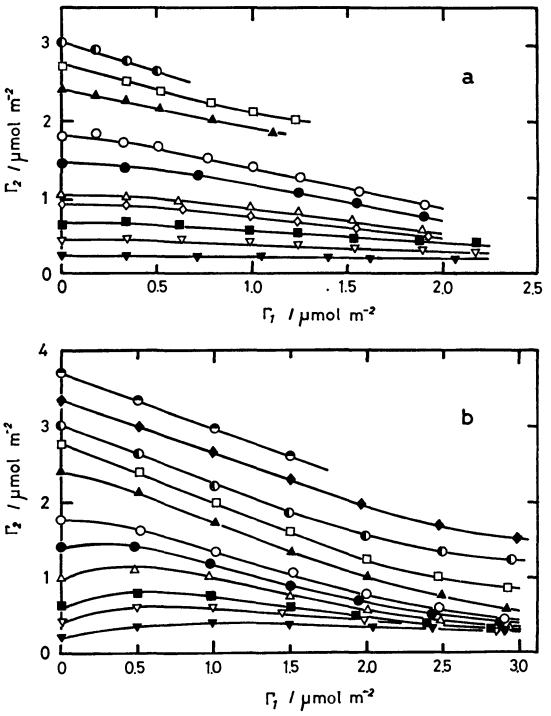

Fig. 2. Γ_1 *vs.* Γ_2 curves for DIL–NDA (a) and DML–NDA (b) at various concentrations of NDA. Signs for each curve are identical with those of Fig. 1 independently of (a) and (b) curves.

Miscibility of Monolayers. Before studying the properties of the penetrated monolayers, the miscibility in monolayer was examined for the DML–NDA and DIL–NDA systems. According to the two-dimensional phase rule,[10] two degrees of freedom are available for one surface phase at constant temperature and pressure in the present systems. Thus the criterion of miscibility is easily made from the relationship in surface pressure and surface fraction at constant total amounts of the monolayers, whose fraction may be chosen by variation in amounts of the spread films and bulk concentration. Here, the surface fraction of NDA, X_2, in the monolayer was obtained by dividing Γ_2 by Γ_t, which was a sum of Γ_1 and Γ_2. The results are shown in Fig. 3. Consequently, the monolayers of both systems were confirmed to be miscible in all surface fractions. In mixing of DML and NDA, there was no indication of the occurrence of a phase separation such as has been observed in mixing of DML and cholesterol on the water surface adsorbed from the dispersed solution.[11]

Area Condensation in Monolayer. The plot of mean molecular area, A, against X_2 in the mixed monolayers of DML–NDA or DIL–NDA is shown at various surface pressures in Fig. 4. The mixing of DIL and NDA in the monolayer was almost ideal at surface pressures lower than 5 mN m^{-1}, but allowed a slight condensation in surface molecular area when surface pressure increased, and approached to the equilibrium spreading pressure of DIL (16.6 mN

m^{-1}). Since the mixing of DIL and NDA does not include the process of interionic interaction, the area condensation observed can be considered to arise mainly from the van der Waals interaction in hydrocarbon chains. On the other hand, the mixing in DML and NDA monolayers is likely to depend in a complicated way on the surface pressure and compositions: for instance, there is the remarkable deviation from the additivity in molecular area at low surface pressure, and also a characteristic kink appears at about 0.3 fraction of NDA, as may be seen in Fig. 4-b. Such behavior in mixing cannot be explained without taking into account the interactions between polar groups as well as hydrocarbon chains in the monolayers. Because both the choline moiety in DML and alanine moiety in NDA possess an amphoteric structure under the conditions of the present work, the ionic interaction can be supposed to occur directly between these moieties. In order to confirm the occurrence of such a binding, some experiments were carried out on the mixture of DML and NDA in the bulk phase.

Confirmation of Ionic Binding of DML and NDA in the Bulk Phase. *DSC Analysis*: The endothermic peak at 63.5 °C was found independently of the mole fraction of the mixture. The plot of the heat of transition at 63.5 °C *vs.* the composition is shown in Fig. 5. Since no peaks are observed at 63.5 °C for each single component, the endothermic peak observed seems to be due to the formation of intermolecular compounds in the DML and NDA mixture. The heat of the corresponding transition was endothermically 20.1 kJ mol^{-1} without any medium.

IR Analysis: IR absorption for the ethyl group in the gauche structure of β-alanine appears at 860 cm^{-1}.[12] Thus, the IR spectra for the mixture of DML and NDA were measured at the various temperatures and compositions. The spectra from 780 to 940 cm^{-1} are shown in Fig. 6. For the equimolar mixture the gauche structure almost disappears near the temperature at which the endothermic peak has been found by the DSC measurement. On 68.4% NDA

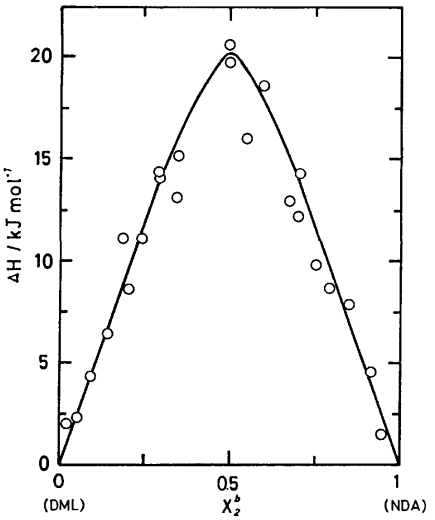

Fig. 5. Heat *vs.* NDA fraction, X_2^b, curve relation to endothermic peaks at 63.5 °C by DSC analysis for DML–NDA mixture.

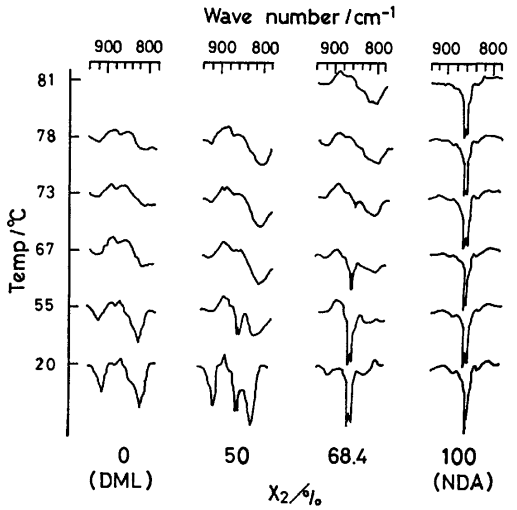

Fig. 6. IR spectra from 780 to 940 cm^{-1} for DML–NDA mixture at various temperatures and compositions.

mixture, however, the corresponding absorption was still observed at 73 °C. This signifies that NDA molecules in more than equimolar quantities exist in the mixture as single molecules. The reason is that the absorption at 860 cm^{-1} for pure NDA remains unchanged while the temperature is increased up to the melting point of NDA, except for the negligible temperature dependence of absorption intensity for each group. It may be concluded that the mixture of DML and NDA converts into an intermolecular compound of 1:1 by heating.

NMR Spectrum: In order to elucidate the contribution of the polar groups to the formation of ionic binding, measurements were made on proton chemical shift for DML, NDA, and their equimolar mixture in the deuteriochloroform solutions. Table 1 shows the proton chemical shift before and after mixing of the DML and NDA solutions. By mixing, $-N^+H_2-$ spectrum of NDA shifted towards the low field, while

TABLE 1. PROTON CHEMICAL SHIFT FOR POLAR GROUPS OF DML, NDA, AND THE EQUIMOLAR MIXTURE IN $CDCl_3$ (ppm) (REFERENCE TMS, 25 °C, 100 MHz)

Groups	DML	NDA	Mixture	$\Delta\delta$[a]
$=N^+H_2$		−8.751	−6.106	+2.65
$-CH_2COO^-$		−2.577	−2.587	−0.01
$\equiv P^-OCH_2-$	−4.118		−4.341	−0.22
$-N^+(CH_3)_3$	−3.340		−3.333	+0.01

a) $\Delta\delta$: Differences of proton chemical shift.

$\equiv P^--O-CH_2-$ spectrum of DML was oppositely shifted towards the high field. However, no difference in chemical shifts was observed for other groups in these compounds within the experimental error (±0.002 ppm). This indicates that the ionic interaction in solution takes place only between the $\equiv P^--O-CH_2-$ group of DML and the $-N^+H_2-$ group of NDA.

From all these experiments, we may conclude that the molecules of DML and NDA, whose polar groups possess both amphoteric structures, form stoichiometrically an intermolecular salt when their mixture is dissolved in a polar solvent or heated up to about 63.5 °C. This may imply the favorable formation of ionic binding with 1:1 of DML and NDA in the penetrated monolayer, provided that the ionic properties of the lipids do not change essentially between the surface and the bulk phases.

Effects of Polar Groups on "Condensing." The condensation at high surface pressure in Fig. 4-b cannot be explained by only the formation of the DML(1):NDA(1) complex as found in the bulk phase. In order to elucidate the unique mixing of DML and NDA in monolayer, one must take into account the difference in the behavior of their polar groups, which depends on the surface pressure and the surface composition. Then the excess free energy of mixing Δg^v, defined by Goodrich,[13] was calculated at 2:1, 1:1, and 1:2 surface compositions at various surface pressures for the DML–NDA and DIL–NDA monolayers. The results are shown in Table 2. A clear difference was found in the mixing behavior of these monolayers. For DML and NDA monolayers, considerably large Δg^v values were appraised even at low surface pressure, compared to those for DIL and NDA monolayer. Since the behavior of hydrocarbon chains in the mixed monolayers is regarded as to be almost

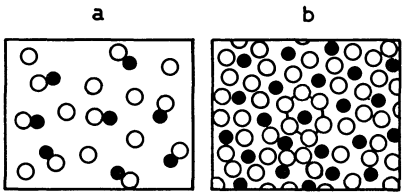

Fig. 7. Schematic representations for mixed monolayer of 2:1 of DML(○) and NDA(●) at low (a) and high (b) surface pressures.

the same between DML–NDA and DIL–NDA, such large values may be considered to be due to the occurrence of ionic binding between DML and NDA in monolayer, as depicted in Fig. 7-a. This consideration coincides with the conclusion obtained in the bulk experiments mentioned above.

The properties of mixed monolayer at high surface pressure are discussed. In the equimolar mixed monolayer at 6 mN m^{-1} the Δg^v values attain a minimum. This is explained by two different origins for the interactive energies caused in mixing: namely, one comes from the ionic binding between polar groups in monolayers and is seen in the low surface density, while the other arises from the condensation between hydrocarbon chains and increases with increasing monolayer density, as may be expected from the Δg^v values for the DIL–NDA system. The surface pressure dependence of Δg^v in the 0.33 fraction monolayer is also interpretable in view of the interaction between the ampholytic moieties of DML and NDA. With increasing film density, the mixed monolayer in all cases is considered to form an ionic network structure which would be more stable rather than remaining in the pair binding of DML(1):NDA(1). Structural formation in monolayer has been also found by Ter-Minassian-Saraga for the mixed monolayer of DML and hexadecyltrimethylammonium chloride.[4] Such a phenomenon turns out to make a unique kink on the A *vs.* X_2 curves in Fig. 4, because the structural monolayer is probably less compressible. A model of mixing at DML(2):NDA(1) composition at high surface pressure is depicted in Fig. 7-b. In DML and cholesterol system, however, the formation of molecular complex of DML(2):CHOL(1) at the surface[11] and bulk[14] phases has been confirmed. Approaching the close packing at about 30 mN m^{-1}, the monolayer which makes a two-dimensional structure becomes so relatively tight and incompressible that the whole system apparently behaves as an ideal one. At 0.66 fraction of NDA the mixed monolayer, however, still keeps the tendency to condense. This is probably because the ionic network structure is gradually broken down by the increases of NDA fraction in the monolayer: the monolayer finally consists of the mixture of DML(1):NDA(1) binding and NDA. Because the dissociation constants of both ampholites at the water surface are $pK_a=3.5$ and $pK_b=3.11$ for NDA[8] and $pK_a=3.32$ and $pK_b=3.55$ for DML[9] at 30 °C, the β-alanine moiety in NDA is considered scarcely to dissociate in water and then to make a hydrated ring structure, compared to the choline moiety in DML. Eventually, NDA molecules in mixed monolayer at

high fraction of NDA tend to be present with the nature like nonionic molecules. Therefore, the maximum condensation occurs at about 0.66 fraction, corresponding to the equimolar mixture of DML–NDA ion pair and NDA. The complicated bahavior in mixing at high surface pressure results from the difference characters in the ampholytic moieties of DML and NDA.

Adsorption of *N*-Dodecyl-β-alanine at the Air-Solution Interface with the Spread Monolayer of Lecithin or Dilaurin. I. Adsorption Isotherms

Takao Tsutsui and Kazuo Tajima*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received May 28, 1980)

The applicability of the Gibbs adsorption isotherm was examined for the adsorption of *N*-dodecyl-β-alanine (NDA) at the air–solution interface with the spread monolayer of lecithin (DML) or dilaurin (DIL). In order to derive adsorption isotherms, the spread monolayer was treated energetically as a part of the adsorbed monolayer. The isotherms were derived for the following cases: (a) a nonideal mixing of the spread and adsorbed molecules and (b) a nonideal adsorption associated with a conformational change due to the complex formation between monolayer molecules. The isotherm derived for case (a) coincided with the observed isotherm of NDA adsorbed into the DIL monolayer, but deviated from the observed isotherm of NDA adsorbed into the DML monolayer. The DML–NDA isotherm was regarded as to be explained by the isotherm derived for case (b). Further, the applicability of the Pethica's isotherm to the adsorption of NDA in both systems was examined.

Some adsorption isotherms of *N*-dodecyl-β-alanine, which adsorbs at the solution surface with the spread monolayer of lecithin or dilaurin, have been reported in the previous paper.[1] From the radiometrical determination of the adsorbed amount, the properties of both mixed monolayers have been described in detail as a function of suface composition or surface pressure. It was clear that the surfactant remarkably condensed with dilaurin or lecithin in monolayer. For such adsorption systems, however, the adsorbed amount of surfactant is expected to obey the Gibbs adsorption isotherm, such as for adsorption of surfactant at the air–solution interface.[2] Pethica[3] and McGregor and Barnes[4] have derived adsorption isotherms by assuming the accessible area for the adsorbing species in the monolayer. However, they are no unique isotherms applicable to every type of adsorption, because each set has been derived under the particular conditions of the highly condensed film of spread monolayer.

In the present study, attempts are made to elucidate the applicability of the Gibbs adsorption isotherm to the adsorption of surfactant at the air–solution interface with the insoluble film. The derivation of isotherms is achieved for the following cases: (a) a nonideal mixing of the spread and adsorbed molecules, and (b) a nonideal adsorption associated with a conformational change of the monolayer molecules. The interaction in the monolayer is introduced as the excess free energy instead of the partial molar surface area in the isotherm. The validity of the isotherms obtained are tested by comparison with the observed isotherms.

Theory

The Gibbs adsorption isotherm for the air–solution interface with spread film (1) and surfactant (2), is given at a constant temperature, assuming that the water surface is taken as the dividing surface:

$$-\mathrm{d}\gamma = \Gamma_1 \mathrm{d}\mu_1^{\mathrm{s}} + \Gamma_2 \mathrm{d}\mu_2^{\mathrm{b}}, \tag{1}$$

where γ denotes the surface tension and Γ_i and μ_i the relative surface excess per unit area and chemical potential for component i, respectively. Superscripts s and b mean the surface and bulk phases. Since the surface tension can be varied with the amount of spread film independently of the chemical potential of surfactant in the bulk phase, the adsorption of the surfactant is considered only for the solution surface which is covered with a fixed amount of spread film. When the spread and adsorbed monolayers coexist on the solution surface A_t of the surfactant of concentration C_2 at surface pressure π, the effective surface area A_2 available for the adsorption decreases by the surface area A_1 occupied by the spread monolayer. As long as the adsorbed monolayer is present in the same surface pressure, μ_2^{s} is equal to μ_2^{b}, so that the spread and adsorbed monolayers may be related by:

$$\mathrm{d}\mu_1^{\mathrm{s}} = \frac{a_1}{a_2}\mathrm{d}\mu_2^{\mathrm{b}}, \tag{2}$$

where a_i denotes the molar surface area of component i in each monolayer. Therefore, the contribution of spread film to the surface energy may be taken into account as a part of the adsorbed monolayer of the surfactant. Using Eq. 2, Eq. 1 is rewritten for the case of ideal penetration as follows:

$$-\mathrm{d}\gamma = \frac{a^{\mathrm{id}}}{a_2}(\Gamma_1+\Gamma_2)\mathrm{d}\mu_2^{\mathrm{b}}, \tag{3}$$

where $a^{\mathrm{id}}=X_1a_1+X_2a_2$, and X_i is the mole fraction of Γ_i.

If the adsorption is nonideal, the following two cases are taken into account: (a) nonideality in the simple mixing of spread and adsorbed molecules, and (b) nonideality in the case that the standard chemical potentials of the spread and/or adsorbed molecules alter due to the change in the conformation of their polar groups by complex formation, chemical reaction, or denaturation in monolayer.

In Case (a). The surface tension change is defined as follows:

$$\mathrm{d}\gamma = \mathrm{d}\gamma^{\mathrm{id}} + \mathrm{d}\gamma^{\mathrm{v}}, \tag{4}$$

where $\mathrm{d}\gamma^{\mathrm{id}}$ is given by Eq. 3. The $\mathrm{d}\gamma^{\mathrm{v}}$ term is the change of surface tension caused by the nonideal mixing of the spread and the adsorbed molecules. From Goodrich's convention for estimating the excess free energy of mixing,[5] we obtain:

$$\mathrm{d}\gamma^{\mathrm{v}} = \frac{\Delta a}{a}\mathrm{d}\gamma, \tag{5}$$

where $\Delta a=a-a^{\mathrm{id}}$, and a is real molar surface area measured by experiment. Substituting Eq. 5 into 4,

we obtain

$$d\gamma = \left(1-\frac{\Delta a}{a}\right)^{-1} d\gamma^{id} \simeq \left(1+\frac{\Delta a}{a}\right) d\gamma^{id} \quad (6)$$

by neglecting higher terms in the expansion with respect to $\Delta a/a$. For the nonideal adsorption, from Eqs. 3 and 6 we obtain:

$$-d\gamma = \frac{a^{id}}{a_2}(\Gamma_1+\Gamma_2)(d\mu_2^b + d\Delta\xi^v), \quad (7)$$

where $d\Delta\xi^v=(\Delta a/a)d\mu_2^b$. Hence, $\Delta\xi^v$ means the excess free energy arising from the nonideal adsorption of a surfactant. Then $d\Delta\xi^v$ may be equated with $(a_2/a^{id})RTd\ln f^v$ thermodynamically; here f^v is the surface activity coefficient at mixing. When $\Delta a=0$ or $f^v=1$, Eq. 7 is reduced to Eq. 3.

Consequently, when the activity coefficient of surfactant in the bulk phase is assumed to be unity,[6] from Eq. 7 Γ_2 is given by:

$$\Gamma_2 = \frac{\left[\frac{-\partial\gamma}{RT\partial\ln C_2}\right]_{\Gamma_1}}{\left[\frac{a^{id}}{a_2}\right]_{\Gamma_1}+\left[\frac{\partial\ln f^v}{\partial\ln C_2}\right]_{\Gamma_1}} - \Gamma_1. \quad (8)$$

In Case (b). We define an equation similar to Eq. 4 as follows:

$$d\gamma = d\gamma^{id} + d\gamma^v + d\gamma^c, \quad (9)$$

where $d\gamma^c$ denotes the surface tension change caused by an alteration in the molecular structure owing to the complex formation or chemical reaction in the monolayer. The $d\gamma^c$ term can not be experimentally separated from the $d\gamma^v$ term, because both are functions of surface compositions of the film. We assume, in this case, that $d\gamma^v$ defined by Eq. 5 refers only to the nonideal mixing of film-forming molecules, after the complex formation or chemical reaction has been completed. Eventually, we have the following equation, analogous to Eq. 7:

$$-d\gamma = \frac{a^{id}}{a_2}(\Gamma_1+\Gamma_2)(d\mu_2^b + d\Delta\xi^v + d\Delta\xi^c), \quad (10)$$

where $d\Delta\xi^c(=(a_2/a^{id})RTd\ln f^c)$ denotes the change of excess free energy resulting from the alteration in the molecular structure due to complex formation. Finally, the adsorbed amount is estimated by:

$$\Gamma_2 = \frac{\left[\frac{-\partial\gamma}{RT\partial\ln C_2}\right]_{\Gamma_1}}{\left[\frac{a^{id}}{a_2}\right]_{\Gamma_1}+\left[\frac{\partial\ln f^v}{\partial\ln C_2}\right]_{\Gamma_1}+\left[\frac{\partial\ln f^c}{\partial\ln C_2}\right]_{\Gamma_1}} - \Gamma_1. \quad (11)$$

The validity of Eqs. 8 and 11 is experimentally tested later.

Experimental

The monolayer of L-α,β-dimyristoyllecithin (DML) or α,α'-dilaurin (DIL) was formed by spreading on the aqueous solution surface of *N*-dodecyl-β-alanine (NDA), *i.e.* 3-(dodecylammonio)propionate. The adsorbed amount was determined by the radiotracer method, using tritiated NDA. Surface tension was registered by the Wilhelmy plate method. The experiments and procedures to measure the surface excess and surface tension have been reported in the preceding paper.[1] All measurements were made at 30±0.2 °C.

Results and Discussion

Figure 1 shows the plots of surface pressure *vs.* bulk concentration of the surfactant solution at various spread amounts of DIL or DML. Figure 2 exhibits the adsorption isotherms of NDA measured by the

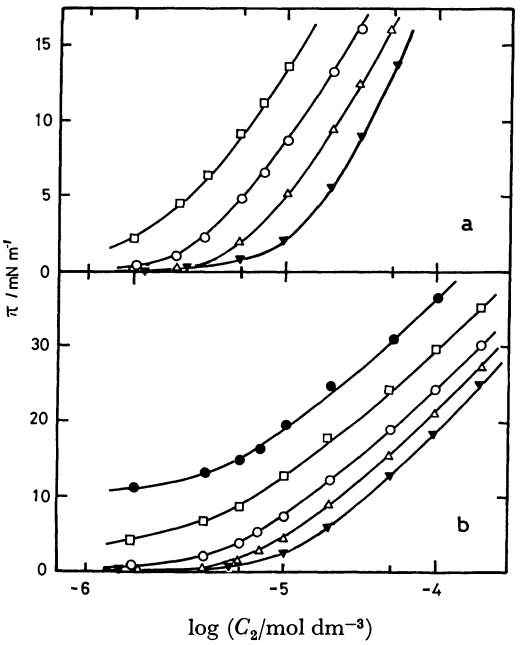

Fig. 1. π *vs.* C_2 curves for DIL–NDA (a) and DML–NDA (b) at various spread amounts (Γ_1/μmol m^{-2}). ▼: 0, △: 0.5, ○: 1.0, □: 1.5, ●: 2.0.

radiometry at various spread amounts of DIL or DML. Figure 3 shows the π *vs.* Γ curves for each spread film of DIL and DML and for the adsorbed film of NDA. The validity of derived theoretical isotherms for the adsorption systems of DIL–NDA and DML–NDA is tested with using the experimental data shown in Figs. 1, 2, and 3.

DIL–NDA System. In the mixed monolayer composed of DIL and NDA, a contraction of surface area has been reported in Ref. 1 as a function of the surface pressure. The contribution of such a contraction to the surface energy is expressed by $(\partial \ln f^{v}/\partial \ln C_2)_{\Gamma_1}$ in Eqs. 8 and 11, which may be estimated from the concentration dependence of the Goodrich's convention. The comparison of Γ_2 calculated by Eq. 8 with the experimental values is shown in Fig. 4. It was found that the calculated values (solid lines) were in good agreement with the observed ones. Since DIL and NDA molecules have been known to form a simple mixed monolayer without forming any complex,[1] the result in Fig. 4 gives an experimental confirmation of the validity of Eq. 8 or Eq. 11 where $f^{c}=1$. However, these equations are not valid for a mixed film in which the surface pressure of single NDA solutions, π_2°, is lower than that of DIL film alone, π_1°: for instance, in the case where Γ_{DIL} is 1.5 μmol m^{-2} π_1° is 1.0 mN m^{-1} and is equal to that of π_2° at NDA concentration of about 8 μmol dm^{-3}, as may be found from Figs. 1 and 3. Hence, below this concentration (corresponding to the arrow in Fig. 6-a) the calculated value from Eq. 8 or 11 gradually deviates from the observed values, because π_1° in this region is higher than π_2°.

Consequently, Eq. 8 or 11 is valid only in mixed films where π_1° is lower than π_2°, according to the requirement of Eq. 2.

DML–NDA System. Figure 5 shows the comparison of the observed and the calculated values for NDA which adsorbs at the solution surface with various amounts of spread DML. Here, the calculation was made according to Eq. 8, using $(\partial \ln f^{v}/\partial \ln C_2)_{\Gamma_1}$ values obtained for DML system. The predicted isotherm of Eq. 8 does not coincide with the observed one, unlike the findings for DIL system. The reason for this deviation seems to be the following. When NDA molecules adsorb at the solution surface with presence of DML molecules, the DML–NDA ion pair is formed in monolayer,[1] so that the standard chemical potentials of these molecules shift because of the structural changes in their polar groups. Therefore, the adsorption of NDA in the present system is considered to obey Eq. 11, according to the arguments described above. Thus the difference between the observed (signs) and the calculated (solid lines) isotherms in Fig. 5 corresponds to the values of the $(\partial \ln f^{c}/\partial \ln C_2)_{\Gamma_1}$ term in Eq. 11. From this reasoning, we can obtain thermodynamic information about the ion pair formed between the ampholytic moieties of DML and

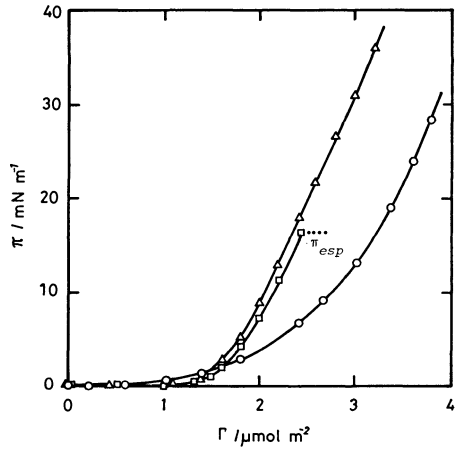

Fig. 3. π *vs.* Γ curves for each spread film of DIL(□) and DML(△) and for the adsorbed film of NDA(○). The curve for the NDA film is calculated from the data in Figs. 1 and 2. π_{esp}: the equilibrium spreading pressure of DIL film (16.6 mN m^{-1}).

NDA in monolayer. Further discussion about this will be made elsewhere.

Pethica's Isotherm. Pethica has derived Eq. 12 for the penetration of sodium dodecyl sulfate at the air-solution interface with a fixed amount of cholesterol:[3]

$$d\pi = \Phi RT\Gamma_2 d \ln C_2 \quad (12)$$

where $\Phi = a_1/(a_1 - \bar{a}_1)$, and $\bar{a}_1$ is the partial molar surface area of the monolayer. The Γ_2 values, which have been calculated by Eq. 12 for the DIL-NDA and DML-NDA systems, are shown by the respective lines in Figs. 4 and 5, and compared with the observed values. These dotted lines deviate greatly from the observed isotherms, except for the low concentrations of the surfactant. Since Eq. 12 should be applied to the adsorption of a surfactant into highly condensed monolayer, the adsorption isotherms in such a case are shown in Fig. 6. It is clear that for DIL-NDA system (Fig. 6-a) the predicted isotherm by Eq. 12 follows the observed one at C_2 less than 3 μmol dm^{-3}, whereas the isotherm given by Eq. 8 coincides above 8 μmol dm^{-3}, as indicated by the arrow in Fig. 6-a: *i.e.*, below this concentration the requirement for Eq. 2 is not satisfied. Therefore, Eq. 12 seems to allow the calculation in the adsorption region unsuitable for Eq. 8. On the other hand, in the DML-NDA system the observed values deviate from the isotherm calculated by Eq. 12 as well as by Eq. 8, even though the solution surface is covered with DML film of 2.0 μmol m^{-2}. Hence, Eq. 12 appears not to be useful for the DML-NDA system.

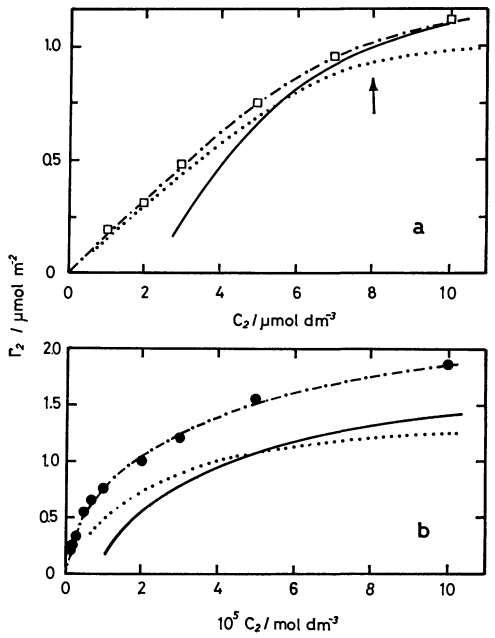

Fig. 6. Comparison of calculated isotherm by Eqs. 8 (solid lines) and 12 (dotted lines) with experimental values (—·□·, —·●—) at spread amount of DIL= 1.5 μmol m^{-2} (a) or of DML=2.0 μmol m^{-2} (b).

In conclusion, Eq. 8, derived for the simple non-ideal adsorption system, could sufficiently explain the observed isotherm for the DIL-NDA system, but could not be applied to the DML-NDA system. Thus, Eq. 11, derived for the complex formation system, was the best one to use for predicting the adsorption of NDA in the DML-NDA system.

(Received May 17, 1980)

The crystal structure and absolute configuration of the title compound, $(-)_{589}$-$[Co(bpy)_3][Fe(CN)_6]\cdot 8H_2O$, has been determined from single-crystal X-ray data. The yellow crystals are triclinic; unit-cell dimensions $a=12.174(3)$, $b=16.742(7)$, $c=10.651(3)$ Å, $\alpha=103.25(3)$, $\beta=104.09(2)$, $\gamma=94.71(3)°$, space group Pl, $Z=2$. The structure was solved by the heavy-atom method and refined to $R=0.076$. The $(-)_{589}$-isomer of $[Co(bpy)_3]^{3+}$ has Δ configuration. The $[Co(bpy)_3]^{3+}$ and $[Fe(CN)_6]^{3-}$ ions have an approximate D_3 symmetry and nearly the same structure as those in other related complexes. All the N atoms in $[Fe(CN)_6]^{3-}$ and the water molecules participate in a three-dimensional hydrogen-bond network.

The absolute configurations of $[Co(bpy)_3]^{3+}$ and tris(1,10-phenanthroline)cobalt(III), $[Co(phen)_3]^{3+}$, have been controversial. Mason and co-workers[1-4] have applied the exciton theory, based on the CD active, long-axis polarized (π, π^*) ligand transition. Hawkins and co-workers[5-7] have proposed an alternative procedure, involving an empirical analysis of both CD and isotropic absorption data of the (d, d*) ligand-field band. The absolute configurations derived by the two methods are not consistent; the former suggests $(-)_{589}$-$[Co(bpy)_3]^{3+}$ to have a Δ configuration, while the latter yields a Λ assignment. The validity of the isotropic absorption analysis has been questioned[8] and the assignment for $(+)_{589}$-$[Co(phen)_3]^{3+}$ has been proposed from the Pfeiffer phenomenon,[9] but the controversy still remains unresolved.

We intend to determine the absolute configuration directly by X-ray analysis, to judge which of the two methods predicts it correctly. Preliminary results of this work have been reported.[10] The absolute configuration thus determined will furnish the basis of the CD theory.

Experimental

The complex of $(-)_{589}$-$[Co(bpy)_3](ClO_4)_3$ was prepared by the method reported,[5] potassium $(+)_{589}$-bistartratoantimonate(III) being used instead of sodium $(+)_{589}$-tartrate.

The crystals of $(-)_{589}$-$[Co(bpy)_3][Fe(CN)_6]\cdot 8H_2O$ were grown by the diffusion method, as shown schematically in Fig. 1. A small glass vessel (A) filled with a solution of $(-)_{589}$-$[Co(bpy)_3](ClO_4)_3$ was placed in the center of a beaker (C). A bent glass pipe with a small opening (B) was filled with a solution of $K_3[Fe(CN)_6]$. Distilled water was poured very carefully down the wall of the beaker until the level was about 1 mm above the opening of the pipe and the vessel. To minimize thermal and photo-racemization, the beaker was kept in the dark at 5 °C. After about 24 h, yellow prismatic crystals were grown on the wall of the central vessel. Found: C, 49.22; H, 3.89; N, 19.28%. Calcd for $[Co(C_{10}H_8N_2)_3][Fe(CN)_6]\cdot 8H_2O$; C, 48.94; H, 4.56; N, 19.02%.

Figure 2 shows the absorption and circular-dichroism spectra in solution, which were recorded on a Simadzu Model MPS-50 spectrometer and JASCO Model ORD/UV-5 spectrometer with CD attachment. These spectra exhibit essentially the same pattern as those of $(-)_{589}$-$[Co(bpy)_3](ClO_4)_3$.[8]

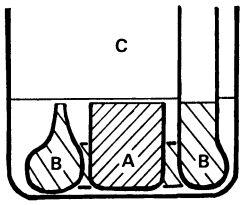

Fig. 1. A schematic drawing of the diffusion method. A small opening of the bent glass pipe is as high as the central vessel.

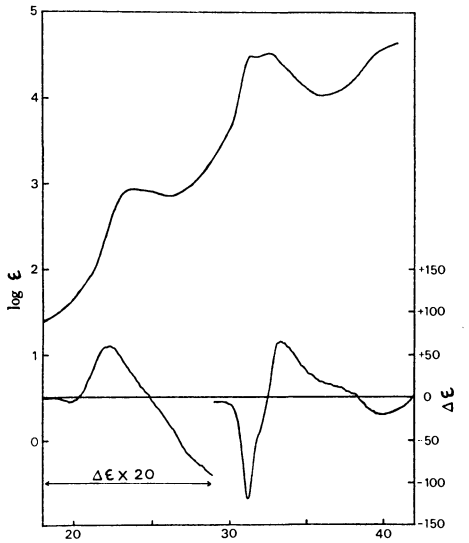

Fig. 2. The absorption (upper curve) and circular dichroism spectra (lower curve) of the $(-)_{589}$-$[Co(bpy)_3][Fe(CN)_6]$ complex in aqueous solution.

The symmetry and approximate cell dimensions of the crystal were determined from oscillation and Weissenberg photographs. The more accurate cell dimensions were obtained by least-squares analysis of 2θ measured on a Rigaku automated four-circle diffractometer. The density was measured by the flotation method in a mixture of carbon tetrachloride and hexane. The crystal data are summarized in Table 1.

Intensity data up to $2\theta \leqq 55°$ were collected on the diffractometer with Mo $K\alpha$ radiation ($\lambda=0.71069$ Å) mono-

chromated by a graphite. An ω-2θ scan was employed with a scan rate of 4° (2θ) min^{-1}. A total of 6348 independent reflections, ($|F_o| \geqq 3\sigma(|F_o|)$), was used for the structure determination. The intensities were corrected for Lorentz and polarization factors but absorption correction was not applied.

Structure Determination

The positions of the two cobalt and two iron atoms were obtained from the three-dimensional Patterson function. Since the arrangement of these four atoms exhibits a non-crystallographic center of symmetry, the two crystallographically independent complex ions were approximately related to each other by the pseudo inversion center on the first Fourier map. The positions of the atoms in four pyridine rings, which are not related by the pseudo inversion, were selected carefully on the successive Fourier maps.

The structure was refined by the block-diagonal least-squares method. After several cycles of the refinement, sixteen oxygen atoms of the water molecules appeared on a difference map. Further refinement revealed that the eight of sixteen oxygen atoms had the decreased occupancy factors.

The positions of the hydrogen atoms in the 2,2′-bipyridine ligands were obtained from the difference map and refined with the isotropic temperature factors. The hydrogen atoms of water molecules could not be found. The weighting scheme in the final refinement, $w=0.2$ if $|F_o|<13.8$ or $|F_o|>138.1$, $w=(0.000956F_o^2-0.157|F_o|+7.58)^{-1}$ if $13.8 \leqq F_o| \leqq 138.1$, was employed. The final R value became 0.076 for 6348 observed reflections. At the final stage, no peaks higher than 0.58 e Å^{-3} were found on the difference map. Atomic scattering factors including the anomalous terms for Mo $K\alpha$ radiation were taken from the International Tables for X-Ray Crystallography.[11] Final positional parameters and their standard deviations are given in Table 2. A list of the anisotropic thermal parameters and a table of the observed and calculated structure factors are kept in the office of the Chemical Society of Japan (Document No. 8104). The computation was done on a FACOM-HITAC system M-160 computer at this Institute.

a) B_{eq} means the equivalent isotropic temperature factor, defined by $B_{eq}=8\pi^2(U_1+U_2+U_3)/3$ where U_1, U_2, and U_3 are the principal components of U matrix. All the values of B and B_{eq} are multiplied by 10.

Friedel pairs (hkl and $\bar{h}\bar{k}\bar{l}$), for which differences in intensities were the largest, were measured on the diffractometer using Ni-filtered Cu $K\alpha$ radiation. The observed and calculated structure factors are compared in Table 3, the anomalous scattering terms being taken from the International Tables.[11] All the relations between $|F_c(hkl)|$ and $|F_c(\bar{h}\bar{k}\bar{l})|$ are consistent with those between $|F_o(hkl)|$ and $|F_o(\bar{h}\bar{k}\bar{l})|$, indicating that $(-)_{589}$-$[Co(bpy)_3]^{3+}$ has the Δ configuration.[12]

The Structure of $[Co(bpy)_3]^{3+}$ *and* $[Fe(CN)_6]^{3-}$. The crystal structure viewed along the a axis is shown in Fig. 3, in which the numbering of the atoms is also given. The two crystallographically independent complexes are approximately related by a non-crystallographic inversion center except for the four pyridine rings including N(A12), N(B1), N(E1), and N(F12). The structures of the two crystallographically independent complexes are not significantly different. Both of the $[Co(bpy)_3]^{3+}$ and $[Fe(CN)_6]^{3-}$ ions, which are shown in Fig. 4(a) and (b), have approximate point-group symmetry D_3.

Bond distances and angles in the coordination sphere of $[Co(bpy)_3]^{3+}$ are given in Table 4. The average Co–N distance and N–Co–N angle are 1.93 Å and 83.3°, respectively. These value are in good agreement with those found in $[Co(bpy)_2(NO_3)]^{2+}$ (1.929 Å and 83.27°, respectively),[13] and distinct from those in $[Co(en)_3]^{3+}$ (en: ethylenediamine), (1.978±0.004 Å and 85.4±0.3°, respectively).[14]

For the $[Co(en)_3]^{3+}$ and other trisbidentate complexes with five-membered rings, the following empirical rule has been proposed; those complexes which show prominent positive circular dichroism in the first absorption region possess Δ absolute configuration.[16] The absolute configuration of the present $(-)_{589}$-$[Co(bpy)_3]^{3+}$ complex conflicts with the empirical rule because the prominent positive circular dichroism is found at 22×10^3 cm^{-1} as shown in Fig. 2. The octahedron around the cobalt atom in the $[Co(bpy)_3]^{3+}$ is compared with that of $[Co(en)_3]^{3+}$ [15] in Fig. 5, in which the characteristic values are given.

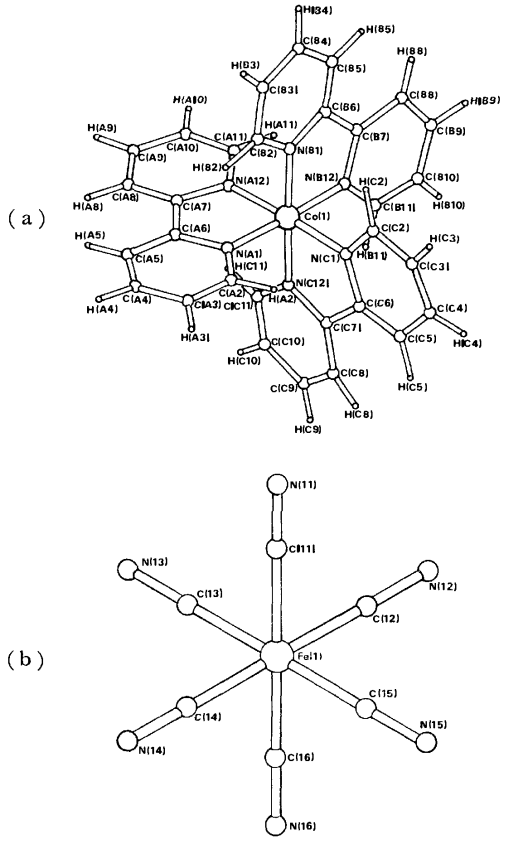

Fig. 4. The molecular structures of $[Co(bpy)_3]^{3+}$, (a), and $[Fe(CN)_6]^{3-}$, (b), viewed along the pseudo three-fold axis. These structures are not significantly different from those of the other crystallographically independent ions.

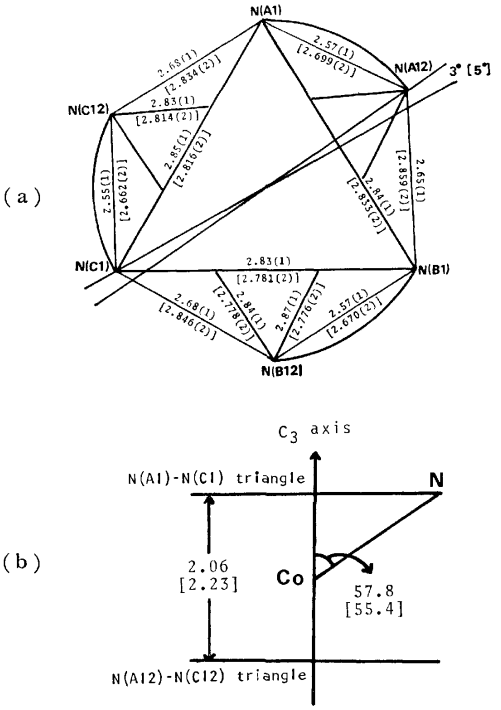

Fig. 5. Comparison of the octahedrons in $[Co(bpy)_3]^{3+}$ and $[Co(en)_3]^{3+}$ (in brackets). (a) Projection down and (b) normal to the pseudo three-fold axis. The values are taken from the present complex including Co(1) and $[Co(en)_3]^{3+}$ in $[Co(en)_3]^{3+}\cdot C_4H_4O_6^{2-}\cdot Cl^-\cdot 5H_2O$.[15]

N(B12)-Co(1)-N(C1)	87.3(4)	N(E12)-Co(2)-N(F1)	93.3(4)
N(B12)-Co(1)-N(C12)	93.8(4)	N(E12)-Co(2)-N(F12)	93.3(4)
N(C1)-Co(1)-N(C12)	83.5(4)	N(F1)-Co(2)-N(F12)	82.9(4)

These values are not so different between the two octahedrons. It seems difficult to ascribe the opposite sign of the circular dichroism to the slight difference in geometries of the two octahedrons. A more rigorous study is necessary to explain the circular dichroism of the (d, d*) transition.

Bond distances and angles in the bipyridine ligands are listed in Table 5. The average values are given in the final column. There is no significant difference between the corresponding values in the present complex and in other related complexes, such as $[Fe(bpy)_3]^{3+}$,[17] $[Co(bpy)_2(NO_3)]^{2+}$,[13] $[Ni(bpy)_3]^{3+}$,[18,19] $[Ni(bpy)(H_2O)_2]^{2+}$,[20] and $[Cu(bpy)_3]^{2+}$.[21] The average distances of C–N, C–C, and C–C (connecting two pyridine rings) in these complexes are 1.35, 1.40, and 1.48 Å, respectively.

The geometries of the five-membered rings in the $[Co(bpy)_3]^{3+}$, $[Fe(bpy)_3]^{3+}$, and $[Ni(bpy)_3]^{2+}$ complexes are compared in Table 6. The complex of $[Cu(bpy)_3]^{2+}$ is omitted because Jahn-Teller effect distorts its octahedron. The N–M–N angle decreases with the increase of the M–N length. It is noteworthy

a) M means Co, Fe, and Ni atoms.

that the M–N–C angles take a constant value. This indicates that the bipyridine ligand has not a planar conformation; otherwise the M–N–C angle should increase with the increase of the M–N distance. The two rings of each bipyridine ligand in $[Ni(bpy)_3]^{2+}$ are twisted along the connecting C–C bond. The twist angles are reported as 5.8—10.9°.[18] On the other hand, the bipyridine ligands of $[Co(bpy)_3]^{3+}$ have more planar conformations. Two rings of the bipyridine ligand in $[Co(bpy)_3]^{3+}$ are not twisted but slightly bent at the connecting C–C bond. The angles between the normals to the pyridine rings in the six bipyridine ligands are 2.3° to 4.7°. For the $[Fe(bpy)_3]^{3+}$ complex, those angles have intermediate values between those in $[Ni(bpy)_3]^{2+}$ and $[Co(bpy)_3]^{3+}$.

Bond distances and angles in $[Fe(CN)_6]^{3-}$ are given in Table 7. The average Fe–C and C–N distances, 1.94 Å and 1.14 Å, are in good agreement with those in other hexacyanoferrate(III) crystals.[22–26] Although the deviation of each Fe–C bond length from the average value is slightly large, similar distorted octahedrons, characterized by widely varying M–C bond lengths, have been observed in other hexacyanometalate(III) complexes.[22]

Hydrogen Bond. The hydrogen bonding scheme is shown in Fig. 3. All the N atoms of $[Fe(CN)_6]^{3-}$ and the water molecules participate in the hydrogen bonds to form a three-dimensional network through the O–H···N and O–H···O hydrogen bonds. The distances of O···N and O···O and angles of O···O···N and O···O···O are given in Table 8. The $[Co(bpy)_3]^{3+}$ cations are packed in the network with the van der Waals contacts.

The occupancy factors of O(9), O(10), O(11), O(12), O(13), O(14), O(15), and O(16) showed the decreased values from 0.5 to 0.2. The water molecules may be partly lost from the crystal during the data collection, as judged by the fragility of the crystal after the experiment.

Four water molecules, O(2), O(3), O(5), and O(15), are approximately related to O(1), O(9), O(4), and O(11), respectively, by the pseudo inversion center. The other water molecules occupy the positions near the bipyridine ligands which are not related by the pseudo inversion. Preliminary experiments showed that the racemic crystal of this complex has the space

Some Properties of Fluorine-adsorbed Active Carbon

Nobuatsu WATANABE* and Kazuo UENO

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received March 19, 1980)

Properties of fluorine-adsorbed active carbon (FAAC), expected to be a new fluorinating agent, were investigated by means of TG, X-ray diffraction, and ESCA. The fluorine in FAAC was desorbed by heat treatment in a vacuum at temperatures higher than 200 °C. The X-ray diffraction and ESCA measurements suggest that fluorine is inserted between the carbon layer planes of the active carbon, and combines with carbon atoms weakly in comparison with the C–F covalent bond. The reactivity of FAAC against several organic compounds was studied. 1-Butanol, 1-butanethiol, and cyclohexylamine were oxidized. Butyryl chloride was fluorinated to give butyryl fluoride.

Direct fluorination of carbon at temperatures 350—600 °C gives two types of graphite fluoride, identified as polycarbon monofluoride, $(CF)_n$, and polydicarbon monofluoride, $(C_2F)_n$.[1] Some kinds of carbon adsorb a large amount of fluorine at room temperature.[2,3] Active carbon shows 30—50% weight increase when it is exposed to fluorine atmosphere at room temperature.[2] While graphite fluoride is chemically and thermally stable, this fluorine-adsorbed active carbon (FAAC) can oxidize other halogen ions at room temperature,

$$\text{FAAC} + X^- \text{ in aq soln} \longrightarrow C + F^- + \frac{1}{2}X_2 \quad (X=Cl, Br, I)$$

where C is the residual active carbon.[2] Thus FAAC is expected to be a new fluorinating reagent.

In this study, FAAC was prepared in a laboratory scale and studied by thermogravimetry (TG), X-ray diffraction, and X-ray photoelectron spectroscopy (ESCA). Fluorination of several organic compounds with FAAC was examined.

Experimental

Commercial granular active carbon (extra pure) and organic compounds (guaranteed grade) were used without further purification. TG study was carried out with a thermobalance specially designed for use in a fluorine atmosphere.[2]

A schematic diagram of the reactor for fluorination is shown in Fig. 1. The reaction vessel (5) is made of stainless steel, and can be used at desired temperatures with an electric furnace or appropriate coolant. The fluorocarbon oil (Daifluoil, Daikin Kogyo Co.) placed on the mercury column in the manometer (4) prevents fluorine from reacting with mercury. The gas reservoir (3) and all tubings were made of copper.

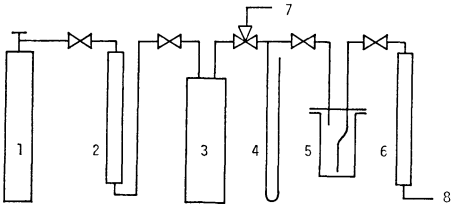

Fig. 1. Schematic diagram of reactor for fluorination. 1: F_2 gas cylinder, 2: HF absorber (NaF pellets heated at 100 °C), 3: gas reservour, 4: Hg manometer, 5: reaction vessel, 6: F_2 absorber (soda-lime pellets), 7: N_2 gas, 8: to vacuum pump.

Results and Discussion

Preparation of Fluorine-adsorbed Active Carbon. FAAC was prepared in the following manner using the apparatus shown in Fig. 1. About 100 g of granular active carbon[4] was placed in the reaction vessel, and heated at *ca.* 150 °C for 2 h in a vacuum to remove water. The vessel was filled with purified nitrogen gas after the active carbon had cooled down to room temperature. Fluorine (0.5 atm) and nitrogen (0.5 atm) were mixed in the gas reservoir. Diluted fluorine was then streamed slowly through the vessel at a flow rate of *ca.* 30 ml/min. The FAAC containing 15—20% fluorine by weight (calculated from the weight increase) was prepared by streaming the gas for 20—30 h. The sample thus obtained had to be washed with nitrogen gas before it was taken out from the reaction vessel. FAAC containing over 20% fluorine would be prepared with further fluorination.

Excessive flow rate of the diluted fluorine sometimes caused explosion in the reaction vessel, or auto-catalytic thermal decomposition of the sample accompanied by a large amount of heat evolution. In the latter case, the sample completely lost the adsorbed fluorine. The reaction vessel should be evacuated as soon as the thermal decomposition takes place, because the inner pressure increases rapidly.

Desorption of Fluorine by Heating. The fluorine adsorbed by FAAC was scarcely desorbed at room temperature even *in vacuo*. This indicates that the fluorine is chemically adsorbed by the active carbon.[2,3] TG was applied in order to study the desorption of

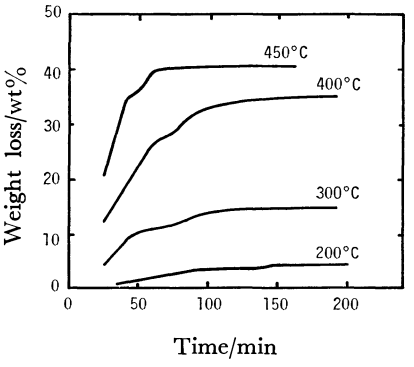

Fig. 2. TG curves for fluorine-adsorbed active carbon at various temperatures in a vacuum.

the fluorine by heating *in vacuo* (Fig. 2). The higher the temperature, the more desorption being observed. The final weight loss at 450 °C corresponds to the desorption of 95% fluorine in FAAC, when no thermal decomposition took place. Various kinds of fluorocarbon were formed in the thermal decomposition of graphite fluoride.[5,6]

Each TG curve was a straight line at first, and then showed slight decrease in the desorption rate, indicating that fluorine is adsorbed heterogeneously. Supposing that the initial desorption rate follows the first order kinetic, the apparent activation energy was calculated to be 28 kJ/mol from the Arrhenius plot of the rate constants. Takenaka[7] found the activation energy for the adsorption of fluorine on graphite to be *ca.* 17kJ/mol. These values are smaller than that for the adsorption of oxygen on graphite.[8] Fluorine might not be combined with carbon covalently like oxides on graphite, but adsorbed weakly on carbon atoms. This was confirmed by ESCA spectra.

Structural Change of Active Carbon by Fluorine Adsorption. The structural change of active carbon was studied by means of X-ray powder diffractometry (Fig. 3). Active carbon has poor regularity as regards carbon layer stacking. Its structure is called turbostratic.[9] A diffused diffraction between 20 and 30° in 2θ corresponds to three to four layers stacked with the same distance of 3.5—3.7 Å (Fig. 3-a). The broad peak disappeared completely when carbon adsorbed fluorine, as shown in Fig. 3-b. However, the regularity of layer packing was recovered by heat treatment at high temperatures such as 300 or 400 °C *in vacuo* because of the desorption of fluorine (Fig. 3-c, d). In the case of graphite, the adsorbed fluorine strained the graphite structure in a direction vertical to the carbon layers, and the stress given to the crystal lattice of graphite was an elastic deformation.[5] The results indicate that the fluorine is not only adsorbed on the surface of the active carbon, but also inserted between carbon layer planes.

ESCA Measurement. In order to elucidate the bonding state of fluorine, FAAC was analyzed by ESCA. In Fig. 4 are shown the spectra for C_{1s}

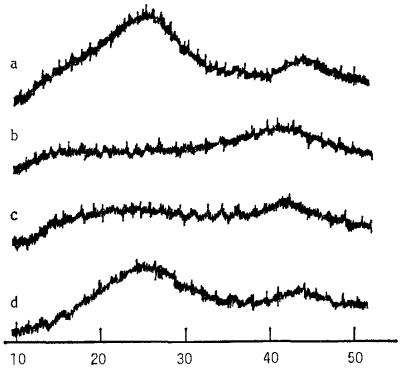

Fig. 3. Variation of X-ray diffraction patterns of fluorine-adsorbed active carbon (FAAC).
a: Original active carbon, b: FAAC, c and d: FAAC after the heat-treatment in a vacuum at 300 and 400 °C, respectively.

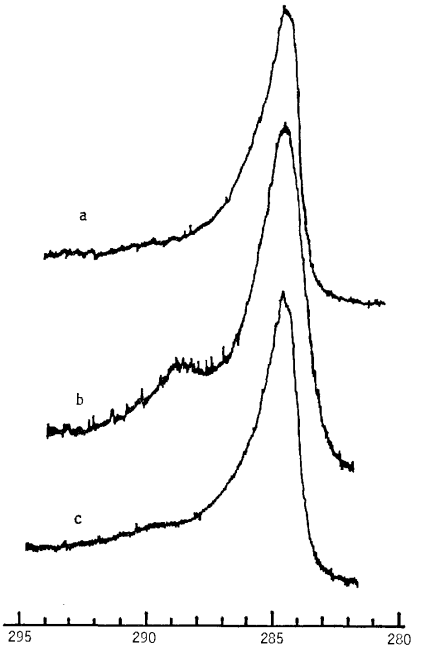

Fig. 4. Variation of ESCA spectra for C_{1s} photoelectron of fluorine-adsorbed active carbon (FAAC).
a: Original active carbon, b: FAAC, c: FAAC after the heat-treatment at 450 °C in a vacuum.

photoelectron of (a) original active carbon, (b) FAAC containing 30% fluorine by weight, and (c) FAAC which is heated at 450 °C for 3 h in a vacuum. The main peak at 284.6 eV corresponds to carbon atoms having no interaction with fluorine.

A new peak appeared at 288.7 eV in the spectrum of FAAC (Fig. 4-b). Since the C–F covalent bond in graphite fluoride has a peak at 290.4 eV,[1] the new peak is due to the interaction between C and F which is weaker than their covalent bond. By heat-treatment, fluorine was desorbed almost completely and a small hump appeared at *ca.* 290 eV, indicating the formation of C–F covalent bond (Fig. 4-c).

A weaker C–F bond was also observed in ESCA spectra of carbon black[3] and natural graphite[15] fluorinated at room temperature. These fluorinated samples have similar oxidizability as FAAC. It is not clear, however, whether the adsorbed fluorine is atom or molecule.

Let us discuss the structure of FAAC and the mechanism of the fluorination of active carbon on the basis of the above results. The composition of FAAC containing 30 wt% of fluorine can be expressed as $C_{3.7}F$. The situation thus differs from the simple adsorption of fluorine on active carbon. FAAC loses the characteristic structure of active carbon. Thus, it is concluded that FAAC is an amorphous solid with no crystallinity, holding fluorine with relatively weak bonding on its layered structure like graphite intercalation compounds. FAAC is similar to the intercalation compound since it permits the reversible insertion and withdrawal of fluorine.

Fluorination of active carbon may be influenced by its structural features rather than surface properties,

Table 1. Reaction of several organic compounds with fluorine-adsorbed active carbon

Run	Substrate	Reaction conditions			Products (Yield/%)
		Solvent	Temp/°C	Time/h	
Oxidation					
1	*n*-BuOH	CCl_4	78	24	$CH_3(CH_2)_2CHO$ (33)

No reaction					
9	C_6H_6	—[a]	80	90	
10	*n*-Bu-X (X=Cl, Br)	CCl_4	78	45	
11	C_6H_5-Br	—[a]	100	24	

a) Solvent was the substrate itself. b) Gas phase reaction in a steel reactor ($3\phi \times 30$ cm) heated by an electric furnace. c) Total yield of CF_4, CF_3Cl, CF_2Cl_2, and $CFCl_3$. They were identified by using IR. d) Calculated from the absorption intensity of the C=O band due to COF group.

since the amount of fluorine taken in far exceeds what is expected for the adsorption. The active carbon having looser structure would hold more fluorine than that having rigid structure.

Reactions of Several Organic Compounds with FAAC. *n*-BuOH and *n*-BuSH were oxidized to their corresponding aldehyde and disulfide, respectively (Table 1). The oxidation of cyclohexylamine gave the adduct with hydrogen fluoride and oily material which could not be identified. When the amine was dropped directly to FAAC at room temperature, it burned violently with a red flame and white smoke. Thus, FAAC can oxidize the compound which easily supplies proton.

Hydrocarbons and alkyl halides were inert to FAAC below 100 °C (Runs 5, 9, 10, and 11), and can be used as an inert solvent. However, at a high temperature such as 250 °C, tetrachloroethylene was fluorinated violently with the rupture of C=C double bond, giving various fluorochlorocarbons.

$$CCl_2{=}CCl_2 \longrightarrow CF_4,\ CF_3Cl,\ CF_2Cl_2,\ CFCl_3$$

The carbon-chlorine bonds were also ruptured, $NiCl_2$ being formed on a nickel sample holder in the reactor. Carbon tetrachloride also gave a small amount of fluorochlorocarbons at this high temperature.

It is interesting to know whether FAAC can be used for selective fluorination. As an example, the chlorine in butyryl chloride was substituted by fluorine with FAAC. The reactions in CCl_4 and in CH_3CN were compared with each other. The yield of butyryl fluoride in CH_3CN was about twice that in CCl_4 under the same conditions. Aprotic polar solvent seems to be preferable for the fluorination of acyl chloride. Attempt to use dimethyl sulfoxide as solvent was unsuccessful because DMSO reacted with the acyl chloride.

Such solvent effects can be explained in terms of the surface polarity of active carbon. Its polarity is nearly zero, and it adsorbs nonpolar molecules preferentially.[10] In CH_3CN, the acyl chloride may be attracted by the surface of FAAC on account of its longer alkyl chain than the solvent. On the other hand, in CCl_4, FAAC may be surrounded by the inert solvent, and the reaction rate will slow down.

Even in CH_3CN, however, the reaction rate is regarded to be small (90% yield after 120 h). This may be due to the slow diffusion of active fluorine from the inner part to the surface of FAAC. Thus, fluorination with FAAC is considered to occur on its surface or near it. The polarities of reactant and solvent should be taken into accout. Stirring of the reaction system is indispensable, and crushing of FAAC in dry atmosphere is effective for better yield.

Synthetic Inorganic Ion-exchange Materials. XXXI. Ion-exchange Behavior of Tervalent Metals and Rare Earth Elements on Crystalline Antimonic(V) Acid Cation Exchanger

Mitsuo ABE,* Masamichi TSUJI, and Masato KIMURA**

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo 152

(Received March 26, 1980)

The increasing order of ion-exchange selectivity for tervalent metal ions: $Al^{3+} \ll Ga^{3+} \leq Yb^{3+} < Fe^{3+} < La^{3+} < In^{3+}$, was established in 1 mol dm^{-3} nitric acid solution on a crystalline antimonic(V) acid (C-SbA) cation exchanger. Strong correlation was found between the selectivity and the effective ionic radii of these ions. Large separation factors for neighboring ions were obtained, as compared with the commercial ion exchange resin. An effective separation of aluminium(III)-iron(III) ion pairs and a group separation of garium(III) and ytterbium(III) ions from lanthanum(III) ion were performed by using a relatively small C-SbA column (4 cm × 0.4 cm i.d.).

Various antimonic(V) acids behave as cation exchangers and can be prepared in three different species: crystalline, amorphous, and glassy.[1] Among these antimonic(V) acids, crystalline antimonic(V) acid (C-SbA), $Sb_2O_5 \cdot 4H_2O$, has received much attention during the last two decades, owing to its high selectivity for certain elements.[2] The C-SbA exhibits the increasing order of selectivity in microquantities: $Li^+ < K^+ < Cs^+ < Rb^+ < Na^+$ for alkali metals,[3] $Mg^{2+} < Ba^{2+} < Ca^{2+} < Sr^{2+}$ for alkaline earth metals,[4] and $Ni^{2+} < Mn^{2+} < Zn^{2+} < Co^{2+} < Cu^{2+} < Cd^{2+}$ for bivalent transition metals[5,6] in nitric acid media. Effective separations can be achieved for alkali metals,[3,4,7] the pairs of Mg^{2+}–Ba^{2+}, Ba^{2+}–Sr^{2+}, Cs^+–Sr^{2+},[8] and Cd^{2+}–(Zn^{2+}, Cu^{2+}).[5,6] Adsorption reactions for all these ions obey the reversible ion-exchange reactions.[9–11]

Slightly different selectivity was observed on polyantimonic(V) acid (PAA)[12] and hydrated antimony pentoxide (HAP)[13]: $Rb^+ < Cs^+ < Na^+$,[12] $Cs^+ < Rb^+ < NH_4^+ < K^+ < Na^+$,[14] and $Ra^{2+} < Ba^{2+} < Ca^{2+} < Sr^{2+}$.[12]

No systematic study has been carried out for the selectivity of tervalent metals, including rare earth metals, on C-SbA.

On the other hand, the ion-exchange separations of rare earth metal ions are very difficult in nitric acid media, because of the extreme closeness of the chemical properties of individual rare earth elements. Chromatographic separations of rare earth elements on cation exchange resins have been reported by use of complexing agents, such as citrate, lactate, edta and α-hydroxyisobutyrate.[15] In recent years, radioactivation analysis is the only method which allows the determination of each individual rare earth element in high purity metals or rock samples. Even here, more effective mutual separation of rare earth elements may be needed, as well as better separation from the matrix.[16–20]

An improved selectivity for tervalent metal ions has been found on synthetic inorganic ion exchangers such as titanium arsenate,[21] zirconium tungstate,[22] tin(IV) arsenate,[23] and titanium tungstate.[24]

This paper describes the ion-exchange selectivity for micro-amounts of some tervalent metal ions and rare earth metal ions on C-SbA cation exchanger in nitric acid media, and some applications to the chromatographic separation.

Experimental

Chemicals. Antimony pentachloride supplied by Yotsuhata Chemical Co., Ltd., was employed without further purification. Other chemicals (Wako Pure Chemical Industries, Ltd.) were of purity over 99.5%. The water used was prepared by distilling water and then passing it through a mixed bed of anion and cation exchange resins. The water showed a conductivity lower than 3×10^{-5} s cm^{-1}.

Sample Solutions and Determinations. Stock solutions containing 0.1 M (1 M = 1 mol dm^{-3}) metal ion in 0.1 M nitric acid solution were prepared by dissolving weighed amounts of each metal, aluminium, indium, and lanthanum, and iron(III) nitrate nona-hydrate and ytterbium(III) oxide in moderately concentrated nitric acid solution in order to prevent any hydrolysis with warming. The concentration of iron(III) ion was determined gravimetrically as iron(III) oxide.

For the measurement of equilibrated distribution coefficients of garium(III), indium(III), lanthanum(III), and ytterbium(III) ions, aliquots of supernatant solutions were taken into polyethylene capsules and activated together with their standard metal ion solution in known amounts with the TRIGA II reactor at Musashi Institute of Technology (thermal flux, 4×10^{11} n cm^{-2} s^{-1}; fast flux, 6.5×10^{10} n cm^{-2} s^{-1}). The irradiating time was selected by reference to the thermal cross section and the resonance integral of each nuclide.[25] After a cooling time appropriate for each radionuclide, the γ-spectra of the indicator nuclides were analysed with the "GAMA" system using Ge(Li) detector connected to 4096 channel analyser.[26] The indicator nuclide and γ-energy used for determination were as follows: ^{72}Ga, 833 kev; ^{116m}In, 1508 kev; ^{140}La, 1595 kev; ^{175}Yb, 396 kev. Good linearity was obtained for the calibration curve of each metal ion.

The determination of iron(III) or aluminium(III) ions in microamounts was carried out by a Varian-Techtron 1100 atomic absorption spectrometer. For atomization of aluminium, a Varian-Techtron carbon rod atomizer equipped with an automatic sample dispenser was employed.

The emf titration method was employed for the determination of hydrogen ions in sample solution by using 0.1 mol dm^{-3} sodium hydroxide solution.

Preparation of C-SbA as an Ion Exchanger. The procedure was described in an earlier paper.[1]

** Present address: Okamoto Riken Gomu Co., Ltd., 3-27-12 Hongo, Bunkyo-ku, Tokyo 113.

Distribution Coefficients (K_d). C-SbA (0.250 g) was immersed in 25.0 cm³ of a solution containing metal ion of 1×10^{-4} M in a nitric acid solution adjusted to a desired concentration with intermittent shaking at (30±0.1) °C. The K_d values were determined by the following equation:

$$K_d = \frac{\text{Amount of metal ions in exchanger}}{\text{Amount of metal ions in solution}} \times \frac{\text{cm}^3 \text{ of solution}}{\text{g of exchanger}} \ (\text{cm}^3/\text{g}).$$

The concentrations of the metal ions in solid and solution phases were deduced from the differences between the initial and the final concentrations in supernatant solution.

Column Operation. One μmol of garium(III), lanthanum(III), and ytterbium(III) ions preactivated with reactor neutrons was loaded onto the C-SbA column of 4 cm×0.4 cm i.d. pretreated with 0.1 M nitric acid solution. Then, an appropriate eluant was passed through with a flow rate of 0.3 cm³/min. The effluent was collected in test tubes by using a photosensitive drop count-type fraction collector (Ohtake Works, Ltd., Japan), followed by γ-counting with a Ge(Li) detector connected to a Northern 1705 1024 channel analyzer.

Thermal Analysis and X-Ray Study. These were carried out in the manner described previously.[11]

Results and Discussion

The results of the DTA, TGA, and X-ray studies of C-SbA in hydrogen form showed a good agreement with the earlier results.[1,27]

Ion-exchange Selectivity. The time dependence of adsorption for different metal ions showed that the equilibrium was attained within about 20 d for indium(III) and lanthanum(III) ions (Fig. 1). An extremely slow rate of adsorption for iron(III) ion was observed, about 100 d being required. The variety of time dependence from element to element may be considered to reflect the rigid structure of the C-SbA cation exchanger, as described earlier.[9]

The plot of log K_d *vs.* log [HNO_3] showed a linear relationship with a slope of −3, indicating an "ideal" 3:1 ion-exchange reaction (Fig. 2).

The observed K_d values (logarithmic scale) in 1 M nitric acid solution were plotted against the atomic number (Fig. 3 top). The profile parallels the change in the effective ionic radii (EIR)[28] (Fig. 3 bottom).

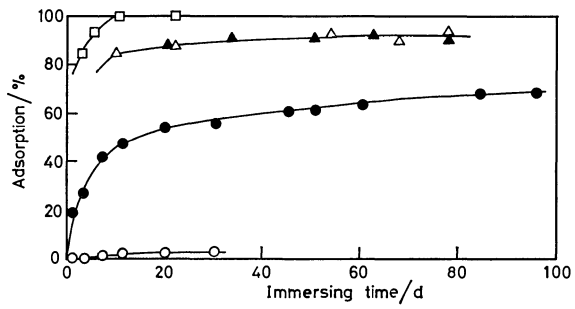

Fig. 1. Time dependence of adsorption of tervalent metal ions on C-SbA.
Ions and concentrations of HNO_3; □: La (0.1 M), △: La (1.0 M), ▲: In (1.0 M), ●: Fe (1.0 M); ○: Fe (4.0 M).

The maximum K_d value was found for ions having about 1 Å of the EIR. Such correlation has been also observed for alkali, alkaline earth, and bivalent transition metal ions, *e.g.*, Na^+ (1.02 Å), Ca^{2+} (1.00 Å), Cd^{2+} (0.95 Å), and Hg^{2+} (1.02 Å). The low K_d values were observed for metal ions having an EIR of about 0.7 Å, *e.g.*, Li^+ (0.74 Å), Mg^{2+} (0.72 Å), and Ni^{2+} (0.700 Å).[5,8-11,29,30] Thus, the ion-exchange reactions are favorable for the ions possessing an EIR of about 1 Å on the C-SbA, if there is a similar situation for the exchange reaction of tervalent metal ions

on the C-SbA.

In aqueous solution, the cations such as Ni^{2+} and Al^{3+} have an octahedral primary solvation shell.[31] If in the C-SbA the exchanging cations maintain a configuration similar to that in the aqueous solution, the electrostatic forces between ion-exchange sites and the hydrated cations may be less than in the case of partially hydrated or non hydrated cations. A thermodynamic treatment of the ion-exchange reactions reveals that the cations having the EIR of 1.0Å, such as Na^+ and Cd^{2+}, are exchanged as less hydrated cations in the C-SbA with rigid structure than those in aqueous solution.[9,29] If the less hydrated cations are exchanged, the electrostatic force may be increased more than in the case in fully hydrated cations. When a large cation such as Cs^+ is exchanged in the C-SbA, the electrostatic force is less than small cations because of the low electron density for large cations.[30] Therefore we conclude that the C-SbA has an ion-exchange site energetically preferable for the ions with an EIR of about 1 Å.

The C-SbA cation exchanger showed the following selectivity sequence for tervalent metal ions, in increasing order:

$$Al^{3+} \ll Ga^{3+} \leq Yb^{3+} < Fe^{3+} < La^{3+} < In^{3+}.$$

Larger separation factors, $\alpha(A/B)=K_d^A/K_d^B$, were observed on the C-SbA, as compared with those on strong acid-type cation exchange resin[32] (Table 1). The selectivity order for tervalent metal ions on the HAP was found to be in the increasing order: $Fe^{3+}<In^{3+}<Sc^{3+}<Yb^{3+}<Ce^{3+}<Eu^{3+}$ in 1 M nitric acid solution.[13]

Separation of Aluminium(III) and Iron(III) Ions. The separation factor for the pair is very small on organic ion-exchange resin in nitric acid media,[32] and it is difficult to separate them without use of a complexing agent such as ammonium tartrate and citrate. Vydra and Galba[33] have achieved the separation of aluminium(III) from iron(III) ions on hydrous silica by using their hydrolytic products. It is evident from the study of the separation factor for this pair in nitric acid media that their effective separation will be much more favorable on the C-SbA.

When 110 cm^3 of 0.1 M nitric acid solution was used as an eluant, 66% of aluminium(III) ion loaded on the C-SbA was eluted, with a sharp peak followed by a long tail. This may be due to the very slow rate of ion-exchange. It is known that addition of ammonium nitrate improves the elution characteristics for sodium ions.[7] A similar effect was observed for ions studied in the present work, except for iron(III) ion. Therefore a mixed solution of nitric acid and ammonium nitrate was employed for more rapid separation.

When a mixed solution of 0.1 M nitric acid and 0.05 M ammonium nitrate was used as an eluant, aluminium(III) ions were detected from the second fraction and eluted quantitatively with a elution volume of 65 cm^3. More effective elution was achieved by the eluant of a mixed solution of 0.1 M nitric acid and 0.1 M ammonium nitrate: only about a half of the eluant volume was needed for the complete elution (Fig. 4).

Iron(III) ions were not eluted with 70 cm^3 of 0.5 M nitric acid solution. When 6 M nitric acid solution was injected, the iron(III) ions were eluted with a sharp front edge, followed by a strong tailing effect. A mixed solution of 6 M nitric acid and 2 M ammonium nitrate as an eluant showed a similar elution curve. This may be due to a slow rate of ion-exchange for iron(III), as expected from Fig. 1. Thus, 6 M hydrochloric acid was more effective (Fig. 4), owing to the negatively charged chloride complex of the iron(III) ion. Thus, an effective separation was achieved.

Elution Behavior of Garium(III), Ytterbium(III), and Lanthanum(III) Ions. Since separation factors for

Bio-Rad[b] AG50W-X8	K_d/cm^3 g^{-1}	74	79	94	118	193	267
	α		1.0_7	1.1_9	1.2_5	1.6_3	1.3_8

a) Separation factor for neighboring ions. b) Ref. 32.

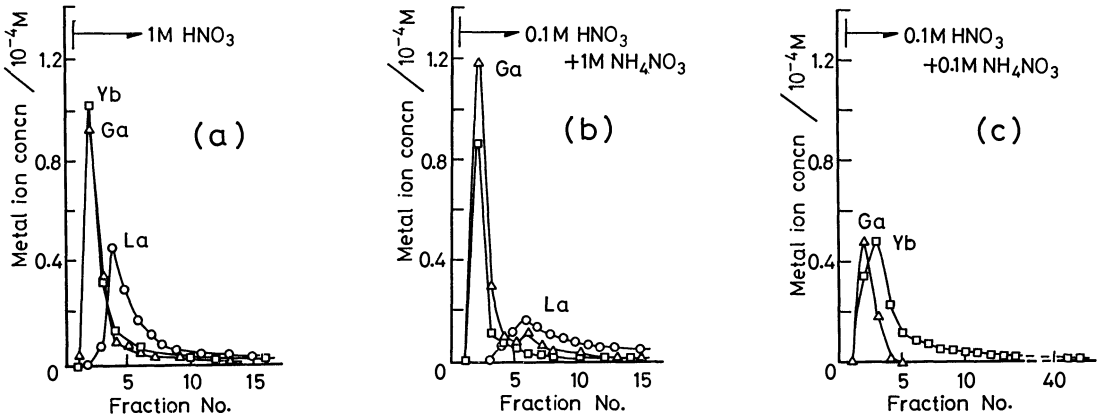

Fig. 5. Elution curves of Ga^{3+}, Yb^{3+}, and La^{3+} with C-SbA column. One fraction=5 cm^3. Column size, 4×0.4 cm i.d. Flow rate, 0.3 cm^3 min^{-1}.

neighboring ions are very small on strong acid-type cation exchange resin in nitric acid media, mutual separations of these tervalent metal and rare earth metal ions can usually be achieved by using aqueous complexing agents or aqueous-organic solvent mixtures.[34] However, even if such a technique is used, much eluant is required for these separations with a large column (*e.g.*, 10 mm i.d.×730 mm h).[18]

On the C-SbA, no ytterbium(III) ions were eluted, but garium(III) ions were partly eluted with 95 cm^3 of a mixed solution of 0.1 M nitric acid and 0.05 M ammonium nitrate. A mixed solution of 0.2 M nitric acid and 0.05 M ammonium nitrate as an eluant showed a similar elution curve for garium(III) ion. A more effective elution was observed for these cations by using a mixed solution containing ammonium nitrate at relatively high concentration (1 M), as in the case of aluminium(III) ions.

Lanthanum(III) ion was not eluted up to 40 cm^3 of 0.5 M nitric-acid solution, and incomplete elution was observed up to 200 cm^3 of the eluant, with a yield of 45%.

Elution peaks with tailings were observed for all elements when 1 M nitric acid (Fig. 5a) and a mixture of 0.1 M nitric acid an 1 M ammonium nitrate (Fig. 5b) were employed as the eluants. The elution order agreed with that of the batch equilibrium data.

The yields up to 16 fractions with 1 M nitric acid solution as an eluant were 95, 89, and 75% for ytterbium(III), garium(III), and lanthanum(III) ions, respectively (Fig. 5a). When a mixed solution of 0.1 M nitric acid and 1 M ammonium nitrate was used as an eluant, these metal ions were eluted with the yields of 70, 65, and 44% for garium(III), ytterbium(III), and lanthanum(III) ions, respectively, up to 13 fractions (Fig. 5b).

The effective group separation was achieved for garium(III) and ytterbium(III) ions from lanthanum(III) ion by using a mixed solution of 0.1 M nitric acid and 0.1 M ammonium nitrate as an eluant (Fig. 5c), while the lanthanum(III) ions adsorbed were completely eluted with a 2 M nitric acid solution. Thus, the C-SbA column can be used repeatedly.

Thanks are due for the assistance by the members of the steering committee of the Radioisotope Laboratory at Tokyo Institute of Technology. The authors wish to express their thanks to Mr. Shogo Suzuki and Dr. Shoji Hirai, Atomic Energy Research Laboratory, Musashi Institute of Technology, for their technical discussions. A part of this work was financially supported by the Japanese Government, The Ministry of Education, under the program for the cooperative use of the TRIGA II reactor installed at Musashi Institute of Technology.

Formation of Zn-bearing Ferrite by Air Oxidation of Aqueous Suspension

Tadao KANZAKI,* Jun-ichiro NAKAJIMA, Yutaka TAMAURA, and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology Ookayama, Meguro-ku, Tokyo 152

(Received April 1, 1980)

Zn-bearing spinel ferrites were obtained by air oxidation of the iron(II) hydroxide suspension of the mole fraction Zn(II) to [Zn(II)+Fe_{total}], r_{Zn}, ranging from 0.029 to 0.33 (except for 0.057) at pH 10.0 and 65 °C, but at r_{Zn}=0.057 only α-FeOOH was formed. The Zn-bearing spinel ferrite obtained at r_{Zn}=0.33 has the normal spinel structure. At pH 8.0, the Zn-bearing spinel ferrite is obtained at r_{Zn}=0.057, but the spinel ferrite is slightly oxidized to γ-Fe_2O_3.

Recently, the conditions for the formation of spinel ferrite from aqueous iron(II) hydroxide suspensions containing other metal ions have been investigated in detail by several workers.[1-4] Kiyama[1] investigated the formation of Mn- and Co-bearing spinel ferrites and reported that, in alkaline suspensions, all the metal ions were incorporated into the spinel ferrites. Katsura *et al.*[2] reported that the oxidized Fe_3O_4–Fe_2TiO_4 solid solution with spinel structure was obtained from the suspension containing titanium(IV) ions. Kaneko *et al.* investigated the formation of Mg-[3] and Cd-[4] bearing spinel ferrites. When the mole fraction of Mg(II) to [Mg(II)+Fe_{total}] or Cd(II) to [Cd(II)+Fe_{total}] in the suspension is below 0.091, almost all the metal ions are incorporated into the spinel ferrite by an oxidation reaction at pH 9.0. When the mole fraction is above 0.091, the excess magnesium(II) produces a basic magnesium(II) sulfate, and the crystalline phases formed from the suspension containing cadmium(II) ion are changed in a complicated way.

In this paper, the reaction conditions for the formation of Zn-bearing spinel ferrite from the suspension containing zinc(II) ion are investigated.

Experimental

Reagents. Chemical reagents of analytical grade were used. A 2 mol/dm³ sodium hydroxide solution was prepared by dissolving sodium hydroxide in distilled water free from carbon dioxide and oxygen. A sulfuric acid solution of 0.856 mol/dm³ zinc(II) sulfate (pH≅3) was prepared from zinc(II) sulfate heptahydrate.

Apparatus. The reaction vessel of the Dewar type used in this study was the same as that employed previously by Kaneko and Katsura.[3]

Procedure. After adding distilled water, zinc(II) sulfate solution, and sodium sulfate to the reaction vessel, nitrogen gas was bubbled into the solution while it was being stirred at 1000 min^{-1} for 1 h to remove the dissolved gases of carbon dioxide and oxygen. Then 12 g of iron(II) sulfate heptahydrate was added to the solution. The resultant volume of the solution was set to 200 cm³, and the total concentration of the sulfate ion was fixed to 65 mmol/200 cm³. pH values were adjusted by using 2 mol/dm³ sodium hydroxide solution and the suspension was let stand for 1 h with stirring under nitrogen at 65 °C (we call this suspension the "initial suspension"). The subsequent procedures were the same as those described by Kaneko and Katsura.[3] The precipitate in this paper means the product obtained by lowering the pH value of the suspension to pH 4.0 with 0.5 mol/dm³ sulfuric acid after the air oxidation. At this pH value, zinc(II) hydroxides and iron(II) hydroxides dissolve completely.

Chemical Analysis. The zinc(II) content was determined by atomic absorption spectrometry after the extraction of an iron with diisopropyl ether. The amounts of iron(II) and iron(III) were determined by the method described by Kaneko and Katsura.[3]

The precipitates were examined by the X-ray powder diffraction method with Fe $K\alpha$ radiation, the electron microscopy, and the Mössbauer spectra measurement at room temperature.

Titration curves were obtained as follows. A sulfuric acid solution containing zinc(II) and/or iron(II) sulfates was titrated with 2 mol/dm³ sodium hydroxide solution at 65 °C. Nitrogen gas was bubbled into the solution during the titration and the values of pH were measured at each point 10 min after the addition of the sodium hydroxide solution.

Results and Discussion

X-Ray Powder Diffraction Patterns, Electron Micrograph, Chemical Composition, and Mössbauer Spectra of the Precipitate obtained by Air Oxidation at pH 10.0. In the X-ray powder diffraction patterns of the precipitate obtained from the suspension of the r_{Zn} values (the r_{Zn} value means the mole fraction of Zn(II) to [Zn(II)+Fe_{total}] in the initial suspension) ranging from 0.029 to 0.33 (except for 0.057), only the peaks for spinel type structure were seen, while at r_{Zn}= 0.057, only the peaks for α-FeOOH were observed. The electron micrographs of the precipitate showed the formation of a spherical or cubic particle of spinel ferrite, except for a needle-like crystal of α-FeOOH for r_{Zn}=0.057. Lattice constants a_0 of the spinel ferrites are plotted against the r_{Zn} values in Fig. 1 (curve A). The lattice constants of completely oxidized samples with spinel type structure are also plotted (curve B). The oxidation of the spinel ferrites was performed by heating at 180 °C in air for 6 h. In the X-ray powder diffraction patterns of the oxidized samples, only the peaks for the spinel type structure were seen. Chemical analyses showed that there was no detectable amount of iron(II) in the oxidized samples. As seen from the curves A and B in Fig. 1, the lattice constants of the spinel ferrites and those of completely oxidized samples increase with increasing the r_{Zn} values. This shows that Fe^{2+} in the spinel ferrite is replaced by Zn^{2+}, and that the amount of Zn^{2+} on the lattice points increases with increasing the r_{Zn} values. Chemical analyses showed that, at the r_{Zn} values ranging from 0.029 to 0.33 (except for 0.057), almost all zinc(II) ions in the initial suspension

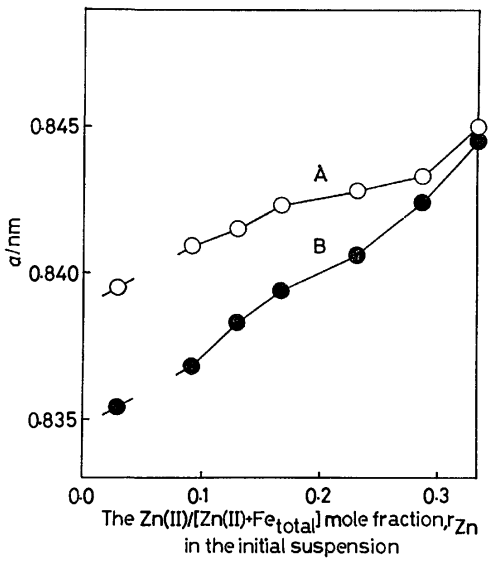

Fig. 1. The relationship between the Zn(II)/[Zn(II)+Fe$_{total}$] mole fraction in the initial suspension and the lattice constants of the spinel ferrite obtained at pH 10.0 or those of the completely oxidized sample with spinel type structure. The curve A: the spinel ferrite, the curve B: the completely oxidized sample, a: the lattice constant.

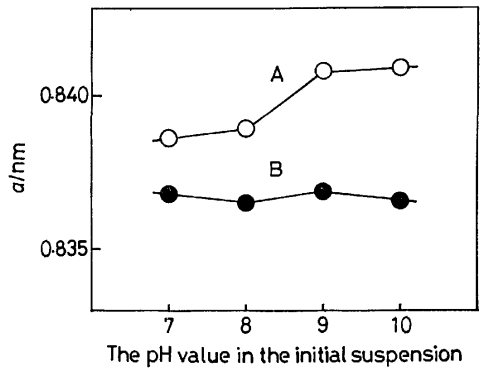

Fig. 2. The relationship between the pH value in the initial suspension and the lattice constants of the spinel ferrite obtained at the Zn(II)/[Zn(II)+Fe$_{total}$] mole fraction of 0.091 in the initial suspension or those of the completely oxidized sample with spinel type structure. The curve A: the spinel ferrite, the curve B: the completely oxidized sample, a: the lattice constant.

(>92%) were taken into the precipitate. The mole fractions of [Zn(II)+Fe(II)] to [Zn(II)+Fe$_{total}$] in the precipitate were 0.30—0.35. These values are close to those of stoichiometric spinel ferrite Fe_3O_4–$ZnFe_2O_4$ (0.333). The lattice constant of the Zn-bearing spinel ferrite at $r_{Zn}=0.33$ (Fig. 1) is very close to that of zinc spinel ferrite $ZnFe_2O_4$ synthesized by the solid state reaction (0.8441 nm).[5]

The Mössbauer spectrum at room temperature of the precipitate obtained at $r_{Zn}=0.33$ showed a quadrupole-split pattern. The isomer shift relative to metallic iron estimated from the quadrupole-split spectrum (0.030 cm s^{-1}) is in good agreement with that of zinc spinel ferrite synthesized by solid state reaction (0.0358 cm s^{-1})[6] within our experimental errors (±0.008 cm s^{-1} as stand. dev.). Thus, the Zn-bearing spinel ferrite obtained at $r_{Zn}=0.33$ and pH 10.0 is concluded to be the zinc spinel ferrite which has the normal spinel structure.

pH *Dependence on the Formation of the Precipitate for* $r_{Zn}=0.091$. In the X-ray powder diffraction patterns of the precipitate obtained by air oxidation of the suspension of $r_{Zn}=0.091$ at pH values ranging from 7.0 to 10.0, only the peaks for spinel type structure were seen, while at pH 11.0 only the peaks for α-FeOOH were observed. The electron micrographs of the precipitate showed the formation of a spherical or cubic particle of spinel ferrite, except for a needle-like crystal of α-FeOOH at pH 11.0. Figure 2 shows the lattice constants a_0 of the spinel ferrites obtained at pH ranging from 7.0 to 10.0 (curve A) and those of the completely oxidized samples with spinel type structure (curve B). As seen from curve B, the lattice constants of the completely oxidized samples are constant within our experimental errors. Chemical analyses showed that almost all zinc(II) ions in the initial suspension (>92%) were taken into the precipitate at the pH values ranging from 7.0 to 10.0, but at pH 11.0, only about 40% of zinc(II) ions were taken in. These results show that, at these pH values, Zn-bearing spinel ferrites which have a constant amount of Zn^{2+} on the lattice points are formed. The mole fractions of [Zn(II)+Fe(II)] to [Zn(II)+Fe$_{total}$] in the precipitate decreased from 0.31 to 0.26 upon decreasing the pH values from 10.0 to 7.0. The lattice constants of the Zn-bearing spinel ferrites obtained at lower pH values, as shown by curve A in Fig. 2, are smaller than those of the spinel ferrites obtained at a higher pH value. These suggest that a Zn-bearing spinel ferrite which is slightly oxidized to γ-Fe_2O_3 is formed at lower pH values. From the electron micrographs, it was shown that the particle size of the Zn-bearing spinel ferrites becomes small at a lower pH value (0.1 and 0.2 μm at pH 7.0 and 10.0, respectively), which seems to cause further oxidation of the spinel ferrites at this lower pH value.

Depression of the Formation of Zn-bearing Spinel Ferrite. As mentioned in a previous section, at $r_{Zn}=0.057$ and pH 10.0 the formation of Zn-bearing spinel ferrite is depressed and α-FeOOH is formed. The depression of the Zn-bearing spinel ferrite was, however, restored, when the pH value in the initial suspension was lowered to pH 8.0, that is, only the peaks for the spinel type structure were seen in the X-ray powder diffraction pattern of the precipitate.

Figure 3 shows the titration curves of the solutions of iron(II) sulfate (curve A), zinc(II) sulfate (curve B) and the mixed solution of zinc(II) and iron(II) sulfates (curve C). Iron(II) sulfate is titrated at pH values around 6.7—8.0 (curve A). However, zinc(II) sulfate is titrated first at pH around 5.5—6.0 (region a—b in curve B), and then around 7.4 (region c—d in curve B). During the titration of zinc(II) sulfate, in the region a—c in curve B, a basic zinc(II) sulfate seems to precipitate, and then in the region c—d, the basic zinc(II) sulfate is converted into $Zn(OH)_2$. The

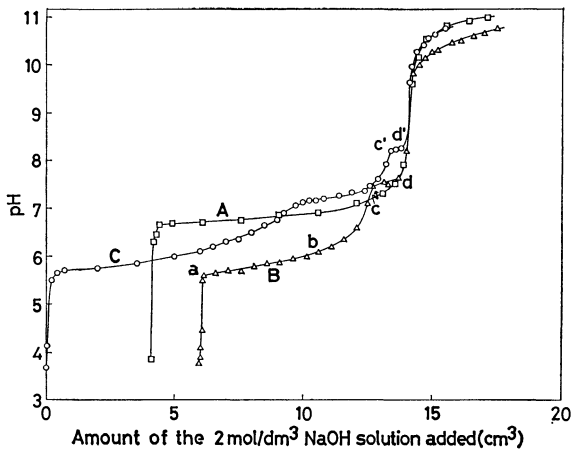

Fig. 3. The titration curves of Fe(II), Zn(II), and Zn(II)+Fe(II) sulfate solutions by 2 mol/dm³ NaOH. The curve A: 1.08×10^{-2} mol Fe(II), the curve B: 8.56×10^{-3} mol Zn(II), the curve C: 8.56×10^{-3} mol Zn(II)+8.53×10^{-3} mol Fe(II). The titration curves of Fe(II) and Zn(II) sulfate solutions are shown from titer of 4.10 cm³ and 6.00 cm³, respectively to compare with that of Zn(II)+Fe(II) sulfate solution. The initial volume of the solutions was fixed to 200 cm³.

point c in curve B represents the addition of 1.5 moles of sodium hydroxide per atom of zinc. Therefore, we can estimate the chemical formula of the hydrolyzed species at this point to be $Zn(OH)_{1.5}(SO_4)_{0.25}$[7] by assuming that the sulfate ion is coprecipitated. In the case of the mixed solution of zinc(II) and iron(II) sulfates, as seen by curve C (Fig. 3), the conversion reaction of the basic zinc(II) sulfate into $Zn(OH)_2$ occurs also at pH around 8.3 (region c'—d' in curve C).

Thus, at pH 8.0 where the depression of the Zn-bearing spinel ferrite formation is restored, the basic zinc(II) sulfate is precipitated in the suspension before air oxidation.

The authors wish to express their thanks to Drs. Masanori Abe and Tadashi Sugihara of Tokyo Institute of Technology for the measurement of the Mössbauer spectra and for helpful discussions.

Yumiko NAKAGAWA,†† and Kōji SAITA††
Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11
(Received April 4, 1980)

The formation and the oxidation-reduction properties of mixed oxides in the Ce–U–O ternary system were examined by means of thermogravimetry and the X-ray diffraction technique. The mixed oxides were prepared by the reactions of CeO_2 with U_3O_8 in air and in hydrogen. The composition of the products heated in air, followed by slow cooling to room temperature, was approximately expressed by this equation: $yCeO_2+(1-y)UO_{2.67}$. By X-ray diffraction, it was shown that the oxides formed at 1100 °C in air were mixtures of $Ce_{0.6}U_{0.4}O_{2.3}$ and α-U_3O_8 in the $y<0.6$ range, while they were in single phases of solid solutions for $y\geq0.6$. When the mixed oxides, MO_{2+x}, where M indicates yCe$+(1-y)$U, were re-heated in air, weight loss due to oxygen liberation was observed above 500 °C, and it was enhanced with a rise in the temperature. The hydrogen reduction of the oxides proceeded in two steps; the first step was the reduction of MO_{2+x} to MO_2 below 600 °C, and the second one was the reduction of MO_2 to MO_{2-x} above 600 °C. The composition of the oxides obtained can be given by this equation: $yCeO_{1.81}+(1-y)UO_{2.00}$. Two separate linear relationships for the lattice parameter of the fluorite-type structure as a function of the cerium content were obtained; one is applicable to the solid solutions with $y\leq0.6$, where the lattice parameter is nearly that of UO_2, and the other to the solid solutions with $y\geq0.4$. The latter obeys Vegard's law between UO_2 and CeO_2. The oxides with $y=0.4$—0.6 were in the two-phase region of the solid solutions.

In the cerium-uranium-oxygen system, it has been shown that there exists a homogeneous region of the solid solution with a fluorite structure. Several workers[1-8] have investigated its composition range, lattice parameter, and thermodynamic properties. A phase diagram of the system at 900 °C was first drawn by Hoch and Furman[4] from the data of Hund[1] and the results of their own quenching experiments. Later, Markin *et al.*[5] constructed a phase diagram between UO_2–U_3O_8 and CeO_2–$CeO_{1.81}$ for temperatures between room temperature and 600 °C using the results obtained by the high temperature X-ray diffraction technique. In spite of their experiments, however, the literature data on the phase relations and the chemical properties seem still to be incomplete.

Cerium is produced in nuclear fuels as one of the fission products of high yields. The knowledge of the Ce–U–O ternary system is, therefore, of basic importance for investigating the irradiation behavior of uranium dioxide fuel in connection with the changes in the phase relations and in the thermodynamic properties caused by accumulated fission products. In addition, cerium is often used in simulation studies of plutonium, a promised fissile material in fast breeder reactor, because of their similar chemical and/or thermodynamic behavior. Therefore, the investigation of this ternary system would contribute to our knowledge of the phase behavior of the Pu–U–O system, too. The physical and chemical properties as well as the phase relations of the Ce–U–O system have, nevertheless, not been systematically studied. In the present experiment, we investigated the formation and the oxidation-reduction properties of the mixed oxide of the Ce–U–O ternary system by means of thermogravimetry and the X-ray diffraction technique. The literature data on the lattice parameter, which were rather scattered, were also re-examined.

Experimental

Materials. CeO_2 of a 99.99% purity was provided by the Shin-etsu Chemical Co. Ltd. The oxide was heated at 1000 °C in air for 3 h before use. U_3O_8 was prepared by heating ammonium diuranate at 900 °C in air for 24 h. Both compounds were weighed so that the cerium contents were 0.10, 0.20, 0.27, 0.40, 0.50, 0.60, and 0.80 atom% in the respective mixtures. Mixing was done in an agate mortar, and the mixtures were compacted at 3×10^8 Pa into cylindrical pellets 10 mm in diameter and about 2 mm thick. The weight of each pellet was about 800 mg.

Apparatus and Procedures. The experiments were mainly carried out by the use of the thermogravimetric technique. The apparatus consists of a Cahn Model-RH electrobalance, a pressure-measurement system, a gas-supply system, and vacuum pumps. The balance was adjusted so as to have a maximum weight change of 500 mg and a sensitivity of 0.01 mg. A fused quartz crucible, 20 mm in height and 18 mm in outer diameter, was suspended from the balance. Then, a quartz reaction tube, 26 mm in outer diameter and 310 mm in length, was connected to the vessel containing the balance. After the reaction system had been evacuated to 10^{-1} Pa, the sample was weighed. The system was then filled with air (or hydrogen in the reduction experiments) and the temperature was raised. Hydrogen from the cylinder was used after having been purified by passage through palladium asbestos heated at 300 °C and through a liquid-nitrogen trap. The weight change due to buoyancy and convection was corrected by using a platinum wire. The sample was weighed again in a vacuum after the reaction.

The temperature of the sample was measured with a Pt/Pt+13%Rh thermocouple placed close to the crucible inside the reaction tube. The furnace temperature was automatically controlled so as to be raised at a constant heating rate or to be held at a desired point. The experiments were made at the heating rate of 2 °C/min.

X-Ray Analysis. The samples were finely ground, loaded into capillaries, and then vacuum-sealed. The X-ray photographs were obtained with a Norelco 114.6 mm camera using nickel-filtered Cu $K\alpha$ radiation. The lattice parameters were obtained by least-squares calculations for the diffraction lines at higher angles.

Results and Discussion

Formation of Mixed Oxides in Air. The reaction of CeO_2 with U_3O_8 was examined by heating mixture pellets with various cerium contents from room temperature to 1100 °C in air. After the temperature had been raised to 1100 °C, the sample was held at that temperature for 3 h; then it was slowly cooled. When heated in air, U_3O_8 began to lose oxygen at about 890 °C, and the O/U ratio was lowered from 2.667 to 2.653 at 1100 °C. On the other hand, the weight loss of CeO_2 was not observed up to 1100 °C. For the mixtures of CeO_2 and U_3O_8, it was found that the weight loss occurred at slightly lower temperatures than that of U_3O_8 in any mixing ratio. The weight loss at high temperatures was augmented by y, which suggests a reaction between CeO_2 and U_3O_8, the mixed oxide thus formed being oxygen-deficient compared with the initial bulk composition of the sum of $y\mathrm{CeO_2}+((1-y)/3)\mathrm{U_3O_8}$. While the sample was held at 1100 °C for 3 h, the O/M ratio decreased slightly with time; here, M indicates $y\mathrm{Ce}+(1-y)\mathrm{U}$. The X-ray patterns of these oxides showed that the products were mixtures of α-U_3O_8 and solid solution for $y=$ 0—0.5, and homogeneous solid solutions for $y\geq 0.6$.

Formation of Mixed Oxides in Hydrogen. The reduction of U_3O_8 with hydrogen began at about 330 °C and finished at 630 °C. The product was $UO_{2.000}$. On the other hand, the reduction of CeO_2 with hydrogen began at 550 °C, and then the O/Ce atom ratio gradually decreased with an increase in the temperature. The O/Ce ratio was 1.815 at 1000 °C, and it was hardly changed even after the sample was kept at that temperature for 3 h. As for the mixtures of CeO_2 and U_3O_8, the weight loss began at about 330 °C, the initiation temperature of the reduction of U_3O_8, for any mixing ratio. When the sample was heated further, a plateau appeared on the TG curve around the O/M ratio of 2.02 at temperatures between 600 and 650 °C. Above 650 °C the O/M ratio was seen to decrease again with increasing temperature. This reaction behavior of the CeO_2 and U_3O_8 mixtures in hydrogen atmosphere is very similar to that of the solid solution, as will be stated below.

Hydrogen Reduction of the Mixed Oxides Prepared in Air. Typical TG curves for the reduction of U_3O_8, CeO_2, and the mixed oxides are shown in Fig. 1. The mixed oxides were prepared by heating mixtures of CeO_2 and U_3O_8 at 1100 °C for 3 h in air. As may be seen in the figure, the mixed oxides were reduced to an O/M ratio of nearly two by heating up to 600 °C. Then, the plateau appeared in the temperature range between 600 and 650 °C, after which the specimens were again reduced, but at slower rates. From this fact, it is deduced that the oxides with O/M

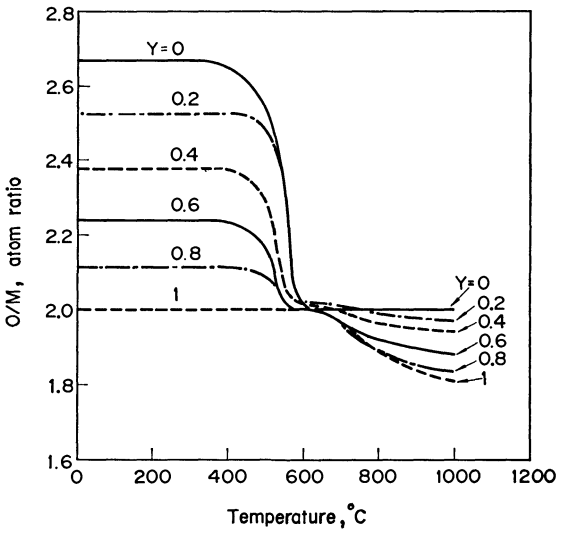

Fig. 1. TG curves for reduction of the mixed oxides MO_{2+x} in hydrogen atmosphere.
Heating rate: 2 °C/min, y: Ce/(Ce+U) ratio.

>2 are reduced more easily than those with O/M<2. This is related to the thermodynamic properties of the solid solution. Thermodynamic studies of $MO_{2\pm x}$ [4,6] show that the curve of the partial molar Gibbs energy of oxygen, $\Delta\overline{G}_{O_2}(MO_{2\pm x})$, against x for any y value changes from a large negative value at O/M<2 to a small negative value at O/M>2 in a sigmoid shape. The large change in $\Delta\overline{G}_{O_2}$ occurs in the vicinity of the stoichiometric composition, O/M≈ 2. As the Gibbs energy of formation of water, $\Delta G^\circ_f(H_2O)$, is close to $\Delta\overline{G}_{O_2}(MO_{\approx 2})$ at temperatures from 600 to 1000 °C, it is reasonable to suppose that the solid solution is readily reduced with hydrogen to the composition with O/M≈ 2. The reduction of the solid solution proceeds by removing the produced water vapor.

The X-ray pattern of the product showed that it was a two-phase mixture with the fluorite-type structure for $0.4\leq y\leq 0.6$, and a single-phase product with the fluorite-type structure for $y\leq 0.3$ and $y>0.6$. The O/M ratio and the lattice parameter of the mixed oxide thus formed are shown in Table 1.

Air Oxidation of the Mixed Oxides Prepared in Hydrogen. Figure 2 shows some typical TG curves for the oxidation of the mixed oxides in air. The mixed oxides used here were prepared by reducing mixtures of CeO_2 and U_3O_8 with hydrogen in situ in a quartz crucible at 1000 °C for 3 h. In a series of experiments to check the completeness of mixing, the reduced pellets were crushed, intimately mixed, and then recompacted into pellets which were used for oxidation. When air was re-introduced into the reaction vessel after evacuation, the sample was slowly oxidized to the O/M ratio of nearly two even at room temperature. This oxidation reaction was accelerated by heating. For the oxidation of UO_2, the formation of U_3O_7 as the intermediate phase was seen on the TG curve. This bend was observed in the oxides of $y=$ 0.1—0.4. Every TG curve for the oxidation of MO_{2-x}

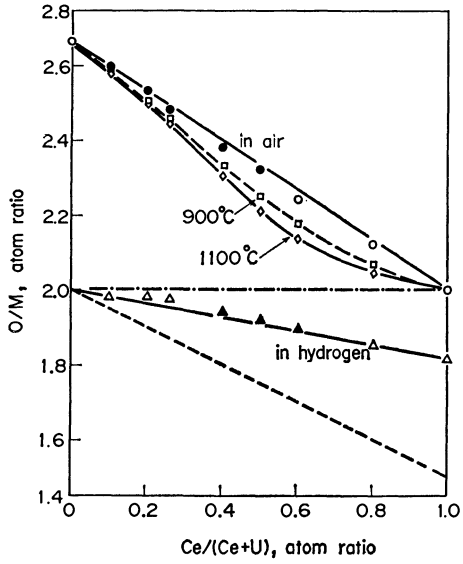

Fig. 3. Variation of the O/M atom ratio of the mixed oxides as a function of cerium concentration.
●: Two-phase mixture below 500 °C in air, ○: single phase below 500 °C in air, □: O/M ratio of the mixed oxides at 900 °C in air,' ◇: O/M ratio of the mixed oxides at 1100 °C in air, △: single phase in hydrogen, ▲: two-phase mixture in hydrogen.

showed a maximum of the O/M ratio at temperatures between 450 and 500 °C. Above 500 °C, the oxides began to lose their oxygen. The decrease in the O/M ratio was enhanced with a rise in the temperature. When the oxides were cooled from higher temperatures than the temperature giving the maximum O/M ratio, the O/M value increased on the line of the heating process up to the maximum O/M ratio, and the value was maintained unchanged on a further lowering of the temperature.

The X-ray pattern of the product revealed that it was a mixture of α-U_3O_8 and the solid solution for $y \leq 0.5$, and was in the single phase of the solid solution for $y \geq 0.6$. For the product of the y values between 0.1 and 0.5, the X-ray intensity of the diffracted α-U_3O_8 lines was weakened with the increase in the cerium content. Although the U_3O_8 phase which was formed accompanying the solid solution has been reported to be in the β modification,[7] it was identified as α-U_3O_8 by the present analysis of the X-ray patterns. The O/M ratio, phase, and lattice parameter for the product slowly cooled from 1100 °C in air are shown in Table 1. It may be seen that the lattice parameter of the cubic fluorite phase remains constant regardless of the cerium content between y=0.1 and 0.5. The products of y=0.6 and 0.8 were found to be in a single phase with the fluorite-type structure, and their lattice parameters were lowered with an increase in the cerium content.

Valence State of Uranium and Cerium in the Mixed Oxides. Figure 3 shows the O/M ratio *vs.* Ce/M ratio for the samples prepared under various reaction conditions. The straight line connecting the circles represents the O/M ratio of the oxides heated in air at 1100 °C, followed by annealing to room temperature. The open circles indicate a single phase, and the filled circles, a two-phase mixture. The other marks represent the

O/M ratio of the samples heated at 900 and 1100 °C in air. The figure shows that the mixed oxide prepared in air is the single phase with a fluorite structure at least below the O/M ratio of 2.24. In the U–O system, the phase diagram shows that the composition range of the fluorite phase extends to O/U=2.25. The O/M ratios of the samples which were obtained by reducing the mixed oxides in a hydrogen atmosphere at 1000 °C for 3 h and then slowly cooling them to room temperature are indicated by △ and ▲ in the same figure, where open and filled marks indicate single-phase and two-phase, respectively. All the oxides prepared in hydrogen had the fluorite structure. The oxides for y=0.4—0.6 consisted of two phases with different lattice parameters. The O/Ce atom ratio of the cerium oxide reduced by hydrogen was 1.815, the same as the ratio reported by Markin *et al.*[5]

For the mixed oxides prepared in air, the O/M ratios of the oxides below 500 °C decrease nearly linearly from 2.667 of U_3O_8 at y=0 to 2.00 of CeO_2 at y=1. This shows that the mean valence state of uranium, +5.33, is not varied by the dissolution of cerium. On the other hand, the O/M ratios of the oxides at 900 and 1100 °C in air are lower than those of the oxides cooled to room temperature. For example, the O/M ratios of the mixed oxides at 900 °C are 2.18 for y=0.6 and 2.07 for y=0.8, the mean valence states of uranium being +4.9 and +4.7 respectively, if cerium is regarded as in the +4 state.

The tendency for the valence state of uranium not to vary or, rather, to be diminished, by the addition or cerium is obviously different from the case of the Sr–U–O system.[9] In this system, the valence state of uranium was raised from +5.33 of U_3O_8 to +6.00 of Sr_2UO_5 with an increase in the content of strontium.

For the mixed oxides prepared in hydrogen, MO_{2-x}, the O/M ratio decreases nearly linearly from 2.00 at y=0 to 1.815 at y=1. This fact shows that the valence state of uranium is +4 and that of cerium is +3.63, neither of which is varied by the Ce/U atom ratio.

Lattice Parameters of the Mixed Oxides. The lattice parameters of the mixed oxides prepared in air and in hydrogen are plotted as functions of the cerium content in Fig. 4, together with the data from the literature.[1–5,7]

The oxide prepared at 1100 °C in air is two-phase mixture for y<0.6. The constant lattice parameter, 5.426 Å, though scattered, indicates that the mixed oxide is in two phases, $Ce_{0.6}U_{0.4}O_{2.3}$+α-U_3O_8. The composition of $Ce_{0.6}U_{0.4}O_{2.3}$ was obtained from Fig. 3 using the intersection between the lattice parameter in the two-phase region of y<0.6, 5.426 Å, and the straight line in the single-phase region of $y\geq$0.6. The lattice parameter of the mixed oxide with $y\geq$0.6 decreases with an increase in the cerium content.

The lattice parameter in the two-phase region of the mixed oxides prepared in air has been determined by many workers.[1–5,7] Although their results are not in complete agreement, it has been found that the lattice parameter has a tendency to increase with a decrease in the y value. On the other hand, the y value at the phase limit of the fluorite solid solution,

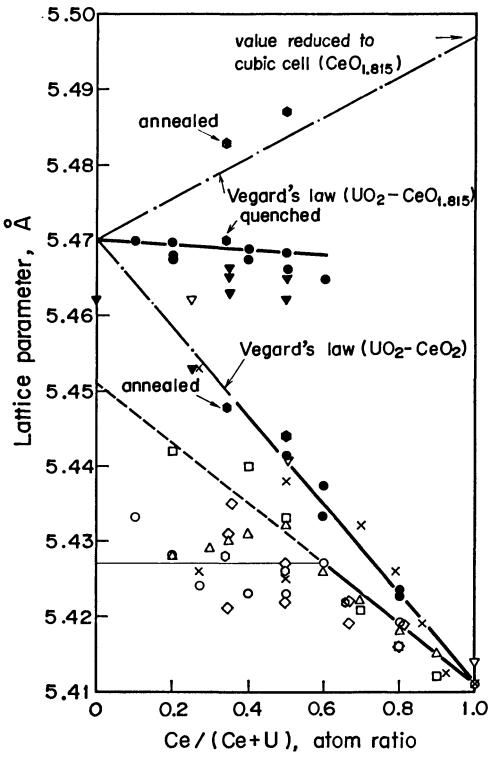

Fig. 4. Lattice parameter of the mixed oxides. □: Hund *et al.*,[1] ◇: Rüdorff and Valet,[2] ×: Zuromsky and Chernock,[3] ▽,▼: Hoch and Furman,[4] ○,●: Markin *et al.*,[5] △: Paul,[7] ○,●: Present work. Open marks and × show the oxides heated in air and filled marks show the oxides heated in hydrogen.

as seen in Paul's results,[7] decreases with a rise in the firing temperature. The lattice parameter value is also varied by the cooling conditions; the value of a quenched sample is larger than that of an annealed one. The difference in the lattice parameters in the literature, therefore, may be caused by the heating and cooling conditions.

The reported values[1,3,7] of lattice parameters in the single-phase region are all in agreement. It is found that the lattice parameter varies linearly against the cerium concentration, except for the results by Hund *et al.*[1] If the line of the lattice parameter *vs.* Ce/(Ce+U) atom ratio is extraporated to y=0, as Rüdorff and Valet[2] have done, 5.451 Å is obtained as the lattice parameter of the cubic uranium oxide. This value is found in the nonstoichiometric region of U_4O_9 the mother structure of which is the fluorite. If the relationship between the lattice parameter and the O/U ratio in U_4O_9 obtained by Lynds *et al.*[10] is applied, the O/U ratio of the extrapolated uranium oxide becomes 2.18. Markin *et al.*[5] obtained oxides with the fluorite-type or U_4O_9-type cubic structure by the partial oxidation of hypostoichiometric oxides, MO_{2-x}, to $MO_{2.25}$ for y<0.4; their lattice parameters are placed on the broken line.

The variation in the lattice parameter of the solid solutions prepared in hydrogen can be shown by two separate lines. One is the line for $y\leq$0.6, with a lower gradient, while the other is the line for $y\geq$0.4,

which follows Vegard's law connecting 5.4700 Å of UO_2 and the 5.4111 Å of CeO_2. The oxides for $y=$ 0.4—0.6 are two-phase mixtures of fluorite structures with different lattice parameters. Markin *et al.*[5] have reported that a two-phase mixture was formed by the phase separation during very slow cooling to room temperature. The lower lattice-parameter values obey Vegard's law. Therefore, it is considered that the oxides with these smaller values correspond to the hypostoichiometric oxides MO_{2-x} formed between UO_2 and $CeO_{2-x'}$, where $2-x'$ is probably much smaller than 1.815.

The larger lattice-parameter values at $y<0.6$ obtained in the present work are in agreement with those by Hoch *et al.*[4] These values are close to the lattice parameter of UO_2. On the other hand, the X-ray pattern of $CeO_{1.815}$ showed the single phase of the fluorite structure with the lattice parameter of 5.4111 Å. The phase diagram of the cerium-oxygen system[11-14] shows that there is a miscibility gap between CeO_2 and $Ce_{11}O_{20}(CeO_{1.818})$. Although $CeO_{1.815}$ has a rhombohedral structure, the psudocubic lattice parameter calculated from the volume of the rhombohedral cell by Brauer and Gingerich[12] and by Ray *et al.*[14] is 5.497 Å. The lattice parameters in the present work are lower than the line of Vegard's law connecting UO_2 and $CeO_{1,815}$, while the data reported by Markin *et al.*[5] are above that line. If our lattice parameters are extrapolated to $y=1$, 5.467 Å is obtained, which corresponds to the $CeO_{1.88}$ of Ray's data.[14]

The Extraction of the Tungsten(VI)-Pyrocatechol Violet Complex with Tridodecylethylammonium Bromide

Yoshio Shijo,* Tokuo Shimizu, and Kaoru Sakai

Department of Environmental Chemistry, Faculty of Engineering, University of Utsunomiya, Ishii-machi, Utsunomiya 321

(Received April 7, 1980)

The extraction equilibria and the fundamental conditions were studied for extracting the tungsten(VI)-Pyrocatechol Violet complex anion in a form of an ionic associate with tridodecylethylammonium salt in carbon tetrachloride. The ternary complex has an absorption maxima at 575 nm in the organic phase. The optimum pH range for the extraction is 4.8—5.6. The distribution ratio and the molar absorptivity are 3.3×10^2 and 4.7×10^4 dm^3 mol^{-1} cm^{-1} respectively. The composition of the ternary complex is estimated to be $WO_2(PV)_2(R_3R'N)_2$. The extraction constant would be:

$$K_{ex}=\frac{[WO_2(PV)_2(R_3R'N)_2]_o}{[WO_2(PV)_2{}^{2-}][R_3R'N^+]^2}.$$

It is given by $\log K_{ex}=13.56$. Many foreign cations can be masked with CyDTA.

The extraction of metal complex anions with quaternary ammonium salts has been successively studied by many workers. Vanadium–4-(2-Pyridylazo)resorcinol,[1] cobalt–4-(2-thiazolylazo)resorcinol,[2] iron–Pyrogallol Red,[3] copper–2-nitroso-1-naphthol-4-sulfonic acid,[4] and magnesium–Xylidyl Blue I[5] complexes have been extracted in the form of the ionic associates with zephiramine. Plutonium–Xylenol Orange,[6] cadmium–8-hydroxyquinoline-5-sulfonic acid,[7] zinc–thiocyanate,[8] and chlorides of many metals[9] have also been extracted with Aliquat 336 (trioctylmethylammonium chloride) in the last two years. Besides, the extraction of metal–pyrocatechol violet(PV) complexes with tridodecylethylammonium bromide (TDEABr) has been studied for extracting copper,[10] tin,[11] aluminium,[12] zirconium,[13] niobium,[14] and iron.[15] Tungsten(VI), as well, is known to react with PV to form a complex, and the absorbance is intensified in the presence of the 1-hexadecylpyridinium cation.[6] Kohara[17] extracted the tungsten(VI)–PV complex in a form of an ionic associate with zephiramine from a 0.6—0.9 mol dm^{-3} hydrochloric acid solution, but the extraction equilibria have not been studied sufficiently. The tungsten(VI)–PV complex has also been extracted with TDEABr in carbon tetrachloride at about pH 5 from a solution containing CyDTA. This extraction system is expected to be selective and sensitive for the spectrophotometric determination of tungsten. In this paper, the extraction equilibria and the fundamental conditions will be discussed for extracting the tungsten(VI)–PV complex with TDEABr.

Experimental

Reagent. A 2.5×10^{-3} mol dm^{-3} tungsten(VI) solution was prepared by dissolving a definite amount of sodium tungstate in a 0.1 mol dm^{-3} sodium hydroxide solution. The solution was diluted as required. A 1×10^{-3} mol dm^{-3} PV solution was prepared by dissolving the Dotite PV in de-ionized water without further purification. TDEABr was prepared by the method described in a previous work.[15] A 5×10^{-3} mol dm^{-3} TDEABr solution was prepared by dissolving TDEABr in purified carbon tetrachloride. A 2 mol dm^{-3} sodium acetate solution was used as a buffer solution. All the other chemicals used were of a guaranteed reagent quality.

Apparatus. A Hitachi 101 spectrophotometer, a Hitachi 200–20 UV-vis. recording spectrophotometer, and a Hitachi Horiba F-7 pH meter were employed.

Standard Procedure. Up to 20 μg of tungsten(VI), a definite amount of 1 mol dm^{-3} sulfuric acid, and 2 cm^3 of a 1×10^{-3} mol dm^{-3} PV solution were mixed in a 100-cm^3 polypropylene beaker. The pH of the solution was adjusted to 5 by the addition of 2 cm^3 of a 2 mol dm^{-3} sodium acetate solution, after which the solution was diluted to 20 cm^3 with deionized water. The solution was transferred into a 35-cm^3 test tube, and 5 cm^3 of 5×10^{-3} mol dm^{-3} TDEABr in carbon tetrachloride were added. The extraction was carried out for 5 min by turning the test tube upside down twice every 5 s. After the phase separation, the organic phase was taken out and centrifuged for 2 min at 3000 min^{-1}. The absorbance of the extract at 575 nm was measured against the reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of the ternary complex extracted into carbon tetrachloride and of the tungsten(VI)–PV complex anion in an aqueous solution, and also the absorption spectra of the respective blank solutions, are shown in Fig. 1. The ternary complex and the tungsten(IV)–PV complex anion have absorption maxima at 575 nm and 538 nm respectively. As compared with the corresponding absorption maxima of the complex anion, that of the ternary complex is shifted toward wavelengths longer by 37 nm.

Effect of pH. The aqueous solution containing tungsten(VI) and PV was adjusted to various pH values with the sodium acetate buffer solution, and the extraction was carried out by the above procedure. The results are shown in Fig. 2. The maximum extraction of the ternary complex is reached in the pH range of 4.8 to 5.6. The extract was stable for at least 1 h. PV itself is readily extracted from an aqueous solution.

Organic Solvents. Several kinds of organic solvents were tested in order to achieve a quantitative extraction of the tungsten(VI)–PV complex anion with TDEABr. The ternary complex is extracted in such solvents as carbon tetrachloride, xylene, butyl acetate, and chloroform. The absorbance of the extract was

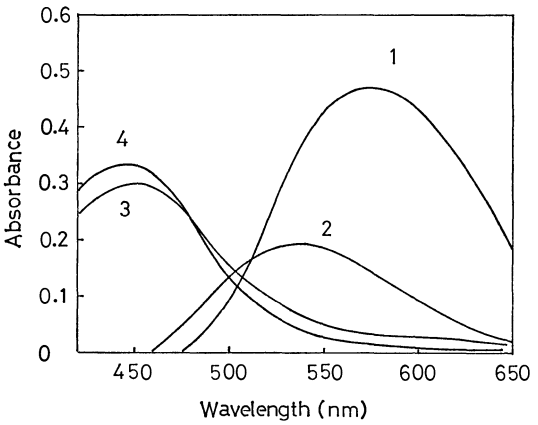

Fig. 1. Absorption spectra of the W–PV–TDEA in carbon tetrachloride and the W–PV complexes in aqueous solution.
pH=5.0, $V_{aq}=20$ cm³, $V_o=5$ cm³, $[TDEABr]_o=5\times10^{-3}$ mol dm⁻³. maximal when carbon tetrachloride was used.

The Effect of the Reagent Concentration. The extraction of tungsten(VI) from an aqueous solution containing PV in various concentrations was examined. The optimum concentration range of PV is from 8×10^{-5} mol dm⁻³ to 1.5×10^{-4} mol dm⁻³. The concentration of TDEABr in the organic phase was varied from 1×10^{-4} mol dm⁻³ to 5×10^{-3} mol dm⁻³. The absorbance of the extract was found to be constant in the concentration range from 9×10^{-4} mol dm⁻³ to 5×10^{-3} mol dm⁻³.

Extractability and Molar Absorptivity. An aqueous solution of 20 cm³ containing 18.4 μg of tungsten(VI) and PV was shaken with 5 cm³ of 5×10^{-3} mol dm⁻³ TDEABr in carbon tetrachloride under the optimum conditions. Extraction was repeated for the remaining aqueous phase after the separation of the extract. The extractability of the tungsten(VI) was calculated from the absorbances of the extracts. It was found

(1): W–PV–TDEA; $[W]+[PV]=5\times10^{-5}$ mol dm⁻³, $[TDEABr]_o=5\times10^{-3}$ mol dm⁻³ pH=5.0, 575 nm, (2): W–PV; $[W]+[PV]=2\times10^{-4}$ mol-dm⁻³, pH=5.0, 540 nm

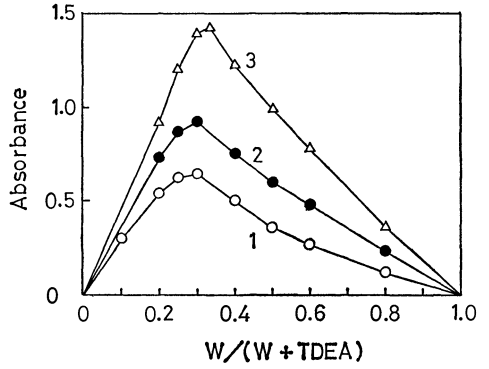

Fig. 4. Continuous variation method applied to the W–PV–TDEA complex (W:TDEA).
W–PV+TDEA=1.5×10^{-6} mol, pH=5.0, (1): 575 nm, (2): 610 nm, (3): 650 nm.

that 98.8% of the tungsten(VI) was extracted by a single extraction. The distribution ratio and the molar absorptivity were 3.3×10^2 and 4.7×10^4 dm³ mol⁻¹ cm⁻¹, respectively. A calibration curve for the determination of the tungsten(VI) was made under the optimum conditions. A good linear relationship was obtained over the concentration range from 1 μg to 20 μg of tungsten(VI) per 5 cm³ of carbon tetrachloride. The coefficient of the variation in ten measurements was 2.4%.

The Composition of the Ternary Complex. Using the continuous-variation method, the mole ratio of tungsten: PV of the ternary complex and of the tungsten(VI)–PV complex anion were found to be 1:2 and 1:1 respectively, as is shown in Fig. 3. The mole ratio of tungsten: TDEA was found to be 1:2, as is shown in Fig. 4. Thus, the composition of the ternary complex was estimated to be $WO_2(PV)_2$–$(R_3R'N)_2$.

Extraction Constant. When the ionic associate of the tungsten(VI)–PV complex anion with the TDEA cation is extracted in the organic phase, the equation representing the extraction equilibria will be:

$$WO_2(PV)_2^{2-} + 2R_3R'N^+ = WO_2(PV)_2(R_3R'N)_{2(o)}. \quad (1)$$

The extraction constant, K_{ex}, is given by:

$$K_{ex} = \frac{[WO_2(PV)_2(R_3R'N)_2]_o}{[WO_2(PV)_2^{2-}][R_3R'N^+]^2}, \quad (2)$$

where the subscript o denotes the organic phase.

The direct determination of each of the component concentrations in Eq. 1 is a difficult problem, because the pure ternary complex can not easily be prepared. The extraction constant, K_{ex}, can, however, be determined by the indirect method, in which the extraction equilibria of the tungsten(VI)–PV complex anion with tridodecylethylammonium 2-naphthalenesulfonate is employed. The corresponding equilibria are written as follows:

$$WO_2(PV)_2^{2-} + 2R_3R'N\cdot NS_{(o)} = WO_2(PV)_2(R_3R'N)_{2(o)} + 2NS^-. \quad (3)$$

The equilibrium constant for Eq. 3 is:

$$K = \frac{[WO_2(PV)_2(R_3R'N)_2]_o[NS^-]_2}{[WO_2(PV)_2^{2-}][R_3R'N\cdot NS]_o^2}, \quad (4)$$

where NS denotes 2-naphthalenesulfonate.

The extraction equilibria of tridodecylethylammonium 2-naphthalenesulfonate may be represented as follows:

$$NS^- + R_3R'N^+ = R_3R'N\cdot NS_{(o)}. \quad (5)$$

The extraction constant for Eq. 5 is:

$$K'_{ex} = \frac{[R_3R'N\cdot NS]_o}{[NS^-][R_3R'N^+]}. \quad (6)$$

Thus, K_{ex}, is given by:

$$K_{ex} = K\times(K'_{ex})^2. \quad (7)$$

The concentration of the $WO_2(PV)_2(R_3R'N)_{2(o)}$ species in Eq. 3 was determined spectrophotometrically as a function of $[NS^-]$, and the value of K was calculated from Eq. 4. The extraction constant, K'_{ex}, in Eq. 6 was also determined by the analogous method from the extraction equilibria between $R_3R'N\cdot NS$ in CCl_4 and the PV anion, the extraction constant of which had already been known. Table 1 shows the value of log K_{ex} calculated from Eq. 7. It is given by

Table 1. Equilibrium extraction data for $WO_2(PV)_2^{2-}$ with $R_3R'N^+$ in carbon tetrachloride at 25 °C

(I=0.005 in an acetate solution and Na_2SO_4 solution) pH=5.0 in an acetate buffer solution (2.0×10^{-3} mol dm^{-3}), $[W]=2.5\times10^{-6}$ mol dm^{-3}, $[PV]=1.25\times10^{-4}$ mol dm^{-3}, $[TDEABr]_o=5\times10^{-3}$ mol dm^{-3}, V_{aq}=20 cm^3, V_o=5 cm^3.

$[NS^-]/10^{-3}$ mol dm^{-3}	log K_{ex}
2.5	13.50
5.0	13.59
7.5	13.56
10	13.59
12.5	13.54
	log K_{ex} = 13.56

All the concentrations in Table 1 show the initial concentrations.

Table 2. Effects of diverse ions on the determination of tungsten(VI)

Ions	Amount added mg	Tungsten(VI) found/μg	Error %
—	—	9.2	0
Be^{2+}	0.1	7.9	−14
Mo(VI)	0.1	18.9	+105
Th^{4+}	0.1	10.4	+13
U(VI)	0.1	10.5	+14
V(V)	0.1	11.6	+26
I^-	10	3.8	−59
SCN^-	10	3.0	−67
ClO_4^-	10	0.6	−93
Citrate	10	0.9	−90
EDTA	10	1.0	−89

log K_{ex}=13.56.

Effect of Foreign Ions. The effect of foreign ions on the determination of 9.2 μg tungsten(VI) was examined upon the addition of 2 cm^3 of 0.05 mol dm^{-3} CyDTA as a masking agent. Portions (0.1 mg) of aluminium, antimony, bismuth, cadmium, cobalt, chromium, copper, gallium, indium, iron, lanthanum, lead, magnesium, manganese, mercury, nickel, tin, and zinc did not interfere, but beryllium, molybdenum, thorium, uranium, and vanadium interfered considerably with the determination of the tungsten(VI). Of the anions tested, 10-mg portions of iodide, thiocyanate, and perchlorate interfered seriously, giving negative errors. Chelating agents, such as EDTA and citrate, also interfered. The main interfering ions are shown in Table 2.

The Coordination of the Perchlorate Ion. I. The Crystal and Molecular Structure of Bis(perchlorato)bis(pyrazine-2,3-dicarboxamide)copper(II)

Masao Sekizaki

College of Liberal Arts, Kanazawa University, Marunouchi, Kanazawa 920

(Received April 9, 1980)

Bis(perchlorato)bis(pyrazine-2,3-dicarboxamide)copper(II) has been prepared, and its crystal and molecular structure has been determined by the X-ray diffraction and the infrared spectroscopic methods. The crystals are triclinic with a space group $P\bar{1}$; $a=10.959(4)$, $b=6.970(3)$, $c=7.666(3)$ Å, $\alpha=116.63(3)$, $\beta=78.14(5)$, and $\gamma=97.27(5)°$, and $Z=1$. The refinement of the crystal structure has been carried out by a block-diagonal least-squares method to give $R=0.054$ for 1727 non-zero reflections. The complex is centrosymmetric, with the two bidentate ligand molecules chelating to the copper atom in *trans* positions through the amide oxygen and pyrazine nitrogen atoms to form a square-plane. The two perchlorate ions coordinate weakly to the copper atom through the oxygen atoms from the top and bottom of this plane; thus, an elongated octahedron is formed. The complex molecules are connected to one another by N-O type hydrogen bonds to form a three-dimensional network. The infrared spectrum has been compared with that of the chloride complex. The KBr region clearly show the symmetry depression of the perchlorate ion from T_d to C_{3v} on coordination.

It is well known that a perchlorate ion scarcely coordinates to the transition metal ions. However, it sometimes acts as a unidentate ligand in the presence of organic ligands.[1-4] The present investigation has been carried out in order to ascertain the structure and properties of the coordinating perchlorate ion in the copper(II) complex of pyrazine-2,3-dicarboxamide (abbreviation, pyda) by the spectroscopic and crystallographic methods.*

Experimental

Preparation of the Complexes. Bis(perchlorato)bis(pyrazine-2,3-dicarboxamide)copper(II), [Cu(ClO$_4$)$_2$(pyda)$_2$]: an ethanolic solution of 2.5 g of newly prepared $Cu(ClO_4)_2\cdot 6H_2O$ was added to a hot aqueous solution of 1 g of pyda (Aldrich Chem. Co.). The mixture was, then, cooled slowly. The deep blue crystals precipitated were washed with ethanol. Yield, 1.5 g. Found: Cu, 10.67; N, 18.63; C, 24.23; H, 2.22%. Calcd for $C_{12}H_{12}N_8O_{12}CuCl_2$: Cu, 10.68; N, 18.84; C, 24.23; H, 2.03%.

Pyrazine-2,3-dicarboxamidecopper(II) Chloride, Cu(pyda)Cl$_2$: Three grams of $CuCl_2\cdot 2H_2O$, dissolved in 200 cm^3 of ethanol, were quickly added to 50 cm^3 of a hot aqueous solution of 1 g of pyda. After the filtration of the precipitate instantaneously formed, the solution was slowly cooled to room temperature. The yellowish-green powder thus obtained was washed with ethanol. Yield, 1.2 g. Found: Cu, 21.18; N, 18.28; C, 23.67; H, 2.24%. Calcd for $C_6H_6N_4O_2CuCl_2$: Cu, 21.14; N, 18.64; C, 23.97; H, 2.01%.

Measurement of the Infrared Spectra. A JASCO DS-402G spectrometer and a Hitachi EPI-L spectrometer were used in the 200—4000 cm^{-1} region. The samples were suspended in Nujol and HCB mulls.

Crystallographic Measurement. A crystal of $0.2\times0.1\times0.1$ mm was selected. The intensities were measured on a Philips PW1100 automatic four-circle diffractometer with Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) monochromated by a graphite plate. The θ-2θ scan technique was used at a scan rate of 0.0668°/s in θ, with a scan width of $(1.0+0.3\tan\theta)°$. The intensities of the three reference reflections, monitored every 2 h, remained constant within the limits of experimental error during data collection. Of 1803 independent reflections measured up to $\theta=78°$, 1727 with $|F|>3\sigma$ were used for the structure analysis. No corrections were made for absorption and extinction effects ($\mu r=0.3$). The cell dimensions were refined on the diffractometer by a least-squares method using the 2θ values of 25 reflections.

Crystal Data: $Cu(ClO_4)_2\{C_4N_2H_2(CONH_2)_2\}_2$. F.W.=594.73. Triclinic, $a=10.959(4)$, $b=6.970(3)$, $c=7.666(3)$ Å, $\alpha=116.63(3)$, $\beta=78.14(5)$, $\gamma=97.27(5)°$. $U=511.9(3)$ Å^3. $D_x=1.929$ g cm^{-3}. $Z=1$. Space group $P\bar{1}$. $\mu=47$ cm^{-1} (Cu $K\alpha$ radiation, $\lambda=1.5418$ Å).

Determination and Refinement of the Crystal Structure

The coordinates of the copper and the chlorine atoms were determined from a Patterson map; successive Fourier syntheses gave the approximate skeletal structure. The copper atom occupies the special positions of the triclinic cell. The block-diagonal least-squares refinement was carried out based on 1727 non-zero reflections. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[5] After several cycles of refinement with isotropic temperature factors, the R-value became 0.15. Anisotropic temperature factors were, then, introduced for all the non-hydrogen atoms. The R-value was reduced to 0.058. The hydrogen atoms were obtained from the difference-Fourier synthesis. Their positional parameters were refined with isotropic temperature factors of 4.0 Å^2. The final R-value was 0.054.

The final atomic parameters are listed in Table 1. A list of the observed and calculated structure amplitudes has been deposited with the Chemical Society of Japan (Document No. 8108).

The refinement of the structure and the drawing of thermal ellipsoids were carried out with HBLS-IV[6] and ORTEP[7] programs respectively. The other calculations were carried out with programs written by the author. A FACOM 230-75 computer at the Computation Center of Nagoya University and a FACOM M-160 computer at the Data Processing Center of Kanazawa University were used.

* The author has noticed a report on the crystal structure of the same complex. Its conclusion is, however, different from the present one. The details will be discussed later in the present report.

Table 1a. Final parameters of non-hydrogen atoms ($\times 10^4$)

The thermal parameters are in the form: $\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+hk\beta_{12}+hl\beta_{13}+kl\beta_{23})]$.
The estimated standard deviations are in parentheses in this table and the other subsequent tables.

Results and Discussion

Crystal Analysis. The molecular structure of the complex is shown in Fig. 1, with anisotropic thermal ellipsoids of the non-hydrogen atoms. The bond lengths are also shown in this figure. The bond angles are listed in Table 2.

The complex is centrosymmetric, with two ligand molecules in *trans* positions. Each of the ligand molecules acts as bidentate through one of the pyrazine nitrogen atoms and the oxygen atom of the *ortho* amide group, thus forming a five-membered chelate ring. The four coordinating atoms form a square-plane around the copper atom. The distances of the coordination bonds are similar to those of the other copper amide complexes.[2,8,9]

The oxygen atom of the perchlorate ion lies on the normal line of this plane passing through the copper atom. The distance between the copper and the oxygen atom is 2.495 Å. This value is larger than those of the usual coordination-bond lengths on the square-plane. However it is smaller than those of the other perchloratocopper(II) complexes (2.61 Å for $[Cu(ClO_4)_2(en)_2]$[1] or 2.52 Å for $[Cu(ClO_4)_2(paaH)_2]$,[2] where paaH denotes 2-pyridylacetamide).

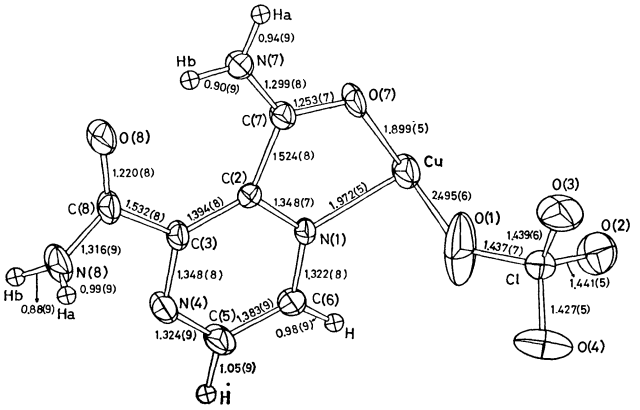

Fig. 1. Structure of the asymmetric unit with the bond lengths (l/Å) and the e.s.d.'s.
Thermal ellipsoids are drawn at 50% probability level. Hydrogen atoms are drawn as spheres with a diameter of 0.2 Å.

Thus, the complex forms a distorted octahedron elongated to the perchlorate oxygen atoms.

The complex molecule is arranged as shown in Fig. 2, with the copper atom occupying the special position of the triclinic unit cell. The hydrogen bonds are listed in Table 3.

The uncoordinated amide group is hydrogen-bonded to that of the neighboring molecule through O(8)···N(8)^{i} to form a column in the [101] direction. The perchlorate ions connect these columns by the hydrogen bonds through O(4)···N(7)^{iv}, O(2)^{ii}···N(8), and O(3)^{ii}···N(8). The van der Waals interactions shorter than 3.2 Å are also observed around the anion. The [101] columns are thus combined with one another by these interactions through the perchlorate ions, thus forming a three-dimensional network.

The perchlorate ion is almost a regular tetrahedron.

O(3)	Hb	N(7)[iii]	2.930(8)	2.50(9)
O(4)	Ha	N(7)[iv]	3.239(7)	2.49(9)

a) A, Hydrogen acceptor; D, Hydrogen donor.
b) Key to symmetry operation.

No mark	x	y	z
i	$1-x$	$-y$	$1-z$
ii	$1+x$	y	z
iii	$-x$	$-y$	$1-z$
iv	x	$1+y$	z

The thermal vibrations of the oxygen atoms are larger than those of the other atoms; especially, the coordinated oxygen atom shows a large anisotropy normal to the coordination bond.

Infrared Spectra. The spectrum in the 700—4000 cm^{-1} region has given only poor results because of too many unassignable bands. But that in the 200—700 cm^{-1} region has given important information on the coordination of the perchlorate ion. It is shown in Fig. 3, together with some tentative assignments.[10,11] Those of the free ligand and the chloride complex are also shown for the sake of comparison.

Most of the bands of the free ligand are also observed in both the complexes. On coordination, some new peaks appear; they are marked with e in Fig. 3. Furthermore, the perchlorato complex gives a broad doublet at *ca.* 580 cm^{-1} and two weak bands at 462 and 431 cm^{-1} (marked with f). They must be due to the unidentately coordinating perchlorate ion. Of the four normal vibrations of the free perchlorate ion, two exist in this region (*ca.* 460 and 610 cm^{-1});[12,13] the latter is infrared-active. If the symmetry is lowered to C_{3v} on coordination, the former becomes infrared-active and the latter splits into two bands. The 580 cm^{-1} doublet is assigned a split band, and either of the two bands at 462 and 431 cm^{-1} corresponds to the former.

a: C-O in-plane bending, b: C-O out-of-plane bending, c: pyrazine ring deformation ,d: pyrazine-amide torsion, e: skeletal vibrations due to octahedral coordination, f: normal vibrations of the perchlorate ion.

Comment on the Report by Mondal and Ray[14]

In the course of this investigation, Mondal and Ray reported the crystal structure of the same complex by the photographic method. According to them, the crystal is triclinic with the space group of $C\bar{1}$ and $Z=2$; the structure is square-planar without any coordination of the ClO_4^- ion.

The space group $C\bar{1}$ can be converted to $P\bar{1}$ by means of the following formula on the unit-cell vectors:

$$\boldsymbol{a} = \boldsymbol{c}_r,$$

$$\boldsymbol{b} = (\boldsymbol{a}_r + \boldsymbol{b}_r)/2,$$

and

$$\boldsymbol{c} = (\boldsymbol{b}_r - \boldsymbol{a}_r)/2,$$

where $\boldsymbol{a}_r$, *etc.* are as defined by Mondal and Ray. The lattice constants thus converted are: $a=11.06$, $b=6.80$, $c=7.58$ Å, $\alpha=116.06$, $\beta=76.68$, and $\gamma=97.33°$, which are approximately coincident with the results of the present investigation.

The ClO_4^- ion indeed seems to be non-coordinated, because the atomic parameters given by them certainly show that the anion is far from the complex cation. However the contact between the cation (x,y,z) and the anion $(x-1/2, y-1/2, z)$ is short so that one of the oxygen atoms of the latter approaches the copper atom with the distance of 2.46 Å, which undoubtedly indicates the weak coordination of the anion. Furthermore, although they have stated that there are no hydrogen bonds around the anion, some short contacts are observed between the anion and the neighboring complex molecules. Perhaps they might have forgotten the discussion of the intermolecular interaction in the unit cell of $C\bar{1}$. A set of the XDC[15] converts the positional parameters of the anion so that the anion is near the complex cation. The bond distances and angles less than 2.5 Å calculated by these parameters agree with the results of the present investigation within the limits of experimental error, including the Cu–O weak coordination bond. It is regrettable that, although Mondal and Ray obtained correct data by means of a troublesome photographic method, they gave an incorrect conclusion as to the molecular structure.

The author is grateful to Professor Yoichi Iitaka of the University of Tokyo for the measurements of the intensities with the diffractometer. This work was supported in part by a Grant-in-Aid for Scientific Research No. 354215 from the Ministry of Education, Science and Culture.

Kinetic and Equilibrium Studies on Substitution Reactions of the Chlorobis(β-diketonato)manganese(III) Complexes with Other β-Diketones

Yoshiaki Ito and Shinichi Kawaguchi*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received May 1, 1980)

The $MnCl(\beta\text{-dik})_2$ complexes, where β-dik stands for an anion of acetylacetone, benzoylacetone, and dibenzoylmethane, were confirmed to have the five-coordinate structure in dichloromethane and their adduct formation constants with various donor solvents were measured. Equilibria and kinetics of substitution reactions of $MnCl(\beta\text{-dik})_2$ with other β-diketones were determined by the spectrophotometric method and the mechanism for these reaction is proposed.

The bis(acetylacetonato)halogenomanganese(III) complexes, $MnX(acac)_2$ (X=Cl, Br, and I), were prepared by the reactions of tris(acetylacetonato)-manganese(III) with an equimolar amount of hydrogen halide in organic solvents.[1] They were characterized by measurements of magnetic susceptibility, electronic and infrared spectra, molecular weight, and electric conductivity and were concluded to exist as five-coordinate molecules in noncoordinating solvents but behave as a uni-uni valent electrolyte in methanol. An analogous iron(III) complex, $FeCl(acac)_2$, was confirmed by X-ray analysis to have a square pyramid structure with the chloride anion at the apical position.[2] Although the pseudohalogenomanganese(III) complexes, $MnX(acac)_2$ ($X=N_3$ and NCS), were reported to have a polynuclear chain structure in crystals in which each manganese(III) ion assumes a tetragonally elongated octahedron with the trans-coordinated pseudohalides as the end-to-end bridging ligand,[3,4] they may be five coordinate in solutions of poorly coordinating solvents.[3]

Stults, et al.[5] showed that the $MnX(acac)_2$ complexes are useful in preparing the biologically important Mn(III)-porphyrin[6] in high purity and yield, although the mechanism of the ligand substitution reaction has not been clarified. Kinetic studies on the ligand substitution reactions of five-coordinate complexes have been rather few and to our knowledge, no reports on the reactions of five-coordinate manganese(III) complexes have appeared as yet. This paper is concerned with the substitution reactions of chlorobis(dibenzoylmethanato and benzoylacetonato)-mangangese(III) with acetylacetone, and kinetic and equilibrium data as well as mechanistic discussion are presented.

Experimental

Materials. Acetylacetone (acacH) of the extra-pure grade was distilled twice before use. Benzoylacetone (bzacH) and dibenzoylmethane (dbmH) were recrystallized twice from methanol and dried over silica gel in an evacuated desiccator. Dichloromethane was washed with a 10% aqueous solution of sodium carbonate followed by pure water, dried by means of Linde molecular sieves (Type 3A), and was then distilled through a fractionating column filled with Widmer spirals. Dichloromethane was used immediately after distillation as the solvent for kinetic studies. Diethyl ether was treated with metallic sodium and distilled. Pyridine of the highest grade for spectroscopy was used without further treatment. Methanol was dried by Linde molecular sieves (Type 3A) and distilled. Other organic solvents such as *N,N*-dimethylformamide (DMF), dimethylsulfoxide (DMSO), benzonitrile (PhCN), and acetonitrile (MeCN) were similarly dried and distilled under reduced pressure of nitrogen. Deuterium oxide of 99.75% purity (Merck) was used for the deuteration studies.

Synthesis of Complexes. Bis(acetylacetonato)chloromanganese(III): The complex was prepared by Isobe's method[1] and recrystallized twice from a mixture of dichloromethane and diethyl ether (1:1 by volume) in a dry box under dry nitrogen atmosphere. Found: C, 41.16; H, 4.84%. Calcd for $MnCl(acac)_2=C_{10}H_{14}O_4ClMn$: C, 41.16; H, 4.89%.

Chlorobis(dibenzoylmethanato)manganese(III), $MnCl(dbm)_2$ and Bis(benzoylacetonato)chloromanganese(III), $MnCl(bzac)_2$: Isobe's method was modified a little. Dibenzoylmethane (5.2 g, 23.2 mmol) was added to a solution of $MnCl(acac)_2$ (0.5 g, 1.7 mmol) in dichloromethane (20 cm^3), and the mixture was allowed to stand for about 2 h to deposit the product (0.31 g) in a 33% yield. Recrystallization was performed in an atmosphere of dry nitrogen from an equivolume mixture of dichloromethane and diethyl ether containing six times as many moles of dibenzoylmethane as compared with the complex. Found: C, 66.18; H, 4.15%. Calcd for $MnCl(dbm)_2=C_{30}H_{22}O_4ClMn$: C, 67.11; H, 4.13%. Bis(benzoylacetonato)chloromanganese(III) was also prepared and recrystallized in a similar manner as above. The yield of a crude product was 0.20 g (28.0%). Found: C, 57.89; H, 4.41%. Calcd for $MnCl(bzac)_2=C_{20}H_{18}O_4ClMn$: C, 58.20; H, 4.40%.

Acetylacetonato(dibenzoylmethanato)- and Acetylacetonato(benzoylacetonato)-chloromanganese(III): In an atmosphere of dry nitrogen $MnCl(acac)_2$ (1.0 g, 3.7 mmol) was dissolved in dichloromethane (20 cm^3), and to this solution was added slowly a dichloromethane solution (100 cm^3) of dibenzoylmethane (1.7 g, 7.5 mmol) followed by diethyl ether (100 cm^3). After the reaction for 1 h, a precipitate was filtered and washed with diethyl ether. The yield was 0.60 g (42%). Found: C, 59.54; H, 3.96%. Calcd for $MnCl(acac)(dbm)=C_{20}H_{18}O_4ClMn$: C, 58.20; H, 4.40%. Acetylacetonato-(benzoylacetonato)chloromanganese(III) was also prepared in a similar manner as above to obtain a crude product in a 38% yield. Found: C, 52.38; H, 4.42%. Calcd for $MnCl(acac)(bzac)=C_{15}H_{16}O_4ClMn$: C, 51.38; H, 4.60%.

Both of the mixed β-diketonato complexes were not recrystallized, since they are not stable in solution, but undergo disproportionation reactions. Thus the results of elemental analysis are not satisfactory.

Preparation of Acetylacetone-methylene-d_2. A mixture of

acetylacetone (10 cm^3, 0.0975 mol) and D_2O (30 cm^3, 1.66 mol) was heated under reflux for 4—5 h, and allowed to stand overnight at room temperature. The mixture was extracted three times with 20 cm^3 portions of dichloromethane. The combined extract was subjected to distillation under reduced pressure to leave the deuterated acetylacetone. The ^1H NMR assay of the neat liquid indicates that the deuterium content of the methylene group is 90.2%. When potassium acetylacetonate was added to make the reaction medium basic, the methyl groups of acetylacetone were also deuterated. This product was not used in the following studies.

Measurements. Water contents of organic solvents were determined by means of an MCI digital water microanalyzer CA-01. Absorption spectra were measured with a Hitachi EPS-3T recording spectrophotometer, and infrared spectra in Nujol with a JASCO DS 701G spectrophotometer. A JEOL JNM MH-100 spectrometer was used to obtain ^1H NMR spectra in CD_2Cl_2 with tetramethylsilane as internal reference.

The ligand substitution reactions were followed spectrophotometrically by means of a Union Stopped-Flow Rapid Scan Spectrophotometer RA-1300. The solution reservoir was covered with a polyethylene bag equipped with gloves and filled with dry nitrogen in order to prevent the stock solution from contacting with air.

Results

Addition Reactions of Donor Molecules to the Chlorobis(β-diketonato)manganese(III) Complexes, $MnCl(\beta\text{-dik})_2$, in Solution. Based on the molecular-weight and other data, $MnCl(acac)_2$ has been considered to exist as five-coordinate molecules in noncoordinating solvents.[1] Now the following spectroscopic studies assure that the sixth coordination site of manganese(III) is really left vacant.

The complex is not so stable in dichloromethane solution, but some kind of decomposition proceeds as evidenced by the change of its spectrum with time. However the spectrum shows no change in the coexistence of an excess (*e.g.* ten times molar) amount of free acacH. Under such circumstances, coordination of an acacH molecule to manganese(III) might happen. To a solution of $MnCl(acac)_2$ in dichloromethane (4.00×10^{-4} mol dm^{-3}) containing water at a constant concentration (5.2×10^{-3} mol dm^{-3}) was added acacH to attain various concentrations in the range of $(3.28—21.84)\times10^{-3}$ mol dm^{-3}, but no change in spectrum was observed. Alternatively, the concentration of acacH was kept constant at 9.61×10^{-3} mol dm^{-3} and that of water was varied in the range of $(4.87—49.8)\times10^{-3}$ mol dm^{-3}. The spectrum showed no change, either. These results may be rationalized if the sixth coordination site of $MnCl(acac)_2$ is occupied preferentially by a molecule of either acacH or water at the given concentrations, or alternatively if the complex retains the five-coordinate structure even in the presence of more than fifty times molar excess of acacH and water. In order to find out which of the three possibilities is the case, the following experiments have been performed.

When an increasing amount of DMF was added to a dichloromethane solution of $MnCl(acac)_2$ containing excess amounts of acacH and water, the absorption spectrum varied successively as is seen in Fig. 1, exhibiting a distinct isosbestic point. Thus the coordination of DMF to manganese as is expressed by Eq. 1 is conceivable.

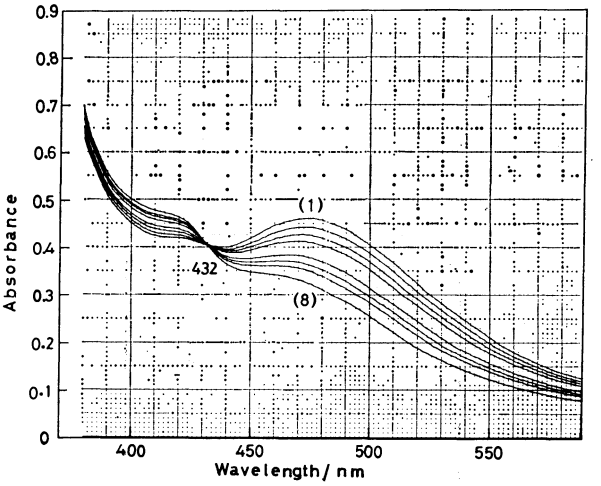

Fig. 1. Absorption spectra of $MnCl(acac)_2$ in dichloromethane at 25.0 °C containing 4.83×10^{-4} mol dm^{-3} complex, 9.80×10^{-3} mol dm^{-3} acacH, and 1.51×10^{-2} mol dm^{-3} H_2O in the absence (curve 1) and presence of DMF at various concentrations: 8.87×10^{-3} (2), 1.77×10^{-2} (3). 2.66×10^{-2} (4), 5.32×10^{-2} (5), 7.10×10^{-2} (6), 8.87×10^{-2} (7), and 1.33×10^{-1} (8) mol dm^{-3}.

$$MnCl(acac)_2X + D \rightleftharpoons MnCl(acac)_2D + X,\ K_{ad}' \quad (1)$$

The equilibrium quotient K_{ad}' is defined by $K_{ad}'=[MD][X]/[MX][D]$, where M and D represent the $MnCl(acac)_2$ moiety and a molecule of donor solvent such as DMF, respectively, and X is either acacH, H_2O, or nil. The observed absorbance per unit path length, A, of the solution is related to the concentration of D by Eq. 2.

$$\frac{1}{\varepsilon_{MX}c_M - A} = \frac{1}{(\varepsilon_{MX}-\varepsilon_{MD})c_M} + \frac{[X]}{(\varepsilon_{MX}-\varepsilon_{MD})c_M K_{ad}'[D]} \quad (2)$$

Here each ε stands for the molar extinction coefficient of the species shown by a subscript, and c_M for the total concentration of the complex. The concentrations of uncoordinated X and D can be approximated by their total concentrations, c, since c_{acacH}, c_{H_2O}, $c_D \gg c_M$. The absorbance at 480 nm was used to calculate the left-hand term of Eq. 2, which was plotted against 1/[D] to result in a good straight line. The slope and intercept of the straight line gave $\varepsilon_{MD}=416$ dm^3 mol^{-1} cm^{-1} at 480 nm and $[X]/K_{ad}'=0.0994$ mol dm^{-3}.

If a water molecule is coordinated to manganese(III) as X, $K_{ad}'(H_2O)$ will be 0.152 since $c_{H_2O}=1.51\times10^{-2}$ mol dm^{-3}. On the other hand, K_{ad}'(acacH) is calculated to be 0.0986 from $c_{acacH}=9.80\times10^{-3}$ mol dm^{-3}. By virtue of these values for the equilibrium quotient of Reaction 1, the absorbance A at various concentrations of X can be calculated from Eq. 3.

$$A = \frac{(\varepsilon_{MX}-\varepsilon_{MD})c_M}{1+K_{ad}'[D]/[X]} + \varepsilon_{MD}c_M \quad (3)$$

The curves in Fig. 2 display the expected change

of A at 480 nm with concentrations of H_2O and acacH as X at a fixed [DMF]. As shown by circles in Fig. 2, the spectra in the 340—700 nm region showed no change under these circumstances, indicating that the coordinated DMF is not replaced at all by H_2O and acacH.

Thus the spectral change depicted in Fig. 1 can not be rationalized by substitution of the H_2O or acacH ligand by DMF, but should be considered to correspond to ligation of DMF at the sixth vacant coordination site according to Eq. 4. Other β-diketonato complexes, $MnCl(bzac)_2$ and $MnCl(dbm)_2$ showed similar behaviors in dichloromethane, indicating that they also reserve the five-coordinate structure in solution.

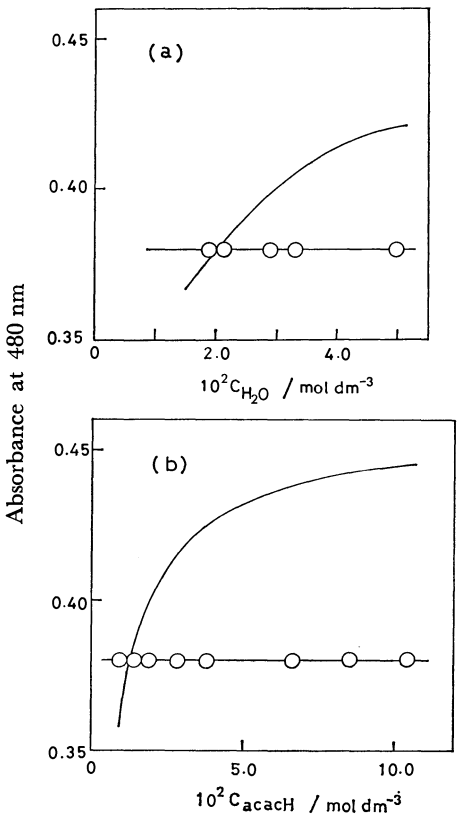

Fig. 2. Dependency of the absorbance at 480 nm of $MnCl(acac)_2$ (4.84×10^{-4} mol dm^{-3}) in CH_2Cl_2 containing DMF (5.84×10^{-2} mol dm^{-3}) on the concentration of (a) water in the presence of acacH (9.62×10^{-3} mol dm^{-3}) and of (b) acacH in the presence of water ($(1.65-2.22)\times10^{-2}$ mol dm^{-3}). Curves represent the calculated values based on the equilibria (1), and circles the observed values.

$$MnCl(\beta\text{-dik})_2 + D \rightleftharpoons MnCl(\beta\text{-dik})_2D \quad (4)$$

$$K_{ad} = [MnCl(\beta\text{-dik})_2D]/[MnCl(\beta\text{-dik})_2][D] \quad (5)$$

Other donor solvents such as pyridine (py), DMSO, methanol (MeOH), MeCN, and PhCN also react with $MnCl(\beta\text{-dik})_2$. The formation constants K_{ad} of these adducts (Eq. 5) were determined in a similar manner as above and are collected in Table 1 together with the molar extinction coefficient of each adduct. The plots of log K_{ad} against the donor number[7] of each solvent gave straight lines (Fig. 3).

When increasing amounts of donor solvents were added to solution of $MnCl(acac)_2$ in dichloromethane, isosbestic points were observed at 434 (py), 431 (DMSO), 432 (DMF), 438 (MeOH), 450 (MeCN), and 447 (PhCN) nm. The reactions of $MnCl(bzac)_2$ with MeOH (432 and 452 nm) and MeCN (426 and 468 nm) also showed two isosbestic points, respectively, while the other donor solvents showed no isosbestic points in the 410—700 nm region. In the case of $MnCl(dbm)_2$, no solvents except MeCN (483 nm) exhibited isosbestic points. These adduct formation reactions are very rapid and could not be followed by the stopped-flow method.

As is exemplified by Fig. 1, a large excess of donor solvents were employed in these experiments, and it was supposed that β-diketone itself might add to $MnCl(\beta\text{-dik})_2$ if a large excess amount was used. Figure 4 shows it is the case in fact. When an increasing amount of acacH was added to a solution of $MnCl(acac)_2$ in dichloromethane, spectral change was observed accompanying an isosbestic point at 443 nm. The resulting spectrum is different from that of $Mn(acac)_3$ and seems to be ascribed to the adduct formed by Reaction 6, although it is not certain whether the acetylacetone molecule is added as a keto or an enol

tautomer.

$$MnCl(acac)_2 + acacH \rightleftharpoons MnCl(acac)_2(acacH) \quad (6)$$

The $MnCl(bzac)_2$–(bzacH) and $MnCl(dbm)_2$–(dbmH) systems were also studied in a similar manner. The formation constants of the three kinds of adduct $MnCl(\beta\text{-dik})_2(\beta\text{-dikH})$ were thus determined and listed in Table 1 together with their extinction coefficients at the given wavelengths. The donor number of each β-diketone was estimated by interpolation of the log K_{ad} *vs.* DN plots in Fig. 3, and was in turn utilized to calculate the prospective formation constants of the adducts according to Eq. 7, which are included in Table 1.

$$MnCl(\beta\text{-dik})_2 + \beta\text{-dik'H} \rightleftharpoons MnCl(\beta\text{-dik})_2(\beta\text{-dik'H}) \quad (7)$$

Equilibria for the β-Diketone Substitution Reactions of $MnCl(acac)_2$. Figure 5 shows the absorption spectra of the $MnCl(\beta\text{-dik})_2$ complexes in dichloromethane. When an increasing amount of bzacH or dbmH is added to a $MnCl(acac)_2$ solution containing uncoordinated acetylacetone to stabilize the complex solution, the spectrum changes successively to approach that of $MnCl(bzac)_2$ or $MnCl(dbm)_2$, respectively. The points plotted in Fig. 6 show the observed absorbances at 450 nm as a function of the dbmH concentration added to the solution of $MnCl(acac)_2$ in dichloromethane. These results conform with the following equilibria.

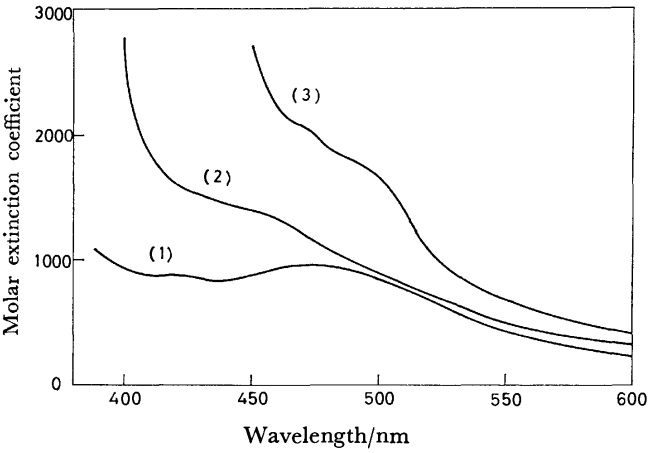

Fig. 5. Absorption spectra of $MnCl(acac)_2$ (curve 1), $MnCl(bzac)_2$ (2), and $MnCl(dbm)_2$ (3) in dichloromethane.

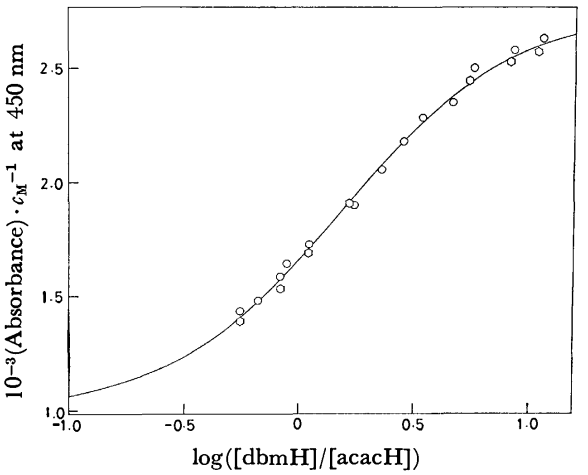

Fig. 6. The absorbance at 450 nm of $MnCl(acac)_2$ solution in dichloromethane at 25 °C as a function of log ([dbmH]/[acacH]), c_M being 2.00×10^{-4} (○) and 2.13×10^{-4} (○) mol dm^{-3}, and c_{acacH} 4.30×10^{-3}. The curve represents the calculated values based on $K_1=0.847$, $K_2=0.401$, and ε for $MnCl(acac)(dbm)=$ 1980 cm^{-1} mol^{-1} dm^3 at 450 nm.

$$MnCl(acac)_2 + \beta\text{-dikH} \rightleftharpoons MnCl(acac)(\beta\text{-dik}) + acacH,\ K_1 \quad (8)$$

$$MnCl(acac)(\beta\text{-dik}) + \beta\text{-dikH} \rightleftharpoons MnCl(\beta\text{-dik})_2 + acacH,\ K_2 \quad (9)$$

The observed absorbance of the reaction mixture is expressed by Eq. 10,

$$A = \varepsilon_{Ma_2}[Ma_2] + \varepsilon_{Mab}[Mab] + \varepsilon_{Mb_2}[Mb_2] = \bar{\varepsilon} c_M, \quad (10)$$

where Ma_2, Mab, and Mb_2 represent $MnCl(acac)_2$, MnCl(acac)(β-dik), and $MnCl(\beta\text{-dik})_2$, respectively. The mean molar absorptivity $\bar{\varepsilon}$ can be calculated by

$$\bar{\varepsilon}_{calcd} = \frac{\varepsilon_{Ma_2} + \varepsilon_{Mab}K_1([\beta\text{-dikH}]/[acacH]) + \varepsilon_{Mb_2}K_1K_2([\beta\text{-dikH}]/[acacH])^2}{1 + K_1([\beta\text{-dikH}]/[acacH]) + K_1K_2([\beta\text{-dikH}]/[acacH])^2}, \quad (11)$$

where K_1 and K_2 are the equilibrium constants for the stepwise substitution Reactions 8 and 9.

$$K_1 = \frac{[Mab][acacH]}{[Ma_2][\beta\text{-dikH}]}, \quad K_2 = \frac{[Mb_2][acacH]}{[Mab][\beta\text{-dikH}]}. \quad (12)$$

Since acacH and β-dikH were used in more than twenty times molar excess than c_M, [acacH] and [β-dikH] may be approximated by the total concentrations c_{acacH} and $c_{\beta\text{-dikH}}$, respectively. A generalized least squares method was applied in order to minimize the error square sum $\Sigma(\bar{\varepsilon}_{obsd} - \bar{\varepsilon}_{calcd})^2$ for the set of constants K_1, K_2, and ε_{Mab}. The constants thus obtained for both the $MnCl(acac)_2$–bzacH and $MnCl(acac)_2$–dbmH systems are listed in Table 2. The solid curve in Fig. 6 representing absorbance calculated for the $MnCl(acac)_2$–dbmH system conforms satisfactorily with the experimental data, supporting presumed participation of the mixed-ligand complex. In fact MnCl(acac)(bzac) and MnCl(acac)(dbm) were prepared and isolated as described in the Experimental section.

Table 2. The equilibrium constants in dichloromethane at 25.0 °C for the substitution reactions of $MnCl(acac)_2$ with benzoylacetone and dibenzoylmethane according to Eqs. 8 and 9

β-Diketone	K_1	K_2	ε(At λ/nm)[a]
bzacH	1.09±0.01	0.43±0.02	1184±10 (434)
dbmH	0.85±0.01	0.40±0.02	1980±20 (450)

a) For the mixed ligand complex MnCl(acac)(β-dik).

Kinetics of the β-Diketone Substitution Reactions of MnCl(β-dik)₂. As is shown in Table 2, the equilibria for the β-diketone substitution reactions of $MnCl(acac)_2$ are rather favorable to the acetylacetonato complex. Thus reactions (13) were studied under the pseudo first order conditions employing excess amounts of acacH.

$$MnCl(\beta\text{-dik})_2 + 2\,acacH \longrightarrow MnCl(acac)_2 + 2\beta\text{-dikH} \quad (13)$$

The spectral change during reactions was recorded over the 405—495 nm region by means of a rapid scan instrument. As was anticipated from the spectra in Fig. 5, no isosbestic point was observed, but the absorbance of the reaction mixture decreased monotonously with time in either case. The progress of reaction was followed spectrophotometrically at an appropriate wavelength by the stopped-flow method.

Figure 7(a) exemplifies a plot of $\ln(A - A_\infty)$ against time for the reaction of $MnCl(dbm)_2$ with acacH in dichloromethane at 25.0 °C which was followed at 450 nm. The observed points in the later stage of reaction fall on a straight line, but those in the earlier stage deviate appreciably from it. This behavior may be rationalized on the assumption that the overall reaction is composed of two consecutive steps (14) and (15), since the existence of the metastable mixed ligand complex was revealed by the foregoing equilibrium studies.

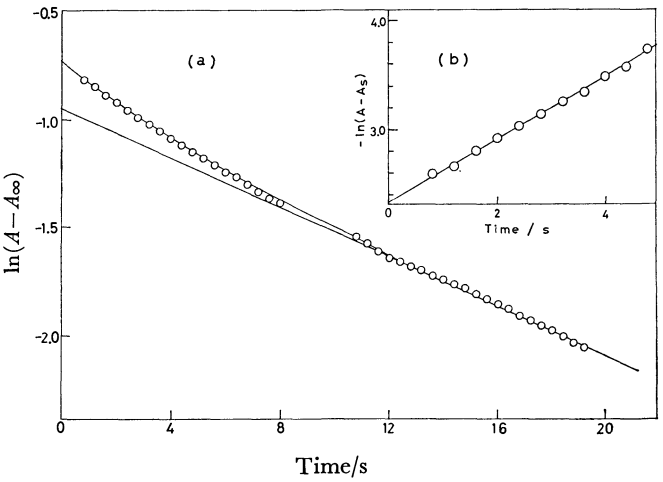

Fig. 7. (a) Pseudo first order plot for the reaction of $MnCl(dbm)_2$ with acetylacetone in dichloromethane at 25.0 °C, c_M, c_{dbmH}, c_{acacH} and c_{H_2O} being 2.47×10^{-4}, 2.47×10^{-3}, 9.74×10^{-2}, and 7.42×10^{-3} mol dm^{-3}, respectively. (b) Linear plot for the earlier part of the above reaction.

$$MnCl(\beta\text{-dik})_2 + acacH \longrightarrow MnCl(acac)(\beta\text{-dik}) + \beta\text{-dikH},\ k_1 \quad (14)$$

$$MnCl(acac)(\beta\text{-dik}) + acacH \longrightarrow MnCl(acac)_2 + \beta\text{-dikH},\ k_2 \quad (15)$$

Under the pseudo first order conditions, the absorbance of a reaction mixture at time t is related to k_1 and k_2 by

$$A - A_\infty = a_1 \exp(-k_1 t) + a_2 \exp(-k_2 t), \quad (16)$$

since A is expressed by Eq. 10 and $A_\infty = \varepsilon_{Ma_2} c_M$, a_1, and a_2 in Eq. 16 being given by

$$a_1 = \frac{(\varepsilon_{Mb_2} - \varepsilon_{Mab})k_1 + (\varepsilon_{Ma_2} - \varepsilon_{Mb_2})k_2}{k_1 - k_2} c_M \quad (17)$$

$$a_2 = \frac{(\varepsilon_{Mab} - \varepsilon_{Ma_2})k_1}{k_1 - k_2} c_M. \quad (18)$$

The later linear part of the $\ln(A - A_\infty)$ *vs.* t plot in Fig. 7(a) gives the slower one of the two rate constants, $k_S = 0.0573\ s^{-1}$, and the ordinate intercept, ln

$a_S=\ln(A_S-A_\infty)=\ln(9.85\times10^{-2})$. Then the values $A-A_S$ were calculated for the absorbance data in the earlier part of reaction and $\ln(A-A_S)$ was plotted against time to result in a straight line in Fig. 7(b). The slope and intercept of this straight line gave the faster rate constant $k_F=0.293\ s^{-1}$ and $\ln a_F=\ln(A_0-A_S)=\ln(3.83\times10^{-1})$. The solid curve in Fig. 7(a) reproduces the calculated values of $\ln(A-A_\infty)$ based on k_S, k_F, a_S, and a_F.

Equation 19 was derived from Eqs. 17 and 18 and utilized to assign k_S and k_F correctly to k_1 and k_2 in Eq. 16.

$$\frac{k_2}{k_1}=\frac{\varepsilon_{Mab}-\varepsilon_{Ma_2}}{\varepsilon_{Ma_2}-\varepsilon_{Mb_2}}\left(\frac{a_1}{a_2}-\frac{\varepsilon_{Mb_2}-\varepsilon_{Mab}}{\varepsilon_{Mab}-\varepsilon_{Ma_2}}\right) \quad (19)$$

If it is assumed that $k_S=k_1$ and $k_F=k_2$, the left-hand side of Eq. 19 becomes 5.1, whereas the right-hand side is -1.7. On the other hand, the reverse assignment that $k_S=k_2$ and $k_F=k_1$ results in fair coincidence between the two values: the left-hand side=0.20 and the right-hand side=0.29. Therefore the latter assignment is reasonable and the pseudo first order rate constants thus obtained will be referred to k_1(obsd) and k_2(obsd) in the following discussion.

The pseudo first order rate constants obtained in dichloromethane at 25.0 °C containing various concentrations of acetylacetone and water are listed in Table 3. When c_{acacH} is maintained constant, k_1(obsd) and k_2(obsd) do not show appreciable change beyond the experimental error even if c_{H_2O} is varried in the 5.87—16.83$\times10^{-3}$ mol dm^{-3} region for MnCl(bzac)$_2$ and in the 1.22—8.16$\times10^{-3}$ mol dm^{-3} region for MnCl(dbm)$_2$. On the other hand both k_1(obsd) and k_2(obsd) increase with c_{acacH} and the slopes of each two straight lines in Figs. 8(a) and (b) give the second order rate constants k_1 and k_2 for the reactions of MnCl(bzac)$_2$ and MnCl(dbm)$_2$ with acacH, respectively. By combining these values with the equilibrium constants listed in Table 2, the second order rate constants for the forward reactions of (8) and (9) were obtained. Table 4 summarizes these rate data.

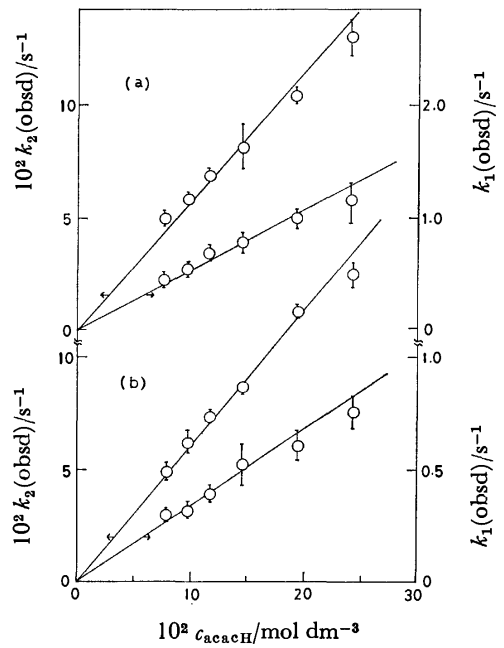

Fig. 8. Dependences on c_{acacH} of k_1(obsd) and k_2(obsd) for the reactions of MnCl(bzac)$_2$ (a) and MnCl(dbm)$_2$ (b) with acacH in dichloromethane at 25.0 °C.

The plots of k_1(obsd) and k_2(obsd) for the reaction of MnCl(dbm)$_2$ with acetylacetone-d_2 (Table 3) against c_{acacH} resulted in straight lines passing through the origin, of which slopes gave $k_1(D)=11.4\pm0.05\ s^{-1}$ and $k_2(D)=0.281\pm0.031\ s^{-1}$. Thus the apparent rate ratios are $k_1(H)/k_1(D)=2.96$ and $k_2(H)/k_2(D)=2.16$. Taking into account the fact that the isotopic purity of the acetylacetone-d_2 used is 90.2%, the kinetic isotope effect is calculated as $k_1(H)/k_1(D)=3.76$ and $k_2(H)/k_2(D)=2.47$. The calculation is based on the assumption that the isotope exchange between acetylacetone-d_2 and water is so slow under the given conditions that the deuterium content of the acetylacetone-d_2 is unaltered during the rate measurements.

Discussion

Addition Equilibria of Donor Molecules to $MnCl(\beta\text{-dik})_2$. As is seen in Figs. 1 and 4, the reaction of $MnCl(\beta\text{-dik})_2$ with a donor slovent in large excess is accompanied by an appreciable change in the absorption spectrum, which suggests some alteration in the coordination sphere. It seems reasonable to suppose that a donor molecule added to $MnCl(\beta\text{-dik})_2$ attains six coordination (Eq. 4). In fact adducts such as $MnCl(acac)_2$(pyridine *N*-oxide),[1] $MnBr(acac)_2$(4-Me-py),[1] $MnBr(acac)_2$(dioxane)$\cdot H_2O$,[1] and $MnNCS(acac)_2(py)$[8] have been prepared and characterized, supporting the existence of addition equilibria represented by Eq. 4 in solution.

The formation constant of adducts, K_{ad}, increases with the donor number of addendum (Table 1), and the $\log K_{ad}$ *vs.* DN plots afford straight lines (Fig. 3) which are reproduced by the following equations based on the least squares treatment, r giving the correlation coeffecient in each case.

$$MnCl(acac)_2: \log K_{ad} = 0.125DN - 2.24 \quad (r=0.994) \quad (20\text{-}1)$$

$$MnCl(bzac)_2: \log K_{ad} = 0.142DN - 2.54 \quad (r=0.981) \quad (20\text{-}2)$$

$$MnCl(dbm)_2: \log K_{ad} = 0.146DN - 2.63 \quad (r=0.984) \quad (20\text{-}3)$$

Such a linear relationship between the adduct formation constant and the donor number of addendum has seldom been noted for five-coordinate complexes. Gutmann found that adduct formation constants of antimony(V) chloride with various donor solvents increase with the donor number.[7] The linear relation is expressed by $\log K_{DSbCl_5}=0.580$ DN-5.44 ($r=0.984$). Carlin and Walker studied the adduct formation of $VO(acac)_2$ with a variety of N- and O-donors in nitrobenzene by the calorimetric and spectroscopic methods, and determined the equilibrium constants as well as thermodynamic functions.[9] Of their data, those for pyridine, piperidine, methanol, and hexamethylphosphoric triamide of which DN values are available satisfy the linear relation: $\log K_{ad}=0.101$ DN-1.94 ($r=0.979$). It is very interesting that both of the slope and intercept show a close resemblance to those in the present system (Eqs. 20) in spite of the difference in the nature of complex and the solvent used. Both of these slopes are much gentle compared with that for $DSbCl_5$, revealing that $VO(acac)_2$ and $MnCl(\beta\text{-dik})_2$ are less sensitive than $SbCl_5$ as the indicator of relative base strength.

