House and Rasmusson[8] reported that the Wittig condensation of [1-(methoxycarbonyl)ethylidene]triphenylphosphorane with acetaldehyde gave a 27.6 : 1 mixture of methyl tiglate and methyl angelate, while the reaction of ethylidenetriphenylphosphorane and methyl pyruvate provided a 2.13 : 1 mixture of tiglate and angelate. As the second approach to **7a** or **7b**, we condensed methyl pyruvate with the reactive ylide formed from a triphenylphosphonium salt, such as **13a** or **13b**. The allylic alcohol, **10a** or **10b**, was then transformed into the corresponding allylic bromide, **12a** (79%) or **12b** (90%), by treatment with mesyl chloride and a mixture of triethylamine, lithium bromide, and dichloromethane.[9] The reaction of **12a** or **12b** with triphenylphosphine in benzene afforded **13a** or **13b** in a quantitative yield. The phosphonium bromide, **13a** or **13b**, was treated with butyllithium in THF at −75 °C and then allowed to react with methyl pyruvate at the same temperature to give a 4 : 5 mixture of **7a** and **7'a** or an 1 : 1 mixture of **7b** and **7'b** in a 62 or 81% yield respectively (Reaction 2). The desired condensation product, **7a** (28%) or **7b** (39%), was separated from the isomer, **7'a** or **7'b**, by alumina-column chromatography or by preparative layer chromatography (PLC) on silica gel, which was identical with the aforesaid corresponding sample. The structure of isomeric product, **7'a**, was confirmed by the ^{1}H-NMR data.

A recent publication[10] described a new stereospecific process for the conversion of an aldehyde to a 5-substituted (2*Z*,4*E*)-2-methyl-2,4-pentadienoic acid *via* the lactone of 5-substituted 5-hydroxy-2-methyl-2-pentenoic acid. This reaction process, reported after our work had been completed, is undoubtedly better than our five-step process starting with **4a**, provided that the new process is applicable to **4a** for the synthesis of **1a**. Although Reaction 2 seems to be almost non-stereoselective, it is noteworthy that the reaction yielded a significant amount of (*Z*)-olefins compared with Reaction 1. Furthermore, when the Wittig reaction (2) is carried out by an intramolecular version[11] for the purpose of the construction of the medium ring of unsaturated lactone or the macrocyclic lactam ring of rifamycins, it may be expected that the tendency to form the desired (*Z*)-olefin is strengthened, because the formation of the intermediate betaine with the erythro configuration,[12] the precursor of (*Z*)-olefin, might be kinetically

more favored in the intramolecular cyclization of the lactone or the lactam than in the intermolecular reaction.

The last step of the synthesis of **1a** was the selective deacetonation of **7a**, which was effected with 50% difluoroacetic acid (DFA) at 0 °C to afford **1a** in an 80% yield. The treatment of **7b** with 90% TFA at 0 °C gave **1b**, which could then be converted into **1a** by debromination.[2)]

Experimental

The melting points were determined on a micro hot-stage Yanaco MP-83 and are uncorrected. The specific rotations were measured with a Carl Zeiss photoelectric polarimeter. The ^{1}H-NMR spectra were determined in $CDCl_3$ with either a Varian A60 or EM-390 spectrometer, using TMS as the internal standard. The TLC was performed on Merck TLC plates, 60F-254 0.25 mm. The PLC was carried out on precoated PLC plates (20×20×0.5 mm) of Merck Kieselgel 60F-254. The column chromatography was performed on silica gel, Wakogel C-200. In general, evaporation was conducted under reduced pressure below 30 °C.

*Methyl [Methyl 7,9-Di-*O*-acetyl-2,4,6,8,10,11,12,13,14-nona-deoxy-4,6,8,10,14-penta-*C*-methyl-3-*O*-methyl-*L*-manno-β-*D*-galacto(11E, 13Z)-11,13-pentadecadienopyranosid]uronate (3a) and 13E-Isomer (3'a).* A mixture of **1a** (253 mg, 0.590 mmol), acetic anhydride (1.35 ml, 14.3 mmol), and dry pyridine (2.5 ml) was allowed to stand at 40 °C for 6 d. The mixture was then poured into ice water and extracted with ether. The ether layer was washed with water and a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatcgraphed on silica gel (30 g) with 10: 1 benzene–acetone to afford the following four fractions: **3a**, 45 mg (15%); R_f 0.37 (8: 1 benzene–acetone); mp 132—133 °C (ether); $[\alpha]_D^{29}$ +30° (*c* 1.0, MeOH); UV_{max} (EtOH) 262 nm (ε 23100); IR (KBr) 1732, 1710, 1641, and 1607 cm^{-1}; ^{1}H-NMR δ=0.8—1.1 (12H, m, 4, 6, 8, and 10-Me), 1.94 (6H, broad s, 14-Me and OAc), 2.01 (3H, s, OAc), 3.32 and 3.34 (each 3H, each s, OMe×2), 3.76 (3H, s, COOMe), 4.7—5.2 (3H, m, H-1,7, and 9),5.68 (1H, dd, H-11, $J_{10,11}$= 8.9 Hz, $J_{11,12}$=15.0 Hz), 6.32 (1H, m, H-13, $J_{12,13}$=11.0 Hz, $J_{13,Me}$=1.9 Hz), and 7.08 (1H, dd, H-12) [Found: C, 63.16; H, 8.52%. Calcd for $C_{27}H_{44}O_9$: C, 63.26; H, 8.65%]; **3'a**, 68 mg (22%); R_f 0.33; mp 146—147 °C (acetone); $[\alpha]_D^{31}$ −33° (*c* 0.9, MeOH); UV_{max} (EtOH) 263 nm (ε 26600); IR (KBr) 1732, 1703, and 1641 cm^{-1}; ^{1}H-NMR δ=0.8—1.1 (12H, m, 4, 6, 8, and 10-Me), 1.94 (6H, broad s, 14-Me and OAc), 2.01 (3H, s, OAc), 3.32 and 3.34 (each 3H, each s, OMe×2), 3.73 (3H, s, COOMe), 4.7—5.2 (3H, m, H-1,7, and 9), 5.91 (1H, dd, H-11, $J_{10,11}$=8.2 Hz, $J_{11,12}$=14.8 Hz), 6.34(1H, dd, H-12, $J_{12,13}$=10.4 Hz), and 7.10 (1H, m, H-13, $J_{13,Me}$=1.5 Hz) [Found: C, 63.08; H, 8.44%. Calcd for $C_{27}H_{44}O_9$: C, 63.26; H, 8.65%]; monoacetate of **1a**, 54 mg (20%); R_f 0.24; ^{1}H-NMR δ=1.96 (3H, s, 7 or 9-OAc), 5.74 (1H, dd, H-11, $J_{11,12}$=15 Hz, $J_{10,11}$=9.0 Hz), 6.34 (1H, dd, H-13, $J_{12,13}$=11.0 Hz), and 7.09 (1H, dd, H-12), and monoacetate of 13*E*-isomer of **1a**, 49 mg (18%); R_f 0.21; ^{1}H-NMR δ=1.96 (3H, s, 7 or 9-OAc), 5.91 (1H, dd, H-11, $J_{11,12}$= 14.7 Hz, $J_{10,11}$=8.0 Hz), 6.34 (1H, dd, H-12, $J_{12,13}$=10.0 Hz), and 7.11 (1H, dd, H-13, $J_{13,Me}$=1.0 Hz).

(R)-2-Bromo Deivative (3b). A mixture of **1b** (199 mg, 0.393 mmol), acetic anhydride (0.371 ml, 3.93 mmol), DMAP (106 mg, 0.864 mmol), and ethyl acetate (2 ml) was stirred at 45 °C for 24 h. The mixture was then diluted with ethyl acetate (18 ml) and washed with saturated aqueous $KHSO_4$, $NaHCO_3$, and NaCl solutions successively, dried, and evaporated. The residual brown syrup (270 mg) was chromatographed on silica gel (23 g) with 8: 1 benzene–ethyl acetate to afford **3b** (210 mg, 90%) as a colorless syrup: $[\alpha]_D^{29}$ +16° (*c* 0.77, MeOH); UV_{max} (EtOH) 264 nm (ε 21300); IR (CCl_4) 1737, 1641, and 1605 cm^{-1}, ^{1}H-NMR δ=0.88—1.08 (12H, m, 4, 6, 8, and 10-Me), 1.93 (6H, s, 14-Me and OAc), 2.00 (3H, s, OAc), 3.16 (1H, dd, H-3, $J_{2,3}$=3.0 Hz, $J_{3,4}$=10.0 Hz), 3.35 (6H, s, OMe×2), 3.74 (3H, s, COOMe), 4.28 (1H, dd, H-2, $J_{1,2}$=1.5 Hz), 4.8—5.1 (3H, m, H-1,7, and 9), 5.64 (1H, dd, H-11, $J_{10,11}$=9.0 Hz, $J_{11,12}$=15.1 Hz). 6.30 (1H, m, H-13, $J_{12,13}$=10.7 Hz, $J_{13,Me}$=1 Hz), and 7.07 (1H, dd, H-12).

Found: C, 54.53; H, 7.18; Br, 13.27%. Calcd for $C_{27}H_{43}O_9Br$: C, 54.82; H, 7.33; Br, 13.51%.

*Methyl 7,9-Di-*O*-acetyl-2,4,6,8,10-pentadeoxy-4,6,8,10-tetra-*C*-methyl-3-*O*-methyl-*L*-manno-β-*D*-galacto-undecodialdopyranoside-(1,5) (4a).* A mixture of **3a** and **3'a** (74 mg, 0.144 mmol) was dissolved in dry dichloromethane (3.68 ml), and then the mixture was cooled to −75 °C. Ozonolyzed oxygen gas (475 ml) containing 0.287 mmol of ozone was passed through the solution at the rate of 23.8 ml/min. To the resulting solution was added dimethyl sulfide (0.105 ml, 1.44 mmol) at the same temperature. The mixture was gradually warmed to room temperature over the period of 3 h and then washed with water and a saturated aqueous NaCl solution, dried, and evaporated. The residual syrup was chromatographed on silica gel (3 g) with 8: 1 benzene–acetone to give **4a** (46 mg, 77%) as a pale yellow syrup: ^{1}H-NMR δ=0.85—1.15 (12H, m, 4,6,8, and 10-Me), 2.02 and 2.04 (each 3H, oach s, OAc×2), 3.32 and 3.37 (each 3H, each s, OMe×2), 4.8—5.5 (3H, m, H-1,7, and 9), and 9.50 (1H, d, H-11, $J_{10,11}$=3.3 Hz).

(R)-2-Bromo Derivative (4b) and Its 11-Ethylene Acetal (5b). A sample (163 mg) of **3b** was ozonolyzed by the procedure described in the preparation of **4a** and then worked-up to afford the crude aldehyde, **4b**, as a syrup. A mixture of the crude **4b** (137 mg), ethylene glycol (0.153 ml), anhydrous *p*-toluenesulfonic acid (4.8 mg), and dry acetonitrile (1.4 ml) was stirred at room temperature for 0.5 h. The reaction mixture was then poured into ice-cooled water containing $NaHCO_3$ (2.3 mg) and extracted with chloroform. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated. The residual syrup (218 mg) was chromatographed on silica gel (20 g) with 4 : 1 benzene–ethyl acetate to give **5b** (78 mg, 53%) as a colorless solid. Recrystallization from 1 : 1 acetone–hexane afforded needles of **5b**: mp 142—143 °C; $[\alpha]_D^{30}$ −47° (*c* 0.96, MeOH); IR (KBr) 1737 cm^{-1}; ^{1}H-NMR δ=0.92, 0.95, 0.98, and 1.00 (each 3H, each d, 4,6,8, and 10-Me, *J*=7 Hz), 2.02 (6H, s, OAc×2), 3.17 (1H, dd, H-3, $J_{2,3}$=3.5 Hz, $J_{3,4}$=9.9 Hz), 3.37 (6H, s, OMe×2), 3.7—4.0 (4H, m, $-OCH_2CH_2O-$), 4.35 (1H, dd, H-2, $J_{1,2}$=1.6 Hz), 4.73 (1H, d, H-11, $J_{10,11}$=3.4 Hz), 4.92 (1H, d, H-1), and 5.0—5.4 (2H, m, H-7 and 9).

Found: C, 51.30; H, 7.16; Br, 14.71%. Calcd for $C_{23}H_{39}O_9Br$: C, 51.21; H, 7.29; Br, 14.81%.

A sample (65 mg) of **5b** was dissolved in 70 (v/v)% aqueous TFA (0.65 ml) and allowed to stand at 0—2 °C for 20 h. The reaction mixture was then poured into cold chloroform and neutralized with solid $NaHCO_3$. The organic layer thus separated was washed with water and a saturated aqueous NaCl solution, dried, and evaproated to give a practically pure sample of **4b** (60 mg, 100%); ^{1}H-NMR δ=0.94, 0.99, 1.02, and 1.10 (each 3H, each d, 4,6,8, and 10-Me, *J*=6.5 and 7.0 Hz), 2.01 and 2.03 (each 3H, each s, OAc×2), 3.17 (1H, dd, H-3, $J_{2,3}$=3.4 Hz, $J_{3,4}$=10.1 Hz), 3.37 (6H, s, OMe×2), 4.34 (1H, dd, H-2, $J_{1,2}$=1.5 Hz), 4.91 (1H, d, H-1), 4.9—5.2 (1H, m, H-7 or H-9), 5.39 (1H, dd, H-7 or

H-9, J=2.0 and 9.4 Hz), and 9.56 (1H, d, H-11, $J_{10,11}$=3.2 Hz).

11-Ethylene Acetal (5a). To a solution of **5b** (81 mg, 0.150 mmol) in dry benzene (2.0 ml) was added tributylstannane (0.048 ml, 0.180 mmol) and α,α'-azobisisobutylonitrile (AIBN) (4.9 mg, 0.03 mmol). The mixture was then stirred at 60 °C for 6 h under argon. The reaction mixture was evaporated, and the residue (198 mg) was chromatographed on silica gel (10 g) with 3: 1 benzene–ethyl acetate to afford **5a** (44 mg, 64%) as a colorless solid. Recrystallization from 1: 2 acetone–hexane gave colorless plates: mp 113—114 °C; $[\alpha]_D^{20}$ −85° (*c* 1.0, MeOH); IR (KBr) 1731 cm^{-1}; ^{1}H-NMR δ=0.86−1.08 (12H, m, 4, 6, 8, and 10-Me), 1.2—1.7 (1H, m, H-2ax), 2.05 (6H, s, OAc×2), 3.35 and 3.37 (each 3H, each s, OMe×2), 3.8—4.0 (4H, m, $-OCH_2CH_2O-$), 4.76 (1H, d, H-11, $J_{10,11}$=3.5 Hz), and 4.7—5.4 (3H, m, H-1,7, and 9).

Methyl [Methyl 7,9-Di-O-acetyl-2-bromo-2,4,6,8,10,11,12-heptadeoxy-4,6,8,10-tetra-C-methyl-3-O-methyl-L-glycero-L-talo-β-L-manno-(E)-11-tridecenopyranosid]uronate (6b). To a solution of the crude sample of **4b** (60 mg) in dry benzene (1.2 ml) was added (methoxycarbonylmethylene)triphenylphosphorane (61 mg, 0.182 mmol). The mixture was refluxed for 3 h under argon and then evaporated. The residual syrup was chromatographed on silica gel (7 g) with 6: 1 benzene–ethyl acetate to afford **6b** (56 mg, 84%) as a colorless solid. Recrystallization from ether gave needles of **6b**: 131—133 °C; $[\alpha]_D^{22}$ −34° (*c* 0.88, MeOH); IR (KBr) 1731 and 1662 cm^{-1}: ^{1}H-NMR δ=0.91−1.12 (12H, m, 4,6,8, and 10-Me), 2.00—2.04 (each 3H, each s, OAc×2), 3.20 (1H, dd, H-3, $J_{2,3}$=3.3 Hz, $J_{3,4}$=10.5 Hz), 3.40 (6H, s, OMe×2), 3.75 (3H, s, COOMe), 4.38 (1H, dd, H-2, $J_{1,2}$=1.1 Hz), 4.96—5.20 (3H, m, H-1,7, and 9), 5.83 (1H, d, H-12, $J_{11,12}$=15.6 Hz), and 6.83 (1H, dd, H-11, $J_{10,11}$=9.0 Hz).

Found: C, 52.50; H, 7.13; Br, 14.38%. Calcd for $C_{24}H_{39}O_9Br$: C, 52.27; H, 7.13; Br, 14.49%.

Methyl [Methyl 7,9-Di-O-acetyl-2,4,6,8,10,11,12-heptadeoxy-4,6,8,10-tetra-C-methyl-3-O-methyl-L-manno-β-D-galacto-(E)-11-tridecenopyranosid]uronate (6a). A solution of **6b** (137 mg, 0.248 mmol), tributylstannane (0.080 ml, 0.298 mmol), and AIBN (8 mg, 0.05 mmol) in dry benzene (2.7 ml) was stirred under argon at 60 °C for 3 h, and then the solvent was removed. The residue (300 mg) was chromatographed on silica gel (12 g) with 3: 1 benzene–ethyl acetate to give **6a** (111 mg, 95%) as colorless crystals. Recrystallization from hexane afforded colorless needles: mp 100—101 °C; $[\alpha]_D^{17}$ −61° (*c* 1.22, MeOH); IR (KBr) 1728 and 1653 cm^{-1}; ^{1}H-NMR δ=0.8−1.1 (12H, m, 4, 6, 8, and 10-Me), 1.41 (1H, ddd, H-2ax, $J_{2ax,2eq}$=11.0 Hz, $J_{2ax,3}$=9.0 Hz, $J_{1,2ax}$=3.6 Hz), 2.00 and 2.04 (each 3H, each s, OAc×2), 3.35 and 3.37 (each 3H, each s, OMe×2), 3.76 (3H, s, COOMe), 4.75—5.25 (3H, m, H-1,7, and 9), 5.84 (1H, d, H-12, $J_{11,12}$=16.0 Hz), and 6.86 (1H, dd, H-11, $J_{10,11}$=8.9 Hz).

(R)-2-Bromo Derivative of 7a (7b). A sample (205 mg) of **1b** was acetonated by the procedure described in the preparation of **7a** and then worked-up. The crude syrup (281 mg) of **7b** was chromatographed on silica gel (22 g) with 17: 1 benzene–ethyl acetate to afford a pure sample (168 mg, 76%) of **7b** as a syrup: $[\alpha]_D^{27}$ +4° (*c* 0.70, MeOH); UV_{max} (EtOH) 267 nm (ε 23000); IR (CCl_4) 1709, 1640, and 1601 cm^{-1}; ^{1}H-NMR δ=0.88−1.04 (12H, m, 4,6,8, and 10-Me), 1.27 and 1.30 (each 3H, each s, CMe_2), 1.96 (3H, s with a little long-range coupling with H-13, 14-Me), 3.20 (1H, dd, H-3, $J_{3,4}$=7.5 Hz, $J_{2,3}$=3.1 Hz), 3.38 (6H, s, OMe×2), 3.76 (3H, s, COOMe), 4.39 (1H, dd, H-2, $J_{1,2}$=1.5 Hz), 4.97 (1H, d, H-1), 5.98 (1H, dd, H-11, $J_{10,11}$=7.0 Hz, $J_{11,12}$=15.4 Hz), 6.40 (1H, dd, H-13, $J_{12,13}$=11.0 Hz), and 7.17 (1H, dd, H-12).

Found: C, 57.32; H, 7.84; Br, 14.37%. Calcd for $C_{26}H_{43}O_7Br$: C, 57.04; H, 7.92; Br, 14.59%.

Methyl [Methyl 2,4,6,8,10,11,12-Heptadeoxy-7,9-O-isopropylidene-4,6,8,10-tetra-C-methyl-3-O-methyl-L-manno-β-D-galacto-(E)-11-tridecenopyranosid]uronate (9a). Ozonized oxygen gas containing 1.11 mmol of ozone was passed slowly through a solution of **7a** (260 mg, 0.555 mmol) in dry dichloromethane (13 ml) at −75 °C. To the resulting solution was added dimethyl sulfide (0.1 ml, 5.55 mmol) at the same temperature. The mixture was gradually warmed to room temperature, washed with water and a saturated aqueous NaCl solution, dried, and evaporated. The resulting crude aldehyde **8a** (207 mg) was dissolved in dry benzene (4 ml). To this was added (methoxycarbonylmethylene)triphenylphosphorane (225 mg, 0.675 mmol), and the mixture was refluxed for 4 h under argon. After the removal of the solvent, the residual syrup was chromatographed on silica gel (20 g) with 4 : 1 benzene–ether to afford **9a** (209 mg, 89%) as a colorless syrup: $[\alpha]_D^{27}$ −35° (*c* 0.71, $CHCl_3$); IR (CCl_4) 1713 and 1625 cm^{-1}: ^{1}H-NMR δ=0.8−1.0 (12H, m, 4,6,8, and 10-Me), 1.26 and 1.30 (each 3H, each s, CMe_2), 3.37 (6H, s, OMe×2), 3.74 (3H, s, COOMe), 4.8−4.9 (1H, m, H-1), 5.85 (1H, d, H-12, $J_{11,12}$=15.6 Hz), and 7.04 (1H, dd, H-11, $J_{10,11}$=7.2 Hz).

Found: C, 64.56; H, 9.26%. Calcd for $C_{23}H_{40}O_7$: C, 64.46; H, 9.41%.

(R)-2-Bromo Derivative of 9a (9b). A sample (168 mg) of **7b** was ozonolyzed by the procedure described in preparation of **9a** to afford a crude aldehyde, **8b** (138 mg). A solution of this sample of **8b** (138 mg) and (methoxycarbonylmethylene)triphenylphosphorane (204 mg) in dry benzene (2.9 ml) was refluxed for 5 h under argon. The reaction mixture was then evaporated, and the residue was chromatographed on silica gel (20 g) with 15: 1 benzene–ethyl acetate to give **9b** (109 mg, 70%) as a colorless syrup: $[\alpha]_D^{25}$ −12° (*c* 0.64, MeOH); IR (CCl_4) 1728 and 1658 cm^{-1}; ^{1}H-NMR δ=0.88−1.05 (12H, m, 4,6,8, and 10-Me), 1.27 and 1.30 (each 3H, each s, CMe_2), 3.38 (6H, s, OMe×2), 3.37 (3H, s, COOMe), 4.37 (1H, dd, H-2, $J_{2,3}$=3.2 Hz, $J_{1,2}$=1.5 Hz), 4.97 (1H, d, H-1), 5.83 (1H, dd, H-12, $J_{11,12}$=15.9 Hz, $J_{10,12}$=1.0 Hz), and 7.01 (1H, dd, H-11, $J_{10,11}$=7.3 Hz).

O_7Br: C, 54.44; H, 7.75; Br, 15.75%.

*Methyl 2,4,6,8,10,11,12-Heptadeoxy-7,9-O-isopropylidene-4,6,8,10-tetra-C-methyl-3-O-methyl-*L*-manno-β-*D*-galacto-(E)-11-tridecenopyranoside-(1,5) (**10a**).* *(A)*: A 27.5 (W/W)% DIBAL in hexane (0.460 ml, 0.803 mmol) was added dropwise to a stirred cooled solution (−75 °C) of **9a** (172 mg, 0.401 mmol) in dry toluene (17.2 ml). Once the addition of the DIBAL was complete, the reaction mixture was stirred at −75 °C for 30 min. It was then warmed to 0 °C, and to this mixture 50% aqueous acetic acid (0.08 ml) and ethyl acetate (4 ml) were added successively. The resulting insoluble matter was filtered through Celite and washed with ethyl acetate. The combined filtrate and washings were evaporated. The residual syrup (180 mg) was chromatographed on silica gel (8 g) with 2 : 1 benzene–ethyl acetate to afford **10a** (112 mg, 70%) as a colorless syrup: $[\alpha]_D^{25}$ −30° (*c* 1.16, $CHCl_3$); ^{1}H-NMR δ=0.8−1.0 (12H, m, 4,6,8, and 10-Me), 1.29 and 1.33 (each 3H, each s, CMe_2), 2.23 (1H, ddd, H-2eq, $J_{2eq,2ax}$ =13.1 Hz, $J_{2eq,3}$=4.7 Hz, $J_{1,2eq}$=1.6 Hz), 3.40 (6H, s, OMe×2), 4.0—4.2 (2H, m, H-13×2), 4.86 (1H, dd, H-1, $J_{1,2ax}$=4.0 Hz), and 5.7—5.8 (2H, m, H-11 and 12).

Found: C, 66.22; H, 9.87%. Calcd for $C_{22}H_{40}O_6$: C, 65.97; H, 10.07%.

(B): To a stirred solution of **6a** (75 mg, 0.158 mmol) in dry toluene (3.7 ml) was added dropwise 27.5% DIBAL in hexane (0.040 ml, 0.07 mmol) at −75 °C. After being stirred at the same temperature for 10 min, the reaction mixture was warmed to 0 °C and treated with a 50% aqueous acetic acid (0.079 ml) and ethyl acetate (1 ml). After the removal of the resulting insoluble matter by filtration, the filtrate was evaporated to give a colorless syrup (52 mg, 92%) of the triol. A mixture of the crude triol (52 mg), DMP (0.036 ml, 0.29 mmol), and dry DMF (0.52 ml) was stirred at room temperature for 5 h. The mixture was then neutralized with triethylamine and evaporated. The residue was chromatographed on silica gel (5 g) with 2 : 1 benzene–ethyl acetate to afford **10a** (43 mg, 73%).

*(R)-2-Bromo Derivative of **10a** (**10b**).* A solution of **9b** (96 mg, 0.189 mmol) in dry toluene (9.6 ml) was treated with a 27.5% DIBAL in hexane (0.215 ml, 0.378 mmol) at −75 °C for 10 min and then worked-up by the procedure described in the preparation of **10a** from **9a**. The crude syrup of **10b** (108 mg) thus obtained was chromatographed on silica gel (10 g) with 3: 1 benzene–ethyl acetate to afford a colorless syrup of **10b** (87 mg, 96%): $[\alpha]_D^{22}$ −7° (*c* 1.40, MeOH); ^{1}H-NMR δ=0.89−1.03 (12H, m, 4,6,8, and 10-Me), 1.27 and 1.31 (each 3H, each s, CMe_2), 3.20 (1H, dd, H-3, $J_{3,4}$=7.1 Hz, $J_{2,3}$=3.1 Hz), 3.39 (6H, s, OMe×2), 4.0—4.2 (2H, m, H-13×2), 4.39 (1H, dd, H-2, $J_{1,2}$=1.5 Hz), 4.98 (1H, d, H-1), and 5.65—5.79 (2H, m, H-11 and 12).

Found: C, 54.89; H, 7.98; Br, 16.38%. Calcd for $C_{22}H_{39}O_6Br$: C, 55.11; H, 8.20; Br, 16.67%.

*Methyl 2-Bromo-2,4,6,8,10,11,12-heptadeoxy-7,9-O-isopropylidene-4,6,8,10-tetra-C-methyl-3-O-methyl-*L*-glycero-*L*-talo-β-*L*-manno-(E)-11-tridecenodialdopyranoside-(1,5) (**11b**).* A mixture of chromium trioxide (71 mg, 0.716 mmol) and dry HMPA (0.21 ml) was stirred at room temperature for 2.5 h, and a solution of **10b** (172 mg, 0.358 mmol) in HMPA (0.34 ml) was then added. Stirring was continued for 1 week at room temperature, after which the mixture was poured into ice water and extracted with ether. The ether layer was washed successively with a 5% aqueous NaOH solution, water, and a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (8.3 g) with 10 : 1 benzene–ethyl acetate to give **11b** (106 mg, 62%) as a colorless crystal. Recrystallization from ether–petroleum ether afforded colorless needles of **11b**: mp 129—130 °C; $[\alpha]_D^{25}$ −10° (*c* 0.96, MeOH); IR (KBr) 1689 and 1634 cm^{-1}; ^{1}H-NMR δ=0.94, 0.98, 1.01, and 1.05 (each 3H, each d, 4,6,8, and 10-Me, J=6—7 Hz), 1.27 and 1.32 (each 3H, each s, CMe_2), 3.23 (1H, dd, H-3, $J_{2,3}$=3.1 Hz, $J_{3,4}$=9.9 Hz), 3.39 (6H, s, OMe×2), 4.40 (1H, dd, H-2, $J_{1,2}$=1.6 Hz), 4.98 (1H, d, H-1), 6.14 (1H, ddd, H-12, $J_{11,12}$=15.9 Hz, $J_{12,13}$=7.7 Hz, $J_{10,12}$=1.0 Hz), 6.96 (1H, dd, H-11, $J_{10,11}$=6.5 Hz), and 9.53 (1H, d, H-13).

Found: C, 55.38; H, 7.64; Br, 16.50%. Calcd for $C_{22}H_{37}O_6Br$: C, 55.35; H, 7.81; Br, 16.74%. On column chromatography, unchanged **10b** (37 mg, 22%) was recovered.

*13E-Isomer of **7b** (**7'b**); Condensation of **11b** with **14**.* To an ice-cooled suspension of NaH (3.6 mg, 0.082 mmol; 55% dispersion in mineral oil) in dry THF (0.27 ml), **14**[13] (15 mg, 0.074 mmol) was added, and the mixture was stirred at room temperature for 1 h. It was then cooled to −75 °C, and a solution of **11b** (29.6 mg, 0.062 mmol) in dry THF (0.3 ml) was added. Stirring was continued at −60——65 °C for 1 h. The reaction mixture was then poured into ice water and extracted with ether. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was preparatively thin-layer chromatographed on Merck Kieselgel 60-F_{254} (0.5 mm) with 25 : 1 and 30 : 1 benzene–ethyl acetate (two passes), to afford **7b** (0.5 mg, 1.5%) and **7'b** (28 mg, 83%): $[\alpha]_D^{20}$ 0° (*c* 0.78, MeOH); UV_{max} (EtOH) 266 nm (ε 28800); IR (CCl_4) 1711 and 1641 cm^{-1}; ^{1}H-NMR δ=0.88−1.05 (12H, m, 4,6,8, and 10-Me), 1.27 and 1.30 (each 3H, each s, CMe_2), 1.94 (3H, d, 14-Me, $J_{13,Me}$=1.0 Hz), 3.20 (1H, dd, H-3, $J_{3,4}$=7.1 Hz, $J_{2,3}$=3.0 Hz), 3.38 (6H, s, OMe×2), 3.77 (3H, s, COOMe), 4.38 (1H, dd, H-2, $J_{1,2}$=1.6 Hz), 4.97 (1H, d, H-1), 6.03 (1H, dd, H-11, $J_{11,12}$= 15.0 Hz, $J_{10,11}$=6.0 Hz), 6.42 (1H, dd, H-12, $J_{12,13}$=10.0 Hz), and 7.19 (1H, dd, H-13).

Found: C, 57.37; H, 7.97; Br, 14.26%. Calcd for $C_{26}H_{43}O_7Br$: C, 57.04; H, 7.92; Br, 14.59%.

*Allylic Bromide (**12a**) and Triphenylphosphonium Salt (**13a**).* Triethylamine (0.05 ml, 0.315 mmol) and lithium bromide (20 mg, 0.23 mmol) were added to a solution of **10a** (83 mg, 0.21 mmol) in dichloromethane (1.6 ml), and then the new mixture was cooled at 0 °C. To this cooled suspenion, mesyl chloride (0.02 ml, 0.24 mmol) was added under stirring. Stirring was continued at 0 °C for 1 h at room temperature for 12 h. The reaction mixture was then diluted with acetone, and the precipitates were filtered off using Celite and washed with ethyl acetate. The filtrate and washings were combined and evaporated to afford a yellow syrup. The syrup was chromatographed on silica gel (Kieselgel 60, 8 g) with 9: 1 hexane–ethyl acetate to give **12a** (77 mg, 80%) as a colorless crystalline solid: ^{1}H-NMR δ=0.8−1.0 (12H, m, 4, 6, 8, and 10-Me), 1.28 and 1.32 (each 3H, each s, CMe_2), 3.36 (6H, s, OMe×2), 3.9—4.0 (2H, doublet like, H-13 and 13'), 4.85 (1H, m, H-1), and 5.7—5.9 (2H, m, H-11 and 12). A solution of **12a** (30 mg, 0.06 mmol) and triphenylphosphine (17 mg, 0.065 mmol) in dry ether (0.3 ml) was stirred under argon at 30 °C for 2 d. The resulting solid was separated from ether by decantation and triturated with ether to afford a colorless powder of **13a** (46.5 mg, 100%); IR (KBr) 1430, 1110, 1000, 730, and 710 cm^{-1}.

*Allylic Bromide (**12b**) and Triphenylphosphonium Salt (**13b**).* By the procedure described in the preparation of **12a**, a sample (91 mg) of **10b** was converted into a crude bromide, **12b**, which was then purified by column chromatography, using Kieselgel 60 (10 g) with 50: 1 benzene–ethyl acetate, to afford a practically pure sample of **12b** (93 mg, 90%) as colorless needles: mp 126—127 °C; ^{1}H-NMR δ=0.97 (doublet like, 12H, 4, 6, 8, and 10-Me), 1.27 and 1.31 (each 3H, each s, CMe_2), 3.20 (1H, dd, H-3, $J_{2,3}$=3.5 Hz, $J_{3,4}$=6.6 Hz), 3.40 (6H, s,

OMe×2), 4.40 (1H, dd, H-2, $J_{1,2}$=1.6 Hz), 4.99 (1H, d, H-1), and 5.69—5.87 (2H, m, H-11 and 12). A solution of **12b** (92 mg, 0.17 mmol) and triphenylphosphine (89 mg, 0.339 mmol) in dry benzene (0.28 ml) was stirred under arogn at 55 °C for 5 d. After the subsequent removal of the solvent by evaporation, the resulting solid was washed with hexane by trituration to afford a colorless powder of **13b** (136 mg, 100%): IR (KBr) 1440, 1118, 998, and 724 cm^{-1}.

Wittig Condensation of Methyl Pyruvate with Triphenylphosphorane Generated from ***13a*** *or* ***13b***. *(A)*: A 1.6 M butyllithium in hexane (0.027 ml, 0.043 mmol) was added, under argon, to a stirred, cooled solution (−75 °C) of **13a** (46.5 mg, 0.064 mmol) in dry THF (0.5 ml). After the solution had been stirred at −75 °C for 1 h, to the deep red solution was added a solution of methyl pyruvate (4.4 mg, 0.043 mmol) in dry THF (0.1 ml). Stirring was continued at −75 °C for 0.5 h, and then it was evaporated. Ether was added to the residual syrup, and the precipitates were filtered off and washed with ether. The combined filtrate and washings were then evaporated to afford a yellow syrup (40.3 mg). The crude product was purified by PLC with 10 : 1 benzene–ethyl acetate to give a mixture of **7a** and its 13*E*-isomer, **7'a** (11.9 mg). The mixture was chromatographed on alumina (Woelm grade I, 1 g) with 3: 1 benzene–chloroform to afford **7a** [R_f 0.51 (2: 1 hexane–ether, two passes)] as a colorless syrup [4 mg (28%)] and **7'a** [R_f 0.49 (2: 1 hexane–ether, two passes)], also as a colorless syrup [5 mg (34%)]: $[\alpha]_D^{30}$ −9° (*c* 1.29, MeOH); UV_{max} (EtOH) 266 nm (ε 35700); IR (CCl_4) 1709 and 1641 cm^{-1}; ^{1}H-NMR δ=0.85—1.05 (12H, m, 4, 6, 8, and 10-Me), 1.27 and 1.31 (each 3H, each s, CMe_2), 1.95 (3H, d, 14-Me, $J_{13,Me}$=1.5 Hz), 3.34 (6H, s, OMe×2), 3.75 (3H, s, COOMe), 4.81 (1H, dd, H-1, $J_{1,2ax}$=3.5 Hz, $J_{1,2eq}$=1.5 Hz), 6.4 (1H, dd, H-11, $J_{11,12}$=14.6 Hz, $J_{10,11}$=6.2 Hz), 6.40 (1H, dd, H-12, $J_{12,13}$=10.0 Hz), and 7.17 (1H, dd, H-13).

Found: C, 66.37; H, 9.45%. Calcd for $C_{26}H_{44}O_7$: C, 66.64; H, 9.46%.

(B): A 1.6 M butyllithium in hexane (0.089 ml) was added, under argon, to a stirred, cooled solution (−75 °C) of **13b** (77 mg) in dry THF (0.77 ml). After the mixture had been stirred at −75 °C for 15 min, methyl pyruvate (19 mg) was added to the deep-red solution. The solution immediately turned pale yellow. It was then poured into ice-cooled water, and the mixture was extracted with chloroform. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue (116 mg) was preparatively thin-layer chromatographed on two PLC plates (in two passes) with 25: 1 and 30: 1 benzene–ethyl acetate to afford **7b** [R_f 0.47 (15: 1 benzener–ethyl acetate)] as a pale yellow viscous syrup [21 mg (40%)] and **7'b** [R_f 0.42 (15: 1 benzene–ethyl acetate)] also as a pale yellow viscous syrup [22 mg (42%)]; these two substances were found by ^{1}H-NMR analysis and TLC to be identical with the corresponding authentic samples.

Methyl [*Methyl 2,4,6,8,10,11,12,13,14-Nonadeoxy-4,6,8,10,14-penta-*C*-methyl-*3*-O-methyl-*L*-manno-β-*D*-galacto (11*E*, 13*Z*)-11,13-pentadecadienopyranosid*]*uronate (**1a**)*. A sample of **7a** (15 mg) was dissolved in 50 (v/v)% aqueous DFA (0.15 ml), after which the mixture was stand at 0 °C for 25 min. The solution was then neutralized with solid $NaHCO_3$ and extracted with ether. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated. Chromatographic purification using silica gel (1 g) with 3: 2 benzene–ethyl acetate afforded **1a** (11 mg, 80%) as a colorless syrup; this syrup was identical with the authentic sample.

(R)-2-Bromo Derivative of ***1a*** *(****1b****)*. A solution of **7b** (27 mg) in 90 (v/v) % TFA (0.27 ml) was kept at 0 °C for 15 min. The subsequent removal of the solvent, followed by column chromatography on silica gel (2.5 g) with 3: 1 benzene–ethyl acetate, gave a pale yellow syrup of **1b** (25 mg, 100%), whose ^{1}H-NMR, IR, and UV spectra were identical with those of the authentic sample.

We wish to thank Mr. Saburo Nakada for carrying out the microanalyses and the Daiichi Seiyaku Co., Ltd., for the kind supply of rifampicin. The authors are also grateful to the Institute of Microbial Chemistry for its financial support.

The Reaction of Acetophenones with Manganese(III) Acetate

Kazu KUROSAWA* and Katsutoshi YAMAGUCHI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received August 12, 1980)

The reaction of 4′-methoxyacetophenone with manganese(III) acetate in the presence of ammonium chloride yielded 2-chloro-4′-methoxyacetophenone (**2a**) and 2,2-dichloro-4′-methoxyacetophenone (**3a**). The reaction of **2a** with these reagents gave **3a**, 4′-methoxy-2,2,2-trichloroacetophenone, and 1,4-bis(4-methoxyphenyl)-2,2,3,3-tetrachloro-1,4-butanedione (**8a**). The reactions of **2a** and 2-bromoacetophenone with manganese(III) acetate yielded the corresponding 2,3-dihalo-1,4-diphenyl-1,4-butanediones, 1,4-diphenyl-2-halo-2-butene-1,4-diones, 2,3-dihalo-2-butene-1,4-diones, 2,2-dibromoacetophenone, and **8a**. The reaction pathways are discussed.

It has been reported that the reaction of acetophenone with oxygen in the presence of manganese(III) acetate in butyric acid gave benzoic acid.[1] The reactions of aliphatic and cyclic ketones with manganese(III) acetate have also been reported to give α-acetoxy ketones as the major product when the reaction was conducted under nitrogen.[2] The reactions of ketones with manganese(III) acetate in the presence of olefins have been reported by many investigators.[2-6] It seems that the chloride ion, in place of olefins, oxygen and acetate ion, will react with the benzoylmethyl radical formed from acetophenone. The acetophenone derivatives examined are 4′-methoxyacetophenone (**1a**) and 2-chloro-4′-methoxyacetophenone (**2a**). The reactions were carried out in boiling acetic acid. The structure of the reaction products were determined by means of the study of their IR, NMR, and mass spectra, by elemental analyses, and by comparison with authentic samples.

When **1a** was oxidized with manganese(III) acetate–ammonium chloride in acetic acid containing acetic anhydride, 2-chloro-4′-methoxyacetophenone (**2a**) and 2,2-dichloro-4′-methoxyacetophenone (**3a**) were obtained (Table 1, Entries 2—9), in contrast to the reaction in the absence of ammonium chloride (Entry 1), which gave 2-acetoxy-4′-methoxyacetophenone (**2b**) and *p*-anisic acid (**4a**). The yields of **2a** were first increased and then decreased with the increase in the oxidant, while the yields of **3a** were increased (Entries 2, 4, and 8). The total yields decreased with a higher molar ratio of the oxidant to the substrate, because of the formation of a number of undefined products. It was also found that acetic anhydride added to the reaction mixture effected the yield of **3a** more than that of **2a** (Entries 3, 4, 5, and 6), although no rational explanation could be given. Lithium chloride and hydrochloric acid were also employed as chloride-ion sources; the results are shown in the table (Entries 10 and 11). It could be assumed that the reaction is initiated by the formation of the benzoylmethyl radical[1] (Ia in Scheme 1), which captures the chloride ion in the presence of manganese(III) acetate, but this is the least possible because it is difficult for the three species to get together at one time. It seems reasonable to

$$ArCOCH_2^{\cdot} + Cl^- + Mn(III) \longrightarrow ArCOCH_2Cl + Mn(II)$$

assume that the chloride ion either forms a complex

Table 1. The reactions of 4′-methoxyacetophenone (**1a**) and 2-chloro-4′- methoxyacetophenone (**2a**) with manganese (III) acetate in the presence of ammonium chloride in acetic acid containing acetic anhydride at the reflux temperature

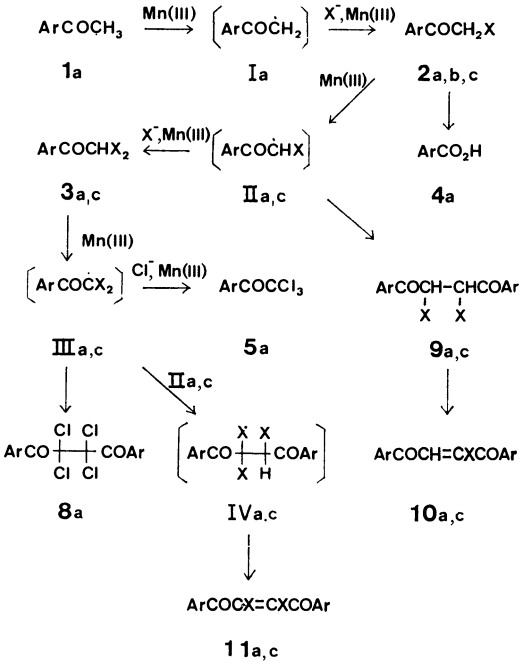
with manganese(III) acetate such as $[Mn(OAc)_3Cl]^-$ or replaces some of the acetate ions to form $Mn(OAc)_{3-n}Cl_n$, which then reacts with Ia. In fact, the visible spectrum of manganese(III) acetate in acetic acid showed a maximum at 470 nm (ε 288) which was shifted to 530 nm (shoulder, ε 439) by the addition of lithium chloride. It has been reported that a similar shift was caused by the addition of potassium acetate.[7] **2a** can be further chlorinated in the same way to **3a** and **5a** (Table 1, Entries 12 and 13, and Scheme 1).

The reaction of **1a** with chlorine in acetic acid gave 3′-chloro-4′-methoxyacetophenone (**6**) and 2,3′-dichloro-4′-methoxyacetophenone (**7**), along with **2a**. The absence of the nuclear chlorinated compounds among the manganese(III) acetate–ammonium chloride oxidation products from **1a** eliminated the pathway in which the chloride ion is oxidized to chlorine, with the latter then reacting with **1a** to give **2a** and **3a**. Other nucleophiles, such as methanol and benzoic acid, failed to react with **1a**, and **2b** was obtained in poor yields (10 and 6% respectively). When ammonium bromide was used, bromine was liberated.

When 2-chloro-4′-methoxyacetophenone (**2a**) was treated with manganese(III) acetate–ammonium chloride, 1,4-bis(4-methoxyphenyl)-2,2,3,3-tetrachlorobutanedione (**8a**) was obtained, together with **3a** and 4′-methoxy-2,2,2-trichloroacetophenone (**5a**) (Entry 13). **8a** can be formed by the dimerization of the benzoyldichloromethyl radical (IIIa), which is derived from **3a** by the action of manganese(III) acetate. This led us to examine the reactions of **2a** and 2-bromoacetophenone (**2c**) with manganese(III) acetate.

When 2-bromoacetophenone (**2c**) was oxidized with manganese(III) acetate, 2,2-dibromoacetophenone (**3c**), 2,3-dibromo-1,4-diphenyl-1,4-butanedione (**9c**), 2-bromo-1,4-diphenyl-2-butene-1,4-dione (**10c**), and (*E*)-2,3-dibromo-1,4-diphenyl-2-butene-1,4-dione (**11c**) were obtained (Table 2). The yields of the reaction products depended on the molar ratio of the oxidant to the substrate (Entries 2 and 3) and were decreased by the presence of acetic anhydride, which shortened the reaction time considerably (Entry 4). In boiling acetic acid, **9c** was converted to **10c** with the loss of hydrogen bromide. The configurations of **9c** and **10c** could not be determined. When 1 : 1 mixture of **2c** and **3c** was oxidized with manganese(III) acetate, **11c** was obtained in an increased yield, at the expense of decreased yields of **9c** and **10c** (Entry 5). The reaction pathway may be explained as follows. The reaction of **2c** with manganese(III) acetate gives the benzoylbromomethyl radical (IIc), which dimerizes to **9c**. The dehydrobromination of **9c** yields **10c**. IIc, on the other hand, reacts with the hydrogen bromide now present in the reaction mixture to give **3c**. The benzoyldibromomethyl radical (IIIc), which is formed from **3c** by manganese(III) acetate, reacts with IIc to give IVc. The dehydrobromination of IVc gives **11c**. The reaction of 2-chloro-4′-methoxyacetophenone (**2a**) with manganese(III) acetate in acetic acid gave similar products except for the presence of **8a** and the absence of **3a** among the reaction products. The difference in the product distributions in Entry 11 of Table 1 and in Entry of Table 2 may be ascribed to the difference in the chloride-ion concentration. **3a** was converted to **8a** with manganese(III) acetate (Entry 6). These values are shown in Scheme 1.

It is thus concluded that the benzoylmethyl radical



Scheme 1. **a**: Ar=4-methoxyphenyl, X=Cl; **b**: Ar=4-methoxyphenyl, X=OAc; **c**: Ar=phenyl, X=Br.

(Ia) and the benzoylhalomethyl radicals (IIa and IIc) derived from the corresponding acetophenone with manganese(III) acetate can react with the halide ion in the presence of manganese(III) acetate to give **2a**, **3a**, **3c**, and **5a**, and that the benzoylhalomethyl radicals (IIa, IIc, IIIa, and IIIc) tend to dimerize to form **8a**, **9a**, **9c**, **10a**, **10c**, **11a**, and **11c** in low halide-ion concentrations.

Experimental

All the ^{1}H NMR spectra were recorded with a Hitachi-Perkin-Elmer R 24 spectrometer, with tetramethylsilane as the internal reference. The IR spectra were taken for the chloroform solution on a JASCO grating spectrometer, while the UV spectra were recorded for the methanol solution with a Hitachi EPS-3T spectrophotometer. The mass spectra were recorded with a JMS-01 SG-2 instrument. The melting points were determined with a Yanagimoto micro-melting point apparatus and were not corrected.

Acetophenones. The 4′-methoxyacetophenone (**1a**) and 2-bromoacetophenone (**2c**) were commercial samples from Wako Pure Chemical Industries, Ltd. The 2-chloro-4′-methoxyacetophenone (**2a**)[8] and 2,2-dichloro-4′-methoxyacetophenone (**3a**)[9] were prepared by the standard procedure.

Oxidations of 4′-Methoxyacetophenone (1a) and 2-Chloro-4′-methoxyacetophenone (2a) with Manganese(III) Acetate–Ammonium Chloride. The general procedure for the oxidations of **1a** and **2a** with manganese(III) acetate–ammonium chloride was as follows. A mixture of **1a** (or **2a**) (2 mmol), manganese(III) acetate dihydrate,[10] acetic acid (20 ml), acetic anhyride and ammonium chloride (19 mmol) was heated under reflux for the time shown in Table 1. After the removal of the solvent *in vacuo*, 2 M hydroric acid (40 ml) was added to the reaction mixture and the mixture was extract with benzene (30 ml). The benzene solution was washed with aqueous sodium hydrogencarbonate and then evaporated *in vacuo*. The resulting liquid was chromatographed on TLC (Wakogel B10), with benzene or chloroform as the developing solvent. The yields are summarized in Table 1.

2-Chloro-4′-methoxyacetophenone (2a): Mp 100—102 °C (CCl_4) (lit,[8] mp 101—102 °C); IR 1700 and 1710 cm^{-1}; NMR ($CDCl_3$) δ=3.83 (3H, s, OCH_3), 4.58 (2H, s, $-CH_2-$), 6.95 (2H, m, $H_{(3')}$ and $H_{(5')}$), and 7.91 (2H, m, $H_{(2')}$ and $H_{(6')}$).

2,2-Dichloro-4′-methoxyacetophenone (3a): Mp 78—79 °C (CCl_4) (lit,[9] mp 74—75 °C); IR 1700 and 1718 cm^{-1}; NMR (CCl_4) δ=3.82 (3H, s, OCH_3), 6.43 (1H, s, >CH–), 6.79 (2H, m, $H_{(3')}$ and $H_{(5')}$), and 7.90 (2H, m, $H_{(2')}$ and $H_{(6')}$).

4′-Methoxy-2,2,2-trichloroacetophenone (5a): Liquid (lit,[11] mp 33—34.5 °C); IR 1720 cm^{-1}; NMR (CCl_4) δ=3.86 (3H, s, OCH_3), 6.87 (2H, m, $H_{(3')}$ and $H_{(5')}$), and 8.20 (2H, m, $H_{(2')}$ and $H_{(6')}$).

1,4-Bis(4-methoxyphenyl)-2,2,3,3-tetrachloro-1,4-butanedione (8a): Mp 145—146 °C (CCl_4); IR 1708 cm^{-1}; UV λ_{max} 229 (12000) and 304 nm (25900); NMR ($CDCl_3$) δ=3.84 (6H, s, 2×OCH_3), 6.89 (4H, m, $H_{(3')}$, $H_{(3'')}$, $H_{(5')}$, and $H_{(5'')}$), and 8.25 (4H, m, $H_{(2')}$, $H_{(2'')}$, $H_{(6')}$, and $H_{(6'')}$). Found: C, 49.33; H, 3.34%. Calcd for $C_{18}H_{14}Cl_4O_4$: C, 49.57; H, 3.24%.

Chlorination of 4′-Methoxyacetophenone (1a) with Chlorine in Acetic Acid. Through a solution of **1a** (1 g) in acetic acid (10 ml), chlorine gas was passed (The weight of the chlorine absorbed was 0.5 g), after which the solution was left at room temperature for 30 min. After the removal of the acetic acid *in vacuo*, the resulting mixture was chromatographed on TLC, with benzene as the developing solvent, giving unchanged **1a** (74 mg, 7%), 3′-chloro-4′-methoxyacetophenone (**6**) [237 mg, 19%, mp 73—74 °C (MeOH) (lit,[12] mp 71—73 °C)], **2a** (358 mg, 29%), and 2,3′-dichloro-4′-methoxyacetophenone (**7**) [207 mg, 14%, mp 89—90 °C (EtOH); IR 1700 cm^{-1}; NMR ($CDCl_3$) δ=3.96 (3H, s, OCH_3), 4.62 (2H, s, $-CH_2-$), 7.00 (1H, d, J=8.0 Hz, $H_{(5')}$), 7.75—8.05 (2H, m, $H_{(2')}$ and $H_{(6')}$). Found: C, 49.43; H, 3.79%. Calcd for $C_9H_8Cl_2O_2$: C, 49.34; H, 3.68%].

Oxidation of Acetophenones (1a, 2a, 2c, 3a, and 3c) with Manganese(III) Acetate. The general procedure for the oxidation of acetophenones was as follows. A mixture of an acetophenone (2 mmol), manganese(III) acetate dihydrate, and acetic acid (40 ml) was heated under reflux until the color of the manganese(III) ion disappeared. The reaction mixture was then worked-up in a manner similar to the above. The yields are summarized in Table 2.

Oxidation Products of 1a. *2-Acetoxy-4′-methoxyacetophenone (2b)*: Liquid (lit,[13] mp 58—59 °C; IR 1718 (C=O) and 1760 cm^{-1} (OAc); NMR (CCl_4) δ=2.08 (3H, s, OAc), 3.73 (3H, s, OCH_3), 5.07 (2H, s, $-CH_2-$), 6.78 (2H, m, $H_{(3')}$ and $H_{(5')}$), and 7.73 (2H, m, $H_{(2')}$ and $H_{(6')}$).

p-*Anisic Acid (4a)*: Mp 185 °C.

Oxidation Products of 2a. *1,4-Bis(4-methoxyphenyl)-2,3-dichloro-1,4-butanedione (9a)*: Mp 190—191 °C (dec) (CCl_4); IR 1696 cm^{-1} (C=O); UV λ_{max} (ε) 229 (16600) and 300 nm (35000); NMR ($CDCl_3$) δ=3.85 (6H, s, 2×OCH_3), 5.68 (2H, s, >CH–), 6.93 (4H, m, $H_{(3')}$, $H_{(3'')}$, $H_{(5')}$, and $H_{(5'')}$), and 8.00 (4H, m, $H_{(2')}$, $H_{(2'')}$, $H_{(6')}$, and $H_{(6'')}$). Found: C, 58.56; H, 4.45%. Calcd for $C_{18}H_{16}Cl_2O_4$: C, 58.87; H, 4.39%.

1,4-Bis(4-methoxyphenyl)-2-chloro-2-butene-1,4-dione (10a): Liquid; IR 1680 cm^{-1} (C=O); UV λ_{max} (ε) 227 (14600) and 305 nm (19900); NMR (CCl_4) δ=3.68 (s, OCH_3), 3.72 (s, OCH_3), 6.65—6.95 (m, $H_{(3')}$, $H_{(3'')}$, $H_{(5')}$, and $H_{(5'')}$), 7.12 (s, =CH–), 7.30 (s, =CH–), and 7.6—7.9 (m, $H_{(2')}$, $H_{(2'')}$, $H_{(6')}$, and $H_{(6'')}$). The presence of two singlets with nearly equal intensities at δ=7.12 and 7.30 indicated that this substance was a mixture of (*Z*)- and (*E*)-isomers in a 1 : 1 molar ratio. MS *m/e* 330 (M^+), 295 ($M^+ - Cl$), 223 ($M^+ - C_6H_4OCH_3$), 207, 195 ($M^+ - COC_6H_4OCH_3$), 135 ($CH_3OC_6H_4CO^+$), 107, and 92.

1,4-Bis(4-methoxyphenyl)-2,3-dichloro-2-butene-1,4-dione (11a): Mp 132.5—134 °C (CCl_4); IR 1680 cm^{-1} (C=O); UV λ_{max} (ε) 228_{sh} (15200) and 309 nm (25800); NMR (CCl_4) δ=3.78 (6H, s, 2×OCH_3), 6.80 (4H, $H_{(3')}$, $H_{(3'')}$, $H_{(5')}$, and $H_{(5'')}$), and 7.68 (4H, m, $H_{(2')}$, $H_{(2'')}$, $H_{(6')}$ and $O_{(6')}$: Found: C, 59.02; H, 3.62%. Calcd for $C_{18}H_{14}Cl_2O_4$: C, 59.20; H, 3.86%.

1,4-Bis(4-methoxyphenyl)-2,2,3,3-tetrachloro-1,4-butanedione (8a): Mp 145—146 °C.

Oxidation Products of 2c. *2,2-Dibromoacetophenone (3c)*: Liquid (lit,[14] mp 36—37 °C); IR 1695 and 1718 cm^{-1}; NMR (CCl_4) δ=6.55 (1H. s. >CH–), 7.2—7.7 (3H, m, $H_{(3')}$, $H_{(4')}$, and $H_{(5')}$), and 7.9—8.2 (2H, m, $H_{(2')}$ and $H_{(6')}$).

2,3-Dibromo-1,4-diphenyl-1,4-butanedione (9c): Mp 180—182 °C (dec) (CCl_4); IR 1710 cm^{-1} (C=O); UV λ_{max} (ε) 264 nm (24200); NMR ($CDCl_3$) δ=5.99 (2H, s, >CH–), 7.2—7.8 (6H, m, $H_{(3')}$, $H_{(3'')}$, $H_{(4')}$, $H_{(4'')}$, $H_{(5')}$, and $H_{(5'')}$), and 8.0—8.25 (4H, m, $H_{(2')}$, $H_{(2'')}$, $H_{(6')}$, and $H_{(6'')}$). Found: C, 48.20; H, 3.07%. Calcd for $C_{16}H_{12}Br_2O_2$: C, 48.52; H, 3.05%.

2-Bromo-1,4-diphenyl-2-butene-1,4-dione (10c): Liquid; IR 1690 cm^{-1} (C=O); UV λ_{max} (ε) 270 nm (20200); NMR (CCl_4) δ=7.2—7.7 (6H, m, $H_{(3')}$, $H_{(3'')}$, $H_{(4')}$ $H_{(4'')}$, $H_{(5')}$, and $H_{(5'')}$), 7.60 (1H, s, =CH–), and 7.7—8.0 (4H, m, $H_{(2')}$. $H_{(2'')}$, $H_{(6')}$, and $H_{(6'')}$); MS *m/e* 314 (M^+), 235 ($M^+ - Br$), 105 ($PhCO^+$), and 77 (Ph^+). **10c** could be a mixture of (*Z*)- and (*E*)-isomers.

(E)-2,3-Dibromo-1,4-diphenyl-2-butene-1,4-dione (11c): Mp 208—210 °C (CCl_4–light petroleum) (lit,[15,16] mp 213 °C);

IR 1685 cm^{-1} (C=O); UV λ_{max} (ε) 266 (16600) and 293 nm (shoulder) (6220); NMR (CCl_4) δ=7.2—7.7 (6H, m, $H_{(3')}$, $H_{(3'')}$, $H_{(4')}$, $H_{(4'')}$, $H_{(5')}$, and $H_{(5'')}$), and 7.7—7.95 (4H, m, $H_{(2')}$, $H_{(2'')}$, $H_{(6')}$, and $H_{(6'')}$). Found: C, 49.07; H, 2.66%. Calcd for $C_{16}H_{10}Br_2O_2$: C, 48.77; H, 2.56%. MS *m/e* 392 (M^+), 313 (M^+ −Br), 129 ($PhCOC{\equiv}C^+$), 105 ($PhCO^+$), and 77 (Ph^+).

Oxidation Products of a Mixture of ***2c*** *and* ***3c***.

*2,3-Dibromo-1,4-diphenyl-1,4-butanedione (****9c****)*: Mp 180—182 °C (dec).

*2-Bromo-1,4-diphenyl-2-butene-1,4-dione (****10c****)*: Liquid.

*(E)-2,3-Dibromo-1,4-diphenyl-2-butene-1,4-dione (****11c****)*: Mp 208—210 °C.

Oxidation Products of ***3a***. *1,4-Bis(4-methoxyphenyl)-2,2,3,3-tetrachloro-1,4-butanedione (****8a****)*: Mp 145—146 °C.

Dehydrobromination of ***9c***. A solution of **9c** (40 mg) in acetic acid (1 ml) was heated under reflux for 35 min. The reaction mixture was then worked-up as has been described previously, giving **10c** (18.5 mg, 45%) identical with the sample obtained by the reaction of **2c** with manganese(III) acetate dihydrate, and also unchanged **9c** (12 mg, 30%).

We wish to thank Professor J. F. W. McOmie of Bristol University, England, and Assistant Professor Fumiaki Kai of the Department of Chemistry, Kumamoto University, for their helpful discussions, and Mr. Shuichi Ueda at the Taiho Pharmaceutical Co., Tokushima, for his measurements of the mass spectra.

Multiple Paths for Photo-alkylation and -alkoxylation of 3-Pyridinecarboxylic Ester in Alcohol. Simultaneous Contribution of Several Kinds of Excited States

Akira SUGIMORI,* Etsuo TOBITA, Yasuyuki KUMAGAI, and Gen P. SATÔ

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102

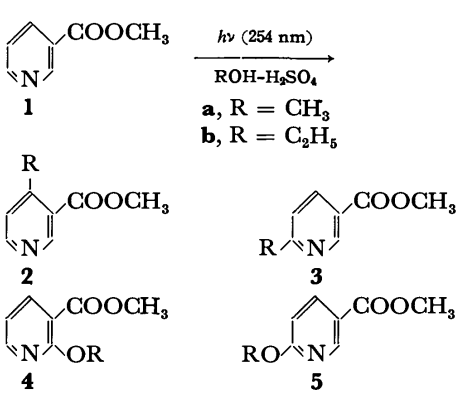
(Received August 27, 1980)

UV-irradiation of methyl 3-pyridinecarboxylate (**1**) in acidic alcoholic solutions brings about the alkoxylation and alkylation at the pyridine ring. Photoalkylation occurs in several paths: 1) alkylation initiated by the triplet π-π^* state, 2) alkylation initiated by the triplet n-π^* state of the carbonyl moiety of the ester group, 3) alkylation initiated by an exciplex between a free base form of **1** and a pyridinium form of **1**, and 4) alkylation promoted by chloride ions. Photoalkoxylation originates from a singlet excited state of **1**. In the photoreactions of **1** in strongly acidic methanolic solutions acidified with H_2SO_4, three kinds of excited states (two kinds of triplet states for alkylation and a singlet state for alkoxylation) contribute simultaneously.

Photochemical reactions of azaaromatic compounds with alcohols have been extensively investigated.[1] Previously we reported alkylation and alkoxylation in the photoreactions of pyridinecarboxylic acid derivatives.[2] Stermitz *et al.* explained the photoalkylation at α- and γ-positions of the pyridine ring according to the mechanism of hydrogen abstraction by excited protonated pyridines from alcohol, followed by the geminate radicals and dehydration.[3] Castellano *et al.* proposed a mechanism for photoalkylation *via* the monophotonic hydrogen abstraction by n-π^* state-pyridine in neutral alcoholic solutions, and *via* biphotonic electron transfer in alcoholic solutions acidified with HCl.[4] In the latter case they did not detect the formation of Cl atoms. We report here that the photoalkylation and photoalkoxylation of 3-pyridinecarboxylic ester in alcohol proceed in several different pathways.[5] The 3-pyridinecarboxylic ester–alcohol system is a very interesting system in which several excited states of the same multiplicity contribute simultaneously. β,γ-Unsaturated ketone is another system in which $^3(\pi$-$\pi^*)$ and ^{3}(n-π^*) contribute simultaneously.[6]

Results and Discussion

The UV-irradiation of methyl 3-pyridinecarboxylate (**1**) in alcohols in the presence of mineral acids brings about two types of substitution by the groups derived from the solvent alcohols: alkylation and alkoxylation. The substitution occurs at the α- and γ-positions of the pyridine ring. In the methanolic solutions acidified with sulfuric acid, two alkylation products (**2a** and **3a**) and two alkoxylation products (**4a** and **5a**) are formed by the irradiation with 254 nm light.



The yields of the products are linear with the irradiation time, as exemplified by the photoreaction under the conditions of $[\mathbf{1}]=1\times10^{-2}$ mol dm^{-3} and $[H_2SO_4]=5\times10^{-2}$ mol dm^{-3} (Fig. 1).

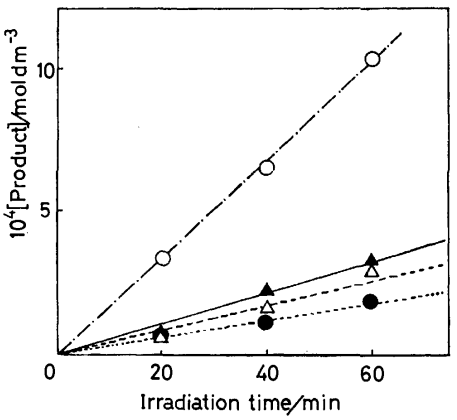


Fig. 1. Relation between the product yield and the irradiation time. Irradiated with 254 nm light in methanol.
$[\mathbf{1}]=1\times10^{-2}$ mol dm^{-3}; $[H_2SO_4]=5\times10^{-2}$ mol dm^{-3}.
---△---: **2a**, —▲—: **3a**, -·-○-·-: **4a**, ···●···: **5a**.

The photo-alkylation and -alkoxylation of 3-pyridinecarboxylic ester are dependent upon the reaction conditions: 1) the concentration of the substrate, 2) the mineral acid added, 3) the concentration of the added acid, 4) the nature of the solvent alcohol, and 5) additives.

Figure 2 shows the dependences of photoreactions on the concentrations of sulfuric acid at 1×10^{-3}, 3×10^{-3}, and 1×10^{-2} mol dm^{-3} concentrations of methyl 3-pyridinecarboxylate.

As is seen typically in Figs. 2—3, the acidity dependence of the photoreactions of **1** is complex, with photoalkylation and -alkoxylation competing. The region where photoalkylation is effective is divided into two parts.

In the higher acidity region (Region B), alkylation and alkoxylation are comparable. The peak of alkyla-

tion in the lower acidity region (Region A) moves depending on the concentration of the substrate (**1**). As the concentration of **1** becomes lower, the acid concentration which gives the peak becomes lower and the peak height goes down.

The acidity dependence of the molar absorption coefficient of **1** in methanol (Fig. 3) indicates that **1** exists in the pyridinium form in Region B. In Region A the pyridinium form and the free base-form of **1** coexist.

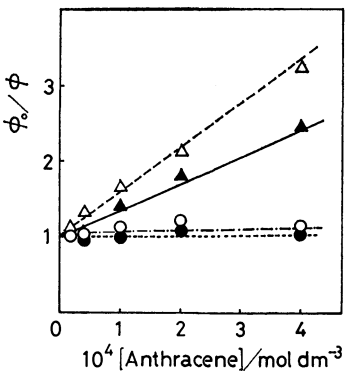

Fig. 4. Effect of anthracene on the photoreactions of **1**.

--△--: **2a**. —▲—: **3a**, -·-○-·-: **4a**, ···●···: **5a**.

The excited states responsible for the photo-alkylation and -alkoxylation in the higher acidity region were assigned by the effects of additives, solvents, and temperature.

Figure 4 shows Stern-Volmer plots for the quenching by anthracene, a triplet quencher ($E_T=176$ kJ mol^{-1}). Because anthracene absorbs the light of 254 nm competitively with the substrate, the quantum yields are normalized on the basis of the light absorbed by the substrate by the following formula:

$$\phi_0/\phi = \mathrm{L/Y},$$

$$\mathrm{Y} = \frac{\text{Yield in the presence of quencher}}{\text{Yield in the absence of quencher}},$$

$$\mathrm{L} = \frac{\text{Light absorbed by the substrate}}{\text{Light absorbed by the substrate} + \text{Light absorbed by the quencher}}.$$

The Stern-Volmer plots indicate that the alkylation and the alkoxylation originate from triplet and singlet exited states, respectively. Furthermore, the different dependences of anthracene on the two alkylation reactions suggest that the product alkylated at α- and γ-positions originate from the triplet excited states of different character.

This view is supported by the temperature dependence of the photoreactions. Figure 5 is the plot of ln(relative

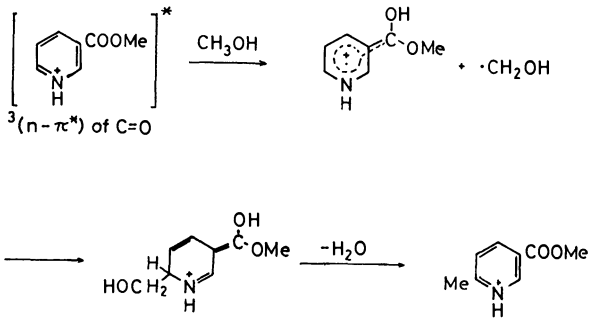
yield) *vs.* the reciprocal of temperature; the slope of the plot gives the difference in the activation energies between a given reaction and the standard reaction (in this case the formation of **2a**).

The plots for the two alkoxylation reactions have the same temperature dependence, whereas the photoalkylations at α- and γ-positions differ in temperature dependence.

The effects of benzene, naphthalene, and anisole (Table 1) (small effects on the photoalkoxylation, large effects on the photoalkylation, and different effects on the two alkylation reactions) also support the view.

The results obtained in the irradiation in ethanol are compared with those in methanol (Table 2). The irradiation in ethanol depresses the alkoxylation, but the change in the ratio of the isomers is small. Alkylation becomes dominant and the product ethylated at the 6-position is selectively formed. The solvent effect indicates that the triplet states responsible for the alkylation at the 6-position and the 4-position are of n-π^* and π-π^* character, respectively.

As the photoreactions occur in acidic solutions, the n-π^* state should not be the excitation of the electrons at N atom, because the lone pair electrons are donated to a proton. However, the excitation of the lone pair electrons located at O atom of the ester C=O is possible. In the UV-irradiation of 2-pyridinecarboxylic ester in methanol, methylation occurs at the 5-position.[5] This indicates the participation of the excited C=O moiety in the alkylation. The hydrogen abstraction by the excited C=O of the ester group (or the electron transfer followed by the proton transfer) has been reported for some aromatic esters.[7] These facts suggest that the excitation of the ester C=O can contribute to the photoreactions of 3-pyridinecarboxylic ester. If the excitation of a non-bonding electron of C=O is taken into account, the alkylation at the 6-position can be explained as is shown in Scheme 1.



Scheme 1.

The alkylation at the 4-position can be explained by the reaction of π-π^* state through the mechanism proposed by Stermitz *et al.*[3]

The results of quenching, solvent effects, and temperature dependence show that the two alkoxylation products are due to the same excited state. Alkoxylation occurs presumably *via* the nucleophilic attack of alcohol to the polar, singlet excited-state substrate.

The fact that, in Region A, pyridinium and free base forms of **1** coexist suggest that the alkylation in Region A is brought about by the cooperation of the pyridinium and free base forms.

The effects of benzene, naphthalene, and anisole on the photoalkylation in Region A are different from those in Region B (Table 1). This also suggests that the mechanism for alkylation reactions in Regions A and B are different.

We propose two mechanisms for alkylation in Region A: *via* an excited complex between the excited pyridinium and the ground-state free base and *via* that between the excited free base and the ground-state pyridinium; these are shown in Scheme 2.

In the Scheme, Py and PyH^+ stand for the free base and pyridinium forms of 3-pyridinecarboxylic esters, respectively. K is the equilibrium constant and k's are the rate constants of the corresponding reactions, and ε_A and ε_B are the molar absorption coefficients of the pyridinium and free base forms of **1** at the wavelength

Mechanism A

$$Py + H^+ \overset{K}{\rightleftharpoons} PyH^+$$

$$PyH^+ \overset{h\nu,\ k_2}{\underset{k_{-2}}{\rightleftharpoons}} (PyH^+)^* \qquad k_2 = \frac{I\varepsilon_A[PyH^+]}{\varepsilon_A[PyH^+] + \varepsilon_B[Py]}$$

$$(PyH^+)^* + Py \xrightarrow{k_3} (PyHPy^+)^*$$

$$(PyHPy^+)^* \xrightarrow{k_4} PyH^+ + Py$$

$$(PyHPy^+)^* \xrightarrow{k_5} \longrightarrow \text{Alkylation product}$$

Mechanism B

$$Py + H^+ \overset{K}{\rightleftharpoons} PyH^+$$

$$Py \overset{h\nu,\ k_2'}{\underset{k'_{-2}}{\rightleftharpoons}} Py^* \qquad k_2' = \frac{I\varepsilon_B[Py]}{\varepsilon_A[PyH^+] + \varepsilon_B[Py]}$$

$$Py^* + PyH^+ \xrightarrow{k_3'} (PyHPy^+)^*$$

$$(PyHPy^+)^* \xrightarrow{k_4'} PyH^+ + Py$$

$$(PyHPy^+)^* \xrightarrow{k_5'} \longrightarrow \text{Alkylation product}$$

Scheme 2.

of the irradiating light (intensity, I).

The mechanisms A and B can explain a) the appearance of the peak for the alkylation at an acid concentration and b) the fact that the peak height (maximum quantum yield) increases with the increase in the substrate concentration.

According to mechanism A, the quantum yield of the product (ϕ) is:

$$\phi = \frac{k_3k_5}{k_4 + k_5} \frac{c}{k_{-2}(1+K[H^+]) + k_3c} \frac{K[H^+]}{K[H^+] + \varepsilon_B/\varepsilon_A},$$

where $c=[Py]+[PyH^+]$.

The quantum yield of the photoreaction reaches the maximum at $[H^+]_{max}$:

$$[H^+]_{max} = \frac{1}{K}\sqrt{\frac{\varepsilon_B k_3}{\varepsilon_A k_{-2}}\left(c + \frac{k_{-2}}{k_3}\right)}.$$

The maximum quantum yield, ϕ_{max}, at $[H^+]_{max}$ is

$$\phi_{max} = \frac{\dfrac{k_3c}{k_{-2}}}{\left\{2\sqrt{\dfrac{\varepsilon_B}{\varepsilon_A}\left(1+\dfrac{k_3c}{k_{-2}}\right)} + \left(1+\dfrac{\varepsilon_B}{\varepsilon_A}\right) + \dfrac{k_3c}{k_{-2}}\right\}\left(1+\dfrac{k_4}{k_5}\right)}.$$

The ϕ_{max} value thus obtained is 0 at $c=0$ and increases monotonously with c to reach the limiting value of $(1+k_4/k_5)^{-1}$. A similar conclusion can be deduced from mechanism B.

Mechanisms A and B can explain qualitatively the results shown in Fig. 2, where the vertical axis is expressed in the concentrations of the products formed after 60 minutes' irradiation. The values are proportional to the quantum yields for the products. No direct evidence for the participation of an excited complex is obtained, because methyl 3-pyridinecarboxylate is not fluorescent under any conditions. At present we have no experimental results from which we decide which mechanism actually operates.

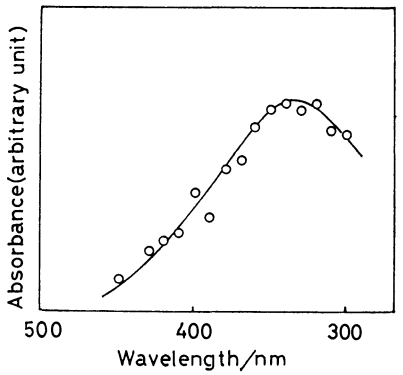

Fig. 7. Absorption spectrum in the flash photolysis of the 3-pyridinecarboxylic acid–HCl–H_2O system. Spectrum of 2 μs after the flash. [3-Pyridinecarboxylic acid]$=5\times10^{-4}$ mol dm^{-3}, [HCl]$=1$ mol dm^{-3}.

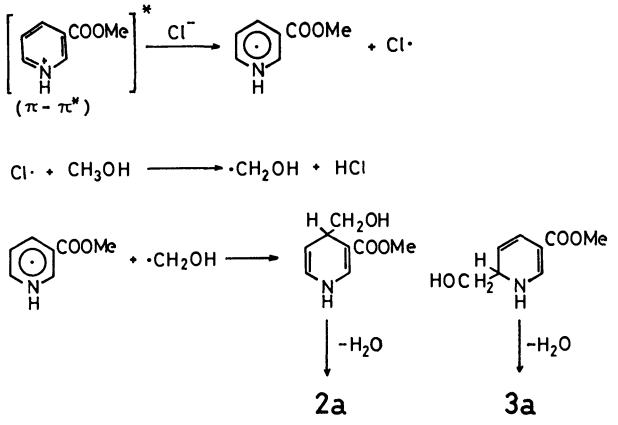
Dependences of the photoreactions on the concentration of hydrochloric acid are shown in Fig. 6. The presence of hydrochloric acid depresses the alkoxylation



Scheme 3.

and instead promotes the alkylation. The inhibition of alkoxylation and the promotion of alkylation are remarkable in the higher concentration region of hydrochloric acid.

The promotion of alkylation by hydrochloric acid can be attributed to the participation of chloride ions; the addition of lithium chloride promotes the alkylation and depresses the alkoxylation (Table 3).

As the mechanism for the promotion of alkylation by chloride ions, two paths are conceivable: the acceleration of intersystem crossing by the external heavy atom effect and/or a reaction involving chloride ions. At present we can not conclude which mechanism operates. However, the results of the flash photolysis favor the latter mechanism.

In the microsecond flash photolysis of aqueous 3-pyridinecarboxylic acid acidified with hydrochloric acid (photolyzing light, emission from Ar; duration of a flash, 4 μs; energy of a flash, 10 J), a transient absorption was observed at $\lambda_{max}=340$ nm, which is similar to that of Cl_2^- reported by Anbar and Thomas.[8]

The promotion of alkylation by chloride ions thus can be explained by a mechanism *via* chlorine atoms formed in the electron transfer from chloride ions to the excited pyridinium, which should undergo electrophilic alkoxylation in the absence of chloride ions. The alkylation of 3-pyridinecarboxylic ester *via* chlorine atoms should proceed as in Scheme 3.

The photoreactions of 3-pyridinecarboxylic ester in the region of higher concentration of acids are summarized in Scheme 4.

Experimental

Materials. Commercial methyl 3-pyridinecraboxylate (GR grade reagent of Tokyo Kasei Co.) was purified by vacuum distillation. Mp, 36—37 °C. Anthracene (standard reagent for elemental analysis made by E. Merck Co.) was used for the quenching experiment.

UV-irradiation. Methanolic or ethanolic solutions containing methyl 3-pyridinecarboxylate (10^{-3} —10^{-2} mol dm^{-3}), sulfuric acid or hydrochloric acid (10^{-5}—1 mol dm^{-3}), and the additive in the quenching experiment were deaerated by bubbling nitrogen or argon for 30 min before irradiation. The solutions were irradiated with a low pressure mercury lamp in a merry-go-round type irradiation apparatus normally at 32 °C.

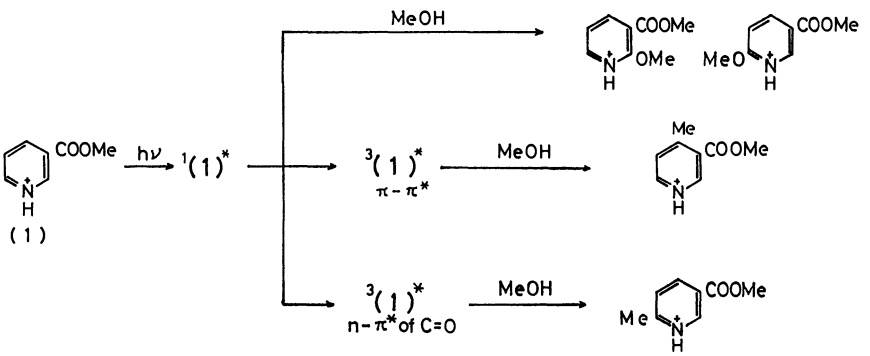
Isolation and Identification of Products. After the irradiation the solution was concentrated under reduced pressure. The solution was neutralized with sodium hydrogencarbonate and the products were extracted repeatedly with dichloromethane. The products were separated by means of thin-layer chromatography (plate, GF_{254} (Type 60) of E. Merck Co.; developing solvent, ethyl acetate–dichloromethane 1 : 1 v/v).

Methyl 2-methoxy-3-pyridinecarboxylate (**4a**), liquid (lit,[9] 28—29 °C), IR, 2980, 2950, 2850 (C-H), 1732 (ester C=O), 1270, 1130, 1082 (C-O-C), and 790 cm^{-1} (bending of C-H in the pyridine ring); NMR($CDCl_3$) $\delta=8.27$ (1H, dd, $J=5.1$ and 2.5 Hz, H at the 6-position), 8.09 (1H, dd, $J=7.9$ and 2.5 Hz, H at the 4-position), 6.92 (1H, q, $J=7.9$ and 5.1 Hz, H at the 5-position), 4.09 (3H, s, OCH_3), and 3.91 (3H, s, $COOCH_3$).

Methyl 6-methoxy-3-pyridinecarboxylate (**5a**) was identified by the accordance of its NMR spectra with those obtained by Deady *et al.*[10]

Methylation products (the products methylated at 4- and 6-positions) could not be isolated by means of TLC. Methyl 6-methyl-3-pyridinecarboxylate (**3a**), one of the methylation products, was identified by the accordance of NMR and GLC with those of the authentic sample synthesized by the method of Graf.[11] The other component in the mixture was identified NMR-spectroscopically. The following NMR spectra were ascribed to methyl 4-methyl-3-pyridinecarboxylate (**2a**). NMR($CDCl_3$) $\delta=9.10$ (1H, s, H at the 2-position), 8.52 (1H, d, $J=6.0$ Hz, H at the 6-position), 7.15 (1H (1H, d, $J=6.0$ Hz, H at the 5-position), 3.9 ($COOCH_3$), and 2.6 (CH_3).

The corresponding ethylation and ethoxylation products were identified by comparing their NMR and IR spectra with those of the corresponding methylation and methoxylation products.



Scheme 4.

Determation of the Yields of Products. After the irradiation the reaction mixture was concentrated under reduced pressure and was neutralized with sodium hydrogencarbonate. The products were extracted with dichloromethane and were analyzed by means of GLC (column, 3 m column of PEG 20M (10%) on Celite 545; column temperature, 165 °C) with a Shimadzu gas-chromatograph Model GC-6A. The gas-chromatographic sensitivy of each compound was determined by using the solution of the known concentration. For **2a**, which could not be obtained in pure form, the same sensitivity as for **3a** was presumed.

Flash Photolysis. The experimental detail of the flash photolysis has been described elsewhere.[12)]

The authors wish to express their thanks to Dr. Horst Hermann and Mrs. Ch. Kuling of Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung in West Germany for the measurement of flash photolysis and Professor L. W. Deady of La Trobe University in Australia for sending us the spectral data of pyridinecarboxylic acid derivatives.

Cyclization of Isothiosemicarbazones. IV.[1] Synthesis of the [1,2,4]Triazolo[1,5-*c*]pyrimidine Ring System

Chiji YAMAZAKI

Department of Chemistry, School of Hygienic Sciences, Kitasato University, Kitasato, Sagamihara, Kanagawa 228

(Received October 29, 1980)

Condensation of isothiosemicarbazones with ethoxymethylenemalononitrile gave 2,3-dihydro[1,2,4]triazolo-[1,5-*c*]pyrimidines in moderate to high yields. The 2,3-dihydro compounds were readily oxidized in dimethyl sulfoxide to give the corresponding [1,2,4]triazolo[1,5-*c*]pyrimidines.

Isothiosemicarbazones (**1**) are polyfunctional nucleophiles for the reaction with α-halo carbonyl compounds leading to the formation of nitrogen-containing heterocycles.[1,2] The internal nitrogen (N-2) of **1** preferentially attacks the halogen-bearing carbon of the halo compound to displace the halide and is considered to be a softer nucleophilic center[3] than the terminal nitrogen (N-4). On the other hand, N-4 invariably becomes attached to the carbonyl carbon whether it is unsubstituted[2] or monosubstituted.[1] In the present work, an attempt was made to initiate the cyclization of **1** at N-4 by the reaction with ethoxymethylenemalononitrile (**2**) and to examine the formation of a six-membered heterocycle. If **1** reacts with **2** at N-4, 3,4-disubstituted isothiosemicarbazone (**3**) might initially be formed, undergoing intramolecular cycloaddition to give a 1-(alkylidene- or benzylideneamino)-5-cyano-6-imino-2-mercapto-1,6-dihydropyrimidine derivative (**4**) in a similar way to that for pyrimidine formation from *S*-alkylisothioureas.[4]

It was found that the reaction of **1** with **2** leads directly to the formation of 2,3-dihydro[1,2,4]triazolo-[1,5-*c*]pyrimidines (**5**) and that, when R^2 is hydrogen, the dihydro compound (**5**) easily undergoes oxidation to [1,2,4]triazolo[1,5-*c*]pyrimidines (**6**) (Scheme 1). Among many condensed pyrimidine derivatives, few examples are known for the preparation of [1,2,4]-triazolo[1,5-*c*]pyrimidines,[5] no reports having been published on a one-step synthesis of the bicyclic pyrimidines from an open-chain, flexible molecule. This paper deals with the preparation and structure of a new series of 2,5-disubstituted and 2,2,5-trisubstituted 8-cyano-2,3-dihydro[1,2,4]triazolo[1,5-*c*]pyrimidines (**5a—n**) and 2,5-disubstituted 8-cyano[1,2,4]triazolo-[1,5-*c*]pyrimidines (**6a—i**).

Results and Discussion

The reaction was performed by allowing a solution of **1** and **2** in a 1 : 1.15 molar ratio in benzene to stand at room temperature (Procedure A). Except for **5i** and **5n**, most of **5** crystallized out of the reaction mixture in a substantially pure form, yields depending in part on the reaction period. For example, **5a** was obtained in 97% yield after the reaction mixture had been left to stand for one week, but the yield decreased to 82 and 56% with the elapse of 18 and 3 h, respectively (Table 1). Prolonged periods of time, however, may cause discoloration of the product, analytically pure compounds being obtained within no more than 1 d. The reaction can also be performed by heating a mixture of **1** and **2** (1 : 1.15) at 95—100 °C in the absence of solvent (Procedure B). The melted mixture rapidly solidifies within a few minutes, giving **5** in 55—86% yields after

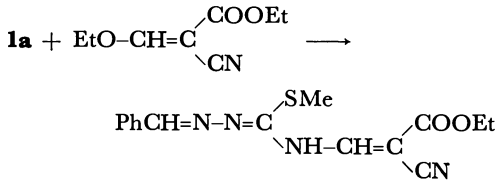
a) $R^3=CD_3$. b) Triplet, J=7.1 Hz.

washing with appropriate solvents. Procedure B was satisfactory for **1i** and **1n** from which no **5** was obtained by Procedure A. With ketone isothiosemicarbazones **1k** and **1l**, refluxing in benzene or EtOH gave good results. The reaction of aliphatic aldehyde isothiosemicarbazones (**1**: R^1=Et or *n*-Pr, R^2=H, R^3=Me or *p*-$ClC_6H_4CH_2$) with **2** under these conditions gave a complex mixture from which no expected product was isolated. Attempts to cyclize benzaldehyde 4-methyl- or 4-phenylthiosemicarbazone were unsuccessful with total recovery of the starting thiosemicarbazone.

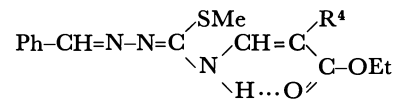
In view of the high yields of hindered compounds (**5d**, **5i** and **5n**), no steric factor may be involved in the 2,3-dihydro-1,2,4-triazole ring formation. Although no intermediate has been detected on the NMR time-scale in the reaction carried out in C_6D_6, C_5D_5N or dimethyl-d_6 sulfoxide (DMSO-d_6), the reaction should proceed through a 3,4-disubstituted isothiosemicarbazone (**3**). In line with the proposed intermediacy, the reaction of **1a** with ethyl ethoxymethylenecyanoacetate gave the open-chain product **7**, the structure of which was established by elemental analysis and spectral data, particularly by the large coupling constant between N^4H and the methine proton (J=13.2 Hz).[6] If a



7

nucleophilic attack of N-2 in **3** on the cyano carbon had occurred, **4** would have been formed which might consecutively undergo intramolecular addition of the 6-imino group to the azomethine double bond at the 1-position giving **5**, although the ring closure of **4** to **5** is disfavored according to the rules proposed by Baldwin.[7] A mechanistic study on the ring formation is now being continued with related compounds including **7**.

Intramolecular hydrogen bonding between the N^4H and the carbonyl oxygen in **7** might stabilize the



8: R^4=CN
9: R^4=COOEt

conformation **8** and prevent N-2 from approaching the cyano group. The resulting insusceptibility to cyclization makes it possible to isolate **7** at the open chain stage. In the infrared spectrum of **7**, N^4-H and the carbonyl stretching frequencies (νNH 3195 and νC=O 1690 cm^{-1}) observed at 4×10^{-3} mol dm^{-3} in carbon tetrachloride were comparable with those of **9** (νNH 3195 and νC=O 1697 cm^{-1}) obtained at the same concentration in carbon tetrachloride. The diester **9**, however, exhibited an additional carbonyl band at a higher frequency (νC=O 1730 cm^{-1}). This band can unambiguously be assigned to the free stretching vibration of the remaining ethoxycarbonyl group which is not involved in the internal bonding. The anomalously downfield resonance (lower than δ 12 ppm) of the N^4H protons of **7** and **9** in chloroform-*d* might also account for the hydrogen bond.[8]

Oxidation of **5** (R^2=H) to the corresponding [1,2,4]-triazolo[1,5-*c*]pyrimidines (**6**) was performed simply by leaving a solution of **5** in DMSO in an open vessel to stand at ambient temperature (Method A), a relatively insoluble **6** crystallizing out of the solution. In another procedure, the reaction between **1** and **2** was conducted in the absence of solvent, and the crude **5**, without isolation, was dissolved in DMSO to give **6** in moderate overall yields (Method B). The oxidation was also carried out with iron(III) chloride in aqueous acetic acid with poor yields of **6** (Method C), although **6i** was obtained only by this procedure in satisfactory purity. Some of **5** in which R^1 is unsubstituted or para-substituted phenyl group were particularly susceptible to oxidation and could not be recrystallized without contamination with the oxidized product.

The structures of the compounds **5** and **6** have been established on the basis of spectral measurements and elemental analyses. Partial spectral data are given in Tables 3 and 4 together with those for certain deuterated compounds. In mass spectrometry, molecular ions were obtained for all the compounds **5a**—**n**, with the intensity depending upon steric crowding at the 2-position (2—65%). Abundant ions M^+-R^1 and M^+-R^2 observed in the spectra of **5** characterized the 2,3-dihydro-1,2,4-triazole structure. The fragmentation pathways were confirmed by the mass spectra of deuterated compounds of **5a**, **5k**, and **5l**, in which R^2 is D, CD_3, and CD_3, respectively. The dehydrogenated compounds **6** showed a much more intense peak for M^+ ion than that of **5**, indicating their extended conjugation systems (24—100%). A characteristic fragment ion $R^1C{\equiv}\overset{+}{N}H$ (6—31%) observed in the spectra of **6** should be formed by hydrogen transfer from R^3 group to N-3 probably through a six-membered transition state as evidenced by the spectra of trideuterated compounds of **6b**, **6e**, and **6f** (R^3=CD_3), confirming the proposed arrangements of **5** and **6**. In NMR spectroscopy, two protons H-2 and H-3 on the dihydro-1,2,4-triazole ring of **5** (R^2=H) appear as two AB-type doublets with coupling constants of 9.1—10.0 Hz. The peak assignment is based on the observation that the upfield resonance collapses to a singlet while the downfield one disappears on addition of methanol-d_1. The spectrum of 2-deuterated **5a** (R^2=D) lacks the upfield resonance, exhibiting the H-3 proton as a singlet. The chemical shift values of the H-2 proton in **5** are *ca.* 2.0 ppm higher than those of the azomethine proton in the corresponding isothiosemicarbazones, reflecting rehybridization of the carbon atom (C-2) from sp^2 in **1** to sp^3 in **5**. The 2-methyl protons of **5k**—**m** (R^2=Me) resonate at 0.6—0.7 ppm higher than those of the corresponding **1k**—**m**, also indicating the rehybridization of C-2. In line with the rehybridization of C-2, the anisotropic deshielding (0.43 ppm in DMSO-d_6) of phenyl protons ortho to the azomethine double bond in **1a** disappears in **5a** which exhibits only a single signal for the phenyl protons at δ 7.36. The effect recommences in **6a** in which the ortho protons (H^o) of 2-phenyl group are deshielded by 0.49 ppm (trifluoroacetic acid-*d*) relative to the remaining aromatic protons ($H^{m,p}$) due to the resonance interaction with the heteroaromatic ring system.[9] Substantially constant values of the chemical shifts of H-7 proton in **5** or **6** when R^1–R^3 were widely changed in structure are in line with the assigned structures.

Experimental

General. Melting points were taken in open glass capillaries and are uncorrected. Infrared spectra were recorded on a Hitachi EPI-G2 or 260-30 spectrophotometer, and calibrated by comparison with a standard polystyrene film sample. Proton nuclear magnetic resonance spectra were obtained with a Hitachi R-24 spectrometer at 60 MHz. Unless otherwise stated, chemical shifts are given in parts per million (δ scale) downfield from internal tetramethylsilane (TMS). Solvents used are DMSO-d_6 for 2,3-dihydro-1,2,4-triazolo compounds (**5**) and trifluoroacetic acid-*d* for 1,2,4-triazolo compounds (**6**). The mass spectra (75 eV) were recorded on a JMS-D100 mass spectrometer. Ethoxymethylenemalononitrile (**2**) (Aldrich Chemical Co. Inc.) was used after removal of insoluble substances in benzene at room temperature.

Isothiosemicarbazones. The compounds **1a**—**n** were prepared by the method reported.[8] *S*-(Methyl-d_3)isothiosemicarbazones were obtained by using methyl-d_3 iodide in place of methyl iodide in the usual procedure. Other deuterated isothiosemicarbazones were similarly prepared from the corresponding deuterated carbonyl compounds, acetone-d_6 (CD_3COCD_3), acetophenone-α,α,α-d_3 ($C_6H_5COCD_3$), and benzaldehyde-*formyl-d* (C_6H_5CDO). New compounds are: 2,6-dichlorobenzaldehyde *S*-allylisothiosemicarbazone (**1i**): pale yellow prisms (from *i*-Pr_2O), mp 99—101 °C; NMR ($CDCl_3$) δ=3.76 (2H, dt, *J*=6.5 and 0.8 Hz, SCH_2), 5.5—6.3 (5H, m, CH_2=CH and NH_2), 7.06—7.45 (3H, m, aromatic), 8.62 (1H, s, CH=N). Found: C, 45.54; H, 3.79; N, 14.83%. Calcd for $C_{11}H_{11}Cl_2N_3S$: C, 45.84; H, 3.85; N, 14.58%. *p*-Chloroacetophenone *S*-methylisothiosemicarbazone (**1m**): colorless needles (from aqueous EtOH), mp 231 °C (HBr salt); NMR ($CDCl_3$) (free base): δ=2.38 (3H, s, CCH_3), 2.47 (3H, s, SCH_3), 5.41 (2H, bs, NH_2), 7.30 (2H, d, *J*=8.3 Hz, aromatic), 7.75 (2H, d, *J*=8.3 Hz, aromatic). Found: C, 37.30; H, 3.96; N, 13.30%. Calcd for $C_{10}H_{13}BrClN_3S$: C, 37.22; H, 4.06; N, 13.02%. Benzophenone *S*-methylisothiosemicarbazone (**1n**): colorless fine needles (from EtOH), mp 135.5—136 °C; NMR ($CDCl_3$) δ=2.20 (3H, s, SCH_3), 5.35 (2H, bs, NH_2), 7.35 (5H, s, aromatic), 7.21—7.73 (5H, m, aromatic). Found: C, 66.95; H, 5.57; N, 15.91%. Calcd for $C_{15}H_{15}N_3S$: C, 66.90; H, 5.61; N, 15.61%.

8-Cyano-2,3-dihydro-5-methylthio-2-phenyl[1,2,4]triazolo[1,5-c]-pyrimidine (5a) (A Typical Example of Procedure A). A solution

of **1a** (0.19 g, 1 mmol) and **2** (0.14 g, 1.15 mmol) in benzene (1 ml) was allowed to stand at room temperature. After *ca.* 30 min, yellow prisms began to separate and the reaction was allowed to proceed for 18 h. The crystals were collected by filtration, washed with benzene, and air-dried, giving 0.22 g (82%) of analytically pure **5a**; mp 181—182 °C (dec); IR (KBr) 2220 (CN) cm^{-1}; NMR δ=2.53 (3H, s, SCH_3), 6.26 (1H, d, J=9.7 Hz, H-2), 7.24 (1H, d, J=9.7 Hz, H-3), 7.36 (5H, s, aromatic), 8.04 (1H, s, H-7); MS, *m/e* (rel intensity), 269 (29) (M^+), 268 (56) ($M^+ - H$), 192 (100) ($M^+ - C_6H_5$).

The 2-deuterio compound of **5a** was similarly obtained from benzaldehyde-*formyl-d* *S*-methylisothiosemicarbazone [Ph-CD=N-N=C(SMe)NH_2] as yellow prisms, mp 181 °C (dec); NMR δ=2.51 (3H, s, SCH_3), 7.20 (1H, s, H-3), 7.34 (5H, s, aromatic), 8.03 (1H, s, H-7); MS, *m/e* (rel intensity), 270 (25) (M^+), 268 (40) ($M^+ - D$), 193 (100) ($M^+ - C_6H_5$).

8-Cyano-2-(2,6-dichlorophenyl)-2,3-dihydro-5-methylthio[1,2,4]-triazolo[1,5-c]pyrimidine(5d) (A Typical Example of Procedure B). A mixture of **1d** [hydriodide, mp 200—200.5 °C (dec)(lit,[10] mp 209—211 °C (dec)); Found: C, 27.88; H, 2.60; N, 11.00%. Calcd for $C_9H_{10}Cl_2IN_3S$: C, 27.71; H, 2.58; N, 10.77%] (0.26 g, 1 mmol) and **2** (0.14 g, 1.15 mmol) was heated on a boiling water bath to melt the solids. The liquid formed, still of low viscosity, was thoroughly agitated in order to confirm complete homogeneity. The mixture rapidly solidified within 30 s and heating was continued for 5 min to allow the by-product EtOH to evaporate. After cooling, the solid was triturated with acetone, collected by filtration, washed with acetone, and air-dried to give 0.29 g (86%) of **5d** as yellow crystalline powder, mp 175—178 °C. This was recrystallized from an EtOH–MeCN mixture (1 : 1 by volume) giving sparkling yellow prisms, mp 191 °C; IR (KBr) 2220 (CN) cm^{-1}; NMR δ=2.55 (3H, s, SCH_3), 7.14 (1H, d, J=9.7 Hz, H-2), 7.43 (3H, s, aromatic), 7.79 (1H, d, J=9.7 Hz, H-3), 8.09 (1H, s, H-7); MS *m/e* (rel intensity), 337 (8) (M^+), 336 (7) ($M^+ - H$), 192 (100) ($M^+ - C_6H_3Cl_2$).

When Procedure A was applied to the preparation of **5d**, a product, mp 189—190 °C, was obtained in 65% yield after standing for 6 h.

8-Cyano-5-methylthio-2-phenyl[1,2,4]triazolo[1,5-c]pyrimidine (6a) (A Typical Example of Method A; One-step Synthesis from Isothiosemicarbazones). A mixture of **1a** (0.1 g, 0.52 mmol) and **2** (0.07 g, 0.58 mmol) was heated in an open vessel on a boiling water bath with constant shaking, the ethanol formed being allowed to evaporate for 5 min. The resulting crystalline mass was dissolved still hot in DMSO (1 ml) and the solution was allowed to stand at room temperature for 1 d. The separated crystals were collected by filtration, washed with DMSO and water and then air-dried, giving analytically pure **6a** in 57% overall yield as colorless needles, mp 255.5—256 °C. Recrystallization from an EtOH–pyridine mixture (1 : 1 by volume) gave colorless needles, mp 256 °C; IR (KBr) 2220 (CN) cm^{-1}; NMR δ=3.00 (3H, s, SCH_3), 7.73 (3H, m, $H^{m,p}$ of phenyl), 8.22 (2H, m, H^o of phenyl), 9.02 (1H, s, H-7); MS, *m/e* (rel intensity), 267 (100) (M^+), 164 (85) ($M^+ - C_6H_5CN$), 104 (31) ($C_6H_5C{\equiv}\overset{+}{N}H$), 103 (27).

2-(o-Chlorophenyl)-8-cyano-5-methylthio[1,2,4]triazolo[1,5-c]pyrimidine (6b) (A Typical Example of Method B). A solution of **5b** (0.1 g) in DMSO (1 ml) was allowed to stand at room temperature for 1 d and separated crystals were collected by filtration, washed with DMSO and water and then air-dried, giving **6b** in 50% yield as colorless needles, mp 226—226.5 °C. Recrystallization from an EtOH–pyridine mixture (1 : 1 by volume) did not change the mp or appearance. IR (KBr) 2230 (CN) cm^{-1}; NMR δ=3.00 (3H, s, SCH_3), 7.50—8.07 (4H, m, aromatic), 9.04 (1H, s, H-7); MS, *m/e* (rel intensity), 301 (66) (M^+), 266 (53) ($M^+ - Cl$), 164 (24) ($M^+ - ClC_6H_4CN$), 138 (29) ($ClC_6H_4C{\equiv}\overset{+}{N}H$), 137 (100).

The 5-methylthio-d_3 compound of **6b** was obtained from the corresponding trideuterated **5b** by Method B as colorless needles, mp 225—226 °C; NMR δ=7.48—8.07 (4H, m, aromatic), 9.04 (1H, s, H-7); MS, *m/e* (rel intensity), 304 (100) (M^+), 269 (84) ($M^+ - Cl$), 167 (95) ($M^+ - ClC_6H_4CN$), 139 (33) ($ClC_6H_4C{\equiv}\overset{+}{N}D$).

5-Allylthio-8-cyano-2-(2,6-dichlorophenyl)[1,2,4]triazolo[1,5-c]-pyrimidine (6i) (Method C). To a solution of **5i** (0.09 g, 0.25 mmol) in AcOH (2 ml) was added 0.5 ml of a solution containing 1 mmol/ml of iron(III) chloride in 60% aqueous AcOH and the mixture was allowed to stand at room temperature with occasional agitation for 10 d. After being diluted with water, separated crystals (0.07 g), mp 127—140 °C, were recrystallized from a benzene–EtOH mixture (1: 1 by volume) to give 0.05 g (56%) of **6i** as colorless prisms, mp 140.5—142.5 °C; IR (KBr) 2230 (CN) cm^{-1}; NMR δ=4.26 (2H, d, J=6.6 Hz, SCH_2), 5.26—6.34 (3H, m, $CH{=}CH_2$), 7.55 (3H, s, aromatic), 8.95 (1H, s, H-7); MS, *m/e* (rel intensity), 361 (61) (M^+), 190 (80) ($M^+ - Cl_2C_6H_3CN$), 172 (25) ($Cl_2C_6H_3C{\equiv}\overset{+}{N}H$), 121 (100), 41 (77) (allyl cation).

Benzaldehyde 3-Methyl-4-[2-cyano-2-(ethoxycarbonyl)vinyl]isothiosemicarbazone (7). A mixture of **1a** (0.19 g, 1 mmol), ethyl ethoxymethylenecyanoacetate (0.19 g, 1.15 mmol), and benzene (0.5 ml) was heated at 70 °C for 1 h. On cooling, the separated solid was collected by filtration, washed with EtOH and air-dried, giving 0.27 g (84%) of **7** as pale yellow crystalline powder, mp 140—143 °C. Recrystallization twice from EtOH provided pale yellow needles, mp 145 °C; IR (CCl_4) 3195 (NH), 2220 (CN), 1690 (C=O) cm^{-1}; NMR ($CDCl_3$) δ=1.39 (3H, t, J=7.2 Hz, $CH_2C\underline{H}_3$), 2.60 (3H, s, SCH_3), 4.34 (2H, q, J=7.2 Hz, $C\underline{H}_2CH_3$), 7.43 (3H, m, $H^{m,p}$ of phenyl), 7.69 (1H, d, J=13.2 Hz, NH=C$\underline{H}$), 7.90 (2H, m, H^o of phenyl), 8.47 (1H, s, CH=N), 12.40 (1H, d, J=*ca.* 13 Hz, N$\underline{H}$-CH).

Found: C, 56.97; H, 5.09; N, 17.52%; M^+, 316. Calcd for $C_{15}H_{16}N_4O_2S$: C, 56.96; H, 5.10; N, 17.71%; M, 316.

Benzaldehyde 3-Methyl-4-[2,2-bis(ethoxycarbonyl)vinyl]isothiosemicarbazone (9). A mixture of **1a** (0.19 g, 1 mmol) and diethyl ethoxymethylenemalonate (0.22 g, 1 mmol) in benzene (0.5 ml) was refluxed for 4 h, the solvent being evaporated. Recrystallization of the crystalline residue from EtOH gave **9** as pale yellow prisms (0.27 g, 74%), mp 99—100 °C; NMR ($CDCl_3$) δ=1.31 (3H, t, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.36 (3H, t, J=7.0 Hz, $CH_2C\underline{H}_3$), 2.60 (3H, s, SCH_3), 4.18 (2H, q, J=7.0 Hz, $C\underline{H}_2CH_3$), 4.29 (2H, q, J=7.0 Hz, $C\underline{H}_2CH_3$), 7.41 (3H,m, $H^{m,p}$ of phenyl), 7.88 (2H, m, H^o of phenyl), 8.22 (1H, d, J=13.3 Hz, C$\underline{H}$-NH), 8.42 (1H, s, CH=N), 12.28 (1H, d, J=13.3 Hz, CH-N$\underline{H}$).

Found: C, 56.11; H, 5.83; N, 11.67%; M^+, 363. Calcd for $C_{17}H_{21}N_3O_4S$: C, 56.19; H, 5.83; N, 11.57%; M, 363.

The author wishes to thank Miss Yoko Ishizuka for assistance in the preparation of compounds.

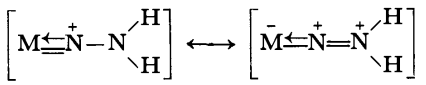
(Received November 12, 1980)

Nucleophilic attack of the $WNNH_2$ group in the hydrazido(2-) complex $[WF(NNH_2)(dpe)_2][BF_4]$ (dpe=$Ph_2PCH_2CH_2PPh_2$) on succinyl dichloride gives a novel ethanedioylhydrazido(2-) complex, $[WF(\overline{NNCOCH_2CH_2CO})(dpe)_2][BF_4]$. X-Ray structural analysis shows that the carbon, nitrogen, and oxygen atoms of the ethanedioylhydrazido(2-) ligand lie nearly in the same plane, indicating sp^2 character of the nitrogen atom bearing the two carbonyl groups. Phenyl isocyanate also undergoes nucleophilic attack by the hydrazido(2-) complex $[MBr(NNH_2)(dpe)_2]Br$ (M=Mo or W) to yield the phenylsemicarbazido(2-) type complex, $[MBr(NNHCONHPh)(dpe)_2]Br$. Treatment of the semicarbazido(2-) complex with triethylamine gives a new diazenido complex $[MBr(NNCONHPh)(dpe)_2]$.

Many hydrazido(2-) complexes containing the $MNNH_2$ moiety have been isolated by the reaction of dinitrogen complexes $[M(N_2)_2L_4]$ (M=Mo or W; L=phosphine) with acids.[1,2] These complexes are important intermediates in the reduction of ligating dinitrogen to both ammonia[3] and hydrazine.[4-6] The X-ray structural analyses of $[MoF(NNH_2)(dpe)_2][BF_4]$[2] and $[WCl(NNH_2)(dpe)_2][BPh_4]$[7] show that the M–N–N bond distances give a bond order greater than unity, the M–N bond distances being in line with considerable multiple bonding between the metal and nitrogen. This result is interpreted in terms of two resonance structures (i) and (ii). The basicity of the terminal nitrogen in



(i) (ii)

the $MNNH_2$ moiety is, thus, expected to be weaker than that of hydrazine and amines. However, hydrazido(2-) complexes, $[MF(NNH_2)(dpe)_2][BF_4]$ and $[MX(NNH_2)(PMe_2Ph)_3]$ (M=Mo or W; X=Cl or Br), have been found to undergo condensation with a variety of aldehydes and ketones in a similar way to that for hydrazines, giving diazoalkane complexes containing the M≡N–N=CRR′ moiety.[8-11] In this paper, we wish to describe other nucleophilic reactions of hydrazido(2-) complexes with succinyl dichloride and phenyl isocyanate.