Equations 20 were utilized to obtain the DN values of β-diketones based on the observed K_{ad} for $MnCl(\beta\text{-dik})_2(\beta\text{-dikH})$. The DN values were used in turn to calculate K_{ad} for the $MnCl(\beta\text{-dik})_2(\beta\text{-dik'H})$ adducts which can not be determined experimentally since the ligand substitution occurs. As is seen in Table 1, DN of β-diketone increases in the sequence of acacH< bzacH<dbmH and K_{ad} for a given $MnCl(\beta\text{-dik})_2$ also shows the same sequence. The infrared study on $Cu(\beta\text{-dik})_2$[10] and ^1H NMR study on β-diketones[11] show the ability of the aromatic substitutents to supply electron density to the chelate or enolic ring by resonance, and the pK_a values determined in aqueous dioxane (50% by volume) at 25 °C increase in the sequence of acacH(10.28) < bzacH(10.43) < dbmH (11.26).[12] The observed trend of K_{ad} also reflects the electron relasing effect of the phenyl substitutent in bzacH and dbmH. On the other hand, the K_{ad} values for the three $MnCl(\beta\text{-dik})_2$ complexes with a particular β-dikH show a slight decrease in the sequence of $MnCl(acac)_2>MnCl(bzac)_2>MnCl(dbm)_2$. Better β-diketonate ligands seem to suppress the acidity of $MnCl(\beta\text{-dik})_2$.

Water exists as a discrete molecule in benzene,[13] toluene,[14] and cyclohexane[14] solutions, but partially forms a dimer in chlorinated solvents such as chloroform,[13a] 1,2-dichloroethane, and 1,1,2,2-tetrachloroethane.[14] Although the behavior of water in dichloromethane has not yet been reported, the dimerization constants determined in chloroform (0.47) and 1,2-dichloroethane (0.54) at 25 °C[13a] may be used to estimate the degree of dimerization of water in dichloromethane. In the present investigation, the concentration of water has been kept around 10^{-3} mol dm^{-3} and was 5×10^{-2} mol dm^{-3} at most. Under these conditions, the estimated fraction of dimer is less than 2%, and most part of water molecules exist as monomer in dichloromethane. The DN value (18.0) of water was obtained by Gutmann in 1,2-dichloroethane and refers to the monomeric species. Substituting this value into Eqs. 20, we can estimate the adduct formation constants of water with the $MnCl(\beta\text{-dik})_2$ complexes to be 1.02, 1.04, and 0.995 for β-dik=acac, bzac, and dbm, respectively. These figures rationalize the failure of water in affecting the absorption spectrum of $MnCl(acac)_2$ in dichloromethane.

Substitution Equilibria. Most of the equilibrium constants K_1 and K_2 for the substitution reactions of $MnCl(acac)_2$ with benzoylacetone and dibenzoylmethane according to Eqs. 8 and 9 are smaller than 1. This fact might look to contradict the above-mentioned

basicity sequence of the β-diketonate anions: $acac^- < bzac^- > dbm^-$. However it should be noted that Equilibria 8 and 9 involve the β-diketone molecules instead of the β-diketonate anions. The equilibrium constant K_1' for the reaction

$$MnCl(acac)_2 + \beta\text{-dik}^- \rightleftharpoons MnCl(acac)(\beta\text{-dik}) + acac^- \quad (21)$$

will be certainly larger than 1 for $\beta\text{-dik}^- = bzac^-$ and dbm^-, but K_1 is related by K_1' by

$$\log K_1 = \log K_1' - (pK_a \text{ of } \beta\text{-dikH} - pK_a \text{ of acacH}). \quad (22)$$

Since the pK_a values of bzacH and dbmH are larger than that of acacH, $\log K_1$ becomes smaller than $\log K_1'$ by the pK_a difference between the β-diketones.

Mechanism of the Substitution Reactions. Based on the information obtained from the equilibrium and kinetic studies described above, the scheme depicted in Fig. 9 is proposed as a mechanism of substitution reaction of $MnCl(\beta\text{-dik})_2$ with another β-diketone such as acacH. The first step, coordination of an acacH molecule to manganese at the sixth vacant site is evidenced by the equilibrium measurements. Although dbmH exists solely as enol molecules, bzacH and acacH are composed of two tautomers, neat liquids containing 98 and 79% enol, respectively, at 38 °C.[15] The enol content is further increased in inert solvents, and that of acacH was reported to be 87% in chloroform and 96% in carbon tetrachloride at 33 °C.[16] In the present study, acacH and bzacH in dichloromethane at 23 °C were found to contain 83.4 and 97.9% enol, respectively.

The enol tautomer of acetylacetone reacts with the copper(II) ion much faster than the keto form in water and methanol.[17] In the case of thenoyltrifluoroacetone only the enol tautomer was reported to react with nickel(II), cobalt(II), copper(II), and iron(II) in aqueous solution.[18] Although the tautomerization rate is estimated as low as 10^{-5} s^{-1} in aprotic solvents by extrapolation from data in mixed aqueous media,[19] it is difficult to distinguish the contribution of both tautomers in the present case. However mainly the enol tautomer seems to contribute to the overall rate because of its predominant abundance

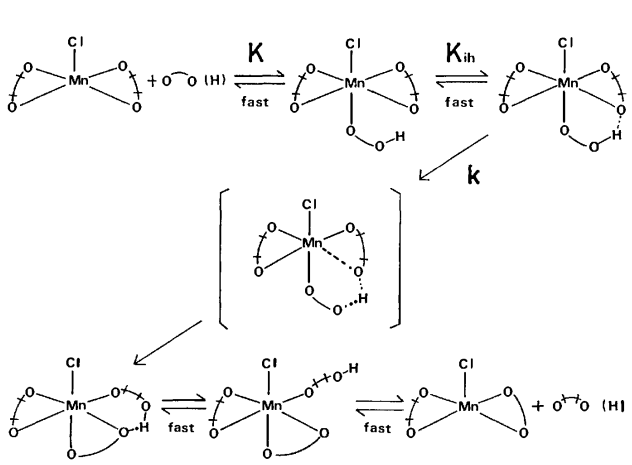

Fig. 9. Proposed mechanism for the ligand substitution reaction of $MnCl(\beta\text{-dik})_2$ with another β-diketone molecule.

and higher deprotonation rate[20] as compared with the keto tautomer. In recent years many kinds of metal complexes containing β-dicarbonyl compounds as a neutral ligand have been prepared.[21] Most of them contain the keto tautomer,[22] but $UO_2(acac)_2(acacH)$,[23] $MnBr_2(acacH)_2$,[24] $[ReCl(CO)_3(bzacH)]_2$,[25] and $PtCl(acac)(acacH)$[26] involve the enol tautomer.

As the second step of the reaction scheme, hydrogen-bonding interaction between the coordinated acacH and a neighboring β-diketonate ligand is presumed. Both ^1H NMR spectra[16] and cryoscopic measurements[27] of acacH in cyclohexane were consistent with intermolecular association. Hydrogen-bonding interaction between the coordinated β-diketonate ligand and various proton donors has also been evidenced by infrared[28] and electronic[29] absorption spectroscopy. X-Ray analysis of $VO(acac)_2(p\text{-}NO_2C_6H_4OH)$ revealed that a p-nitrophenol molecule is linked with one oxygen atom of an acac ligand *via* hydrogen bonding with the OH···O distance of 2.68 Å.[30] Thus the interligand hydrogen bonding presumed in the scheme seems reasonable.

Succeeding intramolecular dissociative interchange, that is, proton transfer from acacH to a leaving β-dik ligand, chelate-ring opening of the β-dik ligand, and chelation of the acac ligand in a synchronous fashion is presumed as the rate-determining step. The observed deuterium isotope effect may be caused by the hydrogen-bonding preequilibrium (K_{ih}) and proton transfer *via* this linkage (k). Thompson and Allred[27] compared the keto-enol equilibria in acetylacetone and acetylacetone-d_2 at various temperatures and concluded that protium forms a stronger hydrogen bond in this system than does deuterium, but the difference is not substantial at ambient temperature. Long and Watson[31] measured the rates of bromination of γ-methylacetylacetone and its γ-deuterio analogue in aqueous solution at 25 °C. The k_H/k_D ratios for the proton transfer from the keto molecule to water and acetate anion were 3.5 and 5.5, respectively, and those for the proton transfer from the enol molecule were also calculated to be 3.4 and 5, respectively. The observed values of k_H/k_D, 3.76 and 2.47 for k_1 and k_2, respectively, for the present system seem to accord with the proposed reaction scheme.

Recently Nishizawa and Saito studied the ligand exchange reaction between $VO(acac)_2$ and acacH-^{14}C in 1,2-dichloroethane.[32] They estimated the donor number of acacH to be 20 by a spectroscopic method, which is a little larger than the value (15.6) obtained in the present study. They also proposed a mechanism which involves the unidentate coordination of acacH to $VO(acac)_2$ ($K_{ad}=0.14$ dm^3 mol^{-1}) as the first step and its chelation associated with the proton transfer to a leaving acac ligand as the rate-determining step, since the observed k_H/k_D value of 1.3 is not so large as to rationalize the assumption of a proton-transfer step as an independent rate-determining step.[32]

Based on the proposed scheme in Fig. 9, the overall rate of reaction is given by Eq. 23.

$$\text{rate} = \frac{kKK_{ih}[acacH]}{1+(1+K_{ih})K[acacH]}[MnCl(\beta\text{-dik})_2] \quad (23)$$

Here $(1+K_{ih})K$ corresponds to K_{ad} of which values are given in Table 1, and $1 \gg (1+K_{ih})K[\text{acacH}]$ under most of the experimental conditions listed in Table 3. Then Eq. 23 is reduced to

$$k_{obsd} = kKK_{ih}[\text{acacH}]. \quad (24)$$

Thus the second order rate constants in Table 4 are composite in reality. The value of K will be large for an entering ligand whose DN is large, while K_{ih} and k will be larger for a more acidic entering ligand. Table 4 indicates that the rate of reaction of $MnCl(acac)_2$ with bzacH is larger than that with dbmH, although K_{ad} for bzacH is smaller than that for dbmH (Table 1). More acidic bzacH seems to have large K_{ih} and k overcompensating for disadvantage in K as compared with dbmH.

On the other hand, the rate of reaction of acacH with $MnCl(bzac)_2$ is a little faster than that with $MnCl(dbm)_2$ at 25.0 °C (Table 4). Since the K_{ad} values are estimated to be comparable for the two systems (Table 1) and K_{ih} seems favorable to more basic dbm ligand, lower rate for $MnCl(dbm)_2$ may stem from the k factor, cleavage of the Mn–O(dbm) bond being a little more difficult as compared with the Mn–O(bzac) bond.

We wish to thank Mr. Junichi Gohda for the elemental analysis and also the Ministry of Education, Science and Culture, for the Grant-in-Aid for Scientific Research (Grant No. 243014).

Preparation and Oxidation of Europium(II) Niobium Bronze Eu_xNbO_{3-y}

Kenji Ishikawa, Gin-ya Adachi,* Midori Tanida, and Jiro Shiokawa
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565
(Received May 2, 1980)

Mixed oxides containing bivalent europium, Eu_xNbO_{3-y} ($0.5<x<1.0$), were synthesized by the solid state reaction of Eu_2O_3, Nb_2O_5, and Nb powder. The structural change of Eu_xNbO_{3-y} from a tetragonal to cubic form takes place at $x=0.65$. The mechanism of oxidation for the bronzes was studied. Each bronze shows different behavior in oxidation, the cubic bronze giving an amorphous phase and the tetragonal bronze complex crystalline products. $EuNbO_4$ was crystallized from both the amorphous and crystalline phases at 950 K and 1070 K, respectively. TG-DTA and magnetic studies indicated that the oxidized phases play an important role in the rate-determining step of oxidation for the bronzes.

Europium (II) niobium bronzes are nonstoichiometric compounds. Fayolle *et al.*[1] reported the preparation of the bronzes. They found a cubic form for a high Eu^{2+} content region and a tetragonal form for a low Eu^{2+} content region. Oxidation of the bronzes has attracted our attention because each phase undergoes changes in different ways. Krylov *et al.*[2] reported on the oxidation of the bronze whose composition is $EuNbO_3$ and concluded that $EuNbO_4$ is an oxidized product of $EuNbO_3$. So far stoichiometry of oxygen of the bronzes has not been considered seriously. However, oxygen content is a very influential factor for understanding the physical and chemical properties of the bronzes, since the valence state of niobium is controlled by the amount of oxygen. We have determined the oxygen content thermogravimetrically, and found that the bronze is described by a general formula, Eu_xNbO_{3-y}. Discussion is given on the oxidation process of the bronze.

Experimental

Reagents. Europium sesquioxide (Shin-etsu Chemical Corp., minimum purity 99.99%), diniobium pentaoxide and niobium metal (Wako Chemical Industries, Ltd., purity 99.99%, and 99.9%, respectively). Europium sesquioxide and diniobium pentaoxide were calcinated at 1000 K for half an hour in the air before being weighed.

Preparative. Mixtures of Eu_2O_3, Nb_2O_5, and Nb with various compositions were ground together in an agate mortar, pressed into pellets and heated in a vacuum (10^{-2} Pa) at 1173 K for 2 h. After cooling, the pellets were ground-ed and pressed into pellets again. They were packed into a Mo box, sealed in a vacuum (10^{-3} Pa) in a silica capsule and heated at 1473 K for 48 h. The reaction was assumed to occur according to the reaction

$$5xEu_2O_3 + a(6x-2)Nb + (5+a-3ax)Nb_2O_5 \longrightarrow 10Eu_xNbO_{3-y}. \quad (1)$$

Niobium metal was taken a times the amount needed to prepared Eu_xNbO_3 in order to compensate slight oxidation loss of the bronzes during the course of synthesis. Reaction conditions and analytical values of the bronzes are summarized in Table 1.

Analytical Method. The atomic ratios (Eu:Nb) in the compounds obtained were determined with a Rigaku Denki energy dispersion type X-ray fluorescent spectrograph unit, "Ultra trace system," having a tungsten target X-ray tube, a stannum second target, and a Si(Li) semiconductor detector. The oxygen content was determined by oxidation of the bronzes in the air. Assuming that the reaction is

$$Eu_xNbO_{3-y} + zO_2 \longrightarrow \frac{x}{2}Eu_2O_3 + \frac{1}{2}Nb_2O_5, \quad (2)$$

y can be determined by means of Eu content (x) and the increase in mass due to oxidation (z). The phase purity and structure type of materials were characterized by X-ray powder data, using a Rigaku Denki "Rotor-flex" diffractometer (Table 2).

Magnetic Measurements. The magnetic susceptibility data of the resulting materials were obtained with a Shimadzu "MB-11" magnetic balance (Table 2).

Thermal Measurements. Differential thermal analysis (DTA) and thermogravimetric analysis (TGA) were carried out in the air at a heating rate of 10 K/min in the tempera-

ture range 300—1173 K. All thermal measurements were performed on a Rigaku Denki DTA "Thermoflex." Powder samples (30—60 mg) were used, alumina powder (99.9%) being employed as a reference. The heat of oxidation for the bronzes was measured with a differential scanning calorimeter (DSC). Measurements were carried out in the air at a heating rate of 10 K/min in the temperature range 300—1173 K. The heat of oxidation was determined from the area beneath a DSC peak. The heat of oxidation of NbO_2 to Nb_2O_5 was used as a standard.[8]

Results and Discussion

X-Ray Data. X-Ray analysis revealed that the samples having europium concentration $x=0.5$—0.65 are of tetragonal symmetry, and those with $x=0.65$—1.0 cubic symmetry (Table 2). A small amount of Eu_3NbO_6 confirmed by the X-ray technique was assigned to a second phase for the slightly oxidized bronzes of high europium concentration ($x>0.9$). Oxidation tendency of the bronzes seemed to increase with x, 1.2 times excess of reducing agent being required for the preparation of single phase bronzes. The niobate Eu_3NbO_6 seems to be formed by the solid state reaction in the bronze of high x. A plot

$$Eu_xNbO_{3-y} \longrightarrow a Eu_3NbO_6 + (1-a)Eu_{\frac{x-3a}{1-a}}NbO_{\frac{3-y-6a}{1-a}} \quad (3)$$

of the lattice constant *vs.* the europium concentration of the cubic phase for $x=0.65$ to 1.0 is given in Fig. 1. Ridgley and Ward[9] reported that the lattice constant for an analogous bronze, Sr_xNbO_3, of cubic symmetry is proportional to x. However, our observation (Fig. 1) does not agree with theirs. The result of X-ray analysis supports the assumption that the solid state reaction (Eq. 3) takes place at high x.

Magnetic Susceptibilities. The magnetic susceptibilities χ_m of the bronzes obey the Curie-Weiss law in the range 77—300 K. The observed and calculated values of effective magnetic moments for the bronzes are summarized in Table 2. The observed moments are close to the calculated values, small lowering of the observed magnetic moments exceeding experimental errors being observed. Europium ions in the starting material are considered to be substantially reduced to the Eu (II) state. However, the reduction power of niobium is not strong enough to reduce all of Eu^{3+} to Eu^{2+},[4] a small amount of Eu^{3+} remaining with Eu^{2+}. The lowering observed in our products would also be interpreted in terms of the reduction power of niobium.

curves for the tetragonal and the cubic phases are shown in Fig. 2. An abrupt weight gain is observed in the TGA curve for the tetragonal sample at 550—700 K, and a moderate weight gain at 550—900 K for the cubic one. We see that the oxidation proceeds in two steps for both the tetragonal and cubic phases. Magnetic susceptibility measurements were carried out for the same sample in the air in the temperature range 300—1173 K, at a heating rate of 10 K/min (Fig. 3). The magnetic moments of Eu^{2+}, Eu^{3+}, Nb^{4+}, and Nb^{5+} are 7.94, 3.4, 1.73, and 0 μ_B, respectively. The decrease in the magnetic moment is much larger in the oxidation of Eu^{2+} to Eu^{3+} than in the oxidation of Nb^{4+} to Nb^{5+}. From a comparison of the TG-DTA curves (Fig. 2) with the χ_m^{-1} *vs.* T curves (Fig. 3), we see that the initial stage of the oxidation would be due to the oxidation of Eu^{2+}, the second to the oxidation of Nb^{4+}. Figure 3 also shows that the initiating temperature of the oxidation of Eu^{2+} is 550 K for both the tetragonal and cubic phases, the rate of oxidation of Eu^{2+} being larger for the tetragonal phase than for the cubic phase.

The stability of the bronze against oxidation mainly depends on that of Eu^{2+}. The temperature at which oxidation of Eu^{2+} starts is the same for both the tetragonal and cubic phases. The stability of Eu^{2+} to oxidation seems to be of the same order for both bronzes. The rate of oxidation of Eu^{2+} is considered to determine the rate of oxidation of the bronzes. The thermal analyses (TGA and DTA) were carried out for EuO under the same conditions as those for the bronzes. EuO oxidized at 520—580 K, showing that the rate of oxidation of Eu^{2+} in EuO is much greater than that in the bronzes. The oxidation of Eu^{2+} proceeds from the surface to the bulk of the bronze grain. The rate of oxidation of Eu^{2+} in the bulk should be determined by the probability of Eu^{2+} encounter with oxygen. Thus the rate of diffusion of oxygen in the oxidized product layer should control the rate of oxidation of Eu^{2+}.

X-Ray analysis was carried out for the bronzes oxidized at various temperatures. Oxidation of the cubic bronze gave an amorphous phase crystallizing

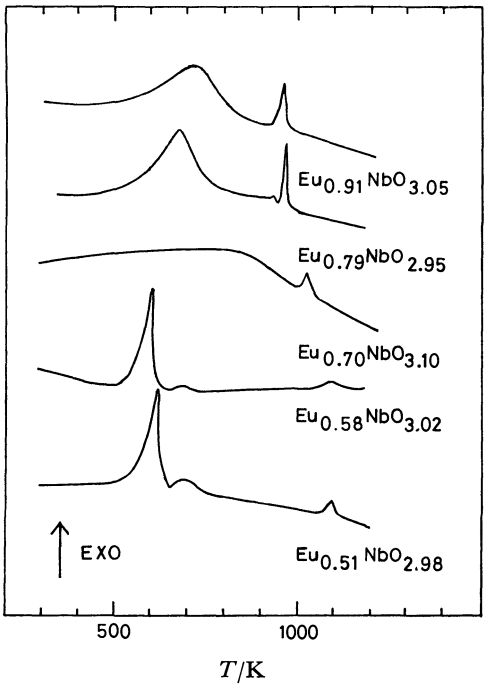

Fig. 4. DTA curves for Eu_xNbO_{3-y}.

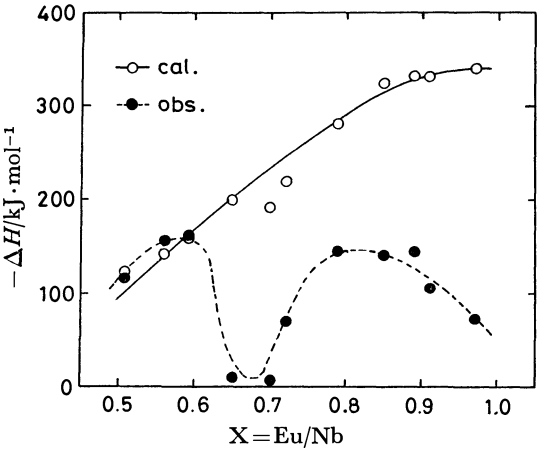

Fig. 5. Heat of oxidation for Eu_xNbO_{3-y}.

at 950 K. On the other hand, the tetragonal phase underwent oxidation giving complex crystalline products which recrystallized at 1070 K. The difference in the rate of oxidation between the tetragonal and cubic phases can be attributed to the difference in the rate of diffusion of oxygen in the layer of the oxidized product. The diffusion coefficient of oxygen for the product obtained by the oxidation of the tetragonal phase should be much larger than that for the amorphous phase resulting from the cubic phase.

On heating the bronzes in the air, $EuNbO_4$ appeared at 1070 K for the tetragonal bronze and at 950 K for the cubic bronze. Exothermic peaks, 950 and 1070 K, due to crystallization are seen in the DTA curves with no weight change (Figs. 2 and 4), suggesting that the amorphous phases are less stable than the crystalline phases. The difference in the stability of the intermediate states affects the heats of oxidation for the bronzes. Figure 5 shows the

observed and calculated heats of oxidation for the bronzes of various Eu^{2+} contents. Both the observed and calculated values show a minimum at $x=0.65$. For the evaluation of the heat of oxidation, the bronze is assumed to be a mixture of EuO, NbO_2, and Nb_2O_5,

$$Eu_xNbO_{3-y} = xEuO + [2(x+1)-1]NbO_2 + (1-x-y)Nb_2O_5. \quad (4)$$

The oxidation reaction is assumed to proceed as follows:

$$Eu_xNbO_{3-y} + \left(\frac{3}{4}x+\frac{y}{2}-\frac{1}{4}\right)O_2 \longrightarrow \frac{x}{2}Eu_2O_3 + \frac{1}{2}Nb_2O_5. \quad (5)$$

The minimum of the heat of oxidation at $x=0.65$ corresponds to the phase transition.

The heats of oxidation for the tetragonal phases are almost equal to the calculated values. The result indicates that the heat of formation for the crystalline phase is close to that for the mixture of Eu_2O_3, and Nb_2O_5 represented by Eq. 4. The heat of transformation from an unknown crystalline phase to the final products, mainly $EuNbO_4$, as well as $EuNb_3O_9$ and $EuNb_5O_{14}$, might be very small. Thermal analysis (TGA-DTA) supports the assumption.

The heat of oxidation for the cubic phases is much lower than that for the calculated ones, a maximum being obtained at $x=0.85$. The result indicates that the heat of formation for the amorphous phase obtained from oxidation of the cubic bronzes is considerably larger than that for the mixture of Eu_2O_3 and Nb_2O_5 shown by Eq. 4. A second cubic phase, Eu_3NbO_6, appears at $x>0.9$. The heat of formation for the existing cubic bronzes, $Eu_xNbO_{3-y}+Eu_3NbO_6$, seems to be smaller as compared with that for single-phased Eu_xNbO_{3-y}, the apparent heat of oxidation decreasing for $x>0.9$. The minimum of the heat of oxidation at $x=0.65$ is due to the difference in stability of these two intermediate phases.

Transition-metal Complexes of Pyrrole Pigments. XVII. Preparation and Spectroscopic Properties of Corrole Complexes†

Yukito Murakami,* Yoshihisa Matsuda, Kazunori Sakata,†† Sunao Yamada, Yasuhiro Tanaka, and Yasuhiro Aoyama

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 9, 1980)

Nickel(II), copper(II), and cobalt(III) complexes were prepared with corroles; 2,3,7,8,12,13,17,18-octaethylcorrole (OEC), 2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrole (MEC), and 8,12-bis[2-(ethoxycarbonyl)ethyl]-2,3,7,13,17,18-hexamethylcorrole (PMC). For the coordination with nickel and copper ions, the corroles acted as dianionic ligands to yield electrically neutral complexes. These complexes exhibited metalloporphyrin-like electronic spectra, while they showed spectra which bear a much closer resemblance to those for metalloporphyrins as the anionic complexes were formed upon addition of alkali. The corroles coordinate to tervalent cobalt as trianionic ligands to form neutral complexes, which were reduced to the corresponding cobalt(II) complexes with sodium hydroborate. These reduced species gave a unique set of g-values ($g_1 \gg g_2 > g_3$) for the complexes of macrocyclic ligands with conjugated double bond system. The plausible coordination geometry as well as the structural properties of the corrole ligands has been discussed.

Corrole (**1**) and tetradehydrocorrin (**2**) are unique macrocyclic tetrapyrroles, having a highly conjugated π-electron system like porphyrin and phthalocyanine. However, the direct linkage between A and D pyrrole rings involved in the former two macrocycles acts to provide a deformation effect on the macrocyclic skeleton so that those rings can not take complete planar structure. A significant structural difference between corrole and tetradehydrocorrin is in orbital hybridization of carbon atoms at 1- and 19-positions. The particular atoms concerned are considered to possess sp^2 hybrid orbitals for corrole while sp^3 for tetradehydrocorrin. Thus, it is interesting to shed light on the unique electronic structure of corrole and the possible consequences of ring deformation in its coordination with transition-metal ions. The synthesis of corrole and its cobalt(III), nickel(II), and copper(II) complexes was reported first by Johnson *et al.*[1,2] However, they did not investigate the electronic structure of these complexes in any detail by spectroscopic means.

Three corroles having different peripheral substituents were employed in the present study; *i.e.*, 2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrole (MEC), 2,3,7,-8,12,13,17,18-octaethylcorrole (OEC), and 8,12-bis[2-(ethoxycarbonyl) ethyl]-2,3,7,13,17,18-hexamethylcorrole (PMC). The corresponding linear tetrapyrroles, biladiene-ac dihydrobromides, underwent cyclization to afford the corroles under irradiation with visible light. The metal complexes were prepared directly from biladiene-ac's by template reaction as functioned by metal ions. Stereochemistry and electronic structures have been discussed for both ligands and complexes.

Experimental

Electronic absorption spectra were recorded on a Hitachi EPS-2 spectrophotometer at room temperature; chloroform was used as solvent unless otherwise stated. ESR spectra were obtained with a JEOL JES-ME-3 X-band spectrometer equipped with 100-kHz field modulation unit; a standard MgO/Mn(II) sample calibrated with a NMR magnetometer was employed for calibration of the magnetic field. NMR spectra were taken on a Varian A-60 spectrometer for chloroform-*d* solutions; tetramethylsilane being used as an internal reference.

1,19-Dideoxy-2,3,17,18-tetramethyl-7,8,12,13-tetraethylbiladiene-ac dihydrobromide and 1,19-dideoxy-2,3,7,8,12,13,17,18-octaethylbiladiene-ac dihydrobromide were obtained as described previously.[3]

1,19-Dideoxy-8,12-bis[2-(ethoxycarbonyl)ethyl]-2,3,7,13,17,18-hexamethylbiladiene-ac Dihydrobromide. Aqueous ammonia (28%) was added dropwise to a suspension of 3,3′-bis[2-(ethoxycarbonyl)ethyl]-4,4′-dimethyl-5,5′-dicarboxydipyrromethane[4] (5.0 g) and 2-formyl-3,4-dimethylpyrrole[5] (2.65 g) in methanol (200 ml) until a clear solution was obtained. Aqueous hydrobromic acid (47%, 25 ml) was added to the mixture in one portion at 120 °C. After being refluxed for 1 min, the dark red solution was allowed to stand in a freezer for 1 h. The product was recovered, washed with water, methanol, and ether, and then recrystallized from chloroform to give red crystals with green luster; yield 6.9 g (86%), mp>300 °C. UV_{max} ($CHCl_3$): 370, 427, 455, and 518 nm. IR (KBr): 1608 (biladiene skeletal str.) and 1722 cm^{-1} (C=O str.). NMR (CF_3CO_2H): δ 1.38 (6H, t, J=7.0 Hz, $-CH_2CH_2CO_2CH_2C\underline{H}_3$), 2.18, 2.43, and 2.46 (18H, s, $-CH_3$ on pyrrole ring), 2.23—3.27 (8H, m, $-C\underline{H}_2C\underline{H}_2CO_2C_2H_5$), 4.35 (4H, q, J=7.0 Hz, $-CH_2CH_2-CO_2C\underline{H}_2CH_3$), 4.75 (2H, s, $-CH_2-$ at 10-position), 7.66 (2H, s, -CH=), 8.01 (2H, d, J=4.0 Hz, 1- and 19-H), 11.39 (2H, br s, NH), and 11.55 (2H, br s, N^+H).

2,3,17,18-Tetramethyl-7,8,12,13-tetraethylcorrole (MEC). A mixture of 1,19-dideoxy-2,3,17,18-tetramethyl-7,8,12,13-tetraethylbiladiene-ac dihydrobromide (200 mg) and methanol (100 ml) was heated to obtain a homogeneous solution, to which 28% aqueous ammonia (4 ml) was added subsequently. The refluxing green solution was irradiated with a 200-W tungsten lamp for 1 h, and then allowed to stand in a freezer for 2 h. Dark fine crystals were recovered and recrystallized from chloroform–methanol to give purple needles; yield 90 mg (61%). IR (Nujol mull): 3350 cm^{-1} (N–H str.).

Found: C, 79.41; H, 8.15; N, 11.98%. Calcd for $C_{31}H_{38}N_4$: C, 79.77; H, 8.22; N, 12.01%.

The following two corroles were prepared by similar photocyclization of the corresponding biladiene-ac dihydrobromides.

† Contribution No. 579 from this Department.

†† Present address: Kyushu Institute of Technology, Tobata-ku, Kitakyushu 804.

2,3,7,8,12,13,17,18-Octaethylcorrole (OEC): purple needles, yield 19%. IR (Nujol mull): 3345 cm^{-1} (N–H str.). Found: C, 79.38; H, 8.68; N, 11.03%. Calcd for $C_{35}H_{46}N_4$: C, 80.40; H, 8.89; N, 10.72%.

8,12-Bis[2-(ethoxycarbonyl)ethyl]-2,3,7,13,17,18-hexamethylcorrole (PMC): purple needles, yield 51%. IR (KBr): 3360 cm^{-1} (N–H str.). Found: C, 71.90; H, 7.29; N, 9.65%. Calcd for $C_{35}H_{42}N_4O_4$: C, 72.14; H, 7.27; N, 9.61%.

Pyridine(2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrolato)cobalt(III) [*Co(MEC)Py*] *and (2,3,7,8,12,13,17,18-octaethylcorrolato)cobalt(III)* [*Co(OEC)*] were prepared as described previously.[3]

Pyridine{8,12-bis[2-(ethoxycarbonyl)ethyl]-2,3,7,13,17,18-hexamethylcorrolato}cobalt(III) [*Co(PMC)Py*] was prepared by essentially the same procedure as employed for the preparation of Co(MEC)Py and obtained as purple prisms; yield 43%. IR (Nujol mull): 1603 (pyridine skeletal str.) and 1728 cm^{-1} (C=O str.). Found: C, 67.71; H, 6.08; N, 10.68%. Calcd for $C_{40}H_{44}N_5O_4Co$: C, 66.94; H, 6.18; N, 9.76%.

(2,3,17,18-Tetramethyl-7,8,12,13-tetraethylcorrolato)cobalt(III) [*Co(MEC)*]. A solution of pyridine(2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrolato)cobalt(III) (100 mg) in chloroform (4 ml) was refluxed for 3 min. Hot methanol (12 ml) was added to the solution, which was subsequently allowed to stand in a freezer for 2 h. Dark precipitates were recovered and washed with methanol to give glittering black prisms; yield 80 mg (92%).

Found: C, 71.43; H, 6.59; N, 11.37%. Calcd for $C_{31}H_{35}N_4Co$: C, 71.24; H, 6.76; N, 10.72%.

(2,3,17,18-Tetramethyl-7,8,12,13-tetraethylcorrolato)nickel(II) [*Ni(MEC)*]. A mixture of 1,19-dideoxy-2,3,17,18-tetramethyl-7,8,12,13-tetraethylbiladiene-ac dihydrobromide (300 mg), nickel(II) acetate tetrahydrate (300 mg), methanol (50 ml), and 28% aqueous ammonia (6 ml) was irradiated with a 200-W tungsten lamp for 20 min. The green solution turned to red and finally to dark brown. The reaction mixture was then allowed to stand at 0 °C overnight, and precipitates were recrystallized from chloroform–methanol (2:1 v/v) to give glittering dark green prisms; yield 100 mg (40%), mp>250 °C.

Found: C, 70.83; H, 6.66; N, 10.66%. Calcd for $C_{31}H_{36}N_4Ni$: C, 71.13; H, 6.95; N, 10.71%.

{8,12-Bis[2-(ethoxycarbonyl)ethyl]-2,3,7,13,17,18-hexamethylcorrolato}nickel(II) [*Ni(PMC)*] was prepared in a manner similar to that employed for the preparation of Ni(MEC): yield 57%, *m/e* 638 (M^+).

(2,3,17,18-Tetramethyl-7,8,12,13-tetraethylcorrolato)copper(II) [*Cu(MEC)*]. A mixture of 1,19-dideoxy-2,3,17,18-tetramethyl-7,8,12,13-tetraethylbiladiene-ac dihydrobromide (315 mg) and copper(II) acetate monohydrate (300 mg) in methanol (150 ml) was stirred at room temperature for 10 min. Precipitates were washed with methanol and recrystallized from chloroform–methanol (2:1 v/v) to give reddish brown needles; yield 50 mg (19%), mp>250 °C.

Found: C, 70.41; H, 6.60; N, 10.55%. Calcd for $C_{31}H_{36}N_4Cu$: C, 70.48; H, 6.88; N, 10.61%.

{8,12-Bis[2-(ethoxycarbonyl)ethyl]-2,3,7,13,17,18-hexamethylcorrolato}copper(II) [*Cu(PMC)*] was prepared by essentially the same procedure as employed for the preparation of Cu(MEC): yield 47%, *m/e* 643 (M^+).

Results and Discussion

Electronic Spectra. Characteristic transition energies and the corresponding molar absorption coefficients (ε) are summarized in Table 1 for the three corrole ligands. The strong absorption bands in the region of 24000—26000 cm^{-1} are presumably due to transitions similar to those observed for porphyrins as B-band. The nature of transitions for the bands in the region of 15000—19000 cm^{-1} is presumably similar to that for Q-bands of porphyrins. The electronic transitions, which result in B- and Q-bands, have not been characterized because multiple transitions with similar energies were observed in these regions due to lower symmetry of the corrole skeleton relative to the porphyrin framework.

The nickel(II) and copper(II) complexes of MEC and PMC were obtained as electrically neutral molecules without additional ligand or counter ion. This fact indicates that the corroles coordinate to nickel(II) and copper(II) as dianionic ligands. The complexes exhibited metalloporphyrin-like spectra, but a number of absorption bands is larger for the corrole complexes than for the corresponding metalloporphyrins. Both nickel(II) and copper(II) complexes of corrole showed much sharper absorption bands upon addition of sodium hydroxide to their DMSO solutions. The characteristic absorption bands are summarized in Table 2 along with molar absorption coefficients for the neutral complexes. The absorption bands for each complex are obviously classified into the following groups: group A, weak bands with transition energy less than 10000 cm^{-1}; group B, bands with intermediate intensity in the region of 10000—20000 cm^{-1}; and group C, very intense bands with high transition energy (greater than 20000 cm^{-1}).

TABLE 1. ELECTRONIC ABSORPTION BANDS FOR CORROLES IN CHLOROFORM AT ROOM TEMPERATURE

Corrole	MEC	OEC	PMC
Absorption maxima/cm^{-1} (ε)	14700^{sh} (1000)	14700^{sh} (1220)

a) Measured in chloroform. b) Measured in *N,N*-dimethylformamide in the presence of NaOH.

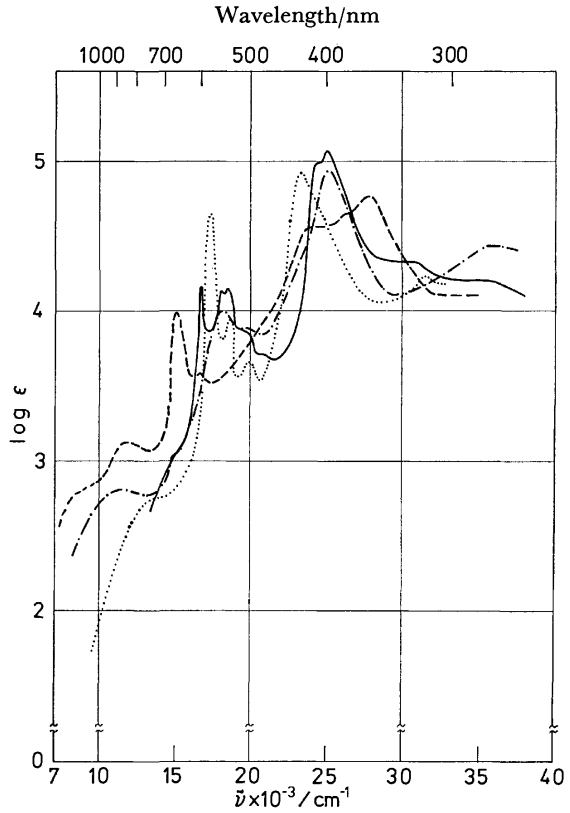

Fig. 1. Electronic absorption spectra of MEC and its metal complexes at room temperature.
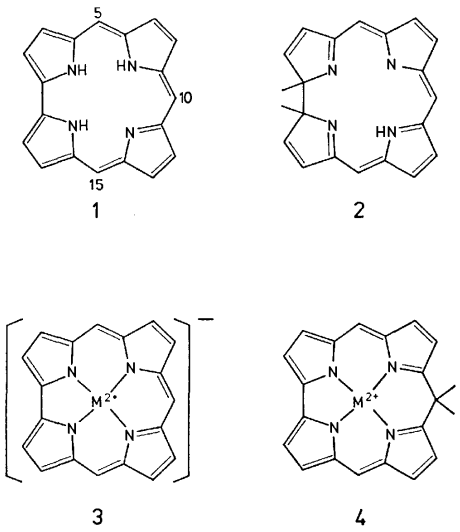
——: Metal-free MEC in $CHCl_3$, ----: Ni^{II}(MEC) in $CHCl_3$, —·—: Cu^{II}(MEC) in $CHCl_3$, ·····: Co^{III}(MEC) in pyridine.

The local structure about the central metal may be assumed to be square planar with slight distortion. For such cases, the d-d transitions of nickel(II) and copper(II) are generally expected to appear in the region of 10000—20000 cm^{-1}. The absorption bands classified as group A are, therefore, not attributed to d-d transitions, but rather to charge-transfer transitions. The absorption bands of group B have molar absorption coefficients larger than 1000; they are too large to be assigned to d-d transitions. These bands may be attributed to π-π^* transitions which have similar character as those for the Q-bands of metalloporphyrins. The absorption bands of group C are attributed to transitions from π- to higher π^*-orbitals, corresponding to B-bands of metalloporphyrins. The neutral nickel(II) complex exhibited at least three absorption bands in the B-band region while the corresponding copper(II) complex showed only one band. However, this high energy band for the copper complex is very broad so that it must consist of two or more unresolved absorptions. The corresponding absorption band for the anionic complexes, [Ni(MEC)]$^-$ and [Cu(MEC)]$^-$, is remarkably sharp in a manner as observed for metalloporphyrins.



Above observation indicates a large difference in π-conjugation between anionic and neutral complexes. Nine double bonds of the corrole macrocycle (**1**) seem to be conjugated throughout the whole molecule for the anionic complex[6] (**3**) while the protonated structure (the neutral complex) interferes with such a conjugation effect. Structures of the neutral complexes are not established at present, but most plausibly shown by **4**.

Cobalt complexes with the corrole ligands were isolated only in the tervalent cobalt state as Co(corrole) and Co(corrole)Py. We reported previously the following equilibria in solution.[3]

$$n\text{Co(corrole)} \rightleftharpoons [\text{Co(corrole)}]_n \quad (1)$$

$$\text{Co(corrole)} \overset{\text{Py}}{\rightleftharpoons}$$

$$\text{Co(corrole)Py} \overset{\text{Py}}{\rightleftharpoons} \text{Co(corrole)(Py)}_2 \qquad (2)$$

Thus, an absorption spectra for the bis(pyridine) adduct can be obtained directly in the presence of excess pyridine. Electronic spectral data for the cobalt(III) complexes in pyridine are summarized in Table 3. For both complexes, absorption bands in the region of 12000—15000 cm^{-1} are attributed to charge-transfer transitions while higher energy bands are attributed to Q- and B-type transitions.

NMR Spectra. Proton NMR chemical shifts for the selected absorptions of Co(MEC)Py and Co(PMC)Py are listed in Table 4 along with the corresponding data for dicyano(8,12-diethyl-1,2,3,7,13,17,-18,19-octamethyltetradehydrocorrinato)cobalt(III) and dicyano(8,12-diethyl-1,2,3,7,13,17,18,19-octamethyl-AD-bisdehydrocorrinato)cobalt(III) [abbreviated as Co(TDHC)$(CN)_2$ and Co(BDHC)$(CN)_2$, respectively]. The meso-protons at 5-, 10-, and 15-positions and methyl-protons at 2-, 3-, 17-, and 18-positions provide an useful information: these signals shift to lower field in going from Co(BDHC)$(CN)_2$ to Co(TDHC)-$(CN)_2$, Co(MEC)Py, and Co(PMC)Py; those protons involved in the corrole complexes resonate at the lowest field. The result indicates that the significant ring current effect is exercised undoubtedly by the corrole ring on the peripheral protons. The axial pyridine ligand in the corrole complexes is placed in a shielding zone of the ring current, and the pyridine protons resonate at a considerable higher field (δ 5.06—6.30) relative to those in $Co(NH_3)_5Py$ (δ 7.75—8.33 in D_2O).[8]

Table 5 summarizes chemical shifts for metal-free OEC and 2,3,7,8,12,13,17,18-octaethylporphyrin (OEP). OEC exhibits a deshielding effect on the imino-protons and a shielding effect on the meso-protons, but such effects are more pronounced for OEP. This is most plausibly caused by the deviation of the corrole skeleton from ideal planar configuration, which results in reduction of the extent of π-conjugation compared with porphyrins.

Except for the case of OEC, the metal-free corroles showed only broad NMR signals, presumably caused by paramagnetic contamination. This was confirmed by the presence of a sharp ESR signal at $g=2.0$. The paramagnetic species responsible for the observation is presumably radical species of corrole itself generated during photo-cyclization of biladiene-ac's. It is not clear at present whether the formation of such species is influenced by the nature of substituents or simply a matter of slight difference in experimental conditions. The paramagnetic species disappeared upon addition of thiophenol.

ESR Spectra. Copper(II) complexes of the corroles exhibited ESR spectra typical of the planar coordination structure. The X-band ESR spectrum for neutral Cu(MEC) at 77 K is shown in Fig. 2.

Table 3. Electronic absorption bands for cobalt(III) complexes in pyridine at room temperature

Ligand	MEC	OEC
	13300[sh] (530)	12500[sh] (377)
		15200 (1000)
Absorption	17300 (43800)	17200 (56500)
maxima/cm^{-1} (ε)	18500 (8660)	18500 (10800)
	19900 (4520)	19800 (6080)
	23400 (79200)	23500 (11300)

Table 4. Proton NMR chemical shifts for the cobalt(III) complexes of corroles and dehydrocorrins at room temperature[a]

Complex	Medium	δ CH_3 (2, 3, 17, 18)	δ =CH- (5, 15)	=CH- (10)
Co(MEC)Py	CS_2	3.47, 4.30	8.43	8.08
Co(PMC)Py	CS_2	3.31, 3.48, 3.92[b]	9.20	8.99
Co(TDHC)$(CN)_2$[c]	$CDCl_3$	2.36, 2.48	6.99	6.95
Co(BDHC)$(CN)_2$[d]	$CDCl_3$	2.11, 2.29	5.97	5.91

a) Chemical shifts needed for discussion are given. b) One of the three values must be attributed to methyl protons at 7- and 13-positions. c) As for preparation, see: D. Dolphin, R. L. N. Harris, J. L. Huppatz, A. W. Johnson, I. T. Kay, *J. Chem. Soc., C*, **1966**, 30. d) Cited from Ref. 7.

Table 5. Proton NMR chemical shifts for OEC and OEP measured in chloroform-*d* at room temperature

Compound	δ NH	=CH-	CH_3	CH_2
OEC	−2.47	9.39, 9.22[a]	1.75	3.82
OEP	−3.78	10.00	1.89	4.11

a) For 5- and 15-positions, 9.39; for 10-position, 9.22.

a) Cited from Ref. 9. b) Cited from Ref. 10. c) Measured at 293 K. d) Measured at 77 K.

Spin Hamiltonian parameters for MEC and PMC complexes are summarized in Table 6 along with those for the copper complexes of 5,10,15,20-tetraphenylporphine (TPP) and phthalocyanine (PC). As mentioned earlier, the complexes would possess planar structure with slight rhombic distortion. Rhombic parameters (g_1, g_2, and g_3), however, were not obtained because of the complexity of the spectra in the perpendicular component range. The parameters were evaluated, in any event, for pseudo-tetragonal coordination having C_{4v} local symmetry around the copper atom. Both $g_{\parallel}$ and $g_{\perp}$ for the corrole complexes are significantly smaller than those for the TPP and PC complexes. This observation reflects the deformation of the corrole complexes from planar structure. As mentioned above, the extent of π-conjugation in the neutral complex is much lower than that for metalloporphyrins. In addition, the direct linkage of A and D pyrrole rings stands in favor of such deformation.

A remarkable medium effect on hyperfine splitting constants was observed: the complexes gave larger A-values in frozen solution (benzene–xylene, 4:6 v/v) relative to those for the samples diluted with the corresponding metal-free corroles, while g-values were not affected significantly by the nature of media. The complexes also gave larger A^N-values in frozen solutions compared with those in the solid matrices. These facts suggest that both extent of mixing of 4s orbital with $3d_{x^2-y^2}$ and covalent character of the coordinate bonds are more pronounced in solution state rather than in the matrix of metal-free ligand. Lack of d-d transition energies makes it difficult to evaluate the effect of host structure quantitatively. The neutral copper(II) complexes presumably have a molecular geometry different from those of the corresponding anionic complexes and metal-free ligands. Thus, the neutral complexes are subjected to deformation in the matrices of metal-free corroles which tends to raise the molecular symmetry, while their coordination geometry is less affected in organic solvents. Such deformation is responsible for reduction of the covalency of coordinate bonds and of the mixing of s-orbital with $d_{x^2-y^2}$. Meanwhile, the anionic copper(II) complexes, which have more extensive π-conjugation system relative to the neutral ones, may be stabilized upon protonation to yield the latter complexes because the internal strain provided by the direct A-D linkage is relaxed through such a process (refer to **4**).

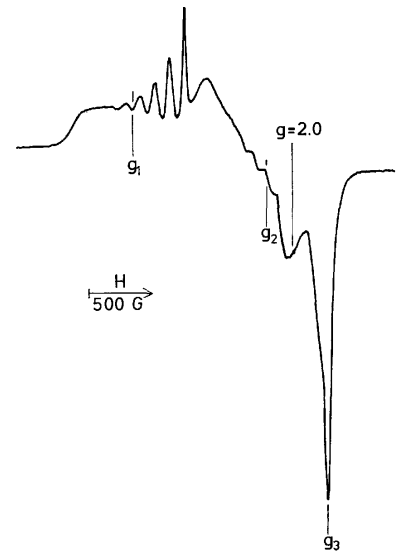

Fig. 3. ESR spectrum of $[Co^{II}(MEC)]^-$ in DMF at 77 K.

The cobalt(II) complexes, generated by reduction of the corresponding cobalt(III) complexes with $NaBH_4$ in *N*,*N*-dimethylformamide(DMF), showed intense ESR signals at 77 K as shown in Fig. 3. The samples did not give such ESR signals at room temperature due to short spin-lattice relaxation time of the low spin d^7 configuration. An ESR spectrum for the pyridine adduct of a reduced cobalt complex was observed upon addition of pyridine to the DMF solution (Fig. 4); except for the appearance of an additional superhyperfine splitting due to the nitrogen nucleus of pyridine, the spectra of both adduct and pyridine-free complex are essentially identical. The spin Hamiltonian parameters for $S=1/2$ and $I=7/2$ were obtained as summarized in Table 7. The spectral feature suggests that the cobalt(II) complexes assume a rhombic symmetry at the coordination site. Since the spectral features of both Figs. 3 and 4 bear a close resemblance to each other as stated above, the spatial arrangement of cobalt and four pyrrole-nitrogen atoms remains practically unchanged regardless of pyridine coordination. Since the superhyperfine splitting shown in Fig. 4 consists of three lines, the coordination of pyridine takes place only at the fifth coordination site; suggesting strongly a pyramidal structure for the original corrole complex with the cobalt atom placed at the top so that pyridine can approach to the metal from only one side of the molecular plane. The

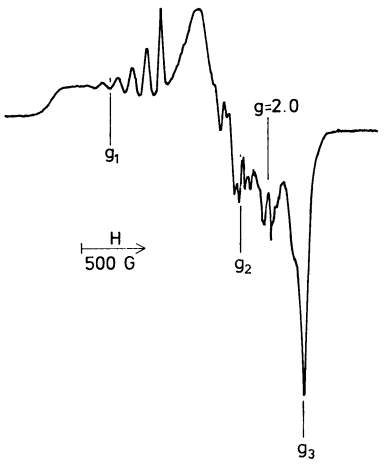

Fig. 4. ESR spectrum of $[Co^{II}(MEC)]^-$ in DMF at 77 K; pyridine was added.

four nitrogen atoms involved in the corrole complexes can not occupy vertices of square even if they are placed on the same plane, because the A and D pyrrole rings are linked directly. The coordination site around the cobalt atom assumes, therefore, C_s local symmetry, distorted from C_{4v}.

The cobalt(II)–corrole complexes provide g-values of $g_1 \gg g_2 > g_3$ as seen in Table 7. Cobalt(II) complexes other than the corrole complexes, given in Table 7, require g-values of $g_1 = g_2 \gg g_3$; local symmetry of C_{4v}. The coordination geometry around the cobalt atom for C_{4v} local symmetry is shown in Fig. 5. Four nitrogen atoms are placed in xy-plane on lines bisecting angles between x and y axes. Therefore, a d-orbital with the largest contribution to σ coordinate bonds is d_{xy} which occupies the highest energy level among d-orbitals. The hole formalism represents the ground

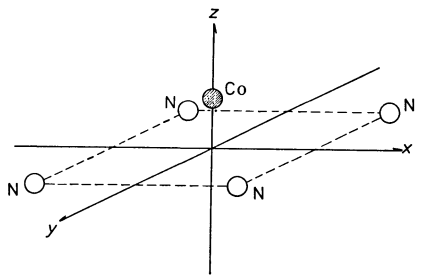

Fig. 5. Coordination geometry around the cobalt atom for C_{4v} local symmetry; four nitrogen atoms are placed in xy-plane while the cobalt atom is displaced upward from xy-plane along z-axis.

state for d^7 configuration by one of the following four configurations: $(d^2_{xy}, d_{x^2-y^2})$, (d^2_{xy}, d_{z^2}), (d^2_{xy}, d_{xz}), and (d^2_{xy}, d_{yz}); the last two configurations are degenerate in C_{4v} while referred to different energy states in C_s. g-Values are represented as shown in Table 8 for the above hole configurations. A relation, $g_{xx} \simeq g_{yy} > g_{zz} = 2$, is obtained for the ground state configuration of (d^2_{xy}, d_{z^2}). Co(II)(TPP) in TPP matrix and Co(II)(PC) diluted with Zn(II)(PC) are included in this category (refer to Table 7). The ground-state configuration can not be established for the corrole complexes on the basis of g-values alone. Nevertheless, either (d^2_{xy}, d_{xz}) or (d^2_{xy}, d_{yz}) is referred to the ground state judging from their coordination geometry. For either of the configurations, the relative magnitude of g-values depends on the energies of excited configurations. Since (d^2_{xy}, d_{xz}) and (d^2_{xy}, d_{yz}) are transformed into each other by interchange of x and y axes, we discuss the situation for the former as the ground state.

Suppose the following correlations are satisfied.

$$E(d_{xy}, d^2_{xz}) \gg E(d^2_{xy}, d_{yz}) \quad (3)$$

TABLE 7. SPIN HAMILTONIAN PARAMETERS FOR THE COBALT(II) COMPLEXES OF MACROCYCLIC LIGANDS AT 77 K

TABLE 8. REPRESENTATION OF g-VALUES FOR THE GROUND STATE CONFIGURATIONS BASED ON HOLE FORMALISM[a]

Hole configuration for the ground state	Δg_{xx}	Δg_{yy}	Δg_{zz}
$(d^2_{xy}, d_{x^2-y^2})$	$-2\lambda/\Delta E(d^2_{xy}, d_{yz})$	$-2\lambda/\Delta E(d^2_{xy}, d_{xz})$	$8\lambda/\Delta E(d^2_{xy}, d_{x^2-y^2})$
(d^2_{xy}, d_{z^2})	$-6\lambda/\Delta E(d^2_{xy}, d_{yz})$	$-6\lambda/\Delta E(d^2_{xy}, d_{xz})$	0
(d^2_{xy}, d_{xz})	$2\lambda/\Delta E(d_{xy}, d^2_{xz})$	$-2\lambda/\Delta E(d^2_{xy}, d_{x^2-y^2})$ $-6\lambda/\Delta E(d^2_{xy}, d_{z^2})$	$-2\lambda/\Delta E(d^2_{xy}, d_{yz})$

a) ΔE denotes an energy difference between ground state and excited state configurations, the latter being given in parentheses after ΔE; $\Delta g_{ii} = g_{ii} - g_0$.

$$E(d_{xy}^2, d_{x^2-y^2}) > E(d_{xy}^2, d_{yz}) \quad (4)$$

$$E(d_{xy}^2, d_{z^2}) \gg E(d_{xy}^2, d_{yz}) \quad (5)$$

g-Values are interrelated by Eq. 6.

$$g_{zz} \gg g_{yy} > g_{xx} \quad (6)$$

On the other hand, a relationship among g-values is provided by Eq. 8 for an energy correlation given by Eq. 7.

$$E(d_{xy}^2, d_{yz}) \simeq E(d_{xy}^2, d_{z^2}) \quad (7)$$

$$g_{yy} \gg g_{zz} > g_{xx} \quad (8)$$

If (d_{xy}^2, d_{xz}) is referred to the ground state, either of the above conditions [(3), (4), and (5); or (7)] must be satisfied in order to observe the g-value correlation for the present corrole complexes: $g_1 \gg g_2 > g_3$ (refer to Table 7); other ground-state configurations listed in Table 8 are not consistent with this relation.

The cobalt atom is displaced most plausibly from the plane of the four pyrrole-nitrogen atoms to yield a pyramidal geometry as stated earlier. Under such circumstances, d_{xz} and d_{yz} orbitals contribute extensively to the formation of σ-antibonding orbitals. Although strong out-of-plane $p\pi$-$d\pi$ interactions between cobalt and pyrrole-nitrogen atoms may be in favor of the present experimental sequence of g-values, such interactions are expected for all the complexes cited in Table 7. Thus, the π-bonding effect does not explain the difference in interrelation of g-values among these complexes.

Conclusion

Corrole involves a significant internal strain in its macrocyclic skeleton due to the direct linkage between A and D pyrrole rings. This strain may cause deviation of the skeleton from complete planar configuration and consequently results in reduction of the extent of π-conjugation compared to porphyrin. Such an internal strain effect seems to be relaxed to some extent through formation of the bivalent metal complexes, in which corrole acts as a dianionic ligand. The π-conjugation throughout the whole complex molecule is interfered with by the presence of a methylene group at 10-position. Such bivalent metal complexes of neutral charge were transformed into anionic complexes upon losing a proton of 10-position with base.

Corrole is coordinated to the tervalent cobalt as a trianionic ligand. The cobalt(II) complex, generated by reduction of the corresponding cobalt(III) complex with $NaBH_4$, must assume C_s local symmetry at the coordination site; the cobalt atom is placed at the top of a pyramidal structure. Either (d_{xy}^2, d_{xz}) or (d_{xy}^2, d_{yz}) is referred to the ground state configuration (hole) with extensive contribution of d_{xz} and d_{yz} to the formation of σ-antibonding orbitals. The interrelation of experimental g-values ($g_1 \gg g_2 > g_3$) is consistent with such circumstances along with requirement given by (3), (4), and (5); or (7).

aratory funnel was used. Each complex was dried *in vacuo* at 100 °C. When the complex was dried *in vacuo* at room temperature, a mixture of MoO(tpp)F and MoO(tpp)F·HF or a mixture of MoO(tpp)Cl and MoO(tpp)Cl·HCl was obtained. The synthesis of the complex, MoO(tpp)Cl, by different method was reported by Ledon *et al.*[6] The visible absorption spectra of the complex, MoO(tpp)Cl, was almost the same as that of Ledon's complex.

The complexes, $MoO(tpp)N_3$ and MoO(tpp)NCO, were prepared in the same manner as described for the synthesis of the halo complexes. The aqueous solution of free acids, HN_3 or HOCN, was freshly prepared by passing the aqueous solution of NaN_3 or KOCN through a column of a cation-exchange resin, Dowex 50W-X8, in the hydrogen-form. Purity of the complexes was confirmed by the elemental analyses (see Table 1).

Trials for the Syntheses of Other TPP Complexes. The synthesis of the iodo complex, MoO(tpp)I, was tried in the same manner as described in the preparation of other halo complexes; the bromo complex, MoO(tpp)Br, was used as a starting material. The IR spectra of the brown crystals thus obtained showed no evidence for the Mo=O bond. The feature of the visible absorption spectrum was different from that of the spectra of other halo complexes.

The synthesis of the perchlorato complex, $MoO(tpp)ClO_4$, was also tried. The visible absorption spectra in dichloromethane of the obtained compound show three peaks in the region of the α and the β bands, suggesting the formation of a complex of a different formula or a mixture containing some other complexes.

ESR Spectra. The ESR spectra of the complexes, MoO(tpp)X, always consisted of six weak lines due to $^{95,97}Mo$ nuclei ($I=5/2$) (abundance *ca.* 25%). The hyperfine structure revealed d^1 Mo(V) state of the central molybdenum atom in all the complexes synthesized. The g-values were found to be 1.967 ± 0.005 for all complexes. A strong central line due to the molybdenum nucleus with $I=0$ was split into nine lines. This superhyperfine structure was assigned to the interaction of the Mo nucleus ($I=0$) with four nitrogen nuclei ($I=1$) of the ligand, TPP. The ESR parameters for several complexes were already reported.[7]

IR Spectra. An intense IR absorption band ascribed to the Mo=O stretching was observed around 935—938 cm^{-1} for each complex, suggesting that synthesized complexes are all oxomolybdenum(V) complexes. The values of ν(Mo=O) are not different among F, Cl, and Br complexes (see Table 2). The BF_4, N_3, and NCO complexes have the absorption peak for the Mo=O stretching in the region of 940 cm^{-1}. The doublet IR bands ascribed to the CN stretching for the complex, MoO(tpp)NCO, were observed at 2060 and 2080 cm^{-1}. The band corresponding to the CN stretching for the complex, MoO(tpp)NCS, was observed at 2075 cm^{-1}. These results suggest that the ligands, NCO^- and NCS^-, in the complexes are coordinated to the central molybdenum atom with N atoms.

Visible Absorption Spectra. The values of λ_{max} and ε_{max} for the electronic spectra of the complexes, MoO(tpp)Br and MoO(tpp)Cl·HCl, were previously reported by the present authors.[7] However, in the detailed characterization of the synthesized complexes, we noticed that the visible absorption spectra of these complexes, especially of MoO(tpp)Br, are very sensitive to impurities in the organic solvents applied.[8] Therefore, the absorption spectra of these complexes were remeasured and corrected. The values of λ_{max} and ε_{max} of the absorption spectra for the complexes in pure dichloromethane are listed in Table 3, suggesting that the complexes, MoO(tpp)X, belong to d-type hyperporphyrin.[1] A typical absorption spectrum is given in Fig. 1. The most intense absorption peak in the visible region, the B or the Soret band, was observed around 460—500 nm, and the other intense bands, the Q or the β and the α bands between

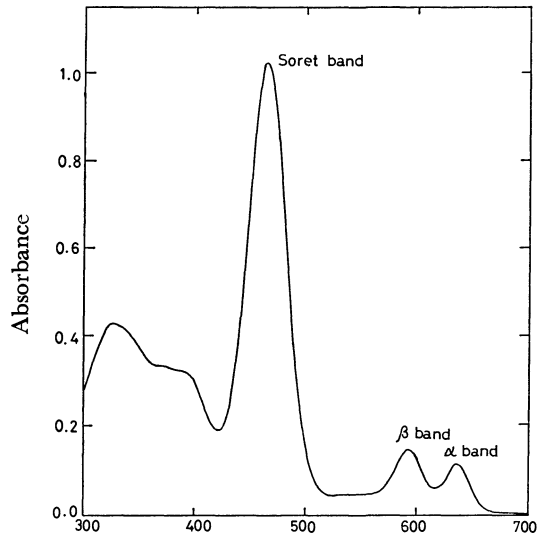

Fig. 1. Absorption spectrum of the complex, MoO(tpp)F, in CH_2Cl_2 at 25 °C. [MoO(tpp)F] = 1.08×10^{-5} mol dm^{-3}.

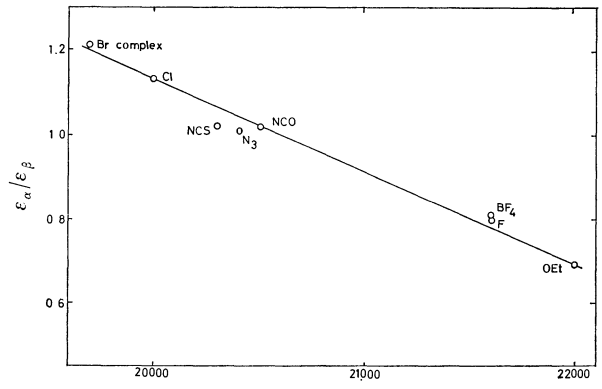

Fig. 2. The correlation between the ratios $\varepsilon_\alpha/\varepsilon_\beta$ and the wavenumbers of the Soret bands in the visible absorption spectra of the complexes, MoO(tpp)X.

550 and 700 nm, respectively. The Soret band would be assigned to charge-transfer (CT) transitions,[1,9] $a_{1u}(\pi)$, $a_{2u}(\pi) \rightarrow e_g(d,\pi)$, and/or the CT transition mixed with a $\pi \rightarrow \pi^*$ transition as assigned for the manganese(III) etioporphyrin complex.[10] The visible absorption spectra of the complexes, MoO(tpp)X, strongly depend on the anionic ligand X^-. Change in the axial ligand X, caused a red shift of the absorption peaks in the visible region relative to those of MoO(tpp)OC_2H_5; the red shift of the Soret band was accompained with the red shift of the α and the β bands. The Soret band and the β band, and the β and the α bands were separated from each other by *ca.* 125 and 40 nm, respectively. The values of the red shift are increased in the order: $X = OC_2H_5 < F \simeq BF_4 < NCO < N_3 < NCS < Cl < Br$.

The red shifts of the visible absorption peaks are also accompanied with the change in the values of ε_{max} of these three peaks; the values of ε_{Soret}, ε_α, and ε_β decreased with increase in the red shift. A linear relationship was observed between the ratio $\varepsilon_\alpha/\varepsilon_\beta$ and the wave number of the Soret band (Fig. 2). This strong correlation between the ratio $\varepsilon_\alpha/\varepsilon_\beta$ and the wavenumber of the Soret band suggests the contribution of the configurational interaction between the transitions for the Soret band and those for the α and the β bands of the complexes, MoO(tpp)X, as suggested for the metalloporphyrins by Gouterman based on his four-orbital model.[11]

Similar red shifts were reported for the complexes, Sn^{IV}(etio)X_2 (etio=etioporphyrin),[12] Mn^{III}(etio)X·H_2O,[13,14] and Zn^{II}(tpp)X^-.[2] The order of the red shifts is F<Cl<Br<I for the Soret bands of these complex series and also F<Cl for the complexes, MoO(oep)X.[1] The intensity ratio $\varepsilon_\alpha/\varepsilon_\beta$ also increased in the same order for Zn(tpp)X^- and in the reversed order for Sn(etio)X_2. Similar reversed relationship between the ratio $\varepsilon_\alpha/\varepsilon_\beta$ and the red shift was previously observed for a series of metalloporphyrins;[1,11] $\varepsilon_\alpha/\varepsilon_\beta$ decreases with increasing red shift of the Soret band for etioporphyrin, octaethylporphyrin, mesoporphyrin IX, and porphyrin IV complexes, but increases for TPP complexes.[2]

The orders of the red shift and of the ratio $\varepsilon_\alpha/\varepsilon_\beta$ for the complexes, MoO(tpp)X, are the same as those for the complexes Zn(tpp)X^- (see Table 4). It is interesting to note that no difference is observed in the spectral behavior between the closed-shell d^{10} zinc(II) porphyrin complexes and the open-shell d^1

Table 4. The orders of the red shift and of the ratio $\varepsilon_\alpha/\varepsilon_\beta$ in the visible absorption spectra of the halo complexes

Complex	Red shift	$\varepsilon_\alpha/\varepsilon_\beta$
Zn(tpp)X^{-}[a]	F < Cl < Br	F < Cl < Br
Sn(etio)X_2[b]	F < Cl < Br	F > Cl > Br
MoO(tpp)X	F < Cl < Br	F < Cl < Br

a) Ref. 2. b) Ref. 12.

oxomolybdenum(V) porphyrin complexes. The order of the red shift for closed-shell metalloporphyrin depends largely on the electronegativity of the central metal atom[12] and on that of the axial ligand X.[2,12] In the series of the halo complexes, MoO(tpp)X (X= F, Cl, and Br), the IR band ascribed to the Mo=O stretching was observed at almost the same frequency 935—938 cm^{-1} and the *g*-values for the complexes were all observed at 1.967±0.005. These data suggest the slight differences in the electronic state of the central molybdenum(V) atom (d^1) in the given complexes. Thus, decreasing electronegativity of the axial halo ligands, X=F, Cl, and Br, should primarily causes the increased electron density in the porphyrin ring *via* the central molybdenum(V) atom, resulting in the red shift and the increase in the ratio $\varepsilon_\alpha/\varepsilon_\beta$. For the NCS, NCO, and N_3 complexes, the correlation of the red shift and the electronegativity of the ligands could not be directly discussed, since the data on the electronegativity of the coordinated ligands, NCS, NCO, and N_3, are not estimated. However, from the order of the red shift, we deduce the order of the magnitude for ligand X to donate electrons to the porphyrin ring through the central moiety O=Mo–X as follows:

$$O{=}Mo{-}OC_2H_5 < O{=}Mo{-}BF_4 \simeq O{=}Mo{-}F < O{=}Mo{-}NCO < O{=}Mo{-}N_3 < O{=}Mo{-}NCS < O{=}Mo{-}Cl < O{=}Mo{-}Br.$$

As in Table 3, the absorption spectra in UV and visible regions of the dichloromethane solutions of the complexes, MoO(tpp)NCS, MoO(tpp)NCO, and MoO(tpp)N_3, give almost the same values of λ_{max} and ε_{max}. This fact indicates that the thiocyanate are the cyanate anions coordinate to the central molybdenum(V) atom *via* N atom as suggested by the data of IR spectra of these complexes. Similar phenomenon was also observed for the complexes, MoO(tpp)BF_4 and MoO(tpp)F; the values of λ_{max} and ε_{max} of the absorption spectra of these complexes are alomst the same (Table 3). These results indicate that in the small ligand it is the donor atom in the ligand coordinated to the central atom that is predominantly responsible for the absorption spectra of the complex, MoO(tpp)X; the values of λ_{max} and ε_{max} in the UV and the visible absorption spectra are primarily determined by the donor atom in the axial ligand X.

Correlation of the Value of ε_{Soret} with the Integrated Intensity of the Sored Band. In connection with the correlation of the red shifts of λ_{max} in the visible absorption spectra of the complex, MoO(tpp)X, with the values of ε_{Soret}, ε_α, and ε_β it was observed that the degree of the broadening of the Soret band is also in the same order as that of the red shift and that the values of ε_{Soret} and the integrated intensity of the Soret band decrease with the red shifts. These facts should be explained in terms of the decrease in the magnitude of transitions in the Soret band with increase in the order of the red shift, though the Soret band becomes broader and less intense with increasing red shift. Relative integrated intensities of the Soret bands of the complexes, MoO(tpp)X, are decreased in the order: F(285)≳BF_4(280)>NCS≃N_3≃NCO(200)>Cl(185)>Br(170).

UV Absorption Spectra. For all complexes, MoO(tpp)X, in dichloromethane a distinct intense absorption band was observed around 330 nm (see Table 3). The order of the red shift of this band with respect to the axial ligand X was found to be the same as that of the red shift of the Soret band, except for the absorption peak of the complex MoO(tpp)N_3. The UV and the Soret bands for the complexes are separated from each other *ca.* 150 nm. The value of ε_{max} of the band, ε_{UV}, increases with the red shifts of the UV band as well as the Soret band, which is in the reversed order of ε_{Soret}; the values of ε_{UV} of the complex are increased in the following order: X=OC_2H_5($\varepsilon_{UV}\times10^{-4}$=3.42)<F(3.70)<$BF_4$(4.01)<$N_3$(4.17)<NCO(4.76)<NCS(5.42)<Cl(6.12)<Br(6.40). Thus the ratio $\varepsilon_{Soret}/\varepsilon_{UV}$ decreases in the order: X=OC_2H_5($\varepsilon_{Soret}/\varepsilon_{UV}$=4.62)>F(2.62)>$BF_4$(2.41)>$N_3$(1.04)>NCO(0.98)>NCS(0.84)>Cl(0.68)>Br(0.54). This tendency is very similar to that of the intensity ratio of the bands V and VI reported for the complexes, Mn^{III}(etio)X·H_2O, in chloroform,[13,14] and for the complexes, MoO(oep)X (X=OCH_3, F, and Cl).[1] The values of ε_{UV} for the complexes, MoO(tpp)Br, MoO(tpp)Cl, and MoO(tpp)NCS, are larger than those of ε_{Soret} for these complexes. Similar relation is observed for $\varepsilon_\alpha/\varepsilon_\beta$ (Fig. 2). These results suggest that the electronic transitions responsible for the three bands, the band around 330 nm, the B band, and the Q band, for the complexes, MoO(tpp)X, are also conjugated with each other, though the assignments of these bands for the given complexes are not yet established.

Comparison of the Visible Absorption Spectra with the IR Spectra. Based on the Raman spectral studies for the complex, $Mo^{V}O$(mec) (mec=2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrole), it was reported that the strong absorption band observed at 455 nm is largely due to a ligand-metal charge-transfer transition;[15] the intensity of the absorption peak observed at 950 cm^{-1} (Mo=O stretching) in the Raman spectra of MoO(mec) was enhanced to a larger extent than that expected for the core vibrations when the exciting frequency approaches the frequency of the strong band at 455 nm. The Mo=O stretching frequency is also suggested to be a sensitive probe for the surrounding.[3] Therefore it was expected that the peak ascribed to the Mo=O stretching of the complex, MoO(tpp)X, was correlated with the λ_{max} and ε_{max} of the absorption spectra in dichloromethane. However no clear correlation was observed for the complexes, MoO(tpp)-X. The trans effect of an axial ligand X on the frequency of the Mo=O stretching of the complexes,

MoO(tpp)X, must be small except for the complex, $MoO(tpp)OC_2H_5$. The Mo=O stretching for the complex, $MoO(tpp)OC_2H_5$, was observed at the low frequency, 904 cm^{-1}, as shown in Table 2. The M=O stretching was also observed at low frequency for other complexes, $MoO(oep)OCH_3$ (896 cm^{-1}) and $WO(oep)OCH_3$ (901 cm^{-1}).[3] These phenomena could be attributed to the strong π-donor trans effect of alkoxo ligand.[3]

Note added in proof: When alcohol is absent in the reaction system, the complex, $Mo^{V}O(tpp)NCS$, is reduced by O_2^- to form the complex, $Mo^{IV}O(tpp)$.

Studies on Window Sweep Chronopotentiometry. I. Fundamental Concept, Methodology, and Analytical Application

Yoshikiyo KATO,* Akifumi YAMADA, Norimasa YOSHIDA,†
Kei UNOURA, and Nobuyuki TANAKA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received June 12, 1980)

Window sweep chronopotentiometry, a new galvanostatic method, has been worked out, the electronic circuit of a window sweep chronopotentiograph and digital simulation of the window sweep chronopotentiogram being presented. Analytical application demonstrating the increase in sensitivity of the galvanostatic method for quantitative analysis is presented.

In the galvanostatic method graphical technique has been utilized for the measurement of transition time and the determination of potential-time relationship in an effort to overcome or compensate the double-layer charging.[1-5] The method requires graphical extrapolation which is time-consuming, complicated and inaccurate. The analytical sensitivity of galvanostatic method was limited to 10—100 μM.[6-8]

Derivative chronopotentiometry, reported for transition time measurement,[9-19] is a sensitive electrochemical method, but the frequency response of the derivative circuit has had to be sacrificed for the sake of noise reduction.

Kato *et al.* studied the application of a differential (or subtraction) method to galvanostatic measurement, and developed a sensitive and noise-free method,[20] as application of the differential method. The method, window sweep chronopotentiometry (w. s. chronopotentiometry), is a kind of pseudo-derivative chronopotentiometry.

In this report, the theoretical background, methodology, instrumentation and computer simulation of the method are presented, its analytical application also being reported.

Theoretical

A simplified potential-differential time relationship of reversible and irreversible electrode processes is considered for the cathodic process when only the oxidant is present in the solution.

Reversible Process. Consider the simple first order electrode reaction,

$$\mathrm{Ox} + ne \rightleftharpoons \mathrm{Red}, \tag{1}$$

where Ox and Red indicate the oxidized and the reduced forms, respectively, both being soluble in solution and in electrode. The potential-time relation at constant current can be given[21] by

$$t = \tau[\exp\left\{\frac{nF}{RT}(E-E_{1/2})\right\}+1]^{-2}, \tag{2}$$

with[22]

$$\tau^{1/2} = \frac{nF\pi^{1/2}D_0^{1/2}c_0^\circ}{2j}, \tag{3}$$

where E is electrode potential, $E_{1/2}$ polarographic half-wave potential, τ transition time, t time, D_0 diffusion coefficient, c_0° concentration in the bulk of the solution, and j controlled current density, the other symbols having their usual meanings.

The differential time Δt corresponding to the voltage window ΔE is given by

$$\Delta t = \tau([\exp\left\{\frac{nF}{RT}(E-E_{1/2}-\Delta E)\right\}+1]^{-2} - [\exp\left\{\frac{nF}{RT}(E-E_{1/2})\right\}+1]^{-2}). \tag{4}$$

The peak potential E_p of differential-time potential curve, w. s. chronopotentiogram is obtained by differentiation of Eq. 4 with E.

$$E_p = E_{1/2} - \frac{RT}{nF}\gamma \tag{5a}$$

$$\gamma = \ln[\exp\left\{\frac{nF}{3RT}(-\Delta E)\right\}[\exp\left\{\frac{nF}{3RT}(-\Delta E)\right\}+1]]. \tag{5b}$$

Irreversible Process. The potential-time relation for irreversible electrode reaction is given by[23]

$$j = nFk_c c_0^\circ - \left\{\frac{2}{\sqrt{\pi}}\left(\frac{k_c}{\sqrt{D_0}}+\frac{k_a}{\sqrt{D_R}}\right)\right\}j\sqrt{t} \tag{6}$$

$$k_c = k_s \exp\left\{\frac{-\alpha nF}{RT}(E-E_o)\right\} \tag{7}$$

$$k_a = k_s \exp\left\{\frac{(1-\alpha)nF}{RT}(E-E_o)\right\}. \tag{8}$$

Equation 6 can be written as

$$t = \frac{\pi}{4}\left\{(nFk_c c_0^\circ - j)\Big/\left(\frac{k_c}{\sqrt{D_0}}+\frac{k_a}{\sqrt{D_R}}j\right)\right\}^2. \tag{9}$$

From Eqs. 3 and 9 we get

$$\Delta t = \left\{\frac{\tau^{1/2}-\sqrt{\pi D_0}/2k_c}{1+\sqrt{D_0}k_a/\sqrt{D_R}k_c}\right\}^2 - \left\{\frac{\tau^{1/2}-\sqrt{\pi D_0}/2k_c\exp\left(\frac{nF}{RT}\Delta E\right)}{1+\sqrt{D_0}k_a/\sqrt{D_R}k_c\exp\left(\frac{nF}{RT}\Delta E\right)}\right\}^2. \tag{10}$$

Totally Irreversible Process. The potential-time-current relationship at constant current for a simple first-order totally irreversible electrode reaction 1 can be expressed by[1]

$$\frac{j}{nF} = k_c^\circ\left(c_0^\circ - \frac{2jt^{1/2}}{nF\pi^{1/2}D_0^{1/2}}\right)\exp\left\{\frac{\alpha nF}{RT}E\right\}, \tag{11}$$

where k_c° is the cathodic rate constant at $E=0$. This can be written, after introduction of τ from Eq. 3, as

† Present adress: Kaosekken Tochigi-kenkyusho Bunseki-dainiken, 2606 Akabane, Ichikai-machi, Haga-gun, Tochigi, 321-34.

$$t = \left\{\tau^{1/2} - \frac{\pi^{1/2}D_0^{1/2}}{2k_c^\circ}\exp\left(\frac{\alpha nF}{RT}E\right)\right\}^2. \quad (12)$$

From this we get

$$\Delta t = \left[\tau^{1/2} - \frac{\pi^{1/2}D_0^{1/2}}{4k_c^\circ}\left[\exp\left\{\frac{\alpha nF}{RT}E\right\} + \exp\left\{\frac{\alpha nF}{RT}(E-\Delta E)\right\}\right]\right] \times \frac{\pi^{1/2}D^{1/2}}{4k_c^\circ}\left[\exp\left\{\frac{\alpha nF}{RT}E\right\} - \exp\left\{\frac{\alpha nF}{RT}(E-\Delta E)\right\}\right]. \quad (13)$$

The peak potential can be given by

$$E_p = \frac{RT}{\alpha nF}\ln\left[\frac{2k_c^{\circ\,1/2}\tau^{1/2}}{\tau^{1/2}D_0^{1/2}\{1+1/\exp(\alpha nF\Delta E/RT)\}}\right]. \quad (14)$$

Experimental

All measurements were carried out with a three-electrode cell. A Yanagimoto Type-C dropping mercury electrode (DME) was used as the working electrode, synchronization of DME being made with an electro-mechanical knocker (Horseman Solenoid). A saturated calomel electrode (Hitachi Horiba 2410-05t) was used as the reference electrode, a spiral platinum wire electrode of 9.43 cm^2 in surface area being used as the counter electrode. The solution was deaerated with pure nitrogen and kept under nitrogen atmosphere. The temperature of the solution was kept at 25±0.1 °C. All solutions were prepared in twice distilled water, all chemicals being of analytical grade.

Apparatus. A block diagram and the electronic circuit of the system are shown in Figs. 1 and 2, respectively. When a drop begins to grow, it is held at the potential set by the initial potential source (OA-10). The DME can be also kept free from the potential source by opening the switch G-3 independent of the sequence controller. After the lapse of predetermined period t_m(1—6 s), the sequence controller turns the switch G-3 off. The cell is then disconnected from the potential source (OA-10). Simultaneously switches G-2, G-4, and G-6 are opened, switches G-1 and G-5 being closed.

The balance between the electrode potential and the output of ramp generator(OA-12) is supplied to the window comparator by a follower (OA-2), an adder (OA-3) and/or an inverter (OA-4). The window comparator generates a pulse corresponding to the elapsed time for the change of electrode potential from E to $E-\Delta E$. The output of the TVC, which corresponds to the differential time Δt, is stored on a sample and hold circuit (OA-8). After the lapse of the desired time from t_m the switches G-2, G-3, G-4, and G-6 are closed, switches G-1 and G-5 are opened. Simultaneously the DME knocker dislodges the mercury drop. The measurement cycle is completed and the sequence is repeated. The values of Δt are displayed on an x-y recorder (Riken-denshi F-3EP) as a function of E. The w. s. chronopotentiograph and the x-y recorder were calibrated with a Digital Multimeter (Takedariken TR-6854) and a Digital Counter (Iwasakitsushinki UC-6131).

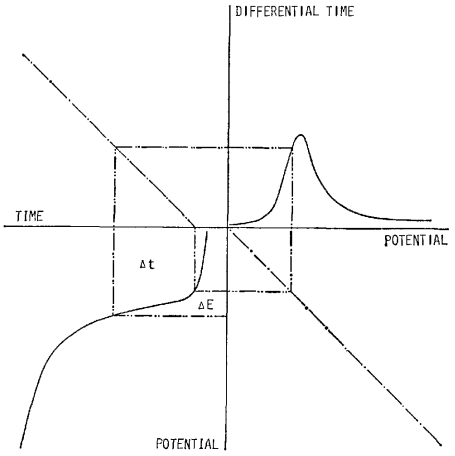

Fig. 3. The schematic diagram of the principle of w. s. chronopotentiometry.

The relation between a w. s. chronopotentiogram and the corresponding conventional chronopotentiogram is given in Fig. 3, the w. s. chronopotentiogram and corresponding conventional chronopotentiogram being shown in the first third quadrants, respectively. The vertical and horizontal axes show differential time and potential, respectively, in the first quadrant, and potential and time, respectively, in the third quadrant. Relations between these quantities are shown by dot-dash-lines.

Results and Discussion

Digital Simulation. W. s. chronopotentiograms were computed on reversible electrode reactions. Change of display with window voltage is shown in

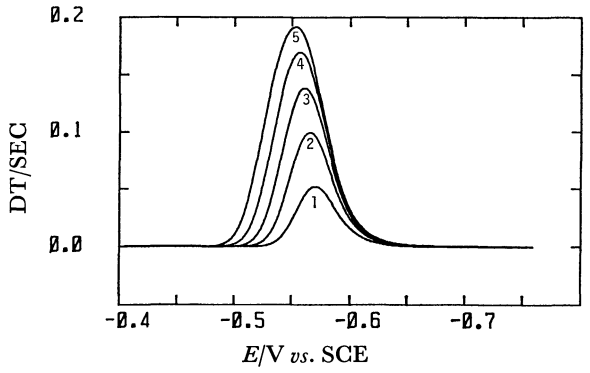

Fig. 4. The w. s. chronopotentiograms simulated with various values of window voltage.
$n=2$, $c_0=1$ mM, $D_0=7.9\times10^{-2}$, $E_0=-0.571$ V. *vs.* SCE, $\Delta E=$(1) 10, (2) 20, (3) 30, (4) 40, (5) 50 mV, temp=25 °C, $t_m=6$ s).

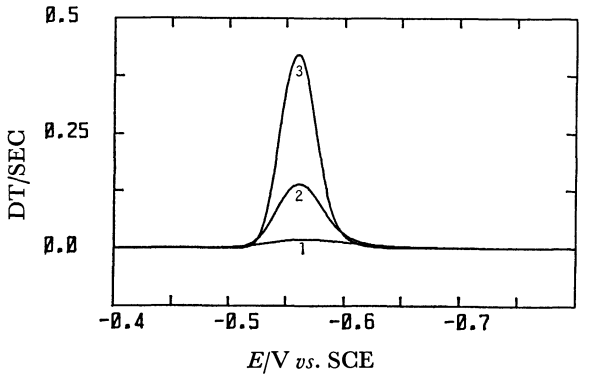

Fig. 5. The w. s. chronopotentiograms simulated with various numbers of electrons. The peak heights are normalized to the case of $n=3$.
$n=$(1) 1, (2) 2, (3) 3, $c_0=1$ mM, $D_0=7.9\times10^{-6}$ cm^2 s^{-1}, $j=1$ mA cm^{-2}, $E_0=-0.571$ V *vs.* SCE, $\Delta E=$ 30 mV, temp=25 °C, $t_m=6$ s.

Fig. 4. The peak potential, peak height, and the half height width of these curves change with the window voltage. In quantitative analysis, a greater window voltage should improve the sensitivity, but, the separability would be reduced.

Change of simulated curves with the number of electrons involved in the electrode reactions is shown in Fig. 5. The peak height and half-height width change markedly with the number of electrons, which can be determined from the peak height and the half-height width.

System Evaluation. For evaluation of the complete system, the reduction of cadmium(II) in a solution of 1 M $NaNO_3$ was studied. The data are shown in Fig. 6 with the corresponding simulated display. Simulation was carried out taking the expansion of mercury drop into consideration. The results are satisfactory, comparable with simulated display. The small difference at the potential over −0.6 V *vs.* SCE is due to the effect of double layer charging.

Effect of Window Voltage. Measurement of the change of w. s. chronopotentiograms with window voltage was carried out by use of 100 μM Cd(II) in 1 M $NaNO_3$. The results are shown in Fig. 7. The dependence of peak potential, peak height, and peak

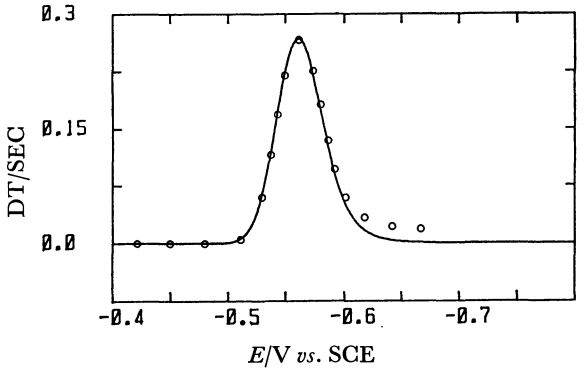

Fig. 6. Experimental data (circle) and the corresponding digital simulation (solid-line) for 1 mM $Cd(NO_3)_2$ in 1 M $NaNO_3$.
$n=2$, $c_0=1$ mM, $D_0=7.9\times10^{-6}$ cm^2 s^{-1}, $j=730$ μA cm^{-2}, $E_0=-0.571$ V *vs.* SCE, $\Delta E=30$ mV, temp= 25 °C, $t_m=6$ s.

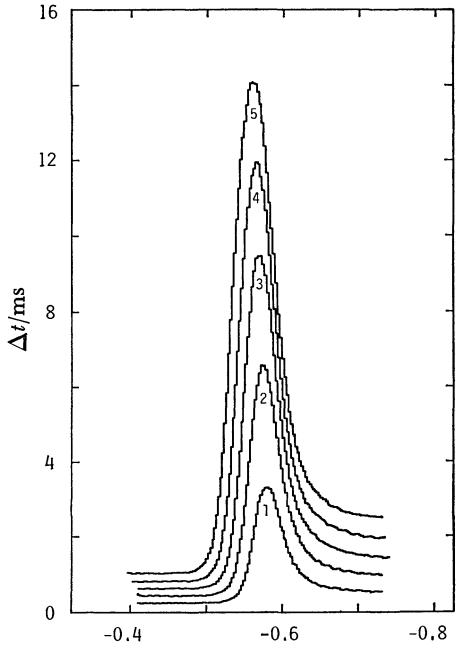

Fig. 7. Effects of voltage window width on w. s. chronopotentiograms of 100 μM $Cd(NO_3)_2$ in 1 M $NaNO_3$ at 25 °C.
$\Delta E=$(1) 10, (2) 20, (3) 30, (4) 40, (5) 50 m V, $j=124$ μA cm^{-2}, $t_m=4$ s.

width on window voltage is in line with expectation.

According to Eq. 5, γ should be a linear function of potential E. Plots for Cd(II)/Cd(Hg) are shown in Fig. 8. The points appear to fall extremely close to the least-square line passing through them. The slope of the line is 13.5 mV and the potential at which γ equals 0 is −0.570 V *vs.* SCE. The results agree with the expected values of slope and potential which are RT/nF and polarographic half-wave potential, respectively.

Effect of the Number of Electrons Involved in Reaction. The w. s. chronopotentiograms of the Tl(I)/Tl(Hg), Cd(II)/Cd(Hg), and Sb(III)/Sb(Hg) are shown in Figs. 9a, 9b, and 9c, respectively, as examples of the

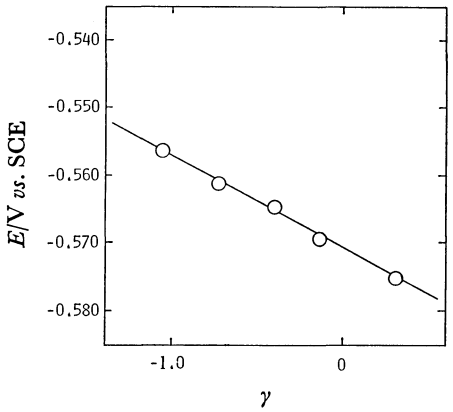

Fig. 8. Plot of electrode potential *versus* values of γ for 100 μM $Cd(NO_3)_2$ in 1 M $NaNO_3$ at 25 °C. $j=124$ μA cm², $t_m=4$ s.

electrode reactions involving one, two and three electrons, respectively.

Irreversible Process. The Zn(II)/Zn(Hg) system was evaluated as an irreversible process. The w. s. chronopotentiogram is shown in Fig. 10. The half-height width of Zn(II)/Zn(Hg) system (112.8 mV) is twice as great as that of the Cd(II)/Cd(Hg) system, which is 59.9 mV and almost equal to the theoretical value 45.5 mV. The peak height of the w. s. chronopotentiogram of Zn(II)/Zn(Hg) system (57 ms) is half as much as that of the Cd(II)/Cd(Hg) system (138.5 ms). The peak height and half height width of w. s. chronopotentiogram would be useful for examining the reversibility of electrode reaction.

Correction of Double Layer Charging. A merit of w. s. chronopotentiometry is the simplicity of procedure for correction in double layer charging. The procedure is suitable for correcting the peak of differential times and the faradaic current for a very dilute solution. The principle of the correction (Fig. 11) is as follows: The charging current density j_c at the potential where electrode reaction occurs is given by

$$j_c = C_{dl}\left(\frac{dE}{dt}\right) \simeq C_{dl}\left(\frac{\Delta E}{\Delta t_{pt}}\right), \quad (15)$$

where j_c is charging current density, C_{dl} differential capacity assumed to be a linear function of potential for the sake of simplicity, dE/dt the gradient of potential-time curve, and Δt_{pt} total peak height. In the absence of electroactive species, the w. s. chronopotentiogram of the solution will be that connected with the solid line. Thus the differential capacity at that potential can be written as

$$C_{dl} = j_t\left(\frac{dt}{dE}\right) = j_t\left(\frac{\Delta t_{pc}}{\Delta E}\right), \quad (16)$$

where j_t is controlled current density and Δt_{pc} charging time. Introducing Eq. 16 into Eq. 15 we get

$$j_c = j_t\left(\frac{\Delta t_{pc}}{\Delta t_{pt}}\right). \quad (17)$$

From this and the relation $j_t=j_c+j_f$ we get

$$j_f = j_t\left(\frac{\Delta t_{pf}}{\Delta t_{pt}}\right), \quad (18)$$

where j_f is the faradaic current density and Δt_{pt} the corrected differential time.

Analytical Application. Analytical application, of w. s. chronopotentiometry, a direct method, and an indirect "enhancement" method, were studied.

Direct Method. The method is based on Eq. 4 which shows the linear relation between $j_f\,\Delta t_{pf}^{1/2}$ and c_i°. A series of measurements were made using cadmium ion to verify the proportionality. The results are shown in Fig. 12. The effects of double layer charging were corrected as regards both current density and time. The corrected points lie very close to the least square line passing through them and origin. The sensitivity of the method seems to be 2—5 μM.

Indirect Method. The signal enhancement of

post-electrolytic substances obtained in the presence of pre-electrolytic ones was utilized for precise determination of trace amount.[24,25] Consider the following electrochemical reactions involving different substances.

$$Ox_1 + n_1e \rightleftharpoons Red_1 \quad (19)$$

$$Ox_2 + n_2e \rightleftharpoons Red_2 \quad (20)$$

Pre-electrolytic substance (reactant Ox_1) is reduced at less cathodic potential less than that of post-electrolytic substance (reactant Ox_2). When Ox_1 and Ox_2 are reduced at sufficiently different potentials, the potential-time curve exhibits two steps, and the w. s. chronopotentiogram two peaks. Since the reduction of Ox_1 and Ox_2 takes place simultaneously after transition time for the reduction of Ox_1, the current efficiency for the reduction of Ox_2 is less than 100%. The transition time and the peak of w. s. chronopotentiogram for the reduction of Ox_2 are greater than would be the case where only the substance

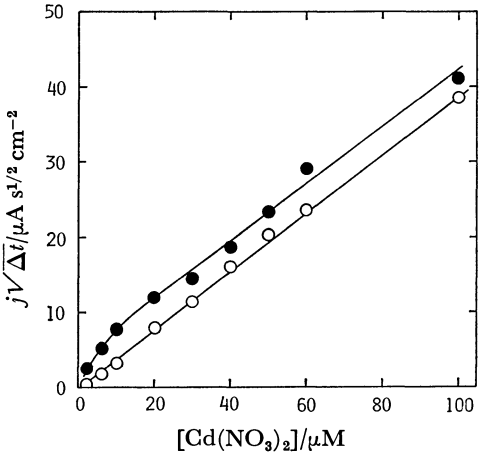

Fig. 12. Plot of $j_f\sqrt{\Delta t_{pf}}$ and $j_t\sqrt{\Delta t_{pt}}$ *versus* concentration of $Cd(NO_3)_2$ in 1 M $NaNO_3$ at 25 °C.
○ for $j_f\sqrt{\Delta t_{pf}}$, ● for $j_t\sqrt{\Delta t_{pt}}$.

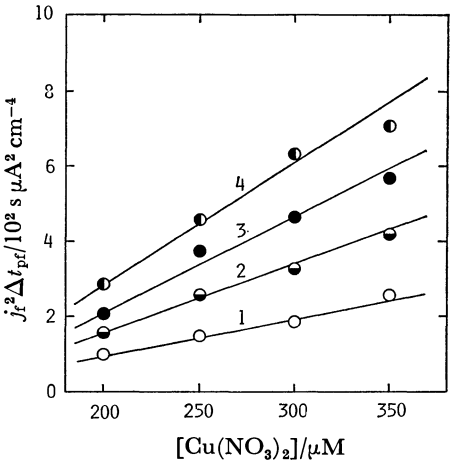

Fig. 13. Plot of $j_f^2\Delta t_{pf}$ for $Cd(NO_3)_2$ versus concentration $Cu(NO_3)_2$ in 1 M KCl at 25 °C.
$[Cd(NO_3)_2]$=(1)4, (2) 6, (3) 8, (4) 10 μM, t_m=8 s, ΔE=40 mV.

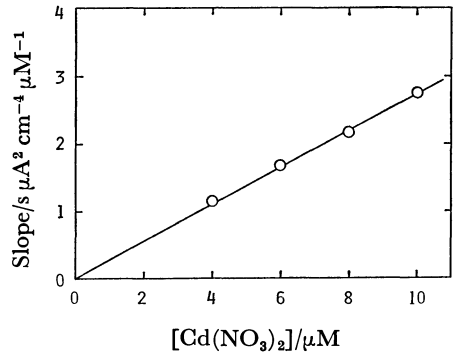

Fig. 14. Plot of the slope of least square line given in Fig. 13 *versus* the concentration of $Cd(NO_3)_2$ in 1 M KCl at 25 °C.

Ox_2 is reduced. Thus the transition time and the peak of w. s. chronopotentiogram for the reduction of Ox_2 depend on the concentration of reactants Ox_1 and Ox_2.

$Cu(NO_3)_2$ was found to be an appropriate pre-electrolytic substance (enhancement reagent), because its polarographic half-wave potential is most positive (0.03 V *vs.* SCE) on mercury electrode. In the presence of $Cu(NO_3)_2$, the enhancement method can be utilized for substances which are reduced at more cathodic potentials than 0.03 V *vs.* SCE.

W. s. chronopotentiograms of Cd(II) were obtained in the presence of various concentrations of $Cu(NO_3)_2$. Figure 13 shows the variation of $j_f^2 \Delta t_{pf}$ of $Cd(NO_3)_2$ with the concentration of $Cu(NO_3)_2$. Figure 14 shows the plots of the slopes of least square lines shown in Fig. 13 as a function of the concentration of $Cd(NO_3)_2$. The curve obtained (Fig. 14) gave an excellent linear relation down to micro molar concentration. For the determination of trace amount, the utilization of enhancement effect improves the sensitivity and accuracy of w. s. chronopotentiometry.

A part of the work was carried out with Grant-in-Aid for Scientific Research No. 472570091668 from the Ministry of Education, Science and Culture.

(Received June 26, 1980)

The reaction of platinum(II) chloride with neat benzonitrile gave bis(benzonitrile)dichloroplatinum(II) as a mixture of cis and trans isomers in variable proportions, depending on the temperature. The geometry of the chromatographically separated isomers was identified on the basis of the dipole-moment and IR data. The ^{13}C NMR spectra in $CDCl_3$ also enabled us to discriminate between isomers in both chemical shift and coupling to the ^{195}Pt of the cyanide carbon, the resonance peak of which was utilized to follow the isomerization. The rate constant (k_c) for the cis-to-trans isomerization was found to be $(3.8\pm0.3)\times10^{-6}$ s^{-1} in $CDCl_3$ at 25 °C, ten times larger than that [$k_t=(2.9\pm0.2)\times10^{-7}$ s^{-1}] of the reverse reaction. The equilibrium between cis and trans strongly favored trans in $CDCl_3$ at 25 °C, whereas in benzonitrile the cis form was the dominant species at room temperature, while the trans form was dominant at higher temperatures.

Bis(benzonitrile)dichloroplatinum(II), $[PtCl_2(PhCN)_2]$, is frequently used as the starting material for the preparation of organoplatinum(II) complexes.[1] The complex was first prepared by Hofmann and Bugge,[2] followed by Ramberg,[3] from potassium tetrachloroplatinate(II) and benzonitrile according to Reaction 1. This preparative method, however requires a long period of over two weeks to obtain the product and gives a poor yield. A more convenient method, starting from platinum(II) chlorides, as represented by Reaction 2, was proposed by Kharasch *et al.*[4] and recommended by Hartley in his review article[1] because of its almost quantitative yield.

$$K_2[PtCl_4] + 2C_6H_5CN \longrightarrow [PtCl_2(C_6H_5CN)_2] + 2KCl \quad (1)$$

$$PtCl_2 + 2C_6H_5CN \longrightarrow [PtCl_2(C_6H_5CN)_2] \quad (2)$$

While the palladium(II) analogue, $[PdCl_2(PhCN)_2]$, has the trans structure,[5] the stereochemistry of $[PtCl_2(PhCN)_2]$, which was obtained from Reaction 1, was ascertained to be cis by Jensen's measurement of the dipole moment in benzene;[6] IR studies in the solid state confirmed this structure.[7] In the present study, we have carried out a detailed examination of the product from Reaction 2 and have found it to be a mixture of cis and trans isomers, the composition of which depends on the reaction temperature. Recently, we briefly reported[8] on the separation of the product into the two isomers and on our isomerization studies by ^{13}C NMR spectroscopy. These results, together with the data on the measurement of the dipole moment, are presented in full below.

Experimental

Commercially available platinum(II) chloride, potassium tetrachloroplatinate(II), and benzonitrile were used without further purification. Dichloromethane over a molecular sieve (type 3A) was decanted, dried further over calcium hydride, and then distilled. The benzene and chloroform which were used as solvents for the measurement of the dipole moment were purified by fractional distillation through a 100-cm column after the usual pretreatment.[9]

Synthesis of ^{13}C*-Enriched Benzonitrile.* Benzoic-carboxy-^{13}C (99%) acid was converted into acid chloride by the usual method.[10] The chloride in benzene was treated with an excess of concentrated aqueous ammonia at 0 °C to give benzamide in an 80% yield. The crude amide (1.76 g) was mixed with 1.6 g of diphosphorus pentaoxide and heated at 200 °C under slightly reduced pressure. The distillate (1.32 g; 88% yield) was used in the preparation of the complex without further purification.

cis- *and* trans-*Bis(benzonitrile)dichloroplatinum(II). Syntheses and Separation by Column Chromatography. (1) Kharasch's Method*:[1,4] When a suspension of $PtCl_2$ (0.255 g) in PhCN (20 cm^3) was stirred at room temperature (26 °C), a clear solution resulted after 7 h. After filtration, a yellow precipitate (0.417 g) was obtained in a 92% yield on the addition of petroleum ether to the filtrate. The chromatographic separation of the crude product through a column ($20\times\phi2$ cm) of silica gel (Merck $60F_{254}$, 70—230 mesh), with CH_2Cl_2 as the eluent, gave *trans*- and *cis*-$[PtCl_2(PhCN)_2]$ in 26 and 58% yields, in this sequence. Found for the trans-isomer: C, 35.1; H, 2.14; N, 5.80%. Mol wt in CH_2Cl_2 at 37 °C, 497. Found for the cis-isomer: C, 35.5; H, 2.12; N, 5.85%. Mol wt, 501. Calcd for $C_{14}H_{10}N_2Cl_2Pt$: C, 35.6; H, 2.14; N, 5.93%. Mol wt, 472. The same procedure was also performed at different reaction temperatures of 60, 100, and 180 °C; this gave increasing trans/cis ratios in this order.

(2) A Slight Modification of Hofmann's Procedure:[2,3] When an aqueous solution (20 cm^3) of $K_2[PtCl_4]$ (0.304 g) was mixed with PhCN (3 cm^3) and then stirred for 4 d at room temperature, the organic layer turned yellow. The yellow precipitate which developed on the interface was collected, washed successively with methanol and ether, and then dried *in vacuo*; yield, 0.220 g; 63%. The filtrate was extracted with CH_2Cl_2, and the extract was concentrated to obtain a yellow product on the addition of petroleum ether; yield, 0.064 g; 18%. While the former product included the cis isomer exclusively, the latter was as a mixture of trans and cis, from which the two isomers were isolated separately by column chromatography as has been described above. The trans/cis ratio was 0.72.

Synthesis of [CN-^{13}C-*Enriched*]-*bis(benzonitrile)dichloroplatinum (II).* The PhCN-[*CN-*^{13}*C*(99%)] (1.3 g) was diluted with unlabeled PhCN (1.3 g), and then $PtCl_2$ (0.363 g) was suspended in the mixture. When the suspension was stirred for 15 h at room temperature, a yellow precipitate gradually increased as the mass of the $PtCl_2$ decreased. The precipitate, with a further crop obtained on the addition

of petroleum ether to the mixture, was collected, washed successively with petroleum ether and ether, and dried *in vacuo*; yield, 0.567 g; 88%. The crude product was separated chromatographically into trans and cis isomers as has been described above.

Rate Determination of cis-trans Isomerization. The *cis*-$[PtCl_2(PhCN)_2]$-$[CN\text{-}^{13}C]$ (60 mg) was suspended in $CDCl_3$ (2 cm^3) in an NMR tube (10 mmϕ) to initiate isomerization. As the reaction proceeded, the solid of the cis isomer gradually dissolved, disappearing completely after 127 h, while the relative concentration of trans to cis in the solution increased slowly and attained an equilibrium of isomerization after *ca.* 70 d. The spectral change in the cyanide-carbon peaks (*vide infra*) of both isomers with time was followed by means of the ^{13}C FT NMR at *ca.* 25 °C and recorded, at appropriate time-intervals, 12 times during the total reaction time of 1675 h. The trans/cis isomer ratio in each set of measurements was determined on the bases of their relative peak areas. The mid-time for the accumulation of spectral data was taken as the time at which a spectrum was measured.

Measurements. The IR spectra (4000—200 cm^{-1}) were measured in Nujol mull with a JASCO DS701G spectrophotometer. The FT ^{13}C NMR spectra were recorded at 25.05 M Hz on a JEOL FX-100 spectrometer. The chemical shifts (δ) are quoted relative to the central peak of chloroform-*d* (δ; 77.1 ppm). The molecular weight was determined with a vapor-pressure osmometer manufactured by Knauer, West Berlin, West Germany.

The measurement of the dielectric constant, ε, was carried out with an apparatus devised by Le Fevre and his collaborators.[11] The specific volume, v, and the refractive index, n, were measured by the usual methods. All the data necessary to calculate the electric dipole moment, μ, were obtained at 25.00±0.02 °C. Benzene and chloroform were used as the solvents. Measurements were made on solutions up to about 0.005 in the weight fraction, w, of solutes.

Results and Discussion

Although $[PtCl_2(PhCN)_2]$ has long been thought to be exclusively cis on the basis of the data of the dipole moment,[6] the isomers of both cis and trans were first isolated separately by column chromatography, as has been shown in the Experimental Section. These isolated isomers are mononuclear in CH_2Cl_2. The trans isomer is eluted from the column prior to the cis and is more soluble in the nonpolar solvents, such as C_6H_6, $CHCl_3$, CH_2Cl_2, and $(CH_3)_2CO$, than the cis, reflecting its geometry. The isomeric composition of the product obtained by Kharasch's method depends on the reaction temperature, the trans/cis ratios being 0.45, 0.69, 4.4, and 5.4 at 26, 60, 100, and 180 °C respectively. Thus, the approximate ΔH of the cis⇌trans isomerization in PhCN is 18 kJ/mol if these values are presumed to give the equilibrium constants at given temperatures.

Determination of cis and trans Configurations by Measurements of the Dipole Moments. As a means of determining the cis and trans configurations of the square-planar metal complexes inert in solution, the measurement of the dipole moment is most useful. In order to confirm the structures of both isomers isolated in the present investigation, we have measured their electric-dipole moments in C_6H_6 and $CHCl_3$ at 25 °C. The symbols I and II are used tentatively for the isomers eluted from the silica-gel column, in this sequence.

Table 1. Polarization data[a] of I and II isomers of $[PtCl_2(PhCN)_2]$

Solvent		I	II
C_6H_6	ε	$2.2726+1.27w$	
	v	$1.1462-0.705w$	
	p_2	0.3711 cm^3	
	P_2	175.2 cm^3	
	μ	0.82D	—
$CHCl_3$	ε	$4.8780-2.80w$	$4.8880+85.5w$
	v	$0.6803-0.208w$	$0.6807-0.222w$
	p_2	0.1455 cm^3	2.1054 cm^3
	P_2	68.7 cm^3	1866.2 cm^3
	μ	—	9.13D[b]
			11.63D[c]

a) The values of the square of the refractive index, n^2; the specific refraction for the sodium D line, r, and the molar refraction, R_D, were determined by employing a $CHCl_3$ solution of I and were then also used in the calculations for II: n^2, $2.0858+1.64w$; r, 0.3260 cm^3; R_D, 153.9 cm^3. b) Value obtained by Halverstadt-Kumler's method.[12] c) Value obtained by Onsager's method.[13]

The polarization data of I and II in C_6H_6 and $CHCl_3$ are summarized in Table 1. The data of II in C_6H_6 are lacking, however, since the solubility was insufficient. The notations p_2 and P_2 in Table 1 represent the specific and the molar polarizations respectively. The dielectric data were analyzed according to the Halverstadt-Kumler method.[12] The calculation of the dipole moments of both isomers was carried out on the following assumptions: 1) the distortion polarization of I is equal to $1.05R_D$; 2) the distortion polarizations of I and II are equal in magnitude, since these complexes have the same composition, $PtCl_2(PhCN)_2$, and 3) chloroform is regarded as nonpolar; since it has a low dielectric constant (4.8 at 20 °C).

The electric-dipole moment of the I isomer was found to be 0.82 D in C_6H_6, but the moment of I in $CHCl_3$ was not calculated since $1.05R_D$ exceeded the P_2 value. On the other hand, the electric-dipole moment of II in $CHCl_3$ was calculated to be 9.13 D. Either value (175.2 or 68.7 cm^3) of the molar polarization of the I isomer in C_6H_6 and $CHCl_3$ in much smaller than that (1888.2 cm^3) of the II isomer in $CHCl_3$, and either is close to the distortion polarization, $1.05R_D$, of I. These results lead to the conclusion that the configurations of the I and II isomers are trans and cis respectively, as is to be expected from the differences in their solubilities and in their elution rates in column chromatography.

Further, we tried to estimate the more exact electric-dipole moment for the cis isomer II by the application of the dielectric theory of polar liquids proposed by Onsager.[13] The value thus obtained, 11.63 D, agrees very closely with the value of 12.5 D in C_6H_6 which was given by Jensen,[6] although we have failed in our

attempt to measure it in the same solvent.

Characterization of the Isomers trans- *and* cis-$[PtCl_2(PhCN)_2]$. *IR Spectra*: The IR spectra of the *trans*- and *cis*-$[PtCl_2(PhCN)_2]$ isomers are very similar to each other except for the bands assignable to the vibrations of ν(C≡N), π(CH) of the phenyl groups, and ν(Pt–Cl). These characteristic bands are shown in Table 2 in comparison with those for *cis*-$[PtBr_2(PhCN)_2]$ and *trans*-$[PdCl_2(PhCN)_2]$, whose configurations were assigned by Walton[7] on the basis of their IR data. As may be seen in Table 2, *trans*-$[PtCl_2(PhCN)_2]$ exhibits a single ν(C≡N) band at 2285 cm^{-1}, while the corresponding band at 2282 cm^{-1} for cis is accompanied by a minor peak at 2290 cm^{-1}. The most remarkable difference in the IR spectra in Nujol is observed in the 800—650 cm^{-1} region. The trans isomer shows two very strong bands at 766 and 688 cm^{-1}, associated with the out-of-plane CH deformation vibrations of the phenyl groups. Each of these bands is split into two well-defined peaks in the spectrum of the cis complex, giving rise to four strong bands at 779, 758, 695, and 684 cm^{-1}. A similar situation was observed in the IR spectra of *cis*-$[PtBr_2(PhCN)_2]$ and *trans*-$[PdCl_2(PhCN)_2]$ listed in Table 1. Thus, these bands are most diagnostic for the determination of the cis- and trans-geometries. In the square-planar complexes of MX_2L_2 (X=halide) type, trans isomers generally exhibit a single ν(MX) band in the IR spectra, while cis isomers generally exhibit two bands. Therefore, the ν(M–X) band has been effectively utilized to identify the configuration of these complexes.[14] In fact, *cis*-$[PtCl_2(PhCN)_2]$ exhibits two bands, at 356 and 350 cm^{-1}, in the region of ν(Pt–Cl), but trans exhibits three bands, at 356, 348, and 310 cm^{-1}. We cannot immediately determine which of these bands is assignable to the ν(Pt–Cl) vibration. Thus, the ν(Pt–Cl) bands are not of diagnostic use in identifying the trans-cis geometry in the present case.

^{13}C *NMR*: The ^{13}C NMR data for the *trans*- and *cis*-$[PtCl_2(PhCN)_2]$ isomers in $CDCl_3$ at 25 °C are listed in Table 3 in comparison with those for free PhCN and *trans*-$[PdCl_2(PhCN)_2]$. In order to detect the cyanide-carbon peaks of very weak intensities, a carbon-13 enriched compound, *cis*-$[PtCl_2(PhCN)_2]$-$[^{13}C\text{-}CN]$, was prepared, and its spectrum was measured.

Both the spectral pattern and the chemical shifts for the isomers were similar to those for free PhCN; this facilitated the assignment of each of the resonances as is shown in Table 3. No significant difference in the chemical shifts between the corresponding peaks of these isomers was observed; only the coupling $^2J(Pt\text{–}C^7)$ of the cyanide carbon to ^{195}Pt showed a serious difference between these isomers. These values for the trans and cis isomers are 289 and 234 Hz respectively, much larger than the corresponding value

a) Chemical shifts (δ) are quoted relative to the central peak of chloroform-*d* (δ; 77.1 ppm) and converted to values from TMS. Coupling constants (J) in Hz.

of 82 Hz for *trans*-[MePt(*p*-$MeOC_6H_4CN$)L_2]PF_6 (L= $AsMe_3$ or PMe_2Ph),[15] which bears an analogous nitrile ligand. Thus, a rough "NMR trans-influence series"[16] can be drawn as follows: $CH_3 \gg Cl > PhCN$. Because of their long-range interactions, the coupling constants between other carbon atoms and ^{195}Pt are too small for us to evaluate such a trans influence. Also, we could not detect ^{195}Pt satellite bands on C^1 for the cis isomer because of the very weak intensity of the parent peak.

In recent studies, we have found that $[PdCl_2(PhCN)_2]$ reacted with acetylacetone in acetone at room temperature to produce bis(η^3-1-acetyl-2-hydroxyallyl)di-μ-chloro-dipalladium(II), liberating PhCN molecules.[17] On the contrary, no reaction occurred between $[PtCl_2(PhCN)_2]$ and acetylacetone, not even in refluxing acetone, but the complex did react with acetylacetonate carbanions $(CH_3CO)_2CH^-$ in CH_2Cl_2 at room temperature, giving rise to a nucleophilic attack on the cyanide carbons.[18] The C^7-carbon of $[PdCl_2(PhCN)_2]$ is deshielded, exhibiting C^7-resonance at a field (122.3 ppm) lower by 5 to 7 ppm than those for the analogous Pt(II)-complexes, as is shown in Table 3. Therefore, it is unlikely that the above difference in reactivity between the Pd(II) and Pt(II) complexes was brought about by the difference in the shielding effects on the C^7-carbon atoms. No appreciable difference in ν(CN) was observed between the IR spectra of the *trans*-$[MCl_2(PhCN)_2]$, M=Pd(II) and Pt(II), complexes. It seems likely that the difference in the labilities of these two metal centers is mainly concerned with these reaction patterns.

Cis-trans Isomerization Studies by ^{13}C NMR Spectroscopy. In the presence of the cis isomer which remains undissolved, the solution is saturated with the cis isomer of a constant concentration during the reaction. At the initial stage of the reaction, during which the contribution of the reverse reaction to the overall isomerization is regarded as negligible, therefore, the zeroth-order reaction is set up for the cis-to-trans isomerization. In fact, within *ca.* 30 h, the plot of the [trans]/[cis] ratio against the time, t, gave a straight line, as is shown in Fig. 1. The rate constant, k_c, of the cis-to-trans isomerization expressed by Reaction 3 was obtained as:

$$cis\text{-}[PtCl_2(PhCN)_2] \xrightarrow{k_c} trans\text{-}[PtCl_2(PhCN)_2] \quad (3)$$

$(3.8\pm0.1)\times10^{-6}\ s^{-1}$ at 25 °C from the slope of the linear plot drawn by the least-squares method.

After the complete dissolution of the cis isomer, the kinetics can be treated as a reversible first-order reaction as is expressed by Reaction 4. The concentration of each of the cis and trans isomers was calculated from the total amount (60 mg) of the complex

$$cis\text{-}[PtCl_2(PhCN)_2] \underset{k_t}{\overset{k_c}{\rightleftharpoons}} trans\text{-}[PtCl_2(PhCN)_2] \quad (4)$$

used and the [trans]/[cis] ratio. The cis-trans equilibrium was attained at 1516 h after the complete dissolution of the cis isomer. The equilibrium constant, K_e, in Reaction 4 was found to be 13.0 from the data at that time. The $([cis]_t-[cis]_\infty)$ *vs.* t plot is given in Fig. 2. The (k_c+k_t) value was obtained as

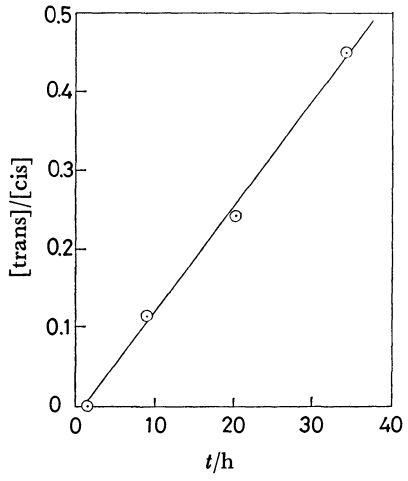

Fig. 1. The [trans]/[cis] *vs.* t plot in the presence of undissolved *cis*-$[PtCl_2(PhCN)_2]$-[^{13}C-*CN*].

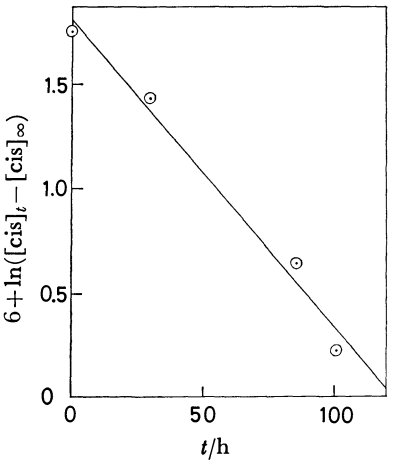

Fig. 2. The $\ln([cis]_t-[cis]_\infty)$ *vs.* t plot for the data obtained after complete dissolution of *cis*-$[PtCl_2(PhCN)_2]$-[^{13}C-*CN*].

$(4.1\pm0.3)\times10^{-6}\ s^{-1}$ from the slope of the straight line drawn by the least-squares method. From this and the K_e values, the rate constants, k_c and k_t, for the forward and the reverse isomerizations were calculated to be $(3.8\pm0.3)\times10^{-6}$ and $(2.9\pm0.2)\times10^{-7}\ s^{-1}$ respectively at 25 °C. The former value is in good agreement with the experimental value in the first step, in which the reverse reaction was ignored.

Considerations of the cis-trans Isomerization Rates. Although *trans*-$[PtCl_2(PhCN)_2]$ has not been prepared, we can find some cases in the literature in which the products obtained from reactions between $[PtCl_2(PhCN)_2]$ and substrates existed eventually in a trans form. For example, Lauhen and Ibers[19] determined the crystal structure of an adduct $[Pt(DISN)_2][PtCl_2(PhCN)_2]$ which had been prepared by mixing stoichiometric quantities of bis(diiminosuccinonitrilo)platinum(II) and $[PtCl_2(PhCN)_2]$ in a $CHCl_3$ solution at the ambient temperature; they found that the latter component has a trans geometry in crystals. Recently Braunstein *et al.*[20] obtained *trans*-(*P*,*N*)-$[Pt\{P(Ph)_2C(Y)=C(Ph)NH\}_2]$ (Y=CO_2Et and CN) by the reactions of $[PtCl_2(PhCN)_2]$ with the Ph_2PCHY

carbanions in THF at 0 °C. In each of these two cases, it is not convincing to argue that *cis*-$[PtCl_2(PhCN)_2]$ was isomerized to the trans form during the prompt reaction, which occurred under quite mild conditions. In fact, the k_c value which was obtained in $CDCl_3$ at 25 °C in the present study is too small to justify the isomerization of *cis*-$[PtCl_2(PhCN)_2]$ to trans in the course of the reactions described above, although k_c is ten times larger than k_t.

The K_e value of 13.0 shows that the equilibrium strongly favors trans in $CDCl_3$ at 25 °C, whereas in PhCN it was found that the cis form is the dominant species at room temperature, but trans at higher temperatures. Therefore, we could prepare the trans isomer in good yields at temperatures above 100 °C by Kharasch's method, although cis was produced exclusively in the preparation at room temperature by Hofmann's method. Contrary to the case in $CDCl_3$, the preference of the cis form in PhCN to trans at room temperature appears probable as behavior in a polar solvent. Walton refers in his paper[7] to the unexpected formation of the trans isomer during the preparation of *cis*-$[PtBr_2(PhCN)_2]$ by Hofmann's method. This might be related to our observation that *trans*-$[PtCl_2(PhCN)_2]$ was included in the filtrate after the isolation of the cis isomer in the preparation according to Hofmann's method.

The authors wish to express their thanks to Professor Yuho Tsuno of Kyushu University for his kindness in supplying the carbon-13 enriched benzoic acid. Thanks are also due to Mr. Junichi Gohda for the elemental analysis. The present work was partly supported by a Grant-in-Aid for Scientific Research (Grant Number 243014) from the Ministry of Education, Science and Culture.

sino)ethane by a method similar to the above. Yield, 136 mg (69%). $[\alpha]=+49°$ (*c* 0.10, CH_3OH).

(+)-[Pd(damf)(py)$_2$]PF$_6$. A mixture of 230 mg (0.50 mmol) of (+)-[Pd(damf)(*S*-pro)], 160 mg (2.0 mmol) of pyridine, and 250 mg (1.5 mmol) of sodium hexafluorophosphate in 20 cm^3 of ethanol was heated with stirring for 2 h and filtered. The filtrate was concentrated to *ca.* 2.5 cm^3 and stored in a refrigerator for a few days. Yellow precipitate was collected, washed with ethanol, and dried in air. Yield, 150 mg (46%). $[\alpha]=+194°$ (*c* 0.17, CH_3OH).

[Pd(X)(damf)(py)] (X=Cl and Br). A mixture of 230 mg (0.30 mmol) of $[PdCl(damf)]_2$ and 100 mg (1.3 mmol) of pyridine in 30 cm^3 of dichloromethane was stirred at room temperature for 30 min. The resulting solution was filtered and 10 cm^3 of ethanol was added to the filtrate. Upon concentration yellow crystals (X=Cl) were obtained, which were washed with a small amount of ethanol and dried in air. Yield, 190 mg (68%).

The yellowish brown bromo complex was prepared by metathesis of the chloro complex with excess lithium bromide in hot ethanol. Yield, 73%.

Results and Discussion

A pair of diastereomers of [Pd(damf)(*S*-pro)] are efficiently separated by solubility difference (Fig. 1). In the ^{1}H NMR spectra, the less soluble isomer, (+)-[Pd(damf)(*S*-pro)], in a mixture of chloroform–acetone (1:4) shows sharp signals of the N–CH_3 at 2.87 (s) and 3.09 (s) ppm and that of the C_5H_5 group at 4.23 (s), while the other, (−)-[Pd(damf)(*S*-pro)], at 2.87 (s) and 3.14 (s), and at 4.15 (s), respectively (Table 2). The sharp signals are used as an indication of complete separation of the isomers. The electronic spectra of the two are very similar, while the CD spectra are nearly enantiomeric to each other (Fig. 2). This suggests that the two are a pair of diastereomers resulting from the planar chirality. The geometrical isomer (*trans-N,N*) shown in Fig. 1 is assumed,

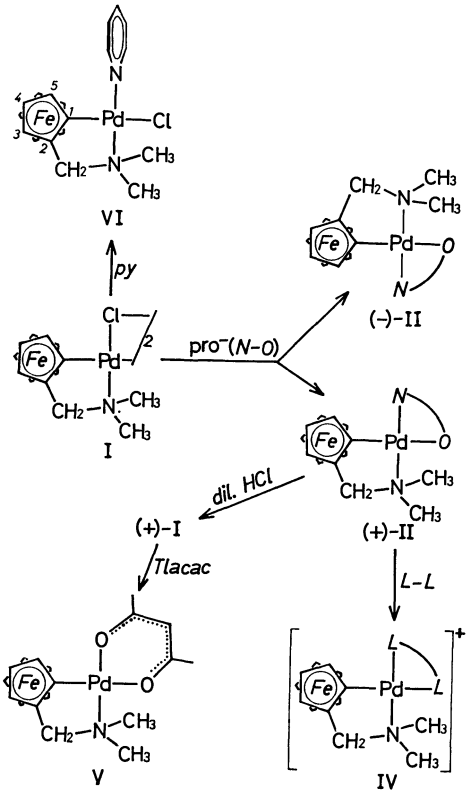

Fig. 1. Cyclo-palladated (dimethylaminomethyl)ferrocene and its derivatives. L–L in IV is en, diphos, diars, or 2py.

since a similar ortho-palladated complex, (*N,N*-dimethylbenzylamine-2*C,N*)(*N*-phenylsalicylideneaminato)-palladium(II)[14] has a *trans-N,N* structure.

A reaction of (+)-[Pd(damf)(*S*-pro)] with dilute hydrochloric acid regenerates the original dimer, (+)-$[PdCl(damf)]_2$. The absorption and CD spectra are

a) s=singlet, d=doublet, t=triplet, m=multiplet, and b=broad. b) Overlapped by the signal of C_5H_5. c) CH_3 of acac resonates at 1.95 s and 1.99 s ppm and methine-H of acac at 5.29 s.

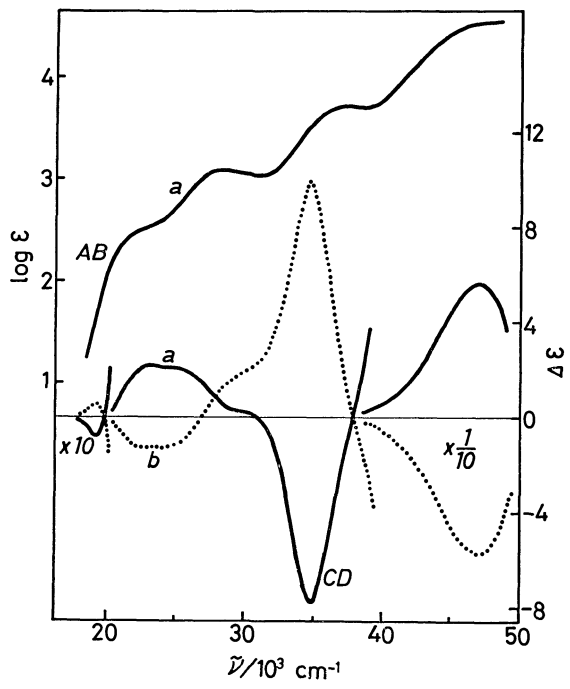

Fig. 2. Absorption (AB) and CD spectra of methanol solutions of a: (+)-[Pd(damf)(*S*-pro)] and b: (−)-[Pd(damf)(*S*-pro)].

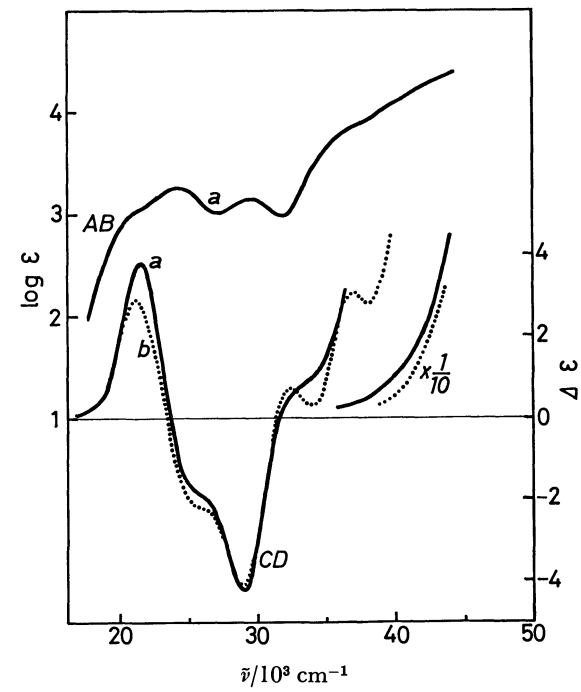

Fig. 3. Absorption (AB) and CD spectra of dichloromethane solutions of a: (+)-[PdCl(damf)]$_2$ and b: (*R*)-[PdCl(*S*-daef)]$_2$.

shown in Fig. 3 together with the CD spectrum of (+)-(*R*)-[PdCl(*S*-daef)]$_2$.[12] The similarlity in CD spectra suggests that (+)-[PdCl(damf)]$_2$ has the same absolute configuration *R* for the ferrocene moiety.

From the separated isomer, (+)-[Pd(damf)(*S*-pro)], the optically active complexes, $[Pd(damf)(L\text{-}L)]^+$ are derived, where L-L are en, diphos, diars, and 2py (Table 1 and Fig. 1). The (+)-[Pd(damf)(acac)] complex was obtained from (+)-[PdCl(damf)]$_2$. Some of the ^{1}H NMR spectral data are given in Table 2.

The CD spectra of (+)-[Pd(damf)(en)]BF_4 and (+)-[Pd(damf)(acac)] are compared with those of (*R*)-[Pd(*S*-daef)(en)]BF_4 and (*R*)-[Pd(*S*-daef)(acac)], respectively (Fig. 4). The absolute configuration of the enantiomer (*S*)-[Pd(*R*-daef)(acac)] has been determined by the X-ray method.[15] The results also show that the absolute configuration of the ferrocene moiety in (+)-[Pd(damf)(en)]BF_4 and (+)-[Pd(damf)(acac)] is *R*. The CD spectra of the other complexes are shown in Fig. 5.

The cyclo-palladated (dimethylaminomethyl)ferrocene complexes change the CD spectra remarkably depending on the kind of ligands (L-L) (Figs. 2—5) and there seems to be no regularity among the spectra. The diphos and diars complexes are a unique pair to give similar spectra. Nevertheless a shoulder absorption observed at *ca.* 22000 cm^{-1} for all the complexes appears to arise mainly from d-d transitions of the iron(II) ion, since the free Hdamf ligand gives a band due to the d-d transitions at 22300 cm^{-1} (ε=107).[16] The CD extremes corresponding to this shoulder (Figs. 2—5) are always positive and the positive extremes seem to be a representative of a (*R*)-ferrocenyl group. A chiral ferrocenylphosphine, (+)-(*R*)-[2-(dimethylaminomethyl)-1-ferrocenyl] diphenylphosphine (VII)

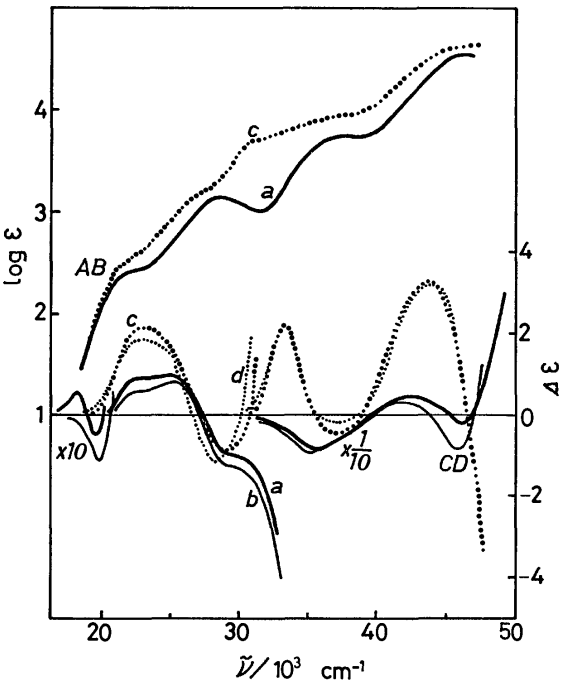

Fig. 4. Absorption (AB) and CD spectra of methanol solution of a: (+)-[Pd(damf)(en)]BF_4, b: (*R*)-[Pd-(*S*-daef)(en)]BF_4, c: (+)-[Pd(damf)(acac)], and d: (*R*)-[Pd(*S*-daef)(acac)].

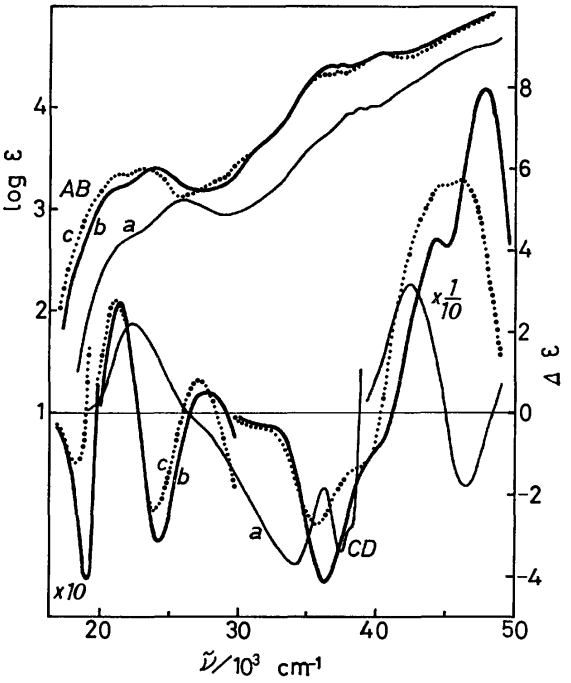

Fig. 5. Absorption (AB) and CD spectra of methanol solutions of a: (+)-[pd(damf)$(py)_2$]PF_6, b: (−)-[Pd(damf)(diphos)]PF_6, and c: (+)-[Pd(damf)-(diars)]PF_6.

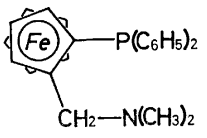
has recently been reported to show a positive CD extreme in this region;[10,11] $\Delta\varepsilon = +0.52$ at 21800 cm^{-1}.

The protons of unsubstituted cyclopentadienyl rings of (−)-[Pd(damf)(diphos)]PF_6 and (+)-[Pd(damf)-(diars)]PF_6 resonate at a considerably higher field than those of the other complexes (Table 2). The properly oriented phenyl rings of diphos and diars are expected to bring about the shielding effect by



VII

their magnetic anisotropy.[17] In the ^1H NMR spectra of [PdCl(damf)(py)] and [PdBr(damf)(py)] a doublet at a very high field (3.23 (Cl) and 3.18 (Br) ppm) is observed in contrast to those of the other complexes. The doublet can be assigned to 5-H of the substituted cyclopentadienyl ring since this proton should be shielded by the ring current of the coordinated pyridine (Fig. 1, VI), when [PdX(damf)(py)] (X=Cl and Br) has a *trans-N,N, trans-C,X* arrangement like other ortho-palladated complexes, [PdX(C–N)(py)] (C–N= ortho-palladated ligand).[1,18] The structure is supported by appearance of a low frequency ν(Pd–Cl) band at 268 cm^{-1}.[19]

The present work was supported by a Grant-in-Aid for Scientific Research No. 243013 from the Ministry of Education, Science and Culture.

Preparation and Absorption and Circular Dichroism Spectra of Cobalt(III) Complexes with *N,N,N',N'*-Tetrakis(2-aminoethyl)-1,2-ethanediamine, -1,3-propanediamine, -1,4-butanediamine, and -(*R,R*)- and -(*R,S*)- 2,4-pentanediamine

Kazumasa HATA, Myung-Ki DOH,† Kazuo KASHIWABARA, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 7, 1980)

Cobalt(III) complexes of new sexidentate ligands, *N,N,N',N'*-tetrakis(2-aminoethyl)-1,3-propanediamine (ttn), -1,4-butanediamine (ttmd), and -(*R,R*)- and -(*R,S*)-2,4-pentanediamine (tptn) were prepared and resolved except the *RR*-tptn complex which formed the *Δ*-isomer stereoselectively. The monocyano complexes of *N,N,N',N'*-tetrakis(2-aminoethyl)-1,2-ethanediamine (ten) and ttn, in which the ligands act as a quinquidentate, were also prepared. Absorption and CD spectra of these complexes and the known $[Co(ten)]^{3+}$ complex were compared with one another. The first d-d absorption bands of the sexidentate complexes, $[Co(A)]^{3+}$ are shifted to smaller wave numbers in the order, ttn>ten>ttmd for A, but those of $[Co(CN)(HA)]^{3+}$ are in the reverse order, ten>ttn. The d-d absorption bands of $[Co(RS\text{-tptn})]^{3+}$ which contains one axial methyl group show the remarkable red shift and the hyperchromic effect as compared with those of $[Co(RR\text{-tptn})]^{3+}$ with two equatorial methyl groups.

N,N,N',N'-Tetrakis(2-aminoethyl)-1,2-ethanediamine (ten) can act as a sexidentate ligand to give metal complexes structurally similar to those of ethylenediaminetetraacetate (edta).[1] Emmenegger and Schwarzenbach[2] found that the first absorption band of $[Co(ten)]^{3+}$ shows a remarkable red shift (13 nm) as compared with that of $[Co(NH_3)_6]^{3+}$, and attributed it to the reduction of ligand field strength caused by a strained structure of the complex ion. Muto *et al.*[3] found by the X-ray structure analysis that the coordination octahedron of this complex ion is largely distorted. Similar strain is involved in the structurally related $[Co(edta)]^-$ ion.[4] The strain or distortion in such sexidentate complexes might be diminished or enhanced by changing ring members of the central diamine chelate rings. The strain would also be reduced by opening one chelate ring to form a complex of the type, $[Co(X)(Hten)]^{n+}$ (X=unidentate ligand).

This paper reports the preparation, resolution, and absorption and circular dichroism (CD) spectra of cobalt(III) complexes with sexidentate *N,N,N',N'*-tetrakis(2-aminoethyl)-1,2-ethanediamine (ten), -1,3-propanediamine (ttn), -1,4-butanediamine (ttmd), and -2,4-pentanediamine (tptn) of (*R,R*) and (*R,S*) forms. When the last sexidentate (*RS*)-tptn ligand forms an octahedral complex, one methyl group of the ligand takes necessarily an axial disposition. The complexes of the type, $[Co(CN)(HA)]^{3+}$ (HA=$Hten^+$ and $Httn^+$) in which the hexamine ligands act as a quinquidentate with a free aminoethyl branch are also described in this paper.

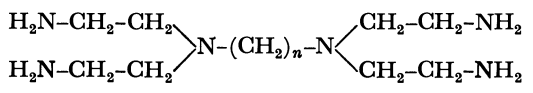
Experimental

Preparation of Ligands. All the hexamine ligands were prepared according to a method similar to that for ten reported by Moser and Schwarzenbach.[1]

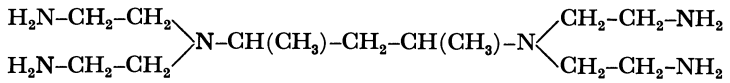
N-(Phenylsulfonyl)aziridine was prepared from aziridine[5] and benzenesulfonyl chloride by the method of Moser and Schwarzenbach.[1] (*R,R*)- and (*R,S*)-2,4-Pentanediamine (ptn) were obtained by the method of Bosnich and Harrowfield.[6] Other diamines, 1,2-ethanediamine (en), 1,3-propanediamine (tn), and 1,4-butanediamine (tmd) were purchased (Tokyo Kasei) and used without further purification.

Benzene solutions of *N*-(phenylsulfonyl)aziridine (0.33 mol in 100 cm^3) and a diamine (0.058 mol in 10 cm^3) were dried with Na_2SO_4 (4 °C) and molecular sieves 4A 1/16 (room temperature), respectively, for 1 d. To the former solution was carefully added the latter solution dropwise with stirring, the solution being kept at *ca.* 20 °C. The resulting solution was stirred at *ca.* 30 °C for 2 d to give the tetrakis(phenylsulfonyl)derivative. The derivatives from en, tmd, and *RR*-ptn were fine white crystalline products, which were filtered, washed three times with benzene, and dried *in vacuo*, but those from the other diamines were faintly brown colored oily products, and the benzene was removed by evaporating under reduced pressure.

The tetrakis(phenylsulfonyl)derivatives (0.05 mol) were hydrolyzed by heating at 150 °C in a mixture of concd H_2SO_4 (60 g) and water (15 g) for 17 h. Each of the resulting brown solutions was cooled to room temperature, mixed with water (*ca.* 50 cm^3), and adjusted the pH to *ca.* 8 with a concd aqueous KOH solution. After cooling, K_2SO_4



n=2(ten), 3(ttn), and 4(ttmd)



R,R- and *R,S*-tptn

† On leave from the Department of Chemistry, Yeung Nam University, Korea, 1979.

and potassium benzenesulfonate precipitated were filtered off and the precipitate was washed well with ethanol. The filtrate and washings were combined and evaporated under reduced pressure. From the residue the free ligand was extracted with ethanol and the extract was evaporated. This procedure was repeated until the oily ligand was free from potassium benzenesulfonate. All the ligands thus prepared were used for the preparation of complexes without distillation because of their high boiling points. However, all the ligands showed satisfactory ^{1}H NMR spectra in $CDCl_3$ and their metal complexes gave good analytical results.

Preparation of Complexes. *[Co(ten)]$Br_3\cdot 2H_2O$*: Emmenegger and Schwarzenbach[2] first prepared this complex by heating a mixture of ten and $[CoBr(NH_3)_5]Br_2$ over a flame. Yoshikawa *et al.*[7] obtained the complex by stirring an aqueous solution containing the same reactants with active charcoal at room temperature. In the present study, the complex was prepared from *trans*-$[CoCl_2py_4]Cl\cdot 6H_2O$ (py=pyridine)[8] and ten in methanol in the absence of active charcoal.

A methanol solution (50 cm^3) of ten (1 g, 4.3 mmol) was added to a methanol solution (200 cm^3) of *trans*-$[CoCl_2py_4]Cl\cdot 6H_2O$ (3 g, 5.1 mmol). The solution was stirred for several hours at room temperature and then the methanol was evaporated under reduced pressure. The residue was dissolved in 2 dm^3 of water and the pH of the solution was adjusted to *ca.* 3 with hydrochloric acid. This was poured on a column (ϕ5 cm$\times$40 cm) of SP-Sephadex C-25 resin and the product adsorbed was chromatographed with a 0.2 mol/dm^3 Na_2SO_4 solution. To the main red orange eluate was added an aqueous solution of $K_3[Co(CN)_6]$ (*ca.* 2 g). After 1 d, hardly soluble red orange crystals of [Co(ten)]-$[Co(CN)_6]$ formed were filtered, washed with cold water, and then mixed with Dowex 1$\times$8 resin in the bromide form in water in order to convert into bromide. The resin was filtered off and the filtrate was evaporated to *ca.* 3 cm^3 under reduced pressure. The concentrate was mixed with ethanol and stored in a refrigerator for several days to give red orange crystals which were filtered, washed with ethanol and then ether, and air dried.

[Co(ttn)]$Br_3\cdot H_2O$, *[Co(*RR*-tptn)]$Cl_3\cdot 2H_2O$*, *and [Co(*RS*-tptn)]$Cl_3\cdot 2H_2O$*: These complexes were obtained as orange, orange, and red crystals, respectively, by a method similar to that for the ten complex. The *RR*-tptn complex was crystallized by adding acetone instead of ethanol, since the complex is soluble in a mixture of ethanol and water.

[Co(ttmd)]$Br_3\cdot H_2O$: Since the complex contains a seven-membered chelate ring, the reaction was carried out in a dilute solution in order to avoid the formation of polynuclear complexes.[9]

Methanol solutions of *trans*-$[CoCl_2py_4]Cl\cdot 6H_2O$ (1 g in 500 cm^3) and ttmd (0.4 g in 500 cm^3) were simultaneously added to 500 cm^3 of methanol dropwise with stirring over a few hours at room temperature. The resulting solution was stirred for 1 d at room temperature. The methanol was evaporated to dryness under reduced pressure and the residue was dissolved in 2 dm^3 of water. The solution was adjusted to pH *ca.* 3 with hydrochloric acid and poured on a column (ϕ5$\times$40 cm) of SP-Sephadex C-25 resin. By elution with 0.25 mol/dm^3 Na_2SO_4, several bands were eluted from the column, a small amount of high charged species remaining on the top of the column. The red main eluate was rechromatographed by the same method after dilution with water. From the eluate, red crystals of [Co(ttmd)]-$[Co(CN)_6]$ were obtained and converted into bromide by the same method as that for the ten complex.

[Co(CN)(Hten)]$Br_3\cdot 2H_2O$: To a cold (*ca.* 4 °C) aqueous solution (100 cm^3) containing $[Co(ten)]Br_3\cdot 2H_2O$ (0.5 g) and KCN (0.07 g) was added a small amount of active charcoal and the mixture was allowed to stand at *ca.* 4 °C for 5 h with occasional shaking. The active charcoal was filtered off and the filtrate was diluted to 2 dm^3 with water. This was poured on a column (ϕ2.7$\times$60 cm) of SP-Sephadex C-25 resin. The column was thoroughly washed with water and the product adsorbed was eluted with a 0.2 mol/dm^3 Na_2SO_4 solution adjusted the pH to *ca.* 9 with Na_2CO_3. Three bands, yellow, orange, and red orange were eluted in succession, the second orange band being the largest amount. The first yellow and the third red orange bands were presumed from the absorption spectra to involve a dicyano and the starting complexes, respectively. The second orange eluate was diluted ten times with water and the solution was poured again on a small column (ϕ2.7$\times$5 cm) of SP-Sephadex C-25 resin. After the column had been washed with 0.01 mol/dm^3 hydrobromic acid in order to remove Na^+ ions, the complex was eluted with 2 mol/dm^3 hydrobromic acid. The eluate was mixed with acetone and allowed to stand for several days at room temperature to give orange crystals of $[Co(CN)(Hten)]Br_3\cdot 2H_2O$.

[Co(CN)(Httn)]$Br_3\cdot nH_2O$: An aqueous solution (150 cm^3) containing $[Co(ttn)]Br_3\cdot H_2O$ (0.95 g), KCN (0.13 g), and a small amount of active charcoal was stored in a refrigerator (*ca.* 4 °C) for 3 d with occasional shaking. After filtering off the active charcoal, the filtrate was diluted with water to 3 dm^3 and the solution was poured on a column (ϕ2.7$\times$120 cm) of SP-Sephadex C-25 resin. The column was washed with water and the product adsorbed was then eluted with a 0.2 mol/dm^3 Na_2SO_4 solution adjusted the pH to *ca.* 3 with hydrochloric acid. Three orange bands, I, II, and III were eluted in succession. Band I was found to be contaminated with a small amount of the starting complex, so that the eluate was rechromatographed by use of a 0.2 mol/dm^3 Na_2SO_4 solution adjusted the pH to *ca.* 9 with Na_2CO_3 as an eluent, the starting complex being eluted much slower. From bands I and III, orange crystals of $[Co(CN)(Httn)]Br_3\cdot H_2O$ (A) and $[Co(CN)(Httn)]Br_3\cdot 2H_2O$ (B) were obtained, respectively, by the same method as that for the corresponding ten complex. The amount of band II was too small to isolate the complex.

No reaction took place between *[Co(*RR*-tptn)]$Cl_3\cdot 2H_2O$* and KCN even at a higher temperature. Reactions of *[Co(*RS*-tptn)]$Cl_3\cdot 2H_2O$* or $[Co(ttmd)]Br_3\cdot H_2O$ with KCN resulted in decomposition of the complexes to yield cobalt(II) species and other unknown complexes, no mono cyano complexes being found in both reaction products.

Optical Resolution. The $[Co(ttn)]^{3+}$, $[Co(ttmd)]^{3+}$, and *[Co(*RS*-tptn)]$^{3+}$* complexes were resolved by the same SP-Sephadex column chromatographic method as that for $[Co(ten)]^{3+}$ reported by Yoshikawa *et al.*[7]

By elution with 0.2 mol/dm^3 sodium $(+)_{589}$-tartratoantimonate(III), each of $[Co(ten)]^{3+}$, $[Co(ttmd)]^{3+}$, and *[Co(*RS*-tptn)]$^{3+}$* was completely resolved giving two well separated bands of enantiomers. In the case of $[Co(ttn)]^{3+}$, however, the separation of bands was poor, so that the eluate was fractionated into 10 cm^3 and optical purity of each fraction was examined by taking a ratio of CD strength to optical density at 505 nm, the fractions with the ratio of a constant value being collected. The enantiomers eluted faster are $(-)_{589}$-$[Co(ten)]^{3+}$, $(+)_{589}$-$[Co(ttn)]^{3+}$, $(-)_{589}$-$[Co(ttmd)]^{3+}$, and $(-)_{589}$-*[Co(*RS*-tptn)]$^{3+}$*. For each complex, the optically pure fractions were collected, diluted about ten times with water, and poured on a small column of SP-Sephadex C-25 resin. After washing the column with 0.01 mol/dm^3 hydrochloric acid, the complex was eluted with

TABLE 1. ANALYTICAL DATA OF THE NEW COMPLEXES

ten = $C_{10}H_{28}N_6$, ttn = $C_{11}H_{30}N_6$, ttmd = $C_{12}H_{32}N_6$, tptn = $C_{13}H_{34}N_6$.

2 mol/dm³ hydrochloric acid and the eluate was used for the measurement of CD spectra. The optically active complexes were not isolated because of small amounts. The $\Delta\varepsilon$ values were determined with the aid of ε values of the racemates.

Analytical data of the new complexes are given in Table 1.

Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40 CS spectropolarimeter, respectively. ^1H NMR (D_2O, TMS) and ^{13}C NMR (D_2O, dioxane) were obtained with a JEOL JNM-PMX 60 and a JEOL FX-100 spectrometer, respectively.

Results and Discussion

Absorption Spectra. The ten, ttn, and ttmd Complexes: The $[Co(ten)]^{3+}$, $[Co(ttn)]^{3+}$, and $[Co(ttmd)]^{3+}$ complexes contain a five-, six-, and seven-membered chelate ring, respectively, for the central ditertiary diamine chelate ring. In general, the first absorption band of a tris(diamine)cobalt(III) complex is shifted to smaller wavenumbers as the number of ring members increases. For example, $[Co(en)_3]^{3+}$, $[Co(tn)_3]^{3+}$, and $[Co(tmd)_3]^{3+}$ give the first absorption band at 21400, 20400, and 19900 cm^{-1}, respectively.[10] However, those of the ten-type complexes are shifted to smaller wavenumbers in the order of $[Co(ttn)]^{3+}$, $[Co(ten)]^{3+}$, and $[Co(ttmd)]^{3+}$, the order of the first two complexes being opposite to that expected from the tris(diamine) complexes (Table 2 and Fig. 1). Emmenegger and Schwarzenbach[2] first found the red shift of the first absorption band for $[Co(ten)]^{3+}$ from a comparison with $[Co(NH_3)_6]^{3+}$ (21000 cm^{-1}) and attributed it to a strained structure of the complex ion. The strained structure was confirmed by the X-ray structure analysis on $(+)_{589}$-$[Co(ten)][Co(CN)_6] \cdot 2H_2O$;[3] the six nitrogen donor atoms forms a distorted octahedron, the N–Co–N angles (83.3—102.2°) largely deviating from that of the regular octahedron (90°), and the distortion of the two chelate rings linked meridionally with the central ethylenediamine chelate ring is particularly noticeable. Such a distortion might weaken the ligand field strength to cause the red shift of the first absorption band in $[Co(ten)]^{3+}$. The strain or distortion in $[Co(ttn)]^{3+}$ would be much reduced as compared with that in $[Co(ten)]^{3+}$, since $[Co(ttn)]^{3+}$ containing a six-membered chelate ring gives the first absorption band at a higher wavenumber than that of $[Co(ten)]^{3+}$.

Dreiding molecular models clearly indicate that $[Co(ttn)]^{3+}$ is much less strained than $[Co(ten)]^{3+}$. In the model of $[Co(ten)]^{3+}$, considerable strains are involved in the three five-membered chelate rings fused in a plane with the cobalt(III) ion as confirmed

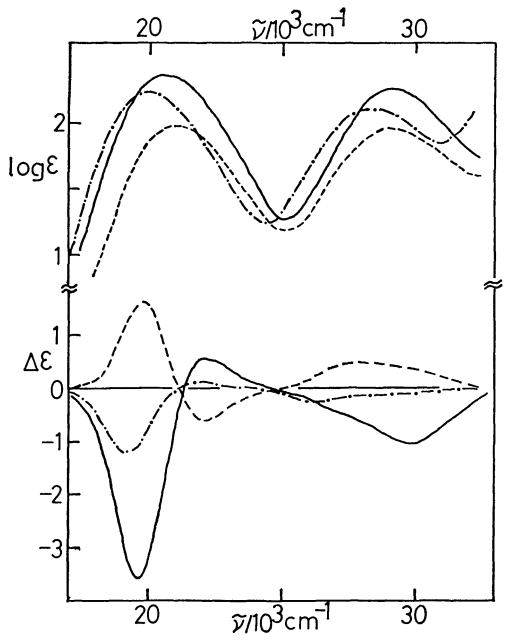

Fig. 1. Absorption and CD spectra of $(-)_{589}$-[Co(ten)]$^{3+}$ (——), $(+)_{589}$-[Co(ttn)]$^{3+}$ (– – –), and $(-)_{589}$-[Co(ttmd)]$^{3+}$ (—·—).

by the X-ray structure analysis. For [Co(ttn)]$^{3+}$, however, neither the corresponding five-six-five-membered chelate rings nor the other chelate rings appear to involve remarkable strain. Thus it is presumed that the reverse order in the first absorption maxima of the two complexes is caused by the strained structure of [Co(ten)]$^{3+}$. On the other hand, [Co(ttmd)]$^{3+}$ shows the first absorption band at the smallest wavenumbers among the three complexes. A molecular model indicates that this complex ion involves no remarkable strain for the skeleton of all the chelate rings, but forms a very crowded structure, some methylene protons coming very close to one another. A crowded complex would expand the molecular volume in order to reduce non-bonded interactions among atoms. The expansion might lengthen the metal-ligand distances to weaken the ligand field strength. In fact, the Co–N distances of [Co(en)$_3$]$^{3+}$,[11] [Co(tn)$_3$]$^{3+}$,[12] and [Co(tmd)$_3$]$^{3+}$ [13] are 1.959—1.979, 1.966—1.999, and 1.986—2.000 Å, respectively, and with an increase in the Co–N distance the absorption maxima are shifted to smaller wavenumbers (*vide infra*).

In contrast with the first absorption band, the second absorption bands are in the usual order of [Co(ten)]$^{3+}$, [Co(ttn)]$^{3+}$, and [Co(ttmd)]$^{3+}$. Accordingly, the energy difference between the first and the second bands becomes larger in [Co(ten)]$^{3+}$ (8700 cm^{-1}) than in [Co(ttn)]$^{3+}$ (8000 cm^{-1}). For a low-spin, octahedral cobalt(III) complex, the energy difference between the first ($^1T_{1g} \leftarrow {}^1A_{1g}$, 10Dq−C) and the second ($^1T_{2g} \leftarrow {}^1A_{1g}$, 10Dq+16B−C) absorption bands is expressed by 16B, where Dq is the parameter of ligand field strength and B and C those of Racah of interelectronic repulsion.[14] The B value is known to be a measure for representing covalent character of the bond between a ligand and a metal ion, the smaller the value the more the covalent character.[15] The B values for the ten and ttn complexes are 544 and 500 cm^{-1}, respectively. Since the values for a series of complexes, [Co(en)$_x$(tn)$_y$(tmd)$_z$]$^{3+}$ [10] are almost constant, 500—506 cm^{-1}, the value of 544 cm^{-1} for [Co(ten)]$^{3+}$ appears to be fairly large and to have relations with the strained structure. Donor atoms in a strained complex would deviate from the regular octahedral coordination sites. The deviation might cause misalignment of the lone-pair orbital of the donor atom to orbitals of the metal ion to decrease the overlap of orbitals between them. The decrease in overlap, or the decrease in covalent character would correspond to an increase in the B value. The [Co(ttmd)]$^{3+}$ complex shows the B value of 519 cm^{-1}. This value indicates that the complex is not so strained as [Co(ten)]$^{3+}$ as the molecular model suggested.

The strain in [Co(ten)]$^{3+}$ would be reduced by forming a quinquidentate complex, [Co(X)(Hten)]$^{n+}$ (X=unidentate ligand), liberating one chelate ring. Emmenegger and Schwarzenbach[2] prepared such complexes with various unidentate ligands. In this study, [Co(CN)(Hten)]$^{3+}$ was newly prepared, since the ttn ligand gave a quinquidentate complex only with a cyanide ion. Although quinquidentate complexes of ten and ttn have two and three possible geometrical isomers, respectively, the cyanide complexes obtained are one and two isomers for ten and ttn, respectively. The structures of the isomers could not be assigned. The structurally related [Co(X)(Hedta)]$^{n-}$ complexes always give only one isomer in which the X ligand occupies the coordination site meridional to the nitrogen atoms of ethylenediamine.[16,17] No corresponding 1,3-propanediaminetetraacetato complex is known, but similar triacetato complexes with H_2O or Cl^- give all of the possible three isomers.[18] In the present quinquidentate complexes, the first absorption band of [Co(CN)(Hten)]$^{3+}$ is observed at a higher wavenumber than those of either isomer of [Co(CN)(Httn)]$^{3+}$ (Table 2 and Fig. 2). The result supports that [Co(ten)]$^{3+}$ is strained and the strain is reduced to a great extent by releasing one chelate ring from the coordination sphere. The ttmd complex gave no monocyano complex.

Reactivity of the sexidentate complexes toward strong bases such as OH^- or CN^- seems to be related with the stability of these complexes expected from the maximum wavenumbers of the first absorption bands. The [Co(ten)]$^{3+}$ complex readily reacts with OH^- [2] or CN^- to yield quinquidentate complexes, opening

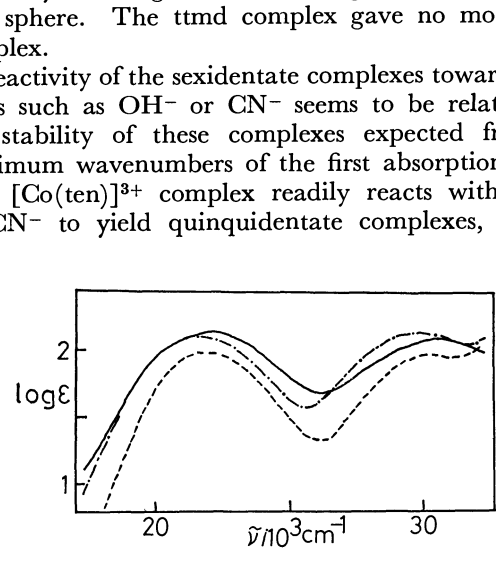

Fig. 2. Absorption spectra of [Co(CN)(Hten)]$^{3+}$ (——), and the two isomers of [Co(CN)(Httn)]$^{3+}$, (A) (– – –) and (B) (—·—).

one chelate ring. The $[Co(ttn)]^{3+}$ complex also gives the mono cyano complex, but the reaction is rather slow as compared with the case of $[Co(ten)]^{3+}$ (Experimental). The ttn complex does not react with OH^-. The $[Co(ttmd)]^{3+}$ complex affords no quinquidentate complex by the reaction with CN^- or OH^-, but gives cobalt(II) species and a small amount of unknown cobalt(III) complexes.

The RR- *and* RS-*tptn Complexes*: The two methyl groups in each *RR*(or *SS*)- and *RS*-ptn chelate ring become equatorial in a λ(or δ)-skew and a chair conformation, respectively.[19] The skeletons of *RR*- and *RS*-tptn ligands in sexidentate complexes should be similar to that of ttn in $[Co(ttn)]^{3+}$, the conformation of the six-membered 1,3-diamine part being in a skew form. When this part forms a chair conformation, both *RR*- and *RS*-tptn ligands can not act as a sexidentate in an octahedral complex. Accordingly, one methyl group in the sexidentate $[Co(RS\text{-tptn})]^{3+}$ complex adopts necessarily an axial disposition. The axial methyl group comes very close to one of the two five-membered chelate rings apical to the six-membered ring and hence $[Co(RS\text{-tptn})]^{3+}$ would be less stable than $[Co(RR\text{-tptn})]^{3+}$. The structurally related ligands, (*R*,*R*(or *S*,*S*))- and (*R*,*S*)-2,4-pentanediaminetetraacetate (ptnta) form stereoselectively Δ(or Λ)-[Co(*RR*(or *SS*)-ptnta)]$^-$ and [Co(Cl)(*RS*-Hptnta)]$^-$, respectively.[20] The *RS*-ptnta in the latter complex functions as a quinquidentate, leaving a free acetate branch, and the six-membered chelate ring forms a chair conformation with two methyl groups disposed equatorially. This indicates that ptnta is not a so strong ligand as it forms a sexidentate complex by overcoming the unstabilization caused by the axial methyl group.

The orange $[Co(RR\text{-tptn})]^{3+}$ and red $[Co(RS\text{-tptn})]^{3+}$ complexes show the first absorption band at 20800 and 20000 cm^{-1}, respectively (Table 2 and Fig. 3). While the maximum wavenumber of the former is nearly the same as that of $[Co(ttn)]^{3+}$, the wavenumber of the latter is as small as that of the crowded $[Co(ttmd)]^{3+}$ complex. Both tptn complexes lose the water of crystallization by heating *in vacuo* without the change of color. Absorption spectra of the complexes do not depend on pH of the solutions. ^{13}C NMR spectra (100 MHz) of the *RR*- and *RS*-tptn complexes in D_2O solutions exhibit seven and twelve (one strong peak due to accidental degeneracy) signals in accordance with the symmetry argument. All the facts lead to the conclusion that both *RR*- and *RS*-tptn ligands act as a sexidentate in the complexes. Thus the red shift of the first absorption band in $[Co(RS\text{-tptn})]^{3+}$ can be attributed to the crowded structure due to the presence of the axial methyl group. On the other hand, the B value (506 cm^{-1}) of this complex is nearly the same as those of $[Co(RR\text{-tptn})]^{3+}$ (493 cm^{-1}) and $[Co(ttn)]^{3+}$ (500 cm^{-1}). This suggests that the red $[Co(RS\text{-tptn})]^{3+}$ complex is not distorted like $[Co(ten)]^{3+}$ and the red shift of the first absorption band is caused by the crowded structure as described for $[Co(ttmd)]^{3+}$. A complex which contains an axial methyl group is known for Λ-β-[Co(ox)(*R*,*R*-2,3″,2-tet)]$^+$ (ox=oxalate ion, *R*,*R*-2,3″,2-tet=(4*R*,6*R*)-4,6-dimethyl-3,7-diazanonane-1,9-diamine), in which the central six-membered chelate ring adopts a chair conformation with one methyl group axial and the other equatorial.[21] This complex, however, shows the first absorption band (19800 cm^{-1}) at a little smaller wavenumber than that of the corresponding *R*,*S*-2,3″,2-tet complex (19920 cm^{-1}), in which the six-membered chelate ring is also in a chair form, but both methyl groups are disposed equatorially.[22] For the *RR*- and *RS*-tptn complexes which contain a skew six-membered chelate ring, the wavenumber difference in the first absorption bands amounts to 800 cm^{-1}.

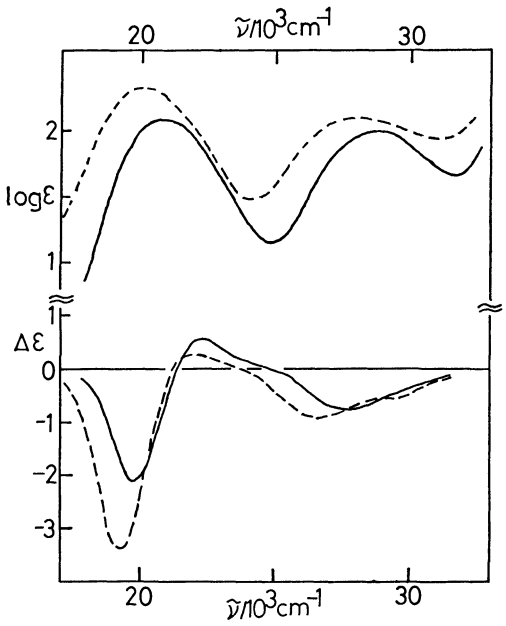

Fig. 3. Absorption and CD spectra of $(-)_{589}$-[Co(*RR*-tptn)]$^{3+}$ (——) and $(-)_{589}$-[Co(*RS*-tptn)]$^{3+}$ (– – –).

Circular Dichroism Spectra. The CD spectra of $(-)_{589}$-$[Co(ten)]^{3+}$, $(+)_{589}$-$[Co(ttn)]^{3+}$, and $(-)_{589}$-$[Co(ttmd)]^{3+}$, all of which were enantiomers eluted faster by SP-Sephadex column chromatography, are compared in Fig. 1. The absolute configuration of $(+)_{589}$-$[Co(ten)]^{3+}$ has been determined by the X-ray method to be Λ.[3] On the basis of the CD pattern in the region of the first absorption band of $(-)_{589}$-Λ-$[Co(ten)]^{3+}$, $(+)_{589}$-$[Co(ttn)]^{3+}$ and $(-)_{589}$-$[Co(ttmd)]^{3+}$ can be assigned to the Λ and Δ configurations, respectively. The strengths of main CD bands in this region decrease with an increase in ring members of the central chelate ring. In the Λ-$[Co(en)_x(tn)_y(tmd)_z]^{3+}$ complexes, the positive CD bands reduce the strength remarkably with an increase in the ring members, the main CD band of Λ-$[Co(tmd)_3]^{3+}$ showing strong negative.[10] The spectral changes in CD among the ten-type complexes appear to be the same case. The CD spectra in the other region are rather complicated and no discussion can be made.

The CD spectra of $(-)_{589}$-$[Co(RR\text{-tptn})]^{3+}$ and $(-)_{589}$-$[Co(RS\text{-tptn})]^{3+}$ are shown in Fig. 3. The $[Co(RR\text{-tptn})]^{3+}$ complex should have the Λ configuration stereoselectively owing to the equatorial preference of the methyl groups.[20] The CD spectrum of

this complex is almost the mirror image of that of $(+)_{589}$-[Co(ttn)]$^{3+}$ in Fig. 1. The result supports the previous assignment for Λ-$(+)_{589}$-[Co(ttn)]$^{3+}$. The $(-)_{589}$-[Co(*RS*-tptn)]$^{3+}$ complex which was eluted faster in column chromatography shows a CD spectral pattern similar to that of $(-)_{589}$-Δ-[Co(*RR*-tptn)]$^{3+}$, indicating the same Δ configuration. The similarlity also supports that the *RS*-tptn ligand acts as a sexidentate in the complex. In the first absorption band, both CD strength and absorption intensity of the *RS*-tptn complex are stronger than those of the *RR*-tptn complex and the values of the dissymmetry factor g ($\Delta\varepsilon/\varepsilon$) are nearly the same (*ca.* 0.017). A similar, but smaller difference is seen in the CD and absorption spectra between Λ-β-[Co(ox)(*R*,*R*-2,3″,2-tet)]$^{+}$ and -[Co(ox)(*R*,*S*-2,3″,2-tet)]$^{+}$.[22] The presence of an axial methyl group in a complex seems to cause the red shift and the hyperchromic effect on the absorption and CD spectra.

The authors wish to thank Dr. T. Ito of Institute for Molecular Science for obtaining ^{13}C NMR spectra. This work was partially supported by Grant-in-Aid for Scientific Research No. 243013 from the Ministry of Education, Science and Culture.

On Some Mixed Chelates of Nickel(II) Which Are Highly Volatile, Fusible, and Soluble in Nonpolar Solvents

Yoko Saito, Toshio Takeuchi,** Yutaka Fukuda, and Kozo Sone*

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

***Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102*

(Received July 30, 1980)

It was found that the mixed chelates of nickel(II) with the general formula [Ni(diam)(β-dik)$_2$], where diam means an *N,N*- or *N,N'*-alkylated ethylenediamine and β-dik a β-diketonate anion, are highly volatile, fusible, and often amazingly soluble in nonpolar solvents like CCl_4, benzene, or heptane. Representative data on these properties are presented and their correlations with the structures of the ligands are discussed.

It is very well known that metallic acetylacetonates, and other β-diketonates like hexafluoroacetylacetonates and dipivaloylmethanates, are remarkably volatile, and soluble in a number of organic solvents. These properties have often been applied to the separation of metals by means of gas chromatography and extraction techniques.[1-4]

Recently, Hoshino *et al.* found that a mixed chelate of nickel(II) containing acetylacetonate anion, [Ni tmen (acac)$_2$],*** is highly volatile and can be sublimed at *ca.* 60 °C in a vacuum, when it is formed by the thermal disproportionation of the chelates Ni tmen acac X·nH$_2$O (X=halide ions).[5,6] This interesting observation lead us to a comparative study of the volatilities, melting points, and solubilities of this and related chelates to be reported here.

Experimental

All the chelates studied were prepared according to the literatures,[7-9] sometimes with certain modifications, and their identities were checked by elemental analyses. TG-DTA measurements on them were performed with a Rigaku Denki M8075 instrument in static air (heating rate 5 °C/min, sample weight *ca.* 9 mg, standard:Al_2O_3). Spectral measurements of their solutions in CCl_4, benzene, or heptane (all "Extra Pure") were made with a Hitachi 340 Recording Spectrophotometer from 7 to 25 kK (1 kK=1000 cm^{-1}), using 1 cm quartz cells at room temperature (*ca.* 20 °C).

Results

The chelates prepared are shown in Table 2. As reported formerly,[7-9] the mixed chelates I—XI are all blue to green crystals, and are typical 6-coordinate high-spin nickel(II) complexes.

Melting Points and Volatilities. The TG-DTA data of the mixed chelates studied are classified into three patterns A,B, and C (*cf.* Fig. 1). In the case of A, a sharp endothermic peak is observed on the DTA curve. The fact that this peak corresponds to the melting point of the chelate can be confirmed by visual observation. The chelate then begins to evaporate at a somewhat higher temperature(t_i), where a remarkable drop of the TG curve and a broad endothermic peak on the DTA begins to appear. In some cases t_i is lower than mp, that is, the evaporation begins to occur already in advance of melting.

Nearly quantitative evaporation takes place with some chelates; in such case, the ratio of the final weight (w_f) to the initial weight (w_i) of the chelate, w_f/w_i, is nearly zero. In many cases, however, decomposition of the chelates seems to occur at a later stage of evaporation and the sample remaining in the crucible is converted into a black nonvolatile residue, making the ratio w_f/w_i much higher.

The pattern B is observed when the chelate has water of crystallization. Here two peaks appear on the DTA curve, one corresponding to the dehydration temperature (t_d), and the other to the mp. The TG curve also decreases in two steps, the first of which indicates the quantitative loss of water in the formula.

The pattern C also show two DTA peaks, but here the chelate is anhydrous, and the first peak probably indicates some kind of solid phase transition, which takes place in advance of melting. This temperature is designated as t_t.

All these data are summarized in Table 2, together with those of the simple acetylacetonates of nickel (II) and copper(II).

The volatilities of these chelates can now be studied by taking the temperature at which 25% of the weight of a chelate is lost by evaporation ($t_{1/4}$; *cf.* Table 2),

Table 2. TG-DTA data of the mixed chelates, $Ni(acac)_2$ and $Cu(acac)_2$
As to the meaning of t_i, t_f *etc.*, *cf.* text and Fig. 1.

	Chelate	Pattern	Mp	t_i	t_f	t_d	t_t	w_f/w_i	$t_{1/4}$
I	Ni(teen)(acac)$_2$	A	90	95	322			0.43	180
II	Ni(Et$_3$en)(acac)$_2$·H$_2$O	B	59	112	236	45		0.38	187
III	Ni(*sym*-deen)(acac)$_2$·H$_2$O	B	78	108	216	74		0.21	184
IV	Ni(*unsym*-deen)(acac)$_2$·H$_2$O	B [a]	151	137	216	72, 119		0.65	202
V	Ni(tmen)(acac)$_2$	A	97	114	208			0.067	170
VI	Ni(Me$_3$en)(acac)$_2$·H$_2$O	B	100	104	230	48, 59[c]		0.17	173
VII	Ni(*sym*-dmen)(acac)$_2$·H$_2$O	B	134	118	255	82, 104[c]		0.24	186
VIII	Ni(*unsym*-dmen)(acac)$_2$	A	187	135	230			0.37	204
IX	Ni(tmen)(hfa)$_2$	C	130	80	185		102	0.018	153
X	Ni(tmen)(tfa)$_2$	A	81	114	199			0.013	163
XI	Ni(tmen)(dpm)$_2$	A	162	148	264			0.017	221
	Ni(acac)$_2$	[b]		224	338			0.72	315
	Cu(acac)$_2$	[b]		178	260			0.043	228

a) The DTA curve of this chelate was anomalous, and showed one more strong peak of unknown nature at 157 °C, *i.e.*, just above the mp. This may be related to the high value of w_f/w_i, *i.e.*, the remarkable tendency for thermal decomposition of this chelate. b) Simple sublimation without melting; with Ni(acac)$_2$, much decomposition took place along with it. c) These double peaks may be an indication for stepwise dehydration, *e.g.* by way of hemihydrate formation.

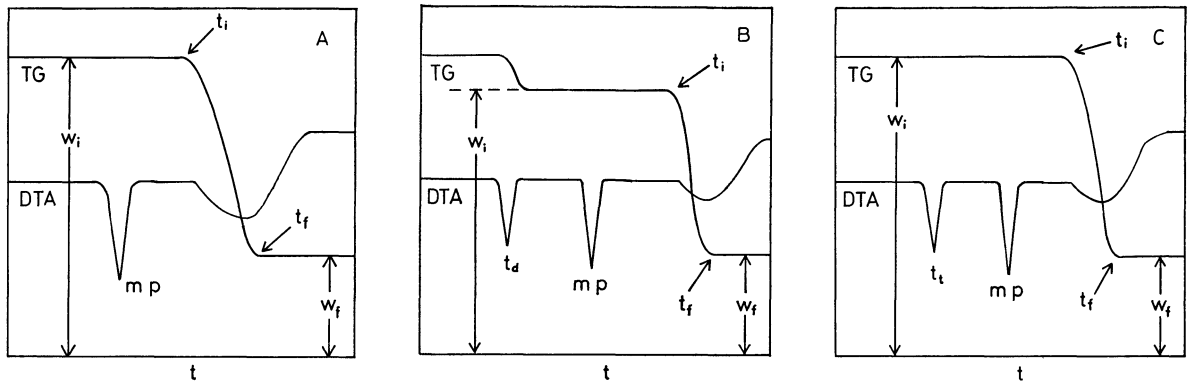

Fig. 1. Typical patterns of the TG-DTA curves (schematic).

and comparing it with those of other chelates.**** The following general trends can be deduced in this way.

1) All the mixed chelates are readily fusible, with melting points which are sometimes much lower than 100 °C. They are also highly volatile, even in static air of 1 atm pressure. In contrast to these observations, the simple acetylacetonates Ni(acac)$_2$ and Cu(acac)$_2$ do not melt by heating, and they are much less volatile (in the case of Ni(acac)$_2$, much part of it is thermally decomposed before sublimation) under the same conditions.

2) Among the mixed chelates with acac and methylated diamines, the volatility increases in the following order of diamines:

$$\text{tmen} \gtrsim \text{Me}_3\text{en} > \textit{sym}\text{-dmen} > \textit{unsym}\text{-dmen}. \quad (1)$$

3) Among the mixed chelates with acac and ethylated diamines, the volatility increases in the following order of diamines:

$$\text{teen} > \text{Et}_3\text{en} \lesssim \textit{sym}\text{-deen} > \textit{unsym}\text{-deen}. \quad (2)$$

4) The volatilities of the *unsym*-dmen and *unsym*-deen chelates are comparable, but among other mixed chelates with acac, those of methylated diamines are slightly more volatile than those of ethylated diamines.

5) Among the mixed chelates containing tmen and various β-diketonate anions, the volatility increases in the following order of β-diketonates:

$$\text{hfa} > \text{tfa} > \text{acac} \gg \text{dpm}.$$

The plot of $t_{1/4}$ in Fig. 2 illustrates these trends.

Solubilities in Nonpolar Solvents. The high volatilities and fusibilities of chelates clearly show that the intermolecular forces acting in their crystals are quite weak. Thus we can expect that they will be soluble in nonpolar solvents. The measurements of their solubilities in C_6H_6, CCl_4, and heptane, which were carried out spectrophotometrically, confirmed this expectation.