Experimental

All reactions were carried out under pure nitrogen atmosphere. Solvents were purified by the usual methods, thoroughly dried, and distilled under nitrogen atmosphere. Commercial succinyl dichloride, phenyl isocyanate, triethylamine, and sodium tetraphenylborate were used without further purification. The complexes *trans*-$[Mo(N_2)_2(dpe)_2]$[1,12] *trans*-$[W(N_2)_2(dpe)_2]$,[1] $[WF(NNH_2)(dpe)_2][BF_4]$,[9] $[MBr(NNH_2)(dpe)_2]Br$ (M=Mo or W),[1] and $[WBr(NNH)(dpe)_2]$[1] were prepared by the methods reported. IR spectra were determined with a Hitachi 215 spectrometer, ^{1}H-NMR spectra of the complexes $[MBr(NNHCONHPh)(dpe)_2]Br$ (M=Mo or W) with a Hitachi R-600 FT-spectrometer because of low solubility, and spectra of the other complexes with a JEOL PS-100 spectrometer. Analytical data are given in Table 1.

$[WF(\overline{NNCOCH_2CH_2CO})(dpe)_2][BF_4]$. To a yellow solution of $[WF(NNH_2)(dpe)_2][BF_4]$ (255 mg, 0.228 mmol) in dichloromethane (7.5 ml) was added succinyl dichloride (0.21 ml, 8 mol equiv.) at room temperature, and the mixture was stirred for 20 h. The red solution obtained was concentrated under reduced pressure to about half its volume, hexane (10 ml) then being added to precipitate the pinkish red crude product (246 mg, 90%). The product was recrystallyzed from chloroform–hexane (3—8 ml) and then chloroform–ether (3—6 ml) to give pure crystals which were dried *in vacuo* (97 mg, 35%). Suitable crystals for X-ray analysis were selected.

$[MoBr(NNHCONHPh)(dpe)_2]$. To a brown suspension of $[MoBr(NNH_2)(dpe)_2]Br$ (322 mg, 0.315 mmol) in tetrahydrofuran (10 ml) was added phenyl isocyanate (0.28 ml, 8 mol equiv.), and the mixture was stirred at refluxing temperature for 10 h. The green supension obtained was filtered off and the residue was crystallyzed from dichloromethane–hexane (15—15 ml). Green crystals were filtered off, washed with hexane, and then dried *in vacuo* (171 mg, 45%).

$[WBr(NNHCONHPh)(dpe)_2]Br$. This complex was prepared by the same method as described above for molybdenum analogue. From 219 mg of $[WBr(NNH_2)(dpe)_2]Br$ was obtained 114 mg of $[WBr(NNHCONHPh)(dpe)_2]Br$ as red crystals in 47% yield.

$[MoBr(NNCONHPh)(dpe)_2]$. To a stirred green suspension of $[MoBr(NNHCONHPh)(dpe)_2]$ (49 mg, 0.041 mmol) in tetrahydrofuran (3 ml) was added triethylamine (5.7 μl, 1 mol equiv.) After 2 h, to the orange homogeneous solution obtained was added ether (6 ml), affording orange crystals of $[MoBr(NNCONHPh)(dpe)_2]$ which were filtered off, washed with ether and dried *in vacuo* (23 mg, 50%).

$[WBr(NNCONHPh)(dpe)_2]$. *1)*: From 216 mg of $[WBr(NNHCONHPh)(dpe)_2]Br$ was obtained 64 mg of $[WBr(NNCONHPh)(dpe)_2]$ as orange crystals in 32% yield by the same method as described above for the molybdenum analogue.

2): To a yellow suspension of $[WBr(NNH)(dpe)_2]$ (95 mg, 0.087 mmol) in tetrahydrofuran (5 ml) was added phenyl isocyanate (76 μl, 8 mol equiv.) and the mixture was stirred at refluxing temperature for 2 h. From the brown solution obtained, red crystals of $[WBr(NNCONHPh)(dpe)_2]$ were precipitated by addition of ether, which were filtered off,

† Preparation and Properties of Molybdenum and Tungsten Dinitrogen Complexes 15. For part 14 of this series, see M. Hidai, T. Takahashi, I. Yokotake, and Y. Uchida, *Chem. Lett.*, **1980**, 645.

Table 1. Analytical and spectroscopic data of the new complexes

Complex	Found (Calcd)(%) C	H	N	IR (cm^{-1})[a] ν(C=O)	ν(N–H)	δ(N–H)	^{1}H-NMR δ/ppm[b]

washed with ether and then dried *in vacuo* (8 mg, 7%).

[WBr(NNHCONHPh)(dpe)$_2$][BPh$_4$]. A solution of [WBr(NNHCONHPh)(dpe)$_2$]Br (280 mg, 0.217 mmol) in dichloromethane (18 ml) and a solution of sodium tetraphenylborate (297 mg, 4 mol equiv.) in dichloromethane–tetrahydrofuran (5—5 ml) were combined and stirred at room temperature. After 2 h, the reaction mixture was evaporated to dryness *in vacuo*, and the residue was extracted by dichloromethane (3 ml). Addition of hexane (5 ml) to the extract gave red crystalline solid of [WBr(NNHCONHPh)(dpe)$_2$]-[BPh$_4$], which was filtered off, washed with hexane, and then dried *in vacuo* (221 mg, 67%).

Results and Discussion

Dinitrogen complexes [M(N$_2$)$_2$(dpe)$_2$] and [M(N$_2$)-(RCN)(dpe)$_2$] (M=Mo or W; R=aryl) react with acyl or aroyl chlorides to give acyl- or aroyldiazenido complexes, [MCl(NNCOR')(dpe)$_2$] (R'=acyl or aroyl), which, on treatment with hydrochloric acid, are converted into acyl- or aroylhydrazido(2-) complexes, [MCl(NNHCOR')(dpe)$_2$]Cl.[13,14] The latter complexes are also obtained by nucleophilic reactions of the hydrazido(2−) complex [WCl(NNH$_2$)(dpe)$_2$]Cl with acyl halides.[15] We have found that the hydrazido (2−)complex [WF(NNH$_2$)(dpe)$_2$][BF$_4$] reacts smoothly with succinyl dichloride to give ethanedioylhydrazido (2−) complex as follows.

$$[WF(NNH_2)(dpe)_2][BF_4] \xrightarrow{ClCOCH_2CH_2COCl} [WF(NN\overset{O}{\overset{\|}{C}}-CH_2-CH_2-\overset{O}{\overset{\|}{C}}N)(dpe)_2][BF_4] + 2HCl$$

1

When an excess of succinyl dichloride was added to an orange solution of [WF(NNH$_2$)(dpe)$_2$][BF$_4$] at room temperature, a red solution was obtained after *ca.* 20 h, from which pink crystals of [WF(NNCOCH$_2$CH$_2$CO)-(dpe)$_2$][BF$_4$] (**1**) were isolated. When adipoyl dichloride and phthaloyl dichloride were used instead of succinyl dichloride, no analogous products were obtained, probably because of steric effects. Treatment of another complex, [WBr(NNH$_2$)(dpe)$_2$]Br, with succinyl dichloride did not proceed satisfactorily under the same conditions. The lower reactivity of the latter is caused by the lower nucleophilicity of the terminal nitrogen atom relative to that of [WF(NNH$_2$)(dpe)$_2$][BF$_4$], as estimated by the δ-value of the hydrazido protons in the ^{1}H-NMR spectra ([WBr(NNH$_2$)(dpe)$_2$]Br: 6.3 ppm;[1] [WF(NNH$_2$)(dpe)$_2$][BF$_4$]: 4.5 ppm[9]).

In the IR spectrum of **1**, a strong absorption band assignable to ν(C=O) was observed at 1720 cm^{-1}, higher by 25 cm^{-1} than that of succinimide. This shows that the carbonyl groups in complex **1** have no single bond character and the lone pair electrons on the terminal nitrogen atom do not flow over the carbonyl groups. Four succinyl protons appeared in the ^{1}H-NMR spectrum at 2.0 ppm as a singlet peak, indicating that four protons are completely equivalent.

X-Ray analysis was performed to determine the

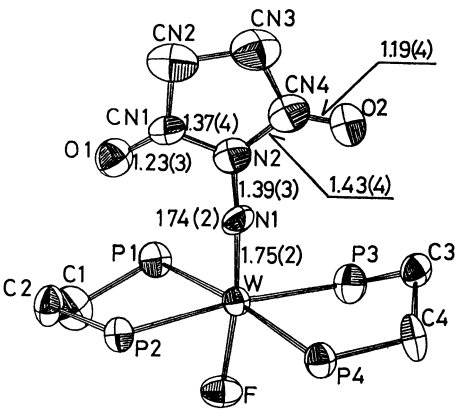

Fig. 1. Perspective view of [WF(NNCOCH$_2$CH$_2$CO)-(dpe)$_2$][BF$_4$]. The shapes of the atoms on this drawing represent 50% probability contours of thermal motions. The bond angles are as follows: W–N1–N2=174.16°, N1–N2–CN1=120.50°, N1–N2–CN4=125.85°, CN1–N2–CN4=113.64°, N2–CN1–O1=122.01°, CN2–CN1–O1=123.99°, CN2–CN1–N2=113.86°.

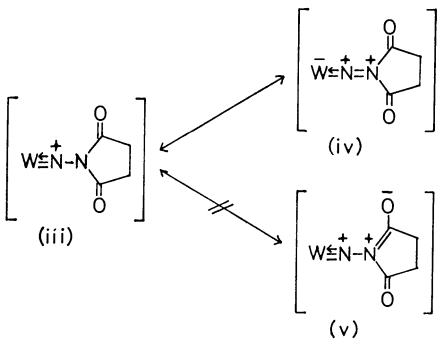
structure of ethanedioylhydrazido(2−) ligand. However, since a good crystal could not be obtained, the final residuals were R=0.109 and Rw=0.097 using block-diagonal least squares with anisotropic thermal factors for nonhydrogen atoms, and further refinement was no longer carried out.[16]

Analysis shows that this complex has an octahedral geometry with the ethanedioylhydrazido(2−) ligand and fluoride anion in a trans position (Fig. 1). The W–N–N linkage is essentially linear. From the result of angle summations around the terminal nitrogen and two carbonyl carbon atoms, it is concluded that two nitrogen, four carbon, and two oxygen atoms lie in the same plane. This indicates that the terminal nitrogen atom is predominantly sp^2 hybridized. Considering the fact that the lone pair electrons on the terminal nitrogen do not flow over the carbonyl groups, the canonical structures (iv), rather than structure (v), might take part in the formation of structure (iii) to some extent.



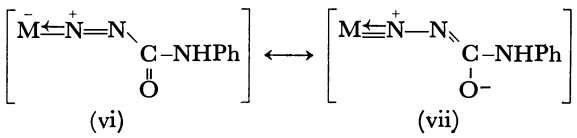
We have found that hydrazido(2−) complexes [MBr(NNH$_2$)(dpe)$_2$]Br (M=Mo or W) react with phenyl isocyanate to give the semicarbazido type complexes [MBr(NNHCONHPh)(dpe)$_2$]Br.

The reaction is understood as the nucleophilic addition of the terminal nitrogen in the hydrazido(2−) ligand to the electron-defficient carbon in phenyl isocyanate.

When the hydrazido(2−) complexes [MBr(NNH$_2$)(dpe)$_2$]Br suspended in tetrahydrofuran were treated with excess phenyl isocyanate at refluxing temperature for 10 h, the semicarbazido type complexes [MBr(NNHCONHPh)(dpe)$_2$]Br precipitated from the reaction mixture as a green (M=Mo) or red (M=W) solid. The complexes were obtained as pure crystals by crystallization from dichloromethane–hexane. In their IR spectra (Table 1), strong absorption bands characteristic of the amide group were observed (M=Mo: ν(C=O)=1715 cm^{-1}, δ(N–H)=1530 cm^{-1}; M=W: ν(C=O)=1710 cm^{-1}, δ(N–H)=1540 cm^{-1}). As regards the tungsten complex, frequencies assigned to ν(N–D) and δ(N–D) were observed on deuteration by D_2O. The shift to low frequency and the peak broadening of the N–H stretching bands are interpreted in terms of hydrogen bonding between the proton and bromide anion. This hydrogen bonding seems to be formed between the more electropositive hydrazido proton and bromide anion; the lower stretching band is due to the NH moiety in the NNH and the higher one to that in the amide group. The existence of hydrogen bonding is also supported by the result obtained from the ^{1}H-NMR spectra of these complexes (Table 1), that is, NNH protons were observed at 11.7 ppm for Mo and 10.5 ppm for W. The shift to a lower field from the usual NH region is due to the hydrogen bonding with bromide anion. Similar observations have been reported for [WHClBr(NNH$_2$)(PMe$_2$Ph)$_3$]Br[6] and [WBr(NNH$_2$)L(PMe$_2$Ph)$_3$]Br (L=N⟨⟩–Me *etc.*).[16] On the other hand, the amido protons appeared at relatively high field (M=Mo and W; 1.5 ppm) which may be explained by the shielding effect of the phenyl groups of dpe ligands. Analogous results have been found in the methyl protons of the complex, [WF{NN=C(CH$_3$)-CH$_2$COCH$_3$}(dpe)$_2$][BF$_4$]·THF[9] and [WBr{NN=C(CH$_3$)CH$_3$}(dpe)$_2$]Br.[18]

When the semicarbazido type complex [WBr(NNHCONHPh)(dpe)$_2$]Br was treated with excess sodium tetraphenylborate, anion exchange took place to afford the red complex [WBr(NNHCONHPh)(dpe)$_2$][BPh$_4$]. Since hydrogen bonding between NNH proton and the anion no longer exists in this complex, the NH stretching band in the IR spectrum and the NH resonance in the ^{1}H-NMR spectrum appear in the usual neutral NH region. The amido proton is observed at 5.2 ppm in the ^{1}H-NMR spectrum, lying in the common amido proton region. The cleavage of the hydrogen bonding might give rise to the conformational change, the amido proton being freed from the position shielded by the phenyl groups of dpe ligands. Spectroscopic data are summerized in Table 1.

The semicarbazido type complexes [MBr(NNHCONHPh)(dpe)$_2$]Br (M=Mo or W) easily react with a weak base such as triethylamine to afford the new diazenido complexes [MBr(NNCONHPh)(dpe)$_2$]. Strong absorption bands characteristic of the amide group were observed in the IR spectra, and amido protons appearing in the common amido region in the ^{1}H-NMR spectra. The relatively low ν(C=O) frequencies observed (M=Mo: 1630 cm^{-1}; M=W: 1620 cm^{-1}) as compared with the semicarbazido type complexes (M=Mo: 1715 cm^{-1}; M=W: 1710 cm^{-1}) can be explained by the large contribution of the structure (vii), which is formed by the electron flow from the metal to the carbonyl group.



The combination of resonance structures has been proposed for the diazenido complex, [MoCl(NNCOPh)(dpe)$_2$].[14,19] Spectroscopic data of the new diazenido complexes are also given in Table 1.

This diazenido complex, [WBr(NNCONHPh)(dpe)$_2$], can also be prepared by way of another route. The diazenido complex, [WBr(NNH)(dpe)$_2$], obtained by the reaction of [WBr(NNH$_2$)(dpe)$_2$]Br with triethylamine, reacts with phenyl isocyanate to give the complex [WBr(NNCONHPh)(dpe)$_2$]. This shows that the terminal nitrogen atom of the NNH ligand also has considerable nucleophilicity.[20] These synthetic routes are summarized as follows.

$$\begin{array}{ccc} [MBr(NNH_2)(dpe)_2]Br & \xrightarrow{PhNCO} & [MBr(NNHCONHPh)(dpe)_2]Br \\ \downarrow NEt_3 & & \downarrow NEt_3 \\ [MBr(NNH)(dpe)_2] & \xrightarrow{PhNCO} & [MBr(NNCONHPh)(dpe)_2] \end{array}$$

As regards the nucleophilicity of the NNH ligand, Colquhoun has found that the NNH ligand in the complexes $[WX(NNH)(dpe)_2]$ (X=F or Br) undergoes nucleophilic attack to 2,4-dinitrobenzene to give the dinitrophenylhydrazido complexes or, by successive deprotonation, dinitrophenyldiazenido complexes.[21]

The authors are grateful to Dr. Takashi Tatsumi for recording FT-NMR and Mr. Masayuki Nishina for experimental assistance.

A Convenient Synthesis of Condensed Cyclopentane System. Annelation by Intramolecular 1,3-Dipolar Addition of Nitrones

Satoru TAKAHASHI, Takenori KUSUMI, Yoko SATO, Yoshinobu INOUYE, and Hiroshi KAKISAWA*

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305

(Received November 22, 1980)

Intramolecular 1,3-dipolar addition reactions of nitrones were investigated. Four alkenyl nitrones were studied: 2-allyl-, 2-(3-butenyl)-, 2-(4-pentenyl)-, and 2-(9-decenyl)-*N*-methylcyclohexanimine *N*-oxides. Among these, 2-(3-butenyl)-*N*-methylcyclohexanimine *N*-oxide was found to cyclize most smoothly, giving a perhydroindene derivative as a single regio- and stereoisomer. A perhydroazulene derivative was obtained by cyclization of 2-(3-butenyl)-*N*-methylcycloheptanimine *N*-oxide.

1,3-Dipolar addition reactions are currently of interest in the synthesis of natural products. The reaction between nitrones and olefins is frequently applied for the synthesis of alkaloids.[1] Both intra-[2] and intermolecular[3] 1,3-dipolar reactions are used, depending on the target molecules. Usually nitrones react with olefins stereo- and regiospecifically,[4] giving versatile 1,3-dipolar adducts. When a nitrone reacts intramolecularly with an olefin group as in the following system, a new carbocyclic ring is formed along with an isoxazolidine ring.

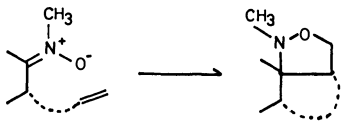

Fig. 1.

In order to develop a new annelation method, the authors studied the cyclization of the compounds **5**—**8**,[5] each of which has both a nitrone and an olefin group in the same molecule. These nitrones were easily prepared by treatment of the corresponding alkenylcyclohexanones **1**—**4** with *N*-methylhydroxylamine.

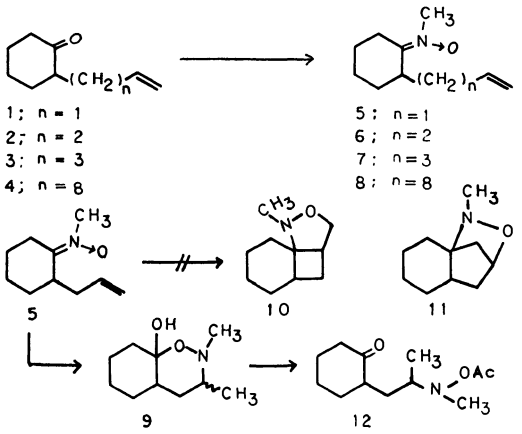

Fig. 2.

When the nitrone (**5**) having an allyl side chain was heated in refluxing benzene, it decomposed into a complex mixture, from which the expected cyclization products, **10** and **11**, could not be extracted. However, when **5** was allowed to stand at room temperature for one week, an unexpected oxazine (**9**) was obtained in 43% yield. The structure was assigned on the basis of spectroscopic data of **9** and its acetate (**12**), which was produced by the treatment of **9** with acetic anhydride in pyridine.

A possible mechanism for the formation of **9** is suggested by the equation in Fig. 3.

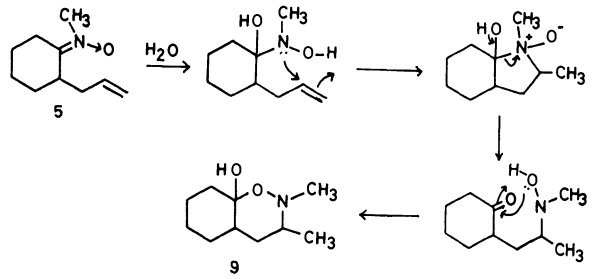

Fig. 3.

However, the nitrone (**6**), carrying a butenyl side chain, cyclized at room temperature to yield the expected cycloadduct (**13**) in a quantitative yield. In this case, neither the regioisomer (**16**) nor the oxazepine analog of **9** was formed; the reaction afforded a stereochemically single product.

Attempts to cleave the N–O bond with catalytic hydrogenation (on Pd/C or PtO_2) were unsucessful. Irradiation[6] of UV light (high pressure mercury lamp using a Pyrex filter) on a hexane solution of **18** in the presence of fluorenone gave rise to an oxazine (**21**) in 39% yield. The oxazine ring of **14** was cleaved with lithium aluminium hydride to give an amino alcohol (**15**). The N–O bond of **13** was cleaved more effectively with titanium(III) chloride, to yield the same compound (**15**).

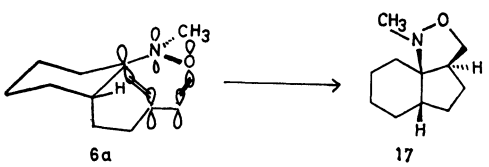

Fig. 4.

The stereochemistry of **13** was tentatively described as **17**; thus, the most favorable transition state leading to **13** seemed to be **6a**, because it permitted the maximum overlapping of the π orbitals of the nitrone and the side chain olefin groups.

Unlike **6**, the nitrone (**7**) resisted cyclization at room temperature for one week. However, when **6** was

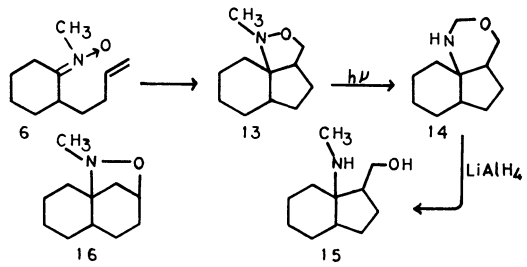

Fig. 5.

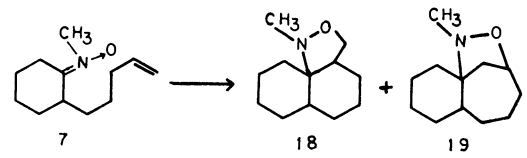

Fig. 6.

refluxed in benzene for 16 h, it gave rise to a 1 : 1 mixture of the intramolecular adducts, **18** and **19**. These adducts were separated by column chromatography.

The nitrone (**8**), which has a 9-decenyl side chain, gave no cyclized product. Thus, heating of **8** at 60 °C for 24 h resulted in the recovery of **8**, and heating at 120 °C for 1 h brought about decomposition.

From these results, a system bearing the 3-butenyl side chain such as in **6** was considered to be most suitable for annelation which would result in the formation of a cyclopentane ring. In order to confirm the utility of this annelation, we tried to synthesize a perhydroazulene system, which is a common skeleton of some sesquiterpenes.

A mixture of 2-(3-butenyl)cycloheptanone (**20**) and *N*-methylhydroxylamine in methanol was heated at reflux. The NMR of the reaction mixture showed a strong *N*-methyl signal (δ=3.67) due to the nitrone (**21**) after several hours. This signal gradually decreased, and it completely disappeared after 44 h; an intense *N*-methyl signal (δ=2.52) due to the cyclized product (**22**) remained. By simple purification, a perhydroazulene compound (**22**) was isolated in 84% yield as a single product.

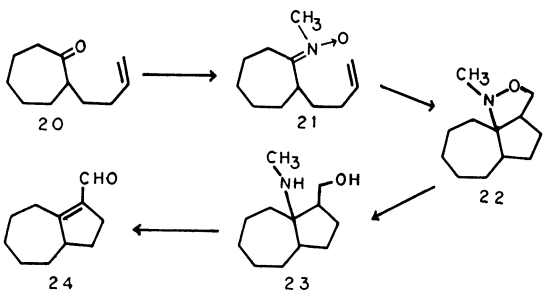

Fig. 7.

Although the N–O bond of substituted isoxazolidine or isoxazolidinium can be cleaved by reduction with zinc–acetic acid,[7] lithium aluminium hydride,[8] or catalytic hydrogenation,[9] these methods are not suitable for the compounds having easily reducible functions such as halogens, ketones, or esters. We found that the N–O bond of **22** can be cleaved by simple treatment with titanium(III) chloride in refluxing ethanol, affording an amino alcohol (**23**). Treatment of **23** with chromium trioxide–pyridine hydrochloride complex[10] effectively yielded **24**, Thus the nitrone-annelation would provide a new method for syntheses of hydroazulene derivatives.

Experimental

^{1}H-NMR spectra were recorded on a Hitachi H-60 instrument, TMS being used as an internal standard (ppm). IR spectra were taken on a Hitachi EPS-3T spectrometer. Mass spectra were obtained with a Hitachi RMU-6M spectrometer.

8a-Hydroxy-2,3-dimethyl-3,4,4a,5,6,7,8,8a-octahydro-2H-1,2-benzoxazine(9). To a solution of *N*-methylhydroxylamine hydrochloride (889 mg, 10.6 mmol) in 5 ml of methanol was added a solution of potassium hydroxide (664 mg, 11.5 mmol) in 3 ml of methanol, followed by the addition of allylcylohexanone (865 mg, 6.27 mmol). The mixture was stirred overnight, and diluted with ether. The precipitate was removed by filtration, and the filtrate was concentrated to give crude **5** (830 mg) as an oil; IR($CHCl_3$) 3300 (H_2O), 1640, 990, and 910 (–CH=CH_2), 1590 (nitrone) cm^{-1}; NMR ($CDCl_3$) δ=5.75 (1H, m), 5.00 (2H, m), 3.75 (3H, s, CH_3–N(→O)=), 2.5—0.8 (11H, m). The crude nitrone **5** (830 mg) was allowed to stand at room temperature for 7 d. The resulting oil was chromatographed on silica gel, giving allylcyclohexane (650 mg), the unchanged nitrone **5** (298 mg), and a mixture of the oxazine stereoisomers **9** (316 mg, 43% from allylcyclohexanone): bp 59 °C/0.3 Torr†; IR(film) 3450 (OH), 1015 (C–O) cm^{-1}; NMR($CDCl_3$) δ=4.28 (1H, s, OH), 2.60 (3H, s, N–CH_3), 2.50 (1H, m, CH_3–C<u>H</u>–N), 1.05 (3H/2, d, J=6.5 Hz, C<u>H</u>$_3$–CH–N), 0.97 (3H/2, d, J=6.5 Hz, isomeric C<u>H</u>$_3$–CH–N), 2.0—1.0 (12H, m); ^{13}C-NMR($CDCl_3$) 98.14(s), 61.69(d), 61.54(d), 43.70(d), 43.55(d), 42.88(q), 35.62(t), 35.47(t), 35.31(t), 35.14(t), 28.97(t), 28.81(t), 25.83(t), 25.70(t), 23.19(t), 23.04(t), 22.84(q), 19.03(q). Found: C, 64.49; H, 10.15; N, 7.25%. Calcd for $C_{10}H_{19}NO_2$: C, 64.83; H, 10.34; N, 7.56%.

By repeated chromatography of the diastereomeric mixture **9** (500 mg) using benzene–ethyl acetate (10 : 1) as an eluting solvent, one isomer of **9** was obtained as a colorless oil (45 mg): NMR($CDCl_3$) δ=2.60 (3H, s), 2.50 (1H, m), 1.05 (3H, d, J=6.5 Hz); ^{13}C-NMR($CDCl_3$) 98.21(s), 61.54(d), 43.54(d), 43.88(q), 35.46(t), 35.13(t), 28.80(t), 25.79(t), 23.04(t), 19.03(q).

2-[2-(N-Acetoxymethylamino)propyl]cyclohexanone(12). A solution of diastereomers(**9**) (73 mg, 0.40 mmol) in 2 ml of pyridine was treated with acetic anhydride (2 ml), and the mixture was allowed to stand overnight. After the usual work-up, the resulting oil (91 mg) was chromatographed on silica gel, giving **12** (66 mg, 73%) as an oil: IR($CHCl_3$) 1750 (AcO), 1700 (C=O) cm^{-1}; NMR($CDCl_3$) δ=3.05 (1H, m, CH–N), 2.72 (3H, s, CH_3–N), 2.02 (3H, s, AcO), 1.08 (3H, d, J=6.5 Hz), 2.5—1.0 (11H, m).

Hydrolysis of **12** with potassium hydroxide in methanol afforded a diastereomeric mixture **9** in a quantitative yield.

Attempt at Cyclization of 5. The nitrone **5** exhibited a strong absorption band at 3300 cm^{-1} in its IR spectrum due to water. The nitrone in this state was labile to heat; thus, vaccum distillation at 65 °C/0.15 Torr produced a distillate, which showed at least six spots in TLC. The NMR spectrum

† 1 Torr=133.322 Pa.

of the distillate showed no singlet at 3.73 ppm due to the *N*-methyl group of **5**. Similarly, a complex mixture was obtained when **5** was heated in refluxing benzene. By chromatography of the product, minor amounts of **9** and 2-allylcyclohexanone were isolated. However, the expected cyclization product, **10** or **11**, was not detected.

12-Methyl-11-ox-12-azatricyclo[7.3.0.0^{1,6}]dodecane(13). Treatment of 2-(3-butenyl)cyclohexanone **2** with *N*-methylhydroxylamine afforded crude nitrone **6**: IR(film) 3300 (H_2O), 1635, 990, 910 (-CH=CH_2), 1590 (nitrone) cm^{-1}; NMR($CDCl_3$) δ=4.10 (1H, t, J=8.0 Hz), H_A of O-CH_AH_B-CH_X), 3.48 (1H, dd, J=3.5, 8.0 Hz, H_B of O-CH_AH_B-CH_X), 2.63 (3H, s, CH_3-N), 2.7—1.0 (14H, m); MS (70 eV), *m/e* (rel intensity), 181 (M^+, 100), 138 (72), 135 (84), 127 (77). An analytical sample was obtained by short-path distillation: bp 98—103 °C/17 Torr. Found: C, 72.79; H, 10.45; N, 7.65%. Calcd for $C_{11}H_{19}NO$: C, 72.88; H, 10.56; N, 7.72%.

1-Methylamino-9-(hydroxymethyl)bicyclo[4.3.0]none (15). A solution of **13** (194 mg, 1.07 mmol) in 40 ml of hexane was irradiated for 18 h in the presence of fluorenone (23 mg, 0.13 mmol) with a high pressure mercury lamp (450 W) using a Pyrex filter. After removal of the hexane, the residue was chromatographed on silica gel. Elution with benzene gave fluorenone; further elution with benzene–ethyl acetate (3 : 1) gave **14** as an oil in a pure state (TLC). IR(film) 3300 (NH) cm^{-1}; NMR($CDCl_3$) δ=4.35 (2H, s, N-CH_2-O), 3.70 (2H, m, CH_2-O), 1.85 (1H, s, NH), 2.5—0.8 (14H, m). The oxazine **14** (49 mg, 0.27 mmol) was treated with lithium aluminium hydride (50 mg, 1.3 mmol) in 5 ml of tetrahydrofuran, and the mixture was stirred at room temperature overnight. The excess hydride was decomposed with water, 15% sodium hydroxide solution, and water, the precipitate being filtered. The filtrate was concentrated, and the residue was crystallized from ether, affording needles (33.8 mg, 68%): mp 188—190 °C; IR(KBr) 3325 (OH and NH); NMR($CDCl_3$) δ=3.78 (2H, br.s, NH and OH), 3.68 (2H, d, J= 5.0 Hz, CH_2-O), 2.42 (3H, s, CH_3-N), 2.3—1.0 (14H, m). An analytical sample was obtained by bulb-to-bulb distillation: bp 130 °C/2 Torr. Found: C, 72.23; H, 11.69; N, 7.30%. Calcd for $C_{11}H_{21}NO$: C, 72.08; H, 11.54; N, 7.64%.

13-Methyl-12-ox-13-azatricyclo[8.3.0.0^{1,6}]tridecane (18) and 12-Methyl-11-ox-12-azatricyclo[8.2.1.0^{1,6}]tridecane (19). The nitrone **7** was prepared from the pentenylcyclohexanone **3** by a method similar to that described above. A solution of the nitrone **7** (2.2 g, 11.3 mmol) in benzene (100 ml) was heated under refluxing in a nitrogen atmosphere for 16 h. The solvent was evaporated, and the residue (2.51 g) was chromatographed on silica gel. Elution with benzene–ethyl acetate (10 : 1) produced **19** (260 mg, 11.8%), a mixture of **19** and **18** (820 mg, 37.3%), and **18** (162 mg, 7.4%). Analytical samples were prepared by short-path distillation: **18**: 60 °C/2 Torr; NMR(C_6D_6) δ=3.98 (1H, dd, J=10.0, 7.0 Hz, CH_2-O), 3.47 (1H, dd, J=9.0, 7.0 Hz, CH_2-O), 2.43 (3H, s, CH_3-N). Found: C, 73.92; H, 10.95; N, 7.48%. Calcd for $C_{11}H_{21}NO$: C, 73.79; H, 10.83; N, 7.17%. **19**: 80 °C/2 Torr: NMR(C_6D_6) δ=4.45 (1H, m, CH-O), 2.43 (3H, s, CH_3-N), 1.96 (1H, dd, J=12.5, 8.5 Hz, CH_AH_B-CH-O), 1.65 (1H, dd, J=12.5, 2.5 Hz, CH_AH_B-CH-O). Found: C, 73.91; H, 10.92; N, 7.43%. Calcd for $C_{12}H_{21}NO$: C, 73.79; H, 10.83; N, 7.17%.

Attempt at Cyclization of the Nitrone 8. 2-(9-Decenyl)-cyclohexanone **8**; bp 112—125 °C/13 Torr, was prepared in 78% yield by treating the pyrrolidine enamine of cyclohexanone with 10-iodo-1-decene. The decenylcyclohexanone **8** (213 mg, 0.9 mmol) was dissolved in methanol (6 ml), and *N*-methylhydroxylamine hydrochloride (178 mg, 2.1 mmol) was added. The solution was treated with a solution of potassium hydroxide (171 mg, 3.1 mmol) in methanol (1 ml), and the reaction mixture was heated at refluxing temperature for 18 h. The mixture was diluted with ether, the precipitate was filtered, and the filtrate was concentrated to a brown oil (202 mg). The formation of the nitrone **8** was confirmed by the absence of the carbonyl absorption in the IR spectrum, and the appearance of a singlet at δ 3.75 (3H) due to *N*-methyl of the nitrone group in the NMR. The oil was heated in benzene at 60 °C for 24 h. The NMR spectrum of the product exhibited no signal at δ 3.75. Although the product was cautiously chromatographed on silica gel, no cyclization product could be isolated.

13-Methyl-12-ox-13-azatricyclo[8.3.0.0^{1,7}]tridecane (22). A solution of 2-(3-butenyl)cycloheptanone **20** (520 mg, 3.13 mmol), *N*-methylhydroxylamine hydrochloride (449 mg, 3.74 mmol), and potassium hydroxide (238 mg, 4.24 mmol) in methanol (20 ml) was heated at refluxing. After 4 h, a small portion of the reaction mixture was taken out. The NMR spectrum exhibited a singlet at δ 3.67 due to the *N*-methyl group of the nitrone **21**, together with a singlet at δ 2.52 due to the *N*-methyl group of the cyclization product **22**. The reaction mixture was heated for an additional 44 h, and diluted with ether. The precipitate was filtered and the filtrate was concentrated. The residual oil was distilled with a Kuhgel-Rohr apparatus, affording **22** (514 mg, 84% from **20**): NMR ($CDCl_3$) δ=3.82 (1H, t, J=8.0 Hz, O-CH_AH_B-CH_X), 3.23 (1H, dd, J=4.5, 8.0 Hz, O-CH_AH_B-CH_X), 2.52 (3H, s, CH_3-N). An analytical sample was obtained by short-path distillation: 140 °C/17 Torr. Found: C, 73.65; H. 10.92; N, 7.00%. Calcd for $C_{12}H_{21}NO$: C, 73.79; H, 10.83; N, 7.17%.

10-Hydroxymethyl-1-(methylamino)bicyclo[5.3.0]decane (23). To a solution of **22** (435 mg, 2.2 mmol) in ethanol (80 ml) was added 20% aqueous titanium(III) chloride solution (22 ml), and the mixture was allowed to reflux under an argon atmosphere overnight. The solvent was removed on a rotary evaporator, and the pH of the residual mixture was brought to 14 with a potassium hydroxide solution. The alkaline mixture was continuously extracted with ether for 24 h, and the ethereal extract was concentrated. The resultant oil was distilled with a Kuhgel-Rohr apparatus, giving **23** (302 mg, 89%) as a colorless oil: bp 170 °C/4 Torr; IR(film) 3300 cm^{-1}; NMR($CDCl_3$) δ=3.73 (2H, m, CH_2O), 3.08 (2H, s, NH and OH), 2.34 (3H, s, CH_3-N). Found: C, 72.75; H, 11.69; N, 6.81%. Calcd for $C_{12}H_{23}NO$: C, 73.04; H, 11.74; N, 7.09%.

Bicyclo[5.3.0]dec-1(10)-ene-10-carbaldehyde (24). A solution of the alcohol **23** (30 mg, 0.15 mmol) in dichloromethane (1.5 ml) was treated with chromium trioxide–pyridine hydrochloride complex (41 mg, 0.34 mmol), and the mixture was stirred at room temperature for 1 h. The mixture was diluted with ether, and water was added. The organic layer was separated, dried, and concentrated. After column chromatography of the residue on silica gel, a colorless oil **24** (12 mg, 52%) was obtained: IR(film) 2710, 1660 (CHO) cm^{-1}; NMR($CDCl_3$) δ=9.96 (HCO). High resolution mass spectrum: Found, M. W. 164.1185; Calcd for $C_{11}H_{16}O$, 164.1197.

(Received December 22, 1980)

Several *O*-acyl-*N*-[2-(methylthio)benzoyl]-*N*-*t*-butylhydroxylamines (**1**) were prepared and their thermal decompositions were studied. The thermal decomposition of **1** at 200 °C in *o*-dichlorobenzene gave *N*-*t*-butyl-2-(acyloxymethylthio)benzamide (**4**), the carboxylic acid derived from the acyl part of **1**, and 2-*t*-butyl-1,2-benzothiazol-3(2*H*)-one as the main products, together with small amounts of 4*H*-3,1-benzoxathiin-4-one, *N*-*t*-butyl-2-(methylthio)benzamide, methyl ester of the carboxylic acid, and *N*-*t*-butylamide. The benzamide (**4**) was found to be an initial product of the thermolysis and the subsequent decomposition gave the carboxylic acid and other products. Pummerer type reaction, *via* acylaminosulfonium ion as the intermediate, was suggested for the thermal decomposition of **1** since similar products were also obtained by the Pummerer reaction of *N*-*t*-butyl-2-(methylsulfinyl)benzamide with acylating reagents.

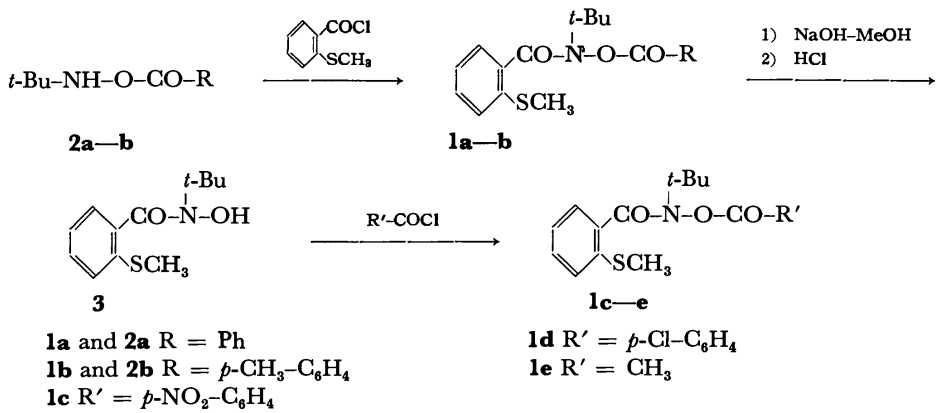
N,O-Diacylhydroxylamines have been known to react with nucleophiles both at the carboxyl carbon atom and at the nitrogen atom depending on the nature of the nucleophiles. In general, nucleophiles such as amines,[2] sulfide,[3] alkoxide,[1,3] azide,[3] and cyanide ions[3] attack the carboxyl carbon atom of the *N,O*-diacylhydroxylamines. On the other hand, Ohta *et al.* have shown the substitution reaction at the nitrogen atom by the reaction of *O*-acetyl-*N*-benzoyl-*N*-(4-methoxyphenyl)hydroxylamine with phenols, pyrrole, and indoles.[4] In the previous paper, we have reported that *N,O*-diacyl-*N*-*t*-butylhydroxylamines were decomposed thermally to afford amides and carboxylic acids in good yields. A mechanism involving nucleophilic substitution at the nitrogen atom has been suggested for the thermolysis of the hydroxylamines.[1]

Meanwhile, formations of acylaminosulfonium salts by the nucleophilic substitution at the amide-nitrogen atom have been known for the reaction of *N*-haloamides with dialkyl sulfides.[5] In this connection, thermolysis of a *N,O*-diacylhydroxylamine bearing a nucleophilic group at an appropriate position would take place by a different way, that is, an intramolecular substitution. Thus, we have prepared several *N,O*-diacyl-*N*-*t*-butylhydroxylamines (**1**) and studied their thermal decompositions. An intramolecular substitution reaction at the nitrogen atom by the methylthio-sulfur atom has been found as was expected.

Results and Discussion

Preparation of O-*Acyl*-N-[*2-(methylthio)benzoyl*]-N-t-*butylhydroxylamines (1).* Several title hydroxylamines (**1**) were prepared by the acylation of *O*-acyl-*N*-*t*-butylhydroxylamines (**2**) or *N*-[2-(methylthio)-benzoyl]-*N*-*t*-butylhydroxylamine (**3**) with corresponding acyl chlorides in the presence of pyridine (Scheme 1). Syntheses of **1a** and **1b** were performed by the reactions of 2-(methylthio)benzoyl chloride with **2a** and **2b**, respectively, in good yields. By the reaction of **2c** and **2d**, **1c** and **1d**, however, were obtained, respectively, in only poor yields. Alternatively, **1a** was hydrolized giving **3** which was acylated by appropriate acyl chlorides giving **1c—e** in satisfactory yields. Yields, physical properties, and analyses of **1** are summarized in Table 1.

Thermal Decomposition of N,O-*Diacyl*-N-t-*butylhydroxylamine (1).* On heating at 200 °C for 25 h in *o*-dichlorobenzene, 78% of **1a** was decomposed to give *N*-*t*-butyl-2-(benzoyloxymethylthio)benzamide (**4a**), benzoic acid (**5a**), 2-*t*-butyl-1,2-benzothiazol-3(2*H*)-one (**6**), 4*H*-3,1-benzoxathiin-4-one (**7**), *N*-*t*-butyl-2-(methylthio)benzamide (**8**), methyl benzoate (**9a**), and *N*-*t*-butylbenzamide (**10a**). The yields of the products



1a and **2a** R = Ph
1b and **2b** R = *p*-CH_3-C_6H_4
1c R′ = *p*-NO_2-C_6H_4
1d R′ = *p*-Cl-C_6H_4
1e R′ = CH_3

Scheme 1.

Table 1. Yields and physical properties of *O*-acyl-*N*-[2-(methylthio)-benzoyl]-*N*-*t*-butylhydroxylamines (**1a—e**)

Compd	Starting compd	Yield %	Mp(Bp) °C	IR (KBr) $\tilde{\nu}$(C=O)/cm^{-1}	Found (Calcd) (%) C	H	N
1a	**2a**	83	116.5—117.5	1760, 1640	66.37 (66.45)	5.98 (6.16)	4.02 (4.08)
1b	**2b**	69	70.5— 71.5	1750, 1650	67.27 (67.20)	6.43 (6.49)	3.75 (3.92)
1c	**3**	82	119.0—120.0	1760, 1670	58.58 (58.75)	5.13 (5.19)	7.30 (7.21)

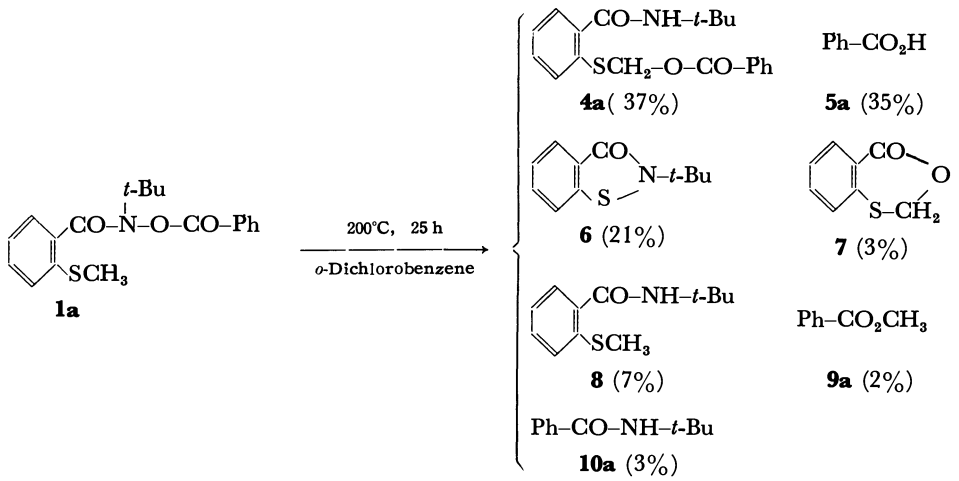
††Through this paper 1 mmHg=133.322 Pa.



Scheme 2.

were estimated by means of GLC (Scheme 2).

The structures of the products were ascertained on the basis of the spectral and chemical evidences. The NMR spectrum of **4a** in carbon tetrachloride showed singlets at δ 1.38 (9H) and δ 5.57 (2H), broad singlet at δ 6.10 (1H), and multiplet at around δ 7.1—8.1 (9H). The characteristic amide and ester bands of **4a** were observed at 3290 (N–H), 1720 (ester C=O), 1630 (amide C=O), and 1540 cm^{-1} (N–H) in its IR spectrum. In addition, the structure of **4a** was confirmed by comparision these physical properties with those of an authentic sample prepared by the reaction of *N*-*t*-butyl-2-(methylsulfinyl)benzamide (**11**) with benzoic anhydride.

The NMR spectrum of **6** in carbon tetrachloride showed a singlet at δ 1.68 (9H) and aromatic proton signals at δ 7.3—8.0 (4H). The IR spectrum of **6** consisted with amide carbonyl absorption at 1650 cm^{-1}. The elemental analysis also did not conflict with the structure. The compound **6** was synthesized by a different route. Namely, the reaction of *N*-*t*-butyl-2-(methylsulfinyl)benzamide (**11**) with acetyl or thionyl chlorides gave **6** in good yields. The structure of **7** was confirmed by comparing physical properties with those of the authentic sample prepared by the method of Numata and Oae.[6]

Table 2. Thermal decomposition of *O*-acyl-*N*-[2-(methylthio)benzoyl]-*N*-*t*-butylhydroxylamines at 200 °C in *o*-dichlorobenzene (0.1 mol/dm^3)

Compd	Time h	Conversion %	Products yield/%[a] 4	5[b]	6	7	8	9	10

a) Based on the starting **1**. Estimated by GLC. b) The amounts of the acid were estimated after methylation with diazomethane. c) Isolated yield. d) Not determined.

The rearranged products (**4b—e**) were obtained similarly together with **5**, **6**, **7**, **8**, **9**, and **10** by the thermal decompositions of **1b—e**. These results are summarized in Table 2. Physical properties and analyses of **4** are summarized in Table 3.

Inspection of the results given in Table 2 reveals that

Table 3. Physical properties of *N*-*t*-butyl-2-(acyloxymethylthio)benzamides

Compd	Mp °C	IR (KBr) $\tilde{\nu}$/cm^{-1} (N–H)	IR (KBr) (Ester C=O)	IR (KBr) (Amide C=O)	Found (Calcd) (%) C	H	N

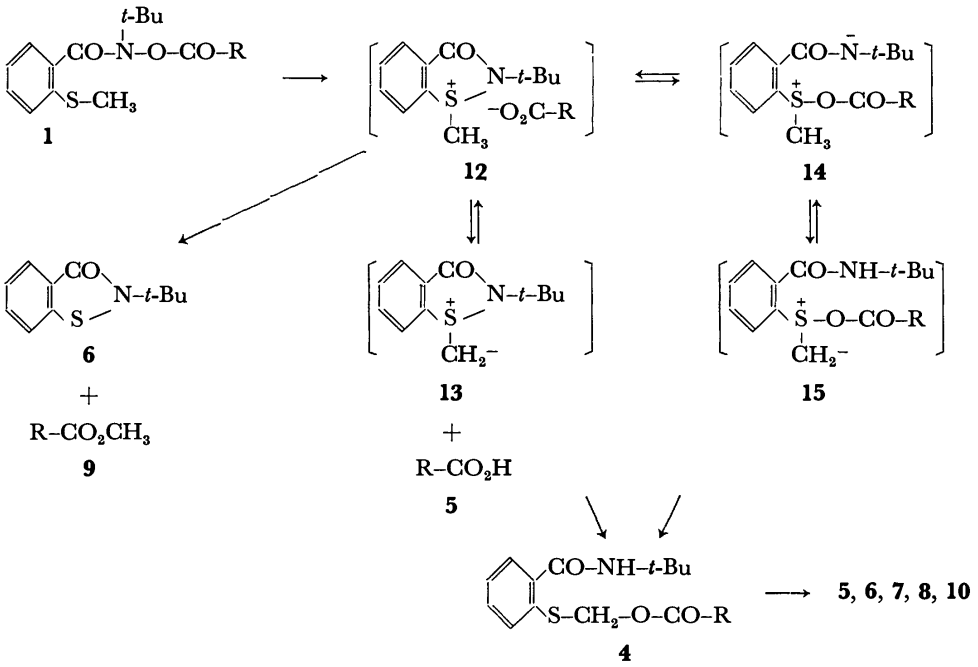
4d	83.0— 84.0	3290	1720	1630	60.38 (60.39)	5.29 (5.34)	3.77 (3.71)
4e	69.5— 70.5	3350	1730	1660	60.00 (59.76)	6.95 (6.81)	5.01 (4.98)

the rates of the decompositions of **1** were affected by the substituent of the *O*-acyl group. Electron-withdrawing groups accelerated the reaction. Namely, the thermal decomposition of **1c** which has 4-nitrobenzoyl group, completed within 7 h on heating at 200 °C, while, 33 and 44% of the starting materials were recovered by the decompositions of **1b** and **1e**, respectively, under the same reaction conditions. The yields of **4** were found to be depressed by prolonged heating as shown in Table 2. In a control experiment, **4a** was found to be decomposed under the same reaction conditions (200 °C, 25 h) giving **5a**, **6**, **7**, **8**, and **10a** in 46, 6, 7, 10, and 5% yields, respectively, with 60% decomposition of the starting material. These results suggest a successive decomposition of **4** giving the products, **5**—**8** and **10**, for the decomposition of **1**, although the yield of **6** from **4** (6%) could not account for that from **1** (21%).

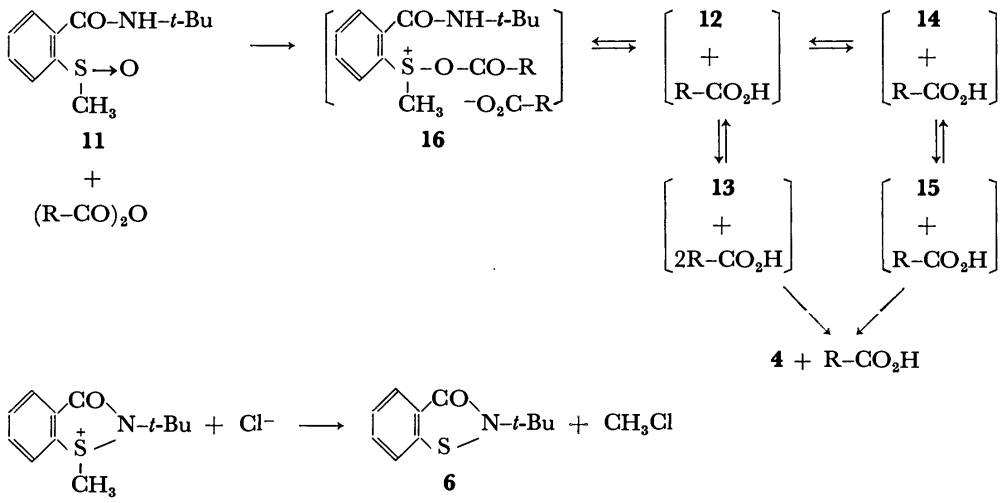
A probable mechanism leading to the rearranged product, **4**, from **1** would involve an intramolecular nucleophilic attack of sulfur atom on the nitrogen atom giving acylaminosulfonium salt, **12**, as the intermediate. The salt **12** would afford **4** by subsequent Pummerer rearrangement *via* ylid **13**. An alternative possible pathway leading to **4** from **12** may involve attack of the anion on the sulfur giving sulfonium salt **14** and proton migration would give the ylid **15**. Pummerer rearrangement of **15** may afford **4** as shown in Scheme 3. Direct formation of the sulfonium amide **14** by the attack of the sulfur on the ester oxygen of **1** seems to be unlikely by considering differences in leaving abilities of carboxylate and amide anions, and also in electronegativities of oxygen and nitrogen atoms. In fact, acceleration of the rate by the electron-withdrawing substituent on the *O*-acyl group is in accordance with the proposed mechanism involving the carbooxylate ion as the leaving group.

As mentioned above, another pathway would be required to account for the yield of **6**. This may be a demethylation reaction of the acylamisosulfonium ion (**12**) by a nucleophile. The formation of methyl ester (**9**) by the decomposition of **1** would support this prosess.

Pummerer Reactions of N-t-*Butyl-2-(methylsulfinyl)benzamide (11).* In order to prove the intermediacy of the acylaminosulfonium ion (**12**) for the thermolysis



Scheme 3.



Scheme 4.

of **1**, Pummerer reaction of **11** with acylating reagents, such as benzoic anhydride, acetic anhydride, acetyl chloride, and thionyl chloride were examined. In Pummerer reaction of **11**, the acylaminosulfonium ion **12** and/or the sulfonium salt **14** would be the intermediate. The sulfoxide **11** was heated at 180 °C for 10 h with 1.2 equiv. of benzoic anhydride in *o*-dichlorobenzene. The product **4a** (55%) was obtained together with small amount of **6** as was expected. The reaction of **11** with acetic anhydride gave **4e** and **6** similarly. On the other hand, the reaction of **11** with acetyl chloride or thionyl chloride proceeded at room temperature affording **6** in good yields. When excess of thionyl chloride was added to carbon tetrachloride solution of **11**, the NMR signals of *t*-butyl protons (δ 1.47, s) and *S*-methyl protons (δ 2.73, s) disappeared and new signals appeared at δ 1.73 (s), 1.80 (s), 2.99 (s), and 3.70 (s). During the reaction, the intensities of the signals at δ 1.80 and 3.70 decreased and the signals at δ 1.73 and 2.99 increased. The down field shift to δ 1.80 and 3.70 of the *t*-butyl and *S*-methyl signals, respectively, would apparently due to a positive charge which in turn suggest the formation of acylaminosulfonium ion (**12**) as the intermediate. After about 20 min, the signals at δ 1.80 and 3.70 disappeared and the ratio of the intensities of the signals at δ 1.73 and 2.99 was about 3 : 1. These signals were assigned to be *t*-butyl protons of **6** and methyl protons of chloromethane, respectively.

The reaction of **11** with acylating reagents can be explained by the mechanism shown in Scheme 4. The sulfonium salt **16**, initially formed by the reaction of **11** with acylating reagents gives **12** and/or **14**,[7] then rearranges to **4** by Pummerer reaction.[8] In the reactions of **11** with acetyl and thionyl chlorides, the acylaminosulfonium ion (**12**) is attacked by chloride ion giving **6** and chloromethane. Thus, the intermediacy of the acylaminosulfonium ion (**12**) for the thermal decomposition of **1** has been confirmed by the Pummerer reaction of the corresponding sulfoxide.

Experimental

All the melting points and the bioling points are uncorrected. The IR spectra were recorded on a Shimazdu IR-430 infrared spectrometer. The NMR spectra were recorded on a Varian EM-360 spectrometer using TMS as the internal standard.

Preparation of O-*Acyl*-N-[*2-(methylthio)benzoyl*]-N-t-*butylhydroxylamines (1)*. *Typical Procedure (a)*: A solution of 2-(methylthio)benzoyl chloride (58.0 g, 300 mmol), *O*-benzoyl-*N*-*t*-butylhydroxylamine (58.0 g, 310 mmol),[1] and pyridine (25.0 g, 320 mmol) in dry benzene (200 cm^3) was stirred at 75 °C for 20 h. The reaction mixture was washed with aq NH_3, dil NaOH, dil HCl, and water, and then dried over Na_2SO_4. The solvent was evaporated *in vacuo*, and the residue was recrystallized from benzene giving **1a** (86.0 g, 83%).

By the reaction of *O*-(4-methylbenzoyl)-*N*-*t*-butylhydroxylamine[1] with 2-(methylthio)benzoyl chloride, **1b** was prepared similarly.

(b): A solution of *N*-[2-(methylthio)benzoyl]-*N*-*t*-butylhydroxylamine (**3**) (12.0 g, 50 mmol), 4-chlorobenzoyl chloride (10.5 g, 60 mmol), and pyridine (4.7 g, 59 mmol) in dry benzene (150 cm^3) was stirred at 75 °C for 20 h. The reaction mixture was washed with aq NH_3, dil NaOH, dil HCl, and water, and then dried over Na_2SO_4. The solvent was evaporated *in vacuo* and the residue was recrystallized from CH_2Cl_2–petroleum ether giving **1d** (15.2 g, 80%).

By the same procedure, **1c** and **1e** were prepared by the reaction of **3** with 4-nitrobenzoyl chloride and acetyl chloride, respectively. The yields and physical properties are summarized in Table 1.

Preparation of N-[*2-(Methylthio)benzoyl*]-N-t-*butylhydroxylamine (3)*. A solution of NaOH (10.0 g, 250 mmol) in water (40 cm^3) was added to a solution of **1a** (34.3 g, 100 mmol) in methanol (200 cm^3). The mixture was stirred at room temperature for 3 h. After evaporation of the solvent, the residue was dissolved in water (200 cm^3), washed with diethyl ether, and acidified with HCl. The separated crystals were extracted with CH_2Cl_2, and the organic layer was washed with aq $NaHCO_3$ and water, and then dried over Na_2SO_4. The solvent was evaporated and the residue was recrystallized from benzene to give **3** (19.7 g, 82%); mp 145.0—146.0 °C. Found: C, 60.36; H, 7.31; N, 5.78%. Calcd for $C_{12}H_{17}O_2S$: C, 60.22; H, 7.16; N, 5.85%. IR: (KBr) 3150 (O–H) and 1600 cm^{-1} (C=O). NMR: ($CDCl_3$, δ) 1.38 (9H, s), 2.48 (3H,

s), 7.1—7.4 (4H, m), and 8.33 (1H, s).

Thermal Decomposition of **1**. A solution of **1** in *o*-dichlorobenzene (0.1 mol/dm³, 10 cm³) was sealed in a degassed tube and then heated in a constant-temperature bath at 200 °C. The tube was opened and 60 mg of biphenyl was added to the reaction mixture as an internal standard. The mixture was subjected to GLC analysis. In order to estimate the yield of carboxylic acid, an excess of an diethyl ether solution of diazomethane was added to a portion of the sample, and the mixture was allowed to stand for 1 h. After the evaporation of the ether *in vacuo*, the reaction mixture was subjected to GLC analysis. The following five columns were used; a 45 cm column packed with Silicone GE SE-30 (5%) on Shimalite W to analyze **1a**, **1**, **1d**, **4a**, **4b**, and **4d**; a 1 m column packed with Silicone GE SE-30 (5%) on Shimalite W to analyze **1e**, **4e**, **6**, and **8**; a 2 m column packed with Apiezon Grease L (30%) on Cerite 545 to analyze **6**, **7**, **8**, **9b**, **10a**, **10c**, and **10d**; a 2 m column packed with Thermon 1000+H_3PO_4 (5+0.5%) on Chromosorb W to analyze **9c**, and a 5 m column packed with polyethylene glycol 20 M (25%) on Shimalite 101 to analyze **9a** and **9d**.

For the isolation of the products, the thermal decompositions of **1** were carried out in a large scale. Typical procedure was as follows: A solution of **1c** (2.000 g, 5.15 mmol) in *o*-dichlorobenzene (40 cm³) was sealed in a degassed tube and heated at 200 °C for 7 h. The reaction mixture was washed with aq Na_2CO_3 and water. The alkaline solution was acidified with HCl to give **5c** (65 mg, 8%). The organic layer was dried over Na_2SO_4 and the solvent was evaporated *in vacuo*. The residue was chromatographed on silica gel with CH_2Cl_2 to give crude **4c**, **6**, and **7**. The crude **4c** was purified by recrystallization from ethanol (820 mg, 41%). The crude **6** and **7** were purified by preparative GLC.

Thermal Decomposition of **4a**. A solution of **4a** (343.4 mg, 1 mmol) in *o*-dichlorobenzene (10 cm³) was sealed in a deassed tube and then heated in a constant-temperature bath at 200 °C for 25 h. Biphenyl (60 mg) was added to the reaction mixture as an internal standard. The mixture was subjected to GLC analysis.

Preparation of N-t-*Butyl-2-(methylthio)benzamide* (**8**). A solution of 2-(methylthio)benzoyl chloride (37.3 g, 200 mmol) in dry benzene (100 cm³) was added to a solution of *t*-butylamine (30.7 g, 420 mmol) in dry benzene (200 cm³) with stirring. The mixture was refluxed for 1 h, washed with dil HCl, aq $NaHCO_3$, and water, and then dried over Na_2SO_4. The benzene was evaporated, and the residue was recrystallized from benzene–petroleum ether giving **8** (38.1 g, 85%); mp 133.0—134.0 °C.

Preparation of N-t-*Butyl-2-(methylsulfinyl)benzamide* (**11**). A solution of sodium metaperiodate (21.4 g, 100 mmol) in water (80 cm³) was added to a solution of *N-t*-butyl-2-(methylthio)benzamide (**8**) (22.3 g, 100 mmol) in methanol (200 cm³). The mixture was stirred for 3 h at room temperature. The reaction mixture was filtered and the filtrate was condensed to dryness. Water (50 cm³) and CH_2Cl_2 (150 cm³) was added to the residue, and the organic layer was separated. The extract was dried over Na_2SO_4 and the solvent was evaporated. The residue was recrystallized from CH_2Cl_2–petroleum ether to give **11** (22.1 g, 92%); mp 150.0—151.0 °C. Found: C, 59.93; H, 7.34; N, 5.78%. Calcd for $C_{12}H_{17}NO_2S$: C, 60.22; H, 7.16; N, 5.85%. IR (KBr): 3250 (N–H) and 1640 cm⁻¹ (C=O). NMR: ($CDCl_3$, δ) 1.48 (9H, s), 2.86 (3H, s), 6.57 (1H, broad s), and 7.4—8.2 (4H, m).

Reaction of **11** *with Acid Anhydrides*. A mixture of **11** (2.4 g, 10 mmol) and benzoic anhydride (2.7 g, 12 mmol) in *o*-dichlorobenzene (20 cm³) was refluxed for 10 h. The solvent was removed *in vacuo*, and the residue was dissolved in diethyl ether (50 cm³), washed with aq NH_3, Na_2CO_3, and water. The ether was evaporated after being dried over Na_2SO_4 and the residue was chromatographed on silica gel with CH_2Cl_2 as the eluant to give a mixture of **4a** and **6**. The mixture was recrystallized from CH_2Cl_2–petroleum ether giving **4a** (1.9 g, 55%).

The reaction of **11** with acetic anhydride was carried out in the same manner as mentioned above giving **4e** (1.7 g, 60%).

Reaction of **11** *with Acetyl Chloride*. Acetyl chloride (0.9 g, 10 mmol) was added to a solution of **11** (2.4 g, 10 mmol) in CH_2Cl_2 (20 cm³). The mixture was allowed to stand over night at room temperature, washed with aq NH_3 and water, and dried over Na_2SO_4. The solvent was removed and the residue was distilled under reduced pressure to give **6** (1.6 g, 77%); bp 165—166 °C/2.5 mmHg (lit,[9] bp 142 °C/0.5 mmHg). The distillate was recrystallized from petroleum ether; mp 57.0—58.0 °C. Found: C, 63.66; H, 6.55; N, 6.66%. Calcd for $C_{11}H_{13}NOS$: C, 63.74; H, 6.32; N, 6.76%. IR (KBr): 1650 cm⁻¹ (C=O). NMR (CCl_4, δ): 1.67 (9H, s) and 7.2—8.0 (4H, m).

Reaction of **11** *with Thionyl Chloride*. Thionyl chloride (1.8 g, 15 mmol) was added to a solution of **11** (2.4 g, 10 mmol) in CH_2Cl_2 (20 cm³). The mixture was allowed to stand for 1 h at room temperature, washed with aq Na_2CO_3 and water, and then dried over Na_2SO_4. The solvent was removed and the residue was distilled under reduced pressure to give **6** (1.6 g, 77%).

Preparation of 2-(Methylsulfinyl)benzoic Acid. Sodium metaperiodate (25.7 g, 120 mmol) in water (80 cm³) was added to a solution of 2-(methylthio)benzoic acid (20.0 g, 119 mmol) in methanol (250 cm³). The mixture was stirred for 4.5 h at room temperature and filtered. The filtrate was condensed to dryness and the residue was recrystallized from methanol–water to give 2-(methylsulfinyl)benzoic acid (18.4 g, 84%); mp 170.0—171.0 °C (dec) [lit,[10] mp 172 °C (dec)].

Preparation of 4H-*3,1-Benzoxathiin-4-one* (**7**). A mixture of 2-(methylsulfinyl)benzoic acid (5.0 g, 27 mmol) and acetic anhydride (4.1 g, 40 mmol) was refluxed for 15 h. The excess acetic anhydride was removed by distillation. The residue was dissolved in diethyl ether and washed with aq $NaHCO_3$ and water. The solvent was removed after being dried over Na_2SO_4, and the residue was recrystallized from CCl_4–petroleum ether giving **7** (3.9 g, 87%); mp 47.0—48.0 °C (lit,[11] 47 °C). IR (KBr): 1720 cm⁻¹ (C=O). NMR (CCl_4, δ): 5.38 (2H, s), 7.1—7.5 (3H, m), and 8.0—8.3 (1H, m).

Preparation of N-t-*Butylbenzamide* (**10a**). A solution of benzoyl chloride (14.0 g, 100 mmol) in dry benzene (50 cm³) was added to a solution of *t*-butylamine (18.0 g, 246 mmol) in dry benzene (150 cm³) with stirring. The reaction mixture was refluxed for 1 h, washed with aq NH_3, dil HCl, aq Na_2CO_3, and water, and then dried over Na_2SO_4. The solvent was removed, and the residue was recrystallized from CH_2Cl_2–petroleum ether giving **10a** (17.2 g, 97%); mp 134.0—135.0 °C (lit,[12] mp 134.0—134.5 °C).

By the same procedures. **10b—d** were prepared by the reactions of *t*-butylamine and the corresponding acyl chlorides. **10b**: mp 115.5—116.5 °C. **10c**: mp 159.0—160.0 °C. **10d**: mp 137.0—138.0 °C.

Catalysis by Mixed Oxide Perovskites. II. The Hydrogenolysis of C_3—C_5 Hydrocarbons on $LaCoO_3$

Kenji Ichimura, Yasunobu Inoue,* and Iwao Yasumori

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 25, 1980)

The catalytic hydrogenolysis of C_3—C_5 alkanes on $LaCoO_3$ perovskite oxide was found to show a highly selective formation of methane in the temperature range of 350—620 K. The reaction order with respect to the hydrocarbon pressure was unity in every hydrogenolysis, whereas the hydrogen order increased from zero for propane to 1.0 for butane and isobutane and to 2.0 for pentane, isopentane, and neopentane. The activation energies of the reactions ranged from 120 for propane to 32 kJ mol^{-1} for butane. The reaction of propane or butane with D_2 on $LaCoO_3$ provided large fractions of methane [D_3] and [D_4], but a negligible amount of deuterium-exchanged alkanes. An equilibrium among the gaseous H_2, HD, and D_2 was reached. These hydrogenolyses are described by a mechanism involving the almost concurrent repture of all the carbon-carbon bonds in the alkanes by the attack of adsorbed hydrogen atoms, and were proposed to be catalyzed by a synergetic effect; the CO^{3+} ion is effective in breaking the C–C bond, whereas the La^{3+} and O^{2-} ions serve to supply hydrogen atoms to the decomposed species. The reaction of propene or butenes with hydrogen produced the corresponding alkanes and methane. The kinetic analyses showed that the fractions of methane produced consecutively *via* the alkanes amounted to 16% for propene and to more than 93% for butenes. The observed pressure dependence and deuterium distributions in the alkene hydrogenation were interpreted in terms of the associative mechanism. The correlation between the structures of the reactant molecules and of the active sites present on $LaCoO_3$ was briefly discussed.

In the first paper of this series,[1] we reported the noteworthy catalytic properties of $LaCoO_3$ for the hydrogenolysis of ethylene and ethane. This mixed oxide exhibited a stable and high catalytic activity and retained its original perovskite structure even after several runs in a reducing atmosphere. At reaction temperatures above 420 K, the ethylene hydrogenolysis to form methane was found to proceed in a consecutive way *via* ethane as a stable intermediate, accompanied by a minor side-reaction of the direct methane formation. The X-ray photoelectron spectroscopic studies emphasized the importance of the trivalent state of the cobalt ion in rupturing the C–C bond, and the active structures were proposed to be composed of the (110) plane.

The catalytic hydrogenolysis of C_3—C_{10} hydrocarbons has been extensively studied on transition-metal catalysts,[2-6] but no detailed kinetic analyses have yet been done well because of complexities in the product distributions and because of the fast deactivation of the metal catalysts during the hydrogenolysis. In view of the remarkable selectivity and stable activity of $LaCoO_3$, it is of interest to examine the hydrogenolysis of alkanes and alkenes with longer carbon or side-carbon chains. Furthermore, we can expect that the employment of a variety of reactant molecules with different stereochemical conformations might be useful in obtaining information on the structure and distributions of the active sites exposed at the perovskite surface. In the present work, therefore, we investigated the hydrogenolysis of propene, butenes, and a series of alkanes from propane to pentane isomers by performing detailed kinetic studies, which were supplemented by a tracer work using D_2.

Experimental

The preparation of the mixed oxide perovskite, $LaCoO_3$, was described in the previous paper.[1] This perovskite catalyst was activated by heating *in vacuo* in the temperature range of 600—800 K in order to obtain a constant catalytic activity; the activity was reproducible enough for more than ten successive hydrogenolysis runs of C_2—C_5 hydrocarbons, except for that of acetylene.

The reaction of hydrocarbons with hydrogen was studied in a closed circulating system at temperatures between 350 and 620 K in the pressure range of 5—30 Torr (1 Torr = 133.3 Pa) for hydrocarbons and in that of 50—150 Torr for hydrogen. The procedures of kinetic study and of the analysis of the deuterium-distributed reactant and products in the reaction with D_2 were much the same as those employed previously.[1]

Reactant gases such as hydrogen (99.98% in purity), deuterium (containing less than 0.4% HD), propene (99.9%), propane (99.9%), butenes (99.0%), and butane (99.7%) were purchased from the Takachiho Shoji Co. and were used without further purification. Pentane and isopentane of an extra pure grade, obtained from the Wako Chemical Co., and neopentane from the Tokyo Kasei Co., were distilled and then subjected to several freeze-evacuation-thaw cycles to remove gaseous impurities.

Results

Hydrogenolysis of Alkanes. In the temperature and pressure ranges employed here, the hydrogenolysis of C_3 to C_5, *i.e.*, propane, butane, isobutane, pentane, isopentane, and neopentane, on $LaCoO_3$ produced only methane as a product. Neither the corresponding alkenes nor the fragmented hydrocarbons were detected in the gas phase.. The rates of hydrocarbon consumption fell within the same order of magnitude, $0.5—1.5 \times 10^{13}$ molecule s^{-1} cm^{-2} at 573 K, irrespective of the alkanes, except for the case of butane, which gives a higher rate of 7×10^{13} molecule s^{-1} cm^{-2}. The kinetic analysis of the reaction showed that the reaction orders with respect to the hydrocarbon pressure, $P_{C_nH_{2n+1}}$, were unity for all the reactions. Figure 1 shows the dependence of the rate on the hydrogen pressure, P_{H_2}; the hydrogen orders increased with the number of carbon atoms involved in the reactant hydrocarbons and were found to be 0.0, 1.0, and 2.0 for the reactions of C_3H_8, C_4H_{10},

and C_5H_{12} respectively. The Arrhenius plots of the reaction are demonstrated in Fig. 2. The values of the activation energy and other kinetic parameters are summarized in Table 1, together with the previous results on ethane hydrogenolysis. It should be noted that the activation energy was remarkably high for propane and neopentane, but low for ethane, butane, pentane, and isopentane hydrogenolysis. An intermediate value was obtained for isobutane hydrogenolysis.

Table 2 shows the deuterium distributions in the reactant and products in the reaction of propane and butane with D_2 at 573 K and compares them with the results for ethane hydrogenolysis. A common distribution pattern was observed in these three reactions; at conversions of 16—23%, an equilibrium among H_2, HD, and D_2 in the gas phase is established. The formation of the deuterium-exchanged ethane, propane, and butane was negligibly small, whereas the product, methane, consisted mainly of [D_3] and [D_4] species.

Hydrogenolysis of Propene and Butenes. The reaction of propene with hydrogen at 573 K produced a considerable amount of methane, together with propane at the initial stage of reaction. This behavior contrasts with the predominantly consecutive formation of methane which was observed in the case of ethylene hydrogenolysis.

The reaction of 1-butene, *trans*-2-butene, or *cis*-2-butene with hydrogen at 573 K underwent rapid isomerization, followed by the formation of butane and then methane; the ratio of the produced butene isomers, R(*cis*-2-butene/*trans*-2-butene), R(*cis*-2-butene/1-butene), and R(*trans*-2-butene/1-butene), were determined to be 1.0, 1.8, and 1.8 respectively. These ratios remained almost unchanged until the disappearance of the reactant butene. Table 3 shows the deuterium distributions of the reactant and products in the deuterogenation of propene and 1-butene at 573 K. There existed common features in the distributions for both reactions;

a) $P_{C_3H_6}=11$ and $P_{D_2}=96$ Torr; conversion=11%. b) $P_{1\text{-}C_4H_8}=11$ and $P_{D_2}=97$ Torr; conversion=71%.

the gaseous composition of H_2, HD, and D_2 nearly reached equilibrium. Propene and 1-butene used as reactants gave rise to wide distributions of deuterium ranging from $[D_0]$ to $[D_4]$. The products involved deuterium-exchanged propane and butane distributed from $[D_0]$ to $[D_4]$. The subsidiary isomerization of 1-butene during hydrogenolysis gave *cis*- and *trans*-2-butenes possessing almost the same distributions of deuterium. Methane contained highly-exchanged methane $[D_3]$ and $[D_4]$, in which the fraction of the latter species amounted to as much as 70—90% of the total methane.

In the reaction of acetylene with hydrogen, ethylene was the only product, and the catalytic activity was drastically decreased during the course of reaction. The initial rate was about one hundredth that of ethylene hydrogenation at 473 K.

Discussion

The features of the hydrogenolysis of propene and butenes on $LaCoO_3$ are similar to those of ethylene hydrogenolysis in that there existed no products other than methane and the corresponding alkanes (except for the butene isomers). Thus, the change in the gaseous compositions of the reactant and products as a function of the time was analyzed by the same procedure as was used in the previous study of the ethylene hydrogenolysis:[1]

$$\begin{array}{ccc} & C_nH_{2n} & \\ & \text{I}\swarrow H_2 \quad nH_2 \searrow \text{II} & \\ C_nH_{2n+2} & \xrightarrow[\text{III}]{(n-1)\,H_2} & n\,CH_4. \end{array} \qquad (1)$$

By assuming that the reaction order with respect to the partial pressure of respective hydrocarbons was unity, the following rate equation can be derived for the consumption of the alkene and alkane under the conditions of an excess of hydrogen:

$$\frac{dP_{C_nH_{2n}}}{dt} = -(k_1+k_2)\,P_{C_nH_{2n}} \qquad (2)$$

$$\frac{dP_{C_nH_{2n+2}}}{dt} = k_1P_{C_nH_{2n}} - k_3P_{C_nH_{2n+2}} \qquad (3)$$

$$\frac{dP_{CH_4}}{dt} = n(k_2P_{C_nH_{2n}}+k_3P_{C_nH_{2n+2}}), \qquad (4)$$

where k_i denotes the rate constant for Process i in Scheme (1). The values of k_i as parameters were determined by applying the non-linear least-squares method so as to give the curves best-fitting the experimental plots. For the reaction with propene, the determined values were $k_1=0.023$, $k_2=0.123$, and $k_3=0.167\ h^{-1}$ at 573 K ($P_{H_2}=100$ Torr), which indicates that the fraction of the direct hydrogenolysis *via* Process (II) is about 84%.

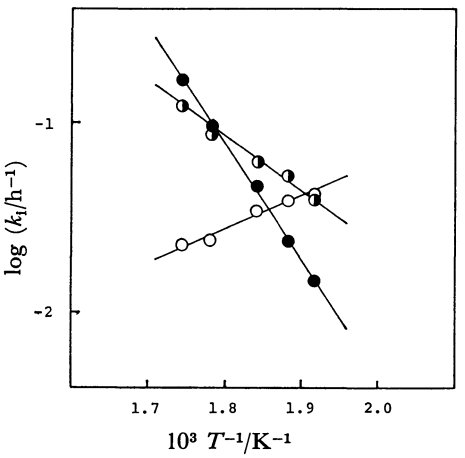

Fig. 3. Arrhenius plots of k_i.
○: k_1, ◑: k_2, ●: k_3.

Figure 3 shows the temperature dependence of k_i; the values of the activation energy, E_a, for Process (I), (II), and (III) were determined to be −33, 52, and 119 kJ mol^{-1} respectively. The analysis of the reaction with different initial hydrogen pressures provided the hydrogen order of unity for both Process (I) and (II) and of zero for Process (III). These results are summarized in Table 4. It should be noted that the rate, the activation energy, and the rate equation for Process (III) were in substantial agreement with the respective values in the propane hydrogenolysis (*cf.* Tables 1 and 4).

Since there was no marked difference in the observed rates of the hydrogenation of 1-butene, *trans*-2-butene, and *cis*-2-butene, the average of these rates could be employed as that of butene hydrogenation. The kinetic analysis gave the values of $k_1=0.040$, $k_2\approx0.003$, and $k_3=0.95\ h^{-1}$ at 573 K, indicating that the fraction of the direct formation of methane from butene was about 7%. As is demonstrated in Tables 1 and 4, there also exists a good agreement in the kinetic parameters and reaction rates between Process (III) and butane hydrogenolysis. These close coincidences give support to the analytical procedure employed here for

Table 4. Kinetic parameters in the hydrogenolysis of propene and butenes

the propene and butene hydrogenolysis.

The previous kinetic study of the ethylene hydrogenation[1] over $LaCoO_3$ revealed that the reaction proceeded mainly on the La and O ions *via* the associative mechanism and that, as the reaction temperature increased, the slow step varied from the dissociative adsorption of hydrogen to the hydrogenation of an ethyl radical. The reaction orders and the way of deuterium distribution in the present hydrogenation of propene and butene were quite similar to those observed in the ethylene hydrogenation in the high-temperature region. Thus, we can safely adopt the associative mechanism as well as the same active-site structure for both reactions, and the rate equation is given[1] by:

$$R_h=k_hK_sK_aK_h\,P_{C_nH_{2n}}\;P_{H_2}=k\,P_{C_nH_{2n}}\,P_{H_2}, \qquad (5)$$

in a simplified form, where k_h is the rate constant for the hydrogenation of the half-hydrogenated species. The constants, K_h, K_a, and K_s, denote, respectively, the equilibrium constants for the adsorption of hydrogen, the adsorption of alkenes, and the surface reaction between adsorbed alkenes and a hydrogen atom. This equation accords well with the experimental pressure dependence.

Alkane Hydrogenolysis. The hydrogenolysis of alkanes has thus far been mostly confined to those catalyzed by transition-metal catalysts;[2] these reactions are characterized by negative orders with respect to P_{H_2} and, generally, by a wide variety of products, coinsisting of fragmented hydrocarbons, except for the selective formation of methane in the case of Ni.[6,7] The proposed mechanism involves the dissociative adsorption of alkanes, liberating a hydrogen atom on the surface, followed by the step-by-step scission of carbon-carbon bonds. The most striking features in the present hydrogenolysis on $LaCoO_3$ are the high reaction order with respect to P_{H_2} and the formation of only methane as the product. Neither the other fragmented nor dehydrogenated hydrocarbons were produced in the gas phase. Therefore, it is evident that the catalysis by this perovskite is essentially different from those by the transition metals, and so the above-mentioned mechanism can not be applied to the present reaction system.

The deuterium distributions in the reaction of the alkanes with D_2 showed a common feature irrespective of the alkanes employed: large amounts of methane [D_3] and [D_4] were produced even at the initial stage of hydrogenolysis, whereas the fractions of the deuterium-exchanged alkanes were negligibly small. These results clearly indicate that the adsorption of alkanes is irreversible, but the surface species thus produced undergo a rapid hydrogen exchange. Another important finding is that the reaction order with respect to the alkane pressure was unity in all cases, but the hydrogen order increased with the number of carbon atoms in the alkanes, independently of their molecular structure (*i.e.*, 0.0, 1.0, and 2.0 for the hydrogenolyses of C_3H_8, C_4H_{10}, and C_5H_{12} respectively). The value of −0.5 obtained previously for the ethane hydrogenolysis is also in line with this tendency.[1] It should be noted that such a variation in the hydrogen order is not observed for the alkane hydrogenolysis on the transition-metal catalysts. These findings on the present hydrogenolysis indicate that the slowest elementary step involves not only the simultaneous rupture of the C–C bonds to produce monocarbon species, but also the attack of hydrogen atoms, the number of which is strongly related to that of the resulting monocarbon species.

A comparative study of hydrogenolysis by perovskite compounds, such as $LaAlO_3$, $LaFeO_3$, and $LaCoO_3$,[8] and by component oxides, such as La_2O_3 and Co_2O_3,[1] revealed that only $LaCoO_3$ and Co_2O_3 can accelerate the hydrogenolysis; this indicates that the cobalt ion plays an impotant role in breaking the C–C bond. The study also showed that La_2O_3 can effectively catalyze the H_2-D_2 equilibration reaction as well as ethylene hydrogenation, indicating the capability of adsorbing hydrogen dissociatively.[1] These findings lead to the consideration that the peculiar activity of $LaCoO_3$ arises from the synergetic effect of La, Co, and O ions; the Co ion is responsible for the C–C bond rupture, whereas the La and O ions contribute mainly as sites for supplying hydrogen atoms to the decomposed species. Furthermore, the application of X-ray photoelectron spectroscopy to the active and deactivated $LaCoO_3$ catalysts showed that the presence of a trivalent cobalt ion rather than a divalent one is essential for the activity.[1,8] Accordingly, we would like to propose the following mechanism as the most plausible pathway for the reaction of the C_3 to C_5 alkanes, which involves surface intermediates analogous to those suggested in the ethane hydrogenolysis:

$$H_2 \rightleftharpoons 2H(a) \qquad (6)$$

$$H_2 \rightleftharpoons 2H(a^*) \qquad (7)$$

$$C_nH_{2n+2} + 2(n-2)H(a) \longrightarrow 2CH_3(a^*) + (n-2)[H\cdots CH_2(a)\cdots H] \quad (8)$$

$$\left.\begin{array}{l} CH_3(a^*) \rightleftharpoons CH_2(a^*) + H(a) \\ [H\cdots CH_2(a)\cdots H] \rightleftharpoons CH_3(a) + H(a) \\ CH_3(a) \rightleftharpoons CH_2(a) + H(a) \end{array}\right\} \quad (9)$$

$$\left.\begin{array}{l} CH_3(a^*) + H(a) \longrightarrow CH_4 \\ [H\cdots CH_2(a)\cdots H] \longrightarrow CH_4 \end{array}\right\}, \quad (10)$$

where the symbols (a*) and (a) represent the adsorbed species on the Co^{3+} ion and those on the other sites respectively. The surface species, $[H\cdots CH_2(a)\cdots H]$, denotes a precursor of desorbing methane. The absence of deuterium-exchanged alkanes in the gas phase suggests that Step (8) is rate-determining, and the following rate equation is given to the hydrogenolysis by assuming that the requisite number of the site on the Co^{3+} ion is two for the selective adsorption of methyl groups in the alkane molecules:

$$R = k_8 P_{C_nH_{2n+2}} \theta_v^{*2} \theta_H^{2(n-2)}, \quad (11)$$

where θ_v^* denotes the fraction of the vacant Co^{3+} sites, and θ_H, the fractions of the La^{3+} and O^{2-} sites, occupied by hydrogen atoms. Provided that the fraction of the sites covered with hydrocarbon species is negligibly small, these fractions can be expressed, respectively, as;

$$\theta_v^* = 1/(1+\sqrt{K_h^* P_{H_2}}) \quad (12)$$

and

$$\theta_H = \sqrt{K_h P_{H_2}}/(1+\sqrt{K_h P_{H_2}}), \quad (13)$$

where K_h^* and K_h are equilibrium constants. After introducing Eqs. 12 and 13 into Eq. 11, the rate equation is written as;

$$R = k_8 K_h^{n-2} P_{C_nH_{2n+2}} P_{H_2}^{n-2}/(1+\sqrt{K_h^* P_{H_2}})^2 (1+\sqrt{K_h P_{H_2}})^{2(n-2)}. \quad (14)$$

Under the conditions of a strong hydrogen adsorption on the Co^{3+} sites, $1 \ll \sqrt{K_h^* P_{H_2}}$, and a weak adsorption on the other sites, $1 \gg \sqrt{K_h P_{H_2}}$, Eq. 14 is simplified to;

$$R = k_8 \frac{K_h^{n-2}}{K_h^*} P_{C_nH_{2n+2}} P_{H_2}^{n-3}. \quad (15)$$

For normal and side-chain alkanes with the three to five carbon atoms, the observed pressure dependences of the rate are well represented by Eq. 15. Step (8) might proceed rapidly in a consecutive way involving the step-by-step C–C bond scission, but it is regarded as being a simultaneous step, as far as the kinetics is concerned, and the surface intermediates produced are not desorbed in the gas phase. In the above-mentioned mechanism, the surface Co^{3+} ion favors the adsorption of the methyl group rather than the methylene group. This is not unexpected, since a similar selective adsorption occurred on the Cr^{3+} ion in α-Cr_2O_3.[9] The formation of highly deuterium-exchanged methane is ascribable to the rapid hydrogen exchange between monocarbon species, such as methyl and carbene, as is shown in Step (9). The presence of surface carbene as an intermediate is possible, since this species was recently, by means of ultraviolet photoelectron spectroscopy, confirmed in the adsorption of C_2H_2 on the Ni (110) surface.[10]

The formation of methane *via* the direct hydrogenolysis of propene was expressed by a rate equation of the first order with respect to both the hydrogen and propene pressures (Table 4); the hydrogen order was different from that observed in the case of propane hydrogenolysis. One possible interpretation for this pressure dependence might be given by assuming the same surface intermediates as those described in Step (8). This assumption leads to this pathway;

$$C_3H_6 + 4H(a) \longrightarrow 2CH_3(a^*) + [H\cdots CH_2(a)\cdots H]. \quad (16)$$

Thus, it follows that the insertion of a stoichiometry number, $n=4$, of hydrogen atoms into Eq. 15 provides the same rate equation as the observed one.

The alkane hydrogenolysis showed a variety of activation energies, as is demonstrated in Table 1; E_a is high for propane and neopentane, intermediate for isobutane, and low for pentane, butane, isopentane, and ethane. It is difficult at present to give a clear interpretation for this variation, especially the extremely high value for propane. One might argue that the C–C bond between methylene groups in alkanes dissociates more readily than that between methylene and methyl group and that, thus, the number of the CH_2 group in the respective alkanes would govern the activation energy of reaction. This view, however, is unlikely, because the energy difference between those bonds (13 kJ mol^{-1})[11] is too small to explain the large variation in E_a, and no correlation between them exists. The following consideration of the conformation of alkane molecules and the $LaCoO_3$ surface appears to be useful. In previous studies,[1,8] the (110) plane of $LaCoO_3$ was supposed to be active for the hydrogenolysis because of the high density of the exposed Co, La, and O ions. The distance between the adjacent surface Co ions is 5.42 Å. The carbon-atom chain of butane or higher alkanes is long and flexible enough to interact with two Co ions in a bridged form, as shown in Fig. 4. Although the La^{3+} and O^{2-} ions fail to adsorb alkanes dissociatively, both ions are likely to accommodate the methyl and carbene groups formed as a result of the bond rupture. Thus, such bridged adsorption makes the nearby La^{3+} and O^{2-} ions effective in supplying hydrogen atoms to the decomposed species, thus lowering the activation energy. On the other hand, propane and neopentane can hardly take the bridged configuration because of their smaller size and less flexible shape. The adsorption

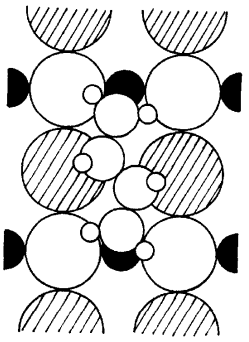

Fig. 4. Schematic representation of butane configuration on the (110) plane of $LaCoO_3$.
●: La^{3+}, ○: O^{2-}, ●: Co^{3+}, ○: carbon atom, ○: hydrogen atom.

of these molecules on a single Co ion results in a larger steric hindrance, which makes the activation energy higher. In this regard, the small E_a in the ethane hydrogenolysis is exceptional, but presumably due to a lesser extent of the steric hindrance. As for the propane hydrogenolysis, the extremely larger E_a seems to be related to the specificity in the propene hydrogenolysis; *i.e.*, the direct methanation of propene was remarkably favored, compared to those of the ethylene and butene hydrogenolyses. This consideration is certainly supported by the fact that the E_a of the direct methane formation from propene was as low as 52 kJ mol^{-1}.

In order to reveal the peculiar behavior of propene and propane in the hydrogenolysis reaction, further information on the adsorbed states of the hydrocarbons on $LaCoO_3$ is needed; a thermal-desorption study is now in progress.

Conformational Change of Poly(L-lysine) by Sodium Octyl Sulfate as Studied by Stopped-flow Circular Dichroism Method

Kunio TAKEDA,* Akira IBA, and Keishiro SHIRAHAMA†

Department of Applied Chemistry, Faculty of Science, Okayama University of Science, Ridai-cho 1-1, Okayama 700
†Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received October 27, 1980)

Circular dichroism (CD) studies were made on the conformational changes of poly(L-lysine) (PLL) induced by sodium octyl sulfate (SOS). The conformation of PLL has a negative double maximum characterizing the α-helix in $4.0—6.0\times10^{-3}$ mol/dm^3 SOS solutions. At a higher concentration of SOS, PLL takes the β-structure, the random coil remaining below it. These conformational changes were followed by measuring ellipticities at 192, 207, and 221 nm according to a CD stopped-flow method. The rate constant was *ca.* 2.7×10^{-1} s^{-1} for the coil-helix transition, the transition rate from coil to β-structure being high depending on SOS concentration. The β-structure was attained by adding a small amount of 1-octanol to the α-helical PLL in 5.0×10^{-3} mol/dm^3 SOS. The effect of the surfactant on the triphasic conformation changes is discussed in terms of hydrophobic environment.

Conformational changes of polypeptides and proteins have been extensively studied by circular dichroism (CD) measurements. Poly(L-lysine) (PLL) has been frequently selected as a typical substance because of its diversity in conformations.[1-3] Satake and Yang gave an evidence that PLL adopts β-structure in the presence of sodium alkyl sulfates which have longer hydrocarbon chains than 10 carbons. They obtained a distorted CD spectrum reminiscent of α-helix,[3] which should show a characteristic CD spectrum with a double negative maximum. It has not been clarified which conformation PLL takes in a SOS solution. This paper reports the SOS concentration dependence of PLL conformation as well as the kinetics of conformational changes studied by the CD stopped-flow method.

Experimental

The surfactant, SOS, was prepared from 1-octanol (purity: 99%, Aldrich Chemical Co.) by the method of Dreger *et al.*,[4] and recrystallized twice from 2-propanol and once from pure water. The critical micelle concentration of the surfactant was determined to be 148 mM (as concentration unit, 1 M= 1 mol/dm^3, is used) at 25 °C by means of electric conductivity in agreement with that reported.[5] The hydrobromide salt of PLL (degree of polymerization: 140, Sigma Chemical Co.) was converted into hydrochloride by dialysis against 0.1 M HCl and then water. The concentration of PLL was determined by colloid titration.[6,7]

Measurements of CD were carried out with a JASCO-J500A spectropolarimeter (Japan Spectroscopic Co.) equipped with a DP-501 data processor. The data processor was partially modified to follow rapid reactions. The sampling time required for 5 data points/nm on a chart in both X and Y directions was selected from 1.0×10^{-4} to 1.0×10^{-1} s for kinetic measurements. The stopped-flow measurements by CD detection were carried out with a rapid mixer (Union Giken Co.) and a specially designed observation cell whose lightpath length and incident area being 1.0 mm and 1.0 cm^2, respectively. The dead volume beyond the mixer was calculated to be 250 μl for the stopped-flow system. The stopped-flow system was driven by *ca.* 2.0 kg/cm^2 compressed air.

Results and Discussion

Figure 1 shows typical CD spectra of PLL in the absence and the presence of 5.0 mM SOS and the difference CD spectrum between them. The conformation of PLL in the SOS concentrations between 4.0 and 6.0 mM seems to be the α-helical structure characterized by a double negative maximum. Satake and Yang reported that the CD spectrum of poly(L-ornithine)(PLO)-sodium dodecyl sulfate (SDS) complex is characteristic of a helical conformation with a double negative maximum, but the PLO–SOS and PLL–SOS complexes display the CD spectrum with a negative maximum at 225 nm and a shoulder near 210 nm suggesting a helical conformation.[3] The CD spectrum of PLL–SOS complex closely resembles that of PLO-

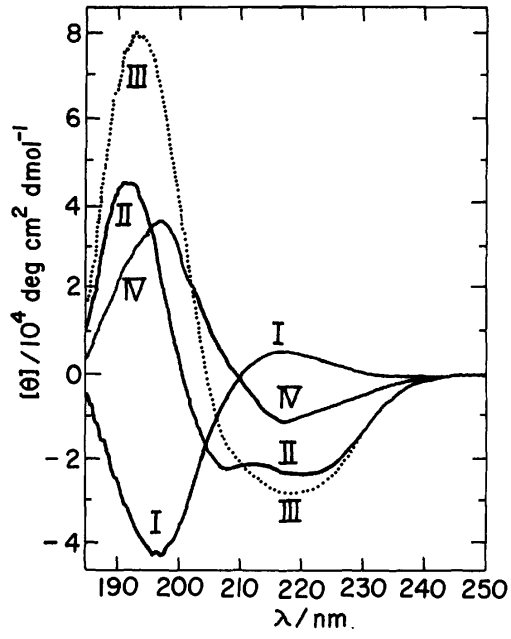

Fig. 1. Typical CD spectra of PLL solutions in the absence (curve I) and the presence (curve II) of 5.0 mM SOS and the difference CD spectrum between them (curve III) at 20 °C. Curve IV represents the CD spectrum of PLL in 7.5 mM SOS solution. The concentration of PLL was 2.8×10^{-4} M. The thickness of cell used was 1.0 mm. The time constant and the scanning speed of spectropolarimeter were 1.0 s and 20 nm/min, respectively. These spectra are averaged over 8 repetitions.

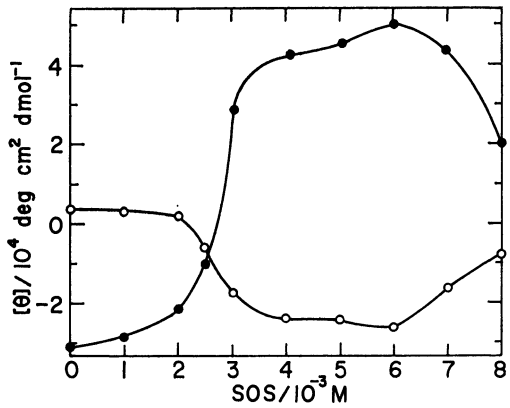

Fig. 2. Plots of $[\theta]_{192}$ (●) and $[\theta]_{221}$ (○) *vs.* concentration of SOS at 20 °C. These data were obtained from the measurements under the same experimental conditions as stated in Fig. 1.

SDS complex in their work. The magnitude of ellipticity of the PLL–SOS complex around 220 nm is considerably smaller than that of ordinary α-helical PLL.[1,2,8,9] It is not clear whether this is due to an environment effect of the bound surfactant ions on the rotational strength of the n-π* transition as pointed out by Grourke and Gibbs[10] and Satake and Yang,[3] or incomplete helix formation due to very low SOS concentration.

Figure 2 shows the dependence of residue ellipticities, $[\theta]_{192}$ and $[\theta]_{221}$ on SOS concentration. PLL is seen to be α-helical only in the range 4.0—6.0 mM SOS, taking disordered structure and β-structure below and above the SOS concentration range, respectively.

The conformational change of the PLL induced by

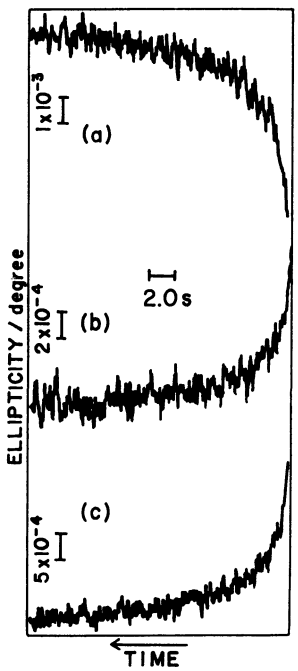

Fig. 3. Typical traces of ellipticity changes at 192 (a), 207 (b), and 221 nm (c) at 20 °C. The trace (a) is average of 32 repetitions and the traces (b) and (c) are averages of 8 repetitions. The final concentrations of PLL and SOS were 2.8×10^{-4} M and 6.0 mM, respectively.

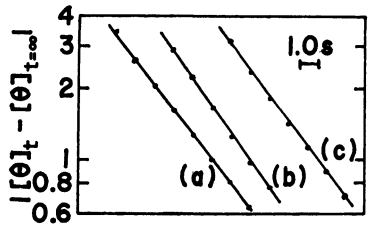

Fig. 4. Semilogarithmic first order plots for the approach to equilibrium on the three time courses in Fig. 3. The quantities representing $|[\theta]_t-[\theta]_{t=\infty}|$ are expressed in units in (a) 1×10^{-3}, (b) 2×10^{-3}, and (c) 5×10^{-4} degree, respectively, on the basis of best fit curve drawn on time course in each case.

SOS was followed by CD changes at 192 (wavelength at which the positive maximum appears in the difference CD spectrum directly obtained by use of a data processor; dotted curve III, Fig. 1), 207 and 221 nm (wavelengths at which the negative maximum appears in SOS solution, Fig. 1). Typical time courses are given in Fig. 3. As anticipated from the changes in the CD spectra (Fig. 1), the ellipticity at 192 nm changed from negative to positive, the negative ellipticities at 207 and 221 nm increasing with time. Although only half of the total ellipticity change with time near new equilibrium was observed at each wavelength due to the large dead volume of the stopped-flow system, the directions of the ellipticity changes with time at the three wavelengths were in line with the changes expected from the CD spectra (Fig. 1). This result and the identical rate constants calculated at three wavelengths led us to conclude that the observed process is the conformational change of PLL from the disordered structure to the α-helix, free from any possible artifacts which might be occasionally observed in stopped-flow measurements.[11] The forward rate constant for the conformational change from the coil to α-helix was determined by assuming that the conformational change of PLL is a first order reaction. The first order plot gives a linear relationship between $|[\theta]_t-[\theta]_{t=\infty}|$ and time, t (Fig. 4). The time courses at the three wavelengths approximately gave the same rate constant, k being almost independent of the SOS concentration between 4.0 and 6.0 mM (Fig. 5).

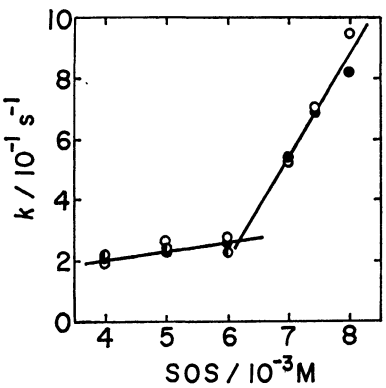

Fig. 5. Dependence of rate constant, k on SOS concentration at 20 °C. The rate constants were obtained from time courses at 192 (○), 207 (◐), and 221 nm (●). Final concentration of PLL was 2.8×10^{-4} M.

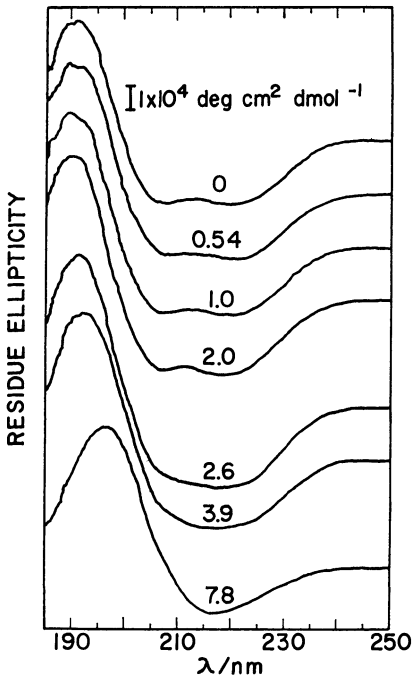

Fig. 6. Changes of CD spectrum of PLL in 5.0 mM SOS by addition of small amounts of 1-octanol at 20 °C. Numerical values in the figure denote concentrations of the 1-octanol in mM.

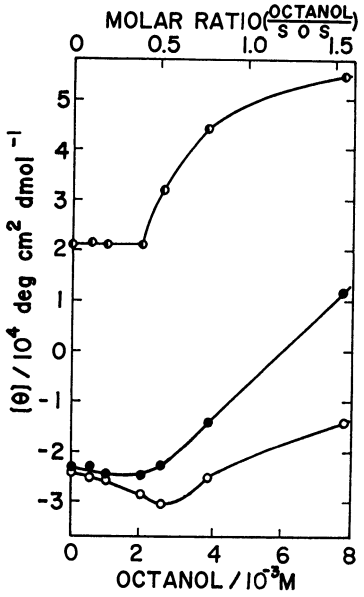

Fig. 7. Plots of $[\theta]_{197}$ (◐), $[\theta]_{207}$ (●), and $[\theta]_{221}$ (○) *vs.* concentration of 1-octanol and molar ratio of octanol/SOS at 20 °C. The concentration of SOS was 5.0 mM.

On the other hand, PLL adopts the β-structure above 7.0 mM SOS. Addition of a small amount of 1-octanol to α-helical PLL in 4.0—6.0 mM SOS caused the β-structure as shown in Fig. 6. The residue ellipticities at 197, 207, and 221 nm, $[\theta]_{197}$, $[\theta]_{207}$, and $[\theta]_{221}$ *vs.* 1-octanol and 1-octanol/SOS molar ratio plot is shown in Fig. 7. Above the octanol/SOS molar ratio=0.5, $[\theta]_{197}$, $[\theta]_{207}$, and $[\theta]_{221}$ gradually change with increase in the ratio of octanol/SOS. The PLL conformation is in a delicate balance between the coil, α-helix, and β-structure state. A slight change in circumstances may cause the interchange among the three states. Bound SOS neutralizes the charges on PLL, giving rise to ordered structures, especially α-helix at first. Increased degree of binding gives more hydrophobic atmosphere to the host polymer, the β-structure being enhanced. Addition of octanol also gives the α-helical PLL–SOS complex a more hydrophobic atmosphere, making it adopt the β-structure. The tendency that more hydrophobic environment favors β-structure is seen in Satake and Yang's study in which alkyl sulfates longer than SOS exclusively bring about the β-structure.[3] Alkyl sulfates bound to the charged sites on polymer would be in contact with each other more efficiently on the β-structure than the α-helix, since the alkyl sulfates are implanted radially on the α-helix, while they are oriented in the same direction on the β-structure. Such a difference in mutual contact is also reflected on a binding isotherm which is much steeper for the β-structured polypeptide than the α-helical one.[12]

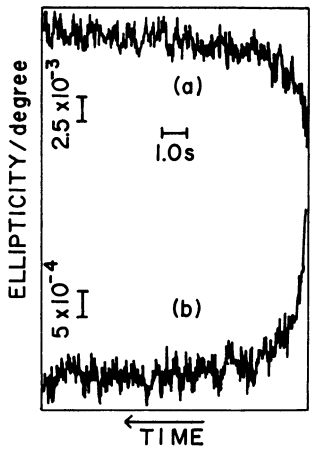

Fig. 8. Typical traces of ellipticity changes at 192 (a) and 221 nm (b) at 20 °C. The traces (a) and (b) are averages of 16 and 8 repetitions, respectively. The final concentrations of PLL and SOS were 2.8×10^{-4} M and 7.5 mM, respectively.

The ellipticity changes with time were observed above 7.0 mM SOS (Fig. 8). The change seems to be due to the conformational change of PLL from coil to β-structure, the rate constant sharply increasing with SOS concentration (Fig. 5).[13] There is no possibility that PLL passes through the α-helical state before attaining β-structure in the higher SOS concentration range, since no corresponding process was observed in such time courses as shown in Fig. 8. The disordered structure of PLL directly turned to the β-structure.

The octanol-induced conformational change of PLL was followed by the CD stopped-flow method. Typical time courses are shown in Fig. 9. The directions of the ellipticity changes in this case, as expected from a comparison of curve II with curve IV in Fig. 1, were reversed in contrast with those in the conformational change from the coil to α-helix or β-structure. Most of the total ellipticity change could be observed through-

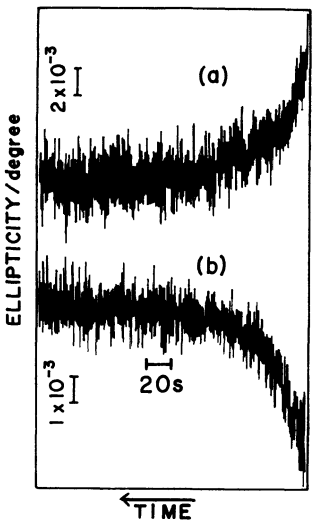

Fig. 9. Typical traces of ellipticity changes at 192 (a) and 221 nm (b) at 20 °C. This is the case of mixing PLL solution containing 5.0 mM SOS with a solution of 5.0 mM SOS containing slight amounts of 1-octanol. The final concentrations of the PLL and the octanol were 2.8×10^{-4} M and 7.8 mM, respectively. The traces (a) and (b) are averages of 8 and 2 repetitions, respectively.

out the time courses at these wavelengths, since the rate was one order of magnitude lower than those of the other two processes, the coil to α-helix or β-structure. The observed processes in Fig. 9 reflect the conformational change of PLL, from the α-helix to β-structure. The time courses at 192 and 221 nm gave an identical rate constant, 7.2×10^{-2} s^{-1} at 20 °C. Such a slow process would be responsible for destruction-reconstruction mechanism: α-helix is unfolded and then the highly ordered β-structure is constructed. The conformational change of PLL from coil to β-structure was also observed in mixing the PLL solution with 5.0 mM SOS solution containing 7.8 mM 1-octanol (both final concentrations). The observed time courses in this case also gave a similar rate constant, 5.5×10^{-1} s^{-1}, to those obtained in the conformational change from coil to β-structure in the presence of 7.0 mM SOS. The process may proceed without passing through α-helix, implying lack of destruction of α-helix.