From the data in Table 3, we can deduce the following trends:

****Nearly the same trends are observed when we take the temperature at which 5 or 10% of the weight is lost; at these earlier stages of evaporation, the effect of thermal decomposition thus seems to be negligible. The identity of the sublimed chelates with the original ones was also confirmed by their visible and IR spectra.

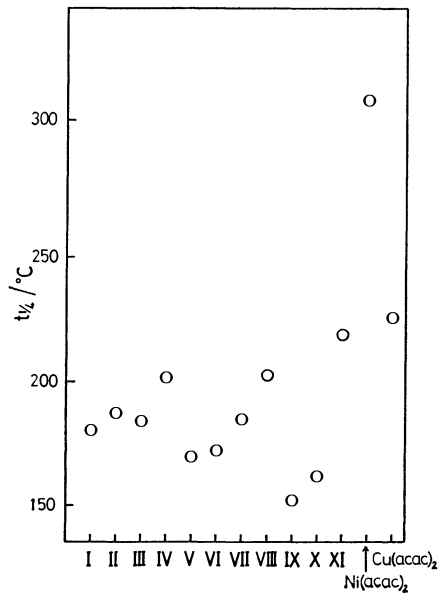

Fig. 2. $t_{1/4}$ values of the chelates. I—XI are those for the mixed chelates (*cf.* Table 2).

Table 3. Solubilities (10^{-2} mol/dm^3, 20 °C) of the mixed chelates, Ni(acac)$_2$ and Cu(acac)$_2$

Chelate	C_6H_6	CCl_4	Heptane
Ni(teen)(acac)$_2$	100	140	55
Ni(Et$_3$en)(acac)$_2$·H_2O	46	65	16
Ni(*sym*-deen)(acac)$_2$·H_2O	13	7.6	0.30
Ni(*unsym*-deen)(acac)$_2$·H_2O	16	7.3	0.30
Ni(tmen)(acac)$_2$	140	100	60
Ni(Me$_3$en)(acac)$_2$·H_2O	130	77	13
Ni(*sym*-dmen)(acac)$_2$·H_2O	33	22	0.60
Ni(*unsym*-dmen)(acac)$_2$	14	14	0.23
Ni(tmen)(hfa)$_2$	39	5.0	1.4
Ni(tmen)(tfa)$_2$	130	64	13
Ni(tmen)(dpm)$_2$	43	28	29
Ni(acac)$_2$	0.97	a)	a)
Cu(acac)$_2$[b]	0.32	—	0.025

a) Too insoluble to measure. b) Taken from Ref. 10.

1) The mixed chelates studied are all highly soluble in typically nonpolar solvents. For example, the solubility of [Ni(*unsym*-dmen)(acac)$_2$] in heptane is 48 g/dm^3, and that of [Ni(tmen)(acac)$_2$] in the same solvent is 220 g/dm^3 (in CCl_4 it is still higher, being 370 g/dm^3!). These figures are very much higher than those of Ni(acac)$_2$ and Cu(acac)$_2$.

2) Among the mixed chelates with acac, there are certain relations between the volatilities and solubilities. For example, in CCl_4 and heptane, the solubility increases with the number of alkyl groups in both the methylated and ethylated diamine series. However, the relation among the chelates with different β-diketonate anions is not clear as yet.

Discussion

All the data obtained show that the intermolecular forces acting among the mixed chelate molecules in crystal are very much weaker than those acting in the crystals of simple acetylacetonates of Ni(II) and Cu(II). This is evidently the consequence of structural differences; it is known that the crystals of Ni(acac)$_2$ is composed of complicated trimeric molecules, and those of Cu(acac)$_2$ contain planar monomeric molecules, in which Cu^{2+} and polar ligand groups are exposed to outer influence.[11,12] Thus we can imagine that a lot of energy is needed to sublime them, or to dissolve them in solvents with nearly no solvating power, because the intermolecular forces in them will be relatively high, and, in the case of Ni(acac)$_2$, energy will also be needed to dissociate the trimer into monomeric gaseous molecules.†

On the other hand, all the mixed chelates studied here are monomeric octahedral, and their polar groups are buried deep under a large number of protruding alkyl (or fluoroalkyl) groups, so that the intermolecular forces acting in them will be essentially weaker than those in Ni(acac)$_2$ or Cu(acac)$_2$. It will be especially weak when the number of alkyl groups on the diamine is large†† (*cf.* the order (1) and (2) mentioned above); however, when their size is too large, the increase of van der Waals force will make the chelate slightly less volatile (*cf.* the $t_{1/4}$ values of the methylated and ethylated complexes). The same effect may be responsible for the lower volatility of the dpm chelate. The higher volatilities of the tfa and hfa chelates are probably due to the partial negative charge on their fluorine atoms, which act to decrease the intermolecular attraction; similar increase in volatility in going from acac to tfa and hfa is already well known among their simple chelates.[1,2]

Our results thus clearly show that the volatility, fusibility, and solubility in nonpolar solvents of a chelate can be drastically augmented by mixed chelate formation with ligands containing bulky groups.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 347033 from the Ministry of Education, Science and Culture.

Kinetic and Equilibrium Studies on the Esterification of Monomeric and μ-Oxo Dimeric Vanadium(V) Complexes with Butyl Alcohols in Chlorobenzene

Akio YUCHI, Yumi YAGISHITA, Shinkichi YAMADA, and Motoharu TANAKA*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received August 27, 1980)

Kinetic and equilibrium studies were made on the esterification of the μ-oxo dimeric vanadium(V) complexes with monoanionic bidentate ligands(HL) such as 8-quinolinol, 5-chloro-8-quinolinol, 5,7-dibromo-8-quinolinol, and 4-isopropyltropolone by butyl alcohols (ROH) in chlorobenzene. The stoichiometry and the rate equation are expressed as follows:

$$V_2O_3L_4 + 2ROH \rightleftharpoons 2VO(OR)L_2 + H_2O : K_{DE};$$

$$-\frac{d[V_2O_3L_4]}{dt} = \frac{1}{2} \times \frac{d[VO(OR)L_2]}{dt} = (k_1 + k_2[H_2O])[V_2O_3L_4][ROH].$$

The more basic the bound ligand L^-, the lower the water-independent rate constant k_1 is. For less sterically crowded alcohols, k_1 is higher, giving the reactivity order: $n->i->s->t-$. Water, presumably hydrogen bonded to the terminal oxo group of the complexes, *accelerates* the esterification(k_2 path). The equilibrium constant K_{DE} is linearly correlated with the rate constant k_1. The esterification kinetics of the monomeric complex with 2-methyl-8-quinolinol(HL'), which corresponds to the proposed reactive intermediate in the esterification of the μ-oxo dimeric complexes, is also investigated and found the rate equation to be expressed as

$$-\frac{d[VO(OH)L'_2]}{dt} = \frac{d[VO(OR)L'_2]}{dt} = k_{M,1}[VO(OH)L'_2][ROH].$$

$k_{M,1}$ is 5 times higher than the estimated for the corresponding dimeric complex. Large negative values of ΔS_1^* and $\Delta S_{M,1}^*$ point to an associative nucleophilic attack of alcohol to the vanadium center of both dimeric and monomeric complexes. The difference of the reactivity of complexes and alcohols and the detailed mechanism will be discussed.

With 8-quinolinol(HQ) vanadium(V) forms a *black* water-insoluble complex in weakly acidic media.[1-3] The black solution of this complex dissolved in organic solvents gives rise to a *red* coloration in the presence of alcohols(ROH). This reaction, first ascribed to *cis-trans* isomerization of the complex,[4] was found to be the esterification of the complex with alcohols to give their esters, $VO(OR)Q_2$,[5,6] and has been utilized for the detection and photometric determination of alcohols.[7-14] On the other hand extensive studies on the black complex have given an erroneous composition of $VO(OH)Q_2$.[15-18] Alcohols have been believed to react with this monomeric complex according to the following reaction: $VO(OH)Q_2 + ROH \rightleftharpoons VO(OR)Q_2 + H_2O$.[6,19-22]

Recently we have revealed this black complex to be the oxo-bridged dimer, VOQ_2–O–VOQ_2.[23-25] The crystal structure of the ester has been established by X-ray crystallographic study.[26] Thus the reaction of this dimeric complex with alcohols comes to the stage to be reexamined. In the present paper the esterification of the oxo-bridged dimeric vanadium(V) complexes with 8-quinolinol, 5-chloro-8-quinolinol(H5-Cl-Q), 5,7-dibromo-8-quinolinol (H5,7-Br_2-Q), and 4-isopropyltropolone(H4-Pr-T) by butyl alcohols is investigated from the kinetic and the thermodynamic points of view. The results are compared with the esterification of the *yellow* monomeric complex with 2-methyl-8-quinolinol(H2-Me-Q), $VO(OH)(2\text{-Me-Q})_2$.

Experimental

Materials. All the butyl alcohols were refluxed over freshly ignited calcium oxide, and then with magnesium turnings, and finally distilled. 5-Chloro-8-quinolinol and 5,7-dibromo-8-quinolinol were recrystallized twice from ethanol and acetone, respectively. Chlorobenzene, 8-quinolinol, 4-isopropyltropolone, 2-methyl-8-quinolinol, and ammonium metavanadate were purified as described previously.[23-25]

Vanadium(V) complexes with 8-quinolinol, $V_2O_3Q_4$,[5,6] with 4-isopropyltropolone, $V_2O_3(4\text{-Pr-T})_4$,[25] and with 2-methyl-8-quinolinol, $VO(OH)(2\text{-Me-Q})_2 \cdot 2H_2O$[15] were prepared as described elsewhere. Other complexes with 5-chloro-8-quinolinol, $V_2O_3(5\text{-Cl-Q})_4$, and with 5,7-dibromo-8-quinolinol, $V_2O_3(5,7\text{-}Br_2\text{-Q})_4$ were prepared by mixing dioxovanadium(V) perchlorate solution with the corresponding ligand dissolved in perchloric acid solution and adjusting pH to 4 with ammonia. Found: C, 31.8; H, 1.1; N, 4.2%. Calcd for $V_2C_{36}H_{16}N_4O_7Br_8$: C, 31.85; H, 1.19; N, 4.13%. Found: C, 49.6; H, 2.4; N, 7.3%. Calcd for $V_2C_{36}H_{20}$-

Table 1. Summary of the properties of vanadium(V) complexes

Complex	λ_{max}[a] nm	ν(V=O)[b] cm^{-1}	ν(V-O-V)[c] cm^{-1}
$V_2O_3Q_4$	550	950	715
$V_2O_3(5\text{-Cl-Q})_4$	580	959 (971)[d]	715
$V_2O_3(5,7\text{-}Br_2\text{-Q})_4$	570	970 (945)[d]	720
$V_2O_3(4\text{-Pr-T})_4$	530	950	715
$VO(OH)(2\text{-Me-Q})_2 \cdot 2H_2O$	340	925	—

a) λ_{max} is the wavelength of the absorption maximum in the ultraviolet and visible spectrum. b,c) ν(V=O) and ν(V-O-V) are the wavenumbers of infrared absorption of V=O and V-O-V measured by pottasium bromide disc technique, respectively. d) These absorptions are weak and not assignable.

$N_4O_7Cl_4$: C, 50.03; H, 2.33; N, 6.48%.

Infrared, visible, and ultraviolet spectral data for these complexes are summarized in Table 1. The presence of ν(V-O-V) at near 715 cm^{-1} and absorption near 550 nm indicates the μ-oxo dimeric structure of these complexes. The complex with 2-methyl-8-quinolinol is monomeric because of steric hindrance of methyl group as described previously.[24]

Measurement. All the experiments were performed in a room thermostated at 25±0.5 °C. All the measurements were done using the circulating bath thermostated at each temperature within ±0.1 °C. The volume change of the solvent due to the temperature change was taken into consideration.[27]

Ultraviolet and visible spectra were recorded on a UNION High Sens Spectrophotometer SM-401. A JASCO infrared spectrophotometer A-3 was used for the IR spectral study by potassium bromide disc technique.

Equilibrium study was performed by measuring the absorbance at 480 nm with Zeiss spectrophotometer model 1 PMQ II, after the complete equilibration of the reaction mixtures in stoppered tubes. The reaction was followed spectrophotometrically at 600 nm after the conventional mixing of the reactants.

The water concentration was varied by mixing the dehydrated chlorobenzene ($C_{H_2O}=4\times10^{-3}$ mol dm^{-3}) and the chlorobenzene saturated with water ($C_{H_2O}=2\times10^{-2}$ mol dm^{-3}) at different ratio. The water concentration was checked by the Karl-Fischer method with the coulometric generation of iodine.

Results

Equilibrium. Just dissolved in wet chlorobenzene, vanadium(V) complexes are partially hydrolyzed and give rise to lower species, VO_2L.[25] In the presence of alcohols, furthermore, substitution of the bound ligand by alcohols is also anticipated to yield vanadium(V) alkoxides.[28–30] Actually in the absence of excess ligand, the addition of alcohol causes the color change from black *via* red to yellow, which is characteristic of trialkoxooxovanadium(V), $VO(OR)_3$. To avoid these side reactions an excess amount of ligand (≈0.01 mol dm^{-3}) was added in all experiments. The addition of excess ligand (up to 0.05 mol dm^{-3}) was confirmed to exert no effect on the esterification.

Visible spectra were recorded for complex solutions with different concentrations of alcohols. The time necessary for equilibration at 25 °C is as follows: V_2O_3(4-Pr-T)$_4$ takes 12 h for *n*- and *i*-, 24 h for *s*-, and 48 h for *t*-BuOH; V_2O_3(5-Cl-Q)$_4$ takes 96 h for *n*-BuOH; $V_2O_3Q_4$ takes 120 h for *n*-BuOH. Two distinct isosbestic points near 430 and 530 nm observed for all systems point to the presence of only one equilibrium, which is expressed by Eq. 1.

$$V_2O_3L_4 + 2ROH \rightleftharpoons 2VO(OR)L_2 + H_2O : K_{DE} \quad (1)$$

As the water concentration is large excess and may be regarded as constant, the conditional esterification constant K_{DE}' is given by Eq. 2.

$$K_{DE}' = K_{DE}[H_2O]^{-1} = \frac{[VO(OR)L_2]^2}{[V_2O_3L_4][ROH]^2} \quad (2)$$

The apparent molar absorption coefficient, $\bar{\varepsilon}=\frac{A}{C_V}$, is related with K_{DE}' by Eq. 3.

$$\frac{(2\bar{\varepsilon}-\varepsilon_D)^2}{\varepsilon_E-\bar{\varepsilon}} \times \frac{C_V}{2\varepsilon_E-\varepsilon_D} = K_{DE}'[ROH]^2, \quad (3)$$

where [ROH] is given by

$$[ROH] = C_{ROH} - \frac{2\bar{\varepsilon}-\varepsilon_D}{2\varepsilon_E-\varepsilon_D} \times C_V,$$

and ε_D and ε_E are the molar absorption coefficients of the dimeric vanadium(V) complex and its ester, respectively, and C_{ROH} and C_V are the total concentrations of alcohol and vanadium(V) as a monomeric species, respectively. The logarithm of the left hand side of Eq. 3 being plotted against log[ROH], the straight line with a slope of two and an intercept of log K_{DE}' should be obtained.

In Fig. 1 are shown the results on the systems of V_2O_3(4-Pr-T)$_4$ and $V_2O_3Q_4$ at a fixed water concentration. At different water concentrations the plots gave different straight lines with a slope of two. From

these plots we obtained the conditional equilibrium constants summarized in Table 2. The resulted log K_{DE}' value is plotted against log[H_2O] in Fig. 2. The plots fall along a straight line with a slope of −1 (Eq. 2). This confirms the validity of Eq. 1. The equilibrium constants for the esterification at 25 °C obtained from the intercepts of these plots are summarized in Tables 3 and 4.

Kinetics of the Esterification of the Dimeric Complexes. Kinetics of the esterification was studied with large excess alcohol, so that the back reaction can be neglected. The first-order plot gave a good straight line over 95% conversion.

The rate equation for the dimeric complexes is expressed by Eq. 4,

$$-\frac{d[V_2O_3L_4]}{dt} = \frac{1}{2}\times\frac{d[VO(OR)L_2]}{dt} = k_{0(ROH,HL,H_2O)}[V_2O_3L_4], \quad (4)$$

where $k_{0(ROH,HL,H_2O)}$ is the conditional esterification rate constant involving the concentrations of alcohol, excess ligand, and water. This rate constant was determined from the slope of the first-order plot.

The conditional rate constant was plotted against the alcohol concentration. The results for V_2O_3(4-Pr-T)$_4$ are given in Fig. 3. The plots show the first-order alcohol dependence of $k_{0(ROH,HL,H_2O)}$:

$$k_{0(ROH,HL,H_2O)} = k_{0(HL,H_2O)}[ROH].$$

In each system the ligand was added in a sufficient excess to prevent the formation of the lower complex[25] or alkoxide[28-30] in equilibrium. Addition of the excess ligand was found to exert no effect on the rate. Then,

$$k_{0(ROH,HL,H_2O)} = k_{0(H_2O)}[ROH].$$

Table 4. Equilibrium and rate constants, and activation parameters for the esterification of the μ-oxo dimeric vanadium(V) complexes with *n*-BuOH

Complex		$V_2O_3Q_4$	V_2O_3(5-Cl-Q)$_4$	V_2O_3(5,7-Br_2-Q)$_4$

	30 °C	1.54×10^{-1}	1.05×10^{-1}	2.0×10^{-2}
	35 °C	1.78×10^{-1}	1.28×10^{-1}	3.3×10^{-2}
ΔH_2^* / kJ mol^{-1}		24±2	25±2	73±4
ΔS_2^* / J $mol^{-1}\,K^{-1}$		−181±8	−181±8	−30±15

a) At 25 °C. b), c) All the values have errors of ±1—3 and ±3—8%, respectively.

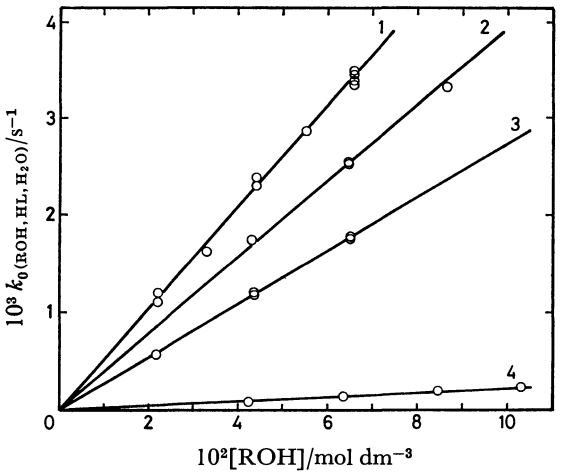

Fig. 3. Plot of $k_{0(ROH,HL,H_2O)}$ for V_2O_3(4-Pr-T)$_4$ *vs.* [ROH]. $C_v=6.73\times10^{-5}$ mol dm^{-3}; $C_{HL}=9.83\times10^{-3}$ mol dm^{-3}; $C_{H_2O}=0.007$—0.020 mol dm^{-3}. ROH: *n*-BuOH(1); *i*-BuOH(2); *s*-BuOH(3); *t*-BuOH(4).

In the absence of the excess ligand enough to prevent the formation of lower species, the esterification proceeds faster. This is attributable to the faster reaction of monomeric VO_2L with alcohol.

Finally $k_{0(H_2O)}$ was plotted against [H_2O]. The results are shown for $V_2O_3Q_4$ with *n*-BuOH in Fig. 4. According to this Figure, $k_{0(H_2O)}$ is rewritten as

$$k_{0(H_2O)} = k_1 + k_2[H_2O].$$

V_2O_3(5-Cl-Q)$_4$ and V_2O_3(5,7-Br_2-Q)$_4$ showed the similar behavior, whereas V_2O_3(4-Pr-T)$_4$ had negligibly small k_2[H_2O] term as compared to k_1.

Thus $k_{0(ROH,HL,H_2O)}$ is expressed by Eq. 5.

$$k_{0(ROH,HL,H_2O)} = (k_1+k_2[H_2O])[ROH] \quad (5)$$

Rate constants at 25, 30, and 35 °C, and activation parameters are summarized in Tables 3 and 4.

Kinetics of the Esterification of the Monomeric Complex. The rate equation for the monomeric 2-methyl-8-quinolinolate complex is expressed by Eq. 6.

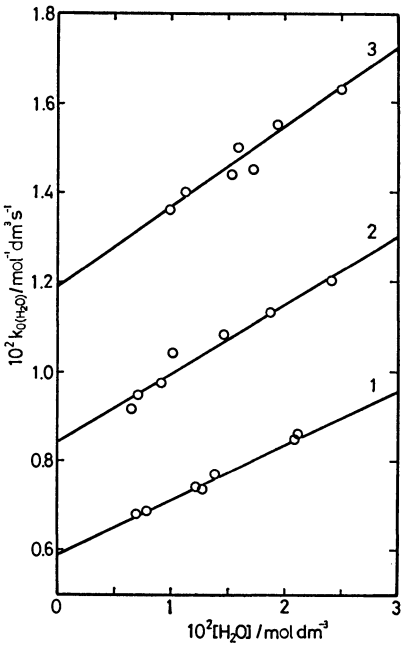

Fig. 4. Plot of $k_{0(H_2O)}$ for $V_2O_3Q_4$ with *n*-BuOH *vs.* [H_2O]. $C_v=5.67\times10^{-5}$ mol dm^{-3}; $C_{HL}=8.00\times10^{-3}$ mol dm^{-3}. At 25 °C(1) ; 30 °C(2) ; 35 °C(3).

$$-\frac{d[VO(OH)(2\text{-Me-Q})_2]}{dt} = \frac{d[VO(OR)(2\text{-Me-Q})_2]}{dt}$$

$$= k_{M,0(ROH,HL,H_2O)}[VO(OH)(2\text{-Me-Q})_2] \quad (6)$$

The kinetic data were analyzed by the treatment similar to that in the case of the dimeric complexes. Despite a very small contribution from the water-dependent path (1—2% acceleration in chlorobenzene saturated with water), the conditional rate constant $k_{M,0(ROH,HL,H_2O)}$ is reasonably expressed by Eq. 7 for *n*- and *i*-BuOH.

$$k_{M,0(ROH,HL,H_2O)} = k_{M,1}[ROH] \quad (7)$$

For *s*- and *t*-BuOH the esterification can not be successfully analyzed because of the concurrent ligand

dissociation reaction in the presence of these alcohols. Rate constants at 25, 30, and 35 °C, and activation parameters are summarized in Table 5.

Discussion

All but 2-methyl-8-quinolinolate complexes have the μ-oxo dimeric structure. No X-ray structural analysis being reported for the μ-oxo dimeric vanadium(V) complex, it was reasonably supposed to have the terminal oxo *cis* to the bridging oxo group from the analogy of many molybdenum(V) complexes[31] and the mixed valence vanadium(IV,V) complex.[32] The strong absorption near 550 nm, which is ascribed to a delocalized three-center pi bond, is characteristic of this configuration.[31] The two oxo groups attached to each vanadium atom in dimeric complexes have a possibility to be *cis* or *trans* to each other. Whereas according to the X-ray structural analysis the ester has the terminal oxo *cis* to the alkoxo group, and these groups are *trans* to the nitrogen atoms of quinoline rings.[26] Thus it will be pertinent to conclude that the rupture of the bridging bond must occur during the esterification of the dimeric complexes and that the *cis* configuration of oxo groups is retained. Since the 2-methyl-8-quinolinolate complex is monomeric because of the steric hindrance of methyl group,[24] the esterification of this complex is the simple nucleophilic substitution reaction of hydroxide by alkoxide group.

Reaction Mechanism. The esterification of the μ-oxo dimeric vanadium(V) complexes is first-order in the alcohol concentration. The reaction involves the water-independent path(k_1 path) and the other path first-order in the water concentration (k_2 path). Since in k_1 path, only one molecule of alcohol is involved in the rate equation, the reactive species VO(OH)L$_2$ must be formed in addition to the final product VO(OR)L$_2$ (Eq. 8). VO(OH)L$_2$ must react rapidly with one more alcohol to yield VO(OR)L$_2$ (Eq. 9).

$$V_2O_3L_4 + ROH \xrightarrow{\text{slow}} VO(OR)L_2 + VO(OH)L_2 \quad (8)$$

$$VO(OH)L_2 + ROH \xrightarrow{\text{fast}} VO(OR)L_2 + H_2O \quad (9)$$

To estimate the bound ligand effect on the reaction rate, log k_1 value is plotted against ΣpK_a, which is the sum of the logarithmic protonation constants of the two ligands coordinated to vanadium and is a measure of electron donation from the ligands to vanadium(V) (Fig. 5). Except the sterically crowded ligand (5,7-dibromo-8-quinolinol), fairly good linear relationship is observed. This implies that the more the coordinated ligand donates, the lower the positive charge on vanadium(V) becomes, resulting in slower esterification. Thus the reaction may be regarded as a nucleophilic attack of alcohol at the vanadium center. However for a given complex (see Table 3) the reactivity of four butyl alcohols does not parallel to nucleophilicity (*t*->*s*->*i*->*n*-), but to sterical freedom (*n*->*i*->*s*->*t*-). Accordingly the difference in reactivity of alcohols mainly stems from the steric factor.

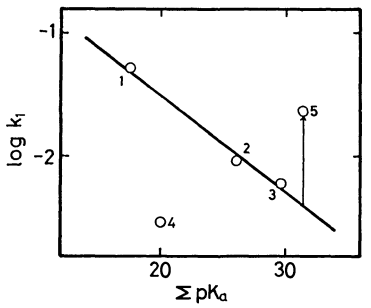

Fig. 5. Correlation of the rate constant for the esterification of vanadium(V) complexes by *n*-BuOH with ΣpK_a of the bound ligand. Complex: 1, V_2O_3(4-Pr-T)$_4$ (Ref. 33); 2, V_2O_3(5-Cl-Q)$_4$ (Ref. 34); 3, $V_2O_3Q_4$ (Ref. 34); 4, V_2O_3(5,7-Br$_2$-Q)$_4$ (Ref. 35); 5, VO(OH)(2-Me-Q)$_2$ (Ref. 34). The pK_a values are taken from the references cited in parentheses. The starting point of an arrow denotes the rate constant for the hypothetical dimeric vanadium(V) complex with 2-methyl-8-quinolinol.

The reactivity of the dimeric complexes is then compared with that of the 2-methyl-8-quinolinolate complex. This complex may be regarded as the proposed reactive intermediate in the esterification of the dimeric complexes (Eq. 8). Although the corresponding dimeric complex with 2-methyl-8-quinolinol has also been synthesized, it is not stable and dissociates to the monomeric complex in wet chlorobenzene.[24] Accordingly the rate constant for the esterification of this unstable dimeric complex is not directly obtained, but it is reasonably estimated by reading the log k_1 value for the ΣpK_a of this ligand (the origin of an arrow in Fig. 5). The experimental rate constant of the monomeric complex (2.29×10^{-2} mol^{-1} dm^3 s^{-1} at 25 °C) is at least 5 times as large as this expected value for the dimeric complex (4×10^{-3} mol^{-1} dm^3 s^{-1} at 25 °C). Thus VO(OH)L$_2$ type complex should be more reactive than the corresponding dimeric complex (Eq. 9). In contrast to the dimeric complexes, the reactivity of alcohols towards the monomeric complex parallels to nucleophilicity (*n*->*i*-).

Exceptionally large negative values of ΔS^* point to an associative mode of activation(S_N2) in both monomeric and dimeric complexes. In the dimeric complexes, ΔH^* is larger with increasing bulkiness of both attacking alcohol and bound ligand, and larger ΔH^* values are always associated with smaller negative ΔS^* values. These findings, taken together

with the reactivity order with alcohols, suggest that steric factor plays an important role in these systems. For the monomeric complex, the smallest ΔH^* values are associated with the negatively largest ΔS^* values.

In the dimeric complexes, due to the other vanadium half-unit linked with the bridging oxo group, the nucleophilic attack of alcohol to vanadium center is sterically hindered and the extra bond-weakening energy is necessary to make alcohol close to vanadium center. The mechanism is explained by a concerted bimolecular reaction, in which a molecule of alcohol attacks associatively the vanadium center and at the same time the bond between vanadium and bridging oxo ligand is weakened. This makes ΔH^* value considerably larger for more sterically crowded system. For a given complex, ΔH^* value increases in the order *n*-<*i*-<*s*-<*t*- and for a given alcohol $V_2O_3Q_4$< V_2O_3(5-Cl-Q)$_4$<V_2O_3(5,7-Br_2-Q)$_4$. The small negative ΔS^* value associated with large positive ΔH^* value suggests that the bond-weakening contribution to the overall activation is more significant as compared to the bond-making, thus the reaction between crowded alcohol and complex becomes less associative. On the other hand in the monomeric complex, alcohol can easily approach to vanadium center without being suffered significant steric hindrance. This makes the reaction more associative. Furthermore since no extra bond-weakening energy is necessary for the activated state, the reactivity order is mainly governed by electronic factor.

Water-dependent Path. The water-dependent rate constant in the esterification of the dimeric complexes, k_2 was constant even in changing the concentration of the excess ligand. Accordingly water must not substitute the bound ligand of the dimeric complexes to yield a reactive lower complex, but it interacts with any site in the complexes such as terminal or bridging oxo group to yield a reactive intermediate. Since a small but definite water-dependent path is observed also in the case of the monomeric complex, the interaction with basic terminal oxo group seems plausible. Moreover, this postulation is supported by the fact that the esterification was much more accelerated in the presence of more acidic substance such as phenol.[36]

As can be seen from the relative changes in k_2 and ΔH_2^* in the presence of water, the acceleration by water becomes higher with increasing ΣpK_a of the bound ligand. That is, the interaction of water is stronger with more basic oxo group in complexes having more basic ligand. The acceleration relative to k_1 (log k_2/k_1: 1.32 for $V_2O_3Q_4$; 0.99 for V_2O_3(5-Cl-Q)$_4$; 0.61 for V_2O_3(5,7-Br_2-Q)$_4$.) is linearly correlated with ΣpK_a. Judging from the extrapolated k_2(0.4) for V_2O_3(4-Pr-T)$_4$, the negligibly small contribution of water-dependent path in the reaction with *n*-BuOH as compared to the k_1 is anticipated and this agrees with our results. In the monomeric complex the same type of acceleration will be anticipated. However the intramolecular hydrogen bonding between terminal oxo and hydroxo groups prevents the formation of a reactive intermediate and the reaction will not be accelerated so much as expected from the estimated k_2 (5.8×10^{-1} mol^{-1} dm^3 s^{-1}). The k_2 path reaction has an energy of activation (ΔH_2^*) less than for the corresponding reaction not involving such an intermediate (ΔH_1^*) by about the heat of formation of the hydrogen bond. Larger negative ΔS_2^* value as compared to ΔS_1^* is also attributable to this pre-equilibrium.

Relationship between K_{DE} *and* k_1. The detailed reaction scheme is expressed as

$$V_2O_3L_4 + ROH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} VO(OR)L_2 + VO(OH)L_2$$

$$VO(OH)L_2 + ROH \underset{k_{EM}}{\overset{k_{ME}}{\rightleftharpoons}} VO(OR)L_2 + H_2O.$$

Then the overall esterification equilibrium constant is equated to

$$K_{DE} = \frac{k_1}{k_{-1}} K_{ME},$$

where $K_{ME}=k_{ME}/k_{EM}$. Using the dimerization constant given by

$$2VO(OH)L_2 \rightleftharpoons V_2O_3L_4 + H_2O : K_{MD}.$$

k_1 is expressed by

$$k_1 = k_{-1}(K_{DE}/K_{MD})^{1/2}.$$

k_{-1} corresponds to the rate constant of the nucleophilic attack of the oxo group in the monomeric complex to the vanadium center of the ester. In this reaction, alcohol accommodated as alkoxide in the ester will not largely affect the rate k_{-1} both electronically and sterically for the complexes with the same bound ligand. Furthermore K_{MD} being constant for the complex with the same ligand, in the reaction system of V_2O_3(4-Pr-T)$_4$ with butyl alcohols log k_1 should be linearly correlated with log K_{DE} with a slope of 1/2 as in Fig. 6. On the other hand, the results obtained in the systems of $V_2O_3Q_4$ and V_2O_3(5-Cl-Q)$_4$ with *n*-BuOH are also well accommodated in the correlation given in Fig. 6. It appears unlikely that k_{-1} and K_{MD} are both constant irrespective of the bound ligand. Thus the linear correlation of log k_1 with log K_{DE} may be resulted from the adequate compensation of k_{-1} and K_{MD} making (log k_{-1}−1/2 log

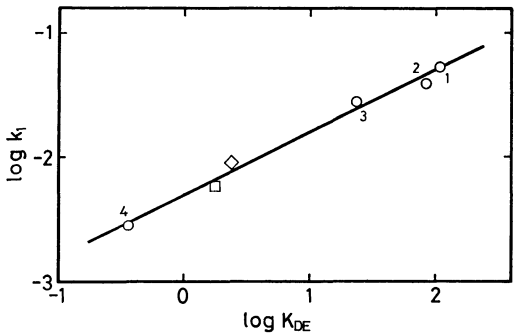

Fig. 6. Correlation of the rate constant for the esterification of the μ-oxo dimeric vanadium(V) complex with its equilibrium constant. Reaction system: V_2O_3(4-Pr-T)$_4$ (○) with *n*-BuOH(1); *i*-BuOH(2); *s*-BuOH(3); *t*-BuOH(4); $V_2O_3Q_4$ (□) with *n*-BuOH; V_2O_3(5-Cl-Q)$_4$ (◇) with *n*-BuOH. The solid line is the straight line with a slope of 1/2.

K_{MD}) constant. In any event, the lower the activation energy for the esterification, the stabler the resulted ester is.

The Polarographic Behavior of Bis(acetylacetonato)nickel(II) and Bis(hexafluoroacetylacetonato)nickel(II) in Dimethyl Sulfoxide

Setsuko KUDO,† Akio IWASE,* and Nobuyuki TANAKA**

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-machi, Yamagata 990

***Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980*

(Received April 14, 1980)

The d.c. polarographic reduction of $Ni(acac)_2$ and $Ni(hfac)_2$ was studied in detail in dimethyl sulfoxide. Two kinds of tetraalkylammonium perchlorates and sodium perchlorate were used as supporting electrolytes. $Ni(acac)_2$ gave three waves in all the supporting electrolytes, while $Ni(hfac)_2$ gave two waves in the presence of tetraalkylammonium perchlorate. These waves were explained on the basis of the polarographic properties, molecular weights, and conductivities. The electrode reaction mechanism of $Ni(acac)_2$ can be expressed by:

$$Ni(acac)^+ \rightleftharpoons Ni(acac)_2 \rightleftharpoons [Ni(acac)_2]_2 \rightleftharpoons \cdots\cdots \rightleftharpoons [Ni(acac)_2]_p$$

$$\downarrow 2e \qquad \downarrow 2e \qquad \downarrow 4e \qquad \downarrow (2p)e$$

1st wave 2nd wave 3rd wave

where the second wave includes a kinetic current. The first wave of $Ni(hfac)_2$ is due to the reduction of $Ni(hfac)^+$ and $Ni(hfac)_2$ themselves; the second wave corresponds to that of free hexafluoroacetylacetonate.

The nonaqueous electrochemistry of bis(β-diketonato)nickel(II) complexes has been reported by several investigators. Murray and Hiller[1] gave preliminary data on bis(acetylacetonato)nickel(II) in acetonitrile from the standpoint of the supporting-electrolyte effect. The number of electrons participating in the electrode processes, n, is particularly interesting, for certain complexes may partly polymerize even in coordinating solvents. According to the results of Dessy *et al.*,[2] the n value of bis(acetylacetonato)nickel(II) was equal to unity in 1,2-dimethoxyethane. Bond *et al.*[3] presumed a one-electron transfer step for the reduction wave observed in the d.c. polarography of bis(dipivaloylmethanato)nickel(II) in acetone. Recently, Gritzner *et al.*[4] reported on the polarographic and voltammetric behavior of various acetylacetonato and hexafluoroacetylacetonato complexes in acetonitrile. They determined the n value of two for bis(acetylacetonato)nickel(II) coulometrically.

The present paper will report the results of a detailed investigation of the d.c. polarographic reduction of bis(acetylacetonato)nickel(II), $Ni(acac)_2$, and bis(hexafluoroacetylacetonato)nickel(II), $Ni(hfac)_2$, in dimethyl sulfoxide (DMSO).

Experimental

Reagents. Merck analytical reagent-grade DMSO was used without further purification. The content of water was determined with a gas chromatograph. The DMSO contained 0.02—0.06% water.

Sodium perchlorate was dried *in vacuo* for 24 h prior to use. The Nakarai Chemicals tetramethylammonium perchlorate (TMAP) and tetrabutylammonium perchlorate (TBAP) purified for polarography were dried *in vacuo* for 12 h. The Kishida Chemicals nickel(II) perchlorate hexahydrate was brought to a constant weight in a desiccator over magnesium perchlorate.[5] Hexafluoroacetylacetone (Hhfac) from Nakarai Chemicals, Ltd., was used without further purification.

† Present address: Chemical Laboratories, Yamagata Building Service Co., Ltd., Iizuka-machi, Yamagata 990.

Two extra-pure-reagents, $Ni(acac)_2$ and $Ni(hfac)_2$, were obtained from Nakarai Chemicals, Ltd. These compounds were identified as $Ni(acac)_2 \cdot 2H_2O$ and $Ni(hfac)_2 \cdot H_2O$ by elemental analysis.

Potassium acetylacetonate was prepared by the following procedure. Into a solution of 6 cm^3 of acetylacetone (Hacac) in 30 cm^3 of methanol–water (1:1), 2 mol dm^{-3} potassium hydroxide in methanol–water (1:1) was dropwise added until a pH value of 9.0 was reached. The precipitated salt was filtered off and dried *in vacuo*. The analysis of potassium acetylacetonate gave the following results. Found: C, 38.20; H, 5.76%. Calcd for $C_5H_9O_3K$: C, 38.44; H, 5.81%.

Reagent-grade chemicals were used unless otherwise stated.

Apparatus and Procedures. The current-potential curves were obtained with a Yanagimoto Polarograph PA-101 and a Yanagimoto Potentiostat PT-P8.

The polarographic measurements were made at 25.0± 0.2 °C except for the experiments of the temperature effect. An H-type electrolysis cell was used for the measurements. An aqueous SCE-KCl was isolated from the test solution by the use of a compartment with a glass filter (G-4). All the solutions were deaerated with nitrogen gas. Two dropping-mercury electrodes were used. The A electrode had an m value of 1.06_2 mg s^{-1} and a drop time, t_d, of 6.18 s in a deaerated 0.05 mol dm^{-3} TMAP–DMSO solution at −1.0 V and at a height of the mercury reservoir, h, of 47 cm. The B electrode had an m value of 1.24_8 mg s^{-1} and a t_d value of 4.95 s in a deaerated 0.1 mol dm^{-3} TBAP–DMSO solution at −1.0 V and h=45 cm.

In the following sections, i and $\bar{i}$ denote the maximum current and the average current respectively.

The n values were determined on a Yanagimoto Controlled Potential Electrolyzer and a Nikko Keisoku Digital Coulometer NDCM-2.

The conductivities were measured with a Yanagimoto Conductivity Outfit MY-8. The absorption spectra in the visible and ultraviolet regions were obtained with a Spectronic 88-UV Shimadzu-Bausch & Lomb Spectrophotometer at room temperature. The molecular weights were measured in DMSO at 18 °C by cryoscopy, with tris(acetylacetonato)cobalt(III) as the standard material.

a) The half-wave potentials for $Ni(acac)_2$ were obtained at the concentration of 2 mmol dm^{-3}. b) The slopes of the log-plot analyses for $Ni(acac)_2$ were obtained at the concentration of 5 mmol dm^{-3}. c) The i_j/i_t ratios for $Ni(acac)_2$ were obtained at the concentration of 1 mmol dm^{-3}. The meanings of i_j and i_t are shown in Fig. 1.

ductivity measurements at 25 °C indicate that $Ni(acac)_2$ is little dissociated into ionically-conducting species, while $Ni(hfac)_2$ is dissociated into the 1:1 electrolyte.

The apparent molecular weights of $Ni(acac)_2$ in DMSO are given in Table 1. This complex was polymeric in the concentration range studied here. On the other hand, the cryoscopic results of $Ni(hfac)_2$ were in conflict with the conductance data, showing the molecular weight of undissociated $Ni(hfac)_2 \cdot 2DMSO$. The cryoscopy of $Ni(hfac)_2$ appears to afford no true information; however, the reason for this is not known.

The spectoscopic data indicate that the complexes are of a hexa-coordinate octahedral structure,[6,7] though the cryoscopic data of $Ni(acac)_2$ seem to suggest a penta-coordinate structure.

Reduction of the Complexes in DMSO. Some typical polarograms and polarographic data of the complexes in DMSO are shown in Fig. 1 and Table 2. Sodium perchlorate, tetramethylammonium perchlorate, and tetrabutylammonium perchlorate were used as supporting electrolytes. $Ni(acac)_2$ gave three reduction waves, of which the one at the most negative potential was very irreversible, regardless of the kind of supporting electrolyte used. When TBAP was used as a supporting electrolyte, the first two waves at less negative potentials overlapped; hence, the polarogram of 1 mmol dm^{-3} $Ni(acac)_2$ appeared just like two steps.

$Ni(hfac)_2$ gave two reduction waves in the presence of tetraalkylammonium perchlorate as the supporting electrolyte. When sodium perchlorate was used as the supporting electrolyte, the second wave, at a far

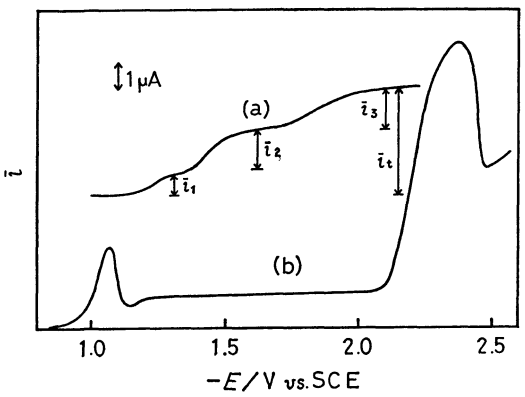

Fig. 1. Polarograms of (a) 3.0 mmol dm^{-3} $Ni(acac)_2$ and (b) 0.5 mmol dm^{-3} $Ni(hfac)_2$ in 0.05 mol dm^{-3} TMAP–DMSO. With the DME (A).

negative potential, overlapped with the sodium-ion reduction. Interestingly, the first wave of $Ni(hfac)_2$ resembled the wave of nickel(II) perchlorate in its polarographic properties. When 0.1 mol dm^{-3} TBAP was chosen as the supporting electrolyte, the maximum at the first wave disappeared and the second wave was a well-defined one (see Fig. 2 and Table 2). The ratio of their heights was equal to 1:4 for the first and the second wave under the controlled drop time. The polarogram of $Ni(hfac)_2$ is compared with that of hexafluoroacetylacetone in Fig. 2. Hexafluoroacetylacetone gave two waves: the first wave is considered to be a hydrogen reduction of the enol form, and the second wave, to be an enolate reduction.[8] The second

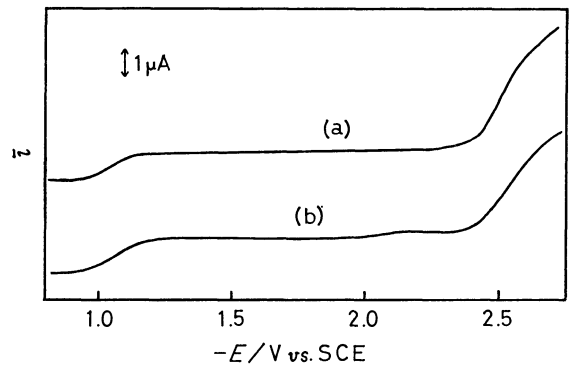

Fig. 2. Polarograms of (a) 0.5 mmol dm^{-3} Ni(hfac)$_2$ and (b) *ca.* 0.9 mmol dm^{-3} Hhfac in 0.1 mol dm^{-3} TBAP-DMSO. With the DME (B).

wave of Ni(hfac)$_2$ appeared at the same potential as that of hexafluoroacetylacetone.

The first limiting currents (i) of Ni(acac)$_2$ and Ni(hfac)$_2$ were proportional to $h^{1/2}$ in all the supporting electrolytes used. The measurements of the current-time (i-t) curve were made in the potential region giving each limiting current of three waves of Ni(acac)$_2$ in 0.05 mol dm^{-3} solution of each supporting electrolyte during the life of a mercury drop. In a TMAP or TBAP solution, the slopes of the plots for log i *vs.* log t were larger than those in a sodium-perchlorate solution. This finding is related to the supporting-electrolyte effect on the total limiting current, $\bar{i}_t$, of Ni(acac)$_2$ to be described later.

All the waves of Ni(acac)$_2$ were not due to the reduction of the ligand, because acetylacetonate itself gave no wave in the potential range observed. The polarographic waves of 1 mmol dm^{-3} Ni(acac)$_2$ were affected by the addition of a small amount of acetylacetonate. The first wave disappeared after the addition of 0.5 mmol dm^{-3} acetylacetonate. The $\bar{i}_t$ decreased as the concentration of acetylacetonate increased. The dependence of the $\bar{i}_t$ on the acetylacetonate concentration suggested the formation of electroinactive Ni(acac)$_3^-$. When 1 mmol dm^{-3} nickel(II) perchlorate was made to react with 1 mmol dm^{-3} potassium acetylacetonate, the polarogram had two waves in the presence of each supporting electrolyte of 0.05 mol dm^{-3}: one was the wave of the nickel ion, and the other was that of Ni(acac)$^+$, which appeared at *ca.* −1.2 V in the TMAP solution. Accordingly, the first wave of Ni(acac)$_2$ corresponds to the reduction of Ni(acac)$^+$.

In Fig. 3 the limiting currents of Ni(acac)$_2$ and Ni(hfac)$_2$ are plotted against their concentrations. In contrast to the linearity of plots for the first wave of Ni(hfac)$_2$, that for the $\bar{i}_t$ of Ni(acac)$_2$ gave curves. The supporting-electrolyte effect on the $\bar{i}_t$ was observed after the correction for the drop time; that is, the $\bar{i}_t$ was low in the presence of tetraalkylammonium perchlorate. This may be explained by the double-layer effect on the reduction rate,[9] judging from the i-t curve data mentioned above.

The plots of the $\bar{i}_j$ and $\bar{i}_t$ values of Ni(acac)$_2$ *vs.*

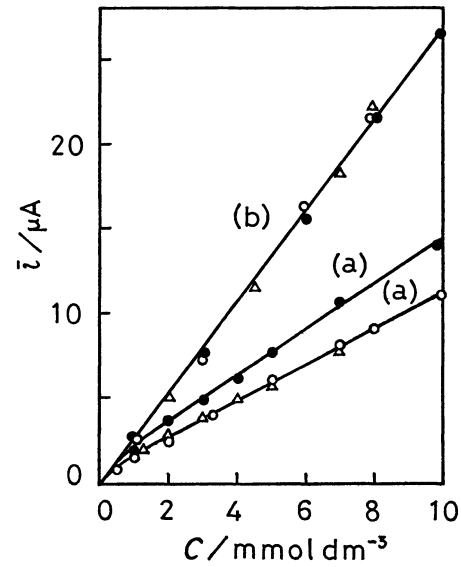

Fig. 3. Dependence of (a) the total limiting current of Ni(acac)$_2$ and (b) the first limiting current of Ni(hfac)$_2$ on the concentration of each complex in DMSO. Supporting electrolyte: (○) TMAP, (△) TBAP and (●) sodium perchlorate. Each in 0.05 mol dm^{-3}. With the DME (A).

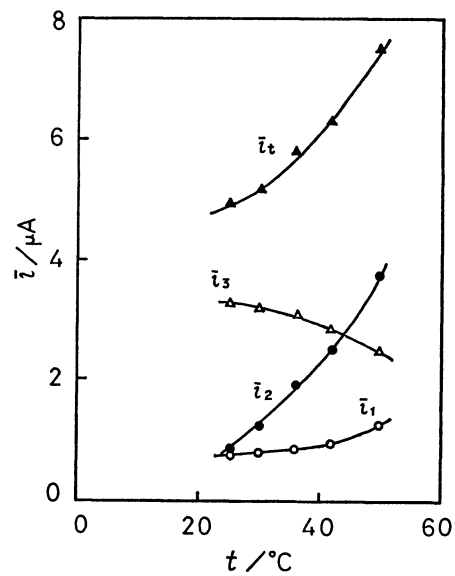

Fig. 4. Effect of temperature on the limiting currents of 3.0 mmol dm^{-3} Ni(acac)$_2$ in 0.05 mol dm^{-3} sodium perchlorate-DMSO. For $\bar{i}_j$ (j=1—3), see Fig. 1. With the DME (A).

the temperature gave the curves shown in Fig. 4. With an increase in the temperature, the $(\bar{i}_1+\bar{i}_2)/\bar{i}_t$ ratio increased and the $\bar{i}_3/\bar{i}_t$ ratio decreased: in a 3 mmol dm^{-3} Ni(acac)$_2$–0.05 mol dm^{-3} sodium perchlorate solution, these ratios were 0.34 and 0.66 respectively at 25 °C, while they were 0.67 and 0.33 respectively at 50 °C.

The controlled potential coulometric experiments were carried out at −1.70 V for 0.5 mmol dm^{-3} Ni(hfac)$_2$ and at −2.30 V for 0.5 mmol dm^{-3} Ni(acac)$_2$

in the presence of 0.05 mol dm^{-3} TMAP. These coulomertic data gave 2.0 and 1.9 respectively as the apparent numbers of electrons per nickel atom.

The effect of water on the polarographic waves was examined below 10%. When 0.05 mol dm^{-3} TMAP was used as the supporting electrolyte, there was no variation in $Ni(acac)_2$ after the addition of 10% water. When 0.05 mol dm^{-3} sodium perchlorate was used as the supporting electrolyte, though, the i_2/i_t ratio increased and the i_3/i_t ratio decreased as the content of water increased in the range of 2—10%. The effect on $Ni(hfac)_2$ was checked in the presence of 0.1 mol dm^{-3} TBAP, for these conditions gave two well-defined waves. The addition of 5% water led to more irreversible waves. Further, the first and second waves shifted a little to more negative and less negative potentials respectively.

Discussion

Many chemists have been interested in the structures of β-diketone chelate compounds in various nonaqueous solvents. They have mainly investigated them by means of NMR, ESR, electronic-spectra, molecular-weight measurements, *etc.* It is well known that the anhydrous $Ni(acac)_2$ exists as a trimer with an octahedral coordination about the nickel(II) in crystals and also in noncoordinating solvents.[7] Yoshida *et al.*[10] have proposed a dimer, $(NiL_2 \cdot H_2O)_2$, for each prevalent form of bis(1,5-dialkyl-2,4-pentanedionato)-nickel(II) monohydrate complexes in noncoordinating solvents, where L represents a β-diketonato anion. Using the rotating-disk-electrode method, Ritzler and Gross[11] have proposed a dimer for the prevalent form of about 1 mmol dm^{-3} $Co(acac)_2$ in propylene carbonate. The present work affords useful information on the molecular association of $Ni(acac)_2$ in DMSO with a great donor-number.

$Ni(acac)_2$ and $Ni(hfac)_2$ in DMSO are involved in the following chemical equilibria:

$$[Ni(acac)_2]_p \rightleftharpoons \cdots \rightleftharpoons [Ni(acac)_2]_2 \rightleftharpoons Ni(acac)_2 \rightleftharpoons Ni(acac)^+ + acac^- \quad (1)$$

$$Ni(hfac)_2 \rightleftharpoons Ni(hfac)^+ + hfac^-, \quad (2)$$

on the basis of the conductance and the molecular-weight data. The degree of the dissociation of $Ni(acac)_2$ to the ions is negligibly small in the absence of a supporting electrolyte, as has been mentioned in the preceeding section.

The polarographic behavior of $Ni(hfac)_2$ is very similar to that of the only species which is diffusion-controlled, judging from the linearity of the limiting current on $h^{1/2}$ and the complex concentration. Further, the apparent diffusion-current constant of the first wave was approximately equal to that of the wave of the nickel(II) ion, which follows a two-electron reduction process to the metal.[12] The n value, determined coulometrically, is consistent with this finding. Both $Ni(hfac)^+$ and $Ni(hfac)_2$ participate, presumably as electroactive species, in the first wave. A comparison between the polarograms of (a) and (b) in Fig. 2 indicates that the second wave of $Ni(hfac)_2$ comes from free hexafluoroacetylacetonate. The complex gave a nickel anodic stripping peak (spike pattern) at −0.1 V in cyclic voltammetry at a platinum electrode; such a peak was also found in nickel perchlorate. This suggests that the ligand is liberated after the reduction of the complex itself at the first wave. Thus, the second wave does not mean the reduction of the only free ligand from the dissociation reaction in the bulk of the solution.

The first wave of $Ni(acac)_2$ does not include the kinetic current due to the preceding chemical reaction, judging from the dependence of the limiting current on $h^{1/2}$. The first wave is due to the reduction of $Ni(acac)^+$, judging from the disappearance of the wave after the addition of acetylacetonate and from the agreement between the half-wave potential of $Ni(acac)^+$ and that of the first wave of $Ni(acac)_2$. However, the i_1/i_t ratio is too large to explain the conductance data. It is, therefore, reasonable to consider the dissociation of $Ni(acac)_2$ to $Ni(acac)^+$ in the bulk of the solution in the presence of a supporting electrolyte. The second and third waves come from the reduction of the monomeric $Ni(acac)_2$ and the polymeric species respectively, judging from the dependence of the i_2 and i_3 on the temperature and from that of the i_t on the complex concentration. Consequently, the electrode reaction mechanism can be expressed by:

$$\begin{array}{ccccccc} Ni(acac)^+ & \rightleftharpoons & Ni(acac)_2 & \rightleftharpoons & [Ni(acac)_2]_2 \rightleftharpoons \cdots \rightleftharpoons & [Ni(acac)_2]_p \\ \downarrow 2e & & \downarrow 2e & & \downarrow 4e \quad\quad \downarrow (2p)e & \\ \text{1st wave} & & \text{2nd wave} & & \text{3rd wave} & \end{array} \quad (3)$$

where the $Ni(acac)_2 \rightleftharpoons Ni(acac)^+ + acac^-$ reaction is so slow that it practically does not proceed in the vicinity of the electrode surface during electrolysis. The i_2/i_3 ratio was dependent on the drop time; the temperature effect on the i_2 can not be interpreted merely by the chemical equilibria shift in the bulk of the solution, so that the second wave includes the kinetic current due to the preceding reaction, the polymeric species$\rightleftharpoons$ $Ni(acac)_2$, in Eq. 3.

The dissolved state is apparently dependent on the nature of the ligands of the complexes. Such behavior of other bis(β-diketonato)nickel(II) complexes will be discussed in the following paper.

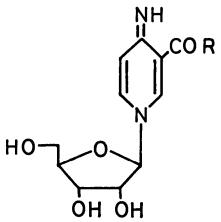
(Received February 28, 1980)

Two β-NAD-analogs were prepared utilizing a base-exchange reaction catalyzed by pig-brain NADase. These analogs were proved to contain a methyl 1,4-dihydro-4-iminonicotinate and a 1,4-dihydro-4-iminonicotinamide moiety. By successive hydrolytic degradations of these analogs, 1,4-dihydro-4-iminopyridine β-ribosides with 3-carboxyl and 3-carbamoyl groups were prepared in good yields. The former compound was identical with clitidine, a toxic pyridine nucleoside recently isolated from a toadstool. The present synthesis confirmed the 1,4-dihydro-4-imino β-riboside structure of clitidine. Preliminary biological tests showed that the 3-carbamoyl compound was more toxic than clitidine, suggesting that the amide derivative of clitidine is an essential toxic substance in the toadstool.

Recently, Konno *et al.*[2)] have isolated a new pyridine nucleoside, clitidine, as a toxic substance from a toadstool, *Clitocybe acromelalga*. Although the structure, 1-(β-D-ribofuranosyl)-1,4-dihydro-4-iminonicotinic acid (**1**), was assigned to the nucleoside by synthesis, no clear evidence has been given for the 1,4-dihydropyridine form and the β-configuration of the glycosidic linkage.

The pharmaceutical properties of clitidine were investigated in detail[3)] and it was pointed out that its toxicity was relatively weak for a toxic substance from a toadstool. We, therefore, had a doubt whether clitidine itself was a major component of the toxic substance or not. It was assumed that the substance might be an amide form (**2**) in the toadstool.



1 R = OH
2 R = NH_2

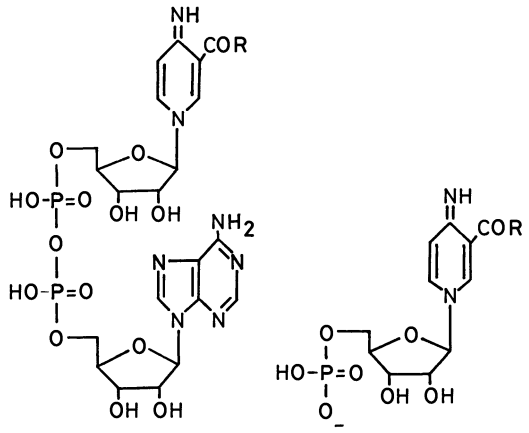
In order to clarify the ambiguous points, we tried to synthesize these pyridine nucleosides by enzyme-catalyzed reactions. Compared with the chemical synthesis by Konno *et al.*,[2)] which consists of six steps involving a laborious process, the enzymatic synthesis can be performed in three steps with high stereospecificity and good yield of product under mild conditions.

Nicotinamide ribonucleoside[4)] has been prepared by successive enzymatic cleavages of β-NAD. On the other hand, many NAD-analogs[5)] have been prepared by utilizing pig-brain NADase which has β-transglycosidase action along with glycohydrolase activity. These methods were successfully applied to the case of the derivatives of 4-aminonicotinic acid.

The present paper describes details of the preparation of the new NAD-analogs (**4**, **6**), and the degradative synthesis of clitidine (**1**) and its amide derivative (**2**) from the analogs.

Results and Discussion

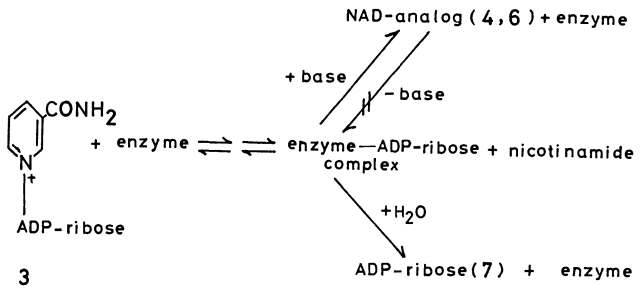
Preparation of NAD-analogs. When 4-aminonicotinic acid and β-NAD were incubated with pig-brain NADase, only ADP-ribose was produced and no NAD-analog could be detected in which a nicotinamide moiety was replaced by 4-aminonicotinic acid. On the other hand, when methyl 4-aminonicotinate was used as a replacing base, the exchange reaction occurred successfully and yielded the expected analog together with ADP-ribose. These two compounds could be separated and purified by chromatography on DEAE-Sephadex; they provided the ester analog (**4**) and ADP-ribose (**7**) in a ratio of about 2:1. The IR spectrum of **4** showed an ester carbonyl band at 1715 cm^{-1} in place of an amide carbonyl band. The ^{1}H-NMR spectrum also showed an ester methyl group at δ 3.95 (s, 3H) and three protons on the 3,4-disubstituted pyridine ring, together with those of an ADP-ribosyl group (Table 2), indicative of the NAD-analog containing a methyl 4-aminonicotinate moiety.



4 R = OCH_3
5 R = OH
6 R = NH_2

10 R = OCH_3
11 R = OH
12 R = NH_2

The formation of a NAD-analog in this base-exchange reaction is considered to proceed in competition with water for an enzyme–ADP-ribose complex



Scheme 1.

(Scheme 1).[6] According to this assumption, a base concentration would have a marked influence on the formation of the analog. In fact, the yield of **4** (based on NAD used) was apparently dependent on the base concentration (Table 1). When NAD was kept at a definite concentration, the yield increased with the concentration of methyl 4-aminonicotinate, becoming almost constant above 25 mM, where the reaction mixture attained a nearly saturated solution of the base. However, the yield was essentially unaffected by the NAD concentrations (Table 1). In the previous communication,[1] the base/NAD in 4:1 ratio has been proved to be useful for this reaction. Accordingly, it was practical to perform the reaction around 7 mM (1 M=1 mol dm^{-3}) NAD and at not less than 25 mM base.

The amide analog (**6**) was also prepared from 4-aminonicotinamide and NAD in a similar manner. In this case, the base concentration could be raised above 45 mM, resulting in a notably higher yield of **6** as compared with that of **4** (Table 1). The ^{1}H-NMR spectrum of **6** showed essentially the same pattern as that of **4** except for the absence of the signal at δ 3.95.

The demethylated analog (**5**) was obtained in 84% yield by treating **4** with 0.2 M NH_4OH at 40 °C for 12 h. In this case, no cleavage of the glycosidic linkage between pyridine and ADP-ribose moieties was observed during the reaction, although NAD was easily cleaved under the same conditions.

The NAD-analogs prepared by Kaplan *et al.*[5] were all susceptible, more or less, to the hydrolase action of NADase. On the other hand, the new analogs (**4**—**6**) were resistant to this action even if they were incubated with NADase for 24 h. These findings show the irreversible formation of the new analogs at the final step (Scheme 1), suggesting the difference in the character of glycosidic linkage between the two kinds of analogs.

Table 1. Effect of the base concentration on the yield of the analogs

Base concn/mM	Yield (%)[a] of analogs			
	4		**6**	
	4 mM NAD	8 mM NAD	4 mM NAD	8 mM NAD
5	23	14	39	32
10	31	40	52	54
15	49	52	65	64
20	55	57	70	73
25	62	63	74	76
30	63	65	76	77
40	—	—	79	78
50	—	—	79	80

a) The yield was estimated on TLC using a thin layer scanner (see Experimental).

Degradation of NAD-analogs. Nucleosides were prepared *via* mononucleotides by hydrolytic cleavages of the analogs obtained above.

By treatment with phosphodiesterase (PDE, optimum pH 9), followed by chromatographic purification, compounds **5** and **6** gave demethyl and amide mononucleotides (**11**, **12**) in quantitative yield, respectively, along with adenylic acid (**13**).

Compound **4** was found to demethylate slowly during the incubation at pH 9, although methyl 4-aminonicotinate itself remained unchanged under the same conditions. Thus, treatment of **4** with PDE resulted in the formation of a mixture of ester mononucleotide (**10**) and **11** in a ratio of about 1:1. On the other hand, treatment of **4** with pyrophosphatase (optimum pH 7) gave **10** predominantly in 85% yield together with a small amount of **11**. Accordingly, it is preferable to use pyrophosphatase for the preparation of **10**, though the reaction rate is slower than for PDE because of the product inhibition[7] by the adenylic acid formed.

Incubation of **11** with 5′-nucleotidase at pH 9, followed by column chromatography, provided the desired nucleoside (**1**) quantitatively; on crystallization from aqueous ethanol it gave white needles: mp 205—207 °C (dec), $[\alpha]_D^{20}=-53.4°$ (H_2O), λ_{max} 271 nm (log ε 4.32, H_2O). The mixed mp of **1** with authentic clitidine was undepressed, and the spectral properties and TLC mobility were also in good agreement with those of the sample.

In a similar manner, an amide nucleoside (**2**) was obtained in nearly quantitative yield by dephosphorylation of **12**. However, unlike the case of **1**, the purification of **2** could not be achieved by the ion exchange chromatography alone owing to concomitance with inorganic salts. In order to remove the impurities, further repeated chromatography on Sephadex G-10 was required and the nucleoside was purified to give a white crystalline mass: mp 145—147 °C (dec), $[\alpha]_D^{20}=-62.8°$ (H_2O), λ_{max} 272 nm (log ε 4.30, H_2O).

Dephosphorylation of **10** was also attempted at pH 8, where the ester moiety remained unchanged. Although the reaction was observed to proceed successfully on TLC, the ester nucleoside could not be obtained, contrary to our expectation, because the ester was readily hydrolyzed during the purification procedures (pH 7).

Some Chemical Aspects of the Compounds Obtained. In the ^{1}H-NMR spectra (Table 2), two anomeric protons of the new analogs (**4**, **6**) appeared as two clear doublets around δ 5.6 (J=5.0 Hz) and δ 6.0 Hz (J=5.5 Hz), separately. Based on the spectral pattern of the mononucleotides (**10**—**12**) and adenylic acid (**13**), the former doublet was assigned to the anomeric proton of the pyridine side. On the other

Table 2. The ^{1}H-NMR spectra of major products and related compounds[a)]

a) The spectra were measured in D_2O at 60 MHz, and the abbreviations "py-H_2 and ad-H_2" refer to the protons at C_2 of pyridine and adenine nuclei, respectively. b) The chemical shifts of the ribose protons fell within δ 3.8—4.5 as a broad peak (**4**, **6**) or two broad singlets (**11**, **12**, **1**, **2**). c) The coupling constants were estimated by first-order approximation. d) $J_{H_1'H_2'(py)}$ and $J_{H_1'H_2'(ad)}$ were 5.0 and 5.5 Hz, respectively, for all compounds except for **3** and **9**.

hand, two anomeric protons of the analogs so far prepared including isonicotinic acid-, and 4-methylnicotinamide analogs (**8**, **9**)[8,9] as well as NAD (**3**), which are known to take a pyridinium form, appeared at *ca.* δ 6.0 as a broad doublet.

The coupling constant between H_5 and H_6 on the pyridine nucleus was estimated to be 7.5 Hz for the new compounds, whereas it was 6.0 Hz for the compounds of the pyridinium form. According to Renault *et al.*,[10] the coupling between H_2 and H_3 on the nucleus of 4-aminoquinoline was 8 Hz for the imino form and 5 Hz for the amino form.

In the UV spectra, compounds **4** and **6** showed a strong absorption maximum at 264 nm in spite of the fact that the pyridine bases and ADP-ribose had the maximum at 252 and 259 nm, respectively. As the analogs were cleaved in turn to the nucleoside, a further bathochromic shift was observed from 264 nm to 271 nm or above. In addition, it was reported previously[11] that 4-aminopyridine exhibited the absorption peak at 242 nm in contrast to that of *N*-methyl-1,4-dihydro-4-iminopyridine at 268 nm.

These observations confirmed the 1,4-dihydro-4-imino β-riboside structure of the compounds prepared here.

Toxic Activity and Stability of Nucleosides. LD_{50}-values of clitidine (**1**) and its amide derivative (**2**) were estimated to be 100 and 16 mg/kg by preliminary tests (mice, intraperitoneal).

The carbamoyl group of **2** proved to be quite susceptible to hydrolysis, based on the results from TLC. When treated with boiling water for 5 h, compound **2** was completely hydrolyzed to yield **1**, and with hot water (70 °C) about 70% of **2** was converted to **1**. On the other hand, 4-aminonicotinamide was quite stable under these conditions. Additionally, compound **2** was completely converted to **1** on standing in 0.1 M NaOH at ambient temperature for 24 h, whereas it remained essentially unchanged on standing in water under the same conditions.

These results suggest the possible existence of the amide nucleoside (**2**) in the toadstool and conversion of **2** into **1** during extraction procedures.

Experimental

All melting points were uncorrected. IR and UV spectra were recorded on a Shimadzu IR-27G and a Hitachi 200-20 spectrophotometers, respectively. ^{1}H-NMR spectra were determined on a Hitachi R-20B (60 MHz) spectrometer in deuterium oxide with sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard. The abbreviations "s, d, dd, br, bs, and bd" denote "singlet, doublet, double doublet, broad, broad singlet, and broad doublet", respectively Optical rotations were measured with a Union PM 101 polarimeter. All the reactions were monitored by TLC on silica gel $60F_{254}$ plates (Merck, 10×10 cm) developed with 2-propanol–0.3% aqueous ammonia (7:3, v/v). The analyses of the chromatograms obtained were performed by a Shimadzu CS-910 scanner equipped with a chromatopack C-R1A. Column chromatographies[12] were carried out on DEAE-Sephadex A-25 connected to LKB Uvicord II (254 nm), unless stated otherwise. β-NAD (Grade III), phosphodiesterase (EC 3.1.4.1, snake venom, Type II), nucleotide pyrophosphatase (EC 3.6.1.9, snake venom, Type II), and 5′-nucleotidase (EC 3.1.3.5, snake venom, Grade IV) were purchased from Sigma Chemical Co.

Pig-brain NADase. The crude enzyme was prepared by the method of Zatman *et al.*[5a] The colloidal supernatant fluid obtained containing about 0.4 U[13] of NADase activity per ml was used without further purification.

4-Aminonicotinic Acid. Prepared from 3-methylpyridine in four steps, and recrystallized from water: mp 318—320 °C (dec) [lit,[14] 330 °C (dec)].

Methyl 4-Aminonicotinate. Prepared by esterification of the above compound, and recrystallized from water: mp 171—173 °C (lit,[15] 174—176 °C).

4-Aminonicotinamide. Prepared from 3-methylpyridine in six steps, and recrystallized from benzene: mp 227—229 °C (lit,[16] 232—234 °C).

Methyl 1,4-Dihydro-4-iminonicotinate Analog of NAD (4). Methyl 4-aminonicotinate (4.8 mmol, 730 mg) and NAD (1.2 mmol, 800 mg, neutralized with 2 M NaOH to pH 7) were incubated with pig-brain NADase (12 U, 30 ml) in 0.1 M Tris-HCl (pH 7.4, 130 ml) at 37 °C for 8 h. After removal of denatured protein by addition of 70% trichloroacetic acid (2 ml), cold acetone (800 ml) was added to the

clear supernatant to give a yellowish hygroscopic powder (720 mg). The crude product thus obtained was dissolved in water (20 ml) and applied to a column of DEAE-Sephadex (HCO_2^--form) (column size; 2.5 cm × 45 cm). The column was eluted with 300 ml portions of 0.02, 0.2, and 0.5 M HCO_2NH_4 (pH 7), successively. The first major component was eluted with the 0.2 M solution. The eluate (70 ml) showing an UV-absorbing peak at 264 nm was collected and lyophilized repeatedly to give **4** (420 mg) as the ammonium salt. An analytical sample of **4** was obtained by further chromatography and drying over P_2O_5 *in vacuo* for 12 h at 40 °C: $[\alpha]_D^{20} = -26.7°$ (*c* 3.22, H_2O); IR (KBr), 3300—2800, 1715, 1655, 1200, 1100, 1065 cm^{-1}; UV (H_2O), λ_{max} 264 nm (log ε 4.27); ^{1}H-NMR (Table 2). Found: C, 35.92; H, 5.13; N, 16.85%. Calcd for $C_{22}H_{29}N_7O_{15}P_2 \cdot 2NH_3$: C, 36.49; H, 4.83; N, 17.41%.

The second major component was eluted with the 0.5 M solution. The eluate (80 ml) showing an UV-absorbing peak at 259 nm was treated in a similar manner to give the product (190 mg), which was identical with authentic ADP-ribose on spectral comparisons.

*1,4-Dihydro-4-iminonicotinamide Analog of NAD (**6**).* 4-Aminonicotinamide (9.3 mmol, 1270 mg) and NAD (2.2 mmol, 1500 mg) were incubated with NADase (16 U, 40 ml) in 0.1 M Tris-HCl (160 ml) for 7 h. The reaction mixture was treated in a similar manner to that described above to give the crude product (1346 mg), which was dissolved in water (30 ml) and applied to a column (HCO_3^--form). The column was eluted with aqueous NH_4HCO_3 (pH 8) in a similar manner to that described above. The first major component was eluted with the 0.2 M solution. The eluate (80 ml) showing a UV maximum at 264 nm was collected and lyophilized repeatedly to give **6** (1035 mg) as the ammonium salt: $[\alpha]_D^{20} = -32.6°$ (*c* 0.37, H_2O); IR (nujol), 3400—2700, 1675, 1580, 1235 cm^{-1}; UV (H_2O), λ_{max} 264 nm (log ε 4.29); ^{1}H-NMR (Table 2). Found: C, 34.25; H, 4.71; N, 19.62%. Calcd for $C_{21}H_{28}N_8O_{14}P_2 \cdot 2NH_3 \cdot H_2O$: C, 34.52; H, 4.93; N, 19.18%.

*Yield Determination of **4** and **6**.* A series of mixtures (1 ml), containing various amounts of methyl 4-aminonicotinate or 4-aminonicotinamide, 4 or 8 μmol of NAD, and NADase (0.12 U) was incubated for 6 h. The aliquots of the reaction mixture were analyzed by TLC using a thin layer scanner with a chromatopack. On the basis of the chromatograms thus obtained, the ratios of the analogs (**4**, **6**) to ADP-ribose (**7**) were evaluated. This method was based on the fact that **4** or **6** and **7** had nearly the same ε-values at 262 nm. The data shown in Table 1 display the averages of three measurements.

*1,4-Dihydro-4-iminonicotinic Acid Analog of NAD (**5**).* Compound **4** (300 mg) was treated with 0.2 M NH_4OH (3 ml) for 12 h at 40 °C. The residue obtained on evaporation of the resulting solution was purified as described for **6** to give **5** (245 mg) as an ammonium salt: $[\alpha]_D^{20} = -31.5°$ (*c* 0.72, H_2O): UV (H_2O), λ_{max} 263 nm (log ε 4.30); ^{1}H-NMR (δ, D_2O), 4.2—4.6 (10H, br, riboses), 5.60 (1H, d, J=5.0 Hz, py-C$_i$H), 6.05 (1H, d, J=5.5 Hz, ad-C$_i$H), 6.80 (1H, d, J=7.5 Hz, py-H$_5$), 8.06 (1H, dd, J=7.5, 1.5 Hz, py-H$_6$), 8.17 (1H, s, ad-H$_2$), 8.43 (1H, s, ad-H$_8$), 8.50 (1H, d, J=1.5 Hz, py-H$_2$). Found: C, 35.02; H, 4.96; N, 15.22%. Calcd for $C_{21}H_{27}N_7O_{15}P_2 \cdot 2NH_3$: C, 35.34; H, 4.63; N, 15.17%.

*1,4-Dihydro-4-iminonicotinic Acid Mononucleotide (**11**).* Compound **5** (539 mg) was incubated with PDE (20 U) in 0.2 M Tris-HCl (pH 9.0, 5 ml) containing $MgCl_2$ (3 mg) at 37 °C for 12 h. In order to reduce the ionic strength, the reaction mixture was diluted with water (250 ml) and applied to a column (HCO_3^--form), followed by successive elution with 200 ml portions of 0.02, 0.2, and 0.5 M NH_4HCO_3 (pH 8). The first major component was eluted with the 0.2 M solution. The eluate (70 ml) showing UV maximum at 268 nm were collected and lyophilized repeatedly to give **11** (260 mg) as the ammonium salt: $[\alpha]_D^{20} = -52.3°$ (*c* 0.65, H_2O); UV (H_2O), λ_{max} 268 nm (log ε 4.31); ^{1}H-NMR (Table 2). Found: C, 35.62; H, 5.07; N, 11.85%. Calcd for $C_{11}H_{15}N_2O_9P \cdot NH_3$; C, 35.97; H, 4.90; N, 11.44%.

Similar treatment of the second major component eluted with the 0.5 M solution gave **13** (255 mg), which was identical with authentic ammonium adenylate on spectral comparisons.

*Methyl 1,4-Dihydro-4-iminonicotinate Mononucleotide (**10**).* Compound **4** (184 mg) was incubated with pyrophosphatase (15 U) in 0.2 M Tris-HCl (pH 7.4, 4 ml) containing $MgCl_2$ (3 mg) for 22 h. The reaction mixture on dilution with water (80 ml) was applied to a column (HCO_2^--form). The column was eluted with aqueous HCO_2NH_4 (pH 7) as described for **11**, followed by lyophilization of the major components eluted with the 0.2 M solution, to give **10** (76 mg) and small amounts of **11** (8 mg). Analytical sample of **10** was obtained by further chromatography and drying over P_2O_5 *in vacuo* for 12 h at 40 °C: $[\alpha]_D^{20} = -50.8°$ (*c* 3.23, H_2O); UV (H_2O), λ_{max} 269 nm (log ε 4.28); ^{1}H-NMR (δ D_2O), 4.00 (3H, s, CO_2CH_3), 4.2 (2H, bs, ribose), 4.45 (3H, bs, ribose), 5.76 (1H, d, J=5.0 Hz, py-C$_i$H), 7.20 (1H, d, J=7.5 Hz, py-H$_5$), 8.47 (1H, dd, J=7.5, 1.5 Hz, py-H$_6$), 9.03 (1H, d, J=1.5 Hz, py-H$_2$). Found: C, 37.47; H, 5.42; N, 10.88%. Calcd for $C_{12}H_{17}N_2O_9P \cdot NH_3$: C, 37.80; H, 5.25; N, 11.02%.

*1,4-Dihydro-4-iminonicotinamide Mononucleotide (**12**).* Compound **6** (750 mg) was incubated with PDE (20 U) in 0.2 M Tris-HCl (pH 9.0, 6 ml) containing $MgCl_2$ (4 mg) for 16 h. The reaction mixture was treated as described for **11** to give **12** (328 mg) as ammonium salt: $[\alpha]_D^{20} = -55.2°$ (*c* 0.85, H_2O); UV (H_2O), λ_{max} 269 nm (log ε 4.30); ^{1}H-NMR (Table 2). Found: C, 35.71; H, 5.40; N, 15.62%. Calcd for $C_{11}H_{16}N_3O_8P \cdot NH_3$: C, 36.07; H, 5.19; N, 15.30%.

*1,4-Dihydro-5-iminonicotinic Acid Ribonucleoside (**1**).* Compound **11** (260 mg) was incubated with 5′-nucleotidase (40 U) in 0.2 M Tris-HCl (pH 9.2, 3.5 ml) containing $MgCl_2$ (8 mg) for 12 h. The mixture was maintained at pH 9 by occasional addition of 0.2 M NaOH. The precipitated phosphate salt was removed by filtration. The filtrate was then diluted with water (60 ml) and applied to a column (HCO_3^--form), which was eluted with 0.02 M NH_4HCO_3. The eluate (60 ml) having UV absorption was lyophilized to give **1** (192 mg) as a white crystalline mass, which on recrystallization from aqueous ethanol gave an analytical sample as white needles: mp 206—208 °C (dec) (lit,[2] 189—191 °C); $[\alpha]_D^{20} = -56.8°$ (*c* 0.75, H_2O); IR (nujol), 3400—3000, 1665, 1580, 1190 cm^{-1}; UV (H_2O), λ_{max} 271 nm (log ε 4.31); ^{1}H-NMR (Table 2). Found: C, 46.39; H, 5.35; N, 9.55%. Calcd for $C_{11}H_{14}N_2O_6 \cdot H_2O$: C, 45.83; H, 5.60; N, 9.72%.

*1,4-Dihydro-4-iminonicotinamide Ribonucleoside (**2**).* Compound **12** (255 mg) was incubated with 5′-nucleotidase (40 U) in 0.2 M Tris-HCl (pH 9.2, 3.5 ml) containing $MgCl_2$ (8 mg) for 10 h. The mixture was maintained at pH 9 during the reaction by occasional addition of 0.2 M NaOH. The resulting mixture was treated as described for **1**, followed by further repeated chromatography on Sephadex G-10 (column size; 2.5 × 100 cm) to give **2** (188 mg) as a white crystalline mass: mp 145—147 °C (dec); $[\alpha]_D^{20} = -62.8°$ (*c* 0.875, H_2O); IR (nujol), 3350—2700, 1675, 1600, 1290 cm^{-1}; UV (H_2O), λ_{max} 272 nm (log ε 4.30); ^{1}H-NMR (Table

2). Found: C, 43.55; H, 6.13; N, 13.88%. Calcd for $C_{11}H_{15}N_3O_5 \cdot 2H_2O$: C, 43.27; H, 6.26; N, 13.76%.

The authors wish to thank Prof. J. K. Seydel, Forschungsinstitut Borstel, West Germany, for his continuing interest and encouragement. They are also grateful to Prof. I. Azuma and Dr. I. Sekikawa for their helpful dicussions and suggestions during this work.

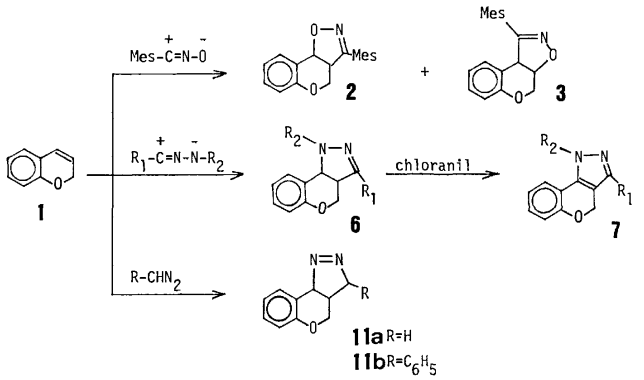
Syntheses of [1]Benzopyrano[4,3-*c*]pyrazoles and -[3,4-*d*]isoxazoles

Tomio SHIMIZU,* Yoshiyuki HAYASHI, Kazunari YAMADA,
Toshiyuki NISHIO, and Kazuhiro TERAMURA
Department of Dyeing, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606
(Received March 31, 1980)

The reaction of 2*H*-1-benzopyran with several 1,3-dipoles gives cycloadducts in good yields. The orientation of the cycloaddition is qualitatively interpreted in terms of FMO theory. These heteropolycyclic compounds were also obtained from hydrazones of 3-aroyl-2*H*-1-benzopyrans, prepared from 3-cyano-2*H*-1-benzopyran.

Interest in the pharmacological activity[1a] and industrially useful chemical properties[2b] of a wide variety of heteropolycyclic compounds, for example, benzopyranopyrazoles,[2] -isoxazoles,[3] and -pyrroles,[4] has considerably increased in the past several years. These compounds have thus far prepared conveniently by intramolecular 1,3-dipolar cycloaddition reactions.[5]

Although the intermolecular reactions of various 1,3-dipoles with polycyclic compounds, such as benzofuran,[6,7] 1-benzothiophene,[6] indene,[7] and 2*H*-1-thiobenzopyran,[8] have been investigated, the reaction with 2*H*-1-benzopyran(**1**) has not been reported. The present paper describes a new, direct synthesis of [1]benzopyrano[4,3-*c*]pyrazoles by the reaction of 2*H*-1-benzopyran with several 1,3-dipoles and the structural determination of the cycloadducts.



Scheme 1.

Results and Discussion

2*H*-1-Benzopyran(**1**) reacts readily with mesitonitrile oxide (MNO) in refluxing ether for over 4 h. The products are a mixture of the two regioisomers of a simple 1:1 cycloadduct (**2a** and **3a** in 35 and 4% yields respectively). Each regioisomer was isolated and characterized on a crystalline basis (see Table 1). In **3a**, the two benzene rings may lie on planes parallel to each other for steric reasons. Thus, the He proton in the benzopyran benzene ring is shielded and shifts upfield[9] (δ 6.4). While the chemical shift of normal *o*-methyl in the mesityl group usually appears about δ 2.2 (in **2a**, they appear at δ 2.33), one of the *o*-methyl group of **3a** does appear at δ 1.47. This upfield shift can also be ascribed to the shielding effect of the benzopyran benzene ring. One proton doublet at δ 5.6 is only compatible with the methine of benzyl ether (Ha in **2a**) (Table 1).

Benzonitrile oxide(BNO) failed to yield an isolable adduct with **1** under a variety of conditions, and 1,2,5-oxadiazole *N*-oxide (furoxan; a dimer of BNO) was the only isolable compound from the reaction mixture. The difference in the chemical reactivity between BNO and MNO and the regioselectivity of the cycloaddition may be explained in terms of the frontier molecular orbital (FMO) interactions[10] (Scheme 2). BNO has a much higher LUMO (2.19 eV) energy and a lower HOMO (−11.03 eV) energy[10a] than

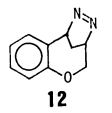
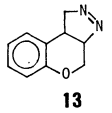
a) A; Prepared by the cycloaddition reaction, B; Prepared by the reaction of **4** with aryl(or tosyl)hydrazines. b) Recrystallized from ethanol. c) **6b**, **6e**, **6f**, **14a**, and **14b** were dissolved in DMSO-d_6, the others were dissolved in $CDCl_3$. d) Lit,[2d] mp 230—233 °C. e) Lit,[2d] mp 197—202 °C. f) The IR and NMR spectra of these compounds were completely identical with authentic specimens.[2d]

pared by the intramolecular 1,3-dipolar cycloaddition reaction of *o*-allyloxyphenyldiazomethane (**10**). This result suggests that the structure of the intramolecular cycloadduct of **10** and the intermolecular cycloadduct of **1** with diazomethane is the same one (**11**), inconsistent with the regioisomers (**12** and **13** respectively).



12



13

The regioselectivity of this reaction may be explained in terms of a dipole-HOMO controlled 1,3-dipolar cycloaddition (see Scheme 2). The treatment of phenyldiazomethane with **1** under similar conditions also gave an oily product, which was found to be compatible with the assigned structure (**11b**, R=C_6H_5). Several attempts to isolate the cycloadducts in the crystalline state were unsuccessful, and it is known that the pyrazolines(**11**) generally exhibit low melting points and are moderately sensitive to heating.[2c]

1 failed to undergo cycloadditions with other 1,3-dipoles, such as phenylazide or diphenylnitrone, under a variety of conditions.

While the 1,3-dipolar cycloadditions reported here gave reasonable yields of polycyclic heterocycles, it is hoped to develop methods of preparing authentic specimens with an unequivocal regiochemistry. In our previous paper,[2d] [1]benzopyrano[4,3-*c*]pyrazoles (**14**) were prepared from the reaction of **9** with Pb(OAc)$_4$ and subsequent treatment with potassium hydroxide. The structures of these pyrazoles were determined by comparison with an authentic specimen, prepared by the reaction of 3-formyl-4-chromanone (**15**) with hydrazine hydrochloride.[9] This latter method is rather cumbersome, however, because the synthesis of **15** involves multistep reactions. We found that the synthesis of **14** from 3-cyano-2*H*-1-benzopyran (**8**) shown in Scheme 3 gave more satisfactory results.

While the synthesis of benzopyrano derivatives using the Wittig reaction is very useful,[13] it is generally difficult to prepare 3-substituted-2*H*-1-benzopyran by this method.[14] A convenient one-step synthesis[16] of **8** (20% yield) is known, it is shown below. A modification of this preparative method was used, since, in our hands, it gave more satisfactory results (40—50% yield) when the reaction mixture was distilled. The **8** was treated with Grignard reagents, and the subsequent hydrolysis of the adducts gave 3-aroyl (or acetyl)-2*H*-1-benzopyrans (**4**). The treatment of **4** with arylhydrazines, *p*-tolylsulfonylhydrazine, or hydroxylamine gave the corresponding arylhydrazones (**16**), *p*-tolylsulfonylhydrazone (**17**), and oxime (**18**) respectively. The yields, melting points, and analytical data for these compounds (**4**, **16**—**18**) are given in Table 3. The treatment of **16** with acetic acid at 110 °C, or the treatment of the mixture of **4** and arylhydrazines with acetic acid at the same temperature, gave cyclized compounds which showed the same physical properties as the **6** prepared by the reaction of **1** with nitrilimines. The treatment of **17** with potassium hydroxide gave cyclized compounds which have the same physical properties as the specimens previously reported.[2d] All attempts to cyclize **18** to **2** failed.

Experimental

Measurements. All the melting and boiling points are uncorrected. The IR spectra were recorded with a Hitachi 215 Infrared Spectrophotometer. The NMR spectra were measured on a Varian T-60A instrument, with TMS as an internal standard.

Materials. 2*H*-1-Benzopyran was prepared by the method of Ide *et al.*[17]

*Preparation of 3-Cyano-2*H*-1-benzopyran(8).* The reaction of salicylaldehyde with acrylonitrile was carried out according to the literature.[16] The reaction mixture was poured into water and extracted with ether several times. A modification of a work-up by distillation *in vacuo* gave **8** (40—50% yield), which solidified in the condenser; bp 105—110 °C/2 mmHg, mp 48—49 °C (from ethanol) (lit,[16] 48—49 °C).

*Preparation of 3-Aroyl(or Acetyl)-2*H*-1-benzopyrans(4).* To an anhydrous ether solution of phenylmagnesium bromide (0.12 mol), we added, drop by drop, an anhydrous ether solution of **8** (0.1 mol) at 10—20 °C. After insoluble materials had thus been precipitated, the mixture was refluxed for 6 h. After cooling, 30% sulfuric acid (100 ml) was added, drop by drop, at 5—10 °C, and then the mixture was refluxed for 2 h. The insoluble material was filtered off using a Celite bed, and the ethereal layer was washed with a 5% sodium carbonate solution and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent yielded an oily material, which was subsequently distilled *in vacuo* to give **4a** in a 40% yield; bp 171—173 °C/4 mmHg. The spectral data are shown in Table 3.

Reaction of 1 with Mesitonitrile Oxide. A mixture of **1** (8 g, 60 mmol), mesitonitrile oxide (5 g, 31 mmol), and ether (70 ml) was refluxed for 4 d. The subsequent evaporation of the solvent yielded white crystals. Recrystallization from ethanol gave colorless needles of the cycloadduct (**2a**) (mp 140—142 °C, 3.2 g) and then **3a** (mp 127—130 °C, 350 mg). The spectral data are shown in Table 1.

Reaction of 1 with Nitrilimines. To a mixture of **1** (4 g, 30 mmol), triethylamine (4 g, 40 mmol), and benzene (50 ml), we added a benzene solution of hydrazonoyl chlorides (30 mmol), after which the mixture was refluxed for 20 h. The mixture was washed with water, and the subsequent evaporation of the solvent yielded pale yellow crystals. Recrystallization from ethanol gave the cycloadducts (**6**). The spectral data are shown in Table 2.

Dehydration of 6. The dehydration of **6** to **7** was carried out according to the literature.[18]

Reaction of 1 with Diazomethane. To an ether solution of **1** (5 g, 38 mmol), we introduced diazomethane gas (about 0.1 mol) at −15 °C in the dark, after which the mixture was stirred for 4 h at that temperature. Then the mixture was further stirred for 4 d at room temperature. After the evaporation of the solvent, the unreacted 2*H*-1-benzopyran was distilled *in vacuo* (2 mmHg). The NMR spectrum of the residue is completely identical with a previously reported one.[2c]

The Reaction of 4 with Aryl(or p-*Tolylsulfonyl)hydrazines.* An ethanol solution of **4** (20 mmol) and aryl (or *p*-tolylsulfonyl)hydrazines (20 mmol) was refluxed for 6 h. The subsequent evaporation of the solvent yielded a viscous oily material which solidified upon scratching with a glass rod. Recrystallization from ethanol gave colorless needles (**16** or **17**). The spectral data are shown in Table 3. We may also carry out this reaction at room temperature in acetic acid.

The Reaction of 4 with Hydroxylamine. This reaction was carried out in the manner described above.

The Treatment of 4 with Aryl (or p-*Tolylsulfonyl)hydrazines in Acetic Acid.* A mixture of **4** (20 mmol) and aryl (or *p*-tolylsulfonyl)hydrazines in acetic acid (100 ml) was refluxed for 4 h, poured into water, and extracted with benzene. The organic layer was dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent yielded pyrazolines (**6**) in good yields.

The Treatment of 16 with Acetic Acid. A solution of **16** in acetic acid was refluxed for 3 h. The treatment of the reaction mixture in the manner described above yielded pyrazolines (**6**) in good yields.

The Treatment of 17 with Potassium Hydroxide. To a solution of potassium hydroxide (0.4 g, 3 mmol) in 95% aqueous ethanol (50 ml), we added **17** (2 mmol), after which the mixture was stirred for 1 h under refluxing. After the subsequent removal of the solvent from the reaction mixture, the residue was treated with water (50 ml) and extracted with ether (50 ml). The ethereal layer was then dried over anhydrous sodium sulfate. The evaporation of the solvent yielded **14** (about 70% yields).

*Reaction of 3-Benzoyl-2*H*-1-benzopyran with Benzonitrile Oxide (BNO).* To a benzene solution of **4a** (4.7 g, 20 mmol) and α-chlorobenzaldoxime (4 g, 26 mmol), we added a dilute solution of triethylamine (3 ml) in benzene (20 ml) at 5 °C and the mixture was further stirred at room temperature overnight. The mixture was washed with water and the organic layer was dried over sodium sulfate. The evaporation of the solvent yielded **5** in a 30% yield (2.1 g); mp 178—179 °C (from ethanol). NMR ($CDCl_3$) δ: 4.2 (d, 1H, J=11 Hz), 4.95 (d, 1H, J=11 Hz), 6.0 (s, 1H), 6.8—7.8 (m, 12H), and 7.8—8.1 (m, 2H). IR (Nujol): 1680 cm^{-1} (C=O). Found: C, 77.0; H, 4.85; N, 3.88%. Calcd for $C_{23}H_{17}O_3N$; C, 77.7; H, 4.82; N, 3.94%.

Stereochemical Studies of the Hydrogenation with an Asymmetrically Modified Raney Nickel Catalyst. The Hydrogenation of Acetylacetone

Akira TAI,* Kazuhisa ITO, and Tadao HARADA
Institute for Protein Research, Osaka University, Yamada-Kami, Suita, Osaka 565

(Received April 4, 1980)

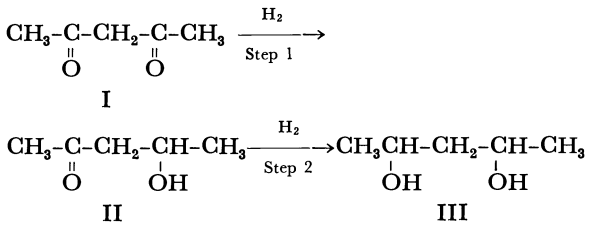
The hydrogenation of acetylacetone (I) over asymmetrically modified Raney nickel (MRNi) proceeded, step by step, as follows: acetylacetone (I) $\xrightarrow{\text{Step 1}}$ 4-hydroxy-2-pentanone (II) $\xrightarrow{\text{Step 2}}$ 2,4-pentanediol (III). It was demonstrated that the optical yield of Step 1 and the diastereomer excess of Step 2 are governed by the ratio of the stereo-differentiating reaction site to the non-stereo-differentiating reaction site on the catalyst. The stereochemistry of each step was also discussed based on the mode of the intermolecular hydrogen bondings between the substrate and tartaric acid adsorbed on the catalyst. RNi modified with a mixture of tartaric acid and NaBr (TA–NaBr–MRNi) gave the best result with respect to both Step 1 and Step 2.

In a previous communication, we have briefly reported that the modification of Raney nickel (RNi) with an aqueous solution of tartaric acid (TA) and NaBr gave an excellent catalyst (TA–NaBr–MRNi) for the stereo-differentiating (asymmetric) hydrogenation of acetylacetone (I) to 2,4-pentanediol (III).[1]

Although the hydrogenation of I over various MRNi's has been conducted by our research group[2] and others,[3] and although some important features of the reaction have been reported, the details of the mechanism of the stereo-differentiation have not yet been made clear.

The stereochemical studies of this reaction with the use of the effective enantio-differentiating catalyst (TA–NaBr–MRNi) enable us to obtain clear-cut information for understanding the reaction mechanism of the modified catalyst.

As has been reported,[2] the hydrogenation of I over RNi proceeds by a successive two-step process, as is shown in Scheme 1:



Scheme 1.

In this report, the study of each step will be described first, and then the relation of the two steps will be discussed.

Results and Discussion

Enantioface-differentiating Hydrogenation of I to II. The reaction of Step 1 with an asymmetrically modified catalyst is classified as an enantioface-differentiating reaction.[4] When the hydrogenation of I was stopped at the stage when the consumption of hydrogen reached a 1.1 molar equivalent to I, a mixture of I, II, and III was obtained. The results of the reactions carried out over three types of catalyst (RNi, TA–MRNi, and TA–NaBr–MRNi) are summarized in Table 1. The use of TA–NaBr–MRNi gave a higher optical yield than that of TA–MRNi. A comparable result has been obtained in the hydrogenation of methyl acetoacetate (MAA) to methyl 3-hydroxybutyrate (MHB).[5]

Our recent study[6] has shown that the optical yield of the MAA to MHB reaction is closely related to the ratio of the stereo-differentiating reaction site (the site where the substrate is converted to an optically active product by the aid of TA) to the non-stereo-differentiating reaction site (the site where a racemic product is produced) on the catalysts (hereafter, the abbreviations s.d. and non-s.d. will refer to the stereo-differentiating and non-stereo-differentiating reaction sites respectively). Furthermore, it has also been made clear that the proportion of the s.d. on the catalyst increases in the following order: RNi<TA–MRNi< TA–NaBr–MRNi. The NaBr on TA–NaBr–MRNi is considered to be adsorbed on the non-s.d. and to block the activity of the non-s.d. From the resemblance of the present results to those of MAA to MHB, the s.d. for the hydrogenation of MAA may also be said to function as the s.d. for the hydrogenation of I to II.

As may be found in Table 1, the catalyst giving a higher optical yield gives II in a larger proportion. This fact strongly suggests that both the optical purity and the proportion of II are governed by the ratio of the s.d. to non-s.d. The predominant formation of II in the case of TA–NaBr–MRNi indicates that the rate of Step 2 is appreciably slower than the rate of Step 1 at the s.d. From a comparison of the results with three catalysts (Table 1, Entries 1, 2, and 3), it is also evident that the rate of Step 2 at non-s.d. is higher than that at the s.d. That is, the s.d. and non-s.d. have different kinetics features.

I and MAA give (*R*)-II and (*R*)-MHB respectively in the hydrogenations with the catalyst modified with (*R,R*)-TA. When the structural similarity of I to MAA is taken into account, the mode of enantioface-differentiation of I with TA can be expected to be the same as that of MAA reported before.[7] The mode of the interaction between I and (*R,R*)-TA on the s.d. of the catalyst is shown in Figs. 1a and 1b. As may be found in Fig. 1b, one of the carbonyl groups in I to be hydrogenated comes close to the catalyst surface, with its si-face facing the catalyst, while the other, which remains unchanged, is located far from the catalyst. The considerable optical yield in the

reaction of I to II suggests that almost all of the I which has been adsorbed on the catalyst by interacting with (*R,R*)-TA is hydrogenated to (*R*)-II.

Diastereoface-differentiating Hydrogenation of II to III. 4-Hydroxy-2-pentanone, a substrate of Step 2, is a chiral compound. Therefore, the reaction of II to III is classified as a "diastereoface-differentiating reaction."[4] The efficiency of the reaction is expressed by the diastereomer excess (d.e.$=|(R^*,R^*)-(R^*,S^*)|/\{(R^*,R^*)+(R^*,S^*)\}$) of the product.

The results of the hydrogenation of II over various nickel catalysts are listed in Table 2. In the diastereo-differentiating reaction, the use of either an optically pure substrate or a racemic substrate can be expected to give a product with the same d.e. in principle so long as an achiral reagent or catalyst is used.[4]

In the hydrogenation with an unmodified RNi (Entries 1 and 2, Table 2), however, racemic II produces (*R**,*R**)-III in excess, while (*R*)-II gives (*R**,*R**)-III and (*R**,*S**)-III in almost the same ratio. This unusual result indicates that at least two chiral molecules, such as a substrate and a substrate, or a substrate and a product, are involved in the diastereo-differentiation step of the reaction. From the results presented above, the estimation of the inherent diastereoface-differentiating ability of RNi is found to be impossible. At any rate, a high d.e. is not expected in the reaction of II over unmodified RNi.

Entries 3 and 4, Table 2, show the results of the hydrogenation of (*R*)-II over (*R,R*)-TA–MRNi and (*R,R*)-TA–NaBr–MRNi. When (*R,R*)-TA–NaBr–MRNi was used, (*R*)-II was converted to (*R,R*)-III with 80% d.e.

On the other hand, the use of (*R,R*)-TA–MRNi resulted in the formation of (*R,R*)-III with a considerably low d.e. (28%). This great decrease in the d.e. is attributed to two characteristics of the non-s.d. remaining in the catalyst: 1) the d.e. at the non-s.d. is almost zero, as is expected from the result for RNi (Entry 2, Table 2) and 2) the hydrogenation rate at the non-s.d. is higher than that at the s.d., as has been mentioned in the previous section, so that a large portion of the substrate is hydrogenated at the non-s.d.

As is shown in Entries 4 and 5, Table 2, the hydrogenation of (*R*)-II over (*S,S*)-TA–NaBr–MRNi gave an extremely low d.e., in contrast with the high d.e. of the reaction of (*R*)-II over (*R,R*)-TA–NaBr–MRNi. That is, (*R,R*)-TA–NaBr–MRNi has a much higher diastereoface-differentiating ability than (*S,S*)-TA–NaBr–MRNi toward (*R*)-II. The origin of the high

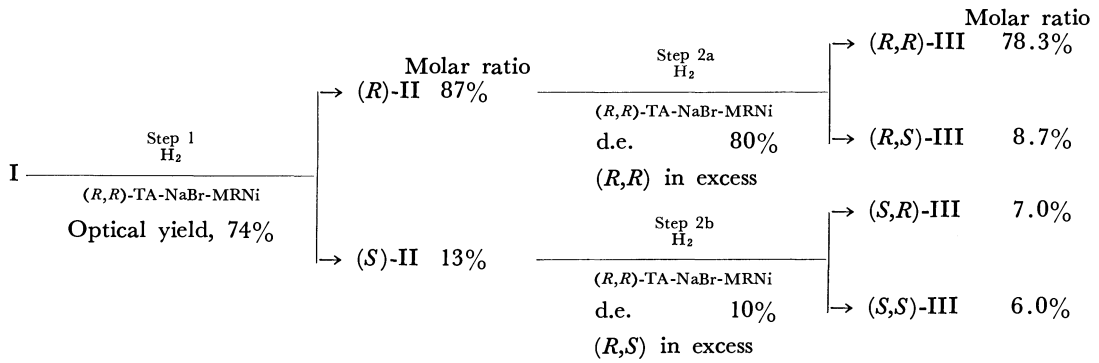

Scheme 2.

d.e. in the combination of *(R)*-II and *(R,R)*-TA–NaBr–MRNi will be explained in the following section.

Enantiomer-differentiating Hydrogenation of Racemic II over TA–NaBr–MRNi. Since II is a chiral compound and TA–NaBr–MRNi is an optically active catalyst, an enantiomer-differentiating hydrogenation could be involved in the course of the reaction of Step 2 if II is a mixture of *(R)*- and *(S)*-II.

As the enantiomer-differentiating reaction and the diastereoface-differentiating reaction are intimately related to each other from the stereochemical viewpoint, a comparison of these two reactions should provide useful information about the stereo-differentiation of the reaction, II to III. In this regard, the partial hydrogenation of racemic II was carried out over *(R,R)*- and *(S,S)*-TA–NaBr–MRNi. The optical purity of the II recovered and the d.e. of the III produced around 50% conversion are listed in Table 3.

As may be found in Table 3, *(R,R)*-TA–NaBr–MRNi hydrogenated *(R)*-II much faster than *(S)*-II. The reaction with *(S,S)*-TA–NaBr–MRNi gave the same results except for the reverse stereochemistry.

The existence of a large enantiomer-differentiation is attributed to the selective adsorption of *(R)*-II on *(R,R)*-TA–NaBr–MRNi, which is brought about by the preferential interaction between *(R)*-II and *(R,R)*-TA. The results in Table 3 also indicate that, if the stereochemistry of II and TA is compatible, thus making for interaction between them, *(R*,R*)*-III is obtained in a high d.e.

From the fact that the hydrogenations of both I and *(R)*-II over *(R,R)*-TA–NaBr–MRNi produce chiral centers with an *R* configuration, the interaction between *(R)*-II and *(R,R)*-TA is expected to be close to that between I and *(R,R)*-TA.

The mode of interaction between *(R)*-II and *(R,R)*-TA is shown in Fig. 2. In this case, two components are brought into a well-fitting interaction by making two hydrogen bondings between them. On the other hand, *(R)*-II and *(S,S)*-TA could not interact well, as is the case of *(R,R)*-TA in any type of arrangemant. The lack of interaction with two hydrogen bondings between TA and II should cause a loss not only of the rigorous stereo-differentiation, but also of the potency of the associative adsorption of II on the catalyst.

From the all discussion presented above, the ratio of diastereomers in the reaction of II to III is governed by both the ratio of s.d. to non-s.d. on the catalyst and the stereochemical compatibility of II and TA.

The Participations of the Enantioface-, Diastereoface-, and Enantiomer-differentiating Reactions in the Process of the I to III Reaction. Based on the data of the separate reactions, I to II and II to III (Entry 3 in Table 1 and Entries 4 and 5 in Table 2), the material balance of the I to III reaction over *(R,R)*-TA–NaBr–MRNi is estimated to be as is shown in Scheme 2. Table 4 shows the proportion of diastereomers and the optical purity of *(R*,R*)*-III observed in the hydrogenation of I to III at a 100% conversion (Entry 2) and those calculated from the figures in Scheme 2 (Entry 3). The good agreement between the observed and calculated values clearly shows that the hydrogenation of the first and second carbonyl group proceeds step by step.

As may be found in Scheme 2, both the enantio-differentiation in Step 1 and the diastereo-differentiations in Steps 2a and 2b serve to give *(R*,R*)*-III with a high optical purity and a high d.e. In the hydrogenation of II to III, the reaction of Step 2a is

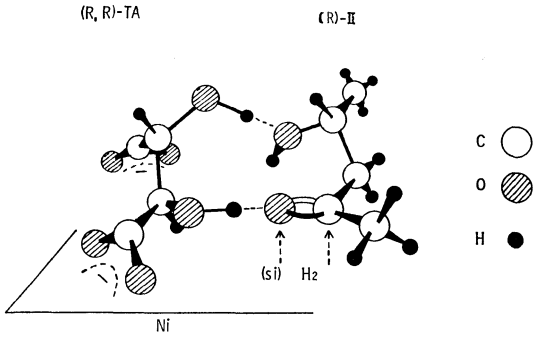

Fig. 2. Schematic representation of the interaction between (*R,R*)-TA and 4-hydroxy-2-pentanone (II).

Table 4. Hydrogenation of I to III over (*R,R*)-TA-NaBr-MRNi

	Conversion %	Hydrogenation products (molar %) (*R*,R**)-III	(*R*,S**)-III	Optical purity of (*R*,R**)-III
1	70	92	8	98
2	100	87	13	86
3	Calculated values based on the data in Scheme 2	84	16	86

expected to proceed predominantly at the early stage of the reaction for the sake of the enantiomer-differentiating reaction with *(R,R)*-TA–NaBr–MRNi, as has been mentioned in the previous section. Therefore, the *(R*,R*)*-III produced at the early stage of the reaction should consist exclusively of *(R,R)*-III.

As is shown in Entry 1, Table 4, the optical purity of *(R*,R*)*-III in the reaction product had reached 98% when the reaction was discontinued at conversion of 70%.

It is evident that the hydrogenation of I to III over TA–NaBr–MRNi is the ideal stereo-differentiating reaction; that is, all three types of the stereo-differentiating reactions, enantioface-differentiation in Step 1, and diastereoface- and enantiomer-differentiations in Step 2, serve to increase the optical purity of *(R*,R*)*-III, the final hydrogenation product.

Experimental

The analytical GLC was carried out with a Shimadzu GC-4A-PF gas chromatograph using a 3 m-5 mm o.d. glass column packed with 15% Ucon 50-HB-2000 on Chromosorb W. The ^{1}H-NMR spectra were taken with a JEOL-FX-100 instrument. The optical rotations were measured with a Perkin Elmer 241 polarimeter.

All the chemicals except for those listed below were obtained from commercial sources and were used without further purification.

The catalysts used in this study were prepared by the method reported before.[5] The THF employed as a solvent of the hydrogenation was prepared as follows: commercial THF was dried over NaH overnight and was then distilled under a nitrogen atmosphere. (*R,R*)- and (*S,S*)-2,4-pentanediol (III) were prepared by the method previously reported.[1] *(R,R)*-III, mp 50.5 °C, bp 111—113 °C/19 mmHg, Found: C, 56.50; H, 11.77%. Calcd for $C_5H_{12}O_2\cdot(0.1\ H_2O)$: C, 56.67; H, 11.62%, $[\alpha]_D^{20}$ −54.5° (*c* 10, ethanol), NMR ($CDCl_3$, TMS) δ, 1.30 (d, J=6.3 Hz, 6H, two $C\underline{H}_3$–CH(OH)–), 1.65 (t, J=6.2 Hz, 2H, –CH(OH)–$C\underline{H}_2$–CH(OH)–) 2.75 (broad signal, 2H, two O$\underline{H}$), 4.23 (m, 2H, two CH_3–$C\underline{H}$(OH)–). The IR spectra of the sample were almost identical to those listed in the literature.[8] The analytical GLC (Ucon/80 °C) showed a single peak. *(S,S)*-III, $[\alpha]_D^{20}$ +54.2° (*c* 10, ethanol). All the other data of this compound were identical to those of *(R,R)*-III. *(R,R)*- and *(S,S)*-2,4-diacetoxypentane (V) were prepared by the treatment of acetic anhydride to III in the presence of pyridine, followed by purification with the preparative GLC of the sample. *(R,R)*-V, $[\alpha]_D^{20}$ −40.5° (*c* 10, ethanol). The analytical GLC (NPGS/80 °C) showed a single peak (retention time 79 min). The NMR spectra (TMS, $CDCl_3$) of V showed signals at δ, 1.22 (d, J=6 Hz, 6H, two $C\underline{H}_3$–CHOAc–), 1.71 and 1.77 (two d, J=7 Hz, 2H, –CH(OAc)–$C\underline{H}_2$–CH(OAc)–), 2.00 (s, 6H, two $C\underline{H}_3C(=O)$–O–), and 4.98 (m, 2H, two –$C\underline{H}$(OAc)–). The NMR spectra were also measured with a solution of V (10 mg) and Eu(hfmc)$_3$ (130 mg) in $CDCl_3$ (0.4 ml). V derived from *(R,R)*-III showed no detectable signal of the antipode. The difference in the chemical shift for acetyl groups (singlet) of *(R,R)*- and *(S,S)*-V was 4 Hz. *(S,S)*-V was obtained from *(S,S)*-III by the procedure described above. All the data were identical with those for *(R,R)*-V except for the value of $[\alpha]_D^{20}$ +40.2° (*c* 10, ethanol). *(R)*- and *(S)*-4-hydroxy-2-pentanone (II) were prepared by the partial oxidation of optically pure *(R,R)*- and *(S,S)*-III as follows: into a slurry of pyridinium chlorocromate (86 g) in 500 ml of CH_2Cl_2, a 40-g portion of *(R,R)*- or *(S,S)*-III, dissolved in 100 ml of CH_2Cl_2, was added all at once, after which the mixture was kept for 2 h with stirring at room temperature. The reaction mixture was then added to dry ether (3 l), and the resulting slurry was kept for another hour under stirring. The slurry was then passed through a column packed with 400 ml of Florisil, and the elute was concentrated under reduced pressure at room temperature. The distillation of the condensate under reduced pressure gave II in a yield of 12 g. *(R)*-II, bp 59—60 °C/20 mmHg, $[\alpha]_D^{20}$ −23.5° (neat), NMR ($CDCl_3$, TMS) δ 1.18 (d, J=0.6 Hz, 3H, $C\underline{H}_3$–CH(OH)–), 2.17 (s, 3H, $C\underline{H}_3$–C(=O)–), 2.56, 2.58 (two d, J=7.1 and 4.70 –C(=O)–$C\underline{H}_2$–CH(OH)–), 4.22 (m, –$C\underline{H}$(OH)–), IR (neat), 3300 (OH) and 1700 cm^{-1} (C=O). The GLC analysis showed a 99% purity. *(S)*-II, $[\alpha]_D^{20}$ +23.4° (neat). All the data of this compound were the same as those of *(R)*-II. A small portion of the sample was treated with acetic anhydride in the presence of pyridine. The resulting 4-acetoxy-2-pentanone (IV) was purified by preparative GLC (Ucon/20 min/100 °C). The analytical GLC (Ucon/85 °C) of the purified sample showed a single peak (retention time, 44 min). The purified IV showed NMR (TMS, $CDCl_3$), δ 1.22 (d, J=6.0 Hz, 3H, $C\underline{H}_3$–CH(OAc)–), 2.00 (s, 3H, $C\underline{H}_3C(=O)$–O–), 2.18 (s, 3H, $C\underline{H}_3C(=O)$–CH_2–), 2.62 and 2.80 (two d, J=7 Hz each, 2H, –CH(OAc)–$C\underline{H}_2$–CH(OAc)–), and 4.95 (m, 2H, –$C\underline{H}$(OAc)–). Racemic II was prepared by the partial hydrogena-

tion of I over racemic-TA–NaBr–MRNi, as will be described below, and the fractional distillation of the product (bp 90—91 °C/38 mmHg).

Partial Hydrogenation of I. Into an autoclave (100-ml capacity), 11.5 ml (0.112 mol) of I, 0.2 ml of acetic acid, and 1.2 g of a catalyst suspended in 23 ml of THF were introduced. Thus, the volume to be occupied by hydrogen became *ca.* 65 ml. (The depression of 1 kg/cm^2 of the hydrogen pressure corresponds to 0.0021 mol of the consumption of H_2 at 100 °C.) After the evacuation of air from the autoclave, H_2 was charged to a pressure of 95 kg/cm^2 at room temperature (this value corresponded to 121 kg/cm^2 at 100 °C), and then heating was commenced. After the temperature of the reaction mixture had become 100 °C, this temperature was maintained until the hydrogen pressure became 58 kg/cm^2 (the consumption of H_2 amounts to 0.135 mol).

The autoclave was quickly cooled in an ice–water bath, and the H_2 was evacuated. After the removal of the catalyst from the reaction mixture, the filtrate was concentrated under reduced pressure to give a crude product. The relative amounts of I, II, and III in the crude product were determined by analytical GLC (Ucon/100 °C). The retention times of I, II, and III (the *(R*,R*)* and *(R*,S*)* isomers were partially resolved into two peaks) were 8, 24, 79, and 84 min respectively. A major portion of the crude product was distilled through a short column (a 5 cm × 10 mm o.d. glass column packed with a small glass helix 3 mm in diameter) under reduced pressure and fractionated into eight fractions. A fraction of pure II (bp 90—91 °C/38 mmHg) was found by the aid of the GLC analysis of each fraction. From the optical rotation of the purified II, the optical yield of the reaction, I to II, was calculated based on the $[\alpha]_D^{20}$ −23.5° (neat) for optically pure *(R)*-II.

Hydrogenation of I to III. The hydrogenation of I was carried out under the same conditions as before until no more consumption of hydrogen was observed. After removing the catalyst from the reaction product by filtration, the filtrate was concentrated under reduced pressure to give a crude product. The ratio of *(R*,R*)*-III to *(R*,S*)*-III in the crude product was determined by analytical GLC (Ucon/85 °C). The retention times of *(R*,R*)*-III and *(R*,S*)*-III were 174 and 189 min respectively. The attempted separation of *(R*,R*)*-III and *(R*,S*)*-III by the preparative GLC failed. However, when they were converted to diacetate (V), the separation by preparative GLC was possible. Thus, the optical purity of *(R*,R*)*-III was evaluated from the optical purity of the *(R*,R*)*-V derived from the crude product.

A 1-g portion of the crude product was converted to V by the method described before. The preparative GLC (NPGS/80 °C) of the crude V gave pure *(R*,R*)*-V. From the optical rotation of the purified *(R*,R*)*-V, the optical purity of *(R*,R*)*-V was calculated based on the $[\alpha]_D^{20}$ −40.5° (*c* 10, ethanol) for optically pure *(R,R)*-V.

Hydrogenation of II to III. The hydrogenation of II was carried out under the conditions described before. After removing the catalyst by filtration, the filtrate was subjected to analytical GLC (Ucon/85 °C). The ratio of *(R*,R*)*-III to *(R*,S*)*-III was evaluated from the peak areas of the corresponding compounds.

Partial Hydrogenation of Racemic II. The hydrogenation of racemic II (0.112 mol) was carried out under the same conditions as above until the consumption of hydrogen became 0.062 mol. After the removal of the catalyst by filtration, the filtrate was concentrated under reduced pressure to give a crude product.

The relative amounts of II, *(R*,R*)*-III, and *(R*,S*)*-III in the crude product were determined by analytical GLC (Ucon/85 °C). A major part of the crude product was distilled through a short column, as mentioned before, under a vacuum, and then fractionated into five fractions. A fraction of pure II (bp 59—60 °C/10 mmHg) was picked out of each fraction by the aid of GLC analysis. The pure II thus isolated from the reaction mixture was subjected to the determination of its optical purity by polarimetry. The optical purity of *(R*,R*)*-III was determined by the procedure previously described.

The authors wish to express their thanks to Professor Yoshiharu Izumi for his helpful suggestions. This work was supported in part by a Grant-in-Aid for Scientific Research No. 403531 from the Ministry of Education, Science and Culture.

Proton Equilibria of a 5-Dimethylamino-1-naphthalenesulfonyl Group Conjugated to Bovine Serum Albumin. I. Effects of The Conjugation on Structural Alternation

Nobuo Ikuta, Joichi Koga,* and Nobuhiko Kuroki

Department of Applied Chemistry, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received May 16, 1980)

The proton equilibria of an optical probe, the 5-dimethylamino-1-naphthalenesulfonyl group, conjugated to bovine serum albumin with various molar ratios to the protein in an acidic solution, were investigated by means of the change in the fluorescence intensity as well as that in the absorbance. Below the molar ratio of 1.7 the apparent pK values for the dimethylamino moiety of the optical probe decreased remarkably with a decrease in the pH of the solution, accompanying conformational changes of the protein caused by the proton binding to the protein. For molar ratios of more than 2.0, the alternation of the higher structure of the protein induced by the conjugation of the probe was detected by ORD measurements, while the pK values of those conjugated probes were lowered at pH's higher than 3.0. For comparison, the probe conjugated with glycine as its free state gave the pK value of 3.99 in an aqueous solution. The shifts of the apparent pK values of the conjugated probe in the protonated protein compared with those for the free probe were, particularly, too large to arise from the Debye-Hückel electrostatic shielding effect. These results are, therefore, interpreted in terms of a change in the short-range interaction in the neighboring residues surrounding the probe.

The interpretation of the ionization of acid-base groups on a protein molecule is complicated in part by the fact that the measurements reflect the composite behavior of a large number of groups. Even in an acidic solution the groups participating in the proton equilibria of acid-base groups on a protein include not only a large number of carboxyl groups, but also imidazole or tyrosine residues in an appreciable number. Their proton equilibria overlap one another, so that a sharp separation cannot be made by means of the potentiometric titration technique.

In order to avoid obscure titration curves, the spectral titration curves are often obtained for tyrosine residues.[1] A useful method for the same purpose is the attachment of an optical probe which has a desirable acidity constant to proteins by means of a covalent linkage.[2-5] The ionization of the probe is usually accompanied by a significant change in both the absorption and emission spectra. It is thus very easy to obtain the titration curve for this group alone. An optical probe of the kind which has been successively employed in protein studies is the 5-dimethylamino-1-naphthalenesulfonyl (DNS) group. Klotz and Fiess[3] reported the proton equilibria of DNS attached chiefly to amino groups on bovine serum albumin (BSA) by means of absorption measurements. Their equilibria indicated a significant difference from those of DNS-amino acid conjugates and were independent of the pH values of the solution in which BSA undergoes a conformational change by ionization. The DNS group conjugated to BSA (DNS-BSA) prepared by them contained 4 to 11 mol of DNS to 1 mol of the protein. There is, therefore, a fear of the alternation of the secondary and tertiary structures of the conjugated protein in their results.

The present investigation was undertaken to see if the proton equilibria of DNS-BSA followed the conformational change on the acid denaturation of the conjugated BSA, the fine structure of which was not grossly altered by the limited degree of conjugation. The degree of protonation of the DNS conjugate was determined from the fluorescent spectra, which have a better sensitivity, in order to measure the quenching by the protonation of the DNS group at a low degree of conjugation.

Experimental

Materials. BSA (crystallized and lyophilized) from the Sigma Chemical Co. (Lot. 17C-8145) and 5-dimethylamino-1-naphthalenesulfonyl chloride (DNS-Cl) from the Tokyo Chemical Co. (Tokyo) were used without further treatment. DNS-glycine conjugate (DNS-Gly) was purchased from the Sigma Chemical Co. (Lot. D-0875). The DNS-L-phenylalanine conjugate (DNS-Phe) was prepared from DNS-Cl and L-phenylalanine according to the method of Gray and Hartley.[6] The stock solution of these conjugates to amino acids were prepared by dissolving the conjugates in ethanol. All the acids, bases, and salts were reagent-grade.

Preparation of DNS-BSA. A solution of BSA was prepared containing 320 mg of protein in 80 ml of 0.1 M Na_2HPO_4 (1 M = 1 mol dm^{-3}). To this cooled solution was added 4 ml of a cold acetone solution containing 0.5—8 mg of DNS-Cl. The mixture was kept in a refrigerator and shaken sometimes for 24 h. The reaction by-products was then removed by dialysis in the cold for 24 h against three successive portions of 0.01 M acetic acid and thereafter for several days against distilled water. The dialysates were monitored for their gradual disappearance. The fluorescence intensity of the dialysate in the final dialysis could not be detected at the maximum sensitivity of the monitoring fluorescence spectrofluorometer. The protein solution was diluted in a volumetric flask and stored in a refrigerator. The stock solution was not used after one month from the time of preparation. The moles of the DNS conjugates to the protein were calculated from the measurement of the absorption at 340 nm using an extinction coefficient of 3.36×10^6 M^{-1} cm^{-1}.[7]

Fluorescence Titration of DNS Conjugate. In order to prevent concentration quenching, a portion of the stock solution of conjugates to BSA or amino acids was diluted with distilled water to give a solution with an optical density of less than 0.1 at 340 nm. To this diluted solution a measured quantity of hydrochloric acid was then added from a micropipet, after which the pH value and the fluorescence spectrum of the solution were measured. The procedure

was repeated with further samples of the solution and different quantities of the acid. Suitable corrections were made for the dilution of the solution by the added acid or base. The pH was measured at 25.0 °C with a Hitachi-Horiba F-7AD pH meter and a 6326-05C combination electrode. The fluorescence emission spectra were measured at the same temperature with a Hitachi Perkin-Elmer MPF-2A fluorescence spectrophotometer. The excitation wavelength (λ_{exc}) was taken at 340 nm. Both the excitation and emission slits were to cover wavelength ranges of 10 nm. Solutions of quinine sulfate in 0.1 M H_2SO_4 were used as the reference in the range of concentration of 10^{-7} to 10^{-5} M.

The protonation of the dimethylamino moiety of the DNS group gave rise to a quenching of the fluorescence of DNS at $\lambda_{exc}=340$ nm, so that the fraction, α, of the DNS group in the basic form was calculated by means of the following equation:

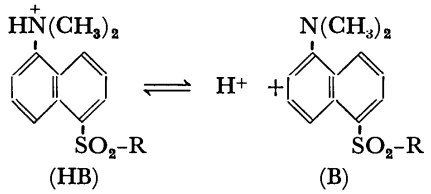
$$\alpha = \frac{\text{(maximum intensity of fluorescence at the pH value of the soln.)}}{\text{(maximum intensity of fluorescence in the basic soln.)}} \quad (1)$$

The emission spectra described in the results were corrected for variations in the detector system by using the known emission spectra of quinine sulfate. In the present experiments, the α values calculated from uncorrected spectra were equal to those from corrected spectra.

Results

Proton Equilibria of Free Probe. The acidity constant of a probe obtained from fluorometric analysis may be evaluated by means of the equilibria containing the components an acid and/or base existing in the excited state. In order to investigate the proton equilibria of the probe conjugates in the ground state, it is necessary to take into account the contribution of the excited probe molecules to the acid dissociation in the ground state. The absorption method is usually employed to determine the proton equilibrium constant in the ground state.

The proton equilibria of DNS conjugated in the ground state may be represented by the following equation:



(HB) (B) (2)

When R is replaced by a small molecule such as a glycine residue, $-NHCH_2COOH$, this dissociation can be described quantitatively by the familiar Henderson-Hasselbalch expression:

$$pH = pK_a + \log\frac{\beta}{1-\beta} \quad (3)$$

where pK_a is the apparent acidity constant of the dimethylamino moiety in the DNS group, and β, the fraction of the DNS group in the unprotonated ground state. The absorption spectra of 1.00×10^{-4} M DNS-Gly, as a model of free probes obtained at various pH values, are shown in Fig. 1, where the absorbance is given as a function of the wavelength, λ. The results exhibited isosbestic points at 268 and 304 nm which were identical with those reported for the DNS group conjugated to diaminoethane.[5] The curves corresponding to the highest and lowest pH values in Fig. 1 represent the spectra of the unprotonated (B) and protonated (HB) forms respectively; hence, the fraction of the probe in the protonated ground state, β, is commonly calculated from the amount of the absorption change at each pH value. According to Eq. 3, the plots of the pH values in solution *versus* $\log[\beta/(1-\beta)]$ give a slope of one and a pK_a value which is equal to a pH value at $\log[\beta/(1-\beta)]=0$. For DNS-Gly and DNS-Phe in water, the pK_a values were given as 3.99[8] and 4.00 respectively.

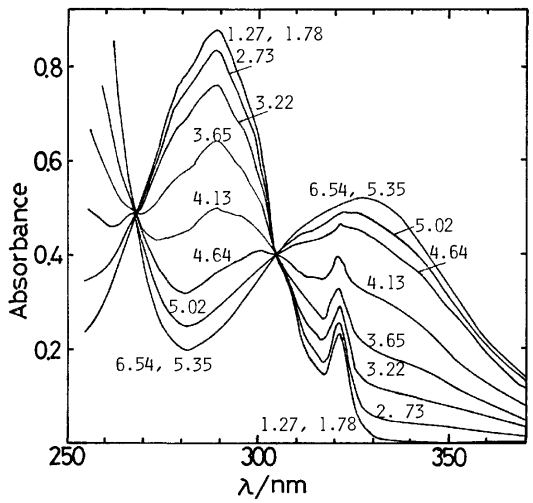


Fig. 1. Absorption spectra of 1.00×10^{-4} M DNS-Gly in water at various pH. Curves are labeled with appropriate pH values. Cell length 1 cm.

The emission spectra of 1.68×10^{-5} M DNS-Gly excited at 340 nm were measured at various pH in water, as is shown in Fig. 2. The spectra were characterized by one band near 590 nm at which the maximum intensity decreased with a decrease in the pH. As is shown in Fig. 1, the absorption at 340 nm was absent in the solution of a lower pH, where all of the dimethylamino moiety of DNS group was protonated. This fact indicates that the DNS molecules are excited only in the unprotonated form when exposed to the light of the 340 nm wavelength. The emission band, therefore, corresponds to the fluorescence from the excited state of the DNS group with the dimethylamino moiety in its unprotonated ground state.

The unprotonated excited molecules, denoted by B*, are treated by the insertion of an additional component in Eq. 2 to give:[9]

$$HB \rightleftharpoons B \rightleftharpoons B^*. \quad (4)$$

The fraction of the unprotonated DNS group in both the excited and ground states make it difficult to estimate from the fluorescence in the above successive equilibrium. The intensity of the emission peak was,

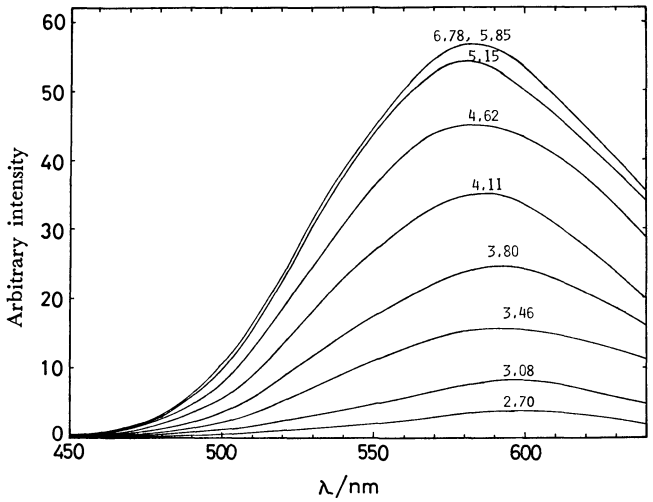

Fig. 2. Corrected emission spectra of 1.68×10^{-5} M DNS-Gly in water at various pH. Curves are labeled with appropriate pH values.

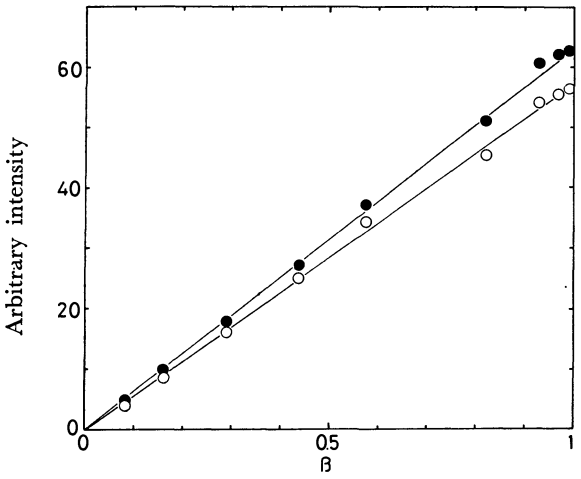

Fig. 3. Maximum intensity of corrected and uncorrected fluorescence spectra of DNS-Gly as a function of the fraction in unprotonated ground state (β). Ordinate scale, I_{max}, is arbitrary intensity of peaks in the corrected (○) and uncorrected (●) spectra.

however, proportional to the fraction of the DNS molecules in the unprotonated ground state (β), as calculated from absorption, as is shown in Fig. 3. The linear relationship implies that the equilibrium between B and HB is scarcely shifted by the processes of excitation and emission between B and B*, which are much faster than those of protonation and unprotonation. Consequently, the fraction of the unprotonated form in the ground state can be calculated from the fluorescence intensity of the DNS group in the same way as from the absorption titration. From the pH value in solution and the α obtained by fluorescence measurement, the pK_a values were obtained as 3.99 and 4.00 for DNS-Gly and DNS-Phe respectively. These values were, as expected, identical with those obtained by the absorption method. Hence, the fraction of the DNS group in the unprotonated form obtained from fluorescence measurements, α, is equal to the β obtained by the absorption method and Eq. 3 can be rewritten as follows:

$$pH = pK_a + \log\frac{\alpha}{1-\alpha}. \quad (5)$$

Proton Equilibria of DNS-BSA Conjugates. The corrected emission spectra of DNS-BSA conjugates with the molar ratio of 1.7 mol of the probe to 1 mol of protein obtained in water as a function of the pH are shown in Fig. 4. The spectra are different from those described before for the free probe. The 580 nm peak of the free probe is remarkably blue-shifted when the DNS group is conjugated to BSA, to 515 nm at high pH values and to 530 nm at low pH values. The large shift is attributable to the hydrophobic environment of the protein at which DNS group is attached. The small red-shift from a high to a low pH corresponds to an energy change of about 0.55×10^3 cm^{-1}, which is slightly larger than that of about 0.48×10^3 cm^{-1} in the case of the free probe. This finding exhibits the effect of the structure change on the environment of the DNS group. The lowering of the quantum yield of the DNS conjugate in unprotonated form with the red-shift may be neglected compared with the quenching by the protonation of the probe. Thus, the proportionality between the fraction of the probe in the unprotonated form and the fluorescence intensity is maintained in DNS-BSA as well as in the free probe, as has been described before. The fraction of DNS conjugates in the unprotonated form can, therefore, be calculated by the same method as in the free probe.

When the DNS group was conjugated to BSA with the molar ratios of 0.9, 2.0, and 2.7 mol of the probe to 1 mol of protein, Eq. 5 was no longer adequate to represent the dissociation over the pH range measured. As is shown in Fig. 5, Henderson-Hasselbalch plots of the DNS-BSA conjugates in aqueous solutions gave three successive straight lines, indicating the three dissociation characteristics, denoted by I, II, and III,

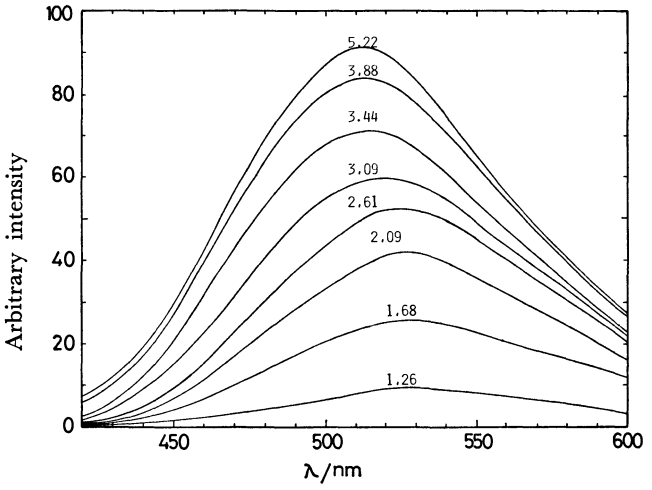

Fig. 4. Corrected emission spectra of 1.08×10^{-5} M solutions of DNS-BSA conjugates with the molar ratio of 1.2 mol probe to 1 mol protein in water at several pH. Curves are labeled with appropriate pH values.

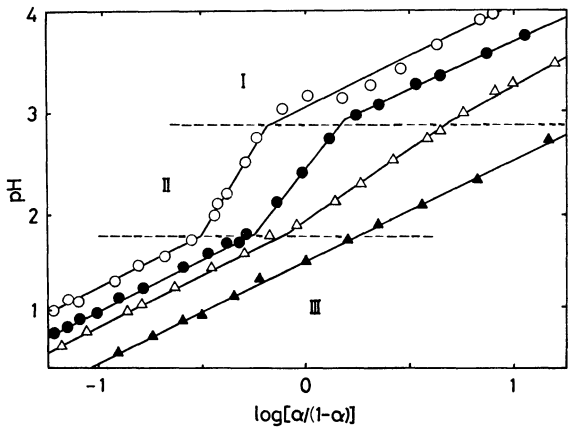

Fig. 5. Henderson-Hasselbalch plots of DNS-BSA conjugates with the molar ratio of 0.9 (○), 2.0 (●), 2.7 (△), and 7.2 (▲) mol probe to 1 mol protein. Two dashed lines divide the plots into three regions denoted by I, II, and III.

in the order of decreasing pH. The slopes were nearly one in I and III, but more than one in II: hence, the apparent pK_a values in both the I and III regions, as calculated from Eq. 5, were almost constant, but those in the II region were not. In the II region it is adjustable to a generalized Henderson-Hasselbalch expression with a parameter, denoted by n, of interaction among dissociation groups in a polyelectrolyte as follows:[10]

$$pH = pK_a + n \log \frac{\alpha}{1-\alpha}. \quad (6)$$

In this study, n may be attributed to the interaction between the DNS group and the other residues in the protein. We should note that the apparent pK_a in the II region obtained from Eq. 6 makes it difficult to discuss quantitatively the proton equilibria of DNS group conjugated to BSA, because the parameter, n, is physicochemically ambiguous in the process of the extension of the simple Maxwell-Portington equation,[11] as described by Katchalsky and Spitnik.[10] The apparent pK_a value in the II region is useless for comparison with the pK_a values in other regions; hence, the value has not been determined. In the case of the DNS-BSA conjugate with the molar ratio of 7.2, Henderson-Hasselbalch plots gave one straight line, from which the constant pK_a and a slope of 1.0 were calculated over the pH range measured. The results of the pK_a values and slopes in each region, summarized in Table 1, show the two following features. Firstly, the pK_a values in the I region are greater than those in the III region except in the case of the molar ratio of 7.4. Secondly, the pK_a values in the I region come close to those in the III region and the slope in the II region decreases to one with an increase in the molar ratio of the conjugates. The former may be attributed to the conformational change on acid denaturation, and the latter to the alternation of the protein by the conjugation of the probe, as was pointed out by Takagi *et al.*[12,13]

The α-helix contents of the DNS-BSA conjugates

Table 1. Apparent pK_a and slope n of DNS-BSA conjugates in water

Molar ratio[a]	Region I		Region II	Region III	
	n	pK_a	n	n	pK_a
0.9	1.0	3.05	3.5	1.0	2.30
2.0	1.0	2.70	2.6	1.0	2.05
2.7	1.0	2.18	1.5	1.0	1.90
7.4[b]	$n=1.0$, $pK_a=1.55$				

a) Moles of dansyl group conjugated to 1 mol of BSA.
b) The regions were indistinguishable in Fig. 5.

were calculated from the ORD measurement with the Moffitt-Yang equation in order to elucidate the alternation of the protein by the conjugation of the probes and the protonation of the ionizable groups in the protein. The α-helix contents of the conjugated proteins with the molar ratios of 0.7 and 5.2 were 46 and 28% in pH 5.0, and 28 and 23% in pH 2.0, respectively. In the unconjugated protein, the α-helix contents were 46% in pH 5.0 and 27% in pH 2.0. It can be seen from the ORD data that both the conjugation of the probe and the binding of the proton to the protein cause a lowering of the α-helix content of the native protein in a neutral solution. Because of the similar α-helix content of the conjugated protein even with the molar ratio of 5.2 in pH 2.0 and 5.0, the constant pK_a obtained for the conjugated protein with the molar ratio of 7.4 should be attributable to the impaired protein, which maintains its structure regardless of the protonation of the protein.

In the case of DNS-BSA, with an average molar ratio below 1.7, it can be seen that the proton equilibria of the DNS group present the same behavior, as is shown in Fig. 6. This finding implies that the BSA conjugated with DNS group with a small molar ratio consists of a conformation which is similar to that of unconjugated BSA, judging from the agreement in α-helix content between the unconjugated BSA and the conjugated BSA with the molar ratio of 0.7.

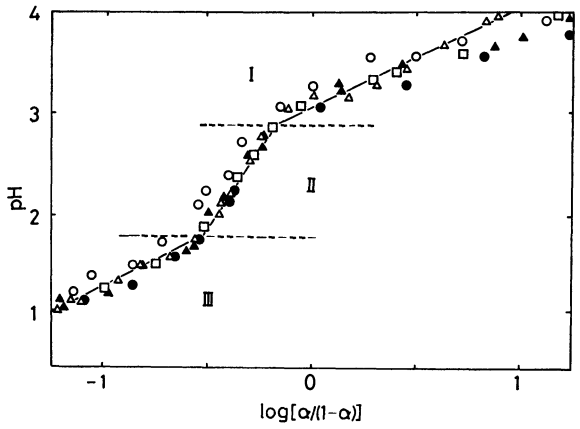

Fig. 6. Henderson-Hasselbalch plots of DNS-BSA conjugates with the molar ratio of 0.3 (○), 0.5 (●), 0.9 (△), 1.6 (▲), and 1.7 (□). Two dashed lines are drawn at the same position of pH values in Fig. 5.

Discussion

BSA undergoes a marked structure change in the region near pH 4, termed "N-F transition," from the normal state (N) to a form (F) having a faster rate of migration in electrophoresis.[14] Futhermore, the protein structure of the F-form is changed into a structure with an expanded form (E) in the region below pH 3.5.[15]

As is shown in Fig. 6, the pH value of the boundary between the I and II regions is 3.0, in agreement with the pH value beginning to occur upon the unfolding by means of the acid expansion. A possible explanation for the agreement may be that, in the I and III regions, the conjugated DNS group exists in two different environments, in the protein of the N- or F-form and in that of the E-form respectively, and that in the II region a transfer of the DNS group proceeds along with the expansion of the protein structure. As has been described in the Results section, the protein conjugated with the molar ratio below 1.7 showed the same behavior on acid denaturation as the unconjugated protein, so the variation in pK_a values against the pH depends only on the effect on the conformational change upon acid denaturation.

The fact that all of the pK_a values obtained for DNS-BSA are smaller than that for DNS-Gly, denoted by pK_o, shows that the protein environment has a profound effect on the ionizing abilities of the dimethylamino moiety. Such an effect can be expressed thermodynamically from the difference between pK_a and pK_o values in the following equation:

$$pK_a = pK_o - 0.434\frac{\Delta G_p}{RT}, \qquad (7)$$

where ΔG_p is the free-energy change resulting from the transfer of the probe from water to a inside of the protein in the solution of a pH value, and where pK_o is estimated for the free probe in the solution which consists of the same solute as in the determination for DNS-BSA; pK_o=3.99 in the present case. The left-hand side in Eq. 7, pK_a, can be calculated from the pH value of a solution and the fraction, α, in Eq. 5; hence, ΔG_p may be estimated. In Fig. 7 the experimental pK_a values are plotted against the pH values in the case of those of DNS-BSA in Fig. 6; the ΔG_p scale at 25.0 °C is indicated on the right-hand side.

If ΔG_p depends only upon the Debye-Hückel electrostatic shielding effect, Eq. 7 can be expressed by the following equation containing Linderstrøm-Lang's parameter:[18]

$$pK_a = pK_o - 0.434\frac{\Delta G_{el}}{RT}\bar{Z}_p, \qquad (8)$$

where ΔG_{el} is the electrical free-energy change for charging an assumed-spherical protein molecule uniformly with a total unit charge and where $\bar{Z}_p$ represents the mean net charge of the protein molecule. Although the values of $\Delta G_{el}/RT$, usually represented by 2ω, may be computed on the basis of the electrostatic theory,[19,20] we shall obtain ω as an experimental parameter and adopt the numerical values for it which have been found by Tanford, Swanson, and Shore to fit the potentiometric titration data.[19] We must also choose values for $\bar{Z}_p$ which are primarily due to a bound or dissociated proton, but which are also influenced by bound salt. In a rough approximation, however, it may be assumed that $\bar{Z}_p$ is equal to the number of protons bound by BSA the values of which can be computed from the data of Tanford, Swanson, and Shore.[19]

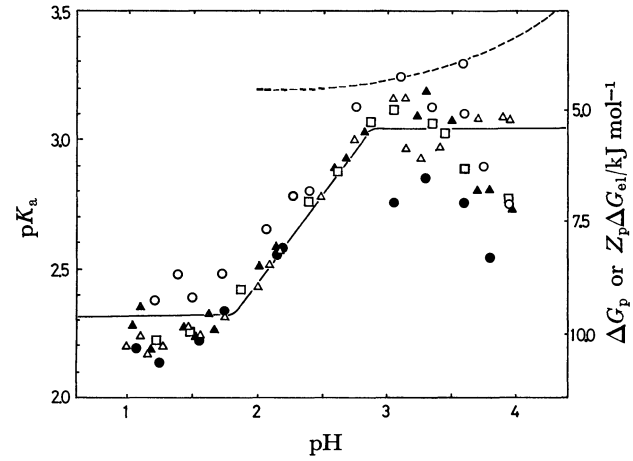

Fig. 7. Apparent pK_a values of DNS-BSA conjugates as a function of pH in aqueous solutions. The pK_a values in symbols and solid line were calculated from the data in Fig. 6 with Eq. 5. BSA conjugates have the molar ratio of below 1.7 mol probe to 1 mol protein. Symbols as in Fig. 6. Dashed line was estimated with Eq. 8 from data of Tanford, Swanson, and Shore.[19]

The calculated results are also illustrated in Fig. 7 for a solution with an ionic strength of 0.03. The experimental curves are shifted greatly from the curves computed on the basis of electrostatic considerations, especially in the lower-pH range. This feature suggests that ΔG_p is constituted not only of ΔG_{el} depending on long-range electrostatic force, but also of the free-energy changes proceeding from several short-range interactions, such as the hydrophobic effect, the hydrogen-bonding, and the alternation of the solvent structure by the intensive electrical field around the protein. Such interactions, resulting from the displacement between the experimental and computed curves, must be greatly changed with the conformational transition accompanying the acid expansion. As Klotz and Fiess have pointed out,[3] the dimethylamino group contributes its pair of electrons to a resonance with the aromatic ring; hence, it cannot be a good acceptor of a hydrogen-bonding. Thus, the difference between ΔG_p and ΔG_{el} is unlikely to involve the contribution of any hydrogen-bonding, and the short-range interactions must arise from some other causes.

Klotz and Fiess,[3] in their study of DNS-BSA similar to this paper, have found that the pK of the dimethylamino group is 1.67 when attached to BSA and 3.99 when attached to glycine. The DNS-BSA conjugates prepared by them, however, have the molar ratio

of 5.9 at which the conjugation causes an alternation of the protein structure because of our results that, at molar ratios of more than 1.7, the normal protein structure no longer maintains its structure, even in a solution near the isoionic point in the I region. They have preferred to interpret their results in terms of a postulated ice-like character of the hydration water in the vicinity of the nonpolar portions of the protein, including the DNS group. Such an environment would tend to stabilize the uncharged form of the dimethylamino group, as the creation of a charged group in place of the uncharged one would require some breakdown of the ice lattice. Thus, the factor of ice lattice is unlikely to contribute to the shift of ΔG_p.

Strauss and Vesnaver,[5] studying the acid-base equilibria of the DNS group conjugated to a copolymer of maleic acid and butyl vinyl ether, have found that the pK values of the dicarboxylate groups and of the dimethylamino group of the probe pass through a maximum as the macromolecule undergoes a transition from a compact to a random-coil conformation. These results have been interpreted in terms of changes in the local solvent surrounding the probe, taking into account both the electrostatic forces due to the negative carboxylate groups and the influence of the nonpolar or hydrophobic butyl groups. The former effect is acid-weakening, and the latter, acid-strengthening, with regard to the $(CH_3)_2NH^+$ group.

In the case of DNS-BSA, BSA can be regarded as a polycation instead of the polyanion studied by Strauss and Vesnaver,[5] so the electrostatic and nonpolar environment effects would reinforce one another, both acting to increase the acid strength of the probe. The integrity of the albumin internal structure may be essential for both the effects, possibly as a consequence of the environment of the DNS group in nonpolar or hydrophobic regions of the intact protein. Such a hydrophobicity would favor the neutral basic form of the dimethylamino group over the ionic acidic form. The cationic charges in $\bar{Z}_p$ neighboring the hydrophobic environment have an intensive electric shielding effect in the inert protein involving the probe compared with that in bulk water.

On account of the hydrophobic residues in the protein, the charges formed by proton binding on the protein are considered to have interesting effects on the pK_a values. The effects of the charges should be investigated further in the proton equilibria of DNS-BSA in aqueous solutions of electrolytes and/or denaturants.

The present work was partially supported by a Grant-in-Aid for Development Research from the Ministry of Education, Science and Culture.

Migrated Lupane Derivatives. Boron Trifluoride Etherate-catalyzed Backbone Rearrangement of 3α,4α- and 3β,4β-Epoxy-*D*:*A*-friedo-18β,19α*H*-lupanes and Solvent Effects[1]

Yasushi YOKOYAMA, Yoshihiko MORIYAMA,† Takahiko TSUYUKI, and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
† *Institute of Chemistry, Kyoto Prefectural University of Medicine, Taishogun, Kita-ku, Kyoto 603*

(Received May 28, 1980)

Backbone rearrangements of 3α,4α- and 3β,4β-epoxy-*D*:*A*-friedo-18β,19α*H*-lupanes catalyzed by boron trifluoride etherate gave 18β,19α*H*-lup-12-en-3-ols, lup-18-en-3-ols, and lup-19-en-3-ols, besides known *D*:*B*-friedo-18β,19α*H*-lup-5-en-3-ols and -5(10)-en-3-ols. *D*:*B*-Friedo-18β,19α*H*-lup-1(10)-en-3α-ol and 3β,10β-epoxy-*D*:*B*-friedo-18β,19α*H*-lupane were also obtained from α- and β-epoxides, respectively. Solvent effects on these reactions were examined.

Acid-catalyzed backbone rearrangements of unsaturated or epoxy triterpenes usually proceed in a reverse direction of their biogenesis,[2] affording a number of migrated triterpenes derived from intermediate cations or their equivalent species corresponding to various biogenetic stages. In previous papers, reports were given on boron trifluoride etherate-catalyzed backbone rearrangement of 3β,4β-epoxyfriedelane (**1**)[3] and 3α, 4α- and 3β,4β-epoxyshionanes (**2** and **3**),[4] migrated friedooleanane and friedobaccharane derivatives being obtained.

So far only a few migrated lupane derivatives have been isolated from natural sources,[5] investigations on these compounds[6,7] not being as extensive as those on migrated oleanane, ursane, and hopane derivatives.[8] In connection with the structural study of guimarenol, formation of *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol from 3β,4β-epoxy-*D*:*A*-friedo-18β,19α*H*-lupane by tratment with boron trifluoride etherate in benzene has been reported.[9] Examination was carried out on the backbone rearrangement of 3α,4α- and 3β,4β-epoxy-*D*:*A*-friedo-18β,19α*H*-lupanes[9] (**4** and **5**) in various solvents catalyzed by boron trifluoride etherate to give a series of migrated lupane derivatives. Solvent effects on the reaction were also examined.

3α,4α-Epoxy-*D*:*A*-friedo-18β,19α*H*-lupane (**4**), derived from friedelin (friedelan-3-one)[7,9] was treated with boron trifluoride etherate in tetrahydrofuran at room temperature until the epoxide (**4**) was consumed. The reaction give a complex mixture, which was separated by preparative thin-layer chromatography (TLC), followed by column chromatography on silica gel impregnated with silver nitrate to afford three compounds **A**, **B**, and **C** in 11, 60, and 5% yields, respectively.

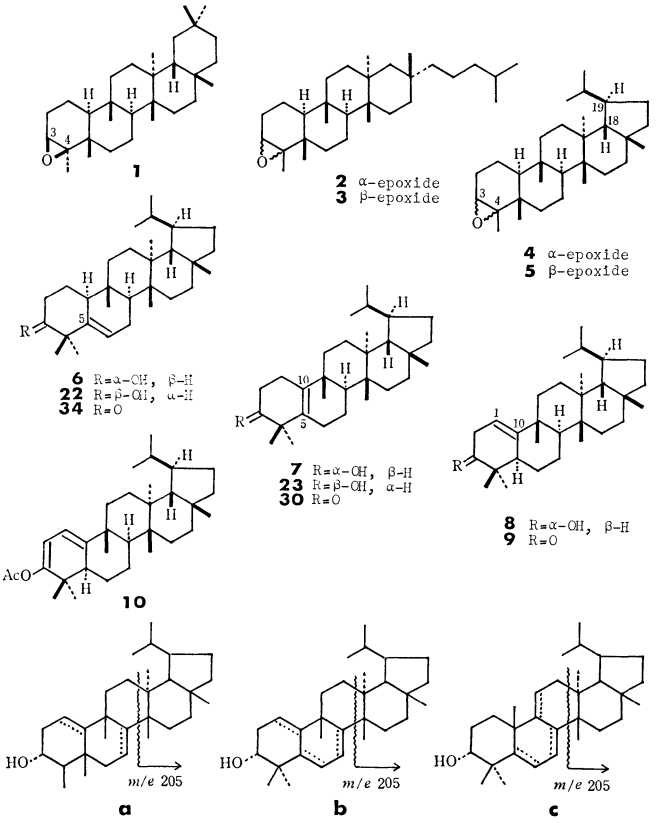
The most polar compound **A** was found to be *D*:*B*-friedo-18β,19α*H*-lup-5-en-3α-ol (**6**) and the less polar compound **B** *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3α-ol (**7**) by comparison with authentic specimens.[9]

Spectral data [IR 3400 and 908 cm^{-1}; ^1H NMR δ 3.34 (1H, m) and 5.22 (1H, m)] showed the least polar compound **C**, $C_{30}H_{50}O$, mp 103—109 °C, to be a new alcohol with a trisubstituted double bond. A fragment ion peak at *m/e* 205 in the mass spectrum[10] indicates that the double bond should be located at $\Delta^{1(10)}$ or Δ^7 of a *D*:*A*-friedolupane framework (**a**), $\Delta^{1(10)}$, Δ^5, or Δ^7 of a *D*:*B*-friedolupane framework (**b**), or Δ^5, Δ^7, or $\Delta^{9(11)}$ of a *D*:*C*-friedolupane framework (**c**). Among them, alcohols with the *D*:*A*-friedo-type framework, *D*:*B*-friedo-Δ^7-type framework, and *D*:*C*-friedo-Δ^5-type framework are not feasible on the basis of their formation mechanism. 5-En-3α-ol with the *D*:*B*-friedo-type framework is compound (**6**). Thus compound **C** should be formulated as either *D*:*B*-friedo-18β,19α*H*-lup-1(10)-en-3α-ol (**8**), *D*:*C*-friedo-18β,19α*H*-lup-7-en-3α-ol, or -9(11)-en-3α-ol.

Oxidation of compound **C** with the Jones reagent gave an unsaturated ketone (**9**), $C_{30}H_{48}O$, IR 1710 cm^{-1}. In the ^1H NMR spectrum, allylic methylene protons resonate at δ 2.75 and 3.01 (each 1H, dt, J=21 and J=3 Hz) and an olefinic proton at δ 5.43 (1H, m). Furthermore, another allylic proton resonates at δ 2.35 (1H, m). These observations suggest the existence of a partial structure $-\overset{O}{\overset{\|}{C}}_{(3)}-C_{(2)}H_2-C_{(1)}H=C_{(10)}-C_{(5)}H-$ and *D*:*B*-friedo-18β,19α*H*-lup-1(10)-en-3-one for the unsaturated ketone (**9**). On irradiation at δ 5.43, the signal due to the methylene at $C_{(2)}$ turned into two pairs of double doublet signals (each 1H, J=21 and J=3 Hz), showing that the coupling constant values between the $C_{(1)}$-proton and the $C_{(2)}$-methylene protons are both 3 Hz, and the $C_{(2)}$-protons coupled with the $C_{(5)}$-methine proton with a coupling constant, J=3 Hz. Irradiation of a frequency around δ 2.9 due to the $C_{(2)}$-methylene protons resulted in the change of the signal of $C_{(1)}$-proton to a doublet signal (1H, J=2 Hz). This suggests that the coupling constant between the olefinic proton and the $C_{(5)}$-allylic methine proton is 2 Hz. When the signal around δ 2.35 was irradiated, the signal at δ 5.43 due to the $C_{(1)}$-proton turned to a triplet (1H, J=3 Hz).

Treatment of the β,γ-unsaturated ketone (**9**) with isopropenyl acetate in the presence of *p*-toluenesulfonic acid under reflux gave a conjugated dienol acetate (**10**) [UV 273 nm (ε *ca.* 8000); $C_{32}H_{50}O_2$]. Thus, the structure of *D*:*B*-friedo-18β,19α*H*-lup-1(10)-en-3α-ol (**8**) is given for compound **C**.

Reaction of the α-epoxide (**4**) with boron trifluoride etherate in benzene at room temperature gave *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3α-ol (**7**; yield 34%), -5-en-3α-ol (**6**; trace), and an alcohol mixture **D**. The mixture showed two peaks on GLC, but could not



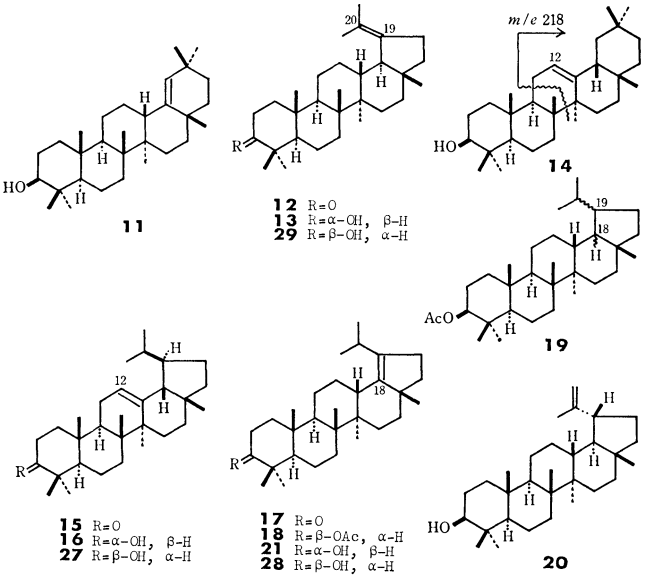
be separated by TLC nor column chromatography. Oxidation of the mixture with the Jones reagent gave the corresponding ketone mixture, which was separable by high performance liquid chromatography (HPLC) to afford three compounds, $\mathbf{D}_1$, $\mathbf{D}_2$, and $\mathbf{D}_3$ in 3, 11, and 6% yields, respectively.

The compound $\mathbf{D}_1$, $C_{30}H_{48}O$, is a ketone with an isolated double bond, the ^1H NMR spectrum showing the presence of two olefinic methyls besides six tertiary methyls. No signal due to olefinic proton was observed. From the fact that germanicol (**11**) was obtained as an ultimate product in friedelane-oleanane rearrangement in benzene,[3b] the compound $\mathbf{D}_1$ should be formulated as lup-19-en-3-one (**12**) in accordance with the ^1H NMR spectral data. The original alcohol in the mixture **D** could be formulated as lup-19-en-3α-ol (**13**).

The compound $\mathbf{D}_2$ showed a molecular ion peak at *m/e* 424.3708 ($C_{30}H_{48}O$) and a prominent peak at *m/e* 218.2004 corresponding to a fragment ion $C_{16}H_{26}^+$. Since Δ^{12}-triterpenes such as β-amyrin (**14**), α-amyrin, and bacchar-12-en-3-one show a prominent peak at *m/e* 218 due to retro-Diels-Alder fragmentation,[11] compound $\mathbf{D}_2$ might be 18β,19α*H*-lup-12-en-3-one (**15**). The proposed structure is supported by its ^1H NMR spectrum; a signal due to an olefinic proton observed at δ 5.21 (t, J=4 Hz) is nearly the same as that (δ 5.20, t, J=4 Hz) of β-amyrin (**14**). The original alcohol should be represented as 18β, 19α*H*-lup-12-en-3α-ol (**16**).

The third compound $\mathbf{D}_3$, $C_{30}H_{48}O$, mp 167—168 °C, was found to be a tetrasubstituted olefinic ketone by its ^1H NMR spectrum which showed the absence of the olefinic proton and the presence of an allylic proton (δ 2.98, 1H, J=6 Hz). The signal resonating at δ 2.98 seems to be central three peaks of a heptet signal due to an isopropyl methine proton on the allylic position. Thus the structure of lup-18-en-3-one (**17**) is suggested for compound $\mathbf{D}_3$.

We prepared a mixture of lup-18-en-3β-yl acetate (**18**) and 18ξ,19ξ*H*-lupan-3β-yl acetate (**19**) from lupeol (**20**) according to the method of Baddeley *et al.*[12] The mixture was treated with lithium aluminium hydride to give an alcohol mixture, which was oxidized with the Jones reagent. The reaction mixture was subjected to separation by HPLC to afford the authentic lup-18-en-3-one (**17**), which was identical with compound $\mathbf{D}_3$. Thus the original alcohol is formulated as lup-18-en-3α-ol (**21**).



The reactions of 3β,4β-epoxy-*D*:*A*-friedo-18β,19α*H*-lupane (**5**), derived from friedelin,[7,9] with boron trifluoride etherate were investigated under the same conditions as in the case of the α-epoxide (**4**). Treatment of the β-epoxide (**5**) in tetrahydrofuran gave a mixture which was separated into three compounds, **E**, **F**, and **G** in 7, 40, and 11% yields, respectively. The most polar compound **E** and the less polar one **F** were identified as *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**22**) and -5(10)-en-3β-ol (**23**) by direct comparison with authentic samples,[9] respectively.

The least polar compound **G**, mp 171 °C, seems to be a fluorohydrin (**24**). Its ^1H NMR spectrum showed a multiplet signal centered at δ 3.68 (1H, $W_{1/2}$=13 Hz) due to a proton on a carbon atom bearing a hydroxyl group. A doublet signal appearing at δ 1.33 (J=24 Hz) indicates the presence of a methyl group attached to a fluorine-bearing carbon atom. The coupling constant value, $J_{F,H}$=24 Hz, is the same as that ($J_{F,H}$= 24 Hz) observed for 4α-fluoroshionan-3β-ol (**25**).[4b] The mass spectrum showed a molecular ion peak at *m/e* 446 (1%) and a characteristic peak at *m/e* 426 (8%) due to $(M-HF)^+$ ion together with a base peak at *m/e* 123. The results together with the fact that a fluorohydrin is often generated by treatment of an

epoxide with boron trifluoride etherate,[3,4b] lead to the conclusion that compound **G** can be formulated as 4α-fluoro-*D*:*A*-friedo-18β,19α*H*-lupan-3β-ol (**24**).

The reaction of β-epoxide (**5**) in benzene gave three products, *D*:*A*-friedo-18β,19α*H*-lupan-3-one (**26**: yield 1%),[9] a fluorohydrin (**24**; yield 13%), and *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**22**; yield 9%), other than an alcohol mixture (**27**—**29**) as main products. The mixture, after oxidation with the Jones reagent, was separated by HPLC to afford *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3-one[9] (**30**; yield 7%), lup-19-en-3-one (**12**; yield 7%), 18β,19α*H*-lup-12-en-3-one (**15**; yield 31%), and lup-18-en-3-one (**17**; yield 13%).

The reaction of β-epoxide (**5**) in diethyl ether was carried out at 0 °C for 20 min. The reaction mixture was separated by preparative TLC into five compounds. The least polar compound **H** (**31**; yield 22%), $C_{30}H_{50}O$, mp 136—138 °C, showed no characteristic absorption bands in its IR spectrum. A doublet signal at δ 3.72 (1H, J=5.5 Hz), resembling a characteristic signal due to $C_{(3)}$-proton of dendropanoxide (**32**)[3a] (δ 3.75, 1H, d, J=4.8 Hz) and of dihydrobaccharis oxide (**33**)[4b] (δ 3.73, 1H, d, J=5 Hz), was observed in the ^{1}H NMR spectrum. Thus compound **H** was confirmed to be 3β,10β-epoxy-*D*:*A*-friedo-18β,19α*H*-lupane (**31**). The other four compounds were found to be *D*:*A*-friedo-18β,19α*H*-lupan-3-one (**26**; yield 2%), a fluorohydrin (**24**; yield 20%), *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**22**; yield 11%), and -5(10)-en-3β-ol (**23**; yield 27%) by spectral data and comparison with authentic specimens.

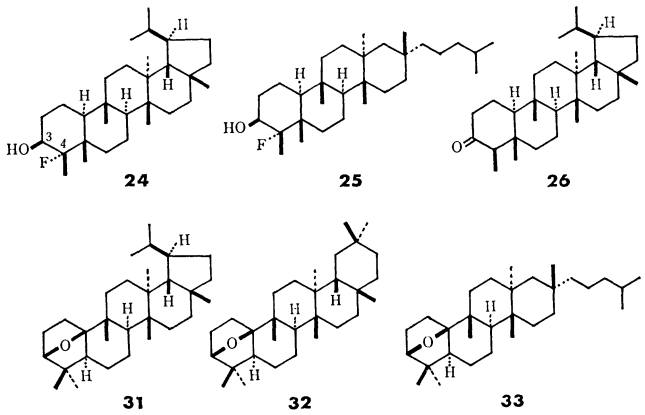


TABLE 1. RELATIVE AMOUNT RATIOS OF PRODUCTS IN THE REACTION OF 3α,4α-EPOXIDE (**4**) WITH $BF_3 \cdot OEt_2$ AT ROOM TEMPERATURE[a]

Solvent	Time / min	5-ene (**6**)	5(10)-ene (**7**)	1(10)-ene (**8**)	12-ene (**16**)	18-ene (**21**)	19-ene (**13**)

a) Room temperature, 20—28 °C. b) Determined by GLC before oxidation for small-scale experiments. c) Determined by small-scale experiments, reaction products being subjected to Jones oxidation. Relative yields of 1(10)-, 12-, 18-, and 19-enes estimated from the peak area of the corresponding ketones on HPLC under the conditions given in General. A mixture containig *D*:*B*-friedo-18β,19α*H*-lup-5-en-3-one (**34**) and -5(10)-en-3-one (**30**) was separated by HPLC and examined by GLC to determine relative yields of 5- and 5(10)-enes. d) Determined by isolation of the product. e) Determined by conversion of the product into the corresponding ketone, isolated by means of preparative HPLC. f) Correct data, inverse data in preliminary report (Ref. 1). g) Reaction carried out at 0 °C.

Small-scale experiments using the 3α,4α-epoxide (**4**) or the 3β,4β-epoxide (**5**) (each *ca.* 10 mg) and boron trifluoride etherate (0.1 ml) were carried out in solvents (5—10 ml) such as hexane, dichloromethane, acetonitrile, and 1,2-dimethoxyethane (DME). The results together with those obtained for the reactions in other solvents are summarized in Tables 1 and 2.

Since the rearrangement of **4** and **5** in a solvent with low nucleophilicity proceeds up to the C, D, or E ring,[3,4] highly rearranged products with 12-ene, 18-ene, and 19-ene structures were obtained in the reaction in hexane, acetonitrile, benzene, and dichloromethane. On the other hand, the rearrangement in a solvent with high nucleophilicity, such as diethyl ether or tetrahydrofuran, was interrupted in an early stage to afford *D*:*A*-friedolupane derivatives or *D*:*B*-friedolup-5-ene and -5(10)-ene derivatives. Neither *D*:*C*-friedolup-7-ene nor -8-ene derivative was detected in any solvent. These migratory aptitudes have a strong resemblance to those observed for 3β,4β-epoxyfriedelane (**1**)[3b] of a *D*:*A*-friedooleanane-type rather than those for 3α,4α- and 3β,4β-epoxyshionanes (**2** and **3**)[4b] of a *D*:*A*-friedobaccharane-type. The difference may be due to the existence of the E ring; the fact that the rearrangements of **1**, **4**, and **5** do not stop at the stages giving the *D*:*C*-friedo-type derivatives, but proceed up to the D and E rings, may be explained by release of the intracyclic tension due to the *cis*-fused D/E ring and partly due to 1,3-diaxial methyl groups.

A series of migrated lupanes were thus derived from friedelin. Since the total synthesis of friedelin has been accomplished,[13] the present work constitutes formally the total synthesis of these migrated lupanes.

Experimental

General Procedure. Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncorrected. IR spectra were measured in Nujol mull with a Hitachi EPI-G2 spectrometer or a Hitachi 260-30 spectrometer, UV spectra with a Hitachi 340 spectrophotometer, mass spectra with a Hitachi RMU-6-Tokugata mass spectrometer at 70 eV with a direct inlet system, high resolution mass spectra with a JMS-D300 (JEOL) mass spectrometer, the relative intensity being given in parentheses, and ^{1}H NMR spectra with a Hitachi R-20B (60 MHz) spectrometer, a Varian EM-390 (90 MHz) spectrometer or a JNM-FX-60 FT-NMR (60 MHz) spectrometer (JEOL). Chemical shifts are expressed in δ downfield from TMS as an internal standard and coupling constants in Hz. GLC analysis was carried out on a Shimadzu Gas Chromatograph GC-6A equipped with a hydrogen flame ionization detector (column: Dexsil 300GC, temperature 270—290 °C). Analytical and preparative HPLC were carried out on a Waters Liquid Chromatograph ALC/GPS 202/401 at room temperature with an RI detector (column: μ-Porasil 1/4 (inch)$\times$1 (foot); solvent system: 1.5% diethyl ether–hexane; flow rate: 3 ml/min; pressure: 700 psi). TLC was carried out on Kieselgel 60 GF_{254} (E. Merck) coated in 0.25 mm thickness (for analytical) and in 0.5 mm thickness (for preparative). Wakogel C-200 (Wako) was used for silica gel column chromatography.

Boron Trifluoride Etherate-catalyzed Backbone Rearrangement of 3α,4α-Epoxy-D:A-*friedo-18β,19α*H*-lupane (**4**) in Tetrahydrofuran.* A solution of α-epoxide[9] (**4**; 84.0 mg) in tetrahydrofuran (20 ml) was treated with freshly distilled boron trifluoride etherate (0.5 ml) at room temperature for 45 min. A saturated aqueous sodium hydrogencarbonate solution (5 ml) was added, stirring being continued for 30 min. The usual work-up gave a mixture, which was separated by preparative TLC (developed with benzene–diethyl ether, 19:1) to afford *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3α-ol[9] (**7**; 50.0 mg) and crude 1(10)-en-3α-ol (**8**) and 5-en-3α-ol[9] (**6**). The crude alcohol (**8**) was further purified by column chromatography on silica gel impregnated with 25% silver nitrate. Elution with benzene gave pure **8** (4.3 mg). The crude alcohol (**6**) was subjected to further separation by preparative TLC (developed with benzene–diethyl ether, 19:1) to give pure **6** (9.6 mg). **8**: mp 103—109 °C (crystallized from methanol); IR 3400 and 908 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.63, 0.82, 1.01, 1.10 (each 3H, s), 0.89 (6H, d, J=6 Hz; (C$\underline{H}_3$)$_2$CH–), 0.96 (6H, s), 3.34 (1H, m, $W_{1/2}$=7 Hz), and 5.22 (1H, m, $W_{1/2}$=8 Hz); MS *m/e* (%) 426 (M^+; 41), 408 (100), and 205 (40); Found: *m/e* 426.3847. Calcd for $C_{30}H_{50}O$: M, 426.3860.

D:B-*Friedo-18β,19α*H*-lup-1(10)-en-3-one (**9**).* The Jones reagent (one drop) was added to a solution of **8** (7.0 mg) in acetone (5 ml) at 0 °C, and the reaction mixture was stirred at 0 °C for 20 min. The usual work-up gave a residue (6.9 mg), which was purified by preparative TLC (developed with benzene) to afford *D*:*B*-friedo-18β,19α*H*-lup-1(10)-en-3-one (**9**; 4.1 mg), mp 215—218 °C (crystallized from acetone); IR 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.8—0.95 (9H, 3$\times$$CH_3$), 0.96, 0.99, 1.01, 1.08, 1.15 (each 3H, s), 2.35 (1H, m), 2.75 (1H, dt, J=21 and J=3 Hz), 3.01 (1H, dt, J=21 and J=3 Hz), and 5.43 (1H, m, $W_{1/2}$=9 Hz); MS *m/e* (%) 424 (M^+; 55), 205 (100), and 123 (86); Found: *m/e* 424.3710. Calcd for $C_{30}H_{48}O$: M, 424.3705.

3-Acetoxy-D:B-*friedo-18β,19α*H*-lupa-1(10),2-diene (**10**).* A mixture of **9** (0.7 mg), isopropenyl acetate (2 ml), and *p*-toluenesulfonic acid (catalytic amount) was refluxed for 10 h. The usual work-up gave a residue, which was purified by preparative TLC (developed with benzene) to give 3-acetoxy-*D*:*B*-friedo-18β,19α*H*-lupa-1(10),2-diene (**10**; 0.1 mg), UV_{max} (dioxane) 273 nm (ε *ca.* 8000); MS *m/e* (%) 466 (M^+; 4) and 123 (100); Found: *m/e* 466.3822. Calcd for $C_{32}H_{50}O_2$: M, 466.3811.

Boron Trifluoride Etherate-catalyzed Backbone Rearrangement of 3α,4α-Epoxy-D:A-*friedo-18β,19α*H*-lupane (**4**) in Benzene.* A solution of α-epoxide (**4**; 30.1 mg) in benzene (15 ml) was treated with boron trifluoride etherate (0.3 ml) at room temperature for 1 h. A saturated aqueous sodium hydrogencarbonate solution (10 ml) was added, stirring being continued for 20 min. The usual work-up gave a mixture, which was subjected to separation by preparative TLC (developed with benzene–diethyl ether, 9:1) to afford *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3α-ol (**7**; 10.1 mg), -5-en-3α-ol (**6**; trace), and a mixture (9.7 mg) of alcohols. This mixture, dissolved in acetone (5 ml), was oxidized with the Jones reagent (one drop) at 0 °C, and the solution was stirred at 0 °C for 1 h. After the usual work-up, the reaction mixture was purified by preparative TLC (developed with benzene) to give a mixture (7.7 mg) of 3-oxo compounds. The mixture was separated by preparative HPLC into lup-19-en-3-one (**12**; 1.0 mg), 18β,19α*H*-lup-12-en-3-one (**15**; 3.2 mg), and lup-18-en-3-one (**17**; 1.8 mg). **12**: mp 174—177 °C (crystallized from acetone); IR 1712 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.77, 0.91, 0.95, 1.06 (each 3H, s), 1.01 (6H, s; 2$\times$$CH_3$), 1.53 and 1.55 (each 3H, s; >C=C(C$\underline{H}_3$)$_2$); MS *m/e* (%) 424 (M^+; 65) and 257 (100); Found: *m/e* 424.3711. Calcd for $C_{30}H_{48}O$: M, 424.3705. HPLC R_t=28.8 min.

15: mp 152.5—153 °C (crystallized from acetone); IR 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.77, 0.87 (each 3H, d, J= 6 Hz), 0.94, 1.01 (each 3H, s), 1.07, 1.13 (each 6H, s; 2× CH_3), and 5.21 (1H, t, J=4 Hz); MS *m/e* (%) 424 (M^+; 100) and 218 (88); Found: *m/e* 424.3708. Calcd for $C_{30}H_{48}O$: M, 424.3705. HPLC R_t=31.3 min. **17**: mp 167—168 °C (crystallized from acetone); IR 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.82—1.05 (21H; 7×CH_3), and 1.07 (3H, s); MS *m/e* (%) 424 (M^+; 100); Found: *m/e* 424.3691. Calcd for $C_{30}H_{48}O$: M, 424.3705. HPLC R_t=32.2 min.

Preparation of Lup-18-en-3-one (17). A mixture[12] (32.4 mg) of lup-18-en-3β-yl acetate (**18**) and 18ξ,19ξ*H*-lupan-3β-yl acetate (**19**) was dissolved in tetrahydrofuran (20 ml), and treated with lithium aluminium hydride (51 mg) under reflux for 2 h. The usual work-up gave a mixture (34.0 mg) of lup-18-en-3β-ol and 18ξ,19ξ*H*-lupan-3β-ol. A portion (17 mg) of this mixture was dissolved in acetone, a drop of the Jones reagent being added at 0 °C. After the reaction mixture had been stirred for 50 min, the usual treatment gave a residue, which was subjected to separation by preparative HPLC to afford lup-18-en-3-one (**17**; 8.9 mg).

*Boron Trifluoride Etherate-catalyzed Backbone Rearrangement of 3β,4β-Epoxy-*D:A*-friedo-18β,19α*H*-lupane (5) in Tetrahydrofuran.* A solution of β-epoxide[9] (**5**; 31.2 mg) in tetrahydrofuran (15 ml) was treated with freshly distilled boron trifluoride etherate (0.3 ml) at room temperature for 45 min. The same work-up as in the case of α-epoxide (**4**) gave a mixture, which was separated by preparative TLC (developed with benzene–diethyl ether, 9:1) to give *D:B*-friedo-18β,19α*H*-lup-5(10)-en-3β-ol[9] (**23**; 12.4 mg) and a mixture (7.3 mg) of 5-en-3β-ol[9] (**22**) and 4α-fluorohydrin (**24**). The mixture was subjected to separation by column chromatography on silica gel impregnated with 25% silver nitrate. Elution with benzene gave **24** (3.3 mg) and **22** (2.2 mg). **24**: mp 171 °C (crystallized from methanol); IR 3470 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.84—0.93 (15H; 5×CH_3), 1.07, 1.25 (each 3H, s), 1.33 (3H, d, J=24 Hz), and 3.68 (1H, m, $W_{1/2}$=13 Hz); MS *m/e* (%) 446 (M^+; 1), 426 (8), and 123 (100); Found: *m/e* 446.3935. Calcd for $C_{30}H_{51}OF$: M, 446.3924.

*Boron Trifluoride Etherate-catalyzed Backbone Rearrangement of 3β,4β-Epoxy-D:A-friedo-18β,19α*H*-lupane (5) in Benzene.* A solution of β-epoxide (**5**; 47.0 mg) in benzene (25 ml) was treated with boron trifluoride etherate (0.3 ml) at room temperature for 1 h. The same work-up gave a mixture, which was subjected to separation by preparative TLC (developed with benzene) to afford *D:A*-friedo-18β,19α*H*-lupan-3-one[9] (**26**; 0.5 mg), 4α-fluoro-*D:A*-friedo-18β,19α*H*-lupan-3β-ol (**24**; 1.5 mg), *D:B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**22**; 4.4 mg), and a mixture (37.2 mg) of alcohols (**27**—**29**). This mixture was dissolved in acetone (10 ml), the Jones reagent (3 drops) being added at 0 °C. The solution was stirred at 0 °C for 15 min. After the usual treatment, the residue was purified by preparative TLC (developed with benzene) to afford a mixture (31.9 mg) of 3-oxo compounds, which was separated by preparative HPLC into *D:B*-friedo-18β,19α*H*-lup-5(10)-en-3-one[9] (**30**; 3.4 mg), lup-19-en-3-one (**12**; 3.5 mg), 18β,19α*H*-lup-12-en-3-one (**15**; 14.5 mg), and lup-18-en-3-one (**17**; 6.2 mg).