The rate constants for three kinds of conformational changes of PLL in SOS solution seem to be low as compared with the reported values for conformational changes of polypeptides.[14] The difference is probably due to the characteristic situation in surfactant solutions as follows. The binding of SOS to PLL causes a discharge of the cationic groups of PLL, but the amount of bound SOS is not enough to discharge all of them. The surfactants are forced to move from the first binding sites to other vacant sites with the progress of conformational change of the polypeptide, since the bulky hydrophobic groups of surfactants should find minimal free energy in order to reconcile the structure formation with maximal contact between the hydrophobic groups of bound surfactants and the hydrophobic parts of the polypeptide. Such rearrangements of bound surfactants to the polypeptide require a much longer time in comparison with conformational change induced by proton which is more effective than the surfactant in reactivity and mobility because of its small size. The conformational change of polypeptide in the surfactant solution seems to occur accompanied by strong interaction.

(Received November 22, 1980)

Electronic structures of uracil and its anions were theoretically investigated by a modified CNDO-CI method. Theoretical results were in good agreement with the observed spectra of uracil and of both the uracil-3-ide and uracil-1-ide anions, indicating that the second π-π^* band of uracil may tentatively be assigned to the 215 nm band observed in circular dichroism spectrum, and that the lowest singlet and triplet states of uracil are n-π^* and π-π^* states, respectively, in accord with the observed solvent dependence on emission properties. The first π-π^* band of uracil-1-ide anion was correctly predicted by the method at longer wavelengths than the corresponding band of uracil-3-ide anion. For the purpose of comparison, a modified INDO-CI, CNDO/S-CI, and a modified π-SCF-MO-CI methods were also applied to the molecules under consideration. The results were only partly successful in predicting the observed spectra.

Electronic structures and spectra of pyrimidinic nucleic acid bases and their model compounds have been studied extensively from experimental and theoretical points of view.[1,2] As for uracil and thymine, electronic spectra were predicted less satisfactorily by the semi-empirical calculations[1-7] compared with the results for other pyrimidinic bases.[1,2,8] This is partly because the σ-core charge in atomic valence state usually taken to be an integral number in π-electron approximation changes significantly in the actual molecule by redistribution of σ-electrons over the whole molecule,[9] and is partly related to the unestablished band assignment concerning the 215 nm band observed in circular dichroism (CD) spectrum of uridine.[10]

The ordering of the lowest n-π^* and π-π^* states is important in understanding the photophysical properties of nucleic acid bases. Fluorescence and phosphorescence lifetimes and quantum yields of uracil and thymine were found to be largely affected by a variety of solvents.[11] The experimental results strongly suggested that in aprotic solvents the lowest singlet state is of highly forbidden character.[11] Theoretical investigation of the lowest excited state is necessary in order to interpret the photophysical properties of uracil.

Studies on the electronic structure of anionic species are few.[1,4,9,12] In aqueous alkaline solution, uracil exists as a mixture of two monoanionic species (*i.e.*, uracil-3-ide and uracil-1-ide anions) of comparable amounts.[1] The electronic spectra of these monoanions differ from each other, particularly in the nearest ultraviolet (UV) region.[13,14] The relative positions of the first π-π^* band of the anions could not be predicted correctly by the CNDO/S calculation.[9]

Under these circumstances, in order to interpret satisfactorily the experimental results, the electronic structures of uracil and of its anions have been investigated by a modified CNDO-CI method[15] by employing new semiempirical parameters for C, N, and O atoms. The calculated results have been compared with the observed results and also with the theoretical ones calculated by CNDO/S-CI method,[16] a modified INDO-CI method,[17] and a modified π-SCF-MO-CI method[9,18] which considers the effect of σ-core charge in the π-electron approximation.

Theoretical

Modified CNDO-CI Method. A modified CNDO-CI (mCNDO-CI) method[15] was applied by evaluating the two-center Coulomb repulsion integrals by Nishimoto-Mataga approximation.[19] To choose the best semiempirical parameters, various sets of the bonding parameters (β^0's) and one-center Coulomb repulsion integrals (γ_{AA}'s) which consider several atomic valence states of C, N, and O atoms were tested in the preliminary calculations of benzene, pyridine, pyrrole, aniline, formaldehyde, and phenol. Considering the agreement with the observed orbital sequences[21-25] and transition energies,[26-30] the semiempirical parameters listed in Table 1 were finally employed in the present paper. In the course of the preliminary calculations, it was found that the adoption of the Nishimoto-Mataga equation instead of the Klopman's equation[20] results in an SCF procedure that often converges very slowly and sometimes practically does not converge at all. Taking the one-center Coulomb repulsion integrals of σ-AO's to be equal to those of π-AO's, as in the case of CNDO/S method,[16] is in some cases necessary and in others effective in improving convergence of the SCF procedure. The parameters for N atom were mainly

Table 1. One-center Coulomb repulsion integral (γ_{AA}/eV) and bonding parameter (β_A°/eV)) for H, C, N, and O atoms used in the modified CNDO-CI method

	H	C		N		O

β_A°	−12.0	−16.8	−12.1	−23.2	−16.4	−31.4	−20.4

† Present address: Department of Image Science and Engineering, Faculty of Engineering, Chiba University, Chiba 260.

determined from the calculated result of pyridine. Somewhat different parameters for N atom are acceptable in pyrrole and aniline, but for simplicity of the following calculations the same set of the semi-empirical parameters were used for all the valence states of N atom.

The $(I+A)/2$ values needed for the evaluation of one-center core matrix elements,[15,31] $U_{\mu\mu}$, were taken to be the same as the original values[31] for C and N atoms, and for O atom to be 24.390 eV for the 2s AO and 8.111 eV for the $2p_x$, $2p_y$, and $2p_z$ AO's as in a previous paper.[15]

In the configuration interaction (CI) treatment, 40 singly excited π-π^* and σ-σ^* configurations, 23—25 singly excited π-σ^* configurations, and 20 singly excited n-π^* and σ-π^* configurations were taken into account.

Modified π-SCF-MO-CI (mPPP) Method. In order to avoid the problems which appear in the description of anionic forms of heterocyclic molecules within the original π-SCF-MO-CI (Pariser-Parr-Pople) method,[32,33] the modification in view of polarizable σ-core was introduced[9] in the evaluation of core integral, W_i, core potential, V_i, and resonance integrals, β_{ij}. The modified diagonal and off-diagonal elements[9,18,34] of the π-electron Hartree-Fock matrix are

$$F_{ii} = \left(1 + \kappa \frac{\delta Z_i}{Z_i}\right)[-I_i - (n_i - 1)\gamma_{ii}] + 1/2\, P_{ii}\gamma_{ii} + \sum_{j \neq i}\left[P_{jj} - \left(1 + \frac{\delta Z_j}{Z_j}\right) n_j\right]\gamma_{ji},$$

and

$$F_{ij} = \beta_{ij}\left[1 + 0.5\left(\frac{\delta Z_i}{Z_i} + \frac{\delta Z_j}{Z_j}\right)\right] - 1/2\, P_{ij}\gamma_{ij},$$

where Z_i is the formal core charge with integral number in the valence state of isolated atom, i, and δZ_i stands for the change of σ-charges introduced by redistribution of σ-electrons over the whole molecule. The symbol κ denotes the empirical "scaling" parameter which has been fixed[9] to be 0.85 in the present calculation.

A more precise expression for the diagonal element, F_{ii}, which includes penetration integrals shows that the expression for the one-center Coulomb integral for the difinite atom i (*i.e.*, from which a proton was removed) in the anionic species differs from that in the neutral species. The integral for atom i in the anion decreases mainly by the penetration integral between atom i and removed proton. For a series of hydroxy-pyridines,[34] the decrease of the integral for N atom was calculated to be of the order 2.7—3.1 eV. In the present calculation for the uracil anions, an average value of 3.0 eV was taken as the decrement of the integral for the N_3 or N_1 atom. This means that in the case of the anions, the ionization potential, I_i, for N_3 or N_1 atom was increased by 3.0 eV compared to the

value of I_i for the neutral molecule. The two-center Coulomb repulsion integrals were evaluated by the Nishimoto-Mataga equation. The other semiempirical parameters adopted in the present mPPP method are the same as used previously.[35,36] In the CI treatment, all the singly excited configurations were taken into account.

Molecular Structure. Considering the results of X-ray crystal analysis[37] and of theoretical calculation,[38] molecular structure of uracil was assumed as is shown in Fig. 1. The molecular structures of uracil-3-ide and uracil-1-ide anions were assumed to be the same as the one of the neutral molecule, except that one proton bonded to N_3 and N_1 atoms, respectively, was removed.

Results and Discussion

The electronic structures of uracil calculated by mCNDO-CI, CNDO/S-CI, INDO-CI, and mPPP methods are presented in Table 2. Comparison of the result calculated by mCNDO-CI method with the observed spectrum in the vapor phase[39] and with the CD spectrum[10] strongly suggests that the first, third, and fourth π-π^* states predicted at 5.28, 6.17, and 6.59 eV, respectively, can be assigned to the 244 nm (5.08 eV), 205 nm (6.05 eV), and 187 nm (6.63 eV) bands in the vapor phase,[39] respectively. The weak second π-π^* band predicted at 5.95 eV may correspond to the 215 nm (5.77 eV) band in the CD spectrum.[10]

As tabulated in Table 2, INDO-CI and mPPP methods predict that the transition energies for π-π^* states agree semiquantitatively well with the result by mCNDO-CI method, but the transition intensity to the second π-π^* state is not weak. CNDO/S-CI method, on the other hand, predicts the second π-π^* band being weak, although the calculated transition energies for π-π^* states are high. The theoretical result presented by only one of the above three methods is not conclusive to support any assignments of the spectrum (see Ref. 1 for more detailed discussion of the excited states of uracil), bu they altogether suggest that the assignment based on mCNDO-CI method mentioned above is a plausible one for uracil.

The ordering of the lowest π-π^* and n-π^* states is important to understand the photophysical properties of pyrimidine bases.[11] In mCNDO-CI method, calculated transition energies for n-π^*, σ-π^*, and π-σ^* states correspond to those of the triplet manifold.[15] Preliminary calculation of formaldehyde by mCNDO-CI method has shown that the calculated transition energy (2.31 eV) of the lowest n-π^* triplet state is $\approx$0.7 eV lower than the observed value (3.0 eV).[40] Considering this underestimation of transition energy of the n-π^* triplet state, nearly degenerate n-π^* and π-π^* triplet states of uracil predicted at $\approx$2.8 eV by mCNDO-CI method can be ordered as the π-π^* state being the lowest triplet in agreement with the suggestion by Becker *et al.*[11] The singlet-triplet separation of n-π^* state is expected to be $\approx$1 eV or less. In the singlet manifold, the n-π^* state is predicted to be lower than the first π-π^* state. This agrees with the prediction based on fluorescence lifetime measurement.[11]

In Table 3, the orbital energies calculated by mCNDO method are compared with the observed and theoretical values reported previously.[41,42] The predicted order of the occupied molecular orbitals, $\pi > n > \pi > n > \pi$, is in

good agreement with the result by photoelectron spectroscopy.[41,42]

The dipole moment of the ground state calculated by mCNDO method is 4.60 Debye,** in agreement with the observed value (4.16 Debye in dioxane).[43]

Tables 4 and 5 present the calculated results for uracil-3-ide and uracil-1-ide anions, respectively. As can be seen from the tables, the agreement between the observed[13,14] and predicted values for uracil-1-ide anion is satisfactory by all the methods presented here, but the spectrum of uracil-3-ide anion[13,14] can be predicted satisfactorily only by mCNDO-CI method. It is worth noting that the first π-π^* band of uracil-1-ide anion is correctly predicted at longer wavelengths than the corresponding band of uracil-3-ide anion only by mCNDO-CI and mPPP methods. CNDO/S-CI method as well as INDO-CI method failed to predict the first π-π^* band position of uracil-3-ide anion. Very recent calculation using CNDO/S-CI method[4] has predicted correctly the absorption band positions of both monoanions of uracil; however the authors have not described the details of the parametrization of the method.

This work was initiated during the stay of J.S.K. at the Institute for Solid State Physics, the University of Tokyo. J.S.K. wishes to thank the Japan Society for the Promotion of Sciences for support of his stay in Japan. This work was also supported in part by the Polish Academy of Sciences within the project 09.7. The authors wish to express their thanks to Professor Saburo Nagakura, the University of Tokyo, for valuable discussions, and to Dr. J. Lipiński, Technical University, Wrocław, Poland, for calculation of the spectra of uracil and its monoanions by means of his modified INDO-CI method.

The Structure of Liquid Water by Neutron Scattering

Norio Ohtomo,† Kazuo Tokiwano,† and Kiyoshi Arakawa*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

†*Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received January 9, 1981)

A comprehensive analysis of the structure of liquid water was performed by combining neutron and X-ray diffraction data. A formula expressing the structure factor of fluids composed of small molecular clusters was obtained and applied to the analysis. In the interpretation of the diffraction data, the tetrahedral pentamer model as an aggregate of the regular tetrahedral pentamers is considered to be the best structure model of liquid water from the excellent agreement between calculated structure factors and experimental data. Some critical discussions about other structure models were made.

Recent diffraction studies of liquid water have brought much valuable information on the structure of the liquid. Among them, the followings are distinguishable: X-ray diffraction studies by Narten and Levy[1] and Hajdu *et al.*,[2] electron diffraction studies by Kálmán *et al.*,[3] and neutron diffraction studies by Page and Powles,[4] Narten[5] and the authors.[6,7] However, the conclusions drawn from the diffraction results by these workers are found to be contradictory to each other. The most important reason for the circumstances is, of course, the "complexity" of the liquid structure of water and the lack of the reasonable general method of analysis for diffraction data by liquids. At the present stage of the development of studies in this field, the combined and comprehensive interpretation of diffraction results[8] is strongly required.

Concerning the X-ray studies, observed intensity data agree well with each other in the low Q range (<5 Å^{-1}), though, for large Q, marked discrepancies are found there, for example, between the data reported by Hajdu *et al.*[2] and that by Narten *et al.*[1,9] In addition, the proposed structure models in those papers are considered to have implausible aspects in several respects: Hajdu's model consists of a fundamentally anisotropic nearest neighbor arrangement of water molecules[10] and Narten's earlier model ("interstitial model") in 1967[9] has a "largely extended lattice structure."

With respect to the neutron studies, the observed structure factors are found to agree virtually with each other, taking the differences of the experimental method into consideration.[6,7] However, the conclusions on the structure model of water are largely inconsistent with each other.[4-6] The authors mentioned earlier the cause of the marked discrepancies.[6,7] It has turned out that Narten's "near-neighbor model" is physically unacceptable and also that Page and Powles' conclusion disproving all the structure models treated is too severe. We analyzed the neutron data using a "revised watery model," which is a modification of Page and Powles' "watery model." However, the agreement between calculated and experimental structure factors was still insufficient.[6,7]

Despite these incompatible results, it has become certain through those recent X-ray and neutron diffraction studies that the most dominant local environment of a water molecule within liquid water is nearly tetrahedral on the average. Furthermore, a large amount of information accumulated so far by various experimental[11] and theoretical studies[12-15] have also ascertained the fact. However, further knowledge on the nearest neighbor coordination shell remains quite undetermined. Concerning the nearest neighbor coordination number, for example, it has been believed to be slightly larger than 4 since the pioneering study by Morgan and Warren, while according to the recent study by Hajdu *et al.*, it is smaller than 4, though slightly.

The major reason for the existence of those contradictory circumstances stated here is supposed to be attributed to the inadequacy of the method of analysis as well as to the experimental difficulties. Thus, we have attempted to perform a combined analysis of the neutron and X-ray diffraction data from various sources including our own, and then to propose a structure model of liquid water. The main purpose of our present analysis is the direct confirmation of the basic structural entities by the combined interpretation of neutron and X-ray diffraction data through the presentation of a new method of analysis. Though the number of the nearest neighbor coordination is believed to be nearly equal to 4, it is not sure whether the average configuration of the nearest neighbor molecules is regular-tetrahedral or not. In another word, it is still a central problem whether the regular tetrahedral pentamer is the primary entity (of course, on the average) or not. This is the most important point as the object of debate with respect to the structure model of liquid water. The details of the present analysis are written in the following.

Neutron and X-Ray Diffraction Data

For the present purpose, we used the X-ray diffraction data of Narten *et al.*[1,9] and of Hajdu *et al.*[2] As to the neutron diffraction our own data was used.

Neutron Diffraction Data. In addition to the structure factor $S_m(Q)$ data in the low Q region (<10 Å^{-1}),[6,7] the factors in the higher Q region (<25 Å^{-1}) were obtained by LINAC-TOF neutron diffraction method.[16] Details of the experimental apparatus have been stated in the preceding papers together with the correction and calibration procedures.[6,7,16] The neutron structure factor $S_m(Q)$ over a wide range of Q (1—25 Å^{-1}) obtained by combining the low Q data with the higher Q data,[17] are shown in Fig. 1. The $S_m(Q)$ data in the low Q region, 1—8 Å^{-1}, agree well with those reported previously, though the slight differences of a main peak at 2 Å^{-1} and a broader

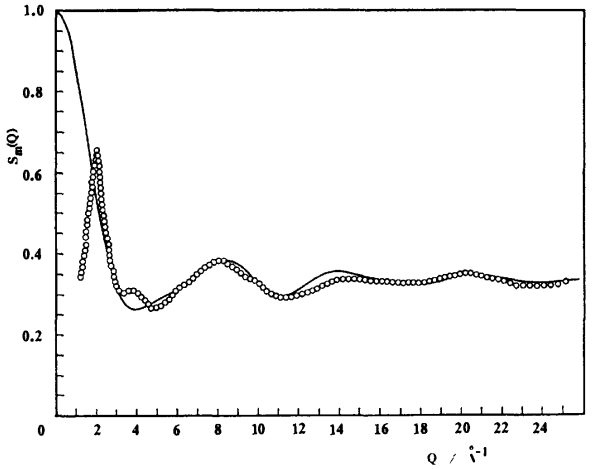

Fig. 1. Observed neutron structure factors $S_m(Q)$ for heavy water at room temperature (15 ± 1 °C), compared with the calculated intramolecular structure factor $S_m^{(1)}(Q)$.
○: $S_m(Q)$ observed ——: $S_m^{(1)}(Q)$ calculated (r_{OD}= 0.98 Å, r_{DD}=1.60 Å, and DOD angle=109.5°).

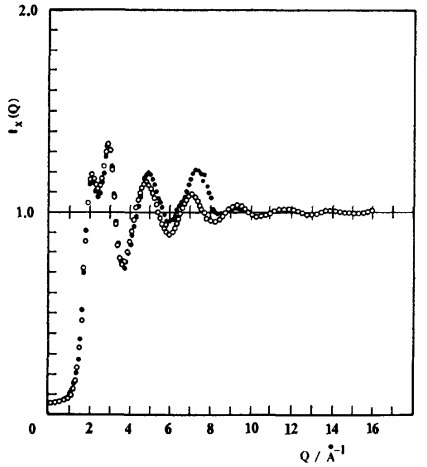

Fig. 2. Observed X-ray intensity function $I_x(Q)$.
○: $I_x(Q)$ by Narten *et al.* (20 °C),[1,9] ●: $I_x(Q)$ by Hajdu *et al.* (25 °C).[2]

peak at *ca.* 8 Å^{-1} are observed.[6,7] It is noticeable that the $S_m(Q)$ data for D_2O obtained by the authors at LINAC are found to agree virtually with Page and Powles' and Narten' data at reactor, taking the experimental uncertainities as well as the small difference in temperature into consideration. The reproducibility of the neutron data in the low Q region is thus confirmed with sufficient accuracy.

X-Ray Diffraction Data. Many X-ray diffraction data of liquid water have been reported. Among them, the data of Narten *et al.*[1,9] and those of Hajdu *et al.*[2] are available for the present purpose. "Molecular" modified intensity functions given in those papers are shown in Fig. 2. The two data are found in good agreement with each other in the low Q range, though marked discrepancies are observed in the higher Q range ($Q\gtrsim5$ Å^{-1}).

Theoretical Procedures of Analysis

Coherent Neutron Structure Factor. The coherent neutron scattering cross-section $(d\sigma/d\Omega)_{coh}$ is given in the static approximation by

$$\left(\frac{d\sigma}{d\Omega}\right)_{coh} = N_m\Sigma^2 S_m(Q), \quad (1)$$

where $\Sigma=\sum_n b_n$. Equation 1 defines the coherent neutron structure factor $S_m(Q)$ for molecular liquid.[4] N_m is the number of molecules in the sample and b_n the scattering length of nucleus n. $\sum$ is over all the nuclei in the molecule. $\vec{Q}(=\vec{k}_0-\vec{k}_s)$ is the scattering vector and $|\vec{Q}|=Q=(4\pi/\lambda)\sin\theta$, where $\vec{k}_0$ and $\vec{k}_s$ are the incident and scattered wave vectors, respectively.

In this study we attempt to determine the best structure model of water for the interpretation of its diffraction data. For that purpose, we will give here a general expression of $S_m(Q)$ for liquid which can be regarded as an aggregate of small clusters composed of molecules. The derivation of the $S_m(Q)$ is as in the following.

Structure Factor $S_m(Q)$ for Fluids Composed of Molecular Clusters. The coherent neutron structure factor $S_m(Q)$ in Eq. 1 is given in general by

$$S_m(Q) = N_m^{-1}\Sigma^{-2}\langle\sum_{i\neq j}\sum_{n_i,n_j} b_{n_i}b_{n_j}\exp(i\vec{Q}\cdot\vec{r}_{n_in_j})\rangle, \quad (2)$$

where i and j label molecules in a liquid and n_i denotes the n-th nucleus in the molecule i. $\vec{r}_{n_in_j}$ is the vector distance between the nuclei n_i and n_j, and b_{n_i} the scattering length of nucleus n_i. We sum over all the scatterers in the N_m molecules in the system.

Then, in the right hand side of Eq. 2, the separation of the contribution of atom-pair interactions within the clusters from the "inter-cluster" contribution is permitted in general, because a liquid can always be regarded virtually as an aggregate of small clusters of various sizes. We have

$$S_m(Q) = f_1^c(Q) + N_m^{-1}\Sigma^{-2}\langle\sum_{\alpha\neq\beta}\sum_{l_\alpha,l_\beta}\sum_{n_{l_\alpha},n_{l_\beta}} b_{n_{l_\alpha}}b_{n_{l_\beta}}\exp(i\vec{Q}\cdot\vec{r}_{n_{l_\alpha}n_{l_\beta}})\rangle \quad (3)$$

and

$$f_1^c(Q) = N_m^{-1}\Sigma^{-2}\langle\sum_{\alpha}\sum_{l_\alpha,l'_\alpha}\sum_{n_{l_\alpha},n_{l'_\alpha}} b_{n_{l_\alpha}}b_{n_{l'_\alpha}}\exp(i\vec{Q}\cdot\vec{r}_{n_{l_\alpha}n_{l'_\alpha}})\rangle, \quad (4)$$

where l and l′ label molecules within a given cluster, and l_α denotes the l-th molecule in the cluster α. The transformation of Eq. 2 to Eq. 3 is only mathematical and it should be noted that the two equations are physically identical.

Let us use $\vec{r}_{c_{l_\alpha}l_\beta}$ to denote the vector distance from the center of the molecule l_α to that of the molecule l_β. Since $\vec{r}_{n_{l_\alpha}n_{l_\beta}}=\vec{r}_{c_{l_\alpha}l_\beta}-\vec{r}_{cn_{l_\alpha}}+\vec{r}_{cn_{l_\beta}}$ where $\vec{r}_{cn_{l_\alpha}}$ is the vector distance from the center of the molecule l_α to its n-th nucleus within the cluster α, Eq. 3 is written as

$$S_m(Q) = f_1^c(Q) + N_m^{-1}\Sigma^{-2}\langle\sum_{\alpha\neq\beta}\sum_{l_\alpha,l_\beta}\exp(i\vec{Q}\cdot\vec{r}_{c_{l_\alpha}l_\beta}) \times\sum_{n_{l_\alpha},n_{l_\beta}} b_{n_{l_\alpha}}b_{n_{l_\beta}}\exp[i\vec{Q}\cdot(-\vec{r}_{cn_{l_\alpha}}+\vec{r}_{cn_{l_\beta}})]\rangle. \quad (5)$$

Equation 5 is quite general, and we now consider

the case of a system consisting of identical clusters, each of which is composed of N_c molecules. Further, we assume that $\vec{r}_{cn|\alpha}$, $\vec{r}_{cn|\beta}$, and $\vec{r}_{cl\alpha|l\beta}$ are all stasistically independent. That is, the molecules belonging to different clusters are assumed to be orientationally-uncorrelated. Then, Eq. 5 becomes

$$\begin{aligned} S_m(Q) &= f_I^c(Q) + N_m^{-1}\Sigma^{-2}\langle\sum_{\alpha\neq\beta}\sum_{l\alpha,l\beta}\exp(i\vec{Q}\cdot\vec{r}_{cl\alpha|l\beta})\rangle \\ &\times[\sum_n b_n\langle\exp(i\vec{Q}\cdot\vec{r}_{cn})\rangle]^2, \\ &= f_I^c(Q) + \Sigma^{-2}[\sum_n b_n\langle\exp(i\vec{Q}\cdot\vec{r}_{cn})\rangle]^2 N_m^{-1} \\ &\times[\langle\sum_{I\neq J}\exp(i\vec{Q}\cdot\vec{r}_{cIJ})\rangle \\ &-\frac{N_m}{N_c}\langle\sum_{I\neq I'}\exp(i\vec{Q}\cdot\vec{r}_{cII'})\rangle], \end{aligned} \tag{6}$$

where $\vec{r}_{cn}$ is the vector distance from the center of a molecule to its n-th nucleus.

Thus, we can write the $S_m(Q)$ as in the form,

$$S_m(Q) = f_I^c(Q) + f_{2U}(Q)[S_C(Q) - f_3(Q) - 1], \tag{7}$$

$$f_I^c(Q) = \Sigma^{-2}N_c^{-1}\langle\sum_{I,I'}\sum_{n_I,n_{I'}} b_{n_I}b_{n_{I'}}\exp(i\vec{Q}\cdot\vec{r}_{n_In_{I'}})\rangle, \tag{8}$$

$$f_{2U}(Q) = \Sigma^{-2}[\sum_n b_n\langle\exp(i\vec{Q}\cdot\vec{r}_{cn})\rangle]^2, \tag{9}$$

$$S_C(Q) = 1 + N_m^{-1}\langle\sum_{I\neq J}\exp(i\vec{Q}\cdot\vec{r}_{cIJ})\rangle, \tag{10}$$

and

$$f_3(Q) = N_c^{-1}\langle\sum_{I\neq I'}\exp(i\vec{Q}\cdot\vec{r}_{cII'})\rangle, \tag{11}$$

where $f_I^c(Q)$ is the contribution of atom-pairs within the cluster, $S_C(Q)$ the molecular-centers structure factor of the liquid, $f_3(Q)$ a factor resulting from the molecular-center pairs within the cluster, and $f_{2U}(Q)$ a factor resulting from the completely uncorrelated orientational configuration between molecules.

In the following of this section the formula for the analysis of diffraction data will be given according to the theoretical procedure described above to examine structure models of liquid water.

Regular Tetrahedral Pentamer Model. We will give here the $S_m(Q)$ for the regular tetrahedral pentamer model where the structural unit as the basic entity of liquid water is the regular tetrahedral pentamer. In the model water is considered to be an aggregate of the pentamers on the average which are packed to give the density of 1 g/cm³. The central oxygen atom in the pentamer is tetrahedrally surrounded by four oxygen atoms at the corners of a regular tetrahedron, each pair of the central and peripheral oxygens being connected by a straight hydrogen bond (Fig. 3).

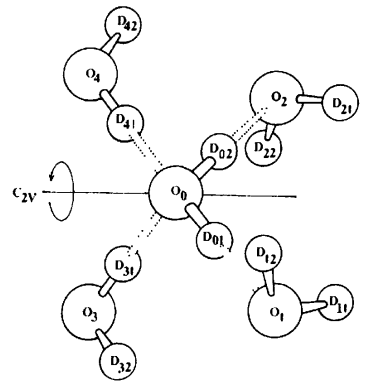

Fig. 3. The structure of the regular tetrahedral pentamer model with the C_{2v} symmetrical coordination. O_m indicates oxygen in the m-th molecule with the pentamer and D_{mn} the n-th deuteron in the m-th molecule. The dotted line denotes the hydrogen bond.

In this case, Eq. 7 becomes

$$S_m(Q) = S_m^p(Q) + f_{2U}(Q)[\{S_C(Q) - S_{m.p}^{(OO)}(Q)\} - 1], \tag{12}$$

where the intra-pentamer contribution $S_m^p(Q)(\equiv f_I^c(Q))$ is[18]

$$\begin{aligned} S_m^p(Q) &= S_m^{(1)}(Q) + 0.092S_{m.p}^{(OO)}(Q) + 0.422S_{m.p}^{(OD)}(Q) \\ &+ 0.486S_{m.p}^{(DD)}(Q), \end{aligned} \tag{13}$$

and

$$f_{2U}(Q) = \Sigma^{-2}[b_O + 2b_D Y_{OD}(Q)]^2. \tag{14}$$

$S_m^{(1)}(Q)$ is the intramolecular contribution and the $S_{m.p}^{(OO)}(Q)$ ($\equiv f_3(Q)$[19]), $S_{m.p}^{(OD)}(Q)$, and $S_{m.p}^{(DD)}(Q)$ are the intra-pentamer part of the contributions of the O–O, O–D, and D–D pairs, respectively. $Y_{nn'}(Q) = j_0(Qr_{nn'})\exp(-\gamma_{nn'}Q^2)$, where $j_0(\chi) = \sin\chi/\chi$, $r_{nn'}$ is the distance between the n-th and n'-th nuclei, and $2\gamma_{nn'}$ the mean-square variation to the distance $r_{nn'}$. Thus, we can calculate the $S_m(Q)$ by using Eq. 12. Each term in Eqs. 12 and 13 will be specified in the following.

The $S_m^{(1)}(Q)$ for heavy water molecules is

$$S_m^{(1)}(Q) = \Sigma^{-2}[b_O^2 + 2b_D^2 + 4b_O b_D Y_{OD}(Q) + 2b_D^2 Y_{DD}(Q)]. \tag{15}$$

For the regular tetrahedral pentamer model as shown in Fig. 3 the $S_{m.p}^{(OO)}(Q)$ becomes

$$S_{m.p}^{(OO)}(Q) = \frac{4}{5}[2Y_{OO}(Q) + 3Y_{O_1O_1}(Q)]. \tag{16}$$

In order to obtain the expression of the $S_{m.p}^{(OD)}(Q)$ and $S_{m.p}^{(DD)}(Q)$, we consider two extreme cases with respect to the orientation of the peripheral molecules within the pentamer: the one orientation where deuterium atoms of those molecules are located in the positions of the C_{2v} symmetry (Fig. 3) and the other orientation where the peripheral molecules are rotating freely around the axis on a straight line joining the central and peripheral oxygens.

Thus, for the C_{2v} symmetry cluster the contributions of the intra-pentamer O–D and D–D pairs, $S_{m.p}^{(OD)}(Q)$ and $S_{m.p}^{(DD)}(Q)$, become

$$\begin{aligned} S_{m.p}^{(OD)}(Q) &= \frac{1}{5}[2Y_{O_1D_{II}}(Q) + 3\{Y_{O_1D_{I}}(Q) + Y_{O_1D_{II}}(Q)\} \\ &+ 6\{Y_{O_ID_{II}}(Q) + Y_{O_ID_{II}}(Q)\}] \end{aligned} \tag{17}$$

and

$$\begin{aligned} S_{m.p}^{(DD)}(Q) = \frac{1}{5}\Big[&\frac{1}{2}\{Y_{D_{I}D_{II}}(Q) + Y_{D_{II}D_{II}}(Q)\} \\ &+ Y_{D_{I}D_{II}}(Q) + Y_{D_{II}D_{II}}(Q) + Y_{D_{II}D_{II}}(Q) \\ &+ 2\{Y_{D_{I}D_{II}}(Q) + Y_{D_{II}D_{II}}(Q)\} \\ &+ 4\{Y_{D_{I}D_{II}}(Q) + Y_{D_{II}D_{II}}(Q) + Y_{D_{II}D_{II}}(Q)\}\Big], \end{aligned} \tag{18}$$

respectively. For the model with freely rotating peripheral molecules, we assumed that the positions of six deuterons at a larger distance within the peripheral molecules are reduced approximately to the positions

of peripheral oxygens on the average. Then, the $S^{(OD)}_{m,p}(Q)$ and $S^{(DD)}_{m,p}(Q)$ can be written as

$$S^{(OD)}_{m,p}(Q) = \frac{1}{5}[2Y_{O,D_{II}}(Q)+3Y_{O,D_{II}}(Q)+6Y_{O,D_{II}}(Q) + 9Y_{O,O_{I}}(Q)] \quad (19)$$

and

$$S^{(DD)}_{m,p}(Q) = \frac{1}{10}[Y_{D_{I},D_{II}}(Q)+8Y_{O,D_{II}}(Q)+10Y_{O,D_{II}}(Q) + 3Y_{O,O_{I}}(Q)], \quad (20)$$

respectively.

Finally, for the $S_C(Q)$ required in the calculation of the inter-pentamer contribution (the second term in the right hand side of Eq. 12), we can use the observed X-ray intensity data assuming the molecular center to be at the oxygen nucleus.

Interpretation of Experimental Data

We calculated first the total neutron structure factor $S_m(Q)$ for the tetrahedral pentamer model using Eqs. 12—20, compared the calculated curves with the experimental data.

Calculation of the $S^p_m(Q)$. The intra-pentamer contribution $S^p_m(Q)$ (the first term of Eq. 12) was calculated by using Eq. 15 together with Eqs. 16—20, and the curves obtained at each stage of the calculations were compared with the corresponding experimental data.

The intramolecular contribution $S^{(1)}_m(Q)$ calculated by use of Eq. 15 are shown in Fig. 4 for four possible cases assumed for the intramolecular structure: (1) the intramolecular oxygen-to-deuteron distance $r_{OD}=0.96$ Å and the deuteron-to-deuteron distance $r_{DD}=1.52$ Å, corresponding to the molecule in the vapor when all the DOD angle is 104.5°, (2) $r_{OD}=1.01$ Å and $r_{DD}=1.65$ Å, corresponding to the molecule in heavy ice-I when all the DOD angle is 109.5°, (3) the earlier "revised watery model,"[6,7,16] and (4) the equally weighted average values, $r_{OD}=0.98$ Å and $r_{DD}=1.60$ Å, when all the DOD angle is taken to be 109.5°. The $S^{(1)}_m(Q)$ calculated for the case (3) is found to be quite identical with that for the case (4) over all range of Q. For the calculated curves (Fig. 4) in comparison with the observed data (Fig. 1), the best fit curve with observed $S_m(Q)$ for the larger Q region ($Q \gtrsim 6$ Å^{-1}) is obtained in the cases (3) and (4). The calculated $S^{(1)}_m(Q)$ curve for the case (4) is indicated in Fig. 1. Then, in the analysis of diffraction data in the following sections, we shall use the values of the case (4) for intramolecular parameters.

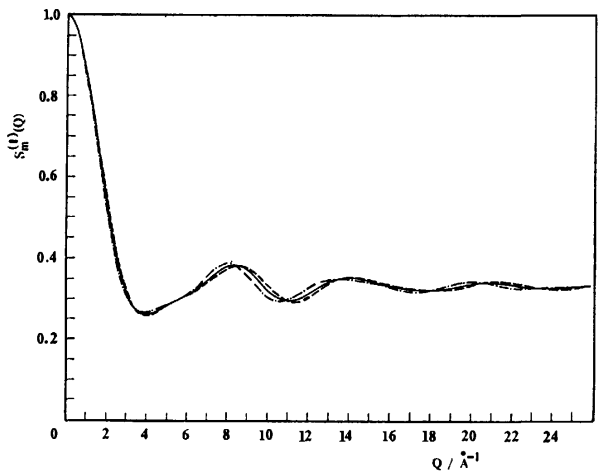

Fig. 4. Calculated intramolecular structure factor $S^{(1)}_m(Q)$ for heavy water.
——: $S^{(1)}_m(Q)$ for the averaged intramolecular parameters ($r_{OD}=0.98$ Å, $r_{DD}=1.60$ Å, and DOD angle=109.5°) and that for the revised watery model,[6,7] ($\varepsilon=0.0047$), ------: $S^{(1)}_m(Q)$ for the vapor molecule ($r_{OD}=0.96$ Å, $r_{DD}=1.52$ Å, and DOD angle=104.5°), ($\varepsilon=0.0057$), -·-·-: $S^{(1)}_m(Q)$ for the heavy ice-I molecule ($r_{OD}=1.01$ Å, $r_{DD}=1.65$ Å, and DOD angle=109.5°), ($\varepsilon=0.0061$). ε is a measure for indicating the deviations of $S^{(1)}_m(Q)$ from the experimental data, and it is expressed as[16]

$$\varepsilon = \{\sum_{i=1}^{N}[S_m(Q_i)_{obsd} - S^{(1)}_m(Q_i)^2]\}^{1/2}/\sum_{i=1}^{N}[S_m(Q_i)_{obsd}],$$

where N is the number of data points in the fitting range of Q, 8—25 Å^{-1}.

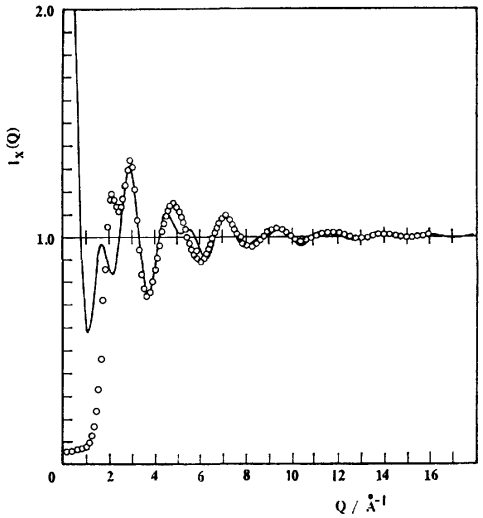

Fig. 5. The comparison between the calculated $[1+S^{(oo)}_{m,p}(Q)]$ and the observed X-ray intensity function $I_x(Q)$.
○: Observed $I_x(Q)$ by Narten *et al.*,[1,9] ——: calculated $[1+S^{(oo)}_{m,p}(Q)]$ for the regular tetrahedral pentamer model.

The $S^{(oo)}_{m,p}(Q)$ was calculated by using Eq. 16. The value of distance r_{oo} for the hydrogen-bonded O–D···O was taken to be 2.85 Å from various sources,[1,2,5,9,12,15,20,21] and the O-O-O angle was taken to be the tetrahedral angle (109.5°). The factor $S^{(oo)}_{m,p}(Q)$ is also known from X-ray diffraction. The X-ray diffraction pattern is almost completely determined by oxygen-oxygen pairs only. Then, the calculated values of $[1+S^{(oo)}_{m,p}(Q)]$ for the model proposed can be compared with the X-ray data. The function $[1+S^{(oo)}_{m,p}(Q)]$ calculated from Eq. 16 is shown in Fig. 5 together with the total experimental data. The calculated curve is in agreement with the data of Narten *et al.* on the whole, except for the deviation in the first peak at 2.1 Å^{-1} and that in the range of $Q=4.5$—6 Å^{-1}. The main contribution

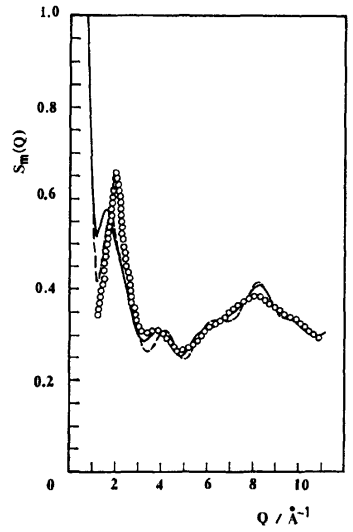

Fig. 6. The comparison between the calculated $S_m^P(Q)$ for the regular tetrahedral pentamer model and the observed neutron structure factor $S_m(Q)$.
○: Observed $S_m(Q)$, ——: calculated $S_m^P(Q)$ for the C_{2v} symmetry structure, ------: calculated $S_m^P(Q)$ for the freely rotating structure.

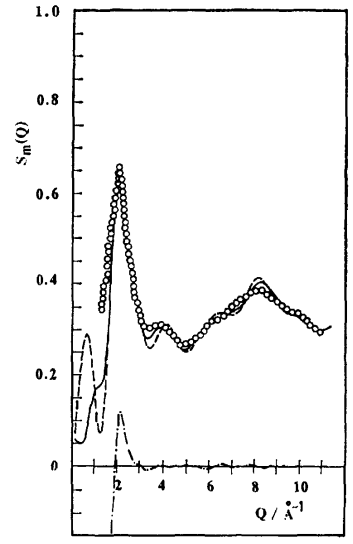

Fig. 7. The comparison between the calculated $S_m(Q)$ for the regular tetrahedral pentamer model and the observed neutron structure factor $S_m(Q)$.
○: Observed $S_m(Q)$, ——: calculated $S_m(Q)$ for the C_{2v} symmetry structure, ------: calculated $S_m(Q)$ for the freely rotating structure, -·-·-: $f_{2U}(Q)$-$[S_C(Q)-S_{m,p}^{(oo)}(Q)-1]$.

to the diffraction data at low Q region ($Q \lesssim 2$ Å^{-1}) comes from the long range interactions of molecules and so the contribution from the interaction pairs between pentamers is expected to recover the deviation of the first peak. Then, the result of the analysis of X-ray data suggests the essential effectiveness of the regular tetrahedral pentamer model.

In order to obtain the $S_m^P(Q)$, the calculation of $S_{m,p}^{(OD)}(Q)$ and $S_{m,p}^{(DD)}(Q)$ as the intra-pentamer contribution is required further, and we performed it for the C_{2v} symmetry model by using Eqs. 17 and 18, and also for the freely rotating model by using Eqs. 19 and 20. The $S_m^P(Q)$ thus obtained are shown in Fig. 6 together with the total experimental data. As clearly seen in Fig. 6, the curve for the freely rotating model is slightly deviated from that for the C_{2v} symmetry model, but, except for the first peak region ($Q \lesssim 3$ Å^{-1}) which is attributed to the long range (inter-pentamer) interactions of molecules, the agreement between the two calculated $S_m^P(Q)$ curves and the experimental data is essentially satisfactory. The comparison between the calculated $S_m^P(Q)$ and the observed total $S_m(Q)$ shows that the structure factor of liquid water is well-reproduced by the $S_m^P(Q)$ only except for the lower Q region ($Q \lesssim 3$ Å^{-1}), that is, $S_m(Q) \simeq S_m^P(Q)$ for $Q \gtrsim 3$ Å^{-1}.

Calculation of the Total Structure Factor $S_m(Q)$.
In the calculated values shown in Figs. 5 and 6 the contribution from the inter-pentamer atomic pairs (the second term in Eq. 12) is not contained. In order to estimate that contribution, we calculated the second term $f_{2U}(Q)[S_C(Q) - S_{m,p}^{(oo)}(Q) - 1]$ using Eqs. 14 and 16 for the $f_{2U}(Q)$ and $S_{m,p}^{(oo)}(Q)$ together with the observed X-ray intensity data for the $S_c(Q)$. Its values are shown in Fig. 7 as a dash-dot line. As seen in Fig. 7, the inter-cluster term contributes only in the lower Q region, $Q \lesssim 3$ Å^{-1}.

The total $S_m(Q)$ curves thus calculated as the sum of all terms described in the preceding items by using Eq. 12 together with Eqs. 13—20 for the two orientational arrangements (the C_{2v} symmetry model and the freely rotating model) are shown in Fig. 7 in comparison with the observed $S_m(Q)$. The agreements between the calculated curves and the scattering data are excellent on the whole, though the detailed shape of $S_m(Q)$ is less well-reproduced for the freely rotating model compared with the C_{2v} model. The result suggests that the extent of orientational correlation of liquid water lies between these two extremes.

We see that the behavior of the curve near 4 Å^{-1} is essential for the adequacy of the model as stated in Page and Powles' paper.[4] From this point of view, it is noticeable that the agreement with respect to the bump at *ca.* 4 Å^{-1} is achieved satisfactorily without any adjustable parameters. Especially, in addition to this agreement concerning the bump at *ca.* 4 Å^{-1}, the excellent agreement with respect to the first peak justifies the assumption that liquid water is composed of the aggregate of the regular tetrahedral pentamers on the average. Thus, we can conclude from the present result that the regular tetrahedral pentamer model is considered to be one of the best structure models of liquid water.

Discussion

Comparison with the Page and Powles' Analysis.[4]
Page and Powles' analysis of the neutron diffraction data of liquid heavy water has a marked feature in which the orientational correlation between molecules is separated from the positional one between molecular centers. This separation is exact when there is no orientational correlation for any intermolecular distances

(the completely uncorrelated orientation model), and then, the structure factor $S_m(Q)$ becomes

$$S_m(Q) = f_1(Q) + f_{2U}(Q)[S_C(Q) - 1], \quad (21)$$

where

$$f_1(Q) = \Sigma^{-2}\langle|\sum_n b_n \exp(i\vec{Q}\cdot\vec{r}_{cn})|^2\rangle. \quad (22)$$

$f_1(Q)$ is identical with $S^m_{(1)}(Q)$ in the present paper. On the other hand, Eq. 12 is rewritten as follows,

$$S_m(Q) = S^{(1)}_m(Q) + f_{2U}(Q)[S_C(Q) - 1] + [S^p_m(Q) - S^{(1)}_m(Q) - f_{2U}(Q)S^{(00)}_{m,p}(Q)]. \quad (23)$$

The third term in Eq. 23 clearly originates from the orientational correlation of molecules within the clusters (see Appendix).

From the comparison of Eq. 23 with Eq. 21, the feature of our present analysis can be understood. The most important point is the presence of additional terms in Eq. 23 resulting from the pentamer structure. The terms vanish for the completely-uncorrelated orientation model and then Eq. 23 reduces to Eq. 21.

In another extreme of Page and Powles' treatment, that is, for the completely-correlated orientation model (Eq. 7 in Ref. 4), the $S_m(Q)$ was expressed as

$$S_m(Q) = f_1(Q) + f_{2C}(Q)[S_C(Q) - 1]. \quad (24)$$

The orientational correlation between molecules was introduced through the replacement of $f_{2U}(Q)$ by $f_{2C}(Q)$. This is compared with the feature in our model that the third term in Eq. 23 expresses directly the correlated-orientation effect between molecules within clusters. Page and Powles' assumption of complete correlated orientation which is independent of the distance apart is, however, too severe in principle. In the analysis carried out by Page and Powles, they could not succeed to reproduce the bump at 4 Å^{-1} in the $S_m(Q)$ curve calculated, and they rejected all the model treated in their paper. The most important reason for their failure is considered to lie in their procedure of analysis.

Interstitial Model. We examine the "interstitial model," which consists of the regular tetrahedral pentamers and non-hydrogen-bonded monomers, where the positions of its monomer oxygens are restricted to the four triad axes of the regular tetrahedron formed by pentamer oxygens. Then, one tetrahedral pentamer plus N_i monomers ($N_i \lesssim 4$) is regarded as the basic structure unit of this model.

The X-ray intensity function $I^{in}_x(Q)$ which corresponds to $[1 + f_3(Q)]$ in Eq. 7 becomes

$$I^{in}_x(Q) = 1 + S^{(00)}_{m,p}(Q) + \frac{1}{(N_c + N_i)}[2(N_i - 1)Y_{O_iO_i}(Q) + 2N_i\{Y_{O_iO_c}(Q) + Y_{O_iO_c}(Q) + Y_{O_iO_c}(Q)\}], \quad [N_i = 1, 2, 3, \text{and } 4] \quad (25)$$

where N_c is the number of molecules within a cluster, being taken to be 5 for the pentamer. O_i denotes the oxygen atom of the interstitial molecules. The number of interstitial molecules N_i per pentamer is considered to be not larger than one practically.[11,22] Then, for the present purposes, it is sufficient for us to take into consideration the following two cases only: $N_i = 1$ and 2. The calculated $I^{in}_x(Q)$ curves are shown in Fig. 8 in comparison with the experimental data. The two

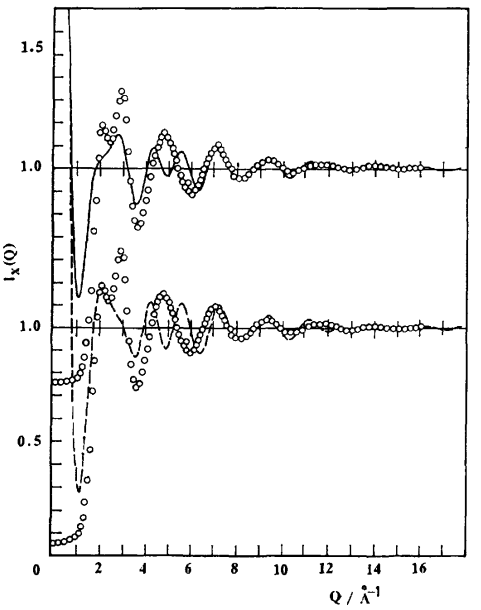

Fig. 8. The comparison between the calculated $I^{in}_x(Q)$ for the interstitial model with variation of the number of interstitial molecules N_i and the observed X-ray intensity function $I_x(Q)$.
○: Observed $I_x(Q)$ by Narten *et al.*,[1,9] ——: calculated $I^{in}_x(Q)$ ($N_i = 1$), ------: calculated $I^{in}_x(Q)$ ($N_i = 2$).

$I^{in}_x(Q)$ curves deviate appreciably from the experimental data, and thus, the interstitial model should be rejected.

Comment on Narten's Near-neighbor Model. The authors pointed out formerly that Narten's later model (the "near-neighbor model") was physically unacceptable despite its success in the calculation of $QS_m(Q)$ curves because several unplausible parameters were used.[6] Here, we discuss the defect of Narten's model in comparison with the present analysis.

Narten's near-neighbor model consists of a tetrahedral arrangement of molecules around a central molecule and a continuum region outside of the discrete near-neighbor structure.[5] In the calculation of $S_m(Q)$ by this model, the contribution of atomic pairs at various distances from a central molecule were summed up, where the molecule was taken as the origin. Accordingly, the contribution of the atomic pairs between the peripheral molecules within the discrete structure, for example, is not contained substantially in the calculation of the contribution of the discrete structure. In this respect, Narten's model differs from our tetrahedral model essentially. As the result, the curve calculated from the discrete structure only is found to deviate largely from the observed data. Thus, there appears an intensive contribution from the continuum region beyond a distance r_c taken as a measure of the extent of the discrete structure as described in his paper,[23,24] and the latter contribution is found to play a dominant role for the overall agreement between the calculated $S_m(Q)$ and the observed data by using r_c as a disposable parameter.

According to the same procedures as described in Narten's paper,[5,23] we calculated $S_m(Q)$ using quite identical parameters except for the value of r_c, its

magnitude being not specified in those papers.[5,23] As reported previously by the authors,[6] a practically complete fit of the calculated $S_m(Q)$ curve with the observed data was obtained for the assignment of $r_c=3$ Å. For values larger than 3 Å a good fit was not obtained. Thus, in the analysis using Narten's near-neighbor model, the fitness of the calculated curve with the observed data is influenced decisively by the assignment of the value r_c.[6,25] Narten stated later in his review[24] that "the contribution of longer distances can be estimated as arising from a uniform distance distribution starting at r_c, the radius of sphere of volume $(N+1)/\rho_0$, ρ_0 being the bulk density of liquid water. Using Eq. 7 (in his review; Ref. 24) and adjusting by least squares the distance r_0 and the mean-square variations in both r_0 and r_c, we find that a value of $N=4.4$ gives the best agreement with the experimental curves for water at all temperatures." According to this description the magnitude of r_c is given to be about 3 Å from the relation: $(N+1)/\rho_0=(4\pi/3)r_c^3$ using $N=4.4$. Considering from the size of the discrete structure, however, the magnitude of $r_c=3$ Å is clearly too small and physically unacceptable, of course.

Thus, from all the consideration described above Narten's model should be said to be implausible physically in spite of its successful appearance.

Concluding Remarks

A general expression of the neutron structure factor for liquid regarded as an aggregate of small molecular clusters was obtained. The equations derived are widely applicable to liquids for analyzing diffraction data under due assumptions. We applied it to water and obtained the following conclusions:

1) The regular tetrahedral pentamer model is the best as a structure model of water in interpreting neutron diffraction data combined with X-ray results,

2) The interstitial model composed of tetrahedral pentamers and unbonded monomers is rejected because of the large deviations of calculated curves from experimental data,

3) Narten's near-neighbor model can not be accepted, because it is impossible to obtain calculated structure factor fitted with experimental data without assigning unreasonable value to its main disposable parameter r_c,

4) Page and Powles' (completely-correlated) orientation model has turned out to bring a too severe restriction with respect to orientational correlation compared with the authors' model which is considered to be the main reason of the deviation of their calculated curves from experimental data.

Appendix

In the right hand side of Eq. 6, we can separate the intramolecular terms from the intermolecular contributions. Then, Eq. 6 becomes

$$S_m(Q)=f_1(Q)+f_{2U}(Q)[S_C(Q)-1]$$
$$+\Sigma^{-2}N_c^{-1}\{\langle\sum_{l\neq l'}\exp(\vec{r}_{cll'})\sum_{n_l,n_{l'}}b_{n_l}b_{n_{l'}}\exp[i\vec{Q}\cdot(\vec{r}_{cn_l}-\vec{r}_{cn_{l'}})]\rangle$$
$$-\langle\sum_{l\neq l'}\exp(i\vec{Q}\cdot\vec{r}_{cll'})\rangle[\sum_n b_n\langle\exp(i\vec{Q}\cdot\vec{r}_{cn})\rangle]^2\}.$$

The third term in Eq. 23 corresponds to the last term of this equation which means the orientational correlations of molecules within the clusters.

Kinetic Studies of the Stripping of Bis(2,4-pentanedionato)beryllium in Various Liquid-Liquid Partition Systems

Hitoshi WATARAI and Nobuo SUZUKI*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received August 8, 1980)

The rate constant, k_{st}, for the stripping of bis(2,4-pentanedionato)beryllium from inert solvents into water or a mixed solvent of water with a miscible organic solvent, such as ethylene glycol, methanol, acetonitrile, and pimethyl sulfoxide, was determined and discussed in connection with the dissociation rate constant, k_d, of the chelate in the aqueous phase and the liquid-liquid partition coefficient, P, of the chelate. The $k_{st}=k_d/(1+P)$ relationship was found to hold true in all systems studied. The solvent effect of the aqueous mixed solvents on k_d was discussed in terms of the transfer activity coefficient.

The solvent extraction technique is widely employed in analytical chemistry to separate or concentrate a metal ion in an aqueous phase by removing it into an organic phase. Kinetic studies of a solvent-extraction mechanism of metal ions have been carried out by many workers. The rate-determining step of a chelate extraction has, in many cases, been reported to be a chelate-formation process in an aqueous phase.[1] The importance of an interfacial reaction for chelate formation has recently been pointed out for the extraction of calcium with bis(2-ethylhexyl)hydrogenphosphate[2] and copper with *o*-hydroxybenzaldehyde oximes.[3] On the other hand, the process of removing a metal compound from an organic phase into an aqueous phase, say stripping, is also important for an effective separation between metal ions.[4] However, on the stripping rate and the mechanism of the metal chelate there is no detailed information at present.

In this study, the rate and mechanism of the stripping reaction of the β-diketonato complex have been investigated utilizing bis(2,4-pentanedionato)beryllium as an example of the β-diketonates; it was chosen because of its moderate substitution lability and its simple dissociation behavior.[5] The stripping rate of the metal ion is expected to be influenced by the partition coefficient of the metal chelate and the dissociation behavior of the chelate in the aqueous phase. Therefore, the solvent effect of an aqueous phase is particularly interesting. In this study, various mixed solvents were used for the strip solution, *i.e.*, water–ethylene glycol, water–methanol, water–acetonitrile, and water–dimethyl sulfoxide. The stripping mechanism and solvent effect were studied from the measurements of the stripping rate constant, the hydrolysis rate constant in the aqueous phase, and the partition coefficient of the chelate. The partition coefficient is not only a measure of the extractability of a chelate from a nonpolar phase into a polar phase, but also a measure of the solution free-energy difference of the chelate in given solvents. With this in view, the kinetic solvent effect of the mixed solvent on the stripping rate will be discussed by correlating the rate constant with the partition coefficient.

Experimental

Chemicals. Bis(2,4-pentanedionato)beryllium(II) (Dotite, G. R.) was purified by vacuum sublimation at 80 °C. Organic solvents of dodecane, heptane, carbon tetrachloride, ethylene glycol, methanol, acetonitrile, and dimethyl sulfoxide were purified by ordinary methods.[6] Reagent-grade perchloric acid was used without further purification. Sodium perchlorate commercially purchased was purified by recrystallization. Redistilled water was used throughout. The stock solution of the acid was standardized by sodium carbonate titration. The mixed solvent of water and organic solvent was prepared by weight. The ionic strength in the aqueous phase used was adjusted to 0.1 M (1 M=1 mol dm^{-3}) by the use of sodium perchlorate.

Kinetic Measurements. The stripping rates of beryllium were observed by means of an ordinary batch method, except for the experiment in the carbon tetrachloride/water system. An organic solution of $Be(acac)_2$ (10^{-4} M) was agitated with an aqueous phase. The shaking speed of the partition tube, which contained 5 ml for each phase, had to be as high as 430 tpm to establish a rapid mass transfer across the interface. Under these conditions, the observed stripping rate reflects purely the chemically rate-controlled process. In practice, a shaking rate of 460 tpm was adopted for all measurements. The stripping-rate constant was calculated from the absorbance decrease in the chelate in the organic phase. The absorbance change was observed intermittently at given shaking-time intervals. Although the absorption maximum of $Be(acac)_2$ in an inert solvent is at 293 nm, the absorbance change was observed at 310 nm to prevent any interference due to acetylacetone produced from the hydrolysis of the chelate. For the kinetic experiment in the carbon tetrachloride/water system, the continuous partition method, described previously in detail,[7] was applicable because of the large difference in the densities of the two phases. Fifty μl of 0.03 M $Be(acac)_2$ in carbon tetrachloride was spiked into the two-phase system which had been agitated in a continuous-partition vessel. The decrease in the absorbance of the complex in the organic phase, observed at 310 nm soon after the injection, was recorded as a function of the time. A first-order analysis of the results gave the stripping-rate constant. The sample preparation and the batch experiment were carried out in a thermostated room at 25±1 °C.

The rate of the acid hydrolysis of $Be(acac)_2$ in the aqueous phase was observed photometrically. The absorbance change at 310 nm was observed as a function of the time after the injection of 15 μl of a 0.01 M dioxane solution of $Be(acac)_2$ into 3 ml of an aqueous solution contained in an optical cell thermostated at 25±0.1 °C. The reproducibility of the rate constant thus determined is within ±5%.

Partition Experiment. The partition coefficient of $Be(acac)_2$ was determined by means of the kinetic method at 25±1 °C. A 5-ml portion of an organic solution of the chelate was agitated with an equal volume of the aqueous phase for a given period, and then the absorbance of the

organic phase was observed. From the absorbance change observed at four different periods at least, the absorbance at $t=0$ was estimated by extraporation and has then used to calculate the partition coefficient. All of the photometric measurements in this study was performed by means of a UVIDEC-2 or Hitachi 356 spectrophotometer.

Results

Stripping in Inert Solvent/Water Systems. Stripping-rate constant, k_{st}, in the carbon tetrachloride/water system is shown in Fig. 1 as a function of the hydrogen-ion concentration in the aqueous phase. The k_{st} is linearly proportional to $[H^+]$ in the concentration range from 0.001 M to 0.004 M. The observed rate constants for the acid hydrolysis of $Be(acac)_2$, shown in Fig. 2, are also linearly proportional to $[H^+]$ in the concentration range from 0.001 M to 0.012 M and coincide with those reported by Pearson and Moor.[5] The stripping data obtained in the three inert solvent/water systems are summarized in Table 1. The partition coefficients of $Be(acac)_2$ greatly depend on the solvents, and the stripping-rate constant appears to be proportional to the partition coefficient.

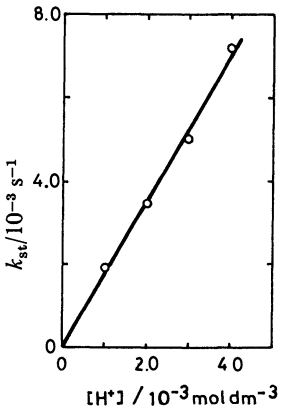

Fig. 1. Correlation between k_{st} and hydrogen ion concentration in aqueous phase. Organic phase: CCl_4.

Stripping in Dodecane/Water–Organic Solvent Mixture. The stripping-rate constants in the systems of dodecane/water–organic solvent mixtures at a constant hydrogen-ion concentration of 0.001 M are shown in Fig. 3.

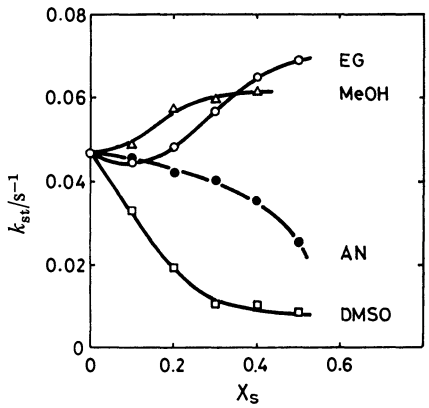

Fig. 3. Effect of aqueous mixed solvent on the stripping rate constant. $[H^+]=0.001$ M.

The stripping-rate constant is found to be greatly affected by the co-solvent. Remarkably, in system of the both H_2O–EG and H_2O–MeOH, the k_{st}'s increase with an increase in the mole fraction of the co-solvents. The rate constants for the solvolysis also greatly depend on the mixed solvent, as is shown in Fig. 4, where an increase of k_d in the H_2O–EG system is noticeable. In the mixed solvent systems also, the k_d raises with an increase in the hydrogen-ion concentration, as is shown in Fig. 5. The variation of the partition coefficient of $Be(acac)_2$ with the mole fraction of the co-solvent in

the mixed-solvent phase is shown in Fig. 6. A maximum in the partition coefficient was observed in the dodecane/H_2O–EG system.

Discussion

Mechanism of the Stripping Reaction. As is shown in Figs. 1 and 2, both k_{st} and k_d depend on the hydrogen-ion concentration. The plot of k_{st} against k_d showed a simple linear relationship, $k_{st}=C\,k_d$, where C is a proportional constant. Therefore, we assumed the following scheme for the stripping reaction:

$$Be(acac)_{2,org} \rightleftharpoons Be(acac)_{2,aq} \quad (1)$$

$$Be(acac)_2 + H^+ \longrightarrow Be(acac)^+ + Hacac. \quad (2)$$

Processes 1 and 2 are represented by the partition coefficient, $P=[Be(acac)_2]_{org}/[Be(acac)_2]_{aq}$, and the dissociation rate constant, k_d, respectively. The rate equation for the stripping reaction:

$$-d[Be(acac)_2]_{org}/dt = k_{st}[Be(acac)_2]_{org} \quad (3)$$

gives the relation among k_{st}, k_d, and P:

$$k_{st} = k_d/(1+P). \quad (4)$$

Equation 4 strongly supports the proportionality between k_{st} and k_d observed experimentally. According to this equation, k_{st} was calculated and compared with the observed one. The results for the three solvent systems are listed in the last column of Table 1. The agreement between $k_{st,calcd}$ and k_{st} is satisfactory; this confirms the proposed scheme of Eqs. 1 and 2. For the mixed solvent systems also, the linear relationship between k_{st} and $k_d/(1+P)$ was confirmed, as is shown in Fig. 7, and the proposed mechanism was supported.

Solvent Effect on the Acid Solvolysis. Equation 4 indicates that the solvent effect on the stripping rate is due to the effects on the dissociation rate and the partition equilibrium. The partition coefficient of $Be(acac)_2$ in the dodecane/aqueous mixed solvent system is related to the transfer-activity coefficient, y_s, of $Be(acac)_2$ from water to a mixed solvent by means of Equation 5:[8]

$$y_s = P/P_o, \quad (5)$$

where the subscript o denotes the reference value

observed in a pure-water system. On the other hand, the rate equation for the acid hydrolysis can be represented by the following equation under the conditions of a dilute acid concentration:

$$-\mathrm{d}[\mathrm{Be(acac)_2}]/\mathrm{d}t = k[\mathrm{H^+}][\mathrm{Be(acac)_2}], \quad (6)$$

where k is a constant in the equation of $k_d=k[H^+]$. In terms of the transfer-activity coefficient, the solvent effect on the dissociation rate can be represented by the next equation:[9]

$$k_d/k_{d,o} = y_s y_{H^+}/y_*, \quad (7)$$

where y_{H^+} and y_* are the transfer-activity coefficients from water to a mixed solvent of proton and the transition state. Equation 7 shows that the solvent effect of the mixed solvent on k_d can be represented by the three transfer-activity coefficients of y_s, y_{H^+}, and y_*. The substitution of Eq. 5 for y_s in Eq. 7 gives the next equation:

$$\log (y_*/y_{H^+}) = \log (P/P_o) - \log (k_d/k_{d,o}). \quad (8)$$

The values of $\log (y_*/y_{H^+})$ calculated from the above equation are plotted in Fig. 8 for the four mixed-

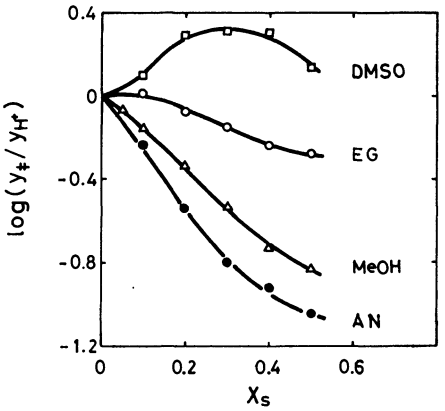

Fig. 8. Variation of $\log (y_*/y_{H^+})$ with solvent composition.

solvent systems. This figure shows that $\log (y_*/y_{H^+})$ decreases in the order of H_2O–DMSO>H_2O–EG>H_2O–MeOH>H_2O–AN in every solvent composition studied and that the value of the ratio of y_*/y_{H^+} is larger than unity for H_2O–DMSO and smaller than unity for the other systems. The large value of y_*/y_{H^+} observed in H_2O–DMSO system can be explained by the small value of y_{H^+} in the mixed solvent.[10] However, for the H_2O–EG and H_2O–MeOH systems, the reported order of y_{H^+}, *i.e.*, H_2O–EG>H_2O–MeOH,[11,12] is in disagreement with the order of $-\log (y_*/y_{H^+})$ in the two systems. This suggests that the solvent effect on y_{H^+} is not the only factor governing the solvent effect on the solvolysis of $Be(acac)_2$, the variation in y_* with the solvent composition being also an important factor. At the present stage, the evaluation of y_* is difficult because of the lack of reliable data for y_{H^+}. However, a test of the correlation between $\log (y_*/y_{H^+})$ and $\log y_s$ will be worthwhile in order to get a clue as to the solvent effect on the transition state. Figure 9 shows the linear proportionality of $\log (y_*/y_{H^+})$ to $\log y_s$ in the three systems except H_2O–DMSO, which shows a curved line with a

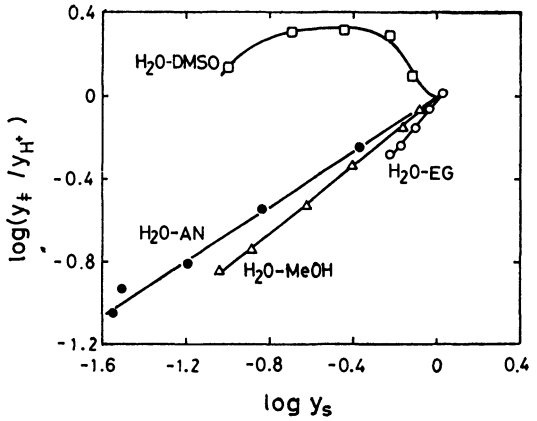

Fig. 9. Correlation between $\log (y_*/y_{H^+})$ and $\log y_s$.

maximum and a great difference from the others. Because the transition state in the acid hydrolysis can be expected to be a positively charged species, $\log y_*$ can be expected to include the two contributions to solute-solvent interaction, *i.e.*, ionic and nonionic interaction. The linear relationship, shown in Fig. 9, suggests that the ionic contributions to $\log y_*$ and $\log y_{H^+}$ may be compensated for each other and/or be proportionate to $\log y_s$ which is a measure of the nonionic interaction between $Be(acac)_2$ and a polar solvent. The great discrepancy in the plot in H_2O–DMSO suggests a strong proton affinity of the mixed solvent.[10]

The hydrogen-ion-concentration dependence of k_d in the H_2O–EG (X_s=0.30) and H_2O–DMSO (X_s=0.30) mixed solvents was discussed according to the general scheme proposed for the acid hydrolysis of acetylacetonates in an aqueous solution:[5]

$$\mathrm{Be(acac)_2} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{Be(acac)(acac')} \quad (9)$$

$$\mathrm{Be(acac)(acac')} + \mathrm{H^+} \overset{K_1}{\rightleftharpoons} \mathrm{Be(acac)(Hacac)^+} \quad (10)$$

$$\mathrm{Be(acac)(Hacac)^+} \overset{k_2}{\longrightarrow} \mathrm{Be(acac)^+ + Hacac}, \quad (11)$$

where (acac') denotes a half-bonded acetylacetone. This mechanism is represented by the next equation:

$$\frac{1}{k_d} = \frac{k_{-1}}{k_1 k_2 K_1}\frac{1}{[\mathrm{H^+}]} + \frac{1}{k_1}. \quad (12)$$

Following Eq. 12, the dissociation-rate constants in H_2O–EG and H_2O–DMSO systems, shown in Fig. 5, were analyzed. An intercept of the linear plot between k_d^{-1} and $[H^+]^{-1}$ gave the values of k_1; 0.75 s^{-1} for H_2O–DMSO (X_s=0.30) and 1.10 s^{-1} for H_2O–EG (X_s=0.30). Both of these values are smaller than the reported value in an aqueous solution, 6.5 s^{-1}.[5] The decreasing order of k_1 values: H_2O (P=1.61)>H_2O–EG (X_s=0.30) (P=1.28)>H_2O–DMSO (X_s=0.30) (P=0.58) corresponds to that in the partition coefficient. This indicates that the larger the solvation free energy of $Be(acac)_2$ in the mixed solvent, the slower the rate of the Be–O bond rupture.

In this study, the kinetic mechanism of the stripping of $Be(acac)_2$ was elucidated. For the purpose of practical separation using the stripping method, a solvent system with a smaller P value and a larger k_d value is promised

from the present results. A further investigation of the other metal chelates will provide insight into the solvent's role in the solvolysis of metal chelate and into the separation mechanism of metal ions in extraction chromatography.

(Received September 3, 1980)

Twenty-eight cobalt(III) complexes of these types: $[Co(LL)_3]^{3+}$ and $[CoXX(LL)_2]^{n+}$ (LL=2,2′-bipyridine or 1,10-phenanthroline, and XX=$2CN^-$, $2NO_2^-$, ethylenediamine, $2NH_3$, glycinate ion, $2H_2O$, $C_2O_4^{2-}$, CO_3^{2-}, $2SCN^-$, $2N_3^-$, $2CH_3COO^-$, $2Cl^-$, or $2Br^-$), were prepared, and their ^{13}C NMR spectra were recorded. Most of the resonances in the complexes were assigned mainly by the technique of selective proton decoupling. In the bpy complexes, the chemical-shift difference between corresponding carbon atoms was the greatest in the C-6 and C-6′ pair. The phen complexes also gave parallel results. The main factor responsible for the chemical-shift differences of the C-6 and C-6′ pair is explained as resulting from the difference in σ-bonding ability between the pyridyl group and the ligand, X.

Recently the ^{13}C NMR technique has been widely used as a useful tool in investigating the structures of organic[1] and organometallic compounds.[2] The application of ^{13}C NMR to the study of transition-metal complexes is also increasing, but it has not yet been systematized. The spectra of ^{13}C NMR were reported for the complexes containing a quadridentate ligand (trimethylenediamine-*N,N′*-diacetate, ethylenediamine-*N,N′*-diacetate ion) and a bidentate ligand (2,2′-bipyridine, 1,10-phenanthroline, *etc.*) by Gailey *et al.*[3] and for the platinum complexes containing 2,2′-bipyridine and various diamines by Erickson *et al.*[4] However, there exists a partial disagreement between the two sets of assignments; *i.e.*, the assignments for the C-3 and C-5 carbons of 2,2′-bipyridine differ.

The present study was undertaken in order to ascertain the assignments of the ^{13}C NMR spectra of a series of bis-type cobalt(III) complexes, $[CoXX(LL)_2]^{n+}$, where LL=2,2′-bipyridine or 1,10-phenanthroline and where XX represents unidentate ligands or a bidentate ligand, and in order to find the relationship between the chemical shift and the nature of the second ligand, X.

Experimental

Materials. *Preparation of 2,2′-Bipyridine Complexes*: Most of the 2,2′-bipyridine complexes were prepared according to the literature, with a minor modification. The dichloro complex was prepared by the method of Vlcek.[5] The carbonato complex, $[Co(CO_3)(bpy)_2]^+$, was prepared by the reaction of $K_3[Co(CO_3)_3]$ with 2,2′-bipyridine; it was then used as the starting material for the preparation of diaqua, oxalato, and diacetato complexes.[6] The dinitro, dithiocyanato, and diazido complexes were prepared by Maki's method with the modification that *cis*-$[CoCl_2(bpy)_2]Cl$ or *cis*-$[Co(H_2O)_2(bpy)_2](ClO_4)_3$ was used as the starting material instead of the compound reported as "*trans*-$[CoCl_2(bpy)_2]Cl$".[7] Each crude complex was adsorbed on a small amount of SP-Sephadex C-25. Elution with 0.1 M (1 M=1 mol dm^{-3}) NaCl, followed by the evaporation of the eluent with a rotatory vacuum evaporator, gave each pure substance. The glycinato complex was prepared by the method of Murakami *et al.*[8] and subsequently purified by using a column of SP-Sephadex C-25, with 0.3 M NaCl as the eluent.

Ethylenediaminebis(2,2′-bipyridine)cobalt(III) Chloride, $[Co(en)(bpy)_2]Cl_3 \cdot 4H_2O$: The carbonato complex, $[Co(CO_3)(bpy)_2]Cl \cdot H_2O$, weighing 0.97 g (2 mmol), was dissolved in 4.2 cm^3 of 1 M HCl with heating at about 50 °C, and then 0.53 g (4 mmol) of ethylenediamine dihydrochloride, 0.15 cm^3 (2.3 mmol) of ethylenediamine, and 0.1 g of active charcoal were added. After it had stood overnight, the resulting yellow solution was filtered. The filtrate and washings were collected, and the cationic species were adsorbed at the top of a column of SP-Sephadex C-25 (120 cm long and 3 cm in diameter) and eluted with a solution of sodium pyrophosphate (pH=6.7). The first fraction was found to contain a mixture of $[Co(bpy)_3]^{3+}$ and $[Co(en)(bpy)_2]^{3+}$. They were separated on a column of SP-Sephadex C-25, using a 0.5 M NaCl solution as the eluent.

Found: C, 43.81; H, 5.17; N, 13.69; H_2O, 11.87%. Calcd for $C_{22}H_{32}N_6O_4Cl_3Co$: C, 43.33; H, 5.29; N, 13.78; H_2O, 11.82%. Absorption spectrum $\tilde{\nu}_{max}/cm^{-1}$ (log ε) 21600 (2.00).

cis-*Diamminebis(2,2′-bipyridine)cobalt(III) Perchlorate,* cis-$[Co(NH_3)_2(bpy)_2](ClO_4)_3 \cdot 2H_2O$: This complex was prepared and separated in a manner similar to that used in the preparation of the ethylenediamine complex.

Found: C, 32.49; H, 3.38; N, 11.34; H_2O, 4.86%. Calcd for $C_{20}H_{26}N_6O_{14}Cl_3Co$: C, 32.45; H, 3.54; N, 11.36; H_2O, 4.87%. Absorption spectrum $\tilde{\nu}_{max}/cm^{-1}$ (log ε) 21700 (1.82).

cis-*Dicyanobis(2,2′-bipyridine)cobalt(III) Chloride,* cis-$[Co(CN)_2(bpy)_2]Cl \cdot 4.5H_2O$: Into a solution of 1.38 g (2 mmol) of $[Co(bpy)_3]Cl_3 \cdot 3H_2O$ in 10 cm^3 of water, 0.1 g of active charcoal and 0.27 g (4.15 mmol) of KCN were stirred. Although the reaction seemed to take place within about five minutes, the solution was kept in a refrigerator overnight. It was then filtered to remove the charcoal, which was washed several times with hot water. The filtrate and washings were collected, and the cationic species in the solution were adsorbed on a small amount of SP-Sephadex C-25. The adsorbed species were eluted with 0.1 M hydrochloric acid, and the eluate was evaporated almost to dryness. The residue was washed with a small amount of cold water. It was then recrystallized from hot water and air-dried at room temperature.

Found: C, 48.77; H, 4.20; N, 15.74; H_2O, 14.91%. Calcd for $C_{22}H_{25}N_6O_{4.5}ClCo$: C, 48.95; H, 4.67; N, 15.57; H_2O, 15.02%. Absorption spectrum $\tilde{\nu}_{max}/cm^{-1}$ (log ε) 26000sh. (2.2).

cis-*Dibromobis(2,2′-bipyridine)cobalt(III) Perchlorate,* cis-$[CoBr_2(bpy)_2]ClO_4$: To a solution of 1.41 g (2 mmol) of $[Co(H_2O)_2(bpy)_2](ClO_4)_3$ in 1.5 cm^3 of water, 2 cm^3 of a 2 M KBr solution and 50 cm^3 of ethanol were added. After the mixture had stood overnight in a refrigerator, it was filtered and the filtrate was evaporated to dryness with a rotatory vacuum evaporator at a bath temperature of 60 °C. The

residue was redissolved in about 150 cm^3 of hot ethanol, and then, to the filtrate, an ethanol solution of $LiClO_4 \cdot 3H_2O$ was added to give the perchlorate crystals.

Found: C, 37.57; H, 2.19; N, 9.11%. Calcd for $C_{20}H_{16}N_4O_4Br_2ClCo$: C, 38.10; H, 2.56; N, 8.89%.

Preparation of 1,10-Phenanthroline Complexes: The complexes, $[Co(phen)_3]Cl_3 \cdot 4H_2O$,[9] $[Co(CN)_2(phen)_2]Cl \cdot 4H_2O$,[7] $[Co(H_2O)_2(phen)_2](NO_3)_3 \cdot 2H_2O$,[10] $[Co(SCN)_2(phen)_2]NCS$,[10] $[Co(CO_3)(phen)_2]Cl \cdot 5H_2O$,[11] and $[CoBr_2(phen)_2]Br \cdot 3H_2O$,[11] were prepared by the known methods. For the other complexes, the methods were essentially the same as those used for the preparation of the corresponding 2,2′-bipyridine complexes. The diammine complex was prepared by a method, which was different from that previously reported.[12]

cis-Diamminebis(1,10-phenanthroline)cobalt(III) Chloride, cis-$[Co(NH_3)_2(phen)_2]Cl_3 \cdot 3H_2O$: The complex, $[Co(NO_3)_2(phen)_2]NO_3$, was prepared by heating $[Co(H_2O)_2(phen)_2](NO_3)_3$ in an air bath at 110 °C for 4—5 h. The dinitrato complex, weighing 1.0 g, was added to 20 cm^3 of dimethyl sulfoxide, taking up sufficient ammonia gas. The resulting yellow solution was kept at room temperature for 2—3 h and then diluted with 30 cm^3 of water. The complex was adsorbed on a small amount of SP-Sephadex C-25 and eluted with 0.5 M HCl. The eluate was concentrated by evaporation, and then the chloride of the complex was precipitated by adding ethanol to the concentrated solution.

Found: C, 47.36; H, 4.26; N, 13.70; H_2O, 8.67%. Calcd for $C_{24}H_{28}N_6O_3Cl_3Co$: C, 46.96; H, 4.60; N, 13.69; H_2O, 8.80%. Absorption spectrum $\tilde{\nu}_{max}$/cm^{-1} (log ε) 21600 (1.87).

Identification of the Complexes. The complexes prepared were identified by comparing their electronic absorption spectra with those reported in the literature. The spectra of the dicyano and dibromo complexes were different from the reported ones; *i.e.*, the latter complex showed no maxima in the d-d band region, but only some undefined shoulders. The absorption maximum of the dicyano complex is given above. The elemental analyses were performed on dicyano, dibromo, and newly prepared compounds. The water contents were also determined by measuring the weight loss under the conditions of 100 °C and 20 mmHg.

It is well established that bis-type cobalt(III) complexes of 2,2′-bipyridine or 1,10-phenanthroline take only the *cis*-configuration because of the repulsion between the ligands. The *cis* configuration of all the present complexes was confirmed by the ^{13}C NMR spectra, as will be discussed later.

Physical Measurements. The electronic absorption spectra were measured using a Shimadzu MPS-50L spectrophotometer. The ^{13}C NMR spectra were measured at 15.04 MHz on a JEOL JNM-FX60 spectrometer equipped with a Fourier transform accessory under the condition of a noise-modulated proton decoupling. A sweep width of 2500 Hz, a pulse width of 9 μs (corresponding to the tipping angle of about 90°), and a pulse interval of 3 s were employed. The free-induction signal derived after each pulse was accumulated in a JEOL JEC-980A computer (8K). From approximately 500 up to 60000 accumulations were made for each spectrum. The ambient temperature was 35 °C. The solvents used were H_2O, $CHCl_3$, CH_3NO_2, CH_3OH, and a mixture of CH_3NO_2 and DMSO, and the concentrations of the samples were 0.3 M or lower depending on the solubilities. The spectra were obtained from samples contained in 10-mm-diameter tubes; D_2O in an inner coaxial tube 5-mm in diameter was used to provide a field-frequency lock signal. The external standard used was a dioxane–tetramethylsilane (TMS) mixture contained in a capillary (approximately 1-mm). Dioxane had a δ-value of 67.37 (downfield from TMS). All the chemical shifts are given relative to TMS, with a digital resolution of 0.6 Hz.

Selectively proton-decoupled ^{13}C NMR spectra were also measured for 2,2′-bipyridine (in $CDCl_3$), $[Co(bpy)_3]Cl_3$ (in D_2O), *cis*-$[CoCl_2(bpy)_2]Cl$ (in DMSO-d_6), and *cis*-$[Co(CN)_2(bpy)_2]Cl$ (in D_2O) in 5-mm-diameter tubes. Prior to each ^{13}C NMR measurement, the ^1H NMR spectrum of the same sample solution was recorded at 59.80 MHz. The internal standards used were TMS for the free ligand and sodium trimethylsilylpropanesulfonate (DSS) for the complexes.

In order to avoid the dissociation of the unidentate ligand and to obtain a sufficient solubility of the complex, nitromethane and dimethylsulfoxide were used as the solvent instead of water in some cases. The solvent effects on the ^{13}C NMR spectra of 2,2′-bipyridine complexes were measured for dicyano, dinitro, carbonato, diacetato, and tris-type complexes. In general, carbon resonance positions shifted to fields higher by 0.3—0.4 ppm for nitromethane solutions than for aqueous solutions. The greatest solvent effect was observed in the chemical-shift difference between the C-6 and C-6′ signals of the diacetato complex (1.07 ppm in the aqueous solution and 2.24 ppm in the nitromethane solution); the second largest was the C-6 and C-6′ pair of the carbonato complex (1.83 ppm in the aqueous solution and 2.62 ppm in the nitromethane solution). However, these large changes are exceptional. The solvent dependence of the chemical-shift differences is small in other resonances of these complexes and in all the resonances of the other complexes.

Results and Discussion

The ^{13}C NMR spectra with noise-modulated and selective proton decoupling are given in Fig. 1 for 2,2′-bipyridine dissolved in deuterated chloroform and for $[Co(bpy)_3]Cl_3 \cdot 3H_2O$ in deuterium oxide. The three signals appearing in the lower field in the proton-decoupled bipyridine spectrum were identified as those

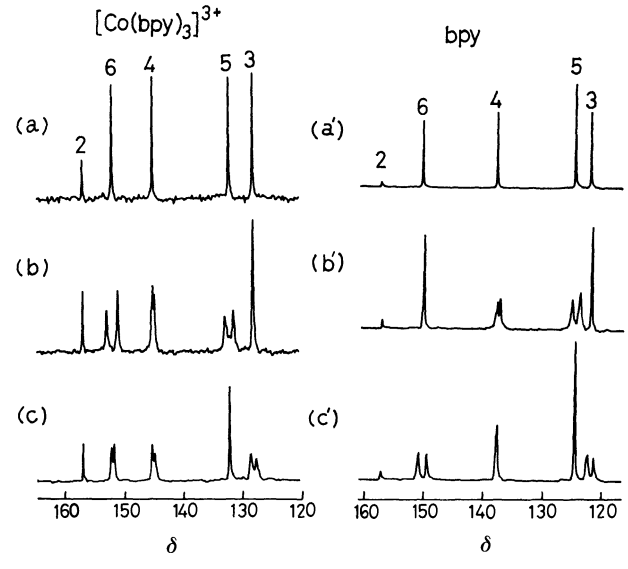

Fig. 1. Noise-modulated and selective proton-decoupled ^{13}C NMR spectra of $[Co(bpy)_3]Cl_3$ in D_2O and 2,2′-bipyridine in $CDCl_3$. (a) and (a′): Noise-modulated spectra, (b) and (b′): H-3 proton-decoupled spectra irradiated at 536 Hz from DSS and 501 Hz from TMS, respectively, (c) and (c′): H-5 proton-decoupled spectra irradiated at 475 Hz from DSS and 434 Hz from TMS, respectively.

of C-2, C-6, and C-4, in agreement with the literature.[3,4,13,14] The assignment of the C-4 signal was confirmed by comparing the spectral feature with that of 4,4′-dimethyl-2,2′-bipyridine (Fig. 2). The low intensity of the signal appearing at the lowest field is consistent with the absence of hydrogen atoms attached to C-2. The two signals appearing at the higher fields were identified as those of C-5 and C-3 in the order shown in Fig. 1 by measurement with selective proton decoupling (Figs. 1b, b′, c, and c′).

The assignments are consistent with those of Erickson *et al.*,[4] but different from those of Gailey *et al.*[3] in the C-3 and C-5 signals.

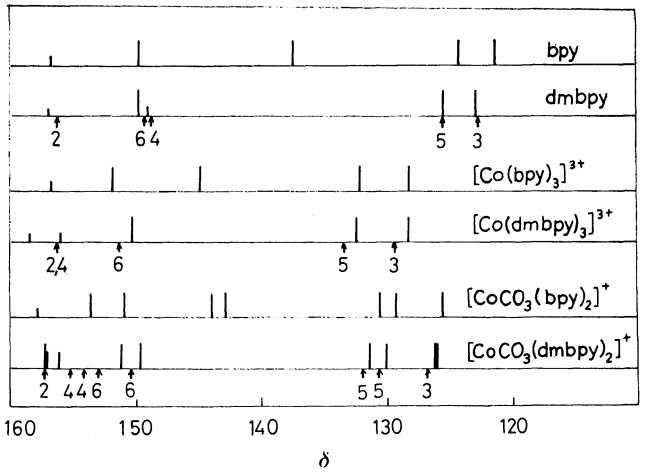

Fig. 2. Noise-modulated ^{13}C NMR spectra of 2,2′-bipyridine and 4,4′-dimethyl-2,2′-bipyridine (dmbpy) in $CHCl_3$, and their complexes in H_2O.

In Fig. 2, schematic comparisons of the ^{13}C NMR spectra are made between bipyridine and its 4,4′-dimethyl derivative, and also between their cobalt(III) complexes. The arrows under the spectra of the dimethyl derivative and its complexes show the positions of the signals predicted on the assumption that the methyl substitution at the 4 sites of bipyridine and its complexes would result in chemical-shift changes of the same magnitudes as those resulting from the corresponding substitution in pyridine.[1] The signals of the 4,4′-dimethyl derivative and its complexes appear near the predicted positions. Thus, each signal may be assigned as indicated by the nearby arrow.

The ^{13}C NMR spectra due to aromatic carbons of the $[CoXX(bpy)_2]^{n+}$-type complexes are listed in Fig. 3 in the order of the decreasing wavenumber of the first absorption band of the complex. As expected, each of the five resonance lines found in $[Co(bpy)_3]^{3+}$ splits into two in the $[CoXX(bpy)_2]^{n+}$-type complexes, except for the carbonato complex, in which the splitting was not detected in the C-2 and C-3 signals. The spectra of the 1,10-phenanthroline complexes also exhibit patterns similar to those of the bipyridine complexes. The assignment of the spectra of 1,10-phenanthroline and its complexes was made in a manner similar to the case of bipyridine, excepting that the C-5 and C-7 resonances of the complex can not be unambiguously differentiated.

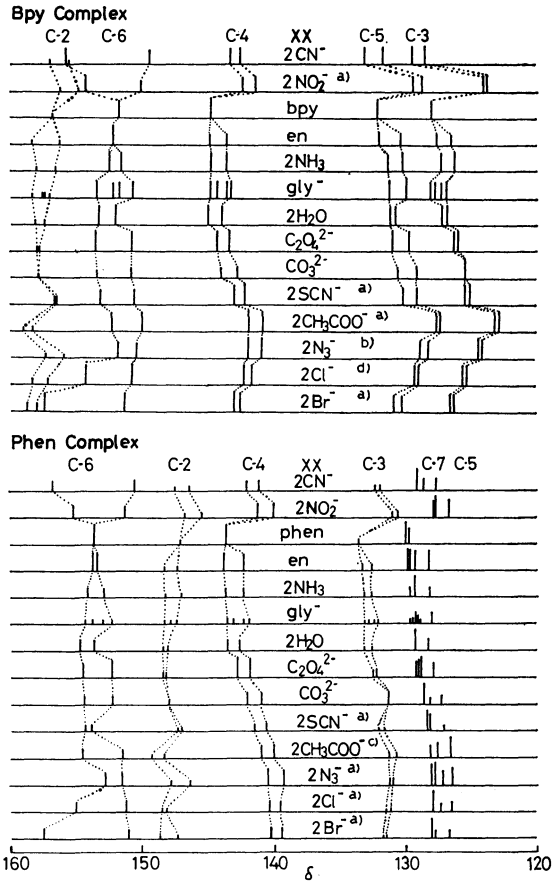

Fig. 3. Noise-modulated ^{13}C NMR spectra of cobalt(III) complexes of 2,2′-bipyridine and 1,10-phenanthroline in aqueous solutions.
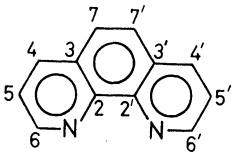
a): Nitromethane solution, b): dimethyl sulfoxide solution, c): methanol solution, d): nitromethane-dimethyl sulfoxide (1 : 1) solution.

For the convenience of a ready comparison with bipyridine, the numbering system given below is here used for 1,10-phenanthroline:



In both series of complexes, the magnitude of the splitting, *i.e.*, the chemical-shift difference between corresponding carbon atoms, is the largest between C-6 and C-6′.

It is well-known that diamagnetic shielding due to the ring current of the pyridyl group causes a drastic shift of proton resonances toward a higher field.[15] Therefore, in the present complexes, $[CoXX(bpy)_2]^{n+}$ and $[CoXX(phen)_2]^{n+}$, it can be expected that the H-6 proton lying above the plane of the pyridine ring of a neighboring ligand group resonates at the highest field, and the H-6′ proton lying near the expansion of the pyridine plane, at a lower field.

Taking these facts into account, the C-6 and C-6′ signals of the spectra of $[CoCl_2(bpy)_2]Cl$ and $[Co(CN)_2$-

$(bpy)_2]Cl$ were assigned by the selective proton-decoupling technique. When each complex was irradiated with the resonance frequency of the H-6 proton at the highest field, one of the ^{13}C signals at a lower field in the C-6 region split into two, while the other, at a higher field, remained unsplit; the latter is identified as a C-6 signal. This C-6 carbon nucleus is situated next to the nitrogen atom at the *trans* site of X in $[CoXX(bpy)_2]^{n+}$. Thus, for all complexes of the $[CoXX(LL)_2]^{n+}$ type (LL=bpy or phen), the resonances at the higher field may be assigned to C-6, and those at the lower field, to C-6′.

The chemical shifts of ^{13}C NMR were also measured of *N,N′*-bis(2-pyridylmethyl)ethylenediamine (penp) complexes, *cis*-α-$[CoXX(penp)]^{n+}$ (XX=2CN$^-$, en, $2NH_3$, $2H_2O$, $2N_3^-$, $2Cl^-$, and $2Br^-$), in which two pyridyl groups are located in positions *trans* to each other. The signal of the pyridyl C-6 of each complex of this series appeared near the C-6′ signal of the corresponding bis(bipyridine) complex.[16] This is consistent with the assignment given above for the C-6′ signal.

The difference between the C-6 and C-6′ chemical shifts in $[CoXX(LL)_2]^{n+}$ might be due to diamagnetic shielding, analogously to the cases of H-6 and H-6′. However, the observed shift differences are too large to be attributed to this effect only.

Recently, Nakashima *et al.*[17] gave a theoretical equation for use in calculating the chemical shift of a ligand proton under the influence of the paramagnetic anisotropy of the central cobalt(III) ion of a complex. The chemical-shift differences estimated for the present phenanthroline complexes after Nakashima *et al.*[17] are much smaller than the observed splittings; thus, the paramagnetic anisotropy of the cobalt(III) ion cannot be the main cause of the chemical-shift differences observed between the corresponding atoms of each ligand.

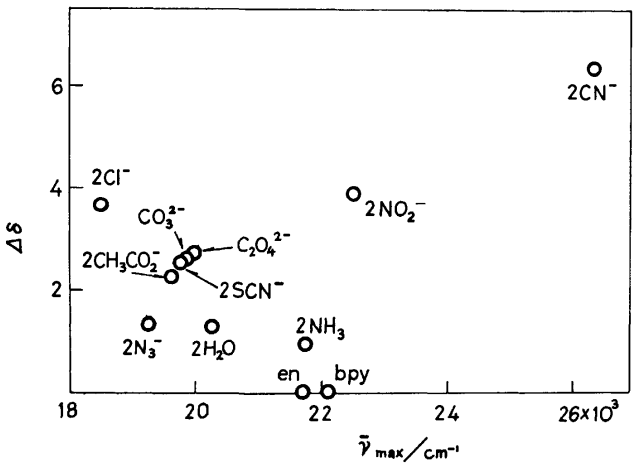


Fig. 4. A plot of the chemical-shift difference of C-6 and C-6′ carbons *vs.* the $\bar{\nu}_{max}$ value of the first absorption band of the complex, $[CoXX(bpy)_2]^{n+}$.

When the difference between the C-6 and C-6′ chemical shifts is plotted against the wavenumber of the first absorption band for each complex of the $[CoXX(LL)_2]^{n+}$ type (LL=bpy or phen), a roughly linear relationship can be observed (Fig. 4). The dinitro and dicyano complexes, however, greatly deviated from the linear relationship. This may be due to the strong π-interaction of NO_2^- and CN^-. Thus, the difference between the C-6 and C-6′ chemical shifts seems to be related to the σ-donating ability of the ligand, XX. For other carbon atoms, however, no simple relationship was observed between the chemical-shift difference and the ligand-field strength.

The present work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

(Received September 25, 1980)

A kinetic study of the aluminium ion-assisted aquation of $CoF(NH_3)_5^{2+}$ was carried out. The pseudo-first-order rate constant obtained can be expressed as $k_{obsd}=k_{Al}[Al^{3+}]$, where $k_{Al}=(1.6\pm0.2)\times10^{-3}$ dm^3 mol^{-1} s^{-1} (I=2.0 mol dm^{-3}, 25 °C). The reaction rate is independent of the pH in the $(pH)_{obsd}<3.3$ range, in contrast with the pH-dependent rate for the $CrF(NH_3)_5^{2+}$–Al^{3+} system. The different behavior between $CoF(NH_3)_5^{2+}$ and $CrF(NH_3)_5^{2+}$ in aquation can be explained in terms of their electronic structures, as calculated on the basis of the CNDO/2 method.

There has been much interest in the reactions of the metal ion-assisted aquations of transition-metal complexes.[1] We ourselves have been studying this type of reaction from the point of view that this is a good and simple model to explain the mechanism of an inorganic reaction.[2,3]

In a previous paper, we reported the kinetics for the aluminium ion-assisted aquation of the pentaammine-fluorochromium(III) ion and attributed the pH dependency of the reaction rate to an easy protonation of $CrF(NH_3)_5^{2+}$.[3] The present paper is concerned with an aluminium ion-assisted aquation of $CoF(NH_3)_5^{2+}$, which showed a pH dependence entirely different from that of $CrF(NH_3)_5^{2+}$.

Different behavior has also been observed between $CrF(NH_3)_5^{2+}$ and $CoF(NH_3)_5^{2+}$ in their spontaneous aquation.[3,4] In order to understand the differences, the CNDO/2 calculation has been carried out on these complexes.

Experimental

Materials. Pentaamminefluorocobalt(III) nitrate was prepared according to the literature.[5] The nitrate was converted to perchlorate by the addition of $NaClO_4$. The purity of the crystals was confirmed by means of SP-Sephadex column chromatography with spectrophotometric detection. Found: Co, 15.80; N, 18.90; H, 3.93%. Calcd for $[CoF(NH_3)_5](ClO_4)_2$: Co, 16.28; N, 19.34; H, 4.17%.

The preparation of sodium perchlorate and aluminium perchlorate and the confirmation of their purity were carried out as previously described.[3]

The other chemicals used were guaranteed reagents from Wako Pure Chemicals Industries, Ltd.

Kinetic Procedure. Kinetic measurements were made in a manner similar to that previously described.[3] The concentration of the complex was controlled to 5.0×10^{-3} mol dm^{-3}. The absorbance changes were followed at 330 nm for all the sample solutions. The pseudo-first-order rate constants were determined by plotting $\ln(D_t-D_\infty)$ against the time, where D_t and D_∞ are the absorbances at the time t and at an infinite time respectivey.

pH Measurements. The procedure of pH measurements has been described previously.[3] We used this relation: $(pH)_{obsd}+\log[H^+]=-0.21$ for a 0.1 mol dm^{-3} $Al(ClO_4)_3$ solution. The pH of the sample solution was controlled by mixing a 0.2 mol dm^{-3} $Al(ClO_4)_3$ solution with a NaOH solution of an appropriate concentration.

^{19}F NMR Measurements. A JEOL FX 60Q spectrometer was used in the pulse Fourier transform mode at 56.26 MHz, with a deuterium lock to obtain the ^{19}F spectra. The water used in the sample solution was doubly distilled; it contained 5% by volume D_2O to provide a lock signal for the NMR spectrometer. The sample temperature was controlled to 30±1 °C, and the concentration of the complex was controlled to 0.05 mol dm^{-3}. All samples were examined in 5-mm tubes using $BF_3(C_2H_5)_2O$ as an external reference. The values of the chemical shifts obtained with reference to the external $BF_3(C_2H_5)_2O$ was converted to those with reference to F^- (in a neutral aqueous solution); the latter will be designated by δ below.

Calculations

In the present calculation, the standard values[6] are used for the CNDO/2 parameters associated with the H, N, and F atoms. The parameter values for the Co and Cr atoms, including those previously reported,[7] are summarized in Table 1. The geometries of the complexes are given by the experimental data:[8] 1.97 Å (Co–N), 1.87 Å (Co–F), 2.06 Å (Cr–N), 1.96 Å (Cr–F), and 1.01 Å (N–H).

Table 1. CNDO/2 parameters

		Cr	Co
$1/2(I_\mu+A_\mu)$/eV[a]	4s	3.909	4.17
	4p	0.876	1.16
	3d	4.822	5.839

Results and Discussion

Al^{3+}-assisted Aquation. The aquation of $CoF(NH_3)_5^{2+}$ yielding $CoOH_2(NH_3)_5^{3+}$ was promoted by aluminium ions. The spectrum of the sample solution changed with the time, showing isosbestic points at 360 and 506 nm, which indicates that no by-products were formed. Table 2 shows that the pseudo-first-order-rate constant obtained is approximately proportional to the aluminium-ion concentration, *i.e.*, $k_{obsd}=$

Table 2. Dependence of the rate constant on the concentration of the aluminium ion
(The ionic strength is controlled to 2.0 mol dm^{-3} by $NaClO_4$; at 25 °C, pH 2.5, and [complex]= 5.0×10^{-3} mol dm^{-3}.)

$[Al^{3+}]$ / mol dm^{-3}	k_{obsd}/s^{-1}	$\frac{k_{obsd}}{[Al^{3+}]}$/dm^3 mol^{-1} s^{-1}
0.030	4.54×10^{-5}	1.51×10^{-3}
0.050	7.59×10^{-5}	1.52×10^{-3}
0.10	1.57×10^{-4}	1.57×10^{-3}
0.15	2.46×10^{-4}	1.64×10^{-3}
0.20	3.58×10^{-4}	1.79×10^{-3}

$k_{Al}[Al^{3+}]$, where $k_{Al}=(1.6\pm0.2)\times10^{-3}$ dm^3 mol^{-1} s^{-1}. The small systematic variation in k_{Al} may result from the change in the perchlorate concentration (1.91—1.40 mol dm^{-3}) for the solutions of equal ionic strength. Considering the results of Swaddle and Jones[4] and of Chan,[9] we can write the total rate constant as:

$$k_{obsd} = k_0 + k_H[H^+] + k_{Al}[Al^{3+}],$$

where $k_0=3.3\times10^{-7}$ s^{-1} [4] (2.44×10^{-7} s^{-1} [9]), $k_H=5.2\times10^{-4}$ dm^3 mol^{-1} s^{-1} [9] at 35 °C and I=0.112—0.12 mol dm^{-3}. Under the present conditions, the first and second terms can be neglected in comparison with the third term.

The dependency of the reaction rate on the pH is shown in Fig. 1, together with the degree of hydrolysis of aluminium ions.[10] Previous results for the $CrF(NH_3)_5^{2+}$–Al^{3+} reaction are also depicted for comparison.

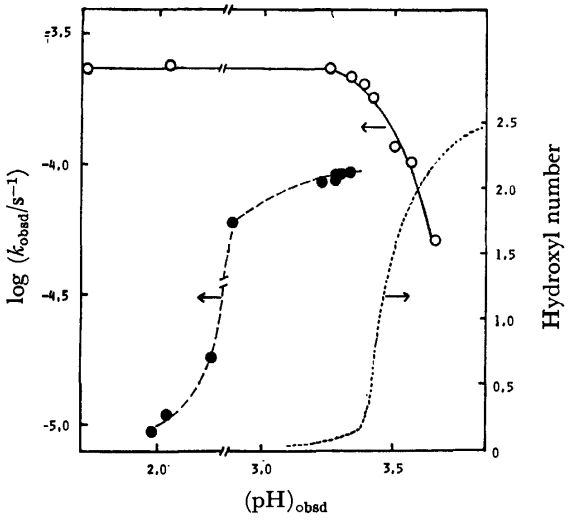

Fig. 1. pH dependence of the pseudo-first-order rate constants for $CoF(NH_3)_5^{2+}$–Al^{3+} system (—○—) and for $CrF(NH_3)_5^{2+}$–Al^{3+} system (---●---),[3] and the degree of hydrolysis of aluminium ions (------).[10] The hydroxyl number means the $[OH^-]/[Al^{3+}]$ ratio in hydrolysis products. Aveston (Ref. 10) gave the degree of the hydrolysis as a function of log[H$^+$], which is transformed to $(pH)_{obsd}$ (see pH measurements in the text). The experimental conditions for the reaction rates are: [complex]=5.0×10^{-3} mol dm^{-3}, $[Al(ClO_4)_3]$=0.10 mol dm^{-3}, and at 35 °C, and for the hydrolysis: $[Al(ClO_4)_3]$=0.10 mol dm^{-3}, at 25 °C.

A distinct difference exists in the reactivity between the chromium(III) and cobalt(III) complexes. The chromium(III) complex was considered to be easily protonated at the site of the fluoro ligand, and the complex is blocked from the approach of aluminium ions in the pH region lower than 3.0.[3] On the other hand, the present results show that the cobalt(III) complex is not so easily protonated as the chromium(III) complex and that the contribution of the protonated species to the reaction can be neglected even at a pH lower than 3.0. The reaction rate decreases with an increase of pH above $(pH)_{obsd}$=3.4, where a marked change occurs in the degree of hydrolysis of aluminium ions. According to Aveston[10] and Turner,[11] the formation of polycationic complexes begins to occur around this pH region, and their reactivity may be considerably smaller than that of Al^{3+} or $AlOH^{2+}$.

Table 3. Second-order rate constants at various temperatures
([complex]=5.0×10^{-3} mol dm^{-3}, $[Al^{3+}]$=0.10 mol dm^{-3}.)

t/°C	k_{Al}/dm^3 mol^{-1} s^{-1}
20	4.9×10^{-4}
25	1.2×10^{-3}
30	1.7×10^{-3}
35	2.6×10^{-3}
40	4.2×10^{-3}

Table 3 lists the rate constants at different temperatures; those rate constants give the values of ΔH^* and ΔS^* as 74 ± 5 kJ mol^{-1} and -72 ± 15 J mol^{-1} K^{-1} respectively. On the other hand, the activation parameters for the electron-transfer reaction, $CoF(NH_3)_5^{2+}+Fe^{2+}\rightarrow Co^{2+}+FeF^{2+}+5NH_3$, are $\Delta H^*=56$ kJ mol^{-1} and $\Delta S^*=-96$ J mol^{-1} K^{-1}.[12] The comparison of the ΔS^* values for the aquation and the reduction satisfies the general tendency that more stringent geometrical conditions have to be satisfied in the reduction.[13]

^{19}F NMR Study. The ^{19}F NMR signal of $CoF(NH_3)_5^{2+}$ cannot be detected even by 5000 scans for a 0.15 mol kg^{-1} solution of the complex. However, when an excess of aluminium ions was added to the solution of the cobalt(III) complex, a signal appeared which was assigned to the AlF^{2+} species (chemical shift $\delta=-36.1$ ppm from F$^-$).[14] As the reaction proceeds, the signal grows and approaches a constant height. This change corresponds to the formation of AlF^{2+} in the $CoF(NH_3)_5^{2+}+Al^{3+}\rightarrow CoOH_2(NH_3)_5^{3+}+AlF^{2+}$ reaction. When the aluminium-ion concentration was so low as to be compared with the $CoF(NH_3)_5^{2+}$ concentration ($[Al^{3+}]/[CoF(NH_3)_5^{2+}]<5$), an additional peak appeared. This peak had a chemical shift 0.65 ppm lower than that of the AlF^{2+} peak and was assigned to AlF_2^+.[14] All the kinetic studies were, therefore, carried out in the concentration range of $[Al^{3+}]/[CoF(NH_3)_5^{2+}]>5$, where the formation of by-products can be disregarded.