*Boron Trifluoride Etherate-catalyzed Backbone Rearrangement of 3β,4β-Epoxy-*D:A*-friedo-18β,19α*H*-lupane (5) in Diethyl Ether.* A solution of β-epoxide (**5**; 41.8 mg) in diethyl ether (20 ml) was treated with boron trifluoride etherate (0.4 ml) for 20 min at 0 °C. A saturated aqueous sodium hydrogencarbonate solution (10 ml) was added, stirring being continued for 20 min. The usual work-up gave a mixture, which was separated by preparative TLC (developed with benzene) to afford 3β,10β-epoxy-*D:B*-friedo-18β,19α*H*-lupane (**31**; 9.0 mg), *D:A*-friedo-18β,19α*H*-lupan-3-one (**26**; 1.0 mg), 4α-fluoro-*D:A*-friedo-18β,19α*H*-lupan-3β-ol (**24**; 8.7 mg), *D:B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**22**; 4.6 mg), and -5(10)-en-3β-ol (**23**; 11.4 mg). **31**: mp 136—138 °C (crystallized from acetone); ^1H NMR ($CDCl_3$) δ 0.84—1.03 (18H; 6×CH_3), 1.67 (6H, s; 2×CH_3), and 3.72 (1H, d, J=5.5 Hz); MS *m/e* (%) 426 (M^+; 79) and 411 (100); Found: *m/e* 426.3861. Calcd for $C_{30}H_{50}O$: M, 426.3860.

*Solvent Effects on the Backbone Rearrangement of 3α,4α-Epoxy-*D:A*-friedo-18β,19α*H*-lupane (4).* Five portions of α-epoxide (**4**; each *ca.* 10 mg) were dissolved in hexane (5 ml), dichloromethane (5 ml), acetonitrile (10 ml), diethyl ether (5 ml), and 1,2-dimethoxyethane (5 ml), respectively, each solution being treated with boron trifluoride etherate (0.1 ml) at room temperature for 30 min. A residue, obtained after the usual work-up, was dissolved in acetone (5 ml) and treated with the Jones reagent (0.1 ml) at 0 °C for 1 h. After purification by preparative TLC (developed with benzene), a mixture of the 3-oxo compounds was examined by HPLC. Since *D:B*-friedo-18β,19α*H*-lup-5-en-3-one[9] (**34**) and -5(10)-en-3-one (**30**) showed the same retention time (R_t=27.3 min) under these conditions, a fraction with R_t=27.3 min was separated by HPLC, the relative amounts of two compounds, **34** (R_t=14.3 min) and **30** (R_t=12.3 min) being examined by GLC.

*Solvent Effects on the Backbone Rearrangement of 3β,4β-Epoxy-*D:A*-friedo-18β,19α*H*-lupane (5).* Four portions of β-epoxide (**5**; each *ca.* 10 mg) were dissolved in hexane (5 ml), dichloromethane (5 ml), acetonitrile (10 ml), and 1,2-dimethoxyethane (5 ml), respectively, each solution being treated with boron trifluoride etherate (0.1 ml) at room temperature for 1 h. A part of the residue, obtained by the usual treatment, was examined by GLC to determine the relative amount ratios of 4α-fluoro-*D:A*-friedo-18β,19α*H*-lupan-3β-ol (**24**; R_t=19.9 min), 3β,10β-epoxy-*D:B*-friedo-18β,19α*H*-lupane (**31**; R_t=9.6 min), and *D:A*-friedo-18β,19α*H*-lupan-3-one (**26**; R_t=16.5 min). The remaining part of the residue was oxidized with the Jones reagent (0.1 ml) in acetone (5 ml) at 0 °C for 1 h, the oxidized product being purified by preparative TLC (developed with benzene). Relative amount ratios of the 3-oxo compounds were estimated in the same way as in the case of α-epoxide (**4**).

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 343008 from the Ministry of Education, Science and Culture.

The Reaction of Diazo Ketones in the Presence of Metal Chelates. VIII. The Stereochemistry of the 1,3-Dipolar Cycloaddition of 1-Methoxy-2-benzopyrylium-4-olates to Ethylenic Dipolarophiles

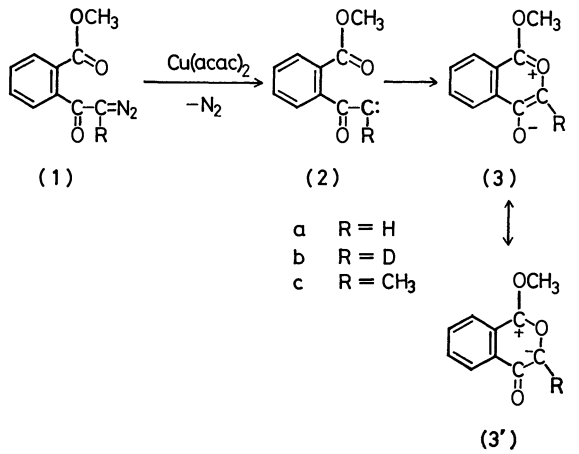
Toshikazu IBATA,* Kimiko JITSUHIRO, and Yoshie TSUBOKURA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received May 31, 1980)

1,3-Dipolar cycloadducts were obtained in the reactions of 1-methoxy-2-benzopyrylium-4-olate (**3a**) with ethylenic dipolarophiles, such as dimethyl fumarate, dimethyl maleate, maleic anhydride, *trans*-1,2-dibenzoylethylene, *N*-substituted maleimides, and acenaphthylene. The configuration of the adducts was determined on the basis of the NMR coupling pattern of the methine protons of the adducts in connection with a deuterium experiment. The previously reported structure of the adduct of **3a** with dimethyl fumarate was corrected according to the experimental results obtained using 3-deuterated **3a**. The stereospecificity of the cycloaddition was confirmed in the reactions of dimethyl fumarate, dimethyl maleate, and *trans*-1,2-dibenzoylethylene; this stereospecificity was explained by the concerted ($_{\pi}2_S+_{\pi}4_S$) mechanism. The *exo*/*endo* ratios of the adducts of *N*-substituted maleimides may be explained by the combination of the steric repulsion and π-π interaction of the phenyl ring of **3** and the substituent on the *N*-atom of maleimides. The cycloadditions of 1-methoxy-3-methyl-2-benzopyrylium-4-olate with *N*-substituted maleimides were also explained in a similar manner.

The 1,3-dipolar cycloaddition of pyridinium-3-olate has recently been studied extensively by Katritzky and his co-workers.[1] However, only a few papers are to be found on the reaction of pyrylium-3-olates,[2] which is isoelectronic with pyridinium-3-olate. In the previous papers of this series, we reported the transient formation of 1-methoxy-2-benzopyrylium-4-olate (**3a**: R=H) in the copper chelate-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**1a**: R=H) *via* an intramolecular carbene-carbonyl reaction.[3] The 2-benzopyrylium-4-olate was found to react as a 1,3-dipole of a type of carbonyl ylide with electron-deficient olefins[3] and acetylenes.[4] In this paper, the stereochemistry of the cycloaddition of **3** will be discussed in detail, using various *cis*- and *trans*-ethylenic dipolarophiles, in order to investigate the mechanism of this reaction.

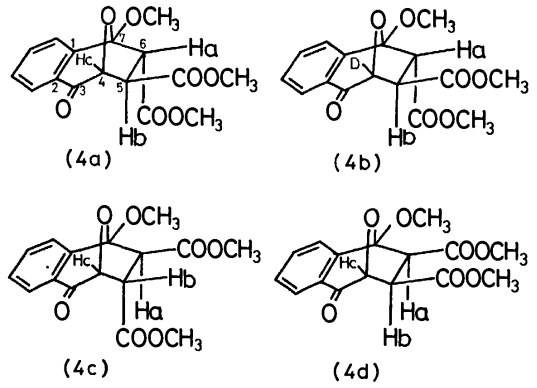


Results and Discussion

The $Cu(acac)_2$ catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**1a**: R=H) in the presence of dimethyl fumarate was reported to give a cycloadduct (**4a**), which was assigned erroneously to 4,7-epoxy-7-methoxy-5-*endo*-6-*exo*-bis(methoxycarbonyl)-1,2-benzocyclohepten-3-one (**4c**).[3] The NMR spectrum of the adduct (**4a**) showed signals of three methine protons, at δ 3.50 (dd), 4.00 (d), and 5.00 (d), besides the three singlets of OCH_3 and a multiplet of aromatic protons (Table 3). The double-doublet signal at δ 3.50 was readily assigned to Hb by reason of its splitting pattern, attributable to the coupling with the adjacent methine protons, Ha and Hc, on its sides. However, for the assignment of the two doublet at δ 4.00 and 5.00, the above data are not sufficient. In order to assign these signals,[4] *o*-methoxycarbonyl-α-diazoacetophenone-α-*d* (**1b**: R=D) was treated similarly in the presence of dimethyl fumarate; a deuterated cycloadduct (**4b**) was thus obtained. The similarity of the structures, **4a** and **4b**, is indicated by the fact that the mixed-melting-point test with **4a** and **4b** does not show any depression (110—111 °C). The IR spectrum of **4b** exhibits a similar pattern almost identical with that of **4a**. In the NMR spectrum of **4b** only two methine protons were observed, δ 4.03 and 3.50, as doublet signals which were coupled each other with J=6.0 Hz. This means that the substitution causes the disappearance of the doublet of **4a** at δ 5.00 and that the double-doublet of **4a** at δ 3.50 is decoupled to form a doublet. Therefore, the signals at 4.00 (d) and 5.00 (d) of **4a** were assigned to Ha and Hc respectively.

The steric relationship between Hb and Hc is determined to be *trans* on the basis of the small value of the coupling constsnt, J_{bc}=1.7 Hz,[6] which indicates an *endo* configuration of Hb. Although the coupling constant, J_{ab}(=6.0 Hz), has a medium value of *cis* and *trans* coupling constants, the steric relationship between Ha and Hb is established as *trans* in comparison with the value of J_{ab} (=9.6 Hz) of the adduct (**4d**) of dimethyl maleate, which has a *cis* configuration of Ha and Hb, as is shown below. The geometry of Hb and Hc of **4d** is confirmed to be *trans* (J_{bc}=2.6 Hz); hence, the configuration of Hb is concluded to be *endo*.

On a large-scale experiment on **1a** with dimethyl fumarate, the major adduct (**4a**) was obtained in a 70% yield, along with a minor product, colorless crystals (mp 115—117 °C, 4% yield). The minor



product was characterized as the adduct (**4c**) on the basis of its IR and NMR spectra. The similarity of the IR spectra of **4a** and **4c**, expect for a few differences in the finger-print region, indicates that these adducts are structural isomers different in configuration in the two methoxycarbonyl groups. In **4c**, the geometry between Ha and Hb was deduced to be *trans* (J_{ab}=5.4 Hz), and that of Hb and Hc, to be *cis* (J_{bc}=9.0 Hz). Therefore, the configurations of Hb and Ha are *exo* and *endo* respectively. The fact that the *trans* coupling constants, J_{ab} (6.0 and 5.4 Hz), of **4a** and **4c** are larger than the *trans* coupling constants, J_{bc} (1.7 and 2.6 Hz), of **4a** and **4d** is supported by the inspection of the dihedral angle of a Dreiding Model of the adducts (*trans*-Ha–C–C–Hb, 140°; *trans*-Hb–C–C–Hc, 90°).[7]

When the reaction was carried out in the presence of dimethyl maleate, a 1,3-dipolar cycloadduct (**4d**) was obtained in a 51% yield (mp 145—147 °C); this cycloadduct showed different spectral properties and melting point from the adducts, **4a** and **4c**, described above (Tables 1 and 3). The structure of **4d** was confirmed by a comparison of its IR and NMR spectra with those of an authentic sample synthesized by the esterification of the corresponding dicarboxylic acid, which has been obtained by the hydrolysis of the cycloadduct of 2-benzopyrylium-4-olate (**3a**) with maleic anhydride.

The relation with *trans*-1,2-dibenzoylethylene gave two adducts (**5a** and **5c**). The major adduct (**5a**) showed two doublets, at δ 5.32 and 5.03, and a double-doublet at δ 4.68 (Table 3). These signals were assigned to Ha, Hc, and Hb respectively by comparison with the deuterated adduct (**5b**) in a manner similar to that cited above. The relationships between the neighboring methine protons, Ha-Hb and Hb-Hc, are determined to be *trans* on the basis of the coupling constants (J_{ab}=5.6, J_{bc}=1.8 Hz). The smaller coupling constant J_{ab} (=5.5 Hz) and larger J_{bc} (=8.8 Hz) of the minor adduct (**5c**) show *trans* Ha-Hb and *cis*

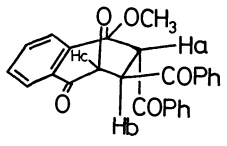
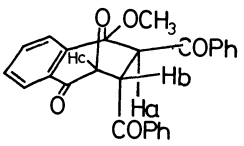
a) Signals of aromatic protons were omitted. b) The NMR spectrum was measured in a $CDCl_3$–pyridine solution.
c) The coupling constant was not determined.

Hb-Hc relationships, which indicate *endo*-Ha and *exo*-Hb configurations.

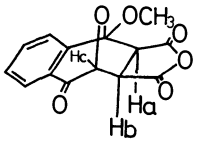
Reaction with maleic anhydride gave only one adduct in a 48% yield, along with isochroman-1,4-dione (**8**, 14%). The IR spectrum and the results of elemental analysis exhibit that the adduct has a structure (**7**) with two carboxyl groups which were derived from the hydrolysis of the primary adduct (**6**) during the silica-gel-column chromatography. The NMR spectrum of **7** shows doublets at δ 3.80 and 5.98 and a double-doublet at δ 3.67. The coupling constants indicate that the carboxyl groups have the *exo* configuration. The esterification of the adduct (**7**) with diazomethane gave a diester which has the same structure as the adduct (**4d**) obtained by the reaction with dimethyl maleate and the 2-benzopyrylium-4-olate (**3a**). In this case, the absence of an adduct with *endo* carboxyl groups may be attributed to the steric replusion between the anhydride group of the dipolarophile and the carbonyl group of **3a**. The low dipolarophilicity of maleic anhydride caused the by-product formation of lactone (**8**) by the attack



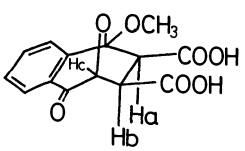
(5a)



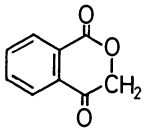
(5b)



(6)



(7)



(8)

on 2-benzopyrylium-4-olate (**3a**) of water contained in a benzene solution as an impurity.

N-Phenylmaleimide gave two adducts in yields of 58 and 29%. The major adduct (**9a**) was established to be the *exo* isomer on the basis of its NMR spectrum, which showed singlet signals of methine protons at δ 3.43 and 5.22. From the lack of coupling between Hb and Hc, the configuration of Hb was confirmed to be *endo*. In other words, the *exo* configuration of the adduct (**9a**) was established.[8] Therefore, a singlet at δ 3.43 was assigned to both Ha and Hb, which happened to be equivalent to each other, while a singlet at δ 5.22 was assigned to Hc. The minor adduct (**10a**) shows methine-proton signals at δ 3.93 (d), 4.30 (t), and 5.20 (d), which were assigned to Ha, Hb, and Hc respectively. The coupling pattern, especially the doublet signal (J=9.0 Hz) of Hc, indicates the *endo* structure of the adduct (**10a**).[8] The triplet signal of Hb may be attributed to the same value of the coupling constants, J_{ab} and J_{bc} (=9.0 Hz). The *endo* structure (**10a**) of the minor product was also supported by the abnormal high-field shifts (6.27—6.47 ppm) of two ortho-protons of *N*-phenyl group, which were caused by the shielding effect of the condensed benzene ring. A Dreiding-Model inspection of the *endo* adduct indicates the benzene ring and *N*-phenyl group close to one another.

N-Ethyl- and *N*-methylmaleimides also gave *exo* (**9b**, 70%; **9c**, 61%) and *endo* adducts (**10b**, 25%; **10c**, 33%) respectively. A similar pattern of methine signals was observed in the NMR spectrum of the adducts. The high-field shifts of the *N*-ethyl (δ 0.27, CH_3; 3.07, CH_2) and *N*-methyl signals (δ 2.37) of **10b** and **10c** are explained by the shielding effect of the benzene ring, located close to the *N*-alkyl groups.

Similar results were observed in the reaction of *N*-substituted maleimides with 1-methoxy-3-methyl-2-benzopyrylium-4-olate (**3c**, R=CH_3), which was generated by the $Cu(acac)_2$-catalyzed decomposition of 2-methoxycarbonyl-α-diazopropiophenone (**1c**), yielding *exo* (**11**) and *endo* (**12**) adducts (Table 2). The *endo* adducts show the shielding effect by the benzene ring on the PMR shift of the *N*-methyl, *N*-ethyl, and *N*-phenyl groups (Table 3).

When **1a** was decomposed in the presence of acenaphthylene, two adducts (**13** and **14**) were obtained accompanying lactone (**8**, 14%) in yields of 9 and 13% respectively. The NMR spectrum of **13** has a singlet signal of Hc at δ 4.90 and a broad singlet of two methine protons, Ha and Hb, at δ 4.2. The lack of coupling between Hb and Hc establishes the *exo* structure of the adduct (**13**).[8] Although the multiplet signal of the methine protons of **14** is not sufficient for the determination of the configuration of **14**, it may be identified as *endo* by comparison with the spectrum of **13**.

(14)

The stereospecificity of the cycloaddition of the 2-benzopyrylium-4-olate (**3a**) to dimethyl fumarate, dimethyl maleate, and *trans*-1,2-dibenzoylethylene indicates that the cycloaddition proceeds in a ($_{\pi}2_s+_{\pi}4_s$)-type concerted mechanism.[10] In the cycloaddition of *trans* dipolarophiles, such as dimethyl fumarate and *trans*-1,2-dibenzoylethylene, the preferential formation of 5-*endo*-6-*exo* adducts (**4a** and **5a**) to 5-*exo*-6-*endo* adducts (**4c** and **5c**) was explained by the predominance of the transition state (**15a**) over the transition state (**15b**), which contained repulsion between a carbonyl group of dipolarophile and that of 2-benzopyrylium-4-olate. The predominance of the *exo* adducts in the reactions of all the *cis* dipolarophiles except acenaphthylene is explained by the larger stability of the anti-transition state (**16a**) than that of the syn-transition state (**16b**). On the other hand, acenaphthylene showed a reverse tendency to give more *endo* adduct (**14**) than the *exo* isomer (**13**). This might be caused by the π-π interaction[11] between the benzene ring of 2-benzopyrylium-4-olate and the naphthalene moiety of acenaphthylene in the double-layer syn-transition state.[9]

The *endo*/*exo* ratios of the adducts of *N*-substituted maleimides with **3a** and **3c** were found to decrease in the order of *N*-methyl>*N*-phenyl>*N*-ethylmale-

TABLE 4. THE *endo/exo* RATIOS OF THE ADDUCTS OF MALEIMIDES WITH **3a** AND **3c**

2-Benzopyrylium-4-olate	Maleimide		
	R=Ph	R=C_2H_5	R=CH_3
3a (R′=H)	0.50	0.36	0.54
3c (R′=CH_3)	0.68	0.42	0.76

imide (Table 4). This tendency may be explained by the combination of the steric repulsion and π-π interaction between the benzene ring of 2-pyrylium-4-olate (**3**) and the substituent (R) on the imide nitrogen in the transition state. The steric replusion of *N*-R in the *endo*-transition state (**17b**) may decrease the yield of the *endo* adduct. However, the *endo/exo* ratios are not in the order of the bulkiness of the R group. The π-π interaction of the *N*-phenyl group with the benzene ring of **3** may increase the *endo* yield a little more than the expected value because of its bulkiness and may thus give a value in between those of *N*-methyl- and *N*-ethylmaleimides. The large *endo/exo* ratios of **3c** adducts (**12/11**), in contrast to those of **3a** adducts, may be attributed to the repulsion between the R on the imide-nitrogen and the R′ on the C-3 of **3c** in the *exo* transition state (**17a**), which decreases the yeild of the *exo* adduct slightly (Table 4).

Experimental

All the melting points were measured on a Yanagimoto Melting Point Apparatus and were not corrected. The IR spectra were taken on a Hitachi Spectrometer, model EPI-S2. The ^{1}H-NMR spectra were recorded on a Varian A-60 or EM-360 Spectrometer in a $CDCl_3$ solution; the chemical shifts were described in ppm downfield from TMS as the internal standard (δ scale).

Materials. o-*Methoxycarbonyl-α-diazoacetophenone* (***1a***) was prepared by the procedure described in the previous paper.[3]

o-*Methoxycarbonyl-α-diazoacetophenone-α-d* (***1b***) was synthesized by the reaction of the DCC complex of methyl hydrogen phthalate with deuterated diazomethane, which had itself been prepared by the reaction of *N*-methyl-*N*-nitrosourea with potassium deuteroxide in D_2O.[12] Crude **1b** containing a trace amount of dimethyl phthalate was used without further purification.

o-*Methoxycarbonyl-α-diazopropiophenone* was synthesized by the DCC method using an excess of diazoethane and purified by column chromatography on Al_2O_3 with an activity of 4; viscous liquid, IR (liquid film): 2050 (diazo), 1700 (ester), 1595 cm^{-1} (diazocarbonyl), NMR: 2.57 (s, 3H, CH_3), 3.87 (s, 3H, OCH_3), 7.4—8.1 ppm (aromatic protons).

All the other reagents were purified by recrystallization or distillation before use.

*General Procedure of the Decomposition of **1** in the Presence of Dipolarophiles.* The $Cu(acac)_2$-catalyzed decomposition of **1** was performed according to the procedure described in the previous paper by refluxing a benzene solution of **1** and a 1.2—1.5 molar equivalent of dipolarophile and a catalytic amount of $Cu(acac)_2$ until no more N_2 was evolved.[3] The reaction mixture was separated by silica gel column chromatography, using benzene as the eluent.

*Esterification of Dicarboxylic Acid (**7**).* An ether solution of diazomethane was slowly added to a suspension of 0.10 g of **7** in ether until no more N_2 was evolved. The subsequent evaporation of the ether under reduced pressure yielded 0.11 g of colorless crystals (mp 145—146 °C), later recrystallized from benzene-heptane solution. The IR and NMR spectra were perfectly superimposable on those of **4d** obtained by the reaction of **3a** with dimethyl maleate.

Applications of Homogeneous Water-gas-shift Reaction. I. Further Studies of the Hydroformylation of Propene with CO and H_2O

Kazuhisa MURATA* and Akio MATSUDA

National Chemical Laboratory For Industry, Tsukuba Research Center, Yatabe, Tsukuba, Ibaraki 305

(Received June 18, 1980)

Polar ether solutions prepared *in situ* from $Co_2(CO)_8$ and 1,2-bis(diphenylphosphino)ethane (diphos) are active catalysts for the hydroformylation of propene with CO and H_2O. Under the hydroformylation conditions employed, butyl(C_4) or isobutyl alcohols, butyric(C_4) acids, and dipropyl ketones were found to be formed as by-products. A pronounced formation of C_4 alcohols was observed as the reaction temperature was increased; in fact, the catalyst solutions described above actively reduce butyraldehyde to butyl alcohol. The effects of the CO pressure and of the propene concentration on the formation of C_4 aldehydes are also examined. It turns out that the water molecule as well as $Co_2(CO)_8$ and diphos are essential for the formation of catalytic intermediates, which are themselves responsible for the hydroformylation activity.

Recently, we have reported the homogeneous catalysis of hydroformylation with CO and H_2O, in which the $Co_2(CO)_8$–diphos system was used in such polar ether solvents as THF, dioxane, and diglyme with no base.[1]

$$CH_3CH{=}CH_2 + 2CO + H_2O \longrightarrow CH_3CH_2CH_2CHO \text{ or } CH_3\underset{\displaystyle CH_3}{\overset{|}{C}}HCHO + CO_2 \quad (1)$$

The use of CO and H_2O in place of hydrogen is not a racent development. It has been well known, for example, that hydrohydroxymethylation(1′) is catalyzed by the $Fe(CO)_5$–organic tertiary amine system.[2] (Reppe Reaction: The reaction(1′) is more stoichiometric than catalytic.)

$$CH_3CH{=}CH_2 + 3CO + 2H_2O \longrightarrow CH_3CH_2CH_2CH_2OH \text{ or } CH_3\underset{\displaystyle CH_3}{\overset{|}{C}}HCH_2OH + 2CO_2 \quad (1')$$

More recently, special attention has been paid to the possibility of using other transition-metal carbonyl complexes as active catalysts in these reactions, (1) and (1′); a variety of Group 8 metal carbonyl clusters can serve as catalyst precursors in the presence of alkali or amine.[3]

Our catalyst system is considerably different from other ones in that: a) diphos is an essential component, and b) alkali or organic amines are absent.

Also, $Co_2(CO)_8$ is a more conventional catalyst than other metal carbonyl clusters, such as $Ru_3(CO)_{12}$, $Rh_6(CO)_{16}$. Therefore, there is the possibility of developing a novel industrial process. Thus, further studies of our catalyst system were undertaken under reaction conditions more catalytically active than those reported previously.[1]

Experimental

Materials. The propene (Research Grade), diphos, and dioxane used as solvent were obtained commercially and were used with no further purification. The $Co_2(CO)_8$ was prepared by the conventional method. The H_2O was distilled under atmospheric pressure prior to use.

Reaction Procedure. The hydroformylation reactions were carried out in a 100-ml stainless-steel autoclave, in which $Co_2(CO)_8$, diphos, H_2O, and dioxane had been placed. After the vessel was sealed, both propene and CO were introduced. The system was then brought to the desired reaction temperature and pressure by the additional charging of CO under heating. Stirring was then begun, and the reaction took place. The CO pressure was kept constant during the reaction by supplying the gas from a 400-ml pressure storage vessel through a pressure regulator. The reaction temperature was controlled within a range of ±1 °C.

The catalytic reductions of butyraldehyde to butyl alcohol were performed in an identical manner, except for the use of butyraldehyde (25 mmol) in place of propene (25 mmol).

Analysis of Products. Gas analysis was performed at 50 °C with a gas chromatograph using a 6-m Carbowax column. The amount of CO_2 was determined by titration methods. The liquid products other than C_4 acids were analyzed at 100 °C by means of a gas chromatograph equipped with FID using a 6-m column packed with polyethylene glycol adipate. C_4 acid analysis was performed at 150 °C using a gas chromatograph equipped with FID and using a 4-m squalane column. The infrared spectra of catalyst solutions were recorded on a Hitachi type 215 spectrometer.

Results and Discussion

Preliminary Studies Involving the Effect of CO Pressure. The $Co_2(CO)_8$-catalyzed hydroformylation of propene with CO and H_2O was carried out in dioxane solvent, since it was greatly effective for this reaction; only a little hydrogen as a co-product was detected in the dioxane. This reaction can proceed catalytically only in the presence of phosphine; of all the phosphines used, diphos was the most effective. A diphos 1: $Co_2(CO)_8$ 1 ratio was used in order to inhibit the partial decomposition of the catalyst.

In a previous report,[1] the reaction was run at 135 °C for 17 h under an initial pressure of 12 kg/cm^2; C_4 aldehydes (9.2 mmol, *ca.* 37% conversion based on propene) were thus produced with 0.04 mmol of C_4 alcohols, (2), (3). In addition, we have recently found that, under the conditions employed, butyric (C_4) acids (1.0 mmol, (4)) and dipropyl ketones (0.8 mmol, (5)) were formed as by-products in detectable amounts.

$$C_3H_7\text{-}CHO + CO + H_2O \longrightarrow C_3H_7\text{-}CH_2OH + CO_2 \quad (2)$$

$$CH_3CH{=}CH_2 + 3CO + 2H_2O \longrightarrow C_3H_7\text{-}CH_2OH + 2CO_2 \quad (3)$$

$$CH_3CH{=}CH_2 + CO + H_2O \longrightarrow C_3H_7\text{-}COOH \quad (4)$$

$$2CH_3CH{=}CH_2 + 2CO + H_2O \longrightarrow (C_3H_7)_2CO + CO_2 \quad (5)$$

Reaction 4 is a cobalt-catalyzed hydrocarboxylation, which is of little interest to us because it is a well-known example of a Reppe Reaction, which proceeds with no production of CO_2. At 165 °C, CO(50 kg/cm²), 13.0 mmol of C_4 aldehydes was obtained at a 5 h-reaction and few C_4 acids were formed, though a higher CO pressure favored the formation of the acids (Fig. 1). As is shown in Fig. 1, the total amounts of C_4 aldehydes (abbreviated as [aldehydes]) decreased with the increase in the CO pressure, which is analogous to observations in a normal $Co_2(CO)_8$-catalyzed hydroformylation using CO/H_2.[4]

Effect of the Temperature. In normal $Co_2(CO)_8$-catalyzed reactions, the C_4 aldehydes which are formed during the hydroformylation are readily reduced to the corresponding C_4 alcohols at a higher reaction temperature.[5]

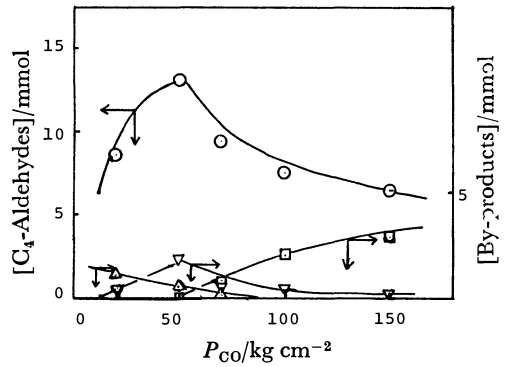

Fig. 1. Effect of CO pressure.
$Co_2(CO)_8$ 2 mmol, diphos 2 mmol, H_2O 60 mmol, dioxane 50 ml, propene 25 mmol, temp 165 °C, time 5 h.
—○—: C_4-aldehydes, —△—: C_4-alcohols, —□—: C_4-acids, —▽—: dipropyl ketones.

The temperature-dependence on the product yields is illustrated in Fig. 2; the reactions were performed using the $Co_2(CO)_8$–diphos system for 5 h under CO (50 kg/cm², const). As one would expect, [aldehydes] rather decreased with the increase in the reaction temperature and there was a pronounced formation of C_4 alcohols. It is not obvious from the data whether the C_4 alcohols are formed step-by-step *via* hydroformylation (1) and then reduction (2), or directly from propene (3). Thus, the possibility of the reduction of butyraldehyde to butyl alcohol with CO and H_2O was tested under the same conditions as those employed in Fig. 2, except that butyraldehyde (25 mmol) was used in place of propene. The reduction (2) occurs, but more slowly than in the hydroformylation of propene; the higher the temperature, the larger the amount of butyl alcohol produced[6] (Fig. 2---,).

Effect of the Propene Concentration. As is shown in Fig. 3, [aldehydes] increased with the initial increase from 25 to 150 mmol of propene, but a further increase of propene resulted in a decrease in the yields. On the other hand, the total amounts of dipropyl ketones ((5), [ketones]) drastically increased, and it turned out, as a result, that the ketones were obtained as the principal products in the reaction of propene with CO and H_2O. Under these conditions, the product molar ratio of 4-heptanone: 2-methyl-3-hexanon: 2,4-dimethyl-3-pentanone was *ca* 1:1.8:0.8; this ratio depends little on the propene concentration.

Generally, dipropyl ketones can be produced under normal oxo conditions in the presence of $Co_2(CO)_8$; the formation of the ketones is favored not only by a high concentration of propene, but also by the use of such hydrogen donors as H_2O, alcohols instead of H_2.[7] Taking into account the fact that H_2O is used as a hydrogen donor in our $Co_2(CO)_8$–diphos system, the findings in Fig. 3 are analogous to those in the normal $Co_2(CO)_8$ system. In the normal system, however, the formation of the ketones does not predominate over that of the aldehydes (or esters,

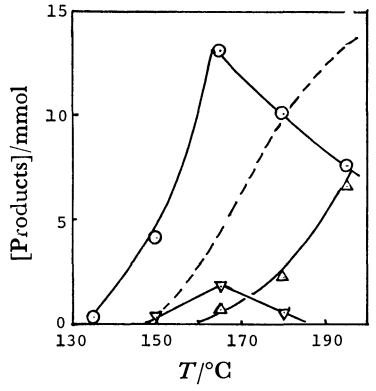

Fig. 2. Effect of temperature.

acids). In this point, the catalytic behavior of $Co_2(CO)_8$ and that of $Co_2(CO)_8$–diphos was quite different. An obvious explanation cannot be obtained from the data shown in Fig. 3; further work is required.

In recent reports on metal carbonyl (cluster)-catalyzed hydroformylation with CO and H_2O, ketone formation has not been referred to at all.[3] According to our additional experiments, an $RhCl_3$– or $RuCl_3$–Et_3N catalyst system can give dipropyl ketones only as minor product under the conditions shown in Fig. 3. Thus, the $Co_2(CO)_8$–diphos system appears to be more desirable for the exclusive formation of dipropyl ketones from propene; the details will be described in the succeeding paper.[8]

Catalytic Behavior as a Function of Time. The hydroformylation of propene was repeated under the conditions where C_4 aldehydes are predominantly formed, and aliquots of the catalyst solutions were withdrawn from the autoclave at several reaction times and analyzed. The results are illustrated in Fig. 4(○), where an induction period of *ca.* 1 h was observed. In our catalyst system, under the conditions employed, aldol condensation, by which butyraldehyde is converted to C_8 aldehyde, occurs to only a slight extent with the progress of the reaction (see Fig. 4(○,●)), partly because alkali or organic amine is absent in the solution.[9]

The presence of an induction period is of interest in connection with the intermediates present in the catalyst solutions. The period disappears on the pretreatment of the solution ($Co_2(CO)_8$–diphos–dioxane) with both CO (50 kg/cm²) and H_2O (60 mmol) at 165 °C for 1 h in the absence of propene (Fig. 4, □),[10a] whereas it does not disappear on the similar pretreatment of the solution with only CO (Fig. 4, △).[10b] These findings indicate that the H_2O molecule is required for the production of intermediates, which are themselves responsible for the hydroformylation with CO and H_2O. Considering that the catalytic behavior of $Co_2(CO)_8$–diphos system using CO–H_2O is relatively similar to those of normal $Co_2(CO)_8$ using CO–H_2 (Figs. 1, 2, and 3), cobalt carbonyl hydride complexes ($HCo(CO)_m(diphos)_n$, (A))[11] may be probable candidates as the key intermediates necessary for the catalysis of the reaction. Rhodium or ruthenium carbonyl hydrides have already been proposed as intermediates active in hydroformylation using CO–H_2O.[3b]

In the absence of propene, the $Co_2(CO)_8$–diphos system is active in the water-gas-shift reaction (WGSR), thoguh its catalytic activity is *ca.* ten times lower than that of the hydroformylation.[1] Therefore, there is a possibility that the catalytic intermediates which catalyze the hydroformylation participate in the WGSR.[12] In fact, the catalyst solutions derived from the $Co_2(CO)_8$–diphos system show the same absorptions in the metal carbonyl regions in both the presence and absence of propene.[13]

Unfortunately, attempts to isolate (A) were not successful.[14] Also, it is not obvious from our data that the catalytic intermediates, (A), which are necessary for the catalysis of the hydroformylation, are in fact involved in the catalysis of the WGSR. However, undoubtedly, intermediates active in the hydroformylation of propene, as well as in the WGSR, can be formed only from $Co_2(CO)_8$, diphos, and H_2O (Fig. 4).

14) More recently, we have found that the ^1H-NMR spectrum of an active water-gas-shift catalyst solution consisting of $Co_2(CO)_8$, diphos, H_2O, and dioxane displays a characteristic resonance at δ −17.2. Further studies of this will be discussed elsewhere.

Applications of Homogeneous Water-gas-shift Reaction. II. The Formation of Dipropyl Ketones as Primary Products from CO and H_2O in the Presence of an Excess Amount of Propene. Cobalt-based Catalytic Hydrocarbonylation

Kazuhisa MURATA* and Akio MATSUDA

National Chemical Laboratory For Industry, Tsukuba Research Center, Yatabe, Tsukuba, Ibaraki 305

(Received June 18, 1980)

The hydrocarbonylation of propene with CO and H_2O to give dipropyl ketones occurs predominantly over forming C_4-aldehydes; the catalyst solutions employed are prepared *in situ* from $Co_2(CO)_8$, various phosphines as ligands, and H_2O, a high molar ratio of propene to $Co_2(CO)_8$ of 300/2 being required. Of the several phosphorus ligands examined, 1,2-bis(diphenylphosphino)ethane (diphos) and bis(diphenylphosphino)acetylene are relatively effective for the formation of the ketones (abbreviated as [ketones]). The effects of the reaction variables (CO pressure, temperature, and H_2O concentration) on [ketones] are also examined using the $Co_2(CO)_8$–diphos system; [ketones] increases with the initial increase in CO pressure, but reaches a maximum at *ca.* 100 kg/cm^2 and decreases thereafter. Pronounced decreases of [ketones] are observed when pyridine as well as hydrogen is added to the catalyst solutions.

Hydrocarbonylation, by which dialkyl ketones are produced from olefins, can proceed under oxo conditions by means of a transition-metal catalyst.[1] However, the selectivity of the reaction is significantly low when olefins other than ethene are used;[2] generally, a mixture of ketones, aldehydes, and other oxygenated products is formed. Accordingly, the hydrocarbonylation reaction, despite its potential synthetic value, has scarcely been investigated at all.

We described in our previous papers that the presence of an excess amount of propene under the hydrocarbonylation conditions using CO–H_2O leads to the formation of dipropyl ketones as primary products,[3] and $Co_2(CO)_8$–phosphine system appeared to be much more effective for the ketone formation than other transition-metal catalysts, being especially active for the homogeneous water-gas-shift reaction (WGSR).[4]

In the present paper, further studies of this cobalt catalyzed-hydrocarbonylation will be described, and the catalytic behavior will be compared with that in hydroformylation.

Experimental

The experimental methods are roughly analogous to those described in the preceding paper.[3] The few differences will be outlined below.

The phosphines and pyridine were obtained commercially.

The hydrocarbonylation reactions were performed in a 300 ml stainless-steel autoclave equipped with a vertical agitator. In all runs, the molar ratio of propene to $Co_2(CO)_8$ was kept constant at 300 mmol/2 mmol.

A certain amount of hydrogen was added to a catalyst solution as soon as the solution had been brought to the reaction temperature (Fig. 5). A small amount of pyridine was mixed with the catalyst solutions ($Co_2(CO)_8$–diphos–dioxane–H_2O) before the reactor was sealed (Fig. 6).

Results and Discussion

All of the hydrocarbonylation experiments were carried out for a 5 h-reaction time[5] with the propene/$Co_2(CO)_8$ molar ratio being held constant at 300/2, since the maximum yield of dipropylketones was achieved at this ratio (see Fig. 3 in the preceding paper[3]). $Co_2(CO)_8$ was also used as a catalyst precursor in the dioxane solvent. As is shown in Table 1, THF (Run 1) and the cobalt carbonyl cluster ($CH_3CCo_3(CO)_9$) (Run 2) lead to a reduction in the ketone formation.

Effects of Several Phosphorus Ligand. The results are summarized in Table 1 (Runs 3,4,9—15). The effectiveness of phosphorus ligands in increasing the formation of the ketones ([ketones]) decrease in this order: diphos > $Ph_2PC{\equiv}CPPh_2$ > PPh_3 > $Ph_2PCH_2PPh_2$ > PBu_3 > $Ph_2P(CH_2)_3PPh_2$ > $(PhO)_3P$ > $Ph_2P(CH_2)_4PPh_2$ = $Ph_2As(CH_2)_2PPh_2$.

The effect of the diphos: $Co_2(CO)_8$ ratio on the [ketones] was also examined (Runs 4—8); the most active catalyst appears to be formed with a *ca.* 0.75:1 ratio (Run 5). As we would expect, however, for the <1:1 ratios, the catalyst partially decomposes during the reaction.[6] In the absence of diphos, 6.5 mmol of the ketones were obtained, with the $Co_2(CO)_8$ being completely decomposed.[6,7] (Run 8) Both the order of reactivity and the ratio effect reported here are quite similar to those observed for the hydroformylation using CO–H_2O with a propene/$Co_2(CO)_8$ molar ratio of 25/2.[8] Hereafter, diphos is here used as a ligand.

Effect of CO Pressure. The [ketones] value is remarkably dependent on such reaction variables as CO pressure(P_{CO}), H_2O concentration, and the temperature. Figure 1 illustrates the P_{CO} dependence. The [ketones] value increased with the initial increase in P_{CO}, but nearly reached a maximum as the P_{CO} increased to *ca.* 100 kg/cm^2 decreased thereafter. The C_4 aldehyde formation ([aldehydes]), on the other hand, smoothly decreased with the increase in P_{CO}.

Effect of Temperature. The temperature dependence under 100 kg/cm^2 of P_{CO} is shown in Fig. 2. The [ketones] value increased with an increase in the temperature from 135 °C to 165 °C, but rather decreased at 180 °C, whereas [aldehydes] successively increased; as a result, the selectivity to the ketones drastically decreased (– – –) at 180 °C.

Effect of H_2O Concentration. Figure 3 displays a plot of the product formation as a function of the H_2O added. The [ketones] value reached a maximum

as the amount of H_2O([H_2O]) increased to *ca.* 120 mmol, and leveled off thereafter. In contrast, [aldehydes] linearly increased with the increase in [H_2O]. Thus, the combined yield (---) increased with [H_2O].

A plot of the product formation as a function of the $Co_2(CO)_8$ concentration, where the diphos/$Co_2(CO)_8$ ratio was kept constant at 1/1, gave results analogous to those shown in Fig. 3.

Catalytic Intermediates. It seems likely that catalytic intermediates(probably $HCo(CO)_m(diphos)_n$, (A)) which catalyze the hydroformylation of propene with CO and H_2O, as has already been described in the preceding paper,[3] also participate in this hydrocarbonylation. In fact, C_4 aldehydes can be formed even during the reaction (Table 1, Figs. 1—3). The influence of phosphorus ligands on the [ketones] value (propene/$Co_2(CO)_8$=300/2, Table 1) is fairly analogous to that on the hydroformylation activity (the ratio=25/2).[8] A smooth increase in the combined yield results when [H_2O] is increased, since the concentration of (A) also increases (Fig. 3). The catalyst solutions active in the hydrocarbonylation have the

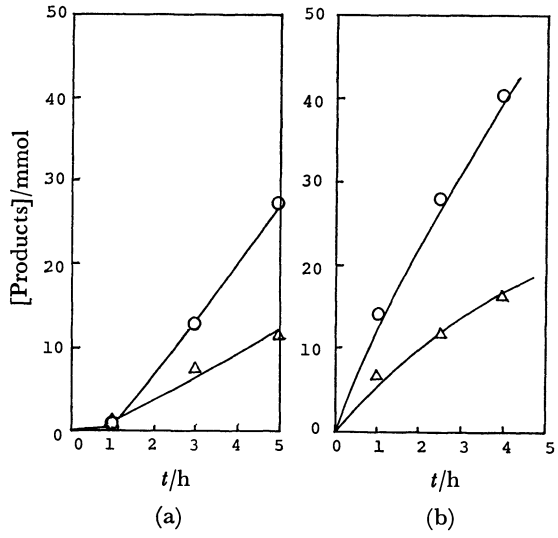

Fig. 4. Cobalt-catalyzed hydrocarbonylation as a function of time.
$Co_2(CO)_8$ 2 mmol, diphos 2 mmol, dioxane 50 ml, P_{CO} 100 kg/cm², H_2O 60 mmol, propene 300 mmol, temp 165 °C.
(a) A standard reaction, (b) a reaction after the pretreatment with both CO (100 kg/cm²) and H_2O (60 mmol) at 165 °C for 1 h, marks (○,△): see footnote of Fig. 1. Other products omitted.

same IR absorptions in the metal-carbonyl region as in hydroformylation. Also, there is an induction period for the ketone formation as well as in the case of aldehydes (Fig. 4a); the period disappears on the pretreatment of the solution ($Co_2(CO)_8$–diphos–dioxane) with both CO (100 kg/cm²) and H_2O (60 mmol) at 165 °C for 1 h in the absence of propene (Fig. 4b).

Thus, if (A) is present, we can postulate the following reaction, which produces acyl complexes (B) as other key intermediates for the hydrocarbonylation as well as hydroformylation. This is analogous to a scheme proposed by Jonassen[9] and Heck[10] with regard

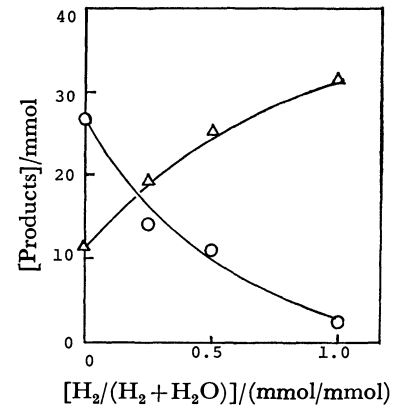

Fig. 5. Effect of added H_2.
$Co_2(CO)_8$ 2 mmol, diphos 2 mmol, dioxane 50 ml, P_{CO} 100 kg/cm², propene 300 mmol, temp 165 °C, time 5 h.
Marks (○,△): See footnote of Fig. 1. Other products omitted.

to these two reactions using a normal $Co_2(CO)_8$ catalyst with CO–H_2.

$$\underset{\text{(A)}}{HCo(CO)_m(\text{diphos})_n} \xrightarrow{CO+CH_3CH=CH_2}$$

$$CH_3CH_2CH_2\text{-}\overset{O}{\overset{\|}{C}}\text{-}Co(CO)_m(\text{diphos})_n$$
(B)

If (B) is rapidly consumed for the formation of C_4 aldehydes (or acids) before the interaction with propene, then the [ketones] value will be diminished. For example, when hydrogen is added to a catalyst solution, a pronounced increase in [aldehydes] results, as is illustrated in Fig. 5, where the total amount of hydrogen donors (H_2O or H_2) was kept constant at 60 mmol, whereas the [ketones] value decreases with an increase in the hydrogen concentration, even at a constant high molar ratio of propene/$Co_2(CO)_8$-(=300/2). A further example was obtained from experiments featuring the addition of a small amount of pyridine; the results are shown in Fig. 6. The rapid reaction of (B) with H_2O takes place, producing C_4 acids (□); as a result, both [ketones] (○) and [aldehydes] (△) decrease. The accelerating effects of pyridine have already been observed on the normal $Co_2(CO)_8$-catalyzed hydrocarboxylation of olefin.[11]

Considering the data described above, it is probable that the intermediates (A) are present. However, because of the possible existence of cobalt carbonyl species different from (B), as is demonstrated by the variations in [ketones] and [aldehydes] with the CO pressure (Fig. 1), the above-mentioned acyl complexes, (B), can be considered only as possible models of the reaction intermediates.

Ozonization of Organic Compounds. V. Aromatic Compounds

Tsuneo Saito, Etsuo Niki,* and Yoshio Kamiya

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 28, 1980)

The ozonization of several aromatic compounds has been carried out at 30 °C in carbon tetrachloride. It was found that three processes proceeded simultaneously; that is, normal and anomalous ozonolyses to give respectively α,β-dicarbonyl and carboxylic compounds and polymerization. Carboxylic acids were the major products. Benzene and hexamethylbenzene gave formic acid and acetic acid respectively, while toluene and 1,3,5-trimethylbenzene gave mixtures of these acids. As the ozonization proceeded, white gummy polymers precipitated, the molecular weight ranged from several hundreds to a few thousands. They contained high concentrations of oxygen which was incorporated into polymer as carbonyl, carboxylic acid, peroxide and/or ether. The polymers were thermally stable below 150 °C.

The interactions of ozone with organic compounds, especially olefins, have been studied quite extensively[1] and this reaction has been applied in preparation and identification of organic compounds. Recently the ozone chemistry has received much attention in the fields of atmospheric oxidation and purification of water. We have previously reported[2] that polypropylene underwent cleavage by ozonization to give lower molecular weight carboxylic acids but that the ozonization of polystyrene brought about crosslinking as well as chain scission, giving rise to broadening of molecular weight distribution.

The ozonization of aromatic ring has also been studied for long time. In 1904, Harries and Weiss[3] found that the ozonization of neat benzene and subsequent hydrolysis gave about 2 equivalents of glyoxal and no hydrogen peroxide. They surmised that the third mole of equivalent of glyoxal reacted with hydrogen peroxide during homolysis to give carbon dioxide and water. Later, in addition to α,β-dicarbonyls, peroxides, and carboxylic acids have been observed as ozonization products from aromatic compounds.[4] Keaveney *et al.*[5] attempted to produce glyoxal from benzene in high yield and they obtained glyoxal in 73 and 52% yields based on ozone absorbed and benzene reacted, respectively. No by-products such as glyoxylic acid, oxalic acid, formic acid, and carbon monoxide were observed. The ozonization of aromatic compounds is not fully understood and much of the data so far obtained are only qualitative.

We have undertaken the study of the ozonization of several aromatic compounds and found that three major processes proceeded simultaneously, that is, normal ozonolysis, anomalous ozonolysis, and polymer formation.

Experimental

Materials. Most of the organic compounds used in this study were those of the highest grade available commercially. They were either used as received or purified when necessary. Ozone was produced in a standard ozone generator, Nippon Ozone Co., Ltd., Model O-3-2, by charging pure oxygen dried beforehand by silica gel.

Procedures. Ozonization was carried out in 100 ml vessel equipped with a condenser. It was started after thermal equilibrium at 30 °C had been reached by bubbling O_3–O_2 gas through the reaction mixture which was stirred with a magnetic stirrer. The gas was introduced at a speed of 100—120 ml/min, the rate of ozone supply being 0.12—0.20 mmol/min.

The amounts of substrate reacted and products formed were measured by gas liquid chromatography and high pressure liquid chromatography. Total amount of peroxides was determined by iodometric titration. Acids were measured by titration and identified by isotachophoretic analysis and liquid chromatography as described previously.[2] Carbon dioxide was also analyzed as previously.[6]

Total yield of carbonyl groups was measured by treating the product solution with a 2 N aqueous hydrochloric acid and by following the consumption of hydrazine spectrometrically, $\lambda_{max}=322$ nm and $\varepsilon=1.10\times10^4$ M^{-1} cm^{-1}.

Polymeric material precipitated from the solution was dissolved into methanol or acetone, dried under vacuum and analyzed. Elemental analysis was carried out at Shonan Analytical Center. Total carbonyl content in the polymer was determined as described above. Double bonds were determined by the Hanus' method.[7] The molecular weight distribution was measured at 40 °C by gel permeation chromatography,[2] Shimadzu-DuPont Model 830. Infrared, ^1H NMR, and ^{13}C NMR spectra were recorded on JASCO spectrometer Model IR-G, Varian EM 360A, and Hitachi NMR Model R-40 respectively.

Thermal decomposition of polymer was performed by dissolving 30 mg dried polymer into 2 ml acetic acid and heating at 150 °C for 2 h in a sealed ampoule under vacuum. The evolved gas was collected by Toepler pump and analyzed by gas chromatography. The solution was analyzed by gas liquid chromatography and gel permeation chromatography.

Results

Table 1 shows the results of ozonization of several aromatic compounds in carbon tetrachloride, a non-participating solvent that does not intreact with carbonyl oxide intermediate. The results in Table 1 show that the reactivities increase in the order of benzene<toluene<1,3,5-trimethylbenzene<hexamethylbenzene in agreement with the previous reports,[4,8–11] suggesting that the attack of ozone to aromatic ring is electrophilic in nature. Since, as shown later, the oxidation of benzylic hydrogens is not important, these reactivities can be taken as those of aromatic ring toward ozone. Runs 4 and 5 show that the rate of ozonization is determined not by concentration of substrate but by ozone dosage. As observed previously,[6] phenols were quite reactive toward ozone and gave similar products as aromatic hydrocarbons.

Runs 1, 2, and 3 show that the ozonization of benzene in carbon tetrachloride gave formic acid as a

major product with minor amounts of peroxide and glyoxal. The peroxide must be mostly ozonide, 1,2,4-trioxolane. Glyoxal is further oxidized to glyoxylic acid, but no oxalic acid was found under the present reaction conditions. One of the interesting features of this reaction is the formation of polymeric products. As the ozonization proceeded, white gummy material precipitated from the reaction mixture. The polymer will be discussed in some more detail later in this text.

Similar results were observed with toluene, 1,3,5-trimethylbenzene, hexamethylbenzene, and phenols. Carboxylic acids were obtained as major products, formic and acetic acids from both toluene and 1,3,5-trimethylbenzene, and acetic acid from hexamethylbenzene. Run 4 shows that 34 and 58% of aromatic carbons of toluene yielded formic and acetic acids respectively. Selectivities for formic and acetic acids from 1,3,5-trimethylbenzene based on reacted aromatic carbons are 23 and 42% respectively, and no 2,4,6-trimethylphenol was observed. The higher yields of acetic acid than formic acid from toluene and 1,3,5-trimethylbenzene may partly because of higher reactivity of formic acid toward ozone than acetic acid.[6] Hexamethylbenzene gave carboxylic acid in lower yield than benzene, toluene, and 1,3,5-trimethylbenzene. Interestingly, malonic acid was formed from *p*-benzylphenol roughly as much as formic acid.

The carbonyl compounds formed by the normal ozonolysis are glyoxal, methylglyoxal, and 2,3-butanedione from benzene, 1,3,5-trimethylbenzene, and hexamethylbenzene respectively. 2,3-Butanedione analyzed by gas liquid chromatography was smaller than that estimated from the disappearance of 2,4-dinitrophenylhydrazine (Runs 7 and 8 in Table 1). It is not clear at present if this discrepancy is due to experimental uncertainty or due to the formation of other carbonyl products. It may be noteworthy, however, that the amounts of 2,3-butanedione estimated from 2,4-dinitrophenylhydrazone formed were in good agreement with those analyzed from the disappearance of 2,4-dinitrophenylhydrazine.

Peroxides are one of the important products but their structure is not clear. Most of peroxides could be reduced by triphenylphosphine and dimethyl sulfide.

Quite a small amount of benzaldehyde was observed in the ozonization of toluene. However, little benzyl alcohol was observed even after the treatment with triphenylphosphine, suggesting that little benzyl hydroperoxide was present. Therefore, it may be concluded that oxidation of benzylic hydrogens is not important under the present reaction conditions. Furthermore, hexamethylbenzene was once oxidized in the presence of 2,6-di-*t*-butyl-4-methylphenol, a typical radical scavenger, and no decrease in rate of ozonization of hexamethylbenzene was observed. This suggests that oxidations by free radicals do not play an important role in this ozonization.[12]

It has been reported[10,11,13] that ozonization intermediates oxidize carboxylic acids to corresponding peroxy acids, but no direct evidence for the formation of peroxy acids could be found.

One of the interesting features of the ozonization of aromatic compounds in carbon tetrachloride is the formation of polymeric materials. As mentioned above, white gummy material precipitated as the ozonization proceeded. The ozonization of hexamethyl-

benzene did not give a precipitate, but the presence of polymeric materials was found by gel permeation chromatography. The precipitated polymer was insoluble in carbon tetrachloride and benzene, but partly soluble in chloroform and very soluble in methanol, acetone, tetrahydrofuran, and acetic acid.

The example of gel permeation chromatogram is shown in Fig. 1. The molecular weight of the precipitated polymer ranges from 200 to 4000, while the product solution contained compounds with a molecular weight of a few hundreds. Some data on the polymers are also included in Table 1. The polymer was pale-yellowish white and very deliquescent. In Runs 2 and 3, 95 and 333 mg of polymers precipitated respectively. The ratio of polymer to formic acid on carbon base in these experiments is 1/1.35 and 1/1.44 respectively, suggesting that the polymers are one of the important major products. The analyses of the polymer obtained in Run 3 are summarized in Table 2. It shows that it contains quite a high ratio of oxygen and that 17 and 28% of oxygen incorporated were found as carboxylic and carbonyl oxygen. The hydroperoxidic oxygen was very small. The remaining 55% of oxygen must be peroxidic and/or ether oxygen. No double bond was observed. The ^1H NMR analysis showed the absence of aromatic and methyl hydrogens. The infrared spectrum also showed the absence of aromatic hydrogen but it showed strong absorption at 3250 and 1750 cm^{-1}, which are ascribed to hydrogen-bonded hydroxyl and carbonyl groups respectively. A broad absorption was also observed between 950 and 1100 cm^{-1}, which must be ascribed to peroxide and/or ether linkage in the polymer. ^{13}C NMR analysis also showed the presence of ether, ester, and carboxylic acid.

In order to examine the stability of the polymer, especially of the peroxidic bond possibly involved, thermal decomposition of the polymer was carried out at 150 °C in 2 h in acetic acid under vacuum. Carbon monoxide and carbon dioxide were found by gas analysis and two unknown volatile products were found by gas chromatography, but their formation was small. Little change was observed in the gel permeation chromatogram after thermal treatment, implying that this polymer is thermally stable. Therefore, this polymer is not a dimeric peroxide of the

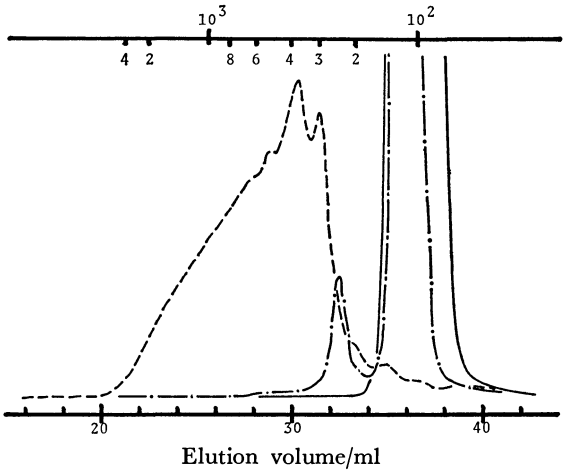

Fig. 1. Gel permeation chromatogram of ozonization products from benzene at 30 °C.
——: Initial solution, —·—: product solution, ----: precipitate.

carbonyl oxides.

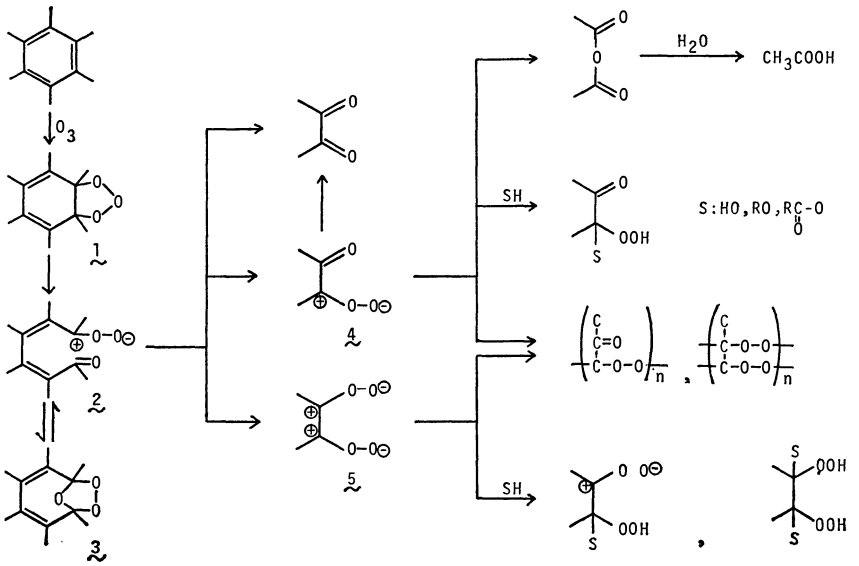
It should be noted on the safe handling of the polymeric material. We usually dissolved the precipitate in methanol or acetone and then the solvent was removed and dried under vacuum to obtain a stable polymeric solid. However, once the precipitate was taken out of the reaction mixture and dried directly at room temperature under vacuum, which brought about an explosion. At any time, this polymeric material should be handled with all precautions.

Discussion

As shown above, three processes proceeded competitively in the ozonization of aromatic compounds; they are normal and anomalous ozonolyses and polymer formation. The normal ozonolysis gives α,β-dicarbonyls, whereas the anomalous ozonolysis gives carboxylic acids. The plausible mechanisms are briefly discussed below.

Scheme 1 summarizes the possible major steps in the ozonization of hexamethylbenzene. The primary step is an electrophilic attack of ozone to aromatic ring to yield primary ozonide **1**. Thus the reactivities of polymethylbenzenes increase as observed with increasing number of methyl groups. The primary ozonide **1** is unstable and readily decomposes to give carbonyl group and carbonyl oxide **2**.

The aliphatic double bonds are more reactive than aromatic ring toward ozone and hence **2** must react with ozone to give eventually 2,3-butanedione and carbonyl oxides **4** and **5**. In non-participating solvents, the carbonyl oxide intermediate undergoes either ozonide formation, rearrangement or dimerization and/or polymerization. The latter reactions must become more important with increasing methyl substitution of the aromatic ring due to the decreased 1,3-dipolarophilic and electrophilic character of a ketone carbonyl in comparison to that of an aldehyde carbonyl.[1] For example, Fliszar and coworkers[14] found in the ozonolysis of tetraphenylethylene that no ozonide was



Scheme 1. Major reaction pathways in the ozonization of hexamethylbenzene.

formed but 57% of diphenylcarbonyl oxide dimerized and 43% formed an peroxidic oligomer. The carbonyl oxide may react with itself, aldehyde, ketone, and also primary ozonide.[15]

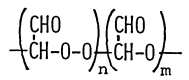
The participating solvents such as water, alcohol, and carboxylic acid react with carbonyl oxide rapidly and convert it into hydroxy, alkoxy, or acyloxy alkyl hydroperoxides.[1]

The carboxylic acids are anomalous ozonolysis products and formed by the rearrangement of carbonyl oxide or ozonide.[1,16] The detailed machamism is not discussed here, but this anomalous ozonolysis is known to occur with special ease when there are carbonyl groups attached to the double bond as in **4** and when the temperature is relatively high.[16,17]

Thus benzene and hexamethylbenzene give formic and acetic acids respectively, while toluene and 1,3,5-trimethylbenzene give mixtures of formic and acetic acids.

As mentioned already, the polymer formation is one of the characteristic points in the present study. The formation of polymer or oligomers in the ozonization of olefins has been observed in several instances from quite a long time ago[1,18] and several mechanisms have been proposed.[1,15] However, there are only a few cases which describe the polymers from aromatic compounds. Several structures have been proposed for polymeric substances[1] such as open chain polymers of carbonyl oxide with some ether linkages,[14,19,20] polyozonide,[21] and cyclic peroxide.[22] Greenwood and Rubinstein[15] concluded that the alkene ozonization polymer does not have any specific structure and that both the dipolar ion fragment and the aldehyde fragment are incorporated into the polymer in varying ratios.

Our data also show that the polymer contained a high ratio of oxygen as carboxylic, carbonyl, peroxidic, and ether oxygen. Although it is not clearly elucidated, the data in Table 2 imply that the most plausible structure of the polymer from benzene may be written as follows.



Some of the aldehyde group must be oxidized to carboxylic acid.

Keaveney *et al.*[22] surmised that glyoxal initially formed in the ozonization of benzene underwent condensation to give polymers, especially since such condensations are acid catalyzed.[23] It is difficult to estimate the importance of this process relative to that involving carbonyl oxide.

Finally, in connection with the ozonization of polystyrene,[2] the above results and discussion show that the aromatic ring of polystyrene is cleaved to give carbonyl oxide such as **6** and **7**, which react with other carbonyl oxide or carbonyl group to yield eventually crosslinked polymer.

Facile Intramolecular Cyclization Reactions of Aromatic Ethers with Cationoids in Triptycene Systems

Giichi Izumi, Shiro Hatakeyama, Nobuo Nakamura, and Michinori Ōki*

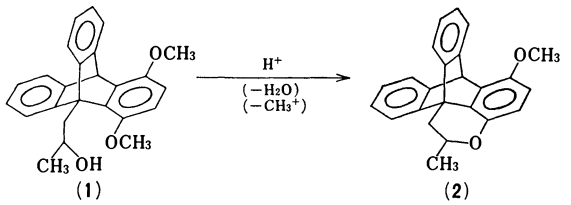
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 28, 1980)

1,4-Dimethoxytriptycenes were found to give cyclic ethers with unusual ease when a substituent at the bridgehead bears a cationoid center. The easy reaction is attributed to the extreme proximity between the methoxyl group and the cationic center. Mechanisms involving a cyclic oxonium ion and subsequent attack by an anion to produce the cyclic ether and a methyl derivative are discussed.

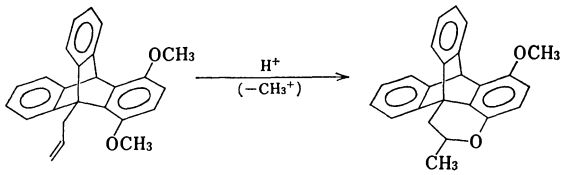
During the course of other study we have encountered a surprisingly facile ring formation of 1,4-dimethoxytriptycenes if a cationoid center is produced in the 2-position of a 9-substituent. This paper reports such findings and discusses the probable mechanisms of the reaction.

When oxidation of 9-(2-hydroxypropyl)-1,4-dimethoxytriptycene (**1**) was attempted with chromium(VI) oxide in the presence of sulfuric acid, a cyclic ether (**2**) was formed instead of the corresponding carbonyl compound. Expecting that the reaction was caused by the action of an acid which formed a cationoid center, we treated **1** with sulfuric acid and obtained **2** as expected.



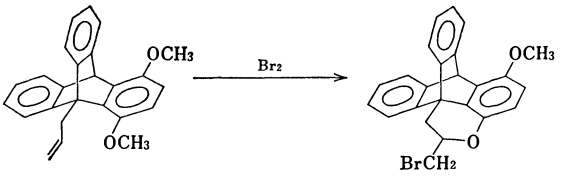
(1) (2)

The reaction is then regarded to proceed *via* an oxonium salt which is formed from the cationoid and the proximate methoxyl group in 1-position. The reaction occurs probably *via* both S_N1 and S_N2 mechanisms, because secondary alcohols undergo other substitution reactions in those fashions[1] and an electron-accepting group in the substituent at the bridgehead should interact strongly with the methoxyl group in the peri-position.[2] If the consideration is valid, 9-allyl-1,4-dimethoxytriptycene (**3**) should give the same product (**2**), when treated with an acid, since addition of a proton to the allyl moiety should produce a cationoid in the 2-position of the 9-substituent. In fact, treating **3** with trifluoroacetic acid gave **2**.



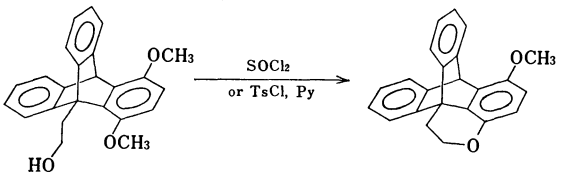
(3) (2)

Being encouraged by the extension, we then proceeded to cationoids which may be developed by a variety of methods. A variety of electrophilic additions to olefins are known to proceed *via* cationoids. We have taken addition of bromine to an olefin as an example.[3] 9-Allyl-1,4-dimethoxytriptycene (**3**) was treated with bromine and was found to give a cyclic ether (**4**).



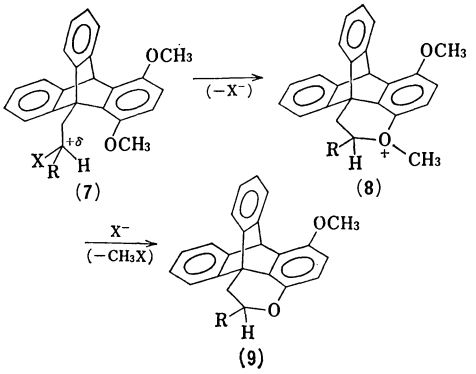
(3) (4)

The facile cyclization is not confined to the propyl derivatives carrying a cationoid in the 2-position. Treating 9-(2-hydroxyethyl)-1,4-dimethoxytriptycene (**5**) with thionyl chloride gave a cyclic ether (**6**). Since the reaction between alcohols and thionyl chloride is known to proceed *via* contact ion pairs,[4] the result was not a great surprise. To our surprise, however, a less cationic species, *p*-toluenesulfonate, cyclized as well: when **5** was treated with *p*-toluenesulfonyl chloride and pyridine at room temperature, the product was **6**. Thus weakly cationic species like sulfonates can react to form cyclic ethers.



(5) (6)

In order to discuss the mechanism of the reaction, the fate of the methyl group which had been in the methoxyl group must be explored. We ran the reaction of **5** with an excess of thionyl chloride in chloroform-*d* in a sealed tube, expecting that the product from the methyl group must be methyl chloride. The ^1H NMR spectrum of the reaction mixture clearly showed the presence of a sharp signal at δ 3.00 which is ascribable to methyl chloride. The formation of methyl chloride was further confirmed by addition of methanol to the mixture and observing the increase in the intensity of the signal at δ 3.00.



(7) (8) (9)

The mechanism of the reaction may be described now as follows. In the first step a cationoid species (**7**) is formed in the 2-position of the 9-substituent by an electrophilic addition to the olefin or by enhancing the leaving group ability of the substituent. In the second step it cyclizes to an oxonium ion (**8**) which is then attacked by an anion at the least hindered methyl to give the cyclic ether (**9**) and a substituted methane.

The reason for the facile cyclization must be proximate arrangement of the two groups. In other triptycene systems, the substituent in the 9-position and the peri-substituent are known to be well in the sum of the van der Waals radii[5,6] and some very weak interactions were detected.[2,7,8] Therefore, as soon as the cationic species is formed, it interacts very strongly with the methoxyl group in the peri-position, leading to the cyclic oxonium ion (**8**). This postulate is substantiated by the following facts. Although neighboring participation of oxygen[9] in bromination reactions is known to be stronger than that of bromine,[10] the yield of a cyclic ether is only 50—60% when 4-penten-1-ol is treated with bromine and, if it is a 6-membered ring, the yield of a cyclization product drops to 5—10%.[9] Since the cyclic ether formed here is 6-membered, the participation of the oxygen is unusually strong relative to the open-chain compounds, although the entropy factor may contribute to some extent.

The ^{13}C NMR spectrum of 9-allyl-1,4-dimethoxytriptycene (**3**) revealed that there were two detectable conformers at a low temperature. Since it will not be possible to observe conformers about the C_{sp^3}–C_{sp^2} bond in the allyl group, it is natural to assume that the conformers are those involving the restricted rotation about the C_9–C_{allyl} bond: the number of carbon atoms detected by the ^{13}C NMR conforms with this assignment. The competitive bromination of **3** with 9-allyltriptycene (**10**) revealed that a negligible amount of **10** reacted, while the color of bromine faded fast to give **4** as a sole product. This high reactivity of **3** cannot be explained if it reacts in the *ap* conformation because its steric environment is the same as **10** and no strong electronic effect is expected, if any. Rather it will be explained by the neighboring participation of the methoxyl group which facilitates the electrophilic attack.

We conclude that the unusually high reactivity of the methoxyl group toward cationoids is caused by the highly congested state in the triptycene system. The results suggest that the triptycene is a good system to find weak interactions which otherwise are not detectable.

Experimental

*9-Allyl-1,4-dimethoxytriptycene (**3**).* A solution of 2.2 g (0.01 mol) of 9-allylanthracene[11] and 1.1 g (0.01 mol) of *p*-benzoquinone in 10 mL of toluene was refluxed for 1 h. The reaction mixture was cooled. The resulting crystals were collected and washed with ether. The crystals in 20 mL of dioxane were treated with 1.0 g of sodium hydroxide in 10 mL of water and then with dimethyl sulfate under a nitrogen atmosphere. The process was repeated 2—3 times until coloration due to the enolate was not observable on addition of the alkali. The resulting mixture was poured into 500 mL of water. The precipitate was collected, dried, and recrystallized from hexane, mp 235—236 °C. The yield was 80%. Found: C, 84.50; H, 6.06%. Calcd for $C_{25}H_{22}O_2$: C, 84.92; H, 6.24%. ^1H NMR ($CDCl_3$, δ): 3.68 (3H, s), 3.78 (3H, s), 3.9—4.3 (2H, m), 5.0—5.7 (2H, m), 5.88 (1H, s), 5.9—6.4 (1H, m), 6.50 (2H, s), 6.8—7.7 (8H, m). ^{13}C NMR ($CDCl_3$, ppm from TMS): 32.9, 46.0, 54.3, 56.7, 57.1, 109.0, 109.7, 113.7, 122.6, 123.5, 123.8, 133.6, 136.6, 138.1, 145.2, 145.5, 147.2, 148.9.

The signals at 32.9 and 54.3 ppm and many at lower fields split into two peaks in a ^{13}C NMR spectrum at −32 °C. From these, the population ratio was calculated as 0.7. Altough it is not possible to tell which isomer is favored in the equilibrium, the ^1H NMR data suggest that the *ap* isomer is favored: the signal at δ 6.50 splits into two peaks at low temperatures and, if the peak at a higher field corresponds to the $\pm sc$ form as were other compounds of this series,[2] then the ratio $\pm sc/ap$ is 0.7.

*2-Methyl-6-methoxy-7,11b-o-benzeno-7,11b-dihydronaphtho[1,2,-3-de]chroman (**2**).* *a)*: To a solution of 420 mg of 9-(2-hydroxypropyl)-1,4-dimethoxytriptycene, which had been prepared by the Grignard reaction of the corresponding aldehyde,[8] in 20 mL of acetone was added sulfuric acid (0.1 mL H_2SO_4 and 0.2 mL H_2O) and the mixture was stirred at 0 °C for 1 h. The solvent was removed *in vacuo* and the residue was washed with dilute alkali after addition of 30 mL of dichloromethane. The organic layer was evaporated after drying. The product was identical with the substance produced by the action of hydrochloric acid on an adduct from 9-allylanthracene and *p*-benzoquinone followed by methylation (see below).

b): A solution of 1.5 g of an adduct from 9-allylanthracene and *p*-benzoquinone in 50 mL of acetic acid was mixed with 10 mL of cencentrated hydrochloric acid and stirred for 24 h at room temperature. The mixture was poured into 1 L of water and the solid was collected. The solid was treated with aqueous sodium hydroxide and dimethyl sulfate under a nitrogen atmosphere, as was for the preparation of **3**. The product was recrystallized from benzene–hexane, mp 230.3—230.8 °C. Yield 82%. Found: C, 84.57; H, 5.95%. Calcd for $C_{24}H_{20}O_2$: C, 84.68; H, 5.92%. ^1H NMR ($CDCl_3$, δ): 1.65 (3H, d), 3.04 (2H, poorly resolved quartet), 3.73 (3H, s), *ca.* 4.3 (1H, m), 5.85 (1H, s), 6.50 (2H, s) 6.9—7.6 (8H, m).

c): To a solution of 20 mg of 9-allyl-1,4-dimethoxytriptycene (**3**) in 1.5 mL of $CDCl_3$ was added a few drops of trifluoroacetic acid. After standing overnight, the mixture was treated with 10% aqueous sodium hydrogencarbonate. The solvent was evaporated from the organic layer and the product was separated by TLC. The main product was identical with the compound described above.

A ^1H NMR spectrum of the mixture showed broadening of the signal due to dialkoxybenzo protons at δ 6.50, indicating rapid exchange between the aromatic protons and that of trifluoroacetic acid. Thus trifluoroacetic acid-*d* was used to see the exchange: the aromatic proton signal vanished during the reaction. After treatment with aqueous sodium hydrogencarbonate, the ^1H NMR spectrum of the product showed the presence of a deuterium in the methyl in 2-position (broad doublet at δ 1.64 in $CDCl_3$) and the signal due to the dialkoxybenzo protons had an intensity corresponding to one proton only. The position of the deuterium in the diakoxybenzo moiety is not known.

*6-Methoxy-7,11b-o-benzeno-7,11b-dihydronaphtho[1,2,3-de]chroman (**6**).* *a)*: A solution of 0.30 g (8.0 mmol) of

9-(2-hydroxyethyl)-1,4-dimethoxytriptycene (**5**)[2] in 30 mL of dichloromethane was stirred for 30 min with 0.3 mL (40 mmol) of thionyl chloride and then heated under reflux for 30 min. The mixture was treated with aqueous sodium hydroxide and the organic layer was evaporated. Chromatography followed by recrystallization, from benzene-hexane, of the product afforded a pure sample, mp 289.5—290.5 °C, in 95% yield. Found: C, 84.90; H, 5.37%. Calcd for $C_{23}H_{18}O_2$: C, 84.64; H, 5.56%. ^{1}H NMR ($CDCl_3$, δ): 3.15—3.40 (2H, m), 3.78 (3H, s), 4.20—4.50 (2H, m), 5.83 (1H, s), 6.50 (2H, s), 6.9—7.7 (8H, m).

b): A solution of 0.20 g (5.6 mmol) of the alcohol (**5**) in 10 mL of pyridine was mixed with 0.20 g (15 mmol) of *p*-toluenesulfonyl chloride and stirred for 24 h at room temperature. The mixture was mixed with 30 mL of dichloromethane and shaken with dilute hydrochloric acid. The product was identical with the above cyclic ether and was obtained in 92% yield after resrystallization from benzene-hexane. If the reaction was stopped at an incomplete stage, a mixture of **6** and the starting material (**5**) was obtained. The results indicate that the cyclization did not take place by the treatment of the alcohol with hydrochloric acid but it was the sulfonate ester which gave **6**.

*2-Bromomethyl-6-methoxy-7,11b-o-benzeno-7,11b-dihydronaphtho-[1,2,3-de]chroman (**4**).* To a solution of 35.4 mg (0.1 mmol) of **3** in 10 mL of chloroform was slowly added a solution of 15 mg (0.096 mmol) of bromine in 20 mL of chloroform at 0 °C. The reaction proceeded instantaneously as fading of the color indicated. After 1 h, the solvent was evaporated and the residue was purified by chromatography on silica gel, using hexane as an eluent. The product was recrystallized from hexane, mp 195—196 °C. The purity was checked by a ^{1}H NMR spectrum and the molecular constitution by high resolution mass spectroscopy. Found: M^+ 418.0545 and 420.0512. $C_{24}H_{19}O_2Br$ requires M^+ 418.05698 for ^{79}Br and 420.05501 for ^{81}Br. The relative intensities of the peaks were in good agreement with those calculated from the natural abundance of the isotopes. ^{1}H NMR ($CDCl_3$, δ): 2.7—3.6 (2H, m), 3.81 (2H, d), 3.79 (3H, s), 5.84 (1H, s), 6.51 (2H, s), 6.9—7.6 (8H. m).

Competitive Bromination of 9-Allyltriptycene and 9-Allyl-1,4-dimethoxytriptlycene. A solution of 15.5 mg (53 μmol) of 9-allyltriptycene and 18.8 mg (53 μmol) of **3** in 10 mL of chloroform containing 10.7 mg of hexachlorobenzene was treated with 8.4 mg (53 μmol) of bromine in chloroform as above. The disappearance of the starting material was checked by taking the internal standard (C_6Cl_6) in the high pressure liquid chromatography. The decrease in the amount of 9-allyltriptycene could not be detected, whereas **3** reacted completely as far as the detecting device could tell.

We whish to acknowledge the receipt of a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture which supported this work.

1,3-Dipolar Cycloaddition Reaction of Vinyl Azides with Enamines. Synthesis of Vinyltriazolines and Vinyltriazoles

Yujiro NOMURA,* Yoshito TAKEUCHI, Shuji TOMODA, and Masato M. ITO

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

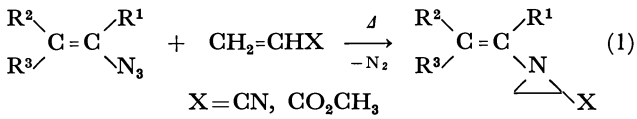
(Received July 3, 1980)

Reaction of α- and β-azidostyrene with enamines gave vinyltriazolines regioselectively in moderate yields. 1-Pyrrolidinyl enamines reacted with α-azidostyrene more readily than piperidino or morpholino enamines. β-Azidostyrene was as reactive as azidobenzene while α-azidostyrene was much less reactive. Vinyltriazolines formed from enamines of ketones were deaminated to yield the corresponding vinyltriazoles.

Although considerable amount of studies on vinyl azides has been cumulated[1] since Hassner and Fowler developed the general synthetic method for vinyl azides in 1968,[2] only few examples have hitherto been reported with regard to their reaction as 1,3-dipole: one with methyl propiolate or dimethyl acetylenedicarboxylate (DMAD)[3] and the other with 2-oxoalkylidenetriphenylphosphoranes.[4]

Extensive studies have been cumulated on 1,3-dipolar cycloaddition reaction of aryl azides.[5-10] Sustman and Trill have reported the correlation of the rate of cycloaddition reaction between azidobenzene and various dipolarophiles with the first ionization potentials (IP) of dipolarophiles, rationalizing the dual property of azides,[9] which are known to react readily with both electron-deficient dipolarophiles, such as DMAD, and electron-rich dipolarophiles, such as enamines. Munk and co-workers have examined the reaction of substituted azidobenzenes and enamines and demonstrated the electrophilic character of the azido group towards enamines.[10]

Previously we reported the thermal reaction of vinyl azides with electron-deficient olefins to give vinylaziridines with evolution of nitrogen (Eq. 1),[11] but



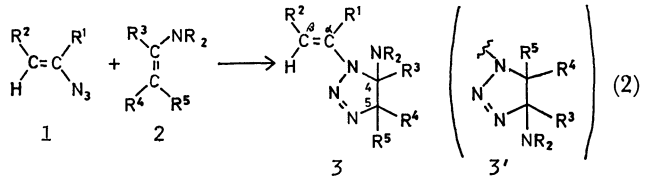
(1)

1,3-dipolar adduct of azide was not isolated. In the course of our further study concerning the 1,3-dipolar reaction of vinyl azides, we have examined the reaction with electron rich olefins, and here we wish to report their reaction with enamines.

Results and Discussion

Reaction of Azidostyrenes with Enamines. Azidostyrenes (**1**) and enamines (**2**) were caused to react at 0 °C without solvent until **1** was completely consumed. The results are summarized in Table 1.

The only product isolated proved to be a 1:1 adduct of azidostyrene and enamine. The structure of the adduct was determined from the spectroscopic inspection. In the case of Entry 4, for example, the two singlet signals at δ 4.85 and 5.36, together with the signals at δ 7.1—7.5, in ^{1}H NMR indicated the existence of 1-phenylvinyl group, the multiplet signals at δ 1.5—1.8 and 2.2—2.6 corresponded to 1-pyrrolidinyl group, and other signals (see experimental) demonstrated the existence of $CH_3\overset{|}{C}H\overset{|}{C}H$-moiety.



(2)

1a: R^1 = Ph, R^2 = H
1b: R^1 = H, R^2 = Ph

	R^3	R^4	R^5	NR_2
2a	$-(CH_2)_4-$		H	N⟨O⟩
2b	H	C_2H_5	H	N⟨ ⟩
2c	$-(CH_2)_4-$		H	N⟨ ⟩
2d	H	CH_3	H	N⟨ ⟩
2e	H	CH_3	CH_3	N⟨ ⟩
2f	H	C_2H_5	H	N⟨ ⟩
2g	H	C_2H_5	H	N⟨O⟩
2h	C_6H_5	H	H	N⟨O⟩

These results suggested the formation of 1,2,3-triazoline ring by the 1,3-dipolar cycloaddition between the azido group of **1a** and the carbon-carbon double bond of the enamine (**2d**). This was further supported by the ^{13}C NMR spectra of the adducts (Table 2): the two signals at δ 75.9 and 74.2 (both a doublet at off-resonance decoupling condition) corresponded to the two tertiary sp^3 carbons of the triazoline ring neighboring with the nitrogen atom.

The cycloadducts obtained are either 4-amino-Δ^1-1,2,3-triazolines (**3**) or their regioisomers, 5-amino derivatives (**3'**). The mass spectra of the triazolines **3d** and **3f** are summarized in Table 3. Molecular ions (M^+) were not detected in both cases. The peaks at *m/e* 228 and 242 corresponded to M-28 fragments (loss of nitrogen) of **3d** and **3f**, respectively. The peaks at *m/e* 199 corresponded to the further loss of C_2H_5 and C_3H_7 from **3d** and **3f**, respectively. This was rationalized from the β-cleavage of **3** (Fig. 1). The alternative structure **3'** was excluded by the existence of *m/e* 199 fragment becauce the cleavages expected from **3'** would not give this fragment.

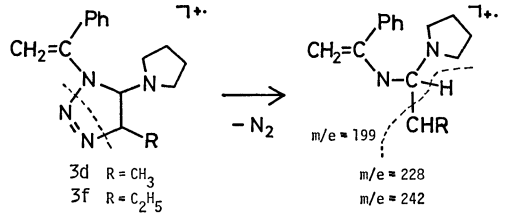


Fig. 1. β-Cleavage to give *m/e*=199 fragment.

TABLE 1. REACTION OF VINYL AZIDES WITH ENAMINES

Entry	Azide	Enamine	Molar ratio (Enamine/Azide)	Reaction time/d[a]	Products	Isolated yield/%
1	 **1a**	 **2a**	1.5	90[b]	**3a** 	40
2	**1a**	 **2b**	1.42	12	**3b** 	86
3	**1a**	 **2c**	1.06	2	**3c** 	66
4	**1a**	 **2d**	2.31	5	**3d** 	64
5	**1a**	 **2e**	1.0	1	**3e** 	95
6	**1a**	 **2f**	1.13	3	**3f** 	86
7	 **1b**	 **2g**	1.03	8[b]	**3g** 	54[d]
8	**1b**	**2a**	1.03	3	**3h** 	62
9	**1b**	 **2h**	1.02	21	**3i** 	63
10	**1b**	**2e**	1.57	2[c]	**3j** 	78

a) Reaction time until **1** was completely consumed, unless otherwise noted. b) Some of **1** still remained unchanged. c) Carried out in diethyl ether to avoid uncontrolled reaction. d) Based on consumed **1b**.

The formation of the 4-amino isomers (**3**) is reasonable since the 1,3-dipolar cycloaddition reaction of azides and enamines unexceptionally gives 4-amino-Δ^1-1,2,3-triazolines.[6-10]

The reaction time necessary for the complete consumption of azides could be a measure of relative reactivity of azides and enamines qualitatively (Table 1). The reactivity of enamines towards azides decreased in the order of 1-pyrrolidinyl>piperidino>morpholino (Entry 1—6), which was the same order

a) See Fig. 1.

as was found for the reaction of azidobenzene with enamines.[8,10] From Entries 1 and 8, it seems that β-azidostyrene (**1b**) is much more reactive than the α-isomer (**1a**); indeed, the reactivity of **1b** towards enamines is comparable with that of azidobenzene.[6]

Frontier Molecular Orbital Treatment. Generally, in the case of 1,3-dipolar cycloaddition of electron-rich olefins, the interaction between LUMO of a dipole and HOMO of a dipolarophile is important.[9,12] The lower the energy of LUMO of azide is, and the higher the energy of HOMO of enamine is, the interaction between these orbitals would be greater so that the reaction should proceed faster.

The order of reactivity of enamines towards α-azidostyrene (**1a**), as was described, corresponded to the energy of HOMO of enamines, which is lowered in the order of 1-pyrrolidinyl, piperidino, and morpholino as was estimated by photoelectron spectra (Fig. 2).

The difference in reactivity between the azides (**1a**, **b**) would be rationalized by the difference in the energies of LUMO of **1a** and **1b**. β-Azidostyrene (**1b**), of which the phenyl group is more extensively conjugated with the azido group, would have a lower energy of LUMO than α-azidostyrene (**1a**). The energies of these orbitals estimated by CNDO/2 calculation supported the above trends (Fig. 2). The lower energy of LUMO of **1b** corresponds to its higher reactivity towards enamines.

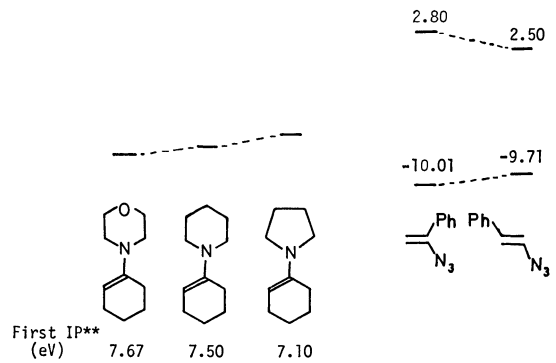

Fig. 2. Energies of frontier orbitals of azides* and enamines.
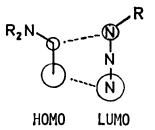
* Orbital energies (eV) of organic azides were estimated from CNDO/2 calculation.[14] ** Obtained from photoelectron spectroscopy by Domelsmith and Houk.[15]

A possible steric effect, interaction between phenyl group and the amino group in the transition state of the reaction, can also be responsible for the lower reactivity of **1a**.

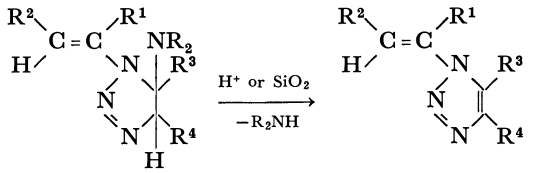
It is known that the reaction between azides and enamines is dipole-LUMO-controlled reaction, and the orientation should therefore be as shown in Table. 4,

TABLE 4. COEFFICIENTS OF LUMO OF AZIDES ESTIMATED WITH CNDO/2 CALCULATION[14]



R =	H[13]	Ph	CH_2=CH	CH_2=CPh	PhCH=CH
	0.37	0.263	0.298	0.169	0.165
	0.76	0.495	0.557	0.425	0.462

which is in fact the case.[12] We attempted the calculation of the coefficients of LUMO of various vinyl azides; it seems that the introduction of a vinyl group to the azide does not alter the relative magnitude of the coefficients of LUMO of simple azides such as hydrazoic acid. These results are consistent with the regioselective formation of the 4-aminotriazolines (**3**).



(3)

*Systhesis of Triazoles (**4**) by Deamination of the Aminotriazolines (**3**).* It is known that the 4-alkyl (or aryl)-4-amino-Δ^1-1,2,3-triazolines are easily deaminated by treatment with acid to give the corresponding 1*H*-1,2,3-triazoles.[6] When the aminotriazolines (**3a**,**c**,**h**,**i**) formed from the enamines of ketones were treated with acetic acid at room temperature or eluted through silica-gel column, deamination readily occurred, giving the corresponding triazoles (**4**) in 40—62% yields (Table 5).

Thus, a simple and useful method for the synthesis of vinyltriazoles from vinyl azides, under mild conditions, with high regioselectivity, and in moderate yields, was achieved. The vinyltriazoles like **4** were otherwise difficult to prepare. A known method with α-azidostyrene and 2-oxoalkylidinetriphenylphosphoranes requires much longer time (about a month) and affords the vinyltriazoles in no more than 54% yields.[4]

Experimental

General. Spectroscopic data were obtained with following apparatus: JEOL JNM-MH100 NMR Spectrometer, VARIAN FT-80A FT-NMR System, JEOL JNM-FX90Q FT-NMR System, JASCO DS-403G Grating Infrared Spectrophotometer, HITACHI EPS-3T Recording Spectrophotometer, and HITACHI RMU-6MG Mass Spectrometer.

α- and β-Azidostyrenes were prepared according to Hassner's method.[2] Enamines of ketones were prepared according to the method described in Organic Syntheses.[16] Enamines of aldehydes were prepared according to Mannich's method.[17]

Melting points were determined with microscopic apparatus and uncorrected.

Reaction of Azidostyrenes with Enamines. The azide (**1**) and the enamine (**2**) were mixed and allowed to stand at 0 °C without solvent until the azide was completely consumed, unless otherwise described. The products were purified with alumina column chromatography (eluting with hexane–dichloromethane (1:1)) and/or with recrystallization from an appropriate solvent.[18]

*3a,4,5,6,7,7a-Hexahydro-7a-morpholino-1-(1-phenylvinyl)-1H-1,2,3-benzotriazole (**3a**)*: The mixture of 4.4 g (30 mmol) of α-azidostyrene (**1a**) and 7.5 g (45 mmol) of 4-(1-cyclohexenyl)morpholine (**2a**) was allowed to stand at 0 °C for 90 d. Hexane (10 ml) was added and the precipitates formed were collected and recrystallized from ethanol to give 3.4 g of **3a** as colorless crystals (40% yield); mp 110—111.5 °C (dec); IR (KBr) 1615 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ 1.1—2.3 (8H, m), 2.43 (4H, m), 4.61 (1H, t, J=5.5 Hz), 4.72 (1H, s), 5.58 (1H, s), and 7.44 (5H, m); UV_{max} (methanol) 246 nm (ε 7700). Found: C, 69.19; H, 8.01; N, 18.13%. Calcd for $C_{18}H_{24}N_4O$: C, 69.20; H, 7.74; N, 17.93%.

*5-Ethyl-3-(1-phenylvinyl)-4-piperidino-Δ^1-1,2,3-triazoline (**3b**)*: The mixture of 2.0 g (14 mmol) of **1a** and 2.8 g (20 mmol) of 1-(1-butenyl)piperidine (**2b**) was allowed to stand at 0 °C for 12 d. Then the mixture was eluted through alumina column to give 3.9 g of **3b** as faint yellow oil (86% yield): IR (neat) 1615 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ 1.06 (3H, t, J=7 Hz), 1.4—1.6 (6H, m), 1.7 (2H, q, J=7 Hz), 2.2—2.6 (4H, m), 4.2—4.4 (2H, m), 4.86 (1H, s), 5.42 (1H, s), and 7.5 (5H, m); UV_{max} (methanol) 240 nm (ε 13000).

*3a,4,5,6,7,7a-Hexahydro-1-(1-phenylvinyl)-7a-(1-pyrrolidinyl)-1H-1,2,3-benzotriazole (**3c**)*: The mixture of 1.0 g (6.9 mmol) of **1a** and 1.1 g (7.3 mmol) of 1-(1-cyclohexenyl)-pyrrolidine (**2c**) was allowed to stand at 0 °C for 2 d. Then the product was eluted through alumina column to give 1.35 g of **3c** as yellowish viscous oil (66% yield): IR (neat)

Dealkylation Reaction of Acetals, Phosphonate, and Phosphate Esters with Chlorotrimethylsilane/Metal Halide Reagent in Acetonitrile, and Its Application to the Synthesis of Phosphonic Acids and Vinyl Phosphates[1)]

Tsuyoshi MORITA,* Yoshiki OKAMOTO, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received July 4, 1980)

A mild and efficient method has been developed for carbon-oxygen bond cleavage using chlorotrimethylsilane/sodium iodide in acetonitrile. It was applied to synthetic transformation under nonaqueous and neutral conditions, such as acetal deprotection and the synthesis of phosphonic acids from the corresponding dialkyl phosphonates *via* methanolysis of their silyl esters. Effectiveness of various kinds of metal or ammonium iodides for this type of dealkylation was examined in the acetonitrile solution by ^{1}H NMR. Satisfactory results were also obtained with lithium or potassium iodide in place of sodium iodide. However, copper(I) or quarternary ammonium iodide was ineffective. Chlorotrimethylsilane/lithium bromide in acetonitrile is effective for selective dealkylation of multifunctional phosphonic esters or dialkyl vinyl phosphates.

Organosilicon compounds have been extensively developed and applied to organic synthesis as reagents, reactive intermediates, and protective groups.[2)] Attention was drawn to a new and efficient method for carbon-oxygen bond cleavage using organosilicon compounds under nonaqueous and neutral conditions, bromotrimethylsilane and iodotrimethylsilane in particular being versatile reagents for synthetic transformation of many functional groups. The chemistry of iodotrimethylsilane has been developed by Olah *et al.*[3)] and Jung *et al.*[4)] with regard to the reactions of carboxylic esters, ethers, acetals, alcohols, carbamates, and sulfoxides. Mckenna *et al.* and Rudinskas *et al.* reported the usefulness of bromotrimethylsilane for the conversion of dialkyl phosphonates into the silyl esters,[5)] sulfoxides into sulfides,[3b)] alcohols into bromides and orthoesters into the corresponding esters.[6)] However, bromotrimethylsilane is of little use for the cleavage of carboxylic esters, ethers, and acetals.

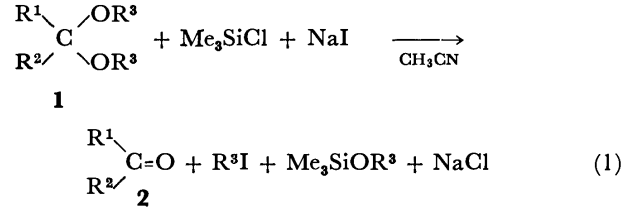
The preparation of bromotrimethylsilane[7)] or iodotrimethylsilane[8)] requires two steps *via* hexamethyldisiloxane from chlorotrimethylsilane, these fuming compounds being easily hydrolyzed in the atmospheric moisture. To overcome the disadvantages inherent in the use of iodotrimethylsilane, two improve methods have been worked out for the preparation of the reagent *in situ* using phenyltrimethylsilane/iodine[9)] or allyltrimethylsilane/iodine[10)] in the presence of carboxylic esters or ethers. The high reactivity of these reagents can be rationalized by the hard and soft acids and base principle,[11)] since they contain both hard acid and soft bases in their molecules. Chlorotrimethylsilane itself is essentially ineffective,[12)] although it is the most easily available reagent and frequently employed as a starting material for many reactive organosilicon compounds in organic synthesis.

In the course of studies on synthesis and biological properties of various phosphonic acids, we have sought a new and mild method for carbon-oxygen bond cleavage in the phosphonic esters with use of the most inexpensive chlorotrimethylsilane itself. In a preliminary communication, we demonstrated that chlorotrimethylsilane/sodium iodide in acetonitrile is an extremely effective reagent for dealkylation of esters, ethers *etc.*[13,14)] Olah *et al.* independently reported a similar use of the reagent in the same reactions.[15)]

In order to avoid an overlap of results, this paper describes the scope and limitation of dealkylation of dialkyl phosphonates and acetals with chlorotrimethylsilane/sodium iodide and the effectiveness of various iodides for this type of reaction. A novel reaction of chlorotrimethylsilane/lithium bromide as a selective dealkylating agent of phsophonic esters having other labile functional groups, and dialkyl vinyl phosphates is also described.

Results and Discussion

Dealkylation of Acetal with Chlorotrimethylsilane/Sodium Iodide. Dealkylation of acetals (**1**) with chlorotrimethylsilane/sodium iodide in acetonitrile was performed under mild and nonaqueous conditions. In most cases, the reaction was virtually complete at 45 °C within 0.5—2.5 h, affording the parent carbonyl compounds (**2**) in one step quantitatively (Eq. 1). The results are summarized in Table 1.



$$\underset{\mathbf{1}}{R^1R^2C(OR^3)_2} + Me_3SiCl + NaI \xrightarrow[CH_3CN]{} \underset{\mathbf{2}}{R^1R^2C{=}O} + R^3I + Me_3SiOR^3 + NaCl \qquad (1)$$

The present method is applicable to both dimethyl and diethyl acetals. However, the case of the ethylene acetal (**1c**) results in relatively poor yield, a similar result being reported on ethylene acetal cleavage with iodotrimethylsilane by Jung *et al.*[4c)] It was found that the acetal cleavage is significantly influenced by the ratio of the reagent to the substrate used. For example, treatment of benzaldehyde dimethyl acetal (**1a**) with 1.5 equiv. of chlorotrimethylsilane/sodium iodide gave a mixture of the acetal (**1a**) and benzaldehyde (**2a**) (14:86) at 45 °C for 0.5 h, in spite of the complete disappearance of the chlorotrimethylsilane signal. The complete conversion of **1a** into **2a** could be achieved by using 2.0 equiv. of the reagent at 45 °C for 0.5 h, the formation ratio of methyl iodide:

Table 1. Acetal dealkylation with chlorotrimethylsilane/sodium iodide

Compound	R^1	R^2	R^3	Temp °C	Time h	Yield[a] of **2** %
1a	Ph	H	Me	45	0.5	88
1b	Ph	H	Et	45	1.5	85
1c	Ph	H	$-CH_2-$	45	2.5	30
1d	$Me(CH_2)_5$	H	Me	45	0.5	91
1e	*p*-$MeOC_6H_4$	H	Me	45	2.5	95
1f	$-(CH_2)_5-$		Me	45	0.5	84
1g	Ph	Me	Me	45	0.5	82

a) Isolated yield. The products were characterized by comparison with authentic samples.

methyl trimethylsilyl ether being 6:1. The results indicate that further dealkylation of the initially formed methyl trimethylsilyl ether occurs competitively.

$$Me_3SiOMe + Me_3SiCl + NaI \xrightarrow[CH_3CN]{} MeI + (Me_3Si)_2O + NaCl \quad (2)$$

A report was given on the useful application of chlorotrimethylsilane/sodium iodide to the conversion of alcohols into iodides *via* their trimethylsilyl ethers.[16]

Effect of Other Iodide. In order to elucidate the effectiveness of various iodides for the dealkylating method using chlorotrimethylsilane, the effect of the salts on the yield was examined, **1a** being selected as a typical substrate and acetonitrile as solvent. The results are summarized in Table 2.

$$\underset{\textbf{1a}}{PhCH(OMe)_2} + Me_3SiCl + MI \xrightarrow[CH_3CN]{} \underset{\textbf{2a}}{PhCHO} + MeI + Me_3SiOMe + MCl \quad (3)$$

We see that the reaction yield is greatly influenced by the kind of salt used, lithium, sodium, and potassium iodide being very effective and giving an excellent yield of **2a** at 45 °C for 0.5 h. However, other salts such as copper(I) or quarternary ammonium iodides are unsatisfactory, the yields of **2a** being invariably lower than 40%, even for the prolonged reaction. This can be explained by the difference in solubility of the chloride (MCl) produced as a by-product in acetonitrile. With the progress of reaction, lithium, sodium, and potassium chloride immediately precipitate, but the ammonium chlorides are highly soluble in the solvent. For the sake of confirmation, we carried out a control experiment in which acetonitrile-soluble phenyltrimethylammonium chloride was added to the acetonitrile solution of chlorotrimethylsilane/phenyltrimethylammonium iodide (entry 9, Table 2). The chloride added prevented the formation of **2a**.[17] The effect of various solvents (carbon tetrachloride, chloroform, or *N,N*-dimethylformamide) on acetal dealkylation using chlorotrimethylsilane/sodium iodide was also examined. Acetonitrile was found to be the most suitable, the reaction in other solvents being slightly slower than that in acetonitrile.

Table 2. Acetal dealkylation with chlorotrimethylsilane in the presence of various iodide salts

Entry	MI	Temp °C	Time h	Yield[a] of **2a** %
1	LiI	45	0.5	100

5	Me_4NI	45	3.0	11
6	Bu_4NI	45	3.0	36
7	$PhNMe_3I$	45	3.0	33
8	$PhNMe_3I$	45	5.0	38
9	$PhNMe_3I$[b]	45	3.0	6

a) Determined by ^1H NMR. b) Control experiment: **1a** (7 mmol), Me_3SiCl (14 mmol), $PhNMe_3I$ (14 mmol), and $PhNMe_3Cl$ (7 mmol) in CH_3CN (5 ml).

Dealkylation of Phosphonic Esters with Chlorotrimethylsilane/Sodium or Potassium Iodide. Phosphonic acids were prepared from the corresponding dialkyl esters by acid-catalyzed hydrolytic dealkylation, by refluxing them with 6 mol dm^{-3} hydrochloric acid for several hours. Many multifunctional phosphonic esters are frequently subjected to undesirable reactions under these acidic conditions.[18]

The exothermic reaction of dimethyl phosphonates (**3**) with chlorotrimethylsilane/sodium iodide occurred rapidly at room temperature to give the corresponding bis(trimethylsilyl) phosphonates (**4**) and methyl iodide quantitatively.[19] The dealkylation monitored by ^1H NMR spectroscopy proceeded to completion within 15 min. The rate of dealkylation of dialkyl phosphonates with the reagent decreases according to the bulkiness of the alkyl group in the order: R^2=Me> Et>*i*-Pr.[20] Treatment of the silyl esters (**4**) with methanol at room temperature gave the corresponding

$$\underset{\textbf{3}}{R^1P(O)(OR^2)_2} + 2\,Me_3SiCl + 2\,NaI \xrightarrow[CH_3CN]{} R^1P(O)(OSiMe_3)_2 + 2\,R^2I + 2\,NaCl \xrightarrow[MeOH]{\textbf{4}} \underset{\textbf{5}}{R^1P(O)(OH)_2} \quad (4)$$

$$\underset{\mathbf{3}}{R^1P(OR^2)_2} + 2\,Me_3SiCl + 2\,LiBr \xrightarrow[CH_3CN]{} \underset{\mathbf{4}}{R^1P(OSiMe_3)_2} + 2\,R^2Br + 2\,LiCl \quad (7)$$

The results for several phosphonates are given in Table 4.

Other salts such as KBr, $MgBr_2$, NEt_4Br, and $PhNMe_3Br$ are ineffective. The rate of dealkylation by the present method is slightly smaller than that with bromotrimethylsilane. The dealkylation of phosphonic ester moiety with chlorotrimethylsilane/lithium bromide proceeds with higher functional group selectivity than that with chlorotrimethylsilane/sodium iodide, indicating no cleavage of other functional groups even when a large excess of the reagent is used. Benzyl acetate hardly reacted at all with this reagent at 75 °C for 9 h.

Dealkylation of Dialkyl Vinyl Phosphate with Chlorotrimethylsilane/Lithium Bromide. From our studies on dealkylation of phosphonic and phosphoric ester using bromotrimethylsilane, we find that no C=COP bond cleavage occurs in dialkyl vinyl or dialkyl phenyl phosphates.[25] The C=COP bond cleavage in the hydrolysis of dialkyl vinyl phosphate under acidic or basic conditions occurs predominantly to yield dialkyl phosphate and carbonyl compounds.[26] Hata *et al.* as well as our group have prepared many kinds of unesterified enolphosphates of biologically interest from the corresponding dialkyl esters by means of bromotrimethylsilane.[27] In order to extend our methodology, the reaction of dialkyl vinyl phosphates with chlorotrimethylsilane/lithium bromide in acetonitrile solution was undertaken.

When dialkyl vinyl phosphates (**6**) reacted with chlorotrimethylsilane/lithium bromide in acetontrile, the corresponding bis(trimethylsilyl) vinyl phosphates (**7**) were obtained in high yields.

$$\underset{\mathbf{6}}{R^1OP(OR^2)_2} + 2\,Me_3SiCl + 2\,LiBr \xrightarrow[CH_3CN]{} \underset{\mathbf{7}}{R^1OP(OSiMe_3)_2} + 2\,R^2Br + 2\,LiCl \quad (8)$$

The silyl esters (**7**), treated with methanol at room temperature, were immediately converted into the corresponding phosphates (**8**) which were isolated as anilinium salts. The results are given in Table 5.

$$\mathbf{7} \xrightarrow{MeOH} \underset{\mathbf{8}}{R^1OP(OH)_2} \quad (9)$$

Alcoholysis of the silyl ester (**7a**) was unsuccessful. No desirable anilinium salt of **8a** could be isolated, resulting in the C=COP bond cleavage.

We have developed a mild and versatile method for carbon-oxygen bond cleavage using easily accessible and inexpensive chlorotrimethylsilane/metal halides, and have demonstrated the applicability of this method to synthetic transformation.

Experimental

Boiling points are uncorrected. Melting points were determined on a Yanagimoto micromelting apparatus and are uncorrected. ^1H NMR spectra were obtained with a JNM FX 100 using TMS or DSS as an internal standard, and IR spectra with a Shimadzu IR-400. GLC analyses were performed on a Shimadzu GC-3AF using stainless steel

columns packed with 25% Silicone DC 550 on Shimalite.

Materials. Commercial chlorotrimethylsilane was dried over CaH_2 and distilled. Acetonitrile and other solvents were dried and distilled by the usual method. Commercial anhydrous inorganic halides were stored in a desiccator. Hygroscopic lithium bromide was dried *in vacuo* at 100 °C just use. All substrates (phosphonic esters, acetals, and phosphoric esters) were prepared by the usual method. All the dialkyl phosphonates (**3a**—**3q**, except **3n** and **3r**) were prepared by the Arbuzov reaction of the corresponding halides with trialkyl phosphite.[18] The phosphonate (**3m**) was prepared from 2-chloro-4,6-dimethoxy-1,3,5-triazine[28] and trimethyl phosphite: yield 80%; viscous oily product; NMR (CCl_4): δ 3.93 (6H, d, J=10.6 Hz, CH_3OP), 4.02 (6H, s, CH_3O); Found: P, 12.31%. Calcd for $C_7H_{12}N_3O_5P$: P, 12.43%. The phosphonate (**3n**) was prepared by the reaction of benzaldehyde with dimethyl phosphonate, followed by acetylation with acetyl chloride in the presence of triethylamine.[18] The phosphonate (**3r**) was prepared from PCl_3 and trimethyl orthoformate.[29] All the phosphates (**6a**—**6c**) were prepared by the Perkow reaction of the corresponding α-halogenocarbonyl compounds with trialkyl phosphite.[26]

General Procedure for Dealkylation of Acetal with Chlorotrimethylsilane/Sodium Iodide. A mixture of acetal (30 mmol), chlorotrimethylsilane (60 mmol), and anhydrous sodium iodide (60 mmol) in dry acetonitrile (15 ml) was heated at 45 °C with stirring, the reaction being monitored by ^1H NMR. When the reaction was completed, the mixture was poured into 5% aqueous solution of $NaHCO_3$ (50 ml), followed by deiodinization with sodium thiosulfate. The resulting organic layer was extracted with ether (50 ml×3), the combined extract being dried over Na_2SO_4. After the removal of low-boiling materials on an evaporator (below 50 °C), the residue was distilled *in vacuo* to afford the pure product.

Effect of Iodide Salts on Dealkylation of Acetal. ^1H NMR analysis was carried out according to the same procedure as that described above. A mixture of benzaldehyde dimethyl acetal (7 mmol), chlorotrimethylsilane (14 mmol), and anhydrous iodide salt (14 mmol) was stirred at 45 °C in dry acetonitrile (5 ml). Conversion of the dimethyl acetal into benzaldehyde was determined by measurement of ^1H NMR spectra of the reaction mixture.

General Procedure for Dealkylation of Dialkyl Phosphonate with Chlorotrimethylsilane/Sodium or Potassium Iodide. Chlorotrimethylsilane (60 mmol) was added dropwise to a mixture of phosphonate (30 mmol) and anhydrous sodium or potassium iodide (60 mmol) in dry acetonitrile (30 ml). The mixture was stirred at 25—35 °C for 15—30 min, the progress of reaction being monitored by ^1H NMR spectroscopy. After complete disappearance of the chlorotrimethylsilane signal, the resulting sodium or potassium chloride was filtered off rapidly and washed with dry ether (20 ml×2). On removing low-boiling materials from the filtrate with an evaporator (below 50 °C), the corresponding silyl esters were obtained as oily residue. The residue was dissolved in methanol (30 ml) containing aniline or cyclohexylamine (60 mmol) and the mixture was concentrated to dryness under reduced pressure to give a white solid, amine salt of phosphonic acid. The crude salts were purified by recrystallization. Some known products were identified by comparison with authenitic samples prepared from dialkyl phosphonates and bromotrimethylsilane.[22] The structures of new compounds were identified by ^1H NMR spectra and elemental analysis.

*Anilinium (Ethoxycarbonylmethyl)phosphonate (Salt of **5h**).* The salt was recrystallized from acetone: yield 85%; mp 134—136 °C; NMR (D_2O): δ 1.27 (3H, t, CH_3C), 4.14 (2H, q, CH_2O), 2.84 (2H, d, J=20.9 Hz, CH_2P), 7.4—7.6 (5H, m, C_6H_5N); Found: C, 46.05; H, 6.29; N, 5.44; P, 11.72%. Calcd for $C_{10}H_{16}NO_5P$: C, 45.98; H, 6.17; N, 5.36; P, 11.86%.

*Anilinium (t-Butoxycarbonylmethyl)phosphonate (Salt of **5i**).* The salt was recrystallized from acetone: yield 77%; mp 115—117 °C; NMR (D_2O): δ 1.46 (9H, s, C_4H_9OCO), 2.74 (2H, d, J=20.8 Hz, CH_2P), 7.4—7.6 (5H, m, C_6H_5N); Found: C, 49.56; H, 6.65; N, 4.95; P, 11.77%. Calcd for $C_{12}H_{20}NO_5P$: C, 49.83 H, 6.97; N, 4.84; P, 10.71%.

*Anilinium (Benzyloxycarbonylmethyl)phosphonate (Salt of **5j**).* The salt was recrystallized from acetone: yield 84%; mp 123—125 °C; NMR (D_2O): δ 2.89 (2H, d, J=20.8 Hz, CH_2P), 5.18 (2H, s, $PhCH_2O$), 7.3—7.6 (10H, m, C_6H_5C, C_6H_5N); Found: C, 55.87; H, 5.50; N, 4.46; P, 8.89%. Calcd for $C_{15}H_{18}NO_5P$: C, 55.73; H, 5.61; N, 4.33; P, 9.58%.

*Anilinium (Ethoxycarbonyl)phosphonate (Salt of **5k**).* The salt was recrystallized from ethanol: yield 85%; mp 143—145 °C; NMR (D_2O): δ 1.28 (3H, t, CH_3C), 4.19 (2H, q, CH_2O), 7.3—7.6 (5H, m, C_6H_5N); Found: C, 44.23; H, 5.89, N, 5.73; P, 12.70%. Calcd for $C_9H_{14}NO_5P$: C, 43.73; H, 5.71; N, 5.67; P, 12.53%.

*Anilinium (Diethylcarbamoyl)phosphonate (Salt of **5l**).* The salt was recrystallized from acetone–ethanol (5/1): yield 88%; mp 142—144 °C; NMR (D_2O): δ 1.10 (3H, t, CH_3C), 1.19 (3H, t, CH_3C), 3.31 (2H, q, CH_2N), 3.69 (2H, q, CH_2N), 7.4—7.7 (5H, m, C_6H_5N); Found: C, 48.32; H, 7.44; N, 10.05; P, 10.95%. Calcd for $C_{11}H_{19}N_2O_4P$: C, 48.18; H, 6.99; N, 10.21; P, 11.29%.

*Anilinium (4,6-Dimethoxy-1,3,5-triazine-2-yl)phosphonate (Salt of **5m**).* The salt was recrystallized from ethanol: yield 91%; dec. 153—155 °C; NMR (D_2O): δ 4.02 (6H, s, CH_3O), 7.3—7.6 (5H, m, C_6H_5N); Found: C, 42.24; H, 4.82; N, 17.82; P, 9.63%. Calcd for $C_{11}H_{15}N_4O_5P$: C, 42.02; H, 4.81; N, 17.83; P, 9.86%.

*Anilinium (α-Acetoxybenzyl)phosphonate (Salt of **5n**).* The salt was recrystallized from methanol: yield 90%; mp 159—161 °C; NMR (D_2O): δ 2.81 (3H, s, CH_3C), 5.82 (1H, d, J=13.0 Hz, CHP), 7.3—7.6 (10H, m, C_6H_5C, C_6H_5N); Found: C, 55.79; H, 5.71; N, 4.24; P, 8.93%. Calcd for $C_{15}H_{18}NO_5P$: C, 55.73; H, 5.61; N, 4.33; P, 9.58%.

*Anilinium (Benzoylmethyl)phosphonate (Salt of **5o**).* The salt was recrystallized from acetone–methanol (10/1): yield 89%; mp 103—104 °C; NMR (D_2O): δ 3.57 (2H, d, J=21.3 Hz, CH_2P), 7.3—8.1 (10H, m, C_6H_5C, C_6H_5N); Found: C, 57.31; H, 5.51; N, 4.81; P, 10.49%. Calcd for $C_{14}H_{16}NO_4P$: C, 57.34; H, 5.50; N, 4.78; P, 10.56%.

*Anilinium (Methoxymethyl)phosphonate (Salt of **5p**).* The salt was recrystallized from acetone: yield 76%; mp 114—116 °C; NMR (D_2O): δ 3.43 (3H, s, CH_3O), 3.59 (2H, d, J=8.5 Hz, CH_2P), 7.3—7.6 (5H, m, C_6H_5N); Found: C, 43.56; H, 6.33; N, 6.37; P, 14.23%. Calcd for $C_8H_{14}NO_4P$: C, 43.84; H, 6.44; N, 6.39; P, 14.13%.

*Anilinium (2,2-Dimethoxyethyl)phosphonate (Salt of **5q**).* The salt was recrystallized from acetone–methanol (10/1): yield 82%; mp 86—88 °C; NMR (D_2O): δ 2.03 (2H, dd, J=18.1 Hz, CH_2P, J=5.9 Hz, $CHCH_2$), 3.36 (6H, s, CH_3O), 7.3—7.6 (5H, m, C_6H_5N); Found: C, 45.28; H, 6.32; N, 5.65; P, 11.52%. Calcd for $C_{10}H_{18}NO_5P$: C, 45.63; H, 6.89; N, 5.32; P, 11.77%.

General Procedure for Dealkylation of Dialkyl Phosphonate with Chlorotrimethylsilane/Lithium Bromide. A mixture of phosphonate (20 mmol), chlorotrimethylsilane (44 mmol for R^2=Me, 56 mmol for R^2=Et) and anhydrous lithium bromide (44 mmol for R^2=Me, 56 mmol for R^2=Et) in dry

acetontrile (15 ml) was vigorously stirred at 45—75 °C for several hours, the reaction being monitored by ^{1}H NMR. When the reaction was completed, the reaction mixture was cooled to room temperature and resulting lithium chloride and the excess of lithium bromide were filtered off. After the removal of low-boiling materials on an evaporator, the residue was distilled under reduced pressure to give the pure trimethylsilyl ester. The products were identified by comparison with authentic samples prepared by use of bromotrimethylsilane.[22]

Bis(trimethylsilyl) Benzylphosphonate (4a). Yield 89%; bp 95—97 °C/0.1 mmHg† (lit,[23] 88—90 °C/0.04 mmHg); IR (neat): 1245 cm^{-1} (P=O); NMR (CCl_4): δ 3.00 (2H, d, J=22.2 Hz, CH_2P), 7.22 (5H, m, C_6H_5C), 0.15 (18H, s, $OSiMe_3$).

Bis(trimethylsilyl) (t-Butoxycarbonylmethyl)phosphonate (4i). Yield 83%; bp 82—84 °C/0.01 mmHg; IR (neat): 1725 (C=O) and 1250 cm^{-1} (P=O); NMR (CCl_4): δ 1.46 (9H, s, C_4H_9O), 2.72 (2H, d, J=22.5 Hz, CH_2P), 0.28 (18H, s, $OSiMe_3$); Found: P, 9.31%. Calcd for $C_{12}H_{29}O_5PSi_2$: P, 9.10%.

Bis(trimethylsilyl) (Benzyloxycarbonylmethyl)phosphonate (4j). Yield 85%; bp 123—125 °C/0.002 mmHg; IR (neat): 1730 (C=O) and 1260 cm^{-1} (P=O); NMR (CCl_4): δ 2.87 (2H, d, J=22.5 Hz, CH_2P), 5.11 (2H, s, $PhCH_2O$), 7.31 (5H, m, C_6H_5C), 0.26 (18H, s, $OSiMe_3$); Found: P, 7.69%. Calcd for $C_{15}H_{27}O_5PSi_2$: P, 8.27%.

Bis(trimethylsilyl) (Methoxymethyl)phosphonate (4p). Yield 88%; bp 123—124 °C/8 mmHg (lit,[23] 73—75 °C/0.02 mmHg); IR (neat): 1250 cm^{-1} (P=O); NMR (CCl_4): δ 3.55 (2H, d, J=8.5 Hz, CH_2P), 3.43 (3H, s, CH_3O), 0.29 (18H, s, $OSiMe_3$).

General Procedure for Dealkylation of Dialkyl Vinyl Phosphate with Chlorotrimethylsilane/Lithium Bromide. Dealkylation of the phosphoric esters (20 mmol) was carried out by the same procedure as that in the case of dialkyl phosphonate. The silyl ester was isolated by distillation *in vacuo*. When the silyl ester (10 mmol) was added to a methanol solution (30 ml) of aniline (20 mmol) and the solution was concentrated to dryness on an evaporator (below 50 °C), anilinium salt was obtained as a white crystalline solid. After recrystallization the structures of the products were characterized by ^{1}H NMR, IR spectra, and elemental analysis.

Bis(trimethylsilyl) 1-Methylethenyl Phosphate (7a). Yield 84%; bp 90—92 °C/8 mmHg (lit,[27] 75—77 °C/1.25 mmHg).

Bis(trimethylsilyl) 2-Methyl-1-phenyl-1-propenyl Phosphate (7b). Yield 81%; bp 110—111 °C/0.01 mmHg; IR (neat): 1680 (C=C) and 1245 cm^{-1} (P=O); NMR (CCl_4): δ 1.70 (3H, d, J=3.0 Hz, CH_3C=COP), 1.88 (3H, d, J=2.4 Hz, CH_3C=COP), 7.2—7.4 (5H, m, C_6H_5C), 0.11 (18H, s, $OSiMe_3$); Found: P, 8.56%. Calcd for $C_{16}H_{29}O_4PSi_2$: P, 8.31%.

Bis(trimethylsilyl) 2,2-Dichloroethenyl Phosphate (7c). Yield 86%; bp 79—81 °C/1 mmHg; IR (neat): 1630 (C=C) and 1245 cm^{-1} (P=O); NMR (CCl_4): δ 6.84 (1H, d, J=5.9 Hz, C=CHOP), 0.30 (18H, s, $OSiMe_3$); Found: P, 9.41. Calcd for $C_8H_{19}O_4PSi_2Cl_2$: P, 9.18%.

Anilinium 2-Methyl-1-phenyl-1-propenyl Phosphate (Salt of 8b). The salt was recrystallized from acetone: yield 93%; mp 142—143 °C; NMR (D_2O): δ 1.71 (3H, d, J=3.1 Hz, CH_3C=COP), 1.75 (3H, d, J=2.2 Hz, CH_3C=COP), 7.3—7.6 (10H, m, C_6H_5C, C_6H_5N); Found: C, 60.16; H, 6.75; N, 4.83; P, 9.85%. Calcd for $C_{16}H_{20}NO_4P$: C, 59.81; H, 6.27; N, 4.83; P, 9.64%.

Dianilinium 2,2-Dichloroethenyl Phosphate (Salt of 8c). The salt was recrystallized from water: yield 95%; dec. 143—147 °C; NMR (CD_3OD): δ 6.9—7.4 (11H, m, C=CHOP, C_6H_5N); Found: C, 44.22; H, 4.58 N, 7.24 P, 8.02; Cl, 18.80%. Calcd for $C_{14}H_{17}N_2O_4PCl_2$: C, 44.34; H, 4.52; N, 7.39; P, 8.17; Cl, 18.70%.

† 1 mmHg=133.3 Pa.

We would like to thank Mr. Syuichi Yoshida for his assistance with dealkylation of acetal. Chlorotrimethylsilane was supplied through the kindness of Shin-Etsu Chemical Industry Ltd.

16) Many alkyl silyl ethers derived from primary, secondary, and tertiary alcohols were readily converted into the corresponding iodides quantitatively: T. Morita, S. Yoshida, Y. Okamoto, and H. Sakurai, *Synthesis*, **1979**, 379.

$$ROH \longrightarrow ROSiMe_3 \xrightarrow[CH_3CN]{Me_3SiCl/NaI} RI$$

17) There is probably an equilibrium shifting toward the left

$$Me_3SiCl + I^- \rightleftarrows Me_3SiI + Cl^-$$

The reaction proceeds *via* the formation of a small amount of iodotrimethylsilane (in equilibrium). This seems to be an acceptable explanation. An alternative mechanism was proposed for phosphonic ester dealkylation.[13a] Olah *et al.* pointed out that the active compound formed from chlorotrimethylsilane/sodium iodide in acetonitrile is silylnitrilium iodide, $[CH_3C{\equiv}N^+{-}SiMe_3]\ I^-$.[15a] We believe that the mechanism involves the initial formation of Me_3SiI from Me_3SiCl and NaI, subsequent rapid silylation of CH_3CN by the Me_3SiI, and the dealkylation of organic substrate by silylnitrilium iodide.

Aldol Reaction of Aluminium Enolate Resulting from 1,4-Addition of R_2AlX to α,β-Unsaturated Carbonyl Compound. A 1-Acylethenyl Anion Equivalent[1)]

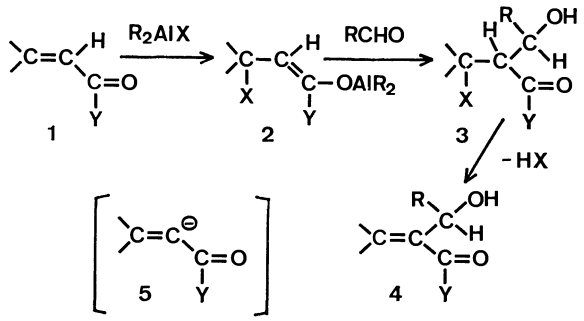
Akira Itoh, Shuji Ozawa, Koichiro Oshima,* and Hitosi Nozaki

Department of Industrial Chemistry, Faculty of Engineering, Kyoto Univesity, Yoshida, Sakyo-ku, Kyoto 606

(Received July 16, 1980)

Organoaluminium reagents R_2AlX (X=SPh, SeMe) easily add to α,β-unsaturated carbonyl compounds in 1,4-fashion. The resulting aluminium enolates react with aldehydes to give aldol adducts in fair to good yields. Formal elimination of HX from the adducts provides α-substituted α,β-unsaturated carbonyl compounds. The overall transformation is an addition of aldehydes to 1-acylethenyl anion equivalent. Diethylaluminium iodide also is found to be an efficient reagent for the same type transformation.

The aldol condensation is one of the most versatile synthetic methods in organic chemistry. Recently, organoaluminium enolates as produced *via* several routes have been utilized as a vast potential agent of the reaction.[2-5)] Conjugate addition of organoaluminium reagents R_2AlX to α,β-unsaturated carbonyl compounds provides another route to aluminium enolates (Scheme 1).[6)] The aldol reaction with an aldehyde component followed by elimination of HX gives α-substituted α,β-unsaturated carbonyl compound **4**. The overall transformation therefore provides an α-carbanion equivalent of the substrate **5** adding to the aldehyde component to form **4**. The sequence gives a solution to the recurring synthetic problem to introduce α-substituent directly to α,β-unsaturated carbonyl compounds.[7)]



Scheme 1.

Among many candidates for R_2AlX, dimethylaluminium benzenethiolate[8)] (reagent A) and dimethylaluminium methaneselenolate[9)] (reagent B) have been found to be effective (Table 1). Dimethylaluminium benzenethiolate was prepared from trimethylaluminium and thiophenol in dichloromethane and dimethylaluminium methaneselenolate from trimethylaluminium and selenium metal in toluene. These reagents were used directly without isolation. In an attempt to find the suitable solvent for the aldol reaction, the reaction between 2-cyclohexenone and acetaldehyde mediated by Me_2AlSPh was examined in various solvents (solvent, isolated yield of **3**): hexane, 42%; CH_2Cl_2, 43%; toluene, 45%; tetrahydrofuran (THF), 94%. After completion of 1,4-addition of R_2AlX (X=SPh, SeMe) to α,β-unsaturated carbonyl compounds, the reaction mixture was diluted with THF which was found to be the best solvent.

Unfortunately dimethylaluminium benzenethiolate was not effective in the reaction of α,β-unsaturated esters because of sluggishly proceeding 1,4-addition, where a quantity of the corresponding thiocarboxylic *S*-ester was formed[11)] The use of a new ate complex $Me_3Al^-SPhLi^+$ (reagent C) has been found to be much more advantageous possibly due to the increased reactivity of thiolate ion itself as well as of the resulting enolate anion corresponding to **2**.

Erythro and threo ratios of the aldol product **3** have been examined. The aldol product 2-(1-hydroxyethyl)-3-phenylthiocyclohexanone was desulfurized with Raney Ni in ethanol. Analysis of the NMR spectra[12)] revealed that the product was a 1:1 mixture of erythro and threo isomers. Similarly, the aldol products between acetaldehyde and methyl vinyl ketone (run 7) or ethyl acrylate (run 11) were found to be 1:1 and 1:2 mixture of isomers by NMR analysis.[13)]

Spontaneous elimination of phenylthio group in the reaction mixture was observed in run 6. More easily the conversion of **3** to **4** was achieved by the oxidation (sodium periodate for SPh and hydrogen peroxide for SeMe), which facilitates successive elimination[14)] as given in Table 1. Moreover, the overall transformation could be performed in one pot, for instance, the addition of copper(II) chloride and sodium acetate directly to the product in the run 1 without workup afforded the desired compound **4** in 52% yield.

Diethylaluminium iodide[15)] was found to be more effective for the same type transformation. Addition of diethylaluminium iodide to a mixture of aldehyde and α,β-unsaturated ketone in dichloromethane gave α-substituted α,β-unsaturated ketone **4** directly. The whole sequence involving conjugate addition of the iodide, aldol condensation of the resulting aluminium enolate, and elimination of HI element proceeded in one pot. The results are summarized in Table 2.

Tetrahydrofuran was not a suitable solvent for the reaction of Et_2AlI because of the ring cleavage producing 4-iodo-1-butanol. Reaction between ethyl acrylate and acetaldehyde gave the adduct **3** (X=I). Elimination of HI did not proceed spontaneously in this case and treatment with 1,8-diazabicyclo[5.4.0]-undec-5-ene was necessary in order to obtain the product **4**.

Although aldehydes successfully trapped the aluminium enolates in high yields, ketones and other electrophiles such as allyl bromide, acetyl chloride, 2-phenyl-1,3-dioxolane, and cyclohexene oxide failed to react.

Table 1. Reaction between α,β-unsaturated carbonyl compounds and aldehydes by means of Me_2AlSPh or $Me_2AlSeMe$

Run	α,β-Unsaturated carbonyl compound	Reagent[a]	Aldehyde RCHO	**3** Yield %	**4** Yield %[b]
1	2-Cyclohexenone	A	$CH_3(CH_2)_7CHO$	90	71
2	2-Cyclohexenone	A	CH_3CHO	94	92
3	2-Cyclohexenone	B	CH_3CHO	77	77
4	2-Cyclohexenone	A	methacrolein	97	84
5		A	CH_3CHO	75	—
6		A	CH_3CHO	—	50[c]
7	CH_2=CHCOCH$_3$	A	CH_3CHO	60	57
8	CH_2=CHCOCH$_3$	B	CH_3CHO	55	50
9	2-Cyclopentenone	A	HCHO	56	80[d]
10	2-Cyclopentenone	A	$CH_3(CH_2)_7CHO$	76	60

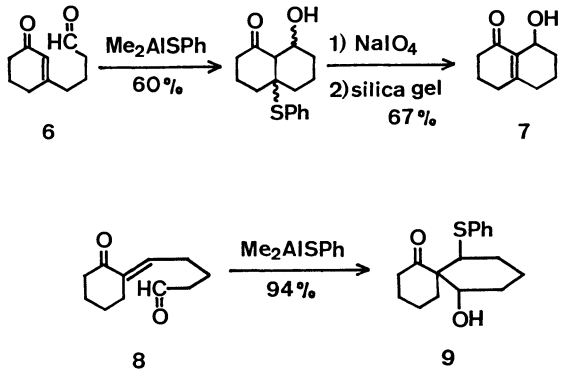
12		C	PhCHO	77	74

a) A: Me_2AlSPh, B: $Me_2AlSeMe$, C: Me_3Al–$SPhLi^+$. b) Yields were based on **3**. c) Phenylthio group has been spontaneously eliminated in this case. d) See Ref. 10.

Table 2. Reaction between α,β-unsaturated carbonyl compounds and aldehydes by means of Et_2AlI

Run	α,β-Uusaturated carbonyl compound	Aldehyde RCHO	**4** Yield/%
1	2-Cyclohexenone	CH_3CHO	81
2	2-Cyclohexenone	$CH_3(CH_2)_7CHO$	88
3	CH_2=CHCOCH$_3$	CH_3CHO	61
4	CH_2=CHCOOC$_2$H$_5$	CH_3CHO	62[a]

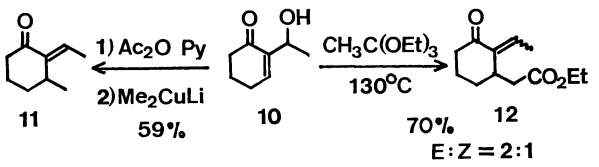
a) Further treatment with DBU was necessary. See experimental part.



Scheme 2.

Treatment of the α,β-unsaturated carbonyl compounds **6**[16] or **8** with dimethylaluminium benzenethiolate provided an efficient method for the cyclization affording **7** or **9**.

Finally, further synthetic applications of the adduct **10** have been examined (Scheme 3). Treatment of the acetate of **10** with lithium dimethylcuprate(I)[17] afforded **11** in 59% yield. No regio- and stereoisomers were detected. Orthoester Claisen rearrangement[18] of **10** gave a stereoisomeric mixture of **12** in 70% yield. These transformations enable us to introduce a variety of groups on α and β positions of α,β-unsaturated carbonyl compounds.



Scheme 3.

Experimental

The infrared spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra on a Hitachi RMU-6L machine; the GLPC analyses on a Yanagimoto GCG-550F; and the NMR spectra on a JEOL C-60H or Varian EM-390H spectrometer. The chemical shifts are given in δ in ppm with TMS as the internal standard. Splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The microanalyses were carried out by the staffs at the Elemental Analyses Center of Kyoto University. All experiments were carried out under an atmosphere of dry argon. Tetrahydrofuran was dried by distillation from sodium-benzophenone. Thin layer or thick layer plates were made of E. Merck PF-254, and preparative columns silica gel E. Merck Art. 7734.

2-(1-Hydroxynonyl)-2-cyclohexenone. A solution of thiophenol (0.26 g, 2.4 mmol) in dichloromethane (2.0 ml) was added to a solution of trimethylaluminium in hexane (1.0 M, 2.4 ml, 2.4 mmol) at 0 °C and the mixture was stirred for 20 min. A solution of 2-cyclohexenone (0.19 g,

2.0 mmol) in dichloromethane (2.0 ml) was added at −78 °C and, after 15 min, the resulting white suspension was diluted with THF (10 ml) to give a colorless solution. After additional 5 min, a solution of nonanal (0.34 g, 2.4 mmol) in THF (2.0 ml) was added and stirring was continued for 20 min at −78 °C. The reaction mixture was poured into ice–water and the organic phase was washed with 1 M HCl twice. The aqueous phase was extracted twice with ethyl acetate and the combined organic layers were washed with brine, dried, and freed of the solvent. Purification by column chromatography on silica gel (hexane:ether=2:1) gave 2-(1-hydroxynonyl)-3-(phenylthio)cyclohexanone (0.64 g, 90% yield): IR (neat) 3450, 1700 cm^{-1}; NMR (CCl_4) δ 0.88 (t, J=4.5 Hz, 3H), 1.20—2.40 (m, 22H), 3.46 (m, 1H), 4.00 (m, 1H), 7.20—7.48 (m, 5H); MS *m/e* (%) 238 (2), 220 (7), 206 (24), 140 (13), 135 (16), 125 (100), 110 (98).

The sulfide (0.28 g, 0.72 mmol) was dissolved in 50% aqueous methanol (5.0 ml) and treated with sodium periodate (0.23 g, 1.1 mmol) at 25 °C for 3 d. After purification by column chromatography on silica gel, the obtained sulfoxide was dissolved in toluene (3.0 ml) and heated at reflux for 30 min to give the title compound (0.12 g, 71% yield based on the hydroxy sulfide): bp 185 °C (bath temp, 2 Torr, 1 Torr=133.322 Pa); IR (neat) 3445, 1665, 1653 cm^{-1}; NMR (CCl_4) δ 0.87 (t, J=4.8 Hz, 3H), 1.28 (m, 14H), 1.82—2.07 (m, 2H), 2.24—2.44 (m, 5H), 4.15 (m, 1H), 6.74 (t, J=3.9 Hz, 1H); MS *m/e* (%) 238 (M^+, 3), 221 (3), 220 (11), 141 (13), 136 (18), 126 (100). Microanalysis was performed after trimethylsilylation of the hydroxyl group.[19] Found: C, 69.56; H, 11.01%. Calcd for $C_{18}H_{34}O_2Si$: C, 69.62; H, 11.04%.

2-(1-Hydroxyethyl)-2-cyclohexenone ***10***. Bp 130 °C (bath temp, 2 Torr); IR (neat) 3440, 1665, 1655 cm^{-1}; NMR (CCl_4) δ 1.23 (d, J=6.5 Hz, 3H), 1.96 (m, 2H), 2.36 (m, 4H), 2.69 (bs, 1H), 4.42 (qd, J=6.5 and 1.2 Hz, 1H), 6.80 (td, J=4.1 and 1.2 Hz, 1H); MS *m/e* (%) 141 (9), 140 (M^+, 38), 139 (9), 125 (100), 97 (54). Found: C, 62.07; H, 9.40%. Calcd for $C_{11}H_{20}O_2Si$: C, 62.21; H, 9.49%.[19]

Joining Reaction of 2-Cyclohexenone and Acetaldehyde Mediated by $Me_2AlSeMe$. A mixture of selenium (0.23 g, 2.9 mg-atom), trimethylaluminium (1.0 M hexane solution, 3.0 ml, 3.0 mmol), and toluene (3.0 ml) was refluxed for 2.5 h.[9] The resulting homogeneous solution was diluted with THF (10 ml) and treated with 2-cyclohexenone (0.11 g, 1.1 mmol) at −78 °C. After 70 min, acetaldehyde (0.1 ml, 1.8 mmol) was added and the mixture was stirred for 30 min at −78 °C and for 5 min at 0 °C. Purification by preparative TLC (hexane:ether=1:2) afforded 2-(1-hydroxyethyl)-3-(methylseleno)cyclohexanone (0.20 g, 0.85 mmol) in 77% yield. The selenide (0.20 g, 0.85 mmol) was dissolved in a mixture of dichloromethane (10 ml) and pyridine (0.35 ml, 4.3 mmol) and treated with 30% H_2O_2 (0.55 g, 4.8 mmol) at 25 °C for 30 min to give **10** (91 mg, 77% yield).

2-(1-Hydroxy-2-methyl-2-propenyl)-2-cyclohexenone. IR (neat) 3430, 1664, 1655, 893 cm^{-1}; NMR (CCl_4) δ 1.65 (s, 3H), 2.01 (m, 2H), 2.38 (m, 4H), 2.85 (bs, 1H), 4.75 (s, 1H), 4.82 (s, 1H), 4.95 (s, 1H), 6.78 (t, J=4.2 Hz, 1H); MS *m/e* (%) 166 (M^+, 47), 165 (18), 151 (27), 149 (12), 148 (16), 147 (20), 137 (100); bp 95 °C (bath temp, 2 Torr).[20] Found: C, 65.21; H, 9.08%. Calcd for $C_{13}H_{22}O_2Si$: C, 65.50; H, 9.30%.[19]

2-(1-Hydroxyethyl)-2-methyl-3-(phenylthio)cyclohexanone. IR (neat) 3460, 1703 cm^{-1}; NMR (CCl_4) δ 1.16 (s, 3H), 1.35 (d, J=6.3 Hz, 3H), 1.63—2.55 (m, 7H), 3.66—4.29 (m, 2H), 7.13—7.50 (m, 5H); MS *m/e* (%) 220 (5), 154 (1), 139 (1), 111 (15), 110 (100), 109 (19), 82 (56); bp 140 °C (bath temp, 2 Torr).[20] Found: C, 64.16; H, 8.44%. Calcd for $C_{18}H_{28}O_2SSi$: C, 64.23; H, 8.39%.[19]

2-(1-Hydroxyethyl)-3-methyl-2-cyclohexenone. IR (neat) 3470, 1643, 1625 cm^{-1}; NMR (CCl_4) δ 1.26 (d, J=6.3 Hz, 3H), 1.95 (s, 3H), 1.75—2.05 (m, 2H), 2.25—2.50 (m, 4H), 4.27 (bs, 1H), 4.52 (q, J=6.3 Hz, 1H); MS *m/e* (%) 154 (M^+, 7), 140 (12), 139 (100), 136 (13), 121 (11), 111 (15); bp 94 °C (bath temp, 2 Torr).[20] Found: C, 63.20; H, 9.91%. Calcd for $C_{12}H_{22}O_2Si$: C, 63.66; H, 9.79%.[19]

4-Hydroxy-3-methylene-2-pentanone. IR (neat) 3415, 1665, 1635, 1088 cm^{-1}; NMR (CCl_4) δ 1.23 (d, J=6.6 Hz, 3H), 2.30 (s, 3H), 2.65 (bs, 1H), 4.53 (q, J=6.6 Hz, 1H), 5.98 (s, 2H); MS *m/e* (%) 114 (M^+, 1), 113 (1), 100 (7), 99 (100), 81 (12), 71 (16); bp 45 °C (bath temp, 2 Torr).[20] Found: C, 57.78; H, 9.67%. Calcd for $C_9H_{18}O_2Si$: C, 58.02; H, 9.74%.[19]

2-Hydroxymethyl-2-cyclopontenone. NMR and IR spectra and mp agreed with published data.[7b]

2-(1-Hydroxynonyl)-2-cyclopentenone. IR (neat) 3432, 1686, 1631 cm^{-1}; NMR (CCl_4) δ 0.86 (t, J=5.4 Hz, 3H), 1.29 (m, 14H), 2.33 (m, 2H), 2.56 (m, 2H), 2.87 (bs, 1H), 4.26 (bt, J=5.1 Hz, 1H), 7.32 (bs, 1H); MS *m/e* (%) 224 (M^+, 0.3), 207 (2), 206 (9), 149 (3), 145 (3), 135 (5), 111 (100); bp 124 °C (bath temp, 2 Torr).[20] Found: C, 68.84; H, 10.84%. Calcd for $C_{17}H_{32}O_2Si$: C, 68.86; H, 10.88%.[19]

Ethyl 3-Hydroxy-2-methylenebutyrate. A solution of trimethylaluminium in hexane (1.0 M, 1.2 ml, 1.2 mmol) was added to a solution of lithium benzenethiolate (1.2 mmol, prepared *in situ* from thiophenol and butyllithium at 0 °C) in THF (5.0 ml) at 0 °C. After 1 h, the mixture was cooled to −78 °C and treated with a solution of ethyl acrylate (0.11 g, 1.1 mmol) in THF (1.0 ml) and kept there for 15 min. Acetaldehyde (0.1 ml, 1.8 mmol) was added and the mixture was stirred for 10 min at −78 °C and for 5 min at 0 °C. The crude product was submitted to preparative TLC (hexane:ether=1:1) to afford ethyl 3-hydroxy-2-(phenylthiomethyl)butyrate (0.21 g, 0.81 mmol) in 73% yield. Following the previously described procedure, this hydroxy ester (0.15 g, 0.6 mmol) was subsequently transformed to the title compound (75 mg, 87% yield): IR (neat) 3440, 1713, 1630 cm^{-1}; NMR (CCl_4) δ 1.29 (d, J=6.4 Hz, 3H), 1.32 (t, J=7.2 Hz, 3H), 2.90 (bs, 1H), 4.17 (q, J=7.2 Hz, 2H), 4.50 (q, J=6.4 Hz, 1H), 5.76 (s, 1H), 6.10 (s, 1H); MS *m/e* (%) 129 (51), 101 (75), 99 (44), 98 (34), 97 (21), 83 (100), 73 (37); bp 54 °C (bath temp, 2 Torr).[20] Found: C, 55.61; H, 9.57%. Calcd for $C_{10}H_{20}O_3Si$: C, 55.52; H, 9.32%.[19]

2-(1-Hydroxybenzyl)-2-buten-4-olide. NMR, IR, and mass spectra were found to be in accord with published data.[6]

Desulfurization of 2-(1-Hydroxyethyl)-3-(penylthio)cyclohexanone with Raney Ni. Stirring the hydroxy sulfide (0.11 g) in ethanol (3.0 ml) with Raney Ni W-2 (0.3 g) under hydrogen atmosphere at 25 °C for 14 h followed by preparative TLC isolation (benzene:ethyl acetate=3:1, two developments) gave 2-(1-hydroxyethyl)cyclohexanone (31 mg) in 51% yield. The NMR spectrum (CCl_4) indicated this being a 1:1 mixture of erythro and threo isomers by exhibiting a pair of multiplets at δ 3.82 and 4.13 in a 1:1 ratio as well as a pair of doublets of equal intensities at δ 1.07 (J=6.6 Hz) and 1.09 (J=6.6 Hz).[12]

One Pot Synthesis of ***10***. After successive treatment of 2-cyclohexenone (92 mg, 1.0 mmol) with Me_2AlSPh (1.2 mmol) and acetaldehyde (0.1 ml, 1.8 mmol) in hexane (3.0 ml) and THF (7.0 ml), the reaction mixture was allowed to react with copper(II) chloride (0.68 g, 5.1 mmol) and sodium acetate (0.44 g, 5.3 mmol). The mixture was re-

fluxed for 2 h, poured into water, and filtered through a pad of Celite 545. The organic phase was washed with brine, dried, and freed of the solvent. The residue was submitted to preparative TLC (hexane:ethyl acetate=1:1, two developments) to give **10** (70 mg, 0.50 mmol) in 52% yield.

Joining Reaction of 2-Cyclohexenone and Acetaldehyde Mediated by Et_2AlI. A solution of diethylaluminium iodide in toluene (1.15 M, 1.6 ml, 1.8 mmol) was added to a solution of 2-cyclohexenone (0.12 g, 1.2 mmol) and acetaldehyde (0.10 ml, 1.8 mmol) in dichloromethane (7.0 ml) at 0 °C. After stirring for 20 min at 0 °C, the mixture was diluted with ether and washed with 1 M HCl and brine. Purification by column chromatography on silica gel (hexane:ethyl acetate=3:1) afforded **10** (0.14 g) in 81% yield.

Joining Reaction of Ethyl Acrylate and Acetaldehyde by Means of Et_2AlI. Similar treatment of a solution of ethyl acrylate (0.15 g, 1.5 mmol) and acetaldehyde (0.13 ml, 2.3 mmol) in dichloromethane (7.0 ml) followed by silica gel column chromatography gave ethyl 3-hydroxy-2-(iodomethyl)butyrate (0.44 g, 72% yield): IR (neat) 3470, 1730 cm^{-1}; NMR (CCl_4) δ 1.05 (d, J=6.0 Hz, 3H), 1.33 (t, J=6.9 Hz, 3H), 2.17 (bs, 1H), 2.66 (m, 1H), 3.36 (d, J=6.6 Hz, 2H), 3.90 (m, 1H), 4.18 (q, J=6.9 Hz, 2H); MS *m/e* (%) 272 (M^+, 3), 227 (5), 145 (6), 101 (100), 73 (70), 55 (80). The iodide (0.44 g, 1.1 mmol) was dissolved in benzene (15 ml) and treated with 1,8-diazabicyclo[5.4.0]-5-undecene (0.66 g, 4.3 mmol) at 25 °C for 1 h to give ethyl 3-hydroxy-2-methylenebutyrate (0.12 g, 0.93 mmol) in 86% yield.

10-Hydroxybicyclo[4.4.0]dec-1(6)-en-2-one **7**. A solution of **6**[16] (0.17 g, 1.0 mmol) in THF (2.0 ml) was added to a solution of Me_2AlSPh (3.0 mmol) in hexane (3.0 ml) and THF (9.0 ml) at 0 °C over a period of 40 min. After stirring for additional 20 min, the mixture was poured into ice–water and extracted with ethyl acetate. The cyclized product (0.17 g, 60% yield) was treated with sodium periodate (0.20 g) in 50% aqueous methanol (6.0 ml) at 25 °C for 1 h. The crude sulfoxide was dissolved in ethyl acetate (6.0 ml) and stirred at 25 °C for 9 h in the presence of silica gel (Merck, PF-254, 1.0 g). The reaction mixture was filtered and the filtrate was concentrated. Purification by preparative TLC (ethyl acetate) gave the title compound **7** (67 mg, 40% yield based on the keto aldehyde **6**): IR (neat) 3480, 1655, 1630 cm^{-1}; NMR (CCl_4) δ 1.60—2.40 (m, 11H), 2.99 (m, 2H), 4.42 (bs, 1H); MS *m/e* (%) 166 (M^+, 32), 148 (6), 138 (41), 123 (14), 120 (15), 110 (100). Found: *m/e* 166.0980. Calcd for $C_{10}H_{14}O_2$: M, 166.0992.

5-(2-Oxocyclohexylidene)pentanal **8**. Following the Corey's procedure,[21] 2-[1-hydroxy-5-(2-tetrahydropyranyloxy)pentyl]cyclohexanone was obtained in 54% yield based on cyclohexanone dimethyldrazone. This hydroxy ketone (5.8 g, 20 mmol) was mesylated at 0 °C and the crude mesylate was treated with sodium methoxide (28% solution in methanol, 42 mmol) in methanol at −78 °C. After 12 min at 0 °C, the mixture was diluted with brine and extracted with ethyl acetate. The product was purified by column chromatography on silica gel to give 2-[5-(2-tetrahydropyranyloxy)pentylidene]cyclohexanone (3.7 g) in 68% yield. The tetrahydropyranyl group was removed by treatment with pyridinium *p*-toluenesulfonate (1.5 g) in methanol (45 ml) at 25 °C for 4 h and the product was oxidized with $CrO_3 \cdot 2py$ in dichloromethane to give the title compound **8** in 34% yield: IR (neat) 1724, 1685, 1616 cm^{-1}; NMR (CCl_4) δ 1.59—2.49 (m, 14H), 6.39 (m, 1H), 9.70 (t, J=1.5 Hz, 1H); MS *m/e* (%) 180 (M^+, 21), 162 (13), 152 (12), 124 (70), 93 (63), 81 (54), 79 (63), 67 (100). Found: *m/e* 180.1162. Calcd for $C_{11}H_{16}O_2$: M, 180.1151.

Cyclization of 8 by Means of Me_2AlSPh. The keto aldehyde **8** (94 mg, 0.5 mmol) was treated with Me_2AlSPh (1.5 mmol) as described above to afford **9** (0.14 g, 94% yield): bp 152 °C (bath temp, 3 Torr); IR (neat) 3440, 1702 cm^{-1}; NMR (CCl_4) δ 1.47—2.09 (m, 12H), 2.28—2.47 (m, 2H), 2.93 (bs, 1H), 3.81 (m, 2H), 7.13—7.48 (m, 5H); MS *m/e* (%) 180 (14), 162 (8), 137 (17), 135 (14), 124 (32), 110 (100). Found: *m/e* 290.1329. Calcd for $C_{17}H_{22}O_2S$: M, 290.1339.

(E)-2-Ethylidene-3-methylcyclohexanone **11**: A solution of the acetate of the keto alcohol **10** (0.13 g, 0.7 mmol) in ether (1.0 ml) was added to a solution of lithium dimethylcuparte (0.9 mmol) in ether (3.0 ml) at −23 °C. After 17 min at −23 °C and 5 min at 0 °C, saturated NH_4Cl solution was added and the mixture was filtered. The filtrate was washed with water and brine, dried, and freed of the solvent. Purification by column chromatography on silica gel afforded **11** (57 mg) in 59% yield. The absence of *Z*-isomer was confirmed by the examination of its NMR spectrum.[22]

Ethyl (2-Ethylidene-3-oxocyclohexyl)acetate **12**: A mixture of **10** (0.13 g, 0.9 mmol) triethyl orthoacetate (1.7 ml, 9.2 mmol), and propionic acid (catalytic amount) was heated at 130 °C for 20 min. The mixture was diluted with ethyl acetate and washed with saturated aqueous solution of sodium hydrogencarbonate. The aqueous phase was extracted with ethyl acetate and the combined organic layer was washed with brine, dried, and freed of the solvent. The crude product was submitted to preparative TLC (hexane:ether=1:1, two developments) to give the title compound **12** (*E*-isomer, 89 mg; *Z*-isomer, 45 mg) in 70% yield. The stereochemical assignment was based on the examination of the NMR spectrum.[23]

E-Isomer: Bp 105 °C (bath temp, 0.5 Torr); IR (neat) 1740, 1695, 1620 cm^{-1}; NMR (CCl_4) δ 1.26 (t, J=7.0 Hz, 3H), 1.79 (d, J=7.5 Hz, 3H), 1.70—1.90 (m, 4H), 2.28 (m, 4H), 3.43 (m, 1H), 4.06 (q, J=7.0 Hz, 2H), 6.45 (qd, J=7.5 and 1.2 Hz, 1H); MS *m/e* (%) 211 (5), 210 (M^+, 10), 165 (17), 153 (11), 123 (100), 122 (79), 95 (56). Found: C, 68.50; H, 8.69%. Calcd for $C_{12}H_{18}O_3$: C, 68.55; H, 8.63%.

Z-Isomer: IR (neat) 1740, 1695, 1635 cm^{-1}; NMR (CCl_4) δ 1.24 (t, J=7.0 Hz, 3H), 1.80 (d, J=7.5 Hz, 3H), 1.70—1.94 (m, 4H), 2.30 (m, 4H), 2.69 (m, 1H), 4.05 (q, J=7.0 Hz, 2H), 5.65 (qd, J=7.5 and 1.4 Hz, 1H); MS *m/e* (%) 211 (3), 210 (M^+, 8), 165 (16), 153 (11), 123 (100), 122 (77), 95 (55). Found: C, 68.49; H, 8.68%. Calcd for $C_{12}H_{18}O_3$: C, 68.55; H, 8.63%.

The authors wish to thank the Ministry of Education, Science and Culture, Japan, for the Grant-in-Aid (403022).

Fluorination with Xenon Difluoride. 23. Fluorination of Ortho Substituted Aromatic Molecules

Boris Šket and Marko Zupan*

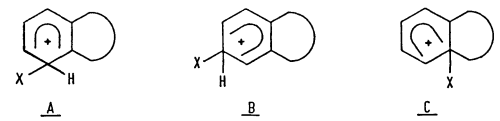
Department of Chemistry and "Jožef Stefan" Institute, Edvard Kardelj University of Ljubljana, Ljubljana, Yugoslavia

(Received March 14, 1980)

The fluorination of 9,10-dihydroanthracene and triptycene with xenon difluoride in the presence of hydrogen fluoride occurred at α and β position with β attack predominating over α attack, while the reaction with acenaphthene resulted in the formation of 2- and 4-fluorosubstituted products, regioselectivity being very little affected by the nature of the catalyst: hydrogen fluoride, boron trifluoride and pentafluorothiophenol. The fluorination of 1,2,3,4-tetrahydro-1,4-methanonaphthalene resulted in the formation of 6-fluoro-1,2,3,4-tetrahydro-1,4-methanonaphthalene, 6,7-difluoro-1,2,3,4-tetrahydro-1,4-methanonaphthalene and rearranged product 1-(2,2-difluoroethyl)indan.

It has been demonstrated that xenon difluoride is a mild fluorinating agent for the fluorination of alkenes, acetylenes, aromatic and heteroaromatic molecules, which has been recently reviewed.[1] It is known that the mechanism of the fluorination of organic molecules with xenon difluoride depends on the following factors: the structure of the molecules, the catalyst used, solvent polarity and temperature, and the formation of free radical intermediates, ion radical intermediates and fluorocarbonium ions has been suggested. It has been demonstrated that the following substrates are convenient catalyst: hydrogen fluoride, hydrogen fluoride–pyridine, trifluoroacetic acid, boron trifluoride etherate, boron trifluoride, pentafluorothiophenol, and bromine.

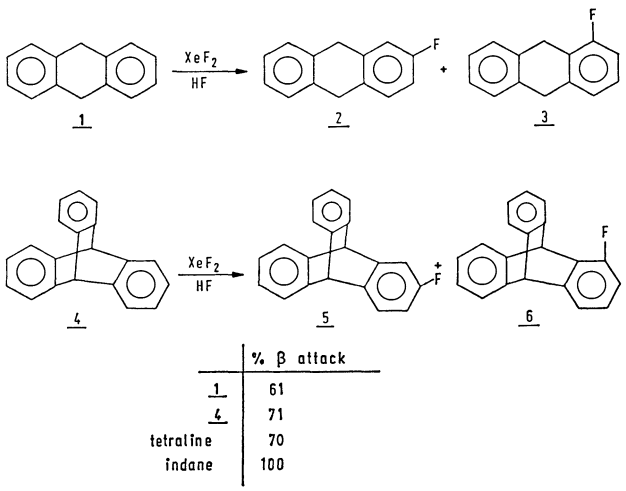
The electrophilic substitution reactions of ortho substituted aromatic molecules received considerable attention from different points of view.[2] There are three possible attacks of electrophilic agent which leads to α, β, or ipso substituted products. The regioselectivity of the substitution depends on the nature of the substituents on the ortho position. We have recently found[3] that the regioselectivity in fluorination of indan, tetralin, and *o*-xylene with XeF_2 has been explained by differences in the stabilization of carbonium ions A and B (Scheme 1) formed after α and β attack of electrophile. We now report results of further investigations on the effect of the structure of orthosubstituted aromatic molecules on regioselectivity in fluorination reactions with xenon difluoride.



Scheme 1.

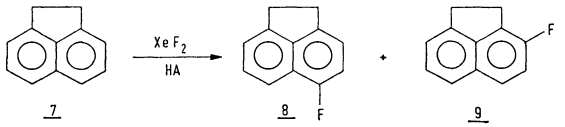
Results and Discussion

Under conditions usually used for the fluorination of organic molecules (1 mmol of organic substrate in 2—5 ml of dichloromethane, 1 mmol of xenon difluoride and hydrogen fluoride as catalyst), polymeric materials resulted in the case of 9,10-dihydroanthracene (**1**), triptycene (**4**), and acenaphthene (**7**). We have found that a much higher dilution (50 ml of solvent for 1 mmol of substrate) must be used. The reaction with 9,10-dihydroanthracene (**1**, Scheme **2**) was completed in 20 min and the reaction mixture was isolated by the usual work-up procedure. The crude reaction mixture shows in its ^{19}F NMR two signals: −126 ppm (dd, 39%) and −137.7 ppm (m, 61%). The products were separated by preparative TLC: 2-fluoro-9,10-dihydroanthracene (**2**), and 1-fluoro-9,10-dihydroanthracene (**3**) were isolated. The fluorination of triptycene (**4**) resulted also in the formation of two products: 2-fluorotriptycene (**5**) and 1-fluorotriptycene (**6**), separated by preparative TLC. It can be seen (Scheme 2) that the regioselectivity of the fluorine attack on triptycene is very similar to that in tetralin,[3] while in the case of 9,10-dihydroanthracene a lower regioselectivity was observed. In both cases, the yields of isolated products (**2**, **3**, **5**, and **6**) were considerably lower than those reported for the fluorination of indan or tetralin,[3] which can be ascribed to a significant amount of polymeric materials formed.



Scheme 2.

The fluorination of acenaphthene (**7**, Scheme 3) must be also carried out in a higher dilution than usual and this resulted in the formation of two products. The structures of the products 3-fluoroacenaphthene (**9**) and 5-fluoroacenaphthene (**8**) were established on the basis of the spectroscopic data, which are in agreement with those in the literature.[5] We have also studied the effect of catalyst (Scheme 3, relative yields) on the regioselec-

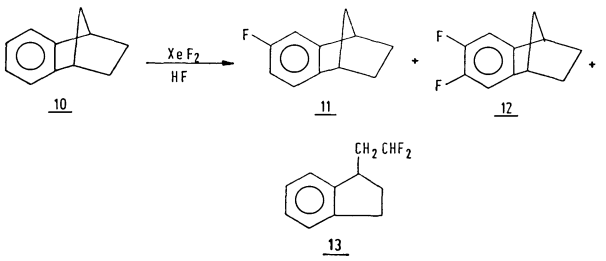


HA	% 8
HF	74
BF_3	74
C_6F_5SH	70

Scheme 3.

tivity of the substitution and found that it is very little influenced. However, it reflected on the yields of products formed. The reaction in the presence of hydrogen fluoride resulted in 50% formation of products **8** and **9**, while the reaction catalyzed by boron trifluoride resulted in only 20% formation of **8** and **9** and was accompanied by a higher amount of polymeric material. The reaction in 50 ml of dichloromethane and in the presence of pentafluorothiophenol was very slow, while the reaction in 10 ml of dichloromethane gave results comparable to those found by HF-catalyzed reaction in a higher dilution (50 ml of dichloromethane).

The fluorination of 1,2,3,4-tetrahydro-1,4-methanonaphthalene (**10**, Scheme 4) resulted in the formation of three products. ^{19}F NMR spectrum of the crude



Scheme 4.

reaction mixture shows three signals: −116 ppm (dt, 26%), −118 ppm (m, 63%), and −142.5 ppm (t, 11%). The products were isolated by preparative GLC, and on the basis of spectroscopic data we have established that the lowest signal in ^{19}F NMR corresponds to 1-(2,2-difluoroethyl)indan (**13**); the next signal to 6-fluoro-1,2,3,4-tetrahydro-1,4-methanonaphthalene (**11**), and the last signal to 6,7-difluoro-1,2,3,4-tetrahydro-1,4-methanonaphthalene (**12**).

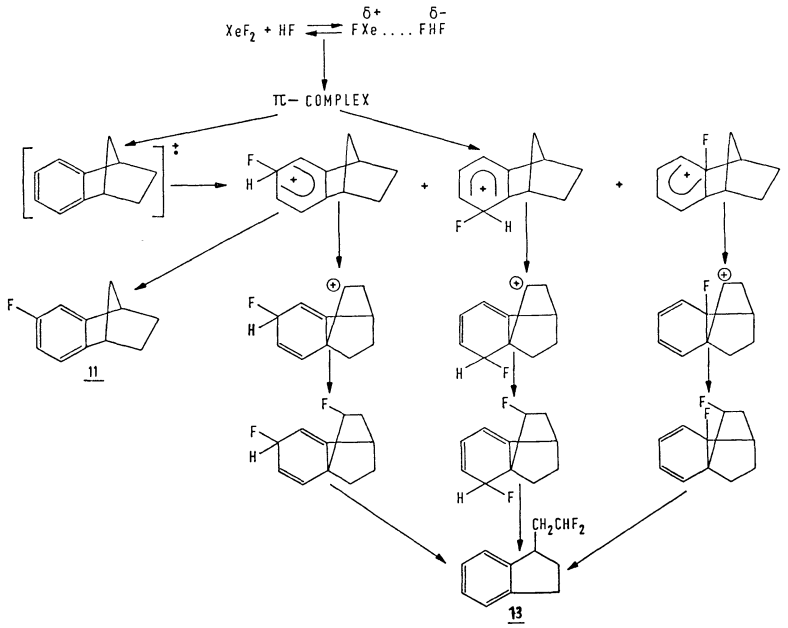
The mechanism of the fluorination with xenon difluoride is very similar to those already suggested.[3] However, on Scheme 5, three possible pathways which can explain the formation of rearranged 1-(2,2-difluoroethyl)indan (**13**) formed by the fluorination of **10**, are presented. The rearranged product could result from three different intermediates, formed after α, β, or ipso attack, followed by a two-step rearrangement.

Experimental

IR spectra were recorded by using a Perkin-Elmer 727 B spectrometer and ^1H and ^{19}F NMR spectra by JEOL-JNM-PS 100 from CCl_4 or $CDCl_3$ solutions with Me_4Si or CCl_3F as internal reference. Mass spectra and high resolution measurements were taken on a CEC 21-110 spectrometer. Gas liquid partition chromatography was carried out on Varian Aerograph Model 1800 and TLC on Merck PSC Fertigplatten Silica gel F 254 (activated for 3 h at 120 °C before use).

Materials. 9,10-Dihydroanthracene and acenaphthene are commercially available and were crystallized before use. Triptycene[6] and 1,2,3,4-tetrahydro-1,4-methanonaphthalene[7] were synthesized. Hydrogen fluoride and boron trifluoride of Fluka Purum quality were used without further purification. Dichloromethane was purified[8] and stored over molecular sieves. Xenon difluoride was prepared by a photosynthetic method[9] and its purity was higher than 99.5%.

1-Fluoro-9,10-dihydroanthracene (3) and 3-Fluoro-9,10-dihydroanthracene (2). To a solution of 1 mmol of **1** in dichloromethane (50 ml), 1 mmol of xenon difluoride was added at



Scheme 5.

25 °C and, under stirring, a catalytic amount of HF was introduced into the reaction mixture. After a few seconds, the colorless solution turned dark blue and xenon gas slowly evolved. After 20 min the gas evolution ceased and the reaction appeared to be complete. The reaction mixture was washed with 10 ml of 5% $NaHCO_3$ aq solution and water, and dried over anhydrous sodium sulfate. The solvent was evaporated *in vacuo*. The crude reaction mixture was separated by preparative TLC (cyclohexane: chloroform=9: 1). 2-Fluoro-9,10-dihydroanthracene (**2**): 42 mg (21%), mp 112—114 °C, NMR spectra: δF=−137.7 ppm, δH=3.2 ppm (broad s, 4H), 7.0—8.1 ppm (m, 7H); mass spectrum: *m/e* 198 (M^+, 100%), 197 (23), 196 (18), 184 (24), 183 (17), 165 (28), 163 (17), 135 (33), 133 (28), 122 (89), 119 (22), 117 (22), 96 (10). Found: C, 84.64; H, 5.29%. Calcd for $C_{14}H_{11}F$: C, 84.82; H, 5.59%. 1-Fluoro-9,10-dihydroanthracene (**3**): 18 mg (9%), mp 76—78 °C, NMR spectra: δF=−126 ppm, δH=3.14 ppm (broad s, 4H), 7.1—8.3 ppm (m, 7H); mass spectrum: *m/e* 198 (M^+, 100%), 197 (23), 184 (21), 183 (24), 135 (35), 133 (22), 123 (25), 122 (64), 109 (72), 96 (25). Found: C, 84.62; H, 5.28%. Calcd for $C_{14}H_{11}F$: C, 84.82; H, 5.59%.

*1-Fluorotriptycene (**6**) and 2-Fluorotriptycene (**5**).* The fluorination and work-up procedure were essentially the same as described for **2** and **3**. The products were separated by preparative TLC (petroleum ether: $CHCl_3$=19: 1). 1-Fluorotriptycene (**6**): 34 mg (12%), mp 243—245 °C, (lit,[10] mp 246—247 °C), NMR spectra: δF=−120 ppm (m), δH=5.4 ppm (d, J=1.5 Hz, 1H), 5.75 ppm (broad s, 1H), 6.6—7.5 ppm (m, 11H); mass spectrum: *m/e* 272 (M^+, 100%), 271 (35), 196 (77), 195 (45), 180 (37), 179 (45), 135 (38), 123 (18), 122 (42), 120 (58), 102 (32), 77 (42), 76 (35). 2-Fluorotriptycene (**5**): 64 mg (23%), mp 228—230 °C (lit,[11] mp 232—234 °C), NMR spectra: δF=−122.25 ppm (m), δH=5.3 ppm (broad s, 2H), 6.6—7.6 ppm (m, 11H); mass spectrum: *m/e* 272 (M^+, 100%), 271 (42), 197 (25), 196 (87), 195 (43), 180 (16), 179 (33), 135 (29), 122 (21), 120 (79), 119 (26), 117 (26), 102 (39), 77 (17), 76 (46).

*3-Fluoroacenaphthene (**9**) and 5-Fluoroacenaphthene (**8**).* To a solution of 1 mmol of **7** in dichloromethane (50 ml in the case of HF, BF_3, and C_6F_5SH catalyzed reaction, and 10 ml in the second experiment catalyzed by C_6F_5SH), 1 mmol of xenon difluoride was added at 25 °C and, under stirring, a trace amount of catalyst (HF or BF_3, and 1 mmol in the case of C_6F_5SH) was introduced into the reaction mixture. After the work-up procedure, the crude reaction mixture was analyzed by ^{19}F NMR, and the relative yields of products **8** and **9** are presented in Scheme 3. We were unable to separate the two isomers, although many different stationary phases in GLC and various solvent systems in TLC were examined. Both isomers were purified by preparative GLC (FFAP-10%, Crom AW, T=120 °C) and the following percentages of the mixture of **8** and **9** were isolated: 50% in the case of HF-catalyzed reaction, 20% in the case of BF_3, and 45% in the case of C_6F_5SH. The reaction mixture shows in its ^{19}F NMR spectrum two signals: δF=126.75 ppm ($\delta F_{1\text{lt}}$=−123.58 ppm for 3-fluoroacenaphthene (**9**)[5] and −134.25 ppm ($F_{1\text{lt}}$=−131.44 ppm for 5-fluoroacenaphthene (**8**)[5]).

*Fluorination of 1,2,3,4-Tetrahydro-1,4-methanonaphthalene (**10**).* The fluorination and work-up procedure were essentially the same as described for **2** or **3**. Products were separated by preparative GLC (FFAP-10%, Crom AW, T=130 °C). 6-Fluoro-1,2,3,4-tetrahydro-1,4-methanonaphthalene (**11**): 52 mg (32%) of volatile liquid product, NMR spectra: δF=−118 ppm (m, J=10.5 Hz and 6 Hz), δH=1.2 ppm (m, 2H), 1.75 ppm (m, 4H), 3.3 ppm (broad s, 2H) and 6.8 ppm (m, 3H); mass spectrum, Calcd for $C_{11}H_{11}F$ *m/e* 162.0844, Found 162.0849, *m/e*: 162 (M^+, 47%), 150 (13), 147 (31), 146 (21), 135 (20), 134 (100), 133 (74), 121 (12), 119 (36), 117 (54), 116 (34), 115 (32), 84 (14), 63 (12), 57 (14). 6,7-Difluoro-1,2,3,4-tetrahydro-1,4-methanonaphthalene (**12**): 13 mg (7%) of volatile liquid product, NMR spectra: δF=−142.5 ppm (*t*, J=9 Hz), δH=1.2 ppm (m, 2H), 1.75 ppm (m, 4H), 3.3 ppm (broad s, 2H), 6.9 ppm (m, 2H); mass spectrum, Calcd for $C_{11}H_{10}F_2$ *m/e* 180.0767, Found: 180.0774, *m/e* 180 (M^+, 26%), 165 (16), 162 (42), 152 (75), 151 (30), 147 (18), 146 (14), 134 (63), 133 (32), 116 (100), 115 (44), 56 (30). 1-(2,2-Difluoroethyl)indan (**13**): 18 mg (10%) of volatile liquid product, NMR spectra: δF=−116.25 ppm (dt, J=60 Hz and 15 Hz), δH=1.8 (m, 2H), 2.31 ppm (tdd, J=15 Hz, 6 Hz and 6 Hz, 2H), 2.85 ppm (t, J=6 Hz, 2H), 3.27 ppm (m, 1H), 5.82 ppm (tt, J=60 Hz and 6 Hz, 1H), 7.05 ppm (m, 4H); mass spectrum: Calcd for $C_{11}H_{12}F_2$ *m/e* 182.0907, Found 182.0896, *m/e*: 182 (M^+, 16%), 117 (100), 116 (16), 115 (36), 91 (16), 51 (15).

We thank Prof. J. Slivnik for the xenon difluoride.

Excess Thermodynamic Functions of the Systems Cyclohexane+Isomeric Xylenes

Eyunni RAJAGOPAL and Saraswatula Venkata SUBRAHMANYAM*

Department of Physics, SVU Autonomous Post-Graduate Centre, Anantapur 515 003, India

(Received January 7, 1980)

The excess volumes V^E, excess heat capacities C_P^E and excess isothermal compressibilities β_T^E of cyclohexane+isomeric xylenes have been determined at 25, 40, and 50 °C. The results are discussed in the light of Flory's theory.

Studies on the excess thermodynamic functions of binary liquid mixtures throw considerable light in understanding the nature of molecular interactions. In these laboratories we have taken up a systematic study of the thermodynamic behaviour of a large number of binary mixtures containing reasonably simple molecules and test of the applicability of Flory's theory.[1,2] The present paper deals with the studies on the thermodynamic behaviour of the binary mixtures of *o*-xylene, *m*-xylene, and *p*-xylene with cyclohexane which form an interesting series of systems involving similar molecular structures which interact very weakly. The excess volumes V^E, excess heat capacities C_P^E, and the excess isothermal compressibilities β_T^E of the above binary systems have been studied and the results are analysed on the basis of Flory's theory.[3]

Experimental

Analytical reagent grade cyclohexane, *o*-xylene, *m*-xylene, and *p*-xylene were purified according to the standard procedures.[4] The densities of the purified samples determined at 25 °C using bicapillary type pycnometer with an accuracy of 2 in 10^5 are 0.77383, 0.87593, 0.85987, and 0.85673 g cm^{-3} respectively for cyclohexane, *o*-xylene, *m*-xylene, and *p*-xylene. These values are in good agreement with those reported in the literature.[5,6]

The excess volumes were measured directly using a mixing cell with an accuracy of ± 0.002 cm^3 mol^{-1}. The molar heat capacities at constant pressure were measured using an adiabatic calorimeter with an accuracy of $\pm 0.3\%$. Ultrasonic velocity in pure liquids and in binary mixtures was determined using a single crystal variable path interferometer working at 3MHz with an accuracy of $\pm 0.01\%$. The details of the above experimental techniques were discussed in our earlier communications.[1,2] The coefficient of thermal expansion (α) of pure liquids and their mixtures were determined from the experimentally determined density data at an interval of 5 °C in the range 20 to 60 °C.

Results

The experimental results of pure liquids are given in Table 1, along with literature values for comparison. The agreement between the two sets of values is quite good. The experimentally determined excess volume data (as many as a 15 sets of V^E values are obtained at each temperature covering the entire concentration range) of the binary mixtures of *o*-xylene,

m-xylene, and *p*-xylene with cyclohexane were fitted to the equation of the form

$$V^E/x_1x_2 = [a_0+a_1(x_2-x_1)+a_2(x_2-x_1)^2], \quad (1)$$

where x_1 and x_2 are the mole fractions of cyclohexane and xylenes respectively. Values of the coefficients determined using the method of least squares are listed in Table 2. The last column of the table contains values of σ, the standard deviation of the fit in each case. The excess volumes of these systems were studied previously by Reddy *et al.*[8] and Jain *et al.*[7] The accuracy of the experimental excess volumes reported by Reddy *et al.*[8] is ± 0.05 cm^3 mol^{-1}. Further they have studied the *p*-xylene system at 32.5 °C, *m*-xylene system at 34 °C, and *o*-xylene system at 35 °C. In view of this, a direct comparison with the values of the present investigation has not been attempted. The excess volumes of Jain *et al.*[7] are slightly higher than the present ones. However no importance has been given to this discrepancy since Jain *et al.*[7] have not stated the errors involved in their measurements. The results of measurement of u, C_p, α, and β_T of binary mixtures of cyclohexane with isomeric xylenes are presented in Table 3.

Discussion

The experimental excess functions are examined in this section for the binary mixtures in the light of Flory's theory. The excess functions V^E, H^E, and β_T^E are related to the properties of pure components *via* the relations

$$H^E = x_1v_1{}^*p_1{}^*\left(\frac{1}{\tilde{v}_1}-\frac{1}{\tilde{v}}\right) + x_2v_2{}^*p_2{}^*\left(\frac{1}{\tilde{v}_2}-\frac{1}{\tilde{v}}\right) + x_1v_1{}^*\theta_2X_{12}/\tilde{v} \quad (2)$$

$$\beta_T^E = \frac{3\tilde{v}^2(\tilde{v}^{1/3}-1)}{p^*[1-3(\tilde{v}^{1/3}-1)]} - \frac{1}{\tilde{v}}[\phi_1\tilde{v}_1\beta_{T_1}+\phi_2\tilde{v}_2\beta_{T_2}] \quad (3)$$

$$p^* = \phi_1p_1{}^* + \phi_2p_2{}^* - \phi_1\theta_2X_{12} = \frac{T\tilde{v}^{4/3}}{(\tilde{v}^{1/3}-1)}\left[\frac{\phi_1p_1{}^*}{T_1{}^*}+\frac{\phi_2p_2{}^*}{T_2{}^*}\right], \quad (4)$$

where

$$\tilde{v} = \phi_1\tilde{v}_1 + \phi_2\tilde{v}_2 + V^E/(x_1v_1{}^*+x_2v_2{}^*), \quad (5)$$

where v_1 and v_2 are the reduced volumes, $v_1{}^*$ and $v_2{}^*$ are the characteristic volumes, $p_1{}^*$ and $p_2{}^*$ are the characteristic pressures, and β_{T1} and β_{T2} are the isothermal compressibilities of the pure components. $\tilde{v}$, p^*, and θ_2 X_{12} are the reduced volume, characteristic pressure and the interaction energy parameter respectively of the mixture.