Electronic Effects on the Aquation of $CrF(NH_3)_5^{2+}$ and $CoF(NH_3)_5^{2+}$. In the spontaneous aquation of $CrF(NH_3)_5^{2+}$, the ammonia ligands are more easily displaced than the fluoro ligand, but the tendency

a) The N atom here refers to the *cis*-N atom to F^-, because *cis*-$[CrF(OH_2)(NH_3)_4]^{2+}$ is the main product in the spontaneous aquation of $CrF(NH_3)_5^{2+}$ (Ref. 3).

is reversed in $CoF(NH_3)_5^{2+}$.[4,9] These results suggest that the Cr–F bond is stronger than the Cr–N bond, but Co–F is weaker than Co–N. The strength of the metal-ligand bond can be measured by the corresponding bond order. Table 4 lists the calculated bond orders of the complexes. The results show that the $3d_\pi$-$2p_\pi$ interaction strengthens the Cr–F bond, but makes no contribution to the Co–F bond, which explains the significantly greater stiffness of the Cr–F bond as compared with the Co–F bonds. On the other hand, the bond-order values show only a slight difference between Cr–N and Co–N. Therefore, it is possible that Cr–F is stronger than Cr–N, but Co–F is weaker than Co–N, although a simple comparison of bond orders cannot predict which is the stronger between bonds of different types, *i.e.*, between ionic M–F and ion-dipolar M–N.

As has been stated above, $CrF(NH_3)_5^{2+}$ is more easily protonated than $CoF(NH_3)_5^{2+}$. This can be explained by the greater value of the net negative charge of F in the chromium complex than in the cobalt analogue, as is shown in Table 5. The experimental results can also be explained qualitatively from the viewpoint of electronegativities; the less electronegative chromium forms a more ionic bond and the F linked to Cr should be more easily protonated than that bonded to Co. Therefore, the pH dependency of the aquation in the $CrF(NH_3)_5^{2+}$–Al^{3+} system can be well understood.

$CrF(NH_3)_5^{2+}$	+0.653	−0.202	−0.387
$CoF(NH_3)_5^{2+}$	+0.480	−0.183	−0.342

Table 4 also gives the results for the protonated complex, $CrFH(NH_3)_5^{3+}$, for the sake of comparison. Although it shows that the Cr–F bond is considerably weakened by the protonation, this is not well reflected in the experimental results shown in a previous paper:[3] the ammonia ligands in $CrF(NH_3)_5^{2+}$ are more easily removed than the fluoro ligand at pH 2, where most of the $CrF(NH_3)_5^{2+}$ should be protonated ($\log K_H = 3.0$).

Thermal Reactions of Metal Complexes under Quasi-isothermal and -isobaric Conditions. II.[1] Formation of Triamminetrihalogenochromium(III) Complexes *via* the Decomposition of Hexaammine, Pentaamminehalogeno, and *trans*-Tetraamminedihalogeno Complexes[2]

Hitoshi Ueno, Akira Uehara, and Ryokichi Tsuchiya*
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received October 2, 1980)

The thermal decomposition of the following chromium(III) complexes was investigated in the solid phase by means of Q-derivatograph under quasi-isothermal and -isobaric conditions (Q-conditions) and D-derivatograph under dynamic conditions (D-conditions): $[Cr(NH_3)_6]X_3$, $[CrX(NH_3)_5]Y_2$, and *trans*-$[CrX_2(NH_3)_4]Y$, where X and Y are chloride and/or bromide ions. The complexes were finally converted into triamminetrihalogeno complexes $[CrBr_xCl_y(NH_3)_3]$ ($x+y=3$; x and $y=0$, 1, 2, or 3) under Q-conditions but decomposed in complicated ways under D-conditions. All the triamminetrihalogeno complexes thus obtained have *mer*-configuration with respect to the positions of the three halide ions.

Methods for preparing triamminetrihalogenochromium(III) complexes are usually based on the use of $[Cr(O_2)_2(NH_3)_3]$ in aqueous media[3] or that of thermal decomposition of ammine complexes in open systems.[4] However, the former is considerably troublesome while the latter has the disadvantage that thermal reactions in open systems do not always proceed uniformly to give pure products. The thermal reactions of metal complexes have been reported to proceed reproducibly and uniformly under quasi-isothermal and -isobaric conditions (Q-conditions),[1] and the intermediates and the final products in each reaction step can be obtained in remarkably pure constitution.[5]

This paper deals with the investigation of (1) the thermal decomposition of various amminechromium(III) complexes under Q-conditions as well as dynamic conditions (D-conditions)[1] and (2) the possibility of the formation of triamminetrihalogeno complexes.

The reactions in this work are classified as follows according to the final products: (A) Formation of $[CrCl_3(NH_3)_3]$ from $[Cr(NH_3)_6]Cl_3$, $[CrCl(NH_3)_5]Cl_2$, and *trans*-$[CrCl_2(NH_3)_4]Cl$; (B) formation of $[CrBr_3(NH_3)_3]$ from $[Cr(NH_3)_6]Br_3$ and $[CrBr(NH_3)_5]Br_2$; (C) formation of $[CrBrCl_2(NH_3)_3]$ from $[CrBr(NH_3)_5]Cl_2$, *trans*-$[CrCl_2(NH_3)_4]Br$, and *trans*-$[CrBrCl(NH_3)_4]Cl$; and (D) formation of $[CrBr_2Cl(NH_3)_3]$ from $[CrCl(NH_3)_5]Br_2$ and *trans*-$[CrBrCl(NH_3)_4]Br$.

Experimental

Preparation of Complexes. The complexes except for the mixed halogeno complexes were prepared according to known procedures.

$[Cr(NH_3)_6]Cl_3$ (I),[6] $[Cr(NH_3)_6]Br_3$ (II),[7] and $[CrCl(NH_3)_5]Cl_2$ (III)[8] were obtained by the methods reported.

$[CrCl(NH_3)_5]Br_2$ (IV) was prepared by adding NaBr to an aqueous solution of $[CrCl(NH_3)_5]Cl_2$ (III).

trans-$[CrCl_2(NH_3)_4]Cl$ (V) and *trans*-$[CrCl_2(NH_3)_4]Br$ (VI) were obtained by the acid cleavage of rhodochromic chloride $[(NH_3)_5Cr(OH)Cr(NH_3)_5]Cl_5$.[9]

$[CrBr(NH_3)_5]Br_2$ (VII) was prepared by the method of Linhard and Weigel.[10]

$[CrBr(NH_3)_5]Cl_2$ (VIII) was obtained by the addition of NH_4Cl to $[CrBr(NH_3)_5]Br_2$ (VII) in ice-cooled water.

trans-$[CrBrCl(NH_3)_4]Cl$ (IX) and *trans*-$[CrBrCl(NH_3)_4]Br$ (X): Chloroerythrochromic bromide $[(NH_3)_5Cr(OH)CrCl(NH_3)_4]Br_4$ prepared from the corresponding chloride[9] was added to a mixture of 60% $HClO_4$ and concd HBr (2: 1) in a loosely stoppered flask. The mixture was left to stand at room temperature for 2 h. The solid product was collected and washed with a small amount of 1 M $HClO_4$. Bright green *trans*-$[CrBrCl(NH_3)_4]ClO_4$ thus obtained was converted into *trans*-$[CrBrCl(NH_3)_4]Cl\cdot nH_2O$ and *trans*-$[CrBrCl(NH_3)_4]Br\cdot nH_2O$ with a saturated solution of NH_4Cl and concd HBr, respectively, and then collected and dried at 100 °C for 5 and 2 h to give the anhydrous chloride and bromide, respectively. Analytical data for the mixed halogeno complexes are given in Table 1.

Measurements. The thermal reactions were traced on MOM D- and Q-derivatographs.[1] Measurements by D-derivatograph were carried out in a constant flow of nitrogen at heating rate 1 °C min^{-1}. The electronic spectra were measured in powder state with a Hitachi EPU-2A spectrophotometer equipped with a standard Hitachi reflection attachment (Type R-3).

Table 1. Analytical data for starting complexes

Complex	H (%)		N (%)		Cr (%)	
	Found	Calcd	Found	Calcd	Found	Calcd
$[CrCl(NH_3)_5]Br_2$ (IV)	4.60	4.51	21.08	21.05	15.32	15.64
$[CrBr(NH_3)_5]Cl_2$ (VIII)	5.31	5.21	24.23	24.31	17.91	18.05
trans-$[CrCl_2(NH_3)_4]Br$ (VI)	4.47	4.43	20.66	20.66	18.97	19.18
trans-$[CrBrCl(NH_3)_4]Cl$ (IX)	4.63	4.43	20.43	20.66	19.22	19.18
trans-$[CrBrCl(NH_3)_4]Br$ (X)	3.85	3.80	17.83	17.75	16.26	16.48

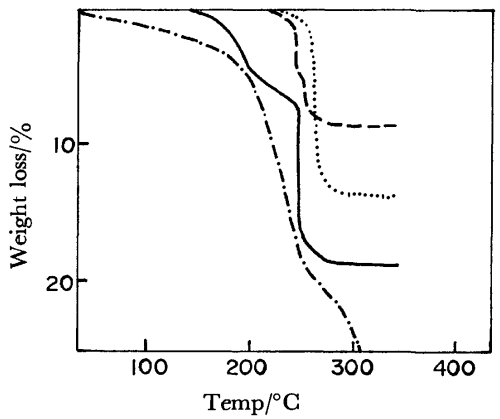

Fig. 1. Q-derivatograms of complexes I (——), III (·····), and V (– – –) together with D-derivatogram of complex I (—·—).

Results and Discussion

Formation of Triamminetrihalogeno Complexes. (A) Formation of $[CrCl_3(NH_3)_3]$ *from* $[Cr(NH_3)_6]Cl_3$ *(I),* $[CrCl(NH_3)_5]Cl_2$ *(III), and* trans-$[CrCl_2(NH_3)_4]Cl$ *(V).* Figure 1 shows the Q-derivatograms of complexes I, III, and V together with the D-derivatogram (TG curve only) of complex I. As seen from the D-derivatogram of complex I, a monotonous decrease takes place and no plateau is obtained in the TG curve, indicating that the complex decomposes gradually in a complicated manner with no formation of uniform products. Since this tendency was found in all the other complexes, their D-derivatograms are omitted in the following discussion.

On the other hand, the Q-derivatogram of complex I shows a gradual weight loss at 150—242 °C due to the evolution of 1 mol of ammonia (Found: 7.61%; Calcd: 6.52%), and then an abrupt weight loss takes place at 242 °C until a plateau is attained. The total weight loss is 18.69% approximately agreeing with that (19.58%) calculated for the formation of $[CrCl_3(NH_3)_3]$. The original yellow color turned green at this stage. The results suggest that complex I undergoes deammonation to be converted into $[CrCl_3(NH_3)_3]$ *via* $[CrCl(NH_3)_5]Cl_2$ without forming $[CrCl_2(NH_3)_4]Cl$.

The Q-derivatogram of complex III shows rapid evolution of 2 mol of ammonia in a narrow temperature range (250—260 °C), after which a clear plateau is obtained, the complex turning green from red. The net weight loss (13.77%) coincides with the value calculated for the formation of $[CrCl_3(NH_3)_3]$ (13.99%).

In the Q-derivatogram of complex V, a sharp change in weight takes place nearly isothermally (230—250 °C) until a distinct plateau appears. The weight loss in 7.73% which is close to that (7.50%) calculated for 1 mol of ammonia.

The analytical data for the triamminetrihalogeno complexes are summarized in Table 2. The observed and calculated values agree, indicating that $[CrCl_3(NH_3)_3]$ is obtained under Q-conditions irrespective of the starting complex.

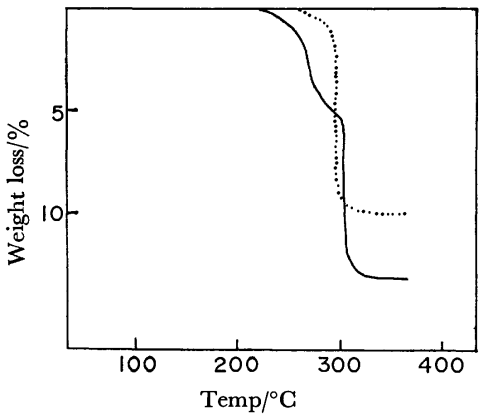

Fig. 2. Q-derivatograms of complexes II (——) and VII (·····).

Table 2. Analytical data for triamminetrihalogeno complexes produced

( ): Calcd

Triammine complex	Starting complex	H (%)	N (%)	Cr (%)
(A) *mer*-$[CrCl_3(NH_3)_3]$	$[Cr(NH_3)_6]Cl_3$	4.19 (4.29)	19.78 (20.04)	24.69 (24.82)
	$[CrCl(NH_3)_5]Cl_2$	4.24 (4.29)	20.01 (20.04)	24.84 (24.82)
	trans-$[CrCl_2(NH_3)_4]Cl$	4.30 (4.29)	19.61 (20.04)	25.02 (24.82)
(B) *mer*-$[CrBr_3(NH_3)_3]$	$[Cr(NH_3)_6]Br_3$	2.53 (2.62)	11.82 (12.24)	14.64 (15.16)
	$[CrBr(NH_3)_5]Br_2$	2.40 (2.62)	12.29 (12.24)	14.95 (15.16)
(C) *mer*-$[CrBrCl_2(NH_3)_3]$	$[CrBr(NH_3)_5]Cl_2$	3.50 (3.54)	16.40 (16.54)	20.50 (20.47)
	trans-$[CrCl_2(NH_3)_4]Br$	3.52 (3.54)	16.91 (16.54)	20.31 (20.47)
	trans-$[CrBrCl(NH_3)_4]Cl$	3.61 (3.54)	16.70 (16.54)	20.15 (20.47)
(D) *mer*-$[CrBr_2Cl(NH_3)_3]$	$[CrCl(NH_3)_5]Br_2$	2.99 (3.02)	14.61 (14.09)	17.66 (17.42)
	trans-$[CrBrCl(NH_3)_4]Br$	3.07 (3.02)	14.23 (14.09)	17.52 (17.42)

(B) Formation of $[CrBr_3(NH_3)_3]$ *from* $[Cr(NH_3)_6]Br_3$ *(II) and* $[CrBr(NH_3)_5]Br_2$ *(VII).* Figure 2 shows the Q-derivatograms of complexes II and VII. They give patterns similar to those of the foregoing chlorides I and III, respectively. The first gradual weight loss for complex II (250—303 °C) is due to the evolution of 1 mol of ammonia (Found: 4.95%; Calcd: 4.31%) and the second rapid weight loss is due to the evolution of 2 mol of ammonia. The TG curve then reaches a plateau. The overall weight loss (12.50%) agrees with that (12.94%) calculated for the formation of $[CrBr_3(NH_3)_3]$.

Complex VII gives only one rapid weight loss step corresponding to the liberation of 2 mol of ammonia (Found: 8.97%; Calcd: 9.02%). The formation of $[CrBr_2(NH_3)_4]Br$ was not detectable in the decomposition pathways of both the complexes.

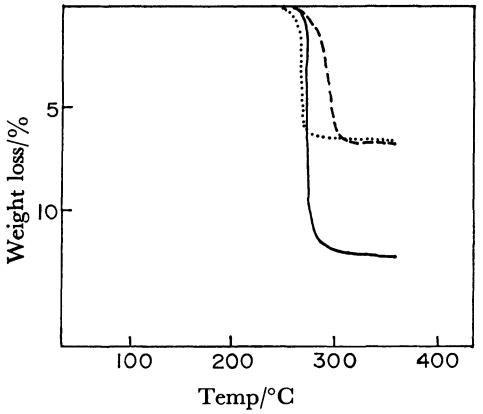

Fig. 3. Q-derivatograms of complexes VIII (——), VI (·····), and IX (---).

(C) Formation of $[CrBrCl_2(NH_3)_3]$ *from* $[CrBr(NH_3)_5]Cl_2$ *(VIII),* trans-$[CrCl_2(NH_3)_4]Br$ *(VI), and* trans-$[CrBrCl(NH_3)_4]Cl$ *(IX).* The Q-derivatograms of complexes VIII, VI, and IX are shown in Fig. 3. Complex VIII evolves 2 mol of ammonia nearly isothermally (275—285 °C), and complexes VI and IX, 2 mol of ammonia at 267—280 °C and 253—290 °C, respectively. The observed weight loss due to the evolution of ammonia is 11.62% (Calcd: 11.81%) for complex VIII, 6.26% (Calcd: 6.27%) for complex VI and 6.34% (Calcd: 6.27%) for complex IX. The analytical data indicate that all the final products have exactly the same composition as $[CrBrCl_2(NH_3)_3]$ (Table 2).

(D) Formation of $[CrBr_2Cl(NH_3)_3]$ *from* $[CrCl(NH_3)_5]Br_2$ *(IV) and* trans-$[CrBrCl(NH_3)_4]Br$ *(X).* We see from Fig. 4 that complexes IV and X evolve 2 mol (Found: 5.46%; Calcd: 5.39%) and 1 mol (Found: 10.26%; Calcd: 10.22%) of ammonia, respectively, at 270—290 °C to form $[CrBr_2Cl(NH_3)_3]$.

Configuration of Triamminetrihalogeno Complexes Obtained. Two configurations are possible for the triamminetrihalogeno complexes, facial and meridional with respect to the positions of the three halide ions (or three ammonia molecules). Such distinction in $[CrX_3N_3]$ chromophore (X denotes halide ion and N nitrogen atom) has been achieved from electronic spectral measurements.[4a,11] *fac*-Form has two bands, whereas *mer*-form has three in d-d transition region, a weak band due to the spin-forbidden transition ($^4A_{2g} \rightarrow {}^2E_g$) appearing in lower wavelength region ($\approx 13 \times 10^3$ cm^{-1}) being characteristic of *mer*-form.

Figures 5—8 show the electronic spectra of $[CrCl_3(NH_3)_3]$, $[CrBr_3(NH_3)_3]$, $[CrBrCl_2(NH_3)_3]$, and $[CrBr_2Cl(NH_3)_3]$. The triamminetrihalogeno complexes obtained from *trans*-dihalogeno complexes have the

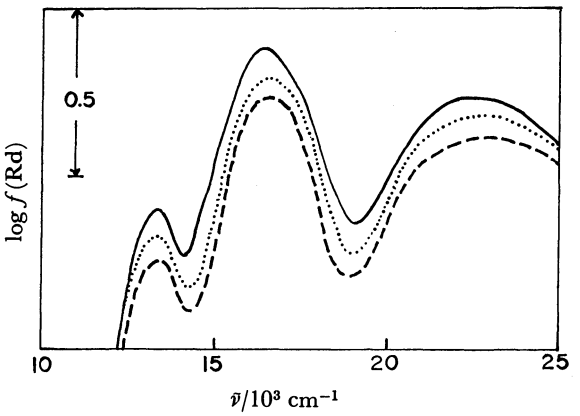

Fig. 5. Electronic spectra of $[CrCl_3(NH_3)_3]$ produced from complexes I (——), III (·····), and V (---).

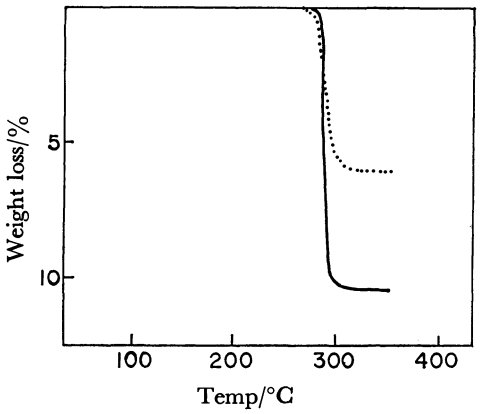

Fig. 4. Q-derivatograms of complexes IV (——) and X (·····).

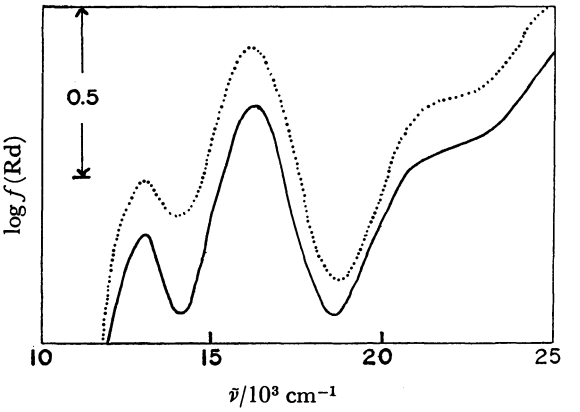

Fig. 6. Electronic spectra of $[CrBr_3(NH_3)_3]$ produced from complexes II (——) and VII (·····).

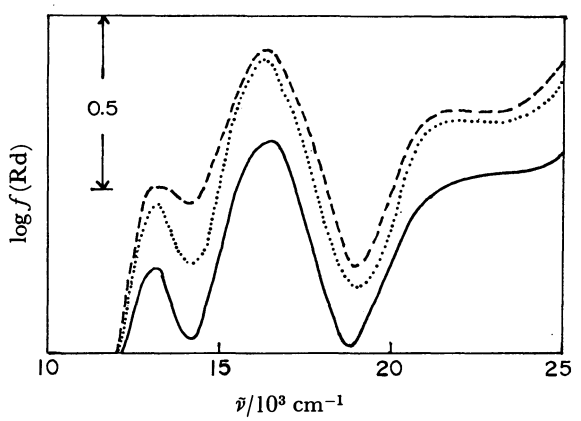

Fig. 7. Electronic spectra of $[CrBrCl_2(NH_3)_3]$ produced from complexes VIII (——), VI (·····), and IX (---).

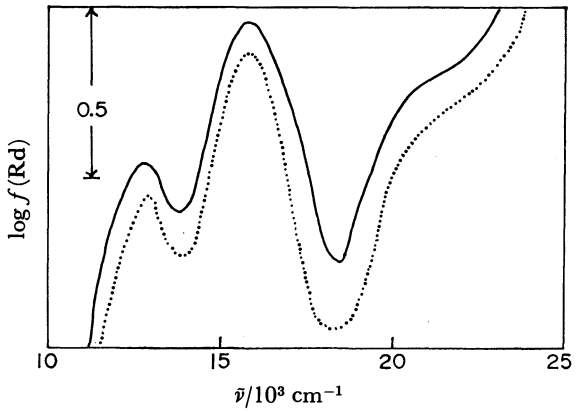

Fig. 8. Electronic spectra of $[CrBr_2Cl(NH_3)_3]$ produced from complexes IV (——) and X (·····).

possibility to take only *mer*-configuration. All the spectra have one weak and two strong bands, indicating that all the triamminetrihalogeno complexes are in *mer*-configuration.

Table 3. Absorption maxima for triamminetrihalogeno complexes

Complex	Maxima ($^4A_{2g} \rightarrow {}^2E_g$) $\tilde{\nu}$/cm^{-1}	Maxima ($^4A_{2g} \rightarrow {}^4T_{2g}$) $\tilde{\nu}$/cm^{-1}
mer-$[CrCl_3(NH_3)_3]$	13400	16700
mer-$[CrBrCl_2(NH_3)_3]$	13100	16200
mer-$[CrBr_2Cl(NH_3)_3]$	12900	16000
mer-$[CrBr_3(NH_3)_3]$	12800	15600

The absorption maxima due to $^4A_{2g} \rightarrow {}^2E_g$ and $^4A_{2g} \rightarrow {}^4T_{2g}$ transitions are given in Table 3. The absorption maxima due to $^4A_{2g} \rightarrow {}^4T_{2g}$ are shifted to the lower energy region according to spectrochemical series in the order $[CrCl_3(NH_3)_3] \rightarrow [CrBrCl_2(NH_3)_3] \rightarrow [CrBr_2Cl(NH_3)_3] \rightarrow [CrBr_3(NH_3)_3]$. Two structures are possible for *mer*-$[CrBrCl_2(NH_3)_3]$ and *mer*-$[CrBr_2Cl(NH_3)_3]$: *viz.*, *cis*-form and *trans*-form regarding chloride and bromide ions, but the question is still pending.

Summary of Thermal Reaction Pathways. The hexaammine complexes are converted into pentaamminehalogeno and then triamminetrihalogeno complexes without forming tetraamminedihalogeno complexes. The pentaamminehalogeno complexes undergo deammonation in one step to yield triamminetrihalogeno complexes, without forming tetraamminedihalogeno complexes. Why no tetraamminedihalogeno complexes can be produced in the reaction pathways of hexaammine and pentaammine complexes is easily understandable from a comparison of the formation temperature of triamminetrihalogeno complexes:

$[CrCl(NH_3)_5]Cl_2 \longrightarrow [CrCl_3(NH_3)_3]$ 250—270 °C

trans-$[CrCl_2(NH_3)_4]Cl \longrightarrow [CrCl_3(NH_3)_3]$ 230—250 °C

$[CrBr(NH_3)_5]Cl_2 \longrightarrow [CrBrCl_2(NH_3)_3]$ 275—285 °C

trans-$[CrBrCl(NH_3)_4]Cl \longrightarrow [CrBrCl_2(NH_3)_3]$ 253—273 °C

$[CrCl(NH_3)_5]Br_2 \longrightarrow [CrBr_2Cl(NH_3)_3]$ 290—300 °C

trans-$[CrBrCl(NH_3)_4]Br \longrightarrow [CrBr_2Cl(NH_3)_3]$ 270—290 °C.

The temperatures of the tetraamminedihalogeno complexes are lower than those of the corresponding pentaamminehalogeno complexes. Thus, even though the tetraamminedihalogeno complexes are produced in each reaction pathway, they are immediately decomposed, forming triamminetrihalogeno complexes.

The authors are grateful to Hungarian Optical Works and Kubota Trading Co. for the use of Q-derivatograph.

Binuclear Metal Complexes. XXXIX.[1] Synthesis and Properties of Binuclear Copper(II) Complexes with [2-(2-Pyridyl)ethylamino]-alkanols and [2-(2-Pyridyl)ethylthio]alkanols

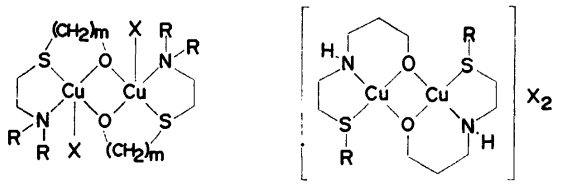
Masaaki NAKAMURA, Masahiro MIKURIYA, Hisashi OKAWA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received January 31, 1981)

Di-μ-alkoxo-bridged binuclear copper(II) complexes, Cu(py-3-3-nno)X, Cu(py-3-2-nso)X, and Cu(py-3-3-nso)X (X=Cl, Br, ClO_4, NO_3, PF_6, BF_4), have been synthesized and characterized, where Hpy-3-3-nno, Hpy-3-2-nso, and Hpy-3-3-nso denote 3-[2-(2-pyridyl)ethylamino]-1-propanol, 2-[2-(2-pyridyl)ethylthio]ethanol, and 3-[2-(2-pyridyl)ethylthio]-1-propanol, respectively. It was found that 2-[2-(2-pyridyl)ethylamino]ethanol (Hpy-3-2-nno) cannot form di-μ-alkoxo-bridged binuclear copper(II) complexes owing to the high strain in the fused ring system. These complexes exhibited a band at 22000—27000 cm^{-1} characteristic of the di-μ-alkoxo-bridged structure, the bands for Cu(py-3-2-nso)X and Cu(py-3-3-nso)X being lower in frequency compared with those for Cu(py-3-3-nno)X. Antiferromagnetic interaction was stronger and reduction potential (Cu(II)-Cu(II)$\rightarrow$Cu(I)-Cu(I)) was higher for Cu(py-3-3-nso)X than those for Cu(py-3-3-nno)X. Cu(py-3-3-nso)Cl and Cu(py-3-2-nso)Br showed two reduction waves at about +0.15 and −0.4 V *vs.* SCE. These results were discussed in terms of the structure in solution on the basis of conductivity measurements.

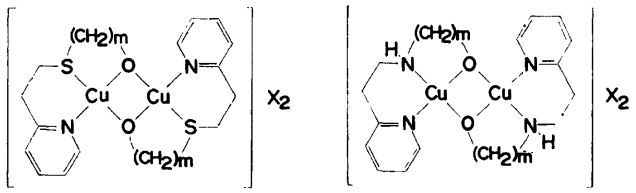
Di-μ-alkoxo-bridged binuclear copper(II) complexes containing a thioether sulfur as a donor atom are of interest as models of Type III copper proteins. In the preceding papers of this series,[2-6] we have reported preparations and properties of di-μ-alkoxo-bridged binuclear copper(II) complexes with the nso- and sno-type ligands (Fig. 1). Substitution of thioether sulfur for aliphatic amino nitrogen resulted in 1) a red shift of the characteristic band of di-μ-alkoxo-bridged binuclear copper(II) complexes in the near ultraviolet region (this band being assigned to the $p_\pi(O)\rightarrow d_\sigma(Cu)$ charge transfer band[7-9]), 2) an enhancement in antiferromagnetic spin-exchange interaction between the two copper(II) ions, 3) a positive shift of the copper(II)$\rightarrow$copper(I) reduction potential, and 4) a strain relaxation in the fused ring system of the binuclear skeleton.



(a) (b)

Fig. 1. Complexes of (a) Cu(R-2-m-nso)X (m=2, 3) and (b) Cu(R-2-3-sno)X.

In order to further investigate the nature of binuclear copper(II) complexes with sulfur-containing ligands, new binuclear copper(II) complexes, Cu(py-3-m-nso)X (X=Cl, Br, ClO_4, NO_3, BF_4, PF_6; m=2, 3) (Fig. 2a), of 2-[2-(2-pyridyl)ethylthio]ethanol (abbreviated as Hpy-3-2-nso) and 3-[2-(2-pyridyl)ethylthio]-1-propanol (Hpy-3-3-nso) have been prepared and their spectral, magnetic, and electrochemical properties were compared with those of Cu(py-3-2-nno)X and Cu(py-3-3-nno)X (X=ClO_4, BF_4, PF_6), where Hpy-3-2-nno denotes 2-[2-(2-pyridyl)ethylamino]ethanol and Hpy-3-3-nno 3-[2-(2-pyridyl)ethylamino]-1-propanol (Fig. 2b).



(a) (b)

Fig. 2. Complexes of (a) Cu(py-3-m-nso)X (m=2, 3) and (b) Cu(py-3-m-nno)X (m=2,3).

Another purpose of this study is to examine the effect of substitution of pyridine-nitrogen for alkyl amine group in binuclear copper(II) complexes of diaminoalcohols.

Experimental

Preparation of the Ligands. Hpy-3-2-nno and Hpy-3-3-nno were prepared by the reaction of 2-vinylpyridine with 2-aminoethanol and 3-amino-1-propanol, respectively.[10] Similarly, Hpy-3-2-nso and Hpy-3-3-nso were prepared by the addition of 2-mercaptoethanol and 3-mercapto-1-propanol to 2-vinylpyridine, respectively.

Preparation of the Complexes. Cu(py-3-3-nno)X (X=ClO_4, BF_4). The preparation was exemplified by Cu(py-3-3-nno)ClO_4. To a solution of Hpy-3-3-nno (0.5 mmol) in absolute ethanol (10 cm^3) was added a solution of copper(II) perchlorate hexahydrate (0.5 mmol) in absolute ethanol (20 cm^3). To this mixture was added triethylamine to precipitate a blue solid. It was collected by filtration and recrystallized from methanol.

Cu(py-3-3-nno)PF_6. A mixture of Cu(py-3-3-nno)-ClO_4 (0.5 mmol) and KPF_6 (0.5 mmol) in acetonitrile (20 cm^3) was stirred for 2 h at room temperature. The solvent was evaporated, and a remaining blue precipitate was collected by filtration and recrystallized from methanol twice to give deep blue needles.

Cu(py-3-2-nso)X and Cu(py-3-3-nso)X (X=ClO_4, Cl, Br, NO_3, BF_4). The compounds were prepared by a method similar to that for Cu(py-3-3-nno)ClO_4. They were recrystallized from methanol.

Cu(py-3-2-nso)PF_6 and Cu(py-3-3-nso)PF_6. These were prepared by the reaction of Cu(py-3-2-nso)ClO_4 and Cu(py-3-3-nso)ClO_4 with KPF_6 in acetonitrile, respectively.

Carbon, hydrogen, and nitrogen analyses were carried out at the Service Center of Elemental Analysis, Kyushu University. The results are given in Table 1.

Measurements. Infrared spectra were measured with a Hitachi grating infrared spectrophotometer Model 215 in the region 4000—650 cm^{-1} on a KBr disk and on a nujol mull. Electronic spectra were measured with a Shimadzu multipurpose spectrophotometer Model MPS-5000 in methanol solutions and on solid samples. Magnetic susceptibilities were measured by the Faraday method in the temperature range from liquid nitrogen temperature to room temperature. The apparatus was calibrated by the use of $[Ni(en)_3]S_2O_3$.[11] All the susceptibilities were corrected for the diamagnetism of the constituting atoms by the use of Pascal's constants.[12] Effective magnetic moments were calculated by the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the atomic magnetic susceptibility and $N\alpha$ is the temperature-independent paramagnetism. Normal pulse polarography (NPP) and differential pulse polarography (DPP) were measured with a Yanagimoto voltammetric analyzer Model P-1000 in *N,N*-dimethylformamide (DMF) containing 0.1 mol dm^{-3} tetraethylammonium perchlorate at room temperature using a three-electrode cell. The saturated calomel electrode (SCE) was used as a reference, which was connected to a sample solution through a salt bridge. A dropping mercury electrode was used as a working electrode. The counter electrode was platinum coil. Conductivity was measured with a Yanagimoto conductivity outfit Model MY-8 for methanol and *N,N*-dimethylformamide solution. The cell constants were determined by the use of NaCl and KBr.[13,14]

Results and Discussion

Among the binucleating ligands utilized in this study, Hpy-3-3-nno, Hpy-3-3-nso, and Hpy-3-2-nso formed di-μ-alkoxo-bridged binuclear copper(II) complexes. On the other hand, we were unsuccessful in isolating Cu(py-3-2-nno)X using Hpy-3-2-nno. The product obtained by the reaction of Hpy-3-2-nno and copper(II) halide was supposed to be $Cu(H_2NCH_2CH_2O)X$ (X=halogenide ion)[9] on the basis of elemental analyses and cryomagnetic properties, and this was confirmed by comparing the infrared spectrum of the product with that of the authentic sample obtained from 2-aminoethanol and a copper(II) halide. Thus, it is evident that Hpy-3-2-nno cleaved into 2-aminoethanol and 2-vinylpyridine in this reaction. The complex, Cu-

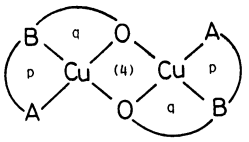

Fig. 3. Representation of the fused chelate-ring system, p-q-(4)-q-p, for binuclear complexes of alcoholic tridentate ligands.

(py-3-2-nno)X, should have a 6-5-(4)-5-6 fused ring system (Fig. 3) which is generally thought to be stable in the complexes with the fully saturated ligands, such as HR-3-2-nno.[7-9] However, the terminal six-membered chelate ring of Cu(py-3-2-nno)X must be small in size and may be comparable to the five-membered ring of a saturated ligand, because of short bond-distance in pyridine ring. So far, binuclear copper(II) complexes with a 5-5-(4)-5-5 fused ring system have not been obtained using diamino alcohols,[15-19] owing to a high strain in this system. A similar strain should exist in the 6-5-(4)-5-6 fused ring system of Cu(py-3-2-nno)X, and should be responsible for the cleavage of Hpy-3-2-nno and the formation of strain-free $Cu(H_2NCH_2CH_2O)X$.

On the other hand, we were successful in isolating Cu(py-3-2-nso)X, although it has the same 6-5-(4)-5-6 fused ring system as Cu(py-3-2-nno)X. It is to be noticed that the chelate ring system in Cu(py-3-2-nso)X contains a thioether group. Previously, we showed that the binuclear copper(II) complexes, Cu(R-2-2-nso)X (HR-2-2-nso=2-(2-dialkylaminoethylthio)ethanol), possessing a fully saturated 5-5-(4)-5-5 fused ring system can be isolated, because of a high flexibility in bond angle and large coordination bond distance of the thioether sulfur atom.[5] It is likely that a similar strain-releasing effect contributes to the formation of Cu(py-3-2-nso)X.

Since no band attributable to OH-stretching vibration was observed, the alcoholic oxygen should be deprotonated and coordinated to copper. The shift of the 990 cm^{-1} band of free pyridine to higher frequency showed the coordination of pyridine nitrogen. The bands due to ClO-stretching vibration in Cu(py-3-3-nno)ClO_4 and Cu(py-3-3-nso)ClO_4 were observed at 1070 cm^{-1}. Practically no splitting of the bands indicates

Table 2. Band maxima of electronic spectra of complexes ($\bar{\nu}/10^3$ cm^{-1})

$Cu(py\text{-}3\text{-}2\text{-}nso)PF_6\cdot 1/2H_2O$	23.3	16.3	24.4(3.16)	15.6(2.24)

that the perchlorate ion is free from coordination.[20] On the other hand, the ClO-stretching vibration of $Cu(py\text{-}3\text{-}2\text{-}nso)ClO_4$ splits into three components at 1120, 1030, and 930 cm^{-1}. This indicates the coordination of the perchlorate ion to the copper(II).[20] The NO-stretching band of the nitrate ion in $Cu(py\text{-}3\text{-}2\text{-}nso)NO_3\cdot 1/2CH_3OH$ was observed at 1320 and 1380 cm^{-1}, suggesting non-coordination of the nitrate ion to the metal.[21]

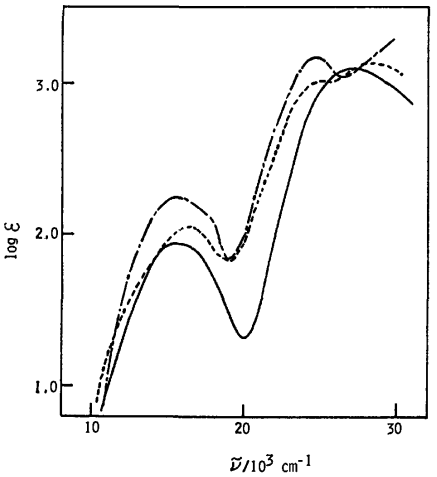

Fig. 4. Electronic absorption spectra of (——)Cu(py-3-3-nno)PF_6, (·····) Cu (py-3-3-nso)PF_6, and (-·-) Cu (py-3-2-nso) PF_6 in methanol.

Electronic spectra of the complexes were measured in methanol and *N,N*-dimethylformamide solutions and on powder samples. Results are given in Table 2. Typical examples of absorption spectra are shown in Fig. 4. Spectra in solution and in solid state resemble each other, indicating essentially the same structure in solid and in solution. The band in the 14000—17000 cm^{-1} region can be assigned to d-d transition band. The d-d band of Cu(py-3-2-nso)X is slightly lower in frequency compared with those of Cu(py-3-3-nso)X and Cu(py-3-3-nno)X in solid state. This suggests that the coordination geometry around the copper ion in Cu(py-3-2-nso)X is distorted from square plane. Among these complexes, the d-d band of Cu(py-3-2-nso)Cl and Cu(py-3-2-nso)Br is notably low in energy. Recently, we determined the crystal structure of $Cu(CH_3\text{-}2\text{-}2\text{-}nso)Br$ by the X-ray diffraction method.[5] The structure consists of alkoxo-bridged binuclear units, $Cu_2(CH_3\text{-}2\text{-}2\text{-}nso)_2Br_2$, where bromide ions coordinate to copper(II) ions and the coordination geometry around each copper ion is a distorted square pyramid. As already mentioned, the strain in the fused ring system of Cu(py-3-2-nso)X is similar to that of Cu(R-2-2-nso)X. Hence, it is likely that Cu(py-3-2-nso)X (X=Cl, Br) takes a distorted square pyramidal structure similar to that of $Cu(CH_3\text{-}2\text{-}2\text{-}nso)Br$. The band with a relatively large intensity (ε=1000—2000) in the 24000—27000 cm^{-1} region is known to be characteristic of the di-μ-alkoxo-bridged binuclear copper(II) structure. Kida *et al.* have assigned this band to the $p_\pi(O)\rightarrow d_\sigma(Cu)$ charge transfer transition.[7-9] This is observed around 26000 cm^{-1} in the case of Cu(py-3-3-nno)X, while the CT band for Cu(py-3-3-nso)X and Cu(py-3-2-nso)X appeared in the region 22000—25000 cm^{-1}. Therefore, the $p_\pi(O)\rightarrow d_\sigma(Cu)$ charge transfer band shifts by 3000—4000 cm^{-1} to lower frequency when one of the amine nitrogen is replaced by a thioether sulfur. The present result is in line with our previous findings that the thioether substitution for amino group causes a red-shift of the charge-transfer band in di-μ-alkoxo-bridged binuclear copper(II) complexes.

The magnetic susceptibilities were measured over the temperature range 80—300 K. The magnetic moments per copper atom are all subnormal at room temperature and decrease with lowering of temperature, indicating the existence of an antiferromagnetic spin-exchange interaction between a pair of copper(II) ions. The temperature dependences of magnetic susceptibility for $Cu(py\text{-}3\text{-}3\text{-}nso)ClO_4$ and $Cu(py\text{-}3\text{-}3\text{-}nno)BF_4$ are shown in Fig. 5 as examples. These magnetic behaviors can be interpreted in terms of the Bleaney-Bowers equation,[22]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha, \qquad (1)$$

where χ_A is susceptibility per copper atom and other symbols have their usual meanings. The $-2J$ (the energy separation between the spin-singlet ground state and the spin-triplet excited state) and $N\alpha$ values were obtained by the best-fit of the experimental susceptibilities to the Eq. 1, assuming g at 2.10. The results are given in Table 3. Table 3 also includes the effective magnetic moments of the complexes at room tempera-

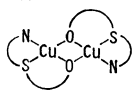
TABLE 3. MAGNETIC DATA OF COMPLEXES

Complex	μ_{eff} [a] / BM	$-2J$ / cm^{-1}	$N\alpha \times 10^6$ / c.g.s. mol^{-1}
Cu(py-3-3-nno)ClO_4	0.88	510	60
Cu(py-3-3-nno)BF_4	0.87	540	60
Cu(py-3-3-nno)PF_6	0.67	700	40
Cu(py-3-3-nso)ClO_4	0.61	705	50
Cu(py-3-3-nso)PF_6	0.47	850	60
Cu(py-3-2-nso)Cl	1.63	170	90
Cu(py-3-2-nso)Br	1.48	225	60
Cu(py-3-2-nso)ClO_4	1.26	300	60
Cu(py-3-2-nso)$NO_3 \cdot 1/2CH_3OH$	0.83	550	60
Cu(py-3-2-nso)$BF_4 \cdot H_2O$	0.71	650	65
Cu(py-3-2-nso)$PF_6 \cdot 1/2H_2O$	0.48	850	60

a) Magnetic moment at room temperature.

ture. The $-2J$ values for Cu(py-3-3-nno)X (X=ClO_4, BF_4, PF_6) range from 510 to 700 cm^{-1}, which are comparable to the $-2J$ values for the binuclear copper(II) complexes with aliphatic diaminoalcohols.[9] Therefore, we can not detect any marked effect of pyridine nitrogen donation on antiferromagnetic spin-exchange interaction in di-μ-alkoxo-bridged binuclear copper(II) complexes. It is to be noted that the $-2J$ values of Cu(py-3-3-nso)X (750—850 cm^{-1}) are much larger than the values of Cu(py-3-3-nno)X. Thus, antiferromagnetic spin-exchange interaction betweem the two copper(II) ions becomes stronger upon substitution of the sulfur donor atom for the nitrogen donor atom. A similar trend was already noticed in Cu(R-2-3-nso)X and Cu(R-2-3-sno)X.[2-6] The $-2J$ values of Cu(py-3-2-nso)X seem to depend on X. Namely, the complexes containing Cl, Br, or ClO_4 ion have smaller $-2J$ values compared with other complexes containing NO_3, BF_4, or PF_6 ion. Since the infrared and electronic reflectance spectral data evidenced the coordination of the anion X, the complexes Cu(py-3-2-nso)X (X=Cl, Br, ClO_4) should have a five-coordinate structure whose



skeleton is much distorted from a coplane. Since spin-exchange interaction is known to be highly dependent on planarity around the metal, this distortion must be the main reason for the reduction in the exchange integral of Cu(py-3-2-nso)X (X=Cl, Br, ClO_4).

TABLE 4. HALF-WAVE POTENTIALS OF NORMAL PULSE (NPP) AND DIFFERENTIAL PULSE (DPP) POLAROGRAPHIES (V *vs.* SCE)

Complex	NPP	DPP	
Cu(py-3-3-nno)ClO_4	−0.40		−0.43
Cu(py-3-3-nno)BF_4	−0.40	−0.39	−0.42
Cu(py-3-3-nno)PF_6	−0.42	−0.40	−0.42
Cu(py-3-3-nso)ClO_4		−0.09	
Cu(py-3-3-nso)PF_6		−0.09	
Cu(py-3-2-nso)Cl		+0.16	−0.56
Cu(py-3-2-nso)Br		+0.11	−0.56
Cu(py-3-2-nso)ClO_4		−0.06	
Cu(py-3-2-nso)$NO_3 \cdot 1/2CH_3OH$		−0.09	
Cu(py-3-2-nso)$BF_4 \cdot H_2O$		−0.08	
Cu(py-3-2-nso)$PF_6 \cdot 1/2H_2O$		−0.09	

The results of normal pulse polarography (NPP) and differential pulse polarography (DPP) are listed in Table 4. The reduction from Cu(II)-Cu(II) to Cu(I)-Cu(I) for Cu(py-3-3-nno)X occured at −0.4 V *vs.* SCE. These reduction potentials are comparable to those of the binuclear complexes with the aliphatic diaminoalcohols.[4] Therefore, it seems that the reduction potential from Cu(II)-Cu(II) to Cu(I)-Cu(I) is little affected by substitution of aromatic amine nitrogen for aliphatic amine nitrogen. The reduction of Cu(py-3-3-nso)X (X=ClO_4, PF_6) at −0.10 V *vs.* SCE positively shifted by *ca.* 300 mV relative to reduction potentials of Cu(py-3-3-nno)X. As was already pointed out in the preceding paper,[4] the positive shift of the Cu(II)-Cu(II)→Cu(I)-Cu(I) reduction potential implies that the optical electronegativity[24] of copper(II) ion increases when a sulfur atom is introduced as a donating atom. Electrochemical property of Cu(py-3-2-nso)X (X=ClO_4, NO_3, BF_4, and PF_6) resembles that of Cu(py-3-3-nso)X, showing a two-electron reduction at about −0.10 V. On the other hand, Cu(py-3-2-nso)Cl and Cu(py-3-2-nso)Br showed two reduction waves at +0.2 and −0.60 V, and +0.10 and −0.40 V, respectively. These complexes bear a marked electrochemical resemblance to Cu(R-2-2-nso)X (X=Cl, Br),[4] which also showed two one-electron reductions at +0.15—+0.20 and −0.30——0.50 V *vs.* SCE. The controlled-potential electrolysis[4] showed that Cu(R-2-2-nso)X (X=Cl, Br) was reduced stepwise as Cu(II)-Cu(II)→Cu(II)-Cu(I)→Cu(I)-Cu(I). Accordingly, it is assumed that Cu(py-3-2-nso)Cl and Cu(py-3-2-nso)Br are also stepwise reduced. In order to clarify the reasons for the difference in electrochemical behaviors between the two groups of the binuclear complexes, *i.e.*, those undergoing two one-electron reductions and those undergoing one two-electron reduction, conductivities were measured in methanol and *N*,*N*-dimethylformamide. The results are shown in Table 5. The conductivities of Cu(py-3-2-nso)ClO_4 and Cu(py-3-2-nso)PF_6 clearly indicate that they are 1 : 2 electrolyte in the solutions.[23] Since two copper(II) ions in a molecule are equivalent in solution, we can reasonably understand

Table 5. Molar conductivity, Λ_M, of complexes at 10^{-3} mol dm^{-1} in methanol and *N,N*-dimethylformamide (Ω^{-1} cm^{-2} mol^{-1})

Complex	MeOH	DMF
$Cu(en)_2(ClO_4)_2$	204	146
Cu(py-3-2-nso)Cl	107	74
Cu(py-3-2-nso)Br	124	72
$Cu(py\text{-}3\text{-}2\text{-}nso)ClO_4$	195	
$Cu(py\text{-}3\text{-}2\text{-}nso)PF_6 \cdot 1/2H_2O$	198	

the one two-electron reduction of these complexes. On the other hand, the conductivities of Cu(py-3-2-nso)Cl and Cu(py-3-2-nso)Br are about one half of those of $Cu(py\text{-}3\text{-}2\text{-}nso)ClO_4$ and $Cu(py\text{-}3\text{-}2\text{-}nso)PF_6$, implying that they are 1 : 1 electrolyte in methanol and *N,N*-dimethylformamide. This suggests that these complexes exist as  in solution, where two inequivalent copper(II) ions are reduced at different potentials. In general, copper(II) ions with a distorted coordination geometry have a high reduction potentials.[25] Therefore, it is likely that the reduction waves at +0.1—+0.2 V and −0.4—−0.6 V are due to the reduction of the five-coordinate copper(II) ion and the four-coordinate copper(II) ion, respectively. In relation to this result, conductivities of Cu(R-2-2-nso)X (X=Cl, Br) were also measured in *N,N*-dimethylformamide. The result again demonstrated the existence of 1 : 1 electrolyte in solution. Thus, we may conclude that Cu(py-3-2-nso)X (X=Cl, Br) as well as Cu(R-2-2-nso)X (X=Cl, Br) contains a five- and a four-coordinate copper(II) ions in solution, which are reduced at $\approx$+0.15 and $\approx$−0.5 V, respectively.

Synthetic Approach toward Antibiotic Tunicamycins

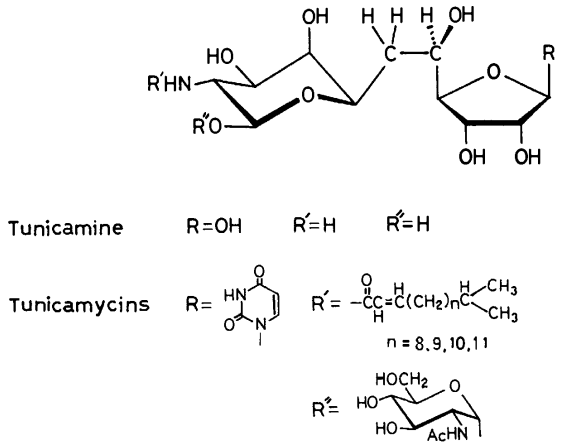
Yoshimasa FUKUDA, Hiroaki SASAI, and Tetsuo SUAMI*

Deparment of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received October 8, 1980)

Higher-carbon carbohydrates, undecose, and dodecose derivatives have been synthesized by base-catalyzed addition between nitro sugar and sugar aldehydes. The addition reaction of 3,5-*O*-benzylidene-6,7-dideoxy-1,2-*O*-isopropylidene-7-nitro-α-D-*gluco*-heptofuranose (**3**) with 2,3 : 4,5-di-*O*-isopropylidene-D-arabinose yielded two isomeric dodecose derivatives. The analogous addition of **3** with 2,4-*O*-ethylidene-D-erythrose afforded an undecose derivative.

The nucleoside antibiotics tunicamycins exhibit broad-spectrum antitumor activity.[1] They have a unique common structure, consisting as they do of uracil, fatty acids, and an undecose derivative named tunicamine as the carbohydrate moiety, together with *N*-acetyl-D-glucosamine. The tunicamine is, in turn, bound to the uracil residue, designated as the tunicaminyl uracil[5] (Scheme 1).



Scheme 1.

The higher-carbon carbohydrates, such as undecose and decose derivatives, have been found in other nucleoside antibiotics, anthelmycin (hikizimycin),[2,3] and sinefungin.[4]

Since carbon-chain elongation toward the higher-carbon carbohydrates has not been well established, a synthesis of tunicamine is an attractive challenging target for a carbohydrate chemist. In synthetic chemistry, several methods of preparing higher-carbon sugar have been described in the literature.[6–10] More recently, two undecose derivatives have been prepared by a method involving the condensation of galactose 6-phosphorane with two pentose aldehydes.[11] A hexadecose derivative has been synthesized by the oxidative dimerization of acetylenic sugar, followed by catalytic hydrogenation.[12]

As one of the methods of lengthening a carbon-chain in carbohydrates, the base-catalyzed addition of nitroalkanes with aldehyde has been applied;[13–16] such reactions have been widely used for ascensions of sugar chains.[17–19] However the reagents are restricted to low-molecular-weight nitro compounds, such as nitromethane,[20] nitroethane,[21] and nitroethanol.[22,23] Furthermore, neither the reaction of nitro sugar with aldehyde nor that of nitro sugar with sugar aldehyde has been described in the literature as a synthetic approach to a higher-carbon carbohydrate. Therefore, as a preliminary synthetic study toward the tunicamine, the possibility of the formation of higher-carbon sugar by the addition reaction between nitro sugar and sugar aldehyde has been explored. In the present article we wish to report the development of addition reactions for undecose and dodecose derivatives.

Results and Discussion

The addition of 3,5-*O*-benzylidene-6,7-dideoxy-1,2-*O*-isopropylidene-7-nitro-α-D-*gluco*-heptofuranose (**3**) to 2,3 : 4,5-di-*O*-isopropylidene-D-arabinose[24] (**4**) and 2,4-*O*-ethylidene-D-erythrose[25] (**9**) afforded dodecose (**5** and **6**) and an undecose derivative (**10**) respectively.

As a starting material, the readily accessible 3,5-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-glucofuranose[26] (**1**) was used. The oxidation of **1** by the Pfitzner-Moffatt method[27,28] afforded 3,5-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-*gluco*-1,6-dialdo-1,4-furanose, which was further converted to the 7-nitro compound (**2**) in a 61% yield by adding nitromethane in the presence of sodium methoxide in methanol.

The dehydration of **2** with acetic anhydride in chloroform, followed by hydrogenation with sodium borohydride, produced the 6-deoxy-7-nitro compound (**3**) in a 47% yield.

When **3** reacted with the arabinose derivative, **4**, in the presence of sodium methoxide, a mixture of two isomeric dodecose derivatives (**5** and **6**) was obtained in a 44% yield after chromatography. Attempts were made to isolate each compound, but only **6** was isolable as crystals. The structure of **6** was established by ^{1}H NMR and IR as 3,5-*O*-benzylidene-6,7-dideoxy-1,2 : 9,10 : 11,12-tri-*O*-isopropylidene-7-nitro-α-dodeco-1,4-furanose.

The catalytic hydrogenation of the mixture of **5** and **6** in ethyl acetate in the presence of Raney nickel afforded a crude mixture of reduction products. The subsequent *N*-acetylation of this mixture, followed by chromatography, produced two crystalline *N*-acetylaminodideoxydodecoses (**7** and **8**) in 51 and 24% yields respectively.

The structures of **7** and **8** were determined by means of the ^{1}H NMR and mass spectra. The ^{1}H NMR spectrum of **7** revealed 18 proton signals at δ 1.2—1.5 attributable to the three *O*-isopropylidene groups, and a sharp singlet of 3-protons at δ 1.85 attributable to the

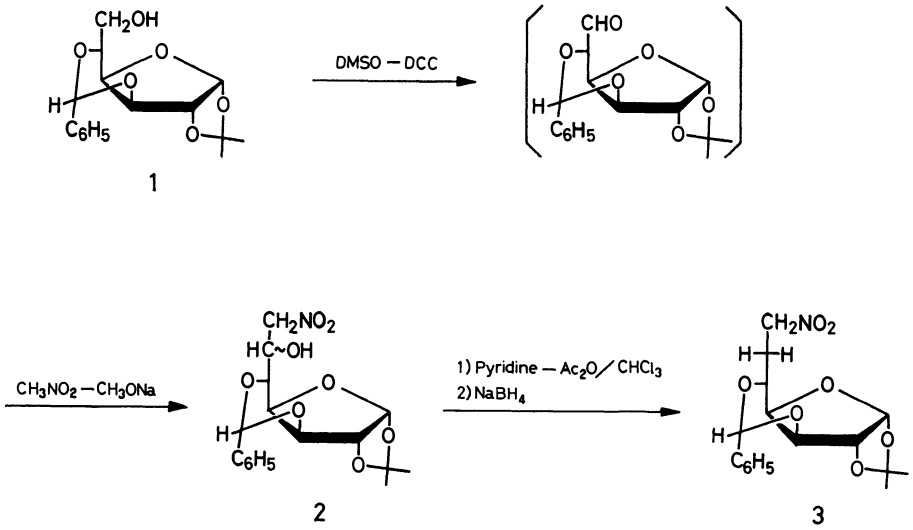
acetamido group. The mass spectrum of **7** yielded the molecular ion peak [M^+] at *m/e* 593 and the fragmentation peak [M^+-15] at *m/e* 578. The ^1H NMR spectrum of **8** showed patterns of the signals similar to those observed for **7**. The mass spectrum of **8** gave the same ion peaks at *m/e* 593 and 578. Concerning the stereochemistry of the two newly introduced chiral centers on C-7 and 8 of the compounds, four diastereomers are theoretically possible, but these configurations have not yet been established.

An analogous addition reaction was carried out between **3** and **9** to give a mixture of the two products. Only the main component (**10**) was isolated as homogeneous crystals in a 32% yield by chromatography. The catalytic hydrogenation of **10** in the presence of Raney nickel, followed by *N*-acetylation, afforded the *N*-acetylaminodideoxyundecose (**11**).

It has been demonstrated by the present study that a higher-carbon carbohydrate is prepared by a base-catalyzed addition between a nitro sugar and a sugar aldehyde. The reaction proceeds quite smoothly and can be used as a general method for the synthesis of higher-carbon complex carbohydrates.

Experimental

General Methods. The melting points were taken in capillary tubes in a liquid bath and are uncorrected. Solutions were concentrated under reduced pressure below 50 °C. The IR spectra were measured with a Hitachi 225 spectrophotometer and are expressed in reciprocal centimeters. The ^1H NMR spectra were obtained on a Varian EM-360A (60 MHz) spectrometer. The chemical shifts are reported as δ values



Scheme 2.

in parts per million relative to tetramethylsilane as an internal standard. The mass spectra were obtained with a Hitachi RMU-6MG spectrometer. The TLC was performed on precoated silica gel 60 F-254 plaques (Merck, Darmstadt; Art. 5715, 0.25 mm thickness). The silica-gel columns used for chromatography utilized Wako gel C-200 (Wako Pure Chemical Industries, Ltd.).

*3,5-O-Benzylidene-7-deoxy-*1,2-O-*isopropylidene-*7-*nitro-*α-DL-glycero-D-gluco-*hepto-*1,4-*furanose (2)*. Into a solution of 3,5-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-glucofuranose[26] (**1**, 2.0 g) in benzene (8 ml) and dimethyl sulfoxide (16 ml) we stirred dichloroacetic acid (0.4 ml), dicyclohexylcarbodiimide (2.0 g), and pyridine (0.8 ml) under ice cooling. After the mixture was stirred for 5 h at an ambient temperature, a suspension of oxalic acid (2.0 g) in methanol (2.0 ml) was added to the solution. The mixture was then diluted with cold water (20 ml) and extracted with chloroform. The chloroform layer was washed with a $NaHCO_3$ solution and brine, dried over Na_2SO_4, and concentrated. To a solution of the residue in methanol (20 ml) we added nitromethane (6 ml) and 1 M methanolic sodium methoxide (6.5 ml). After standing 1 h, the solution was neutralized with Amberlite IR-120B (H^+) resin and concentrated. The resdiue was chromatographed on a silica-gel column using 1: 10 (v/v) 2-butanone–toluene; the product was then recrystallized from benzene–cyclohexane to give 1.45 g (61%) of **2**; mp 176.5—177.5 °C, $[\alpha]_D^{24}$ −58° (*c* 0.5, chloroform). IR(KBr) 3520 (OH), 1565, 1395 cm^{-1} (NO_2).

Found: C, 55.30; H, 5.74; N, 3.64%. Calcd for $C_{17}H_{21}NO_8$: C, 55.58; H, 5.76; N, 3.81%.

*3,5-O-Benzylidene-6,7-dideoxy-1,2-*O-*isopropylidene-7-nitro-*α-D-gluco-*hepto-1,4-furanose (3)*. Into a suspension of **2** (1.28 g) in chloroform (22 ml) we stirred acetic anhydride (1.56 ml) and pyridine (0.8 ml). After 5 h, the chloroform solution was washed with a $NaHCO_3$ solution, and cold water, dried over Na_2SO_4, and concentrated. $NaBH_4$ (0.8 g) was added to a solution of the residue in ethanol (30 ml). After 1 h, the solution was neutralized with Amberlite IR-120B (H^+) resin and concentrated. The residue was recrystallized from ethanol to give 614 mg (47%) of **3**; mp 154 °C, $[\alpha]_D^{24}$ +89° (*c* 1.0, chloroform). IR(KBr) 1555, 1387 cm^{-1} (NO_2).

Found: C, 58.07; H, 5.97; N, 3.93%. Calcd for $C_{17}H_{21}NO_7$: C, 58.11; H, 6.02; N, 3.99%.

*3,5-O-Benzylidene-6,7-dideoxy-1,2: 9,10: 11,12-tri-*O-*isopropylidene-7-nitro-*α-*dodeco-1,4-furanose (5 and 6)*. To a solution of **3** (0.5 g) and 2,3: 4,5-di-*O*-isopropylidene-D-arabinose[24] (**4**, 1.6 g) in methanol (4 ml) and tetrahydrofuran (3 ml) we added 1 M methanolic sodium methoxide (2 ml) under ice cooling. After 3 h at an ambient temperature, the solution was neutralized with Amberlite IR-120B(H^+) resin and concentrated below 30 °C. The residue was chromatographed on a silica-gel column using 20: 1 (v/v) chloroform–ethyl acetate. Fractions homogeneous on TLC (R_f 0.25) in 5: 1 (v/v) chloroform–ethyl acetate gave 75 mg of **6** as crystals; mp 149—150 °C, $[\alpha]_D^{23}$ +38.4° (*c* 0.55, methanol). IR(KBr) 3440 (OH), 1560, 1385 (NO_2), 760, 705 cm^{-1} (C_6H_5).

Found: C, 57.58; H, 6.58; N, 2.47%. Calcd for $C_{28}H_{39}NO_{12}$: C, 57.82; H, 6.76; N, 2.42%.

Compound **5** (R_f 0.34 on TLC) was not obtained as pure crystals. The total yield of the mixture of **5** and **6** was 44% (361 mg).

*7-Acetamido-3,5-*O-*benzylidene-6,7-dideoxy-1,2: 9,10: 11,12-tri-*O-*isopropylidene-*α-*dodeco-1,4-furanose (7 and 8)*. A solution of the mixture of **5** and **6** (75 mg) in ethyl acetate (5 ml) was hydrogenated in the presence of Raney nickel at an initial H_2 pressure of 2.7 kg/cm^2 for 18 h. The catalyst was then filtered off, and the filtrate was concentrated. The *N*-acetylation of the residue with acetic anhydride (0.3 ml) in methanol (3 ml) was followed by purification by column chromatography, using 1: 1 (v/v) chloroform–ethyl acetate, to give 39 mg (51%) of **7** and 18 mg (24%) of **8**.

7: Mp 126—127 °C, $[\alpha]_D^{23}$ +24.6° (*c* 0.3, methanol), R_f 0.29 on TLC in 1: 2 (v/v) chloroform–ethyl acetate. ^1H NMR ($CDCl_3$) δ 1.2—1.5 (m, 18, $3C(CH_3)_2$), 1.85 (s, 3, NAc), 5.84 (s, 1, benzylidene CH), 5.98 (d, 1, $J_{1,2}$=3 Hz, H-1); mass spectrum *m/e* 593 [M+], 578 [M+−15].

Found: C, 60.46; H, 7.27; N, 2.39%. Calcd for $C_{30}H_{43}NO_{11}$: C, 60.70; H, 7.30; N, 2.36%.

8: Mp 188—189.5 °C, $[\alpha]_D^{23}$ +60.8° (*c* 0.67, methanol)

R_f 0.18 on TLC in the same solvent. ^{1}H NMR ($CDCl_3$) δ 1.3—1.5 (m, 18, 3C(CH_3)$_2$), 1.96 (s, 3, NAc), 5.84 (s, 1, benzylidene CH), 6.00 (d, 1, $J_{1,2}$=3 Hz, H-1); mass spectrum *m/e* 593 [M$^+$], 578 [M$^+$−15].

Found: C, 60.46; H, 7.21; N, 2.37%. Calcd for $C_{30}H_{43}NO_{11}$: C, 60.70; H, 7.30; N, 2.36%.

*3,5-O-Benzylidene-6,7-dideoxy-9,11-O-ethylidene-1,2-O-isopropylidene-7-nitro-α-D-undeco-1,4-furanose (**10**).* Into a solution of **3** (368 mg) and 2,4-*O*-ethylidene-D-erythrose[25] (**9**, 300 mg) in tetrahydrofuran (3 ml) and methanol (2 ml) we stirred 1 M methanolic sodium methoxide (1.2 ml). After 3 h, the reaction solution was worked up analogously to the preparation of **5** and **6** to give 167 mg (32%) of **10** as crystals; mp 81—83 °C, $[\alpha]_D^{15}$ +33.4° (*c* 0.35, methanol). IR(KBr) 3430 (OH) 1555, 1380 cm^{-1} (NO_2), ^{1}H NMR($CDCl_3$) δ 1.33, 1.50 (2s, 6, C(CH_3)$_2$), 5.60 (s, 1, benzylidene CH), 6.00 (d, 1, $J_{1,2}$=3 Hz, H-1), 7.33 (broad s, 5, C_6H_5).

Found: C, 55.79; H, 6.30; N, 2.88%. Calcd for $C_{23}H_{31}NO_{11}$: C, 55.53; H, 6.28; N, 2.82%.

Two components were detectable on TLC in the crude product, but the other component was not obtained as a pure crystalline product.

*7-Acetamido-3,5-O-benzylidene-6,7-dideoxy-9,11-O-ethylidene-1,2-O-isopropylidene-α-D-undeco-1,4-furanose (**11**).* A solution of **10** (101 mg) in ethyl acetate (3 ml) was hydrogenated and subsequently worked up analogously to the preparation of **7** and **8** to give 48 mg (46%) of **11**; mp 85—86 °C, $[\alpha]_D^{14}$ +8.4° (*c* 0.5, methanol). IR(KBr) 3390 (OH), 1650 cm^{-1} (C=O). ^{1}H NMR ($CDCl_3$) δ 1.27 (d, 3, J=4.5 Hz, ethylidene CH_3), 1.33, 1.50 (2s, 6, C(CH_3)$_2$), 1.73 (s, 3, NAc), 5.62 (s, 1, benzylidene CH), 5.98 (d, 1, $J_{1,2}$=3 Hz, H-1), 7.37 (broad s, 5, C_6H_5).

Found: C, 59.06; H, 6.97; N, 2.97%. Calcd for $C_{25}H_{35}NO_{10}$: C, 58.93; H, 6.92; N, 2.74%.

The authors wish to thank Professor Gakuzo Tamura, Tokyo University, for his helpful suggestions. They also wish to express their appreciation to Mr. Mikio Munakata, Meiji Seika Kaisha, Ltd., for the mass spectral data, to Mr. Saburo Nakada for the elemental analyses, and to Mr. Hiderou Kitasato for some exploratory experiments related to the work descrived herein.

Structural Studies on the Cyclic Carbamate Derivatives of Kanamycin A

Yasushi TAKAGI, Chikara KOMURO, Tsutomu TSUCHIYA,* and Sumio UMEZAWA
Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211
(Received October 21, 1980)

Treatment of tetrakis(*N*-benzyloxycarbonyl)-6″-*O*-tritylkanamycin A with sodium hydride in *N*,*N*-dimethylformamide, followed by chromatography, afforded 4′,6′ : 3″,4″-, and 4′,6′ : 2″,3″-bis(cyclic carbamate) and 3″,4″- and 2″,3″-mono(cyclic carbamate) (**2**, **3**, and others). The structures of the position isomers **2** and **3** were determined by the NMR spectra at 500 MHz of their *N*-tosyl-*O*-acetyl derivatives.

Simultaneous protection of vicinal trans-equatorial amino and hydroxyl groups of amino sugars is very advantageous in aminoglucoside synthesis. For this purpose we previously reported an efficient and facile procedure[1,2] involving formation of a cyclic carbamate; this procedure has been widely applied. In this paper, we describe the separation and structural determination of the isomeric carbamate derivatives of kanamycin A as an example of the carbamate formation of complex aminoglycosides.

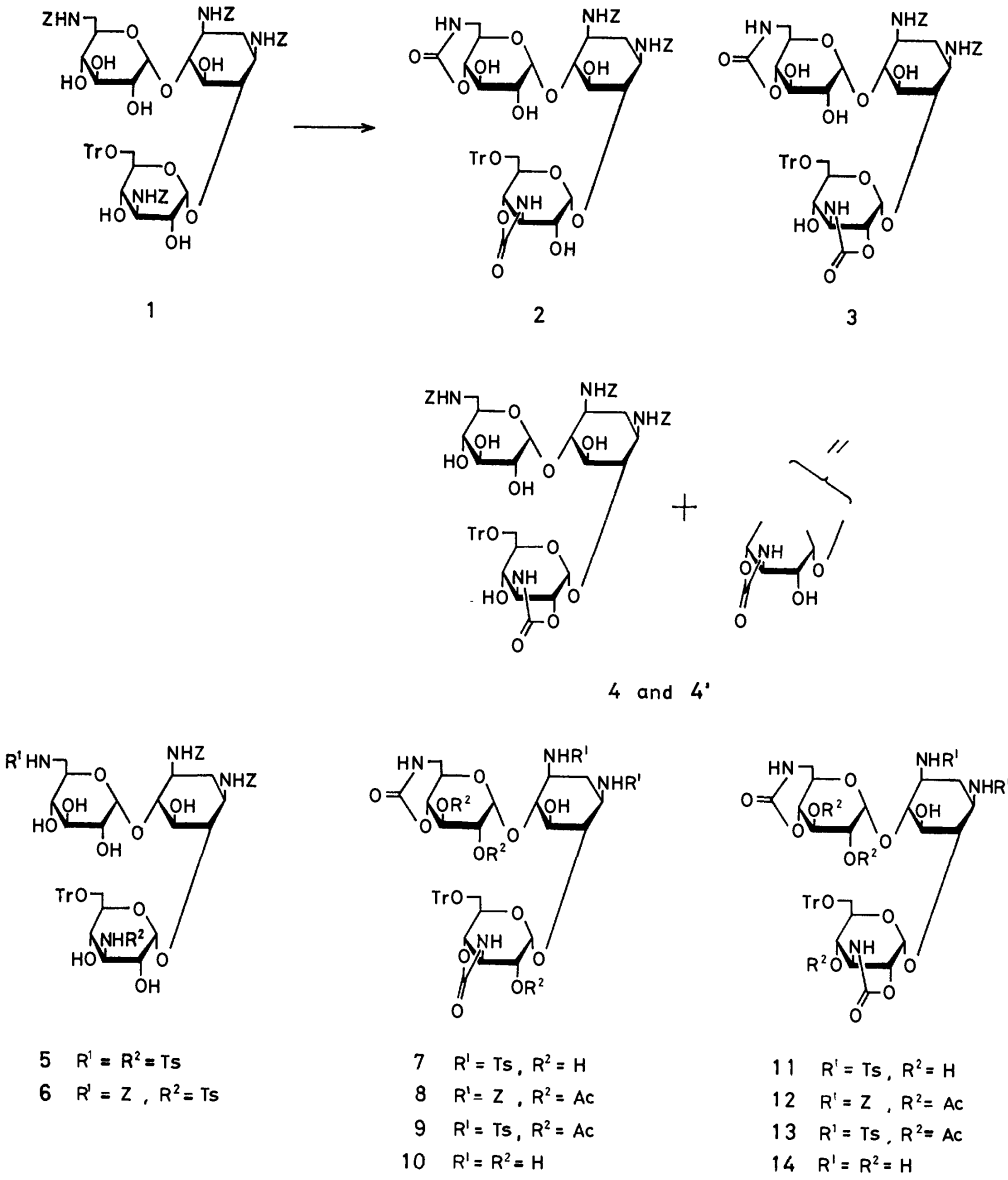
One method[2] for the preparation of cyclic carbamate is to treat an *N*-benzyloxycarbonyl derivative with sodium hydride in *N*,*N*-dimethylformamide (DMF). In the case of kanamycin A, 4′,6′ : 2″,3″-bis(cyclic carbamate) and/or 4′,6′ : 3″,4″-bis(cyclic carbamate) are expected to be formed by this treatment.

Tetrakis(*N*-benzyloxycarbonyl)kanamycin A[3] gave several products which could not be separated[4] by chromatographic separation in pure states owing to their low solubility in common organic solvents. Similar treatment of tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidenekanamycin A[3] did not improve the purification. In order to enhance the solubility of the products, we introduced a trityl group and prepared tetrakis(*N*-benzyloxycarbonyl)-6″-*O*-tritylkanamycin A (**1**). This compound was soluble in most common organic solvents. Treatment of **1** with sodium hydride in DMF, followed by separation of the products by column chromatography, gave two isomers of mono- (**4**,**4′**; 10% in total) and di-carbamates (**2** and **3**, 62% in total in the ratio of about 5 : 2). All products isolated showed the absorption peak at 1760 cm^{-1}, indicating the presence of a five-membered cyclic carbamate.[1] NMR spectra and elemental analysis showed that **2** and **3** had two benzyloxycarbonyl groups and **4** and **4′** had three.

In order to determine the structures of **2** and **3**, several derivatives were prepared. When **2** or **3** was hydrolyzed with a limited amount of barium hydroxide, the cyclic carbamate rings were cleaved selectively to give the same product, 1,3-bis(*N*-benzyloxycarbonyl)-6″-*O*-tritylkanamycin A. Tosylation of the product gave a di-*N*-tosyl derivative (**5**). Acidic hydrolysis (with 8 M aqueous HCl–EtOH=1 : 1 at 100 °C) of **5** followed by detection by TLC of the hydrolyzates showed a single ninhydrinpositive spot for 2-deoxystreptamine, but no spots corresponding to 6-amino-6-deoxy- and 3-amino-3-deoxy-D-glucose or their glucosides were observed. This indicates the location of the tosyl groups of **5** at 6′- and 3″-amino groups; it is therefore clear that the same amino groups in **2** and **3** are protected by the cyclic carbamates. This result was further supported by another experiment. Catalytic hydrogenolysis of the benzyloxycarbonyl groups of **2** and **3**, followed by tosylation of the products, gave 1,3-di-*N*-tosyl derivatives (**7** and **11**). On cleavage of the cyclic carbamates followed by acidic hydrolysis, those derivatives gave 3-amino-3-deoxy- and 6-amino-6-deoxy-D-glucose (detected by TLC), a result which supports the structures of **7** and **11**.

The structures of the position isomers **2** and **3** were clarified by high-resolution NMR spectra of their tri-*O*-acetyl derivatives. Acetylation of **2** and **3** in the usual manner gave the tri-*O*-acetyl derivatives (**8** and **12**). In the NMR spectra of **12** at 200 MHz, H-2′ appeared as a quartet at δ 5.35, (J=3.5 and 10 Hz), and, H-3′ and H-4″ appeared as triplets at δ 6.27 (J=10 Hz) and 5.76 (J=9 Hz). The assignments were made from their shift and J values and suggested that the five-membered cyclic carbamate of **12** is formed between the 3″-amino and 2″-hydroxyl groups; therefore, **8** was deduced to have the 3″,4″-carbamate structure. These results were further verified by the NMR spectra at 500 MHz of **9** and **13**, which were obtained from **8** and **12** by catalytic hydrogenolysis followed by *N*-tosylation. In the NMR spectrum of **9**, H-2′ and H-2″ appeared as quartets at δ 5.30 and 5.51, respectively, and H-3′ appeared as a triplet at 5.80. In the NMR spectrum of **13**, H-2′ appeared as a quartet at δ 5.30 and H-3′ and H-4″ appeared as triplets at 6.04 and 5.69. These assignments were confirmed by the decoupling method. These results clearly showed that **9** and **13**, and consequently **2** and **3**, have the 3″,4″-*N*,*O*- and 3″,2″-*N*,*O*-carbonyl structure, respectively. It is noteworthy that the yield of the 3″,4″-*N*,*O*-carbonyl derivative (**2**, 38%) dominates over that of 3″,2″-derivative (**3**, 15%) in contrast to the results for the 3″,2″-*N*,*O*-carbonyl structure given by Kumar *et al.*[4] Debenzyloxycarbonyl derivatives (**10** and **14**) could not be obtained in pure state from **2** and **3**, but they will be usable as key intermediates for derivations of the 1- and 3-amino groups of kanamycin A.

Similarly, the minor products **4** and **4′** were determined to be monocarbamates. The mixture of **4** and **4′** was subjected to sequential mild alkaline hydrolysis and *N*-tosylation to afford 3″-*N*-tosyl derivative (**6**). Acid hydrolyzate of **6** showed, on TLC, two ninhydrin-positive spots of 2-deoxystreptamine and 6-amino-6-deoxy-D-glucose, suggesting that cyclic carbamate was formed at the 3″-amino group. When the mixture of **4** and **4′** was hydrogenated and then tosylated, two products (**15** and **16**) were obtained in a ratio of 2.4 : 1.



NMR spectra and elemental analysis of **15** and **16** showed that each has three tosyl groups. Decarbamation of **15** and **16** with barium hydroxide, followed by acidic hydrolysis, gave 3-amino-3-deoxy-D-glucose as the sole ninhydrin-positive product (checked by TLC), showing that **4** (and **4'**) is 3″,2″- or 3″,4″-cyclic carbamate. The position of the cyclic carbamate in **4** and **4'** remains unsolved.

Experimental

^{1}H-NMR spectra were recorded at 90, 200, and 500 MHz with Varian EM-390, Varian XL-200, and Bruker WM-500 spectrometers, respectively. TLC was performed on Wakogel B-5 and E. Merck silica gel with sulfuric acid spray for detection and on microcrystalline Avicel SF (Funakoshi Co.) with the spray of 0.5% ninhydrin in pyridine. In the latter case, the solvent system of 1-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1) was used as developer. For column chromatography, silica gel (Wakogel C-200) was used. On the description of reprecipitation, substance was dissolved in the first-cited solvent, and precipitated by adding the last-cited solvent.

*1,3,6′,3″-Tetrakis(*N*-benzyloxycarbonyl)-6″-*O*-tritylkanamycin A (**1**).* To a solution of tetrakis(*N*-benzyloxycarbonyl)-kanamycin A[3] (3.00 g) in dry pyridine (30 ml), trityl chloride (4.14 g, 2 mol equivalents for the starting material) was added and the solution was kept at room temperature for 18 h. The solution showed, on TLC with chloroform–ethanol (15 : 1), a major spot at R_f 0.3 (**1**). After addition of water (3 ml), the solution was poured into an ice-cold aqueous saturated sodium hydrogencarbonate (300 ml) with stirring. The mixture was extracted with chloroform (100 ml×4) and the chloroform solution was washed with aqueous sodium hydrogencarbonate and concentrated with several additions of toluene to give a pale yellow solid (6.76 g). The solid was chromatographed over silica gel with benzene as the developer to remove triphenylmethanol, then with ethyl acetate–chloroform (7 : 1) to elute **1**, 2.98 g (80%). The solid was reprecipitated from chloroform–hexane, $[\alpha]_D^{25}$ +64° (*c* 1, dioxane).

Found: C, 65.35; H, 5.96; N, 4.39%. Calcd for $C_{69}H_{74}N_4O_{19}$: C, 65.60; H, 5.90; N, 4.44%.

*Reaction of **1** with Sodium Hydride in DMF (Formation of **2**, **3**, **4**, and **4'**).* To an ice-cold solution of **1** (20.1 g) in dry

DMF (200 ml), 50% oily sodium hydride (5.02 g, 6.6 mol equivalents for **1**) was added under nitrogen atmosphere and the mixture was stirred at 5 °C for 13 h whereupon a slurry resulted. On TLC with chloroform–ethanol (7 : 1), the slurry showed four spots: R_f 0.36 (trace), 0.30 (**4**, minor), 0.24 (**3**, minor), and 0.21 (**2**, major). The slurry was poured into an ice-cold 1% acetic acid solution (1.6 l) and the mixture was extracted with chloroform (0.5 l×4). The chloroform solution was washed with aqueous sodium hydrogencarbonate and water, dried over sodium sulfate and concentrated with several additions of xylene to give a syrup, which was washed with ether. The resulting pale brown solid (16.9 g) was charged on a silica gel column and eluted with chloroform-ethanol (8 : 1). From the earlier fractions, a mixture of 1,3,6′-tris-(*N*-benzyloxycarbonyl)-3″,2″-*N*,*O*-carbonyl-6″-*O*-tritylkanamycin A (**4**) and its 3″,4″-*N*,*O*-carbonyl isomer (**4′**) were obtained, 1.79 g (10%). This mixture was reprecipitated from chloroform–ether, $[\alpha]_D^{25}$ +60° (*c* 1, dioxane); IR (KBr): 1760 (five-membered cyclic carbamate), 1700, 1520 cm^{-1}.

Found: C, 64.45; H, 5.77; N, 4.81%. Calcd for $C_{62}H_{66}N_4O_{18}$: C, 64.46; H, 5.76; N, 4.85%.

From the middle fractions, a solid of 1,3-bis(*N*-benzyloxycarbonyl)-6′,4′: 3″, 2″-di-*N*,*O*-carbonyl-6″-*O*-tritylkanamycin A (**3**), 2.56 g (15%), was obtained. Since the solid was slightly contaminated with **2**, **4**, and **4′**, it was purified by column chromatography and then reprecipitated from dioxane–water, $[\alpha]_D^{25}$ +46° (*c* 1, dioxane); IR (KBr): 1760 (five-membered cyclic carbamate), 1700, 1510 cm^{-1}.

Found: C, 62.21; H, 5.47; N, 5.15%. Calcd for $C_{55}H_{58}N_4O_{17}\cdot H_2O$: C, 62.02; H, 5.68; N, 5.26%.

From the last fractions, a solid of 1,3-bis(*N*-benzyloxycarbonyl)-6′,4′: 3″,4″-di-*N*,*O*-carbonyl-6″-*O*-tritylkanamycin A (**2**), 6.33 g (38%), was obtained. Since the solid was slightly contaminated with **3**, it was further purified by column chromatography and then reprecipitated from chloroform–ether, $[\alpha]_D^{25}$ +55° (*c* 1, dioxane); IR (KBr): 1760, 1700, 1510 cm^{-1}.

Found: C, 63.32; H, 5.71; N, 5.33%. Calcd for $C_{55}H_{58}N_4O_{17}$: C, 63.09; H, 5.58; N, 5.35%.

From the fractions between the middle and the last fractions, an additional mixture of **2** and **3** (1.50 g, 9%) was obtained.

*1,3-Bis(*N*-benzyloxycarbonyl)-6′,3″-di-*N*-tosyl-6″-*O*-tritylkanamycin A (**5**).* *a) From **2**:* To a solution of **2** (101 mg) in aqueous acetone (1 : 10, 5.5 ml), $Ba(OH)_2\cdot 8H_2O$ (37 mg) was added; the mixture was then stirred at 60 °C for 26 h. More $Ba(OH)_2\cdot 8H_2O$ (15 mg) was added and the mixture was stirred for an additional 3 h. The resultant mixture showed, on TLC with chloroform–methanol–8% ammonia (1 : 1 : 1, lower layer), spots of R_f 0.36 (trace), 0.22 (trace), 0.13 (major), and 0.05 (slight). After introduction of carbon dioxide, the mixture was filtered and the solid was washed thoroughly with dioxane. The filtrate and the washings were combined and concentrated to give a solid, 94 mg. To an ice-cold solution of the solid (94 mg) in aqueous dioxane (1 : 6, 2.5 ml), anhydrous sodium carbonate (24 mg) and tosyl chloride (42 mg) were added and the mixture was stirred at 5 °C for 15 h. On TLC with chloroform–ethanol (15 : 1), the mixture showed spots of R_f 0.39 (trace), 0.34 (trace), 0.20 (**5**, major), and 0.05 (slight). The mixture was poured into ice–water and the precipitate was filtered, washed with water and ether, and dried. The solid (94 mg) was chromatographed over silica gel with chloroform–ethanol (15 : 1). Concentration of the fractions containing only **5** gave a colorless solid, 42 mg (32%), $[\alpha]_D^{25}$ +60° (*c* 1, chloroform); IR (KBr): 1710, 1520, 1320 (ν_{as} SO_2), 1150(ν_s SO_2) cm^{-1}; ^{1}H-NMR (pyridine-d_5): δ 2.10 and 2.12 (each 3H s, CH_3 of Ts).

Found: C, 61.52; H, 5.77; N, 4.18; S, 4.98%. Calcd for $C_{67}H_{74}N_4O_{19}S_2$: C, 61.74; H, 5.72; N, 4.30; S, 4.92%.

*b) From **3**:* Compound **3** (58 mg) was treated as described above to give a solid of **5**, 23 mg (31%), $[\alpha]_D^{25}$ +63° (*c* 1, chloroform). The IR and ^{1}H-NMR spectra were superimposable with those of **5** obtained in *a)*.

*1,3,6′-Tris(*N*-benzyloxycarbonyl)-3″-*N*-tosyl-6″-*O*-tritylkanamycin A (**6**).* To an solution of a mixture of **4** and **4′** (99 mg) in aqueous dioxane (2 : 3, 5 ml), $Ba(OH)_2\cdot 8H_2O$ (28 mg) was added and the mixture was stirred at 60 °C for 14 h. The resultant mixture was then treated as described for **5** to give a colorless solid, 92 mg. The solid was then treated with tosyl chloride (19 mg) and anhydrous sodium carbonate (11 mg) as described for **5** to give a solid of **6**, 50 mg (46%), $[\alpha]_D^{25}$ +53° (*c* 0.8, chloroform); IR (KBr): 1710, 1520, 1320 (ν_{as} SO_2), 1150(ν_s SO_2) cm^{-1}; ^{1}H-NMR (pyridine-d_5): δ 2.11 (3H s, CH_3 of Ts).

Found: C, 63.37; H, 5.94; N, 4.16; S, 2.28%. Calcd for $C_{68}H_{74}N_4O_{19}S_1$: C, 63.64; H, 5.81; N, 4.37; S, 2.50%.

*6′,4′ : 3″,4″-Di-*N*,O-carbonyl-1,3-di-*N*-tosyl-6″-*O*-tritylkanamycin A (**7**).* To a solution of **2** (53 mg) in aqueous dioxane (1 : 5, 3 ml), 0.2 M aqueous hydrochloric acid was added until the pH became 4—5; the solution was then hydrogenated in the presence of palladium black at room temperature for 1.5 h. During the reaction, pH was maintained at 4—5 by occasional additions of diluted hydrochloric acid. Palladium black was removed by filtration. To the ice-cold filtrate, anhydrous sodium carbonate (20 mg) and tosyl chloride (22 mg) were added and the mixture was stirred at 5 °C for 15 h. The reaction mixture showed, on TLC with chloroform–ethanol (7 : 1), a major spot at R_f 0.2 (**7**). Concentration to a small volume followed by addition of water gave a solid, which was washed with water and ether, and dried. The solid (46 mg) was chromatographed over silica gel with the same solvent system to give **7**, 42 mg (76%), $[\alpha]_D^{25}$ −3° (*c* 1, dioxane); IR (KBr): 1760, 1700, 1330, 1160 cm^{-1}. The absorption peak for amide II (≈1510 cm^{-1}) disappeared; ^{1}H-NMR (pyridine-d_5): δ 2.31 (6H s, CH_3 of Ts).

Found: C, 58.33; H, 5.50; N, 4.88; S, 5.72%. Calcd for $C_{33}H_{58}N_4O_{17}S_2$: C, 58.55; H, 5.38; N, 5.15; S, 5.90%.

*2′,3′,2″-Tri-*O*-acetyl-1,3-bis(*N*-benzyloxycarbonyl)-6′,4′ : 3″,4″-di-*N*,O-carbonyl-6″-*O*-tritylkanamycin A (**8**).* To a solution of **2** (327 mg) in dry pyridine (6 ml), acetic anhydride (0.4 ml) was added and the solution was kept at room temperature for 25 h. The solution showed, on TLC with chloroform–ethanol (7 : 1), a single spot of **8** (R_f 0.43). After addition of water (0.4 ml), the solution was concentrated *in vacuo* and the chloroform solution of the concentrate was washed with aqueous potassium hydrogensulfate and water, dried (Na_2SO_4), and concentrated to give a colorless solid 332 mg (91%), $[\alpha]_D^{25}$ +80° (*c* 1, dioxane); ^{1}H-NMR (pyridine-d_5): δ 1.73, 2.00, 2.23 (each 3H s, Ac).

Found: C, 62.52; H, 5.60; N, 4.61%. Calcd for $C_{61}H_{64}N_4O_{20}$: C, 62.45; H, 5.50; N, 4.78%.

*2′,3′,2″-Tri-*O*-acetyl-6′,4′ : 3,″4″-di-*N*,O-carbonyl-1,3-di-*N*-tosyl-6″-*O*-tritylkanamycin A (**9**).* To a solution of **8** (228 mg) in aqueous dioxane (1 : 10, 11 ml), 1 M hydrochloridc acid was added until it became weakly acidic (pH≈4); the solution was then hydrogenated in the presence of palladium black for 2 h. During the reaction, pH was maintained at ≈4 by occasional additions of 1 M hydrochloric acid. The solution was filtered and water (3 ml) was added. To this solution, anhydrous sodium carbonate (70 mg) and tosyl chloride (91 mg) were added, and the mixture was treated as described for **7** to give a solid of **9** (after chromatography with chloroform–ethanol=15 : 1), 144 mg (61%), $[\alpha]_D^{25}$ +73° (*c* 1, dioxane); IR (KBr): 1760 (broad), 1330, 1160 cm^{-1}; ^{1}H-NMR (pyridine-d_5) (at 500 MHz): δ 1.61, 2.01, 2.28, 2.32,

2.38 (each 3H s, Ac and CH_3 of Ts), 3.31 (1H t, $J_{5',6'a}=J_{6'a,6'b}=10$ Hz, H-6'a), 3.41 (1H dd, $J_{5'',6''a}=6$ Hz, $J_{6''a,6''b}=10.5$ Hz, H-6''a), 3.49 (1H dd, $J_{5'',6''b}=3$ Hz, $J_{6''a,6''b}=10.5$ Hz, H-6''b), 3.76 (1H, ddd, $J_{6'b,NH}=4.5$ Hz, $J_{5',6'b}=6.5$ Hz, $J_{6'a,6'b}=10$ Hz, H-6'b), 4.34 (1H, t, $J_{3',4'}=J_{4',5'}=10$ Hz, H-4'), 4.96 (1H, dt, $J_{4',5'}=J_{5',6'a}=10$ Hz, $J_{5,6'b}=6.5$ Hz, H-5'), 5.300 (1H, m, H-5''), 5.51 (1H, dd, $J_{1'',2''}=3.5$ Hz, $J_{2'',3''}=10.5$ Hz, H-2''), 5.302 (1H, dd, $J_{1',2'}=4$ Hz, $J_{2',3'}=10$ Hz, H-2'), 5.80 (1H, t, $J_{2',3'}=J_{3',4'}=10$ Hz, H-3'), 6.33 (1H, d, $J_{1',2'}=4$ Hz, H-1'), 6.47 (1H, d, $J_{1'',2''}=3.5$ Hz, H-1''). The signals assignable to H-5'' cculd only be discerned after resolution enhancement.

Irradiation at δ 5.30 (H-2' and 5'') collapsed the quartet of H-6''a to a doublet, the quartet of H-6''b to a doublet, the triplet of H-3' to a doublet, and the doublet of H-1' to a singlet. Irradiation at δ 5.51 (H-2'') collapsed the doublet of H-1'' to a singlet. Irradiation at δ 6.33 (H-1') collapsed the quartet of H-2' to a doublet. Irradiation at δ 6.47 (H-1'') collapsed the quartet of H-2'' to a doublet.

Found: C, 58.02; H, 5.51; N, 4.35; S, 4.84%. Calcd for $C_{59}H_{64}N_4O_{20}S_2$: C, 58.41; H, 5.32; N, 4.62; S, 5.29%.

6',4': *3'',4''-Di*-N,O-*carbonyl-6''*-O-*tritylkanamycin A (**10**)*. Compound **2** (550 mg) dissolved in ethanol–acetic acid (97 : 3, 28 ml) was hydrogenated with palladium black as described before. Filtration followed by concentration gave a solid which was thoroughly washed with ether to give **10**, 366 mg. The solid was slightly contaminated with an impurity of R_f 0.39 (on TLC developed with the lower layer of chloroform–methanol–20% acetic acid=5 : 7 : 5; *cf* **10**, 0.33). IR (KBr): 1760 (five-membered cyclic carbamate), 1700 cm^{-1} (six-membered cyclic carbamate). No peak for amide II (near 1520 cm^{-1}).[4]

6',4' : *3'',2''-Di*-N, O-*carbonyl-1, 3-di*-N-*tosyl-6''*-O-*tritylkanamycin A (**11**)*. Compound **3** (55 mg) was hydrogenated and tosylated as described for **7**. The crude solid (46 mg, 81%) obtained was chromatographed over silica gel with chloroform–ethanol (7 : 1) to give pure **11**, 34 mg $[\alpha]_D^{25}$ −1° (*c* 1, dioxane); Ir (KBr): 1760, 1700, 1330, 1160 cm^{-1}; ^{1}H-NMR (pyridine-d_5): δ 2.30 (6H s, CH_3 of Ts).

Syntheses of *N*-Substituted 3,3,4-Triaryl- and 3,3,4,4-Tetraphenyl-2-azetidinones

Kailash Nath MEHROTRA* and Surendra Bahadur SINGH
Department of Chemistry, Banaras Hindu University, Varanasi-221005, India
(Received June 28, 1980)

The reactions of 2-diazo-1,2-diphenylethanone with Schiff's bases Ar–CH=N–R gave new substituted 2-azetidinones together with 1,1′,4,4′-tetraphenyl-2,2′-azinodiethanone. 2-Diazo-1,2-diphenylethanone reacts with *N*-benzhydrylidene-*N*′-phenylurea to give 1-(phenylcarbamoyl)-3,3,4,4-tetraphenyl-2-azetidinone.

The cycloaddition of diphenylketene with anils is known to form 2-azetidinones.[1] Diphenylketene, in these cases, has been generated either thermally by dehydrohalogenation of suitable acid chlorides with tertiary bases[2] or photochemically from diazo ketone.[3] On the other hand, diphenylketene has been known to add on carbon-oxygen double bond in α,β-unsaturated ketones to give β-lactones.[4] We now report the cycloaddition of diphenylketene, generated *in situ* by thermal decomposition of 2-diazo-1,2-diphenylethanone (**1**), with Schiff's bases **2a—g** leading to *N*-alkyl-2-azetidinones **3a—g** in fair yields. The reaction of diphenylketene with *N*-benzhydrylidene-*N*′-phenylurea (**5**), having three reactive sites (C=N, C=O, and NH), has shown that C=N group is attacked by diphenylketene in preference to either C=O group or NH group. The products, **3a—g**, show extraordinary stability amongst β-lactams[5] towards common degradative reagents.

Results and Discussion

An equimolecular mixture of 2-diazo-1,2-diphenylethanone (**1**) and *N*-benzylideneisopropylamine (**2a**: Ar=C_6H_5, R=$CH(CH_3)_2$) was heated to reflux in dry benzene for 12 h under stream of nitrogen. The reaction product was separated by fractional crystallization from hexane–ethanol (1 : 1) and vacuum distillation; it consisted of 1,1′,4,4′-tetraphenyl-2,2′-azinodiethanone (**4**, 2%) and 1-isopropyl-3,3,4-triphenyl-2-azetidinone (**3a**, 85%). An authentic sample of product **4** was prepared according to method reported[6] for comparison (IR, NMR, and also melting point). The structural assignment of **3a** was made on the basis of its analytical and spectral data.

Similar treatment of Schiff's bases **2b—f** gave 2-azetidinones **3b—f**, identified on the basis of their analytical and spectral data, together with ketazine (**4**, 3—5%) in each case.

The racemic *N*-benzylidene-α-methylbenzylamine (**2g**) on similar treatment gave two products, a white crystalline solid **3g** (81%) and a yellow crystalline solid, identified as ketazine **4** (3%). The white crystalline solid, mp 94—95 °C, showed absorption band at 1740 (C=O, β-lactam[2]) cm^{-1} in IR spectrum. The NMR spectrum of product exhibited two doublets at δ 1.47 and 1.92, two quartets at δ 4.32 and 5.01 and one singlet at δ 5.02 which may be due to presence of two enantiomeric forms of product **3g**. This would be expected as the starting Schiff's base **2g** is racemic. The elemental analyses and spectral data agree with assigned structure, (±) 1-(α-methylbenzyl)-3,3,4-triphenyl-2-azetidinone (**3g**), to the product.

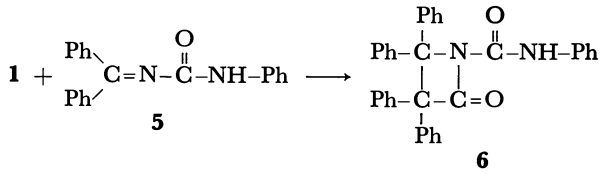
The products **3a—g** were found to be unaffected on treatment with ordinary alkali or acid, whereas, *N*-aryl-2-azetidinones reported earlier[5] have been known to undergo hydrolysis. The formation of products can be explained as in Scheme 1.

	Ar	R
3a	C_6H_5	$CH(CH_3)_2$
3b	C_6H_5	$CH(C_6H_5)_2$
3c	*p*-$CH_3OC_6H_4$	$CH(C_6H_5)_2$
3d	*p*-ClC_6H_4	$CH(C_6H_5)_2$
3e	*p*-$NO_2C_6H_4$	$CH(C_6H_5)_2$
3f	*p*-$(CH_3)_2NC_6H_4$	$CH(C_6H_5)_2$
3g	C_6H_5	$CH(CH_3)C_6H_5$

Scheme 1.

Thermal decomposition of **1** may lead to benzoylphenylcarbene which may combine with **1** to form ketazine **4**. The benzoylphenylcarbene has been known to undergo Wolff rearrangement to give diphenylketene[7] which on reaction with C=N bond of Schiff's bases **2a—g** may lead to 2-azetidinones **3a—g** through the collapse of a possible zwitterionic intermediate. A similar intermediate has been proposed in the reaction of diphenylketene and *N*-benzylideneaniline giving *N*-phenylimidate.[8]

When *N*-benzhydrylidene-*N*′-phenylurea (**5**) was allowed to react with **1**, in an analogous manner, a white crystalline solid (70%) was obtained. The substituted urea **5** contains three possible reactive sites *viz.* C=N, C=O, and NH groups. It is known that interaction of ketene with C=N, C=O, and NH groups leads to the formation of β-lactam,[8] β-lactone[9] (which on decarboxylation gives corresponding olefin) and acetyl derivative[10] of NH group, respectively. The presence of an absorption bands at 1760 cm^{-1}, characteristic of a β-lactam[11] and 1710 (C=O, CONH[11]) cm^{-1}, absence of an absorption band between 1700



and 1600 cm^{-1} in IR spectrum and absence of a signal between δ 6—5 in NMR spectrum strongly support the assigned structure, 1-(phenylcarbamoyl)-3,3,4,4-tetraphenyl-2-azetidinone (**6**), to the product. It appears that diphenylketene adds exclusively on the C=N bond in preference to either C=O or NH bonds. The NH bond in an amide does not react with diphenylketene.[10]

Experimental

Melting points have been determined in capillaries on Büchi melting point apparatus and are uncorrected. The IR spectra were measured in Nujol mull on a Perkin-Elmer 720-spectrophotometer. The NMR spectra were recorded on Varian A-60 MHz spectrometer in $CCl_4/CDCl_3$ with TMS as an internal standard.

Materials. The aldehydes were obtained from BDH, India and 1,[12]-methylbenzylamine,[13] benzhydrylamine,[14] and *N*-benzhydrylidene-*N'*-phenylurea[15] were prepared according to reported methods.

Preparation of Schiff's Bases ***2a—g.*** *General Procedure*: The Schiff's bases **2a—g** were obtained by mixing equimolar amount of aldehyde and amine at room temperature. In all the cases, except **2a** where purification was done by vacuum distillation, the products were purified by fractional crystallization from ethanol. Yield: 80—85%.

Preparation of 2-Azetidinones ***3a—g.*** *General Procedure*: A mixture of 0.01 mol of **1** and 0.01 mol of a Schiff's base **2a—g** was heated to reflux in 80 ml of dry benzene (free from thiophene) for 12 h under stream of nitrogen. The reaction mixture was kept overnight. The solvent was removed on rotatory evaporator and residual matter was crystallised from ethanol to give 2-azetidinone **3a—g**. From the mother liquor 1,1',4,4'-tetraphenyl-2,2'-azinodiethanone (**4**, 2—5%), mp 202—303 °C (lit,[6] mp 202 °C) [UV (EtOH, nm): 255 and 315; IR (Nujol, cm^{-1}): 1680 (C=O) and 1601 (C=N-N=C); NMR ($CDCl_3$, δ ppm): 8.30—7.20 (m, H, aromatic protons). Found: C, 80.35; H, 5.12; N, 6.83%. Calcd for $C_{28}H_{20}N_2O_2$: C, 80.75; H, 4.84; N, 6.73%] was recovered by evaporation of solvent and recrystallization of residual matter from hexane–ethanol (1 : 1).

*1-Isopropyl-3,3,4-triphenyl-2-azetidinone (**3a**)* A yield of 85% obtained, bp 165/0.01 mmHg† (mp 102—103 °C). UV (EtOH, nm): 250, 255, and 260; IR (CCl_4, cm^{-1}): 1740 (C=O, β-lactam); NMR (CCl_4, δ ppm): 7.75—6.90 (m, 15H, aromatic protons); 5.31 (s, 1H, CH, ring); 3.81 (Sept, 1H, CH, isopropyl, J=7 Hz); 1.37 and 1.15 (a pair of doublets, 6H, CH_3, isopropyl, J=7 Hz). Found: C, 84.66; H, 6.72; N, 4.07%. Calcd for $C_{24}H_{23}NO$: C, 84.45; H, 6.74; N, 4.11%.

*1-Benzhydryl-3,3,4-triphenyl-2-azetidinone (**3b**).* A yield of 78% was obtained, mp 159—160 °C. UV (EtOH, nm): 250, 255, and 260; IR (Nujol, cm^{-1}): 1742 (C=O, β-lactam); NMR (CCl_4, δ ppm): 7.73—6.87 (m, 25H, aromatic protons); 5.61 (s, 1H, CH, benzhydryl); 5.45 (s, 1H, CH, ring). Found: C, 87.50; H, 5.64; N, 3.24%. Calcd for $C_{34}H_{27}NO$: C, 87.74; H, 5.80; N, 3.01%.

† 1 mmHg≈133.322 Pa.

*1-Benzhydryl-3,3-diphenyl-4-(p-methoxyphenyl)-2-azetidinone (**3c**).* A yield of 61% was obtained, mp 129—130 °C. UV (EtOH, nm): 260, 265, and 270; IR (Nujol, cm^{-1}): 1730 (C=O, β-lactam) and 1250 (C-O-C); NMR (CCl_4, δ ppm): 7.70—7.00 (m, 20H, aromatic protons); 6.80 and 6.65 (A_2B_2q, 4H, aromatic protons, J=8 Hz); 5.67 (s, 1H, CH, benzhydryl); 5.27 (s, 1H, CH, ring); 3.67 (s, 3H, CH, OCH_3). Found: C, 84.83; H, 5.74; N, 3.04%. Calcd for $C_{35}H_{29}NO_2$: C, 84.84; H, 5.85; N, 2.83%.

*1-Benzhydryl-3,3-diphenyl-4-(p-chlorophenyl)-2-azetidinone (**3d**).* A yield of 59% was obtained, mp 145—146 °C. UV (EtOH, nm): 250, 260, and 270; IR (Nujol, cm^{-1}): 1735 (C=O, β-lactam); NMR (CCl_4, δ ppm): 7.83—7.03 (m, 20H, aromatic protons); 6.97 and 6.71 (A_2B_2q, 4H, aromatic protons, J=9Hz); 5.65 (s, 1H, CH, benzhydryl); 5.27 (s, 1H, CH, ring). Found: C, 81.79; H, 5.34; N, 2.72%. Calcd for $C_{34}H_{26}NOCl$: C, 81.68; H, 5.20; N, 2.80%.

*1-Benzhydryl-3,3-diphenyl-4-(p-nitrophenyl)-2-azetidinone (**3e**).* A yield of 61% was obtained, mp 206—207 °C. UV (EtOH, nm): 278; IR (Nujol, cm^{-1}): 1735 (C-O, β-lactam), 1520 and 1350 (NO_2); NMR ($CDCl_3$, δ ppm): 8.05—7.00 (m, 24H, aromatic protons); 5.91 (s, 1H, CH, benzhydryl); 5.57 (s, 1H, CH, ring); Found: C, 79.80; H, 5.50; N, 5.45%. Calcd for $C_{34}H_{26}N_2O_3$: C, 80.00; H, 5.09; N, 5.49%.

*1-Benzhydryl-3,3-diphenyl-4-(p-dimethylaminophenyl)-2-azetidinone (**3f**).* A yield of 62% was obtained, mp 150—151 °C. UV (EtOH, nm); 265: IR (Nujol, cm^{-1}): 1730 (C=O, β-lactam); NMR (CCl_4, δ ppm): 7.70—7.00 (m, 20H, aromatic protons): 6.75 and 6.48 (A_2B_2q, 4H, aromatic protons, J=9 Hz); 5.51 (s, 1H, CH, benzhydryl); 5.17 (s, 1H, CH, ring); 2.82 (s, 6H, CH, $-N(CH_3)_2$). Found: C, 85.48; H, 6.54; N, 5.72%. Calcd for $C_{36}H_{32}N_2O$: C, 85.67; H, 6.29; N, 5.51%.

*1-(α-Methylbenzyl)-3,3,4-triphenyl-2-azetidinone (**3g**).* A yield of 81% was obtained, mp 94—95 °C. UV (EtOH, nm): 255, 260, and 265; IR (Nujol, cm^{-1}): 1740 (C=O, β-lactam); NMR (CCl_4, δ ppm): 7.67—6.90 (m, 20H, aromatic protons); 5.05 (s, 1H, CH, ring); 5.01 and 4.32 (a pair of quartets, 1H, CH, $CH(CH_3)C_6H_5$, J=7 Hz); 1.92 and 1.47 (a pair of doublets, 3H, CH, $CH(CH_3)C_6H_5$, J=7 Hz). Found: C, 85.90; H, 6.45; N, 3.32%. Calcd for $C_{29}H_{25}NO$: C, 86.35; H, 6.20; N, 3.47%.

Attempted Ring Opening of ***3a—g.*** A mixture containing 0.20 g of **3a**, 15 ml of 85% ethanol and 1 ml of concentrated hydrochloric acid was heated to reflux for 30 h. After the usual work up 0.18 g (90%) of starting material was recovered. Similar treatment of **3a—g** with either 40% aqueous alkali (potassium hydroxide or sodium hydroxide) or saturated ethanolic potassium hydroxide solution resulted in recovery of starting material almost quantitatively.

*Preparation of 1-(Phenylcarbamoyl)-3,3,4,4-tetraphenyl-2-azetidinone (**6**).* A mixture of 0.01 mol of **1** and 0.01 mol of **5** was heated to reflux in 80 ml of dry benzene (free from thiophene) for 8 h under stream of nitrogen. The reaction mixture was kept overnight. The solvent was removed on rotatory evaporator and residual matter was recrystallized from ethanol to give a white crystalline solid **6** (70%), mp 200—202 °C. UV (EtOH, nm): 235, 250, and 260; IR (Nujol, cm^{-1}): 3310 (NH), 1760 (C=O, β-lactam) and 1710 (C=O, CONH–); NMR ($CDCl_3$, δ ppm): 9.10 (b, 1H, NH, D_2O exchangeable); 7.83—7.05 (m, 25H, aromatic protons). Found: C, 82.77; H, 5.42; N, 6.01%. Calcd for $C_{34}H_{26}N_2O_2$: C, 82.59; H, 5.26; N, 5.68%.

We are thankful to Professor B. M. Shukla for providing the facilities and to C.S.I.R., New Delhi, for grant of a fellowship to SBS.

Synthesis of New Chiral Phase-transfer Catalysts and Their Application to Michael Additions

Stefano BANFI, Mauro CINQUINI, and Stefano COLONNA*

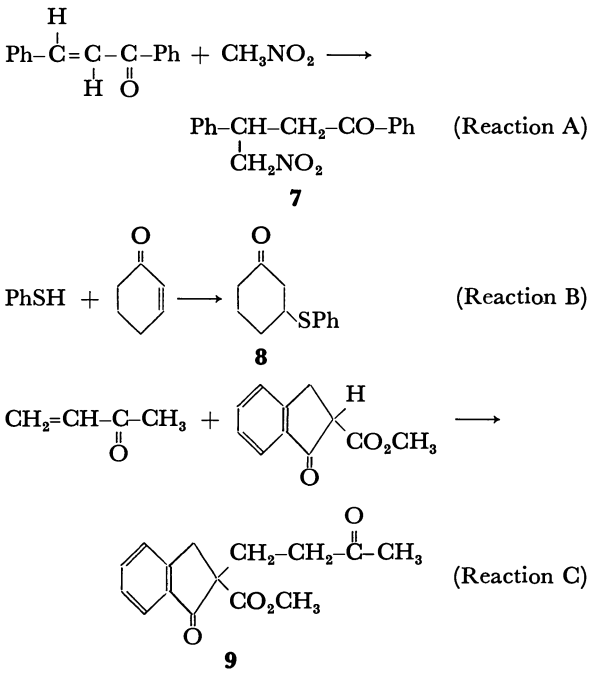
C.N.R. e Istituto di Chimica Industriale dell' Universita', Via C. Golgi 19, 20133 Milano, Italy

(Received July 30, 1980)

A series of chiral onium salts derived from (L)-(+)-methionine have been examined for the catalysis of Michael additions in phase-transfer conditions. The chemical yields are high, but no asymmetric induction was observed. Catalyst **6** represents the first example of an onium salt anchored to a polimeric matrix having a higher catalytic efficiency than its soluble counterpart.

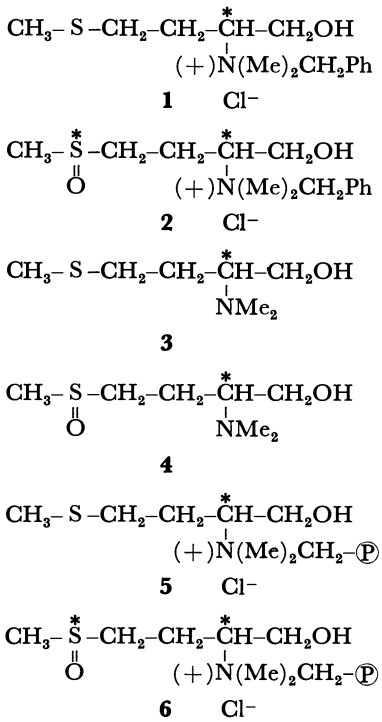
In the last few years much interest has been aroused by stereoselective syntheses under phase-transfer conditions in the presence of chiral "onium salts" as catalysts.[1] The quaternary ammonium salts, usually derived from ephedra or cinchona alkaloids, must have a hydroxyl group in the β-position to the "onium" function in order for asymmetric induction and/or kinetic resolution[1,2] to be observed. In the search for new chiral phase-transfer catalysts, we have now prepared onium salts containing the SO group as an asymmetric centre. The behaviour of the sulfinyl group, compared to other chiral groups, is indeed particularly influenced by ligands very different from each other from a stereoelectronic point of view; an oxygen, a lone pair and two aryl or alkyl groups. This accounts for the high conformational preference of sulfoxides as well as the high stereoselectivity in reactions involving chiral or prochiral groups α or β to the sulfur moiety.[3]

For this reason we have investigated the behaviour of the chiral onium salts (**1**—**2**), derived from (L)-(+)-methionine, in a series of reactions carried out under phase-transfer conditions. These are the Michael additions of nitromethane to *trans*-chalcone and of thiophenol to 2-cyclohexen-1-one, [Reactions A and B respectively] and the addition of methyl vinyl ketone to methyl 1-oxoindan-2-carboxylate (Reaction C). For the sake of comparison the same reactions have been performed in homogeneous medium in the presence of catalytic amounts of catalysts **3** and **4**. The effect of the binding of the catalyst to a polymeric solid support [catalysts **5** and **6**] has also been examined.



Results and Discussion

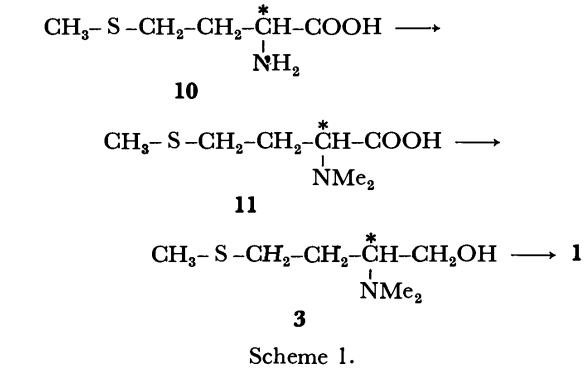
Synthesis of the Catalysts. All catalysts were prepared starting from commercial (L)-(+)-methionine (**10**), $[\alpha]_{546}^{20}$ +28.7°.



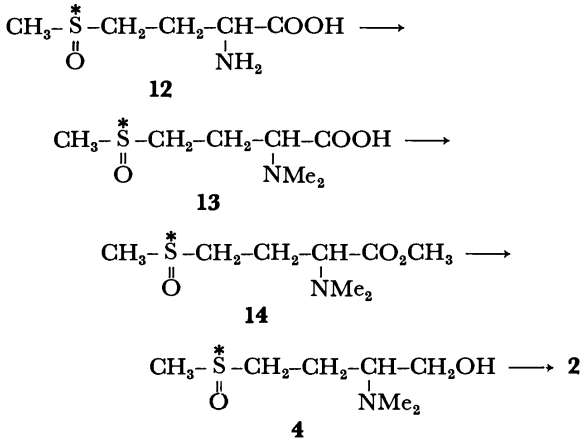
The onium salt **1** was prepared by methylation of (+)-**10**, followed by reduction to give the alcohol **3** and quaternarization of the latter with benzyl chloride (Scheme 1).

Similarly **2** was obtained by methylation of diastereomerically pure[4] (L)-methionine-*d*-*S*-oxide (**12**), followed by esterification with diazomethane to give **14**, which was reduced to the alcohol **4** with $LiAlH_4$ and quaternarizated to **2** with benzyl chloride (Scheme 2).

The catalysts **5** and **6** supported on a polymeric matrix were prepared by reaction of alcohols **3** and **4** with chloromethylated polystyrene in anhydrous DMF



Scheme 1.



Scheme 2.

as solvent (see Experimental).

Michael Additions. The reactions with catalysts **1**, **2**, **5**, and **6**, were carried out at room temperature under solid-liquid phase-transfer conditions in toluene as solvent in the presence of an excess of solid KF. In the case of catalysts **3**, **4** the reactions were performed in the same solvent and in the absence of the inorganic salt.

The results collected in the Table show that conversion into the Michael adducts is more efficient under phase-transfer conditions with catalysts **1**, **2** than in homogeneous medium with catalysts **3** and **4**. The difference is particularly noticeable in the nitromethane addition to *trans*-chalcone; a reaction which occurs only in the presence of the onium salts and potassium fluoride. In homogeneous medium methioninol *S*-oxide (**4**) is a more efficient catalyst than the corresponding sulfide (**3**).

As far as soluble "onium" salts are concerned, catalyst **1** is more efficient than catalyst **2** in the nitromethane addition to *trans*-chalcone, whereas the latter is more efficient in the addition of thiophenol to 2-cyclohexen-1-one. Both **1** and **2** gave similar results in the Michael addition of methyl vinyl ketone to methyl 1-oxoindan-2-carboxylate. The same behaviour was observed with catalysts **5** and **6** supported on a polimeric matrix. It should also be pointed out that in Reactions A and B the yields obtained with catalyst **6** are equal or higher than those obtained with the corresponding soluble onium salts (**2**). To the best of our knowledge this is the first example of an onium salt supported on a polimeric matrix having a catalytic efficiency comparable to that of the corresponding soluble onium salt.[5,6]

Table 1. Michael additions at room temperature in the presence of chiral catalysts 1—6 in toluene as solvent

Catalyst	Yield/%		
	Reaction A[a]	Reaction B[b]	Reaction C[c]
(**3**)	0	40	45[d]
(**1**)	99	68	88[e]
(**5**)	75	93	85[d]
(**4**)	0	54	57[f]
(**2**)	35	87	86[d]
(**6**)	54	96	89[d]
(**15**)	50	80	99[g]

a) Nitromethane 75 mmol, *trans*-chalcone 5 mmol, catalyst 0.5 mmol, 3 d; KF 7.5 mmol in the case of "onium" catalysts. b) Thiophenol 5 mmol, 2-cyclohexen-1-one 6.25 mmol, catalyst 0.02 mmol, 4 h; KF 7.5 mmol in the case of "onium" catalysts. c) Methyl vinyl ketone 4 mmol, methyl 1-oxoindan-2-carboxylate 2 mmol, catalyst 0.025 mmol, KF 2.5 mmol in the case of "onium" catalysts. d) For 3 d. e) For 20 h. f) For 4 d. g) For 3 h.

The last relevant feature of the new phase-transfer catalysts **1** and **2** in comparison with the "classical" *N*-dodecyl-*N*-methyl-ephedrinium bromide (**15**),[1] is that they give higher conversions into the Michael adducts in Reactions A and B, but they are less active than **15** in the reaction of methyl vinyl ketone with methyl 1-oxoindan-2-carboxylate (Reaction C).[7] This suggests that among these catalysts there is selectivity, depending on the nature of the Michael donors and acceptors.

Finally the polymer supported catalysts **5** and **6**, as is normal for this type of reactions, are easily removed from the reaction mixture by a simple filtration and retain their catalytic efficiency after several reactions.[6] Although it was hoped that the optically active catalysts **1**—**6** might lead to asymmetric induction in the chiral Michael adducts, unfortunately all samples were obtained in a racemic form.[8] These results were particularly frustrating in the case of catalysts **2**, **6** in view of the known ability of the sulfinyl group to promote asymmetric induction.[3,9]

Experimental

General. Optical rotations were measured on a Perkin-Elmer 241 polarimeter. Infrared spectra were recorded on a Perkin-Elmer 377 spectrometer. ^1H and ^{13}C NMR spectra were recorded on a Varian HA 100 and/or a Varian A 390 instrument.

Materials. (L)-Methionine-*d*-*S*-oxide was prepared according to the literature; $[\alpha]_D^{20}$ +127° (*c* 1.15, 1 mol dm^{-3} HCl); lit,[4] $[\alpha]_D^{24}$ +131° (*c* 1.8, 1 mol dm^{-3} HCl). It has the (*S*,*S*) absolute configuration.[4] Methyl 1-oxoindan-2-carboxylate was obtained by literature methods.[10]

N,N-*Dimethyl-(*L*)-methionine.* (L)-(+)-Methionine (**10**) was methylated by reductive condensation with formaldehyde and hydrogen in the presence of palladized charcoal for 18 h

according to Bowman.[11] The product, obtained in 86% yield, had mp 186 °C, $[\alpha]_D^{20}$ +57.0° (*c* 1, H_2O) lit,[12] mp 187 °C, $[\alpha]_D^{20}$ +57.9° (H_2O).

N,N-*Dimethyl-(L)-methioninol.* Boron trifluoride etherate (12.2 mmol) was added dropwise under nitrogen at room temperature to a stirred suspension of sulfide **11** (10 mmol) and $NaBH_4$ (12.2 mmol) in anhydrous tetrahydrofuran (40 ml). The mixture was stirred for 15 h, then a second aliquot of boron trifluoride (12.2 mmol) and $NaBH_4$ (12.2 mmol) was added. The mixture was stirred for 48 h, then ethanol (10 ml) was added and the suspension was acidified to pH 1 with 3 mol dm^{-3} hydrochloric acid. The mixture was evaporated off *in vacuo*. Water (15 ml) was added to the residue.

The insoluble material was filtered off and NaOH was added to the solution up to pH 10. Extraction with diethyl ether and evaporation of the solvent afforded the title compound in 75% yield. It had n_D^{20} 1.4949, $[\alpha]_D^{20}$ +35.0° (*c* 1.1, CH_2Cl_2). Compound **3** had been previously obtained[13] by reduction of *N,N*-dimethyl methionine methyl ester with $LiAlH_4$.

Benzyldimethyl (3-Methylthio-1-hydroxymethylpropyl)ammonium Chloride. Compound **1** was obtained by reaction of **3** (2.75 mmol) with benzyl chloride (2.8 mmol) in ethanol (15 ml) at 50 °C for 24 h. After evaporation of the solvent under vacuum and treatment of the residue with pentane, compound **1** was obtained (67%), n_D^{21} 1.5605, $[\alpha]_D^{20}$ +26.9° (*c* 4.95, EtOH). Found: C, 58.00; H, 8.30; N, 4.83%. Calcd for $C_{14}H_{24}ClNOS$: C, 58.02; H, 8.35; N, 4.83%.

N,N-*Dimethyl-(L)-methionine*-d-S-*oxide.* Sulfoxide **12** was methylated as described above in the case of sulfide **10** with a 5 h reaction time. Compound **13** (81%) had mp 196—197 °C, $[\alpha]_D^{20}$ +141.0° (*c* 1.1, 1 mol dm^{-3} HCl). Found: C, 43.40; H, 7.78; N, 7.23%. Calcd for $C_7H_{15}NO_3S$: C, 43.50; H, 7.82; N, 7.25%.

N,N-*Dimethyl-(L)-methionine*-d-S-*oxide Methyl Ester.* Acid **13** (27 mmol) was dissolved in methanol (50 ml), cooled at 0 °C, and esterified with an ethereal solution of diazomethane. The usual work up afforded the crude ester which was purified by column cromatography (SiO_2, CH_2Cl_2/CH_3OH 9: 1). Compound **14** (80%) had mp 55—57 °C, $[\alpha]_D^{20}$ +20.9° (*c* 2.1, CH_2Cl_2). Found: C, 46.27; H, 8.25; N, 6.71%. Calcd for $C_8H_{17}NO_3S$: C, 46.35; H, 8.27; N, 6.76%.

N,N-*Dimethyl-(L)-methioninol*-d-S-*oxide.* Ester **14** (4 mmol) was added at 0 °C under nitrogen to a stirred suspension of $LiAlH_4$ (6 mmol) in anhydrous diethyl ether (40 ml). The mixture was stirred at room temperature for 6 h, monitoring the reaction by IR. Excess of hydride was destroyed and the mixture was evaporated off. The residue was extracted with dichloromethane and the organic layer evaporated off. The alcohol **4** (78%) had mp 58—61 °C, $[\alpha]_D^{20}$ +100.4° (*c* 1.04, CH_2Cl_2). Found: C, 46.70; H, 9.56; N, 7.75%. Calcd for $C_7H_{17}NO_2S$: C, 46.89; H, 9.56; N, 7.81%.

Benzyldimethyl (3-Methylsulfinyl-1-hydroxymethylpropyl)ammonium Chloride. Onium salt **2** was obtained by reaction of **4** with benzyl chloride with a 48 h reaction time as described above in the case of **1**. Compound **2**, a viscous oil, (66%) had $[\alpha]_D^{20}$ +51.1° (*c* 2.0, CH_3OH). Found: C, 55.02; H, 7.88; N, 4.60%. Calcd for $C_{14}H_{24}ClNO_2S$: C, 54.98; H, 7.91; N, 4.58%.

Poly(styrene-divynilbenzene) Onium Salts (5 and 6). Equimolecular amounts of commercial anion-exchange resin in the chloride form Biobeads S-X1 (Cl^-); exchange capacity 1.25 mequiv. Cl/g and sulfide **3** or sulfoxide **4** were heated at 60 °C under stirring in DMF as solvent (10 ml for 1 mmol of substrate) for 3 d.

The resin was filtered off, washed with absolute ethanol, water, 1 mol dm^{-3} HCl, water, absolute ethanol, and anhydrous diethyl ether. The exchange capacity of **5** and **6**, determined by Volhard's method, were 1.156 and 0.84 mequiv Cl/g, respectively.

Michael Additions. Michaels additions of nitromethane to *trans*-chalcone, of thiophenol to 2-cyclohexene-1-one, and of methylvinyl ketone to methyl 1-oxoindan-2-carboxylate in homogeneous and phase-tranfser conditions were carried on according to procedures described in the literature.[2a,14] Reactions with polymer supported catalysts **5** and **6** were performed as the corresponding reactions in the presence of soluble onium salt, except that at the end of the reaction the catalysts **5** and **6** were removed by simple filtration. Adducts **7—9** had physical and spectroscopic properties identical to those of reference samples prepared according to known procedures.[2a,14] Compounds **7**, **8**, and **9**, obtained by using **15** as catalyst had $[\alpha]_{578}^{21}$ −9.8° (*c* 2, CH_2Cl_2),[2a] $[\alpha]_{578}^{25}$ −2.0° (*c* 2, C_6H_6),[2a] and $[\alpha]_{578}^{25}$ −2.56° (*c* 2, C_6H_6); 3.3% e.e.[14]

Synthesis of Oxazolidines, Thiazolidines, and 5,6,7,8-Tetrahydro-1*H*,3*H*-pyrrolo[1,2-*c*]oxazole (or thiazole)-1,3-diones from β-Hydroxy- or β-Mercapto-α-amino Acid Esters†

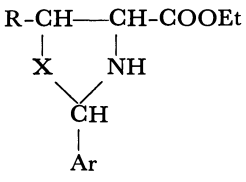
Mahmoud Zarif Amin BADR,* Morsy Mohamed ALY, Atiat Mohamed FAHMY, and Mansour Esmael Younis MANSOUR

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

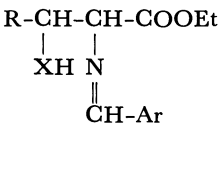
(Received January 10, 1980)

2-Aryl-4-(ethoxycarbonyl)oxazolidines and thiazolidines (**1**) were prepared from the corresponding α-amino acid ethyl esters containing either hydroxyl or mercapto groups in the β-position by fusion with some aromatic aldehydes. Dehydrogenation of **1** with *N*-bromosuccinimide gave the corresponding oxazoles and thiazoles. The oxazolidines and thiazolidines gave Mannich bases on interaction with *p*-nitrobenzaldehyde and piperidine. Acetylation of **1** gave the corresponding *N*-acetylderivatives, which on fusion in the presence of anhydrous $ZnCl_2$ undergo cyclization, giving the corresponding bicyclic compounds, 5,6,7,8-tetrahydro-1*H*,3*H*-pyrrolo[1,2-*c*]-oxazole (or thiazole)-1,3-diones.

Fusion of the β-hydroxy and/or β-mercapto-α-amino acid ethyl esters (L-serine, 3-phenyl-DL-serine, L-threonine, or L-cysteine) with aromatic aldehydes such as benzaldehyde, *p*-anisaldehyde, *p*-chlorobenzaldehyde, and/or *p*-nitrobenzaldehyde gave the corresponding oxazolidines or thiazolidines **1** rather than azomethine derivatives (**2**).



1

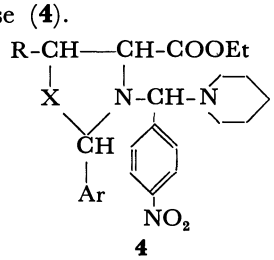


2

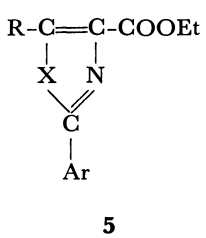
X=O or S;
R=H, CH_3 or C_6H_5;
Ar=C_6H_5, *p*-$CH_3OC_6H_4$, *p*-ClC_6H_4, *p*-$NO_2C_6H_4$, or *p*-BrC_6H_4.

Structure **1** is apparent by elemental analysis data, UV, and IR spectral data, the latter two reasonably agreeing with those of the comparable compounds.[1,2] The alternative structure **2** for the products is excluded by the absence of the NMR signal near δ 7.5 ascribable to azomethine.

The oxazolidines and/or thiazolidines (**1**) on treatment with acetyl bromide in glacial acetic acid afforded *N*-acetyl derivative (**3**) whose IR spectra showed an absorption band at 1570 cm^{-1} due to the amide group (>$NCOCH_3$) but no NH stretching vibration band. On treatment with piperidine and *p*-nitrobenzaldehyde (**1**) gave the corresponding Mannich base (**4**).



4



5

The oxazolidines and thiazolidines (**1**) were converted into the corresponding oxazoles and thiazoles (**5**) on dehydrogenation using *N*-bromosuccinimide in boiling carbon tetrachloride. The IR spectra of the oxazoles and thiazoles (**5**) showed no NH band but an apparent shift in the ester group was observed at 1735—1750 cm^{-1} due to conjugation with the double bond at C_4–C_5.[3] The C=N absorption band at 1590—1550 cm^{-1} is affected by substituents on aryl moiety at C_2; *p*-nitro group causes a decrease in wave number down to 30 cm^{-1}, whereas *p*-methoxyl group causes an increase up to *ca.* 10 cm^{-1}. In addition, characteristic absorptions of oxazole ring[4] were observed in the range 1190—1250 cm^{-1}.

N-Acetyloxazolidines and/or thiazolidines (**3**) undergo cyclization by fusion with anhydrous zinc chloride affording 5,6,7,8-tetrahydro-1*H*,3*H*-pyrrolo[1,2-*c*]oxazole (or thiazole)-1,3-dione (**6**) whose IR spectra showed no absorption of ($COCH_3$) group, but a broad band at 3300 cm^{-1} due to associated OH group, confirming the assumption that the bicyclic structure **6** exists in the enolic form rather than its diketonic tautomer (**7**). The cyclization reaction seems to proceed according to the following mechanism.

Experimental

All melting points are uncorrected. IR spectroscopic analysis was carried out on a Pye-Unicam IR spectrophotometer, Model SP 200 G, UV absorptions were measured on a Pye-Unicam UV spectrophotometer, Model SP 8000, using 95% ethanol as a solvent. NMR spectra were taken with a Varian T-60 instrument in deuterochloroform with tetramethylsilane as an internal standard.

Amino Acids Ethyl Esters. Prepared in more than 80% yield by the general method described by Fischer[5] and used without further purification in the preparation of the oxazolidines and/or thiazolidines.

Preparation of Oxazolidine and/or Thiazolidine Derivatives (1). The amino acid ethyl ester (0.01 mol) was heated with the appropriate aldehyde (0.011 mol) in an oil bath at 80—90 °C for 2 h. Extraction with ethyl acetate gave the corresponding 2-aryl-4-(ethoxycarbonyl)oxazolidines and/or thiazolidines (**1**) which was purified by column chromatography using 1×50 cm column of Davison 950 silica-gel, slurry packed with hexane and eluted with benzene–hexane (3:1 v/v). The results are given in Table 1.

Acetylation of Oxazolidines and Thiazolidines (3). Acetyl bromide (0.01 mol) was added to the oxazolidine or thia-

The mixture was treated with cold dilute hydrochloric acid, the solid formed being collected by filtration. Crystallization of the solid from dilute acetic acid gave 5,6,7,8-tetrahydro-1*H*,3*H*-pyrrolo[1,2-*c*]oxazole-1,3-diones or their thiazole analoges (**7**). The results are given in Table 3.

Dehydrogenation of Oxazolidine and Thiazolidine Derivatives by N-*Bromosuccinimide: Formation of Oxazole and Thiazole Derivatives (**5**).* *N*-Bromosuccinimide (0.02 mol) and benzoyl peroxide were added to the oxazolidine or thiazolidine derivative (0.01 mol) dissolved in carbon tetrachloride (100 ml) and the solution was refluxed for 6 h. The reaction product was filtered off in order to separate the succinimide and the filtrate was concentrated. The oxazole or thiazole derivatives (**5**) obtained were crystallized from petroleum ether (40—60 °C). The results are given in Table 4.

*Preparation of Mannich Bases (**4**).* A mixture of 2-aryl-4(ethoxycarbonyl)oxazolidine or thiazolidine (0.01 mol) *p*-nitrobenzaldehyde (0.01 mol) and piperidine (0.02 mol) in ethanol (50 ml) was refluxed for 6 h. The reaction product was poured onto ice, washed with petroleum ether (40—60 °C) several times and extracted with ether. The Mannich bases (**4**) were crystallized from dilute acetic acid. The results are given in Table 5.

Dielectric Relaxation Processes in Some Substituted Amides in Dilute Solutions

S. K. Saxena,† J. P. Shukla, and M. C. Saxena*
Physics Department Lucknow University, Lucknow, 226007, India
(Received May 16, 1980)

The dielectric measurements have been carried out in the microwave region (3.1 cm) over a range of temperatures on propionamide, *N*-methylpropionamide, *N*,*N*-dimethylpropionamide, and *N*-ethylacetamide. All the molecules except propionamide exhibit high value of distribution parameter. The dielectric dispersion, when resolved by Higasi, Koga, and Nakamura method gives two relaxation times $\tau(1)$ and $\tau(2)$ widely different from each other, suggesting the two separate processes occurring in the system. The enthalpies for different processes involved have been evaluated by the Eyring equations. The comparison with NMR data of enthalpy to $\Delta H_{\tau(1)}$, which is related to the process other than molecular, suggests that the rotation of $-NR_2$ group around the carbonyl carbon nitrogen bond is not feasible. The observed result indicates that this may be due to group inversion process. These results are in agreement with the earlier investigations of Saxena *et al.* on some substituted amides and of Phillips on *N*,*N*-dimethylamide using proton resonance spectra. The substituted amides in dilute solution of benzene exhibit some association with the benzene molecules.

Leader and Gromley[1] reported a remarkable variation in the dielectric constant in the amides and substituted amides. The high values of dielectric constant of monosubstituted amides were suggested to be due to their association as a chain polymerisation. Since his initial work, a series of investigations have been carried out by several workers.[2-10] Jordon *et al.*[11] recently confirmed Debye behaviour for formamide, Itoh *et al.*[12] for *N*-methylacetamide and Srivastava *et al.*[13] for dimethylformamide. Brown and Price[14] have ruled out the molecular flexibility in dimethylacetamide. Karamyan and Shakhparonov[15] confirmed a long frequency dispersion region for *N*-substituted amides with much smaller amplitude at mm wavelength. In order to study the possibility of molecular flexibility and to ascertain the thermodynamics of dipolar relaxation Misra *et al.*[16] recently made a study of *N*-methylformamide, *N*-methylacetamide, dimethylformamide, and dimethylacetamide in the dilute solution of benzene over a range of temperatures. The enthalpies of different relaxation processes observed suggest the possibility of molecular and group inversion processes in the above molecules. Due to interesting results observed in the case of *N*-substituted amides, a further study in this direction has been undertaken. The molecules chosen are propionamide, *N*-methylpropionamide, dimethylpropionamide, and *N*-ethylacetamide so that the effect of propionyl (CH_3CH_2-CO) group in different substituted amides could be studied. The possibility of molecular association as pointed out by other workers[8,10] has also been examined.

Experimental

The chemicals were of purest quality available and the physical properties were checked against literature values. The solvent used in the measurements was benzene (A. R. Grade) obtained from B. D. H., England and was distilled twice before use. The dielectric constant ε' and dielectric loss ε'' at X- band have been measured by the technique given by Dakin and Works.[17] The static dielectric constant ε_0 was measured by dipolmeter and dielectric constant at infinite frequencies ε_∞ was determined from the measured refractive indices of the system ($\varepsilon_\infty = n_D^2$). The slopes a_0, a', a'', and a_∞, the most probable relaxation time τ_{OH} and the distribution parameter 'α' have been evaluated using Higasi method.[18] The details of determining these parameters and the dipolemoments have been reported in our earlier paper.[19] The dielectric absorbtion has been further resolved by using Higasi *et al.* method[20] in terms of two seperate relaxation processes $\tau(1)$ and $\tau(2)$ where $\tau(2)$ stands for the molecular relaxation process and $\tau(1)$ is associated with the group process being an implicit function of τ_1, τ_2, and the weight factor C_2. The parameter $\tau(0)$ stands for the average relaxation time given by $[\tau(0) = \sqrt{\tau(1), \tau(2)}]$ and τ_0 is the average relaxation time (Cole-Cole method) as reported in the literature.[14] Eyring equations[21] have been utilised to evaluate the thermodynamical parameters. The enthalpies associated with different modes of relaxation have been evaluated by plotting the relaxation times against $1/T$. The dipolemoments calculated using Higasi method[18] have been compared with the literature values (Table 2).

Discussion

The distribution parameter 'α' has been found to be low in the case of propionamide but its value is sufficiently high in the case of other three *N*- substituted amides indicating the flexibility of all the three molecules under microwave field. The dielectric dispersion is further resolved by Higasi *et al.* method[20] in terms of molecular relaxation time $\tau(2)$ and the relaxation time associated with group relaxation time $\tau(1)$. The $\tau(1)$ (=23.7 ps) and $\tau(2)$ (=30.5 ps) are not widely different from one another in the case of propionamide. Thus a single Debye dispersion seems to occur for the above molecule. Further $\tau(2)$ and τ_{OH} calculated by Higasi method[18] are close to each other for propionamide, suggesting that the molecular process and the overlapped process are similar to one another in this molecule. The observed single Debye dispersion for this molecule is in agreement with the earlier results of Jordon *et al.*[11] on formamide.

The most probable relaxation time τ_{OH} at 297 K for *N*-methylpropionamide (=22.8 ps) and *N*-ethylacetamide (=26.2 ps) can be compared with our

previous results[16] on *N*-methylformamide (=17.8 ps) and *N*-methylacetamide (=18.0 ps). The observed results are supported by the earlier observations of Dannhauser and Johari[9] establishing that the relaxation times show specific dependence on the shape and size of alkyl group attached to the carbonyl or amino group. The τ_{OH} for dimethylpropionamide (=21.8 ps) can be compared with our earlier work[16] on dimethylformamide (=18.1 ps) and dimethylacetamide (=25.6 ps). The value is comparatively high as regards to τ_0 (6.0—8.4 ps) reported for dimethylacetamide by Brown and Price[14] in benzene at 293 K. The longer value of relaxation time seems to result from the association of disubstituted amide. The association in amides has been observed by many earlier workers.[8,10] Further, $\tau(1)$ and $\tau(2)$ are widely different for all the three *N*-substituted amides showing the non rigid behaviour of these molecules in the microwave region.

The enthalpies corresponding to $\tau(1)$, $\tau(2)$, $\tau(0)$, and τ_{OH} processes have been evaluated. $\Delta H_{\tau(1)}$ and $\Delta H_{\tau(2)}$ are widely different from each other except in case of propionamide, showing again the flexible nature of the molecules in the microwave field. $\Delta H_{\tau_{OH}}$ for *N*-ethylacetamide (=19.1 kJ mol^{-1}), *N*-methylpropionamide (=18.2 kJ mol^{-1}) are comparable with those *N*-methyl acetamide (=14.9 kJ mol^{-1}) and *N*-methyl formamide (=14.2 kJ mol^{-1}) observed in our earlier study.[16] Further $\Delta H_{\tau_{OH}}$ for dimethylpropionamide (=14.2 kJ mol^{-1}) can be compared with the values for dimethylformamide (=13.7 kJ mol^{-1}) and dimethylacetamide (=12.8 kJ mol^{-1}) reported in our previous work.[16] The enthalpies for $\Delta H_{\tau_{OH}}$ and $\Delta H_{\tau(2)}$ are almost equal, showing the probability of the molecular process being predominant. The enthalpy $\Delta H_{\tau(1)}$ for *N*-methylpropionamide could not be evaluated due to irregular variation of $\tau(1)$. However, the observed value of $\Delta H_{\tau(1)}$ for *N*-ethylacetamide and for dimethylpropionamide which represent a process other than molecular has been found to be small when compared with the enthalpy of activation for internal rotation of $-NR_2$ group (>40 kJ mol^{-1}), reported using NMR data.[22,23] Therefore, this value can not be assigned to the internal rotation of –NXR (where R=CH_3, C_2H_5, and X=H, CH_3). This, however, could be assigned to the group inversion process of R and X substituents from their respective position within the –NXR group. This is in agreement with our earlier investigations on *N*-substituted amide[16] and with the studies of Phillips[24] using proton resonance spectra of *N,N*-dimethylamides.

The dipolemoments of all the four molecules have been evaluated by Higasi method[18] and they agree well with the literature values[25-27] wherever available. The slightly higher value of dipolemoments may be due to the association and the interaction of benzene with, *N*-subsituted amide. The observed association is in agreement with the earlier studies of many workers[8,10] and such interactions in the dilute solution of benzene have been prodicted by Ellision and Mayer.[28]

The free energy of activation has been found to be almost of the same order in all the molecules and the entropy values of them have been found to be positive. These have been reported in Table 2.

Conclusion

All the amides studied including propionamide follow Debye behaviour. The propionamide has been found to behave as a rigid molecule. This is in agreement with the earlier work of Jordon *et al.*[11] on formamide.

It is observed that *N*-substituted amides give rise to a high value of the distribution parameter, indicating that the three systems exhibit flexible behaviour which is supported by two discrete relaxation times $\tau(1)$ and $\tau(2)$. There appears to be a possibility of group inversion in amides, which is in agreement with our previous work[16] and also with the studies of Phillips,[24] using proton resonance spectra of *N,N*-dimethylamide.

Also a close study of the molecular process shows that in *N*-substituted amides the relaxation time varies according to the shape and size of the alkyl group attached to the carbonyl or the amino group. This agrees well with the studies made by Dannhauser and Johari.[9] In almost all the cases investigated, the relaxation times associated with the molecular process and with the overlapped process have been found to be longer than the values expected for such species. The dipolemoments have been calculated and found to be slightly higher than the literature values. This indicates the possibility of association of the amide molecules with the solvent benzene. The higher value of dipolemoment in dilute solution of benzene has been reported in an earlier study by Worsham and Hobbs[8] in *N*-substituted amide.

Kinetics and Mechanism of Hydrolysis of Ruheman's Purple in the Absence and Presence of Micelles in Aqueous Medium

Sudhir MALAVIYA and Sarvagya S. KATIYAR*

Department of Chemistry, Indian Institute of Technology, Kanpur-208016, India

(Received May 17, 1980)

The mechanism of acid hydrolysis of Ruheman's purple has been investigated and the effect of micelles on the rate has been examined. First order rate constant for the hydrolysis reaction decreases linearly with decreasing hydrogen ion concentration up to pH 3 and levels off thereafter with no reaction occurring above pH 7. Increasing ionic strength decreases the rate in accordance with the Bronsted-Christiansen equation. The salt effect in the dipole-dipole reaction is probably a reflection of the fast equilibrium steps involving ions preceding the rate-determining step. Solvents like ethylene glycol and dioxane have no effect, indicating that the rate-determining step of the reaction does not involve ionic species. A mechanism of the reaction has been proposed which is consistent with our observed results. In the presence of micelles the reaction rate was strongly inhibited by the cationic micelles of hexadecyltrimethylammonium bromide, whereas anionic micelles of sodium dodecyl sulfate showed a slight enhancement. The micellar data have been analyzed on the basis of available models.

The reaction of amines with ninhydrin yields a color product, Ruheman's purple sometimes erroneously referred to as "azine-bis-indandione. This reaction has immense biological and analytical significance as it serves as a model for several biochemical reactions that occur in the metabolism of deamination and transpeptidation[1,2] as well as it is involved in the most common method for the analysis of amino groups.[3,4] The course and mechanism of ninhydrin reaction has been extensively studied by Friedman and Williams[5] who investigated the effect of various parameters on the formation of Ruheman's purple. However, the mechanism of reverse reaction, namely the decolorization reaction, of Ruheman s purple in the presence of acids has not been investigated in detail. We have undertaken a systematic analysis of the kinetics and mechanism of decolorization reaction of Ruheman's purple in the hope that the data on the reverse reaction might provide insight into the ninhydrin reaction.

The reaction responsible for the hydrolytic instability was also studied in the presence of cationic micelles of hexadecyltrimethylammonium bromide (CTAB), sodium dodecyl sulfate (SDS), and poly(oxyethylene) (23) 1-dodecanol (Brij-35, Lauromacrogol). Micelles are known to affect the rates of reactions due to several factors by differential distribution of the substrates inside and outside the micelles and by perturbing the thermodynamic parameters of the reaction.[6] The interpretation of the mechanism of catalysis or inhibition of reaction rates by micelles has received considerable attention in view of the analogies drawn between the micellar and enzyme-catalysis. The rate of the present reaction is considerably inhibited in the presence of cationic micelles of CTAB. The data obtained have been analyzed quantitatively on the basis of available models.

Experimental

Ruheman's purple (RP) was prepared by the method of Ruheman.[11] The product was further purified by employing a method similar to that of Davidson.[12] The final product was obtained as ammonium salt. Sodium dodecyl sulfate obtained from Fisher Scientific Co. was recrystallized twice from 95% ethanol.[13] CTAB (extra pure, Sisco Research Laboratories) was crystallized twice with hot methanol–ether[13] before use. HCl and KCl of analytical grade(B.D.H.) were used without further purification. Organic solvents (analytical grade, B.D.H.) were further purified by the usual methods[14] before use.

The hydrolysis was studied using a Beckman DU spectrophotometer at the absorption maximum of RP (570 nm).

Results and Discussion

Reaction in the Absence of Micelles. First order rate constant for the reaction of RP in acidic medium was found to increase linearly with the increase in the hydrogen ion concentration (Fig. 1). Graphical analysis of the results gave the value of second order rate constant $k' = 0.94$ mol^{-1} dm^3 s^{-1}, comparable to that obtained earlier by Sattar and Chaturvedi[15] ($k' = 0.86$ mol^{-1} dm^3 s^{-1}). However, when the reaction was studied over the pH range 2—11, the initial

a) Concentration of H^+ ion $=3\times10^{-3}$ mol dm^{-3}.

linear dependence of rate on pH faded at pH≈3. No hydrolysis of RP was observed at pH>7 (Fig. 2). This pattern of change in the rate with increase in pH differs from that observed by Cordes and Jencks[16] for the hydrolytic scission of >C=N- bond in schiff bases. They observed a rate maximum with the increase in pH followed by a pH region where the rate was unaffected by the increase in pH. In the reaction of RP no change in the reaction rate was observed with the change in RP concentration at fixed H^+ ion concentration. This shows that the reaction rate is independent of the initial RP concentration.

Dependence of the RP reaction on neutral salts added was investigated. Reaction rate was found to decrease with the increase in the ionic strength of the medium (Table 1) at constant H^+ ion concentration. Use of the following equation which is an approximation of Bronsted-Christiansen equation[17,18] gives the impression as if the reaction is taking place between two oppositely charged ions. However, despite

$$\log k' = \log k_o' + \frac{1.02 Z_A Z_B \sqrt{\mu}}{1+\sqrt{\mu}} \qquad \text{(i)}$$

the applicability of above equation, observed salt effect seems to be secondary salt effect, a purely thermodynamic effect, arising from the change in activity of the dissociable reactant species. It seems that the salt effect is a reflection of the equilibrium steps involving ions occurring prior to the rate determining step in the overall mechanism (*vide infra*).[19] The magnitude and direction of secondary salt effect on reaction rate depends on concentration terms that appear in the overall rate expression.

Table 2. Effect of solvents on the hydrolysis of RP in acid medium at 25 °C[a)]

Composition of solvent (v/v)	k'/mol^{-1} dm^3 s^{-1}		
	Acetone	Dioxane	Ethylene glycol
5%	0.85	0.84	0.91
10%	0.78	0.84	0.91
15%	0.72	0.84	0.92
20%	0.67	0.82	0.92
25%	0.65	0.84	0.92
30%	0.69	0.88	0.92
40%	—	—	0.90

a) Concentration of H^+ ion $=4\times10^{-3}$ mol dm^{-3}.

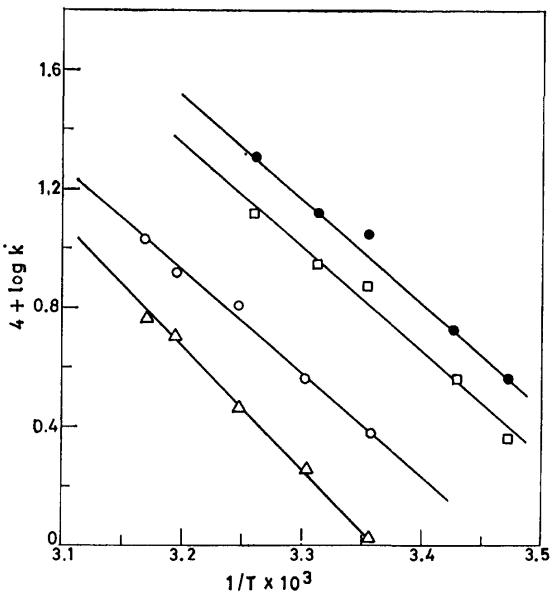

Fig. 3. Effect of temperature on the hydrolysis of RP. Plots of log k' *vs.* $1/T$. (○) μ=0.001; (△) μ=0.501; (□) 25% (v/v) acetone; (●) 36% (v/v) ethylene glycol.

The effect of solvents on the reaction rate was studied in the presence of 5—30% (v/v) of acetone, dioxane, and ethylene glycol in aqueous medium (Table 2). Reaction rate was found to be independent of increasing concentration of ethylene glycol and dioxane but a slight decrease was observed in the presence of acetone. The solvent effects give a positive indication that the rate determining step of the reaction involves no ionic species.

Effect of temperature on the reaction rate was studied in the range 288—320 K at ionic strength of 0.001 and 0.501. In order to examine the influence of temperature on the specific solvent effect, studies were carried out in 25% acetone and 36% (v/v) ethylene glycol, which have the same dielectric constant. The reaction rate was found to follow the Arrhenius equation (Eq. 2) under all the four experimental conditions (Fig. 3). Graphical analysis of

Table 3. Thermodynamic quantities of activation for the hydrolysis of RP at 25 °C

Thermodynamic quantity	Aqueous medium		Acetone 25% (v/v)	Ethylene glycol 36% (v/v)
	μ=0.001	μ=0.501		
E^*/kJ mol^{-1}	66.9	79.5	54.4	54.4
ΔG^*/kJ mol^{-1}	92.0	92.0	92.0	87.8
Z/mol^{-1} dm^3 s^{-1}	2.8×10^8	1.9×10^{10}	3.1×10^6	5.0×10^6
ΔS^*/J K^{-1} mol^{-1}	−87.8	−54.4	−125.5	−125.5
ΔH^*/kJ mol^{-1}	66.9	75.3	37.6	37.6

log k *versus* $1/T$ plot gave the value of activation energy E^* which was then used to calculate other activation parameters, ΔG^*, ΔS^*, ΔH^*, and Z, using Eqs. 3—5. The values of the parameters at 25 °C are

$$\log k' = \log Z - E^*/2.303RT \quad (2)$$

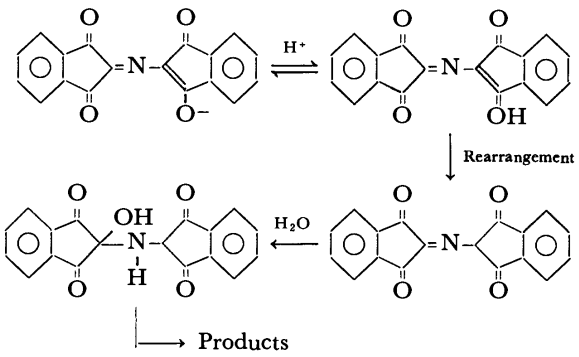
$$\Delta G^* = 2.303RT\left(\log\frac{RT}{Nh} - \log k'\right) \quad (3)$$

$$\Delta S^* = 2.303R\left(\log Z - \log\left(e\frac{RT}{Nh}\right)\right) \quad (4)$$

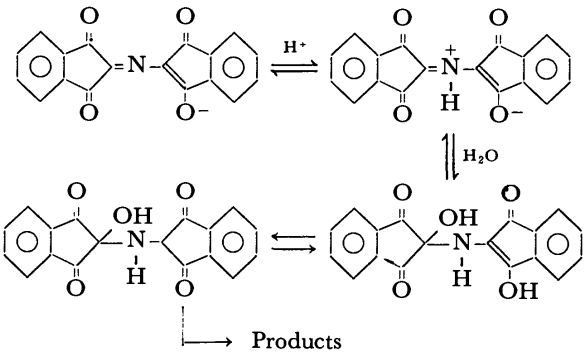
$$\Delta H^* = \Delta G^* + T\Delta S^* \quad (5)$$

given in Table 3. High negative entropy values −90.8 J K^{-1} mol^{-1} and −55.2 J K^{-1} mol^{-1} at μ=0.001 and 0.501, respectively, suggest bimolecular nature of the rate determining step.[20] Moreover, activation energies obtained for isodielectric mixture of 25% acetone (55.6 kJ mol^{-1}) and 36% ethylene glycol (54.8 kJ mol^{-1}) are similar, reflecting the fact that the decrease in rate observed in the presence of acetone is due to nonelectrostatic terms generally associated with the effect of solvent on the reaction rate.[21]

A tentative reaction mechanism for the hydrolysis of RP, proposed by Friedman and Williams,[5] is given in Scheme 1. No justification other than the product analysis has been given by these authors. Moreover, the proposed mechanism can not explain the observed deviation from the linear relationship observed at pH$\geqslant$4. Another objection to proposed mechanism is that RP is known to be strongly acidic (pK_a of RP is almost equal to that of H_2SO_4) p$K_a\leqslant0$,[5] hence, even in fairly strong acidic solution (pH$\approx$2) RP will remain in ionic form and no protonation can occur at the negatively charged oxygen. We propose a reaction mechanism (Scheme 2) which is consistent with our observed results. At relatively low pH, when concentration of H^+ ion is much higher than that of RP, attack of water on the zwitterionic species to give α-hydroxy amine intermediate [x] seems to be the rate determining step. This is supported by the high negative value of entropy (−87.8 J K^{-1} mol^{-1}) and also by the absence of any significant solvent effect. The observed salt effect, though unusual for a dipole-dipole reaction, is not unique for a reaction between two dipoles, where a fast equilibrium step preceeds the rate-limiting step. For example, Sinha and Katiyar[22] and others[23] has also observed a pronounced salt effect on the color-fading reaction of rosaniline. Though this reaction is ion-dipole reaction, it could be cited as an example because theoretically an ion-dipole reaction like a dipole-dipole reaction, should show no pronounced salt effect. Such



Scheme 1.



Scheme 2.

salt effects might be due to reflection of fast equilibrium steps involving ions, in the overall reaction mechanism as pointed out by Hine.[19] The observed deviation from the linear behavior at pH$\geqslant$4 can also be explained by the proposed mechanism. At higher pH, concentration of H^+ ion and RP become similar, and the rate of formation of zwitterion progressively decreases with the increase in pH. No reaction takes place at pH$\geqslant$7 because of absence of first protonation step.

Reaction in the Presence of Micelles. Change in absorption maximum from 570 nm to 579 nm was observed in the presence of 0.01 M CTAB. However, no such shift was detected in the presence of 0.02 M SDS or 0.01 M Brij-35. This indicates binding between RP and CTAB micelles. The reaction was studied at different surfactant concentrations keeping the hydrogen ion concentration constant in each case. An inhibition of reaction rate was observed in the presence of cationic surfactant (CTAB) whereas the reaction rate was slightly enhanced in the presence of anionic micelles of SDS. However, no definite trend of reaction rate emerged in the presence of nonionic surfactant of Brij-35 (Fig. 4). At fixed SDS or CTAB

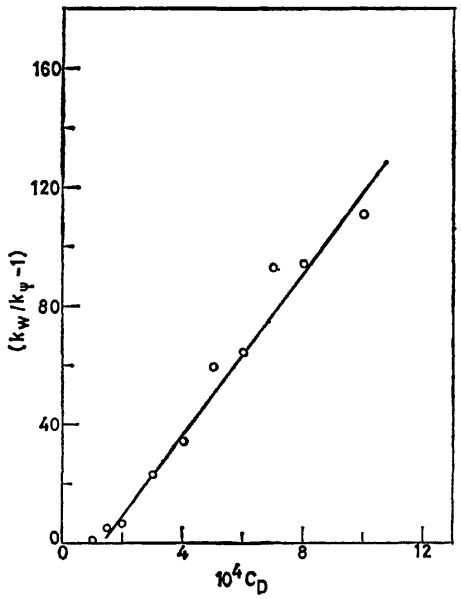

Fig. 5. Variation of $(k_w/k_\psi - 1)$ with the surfactant concentration (mol dm^{-3}) for the hydrolysis of RP at 25 °C in the presence of CTAB.

concentration, a linear increase in reaction rate was observed with increase in hydrogen ion concentration (Fig. 1).

Surfactant micelles provide an unusual medium which may affect the reaction rate in more than one way:[7-10,23] (a) a decrease in entropy of the reactants arising due to their binding on the micellar surface, *i.e.*, by virtue of relatively higher concentration of reactants in micellar phase in comparison to bulk phase, (b) a high degree of closeness attained by reactants in the micellar phase, and (c) relative stabilization or destabilization of substrate arising due to electrostatic and hydrophobic interaction between substrates and micelles. Moreover, in the hydrolysis of RP, the micelles may affect the first equilibrium step where proton gets associated with anion to give zwitterion or the subsequent rate determining attack of water molecule to form an α-hydroxy amine. It appears that in the presence of CTAB, because of favorable hydrophobic as well as electrostatic interactions the anionic imine gets bound with the surface of cationic micelle, shifting the protonation equilibrium towards the lefthand side, retarding the reaction rate. However, in the presence of SDS, hydrophobic forces oppose the electrostatic repulsion. However it seems that a fraction of anionic substrate does bind with the anionic micelles, where it is more prone to proton attack, and hence a slight acceleration in the reaction rate is observed. Thus the effect of micelles on the reaction is consistent with the mechanism we proposed.

Quantitative Treatment of the Micellar Data. Simple kinetic model proposed by Menger and Portnoy[24] (Scheme III) was applied to explain quantitatively

$$\begin{array}{ccc} D_n + S & \overset{K}{\rightleftharpoons} & D_n \cdot S \\ {\scriptstyle k_w}\downarrow & & \downarrow{\scriptstyle k_m} \\ \text{Products} & & \text{Products} \end{array}$$

Scheme 3.

the effect of cationic and anionic micelles on the reaction rate. This kinetic scheme provides the following rate equation:

$$\frac{k_\psi - k_w}{k_m - k_\psi} = \frac{K}{N}(C_D - \text{cmc}), \tag{7}$$

where k_ψ is the observed rate constant and k_w and k_m are the rate constants in aqueous and micellar pseudophases, respectively. K is the equilibrium constant for the association of substrate S with micelle D_n, N is the aggregation number and C_D is the stoichiometric surfactant concentration. This equation predicts a linear relationship between $\frac{k_\psi - k_w}{k_m - k_\psi}$ and C_D. However, for micellar inhibited reaction we can further assume that $k_m = 0$.[8] Hence, we obtain

$$\frac{k_w}{k_\psi} - 1 = \frac{K}{N}(C_D - \text{cmc}). \tag{8}$$

The results obtained in the presence of CTAB were analyzed using Eqs. 7 and 8. Slope of the straight line thus obtained (Fig. 5) gives the value of K/N, which was further utilized to calculate the fraction (α) of RP present in the micellar phase by means of

$$K/N = \frac{\alpha}{1-\alpha} \cdot \frac{1}{C_D - \text{cmc}}. \tag{9}$$

The values of K/N, cmc, and α for the acidic hydrolysis of RP in the presence of CTAB correspond to 1.36×10^4 mol^{-1} dm^3, 1.32×10^{-5} mol dm^{-3} and 99.27%, respectively. Since the effect on the reaction rate is very small, no quantitative analysis was carried out for the catalysis observed in the presence of SDS.

Recently, Piszkiewicz[25] has proposed a different kinetic scheme based on the observed sigmoidal dependence of rate constant on surfactant concentration. According to his model (Scheme 4) a substrate molecule combines with n detergent molecules to form a catalytic aggregate.

$$S + nD \underset{}{\overset{K_D}{\rightleftharpoons}} S\cdot D_n$$

$k_w \downarrow$ Products $k_m \downarrow$ Products

Scheme 4.

Mathematical formulation based on this scheme gives

$$\log\left(\frac{k_\psi - k_w}{k_m - k_\psi}\right) = n \log [D] - \log K_D, \quad (10)$$

which predicts a linear relationship between $\log (k_\psi - k_w)/(k_m - k_\psi)$ and $\log [D]$ with a slope equal to n. In this equation [D] is the total detergent concentration, K_D the dissociation constant of surfactant-substrate complex and n the index of cooperativity. This equation gives a set of parameters which have a different significance from that obtained from Menger and Portnoy's scheme,[24] *e.g.* at $\log (k_\psi - k_w)/(k_m - k_\psi) = 0$, $n \log [D] = \log K_D$. Also at $\log (k_\psi - k_w)/(k_m - k_\psi) = 0$, catalysis by the surfactant shows one-half of its maximum effect, the value of log [D] at this concentration being designated by $\log [D]_{50}$. Another parameter which can be used to compare the effect of micelles is the index of cooperativity '*n*'. Double log plot for the hydrolysis of RP in presence of CTAB is shown in Fig. 6. For the CTAB inhibited reaction, when k_m is assumed to be zero, the values of $\log [D]_{50}$ and *n* obtained from the plot correspond to −4.0 and 2.66 respectively.

Successful application of both the kinetic schemes to the hydrolysis of RP in the acid medium is not surprising. Though the two schemes are based on different assumptions, the final mathematical equations based on them are similar (Eqs. 7 and 10). However, the kinetic parameters associated with these equations have quite different significance. Piszkiewicz's model draws its strength from a model used for enzyme catalysed reactions showing positive homotropic interaction (also called positive cooperativity). Positive cooperativity is reflected in the value of *n*, the index of cooperativity. In the micellar systems, the value of *n* reflects the average number of surfactant molecules associated with each substrate molecule. Another useful parameter which we obtained by the application of Piszkiewicz's model is $\log [D]_{50}$, the concentration of surfactant where it shows half of its maximum effect. On the other hand the scheme of Menger and Portnoy[24] is based on the distribution of substrate into micellar and aqueous pseudophases and has been extensively applied to micelle catalysed and micelle inhibited reactions. It puts more emphasis on the interaction between the substrate and micellar aggregation, whereas Piszkiewicz's model gives prominence to interaction between substrate and surfactant molecule. Hence the simultaneous application of both models provides a better insight and understanding of micellar effects on the reaction rate.

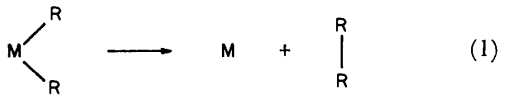
(Received August 30, 1980)

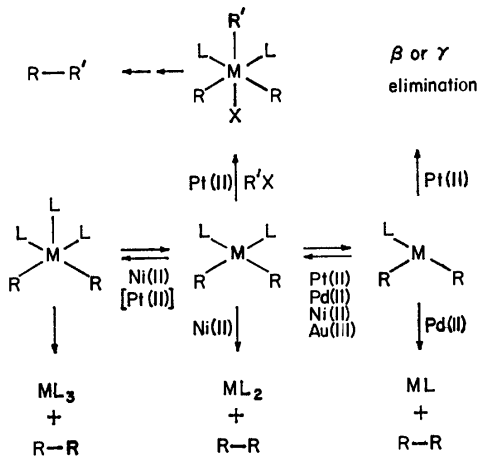
A theoretical analysis of two aspects of the mechanism of reductive elimination is presented—how the choice of central metal and peripheral ligands affects the activation energy for reductive elimination from a four-coordinate $MR_2(PR_3)_2$ complex and how ligand asymmetry controls *cis-trans* rearrangements and elimination pathways proceeding through three-coordinate intermediates. The following conclusions emerge: (1) In the four-coordinate complex, the better the σ-donating capability of the leaving groups, the more facile the elimination; (2) Stronger donor ligands *trans* to the leaving groups will increase the barrier to elimination; (3) The reductive elimination barrier in four-coordinate complexes is controlled by the energy of an antisymmetric b_2 orbital, which in turn depends on the energy of the metal levels. The activation energy for such direct reductive elimination should be, and is, substantially lower for Ni than for Pt or Pd; (4) T-shaped *trans* $PdLR_2$, arising from dissociation of L in PdL_2R_2, will encounter a substantial barrier to polytopal rearrangement to *cis* $PdLR_2$, which in turn has an open channel for reductive elimination of R_2; (5) If the leaving groups are poor donors, *cis-trans* isomerization in the three-coordinate manifold should be easier than elimination.

The coupling of two alkyl moieties into an alkane, *e.g.* (1), is a reaction efficiently accomplished by a number of d^8 transition metal centers—Ni(II), Pd(II),



(1)

Pt(II), Au(III). But the simple form of the summary equation (1) for this process masks a multitude of mechanistic choices. Let us examine some of the possibilities in Scheme 1.

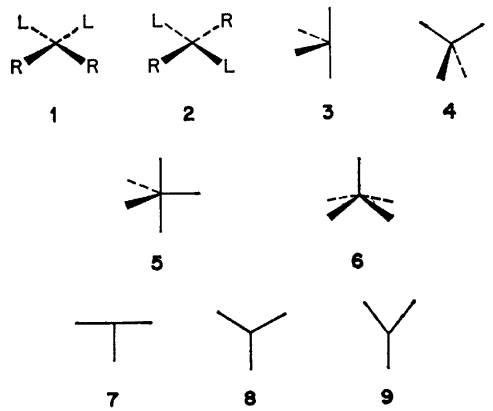


Scheme 1.

The most common starting point for these reactions is a preformed square-planar 16 electron, d^8 dialkyl (or tri-or tetraalkyl for Au(III)) complex which appears in the middle of the Scheme. The two other ligands, marked L, are typically phosphines. Depending on the size and electronic characteristics of the phosphine substituents one may observe associative or dissociative steps away from the four-coordinate complex. Both elementary processes have been clearly demonstrated in the Grubbs system, where M=Ni(II) and R_2 is a tetramethylene bridge.[1,2] Evidence is in fact in hand for the dissociative step in most such reactions.

The four-coordinate complex eliminates R–R cleanly and easily in the Ni(II) case only. For Pd(II) the work of the Yamamoto[3] and Stille[4] groups and for Au(III) of the Kochi group[5] has produced kinetic evidence for elimination from a three-coordinate intermediate. Pt(II) apparently does not eliminate R–R readily.[6] The Whitesides group[6a] has demonstrated β or γ elimination (where feasible) through a three-coordinate intermediate, while Puddephatt and coworkers[7] have found elimination reactions, but only after oxidative addition of an RX.

No stereochemical implications were meant to be drawn from Scheme 1. In fact the mechanistic possibilities are enriched by the range of equilibrium geometries and polytopal rearrangements available to the various intermediates. Some of the geometrical extremes are drawn in **1**—**9**. For the square-planar



geometry one has available the *cis* and *trans* isomers **1** and **2**, and indeed the mechanism of elimination from either starting point has been studied. Some recent theoretical work[8] on the Grubbs system has focussed on another possible low-spin intermediate—the C_{2v} *cis*-octahedral fragment **3**. And at least for Ni(II) one has to worry about the tetrahedral, presumably high-spin,

alternative **4**. Even more geometrical isomers are available for a five-coordinate structure—here we remind ourselves only of the underlying geometries, the trigonal bipyramid **5** and the aquare pyramid **6**. For the three-coordinate geometry the idealized trigonal D_{3h} geometry **8** might seem to be the geometry of choice. But for reasons that are well understood,[5b] this most symmetrical structure is unlikely, and instead we must examine "T" and "Y"-shaped C_{2v} deformations, **7** and **9**. Mind you, these are only idealized geometrical extremes—the real molecules will certainly depart, to a variable degree, from these structures.

Our goal is a comprehensive theoretical understanding of this reaction type. Theoretical analyses of reductive elimination exist—the early and important work of Pearson[9] and of Braterman and Cross,[10] the more comprehensive and detailed approach of Åkermark and coworkers[11]—to mention some of the studies of this reaction. We ourselves have contributed an analysis of competitive elimination from three- and four-coordinate alternatives in the Au(III) system,[5b] and in work to be published still have investigated the nickellacyclopentane fragmenations.[8] All of these studies, those of others and ours as well, encounter one fundamental problem: *The reductive elimination is symmetry-allowed for many (not all) polytopal geometries of the three-, four-, and five-coordinate structures of Scheme 1. Why then does one metal choose one route, while a second metal opts for another?* We will try to give a partial answer to this question in this paper. We will also show how the electronic asymmetry of the ligand set controls the detailed mode of alkane elimination.

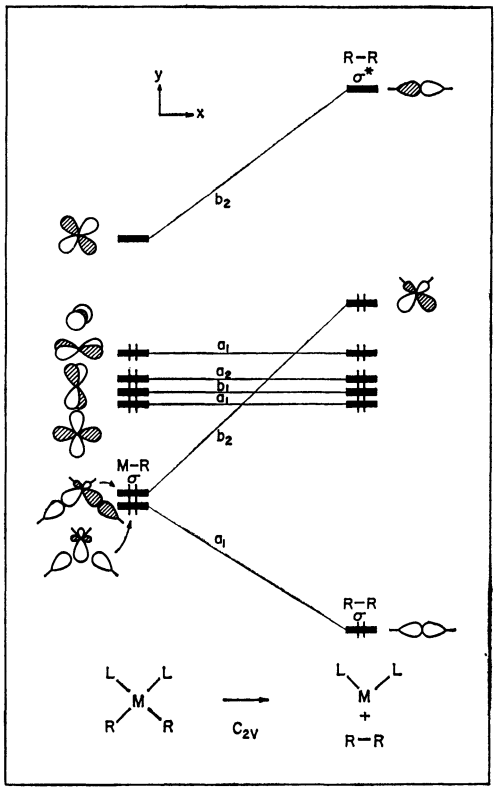


Fig. 1. Schematic correlation diagram for the elimination of R–R from a square-planar d^8 transition metal complex ML_2R_2. The reaction pathway maintains C_{2v} symmetry.

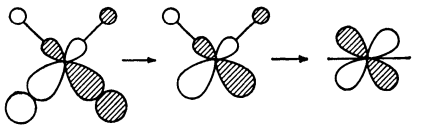
Reductive Elimination from *cis* Four-coordinate Complexes

The basic reaction, *cis* d^8 L_2MR_2 to d^{10} L_2M and R_2, is symmetry-allowed for a least motion C_{2v} departure.[8-11] A schematic correlation diagram to a bent ML_2 (the adjustment in making ML_2 linear is minor) is shown in Fig. 1. As usual these correlation diagrams abstract reality by proceeding from a semi-localized starting point in which only orbitals essential to the reaction are included.[12] Thus in the present case the orbitals in the diagram for L_2MR_2 are the five d-block orbitals of the metal and the two σ orbitals of the MR_2 unit. For ML_2+R_2 we have the R_2 σ and σ^* levels and the five metal d orbitals. The reality must be that these orbitals are not so simple and substantial mixing between the orbitals illustrated, as well as with others, not included in the figure, must occur. The purpose of these diagrams is to decide whether a level crossing does or does not occur—the actual details of the levels we will learn from a full calculation.

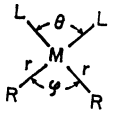
There is nevertheless one general feature of this allowed reaction that is evident from the figure and that we will return to later. This is the required evolution of one MR_2 bonding orbital, b_2 in symmetry,[13] into a primarily metal d orbital of the same symmetry, *i.e.* xy in a linear ML_2. This is indicated in **10**→**11**. Note



10 **11**

the loss of M–R bonding and electron transfer to the metal implied by this correlation. These will be important.

Our detailed analysis of the elimination reaction was carried out by means of extended Hückel calculations, with parameters specified in Appendix I. In several cases three degrees of freedom were studied, as illustrated in **12**: the angle between the leaving groups, φ; the separa-



12

tion from the metal to these leaving R's, r; and the angle between the remaining. ligands, θ. As in our previous study of the Au(III) system[5b] we found that the essential features of the elimination were revealed in angular variations alone, *i.e.* changes of θ and φ at constant M–R separation. This is just as well, for the extended Hückel method is not good at representing correctly degrees of freedom in which distances are varied.

The ligands of course play a vital role in determining the feasibility of any reductive elimination. We carried out calculations with PH_3 and CH_3 ligands. These

led us to focus on the σ donor or acceptor strength of the ligands. Our interpretation was easiest made on a still simpler "hydride model." Here the ligands were simply hydrogen 1s functions with modified valence state ionization potentials. We called the two extremes A and D. A and D are hydrogen atoms, the 1s orbital energies of which are set to be -14.34 and -11.75 eV, respectively. The value -14.34 eV is the calculated orbital energy of a lone pair in PH_3 and -11.75 eV corresponds to that of a lone pair in CH_3^-. Thus A^- may be a model for PH_3 and D^- for CH_3^-. Or one can regard A as a poor donor ligand and D as a strong donor ligand.

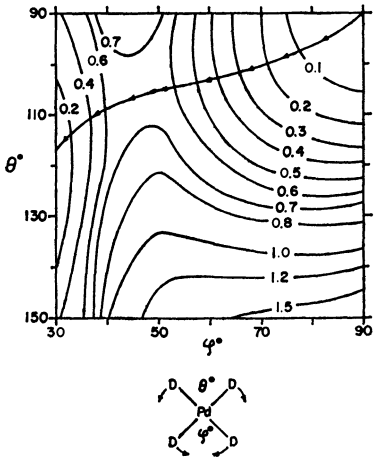


Fig. 2. Potential energy surface for variation of the two D–Pd–D angles, θ and φ, in planar PdD_4^{2-}. The energy contours are in electron volts relative to the square-planar geometry ($\theta=\varphi=90°$). A line with arrows indicates a reaction path corresponding to the elimination of D_2 from PdD_4^{2-}.

A potential energy surface in θ and φ for the elimination of D_2 from PdD_4^{2-} is illustrated in Fig. 2. The reaction path is shown by a line with arrows. In general the surface is quite analogous to that computed earlier by us for $Au(CH_3)_4^-$ [5b] $-\theta$ lags somewhat behind φ. Corresponding energy surfaces for the departure of A_2 and D_2 from PdA_2D_2 are illustrated in Fig. 3.

As these surfaces show, the reactions of these model compounds have a saddle point at around $\theta=100$—$110°$, $\varphi=40$—$50°$. When the two leaving ligands are gradually removed (r increased) at the point $\theta=110°$ $\varphi=30°$, no additional energy barrier was found. Thus each potential surface represents sufficiently well the reductive elimination reaction of a corresponding compound. The calculated activation energies for PdD_4^{2-}, $PdD_2A_2^{2-}$ (A leaving), and $PdA_2D_2^{2-}$ (D leaving) are 0.65, 2.7 (A_2 leaving), and 0.20 eV (D_2 leaving), respectively. We should not rely on these numbers in a quantitative sense, partly because we used the very simplified hypothetical hydride model (we will discuss this later), and partly because the calculational method is rather primitive. However the observed trends are quite suggestive. Here are two conclusions: (1) *The better the σ-donating capability of the leaving groups, the more readily the elimination reaction proceeds.* (2) *Stronger donor ligands which are* trans *to the leaving groups give a higher barrier for the elimination reaction.*

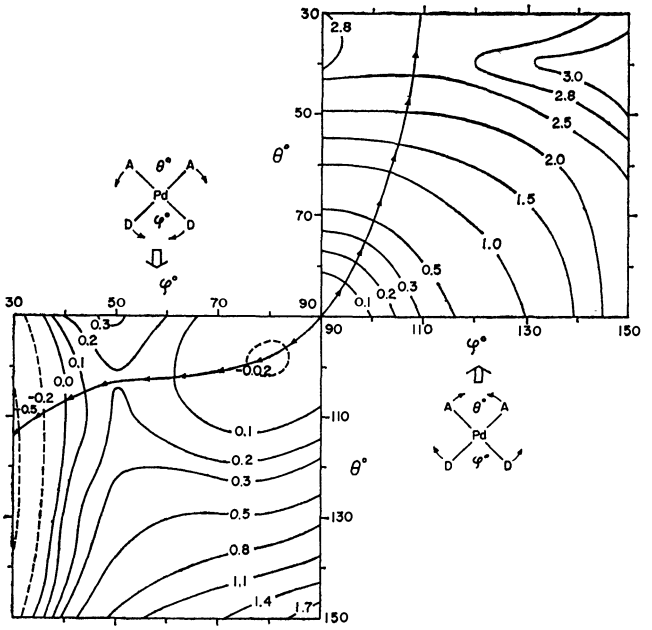

Fig. 3. Potential energy surface for variation of the two angles, θ (A–Pd–A) and φ (D–Pd–D), in planar $Pd-D_2A_2^{2-}$. The energy contours are in electron volts relative to the square-planar geometry ($\theta=\varphi=90°$). A line with arrows corresponds to reaction paths for D_2 elimination, lower left, and A_2 elimination, upper right.

The potential energy surface for $NiA_2D_2^{2-}$ is shown in Fig. 4, in which the leaving groups are the stronger donors D. Although this model compound is just the Ni analogue of $PdA_2D_2^{2-}$, the calculated potential surface of $NiA_2D_2^{2-}$ is quite different from that of $PdA_2D_2^{2-}$. While the elimination reaction of $PdA_2D_2^{2-}$ has a small but obvious energy barrier along the reaction coordinate, the reaction pathway of the Ni analogue is

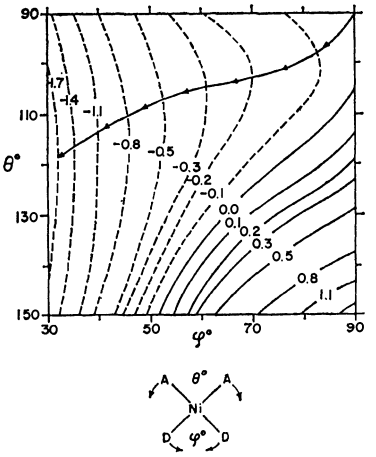

Fig. 4. Potential energy surface for variation of the two angles, θ(A–Ni–A) and φ(D–Ni–D), in planar $NiA_2-D_2^{2-}$. The energy values on the contours are in electron volts relative to the square-planar geometry ($\theta=\varphi=90°$). A line with arrows indicates a reaction path for D_2 elimination from $NiA_2D_2^{2}$.

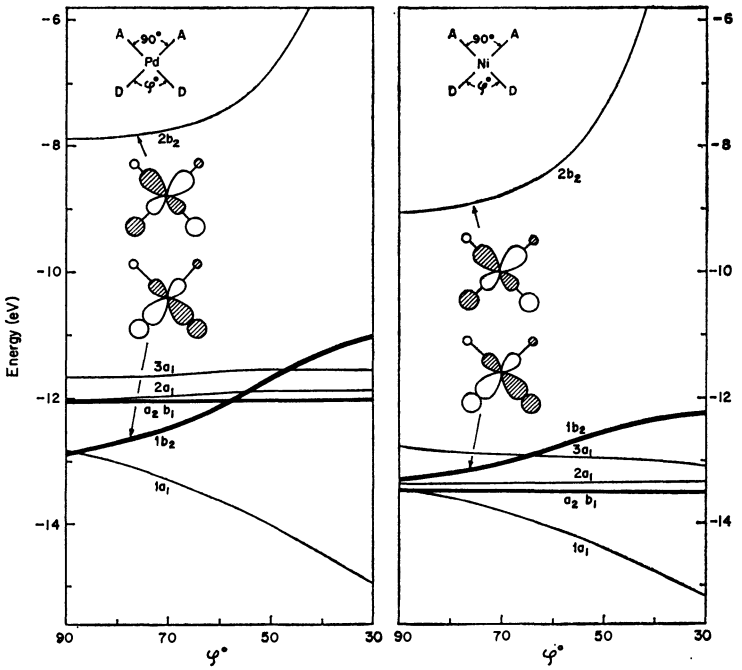

Fig. 5. Computed Walsh diagrams for $PdA_2D_2^{2-}$(left) and $NiA_2D_2^{2-}$(right), for decrease of the D–M–D angle φ. The A–M–A angle is kept at 90°. The $2b_2$ orbital is vacant.

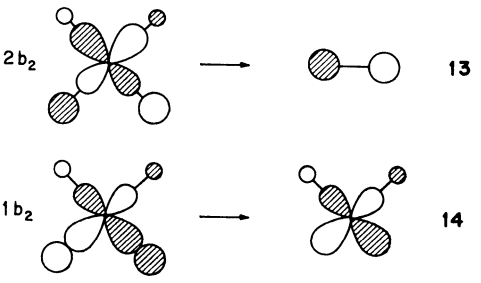
merely downhill in energy and has no barrier.

Why is there such a different pattern for $PdA_2D_2^{2-}$ and $NiA_2D_2^{2-}$? The answer must lie, ultimately, in the Pd 4d *vs.* Ni 3d orbital energies. The effect is traced through Fig. 5, a set of Walsh diagrams. Each of the diagrams shows the variation of the important molecular orbital levels as a function of D–M–D (M=Pd or Ni) angle φ (90—30°), while A–M–A angle is kept at 90°. There are seven levels shown in Fig. 5. To make the correspondence to the schematic correlation diagram of Fig. 1 we can say that five of these seven levels are the d-block orbitals and two are M–D bonding orbitals. The reality is not so simple—there is extensive delocalization in some of the symmetry types. a_2 and b_1 are simple, pure metal yz and xz, unaffected by the elimination. $2a_1$ and $3a_1$ contain substantial d character, z^2 and x^2-y^2. But in fact they are part of a trio of a_1 orbitals which includes $1a_1$. We can think of these orbitals as derived from localized z^2, x^2-y^2 and the a_1 M–D σ bond combination. As the angle φ closes, one of the three a_1's goes down in energy and ends up as the σ bonding MO of D_2. Obviously the main stabilization which drives the elimination reaction is in these a_1 orbitals. However, the contribution to the total energy change of the three a_1 orbitals is quite similar in the Pd and Ni compounds. Thus the a_1 set does not differentiate between the two metals.

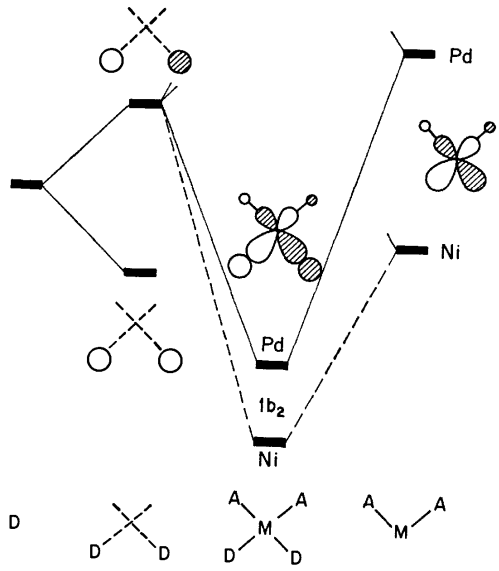
There are two b_2 orbitals in Fig. 5. We can think of them as bonding and antibonding M–D, A σ combinations, alternatively the higher orbital of the two could be thought of as that metal orbital, xy, which is destabilized by the square planar ligand field. Decreasing φ destabilizes both $1b_2$ and $2b_2$. The unoccupied $2b_2$ correlates to the eliminated D_2 σ^* level **13**, while the occupied $1b_2$ correlates to an MA_2 orbital which is nearly pure xy, **14**. The latter correlation was the one alluded to earlier, **10**→**11**.[14]



There is no level crossing for elimination of D_2 in either the Pd or the Ni case, confirming the simplified analysis of Fig. 1. The contrast between the potential energy surfaces for the two metals (Figs. 3 and 4) arises from the difference in slope of the $1b_2$ orbitals. As φ decreases $1b_2$ of $PdA_2D_2^{2-}$ is singificantly more pushed up than that of $NiA_2D_2^{2-}$, producing an energy barrier in the elimination of D_2 from the Pd compound.

The differential $1b_2$ destabilization may arise from two causes—decreasing M–D bonding and increasing D–D antibonding. Either way, it would be anticipated that if the D 1s orbital component in $1b_2$ is large, the destabilization of $1b_2$ will also be large. Indeed the calculated D 1s orbital contribution in $1b_2$ is 54% for Pd and 38% for Ni at $\varphi=90°$, which accords with the larger destabilization of the Pd $1b_2$ level.

There is another way of analyzing this effect. The $1b_2$ orbital of MA_2D_2 is constructed in **15** from the antisymmetric D_2 combinations interacting with a bent MA_2 fragment. This interaction carries in it a substantial fraction of the M–D bond energy. Since the resulting



15

$1b_2$ level of $MA_2D_2^{2-}$ correlates to the b_2 of MA_2 in the D_2 elimination step, a greater energy difference between the $MA_2D_2^{2-}$ b_2 level and the MA_2^{2-} b_2 level would be associated with a greater activation energy for the reaction. The computed energy differences of the b_2 level are 2.1 eV for Pd and 1.3 eV for Ni. This is exactly what would be required to explain the different energy pattern of the Pd and Ni eliminations.

We have assigned the effect of the b_2 levels, but in fact it can be traced deeper. The b_2 level in the MA_2^{2-} fragment left behind is mainly a metal d orbital. It is higher for Pd than for Ni because the Pd and Ni d parameters are in that order. To probe this explanation we performed a numerical experiment in which D_2 was eliminated from a $MA_2D_2^{2-}$, where the M carried the Pd orbitals but with a variable 4d valence state ionization potential. The results shown on Fig. 6 clearly illustrate the dependence of the activation barrier on the metal d energy.

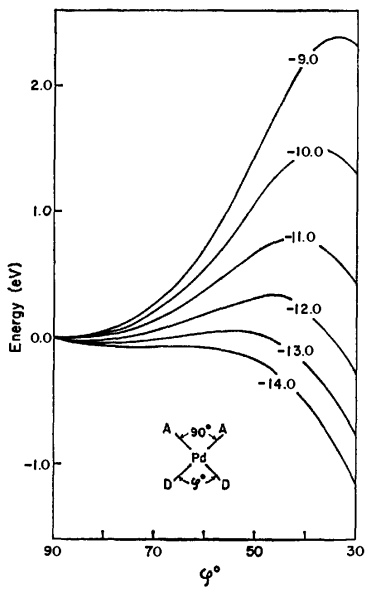


Fig. 6. The total energy of the hypothetical palladium complex $PdA_2D_2^{2-}$ as a function of the D–Pd–D angle φ. Potential curves for various choices of the "Pd" 4d ionization potential are superimposed, so that all curves are referred to an arbitrary zero of energy at $\varphi=90°$.

There is a temptation here to correlate the M–D bond strength, formed in part by this b_2 interaction, with increased activation energy to reductive elimination. Some thought about the matter, with the help of diagram **15**, shows that the relationship is not so simple. When the A_2M orbital is higher in energy than the antisymmetric combination of D orbitals, a more destabilized MA_2 b_2 would lead to a weaker M–D bond, while at the same time it would give a larger energy gap between b_2 levels of MA_2 and $MA_2D_2^{2-}$. The numerical experiment, varying M H_{ii}, that we described above, is useful in testing this supposition. Figure 7 shows how the Pd–D overlap population does not increase monotonically with higher Pd 4d energy, but peaks at the position of resonance with the D_2 antisymmetric combination. Thus, the energy gap is not always an index of the thermodynamic stability of an M–D bond, but it can be an index of the "kinetic" stability of $MA_2D_2^{2-}$ to reductive elimination.

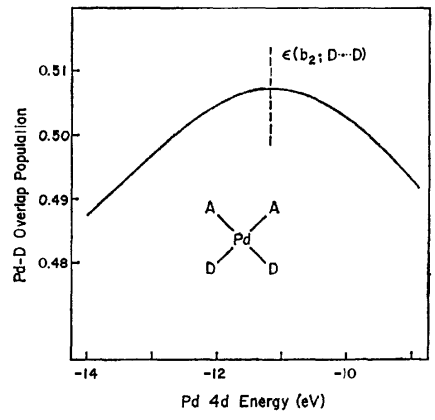

Fig. 7. Pd–D overlap population in the hypothetical palladium complex $PdA_2D_2^{2-}$ as a function of the valence state ionization potential of the Pd 4d level.

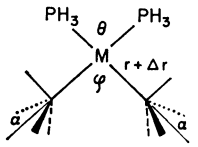
Our third conclusion: A lower positioning of the MA_2 b_2 orbital facilitates the reductive elimination of D_2. A lower MA_2 b_2 energy will be given by a lower metal d orbital energy.

While our major focus was the difference between Ni and Pd, we have also studied, albeit in abbreviated form, the Pt case. A model $PtA_2D_2^{2-}$ elimination surface gives a barrier slightly higher than in the Pd case. The Pt 5d parameters place it between Ni and Pd, but closer to Pd. The b_2 orbital is 50% on the D_2 ligands at $\varphi=90°$, a value again close to that computed for Pd. These theoretical findings are in accord with the experimental observation of difficult reductive elimination from Pt complexes.

Our next objective was to move from the model MA_2D_2 structures to more realistic models. To this end we examine reductive elimination of ethane from $Pd(PH_3)_2(CH_3)_2$, $Pd(CH_3)_4^{2-}$, and $Ni(PH_3)_2(CH_3)_2$. The essence of our orbital symmetry considerations for the hydride model system should and does carry over to those more complicated systems. Then our interest

lies in a rough theoretical estimate of the activation energies. In describing the elimination of ethane, we must consider the elongation of the Pd–C distance and the rocking motion of the methyl groups in addition to the variation of C–Pd–C angle φ and P–Pd–P angle θ. Full geometry optimization was beyond our means, so we constructed two hypothetical reation coordinates. In the first path, the P–M–P angle θ (see **16**) is fixed



16

at 90°, while the C–Pd–C angle φ and the rocking angle α between the local three fold axis of the methyl group and the Pd–C bond extension were varied simultaneously (90—30° for φ, 0—60° for α). At the same time the Pd–C distance was stretched by Δr. The second reaction coordinate allowed θ to open from 90° to 150° while the above mentioned geometrical variations took place. We present the results for the second reaction path, the one which allows the $M(PH_3)_2$ remnant more freedom, in Fig. 8. The first reaction path differs only in destabilization of the product side.

It is clear from Fig. 8 that the calulated activation energies for ethane elimination are in the order $Pd(CH_3)_4^{2-}$>$Pd(PH_3)_2(CH_3)_2$>$Ni(PH_3)_2(CH_3)_2$. This trend accords with our previous conclusions (2) and (3) based on the hydride model calculations. Estimated activation energies (second, more complete reaction coordinate) are around 2.9, 1.7, and 0.6 eV for $Pd(CH_3)_4^{2-}$, $Pd(PH_3)_2(CH_3)_2$, and $Ni(PH_3)_2(CH_3)_2$ respectively. These numbers are all larger than the computed activation energies of the corresponding hydride models, PdD_4^{2-}, $PdD_2A_2^{2-}$, and $PdA_2D_2^{2-}$, probably because of the bulk of the CH_3 groups and/or Pd–CH_3 bond weakening necessitated by the rocking motion.

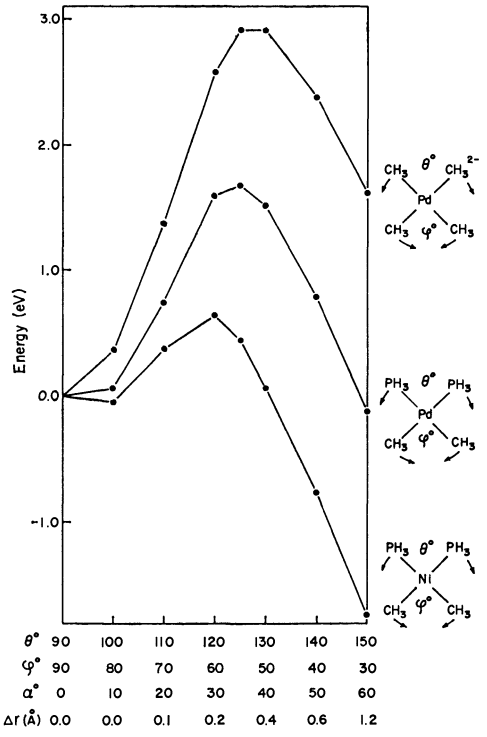


Fig. 8. Total energy changes along the hypothetical reaction path for elimination of ethane from $Pd(CH_3)_4^{2-}$, $Pd(PH_3)_2(CH_3)_2$, and $Ni(PH_3)_2(CH_3)_2$. In the reaction path the three angles and the M–C (of a leaving CH_3) distance, which are defined in **16**, are varied simultaneously. The reaction path is defined by the values or θ, φ, α, and r given at the bottom.

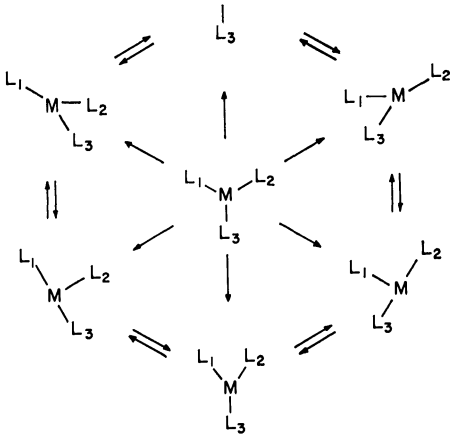
We have investigated briefly the possibility of direct elimination of R_2 from a *trans*-PdR_2L_2 system through a quasi-tetrahedral transition state. The energy required to achieve such a geometry is very high, and we think this reaction mode is unlikely, at least for Pd(II) or Pt(II).

Whether a given four-coordinate complex in Scheme 1 eliminates R_2 or chooses another path, possibly ligand dissociation, depends on the relative activation energies of the various processes. Unfortunately extended Hückel calculations are not reliable for such a comparison. Nevertheless we believe that our calculations on model compounds provide a theoretical framework for understanding why the Ni complexes eliminate alkanes from the four-coordinate geometry, whereas their Pd (and Pt) analogues do different things.

Reductive Elimination from Three-coordinate Complexes.

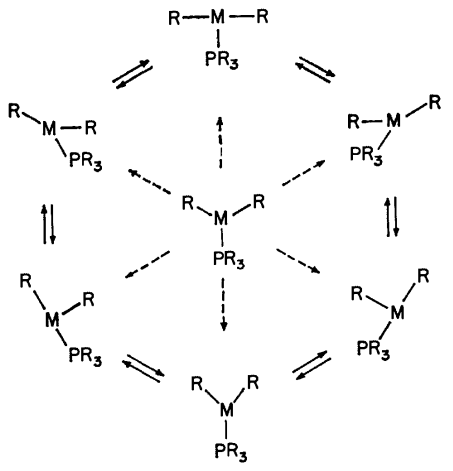
Kinetic studies of *cis* Pd(II)[4,3] dimethyls and Au(III) trimethyls[5] indicate that elimination is preceded by a dissociative step. The resulting MLR_2 intermediate is a representative of the intriguing d^8 ML_3 class of complexes. The geometrically attractive trigonal planar structure (**7**) for these molecules turns out to be Jahn-Teller unstable in the low-spin configuration. Distortions to T or Y shaped structures (**8** or **9**) ensue. The structure of the potential energy surface is summarized in **17**.[5b] Both T and Y shaped structures should be more stable than the trigonal geometry, but which alternative is the absolute minimum cannot be easily predicted. Whichever conformation is preferred, interconversion



17

of isomeric C_{2v} equilibrium structures (if the ligands differ) is most unlikely to occur through the D_{3h} hill in the middle, but may proceed easily by sweeping through less symmetrical C_s waypoints along the periphery of the Jahn-Teller wheel. Direct structural evidence for deformation of d^8 ML_3 complexes is hard to come by because of the coordinative unsaturation of such 14 electron complexes. If ligand steric bulk is used to stabilize such complexes, one has to worry that the very same ligand property will also perturb the equilibrium geometry from its idealized form. One case where one can see a clear T deformation is for $Rh(PPh_3)_3^+$.[15]

What if the ligand set is substantially asymmetric, as in the $Pd(CH_3)_2(PR_3)_2$ decompositions studied by the Stille and Yamamoto groups? If phosphine dissociation occurs we are led to a three coordinate PdR_2PR_3 complex. The ligand isomerization scheme **17** simplifies to **18**. By symmetry the right-hand side of **18** is identical to the left. We will soon present a detailed analysis of this polytopal surface. For the moment let us assume that the scheme summarizes the experimental possibilities and see how it fits the available experimental data.



18

Least-motion departure of a phosphine from *cis* $Pd(CH_3)_2(PR_3)_2$ brings one into a T-shaped entry point in **18**, at 4 o'clock. It is easy to imagine a minor rearrangement to the Y-shapped conformer at 6 o'clock. This geometry is an obvious exit channel for elimination of R_2. Alternatively elimination could proceed directly from the T-shaped entry point.

Now consider the *trans* isomer of $Pd(CH_3)_2(PR_3)_2$. Departure of a phosphine leads one into **18** at 12 o'clock. Elimination from there is most unlikely. If the general features of the ML_3 surface were preserved one would nevertheless expect an easy transit around the Jahn-Teller wheel to 6 o'clock, the ethane exit channel. Apparently this does *not* happen. *trans* Dialkyl Pd complexes appear to be quite stable to simple reductive elimination, and instead often undergo β-elimination where that process is possible. Where reductive elimination occurs it is preceded by isomerization to the *cis* form, assisted either by polar, coordinating solvents,[4]

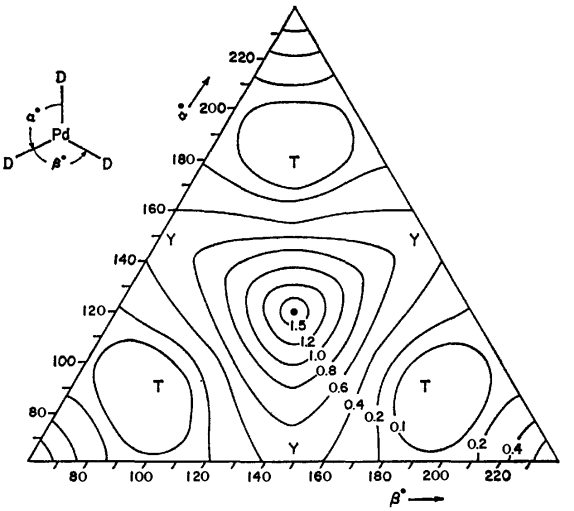


Fig. 9. Potential energy surface calculated for PdD_3^- varying the two D–Pd–D angles α and β. The energies of the contours are in electron volts relative to the T shape.

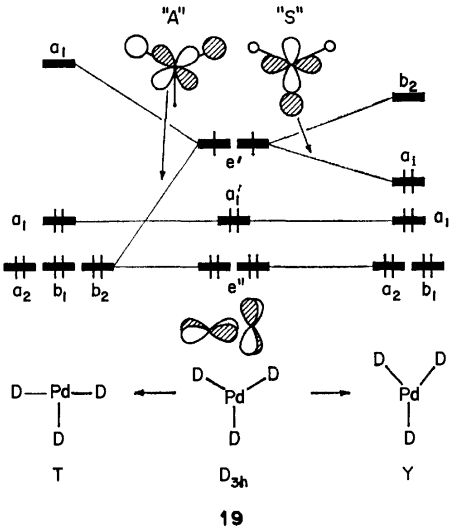
or by addition of the *cis* isomer, in an autocatalytic process.[3] Obviously the simple picture of unrestricted motion around the rim of **18** needs modification. We decided to investigate the effect of ligand electronic asymmetry on polytopal rearrangements in the three-coordinate manifold.

Again we first employ the hydride model, as we did for the four-coordinate complexes. Thus the d^8 molecules studied were PdD_3^-, $PdDA_2^-$, and $PdAD_2^-$. The characteristic features of the Jahn-Teller surface that we first delineated for $Au(CH_3)_3$ are preserved in the PdD_3^- surface (Fig. 9). A high hill of D_{3h} geometry is in the center surrounded by three descending ridges of Y-shaped geometry. Each of three equivalent T-shaped minima is in a round valley between the two ridges and has two open channels leading to reductive elimination. The activation energy for the elimination is about 0.1 eV, while the energy barrier for isomerization from one T-shape to another amounts to 0.4 eV.

The topology of the potential surface is explained by orbital diagram **19**. The half-filled e′ level immediate-



19

ly shows the Jahn-Teller instability of the D_{3h} geometry. When PdD_3^- is distorted to a T-shape, one of the e′ components, "A", is stabilized by decreasing Pd–D antibonding interaction and eventually becomes a pure Pd d orbital. On the other hand, the distortion to a Y-shape stabilizes another component, "S" of e′. But it is not by so much, because some Pd–D antibonding character still remains in the "S" component in the Y geometry. This is why the T-shape is more stable than the Y.

Potential surfaces for $PdAD_2^-$ and $PdDA_2^-$ are shown in Fig. 10. $PdAD_2^-$ will be a model for Pd-$(PR_3)(CH_3)_2$. In spite of the reduced symmetry, these surfaces maintain the basic electronic properties of the more symmetric PdD_3^-. The trigonal geometry is on a hill, and two kinds of approximate T-shapes are local minima.

Let us try to understand the relative stability of the T and Y shapes in these less symmetrical systems. We know from **19** that T is basically more stable than Y.

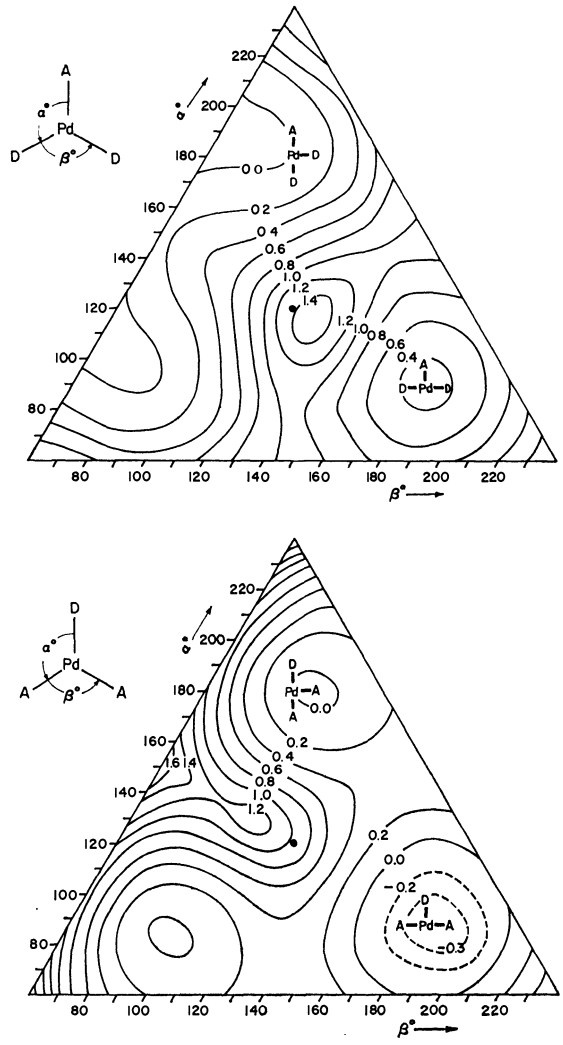


Fig. 10. Potential energy surfaces calculated for Pd-AD_2^-(top) and $PdDA_2^-$ (bottom), varying the two angles α(A–Pd–D) and β(D–Pd–D or A–Pd–A). The energies of the contours are in electron volts relative to the T shape in which one wing is occupied by D and another wing by A.

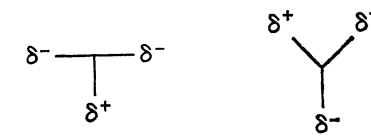
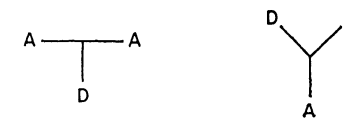
What is required is a procedure for evaluating substituent site preferences in T and Y. In the T form the occupied e′ component is "A" (see **19**) which has some ligand contribution on the wings of the T and so produces the charge distribution **20**. In the Y shape "S" is occupied, and that forces the charge imbalance shown in **21**. This is all relative to the trigonal form, where one can think of both orbitals equally occupied, by symmetry the same electron density on all ligands.



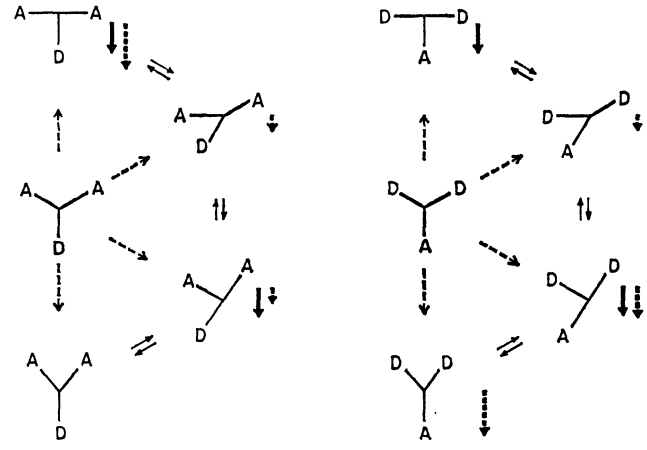
20 **21**

Now we reason that more *electronegative* substituents (poorer σ donors, better σ acceptors) will preferentially go where there is an excess of electron density.[16] The optimum substitution patterns that follow are presented in **22** and **23**. We can now summarize our qualitative



22 **23**

expectations for the relative stabilities of the asymmetric T and Y shapes, in Scheme 2. Beside some of the structures we place one or more arrows. Each indicates a stabilization, a solid arrow for the inherent greater stability of the T, a dashed arrow for fulfilling to a variable extent, the desired substitution pattern summarized in **22** or **23**. There is good qualitative agreement between Scheme 2 and the computed surfaces of Fig. 10.



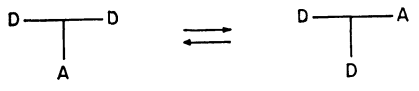
Scheme 2.

The triangular potential energy surfaces of Fig. 10 contain a great deal of interesting information. First note that reductive elimination of D_2 from **24** is just downhill in energy, while steep and high energy barriers

24 **25**

block the elimination of A_2 from **25**. The same trend was observed in reductive elimination from the four-coordinate system (conclusion (1))—*i.e.* a stronger σ-donor is a better leaving group. The similarity between the three- and four-coordinate systems can be traced in some detail, but the argument will not be presented here.

Another interesting consequence of the electronic asymmetry of A and D ligands to be seen from Fig. 10 is the creation of substantial energy barriers to a transit around the Jahn-Teller wheel. The activation energy for going from *trans*-$PdAD_2^-$ **26** to *cis*-$PdAD_2^-$, **27**, is



26 **27**

0.75 eV, and that for the reverse isomerization is 1.1 eV. Corresponding activation energies for $PdDA_2^-$ are 0.6 and 0.3 eV. Thus conclusion (4): *T-shaped* trans-$PdLR_2$, *which might be produced by liberating L from* trans-PdL_2R_2, *will encounter a substantial energy barrier to rearrangement of* cis-$PdLR_2$, *which has an open channel for reductive elimination of* R_2; *and* (5): *When the leaving groups are poor donors, A,* cis-trans *isomerization between two T-shaped geometries should be much easier than elimination of* A_2. *If R is a strong* σ *donor and L is a poor donor or an acceptor then the rearrangement from the* trans-*derived three-coordinate structure to the* cis-*derived one (motion from 12 o'clock to 4 in* ***18****) will not be facile.*

These are model calculations. They were supported by detailed examination of a surface for valence tautomerism in $Pd(PH_3)(CH_3)_2$, Fig. 11. P–Pd–C angles α and C–Pd–C angle β are varied. Note the presence of three T-shaped minima, and an activation energy of 0.5 eV for the *trans*→*cis* $Pd(PH_3)(CH_3)_2$ isomerization and 0.8 eV for the reverse reaction.[23] A hypothetical reaction coordinate for ethane elimination from T- and Y-shaped conformations was also studied, modelled after the first reaction coordinate of the four-coordinate complex, discussed above. The results of such a calculation are shown in Fig. 12. As one might have guessed from the surfaces in which only angles are varied, the elimination need not proceed directly from a Y-shaped locus. Instead one can start out from a T-geometry and pay no greater price in activation energy. The computed activation energy to ethane formation along this highly simplified reaction path is 1.1 eV. The general features of this $Pd(PH_3)(CH_3)_2$ calculation are in accord with the conclusions we reached on the hydride models.

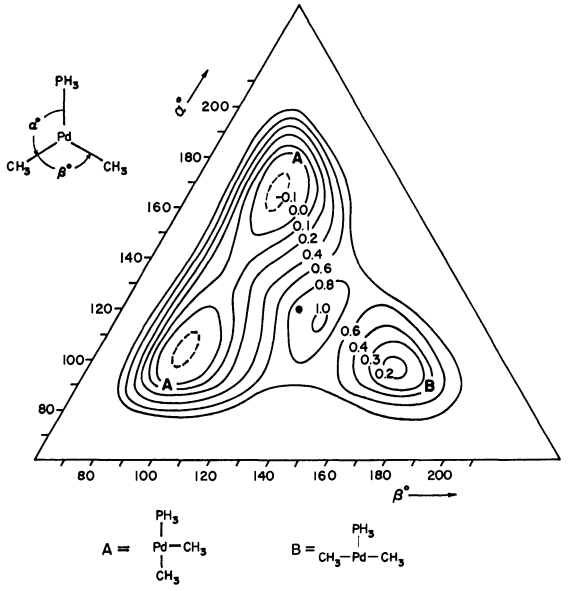


Fig. 11. Potential energy surface calculated for $Pd(PH_3)(CH_3)_2$ varying the two angles α(P–Pd–C) and β(C–Pd–C). The energies of the contours are in electron volts relative to the T shape defined by A below the triangle.

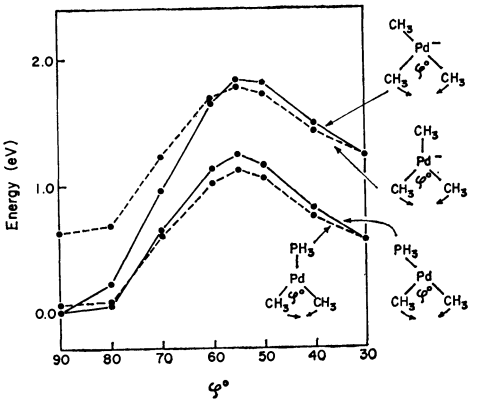

Fig. 12. Total energy changes along the hypothetical reaction path for the elimination of ethane from $Pd(CH_3)_3^-$ and $Pd(PH_3)(CH_3)_2$. The reaction path is the same one as that defined in Fig. 8, except that the angle θ is not included here. The solid lines are for the elimination reaction from the T shape while the dashed lines are for that from the Y shape.

Please return to Scheme 1, the starting point of our analysis. We have tried to elucidate but two aspects of the mechanism of reductive elimination—1. how changing the metal or the electronic properties of the ligands affects the activation energy for reductive elimination directly from the four-coordinate complex and 2. how ligand electronic asymmetry controls polytopal rearrangements, and thereby *cis-trans* isomerization and elimination, in the three-coordinate manifold. So much more remains to be understood.

We are grateful to J. Jorgensen for the drawings, to E. Stolz for the typing to the National Science Foundation for its support of this work through Research Grant CHE 7828048, and to the Exxon Education Foundation, some earlier work on $PtXY_2$ isomerizations had been carried out in our group by D. L. Thorn.

Appendix I

Our calculations are of the extended Hückel type[17] with a weighted H_{ij} approximation.[18] The Coulomb integrals and orbital exponents are listed in Table 1. The metal parameters were taken from the following sources: Exponents of Ni 3d orbitals were taken from the work of Richardson *et al.*,[19] while those of Pd 4d, 5s and 5p, and Pt 5d orbitals were from the Basch and Gray orbitals.[20] Other exponents are those given by previous work.[21] The H_{ii}'s for Pt[21] and Ni[22] are the same as those used previously. For Pd charge iterations were performed on *trans*-$Pd(CH_3)_2(PH_3)_2$ assuming a quadratic dependence of metal H_{ii}'s on charge.

TABLE 1. EXTENDED HUCKEL PARAMETERS USED IN THE CALCULATIONS

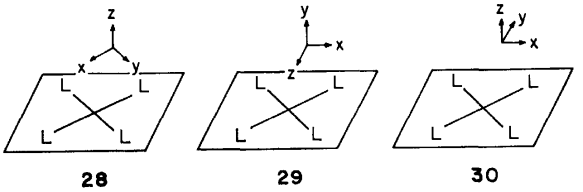
Parameters	H_{ii}/eV	Orbital exponent[a]
Ni 3d	−13.49	5.75(0.5798)+2.30(0.5782)
4s	−9.17	2.10
4p	−5.15	2.10
Pd 4d	−12.02	5.983(0.5535)+2.613(0.6701)
5s	−7.32	2.190
5p	−3.75	2.152
Pt 5d	−12.59	6.013(0.6334)+2.696(0.5513)
6s	−9.077	2.554
6p	−5.475	2.554
C 2s	−21.4	1.625
2p	−11.4	1.625
P 3s	−18.6	1.60
3p	−14.0	1.60
H 1s	−13.6	1.3
"D" 1s	−11.75	1.3
"A" 1s	−14.34	1.3

a) For the d functions a double zeta expansion was used. The expansion coefficients are given in parentheses.

Geometrical assumptions included the following: C–H 1.09, P–H 1.42, Ni–C 2.02, Ni–P 2.23, Pd–C 2.05, Pd–P 2.30, Ni–D(A) 1.60, Pd–D(A) 1.65, Pt–D(A) 1.75Å; PH_3 and CH_3 tetrahedral.

Appendix II

There is no unique way to define the coordinate system in the molecules under study. The "classical" choice for a four-coordinate complex, **28**, is tied to D_{4h} symmetry. It



28 **29** **30**

makes the destabilized d orbital the familiar-sounding $d_{x^2-y^2}$. But the axis system of **28** is cumbersome if one wishes to study a reductive elimination that preserves C_{2v} symmetry, for the C_2 axis preserved is not one of the axes of **28**. Neither are d_{xz} and d_{yz} appropriate symmetry adapted linear combinations. **29** would be more appropriate, but it in turn loses the mnemonic connection to the classical square-planar crystal field. We choose to compromise, using **30**. This retains the z axis where the four-fold axis used to be, and allows the use of d_{xz} and d_{yz}. The price we pay is that the destabilized d orbital is d_{xy}, not $d_{x^2-y^2}$. And we have to use the non-standard character table, Table 2.

TABLE 2. C_{2v} CHARACTER TABLE USED IN THIS WORK

	E	$C_2(y)$	$\sigma(yz)$	$\sigma(xz)$
A_1	1	1	1	1
A_2	1	1	−1	−1
B_1	1	−1	1	−1
B_2	1	−1	−1	1

14) The metal part of the b_2 orbital **14** (or **11**) is here

mainly d_{xy}. In our previous work on tetraalkyl gold the analogous orbital was mainly metal p_x. This is a consequence of the different metal parameters—in the Au(III) case the d orbitals were very low in energy and in metal-ligand interaction mainly metal s and p orbitals were used. In our present calculations the s and p orbitals are relatively high, and it is the metal d functions which interact most. The arguments carry through no matter which metal orbitals are involved.