The interaction energy parameter of the mixture X_{12} which is a measure of the difference of interaction energy between the unlike pairs and the mean of like pairs, can be evaluated using any experimental excess function. This value of X_{12} can be used to evaluate theoretically the other excess functions. The interaction energy term involves implicitly in the expression for V^E and explicitly in that for H^E. Hence it may appear logical to evaluate X_{12} using H^E rather than V^E data. However in view of the higher accuracy of the experimental V^E data and its availability over comparatively wide temperature and concentration range X_{12} has been evaluated *via* V^E in the present work.

According to Flory's theory at any given temperature X_{12} should be a constant independent of the composition of the mixture. An examination of the data presented in Table 4 indicates that X_{12} is reasonably constant at

any particular temperature. Hence the mean value of X_{12} is used to evaluate the excess functions at any given temperature.

The theoretically evaluated excess isothermal compressibilities β_T^E using Eq. 3 are compared with the experimental β_T^E in Table 4. The agreement between the two sets of data is not satisfactory. This disagreement may be attributed to the slight polarity of xylenes. Similar disagreement was also noticed between theoretical and experimental excess parameters of benzene+isomeric xylenes[9] and toluene+isomeric xylenes.[10]

In view of non availability of experimental H^E data for the systems under study at all temperatures and concentrations an attempt is made however to compare the data at 25 °C for equimolar concentrations as can be seen from Table 5. The agreement is not quite good reflecting the inadequacy of Flory's theory in predicting excess functions for these systems under study.

TABLE 5. COMPARISON OF EXPERIMENTAL AND THEORETICAL EXCESS HEATS FOR EQUIMOLAR SOLUTIONS AT 25 °C

TABLE 6. COMPARISON OF EXPERIMENTAL AND THEORETICAL EXCESS HEAT CAPACITIES FOR EQUIMOLAR MIXTURES ($x_2 \simeq 0.5$) AT 37.5 °C

System	C_P^E/J K^{-1} mol^{-1} Exptl	Calcd
Cyclohexane+*o*-Xylene	0.7±0.5	1.7±0.8
Cyclohexane+*m*-Xylene	−1.0±0.5	−1.7±0.8
Cyclohexane+*p*-Xylene	−1.3±0.8	−0.9±0.5

Flory's theory is also useful in predicting the excess heat capacities. The excess heat capacities are related to excess enthalpies *via* the relation

$$C_P^E = \left(\frac{\partial H^E}{\partial T}\right)_p \qquad (6)$$

using Eq. 2 excess enthalpies have been evaluated at 25, 40, and 50 °C. $(\partial H^E/\partial T)_P$ has been evaluated using H^E data at 25 and 50 °C which gives the value of C_P^E at 37.5 °C. The value of C_P^E so evaluated at 37.5 °C for the equimolar solutions are compared in Table 6, with C_P^E values obtained by intrapolating the experimental C_P^E data which are given in Table 4. The agreement between experimental and theoretical C_P^E values is quite good.

Modified Method for the Determination of Stoichiometry and Formation Constant of Molecular Complexes by Differential Refractometry

Ram SAHAI* and Vinod SINGH
Department of Chemistry, V.S.S.D. College, Kanpur University, Kanpur-208002, India
(Received March 17, 1980)

A modified method has been proposed for the determination of stoichiometry and formation constant of molecular complexes by Job method using differential refractometry. A more adequate model has been presented and has been verified on some strong, moderate, and weak systems in different solvents at 35 °C. The formation constants obtained by this method are in good agreement with the literature values.

Recently we have applied the differential refractometric method[1,2] in Yoshida and Ōsawa's equation[3,4] to determine the stoichiometry and formation constant of molecular complexes which has yielded better results. In Yoshida and Ōsawa's method[5] two experimental sets are essential to calculate the equilibrium constant of a molecular complex. In this communication an attempt has been made to calculate the equilibrium constant of these complexes by using only one experimental set. For this purpose differential refractometry has been applied in Job method and a model has been developed which has been verified on strong as well as on weak molecular complexes.

We realize that in molecular complexes from acceptor, A, and donor, D, when $1:n$ complex is formed, it usually is accompanied by the formation of 1:1, 1:2,---, $1:n-1$ complexes. At this we have,

$$A + nD \overset{K_n}{\rightleftharpoons} AD_n \quad (n>1) \tag{1}$$

and

$$K_n = C_{AD_n}/C_A C_D n = C_{AD_n}/(C_A^\circ - C_{AD_n})(C_D^\circ - nC_{AD_n})^n. \tag{2}$$

Let us assume, V_A and V_D are the volumes of A and D respectively, and $V=V_A+V_D$. Then the total concentration C_T is given by

$$C_T = 1/V(V_A C_A^1 + V_D C_D^1) = 1/V[(V-V_D)C_A^1 + V_D C_D^1], \tag{3}$$

where C_A^1 and C_D^1 represent the concentration of the stock solution of A and D, respectively. From Eq. 2 we have

$$\begin{aligned} C_{AD_n} &= K_n(C_A^\circ - C_{AD_n})(C_D^\circ - nC_{AD_n})^n \\ &= K_n[(1-V_D/V)(C_A^1 - C_{AD_n})] \times [V_D/VC_D^1 - nC_{AD_n}]^2. \end{aligned} \tag{4}$$

Let $V_D/V=v$ and $C_D^1/C_A^1=r$. Then

$$C_{AD_n} = K_n[(1-v)(C_A^1 - C_{AD_n})](vC_A^1 r - nC_{AD_n})^n. \tag{5}$$

To find the maximum value of C_{AD_n} by varying v, we calculate

$$\frac{1}{C_{AD}} \cdot \frac{\partial C_{AD_n}}{\partial v} = \frac{-C_A^1 - \partial C_{AD_n}/\partial v}{(1-v)C_A^1 - C_{AD_n}} + n\frac{rC_A^1 - n\partial C_{AD_n}/\partial v}{vrC_A^1 - nC_{AD_n}}. \tag{6}$$

Setting $\partial C_{AD_n}/\partial v=0$, we obtain

$$C_{AD_n}^{n(r-1)} = rC_A^1[v-n(1-v)]. \tag{7}$$

We chose $r=1$, then

$$v = n/(1+n);\ C_T = C_D^1 = C_A^1. \tag{8}$$

In refractometric measurements, we assumed that the refraction per cm³ of solution is due to the complexed and free acceptor refractions which may be expressed as,

$$\phi = \left(\frac{C_A^\circ - C_{AD_n}}{C_A^\circ}\right)\phi_{CD} + \frac{C_{AD_n}}{C_A^\circ}\phi_{AD}. \tag{9}$$

where $\phi_{CD}=\phi-\phi_D$, and solving Eq. 9 we get,

$$C_{AD_n}/C_A^\circ = \phi_D/(\phi_{AD}-\phi_{CD}). \tag{10}$$

Now assuming $\phi_{AD}-\phi_{CD}=\Delta\phi_{AD}$; the maximum refraction per cm³ of complex which may be calculated from the plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes.† Thus Eq. 10 becomes,

$$C_{AD_n} = \phi_D/\Delta\phi_{AD}C_A^\circ. \tag{11}$$

Therefore, if C_{AD_n} is a maximum, then $\phi_D/\Delta\phi_{AD}C_A^\circ$ would also be maximum at $v=n/(1+n)$. Thus by plotting $\phi_D C_A^\circ$ (or $\phi_D/\Delta\phi_{AD}C_A^\circ$) against X_D (mole fraction of donor), the maximum will occur at $X_D=n/(1+n)$ (Fig. 1). At this point we have,

TABLE 1. EQUILIBRIUM CONSTANT (K_1) DATA FOR SOME STRONG, MODERATE AND WEAK MOLECULAR COMPLEXES AT 35 °C

Complex	Solvent	K_1/dm³ mol⁻¹		
		From Eq. 12	Spectrophotometric method	
			K_1	T/°C
Ethanol–naphthalene	Cyclohexane	2.7±0.2		
Phenol–naphthalene	Cyclohexane	4.0±0.2		
Ph_3N–I_2	Cyclohexane	9.2±1.0	12.5 (9)[a]	26
Tryptophan–chloranil	50% aq ethanol	149.0±10.0	176.0 (10)[a]	25
Dimethyl sulfide–I_2	Heptane	178.0±10.0	200.0 (9)[a]	25
Pyridine–I_2	Heptane	257.0±15.0	290.0 (9)[a]	25
Ph_3As–I_2	CCl_4	714.0±25.0	790.0 (11)[a]	30

a) Number in parentheses indicates the reference number.

† The values of ϕ, ϕ_D, ϕ_A, and $\Delta\Omega C_{DA}$ have been calculated as reported earlier.[6-8]

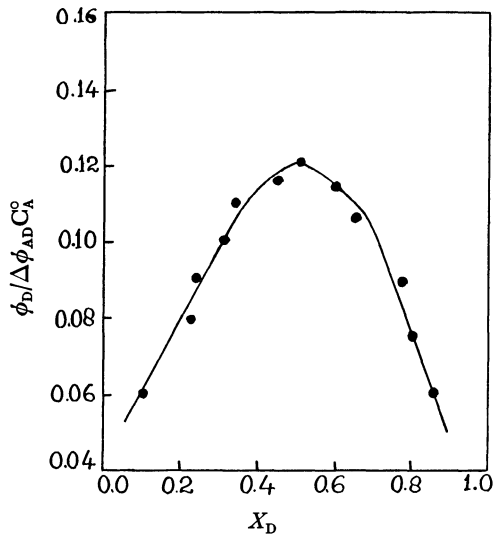

Fig. 1. A plot of X_D *versus* $\phi_D/\Delta\phi_{AD}C_A^\circ$ indicating 1 : 1 stoichiometry of phenol–naphthalene complex.

$$K_n = (\phi_D/\Delta\phi_{AD})/(C_D^\circ)^n(1-\phi/\Delta\phi_{AD})^{n+1} \quad (12)$$

where $C_D^\circ = X_D C_T = n/(1+nC_T)$. Equation 12 has been used to calculate equilibrium constant (K_n) after determining n. Thus the K values calculated for some strong and weak 1 : 1 complexes are listed in Table 1. From this Table it is evident that the K values calculated from Eq. 12 are in good agreement with the spectrophotometric values. The present method involves an experimental simplicity because for one system only one experimental set is sufficient to calculate K but in Yoshida and Ōsawa's and differential refractometric methods, two experimental sets are necessary to get K values.

One of us (VS) is thankful to Kanpur University, Kanpur for providing U. G. C. fellowship. Authors are also thankful to Prof. P. C. Nigam (I. I. T., Kanpur) for providing some experimental facilities.

Determination of the Difference in Hard-sphere Volume of Conformational Isomers from Sound Velocity

Masakatsu Aoi and Kiyoshi Arakawa*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received April 11, 1980)

Synopsis. The difference in hard-sphere volume of conformational isomers $\Delta V/V$ was determined from sound velocity data by a method proposed on the basis of the Lebowitz theory of solutions. The $\Delta V/V$ values between conformers were found to be 6, 9, 12, 7, and 12% for 1,1,2,2-tetrachloroethane, 1,1,2,2-tetrabromoethane, 1-chloropropane, 1-bromopropane, and ethylcyclohexane, respectively.

We proposed an ultrasonic method suitable for the determination of the difference in hard-sphere volume of conformational isomers ($\Delta V/V$) from sound velocity data,[1] based on the Lebowitz theory,[2] and applied the method to halogenoethanes and cyclohexane derivatives[1b] as typical compounds with conformational isomerism.[3-6]

In order to obtain further information on $\Delta V/V$ of conformational isomers, 1,1,2,2-tetrachloroethane ($CHCl_2CHCl_2$), 1,1,2,2-tetrabromoethane ($CHBr_2CHBr_2$), 1-chloropropane ($CH_3CH_2CH_2Cl$), 1-bromopropane ($CH_3CH_2CH_2Br$), and ethylcyclohexane (*c*-$C_6H_{11}C_2H_5$) have been investigated.

An equilibrium mixture of conformational isomers we studied is considered to be a binary mixture of hard spheres. The formula for isothermal compressibility (κ_T) of the equilibrium mixture was derived from the equation of state for the binary mixture of hard spheres.[2] Details of the procedure for analysis were described in the preceding paper,[1b] notations used here being identical with those in it.

For the case of *c*-$C_6H_{11}C_2H_5$, the relaxation frequency f_r is smaller than the frequency f used for the measurement of sound velocity.[7] In this case, κ_T is expressed by

$$\kappa_T = \left[\frac{RT(1+2\xi)^2}{V(1-\xi)^4} - \frac{2}{V}(\Delta H_v - RT)\right]^{-1}. \quad (1)$$

For CHX_2CHX_2 and $CH_3CH_2CH_2X$[5,8,9] ($f_r \gg f$), κ_T is given by

$$\kappa_T = \left[\frac{RT(1+2\xi)^2}{V(1-\xi)^4} - \frac{2}{V}(\Delta H_v - RT)\right]^{-1} + \frac{V(\Delta V/V)^2}{2RT\{1+\cosh(\Delta G/RT)\}}. \quad (2)$$

$\Delta V/V$ is expressed by

$$\frac{\Delta V}{V} = \frac{N_A}{\xi V}(v_2 - v_1) = \frac{v_2 - v_1}{v_a}, \quad (3)$$

where ξ is packing fraction ($=\rho v_a$), v_a average hard-sphere volume, and v_i hard-sphere volume of the i-th component. Putting the experimental values of κ_T into Eq. 1 or Eq. 2, we determine the magnitudes of v_a, v_1, and $\Delta V/V$. The temperature coefficient α_t of the effective hard-sphere volume was calculated in a similar manner to that reported.[1b]

Experimental

Sound velocity v was measured with an interferometer working at 3 MHz and density d with a pycnometer. The temperature was controlled within ±0.05 °C. Samples were carefully purified before measurements. The accuracy of v is ±0.3 m/s. Adiabatic and isothermal compressibilities (κ_S and κ_T) were estimated from density, sound velocity, and other thermodynamic quantities.

Results and Discussion

Values of d, v, κ_S, and κ_T determined for CHX_2CHX_2, $CH_3CH_2CH_2X$ (X=Cl and Br), and c-$C_6H_{11}C_2H_5$ are summarized in Table 1. The results for v_a and $\Delta V/V$ are given in Table 2, together with values of α, C_p, ΔH_v, and ΔH required for the determination of v_a and $\Delta V/V$. Values of α_t were estimated to be −1.6, −1.3, −2.0, −1.9, and -1.7×10^{-4} K^{-1} for $CHCl_2$-$CHCl_2$, $CHBr_2CHBr_2$, $CH_3CH_2CH_2Cl$, $CH_3CH_2CH_2Br$, and c-$C_6H_{11}C_2H_5$, respectively.

It was found from the negative value of $\Delta V/V$ (Table 2) that the value of v_1 is larger than that of v_2. For CHX_2CHX_2 and $CH_3CH_2CH_2X$, v_1 corresponds to the *anti* form, and to the equatorial form for c-$C_6H_{11}C_2H_5$. Wyn-Jones *et al.*[6] and Christian *et al.*[10] also reported similar results for $CHCl_2CH_2Cl$ by means of the ultrasonic absorption method and the pressure effect of infrared spectroscopy. In the case of CHX_2-CHX_2, the value of $|\Delta V/V|$ for chloro compound is smaller than that for bromo compound, while it is reversed for $CH_3CH_2CH_2X$ and CH_2XCH_2X.[1b]

For c-$C_6H_{11}C_2H_5$, the magnitude of $\Delta V/V$ (12%) is nearly equal to that of c-$C_6H_{11}CH_3$ (11%).[1b] It agrees with the results of c-$C_6H_{11}CH_3$[1b] and c-$C_6H_{11}X$ reported by Christian *et al.*[10] that the equatorial form was found to be larger than the axial one.

Our method is convenient and accurate for the determination of $\Delta V/V$ in conformational isomerism, as compared with the ultrasonic absorption method[6] used so far.

(Received March 22, 1980)

Synopsis. *cyclo*-Tetraphosphate (P_{4m}) reacted with L-valine at pH 12 to form a certain phosphorus-containing compound (Compound X). Compound X was obtained in amounts so small as about 3.2% at room temperature after 91 d and about 0.3% at 70 °C after 1 d. Based on the results of paper chromatography, anion-exchange chromatography, and IR spectroscopy, Compound X was proved to be the same orthophosphate derivative of valine, an anion of *N*-(1-carboxy-2-methylpropyl)phosphoramidic acid, as that formed by the reaction of *cyclo*-triphosphate (P_{3m}) with L-valine. The mechanism of the reaction of P_{4m} with L-valine was discussed.

Quimby and Flautt[1] first reported that cyclic phosphates, such as P_{3m}, could be subjected to ring opening with ammonia to form amidophosphates. Since then, the reactions of P_{3m} with alkylamines,[2,3] sodium fluoride,[4] alcohols,[5] and glycine[6] have been actively studied by Feldmann and Rabinowitz. The present authors have already reported that, by the reaction of P_{3m} with L-valine one of the α-amino acids, a P_1-derivative of valine, was produced in the pH range from 10 to 12.[7] Thus, in the present study, the reaction of P_{4m}, one of cyclic phosphates, with L-valine was investigated.

Experimental

Chemicals. Sodium *cyclo*-tetraphosphate tetrahydrate,[8] $Na_4P_4O_{12}\cdot 4H_2O$, was prepared in the following manner: 50 g of diphosphorus pentaoxide was gradually hydrolyzed in 300 cm^3 of cold water, after which the hydrolyzate was neutralized to pH 7 with a cold, concentrated sodium hydroxide solution. Then, by repeating the recrystallization 5 times from water and drying at 40 °C, $Na_4P_4O_{12}\cdot 4H_2O$ was obtained. Reagent-grade L-valine was used without purification.

Reaction between cyclo-*Tetraphosphate and* L-*Valine.* Aqueous solutions of 0.2 mol dm^{-3} of sodium *cyclo*-tetraphosphate tetrahydrate and 0.2 mol dm^{-3} of L-valine were mixed in a volume ratio of 1:1. The pH of the mixture was about 5.97. The solution was adjusted with 6 mol dm^{-3} of a sodium hydroxide solution to pH 12 and then allowed to stand at room temperature and at 70 °C. With the progress of the reaction the pH of the solution was gradually lowered, after which the sodium hydroxide solution was added to maintain the pH 12.

Anion-exchange chromatography, paper chromatography, and IR spectroscopy were carried out by the methods described in a previous paper.[7]

Results and Discussion

Figure 1 shows the anion-exchange chromatograms obtained for the reaction mixtures of P_{4m} with L-valine in a molar ratio of 1:1 after 14 and 91 d at room temperature and at pH 12. In addition to the peaks of ortho-(P_1), pyro-(P_2), tri-(P_3), and tetra-

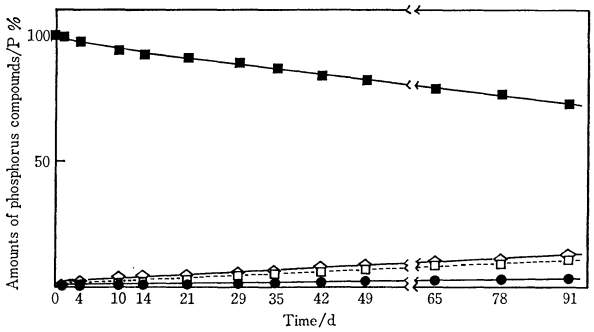

Fig. 2. Change of the amounts of phosphorus compounds in the reaction of P_{4m} with L-valine at room temperature and pH 12.
—●—: P_1-(N)Val, --□--: P_3, —◇—: P_4, —■—: P_{4m}.

phosphate(P_4), the peak of Compound X appeared between those of P_1 and P_2. Though the formation of Compound X was small, it tended to increase gradually with the reaction time. Figure 2 shows the change in the amounts of Compound X, P_3, and P_4, as well as the amount of remaining P_{4m}, determined by means of anion-exchange chromatography. The amounts of P_1 and P_2 formed are omitted here because their amounts were very small (about 0.4 and 0.1% respectively), even after 91 d. The starting material, P_{4m}, decreased gradually with the time, but still about 73% of it remained after 91 d. On the other hand, the yields of P_4, P_3, and Compound X were about 12.5, 11.0, and 3.2% respectively.

Based on the position of the elution peak in the anion-exchange chromatography, and on the results

of paper chromatography, ninhydrin reaction, and IR spectroscopy, Compound X was proved to be identical with the orthophosphate derivative of valine formed by the reaction of P_{3m} and L-valine, *i.e.*, an anion of *N*-(1-carboxy-2-methylpropyl)phosphoramidic acid (P_1-(N)Val), $^{-}O-\overset{\overset{O}{\|}}{P}-NH-\underset{\underset{COO^-}{|}}{CH}-CH\begin{matrix}CH_3\\CH_3\end{matrix}$. Comparing the reaction of P_{4m} and L-valine with that of P_{3m} and L-valine, it was found that, though the same type of phosphate was obtained in both reactions, there were great differences in the yields of the phosphates formed and in the reaction rates.

In the reaction of P_{4m} with L-valine at 70 °C, we obtained the same products as those obtained by the reaction at room temperature, namely P_1, P_2, P_3, P_4, and P_1-(N)Val. Their amounts formed at 70 °C were, however, different from those formed at room temperature. P_3 was predominantly formed at the early stage of the reaction (3—14 d), while P_1 and P_2 were predominant at the later stage (more than 20 d). The formation of P_1-(N)Val was observed immediately after the start of the reaction, but its yield was as low as about 0.3% after 1 d and about 0.1% after 3 d. After 6 d and thereafter, it could not be observed at all. On the other hand, the residual amount of P_{4m} decreased very rapidly, becoming almost zero after 20 d. The fact that, at 70 °C, in spite of the rapid decrease of P_{4m}, P_1-(N)Val was formed in only a very small amount, suggests that the hydrolysis of P_{4m} itself may proceed in preference to the reaction of P_{4m} with L-valine.

It was found that, at room temperature, the reaction of P_{4m} with L-valine is slower than the reaction of P_{3m} with L-valine. This can be understood by analogy with the fact that, in an alkaline solution, the hydrolysis of P_{4m} is slower than that of P_{3m}.

The mechanism of the reaction of P_{4m} with L-valine at pH 12 is summarized in Fig. 3. A phosphorus of P_{4m} may be attacked by the lone pair of the nitrogen of L-valine; consequently, the ring-opening reaction

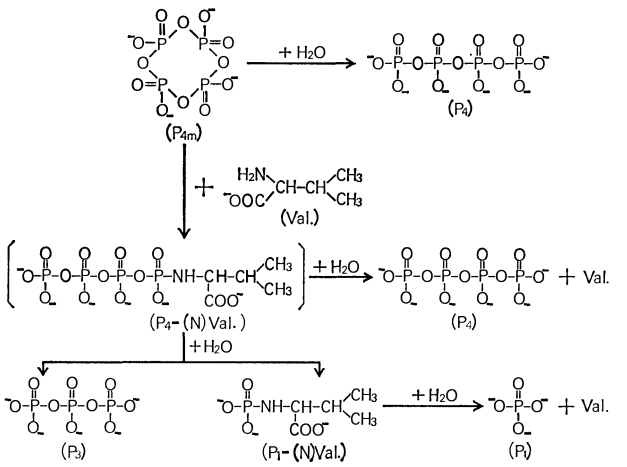

Fig. 3. Mechanism of the reaction of P_{4m} with L-valine.

of P_{4m} may proceed to form a tetraphosphate derivative of valine (P_4-(N)Val), but this compound is very unstable and is immediately hydrolyzed to produce a P_1-(N)Val and P_3. P_2, which is a minor component in the reaction products, may be produced by the hydrolysis of P_3 and P_4.

The Determination of Antimony in Water by Atomic-absorption Spectrophotometry Following Flotation Separation

Susumu NAKASHIMA

Institute for Agricultural and Biological Sciences, Okayama University, Kurashiki, Okayama 710

(Received June 2, 1980)

Synopsis. A flotation method which utilizes an iron(III) hydroxide–surfactant–air system at pH 4 is described for the separation of sub-microgram levels of antimony-(III,V) in water. The antimony content is determined by the generation of stibine, followed by atomic-absorption spectrophotometry with a long absorption cell (60 cm × 1.2 cm i.d.).

From the viewpoints of environmental science and geochemistry, there is an increasing need for a rapid and accurate method for determining low parts per billion (ppb) of antimony in water. At a less than 1 μg dm^{-3} level of antimony in water, a precise direct determination is difficult even by the atomic-absorption spectrophotometry of stibine, which has a high sensitivity.[1-4] Accordingly, the antimony must be concentrated from the water prior to determination.

In previous papers,[5-8] a flotation technique,[9,10] one in which the precipitate of iron(III) hydroxide is floated with the aid of a surfactant and small air bubbles, was used for the pre-concentration of arsenic-(III,V)[5,6] selenium(IV),[7] and tin(II,IV)[8] in water.

The present paper will describe the application of the separation technique mentioned above to the pre-concentration of antimony(III,V), in water and the determination of antimony by atomic-absorption spectrophotometry, following stibine generation.

Experimental

Apparatus. The apparatus employed in this work has all been previously described[5-8] except for the light source, a Hamamatsu TV antimony hollow-cathode lamp.

Reagents. The reagents were the same as those described previously[7,8] except for those mentioned below. The antimony standard solutions were freshly prepared by diluting stock solutions before use. An antimony(III) stock solution (1 mg Sb cm^{-3}) was prepared by dissolving 1.371 g of potassium antimony tartrate hemihydrate in water and then diluting the mixture to 500 cm^3 with water. An antimony(V) stock solution (0.1 mg Sb cm^{-3}) was prepared from the antimony(III) solution by oxidation with a minimum amount of potassium permanganate. A mixed surfactant solution (0.5 mg cm^{-3} for each surfactant) was prepared by dissolving sodium dodecyl sulfate and sodium oleate in 99.5% (v/v) ethanol, with magnetic stirring for sodium oleate. A potassium iodide solution (20% w/v) was prepared by dissolving in water.

Procedure for the Flotation Step. One thousand cm^3 of acidified water is placed in a 1000-cm^3 beaker, and 2 cm^3 of an iron(III) solution (5 mg cm^{-3}) is added. The pH of the solution is adjusted to 4.0±0.2 with an aqueous ammonia solution to precipitate iron(III) hydroxide, and the mixture is stirred for 15 min. After adding 2 cm^3 of the surfactant solution to the beaker, the contents of the beaker are transferred to a flotation cell. Air is passed through at a flow rate of 50 cm^3 min^{-1} from the lower end of the cell for about 2 min to obtain a complete mixing and flotation of the precipitate. Most of the mother liquor is drained from the side arm by opening the cock of the drain pipe. After closing the cock, the residual mother liquor is sucked off through the sintered-glass disk, and the precipitate is washed with 30 cm^3 of water. Four cm^3 of 6 mol dm^{-3} hydrochloric acid is added to the cell to dissolve the precipitate, the filtrate is collected by suction in a 10-cm^3 calibrated flask, the sintered-glass disk is washed with water, the washings are added to the flask, and the mixture is diluted to 9 cm^3 with water. The potassium iodide solution (0.5 cm^3) is added to the flask prior to analysis, and the mixture is diluted to 10 cm^3 with water.

Procedure for the Determination of Antimony. The procedure is similar to that for the determination of tin.[8] A calibration curve is constructed using 2.4 mol dm^{-3} hydrochloric acid solutions containing 1.0 mg cm^{-3} of iron(III), 1.0% of potassium iodide, and 0—0.10 μg cm^{-3} of antimony-(III); this curve is linear within the above range of antimony. The detection limit of antimony was found to be 0.4 ng cm^{-3}.

The atomic-absorption apparatus was operated under the following conditions: wavelength, 217.6 nm; lamp current, 12 mA; gas-flow rates, nitrogen 1.0, hydrogen 1.0, and auxiliary nitrogen 6 dm^3 min^{-1}; spectral bandwidth, 1 nm.

Results and Discussion

The effect of the pH of a 1000-cm^3 solution containing 0.8 μg of antimony(III,V) on the coprecipitation of antimony was investigated. As Fig. 1 shows, satisfactory recoveries of antimony(III,V) were obtained in the pH range of 3.4—7.0. At pH values above 7.5, the efficiency of coprecipitation decreased considerably. When the mixed surfactant solution was used, the surface-foam layer supporting the precipitate of iron(III) hydroxide was stable within the pH range of 3.4—10.1; the pH of 4.0±0.2 was, therefore, used throughout the work.

The presence of up to at least 2.5 mg cm^{-3} of iron-(III) added as a collector did not affect the stibine generation in the presence of potassium iodide.

Table 1 shows the permissible amounts of foreign

ions within a 10% negative or positive error for the determination of 1.0 μg of antimony(III) in 1000-cm³ solutions. As can be seen in Table 1, most foreign ions hardly interfere at all with the determination of antimony(III). In the procedure described here, the addition of potassium iodide overcame suppressive effects by copper(II) and selenium(IV), but did not show much effect on the negative interference by nickel(II). However, when coprecipitation at pH 4 was used, the depressive effect by nickel(II) was found to be largely eliminated in comparison with that which occurs when antimony is directly determined. That is, when the proposed method was used, the value of the permissible amount of nickel(II) increased from 4 to 800 (Ni/Sb in weight) compared with the value permissible in a direct determination. Hydride-forming elements, such as tin(IV), arsenic(III,V), bismuth(III), and tellurium(IV), are coprecipitated with iron(III) hydroxide in the same way as antimony and exert a relatively great effect on the generation of stibine.

The solutions (1000 cm³) containing 0.2—20.0 μg of antimony(III) were analyzed by the procedure described above. The recoveries of the antimony that had been added were greater than 94% in all instances. No blank value was detected throughout the analytical process. The proposed conditions, therefore, appear to be optimal for 1000-cm³ volumes of a solution containing up to 20 μg of antimony(III). The relative standard deviations of ten-times-repeated analyses of the solutions containing 0.4 and 0.8 μg of antimony(III) per 1000 cm³ were 2.7 and 2.4% respectively.

In order to investigate the applicability of this method to surface water, the recoveries of known amounts of antimony(III) added to natural surface water samples were examined by the above procedure. The analyses were carried out on 1000-cm³ aliquots of clear, uncontaminated tap and river waters which had been filtered through 0.45 μm Millipore filters after the addition of hydrochloric acid immediately after sampling. Table 2 indicates that the analytical process gave a satisfactory recovery of antimony from surface waters. The antimony concentrations in the tap and river water samples were low: 0.046 and 0.028 μg dm^{-3} respectively.

The author wishes to thank Professor Atsushi Mizuike and Dr. Masataka Hiraide of Nagoya University for their helpful advice on the flotation technique, and Professor Fuji Morii of Okayama University for her helpful discussions.

(Received June 7, 1980)

Synopsis. New molybdenum oxides, Mo-y(yellow) and Mo-b(blue), were obtained by the reaction between molybdenum powder or molybdenum trioxide and hydrogen peroxide. Their reactivity and structure were examined by iodometry, IR, X-ray, and thermal analyses. Mo-y is an acidic oxidant but Mo-b is acidic.

A new type of molybdenum oxide(Mo-y) was obtained by oxidation of molybdenum powder or molybdenum trioxide with 30% hydrogen peroxide. A blue molybdenum compound(Mo-b) was produced by the reaction of molybdenum powder with an inadequate amount of 30% hydrogen peroxide. On the other hand, an excess 30% hydrogen peroxide produced yellow powder(Mo-y). Mo-y and Mo-b have catalytic activity for the dehydration of alcohols, Mo-y being more reactive than Mo-b. Mo-y oxidizes iodide ion, the content of which was determined by iodometry. The result shows that Mo-y has a reactive oxygen. Mo-b does not oxidize iodide ion. In order to investigate the reactivity, the thermal behavior of the active sites of Mo-y was studied. The structural change of Mo-y caused by heating was investigated by means of IR, TG, DTA, and X-ray.

Results and Discussion

Reaction with Hydrogen Peroxide. The reaction scheme is shown in Fig. 1.

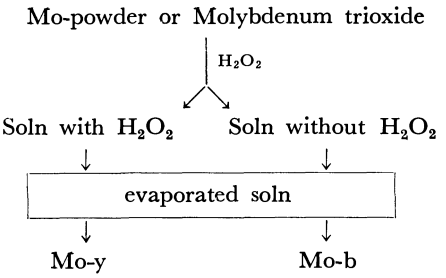

Fig. 1. Reaction path of molybdenum powder or molybdenum trioxide and hydrogen peroxide.

The analysis shows that there is one active oxygen to one atom of molybdenum in Mo-y, indicating the possibility of the existence of a OOH group, while Mo-b has no active oxygen. It seems that Mo-b has OH groups but not a OOH group. Mo-b is synthesized from molybdenum powder but not from molybdenum trioxide. Mo-y, however, is obtained from molybdenum powder or molybdenum trioxide. Glemser and Lutz[1] reported that the structure of molybdenum oxide hydroxide is $MoO_{3-x}(OH)_x$ ($0.5 \leq x \leq 2$). Wilhelmi[2] investigated the MoO_3 and MoO_2 prepared from MoO_3 by reduction with hydrogen at 500 °C and proposed the structure $Mo_4O_{10}(OH)_2$. In this paper, Mo-b is indicated by $MoO_2(OH)_2$ and Mo-y by $MoO_2(OH)(OOH)$.

Differential Thermal Analysis(DTA) and Thermal Gravimetric Analysis(TG). The sample was dried at 30 °C for 72 h under reduced pressure before measurement. DTA and TG curves are shown in Fig. 2. Mo-y showed a gradual decrease in weight up to 200 °C. Above 200 °C, endothermic change takes place with an abrupt decrease in weight, the active oxygen disappearing and Mo-y being transformed into molybdenum trioxide. The weight decrease at 200 °C is calculated from the TG curve to be one mole of water and one gram atom of active oxygen, an endothermic peak was observed and later an exothermic peak, molybdenum trioxide being transformed from amorphous into crystalline form. The weight decrease observed for Mo-b up to 200 °C is calculated to be due to the disappearance of water. The final product was shown to be molybdenum trioxide by IR and X-ray analyses. The DTA curve shows an exothermic peak, the amorphous compound becoming crystalline molybdenum trioxide.

——: TG, ----: DTA, 5 °C/min.

IR Spectrum. For Mo-y, OH stretching frequency and OH deformation vibration were observed at 3450 and 1620 cm^{-1} respectively. The symmetrical terminal Mo–O stretch occurs around 930 cm^{-1} and the antisymmetrical terminal Mo–O stretch at 950 cm^{-1}. The absorption bands are the same as those reported by Mimoun *et al.*[3] and Sotani *et al.*[4] for molybdenum compounds. Absorptions at 980 cm^{-1} are derived from the active oxygen in Mo-y, since the amounts of active oxygen determined by iodometry are associated with the absorbance at 980 cm^{-1} (Fig. 3(A)). The band is assigned to the Mo–O–O stretching vibration. In the case of Mo-b, the region of OH absorption band is the same as that for Mo-y (3400 and 1610 cm^{-1}). The absorption peaks are observed at 970 and 910 cm^{-1}. Probably the band at 930

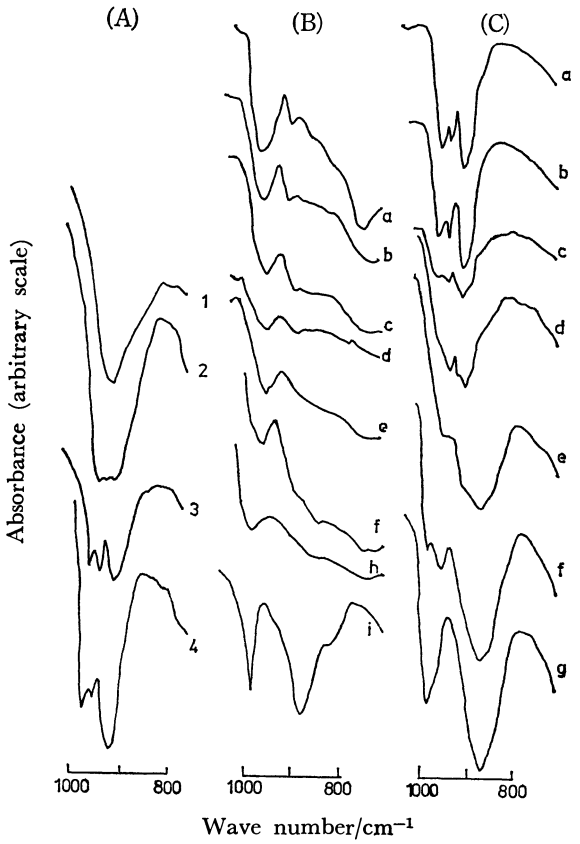

Fig. 3. IR spectra and amount of active oxygen of the molybdenum compound oxidized with hydrogen peroxide (A). Amount of active oxygen (mmol/g); 1: 0.11, 2: 0.13, 3: 3.23, 4: 4.04.
IR spectra of Mo-b(B) and Mo-y(C) at various temperatures of calcination.
a: 30 °C, b: 100 °C, c: 130 °C, d: 160 °C, e: 185 °C, f: 200 °C, g: 220 °C, h: 240 °C, i: 260 °C.

cm^{-1} shifted to the lower wave number region (910 cm^{-1}) owing to the hydrogen bond from absorbed water and the Mo–O bond. The absorption band of the deformation vibration (rocking) mode of the water molecule coordinated with metal was observed at 750 cm^{-1}. Mo-y and Mo-b were dried under reduced pressure in an oven at 30 °C for 72 h. Mo-y treated in the manner described above was calcined under reduced pressure for 1 h at 100, 130, 160, 185, 200, and 220 °C, and Mo-b at 100, 130, 160, 185, 200, 240, and 260 °C. The IR spectra were observed with a KBr tablet. Figure 3(B), (C) show the change of range 1000—800 cm^{-1}. Both compounds turn into molybdenum trioxide above 200—240 °C. The absorption bands of Mo-y at 980, 950 and 930 cm^{-1} assigned to Mo–O gradually decrease by heating up to 200 °C, followed by the disappearance of active oxygen and the appearance of the absorbance of molybdenum trioxide. Upon heating Mo-y, a band was observed at 920 cm^{-1}. It can be assumed that the band at Mo–O shifts to lower wave numbers owing to the increase of polarization of the Mo–O bond. In the case of Mo-b, the Mo–O stretching frequency at 970 cm^{-1} shifts to 990 cm^{-1}. The absorption band at 910 cm^{-1} arising from the Mo–O bond, shifts to 870 cm^{-1}, the band being characteristic of the Mo–O–Mo bond.

X-Ray Analysis. Krebs[5] and Sotani[6] reported on the X-ray analysis of molybdenum oxide, but no report seems to have appeared on the X-ray diffraction analysis of molybdenum oxidized with hydrogen peroxide. The measurement was carried out by the powder method. Mo-b is amorphous, a weak broad diffraction band being observed at 0.307—0.263 nm spacing(d). Mo-y has a high crystallinity and the diffractive band of the spacing at 0.169 nm is very strong. It shows a sheet type structure with 0.619 nm spacing. Molybdenum oxide and molybdenum have 0.53 and 0.567 nm spacing, respectively.[5,6] This difference might arise from the active oxygen in view of the insertion of oxygen between the sheet type structure.

Experimental

Materials. Molybdenum powder (Tokyo Tangusten K.K. Toyama factory: purity 99.985%, diam. 4.2 μm) and hydrogen peroxide (guaranteed reagent 30% Mitsubishi Gas Chemical Co., Ltd.) were used. All other chemicals (Wako Chemicals Co.) were of first grade.

Analysis. Thermal analysis was carried out with a differential thermal gravimetric microbalance (Rigaku TG-DTA), a heating rate of 5 °C/min and static air atmosphere being employed with 18 mg samples in each run. The infrared spectra were obtained with a Hitachi Infrared Spectrophotometer Model 125 on a KBr disk. X-Ray powder patterns were obtained with nickel filtered Cu *K* radiation. Active oxygen was determined by iodometry. EDTA titration[7] was used to measure the content of molybdenum.

Synthesis of Mo-y and Mo-b. Molybdenum powder was added to 30% hydrogen peroxide at 60 °C, a yellow solution being obtained. When the solution became yellow, addition of molybdenum powder was stopped; hydrogen peroxide was then added in order to oxidize the Mo-y satisfactorily. After filtration of unreacted molybdenum powder, the solution was evaporated to give Mo-y as a yellow powder[8]. When molybdenum powder was added to the yellow solution, the color of the solution turned blue. The blue solution was filtered to remove unreacted molybdenum powder, a blue powder being obtained on evaporation of the solution.

This article is gratefully dedicated to Professor Georg Manecke on the occasion of his sixty-fifth birthday.

(Received June 30, 1980)

Synopsis. The solvent extraction of iron(III) in nitric acid (1 to 13.2 mol dm^{-3}) with seven β-diketones into carbon tetrachloride was studied. The extraction curve has a pronounced minimum at from 6 to 7 mol dm^{-3} acid, and the extracted iron(III) species were assumed to be represented by $FeA_a(NO_3)_{3-a}(HA)_n$ (where a and n are from 0 to 3).

The solvent extraction of metal ions with weakly acid chelating extractants(HA) is dependent on the concentration of its dissociated form(A^-), and the distribution ratio increases when the hydrogen-ion concentration is decreased. The extraction of iron(III) with β-diketones such as 2-thenoyltrifluoroacetone (TTA) also shows the above tendency.[1] However, the extractions of metal ions in concentrated acid solutions with weakly acid chelating extractants have also been reported by some authors.[2] For example, titanium(IV) in concentrated hydrochloric acid was extracted with β-diketones.[3] The extractions of zirconium(IV) and hafnium(IV) from concentrated nitric, hydrochloric, and perchloric acid with TTA and *N*-benzoyl-*N*-phenylhydroxylamine are other examples.[4-6] It was also reported that iron(III) was extractable even from concentrated nitric acid with TTA in xylene and that the distribution ratio increased upon an increase in the acid concentration.[7] This extraction was further studied;[8] it was reported that iron(III) was extractable with TTA in xylene both from 10 mol dm^{-3} nitric acid and 10 mol dm^{-3} ammonium nitrate, and that the rate of extraction was higher from the former than the latter. An increase in the rate of the extraction of iron(III) with TTA by the addition of nitrate was also reported and the extraction of the $FeA_2^+NO_3^-$ species was assumed in addition to the FeA_3, although no further details were given.[9]

Experimental

The experiments were carried out at 25±0.3 °C. All the reagents were of an analytical grade. An iron(III) solution prepared by dissolving metallic iron in nitric acid (in some cases, in an acid sodium nitrate solution) and a carbon tetrachloride solution of a β-diketone were placed in a stoppered glass tube, agitated, and centrifuged. Some extractions with TTA was also made by using chloroform as the diluent. In some cases, the iron(III) extracted into the organic phase was agitated with a fresh nitric acid solution and centrifuged. The iron(III) in the organic phase was stripped by a 6 mol dm^{-3} portion of hydrochloric acid. This back-extracted iron(III) and the iron(III) in the equilibrated aqueous phase was determined by atomic absorption, and the distribution ratio was calculated as;

$$D = [\mathrm{Fe(III)}]_{org}/[\mathrm{Fe(III)}]. \quad (1)$$

Results and Discussion

The β-diketones used were as follows: acetylacetone (AA), benzoylacetone(BZA), dibenzoylmethane(DBM), trifluoroacetylacetone (TFA), 2-thenoyltrifluoroacetone (TTA), benzoyltrifluoroacetone(BFA), and hexafluoroacetylacetone(HFA). When the acid concentration was high, the rate of extraction was high; agitation for 1 min was enough to achieve the equiribrium. However, when the acid concentration was lower than 6 mol dm^{-3}, it was low; the extraction of iron(III) in 1 mol dm^{-3} of nitric acid with 0.2 mol dm^{-3} of TTA in chloroform did not reach equilibrium for at least 3 h. In such cases, the distribution ratio at equiribrium was estimated from the extrapolation of the data of the forward extraction from the aqueous phase and of the backward extraction from the organic phase, which had extracted the iron(III) with that β-diketone.

Figure 1 gives the dependence of D on the nitric acid concentration. The extraction with AA was too poor to be determined, and that with HFA was not reproducible for unknown reasons, although its magnitude was between that with TFA and DBM. Judging from these facts, the order of extractability with these β-diketones is: TTA > BFA > TFA > (HFA) > DBM > BZA > AA. As may be seen from Fig. 1, each

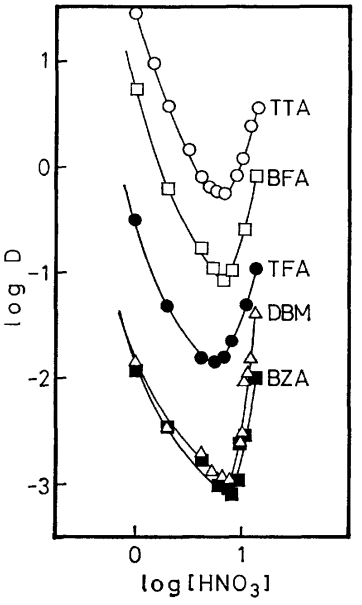

Fig. 1. Distribution ratio of Fe(III) as a function of nitric acid concentration.
Org. phase: CCl_4 initially containing 0.2 mol dm^{-3} of each β-diketone, aq. phase: nitric acid initially containing 5×10^{-4} to 1×10^{-3} mol dm^{-3} Fe(III).

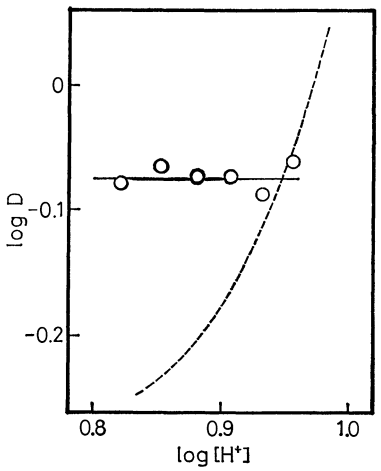

Fig. 2. Dependence of the distribution ratio on H^+ concentration when the aqueous phase was 9.1 mol dm^{-3} (H, Na)NO_3.
Org. phase: CCl_4 containing 0.2 mol dm^{-3} TTA.
The broken line gives the extraction curve when the aqueous phase contains only nitric acid (*cf.* Fig. 1).

extraction curve has a pronounced minimum at about 6 to 7 mol dm^{-3} of the acid. The dependence of the extraction on the β-diketone was determined when the aqueous phase was 13.2 mol dm^{-3} of nitric acid. The slope of the log D *vs.* log $[HA]_{org}$ plot was +3 with TTA, BFA, TFA, and HFA, while it was +2 with DBM and BZA. Figure 2 shows that the extraction with TTA is independent of the hydrogen-ion concentration when the nitrate concentration was 9.1 mol dm^{-3}. The extraction with TTA was also studied by using chloroform as the diluent. It was found that the shape of the curve was rather similar, but the distribution ratio was three to five times higher when the diluent was carbon tetrachloride.

The color of the organic phase which extracted iron(III) from concentrated nitric acid with these β-diketones was similar to that which extracted iron(III) from 1 mol dm^{-3} of nitric acid, except in the case of BZA. The aqueous phase at equiribrium was nearly colorless when the acid concentration was 1 mol dm^{-3} but it was green (TTA and DBM), violet (AA and BZA), pink(BFA and TFA), or colorless (HFA) when the acid was above 6 mol dm^{-3}; the higher the acid concentration, the deeper the color.

Since the ionic concentration in the aqueous phase in Fig. 1 changes with the acid concentration, a quantitative discussion covering all the acid concentration region is difficult. However, since the distribution ratio in Fig. 2 is independent of the hydrogen-ion concentration, the β-diketone in its undissociated form, HA, is assumed to combine with iron(III) nitrate complexes when the nitrate concentration is high. The finding that two molecules of BZA or DBM were enough to extract iron(III) from concentrated nitric acid also seems to support this assumption.

It has been pointed out that the rate of the extraction of iron(III) from acid solutions with the β-diketones as their tris-complexes was low.[10,11] The rate of extraction at low acid concentrations in the present study agrees with this previous finding. The rapid extraction in the concentrated acid region also suggests that type of extraction in this region is different. The observation that an increase in the nitric acid concentration increased the distribution ratio in Fig. 1 may be explained by an increase in the concentration of the iron(III) nitrate complexes (a "salting-out" effect may also contribute). The better extraction when the diluent was carbon tetrachloride than when it was chloroform is similar to the general tendency when solvating-type extractants such as tributyl phosphate are used;[2] this also supports the extraction of the $Fe(NO_3)_3$ complex with two or three molecules of undissociated form β-diketones. Thus, the species extracted from dilute acid solutions should be in the FeA_3 form, but the extracted species should be in the $Fe(NO_3)_3(HA)_n$ (where n is 2 or 3) form from concentrated acid solutions. The extracted species in the intermediate region should be, consequently, mixtures of these two species and the mixed complexes in the form of $FeA_a(NO_3)_{3-a}(HA)_n$ (where a is 1 or 2 and n is smaller than 3). However, an accurate estimation of the composition in the organic phase in this region seems to be difficult because the shape of the absorption curves of the organic phase is not very much affected by the acid concentration, and also because the determination of the molar ratio of Fe^{3+} and NO_3^- in the organic phase by chemical analysis is difficult due to the large amount of nitric acid co-extracted.

We are grateful to Dr. Yoshinori Fujiki of the National Institute for Researches in Inorganic Materials, who encouraged us during this work.

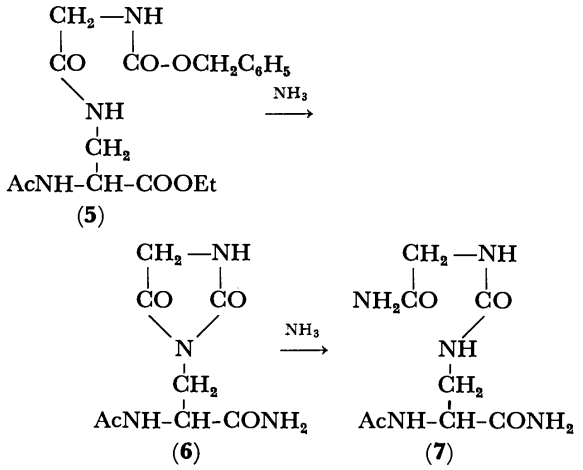
Syntheses of Derivatives of N^2-Acetyl-N^3-glycyl-L-2,3-diaminopropionic Acid and Their Hydrolyses by Trypsin

Yoshihiro MINEMATSU, Shinwon KANG, Michinori WAKI,*
Tetsuo KATO, and Nobuo IZUMIYA
Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
(Received February 22, 1980)

Synopsis. Amide and ethyl ester of N^2-acetyl-N^3-glycyl-L-2,3-diaminopropionic acid replacing an ethylene group in the side chain of lysine by a peptide bond were synthesized. The susceptibility of each derivative to trypsin was compared with that of the corresponding N^2-acetyl-L-lysine derivative. Each derivative was hydrolyzed by trypsin, but was less susceptible than the corresponding L-lysine derivative.

The specificity of trypsin is restricted. The enzyme hydrolyzes selectively the amide and ester bonds containing a carboxyl group of L-lysine or L-arginine. Several lysine-like derivatives such as L-4-thialysine[1] or L-4-oxalysine[2] are susceptible to trypsin; a methylene group in the side chain of lysine is replaced by a sulfur or oxygen atom. In order to examine the influence of replacement of an ethylene group in the side chain of lysine by a peptide bond, we undertook to synthesize an amide (**1**) and an ethyl ester (**2**) of N^2-acetyl-N^3-glycyl-L-2,3-diaminopropionic acid (Ac-L-A_2pr(Gly)-OH[3]) and to subject them to the action of trypsin. Ac-L-Lys-NH_2 (**3**) and Ac-L-Lys-OEt (**4**) were used for references.

We attempted to synthesize a key intermediate, Ac-L-A_2pr(Z-Gly)-NH_2 (**12**), by the action of methanolic NH_3 on Ac-L-A_2pr(Z-Gly)-OEt (**5**). A crystalline compound (mp 209 °C) was isolated, but the result of elemental analysis was not in line with the calculated value **12**. The structure of the compound with mp 209 °C was determined to be L-2-acetamido-3-[N'-(carbamoylmethyl)ureido]propionamide (**7**) by



means of nuclear magnetic resonance and infrared spectroscopy. The result of elemental analysis also agreed with the calculated value as **7**. We assume that the starting compound **5** could be converted into an intermediate hydantoin **6** which is subsequently converted into **7**.

The key intermediate **12** was synthesized as follows. Ac-L-A_2pr(Z)-NH_2 (**10**) was prepared from Ac-L-A_2pr(Z)-OEt (**9**) by the action of methanolic NH_3, **10** being transformed into Ac-L-A_2pr-NH_2 (**11**) by hydrogenolysis. Z-Gly-OH was coupled with β-amino group in **11** by the carbodiimide method, the intermediate **12** being obtained in a good yield. Finally, the desired Ac-L-A_2pr(Gly)-NH_2 (**1**) was prepared by hydrogenolysis of **12**. The ester substrate, Ac-L-A_2pr(Gly)-OEt (**2**) was easily prepared from compound **5** by hydrogenolysis.

TABLE 1. OPTIMUM pH AND C_{max} VALUES OF SUBSTRATES BY TRYPSIN AT 30 °C

Substrate	Optimum pH	C_{max}[a]
1	8.0	0.0049
3	7.8	0.37
2	8.2	12.7
4	8.0	246

a) C_{max} values were estimated from $C_{max}=k_3/2.3\,K_m$, where K_m is a Michaelis constant and k_3 a rate constant.[4]

In order to determine the hydrolytic rates of the amide **1** and the ester **2** by trypsin, the effect of pH was measured for the four substrates. The optimum pH values are given in Table 1. For a comparison of the hydrolytic rates, maximum proteolytic coefficients (C_{max})[4] were determined at the optimum pH. Ac-L-A_2pr(Gly)-NH_2 (**1**) is hydrolyzed at *ca.* 1.3/100 times the rate for Ac-L-Lys-NH_2 (**3**), and Ac-L-A_2pr(Gly)-OEt (**2**) at *ca.* 5.2/100 times that of Ac-L-Lys-OEt (**4**). The lysine-like derivative Bz-L-4-thialysinamide is hydrolyzed at 16/100 times Bz-L-Lys-NH_2.[1] Replacement of a methylene group in L-lysine by an atom such as sulfur and that of an ethylene group by a CONH lead to a decrease in the susceptibility for trypsin.

Experimental

All melting points are uncorrected. Homogeneity of each compound was confirmed by TLC carried out on silica gel G (Merck) with various solvent systems, only the R_f value with *n*-BuOH–AcOH–pyridine–H_2O (4:1:1:2, v/v) being presented. Hydrolytic rates were determined by means of a Hitachi amino acid analyzer KLA-5 under the following conditions: flow rate, 30 ml/h; jacket temperature, 55 °C. Trypsin was salt free, crystalline sample from Nutritional Biochemicals Corporation, Ohio, U.S.A. ^{1}H-NMR spectra were measured in DMSO-d_6 with a Hitachi R-20B spectrometer (60 MHz) using tetramethylsilane as an internal standard.

*H-L-A_2pr(Z)-OEt·HCl (**8**·HCl).* *N*-Carboxy anhydride (NCA) of H-L-A_2pr(Z)-OH was synthesized according to the method of Takagi *et al.*[5] The NCA (0.26 g, 1 mmol) was dissolved in ethanolic 1 M HCl (1.7 ml), and the solution

was left to stand at 50 °C for a few min and at room temperature for 2 d. The solvent was evaporated *in vacuo*, and the residue was recrystallized from hot acetone; yield, 0.27 g (89%); mp 165—166 °C; $[\alpha]_D^{20}$ +5.7° (*c* 2, EtOH); R_f 0.77. Found: C, 51.39; H, 6.30; N, 9.24%. Calcd for $C_{13}H_{19}O_4N_2Cl$: C, 51.57; H, 6.33; N, 9.25%.

*Ac-L-A$_2$pr(Z)-OEt (**9**).* Acetic anhydride (0.51 ml, 5 mmol) was added with stirring to a chilled solution of **8**·HCl (0.30 g, 1 mmol) in pyridine (1.6 ml). After being stirred at 0 °C for 30 min and at room temperature for 3 h, the solvent was evaporated. After the residue had been dissolved in EtOAc, the solution was washed with water, dried (Na_2SO_4), and evaporated. The residue was recrystallized from EtOAc–ether; yield, 0.28 g (91%); mp 115—116 °C; $[\alpha]_D^{20}$ +24.2° (*c* 2, $CHCl_3$); R_f 0.90. Found: C, 58.32; H, 6.51; N, 9.09%. Calcd for $C_{15}H_{20}O_5N_2$: C, 58.43; H, 6.54; N, 9.09%.

*Ac-L-A$_2$pr(Z)-NH$_2$ (**10**).* Compound **9** (1 mmol) was dissolved in methanol (6 ml) saturated with NH_3 at 0 °C, and the solution was left to stand at room temperature for 3 d. The solvent was evaporated, and the residue was recrystallized from EtOH–ether; yield, 97%; mp 187—188 °C; $[\alpha]_D^{20}$ −11.7° (*c* 2, DMF); R_f 0.73. Found: C, 55.82; H, 6.07; N, 14.99%. Calcd for $C_{13}H_{17}O_4N_3$: C, 55.90; H, 6.14; N, 15.05%.

*Ac-L-A$_2$pr-NH$_2$·HCl (**11**·HCl).* Compound **10** (0.28 g, 1 mmol) dissolved in ethanolic 0.2 M HCl (5.5 ml) was treated with hydrogen in the presence of Pd black. After the completion of hydrogenolysis, the filtrate from the catalyst was evaporated to dryness: yield of hygroscopic powder (**11**·HCl), 0.18 g (*ca.* 100%); R_f 0.43.

*Ac-L-A$_2$pr(Z-Gly)-NH$_2$ (**12**).* Compound **11**·HCl (0.18 g, *ca.* 1 mmol) and Z–Gly–OH (0.31 g, 1.5 mmol) were dissolved in DMF (8 ml). To the solution were added at 0 °C Et_3N (0.14 ml, 1.0 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide HCl salt (0.29 g, 1.5 mmol). After being stirred at 0 °C for 3 h and at room temperature overnight, the solvent was evaporated. The residue was dissolved in a mixture of H_2O–MeOH (1:1). The solution was put on a column (0.8×3.5 cm) of Dowex 50X8 (H^+ form) and eluted with the same solvent. The eluate was evaporated, and the residue was recrystallized from EtOH–EtOAc; yield, 0.26 g (74%); mp 144—146 °C; $[\alpha]_D^{20}$ −6.4° (*c* 1, EtOH); R_f 0.71. Found: C, 51.40; H, 5.86; N, 16.17%. Calcd for $C_{15}H_{20}O_5N_4 \cdot 3/4H_2O$: C, 51.50; H, 6.19; N, 16.01%.

*Ac-L-A$_2$pr(Gly)-NH$_2$·HCl (**1**·HCl).* This was prepared from **12** (0.35 g, 1 mmol) in the same way as for **11**·HCl; yield of hygroscopic powder, 0.24 g (*ca.* 100%); R_f 0.31.

*Ac-L-A$_2$pr-OEt·HCl (**13**·HCl).* Compound **9** (2 mmol) was hydrogenated in the same way as for **11**·HCl. The residue was recrystallized from DMF–ether; yield, 85%; mp 176—178 °C (dec); $[\alpha]_D^{20}$ −41.8° (*c* 2, EtOH); R_f 0.76. Found: C, 39.90; H, 7.18; N, 13.32%. Calcd for $C_7H_{15}O_3N_2Cl$: C, 39.90; H, 7.18; N, 13.30%.

*Ac-L-A$_2$pr(Z-Gly)-OEt (**5**).* Z–Gly–OH (1.5 mmol) was coupled with **13**·HCl (1 mmol) in the same way as for **12**. The solvent was evaporated, and the residue was dissolved in EtOAc. The solution was washed successively with 4% $NaHCO_3$, 2% HCl, and water, dried, and evaporated. The residue was recrystallized from EtOH–ether; yield, 71%; mp 116—118 °C; $[\alpha]_D^{20}$ −6.1° (*c* 2, EtOH); R_f 0.77. Found: C, 55.78; H, 6.34; N, 11.44%. Calcd for $C_{17}H_{23}O_6N_3$: C, 55.88; H, 6.35; N, 11.50%.

*Ac-L-A$_2$pr(Gly)-OEt·HCl (**2**·HCl).* Compound **5** was hydrogenated in the same way as for **11**·HCl. The residue was recrystallized from 2-propanol–ether; yield, 77%; mp 194—196 °C (dec); $[\alpha]_D^{20}$ −20.2° (*c* 2, EtOH); R_f 0.58. Found: C, 39.89; H, 6.71; N, 15.53%. Calcd for $C_9H_{18}O_4N_3Cl \cdot 1/4H_2O$: C, 39.71; H, 6.85; N, 15.44%.

*Ac-L-A$_2$pr(Gly)-OH (**14**).* 1 M NaOH (0.22 ml) was added to a solution of **2**·HCl (27 mg, 0.1 mmol) in water (0.2 ml). The solution was left to stand at room temperature for 15 min. It was then put on a column of Dowex 50X8 (H^+ form), and the resin was washed with water and eluted with 2 M NH_4OH. The eluate was evaporated; yield of powder, 18 mg (*ca.* 90%); R_f 0.15.

*L-2-Acetamido-3-[N′-(carbamoylmethyl)ureido]propionamide (**7**).* Compound **5** (1 mmol) was treated with methanolic NH_3 (6 ml) in the same way as for **10**. The solvent was evaporated, and the residue was recrystallized from DMF–ether; yield, 94%; mp 208—209 °C; $[\alpha]_D^{20}$ −2.4° (*c* 2, H_2O); R_f 0.76. IR (KBr) 3370, 3210 (NH_2), 3300 (NH), 1610—1670, 1570, 1300 (amide), 1660 (substituted urea CO), 1360 (CH_3) and 1420 cm^{-1} (CH_2); ^{1}H-NMR (DMSO-d_6) δ=7.90 (1H, d, J=7.5 Hz, –CONHCH–), 7.35 (2H, brd s, –CONH$_2$), 7.04 (2H, brd s, –CONH$_2$), 6.29 (1H, t, J=6 Hz, –CONHCH$_2$–), 6.19 (1H, t, J=6 Hz, –CONHCH$_2$–), 4.20 (1H, m, –NHCHCH$_2$–), 3.63 (2H, d, J=6 Hz, –NHCH$_2$CO–), 3.28 (2H, m, –NHCH$_2$CH–) and 1.90 (3H, s, CH$_3$CO–). Found: C, 38.97; H, 6.14; N, 28.32%. Calcd for $C_8H_{15}O_4N_5$: C, 39.18; H, 6.17; N, 28.56%.

*Ac-L-Lys-NH$_2$·HCl (**3**·HCl), Ac-L-Lys-OEt·HCl (**4**·HCl), and Ac-L-Lys-OH (**15**).* These reference compounds were synthesized according to the methods reported.[6-8] R_f values for the 3 compounds were found to be 0.35, 0.76, and 0.28, respectively.

Determination of Hydrolytic Rates. An aliquot (0.2 ml)[9] of trypsin solution in 0.001 M HCl and 0.5 ml of Tris buffer with a certain pH were placed in a 2-ml assay flask containing either an amide or ester substrate in a certain concentration. The solution was made up to 2.0 ml with water, the final concentration of the buffer being 0.1 M. An aliquot sample (0.2 ml) was withdrawn at certain intervals and placed in a flask containing 0.2 M citrate buffer (0.8 ml) at pH 2.2. A portion of the solution was subjected to assay by means of an amino acid analyzer with a 0.6×10 cm column using 0.35 M citrate buffer at pH 5.28.[10] The extent of % hydrolysis at certain intervals was calculated by the amount of either **14** or **15**. The enzymic hydrolysis of the substrates at various intervals followed the first-order kinetics within experimental error.

The Reaction of *cis*-1,2-Dichloroethylene with Borane in Tetrahydrofuran. The Supply of Monochloroborane in a Tetrahydrofuran Solution

Akira ARASE,* Masayuki HOSHI, and Yuzuru MASUDA
Department of Applied Chemistry, Kitami Institute of Technology, Kitami 090

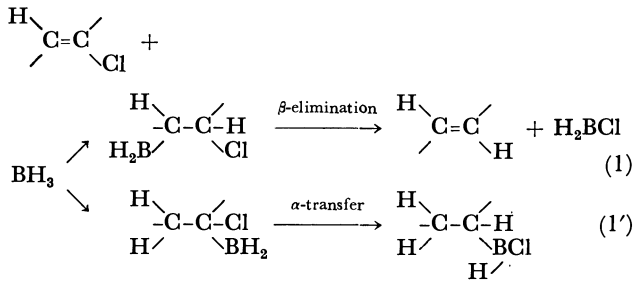
(Received April 25, 1980)

Synopsis. In the reaction of *cis*-1,2-dichloroethylene with borane in THF at 20 °C for 2 h, about 94% of borane was converted to monochloroborane. The resulting solution was stable at 0 °C for several hours.

Monochloroborane (H_2BCl), which has a strongly electronegative chlorine atom, can be expected to show some different properties from borane. For example, the boron atom of H_2BCl adds more selectively to the terminal carbon atom of 1-alkene than does borane.[1,2] The method for the preparation of H_2BCl in a THF solution includes the reaction of hydrogen chloride with BH_3 in THF[3] and the reaction of boron trichloride with BH_3 in THF.[4]

In the course of our study of the reaction using substituted boranes, we needed a less expensive, ready method for the preparation of H_2BCl in a THF solution. It has been reported that, in the hydroboration of alkenyl chloride with BH_3, the boron atom which was once introduced on to a vicinal position of chlorine atom was eliminated rapidly with the chlorine atom to form an olefinic double-bond and H_2BCl. Thus, we tried to prepare H_2BCl in a THF solution utilizing the above elimination reaction.

Polychloroethylenes, bearing chlorine atoms on both doubly bonded carbon atoms, were subjected to the reaction with BH_3 in THF in order to achieve an effective formation of H_2BCl by a β-elimination reaction (1) and to avoid an α-transfer reaction, which would prevent the formation of H_2BCl (1').



(1)

(1')

Polychloroethylene (4 mmol) was added to BH_3 (2 mmol) in THF at 0 °C, and the solution was stirred at 20 °C. After the reaction, the solution was hydrolyzed. The amounts of residual hydride and chloroborane were estimated by measuring the volume of hydrogen gas evolved and by titrating the hydrochloric acid in the solution with a standardized aqueous 0.1 mol dm^{-3} $NaHCO_3$ solution, using Methyl Orange as the indicator. The results are shown in Table 1.

Tetrachloroethylene and trichloroethylene did not show signs of reaction having occured. However, in the cases of *cis*-1,2-dichloroethylene (*c*-DCE) and *trans*-1,2-dichloroethylene (*t*-DCE), the reaction did proceed. In these cases, it was observed that the hydrogen atom on the boron atom (hydride) was consumed in the reaction, and that nearly an equal amount of hydrochloric acid was formed on the hydrolysis of the reaction mixture. On the other hand, an appreciable amount of vinyl chloride was collected in

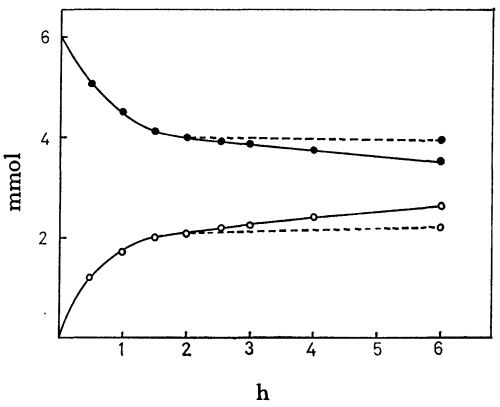


Fig. 1. The amount of hydrogen evolved and hydrochloric acid formed by the hydrolysis in the reaction[a] of *cis*-1,2-dichloroethylene and BH_3 in THF.
●: Hydrogen, ○: hydrochloric acid.
a) 4 mmol of *cis*-1,2-DCE was added to 2 mmol of BH_3 in THF.

Table 1. The reaction of polychloroethylenes or vinyl chloride with BH_3 or H_2BCl in THF at 20 °C

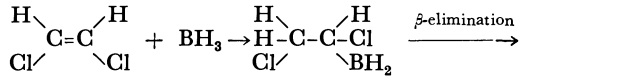
Borane 2 mmol	Chloroethylene 4 mmol	Reaction time h	Hydrogen mmol	Hydrochloric acid mmol
BH_3	Tetrachloroethylene	12	6.00	0
BH_3	Trichloroethylene	12	6.00	0
BH_3	*t*-DCE	2	4.05	2.02
BH_3	*c*-DCE	2	4.01	2.01
BH_3	*c*-DCE	6	3.44	2.52
BH_3	*c*-DCE	6[a]	3.94	2.19
H_2BCl	*c*-DCE	2	4.00	1.98
H_2BCl	Vinyl chloride	2	3.99	1.99

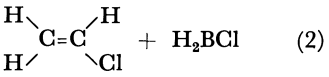
a) After a reaction at 20 °C for 2 h, the reaction temperature was maintained at 0 °C.

a cold trap. As *t*-DCE had the disadvantage in this operation owing to its low boiling property, *c*-DCE was employed for further examinations.

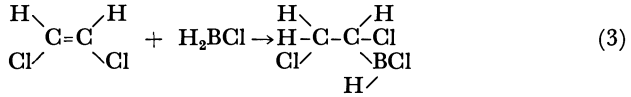
As is shown in Fig. 1, the reaction of the first of the three hydrogen atoms of BH_3 reacted rapidly, but the second and the third did so slowly. When the solution was cooled to 0 °C after a reaction at 20 °C for 2 h, at which point the first hydrogen atom of BH_3 seemed just to have been consumed, the reaction was virtually stopped, as is shown by the dotted line.

The possible reactions which occur upon the addition of *c*-DCE to BH_3 in THF are thought to be as below. However, as is shown in Table 1, H_2BCl

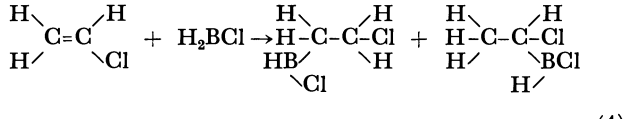




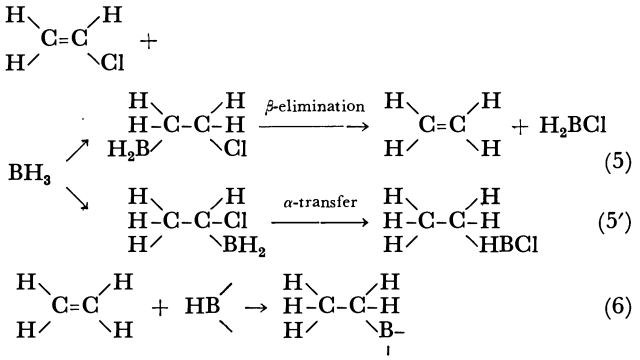
(2)



(3)



(4)



(5)

(5′)

(6)

in a THF solution, prepared from boron trichrolide and BH_3 in THF,[4] hardly reacted with *c*-DCE or vinyl chloride under the same reaction conditions (20 °C, 2 h). Accordingly, the contributions of Reactions 3 and 4 must be negligible. Thus, the source of the hydrochloric acid in the hydrolysed solution is regarded as H_2BCl formed in Reaction 2 and/or 5 and chloroethylborane formed in Reaction 5′. Further, in the reaction of *c*-DCE with BH_3 in THF at 20 °C for 2 h, 0.12 mmol of ethanol was formed by an alkaline–hydrogen peroxide oxidation. This amount corresponds to a 3% loss of the hydride, probably caused by the α-transfer reaction and/or by the hydroboration of ethylene, as is shown in Reactions 5′ and 6. On the other hand, by careful examinations of the reaction mixture and its oxidation product, no compounds were found other than vinyl chloride and ethanol.

These results show that about 94% of BH_3 is converted to H_2BCl in the present reaction. The resulting H_2BCl solution showed nearly the same properties as the H_2BCl solution (THF) obtained by the other established method.[4] For example, the ^{11}B NMR spectrum of the solution showed a triplet at −4.58 ppm (relative to boron trifluoride etherate), with J= 129 Hz (lit,[4] −4.59 ppm, J=131 Hz), and no other signals which should result from BH_3 and H_2BCl[4] were observed. In addition, quite similar results were obtained, both in the yield and in the isomer distribution, on the hydroboration of 1-alkene using such a solution, prepared by a reaction at 20 °C for 2 h.

Experimental

Materials. Commercial tetrachloroethylene, trichloroethylene, *c*-DCE, and *t*-DCE were dried over molecular sieve-5A and distilled before use. BH_3 in a THF solution was prepared as has been described in the literature.[6]

Procedure. A dry, 25-ml flask equipped with a magnetic stirring bar, a septum inlet and an outlet, connected to a cold trap (−70 °C), was flushed with argon. In the flask, 2 mmol of BH_3 in THF was then placed, after which 4 mmol of *c*-DCE was introduced at 0 °C. Then the solution was hydrolyzed with 2 ml of water, and hydrogen evolved was measured by means of a gas meter, connected to an end of the cold trap. On the other hand, hydrogen chloride in the solution was titrated by the use of 0.1 mol dm^{-3} aqueous $NaHCO_3$ solution, using Methyl Orange as the indicator. The solution was then oxidized with alkaline hydrogen peroxide, and the organic layer was analyzed by GLC.

The reaction of vinyl chloride with H_2BCl was examined in a similar manner. In this reaction, a THF solution (5 ml) of vinyl chloride (6 mmol) was added to a THF solution (1.5 ml) of H_2BCl (2 mmol) prepared by the method in Ref. 4.

The ^{11}B NMR spectrum was recorded by means of a Hitachi R-20A spectrometer.

Photochemical Reactions of Azidotriazines with Aromatic Substrates

Shigeru TAMURA, Hisao IMAIZUMI, Yoji HASHIDA,* and Kohji MATSUI*

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

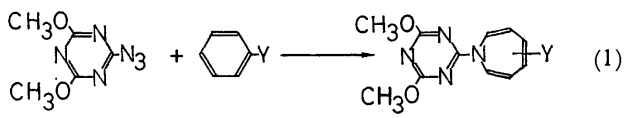
(Received May 14, 1980)

Synopsis. Triazinylnitrene generated photochemically from 2-azido-4,6-dimethoxy-1,3,5-triazine adds to the aromatic ring of alkylbenzenes and halobenzenes to give *N*-triazinylazepines.

Nitrene Chemistry has been extensively studied and is well established.[1] We have reported that the photolyses of azidotriazines in ketones[2,3] and nitriles[2,4] give 1:1 cycloaddition products of the triazinylnitrene and solvent molecule. In this paper we wish to describe the reactions of triazinylnitrene with several aromatic substrates to give *N*-triazinylazepines.

Results and Discussion

During the course of studies on photocycloadditions of triazinylnitrene to nitriles, we have found that irradiation of 2-azido-4,6-dimethoxy-1,3,5-triazine (**1a**) in phenylacetonitrile (**2d**) with a low-pressure mercury lamp resulted in the formation of *N*-(4,6-dimethoxy-1,3,5-triazin-2-yl)azepine (**3d**) in a 30% yield (Eq. 1). The structure of **3d** was indicated by its elemental



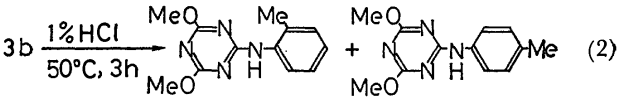
(1)

1a **2** **3**

a: Y=C_2H_5, b: Y=CH_3, c: Y=H, d: Y=CH_2CN, e: Y=Cl, f: Y=F, g=CF_3.

composition and spectral properties. Similar photolyses of azidotriazine (**1a**) in several aromatic substrates also gave *N*-triazinylazepines (**3**); the details are listed in Table 1. Although various azepines have been isolated from the reactions of aromatic substrates with carboxynitrenes,[5-8] sulfonylnitrene,[9] and cyanonitrene,[10] *N*-triazinylazepine is a novel type of the isolable *N*-arylazepine.

Although attempts to determine the isomer distribution were unsuccessful, it is apparent that the *N*-triazinylazepines which were obtained are isomeric mixtures on the basis of the following. For example, the ^{1}H-NMR spectrum of crude triazinylazepine (**3b**) obtained from the reaction with toluene showed singlets at δ 1.85 and 4.00, ascribable to methyl and methoxyl protons respectively. The addition of ^{1}H-NMR shift reagent, however, caused splitting of each peak into two peaks, indicating that at least two isomeric azepines are involved in the crude product. In addition, thermal isomerization of **3b** in acidic solution gave *o*- and *p*-toluidino-1,3,5-triazines in a molar ratio of *ca.* 1:1 (Eq. 2): the ratio was determined by a direct comparison of its ^{1}H-NMR spectrum with those of authentic samples, which were prepared from the reactions of 2-chloro-4,6-dimethoxy-1,3,5-triazine with *o*- and *p*-toluidines.



(2)

On the other hand, in the photoreactions of **1a** in anisole, *N*,*N*-dimethylaniline, and acetophenone, no azepine could be isolated as are shown in Scheme 1: the structures of (**4**), (**5**) and (**6**) were determined by spectral properties and mixed-melting-point tests with an authentic sample.[11]

In order to get an insight into a nature of triazinylnitrene, competitive reactions between benzene and monosubstituted benzene were performed (Table 2).

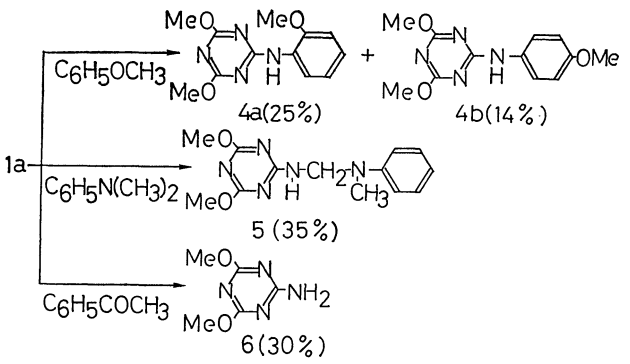

Scheme 1.

TABLE 2. RELATIVE RATES FOR THE REACTIONS OF 4,6-DIMETHOXY-1,3,5-TRIAZINYLNITRENE WITH BENZENES

Aromatic	Relative rate
Ethylbenzene	1.31
Toluene	1.96
Benzene	1.00
Phenylacetonitrile	0.98
Chlorobenzene	0.78
Fluorobenzene	1.10
(Trifluoromethyl)benzene	0.55

The Hammett plots using σ_p-values shows a satisfactory correlation: a least-squares treatment[12] gives an equation, $\log k_x = -0.67\,\sigma_p + 0.07$ with the correlation coefficient (r) of 0.94. The ρ value found is relatively low compared with that in the reaction of ethoxylcarbonylnitrene ($\rho = -1.32$),[13] indicating that the selectivity of triazinylnitrene toward substrate is relatively low. It has been well established[1] that azepines are obtained *via* singlet electrophilic nitrene. Thus, the lower selectivity of triazinylnitrene may be attributed to the electron-withdrawing nature of the triazine nucleus, which enhances the electrophilic reactivity of the nitrene.

On the other hand, the photolysis of 2-azido-4,6-bis(dimethylamino)-1,3,5-triazine (**1b**) in toluene yielded 2-amino-4,6-bis(dimethylamino)-1,3,5-triazine (40% yield), resulting from the hydrogen abstraction by triplet triazinylnitrene.[2] This is easily explained by assuming[2] that, in the photolysis of **1b** bearing highly electron donating dimethylamino groups, the intersystem crossing $^1N \rightarrow {}^3N$ becomes predominant path instead of the reaction of singlet nitrene.

Experimental

Materials. The azidotriazines (**1**) were prepared according to the procedure given in a previous paper.[14]

Irradiation. Let us take as example the photolysis of **1a** in toluene: A solution containing **1a** (2.00 g, 11.0 mmol) in toluene (20 ml) was irradiated for 48 h. After removal of the solvent, the residue was chromatographed on a silica-gel column using benzene–acetone mixture (10:1, v/v) as an eluent to yield crude azepine (**3b**). Recrystallization of crude **3b** from petroleum ether gave 0.65 g of white needles **3b** listed in Table 1.

Irradiations of **1a** in anisole, *N,N*-dimethylaniline, and acetophenone solutions were carried out in the same way to yield **4**, **5**, and **6**, respectively.

4a: mp 135—137 °C; MS *m/e* 262(M^+); ^{1}H-NMR (DMSO-d_6) δ 3.97 (s, 3H), 4.03(s, 6H), 7.00—8.20(m, 4H), 8.85 (s, 1H). Found: C, 55.01; H, 5.36; N, 21.46%.

4b: mp 138—139 °C; MS *m/e* 262(M^+); ^{1}H-NMR($CDCl_3$), δ 3.80(s, 3H), 3.98(s, 6H), 6.80—7.68(m, 4H), 8.35(s, 1H). Found: C, 55.48; H, 5.37; N, 21.56%. Calcd for $C_{12}H_{14}N_4O_3$: C, 54.95; H, 5.38; N, 21.36%.

5: mp 118—119 °C; MS *m/e* 275(M^+); ^{1}H-NMR($CDCl_3$), δ 3.04(s, 3H), 3.98(s, 6H), 5.15(d, 2H), 6.55(t, 1H), 6.70—7.46(m, 5H). Found: C, 56.59; H, 5.92; N, 25.20%. Calcd for $C_{13}H_{17}N_5O_2$: C, 56.71; H, 6.18; N, 25.44%.

Competitive Reactions. After irradiation in a mixed solvent of benzene and monosubstituted benzene (1:1 in volume), known amounts of azobenzene were added into the solution as an internal standard. The products were separated by silica gel TLC using benzene–acetone mixture (20:1, in a typical run) as the developing solvent. From the chromatogram, each product was extracted and diluted with methanol to a fixed volume; then the extinction was measured spectrophotometrically.

The Reaction of Alkyl 3-Alkoxy-2-bromopropanoate with Triethyl Phosphite

Yoshiki Okamoto,* Tsutomu Tone, and Hiroshi Sakurai

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 12, 1980)

Synopsis. Alkyl 3-alkoxy-2-bromopropanoate reacted with triethyl phosphite to give alkyl 2,3-bis(diethoxyphosphinyl)propanoate as the major product.

It is well known that alkyl 2-haloalkanoates react with trialkyl phosphite to give alkyl 2-(dialkoxyphosphinyl)alkanoates by means of an Arbuzov reaction.[1] However, when ethyl 2-bromo-3-ethoxypropanoate(**1**) was treated with triethyl phosphite, the expected product, ethyl 3-ethoxy-2-(diethoxyphosphinyl)propanoate (**2**), was not obtained at all; rather, ethyl 2,3-bis(diethoxyphosphinyl)propanoate(**3**) was obtained as the major product. We now wish to report on these unusual results.

$$ROCH_2CHBrCOOR' + 2P(OR'')_3 \longrightarrow (R''O)_2OPCH_2CH[PO(OR'')_2]COOR' + R''Br + ROR'' \quad (1)$$

The reaction of **1** with three molar equivalents of triethyl phosphite began at 120 °C with the evolution of ethyl bromide, diethyl ether, and ethanol. From the residual mixture, **3**, triethyl phosphate, and ethyl 3-(diethoxyphosphinyl)propanoate(**4**) were obtained by distillation under reduced pressure. The reactions of other alkyl 3-alkoxy-2-bromopropanoates gave similar results, as is summarized in the table.

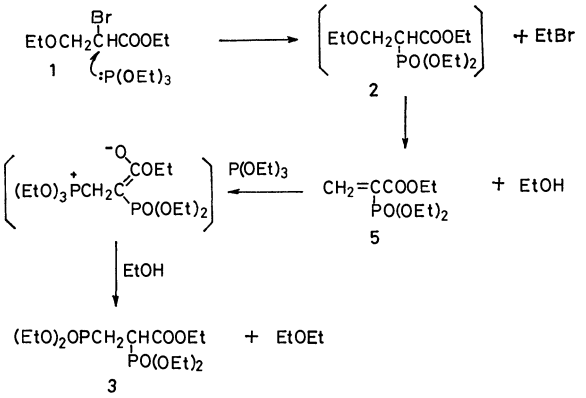
The yields of **3** were slightly decreased with an increase in the bulkiness of the alkyl group of R and/or R′. Even if an excess amount of triethyl phosphite was used, the yield of **3** did not increase. With an equimolar amount of triethyl phosphite, the yield of **3** was only 12%. In the reaction of **1** with trimethyl phosphite, none of the analogous product could be detected. From this mixture, dimethyl methylphosphonate was isolated almost quantitatively, and **1** was recovered, indicating that the rapid isomerization of trimethyl phosphite to dimethyl methylphosphonate by means of methyl bromide produced from the Arbuzov reaction occurred.

Table 1. Yields of alkyl 2,3-bis(dialkoxyphosphinyl)-propanoates from alkyl 3-alkoxy-2-bromopropanoates(**1**) with trialkyl phosphites

R	R′	R″	Bp/10^{-2} mmHg	Yield/%
CH_3	CH_3	CH_3	—	0[a]
CH_3	C_2H_5	CH_3	—	0[a]
CH_3	CH_3	C_2H_5	130—140	61[b]
C_2H_5	C_2H_5	C_2H_5	138—145	56[b]
n-C_3H_7	CH_3	C_2H_5	130—140	50[b]
i-C_3H_7	CH_3	C_2H_5	131—139	46[b]
n-C_4H_9	CH_3	C_2H_5	130—141	36[b]

a) Methyl or ethyl 2-bromo-3-methoxypropanoate respectively was almost entirely recovered. b) These were contaminated by products from the ester exchange.

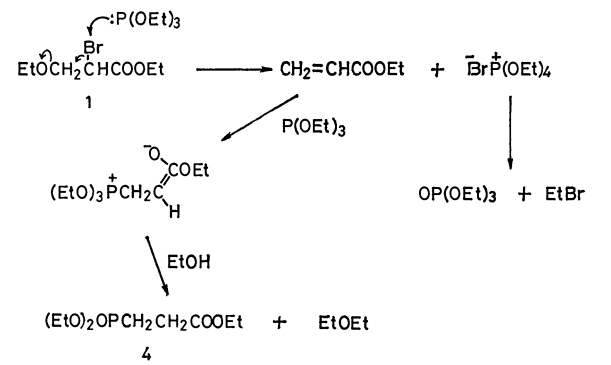
The reaction may proceed as is shown in Scheme 1; the unstable intermediate, **2**, which may be formed by the Arbuzov reaction of **1** with triethyl phosphite, immediately eliminates the ethanol to give ethyl 2-(diethoxyphosphinyl)propenoate(**5**), which reacts subsequently with triethyl phosphite to give **3**.



Scheme 1.

A facile elimination of ethanol has been found in the transformation of diethyl 2-(ethoxymethyl)propanedioate into diethyl 2-methylenepropanedioate.[2] When **5** prepared by another method[3] was treated with triethyl phosphite in the presence of ethanol at 110 °C for 0.5 h, **3** was given in a 62% yield.[5]

The formation of ethyl acrylate and **4** may be interpreted as in Scheme 2. The nucleophilic attack of triethyl phosphite may occur at the bromine center to give ethyl acrylate and tetraethoxyphosphonium bromide.[4] The former reacts with triethyl phosphite to give **4**,[5] and the latter decomposes to ethyl bromide and triethyl phosphate. The nucleophilic attack of triethyl phosphite might occur competitively at the carbon adjacent to the ethoxycarbonyl group and at the bromine, giving **3** and **4** respectively. The more nucleophilic diethyl phosphonate anion attacks preferentially at the bromine center to reduce **1** to



Scheme 2.

ethyl 3-ethoxypropanoate in a high yield at room temperature.

Experimental

*The Reaction of Ethyl 2-Bromo-3-ethoxypropanoate (**1**) with Triethyl Phosphite.* Ethyl 2-bromo-3-ethoxypropanoate (**1**, 15.0 g, 0.067 mol) and triethyl phosphite (33.2 g, 0.21 mol) were placed in a three-necked flask with a gas-inlet tube and a reflux condenser fitted with a tube connected to a trap cooled with Dry Ice–acetone. The mixture was heated at 120—130 °C for 5 h with the bubbling of nitrogen gas, until the evolution of volatile material ceased. The trapped volatile material (6.9 g) was identified as a mixture of ethyl bromide, diethyl ether, ethanol, and a trace amount of ethyl acrylate with GLPC (Shimadzu GC-3AF, a 3 m× 3 mmϕ column packed with 15% PEG 9000 on Uniport B, at 50 °C), but their relative ratio could not be defined with reproducibility. The residual mixture was distilled fractionally to give 1.0 g of a mixture of triethyl phosphate, a trace amount of diethyl ethylphosphonate, 2.1 g of **4** (bp 151—152 °C/1 mmHg,† identified with an authentic sample[6]), and 14.0 g of **3**; bp 138—145 °C/10^{-2} mmHg†. M^+ 374. ^{1}H-NMR (CCl_4) δ=2.40 (2H, m, CH_2), 3.28 (1H, m CH); ^{13}C-NMR ($CDCl_3$–TMS) δ=23.3 (d-d, J_{CP}=140 Hz J_{CCP}=3 Hz, CH_2P), 40.0 (d-d, J_{CP}=127 Hz, J_{CCP}= 3 Hz, CHP); ^{31}P-NMR ($CDCl_3$–85% H_3PO_4) δ=−21.1 (d, J_{PP}=69 Hz, PCH), −27.6 (d, PCH_2).

*The Reaction of Ethyl 2-(Diethoxyphosphinyl)propenoate (**5**) with Triethyl Phosphite.* A mixture of **5** (11.8 g, 0.05 mol), triethyl phosphite (8.3 g, 0.05 mol), and ethanol (9.2 g, 0.2 mol) was heated at 100—110 °C for 2 h in a nitrogen atmosphere. After the reaction, a fraction (11.6 g, bp 139—145 °C/10^{-2} mmHg) was obtained by distillation under reduced pressure. It was found to be identical with **3** by a comparison of the NMR and GLPC data (an 1×3 mmϕ column packed with 10% Silicone SE-30 on Uniport B, at 200 °C).

*The Reaction of Ethyl 2-Bromo-3-ethoxypropanoate (**1**) with Sodium Diethyl Phosphonate.* Stripts of sodium (2.3 g, 0.1 atm) was added, portion by portion, into diethyl phosphonate (52 g, 0.4 mol). After the disappearance of the metal, the reaction mixture was cooled with ice water, and then **1** (11.3 g, 0.05 mol) was added, drop by drop. The resulting mixture was stirred at room temperature for 5 h and then poured into 5% sulfuric acid–ice water. The reaction product was extracted with ether, and the ethereal solution was washed with water and dried over sodium sulfate. After the removal of the ether, ethyl ethoxypropanoate was obtained by distillation (bp 66—68 °C/17 mmHg†,[7] 5.3 g, 72% yield).

Synthesis of *o*-(2-Indolyl)benzoic Acids from Indole

Toshio ITAHARA

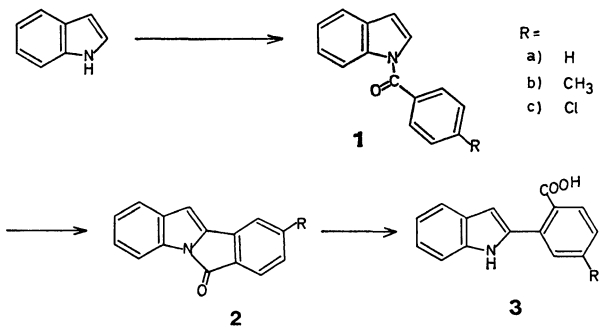
Institute of Chemistry, College of Liberal Arts, Kagoshima University, Kagoshima 890

(Received June 13, 1980)

Synopsis. Treatment of 6*H*-isoindolo[2,1-*a*]indol-6-ones with potassium *t*-butoxide/*t*-butyl alcohol containing a small amount of water at 82° afforded *o*-(2-indolyl)benzoic acids in good yields.

Some 2-arylindoles often have potent physiological activities. However, little attention has been paid to the preparation of some 2-(*o*-substituted phenyl)indoles, such as *o*-(2-indolyl)benzoic acids (**3**), although Pailer *et al.*[1] reported that the reduction of 2-nitrodeoxybenzoin-2'-carboxylic acid afforded *o*-(2-indolyl)benzoic acid (**3a**). On the other hand, we reported the synthesis of 6*H*-isoindole[2,1-*a*]indol-6-ones (**2**) by the oxidation of 1-aroylindoles (**1**) with palladium acetate,[2] although **2** was also prepared by the irradiation of 1-(*o*-iodobenzoyl)indole[3] or of *N*-(*o*-methylphenyl)-phthalimides.[4] As a study of the synthetic application of the reaction, we were interested in the synthesis of **3** by hydrolysis of **2**. The results will provide a new route to prepare 2-arylindoles from indole (Scheme 1).

Attempted hydrolysis of 6*H*-isoindolo[2,1-*a*]indol-6-one (**2a**) in the usual conditions (HCl/MeOH+H_2O and NaOH/MeOH+H_2O) was unsuccessful. On the other hand, Gassman *et al.*[5] previously reported the *t*-BuOK-promoted hydrolysis of amides in diethyl ether containing H_2O. We attempted the hydrolysis of **2** by an application of their method. Treatment of **2a** with *t*-BuOK in *t*-BuOH containing a small amount of H_2O at 82 °C under nitrogen afforded **3a** in 75% yield. Under similar conditions the treatment of **2b** and **2c** with *t*-BuOK gave **3b** (74%) and **3c** (70%), respectively. The structure of **3** was independently confirmed by the elemental analysis, the molecular weight (mass specroscopy), and NMR and IR data. The physiological activities of **3b** and **3c** were examined. The compounds **3b** and **3c** exhibit antifungal activities at concentration of 0.1%. The results are listed in Table 1.



Scheme 1.

Experimental

All the melting points are uncorrected. Elemental analyses were performed by the Analytical Center of Kyoto University. Infrared spectra were recorded with a JASCO IRA-1 spectrometer. Proton magnetic resonance spectra were recorded with a JEOL JNM-60 spectrometer using TMS as the internal reference.

*Treatment of **2** with Potassium* t*-Butoxide.* The solution of **2** (1.0 mmol) in *t*-BuOH (50 ml) and H_2O (5 ml) containing *t*-BuOK (10.0 mmol) was heated at 82° under nitrogen for 12 h. The reaction mixture was evaporated, diluted with a large amount of water, carefully neutralized with diluted HCl, and extracted with ether. The ether extract was dried with sodium sulfate and evaporated to give a brown semicrystalline residue which was triturated with ether/hexane to give **3**, light brown needles from ether/hexane.

*o-(2-Indolyl)benzoic Acid (**3a**)*: Mp 155—157°, partially decomposed at 128—132° (lit.[1] 159°); IR (Nujol): 3430 (NH), 3200—2250 (COOH), 1680 (COOH) cm^{-1}; NMR ($CDCl_3$): δ 6.84 (1H, s), 7.12—8.30 (8H, m), 8.60 (1H, broad), 9.42 (1H, broad); Mass (relative intensity, %): 237 (M^+, 47), 219 (M^+-H_2O, 100). The Mechanism of the Reaction of (Aryloxy)trimethylstannane with Benzyl Bromide giving Aryl Benzyl Ether

Seizi KOZUKA,* Akihiko KIKUCHI, and Shigeru YAMAGUCHI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi, Osaka 558

(Received June 23, 1980)

Synopsis. A kinetic study has been performed for the reaction of (aryloxy)trimethylstannane with benzyl bromide giving aryl benzyl ether and bromotrimethylstannane. Bimolecular nucleophilic attack of the aryloxy-oxygen on the benzyl-carbon has been suggested for the reaction based on the substituent effect.

Recently, we have reported kinetic and stereochemical results of the reactions of (alkylthio and arylthio)trimethylstannanes with haloalkanes.[1] A bimolecular nucleophilic attack of the sulfur atom on

$$Me_3SnSR + R'X \rightarrow [Me_3SnS^{\delta+}(R)\cdots R'\cdots X^{\delta-}] \rightarrow Me_3SnX + RSR'$$

the alkyl-carbon has been suggested for the reaction. A similar reaction has been known for the alkoxy analogue of the (alkylthio)stannane *i.e.*, the reaction of alkoxystannane with haloalkane.[2]

$$Bu_3SnOMe + BuI \rightarrow Bu_3SnI + BuOMe$$

Since the nucleophilicity of oxygen atom is much weaker than that of sulfur, it is doubtful whether the mechanism suggested for the reactions of (alkylthio and arylthio)stannanes is also applicable for that of alkoxystannane. We have extended our mechanistic study to the reaction of alkoxystannane with haloalkane.

The reaction of trimethyl(phenoxy)stannane with benzyl bromide was examined in the present study and found that the reaction gave bromotrimethylstannane and benzyl phenyl ether. The bromostannane was detected by GLC analysis of the reaction solution and the ethereal product was isolated and characterized.

$$Me_3SnOPh + PhCH_2Br \xrightarrow{120\,^\circ C,\ 24\,h} Me_3SnBr + PhCH_2OPh$$

The reaction, however, was found to proceed much slower than that of the (arylthio)stannane with benzyl bromide.[1] Almost no reaction was found under the same reaction conditions used for the reaction of the (arylthio)stannane. Accordingly, the rate of the reaction was measured in a polar solvent at higher temperature with high concentration of the substrate in order to increase the observed rate. A good pseudo-first-order plot was obtained. The results are given in Table 1. Hammett plot of the rates given in Table 1 gave apparently negative ρ value [$\rho_{(\sigma)} = -0.78$] with fair linearity ($\gamma = 0.982$). This would reveal that the nucleophilicity of aryloxy-oxygen played an important role during the reaction although the magnitude of the value appeared somewhat smaller than that obtained for the analogous reaction of (arylthio)stannane.[1] A charge separated 4-center mechanism could not be ruled out by the rather small ρ value alone but is unlikely considering the lower reactivity of the (aryloxy)stannane. The relative reactivity of (aryloxy)stannane toward (arylthio)stannane is consistent with relative nucleophilicities of oxygen and sulfur atoms.[3] Furthermore, the four-center mechanism has recently been ruled out for the bimolecular reaction of this type.[4] Thus, the most plausible mechanism is the nucleophilic attack of the

$$Me_3SnOPh + PhCH_2Br \rightarrow [Me_3Sn{-}O^{\delta+}(Ph)\cdots CH_2(Ph)\cdots Br^{\delta-}] \rightarrow \text{Products}$$

oxygen atom similar to that suggested for the reactions of analogous (alkylthio and arylthio)stannanes with haloalkane.[1] The reaction of alkoxystannane with haloalkane[2] would proceed *via* the same process, that is nucleophilic attack of oxygen atom, since this mechanism has been suggested in the present study even for the less nucleophilic (aryloxy)stannane.

Experimental

(Aryloxy)trimethylstannane. The compounds were prepared either by the reaction of sodium aryl oxide with bromotrimethylstannane in liquid ammonia[5] or by a modified alkoxyl exchange reaction[6] of methoxytrimethylstannane with appropriate phenol. The latter mathod gave better yields with simple procedure. Substituent X of Me_3Sn-OC_6H_4X-*p*, yield, physical properties, and elemental analysis were as follows: H, 36%, 109 °C/8 mmHg (1 mmHg = 133.322 Pa), δ_{CDCl_3} 0.53 ppm (Me_3); CH_3, 21%, mp 87—88 °C (from hexane-chloroform), δ_{CDCl_3} 2.22 (*p*-Me), 0.50 ppm (Me_3). Found: C, 44.06, H, 5.68%. Calcd for $C_{10}H_{16}OSn$: C, 44.33; H, 5.95; OCH_3, 34%. Mp 65—66 °C, bp 137 °C/3 mmHg, δ_{CDCl_3} 3.70 (OCH_3), 0.49 ppm (Me_3). Found C, 41.91; H, 5.25%. Calcd for $C_{10}H_{16}O_2Sn$: C, 41.86; H, 5.62; Cl, 65% (by exchange). Bp 137 °C/3 mmHg, δ_{CDCl_3} 0.53 ppm (Me_3). Found C, 36.60; H, 4.34%. Calcd for $C_9H_{13}ClOSn$: C, 37.10; H, 4.50; NO_2, ≈100% (by exchange). Mp 83.5—84 °C (from hexane–benzene), δ_{CDCl_3} 0.67 ppm (Me_3). Found C, 36.16; H, 4.33%. Calcd for $C_9H_{13}NO_3Sn$: C, 35.81, H, 4.34%.

Product Analysis. Trimethylphenoxystannane (1.2 g, 4.5 mmol) and benzyl bromide (3.8 g, 9.0 mmol) were dissolved in benzonitrile (5 cm^3) and the solution was heated

at 120 °C for 24 h in a sealed tube. The solvent and volatile product were evapolated under reduced press. Bromotrimethylstannane was detected in the volatile components by GLC analysis and benzyl phenyl ether was isolated from the residue by recrystallization, mp 40 °C (from hexane), 68% yield.

Kinetics. In a polar solvent, both the trimethyl signals of trimethylphenoxystannane (δ 0.53 ppm) and bromotrimethylstannane (δ 0.77 ppm) are submerged into one signal due to exchange reaction and the rate could not be measured by integration of those two signals. Accordingly, (aryloxy)-trimethylstannane (1.8×10^{-3} mol) and benzyl bromide (1.8×10^{-2} mol) were dissolved in benzonitrile (total 5 cm^3) with the addition of dichloromethane (5.4×10^{-4} mol) as the internal standard. The solution was devided into ten portions and sealed in glass tubes. The tubes were dipped in a constant temperature bath (120±0.1 °C). The tubes were picked up at time intervals and the amount of benzyl phenyl ether at the time was measured by integration of the benzyl proton signal (δ 4.98 ppm) relative to the internal standard (CH_2Cl_2, δ 5.21 ppm). Rate constant was obtained by least square calculation. The reaction of the (aryloxy)-stannane with dichloromethane was found to be negligible under the reaction conditions used.

Crosslinked Polyvinylpyridine Hydrochloride as a Mild Polymeric Catalyst for Acetalization of Carbonyl Compounds and Esterification of Carboxylic Acids

Jun-ichi YOSHIDA, Jiro HASHIMOTO, and Nariyoshi KAWABATA*

Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received July 19, 1980)

Synopsis. Crosslinked poly(4-vinylpyridine) hydrochloride was found to be an effective catalyst for acetalization of carbonyl compounds and esterification of carboxylic acids. The polymeric catalyst was inert to some acid sensitive functional groups which cannot tolerate under the influence of a strong acid cation exchange resin.

One of the advantages provided by insoluble polymeric catalyst[1] is their easy recovery from the reaction system which prevents the leakage of toxic chemicals. The use of them may be valuable from environmental point of view. Although cation exchange resins[2] are historically one of the earliest examples of the polymeric catalysts, there have been few works available in the literature on milder and more selective polymeric acid catalysts. We have now found that crosslinked poly(4-vinylpyridine) hydrochloride (**1**) was a mild and effective catalyst for acetalization of carbonyl compounds and esterification of carboxylic acids.

The experimental results of the acetalization of carbonyl compounds are given in Table 1. The reaction of cyclohexanone with ethylene glycol proceeded smoothly in the presence of **1** at room temperature to give the corresponding acetal in 96% yield. The spent catalyst was easily rejuvenated by washing with small amounts of organic solvents, and was reused several times with little loss of activity. Acetalization of octanal and citronellal with ethylene glycol also proceeded smoothly in the presence of **1**.

The polymeric catalyst (**1**) was also effective for the esterification of acetic acid with 1-butanol, and the reaction at 80 °C gave butyl acetate in a quantitative yield. In the corresponding esterification of acetic acid with 2-butanol, however, yield of the ester was low. Results are given in Table 2.

Although pyridine hydrochloride has been known as a good catalyst for acetalization of carbonyl compounds,[3] it is very hygroscopic and must be protected from moisture.[4] This disadvantage can be overcome by the use of the polymeric catalyst (**1**) which is non-hygroscopic and very easy to handle in comparison with the monomeric analogue.

A strong acid cation exchange resin containing sulfonic acid group was also an efficient catalyst for the acetalization and the esterification. On the other hand, a weak acid cation exchange resin containing carboxyl group was almost inactive as a catalyst for the reactions. It should be noted, however, that the use of **1** as a catalyst has an advantage over the use of strong acid cation exchange resins, because the use of **1** allowed the application of reactions to the reactants having some acid sensitive functional groups which cannot tolerate the strong acid cation exchange resins. In order to demonstrate this advantage of the use of **1**, esterification of acetic acid with 1-butanol was carried out in the presence of a polymeric catalyst and an additive which contained some acid sensitive functional groups. Results are given in Table 3. For example, 1-phenylethanol used as an additive was recovered quantitatively in the reaction of acetic acid

Table 1. Acetalization of carbonyl compounds with ethylene glycol catalized by polymeric acid catalysts[a]

a) Reactions were carried out with 5.0 mmol of acetic acid, 10.0 mmol of alcohol, and 125 mg of polymeric acid catalyst at 80 °C for 1 h. b) Determined by GLC analysis of the reaction mixture, and was based on acetic acid. c) See footnote (d) in Table 1. d) See footnote (e) in Table 1.

Table 3. Esterification of acetic acid with 1-butanol in the presence of some acid sensitive additives[a)]

Additive	Catalyst	Yield of the ester/%[b)]	Recovered additive/%[b)]
	**1**	93	100
	IR-120B[c)]	98	21[d)]
	**1**	2	20
	IR-120B[c)]	85	0
	**1**	88	100
	IR-120B[c)]	89	45

a) The reactions were carried out with 5.0 mmol of acetic acid, 10.0 mmol of 1-butanol and 2.5 mmol of additive at 80 °C for 1 h. b) Determined by GLC analysis of the reaction mixture. c) See footnote (d) in Table 1. d) Significant amounts of styrene and other unidentified products were formed.

and 1-butanol catalyzed by **1**. On the contrary, in the corresponding reaction catalyzed by the strong acid cation exchange resin, only 21% of 1-phenylethanol was recovered and significant amounts of styrene and other unidentified products were formed. Norcarane contains an acid sensitive cyclopropane ring, but was not affected under the influence of **1**. In contrast, only 45% of norcarane was recovered in the presence of the strong acid cation exchange resin. (Epoxyethyl)benzene was unable to tolerate both of the catalysts.

The results obtained here may suggest the synthetic utility of **1** as a mild and efficient polymeric acid catalyst which provides an attractive alternate to the commercially available cation exchange resins.

Experimental

General. ^{1}H NMR spectra were recorded on a Varian T-60A spectrometer in carbon tetrachloride using tetramethylsilane as internal standard. IR spectra were recorded on a Hitachi 215 grating spectrometer. GLC analyses were performed on a Shimadzu GC-4B or GC-4C gas chromatograph.

Materials. 4-Vinylpyridine provided by Koei Chem. Co. Ltd., Osaka and commercial ethanol were purified by distillation before polymerization. A commercial product of divinylbenzene (*ca.* 55%) was washed with 5% aqueous sodium hydroxide and with deionized water, dried over potassium carbonate, and distilled. Dry hydrogen chloride was prepared by dropping concentrated sulfuric acid on dry lumps of ammonium chloride, and dried by passing through concentrated sulfuric acid. Other chemicals and nitrogen were used as obtained commercially.

*Preparation of Crosslinked Poly(4-vinylpyridine) Hydrochloride (**1**).* Crosslinked poly(4-vinylpyridine) containing 75 mol% 4-vinylpyridine was prepared by a copolymerization of 4-vinylpyridine with divinylbenzene followed by grinding and sifting to 60—80 mesh as was described elsewhere.[5)] The dry copolymer (1.500 g) was placed in a glass tube (5.0 mm diam × 180 mm) and excess dry hydrogen chloride was passed through the tube. To remove excess hydrogen chloride in the resin layer, nitrogen was passed through the tube until no hydrogen chloride was detected at the other end of the tube. After drying *in vacuo*, 1.845 g of **1** was obtained. Elemental analysis of the polymer showed the content of 6.82% of N and 17.98% of Cl, suggesting that the pyridyl group in the resin was quantitatively converted to the hydrochloride form (5.1 mequiv of HCl/dry g).

Resins. For comparison, two commercial resins were used in this work. Amberlite IR-120B and Amberlite IRC-50 supplied by Rohm & Haas Co., Philadelphia, Pa., U.S.A., were used as a strong acid cation exchange resin and a weak acid cation exchange resin, respectively. They were preconditioned and transferred to the H form in usual manners, and were dried *in vacuo* before use. The ion exchange capacity of IR-120B was 4.76 mequiv/dry g, which was determined by titration with standard 0.1 mol/l aqueous NaOH using phenolphthalein as indicator in 1 mol/l aqueous NaCl. The ion exchange capacity of IRC-50 was 10.0 mequiv/dry g, which was determined by back titration with standard 0.1 mol/l aqueous HCl using phenolphthalein as indicator after treatment with a large excess of 0.1 mol/l aqueous NaOH overnight at room temperature.

Acetalization of Carbonyl Compounds. A mixture of carbonyl compound (2.0 mmol), ethylene glycol (10.0 mmol), and a polymeric catalyst (50 mg) was stirred at room temperature for 1 h. After the reaction, the mixture was analyzed by GLC. After removal of the polymeric catalyst by filtration, the products were isolated and identified by comparison of their spectral data with those of authentic materials.

Crosslinked poly(4-vinylpyridine) (**1**) can be reused several times with little loss of activity. In this case, the spent polymeric catalyst was recovered by filtration, and was washed with benzene, methanol, and ether. After dried *in vacuo*, the recovered polymeric catalyst was reused for the acetalization.

Esterification of Carboxylic Acids. A mixture of carboxylic acid (5.0 mmol), an alcohol (10.0 mmol) and a polymeric catalyst (125 mg) was stirred at 80 °C for 1 h, and the mixture was analyzed by GLC. After removal of the catalyst by filtration, the products were isolated and identified by comparison of their spectral data with those of authentic materials.

The esterification reactions of acetic acid with 1-butanol in the presence of an additive were carried out in a similar manner.

The Synthesis of Thermally Stable Oils by the Benzylation of Biphenyl with Benzyl Chloride Catalyzed by Iron(III) Oxide

Makoto Hino and Kazushi Arata*,†

Hakodate Technical College, Tokura-cho, Hakodate 042

† *Hokkaido University of Education, Hachiman-cho, Hakodate, 040*

(Received June 5, 1980)

Synopsis. The benzylation of biphenyl with various amounts of benzyl chloride was performed at 80 °C or at room temperature in the presence of iron(III) oxide prepared by calcining, at 300 °C, iron(III) hydroxide which has been precipitated by hydrolyzing $FeCl_3$ with ammonia. The products with various viscosities were thermally stable up to 200—300 °C, and no chlorine was detected in the products.

Several works concerning the decomposition of PCB by methods using pyrolysis,[1] radiolysis,[2] photolysis[3] and plasma[4] have been reported. On the other hand, some workers have investigated the alkylations of biphenyl in the presence of Friedel-Crafts catalysts in order to use the products as liquid heat stabilizers.[5,6] Biphenyl is also used as a high-boiling heating medium by mixing it with diphenyl ether as a liquid at room temperature.[7] Previously, we reported that the iron(III) oxide thus prepared is an exceedingly effective catalyst for the polycondensation of benzyl chloride, and that the product is poly(*p*-phenylenemethylene) and stable up to 400 °C.[8] In this work, we wish to report that thermally stable oils with various viscosities can be synthesized with ease by the benzylation of biphenyl with benzyl chloride in the presence of the iron(III) oxide catalyst.

Experimental

The iron(III) oxide catalyst was prepared by calcining iron(III) hydroxide in a glass tube in air at 300 °C for 3 h; it was then stored in a glass ampoule until use. The iron(III) hydroxide was precipitated by hydrolyzing $FeCl_3$ with aqueous ammonia. The hydroxide was washed, dried at 100 °C, and finally powdered below 100 mesh. The benzyl chloride (guaranteed reagent of Wako Pure Chemical Co.) and biphenyl (Wako Pure Chemical Co.) were used without further purification.

Benzylation was carried out in bulk following two methods: (A): 10—60 ml of benzyl chloride were stirred, in 2-ml portion, into a mixture of 20 g of biphenyl (mp, 70 °C) and 0.1 g of the catalyst at 80 °C. Each reaction occurred immediately, with a violent evolution of HCl. Benzyl chloride was added at intervals of 10—30 s for the first 20 ml, and afterwards at 1—2 min intervals, without any additional catalyst. (B): 10—50 g of biphenyl were dissolved in 50 ml of benzyl chloride at room temperature, after which the benzylation was performed by stirring with 0.2 g of the catalyst. The reaction started immediately, with an evolution of HCl gas, and was completed within 7—10 min in every reaction. After the reactions by both methods, the reaction mixture was diluted with benzene, separated from the catalyst by filtration, washed with water several times, and dried; finally, the benzene was removed by vacuum evaporation.

Results and Discussion

Table 1 shows the yields and viscosities of the products. Brownish oils with various viscosities were obtained in high yields depending on the amount ratios of benzyl chloride and biphenyl reacted. In the cases of excess amounts of benzyl chloride (Runs 3—6), the products are considered to also contain poly(*p*-phenylenemethylene), judging from the high activity of the catalyst for the polycondensation of benzyl chloride to poly(*p*-phenylenemethylene).[8] Elemental analysis showed no chlorine in any of the products in the table. NMR spectroscopy showed a singlet peak at 3.85 ppm (CH_2) and a multiplet at 6.7—7.5 ppm (phenylene H) in the ratio 1:7 for the samples in Runs 2 and 8.

The TG analyses of the products were done in nitrogen; some of the results are shown in Fig. 1, together with that of biphenyl. The products were thermally stable up to 200—300 °C, above which decomposition occurs, and they decomposed completely at 550 °C. The weight decrease in biphenyl was 100%

Table 1. Benzylation of biphenyl with benzyl chloride

Run	Amount of benzyl chloride / ml	Amount of biphenyl / ml	Reaction temperature / °C	Yield / g	Viscosity[a] η_{rel}
1	10	20	80	25	2.76
2	20	20	80	34	3.37
3	40	20	80	47	4.74
4	60	20	80	60	5.97
5	50	10	RT[b]	43	8.95
6	50	20	RT	53	5.58
7	50	30	RT	65	3.88
8[c]	50	50	35	82	3.31

a) Relative viscosity of a 50 wt% benzene solution to benzene determined at 25 °C in a Cannon-Fenske viscosity. b) Room temperature. c) Since the biphenyl was not all soluble in benzyl chloride at room temperature, the reaction was carried out at 35 °C.

below 200 °C.

The molecular-weight distribution of the sample in Run 3 was determined by gel-permeation chromatography, as is shown in Fig. 2. The main products have a molecular weight of 220—380; this indicates that the degree of the benzylation of biphenyl is predominantly 1—3.

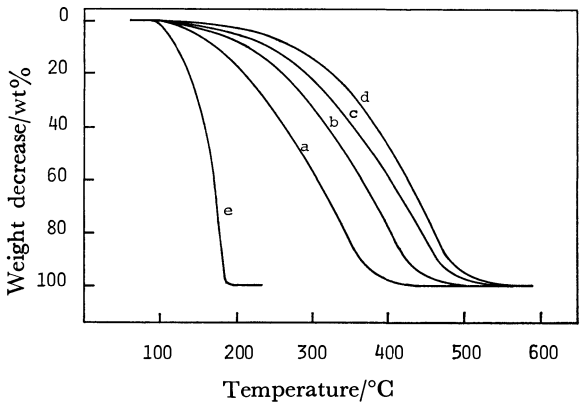

Fig. 1. TG curves of products.
a, b, c, and d refer to the products given by Runs 2, 3, 6, and 4, respectively. e: Biphenyl, heating rate: 5 °C/min.

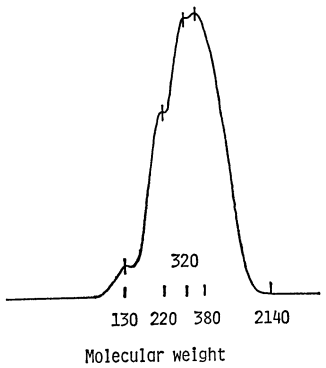

Fig. 2. GPC curve of the sample produced by Run 3. Concentration: 0.4 g in 100 ml of THF, flow rate: 1 ml/min.

The present synthesis was carried out with $AlCl_3$ and $FeCl_3$, typical Lewis acid catalysts, under the same conditions. The reaction was complete when 28 ml of benzyl chloride was added, in 2-ml portions, to a mixture of 20 g of biphenyl and 0.1 g of $AlCl_3$ at 80 °C. However, further reactions did not occur with additional benzyl chloride, in spite of another addition of the catalyst. It is considered that the oily product poisoned the acidic sites of the catalyst surface. Another run was performed at room temperature with 30 g of biphenyl dissolved in 50 ml of benzyl chloride and 0.2 g of $FeCl_3$, but the reaction was extremely slow; 1.38% chlorine was detected in the product after a reaction of 45 min.

The product obtained by the present easy method of synthesis with the conventional and active iron(III) oxide catalyst can replace PCB, whose synthesizing method is to liquidize biphenyl by chlorination. The present method could also be applicable to naphthalene as well as biphenyl, both of which are produced in great quantities in petroleum industries.

The authors are grateful to the Toyota Foundation for its finantial support of the present work.

The Effect of γ-Irradiation on the Biodegradability of Landfill Leachate

Takeshi SAWAI,* Teruko SAWAI, and Masao YAMAZAKI

Tokyo Metropolitan Isotope Research Center, 2-11-1, Fukazawa, Setagaya-ku, Tokyo 158

(Received June 16, 1980)

Synopsis. A preliminary examination of the enhancement of biodegradability for landfill leachate, humic acid, and fulvic acid solutions, and aqueous solutions of polyethylene glycol-6000 by irradiation by ^{60}Co γ-rays under aeration was performed. In all cases, the BOD_5/TOC and BOD_5/COD ratios increased with the dose. This suggests that the γ-irradiation modified these refractory materials to more biodegradable compounds.

The object of the treatment of landfill leachate is to remove organic substances and nitrogen contained in large amounts in the leachate. It is not easy to remove the organic substances by microbial- and physical-chemical treatment processes, because most of these substances consist of high-molecular-weight fulvic-like and humic-like materials.[1] In the determinations of the biodegradability for many kinds of waste water, Murakami *et al.* recently showed that landfill leachate was an especially refractory waste and was hardly treated by a present biological process.[2]

There has been much interest in the possible application of ionizing radiation to the treatment of waste water. The principal effects that can be turned to advantage are related to disinfection, the degradation of organic compounds, modifications in the biodegradability, and changes in the colloidal properties.[3]

The authors have examined the radiation-induced degradation of organic substances in the leachate generated from the landfill in Tokyo Bay by the irradiation of ^{60}Co γ-rays under aeration at room temperature. It was found that these substances were degradated by oxidation reaction, leading to a decrease in the chemical oxygen demand(COD) and the total organic carbon(TOC), and the conversion to lower-molecular-weight compounds, while oxygen-containing compounds, such as organic acids and carbon dioxide, were also produced.[4]

These results suggest that the irradiation is capable of enhancing the biodegradability for the leachate, since the biodegradability is dependent upon the chemical composition[5] and the molecular-weight distribution.[6] In some experiments carried out by Alexander, the irradiation produced a slight decrease in the biodegradability of the primary effluent.[7] Thus, preliminary experiments for the modification of the biodegradability of the landfill leachate by irradiation by ionizing radiation were undertaken.

Experimental

The leachate (COD, about 2000 ppm), solutions of humic acid and fulvic acid separated from the leachate, and dilute aqueous solutions of polyethylene glycol-6000** were used as the samples. These solutions were put into a glass vessel about 30 mm in diameter and irradiated under aeration with γ-rays from a 185 TBq (5 kCi) ^{60}Co source at room temperature. Almost all the irradiations were performed at the dose rate of 95 Gy·s^{-1} (0.57 Mrad·h^{-1}), as determined by means of a ferrous sulfate solution. After irradiation, the COD (permanganate method at 100 °C), TOC (Toshiba-Beckman Type Model 102 Total Organic Carbon Analyzer), and biochemical oxygen demand(BOD_5) were measured. For the determination of BOD_5, the return sludge from a sewage-treatment process was cultured with skim milk, and the filtrate was used for seeding.

**The mean molecular weight is about 6000.

Results and Discussion

There are several methods for determining the biodegradability, but a general method has not yet been established. It is known that, simply, the biodegradability can be estimated from the ratio of the BOD to the theoretical oxygen demand(ThOD) and that it becomes higher with an increase in the ratio. However, the ThOD can not be estimated for such complicated components as the leachate and the samples denatured by irradiation. In such cases, the TOC or COD can be used instead of the ThOD.[8]

The BOD_5, COD, TOC, and pH values in the leachate and in solutions of humic acid, fulvic acid, and polyethylene glycol-6000 are summarized in Table 1 as a function of the dose. As can be seen in Table 1, the COD and TOC in the leachate, humic acid, and fulvic acid decreased monotonously; on the contrary, the BOD_5 increased with an increase in the dose except for the BOD_5 in humic acid at 86 kGy (8.6 Mrad). Then, the BOD_5/COD and BOD_5/TOC ratios increased with the dose from almost zero in unirradiated solutions. The BOD_5/TOC ratios in these solutions are shown in Fig. 1 as a function of

Table 1. Changes in COD, TOC, and BOD_5 by γ-irradiation

the dose. The pH lowered with dose except in the leachate. It is because of the pH value's dependence on the buffer-capacity that there was little change in the pH of the leachate. These facts indicate that the irradiation modified the properties of those organic substances, so that they became more biodegradable compounds.

The same experiments were undertaken for the aqueous solutions of polyethylene glycol-6000, which is a refractory material for a biological-treatment process.[6] In this case, no marked change was seen in the COD and TOC up to at least 34 kGy (3.4 Mrad), while the BOD_5 increased markedly with the dose. Therefore, the ratios of BOD_5 to COD and of BOD_5 to TOC increased with the dose; moreover, these values were higher than those of the leachate (Fig. 1). The polyethylene glycol molecule seems to be easily modified to more biodegradable compounds.

The one reason for the enhancement of the biodegradability of these refractory materials by γ-irradiation may be the formation of lower-molecular-weight substances and of organic acids, such as acetic acid.[4] A typical finding regarding the molecular-weight distribution by gel-permeation chromatography of the humic acid solutions is shown in Fig. 2. From Fig. 2, one can find that the higher-molecular-weight components were degradated to lower ones by irradiation. The drops in the BOD_5/TOC and BOD_5/COD ratios of the humic acid solution at the dose of 86 kGy (8.6 Mrad) may be dependent upon the formation of less biodegradable materials by the high-dose irradiation.

These results show that the irradiation of ionizing radiation might increase the efficiency of the biological treatment process; however, more detailed experiments will be required.

The authors wish to thank Mr. Tomiji Tsuji, Tokyo Metropolitan Cleansing Laboratory, for his many helpful discussions and suggestions and Mr. Makoto Nonomura, Tokyo Metropolitan Industrial Technology Center, for the use of the TOC analyzer.

The Electronic Spectra of Psoralens in Their Ground and Triplet Excited States

Pill-Soon SONG,* Sang Chul SHIM,† and William W. MANTULIN
Department of Chemistry, Texas Tech University, Lubbock, TX 79409, U.S.A.
(Received December 4, 1979)

Synopsis. The first absorption band in psoralens arises from the coumarin moiety, and its location, intensity and polarization are strongly dependent on 5- and 8-substitution. The first two absorption bands in psoralen, angelicin, and methylpsoralens are polarized nearly parallel (angle between them $\Delta\theta \leq 20°$), while methoxypsoralens display wider polarization angles.

Psoralens are photobiologically reactive agents which undergo photocycloaddition to nucleic acids upon irradiation with near UV light.[1] The UV spectra of psoralen and coumarin have already been analyzed by linear dichroism and fluorescence polarization.[2,3] We now extend the spectral analysis to other psoralens.

The T-T absorption spectra of psoralens have been measured.[4,5] In this paper, we attempt to assign the broad absorption bands of psoralen in terms of MO predictions.

Experimental

Absorption spectra were recorded on a Cary 118C spectrophotometer, using a specially built adaptor for the liquid N_2 dewars. Concentrations of all compounds were kept at approximately 50 μM (1 M=1 mol/dm³). The polarized luminescence excitation spectra were recorded on a single photon counting spectrofluorometer (at a spectral resolution of ≈1 nm) by using a pair of Glan-Thompson polarizers under photoselection conditions.[6,7]

Results and Discussion

From the low temperature spectra shown in Figs. 1 and 2, it can be seen that the first absorption band (331 nm for psoralen; Ps) is the most sensitive to perturbation of the furocoumarin system by substitution. 5- and 8-Methoxy substituents exert the strongest perturbation, as the three resolved band system of Ps (Fig. 1) nearly converges into a two band system for 8-MOP and 5-MOP (Fig. 2). While other psoralens show relatively small variations in polarization degree over the first and second absorption bands, 8- and 5-MOP's display polarization differences of *ca.* 0.4 and 0.3, respectively (Fig. 2). This suggests that the angle ($\Delta\theta$) between the two transition moments for the first and second absorption bands is greater (40—50°) than that in other psoralens.

The above noted difference in polarization arises from the fact that the methoxy substitution at position 5 or 8 realigns the transition vector for the first absorption band from the C_3-C_5 axis orientation in Ps to the C_5-C_8 axis orientation in the methoxypsoralens. The polarization of the first band in iPs remains along the long molecular axis (Fig. 1), and is nearly parallel to the polarization direction of the second band, consistent with relatively small differenee in polarization values over the two bands (yielding $\Delta\theta=20°\pm10°$).**

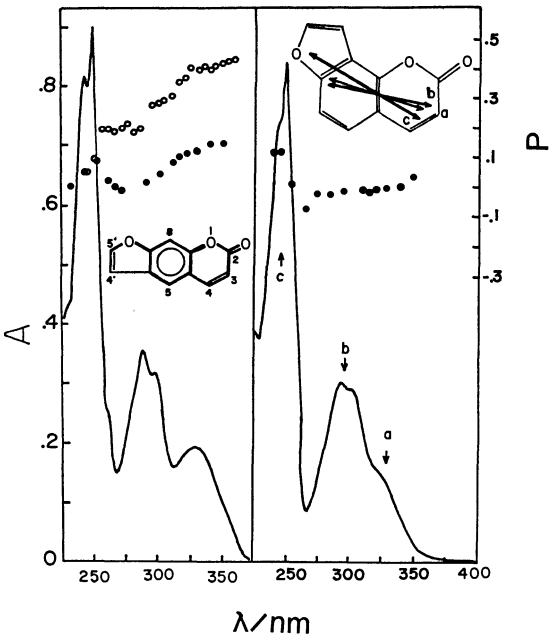

Fig. 1. The absorption spectra of psoralen (left panel) and isopsoralen (right panel) in ethanol at 77 K. Fluorescence excitation polarization (open circle) for psoralen was monitored with respect to emission at 410 nm. Phosphorescence excitation polarization (solid circle) for psoralen and angelicin monitored with respect to the 0-0 phosphorescence at 455 nm. The inset (right panel) shows transition moment directions for the three bands (a, b, c).

In coumarin, the first band is polarized along the long axis, while the second is polarized along the C_2-C_6 axis, with $\Delta\theta=10°\pm5°$.[2] MO calculations are in agreement with the nearly parallel, long axis polarization for the first two bands. For example, MO calculations predict that the first two bands of 7-hydroxycoumarin (λ calculated at 317 and 290 nm) are polarized along the long molecular axis.

Since psoralen is isoelectronic with anthracene, it is reasonable to assign the first and second bands as L_b and L_a origin. The third band in psoralens, which likely contains contribution from a fourth transition,[2] can then be assigned as B_a and/or B_b. It is clear that the first band arises from the coumarin moiety, since the hydrogenation at the pyrone 3,4-C=C bond results in a benzofuran-like spectrum (Fig. 3). The spectral genealogy of psoralens with coumarins is predictable in view of the fact that the first absorption band in both Ps and coumarin is long-axis polarized.[2] In this regard, it is significant that *o*-coumaric acid [3-(2-hydroxyphenyl)propionic acid] ($\lambda_{max}\approx336$ nm) displays an absorption spectrum closely resembling that of coumarin or Ps (Fig. 3), although the two bands

** Fluorescence polarization data (not shown) for angelicin (iPs) are similar to those for Ps shown in Fig. 1.

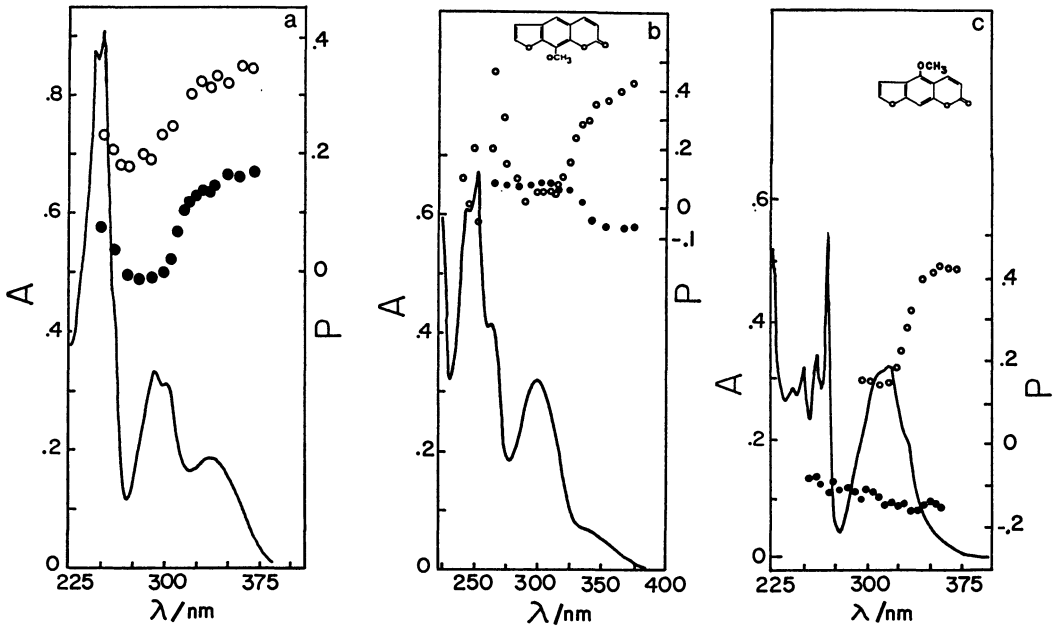

Fig. 2. The absorption spectra of (a) 4,5′,8-trimethylpsoralen, (b) 8-MOP, and (c) 5-MOP in ethanol at 77 K. Fluorescence (open circle) and phosphorescence (solid circle) excitation polarizations were monitored with respect to fluorescence at 415, 435, and 435 nm, respectively, and phosphorescence at 478, 458, and 466 nm, respectively.

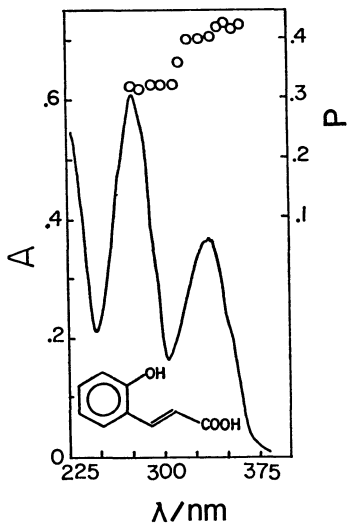

Fig. 3. The absorption spectrum of *o*-coumaric acid in ethanol at 77 K. Fluorescence excitation polarization (open circle) was monitored with respect to fluorescence at 375 nm.

collapse into one overlapping band in *p*-coumaric acid [3-(4-hydroxyphenyl)propionic acid] ($\lambda_{max}\approx318$ nm). Polarization directions for the two bands in *o*-coumaric acid are also nearly parallel, as the fluorescence polarization values differ by only *ca.* 0.1 (Fig. 3).

The phosphorescence of coumarins and psoralens is substantially out-of-plane polarized, particularly 0-0 phosphorescence.[6] This is confirmed by the polarized phosphorescence excitation spectra in Figs. 1 and 2, further suggesting that the first absorption band is largely due to an in-plane polarized $\pi\rightarrow\pi^*$ transition in psoralens and coumarins. However, the phosphorescence polarization over the first absorption band of Ps and trimethyl Ps is not negative (Fig. 1), suggesting that n, π^* perturbations (*e.g.*, vibronic and spin-orbit couplings)[6] are stronger in these molecules than in the others. This may be attributed to the close proximity of the first π, π^* and n, π states in the former.

From MO data calculated (not shown), we tentatively assign the observed T-T absorption maximum at 428 nm to either the $T_1\rightarrow T_9$ or T_8. We further predict that a strong absorption occurs in the near UV region, as suggested by the MO calculation (*i.e.*, $T_1\rightarrow T_{10}$ transition at 324 nm with $f=0.7274$). In coumarin, the intense T-T band is predicted at 283 nm with $f=0.7154$. However, the reported spectrum covers from 300—500 nm, with a broad maximum at 400—460 nm,[8,9] extending to 600 nm.[10] The most intense transitions predicted in this region from MO calculations are at 370 and 319 nm, corresponding to $T_1\rightarrow T_7$ ($f=0.0355$) and $T_1\rightarrow T_8$ ($f=0.0626$), respectively.

Uncatalyzed Chemical Oscillatory Behavior in the Oxidation of Catechol with Acidic Bromate Solution

Punnappillil K. R. NAIR,* Archana MITTAL, and Kotra SRINIVASULU
School of Studies in Chemistry, Vikram University, Ujjain, 456-010, India
(Received September 6, 1979)

Synopsis. A temporal oscillatory behavior of the redox potential in the oxidation of catechol with potassium bromate in sulfuric acid medium is reported.

Uncatalyzed temporal oscillations in bromide ion concentration and redox potential in the oxidation of phenols and anilines with acidic bromate solution have recently been reported by M. Orban and E. Koros, who claim that chemical oscillations do not take place in the oxidation of catechol.[1-3] Our observation shows that catechol is a better substrate to exhibit oscillations in their oxidation with acidic bromate at appropriate concentrations of the reactants. The effect of different catalysts on the system was also observed.

Experimental

Catechol (BDH) was purified by sublimation, $KBrO_3$ (Reidel), H_2SO_4 (BDH) and 1,10-phenanthroline iron(II) sulfate complex (ferroin, BDH) were used. All the solutions were prepared in conductivity water.

Freshly prepared catechol solution (0.25 M†) and H_2SO_4 (18 M) were mixed in a reaction cell thermostated at room temperature (30±0.5 °C) and the reaction was initiated by addition of the required amount of potassium bromate solution (0.4 M). Total volume was kept 25 ml in all cases by addition of the required amount of conductivity water. The reaction was monitored by noting the potential changes from a Systronics (India) pH meter, type 322-1 using Pt–Pt electrodes.[4] In the case of catalysed systems the catalysts were added just before the addition of bromate. Observation was made without stirring, since stirring was found to interfere with the reaction. The boundary concentrations for each reactant to exhibit oscillations were determined by altering the concentration of one of the reactants and keeping that of the rest unaltered. The results are reproducible within the limits of experimental error.

Results and Discussion

Chemical oscillation takes place over narrow ranges of concentration of the reactants, *i.e.* catechol (0.015—0.080 M), bromate (0.048—0.128 M), and acid (0.36—2.88 M). The optimum concentrations for maximum number of oscillations: catechol (0.05 M), bromate (0.096 M), and acid (1.8 M). The oscillations were observed for more than 4 h with decreasing amplitudes as the reaction proceeds (Fig. 1A). Increase in concentration of catechol, bromate or acid, within the boundary conditions, diminished the induction period. Though the reaction starts after the addition of bromate, the oscillatory behavior starts only after an induction (preoscillatory) period of *ca.* 70 min. However, a dark colored species appearing in the system after the addition of bromate vanishes quickly, with a definite potential change.

According to Orban and Koros[2,3] oxidation of catechol with acidic bromate results in the formation of a stable quinone and bromine and thus oscillations do not take place. Though a dark colored species, probably quinone, is formed in the system after bromate addition, it disappears quickly, indicated by the sudden disappearance of the dark color with simultaneous potential change, in the concentration ranges in which reactants exhibit oscillatory behavior. However, the quinone turns into a black or brown precipitate on either side of the boundary conditions of the reactants showing oscillatory behavior. Though bromine is produced in the system, it is consumed probably by brominating the substrate, as evidenced by the gradual disappearance of the brown color from the system before oscillatory behavior appears.

The oscillatory behavior is strongly inhibited by stirring of the reaction mixture; an insignificant number of oscillations could be observed even with slower stirring rate. Inhibitory role of stirring on oscillatory behavior in $BrCH(COOH)_2/BrO_3^-/H_2SO_4/Ce$ system was also reported by Sorensen.[5]

Effect of Catalysts. Belousov-Zhabotiniskii (BZ) catalysts, (Ce(IV), Mn(II), and ferroin) can catalyse the system, ferroin being found to be the most effective one. Introduction of a catalyst decreases the preoscillatory period, while the frequency, number of oscillations and total time for exhibiting oscillations (life time) increase with a slight increase in the amplitude of oscillations (Fig. 1B). Revival of oscillations take place by the introduction of catalyst (2×10^{-4} M ferroin) when the oscillations become insignificant in both uncatalyzed and catalyzed systems. However, no regeneration of oscillations of this type was observed when the catalyst was added at a later stage.

Effect of Halide Ions: Addition of Cl^-, Br^-, or I^- inhibits the reaction. Above 10^{-4} M all the ions inhibit the number and shape of the oscillatory cycles. The inhibitory effect of Cl^- is most prominent.

Effect of Silver Ion: Removal of bromide ions from the system by precipitation of AgBr with Ag^+ ($AgNO_3$) has a pronounced effect on the reaction. By partial removal of bromide ions the oscillations continue, while complete removal inhibits the reaction strongly.

Effect of Radical Scavenger: Addition of acrylonitrile after addition of bromate or in between oscillations suppresses the behavior.

Similar to BZ reaction the uncatalysed bromate oxidation of catechol is controlled by bromide ion and inhibited by chloride ion. The reaction can be explained by means of the Field, Koros and Noyes mechanism,[6] by considering the fact that catechol plays the role of substrate as well as catalyst. The reaction might consist

† 1 M=1 mol dm^{-3}.

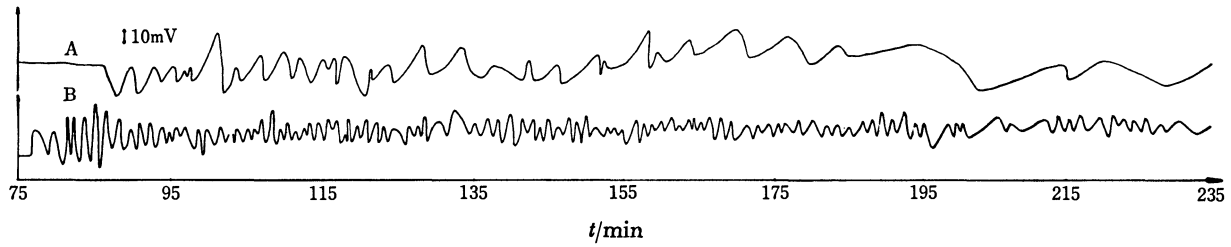

Fig. 1. Oscillatory behavior of the redox potential in the oxidation of catechol with acidic bromate solution.
A. Uncatalyzed system: catechol (0.05 M), bromate (0.096 M), and acid (1.8 M).
B. Catalyzed system: catechol (0.05 M), bromate (0.096 M), acid (1.8 M), and ferroin (2×10^{-4} M).

of two steps of kinetics, the oxidation of catechol by bromate with the subsequent reduction of the latter to bromide ions and bromination of the aromatics. The source of bromide ions for the continuance of the reaction is the brominated products of the aromatics. Brominated products of catechol, *o*-benzoquinone, and 3-bromo-*o*-benzoquinone have been separated from the butanol extract of the reaction mixture by chromatography. So far no bromine has been observed in the BZ reaction.[7,8] However, bromine has been observed in the oscillatory oxidation of catechol.

The authors, P. K. R. and A. M., are grateful to C. S. I. R. (India) for financial assistance and to Prof. M. M. Bokadia, Head of the School, for providing necessary facilities.

Optical Determination of Pair Correlation in π-Electron System

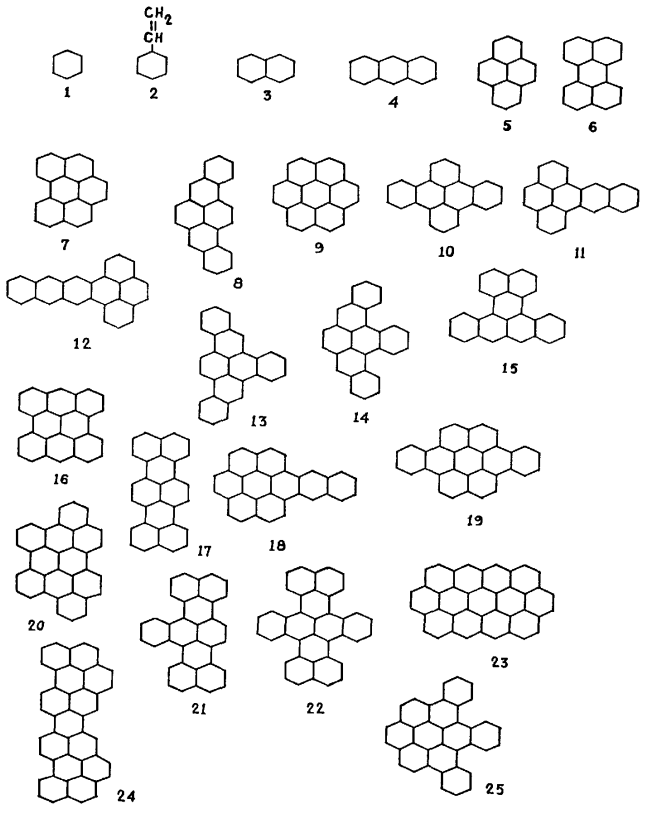
Sadhan Basu

Pure Chemistry Department, University College of Science, 92, Acharya Prafulla Ch. Road, Calcutta-700009, India

(Received January 18, 1980)

Synopsis. α, p, and β bands in the electronic spectra of polynuclear aromatic hydrocarbons have been found to converge to a limiting value. This has been ascribed to pair correlation effect arising from interaction of π-electrons with σ-framework and with molecular vibrations of appropriate symmetry.

Pair correlation effect plays an extremely important role in systems consisting of a large number of Fermi particles. This effect is caused by the presence of attractive force between Fermi particles and are manifested in diverse fields. Thus pair correlation in metals and degenerate semiconductors leads to the development of superconductivity. The pair correlation between nucleons in atomic nucleus explains the regularities observed in the nuclear moment of inertia. The problem of pair correlation of π-electrons in aromatic hydrocarbon has been theoretically analysed by Kresin.[1] Kresin[2] has also shown that such pair correlation is responsible for the characteristic difference in the electronic spectra of perylene and its mono- and dianions.[2] The pair correlation between π-electrons in linear polyene chains has been shown to give rise to convergence in the longest wavelength electron transition with the length of the conjugated chain, *i.e.*, number of π-electrons.[3] This means that pair correlation in π-electron systems may be demonstrated optically. The object of the present note is to analyse if pair correlation could be detected optically in polynuclear aromatic compounds. Clar[4] has prepared hundreds of polynuclear aromatic hydrocarbons where the number or π-electrons ranges from 6 to over 50. Clar has also documented the electronic spectra, which have been divided into α, p, and β regions, for most of these compounds. Since the attraction between electrons is maximum when they have opposite projection quantum numbers, we have selected molecules which have at least one symmetry axis. The frequency of spectral transition (ν) for the α, p, and β bands as well as the number of π-electrons present in the molecules (n) selected are summarised in Table 1. The plot of $\nu(\mathrm{cm}^{-1})$ *vs.* n is given in Fig. 1, where the curves have been drawn by a method of curve fitting.



It may be observed that all the three bands α, p, and β converge to a limiting value. The convergence is faster for the β and α bands but much slower for the p band. In presence of pair correlation, the single particle excitation spectrum is given as[1]

$$E = \sqrt{\xi^2 + \Delta^2}, \quad (1)$$

a) n denotes the number of π-electrons.

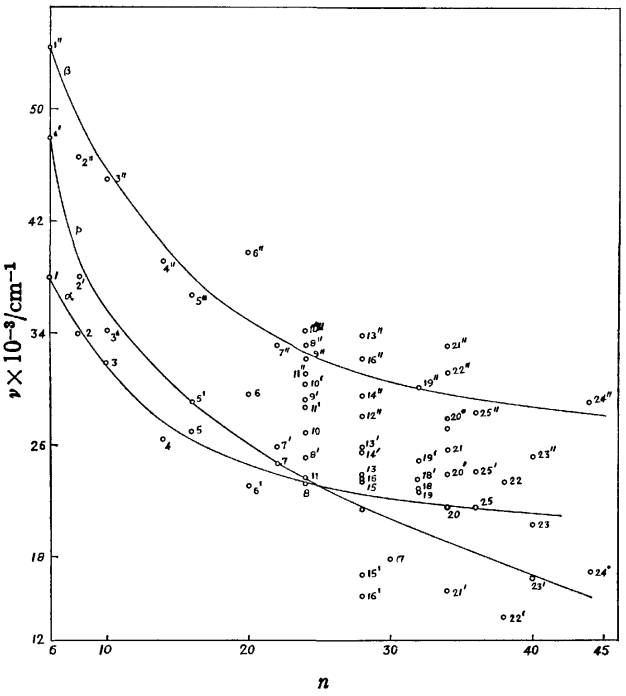

Fig. 1. Longest wavelength transition peaks of the α, p, and β bands in the absorption spectra of poly nuclear aromatic hydrocarbons. The numbers in the figure refer to the serial number in Table 1. Unprimed numbers refer to α, singly primed to p and doubly primed to β transitions.

where $\xi=\varepsilon_b-\varepsilon_a$, ε_b and ε_a being HF energy of an unoccupied and an occupied orbital respectively in absence of pair correlation and Δ is a gap parameter which gives the minimum excitation energy which separates the first excited state from the ground level and it is related to pair correlation energy between electrons having projection quantum numbers of opposite sign. As the number of electrons goes to infinity, ξ goes to zero, and the excitation energy goes to Δ, *i.e.*, Δ gives the convergence limit of the excitation spectrum. From Fig. 1 we get the convergence limit for β, α, and p transitions as 22666, 17333, and 10166 cm^{-1} respectively. The pair correlation energy is largest for a β-transition and smallest for a p-transition, with an α-transition in between. Before searching for a cause for this difference let us first analyse how pair correlation arises in π-electron system.

The major factor which determines the appearance of correlation effect and the energy gap is the presence of attractive force between π-electrons. The primary cause is the polarization of 6-framework, in the field of which the π-electrons move. Due to Coulombic interaction π-electrons cause transition of a σ-electron to a virtual orbital. On return of the σ-electron to the original orbital the energy liberated is transmitted to the π-electrons, which can surmount the repulsive force between similarly charged particles to some extent and the net result is effective attraction between π-electrons. This mechanism will be most effective for allowed π-transitions which have large oscillator strength and can polarise σ-framework. The second mechanism is the interaction of electronic energy with the molecular vibrational quanta. Virtual vibration will be excited and when the oscillator returns to the ground state, the energy transferred to the π-electron will lead to effective attraction. It is obvious that the vibrational quanta is of much lower energy than the electronic quanta, so the first effect will cause stronger correlation than the second.

The various bands observed in the hydrocarbons listed in Table 1 have not been assigned completely. Only for lower members the assignment is agreed upon. If we assume that assignment for the lower members also holds for higher members, then we may propose the following tentative explanation for pair correlation energy.

The presently accepted explanation[5] of the α-band is that they are symmetry forbidden transitions. They are made allowed by simultaneous excitation of some vibrational mode of the molecule so that the product function has proper symmetry to make the transition allowed. It may be suggested that pair correlation in the α-band arises from the interaction of electron with vibrational quanta. The β-bands are orbitally allowed transitions and have high oscillator strength. The polarization of σ-framework therefore may be responsible for pair correlation observed. The p-band is also orbitally forbidden singlet transition made allowed by combination with excited vibrational state. This band is rather diffuse. The pair correlation effect in this band also arises from the interaction of electrons with vibrational quanta, but because of the lower probability of interaction of ground electronic state with excited vibrational state, the correlation energy is low. This phenomenological analysis of the convergence in the absorption bands of various polynuclear aromatic hydrocarbons appears to indicate that a detailed theoretical analysis of the problem must be taken up to establish if the convergence is really due to pair correlation effect as suggested.

Iron Catalyst Local Concentration Fluctuations Found in Dissipative Reactions by X-Ray Microanalysis

Csaba P. Keszthelyi,*,†† József Soós, András G. S. Janossy, and Kristóf Vovács†
Institute of Biophysics, Biological Research Centre, Hungarian Academy of Sciences, H-6701 Szeged, Hungary
†*Department of Silicate Chemistry, Technical University for Chemistry, H-8200 Veszprém, Hungary*
(Received January 26, 1980)

Synopsis. The present work provides the first application of the powerful X-ray microanalysis technique in the study of "Zhabotinskii-type" oscillatory reactions. The modified HNO_3: $KBrO_3$: $[Fe(phen)_3]^{2+}$: malonic acid system is quantitatively described. Systematic variation, spatially correlated with the dissipative structures, was found in the Fe concentration.

The very occurrence of concentration oscillations and temporal periodicity in initially homogeneous chemical systems was a matter of scientific controversy until recent years. His unusual insight into biological morphogenesis led Turing[1] to propose the feasibility of the formation of spatial concentration patterns in an initially uniform chemical medium as early as 1952. Such were the ramifications of the ideas raised by Turing's paper that a new area of thermodynamics, the "far from equilibrium" or "dissipative" branch was born.[2,3] Related research stands out in a unique way: while science is experiencing day to day fragmentation due to the sheer bulk of new results and new techniques, while researchers often fit into the order of things by adopting a mosaic vision, the theories on dissipative structures cut across diverse fields such as biology, chemistry, ecology, mathematics, physics, population dynamics and sociology, once again giving impetus to the quest for fundamental principles and inter-relationships.[3] The topic has claimed the interest of several major research groups, as can be gauged from some excellent review articles.[4] Particularly relevant is the conclusion of Procaccia and Ross,[5] that experimental efforts lag behind theoretical advances in this area.

The present work provides the first application of the powerful X-ray microanalysis technique in the study of "Zhabotinskii-type," dissipative oscillatory chemical reactions. Upon cursory examination, the match between the system of interest and the chosen instrumental technique appears distressing: the oscillatory reactions commonly occur in aqueous solution, whereas no water is admissible to the analytical electron microscope. In devising a suitable procedure, as a first step we found in agreement with Winfree[6] that the oscillatory reactions proceed quite well in membrane filters also. Next it is an easy matter to quench the reaction by immersing the filter bearing the characteristic bands of spatial periodicity into liquid N_2. Subsequent drying of the fixed reaction by vacuum under a temperature gradient is not feasible with the typical mixtures containing H_2SO_4 or $HClO_4$, due to non-volatility of these acids. Nitric acid was found to be an acceptable substituent for H_2SO_4 as reported by Winfree;[6] the modified system is described in conjunction with Fig. 1 as follows. The solutions used to prepare the reaction mixture: **A.** 5 g $KBrO_3$+67 ml H_2O+3 ml concd HNO_3; **B.** 10% aq KBr; **C.** 10% aq malonic acid; **D.** 25 mM aq $[Fe(phen)_3]^{2+}$. Reagent **D** needs to be prepared under rigorously chloride free conditions, in agreement with Winfree's comment. The reagents were mixed in the sequence: 3 ml **A**+0.5 ml **B**, followed by the addition of 0.5 ml **C**. At this stage bromination of the malonic acid occurs within 3—4 min at room temperature. Addition of 0.3—0.5 ml **D** initiates the characteristic temporal oscillations which can be visually followed by observing the red-blue color change of the catalyst. Spatial patterns emerge subsequently, either spontaneously or facilitated.[6]

We measured oscillation period parameters at 27 °C in the standard manner at 550 nm, using a UNICAM SP 1800 spectrophotometer with 5 mm cuvettes. Determined from the data depicted in Fig. 1 by the method of least squares, we obtained with better than 0.99 correlation coefficient:

$$\text{induction period(s)} = 394 \times 0.0227C, \quad (1)$$

$$\text{first oscillation period(s)} = 181.7 \times 2.90C, \quad (2)$$

where C is the concentration (mol/dm^3) of HNO_3.

With the modified system it was possible to produce membrane filters (Sartorius SM 11306) on which the original dissipative structures were preserved intact after drying. Working with ferroin as catalyst had the great advantage of constantly being able to see the status and quality of the samples, and correlate

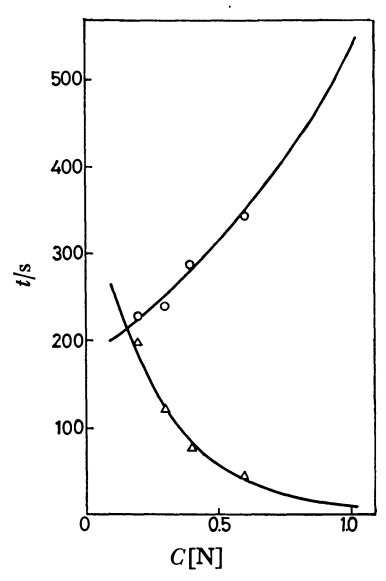

Fig. 1. Temporal oscillatory characteristics of the HNO_3: $[Fe(phen)_3]^{2+}$: $KBrO_3$: malonic acid system.

instrumental readings with visual observations.

From properly prepared filters selected portions *ca.* 3 mm wide and over 1 cm long were introduced to the analytical electron microscope, JEOL JEM 100B. Analysis was performed in the SEI mode, using 20, 40, and 80 kV nominal excitation voltage. Areas of 0.1×0.1 mm^2 were subjected to X-ray microanalysis in steps of 0.25 mm. Utilizing an EDAX 707B X-ray analyser, a typical result is shown in Fig. 2. In the energy dispersive X-ray spectrum covering the 0—10 keV range, Br L_α, K K_α, and Fe K_α peaks are readily identifiable (Cu lines are indigenous to the measuring technique). Over 100 linearly correlated points were individually subjected to microanalysis, and weight ratios were calculated with the 7. EP program of EDAX, Inc. Major fluctuations spatially correlated with the dissipative structures were found in the Fe/K and Fe/Br, but not in the Br/K ratios (Fig. 3). The fact that we did not pick up the small changes in bromide concentration superimposed on a high bromine background was anticipated. The unmistakable correlation between the dissipative structures and total Fe(ferroin+ferriin)based on Fe/K and Fe/Br, on the other hand, indicates that the catalyst participates in the oscillatory reaction dynamics in a more profound manner than commonly envisaged. Although direct measurements of this kind have not been reported, nor are there model calculations which could be called closely relevant, the results on secondary participation in dissipative processes are in qualitative agreement with some recent theoretical advances.[7,8]

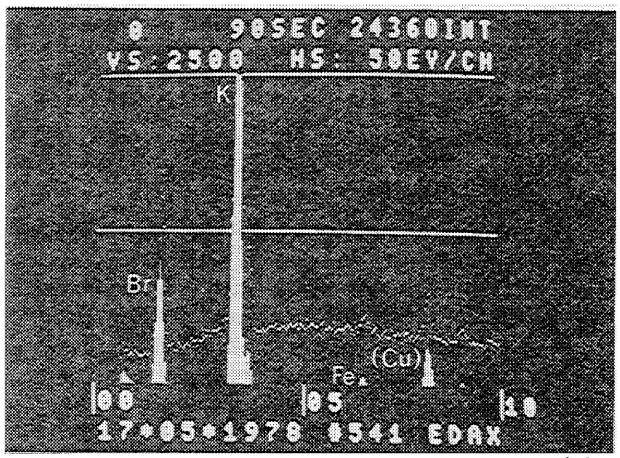

Fig. 2. Typical energy dispersive X-ray spectrum of the Zhabotinskii-type reaction described in Fig. 1. The spectrum shows Br L_α line at 1.48 keV, K K_α line at 3.30 keV, and Fe K_α line at 6.40 keV. Additional peaks at 8.04 and 8.90 keV represent the Cu K_α and K_β lines, and stem from microscope hardware outside the analyzed area excited by scattered electrons and X-rays.

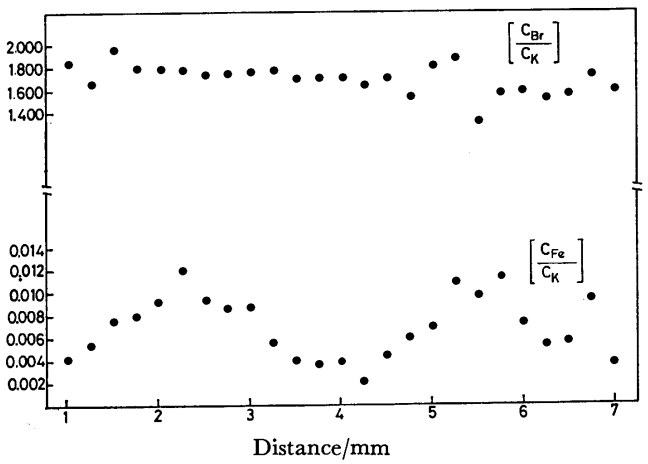

Fig. 3. Weight ratios of Fe/K show fluctuation pattern characteristic of dissipative structures if displayed as a function of distance (here in steps of 0.25 mm). For comparison, Br/K weight ratios show only random variation within limits of accuracy.

In closing we should like to make a few brief remarks about the experimental aspects, deemed so essential by Procaccia and Ross.[5] We have invariably noted, even on the satisfactory samples, a slight broadening of the dissipative structures during the drying process. Such limitation of spatio-featural resolution could be circumvented by using an electron microscope equipped with a cryogenic stage. Additional advantages to consider in this respect are: (1) the cumbersome drying procedure would be bypassed; (2) the frozen samples would be completely free of possible complications arising from different solubility of the oxidized and reduced form of the catalyst. With experimental methodology that does not depend on visual confirmation to the extent afforded by the ferroin-ferriin pair, the investigation of secondary participation effect could be extended to cerium and manganese catalysed reactions, for example, thereby allowing comparison, and promoting fuller theoretical explanation.

Presented at the First Chemical Congress of the Pacific, co-sponsored by the American Chemical Society and the Chemical Society of Japan, held in Honolulu, Hawaii, April 1—6, 1979. Financial support was received from the U. S. National Academy of Sciences/ National Science Foundation.

Potentiometric and Spectroscopic Investigations of the Reaction of Fluorescein Isothiocyanate with an Amine Chemically Bound on Solid Surfaces

Naoto YAMAMOTO,* Yoshikatsu NAGASAWA,** Sadanobu SHUTO, and Hiroshi TSUBOMURA
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received February 18, 1980)

Titanium electrode surface was chemically modified with an aminosilane. The potential of the electrode was shifted to the negative direction by a reaction of fluorescein isothiocyanate in solution with the amine on the electrode surface. The absorption and emission spectra were measured for the fluorescein isothiocyanate, fixed by the reaction with the aminosilane which was chemically bound on the surfaces of tin oxide, titanium oxide and quartz, in solutions and in air. In an alkaline solution, the absorption and emission spectra showed the band ascribable to the dianion of the fluorescein. A peak, attributable to the monoanion, was observed in both absorption and emission spectra measured for the samples kept in air. The surface coverage of the dye was estimated from the absorbances to be about 10^{-6} mol m^{-2} for both tin oxide and quartz. The bound dye fluoresced under exposure to ultraviolet light, due probably to the energy transfer from tin oxide to the dye.

Recently, immobilization techniques of organic molecules on inorganic substrates have been extensively developed by several groups in relation to electrochemical studies.[1-4]

In previous papers, we have described the electrode potential changes arising from antigen-antibody and enzyme-enzyme inhibitor reactions which take place on the electrode surface and proposed an electrical double layer model for the interpretation of these potential changes.[5-7] The applicability of such a potentiometric method to the analysis of very small quantities of biological substances in solutions has also been pointed out.

Numerous studies on surface potentials have so far been made for liquid-gas and solid-gas interfaces, but few potentiometric investigations have been made for solid-liquid interface.[8] The adsorptions of ions and molecules on the electrode surface are known to influence the electrode potential in solution. In cases where the solid surface has an active site interacting only with a particular substance, as in the case of antigen-antibody reactions mentioned above, the surface potential of the solid may change specifically by the interaction. In order to elucidate the relationship between the molecular interaction at an electrode surface and the resultant potential change, the surface reaction of an amine chemically bonded on inorganic substrates with fluorescein isothiocyanate was studied by both potentiometric and spectroscopic methods. The related physicochemical properties of solid surfaces have also been investigated.

Experimental

Materials. (3-Aminopropyl)triethoxysilane (KBE903) and methyltrimethoxysilane (KBM13) from Shinetsu Chemical Co. were used without further purification. Special grade toluene was shaken with concentrated sulfuric acid, dried over anhydrous calcium chloride for 1 d, and distilled. Fluorescein isothiocyanate (isothiocyanatofluorescein) isomer 1, abbreviated as FITC, from Sigma Chemical Co. and fluorescein from Wako Pure Chemical Industries Ltd. were used without further purification.

Preparation of Modified Titanium Electrode. The tip of a titanium wire was heated at about 1000 °C so as to produce thin oxide film on the surface. Silanization of the heat-treated tip was carried out by a method based on Murray's[9,10] as follows. The titanium wire was allowed to stand in an oven at 200 °C for 1 h, the tip was immersed into a 10% toluene solution of (3-aminopropyl)triethoxysilane and the solution was refluxed for 17 h. The tip thus aminosilanized was washed successively with toluene, acetone and distilled water, and attached to a glass tube with epoxy resin as illustrated in Fig. 1a. The electrode thus formed was heated at 80 °C for 1 h to harden the epoxy resin.

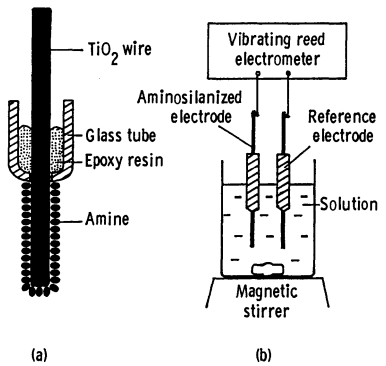

Fig. 1. Aminosilanized titanium electrode (a), and the apparatus for measuring the electrode potential (b).

The reference electrode was similarly prepared by treating the heat-treated wire with a 10% toluene solution of methyltrimethoxysilane for 17 h at 20 °C.

Silanization and FITC Modification of Tin Oxide Film, Quartz and Titanium Oxide Powder. Glass slides coated with tin oxide film were obtained from Hiraoka Glass Co. The tin oxide surface was wiped with a piece of soft cloth damped with commercially available anionic detergent. The glass was then successively washed in an ultrasonic cleaning bath with the washing agent solution for 30 min, distilled water for 10 min, isopropyl alcohol for 10 min and distilled water for 30 min, and soaked in 10 M (1 M=1 mol dm^{-3}) sodium hydroxide solution for 17 h following the method used by Kuwana *et al.*[11] Washed with distilled water in the ultrasonic bath, the glass was dried in an oven for 1 h at 150 °C. Chemi-

** Present address: Toray Research Center, Toray Industries Inc., Sonoyama, 3, Otsu 520.

cal modification of the tin oxide film was performed by the same method as that used for the preparation of titanium electrode.

In order to prepare the FITC bound tin oxide for the spectroscopic measurements, the tin oxide film modified with the aminosilane was allowed to react with 4.4×10^{-4} M FITC solution of 0.05 M carbonate–hydrogencarbonate buffer, pH 10.4, at 5 °C overnight. An ES grade quartz plate from Japan Quartz Co. was modified according to the same method as that for the tin oxide film described above.

The coupling reaction of (3-aminopropyl)triethoxysilane to titanium oxide (rutile) powder, purchased from Merck Co., was performed in the same manner. The aminosilanized powder and *ca.* 2 mg of FITC were added at once to 30 ml of a 0.05 M carbonate–hydrogencarbonate buffer solution, pH 10.4, cooled at 4 °C to prevent the degradation of FITC and allowed to stand overnight. The modified powder was then washed with distilled water in an ultrasonic bath for 10 min and spread on a piece of filter paper and dried for 4 d.

Measurement of the Electrode Potential. The electrical potential between the modified and the reference electrodes was measured in a 30 ml reaction vessel at 20 °C by using a Takedariken TR 84M vibrating reed electrometer in the same manner as described elsewhere (Fig. 1b).[5,6]

Spectroscopic Measurement. The absorption spectra of the modified tin oxide film and quartz plate in air were measured by use of a single beam UV-visible spectrophotometer equipped with a photon counting system.[12] A Shimadzu MPS-50L UV-visible spectrophotometer was used to measure the spectra of the powder and the samples in solution.

The emission spectra were measured by using two Nippon Jarrell–Ash JE 25 monochromators having a focal length of 25 cm, a Hamamatsu R136 photomultiplier and an NF LI 573 lock-in amplifier together with a PAR 125A light chopper. The samples were excited with light of 465 nm in wavelength incident at an angle of 75° with the line normal to the sample face. The emission spectra were not corrected for the response of the monitring system.

Results and Discussion

Reaction with FITC. Figure 2 shows the change of potential with time in the aminosilanized titanium electrode by reaction with FITC. When the solution was replaced with a simple buffer solution (containing no FITC) at a time designated by X in curve a in Fig. 2,

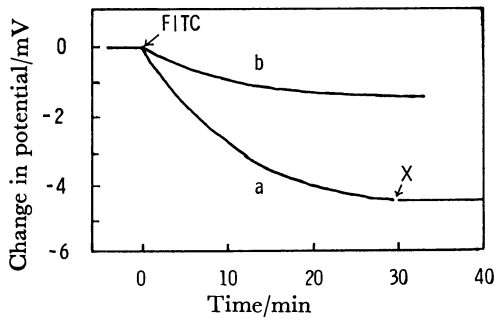

Fig. 2. The change of potential of the aminosilanized titanium electrode caused by the addition of FITC solution. The concentrations of the FITC were 2.1×10^{-4} M for curve a and 7.0×10^{-5} M for curve b. The arrow X indicates the replacement of the solution with a buffer solution.

the potential held the same value as that before the replacement. The magnitude of change in potential was roughly exponential suggesting the first order kinetics of the reaction between the electrode and FITC. This kinetic result is reasonable because the number of FITC molecules in the solution is remarkably larger than that of the amino groups on the electrode surface. The concentration of FITC in the vessel was 2.1×10^{-4} M for curve a and 7.0×10^{-5} M for curve b in Fig. 2. The rate of potential change was nearly proportional to the FITC concentration. Zanker and Peter have shown that fluorescein exists as a dianion in an alkaline solution of pH>7.[13] The negative potential change observed can be explained by the attachment of dianion on the electrode surface.

The vibrating reed electrometer used has the time response less than 0.1 s and the input impedance of 10^5 Ω or more. The observed change in potential as shown in Fig. 2 is too slow to be explained by the change in the redox level of the solution by the addition of FITC. In addition, the potential induced by the reactant is unchanged by replacement of the solution with a simple buffer solution and remained the same for a long time (Fig. 2a), indicating that the observed potential change is caused by the irreversible reaction on the surface, not by the electrochemical properties of the bulk solution. The impedance yielding the potential for the immuno-electrode was measured to be the order of 10^9 Ω,[5] suggesting an existence of highly insulating layer at the interface between electrode and solution. The potential observed is, therefore, understood by taking into account a surface potential formed by the FITC, and other ions bound on the electrode surface.

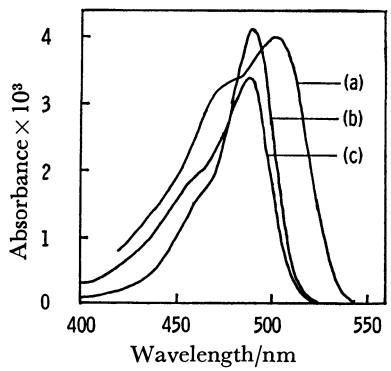

Fig. 3. The absorption spectra of FITC bound on a tin oxide film measured in air (a) and of fluorescein in aqueous solution of pH 5.7 (b) and pH 10.4 (c). The absorption intensities for (b) and (c) are in arbitrary unit.

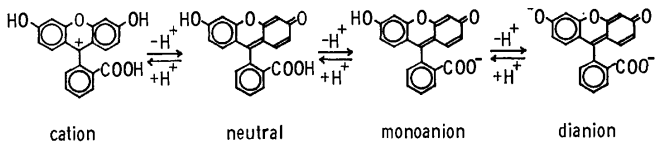
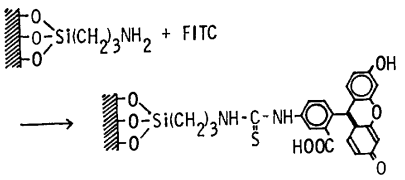
The absorption spectrum of the aminosilanized tin oxide film that reacted with FITC was studied for a sample immersed in the FITC solution for 90 min followed by washing in the ultrasonic cleaning bath and drying (curve a of Fig. 3). Curves b and c in Fig. 3 show the absorption spectra of fluorescein in aqueous solutions of pH 5.7 and 10.4, respectively. Since the FITC bound on the surface maintains the π-electron network of fluorescein, the absorption spectrum of the

bound FITC must be similar to those of fluorescein. Fluorescein in aqueous solutions is in various protolytic equilibria as shown below:



The pH dependence of the absorption and emission spectra of fluorescein in aqueous solution was studied by several investigators.[14-16] Martin and Lindqvist[16] reported that a strong absorption at 491 nm ($\varepsilon=8.8\times10^4$) in the case of an alkaline solution can be identified to the dianion of fluorescein, and that the monoanion existing in a weak acid solution has bands at 475 nm ($\varepsilon=3.1\times10^4$) and at 437 nm. From these assignments the 465 and 500 nm bands of the FITC bound on SnO_2 can be reasonably assigned to the monoanion and the dianion of the fluorescein fragment bound on the solid.

These electrical and spectroscopical results indicate that FITC has certainly reacted with the amino group on the modified solid surfaces as follows.



Assuming that the molar extinction coefficient of the dianion peak of bound FITC is 8.8×10^4, equal to that of fluorescein dianion in alkaline solution, and that of the monoanion of bound FITC is 3.1×10^4 at the absorption peak,[16] the surface coverage of immobilized FITC on the tin oxide and the ratio of the monoanion to dianion can be roughly evaluated from the result in Fig. 3. The resultant coverage is 9.7×10^{-7} mol m^{-2} and the ratio of monoanion to dianion is 1.2: 1, taking account of the fact that the absorbance at 465 nm is expressed by a superposition of the monoanion peak and the dianion tail. Similarly, the coverage on the quartz was estimated to be 6.7×10^{-7} mol m^{-2}, very close to the result on tin oxide. Murray *et al.*[10] estimated from ESCA measurement that organosilanes are bound on the surface to a density of 1 to 2×10^{-6} mol m^{-2} on tin oxide and titanium oxide. Our coverages obtained are in good agreement with their values.

In order to evaluate the reaction rate from absorption spectral measurements, the aminosilanized tin oxide film was immersed into a 4.4×10^{-4} M FITC solution for various periods of time, and the absorption spectrum was measured in air. The optical density at the absorption maximum, 500 nm, of the bound FITC was 1.07×10^{-3}, 4.43×10^{-3}, and 4.71×10^{-3} for the period of 30, 90, and 1440 min, respectively, indicating that the reaction is completed mostly in 90 min, in agreement with the rate of change in electrode potential observed. It was confirmed spectrophotometrically that the FITC thus attached was not removed by washing with water or acetone in the ultrasonic bath for 10 min. In contrast, the tin oxide film which was not modified with organosilane did not show any sign of the absorption spectrum of FITC, indicating that the physical adsorption of FITC onto the tin oxide surface was negligible.

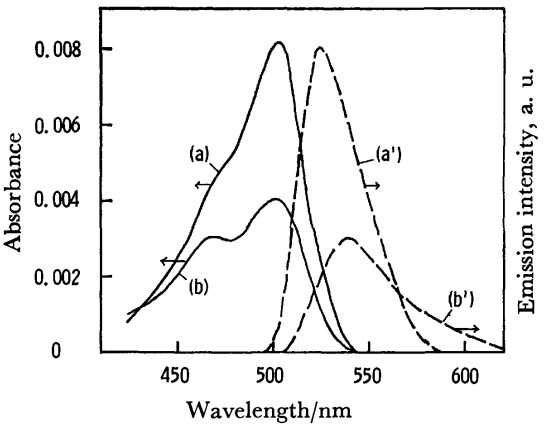


Fig. 4. Absorption and emission spectra of FITC bound on a tin oxide film mesaured in alkaline solution of pH 10.4 : (a) and (a'), and in air : (b) and (b').

Emission Spectra of the Bound Dye. Figure 4 shows the absorption and emission spectra of FITC bound on tin oxide film measured in air and in a carbonate–hydrogencarbonate buffer solution of pH 10.4. In an alkaline solution of fluorescein, both the absorption peak at 493 nm and the emission peak at 515 nm were assigned to the monomeric dianion by Leonhardt *et al.*[15] and Martin and Lindqvist.[16] The equilibrium constant, pK, between the monoanion and the dianion was reported, from absorption measurement, to be 6.7.[15,16] Therefore, the bound FITC is thought to exist mostly in the dianion form when in contact with the alkaline solution, so that the absorption and the emission bands observed in the alkaline solution (Fig. 4 curve a and a') are attributed to the dianion. As the emission band measured in air (Fig. 4, b') is considerably different from that measured in the alkaline solution, it is most reasonably assigned to the monoanion. In the case of titanium oxide powder or quartz used as the substrate, the bound TITC was found to have essentially the same absorption and emission spectra as those in the case of tinoxide film described above.

In the case of FITC bound on a tin oxide film, an emission was observed by excitation with light of 313 nm from a mercury arc lamp. The emission peak was found at 517 nm in water and at 537 nm in air, ascribable to the dye dianion and monoanion, respectively. As the absorption of the dye is very weak at around 313 nm, and the photon energy at 313 nm is much higher than the band gap, 3.2 eV, of tin oxide, the ocurrence of the emission from the bound FITC can only be explained by the excitation of the tin oxide from the valence band to the conduction band followed by the energy transfer from tin oxide to the dye. A similar energy transfer process was pointed out for the system of fluorescein adsorbed on zinc sulfide and zinc oxide crystals by Lendvay.[17]

Theoretical Treatment of Solvent Effects on the Frequency Shifts of Electronic Spectra of Anions

Takehiro Abe

College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received March 13, 1980)

A theoretical expression for the spectral solvent shifts of an anion has been presented by assuming the system to consist of a large anion, its counter cations, and numerous solvent molecules. In the zeroth-order all the component particles in the system do not interact with one another. The interaction energy among the particles for the ith-excited state of the system, in which only the anion is in the ith-excited state, is calculated by the second-order perturbation treatment as the sum of electrostatic interaction energies between pairs of particles. The expression derived from the difference between the interaction energies of the ground and excited states of the system contains the dipole-dipole and dipole-induced dipole interaction terms and the dispersion force terms and is somewhat different from the previous results for neutral solutes (*Bull. Chem. Soc. Jpn.*, **38**, 1314 (1965)). Effects of the counter cations are discussed. This expression is applied to the spectral shifts of an Eosin-Y^{2-} anion, a Meisenheimer complex, and Janovsky complexes.