Mechanisms of Thermal Decomposition of *trans*- and *cis*-Dialkylbis-(tertiary phosphine)palladium(II). Reductive Elimination and *trans* to *cis* Isomerization

Fumiyuki Ozawa, Takashi Ito,** Yoshiyuki Nakamura, and Akio Yamamoto*

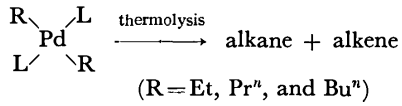
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received August 30, 1980)

Series of *trans*- and *cis*-dialkylpalladium(II) complexes having tertiary phosphine ligands (L) of various basicities and bulkiness have been prepared and their thermolysis and isomerization mechanisms in solution have been studied. Examination of the cause of selective formation of *cis*-dialkyl isomers by using alkyllithium revealed a new type of *trans* to *cis* isomerization promoted by the alkyllithium. A process involving the formation of a trialkylpalladate intermediate is proposed as a mechanism for the *trans* to *cis* isomerization. Evidence to support the mechanism has been obtained by experiments using $LiCD_3$. Thermolysis of *cis*-PdR_2L_2 has been demonstrated to proceed through a unimolecular process initiated by a rate-determining dissociation of L to produce a three-coordinate "*cis*-PdR_2L" which reductively eliminates the R groups. Addition of free ligand to the system containing *cis*-$PdMe_2L_2$ effectively blocks the reductive elimination pathway thus forcing the complex to be thermolyzed by a route involving liberation of methane. The second, novel type of *trans* to *cis* isomerization reaction proceeding *via* an intermolecular methyl transfer process has been discovered. As the crucial intermediate in the process a methyl-bridged complex formed between the partly dissociated three-coordinate species and undissociated complex has been postulated. Thermolysis of *trans*-$PdMe_2L_2$ has been found to proceed *via* initial isomerization to the *cis* form followed by reductive elimination. The *trans-cis* isomerization equilibrium greatly favors the *cis* form for complexes having phenyl-substituted phosphines. For the PEt_3-coordinated palladium dimethyl, however, an equilibrium *trans*/*cis* ratio of 1.2 is reached at 39 °C. Factors influencing the stability of the palladium alkyls having the tertiary phosphine ligand are discussed on the basis of the present results as well as comparison of the thermolysis behavior of *trans*-$PdEt_2L_2$ and other transition metal alkyls. The presence of an energy barrier between the dissociated T-shaped intermediates *trans*-$PdMe_2L$ and *cis*-$PdMe_2L$ has been assumed. A unimolecular reductive elimination pathway proceeding from the T-shaped *cis*-$PdMe_2L$ intermediate through a Y-shaped transition state consistently accounts for the thermolysis as well as isomerization behavior of the *trans*- and *cis*-$PdMe_2L_2$.

Despite the abundance of organic reactions promoted by palladium and its compounds,[1] the fundamental studies on the behavior of alkylpalladium compounds, which may be regarded as key compounds in the Pd-promoted reactions, are still scarce.[2,3] By studying the decomposition mechanisms of palladium alkyls having stabilizing ligands such as tertiary phosphines, one can expect to get important information concerning the factors controlling the cleavage of the Pd–C bond and the subsequent C–C coupling reactions of the alkylpalladium complexes coordinated with the stabilizing ligands. The recent study by Stille and co-workers contributed to unveil part of the decomposition mechanisms of dialkylpalladium complexes having tertiary phosphine ligands,[2] but obviously more studies are required for understanding fundamental properties of the palladium alkyls.

As continuation of our effort to clarify the behavior of various transition metal alkyls,[4] we have prepared series of *cis*- and *trans*-dialkylbis(tertiary phosphine)-palladium(II) and have studied the chemical properties of these complexes. Examination of the thermolysis mechanisms of these isolated *cis* and *trans* complexes provides us a rare opportunity to study the crucial roles of the tertiary phosphine ligands in enhancing the stability of transition metal alkyls, affecting the thermolysis pathways, and determining the configurations of these complexes. In the previous paper we confirmed that *trans*-PdR_2L_2 (R=Et, Pr^n, and Bu^n; L=various tertiary phosphines) is thermolyzed through clean β-elimination pathways, liberating 1 : 1 mixtures of alkane and alkene. The reactions were shown to proceed predominantly from undissociated four-coordinate



(R=Et, Pr^n, and Bu^n)

species.[5] It was noted that the presence of the free tertiary phosphine ligands had small effect in hindering the thermolysis, and we proposed a thermolysis mechanism involving distortion from the square-planar configuration to facilitate the β-hydrogen elimination.

In the present paper we report the results of our mechanistic studies on thermolysis of *cis*- and *trans*-$PdMe_2L_2$, and of *cis*-$PdEt_2L_2$ and on *trans-cis* isomerization of the dimethylpalladium complexes. In contrast to the minor inhibition effect of tertiary phosphine ligands on β-elimination reaction of *trans*-PdR_2L_2 (R=Et, Pr^n, Bu^n), a pronounced inhibition effect of tertiary phosphine ligands on reductive elimination of the alkyl groups from *cis*-PdR_2L_2 type complexes was revealed. Two new types of *trans-cis* isomerization reactions were discovered. The behavior of these palladium alkyls was found to have some similarities with that of AuR_3L type complexes[6] which liberate the coordinated tertiary phosphine ligand in order to initiate reductive elimina-

tion of the alkyl groups and isomerization between trialkylgold isomers having different alkyl groups.

Results and Discussion

Preparation of cis- *and* trans-*PdR_2L_2*. Employment of suitable synthetic methods has been found to lead to selective production of *cis*- and *trans*-PdR_2L_2. The *trans* isomers can be conveniently prepared by treating $Pd(acac)_2$ (acac=2,4-pentanedionato ligand) with $AlR_2(OEt)$ (R=Me, Et, Pr^n, Bu^n), or more preferably with $Al_2R_3(OEt)_3$, in the presence of tertiary phosphines (Method A, Eq. 1).[3,5] The *trans* isomers obtained by Method A are sometimes contaminated with *cis* isomers which may be removed by recrystallization. The *cis* isomers are prepared by alkylating $PdCl_2L_2$ with alkyllithium (Method B, Eq. 2).[7] For some complexes having basic tertiary phosphines such as PEt_3 where the preparation of a *cis* isomer by Method B is not suitable, a ligand exchange reaction of PEt_3 with another *cis* isomer provides an indirect route to selectively prepare the *cis* isomer (Method C, Eq. 3, Scheme 1).

Method A

$$Pd(acac)_2 + \text{excess } AlR_2(OEt) \text{ or } Al_2R_3(OEt)_3 + 2L \xrightarrow[-70 \text{ to } 0\,^\circ C]{Et_2O} \textit{trans}\text{-}PdR_2L_2 (+\textit{cis}\text{-}PdR_2L_2) \quad (1)$$

(I—V)

(R=Me, Et, Pr^n, Bu^n; L=PEt_3, PMe_2Ph, PEt_2Ph, $PMePh_2$, $PEtPh_2$)

Method B

$$PdCl_2L_2 + \text{excess LiR} \xrightarrow[0\,^\circ C \text{ to room temp}]{Et_2O} \textit{cis}\text{-}PdR_2L_2 \quad (2)$$

(**2**—**5**)

(R=Me, Et; L=PMe_2Ph, PEt_2Ph, $PMePh_2$, $PEtPh_2$)

Method C

$$\textit{cis}\text{-}PdMe_2(PMePh_2)_2 + PEt_3 \quad (\textbf{4a}) \xrightarrow[\text{room temp}]{Et_2O} \textit{cis}\text{-}PdMe_2(PEt_3)_2 \quad (3)$$

Scheme 1.

Employment of the chelating diphenylphosphinoethane (dpe) ligand gives the *cis* isomers by the spatial constraint posed by the chelating ligand even by using Method A. The isolated dialkylpalladium complexes are listed in Table 1 with reference to the preparative methods. For differentiation of the isomers we use the Roman letters for describing the *trans* isomers and gothic Arabic numbers for representing the *cis* isomers.

Characterization of the complexes has been made on the basis of elemental analysis and IR and NMR spectroscopy. The characteristic IR and ^1H NMR data of the dimethyl- and diethylpalladium complexes are given in Table 2 (for further details of characterization, see Experimental part).

The trans-cis *Isomerization of $PdMe_2L_2$ Promoted by Alkyllithium.* Examination of the cause of the selective production of the *cis* and *trans* isomers by using different experimental methods led us to the discovery of a new type of isomerization reaction. The ethyl as well as the methyl complexes show similar behavior. Here we deal mainly with the *trans-cis* isomerization of the methyl complexes, since the isomerization of the ethyl complexes are essentially similar but complicated by their thermal instability.

The *trans*-$PdMe_2(PEt_2Ph)_2$ (IIIa) was found to isomerize readily to the *cis* isomer (**3a**) in high yield on treatment with two equivalents of LiMe in ether for 2 h at room temperature. The LiMe was removed by hydrolysis after the isomerization was complete. Treatment of the *trans* isomer (IIIa) with 1.5 equivalents of $AlMe_2(OEt)$ under similar conditions did not give any *cis* isomer and the unreacted IIIa was recovered. It was further established that treatment of *trans*-$Pd(CH_3)_2(PEt_2Ph)_2$ (IIIa) with an equimolar amount of $LiCD_3$ in ether at room temperature gave the *cis* isomer (**3a'**) containing the CD_3 group after removal of the methyllithium by hydrolysis. Thermolysis of **3a'** at 60 °C in toluene containing dimethyl maleate, the presence of which serves to cause the clean thermolysis of the dialkyl complexes (*vide infra* and Ref. 5), released CD_3CD_3, CH_3CD_3, and CH_3CH_3 in a molar ratio of 0.18; 0.48: 0.34. Methyl scrambling was also observed in the reaction of *cis*-$Pd(CH_3)_2(PEt_2Ph)_2$ with an

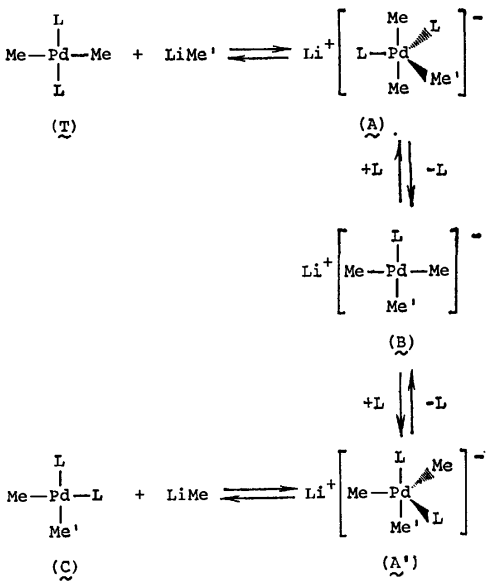
equimolar amount of $LiCD_3$. Thermolysis of the isolated *cis*-$PdMe_2(PEt_2Ph)_2$ containing the CD_3 group librated CD_3CD_3, CD_3CH_3, and CH_3CH_3 in a molar ratio of 0.13: 0.40: 0.47. Since the calculated ratio of the deuterated and undeuterated ethanes expected on the assumption of random scrambling of the methyl groups in the 1: 1 mixture of the methylpalladium and the trideuterio methyllithium is 0.11: 0.45: 0.45, and the separate experiment has established that the thermolysis of **3a** proceeds *via* a unimolecular process as discussed later, the results indicate that complete intermolecular scrambling of the methyl groups takes place on treatment of the *trans*- or *cis*-$PdMe_2(PEt_2Ph)_2$ with methyllithium.

Based on these results, we propose the following isomerization mechanism, which accounts for the predominant formation of the *cis* isomers when alkyllithiums are employed as the alkylating agent for preparation of the palladium alkyls. In this scheme, approach of the methyl anion toward the square-planar complex, forming an ionic penta-coordinated species (**A**) from which the tertiary phosphine ligand is displaced to give a square-planar trimethylpalladate intermediate, (**B**) seems to be a reasonable assumption.[8] Ensuing coordination of the phosphine ligand to the square-planar intermediate would displace one of the methyl groups, reforming a square-planar dimethyl complex. If the displacement reaction by L dispels the methyl group situated at the *cis* position to the remaining L, the regenerated complex formed through the intermediate (**A'**) in Scheme 2 would have the *cis* configuration, whereas displacement of the methyl



Scheme 2. Proposed mechanism for the *trans-cis* isomerization of $PdMe_2L_2$ promoted by methyllithium.

group (Me') *trans* to the remaining L in (**B**) would revert the square-planar intermediate back to the initial *trans* configuration. If one assumes that the *trans* effect of the methyl group in the intermediate (**B**) is greater than that of L, the preferential formation of the *cis* configuration may be reasonably explained. An alternative scheme involving a trigonal-bipyramid containing the phosphine ligands in axial positions as an

intermediate corresponding to (**A**) is also conceivable, although in that case pseudo rotation by a Berry mechanism should be invoked to account for the *trans-cis* isomerization and consequently the mechanism is less straightforward than the one proposed in Scheme 2. The proposed mechanism is reminiscent of the isomerization mechanism of $MCl_2(PR_3)_2$ (M=Pd, Pt) promoted by PR_3.[9] Although there has been no report on preparation of alkylpalladate type complexes, the assumption of the intermediate alkylpalladate does not seem unreasonable in view of the reported examples of the corresponding alkyl analogs of nickel, platinum, and gold.[10]

(Runs 9—11). b) Total amounts (mol/mol of complex)=[(1/2){R-(-H)+R(H)}+RR]/(complex). c) Evolution of a trace amount of C_2H_4 was observed.

Thermolysis Mechanism of PdR_2L_2. In the previous papers thermolysis of PdR_2L_2 in the solid state[3] and of *trans*-PdR_2L_2 (R=Et, Pr^n, Bu^n), in solution[5] has been reported. Having established procedures for selective synthesis of the *cis*- and *trans*-alkyls, we now examine the thermolysis behavior of these complexes in solutions. Table 3 summarizes the distribution of hydrocarbons produced in thermolysis of various palladium methyls and ethyls. For obtaining quantitative data regarding the thermolysis of palladium alkyls it is essential to carry out the thermolysis under conditions which allow the complete liberation of the alkyl groups and prevent the precipitation of palladium metal in the reaction system. Otherwise, accurate measurement of the amounts of the liberated hydrocarbon products is hindered and release of the tertiary phosphine by decomposition of the phosphine-coordinated palladium complexes prevents the thermolysis of the remaining palladium alkyls and may severely distort the thermolysis kinetics. As it has been proved quite useful in the thermolysis study of *trans*-PdR_2L_2,[5] addition of dimethyl maleate (dmm) into the system containing the palladium alkyl under investigation serves quite satisfactorily to trap the $L_2Pd(0)$ complexes displacing all of the olefin produced by β-elimination and prevents the undesirable side reactions which may liberate the tertiary phosphine ligand to affect the thermolysis course. It has been confirmed that addition of dmm did not alter the rate of thermolysis of the palladium alkyls. Table 3 indicates that thermolysis of *trans*- and *cis*-$PdMe_2L_2$ liberates cleanly almost all of the methyl groups as ethane accompanied by formation of a small amount of methane and a negligible amount of ethylene (Runs 1—7). When the *trans*- or

$$\underset{\text{(}trans\text{ and }cis\text{)}}{PdMe_2L_2} \xrightarrow[\text{dmm}]{\text{thermolysis}} Pd(dmm)L_2 + \underset{(>0.95)}{CH_3CH_3} + \underset{(<0.05)}{CH_4} + \underset{(\approx 0)}{CH_2CH_2} \quad (5)$$

cis-$PdMe_2L_2$ were thermolyzed in the presence of free tertiary phosphines, the thermolysis course releasing ethane was severely hindered, making methane the main thermolysis product, albeit in small quantities as shown in Table 4. Thermolysis of *cis*-$Pd(CD_3)_2(PMePh_2)_2$ in C_6D_6 at 60 °C in the presence of 0.25 mol/l of $PMePh_2$ liberated methane composed of 98% of CD_3H and 2% of CD_4. The results suggest that the hydrogen abstraction is taking place probably *via* a process involving an orthometallated intermediate when the *cis*-dimethyl complex is thermolyzed in the presence of free phosphine.

In contrast to the liberation of ethane and ethylene in a 1:1 ratio on thermolysis of *trans*-$PdEt_2(PMe_2Ph)_2$

9	Va	$PEtPh_2$(0.140)	2.8	8.1
10	Va	$PEtPh_2$(0.234)	3.1	10.1

a) Total amounts of evolved gases were below 5% except for Runs 1 and 6. b) **4a**, *cis*-$PdMe_2(PMePh_2)_2$; Va, *trans*-$PdMe_2(PEtPh_2)_2$. c) dmm, dimethyl maleate.

(IIb) and *trans*-$PdEt_2(PEt_2Ph)_2$ (IIIb) (Runs 8 and 9 in Table 3 and Ref. 5), thermolysis of *cis*-$PdEt_2(PMe_2Ph)_2$ (**2a**) and *cis*-$PdEt_2(PEt_2Ph)_2$ (**3b**) in toluene containing dmm (Runs 10 and 11 in Table 3) gave almost quantitative amounts of butane, the reductive elimination product of the palladium diethyls. The dichotomy

$$\begin{array}{l} \mathrm{L\text{–}Pd(Et)\text{–}Et} \xrightarrow{\text{thermolysis}} \mathrm{Et\text{–}Et} \\ \quad \mathrm{L} \\ \quad (\mathrm{L}=\mathrm{PMe_2Ph},\ \mathrm{PEt_2Ph}) \\ \mathrm{L\text{–}Pd(Et)\text{–}L} \xrightarrow{\text{thermolysis}} \mathrm{C_2H_6} + \mathrm{C_2H_4} \\ \quad \mathrm{Et} \\ (\mathrm{L}=\mathrm{PMe_2Ph},\ \mathrm{PEt_3},\ \mathrm{PEt_2Ph},\ \mathrm{PMePh_2},\ \mathrm{PEtPh_2}) \end{array} \qquad (6)$$

of the thermolysis products of the palladium diethyls depending on the configuration of the isomer is intriguing. The fact that the reductive elimination of the *cis*-alkyls is hindered whereas the β-elimination pathway of the *trans*-alkyls is not hindered by addition of free phosphines suggests that the tertiary phosphine ligand is serving to stabilize the *cis*-dialkyls by blocking the route leading to the three-coordinate species, whereas the phosphine does not block the site for β-elimination of *trans*-$PdEt_2L_2$ to take place. The results are in conflict with the generally held view that the tertiary phosphine's role is merely to block the site for the β-elimination to take place.[11]

In contrast to the occurrence of reductive elimination of the ethyl groups from *cis*-$PdEt_2L_2$ having the monodentate phosphine ligands, the thermolysis of *cis*-$PdEt_2$(dpe) having the bidentate ligand (**6b**, Run 12 in Table 3) liberated ethane and ethylene together with butane, indicating that both β-elimination and reductive elimination pathways are operative. Thermolysis of *cis*-$PdMe_2$(dpe), however, gave ethane, the reductive elimination product. The reason for the different thermolysis behavior of **6b** is not clear.

The occurrence of the reductive elimination of ethyl groups from *cis*-$Pd(CH_2CD_3)_2(PMe_2Ph)_2$ without involvement of H–D scrambling in the deuterated ethyl groups was confirmed by examination of the ^1H NMR of the deuterated butane formed on thermolysis. It was revealed that the proton content in the methyl and methylene groups in the butane produced on thermolysis was 7 and 93% respectively.

Kinetic Study of Thermolysis of cis-$PdMe_2(PMePh_2)_2$ (**4a**). In order to obtain further information on the thermolysis mechanism of the *cis*-dialkyl isomers, the thermolysis of *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) was followed by measuring the evolved amount of ethane produced on thermolysis of **4a** in diphenylmethane containing dmm. Complex **4a** was chosen because of the stability of the *cis* isomer concerning the isomerization to the *trans* isomer as well as the convenient temperature range where the thermolysis proceeds at reasonable rates for the kinetic measurement. The thermolysis is first order in the palladium dimethyl concentration up to the decomposition of 80—90% of the complex (Fig. 1). The thermolysis is severely hindered by addition of small amounts of free $PMePh_2$

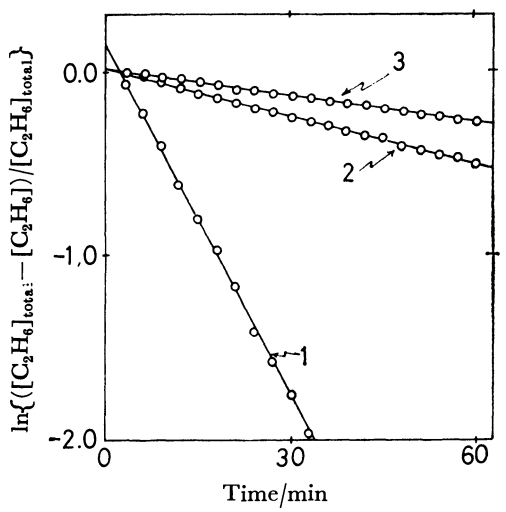

Fig. 1. Pseudo-first order plots for thermolysis of *cis*-$PdMe_2(PMePh_2)_2$ in Ph_2CH_2 containing 0.087 mol/l of dmm at 45.0 °C. [Complex]≈0.025 mol/l. Additive ($PMePh_2$, mol/l): 1) 0.00; 2) 1.25×10^{-3}; 3) 2.50×10^{-3}.

Table 5. The effects of addition of various ligands on thermolysis rates of *cis*-$PdMe_2(PMePh_2)_2$ (**4a**)

Run	Additive (mol/l)	$10^3\ k_{obsd}/s^{-1}$
1	dmm (0.087)	1.1
2	dmm (0.17)	1.1
3	dmm (0.35)	1.2
4	dmm (0.087) $PMePh_2$ (0.75×10^{-3})	0.21
5	dmm (0.087) $PMePh_2$ (1.25×10^{-3})	0.15
6	dmm (0.087) $PMePh_2$ (2.50×10^{-3})	0.08
7	dmm (0.087) Pyridine (0.15)	0.59
8	dmm (0.087) $AsPh_3$ (0.033)	0.37

a) [Complex]≈0.025 mol/l, at 45.0 °C, in Ph_2CH_2.

to the system. The pseudo-first-order rate constant k_{obsd} of thermolysis of **4a** under various experimental conditions are summarized in Table 5. As can be seen from Table 5 the thermolysis rate was not affected by the amount of dmm added to the system, whereas the addition of $PMePh_2$, pyridine, and $AsPh_3$ suppressed the thermolysis. The retardation effect of pyridine and $AsPh_3$ was smaller than that of $PMePh_2$. Plotting of the $1/k_{obsd}$ value *vs.* the concentration of $PMePh_2$ added to the system gave a straight line (Fig. 2). The results suggest that the thermolysis proceeds through a dissociative pathway involving the three-coordinate intermediate formed on partial dissociation of the phosphine ligand from *cis*-$PdMe_2(PMePh_2)_2$ as represented in Scheme 3. Assumptions of the ligand

$$\mathrm{L\text{–}Pd(Me)\text{–}Me} \underset{+\mathrm{L},\ k_{-1}}{\overset{-\mathrm{L},\ k_1}{\rightleftharpoons}} \left[\mathrm{Pd(Me)\text{–}Me}\right] \xrightarrow{k_2} \mathrm{C_2H_6}$$

Scheme 3. Theromlysis mechanism of *cis*-$PdMe_2L_2$ (L=$PMePh_2$).

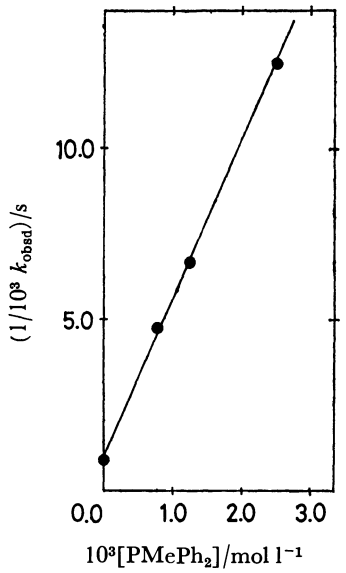

Fig. 2. Plots of $1/k_{obsd}$ *vs.* [$PMePh_2$] in thermolysis of *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) in Ph_2CH_2 containing 0.087 mol/l of dmm at 45.0 °C. [**4a**]≈0.025 mol/l.

dissociation as the rate-determining process and of the steady-state approximation for the concentration of the three coordinate intermediate in Scheme 3 leads to the kinetic equations (7) and (8) which are in agreement with the experimental results as shown in Figs. 1 and 2.

$$-\frac{d[cis\text{-}PdMe_2L_2]}{dt} = \frac{k_1k_2}{k_{-1}[L]+k_2}[cis\text{-}PdMe_2L_2] \quad (7)$$

$$\frac{1}{k_{obsd}} = \frac{k_{-1}}{k_1k_2}[L] + \frac{1}{k_1} \quad (8)$$

Retardation effect of $AsPh_3$ and pyridine is also accommodated by the mechanism shown in Scheme 3. The corresponding *cis*-diethyl analog (**2b**) behaved similarly. An almost quantitative amount of butane was liberated on thermolysis of 0.077 mol/l of **2b** at 55 °C for 5 h in toluene containing dmm. The thermolysis was severely hindered in the presence of 0.17 mol/l of PMe_2Ph under otherwise the same conditions and only *ca.* 2% of butane per complex was released.

In order to see the effect of tertiary phosphine on the stability of the palladium dimethyls having various tertiary phosphine ligands, pseudo-first-order rate constant was measured for each complex in the absence of the added phosphine. The results summarized in Table 6 reflect both electronic and steric effects of the phosphine ligands on stability of the palladium dimethyls. Comparison of the thermolysis rate constants

Table 6. Thermolysis rates of *cis*-$PdMe_2L_2$[a]

$PEtPh_2$	140	4.91	2.0

a) [Complex]≈0.025 mol/l, at 45.0 °C, in Ph_2CH_2 containing 0.087 mol/l of dmm. b) See Ref. 20. c) See Ref. 21.

of **3a** and **4a** having the phosphine ligands of similar cone angles but different basicities indicate that the more basic ligand is more strongly attached to the methyl complex giving rise to a slower thermolysis rate. On the other hand, the $PEtPh_2$-coordinated complex (**5a**) having a larger cone angle than $PMePh_2$ but a similar basicity is thermolyzed at a higher rate than the $PMePh_2$-coordinated complex (**4a**) as a consequence of the steric bulkiness. The PPh_3-coordinated complex is more unstable than **5a** and the thermolysis rate measurement was not attempted. The PEt_3-coordinated complex is much more stable as expected from its high basicity and low steric bulkiness than the complexes coordinated by phenyl-substituted phosphines. Comparison of the thermolysis rate constant of the PEt_3-coordinated complex with thermolysis rate of other complexes, however, was not feasible because of the considerably high rate of the *cis-trans* isomerization occurring concurrently with the thermolysis (*vide infra*). The thermolysis of $PdMe_2$(dpe) (**6a**) at 80 °C in diphenylmethane was almost completely suppressed by addition of about 2 equivalents of dpe. Since the dpe ligand usually serves as a better coordinating ligand than the mono phosphines, the previously mentioned formation of ethane and ethylene and not of butane as the main thermolysis product of $PdEt_2$(dpe) (**6b**) may be partly due to reluctance of the partial dissociation of the dpe ligand from **6b**. Thermolysis without partial dissociation of the ligand may force the complex decomposed by another route. It is noteworthy that addition of the phosphine ligand in thermolysis of $NiMe_2$(dpe)[12] showed no inhibition effect, suggesting a difference in the thermolysis mechanisms of the nickel and palladium congeners.

The unimolecular thermolysis pathway of the *cis* palladium alkyls was further supported by examining the thermolysis product of a mixture of *cis*-$Pd(CH_3)_2(PMePh_2)_2$ (**4a**) and *cis*-$Pd(CD_3)_2(PMePh_2)_2$ in a molar ratio of 0.90: 1.00. The ethane formed on thermolysis of the mixture contained CD_3CD_3, CD_3CH_3, and CH_3CH_3 in a ratio of 0.47: 0.05: 0.48, indicating that scrambling of the methyl groups constitutes only a minor process in thermolysis of **4a**. Stille and coworkers have obtained evidence supporting the involvement of the methyl group in $PMePh_2$ in thermolysis of **4a**.[13] The formation of the minor amount of CD_3CH_3 may have arisen from such a process since thermolysis of *cis*-$Pd(CD_3)_2(PMePh_2)_2$ evolved about 5% of CH_3-CD_3 but the thermolysis result of the mixed CH_3- and CD_3-complexes clearly indicates intramolecular coupling of the *cis* dimethyl groups as the main process. Further support of the unimolecular process in thermolysis of *cis*-PdR_2L_2 was provided by the negligible formation of propane on thermolyses of mixtures of *cis*-$PdMe_2(PMePh_2)_2$ and *cis*-$PdEt_2(PMe_2Ph)_2$.

trans-cis *Isomerization of* $PdMe_2L_2$ *and Mechanism of Thermolysis of* trans-$PdMe_2L_2$. In contrast to the thermolysis behavior of *cis*-$PdMe_2L_2$ which is decomposed by a unimolecular reductive elimination mechanism, the thermolysis of *trans*-$PdMe_2L_2$ deviates from the first-order rate law and shows a marked acceleration in the thermolysis rate as the thermolysis proceeds.

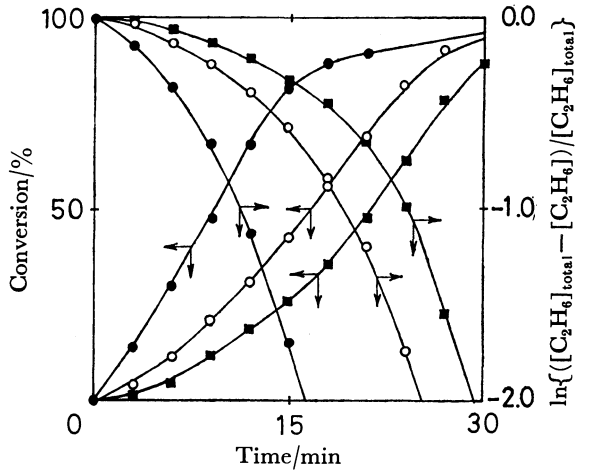

Fig. 3. Time-conversion curves and pseudo-first order plots for thermolysis of *trans*-$PdMe_2L_2$ in Ph_2CH_2 containing 0.087 mol/l of dmm at 62.0 °C. L=PEt_2Ph (IIIa, —■—), $PMePh_2$ (IVa, —○—), $PEtPh_2$ (Va, —●—).

Fig. 4. ^1H NMR spectral change of *trans* to *cis* isomerization of $PdMe_2(PMePh_2)_2$ in CD_2Cl_2 at 36.0 °C.

This indicates the presence of an autocatalytic thermolysis process. The typical time-conversion curves of thermolysis of *trans*-$PdMe_2L_2$ (IIIa, IVa, and Va) are shown in Fig. 3. Further examination of the thermolysis reactions of the *trans*-$PdMe_2L_2$ type complexes revealed the initial isomerization of the *trans* isomer to the *cis* isomer from which the reductive elimination proceeds. By selecting the proper complex and suitable reaction conditions the thermolysis of the palladium dimethyl can be kept minimal and the *trans-cis* isomerization can be conveniently observed. Figure 4 illustrates the typical change of the ^1H NMR spectrum of *trans*-$PdMe_2(PMePh_2)_2$ (IVa) to *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) at 36 °C in CD_2Cl_2. The initial NMR spectrum shows the Pd–Me as well as the methyl signals of $PMePh_2$ as singlets, suggesting exchange between the phosphine ligand liberated from the *trans*-$PdMe_2(PMePh_2)_2$ and the phosphine ligand coordinated to palladium. The liberation and recoordination of the phosphine ligand is a reversible process at this stage, retaining the *trans* configuration since cooling of the solution gives a triplet pattern for the methyl signals of the methyl groups bonded to palladium in the *trans* form. When the solution is kept at 36 °C the signals due to the *trans* isomer decrease. This is accompanied by increase of the signals characteristic of the *cis* isomer. During the isomerization process no change of the chemical shifts of the signals due to the *trans* and *cis* isomers was observed. The isomerization was free of thermolysis up to the 80% conversion. Beyond that stage, formation of ethane in a minor amount was noticed, revealing the occurrence of a slow thermolysis.

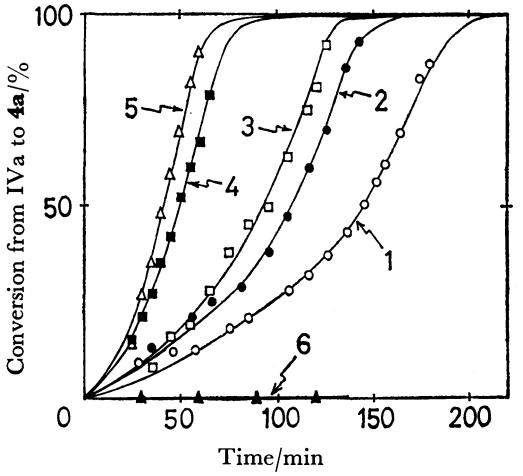

Fig. 5. Time-conversion curves of isomerization of *trans*-$PdMe_2(PMePh_2)_2$ (IVa) to *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) in CD_2Cl_2 at 36.0 °C.

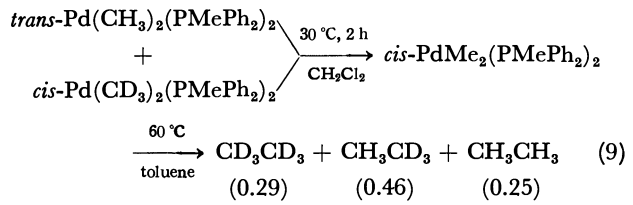
Initial concentration/mol l^{-1}

Run	IVa	Additive	
		4a	$PMePh_2$
1	0.067	0	0
2	0.107	0	0
3	0.064	0.027	0
4	0.069	0.059	0
5	0.071	0.114	0
6	0.090	0	0.050

For the $PMePh_2$-coordinated dimethylpalladium complex the equilibrium lies on the side of the *cis* form. Leaving the acetone-d_6 solution containing the *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) at room temperature for one week led only to the slow decomposition of **4a** without any sign of *cis-trans* isomerization. With increasing replacement of the phenyl groups in the tertiary phosphine ligand by alkyl groups a noticeable effect on the *cis-trans* equilibrium becomes apparent. Although the equilibrium for the $PdMe_2(PMePh_2)_2$ type complex lies far on the side of the *cis* form in CD_2Cl_2 and in acetone-d_6, the PEt_3-coordinated dimethylpalladium complex undergoes *cis-trans* and *trans-cis* isomerization slowly reaching an equilibrium of *trans*/*cis*=1.2 after a few days at room temperature. For **3a** having the less basic and more bulky PEt_2Ph ligand than PEt_3, *cis-trans* isomerization was also observed with an quilibrium *trans*/*cis* ratio of 0.20 at room temperature in acetone-d_6. Apparently both steric and electric factors are involved to determine the *cis-trans* equilibrium, but the electronic factor may be dominant in influencing the equilibrium, as judged from the higher *trans* ratio at equilibrium of the PEt_2Ph-coordinated complex than that of the $PMePh_2$-coordinated complex, both phosphines having the same cone angle.

For the dimethylpalladium complex coordinated with $PMePh_2$, kinetic studies concerning the *trans* to *cis* isomerization have been made by pursuing the decrease of the Pd–Me signal in the ^1H NMR spectra of the *trans* form IVa measured in CD_2Cl_2 at 36.0 °C. This system is free from the reverse, *cis* to *trans* isomerization and the time-conversion curves, as reproduced in Fig. 5, shows a typical autocatalytic acceleration effect. The *trans-cis* isomerization rate is increased with increase of the initial concentration of the *trans* form IVa (Runs 1 and 2 in Fig. 5) and the rate is particularly enhanced on addition of the increasing amount of the *cis* form (**4a**) to the system (Runs 3, 4, and 5). The isomerization was markedly suppressed by adding free $PMePh_2$ to the system (Run 6).

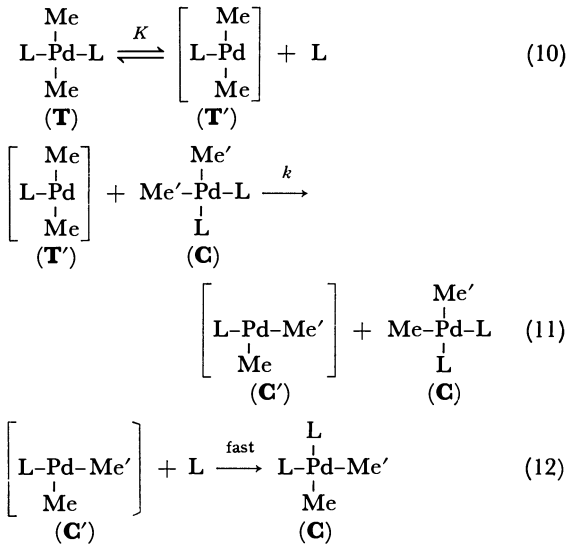
Further examination of the *trans-cis* isomerization using the deuterated dimethylpalladium complex revealed scrambling of the methyl groups during the isomerization process. Examination of the thermolysis product liberated from *cis*-$PdMe_2(PMePh_2)_2$, derived by isomerization of *trans*-$Pd(CH_3)_2(PMePh_2)_2$ in CH_2Cl_2 at 30 °C for 2 h in the presence of an equilmolar amount of *cis*-$Pd(CD_3)_2(PMePh_2)_2$, revealed that the ratio of CD_3CD_3: CH_3CD_3: CH_3CH_3 in the evolved ethane was 0.29: 0.46: 0.25, indicating the complete scrambling of the methyl groups. Since it has been already



(9)

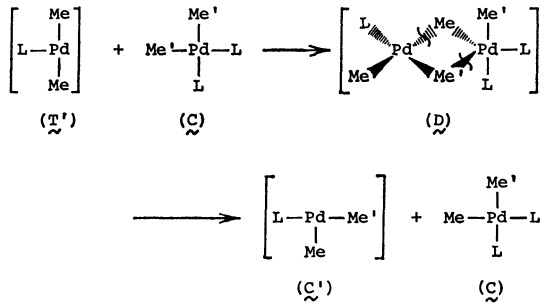
confirmed that the thermolysis of the mixture of *cis*-$Pd(CH_3)_2(PMePh_2)_2$ and *cis*-$Pd(CD_3)_2(PMePh_2)_2$ predominantly gives CD_3CD_3 and CH_3CH_3, the above result clearly indicates the involvement of an intermolecular process causing the exchange of the methyl groups. Since it has been established on the basis of ^1H NMR spectrum that *trans*-$PdMe_2(PMePh_2)_2$ is partly dissociated with retention of the "*trans*" configuration in solution without rapid transformation into the *cis* configuration, it is reasonable to assume the presence of an energy barrier between the three-coordinate species having the methyl groups at mutually *trans* positions (**T′** form in the following equations) and another three-coordinated species having the methyl groups at mutually *cis* positions (**C′**). Our next task is to find a reasonable mechanism which allows the complex led to the *cis* form with the assistance of the *cis*-$PdMe_2L_2$ or *trans*-$PdMe_2L_2$ with involvement of the methyl scrambling.

Since there is no precedent of the *trans-cis* isomerization proceeding by an intermolecular mechanism to our knowledge, examination of various isomerization models merits the consideration. In the first place, the intramolecular isomerization mechanism is excluded on the basis of the kinetic results and the intermolecular scrambling experiment. Secondly, inhibition of the isomerization by addition of free phosphine supports a mechanism involving the partial dissociation of the phosphine ligand from the square-planar complex with exclusion of other mechanisms involving association of non-dissociated four coordinate species. Thirdly, a bimolecular mechanism between two three-coordinated species formed by the ligand dissociation is unlikely on the ground of kinetic results. After exclusion of these other possible mechanisms we are left with the following mechanism to account for the isomerization of *trans*-$PdMe_2L_2$ promoted by *cis*-$PdMe'_2L_2$. As the inter-



Scheme 4. Proposed mechanism for *trans-cis* isomerization of *trans*-$PdMe_2L_2$ promoted by *cis*-$PdMe_2L_2$.

mediate in the crucial intermolecular reaction (11) we postulate the formation of the following methyl bridged species, which on cleavage of the original methyl–palladium bonds may give the dissociated (**C′**) and undissociated *cis*-dimethyl (**C**) complexes. Rapid coordination of the free phosphine ligand to the unsaturat-



(13)

ed species (**C**′) completes the isomerization, giving the product *cis*-PdMeMe′L_2 (Eq. 12). Retention of the *cis* configuration of the added *cis* isomer after departure from the bridged species (**D**), in which a trigonal bipyramidal structure is assumed, is in agreement with the generally observed retention of configuration in the other isomerization reactions of square-planar transition metal complexes.[8] Since the methyl group has a greater *trans* effect than the tertiary phosphine, cleavage of the methyl group in the position *trans* to the terminal methyl group as shown in **D** is reasonable. The rapid coordination of the free phosphine to the split-out species (**C**′) leading to the square-planar *cis*-$PdMe_2L_2$ (Eq. 12) is a likely process in view of the absence of broadening of the ^1H NMR signal of the palladium bonded methyl groups in *cis*-$PdMe_2L_2$.

The *trans-cis* isomerization strongly favors the *cis* form for complexes having phosphines with the phenyl groups as discussed previously. For these cases assumption of Scheme 4, in which rapid equilibrium for Eq. 10, the rate determining step for Eq. 11 and the subsequent rapid trapping of the (**C**′) in Eq. 12 are involved, leads to the kinetic expression given by Eq. 14.

$$-\frac{d[\mathbf{T}]}{dt} = k[\mathbf{T}'][\mathbf{C}] \tag{14}$$

Since $[\mathbf{T}]_0+[\mathbf{C}]_0=[\mathrm{T}]+[\mathbf{C}]$, where $[\mathbf{T}]_0$ and $[\mathbf{C}]_0$ stand for the initial concentrations of the *trans* and *cis* isomers and [**T**] and [**C**] the concentrations of the isomers at time *t*, [**C**] may be expressed as

$$[\mathbf{C}] = [\mathbf{T}]_0 + [\mathbf{C}]_0 - [\mathbf{T}]. \tag{15}$$

From Eq. 10 it follows

$$K = [\mathbf{T}'][\mathrm{L}]/[\mathbf{T}] \quad \text{where } [\mathbf{T}'] = [\mathrm{L}] \text{ and}$$
$$[\mathbf{T}'] = \sqrt{K[\mathbf{T}]}. \tag{16}$$

From Eqs. 14, 15, and 16

$$-\frac{d[\mathbf{T}]}{dt} = k\sqrt{K}\sqrt{[\mathbf{T}]}([\mathbf{T}]_0+[\mathbf{C}]_0-[\mathbf{T}]) \tag{17}$$

$$\int_{[\mathbf{T}]_0}^{[\mathbf{T}]} \frac{d[\mathbf{T}]}{\sqrt{[\mathbf{T}]}([\mathbf{T}]_0+[\mathbf{C}]_0-[\mathbf{T}])} = -\int_0^t k\sqrt{K}\,dt. \tag{18}$$

From Eq. 18 the following equation is derived:

$$\ln\frac{(\sqrt{[\mathbf{T}]_0+[\mathbf{C}]_0}+\sqrt{[\mathbf{T}]})^2}{[\mathbf{C}]} = -k\sqrt{K}\sqrt{[\mathbf{T}]_0+[\mathbf{C}]_0}\cdot t + \ln\frac{(\sqrt{[\mathbf{T}]_0+[\mathbf{C}]_0}+\sqrt{[\mathbf{T}]_0})^2}{[\mathbf{C}]_0}. \tag{19}$$

Plots of $\ln(\sqrt{[\mathbf{T}]_0+[\mathbf{C}]_0}+\sqrt{[\mathbf{T}]})^2/[\mathbf{C}]$ *vs.* *t* as computed from the time-conversion curves shown in Fig. 5 are straight lines as shown in Fig. 6 up to about 60—

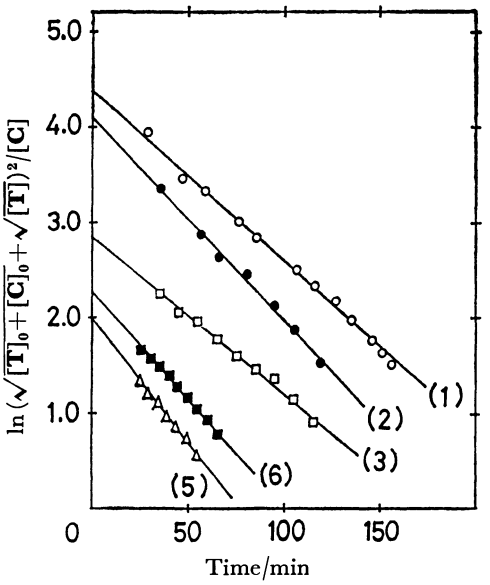


Fig. 6. Plots of $\ln(\sqrt{[\mathbf{T}]_0+[\mathbf{C}]_0}+\sqrt{[\mathbf{T}]})^2/[\mathbf{C}]$ *vs.* *t* in *trans* to *cis* isomerization of $PdMe_2(PMePh_2)_2$.

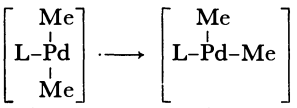
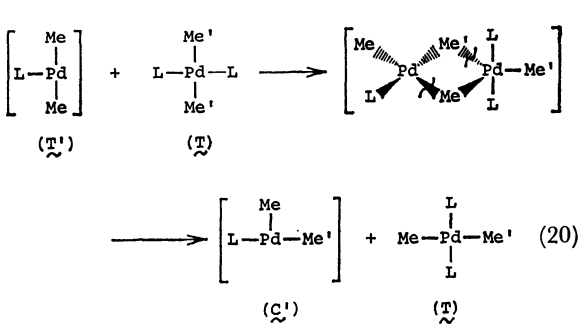
80% conversions. The values obtained by dividing the slopes of these lines in Fig. 6 by $-\sqrt{[\mathbf{T}]_0+[\mathbf{C}]_0}$ give a constant value $(1.0\pm0.1)\times10^{-3}$ s^{-1} $mol^{-1/2}$ $l^{-1/2}$ corresponding to $k\sqrt{k_1}$ in a reasonable agreement with each other value. Thus the isomerization of the *trans* isomer to the *cis* isomer catalyzed by the *cis* isomer can be explained by assuming the mechanism shown in Scheme 4, at least for the most part where the acceleration effect is observed.

The initial period of isomerization, however, where the *cis* isomer is not present, remains to be explained by the other mechanism than the one involving the *cis* isomer. If the slow isomerization of the three-coordinate **T**′ complex to **C**′ complex shown below is excluded



(19)

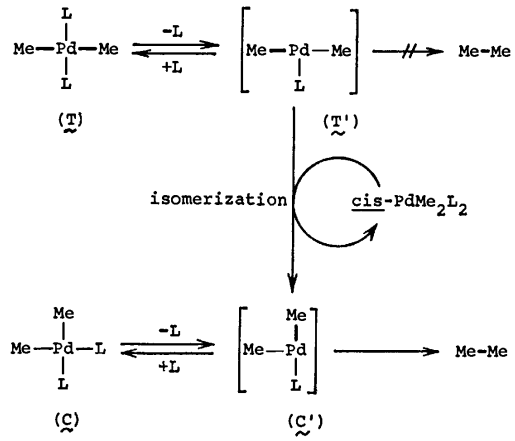
even in the initial period, the remaining reasonable mechanism to account for the isomerization in the initial period is the one assisted by the undissociated *trans* isomer itself. Experimentally it is difficult to get evidence to prove or disprove mechanisms given by Eq. 19 or Eq. 20 for the initial period where the isomerization rate is small. The acceleration effect observed by increasing the initial concentration of the



(20)

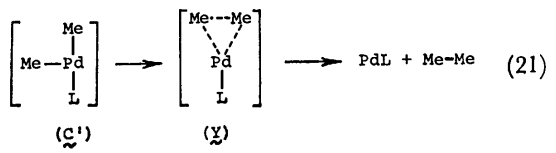
trans isomer suggests an intermolecular mechanism such as Eq. 20. The much enhanced acceleration of the isomerization by addition of the *cis* isomer (*e.g.* Run 3 in Fig. 5 in comparison with Run 2 in which the total concentration is higher than in Run 3) suggests that the reaction proceeds mainly by a mechanism involving acceleration by the *cis* isomer (*e.g.* Scheme 4). For the *cis* to *trans* isomerization, which was noticeable for the PEt_3-coordinated complex **1a** and to a lesser extent for the PEt_2Ph-coordinated complex **3a**, a mechanism following the reverse course of the *trans* to *cis* isomerization as expressed by Scheme 4 may be operative.

With the information concerning the *trans* to *cis* isomerization we are now in a situation to resume the discussion on the thermolysis behavior of the *trans* palladium dimethyls at elevated temperatures as shown in Fig. 3. As can been seen from the figure, the thermolysis rate is markedly accelerated as the reaction proceeds. These results combined with those on the thermolysis of *cis*-$PdMe_2L_2$ previously discussed suggest that the thermolysis of *trans*-$PdMe_2L_2$ proceeds after its isomerization to the (**C′**) type three-coordinate intermediate. This intermediate is also formed by partial dissociation of the ligand in thermolysis of *cis*-$PdMe_2L_2$ as shown in Scheme 5.



Scheme 5. Proposed mechanism of reductive elimination of methyl group from *trans*- and *cis*-$PdMe_2L_2$.

It is noteworthy that the three-coordinate "*cis*" type complex (**C′**) has a moderate stability without being immediately thermolyzed by a reductive elimination pathway. The results suggest intervention of another type of three-coordinate species connected with the transition state for the reductive elimination. A plausible candidate for the species formed by the rearrangement of configuration from the T-shaped species (**C′**) is a planar Y-shaped complex from which the alkyl groups are reductively eliminated. A similar intermediate has been invoked in explanation of the



(21)

thermolysis and isomerization behavior of AuR_3L type complexes.[6]

It is intriguing to note the similarity between thermolysis mechanisms of the alkyl complexes of Group I transition metal, AuR_3L, and of Group VIII transition metal, $PdMe_2L_2$. Furthermore, comparison of the thermolysis behavior of PdR_2L_2 with that of NiR_2L_2 and PtR_2L_2 reveals the contrasting difference in thermolyses of these three, Group VIII dialkyls. Pertinent characteristics in thermolysis patterns of the three dialkyls are as follows. (1) Reductive elimination of $NiMe_2(bpy)$[14] and $NiMe_2(dpe)$[12] is not hindered by the presence of free ligand. This suggests that the reductive elimination from the four-coordinate species can proceed without ligand liberation in contrast to the striking inhibition effect of the phosphine ligand on thermolysis of *cis*-PdR_2L_2. (2) Thermolysis of *cis*-PtR_2L_2 by a β-hydrogen elimination pathway is severely hindered by addition of a free phosphine,[15] whereas the thermolysis of *trans*-$PdEt_2L_2$ proceeding also through a β-hydrogen elimination pathway is not hindered by the presence of the free phosphine.[5]

Attempting to clarify the difference in the thermolysis behavior of *cis*-$PdMe_2L_2$ and *cis*-$NiMe_2L_2$, Tatsumi and Hoffmann recently performed extended HMO calculations.[16] Their results explain most of the thermolysis behavior of *cis*-$PdMe_2L_2$ and *cis*-$NiMe_2L_2$ and suggest the presence of an energy barrier between the T-shaped "*trans*" form (**T′**) and "*cis*" form (**C′**). Their calculation indicates that a lower energy barrier is found for reductive elimination *via* the Y-shaped species rather than directly from the undissociated complex or from **C′** intermediate in the case of palladium dialkyls, whereas the reductive elimination from the undissociated $NiMe_2L_2$ complex may take place with a lower energy barrier than the case for *cis*-$PdMe_2L_2$.

On Factors Influencing the Stability of Palladium Alkyls.

In discussion of the factors influencing the stability of transition metal alkyls one of the most important information regarding the roles of the supporting ligands such as tertiary phosphines and organic nitrogen bases may be obtained by careful kinetic studies of the thermolysis mechanism of the isolated transition metal alkyls. It has been established in the previous report[5] that the tertiary phosphine ligand does not serve in blocking the β-hydrogen elimination pathway effectively in the thermolysis of *trans*-$PdEt_2L_2$ but rather the bulky ligands destabilize the Pd–Et bonds. The present study, however, indicates that thermolysis of the *cis*-dialkylpalladium complexes proceeding through a reductive elimination pathway can be severely hindered by the presence of free tertiary phosphines. In the thermolysis involving the ligand dissociation the nature of the ligands and that of the alkyl groups give mutual influence on the ease of cleavage of the Pd–PR_3 bond and Pd–alkyl bonds. Although the intrinsic bond strength of the Pd–Et bond may certainly differ from that of the Pd–Me bond, the principal factor in determining the stability of the phosphine-coordinated *cis*-palladium dialkyls, may be sought in the ease of release of the phosphine ligand. The ethyl group situated at the *trans* position to one of the phosphine ligands may

have greater *trans* labilizing effect than the methyl group in the rate-determining phosphine dissociating process. This would explain the greater stability of the dimethyl complexes than the corresponding diethyl complexes.

The results obtained in the present study as well as the previous one provide pertinent information not only about the factors concerning the stability of palladium alkyls but also regarding palladium-catalyzed reactions causing the C–C bond coupling. Although the actual catalyst systems, being constituted of a series of elementary steps, are much more complicated than the simple thermolysis of the isolated palladium dialkyls, part of the roles of the added ligands may be connected with the effect of the ligand on reductive elimination of dialkyls as discussed here.

Experimental

All manipulations were carried out under an atmosphere of nitrogen or argon, or *in vacuo*. Solvents were dried in the usual manner, distilled, and stored under a nitrogen atmosphere.

Infrared spectra were recorded on a Hitachi 295 spectrometer using KBr pellets. ^{1}H NMR spectra were measured on a JEOL PS-100, FX-100, and PMX-60 spectrometers. ^{1}H NMR signals are referred to Me_4Si as internal or external standard. Analysis of the gases evolved by the reactions was carried out by gas chromatography (Shimadzu GC-3BF) after collecting gases using a Toepler pump, by which the volumes of gases were also measured. Analysis of the gases dissolved in solution was also carried out by gas chromatography (Shimadzu GC-6A) after collecting the volatile matters in the reaction solution by a trap-to-trap distillation. Micro analyses (C and H) were carried by Mr. T. Saito of our laboratory using Yanagimoto CHN Autocorder Type MT-2. Analysis of the palladium content was performed by colorimetric method using 1-nitroso-2-naphthol as a color-producing reagent.[17] The complete ionization of the palladium in the complex was achieved by treating the sample with a hot aqua regia.

Triethylphosphine (Strem) was used as purchased. Dimethylphenylphosphine, diethylphenylphosphine, diphenylmethylphosphine, and diphenylethylphosphine were prepared by the reactions of $PPhCl_2$ and PPh_2Cl, respectively, with RMgX (R=Me, X=I; R=Et, X=Br). 1,2-Bis(diphenylphosphino)ethane (dpe) was prepared by the literature method starting from PPh_3.[18]

trans-$PdMe_2(PEt_3)_2$ (Ia), *cis*-$PdMe_2$(dpe) (**6a**), *cis*-$PdEt_2$(dpe) (**6b**), and *cis*-$PdPr^n_2$ (dpe) (**6c**) were prepared by the reactions of Pd(acac)$_2$, $AlR_2(OEt)$ (R=Me, Et, Pr^n), and tertiary phosphines according to the method described previously.[3] A series of *trans*-PdR_2L_2 (R=Et, L=PEt_3 (Ib), PMe_2Ph (IIb), PEt_2Ph (IIIb), $PMePh_2$ (IVb), $PEtPh_2$ (Vb); R=Pr^n, L=PEt_3 (Ic), PMe_2Ph (IIc), $PMePh_2$ (IVc); R=Bu^n, L=PMe_2Ph (IId)) were also prepared by the reactions of Pd(acac)$_2$, $AlR_2(OEt)$, and tertiary phosphines.[3,5]

Preparation of trans-*PdMe$_2$(PEt$_2$Ph)$_2$ (IIIa) (Method A).* To the heterogeneous red mixture of Pd(acac)$_2$ (2 g, 6.6 mmol), PEt_2Ph (3 ml, 17.1 mmol) and Et_2O (40 ml) cooled to −70 °C, a hexane solution of $AlMe_2(OEt)$ (5 ml, 19 mmol) was added dropwise. On raising the temperature of the mixture gradually, it became homogeneous at −30 °C. The solution was stirred for several hours at 0 °C. After concentrating the solution to *ca.* 10 ml, the solution was cooled to −70 °C overnight to yield a white precipitate of *trans*-$PdMe_2(PEt_2Ph)_2$ (IIIa), which was filtered, washed with a small amount of Et_2O at the same temperature and dried *in vacuo*. It was confirmed that the crude product of complex IIIa contained only *trans* isomer by means of IR spectroscopy. The product was recrystallized from acetone to yield white crystals of IIIa (1.5 g, 49%). Similarly obtained was *trans*-$PdMe_2(PEtPh_2)_2$ (Va) by using $PEtPh_2$ in place of PEt_2Ph. Complex Va was recrystallized from THF–CH_2Cl_2 (yield, 65%).

trans-$PdMe_2(PMePh_2)_2$ (IVa) was also prepared in a similar way from Pd(acac)$_2$, $PMePh_2$, and $AlMe_2(OEt)$. The crude complex first isolated from the reaction system, however, was a mixture of *trans* isomer (IVa) and *cis* isomer (**4a**). These two isomers were separated by extraction with acetone, in which the *cis* isomer is readily dissolved. The *trans* isomer (IVa) and the *cis* isomer (**4a**) were recrysrallized from THF–CH_2Cl_2 and acetone, respectively (yield; IVa, 14%; **4a**, 32%).

Characterization of these complexes was carried out by means of IR and ^{1}H NMR spectroscopy, and elemental analysis. Anal. (IIIa) Found: C, 56.3; H, 8.2%. Calcd for $C_{22}H_{36}P_2Pd$: C, 56.4; H, 7.7%. (IVa) Found: C, 62.1; H, 5.9%. Calcd for $C_{28}H_{32}P_2Pd$: C, 62.6; H, 6.0%. (Va) Found: C, 64.0; H, 6.5%. Calcd for $C_{30}H_{36}P_2Pd$: C, 63.8; H, 6.4%. (**4a**) Found: C, 63.2; H, 6.5%. Calcd for $C_{28}H_{32}P_2Pd$: C, 62.6; H, 6.0%.

Preparation of cis-*PdMe$_2$(PEt$_2$Ph)$_2$ (3a) (Method B).* To the heterogeneous yellow mixture of *trans*-$PdCl_2(PEt_2Ph)_2$ (3.5 g, 6.8 mmol) and Et_2O (40 ml) containing a small amount of PEt_2Ph (*ca.* 0.2 ml), Et_2O solution of MeLi (*ca.* 60 mmol) was added at −30 °C. The system was stirred at room temperature to give a heterogeneous pale yellow mixture containing a white precipitate of LiCl. Stirring was continued for 2 h. Evaporation (by pumping) of the ether phase, after hydrolysis at 0 °C, afforded a crude product of *cis*-$PdMe_2(PEt_2Ph)_2$ (**3a**) as confirmed by IR spectroscopy. The crude product was recrystallized from Et_2O to yield white crystals of **3a** (2.7 g, 85%). Similarly obtained by Method B was *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) and *cis*-$PdMe_2(PEtPh_2)_2$ (**5a**). These complexes (**4a** and **5a**) were recrystallized from acetone (yield; **4a**, 48%; **5a**, 71%).

Characterization of **4a** was carried out by means of IR spectroscopy. Characterizations of **3a** and **5a** were carried out by means of IR and ^{1}H NMR spectroscopy, and elemental analysis. Anal. (**3a**) Found: C, 56.2; H, 8.0%. Calcd for $C_{22}H_{36}P_2Pd$: C, 56.4; H, 7.7%. (**5a**) Found: C, 63.5; H, 6.5%. Calcd for $C_{30}H_{36}P_2Pd$: C, 63.8; H, 6.4%.

Preparation of cis-*PdMe$_2$(PEt$_3$)$_2$ (1a) by the Ligand Exchange Reaction of* cis-*PdMe$_2$(PMePh$_2$)$_2$ (4a) with PEt$_3$ (Method C).* To a white heterogeneous mixture of *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) (0.53 g, 0.99 mmol) and Et_2O (4 ml), PEt_3 (3.4 mmol) was added at room temperature to instantly yield a pale yellow clear solution. Evaporation of solvent by pumping afforded a pale yellow oil, which was washed with hexane at −70 °C to yield a white precipitate of *cis*-$PdMe_2(PEt_3)_2$ (**1a**). The product was filtered, washed with a small amount of Et_2O at −70 °C, and dried *in vacuo* (0.19 g, 52%). Characterization of **1a** was carried out by IR and ^{1}H NMR spectroscopy, and elemental analysis. Found: C, 45.7; H, 9.9%. Calcd for $C_{14}H_{36}P_2Pd$: C, 45.1; H, 9.7%.

Preparation of cis-*PdEt$_2$(PMe$_2$Ph)$_2$ (2b) (Method B).* To a Schlenk tube containing the mixture of $PdCl_2(PMe_2Ph)_2$ (1.6 g, 3.4 mmol) and EtLi (solid state) (0.28 g, 7.7 mmol) cooled at −70 °C, Et_2O (30 ml) containing a small amount of PMe_2Ph was added. On gradually raising the temperature the mixture became homogeneous at −20 °C. Stirring the solution at −20 °C for several hours yielded LiCl as a white precipitate, the amount of which increased gradually. After

concentration of the mixture to *ca.* 3 ml, hexane (30 ml) was added to the system at −10 °C. The solution was collected by filtration at the same temperature. Concentration of the filtrate to *ca.* 5 ml yielded a pale yellow precipitate, which was filtered, washed with a small amount of hexane at −70 °C and dried *in vacuo*. The product was recrystallized from cold Et_2O containing a small amount of PMe_2Ph to yield white crystals of *cis*-$PdEt_2(PMe_2Ph)_2$ (**2b**) (26%). Similarly obtained was *cis*-$PdEt_2(PEt_2Ph)_2$ (**3b**) by the use of $PdCl_2(PEt_2Ph)_2$ in place of $PdCl_2(PMe_2Ph)_2$ (13%). Since these complexes are too unstable for microanalysis, their characterization was carried out by means of IR and ^1H NMR spectroscopy, macroscopic analysis of Pd, and determination of the amount of ethane evolved on acidolysis with concd H_2SO_4. Anal. (**2b**) Found: Pd, 24.5%. Calcd for $C_{20}H_{32}P_2Pd$: Pd, 24.1%. (**3b**) Found: Pd, 21.1%. Calcd for $C_{24}H_{40}P_2Pd$: Pd, 21.4%. The amounts of ethane evolved by acidolysis with concd H_2SO_4 (mol/mol of complex): **2b**, 2.0; **3b**, 1.9.

Characterization of trans- *and* cis-*PdR_2L_2 by ^1H NMR and IR Spectroscopy (see also Table 2).* The ^1H NMR spectrum of *trans*-$PdMe_2L_2$ gives a triplet for the Pd–Me groups whereas that of *cis*-$PdMe_2L_2$ gives rise to a characteristic pattern of a distorted quartet ($A_3XX'A_3'$ pattern).[3] Other spectral patterns helping the assignment are a quintet pattern for the *trans* isomers and a doublet of triplets pattern for the *cis* isomers having tertiary phosphine ligands with ethyl group(s), and a triplet pattern for the *trans* isomers and a doublet for the *cis* isomers containing tertiary phosphine ligands with methyl group(s).

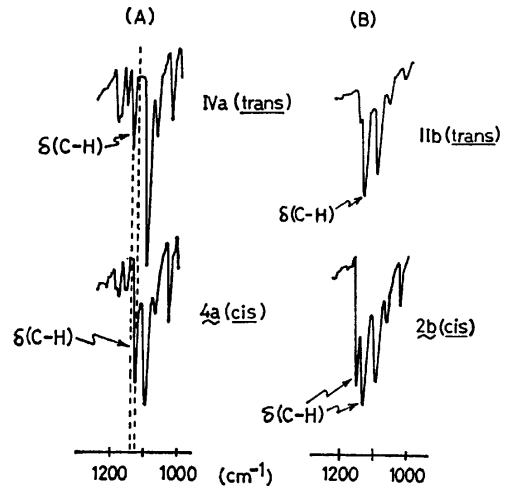


Fig. 7. Characteristic IR absorptions due to δ(C–H) of Pd–R groups of *trans*- and *cis*-PdR_2L_2 (KBr disc). (A) *trans*- and *cis*-$PdMe_2(PMePh_2)_2$. (B) *trans*- and *cis*-$PdEt_2(PMe_2Ph)_2$.

The IR spectra also serve in diagnosis of the isomers. The *trans* isomers show only one ν(Pd–C) band in the range of 455 to 462 cm^{-1} whereas the *cis* isomers give two ν(Pd–C) bands in the region of 465 to 515 cm^{-1}. Other characteristic bands helping to differentiate the *cis* and *trans* isomers are those arising from the C–H deformation of the Pd-bonded alkyl groups as shown in Fig. 7. The δ(C–H) vibration of the methylpalladium complexes gives a single absorption at 1120 cm^{-1} for the *cis* isomers and 1140 cm^{-1} for the *trans* isomers, whereas the δ(C–H) of the ethyl complexes gives two absorptions at 1130 and 1150 cm^{-1} for the *cis* isomers and a single band at 1140 cm^{-1} for the *trans* isomer. Since these absorptions are relatively unperturbed by the tertiary phosphine ligands, observation of these bands helps to determine the configuration of the isomers.

Mass Spectral Analysis of Deuterated Ethanes. Ethane produced by thermolysis was collected by using a Toepler pump through a dry ice–EtOH trap in order to avoid contamination by the solvent, and analyzed by mass spectrometer. To obtain accurate cracking patterns for each component, authentic samples of C_2D_6, CH_3CD_3, and C_2H_6 were prepared. CH_3CD_3 was prepared by the acidolysis of *trans*-$Pd(CH_2CD_3)_2(PMePh_2)_2$ (isotopic purity, 97%)[5] with concd H_2SO_4. CH_3CH_3 was used as purchased (Takachiho Chemical Industry). C_2D_6 was prepared by cracking *cis*-$Pd(CD_3)_2(PMePh_2)_2$ at 60 °C in toluene containing dmm. Since the deuterated ethane thus produced contains a small amount of CH_3CD_3, the true fragmentation pattern of CD_3CD_3 was obtained by subtracting the contribution of peaks due to CH_3CD_3 using the independently obtained fragmentation pattern of CH_3CD_3. The results of mass spectral analysis were reproducible within ±5%.

Reactions of trans-*$PdMe_2(PEt_2Ph)_2$ (IIIa) with MeLi and $AlMe_2(OEt)$.* To a homogeneous Et_2O solution (4 ml) of *trans*-$PdMe_2(PEt_2Ph)_2$ (IIIa) (0.25 g, 0.53 mmol), an ether solution of MeLi (1.1 mmol) was added by means of a syringe at room temperature and the system was stirred for 2 h at the same temperature. After hydrolysis at 0 °C, the solvent was evaporated from the solution to leave a white precipitate, which was washed with a small amount of Et_2O and dried *in vacuo* (0.23 g, 93%). The product was identified as *cis*-$PdMe_2(PEt_2Ph)_2$ (**3a**) on the basis of the IR and ^1H NMR spectroscopy.

On the other hand, the reaction of IIIa (0.098 g, 0.21 mmol) with $AlMe_2(OEt)$ (0.39 mmol) in Et_2O (2 ml at room temperature for 2 h yielded only *trans*-$PdMe_2(PEt_2Ph)_2$ (0.090 g, 92%) after concentration of the solution, washing with hexane at −70 °C, and drying *in vacuo*. Characterization of the product was carried out by IR spectroscopy.

Reactions of trans-*$PdMe_2(PEt_2Ph)_2$ (IIIa) and* cis-*$PdMe_2(PEt_2Ph)_2$ (3a) with CD_3Li.* To a homogeneous Et_2O (2 ml) solution of *trans*-$PdMe_2(PEt_2Ph)_2$ (IIIa) (0.16 g, 0.34 mmol), CD_3Li (isotopic purity, 99%) (0.37 mmol) was added by means of a syringe at room temperature. The system was stirred for 2 h at the same temperature. After hydrolysis at 0 °C, the solvent was removed by pumping to yield a white precipitate (0.14 g). The precipitate was identified as *cis*-$PdMe_2(PEt_2Ph)_2$ containing CD_3 groups on the basis of the IR spectrum (ν(C–D) (KBr disc)=2190, 2080, and 2030 cm^{-1}). Ethane evolved on thermolysis of the reaction product in toluene (2 ml) containing dmm (50 μl) at 60 °C was collected and analyzed by mass spectrometry, and the ratio of CD_3CD_3, CH_3CD_3, and CH_3CH_3 in the ethane was found to be 0.18: 0.48: 0.34.

On the other hand, the reaction of *cis*-$PdMe_2(PEt_2Ph)_2$ (**3a**) (0.15 g, 0.31 mmol) and CD_3Li (0.32 mmol) in ether (2 ml) at room temperature for 2 h also gave *cis*-$PdMe_2(PEt_2Ph)_2$ containing CD_3 groups as a white precipitate after hydrolysis at 0 °C (0.13 g). The ethane evolved on thermolysis of the reaction products in toluene (2 ml) containing dimethyl maleate (50 μl) at 60 °C was determined to be consisted of CD_3CD_3, CH_3CD_3, and CH_3CH_3 in a molar ratio of 0.13: 0.40: 0.47 as measured by mass spectrometry.

Preparation and Thermolysis Products of cis-*$Pd(CD_3)_2(PMePh_2)_2$.* *cis*-$Pd(CD_3)_2(PMePh_2)_2$ was prepared by the reaction of $PdCl_2(PMePh_2)_2$ and CD_3Li (isotopic purity, 99%) in a similar manner to the preparation of **4a** and was identified by means of IR and ^1H NMR spectroscopy: ν(C–D) (KBr disc) =2200, 2090, and 2040 cm^{-1}. In ^1H NMR

spectrum (100 MHz, in acetone-d_6, at room temperature), the complete absence of the signal due to Pd–CH_3 was confirmed.

It was confirmed by mass spectrometry that ethane evolved on thermolysis of *cis*-$Pd(CD_3)_2(PMePh_2)_2$ at 60 °C in toluene (2 ml) containing dmm (50 μl) consisted of CD_3CD_3 and CH_3CD_3 in a molar ratio of 0.95: 0.05.

Thermolysis of the mixture of *cis*-$Pd(CD_3)_2(PMePh_2)_2$ (0.061 g, 0.11 mmol) and *cis*-$Pd(CH_3)_2(PMePh_2)_2$ (0.067 g, 0.12 mmol) in toluene (2 ml) containing dmm (50 μl) at 60 °C gave CD_3CD_3, CH_3CD_3, and CH_3CH_3 in a molar ratio of 0.47: 0.05: 0.48.

Preparation and Thermolysis Products of cis-*Pd(CH_2CD_3)$_2$(PMe_2Ph)$_2$*.* CD_3CH_2Li was prepared by the reaction of CD_3CH_2Br (isotopic purity, 97%)[19] with Li in pentane. *cis*-$Pd(CH_2CD_3)_2(PMe_2Ph)_2$ was prepared by the reaction of $PdCl_2(PMe_2Ph)_2$ and CD_3CH_2Li in a similar manner to the preparation of **2b** and was characterized by means of IR and ^1H NMR spectroscopy: ν(C–D) (KBr disc)=2170, 2145, 2095, and 2040 cm^{-1}. In ^1H NMR spectrum (100 MHz, in acetone-d_6, at −40 °C), only a signal due to Pd–CH_2 was observed as broad $A_2XX'A'_2$ pattern.

Butane produced by thermolysis of *cis*-$Pd(CH_2CD_3)_2(PMe_2Ph)_2$ in toluene containing dmm at room temperature was collected by means of GLC after collecting the volatile materials in thermolysis solution by the trap-to-trap distillation. In ^1H NMR spectrum (100 MHz, in C_6D_6, at room temperature) of collected butane, the ratio of methyl and methylene protons was 7: 93.

Kinetic Studies of Thermolysis of $PdMe_2L_2$. A 30 ml Schlenk tube containing a Ph_2CH_2 solution (4 ml) of the complex (about 0.05 g) and the additive (dmm or tertiary phosphine) was sealed with a gas-tight rubber serum cap and evacuated. The Schlenk tube was placed in a thermostatted bath (HAAKE F2) controlled to ±0.5 °C. The rate constants for thermolysis of the complex were obtained by measureing the amount of ethane evolved with time. The amount of ethane was confirmed by means of GLC using ethylene as an internal standard.

Kinetic Studies of trans *to* cis *Isomerization of $PdMe_2(PMePh_2)_2$.* The appropriate amount of *trans*-$PdMe_2(PMePh_2)_2$ (IVa) and and *cis*-$PdMe_2(PMePh_2)_2$ (**4a**) or $PMePh_2$ were placed in a weighed NMR tube and the tube was connected to a vacuum line with a Teflon joint. After evacuation, CD_2Cl_2 was transferred by the trap-to-trap distillation. The amount of transferred CD_2Cl_2 was determined by weighing, and concentrations of the complexes and $PMePh_2$ were determined by measuring the weight of CD_2Cl_2 added. The sealed tube was placed in a thermostatted NMR probe (±1.0 °C). The amount of IVa on isomerization was determined by measuring the ratio of the area of Pd–Me signals of IVa and **4a**.

Reaction of trans-*Pd(CH_3)$_2$($PMePh_2$)$_2$ and* cis-*Pd(CD_3)$_2$($PMePh_2$)$_2$.* To a Schlenk tube containing *trans*-$Pd(CH_3)_2(PMePh_2)_2$ (IVa) (0.072 g, 0.13 mmol) and *cis*-$Pd(CD_3)_2(PMePh_2)_2$ (0.076 g, 0.14 mmol), CH_2Cl_2 (2 ml) was added by means of a syringe to yield a clear pale yellow solution. After stirring the system for 2 h at 30 °C, the solvent was removed by pumping to yield a white precipitate of *cis*-$PdMe_2(PMePh_2)_2$ containing CD_3 groups (0.14 g). Identification of the product was carried out by IR spectroscopy. Thermolysis of the reaction product in toluene (2 ml) containing dmm (50 μl) at 60 °C liberated CD_3CD_3, CH_3CD_3, and CH_3CH_3 in a molar ratio of 0.29: 0.46: 0.25.

A Reinvestigation of the Crystal and Molecular Structure of the β-Form of 2,4,6-Trimethyl-1,3,5-Trithiane

Kiyotane SEKIDO,* Jun ITOH,† Teruo NOGUCHI,† and Sakutaro HIROKAWA

Department of Chemistry, The National Defense Academy, Hashirimizu, Yokosuka 239

†*Koa Oil Co., Ltd., Ōtemachi, Tokyo 100*

(Received April 28, 1980)

Synopsis. The crystal structure of the title compound has been reinvestgated and refined to a final R factor of 0.057 for 1286 independent reflections. The six-membered ring takes a chair-form. All the three methyl groups are in the equatorial position. The mean values are 1.818 Å and 1.513 Å for the S–C and C–C distances respectively, and 101.3° and 108.5° for the C–S–C and S–C–S angles respectively.

The structure analysis of β-TTA has been reported by Valle *et al.*[1] and by the present authors.[2] The intensity data used in these works were collected by the photographic method, however, so the molecular geometry obtained was not accurate. Recently, the structure analysis of α-TTA using three-dimensional intensities collected by the counter-technique was reported by the present authors.[3] The crystal structure of β-TTA was, therefore, reinvestigated for comparison with that of α-TTA.

Experimental

The single crystals of β-TTA used in the analysis were obtained by the slow evaporation of an acetone solution. They are transparent prisms elongated along a principal axis, having approximately square cross sections.

The cell constants were determined by the least-squares method using various sets of high-angle reflections on a diffractometer. The crystal data are as follows: $C_6H_{12}S_3$, $F.W.$ =180.4, orthorhombic, space group $P2_12_12_1$, a=13.437(13), b=4.740(5), c=14.688(15)Å, V=935.4(1.6)Å^3, D_m=1.274 g cm^{-3}, D_c=1.280 g cm^{-3}, μ(Mo K_α)=7.17 cm^{-1}.

A prismatic crystal of 0.3×0.5×0.8 mm was mounted on a four-circle diffractometer (Rigaku AFC-III) with Mo K_α from a graphite monochrometer, and the intensities were collected for the independent 1614 reflections within $2\theta<60°$, using the ω-2θ scan technique with a scanning speed of 4° min^{-1} in 2θ, while 324 reflections with $|F_o|< 3\sigma(F)$ were designated as unobserved. Corrections for background and the Lorentz-polarization factor were made, but corrections for the absorption or the extinction were omitted.

The atomic parameters determined in the previous work[2] were used as input into the block-diagonal least-squares program on a computer CDC-6600 in the Century Reserch Center Co., Tokyo. At the stage of R=0.096, the hydrogen atoms were located, assuming the tetrahedral angle for each carbon atom and a bond length of 1.09 Å for each C–H bond. Further refinements were made with block-diagonal least-squares using anisotropic thermal parameters for the non-hydrogen, and isotropic B values for the hydrogen, atoms. After six cycles, convergence was attained with R=0.057. The final coordinates and equivalent isotropic temperature factors for the non-hydrogen atoms are given in Table 1.**

Results and Discussion

The thermal vibration ellipsoids[4] scaled to a 50% probability, together with the atomic numbering, are shown in Fig. 1. The intramolecular interatomic distances and angles involving the non-hydrogen atoms are given in Table 2. The mean S–C length is 1.818 Å, the C–S–C angles are 100.2—102.6° (mean 101.3°), and the S–C–S angles are 112.3—114.1° (mean 113.5°). The mean values reported previously were: S–C, 1.814 Å; C–S–C, 98.9°; S–C–S, 114.7° in the unsubsituted 1,3,5-trithiane,[5] 1.818 Å, 101.89°, 113.09° in α-TTA.[3]

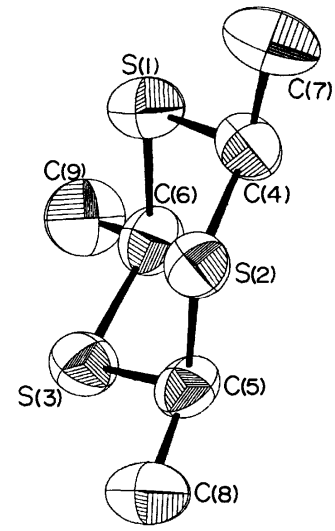

Fig. 1. The thermal vibration ellipsoids of non-hydrogen atoms drawn by ORTEP.[4]

The triangle formed by three sulfur atoms is regular, the averaged length being 3.040 Å (3.029 Å in α-TTA).

** The complete tables of the anisotropic thermal parameters, the F_o–F_c data, the least-squares planes, and the torsion angles are deposited as Document No. 8138 at the Office of the Editor of the Bulletin, the Chemical Society of Japan.

Table 2. Intramolecular interatomic distances(l) and angles ϕ involving the non-hydrogen atoms
Estimated standard deviations are given in parentheses.

C(4) – C(7)	1.508(12)	S(1) – C(4) – C(7)	109.9(6)
C(5) – C(8)	1.514(10)	S(2) – C(4) – C(7)	108.3(6)
C(6) – C(9)	1.518(10)	S(2) – C(5) – C(8)	107.2(5)
S(1)···S(2)	3.045(3)	S(3) – C(5) – C(8)	108.5(5)
S(2)···S(3)	3.053(3)	S(3) – C(6) – C(9)	109.2(5)
S(3)···S(1)	3.022(3)	S(1) – C(6) – C(9)	107.8(5)
C(4)···C(5)	2.840(10)	S(1)···S(2)···S(3)	59.4(1)
C(5)···C(6)	2.807(10)	S(2)···S(3)···S(1)	60.2(1)
C(6)···C(4)	2.789(10)	S(3)···S(1)···S(2)	60.4(1)
S(1)···C(5)	3.452(7)	C(4)···C(5)···C(6)	59.2(3)
S(3)···C(4)	3.440(7)	C(6)···C(4)···C(5)	59.8(3)
S(2)···C(6)	3.434(7)	C(5)···C(6)···C(4)	61.0(3)

The other triangle formed by three ring-membered carbon atoms is also regular, with a length of 2.812 Å (2.833 Å in α-TTA).

The C–C bond distances are in the range of 1.508—1.518 Å, with a mean of 1.513 Å, shorter than the previously reported values (1.58 Å by Valle *et al.*[1] and 1.572 Å by the present authors[2]). However, it agrees with the lengths of C–C_{eq} (from a ring-membered carbon to a methyl carbon in the equatorial position) in α-TTA (1.514 and 1.524 Å). The S–C–C bond angles are in the range of 107.2—109.9°, with a mean of 108.5°, in accordance with the value of α-TTA (107.60°).

The conformation of the chair-form can clearly be seen from the alternative change of sign assigned to each torsion angle. The averaged value of the endocyclic torsion angles is 65.0° (in absolute values), showing a good agreement with the 64.9° in α-TTA. The calculated exocyclic torsion angles (174.4° as a mean in absolute values) show that all three methyl groups are co-ordinated in an equatorial. In α-TTA they are

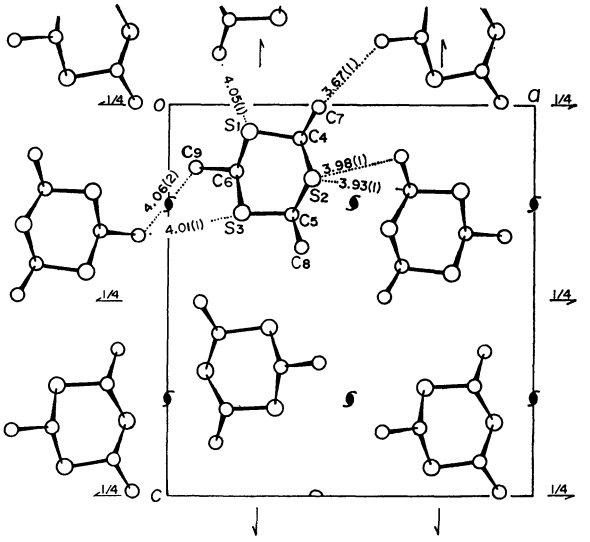

Fig. 2. The molecular packing viewed down **b**, showing all intermolecular distances (the non-hydrogen atoms) of less than 4.10 Å.

175.2° as a mean for the C···C_{eq}, and 68.3° for the C···C_{ax}, rotation.

The molecular packing, together with intermolecular interatomic distances less than 4.10 Å, are shown in Fig. 2. The shortest contact is 3.67 Å between C(7) and C(9) at $(1/2+x, 1/2-y, \bar{z})$. Since this is shorter than the van der Waals contact between two methyl groups, the rotations of the methyl groups may be hindered.

Synopsis. The enthalpies of fusion were measured on the intermediate compounds of the binary systems of KCl and some other chlorides. These were compared with the values calculated using C_p of the component salts according to the additivity. The enthalpies of fusion measured were in good agreement with calculated in K_2LaCl_5 and K_2BaCl_4.

Some intermediate compounds have been known in such binary systems of KCl and some rare earth chlorides as of KCl and alkaline earth chlorides. Enthalpies and entropies of fusion of these compounds are thermodynamically valuable on obtaining theoretical understanding of phase diagrams of these binary or ternary molten chloride systems. In the present work, heats of fusion were measured using a differential scanning calorimeter (DSC) on some intermediate compounds of the binary systems of KCl and some other chlorides and were compared with values calculated using C_p (heat capacity at constant pressure) of component salts.

Experimental

Starting raw materials used were KCl, alkaline earth chlorides ($MgCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$), and rare earth chlorides ($LaCl_3$, $PrCl_3$, $NdCl_3$, $GdCl_3$, and $DyCl_3$). In these chlorides, KCl, $CaCl_2$, $SrCl_2$, and $BaCl_2$, were of reagent grade and separately demoistured by heating under the reduced pressure of about 10^{-3} Torr† at slightly below their melting points for 5—10 h. These were then heated to the molten states and after cooling, they were sealed in test tubes in Ar atmosphere till use.

On the other hand, $MgCl_2$ and rare earth chlorides which were prepared according to the similar procedure in the previous paper,[1] were sublimated to purify at about 1000 °C for 8—10 h under vacuum using the apparatus described elsewhere.[2]

The chlorides were weighed in the mole ratios 1-1, 2-1, and 3-1 corresponding to the compositions $KMgCl_3$, $KCaCl_3$, K_2MgCl_4, K_2BaCl_4, K_2SrCl_4, K_2LaCl_5, K_3PrCl_6, K_3NdCl_6, KGd_3Cl_{10}, and KDy_3Cl_{10}. All kinds of mixtures were weighed in a dry box with purified N_2 gas and heated in a quartz tube ($15^{\phi}\times 300^{mm}$) at about 50 °C lower than the melting point in an electric furnace under vacuum, and then raised temperature to melt in Ar atmosphere. After melting thoroughly, the mixtures were solidified in the inclined quartz tube and kept in sealed test tubes.

These samples were ground to 100—300 mesh in an agate mortar in a dry box with purified N_2 gas. Enthalpies of fusion of the samples were measured using DSC on about 20 mg in a platinum pan ($5^{\phi}\times 5^{mm}$) in Ar atmosphere of a flow rate of 50 ml/min at heating rate of 10 °C/min. The enthalpy was measured from the equation

$$\Delta H = KA/M,$$

where ΔH is an enthalpy of fusion per unit weight of a sample, M a weight of a sample, A an area of peak on a recording chart, and K an apparatus constant. As the apparatus constant K was dependent on temperature, it was determined on calibration curve about heat of transition of some NBS-ICTA** standard materials, that is Ag_2SO_4 (transition temp: 412 °C, heat of transition: 6.09 cal/g), K_2SO_4 (583 °C, 11.13 cal/g), and K_2CrO_4 (665 °C, 12.62 cal/g).

Results and Discussion

The results obtained were summarized in Table 1. Experimental enthalpies were measured from endothermic peaks of DSC curves. The calculated values were derived as follows.

Table 1. Experimental and calculated enthalpies of fusion of the intermediate compounds in binary component salts

End components Against KCl	Intermediate compounds (mp/K)	Enthalpies of fusion / kcal mol^{-1}	
		Exptl	Additive value
$MgCl_2$	K_2MgCl_4(688)	8.9	21.4
$MgCl_2$	$KMgCl_3$ (754)	7.9	15.7
$BaCl_2$	K_2BaCl_4(932)	16.4	15.8
$CaCl_2$	$KCaCl_3$(1021)	16.6	13.0
$SrCl_2$	K_2SrCl_4(865)	13.6	14.6
$LaCl_3$	K_2LaCl_5(902)	25.0	25.4
$PrCl_3$	K_3PrCl_6(938)	20.1	30.7
$NdCl_3$	K_3NdCl_6(961)	22.6	30.8
$GdCl_3$	KGd_3Cl_{10}(833)	13.5	
$DyCl_3$	KDy_3Cl_{10}(830)	19.9	

In each binary system, the heat capacities of the end component salts at their melting points were extrapolated to the melting point of the corresponding intermediate compound. The enthalpy values for the compound were estimated from those for the binary compounds by the relation

$$\Delta H_{C,T} = a\Delta H_{A,T} + b\Delta H_{B,T}, \quad (1)$$
$$(aA + bB \rightarrow A_aB_b = C)$$

where ΔH is heat of fusion and T the melting point of the compound C. And

$$\Delta H_{A,T} = \Delta H_{A,mp} + \int_{mp}^{T} \Delta C_p dT, \quad (2)$$

where, ΔC_p is represented by the relation in the reaction $A(s) = A(l)$,

$$\Delta C_p = C_p(l) - C_p(s). \quad (3)$$

$GdCl_3$ (s)	609	9.6				
$DyCl_3$ (s)	654	7				

of the end component chlorides were shown in Table 2.[3-5]

In the systems of KCl–$LaCl_3$ and KCl–$BaCl_2$, the experimental enthalpies of the compounds of K_2LaCl_5 and K_2BaCl_4 were in good agreement with the calculated and value of K_2SrCl_4 were relatively good. These compounds were all 2 : 1 in mole ratio.

The deviation of the experimental enthalpies from the additivity were very small, especially in K_2LaCl_5 and the experimental were only 0.4 kcal/mol lower than the calculated.

Holm *et al.*[6] studied the binary system of KCl–$MgCl_2$ using a drop-calorimeter and reported that the melting points and enthalpies of fusion of the compounds were 705 K, 10.75 kcal/mol and 755 K, 10.33 kcal/mol in K_2MgCl_4 and $KMgCl_3$, respectively.

Kinetics of the Hydrolysis of Zeolite 4A Surface by the Pressure-jump Relaxation Method

Tetsuya IKEDA, Minoru SASAKI, Raymond D. ASTUMIAN, and Tatsuya YASUNAGA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received December 2, 1980)

Synopsis. Single relaxation was found in the basic zeolite 4A suspension by the pressure-jump method. The relaxation phenomenon was attributed to the hydrolysis of the zeolite 4A surface and the kinetic parameters were obtained.

One important property of zeolite 4A is the existence of sodium ion in surface cage-like structures from where ion exchange with other cations such as Ca^{2+}, K^+, and NH_4^+ occurs.[1-3] It has been determined by surface electrical conductivity measurements and by infrared absorption spectra[4-6] that these cages are terminated by surface hydroxyl groups. In solid catalysis the cage of the zeolite plays an important role, giving rise to ion sieve effects, and thus the determination of the mechanism of the ion exchange, as well as that of the specific adsorption of ions into the cage, is of major importance in understanding the ion sieve action in the ion exchange of the zeolites. However, hydrolysis of the surface hydroxyls also occurs, varying the charge density on the framework of the zeolite, and so the dynamic behavior of these hydroxyls, which differs greatly from that of γ-alumina or titanium dioxide[7,8] must be clarified before the mechanism of ionic adsorption and exchange can be well understood. In this paper we present the results of pressure-jump relaxation experiments on the kinetics of zeolite 4A surface hydrolysis.

Experimental

Zeolite 4A ($Na_2O \cdot Al_2O_3 \cdot 2SiO_2 \cdot nH_2O$) was purchased from the Toyo Soda Co., and was purified as previously described.[8] X-Ray diffraction patterns before and after purification showed no change. Aqueous suspensions of zeolite 4A with NaOH were prepared under nitrogen atmosphere and the measurements were performed with particle concentration of 30 g/dm³ at 25 °C after equilibration for 1 d.

The pressure-jump apparatus used is the same one reported previously.[8] The time constant of the pressure-jump was within 80 μs.

Results and Discussion

Kinetic measurements were carried out by the pressure-jump method with conductivity detection on basic aqueous suspensions of zeolite 4A and a single relaxation process of decreasing conductivity with decreasing pressure on the order of s was observed only above the pH≃11.5. Figure 1 shows the concentration dependence of the reciprocal relaxation time, τ^{-1}, and it may be seen that τ^{-1} increases with increasing concentration of hydroxide ion. Since the sodium ion can enter into the cage of zeolite as mentioned above, one of plausible mechanisms of the relaxation phenomenon observed may be the base catalyzed adsorption-desorption process of the sodium ion. However, in the system to which tetramethylammonium hydroxide was added as the base in the same manner, where the tetramethylammonium ion can not enter into the cage,[9] the same relaxation phenomenon was observed. Therefore, it is clear that the relaxation observed is due to the interaction between the hydroxide ion and the active sites on the zeolite surface.

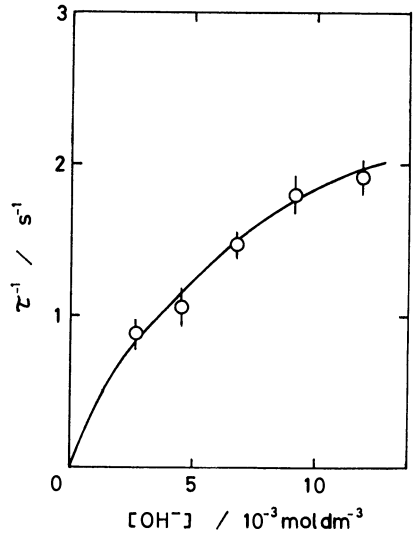

Fig. 1. Dependence of the reciprocal relaxation time on the equilibrium concentration of OH^- in the zeolite 4A–NaOH system at particle concentration of 30 g/dm³ and 25 °C.

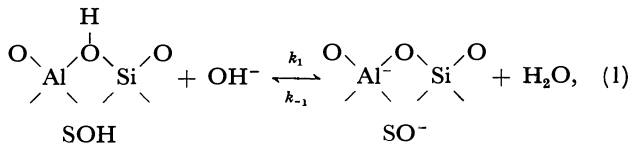
In order to clarify the mechanism of the relaxation, the concentrations of the surface group, SOH, and the dissociated surface group, SO^-, existing on the zeolite

Table 1. Static and kinetic data in aqueous suspensions of zeolite 4A at 25 °C

$\frac{[OH^-]}{10^{-3}\ mol\ dm^{-3}}$	$\frac{[SOH]}{10^{-3}\ mol\ dm^{-3}}$	$\frac{[SO^-]}{10^{-2}\ mol\ dm^{-3}}$	$\frac{\tau^{-1}}{s^{-1}}$	$-pK$
2.63	3.1	1.54	0.88±0.10	3.28
4.57	2.2	1.63	1.06±0.13	3.21
6.76	1.1	1.74	1.47±0.09	3.37
9.12	1.0	1.75	1.80±0.13	3.28
11.8	0.8	1.77	1.91±0.12	3.27

surface were determined from the adsorption isotherm of hydroxide ion[10] and are listed in Table 1. For the hydrolysis of the hydroxyl group on the framework of the zeolite 4A surface in basic region, the following scheme can be written



where k_1 and k_{-1} are the rate constants of the adsorption and the desorption of hydroxide ion, respectively. Henceforth, we use SOH and SO^- for the two surface species, as indicated above. In the present pH region, as can be seen from Table 1, the zeolite surface may be assumed to be fully occupied by the dissociated surface group, with the value of the equilibrium constant calculated from $K(=[SO^-]/[SOH][OH^-])$ being nearly constant. The constancy of the pK's supports the validity of the above assumption. Thus, in the determination of the mechanism we ignored the effect of the variable surface potential. Under the constant surface potential, the equation of τ^{-1} in the above scheme is given by

$$\tau^{-1} = k_1([SOH]+[OH^-]) + k'_{-1}, \quad (2)$$

with

$$k'_{-1} = k_{-1}[H_2O]. \quad (3)$$

The plot of τ^{-1} *vs.* the concentration term of Eq. 2 yields a straight line as shown in Fig. 2. The linearity of this plot confirms the plausibility of the mechanism assumed above. From the slope and the intercept of the line, the values $k_1=1.6\times10^2$ mol^{-1} dm^3 s^{-1} and $k'_{-1}=8.7\times10^{-2}$ s^{-1} respectively, were obtained and the value of negative log of the kinetic equilibrium constant, pK', was determined to be -3.26 from the ratio of the obtained rate constants.

The kinetic equilibrium constant is in good agreement with the static equilibrium constant obtained from the adsorption isotherm. Therefore, this fact also justifies the mechanism described above. Thus, we are led to the conclusion that the relaxation phenomenon observed

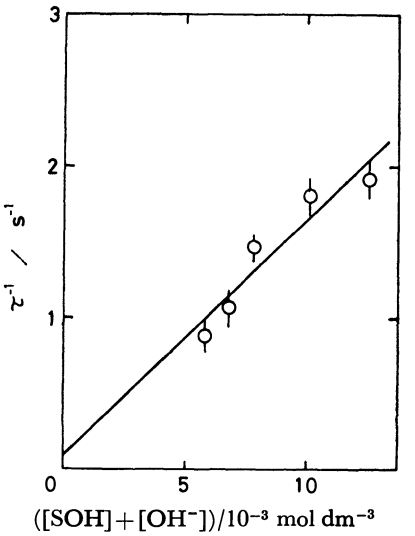


Fig. 2. The plot of τ^{-1} *vs.* the concentration term in Eq. 2.

can be attributed to the adsorption-desorption process of OH^-, *i.e.*, hydrolysis on the zeolite 4A surface.

The Spectrophotometric Determination of Zirconium(IV) by Solvent Extraction with Trioctylphosphine Oxide and Benzophenone

Yasumasa SHIGETOMI and Takehiro KOJIMA*

Department of Chemistry, Okayama College of Science, Ridai-cho, Okayama 700

(Received August 30, 1980)

Synopsis. The colorimetric determination of zirconium(IV) was investigated by means of liquid-liquid extraction, where zirconium in a nitric-acid solution was quantitatively extracted into molten TOPO–benzophenone at about 60 °C. The organic phase solidifies on cooling and is separated and dissolved in methanol. The addition of an ethanolic solution of 1-(2-pyridylazo)-2-naphthol to this solution yields as intense red colour.

Recently, spectrophotometric determination has again, because, with it one is able easily, come to be of interest to determine a number of metals without difficulty. However, one of the major problems is the lack of the specificities of any chromogenic agents except bathophenanthroline, 1,10-phenanthroline, *etc.* On the other hand, tributyl phosphate (TBP), tributylphosphine oxide (TBPO), and trioctylphosphine oxide (TOPO) are well known as selective extractants.[1-4] Also, solvent extraction by using naphthalene or benzophenone has the disadvantage that it must be carried out at a comparatively high temperature (70 °C), but it has the merit that metal ions can be extracted with less volume than when a liquid solvent is used, for, upon cooling, the organic phase separates out as a solid.[5-8]

In this investigation, we studied the selective spectrophotometric determination method of zirconium, combined with such a selective extraction and a conventional colour development.[9]

Experimental

Reagents and Apparatus. All the reagents were of an analytical grade. The standard zirconium(IV) solution was prepared by dissolving 0.2767 g of zirconium nitrate in ion-exchanged water and by then diluting the solution to 100 cm^3. Stock solutions of the other metal salts were prepared by dissolving salts in 0.1 mol dm^{-3} hydrochloric acid or nitric acid. The trioctylphosphine oxide (TOPO), tributylphosphine oxide (TBPO), tris(2-ethylhexyl)-phosphine oxide (TEHPO), and triphenylphosphine oxide (TPPO) were used without further purification. The absorbancy curves of the solution contained in a 1-cm matched-glass cell were measured with a Hitachi 101 spectrophometer.

Procedure. Transfer a solution containing 0—230 μg of zirconium into a 100-cm^3 Erlenmeyer flask with a tight-fitting stopper, and adjust the acidity of the solution to 2 mol dm^{-3} with nitric acid. Add 100 mg of TOPO and 300 mg of benzophenone. Heat the flask on a water bath at about 60 °C untile the TOPO phase melts completely, and then shake it vigorously for 2 min. Remove the flask from the bath, cool the molten extractant rapidly while stirring in cold water, and separate the resulting solidified extract in granular form from the aqueous solution by filtration. Wash the extract several times with water and transfer it to a 10-cm^3 volumetric flask containing 1 cm^3 of a 1-(2-pyridylazo)-2-naphthol (PAN) solution and 0.5 cm^3 of a triethanolamine solution. Dilute the solution to the mark with methanol. Shake well and measure the absorbance of the solution at 545 nm against a reagent blank.

Results and Discussion

Extraction with Various Extractants. The extraction was carried out through the procedures using TOPO, TBPO, TEHPO, and TPPO. TOPO and TBPO would seem to be suitable extractants. However, TBPO interferes with the colour development of zirconium with PAN. Therefore, we used TOPO as an extractant in the following experiments. Also, we simultaneously examined the effect of acidity on the extraction. Zirconium was extracted quantitatively from more than 2 mol dm^{-3} nitric acid. Its extractability from a hydrochloric-acid solution is not so much as that from a nitric-acid solution; for instance, the extraction percentage in a 2 mol dm^{-3} nitric-acid medium showed more than 99%, while that at hydrochloric acid reached only 55% at 50 °C, though it increases with an increase in the temperature and, at 80 °C, reaches 99%.

Effect of Amount of TOPO. The experiments were carried out at temperatures ranging from 50 to 90 °C in order to examine the relation between the amount of TOPO and the extraction percentage. It was found that the elevation of the extraction temperature causes the extractability to increase slightly, and that adding more than 100 mg of TOPO brings to about a quantitative extraction. Further, naphthalene and biphenyl were investigated as diluents instead of benzophenone; however, naphthalene is not sufficiently soluble in methanol, and so it interferes with the colour developing because of forming a opaque solution.

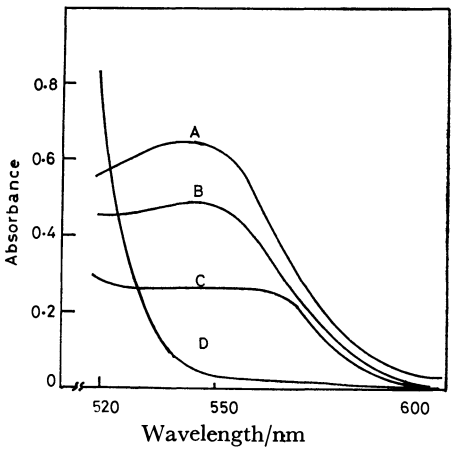

Fig. 1. Absorption curves.
A: 4.6 ppm Zr(IV) *vs.* reagent blank (TOPO), B: 4.6 ppm Zr(IV) *vs.* reagent blank (TBPO), C: 4.6 ppm Zr(IV) *vs.* reagent blank (TEHPO), D: reagent blank *vs.* ethanol, PAN: 1.0 cm^3, buffer: 0.5 cm^3.

Absorption Spectra. Figure 1 show the absorption spectra of the reagent blank and of the PAN–zirconium-(IV) complex in a benzophenone–methanol solution resulting from taking in 46 μg of zirconium through the above procedures. The magnitudes of the absorbance are in this order: TOPO, TBPO, and TEHPO; this order is compatible with that of the extraction percentage. However, no quantitative relation was observed between these values. For instance, the TBPO complex is as extractable as the TOPO one, but the absorbance of the former is only two-thirds that of the latter. We may suppose that TBPO complex is more stable than the TOPO complex; therfore, the exchange reaction does not proceed not so much as in the TOPO complex. Further, we examined how the absorbance varied as a function of the amount of triethanolamine or PAN added. The addition of 0.5 cm^3 of 10% triethanolamine as a buffer sufficed to develop the colour of the zirconium complex. Also, the colour intensity showed a plateau. Adding a large amount of a PAN solution causes the reagent blank to have a colour of a strong intensity. Therefore, the determination was carried out by adding 1 cm^3 of a 0.1% PAN solution to 10 cm^3 of a zirconium solution.

Choice of Solvent. Tests were made with verious solvents in dissolving mixtures of the complex and benzophenone. Such a mixture is soluble in many organic solvents, such as methanol, ethanol, *N,N'*-dimethylformamide, and acetone, but dissolving with cyclohexane, isobutyl methyl ketone, and chloroform formed an opaque solution. Furthermore, to these solutions are also added 1 cm^3 of a 0.1% PAN solution. The spectra observed are shown in Fig. 2. The absorbance is higher in methanol than in the others.

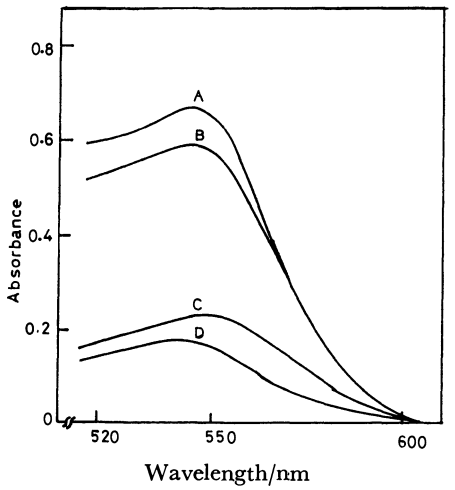

Fig. 2. Effect of the various solvents.
A: CH_3OH, B: C_2H_5OH, C: DMF, D: $(CH_3)_2CO$.
Conditions Zr(IV): 4.6 ppm, PAN: 1.0 cm^3, buffer: 0.5 cm^3, TOPO: 100 mg, benzophenone: 300 mg.

Effects of Diverse Ions. Possible interference was looked for by placing 46 μg of zirconium in 25 cm^3 of a 2 mol dm^{-3} nitric-acid solution. One milligram of the following cations gave no interference; Mg(II), Ca(II), Sr(II), Ba(II), Y(III), La(III), Ce(III), Nd(III), Cr(III), Mn(II), Cu(II), Zn(II), Al(III), Fe(III), V(V), Co(II), and Ni(II), but Sc(III) and U(VI) gave considerable positive interference. As has been mentioned above, the apparent molecular absorptivity, 1.24×10^4 cm^3 mol cm^{-1}, we obtained is not so large as that[10] obtained by combining with the colour development and the solvent extraction with dibutyl hydrogenphosphate. However, zirconium can be determined up to 10^{-5} mol dm^{-3}, as it can be easily concentrated two hundred times by means of the proposed extraction, though allowance must be made for large volumes by shaking for a longer times and by using larger amounts of the extractants.

Dual-wavelength Spectrophotometric Determination of Trace Amounts of Phosphate in the Presence of Large Amounts of Silicate Using Molybdenum Blue

Kousaburo OHASHI,* Toshie ENOMOTO, and Katsumi YAMAMOTO
Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310
(Received September 2, 1980)

Synopsis. A method is described for the determination of trace amounts of phosphate in the presence of large amounts of silicate. It is based on the difference in the absorption spectra of molybdenum blues formed from phosphate and silicate using a dual-wavelength spectrophotometer. The difference in absorbances at 797.3 nm and 825.0 nm is proportional to phosphate concentration over the range 1.60×10^{-7} to 7.00×10^{-5} M (1 M=1 mol dm^{-3}).

The spectrophotometric determinations of phosphate based on the formations of molybdophosphoric acid and molybdenum blue have been widely used. Though many different applications of these methods have been proposed,[1] difficulties are often encountered when two or more ions which can form molybdenum blue are present simultaneously. Many studies on the separation of phosphate from silicate have been reported. Fujinaga *et al.*[2] studied a solvent extractive separation of phosphate from silicate based on the difference in the behavior of molybdophosphoric acid and molybdosilicic acid toward the mixed solvents of 1-butanol–cyclohexane–water and of 1-butanol–isobutyl methyl ketone–water. Recently, a kinetic method for the simultaneous determination of phosphate and silicate, based on the difference in the formation rate of molybdenum blue was reported.[3] This method needs a careful control of the conditions. The present authors have developed a method for the determination of trace amounts of phosphate in the presence of large amounts of silicate based on the difference in the absorption spectra of molybdenum blue formed from phosphate and silicate using a dual-wavelength spectrophotometer.

Experimental

Materials. Molybdenum(VI) solution (1.00×10^{-1} M) was prepared by dissolving 12.09 g of sodium molybdate dihydrate in 500 ml of redistilled water. Working solutions were prepared by dilution with redistilled water to the desired concentrations. Molybdenum(V) ($Mo_2O_4^{2+}$) perchlorate solution was prepared as reported in a previous paper.[4] The concentration of molybdenum(V) solution was determined spectrophotometrically using the molar extinction coefficient ($\varepsilon=103$) at 384 nm.[5] The stock solution of molybdenum(V) perchlorate was stored in a refrigerator. Before use the stock solution was diluted to each desired concentration. This molybdenum(V) solution was stable for at least two months. Phosphate solution was prepared from sodium dihydrogenphosphate dihydrate, and silicate solution by fusing pure silica with anhydrous sodium carbonate. All the other chemicals were of analytical grade.