Many theories have hitherto been proposed for spectral solvent shifts of neutral organic molecules.[1] There are, however, only a few theories relating to anions.[2,3] Miertuš and Kyselǐ[2] have calculated frequencies of some anion radicals in solvents by incorporating the solvent effects into the Hamiltonian operator for the radicals in the restricted SCF MO method. Hirano[3] has extended McRae's theory[4] for neutral molecules to organic anions by considering the effects of their counter cations. Hirano has obtained a general expression involving no dipole-dipole and dipole-induced dipole interaction terms but only the dispersion force contribution. According to his theory, the effects of the counter cations can be ignored.

In order to compare results with Hirano's expression, the author has attempted to derive an expression for the spectral solvent shifts of anions on the basis of the previous theory[5,6] for neutral molecules. The previous expressions[5,6] will be somewhat improved. Moreover, an attempt has been made to clarify the similaritities and differences between McRae's theory[4] and the author's.[5,6]

Theoretical

Model. Electronic spectra of solutions are generally measured at very low concentrations of solutes. Let us, therefore, consider a system consisting of a large anion (A^{n-}), its n counter cations (M^+), and N identical neutral solvent molecules. The anion is not an anion radical or a small anion solvated by coordination of solvent molecules. The cations are monatomic. In the zeroth-order, all the component particles in the system do not interact with one another. Let us consider the ion-pair formation between the anion and the n monovalent cations, because such formation is well-known. The solvent molecules are assumed to form no hydrogen bonds and no complexes with the anion and to have small enough dipole moments that they are not tightly oriented with respect to each other. For convenience, let the origin of the coordinates be the center of mass of the anion. In the spectral measurements of solutes in solutions, one usually chooses solvents that absorb light at much shorter wavelengths than the solutes do. The monovalent cations such as Na^+ and K^+ require transition energies considerably higher than those of the anion and the solvent molecule. One therefore assumes that the solvent molecules and the cations remain in their ground states when a transition from the ground state to the ith excited state occurs in the anion.

The Wave Functions and Energies of the System. Let us write the ith electronic state of the system in the zeroth-order as follows:

$$\Phi_i^\circ = \phi_i^A \prod_{c=1}^{n} \phi_0^c \prod_{s=1}^{N} \phi_0^s. \tag{1}$$

Here the zeroth-order wave functions of ϕ_i^A, ϕ_0^c, and ϕ_0^s denote the ith state of the anion, the ground state of the cth counter cation, and the ground state of the sth solvent molecule, respectively. In the present paper, the suffices and shoulders of A, c and s denote the anion, the cth cation, and the sth solvent molecule, respectively. The ground state of the system is obtained by replacing i by 0 in Eq. 1. Let us assume orthonormality for all the zeroth-order wave functions.

The energy of the ith state of the system in which all the particles interact with one another can be written by the second-order perturbation theory as

$$E_i = E_i^\circ + (\Phi_i^{\circ *}|H'|\Phi_i^\circ) + \sum_{m \neq i} \frac{(\Phi_m^{\circ *}|H'|\Phi_i^\circ)(\Phi_i^{\circ *}|H'|\Phi_m^\circ)}{E_i^\circ - E_m^\circ}, \tag{2}$$

where E_i° is the unperturbed energy corresponding to Φ_i°, E_m° is an unperturbed energy of the mth excited state of the system, and H' is the perturbation due to the interactions among the particles in the system. It may be sufficient to consider transitions only in the anion and the solvent molecules for the mth excited states of the system, because the cation requires much high transition energies, as mentioned above.

A General Expression for the Spectral Solvent Shift. The transition energies from the ground state to the ith excited state of the anion in the vapor and in the solution are denoted by the frequencies of $\nu_{i_0}^\circ$ and ν_{i_0}, respectively. The total interaction energy among the particles in the system of the ith state is obtained by $(E_i - E_i^\circ)$ according to Eq. 1. The difference between $(E_i - E_i^\circ)$ and $(E_0 - E_0^\circ)$ is equal to that between

stabilization energies of the ith-excited and ground states of the anion in the solution, because all the counter cations and the solvent molecules are in their ground states in both the ground and ith-excited states of the system. The spectral solvent shift $(\nu_{i0}-\nu_{i0}^{\circ})$ of the anion is due to the difference between the stabilization energies of the ith-excited and ground states of the anion. Accordingly, the spectral solvent shift is given by $(1/h)\{(E_i-E_i^{\circ})-(E_0-E_0^{\circ})\}$, where h is the Planck constant.

The Frank-Wen model[7] has been accepted for hydration in aqueous solutions. However, solvation numbers of the large picrate anion in organic solvents such as methanol, acetone, acetonitrile, and 1,2-dichloroethane are zero at 25 °C.[8] As described above, the solvent molecules are assumed not to be oriented with respect to each other. The value of $(E_i-E_i^{\circ})$ for the large anion may, therefore, be averaged over all orientations of all the solvent molecules. Thus, one obtains the following expression for the spectral solvent shift:

$$\nu_{i0}-\nu_{i0}^{\circ}=\frac{1}{h}\{<E_i-E_i^{\circ}>_{\mathrm{av}}-<E_0-E_0^{\circ}>_{\mathrm{av}}\}, \quad (3)$$

where $<\ >_{\mathrm{av}}$ denotes the average over all orientations of all the solvent molecules.

An Expression for the Perturbation of H'. According to Böttcher *et al.*,[9] the general expression for the electrostatic interaction energy W_{12} between two unpolarizable particles denoted by 1 and 2 is written as

$$W_{12}=\frac{1}{4\pi\varepsilon_0}\left\{\frac{Q_1Q_2}{R_{12}}-(Q_1\boldsymbol{p}_2-Q_2\boldsymbol{p}_1)\cdot\frac{\boldsymbol{R}_{12}}{R_{12}}-(Q_1\boldsymbol{\theta}_2-\boldsymbol{p}_1\boldsymbol{p}_2+Q_2\boldsymbol{\theta}_1):\boldsymbol{T}_{12}\right\}, \quad (4)$$

where ε_0 is the permittivity of vacuum, Q_1, $\boldsymbol{p}_1$, and $\boldsymbol{\theta}_1$ are the electric charge, permanent dipole moment, and quadrupole moment of particle 1, respectively, and R_{12} is the distance between the centers of masses of the two particles. Here $\boldsymbol{T}_{12}$ is the charge-quadrupole and dipole-dipole interaction tensor of $R_{12}^{-3}(\boldsymbol{I}-3R_{12}^{-2}\boldsymbol{R}_{12}\boldsymbol{R}_{12})$ where $\boldsymbol{I}$ is a unit tensor and $\boldsymbol{R}_{12}$, the position vector from 1 to 2. The dipole and quadrupole moments of the monatomic cation are zero.

On the assumption of the two-body interaction among the particles in the system, one can write H' as

$$H'=H'_{\mathrm{AS}}+H'_{\mathrm{AC}}+H'_{\mathrm{SS}}+H'_{\mathrm{CS}}+H'_{\mathrm{CC}}. \quad (5)$$

Here H'_{AS}, H'_{AC}, H'_{SS}, H'_{CS}, and H'_{CC} are perturbations due to the anion-solvent, anion-cation, solvent-solvent, cation-solvent, and cation-cation interactions, respectively. From Eq. 4, these perturbations can be written as follows:

$$H'_{\mathrm{AS}}=\frac{1}{4\pi\varepsilon_0}\sum_{s=1}^{N}\left\{\frac{ne}{R_s^3}\times\tilde{\boldsymbol{p}}_s\cdot\boldsymbol{R}_s+ne\tilde{\boldsymbol{\theta}}^s:\boldsymbol{T}_{\mathrm{A}s}+\tilde{\boldsymbol{p}}_{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\tilde{\boldsymbol{p}}^s\right\} \quad (6)$$

$$H'_{\mathrm{AC}}=\frac{1}{4\pi\varepsilon_0}\sum_{c=1}^{n}\left\{-\frac{ne^2}{R_c}+\frac{e}{R_c^3}\times\tilde{\boldsymbol{p}}_{\mathrm{A}}\cdot\boldsymbol{R}_c-e\tilde{\boldsymbol{\theta}}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right\} \quad (7)$$

$$H'_{\mathrm{SS}}=\frac{1}{8\pi\varepsilon_0}\sum_{s=1}^{N}\sum_{t=1}^{N}\tilde{\boldsymbol{p}}_s\cdot\boldsymbol{T}_{st}\cdot\tilde{\boldsymbol{p}}_t \quad (8)$$

$$H'_{\mathrm{CS}}=\frac{1}{4\pi\varepsilon_0}\sum_{c=1}^{n}\sum_{s=1}^{N}\left\{-\frac{e}{R_{cs}^3}\times\tilde{\boldsymbol{p}}_s\cdot\boldsymbol{R}_{cs}-e\tilde{\boldsymbol{\theta}}^s:\boldsymbol{T}_{cs}\right\} \quad (9)$$

$$H'_{\mathrm{CC}}=\frac{1}{8\pi\varepsilon_0}\sum_{c=1}^{n}\sum_{d=1}^{n}\frac{e^2}{R_{cd}}. \quad (10)$$

Here e is the elementary charge, a ripple mark denotes an operator, R_s and R_c are the distances from the anion to the sth solvent molecule and the cth cation, respectively, R_{st} is the distance from the sth solvent molecule to the tth solvent one, and R_{cd}, the distance from the cth cation to the dth cation.

Average Values of the Second and Third Terms in Eq. 2. Using Eqs. 5—10, one can calculate average values of the second and third terms on the right hand side of Eq. 2 as below. Here the suffix of double zeros, such as p_{00} and θ_{00}, denotes the moment of the ground state, and p_{ii} and θ_{ii} denote the dipole and quadrupole moments of the ith state. All the dipole moments of the solvent molecules are the same as p_{00}^{S}.

In the calculation of $<E_i-E_i^{\circ}>_{\mathrm{av}}$, one may always neglect terms containing powers higher than the sixth power of $1/R$, because contributions of these terms to the whole are probably negligible. Moreover, for convenience one writes only terms contributing to the frequency shift. The terms are restricted to those surviving through the calculation of $<E_i-E_i^{\circ}>_{\mathrm{av}}-<E_0-E_0^{\circ}>_{\mathrm{av}}$. Common terms appearing in both $<E_0-E_0^{\circ}>_{\mathrm{av}}$ and $<E_i-E_i^{\circ}>_{\mathrm{av}}$ will vanish through the calculation and may be omitted in the expression of $<E_i-E_i^{\circ}>_{\mathrm{av}}$. In the calculation of $<E_i-E_i^{\circ}>_{\mathrm{av}}$, the Boltzmann factor for the ground state of the system is applied even to the distribution of orientations of solvent molecules for the ith-excited state of the system, because the electronic transition in the anion is much faster than reorientations of the solvent molecules according to the Franck-Condon principle.

Paying attention to the assumption of orthonormality for all the zeroth-order wave functions, one obtains

$$\begin{aligned}(\Phi_i^{\circ *}|H'|\Phi_i^{\circ})&=\frac{1}{4\pi\varepsilon_0}\sum_{s=1}^{N}\left\{\frac{ne}{R_s^3}\times\boldsymbol{p}_{00}^s\cdot\boldsymbol{R}_s+ne\boldsymbol{\theta}_{00}^s:\boldsymbol{T}_{\mathrm{A}s}+\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{00}^s\right\}\\&+\frac{1}{4\pi\varepsilon_0}\sum_{c=1}^{n}\left\{-\frac{ne^2}{R_c}+\frac{e}{R_c^3}\times\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{R}_c-e\boldsymbol{\theta}_{ii}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right\}\\&+\frac{1}{8\pi\varepsilon_0}\sum_{s=1}^{N}\sum_{t=1}^{N}\boldsymbol{p}_{00}^s\cdot\boldsymbol{T}_{st}\cdot\boldsymbol{p}_{00}^t\\&-\frac{1}{4\pi\varepsilon_0}\sum_{c=1}^{n}\sum_{s=1}^{N}\left\{\frac{e}{R_{cs}^3}\times\boldsymbol{p}_{00}^s\cdot\boldsymbol{R}_{cs}+e\boldsymbol{\theta}_{00}^s:\boldsymbol{T}_{cs}\right\}\\&+\frac{1}{8\pi\varepsilon_0}\sum_{c=1}^{n}\sum_{d=1}^{n}\frac{e^2}{R_{cd}}. \quad (11)\end{aligned}$$

Then one obtains

$$\begin{aligned}&<(\Phi_i^{\circ *}|H'|\Phi_i^{\circ})>_{\mathrm{av}}\\&=<(\Phi_i^{\circ *}|H'_{\mathrm{AS}}|\Phi_i^{\circ})\exp\{-(\Phi_0^{\circ *}|H'|\Phi_0^{\circ})/kT\}>_{\mathrm{av}}\\&+(\Phi_i^{\circ *}|H'_{\mathrm{AC}}|\Phi_i^{\circ})\\&+<(\Phi_i^{\circ *}|H'_{\mathrm{SS}}|\Phi_i^{\circ})\exp\{-(\Phi_0^{\circ *}|H'|\Phi_0^{\circ})/kT\}>_{\mathrm{av}}\\&+<(\Phi_i^{\circ *}|H'_{\mathrm{CS}}|\Phi_i^{\circ})\exp\{-(\Phi_0^{\circ *}|H'|\Phi_0^{\circ})/kT\}>_{\mathrm{av}}\\&+(\Phi_i^{\circ *}|H'_{\mathrm{CC}}|\Phi_i^{\circ}), \quad (12)\end{aligned}$$

where k is the Boltzmann constant and T is the thermodynamic temperature. For example, calculation of the first term on the right hand side of Eq. 12 is performed first by expanding the exponential part in a Taylor series and then by averaging all the resulting terms over all orientations of the solvent molecules. Thus one obtains

$$\begin{aligned}
&\langle(\Phi_i^{\circ *}|H'|\Phi_i^\circ)\rangle_{\mathrm{av}} \\
&\approx -\frac{1}{(4\pi\varepsilon_0)^2 kT}\sum_{s=1}^{N}\langle(\boldsymbol{p}_{00}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{00}^{s})(\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{00}^{s})\rangle_{\mathrm{av}} \\
&\quad+\frac{1}{4\pi\varepsilon_0}\sum_{c=1}^{n}\left\{\frac{e}{R_c^3}\times\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{R}_c-e\boldsymbol{\theta}_{ii}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right\} \\
&=-\frac{2(p_{00}^{\mathrm{S}})^2(\boldsymbol{p}_{00}^{\mathrm{A}}\cdot\boldsymbol{p}_{ii}^{\mathrm{A}})}{3(4\pi\varepsilon^0)^2kT}\sum_{s=1}^{N}\frac{1}{R_s^6} \\
&\quad+\frac{e}{4\pi\varepsilon_0}\sum_{c=1}^{n}\left\{\frac{\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{ii}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right\}. \qquad (13)
\end{aligned}$$

In view of the mode of transition from the ith state to the mth-excited state, the average value of $I=\langle\sum_{m\neq i}(\Phi_m^{\circ *}|H'|\Phi_i^\circ)(\Phi_i^{\circ *}|H'|\Phi_m^\circ)/(E_i^\circ-E_m^\circ)\rangle_{\mathrm{av}}$ is calculated as the sum of three values, *i.e.*, $I=I_1+I_2+I_3$. Each value results from a different mode of transition and is calculated individually in the manner described below.

The first case is a transition mode in which the anion is excited from the ith-excited state to the jth-excited state and all the other particles remain in their ground states: Let us denote the average of all values of $(E_j^{\mathrm{A}}-E_i^{\mathrm{A}})$ by ΔE_i^{A}, where E_j^{A} is the energy of the jth state (Φ_j^{A}) of the anion except for $j=i$. In this case one obtains $E_i^\circ-E_m^\circ=E_i^{\mathrm{A}}-E_j^{\mathrm{A}}$ and

$$\begin{aligned}
&(\Phi_m^{\circ *}|H'|\Phi_i^\circ) \\
&=\frac{1}{4\pi\varepsilon_0}\sum_{s=1}^{N}\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{00}^{s}+\frac{e}{4\pi\varepsilon_0}\sum_{c=1}^{n}\left\{\frac{\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{ij}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right\}, \qquad (14)
\end{aligned}$$

where $\boldsymbol{p}_{ij}^{\mathrm{A}}=(\phi_i^{\mathrm{A}*}|\tilde{\boldsymbol{p}}^{\mathrm{A}}|\phi_j)$ and $\boldsymbol{\theta}_{ij}^{\mathrm{A}}=(\phi_i^{\mathrm{A}}|\tilde{\boldsymbol{\theta}}^{\mathrm{A}}|\phi_j^{\mathrm{A}})$. Here one denotes an isotropic electric polarizability of the anion in the ith state by $\alpha_{ii}^{\mathrm{A}}=(2/3)\sum_{j\neq i}(|\boldsymbol{p}_{ij}^{\mathrm{A}}|^2/4\pi\varepsilon_0\Delta E_i^{\mathrm{A}})$ in the units of m^3. Then one obtains

$$\begin{aligned}
I_1&=-\Big\langle\sum_{j\neq i}\frac{1}{\Delta E_i^{\mathrm{A}}}(\Phi_m^{\circ *}|H'|\Phi_i^\circ)^2\exp\{-(\Phi_0^{\circ *}|H'|\Phi_0^\circ)/kT\}\Big\rangle_{\mathrm{av}} \\
&\approx-\sum_{j\neq i}\frac{1}{(4\pi\varepsilon_0)^2\Delta E_i^{\mathrm{A}}}\Big[\sum_{s=1}^{N}\langle(\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{00}^{s})^2\rangle_{\mathrm{av}} \\
&\quad+e^2\sum_{j\neq i}\left\{\sum_{c=1}^{n}\left(\frac{\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{ij}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right)\right\}^2\Big] \\
&=-\frac{(p_{00}^{\mathrm{S}})^2\alpha_{ii}^{\mathrm{A}}}{4\pi\varepsilon_0}\sum_{s=1}^{N}\frac{1}{R_s^6} \\
&\quad-\frac{e^2}{(4\pi\varepsilon_0)^2\Delta E_i^{\mathrm{A}}}\sum_{j\neq i}\left\{\sum_{c=1}^{n}\left(\frac{\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{ij}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right)\right\}^2. \qquad (15)
\end{aligned}$$

The second case is a transition mode in which the anion remains in the ith state and one of the N solvent molecules is excited to the lth-excited state: Let us write the average of all values of $(E_l^{\mathrm{S}}-E_0^{\mathrm{S}})$ as ΔE_0^{S}, where E_0^{S} and E_l^{S} are energies of the ground and lth-excited states, respectively, of the solvent molecule. One obtains $E_i^\circ-E_m^\circ=E_0^{\mathrm{S}}-E_l^{\mathrm{S}}$ and

$$\begin{aligned}
&(\Phi_m^{\circ *}|H'|\Phi_i^\circ) \\
&=\frac{1}{4\pi\varepsilon_0}\sum_{s=1}^{N}\left\{\frac{ne}{R_s^3}\times\boldsymbol{p}_{0l}^{s}\cdot\boldsymbol{R}_s+ne\boldsymbol{\theta}_{0l}^{s}:\boldsymbol{T}_{\mathrm{A}s}+\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{0l}^{s}\right\} \\
&\quad+\frac{1}{8\pi\varepsilon_0}\sum_{s=1}^{N}\sum_{t=1}^{N}\boldsymbol{p}_{0l}^{s}\cdot\boldsymbol{T}_{st}\cdot\boldsymbol{p}_{00}^{t} \\
&\quad-\frac{e}{4\pi\varepsilon_0}\sum_{c=1}^{n}\sum_{s=1}^{N}\left\{\frac{\boldsymbol{p}_{0l}^{s}\cdot\boldsymbol{R}_{cs}}{R_{cs}^3}+\boldsymbol{\theta}_{0l}^{s}:\boldsymbol{T}_{cs}\right\}. \qquad (16)
\end{aligned}$$

Then one obtains

$$\begin{aligned}
I_2&\approx-\frac{1}{(4\pi\varepsilon_0)^2\Delta E_0^{\mathrm{S}}}\Big\langle\sum_{m\neq i}(\Phi_m^{\circ *}|H'|\Phi_i^\circ)^2\Big\rangle_{\mathrm{av}} \\
&=-\frac{1}{(4\pi\varepsilon_0)^2\Delta E_0^{\mathrm{S}}}\sum_{s=1}^{N}\sum_{l\neq 0}\langle(\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{0l}^{s})^2\rangle_{\mathrm{av}} \\
&=-\frac{(p_{ii}^{\mathrm{A}})^2\alpha_{00}^{\mathrm{S}}}{4\pi\varepsilon_0}\sum_{s=1}^{N}\frac{1}{R_s^6}, \qquad (17)
\end{aligned}$$

where α_{00}^{S} is the isotropic electric polarizability of the solvent molecule in the ground state.

When any two of the N solvent molecules are simultaneously excited, no terms contributing to the frequency shift appear, because $(\Phi_m^{\circ *}|H'|\Phi_i^\circ)=(1/8\pi\varepsilon_0)\sum_{s=1}^{N}\sum_{t=1}^{N}\boldsymbol{p}_{0l}^{s}\cdot\boldsymbol{T}_{st}\cdot\boldsymbol{p}_{0l}^{t}$ in this case. When more than two of the solvent molecules are simultaneously excited, $(\Phi_m^{\circ *}|H'|\Phi_i^\circ)$ is always zero according to Eqs. 5—10.

The third case is a transition mode in which the anion in the ith state and one of the N solvent molecules in the ground states are simultaneously excited: Since $E_i^\circ-E_m^\circ=E_i^{\mathrm{A}}-E_j^{\mathrm{A}}+E_0^{\mathrm{S}}-E_l^{\mathrm{S}}$ and

$$(\Phi_m^{\circ *}|H'|\Phi_i^\circ)=\frac{1}{4\pi\varepsilon_0}\sum_{s=1}^{N}\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{0l}^{s}, \qquad (18)$$

in this case, one obtains

$$\begin{aligned}
I_3&\approx-\frac{1}{(4\pi\varepsilon_0)^2(\Delta E_0^{\mathrm{S}}+\Delta E_i^{\mathrm{A}})} \\
&\quad\times\Big\langle\sum_{j\neq i}\sum_{l\neq 0}\Big(\sum_{s=1}^{N}\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{T}_{\mathrm{A}s}\cdot\boldsymbol{p}_{0l}^{s}\Big)^2\Big\rangle_{\mathrm{av}} \\
&=-\frac{3\Delta E_0^{\mathrm{S}}\Delta E_i^{\mathrm{A}}\alpha_{00}^{\mathrm{S}}\alpha_{ii}^{\mathrm{A}}}{2(\Delta E_0^{\mathrm{S}}+\Delta E_i^{\mathrm{A}})}\sum_{s=1}^{N}\frac{1}{R_s^6}. \qquad (19)
\end{aligned}$$

Simultaneous excitations of more than two of the N solvent molecules together with the excitation of the anion lead to $(\Phi_m^{\circ *}|H'|\Phi_i^\circ)=0$.

An Expression for ν_{i0}. From Eqs. 3, 13, 15, 17, and 19, one obtains

$$\begin{aligned}
&h(\nu_{i0}-\nu_{i0}^\circ) \\
&=\frac{e}{4\pi\varepsilon_0}\sum_{c=1}^{n}\left\{\left(\frac{\boldsymbol{p}_{ii}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{ii}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right)-\left(\frac{\boldsymbol{p}_{00}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{00}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right)\right\} \\
&\quad+\frac{1}{(4\pi\varepsilon_0)^2}\times\Big[\frac{e^2}{\Delta E_0^{\mathrm{A}}}\sum_{j\neq 0}\left\{\sum_{c=1}^{n}\left(\frac{\boldsymbol{p}_{0j}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{0j}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right)\right\}^2 \\
&\quad-\frac{e^2}{\Delta E_i^{\mathrm{A}}}\sum_{j\neq i}\left\{\sum_{c=1}^{n}\left(\frac{\boldsymbol{p}_{ij}^{\mathrm{A}}\cdot\boldsymbol{R}_c}{R_c^3}-\boldsymbol{\theta}_{ij}^{\mathrm{A}}:\boldsymbol{T}_{\mathrm{A}c}\right)\right\}^2\Big] \\
&\quad+\frac{2(p_{00}^{\mathrm{S}})^2\{(p_{00}^{\mathrm{A}})^2-(\boldsymbol{p}_{00}^{\mathrm{A}}\cdot\boldsymbol{p}_{ii}^{\mathrm{A}})\}}{3(4\pi\varepsilon_0)^2kT}\sum_{s=1}^{N}\frac{1}{R_s^6}
\end{aligned}$$

$$+\frac{(p_{00}^{S})^2(\alpha_{00}^{A}-\alpha_{ii}^{A})}{4\pi\varepsilon_0}\sum_{s=1}^{N}\frac{1}{R_s^6}+\frac{\alpha_{00}^{S}(p_{00}^{A}-p_{ii}^{A})}{4\pi\varepsilon_0}\sum_{s=1}^{N}\frac{1}{R_s^6}$$

$$+\frac{3}{2}\times\left\{\frac{\Delta E_0^{S}\Delta E_0^{A}\alpha_{00}^{S}\alpha_{00}^{A}}{\Delta E_0^{S}+\Delta E_0^{A}}-\frac{\Delta E_0^{S}\Delta E_i^{A}\alpha_{00}^{S}\alpha_{ii}^{A}}{\Delta E_0^{S}+\Delta E_i^{A}}\right\}\sum_{s=1}^{N}\frac{1}{R_s^6}. \quad (20)$$

Both the first and second terms on the right hand side of Eq. 20 are due to the anion-cation interactions and are independent of the solvent. The second term is probably much smaller than the first, because the former contains coefficients of the sixth power of $1/R_c$, while coefficients of the latter are of the third power. The second term may therefore be ignored. The third, fourth, fifth and sixth terms are due to the anion dipole-solvent dipole interactions, the solvent dipole-anion induced dipole ones, the anion dipole-solvent induced dipole ones, and the anion-solvent dispersion forces, respectively. All these terms relating to the solvent contain coefficients of R_s^{-6}. Therefore, the solvent molecules mainly contributing to the frequency shift are attributed to those around the anion. Here one may approximately consider only the closely neighboring solvent molecules. According to the previous treatment,[5,6] this approximation leads to

$$\sum_{s=1}^{N}\frac{1}{R_s^6}\approx\frac{\pi}{(r_A+r_S)^4}\times\left(\frac{4\pi N_A}{3}\right)^{2/3}\left(\frac{d^S}{M_r^S}\right)^{2/3}, \quad (21)$$

where N_A is Avogadro's number, r_A and r_S are radii of the anion and the solvent molecule, respectively, and d^S and M_r^S, the relative density and molecular weight, respectively, of the solvent. For example, r_S is given by

$$r_S=\left(\frac{3M_r^S}{4\pi N_A d^S}\right)^{1/3}. \quad (22)$$

Thus, Eq. 20 is reduced to

$$\nu_{i0}=\nu'_{i0}+A\times\frac{(d^S/M_r^S)^{2/3}(p_{00}^S)^2}{(r_A+r_S)^4}+B\times\frac{(d^S/M_r^S)^{2/3}\alpha_{00}^S}{(r_A+r_S)^4}, \quad (23)$$

where

$$\nu'_{i0}=\nu^\circ_{i0}+\frac{1}{4\pi\varepsilon_0}\sum_{c=1}^{n}\frac{e}{R_c^3}\left\{(\boldsymbol{p}_{ii}^A-\boldsymbol{p}_{00}^A)\cdot\boldsymbol{R}_c+(\boldsymbol{\theta}_{00}^A-\boldsymbol{\theta}_{ii}^A):\left(\boldsymbol{I}-\frac{3}{R_c^2}\boldsymbol{R}_c\boldsymbol{R}_c\right)\right\} \quad (24)$$

$$A=\frac{\pi}{h}\left(\frac{4\pi N_A}{3}\right)^{2/3}\times\left[\frac{2\times\{(p_{00}^A)^2-(\boldsymbol{p}_{00}^A\cdot\boldsymbol{p}_{ii}^A)\}}{3(4\pi\varepsilon_0)^2kT}+\frac{(\alpha_{00}^A-\alpha_{ii}^A)}{4\pi\varepsilon_0}\right], \quad (25)$$

and

$$B=\frac{\pi}{h}\left(\frac{4\pi N_A}{3}\right)^{2/3}\times\left[\frac{(p_{00}^A)^2-(p_{ii}^A)^2}{4\pi\varepsilon_0}+\frac{3}{2}\times\left(\frac{\Delta E_0^A\alpha_{00}^A}{1+\Delta E_0^A/\Delta\bar{E}_0^S}-\frac{\Delta E_i^A\alpha_{ii}^A}{1+\Delta E_i^A/\Delta\bar{E}_0^S}\right)\right]. \quad (26)$$

Although ΔE_0^S varies with the solvent, ΔE_0^S is for convenience replaced by the average $\Delta\bar{E}_0^S$ of values of ΔE_0^S in Eq. 26. Then, A and B may be approximately characteristic of the anion. Equation 24 indicates that ν'_{i0} is independent of the solvent. According to Eq. 23, therefore, values of ν'_{i0}, A, and B can be estimated by the least-squares method from experimental frequencies of the anion in several solutions. From Eq. 24, effects of the ion pairings between the anion and its cations are shown by the second term in Eq. 24 and can be regarded as being involved at a constant magnitude in the experimental frequency (ν_{i0}).

Discussion

As shown by Eq. 20, the solvent shift is due to the dipole-dipole interactions, the induced dipole-dipole ones, and the dispersion forces between the anion and the solvent molecules, because the first and second terms are independent of the solvent. On the other hand, Hirano's expression for the same shift involves only the dispersion force terms.[3] The essential difference between the present treatment and Hirano's seems to arise from the different results of calculations of the first- and second-order terms of Eq. 2. Moreover, according to Hirano, the effects of the counter cations on the frequency shift can be approximately ignored, while in the present treatment the effects are included approximately at a constant magnitude in the experimental frequency. The difference may be attributed to the operation of averaging over all orientations of the counter cations. Hirano has performed this operation; it is not done in the present treatment.

Equation 23 can be applied not only to the large anions but also to neutral molecules, because the effects of charge of the anion are not involved in Eqs. 25 and 26 and ν'_{i0} is equal to ν°_{i0} in the absence of the counter cations. The previous expressions[5,6] have been derived from assuming van der Waals' equation at the beginning for interactions between the neutral solute molecule in the ith state and the solvent molecules. The present treatment is the theoretical basis of the previous theory:[5,6] If the first and second terms are omitted and $(\boldsymbol{p}_{00}^A\cdot\boldsymbol{p}_{ii}^A)$ is replaced by $(p_{ii}^A)^2$ in Eq. 20, Eq. 20 is essentially the same as the previous expressions. Accordingly, the previous expressions can be derived in the same way as in the present treatment, if the Boltzmann factor of exp $\{-(\Phi_i^{\circ *}|H'|\Phi_i^\circ)/kT\}$ is used instead of that of exp $\{-(\Phi_0^{\circ *}|H'|\Phi_0^\circ)/kT\}$ for the ith-excited state of the system. This leads to the conclusion that the Franck-Condon principle has not been considered in the previous expressions. When the principle is considered in the previous expressions,[5,6] the value of $(p_{ii}^A)^2$ appearing in the solute dipole-solvent dipole interaction terms should be replaced by $(\boldsymbol{p}_{00}^A\cdot\boldsymbol{p}_{ii}^A)$.

In McRae's theory[4] the Hamiltonian operator in Eq. 2 consists of instantaneous dipole-dipole interactions between two neutral molecules in the system. In the case of the neutral solute molecule (U), H' is written from Eq. 4 as

$$H'=\sum_{S=1}^{N}\tilde{\boldsymbol{p}}^U\cdot\boldsymbol{T}_{Us}\cdot\tilde{\boldsymbol{p}}^s. \quad (27)$$

Equation 27 is the dipole-dipole interaction operator. Accordingly, the previous treatment[5,6] is fundamentally similar to that of McRae, as also described by Amos and Burrows.[1a] An essential difference between McRae's theory[4] and that of the present author lies in the following point: In McRae's theory the second and third terms in Eq. 2 have been concretely calculated by using reaction fields of the Onsager type,[10] while

in the present treatment these terms have been consistently obtained in terms of the two-body interactions among the particles of the system. Although the value of local relative permittivity in the neighborhood of the solute differs from that of the bulk relative permittivity of the solvent, the local permittivity is not considered at all in deriving the Onsager reaction field. In order to consider the local permittivity, the Block-Walker reaction field[11] should be used instead of the Onsager one in McRae's theory for the neutral molecule. For the description of experimental results for solvent effects on several phenomena, the Block-Walker reaction field is much superior to the Onsager one.[12] In McRae's theory,[4] another problem arises due to the following assumption: A time average of a square field at the solute dipole owing to the presence of permanent dipoles of surrounding solvent molecules is arbitrarily assumed to be equal to three times the squared value of the reaction field. On the other hand, the present treatment is not accompanied by such problems, because the relative permittivity and the reaction field are not used.

Hirano[3] has extended McRae's theory for the neutral molecule to the anion, using the Onsager reaction field. Both the Onsager reaction field and the Block-Walker one are derived from the assumption that the solute molecule has no excess charge and from solving Laplace equations. These reaction fields can not be applied to the anion, because a reaction field for the anion must be derived by solving a Poisson equation. Instead of the Onsager reaction field, the Kirkwood reaction field[13,14] consisting of the Born charging energy[15] and the Onsager reaction field should be used for the anion, but this field is also derived after neglecting the local relative permittivity. Beveridge and Schnuelle[14] have theoretically treated the polarization energy of a charged solute and have presented a general expression definitely containing the local relative permittivity. One, however, finds difficulty in applying the expression, because it is hard to determine values of the local relative permittivity and thickness of a local solvent shell. These values are necessary for applying the expression. Thus, the solvent shift of the anion has been studied by the present treatment.

In the present calculation of the interaction energies between the solute and the solvent molecules, a serious problem arises from the evaluation of the "average energies" such as ΔE_0^{A}, ΔE_i^{A}, and ΔE_0^{S}. It is found that ΔE_0^{A} and ΔE_0^{S} are approximately equal to ionization potentials (I_0^{A} and I_0^{S}) of the solute and solvent molecules, respectively, in their ground states.[16] The replacement of the average energy by the ionization potential has not been justified theoretically.[1a,17] At the present stage, however, there is no approach to this problem other than the replacement. The value of ΔE_i^{A} may be replaced by $I_i^{\mathrm{A}}=I_0^{\mathrm{A}}-hc\nu_{i0}^{\circ}$ as in the previous papers,[5,6] where c is the speed of light *in vacuo* and I_i^{A}, an ionization potential of the anion in the ith state. Amos and Burrows[1a,17] have stated that approximately the same average energies should be taken for both the ground and excited states. So far as the average energy is assumed to be approximated by the ionization potential, the assumption of $I_i^{\mathrm{A}}=I_0^{\mathrm{A}}-hc\nu_{i0}^{\circ}$ is valid for a low-lying excited state: The energy of the ground state of the solute molecule is denoted by $E(^1\Psi_0)$. The energy of the ith-excited state ($^1\Psi_{i0}$) resulting from a transition of an electron from the highest occupied MO (ϕ_0) to the ith vacant MO (ϕ_i) is written as

$$E(^1\Psi_{i0}) = E(^1\Psi_0) + hc\nu_{i0}^{\circ}. \tag{28}$$

According to Roothaan,[18] a singly ionized state ($^2\Psi_0$) obtained by removing either of the two electrons occupying ϕ_0 has an energy given by

$$E(^2\Psi_0) = E(^1\Psi_0) - \varepsilon_0(\Psi_0) = E(^1\Psi_0) + I_0, \tag{29}$$

where $\varepsilon_0(\phi_0)$ is the energy of ϕ_0, and I_0 is the ionization potential of the ground state of the molecule. From Eqs. 28 and 29, one can write the ionization potential of $^1\Psi_{i0}$ as

$$I_i = E(^2\Psi_0) - E(^1\Psi_{i0}) = I_0 - hc\nu_{i0}^{\circ}. \tag{30}$$

If the anion is small and is solvated by coordination of the solvent molecules, the second and third terms in Eq. 2 must be calculated without the operation of averaging over all the orientations of all the solvent molecules. Of course, Eq. 23 can not be applied to such a small anion. In the case of a small solvated anion, one may calculate the second and third terms by considering only the solvating solvent molecules surrounding the anion.

Since a molecule generally has a dipole moment larger than its quadrupole moment, Eq. 24 may be approximated by

$$\nu'_{i0} = \nu_{i0}^{\circ} + \Delta\nu_{\mathrm{C}}, \tag{31}$$

where

$$\Delta\nu_{\mathrm{C}} = \frac{e}{4\pi\varepsilon_0}\sum_{c=1}^{n}\frac{(\boldsymbol{p}_{ii}^{\mathrm{A}}-\boldsymbol{p}_{00}^{\mathrm{A}})\cdot\boldsymbol{R}_{\mathrm{C}}}{R_c^3}. \tag{32}$$

Here $\Delta\nu_{\mathrm{C}}$ is a frequency shift due to the ion pairings between the anion and its counter cations. Equation 32 shows that $\Delta\nu_{\mathrm{C}}$ becomes smaller with increasing values of R_c, *i.e.*, with an increasing radius of the cation. As described above, $\Delta\nu_{\mathrm{C}}$ is contained in the experimental frequency (ν_{i0}). Consequently, as the radius of cation increases in the same solvent, a wavelength corresponding to ν_{i0} will shift to the red if $(\boldsymbol{p}_{ii}^{\mathrm{A}}-\boldsymbol{p}_{00}^{\mathrm{A}})\cdot\boldsymbol{R}_c>0$, because $\Delta\nu_{\mathrm{C}}$ decreases in this case. If $(\boldsymbol{p}_{ii}^{\mathrm{A}}-\boldsymbol{p}_{00}^{\mathrm{A}})\cdot\boldsymbol{R}_c<0$, the shift of the wavelength will be toward the blue, because $\Delta\nu_{\mathrm{C}}$ increases. Because of the negative charge, the dipole moment of the anion varies with the way of setting the origin of the coordinates,[19] and often takes a minus sign, as exemplified below. Accordingly, the minus sign as well as a plus one must be considered for values of $\boldsymbol{p}_{00}^{\mathrm{A}}$ and $\boldsymbol{p}_{ii}^{\mathrm{A}}$ which satisfy an inequality of $(\boldsymbol{p}_{ii}^{\mathrm{A}}-\boldsymbol{p}_{00}^{\mathrm{A}})\cdot\boldsymbol{R}_c\lesseqgtr 0$. Such red shifts seem to be seen in the cases of xanthene and thioxanthene in 2-methyltetrahydrofuran.[20] For example, xanthene shows absorption maxima at 413, 436, 470, and 482 nm owing to the ion pairings with Li^+, Na^+, K^+, and Cs^+, respectively.[20]

The ion pairings of 4,4-dimethoxy-1,3,5-trinitro-2,5-cyclohexadienide anion with $(n\text{-}C_4H_9)_4N^+$, Na^+, Ca^{2+}, and Ba^{2+} in methanol show the first bands at 480, 490, 490, and 500 nm, respectively, and the second bands at 418, 412, 404, and 405 nm, respectively.[21] The first

and second bands tend to shift to the red and to the blue, respectively, with an increasing radius of the cation. In the solution the counter cation is probably held by the four oxygen atoms of two methoxyl groups and two nitro groups on the 3,5-positions.[21] Moreover, a symmetrical structure of crystalline potassium salt of the anion has been determined by the X-ray method.[22] In view of the symmetrical structure of the ion pair between the anion and its cation, all $\boldsymbol{p}^{A}_{00}$, $\boldsymbol{p}^{A}_{ti}$, and $\boldsymbol{R}_c$ probably lie along the same axis of the C_{2v}-symmetry. In the anion, the position vector of the center of negative-charge distribution is much greater in magnitude than that of the positive-charge distribution, though the former magnitude depends on the way of setting the origin. The dipole moment of the anion may, therefore, be in the direction opposite to that of the neutral molecule. One may, therefore, assume that $\boldsymbol{p}^{A}_{00}$ and $\boldsymbol{p}^{A}_{ti}$ are in the opposite direction of $\boldsymbol{R}_c$ in this case. Consequently, one obtains inequalities of $P^{A}_{00}>P^{A}_{ti}$ and $P^{A}_{ti}>P^{A}_{00}$ from the red and blue shifts, respectively. Thus, the dipole moment of the ground state of the anion may be larger than that of the first-excited state but may be smaller than that of the second-excited state.

Equation 32 also shows that, in the case of the same solvent, the shift does not vary with the cation if $P^{A}_{00}\simeq 0$ and $P^{A}_{ti}\simeq 0$ or if $P^{A}_{00}\simeq P^{A}_{ti}$. Such behavior seems to appear in the case of the triiodide anion.[23] The first and second excited states of the triiodide anion as well as its ground state are likely to be nonpolar since their structures consist of three identical iodine atoms. For example, the triiodide anion in diethyl ether shows the first absorption bands at 366.5, 366.7, and 366.4 nm owing to the ion pairings with $(C_2H_5)_4N^+$, $(C_2H_5)_3AsI^+$, and Cs^+, respectively.[23]

In applying Eq. 23, it is convenient to use a wave number σ_{t0} instead of ν_{t0}, because the former is calculated with somewhat greater ease than the latter from the λ_{t0} wavelength observed. Then, ν'_{t0} and ν°_{t0} are replaced by σ'_{t0} and σ°_{t0}. The value of λ_{t0} measured with a spectrophotometer is not a wavelength in the solution but is approximately converted into a wavelength *in vacuo*. In Eq. 23, therefore, ν_{t0} can be replaced by $c\sigma_{t0}$. If λ_{t0} is a value in the solution, ν_{t0} should be replaced by $(c/n_S)\sigma_{t0}$, where n_S is the refractive index of the solvent.

Applications

All the dipole moments and polarizabilities of the anion and the solvent molecule in Eqs. 23—26 are values measured in vapors, because in the zeroth-order approximation all the particles in the system are assumed not to interact with one another. In applying Eq. 23, the temperature was always assumed to be 20 °C and the dipole moments (p^{S}_{00}) of the solvent molecules in vapors were taken from Refs. 24 and 25. Dipole moments of *N,N*-dimethylformamide, *N,N*-dimethylacetamide, dimethyl sulfoxide, 1,2-dimethoxyethane and diethyloxalate were values measured in benzene,[26] since their moments in vapors were not found. Values of α^{S}_{00} were calculated from sums of bond refractions. Unfortunately, few systematic experimental studies have been reported on the spectral solvent shifts of anions.

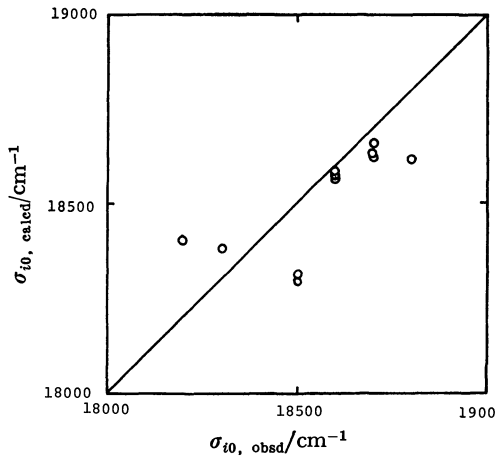

Fig. 1. Correlation of $\sigma_{t0,\ calcd}$ with $\sigma_{t0,\ obsd}$ for the first band of Eosin-Y^{2-} anion.

Eosin-Y^{2-} Anion. Values used for σ_{t0} of Eosin-Y^{2-} were those measured by Hirano.[3] He did not report the kind of counter cation used. The value of r_A was assumed to be 0.56 nm from the molecular volume (0.7—0.8 nm^3) estimated in footnote 25 in Ref. 3. These results were obtained: $\sigma'_{t0}=18990\ cm^{-1}$, $A=5.60\times10^{12}\ J^{-1}\ m^2$, and $B=-5.75\times10^{-6}\ m^2$. The frequencies ($\sigma_{t0.calcd}$) calculated by using these values are plotted in Fig. 1 against the $\sigma_{t0.obsd}$ observed. The correlation of $\sigma_{t0.calcd}$ with $\sigma_{t0.obsd}$ is as good as that in the application of Hirano.[3] The value of σ'_{t0} is smaller than that of σ°_{t0} (19300 cm^{-1}) obtained by Hirano, though σ'_{t0} is interpreted to involve a constant shift due to the ion pairings with cations.

The Meisenheimer Complex of 1,3,5-Trinitrobenzene with Cyanide Ion. An application was made to spectral solvent shifts of the first and second absorption bands of the tetrabutylammonium salt of 4-cyano-1,3,5-trinitro-2,5-cyclohexadienide (**1**).[27] The value of r_A was assumed to be 0.44 nm from crystal data[22] of the potassium salt of 4,4-dimethoxy-1,3,5-trinitro-2,5-cyclo-

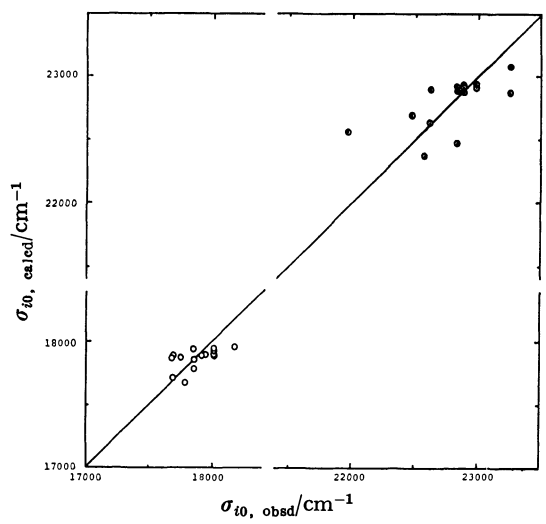

Fig. 2. Correlations of $\sigma_{t0,\ calcd}$ with $\sigma_{t0,\ obsd}$ for the first (○) and second (⊙) bands of **1**.

hexadienide. These results were obtained: $\sigma'_{i0}=18200$ cm^{-1}, $A=-9.32\times10^{11}$ J^{-1} m^2, and $B=-2.271\times10^{-6}$ m^2 for the first band, and $\sigma'_{i0}=23260$ cm^{-1}, $A=-1.153\times10^{13}$ J^{-1} m^2, and $B=-2.571\times10^{-6}$ m^2 for the second band. The frequencies calculated by using these values of σ'_{i0}, A, and B are roughly correlated with those observed, as shown in Fig. 2.

Putting the above values of A and B for the first band into Eqs. 25 and 26, respectively, one obtains the following equations:

$$\{(p^{A}_{00})^2-(\boldsymbol{p}^{A}_{00}\cdot\boldsymbol{p}^{A}_{ii})\}+6.17\times10^{-21}\,\mathrm{J}\times(\alpha^{A}_{00}-\alpha^{A}_{ii})=-0.20\times10^{-49}\,\mathrm{J\,m^3} \quad (33)$$

$$\{(p^{A}_{00})^2-(p^{A}_{ii})^2+1.5\times\left(\frac{\Delta E^{A}_{0}\alpha^{A}_{00}}{1+\Delta E^{A}_{0}/\Delta\bar{E}^{S}_{0}}-\frac{\Delta E^{A}_{i}\alpha^{A}_{ii}}{1+\Delta E^{A}_{i}/\Delta\bar{E}^{S}_{0}}\right)=-77.49\times10^{-49}\,\mathrm{J\,m^3}. \quad (34)$$

Generally, upon an electronic excitation from a ground state to an excited one, an increase in polarizability might be expected, because an orbital of the excited state is larger and more diffuse than that of the ground state. Actually, such increases in polarizabilities have been confirmed experimentally for several neutral molecules.[28] An inequality of $\alpha^{A}_{ii}>\alpha^{A}_{00}$ may also be expected for the anion under consideration. Since (1 Debye)$^2=1.000\times10^{-49}$ J m^3, -77.49×10^{-49} J m^3 in Eq. 34 is rather large. This large negative value is probably due not only to $\alpha^{A}_{ii}>\alpha^{A}_{00}$ but also to $|p^{A}_{ii}|>|p^{A}_{00}|$, because ΔE^{A}_{0} is larger than ΔE^{A}_{i}, according to Eq. 30, and the second term on the left hand side of Eq. 34 is probably not so large that the value can be attributed to it alone. On the other hand, the absolute value of -0.20×10^{-49} J m^3 in Eq. 33 is relatively very small. This small negative value should be due to cancellation between the first and second terms on the left hand side of Eq. 33. This leads to the inequality of $\{(p^{A}_{00})^2-(\boldsymbol{p}^{A}_{00}\cdot\boldsymbol{p}^{A}_{ii})\}>0$, since $\alpha^{A}_{ii}>\alpha^{A}_{00}$. Changes in dipole moments between the ground and excited states of the anion are probably due to those of the π-electron system of 1,3,5-trinitro-2,4-pentadien-1-ide. In view of the symmetric structure of the π-electron system, both p^{A}_{00} and p^{A}_{ii} are approximately in the same direction. Therefore, the inequality of $\{(p^{A}_{00})^2-(\boldsymbol{p}^{A}_{00}\cdot\boldsymbol{p}^{A}_{ii})\}>0$ comes probably from the relation of $p^{A}_{00}>0$ and $0>p^{A}_{ii}$, since $|p^{A}_{ii}|>|p^{A}_{00}|$. Thus, the positive dipole moment of the ground state of **1** is larger than the negative dipole moment of the first-excited state, while the absolute value of the latter is larger than the former. In a similar way the relative large values of both A and B for the second band lead to the opposite conclusion, that the dipole moment of the second-excited state is larger than that of the ground state.

These conclusions are supported by the results ($p^{A}_{00}>p^{A}_{ii}$ (the first-excited state) and $p^{A}_{00}<p^{A}_{ii}$ (the second-excited state)) obtained above from the red and blue shifts due to the ion pairings of 4,4-dimethoxy-1,3,5-trinitro-2,5-cyclohexadienide anion, because the changes in the dipole moments between the ground and excited states of both the anions can be attributed approximately to those of the same π-electron system of 1,3,5-trinitro-2,4-pentadien-1-ide.

The conclusions obtained above from the spectral solvent shifts of **1** are also supported by calculating the dipole moments of the π-electron system. Hosoya *et al.*[29] have reported the SCF MO's and atomic coordinates for the π-electron system of 1,3,5-trinitro-2,4-pentadien-1-ide anion. Using their MO's and coordinates, one obtains the dipole moments of -7.2, -12.2, and -0.8 Debyes for the ground, first-excited, and second-excited states, respectively, of the π-electron system in the same direction of the y axis (the axis of C_{2v} symmetry). When the values of these dipole moments are divided by $-e$, centers of negative-charge distributions may be approximately obtained, because the magnitude of the position vector of the center of the negative-charge distribution is much greater than that of the positive-charge distribution in the anion, as described above. Even if the origin is shifted by y_0, the positions of these centers of the negative-charge distributions do not change and their coordinates only change by y_0. The center of mass of **1** is apparently located above the origin set by Hosoya *et al.* at the position of 1-carbon. When their origin is shifted upward by 0.16 nm along the y axis, one obtains the dipole moments of 0.5, -4.5 and 6.9 Debyes for the ground, first-excited, and second-excited states, respectively. These dipole moments of the π-electron system can explain the conclusions obtained from the spectral solvent shifts of **1**.

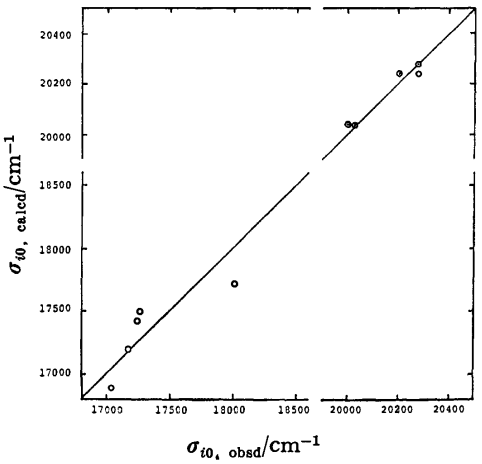

Fig. 3. Correlations of $\sigma_{i0,\,calcd}$ with $\sigma_{i0,\,obsd}$ for the first bands of **2** (○) and **3** (◉).

Janovsky Complexes. Applications were tried to the first absorption bands of the Janovsky complexes of the potassium salts of 4-acetonyl-1,3-dinitro-2,5-cyclohexadienide (**2**) and 4-acetonylidene-1,3-dinitro-2,5-cyclohexadienide (**3**). As in the case of **1**, r_A was assumed to be 0.44 nm. The values of $\sigma'_{i0}=18170$ cm^{-1}, $A=-2.434\times10^{13}$ J^{-1} m^2 and $B=-2.636\times10^{-6}$ m^2 were obtained for **2** and those of $\sigma'_{i0}=20560$ cm^{-1}, $A=6.43\times10^{11}$ J^{-1} m^2 and $B=-2.453\times10^{-6}$ m^2 were obtained for **3**. The correlation of $\sigma_{i0,calcd}$ with $\sigma_{i0,obsd}$ is fairly good, as shown in Fig. 3. The magnitudes of A for **3** and **2** correspond to those of the first and second bands of **1**, respectively. Accordingly, in a similar way as in the case of **1**, one will arrive at the conclusions that in the case of **3** the dipole moment of the ground state may be larger than that of the first-excited state, while in the case of **2** the latter is larger than the former.

A Thermodynamic Study on Hydrolytic Reactions of Lead(II) Ions in an Aqueous Solution and Dioxane-Water Mixtures. II. A Calorimetric Study

Shin-ichi Ishiguro and Hitoshi Ohtaki*

Department of Electronic Chemistry, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 17, 1980)

The hydrolytic reactions of lead(II) ions were calorimetrically studied at 25 °C in an aqueous solution and dioxane-water mixtures (dioxane contents: 0.1 and 0.2 mole fractions, which correspond to 35.21 and 55.01 % w/w, respectively) both containing 3 mol dm^{-3} (Li)ClO_4 as a constant ionic medium. A fully automatic on-line system was used for the calorimetric titrations. Values of enthalpies and entropies for the formation of the $Pb_3(OH)_3^{3+}$, $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$ and $Pb_6(OH)_8^{4+}$ complexes in the aqueous solution, 0.1 and 0.2 mole fraction dioxane solutions were given. For the reaction $qPb^{2+}+pH_2O=Pb_q(OH)_p^{(2q-p)+}+pH^+$, the values of ΔH^*_{pq}/kJ mol^{-1} and $T\Delta S^*_{pq}$/kJ mol^{-1} were determined as follows: $Pb_3(OH)_3^{3+}$: 66.6, −20.7 (in aqueous solution); 72.1, −13.4 (in 0.1 mole fraction dioxane solution); 66.9, −17.7 (in 0.2 mole fraction dioxane solution); $Pb_4(OH)_4^{4+}$: 81.4, −29.5; 84.1, −22.1; 94.7, −14.7; $Pb_3(OH)_4^{2+}$: 61.6, −68.4; 83.4, −41.0, 99.8, −24.3; $Pb_6(OH)_8^{4+}$: 242.8, 1.3, 243.2, 10.6; 236.7, 2.0. The solvent effects on ΔH^*_{pq} were discussed in terms of a function of the formal charge per metal ion of the complex, $z'=(2q-p)/q$. The thermodynamic parameters obtained for the $Pb_6(OH)_8^{4+}$ complex were better explained by assuming the reaction, $2Pb_3(OH)_4^{2+}=Pb_6O(OH)_6^{4+}+H_2O$, than the reaction, $2Pb_3(OH)_4^{2+}=Pb_6(OH)_8^{4+}$, and thus the $Pb_6(OH)_8^{4+}$ complex formally written from the result of the potentiometric measurements will be described as $Pb_6O(OH)_6^{4+}$ which has previously been proposed by X-ray diffraction.

In a previous paper,[1] we have discussed the Gibbs energy ΔG_{pq} of the hydrolytic reaction, $qM^{z+}+pOH^- = M_q(OH)_p^{(zq-p)+}$, of divalent metal ions such as beryllium, copper, nickel, cadmium and lead in aqueous solutions and dioxane-water mixtures containing 3 mol dm^{-3} (Li)ClO_4 as an ionic medium. The Gibbs energy of transfer divided by p, $\Delta G^t_{pq}/p$ [$=\{\Delta G_{pq}(\text{mix})-\Delta G_{pq}(\text{aq})\}/p$], was found to be approximately independent of the composition of the complexes and the kind of the metal ions, and furthermore, the following relation was obtained:

$$\frac{1}{q}\Delta g^t_{pq} \approx \Delta g^t_M + k(z-z'),$$

where Δg^t_{pq} and Δg^t_M denote the partial molar Gibbs energies of transfer of $M_q(OH)_p^{(zq-p)+}$ and M^{z+}, respectively, and z' indicates the formal charge per metal ion of $M_q(OH)_p^{(zq-p)+}$ [$z'=(zq-p)/q$], k being a constant. In the preceding work, on the other hand, we found that the enthalpies and entropies of transfer of the hydroxo complexes of beryllium ion strongly depend on the composition of the complexes.[2] In order to throw more light for elucidating solvent effects on thermodynamic parameters of hydrolytic reactions of metal ions, we examined a calorimetric study on hydrolytic reactions of lead(II) ion in an aqueous solution and dioxane-water mixtures.

Experimental

The calorimetric measurements were carried out in a room thermostated at 25 °C.[2] All the cells used were Dewar vessels, which were immersed in a water bath at (25.00±0.05) °C. Fluctuation of the temperature of the bath during one course of the measurement was within ±0.007 °C. About 150 cm^3 of a test solution which contained hydrolyzed lead(II) ions was placed in a titration vessel, then it was titrated with a standard perchloric acid solution. Initial concentrations of total lead ions in the test solution were changed from 0.005

a) q is estimated by averaging $Q_{ev}(t)$ values from 201 to 300 s (100 points).

to 0.2 mol dm^{-3}. Both the test solution and the titrant contained 3.0 mol dm^{-3} perchlorate ion as a constant ionic medium. The test solutions were prepared by mixing stock solutions of lead perchlorate and lithium hydroxide.

The cell arrangement used was essentially the same as that described in the previous paper.[2] All the procedures for the calorimetric titrations were carried out by using a fully automatic on-line system reported in the previous paper[2] with a slight modification. In the present study, the titrant was automatically added from an automatic piston buret (Dosimat E535, Metrohm, Switzerland) controlled by an electronic computer. Other devices were the same as those used previously. The titrant was added stepwise and the volume of the titrant added in one step was about 0.5—1 cm^3 with an accuracy ± 0.001 cm^3.

We previously described the method of calorimetric determinations of heat evolved.[2] However, the estimation of the heat escaping from the titration vessel was simple in the previous treatment, so that the method was applicable only to systems involving fast reactions which reached equilibria within a few minutes. In the present procedure, a more generalized treatment is adopted to evaluate the heat escaping during the measurement. The total heat which has escaped from the titration vessel until t seconds after the start of the addition of the titrant, $Q_L(t)$, is expressed by

$$Q_L(t) = C_p V \alpha \int_0^t \{\theta(\tau) - \theta_0\} d\tau, \quad (1)$$

where C_p, V, and α stand for the heat capacity per unit volume of the test solution, the total volume of the solution in the vessel and the rate of heat escaping from the titration vessel, respectively. C_p and α were obtained by the same method as that used previously.[2] θ_0 represents the temperature of the test solution at the initial stage where the solution is at the thermal equilibrium with the thermostated bath and $\theta(\tau)$ is the temperature of the test solution at time τ after

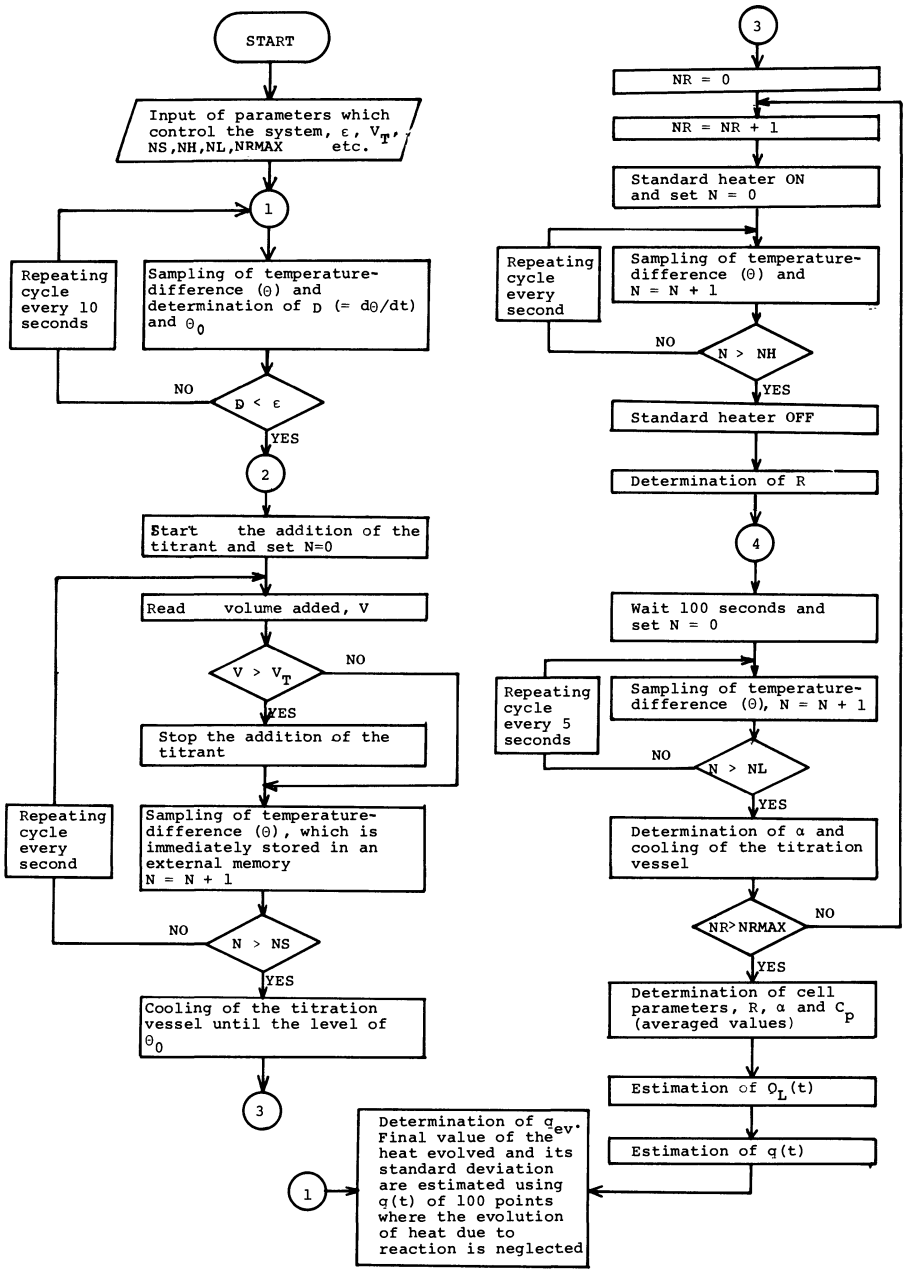

Fig. 1. The flow chart for determination of heat evolved per addition of the titrant.

the start of the addition of the titrant. The temperature change was measured at every second. Then, the heat evolved $Q_{ev}(t)$ until a time t after the start was determined by the following equation:

$$Q_{ev}(t) = k_1 C_p V\{\theta(t) - \theta_0\} + Q_L(t) + k_2, \quad (2)$$

where k_1 and k_2 denote empirical constants (k_1 is close to unity and k_2 is nearly zero joule) which had been determined by separate experiments by using a standard heater. $Q_{ev}(t)$ approaches a constant value q when the evolution of heat due to the reactions becomes negligible. A typical set of $Q_{ev}(t)$ and $Q_L(t)$ as functions of time is shown in Table 1. The heat evolved q was finally estimated by averaging $Q_{ev}(t)$ values of the last 100 points (data from 201 to 300 s in Table 1). The standard deviation was usually within ± 0.03 J.

The flow chart for determination of heat evolved per addition of the titrant is presented in Fig. 1. A least-squares method was employed for the analysis of the set of the data obtained.

Reagents. Stock solutions were prepared by similar ways described in the previous paper.[1)]

Results

The total heat evolved Q by complex formation involving several species is expressed as follows:

$$Q = \sum_j q_j = \sum_i \Delta H_i \cdot \delta n_i, \quad (3)$$

where ΔH_i and δn_i stand for the enthalpy of formation of the complex species i and the amount of the complex species decomposed by the addition of the standard acid solution at each step of titration, respectively. j represents the number of portions of the titrant added in one course of the titation.

We have previously reported that four hydroxo complexes of lead(II) ions, $Pb_3(OH)_3^{3+}$, $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$, and $Pb_6(OH)_8^{4+}$ are formed in both an aqueous solution and dioxane–water mixtures,[1)] and thus, the total heat evolved in the solvent systems is represented in terms of the enthalpy ΔH^*_{pq} of the reaction, $qPb^{2+} + pH_2O = Pb_q(OH)_p^{(2q-p)+} + pH^+$, as follows:

$$Q = \Delta H^*_{33} \cdot \delta n_{33} + \Delta H^*_{44} \cdot \delta n_{44} + \Delta H^*_{43} \cdot \delta n_{43} + \Delta H^*_{86} \cdot \delta n_{86}. \quad (4)$$

δn_{pq} is calculated on the basis of the formation constants previously determined.[1)] Since only $Pb_3(OH)_3^{3+}$ and $Pb_4(OH)_4^{4+}$ complexes are predominant in solutions of pH<6, the total heat evolved in the solutions is approximately written as follows:

$$Q = \Delta H^*_{33} \cdot \delta n_{33} + \Delta H^*_{44} \cdot \delta n_{44}, \quad (5)$$

and hence

$$Q/\delta n_{33} = \Delta H^*_{33} + \Delta H^*_{44}(\delta n_{44}/\delta n_{33}). \quad (6)$$

Therefore, plots of $Q/\delta n_{33}$ against $\delta n_{44}/\delta n_{33}$ should be a straight line with the slope of ΔH^*_{44} and the intercept ΔH^*_{33}. As is seen from Fig. 2, the plots are straight for all the solvent systems examined. The values of ΔH^*_{33} and ΔH^*_{44} are then inserted into Eq. 7 in order to determine the values of ΔH^*_{43} and ΔH^*_{86} by assuming that the four complexes coexist in the region of pH>6.

$$(Q - \Delta H^*_{33} \cdot \delta n_{33} - \Delta H^*_{44} \cdot \delta n_{44})/\delta n_{43} = \Delta H^*_{43} + \Delta H^*_{86}(\delta n_{86}/\delta n_{43}) \quad (7)$$

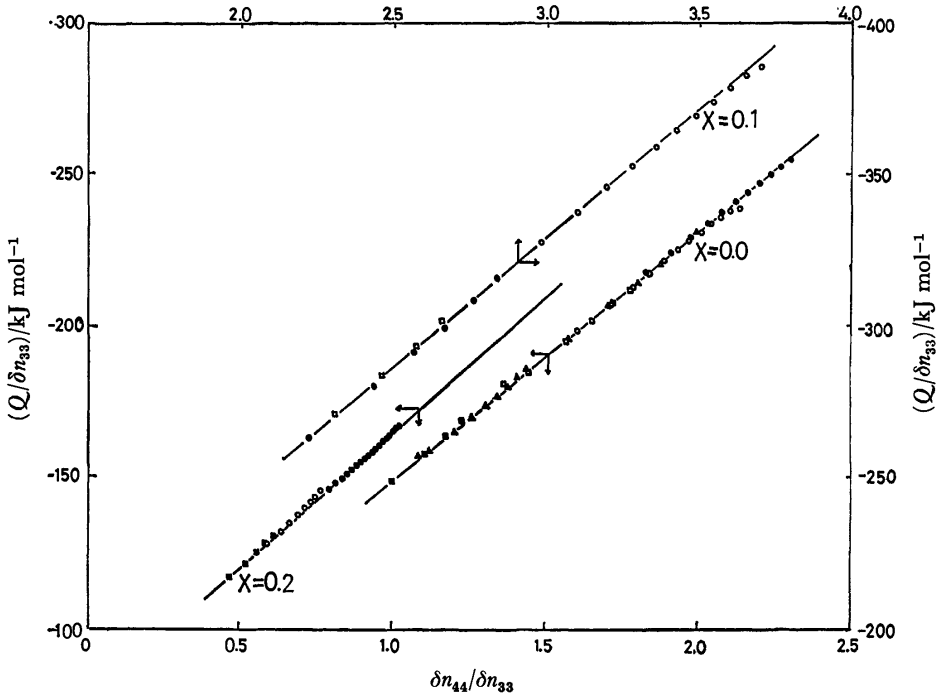

Fig. 2. Determination of the enthalpies, ΔH^*_{33} and ΔH^*_{44} for the hydrolytic reactions of lead (II) ions in the aqueous solution and dioxane–water mixtures containing 3 mol dm^{-3} (Li)ClO_4 as an ionic medium. X denotes the mole fraction of dioxane in the mixtures. Initial concentrations (mol dm^{-3}) of the total lead (II) ions are as follows: Aqueous; ● 0.2040, ○ 0.1503, △ 0.1005, □ 0.07913, ▲ 0.04149, ■ 0.02151: 0.1 mole fraction dioxane; ○ 0.07990, ● 0.05690, □ 0.03756: 0.2 mole fraction dioxane; ● 0.1585, ○ 0.07941, □ 0.04218.

$Pb_6(OH)_8^{4+}$	$-\log *\beta_{86}$	−42.33 (0.01)[a]	−40.75 (0.01)[a]	−41.12 (0.01)[a]
	ΔH^*_{86}	242.8 (1.1)	243.2 (2.3)	236.7 (3.6)
	$T\Delta S^*_{86}$	1.3 (1.2)	10.6 (2.4)	2.0 (3.7)

Uncertaities are given in parentheses as the standard deviation. a) Ref. 1.

The plot of $(Q-\Delta H^*_{33}\cdot\delta n_{33}-\Delta H^*_{44}\cdot\delta n_{44})/\delta n_{43}$ against $\delta n_{86}/\delta n_{43}$ was a straight line in each solvent as shown in Fig. 3, from which the values of ΔH^*_{86} and ΔH^*_{43} were determined.

The enthalpies were finally evaluated by the least-squares method by minimizing $U=\sum(Q-Q_{calcd})^2$ over the whole points measured in a system. The results obtained are summarized in Table 2. Typical calorimetric data obtained for the hydrolytic reactions of lead(II) ion in aqueous solution and the differences between the measured heats and the calculated ones are shown in Table 3.

c_{Pb} denotes the total concentration of lead(II) ion in a test solution. c_{Pb} decreases by dilution by adding the titrant in the course of titration. c_H represents the concentration of analytical excess of hydrogen ion in the test solution. The negative values show that the solutions contain the corresponding excess amounts of hydroxide ions. The initial volume of the test solution is 149.83 cm^3. Concentrations of hydrogen ions in the titrant are 0.9887 mol dm^{-3} for runs 1—3 and 0.3887 mol dm^{-3} for runs 4—6. Q_{calcd} is calculated by using the enthalpies listed in Table 2. V_{add} stands for the total volume of the titrant added.

Discussion

The enthalpies and entropies for the hydrolytic reactions of lead(II) ions in the aqueous solution containing 3 mol dm^{-3} (Li)ClO_4 listed in Table 2 may be compared with those obtained by Carell and Olin[3] in an aqueous solution containing 3 mol dm^{-3} (Na)ClO_4. They have reported the enthalpies, ΔH_{44}^*, ΔH_{43}^*, and ΔH_{86}^*, which are 83.97 110.9 and 206.9 kJ mol^{-1}, respectively. Their ΔH_{44}^* value coincides well with our result, whilst their ΔH_{43}^* and ΔH_{86}^* are appreciably different from ours.

The enthalpy ΔH_D of the reaction

$$2Pb_3(OH)_4^{2+} = Pb_6(OH)_8^{4+} \quad (8)$$

was estimated as $\Delta H_D = \Delta H_{86}^* - 2\Delta H_{43}^*$, and the values in various solvents are shown in Table 4 together with the corresponding Gibbs energies and entropies. The enthalpies and entropies of the reaction were all largely positive. These results are in contrast to those obtained by Carell and Olin,[3] who reported that the enthalpy of reaction (8) was negative.

TABLE 4. THE GIBBS ENERGY (ΔG_D/kJ mol^{-1}), ENTHALPY (ΔH_D/kJ mol^{-1}) AND ENTROPY ($T\Delta S_D$/kJ mol^{-1}) OF THE REACTION, $2Pb_3(OH)_4^{2+} = Pb_6(OH)_8^{4+}$, IN THE AQUEOUS SOLUTION AND DIOXANE–WATER MIXTURES AND THE THERMODYNAMIC PARAMETERS OF TRANSFER FROM THE AQUEOUS SOLUTION TO DIOXANE–WATER MIXTURES (INDICATED BY A SUPERSCRIPT t)

0.1	−16.13	76.4	92.6	2.34	−43.2	−45.5
0.2	−13.44	37.1	50.6	5.03	−82.5	−87.5

In recent years, structural information of the hydroxo complexes of lead(II) ions in aqueous solutions has been obtained by means of X-ray diffraction.[4–7] According to Olin and Söderquist,[6,7] in the $Pb_6(OH)_8^{4+}$ complex one oxygen atom is located at the center of four lead atoms which are tetrahedrally arranged and the other two lead atoms are located outside the tetrahedral unit. If the complex formally written as $Pb_6(OH)_8^{4+}$ exists in the form of $Pb_6O(OH)_6^{4+}$ in solution, the dimerization reaction given in Eq. 8 should be written as Eq. 9:

$$2Pb_3(OH)_4^{2+} = Pb_6O(OH)_6^{4+} + H_2O. \quad (9)$$

The reaction involves a heterolysis of an O–H bond which may be largely endothermic. Thus, reaction (9) can appropriately account for our result that the enthalpy is largely positive. The positive enthalpies of transfer from an aqueous solution to dioxane–water mixtures for reaction (9) can be expected as we will discuss in the following section.

The Solvent Effects on the Thermodynamic Parameters of the Hydrolytic Reactions of Lead(II) Ion. The hydrolytic reaction of lead(II) ions may be expressed as follows:

$$qPb^{2+} + pH_2O = Pb_q(OH)_p^{(2q-p)+} + pH^+, \quad (10)$$

or

$$qPb^{2+} + (p+r)H_2O = Pb_qO_r(OH)_p^{(2q-p-2r)+} + (p+2r)H^+. \quad (11)$$

Combination of the thermodynamic parameters for reaction (10) given in Table 2 with those for the reaction, $H_2O = H^+ + OH^-$,[1,2] leads to Gibbs energies, enthalpies and entropies, ΔG_{pq}, ΔH_{pq} and ΔS_{pq}, respectively, for the following reaction:

$$qPb^{2+} + pOH^- = Pb_q(OH)_p^{(2q-p)+}. \quad (12)$$

The enthalpy of transfer for reaction (12), ΔH_{pq}^t, from an aqueous solution to a dioxane–water mixture is represented as follows:

$$\Delta H_{qp}^t = \Delta H_{pq}(\text{mix}) - \Delta H_{pq}(\text{aq}) = \Delta h_{pq}^t - q\Delta h_{Pb}^t - p\Delta h_{OH}^t, \quad (13)$$

where Δh_i^t denotes the partial molar enthalpy of transfer of species i. The Gibbs energies, enthalpies and entropies of transfer for the hydrolytic reactions of lead(II) ions from an aqueous solution to dioxane–water mixtures examined are summarized in Table 5, together with those quantities divided by the number of hydroxide ions, $\Delta G_{pq}^t/p$, $\Delta H_{pq}^t/p$, and $T\Delta S_{pq}^t/p$. In this table, $Pb_6O(OH)_6^{4+}$ is formally written as $Pb_6(OH)_8^{4+}$ according to reaction (10).

A question whether a complex is a hydroxo or an oxo-hydroxo complex always arises when we discuss the composition of $M_q(OH)_p^{(2q-p)+}$ type complexes. For lead(II)-hydroxo complexes, all of the complexes found, except the $Pb_6(OH)_8^{4+}$ complex, are believed to have only hydroxide ions as the ligands. Therefore,

TABLE 5. THE THERMODYNAMIC PARAMETERS OF TRANSFER (ΔG_{pq}^t/kJ mol^{-1}, ΔH_{pq}^t/kJ mol^{-1}, AND $T\Delta S_{pq}^t$/kJ mol^{-1}) FOR THE HYDROLYTIC REACTIONS OF LEAD(II) IONS FROM THE AQUEOUS SOLUTION TO DIOXANE–WATER MIXTURES: $qPb^{2+} + pOH^- = Pb_q(OH)_p^{(2q-p)+}$

	0.1 mole fraction of dioxane			0.2 mole fraction of dioxane		
	ΔG_{pq}^t	ΔH_{pq}^t	$T\Delta S_{pq}^t$	ΔG_{pq}^t	ΔH_{pq}^t	$T\Delta S_{pq}^t$
$Pb_3(OH)_3^{3+}$	−14.40(−4.83)	1.0(0.3)	15.5(5.2)	−28.59(−9.53)	−13.5(−4.5)	15.1(5.0)
$Pb_4(OH)_4^{4+}$	−21.63(−5.41)	−3.3(−0.8)	18.3(4.6)	−35.84(−8.96)	−5.0(−1.2)	30.8(7.7)
$Pb_3(OH)_4^{2+}$	−22.60(−5.65)	15.8(4.0)	38.4(9.6)	−40.35(−10.1)	19.8(5.0)	60.2(15.0)
$Pb_6(OH)_8^{4+}$	−42.92(−5.37)	−11.6(−1.5)	31.3(3.9)	−75.85(−9.48)	−42.9(−5.4)	33.0(4.1)

Values in parentheses give thermodynamic parameters per hydroxide ion, $\frac{1}{p}\Delta G_{pq}^t$, $\frac{1}{p}\Delta H_{pq}^t$, and $\frac{T}{p}\Delta S_{pq}^t$.

the discussion about the composition of the complexes on the basis of the thermodynamic quantities will be focused on the $Pb_6(OH)_8^{4+}$ complex in the following section.

As we have already described in the previous paper,[1] the $\Delta G^t_{pq}/p$ values of various metal ions such as beryllium(II), copper(II), nickel(II), cadmium(II), and lead(II) have been found to be approximately independent of not only the composition but also the kind of metal ions of the hydroxo complexes.[1] However, the ΔH^t_{pq} values are strongly dependent on the composition of the hydroxo complexes. The solvent effects on the enthalpies of the hydrolytic reactions of beryllium ion from an aqueous solution to dioxane–water mixtures have been previously discussed in terms of the solvent structure of the bulk, the structure of the solvated ions involved in the reactions and the charge distribution within the hydroxo complexes.[2] A similar consideration can be made for interpreting the enthalpies of transfer from an aqueous solution to dioxane–water mixtures for the reactions of lead(II) ions.

As seen from Table 5, the $\Delta H_{44}/4$ value becomes more negative with the increase in the content of dioxane in the mixtures. However, the reverse is found for $\Delta H^t_{43}/4$, which is positive. Therefore, the relation $\Delta H^t_{44}/4 < \Delta H^t_{43}/4$ holds in the solvent systems examined. By using Eq. 13, the relation is rewritten in terms of the partial molar enthalpies of transfer of the relevant species involved in the reactions as follows:

$$\frac{1}{4}\Delta h^t_{44} - \Delta h^t_{Pb} < \frac{3}{4}\left(\frac{1}{3}\Delta h^t_{43} - \Delta h^t_{Pb}\right). \quad (14)$$

As seen in Table 2, the enthalpies of transfer for the reaction, $qPb^{2+} + pH_2O = Pb_q(OH)_p^{(2q-p)+} + pH^+$, are zero or positive $[\Delta H^{*t}_{pq} = \Delta H^*_{pq}(\text{mix}) - \Delta H^*_{pq}(\text{aq}) = \Delta h^t_{pq} + p\Delta h^t_H - q\Delta h^t_{Pb} - p\Delta h^t_{OH}]$. The partial molar enthalpy of transfer of a neutral water molecule will be less than those of the ions involved in reaction (10), and thus the value $q\Delta h^t_{Pb}$ will be more negative than the values Δh^t_{pq} and $p\Delta h^t_H$. Therefore, both sides of Eq. 14 will be positive, thus:

$$\frac{1}{4}\Delta h^t_{44} < \frac{1}{3}\Delta h^t_{43} < 0. \quad (15)$$

The formal charge per metal ion of the $Pb_4(OH)_4^{4+}$ and $Pb_3(OH)_4^{2+}$ complexes are +1 and +0.67, respectively. Therefore, the result obtained in Eq. 15 is consistent with what is expected from the consideration based on the formal charge per metal ion of the complexes, which has been discussed in the previous paper.[2]

Since the formal charge per metal ion z' of the $Pb_3(OH)_3^{3+}$ and $Pb_4(OH)_4^{4+}$ complexes are both +1, the relation $\Delta h^t_{33}/3 \simeq \Delta h^t_{44}/4$ will approximately hold, if we assume as the first approximation that the local charges per metal ion within the complexes are the same. The values of $\Delta H^t_{33}/3$ were +0.3 and −4.5 kJ mol^{-1} for the dioxane systems containing 0.1 and 0.2 mole fraction of dioxane, respectively. If we take into account the uncertainties in ΔH^*_{33} listed in Table 2, it appears that ΔH^t_{33} tends to monotonously decrease as the dioxane content increases (see Table 5). The same trend is also seen in ΔH^t_{44}. Although the value $\Delta H^t_{33}/3$ is more negative than that of $\Delta H^t_{44}/4$ in the 0.2 mole fraction dioxane system, the difference is not significant, and we can assume $\Delta H^t_{33}/3 \simeq \Delta H^t_{44}/4$. The values $\Delta H^t_{33}/3$ of the $Be_3(OH)_3^{3+}$ complex are −2.3 and −5.5 kJ mol^{-1} for 0.1 and 0.2 mole fraction dioxane systems, respectively,[2] which are more negative than the corresponding values of the $Pb_4(OH)_4^{4+}$ or $Pb_3(OH)_3^{3+}$ complex. This seems to be attributed to stronger solvation of beryllium(II) ions than that of lead(II) ions.

As is discussed above, at least at the first step of approach, the formal charge per metal ion of a hydroxo complex is an important factor which controls solvent effects on hydrolytic reactions of metal ions. The formal charge per metal ion of the $Pb_6(OH)_8^{4+}$ complex is +0.67, which is the same as that of the $Pb_3(OH)_4^{2+}$ complex. Therefore, if the approach so far examined for the estimation of the partial molar enthalpy of transfer of a hydroxo complex is applicable to the case of the $Pb_6(OH)_8^{4+}$ complex, the value $\Delta H^t_{86}/8$ would be similar to $\Delta H^t_{43}/4$, that is, it would be positive. In fact, the values $\Delta H^t_{86}/8$ obtained are −1.5 and −5.4 kJ mol^{-1} for the 0.1 and 0.2 mole fraction dioxane systems, respectively. Thus, the value $\Delta H^t_{86}/8$ becomes more negative with an increase in the dioxane content in the mixtures in contradiction to that of $\Delta H^t_{43}/4$. This fact can be explained by assuming the formation of the $Pb_6O(OH)_6^{4+}$ complex instead of the $Pb_6(OH)_8^{4+}$ complex.

The hydrolytic reaction of formation of the $Pb_6O(OH)_6^{4+}$ complex is represented as follows:

$$6Pb^{2+} + 7OH^- = Pb_6O(OH)_6^{4+} + H^+. \quad (16)$$

The enthalpy of transfer for the reaction (16) is written as follows:

$$\Delta H^t_{616} = \Delta h^t_{616} - 8\Delta h^t_{OH} - 6\Delta h^t_{Pb} + (\Delta h^t_H + \Delta h^t_{OH}), \quad (17)$$

which may be compared with that for the reaction, $6Pb^{2+} + 8OH^- = 2Pb_3(OH)_4^{2+}$,

$$2\Delta H^t_{43} = 2\Delta h^t_{43} - 8\Delta h^t_{OH} - 6\Delta h^t_{Pb}. \quad (18)$$

Here ΔH^t_{616} and Δh^t_{616} represent the quantities defined by Eq. 13 for the $Pb_6O(OH)_6^{4+}$ complex.

The formal charge per metal ion of the $Pb_6O(OH)_6^{4+}$ complex is +0.67, and thus, the value Δh^t_{616} will be similar to that of $2\Delta h^t_{43}$. The term $\Delta h^t_H + \Delta h^t_{OH}$ in Eq. 17 is negative.[2] Therefore, even if the value $\Delta h^t_{616} - 8\Delta h^t_{OH} - 6\Delta h^t_{Pb}$ is as largely positive as that $2\Delta H^t_{43}$, the value ΔH^t_{616} will remain negative owing to the term $\Delta h^t_H + \Delta h^t_{OH}$ which is more negative than $\Delta h^t_{616} - 8\Delta h^t_{OH} - 6\Delta h^t_{Pb}$.

The enthalpy of transfer for reaction (9), ΔH^t_D, is expressed as follows:

$$\Delta H^t_D = \Delta h^t_{616} + \Delta h^t_{H_2O} - 2\Delta h^t_{43}. \quad (19)$$

If we assume that

$$\frac{1}{6}\Delta h^t_{616} \simeq \frac{1}{3}\Delta h^t_{43}, \quad (20)$$

we obtain the following equation:

$$\Delta H^t_D \simeq \Delta h^t_{H_2O}. \quad (21)$$

The values ΔH^t_D were found to be −43.2 and −82.5 kJ mol^{-1} for the systems of the dioxane contents of 0.1 and 0.2 mole fractions, respectively (Table 4). Although

the values of $\Delta h^{t}_{H_2O}$ estimated by using Eq. 21 may be too largely negative because of the oversimplified assumption given as Eq. 20, we can conclude that the partial molar enthalpies of transfer of water $\Delta h^{t}_{H_2O}$ from an aqueous solution to dioxane–water mixtures will be negative. This result is consistent with that derived in the previous paper.[2] The hydrogen bonded structure of water in an aqueous solution is broken down by the addition of dioxane,[8,9] and thus, the value of $\Delta h^{t}_{H_2O}$ will be negative by enhancement of the intramolecular O–H bonds within water molecules in dioxane–water mixtures.

The work has been partially supported by a Grant-in-Aid for Scientific Research No. 343011 from the Ministry of Education, Science and Culture.

Catalytic Activity of V-Sn Oxides for Oxidation Reactions

Takehiko Ono,* Yoshiro Nakagawa, and Yutaka Kubokawa
Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591
(Received March 28, 1980)

The rate of oxidation of C_3H_6, C_2H_4, C_3H_8, and CO has been investigated over V-Sn oxides of various compositions. The rate shows two maxima at V-Sn(V/Sn=2/1) and (1/8) oxides. Comparison between the rate of reduction of the oxides with C_3H_6 and that of the corresponding catalytic oxidation suggests that the oxygen species responsible for oxidation differs for V-Sn(2/1) and V-Sn(1/8) oxides. The amount of oxygen desorbed in the temperature range 400—530 °C varies with the composition of the V-Sn oxides, showing a maximum at V-Sn(2/1) oxide. With V-Sn(1/8) oxide, little or no oxygen desorption is observed. On the basis of these results together with those of structural studies, it is concluded that the rate maximum with V-Sn(2/1) oxide arises from formation of an amorphous material from which lattice oxygen is easily released, while the rate maximum with V-Sn(1/8) oxide is associated with the presence of V^{4+} ions dissolved in SnO_2.

It has been shown by many workers that catalytic oxidation over V_2O_5 proceeds *via* lattice oxygen,[1] its activity being promoted by addition of the second component such as MoO_3, SnO_2, *etc.* As regards the V_2O_5–SnO_2 system, several explanations have been proposed for the effect of promoters.[2-5] Sachtler *et al.*[2] reported that the promoter action of SnO_2 in V–Sn oxides is due to the lowering of ΔG for oxygen release from the oxide which arises from the dissolution of V ions in the SnO_2 lattice.

In the present work, the rate of C_3H_6, C_2H_4, C_3H_6, and CO oxidation has been measured over V–Sn oxides of various compositions. Oxygen desorption experiments as well as measurements of the rate of reduction of the oxides with C_3H_6 have been carried out. On the basis of these results together with those of structural studies such as X-ray diffraction, IR, and ESR, the nature of the promoter effect has been discussed.

Experimental

Materials. V–Sn oxide catalysts were prepared as follows. The precipitate obtained from solutions of tin(II) chloride and ammonia was added to a solution containing the required quantity of ammonium metavanadate. The resulting precipitate was washed, dried, and heated in the air at 450 °C. The atomic ratio V/Sn of the catalysts and their surface area determined by the BET method are as follows. (V/Sn=1/0), 2.1; (4/1), 12.3; (2/1), 14.7; (1/2), 26.1; (1/8), 43.2; and (0/1), 6.8 m^2/g.

Apparatus and Procedure. Catalytic oxidation and reduction of the oxides were carried out in a closed circulation system (290 cm^3). In order to obtain the initial rates, the conversions were kept below ≈5%. The reaction products such as acryladehyde, CO_2, and CO were analyzed by gas chromatography. Carbonaceous deposits formed during the course of reduction were converted into CO_2 by oxidization with oxygen at 450 °C. The amount was then determined.

X-Ray diffraction patterns of the catalysts were obtained on a Rigaku Denki D-3F X-ray diffractometer using Cu $K\alpha$ radiation with a Ni filter. IR spectra were recorded on a Hitachi G2 spectrometer, the samples being prepared by the KBr pellet technique, and ESR spectra on a JES-ME-1X spectrometer. Oxygen desorption from V–Sn oxides was investigated by means of a Töpler pump. It was confirmed by gas chromatography that desorbed gas consists entirely of oxygen.

Results

Catalytic Oxidation of C_3H_6 over V–Sn Oxides and Their Reduction with C_3H_6. The rate of C_3H_6 oxidation on various V–Sn oxides at 320 °C (Fig. 1) shows two maxima at V–Sn(2/1) and (1/8) oxides. Similar maxima are observed in low oxygen pressure experiments. Selectivity toward acrylaldehyde formation was determined for all the V–Sn oxides at similar conversion values, which were obtained by adjusting the catalyst weight as well as the reaction time (Fig. 2). The

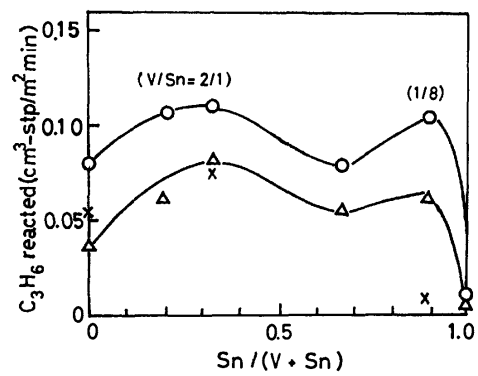

Fig. 1. Rates of C_3H_6 oxidation at 320 °C.
$P_{C_3H_6}$=35 Torr (1 Torr=133.3 Nm^{-2}); P_{O_2}; —△—, 8; —○—, 40 Torr; X, rates of reduction of the oxides with C_3H_6.

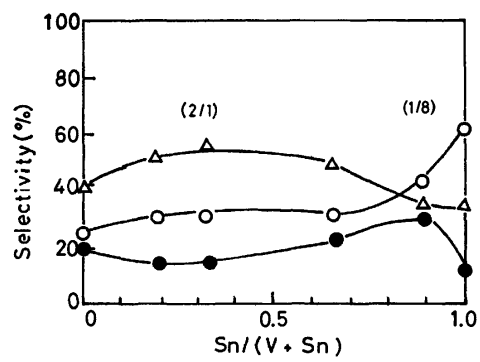

Fig. 2. Selectivities of C_3H_6 oxidation.
Experimental conditions are the same as in Fig. 1.
—●—, Acrylaldehyde; —○—, CO_2; —△—, CO.

selectivity toward acrylaldehyde formation is ≈20% for V_2O_5, ≈15% for V-Sn(2/1) oxide and ≈30% for V-Sn(1/8) oxide. As regards CO and CO_2 formation, with V_2O_5, V-Sn(4/1) and (2/1) oxides the ratio of the amount of CO to that of CO_2 in the products is *ca.* 2, being essentially the same, while with SnO_2 and V-Sn-(1/8) oxide, CO_2 formation is larger than CO formation. This indicates that the same mechanism is involved in CO and CO_2 formation for the former group of oxides.

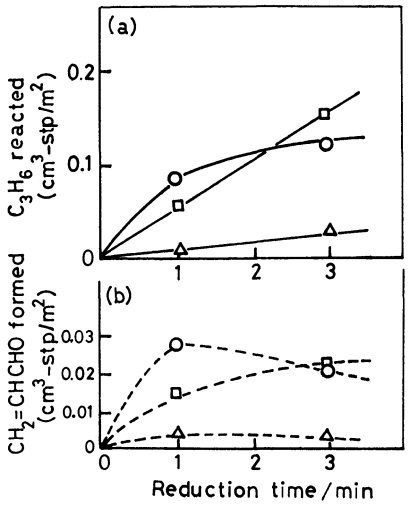

Fig. 3. Reduction of V-Sn oxides with C_3H_6 at 320 °C.
$P_{C_3H_6}$=35 Torr; —○—, V-Sn (2/1) oxide; —□—, V_2O_5; —△—, V-Sn (1/8) oxide.

Figure 3a shows the rate of reduction of various oxides with C_3H_6. The initial rates of reduction obtained from the plots are 0.06—0.05 for V_2O_5, 0.08 for V-Sn-(2/1) oxide and 0.01 cm^3/m^2 min for V-Sn(1/8) oxide. The initial rate values are also given in Fig. 1. Carbonaceous deposits were formed during the course of reduction. The amount formed for one minute was found to *ca.* 0.03 for V_2O_5, 0.05 for V-Sn(2/1) oxide and 0.04 cm^3/m^2 for V-Sn(1/8) oxide. No significant difference among the three catalysts suggests that the extent of inhibition by carbonaceous deposits is essentially the same for all the catalysts.

Comparison of catalytic oxidation at two different oxygen pressures (Fig. 1) yields the reaction order 0.3—0.5 in oxygen for all the V-Sn oxides investigated. The difference between the rate of reduction of the oxides with C_3H_6 and that of the corresponding catalytic oxidation is considerably larger for V-Sn(1/8) oxide than for V_2O_5 and V-Sn(2/1) oxides. It seems that the oxygen species responsible for oxidation differs for both groups of oxides.

In the initial stage of the reaction acrylaldehyde formation is larger over V-Sn(2/1) oxide than over V_2O_5 (Fig. 3b). In fact, the initial selectivity toward acrylaldehyde formation obtained with V-Sn(2/1) oxide is 30%, being higher than the selectivity with V_2O_5(≈20%). As regards the selectivity in the later stage, the situation is reversed. V_2O_5 is more selective than V-Sn(2/1) oxide, indicating that further oxidation of acrylaldehyde to CO and CO_2 occurs more efficiently over V-Sn(2/1) oxide.

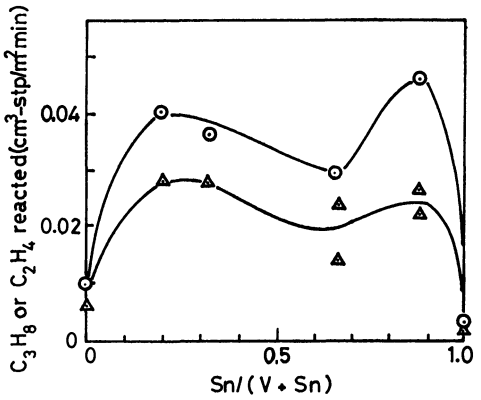

Fig. 4. Rates of oxidation of C_2H_4 and C_3H_8 at 320 °C.
$P_{C_3H_8}$=40 Torr; P_{O_2}=40 Torr; —⊙—, C_2H_4; —△—, C_3H_8.

Catalytic Oxidation of C_2H_4, C_3H_8, and CO. The rates of oxidation of C_2H_4 and C_3H_8 are shown in Fig. 4. With the V-Sn(2/1) and (1/8) oxides, two maximum rates of oxidation similar to those with C_3H_6 oxidation are observed. No partial oxidation products were formed. Rate enhancement by the addition of SnO_2 is more significant for C_2H_4 and C_3H_8 oxidation than for the C_3H_6 oxidation.

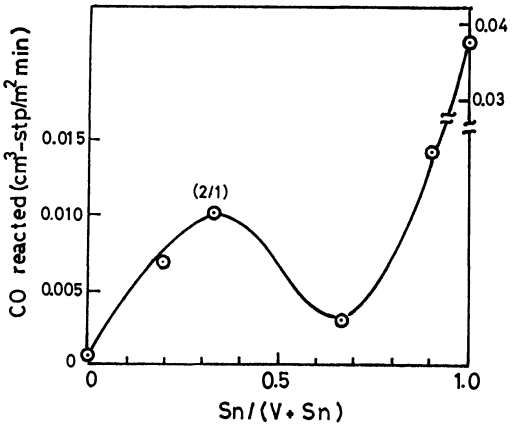

Fig. 5. Rates of CO oxidation at 320 °C.
P_{CO}=40 Torr, P_{O_2}=40 Torr.

The rate of CO oxidation over SnO_2, shown in Fig. 5, is about 140 times higher than that over V_2O_5. If the V-Sn oxide is a mixture of V_2O_5 and SnO_2, its catalytic activity would increase monotonously with increasing SnO_2 content, in disagreement with the result shown. The rate of CO oxidation passes through a maximum at V-Sn(2/1) oxide. Another maximum seems to be masked by a high rate of oxidation of CO over SnO_2. Thus, the existence of two different types of maximum rate of oxidation has been established.

Oxygen Desorption from V-Sn Oxides. Oxygen easily desorbs from V-Sn oxides at 350—500 °C.[2] It was found that the dissociation pressure of oxygen over V-Sn oxides depends upon the amount of sample, decreasing with increase in the amount of oxygen removed from the oxides.[2] Accordingly, dissociation pressure measurements appear to be inadequate for comparison of the ability to release oxygen from various oxides.

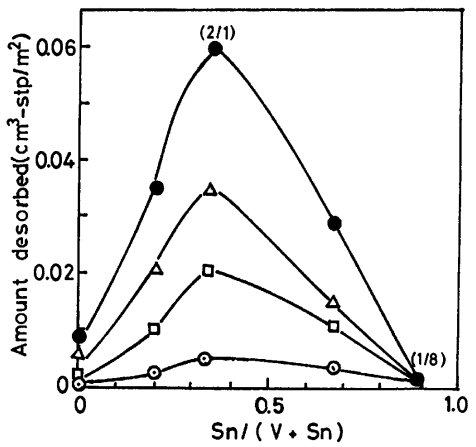

Fig. 6. Oxygen desorption from V–Sn oxides.
—○—, 450 °C; —□—, 500 °C; —△—, 530 °C; —●—, amount desorbed up to 530 °C; desorption time, 1 h at each temperature.

After the catalyst had been treated with oxygen at 400 °C followed by evacuation at 150 °C for 10 h, the temperature of the catalyst was raised stepwise up to 530 °C, the amount of oxygen desorbed being determined. During the course of experiments the pressure over the catalyst was kept below 10^{-2}Torr. As seen in Fig. 6, the amount of oxygen desorbed changes with the composition of V–Sn oxide, showing a maximum at V-Sn(2/1) oxide, in a similar manner to that observed with the rate of oxidation. With V–Sn(1/8) oxide, little or no oxygen desorption is observed. The oxygen desorption begins around 400 °C, being predominant in the temperature range 450—530 °C. This suggests that the oxygen desorbed originates from lattice oxygen and not from adsorbed oxygen. The interaction of vanadium oxide with tin oxide would lead to formation of some active part, from which oxygen release takes place easily.

Structure of V–Sn Oxides. X-Ray Diffraction: X-Ray diffraction studies of the V–Sn oxides showed only diffraction lines due to V_2O_5 and SnO_2. No lines indicating formation of a new compound between V_2O_5 and SnO_2 appeared, in agreement with the results of previous workers.[2,6] It appears that the active part described above exhibits no definite diffraction lines. As a result of the interaction of vanadium oxide and tin oxide an amorphous material might be formed. In fact, with V–Sn(4/1), (2/1), and (1/2) oxides, the intensities of the lines due to V_2O_5 were found to be much smaller than what are expected from the composition of V–Sn oxides. V–Sn(4/1) oxide showed lines due to V_2O_5 alone. With V–Sn(1/8) oxide only lines which are attributed to SnO_2 appeared, the observed lattice constants being somewhat smaller than those of the crystalline SnO_2. The sizes of V_2O_5 and SnO_2 crystals in various V–Sn oxides, determined from the broadening of the diffraction lines,[7] were >200 nm and 10—20 nm, respectively.

IR: IR spectra of V–Sn(2/1) oxide (Fig. 7a) show bands at 1020 cm^{-1} (V=O stretching vibration) and 818 cm^{-1} (V–O–V stretching vibration). Similar spectra were obtained with V–Sn(4/1) and (1/2) oxides.

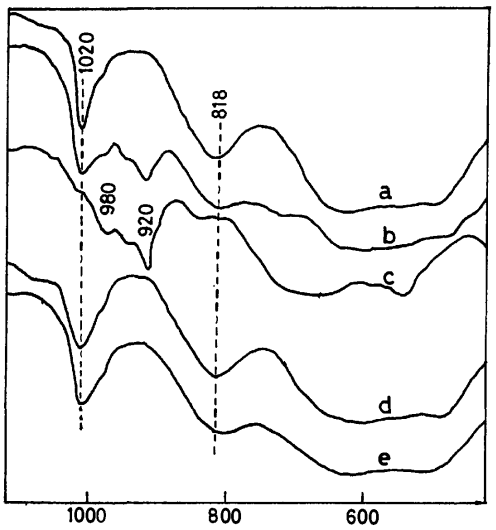

Fig. 7. IR spectra of V–Sn (2/1) oxide before and after the reduction by C_3H_6 and CO.
Before reduction (a), after reduction with C_3H_6 at 320—350 °C; 1.1 atom% (b) or 6.3% (c) of lattice oxygen was removed: After reduction with CO at 450—500 °C; 2.0% (d) or 3.8% (e). 1 wt% of V–Sn oxide in KBr (≈50 mg).

V–Sn(1/8) oxide exhibited no IR absorption due to V_2O_5. IR spectra of SnO_2 showed a broad band at ≈620 cm^{-1}. In order to examine the amorphous part in the V–Sn oxides, the intensity of the band at 1020 cm^{-1} observed with the V–Sn oxides has been determined as a function of the concentration of vanadium ions in the KBr pellets. Similar experiments have been carried out for V_2O_5 with the result that Lambert-Beer's law is applicable (Fig. 8). The intensity of the band at 1020 cm^{-1} with the V–Sn oxides is about 30% of the intensity observed with V_2O_5, suggesting that a considerable fraction of vanadium oxide in V–Sn oxides exhibits no IR absorption. Figure 7a shows that

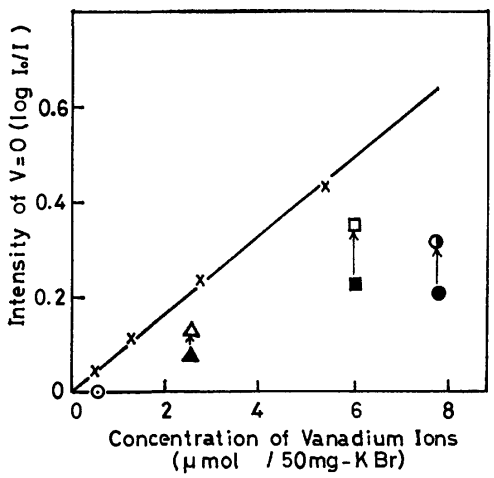

Fig. 8. Estimation of V_2O_5 concentration in V–Sn oxides.
×, V_2O_5; ○, V–Sn (1/8) oxide; ▲, (1/2); ■, (2/1); ●, (4/1); △, □, ◑, After calcination at 600 °C; 2 wt% of V–Sn oxide in KBr.

no alternative new bands appear. So far no explanation can be offered. The new bands might be masked by the bands due to V_2O_5 or SnO_2. It appears that the part which exists in the amorphous state corresponds to the part which exhibits no IR absorption.

It seems necessary to consider the effect of crystal size of the sample upon the intensity of the IR band. Since only V=O groups in the surface layer are responsible for IR absorption, the intensity of the band at 1020 cm^{-1} would increase with increase in the surface area of V_2O_5 crystals, *i.e.*, with decrease in particle size. From the extent of broadening of diffraction lines, it was concluded that the size of V_2O_5 crystals in V–Sn oxides is somewhat smaller than that in V_2O_5 specimen. The fraction of the amorphous state to the total amount of V_2O_5 in the V–Sn oxides seems to be larger than that shown in Fig. 8.

When the V–Sn oxides are calcined at 600 °C, the intensity of the band at 1020 cm^{-1} increase from ≈30% to ≈60% of those expected from the composition of the V–Sn oxides. This suggests that the amorphous part in the V–Sn oxides is decomposed to form V_2O_5 and SnO_2.

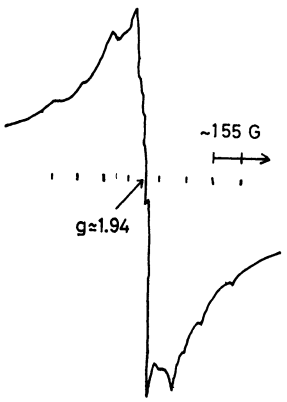

Fig. 9. ESR spectrum of V–Sn (1/8) oxide at 77 K after reduction with C_3H_6.

ESR: ESR measurements have been carried out with V–Sn(2/1) and (1/8) oxides, which exhibited the maximum oxidation activities. With V–Sn(2/1) oxide, only a broad signal appeared at $g=1.96$. After reduction with C_3H_6 there was no hyperfine structure at 77 K. On the other hand, after reduction with C_3H_6 V–Sn(1/8) oxide showed a signal having a hyperfine structure (Fig. 9) with $g=1.94$ and $A\approx155$ G at 77 K, in agreement with the results of Kasai,[8] who reported a signal with $g_z=1.942$ and $A_z=155$ G for V^{4+} ions dissolved in the SnO_2 crystalline. On the basis of these results together with a slight contraction of SnO_2 lattice in V–Sn(1/8) oxide described above, it is concluded that with V–Sn(1/8) oxide some fraction of vanadium ions are dissolved in the SnO_2 lattice as V^{4+} ions.

Discussion

Two maxima are observed at V–Sn(2/1) and (1/8) oxides for the rate of oxidation of various reactants such as C_3H_6, C_2H_4, C_3H_8, and CO, although in the case of CO one maximum is masked by a high activity of pure SnO_2. Considering the marked difference between the rate of reduction of the oxides with C_3H_6 and that of the corresponding catalytic oxidation observed with V–Sn(1/8) oxide, it is concluded that the oxygen species responsible for oxidation differs for V–Sn(2/1) and (1/8) oxides.

The rate of catalytic oxidation as well as of oxygen desorption shows a maximum at the same composition of V–Sn oxide (V/Sn=2/1). From the results together with those of structural studies such as X-ray diffraction and IR absorption, it is concluded that the maximum rate of oxidation observed with V–Sn(2/1) oxide can be attributed to formation of amorphous material from which lattice oxygen is easily released. The fraction of vanadium ions in the amorphous state is roughly constant with V–Sn(4/1), (2/1), and (1/2) oxides, being somewhat in contradiction with the maximum activity observed with V–Sn oxide (Fig. 8). When tin oxide is added to vanadium oxide, both enhancement of the activity due to formation of the amorphous part and decrease in the number of vanadium ions present in unit mass occurs simultaneously. Such a decrease in the number of vanadium ions would cause decrease in the activity of V–Sn oxides resulting from the presence of vanadium ions. Thus, the maximum activity with V=Sn(2/1) oxide is explicable.

The following results suggest that the reactivity of the amorphous material differs from that of the crystalline V_2O_5 and SnO_2. With the reduction of V–Sn(2/1) oxide by CO (Fig. 7), the intensity of the band due to V=O scarcely changes (Figs. 7d, e), while it decreases markedly in the case of the reduction by C_3H_6(b, c). New bands appear in the region 920—980 cm^{-1}. Similar spectra have been reported by Vadelievre *et al.*[9] and Inomata *et al.*[10] There is no marked difference between the amount of oxygen removed by the reduction in both cases. This suggests that the reduction by C_3H_6 proceeds on V_2O_5 crystals as well as on the part which exhibits no IR absorption, *i.e.*, the amorphous part, while the reduction by CO is limited to such an amorphous part alone, thus cofirming the above conclusion.

Another maximum, *i.e.*, the maximum rate observed with V–Sn(1/8) oxide is not associated with the oxygen release. From the results of ESR and X-ray diffraction studies, it appears that the maximum rate observed with V–Sn(1/8) is associated with the presence of V^{4+} ions in SnO_2 lattice. According to the work of Kon *et al.*,[11] Yoshida *et al.*,[12] and Takita *et al.*,[13] the presence of V^{4+} ions appear to facilitate the formation of adsorbed oxygen species which play a significant role in the oxidation reaction. A similar situation would be expected for V–Sn oxides. A marked enhancement in the rate of oxidation of C_3H_6 by the presence of gaseous oxygen observed with V–Sn(1/8) oxide might support this conclusion. However, the reactivity of adsorbed oxygen appears to be similar to that of lattice oxygen, since there is little or no difference between the product distributions for the C_3H_6 oxidation over V–Sn(2/1) and (1/8) oxides. It seems very diffcult to distinguish adsorbed oxygen from surface lattice oxygen,

i.e., adsorbed oxygen can be regarded as a special type of surface lattice oxygen.

Considering the fact that two maximum activities are observed with the V–Sn oxides, it seems unlikely that the lowering of ΔG for oxygen release from the oxide is closely associated with dissolution of V ions in the SnO_2 lattice as suggested by Sachler *et al.*[2] The maximum activity observed with V–Sn oxides containing a small amount of V ions as described above has not been found by Sachtler *et al.*[2] and other workers.[3,4] They used silica or pumice supported V–Sn oxides, in contrast to the present work which deals with unsupported V–Sn oxides. Lack of the maximum rate of oxidation of CO over V–Sn oxides reported by Tarama *et al.*[5] appears to be attributed to the preparation of their catalyst by fusion of mixture of V_2O_5 and SnO_2, where formation of the amorphous material is unexpected.

The authors wish to thank Mr. Shinji Doi for carrying out part of the experiments.

carried out, were directly determined by X-ray diffraction using the methods of Wissenberg and/or precession photographs.

In order to obtain the absorption spectrum from the observed reflection spectrum, we used the dispersion analysis method (the curve-fitting method) by using Helmholtz-Kettler type dispersion functions. The details of this analysis method were described in our previous paper.[12]

Results and Discussion

(NEP)(TCNQ)$_2$. The crystal of (NEP)-(TCNQ)$_2$ is triclinic with the space group $P\bar{1}$, the lattice constants being $a=7.070$ Å, $b=14.993$ Å, $c=8.006$ Å, $\alpha=84.3°$, $\beta=111.9°$, and $\gamma=99.8°$.[14] The unit cell contains one molecular unit of (NEP)(TCNQ)$_2$. The arrangement of TCNQ molecules (or ions) in this crystal is illustrated in Fig. 1. The infinite zigzag chain of TCNQ along the a-axis can be considered to be composed of TCNQ dimers, each of which consists of a pair of crystallographically equivalent TCNQ molecules, having one excess electron delocalized over them. We will express this dimer as $(TCNQ)_2^-$. The average intermolecular separation within the dimer is 3.17 Å, which is appreciably smaller than the average intermolecular separation between the dimers, 3.46 Å.

Figure 2 shows the polarized reflection spectra meausred at room temperature on the well-developed

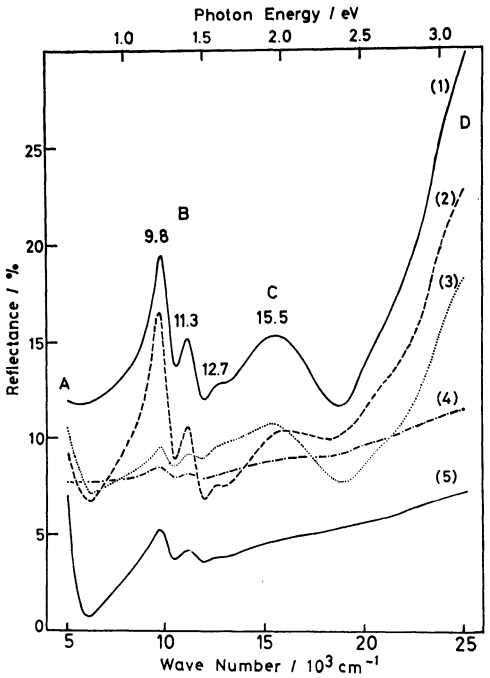

Fig. 2. Reflection spectra on the (100) and (011) crystal faces of (NEP) (TCNQ)$_2$. The number of each spectrum corresponds to that drawn in Figs. 1 (a) and 1 (b).

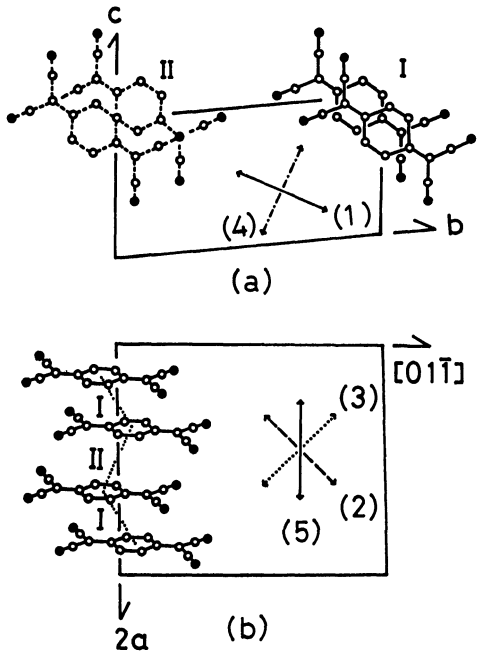

Fig. 1. (a) Projection of the TCNQ molecules onto the (100) plane in the crystal of (NEP) (TCNQ)$_2$. TCNQ molecules drawn by solid line shows the relative orientation of TCNQ molecules in the $(TCNQ)_2^-$ dimer, TCNQ molecules drawn by dashed line shows the relative orientation of TCNQ molecules between the $(TCNQ)_2^-$ dimer.
(b) Projection of the TCNQ molecules onto the (011) plane. The arrows means the directions of the polarization of incident light used to measure the reflection spectra shown in Fig. 2.

(100) and (011) crystal faces. Since $(NEP)^+$ ion has no allowed electronic transition in the observed spectral range, the dispersions observed here are entirely due to the transitions associated with the TCNQ columns. The spectra show that there exist four dispersions in the observed spectral range: The first is located below 5×10^3 cm^{-1}, the second which has a sharp structure, is at about 10×10^3 cm^{-1}, the third at about 16×10^3 cm^{-1} and the fourth above 25×10^3 cm^{-1}. These dispersions must correspond to the four absorption bands which have been reported to be characteristic of the absorption spectra of semiconductive TCNQ complex salts. Thus we will denote them as A, B, C, and D, respectively, as indicated in Fig. 2.

The polarization directions employed to measure these spectra are indicated with arrows in Fig. 1. The number given for each spectrum refers the number of the polarization direction with which the spectrum was obtained. The variation of the amplitude of a dispersion with the change of polarization direction reflects the direction of the transition moment of the electronic transition concerned. Thus one can conclude from the spectra shown in Fig. 2 that the electronic transition concerned with the dispersion A is strongly polarized in the direction of TCNQ column, while the transition concerned with the dispersion D is polarized parallel to the long molecular axis of TCNQ. According to the widely accepted interpretation of the absorption spectra of TCNQ complex salt, the dispersion A is due to the charge transfer form $(TCNQ)^-$ to $(TCNQ)^0$ which we will express as CT1(A→N), and the dispersion D is due to the lowest π-π^* transition of $(TCNQ)^0$ which we will express as LE1(N). The observed polarizations

of these two dispersions are consistent with the assignments mentioned above.

As we have mentioned before, the band B (at about 10×10^3 cm^{-1}) in the spectra of TCNQ complex salts has been assigned to the charge transfer between $(TCNQ)^-$ ions.[6] But the corresponding dispersion (the dispersion B) clearly exhibits a sharp structure in the reflection spectra observed in the present study. We note also that the dispersion B is polarized not in the direction of the TCNQ stacking axis. To know the polarization direction that gives the maximum dispersion amplitude, we observed the variation of the amplitude by rotating the polarization direction within (011) plane. We took the difference between the reflectance values at 9.8×10^3 cm^{-1} (maximum) and 10.5×10^3 cm^{-1} (minimum), R(9800)—R(10500), as the measure of the amplitude around the first peak, and the difference between the reflectance values at 11.1×10^3 cm^{-1} (maximum) and 11.9×10^3 cm^{-1} (minimum), R(11100)—R(11900), as that around the second peak. The result is shown in Fig. 3, where the observed amplitudes are plotted against the angle of polarization direction θ measured from the direction of the a-axis. We can see that the θ dependence of amplitude is exactly the same between the two peaks of the dispersion B, showing a maximum at $\theta\simeq60°$ which is the direction bisecting the angle between the direction of the long molecular axis of TCNQ and that connecting the centers of two TCNQ molecules within the dimer. The fact that the amplitudes of the two peaks exhibit the same angular dependence implies that they are associated with the same electronic transition.

The reflection spectra which were measured at 27 and 298 K on the (100) crystal face for the polarization (1), are shown in Fig. 4. The structure in the region of the dispersion B becomes markedly sharper at 27 K as compared with the spectrum at 298 K, while the

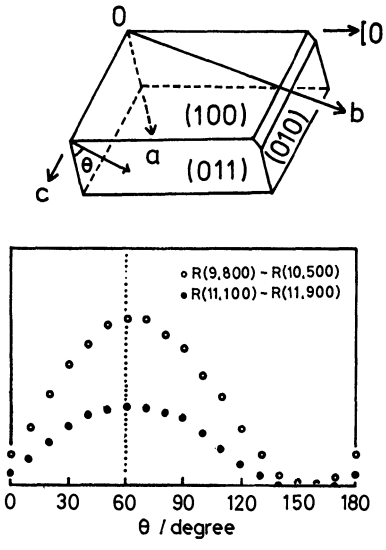

Fig. 3. The crystal shape of $(NEP)(TCNQ)_2$ single crystal used in this study and the angular dependency of the difference of the reflectivity between the crystal axis and polarization direction of incident light. R(9,800) means the reflectivity at 9.8×10^3 cm^{-1}.

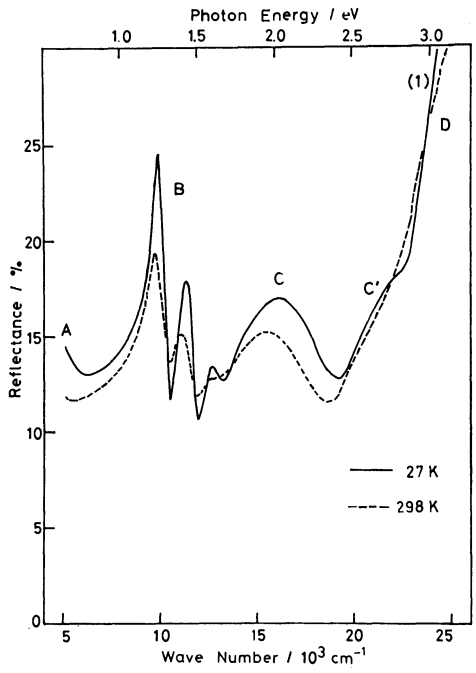

Fig. 4. Low temperature reflection spectrum polarized to the [01$\bar{1}$] direction on the (100) face of $(NEP)(TCNQ)_2$. Room temperature reflection spectrum is drawn by dashed line for the purpose of comparison.

dispersion C remains broad and structureless even at 27 K. In order to see more details of the structure of the dispersion B, we carefully measured at 27 K the reflection spectrum of the concerned region with the resolution of 40 cm^{-1}. The reflectance data thus obtained are shown by points in Fig. 5 where the solid line is the best-fitted curve obtained in the final stage of the curve fitting procedure employing seven Helmholtz-Kettler oscillator functions for the region from 5×10^3 cm^{-1} to 25×10^3 cm^{-1}, three oscillator functions being used for the region of the dispersion B.

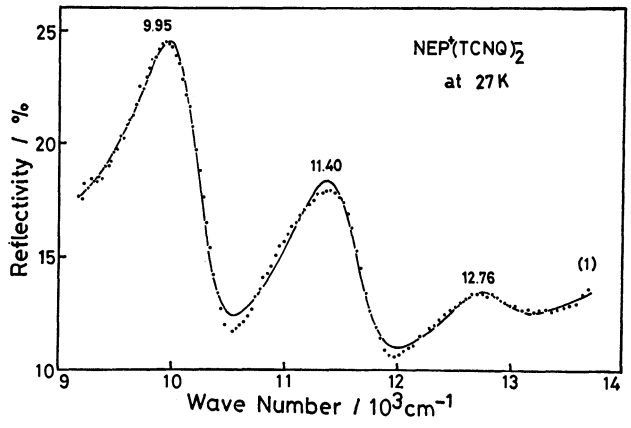

Fig. 5. The low-temperature reflection spectrum of $(NEP)(TCNQ)_2$ single crystal in the range from 9×10^3 cm^{-1} to 14×10^3 cm^{-1}. The dots means the experimental data and the solid line is the best-fitted curve obtained by the Helmholtz-Kettler model functions.

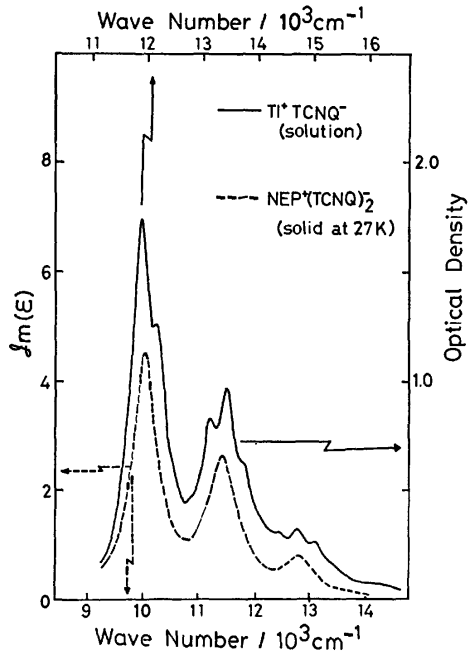

Fig. 6. Comparison between the absorption spectrum of $TCNQ^-$ in acetonitrile solution and the imaginary part of the complex dielectric function obtained by the dispersion analysis of the reflection spectrum at low temperature.

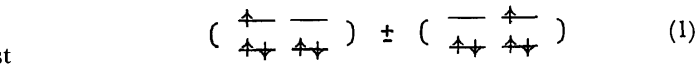
fitting mentioned above, and the solid line is the lowest π-π^* band of $(TCNQ)^-$ ion in the absorption spectrum of the acetonitrile solution of Tl(TCNQ). The both spectra agree quite well with each other. Such a good agreement can be expected only when the dispersion B is mainly due to the lowest π-π^* transition of $(TCNQ)^-$ ion. Thus we assign the dispersion B to LE1(A) not to the charge transfer between $(TCNQ)^-$ ions. Naturally, there must be a mixing with other excited configurations, in particular with CT configurations such as CT1(A→N) as it is suggested from the observed polarization direction of the dispersion B.

Other interesting aspects which we note in the low-temperature spectrum, is a blue shift of the dispersion C and the appearance of a shoulder at about 22×10^3 cm^{-1} which we have denoted as C′ in Fig. 4. The dispersion C is polarized parallel to the long molecular axis of TCNQ. As we have mentioned before, the corresponding absorption band in the absorption spectra of TCNQ complex salts has been considered to be attributable to LE1(A). We can not accept this assignment since we have already shown that it is the dispersion B that should be attributed to LE1(A). Therefore, we have to find out a new interpretation for the dispersion C.

In the ground state of $(TCNQ)^0$, sixteen π electrons are occupying up to the 8th π orbital from the lowest one, and the lowest allowed π-π^* transition which gives a strong absorption band at 24.9×10^3 cm^{-1} in the absorption spectrum of the chloroform solution of TCNQ,[15] is associated with the transition to the singlet excited state which can be mainly expressed by the configuration where an electron has been excited from the 8th MO to the 9th MO. There must be a triplet excited state corresponding to the singlet excited state mentioned above. This lowest triplet excited state of $(TCNQ)^0$ was determined to be located at 2.0 ± 0.2 eV (16×10^3 cm^{-1}) above the ground state by the electron energy loss experiment.[16] In the ground state of $(TCNQ)^-$, π electrons are doubly occupying up to the 8th MO and singly occupying the 9th MO. The lowest π-π^* transition is associated with the excitation of an electron from the 8th MO to the 9th MO.

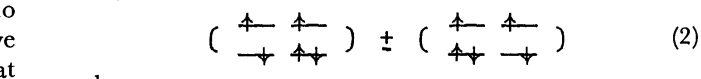
Let us consider the situation in the dimer $(TCNQ)_2^-$, since the structural characteristics of $(NEP)(TCNQ)_2$ suggest that the intermolecular CT interaction is very muth stronger within the dimer than between the dimers, so that the essential features of the observed reflection spectrum are expected to be understandable from the considerations on the electronic states of the dimer. The lowest CT configuration of the dimer must be the one where an electron has been transfered from the 9th MO of $(TCNQ)^-$ to the 9th MO of $(TCNQ)^0$. However this is not a proper expression of the CT excited state of the dimer which is composed of a pair of strictly equivalent molecules. The ground electronic configuration of such a dimer must be expressed by the two doublet configurations which are mutually different as regards the molecular site which has one unpaired electron on its 9th MO. By taking up only the 8th and 9th MO's of the two molecules, we can schematically represent the configuration as follows;



(1)

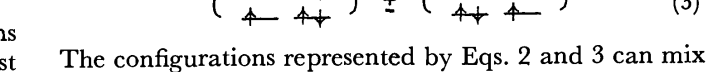
where the plus sign gives the gerade state and the minus sign gives the ungerade state. The gerade state must be energetically lower than the ungerade state, hence the former corresponds to the ground state of the dimer and the latter corresponds to the CT excited state. The lowest CT transition CT1(A→N) is to be considered as the transition between these two states. We will attribute the dispersion A of $(NEP)(TCNQ)_2$ to this CT transition.

Next we will consider the charge transfer from the 8th MO of $(TCNQ)^-$ to the 9th MO of $(TCNQ)^0$, which can be expressed as CT2(A→N). When the total spin of the dimer is considered, there will be doublet and quartet states. Since the optical transition from the ground state (doublet) is possible only to the doublet excited states, we will take up here only the doublet states. The wave function of these state can be schematically represented as follows;



(2)

and



(3)

The configurations represented by Eqs. 2 and 3 can mix with each other and also with the configurations expressed by Eq. 1 since all of them are doublet states of the dimer. When we look at the electronic configurations 2 and 3 from another side, we note that they are equivalent to the expressions of the following LE configurations of the dimer: The expression given by Eq. 2 corresponds to the state where $(TCNQ)^0$ is in

the lowest singlet excited state, and $(TCNQ)^-$ is in the ground state, and the expression given by Eq. 3 correspond to the state where $(TCNQ)^0$ is in the lowest triplet excited state and $(TCNQ)^-$ is in the ground state. Thus one could denote these configurations as LE1(N, singlet) and LE1(N, triplet) states of the dimer, respectively. It should be noted that both of them are, in reality, the doublet excited states of the dimer and, therefore, they can mix with each other as we have already mensioned (Refer the appendix for the theoretical background of the explanation mentioned here).

From these considerations, we can conclude that there will be two kinds of doublet-doublet transition associated with CT2(A→N), one of which has the character of LE1(N, triplet) and the other has the character of LE1(N, singlet), and that the former transition will gain its intensity by borrowing intensity from the latter which is expected to be very strong, provided that an intermolecular CT interaction is strongly taking place in the dimer.

The doublet-doublet transition which has the character of LE1(N, triplet) is expected to appear at the wave number approximately equal to the energy of the lowest triplet state of $TCNQ^0$ (16×10^3 cm^{-1}).[16] The position of the dispersion C of $(NEP)(TCNQ)_2$ is in good agreement with this value. Thus, we attribute the dispersion C to the transition mentioned above, and will denote it as LE1(N, triplet)[CT2(A→N)]. There must by a strong dispersion associated with LE1(N, singlet)-[CT2(A→N)]. We can safely assign the dispersion D to this transition.

The low-temperature spectrum of $(NEP)(TCNQ)_2$ exhibits a shoulder at 22×10^3 cm^{-1}. This shoulder is separated by $(11—12)\times10^3$ cm^{-1} from the dispersion B which we have attributed to LE1(A) transition. This separation agrees with the separation between the first and second π-π^* transitions of $(TCNQ)^-$.[17] Thus we attribute the shoulder to the dispersion mainly associated with LE2(A).

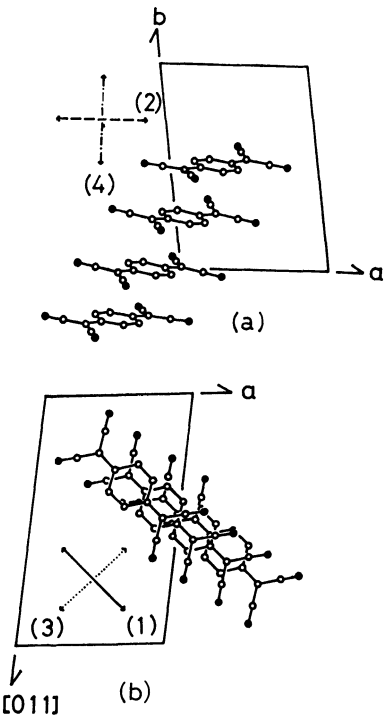


Fig. 7. Projection of the TCNQ molecules onto (a) the (001) and (b) the (01$\bar{1}$) plane in the crystal of (MTPP)$(TCNQ)_2$.

$(MTPP)(TCNQ)_2$. The crystal of $(MTPP)(TCNQ)_2$ is triclinic with the space group P$\bar{1}$, the lattice constants being $a=9.01$ Å, $b=12.89$ Å, $c=18.18$ Å, $\alpha=121.80°$, $\beta=90.58°$ and $\gamma=97.30°$.[18] The unit cell contains one molecular unit of $(MTPP)(TCNQ)_2$. In this crystal TCNQ molecules (or ions) are forming tetramers, and a zigzag TCNQ column is formed by the stacking of these tetramers along the b-axis. The molecular arrangement within a tetramer is shown in Fig. 7. This salt exhibits a phase transition at 315 K between the low-temperature (low spin) phase and the high-temperature (high-spin) phase.[19] According to the results of crystal structure analysis, the molecular arrangement within the TCNQ tetramer remains the same between the two phases, but the separation of TCNQ molecules between tetramers changes from 3.57 Å in the low-temperature phase to 3.55 Å in the high-temperature phase.[20] As compared with the intermolecular separation between tetramers, the molecular separations within a tetramer are appreciably small, which are reported to be 3.24, 3.22, and 3.26 Å. Thus the main feature of the spectrum will be determined by the intermolecular interaction wihtin the tetramer.

The absorption spectrum of the single crystal of $(MTPP)(TCNQ)_2$ was observed by Tanaka *et al.*,[5] and the reflection spectrum was observed by Oohashi and Sakata,[4] both the groups made the measurements only on the (001) crystal face at room temperature. These authors reported that $(MTPP)(TCNQ)_2$ exhibits the four absorption bands which are characteristic of the absorption spectra of TCNQ complex salts.

In the present study, we measured the reflection spectrum of this salts not only on the (001) crystal face, but also on the (01$\bar{1}$) crystal face. The polarization directions employed in those measurements are shown in Fig. 7.

Figure 8 shows the reflection spectra obtained at room temperature. From the comparison of these spectra, we can see that the dispersions denoted as B, C and D are polarized almost in the direction of the long molecular axis of TCNQ, while the dispersion A is polarized in the direction of the TCNQ column. The general features of these spectra are quite similar to the reflection spectrum of $(NEP)(TCNQ)_2$, except that the vibrational structure of the dispersion B less sharply appears in the spectra of $(MTPP)(TCNQ)_2$ than in the spectra of $(NEP)(TCNQ)_2$.

However, as we cool down $(MTPP)(TCNQ)_2$, there appears a new dispersion at about 8×10^3 cm^{-1}, while no corresponding dispersion was found in the case of $(NEP)(TCNQ)_2$. We will denote this new dispersion as A′ (see Fig. 9). It should be noted also that the dispersion B is blue shifted on lowering the temperature while such an appreciable temperature-dependent shift was not found in the case of $(NEP)(TCNQ)_2$. In other respects, the temperature dependence of the reflection

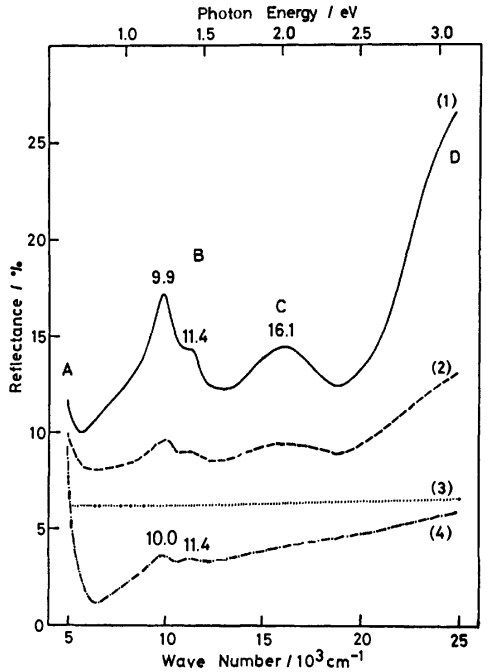

Fig. 8. Reflection spectra on the (100) and the (01$\bar{1}$) crystal faces of (MTPP) $(TCNQ)_2$. The number of each spectrum corresponds to that drawn in Figs. 7 (a) and 7(b).

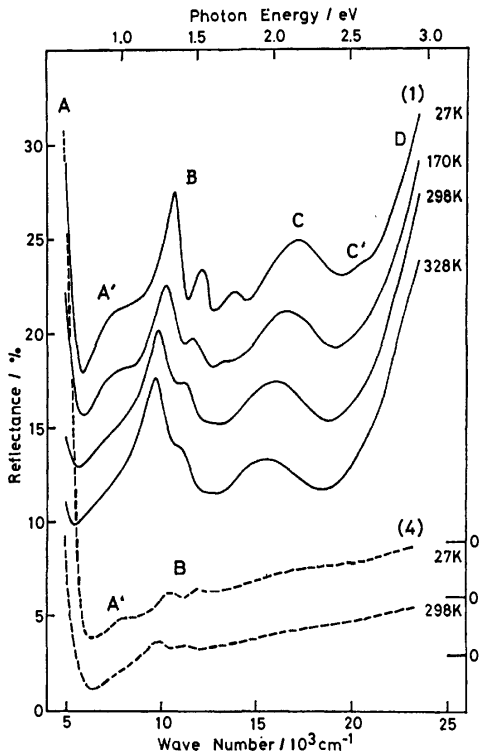

Fig. 9. Temperature dependency of the reflection spectra of (MTPP) $(TCNQ)_2$ single crystal polarized parallel to the [111] direction (solid line) and perpendicular to the a-axis (dashed line).

spectrum of (MTPP)$(TCNQ)_2$ very resembles that of (NEP)$(TCNQ)_2$.

The experimental results described above can be interpreted if we assume a model that the TCNQ tetramer in (MTPP)$(TCNQ)_2$ is essentially composed of two TCNQ dimers, between which a CT interaction can take place. According to this model, the electronic transitions of the TCNQ tetramer can be classified into those mainly associated with the electronic transitions within each dimer and those associated with the charge transfer between the dimers. Let us consider the temperature dependence of the latter transition. Since each dimer $(TCNQ)_2^-$ has one unpaired electron, there will be singlet and triplet state for the ground electronic configuration of the tetramer when the spin state is taken into account. On the other hand, the CT configuration where an electron is transfered from a singly occupied orbital of a dimer to the corresponding orbital of another dimer, is necessarily a singlet state. Consequently, the singlet ground configuration can be stabilized by the mixing with this CT configuration, but not in the case of the triplet ground configuration. The optical transition to the CT singlet state is allowed only from the singlet ground state, so that the intensity of the CT band associated with this transition should increase on lowering the temperature accompanying the increase of the population of the tetramers which are in the singlet ground state. This situation is analogous to the singlet-triplet model proposed for a radical ion dimer.

The ESR signal due to the triplet exciton in (MTPP)-$(TCNQ)_2$ was actually observed by Chesnut and Phillip.[19] The temperature dependence of the paramagnetic susceptibility of this salt was approximately

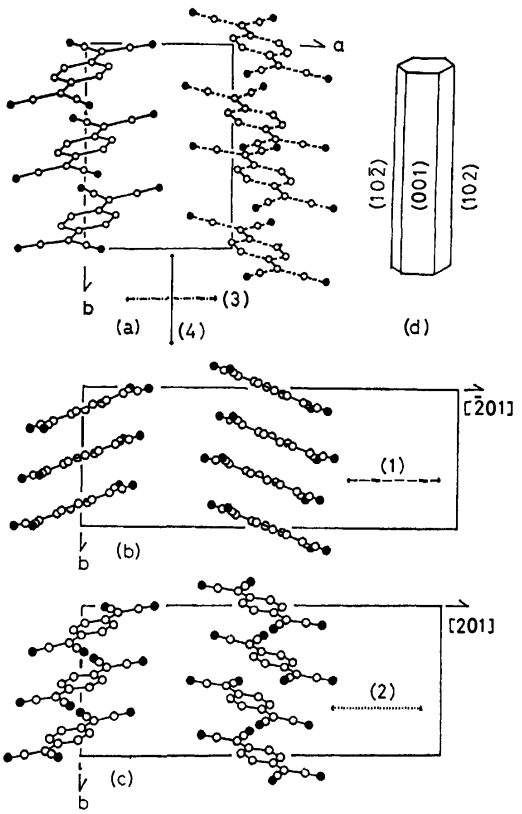

Fig. 10. Projection of the TCNQ molecules onto the crystal faces of (a) (001), (b) (102), and (c) (10$\bar{2}$). (d) Crystal morphology for Cs_2TCNQ_3 single crystal.

explained in terms of the singlet-triplet model with the energy separation of 0.065 eV.[21] This singlet-triplet separation is significantly smaller than the value (0.2—0.4 eV) usually obtained for TCNQ simple salts.[22] This is also understandable from the model described above, since the stabilization of the singlet ground state caused by the CT interaction between dimers must be much smaller than that caused by the CT interaction between closely contacting $(TCNQ)^-$ ions within a $(TCNQ)^-$ dimer.

According to the consideration mentioned above, we will attribute the dispersion A′ which exhibits a marked increase of amplitude at lower temperature, to the charge transfer between dimers, and the remaining dispersions, A, B, C, C′, and D, to the transitions within a dimer, thus attributable to the transitions which we have discussed in the cases of the corresponding dispersions of the spectrum of $(NEP)(TCNQ)_2$.

$Cs_2(TCNQ)_3$. The crystal of $Cs_2(TCNQ)_3$ is monoclinic with the space group $P2_1/c$, the lattice constants being $a=7.34$ Å, $b=10.40$ Å, $c=21.98$ Å and $\beta=97.18°$.[23] The unit cell contains two molecular units of $Cs_2(TCNQ)_3$. The observed molecular geometries of TCNQ in this crystal indicate that the charges in the TCNQ column are rather localized, so that $(TCNQ)^0$ sites and $(TCNQ)^-$ sites are regularly arranged along the column by the repetition of $(TCNQ)^-(TCNQ)^0(TCNQ)^-$ (see Fig. 10). But we should not consider that the TCNQ column is composed of discrete TCNQ trimers since the intermolecular separation is 3.22 Å between $(TCNQ)^0$ and $(TCNQ)^-$ within a trimeric repeating unit and 3.26 Å between $(TCNQ)^-$ ions of the neighboring units.

$Cs_2(TCNQ)_3$ crystallizes as a needle-like crystal, the shape of which is illustrated in Fig. 10(d). The $//b$ and $\perp b$ absorption spectra were previously observed in our laboratory on the (001) face of a single crystal at room temperature, by using a microspectrophotometer for transmission method.[2] The absorption spectra obtained by a similar measurement were reported later by Tanaka *et al.*[5] These two results showed a good agreement with each other. However, no observation of absorption spectrum has been done so far on the crystal faces other than the (001) face. This left some ambiguities as regards interpretation of the spectrum.

Figure 11 shows the reflection spectra measured on the (001), (102), and $(10\bar{2})$ faces of a single crystal of $Cs_2(TCNQ)_3$ at room temperature. The polarization directions employed to obtain these spectra are illustrated in Fig. 10 which shows the projection of the crystal structure onto each crystal face, Cs ions having been omitted in the projections shown there. The number of each spectrum corresponds to the number of the polarization direction by which it was measured.

The spectra (3) and (4) correspond quite well to the reported absorption spectra measured on the same crystal face, (001), with the $\perp b$ and $//b$ polarizations, respectively.[2,6] However, the spectra (1) and (2) reveal the features which have never been found from the measurements on the (001) face only. First, the spectrum (1) shows a strong maximum at 11.3×10^3 cm^{-1}, which is clearly different from the position of

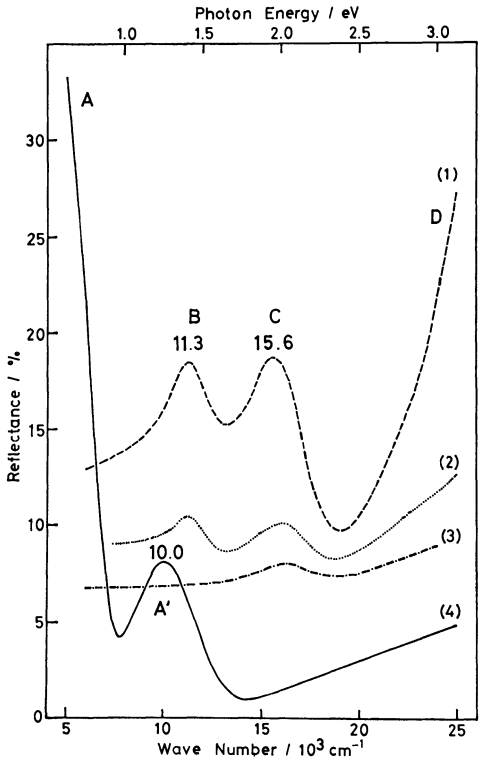

Fig. 11. Reflection spectra on the (001), the (102) and the $(10\bar{2})$ crystal faces of Cs_2TCNQ_3 single crystal. The number of each spectrum corresponds to that drawn in Figs. 10(a), 10(b), and 10(c). The $//b$ spectra measured on the (102) and $(10\bar{2})$ faces were exactly the same as the $//b$ spectrum measured on the (001) face, hence they are not shown here.

the maximum found in the spectrum (1). Second, the maximum at 15.6×10^3 cm^{-1} strongly appears in the spectrum (1) as compared with the spectra obtained with other polarizations, indicating that it is associated with the transition polarized in the direction of the long molecular axis of TCNQ.

The reflection spectra obtained at 27 K for the polarization directions (1) and (4) are shown in Fig. 12, where the broken lines are the corresponding room-temperature spectra. Note that the peak at 11.4×10^3 cm^{-1} becomes sharp and a new small peak does appear at 12.8×10^3 cm^{-1} in the spectrum (1) measured at 27 K. On the other hand, the spectrum (4) at 27 K shows a broad maximum at 10.2×10^3 cm^{-1} which is accompanied by small sharp peaks at 11.6×10^3 and 13.0×10^3 cm^{-1}. Probably the small sharp peaks observed in the spectrum (4) at 27 K are corresponding to the 11.4×10^3 and 12.8×10^3 cm^{-1} peaks of the spectrum (1). This fact implies that the broad maximum (at 10.2×10^3 cm^{-1}) of the spectrum (4) is of an origin entirely different from that of the sharp peaks which strongly appear in the spectrum (1). We note that the spectrum (1) at 27 K closely resembles the spectrum of $(NEP)(TCNQ)_2$, although the TCNQ column of $Cs_2(TCNQ)_3$ has not any discrete dimeric unit corresponding to the dimer $(TCNQ)_2^-$ which has been discussed in the case of $(NEP)(TCNQ)_2$. Seemingly the similarity between the

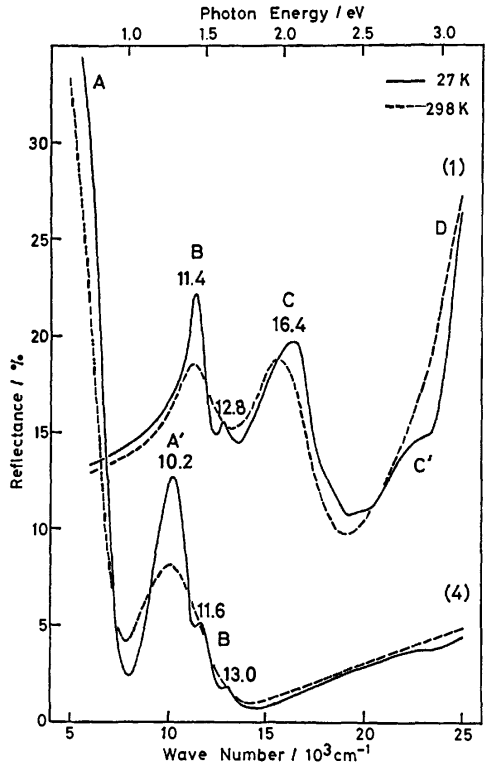

Fig. 12. Low-temperature reflection spectra of Cs_2-$TCNQ_3$ single crystal polarized parallel to the [$\bar{2}$01] and the [010] directions.

spectrum of $Cs_2(TCNQ)_3$ and that of (NEP)$(TCNQ)_2$ arises because the main feature of the former is also determined by the interaction between $(TCNQ)^0$ and $(TCNQ)^-$. Thus, from the analogy with the assignments given for the dispersions of the spectrum of (NEP)-$(TCNQ)_2$, we assign the dispersion B with a relatively sharp peaks at 11.4×10^3 and 12.8×10^3 cm^{-1} to LE1(A) and the dispersion C' which appear as a shoulder at the low-temperature spectrum (1) to LE2(A), and the dispersion C at 16.4×10^3 cm^{-1} to the transition associated with the charge transfer from the second highest occupied orbital (8th MO) of $TCNQ^-$ to the lowest unoccupied orbital (9th MO) of $TCNQ^0$, thus to CT2(A→N). This CT2(A→N) transition must have a character of LE1(N, triplet) as we have pointed out in the case of (NEP)$(TCNQ)_2$. As a matter of fact, the dispersion C is completely polarized in the direction of the long molecular axis of TCNQ. The strong dispersion D which is located above 25×10^3 cm^{-1} can be safely assigned to LE1(N, singlet)[CT2(A→N)].

The dispersion A' which appears as a maximum at 10.2×10^3 cm^{-1} in the spectrum (4), can be assigned to the charge transfer between $(TCNQ)^-$ ions, CT1-(A→A). In the case of TCNQ simple salts, there exists a strong mixing between CT1(A→A) and LE1(A). This makes the absorption band associated with LE1(A) broad and structureless, and, gives at the same time an increase of the separation between CT1(A→A) band and the band which is mainly associated with LE1(A), their separation being usually $(5—6)\times10^3$ cm^{-1} in the absorption spectra of TCNQ simple salts.

In the case of $Cs_2(TCNQ)_3$, the overlap of mutually interacting $(TCNQ)^-$ ions is of the short-axis-shifted mode where one of the ions is shifted against the other along the short molecular axis from the position of the direct overlap. With this mode of molecular overlap, the CT1(A→A) state cannot mix with the LE1(A) state. Probably this might be the reason why the separation between the dispersion A'(CT1(A→A)) and the dispersion B (LE1(A)) is small, and the latter clearly shows a vibrational structure, although there must be a strong CT interaction between $(TCNQ)^-$ ions.

Conclusion and Summary

In this study, we measured the polarized reflection spectra on the single crystals of the three different types of TCNQ complex salt, (NEP)$(TCNQ)_2$, (MTPP)-$(TCNQ)_2$, and $Cs_2(TCNQ)_3$, not only at room temperature but also at low temperatures down to 27 K. We have revealed that the dispersion B which appears at about $(10—11)\times10^3$ cm^{-1} shows a sharp structure corresponding to the vibrational structure of the lowest π-π^* band of the solution spectrum of $(TCNQ)^-$ ion, and is polarized in the direction rather close to the direction of the long molecular axis of TCNQ. We have also found that a new dispersion appears at $(7—8)\times10^3$ cm^{-1} in the low-temperature spectrum of (MTPP)$(TCNQ)_2$ and its amplitude increases on lowering the temperature. The low-temperature spectrum of $Cs_2(TCNQ)_3$ showed that there is a broad dispersion at 10.2×10^3 cm^{-1}, polarized parallel to the TCNQ column, besides a sharp dispersion at 11.4×10^3 cm^{-1} polarized in the direction of the long-molecular axis of $(TCNQ)^-$.

These new results cannot be explained by the interpretations which have been hitherto proposed for the absorption bands of the spectra of semiconductive TCNQ complex salts.

On the bases of those experimental results, we have proposed a new interpretation, particularly for the origin of the dispersion B which appears at about 10×10^3 cm^{-1} with a vibrational structure and the dispersion C which appears at about 16×10^3 cm^{-1}.

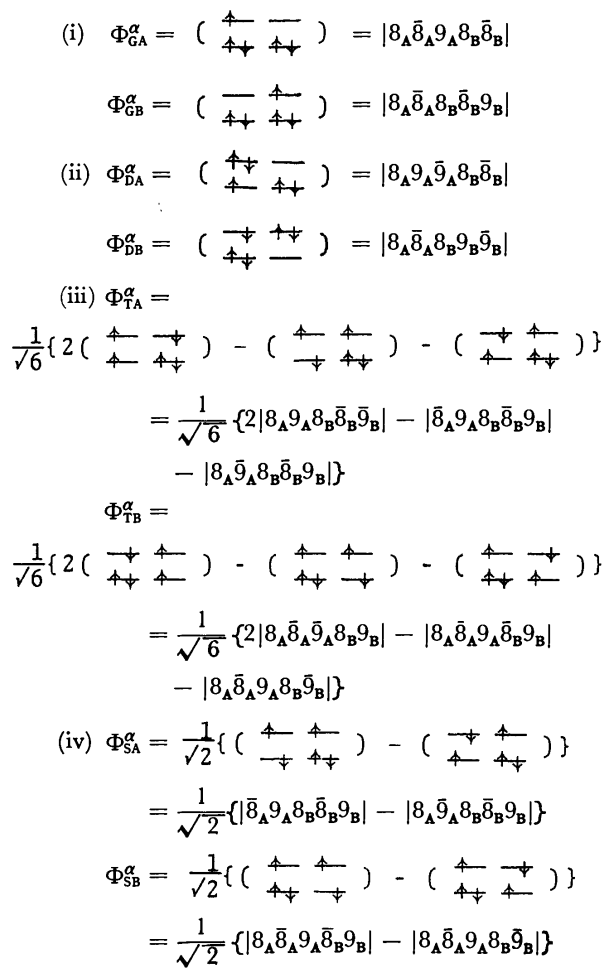
Finally we wish to point out that, as we have revealed in this study, it is extremely important to observe the reflection (or absorption) spectra on various crystal faces with different polarizations, not only at room temperature but also at low temperatures in order to know the true characteristics of the spectra of highly anisotropic organic solids such as TCNQ salts, and to establish the interpretations of the spectra.

The authors wish to thank Mr. Nobuhiro Kosugi for helpful discussion.

Appendix

We will consider the ground and excited states of the dimer $(TCNQ)_2^-$ by using a simple configuration interaction method, in order to reveal the mechanism of the mixing of the states of the doublet-singlet pair and the doublet-triplet pair. To simplify the model we take account only of the 8th and 9th

molecular orbitals of TCNQ. Let us express the wave functions of various configurations of the dimer as follows denoting the molecules in the dimer as A and B, respectively;



where α represents the spin state of the doublet system, 8_A and $\bar{8}_B$ mean the 8th molecular orbital of the molecule A with α spin and that of the molecule B with β spin, and $|8_A\bar{8}_A9_A8_B\bar{8}_B|$ means the Slater determinant.

When we neglect the intermolecular interaction, (i), (ii), (iii), and (iv) correspond, respectively, to the ground configuration, the LE configurations associated with the first excited state of $TCNQ^-$, the ones associated with the first triplet and singlet excited states of $TCNQ^0$. When the intermolecular interaction H_{AB} is introduced, the electronic states of the dimer can be described by the linear combination of these states. As the first approximation, we will take account of the following transfer integrals:

$$
\begin{aligned}
t_0 &= \langle\Phi^\alpha_{GA}|H|\Phi^\alpha_{GB}\rangle \simeq \langle|8_A9_A\bar{9}_A8_B\bar{8}_B|H|8_A9_A8_B\bar{9}_B\bar{8}_B|\rangle \\
&= \langle|8_A\bar{8}_A8_B9_B\bar{9}_B|H|8_A\bar{8}_A\bar{9}_A8_B9_B|\rangle \\
&\simeq -\langle|8_A9_A\bar{9}_A8_B\bar{8}_B|H|8_A\bar{9}_A8_B\bar{8}_B9_B|\rangle \\
&= -\langle|8_A\bar{8}_A8_B9_B\bar{9}_B|H|8_A\bar{8}_A9_A8_B\bar{9}_B|\rangle \\
t_1 &= -\langle|8_A\bar{8}_A9_A8_B\bar{8}_B|H|8_A9_A8_B\bar{8}_B\bar{9}_B|\rangle \\
&= -\langle|8_A\bar{8}_A8_B\bar{8}_B9_B|H|8_A\bar{8}_A\bar{9}_A8_B9_B|\rangle \\
&\simeq \langle|8_A\bar{8}_A9_A\bar{8}_B8_B|H|\bar{8}_A9_A8_B\bar{8}_B9_B|\rangle \\
&= \langle|8_A\bar{8}_A8_B\bar{8}_B9_B|H|8_A\bar{8}_A9_A\bar{8}_B9_B|\rangle \\
t_2 &= \langle|8_A9_A8_B\bar{8}_B\bar{9}_B|H|8_A\bar{8}_A9_A8_B\bar{9}_B|\rangle \\
&= \langle|8_A\bar{9}_A8_B\bar{8}_B9_B|H|8_A\bar{8}_A\bar{9}_A8_B9_B|\rangle \\
&\simeq \langle|\bar{8}_A9_A8_B\bar{8}_B9_B|H|8_A\bar{8}_A9_A\bar{8}_B9_B|\rangle,
\end{aligned}
$$

where, $H=H_0+H_{AB}$. The origin of the energy is chosen so that $\langle\Phi^\alpha_{GA}|H|\Phi^\alpha_{GA}\rangle$ is equal to zero. The matrix of the secular equation will be given by (1) for the gerade states,

$$
\begin{array}{c}
\\
\Phi_G^+ \\
\Phi_D^+ \\
\Phi_T^+ \\
\Phi_S^+
\end{array}
\begin{pmatrix}
t_0 & 0 & -\frac{3}{\sqrt{6}}t_1 & \frac{1}{\sqrt{2}}t_1 \\
 & E_D & \frac{3}{\sqrt{6}}t_0 & \frac{1}{\sqrt{2}}t_0 \\
 & & E_T-\frac{1}{2}t_2 & -\frac{\sqrt{3}}{2}t_2 \\
 & & & E_S+\frac{1}{2}t_2
\end{pmatrix} \qquad (1)
$$

and by (2) for the ungerade states,

$$
\begin{array}{c}
\\
\Phi_G^- \\
\Phi_D^- \\
\Phi_T^- \\
\Phi_S^-
\end{array}
\begin{pmatrix}
-t_0 & 0 & -\frac{3}{\sqrt{6}}t_1 & \frac{1}{\sqrt{2}}t_1 \\
 & E_D & \frac{3}{\sqrt{6}}t_0 & \frac{1}{\sqrt{2}}t_0 \\
 & & E_T+\frac{1}{2}t_2 & \frac{\sqrt{3}}{2}t_2 \\
 & & & E_S-\frac{1}{2}t_2
\end{pmatrix} \qquad (2)
$$

where,

$$
\begin{aligned}
\Phi^\pm_G &= \frac{1}{\sqrt{2}}(\Phi^\alpha_{GA} \pm \Phi^\alpha_{GB}) \\
\Phi^\pm_D &= \frac{1}{\sqrt{2}}(\Phi^\alpha_{DA} \pm \Phi^\alpha_{DB}) \\
\Phi^\pm_T &= \frac{1}{\sqrt{2}}(\Phi^\alpha_{TA} \pm \Phi^\alpha_{TB}) \\
\Phi^\pm_S &= \frac{1}{\sqrt{2}}(\Phi^\alpha_{SA} \pm \Phi^\alpha_{SB})
\end{aligned}
$$

The integrals, t_0, t_1, and t_2, have negative values because of the symmetry of the molecular orbitals[24] and the geometrical configuration of TCNQ molecules in the dimer. Therefore, the ground state of this system will be Φ_G^+, and the optical transition from this state is allowed only to Φ_G^-, Φ_D^-, Φ_T^-, and Φ_S^-. The wave function of the ground state and those of the ungerade states can be expressed as follows when they are calculated by the first order perturbation method.

$$
\begin{aligned}
\Phi_G &= \Phi_G^+ + \frac{\frac{3}{\sqrt{6}}t_1}{E_T-\frac{1}{2}t_2-t_0}\Phi_T^+ - \frac{\frac{1}{\sqrt{2}}t_1}{E_S+\frac{1}{2}t_2-t_0}\Phi_S^+ \\
\Phi_{CT} &= \Phi_G^- + \frac{\frac{3}{\sqrt{6}}t_1}{E_T+\frac{1}{2}t_2+t_0}\Phi_T^- - \frac{\frac{1}{\sqrt{2}}t_1}{E_S-\frac{1}{2}t_2+t_0}\Phi_S^- \\
\Phi_D &= \Phi_D^- - \frac{\frac{3}{\sqrt{6}}t_0}{E_T+\frac{1}{2}t_2-E_D}\Phi_T^- - \frac{\frac{\sqrt{3}}{2}t_0}{E_S-\frac{1}{2}t_2-E_D}\Phi_S^- \\
\Phi_T &= \Phi_T^- - \frac{\frac{3}{\sqrt{6}}t_1}{E_T+\frac{1}{2}t_2+E_D}\Phi_G^- + \frac{\frac{3}{\sqrt{6}}t_0}{E_T+\frac{1}{2}t_2-E_D}\Phi_D^- \\
&\quad - \frac{\frac{\sqrt{3}}{2}t_2}{E_S-t_2-E_T}\Phi_S^-
\end{aligned}
$$

$$\Phi_S = \Phi_S^- + \frac{\frac{1}{\sqrt{2}}t_1}{E_S - \frac{1}{2}t_2 + t_0}\Phi_G^- + \frac{\frac{1}{\sqrt{2}}t_0}{E_S - \frac{1}{2}t_2 - E_D}\Phi_D^- + \frac{\frac{\sqrt{3}}{2}t_2}{E_S - t_2 - E_T}\Phi_T^-$$

The transitions to Φ_{CT}, Φ_D, Φ_T, and Φ_S from Φ_G correspond to CT1(A→N), LE1(A), LE1(N, triplet) and LE1(N, singlet), respectively, and the last two transitions have, at the same time, the nature of CT2(A→N). Thus, the transition $\Phi_G \rightarrow \Phi_T$ can borrow its intensity from the very strong transition of the type $\Phi_G^+ \rightarrow \Phi_S^-$, provided that t_2 is not zero. Although the present formulation has been carried out by taking up only the 8th and 9th MO, the conclusion will not change qualitatively even if we carried out a more elaborate calculation.

The Rate Constants of the Reactions of Hydrogen and Oxygen Atoms with Fluoroethylenes

Ko-ichi SUGAWARA, Kiyoshi OKAZAKI, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 1, 1980)

The pulse-radiolysis technique combined with the atomic resonance absorption method was used for the measurement of the room-temperature rate constants of the reactions of hydrogen and oxygen atoms with fluoroethylenes. The rate constants obtained at 298±2 K are as follows, in units of 10^{-12} cm^3 molecule^{-1} s^{-1} (1 cm^3 molecule^{-1} s^{-1} = 6.022 × 10^{17} m^3 mol^{-1} s^{-1}). The standard deviation is within 10%.

Atoms	C_2H_4	C_2H_3F	CH_2CF_2	C_2HF_3	C_2F_4
H	1.1	0.52	0.36	0.090	0.082
O	1.0	0.52	0.20	0.63	0.81

The correlation between the rate constants and the reactivity index calculated by the INDO method is discussed.

The determination of the absolute rate constants for the addition of hydrogen and oxygen atoms to monoolefins in the gas phase has been the subject of a number of investigations.[1-6] Although some discrepancies still remain in the temperature dependence, the rate constants at room temperature now appear to be established.

Recently we used the pulse-radiolysis technique for the determination of these rate constants and obtained results consistent with previous measurements.[7-9]

Using the product analysis, Jennings and his collaborators determined the relative rate constants for the addition of hydrogen and oxygen atoms to many fluorinated olefins.[10,11] Moss used a similar technique to measure the relative rate constants of the reactions of oxygen atoms with all the fluoroethylenes.[12] The relative rate constants they reported have an interesting dependence on the number of the substitution of fluorine atoms. In the reactions of hydrogen atoms with fluoroethylenes, the increase in the number of substituted fluorine atoms reduces the relative rate constants, while in the case of oxygen atoms, difluoroethylenes have the lowest reactivity. These results are still open to theoretical interpretation.

We, therefore, attempted the measurement of the absolute rate constants of the reactions of hydrogen and oxygen atoms with some fluoroethylenes, and tried to explain the results theoretically by using the reactivity index calculated by the INDO method.

Experimental

The apparatus used for the measurement of the rate constants has been described previously.[9] The time resolved measurements of hydrogen and oxygen atoms are the same as those described in previous papers.[7,9]

Fluoroethylenes were the products of Daikin Co. After a few freeze-pump-thaw cycles at liquid nitrogen temperature, the middle third was retained. The gas chromatographic analysis using a 2-m Porapak N column at room temperature showed that all compounds contain no detectable impurities.

Results

For the reactions of hydrogen atoms, the H_2 pressure ranging from 180 to 900 Torr (1 Torr=133.3 Pa) was used. No H_2-pressure dependence of the rate constant could be observed. All the decay curves obtained on the oscillograms were of the first-order. Figure 1 summarizes the decay rates obtained as functions of the initial pressure of four kinds of fluoroethylenes. For comparison, the decay rates previously obtained with ethylene are plotted.[7]

●: C_2H_4, △: C_2H_3F, ■: CH_2CF_2, ○: C_2HF_3, ▲: C_2F_4.

As the source of oxygen atoms, the mixtures of O_2 (4—10 Torr) and He (100—900 Torr) were used. All the decay curves obtained on the oscillograms were of the first-order. The procedure for the determination of the rate constants of the reactions of oxygen atoms with olefins is the same as that described in the previous paper.[9] Figure 2 summarizes the decay rates obtained as functions of the initial pressure of fluoroethylenes. For comparison, the decay rates previously obtained with ethylene are also plotted.

From the linear plots shown in Figs. 1 and 2, we can calculate the rate constants of the reactions of hydrogen and oxygen atoms with fluoroethylenes. The results are summarized in Fig. 3 as functions of the number of

substituted fluorine atoms.

INDO Calculation

The calculation by the approximate MO theory on fluoroethylenes has already been made by Pople and his colleagues, and the interesting effects of the substitution of fluorine atoms on the charge distribution in the molecules have been discussed.[13] The electron density of the σ-part in the C=C double bond is reduced by the inductive effect of fluorine atoms, while the π-electron density is increased by the so-called mesomeric effect. By performing the INDO calculation, we carefully studied these effects to find if any correlations exist between these electron densities and the rate constants we obtained above, but no clear correlations could be found. The calculation without considering attacking atoms seems to be useless for the discussion on the rate constants. We, therefore, performed the calculation on a model which included the attacking atoms.

According to the recent *ab initio* calculations, when an H atom adds to ethylene, the atom approaches the C atom attached to the double bond from the direction perpendicular to the plane of the ethylene molecule.[14] A similar reaction path has been derived for the addition reaction of O(^{3}P) atom to ethylene,[15,16] although this mechanism seems to be somewhat contradictory to that proposed by Cvetanović.[17] In the present treatment, we assumed that no deformation of the geometry of fluoroethylene molecule occurs during the approach of the attacking atom, and calculated the total energy change as a function of the distance between the attacking atom and the ethylene molecule. The geometry of the calculated model is shown in Fig. 4.

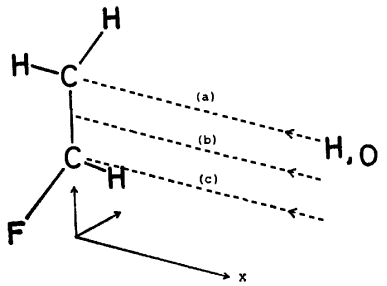

Fig. 4. The geometry used for the INDO calculation.

Among the three calculated reaction paths, the one leading the attacking atom to the C atom which is less substituted by fluorine atoms was found to be the lowest energy path, irrespective of the kind of the attacking atoms. This is consistent with the observations that hydrogen atoms add almost exclusively to the CH_2 group in CH_2CHF and CH_2CF_2,[18] and that oxygen atoms add mainly to the CH_2 group in CH_2CHF.[19] The calculated energy differences, δE, between the total energy change of fluoroethylene, ΔE(fluoroethylene), and that of ethylene, ΔE(ethylene) as functions of the distance, x, between attacking atom and ethylene are shown in Fig. 5. The smaller the value of δE, the more easily can the attacking atoms approach

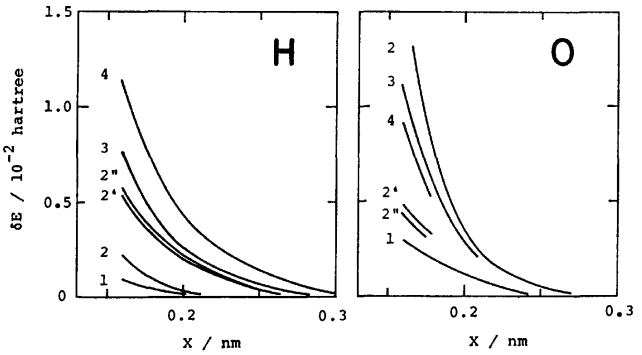

Fig. 5. The energy differences, δE, between the total energy change of fluoroethylene, ΔE(fluoroethylene), and that of ethylene, ΔE(ethylene) in units of hartree (1 hartree=627.51 kcal/mol) as functions of the distance, x, between attacking atom and fluoroethylene, $\Delta E = E(\text{at } x) - E(x \to \infty)$.[27]
1: C_2H_3F, 2: CH_2CF_2, 2′: *trans*-CHFCHF, 2″: *cis*-CHFCHF, 3: C_2HF_3, 4: C_2F_4.

the fluoroethylene. This property may be called approachability. As Fig. 5 shows, the approachability obtained with H atoms decreases with the increase in the number of substituted fluorine atoms, while that obtained with O atoms has a minimum with CH_2CF_2 molecule.

We can find some correlations between the calculated approachabilities and the rate constants obtained in the previous section. The other obtained with H atoms is in agreement with that of the rate constants. In the case of O atoms, the approachability calculated for C_2H_3F seems to be too large. In spite of the discrepancy, the general trend of the order of the rate constants may be said to be explicable by the calculated approachability.

Discussion

Comparison with Other Investigations. In Table 1, the relative rate constants of the reactions of hydrogen atoms with fluoroethylenes obtained by previous investigations are compared with those calculated from the present data. The results obtained by Kilcoyne and Jennings are in good agreement with our data, although our data are not complete because of the difficulty of obtaining *trans*- and *cis*-1,2-difluoroethylenes. The results of Penzhorn and Sandoval are quite different from those of the others.[20] Since possible reasons for this discrepancy have already been discussed by Kilcoyne and Jennings, it is unnecessary to restate them.

Table 2 compares the absolute rate constants of the reactions of oxygen atoms obtained by Huie *et al.*[21] and Gilbert *et al.*[19] with ours and the relative rate constants reported by Moss.[12] Serious disagreement is observed in the case of C_2F_4. For the reaction of $O+C_2H_3F$, Atkinson and Pitts reported 0.27 ± 0.03 in units of 10^{-12} cm^3 molecule^{-1} s^{-1}.[23] Our result seems to be too large. More extensive investigations on this reaction are now in progress. Recently, Koda discussed the absolute rate constant of the reaction of $O+C_2F_4$.[24] The rate constants he estimated are 0.83 and 1.30 in units of 10^{-12} cm^3 molecule^{-1} s^{-1}. Our result agrees with the smaller value. Further investigations are obviously desirable.

Reactivity Index. When Sato and Cvetanović carried out the simple Hückel MO calculation on a series of monoolefins,[25] they anticipated that the calculated parameters such as charge density, bond-order, free valence, or atom localization energy might correlate with the relative rate constants of the reactions of various active species with monoolefins. Actually, the relative rate constants of the reactions of oxygen atoms with monoolefins were found to be well correlated with the excitation energies and bond-orders calculated. When Jennings and Cvetanović determined the relative rate constants of the reactions of hydrogen atoms with a series of monoolefins, they found that these relative rate constants are well correlated with the atom localization energies of the monoolefins.[26] However, when Jennings and his colleagues applied these correlations to the relative rate constants obtained with fluoroethylenes, they failed to find clear correlations.[11] The substitution of fluorine atoms seems to induce an exceptional effect on the molecule.

In the above treatment, the parameters were calculated only on the olefins, one component of the reactants, and the attacking atoms were not included. So, we tried to include the attacking atoms in the calculation, and found some success. We believe that this success is somewhat fortuitous; more extensive investigations are necessary before definite conclusions are drawn from such calculations.

The Precursors of Phenols Produced in the γ-Radiolysis of Aromatic Hydrocarbons in Liquid Carbon Dioxide

Hidetoshi KARASAWA, Rei YUGETA, Akira YAMAGUCHI, and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 17, 1980)

The γ-ray-induced oxidation of toluene in liquid carbon dioxide has been reinvestigated. In order to discuss the precursors of the main products: three kinds of cresols and benzyl alcohol, 1-butene was used as the scavenger of oxygen atoms. The formation of cresols and benzyl alcohol was well explained by the participation of two precursors: one is oxygen atoms and the other is ionic species, O^- or/and CO_3^- ions. The ratio of the *G*-value of oxygen atoms to that of the sum of O^- and CO_3^- ions initially formed was estimated to be 4 : 1 for pure liquid carbon dioxide. The spur model previously proposed was applied to explain the formation of O^- and CO_3^- ions.

The γ-ray induced oxidation of hydrocarbons in liquid carbon dioxide has been extensively investigated by two research groups. Sakurai and his collaborators used a stainless steel autoclave for γ-irradiation. In this a small amount of hydrocarbon was packed with a large amount of carbon dioxide, with a mole fraction larger than 0.9.[1-6] Using a series of methyl-substituted benzene as the substrate, they estimated the relative rate constants for the formation of the corresponding phenols and benzyl alcohols.[3] On the basis of these relative rate constants, they concluded that the precursors of these products are oxygen atoms.

On the other hand, our group used a small glass tube for γ-irradiation at low temperatures, usually −18 °C.[7-10] The mixing ratio of carbon dioxide to hydrocarbon was changed from 0 to 1, and the *G*-values of noncondensable products, mainly carbon monoxide, were measured, as well as those of condensable ones. In a previous paper,[10] we used a series of monoolefins as the substrate and measured the relative rate constants of the reactions of oxygen atoms with seven monoolefins. This estimate was made by measuring the *G*-values of the reaction products: epoxides, aldehydes, and ketones. In these experiments, the formation of several alcohols was also observed. We tentatively assigned these alcohols as the products in the reaction of ionic species with hydrocarbons.

Five years ago, we reported the formation of cresols and benzyl alcohol in the γ-radiolysis of toluene in liquid carbon dioxide, and suggested that the precursors of these products are O^- or/and CO_3^- ions, because the formation of these products was considerably suppressed by the addition of a small amount of sulfur hexafluoride, a well-known electron scavenger.[8] This suggestion is obviously contradictory to the conclusion reached by Sakurai *et al.* This paper will discuss this discrepancy and will estimate what percentage of the oxygen-containing products are formed from oxygen atoms and what percentage from ionic species.

In a previous paper,[11] we reported the γ-ray-induced oxidation of aromatic hydrocarbons in liquid dinitrogen oxide, and showed that the corresponding phenols and benzyl alcohols are produced through two processes: one is the reactions of oxygen atoms and the other is the reactions of ionic species, probably N_2O^- ions, followed by the neutralization reactions with aromatic hydrocarbon cations. A similar technique may be applied to discriminate the precursors in the reactions in carbon dioxide.

Carbon dioxide is known to be an electron scavenger, although the efficiency is much less than that of dinitrogen oxide;[12] however, CO_2^- ions cannot be the precursor for cresols. When this compound is used as the electron scavenger in the γ-radiolysis of cyclohexane, the formation of hydrogen is effectively suppressed, but the formation of carbon monoxide is not balanced by the decrease in the hydrogen yield, suggesting that the neutralization reaction between CO_2^- ions and hydrocarbon cations does not produce carbon monoxide and oxygen atom-added products.

Experimental

The experimental procedures were the same as those described in previous papers.[10,11]

Results

The *G*-values of carbon monoxide from the CO_2–toluene system are shown in Fig. 1 as a function of the electron fraction of CO_2; the values of oxygen-containing products are given in Fig. 2. The fractional yields of three kinds of cresols and of benzyl alcohol are plotted

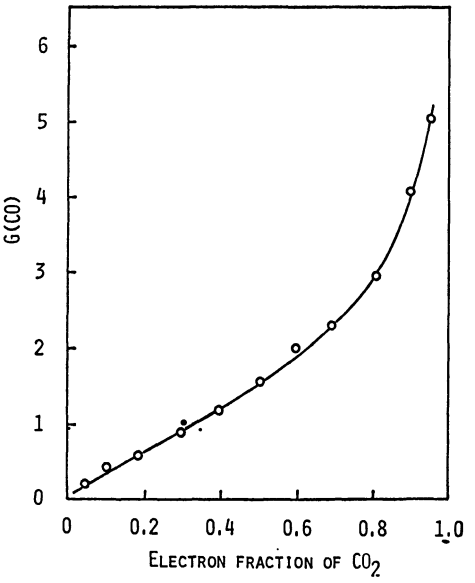

Fig. 1. The *G*-values of carbon monoxide from the toluene–CO_2 system.

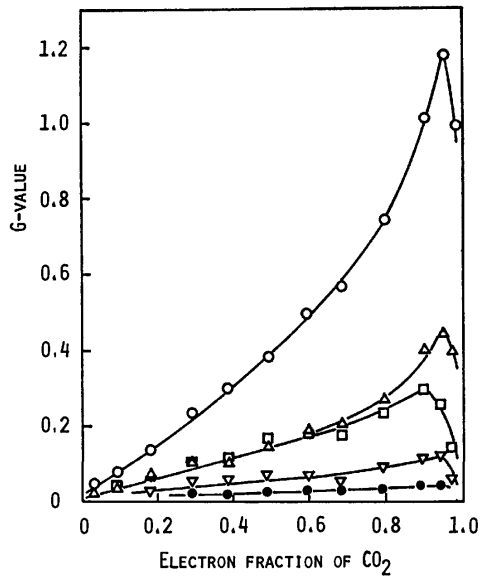

Fig. 2. The *G*-values of *o*-cresol (○), *p*-cresol (△), *m*-cresol (□), benzyl alcohol (▽), and phenol (●) from the toluene–CO_2 system.

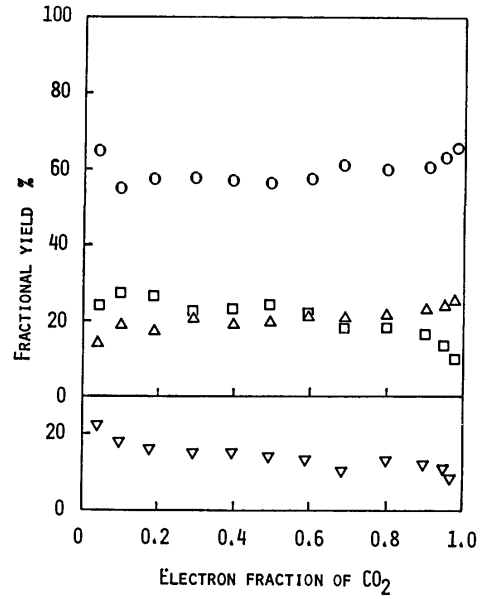

Fig. 3. The fractional yields of *o*-cresol (○), *p*-cresol (△), *m*-cresol (□), and benzyl alcohol (▽) against the sum of three cresols.

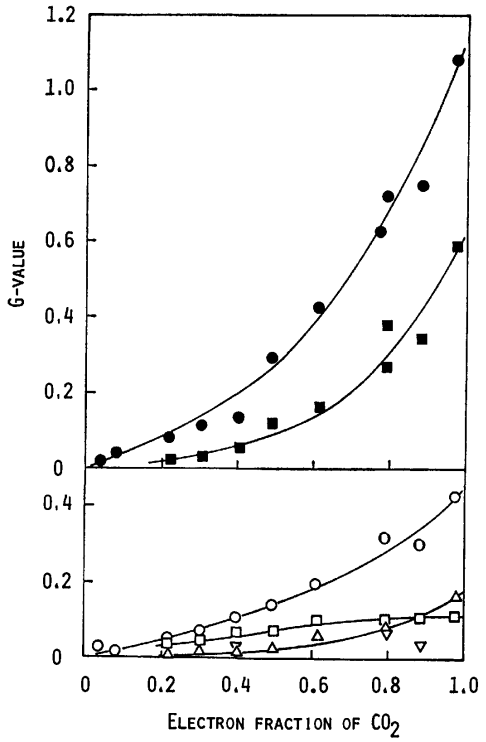

Fig. 4. The *G*-values of 1,2-epoxybutane (●), butanal (■), *o*-cresol (○), *p*-cresol (△), *m*-cresol (□), and benzyl alcohol (▽) from the toluene (0.9)–1-butene (0.1)–CO_2 system. The numbers in parentheses are the mole fractions of each hydrocarbon in the mixture.

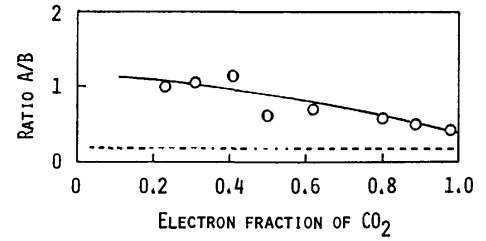

Fig. 5. The ratio of A/B as a function of the electron fraction of CO_2. A is the sum of the *G*-values of three cresols and benzyl alcohol, and B, the sum of the *G*-values of 1,2-epoxybutane and butanal. The dotted line shows 0.18. For this value, see the Text.

Table 1. The effect of sulfur hexafluoride on the γ-radiolysis of the toluene–CO_2 system
The electron fraction of CO_2 is 0.48.

Sulfur hexafluoride	*G*-value						
mol%	CO	H_2	*o*-Cresol	*p*-Cresol	*m*-Cresol	Benzyl alcohol	Bibenzyl
0	1.20	0.13	0.38	0.14	0.14	0.06	0.14
0.71	1.07	0.12					
2.29			0.08	0.02	0.06	0.06	0.36
3.99			0.06	0.02	0.06	0.07	0.40
4.46	0.79	0.12					
8.17	0.68	0.11					
9.10			0.03	0.01	0.03	0.07	0.50

$$CO_2 \rightsquigarrow CO + O \quad (1)$$
$$\rightsquigarrow CO_2^+ + e^- \quad (2)$$
$$[e^- + CO_2] \rightarrow CO_2^- \quad (4)$$
$$[CO_2^+ + CO_2^-] \rightarrow CO + O + CO_2 \quad (5)$$
$$[O + CO_2^-] \rightarrow CO_3^-. \quad (13)$$

The O and CO_3^- thus produced react with aromatic hydrocarbons to produce phenol.

In isolated spurs, the ratio of the amount of oxygen atoms, [O], initially produced, to that of ionic oxidizing species, $[O^-]+[CO_3^-]$, must be independent of the electron fraction of carbon dioxide since no reactions between active species are expected to occur; but in condensed spurs, this ratio should increase with the increase in the electron fraction, since Reaction 5 becomes important for the formation of oxygen atoms.

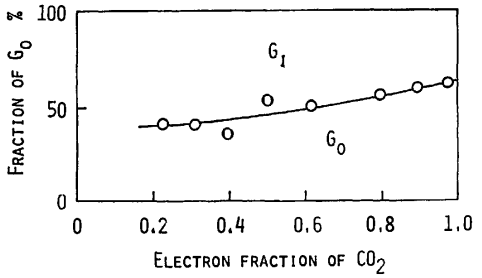

Fig. 6. The fractions of G_0 as a function of the electron fraction of CO_2. G_0 is the fraction of oxygen-containing products produced through the reactions of oxygen atoms with toluene, and G_1, the fraction of oxygen-containing products produced through ionic reactions.

Estimate of the Ratio of the G-value of Oxygen Atoms to That of the Sum of O^- and CO_3^- Ions. As has been discussed in a previous paper,[11] the fraction of 1,2-epoxybutane to the total consumption of oxygen atoms in the reaction with 1-butene is 0.42, while the fraction of oxygen-containing products to the total consumption of oxygen atoms in the reaction with toluene is 0.36. Moreover, we know that the ratio of k(O+1-butene)/k(O+toluene) is about 50, and that 1,2-epoxybutane is produced only in the reaction of oxygen atoms with 1-butene. From this knowledge, we can estimate the G-value of cresols (G_0) produced in the reaction of oxygen atoms with toluene in the CO_2–toluene system. Figure 6 shows the fraction of G_0 in the total G-value of oxygen-containing products observed, as a function of the electron fraction of carbon dioxide. This result suggests that more than 40% of cresols are produced by the ionic process in the entire range of the electron fraction of carbon dioxide.

On the other hand, the rate constant ratio of $k(N_2O^-+1\text{-butene})/k(N_2O^-+\text{toluene})$ was estimated to be 2.5,[11] and the fraction of oxygen-containing products in the total consumption of N_2O^- ions in the reaction with toluene was estimated to be 0.74. These values may be applicable to the reactions of O^- and CO_3^- ions in the present system. Then, we can calculate the ratio of the G-value of oxygen atoms to that of the sum of O^- and CO_3^- ions initially produced, by using the data shown in Fig. 4. The results are shown in Fig. 7; *i.e.*,

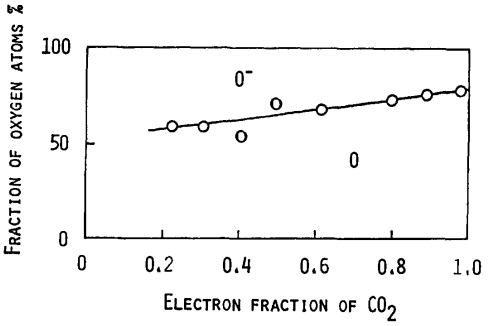

Fig. 7. The fractions of oxygen atoms in the total oxidizing species, O, O^-, and CO_3^-, initially produced in the γ-radiolysis of the toluene–CO_2 system.

$G(O) : G(O^-+CO_3^-)=4 : 1$ for the pure liquid carbon dioxide. With the decrease in the electron fraction of carbon dioxide, this ratio decreases and approaches 3 : 2 at the lower limit of the electron fraction of carbon dioxide.

Effect of Sulfur Hexafluoride. As Table 1 shows, the formation of cresols was considerably suppressed by the addition of a small amount of sulfur hexafluoride, which is known to be an effective electron scavenger. According to Fig. 6, even if all ionic processes should be inhibited, about 50% of cresols should remain as the product; however, this is not the case. We have no proper interpretation for this discrepancy, but we feel that sulfur hexafluoride is not simply an electron scavenger in the systems studied.

In the previous paper,[8] we suggested that cresols are formed only from the reactions of ionic species with toluene. This seems to be the result of a simplified interpretation of the electron scavenging effect of sulfur hexafluoride.

With the increase in the mole fraction of sulfur hexafluoride, the formation of bibenzyl became important. This increase may be due to the reactions of F atoms, which come from the electron scavenging of sulfur hexafluoride, with toluene to produce benzyl radicals.

The formation of bibenzyl is always observed in the radiolysis of toluene; however, the quantitative measurement for this product has not been made in the present experiments since no significant dependence of the G-value on the electron fraction of carbon dioxide has been observed in the absence of sulfur hexafluoride.

An Analysis of the CF_2 Emission Spectrum in a CF_2Cl_2 Plus Metastable He System

Takahiko ISHIGURO,** Yoshiaki HAMADA, and Masamichi TSUBOI*
Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received May 23, 1980)

Ultraviolet chemiluminescence caused by a reaction of metastable He and CF_2Cl_2 was observed. Laser-excited single-vibronic-level fluorescence of the CF_2 radical thus produced was also examined. The main feature in the 250—400 nm region was explained as the CF_2 $\tilde{A}^1B_1$-$\tilde{X}^1A_1$ transition. The observed vibrational-level population of CF_2 ($\tilde{A}^1B_1$) resulting from this reaction exhibits a maximum near $v_2'=5$. This fact implies that the product has a FCF angle of about 104°, which is nearly equal to the FCF angle (105.4°) of the reactant (CF_2Cl_2) molecule, rather than to the equilibrium FCF angle (122°) of the CF_2 ($\tilde{A}^1B_1$) itself.

The difluorocarbene radical, CF_2, an important transient intermediate in fluorocarbon reactions, has been examined by a great number of reseachers.[2] In 1950 Venkateswarlu first observed an emission spectrum between 239.9 and 342.9 nm which was attributed to the CF_2 radical.[3] Its absorption spectrum in the 260 nm region was measured with high dispersion by Mathews in 1967.[4] According to his rotational analysis, the upper and lower electronic states corresponding to this band system are $^1B_1$ and $^1A_1$ respectively, and the molecule is bent with $r_0(CF)=1.32$ Å and $\angle FCF=122.3°$ in the ($^1B_1$) excited state and with $r_0(CF)=1.300$ Å and $\angle FCF=104.94°$ in the ground state. The absorption and emission spectra gave vibrational frequencies $\nu_2'=496$ cm^{-1} and $\nu_2''=668$ cm^{-1}.

Since then, a debate arose as to the location of the CF_2 triplet state, $\tilde{a}^3B_1$. Recently, Quach-Tat-Trung *et al.*[5] noted that an emission band system, 340—450 nm, found in the microwave discharge of CF_2X_2 (X=Cl, Br), probably belonged to the CF_2 $\tilde{a}^3B_1$-$\tilde{X}^1A_1$ transition. Shortly thereafter, however, Koda[6] observed a structured emission spectrum in the region 470—720 nm resulting from the reaction with $O(^3P)$ and CF_2=CF_2, and tentatively assigned this emission to the CF_2 $\tilde{a}^3B_1$-$\tilde{X}^1A_1$ phosphorescence transition. Unfortunately, their discussions are based upon a lower dispersion spectra, and the subject does not yet seem to be fully fixed.

We have observed, with a higher dispersion, an ultraviolet emission spectrum resulting from a reaction of a metastable helium atom and dichlorodifluoromethane CF_2Cl_2 ("freon 12") in a discharge flow system. A laser excited single-vibronic-level fluorescence of the CF_2 radical thus produced was also examined. From the results, a number of new pieces of information have been obtained on the reaction as well as on the CF_2 molecule itself. These will be reported below.

Our special attention has been focused on the FCF angle of the $CF_2(\tilde{A}^1B_1)$ molecule in the initial stage of the reaction, because its equilibrium FCF angle (122.3°) is dramatically different from the FCF angle (105.4°) of the reactant CF_2Cl_2 molecule.[21] A discussion on this point will be given, in the present paper, in more detail than those on other points.

Experimental

The arrangement of the experimental apparatus is shown in Fig. 1. Active species of helium were produced by microwave discharge with a magnetron (2450 MHz, 500 W). The discharge portion was made of a 15 mm i.d. (inside diameter) quartz tube, and the product was admitted into a reaction chamber made of a 40 mm i. d. pyrex tube. The reactant gas, that is CF_2Cl_2, was injected into the reaction chamber through a 0.5 mm i. d. pyrex tube at 15 cm downstream from the discharge portion. The reaction chamber was evacuated with a 500-liter/min mechanical pump.

The pressure in the reaction chamber was measured with a Pirani gauge. The pressure of CF_2Cl_2 was about 0.4 Torr (1 Torr=133 Pa), and the total pressure in the reaction chamber was about 1.0 torr. The helium gas was purified by

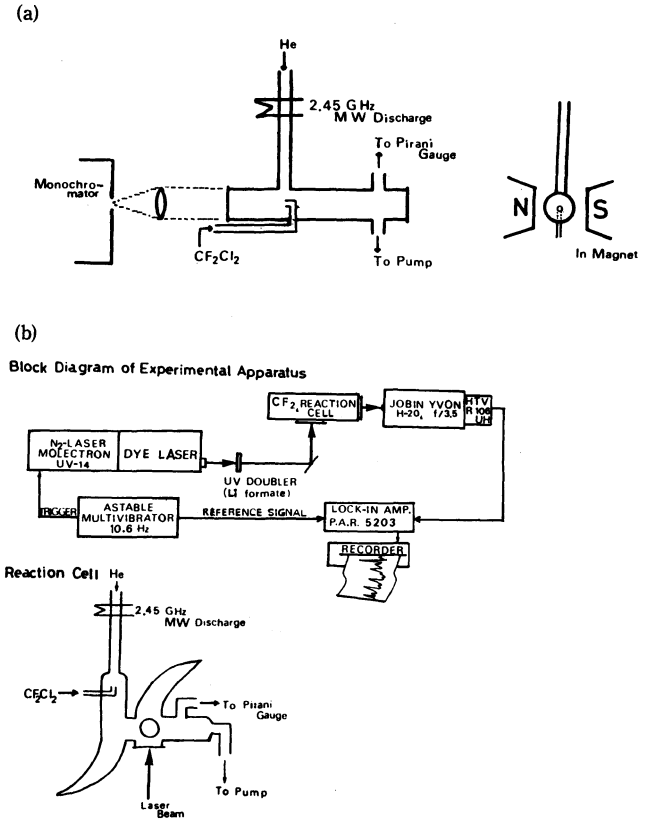

Fig. 1. Experimental set-up (a) for the observation of the CF_2Cl_2+He* chemiluminescence and (b) for the single-vibronic-level fluorescence measurement of CF_2.

** Present address: Todd Wehr Chemistry Building, Marquette University, Milwaukee, Wisconsin 53233, U.S.A.

passing it through a trap at 77 K before it was introduced into the discharge portion. The CF_2Cl_2 gas was purified by the trap to trap distillation method before use.

Emission spectra were observed through a quartz window by a 3.4 m (f) Jarrell-Ash spectrograph. The emission were photographically recorded with exposure times ranging from 8h to 15h on Kodak SA-1 film. The measurements of the spectra were also made by means of a photomultiplier (HTV R106 UH) with the aid of a lock-in amplifier (Princeton Applied Research Model-5203). In case of using the 1st-order diffraction of a 590 grooves/mm (300 nm blaze) grating, the reciprocal dispersion was 0.52 nm/mm. The higher dispersion spectra were also examined with the 2nd and 3rd order diffractions of other gratings.

In Fig. 1, the arrangement of the apparatus for a laser-excited single-vibronic-level (SVL) fluorescence is also shown. The flow of the $He^*+CF_2Cl_2$ reaction products was irradiated downstream from the mixing portion with a pulse laser beam, which was generated by a Molectron UV-14 dye laser system with a Li-formate frequency doubler. The SVL fluorescence was observed through a Jobin-Yvon H-20 monochromator with a HTV R106UH photomultiplier. By detecting the signal synchronized to the laser pulses, only the emission due to the laser excitation was selectively detected.

Results and Discussion

1. General Feature of the Chemiluminescence. The observed spectrum is shown in Fig. 2. Here vibrational bands are arranged in a long progression with the spacing 150 cm^{-1}. As will be detailed below, these bands are assignable to the $A^1B_1 \rightarrow \tilde{X}^1A_1$ transition of the CF_2 molecule. Besides these, the 0-0 transition of the CF $\tilde{A}^2\Sigma^+ \rightarrow \tilde{X}^2\Pi$ system[7] was observed in the vicinity of 247.6 nm (see also Fig. 3). The $\Delta v=0$ and $\Delta v=1$ transitions of the C_2 Deslandres-d'Azambuja system[8] were also observed near 385.2 and 360.7 nm, respectively (Fig. 4). The strong atomic line at 388.9 nm (Fig. 4) was attributable to the He $^3P \rightarrow {}^3S$ transi-

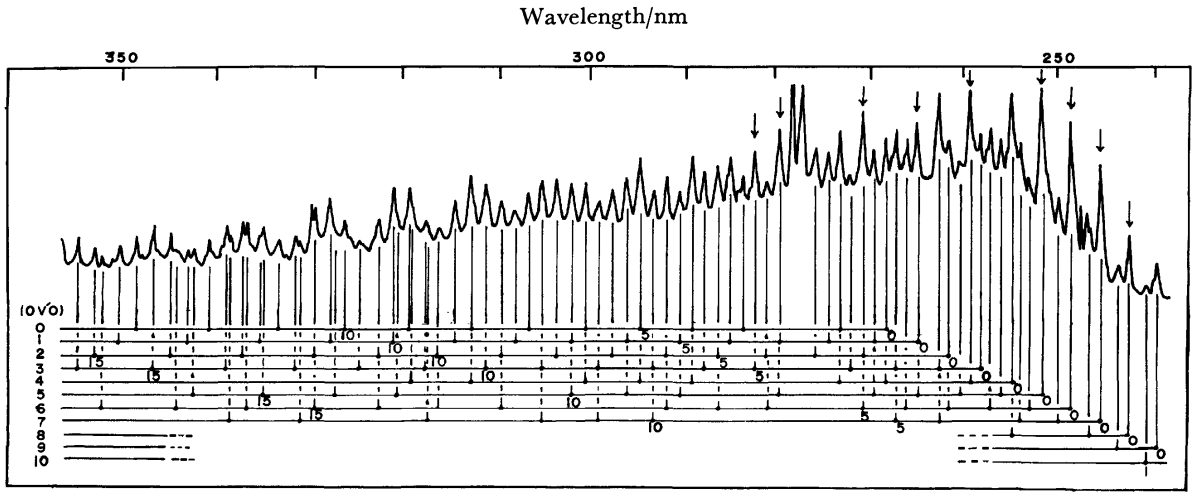

Fig. 2. Chemiluminescence spectrum of the $CF_2Cl_2+He^*$ system. Photo-trace of a spectrogram with a dispersion 0.52 nm/mm (the lst order diffraction from a 300 nm blaze 590 grooves/mm grating), with a slitwidth 20 μm, and with 8 h exposure. The arrows indicate bands for which K-subband structure were observed.

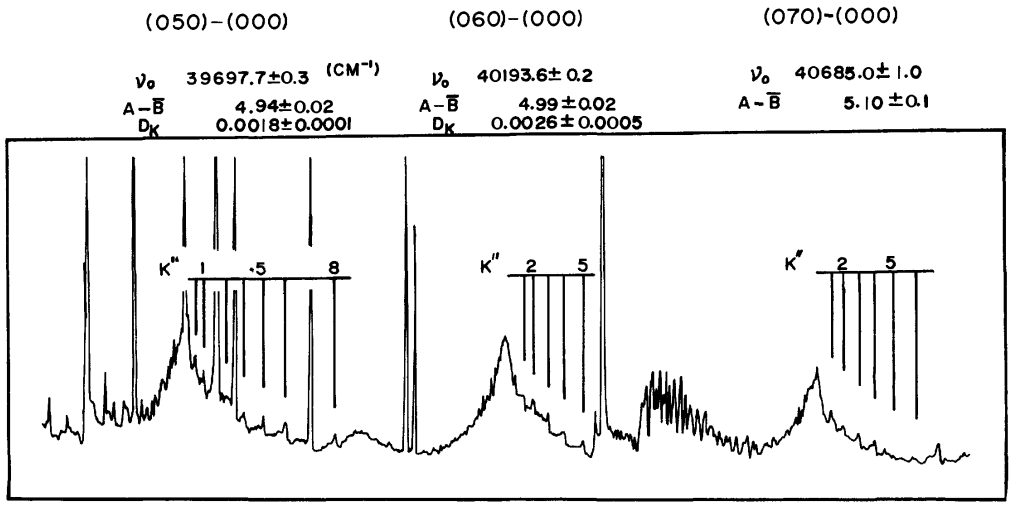

Fig. 3. Chemiluminescence spectrum of the $CF_2Cl_2+He^*$ system. Photo-trace of a spectrogram with a dispersion 0.17 nm/mm (the 3rd order diffraction from a 1000 nm blaze 590 grooves/mm grating) and slitwidth 100 μm.

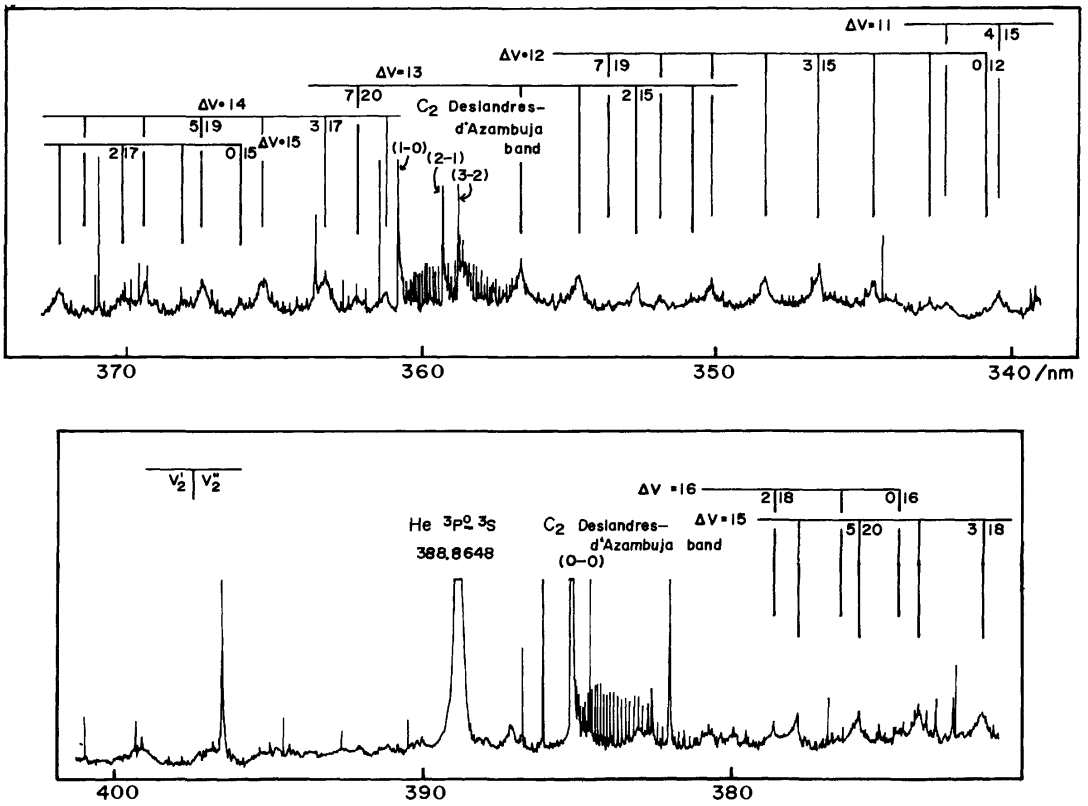

Fig. 4. Chemiluminescence spectrum of the CF_2Cl_2+He* system. Photo-trace of a spectrogram with a dispersion 0.24 nm/mm (the 2nd order diffraction from a 750 nm blaze 590 grooves/mm grating), with a slitwidth 20 μm, and with 13 h exposure.

tion.[9] It is certain that there is the metastable ^3S species involved in the reaction, which has by 19.8 eV higher energy than its ground state, and whose lifetime is a few second at 1 Torr.

2. Rotational Structures of the 2_0^5, 2_0^6, and 2_0^7 Bands. On the basis of a comparison with the absorption spectrum $\tilde{A}^1B_1 \leftarrow \tilde{X}^1A_1$ of CF_2 reported by Mathews,[4] the vibrational bands in the spectral region 240—270 nm, are all assignable to CF_2. In a higher dispersion (0.17 nm/mm) spectrogram (Fig. 3), a K-subband structure for $\Delta K=+1$ was found in each of the 2_0^5, 2_0^6, 2_0^7, and 2_0^8 bands. Here 2 means the ν_2 (bending) vibration and the super- and subscripts mean the vibrational quantum numbers of the upper and lower electronic states, respectively, in the transition. The peak positions ν_0^{sub} are fitted with the equation for a perpendicular-type transitions,

$$\nu_0^{sub} = \nu_0 + (A'-\bar{B}') + 2(A'-\bar{B}')K + [(A'-\bar{B}') - (A''-\bar{B}'')]K^2 - D_k'(K+1)^4 + D_k''K^4, \quad (1)$$

and the band center ν_0, the rotational constant $A'-\bar{B}'$, and the centrifugal distortion constant D_k' of the upper state have been determined as given in the upper part of Fig. 3. The $A''-\bar{B}''$ value for $v_2''=0$ was fixed at what Mathews determined[4] (2.5564 cm^{-1}). The $A'-\bar{B}'$ value (4.94±0.04 cm^{-1}) thus determined for $v_2'=5$ is in agreement with what was given by Mathews[4] (4.879±0.003 cm^{-1}) within our experimental error. The $A'-\bar{B}'$ values for $v_2'=6$ and 7 are now newly obtained. It has been found that $A'-\bar{B}'$ becomes greater with v_2'.

3. Vibrational Structure in the 270—360 nm Region. The vibrational bands in this spectral region are all explained as progression of the bending mode (ν_2) belonging to the same electronic transition $\tilde{A}^1B_1$-$\tilde{X}^1A_1$. The assignments are given in Fig. 2. By assuming that observed frequencies (ν) are given as

$$\nu = \nu_{00} + \nu' v_2' - \nu' x' v_2'^2 - \nu'' v_2'' + \nu'' x'' v_2''^2, \quad (2)$$

and by the use of the observed 81 transitions, the values of parameters, ν' (bending frequency in $\tilde{A}$), $\nu' x'$ (anharmonicity constant in $\tilde{A}$), ν'' (bending frequency in $\tilde{X}$), and $\nu'' x''$ (anharmonicity constant in $\tilde{X}$) were determined. The results are given in Table 1, where the deviations of the frequencies calculated on these parameters from the observed ones are also shown. These values explain the total of 135 vibrational transitions with quantum numbers $v_2'=0$—10, $v_2''=0$—17 in a whole region we observed.

4. Vibrational Structure in the 360—400 nm Region. The spectrum observed with a higher dispersion in this spectral region is illustrated in Fig. 4. The structure appears at first sight to be of different type from that in the 270—360 nm region. Actually, however, all the bands are explained by taking the ν_2 vibration in the $\tilde{A}^1B_1$ state of CF_2 into account; the observed frequencies here also fit with Eq. 2, as those in the 270—360 nm region. The apparent difference is found to be caused by the fact that the spectral region 360—400 nm involves greater Δv(=11—16) transitions whereas the 270—360

a) Deviations of the frequencies calculated on Eq. 2, with $\nu_{00}=37197.1(\pm3.8)$ cm^{-1}, $\nu'=491.4(\pm1.4)$ cm^{-1}, $\nu'x'=-0.52(\pm0.16)$ cm^{-1}, $\nu''=663.1(\pm0.9)$ cm^{-1}, and $\nu''x''=0.50(\pm0.06)$ cm^{-1}.

nm region only smaller $\Delta v(\leqq 11)$ transitions. The observed frequencies are given in Table 2, with those calculated on the same set of parameters as what was used for the 270—360 nm region.

5. SVL Fluorescence of CF_2. This experiment was attempted to confirm the assignments so far made to the vibrational bands in the chemiluminescence spectrum. The $He^*+CF_2Cl_2$ reaction system was irradiated with a laser beam of 255.10 nm or 251.92 nm. The 255.10 nm beam is now known to correspond to the 2_0^4 transition of CF_2, and therefore should repopulate the $v_2'=4$ level of the $\tilde{A}^1B_1$ state of CF_2. Because the radiative lifetime of this level is 61 ± 3 ns,[10] which is much shorter than the vibrational relaxation time (at 1 Torr), a fluorescence only from this level (SVL fluorescence) should now be observed.

Table 2. Vibrational bands in the 340—380 nm region of the chemiluminescence (CF_2)

a) Deviations of the frequencies calculated on Eq. 2, with the same values of the parameters: ν_{00}, ν', $\nu'x'$, ν'', and $\nu''x''$; as those used for the 270—360 nm region (Table 1).

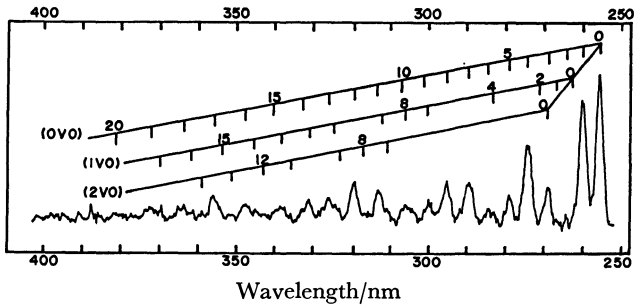

Fig. 5. A single-vibronic-level (SVL) fluorescence spectrum of CF_2, produced by the CF_2Cl_2+He* reaction. The ground state CF_2 molecule was excited to the $v_2'=4$ level of the electronic $\tilde{A}^1B_1$ state by a 255.10 nm laser beam, and the fluorescence spectrum was observed.

This is shown in Fig. 5. As is seen here, a long progression assignable to $2^4_{v''}$ (where $v''=0$, 1, 2, ···, 20) is found to cover the 240—400 nm region. Likewise, a long progression $2^5_{v''}$ was found on the 251.92 nm irradiation, which corresponds to the 2^5_0 excitation of this electronic system. These results support the idea that the He*+CF_2Cl_2 chemiluminescence is solely caused by the $\tilde{A}^1B_1$-$\tilde{X}^1A_1$ transition, not only in the 240—360 nm region but also in the 360—400 nm region.

After we have completed this SVL fluorescence experiment, a similar SVL work on CF_2 independently made by King *et al.*[10] was published. They prepared CF_2 in a different method from ours, but their SVL fluorescence spectra are in agreement with ours.

6. Effect of Magnetic Field. If there is any triplet-state contribution of CF_2 involved in the chemiluminescence spectrum, this would be detected by examining it in a magnetic field. With this expectation in mind, we have observed the chemiluminescence from the He*+CF_2Cl_2 system placed in a 5.3 kG magnetic field (see upper-right corner of Fig. 1). In the vibronic and ro-vibronic bands of CF_2, so far mentioned, however, detectable broadening or intensity shift, as was seen in the case of SO_2 and CS_2,[22] was not observed with our optical resolution of about 0.5 cm^{-1}. Thus, the assignments of these bands to the singlet-singlet transition ($\tilde{A}^1B_1$-$\tilde{X}^1A_1$) of CF_2 are again supported here. An appreciable effect has been found, on the other hand, in the relative amounts of the reaction products. In the magnetic field, all of the $\Delta v=1$ (1-0, 2-1, 3-2, and 4-3) C_2 systems appear as very strong series of lines, while in the spectrum without magnetic field many of these lines are buried in the CF_2 bands. As is shown in Fig. 6, the 247.6 nm band of CF becomes much stronger in the magnet; the intensity ratio of the CF(0-2) over CF_2(6-0) is doubled by the 5.3 kG field.

7. Intensity Distribution among the Vibrational Bands. Having established the assignments of practically all of the vibrational bands in the chemiluminescence

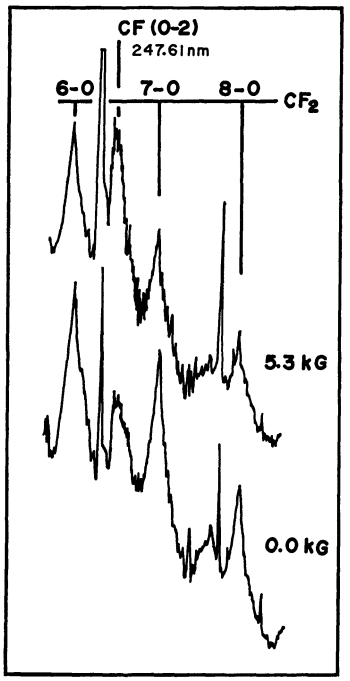

Fig. 6. Chemiluminescence spectrum of the CF_2Cl_2+He* system, with (5.3 kG) and without a magnetic field. Photo-trace of spectrograms with a dispersion 0.52 nm/mm and with a slitwidth 20 μm.

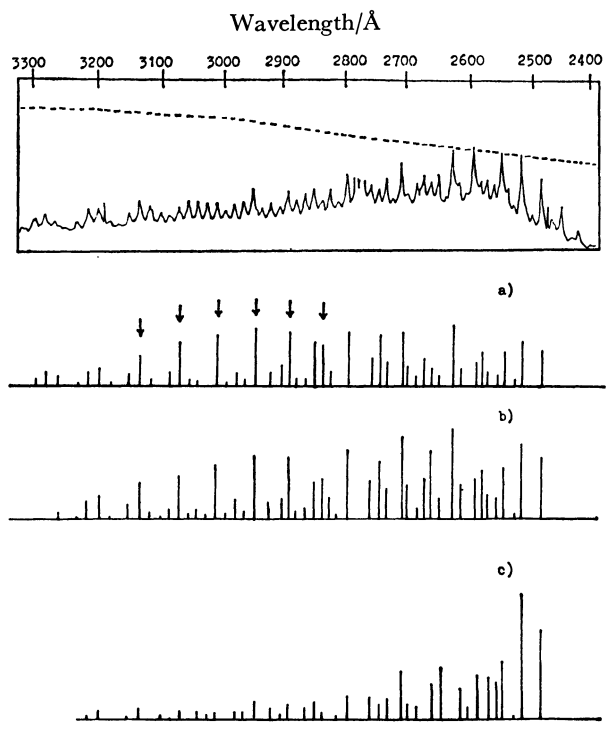

Fig. 7. Observed and calculated intensity distributions among the vibrational bands in the chemiluminescence spectrum of the CF_2Cl_2+He* system. Top: observed with a 3.4 m Jarrel-Ash spectrometer, a 300 nm blaze 590 grooves/mm grating (lst order), 100 μm (entrance) and 150 μm (exit) slitwidths, an HTV R106 UH photomultiplier, and a PAR 5203 lock-in amplifier. The broken line indicates the relative spectral sensitivity of the monochromator and photomultiplier system used in the measurement. Lower three: calculated on the assumptions that the population of the CF_2* molecules in each vibrational level in the excited electronic state $\tilde{A}^1B_1$ is given by a) the Boltzmann distribution at 2100 K, b) the Boltzmann distribution at 3000 K, and c) the distribution shown by the white circles in Fig. 8, which was reached by the least squares fit (that is detailed in the text). The arrows indicate the vibrational bands $2^0_{v''}$ ($v''=3$, 4, 5, 6, 7, and 8), whose intensities are too great on the assumption a) or b).

spectrum, we now proceed to an examination of their intensities. The relative intensities were determined by the use of photoelectronic detection system described above, and the results are shown in Fig. 7 (top). Theoretically, on the other hand, the intensity $I(v_2', v_2'')$ of the band corresponding to the $\tilde{A}^1B_1$, $v_2' \rightarrow \tilde{X}^1A_1$, v_2'' transition is given as

$$I(v_2', v_2'') \propto S(\nu)N(v_2')\nu^4|\langle v_2'|v_2''\rangle|^2, \qquad (3)$$

where $S(\nu)$ is the spectral response of the monochromator and detector system, $N(v_2')$ is the population in the vibrational $(0v_2'0)$ level of the electronic $\tilde{A}^1B_1$ state of CF_2, ν is the transition frequency, and $\langle v_2'|v_2''\rangle$ is the Franck-Condon overlap integral.

For $S(\nu)$, the efficiency-wavelength curve of the grating and spectral response of the photomultiplier (given by the manufacturer) were taken into account. The ultimate $S(\nu)$ value assumed here is given in Fig. 7, (top) with broken line. The $\langle v_2'|v_2''\rangle$ values were obtained primarily from the SVL fluorescence experiments of ourselves (Section 6) as well as of King *et al.*[10] Where the experimental values are not available ($v' \geqq 7$), however, the Franck-Condon overlap integrals were estimated by a calculation on the basis of the geometry and vibrational frequencies of the CF_2 molecule both in $\tilde{A}^1B_1$ and $\tilde{X}^1A_1$ states.[4] In the calculation, the effect of anharmonicity (detectable in the observed frequencies) was first taken into account. The effect, however, has been found to be very small on the Franck-Condon integrals; each perturbed eigenfunction was found to be practically equal to the corresponding unperturbed eigenfunction, the amount of contribution from other unperturbed eigenfunctions being less than 0.1%. Therefore, the effect has finally been ignored. The calculation was made in the two-dimensional space involving the symmetric stretching as well as the bending modes, in order to take a probable Duschinsky effect into acount.[11,12] The calculation was made by the method of Sharp and Rosenstock.[13] A computer program prepared by Professor A. J. Merer (University of British Columbia) was used after some modifications. To reach a proper set of vibrational modes we need a proper set of force constants. In the ground state $\tilde{X}$, this can be fixed by the use of the centrifugal distortion constants obtained by a microwave spectral study.[14] For the excited state $\tilde{A}$, the values of inertial defects[4] in the (000) and (010) states, $\Delta(000)=0.138$ amu·Å^2, and $\Delta(010)=0.314$ amu·Å^2, were used to fix the force constants, in combination with Oka-Morino equation[15] and Meal-Polo equation.[16]

Only the $N(v_2')$ values are now left unknown in Eq. 3. As a first trial, a Boltzmann distribution was assumed for $N(v_2')$. As may be seen in Figs. 7(a) and (b), however, this causes a serious disagreement between the observed intensity distribution and what is calculated on Eq. 3. The observed chemiluminescence spectrum indicates that relative value of $N(v_2'=0)$ is greatly lower than what is expected from a Boltzmann distribution.

8. Population Distribution $N(v_2')$ *among Vibrational Levels of a Nascent* CF_2*.* The relative values of $N(v_2')$ were next determined so as to reach the best fit between the observed intensity distribution among the vibrational bands (Fig. 7, top) and what is calculated on Eq. 3. What are obtained by a least squares method are shown in Fig. 8 with white circles. In this procedure, the values of $N(5)$, $N(6)$, $N(7)$, $N(8)$ are well fixed, because $2^{v'}_0$ bands with $v_2'=5$, 6, 7, and 8 are all well isolated from other bands. While, the uncertainties for the values of $N(0)$, $N(1)$, $N(2)$, and $N(4)$ are great (see the error bars in Fig. 8), because every $2^{v'}_{v''}$ band overlaps with $2^{v''+4}_{v''+3}$ band in the 280—323 nm region. Especially, the fixing of the $N(3)$ value was not found to be practical, because every $2^3_{v''}$ band overlaps with $2^7_{v''+3}$ band; here no experimental values are available of the Franck-Condon overlap integrals $\langle 7|v''+3\rangle$, and very reliable calculations for the Franck-Condon overlap integrals with higher v' and v'' are not practical.

In spite of such an ambiguity, however, it is now quite certain that the initial-state ($\tilde{A}^1B_1$) population $N(v')$ in the chemiluminescence, now in question, is

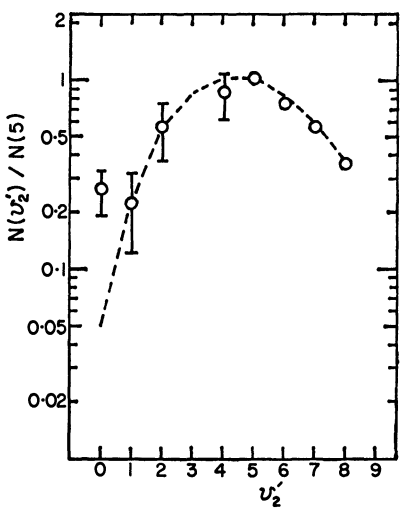

Fig. 8. The population of the CF_2^* molecules, produced by the CF_2Cl_2+He* reaction, in each vibrational level (v_2'=0, 1, ..., or 8) in the excited electronic state $\tilde{A}^1B_1$. White circle: determined by a least squares fit with the observed intensities of the vibrational bands in the 240—330 nm region of the CF_2Cl_2+He* chemiluminescence spectrum. Broken line: calculated on an assumption that the change from the CF_2 moiety of CF_2Cl_2 into CF_2^* (caused by a collision with He* and by throwing Cl_2 away) takes place according to the Franck-Codon priniciple, *i.e.*, vertically upward in the potential energy diagram with the FCF angle along the abscissa.

distributed among the vibrational levels with a great deviation from a Boltzmann distribution. Instead, it shows a maximum at v_2'=5. Since the radiative lifetime of the vibronic levels of the $\tilde{A}^1B_1$ state of CF_2 is 61±3 ns,[10] and since this is much shorter than the vibrational relaxation time ≈(5 μs) at 1 Torr, the population distribution $N(v')$ just found is considered to be exactly what is produced by the CF_2Cl_2+He* reaction.

9. On the CF_2Cl_2+He Reaction Mechanism.* The observed $N(v')$ *versus* v' relation (Fig. 7) is concerned with the mechanism of the CF_2^* production. The result suggests that the scission of the CF_2Cl_2 molecule into CF_2*+Cl_2* (caused by a collision with the metastable He*) takes place so rapidly that no vibration of the CF_2 moiety occurs during this process. The FCF angle of the ground-state CF_2Cl_2 molecule is 105.4±1.0° determined by microwave study[21] and this would tend to be retained in the product when the reaction is sufficiently rapid. This means that the product tends to have a greater population in a higher level of the bending vibration, because the equilibrium FCF angle of the product CF_2*(122°) is greatly different from 105.4°. Let us tentatively assume that the $CF_2Cl_2 \rightarrow CF_2$* change takes place according to the Franck-Condon principle.[17] By assuming that the CF_2 bending is a harmonic oscillation both in the reactant (ground state CF_2Cl_2 molecule) and the product (excited $\tilde{A}^1B_1$ CF_2 radical), and that their frequencies are 458[18] and 491 cm^{-1} (our value), respectively, one-dimensional Franck-Condon overlap (reactant-product) integrals were calculated. The squares of these integrals are to be compared with the observed populations $N(v')$. What were calculated (given in Fig. 8 by broken line) agree with the observed populations, if ΔQ_2 is assumed to be 0.88 Å $amu^{1/2}$. Here ΔQ_2 is the shift of the potential minimum in the bending normal coordinate Q_2 in the reactant (CF_2Cl_2) from that in the product (CF_2*). This ΔQ_2 value corresponds to a shift of about 18° in the FCF angle (*i.e.*, ∠FCF=122−18=104°); this is fairly close to what is expected in the simple model (the CF_2* and CF_2Cl_2 difference in ∠FCF is 122.3°−105.4°=16.9°).

Lastly, let us take a look at the energy balance in the reaction. On the basis of a thermochemical data,[19] approximately 8.8 eV is considered to be required to dissociate the CF_2Cl_2 molecule into CF_2 and Cl_2 and then to excite CF_2 up to CF_2*($\tilde{A}^1B_1$). Because He*($^3S_0$) has 19.8 eV, an excess energy of 2.6 eV is available, even if the Cl_2 molecule takes 8.4 eV to excite itself to $\tilde{D}^3\Pi_{1g}$.[20] The excess energy would be converted into the translational energy of the products (CF_2*+Cl_2*+He), so that Cl_2* would be rapidly removed from the CF_2* moiety after the reaction.

We wish to express our sincere thanks to Professor Saburo Nagakura, the University of Tokyo, for his kindness extended in our use of Jarrel-Ash spectrograph as well as for his valuable discussions. Our thanks are also due to Professor A.J. Merer, the University of British Columbia, for the computer program used in our calculation of two-dimensional Franck-Condon overlap integrals. This work was supported partly by a Grant-in-Aid for Scientific Research No. 354153 from the Ministry of Education, Science and Culture.

Binding of Sodium Decyl Sulfate to a Cationic Polymer

Keishiro SHIRAHAMA,* Hidefumi YUASA, and Shinji SUGIMOTO

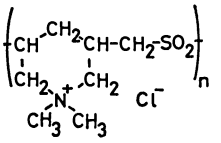
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received May 26, 1980)

Interaction between sodium decyl sulfate and a cationic copolymer of dimethyldiallylammonium chloride and sulfur dioxide was studied by a potentiometric method utilizing a surfactant-selective electrode. Binding occurs suddenly and is completed in a very narrow range of equilibrium concentration, indicating the strongly cooperative nature of the binding process. The characteristic concentration at which binding starts is about two orders of magnitude smaller than the critical micelle concentration. The cooperativeness parameters as estimated by a nearest neighbor interaction model remains almost constant on increasing sodium chloride concentration, affinity for an isolated binding site decreasing.

Surfactants are bound not only to two-dimentional interfaces, but also to linear polymers, *viz.*, synthetic nonelectrolytes such as poly(*N*-vinylpyrrolidone),[1] and poly(ethylene oxide),[2,3] and biological polyelectrolytes such as polypeptides,[4,5] and nucleic acid.[6] The binding process is characterized on a binding isotherm by remarkable cooperativeness: sudden occurrence and completion of binding in a very narrow range of equilibrium concentration.

The present study deals with the binding of an anionic surfactant, sodium decyl sulfate (SDeS), to a synthetic polycation as measured by potentiometry. The polyelectrolyte used is a copolymer of dimethyldiallylammonium chloride and sulfur dioxide with the following structure.[7] The polymer has proportionate hydrophobic character in addition to positive charge, being very stable around neutral pH. This polycation is considered to be a good model compound for examining the effect of electric charge and hydrophobicity in surfactant-polymer interactions. A surfactant-selective electrode was used for potentiometry.[5,8,9]



The results obtained were analyzed in the framework of one-dimentional nearest neighbor interaction model.[4,10]

Experimental

Materials. The polycation (Nittō Bōseki Co., Ltd., PAS-250, degree of polymerization≒800) was purified by dialysis against water for 3 days, the concentration being determined by colloid titration using poly(vinyl potassium sulfate) as a titrant and Toluidine Blue as an indicator.[11] Sodium decyl sulfate was synthesized by esterification of fractionally distilled 1-decanol with concentrated sulfuric acid followed by neutralization with sodium hydroxide. The crude surfactant was recrystallized once from acetone and twice from ethanol. The recrystallized sample was extracted with diethyl ether in a Soxhlet extractor for 40 h in order to remove trace of residual decanol. The critical micelle concentration (cmc) determined by an electric conductivity method was 32 mol m^{-3} in water at 25 °C.[12]

Potentiometry. The carrier used in the surfactant-selective electrode was prepared by suspending equivalent amounts of SDeS and dioctadecyldimethylammonium chloride (Kaō Soap Co., Ltd.,) in water. The resulting white precipitate (dioctadecyldimethylammonium decyl sulfate) was collected by centrifugation (3000 rpm for 30 min) and resuspended in distilled water. Decantation was repeated three times followed by recrystallization from acetone. A mixture of poly (vinyl chloride) (0.6 g) and tritolyl phosphate (2.4 g) was added to a tetrahydrofuran solution (15 cm^3) containing an appropriate amount of the carrier (0.25 mmol kg^{-1} membrane). The resulting mixture was heated (80 °C) to give a clear viscous solution which was then cast on a flat glass plate. The solvent was gradually evaporated in a desiccator for 2 d. The poly(vinyl chloride) gel membrane, *ca.* 0.3 mm thick, was put on one end of a poly(vinyl chloride) tube (i.d. 9 mm, length 11 cm), tetrahydrofuran being found to be a good adhesive. The electrode was annealed in a vacuum at 40 °C for 2 d. The electrode forms a concentration cell,

$$\text{Calomel} \left| \begin{matrix} 1\ \text{mol dm}^{-3} \\ NH_4NO_3 \end{matrix} \right| \begin{matrix} 0.5\ \text{mol m}^{-3}\ \text{SDeS} \\ 20\ \text{mol m}^{-3}\ \text{NaCl} \end{matrix} \left| \begin{matrix} \text{PVC gel} \\ \text{membrane} \end{matrix} \right|$$

$$\left| \begin{matrix} C_s\ \text{SDeS} \\ C_a\ \text{NaCl} \end{matrix} \right| 1\text{mol dm}^{-3}\ NH_4NO_3 \left| \text{Calomel} \right.$$

The electrode was treated in 1 mol m^{-3} SDeS solution for *ca.* 30 min before each run. Potentiometric titration was carried out in a small cocylindrical cell (25 cm^3) thermostated at 25 °C. The electromotive force was measured with an electrometer (Takeda Riken TR-8651) equipped with a paper recorder.

Results and Discussion

The surfactant-selective electrode shows the Nernstian response above 0.2 mol m^{-3} SDeS, slightly deviating from it at lower concentration. The reproducibility is so good that an emf *vs.* log C_s (C_s: SDeS concentration) plot can be used as a calibration curve. A potentiometric curve deviates from the calibration curve when the polymer exists in a solution (Fig. 1) where ΔC is the amount of SDeS bound to the polymer, C_f the corresponding equilibrium concentration. The binding isotherms thus constructed in three NaCl concentrations at 25 °C are shown in Fig. 2, where X (number of bound SDeS/number of cationic groups on polymer) is the degree of binding. The tendency that X becomes unity with increase in equilibrium concentration indicates that binding sites are primarily the cationic groups. Binding occurs all of sudden and concludes within a narrow range of C_f indicating cooperative effect. The isotherm shifts to a higher C_f with increase in the added

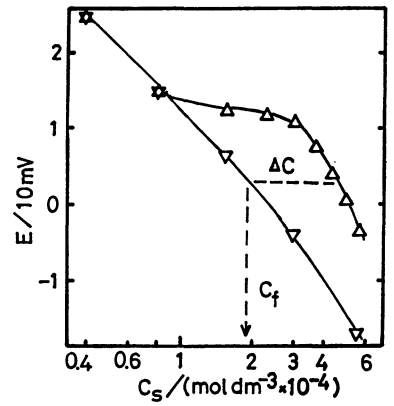


Fig. 1. Emf. *vs.* SDeS concentration plot.
NaCl concentration: 20 mmol dm^{-3}, the polymer concentration: 0.3 mmol dm^{-3} as cationic groups, temperature: 25 °C.

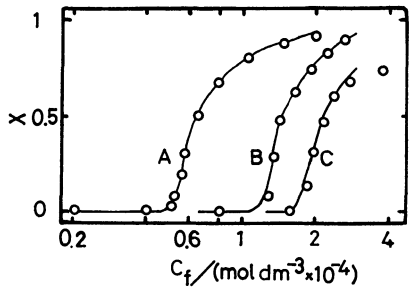

Fig. 2. Binding isotherms of SDeS–PAS systems at 25 °C.

electrolyte, C_a, the surfactant becomes less affinitive. This can be analyzed in terms of the Ising model with the nearest neighbor interaction.[4,10]

Let us consider a system where a polymer molecule binding surfactant molecules is in equilibrium with the surfactant whose equilibrium concentration is C_f. The partition function Z, for the system is

$$Z = (1,1)\begin{pmatrix} 1 & 1 \\ s/u & s \end{pmatrix}^n \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad (1)$$

where s ($=KuC_f$) is a sort of binding "*pressure*," K being a binding constant of a surfactant molecule bound to an isolated binding site on a polymer molecule, u a parameter of interaction between adjacently bound surfactants, or a cooperativeness parameter, and n the number of binding sites on a polymer molecule.[10] Equation 1 furnishes various useful quantities such as[4]

$$K = 1/[uC_f(0.5)], \quad (2)$$

and

$$(\mathrm{d}X/\mathrm{d}\ln C_f)_{X=0.5} = \sqrt{u}/4. \quad (3)$$

In Eq. 2, $C_f(0.5)$ is an equilibrium concentration at X=0.5. The parameters derived from Eqs. 2 and 3 are given in Table 1.

Table 1. Binding parameters

C_a/mol dm^{-3}	0.02	0.05	0.10
u	25.6	26.3	26.1
K/mol^{-1} dm^3	601	271	180
K'/mol^{-2} dm$^6\times10^3$	30.1	5.42	1.80

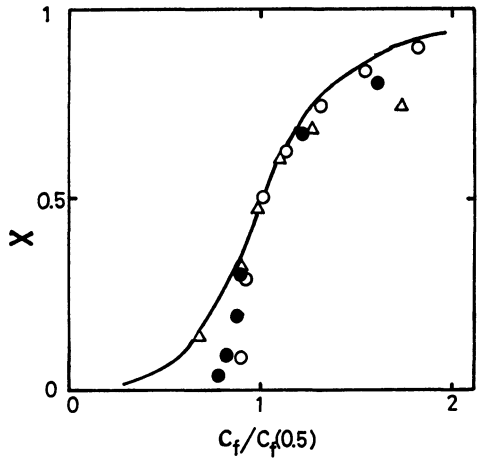

Fig. 3. X *vs.* C_f/C_f (0.5) plot.
NaCl concentration: ○ 20, ● 50, △ 100 mmol dm^{-3}, u=26.

We see how the parameters fit the experimental data in Fig. 3, where X is plotted against $C_f/C_f(0.5)$ (*cf.* Eq. 15 in Ref. 4). The value of K decreases with increase in sodium chloride concentration, u remaining nearly constant. The decrease in the binding affinity should be even steeper, since contribution from the counterions should be taken into account in the binding process of an electrolyte. Ionic product C_fC_a in place of C_f in $s=KuC_f$ and therefore in Eq. 2 should be used. A new equilibrium constant is defined by $K'=K/C_a$ (Table 1). The steeper decrease in K' than K reflects a substantial shielding effect of electrostatic potential of the polymer which overwhelms the effect by the increase in sodium chloride concentration. It is enlightening to compare the characteristic concentration, C_t, at which binding starts, of a nonelectrolytic polymer, poly(ethylene oxide)-SDeS system with that of the present system. C_t was deduced to be about 13 mol m^{-3} for the former[3] and 0.16 mol m^{-3} for the latter, both in 0.1 mol dm^{-3} NaCl. By consideration of free energy we find that the polycation binds SDeS more strongly than poly(ethylene oxide) does by $\Delta G_e=-kT\ln(13/0.16)=-4.4\,kT$. If the free energy is entirely ascribed to an electrostatic term, we have $\Delta G_e=ze\phi$ with ϕ=133 mV. This potential difference might be high, but not unrealistic for ordinary polyelectrolytes.[13] Hydrophobic interaction should be included since the hydrophobicity of the polycation is larger than that of poly(ethylene oxide).

The parameter u changes little in contrast with the drastic change in K'. Once bound onto the polycation, surfactants are scarcely influenced by electrostatic potential, and interact one another through short-range interaction. The parameter u is defined by

$$u = (11)(00)/(01)(01), \quad (4)$$

where (01) denotes the number of bound surfactants on isolated binding sites, (11) that of surfactants bound side by side, and (00) the number of unoccupied sites (*cf.* Eq. 10 in Ref. 4). u is an equilibrium constant for an aggregation process of surfactants on the polymer. The corresponding free energy is

$$\Delta G^\circ = -kT\ln(u) = -3.3\,kT. \quad (5)$$

ΔG° is divided by the free energy of transfer of a methylene group ($1.32\,kT$),[14] to give $m=3.3/1.32=2.5$. It is presumed that the strong cooperativeness is brought about by mutual contact of certain 2—3 methylene groups of adjacently bound surfactants. Takagishi *et al.* reported that anionic dye, Methyl Orange and its homologs are bound to the same polycation in such a way as to give Klotz plots which are quite straight.[15] This indicates that there is no interaction amoung bound dye molecules. Shorter and stiff molecular structures of these dyes are not susceptible to mutual contact on the polycation, longer and flexible decyl chain being ready to interact.

In conclusion, electrostatic force enhances binding and surfactans are anckored on charged groups on the polycation with subsequent interaction between alkyl chains giving rise to marked cooperativeness.

The samples were kindly supplied by Nittō Bōseki Co. Ltd., and Kaō Soap Co., Ltd.

Electronic Structures and Spectra of the Enol Form of Some β-Diketones

Hiroshi MORITA* and Hiroshi NAKANISHI†

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received May 29, 1980)

Near and vacuum UV absorption spectra have been measured with benzoylacetone (BA), dibenzoylmethane (DBM), and 3-phenyl-2,4-pentanedione (PPD) in heptane, in acetonitrile, and in ethanol at room temperature. Theoretical analysis of the spectra with the aid of the composite molecule method clearly shows that the π-electron interaction between the enol ring and the benzene ring is rather strong in BA and DBM, but is weak in PPD. The charge-transfer (CT) bands from the benzene ring to the enol ring are observed at 44000 cm^{-1} in BA, at 40000 and 44000 cm^{-1} in DBM, and at 41500 and 43800 cm^{-1} in PPD. The electronic structure of the enol form of malonaldehyde has been elucidated by a modified CNDO-CI method; the result indicates the first and second σ-σ^* excited states predicted at 8.76 and 9.35 eV being the CT band pertinent to the intramolecular hydrogen-bonding.

Keto-enol tautomerism of β-diketones (1,3-propanediones)[1,2] has been studied by IR[3-9] and NMR[10-12] spectroscopies, special attention being paid to solvent and substituent effects on intramolecular hydrogen-bonding (H-bonding) and on chelating ability to a transition-metal atom in forming coordination compounds.[12-15] From the IR and NMR studies[6,10,12] benzoylacetone (BA), dibenzoylmethane (DBM), 3-phenyl-2,4-pentanedione (PPD), and malonaldehyde (MA) (Fig. 1) are shown to exist predominantly (90—100%) as *cis*-enol form (which has strong intramolecular H-bonding) in pure liquid and in nonpolar solvents.

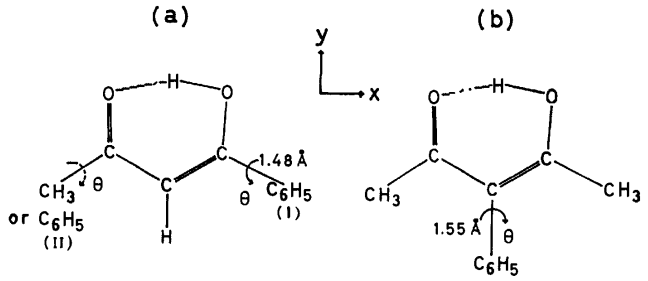

Fig. 1. Molecular structure and parameters for (a) BA and DBM, and (b) PPD. The structure of the enol ring is taken to be the same to the one of MA.

Although the electronic absorption spectra of β-diketones[16-20] and of their chelate compounds[13,17,19,21] have been measured extensively in the visible and near UV regions, the interpretation of the absorption spectra is rather qualitative. As for the simplest β-diketone, *i.e.*, MA, many theoretical calculations[22-25] have been done to investigate molecular geometry and electronic structure in the ground state, special attention being paid to the strong intramolecular H-bonding. Combined with the experimental value of $R(O\cdots O)=2.55$ Å determined by microwave spectroscopy,[26] theoretical results support the molecular geometry of C_s symmetry (asymmetrical H-bond) rather than of C_{2v} symmetry (symmetrical H-bond) in the ground state. Theoretical and experimental investigations of excited states of MA are few.[27,28] Excited states of MA are of particular interest in respect to charge-transfer (CT) character pertinent to H-bond as in the case of acetylacetone (acac) and its fluoro derivatives.[29,30] The elucidation of the CT character in the excited states is the first purpose of the present paper.

Phenyl-substituted β-diketones such as BA, DBM, and PPD are expected to have π-electron interaction between the enol ring and the benzene ring.[6,11,18] To interprete electronic structure of such large molecules, near and vacuum UV absorption spectra have been measured, and π-electron structure has been investigated by the method of composite molecule.[31,32]

Experimental

BA, DBM, and PPD (Tokyo Kasei G. R. grade) were purified by repeated recrystallizations from ethanol and finally by vacuum sublimation. Acetonitrile and heptane (Dotite spectrograde), and ethanol (Wako S. S. grade) were used as solvents without further purification.

Near UV absorption spectra were measured with a Cary recording spectrophotometer model 14, and with a Hitachi recording spectrophotometer model 556, a cell of 1.05 mm light path length being used. Vacuum UV absorption spectra were measured with a spectrophotometer constructed in our laboratory,[30,33] a cell of 0.134 mm light path length being used.

Theoretical

The electronic structure of MA was calculated by a modified CNDO-CI method.[34] The semiempirical parameters of H, C, and O atoms were taken to be the same as reported previously.[30,34] The electronic structures of the π-electron systems for the enol form of BA, DBM, and PPD were calculated by the method of composite molecule[31,32] by considering the configuration interaction (CI) among the ground, locally excited (LE), and CT configurations constructed from π-MO's of benzene[32] and MA (corresponding to the enol ring) calculated above. The four LE configurations ($^1B_{2u}$, $^1B_{1u}$, and $^1E_{1u}$) of the benzene ring and the lower two LE configurations (denoted as ϕ_1 and ϕ_2) of the enol ring were taken into account. The energies of the LE configurations were evaluated from the observed transition energies of benzene (4.86 and 6.08 eV in heptane,[35] 6.98 eV in the vapor phase[32]), of acac (4.56 and 7.04 eV in perfluorohexane[29]), and of MA (5.08 eV in ethanol,[28] 7.87 eV calculated in the present

† Present address: Toshiba Research and Development Center, 1, Toshiba-cho, Komukai, Saiwai-ku, Kawasaki 210.

paper (Table 4)) combined with the electrostatic interaction energies between excited configuration of the benzene ring and the ground configuration of the enol ring.

Concerning the combination of each of the benzene rings with the enol ring, four CT (from benzene to the enol ring) and four back CT (from the enol ring to benzene) (BCT) configurations were considered. Their energies were evaluated by the usual formula;[31,32] $I-A-Q$, where I is the ionization potential of electron donor, A, the electron affinity of electron acceptor, and Q, the electrostatic energy between electron donating and electron accepting MO's including electrostatic interaction energy between the ground configuration of the enol ring and the vacant MO's of the benzene ring. Ionization potentials were taken from the study by photoelectron spectroscopy of benzene,[36] acac,[37,38] and MA.[38] The electron affinity was taken to be −1.0 eV for the benzene ring,[32] and assumed for the lower two vacant π-orbitals of the enol ring to be 0 eV and −2.4 eV in both BA and DBM, and to be 0.5 eV and −1.9 eV in PPD. Two-center Coulomb repulsion integrals necessary for the evaluation of Q were calculated by the use of Klopman's equation.[34,39]

The resonance integral, β, in the off-diagonal matrix elements[31,40] of the total electronic Hamiltonian was considered only to the C–C bond between the benzene ring and the enol ring by the formula, $\beta=9.73\times S$, where S is the overlap integral between the 2pπ AO's of bonded C atoms.

The full matrices (15×15 for BA and PPD, 27×27 for DBM) of the total electronic Hamiltonian were solved to obtain energy levels and wave functions of the whole molecules. Oscillator strength for each absorption band was calculated by taking transition dipole moments between all pairs of the configurations into account. Each transition moment was evaluated including all the terms up to the first order in overlap, S.

The bond lengths and bond angles of MA were taken from the *ab initio* calculations by Karlström, *et al.*[24] and by Del Bene and Kochenour,[25] respectively. The O···O distance was taken to be 2.55 Å from the analysis of microwave spectrum,[26] and the position of the hydrogen-bonded hydrogen atom, from the X-ray crystal analysis of DBM.[41]

In BA, DBM, and PPD, the benzene ring(s)[41] with r(C–C) = 1.389 Å is(are) bonded to the enol ring through the C–C bond(s) of 1.48 Å in BA and DBM,[41] and of 1.55 Å in PPD. The angle, θ, between the planes of the enol ring and the benzene ring was treated as a variable in the actual calculations. As is shown in Fig. 1, BA is enolized toward the phenyl group.[6]

Results and Discussion

Near and Vacuum UV Absorption Spectra of BA, DBM, and PPD. Near and vacuum UV absorption spectra observed with the heptane solutions of BA, DBM, and PPD are shown in Fig. 2. The spectra measured in ethanol and acetonitrile show only a slight shift of the bands, and are essentially the same as the spectra of the corresponding molecules in heptane. The observed band positions and intensities are tabulated in Tables 1—3. As pointed out by the NMR[10,12] and IR[6] spectroscopic studies, the β-diketones under considerations predominantly exist as the *cis*-enol form at room temperature. The spectra shown in Fig. 2 and Tables 1—3 are due to the enol form. Compared to the spectrum of acetylacetone reported previously,[29] the first allowed band at ≈300 nm shifts to longer wavelengths with increasing intensity in the order of acac ≲PPD<BA<DBM.

Electronic Structure of MA. Preliminary calculations of MA have been done on the basis of different

molecular geometries predicted by several investigations;[24-26,41,42] the results showed that the electronic structure of MA is sensitive to the change of molecular geometry, especially to the position of intramolecularly H-bonded O and H atoms. From the comparison with the observed spectra[28] and by referring to the experimental results of microwave spectrum[26] and of X-ray crystal analysis of DBM,[41] we have chosen the nonlinear asymmetrical H-bond with $R(O\cdots O)=2.55$ Å and $r(O-H)=1.18$ Å as one of the plausible structure of MA.

The electronic structure of MA calculated by the modified CNDO-CI method is tabulated in Table 4, together with the observed values.[28] The agreement between the theoretical and observed values is satisfactory for the lower excited states. It is noteworthy that the first and the second σ-σ^* bands predicted at 8.76 and 9.35 eV, respectively, is the CT band pertinent to the H-bond in the sense that the CT configurations, 13—17 and 13—18 in the H-bond (corresponding to the transition from O-H···O structure to O···H-O structure in the valence-bond scheme[29]) mainly contribute

a) Observed value in the vapor phase taken from Ref. 28. b) Oscillator strength is calculated for the singlet manifold. The direction of transition moment is shown in parentheses, x-, y-, and z-axes being taken as in Fig. 1. c) Singly excited configuration, $i-j$, denotes one-electron excitation from the i-th occupied MO to the j-th vacant MO. The 14th MO is the highest occupied one. d) Observed value in ethanol. e) x- and y-components of transition moment contribute equally with opposite signs.

to the first (55.8%) and to the second (53.5%) σ-σ* excited states. The CT configurations also contribute considerably (11.6%) to the first π-π* excited state of MA as in the case of the corresponding band of the enol form of acac and its fluoro derivatives.[29,30]

Electronic Structures of BA, DBM, and PPD. The electronic structures of the π-electron systems of BA, DBM, and PPD were calculated by the method of composite molecule[31,32] in which the β-diketone is divided into the enol ring and the benzene ring(s). The rotating angle, θ, between the enol ring and the benzene ring (Fig. 1) was treated as a variable. Figure 3 shows the θ-dependence of energy levels calculated for BA, DBM, and PPD.[43] By referring to the absorption spectra in Fig. 2, and also by referring to the observed θ-value of DBM (16.9°)[41] and tetraacetylethane (89°)[42] in crystalline state, theoretical results with θ=20° are taken to BA and DBM, and the result with θ=70°, to PPD, as tabulated in Tables 1—3. The theoretical energy diagrams of BA and DBM are illustrated in Fig. 4 and the one of PPD, in Fig. 5.

As is shown in Table 1 and in Fig. 4, the first allowed

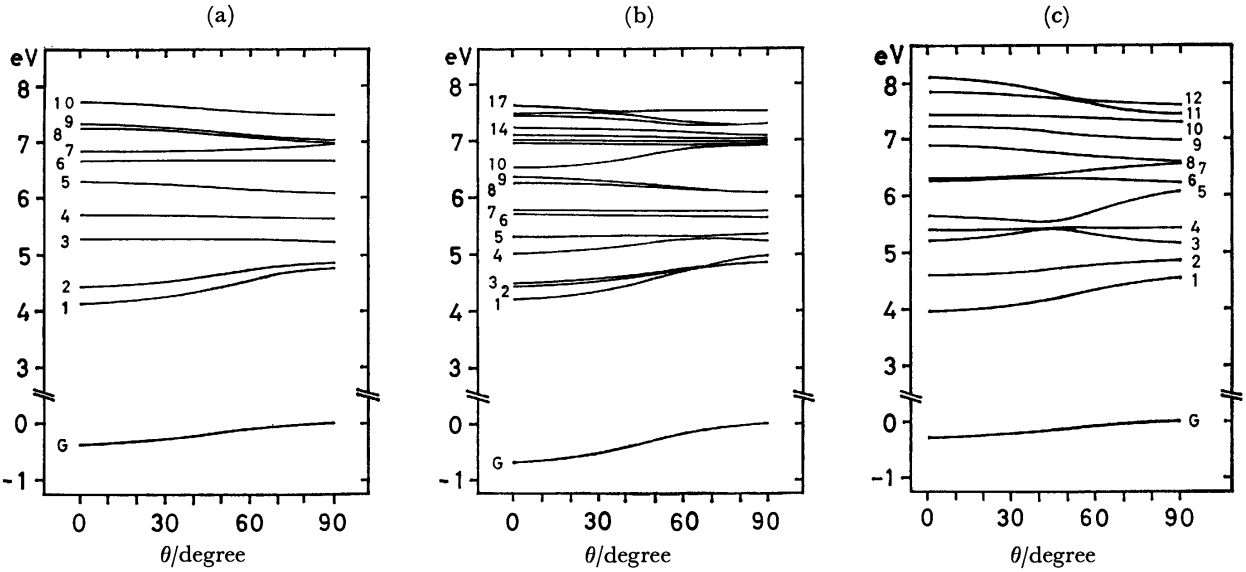

Fig. 3. θ-dependence of energy levels calculated for (a) BA, (b) DBM, and (c) PPD.

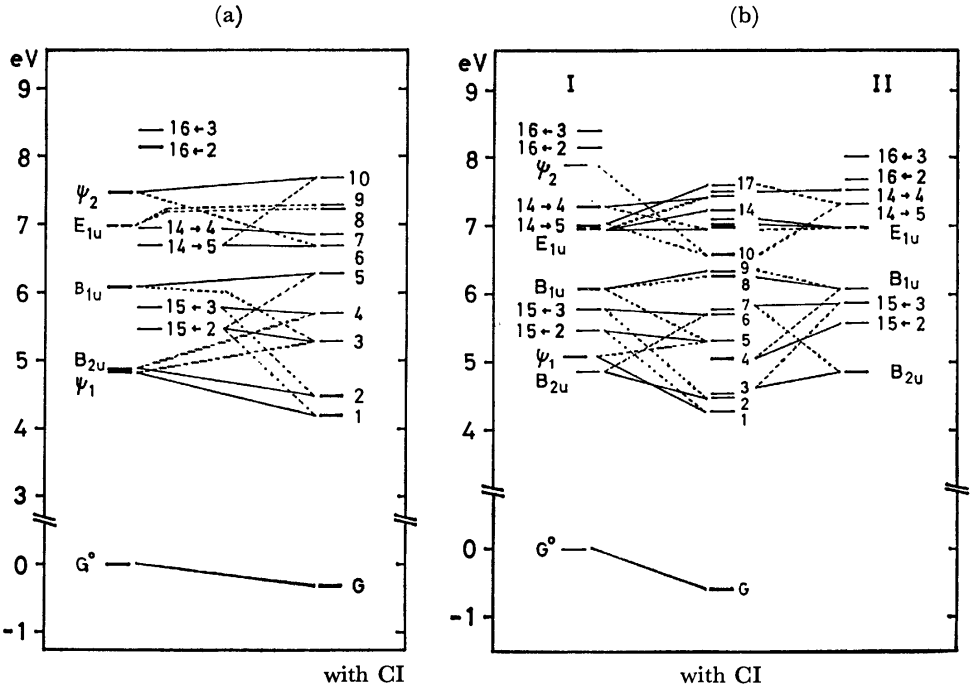

Fig. 4. Energy levels calculated with and without CI treatment for (a) BA and (b) DBM. In DBM, the configurations related to the benzene ring I and the LE configurations of the enol ring are shown on the left column and the configurations related to the benzene ring II, on the right column. For the CT or BCT configuration, i—j, see the footnote (b) in Table 1.

band of BA observed at 32700 cm^{-1} in heptane can safely be assigned to the LE state of the enol ring, ϕ_1 (60.3%) mixed with the CT (from the benzene ring to the enol ring) (18.5%) and BCT (from the enol ring to the benzene ring) (9.6%) configurations. The second excited state of BA which is mainly (73.2%) composed of B_{2u} state of the benzene ring and the absorption intensity of which is predicted to be weak may be covered with the first π-π^* band. The assignment may be supported from the fact that the corresponding band of DBM is observed near 33800 cm^{-1} as a shoulder. The 40500 cm^{-1} band of BA can be assigned to the third excited state which is mainly composed of the 15←2 CT (42.4%), and ϕ_1 (26.7%) and B_{1u} (19.6%) LE configurations. The 44000 cm^{-1} band has two peaks at 43000 and 44500 cm^{-1} in heptane and can be assigned to the fourth excited state which is mainly composed of the 15←3 CT (55.8%) and B_{2u} LE (22.7%) configurations. The 44000 cm^{-1} band is the CT band between the benzene and enol rings.

From the comparison with the theoretical result, we can expect three bands in the 45000—53000 cm^{-1} region. The shoulder at $\approx$46100 cm^{-1} is assigned to the fifth excited state which is mainly composed of the B_{1u} LE (61.8%) and 15←2 CT (20.1%) configurations. To the 6th and 7th excited states, BCT configurations contribute significantly. The 6th excited state is mainly composed of the 14→5 BCT (41.9%), and ϕ_2 (24.1%), ϕ_1 (9.4%), E_{1u} (11.1%), and B_{1u} (9.2%) LE configurations, and is tentatively assigned to the weak shoulder near 47400 cm^{-1}. The 7th excited state which is safely assigned to the 50800 cm^{-1} band is the BCT band to which the 14→4 BCT (64.8%) and E'_{1u} LE (19.4%) configurations mainly contribute.

The very strong 56500 cm^{-1} band is predicted to be composed of three bands, *i.e.*, 8th—10th excited states. The 8th and 9th excited states are mainly composed of the E_{1u} and E'_{1u} LE configurations (47.4% and 18.6%, respectively, for the 8th, and 26.2% and 31.6%, respectively, for the 9th excited state) mixed with BCT and CT configurations. The 10th excited state is mainly composed of the ϕ_2 LE (51.9%) and 14→5 BCT (20.8%) configurations.

The electronic structure of DBM is illustrated in Fig. 4, compared with the one of BA. Because two benzene rings, I and II interact with the enol ring, the 2nd and 3rd, 4th and 5th, 6th and 7th, and 8th and 9th excited states of DBM appear in pairs with the corresponding character related to each benzene ring. As is shown in Table 2, the observed bands at 29800, 33800, 40000, and 44000 cm^{-1} in heptane can be assigned to the first, 2nd and 3rd, 4th and 5th, and 6th and 7th excited states, respectively. The character of the bands is semiquantitatively the same to the corresponding first four bands of BA. The 44000 cm^{-1} band has two peaks at 43300 and 44600 cm^{-1} as in the case of BA. In the 46000—50500 cm^{-1} region, three bands, *i.e.*, 8th—10th excited states are predicted to overlap. The character of the pair (*i.e.*, the 8th and 9th) and the 10th excited states corresponds to the one of the 5th and 6th excited states of BA, respectively. In the very strong 54100 cm^{-1} region, six bands corresponding to the 11th—16th excited states are expected to locate. The 11th—14th states are mainly composed of the E_{1u} and E'_{1u} LE configurations of two benzene rings, and the 15th and 16th excited states, of the 14→4 BCT configuration from the enol ring to each benzene ring.

In conclusion, theoretical investigation of the spectra clearly shows strong π-electron interaction between the enol and benzene rings in BA and DBM.

Contrary to BA and DBM, the spectrum of PPD is well reproduced when θ value around 70° is employed, indicating that π-electron interaction between the enol and benzene rings is weak. The theoretical result of PPD with $\theta=70°$ is shown in Table 3 and in Fig. 5. Because the PPD molecule is of approximate C_2 symmetry and because the π-electron interaction between the rings is rather weak, configuration interaction in PPD is more limited than in BA. As is shown in Table 3, qualitative assignment for each band is similar to the one of BA. The 35200 cm^{-1} band assigned to the first excited state is the LE state, ϕ_1 (87.3%), and the

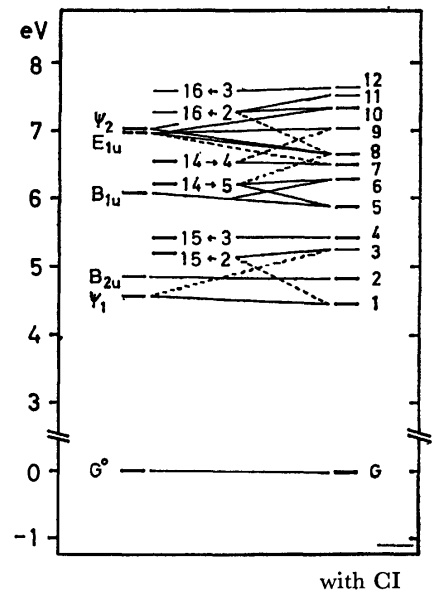

Fig. 5. Energy levels calculated with and without CI treatment for PPD. For the CT or BCT configuration, *i*—*j*, see the footnote (b) in Table 1.

second excited state is B_{2u} state of the benzene ring (97.4%). The latter band is again too weak to be observed. The 41500 cm^{-1} band assigned to the third excited state is the 15←2 CT state (86.3%), and the 43800 cm^{-1} band assigned to the 4th excited state is the 15←3 CT state (97.8%).

The B_{1u} LE and 14→5 BCT configurations contribute predominantly to the 5th (50.9% and 34.7%, respectively) and to the 6th (47.1% and 39.3%, respectively) excited states, which are tentatively assigned to the shoulders at 46900 cm^{-1} and 49000 cm^{-1}, respectively. To the strong 52500 cm^{-1} region, the 7th (14→4 BCT (85.8%)) and the 8th (ϕ_2 (32.4%)+E_{1u} (32.1%)+14→5 BCT (24.7%)) excited states can be assigned. To the very strong 55400 cm^{-1} region, the strong 9th (E'_{1u} (82.6%)) and 10th (E_{1u} (39.4%)+16←2 CT (51.3%)) excited states mainly contribute.

Theoretical oscillator strength of the first band predicts well the increase of the observed transition intensity in the order of PPD<BA<DBM. Table 5 shows coefficients of several main configurations in the ground and the first excited states. The wave functions clearly show that the increase of the interaction of the 15←2 CT configuration with the ground and ϕ_1 LE configurations is mainly responsible for the increase of the transition intensity.

UV Absorption Spectra in KOH Aqueous Solution. Near UV absorption spectra measured with the KOH aqueous solutions of BA, DBM, PPD, and acac are shown in Fig. 6. The strong bands at 320.5 nm of BA, at 347 nm of DBM, and at 304.5 nm of PPD can be assigned to the first π-π* band of the anion with planar chelate ring as in the case of the 292.5 nm band of the acac anion.[29] As is shown in Fig. 6, the spectra of the KOH aqueous solutions were found to change with time, and the strong bands at 300—350 nm finally disappear. In Fig. 7, time dependence of the absorbance, $\Delta A(=A(t)-A(t=\infty))$, for the 320.5 nm band of the

anions, indicating that the spectral change is due to the unimolecular reaction, A→A′, of the anions. The rate constants (k) under several experimental conditions are listed in Table 6. In the BA, DBM, and acac anions, the rate constant is roughly proportional to the concentration of KOH, strongly suggesting that the planar structure of the chelate ring is broken by the action of the KOH molecules. Under the fixed concentration of KOH, the rate constant increases in the order of the BA<acac<DBM≪PPD anions. The true absorption intensity of the 300—350 nm band of the anion can be evaluated from the extrapolated absorbance at $t=0$ (ΔA_0) with the correction of the final absorbance ($A(t=\infty)$). The results are tabulated in Table 6. The absorption intensities are rather equal for the PPD, BA, and DBM anions in contrast to the ones of the corresponding bands in neutral species.

The authors wish to express their sincere thanks to Professor Saburo Nagakura, the University of Tokyo, for valuable discussions and for reading manuscript carefully.

The Photoelectrochemical Reaction of the Chlorophyll-Irisquinone Electrode

Fujio Takahashi,* Katsura Seki, Ryohei Kaneko, Kenji Sato, and Yasushi Kusumoto

Faculty of Engineering, Utsunomiya University, Utsunomiya 321

(Received May 30, 1980)

The role of irisquinone (IQ) in the chlorophyll-IQ electrode was studied by measuring the photoresponse under illumination and the photocurrent at the controlled potential. It was concluded that the hydrophobic property of IQ was necessary for the photoresponse to occur at the chlorophyll electrode, and that the photoexcited chlorophyll was likely to eject electrons to a counter electrode *via* an outer circuit and to pull electrons from the reduced IQ, which had been produced by the oxidation of a reducing compound in the electrolyte on the chlorophyll-IQ electrode.

Recently many photoelectrochemical studies of chlorophyll lined on the electrode have been reported.[1,2] We have already contributed to this field: We found that the potential shifts to a less noble value under illumination on the platinum electrode coated with a mixture of chlorophyll and quinone, such as 1,4-naphthoquinone or chloranil.[3] The conductive adhesive was used as the binder of quinone with an electrode to prevent the quinone spread on the chlorophyll layer from dissolving into the electrolyte. However, the existence of the conductive adhesive made it difficult to speculate on the role of quinone in producing a photocurrent from the electrode in the light. It was, therefore, thought to be necessary to investigate the photoelectrochemical reaction on the chlorophyll quinone electrode without the conductive adhesive.

Two of the present authors isolated a new quinone from the seed oil of *Iris pseudacorus* L.[4] The structure of the quinone has been identified as 2-(*cis*-10-heptadecenyl)-6-methoxy-*p*-benzoquinone,** which is insoluble in water, miscible with chlorophyll, and adhesive to the electrode. These properties were thought to be suitable for the study of the chlorophyll-quinone electrode.

This paper will present the results of photoelectrochemical studies of the chlorophyll-IQ electrode undertaken in order to clarify the role of quinone.

Experimental

Materials. The chlorophyll was purchased from Nihon Chlorophyll Kogyo Co., Ltd., and was purified to separate it from an oily material by elution through the talc column with 80% acetone. The chlorophyll used was a mixture of chlorophyll a and b. The chlorophyll was determined by the spectrophotometric method.[5] The IQ used was isolated by the method described in a previous paper.[4] All the other chemicals were of a reagent grade or were the best commercially available.

Electrodes and Electrolytes. A chlorophyll or IQ solution in hexane or acetone and a cholesteryl oleate solution in hexane were prepared. The requisite amounts of the chlorophyll solution or the mixture of these stock solutions were spread onto the platinum electrode (1 × 1 cm) and then dried to produce a homogeneous chlorophyll layer. The chlorophyll-coated electrode was then immersed in a M/40 phosphate-buffer (pH 6.9) or carbonate-buffer electrolyte adjusted at each pH; various redox compounds had been dissolved in the electrolytes. All the experiments were carried out at 35 °C by using 50-ml dual beaker containing the electrolyte, with nitrogen gas being passed through.

Equipment. The potential was measured by means of a Kikusui Denshi volt-ammeter model 116 connected to the recorder, with a calomel electrode as the reference electrode. A Hokuto Denko potentiostat HA101 and a linear scanner were used for the measurement of the photocurrent at each controlled potential. A platinum plate was used as a counter electrode. The potential-current curves were obtained by using a Yokogawa Denki Type 3036 X-Y recorder, with the scanning set at a rate of 100 mV/s. The projector lamp (100 V, 150 W) was used as the source of light. The light of wavelengths shorter than 460 nm was cut off by a color filter (V-Y46) to avoid the complication arising from the simultaneous photochemical reaction of IQ, which exhibited its λ_{max} at 363 nm.[4]

Results and Discussion

Photoresponse of the Chlorophyll-IQ Electrode. To investigate the effect of IQ on the electrode with respect to the photoresponse, the electrode was prepared by covering 0.01 μmol/cm² of a layer containing chlorophyll and IQ mixed in various molar ratios. Same typical results of the potential-time curve are shown in Fig. 1. In Fig. 2 the values of photovoltage (the potential under illumination subtracted that in the dark) of all the electrodes are plotted against the molar ratio of IQ to the total amount of chlorophyll and IQ. The photovoltage of the chlorophyll electrode was found to shift to a positive value under illumination. On the other hand, the photovoltage turned into a

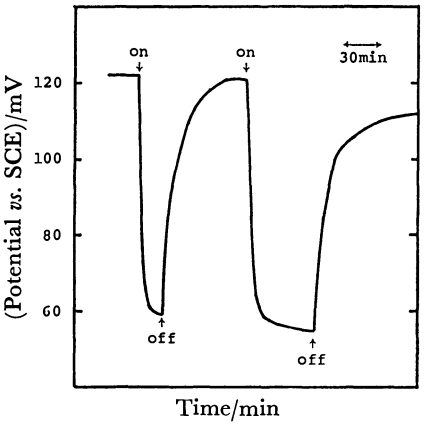

Fig. 1. Photoresponse of chlorophyll-IQ electrode. pH 6.9, 35 °C, 6 × 10⁴ lx, [Chl]+[IQ]=0.01 μmol/cm², [Chl] : [IQ]=1 : 3.

** Abbreviated to IQ, because we named it Irisquinone.

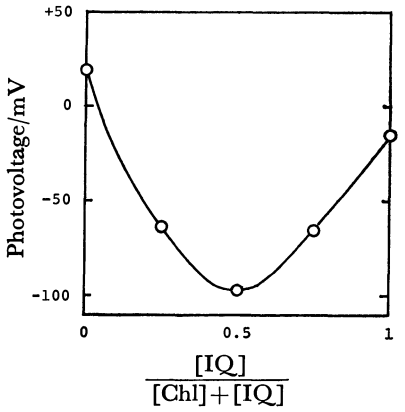

Fig. 2. Influence of the molar ratio to the photovoltage of chlorophyll-IQ electrode.
pH 6.9, 35 °C, 6×10^4 lx, [Chl]+[IQ]=0.01 μmol/cm².

negative value as the IQ content in the layer of the electrode increased. The maximum photoresponse was obtained at the molar ratio of IQ to chlorophyll of 1 : 1. The magnitude of the photovoltage became smaller at higher molar ratios of IQ, caused by the decrease in the amount of chlorophyll, which exhibited a photoconductive property. The values of the photovoltage were measured at various thicknesses of the chlorophyll-IQ layer (with the molar ratio of 1 : 1). The results are shown in Fig. 3a. The photovoltage was nearly constant at layer thicknesses thicker than 0.01 μmol/cm².

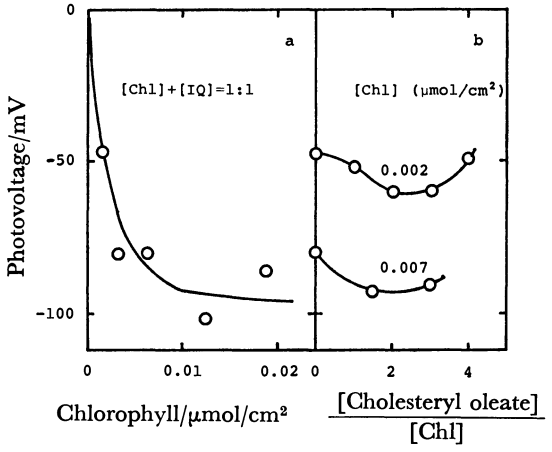

Fig. 3. Influence of the thickness of chlorophyll layer and the ratio of cholesteryl oleate to chlorophyll to the photovoltage.
pH 6.9, 35 °C, 6×10^4 lx.

It is very plausible that chlorophyll molecules are located in the hydrophobic region as a result of the existence of excess IQ, which is hydrophobic itself, and that, in turn, the chlorophyll-IQ electrode generates the photovoltage due to the photoexcitation of chlorophyll in the hydrophobic region. The chlorophyll-IQ-cholestery oleate electrode was prepared and illuminated in order to verify the influence of hydrophobicity on the photovoltage. Cholesteryl oleate is hydrophobic, miscible to chlorophyll and IQ, and exhibits the property of a liquid crystal. It is known that not only the molecules of a liquid crystal, but also guest molecules will be oriented in the electric field.[6] It was expected that the photovoltage might increase by the orientation of the photo-conductive chlorophyll molecules in the layer. The results of the photovoltage of the chlorophyll-IQ-cholesteryl oleate electrode are shown in Fig. 3b. The molar ratio of chlorophyll and IQ is 1 : 1, and the total amounts of chlorophyll and IQ in the layer were kept constant when the amount of cholesteryl, oleate was varied. The photovoltage was found to increase up to the molar ratio of chlorophyll, IQ, and cholesteryl oleate of 1 : 1 : 2, and then decrease as more cholesteryl oleate was added. It is said that the following reaction may occur in the hydrophobic region:[7]

$$\mathrm{Chl}^* + \mathrm{Q} \longrightarrow \mathrm{Chl}^+ + \mathrm{Q}^-, \qquad (1)$$

where Chl*, Chl^+, and Q^- are a photoexcited chlorophyll, a cation of chlorophyll, and an anion of quinone, respectively. In a nonaqueous solvent, one-electron-reduced ubiquinone is known to be stable and to exhibit a remarkably negative (less noble) reduction potential.[8] Judging from the fact that the photoresponse of the chlorophyll-IQ electrode was observed in a negative direction, like an n-type semiconductor, an anion of IQ seems to exist inside the chlorophyll-IQ layer, apart from the interface of the electrode and the electrolyte.

The Redox Compounds in the Electrolyte. The electrolyte should contain an equi-molar concentration of the oxidized and reduced forms of the redox compound in order to keep the composition of the electrolyte constant during the photoelectrochemical reaction, so that the oxidized form of the redox compound might be reduced at the cathode and the reduced form might be oxidized at the anode. Therefore, the redox compounds were surveyed for a photocell producing as

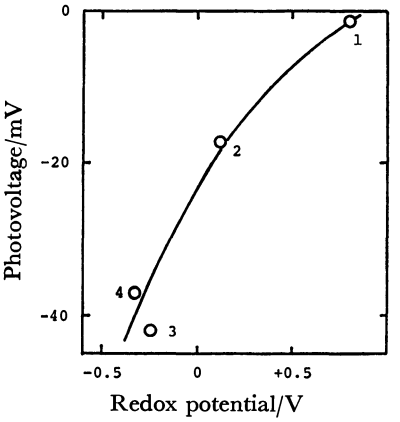

Fig. 4. Relation between the redox potential and the photovoltage. Total concentration of redox compound 2 mM. Molar ratio of oxidized and reduced form=1 : 1.
1: Quinone hydroquinone (+0.80V), 2: Fe^{3+}EDTA/Fe^{2+}EDTA (+0.12 V), 3: 1/2 GSSG/GSH (−0.24 V), 4: NAD^+/NADH (−0.32 V), pH 6.9, 35 °C, 5×10^4 lx, chlorophyll-IQ electrode: [Chl] : [IQ]=1 : 5, thickness of chlorophyll: 0.02 μmol/cm².

high a photovoltage and photocurrent as possible. The photovoltage was measured on the system of a chlorophyll-IQ (the molar ratio: 1 : 5) electrode immersed into an electrolyte containing a different redox compound. The concentrations of the oxidized and reduced forms of the redox compound were 1 mM each. The results are shown in Fig. 4. The photovoltage was found to shift to a more negative value as the oxidation-reduction potential of the redox compound became less noble. The highest photovoltage was obtained when the mixture of glutathione-oxidized (GSSG) and -reduced (GSH) was used. The photovoltage in the system of the chlorophyll-IQ electrode connected with GSSG or GSH alone in the electrolyte was −58 or −45 mV, while that in the system of the chlorophyll electrode connected with GSSG or GSH alone was +53 or +39 mV respectively.

The Photocurrent at the Controlled Potential. In order to clarify the role of IQ on the chlorophyll-IQ electrode, the photocurrent was measured at the controlled potential on the various electrodes immersed into the electrolyte. The molar ratio of chlorophyll to IQ or

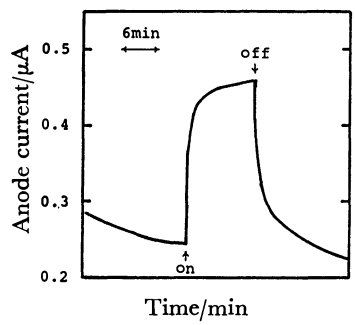

Fig. 5. Photocurrent at controlled potential.

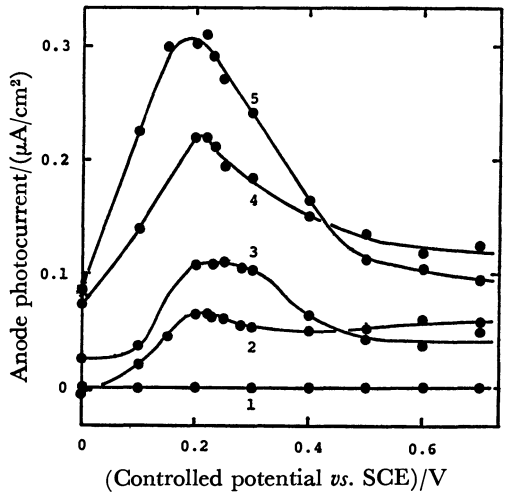

Fig. 6. Anode photocurrent at controlled potential.
pH 6.9, 35 °C, 5×10^4 lx, 0.02 μmol/cm² chlorophyll, molar ration of Chl : IQ=1 : 5, 1: E(none)/buffer, 2: E(Chl)/buffer, 3: E(Chl, IQ)/buffer, 4: E(Chl, IQ)/1 mM GSH, 5: E(Chl, IQH_2)/buffer.

that of chlorophyll to reduced IQ (IQH_2) in the layer of the electrode was 1 : 5. A typical anodic photocurrent-time curve is shown in Fig. 5, while the curves of the photocurrent at various controlled potentials are shown in Fig. 6. The maximum photocurrent was obtained around +0.2 V *vs.* SCE in every case. The same reaction may occur by the photoexcitation of chlorophyll in all cases. It is known that the half-wave oxidation potential of the chlorophyll a appears at +0.52 V (SCE) in acetonitril.[9] This is not a photoelectrochemical reaction. Judging from these facts, the photocurrent may be produced by the following reaction:

$$Chl + h\nu \longrightarrow Chl^* \longrightarrow Chl^+ + e. \quad (2)$$

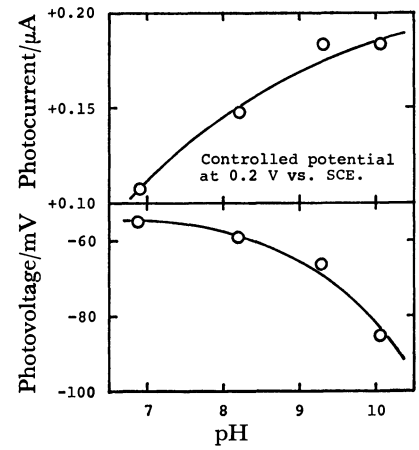

Fig. 7. Influence of pH to photovoltage and photocurrent. 35 °C, 5×10^4 lx, 0.02 μmol/cm² chlorophyll, molar ratio of Chl : IQ=1 : 5.

The anodic photocurrent at +0.2 V on the chlorophyll-IQ electrode was found to increase at higher pH values, in other words, at higher concentrations of OH^-, as is shown in Fig. 7. OH^- is as the only anode-active substance in the electrolyte. It may, therefore, be assumed that the IQ on the electrode is reduced in the process of the anodic reaction of OH^- and, in turn, that reduced IQ reacts with Chl^+ to reproduce IQ and chlorophyll. The assumptions can be expressed as follows:

$$IQ \xrightarrow{OH^-} IQH_2 \quad (3)$$

$$2\,Chl^+ + IQH_2 \longrightarrow 2\,Chl + IQ + 2\,H^+. \quad (4)$$

This is plausible, because the photocurrent in the case of the chlorophyll-IQ electrode is larger than that in the case of the chlorophyll electrode, and because the photocurrent produced by the chlorophyll-IQH_2 electrode is 2.8 times as large as that of the chlorophyll-IQ electrode, as is shown in Fig. 6.

The photocurrent and the dark current of the system of the GSH-containing electrolyte were twice and 1.4 times as large as these of the system omitting GSH. It is very possible that the IQ on the electrode is reduced to form IQH_2 in the dark as follows:

$$IQ + 2GSH \longrightarrow IQH_2 + GSSG. \quad (5)$$

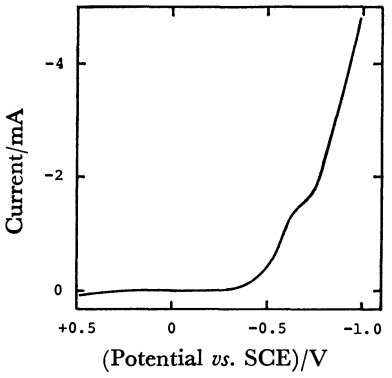

Fig. 8. Potential-current curve of IQ on Pt electrode.
pH 6.9, 35 °C, 0.05 μmol of IQ on Pt (1×1 cm^2), The potential was scanned at a rate of 100 mV/s.

Then, the photocurrent can be obtained in the same way as with the chlorophyll-IQH_2 electrode.

The IQ layer was spread onto the platinum electrode to determine the reduction potential, because the redox potential of IQ was not yet known. The reduction wave of IQ appeared around −0.5 V (SCE), as is shown in Fig. 8. This fact suggests that IQ^- tends to release electrons. The electrons could transfer from IQ^- to platinum at +0.2 V. Then, the chlorophyll-IQ electrode produced the anodic photocurrent by means of Eqs. 1 and 2 at +0.2 V. No matter ho w Eq. 1 might participate, the maximum photocurrent was produced at the same potential in every system in Fig. 6. Therefore, the reaction of Eq. 2 appears to occur predominantly rather than the reaction of Eq. 1. It is concluded that the IQ on the electrode plays a role in the accelaration of the anodic reaction.

^{14}N Nuclear Quadrupole Resonance of the Molecular Complexes of Urea

Hisao Negita,* Tsuneo Kubo, and Hitoshi Kato

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received June 21, 1980)

The ^{14}N nuclear quadrupole resonance (NQR) was studied in four kinds of molecular complexes of urea, such as urea-nitric acid, urea-phosphoric acid, urea-oxalic acid, and urea-ammonium chloride. The ^{14}N quadrupole coupling constants and asymmetry parameters at liquid nitrogen temperature are as follows: $|e^2Qq/h|=3.157$ MHz and $\eta=0.475$ for the HNO_3 complex; $|e^2Qq/h|=3.277$ MHz and $\eta=0.414$ for the H_3PO_4 complex; $|e^2Qq/h|=3.456$ MHz and $\eta=0.363$ for the $(COOH)_2$ complex; and $|e^2Qq/h|=3.544$ MHz and $\eta=0.298$ for the NH_4Cl complex. From the temperature dependence of the resonance lines in these complexes, the strength of hydrogen bonds are discussed. The differences of the electron densities at the nitrogen atoms between urea and its complexes were derived from the corresponding NQR parameters, and the bond characters in these complexes are discussed.

It is well known that urea forms molecular complexes with a number of compounds, being held together by hydrogen bonding. These hydrogen bonds have been investigated by various spectroscopic methods.[1,2] It is interesting to study the hydrogen bonds in these complexes by means of the nuclear quadrupole resonance (NQR) of nitrogen-14. The molecular complexes of urea examined are urea–nitric acid (1 : 1) (HNO_3 complex), urea–phosphoric acid (1 : 1) (H_3PO_4 complex), urea–oxalic acid (2 : 1) ($(COOH)_2$ complex), and urea–ammonium chloride (1 : 1) (NH_4Cl complex). On the basis of the ^{14}N NQR results, the strength of the hydrogen bonds and the charge distributions at nitrogen atoms were compared with those in urea itself.

Experimental

^{14}N NQR measurements were carried out using a pulse spectrometer described previously.[3] The resonance lines were observed by the spin-echo signals using a 90—180° pulse sequence series. The pulse width of a 90° pulse was about 50 μs. The spin-echo signal was averaged in a Nicolet Instrument Model 527 signal averager. The temperature was controlled by the method of Abe.[4] The temperature was measured by the use of a copper-constantan thermocouple and stabilized within ±0.1 K. The frequency was checked by means of a frequency counter, TR-5104, from Takeda Riken Co.

The sample of the HNO_3 complex was prepared by crystallization at 0 °C from an aqueous solution containing an equimolar amount of urea and nitric acid, and was purified by recrystallization from methanol.[5] Found: C, 9.95; H, 4.13; N, 34.42%. Calcd for $CH_5N_3O_4$: C, 9.76; H, 4.10; N, 34.14%. The sample of the H_3PO_4 complex was obtained by slowly evaporating an equimolar solution of urea and phosphoric acid.[6] Found: C, 7.60; H, 4.54; N, 17.63%. Calcd for $CH_7N_2O_5P$: C, 7.60; H, 4.46; N, 17.72%. The sample of the $(COOH)_2$ complex was obtained from an aqueous solution of urea and oxalic acid in the stoichiometric ratio.[7] Found: C, 22.91; H, 4.84; N, 26.51%. Calcd for $C_3H_6N_2O_5$: C, 22.86; H, 4.80; N, 26.66%. The sample of the NH_4Cl complex was prepared by slowly evaporating a solution containing urea and ammonium chloride in a molar ratio of 1 : 1.[8] Found: C, 10.69; H, 7.17; N, 36.78; Cl, 30.8%. Calcd for CH_8ClN_3O: C, 10.58; H, 7.10; N, 37.01; Cl, 31.2%. All the samples were ground into powder after drying, and about 20 g of the samples were used for the measurements.

Results and Discussion

For the case of nitrogen-14 one observes in general a spectrum consisting of two NQR absorption lines ν_- and ν_+:

$$\nu_\pm = \frac{|e^2Qq|}{4h}(3\pm\eta), \qquad (1)$$

where $|e^2Qq/h|$ and η are the quadrupole coupling constant and asymmetry parameter, respectively. In the cases of the HNO_3 complex, the H_3PO_4 complex, and the $(COOH)_2$ complex, two pairs of resonance lines were observed at liquid nitrogen temperature. On the other hand, three closely spaced pairs of resonance lines were observed in the NH_4Cl complex. These lines could not be paired because the third possible resonance line $\nu_d=\nu_+-\nu_-$ could not be observed on account of its very low frequency. Accordingly, the quadrupole coupling constants and the asymmetry parameters in these complexes were derived from the average values of ν_- and ν_+; they are listed in Table 1.

The average temperature coefficient $\langle\alpha\rangle$ was calculated by the following equation:

$$\langle\alpha\rangle = 2(\nu_1-\nu_2)/[(\nu_1+\nu_2)(T_1-T_2)], \qquad (2)$$

where ν_1 and ν_2 are the resonance frequencies of the ν_+ lines at liquid nitrogen temperature (T_1) and about 275 K (T_2), respectively. These coefficients in the complexes are calculated as listed in Table 1, and decrease in the order of the $(COOH)_2$ complex, the HNO_3 complex, and the H_3PO_4 complex. Every coefficient is smaller than the value in urea, which is calculated from the reference[9] to be 13.43×10^{-5} deg^{-1}. This fact suggests that the vibrations of the nitrogen atoms in the urea molecules are suppressed in the order of urea, the $(COOH)_2$ complex, the HNO_3 complex, and the H_3PO_4 complex, that is, the strength of the hydrogen bonds, N–H···O, increases in this order. On the other hand, in the NH_4Cl complex, the temperature dependence of three ν_+ lines was nearly equal, and the resonance line ($\nu=2.9318$ MHz), the intensity of which was largest among in these lines, could be observed at about 200 K, whereas the other two lines were able to be observed at about 190 K. Therefore, the average temperature coefficient was calculated between liquid nitrogen temperature and about 200 K for the line ($\nu=2.9318$ MHz); the value

TABLE 1. NQR PARAMETERS AND THE AVERAGE TEMPERATURE COEFFICIENTS IN UREA COMPLEXES

Complex	ν_- / MHz	ν_+ / MHz	$\lvert e^2Qq/h\rvert$ / MHz	η	$\langle\alpha\rangle$ / deg^{-1}
$OC(NH_2)_2 \cdot HNO_3$	2.0505 1.9347	2.7828 2.7015	3.157	0.475	8.37×10^{-5}
$OC(NH_2)_2 \cdot H_3PO_4$	2.1476 2.0901	2.8159 2.7783	3.277	0.414	4.95×10^{-5}
$OC(NH_2)_2 \cdot (COOH)_2$	2.3701 2.1863	2.9634 2.8484	3.456	0.363	11.24×10^{-5}
$OC(NH_2)_2 \cdot NH_4Cl$	2.4335 2.4006 2.3473	2.9488 2.9318 2.8853	3.544	0.298	14.97×10^{-5}

is listed in Table 1. The temperature coefficient in the NH_4Cl complex is larger than that in urea. This suggests that the hydrogen bond in this complex, N–H···Cl, is weaker than the bond in urea, N–H···O. This may be explained by the difference of the electronegativities between a chlorine atom and an oxygen atom.

According to the results of the neutral diffraction study of the HNO_3 complex[5] and the X-ray diffraction studies of the H_3PO_4 complex and the $(COOH)_2$ complex,[6,7] the geometry of the NH_2 groups in these complexes is nearly equal to that in urea; we thus assumed the nitrogen σ-bond orbitals to be sp^2-hybrids. In the case of the NH_4Cl complex, there are three crystallographically nonequivalent nitrogen atoms, and each nitrogen atom forms two weak hydrogen bonds with a chlorine ion of ammonium chloride, the length of which is in the range from 3.14 to 3.40 Å.[8] Therefore, the electronic state of nitrogen atom in the NH_2 group may be considered not to be largely different from that in urea; we thus assumed that the nitrogen σ-bond orbitals are sp^2-hybrids.

The electron densities at the nitrogen atoms in these complexes can be calculated by means of the following equations:[10]

$$\alpha = |e^2Qq/e^2Qq_p| = n - (2/3)\sigma_{NH} - (1/3)\sigma_{NC}, \qquad \alpha\eta = \sigma_{NH} - \sigma_{NC}, \tag{3}$$

where n is the electron density in the lone-pair orbital; σ_{NH} and σ_{NC} are the σ-electron densities in the N–H and N–C bonds, respectively; and $|e^2Qq_p/h|$ is the quadrupole coupling constant due to one 2p-electron of a nitrogen atom. The α and $\alpha\eta$ values in urea and its complexes are denoted by α^u, $(\alpha\eta)^u$, α^c, and $(\alpha\eta)^c$. Defining the differences in the α and $\alpha\eta$ values between urea and its complexes by $\Delta\alpha=\alpha^u-\alpha^c$ and $\Delta(\alpha\eta)=(\alpha\eta)^u-(\alpha\eta)^c$,

$$\Delta\alpha = (n^u-n^c) - (2/3)(\sigma^u_{NH}-\sigma^c_{NH}) - (1/3)(\sigma^u_{NC}-\sigma^c_{NC}), \qquad \Delta(\alpha\eta) = (\sigma^u_{NH}-\sigma^c_{NH}) - (\sigma^u_{NC}-\sigma^c_{NC}) \tag{4}$$

are obtained. Letting

$$\Delta n = n^u - n^c, \ \Delta\sigma_{NH} = \sigma^u_{NH} - \sigma^c_{NH}, \text{ and } \Delta\sigma_{NC} = \sigma^u_{NC} - \sigma^c_{NC} \tag{5}$$

then

$$\Delta\alpha = \Delta n - (2/3)\Delta\sigma_{NH} - (1/3)\Delta\sigma_{NC}, \qquad \Delta(\alpha\eta) = \Delta\sigma_{NH} - \Delta\sigma_{NC}. \tag{6}$$

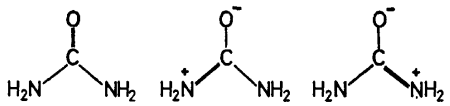
Assuming that in these complexes $\Delta\sigma_{NC}=0$ and $|e^2Qq_p/h|=9$ MHz, the $\Delta\sigma_{NH}$ and Δn values can be calculated from Eq. 6; the values are listed in Table 2.

TABLE 2. THE $\Delta\sigma_{NH}$ AND Δn VALUES IN THE MOLECULAR COMPLEXES OF UREA

Complex	$\Delta\sigma_{NH}$	Δn
$OC(NH_2)_2 \cdot HNO_3$	−0.04	−0.01
$OC(NH_2)_2 \cdot H_3PO_4$	−0.03	−0.01
$OC(NH_2)_2 \cdot (COOH)_2$	−0.01	0
$OC(NH_2)_2 \cdot NH_4Cl$	+0.01	0

The $\Delta\sigma_{NH}$ values in the HNO_3 complex, the H_3PO_4 complex, and the $(COOH)_2$ complex are negative. This indicates that the hydrogen bonds in these complex are stronger than that in urea. On the contrary, in the case of the NH_4Cl complex, the $\Delta\sigma_{NH}$ value is positive so that the hydrogen bond in this complex is weaker than the bond in urea.

On the other hand, the Δn values in the HNO_3 complex and the H_3PO_4 complex are positive, that is, the electron populations in the lone-pair orbitals of the nitrogen atoms in the urea molecules are smaller in these complexes than in urea. This may be explained by the decrease of the lone-pair electron population due to the formation of the hydrogen bond such as N···H–N, in which the lone-pair orbital of a nitrogen atom is used, or to the increase of the contribution of the following resonance structures II and III. However,



I II III

the hydrogen bond such as N···H–N is absent in these complexes[5,6] and urea.[10] Therefore, the decrease of the lone-pair electron is attributed to the latter reason. The resonance structures bring about the increase of the double-bond character in the N–C bond in the urea molecule, resulting in the shortening of this bond. The average N–C bond lengths are 1.314 Å in the HNO_3 complex and 1.322 Å in the H_3PO_4 complex, whereas the value in urea is 1.352 Å.[11] Furthermore, it is considered that the negative charge on the oxygen atom of the urea molecule increases and the C–O bond becomes longer because of the contribution of the structures II and III in these complexes. From these combined effects, the strong hydrogen bond, O···H–O, is formed. In fact, the C–O distances in urea, the HNO_3 complex, and the H_3PO_4 complex, are 1.260, 1.298, and 1.281 Å, respectively. The O···H–O dis-

tances in the HNO_3 complex and the H_3PO_4 complex are 2.596 and 2.424 Å respectively, and the acidic protons are attached to the carbonyl oxygen atom of urea.

Electron Spin Resonance Study on the Difference of Structure in Diastereomeric Nitroxyl Radicals

Yashige KOTAKE* and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 5, 1980)

Electron spin resonance spectra of nitroxyl radicals bearing two asymmetric carbons were observed. The radicals were produced by the abstraction of a hydrogen atom from ethers and amines by photoexcited benzophenone, followed by spin trapping with phenyl-*N*-*t*-butylnitrone. The spectra showed the presence of two radical species assignable to diastereomers in most cases. The presence of isomers was seen more clearly in ESR spectra of radicals produced from ethers than those from amines. The origin of the different ESR parameters of the isomer was discussed in detail and it was concluded that the functional group on β-carbon acts as a group of proximity to nitroxyl function. The difference of the electronegativity of the atom in each functional group causes the difference of the extent of the separation of isomers. The effects of proximity groups on observed ESR parameters are concluded to be the same as the solvent effect.

Diastereomers have chemically different properties. Different spectroscopic properties are also found, which are caused by the difference in the interaction of substituents.

As for free radicals having two chiral centers, it is possible to identify each diastereomer by ESR spectroscopy. Jonkman *et al.* detected the difference of hyperfine structure (hfs) in nitroxyl radicals having two asymmetric carbons on both sides of the nitroxyl function.[1] Also, Laroff *et al.* observed the difference of hfs in anion radicals from both ascorbic and araboascorbic acid.[2] However, the difference has not been discussed in relation to the structure of the radical because of the difficulty in systematic production of radicals.

Recently, it was pointed out that the spin trapping reaction using phenyl-*N*-*t*-butylnitrone (PBN, *N*-benzylidene-*t*-butylamine *N*-oxide) is an effective way of producing nitroxyl radicals having two asymmetric carbons on one side of the nitroxyl function.[3] In the case of spin adducts produced from alcohol, a clear separation of hfs of the isomer was detected in an aprotic solvent; this was attributed to the formation of an intramolecular hydrogen bond. In the present study the difference of ESR parameters was also observed in open chain diastereomeric nitroxyls.

The condition which should be fulfilled for the detection of the difference in ESR parameters in an open chain diastereomeric nitroxyl radical is that the substituents attached to the asymmetric carbons should be bulky. The nitroxyl radicals produced by the addition of the radical formed by the abstraction of a hydrogen atom from an etherial compound have an alkoxyl group on β-carbon. Also, those from amines have amino or alkylamino group on β-carbon. In these radicals most of the substituents on β-carbon are bulky. In addition, there is no functional group to form tight hydrogen bonding.

The notable experimental result shown in this report is that the separations of isomers in spin adducts from ethers were much larger than those from amines. Moreover, the reproduction of the spectrum by the spectrum simulation showed that the difference of the g-value and hfs of $^{14}N(A_N)$ play a dominant role in giving the characteristic overlapped spectrum pattern. The hfs of β-H ($A_{\beta H}$) depends on the magnitude of the dihedral angle, which is directly derived from the steric conformation. The g-value and A_N depend on the electronic and steric structure of nitroxyl group. Thus, the result was interpreted by the difference of the dipole moment of CO bond and CN bond when they act as a group of proximity to the nitroxyl group. This leads to the conclusion that the difference of g- and A_N-value in stereoisomer of spin adducts from ether is based on the difference in the distance between oxygen atom and nitroxyl group. The effect of a proximity group is shown to be the same as the solvent effect on nitroxyl radicals.

Experimental

Approximately 10^{-4} mol PBN and 10^{-4} mol benzophenone was dissolved in 1 cm^3 ether and amine. The solution was packed into a pyrex ampoule having an ESR sample tube as a side arm and was degassed by the freeze-pump-thaw method. Radicals are produced by the irradiation of UV light from an 1 kW mercury arc.[3,4] The period of irradiation was 5 to 10 min, depending on the yield of radicals.

The PBN used was purified by the sublimation technique. Benzophenone was recrystallized twice from a petroleum ether solution. Guaranteed grade ethers were treated with potassium hydroxide to remove peroxy derivatives and were dried over Na–K alloy. Amines were distilled and stored over potassium hydroxide. The ampoule were charged with ether or amine by vacuum distillation.

The solvent effect on the spectral pattern was examined in some cases with the use of same technique as described elsewhere.[3]

The hfs and g-value were determined by use of aqueous solution of potassium peroxylamine disulfonate buffered with 0.2 M K_2CO_3 solution. The solution was packed in a capillary tube and attached on the sample tube, ESR spectra being recorded simultaneously. The g-value and ^{14}N hfs have been reported to be 2.005560 ± 0.000004[5] and 13.091 ± 0.004,[6] respectively. Computer spectrum simulation was applied to analyze the overlapped spectra.

Results and Discussion

Ether. It is well known that photoexcited benzophenone abstracts hydrogen on the carbon adjacent to the etherial oxygen.[4–10] When one applies the spin trapping reaction with PBN, the assignment

of the resulting radical is sometimes ambiguous because of the absence of the hfs from the trapped group. However there have been some examples in which the hfs from the trapped group appears.[11] Also, the ENDOR study of spin adducts has clearly shown the presence of the hfs from trapped groups.[12] In the present experiment, the spin adducts from anisole showed the hfs of methylene proton in phenoxymethyl group. Therefore, it is reasonable to assign the nitroxyl radicals as spin adducts of a radical hydrogen abstracted from the carbon adjacent to the etherial oxygen.

The ethers chosen as radical sources are symmetric to avoid a system which would produce two different radicals to be trapped. The reaction scheme for the production of the nitroxyl radical is as follows:

$$(RCH_2)_2O \longrightarrow R\dot{C}HOCH_2R$$

$$R\dot{C}HOCH_2R + \text{Ph-CH=N}(\text{O})\text{-}C(CH_3)_3 \longrightarrow \text{Ph-}\overset{*}{C}H(\text{R-}\overset{*}{C}H\text{-OCH}_2R)\text{-N}(\dot{O})\text{-}C(CH_3)_3 \quad (1)$$

The formed radical should have an open chain structure because there is no donative hydrogen which is capable of forming an appreciable intramolecular hydrogen bond. The fact that the hfs of β-hydrogen was very insensitive to the change of solvent from aprotic to protic shows the absence of intramolecular hydrogen bonds.

Figure 1A shows a typical ESR spectra observed in the etherial system. In tetrahydrofuran, the spectrum shows an asymmetric pattern due to the presence of two radical species. These are reproducible by means of spectrum simulation by overlapping two ESR spectra which have four different parameters, namely $A_{\beta H}$, A_N, g-value, and linewidth. The stick spectrum in Fig. 1A shows the position of the ESR lines from each radical. Almost all ethers tried in this experiment gave ESR spectra which showed the presence of two radical species which have different hfs and g-value. The result of the analysis for several etherial spin adducts are listed in Table 1.

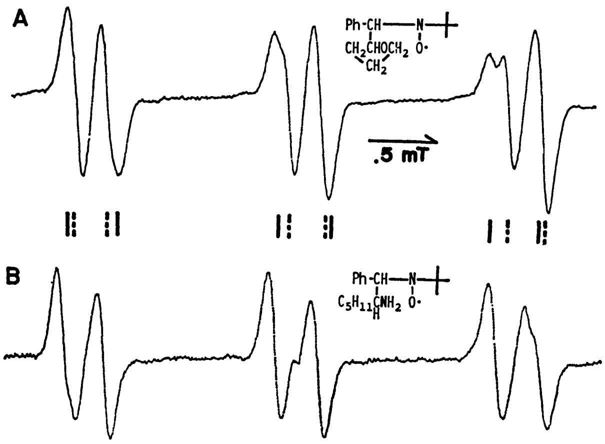

Fig. 1. ESR spectra of nitroxyl radicals produced by spin trapping with PBN.
A: From tetrahydrofuran, B: from *n*-hexylamine. Stick spectrum shows the line position of spectrum A.

In order to confirm that the overlapped spectrum is due to two asymmetric carbons, some radical sources which cannot produce the spin adducts with two asymmetric carbons by reaction (1) were examined. Diisopropylether, anisole (Fig. 2A), and 1,3,5-trioxane were chosen for this purpose. All of the resulting spin adducts showed a symmetric line shape and can be assignable to single radical species.

Table 1 shows that the radical with larger $A_{\beta H}$ has smaller A_N and larger g-value. Therefore the resolution

a), b), c) Substituents in the structure shown as $\text{Ph-CH(R-C(R')-OR'')-N}(\dot{O})\text{-}C(CH_3)_3$. d) First set minus second set. 10^{-4} T corresponds to the g difference of 0.0007 at the observed external field. e) Maximum slope line width of Gaussian line shape used for spectrum simulation. f) $A_{\gamma H}=0.4\times10^{-4}$ T (2H).

of lines from each radical is the best for the high field doublet, as is noticed in the spectra of Fig. 1A. It is also noted that the ESR parameters do not largely depend on the difference of R′ and R″.

Amine. Photoexcited benzophenone also abstracts hydrogen on the carbon adjacent to each amino group.[13-15] To avoid the formation of spin adducts of different substituents from a single amine source, chosen secondary and tertiary amines have a symmetric structure in which alkyl groups are the same. The reaction scheme of the formation of the radical in a primary amine is as follows:

$$RCH_2NH_2 \longrightarrow R\dot{C}HNH_2$$

$$R\dot{C}HNH_2 + Ph\text{-}CH{=}N^{+}(O^{-}) \longrightarrow Ph\text{-}\overset{*}{C}H\text{-}N^{+}(O\cdot)\text{-}\overset{*}{C}(H)(R)\text{-}NH_2 \quad (2)$$

Figure 1B shows the typical recorder trace for the adduct from hexylamine. The difference in the ESR spectral pattern in diastereomer is small compared to the radical from ether. The results of the analysis using spectrum simulation are listed in Table 2. The difference of the ESR parameters of isomers is mainly characterized by the magnitude of $A_{\beta H}$. However, the difference within an isomer is very small when R and R′ are small substituents. Isopropylamine was chosen as a source of radical which cannot produce diastereomers. The ESR spectrum shows the presence of a single radical (Fig. 2B).

The solvent effect on the spectral pattern was also very poor in both protic and aprotic solvents, which showed that the structure of the alkylamino adduct is open chain.

Interpretation of the Difference of ESR Parameters in Isomer. By the inspection of the ESR parameters summarized in Tables 1 and 2, one can find some

contrast due to the difference of radical sources. The difference within each diastereomer is larger for the spin adducts from ether than those from amines. This is illustrated in Fig. 3 as the comparison of the ESR spectra of the adducts produced from dibutyl ether and dibutylamine. In spite of the similarity of the structure of the radical, the extent of the separation of the isomer in ESR spectra is very different. In particular, the difference of A_N and g-value can be noted from Table 1. It is also noted that the dependence of ESR parameters on the bulkiness of R, R′, and R″ is poor. The origin of the difference is discussed in connection with the steric structure of radicals.

Conformation of Radical: Though the radical has an open chain structure, the most probable conformation of the molecule can be specified because of the bulkiness of the substituents. Based on the fact that the magnitude of the $A_{\beta H}$ is 0.2 to 0.3 mT, the dihedral angle between C–H_β and the unpaired electron orbital is estimated to be around 70° to 80° by McConnell's $\cos^2\theta$ rule.[16,17]

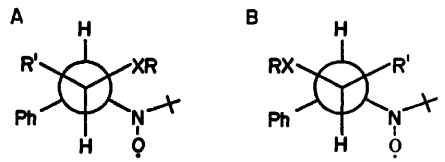

Fig. 4. Steric conformation of diastereomeric nitroxyls. Note the distance between X and N.

The most probable conformation around C_α and C_β is *trans* with respect to two hydrogens considering the smallest possible interaction between substituents.[18] Then the difference of the configuration in diastereomer produces the difference of the conformational structure, as illustrated in Fig. 4. It is noted that in one stereoisomer (Fig. 4A) the distance between XR and NO is closer than in the other. In the structure shown in Fig. 4, the dominant steric interactions between substituents are (R′-Ph) and (XR-NO) for Fig. 4A and (R′-NO) and (XR-Ph) for Fig. 4B. The repulsive interactions among (XR-Ph) and (R′-Ph) are effective for the determination of the equilibrium conformations which cause the characteristic $A_{\beta H}$ for each radical. In contrast, the interactions shows (XR-NO) and (R′-NO) should be effective not only in determining the conformation but in changing the electronic structure of the nitroxyl group. The change of the electronic state of nitroxyl group reflected on the g-value and A_N.

By taking into account the fact that the bond angles of C–O–C and C–N–C are around 110°, the total structures of the spin adducts from dialkyl ether and dialkylamine are very similar. In spite of such similarities of the structure, the extents of the separation of the ESR parameters are very different.

It is now almost clear that the difference is caused by the presence of oxygen and nitrogen atoms in the side chain of each radical. The difference of the magnitude of the perturbation from oxygen and nitrogen decides the difference of the spectral pattern.

Proximity Effect on Nitroxyl Group: As has been discussed by many investigators, the solvent effects on the ESR parameters of nitroxyl radicals can be explained qualitatively by the amount of contribution from each resonance structure shown below:

$$\underset{\text{I}}{\text{N-O}\cdot} \rightleftharpoons \underset{\text{II}}{\dot{\text{N}}^{+}\text{-O}^{-}}.$$

The effect of increasing the dipole moment of the solvent results in the increase of the contribution from structure II. This also explains the result of the present experiment: If one replaces the dipole moment of the solvent by the bond moment[19] of the proximity group, the larger bond moment of C–O bond explains that the separation of the isomer in the spin adducts from ether is larger than in those from amines which are perturbed by the bond moment of C–N.

The present experimental result of the solvent effect on A_N and g-value also supports the interpretation. The shifts of A_N and g-value are almost the same for the isomer in various solvents. Also, $A_{\beta H}$ did not change appreciably by the solvent. As a result the manner of the overlap of the two spectra of isomer did not change. This shows that the interaction which determines the spectral pattern is an intramolecular one which acts in a way additive to the solvent effect.

The solvent effect on the ESR parameters of the nitroxyl radicals has been analyzed on a molecular orbital basis. Kawamura *et al.* thoroughly described the solvent effect on g-value and A_N of di-*t*-butyl nitroxyl radical on the basis of a molecular orbital treatment.[20] As regards the A_N of the present system the effect of the neighboring group on each nitroxyl function can be explained by a simple MO scheme. The inspection of Dreiding model tells us that the hetero atom (X) in Fig. 4B is very close to the p orbital of nitrogen atom. The simplest MO feature of nitroxyl group is that the three electrons are in orbitals derived from linear combinations of the nitrogen and oxygen 2p orbitals. The bonding orbital is occupied by two electrons and the antibonding orbital is occupied by the unpaired electron. The effect of the nearby electronegative group on the 2p atomic orbital of the nitrogen atom is identical to the decrease of the absolute value of the Coulomb integral of the nitrogen. Consequently, the nitrogen character of π^* orbital increased, resulting in the increase of the A_N. The extent of the increase depends on the electronegativity of the hetero atom in the neighboring group. Therefore, the larger separations of the isomer in the adducts from ether than in those from amines can be explained.

Moreover the discussion above makes the assignment of the isomer possible. The isomer which has larger A_N value is assignable to the structure shown in Fig. 4B.

In alkylamino adduct the presence of diastereomer was detected clearly when the higher alkylamine was chosen as the radical source. The inspection of Table 2 tells us that the difference of g-value was small and the spectrum pattern was characterized mainly by the difference of β-hydrogen hfs. It is concluded that steric hindrance is the main cause of the separation in alkylamino adduct.

Liposomal Membranes. IX. Fluorescence Depolarization Studies on *N*-Dansylhexadecylamine in Liposomal Bilayers

Kiyoshi Iwamoto and Junzo Sunamoto*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received August 9, 1980)

A fluorescent probe, *N*-dansylhexadecylamine (DSHA), was found to aggregate in aqueous media by monitoring the emission maximum, relative intensity, and polarization of fluorescence as functions of solvent polarity and probe concentration. In aqueous methanol, the *critical solvent polarity* for DSHA at a given concentration to form self-aggregates corresponded to 57% (v/v) aqueous methanol, while the *critical aggregate concentration* for the probe was 2.3×10^{-6} M in 50% aqueous methanol. In liposomal bilayers, the dansyl moiety seemed to be localized in a polar region close to the surface of membranes. Fluorescence characteristics of DSHA in liposomes as a function of incubation temperature revealed the phase transition of liposomal bilayers, which was almost consistent with those previously estimated by other methods. As the salt concentration was increased up to about 1.5 M, DSHA in liposomes underwent the phase separation and formed self-aggregates even in liposomal bilayers.

In recent years fluorescence techniques have been extensively applied to study on the dynamic and static nature of biological membranes,[1] liposomes,[2] and aqueous[3] or reversed micelles.[4] Since the rotation rate of fluorescent probes closely relates to the resistance offered by the microenvironment against the mobility of the probes,[5] fluorescence depolarization provides useful information about the apparent "microviscosity" in terms of the environmental resistance. Shinitzky and Barenholz have recently studied on the fluidity and phase transition characteristics of single-walled and multilamellar liposomes of synthetic phospholipids using 1,6-diphenyl-1,3,5-hexatriene (DPH) as a probe to know the nature of hydrophobic domain of liposomal bilayers.[6,7] On the other hand, to obtain the information about the surface of membranes 8-anilino-1-naphthalenesulfonate (ANS) has been employed.[8] Romero *et al.* adopted *N*-dansyloctadecylamine(DSOA) to obtain a knowledge about the less polar region of phospholipid bilayers,[9] since the fluorophore is localized in the vicinity of the phospholipid ester moiety.[10] The present studies have been undertaken using *N*-dansylhexadecylamine (DSHA) to measure the fluidity and microenvironment of the region close to the hydrophilic surface of bilayers as a function of incubation temperature or ionic strength. Besides these problems, in conjunction with Nagaraj and Balaram's postulate that the dansylated hydrophobic peptides aggregate in water,[11] we have studied also on the self-aggregation of DSHA by measuring fluorescence spectra and depolarization at very low concentrations in aqueous media and in bilayers as well.

Experimental

Materials. Egg yolk lecithin (egg L) was isolated and purified from fresh egg yolk as described before.[12,13] Dipalmitoyl-DL-α-phosphatidylcholine (DPPC) was purchased from Sigma Chemical Co., St. Louis, Mo. Phospholipids employed were found to be pure on TLC (a precoated silica gel plate, Spotfilm, Tokyo Kasei, Tokyo) as developed with chloroform/methanol/water (65 : 25 : 4, by vol).[12,13] *N*-Dansylhexadecylamine was prepared according to the method described in literature[9,14] with minor modification. A mixture of hexadecylamine (482 mg, 2.0 mmol) and dansyl chloride (593 mg, 2.1 mmol) was refluxed for 14 h in 20 ml of chloroform containing 3.0 ml of triethylamine. The resulting reaction mixture was washed six times with 50 ml of 10% aqueous citric acid and then twice with 50 ml of water, and the chloroform layer was dried over anhydrous magnesium sulfate. Removing off the solvent *in vacuo* gave a pale yellow crystalline mass, which was recrystallized from ether; yield, 540 mg (57%); mp 59—61 °C. Found: C, 70.16; H, 9.88; N, 5.77%. Calcd for $C_{28}H_{46}N_2O_2S$: C, 70.85; H, 9.77; N, 5.90%. IR (KBr): ν_{NH}, 3290; ν_{C-H}, 2930, 2860, 1592; ν_{S-O}, 1320 and 1150 cm^{-1}. Other organic and inorganic reagents were commercially available as analytical grade and used without further purification.

Preparation of Liposomes. Single-walled liposomes of egg L and DPPC were formed and isolated by the same method as that described previously.[12,15] Gel-filtration was carried out on a Sepharose 4B column (1.8×38 cm) equilibrated in water containing a given amount of sodium chloride. The concentration of liposomal suspension was determined as inorganic phosphate according to Allen's procedure.[16] The molar ratio of phospholipid to DSHA was in a range of 250—300.

Fluorescence and Depolarized Fluorescence Measurements. Fluorescence spectra and depolarization were measured by the essentially same procedures as those described before.[17,18] All the spectral measurements were run on a Hitachi 650-10S fluorospectrophotometer equipped with a thermoregulated cell compartment connecting to a Toyo Thermo Electric TE-104S.

The fluorescence polarization p is calculated by Eq. 1:

$$p = \frac{I_{VV} - C_f I_{VH}}{I_{VV} + C_f I_{VH}}, \quad (1)$$

where I is the fluorescence intensity and subscripts V and H refer to the vertical and horizontal orientations of the excitation (first) and analyzer (second) polarizers, respectively. C_f ($=I_{HV}/I_{HH}$) is the grating correction factor.[19] Depolarization measurements were run on a Union Giken fluorescence polarization spectrophotometer FS-501S using a sharp cut-filter Y-46 (Hoya Glass Works, Tokyo), of which cell compartment was connected to a Komatsu-Yamato Coolnics Model CTR-120. A Sord Microcomputer M 200 Mark II system was adopted to control the measurement conditions and to collect all the data.

Results and Discussion

Fluorescence Characteristics of DSHA in Homogeneous System. Both the emission maximum and intensity of DSHA were highly sensitive to solvents adopted as

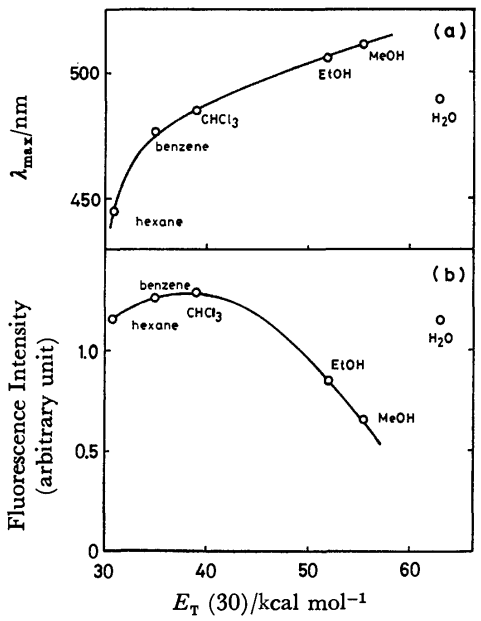

Fig. 1. Emission maximum (a) and relative intensity (b) of fluorescence from DSHA (8.6×10^{-6} M (1M=1 mol dm^{-3})) as a function of solvent polarity at 25.0 °C.

shown in Fig. 1. In apolar solvents, increasing the solvent polarity brings about a red shift of the maximum and a hypsochromic effect on the intensity. Interestingly, on the other hand, in polar protic solvents such as alcohols and water further increasing the solvent polarity causes a decrease in the intensity. In any event, the fluorescence characteristics of DSHA in water is rather different from those in organic solvents (Fig. 1).[9]

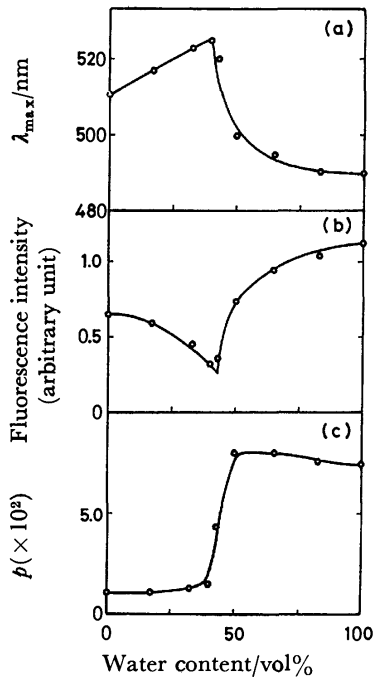

Fig. 2. Emission maximum (a), relative intensity (b), and polarization (c) of fluorescence from DSHA (8.6×10^{-6} M) in methanol as a function of water content at 25.0 °C.

When DSHA is excited at 340 nm in water, it emits the fluorescence at 487 nm. At first glance, this suggests that the microenvironment around the dansyl moiety of DSHA is close to that with the polarity of chloroform (Fig. 1). This is very interesting but unlikely. Figure 2 shows the maxima of fluorescence from DSHA in methanol as a function of water content. Up to 40% of water, the emission maximum first shifts toward a longer wavelength with an increase in the solvent polarity and further increasing the water content drastically shifts the maximum toward a shorter wavelength. Above 80% of water, it becomes almost constant (Fig. 2). The blue shift of the maximum means the translocation of the dansyl fluorophore from a polar environment to a less polar one, which means that DSHA may entangle by itself or form aggregates in aqueous media. On the basis of an evidence that a fluorophore-labeled peptide shows a blue shift of the emission maxima in an aqueous solution, Nagarj and Balaram have previously postulated an idea that peptides form micelles in water.[11] In order to confirm the self-aggregation of DSHA in aqueous media, hence, the fluorescence polarization p in methanol as a function of water content was measured (Fig. 3-c). The change of the p-value as a function of water content in methanol closely correlates with that of the emission maximum (Fig. 2-a). This suggests that DSHA molecules start to aggregate in methanol containing 43% (v/v) of water, giving rise to a decrease in the mobility. This point may be called the *critical solvent polarity* for the self-aggregation of DSHA at a given concentration. The relative intensity of fluorescence emission as a function of water content also reveals evidence for the aggregate formation of DSHA (Fig. 2-b). The self-aggregation is effected also by the DSHA concentration itself: for example, in 50% aqueous methanol the *critical aggregate concentration* for DSHA was found to be about 2.3×10^{-6} M by measuring the fluorescence spectra and depolarization. The *critical aggregate concentration* in methanol decreases with an increase in the water content.

Microenvironment around DSHA in Liposomal Bilayers. Various techniques such as NMR,[20,21] ESR,[22] and fluorescence spectroscopies[1,23] have been utilized so far to obtain information about the dynamic nature of lipid membranes. On the basis of the above results in homogeneous system where DSHA is sensitive enough to know the microscopic polarity and viscosity around the probe, in this work the fluorescence characteristics of DSHA in the liposomal bilayers were investigated. The emission maximum of DSHA in single-walled liposomes of egg L was 518 nm, while that in DPPC liposomes was 512 nm at 25.0 °C as seen in Fig. 3. The slight difference between the two liposomes must come from the difference in the state of bilayers at the temperature adopted; that is, single-walled liposomes of egg L are in a liquid-crystalline state,[24] while DPPC liposomes are in a gel state at 25.0 °C. In any event, using the ruler established for the microenvironmental polarity (Fig. 1), for both liposomes the fluorescent moiety of DSHA seems to be located in an environment with a polarity close to that of methanol. This means that the

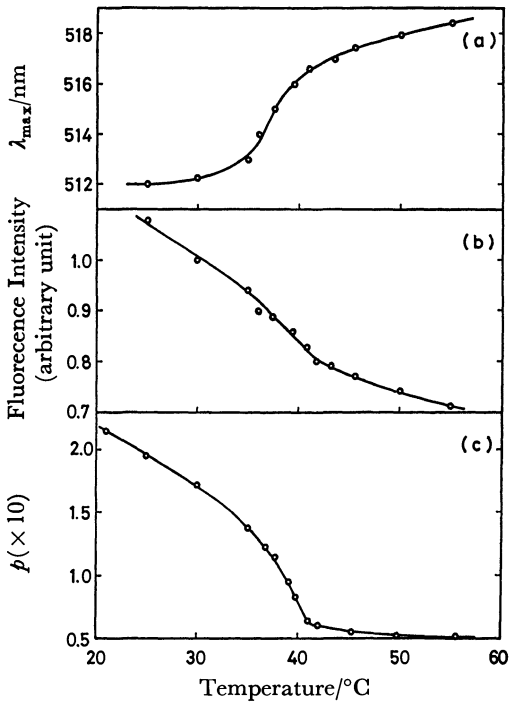

Fig. 3. Emission maximum (a), relative intensity (b), and polarization (c) of fluorescence from DSHA (4.0×10^{-6} M) as a function of incubation temperature in DPPC single-walled liposomes (8.0×10^{-4} M) dispersed in 0.1 M aqueous sodium chloride solution.

dansyl moiety is in a region close to the surface of liposomal bilayers.[9] At 55.0 °C the emission maximum of DSHA in DPPC single-walled liposomes shifts to 518.5 nm. At the temperature, DPPC liposomes are in a liquid crystalline state.[25]

Figures 3-a and -b show the maximum and relative intensity of fluorescence from DSHA in DPPC single-walled liposomes as a function of incubation temperature. Raising the incubation temperature of liposome suspension causes a red shift of the emission maximum and a simultaneous decrease in the quantum yield. Especially at temperatures between 35 and 45 °C, an abrupt change in the fluorescence characteristics was observed. The temperature-emission maximum profile reveals the phase transition between the gel and liquid crystalline states of bilayers (Fig. 3-a). Table 1 gives the phase transition temperatures determined by different techniques for DPPC liposomes, which indicates

Table 1. Phase transition temperature of DPPC single-walled liposome estimated by various techniques

Method	Phase transition temp/°C	Reference
(1) DSHA fluorescence polarization	38.4±0.5	this work
(2) DSHA fluorescence spectrum	39.0±0.5	this work
(3) Dilatometry	39	26
(4) DPH fluorescence polarization	36.4±0.5	7
(5) DPDL excimer formation	36.7±0.5	17
(6) Differential scanning calorimetry	36.9±0.9	25

that the phase transition temperature estimated in this work is in good agreement with those by other methods. As expected,[32] although the fluorescent moiety of the probe is located in the vicinity of the membrane surface, it is considerably sensitive to the phase transition of the hydrophobic domain. Table 1 also reveals that there may exist a temperature lag in the phase transition between hydrophilic and hydrophobic parts of bilayers: Methods 1—3 may reflect mostly the phase transition at the surface of bilayers, while Methods 4—6 at the deep hydrophobic domain. The most acceptable model for the conformation of phospholipid headgroups is that the headgroups lie parallel to the surface of bilayers and engage to the intermolecular electrostatic interaction with neighboring phospholipids.[27] It is well known that the motion and conformation of lecithin headgroup also change with the phase transition.[28,29] Above the phase transition temperature, the inter-headgroup interaction of lecithins is weakened and the distance between phosphorous atom and choline methyl group is far apart,[30,31] resulting in an increase in the hydration of the membrane surface.[27,32] Therefore, the red shift of emission maximum of DSHA is interpreted in terms of the increase in the polarity of the microenvironment around the probe. The correlation between the incubation temperature and the relative intensity of fluorescence was consistent with that between the temperature and the emission maximum (Fig. 3-b).

In order to monitor the mobility of the probe in egg L and DPPC single-walled liposomes, the fluorescence polarization p was measured (Figs. 3-c and 4). The increase in the fluidity of lipid membrane with raising the incubation temperature is reflected on the increase in the mobility of DSHA in bilayers. The fluorescence polarization-temperature profile also revealed the exsistence of a phase transition in the DPPC liposomes (Table 1 and Fig. 3-c). For the egg L liposomes, on the other hand, no abrupt change in the profile is observed (Fig. 4), since the egg L liposomes are in a liquid crystalline state over the temperature range adopted.[24]

The effect of ionic strength in the bulk aqueous phase on the fluorescence characteristics of DSHA in liposomal bilayers is of much interest. Above and below 1.5 M

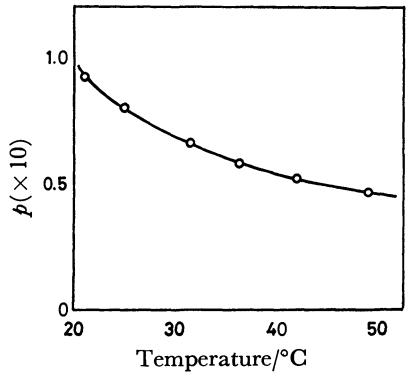

Fig. 4. Fluorescence polarization of DSHA (3.5×10^{-6} M) in egg L single-walled liposomes (8.0×10^{-4} M) dispersed in 0.1 M aqueous sodium chloride solution as a function of incubation temperature.

Photoelectrochemical Properties of $CdSnO_3$ and $LaRhO_3$ Electrodes in Aqueous Solutions

Hiroshi YONEYAMA,* Toshikazu OHKUBO, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received August 21, 1980)

$CdSnO_3$ sinter electrodes work as n-type photoanodes with a high electrochemical stability in alkaline solutions. A thin film $LaRhO_3$ electrode prepared on a substrate platinum plate shows p-type photoresponse in aqueous solutions, giving rise to the hydrogen evolution with a fair stability. The threshold wavelength beyond which no photoresponse appears is *ca.* 700 nm for the former and 950 nm for the latter electrode.

The photovoltaic effect that appears on illumination of semiconductor electrodes immersed in electrolytes can be utilized to convert solar energy into either electricity or chemical substances, or the both in photoelectrochemical cells or heterogeneous chemical reaction systems.[1-8] The stability of semiconductors is essential in these applications, but most of semiconductor materials are unstable in aqueous solutions, suffering either anodic decomposition or the cathodic decomposition or the both.[9] Although a principle for stabilizing unstable semiconductor electrodes has been proposed,[10,11] semiconductors of high electrochemical stability are still desirable for elimination of any corrosion problem of photoelectrodes.

Until now several n-type semiconducting oxides have been found to possess high stabilities under anodic bias,[3,4] but searches for another stable materials are still important in the following two respects. (1) Through such investigations, a material of high electrochemical stability and negative flat-band potentials, which are essential for photoanodes in water photolysis cell,[1] may be found. (2) Besides photoelectrodes in photoelectrochemical cells, semiconductors are useful as photocatalysts. Studies in this area are steadily growing. In order to find an efficient heterogeneous reaction system using photocatalysts, investigations on the activity of photocatalysts for an objective reaction are desirable to be done for as many photocatalysts as possible, because the prediction of the activity of photocatalysts is impossible to be done in the present status. The kind of stable semiconductors is quite limited and not much enough to satisfy such requirements. By these reasons, we have been investigating photoelectrochemical properties of a variety of oxides. This paper describes our findings obtained by the investigations with such purposes.

We have found that $CdSnO_3$ having the n-type conductivity shows a high electrochemical stability with a large photoresponse which is comparable to α-Fe_2O_3, although a result showing the photoresponse has recently been reported.[12] Besides this material, we have observed that a $LaRhO_3$ thin film prepared on a substrate platinum plate shows a fairly stable p-type photoresponse in aqueous solutions. It has already been reported from studies in solid states that both $CdSnO_3$[13] and $LaRhO_3$[14] possess semiconductivity, but no conductivity type has been reported. As for the former material, however, the n-type conductivity is suggested from the finding[12] that it shows the photoresponse under anodic bias. To our knowledges, no optical properties of $CdSnO_3$ and $LaRhO_3$ have been investigated to date.

Electrochemical stabilities of these materials cannot be predicted in advance. In order to do this, we need knowledges on flat-band potentials and energy gaps of these materials.[10,11] The flat-band potentials can in principle be estimated by combining the energy gap value and the bulk electronegativity of the material[15,16] which is calculated by employing the Nethercot's hypothesis.[17] The lack of knowledge on the energy gap of $CdSnO_3$ and $LaRhO_3$, however, makes it impossible to take such an approach. In the present study, therefore, basic properties has been obtained.

Experimental

The preparation of $CdSnO_3$ was made in a manner similar to that reported by Smith.[18] Reagent grade CdO and SnO_2 powders in a molar ratio 1 : 1 were mixed in an agate mortar, and pressed into 13 mm diameter and 1 mm thickness. The pressed disc was then fired at 1000 °C for 6 h in air. According to X-ray diffraction patterns of the prepared oxide, it consisted of a $CdSnO_3$ single phase. The prepared oxide sinter was then subjected to water proofing in the following manner. The sinter was immersed in 1% polystyrene in benzene, and evacuation was made until no gas bubble was evolved from the sinter surface, followed by heating up to 100 °C to evaporate benzene. After repeating such water-proofing procedures several times, the surface of the sinter was gently polished with #2000 emery papers to remove off surface-covered polystyrene. Indium was then evaporated onto the one end face and an electrical lead wire was attached there. Finally, the sinter was mounted in a glass tube with epoxy resin to serve as an electrode.

$LaRhO_3$ was prepared on a substrate Pt plate. The Pt plate was polished with #1500 emery papers, followed by immersion in aqua regia. After boiling in a mixed solution of NaOH and Na_2CO_3 as a defatting procedure, it was washed with de-ionized water. 0.1 mol·dm^{-3} solutions of $LaCl_3 \cdot 7H_2O$ and $RhCl_3 \cdot 3H_2O$ were mixed with the same volume, and the mixed solution was applied to one side of the Pt plate in five successive coatings to give 1.2×10^{-5} mol of metal/cm^2. After each coating, the solution was dried at *ca.* 100 °C in a drying oven. The sample was then pre-heated at 480 °C for 1 h to decompose the chlorides, followed by firing at 1100 °C for 34 h in air. X-Ray diffraction peaks of the prepared sample were composed of reported diffraction peaks of Pt and $LaRhO_3$.[19] The back face and edge portions of the substrate Pt were coated with silicone adhesive(Silicone Sealant, Shinetsu Chemicals) to serve as an electrode.

Polarization measurements were carried out by using a Nikko Keisoku model DPGS-1 potentiogalvanostat. A 500 W super high pressure mercury arc lamp was used as a light

source except where measurements of action spectra of photocurrents were carried out. The action spectra were obtained with monochromatic light which was obtained by using a 500 W xenon lamp as a light source and a grating monochrometer (JASCO, model CT-25), and were not corrected for the intensity variation of the lamp-monochrometer output. Electrode capacitance *vs.* potential relations were obtained by using the bridge method as described previously.[20]

Results and Discussion

Photoelectrochemical Properties of $CdSnO_3$ Electrodes. The resistivity of the prepared samples was in a range between 1 and 10 Ω cm, as determined by the four probe method. Figure 1 shows steady state current-potential curves of the prepared electrode in 1 mol·dm^{-3} NaOH and 0.5 mol·dm^{-3} H_2SO_4. Also given in this figure are current-potential curves obtained with illumination of chopped light at 2 Hz in a mixed solution of 0.5 mol·dm^{-3} acetic acid and 0.5 mol·dm^{-3} sodium acetate. It is seen in this figure that the onset potential of the anodic photocurrents shifts towards the negative direction with a decrease in acidity, as usually observed at other oxide semiconductor electrodes.

Shottky-Mott plots of electrode capacitance *vs.* potential relations are given in Fig. 2. Although a large frequency dispersion is observed in the plots, the potentials which are obtained by extrapolating $1/C^2$ to the potential axis are in good agreements with each other between 1 and 5 kHz. Therefore, the flat-band potential determined by such plots, which is *ca.* 0.3 V *vs.* SCE in 0.5 mol·dm^{-3} H_2SO_4 and *ca.* −0.4 V *vs.* SCE in 1 mol·dm^{-3} NaOH, is of significance. The onset potential of the anodic photocurrents, given in Fig. 1, is in rough accord with the determined flat-band potentials.

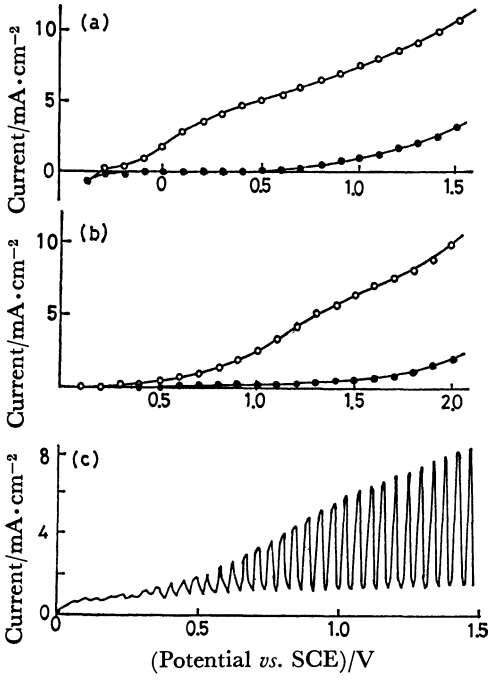

Fig. 1. Current-potential curves of $CdSnO_3$ electrode in (a) 1 mol·dm^{-3} NaOH and (b) 0.5 mol·dm^{-3} H_2SO_4 under steady state conditions, and (c) 0.5 mol·dm^{-3} acetic acid+0.5 mol·dm^{-3} sodium acetate with illumination of chopped light at 2 Hz.

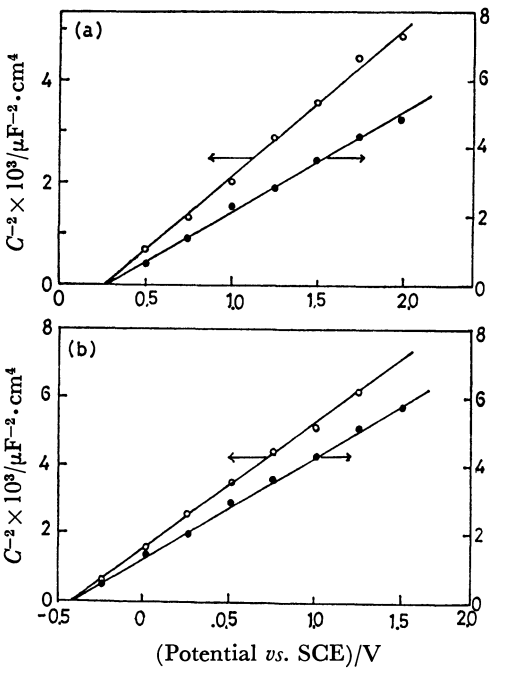

Fig. 2. Schottky–Mott plots of electrode capacitance *vs.* potential relations in (a) 0.5 mol·dm^{-3} H_2SO_4 and (b) 1 mol·dm^{-3} NaOH.
Frequency chosen; ○: 1 kHz, ●: 5 kHz.

By anodic polarization in 0.5 mol·dm^{-3} H_2SO_4, the electrode surface was gradually changed from yellow to white, suggesting that the electrode is unstable in acidic solutions. X-Ray diffraction patterns of the color-changed surface showed the existence of SnO_2. Similar observations have recently been reported for Cd_2SnO_4 electrodes.[21,22] In alkaline solutions, however,

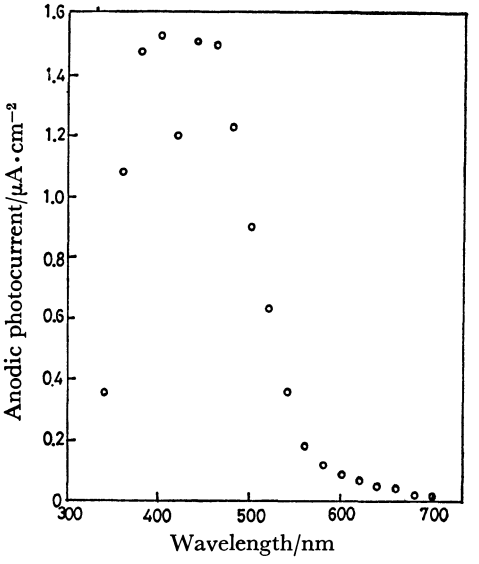

Fig. 3. Action spectrum of anodic photocurrents at $CdSnO_3$ electrode at 0.5 V *vs.* SCE in 1 mol·dm^{-3} NaOH.

the electrode was found to be fairly stable. The anodic polarization to give the total charge of 9.86 C in 0.2 mol·dm^{-3} NaOH caused anodic dissolution of the electrode less than 0.1% of the current efficiency, as determined by atomic absorption analysis of dissolved cadmium. The rest of the charge was believed to be consumed in the evolution of oxygen.

An anodic photocurrent spectrum obtained in 1 mol·dm^{-3} NaOH at 0.5 V *vs.* SCE is shown in Fig. 3, from which the response to light of wavelengths shorter than 700 nm is appreciable. A hollow in the action spectrum, observed in wavelengths between 400 and 440 nm, is believed to be due to the intensity variation in monochromatic light which is characteristics of the xenon lamp. If the assumption is made that the photoresponse is due to band-band transitions, the bandgap of $CdSnO_3$ is then obtained to be 1.77 eV.

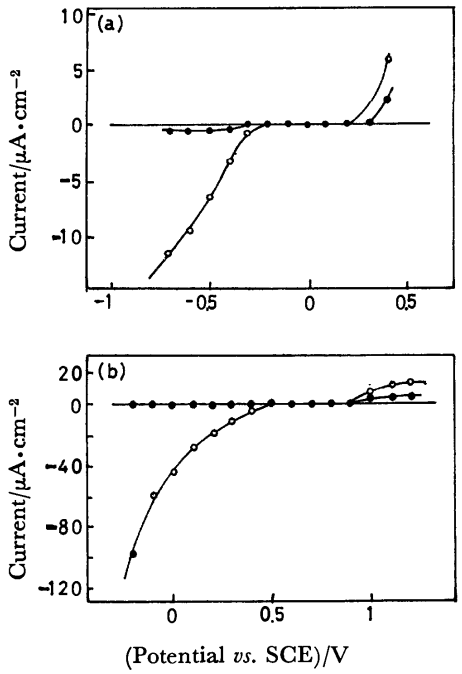

Fig. 4. Steady state current-potential curves of $LaRhO_3$ electrode in (a) 1 mol·dm^{-3} NaOH and (b) 0.5 mol·dm^{-3} H_2SO_4.

Photoelectrochemical Properties of $LaRhO_3$ Prepared on the Substrate Pt Plate. Figure 4 shows current-potential curves of the prepared electrode in 1 mol·dm^{-3} NaOH and 0.5 mol·dm^{-3} H_2SO_4. As this figure shows, noticeable photoresponses appear in the cathodic branch. A result obtained for a stability test is given in Fig. 5. As shown in this figure, the photocurrent usually showed a spike at the instant of the on- and off-time of illumination. The appearance of the spike seems to be due to charging currents in capacitive components of the electrode which is not well known at present. It is seen in Fig. 5 that the cathodic photocurrent is so stable as to give almost the constant photocurrent with polarization for as long as 30 min.

Among a variety of oxides, Cu_2O is known to show p-type photoresponse.[10,23] However, this material is

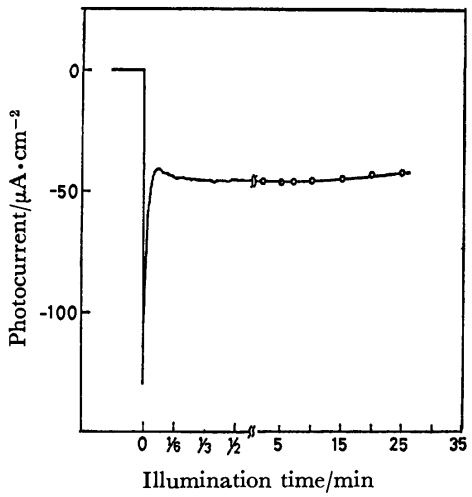

Fig. 5. Stability test of cathodic photocurrent at $LaRhO_3$ electrode at 0 V *vs.* SCE in 0.5 mol·dm^{-3} H_2SO_4.

quite easily decomposed by both anodic and cathodic polarizations. Compared to this material, $LaRhO_3$ showed no such a serious instability. Judging from the stability of photocurrents shown in Fig. 5, a large part of the cathodic charge consumed during the electrolysis for 30 min must concerned with the evolution of hydrogen. There will be of no doubt, however, that the hydrogen evolution on oxide surfaces must be accompanied with their reduction more or less. A slight decrease in the photocurrent in Fig. 5, observed after the electrolysis for 15 min, may be connected to such an electrode reduction, but still $LaRhO_3$ will be useful as a photocathode at least in aqueous solutions containing another electroactive species besides proton and water if the redox potential of the species is more positive than the hydrogen electrode potential.

An action spectrum of the cathodic photocurrent is shown in Fig. 6. Effects of the intensity variation of monochromatic light are again reflected in the action spectrum in the wavelengths between 400 and 440 nm and between 800 and 950 nm. If the threshold wavelength of the electrode, 950 nm, is assumed to be

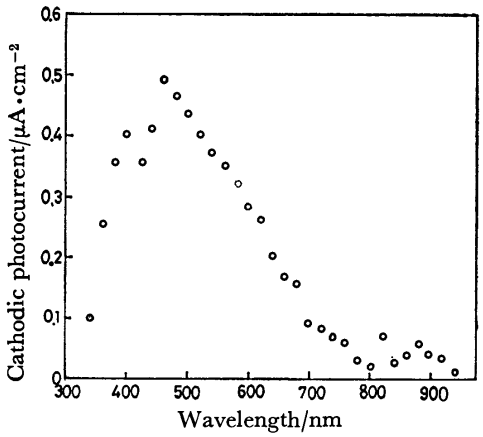

Fig. 6. Action spectrum of cathodic photocurrent at $LaRhO_3$ electrode at 0 V *vs.* SCE in 0.5 mol·dm^{-3} H_2SO_4.

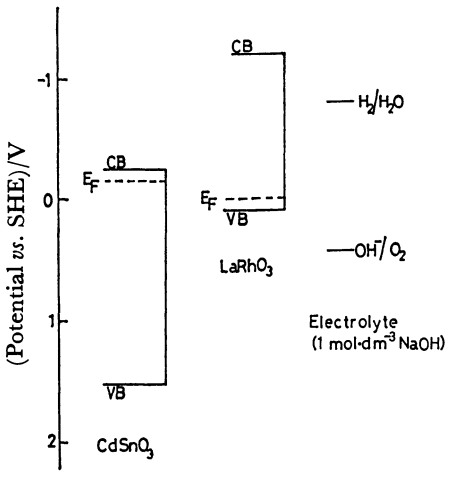

Fig. 7. Energetic correlation between electrodes and 1 mol·dm^{-3} NaOH.
CB, VB, and E_F denote the conduction band, the valence band and the Fermi level of the electrode.

determined by the bandgap of the material, it will then be 1.35 eV.

Energetic Correlation of the Electrode and Electrolytes. Figure 7 shows energetic correlations of $CdSnO_3$ and $LaRhO_3$ electrodes to the hydrogen and oxygen electrodes in 1 mol·dm^{-3} NaOH (pH=13.8). For illustration of this figure, the followings are assumed. (1) The Fermi level of the electrodes locates at 0.1 eV below the conduction band edge for $CdSnO_3$ and above the valence band edge for $LaRhO_3$. (2) The flat-band potential of $LaRhO_3$ electrodes is equal to the onset potential of the cathodic photocurrents.

As shown in this figure, these materials do not efficiently work as photoelectrodes in water photolysis cells, because the efficient photoelectrodes must have both of the energy levels of the hydrogen and oxygen evolution reactions within their bandgaps.[1] In this respect, photoelectrochemical properties of these materials are unsatisfactory. However, these semiconductors may find application fields as photocatalysts in aqueous solutions. An important point lies in that these are superior to other stable semiconductor materials in the point of spectral response to solar energy.

Vacuum UV Photoelectron Intensity of Gaseous Compounds. II. Experimental Processes of Determination of Differential and Partial Photoionization Cross Sections

Yohji ACHIBA,*,† Tomoko YAMAZAKI, and Katsumi KIMURA†

Institute of Applied Electricity, Hokkaido University, Sapporo 060

†*Institute for Molecular Science, Okazaki 444*

(Received September 11, 1980)

Experimental processes recently developed to determine differential and partial photoionization cross sections of molecules are described in detail, based on photoelectron intensity measurements using a gaseous binary mixture of a sample with a standard gas. The quantities obtained here in these processes are 1) relative photoelectron peak heights, 2) normalized photoelectron spectra, 3) relative photoelectron band areas, and 4) differential and partial photoionization cross sections. Corrections are made for electron collecting efficiency. In connection with the photoelectron intensity determination, we propose here a method of obtaining the mole ratio of the components of a binary mixture entered into the ionization chamber of a photoelectron spectrometer. Satisfactory results on partial photoionization cross sections have been obtained for several testing samples.

In molecular photoelectron spectroscopy, much attention has been devoted to studies of ionization energies rather than photoelectron intensities, so that its quantitative character is still very poor. It seems quite important to study relative photoelectron intensities from molecule to molecule not only analytical points of view but also theoretical points of view. If intensity-normalized spectra for a number of molecules are obtained with respect to a certain peak of a standard molecule, photoelectron spectroscopy will strengthen its ability as an analytical tool. On the other hand, the band intensity for each photoelectron band is closely associated with the partial photoionization cross section or the branching ratio which is the probability of producing a specific ionic state, so that experimental intensity data are important for testing theoretical models of photoionization processes.

Previously we have reported an essence of our photoelectron intensity determination, together with some preliminary results of its application to simple molecules.[1] Since then we have been developing the system using a mini-computer based data-processing system.

The purpose of the present paper is to describe our detailed processes of intensity determination which were not reported in our previous paper.

Most of photoelectron intensity works published so far have been limited to relative band intensities within molecule for various molecules.[2-4] Concerning relative band intensities among different compounds, only several works have been published in which rare gas atoms and several simple molecules are treated.[5-9] This may be partly due to serious requirement for the knowledge of various instrumental parameters in comparing photoelectron intensities among different molecules.

Partial photoionization cross section of a molecule can be determined by combining the total photoionization cross section and branching ratios. The total photoionization cross section has traditionally been obtained from optical absorption measurements,[10,11] while the branching ratio can be obtained from photoelectron intensity measurements. Combining optical absorption data with photoelectron intensity data, Blake and Carver[12,13] earlier obtained partial photoionization cross sections (as a function of the incident photon energy) for several simple compounds. Samson[10] has proposed a method of using a double ionization chamber to obtain total photoionization cross sections, and they have determined partial photoionization cross sections for several simple molecules at various photon energies. This is probably the most orthodox method of determining the partial photoionization cross section.

Kemeny *et al.*[8,9] have first shown the use of photoelectron intensities of binary mixtures to determine partial photoionization cross sections of the rare gas atoms (Ar, Kr, and Xe), using a relation of the inverse square root of mass to determine mole fractions of the binary mixture. However, such correction may not be always valid for molecules, especially for large molecules. It seems to be important to determine experimentally the real mole fractions of each binary mixture entered into the ionization chamber of a spectrometer.

In order to obtain partial photoionization cross sections for various molecules, we have recently developed our own experimental system applicable to a wide range of molecules, which is somewhat similar to that of Kemeny.[8,9] In the present work we have established an experimental procedure of determining mole fractions of a binary mixture entered into the ionization chamber.

Principle of the Method

The differential photoionization cross section $I_j(\theta) = d\sigma_j/d\Omega$ for producing the jth ionic state in the solid angle $d\Omega$ at the angle θ for unpolarized light is related to the corresponding partial photoionization cross section σ_j by[10]

$$I_j(\theta) = (\sigma_j/4\pi)\{1-(\beta_j/4)(3\cos^2\theta-1)\}, \quad (1)$$

where θ is the angle between the incident photon, beam and the direction of photoelectron detection and β_j is the asymmetry parameter.

When photoelectron measurements are carried out with a pulse counting technique under conditions that the gas pressure is kept constant in the ionization chamber and electron scattering by the gas is not

significant, the number of counts per unit time at the jth photoelectron band may be expressed by

$$N_j \propto I_0 n S I_j(\theta) C(E_j), \quad (2)$$

where I_0 is the incident photon flux, n is the density of molecules in the effective ionization volume, S is the sample factor, and $C(E_j)$ is the spectrometer collecting efficiency for electrons with kinetic energy E. The relation (2) is the same as represented by Gardner and Samson[14] except for S which should be taken into account since sensitivity of a channeltron depends more or less on gaseous samples.

For a binary mixture of A (standard) and B (sample), the following formula can be obtained from the relation

$$\frac{N_j^B}{N_1^A} = \frac{n^B I_j(\theta)^B C(E_j)^B}{n^A I_1(\theta)^A C(E_1)^A} \quad (3)$$

(2) under the same apparatus conditions. Using this relationship we can obtain the relative intensity of the jth band of B with respect to the first band of A. The advantage of this method is that the both instrumental factors I_0 and S are excluded in Eq. 3. If the mole fraction of the binary mixture and the electron collecting efficiencies are known, then differential photoionization cross sections I_j^B can be obtained relatively with respect to I_1^A. Furthermore, partial photoionization cross sections may also be evaluated relatively with respect to σ_1^A, if assymmetry parameter β_j^B are known. Therefore, differential and partial photoionization cross sections of molecules may be determined in absolute values on the basis of those of the standard molecule.

Experimental

Apparatus. A block diagram of the whole experimental apparatus is shown in Fig. 1. All of the gas inlet system, the data-processing system, and data-recording system have been constructed for the present purposes. A HeI photoelectron spectrometer with a hemispherical electrostatic analyzer is essentially the same as used previously.[15]

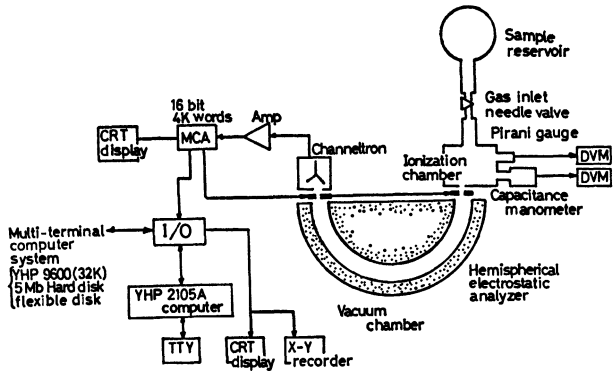

Fig. 1. A block diagram of the photoelectron spectrometer and the data-processing system.

The sample reservoir system is attached to the ionization chamber across a variable leak valve, consisting of three 2-l glass bulbs in which binary gaseous mixtures of the sample and the standard (mainly, N_2) were filled with different mole ratios at total pressures of about 50 Torr. The ionization chamber (20 × 20 × 30 mm) has a rectangular slit (0.4 mm × 10 mm) through which photoelectrons are emitted. The sample gas introduced into the ionization chamber is evacuated also through this slit. The sample pressure in the ionization chamber was monitored with two kinds of different pressure gauges, one of which is an MKS Baratron pressure gauge (Model 220) and the other is an Edwards Pirani gauge (Model 11). Outputs of the two pressure gauges were fed into the data processing system.

Photoelectron measurements were carried out by varying accelerating/retarding voltages on the analyzer entrance slit in synchronization with the channel-advance clock of the multichannel analyzer. Pulse signals detected by a channeltron electron multiplier were preamplified and shaped, and then counted by a multichannel analyzer with 16 bit-4K words. Intensity data stored in the multichannel analyzer were then transferred to a minicomputer (Model YHP 2105A) through input-output interfaces (I/O) for further data processing. Numerical data of normalized photoelectron spectra were stored in a floppy disk through an online-multiterminal computer system (Model YHP 9600) of the Institute of Applied Electricity, Hokkaido University.[16] In this computer system, the programming is allowed in only FORTRAN language by using some PROMs for code conversions.

Determination of Mole Fraction. In the present gas inlet and outlet systems, it is considered that the mole fraction of the binary mixture in the ionization area differs from that in the gas reservoir. This is probably true for commonly used photoelectron spectrometers. (In such a gas flowing system there may be some deviation in the mole fraction from the law of the inverse square root of the mass.)

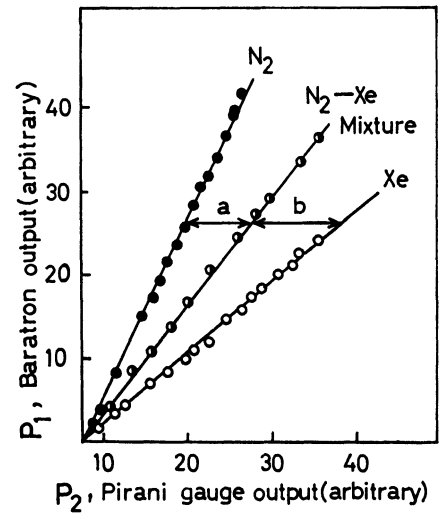

Fig. 2. Plots of the Baratron and Pirani outputs measured for Xe, N_2, and Xe–N_2 mixture, indicating that the mole ratio in the ionization chamber is given by $a:b$. (The initial mole ratio of Xe to N_2 in the mixture in the gas reservoir was 1 : 3 in the present case.)

An example of the mole fraction determination is illustrated in Fig. 2, in which various output data of the Baratron gauge are plotted against those of the Pirani gauge in the case of a binary mixture of N_2 and Xe. The three kinds of plots in Fig. 2 show approximately linear lines with different slopes in the pressure range studied. The partial prassures of Xe and N_2 should be proportional to a and b in Fig. 2, respectively.

Electron Collecting Efficiency Curve. Since the electron collecting efficiency $C(E)$ depends on the photoelectron energy, it is necessary to construct a curve of $C(E)$ as a function of E

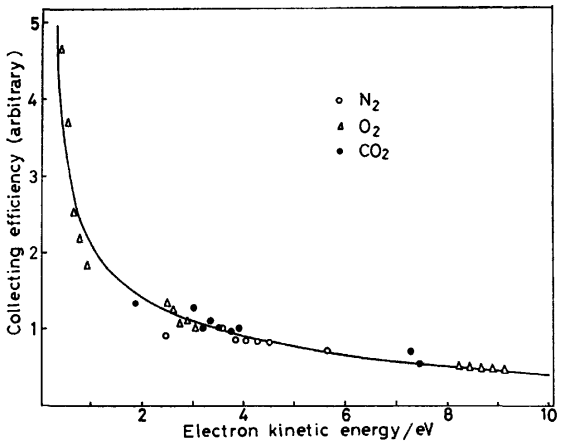

Fig. 3. The electron collecting efficiency curve of the photoelectron spectrometer used here. The solid curve was obtained by a least squares fitting.

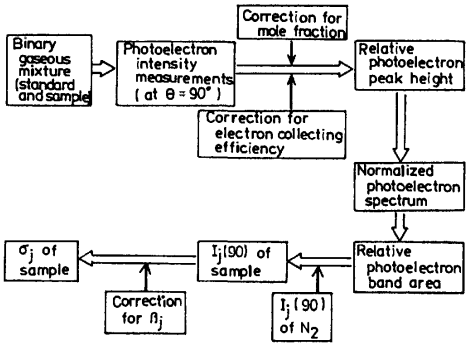

Fig. 4. A flowchart for the determination of differential and partial photoionization cross sections.

in order to obtain real photoelectron intensities. In the present work a curve of $C(E)$ was constructed by correlating our photoelectron peak intensities of N_2, O_2, and CO_2 with the corresponding data of Gardner and Samson.[17] Many typical data thus obtained for electron collecting efficiency are plotted in Fig. 3, the solid curve being obtained by a least-squares fitting with a fifth-order polynominal. The standard error involved is about 4% below 19 eV, while it is 15% above 19 eV.

Data Processing. All the processes included in the determination of differential and partial photoionization cross sections are shown by a flowchart in Fig. 4. Experimental data obtained from HeI spectrum in this scheme are : 1) relative peak heights with respect to the nitrogen first peak, 2) normalized spectra, 3) relative band areas with respect to the nitrogen first band, 4) differential photoionization cross sections, and 5) partial photoionization cross sections. During these processes, corrections are made for 1) the mole fraction of the binary mixture in the ionization area, 2) the electron collecting efficiency of the spectrometer, and 3) the photoelectron angular distribution. In the evaluation of differential and partial photoionization cross sections of molecules, a value of $I_1(90)=0.78\pm0.05$ Mb of the nitrogen first band was used as a reference, that is derived from Eq. 1 with $\sigma_1=8.4\pm0.3$ Mb and $\beta_1=0.68\pm0.05$ reported by Samson *et al.*[18]

Normalized Photoelectron Spectra. HeI 'normalized' photoelectron spectra were obtained with respect to the first photoelectron peak of N_2. Some examples of the normalized spectra are shown in Fig. 5. Photoelectron intensity measurements were carried out several times repeatedly for each photoelectron band with a reproducibility within 3%. Background

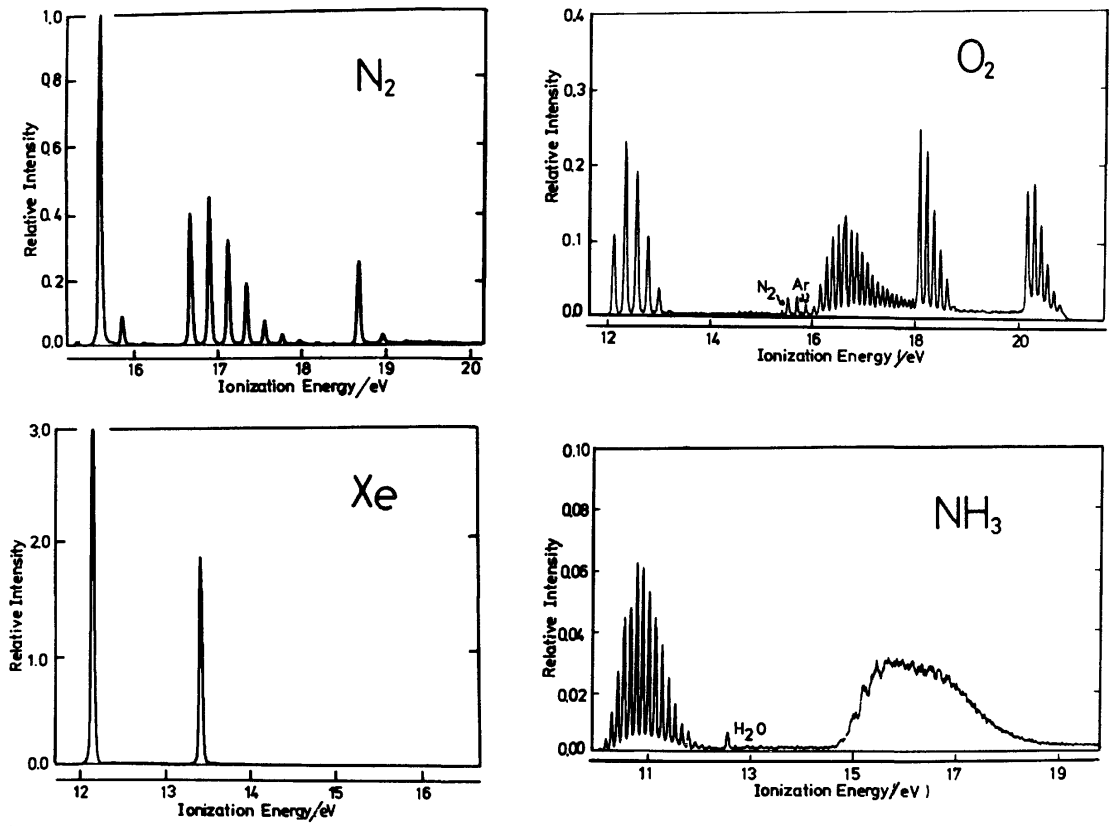

Fig. 5. HeI normalized photoelectron spectra obtained here for N_2, Xe, O_2, and NH_3. The first peak of N_2 is taken as unity. (The spectra were obtained at 90° with respect to the unpolarized light.)

signals were subtracted prior to the normalization process of HeI spectra.