Apparatus. A Hitachi 356 type dual-wavelength spectrophotometer was used for the measurements of difference in absorbances at two different wavelengths.[6]

General Procedure for the Determination of Phosphate. For each run, 2 ml of 1.0 M perchloric acid, 8 ml of 2.00×10^{-2} M molybdenum(VI), 6 ml of 1.60×10^{-2} M molybdenum(V) in 2.0 M perchloric acid, and 3 ml of 4.00×10^{-4} M phosphate and 5 ml of 3.34×10^{-3} M silicate solutions were pipetted into a 50-ml measuring flask. After dilution to 50 ml with redistilled water, the solution was thermostated for 20 min at 80 °C. Below 8.00×10^{-7} M phosphate, the thermostating time was 50 min at 80 °C. The difference in absorbances at 797.3 nm and 825.0 nm was measured by a dual-wavelength spectrophotometer; two wavelengths were chosen: 825.0 nm, which is the absorption maximum of the molybdenum blue from phosphate; and 797.3 nm, at which the molydenum blue from silicate gives the same molar extinction coefficient as that at 825.0 nm.

Results and Discussion

Absorption Spectra of Molybdenum Blue Formed from Phosphate and Silicate. The absorption spectra of the molybdenum blue formed from phosphate and silicate with a mixture of 1.80×10^{-3} M molybdenum(V) and 3.20×10^{-3} M molybdenum(VI) in 0.28 M perchloric acid are shown in Fig. 1; the spectrum was measured after the solution had been thermostated for 20 min at 80 °C. The absorption maximum of molybdenum blue from phosphate appears at 825 nm (curve (A)). Curve (B) is the absorption spectrum (λ_{max} 810 nm) of the molybdenum blue from silicate. The thermostating for 20 min at 80 °C provides complete formation of molybdenum blue from phosphate, but only a partial formation of molybdenum blue from silicate, because of the small rate of molybdenum blue formation. The effect of the perchloric-acid concentration on the formation of molybdenum blue from phosphate showed that the

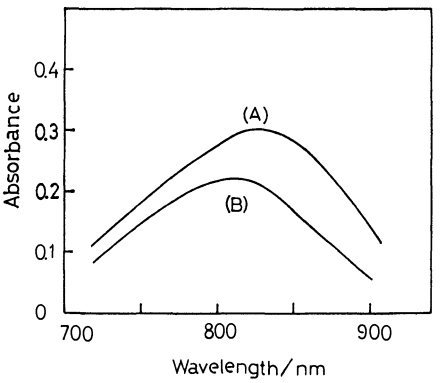

Fig. 1. The absorption spectra of molybdenum blues. (A): 1.60×10^{-5} M phosphate, (B): 2.00×10^{-4} M silicate (SiO^{2+}), both with 3.20×10^{-3} M Mo(VI), 1.80×10^{-3} M Mo(V), 0.28 M $HClO_4$. The absorption spectra (A) and (B) were measured after thermostating 20 min at 80 °C.

maximum absorbance was obtained in the range from 0.20 to 0.41 M with 2.90×10^{-5} M phosphate, 1.76×10^{-3} M molybdenum(V), and 3.20×10^{-3} M molybdenum(VI) by thermostating at 80 °C for 20 min. The rate of the formation of molybdenum blue from silicate decreases with the increase in the perchloric-acid concentration in the range from 0.25 to 5.0 M. For concentrations below 0.20 M perchloric acid, molybdenum(VI) reacts with molybdenum(V) to give isomolybdenum blue. In this work the perchloric-acid concentration of the reaction solution was adjusted to 0.28 M, and the reaction solution was thermostated for 20 min. Almost the same concentrations of molybdenum(V) and molybdenum(VI) as used previously for the determination of phosphate[4] were adopted for the determination of phosphate using a dual-wavelength spectrophotometer.

Calibration Curve. The calibration curve was obtained by the general procedure for the determination of phosphate. The calibration curve is linear in the phosphate range of 1.60×10^{-5} to 7.00×10^{-5} M (0—1.0 full scale), 1.80×10^{-6}—8.00×10^{-6} M (0—0.1 full scale), and 1.60×10^{-7}—8.0×10^{-7} M (0—0.01 full scale).

Table 1. Determinations of phosphate in the presence of 3.34×10^{-4} M silicate

PO_4^{3-} added/M	PO_4^{3-} found/M	Error/%
6.3×10^{-7}	5.8×10^{-7}	−9.2
2.4×10^{-6}	2.3×10^{-6}	−4.2
6.3×10^{-6}	6.6×10^{-6}	4.8
9.8×10^{-6}	9.7×10^{-6}	−1.0
3.0×10^{-5}	2.9×10^{-5}	−3.3

$[Mo(V)]=3.20\times10^{-3}$ M, $[Mo(V)]=1.80\times10^{-3}$ M, $[HClO_4]=0.28$ M.

Table 1 shows the results of the determination of phosphate in the presence of 3.34×10^{-4} M silicate.

Effect of Diverse Ions. The effect of diverse ions on the determinations of phosphate was previously examined in detail.[4] In the present work, these effects were not reexamined. Metal ions such as Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}, Fe^{3+}, Al^{3+}, Cr^{3+}, and UO_2^{2+} do not interfere with the determination of phosphate, in concentrations up to *ca.* 100 molar amounts. The presence of more than 500 molar amounts of Fe^{3+} can be tolerated by adding sodium hydrogensulfite solution. The presence of an equimolar amount of As(V) interferes somewhat with the determination of phosphate.

Determination of Phosphate in the Hinuma River. One liter of the sample was evaporated to 100 ml. A 10 ml of 1.6 M HNO_3 was added to the solution, and then the solution was evaporated to 20 ml on a sand bath. After neutralization with sodium hydroxide solution and dilution to 100 ml with redistilled water the solution was filtered. The phosphate concentration was determined by the general procedure. The phosphate concentration was found to be 7.0×10^{-6} M.

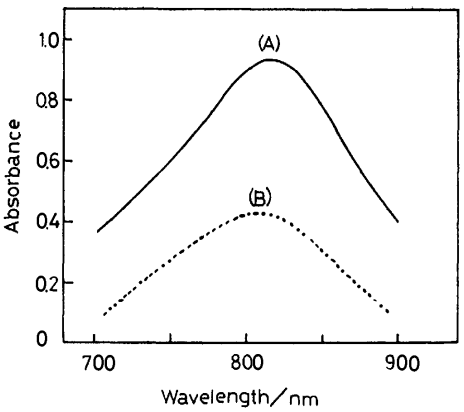

Fig. 2. The absorption spectra of molybdenum blue. (A): 12 ml of the 10-fold concentrated sample, conditions as for Fig. 1. (B): Absorption spectrum obtained by the subtraction of the spectrum of molybdenum blue obtained using the determined phosphate concentration from a curve (A).

Curve (A) in Fig. 2 is the absorption spectrum of the molybdenum blue formed by the general procedure for the color development of molybdenum blue. Curve (B) is the absorption spectrum obtained by subtraction of the absorption spectrum of the molybdenum blue prepared using the phosphate concentration determined from curve (A). The spectrum coincides with that of the molybdenum blue from silicate. A trace amount of phosphate in the Hinuma River, which contains large amounts of soluble silicate, was determined by the present method.

The method described here will be widely applicable to the determination of phosphate in samples containing silicate.

Phosphorylation with Pyrophosphoric Acid

Hachiro YAMAGUCHI,* Fumio OGURA, Tetsuo OTSUBO, and Yasuhiro IKEURA

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Naka-ku, Hiroshima 730

(Received October 27, 1980)

Synopsis. Dihydrogenphosphates of primary and secondary aliphatic alcohols as well as phenol were prepared by a very simple procedure with pyrophosphoric acid. *t*-Butyl and benzyl dihydrogenphosphates could be obtained by a slight modification of the reaction conditions. For the purpose of phosphorylation pyrophosphoric acid was more reactive than orthophosphoric acid.

Organic phosphoric acid esters play a very important role in many fields of organic and biological chemistry, and they are attractive objectives in synthetic organic chemistry. Various synthetic methods and reagents for phosphorylation have been used.[1] Pyrophosphoric acid (abbreviated below as PPA) as well as polyphosphoric acid has been used as a phosphorylating agent by many workers. To elucidate and utilize the presumed remarkable phosphorylating ability of PPA,[2] we also studied its reaction with various alcohols and phenol. Mere by mixing and warming with equimolar PPA, primary and secondary aliphatic alcohols as well as phenol afforded the dihydrogenphosphates, which were isolated as Ba salts and identified as anilinium salts (Table 1). The effect of temperature on the yield of phosphate was studied with reference to EtOH, and the highest yield was obtained at *ca.* 90 °C. Bisethylation became apparent above the temperature and the yield of diethyl ester gradually increased from 1.4% (80 °C) to 7.8% (140 °C). Orthophosphoric acid (100%) gave $EtOPO_3H_2$ in only 2.3% yield at 90 °C.[3] This result clearly indicated the higher reactivity of PPA than H_3PO_4. With regards to secondary alcohols, considerable dehydration occured at higher temperature to decrease the yield of $ROPO_3H_2$.[4] *t*-Butyl and benzyl alcohols did not give the desired phosphates by the simple procedure. But in the presence of CCl_3CN and 2 molar Et_3N, phosphorylation proceeded successfully to yield dihydrogenpyrophosphates, which were isolated as cyclohexylammonium salts and converted to anilinium hydrogenphosphates by ion exchange and concomitant hydrolysis (Table 1). The active phosphorylating agent was probably the imidoylpyrophosphate, which was formed from the PPA dianion and CCl_3CN and reacted with alcohols to give pyrophosphates and trichloroacetamide.[1b,6]

Experimental

Apparatus and Measurements. The melting points were

a) See Ref. 5. b) Corresponding dianilinium salt was reported, but we could not obtain it.

measured on a Yanagimoto MP-J3 apparatus and corrected. The IR spectra (KBr) were obtained on a JASCO IR-S spectrometer. The ^{1}H-NMR spectra were recorded on a JEOL PMX-60 spectrometer in D_2O using DSS as an internal standard, unless otherwise stated, and given in δ units.

Procedures and Results. Pyrophosphoric acid was prepared from 86% H_3PO_4 (199 g) and P_2O_5 (188 g) as colorless crystals (360.8 g, 97.3%).[7] The spectral data and melting points for all the anilinium hydrogenphosphates were summarized in Table 1. All the compounds described in this paper gave satisfactory elementary analyses. The equivalent weights of Ba salts determined by acid titration (Methyl Orange) were in good agreement with the calculated values. Dihydrogenphosphates of primary and secondary aliphatic alcohols and phenol were prepared by essentially the same procedure described below for the typical ethyl alcohol case.

Ethyl Dihydrogenphosphate: Ethanol (5.0 g, 108.5 mmol) was added dropwise to PPA (18.36 g, 103.2 mmol) with stirring. The mixture was warmed up to 90 °C and kept for 60 min. After cooling down and dilution with water (80 ml), the reaction mixture was neutralized with saturated aqueous $Ba(OH)_2$ (phenolphthalein) and the precipitated $Ba_3(PO_4)_2$ was filtered. Carbon dioxide was bubbled into the filtrate until the red color of indicator disappeared. Then the mixture was again filtered to remove $BaCO_3$ and concentrated under reduced pressure. The residue was triturated with EtOH to obtain $EtOPO_3Ba$ as colorless crystals (21.8 g, 76.9%). The Ba salt (3 g) was dissolved in water (200 ml) and treated with Na_2CO_3 (1.22 g). After removal of $BaCO_3$, the filtrate was subjected to ion exchange (Amberlite CG 120 H^+ form) to yield the free dihydrogenphosphate. The eluent was mixed with a slight excess aniline and concentrated under reduced pressure. The crude crystals (1.76 g) of anilinium ethyl hydrogenphosphate were washed and recrystallized with acetone. As an alternative and simple procedure, the salt could be prepared by treatment of $EtOPO_3Ba$ with equimolar anilinium sulfate in water. Anilinium diethyl phosphate; mp 72—75 °C; IR: 2860 (νNH_3), 1500 (δNH_3), 1200 (νP=O), 1050 (νP–O–C) cm^{-1}; ^{1}H-NMR ($CDCl_3$, TMS): 1.21 (t, J= 7 Hz, 6H, CH_3), 3.92 (ap. quin, J=7 Hz, J_{HP}=8 Hz, 4H, CH_2), 7.03—7.50 (m, 5H, aromatic), 9.36—9.83 (m, 3H, NH).

2-Hydroxyethyl Dihydrogenphosphate: Crude Ba salt (4.74 g), obtained as a mixture of mono-, bis-, and cyclic phosphates by the reaction (1 h) of $HOCH_2CH_2OH$ (2.23 g, 35.5 mmol) and PPA (6.24 g, 34.7 mmol) at 100 °C, was mixed with $Ba(OH)_2$ (3.43 g, 20 mmol) in water (150 ml) and heated to reflux for 30 min. After cooling down, the mixture was neutralized (phenolphthalein) with CO_2 and filtered to remove $BaCO_3$. The filtrate was concentrated under reduced pressure and the residue was triturated with methanol to crystallize the desired salt, $HOCH_2CH_2OPO_3Ba$ (4.92 g, 51.1%); cyclohexylammonium salt; mp 165—167 °C.[1c]

The Yields of Other Ba Salts were Shown Below with the Reaction Temperatures of Synthses: Methyl, 65 °C, 80.6%; propyl, 90 °C, 84.3%; butyl, 90 °C, 70.6%; isopropyl, 90 °C, 60.9%; *s*-butyl, 50 °C, 30.7% (60 °C, 10.5%; 90 °C, 0%); cyclohexyl, 80 °C, 49.5%; phenyl, 70 °C, 22.3%.

t-Butyl Dihydrogenphosphate: To the mixture of PPA (5.08 g, 28.5 mmol) and CCl_3CN, Et_3N (5.77 g, 57.1 mmol) was added. *t*-Butyl alcohol (8.44 g, 114.1 mmol) was added dropwise to this mixture and warmed at 35 °C for 60 min with stirring. The reaction mixture was poured into cyclohexylamine (20 g, 200 mmol) in acetone (200 ml) and stored in a freezer overnight. Light yellow precipitates obtained were washed with chilled acetone and recrystallized from EtOH (100 ml) containing cyclohexylamine (10 ml). By a usual ion exchange followed by neutralization with aniline, the salt was converted to the anilinium salt, which was recrystallized from acetone (0.78 g, 11.1%.) The crystals were identical with the authentic specimen synthesized.[6b]

Benzyl Dihydrogenphosphate: The mixture of PPA (5.15 g, 28.9 mmol), CCl_3CN (25.2 g, 175 mmol) and Et_3N (5.84 g, 57.8 mmol) was stirred for 60 min at room temperature. Benzyl alcohol (12.50 g, 115.7 mmol) was added to the mixture and heated to 75 °C for 2 h with stirring . The reaction mixture was poured into water and extracted with ether. The aqueous layer was mixed with cyclohexylamine (20 g, 200 mmol) and concentrated *in vacuo*. The residue was recrystallized from water (60 ml) to yield the bis(cyclohexylammonium) dibenzyl pyrophosphate. Vacuum concentration of the mother liquor afforded the cyclohexylammonium dibenzyl phosphate, which was recrystallized from acetone–H_2O (2 : 3 v/v). Both of the crystals were converted to the free acids by ion exchange and neutralized with aniline to yield dianilinium dibenzyl pyrophosphate (1.39 g, 8.8%, mp 151—153 °C; ^{1}H-NMR: 4.83—5.10 (m, 4H, CH_2), 7.20—7.68 (m, 20H, aromatic)) and anilinium dibenzyl phosphate (1.00 g, 9.3%, mp 115—117 °C; ^{1}H-NMR ($CDCl_3$, TMS): 5.78 (d, J_{HP}=7 Hz, 4H, CH_2), 6.93—7.42 (m, 15H, aromatic), 8.03—8.45 (m, 3H, NH_3)) respectively. The aqueous solution (160 ml) of free dibenzyl pyrophosphate (2.24 mmol) was refluxed for 2 h to obtain the benzyl dihydrogenphosphate, which was identified as anilinium salt (1.6 mmol).[5,6a]

The authors are grateful to Mr. Masayuki Watanabe for his assistance in purifying the anilinium benzyl hydrogenphosphate.

Synthesis of 7-Halo-6*H*-benz[*cd*]azulen-6-ones

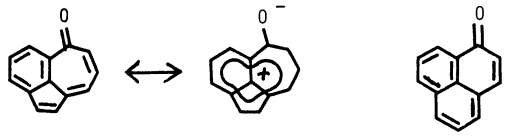
Shigeyasu KURODA,* Masaru SUGIMORI, Shinya KAWAHIGASHI, Nobuo MATUZAKI, Toshihiro NISHIYAMA, and Syuzi HIROOKA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka, Toyama 933

(Received September 24, 1980)

Synopsis. 7-Bromo-6*H*-benz[*cd*]azulen-6-one, 7-Chloro-6*H*-benz[*cd*]azulen-6-one and its derivative were prepared in four steps starting from tetrahydroacenaphthene. Formation of the corresponding cations in strong acid is suggested on the basis of ^{1}H NMR and UV spectra.

6*H*-Benz[*cd*]azulen-6-one (**A**), one of the isomers of phenalenone (**B**),[1] was synthesized from acenaphthene,[2] but although its physical properties were reported no ^{1}H NMR spectral data were given on its cation. Because of the poor yield, chemical and biological properties have not been examined. We wish to report an alternative preparation of the title compounds in good yields, together with the ^{1}H NMR and UV spectra of their cations in strong acid.



(A) (B)

The reaction of 2*a*,3,4,5-tetrahydroacenaphthen-5-one (**1**)[3] with triethyl orthoformate in the presence of a catalytic amount of *p*-toluenesulfonic acid gave enol ether (**2**) as colorless crystals. Dihalocyclopropanation[4] of **2** proceeded smoothly by using chloroform and bromoform in the presence of potassium *t*-butoxide in cyclohexane to give dihalocyclopropyl ethers (**3a**) and (**3b**) as colorless needles in 73% and 25% yields, respectively. Treatment of **3a** and **3b** with silver nitrate in aqueous methanol[5] afforded ring expanded halo enones (**4a**) and (**4b**) as colorless needles in 64% and 66% yields, respectively. Treatment of **4a** with *o*-chloranil in refluxing benzene gave a trace amount of the desired fully conjugated compound (**5a**) together with colorless crystals (**6**), presumably formed by cyclo-addition of the ene moiety of **4a** with *o*-chloranil.[6] Dehydrogenation of **4a** was achieved by using 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in refluxing dioxane to give **5a** as reddish needles in 75% yield. Bromo compound **4b** also gave (**5b**) under the same reaction conditions. Dehydrogenation of **4a** with *N*-bromosuccinimide (NBS) afforded 2-bromo-7-chloro compound (**7**) as deep red needles in 58% yield. Its structure was assigned by comparison of ^{1}H NMR spectra with those of **5a**. The fact that the treatment of **5a** with NBS resulted only in the recovery of the starting material is significant as regards the mechanism of formation of **7**. The ^{1}H NMR and UV spectra of **5a**, **5b**, and **7** in strong acid such as concd sulfuric acid suggest the formation of cations **5a**′, **5b**′, and **7**′, respectively. The chemical shifts of **5a**, **5b**, and **7** in concd H_2SO_4 are about 0.6—1.6 ppm lower than those in $CDCl_3$ (Table 1). The UV spectra of these compounds in the acid show absorption maxima at around 550—600 nm, in a greater wavelength by *ca.* 200 nm than those in EtOH. These cations regenerated the original ketones quantitatively when diluted with a large amount of water.

spectrometer, IR spectra on a JASCO IRA-1, UV spectra on a Hitachi EPS-3T spectrometer, and ^{1}H NMR on a JEOL JNM-MH-100 (100 MHz) and Hitachi R-24B (60 MHz) spectrometer in deuteriochloroform and concd sulfuric acid containing tetramethylsilane and dichloromethane as an internal standard, respectively.

2a,3-Dihydro-5-ethoxyacenaphthene (2). Triethyl orthoformate (72 ml, 0.44 mol) and *p*-toluenesulfonic acid (0.72 g) were added at 25 °C to a solution of ketone (**2**)[3] (28 g, 0.16 mol) in dry ethanol (540 ml). The mixture was stirred at room temperature for 12 h and then distilled under reduced pressure to give 33 g (98%) of enol ether (**2**); bp 110—112 °C/5 Torr, (1 Torr=133.322 Pa), which crystallized on standing. Recrystallization from ethanol gave colorless needles; mp 79—81 °C. IR (neat) 2950, 1630 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 7.85—7.20 (m, 4H), 4.70 (q, 2H, J=7.2 Hz), 3.52 (m, 4H), 2.40 (m, 1H), 1.45 (t, 3H, J=7.2 Hz), 1.52 (m, 1H); MS *m/e* 200 (M$^+$). Found: C, 83.93; H, 7.79%. Calcd for $C_{14}H_{16}O$: C, 83.96; H, 8.05%.

Dichlorocyclopropanation of 2. Potassium *t*-butoxide (20 g, 18 mmol) was added to a solution of 3.7 g (19 mmol) of **2** in 90 ml of dry cyclohexane, and the solution was cooled to 10 °C in an ice bath. Freshly distilled chloroform (50 g, 42 mmol) was then added to the solution over a period of 12 h. After addition of 100 ml of water, the mixture was extracted with chloroform and worked up in the usual way. The crude product was chromatographed on silica gel (hexane and benzene, 1 : 1) to give 4.8 g (73%) of **3a**, which was recrystallized from hexane to give colorless needles; mp 98—100 °C; IR (KBr) 3020, 2950, 1540 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 7.42 (m, 3H), 3.52 (q, 2H, J=7.2 Hz), 3.12 (m, 1H), 2.86 (m, 3H), 2.32 (m, 1H), 2.04 (m, 1H), 1.52 (m, 1H), 1.16 (t, 3H, J=7.2 Hz); MS *m/e* 284 (M$^+$). Found: C, 63.70; H, 5.79%. Calcd for $C_{15}H_{16}Cl_2O$: C, 63.62; H, 5.70%.

Dibromocyclopropanation of 2. The dibromo compound (**3b**) was prepared from **2** (6.0 g 30 mmol) by the same method as described above in 25% (2.6 g) yield. It was then recrystallized from hexane to give colorless needles; mp 101—102 °C; IR (KBr) 2960, 1460 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 7.08 (m, 3H), 3.40 (q, 2H, J=8 Hz), 3.04 (m, 1H), 2.76 (m, 3H), 2.24 (m, 1H), 1.44 (m, 1H), 1.14 (t, 3H, J=8 Hz); MS *m/e* 372 (M$^+$). Found: C, 48.13; H, 4.31%. Calcd for $C_{15}H_{16}Br_2O$: C, 48.42; H, 4.33%.

7-Chloro-1,2,6,9,9a-pentahydrobenz[cd]*azulen-6-one (4a).* A solution of silver nitrate (18 g, 116 mmol) in 530 ml of water was added to a solution of **3a** (7.3 g, 26 mmol) in 1.5 l of ethanol, and then the resulting solution was refluxed for 24 h. After being worked up in the usual way, the crude product was chromatographed on silica gel (benzene) to give 3.6 g (64%) of **4a** and 2.4 g (33%) of **3a**. A pure sample of **4a** was obtained by recrystallization from hexane as colorless needles; mp 66.2—68 °C; IR (KBr) 1640, 1610 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 7.78 (d, 1H, J=8 Hz), 7.14 (m, 3H), 3.52 (m, 1H), 2.29 (m, 2H), 2.44 (m, 3H), 1.72 (m, 1H); MS *m/e* 220, 218 (M$^+$). Found: C, 71.13; H, 5.15%. Calcd for $C_{13}H_{11}ClO$: C, 71.40; H, 5.07%.

7-Bromo-1,2,6,9,9a-pentahydrobenz[cd]*azulen-6-one (4b).* The bromo compound (**4b**) was obtained from **3b** (2.6 g) by the same method as described above in 66% (1.2 g) yield. It was then recrystallized from ethanol to give colorless needles; mp 87.5—89.5 °C; IR (KBr) 1640, 1610 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 7.80 (d, 1H, J=8 Hz), 7.32 (m, 3H), 3.52 (m, 1H), 2.88 (m, 2H), 2.40 (m, 3H), 1.66 (m, 1H); MS *m/e* 264, 262 (M$^+$). Found: C, 59.18; H, 3.94%. Calcd for $C_{13}H_{11}BrO$: C, 59.34; H, 4.21%.

*7-Chloro-6*H*-benz*[cd]*azulen-6-one (5a)* A solution of **4a** (1.5 g, 6.7 mmol) and DDQ (3.7 g, 16 mmol) in 50 ml of dry dioxane was refluxed for 30 h. The resulting solution was chromatographed on silica gel (benzene) to give 0.39 g (30%) of **5a** and 0.98 g (66%) of **4a**. The yield of **5a** was 75% accumulatively after repetation of the reaction three times with recovered **4a**. Recrystallization from ethanol gave red needles; mp 109—111 °C; IR (KBr) 1620, 1600, 745 cm^{-1}; UV (EtOH) nm (log ε) 240 (4.55), 283 (4.08), 335 (3.43), 385 (4.01); MS *m/e* 216, 214 (M$^+$). Found: C, 72.48; H, 3.18%. Calcd for $C_{13}H_7ClO$; C, 72.74; H, 3.29%.

5a': UV (concd H_2SO_4) nm (log ε) 251 (4.45), 284 (4.17), 292 (4.19), 332 (3.43), 348 (3.48), 402 (3.08), 422 (3.95), 590 (2.59).

*7-Bromo-6*H*-benz*[cd]*azulen-6-one (5b).* A solution of **4b** (0.81 g, 3.1 mmol) and DDQ (1.9 g, 8.2 mmol) in 28 ml of dry dioxane was refluxed for 12 h. The resulting solution was worked up by the same method as described above to give **5b** in 11% (0.09 g) yield and 0.02 g (3%) of recovered **4b**. Recrystallization from ethanol gave deep red needles; mp 123—124.5 °C; IR (KBr) 1610, 1600, 1590 cm^{-1}; UV (EtOH) nm (log ε) 236 (4.60), 275 (4.09), 280 (4.11), 337 (3.83), 385 (4.07); MS *m/e* 260, 258 (M$^+$). Found: C, 59.98; H, 3.00%. Calcd for $C_{13}H_7BrO$: C, 60.26; H, 2.72%.

5b': UV (concd H_2SO_4) nm (log ε) 245 (4.60), 270 (4.36), 291 (4.75), 330 (3.55), 364 (3.31), 408 (3.81), 418 (3.90), 427 (3.96), 450 (3.43), 470 (2.95), 560 (2.59).

*2-Bromo-7-chloro-6*H*-benz*[cd]*azulen-6-one (7).* A solution of 3.1 g (1.4 mmol) of **5a** and 5.0 g (2.8 mmol) of NBS in 45 ml of CCl_4 was refluxed for 3.5 h under irradiation with a 100-W tungsten lamp. The reaction mixture was cooled, filtered and chromatographed on silica gel (benzene) to afford 2.4 g (58%) of **7**, which was recrystallized from ethanol to give deep red needles; mp 171—174 °C; IR (KBr) 1610, 1590, 755 cm^{-1}; UV (EtOH) nm (log ε) 280 (4.19), 336 (3.90), 384 (4.12); MS *m/e* 294 (M$^+$). Found: C, 52.93; H, 1.81%. Calcd for $C_{13}H_6BrClO$: C, 53.19; H, 2.06%.

7': UV (concd H_2SO_4) nm (log ε) 244 (4.49), 269 (4.45), 287 (4.61), 327 (3.70), 360 (3.52), 540 (2.94).

Cycloadduct of 4a with o-Chloranil. A solution of 1.0 g (4.5 mmol) of **4a** and 2.7 g (11 mmol) of *o*-chloranil in 35 ml of dry dioxane was refluxed for 30 h. The solution was cooled, filtered and chromatographed on silica gel (benzene) to give 0.61 g (29%) of **6** and a trace amount of **5a**. Recrystallization from acetone gave colorless needles; mp 250 °C; IR (KBr) 1700 cm^{-1}; ^{1}H NMR (DMSO-d_6-TMS) δ 7.50—6.90 (m, 4H), 2.30—1.70 (m, 7H); MS *m/e* 468 (M$^+$). Found: C, 49.08; H, 2.45; Cl, 38.20%. Calcd for $C_{19}H_{11}Cl_5O$: C, 49.12; H, 2.45; Cl, 38.16%.

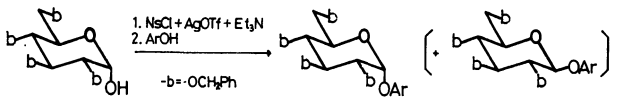
(Received October 8, 1980)

Synopsis. An α-glucosylation of phenols with 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose is described. This uses a mixture of *p*-nitrobenzenesulfonyl chloride, silver trifluoromethanesulfonate and triethylamine in dichloromethane in a two-stage treatment.

Continuing our study of glucosylation using 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose (**1**),[1] we have found a novel α-glucosylation of phenols in two stages, as shown by Eq. 1. Although there have been several procedures reported for α-glucosylation of phenols,[2] the recommended one seems to give the product only in low yields.[3]



Eq. 1

When **1** was pre-treated with an equimolar mixture of *p*-nitrobenzenesulfonyl chloride, silver trifluoromethanesulfonate, and triethylamine in dichloromethane

Table 1. Results of glucosylation of 2-methylphenol[a]

Run	Reaction time/h[b]	Yield/%	
		α-Anomer	β-Anomer
23	0.1	21	7
24	0.5	42	14
2	3.0	47	16
25	5.0	46	17
26[c]	3.0	46	19
27[d]	3.0	14	17

a) The first stage was conducted at −10 °C for 0.5 h. b) Reaction time for the second stage. c) An excess amount (5.0 equiv.) of the phenol was used. d) An equimolar mixture of the phenol and triethylamine in dichloromethane was used.

at −10 °C[1a] and then reacted with phenol, we found that phenyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranoside (**2**) was formed predominantly. This is in contrast with the fact that a similar glucosylation of alkanol with **1** gave β-anomer preferentially.[1a,b] The ratio of anomers measured by ^{1}H NMR spectroscopy in the case of 2-methylphenol was constant throughout the reaction (Table 1). Various phenols were glucosylated with **1** in a similar way (Table 2). Except for 2,6-dimethylphenol, α-glucosides were formed prepondantly. But in the reaction of **1** with triethylammonium 2-methylphenolate, the β-glucoside was formed in a significant yield.

Our procedure is useful for preparing a compound such as 4-phenoxylcarbonylphenyl α-D-glucopyranoside (**25**), which was prepared through glucosylation of the phenol with **1** and subsequent catalytic hydrogenolysis to remove benzyl groups.

Experimental

Specific rotations were measured at 20 °C in a 1-dm cell. Column chromatography was carried out on silica gel (Kanto Kagaku). Silica gel (Merck, No. 7731) was used for TLC.

General Procedure for Glucosylation. To a mixture of **1** (270 mg, 0.5 mmol), *p*-nitrobenzenesulfonyl chloride (122 mg, 0.55 mmol), and silver trifluoromethanesulfonate (141 mg, 0.55 mmol) in dichloromethane (2.7 ml), triethylamine (77 μl, 0.55 mmol) was added at −10 °C. After stirring for 0.5 h, a phenol (0.65 mmol) was added to the mixture, which was then stirred for 3 h at 0 °C. After filtration the reaction mixture was chromatographed using appropriate solvent systems (Table 2) to give aryl 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranoside. Usually, the β-anomer was isolated as a by-product.

Anomeric Phenyl 2,3,4,6-Tetra-O-acetyl-α- and β-D-glucopyranosides ***24*** *and* ***24β***. An anomeric mixture (70 mg) of **2** and **2β** (Run 1) was hydrogenated in acetic acid (3 ml) containing water (1 ml), methanol (3 ml), and palladium black (80 mg, Wako) at 340 kPa, acetylated with acetic anhydride and pyridine, and then chromatographed using benzene containing butanone (gradient) to give first **24** (35 mg): mp 113—114 °C; $[\alpha]_D$ +165° (*c* 1, $CHCl_3$) [lit,[4] mp 115 °C; $[\alpha]_D^{20}$ +169.7° (*c* 2, $CHCl_3$)], and then **24β** (8 mg): mp 124.5—125.5 °C; $[\alpha]_D$ −21° (*c* 0.6, $CHCl_3$) lit,[4] mp 125—126 °C; $[\alpha]_D^{20}$ −22.5° (*c* 2, $CHCl_3$).

*4-(Phenoxycarbonyl)phenyl α-D-Glucopyranoside (****25****).* Compound **17** (60 mg, 0.8 mmol) was hydrogenated in acetic acid (3.7 ml) containing methanol (3.5 ml), water (1.2 ml), and palladium black (60 mg) at 340 kPa overnight, purified chromatographically using chloroform containing methanol (20%), and crystallized from ethanol to give **25** (26 mg, 84%): 155—157 °C; $[\alpha]_D$ +151° (*c* 0.7, MeOH). Found: C, 60.04; H, 5.38%. Calcd for $C_{19}H_{20}O_8$: C, 60.63; H, 5.36%.

Alternative Synthesis of ***2*** *and* ***2β***. A mixture of phenyl α-D-glucopyranoside (60 mg, 0.23 mmol), benzyl bromide (Tokyo Kasei 0.86 ml), barium oxide (1.08 g), and barium hydroxide octahydrate (0.42 g) in *N,N*-dimethylformamide (1.2 ml)[5] was stirred at 25 °C overnight, filtered, and evaporated *in vacuo*. The residue was chromatographed using benzene containing butanone (2%) to give **2** (53 mg, 56%), $[\alpha]_D$ +83° (*c* 3.0, $CHCl_3$).

Phenyl β-D-glucopyranoside[4] (0.54 g, 2.1 mmol) was converted in a similar way into **2β** (0.44 g, 34%): mp 83.5—85 °C; $[\alpha]_D$ −13° (*c* 0.4 EtOH), −12° (*c* 1.0, $CHCl_3$) [lit,[6] mp 82 °C; $[\alpha]_D^{18}$ −13.5° (EtOH)].

A Convenient Preparation of Some *N*-Alkylcarbazoles and *N*-Alkylacridones

Hisao Nishi,* Hisao Kohno, and Toshihiro Kano

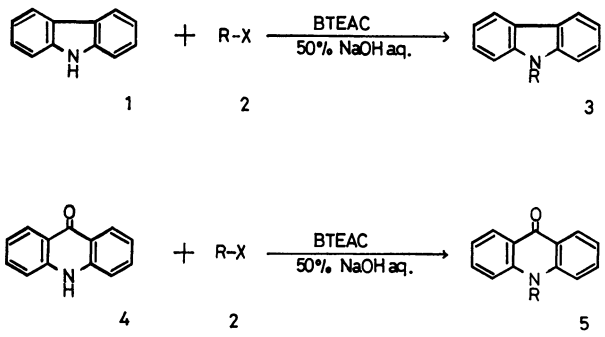
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-Okubo, Urawa 338

(Received October 24, 1980)

Synopsis. *N*-Alkylation of aromatic compounds involving nitrogen heterocycles such as carbazole and acridone with alkyl halide in the presence of caustic solution and benzyl triethyl ammonium chloride (BTEAC) as a phase-transfer catalyst readily proceeded under mild conditions. These results show that this procedure is effective for the preparation of the title compounds in high yields.

A few investigations of *N*-alkylation of aromatic compounds involving nitrogen heterocycles with alkyl halide under phase-transfer catalytic conditions have been reported. Makosza,[1] for example, synthesized some *N*-alkylindoles and *N*-butylcarbazole by the use of phase-transfer catalysis in more than 80% yield under mild conditions. On the other hand, Kricka *et al.*[2] studied the synthesis of *N*-alkylcarbazoles, which were prepared by the reaction of carbazole, alkyl halide, and thallium(I) ethoxide under mild conditions.

Recently, Galy *et al.*[3] have reported the reaction of acridone with alkyl halide by the use of the phase-transfer catalysis under severe conditions (refluxing in toluene for 5 d). This procedure afforded a mixture of *N*-alkylacridones (41—65%) and *O*-alkyl-acridones.



Scheme 1.

In the course of our synthetic studies of nitrogen heterocycles as intermediates of dyes and pigments, we have attempted to extend the phase-transfer catalytic reaction on *N*-alkylation of carbazole and acridone derivatives. We selectively obtained the desired *N*-alkyl compounds in high yields under milder conditions than those in Galy's procedure. *N*-Alkylation takes place as shown in Scheme 1.

The results are summarized in Table 1.

Experimental

The products were identified by the examinations of their melting points and N elemental analysis. Typical procedures are as follows:

*9-Methylcarbazole (**3a**).* To a mixture of 10.03 g (0.06 mol) of carbazole, 35 ml of aqueous 50% sodium hydroxide, 5 ml of benzene as a solvent and 410 mg (1.8 mmol) of BTEAC, a 5.6 ml (0.09 mol) of methyl iodide was added dropwise under stirring. It was continued at room temperature for 2 h. The reaction mixture was poured into hot water and left overnight at room temperature. The precipitated solid was collected, washed with water and dried. Recrystallizations from ethanol afforded 8.95 g of colorless plates (mp 88—89 °C) in the yield of 82.3%.

*10-Methylacridone (**5a**).* Methyl iodide (1.64 ml, 0.0263 mol) was added dropwise under stirring to a mixture of 3.42 g (0.0175 mol) of acridone, 13.5 ml of aqueous 50% sodium hydroxide, 13.6 ml of ethyl methyl ketone as a solvent, and 120 mg (0.527 mmol) of BTEAC, and was stirred at 55—60 °C for 3 h. The reaction mixture was poured into hot water, and separated solid worked up in the manner used for **3a**. Recrystallizations from ethanol provided 3.30 g of pale yellow needles (mp 200—201 °C) in the yield of 82.7%.

Homogeneous Hydrogenation of α,β-Unsaturated Ketones and Aldehydes Catalyzed by $Co_2(CO)_8$–Di(tertiary phosphine) Complexes

Kazuhisa MURATA* and Akio MATSUDA

National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Tsukuba, Ibaraki 305

(Received November 26, 1980)

Synopsis. The cobalt complexes modified by some di(tertiary phosphine)s as ligands were found to be much more active catalysts than $Co_2(CO)_8$ for the hydrogenation of α,β-unsaturated ketones and aldehydes under hydroformylation conditions.

When an α,β-unsaturated ketone or aldehyde is treated with a cobalt catalyst under hydroformylation conditions, the olefinic linkage is hydrogenated rather than hydroformylated.[1] However, since the rate of hydrogenation is much slower than that of hydroformylation, little attention has been paid to the cobalt-catalyzed hydrogenation.

Recently, we reported that complexes prepared *in situ* from $Co_2(CO)_8$ and various di(tertiary phosphine)s are more active catalysts for the homogeneous hydroformylation of methyl acrylate than $Co_2(CO)_8$.[2] We find that these cobalt complexes can be successfully used as catalysts effective for the hydrogenation of α,β-unsaturated ketones and aldehydes to give the corresponding saturated carbonyl compounds. We describe here the results of some of our studies on the hydrogenation under hydroformylation conditions.

$CH_2{=}C(R){-}COCH_3 \longrightarrow CH_3CH(R){-}COCH_3$

1 **2**

$CH_2{=}C(R){-}CHO \longrightarrow CH_3CH(R){-}CHO$

3 **4**

[a: R=H, b: R=CH_3]

The results are listed in Table 1, where the initial rate of the reaction was taken as a measure of the catalytic activity. The hydrogenation of 2-butenone (**1a**) preferentially occurred under the experimental conditions to give 2-butanone (**2a**) in high yield; the catalytic activity of $Co_2(CO)_8$-1,2-bis(diphenylphosphino)ethane(diphos) complex was *ca.* 30 times or above that of $Co_2(CO)_8$[3] (Compare Runs 3 and 6). The reaction can proceed even at a temperature as low as 50 °C (Run 7). $Co_2(CO)_8$–diphos system was effective for the hydrogenation of **1b**, **3a**, and **3b** (Runs

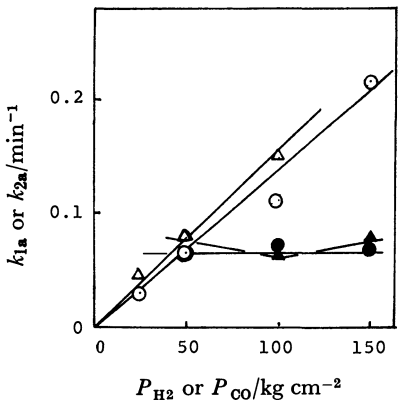

Fig. 2. Effect of partial pressure of hydrogen or CO. Toluene 50 ml, substrate 50 mmol, temp 110 °C, $Co_2(CO)_8$ 1 mmol (**1a**), 2 mmol (**2a**), diphos 0.75 mmol (**1a**), 1.5 mmol (**2a**).
—○—: **1a** (P_{CO}=50 kg/cm², const.), —△—: **2a** (P_{CO}=50 kg/cm², const.), —●—: **1a** (P_{H_2}=50 kg/cm², const.), —▲—: **2a** (P_{H_2}=50 kg/cm², const.).

9, 11, and 13).

In the hydroformylation of methyl acrylate, the maximum activity has been achieved when the molar ratio of diphos to $Co_2(CO)_8$ was *ca.* 0.5—0.75.[2] The results listed in Table 1 (Runs 1—6) are similar to this. The effect of phosphine structure on the activity was examined: the order of reactivity was in accordance with that of hydroformylation.[4]

Using **1a** and **2a**, kinetic behaviors were briefly examined. The rate of hydrogenation exhibits a first order dependence on the concentration of **1a** or **2a**, the rate constant k_{1a} or k_{2a} being calculated (See Table 1 (Runs 3 and 11)). Good Arrhenius plots of the constants provide the apparent activation energies of 12.3 kcal/mol with respect to k_{1a} and 9.1 kcal/mol to k_{2a} (temperature range: 90—120 °C).

As shown in Fig. 1, these constants increase with increase in $Co_2(CO)_8$ concentration. Also, plots of the constants *vs.* partial pressure of hydrogen reveal first order behaviors, while those *vs.* CO pressure give zero order (Fig. 2). These observations are identical with those described in the hydroformylation, with the exception of the CO pressure effect (Figs. 1, 2).

Experimental

Materials. Phosphines and toluene were obtained commercially and used with no further purifications. All α,β-unsaturated carbonyls were distilled prior to use.

Reaction Procedure. A catalyst solution containing $Co_2(CO)_8$ (1—4 mmol), phosphine (0.25—2 mmol), and substrate (50 mmol) in toluene (50 cm³) was placed in a stainless-steel autoclave (100 cm³), which was subsequently charged with a mixture of H_2 and CO (*ca.* 1/1 ratio).[5] The reaction was carried out at 120 °C under 100 kg/cm² of total pressure (const.) and aliquot samples were withdrawn from the vessel at several reaction times and analyzed by GLC (determination of the initial rate, Table 1).

Kinetic measurements were performed as follows. The hydrogenation system described above was brought to the desired reaction temp and the total pressure was kept constant during the reaction by supplying hydrogen from a 100 ml pressure storage vessel through a pressure regulator. The amount of hydrogen consumed was calculated from the pressure drop in the storage (Figs. 1 and 2).

3) It has been reported that in the absence of phosphine the hydrogenation is slow (See Table 1, Run 6), because a stable π-oxapropenyl complex (A) is formed.[1] Therefore, the phosphine ligand may play an important role in further hydrogenation of (A) to form the products, but there is no more evidence at the present time.

4) Diphos (2.2) > $Ph_2PC{\equiv}CPPh_2$ (1.5) > *cis*-$Ph_2PCH{=}CHPPh_2$ (1.0) > $PhP(CH_2CH_2PPh_2)_2$ (0.64) > $Ph_2P(CH_2)_3PPh_2$ (0.40) > $Ph_2PCH_2PPh_2$ (0.16) > $Ph_2P(CH_2)_2AsPh_2$ (0.14) > none (0.07) > PPh_3 (0.04) (numerical values refer to the initial rate in Table 1).

5) In the absence of CO, a perfect decomposition of $Co_2(CO)_8$ occurred.

Photolysis of Dispiro-substituted 3-Thioxo-1-cyclobutanones

Koji KIMURA,* Yoshihiro FUKUDA, Toshihiko NEGORO, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received December 6, 1980)

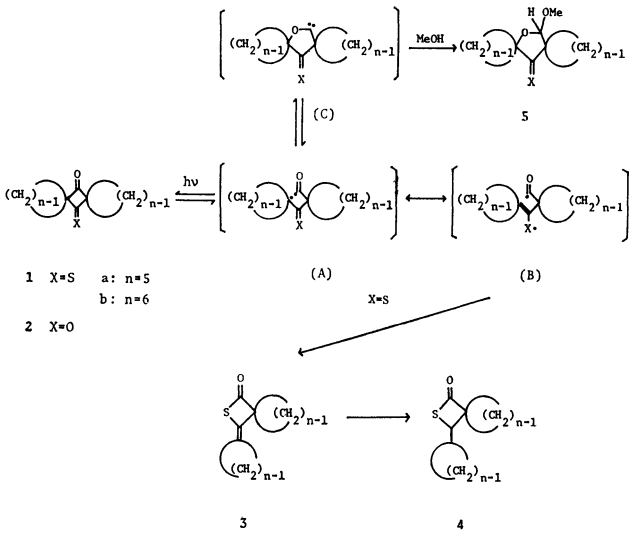
Synopsis. Photolysis of dispiro-substituted 3-thioxo-1-cyclobutanones in dichloromethane or even in methanol gave rise to the photoisomerization to afford thiolactones preferentially.

As part of our studies on the photolysis of 1,3-cyclobutanediones, we previously reported[1] that three primary competing photochemical processes,[2] consisted in α-fission, β-fission (cycloelimination), and ring expansion (the formation of α-oxacarbene), were markedly affected by the ring size of spiro alicyclic groups substituted at the 2- and 4-positions of the diones. In this connection, our interest is focused on the effect of the ring size of 2,4-dispiro alicyclic substituents on the photochemical behavior of 3-thioxo-1-cyclobutanones, being similar in structure to 1,3-cyclobutanediones. However, little is known concerning the photochemistry of 3-thioxo-1-cyclobutanones except for only one report on the photooxygenation of 2,2,4,4-tetramethyl-3-thioxo-1-cyclobutanone to give the corresponding 1,3-cyclobutanedione.[3]

Accordingly, we wish to report in the first place on the alternative photochemical behavior of dispiro-substituted 3-thioxo-1-cyclobutanones, compared with that of the corresponding 1,3-cyclobutanediones. In addition, the effect of the ring size of 2,4-dispiro alicyclic substituents on the product-formation is mentioned.

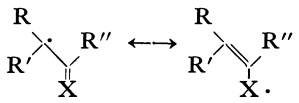
When 12-thioxodispiro[4.1.4.1]dodecan-6-one (**1a**) was irradiated in dichloromethane in a degassed sealed Pyrex tube at −70 °C for 50 h,[4] photoisomerization took place to afford the unsaturated thiolactone (**3a**) almost quantitatively. Moreover, photolysis of **1a** under the similar conditions in methanol,[5] a good trapping agent of an α-oxacarbene intermediate, led to the formation of **3a** (26%) along with the ring-expanded acetal (**5a**, X=S, 38%) *via* an α-oxacarbene intermediate (**C**, X=S).[6] Since the most preferential photoprocess of cyclobutanones or cyclobutanediones in methanol is widely known to be the ring expansion *via* an α-oxacarbene intermediate,[2] it is very significant that the photoisomerization takes place appreciably even in methanol. In the similar irradiation of the dichloromethane solution of 14-thioxodispiro[5.1.5.1]-tetradecan-7-one (**1b**), the photoisomerization also proceeded predominantly. In this case, however, the formation of the unsaturated thiolactone (**3b**, 6%) was minor and, interestingly, the saturated thiolactone (**4b**, 46%) was obtained as the major product. Furthermore, photolysis of **1b** in methanol afforded **4b** (40%), accompanied by the ring-expanded acetal (**5b**, X=S, 23%). On the other hand, no formation of **3b** was observed.

The photolysis of **1a** and **1b** may be considered to proceed in the following scheme.



Scheme 1.

Unlike the case of the corresponding dispiro-1,3-cyclobutanediones (**2a** and **2b**), the preferential occurrence of photoisomerization in **1a** and **1b**, regardless of the ring size of spiro substituents and solvents, may be explained on the basis of the great differences in contribution between two canonical formula of the radical of allylic structures, (**6A′**) and (**6B′**), which are each part of 1,4-biradical intermediates, that is, the 1-acyl 4-cycloalkyl biradical (**A**, X=S) and the 1-acyl 4-thiyl biradical (**B**, X=S), derived from the initial α-fission of **1a** and **1b**.



6 X=S (A′) (B′)
7 X=O

Of two canonical formula, (**6A′**) and (**6B′**), the contribution of (**6B′**) to the radical of allylic structure, in which the unpaired electron is localized on sulfur atom, is greater than that of (**6A′**), because radical stabilization energies[7,8] are strongly influenced by the electronegativity of the atom bearing the unpaired electron and the stabilization energies of a series of structually related oxygen, carbon, and sulfur centered radicals increase in this order. Consequently, it appears that (**B**, X=S) would form thiolactone (**3**) by ring closure. In the case of **7**, on the contrary, the contribution of (**A′**) is greater than that of (**B′**).[9,10] Therefore, in the case of 1,3-cyclobutanediones (**2**), no isomerized product was obtained. In conclusion, the difference in the electronegativities of sulfur and oxygen plays a key role in determining the reaction pathways after the photochemical α-fission.

In addition, it was found that the ring size of spiro alicyclic groups substituted at 2- and 4-positions affected the process of product-formation in a striking manner. In order to clarify the photochemical conversion of **3b**

into **4b**, **3b** was irradiated in dichloromethane or deuterodichloromethane under the similar conditions. As expected, the photochemical hydrogen abstraction of **3b** proceeded smoothly to give **4b**, and, moreover, the NMR spectrum of reaction product in dichloromethane showed the doublet peak (δ 2.92, 1H) assigned to the signal of the methine proton attached to the position α to the sulfur atom in **4b**, whereas, in the case of deuterodichloromethane, such peak was absent. Concerning the high reactivity of **3b** toward hydrogen abstraction, it is not clear at present, but we tentatively infer that the rotation around the double bond of **3b** in the excited state may be fairly restricted owing to the nonbonded interaction of hydrogens between the adjacent two cyclohexyl substituents, just like the photochemically excited triplet olefin.[11] Further study on the above photochemical hydrogen abstraction is now undertaken.

Experimental

Materials. 12-Thioxodispiro[4.1.4.1]dodecan-6-one (**1a**) and 14-thioxodispiro[5.1.5.1]tetradecan-7-one (**1b**) were prepared by the modification of the method of Krapcho.[12] **1a**, mp 35—36 °C; IR (KBr) 1780 cm^{-1}; NMR (CCl_4) δ 1.9 (m, 16H); Mass (*m/e*) 208 (M^+); UV (MeOH) λ_{max} 241 (ε, 7160), 326 (90), 513 (8), 527 nm (8); Found: C, 69.21; H, 7.71; S, 15.53%. Calcd for $C_{12}H_{16}OS$: C, 69.18; H, 7.74; S, 15.39%. **1b**, mp 113—114 °C (lit,[12] 113—115 °C); IR (KBr) 1765 cm^{-1}; UV (MeOH) λ_{max} 237 (ε, 8940), 326 (104), 514 nm (8).

General Irradiation Procedure. A solution of **1a** or **1b** (0.2 mol dm^{-3}) was irradiated in a degassed sealed Pyrex tube at −70 °C for 40—50 h. After the solvent was evaporated, the residue was chromatographed on silica gel and was subjected to purification by preparative GLC. The yields were determined by GLC analysis (10% FFAP).

Irradiation of 1a. *In CH_2Cl_2*: Preparative GLC afforded the isomeric product (**3a**) almost quantitatively. **3a**, IR (neat) 1770, 1675 cm^{-1}; NMR (CCl_4) δ 1.6—2.8 (m, 16H); Mass (*m/e*) 208 (M^+), 180; Found: C, 69.23; H, 7.69; S, 15.51%. Calcd for $C_{12}H_{16}OS$: C, 69.18; H, 7.74; S, 15.39%.

In MeOH: Analysis of the photolysate by GLC revealed the isomeric product (**3a**, 26%), the ring-expanded acetal (**5a**, 38%), and the unidentified product (16%). **5a**, IR (neat) 1180, 1085, 1015 cm^{-1}; NMR (CCl_4) δ 1.4—2.2 (b, 16H), 3.3 (s, 3H), 4.7 (s, 1H); Mass (*m/e*) 240 (M^+), 207, 180; Found: C, 65.16; H, 8.39; S, 13.34%. Calcd for $C_{13}H_{20}O_2S$: C, 64.96; H, 8.39; S, 13.42%.

Irradiation of 1b. *In CH_2Cl_2*: Analysis of the photolysate by GLC revealed the following products: the unsaturated thiolactone (**3b**, 6%), the saturated thiolactone (**4b**, 46%). **3b**, IR (neat) 1760, 1675 cm^{-1}; NMR (CCl_4) δ 1.4—1.8 (m, 20H); Mass (*m/e*) 236 (M^+), 208; UV (CH_2Cl_2) 268 nm (ε, 69); Found: C, 71.28; H, 8.39; S, 13.61%. Calcd for $C_{14}H_{20}OS$: C, 71.14; H, 8.53; S, 13.56%. **3b** was also confirmed by the comparison of the sample which was synthesized by the treatment of **1b** with sodium methoxide. **4b**, IR (neat) 1755 cm^{-1}; NMR (CCl_4) δ 1.1—1.8 (m, 21H), 2.9 (d, 1H); Mass (*m/e*) 238 (M^+), 210; Found: C, 70.44; H, 9.46; S, 13.23%. Calcd for $C_{14}H_{22}OS$: C, 70.54; H, 9.30; S, 13.45%. Irradiation of **3b** in CH_2Cl_2 at −70 °C for 2 h gave **4b**, on the other hand, reflux of **3b** in CH_2Cl_2 failed to form **4b**.

In MeOH: Saturated thiolactone (**4b**) and the ring-expanded acetal (**5b**) were obtained in 40% and 23% yields, respectively, along with trace of methyl cyclohexanecarboxylate. **5b**, IR (neat) 1230, 1130, 1100 cm^{-1}; NMR (CCl_4) δ 1.2—2.2 (m, 20H), 3.4 (s, 3H), 5.1 (s, 1H); Mass (*m/e*) 268 (M^+), 237, 208; Found: C, 67.29; H, 8.87; S, 11.58%. Calcd for $C_{15}H_{24}O_2S$: C, 67.12; H, 9.01; S, 11.95%.

Quantum Yield Measurement. The quantum yields for disappearance of **1a** and **1b** were measured according to the method of Jones[13] by employing a merry-go-round apparatus and valerophenone as the actinometer.[14]

Optical Resolution of Heterohelicenes by High Performance Liquid Chromatography

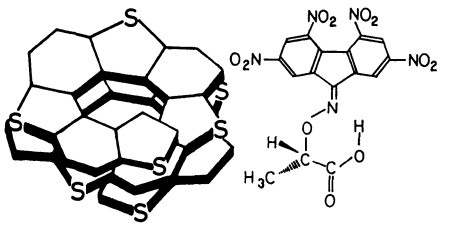
Hiroko NAKAGAWA, Susumu OGASHIWA, Hisao TANAKA, Koh-ichi YAMADA, and Hiroshi KAWAZURA*

Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02

(Received December 22, 1980)

Synopsis. Heterohelicenes up to 15 rings were resolved by high performance liquid chromatography (HPLC) on silica gel covalently linked with a chiral charge transfer complexing agent 2-(2,4,5,7-tetranitro-9-fluorenylideneamino-oxy)propionic acid(TAPA). The efficiency of resolution was discussed in terms of the helical structure of heterohelicenes.

In the course of our work on heterohelicenes, optical resolution was found to be necessary, since their chiroptical properties require isolation of the pure enantiomers. Mikes *et al.* reported the resolution of helicenes by HPLC on a short column containing chiral reagents which function as a selector,[1] and achieved resolution for carbohelicene series. However, they examined only a few heterohelicenes containing sulfur atoms in a molecule, separation between enantiomers being poor.



(P)-(+)-[15] (S)-(+)-TAPA

Fig. 1

We describe here a better resolution of heterohelicenes up to 15 rings consisting of alternant thiophene and benzene nucleus (Fig. 1) by HPLC with a chiral TAPA-bonded silica-gel column. TAPA is a chiral charge transfer (CT) complexing agent in which tetranitro-fluorenylidene moiety provides a strong binding power, oxypropionic acid moiety playing the chiral recognition for the electron donating heterohelicenes.

The chromatogram of [7] to [15] heterohelicenes (Fig. 2) was obtained by using a 30 cm silica-gel (5 μ)

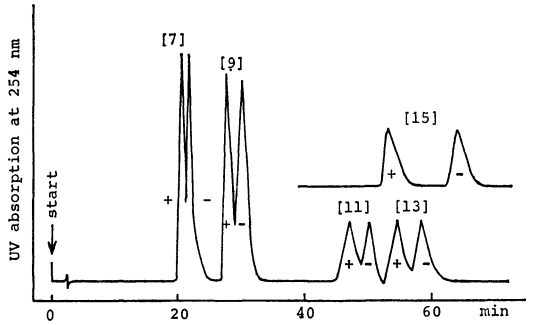


Fig. 2. Chromatogram of heterohelicenes. Column: 11% (*S*)-(+)-TAPA bonded on 5 μ silica gel, mobile phase: 50% dichloromethane–hexane.

Table 1. Resolution of heterohelicenes by HPLC using a (*S*)-(+)-TAPA-bonded silica-gel column

Heterohelicene	k'	$r^{a)}$	$[\alpha]_{500}^{23}$
[7]	5.97 6.42	1.076	2990 −2980
[9]	8.24 9.38	1.138	3760 −3700
[11]	16.88 18.09	1.072	4440 −4550
[13]	19.68 21.20	1.077	8170 −8290
[15]	19.15 23.02	1.202	b) b)

a) $r=k'_-/k'_+$, where k'_- is k' for a minus enantiomer and k'_+ for a plus enantiomer. b) Amount separated too small to measure $[\alpha]_{500}^{23}$.

column linked with 11% (*S*)-(+)-TAPA. The parameters for resolution are given together with the optical rotations of alternatives isolated by the preparative HPLC in Table 1. The capacity factor k' denoting the ratio of partition coefficients between stationary and mobile phase depends upon the strength of CT interaction of a selector with a selectand. Higher heterohelicene having more powerful electron donating ability gave a larger k' value. (*S*)-(+)-TAPA interacted more strongly with (*M*)-(−)-heterohelicene than with its antipode.

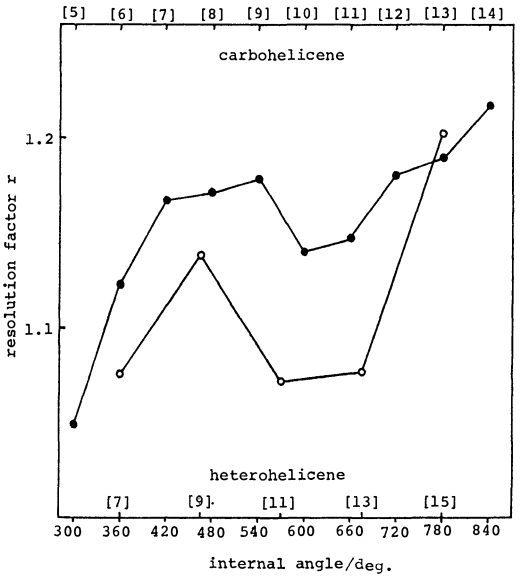

Fig. 3. Relationship between resolution factor and internal angle of helicenes. The data for carbohelicenes were quoted from the literature.[1]
○: Heterohelicene, ●: carbohelicene.

The absolute values of $[\alpha]_{500}^{23}$ for each antipode were almost the same, indicating that satisfactory separation was achieved. $[\alpha]_{500}^{23}$ increased abruptly with an increase in the number of rings.

Figure 3 shows the relationship of the resolution factor r against the internal angle evaluated by allocating 45° for a thiophene ring and 60° for a benzene ring.[2] The curve for heterohelicenes as well as that for carbohelicenes have no monotonically increasing slope with the progression of helix, but a concave in the range 540°—720° where separation is worse. The range of angle corresponds to a helix possessing 1—1.5 turns. This might be explained in terms of the steric repulsion of the methyl group attached to an asymmetric carbon atom of TAPA against the terminal ring of helicenes, in which a chiral recognition is effectuated. The steric repulsion should give a predominant influence on the r value, since this value refers to the difference in the diastereomeric interaction of TAPA with each enantiomer. On the other hand the k' values are mainly determined by the strength of CT interaction. [11] and [13] heterohelicene have a relatively large k', but small r value, as compared with those of [9] and [15] respectively. Thus, helicenes of the helical structure with 1.5—2 turns undergo a stronger CT interaction owing to the smaller repulsion, resulting in smaller chiral selection from TAPA.

Experimental

Materials. The synthesis of heterohelicenes has been reported.[3] Chiral (*R*)-(−)- and (*S*)-(+)-TAPA were prepared according to the method of Block and Newman.[4] Aminated silica gel (5 μ, Polygosil 60-5 NH_2, Macherey-Nagel Co.) was used as a fixer of TAPA. Silica gel covalently linked with chiral TAPA was prepared according to the method of Mikes.[1] A TAPA content in the silica gel was calculated from the nitrogen content obtained by elemental analysis.

Apparatus. HPLC system (Model 204, Waters assoc.), slurry packing apparatus (Model 124, Chemco), and columns (0.39 cm O. D. × 30 cm I. D. and 0.8 cm × 25 cm) were used. Optical rotations were measured on an automatic recording spectropolarimeter (Model J-20A. Japan Spectroscopic Co.).

The Stability of the Supersaturation State in Optical Resolution by the Preferential Crystallization Procedure

Chikara HONGO,* Shigeki YAMADA, and Ichiro CHIBATA

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received May 28, 1980)

In the optical resolution process of DL-serine *m*-xylene-4-sulfonate dihydrate by the preferential crystallization procedure, the stability of the supersaturation state of the unseeded isomer was investigated in connection with the cooling conditions. The experiment was initiated with the model solution and was then extended to the actual resolution process. The metastable region of the unseeded isomer on a two-dimensional diagram with the supersaturation degree and cooling time could be divided into the first and the second metastable regions. The limits of the first and the second metastable regions were expressed by a supersaturation degree and by an area on the diagram respectively. Both limiting values were constant, independent of cooling speed and the lowest arrival temperature, if the conditions for the crystallizer, the initial concentration of the DL-form, the amount of the seed crystals, and the degree of stirring were fixed.

The advantages of the optical resolution of DL-amino acids by the preferential crystallization procedure have been well recognized, and many DL-amino acids have been resolved successfully by this procedure.[1-5] Although several requirements must be fulfilled to achieve the resolution by this procedure, it is most important that the racemic modification be crystallized as a racemic mixture and not as a racemic compound. The resolution is carried out in the following manner. The crystals of a desired isomer (for example, L-isomer) are seeded into a supersaturated solution of a racemic modification. Only the L-isomer crystallizes preferentially, and the crystallized L-isomer is separated in an appropriate manner from the mother liquor before the spontaneous crystallization of the unseeded D-isomer. During the preferential crystallization, the same amount of the D-isomer as that of the crystallized L-isomer remains in the liquid phase as a supersaturation state. After a certain time, however, the unseeded D-isomer also begins to crystallize spontaneously because of the limitation of the stability of the supersaturation state. The situation in this process is shown in Fig. 1.

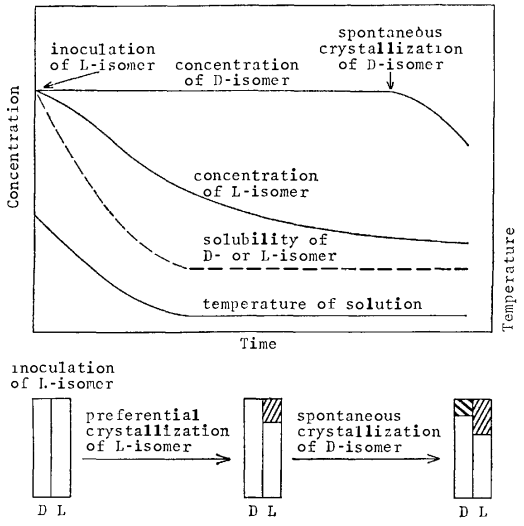

Fig. 1. Time course of optical resolution process by preferential crystallization procedure.

□: D- or L-Isomer in solution, ▨: crystals of L-isomer, ▨: crystals of D-isomer.

To avoid the crystallization of the unseeded D-isomer, and to crystallize only the desired L-isomer in an optically pure form, it is also important to know the limitations of the stability of the supersaturation state of the D-isomer, especially the starting time of the spontaneous crystallization of the unseeded D-isomer. Although a few non-quantitative descriptions of the stability of supersaturation in the preferential crystallization process have appeared,[6-8] no quantitative study of the prediction of the waiting time for the spontaneous crystallization of the unseeded isomer has yet been reported.

In our previous report on the optical resolution of DL-serine,[1] DL-serine *m*-xylene-4-sulfonate dihydrate (DL-Ser·mXS·$2H_2O$) was found to form a racemic mixture and to be easily resolved by the preferential crystallization procedure. In the present experiment, the stability of the supersaturation state of the unseeded isomer was investigated in order to predict the waiting time for the spontaneous crystallization of the unseeded isomer in this optical resolution process. Although the stability of the supersaturation state is influenced by various factors, it was examined under a variety of cooling conditions, *i.e.*, cooling speed and the lowest arrival temperature, which are the most important factors in industrial operations. The experiments were initiated with the model solution, assuming a situation of the resolution process, and then extended to the actual resolution process.

Materials and Methods

Materials. Optically active and racemic Ser·mXS·$2H_2O$ were prepared according to the previous report[1] and dried at 35 °C in a chamber with a relative humidity of 67%.

Apparatus and Cooling Methods. A 2*l*-cylindrical glass vessel with a jacket was employed as the crystallizer. Schematic drawings of the crystallizer and their dimensions are shown in Fig. 2. The solution was stirred at 210 rpm with poly(vinyl chloride)-paddle and cooled under the various cooling patterns shown in Fig. 3, which were achieved by using a Chino

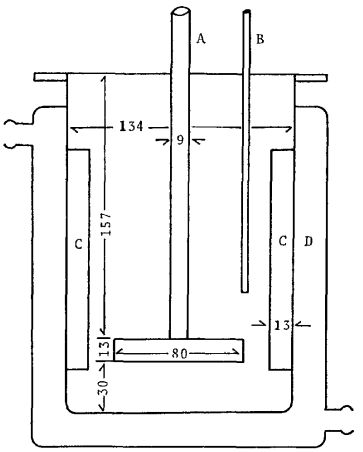

Fig. 2. Schematic drawings of the crystallizer and their dimensions (in millimeter).
A: Poly(vinyl chloride)-agitator, B: glass-thermistor (diameter, 6 mm), C: glass-baffle plate, D: jacket.

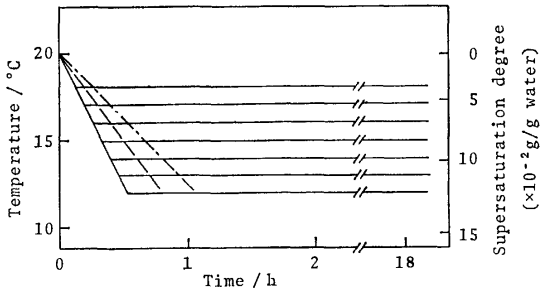

Fig. 3. Cooling patterns and supersaturation degree. The solution is saturated with D-Ser·mXS·$2H_2O$ at 20 °C (C_D=0.360 g/g water). Cooling speed is 1/4 °C per min (——), 1/6 °C per min (— — —), or 1/8 °C per min (———).

program setter, PMS-2, and a Chino electronic recording controller, ET-2p (Chino Works Ltd., Japan). The ranges of experimental variables for cooling were as follows: cooling speed, 1/4, 1/6, and 1/8 °C per min; the lowest arrival temperature, 12, 13, 14, 15, 16, 17, and 18 °C.

Analysis of Solution. The total concentration of D- and L-isomers in the sample solution, C_D+C_L [g/g(water)], was determined from the standard curve and the refractive index which was measured with a Karl Zeiss immersion refractometer, where C_D and C_L are the concentrations of D- and L-isomers [g/g(water)] respectively.

The concentration of the optical isomer (for example, D-isomer) existing in excess, C_D-C_L [g/g(water)], was obtained by the measurements of the rotation angle of the sample solution, its density, and the total concentration of D- and L-isomers according to the following calculation. The specific rotation of the D-isomer existing in excess in the solution is expressed as:

$$[\alpha]_D^{35} = 100 \times \frac{\alpha}{c}, \quad (1)$$

where α is the rotation angle and where c is the weight in grams of the D-isomer existing in excess per 100 ml of solution. c is expressed as:

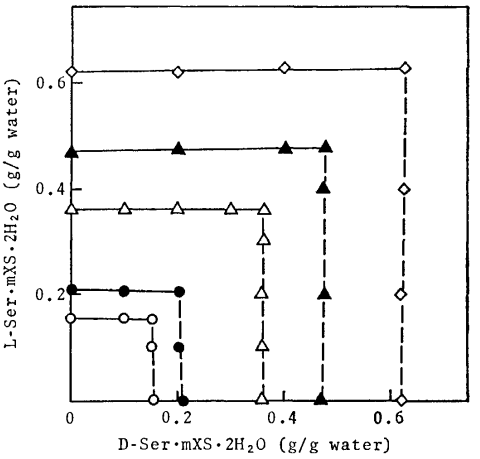

Fig. 4. Solubility of L- and D-Ser·mXS·$2H_2O$ in the coexisting system.
——: Solubility curve for L-isomer, — —: solubility curve for D-isomer, ○: at 5 °C, ●: at 10 °C, △: at 20 °C, ▲: at 25 °C, ◇: at 30 °C.

$$c = 100 \times \frac{C_D - C_L}{(1+C_D+C_L)/d}, \quad (2)$$

where d is the density of the solution.

The value of the specific rotation of D-Ser·mXS·$2H_2O$ was observed to be $[\alpha]_D^{35}=+5.787°$ under the conditions employed ($0.5<C_D+C_L<1.0$, $0<C_D-C_L<0.12$ g/g(water)). From Eqs. 1 and 2, C_D-C_L is expressed as:

$$C_D - C_L = \frac{\alpha(1+C_D+C_L)}{5.787\,d}. \quad (3)$$

From Eq. 3, C_D-C_L can be obtained by measuring the values of α, d, and C_D+C_L. The optical rotation was measured in a 1-dm tube at 35 °C with sodium light by means of a Perkin-Elmer 141 automatic polarimeter. The density was determined with a hydrometer.

The concentrations of the D- and L-isomers, C_D and C_L, were calculated from the values of C_D+C_L and C_D-C_L respectively.

Determination of Waiting Time. The waiting time for the spontaneous crystallization of the D-isomer was determined by measuring the concentration of the D-isomer, and the time when the concentration decreased by 0.002 [g/g(water)] was taken as the starting time of the spontaneous crystallization. Also, a sudden spontaneous crystallization could be determined by visual observation.

Results and Discussion

Solubility of L- and D-Ser·mXS·$2H_2O$ in the Coexisting System. Mixtures of L- and D-isomers in various proportions were dissolved in water at an elevated temperature and equilibrated at different temperatures. The concentrations of both the isomers in the equilibrium solution were determined. The equilibrium compositions of the coexisting system are shown in Fig. 4. The figure shows that: (i) the solubility of an optical isomer is little influenced by the concentration of the opposite isomer coexisting in the solu-

Table 1. Composition of model solution

Solution No.	I	II	III	IV
D-Ser·mXS·$2H_2O$ (g)	468	468	468	468
L-Ser·mXS·$2H_2O$ (g)	468	393	351	295
Water (g)	1300	1300	1300	1300
Ratio of L/D	1.00	0.84	0.75	0.63

Each solution was saturated with the D-isomer in the presence of various amounts of the L-isomer at 20 °C.

tion, (ii) the solubility of the racemic modification is nearly equal to the sum of the individual solubilities of both isomers, and (iii) the saturated solution of the racemic modification no longer dissolves an optical isomer. These properties show that DL-Ser·mXS·$2H_2O$ crystallized from water forms a typical racemic mixture and that there is no appreciable interaction between the two isomers on the respective solubilities. Therefore, the supersaturation degree for each optical isomer was expressed as C_D-C_S (for the D-isomer) or C_L-C_S (for the L-isomer) [g/g(water)], regardless of the concentration of the coexisting opposite isomer, where C_S [g/g(water)] is the solubility of the D- or L-isomers at a given temperature. From Fig. 4, the solubilities of optically active and racemic Ser·mXS·$2H_2O$ could be expressed as a function of the temperature, t, by following empirical formulas over a range from $t=5$ to 30 °C respectively:

$$\log C_S = 2.34 \times 10^{-2} t - 9.12 \times 10^{-1},$$

$$\log C_{SR} = 2.48 \times 10^{-2} t - 6.39 \times 10^{-1},$$

where C_{SR} [g/g(water)] is the solubility of DL-Ser·mXS·$2H_2O$.

Stability of Supersaturation in Model Solution. The First Metastable Region and Its Width, S_I: Assuming, in the resolution process of DL-Ser·mXS·$2H_2O$, that the L-isomer is preferentially crystallized, while the D-isomer remains in the initial concentration as a supersaturation state, the model solutions were prepared as is shown in Table 1. The mixtures of the D-isomer and the L-isomer in different proportions were dissolved by heating at 35 °C. The solutions were saturated at 20 °C with the D-isomer in the presence of various amount of the L-isomer. The solutions were cooled at various speeds (1/4, 1/6, and 1/8 °C per min) to given temperatures ranging from 12 °C to 18 °C, as is shown in Fig. 3, under a constant stirring speed; 0.2 g of D-Ser·mXS·$2H_2O$ (28—35 meshes) was added at 20 °C in the course of cooling. The addition of the crystals was preferable for the reproducibility of the waiting time. No significant decrease in the concentration of the D-isomer attributable to the growth of the added crystals was observed until the spontaneous crystallization of the supersaturated D-isomer took place. In other words, the first significant decrease in the concentration was mainly attributed to the spontaneous crystallization of the D-isomer. Under the above cooling conditions, the temperature of the solution was recorded and the waiting time for the D-isomer was determined. The range in the waiting times observed in these experiments was from 30 min to about 15 h. One example

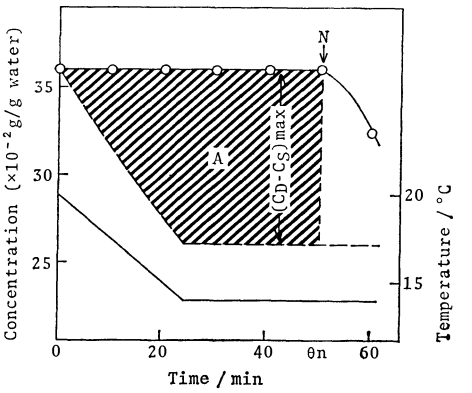

Fig. 5. Time course of supersaturation degree of D-isomer in model solution. The model solution I described in Table 1 was cooled at 1/4 °C per min to 14 °C and maintained at 14 °C
——: Temperature of solution, — — —: solubility of D-isomer (C_S) at the temperature of solution, —O— O—: concentration of D-isomer (C_D), N: the point occurring a large spontaneous crystallization, A: the area given by $A=\int_0^{\theta n}(C_D-C_S)d\theta$.

of the time course for model solution I is shown in Fig. 5, indicating that the supersaturation degree of the D-isomer, (C_D-C_S), increases with a decrease in the temperature and that a large spontaneous crystallization of the D-isomer begins suddenly at the point N (time θn, 50 min). This point, N, varied with the cooling speed and with the lowest arrival temperature. That is to say, it varied not only with the cooling speed, but also with the maximum supersaturation degree, $(C_D-C_S)_{max}$, depending on the lowest arrival temperature.

To obtain the relationship between the waiting time, θn, and the cooling conditions described above, a certain area, A, expressed as a shaded part in Fig. 5 was considered. The area may be expressed mathematically as follows:

$$A = \int_0^{\theta n}(C_D-C_S)\mathrm{d}\theta \quad [\mathrm{g\cdot min/g(water)}], \tag{4}$$

where θ is the time and where θn is the time when spontaneous crystallization is observed at point N. In this study, the A area was graphically eva.uated.

For each model solution shown in Table 1, the evaluation of A was carried out under various cooling conditions. The logarithm of A was plotted against $(C_D-C_S)_{max}$ on semilogarithmic graph paper. The results obtained when the cooling speed was 1/4 °C per min are shown in Fig. 6. In the case of any model solution, the log A decreased linearly with $(C_D-C_S)_{max}$, but the slope of the straight line changed at the point of $(C_D-C_S)_{max}=6.6\times10^{-2}$ [g/g(water)], expressed as S_I in Fig. 6. Furthermore, the figure shows that the value of A is markedly large when $(C_D-C_S)_{max}$ is lower than S_I. In this range, the spontaneous crystallization of the D-isomer did not occur for a longer time, and the supersaturation state was more stable than in the other range. Thus, the region where the supersaturation degree is within S_I was termed "the first metastable region".

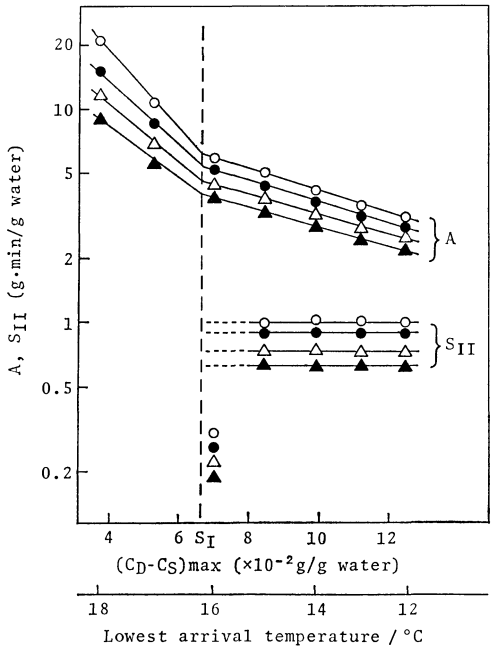

Fig. 6. Relationship among A, S_I, S_{II}, and $(C_D-C_S)_{max}$ in model solution. The solutions were cooled at 1/4 °C per min to given temperatures ranged from 12 °C to 18 °C.

$A=\int_0^{\theta n}(C_D-C_S)d\theta$, $S_{II}=\int_0^{\theta n}(C_D-C_S-S_I)d\theta$.

○: Model solution I ($C_L/C_D=1.00$), ●: model solution II ($C_L/C_D=0.84$), △: model solution III ($C_L/C_D=0.75$), ▲: model solution IV ($C_L/C_D=0.63$).

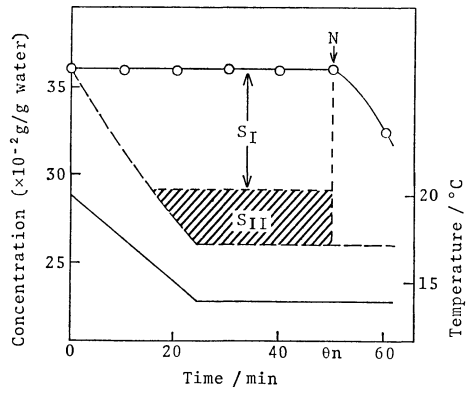

Fig. 7. Illustration of the first and the second metastable regions. The experiment was the same as that in Fig. 5. S_I represents the width of the first metastable region. S_{II} represents the area of the second metastable region.

The Second Metastable Region and Its Area, S_{II}: In the above experiments, the supersaturation was relatively unstable in the region where the supersaturation degree was higher than S_I. Then, an area, S_{II}, expressed as a shaded part in Fig. 7, was considered. This may be expressed mathematically as follows:

$$S_{II}=\int_0^{\theta n}(C_D-C_S-S_I)d\theta \quad [\text{g·min/g(water)}], \qquad (5)$$

where the integration is restricted to cases of $C_D-C_S \geqq S_I$.

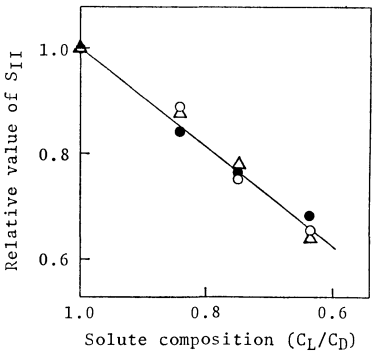

Fig. 8. Relationship between the value of S_{II} and C_L/C_D.
Cooling speed: ○; 1/4 °C/min, ●; 1/6 °C/min, △; 1/8 °C/min.

In this paper, the value of S_{II} was graphically evaluated. The logarithm of S_{II} is plotted against $(C_D-C_S)_{max}$ in Fig. 6. The figure indicates that the values of S_{II} for the solution with a constant ratio of C_L/C_D are constant independent of the maximum supersaturation degree, with the exception of the case when $(C_D-C_S)_{max}$ closely approaches S_I. However, these values decreased with a decrease in the ratio of C_L/C_D. The relationship between S_{II} and the ratio of C_L/C_D is shown in Fig. 8.

Also, in case where the cooling speed was 1/6 or 1/8 °C per min, the values of S_I and S_{II} themselves were the same as those at the cooling speed of 1/4 °C per min, as is shown in Fig. 8. Generally, it may be concluded that the values of S_I and S_{II} are constant, independent of the cooling speed and the lowest arrival temperature. Thus, the region shown as a shaded part in Fig. 7 was termed "the second metastable region," and its area was expressed as S_{II}.

Ting and McCabe[9] and also Tanimoto *et al.*[10] found that two points existed in the supersaturation region for magnesium sulfate or copper sulfate. One was the first supersaturation point, where new nuclei was first observed, while the other was the second supersaturation point, where a sudden increase in the rate of formation of new crystals was observed. The conception of the first and second metastable regions in the present paper seems to correspond to the conception proposed by them. In fact, at a supersaturation degree lower than S_I, the spontaneous crystallization did not occur for a long time. In the second metastable region, where the integral in Eq. 5 is within S_{II}, the spontaneous crystallization was rarely observed for a period sufficient to achieve the optical resolution by the preferential crystallization procedure. In the supersaturation region where the integral in Eq. 5 is beyond S_{II}, a large amount of crystals appeared suddenly and grew rapidly.

Stability of Supersaturation in Actual Resolution Process. A Correction of the S_{II} Value by the Ratio of the L-*Isomer to the* D-*Isomer*: The above experiments with the model solutions were carried out when the initial ratios of C_L/C_D were different, as is shown in Table 1, but the ratio in each individual solution was kept constant during the experiment. Under such conditions, the

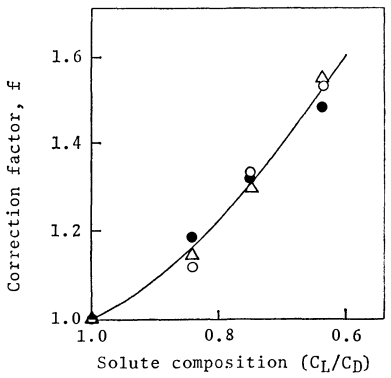

Fig. 9. Relationship between correction factor f and C_L/C_D.
Cooling speed: ○; 1/4 °C/min, ●; 1/6 °C/min, △; 1/8 °C/min.

value of S_{II} was found to be constant, independent of the cooling speed and the lowest arrival temperature. However, it decreased with a decrease in the initial ratio of C_L/C_D, as is shown in Fig. 8. On the other hand, in the actual resolution process, the ratio of C_L/C_D is the solution decreases gradually with the progress of the preferential crystallization of the L-isomer. Therefore, in order to estimate the value of S_{II} in the actual resolution process, the S_{II} shift resulting from the change in the ratio of C_L/C_D should be compensated for. From the data of Fig. 8 showing the relationship between S_{II} and C_L/C_D, the correction factor, f, was determined so that the values of $f_i \cdot S_{II,i}$ became constant:

$$f_i \cdot S_{II,i} = S_{II,1},$$

where f_i and $S_{II,i}$ are the values of f and S_{II} respectively when the ratio of C_L/C_D is i, and where $S_{II,1}$ is the value of S_{II} when the ratio of C_L/C_D is 1.00. The relationship between the correction factor, f, and the ratio of C_L/C_D is shown in Fig. 9. In order to extend the rule obtained on the model solutions to the actual resolution process, in which the ratio of C_L/C_D changes from moment to moment, the evaluation of the S_{II} value in the actual resolution process should be carried out by using the correction factor, f, and the S_{II} value in the actual resolution process should be expressed by the following equation:

$$S_{II} = \int_0^{\theta n} f(C_D - C_S - S_I)d\theta \quad [g \cdot min/g(water)], \qquad (6)$$

where the integration is restricted to cases of $C_D - C_S \geqq S_I$ and where f is a function of the ratio of C_L/C_D, which changes from moment to moment with the progress of the preferential crystallization of the L-isomer. In this paper, the S_{II} value may be graphically evaluated from the sum of the individual $f_i \cdot (C_D - C_S - S_I) \cdot \Delta\theta$ values between zero and θn by using the f_i shown in Fig. 9.

Supersolubility in Actual Resolution Process: According to the above manner, the values of S_{II} were determined in the actual resolution process, in which the L-isomer was preferentially crystallized from the supersaturated solution of DL-Ser·mXS·$2H_2O$ and the D-isomer remained in a supersaturated state.

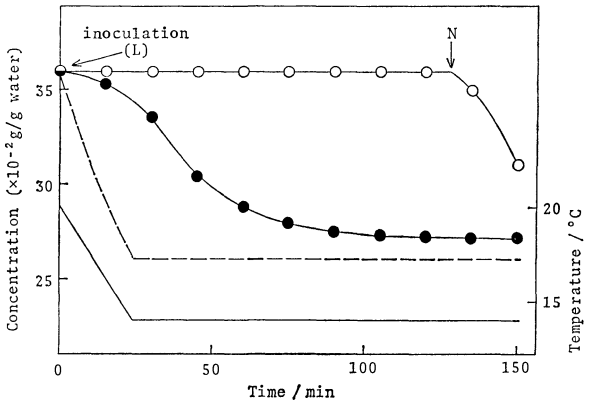

Fig.10. An example of time course of actual resolution process. The solution consisting of 936 g of DL-Ser·mXS·$2H_2O$ and 1300 g of water was seeded with 2 g of L-Ser·mXS·$2H_2O$ (100—200 meshes) at 20 °C, and was cooled at 1/4 °C per min to 14 °C. ——: Temperature of solution, — — —: solubility of D-isomer at the temperature of solution, —●—●—: concentration of L-isomer, —○—○—: concentration of D-isomer, N: the point occurring a large spontaneous crystallization.

A mixture of DL-Ser·mXS·$2H_2O$ (936 g) and water (1300 g) was dissolved by heating it at 35 °C for 1 h. The saturation temperature of each isomer in the solution was 20 °C. The solution was then seeded with 2.0 g of L-Ser·mXS·$2H_2O$ (100—200 meshes) at 20 °C and subsequently cooled at the cooling speed of 1/4 °C per min to a given temperature at a constant stirring speed. During the preferential crystallization of the L-isomer, the temperature was recorded and the concentration of each individual isomer was measured. In this case, a good reproducibility of the waiting time was obtained, though the crystals of the D-isomer were absent, because the crystals of the L-isomer were always present during the preferential crystallization of the L-isomer. The range of the waiting times observed in these experiments was from 30 min to about 15 h. One example of the time course of an actual resolution process is shown in Fig. 10. In the same manner as was described in connection with the model solution, the A area in Eq. 4 was graphically determined. The logarithm of A obtained under various cooling conditions was then plotted against the maximum supersaturation degree, $(C_D - C_S)_{max}$, on semilogarithmic graph paper. The results are shown in Fig. 11. The $\log A$ changed linearly with $(C_D - C_S)_{max}$, but the slope of the straight line was changed at the point of 6.6×10^{-2} [g/g(water)], which is shown as S_I in the figure. This result was similar to that obtained for the model solution.

In the region where the supersaturation degree was higher than 6.6×10^{-2} [g/g(water)], the value of S_{II} expressed by Eq. 6 was graphically evaluated in individual experiments. The values were then plotted against $(C_D - C_S)_{max}$ in Fig. 11, much as in the case of the model solution. The figure shows that the S_{II} values thus obtained were constant 4.49 [g·min/g (water)], independent of $(C_D - C_S)_{max}$, with the exception of the case where $(C_D - C_S)_{max}$ closely approached

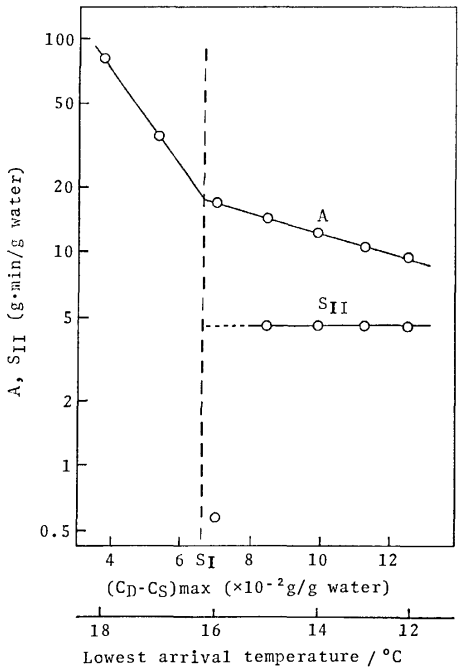

Fig. 11. Relationship among A, S_I, S_{II}, and $(C_D-C_S)_{max}$ in actual resolution process.

$$A=\int_0^{\theta n}(C_D-C_S)d\theta,\quad S_{II}=\int_0^{\theta n}f(C_D-C_S-S_I)d\theta.$$

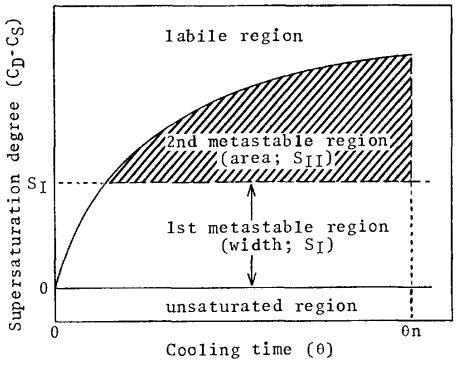

Fig.12. Time course of supersaturation degree of D-isomer and relationship between the first and the second metastable regions.
——: Increase in supersaturation degree of D-isomer due to cooling, θn: starting time of spontaneous crystallization of D-isomer. S_I and S_{II} are constant, independent of cooling speed and the lowest arrival temperature.

S_I. However, the value of S_{II} in the actual resolution process, 4.49 [g·min/g(water)], was different from that of the model solution, 1.00 [g·min/g(water)]. This discrepancy in the S_{II} value for the D-isomer is considered to arise from the following difference. In the case of the model solution, a small amount of crystals of the D-isomer was added to obtain the reproducibility. On the other hand, in the actual resolution process, the crystals of the D-isomer were absent, though the crystals of the L-isomer were present.

Consequently, the conception for the supersaturation state of the model solution was found to be applicable to the actual resolution process.

The results obtained in the actual resolution process of DL-Ser·mXS·$2H_2O$ can be summarized as follows; they are illustrated in Fig. 12.

(1) The metastable region on a two-dimensional diagram with the supersaturation degree of the unseeded D-isomer and cooling time could be divided in two regions, the first metastable region and the second metastable region.

(2) The first metastable region was the one where the supersaturation degree was lower than a constant value, $S_I=6.6\times10^{-2}$ [g/g(water)]. In this region, no spontaneous crystallization was observed for about 4 h or more.

(3) The second metastable region was the one where the supersaturation was stable for a certain time (within 4 h). This range was limited by the constant value of the integral in Eq. 6, $S_{II}=4.49$ [g·min/g(water)]. In other words, no spontaneous crystallization took place until the integrated area of the supersaturation degree as a function of the cooling time reached 4.49 [g·min/g(water)].

(4) The limiting values of both the first metastable region and the second metastable region were constant, independent of the cooling speed and the lowest arrival temperature.

Although the present work was carried out under fixed conditions with respect to type of crystallizer, the initial concentration of DL-form, the amount of seed crystals, and the degree of stirring, the metastable region of the unseeded isomer existing as a supersaturation state in the actual resolution process of DL-Ser·mXS·$2H_2O$ could be quantitatively defined. Then, the preferential crystallization should be achieved in the second metastable region. If the increase in supersaturation degree due to cooling the solution and the change in the ratio of the L- and D-isomers due to the preferential crystallization of L-isomer can be predicted, it is also possible to predict the waiting time for the spontaneous crystallization of the unseeded D-isomer. Our study of the prediction will be reported next.

The Prediction of the Optical Resolution Process by the Use of the Preferential Crystallization Procedure

Chikara HONGO,* Shigeki YAMADA, and Ichiro CHIBATA

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received May 28, 1980)

In the optical resolution of DL-serine *m*-xylene-4-sulfonate dihydrate by the preferential crystallization procedure, the prediction of the resolution process was studied. The solution saturated with the DL-form at 20 °C was cooled under a programmed cooling pattern and was seeded with the L-isomer. The decrease in the concentration of the L-isomer during the process was predicted by a conventional calculation method. Then, the waiting time for the spontaneous crystallization of the D-isomer was predicted by using the limiting values of the first and the second metastable regions, which were discussed in a previous report. As a result, a good agreement was obtained between the predicted results and the experimental results.

In the previous report,[1] the waiting time for the spontaneous crystallization of the unseeded isomer was investigated in an attempt to perform successfully the optical resolution DL-serine *m*-xylene-4-sulfonate dihydrate (DL-Ser·mXS·$2H_2O$) by the preferential crystallization procedure. As a result, it was found that the spontaneous crystallization of the unseeded isomer did not occur until the value of S_{II} expressed by the equation of $S_{II}=\int_0^{\theta n} f(C_D-C_S-S_I)d\theta$ reached a constant value independent of the cooling speed and the lowest arrival temperature. Here, S_I and S_{II} are the limiting values of the first and the second metastable regions for the unseeded D-isomer respectively: C_D, the concentration of the D-isomer; C_S, the solubility of the D-isomer; f, the correction factor approximated by C_D/C_L; θ, the cooling time; and θn, the waiting time for the spontaneous crystallization of the unseeded D-isomer. Therefore, the waiting time for the spontaneous crystallization of the unseeded D-isomer might be predicted if the increase in the supersaturation degree due to cooling and the decrease in the concentration of the seeded L-isomer due to preferential crystallization were previously known.

In the present paper, the decrease in the concentration of the seeded L-isomer in the optical resolution process of DL-Ser·mXS·$2H_2O$ under given cooling conditions was predicted according to the usual methods.[2-4] Then, the waiting time for the unseeded D-isomer, θn, was predicted from the above equation by using the values of S_I and S_{II} determined in the previous report. As a result, a good agreement was obtained between the predicted results and the experimental results.

Materials and Methods

Materials, Apparatus, and Analytical Methods. The materials, experimental apparatus, analytical methods, expression of the supersaturation degree, and operation of the preferential crystallization procedure were described in the previous report.[1]

Cooling Methods. The solution for preferential crystallization was cooled under cooling patterns previously programmed. Two cooling patterns were used. One was cooled at the rate of 1/8 °C per min and maintained at 12.0 °C. The other was cooled at the rate of 1/2 °C per min and maintained at 14.5 °C.

Prediction of the Decrease in the Concentration of the Seeded L-Isomer, C_L. The crystal growth rate of the seeded L-isomer in the process of preferential crystallization can be expressed as the following general equation:[2-4]

$$-\frac{dC_L}{d\theta} = aK(C_L-C_S)^n, \quad (1)$$

where C_L is the concentration of the L-isomer; K, the overall crystal-growth coefficient; a, the surface area of the crystals; n, the crystal-growth rate order; and C_S, the solubility of the L-isomer as a function of the temperature, t. The value of a increases with the growth of the seed crystals. In this report, it was assumed that a increased in proportion to $(W/W_0)^{2/3}$,[2,3] namely:

$$a = (W/W_0)^{2/3}\cdot a_0, \quad (2)$$

where W_0 is the initial weight of the seed crystals, W is the weight of the crystals at time θ, and a_0 is the initial surface area corresponding to W_0.

Substituting Eq. 2 into Eq. 1 gives:

$$-\frac{dC_L}{d\theta} = \left(\frac{W}{W_0}\right)^{2/3}\cdot a_0K\cdot(C_L-C_S)^n. \quad (3)$$

Taking logarithms, Eq. 3 gives:

$$\log\left\{\left(-\frac{dC_L}{d\theta}\right)\Big/\left(\frac{W}{W_0}\right)^{2/3}\right\} = n\log(C_L-C_S) + \log a_0K. \quad (4)$$

Equation 4 means that the plot of $\log\{(-dC_L/d\theta)/(W/W_0)^{2/3}\}$ against $\log(C_L-C_S)$ is a straight line, and that the values of n and a_0K can be evaluated from the slope and the intercept of the straight line respectively. In order to determine the values of a_0K and n, the time course of the decrease in C_L was obtained under the following conditions. The supersaturated solution of DL-Ser·mXS·$2H_2O$ (936 g) and water (1300 g) was maintained at a constant temperature of 14.5 °C or 12.0 °C, seeded with 2 g of L-Ser·mXS·$2H_2O$ (100—200 meshes), and allowed to crystallize. From the slope of the tangent on the time course of the decrease in C_L, the value of $(-dC_L/d\theta)$ was determined. The value of W was calculated from the decrease of C_L. A plot of $\log\{(-dC_L/d\theta)/(W/W_0)^{2/3}\}$ against $\log(C_L-C_S)$ gave a straight line, as is shown in Fig. 1. Then, the values of n and a_0K could be

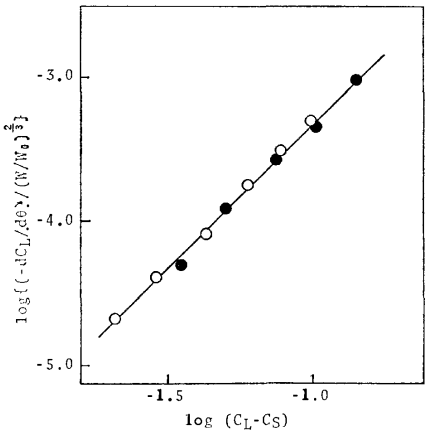

Fig. 1. Plots of $\log\{(-dC_L/d\theta)/(W/W_0)^{2/3}\}$ against $\log(C_L-C_S)$.
○: 14.5 °C, ●: 12.0 °C.

determined from the straight line; they were $n=2[-]$ and $a_0K=6.49\times10^{-2}$ [min^{-1}].

On the other hand, the relationship between C_S in Eq. 3 and t was already obtained in the previous report at the following empirical equation:

$$\log C_S = 2.34\times10^{-2}t - 9.12\times10^{-1}. \quad (5)$$

Since the solution is cooled under a programmed pattern, t is already given. Therefore, C_S is known.

Consequently, the decrease in C_L due to preferential crystallization can be predicted by means of calculations based on Eq. 3 on the assumption that the n and K obtained above are constant during the preferential crystallization procedure.

Prediction of Waiting Time for the Spontaneous Crystallization of the D-*Isomer, θn.* The previous report showed that the supersaturation state of the unseeded D-isomer in the actual resolution process on the solution saturated with DL-Ser·mXS·$2H_2O$ at 20 °C was stable until the value of S_{II} in Eq. 6 reached 4.49 [g·min/g(water)].

$$S_{II} = \int_0^{\theta n} f(C_D - C_S - S_I)d\theta, \quad (6)$$

where the integration is restricted to cases of $C_D-C_S \geqq S_I$; f is the correction factor against the change in the ratio of C_L/C_D, which may be empirically approximated by $f=C_D/C_L$, judging from the result of our previous report.

The values of S_I and S_{II} are known to be 6.6×10^{-2} [g/g(water)] and 4.49 [g·min/g(water)] respectively; C_D is the initial concentration until the spontaneous crystallization takes place, C_S is obtainable from Eq. 5, and f is also obtainable because C_L is obtained from Eq. 3. Therefore, the waiting time for the spontaneous crystallization of the D-isomer can be predicted by calculating θn from Eq. 6.

Results and Discussion

As an example, it was assumed that the optical resolution of DL-Ser·mXS·$2H_2O$ was carried out as follows. DL-Ser·mXS·$2H_2O$ (936 g) was dissolved in water (1300 g) by heating it at 35 °C for one hour in a 2l-cylindrical glass vessel. The solution was then

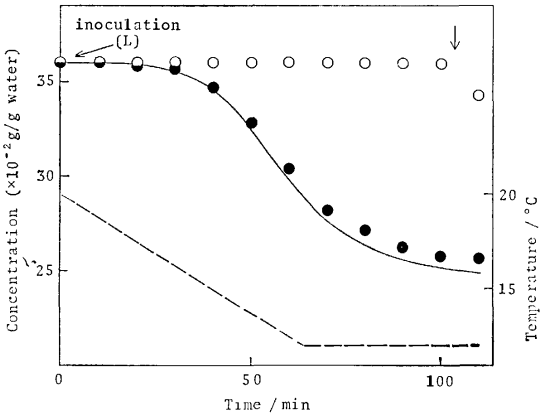

Fig. 2. Comparison between calculated results and experimental data in the optical resolution process of DL-Ser·mXS·$2H_2O$.
——: Calculated curve, ○, ●: experimental data of concentrations of D-isomer (○) and L-isomer (●), ↓: predicted point of spontaneous crystallization of D-isomer, — — —: temperature curve programmed so as to cool at the rate of 1/8 °C per min to 12 °C.

stirred at a constant speed (210 rpm), subsequently cooled at the rate of 1/8 °C per min, and thereafter maintained at 12.0 °C. Two grams of L-Ser·mXS·$2H_2O$ (100—200 meshes) was seeded at 20 °C in the course of cooling, and only the L-isomer was preferentially crystallized.

In order to calculate the decrease in the concentration of the L-isomer according to Eqs. 3 and 5, the numerical values of the constants in those equations were obtained as has been described in the section on Materials and Methods. The product of the overall crystal-growth coefficient and the surface area of the seed crystals, a_0K, was 6.49×10^{-2} [min^{-1}]; the crystal-growth rate order was $n=2$ [—].

Under the present experimental conditions, the initial values of C_L, C_D, and W were 0.360 [g/g (water)], 0.360 [g/g(water)], and 0.00154 [g/g(water)] respectively. Using these values and according to Eqs. 3 and 5, the decrease in C_L due to the preferential crystallization of the L-isomer under the programmed cooling pattern described above was calculated. The calculated result for the decrease of C_L is shown in Fig. 2.

To predict the waiting time for spontaneous crystallization, θn, the value of S_{II} was caluclated according to Eq. 6. The waiting time, θn, at which the value of S_{II} reached 4.49 [g·min/g(water)] was 104 [min]. That is, it was predicted that the spontaneous crystallization of the unseeded D-isomer would occur 104 min after the time of inoculation of the L-isomer, as is shown in Fig. 2.

On the other hand, the actual resolution was carried out under the same conditions as have been described in the above illustrative example. The experimental data are also plotted, together with the predicted results, in Fig. 2, indicating that these were in good agreement.

As another example, the prediction of the preferential crystallization process was carried out on the assumption that the solution was cooled at the rate

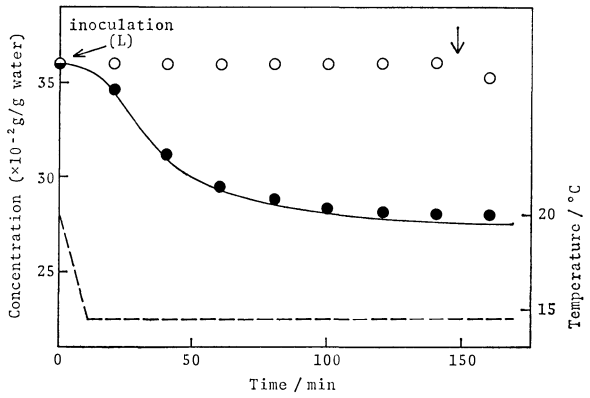

Fig. 3. Comparison between calculated results and experimental data in the optical resolution process of DL-Ser·mXS·$2H_2O$.
——: Calculated curve, ○, ●: experimental data of concentrations of D-isomer (○) and L-isomer (●), ↓ : predicted point of spontaneous crystallization of D-isomer, — — —: temperature curve programmed so as to cool at the rate of 1/2 °C per min to 14.5 °C.

of 1/2 °C per min and thereafter maintained at 14.5 °C. The results ($\theta n = 148$ [min]), predicted in the manner described above, and the experimental data are shown in Fig. 3, indicating that these were also in good agreement.

These results show that the our quantitative approach to ascertaining the limit of the metastable region in the preferential crystallization process is proper and that the waiting time for the spontaneous crystallization of the unseeded isomer can be successfully predicted. Although we did not study the optimization of the optical resolution process of DL-Ser·mXS·$2H_2O$, it seems to be possible to do so by the method presented here. It would also be interesting to learn whether such a prediction method can be applied for the optical resolution processes of other racemic mixtures.

Amination Kinetics of Chloromethylated Polystyrene Accompanied by Acceleration and Deceleration[1)]

Hiroshi KAWABE

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received August 30, 1980)

Procedures to evaluate rigorously the rate constants in the aminations of chloromethylated polystyrene which are accompanied by acceleration and deceleration have been developed. The calculated fractional conversions in the reaction of chloromethylated polystyrene with 2-amino-1-butanol in dioxane, accompanied by acceleration, and the reaction with triethylamine in dimethyl sulfoxide, accompanied by deceleration, are proved to be in good agreement with the observed ones. The activation parameters of these reactions, in addition to the kinetic data in *N,N*-dimethylformamide, support the conclusion that the acceleration and the deceleration are due to the formation of the hydrogen bond and to the electrostatic effect from the neighboring groups in the respective transition states.

The rate constants of the chemical reactions of ploymers with small molecules in homogeneous solutions sometimes increase or decrease during the reactions, as observed in the aminations of chloromethylated polystyrene (CMPS). Although the reaction of CMPS with 2-amino-1-butanol in *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) follows the second-order kinetics, the rate constant increases during the reaction in dioxane.[2)] Such acceleration was also observed in the amination of CMPS with diethanolamine in dioxane and it was considered to be caused by the hydroxyl groups of the already-aminated neighbors in the macromolecule.[3)] Similar acceleration was reported by Drăgan *et al.*[4)] in the reaction of CMPS with 1-dimethylamino-3-propanol and 1-dimethylamino-2-propanol in dioxane and dimethylacetamide. Tsuchida and Irie[5)] observed the acceleration during the reaction of CMPS with γ-picolin in DMF.

On the other hand, the rate constant of the reaction of CMPS with butylamine decreases during the reaction in dioxane, though the reaction in DMF follows the second-order kinetics.[6,7)] Such deceleration was also observed in the reaction of CMPS with diethylamine in both dioxane and DMF and in the reaction with diethanolamine in both DMF and DMSO. The deceleration in these reactions was considered to due to the steric effect of the already-aminated neighboring groups.[3,8)]

The reaction kinetics in polymer solutions which deal with the deceleration was first proposed by Fouss *et al.*,[9)] who studied the quaternization of poly(4-vinylpyridine) with butyl bromide in sulfolane and propyrene carbonate. Since then, deceleration during the quaternization of poly(vinylpyridine) in sulfolane has been investigated kinetically by many investigators,[10-13)] who ascribed it to the steric hindrance or the electrostatic effect by the already-reacted groups in the polymer. But the quaternization of triethylamine with CMPS in DMF was reported to obey the ordinary second-order rate equation by Noda and Kagawa.[14)] Yet the deceleration in DMF was observed in the quaternization of poly(4-dimethylaminostyrene) with methyl iodide by Arcus and Hall[15)] and in the quaternization of poly(4-vinylpyridine) with benzyl chloride by Tsuchida and Irie;[5)] Kawabe and Yanagita[3)] observed also that the quaternization of poly[4-[bis(2-hydroxyethyl)aminomethyl]styrene] with methyl iodide decelerated in an aqueous DMF solution.