Results and Discussion

Separation factors obtained here for several binary mixtures with an original mole ratio of 1 : 1 are summarized in Table 1, compared with those estimated from the law of the inverse square root of the mass. It is seen from Table 1 that there is a large discrepancy only in the case of benzene, while good agreements are obtained in the other cases, even in rather extreme cases of H_2 and Xe which largely differ from N_2 in the masses. For large molecules such as benzene, such mole fraction determinations are especially important. Probably a more or less similar situation occurs for other conventional spectrometers. It is desirable to construct a new apparatus with a molecular-beam gas inlet system for photoelectron intensity measurements, since the mole fraction separation of binary mixture completely obeys the law of the inverse square root of the mass of its component.

Table 1. Ratios of partial pressures of binary mixtures in the ionization chamber (the initial mole ratio in the gas reservoir is 1 : 1)

Mixture (A+B)	(p_B/p_A)[a)]	$(\sqrt{m_B/m_A})$[b)]
N_2+Ar	1.2	1.2
N_2+Kr	1.6	1.7
N_2+Xe	2.1	2.2
N_2+H_2	0.27	0.27
N_2+CH_4	0.81	0.76
N_2+NH_3	0.78	0.78
N_2+benzene	1.0	1.6

a) p_A and p_B are the partial pressures of A (N_2) and B (sample), respectively, in the ionization chamber. b) m_A and m_B are the masses of A (N_2) and B (sample), respectively.

Table 2. Partial photoionization cross sections (σ_j/Mb) of the rare gas atoms (Ar, Kr, and Xe) at 58.4 nm

Atom	This work	Samson and Cairns[19)]	West and Marr[20)]	Kemeny *et al.*[8,9)]
Ar	37.1	36.4	36.5	36.4
Kr	39.2	36.5	35.7	42.6
Xe	32.0	29.5		33.3

It should be mentioned that there are some gases such as CO which is very similar in the Baratron-Pirani curve to N_2. In such cases another gas instead of N_2 should be selected as a standard.

Partial photoionization cross sections obtained here at 58.4 nm are summarized in Table 2, together with available data.[8,19,20)] The purpose of studying the rare gas atoms in the present work is only to test the validity of the whole procedure proposed here. As can be seen from Table 2, satisfactory results have been obtained.

Only the HeI resonance line has been used in the present work. The purpose of this was to establish the whole system at first. Samson *et al.*[18)] have recently studied energy dependence of partial photoionization cross sections for several simple compounds by a combination of photoelectron spectroscopy and ion current measurements, using a variety of resonance lines through a monochromator. Brion *et al.*[21)] have also studied the energy dependence for several simple molecules, using an electron impact ionization technique. Synchrotron radiation is of course a very useful source to carry out such studies in wide energy range. The present method proposed here may be applicable to any light sources, and its future application to various molecules with synchrotron radiation seems to be very interesting.

The advantage of the present method is that the partial photoionization cross sections of molecules can be obtained from only photoelectron intensity measurements with a conventional photoelectron spectrometer. It is also desirable to carry out photoelectron measurements at the magic angle rather than at right angle as already pointed out by Samson.[10)]

The authors wish to thank Mr. Y. Shindo of Hokkaido University for his expert advice on the construction of the whole data processing system. They also wish to thank Dr. S. Katsumata for many useful discussion and Mr. S. Mitani and Mr. M. Morishita for their contributions to the initial stages of the photoelectron intensity measurements.

Redox Reaction of the Central Metal Ions Coordinated to Tetra-(*p*-sulfophenyl)porphine(TPPS). I. Photoreduction of Co(III)TPPS by Methanol and 2-Propanol

Keiichiro HATANO,* Kiyoko USUI, and Yoshitaka ISHIDA

Department of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467

(Received March 19, 1980)

Trivalent cobalt ion coordinated to 5,10,15,20-tetra(*p*-sulfophenyl)porphine (TPPS) in deaerated solution was reduced to the divalent ion on illumination of light with simultaneous oxidation of alcohols. The resulting divalent ion in the porphyrin was reoxidized by admission of dioxygen or air into the solution. It was found that the metalloporphyrin played a photocatalytic role in the autoxidation of alcohols. The kinetic study on the photoreduction revealed that the reduction rate of Co(III) followed the pseudo-first-order rate expression at 20 °C and pH 6.5 to 11.5 in the presence of excess methanol or 2-propanol. The observed rate constants were dependent on [alcohol] and/or pH. Possible mechanism for the photoreduction of Co(III)TPPS in the aqueous solution was discussed in terms of preequilibrium reactions of the axial ligation of substrates to the metalloporphyrin.

Very few papers have been published on the photoreduction reactions involving changes only in oxidation state of the central metal of metalloporphyrins,[1] although a number of papers have dealt with photohydrogenation of the peripheral porphyrin ring.[2] This paper describes a light-induced redox reaction of cobalt ion coordinated to 5,10,15,20-tetra(*p*-sulfophenyl)porphine (abbreviated as TPPS[3]) with the concomitant catalytic oxidation of alcohols, *i.e.*, photoreduction of Co(III)TPPS by alcohols and the subsequent oxidation of Co(II)TPPS by O_2 without the degradation of the porphyrin ring. A closely related "respiratory" reaction of manganese phthalocyanine and etioporphyrin was reported by Engelsma *et al.*[4] in relation to the photosynthesis reactions. Moreover, clarifying the oxidation state of metal ions, axial ligands, and reducing reagents involved in the photochemical reactions of metalloporphyrins in view of recent advances in the spectral and structural characterization of metalloporphyrins[5] seemed appropriate.

The present work was initiated with the aim of understanding the function-structure relationship of metalloporphyrin enzymes. When we observed the spectral changes induced by light in stock solutions of metalloporphyrins, we were intersted in the photocatalytic activity of them and the possibility of interconversion of photonic energy into chemical energy. Since metalloporphyrins, beside being the analogy of chlorophylls, have intense absorption bands in the visible and near ultraviolet region, they are expected to be good photosensitizers. Furthermore, the redox reaction of metalloporphyrins is of interest with respect to understanding the function of the biologically important hemeproteins such as electron transfer reactions in the photosynthesis. Metal-TPPS, which are easily soluble in water, appear to offer more information with respect to quantitative kinetic studies of the photochemical reactions.

In this paper we show that the cobalt ion in CoTPPS is a photo-catalytic active center in the autoxidation of alcohols. The kinetic results suggest that the manner of the axial coordination of alcohols is crucial to the photoreaction leading to the exclusive metal ion reduction.

Experimental

Materials. Sodium salt of TPPS ($TPPSNa_4$) was prepared as described by Fleischer *et al.*[6] Since Co(II)TPPS is oxidized slowly in aerobic aqueous solution, all the synthetic processes were carried out in nitrogen stream. TPPS was metallized in water using reagent grade $Co(CH_3COO)_2 \cdot 4H_2O$, and the water was removed by rotary evaporation from the reaction mixtures. The resulting solid was extracted with methanol. Co(II)TPPS was purified as a sodium salt by treatment of crude product in methanol with sodium methoxide several times.

Found: C, 43.28; H, 3.61; N, 4.25; S, 11.07%. Calcd for $CoTPPSNa_4 \cdot 8H_2O$, $C_{44}H_{40}N_4S_4O_{20}CoNa_4$: C, 43.18; H, 3.29; N, 4.58; S, 10.48%. UV-Visible spectra in pH 5.0 phosphate buffer; λ_{max}, nm(ε, $M^{-1}\,cm^{-1}$):[7a] 526 (1.2×10^4), 413 (2.1×10^5).

Co(III)TPPS formed in aqueous solution by autoxidation was found to be diamagnetic by electron paramagnetic resonance (EPR) at 77 K, but was not isolated. Spectral data of Co(III)TPPS; λ_{max} (ε), 538 (1.3×10^4), 424 nm ($2.7\times10^5\ M^{-1}\,cm^{-1}$) were observed in pH 5.0 phosphate buffer. The molar extinction coefficient at 424 nm diminished to $2.4\times10^5\ M^{-1}\,cm^{-1}$ in the pH 8.0 to 10.0.

Water was deionized through ion exchange resins and doubly distilled. 2-Propanol (spectroscopic grade, Katayama Chem. Co.) was used. Methanol of reagent grade was doubly distilled. Phosphate–borate (pH 6.0 to 9.2), borate-carbonate (pH 9.2 to 11.0), and borate-Hydroxide ($\geq$pH 11.0) buffers were prepared according to the reported methods[7b] with the ionic strength maintained at $\mu=0.1$. pH was adjusted with a pH meter (TOA, HM-7B model).

Instrumentation. Light irradiation was carried out with light source of (a) tungsten projection lamp (either unfiltered or filtered by Toshiba glass filters), or (b) four 700 W medium-pressure mercury lamps equipped with a plant growing apparatus 'phytotron'.

UV-visible absorption spectra and EPR spectra were recorded on a Shimadzu Model 200S spectrophotometer and a JEOL-PElX X-band spectrometer with 100 kHz field modulation, respectively.

Procedures. A solution of Co(III)TPPS in an appropriate buffer was degassed by three cycles of freeze-pump-thaw in a pyrex tube (i.d. 19 mm) with two side arms: a quartz cell (10 mm light pass) for spectral measurements and a container with a deaerated buffer solution of alcohols. The

alcohol solution was poured into the pyrex tube in the dark *in vacuo*, then irradiated by light. The irradiation was carried out at 20 °C in a water bath or an air bath of the phytotron. The intensity of the incident light in the phytotron measured by means of the trioxalatoferrate (III) actinometer[8] using the quantum yield 1.10 in the region 430—300 nm corresponding to the major absorption of the metalloporphyrin, was of the order of 7×10^{16} quanta/ml min. The quantum yield for the present reactions was obtained by one of two methods; (a) spectrometric method using the ratio of absorbed quanta to the incident light intensity (derived by comparison of the actinometer irradiated by the light passed through a dilute Co(III)TPPS solution with that through water using a coaxial photolysis cell[9]), (b) measurement of the quantity of formaldehyde produced in the methanolic solution of about 10^{-2} M CoTPPS which was considered to absorb the full incident light.

Formaldehyde was detected by the chromotropic acid method[10] on a sample condensed from the photolyzed solution by vacuodistillation. Acetone was tested qualitatively by the nitroprusside method.

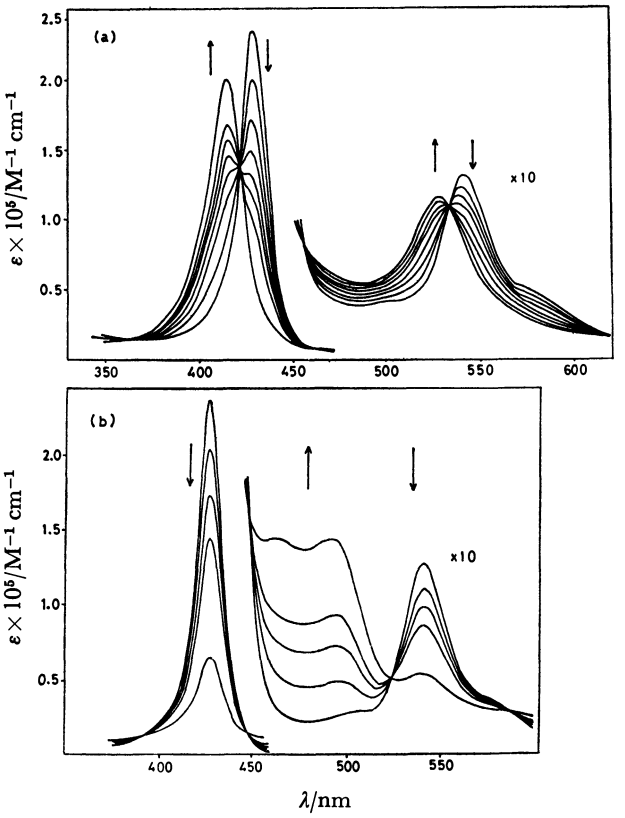
The kinetic studies on the photoreduction and oxidation reactions were carried out by monitoring the changes in the absorption spectra during the light illumination and after O_2 introduction.

Results and Discussion

Photoreduction of Co(III) TPPS. In aqueous solution, the electronic absorption spectra of Co(III)TPPS change slightly with the pH variation and addition of alcohols. However, the fact that the Lambert-Beer law holds for the solution over wide range of concentration (10^{-6} to 10^{-3} M) eliminates the possibility of the participation of oligomeric species in a dilute Co(III)-TPPS solution.[11] Although it is probable that there are several equilibrating reactions involving five- and six-coordination of various solvents and solutes to Co(III)TPPS, the magnitude of the spectral changes is too small and complicated to determine these species definitely.

The typical spectral changes during photolysis of the deaerated Co(III)TPPS solution in the presence of 0.67 M methanol (Fig. 1(a)) have distinct isosbestic points at 360, 419, 454, 534, and 615 nm. The new spectrum appearing on prolonged irradiation is identical with that of Co(II)TPPS prepared and measured in the absence of air.

In order to obtain more information on the nature of species in this photo-reaction, the process was followed by EPR. No signals were detected in the original solution of CoTPPS at 77 K (Fig. 2(a)). As the photolysis proceeds, a new spectrum, having approximate parameters of $g_\perp=2.4$, $g_{//}=2.02$, $A_\perp=55\times10^{-4}$ cm^{-1}, and $A_{//}=105\times10^{-4}$ cm^{-1}, increases its intensity (Fig. 2(b)). By the addition of imidazole to the solution, the spectrum altered into a prototype spectrum of the five-coordinate Co(II)porphyrins with a nitrogen base at the fifth position[12] (Fig. 2(c)). The results show that the photoreduction of CoTPPS occurs at the metal ion of the metalloporphyrin and that the original solution contains the diamagnetic Co(III)species[13] and no paramagnetic species such as Co–O_2. The product can be assigned to a five-coordinate Co(II)TPPS in



Fif. 1. Spectral changes of Co(III)TPPS during photolysis as a function of reaction times in the order shown by arrows; (a) 0, 20, 40, 60, 80, 100, 120, and 180 min in the 0.67 M methanol solution; (b) 0, 20, 40, 60, and 120 min in the 0.54 M 2-propanol solution. Both runs were carried out at pH 8.7 and 20 °C.

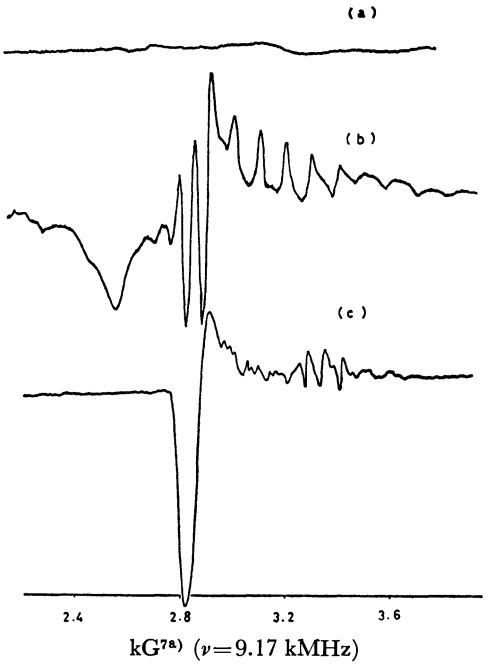


Fig. 2. The EPR spectra of CoTPPS species appearing in the photolysed solution (see text and note).

which the fifth position is occupied weakly by water (or methanol) consistent with the spectra reported by Walker.[14] Our EPR parameters of the product most resemble those of CoTTP(or CoTAP)–acridine system in her paper. The steric constraint of acridine (hindered base) is considered to prevent the metal ion from strong bonding to the base. Thus the EPR parameters should be similar to weakly bonded complexes.

The dependence of the photoreduction on the wavelength of the incident light was examined by setting glass filters in the light path from the projection lamp. The reaction rate resulting from light of 430 nm$>\lambda>$330 nm was compared with that of $\lambda>450$ nm and it was suggested that the light absorbed in the Soret region was more effective in driving the reaction than light in the visible region. However, an accurate determination of the quantum yields in the two regions has not been achieved.

The apparent quantum yield of the formaldehyde formation in degassed solution of *ca.* 10^{-2} M CoTPPS and 0.67 M methanol at pH 8.7 by 30 h irradiation was 0.9×10^{-3}. No gaseous products were detected manometrically in that run. The quantum yield of Co(II)TPPS determined by the spectrometric procedure was 2.2×10^{-3} in solutions of 10^{-6}—5×10^{-5} M CoTPPS and 0.67 M methanol at pH 8.7. The results are consistent with the following stoichiometric reaction within experimental errors. The lack of the evolution

$$2\,\text{Co(III)TPPS} + \text{CH}_3\text{OH} \xrightarrow{h\nu} 2\,\text{Co(II)TPPS} + \text{H}_2\text{CO} + 2\text{H}^+ \quad (1)$$

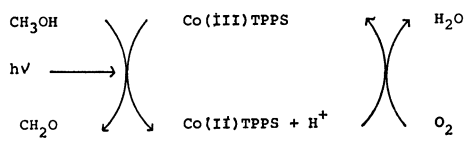
of molecular hydrogen also supports one electron photoreduction of Co(III) in this equation.

The primary and secondary alcohols, *e.g.*, methanol, ethanol, and 2-propanol, were found to be effective reducing reagents. However, t-butyl alcohol did not bring about the photoreduction. This suggests that the photooxidation of alcohols occurs with a proton elimination at α-carbon position.

Autoxidation of Co(II) TPPS. With O_2 or air introduction into the solution photolyzed, the spectrum of Co(II)TPPS returns to the initial Co(III)TPPS spectrum *via* the exact reverse course of the spectral changes in the photoreduction. The ultimate spectrum of Co(III) TPPS is restored with more than 95% of its initial intensity. The reaction must be the following autoxidation of Co(II)TPPS:[15]

$$2\,\text{Co(II)TPPS} + 1/2\text{O}_2 + 2\text{H}^+ \longrightarrow 2\,\text{Co(III)TPPS} + \text{H}_2\text{O}. \quad (2)$$

Therefore, the overall photochemical reaction is found to be the autoxidation of alcohols catalyzed by CoTPPS:



The kinetic study of the oxidation of Co(II)TPPS by O_2 reveals the following rate expression which is substantially identical to the analogous study reported by Stynes *et al.*[16]

$$-\text{d[Co(II)TPPS]}/\text{d}t = k'\text{[Co(II)TPPS][O}_2\text{]},$$

where k' is the observed rate constant. A value of 1.8×10^{-4} min^{-1} Torr^{-1} for k' was obtained in the aqueous 2-propanol (1.0×10^{-2} M) solution at 25 °C without buffer. This is comparable with 4.2×10^{-4} min^{-1} Torr^{-1} which is extrapolated from the reported result of the oxidation of CoTTP in toluene with 0.002 M imidazole at 23 °C.[16] It is surprising to obtain such apparently consistent data despite the vastly different properties of the solution and substances.

Other Photochemical Reactions of CoTPPS. In the absence of alcohols and/or organic amines such as piperidine, Co(III)TPPS in aqueous solution is considerably stable against light irradiation. In the case of methanol or ethanol as reducing agent, the photoreduction of Co(III) ion of the metalloporphyrin is predominant over wide range of pH and alcohol concentration [A]. The recovery of Co(III)TPPS, even after several cycles of the photoreduction-autoxidation, usually exceeds 70% of the initial amount. A drastic change in spectral aspects for the photoreaction is observed in solution containing relatively high concentrations of 2-propanol (10^{-1} M). The spectral changes shown in Fig. 1(b) also have some isosbestic points. However, the spectrum of the product shows no recovery to the spectrum of Co(III)TPPS by the admission of air into the cell. The monotonic decrease of the Soret band may be related to the degradation of peripheral porphyrin ring of CoTPPS; although the chemical characterization of the product has not yet been done. Meanwhile the Co(II)TPPS generated by photoreduction in the presence of 2-propanol was found to be stable against long irradiation of light. This rules out the stepwise photodegradation reaction *via* the formation of Co(II)TPPS. The degradation reaction seems to occur *via* a direct process from a Co(III) species formed in the high [2-propanol] solution. The formation of such a species in methanolic or ethanolic solution may be restricted by its stability constant.

Formaldehyde, acetaldehyde, and acetone in water did not function as the reducing reagents for the reaction.

Kinetic Experiments of the Photoreduction of Co(III) TPPS. The reaction rates of the photoreduction at 20 °C were determined by monitoring changes in the optical density at 424 nm (decrease) and 413 nm (increase) with complementary measurements in the visible region for high [Co(III)TPPS]. The different original intensity at 424 nm depending on the nature of solution did not affect the present kinetic treatment, since, during most kinetic runs, satisfactory isosbestic points were obtained. This is expected for a fixed distribution of various coordination states of Co(III)TPPS being reduced to one five coordinate Co(II) species. Two different kinds of photoreaction took place in certain ranges of [2-propanol]. The determination of the photoreduction rate in such cases has been done at the initial stage of the reaction where the conversion of Co(III)TPPS was less than 40% and the recovery by the autoxidation exceeded 85% of the initial intensity.

Plots of $\ln([\text{Co(III)TPPS}]_t/[\text{Co(III)TPPS}]_0)$ *vs.* time,

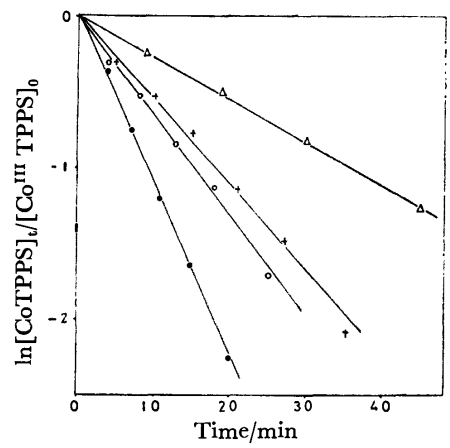


Fig. 3. The first-order rate dependence on Co(III)-TPPS for various methanol concentrations; (△) 1.67 M, (+) 3.21 M, (○) 4.29 M, (●) 6.25 M; in the solution of $[Co(III)TPPS]_0=6.6\times10^{-6}$ M and pH 9.7.

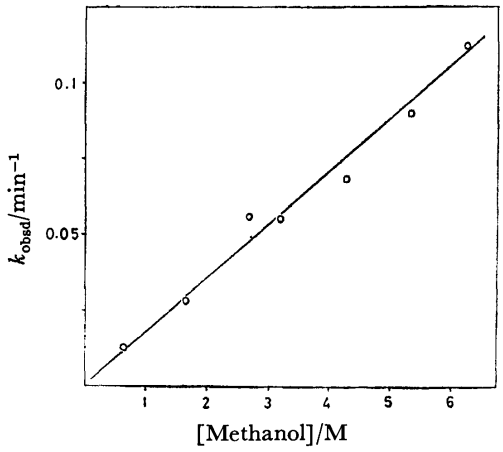

Fig. 4. The k_{obsd} *vs.* [methanol] plots. Conditions are the same as Fig. 3.

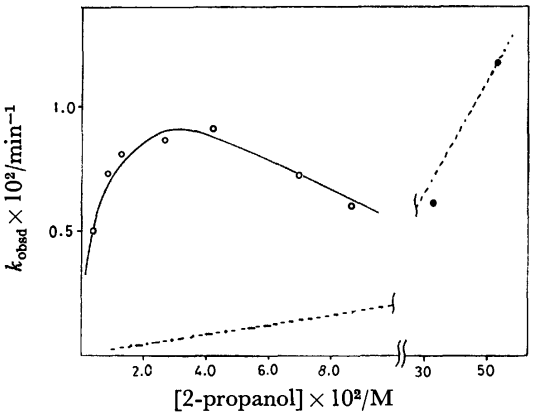

Fig. 5. The k_{obsd} *vs.* [2-propanol] plots, $[Co(III)-TPPS]_0=3.3\times10^{-6}$ M, pH 8.7. The (●) and dashed line denote experimental and estimated rate constants, respectively, for the degradation reaction.

where the subscripts denote time t and zero, are shown in Fig. 3. The linear relationship indicates a first-order rate dependence on Co(III)TPPS. Pseudo-first-order rate constants, k_{obsd}, were obtained from the slope of the plots, and found to be dependent on the concentration of alcohols and/or pH. The profile of k_{obsd} to [methanol] (Fig. 4) shows a first-order relationship to the methanol concentration. However, the dependence of k_{obsd} on [2-propanol] is unusual (Fig. 5). At low [2-propanol] (2×10^{-2} M), the dependence seems to be of first-order, decreasing toward zero to minus with increasing concentration. There is an obvious maximum in the k_{obsd} *vs.* [2-propanol] curve *ca.* $3—4\times10^{-2}$ M 2-propanol at pH 8.7. The photo-degradation reaction is appreciable at higher [2-propanol] than that corresponding to the maximum. However, the increase of the degradation rate (estimated from the data at high [2-propanol] by assuming the first-order dependence on the alcohol concentration) is not responsible for the decrease of photoreduction rate. The anomaly in the curve demonstrates that there are at least two coordination states formed by stepwise attachment of 2-propanol to Co(III)TPPS.

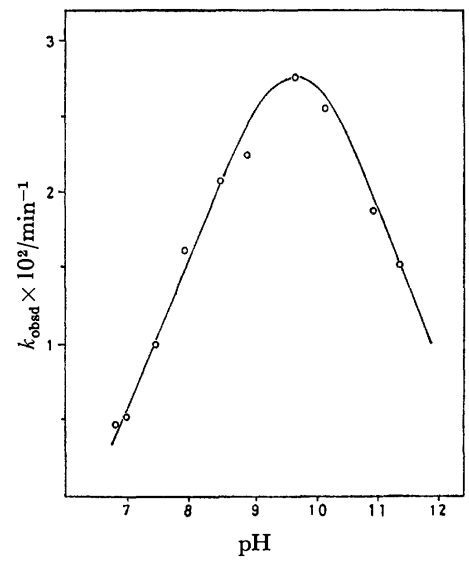

Fig. 6. The pH profile of k_{obsd}, $[Co(III)TPPS]_0=6.6\times10^{-6}$ M, [methanol]=1.67 M, ionic strength=0.1.

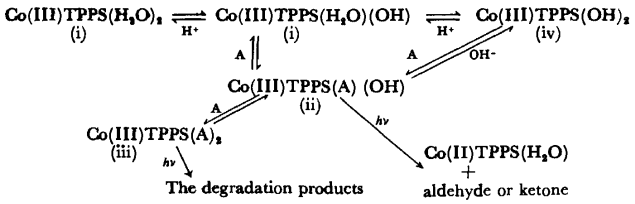
The k_{obsd} are also dependent on pH (Fig. 6). The profile of k_{obsd} is volcano-shaped in the solution of constant [methanol], having a peak around pH 9.5 to 10.0. Studies of the rate dependence on pH in 2-propanol solution were not carried out since the rates are very slow at low [2-propanol] where the first-order rate on the alcohol can be expected.

The kinetic studies imply that various coordination states of Co(III)TPPS presented in the aqueous solution behave differently toward light irradiation.

Preequilibrium Reactions in the Aqueous Solution. Both water and alcohol molecules are known to associate with some metalloporphyrins by the definitive X-ray structure determination.[17] However, the stability constants are seldom clear for such weakly bonded molecules owing to the difficulty of spectroscopic characterization of the complexes in solution. Let us assume that Co(III)TPPS has two axial sites to bind ligands, solvents and solutes. Participation of

dimeric metalloporphyrin species such as CoTPPS–O_2–CoTPPS[13] can be ruled out in dilute solution, since the first-order rate laws in cobalt metal are confirmed in both photoreduction and autoxidation processes in conjunction with the EPR evidence of Co(II)TPPS monomer. The observed rate dependence of the photoreduction on pH and [A] can be interpreted by a mechanism in which competitive ligation of alcohols, water, and hydroxide ion to the two axial sites occurs prior to the photoreaction. Accounting for these, we can classify coordination states of Co(III)TPPS in aqueous solution into at least four groups: (i) light-insensitive species formed predominantly in acidic solution and/or in the absence of alcohol, (ii) species to be photoreduced at the central metal ion, (iii) species to be degradated by light, which is appreciable at high [A], especially, [2-propanol], (iv) species which appear at high pH region and depress photoreactions.

Since a limited number of structural determinations[18] and reliable stability constants for Co(III)porphyrins ligated by weakly bonded molecules are available, we can only speculate about the coordination states of each species and the mechanism involving them. The key species for the photoreduction belongs to group (ii) and can be assigned to Co(III)TPPS(A) (OH) where A denotes a general alcohol. The substance is formed by coordination (or substitution) of alcohol and/or hydroxide ion to species (i) which are represented by Co(III)TPPS(H_2O)$_2$ and Co(III)TPPS(H_2O)(OH). Co(III)TPPS(A)$_2$ and Co(III)TPPS(OH)$_2$ may represent species (iii) and (iv), respectively. Beside the four representative species, there may be many other states and reactions in the actual solution, so that it seems neither feasible nor significant to analyse the kinetic data quantitatively. The following scheme may help elucidate the parts of kinetic data, *i.e.*, the presence of maxima (Figs. 5 and 6). The photoreduction is



considered to occur *via* formation of Co(III)TPPS(A)-(OH) located in the middle of the scheme. The rate constants, k_{obsd}, are dependent solely on the concentration of this particular species as a function of [A] and pH inasmuch as a constant quantum efficiency is imposed on the photoreduction of the species. Thus, the efficient photoreduction requires optimal control of pH and [A]. In methanolic solution, the equilibrium constant for the second step of methanol coordination is very small as compared with that of 2-propanol. This is rationalized by the photo-degradation reaction which occur *via* formation of bis-alcohol species. The degradation of CoTPPS in methanolic solution was almost negligible under the usual experimental conditions.

It is intriguing to note that the proposed mechanism involving two binding sites for substrates in the catalyst provides similar kinetic aspects to those of certain enzymatic reactions, *e.g.*, fumarase reaction although its active site is not metal ion[19a] and nitric oxide reductase reaction with NO.[19b]

The relative broad curve observed in the k_{obsd} *vs.* pH plot (Fig. 6) suggests that the mono-hydroxy attachment to Co(III)porphyrins is favorable in the pH region 8—11 which corresponds to hydroxide concentration 10^{-6}—10^{-3} M. Isolation of such a species may be possible in analogous system. The occupation of two OH ions on the axial sites is possible, since two CN anion ligands have been confirmed in the X-ray structure of FeTPP(CN)$_2$ anion.[20]

Mechanistic Consideration of the Photoreduction. The observed maximum value of the quantum yield of Co(II) is *ca.* 0.025 under the conditions [methanol]= 6.25 M at pH 9.7. The quantum efficiency[21] could be enhanced by increasing methanol concentration and we could predict the best efficiency to reach the order of 10^{-1} if the solubility of CoTPPS and other solutes allowed the conditions. The relatively high quantum yield observed or predicted suggests that the photoreduction conjugates with the most efficient deactivation of the metalloporphyrin *via* an allowed electronic transition state induced by light absorption in the Soret region. However, very low yield and short life, if any, of the luminescent excited state of Co(III)-porphyrins are known even in rigid media at low temperatures.[22] Consequently, the primary photochemical process of Co(III)TPPS can be attributed to the radiationless and direct chemical reaction from the excited Franck-Condon state of the coordinated complexes. An immediate assignment to this process is attained by the photodissociation of a proton at the α-carbon position of the coordinated alcohol molecule. However, such a dissociation reaction is considered to proceed fast with a fast reverse reaction. Thus the primary process can be treated as an additional preequilibrium reaction induced by light irradiation. In order to adjust the additional reaction and keeping consistency with kinetic data, especially, pH dependence, we could rewrite the process as an innersphere proton transfer of Co(III)TPPS(A)(OH).

The determining step of the quantum yield, which we assign to an intramolecular electron transfer from ligand to metal ion of the metalloporphyrin, can be placed after the primary processes. The speculations are summarized by formulation in the case of methanol as follows:

$$\text{Co(III)TPPS(CH}_3\text{OH)(OH)} \overset{h\nu}{\rightleftharpoons} \text{Co(III)TPPS(CH}_2\text{OH}^-\text{)(H}_2\text{O)}$$

$$\text{Co(III)TPPS(CH}_2\text{OH}^-\text{)(H}_2\text{O)} \longrightarrow \text{Co(II)TPPS(}\dot{\text{C}}\text{H}_2\text{OH) + H}_2\text{O.}$$

A following fast reaction is required to complete the stoichiometry of the photoreduction.

$$\text{Co(II)TPPS(}\dot{\text{C}}\text{H}_2\text{OH) + Co(III)TPPS(H}_2\text{O)(OH)} \longrightarrow 2\,\text{Co(II)TPPS(H}_2\text{O) + CH}_2\text{O}$$

(or any Co(III)TPPS)

To estimate the difference of free energies in the

photoreduction processes is of interest in relation to the possibility of photonic energy utilization. The free energy difference of overall reaction, *i.e.*, autoxidation of methanol to formaldehyde, is exothermic. The value is obtained from the thermodynamic standard data by ignoring solvation energy and estimating coordination energy of methanol as 10 kJ/mol. Based

$$CH_3OH + 1/2\,O_2 \rightleftharpoons CH_2O + H_2O$$
$$\Delta G = -150\ \text{kJ/mol}$$

on the standardization, $\Delta G=0$ for $H_2=2H^+ + 2e^-$ on a platinum electrode (SHE), the energy level of a hypothetical system, $CH_2O+2H^+ + 2e^-$ or CH_2O+H_2, can be put at 237 kJ/mol above the product level or 87 kJ/mol above the reactants level (Fig. 7). Since the electrochemical redox properties of CoTPPS have not yet been determined, the free energy difference in the Eq. 1 is estimated by the voltametric data of analogous complexes. The reported value of 0.32 V *vs.* the saturated calomel electrode (SCE) (0.59 V *vs.* SHE was presumed) for the anodic half-wave potential of CoTPP in butyronitrile was used.[23] Therefore, the energy level of the right-hand term of Eq. 1 is calculated as the difference between the hypothetical level by assuming 0.59 V for Co(III)TPPS$+e^-$=Co(II)TPPS and using the relationship, $\Delta G=-nFU=(-2)(96500)(0.59)=-114$ kJ/mol. Thus we have the free energy diagram shown in Fig. 7. The free energy difference of Eq. 1 is *ca.* −27 kJ/mol.

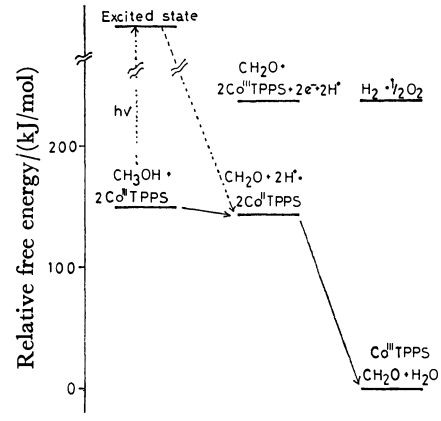


Fig. 7. Energy level diagram for photoreduction of Co(III)TPPS by methanol.

The semi-quantitative treatment leads to the conclusion that the present photoreduction of Co(III)TPPS may not acquire photonic energy in chemical forms, but merely the activation energy by light absorption. However, if there are other metal-TPPSes whose redox potentials are comparable to SHE, it may be possible to interconvert photonic energy into chemical one. We have observed that iron and manganese TPPS undergo similar photoreduction-oxidation reactions in alcoholic solution.

We thank Drs. A. Hanaki, H. Yamamoto, and T. Ozawa for EPR measurements and Prof. W. R. Scheidt for reviewing this manuscript before publication. This work was supported in part by a Grant-in-Aid from the Ministry of Educations, Science and Culture.

Studies on Mixed Chelates. XI. Syntheses and Comparative Study of a New Series of Mixed Nickel(II) Chelates with Halide and Pseudohalide Ligands[1)]

Naomi Hoshino, Yutaka Fukuda, and Kozo Sone*

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

(Received May 12, 1980)

A new series of mixed chelates of nickel(II), Ni(diam)(β-dik)X·nH$_2$O (X=halide or pseudohalide anion, n=0—2), was prepared, and their structures in solid state and in various organic solvents were studied. Most of the chelates were octahedral, many of them being obtained as mono- or dihydrates. When the solid chelates were heated at reduced pressure, the main reactions were dimerization (X=pseudohalide), dehydration (X=I), and disproportionation (X=Br or Cl). On the other hand, the chelates showed complicated structural changes in organic solvents, some of which were not observed in solids, depending upon the nature of X and the polar characteristics of the solvent.

We previously reported that the mixed nickel(II) chelate, Ni(tmen)(acac)NCS·nH$_2$O(n=0 or 1)† shows interesting structural changes in various organic solutions.[2)] In a solvent of poor coordination ability(1,2-dichloroethane=DCE), it exists as a square pyramidal 5-coordinate complex [Ni(tmen)(acac)NCS] in a very dilute solution. However, with increase in concentration it forms a 6-coordinate species, probably a dimer formulated as [(tmen)(acac)Ni$\overset{NCS}{\underset{SCN}{<\!\!>}}$Ni(tmen)(acac)]. In nitromethane, (=NM), ionic dissociation of these species leads to the formation of a small amount of square planar species [Ni(tmen)(acac)]$^+$. In more polar solvents, 6-coordinate solvated complexes such as [Ni(tmen)(acac)(Solv.)$_2$]$^+$ or [Ni(tmen)(acac)NCS(Solv.)] predominate.

A report was given on two related chelates, Ni(tmen)(acac)X·2H$_2$O(X=Br$^-$ or I$^-$).[1)] In this same study, we found that the bromide is thermally unstable, easily undergoing disproportionation by slight heating into [Ni(tmen)Br$_2$] and [Ni(tmen)(acac)$_2$], *i.e.* a tetrahedral 4-coordinate complex and an octahedral one. With the iodide, however, such disproportionation occurs only slightly, its main part being converted into [Ni(tmen)(acac)]I with the square planar cation by heating. When dissolved in DCE, both the bromide and iodide undergo disproportionation remarkably even at room temperature,†† but here again the ionization into [Ni(tmen)(acac)]$^+$ and X is favored in nitromethane.

We also prepared related complexes with other halide (Cl$^-$) and pseudohalide (NCO$^-$, NCSe$^-$, and N$_3^-$) ions. A comparative study of all these complexes is given in this paper.

† Abbreviations: diam=*N*-alkylated ethylenediamine such as *N*,*N*,*N*′,*N*′-tetramethylethylenediamine(tmen) or *N*,*N*-*N*,*N*′-triethylethylenediamine(Et$_3$en); β-dik=β-diketonate ion such as acetylacetonate(acac), benzoylacetonate(bza), or dipivaloylmethanate (dpm); X=halide or pseudohalide ions such as Cl$^-$, Br$^-$, I$^-$, NCS$^-$, NCSe$^-$, NCO$^-$, or N$_3^-$.

†† This view is different from that reported;[1)] for detail, see text.

Experimental

Preparation of the New Complexes. The general method of preparation adopted is shown in Scheme 1.

i) NCS-complexes: In addition to the complex Ni(tmen)(acac)NCS·nH$_2$O(n=0 or 1) reported,[2)] three new complexes Ni(tmen)(bza)NCS·H$_2$O, Ni(tmen)(dpm)NCS, and Ni(Et$_3$en)(acac)NCS·H$_2$O were prepared. In the course of preparation, crystals of [Ni(diam)(β-dik)$_2$] and [Ni(tmen)(NCS)$_2$] sometimes appeared first, obstructing isolation of the desired product. In general, the best yield could be obtained when the solution was concentrated at a relatively high temperature and quickly filtered after being cooled down to room temperature.

ii) NCSe-complex: Only Ni(tmen)(acac)NCSe·H$_2$O could be obtained. All operations had to be carried out under cooling: even at 25 °C, NCSe$^-$ ion tends to decompose, separating out red selenium. The decomposition also occurs when the isolated complex is heated gently in solid state or in solution, so that it must be kept in a freezer.

iii) NCO- and N_3-complexes: These complexes, both with tmen and acac, were hard to obtain in pure state; the products obtained by the general method were always impure, containing much ClO$_4^-$. Very small amounts of reasonably pure complexes were obtained when the filtrates of these trials were kept in a refrigerator for several months.

iv) Halide Complexes: In addition to the complexes Ni(tmen)(acac)X·2H$_2$O(X=Br$^-$ or I$^-$),[1)] Ni(tmen)(acac)Cl·H$_2$O, Ni(tmen)(bza) I·nH$_2$O(n=1 or 2), and Ni(tmen)(dpm)I·2H$_2$O were obtained. The two hydrates of the bza complex were obtained depending on the solvent for recrystallization, *i.e.* the dihydrate from methanol and monohydrate from an acetone-DCE mixture. The dpm complex loses its water easily in a desiccator or in dry open air, yielding a reddish orange, diamagnetic anhydrous chelate.

Chemicals. "Extra Pure" reagents and solvents were used. Nitromethane, DCE, acetone, and DMSO were distilled after being dried with Wako synthetic zeolite A-3.

Physical Measurements. Electronic spectra of solutions were obtained with Shimadzu MP-5000 and Hitachi 340 spectrophotometers, using quartz cells of 5 mm to 5 cm. Solid reflectance spectra were recorded with the latter instrument with a visible and near IR integrating sphere attachment, using BaSO$_4$ as a reference. Other instruments used in IR spectral, magnetic, and conductmetric studies were the same as those reported.[2)]

Scheme 1. Preparation of the complexes, Ni(diam) (β-dik)X·nH_2O (n=0, 1, or 2)

a) When X=NCS^- and diam=Et_3en, acetone or methanol should be used instead of DCE, and the solution must be kept in a refrigerator. b) When X=Cl^-, this method was found to be inadequate, so that the complex was obtained by direct reaction of $NiCl_2 \cdot 6H_2O$, tmen and acac in methanol.

Results and Discussion

The analytical data of the new mixed complexes together with those reported are summarized in Table 1, and their magnetic moments and $\tilde{\nu}_{max}$ values of their reflectance spectra in Table 2. All the complexes are blue to green and in high spin state (μ_{eff}: 3.0—3.2 BM) except XII which is reddish orange and diamagnetic (*cf.* Experimental). These results and the spectral evidence given below lead to the formulation of the complexes as shown in Table 2.

Table 1. Analytical data of complexes[a]

No.-n[b]	Complex	C/%	H/%	N/%
I-1	Ni(tmen)(acac)(NCS)(H_2O)	40.48 (41.16)	7.06 (7.21)	12.11 (12.00)

XII	Ni(tmen)(dpm)(I)	41.03 (42 09)	7.16 (7 22)	5.73 (5.77)

a) Calculated values are in parentheses. b) Number of water molecules. 0 is omitted for n=0.

(A) Pseudohalide Complexes.

(i) Solid Structures: All the pseudohalide complexes (Table 2, I-1 to VII-1) show two d-d bands in their reflectance spectra which can be ascribed to $\tilde{\nu}_1(^3T_{2g} \leftarrow {}^3A_{2g})$ and $\tilde{\nu}_2(^3T_{1g} \leftarrow {}^3A_{2g})$ of octahedral complexes of Ni(II).

As in the case of I-1 formulated formerly as [Ni(tmen)-(acac)(H_2O)NCS], the complexes II-1, V-1, and VII-1 can be formulated as [Ni(tmen)(β-dik)(H_2O)NCX]; the IR data (Table 3) which indicate the N-coordination of NCS^- or $NCSe^-$ in the complexes also support these formulas. The water molecules are only loosely held, and driven off by slight heating or mere dissolution in

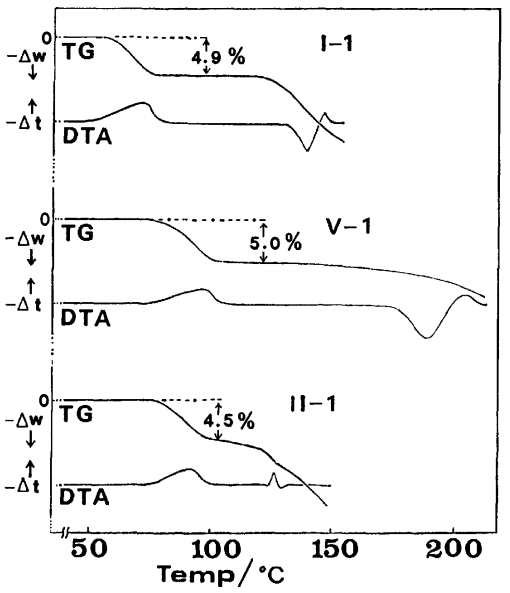

Fig. 1. TG and DTA data of three monohydrated complexes; I-1, V-1, and II-1. Numbers (%) on TG curves show the observed mass losses; the theoretical values are 5.1%, 4.4%, and 4.5%, respectively.

a) ν_a(NCO) and ν_a(NNN) for III and IV. b) ν_s(NCO) and ν_s(NNN) for III and IV. c) The value in the former report (2170 cm^{-1})[2] was a misprint. d) This band could not be assigned clearly.

nonpolar solvents; TG measurements in static air (heating rate: 1°/min) show that I-1, II-1, and V-1 lose their water quantitatively at 58—76, 78—100, and 75—100 °C, respectively (Fig. 1). The anhydrous complexes of I and V could be easily prepared in this way, but decomposition of $NCSe^-$ ion hindered the preparation of anhydrous II. On the other hand, no monohydrate could be obtained in the system tmen–dpm–NCS, only the anhydrous complex VI being isolated. Since the anhydrous complexes V and VI are also of high spin and show octahedral spectra (Table 2, VI), they are probably dimeric chelates with bridging pseudohalide ions, such as [(tmen)(acac)-Ni$\begin{smallmatrix}\diagup\text{NCS}\diagdown\\ \diagdown\text{SCN}\diagup\end{smallmatrix}$Ni(tmen)(acac)].[2] Similar dimeric structures can be tentatively assigned to the complexes of NCO^- and N_3^- (III and IV) which are also anhydrous, of high spin and similar in color, although other types of bridging and polymerization can not be ruled out.[5,6]

A few interesting trends may be pointed out as to the ease of dehydration of these complexes. In the series [Ni(tmen)(β-dik)(H_2O)NCS], the water beoomes more tightly held in the order:

$$\text{dpm (no hydrate isolated)} \ll \text{acac} < \text{bza}$$

and in the series [Ni(tmen)(acac)(H_2O)X]:

$$NCO^- \approx N_3^- \text{ (no hydrate isolated)} \ll NCS^- < NCSe^-$$

The order seems to indicate that the bonding of water is strengthened by the weakening of the ligand field strength (l.f.s.) produced by other ligands.[3,7]

Another interesting complex prepared was [Ni(Et_3en)(acac)(H_2O)NCS] (VII-1), containing a diamine with very bulky alkyl groups. The spectral feature is essentially similar to that of (I-1), showing that H_2O can still be coordinated in this complex. No corresponding complex with Et_4en(teen),[8] [Ni(teen)(acac)(H_2O)-NCS], could be isolated, but the formation of a 5-coordinate complex (probably [Ni(teen)(acac)NCS]) in

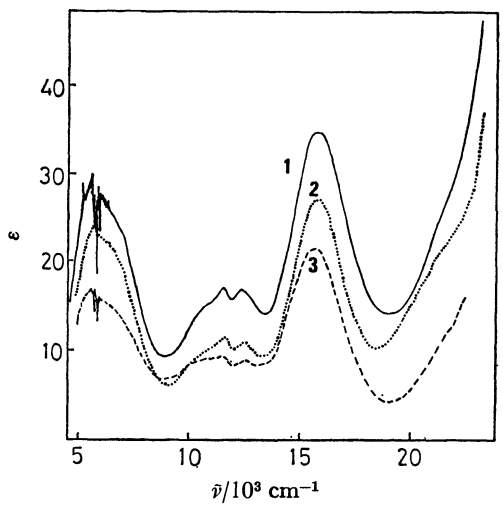

Fig. 2. Electronic spectra of VII-1 in various organic solvents (1=DCE; 2=NM; 3=acetone). Strong noises observed at *ca.* 6×10^3 cm^{-1} in the spectra of 1 and 3 were due to the absorption bands of the solvents.

an acetone solution of its components could be confirmed by its electronic spectrum. Coordination of solvent molecule is thus strongly hindered by the increase of the number of ethyl groups in the diamine (see below).

(ii) Structures in Organic Solutions: The structural changes of the complexes I-1 and I in various organic solvents were described in detail.[2] The spectral curves of VII-1 (Fig. 2) are most interesting in this connection; the curve in DCE is typically square pyramidal,[9] showing four bands assigned as follows:

$^3E(F) \leftarrow {}^3B_1(F)$, 5750 cm^{-1}; $^3A_2(F) \leftarrow {}^3B_1(F)$, 11550 cm^{-1}; $^3B_2(F) \leftarrow {}^3B_1(F)$, 12470 cm^{-1}; $^3E(F) \leftarrow {}^3B_1(F)$, 15900 cm^{-1}.

Two other spin allowed bands ($^3A_2(P)\leftarrow{}^3B_1(F)$ and $^3E(P)\leftarrow{}^3B_1(F)$) are probably under the strong CT band observed in the ultraviolet. Thus the water molecule escapes easily on dissolution, causing a structural change from 6- to 5-coordination. The 5-coordinate structure is also retained fairly well in more polar solvents (nitromethane or acetone), but the decrease in band intensity suggests that it is partially converted into other forms, such as planar $[Ni(Et_3en)(acac)]^+$ (in nitromethane) or $[Ni(Et_3en)(acac)(solv.)NCS]$ (in acetone), as in the case of I. However, it can be seen that the dimerization observed with I in DCE or nitromethane is hindered by the bulky substituents in Et_3en, and the 5-coordinate structure is notably stabilized in comparison with the case of I.

The case of VI (Fig. 3) is in strong contrast with that of VII-1. Here the spectrum depends much more (and seemingly more than I) on the solvent, and the 5-coordinate species in DCE (which coexists with some $[Ni(tmen)(dpm)]^+$, as indicated by a notable hump at about 20000 cm^{-1}) is converted easily into $[Ni(tmen)(dpm)]^+$ in nitromethane, and solvated 6-coordinate species (probably $[Ni(tmen)(dpm)(Solv.)NCS]$) in acetone. The bulky substituents in dpm are somewhat apart from the central metal ion, so that the 5th and 6th coordination sites around it are not so sterically

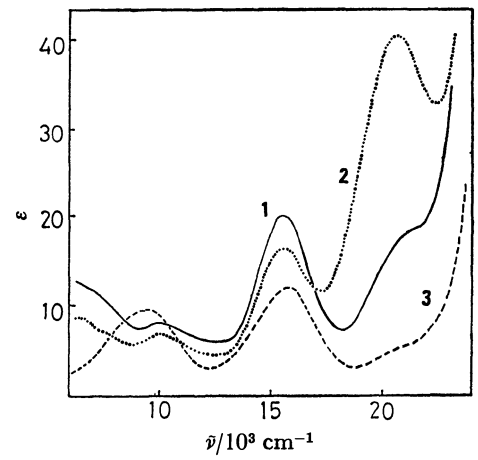

Fig. 3. Electronic spectra of VI in various solvents. For the numbering of curves, *cf.* Fig. 2.

hindered as in the case of VII-1. The NCS^- can be dissociated away in nitromethane of relatively high dielectric constant (35.9), while a polar solvent molecule can enter into the coordination sphere. The effect of dimerization on the spectra is not so apparent as with I, probably owing to the stronger ligand field of dpm and larger interligand repulsion in the dimer.

As regards the complex with $NCSe^-$ (II-1), its spectrum in DCE is generally similar to spectra of I-1 and V-1, indicating an equilibrium between 5- and 6-coordinate species. Not much could be done with this complex, however, owing to its thermal instability.

The complexes with NCO^- (IV) and N_3^- (VI) could not be studied in sufficient detail owing to their poor yield, but they show typically octahedral spectra in DCE. This fact, and the non-conductivity of their solutions, indicate that their 6-coordinate dimeric (or polymeric) structure is retained also in solution, probably owing to the higher coordination and bridge formation ability of the NCO^- and N_3^- ions than NCS^- and $NCSe^-$ ions.[5,6] The $\bar{\nu}_{max}$ and ε_{max} values of the solution spectra are summarized in Table 4.

(B) Halide Complexes. (i) Solid Structures: Unlike the pseudohalide complexes, almost all the complexes obtained (Table 1) are dihydrates. Their appearance and solid spectra are very similar to those of $[Ni(tmen)(acac)(H_2O)_2]ClO_4$,[3] suggesting their formulation as $[Ni(diam)(\beta\text{-dik})(H_2O)_2]X$.

When β-dik=bza and X=I^-, both the mono- and dihydrate can be obtained, the latter being partially transformed into the former in a desiccator (*cf.* Experimental). Careful observation of the dehydration process of IX-2 by heating also shows that it is first converted into a yellowish green mass, apparently very similar to the complex $[Ni(tmen)(bza)(H_2O)I]$. Thus the number (n) in the hydrates $Ni(tmen)(\beta\text{-dik})X\cdot nH_2O$ varies as follows:

a) β-dik=acac

X=	I	Br	Cl
n=	2	2	—
	—	(1)	1

b) X=I

β-dik=	dpm	acac	bza
n=	2	2	2
	—	—	1

We see that there is a competition between the water molecules and halide ions in the coordination sphere, and the nature of the β-diketonate (probably its steric requirement) also affects this competition. The water molecules are combined only weakly,[3] and easily lost on dissolution in relatively nonpolar solvents.

[Ni(tmen)(dpm)]I, a reddish orange diamagnetic solid with a typically square planar reflectance spectrum (a band at 20500 cm^{-1}), is obtained easily from the hydrate (*cf.* Experimental). On the other hand, the complexes VIII-2 and XI-1 dehydrate with more difficulty, losing their water at 80—120 and 100—145 °C, respectively, under the same conditions as in the case of pseudohalide complexes.††† Their anhydrous complexes are both reddish orange but slightly paramagnetic ($\chi_g = 3.4 \times 10^{-6}$ and 4.3×10^{-7}, respectively) and show weak bands (9300, 11000(sh), and 12150 cm^{-1} in XI, and 9550 cm^{-1} in VIII) together with a strong square planar band (20500—21000 cm^{-1}). VIII is remarkably hygroscopic; its paramagnetism may be due to the formation of its hydrate during storage. However, XI is apparently not very hygroscopic and a very small amount of blue crystals were observed to deposit at the top of the vessel during the course of dehydration in a vacuum (50—60 °C, 2 d). Thus the paramagnetism of XI, and at least a part of that of VIII, seem to be due to the product of decomposition which, to a small extent, accompanies their dehydration.

The nature of decomposition is understandable, if we compare the results with those of IX-2 and X-1.[1] With IX-2, the water is lost between 70 and 100 °C, but the weight decreases steadily on further heating, and when it is heated at under 60 °C for 17 d, it separates into a violet powder and a pale blue sublimate. The analysis of the latter (Found: C, 51.49; H, 8.08; N, 7.61%. Calcd: C, 51.50; H, 8.10; N, 7.51%) confirms its formulation as [Ni(tmen)$(acac)_2$], while that of the former indicates that it is chiefly composed of [Ni(tmen)-Br_2] (Found: C, 23.29; H, 4.82; N, 7.77%. Calcd for: C, 21.53; H, 4.82; N, 8.37%). The deviations from the calculated values can be ascribed to a small amount of red crystals contained in the former (probably [Ni(tmen)(acac)]Br) which can be discerned by careful observation. Thus the decomposition of this complex can be formulated as:

$$[Ni(tmen)(acac)(H_2O)_2]Br \longrightarrow \begin{cases} [Ni(tmen)Br_2] + [Ni(tmen)(acac)_2] \cdots\cdots (A) \\ \qquad\qquad\qquad\qquad \text{Disproportionation}\dagger\dagger\dagger\dagger \\ [Ni(tmen)(acac)]Br \cdots\cdots (B) \quad \text{Dehydration.} \end{cases}$$

(A) is the main reaction. With X-1, this reaction seems to occur nearly exclusively; after being heated at 90 °C for 7 d it decomposed perfectly into [Ni(tmen)$(acac)_2$] (subliming away from the vessel) and green [Ni(tmen)-Cl_2] with no trace of red complex.

Thus we can summarize the thermal decompositions of XII-2, VIII-2, XI-1, IX-2 (or IX-1), and X-1 as follows:

$$\text{XII-2} \rightarrow \text{(B) (no(A))} \qquad \left.\begin{matrix}\text{VIII-2}\\ \text{XI-1}\end{matrix}\right\} \nearrow \text{(B)} \; \searrow \text{(A)}$$

$$\text{IX-2} \nearrow \text{(B)} \; \searrow \text{(A)} \qquad \text{X-1} \rightarrow \text{(A) (no (B))}$$

if we assume that the reaction (A) occurs to a small extent with VIII-2 and XI-1, producing the blue sublimate observed with VIII-2, and paramagnetic impurity (presumably [Ni(tmen)I_2]) in the dehydration products.

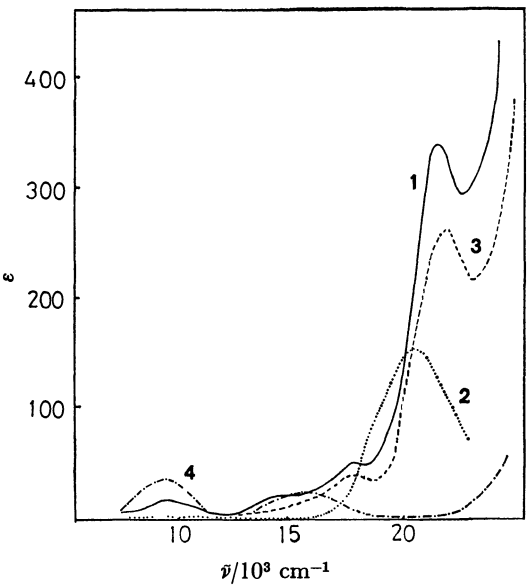

Fig. 4. Electronic spectra of VIII-2 in various solvents (1=DCE; 2=NM; 3=acetone; 4=DMSO ($\varepsilon \times 5$ as ordinate)).

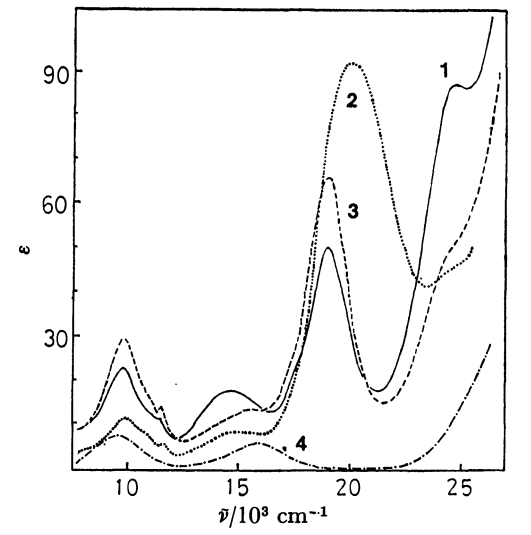

Fig. 5. Electronic spectra of IX-2 in various solvents. For the numbering of curves, *cf.* Fig. 4.

††† The ease of dehydration is in the order dpm ≫acac> bza, *i.e.* the same as in the case of pseudohalide complexes. XI-1 and XI-2 both melt between 98 and 104 °C, seemingly leading to the same product.

†††† This reaction can be reversed, *i.e.*, when we mix the violet powder and blue sublimate in a 1 : 1 molar ratio in DCE, concentrate, and add some acetone, the crystals of [Ni-(tmen)(acac)$(H_2O)_2$]Br appear again.

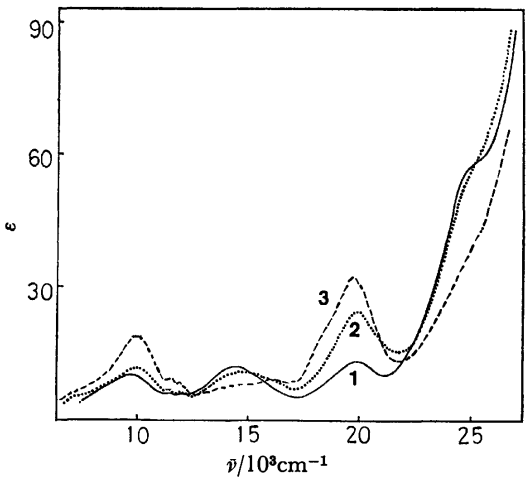

Fig. 6. Electronic spectra of X-1 in various solvents. For the numbering of curves, *cf.* Fig 2.

(ii) Structures in Organic Solutions. Figures 4, 5, and 6 show the spectra of VIII-2, IX-2, and X-1 in various organic solvents. Their $\tilde{\nu}_{max}$ and ε_{max} values are summarized in Table 5.

In general, in highly polar and coordinating solvents like DMSO or methanol, the spectra show that the complexes tend to form 6-coordinate species ([Ni(tmen)(acac)(Solv.)$_2$]$^+$ or [Ni(tmen)(acac)(Solv.)X]), as in the case of the pseudohalide complexes. However, the situation is quite different in solvents of low polarity and/or coordination ability (DCE, nitromethane, or acetone).

As to IX-2 (Fig. 5), the curve in DCE indicates the occurrence of reaction (A),[1] since it is very similar to that of 1 : 1 mixture of the products, [Ni(tmen)Br$_2$] and [Ni(tmen)(acac)$_2$]. The similarity is still more pronounced in acetone, and the band at 14600 cm^{-1}, which should be ascribed to some unidentified by-product formed in DCE, apparently disappears. Thus it is clear that reaction (A) occurs quite easily by mere dissolution of this complex in these solvents.

In nitromethane, however, a strong band at *ca.* 20000 cm^{-1} appears, showing a remarkable dissociation into [Ni(tmen)(acac)]$^+$ and Br$^-$ (*ca.* 60%, if the true ε_{max} of this band is assumed to be *ca.* 150).[3] On the other hand, the bands of products of reaction (A) are correspondingly weakened. This indicates that the higher polarity of nitromethane as an ionizing medium as compared with those of DCE and acetone (*cf.* their dielectric constants and E_T values,[11] and note that the latter decreases as nitromethane$\gg$DCE$\approx$acetone) favors the formation of charged species (*i.e.* ionization) in comparison with that of non-charged species (*i.e.* reaction (A)).

The data on X-1 (Fig. 6) can be understood on the same basis. Here the curve for acetone is similar to that of IX-2, indicating that reaction (A) occurs remarkably. The curves in nitromethane and DCE are essentially similar to that in acetone, although a band of some unidentified byproduct appears again at 14400—14600 cm^{-1}, and the band at *ca.* 10000 cm^{-1} and 19900 cm^{-1} are weakened. The band at 19900 cm^{-1} in nitromethane is much higher than that in DCE; this is probably due to the partial ionization (*ca.* 10%) into [Ni(tmen)(acac)]$^+$ and Cl$^-$ which takes place in nitromethane (Table 6), and the overlap of the band of [Ni(tmen)(acac)]$^+$ on that of [Ni(tmen)Cl$_2$] which is in the same region.

Table 6. Conductivity of DCE and NM solutions (1.0×10^{-3} M, 25 °C; Λ_M/Ω^{-1} cm^2 mol^{-1})[a]

		DCE	NM
I-1	[Ni(tmen)(acac)(H$_2$O)(NCS)]	$\approx$0	16.6
I	[Ni(tmen)(acac)(NCS)]$_2$	$\approx$0	18.8
III	[Ni(tmen)(acac)(NCO)]$_2$	1.1	—
VI	[Ni(tmen)(dpm)(NCS)]$_2$	2.5	—
VIII-2	[Ni(tmen)(acac)(H$_2$O)$_2$]I	19.0[b]	85.0
IX-2	[Ni(tmen)(acac)(H$_2$O)$_2$]Br	2.1	67.1
X-1	[Ni(tmen)(acac)(H$_2$O)Cl]	0.7	21.0
XII	[Ni(tmen)(dpm)]I	24.3	—
Standard 1 : 1 electrolytes		10—24	75—95

a) Care must be taken in comparing these data with the spectral ones, since the latter were mostly obtained with much more concentrated solutions. b) At 5×10^{-3} M, Λ_M drops to 12 Ω^{-1} cm^2 mol^{-1}.

The data on VIII-2 (Fig. 4) are more complicated. However, it is clear that, in nitromethane, there is almost perfect ionization into [Ni(tmen)(acac)]$^+$ and I$^-$, since the spectrum is very similar to those of [Ni(tmen)(acac)]X(X=ClO$_4^-$ or B(C$_6$H$_5$)$_4^-$) in highly non-coordinating media.[3] Comparing the data of the three complexes in nitromethane, we can conclude that: (i) the coordinated water is easily lost on dissolution, (ii) the complex then either ionizes into [Ni(tmen)(acac)]$^+$ and X, or undergoes disproportionation into [Ni(tmen)X$_2$] and [Ni(tmen)(acac)$_2$]. The ionization is nearly complete when X=I$^-$, and occurs strongly when X=Br$^-$, but only weakly when X=Cl$^-$. The anions tend to remain coordinated in the order I$^-$<Br$^-$<Cl$^-$, as can be expected from their l.f.s.

The spectra of VIII-2 in DCE and acetone present some questions. Since their general appearance is similar to the spectrum of the trigonal bipyramidal [Ni(tren-Me)Cl]Cl reported by Ciampolini *et al.*,[10] we mistakenly ascribed the curves to the complex [Ni(tmen)(acac)I].[1] We have found, however, that they are very similar to the spectrum of [Ni(tmen)I$_2$][4] in DCE. The bands in the former spectra are much weaker, and it can be estimated that only 10—15% of VIII-2 dissolved in DCE are converted into [Ni(tmen)I$_2$], *i.e.* 20—30% undergo disproportionation into [Ni(tmen)I$_2$] and [Ni(tmen)(acac)$_2$] (the bands of [Ni(tmen)(acac)$_2$] are much weaker than those of [Ni(tmen)I$_2$], and will be completely covered by them, if the two species coexist in equimolar amounts).

On the other hand, the Λ_M values (Table 6) show that a large part of VIII-2 (50% or more in a 5×10^{-2} M solution) is converted into ionic species in DCE. A similar situation is also expected in acetone. There is no spectral indication for these ionic species, but this may be due to the fact that the bands of the expected ionic species ([Ni(tmen)(acac)]$^+$, [Ni(tmen)(acac)(acetone)$_2$]$^+$, and possibly [Ni(tmen)(H$_2$O)$_4$]$^{2+}$ produced

by the hydrolysis of [Ni(tmen)I_2]) are considerably weaker than those of [Ni(tmen)I_2]. They would thus be nearly buried under the strong bands of [Ni(tmen)I_2], even if a considerable amount of the ionic species is present in solution.

Comparing the data in DCE and acetone, we see that reaction (A) takes place with IX-2 or X-1 but VIII-2 mainly ionizes, showing that I^- is held more weakly to the metal ion than Br^- and Cl^-.

Spectral data were also obtained in DCE with complexes XI-1 and XII, containing bza and dpm instead of acac. XI-1 shows nearly the same spectrum as VIII-2; the curve of XII, however, is similar to that of VIII in nitromethane, and together with the high Λ_M value of its solution (Table 6), shows that most of it is dissociated into [Ni(tmen)(dpm)]$^+$ and I^- in DCE, although a weak band at 14400 cm^{-1} might indicate a slight occurrence of reaction (A). This is evidently due to the bulkiness and strong l.f.s. of dpm, which stabilizes the square planar cation.

Concluding Remarks. Although only limited information could be obtained with complexes containing NCO^-, $NCSe^-$, and N_3^-, there are clear-cut differences between the behavior of the pseudohalide complexes and that of the halide complexes. The most characteristic feature of the latter is the peculiar disproportionation reaction (A), which occurs both in solid state and in non-polar solvents, with ease which increases with the l.f.s. of the halide anion. The behavior of all these complexes in solution is governed not only by the donor number of the solvent, but also by other polarity parameters, such as dielectric constant and E_T value, especially when the polarity is relatively low.

Some of these solutions are notably thermochromic; for example, when an acetone solution of IX-2 was frozen in liquid nitrogen, and the spectral change of its melt with the rise of temperature was followed up to room temperature, the band *ca.* 19000 cm^{-1} was found to increase several times, indicating strong shift of the disproportionation equilibrium.

Cordial thanks are due to Dr. Kenzo Nagase, Tohoku University, who kindly carried out the TG-DTA measurements of the new complexes. This work was supported in part by a Grant-in-Aid for Scientific Research No. 347033 from the Ministry of Education, Science and Culture.

Studies on Mixed Chelates. XII. Formation and Electronic Spectra of 5-Coordinated Mixed Copper(II) Chelates Containing *N*-Alkylated Ethylenediamine, Acetylacetonate, and Pseudohalide Anions[1]

Yutaka FUKUDA,* Noriko SATO, Naomi HOSHINO, and Kozo SONE
Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo 112
(Received June 5, 1980)

The visible absorption spectra of three new mixed chelates of copper(II), Cu(tmen)(acac)X (tmen=*N,N,N',N'*-tetramethylethylenediamine, acac=acetylacetonate ion, X=NCS, N_3, or NCO) were studied in various organic solvents. It was found that the $\tilde{\nu}_{max}$ values of their d-d bands depend strongly on the nature of the solvent, and shift in the opposite direction as compared with the case of $[Cu(tmen)(acac)]ClO_4$ studied before, where $\tilde{\nu}_{max}$ shifted to red with the increase of the donor number (DN) of the solvent. Here the magnitude of the red shift is affected not only by the DN, but also by other parameters of the solvent polarity, such as Kosower's Z or Reichardt's E_T. The obtained data can reasonably be explained, if an equilibrium

$$\underset{\text{(5-coordinated)}}{[Cu(tmen)(acac)X]} \rightleftharpoons \underset{\text{(4-coordinated)}\\\text{(with axial solvation)}}{[Cu(tmen)(acac)]^+} + X^-$$

is assumed to exist in such solutions.

It was pointed out by Fukuda *et al.*[2] that the visible absorption spectra of the mixed copper(II) chelates [Cu(tmen)(acac)]X (X=ClO_4, or NO_3) in organic solvents are strongly influenced by the nature of the solvent used. In general, it was observed that the d-d band is shifted to the red with the increase of the donor number (Gutmann's DN) of the solvent. The effect was explained as the result of the strengthening of the axial solvation, which decreases the apparent ligand field strength observed as $\tilde{\nu}_{max}$.

Recently we prepared three new complexes with the general formula Cu(tmen)(acac)X (X=NCS, N_3, or NCO), and studied their spectra in organic solvents. A number of fundamentally different behaviors were found out, as compared with the case of perchlorate or nitrate chelate. These results and their probable explanations will be presented in this paper.

Experimental

Preparation of the New Complexes. *i) Cu(tmen)(acac)(NCS)*: A large excess of KNCS(*ca.* 50 mmol) was added to a solution of $[Cu(tmen)(acac)]ClO_4$[2] in 1,2-dichloroethane (=DCE, 10 mmol in *ca.* 50 cm^3). A few drops of methanol were added to the mixture, and it was heated at *ca.* 40 °C for several hours under constant stirring. The color of the solution changed from reddish violet to indigo, and then finally to deep green. Stirring was continued for a while after completion of this color change, and then the solution was cooled thoroughly by keeping it in a freezer for several hours. After filtering off the white precipitate formed ($KNCS+KClO_4$), the filtrate was evaporated to dryness, and further dried in vacuum. Since the green product obtained was seemingly quite raw, it was dissolved in DCE, and the solution was filtered and concentrated until it became noticeably viscous, and kept in the freezer again. The crystalline product obtained was further recrystallized from DCE. Deep green prismatic crystals were thus obtained.

ii) Cu(tmen)(acac)NCO: This complex could be obtained in the same way as i), using KNCO instead of KNCS. Deep green prismatic crystals were obtained.

iii) Cu(tmen)(acac)N_3: This complex could not be obtained in the same way as *i*). For its preparation, an excess of NaN_3 (15 mmol) was added to a solution of $[Cu(tmen)(acac)]NO_3$ in methanol(MeOH) (10 mmol in *ca.* 50 cm^3), and the mixture was stirred for some time. The color of the solution changed gradually from indigo to olive green; this solution was filtered to remove the white precipitate formed (NaN_3+NaNO_3), and transferred into a flask (A), which was connected with an inverted U-tube with another flask (B). The content of A was frozen with liquid nitrogen, and the whole system was evacuated and closed. The liquid N_2 around A was then removed, and B was cooled with it instead. Nearly all of the solvent in A was thus distilled into B, leaving the raw complex which crystallized out. The complex was separated from the mother liquor by filtration, dissolved in dichloromethane and filtered again. Similar procedures (*i.e.* dissolution in dichloromethane, filtration, and distillation of the solvent at low temperature) were repeated until a product of sufficient analytical purity was obtained. It was a bluish green powder, which had to be kept in a vacuum in a refrigerator, since spontaneous decomposition seemed to take place.

iv) Cu(tmen)(acac)NCSe: Deep green crystals which were very similar in appearance to Cu(tmen)(acac)NCS were obtained by the method i), using KNCSe instead of KNCS, but they were very unstable and decomposed in the course of recrystallization. Their identification with Cu(tmen)(acac)(NCSe) was, however, also supported by the close resemblance of its IR spectrum to that of the NCS-complex.

Physical Measurements. The electronic spectra of the solutions (350—850 nm) were measured with a Hitachi 340 Recording Spectrophotometer at room temperature (20—25 °C), using 10 mm quartz cells. The reflection spectra of the solid samples (300—800 nm) were measured with the same instrument, using $BaSO_4$ as the reference. IR spectra (600—5000 cm^{-1}) were measured in nujol mulls with a JASCO IR-A3 Grating IR Spectrophotometer. Magnetic susceptibility measurements were performed with a Shimadzu Tortion Magnetometer MB-100 (NCS- and NCO-complexes at 31 °C, N_3-complex at 17 °C). Electric conductivities of the solutions were measured with a Yanagimoto Conductivity Outfit Model MY-7 at 25 °C.

Results and Discussion

Properties of the Solid Chelates. Table 1 summarizes the analytical data, colors and magnetic moments of the

three new chelates. All of them show normal magnetic moments expected for monomeric copper(II) chelates, but their colors are notably different from that of [Cu(tmen)(acac)]ClO_4 (reddish violet). The IR spectra of these chelates show sharp bands of the pseudohalide ions, and their positions shown in Table 2 indicate that all of these ions are coordinated to Cu(II) with their N atoms.[4]

Electronic Spectra of the Chelates. As expected from the colors, the visible reflection spectra of these solid chelates are all quite different from that of [Cu(tmen)(acac)]ClO_4. These chelates are all readily soluble in various organic solvents, but the visible absorption spectra observed in them are also remarkably different from those of [Cu(tmen)(acac)]ClO_4 in the same solvents. As an example, the spectra of Cu(tmen)(acac)NCS in four solvents are given in Fig. 1. The observed values of $\bar{\nu}_{max}$ and ε_{max} for all three chelates are summarized in Table 3 and the shifts of $\bar{\nu}_{max}$ of each chelate are shown in Fig. 2, in comparison with the data of [Cu(tmen)(acac)]ClO_4.[2]

As stated in the introduction, the $\bar{\nu}_{max}$ value of the perchlorate shifts to the red approximately in the order of the donor number of the solvent. However, the data shown above clearly show that the $\bar{\nu}_{max}$ of the

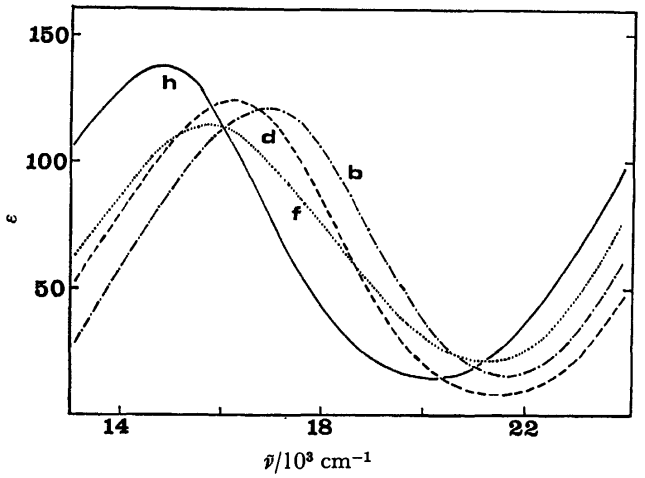

Fig. 1. Absorption spectra of [Cu(tmen)(acac)NCS] in various organic solvents. As to the symbols on the curves, *cf.* Fig. 2. Concentration: 5.5×10^{-3} M.

$C_2H_4Cl_2$(DCE)	14.71(153)	14.12(159)	13.32(118)
$(CH_3)_2CO$	14.79(138)	14.12(157)	13.30(107)

a) $\bar{\nu}_{max}$ in 10^3 cm^{-1}, ε_{max} in parentheses. b) Concentrations: 5.18—5.28×10^{-3} M in organic solutions of the NCS⁻ complex, and 5.92×10^{-3} M in its aqueous solution; 5.06—5.51×10^{-3} M in solutions of the N_3⁻ complex, and 7.23—7.50×10^{-3} M in those of the NCO⁻ complex, respectively (1 M=1 mol dm^{-3}).

pseudohalide complexes shift to the red with the decrease of solvent polarity, *i.e.* in apparently opposite direction as compared with the case of the perchlorate. The order of $\bar{\nu}_{max}$ in various solvents is, nearly in all three cases, expressed as:

$$H_2O > MeOH > EtOH > DMSO > DMF > NM > AN > DCE \approx Acetone. \quad (i)$$

Now it can be noted that this order (i) is not the order of DN of the solvents, but can better be correlated with the order of Kosower's Z values,[5] or Reichardt's E_T values,[6] which are other parameters of solvent polarity. Table 4 shows these correlations.

TABLE 4. DN, Z, AND E_T VALUES OF THE SOLVENTS[a]

Solvent	DN	Z	E_T
H_2O	18.0	94.6	63.1
MeOH	23.5	83.6	55.5
EtOH	30.0	79.6	51.9
DMSO	29.8	71.1	45.0
DMF	26.6	68.5	43.8
NM	2.7	—	46.3
AN	14.1	71.3	46.0
DCE	0.0	—	41.9
$(CH_3)_2CO$	17.0	65.7	42.2

a) See Refs. 5—7. The DN values of MeOH and EtOH are those of DeWitte and Popov,[13] and may not be strictly comparable with those of the other solvents proposed by Gutmann.

Thus we can understand that the order (i) is the order of the increase of Z or E_T, except a few small discrepancies. Since Z and E_T are linear functions of each other,[5] and more E_T values are available for the present study, we shall use E_T in our following discussions.

Before going further, it may be of interest to compare the meanings of these polarity parameters. The DN is a measure of the donor ability of the solvent or its Lewis basicity, *i.e.* its tendency to donate an electron pair to a positive solute particle. On the other hand, E_T is a measure of the polar influence of the solvent on the interactions between charged particles (or between charged parts inside of a large molecule) dissolved in it.

Now the pseudohalide ions (NCS^-, N_3^-, and NCO^-) are all good ligands, and their coordination ability is generally expected to be much higher than that of common organic solvents. Therefore, it will be possible to explain our spectral results of the NCS-complex in the following way:

(i) In a highly polar solvent like H_2O or MeOH, where the E_T values are highest among the solvents tried, the Cu–NCS bond is remarkably weakened, and remarkable dissociation of the complex into $[Cu(tmen)(acac)]^+$ and NCS^- takes place. The $[Cu(tmen)(acac)]^+$ planar cation formed has vacant coordination sites above and below it, and they are immediately occupied (*i.e.* solvated) by the solvent molecules. This is the reason why the $\bar{\nu}_{max}$ of the complex in these solvents are nearly the same as those of the perchlorate in the same solvents, where similar nearly complete dissociation of the anion is expected to occur.

It is interesting to note that the very important step involved in these changes is the dissociation of the strongly coordinated NCS^- ion from the complex, since the surrounding solvent molecules will spontaneously occupy the coordination sites which are open to them. In other words, the effect of E_T (polar influence of the solvent to weaken the polar bond (Cu–NCS) in the solute) is seemingly more important than that of DN (the ease of coordination of the solvent molecules to the vacant coordination sites produced around Cu^{2+}) in these changes. Further supports of this view will be found in the following examples.

(ii) In a highly non-polar solvent like DCE, where both the E_T and DN values are the lowest, the solvent can neither drive out the NCS^- ion from the complex, nor occupy its coordination site. Thus the complex is dissolved in the form of the 5-coordinated molecule, [Cu(tmen)(acac)(NCS)], which shows a d-d band of much lower $\bar{\nu}_{max}$ and somewhat higher ε_{max} than those of the solvated tetragonal ions formed in highly polar solvents.

(iii) In a solvent of intermediate polarity such as EtOH, DMSO, DMF, NM, or AN, the situations are more complicated. In the first three solvents, the DN values are even much higher than those of H_2O and MeOH, but the E_T values are noticeably lower. So it is more difficult to drive off the NCS^- ion in these solvents. In NM and AN, on the other hand, the DN values are much lower, but the E_T values are comparable to those of DMSO or DMF. These solvents will be able to drive out NCS^- ions from the complex to some extent, *i.e.* more or less like DMSO and DMF, but will not be able to occupy the vacant sites produced so readily. At any rate, in these solvents, there will be incomplete dissociation of NCS^- from the complex, leading to an equilibrium

$$\underset{\text{(5-coordinated)}}{[Cu(tmen)(acac)(NCS)]} \rightleftarrows \underset{\text{(4-coordinated) (with axial solvation)}}{[Cu(tmen)(acac)]^+} + NCS^- \quad (1)$$

which shifts to the right hand side with the increase of DN and E_T. As the d-d bands of the complexes on both sides of (1) are broad and of comparable intensity, they will mutually overlap, and lead to the formation of an apparent spectral maximum, which will shift to the red with the increase of [Cu(tmen)(acac)(NCS)] in the equilibrium mixture, *i.e.* with the decrease of DN and E_T. The fact that the observed shift is more closely related to E_T than to DN indicates that the main driving force of the forward reaction of (1) is the weakening of Cu–NCS bond, and not the strength of solvation. The most striking evidence for this view is the case of acetone, which has a DN much higher than those of NM or AN, but a E_T which is very low and comparable with that of DCE. The observed $\bar{\nu}_{max}$ in acetone is in the vicinity of that in DCE, showing that no coordination of the solvent can occur unless it can drive out the NCS^- by its polar influence.

The results of the N_3- and NCO-complexes can be explained in the same way, but the comparison of the three pseudohalide complexes shows that the ease of 5-coordinate complex formation increases in the order:

$$NCS^- < N_3^- < NCO^-. \quad (ii)$$

This can most clearly be seen by comparing the data of the NCS-complex with those of the NCO-

complex. In the latter case, all the $\tilde{\nu}_{max}$ values shift to the red, and flock together at the left end of Fig. 2, leaving only the values in very polar solvents (H_2O and MeOH) which remain nearly unchanged from those of the perchlorate. This means that NCO^- is bound strongly to Cu(II), so that even solvents like DMSO or EtOH can ionize it only partially. It is also clear that N_3^- comes just between NCS^- and NCO^- in its coordination power.

This order of the coordination ability of pseudohalide ions may be related to the values of their "optical electronegativities," proposed by Jørgensen.[8] The values for the σ- and π-optical electronegativities of halide and pseudohalide ions are:

Ligand	σ	π	Ligand	σ	π
Cl^-	3.4	3.0	NCO^-	—	3.0
Br^-	3.3	2.8	NNN^-	—	2.8
I^-	3.0	2.5	NCS^-	—	2.6

Although the σ-values for the pseudohalide ions are lacking, we can see that the π-values of Cl^-, Br^-, and I^- are comparable to those of NCO^-, N_3^-, and NCS^-, respectively. It is well known that the coordination tendencies of the halide ions toward 3d transition metal cations are, in general, in the order $Cl^- > Br^- > I^-$, so we can suppose that the order of the pseudohalide ions should be $NCO^- > N_3^- > NCS^-$, as is observed in Fig. 2. One can also imagine that the "hardness" of these ions increases just in the order (ii), *i.e.* from NCS^- with the soft S to N_3^- with highly delocalized π-system and then to NCO^- with much more rigid electronic structure, and that the coordination of an anion onto $[Cu(tmen)(acac)]^+$ is favored when it is hard, since the interaction may be weak and chiefly electrostatic in nature.

Table 5. Molar conductivities of the chelates (Ω^{-1} cm^2 mol^{-1}, 25 °C) and approximate degrees of dissociation (%, in parentheses)[b]

X-	DCE	NM	DMSO
NCS^-	1.1(6)	56.6(65)	39.8(100)
N_3^-	1.0(5)	27.0(32)	32.0(92)
NCO^-	0.5(3)	21.7(26)	14.8(42)

a) Concentration of the solutions: $\approx 10^{-3}$ M.
b) Calculated on the assumption that the Λ_M values of a typical 1 : 1 electrolyte in these three solvents are 20, 85, and 35 Ω^{-1} cm^2 mol^{-1}, respectively (see Ref. 9).

To confirm all these points of view, further spectral and conductometric measurements were carried out. Some data of them are shown in Table 5; it can clearly be seen that all the three chelates are nearly non-electrolytes in DCE, and the NCS- and N_3-chelates are nearly 1 : 1 electrolytes in DMSO, while in all other cases there is an ionization equilibrium, and the degree of ionization increases, in every case, in the order of DCE<NM<DMSO and $NCS^- < N_3^- < NCO^-$ just as expected from the above discussions.

As to the spectral measurements, a number of observations were made with the NCS-chelate which is the easiest to prepare. It was found first that the spectrum

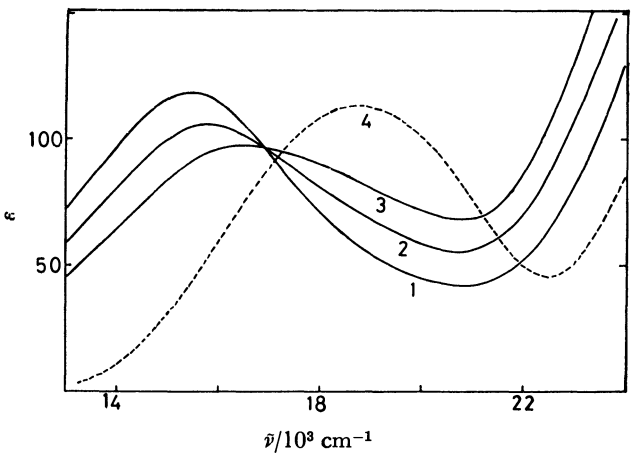

Fig. 3. Concentration dependence of the absorption spectra of [Cu(tmen)(acac)NCS] in NM, curves 1, 2, and 3 are those for 5.24×10^{-3}, 2.52×10^{-3} and 1.27×10^{-3} M solutions, respectively. Curve 4 is that of $[Cu(tmen)(acac)]ClO_4$ in the same solvent.

of this chelate in NM is remarkably dependent on concentration (*cf.* Fig. 3); its $\tilde{\nu}_{max}$ shifts to the red with increasing concentration and its ε_{max} increases, just as observed with the decrease of solvent polarity. Furthermore, the addition of KNCS to such a solution causes similar spectral changes, while the substitution of a part of NCS^- with ClO_4^- (this can conveniently be done by mixing the nitromethane solutions of $[Cu(tmen)(acac)]ClO_4$ and [Cu(tmen)(acac)(NCS)]) shifts the band in the opposite way. In all cases, a clear-cut isosbestic point appears on the curves, showing the existence of an equilibrium between two distinct species (*cf.* Fig. 4).** All these evidences indicate the existence of the equilibrium of the type (1) in these solutions. Very similar spectral changes were also observed in AN. The spectra of the same complex in H_2O or DCE are, on the other hand, not remarkably dependent on concentration, showing that they are either perfectly ionized or unionized, and that in acetone (which is very much like that in DCE) is affected only slightly by the addition of KNCS. All these facts are in line with the viewpoints proposed above. It may be added that the curve 6 of Fig. 4, *i.e.*, that of a NM solution of $[Cu(tmen)(acac)]^+$ with a large excess of NCS ($\tilde{\nu}_{max}$: 15.15×10^3 cm^{-1}, ε_{max}: 126), is very similar to those of the complex [Cu(tmen)(acac)-NCS] in DCE or acetone, indicating again the formation of the 5-coordinated species in NM, and also the fact that its spectrum is influenced only little by the solvent, *i.e.*, the 5-coordinated complex is only weakly solvated

** Strangely, the curve of $[Cu(tmen)(acac)]ClO_4$ itself slightly deviates from the isosbestic point, and its UV absorption is remarkably weaker than that of all other systems in Figs. 3 and 4. The reason for such deviations is not clear as yet, but may be due to the effect of ion-pair formation,[10] or the coexistence of a small amount of another species with strong ultraviolet absorption in the NCS^--containing solutions. These and other problems (e.g. solubility relationship) are hindering the estimation of K values of (1) from these data at present.

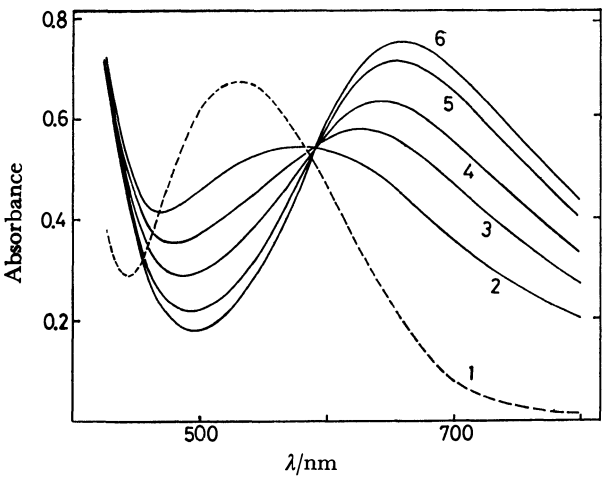

Fig. 4. The effect of NCS^- ions on the spectrum of $[Cu(tmen)(acac)]^+$(concentration: 6×10^{-3} M) in NM. The curve 1 is that of $[Cu(tmen)(acac)]ClO_4$ and curves 2 to 6 correspond to solutions in which the ratios $[Cu(tmen)(acac)]^+$: NCS^- are 1 : 0, 1 : 0.5, 1 : 0.75, 1 : 1, 1 : 1.5, and 1 : 2 respectively.

in solution.†

Finally, mention may be made of the structure of these three chelates in solid state. The comparison of the $\tilde{\nu}_{max}$ values of the solids (*cf.* Table 3) with those of the solutions indicates that the NCS-complex is typically 5-coordinate in its solid and to be formulated as [Cu(tmen)(acac)X]. The same can probably be said as to the NCO-complex. In the case of N_3-complex, the $\tilde{\nu}_{max}$ value is noticeably higher to be purely 5-coordinate: here the N_3-ions may be forming bridges between the $[Cu(tmen)(acac)]^+$ cations, making the Cu^{2+} in it to some extent 6-coordinate.[11] Some such bridge formation may also be present in the NCO-complex, in which the $\tilde{\nu}_{max}$ is slightly higher than that in DCE and comparable with those in NM or AN.[12]

Thus it is evident that these three new chelates are interesting examples of the stereochemistry of copper(II), with which one can easily observe the competition of pseudohalide ions and solvents for the coordination sites above or below the chelate plane with the aid of their visible spectra.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 347033 from the Ministry of Education, Science and Culture.

† The viewpoints stated here are supported further by the comparison of these data with those of the corresponding halide complexes,[14] which will be reported in another paper.

Bridges in Polynuclear Complexes. II.† An X-Ray Investigation of the Coordination of Silver Ion to the μ-Peroxo Bridge of a Dinuclear Cobalt(III) Complex

Takashi SHIBAHARA,*,** Masayasu MORI, Keiji MATSUMOTO, and Shun'ichiro OOI

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received May 15, 1980)

The crystal structure of $[(en)_2Co(NH_2)(O_2)Co(en)_2](NO_3)_3 \cdot 15/8(AgNO_3) \cdot H_2O$ has been determined from X-ray diffraction data collected by the counter method. The crystal is monoclinic with the space group C2/c and with $a=8.710(3)$, $b=16.413(5)$, $c=20.024(8)$ Å, $\beta=90.30(4)°$, and $Z=4$. The structure was refined by the block-diagonal least-squares method to $R=0.107$ for 2157 independent reflections. It has been elucidated that the Ag atom is bound to each of the two peroxo oxygen atoms with the Ag–O bond length of 2.27(1) Å. Each Ag atom is also surrounded by two more oxygen atoms belonging to the nitrate anions and these Ag–O bond lengths are 2.45(2) and 2.50(2) Å. The central five-membered ring has a symmetric envelope conformation, with the peroxo O atom deviating from the Co, N, Co plane, by 0.38 Å. The crystals contain an equal amounts of the enantiomeric forms $(^{\delta}_{\delta}\Lambda\delta\Lambda^{\delta}_{\delta})$ and $(^{\lambda}_{\lambda}\Delta\lambda\Delta^{\lambda}_{\lambda})$. The formation constant of Ag^+ and $[(en)_2Co(NH_2)(O_2)Co(en)_2]^{3+}$ in aqueous solution was found to be less than 0.5.

The peroxo moiety of μ-amido-μ-peroxo dicobalt complex can be regarded as a Lewis base. The protonation to the peroxo moiety of the μ-amido-μ-peroxo dicobalt complex and subsequent isomerization was suggested by Mori and Weil from the analysis of kinetic data[1] and was confirmed by Thewalt by the X-ray structure analysis.[2]

Werner[3] reported the preparation of an addition compound, $[(en)_2Co(NH_2)(O_2)Co(en)_2](NO_3)_3 \cdot 5/3(AgNO_3)$. As the peroxo bridge of the complex is a Lewis base and the silver ion a Lewis acid, it seemed of interest to know whether a coordinate bond between the silver ion and the peroxo moiety is realized in this compound, and, if so, to determine the mode of coordination of the peroxo bridge to the cobalt atoms in connection with the isomerization scheme stated previously.

In the course of the study to elucidate this kind of problem, the addition compound obtained after Werner's description was shown by elemental analysis to have the composition $[(en)_2Co(NH_2)(O_2)Co(en)_2](NO_3)_3 \cdot 15/8(AgNO_3) \cdot H_2O$. The present paper reports the result of the X-ray structure analysis of this addition compound.

Experimental

Preparation of the Complex $[(en)_2Co(NH_2)(O_2)Co(en)_2](NO_3)_3 \cdot 15/8(AgNO_3) \cdot H_2O$. The addition compound of the above formula was prepared by Werner's method.[3] Recrystallization from water containing a large excess of silver nitrate gave deep red crystals suitable for the X-ray structure analysis.

Found: C, 10.38; H, 3.92; N, 21.27; NO_3^-, 32.58; Co, 12.53; Ag, 21.47; loss in wt over P_2O_5, in a vacuum, 1.71%. Calcd for $[Co_2C_8H_{34}N_9O_2](NO_3)_3 \cdot 15/8(AgNO_3) \cdot H_2O$: C, 10.34; H, 3.91; N, 20.92; NO_3^-, 32.54; Co, 12.69; Ag, 21.77; H_2O, 1.94%. The above composition appears to be maintained even when the amount of the silver nitrate was varied to some extent.

For comparison, the calculated values for two other different formulae are given. Calculated for $[Co_2C_8H_{34}N_9O_2](NO_3)_3 \cdot 2(AgNO_3)$: C, 10.31; H, 3.68; N, 21.04; Co, 12.65; Ag, 23.15; NO_3^-, 33.06%. Calcd for $[Co_2C_8H_{34}N_9O_2](NO_3)_3 \cdot 5/3(AgNO_3)$ (Werner's formula); C, 10.89; H, 3.91; N, 21.87; Co, 13.46; Ag, 20.54; NO_3^-, 33.06%.

X-Ray Data Collection. The specimen employed for data collection had a shape of an approximate sphere and its diameter was 0.23 mm. The Laue symmetry, space group, and approximate unit-cell dimensions were determined from oscillation and Weissenberg photographs taken with Cu Kα radiation. Crystal Data: $[Co_2C_8H_{34}N_9O_2](NO_3)_3 \cdot 15/8(AgNO_3) \cdot H_2O$, $M=929.12$, monoclinic, $a=8.710(3)$, $b=16.413(5)$, $c=20.024(8)$ Å, $\beta=90.30(4)°$, $V=2862.6(15)$ Å^3, $Z=4$, $D_m=2.15$, $D_c=2.16$ g·cm^{-3}, space group C2/c, λ(Mo Kα)=0.7101 Å, μ(Mo Kα)=25.2 cm^{-1}. Both the structure refinement and piezoelectric test suggest that the centrosymmetric space group C2/c is the correct choice. The unit-cell dimensions were refined by the least-squares analysis of the 36θ values measured on a Philips PW1100 automated diffractometer. The intensity data with $2\theta \leqq 55°$ were collected at room temperature by the use of graphite-monochromated Mo Kα radiation. The ω-2θ scan technique was employed. The scan range was $(0.9+0.2\tan\theta)°$, and the scan speed, 1°/min in ω: the background was counted for half of the scan time at each end of the scan. The three standard reflections, 200, 080, and 006, monitored every 180 min, showed no appreciable decay. A total of 2159 intensities with $F^2 \geqq 3\sigma(F^2)$ were observed and used for the structure analysis. A spherical absorption correction was applied.[4]

Structure Determination and Refinement. The structure was solved by the heavy-atom technique. The parameters were refined by the block-diagonal least-squares method using isotropic temperature factor for each atom. The R factor was 0.16. Further refinement, based on the anisotropic temperature factores for the Co and Ag atoms, resulted in $R=0.107$ and the refinement was terminated at this point. When the anisotropic temperature factors were applied to all non-hydrogen atoms, the R-factor decreased to 0.085. There is some doubt, however, as to the meaning of this value, since all the nitrate anions and water of crystallization were found to be disordered. The minimized function was $\sum w(F_o - |F_c|)^2$ and weighting scheme, $w=(24.7/F_o)^2$ for $F_o > 24.7$, $w=1$ for $24.7 \geqq F_o \geqq 16.5$, $w=0.9$ for $F_o < 16.5$ was used.

† Part I: S. Kubo, T. Shibahara, and M. Mori, *Bull. Chem. Soc. Jpn.*, **52**, 101 (1979).

** Present address: Department of Chemistry, Okayama University of Science, 1-1 Ridai-cho, Okayama 700.

Full occupation of the general position in the C2/c system suggests the formula $[(en)_2Co(NH_2)(O_2)Co(en)_2](NO_3)_3 \cdot 2AgNO_3 \cdot H_2O$, but the actual composition was $[(en)_2Co(NH_2)(O_2)(Co(en)_2](NO_3)_3 \cdot 15/8(AgNO_3) \cdot H_2O$. In order to accomodate this descrepancy, the occupation factor of 0.938 (15/16) was used for the Ag ions. For the nitrate ions, the occupation factor of 0.975 based on an equal partition of the nitrate shortage (0.125) over all the five nitrate positions was adopted, because it has been difficult to determine the extent of lattice defect to each nitrate position. Application of the occupation factors different from unity as above, however, did not produce any significant difference of structural parameters. In the final cycle of the refinement, all the parameter shifts were less than their standard deviations. The large peaks in the final difference synthesis were 3.5 and 2.2 $eÅ^{-3}$ in the vicinity of the Ag atom and H_2O molecules, respectively. No attempt was made to locate the hydrogen atoms. The atomic scattering factors of the Ag, Co, O, N, and C atoms were taken from Ref. 5. The real part of the anormalous dispersion correction were applied for the Co and Ag atoms.[5] A complete list of the F_o and F_c tables is preserved by the Chemical Society of Japan (Document No. 8112). All the computation were carried out by the FACOM 230-60 computer at Osaka City University. The programs used included a local version of the UNICS.[6]

Measurement of Ag^+ activity in the Aqueous Solution. The activity of Ag^+ in the presence of Co complexes was measured by using a Horiba CN^- ion electrode 8001 and a Horiba ion meter N-7 ⟨ION⟩.

Results and Discussion

Figure 1 gives two projections of the complex ion which show the coordination mode of the Ag atom to the peroxo oxygen atom. Figure 2 shows the crystal structure viewed down the a axis. The nearest neighbor to the Ag atom is the oxygen atom of the peroxo moiety of the complex ion (Fig. 2). The Ag–O(1) bond distance of 2.27(1) Å, indicating the presence of a coordinate bond between the Ag and O(1)$(1/2-x, -1/2+y, 1/2-z)$ atoms, is somewhat longer than the strongest Ag–O bond length (2.17 Å) in $Ag_2C_2O_4$.[7] The OA(2) and OA(4) atoms of the nitrate anions lies at a slightly greater distance than that between Ag and O(1). The Ag–OA(2) and Ag–OA(4) bond distances are 2.47(2)

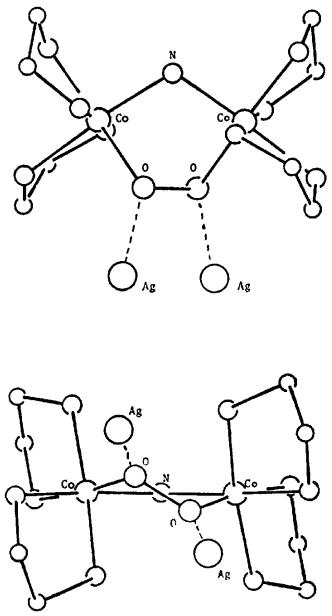

Fig. 1. Perspective drawing of complex ion.

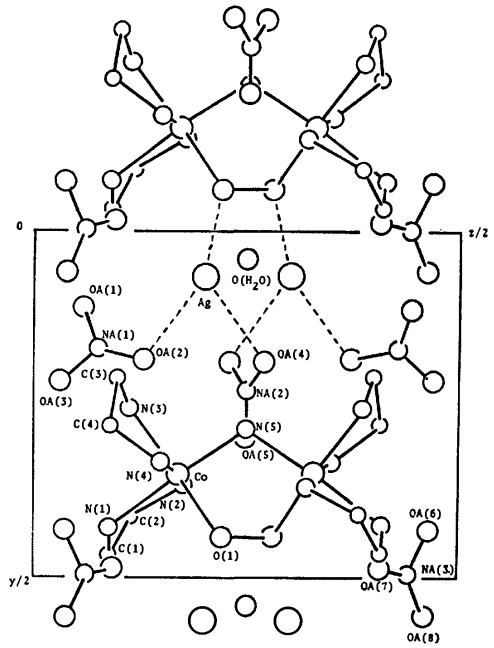

Fig. 2. The crystal structure viewed down the a axis. The dotted lines indicate possible Silver–Oxygen bonds.

The Character of Acid Sites on the Gypsum Surface

Susumu OKAZAKI* and Mituo YAMAZAKI

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316

(Received January 21, 1980)

The maximum value in the number of acid sites per unit of surface area of the gypsum formed in the reaction between $Ca(NO_3)_2$ and H_2SO_4 was observed at the heat-treatment temperature of 200 °C, corresponding to the dehydration temperature for the change from its hemihydrate form to soluble anhydrite. The IR-absorption spectra of the gypsum showed no bands assignable to isolated OH groups or Ca–OH species. The IR spectra of the pyridine adsorbed on the gypsum showed only the bands due to Lewis-acid sites. The gypsum heat-treated at temperatures lower than 500 °C showed catalytic activities for the double-bond isomerization of 1-butene. The *cis-/trans-* ratio of 2-butene was 2—2.5, showing that the catalytic activity was due to Lewis acid, not to Brönsted acid. The isomerization of cyclopropane to propene was scarcely promoted by the gypsum at 250 °C. This fact is another indication of the absence of Brönsted acid sites on the heat-treated gypsum. Most of the weak Lewis acid sites ($H_0 \leqq +4.8$) were ascribable to exposed Ca^{2+} ions surrounded by monodentate sulfate ions on the surface of metastable anhydrite III-$CaSO_4$.

In recent years, gypsum has been obtained in great quantities as a by-product in the SO_2-recovery process from exhaust gases. Accordingly, the development of a new method of utilizing the recovered gypsum is desirable. Use as a filler or a reinforcement agent in composite materials seems to be promising. Because of the polar nature of the gypsum surface, however, surface modification or an increase of lipophilicity is necessary for the two uses mentioned above. As has been shown in the previous study[1] dealing with the increase in lipophilicity of the gypsum surface upon interaction with butylamine, acid sites on the surface may be used for the surface modification.

The presence of acid sites on the calcium-sulfate surface was first reported about thirty years ago.[2] The surface acidity of gypsum has been investigated by subsequent workers.[3–6] Although the acid sites have been assumed to be the Lewis type,[7] the Lewis acidity has not beed substantiated. The absence of Brönsted sites has not yet been examined. Furthermore, the relation between the surface acidity and the catalytic activities for the acid-catalyzed reaction has scarcely been investigated.

In the present work, the character of acid sites on the surface of precipitated gypsum was investigated mainly by means of IR-spectroscopic measurements and by the determination of catalytic activities for the isomerization of 1-butene and the conversion of cyclopropane to propene.

Experimental

Materials. The precipitated gypsum used was prepared by the addition of concentrated sulfuric acid to an aqueous solution of $Ca(NO_3)_2$, followed by aging and completely washing with deionized water. The nitrate ions remaining in the precipitate could be removed with ease by the heat-treatment of the product, as evidenced by the trace amounts of NO_2 gas evolved during the heat-treatment. The carbonate content was determined to be 0.09 wt% by the gas-chromatographic analysis of the gas evolved during the heat-treatment of the sample up to 900 °C.

IR Spectra. Except for the study relating to the coordinations of SO_4^{2-} ions, which was carried out by using KBr pellets, the IR spectra were measured using a self-supporting disc in an *in situ* cell. The samples were compressed into thin discs and were evacuated at different temperatures.

X-Ray Diffraction and Surface Area. The X-ray powder diffraction patterns were recorded using Cu $K\alpha$ as the radiation source. The specific surface area was determined by applying the BET method to the adsorption of N_2 at −196 °C.

Acid Properties. The acid properties of samples were examined by titrating with butylamine in benzene according to Johnson's method.[8] The Brönsted and Lewis acidities were determined by observing the IR spectra of pyridine adsorbed on the samples.

1-Butene Isomerization. The 1-butene isomerization was carried out in a closed gas-circulation reactor having a volume of 0.43 l. Above 0.7 g of the sample was placed in the reactor and degassed for 2 h at various temperatures. After the sample has then been cooled to room temperature, 1-butene of 110 Torr was introduced and circulated for 0.5 h at 200 °C. The products were analyzed by gas chromatography using a 7-m column packed with VZ-7.

The catalytic activity was expressed by the mole percentage of the product per unit of weight of the catalyst (g^{-1}) per unit of time (min^{-1}) determined at the reaction time of 30 min. As an indication of the acid character, the mole ratio of *cis*-2-butene to *trans*-2-butene (abbreviated as *cis-/trans-*) at zero conversion in the isomerization was determined by extrapolation.

Conversion of Cyclopropane to Propene. The conversion was carried out in a glass reactor containing 0.05 g of gypsum which had been heat-treated at various temperatures. Pulses of cyclopropane were injected into the helium-carrier stream from a calibrated, 1.09-ml doser and were passed through the gypsum at a total pressure of 1 atm. The product gas was analyzed by gas chromatography using a 3-m column packed with Porapack N. The conversion of cyclopropane to propene in the first pulse was taken as a measure of the catalytic activity.

Results and Discussion

Changes in Structures and Surface Areas of Gypsum with Increase in Treatment Temperature. As is shown in Table 1, the results of the X-ray diffraction analysis for the sample show that the monoclinic structure of the dihydrate changed into the hexagonal structure of the hemihydrated gypsum (β-$CaSO_4$l/$2H_2O$) or soluble anhydrite (III-$CaSO_4$) at about 100 °C, and then into the orthorhombic structure of the insoluble anhydrite (II-$CaSO_4$) at about 400 °C. The changes in the

Table 1. Crystal structure and specific surface area of gypsum heat-treated at different temperatures

Treatment temp °C	Crystal structure	Specific surface area/$m^2\ g^{-1}$
Room temperature	$CaSO_4 2H_2O$	3.3
100	$CaSO_4 1/2H_2O$ or III-$CaSO_4$	13.5
200	$CaSO_4 1/2H_2O$ or III-$CaSO_4$	7.3
300	$CaSO_4 1/2H_2O$ or III-$CaSO_4$	21.8
400	II-$CaSO_4$	26.8
500	II-$CaSO_4$	26.7
600	—	21.3
700	—	4.3

crystal structure of the sample with the increase in the temperature almost coincided with that reported for gypsum ($CaSO_4 2H_2O$).[9] However, the change of β-$CaSO_4 1/2H_2O$ into III-$CaSO_4$ at 190—210 °C[9] could not be observed, since these two forms are very similar or the almost isomorphous with each other.[10,11]

Table 1 also shows the effect on the surface area of heating up to 700 °C. The specific surface area of the sample depends largely on the heat-treatment temperature. Two maxima are observed at about 100 °C and 400—500 °C. These temperatures are nearly equal to the transition points of the dihydrate to the hemihydrate, and of the soluble anhydrite to the insoluble anhydrite, respectively. These facts suggest that the change in crystal structure may increase the surface area. Because of the similarity in crystal form, the transformation of β-$CaSO_4 1/2H_2O$ to III-$CaSO_4$ may not cause the increase in the surface area.

Surface Acidity Determined by Amine Titration. Figure 1 shows the surface acidities of the sample heat-treated at different temperatures. The sample has no acid sites stronger than those corresponding to an H_0 value (indicator, pK_a) of 3.0, but it does display some weak acidity in the range of H_0 from 4.8 to 3.0. The acid amount per unit of weight showed a maximum value at a heat-treatment temperature of 300 °C.

To discuss the acid-site concentration on the surface, the acid amounts per unit of surface were calculated, as is shown by the dotted line in Fig. 1. A maximum in the acid-site concentration is shown at about 200 °C. From a structural point of view, the temperature at which the maximum acid concentration was obtained (200 °C) corresponds to the transition temperature of the hemihydrated gypsum to the soluble anhydrite form.[9] The soluble anhydrite has a crystal structure almost isomorphous with that of hemihydrated gypsum and has an active cleavage plane, on which Ca^{2+} and SO_4^{2-} ions are unevenly distributed.[7] It is well known that the soluble anhydrite is metastable and tends to be converted to the hemihydrated gypsum with the absorption of water. It is probable that the acid sites are formed on the metastable, or soluble, anhydrite.

Infrared Spectroscopy. The Ca^{2+} ions on the plane of the hemihydrated gypsum may be the sites of Lewis acidity (in a general sense). However, it is also possible that the ions may polarize adjacent OH groups or the O–H bonds in H_2O molecules adsorbed on the surface and produce Brönsted acid sites. Hence, the elucidation of the characteristics and behavior of OH groups and H_2O molecules on/in gypsum was attempted by means of IR spectroscopy.

Previously, the presence of a small amount of water in the so-called soluble anhydrite gypsum has been detected in the IR studies using the KBr[12] or Nujol[13] method. However, since the anhydrous form is very hygroscopic, these methods are inadequate for the confirmation of the presence and behavior of H_2O and related OH groups in the course of heat-treatment. Accordingly, the IR absorption analysis was carried out using a self-supporting disc in an *in situ* cell. As is shown in Fig. 2, the broad bands due to OH stretching

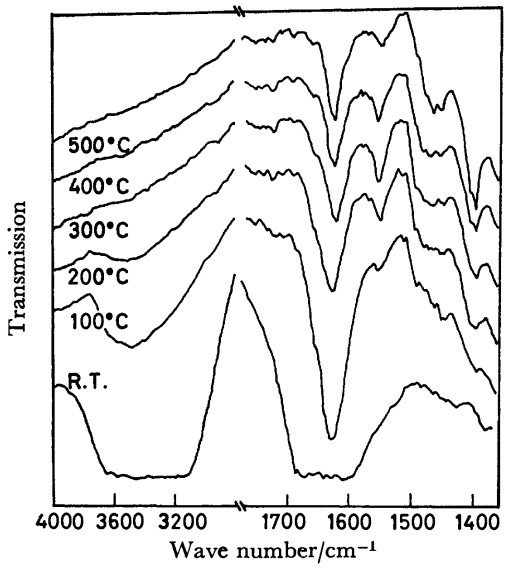

Fig. 2. Infrared spectra for precipitated gypsum evacuated at various temperatures.

and H_2O bending were observed at 3200—3600 cm^{-1} and 1600—1700 cm^{-1} respectively for the evacuation at room temperature. The band at 1600—1700 cm^{-1} was converted into a sharp 1627 cm^{-1} band at 100 °C, and this band still remained at higher temperatures such as 500 °C. Even though this band is ascribable to H_2O bending vibrations, the band assignable to OH stretching disappeared above 300 °C, as is shown in Fig. 2. Therefore, the absorption band which survived above 300 °C may be assigned not to H_2O but to bidentate carbonate, which gives the absorption at 1630 cm^{-1}.[14] Thus, the band at about 1620 cm^{-1} in the spectra observed for the gypsum heat-treated below 300 °C is probably due to both H_2O and carbonate. The bands at 1396 and 1405 cm^{-1} might be due to the asymmetric stretching vibration of the N–O bond belonging to the NO_3^- ion,[15] which could not be completely removed during the preparation. Other bands at 1430—1500 cm^{-1} might be assigned to carbonate or hydrogen carbonate ions.[16]

In general, the bands at 3600—3700 cm^{-1} due to isolated OH groups are observed for many heat-treated metal oxides. As has been shown in the discussion with respect to the surface acidities of Al_2O_3 and SiO_2–Al_2O_3,[17] the isolated OH groups may be acidic, for they are surrounded by three metal atoms, and so would be affected by the greatest induction due to metal atoms. In the case of gypsum, there are no distinct bands due to isolated OH groups in the region of 3600—3700 cm^{-1}. Thus, the existence of Brönsted acid sites due to the isolated OH groups on the gypsum surface seems impossible.

Infrared Spectra of Pyridine on the Surface of Gypsum. Infrared spectroseopic studies of pyridine adsorbed on a solid surface have made it possible to distinguish between Brönsted and Lewis acids.[18] The IR spectra of pyridine on gypsum evacuated at different temperatures were measured in order to elucidate the character of the acid sites. As is shown in Fig. 3, a strong absorption band at 1445 cm^{-1} was observed in the case of gypsum which had been dried in the air at 200 °C for 2 h and then evacuated in a cell at 200 °C for 2 h. As the evacuation temperature was raised, the band at 1445 cm^{-1} became weaker. This band is attributable to hydrogen-bonded (at 1440—1447 cm^{-1} [19]). The band at about 1445 cm^{-1} is not so sharp, as is shown in Fig. 3, the bands due to hydrogen bonding and to coordinative bonding are close to each other. Therefore, it is difficult to determine the character of the active sites merely by the inspection of the IR spectrum of pyridine on the surface. However, the shoulder at 1605 cm^{-1} is more readily attributable to the coordinatively bonded pyridine (at 1600—1663 cm^{-1} [19]) than to the hydrogen-bonded pyridine (at 1580—1600 cm^{-1} [19]). The finding that the absorption band at 1445 cm^{-1} remained after evacuation at 200 °C also supports the presence of Lewis acid sites rather than that of hydrogen-bonding sites, which may be weak with respect to retaining the pyridine molecules.

The absorption bands at 1540 cm^{-1} and about 1640 cm^{-1} are characteristic of pyridinium ions and are generally used for finding of Brönsted-acid sites.[19] The band at about 1540 cm^{-1} is indistinguishable from the bands of gypsum (as shown in the spectrum (B. G.) in Fig. 3). However, the absence of the band at 1640 cm^{-1} suggests that there are no Brönsted-acid sites on gypsum.

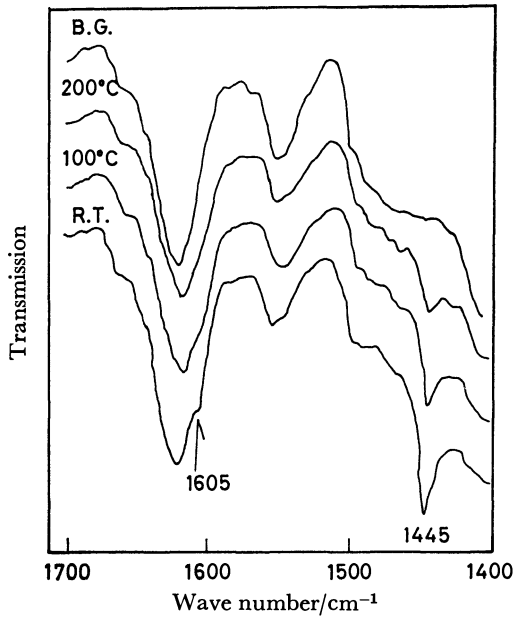

Fig. 3. Infrared spectra for pyridine adsorbed on precipitated gypsum.
B.G.: Background; Precipitated gypsum treated in the air at 200 °C for 3 h and evacuated for 2 h. R.T., 100 and 200 denote the evacuation temperature of samples treated with 10 Torr of pyridine for 10 min.

Table 2. Conversion of cyclopropane to propene[a]

Catalyst	Heat-treatment temperature[b] °C	Conversion %
Gypsum	300	0.7
	400	0.8
	500	0.3

TiO_2	500	100
None		0.4

a) The reaction condition were as follows; temperature: 250 °C, catalyst weight: 50 mg, carrier and its velocity: He, 10 ml/min. b) All the catalysts had been heat-treated for 3 h.

Catalytic Activities for Conversion of Cyclopropane and for the Double-bond Isomerization of 1-Butene. The catalytic activity of heat-treated gypsum in the conversion of cyclopropane was examined at 250 °C. As is shown in Table 2, the conversion of cyclopropane to propene, which should be catalyzed by Brönsted acids,[20] were all less than 1%, irrespective of the heat-treatment temperature, and were close to those obtained in the absence of the gypsum. The conversion of the reaction catalyzed by the commercial SiO_2–Al_2O_3 catalyst, named N 631 (Nikki Chem. Co.), which is a typical Brönsted-acid catalyst, was 65% at such a low

Evacuation was carried out for 2 h at each tretment temperature.

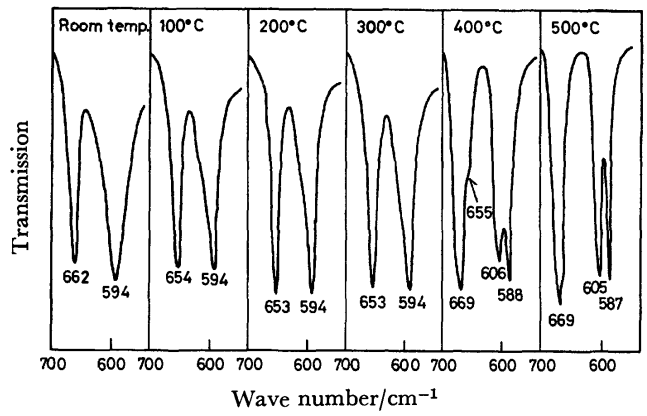

Fig. 5. Infrared spectra for sulfate ions on precipitated gypsum heat-treated at different temperatures

temperature as 150 °C for the same contact time. In addition, the conversion of the reaction at 250 °C catalyzed by TiO_2, which had been prepared from $TiOSO_4$ and which had a considerable quantity of Brönsted-acid sites,[21] was nearly 100%. These contrasted results indicate that there are no Brönsted-acid sites on the gypsum surface.

In order to further investigate the acid character of the gypsum, the isomerization of 1-butene was carried out at 200 °C in the presence of the heat-treated gypsum. The catalytic activity and *cis-/trans-* ratio at zero conversion are plotted as functions of the evacuation temperature in Fig. 4. When the gypsum was evacuated at 200 °C, its catalytic activity was relatively high. The activity decreased with an increase in the evacuation temperature, and almost disappeared when the gypsum was treated at 500 °C under evacuation. For lower evacuation temperatures, such as 200 °C and 300 °C, the initial *cis-/trans-* ratio was 2; this was elevated to 2.5 as the evacuation temperature was raised to 400 °C. It is already known that the *cis-/trans-* ratio in the products of the reaction of 2-butenes is determined by the nature of the active site; that is, if the active site is the Brönsted type, the ratio should be about 1, while if the active site is the Lewis type, the ratio should be about 2.[22] Since the value in Fig. 4 is 2—2.5 throughout the evacuation-temperature range, the acid must be the Lewis type.

Coordination of Sulfate Ions to Calcium Ions. In order to discuss the coordinations of SO_4^{2-} ions to Ca^{2+} ions, the IR spectra due to SO_4^{2-} ions were observed in the wave-number region of about 400 to 1400 cm^{-1}. The IR spectra showed the absorption band (ν_3) due to the stretching vibration of S–O, S=O at 1100—1200 cm^{-1} and that (ν_4) due to the bending vibration of –O–S–O– in the region of 580—680 cm^{-1}. In a previous report,[12] the splitting of ν_3 and ν_4 has already been observed for gypsum heat-treated at 337—390 °C and 358—375 °C respectively; it was there ascribed to the transition from III-$CaSO_4$ to II-$CaSO_4$.

The splitting of ν_3 could also be found in this study. However, the details of the splitting could not be made clear, because the bands are essentially broad. Therefore, the splitting of the sharp band due to –O–S–O– bending was examined. Fig. 5 shows the IR absorption spectra of gypsum heat-treated at different temperatures in the 550—700 region. As is shown in this figure, the spectra gave bands at 594 cm^{-1} and near 653 cm^{-1} which were specific to the monodentate SO_4^{2-} ions.[23] With increases in the heat-treatment temperature, these bands gradually disappeared, while bands appeared at 588, 606, and 669 cm^{-1} when the sample was heat-treated at a temperature higher than 300 °C. According to the study of Nakamoto *et al.*, these bands are ascribable to bidentate SO_4^{2-} ions.[23] Since the X-ray diffraction analysis (shown in Table 1) of the sample showed that soluble anhydrite (III-$CaSO_4$) was transformed into insoluble anhydrite (II-$CaSO_4$) between 300 °C and 400 °C, the monodentate and bidentate ions are considered to be present in soluble and insoluble anhydrite respectively.

Thus, when gypsum was heat-treated at temperatures higher than 300 °C, the metastable anhydrite (III-$CaSO_4$) was converted into stable anhydrous form (II- or I-$CaSO_4$) and Ca^{2+} ions on the surface became closely surrounded by bidentate sulfate ions. In such a configuration, the Ca^{2+} ions on the surface cannot interact with other molecules as electron acceptors. This is possibly the reason why the Ca^{2+} ions on the insoluble, or stable, anhydrite do not function as Lewis-acid sites. On the other hand, the Ca^{2+} ions on the soluble anhydrite, which are less closely surrounded by monodentate sulfate ions, are able to accept electron pairs of other molecules. Thus, the Lewis-acid center may be formed by an empty orbital of the Ca^{2+} ions on the surface of III-$CaSO_4$. A similar phenomenon has also been observed in the dehydration of $NiSO_4xH_2O$, in which strong acid sites ($H_0 \leqq -3.0$) have been found.[24] However, the electronegativity of the Ca^{2+} ion is smaller than that of the Ni^{2+} ion;[25] hence, the Lewis acidity due to the Ca^{2+} ion should not be so

strong. In fact, the acid function (H_0) was determined to be mostly 3.0—4.8, as has been described previously.

The maximum acid-site concentration of heat-treated gypsum (shown in Fig. 1) is about twice that reported for alumina, which is a typical Lewis acid, heat-treated at 500 °C (0.0008 mmol/m^2 at $H_0 \leqq +1.5$).[26] However, the amount is considerably less than that for heat-treated nickel sulfate (0.011 mmol/m^2 at $H_0 \leqq +4.8$ and 0.005 mmol/m^2 at $H_0 \leqq -3.0$).[24] The concentration of Ca^{2+} ions on the surface is much more than that of acid sites. For example, the former concentration on the (001) plane is calculated to be 0.0034 mmol/m^2 on the basis of the lattice constant ($a,b=6.99$ Å, $c=6.34$ Å).[11] As suggested by the comparison between the concentration of the acid sites and Ca^{2+} ions, not all the Ca^{2+} ions on the III-$CaSO_4$ surface can be Lewis-acid sites. The details of the active-site formation must be studied further.

Even if a small amount of water should be occluded in the III-$CaSO_4$ formed at temperatures lower than 300 °C, as has been shown in previous studies,[12,13] the polarization of the surface OH groups and/or H_2O molecules by Ca^{2+} ions must be impossible because Ca^{2+} ions have only a low electrostatic potential (ion valency/radius). Therefore, the weak solid acidity should be of the Lewis type ascribable to the Ca^{2+} ions on the unstable crystal surface.

The authors wish to thank Mr. Akito Kurosaki and Mr. Haruo Ogino of our laboratory for their great assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Aluminium(III) Ion-assisted Aquation of the Pentaammine-fluorochromium(III) Ion

Masayasu IIDA* and Hideo YAMATERA**

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received February 12, 1980)

The aquation of the pentaamminefluorochromium(III) complex was found to be assisted by the aluminium ion. The observed pseudo-first-order rate constant, k_{obsd}, can be written approximately as: $k_{obsd}=k_{Al}[Al^{3+}]$ ($k_{Al}=7.5\times10^{-4}$ dm^3 mol^{-1} s^{-1} at 35 °C, pH 3.0, $I=2.0$ mol dm^{-3}). The rate constant decreased with an increase in the hydrogen-ion concentration, and this hydrogen-ion dependence was explained by assuming that the attack of aluminium ions on $CrF(NH_3)_5^{2+}$ was blocked by the protonation of the fluoro ligand. The analysis of the experimental results gave 3.0 ± 0.1 for the logarithm of the protonation constant. The effects of ClO_4^- and $Co(CN)_6^{3-}$ on the reaction rate were explained by considering the formation of ion-pairs between the anions and the reacting cations.

Among the reactions of transition-metal complexes, metal ion-induced aquation, or metal ion-assisted aquation, is particularly interesting as a model ionic reaction. In order to understand this kind of reaction in more detail, it is significant to extend the study to the reactions of types that have not yet been studied. The greater part of the studies of the metal ion-assisted aquation have been concerned with the reactions of chloro, bromo, and iodo complexes with soft acids, such as Ag^+, Hg^{2+}, and Tl^{3+}. There have been no detailed studies of the aquation of fluoro complexes induced by hard metal ions.[1,2]

The present paper is concerned with a rarely studied type of reaction, *i.e.*, the dissociation of hard basic anions induced by hard metal ions. The investigation of such a type of reaction is expected to disclose some characteristic behavior which has not appeared in the aquations assisted by soft metal ions. Another purpose of this study is to see how the reaction is influenced by the hexacyanocobaltate(III) ion. This ion tends to form a precipitate with soft metal ions; therefore, its effect on the metal ion-assisted aquations cannot be investigated when the metal ion is soft, as is usually the case; however, it can be examined in the present study where a hard metal ion is used to induce the aquation.

Experimental

Materials. Pentaamminefluorochromium(III) perchlorate was prepared from pentaammineaquachromium(III) ammonium nitrate by the method of Zinato *et al.*[3] The purity of the crystals was confirmed spectrophotometrically and by means of SP-sephadex ion-exchange chromatography; the complex was sorbed on the top of the column and was eluted with a 0.1 mol dm^{-3} sodium sulfate solution. The appearance of a well-formed single band indicated the absence of impurities.

Aluminium perchlorate was prepared by dissolving $AlCl_3\cdot6H_2O$ in an aqueous solution containing perchloric acid in excess. The salt was then precipitated in a rotating evaporator and recrystallized twice from water. The crystals were dissolved in an aqueous solution of perchloric acid for the preparation of a stock solution. The aluminium-ion concentration was determined to be Al_2O_3 by precipitating aluminium hydroxide and igniting it at about 1100 °C.

Sodium hexacyanocobaltate(III) dihydrate was prepared by the conventional method,[4] in which potassium cyanide was replaced by sodium cyanide. Anhydrous sodium perchlorate was prepared from a saturated sodium hydroxide solution and perchloric acid. Heavy-metal impurities in the sodium perchlorate solution were precipitated at pH 9. After the evaporation of the solution, crystals of sodium perchlorate were obtained by cooling (above 60 °C).

The other reagents used were of a guaranteed reagent grade from Wako Pure Chemicals Industries, Ltd.

Kinetic Procedure. The kinetic measurements were made with a Hitachi 200-10 spectrophotometer. The concentration of $[CrF(NH_3)_5](ClO_4)_2$ was controlled at 5.0×10^{-3} mol dm^{-3} in all the experiments unless otherwise stated. The change in the absorbance was followed at 510 nm. As the rates were of first-order in the presence of excess aluminium ions (more than five times the amount of the chromium(III) complexes), they were determined by plotting $\ln(D_t-D_\infty)$ against the time, where D_t and D_∞ are the absorbances at the time t and at an infinite time respectively. The pseudo-first-order rate constant, k_{obsd}, was thus obtained as the slope of this plot.

pH *Measurements.* The pH value of the sample solution containing a 0.1 mol dm^{-3} portion of $Al(ClO_4)_3$ was controlled by the addition of Na_2CO_3 crystals. The solution was used one day after the preparation.[5] The $(pH)_{obsd}$ values of the sample solutions were determined by means of a Beckman Century SS-1 pH meter, using a Beckman 39301 glass electrode and a 39402 calomel reference electrode. As the internal solution of the reference electrode, a saturated NaCl solution was used to avoid the precipitation of $KClO_4$. The pH meter was calibrated in terms of the H^+ concentration; *i.e.*, the pH was defined as $-\log[H^+]$ instead of $(pH)_{obsd}$.[6] As the pH dependency of the reaction rate was studied in a 0.1 mol dm^{-3} $Al(ClO_4)_3$ solution, the calibration of $-\log[H^+]$

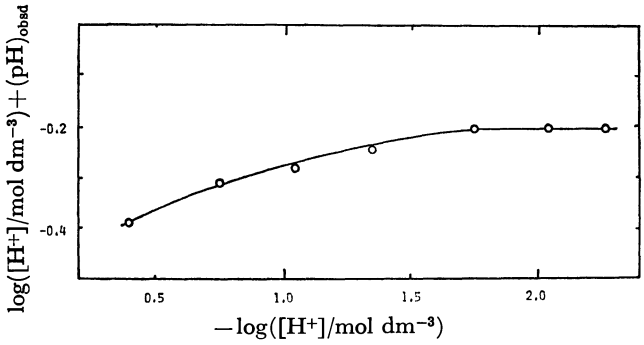

Fig. 1. Deviations of $(pH)_{obsd}$ from $-\log[H^+]$ in a 0.10 mol dm^{-3} $Al(ClO_4)_3$ aqueous solution.

vs. $(pH)_{obsd}$ was carried out for this solution in the pH range where the hydrolysis of aluminium ions could be neglected ($-\log[H^+]<3.2$). The results are shown in Fig. 1. The liquid-junction error is independent of the pH above $-\log[H^+]=1.7$; below that it increases with a decrease in the pH. Therefore, this equation:

$$(pH)_{obsd} + \log[H^+] = -0.21$$

is used above pH 1.7.

Results and Discussion

Spontaneous Aquation. Spontaneous and proton-catalyzed aquations of the pentaammine fluorochromium(III) ion were studied polarographically by Jones and Phillips.[7]

$$CrF(NH_3)_5^{2+} + H_2O \xrightarrow{k_0} Cr(OH_2)(NH_3)_5^{3+} + F^-$$

$$CrF(NH_3)_5^{2+} + H_3O^+ \xrightarrow{k_H} Cr(OH_2)(NH_3)_5^{3+} + HF$$

These reactions were found to be very slow, and the rate constants obtained were $k_0=1.4\times10^{-5}$ s^{-1} (pH range, 1—10.5) and $k_H=3.5\times10^{-5}$ mol^{-1} s^{-1} dm^3 (pH <1) at 65 °C. (The ionic strength was maintained at 1.0 by the addition of sodium perchlorate.) In fact, the mechanism of aquation is complex.[7,8] Fluoro, aqua, and ammine mixed-ligand complexes were formed as the by-products, indicating that the aquation was accompanied by the dissociation of the ammine ligands. To confirm the stoichiometry, we carried out spontaneous aquation at 35 °C in the dark. The $CrF(NH_3)_5^{2+}$ and H^+ concentrations were both controlled to 10^{-2} mol dm^{-3}. The reaction was followed for 10 d with a fluoride-ion electrode and by means of the SP-sephadex chromatographic technique. The former detects the fluoride ion released from the complex, and the latter, the complexes produced by the reaction with the aid of spectrophotometric measurements. Although the analysis hardly led to a quantitative conclusion, the following facts were proved: 1) In the early stage of the reaction, *cis*-$[CrF(OH_2)(NH_3)_4]^{2+}$ ($\lambda_{max}=512$ and 375 nm[9]) is formed. 2) No $[Cr(OH_2)(NH_3)_5]^{3+}$ can be detected throughout the measurement. 3) The release of fluoride ion is much slower than that of ammonia, and less than 5% of the fluoride ions in the complex are released in about 10 d. These results are similar to those obtained by Linhard and Weigel[8] and to those described by Wong and Kirk for the photoaquation of this complex,[10] but they are different from those reported by Jones and Phillips.[7]

No further investigation of the spontaneous aquation has been made, as it is not our present purpose.

Aluminium(III)-assisted Aquation. The hard aquation, $CrF(NH_3)_5^{2+}\rightarrow Cr(OH_2)(NH_3)_5^{3+}$, easily proceeds in the presence of aluminium ions. The spectrum of the complex changes with isosbestic points at 382, 415, and 480 nm, which shows the absence of by-products. In 0.1 mol dm^{-3} of $Al(ClO_4)_3$, the reaction proceeds to completion after about 1 d (pH 3.3, 35 °C). The pseudo-first-order rate constants, k_{obsd}, obtained depend on the concentration of the aluminium ion. The results summarized in Table 1 show that k_{obsd}

Table 1. Dependence of the rate constant on the concentration of the aluminium ion (35 °C)

$[Al^{3+}]$/mol dm^{-3}	k_{obsd}/s^{-1}
$((pH)_{obsd}=2.0, I=3.0$ mol dm$^{-3})$	
0.50	1.5×10^{-4}

0.10	3.5×10^{-5}
$((pH)_{obsd}=2.8, I=2.0$ mol dm$^{-3})$	
0.30	2.1×10^{-4}
0.20	1.4×10^{-4}
0.12	9.5×10^{-5}
0.10	8.2×10^{-5}

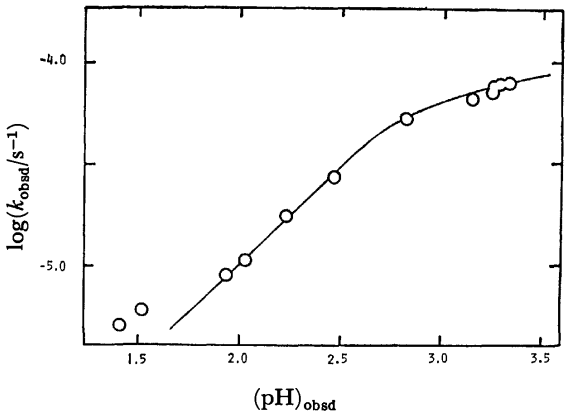

Fig. 2. pH dependence of the pseudo-first-order rate constant (0.10 mol dm^{-3} $Al(ClO_4)_3$ at 35 °C).

can be expressed approximately as $k_{Al}[Al^{3+}]$ if pH is kept constant. An additional term, k_0, for the spontaneous aquation can be neglected under our present experimental conditions.

Figure 2 shows the pH dependency of the reaction rate in the presence of 0.1 mol dm^{-3} of $Al(ClO_4)_3$. The observed rate constant increases with an increase in the pH value and becomes approximately constant at a $(pH)_{obsd}$ value of about 3.2. This pH dependency of the reaction rate has not been observed for the metal ion-assisted aquations hitherto studied. As the reaction proceeds between $CrF(NH_3)_5^{2+}$ and Al^{3+}, the pH dependency is attributed to the pH-dependent properties of the reactants. One of these properties is the hydrolysis of Al^{3+}, which is known to begin around pH($-\log[H^+]$) 3. Gradual hydrolysis proceeds up to a pH of about 3.5, where an abrupt change takes place.[11-13] Only $AlOH^{2+}$ is formed in the experimental pH range, and so polynuclear cationic species need not be considered. Figure 2 shows only a slight change in the rate in the pH range where a marked hydrolysis of Al^{3+} occurs. Therefore, the hydrolysis product, $AlOH^{2+}$, appears to have no appreciable effect on the reaction.

Another possibility is that the pH dependence of the rate is due to the protonation of the fluoro ligand of $CrF(NH_3)_5^{2+}$. Such protonation will block the attack of aluminium ions upon the fluoro ligand. Including the protonated complex, the reaction scheme can be formulated as follows:

$$CrF(NH_3)_5^{2+} + Al^{3+} \xrightarrow{k_1} Cr(OH_2)(NH_3)_5^{3+} + AlF^{2+}$$
$$K_H \uparrow\downarrow$$
$$CrFH(NH_3)_5^{3+} + Al^{3+} \xrightarrow{k_2} Cr(OH_2)(NH_3)_5^{3+} + AlF^{2+} + H^+.$$

In this scheme, k_2 can be assumed to be negligibly small in comparison with k_1. Then, the pseudo-first-order rate constant, k_{obsd}, can be rewritten as:

$$k_{obsd} = (1 + K_H[H^+])^{-1}k_1[Al^{3+}],$$

where K_H is the concentration equilibrium constant for the protonation of pentaammine fluorochromium(III) ions. Beginning with this equation, we can carry out a curve fitting such as is shown in Fig. 2 and obtain $\log(k_1[Al^{3+}]) = -4.00 \pm 0.05$ and $\log K_H = 3.0 \pm 0.1$. The failure of fitting in the lowest pH region may be attributed to such side reactions as the dissociation of the ammine ligands, which may not be ignored at such low k_{obsd} values. The value of $\log K_H$ seems to be too large considering the equilibrium constant for $H^+ + F^- \rightleftharpoons HF$ ($\log K = 3.2 \pm 0.2$ at 35 °C.[14]), because the logarithms of the protonation constants of oxoanions are lowered by 2—3 units by their coordination to the pentaamminecobalt(III) cations.[15] This suggests that the Cr–F bond is considerably ionic and that the F ligand is more easily protonated than expected.

Table 2. First-order rate constants at varying temperatures
($(pH)_{obsd} = 3.2$, $[Al(ClO_4)_3] = 0.10$ mol dm^{-3})

	k_{obsd}/s^{-1}
25 °C	3.2×10^{-5}
30 °C	6.5×10^{-5}
35 °C	8.3×10^{-5}
40 °C	1.6×10^{-4}
45 °C	2.7×10^{-4}

From the rate constants measured at various temperatures (Table 2), the activation enthalpy, ΔH^*, and the activation entropy, ΔS^*, can be estimated: $\Delta H^* = 83 \pm 5$ kJ mol^{-1} and $\Delta S^* = -62 \pm 17$ J K^{-1} mol^{-1}. The activation entropy for a Cr^{2+}-assisted reduction of this complex (-126 J K^{-1} mol^{-1})[16] is about 60 J K^{-1} mol^{-1} smaller than that for this reaction; this relationship holds also between the $CrCl(NH_3)_5^{2+}$–Hg^{2+} system and the $CrCl(NH_3)_5^{2+}$–Cr^{2+} system.[17,18] The minus sign of the activation entropies reflects the formation of halide-bridged binuclear complexes in the transition states. If the electron transfer proceeds adiabatically in the reduction process, the change in the entropy will be nearly zero in this step and the activation entropy can mostly be ascribed to the formation of the bridged complex. In view of this, the difference in the activation entropy between the reduction and the aquation can be said to be due mainly to the difference in the structure of the activated complex.[19] A more stringent geometrical condition may have to be satisfied in the reduction.

Effects of Anions. Table 3 summarizes the effects of the anions. As five-coordinated intermediates are formed in the metal ion-assisted aquation,[20] such anions as SO_4^{2-} and $H_2P_2O_7^{2-}$ may react with the intermediate to form inner-sphere complexes. The instability of the oxoanionopentaamminechromium(III) complexes makes the reactions complicated, however.[21]

Table 3. Effect of anions on the reaction

Anions	
ClO_4^-	Small accelerating effect.
SO_4^{2-}(pH 3)	Formation of sulfato complex, followed by the dissociation of ammine ligands.
$H_2P_2O_7^{2-}$(pH 2)	Formation of some polynuclear complex.[a]
$Co(CN)_6^{3-}$	Large accelerating effect.

a) After the absorbance change had almost terminated (for 0.1 mol dm^{-3} $Na_2H_2P_2O_7$ at 35 °C, one day after the reaction had started), the reaction solution was poured onto a column of SP-sephadex. Then, most of the complex was adsorbed at the top of the column. Elution with one molar sodium sulfate solution did not develop the band. The complex formed is likely to be a highly-charged cation.

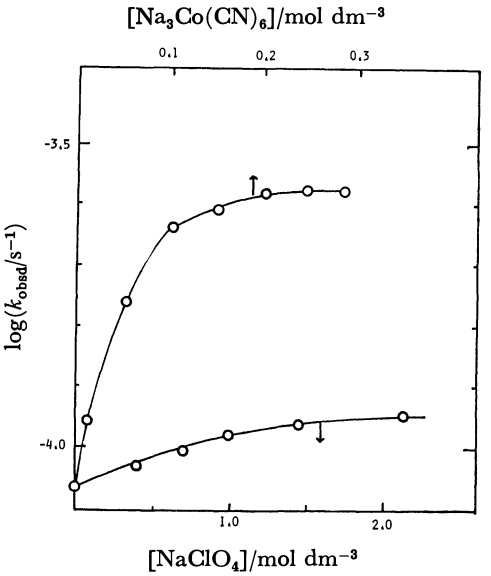

Fig. 3. Effects of anions on the reaction rate ($[Al^{3+}] = 0.10$ mol dm^{-3}, $(pH)_{obsd} = 3.1 \pm 0.1$).

The role of anions such as ClO_4^- and $Co(CN)_6^{3-}$, which are reluctant to coordinate, is to assist the reactant cations in their approaching each other and to increase the chances of the reaction between them. Figure 3 shows the effects of perchlorate and hexacyanocobaltate(III) ions in accelerating the aluminium ion-assisted aquation. The reactions were carried out in the presence of the respective anions at $(pH)_{obsd} = 3.1 \pm 0.1$, where the reacting species can be considered to be $CrF(NH_3)_5^{2+}$ and Al^{3+}. A rough analysis was carried out for the relative magnitudes of the effects of $Co(CN)_6^{3-}$ and ClO_4^- with the following assumptions. Firstly, the effects of anions on the reaction rate are assumed to be mainly determined by the charge and the radius of the anion. Secondly, the effect of added neutral salts is considered to be the formation of ion-pairs between the reacting cations and the mediating anions. The formation of the ion-pairs with Na^+ is neglected,

however. The third is that the activity coefficients of ion-pairs change according to the Davies equation:

$$\log y_i = -0.521\, z_i^{*2}\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3\,I\right), \quad (1)$$

where z_i^* is the effective charge number of the ion-pairs, and I, the ionic strength. On the basis of the above assumptions, we can express the rate constant of the reaction between A and B ions at saturation as follows:

$$k_{AB} = k_{AB}^0 \frac{K_{AB}}{K_{AB}^0} = k_0^0 \frac{K_{AB}}{K_{AB}^0} \exp\left(-\frac{z_A^* z_B^* e^2}{kT\varepsilon a}\right), \quad (2)$$

where the superscript 0 indicates the value at an infinite dilution and where the symbols have the following meanings:

K_{AB}: Equilibrium constant between the activated complex and the reactants.
k_0^0 : Hypothetical rate constant for uncharged ions.
z_A^*e, z_B^*e : Effective charges of A and B ions respectively, decreased by the approach of ions of the opposite sign.
k : Boltzmann constant.
T : Absolute temperature.
ε : Dielectric constant of the solvent.
a : Closest distance of the approach of the A and B ions.

For the present system containing sodium perchlorate, the rate constant at the saturation is:

$$k_{12} = k_0^0 \frac{K_{12}}{K_{12}^0} \exp\left(-\frac{2e^2}{kT\varepsilon a}\right) = k_0^0 \frac{y_1 y_2}{y_{12}} \exp\left(-\frac{2e^2}{kT\varepsilon a}\right), \quad (3)$$

where the subscript 12 indicates $z_A^*=1$ and $z_B^*=2$. Using Eq. 1, Eq. 3 is transformed to:

$$\log k_{12} = \log k_0^0 - 0.521\,(1+4-9)\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3\,I\right) - 0.86,$$

where $T=308$ K and $a=0.7$ nm are used.

The ionic strength at the saturation (Fig. 3) is 1.1 ± 0.2,[22] which is substituted to give this result:

$$\log k_{12}\,(I = 1.1 \pm 0.2) = \log k_0^0 - (0.47 \pm 0.08).$$

On the other hand, ion-pair formation between the reactants and $[Co(CN)_6]^{3-}$ makes $z_A^*=-1$ and $z_B^*=0$; therefore, the pseudo-first-order rate constant, k_{10}, at saturation with $[Co(CN)_6]^{3-}$ will not depend appreciably on the ionic strength. Thus, one obtains this approximate equality:

$$\log k_{10} \approx \log k_{10}^0 \approx \log k_0^0.$$

From the above argument, the saturation rate constant for the Al^{3+}-assisted aquation of $[CrF(NH_3)_5]^{2+}$ can be expected to be greater in the sodium hexacyanocobaltate(III) solution than in the sodium perchlorate solution:

$$\log k_{10} = \log k_{12}\,(I = 1.1 \pm 0.2) + (0.47 \pm 0.08).$$

This calculated difference in the saturation rate constant is in good agreement with the experimental results (Fig. 3):

$$\log k_{10}\,(\text{exp.}) = \log k_{12}\,(\text{exp.}) + (0.39 \pm 0.02).$$

Kinetics of the Formation of Alkoxy-derived Barium Metasilicate

Osamu YAMAGUCHI,* Kazuhiro TOMINAGA, and Kiyoshi SHIMIZU*

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received May 28, 1980)

Amorphous $BaSiO_3$ or a mixture of this and $BaSiO_3 \cdot H_2O$ was formed by the simultaneous hydrolysis of barium and silicon alkoxides. The temperature of hydrolysis and the time of aging influence the crystallization of amorphous $BaSiO_3$ into $BaSiO_3 \cdot H_2O$. The decomposition of $BaSiO_3 \cdot H_2O$ into crystalline $BaSiO_3$ was analyzed by isothermal thermogravimetry. Decomposition isotherms were constructed by the equation $-\ln(1-\alpha)=kt$ and the activation energy was determined as 143.5 kJ/mol. The kinetics of crystallization of amorphous into crystalline $BaSiO_3$ was interpreted by the equation $1-(1-\alpha)^{1/3}=kt$. Activation energies were 276 kJ/mol and 204 kJ/mol for the initial and final stages, respectively.

Barium metasilicate ($BaSiO_3$) can be prepared by two methods: (a) solid state reaction of an equimolar mixture of barium carbonate and silica;[1-4] (b) decomposition of barium metasilicate hydrates. Barium metasilicate hydrates, such as $BaSiO_3 \cdot H_2O$, $BaSiO_3 \cdot 1.5H_2O$, and $BaSiO_3 \cdot 6H_2O$, are formed by the reaction of sodium silicate solutions and either barium chloride or barium hydroxide solutions.[5,6] Krüger and Wieker[6] reported that amorphous barium silicates are precipitated by addition of barium chloride solutions to sodium silicate solutions, and their crystallization into various barium silicate hydrates is dependent on the Na : Si ratio, the concentration of sodium silicate solutions, the Ba : Si ratio and the temperature during precipitation. The hydrothermal reaction using barium silicate hydrates of various compositions was studied.[5] However, no kinetic study on the formation of crystalline $BaSiO_3$ from amorphous $BaSiO_3$ and barium metasilicate hydrates has been carried out.

In the present study, it was found that amorphous $BaSiO_3$ or mixtures of this amorphous compound and $BaSiO_3 \cdot H_2O$ are formed by the simultaneous hydrolysis of barium and silicon alkoxides. Conditions for the crystallization of amorphous $BaSiO_3$ into $BaSiO_3 \cdot H_2O$ during hydrolysis were examined, and kinetic studies made on the decomposition of $BaSiO_3 \cdot H_2O$ and the crystallization of amorphous into crystalline $BaSiO_3$. The kinetic data were analyzed with use of available solid state models.

Experimental

Materials and Procedure. Silicon ethoxide of guaranteed purity was used. Barium isopropoxide was synthesized by heating barium metal (purity 99.9%) in an excess amount of dehydrated 2-propanol at 82 °C for 5 h in a nitrogen atmosphere. An alcoholic solution containing 12 wt% mixed alkoxides prepared in the mole ratio, Ba^{2+}/Si^{4+} 1 : 1, was refluxed under the same conditions. Hydrolysis was carried out as follows. A five-necked flask equipped with a refluxed condenser, a dropping funnel, a strirring rod, a thermometer and a thermo-controller was used. 400 ml of water was introduced into the flask, and then heated to the desired temperature. 100 ml of the mixed alkoxide solution was added dropwise from the dropping funnel to the stirred water in the flask. The resulting suspension was stirred. The product was separated from the suspension by filtration and dried at 60 °C under reduced pressure.

Measurement. Differential thermal analysis (DTA) was performed in the air at a 10 °C/min rate. Alpha-alumina of high purity was used as a reference substance. The products and the heated specimens were identified by means of DTA data and X-ray diffraction using nickel filtered copper K_α. The weight change was recorded as function of time with a thermobalance.

Results and Discussion

Hydrolysis Product. Results obtained under various conditions are given in Table 1. The products at 30 °C were amorphous. Barium silicates other than $BaSiO_3$ and free species were not observed during the course of heating. Thus, the products might be considered to be a compound corresponding to amorphous $BaSiO_3$. The peaks of $BaSiO_3 \cdot H_2O$[7] were recognized when subjected to hydrolysis at 45 °C for 30 min. Their intensity increased gradually with increase in hydrolysis temperature and time. Judging from this and the amount of crystalline $BaSiO_3$ formed by the decomposition of $BaSiO_3 \cdot H_2O$, the temperatures of hydrolysis and the aging time were found to be impor-

TABLE 1. HYDROLYSIS PRODUCT AND THE AMOUNT OF $BaSiO_3$ FORMED BY THE DECOMPOSITION OF $BaSiO_3 \cdot H_2O$ AND BY THE CRYSTALIZATION OF AMORPHOUS $BaSiO_3$

Run	Temp °C	Time min	Identified phase	Fraction/% A[a]	Fraction/% B[b]

tant factors for the crystallization of amorphous $BaSiO_3$ into $BaSiO_3 \cdot H_2O$.

Formation Process of Crystalline $BaSiO_3$. The DTA curves of the products (Table 1, runs 1 and 15) are shown in Fig. 1. An exothermic reaction (run 1) was observed at 700—820 °C. X-Ray diffraction analysis confirmed that the reaction is due to the crystallization of amorphous $BaSiO_3$. On the other hand, a large endothermic peak (run 15) corresponding to the decomposition of $BaSiO_3 \cdot H_2O$ was observed at 280—410 °C. The compound $BaSiO_3 \cdot H_2O$ turned into crystalline $BaSiO_3$ after the completion of decomposition. The small exothermic peak (700—820 °C) is due to the crystallization of amorphous $BaSiO_3$ as in the case of run 1. This suggests that $BaSiO_3$ is formed *via* two stages: (a) decomposition of $BaSiO_3 \cdot H_2O$, (b) crystallization of amorphous $BaSiO_3$.

All the products were heated at 450 °C and 900 °C for 1 h, respectively, and the amount of crystalline $BaSiO_3$ formed at each stage was determined from the height of the peak of d=3.43 Å which is the strongest of the $BaSiO_3$ spectrum.[8] The fractions of crystalline $BaSiO_3$ formed by the decomposition of $BaSiO_3 \cdot H_2O$ and the crystallization of amorphous $BaSiO_3$ are dependent on the starting products which is strongly affected by hydrolysis temperature (Table 1).

Kinetics of the Decomposition of $BaSiO_3 \cdot H_2O$. The decomposition of $BaSiO_3 \cdot H_2O$ (run 15) was analyzed by isothermal thermogravimetric measurement. The product (average particle size *ca.* 800 Å) was heated at 200 °C for 30 min. Figure 2 shows α-t curves obtained at various temperatures, where α is the fractional decomposition and t time. Attempts were made to fit the results to kinetic laws. As shown in Fig. 3, decomposition isotherms are represented by the following equation over the whole range of fraction:

$$-\ln(1-\alpha) = kt. \quad (1)$$

The rate constants were determined from the slopes of the straight lines. The activation energy calculated from the Arrhenius plot is 143.5 kJ/mol. This might represent the activation energy consumed for establishing

active nucleation centers.[9]

Kinetics of the Crystallization of Amorphous $BaSiO_3$. Figure 4 shows the fraction of the crystallized $BaSiO_3$ at different temperatures. The product of run 1 was heated at 550 °C for 1 h. The fractional crystallization of each specimen was determined from the height of the main characteristic peak (d=3.43 Å). A well-crystallized specimen was obtained by heating the starting product at 900 °C for 1 h. Magnesium oxide was used as an internal standard. The data can be interpreted by means of the equation

$$1-(1-\alpha)^{1/3}=kt, \quad (2)$$

where α is the fractional crystallization and t time (Fig. 5).[10] This indicates that crystallization is controlled by the rate of advance of the reaction interface. Two different linear portions, except at 680 °C, can be recognized in each of the plots. The rate constants were determined from the slopes of the straight lines. Activation energies were 276 kJ/mol and 204 kJ/mol for the initial and final stages, respectively.

Metal Complexes of Amino Acids. XIII.[1] The Relationships between the ^{13}C Chemical Shifts and Ligand Field in the *trans(O)*-$[Co(O)_2(N)_4]$ Type Complexes

Tomoharu AMA,* Hiroshi KAWAGUCHI, and Takaji YASUI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received July 10, 1980)

The relationship between the ligand field of the carboxyl groups and the chemical shift of carboxyl carbon or α-carbon has been investigated on the basis of the absorption and ^{13}C-NMR spectral data of the *trans(O)*-$[Co(OCO-R)_2(en)_2]X_n$ type complexes (OCO–R denotes amino acid or fatty acid coordinating unidentately with the carboxyl group to cobalt(III)). The linear correlations were observed between the $\bar{\nu}_{max}$ (^1E_g component of the first absorption band) and the chemical shifts of carboxyl- and α-carbons.

A number of reports containing an application of ^{13}C-NMR to metal complexes have been published, and the technique has proved to be a very powerful tool for the structural investigation of the complexes. For the metal complexes, the ^{13}C-NMR studies have been concentrated on the cobalt(III) complexes, because most of the cobalt(III) complexes are inert and diamagnetic.[2-24]

Only few papers have been reported on the relation between the d-d absorption spectra and ^{13}C chemical shifts of the metal complexes.[23-25] However, it can be expected that some interesting informations concerning the ligand field will be obtained from the ^{13}C chemical shift data, because both the ligand field and ^{13}C chemical shift are related to the electron density on the ligand.[26-29]

Previously, we reported the ^{13}C-NMR of the *trans(O)*-$[Co(OCO-R)_2(en)_2]^{n+}$ type complexes,[30] where OCO–R denotes amino acid or fatty acid which coordinates to cobalt(III) as a unidentate ligand through its carboxyl group. It has been clarified by the report that such unidentate coordinations of the carboxylic acids to cobalt(III) ($R-C_\alpha-C_{oxy}-OOH \rightarrow R-C_\alpha-C_{oxy}-COOCo$) show the different chemical shift changes, $\Delta_{uni}(C_{oxy})$ ($\delta_{uni}(C_{oxy})-\delta(C_{oxy})$) and $\Delta_{uni}(C_\alpha)$ ($\delta_{uni}(C_\alpha)-\delta(C_\alpha)$), and these shift changes can be also correlated to the chemical shifts of the free acids, $\delta(C_{oxy})$ and $\delta(C_\alpha)$, where $\delta_{uni}(C_{oxy})$ and $\delta_{uni}(C_\alpha)$ represent the chemical shifts of C_{oxy} and C_α of the unidentate ligands in the *trans(O)*-$[Co(OCO-R)_2(en)_2]^{n+}$ type complexes, and $\delta(C_{oxy})$ and $\delta(C_\alpha)$ represent those of the free acids in acidic D_2O solutions. The *trans(O)*-$[Co(OCO-R)_2(en)_2]^{n+}$ type complexes are very suitable for the study of the ligand field of the coordinated carboxylic acids, because the ^1E_g component in the first absorption band of the complex is well apart from another component.[31] In the present paper we will describe the relation between the chemical shifts and the first absorption bands of the *trans(O)*-$[Co(OCO-R)_2(en)_2]^{n+}$ type complexes.

Experimental

Preparation of Complexes. trans*(O)-Bis(*N*-propylglycine)-bis(ethylenediamine)cobalt(III) Perchlorate(*trans*(O)-[Co(Hpgly)$_2$(en)$_2$](ClO$_4$)$_3$)*: To an aqueous solution containing 5 g of $[Co(OH_2)_2(en)_2](ClO_4)_3$ in 50 cm^3 of water, 2.5 g of *N*-propylglycine (Hpgly) was added. The mixture was then evaporated almost to dryness on a water bath at about 80 °C. After cooling, the crude product obtained was dissolved in a small amount of hot water. A few drops of 60% perchloric acid were added to the solution and then cooled in an ice bath. The violet-red crystals obtained were washed with cold water and dried in air. Found: C, 23.55; H, 5.44; N, 11.90%. Calcd for $[Co(Hpgly)_2(en)_2](ClO_4)_3 \cdot H_2O$: C, 23.49; H, 5.35; N, 11.74%.

trans*(O)-Bis(*N*-ethylglycine)bis(ethylenediamine)cobalt(III) Perchlorate (*trans*(O)-[Co(Hegly)$_2$(en)$_2$](ClO$_4$)$_3$)*: *N*-Ethylglycine hydrochloride (Hegly·HCl, 3 g) was dissolved in 10 cm^3 of water and the pH of the solution was adjusted to *ca.* 7 by adding 1 M NaOH aqueous solution. The neutralized solution was evaporated to dryness using a vacuum evaporator, and the Hegly in the residue was extracted with 30 cm^3 of methanol. The methanolic solution of Hegly was evaporated to dryness. The resulted residue was dissolved in 10 cm^3 of water, and then the solution was added to a solution containing 5 g of $[Co(OH_2)_2(en)_2](ClO_4)_3$ in 10 cm^3 of water. The mixed solution was evaporated to a few milliliters on a water bath at about 80 °C. After cooling, the complex deposited was filtered. The crude product was recrystallized from hot water. Found: C, 20.34; H, 5.19; N, 11.96%. Calcd for $[Co(Hegly)_2(en)_2](ClO_4)_3$: C, 20.54; H, 5.17; N, 11.98%.

trans*(O)-(Acetato)(glycine)bis(ethylenediamine)cobalt(III) Perchlorate (*trans*(O)-[Co(ac)(Hgly)(en)$_2$](ClO$_4$)$_2$)*: To an aqueous solution containing 3 g of *trans(O)*-$[Co(ac)_2(en)_2](ClO_4)$ (ac=acetate anion) in 30 cm^3 of water was added 1 g of glycine (Hgly). The mixture was then evaporated to a few milliliters on a steam bath. The residual solution was diluted to about 500 cm^3 and then poured into a SP–Sephadex column (C-25, Na^+ form, 4.5 cm × 50 cm). The adsorbed band was separated into three bands by developing with 0.2 M aqueous solution of sodium perchlorate. The solution of the second eluted band was concentrared to a few milliliters in a vacuum evaporator at 30—40 °C. Ethanol was added to the concentrated solution in order to deposit crude complex. The complex was recrystallized from aqueous solution by adding ethanol. Found: C, 18.32; H, 4.99; N, 13.12%. Calcd for $[Co(ac)(Hgly)(en)_2](ClO_4)_2 \cdot H_2O$: C, 18.12; H, 4.94; N, 13.21%.

trans*(O)-(Acetato)(β-alanine)bis(ethylenediamine)cobalt(III) Perchlorate (*trans*(O)-[Co(ac)(β-Hala)(en)$_2$](ClO$_4$)$_2$)*: The mixed ligand complex with acetate and β-alanine (β-Hala) was prepared by a procedure similar to that described for the *trans(O)*-$[Co(ac)(Hgly)(en)_2](ClO_4)_2$. Found: C, 20.51; H, 5.07; N, 13.22%. Calcd for $[Co(ac)(\beta\text{-Hala})(en)_2](ClO_4)_2$: C, 20.54; H, 4.98; N, 13.31%.

Other complexes, *trans(O)*-$[Co(Haa)_2(en)_2]^{3+}$ (Haa=L-alanine, β-alanine, γ-aminobutyric acid, hydroxyl-L-proline, glycine, L-leucine, L-proline, and L-serine)[32] and *trans(O)*-

[Co(a)$_2$(en)$_2$]$^+$ (a=acetate, propionate, and butyrate anions),[30] examined in this study, were prepared by the methods described in the references.

Measurements. The electronic absorption spectra of the complexes were measured with Hitachi 557 spectrophotometer in aqueous solution. The ^{13}C-NMR spectra were measured on a JEOL Model MFT-100 spectrometer in pulsed Fourier transform/proton noise decoupled mode at 25.15 MHz in deuterium oxide solution. The ^{13}C chemical shifts were measured relative to benzene (capillary) and converted into chemical shifts from TMS by the relation

$\delta_{TMS}=\delta_{benzene}-128.5$ (ppm).[26]

Results and Discussion

At least three factors are important in determining carbon chemical shifts. These are the diamagnetic term (σ_d), the paramagnetic term (σ_p), and the anisotropy of neiboring atoms (σ_{others}).[29] Of these terms, σ_p makes major contribution to carbon chemical shifts.[26] The σ_p was related to the charge density, bond order of the carbon, and other factors (the averaged excitation energy (ΔE), the mean inverse cube radius for the carbon 2p orbitals ($\langle r^{-3}\rangle_{2p}$), and so on) by Karplus *et al.*[26] The ^{13}C chemical shifts are mainly influenced by the electron density of the carbons in a series of related compounds, if the differences in the σ_d, σ_{others}, and ΔE among the carbons under consideration are small. This was experimentally demonstrated by Horsley *et al.*[27] and Miyajima *et al.*[28] who plotted the ^{13}C chemical shifts against the charge density changes of the carbons in the substituted compounds relative to the parent compound.

The change of the substituent at α-carbon of carboxylic acid is attended with the change in the electron density at the carboxyl group, which is one of the reasons of the chemical shift change of the carboxyl carbon in the acid. It is expected that the change in the electron density at the carboxyl group also brings about the band shift in the first absorption band region of the cobalt(III) complex. The complex of the type *trans*(*O*)-[Co(OCO-R)$_2$(en)$_2$]$^{n+}$ is suitable to study this effect, because the ^1E_g component in the first absorption band is sufficiently apart from another component[30,31] ($^1A_{2g}$) in the same band (Fig. 2).

The plots of $\bar{\nu}_{max}$ (^1E_g component of the first absorption band) *vs.* $\delta_{uni}(C_{oxy})$ and $\bar{\nu}_{max}$ *vs.* $\delta_{uni}(C_\alpha)$ are shown in Fig. 3. The data provided here reveal that

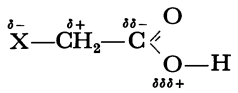
(A): For carboxyl carbon (C_{oxy}), (B): for α-carbon (C_α).
1: Acetic acid, 2: butyric acid, 3: propionic acid, 4: glycine, 5: L-alanine, 6: L-leucine, 7: L-proline, 8: hydroxy-L-proline, 9: L-serine, 10: *N*-ethylglycine, 11: *N*-propylglycine, 12: β-alanine, 13: γ-aminobutyric acid.

the linear correlations are present between $\bar{\nu}_{max}$ and $\delta_{uni}(C_{oxy})$ and between $\bar{\nu}_{max}$ and $\delta_{uni}(C_\alpha)$. That is to say, both the $\delta_{uni}(C_{oxy})$ and $\delta_{uni}(C_\alpha)$ values are closely related to the ligand field of the carboxylic acid. The sign of the slope of Fig. 3(A) is opposite to that of the slope of Fig. 3(B). If we assume that the chemical shift of the carbon is related to the electron density as mentioned above, the following consideration is possible. The substituent at α-carbon which causes a decrease of the electron density on the α-carbon will cause an increase of the π-electron density on the carboxyl carbon

neighboring to the α-carbon and cause a decrease of the electron density on the oxygen atom of the carboxyl group. These processes are shown in the following scheme. A decrease of the electron density on the



(as compared with CH_3COOH)

coordinated oxygen atom weakens the ligand field of the carboxylic acid, and increases of the electron densities on the α- and carboxyl carbon cause the shift changes of their ^{13}C-NMR to higher field side. Accordingly, the $\bar{\nu}_{max}$ value becomes larger as the $\delta_{uni}(C_{oxy})$ value becomes larger (to lower field) and the $\delta_{uni}(C_\alpha)$ becomes smaller (to higher field).

The consideration mentioned above is based on the effect from the substituent at α-carbon. Another effect to be taken into account is that from the cobalt(III) chromophore. Making a rough estimation, the substituent effect at α-carbon nearly equals in both *trans*(*O*)-$[Co(OCO\text{–}R)_2(en)_2]^{n+}$ and free carboxylic acid. Therefore, the effect from the substituent at α-carbon may be cancelled for the $\Delta_{uni}(C_\alpha)$. The $\Delta_{uni}(C_\alpha)$ value should be related rather to the residual effect which will originate from the cobalt(III). Accordingly, the relation between $\Delta_{uni}(C_\alpha)$ and $\bar{\nu}_{max}$ may be more intimate than that between $\delta_{uni}(C_\alpha)$ and $\bar{\nu}_{max}$. Similarly, the relation between $\Delta_{uni}(C_{oxy})$ and $\bar{\nu}_{max}$ may be more intimate than that between $\delta_{uni}(C_{oxy})$ and $\bar{\nu}_{max}$. Figure 4 shows the plots of $\Delta_{uni}(C_{oxy})$ *vs.* $\bar{\nu}_{max}$ and $\Delta_{uni}(C_\alpha)$ *vs.* $\bar{\nu}_{max}$. There are linear relations between them. These relations can be represented by the following equations. Where r and N are correlation

$$\Delta_{uni}(C_{oxy})/ppm = 12.37\,\bar{\nu}_{max}/10^3\,cm^{-1} - 216.62 \quad (r = 0.96,\ N = 13)$$

$$\Delta_{uni}(C_\alpha)/ppm = 13.79\,\bar{\nu}_{max}/10^3\,cm^{-1} - 248.22 \quad (r = 0.95,\ N = 13)$$

coefficient and number of measurements, respectively. The slopes for the two equations are nearly equal to each other with the same sign. Though one might think that the Δ_{uni} value results from the magnetic anisotropy arising from the cobalt(III) chromophore,[33] the calculated chemical shift changes based on the anisotropy are much smaller than the observed ones.

In the present study, we prepared the mixed ligand complexes of the type *trans*(*O*)-$[Co(OCO\text{–}R)(OCO\text{–}R')(en)_2]^{n+}$. The $\bar{\nu}_{max}$ values of the mixed type complexes are nearly equal to the mean value of the two $\bar{\nu}_{max}$ of *trans*(*O*)-$[Co(OCO\text{–}R)_2(en)_2]^{n+}$ and -$[Co(OCO\text{–}R')_2(en)_2]^{n+}$. That is, the $\bar{\nu}_{max}$ of *trans*(*O*)-$[Co(ac)(Hgly)(en)_2]^{2+}$ ($18.21\times10^3\,cm^{-1}$) is nearly equal to the mean value ($18.21\times10^3\,cm^{-1}$) of the two $\bar{\nu}_{max}$ of *trans*(*O*)-$[Co(ac)_2(en)_2]^+$ ($18.30\times10^3\,cm^{-1}$) and *trans*-(*O*)-$[Co(Hgly)_2(en)_2]^{3+}$ ($18.12\times10^3\,cm^{-1}$). Similar relation was observed for *trans*(*O*)-$[Co(ac)(\beta\text{-Hala})(en)_2]^{2+}$, -$[Co(ac)_2(en)_2]^+$, and -$[Co(\beta\text{-Hala})_2(en)_2]^{3+}$ (Table 1). These results suggest that the ^1E_g component of the mixed type complex can be expressed by the two ligand fields of *trans*-position. On the other hand, the $\Delta_{uni}(C_{oxy})$ and $\Delta_{uni}(C_\alpha)$ values of the mixed

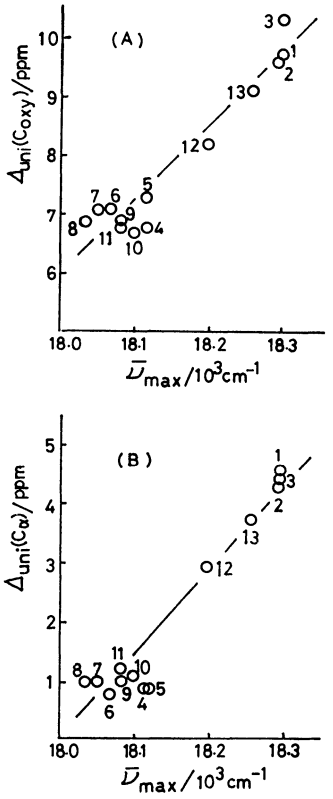


Fig. 4. Plots of ^{13}C chemical shift changes *vs.* first absorption maxima of the *trans*(*O*)-$[Co(O)_2(N)_4]$ type complexes.
(A): For carboxyl carbon (C_{oxy}), (B): for α-carbon (C_α). Numbers making the data plots correspond to the ordinal numbers of the complexes in Fig. 3.

Table 2. Chemical shift changes of the *trans*(*O*)-$[Co(OCO\text{–}R)_2(en)_2]^{n+}$ type complexes

Carboxylic acid[a]	*trans*(*O*) type complexes	$\Delta_{uni}(C_{oxy})$ ppm	$\Delta_{uni}(C_\alpha)$ ppm
ac	$[Co(ac)_2(en)_2]^+$	+9.7	+4.5
Hgly	$[Co(Hgly)_2(en)_2]^{3+}$	+6.8	+0.9
β-Hala	$[Co(\beta\text{-Hala})_2(en)_2]^{3+}$	+8.2	+2.9
ac	$[Co(ac)(Hgly)(en)_2]^{2+}$	+9.7	+4.5
Hgly		+6.7	+1.0
ac	$[Co(ac)(\beta\text{-Hala})(en)_2]^{2+}$	+9.9	+3.8
β-Hala		+8.2	+2.4

a) ac=CH_3COO^-, Hgly=$CH_2(NH_3^+)COO^-$, and β-Hala=$CH_2(NH_3^+)CH_2COO^-$.

type complex are nearly equal to those of the corresponding ligands in the *trans*(*O*)-[Co(OCO–R)$_2$(en)$_2$]$^{n+}$ and -[Co(OCO–R')$_2$(en)$_2$]$^{n+}$ complexes but not to the mean value (Table 2).

Ćelap *et al.*[23,24] and Stewrat *et al.*[11] pointed out that the ^{13}C chemical shift of a ligand is affected by another ligand at *trans*-position to it. However, no distinctive difference of the *trans*-effect was observable for the complexes examined in the present study. That is to say, the ^{13}C resonance peaks of a carboxylate ligand in the mixed complex appears independently of another carboxylate ligand at *trans*-position. These results suggest that the *trans*-effect is not necessarily to be connected directly with the linearities in Figs. 4(A) and 4(B). Therefore, one should consider the effects (the through-space and through-bond effects of cobalt(III) ion, *etc.*) other than the *trans*-effect, which is responsible for the difference of the Δ_{uni} values, relating to the electron density. What effect is most responsible to the Δ_{uni} values is very interesting problem. However, there are some uncertain points remaining at present stage, although some of them were clarified by this study.

It has been clarified by this study that the chemical shifts of the coordinated carboxylic acids are closely related to the ligand fields of the acids and demonstrated that the ^{13}C chemical shifts are useful to estimate the ligand fields of the carboxylic acids.

The authers wish to thank Professor Yoichi Simura of Osaka University for his valuable suggestion and discussion.

Transition-metal Complexes of Pyrrole Pigments. XIX. Electrochemical and Coordination Behaviors of (5,10,15,20-Tetraphenylporphinato)niobium(V) Complexes†

Yoshihisa MATSUDA, Sunao YAMADA, Takashi GOTO, and Yukito MURAKAMI*

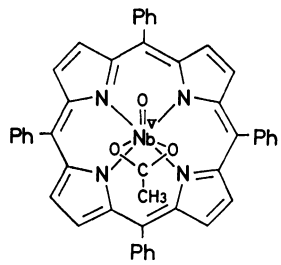
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 11, 1980)

The redox chemistry of acetato(5,10,15,20-tetraphenylporphinato)oxoniobium(V) (**1**) was investigated in dichloromethane by means of cyclic voltammetry and controlled potential electrolysis. One-electron reduction potentials were observed at −0.89, −1.05, and −1.41 V *vs.* SCE for the range from 0 to −2.0 V; the reduction of niobium(V) to niobium(III) occurred prior to ligand-reduction. The potential separation between first and second metal-reductions ($\Delta E_{1/2}$) for **1** is 0.16 V, while $\Delta E_{1/2}$ between reductions of the Mo^{VI} and Mo^{V} species for the corresponding molybdenum complex is 1.24 V. In order to elucidate the origin of such potential difference between the niobium and molybdenum complexes, the change of coordination structures which takes place in the course of redox reactions was examined. The coordination reaction of **1** with pyridine was also studied.

As a step toward preparation of one-dimensional electric conductors by stacking planar complexes with the formation of metal–metal bonds, molybdenum and niobium complexes of macrocyclic tetrapyrroles are plausible ones for this purpose since the metal ions have a strong tendency to form metal to metal bonds in their low oxidation states. The redox behaviors of these metal complexes needs to be investigated in order to establish chemical conditions for the formation of complexes involving low valency metals. We have previously studied the redox properties of several molybdenum(V) complexes of macrocyclic tetrapyrroles.[1] Acetato(5,10,15,20-tetraphenylporphinato)oxoniobium(V) [Nb^{V}(O)(TPP)(AcO), **1**][2] and tri-μ-oxo-bis[(5,10,15,20-tetraphenylporphinato)niobium(V)] [$Nb^{V}_2(O)_3(TPP)_2$, **2**][3,4] have been prepared and their crystallographic structures determined. However, the redox chemistry of these niobium complexes has not been examined so far.

We have investigated in the present work the redox properties of Nb^{V}(O)(TPP)(AcO) by cyclic voltammetry and controlled potential electrolysis in reference to the behavior of the corresponding molybdenum(V) complex, Mo^{V}(O)(TPP)(AcO), and the niobium(III) species was produced electrochemically for the first time. Since Nb^{V}(O)(TPP)(AcO) and $Nb^{V}_2(O)_3(TPP)_2$ assume a unique hepta-coordination geometry around the niobium(V) atom, the coordination interactions of both complexes with pyridine as well as the interaction of the latter complex with acetic acid have also been studied.



Nb(O)(TPP)(AcO)

† Contribution No. 596 from this Department.

Experimental

Materials. Acetato(5,10,15,20-tetraphenylporphinato)-oxoniobium(V) [Nb^{V}(O)(TPP)(AcO), **1**] and tri-μ-oxo-bis[(5,10,15,20-tetraphenylporphinato)niobium(V)] [$Nb^{V}_2(O)_3(TPP)_2$, **2**] were prepared by the methods of Lecomte and Protas.[2] Dichloromethane was treated with concentrated sulfuric acid, neutralized with aqueous sodium hydroxide, washed with distilled water, and refluxed over anhydrous calcium chloride for 2 d. After being fractionally distilled, dichloromethane thus purified and dried was stored over molecular sieve (3A, 1/16; Ishizu Pharmaceutical Co.). Pyridine was refluxed over potassium hydroxide and fractionally distilled. Tetrabutylammonium perchlorate (TBAP) of polarographic grade (Nakarai Chemicals) was used without further purification.