The aminations of CMPS accompanied by the deceleration were previously reported by Kawabe and Yanagita[3,6-8)] to conform to a modified second-order rate equation. Recently the present author has also found that the quaternization of triethylamine with CMPS in DMSO is accompanied by deceleration and that the reaction kinetics conforms to the modified rate equation. In the amination of CMPS with 2-amino-1-butanol, which is accompanied by acceleration, however, the conformity of the kinetic data to a similarly modified second-order rate equation was not so excellent, as reported previously.[2)] This reaction is re-examined and a procedure to evaluate the rate constants rigorously is described in this paper. The activation parameters of these reactions will be discussed in relation to their reaction mechanism.

Experimental

Materials. Chloromethylated polystyrenes (chlorine content: 21.4—22.8%, degree of chloromethylation: 0.89—0.97, mol wt: about 1×10^5) were prepared and purified by the procedures described in previous papers.[2,6)] (*R*)-2-Amino-1-butanol was prepared as reported previously.[2)] Triethylamine and solvents were of reagent grade and were distilled before use; they were proved to be pure by their refractive indices.

Kinetic Measurements. The procedures of the kinetic measurements in the amination of CMPS and benzyl chloride were the same as those described previously.[2,6)] The temperature of the reaction mixture was kept constant within ±0.1 K. The initial concentration of chloromethyl group was 0.04 mol dm^{-3}, that of 2-amino-1-butanol was 0.40—0.86 mol dm^{-3}, and that of triethylamine was 0.04 mol dm^{-3}.

Rate Equations

All the reactions of benzyl chloride with 2-amino-1-butanol and triethylamine conform to the second-order rate equation, Eq. 1. The reactions of CMPS with both amines in DMF also conform to Eq. 1:

$$kt = \frac{1}{a-b}\ln\frac{b(a-x)}{a(b-x)} = \frac{1}{a-b}\ln\frac{1-\alpha}{1-\beta} \equiv \bar{k}t, \qquad (1)$$

where a is the initial concentration of the amines; b, that of the chloromethyl groups; x, the concentra-

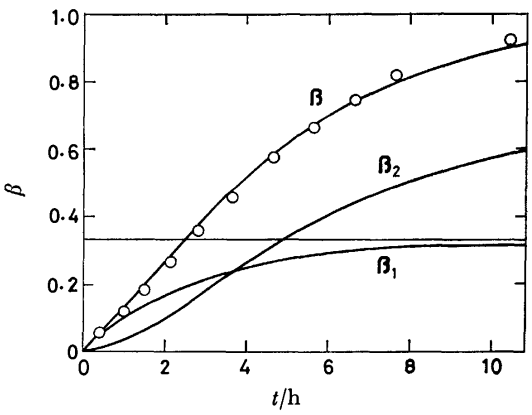

Fig. 1. Amination of CMPS with 2-amino-1-butanol in dioxane at 333.2 K.

tion of chloride ions at time t; and where $\alpha=x/a$ and $\beta=x/b$.

Amination of CMPS with 2-Amino-1-butanol in Dioxane. The second-order rate constant of the reaction of CMPS with 2-amino-1-butanol (k in Eq. 1) increases as the reaction proceeds, and k is a linear function of β:[2]

$$k = k_0(1+m\beta), \tag{2}$$

where k_0 and m are constants. On the basis of a model which represents the neighboring-group effect, β was expressed by Eq. 3 under the condition that a large excess of the amine is present ($a \gg b$):[2]

$$\beta = 1 - A' \exp(-3k_1at) - B' \exp(-k_2at), \tag{3}$$

$$k_1t = \frac{1}{D'a-b} \ln \frac{1-\alpha}{1-D'\beta} \equiv \overline{k_1t} \quad (\beta<1/3), \tag{4}$$

$$k_2t = \overline{kt} - C' \quad (\beta>1/3), \tag{5}$$

where $A'=(k_1-k_2)/(3k_1-k_2)$, $B'=2k_1/(3k_1-k_2)$, $D'=3-2k_2/k_1$, and $C'=\ln[(1-\chi'/a)/(1-\chi'/b)]/(a-b)-k_2\tau'$; τ' and χ' are the values of t and x when $x_1 \simeq b/3$. The k_2 value was obtained from the plot of $\overline{kt}$ against t by virtue of Eq. 5 within the range $\beta>1/3$, while k_1 was obtained on the basis of Eq. 4 by the use of the k_2 value and an approximate value of k_1 which was determined by Eq. 1 in the range $\beta<1/3$.

The over-all course of the reaction was expressed on the basis of Eq. 3 by the use of the k_1 and k_2 values thus obtained; however, the agreement between the calculated and observed values was not so excellent.[2] To explain this discrepancy, the following points need clarification: (i) evaluation of k_1 and k_2, (ii) conditions of the reaction, (iii) the character of the group interaction, and (iv) the model from which the rate equations are derived.

Let us first re-examine the estimation of the rate constants. Taking a glance at Fig. 1, where β is divided into $\beta_1(=x_1/b)$ and $\beta_2(=x_2/b)$ by Eq. 6, we realize that the over-all reaction rate is still controlled by k_1 in a range far beyond the β value of 1/3; β_1 is given by

$$\beta_1 = x_1/b = [1-\exp(-3k_1at)]/3. \tag{6}$$

This may arise owing to the facts that $k_2>k_1$, where k_1 and k_2 are the rate constants of the elementary reactions which are independent of the neighboring group and under the influence of it respectively, and that the elementary reaction characterized by k_1 takes place in a range where β is still larger than 1/3. The k_2 value obtained simply by means of Eq. 5 will have to be corrected in this case, since it does not represent the genuine k_2.

From Eq. 3, we obtain

$$\left.\begin{aligned} k_2t &= -\ln X'/a \equiv \overline{k_2t}, \\ X' &\equiv [(1-\beta)-A' \exp(-3k_1at)]/B'. \end{aligned}\right\} \tag{7}$$

The k_1 value used in the computation is first obtained from a linear plot of $\overline{k_1t}$ against t in a range of $\beta<1/3$ on the basis of Eq. 4. After repeating the computation according to Eq. 7, one may obtain finally a linear plot of $\overline{k_2t}$ against t, which starts from the origin and covers data in a whole range of β; the corrected value of k_2 is thus obtained from the slope of this line. The value of k_1 may further be corrected, if necessary, on the basis of the following equations, which are derived also from Eq. 3:

$$\left.\begin{aligned} k_1t &= -\ln Y'/3a \equiv \overline{k_1t}, \\ Y' &= [(1-\beta)-B' \exp(-k_2at)]/A'. \end{aligned}\right\} \tag{8}$$

After repeating the computation, the final plot of $\overline{k_1t}$ against t will be represented by a straight line which starts from the origin and covers the whole range of β. When neccesary, one may repeat the computations by means of Eqs. 7 and 8 until fixed values of k_1 and k_2 are obtained. In the following section of this paper, it is shown that, in the amination of CMPS with 2-amino-1-butanol, Eq. 7 yields a somewhat greater k_2 value than that determined on the basis of Eq. 5, though Eqs. 4 and 8 yield the same k_1 value.

Quaternization of Triethylamine with CMPS in DMSO. The present author has found that the second-order rate constant (k in Eq. 1) of the reaction of CMPS with triethylamine decreases with the progression of the reaction and that the kinetic data fit Eq. 9; the equation was derived previously on the assumption that the reactivity of a group present between two already-reacted neighboring groups decreases owing to neighboring-group interaction:[3]

$$\beta = 1 - A \exp(-2k_1at) - B \exp(-k_2at), \tag{9}$$

$$k_1t = \frac{1}{Da-b} \ln \frac{1-\alpha}{1-D\beta} \equiv \overline{k_1t} \quad (\beta<1/2), \tag{10}$$

$$k_2t = kt - C \quad (\beta>1/2), \tag{11}$$

where $A=(k_1-k_2)/(2k_1-k_2)$, $B=k_1(2k_1-k_2)$, $D=2-k_2/k_1$, and $C=[(1-\chi/a)/(1-\chi/b)]/(a-b)-k_2\tau$; τ and χ are the values of t and x when $x_1 \simeq b/2$. Not only the present quaternization reaction but also many amination reactions of CMPS accompanied by deceleration fit Eq. 9 with k_1 and k_2 values estimated by Eqs. 10 and 11.[3,6,8] This may be understood by referring to Fig. 4 (also refer to Fig. 9 in Ref. 6), where β of the reaction at 303 K is divided into β_1 and β_2 by virtue of the equation;

$$\beta_1 = [1-\exp(-2k_1at)]/2. \tag{12}$$

Since $k_1>k_2$ in these cases, k_1 is no longer an important kinetic parameter in a range beyond $\beta>1/2$. In cases

where k_1/k_2 is not large, however, the agreement between observed and calculated values may not be so excellent. Rigorous treatment of this kinetics then requires the correction of k_2 and also k_1, if necessary, on the basis of the following equations which are derived from Eq. 9:

$$\left.\begin{aligned} k_2 t &= -\ln X/a \equiv \overline{k_2 t}, \\ X &\equiv [(1-\beta) - A\exp(-2k_1 at)]/B, \end{aligned}\right\} \quad (13)$$

$$\left.\begin{aligned} k_1 t &= -\ln Y/2a \equiv \overline{k_1 t}, \\ Y &\equiv [(1-\beta) - B\exp(-k_2 at)]/A. \end{aligned}\right\} \quad (14)$$

Results and Discussion

Amination Kinetics of CMPS and Benzyl Chloride with 2-Amino-1-butanol in Dioxane. The previously reported kinetic data of the amination of CMPS with 2-amino-1-butanol in dioxane (a=0.86 and b=0.043 mol dm^{-3})[2)] have been re-examined by the procedures described in the preceding section. The rate constants k_1 and k_2, evaluated on the basis of Eqs. 7 and 8, are listed in Table 1. Although the numerical values of k_1 thus obtained are the same as those obtained by means of Eq. 4 and also the same as the k_0 values obtained by Eq. 2, the k_2 values are a little greater than those obtained by Eq. 5. The plots of β against t represented by the solid lines in Fig. 2 are calculated on the basis of Eq. 3; they are in good agreement with the observed values represented by the circles. In the figure, the dotted lines are the previously reported ones, which were computed by using the k_2 values determined by means of Eq. 5. It may therefore be concluded that the disagreement between the calculated and observed values shown in the previous paper[2)] originated in the fact that the evaluation of the rate constants, especially k_2, was not accurate. This correction of k_2, nevertheless, does not cause any change in activation energy, E_a, though the frequency factor, A, for k_2 (Eq. 7) is a little greater than that for k_2 (Eq. 5).

The second problem we concern ourselves with is the effect of the reaction conditions, such as the initial concentration of 2-amino-1-butanol and the reaction temperature. Although the amination kinetics of benzyl chloride fits Eq. 1, k has been found to be dependent on the initial concentration of 2-amino-1-butanol, a, as shown in Table 2. The kinetic data in the amination of CMPS in various conditions have been treated on the basis of Eqs. 2, 4, 5, 7, and 8; the results are summarized in Table 3. The table shows that the k_0 values, which are equal to the k_1 values obtained on the basis of both Eq. 4 and Eq. 8, are also dependent on a, and that the k_2 values obtained by Eq. 5, which are almost equal to the k values extrapolated to β=1 according to Eq. 3, are independent of a. The agreement between the calculated and observed β values is better when the k_2 values obtained on the basis of Eq. 7, instead of Eq. 5, are used.

Tables 2 and 3 indicate that k of benzyl chloride is equal to k_0 of CMPS at the same a and that they increase a little with a, while k_2 of CMPS is independent

of a. Figure 3 shows that k and k_0 increase linearly with a according to the relation:

$$(k_0 \text{ and } k) = k_{int}(1+Ka), \quad (15)$$

where k_{int} and K are constants. The numerical values of k_{int} and K are listed in Table 4; E_a for k_{int} is greater than that for k_0 in Table 1. Consider that the hydroxyl group of 2-amino-1-butanol can form a hydrogen bond, in a non-polar solvent such as dioxane, with the chlorine of the chloromethyl group in the transition state to accelerate the reaction. Then an expression similar to Eq. 15 is easily derived according to the theory of transition states, on the assumption that two kinds of activation complexes coexist, the ordinary one and the hydrogen-bonded one. The physical meaning of the constants in Eq. 15 may thus be realized by considering that k_{int} corresponds to the intrinsic rate constant independent of the hydrogen bond and K is a measure of the force of the hydrogen bond.

The acceleration during the amination of CMPS may be explained by assuming that it is caused by the intramolecular hydrogen bond between the hydroxyl group of the already-aminated neignbor and the chlorine in the transition state. Provided that the intramolecular hydrogen bond is stronger than the intermolecular hydrogen bond, k_2 will be independent of a. The ratio, k_2/k_{int}, is also interpreted as a measure of the intramolecular hydrogen bond. Table 4 indicates that both K and k_2/k_{int} decrease

Table 4. Intrinsic rate constants in the amination of benzyl chloride and CMPS with 2-amino-1-butanol in dioxane

with the increase of temperature; this is not inconsistent with the assumption of the hydrogen bonds.

Quaternization Kinetics of Triethylamine with CMPS and Benzyl Chloride in DMF. In DMF, the quaternization of triethylamine with CMPS as well as with benzyl chloride fits to the ordinary second-order rate equation, Eq. 1. The results are shown in Table 5.

Quaternization Kinetics of Triethylamine with CMPS and Benzyl Chloride in DMSO. Although the quaternization of triethylamine with benzyl chloride fits Eq. 1, that with CMPS is accompanied by deceleration and its rate constants are computed on the basis of Eqs. 10, 11, and 13. The results are summarized in Table 6. Equation 13 gives slightly smaller values of k_2 than those obtained by Eq. 11. The plots of β against t calculated on the basis of Eq. 9, represented by the solid lines in Fig. 4, are in excellent agreement with the observed values represented by the circles.

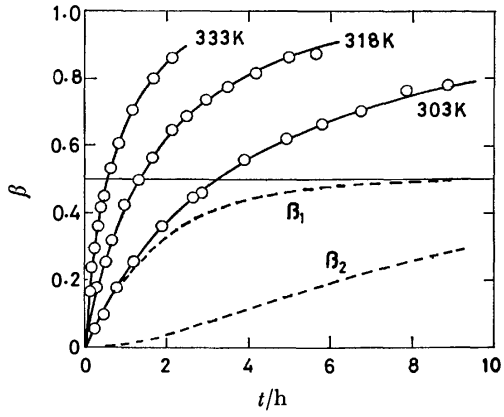

Fig. 4. Amination of CMPS with triethylamine in DMSO.

Activation Parameters. The activation parameters of the reactions are listed in Table 7. In dioxane the ΔG^* values for k_1 and k_2 are lower than that for k_{int} owing to their lower ΔH^* values; this fact supports the assumption that the hydroxyl group of 2-amino-1-butanol in the solution or the already-aminated neighbor in the polymer forms the inter- or intramolecular hydrogen bond with the chlorine of the chloromethyl group in the transition state. On the other hand, the lower ΔG^* value for k_2 than for k_1 is ascribed to the higher ΔS^* value; this suggests that the intramolecular hydrogen bond is formed in preference to the intermolecular one because the former is favorable with respect to entropy.

In the amination with 2-amino-1-butanol of a definite concentration, a, the ΔG^* values of both CMPS and benzyl chloride are the same, since k_0 (or k_1) of CMPS is equal to k of benzyl chloride, as shown in Fig. 3. In the quaternization of triethylamine in DMF, the ΔG^* of CMPS is lower than that of benzyl chloride owing to its lower ΔH^*; the same trend is noticed also in DMSO, when one compares the ΔG^* and ΔH^* values of benzyl chloride and CMPS (k_1).

The present work finds that the quaternization of triethylamine with CMPS in DMF conforms to the ordinary second-order rate equation, as was already reported by Noda and Kagawa,[14] whereas Arcus and Hall[15] found that the quaternization of poly(4-dimethylaminostyrene) with methyl iodide in DMF was accompanied by deceleration. They concluded that this deceleration was caused by the accumulation of positive charges on the polymer. Arcus and Hall[16] also noticed the reduction of rate during the quaternization of poly(4-vinylpyridine) with butyl bromide in sulfolane, as had been reported by Coleman and Fouss,[17] though they found that the reaction followed the second-order kinetics in DMF. It is interesting to note that the quaternization of poly(vinylpyridine) with butyl bromide and the quaternization of triethylamine with CMPS have the similar feature that they behave "normally" in DMF but "autodecelerate" in more polar solvents, such as DMSO and sulfolane.[18] In these cases, the deceleration may be explained by the electrostatic effect of the neighboring quaternary groups rather than by the steric obstruction by the neighbors. The more polar the solvent is, the more easy the ionization of quaternary ammonium chloride formed by the reac-

tion on the polymer may become. As the reaction proceeds, the formation of a positive activation complex may become more difficult owing to the electrostatic effect of the positive charges of the neighboring quaternary ammonium groups. Table 7 indicates that, in the quaternization of triethylamine in DMSO, the ΔG^{*} for k_2 is higher than that for k_1, owing to the higher ΔH^{*}.

Table 7 indicates also that ΔG^{*} values of the quaternization in DMSO are lower than those in DMF owing to the lower ΔH^{*} values. The same fact was also found in the amination of CMPS and benzyl chloride with 2-amino-1-butanol and diethanolamine.[7,21] This may be explained, as discussed in a previous paper,[1] by assuming that the positive activation complex is stabilized by solvation in dipolar aprotic solvents and that the solvated complex is more stable in DMSO than in DMF.

The author wishes to express his thanks to Dr. Masaya Yanagita for his valuable discussions. He is also grateful to Mr. Masaaki Kodera and Mr. Yukio Uesugi for their generous assistance in carrying out the measurements.

NQR Zeeman Study of Bis(triphenylphosphine)copper(I) Bromide

Tsutomu Okuda,* Morio Hiura, and Hisao Negita
Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730
(Received November 4, 1980)

Zeeman effects of ^{63}Cu and ^{81}Br NQR spectra of bis(triphenylphosphine)copper(I) bromide, $CuBr(PPh_3)_2$, have been studied at room temperature. The asymmetry parameters and the quadrupole coupling constants (e^2Qq/h) have been found to be 0.113 and 64.58 MHz for ^{63}Cu and 0.518 and 105.91 MHz for ^{81}Br. The large asymmetry parameter of the ^{81}Br NQR line is caused by the π-bonding character of the copper-bromine bond. The bonding scheme between the copper and bromine atoms is discussed on the basis of the obtained directions of the electric field gradient axes.

A trigonal planar coordination is occasionally seen in copper(I) compounds, though it is rarely found in the other transition metal complexes. The X-ray analysis of $CuBr(PPh_3)_2 \cdot 0.5C_6H_6$ (PPh_3=triphenylphosphine) has shown that the $CuBr(PPh_3)_2$ molecule is monomeric and the coordination geometry about its copper atom is trigonal planar.[1] NQR (nuclear quadrupole resonance) is very useful for the study of bonding character in copper(I) halide compounds, since both copper and halogen atoms have nuclear quadrupole moments. The ^{63}Cu NQR frequency in $CuBr(PPh_3)_2 \cdot 0.5C_6H_6$ has been reported.[2]

In the present study, both the ^{63}Cu and ^{81}Br NQR lines were observed for two compounds, $CuBr(PPh_3)_2$ and $CuBr(PPh_3)_2 \cdot 0.5C_6H_6$. Furthermore, since ^{63}Cu and ^{81}Br both have a nuclear spin $I=3/2$, a Zeeman study of NQR was carried out to determine the nuclear quadrupole coupling constant e^2Qq_{zz}/h, the electric field gradient (efg) principal axes x, y, z, and asymmetry parameter $(q_{xx}-q_{yy})/q_{zz}$. These can be used to describe more explicitly the nature of the bonding.

Experimental

$CuBr(PPh_3)_2 \cdot 0.5C_6H_6$ was prepared according to the method described by Davis *et al.*[1] $CuBr(PPh_3)_2$ was obtained by recrystallization from the ethanol solution of $CuBr(PPh_3)_2 \cdot 0.5C_6H_6$. Found: C, 66.05; H, 4.38%. Calcd for $CuBrP_2C_{39}H_{33}$: C, 66.25; H, 4.56%. Found: C, 64.37; H, 4.66%. Calcd for $CuBrP_2C_{36}H_{30}$: C, 64.72; H, 4.54%. A single crystal of $CuBr(PPh_3)_2$ was obtained by the Bridgman-stockbarger method.

The NQR spectrometers used were super-regenerative oscillators employing a frequency modulation or a Zeeman modulation mode. The resonance lines due to four isotopes: ^{63}Cu, ^{65}Cu, ^{79}Br, and ^{81}Br were assigned on the basis of the known quadrupole moment ratios, $Q(^{63}Cu)/Q(^{65}Cu)=1.0806$ and $Q(^{79}Br)/Q(^{81}Br)=1.1974$. The Zeeman effect on the resonance line was examined by means of the zero-splitting cone method at room temperature with the magnetic field of about 2.5×10^{-2} T. The Zeeman-split signals were displayed on an oscilloscope. The magnetic field orientation for the zero-splitting was determined in polar coordinates (Φ, Θ), where Φ is the azimuthal angle and Θ is the polar angle.

Results and Discussion

The observed frequencies are listed in Table 1. The crystal structure for the benzene solvated compound $CuBr(PPh_3)_2 \cdot 0.5C_6H_6$ is available,[1] but that for unsolvated $CuBr(PPh_3)_2$ is not. From the small difference in both ^{63}Cu and ^{81}Br NQR frequencies, however, it is reasonable to consider that the molecular structure of the unsolvated crystal is essentially the same as that in the solvated crystal, that is, the individual $CuBr(PPh_3)_2$ molecules are monomeric and have the trigonal planar coordinations in the unsolvated crystal.

The zero-splitting patterns obtained for both the ^{63}Cu and ^{81}Br nuclei of $CuBr(PPh_3)_2$ are shown in Fig. 1. From these zero-splitting patterns the asymmetry parameters (η) and the directions of the efg axes were obtained. The quadrupole coupling constant e^2Qq_{zz}/h can be calculated by substituting the value of η in the following relation:

$$\nu = (e^2Qq_{zz}/2h)(1+\eta^2/3)^{1/2}. \quad (1)$$

The values of e^2Qq_{zz}/h derived in this way are listed in Table 1. For comparison, Table 1 includes the ^{63}Cu and ^{81}Br NQR frequencies of $(Bu_4N)CuBr_2$ (Bu=C_4H_9) reported by Bowmaker *et al.*[3] $(Bu_4N)CuBr_2$ has a linear dibromocuprate(I) ion, so that the asymmetry parameters of Cu and Br atoms are assumed

to be zero.

One of the interesting features obtained from the Zeeman experiments is the large asymmetry parameter, 0.519, for the bromine atom. In this complex the bromine atom is considered to link to only one copper atom, as in the solvated compound. However, the obtained, asymmetry parameter is too large for a singly-bonded halogen atom. Accordingly, we can consider that the extraordinarily large asymmetry parameter results from the existence of the π-bond. Since the trigonal copper atom is considered to form sp^2-hybridized orbitals, the p_z orbital of copper is nonbonding, and can be used for π-bonding with ligands. In the previous NQR study and X-ray analysis of $Cu_2X_2(PPh_3)_3$ (X=Cl, Br, and I),[4,5] it was suggested that the p_π-p_π double bonding must occur in the bonds between copper and halogen atoms. In the present study, this suggestion has been confirmed by the large asymmetry parameter obtained for the bromine atom. The Zeeman study using a single crystal, furthermore, has revealed the relative orientations of the efg principal axes for both the ^{63}Cu and ^{81}Br atoms, *i.e.*, the efg x-, y-, and z-axes for the Br atom are along the z-, y-, and x-axes for the copper atom, respectively, as shown in Fig. 1. The z-axis of terminal halogen atom, in general, points along its bond direction. In the case of trigonal planar copper atoms it has become apparent from the Zeeman studies of $KCu(CN)_2$,[6] $Cu_2Cl_2(PPh_3)_3$, and $Cu_2I_2(PPh_3)_3$[4] that the efg z-axis of the three coordinated copper atom is perpendicular to the plane formed by three ligands. Therefore, both the y- and x-axes of the copper atom lie on the coordinate plane. On the basis of these results, the directions of the principal efg axes for both nuclei could be determined in a discrete molecule $CuBr(PPh_3)_2$, as shown in Fig. 2. The x-axis direction of the bromine atom is parallel to the z-axis direction of the copper atom, that is, it is perpendicular to the ligand plane. The y-axis direction of the bromine atom is normal to both its x-axis and its z-axis. This situation is similar to those of the trigonal planar species BBr_3 and BI_3,[7,8] which have p_π-p_π double bondings.

For the Cu–Br bond, one simple bonding model is proposed. The p_x, p_y, and p_z orbitals at the bromine atom are taken to be pointed toward the efg x-, y-, and z-axes, respectively. The p_z orbital forms a σ-bond with one of the sp^2-hybridized orbitals on the three-coordinated copper, and the p_x orbital can form a π-bond with the remaining p orbital on the copper atom. The p_y orbital is thought to have little interaction with the orbitals of the copper atom, so we can assume that the p_y orbital of the bromine atom does not take part in the Cu–Br bond formation. Then, e^2Qq_{zz}/h and the asymmetry parameter (η) are given by

$$e^2Qq_{zz}/e^2Qq_o = N_z - (N_x+N_y)/2, \quad (2)$$

$$\eta = 3(N_x-N_y)/2[N_z-(N_x+N_y)/2], \quad (3)$$

where e^2Qq_o/h is the quadrupole coupling constant for one 4p electron of the ^{81}Br, and N_x, N_y, and N_z denote the number of electrons in the p_x, p_y, and p_z orbitals of the bromine atom, respectively. Assuming $N_y=2$, the occupation numbers N_x and N_z are calculated, to be $N_x=1.943$ and $N_z=1.807$. This N_z value is compared with the ^{81}Br NQR data of the centrosymmetric $CuBr_2^-$ ion,[3] in which $N_z=1.812$ at 298 K, assuming that the bromine atom is singly bonded to the copper(I) atom ($N_x=N_y=2$).

Bersohn[9] has shown that the Townes and Dailey analysis of the halogen coupling constants leads to the following relationship between the fractional π-bonding character, Π, and the coupling constants

$$\Pi = (2/3)(e^2Qq_{zz}/e^2Qq_o)(\eta). \quad (4)$$

The partial π-bonding character calculated according to this equation is 5.7%. This value is significantly smaller than the π-bonding character of the trigonal planar BBr_3 and BI_3 molecules: 13.3% and 15.6% for the boron-bromine and boron-iodine bonds, respectively,[7,8] although the asymmetry parameter of $CuBr(PPh_3)_2$, $\eta=0.519$, is slightly larger than those of the boron trihalides, $\eta=0.45$ for BBr_3 and $\eta=0.456$ for BI_3.[7,8] Thus, the small π-bonding character of the Cu–Br bond results from the fact that the e^2Qq_{zz}/e^2Qq_o ratio of the bromine atom in $CuBr(PPh_3)_2$ is significantly smaller than those of BBr_3 and BI_3. Therefore, it is concluded that the ionic character of the copper-bromine bond is larger than those of the boron-bromine and boron-iodine bonds.

On the other hand, the Cu atom in $CuBr(PPh_3)_2$ has a larger value of e^2Qq_{zz}/h (64.58 MHz) than that of the three-coordinated copper atom in $Cu_2Br_2(PPh_3)_3$ (55.82 MHz at room temperature) in which the copper atom is linked by one triphenylphosphine and two bromine atoms. The e^2Qq_{zz}/h of an sp^2 hybridized

copper atom is considered to be caused by the 4p valence electron donated from three ligands. It is well known that a triphenylphosphine ligand is a better donor than halogen atoms. Therefore, the larger value of e^2Qq_{zz}/h found in $CuBr(PPh_3)_2$ is explained by the increase in the number of the coordinate phosphine ligands, from one to two. In addition, although the efg y-axis was nearly along the Cu–P bonding direction in the case of $Cu_2Br_2(PPh_3)_3$, the y-axis direction in $CuBr(PPh_3)_2$ is normal to the bisector of the P–Cu–P angle. This finding is consistent with the idea that the copper(I) atom receives more electrons from the triphenylphosphine ligand than the halogen atom.

(Received November 19, 1980)

The ESR spectra of the paramagnetic species generated electrochemically from $\alpha,\beta,\gamma,\delta$-tetraphenylporphinatocobalt(II), [Co^{II}(tpp)], have been observed under the conditions of low-temperature, in chlorinated or non-chlorinated solvents, and in the presence of various supporting electrolytes. From the ESR parameters obtained, three different paramagnetic species, [Co^{III}(tpp)]$^{2+}$(X^-)$_2$, [Co^{III}(tpp)]$^{2+}$(Y^-)$_2$, and [Co^{III}(tpp)]$^{2+}$(X^-)(Y^-), have been confirmed. The ESR spectrum of thermally and optically accessible paramagnetic species in the solution of chlorotetraphenylporphinatocobalt(III) has been reproduced by the pertinent combination of solvent and supporting electrolyte, and well interpreted by assuming the formation of [Co^{III}(tpp)]$^{2+}$(Cl^-)$_2$. Arguing from a correlation between the hfcc of cobalt and nitrogen nuclei in this species, a spin-polarization mechanism is proposed to interpret the cobalt hfcc.

The application of electrochemical techniques to the study of biologically important metal-complexes has some advantages over the usual physico-chemical techniques: One is a selective formation of paramagnetic species by applying a pertinent potential comparable to the polarographic half-wave potential ($E_{1/2}$) of the compound under consideration, and another is a close correlation of the electrochemical reaction with the biological redox reactions.[1,2] On the other hand, the ESR measurements are very powerful for the detection of paramagnetic species.[2,3] It is quite natural, therefore, to combine these techniques for a more quantitative investigation of the metal-complexes.

One of the present authors (H.O.) recently developed a simple two-electrode cell using a helix for variable temperature ESR measurements which has several advantages over the commonly used electrolysis cell for ESR in obtaining the spectra of unstable radicals.[4] Using the cell, we have succeeded in obtaining ESR spectra from which the paramagnetic species oxidized electrochemically in the solution of [Co^{II}(tpp)] could be identified as a π-cation radical of six-coordinate [Co^{III}(tpp)]$^{2+}$ having two axial ligands.

It has been reported previously[5] that [Co^{III}(tpp)]$^+$(Cl^-) is a five-coordinate Co(III) complex of tpp which has a square-pyramidal structure with the chlorine atom at the apex. Subsequent ^{1}H FT-NMR[6] and ESR[7] studies have shown that this complex in chlorinated solvents changes partially into paramagnetic species by thermal and light activations. The formation of this species in the solutions occurs reversibly with small enthalpy difference. Such behavior of [Co^{III}(tpp)]$^+$(Cl^-) can be related to the enzymatic reactions of metalloporphyrins and their related compounds. In order to obtain a complete understanding about the behavior of [Co^{III}(tpp)]$^+$(Cl^-), it is necessary first to identify the paramagnetic species generated thermally in the solution of the complex. Secondly it is desirable to determine the molecular and electronic structures of this species.

In this paper we first describe the three kinds of spectra obtained by electrochemical oxidation of [Co^{II}(tpp)] and [Co^{III}(tpp)]$^+$(Cl^-) in chlorinated and non-chlorinated solvents, using various supporting electrolytes, and explain the results by an axial-ligand effect on the π-cation radical of [Co^{III}(tpp)]$^{2+}$. Secondly, the identification of the paramagnetic species formed thermally in the solution of [Co^{III}(tpp)]$^+$(Cl^-) is given. Thirdly, the molecular and electronic structures of the species are discussed based on the ESR parameters obtained experimentally.

Model compounds such as are treated here are sometimes amenable to a more detailed ESR investigation than the bilogical system itself. Therefore the definitive ESR characterization of the compound can provide a framework for understanding the spin states and the electronic structures of active sites of the biological system.

Experimental

[Co^{II}(tpp)], [Co^{III}(tpp)]$^+$(Cl^-), and pyridine-coordinated [Co^{III}(tpp)]$^+$(Cl^-), [Co^{III}(tpp)]$^+$(Cl^-)(py), were prepared using the methods described previously.[5,8] They were identified by elemental analysis and absorption spectra. Commercially available dichloromethane(DCM), 1,1,2,2-tetrachloroethane(TCE), and propionitrile(PCN) of special grade were dried with Woelm 200 neutral alumina. Tetrabutylammonium chloride(TBCl), tetrabutylammonium tetrafluoroborate(TBFB) of special grade for polarography were dried in vacuo before use. Electrochemical oxidation of 10^{-2} mol solution flushed with pure nitrogen gas after degassing by the freeze-thaw-pumping cycle was carried out inside the cavity, using the cell consisting of a helix and a gold wire going through the inside of the helix. The details of the cell construction were given previously.[4] It should be noted here that no reference electrode was used, in order to simplify the electrolysis apparatus. Alternatively, as an indicator of the electrochemical reactions we used the minimum voltage, V_a, applied between two electrodes, at which the ESR spectrum of the radicals generated during the electrolysis appears. The cyclic voltammogram of [Co^{II}(tpp)] was measured using a Hewlett-Packard 3310A function generator in conjunction with a Princeton Applied Research 173 Potentio-Galvanostat equipped with I/V convertor, Model 176. The ESR spectra were taken with a JEOL PE-3X spectrometer equipped with a temperature controller. The g-value of the Cr(III) ion in MgO used as the secondary standard for the determination of g-value was calibrated as 1.9800 ± 0.0001 by that of potassium ni-

trosylbis(sulfate) ($K_2(SO_3)_2NO$, 2.0057).

Results and Discussion

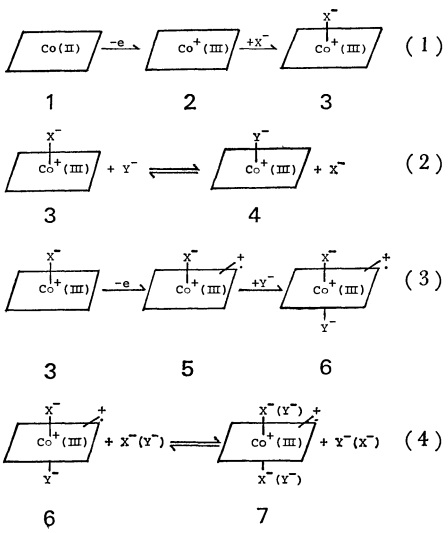
Oxidation of [Co^{II}(tpp)] and [Co^{III}(tpp)]$^+$(Cl$^-$). The cyclic voltammogram of [Co^{II}(tpp)] in benzonitrile with TBFB showed three one-electron reversible oxidation steps corresponding to $E_{1/2}$ *vs.* SCE. Here the

$$[Co^{II}(tpp)] \xrightarrow[(0.52\,V)]{0.45\,V} [Co^{III}(tpp)]^+ \xrightarrow[(1.19\,V)]{1.13\,V} [Co^{III}(tpp)]^{2+} \xrightarrow[(1.42\,V)]{1.41\,V} [Co^{III}(tpp)]^{3+}$$

Scheme 1.

values in parentheses are the data reported by Wolberg and Manassen.[9] The neutral species [Co^{II}(tpp)] (**1**) is paramagnetic, with spin 1/2 compatible with a square-planer $3d^7$ configuration, but can not be detected by ESR measurements in solution, because of its short spin-lattice relaxation time. The first and third oxidation products are expected to be diamagnetic species with the configurations $(3d)^6(a_{2u})^2$ and $(3d)^6(a_{2u})^0$, respectively; indeed, no ESR signal was observed. Therefore, only the second oxidation product, [Co^{III}(tpp)]$^{2+}$, takes part in the ESR spectrum.

[Co^{III}(tpp)]$^+$ (**2**) requires a counter ion with which a five-coordinate complex (**3**) is expected to be formed (see Scheme 2, Eq. 1). Because **3** is diamagnetic, we can not directly observe its formation by the ESR measurements; but we can presume the formation of **3**, because the five-coordinate complex formation after one electron oxidation of **1** was well established by X-ray diffraction of [Co^{III}(tpp)]$^+$(Cl$^-$) single crystal.[5] Further support for Eq. 1 is available in the complexes [M^{II}(tpp)]$^+$(X$^-$) (M=Mg and Zn).[10] Eq. 2 postulates an equilibrium between two five-coordinate complexes formed in the presence of two different anions in solution. If the association power of Y$^-$ is stronger than that of X$^-$, the equilibrium proceeds to the right hand side of Eq. 2. When species **3** is oxidized further at the voltages between



Scheme 2.

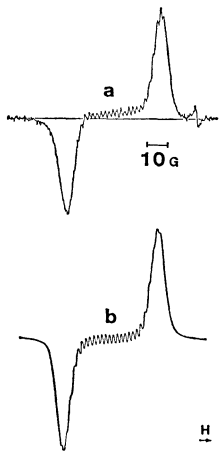


Fig. 1. The ESR spectrum of the paramagnetic species generated by electrochemical oxidation of [Co^{II}(tpp)] in PCN at −70 °C (a). Supporting electrolyte: TBFB. Simulation (b) assumes one cobalt a_{Co}= 6.00 G and four nitrogens a_N=1.85 G.

1.1 and 1.4 V SCE the first ligand oxidation proceeds (Eq. 3). In a manner similar to Eq. 1, the π-cation radical (**5**) produced is followed by the formation of a six-coordinate complex (**6**) with the anion Y$^-$. If X$^-$ (Y$^-$) exists sufficiently in excess, or the association power of X$^-$ (Y$^-$) is sufficiently stronger than that of Y$^-$ (X$^-$), the equilibrium of Eq. 4 proceeds to the right hand side. As the result of two one-electron oxidations of **1** or one-electron oxidations of **3** in various atmospheres, it is presumed that three different paramagnetic species: [Co^{III}(tpp)]$^{2+}$(X$^-$)$_2$, [Co^{III}(tpp)]$^{2+}$(X$^-$)(Y$^-$), and [Co^{III}(tpp)]$^{2+}$(Y$^-$)$_2$ are generated.

[Co^{III}(tpp)]$^{2+}$(X$^-$)$_2$(X=BF$_4$ and ClO$_4$). **1** was dissolved in chlorinated solvent, DCM or TCE, or non-chlorinated solvent, PCN, including a supporting electrolyte with a weak-ligand anion such as ClO_4^- or BF_4^-. After the temperature of the solution of PCN with BF_4^- was decreased to −70 °C, the voltage applied between the two electrodes was increased until the ESR signal could be observed on a recorder with the modulation amplitude of 4 G.** As the voltage reached V_a, corresponding to the second oxidation, an ESR signal (g=2.0034) with partially resolved hyperfine structure (hfs) appeared, as shown in Fig. 1a. V_a depended on the combination of solvent and supporting electrolyte:[4] For example, 2.5 V for PCN with BF_4^- or ClO_4^-, 1.7 V for DCM with BF_4^-, and 1.3 V for TCE with BF_4^-. When the temperature was increased to −50 °C, the spectrum showed appreciable broadning and coincided with that reported in the literature.[9] When DCM and TBPC(TBFB) were used as solvent and supporting electrolyte, respectively, the g-value and the hyperfine coupling constant(hfcc) of ^{59}Co of the spectrum were very similar (see Table 1). As the temperature of the solution was increased above −50 °C, a new signal superposed to the original one appeared. The g-value and the peak-to-peak width ΔH of this signal were

2.0052 and 49 G, respectively. This paramagnetic species was identified as a mixed-ligand complex attached by one chlorine anion, as will be discussed later.

The small variations of the hfcc of cobalt and g-values in Table 1 can be attributed to the solvent and axial-ligand effect, as was extensively investigated in the ion-pairs of aromatic hydrocarbon anion radicals with counter ions.[11] The spectrum simulation of Fig. 1a was carried out using $a_{Co}=6.0$ G for one cobalt and $a_N=1.85$ G for four nitrogens (Fig. 1b), which led to the best fit to the experimental data. We note here that the Lorentzian line shape with the line-width of 3.5 G is used and the unresolved hfs due to eight equivalent protons of phenyl rings ($a_H=0.3$ G)[11] are included; the contribution of the protons attached to the meso-phenyl rings to the line-width is also taken into account. This procedure was useful in improving the spectrum simulation. The g-value and a_N of this paramagnetic species are very close to those of $[M^{II}(tpp)]^+$ (M=Mg, Zn, and Cd), as was already reviewed by Fajer and Davis.[10] Such a nice coincidence of these values indicates that the paramagnetic species generated by the oxidation of **1** is a π-cation radical similar to $[M^{II}(tpp)]^+$. Further, the value of a_N measured at temperatures below −60 °C guides us to the quantitative discussion of the spin distribution in the highes occupied molecular orbitals (HOMO) of the porphyrins.

$[Co^{III}(tpp)]^{2+}(Y^-)_2(Y=Cl)$. The ESR spectrum of the radical obtained by the electrochemical oxidation of **1** in DCM or PCN at 1.4 V, changing the anion of electrolyte from BF_4^-(ClO_4^-) to an intermediate-ligand, Cl^-, was somewhat different from those mentioned above. The most resolved spectrum measured at −70 °C is shown in Fig. 2 together with simulated ones. The spectra measured at temperatures above −50 °C agreed entirely with that of the paramagnetic species derived thermally from $[Co^{III}(tpp)]^+(Cl^-)$ in DCM.[7] In Fig. 2a, one can recognize hfs in addition to the hfs due to ^{59}Co, which could be resolved at temperatures below −60 °C. The hfcc were determined by comparing the observed spectrum with the simulated ones. Figures 2b and 2c were obtained using $a_{Co}=10.3$ G and $a_N=2.80$ G without and with the hfcc due to two chlorine atoms, respectively. In both cases the contribution of the unresolved proton hfcc ($a_H=0.3$ G) is taken into account. Figure 2c was obtained by the superposition of two simulation spectra, corresponding to the existence of two chlorine isotopes ($a_{^{35}Cl}=2.20$ G and $a_{^{37}Cl}=1.80$ G). Figure 2b is similar to the observed one, but the intensity sequences of the absorption lines and the tails of both wings of the spectrum do not coincide with the observed spectrum. The simulated spectrum, Fig. 2c, which includes the splittings due to two chlorine nuclei, coincided excellently with the observed one. The values of hfcc used for the simulations are listed in Table 1, with the measured

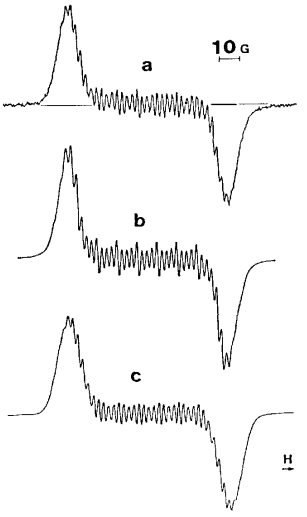

Fig. 2. The ESR spectrum of the paramagnetic species generated by electrochemical oxidation of $[Co^{II}(tpp)]$ in DCM at −70 °C (a). Supporting electrolyte: TBCl. Simulation (b) assumes one cobalt $a_{Co}=10.3$ G and four nitrogens $a_N=2.80$ G. Simulation (c) assumes one cobalt $a_{Co}=10.3$ G, four nitrogens $a_N=2.80$ G, and two chlorines $a_{^{35}Cl}=2.20$ G ($a_{^{37}Cl}=1.80$ G). Contribution of the isotope to the spectrum is included.

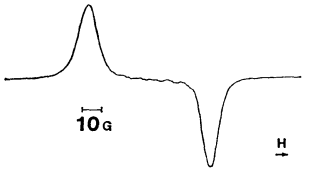

Fig. 3. The ESR spectrum of the paramagnetic species generated by electrochemical oxidation of $[Co^{III}(tpp)]^{2+}(Cl^-)(py)$ in DCM at −90 °C. Supporting electrolyte: TBCl.

g-values. The detection of the hfs due to two equivalent chlorines in addition to those due to ^{59}Co and ^{14}N reflects unequivocally the fact that two axial positions of **3** are occupied by chlorine anions. Thus the radical generated by the oxidation of **1** in DCM and PCN with Cl^- is identified as a π-cation radical of six-coordinate $[Co^{III}\ tpp)]^{2+}$, having two chlorine anions as axial ligands.

It was established in the metal complexes of meso-tetraphenylporphyrins[10] that meso-positions carry large spin density, whereas the nitrogen splittings (a_N= 1.2—1.9 G) show about 20% of the total spin with only limited variations in a_N. The nitrogen hfcc in $[Co^{III}(tpp)]^{2+}(Cl^-)_2$ is a little large compared with those of $[Co^{III}(tpp)]^{2+}(X^-)_2$(X=$BF_4$ and ClO_4) and of $[M^{II}(tpp)]^{+}$(M=Mg, Zn, and Cd), but it is reasonable to conclude that the unpaired electron is mostly localized in a_{2u} orbital of the porphyrin ligand. The metal hfcc of 10.3 G reflects only a small unpaired electron density, of the order of 0.01.[10] The large *g*-value and ^{59}Co hfcc of $[Co^{III}(tpp)]^{2+}(Cl^-)_2$, compared with those of $[Co^{III}(tpp)]^{2+}(X^-)_2$(X=$BF_4$ and ClO_4), may indicate that the chlorine ligation enhances the localization of spin density at nitrogens, which leads to the large spin polarization at the cobalt nuclei.

$[Co^{III}(tpp)]^{2+}(Cl^-)(Z)$ (Z=py and BF^-_4). The possible alternative species generated by the oxidation of **1** is the one in which different ligands are present in the two axial positions. Such a configuration of the ligands could first be visualized by the oxidation of pyridine-coordinated $[Co^{III}(tpp)]^{+}(Cl^-)$, in which one of the two ligand positions is strongly masked by a pyridine molecule. Figure 3 shows the spectrum of the paramagnetic species obtained by the oxidation of $[Co^{III}(tpp)]^{+}(Cl^-)(py)$ in DCM with Cl^- (V_a=2.0 V). The hfs due to ^{59}Co could only be resolved at temperatures below −50 °C (a_{Co}=8.0 G). The *g*-value, 2.0056, was appreciably larger than those described above.

The oxidation of $[Co^{III}(tpp)]^{+}(Cl^-)$ in DCM with BF_4^-, on the other hand, showed the spectrum due to the new radical species with *g*-value of 2.0052 and peak-to-peak width of 49 G, which was superimposed on that of $[Co^{III}(tpp)]^{2+}(Cl^-)_2$. It was found from the temperature variation of the spectrum that these two species are in equilibrium. Therefore, one can conclude that the new signal corresponds to the $[Co^{III}(tpp)]^{2+}(Cl^-)(BF_4^-)$, which shows larger *g*-value and smaller ^{59}Co hfcc, compared with those of $[Co^{III}(tpp)]^{2+}(Cl^-)_2$. We note here that this signal could also be observed when $[Co^{II}(tpp)]$ in DCM with BF_4^-, the condition without chlorine anion, was oxidized at temperatures above −50 °C. This means that the radical substracts the chlorine anion from the solvent used.

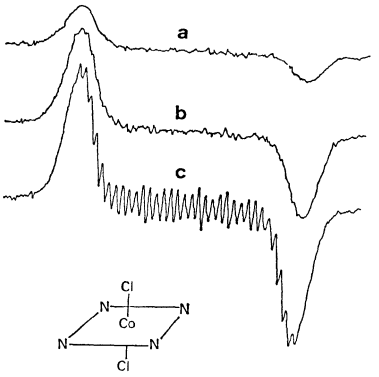

Fig. 4. Temperature dependence of the ESR spectrum of $[Co^{III}(tpp)]^{2+}(Cl^-)_2$ in DCM generated by electrochemical oxidation at −20, −35, and −70 °C (a, b, and c, respectively).

Consequently, $[Co^{III}(tpp)]^{2+}(X^-)_2$ (X=BF_4 and ClO_4) showed a nearly free *g*-value and small ^{59}Co hfcc of 5.0 to 6.0 G. The *g*-value of $[Co^{III}(tpp)]^{2+}(Cl^-)_2$ is also very close to the free *g*-values, but the hfcc of ^{59}Co is about twice as large as those of the former. The mixed-ligand complex can be characterized by a large *g*-value compared with those described above, although the value of the hfcc of ^{59}Co is in the middle.

π-Cation Radical of $[Co^{III}(tpp)]^{2+}$ Formed Thermally in the Solution of $[Co^{III}(tpp)]^{+}(Cl^-)$. The solution of $[Co^{III}(tpp)]^{+}(Cl^-)$ in chloroform, DCM, and TCE (10^{-3} mol dm^{-1}) showed an ESR spectrum at room temperature even in the presence of air.[7] The spectrum showed reversible temperature dependence, the enthalpy difference being about 4 kJ mol^{-1}. By comparing the spectrum in DCM with that of $[Co^{III}(tpp)]^{2+}(Cl^-)_2$ in DCM oxidized electrochemically at temperatures above −50 °C, as shown in Fig. 4, we could unequivocally identify the species as $[Co^{III}(tpp)]^{2+}(Cl^-)_2$. On the other hand, $[Co^{III}(tpp)]^{+}(Cl^-)$ in TCE exhibited the temperature dependent ESR spectra, which were nicely reproduced by the electrochemical oxidation of $[Co^{III}(tpp)]^{+}(Cl^-)$ in TCE with Cl^-. Comparison of the ESR parameters of this spectra with those listed in Table 1 leads to an equilibrium between two species

$$[Co^{III}(tpp)]^{2+}(Cl^-)_2 + S \rightleftharpoons [Co^{III}(tpp)]^{2+}(Cl^-)(S) + Cl^-. \quad (5)$$

S: Solvent molecule

The details of the experiments described here will be given separately.

The Electronic Configuration of $[Co^{III}(tpp)]^{2+}$. As was already pointed out, the observation of the hfs due to ^{35}Cl in addition to those due to ^{59}Co and ^{14}N led to the definite electronic structure and wave function of the radical. It was well established that the neutral species $[Co^{II}(tpp)]$ is paramagnetic with an effective electron spin 1/2 with a square-planer $3d^7$ configuration: $(3d_z)^4(3d_{xy})^2(3d_{z^2})^1$. The two-electron oxida-

tion product, on the other hand, showed definite free radical parameters which can be interpreted by a formal electronic configuration $(3d_\pi)^4(3d_{xy})^2(a_{2u})^1$: a_{2u} π-orbital has a spin distribution characterized by the appreciable localization (76%) at meso-carbon atoms, followed by 20% spin density at four nitrogen atoms. This spin distribution was experimentally confirmed by the observation of four nitrogen hfcc of 1.85 to 2.8 G in our case. The nearly free g-value of the radical tells us that 3d orbitals do not contribute to the HOMO of the radical. The almost isotropic hfcc due to ^{59}Co indicates that the configuration of the central metal-ion is mainly $(3d_\pi)^4(3d_{xy})^2$ and the contribution to the hfcc is almost due to the Fermi contact term polarized by the spin on the neighboring π-orbital of the ligand.

One can consider the following mechanism to interpret ^{59}Co hfcc: 1) The spin polarization of σ-electron in the Co–N bonds by the σ-electron spin density on the nitrogen nuclei produces a spin density at the cobalt nucleus: This is essentially an extension of McConnell relation[12] developed originally to interpret the proton hfcc in the fregment of C–H. It should be noted that in this case the spin density at the Co nucleus is of opposite sign to that of the spin density at the π-orbital of the N atoms. 2) The direct overlap of the Co atomic orbital with the π-orbital of the ligand induces a net plus spin density at the Co nucleus. The π-orbital of tpp on which the unpaired electron resides has a nodal plane which coincides with the tpp molecular plane. Therefore, it is necessary to deviate from this plane for the Co atom to have the direct overlap. Then one can describe the a_{Co} as

$$a_{Co} = Q^{Co}_{N-Co} \times \rho^{\pi}_{N} + \alpha, \quad (6)$$

where Q^{Co}_{N-Co} is a proportionality constant and α means a contribution from the direct overlap.

Figure 5 shows a correlation between a_{Co} and a_N listed in Table 1, in addition to those of other Co(III) porphyrins reported previously.[9,13,14] We assume here that the sign of a_{Co} of Co(III) meso-substituted porphyrin cation radicals is negative. The data points are not so many, but one can conclude that the a_{Co} is roughly expressed by a linear function of a_N, which results in a linear relationship between a_{Co} and ρ^{π}_{N}, because a_N is usually expressed as $a_N = Q^{\pi}_{N} \times \rho^{\pi}_{N} - \sum_i Q_{NC} \times \rho_{C_i}$ and $\rho_{C_i} \cong 0$ for the a_{2u} orbital of tpp. It is now difficult to explain quantitatively the variation of the a_{Co} depending on the axial ligands and solvent used, but we can regard its variety as the result of the spin-polarization mechanism in the clouds of the a_{2u} π-orbital of tpp, which changes according to the axial ligands and the solvent molecules.

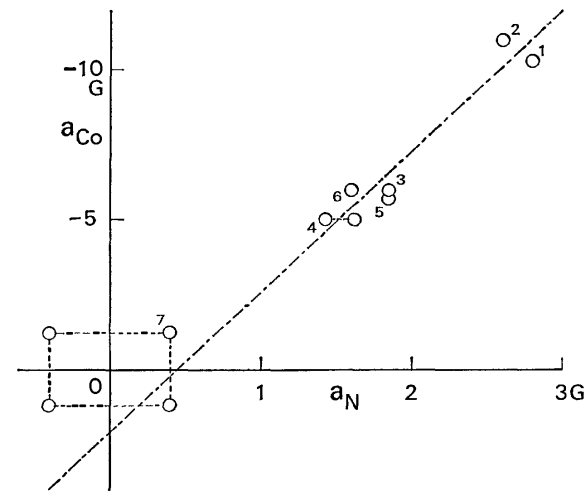

Fig. 5. A correlation between a_{Co} and a_N of some six-coordinate Co(III) porphyrin cation radicals; 1: $[Co^{III}(tpp)]^{2+}(Cl^-)_2$ (in DCM), 2: $[Co^{III}(tpp)]^{2+}(Cl^-)_2$ (in PCN), 3: $[Co^{III}(tpp)]^{2+}(BF_4^-)_2$ (in PCN), 4: $[Co^{III}(tpp)]^{2+}(ClO_4^-)_2$ (in DCM), 5: $[Co^{III}(tpp)]^{2+}(ClO_4^-)_2$ (in butyronitrile (BCN)) 6: $[Co^{III}((pr)_4p)]^{2+}(ClO_4^-)_2$ (in BCN), and 7: $[Co^{III}(oep)]^{2+}(ClO_4^-)_2$. For numbers 4, 5, 6, and 7, a_N of corresponding cation radicals of the Zn(II) complexes were used. Four points for number 7 correspond to the possibilities by the combination of the signs of a_{Co} and a_N.

Collision Induced Perturbations on the Long-lived Fluorescence of Pyrazine in S_1

Hisao IGARASHI and Koji KAYA*,†

Department of Chemistry, Faculty of Science, Tohoku University, Aza-Aoba, Aramaki, Sendai 980

(Received December 5, 1980)

Collision induced intersystem crossing (slow fluorescence quenching and phosphorescence induction) from selected vibronic levels of pyrazine in $S_1(n\pi^*, B_{3u})$ was investigated. It was found that slow fluorescence quenching rate at the zero point level exceeds the hard sphere collision rate several times and rapidly approaches it as the excitation energy is increased. On the other hand, phosphorescence induction rate was found to be nearly equal to the collision rate and to have little excitation energy dependence. These differences were discussed on the basis of the collision induced relaxation mechanisms.

In the past decade, the photophysical properties of the electronic excited states of polyatomic molecules in an isolated molecular condition have been studied extensively both from experimental and theoretical points of view and the concept of the intramolecular radiationless transition has been established. On the basis of the understanding of the unimolecular processes, the subsequent problem to be studied seems to be the collision induced intramolecular relaxations which are essentially important in understanding the photochemical reactions. Despite the importance of the collision induced processes, the theoretical interpretation does not seem to be successful yet. This comes from, (1) the lack of the accumulation of the experimental results which are worthwhile to be analyzed theoretically and, (2) the difficulty in dealing with the intermolecular interaction as the perturbation due to the collision.

Spectroscopic and dynamical properties of S_1 ($n\pi^*$, $^1B_{3u}$) pyrazine have been investigated thoroughly by many workers.[1-20] Individual vibronic levels of S_1 up to 1000 cm^{-1} from the 0-0 band have been assigned by the absorption,[1-7] SVL fluorescence[13,14] and pre-resonance Raman scattering works.[8-12] Under the collision free condition, the fluorescence of pyrazine from the S_1 state exhibits bi-exponential decay that is typical of the intermediate strong coupling molecule as reported by Lahmani *et al.*[16] In pyrazine, the short-lived component of the fluorescence has the lifetime shorter than 10^{-9} s and the long-lived one is of the order of 10^{-7} s.

When one looks at the effect of collision on the prompt fluorescence, one is able to study the vibrational relaxation within S_1 manifolds. The vibrational mode dependence of V-V transfer rate has been investigated by us on the selected vibronic levels of S_1 pyrazine.[21]

The long-lived fluorescence derives from the interaction of S_1 with the isoenergetic triplet ro-vibronic levels. The effect of the collision appears on the two optical phenomena, *i.e.*, (1) the quenching of the slow fluorescence and (2) the induction of the phosphorescence from T_1. In the present work, we have investigated the excitation energy dependences of the quenching rate of the slow fluorescence and the induction rate of the phosphorescence under the SVL excitation condition. The amount of the energy loss within the triplet manifolds by a collision has been also obtained under the assumption of the step-ladder relaxation model.

Experimental

As an exciting light source, the second harmonics of a tunable dye laser (Rh-640) pumped by a Molectron nitrogen laser (UV-22) was used. Either RDP or ADA was used as an SHG crystal. The emission intensity was measured by an HTV-R-562 photomultiplier averaged by a boxcar integrator (Brookdeal 9415 and 9425). In order to distinguish fluorescence from phosphorescence, a Nikon P-250 monochromator of 6 nm slit width with a fixed wavelength (345 nm for fluorescence or 390 nm for phosphorescence) was placed in front of the photomultiplier. Moreover, a delay time of the boxcar integrator was adjusted to get the best separation between them. As a collision partner, isopentane whose pressure extends from 0 to 20 Torr (1 Torr= 133.322 Pa.) was added to 2×10^{-2} Torr pyrazine. The gas pressure was measured by a Baratron 222A capacitance manometer. Pyrazine was purified by vacuum sublimations and spectral grade isopentane was used without further purification. The samples were degassed by the freeze-thaw cycles prior to the experiments.

By varying the excitation wavelength up to 1000 cm^{-1} above the 0-0 of S_1-S_0 absorption and the pressure of isopentane, wavelength and pressure dependences of the fluorescence and the phosphorescence were measured by the following procedures. As mentioned above, the fluorescence contains the prompt and slow components. The former component is affected only by adding high pressure gas exceeding 100 Torr. Still the latter one is sensitive to the trivial amount of a foreign gas and is quenched completely in the presence of 20 Torr isopentane. Then, the intensity of the long-lived fluorescence $I_{sf}(P)$ at the pressure P($P<20$ Torr) is given by

$$I_{sf}(P) = I_{345}(P) - I_{345}(P=20\ \text{Torr}).$$

Where $I_{345}(P)$ is the fluorescence intensity observed at 345 nm with the spectral slit width of 6 nm. The phosphorescence of pyrazine at the pressure P as denoted $I_{ph}(P)$ is dispersed around 390 nm and is overlapped with the fluorescence. By noting the fact that the phosphorescence is induced by collisions, the phosphorescence component is extracted from the total emission observed at 390 nm by the following correction.

$$I_{ph}(P) = I_{390}(P) - I_{345}(P) \times \frac{I_{390}(P=0)}{I_{345}(P=0)}$$

$I_{390}(P)$ is the total (phosphorescence and fluorescence) emis-

† Present address: Department of Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223.

sion intensity at 390 nm and $I_{345}(P)$ is the fluorescence intensity observed at 345 nm at the pressure P. The emission intensity at 390 nm extrapolated at zero pressure $I_{390}(P=0)$ contains only the fluorescence. Thus, the second term of the above equation gives the fluorescence component at 390 nm at the pressure P.

Results and Discussion

The observed fluorescence and phosphorescence intensities against the excitation wavelength and the foreign gas pressure inform us of three physical quantities of the collision induced relaxation. They are, the slow fluorescence quenching rate, the phosphorescence induction rate or the vibrational relaxation rate within the triplet levels and the energy removed per an effective collision. First, the kinetic scheme is given to describe the collision induced relaxation processes from S_1 pyrazine. Then, the experimental results will be discussed on the basis of the kinetic scheme.

The Kinetic Scheme. Temporal behavior of the excited state of an intermediate size molecule like pyrazine has been described quantum mechanically by Lahmani *et al.*[16] van der Werf *et al.*[23] have adopted a kinetic scheme to explain the electronic relaxation of biacetyl. In the present wotk, the kinetic description was used for the evaluation of the above mentioned physical quantities from the experimental data.

Bi-exponential dacay of an excited intermediate size molecule with strong S-T coupling is described by

$$1/\tau_{f1} \simeq \Delta_{ST}, \tag{1}$$

$$1/\tau_{f2} = \bar{\gamma}_n \simeq \bar{\gamma}_S/N + \gamma_T. \tag{2}$$

τ_{f1} and τ_{f2} are the lifetimes of the fast and slow fluorescence, respectively. Δ_{ST} stands for the coupling strength between a vibronic level of the singlet state and N triplet levels. Total decay widths of a S state and a T state are defined as γ and γ which are given as superpositions of individual decay channels by

$$\gamma_S = \Gamma_S + \Delta_{ST} + \gamma_{SS_0}, \tag{3}$$

$$\gamma_T = \Gamma_T + \gamma_{TS_0}. \tag{4}$$

Here Γ_S and Γ_T are the radiative widths of the S and T states, respectively. γ_{SS_0} and γ_{TS_0} indicate the nonradiative decay widths between S and S_0 and between T and S_0, respectively. γ_n represents the total decay width of $(N+1)$ quasistationary states which are formed by the interaction between a S state and N triplet states ($N \approx 10^3$). $\bar{X}$ implies the mean value of the physical quantity X. Because Δ_{ST} is much larger than γ_n, the influence of the collision appears mainly on the $\bar{\gamma}_n$ or γ_T values at relatively low pressure (<20 Torr). That is to say, the collisional perturbation affects only the long-lived fluorescence with a negligible influence on the prompt component as described by

$$\gamma_T(P) = \gamma_T(P=0) + k_q P, \tag{5}$$

where k_q is the quenching rate constant of the slow fluorescence and is obtained by the following Stern-Volmer relation.

$$I_{sf}(P=0)/I_{sf}(P) = 1 + A_f P \tag{6}$$

$$A_f = k_q \tau_{f2} \tag{7}$$

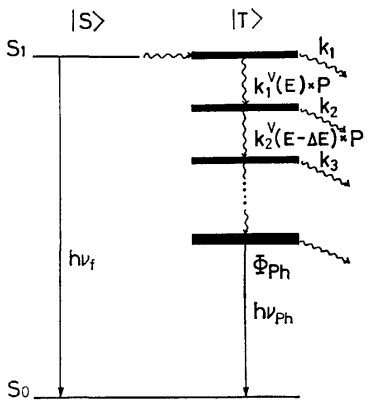

Fig. 1. Step-ladder scheme of vibrational relaxation within triplet manifolds. Symbols are defined in the text.

Here $I_{sf}(P)$ represents the intensity of the slow fluorescence at the pressure P.

It is already known that the phosphorescence of pyrazine is the induced one by collisions after the excitation of a S_1 vibronic level. The pressure dependence of the collision induced phosphorescence intensity informs us of the vibrational relaxation rate within the triplet manifolds and the amount of the removed energy per an effective collision by assuming the step-ladder relaxation model as illustrated in Fig. 1. In the figure, k_i represents the unimolecular decay constant from the triplet manifolds and k_i^v is the collision induced vibrational relaxation rate. ΔE stands for the removed energy by an effective collision. Then, the intensity of the collsion induced phosphorescence at the pressure P is given by

$$I_{ph}(P) = \Phi_{ph} \prod_{i=1}^{n} k_i^v P/(k_i + k_i^v P). \tag{8}$$

Here n is the number of the effective collisions to induce the phosphorescence. Φ_{ph} indicates the quantum yield of the phosphorescence. The reciprocal of the $I_{ph}(P)$ in Eq. 8 can be expanded in the form of the power series of P^{-1} up to the n-th order. k_i values

$$I_{ph}^{-1}(P) = C(1 + \alpha P^{-1} + \beta P^{-2} + \cdots) \tag{9}$$

$$\alpha = \sum_{i=1}^{n} k_i/k_i^v \tag{10}$$

$$\beta = \sum_{i<j} k_i k_j/k_i^v k_j^v \tag{11}$$

can be obtained experimentally only at the initial (i=1) and the final (i=n) level of the step-ladder relaxation from the known slow fluorescence and phosphorescence lifetimes, respectively. k_i for the intermediate step was estimated from the semilogarithmic plot of k_i against the excess energy from T_1. As will be discussed in the later section, the removed energy by a collision was found to be around 1200 cm^{-1}, k_i decreases rapidly as the vibrational relaxation proceeds to the lower step. On the other hand, k_i^v can be assumed to have no appreciable energy dependence as has been found in S_1 pyrazine.[21] Thus, the relation $k_i/k_i^v \gg k_{i+1}/k_{i+1}^v$ may hold for each step. Under these assumptions, Eqs. 10 and 11 can be approximated as

a) Our result using isopentane as a collision partner. b) Result using SF_6 as a collision partner by Lahmani *et al.* in Ref. 16.

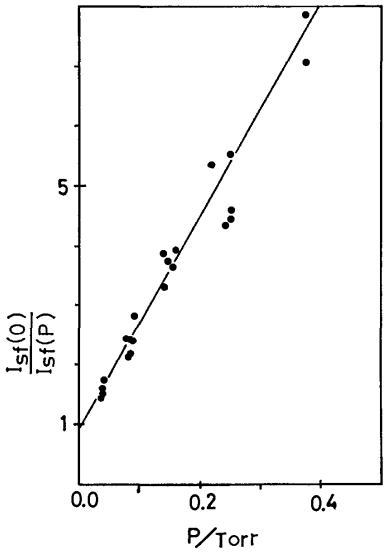

Fig. 2. Stern-Volmer plot of slow fluorescence intensity from the zero point level of S_1. P indicates isopentane pressure. The slope gives the A_f value in Eq. 7.

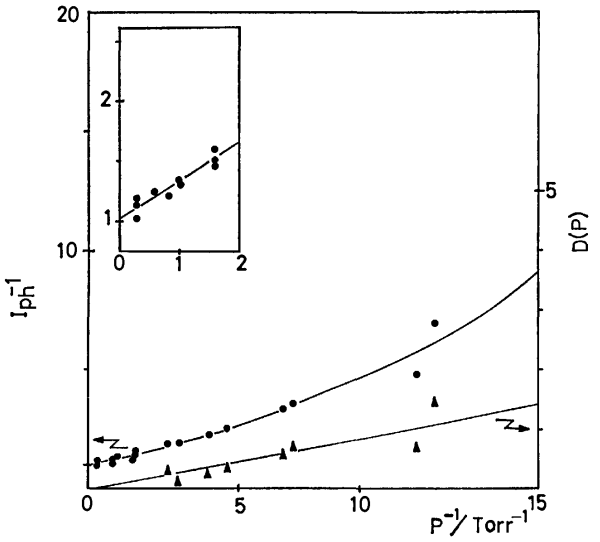

Fig. 3. Phosphorescence induction after the excitation in the zero point level of S_1. I_{ph}^{-1} is plotted against P^{-1} (—●—). The region of 0—2 $Torr^{-1}$ is expanded and its slope gives α value in Eq. 12. The deviation from the linearity is also plotted (—▲—) in the from of the function $D(P)=\{I_{ph}^{-1}-(1+\alpha P^{-1})\}^{1/2}$ and its slope ($\sqrt{\beta}$) gives β value in Eq. 13.

$$\alpha(E) = k_1(E)/k_1^v(E), \tag{12}$$

$$\beta(E) = k_1(E)k_2(E-\Delta E)/k_1^v(E)k_2^v(E-\Delta E) = \alpha(E)\alpha(E-\Delta E). \tag{13}$$

First, the reciprocal of the phosphorescence intensity is plotted against the inverse of the pressure. The linear slope and the deviation from the linearity give the values α and β. Because $1/k_1$ is the experimentally observed lifetime of the long-lived fluorescence from a selected vibronic level of S_1, the vibrational relaxation rate k_1^v can be evaluated from the α and the k_1 values. In the next step, α and β/α values are plotted against the excitation energy. The energy separation that gives the identical values of α and β/α corresponds to the removed energy ΔE per an effective collision.

The Slow Fluorescence Quenching Rate. By use of the Eqs. 6 and 7, the slow fluorescence quenching rates for the individual vibronic levels of S_1 pyrazine were evaluated on the basis of the observed slow fluorescence intensities $I_{sf}(0)$ and $I_{sf}(P)$. The result is illustrated in Fig. 2 taking the 0-0 band excitation as an example. k_q and A_f values for the individual levels are tabulated in Table 1. One notices easily that k_q values in the excitation around the 0-0 band exceed several times the hard sphere collision value ($\approx 10^7\ s^{-1}\ Torr^{-1}$). Moreover, the value decreases rapidly to reach the hard sphere collision one as the excitation energy is increased.

The Vibrational Relaxation Rate within the Triplet Levels. As the intensity of the slow fluorescence is decreased by collisions, the phosphorescence from T_1 is induced *via* the collision induced vibrational relaxation from the higher triplet levels. Thus, one can evaluate the vibrational relaxation rate from the pressure dependence of the phosphorescence induction. In Fig. 3, the reciprocal intensity of the phosphorescence is plotted against the inverse pressure taking the 0-0 band excitation as an example. The α value that contains the information of two body collision gives us the vibrational relaxation rate within the triplet manifolds. k_1^v values obtained from the α values for the individual vibronic levels of S_1 are of the order of the hard sphere collision rate as seen in Table 1. They do not exhibit appreciable variation as the excitation energy is increased, which is in contrast to k_q.

Discussion on the Slow Fluorescence Quenching and the Phosphorescence Induction Mechanisms. As seen in the

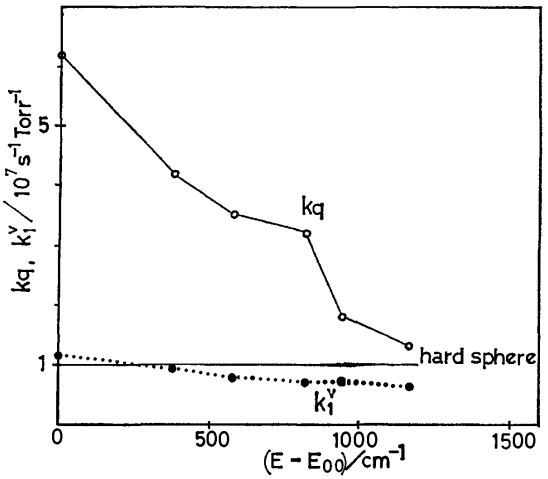

Fig. 4. Excitation energy dependence of the collision induced relaxation rate constant. Slow fluorescence quenching rate k_q(—○—) and phosphorescence induction rate k_1^v(···●···) are shown. The calculated hard sphere collision rate (——) is shown for comparison. The ordinate is the rate constant in 10^7 s^{-1} Torr^{-1} scale and the abscissa is the vibrational energy above the zero point level of S_1 in cm^{-1} unit.

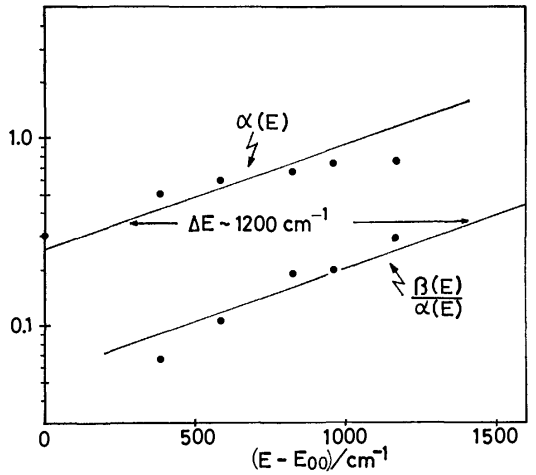

Fig. 5. Vibrational energy removed by an effective collision.

previous sections, the evaluated k_1^v's and k_q's differ greatly each other in their magnitudes and excitation energy dependences. This indicates that the quenching of the long-lived fluorescence and the induction of the thermally equilibrated T_1 phosphorescence are caused by different collision processes. As discussed already in the previous section, the slow fluorescence is quenched by the relaxation of the excited molecule from the interaction region of the width Δ_{ST} to the non-interacting one where there is no strong activity of emitting the radiation. Because Δ_{ST} is of the order of 10^{-2} cm^{-1},[16,17] even a single rotational relaxation is enough to cause the slow fluorescence quenching. This may explain the observed large value of k_q in contrast to k_1^v. It is also suggested that the optical experiment by the use of an ordinary optical cell at low pressure ($\approx 10^{-3}$ Torr) does not satisfy the isolated molecule condition and that the condition will be met only by a molecular beam. The results of the lifetime measurement of the slow fluorescence of pyrazine under the supersonic expanded beam condition will be published soon.[22]

In going from the lower to the higher energy side, k_q tends to the hard sphere collision value as seen in Fig. 4. Van der Werf *et al.* have found the similar behavior of k_q values in biacetyl and explained it in terms of the overlap of the emitting regions in the higher vibronic levles. However, in pyrazine the overlap cannot be expected in the region up to 1000 cm^{-1} above the 0-0 level of S_1 because each vibronic state in that region is well defined as viewed from the absorption and SVL fluorescence studies. Recently, rotational level dependence of the slow fluorescence has been reported by Baba *et al.*[18] Strong j dependence of the slow fluorescence intensity and decaying rate has been found in the supersonic beam which will be published elsewhere.[22] The excitation energy dependence of k_q values is now under investigation from that point of view.

The vibrational relaxation rate k_1^v within the triplet mainfolds of pyrazine has the value around the hard sphere collision one as seen in Fig. 4 and Table 1. They are as comparably large as the vibrational relaxation rate within S_1, which is seen in Table 1 of our previous paper.[21] In the figure and table, gradual decrease of k_1^v is seen as the excitation energy is increased, which is in conflict to the expectation that k_1^v may increase in the higher energy side due to the increase in the vibrational state density and the anharmonicity. It should be noted that k_1^v stands for the overall rate of the vibrational relaxation from the level i and contains the relaxation rates of various removed energy even though the effective energy loss ΔE has been evaluated to be 1200 cm^{-1}. The relaxation among the triplet levels both of which are located above the 0-0 of S_1 commences to occur increasingly as the excitation wavelength is increased from the 0-0 to the higher vibronic level of S_1. In that energy region, the non-radiative decay rate estimated from the slow fluorescence lifetime does not exhibit appreciable energy dependence. Thus it is suggested that the $k_1/k_1^v(i \geqq 2)$ terms make non-negligble contributions to α in addition to k_1/k_1^v in Eq. 12. This results into the apparent decrease of k_1^v in the higher vibronic level excitation.

The Removed Energy by an Effective Collision. In Fig. 5, α and β/α values are plotted against the excitation energy. From that figure, the amount of the energy loss per an effective collision was evaluated to be $\approx$1200 cm^{-1}. The value is qualitatively in agreement with those of biacetyl in the triplet levels[23] and *p*-difluorobenzene in S_1.[24] This gives us the qualitative picture of the relaxation that the excited pyrazine molecule undergoes 3 or 4 effective collisions before it reaches the phosphorescence emitting level of T_1. To confirm the picture, it seems necessary to find a hot phosphorescence from the higher vibronic level of T_1 pyrazine.

Comparison of the Present Results with Those by Lahmani et al. In the work by Lahmani *et al.*,[15,16] A_f and A_{ph} ($=1/\alpha$) values have been evaluated by using

SF_6 as the collision partner. As to the former value, the present result is in good agreement with their result. However, with regard to the A_{ph}, our value exceeds several times that by Lahmani *et al.* This comes from the fact that the collision partner in the present work is isopentane instead of SF_6. In other words the rotational relaxation (or the relaxation of the small energy loss) is insensitive to the shape of the collision partner because the long range interaction governs the relaxation, which is reflected in the large value of k_q. Still, because the vibrational relaxation rate is of the order of the hard sphere collision, the intermolecular coupling that induces the relaxation of the large energy loss of 1200 cm^{-1} is restricted to the shorter range one which is sensitive to the difference in the molecular shape.

Prof. Ito and Dr. Mikami are acknowledged for their stimulating discussion and suggestions.

(Received December 22, 1980)

The chloride–water mixture and the chloride–water–acetone mixtures were studied by measuring the ^{35}Cl NMR spectra. From the line-width analyses, it has been concluded that the line-widths of the chloride solutions are affected only by the nearest neighbours of the chloride ions, which makes it possible to study the interaction between the chloride ion and the solvent molecules microscopically. The problem concerning the ion pair formation in solutions was discussed. It has been shown that the observation of the concentration dependence of line-widths can be very powerful method for the detection of contact ion pairs formed in the solutions.

The behaviour of electrolytes in solution has multifold importance in solution chemistry. The change in the solution structures caused by the addition of electrolytes affords important clue for elucidating the structures of the solutions and the interaction between solvents and solutes. Many physicochemical and biological properties of electrolyte solutions can also be interpreted in terms of the equilibria between ionic species.

Conductivity measurements are the conventional and the most well-established means for investigating equilibria in ionic species. This method, however, is not of universal validity for elucidating various phenomena. Since the conductivity is a macroscopic property, it has limitations in elucidating the behaviour of electrolytes at the molecular level. Besides, theoretical formulae which describe the conductivity in an ionic solution are valid only in highly dilute concentrations ($c<10$ mmol dm^{-3}).

On the other hand, the recently developed multinuclear FT-NMR technique can be expected to give information on electrolyte solutions from a different point of view. First, the information obtained can be discussed at the microscopic level and should provide direct information about the first nearest neighbours. Secondly, information over a wide range of concentrations (from several mmol dm^{-3} to several mol dm^{-3}) is made available by this method of measurement. Thirdly, by selecting the nucleus to observe, one can get information about individual ions in the presence of many different ions. These characteristics give this method a great potentiality for investigating a complex mixture of ionic species, although the theoretical interpretation of data has not yet been fully established.

The relaxation time of a nucleus having a quadrupole moment, such as ^{35}Cl, ^{17}O, and ^{14}N, is controlled by the quadrupolar relaxation. If the rotation is much faster than the observing frequency ω, the line width can be expressed as:[1]

$$\Delta\nu = \frac{2\pi}{5}\left(1+\frac{\chi_a^2}{3}\right)\left(\frac{e^2qQ}{h}\right)^2\tau_c, \qquad (1)$$

where χ_a is the asymmetric parameter; e^2qQ, the quadrupole coupling constant; q, the electric field gradient at the nucleus; Q, the quadrupole moment; τ_c, the correlation time of a chloride ion, and h, Planck's constant. Ignoring the asymmetric factor ($0\leq\chi_a\leq 1$), the line-width is considered to be proportional to the product of the square of the quadrupole coupling constant and the rotational correlation time. Therefore, after an appropriate estimation of the rotational correlation time, the line-width should give information about the magnitude of the quadrupole coupling constant or about the electric field gradient, q, at the nucleus.

It is well known that a quadrupole coupling constant depends largely on the ionic character of the bond in question.[2] For instance, the values of the quadrupole coupling constants of KCl, TlCl, ICl, and BrCl are 0.04, 15.8, 82.5, and 103.6 MHz respectively, while the differences in the electronegativities of the atoms forming these bonds are 2.35, 1.75, 0.50, and 0.20 respectively. One can notice the clear tendency that the quadrupole coupling constant increases as the ionic character of the bond decreases. Thus, the line-width in ^{35}Cl NMR is a powerful tool for investigating the bond character involving chlorine atoms. In fact, the line-width is only about 10 Hz in aqueous sodium chloride, where chlorine exists as an ionic form, while it reaches as much as 14.5 kHz in carbon tetrachloride, where chlorine forms a covalent bond.

One of the intriguing applications utilizing this dramatic change of line-width is to see the environment of chloride ions in solution discussed above. Stengle *et al.* reported the line-widths of several perchlorates in various organic solvents, and they discussed the effect of solvents on the dissociation of ions.[3] Baldeschwieler *et al.* applied the line-broadening phenomena caused by the exchange of chloride ions between different environmental sites to the quantitative analysis of the active sites in the proteins.[4]

In the present study, we have examined the factors which affect the ^{35}Cl NMR line-widths of electrolyte solutions and attempted to analyze the line-widths quantitatively in terms of the equilibria of the ionic species.

Experimental

The acetone and all the electrolytes were commercially available in a guaranteed grade, and they were used without further purification. The water was distilled and passed through an ion-exchange resin.

The ^{35}Cl NMR spectra were recorded on a Varian FT80A spectrometer at 7.794 MHz. For a spectral width of 4000

Hz and an aquisition time of 0.1 s, 800 data points are available in the time-domain spectra. The Fourier number was kept at 16384. About 5×10^4 transients were accumulated to give a good S/N ratio for the 3%(w/w) solution of electrolytes. A weighting function was not applied to avoid the artificial broadening of the line-widths. The errors in measuring a half-line-width were estimated to be ±3%. The temperature variation was less than ±0.5 °C.

The viscosity was measured by means of a Tokyo Keiki VISCONIC ED. The errors in measuring the viscosity were ±0.005 cP.

Results and Discussion

Estimation of the Correlation Time of Rotational Motion. The half-line-width, $\Delta\nu$, of the ^{35}Cl NMR spectrum is expressed by Eq. 1. In order to get information only about the ion pairing of the chloride ions in an aqueous solution from the line-width measurements, τ_c should be estimated in advance. The value of τ_c is given by the following equation, using Stokes' formula:

$$\tau_c = V\eta/kT, \quad (2)$$

where V is the volume of a chloride ion; η, the viscosity; k the Boltzmann constant, and T, the temperature. We neglect the volume change of a chloride ion, although it may vary slightly as the concentration is changed.

In practice, we calculated a viscosity-corrected half-line-width, $\Delta\nu^\circ$, as follows using the measured half-line-width, $\Delta\nu$, and the viscosity, η:

$$\Delta\nu^\circ = \Delta\nu/(\eta/\eta_0), \quad (3)$$

where $\Delta\nu$ is the observed half-line-width; η is the viscosity, and η_0 is equal to 1cP (1P=0.1Pa s). Hereafter, we will use this newly defined half-line-width for the discussion of the behaviour of a line-width.

Concentration Dependence of the Line-widths in the Aqueous Tetraethylammonium Chloride and the Aqueous Potassium Chloride Systems. The concentration dependences of $\Delta\nu$ and $\Delta\nu^\circ$ in the aqueous tetraethylammonium chloride and the aqueous potassium chloride systems are shown in Figs. 1 and 2. The concentration dependences of η in both systems are shown in Fig. 3.

The Line-width in Dilute Solutions: We could measure the ^{35}Cl NMR spectra with a reasonable S/N ratio (>5) up to a solution of several mmol dm^{-3} in both systems. We found that the line-width is about 12 Hz in this highly dilute concentration range. Since the salts dissociate perfectly in this concentration range, we may conclude that the line-width of the "free ion" is *ca.* 12 Hz. Here, the "free ion" means the chloride ion being solvated only by water molecules and not interacting with cations.

The Line-width in the Concentrated Solutions: Let us consider the aqueous potassium chloride system first. Within the concentration range studied, potassium and chloride ions can exist partly as "solvent separated ion pairs." In 3.8 mol dm^{-3} aqueous potassium chloride solution, which is the most concentrated solution studied, the molar ratio of (potassium ion) : (chloride

ion) : (water) is about 1:1:13. Therefore, each ion is surrounded by only six or seven molecules, and there are no excess free-water molecules left; that is, the ions are separated from each other by two layers of water molecules. One might think that this would increase the line-width to some extent. Nevertheless, the line-width remains *ca.* 12 Hz throughout the concentration range studied. Here, we may draw the important conclusion that the line-width of chloride ions in "solvent separated ion pairs" is also 12 Hz. In other words, the line-width of a chloride ion is not affected by the other cations which are separated from the ion in question by at least two layers of water molecules. That is, the line-width is determined only by the nearest neighbours of the chloride ions.[5]

Next we shall consider the behaviour of the line-width in the aqueous tetraethylammonium chloride system. As is shown in Fig. 1, the line-width varies remarkably with the change in the concentration, which is in good contrast to the concentration dependence of the line-width observed for the aqueous potassium chloride system (see Fig. 2). It is said that tetraethylammonium ions and chloride ions partly exist as "contact ion pairs" in aqueous solutions.[6] Taking this into account together with the above conclusion that the line-width is affected only by the nearest neighbours of chloride ions, we may conclude that the concentration dependence of the line-width in Fig. 1 originates from the formation of "contact ion pairs," in which the chloride ions associate directly with tetraethylammonium ions. It is easily recognized that the line-width is larger when a "contact ion pair" is formed because the electric field gradient at the nucleus must become larger, and this causes a rapid quadrupolar relaxation.

Quantitative Consideration of the Line-widths.[6] In highly dilute aqueous tetraethylammonium chloride solutions, the following equilibria may be realized:[7]

$$Et_4N^+ + Cl^-(H_2O)_n \underset{K_1}{\rightleftharpoons} Et_4N^+(H_2O)_nCl^- \underset{K_2}{\rightleftharpoons} Et_4N^+Cl^-(H_2O)_{n-1} + H_2O, \quad (4)$$

where K_1 and K_2 are the association constants defined as:

$$K_1 = [Et_4N^+(H_2O)_nCl^-]/[Et_4N^+][Cl^-(H_2O)_n],$$
$$K_2 = [Et_4N^+Cl^-(H_2O)_{n-1}][H_2O]/[Et_4N^+(H_2O)_nCl^-]. \quad (5)$$

According to the conclusion of the previous section, the line-width of the chloride ion in a "solvent separated ion pair," $Et_4N^+(H_2O)_nCl^-$, should be nearly equal to that of a "free chloride ion," which we will represent as $\Delta\nu_f$ from now on. On the other hand, the line-widths of "contact ion pairs," $Et_4N^+Cl^-(H_2O)_{n-1}$, which we express as $\Delta\nu_p$ here-after, should be much larger than $\Delta\nu_f$. The observed line-widths may, then, be expressed as:[8]

$$\Delta\nu = (1-\alpha)\Delta\nu_p + \alpha\Delta\nu_f \quad (6)$$

with

$$\alpha = ([Cl^-(H_2O)_n] + [Et_4N^+(H_2O)_nCl^-])/c_{Et_4NCl}, \quad (7)$$

where c_{Et_4NCl} is the concentration of tetraethylammonium chloride. In order to confirm that the behaviour of ion pairing of chloride ions can be known through the line-width measurements, we calculated $\Delta\nu_f$ and $\Delta\nu_p$ using Eqs. 6 and 7.

Table 1. The concentration dependence of conductivity in aqueous tetraethylammonium chloride at 25 °C

The data are cited from Landolt-Börnstein.

Concentration $10^4\,c$/mol dm^{-3}	Conductivity Λ/Ω^{-1} cm^2 mol^{-1} dm^3
0.1	109.14
0.5	108.93
0.7	108.84
1.0	108.69
2.0	108.28
5.0	107.43
10.0	106.53
6.919	106.7
11.76	106.0
12.09	105.8
17.33	105.4
26.94	104.4
34.74	103.8
44.79	103.0

Table 2. The parameter values used for the calculations of K_a and K_1

$\Lambda_0=109.1\ \Omega^{-1}$ cm^2 mol^{-1} dm^3	$a=8$ Å
$T=298.16$ K	$T=298.16$ K
$D=78.57$ Debye	$e=4.770\times10^{-10}$ esu.
$\eta=0.895$ cP	$D=78.3$ Debye
$a=8$ Å	
$e=4.770\times10^{-10}$ esu.	
$K_a=3.7$ mol^{-1} dm^3	$K_1=3.14$ mol^{-1} dm^3
	$K_2=9.8$ mol^{-1} dm^3

The equilibrium constants, K_1 and K_2, can be calculated by the use of the Matesich method.[7] First, the apparent association constant, K_a, is calculated from the conductivity data of Table 1 by the method of Fuoss and Krauss:[9]

$$K_a = c(\text{ion pairs})/(c_{R_4N^+})(c_{Cl^-(H_2O)_n})$$
$$= K_1(1+K_2/c_{H_2O}), \quad (8)$$

and K_1 is estimated by using the Fuoss-Eigen equation.[6] As a result, K_2 can be calculated by substituting the observed values of K_a and K_1 into Eq. 8. The equilibrium constants finally obtained, K_a, K_1, and K_2, and the parameters used in the calculation of K_a and K_1 are summarized in Table 2.

The line-widths in this system were measured under the same conditions as those used for the electric-conductivity measurements; that is, the temperature was kept at 25 °C, and the concentrations of the salts were smaller than, or nearly equal to, 10 mmol dm^{-3}. The viscosities of these solutions are 0.89 cP, which equals that of pure water at 25 °C.

The degree of dissociation, α, was calculated at six different concentrations (see Table 3), and the intrinsic line-widths, $\Delta\nu_p$ and $\Delta\nu_f$, were determined by the least-squares method using Eq. 6. The calculated values are; $\Delta\nu_p=546\pm195$ Hz[9] and $\Delta\nu_f=$

TABLE 3. THE CONCENTRATION DEPENDENCE OF THE LINE-WIDTHS IN AQUEOUS TETRAETHYLAMMONIUM CHLORIDE AT 25 °C

The observed viscosities are 0.089 cP in all solutions.

Concentration of Et_4N^+Cl/mol dm^{-3}	$\Delta\nu$/Hz	$\Delta\nu^\circ$/Hz
3.16	11.1	12.5
4.78	11.82	13.3
5.99	11.9	13.4
8.42	12.4	13.9

(○): The observed value, (●): the viscosity corrected value (see Eq. 3 in the text).

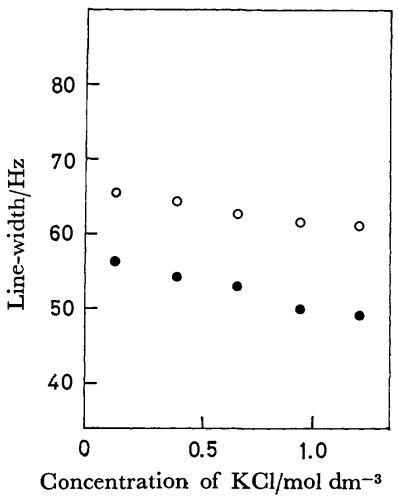

Fig. 5. Concentration dependence of the half-line-width of the potassium chloride–aqueous acetone system at 30 °C (the mole fraction of acetone is 0.14).
(○): The observed value, (●): the viscosity corrected value (see Eq. 3 in the text).

11.6±0.3 Hz. The obtained line-widths of "free ions" or "solvent separated ion pairs" are reasonably close to those estimated in the former sections; the line-width of "contact ion pairs" also seems to be reasonable, because the line-width is about 380 Hz in a pure acetone solution of tetraethylammonium chloride, in which the contribution of "contact ion pairs" is known to be significant ($\alpha \simeq 0.3$).

The above consideration confirm our approach and so we propose this line-width-measurement method as a convenient and straightforward method for judging whether or not chlorine ions form "contact ion pairs" in aqueous solutions.

Line-width in the Tetraethylammonium Chloride and Potassium Chloride in an Aqueous Acetone System. The concentration dependences of the line-widths in tetraethylammonium chloride and potassium chloride in the aqueous acetone systems were also observed: the results are shown in Figs. 4 and 5, where the mole fraction of acetone is fixed at 0.14.

We can point out from the concentration dependence of the line-width in the tetraethylammonium chloride system that "contact ion pairs" are also formed in this system, while the concentration-independent line-width in the potassium chloride system indicates that in this system, "contact ion pairs" do not contribute to any detectable extent.

Aside from this, we can point out two peculiar phenomena in Figs. 4 and 5. The observed values of the line-widths ($\simeq$60 Hz) in the potassium chloride system are larger than those in the aqueous solution, and the line-width of the tetraethylammonium chloride system in the very dilute solutions ($\simeq$70 Hz) is also larger than that in an aqueous solution (12 Hz).

To make clear the reason for these peculiar phenomena, we also measured the line-width by changing the fraction of acetone in an aqueous acetone solution. The results are shown in Figs. 6 and 7. The observed line-width becomes broader according to the increase in the fraction of acetone in both cases.

There are at least two possible explanations. One is that the acetone molecules enter the first coordination sphere of chloride ions to make the electric field gradients at the nuclei larger; the other is that acetone molecules break the structure of the first coordination sphere, which results in the breaking down of the spherical symmetry around the chloride ion. The MO calculations may shed light upon this problem, and so investigations along this line are now under way.

Line-width Broadening Due to Common-ion Effect. If our interpretation that the line-width broadening is caused by the existence of the "contact ion pair" in the equilibria is correct, the ^{35}Cl line-width should be broadened by adding other salts containing the common ion, that is, the tetraethylammonium ion, judging from the mass-law effect. Therefore, we measured the change in the ^{35}Cl line-width of tetraethylammonium chloride by adding tetraethylammonium bromide. One should notice that the added bromine has a dual effect on the ionic equilibria. That is, because of the mass-law effect, it makes the concentration of "paired species" larger on one band, while

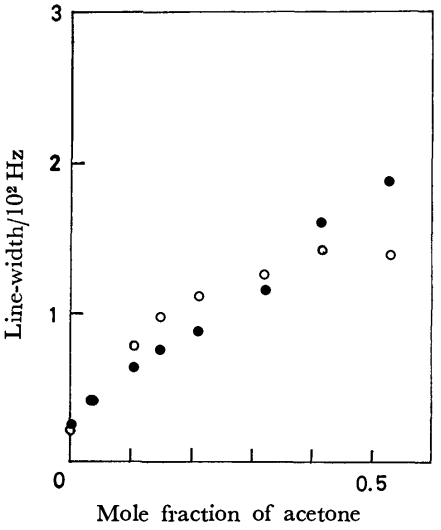

Fig. 6. Dependence of the half-line-width of the tetraethylammonium chloride–aqueous acetone system on the mole fraction of acetone at 30 °C (the concentration of tetraethylammonium chloride is 0.1 mol dm^{-3}). (○): The observed value, (●): the viscosity corrected value (see Eq. 3 in the text).

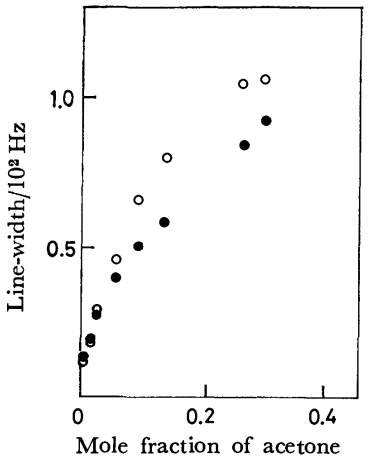

Fig. 7. Dependence of the half-line-width of the potassium chloride system on the mole fraction of acetone at 25 °C (the concentration of potassium chloride is 0.2 mol dm^{-3}).
(○): The observed value, (●): the viscosity corrected value (see Eq. 3 in the text).

on the other it makes "paired species" dissociate to "free ions" as a result of an increase in the ionic strength of the solution.

The results are shown in Fig. 8. A tendency for the line-width to increase is clearly recognized. This shows that the net effect of the added common ion in this case results in the increase in the concentration of "contact ion pairs," which in turn causes the line broadening in the ^{35}Cl NMR.

Summary. In summary, the line-widths of ^{35}Cl NMR spectra are found to reflect the circumstances of the first coordination sphere around chloride ions quite sensitively. The dependence of the line-widths on the concentration of ions can afford important information on "contact ion pair" formation. By ana-

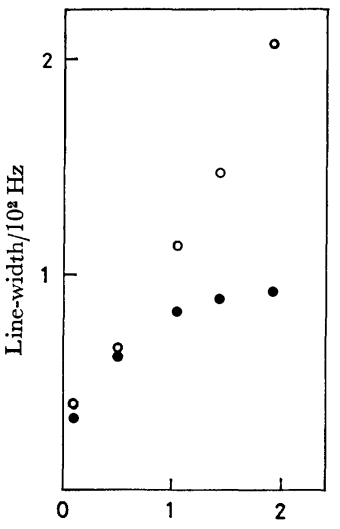

Fig. 8. Dependence of the half-line-width of the aqueous tetraethylammonium chloride system on the concentration of tetraethylammonium bromide.
(○): The observed value, (●): the viscosity corrected value (see Eq. 3 in the text).

lyzing the concentration dependence of line-widths in the dilute concentration range, we have proposed values of the intrinsic line-width of the "contact ion pair" ($\Delta\nu_p$=546±195 Hz) and that of "free ions" or "solvent separated ion pairs" ($\Delta\nu_f$=11.6±0.3 Hz).

This methodology may be found to be quite unique when it is compared with the conventional one based upon conductivity data. While the latter can distinguish "free ions" from "ion pairs," our present method distinguishes a "contact pair" from a "solvent separated" one.

The ^{35}Cl NMR method promises to afford fruitful information on solvation or ion pairing phenomena from the point of view of the microscopic aspects over the range from dilute to highly concentrated solutions.

5) The effect of cations separated by one layer of water molecules can not be specified in this experiment. The broadening of the line-width might be caused by this kind of ion pair, namely, "solvent shared ion pairs," to some extent. If this is the case, the contribution of "solvent shared ion pairs" is included by "contact ion pairs" in the present study.

6) Hertz *et al.* reported that the line-width of the ^{81}Br NMR of inorganic salts, such as sodium bromide and rubidium bromide, was broadened by adding tetraethylammonium bromide and that the line-width of tetraethylammonium

bromide showed a concentration dependence. They interpreted those phenomena in terms of an electrostatic theory (see H. G. Hertz and M. Holz, *J. Phys. Chem.*, **78**, 1002 (1974)). The ^{81}Br NMR line-width of the bromide ion in an aqueous dilute solution is about 290 Hz (see T. R. Collins, Z. Starcuk, A. H. Burr, and E. J. Wells, *J. Am. Chem. Soc.*, **95**, 1469 (1973); this value is much larger than the corresponding value of the ^{35}Cl NMR line-width of chloride in a dilute aqueous solution. This difference becomes rather critical when measuring a very dilute solution. Apparently ^{35}Cl NMR has an advantage in this respect (see also H. Wennerstrom, B. Lindman, and S. Forsen, *J. Phys. Chem.*, **75**, 2936 (1971)).

7) S. M. A. Matesich, J. A. Nadas, and D. F. Evans, *J. Phys. Chem.*, **74**, 4568 (1970).

8) Since exchange among "free ions," "solvent separated ion pairs," and "contact ion pairs" is fast compared to the reciprocal of the line-width (<2 ms), the observed spectra are composite lines. Therefore, the line-width can be expressed as the average of the intrinsic line-widths of "free," "solvent separated," and "contact" ion pairs. In the present system, the conditions of the fast exchange and extreme motional narrowing conditions are realized (see A. G. Marshall, *J. Chem. Phys.*, **52**, 2527 (1970)).

9) R. M. Fuoss and C. A. Krauss, *J. Am. Chem. Soc.*, **55**, 1019 (1933).

10) Since $\Delta\nu_p$ was calculated from the data at very dilute concentrations, the errors are inevitably large. Substituting the value of the line-width for "free ions" ($\Delta\nu=12$ Hz) into Eq. 1, e^2qQ can be calculated to be 3 MHz, assuming $\tau_c=1$ ps. As for "contact ion-pairs" ($\Delta\nu=300$ Hz), e^2qQ becomes 15 MHz.

(Received December 22, 1980)

The structure of the 12-hydroxyoctadecanoic acid–benzene gel was studied by the use of the light scattering spectrometer. The scattering angular dependence of the scattering intensity and the time correlation function of the electric field were measured. It was found that the coarse mesh network and the fine mesh network coexist in this gel. The former was detected by the intensity measurement, while the latter was detected by intensity-fluctuation spectroscopy. The usefulness of the light scattering technique was emphasized.

A measurement of light scattered by the fluctuation of a dielectric constant is a preferred method for studying a molecular arrangement in a dimension of several hundred or several thousand angstroms. Gels are interesting objects to study by the light scattering method, as has been shown by the reports of Prins *et al.*[1] and Tanaka *et al.*[2] on the structure determination of the agarose or polyacrylamide gel.

In the present work, we study a gel made of 12-hydroxyoctadecanoic acid (12HOA hereafter) and benzene in order to examine the structure utilizing the features of the light scattering method. The 12HOA–benzene gel has already been studied in detail by Tachibana *et al.* using the X-ray diffraction method, circular dichroic spectroscopy, an electron microscope, and other methods.[3] According to their conclusions, the 12HOA molecules construct fiber-like crystallites in which 12HOA molecules are aligned to form a chiral smectic structure. These fiber-like crystallites enmeshing the gel may be thinner than 10—100 nm, as estimated from the observation of the dried gel (the solvent having been evaporated) under an electron microscope.

The purpose of the present study is to get direct information about the structure of network constructed by the fiber-like crystallites. Using the light scattering method, we can study the structure of the gel state without evaporating the solvent. We measured the angular dependence of the scattered light intensity and the time correlation function of the electric field of the scattered light. The light is scattered essentially by the crystallites in this gel.

Experimental

A schematic diagram of the light scattering spectrometer constructed in this laboratory is shown in Fig. 1. The light source is an argon-ion laser (Spectra-Physics Model 165-09). The scattering angle, θ, is varied by adjustable mirrors, M_1 and M_2, and is defined by two pinholes, P_1 and P_2, with a diameter of 1 mm. P_1 and P_2 are approximately 50 cm apart from each other. The incident light is focused into a sample cell ($12\times15\times16$ mm^3) made of fused quartz.

The photomultiplier tube, PM, has a S-20 response (Hamamatsu TV, R-374) and is operated at 840 V at room temperature. The photomultiplier, and the output power is integrated at a time constant of 1 s and is read out on an oscilloscope. The autocorrelation function of the photocurrent is observed by means of a 400-channel correlation and probability analyzer (KANOMAX, SAI 43A).

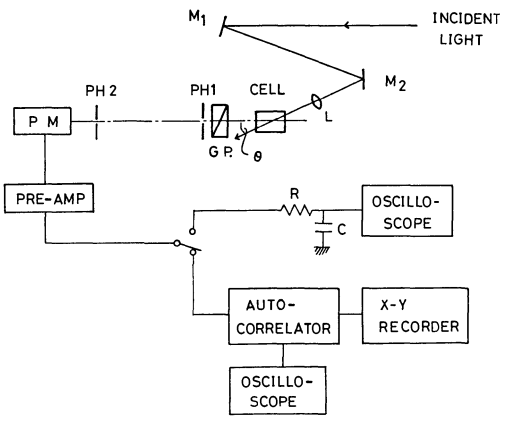

Fig. 1. The block diagram of the light-beating spectrometer.

All the measurements were performed at 24±1 °C. The power of the incident light was controlled within 60—15 mW by the use of ND filters in order to avoid any temperature elevation in the sample.

12HOA was purified from commercial products following the method described in the literature.[4] The purity was ascertained to be more than 99% by observing the presence of the methyl ester by gas chromatography. The concentration of 12HOA in this gel was about 33 mmol dm^{-3}.

12HOA was dissolved in benzene at 50 °C. Then, it was made dust-free by the use of a millipore filter FG of 0.1 μm pore size and was injected into the sample cell. This sample was cooled down from 50 °C to 24 °C with the cooling rate of 2 °C/h. Further, the sample was left for about one day at 24 °C. The gel finally obtained was an aggregate of spherulitical domains, as has been reported by Tachibana *et al.*[3] For the actual measurement, we used a gel whose spherulitical domains were larger several centimeters in diameter so that we could avoid the reflection effect at the boundaries of these domains. This gel was transparent to the human eye.

For the polarization measurements, Glan-Thompson prisms (1×1 cm^2 in section) were used to define the polarization direction of the light.

Results and Discussion

The power spectrum of the light scattered from the gel corresponds to the fluctuation of the dielectric constant in space and time, as expressed by these relations:[5]

$$I(\tilde{q},\ \omega) = \frac{1}{2\pi}\int \langle \tilde{E}_s(\tilde{q},\ t)\tilde{E}_s(\tilde{q},\ 0)\rangle e^{i\omega t}dt$$
$$= \frac{A}{2\pi}\int \left\{\int_V \langle \Delta\varepsilon_{si}(\tilde{r},\ t)\Delta\varepsilon_{si}(O,\ 0)e^{i\tilde{q}\cdot\tilde{r}}d^3r\, e^{i\omega t}dt\right.$$
$$= \frac{A}{2\pi}\int \gamma(\tilde{q},\ t)e^{i\omega t}dt, \quad (1)$$

with

$$\Delta\varepsilon_{si} = \tilde{n}_s\cdot\Delta\varepsilon\cdot\tilde{n}_i, \quad (2)$$

$$\gamma(\tilde{q},\ t) = \int_V \langle \Delta\varepsilon_{si}(\tilde{r},\ t)\Delta\varepsilon_{si}(O,\ 0)\rangle e^{i\tilde{q}\cdot\tilde{r}}\, d^3r, \quad (3)$$

and

$$A = k_s^4 E_0^2 V/16\pi^2 R^2 \varepsilon_0^2, \quad (4)$$

where $E_s(\tilde{q},t)$ is the electric field of the scattered light at time t and for a scattering vector, $\tilde{q}$, $\Delta\varepsilon_{si}$ the element of the dielectric-constat fluctuation tensor, $\Delta\varepsilon$; $\tilde{n}_s$ and $\tilde{n}_i$, the directions of the electric field of the scattering and incident light respectively; V, the scattering volume; $\tilde{k}_s$, the wave vector of the scattered light in the medium; E_0, the electric field of the i-component of the incident light; R, the distance between the scattering volume and the detector, and ε_0, the macroscopic dielectric constant; the suffixes i and s identify the polarization directions of the incident and scattered lights respectively.

Integrating Eq. 1 over the frequency, one gets:

$$I(\tilde{q}) = A\int_V \langle \Delta\varepsilon_{si}(\tilde{r})\Delta\varepsilon_{si}(O)\rangle e^{i\tilde{q}\cdot\tilde{r}}\, d^3r, \quad (5)$$

which shows that the integrated intensity of a Rayleigh line can afford information about the dielectric-constant fluctuation.

On the other hand, the photo-current correlation function, $\langle i(t)i(0)\rangle$, is related to the field correlation function by this formula:[5]

$$\langle i(t)i(0)\rangle \propto \langle |\boldsymbol{E}(\tilde{q},\ 0)|^2\rangle + |\langle \boldsymbol{E}(\tilde{q},\ t)\cdot\boldsymbol{E}(\tilde{q},\ 0)\rangle|^2 \quad (6)$$

so long as the optical field obeys Gaussian statistics. A comparison of Eqs. 1 and 6 leads to the conclusion that it is possible to obtain the square of the field correlation function experimentally, because we can observe the photocurrent correlation function with the use of our instrument, in which an analog correlator is installed.

Angular Dependence of the Intensity of the Scattered Light. We consider here only the intensity of the light scattered from the isotropic fluctuation of the dielectric constant, because the intensity of the depolarized component is only about 8% that of the polarized one in this gel. Although several kinds of fluctuations can cause the dielectric-constant fluctuation, the existence of the fiber-like crystallites of 12HOA has the decisive effect. Other fluctuations—for example, the thermally excited density fluctuation of a solvent and the density and orientation fluctuation of 12HOA in each crystalline, have negligibly small effects on the fluctuation of the dielectric constant.

If we expand the exponential term in the right-hand side of Eq. 5 and neglect the terms higher than cubic, we obtain these relations:

$$I(\tilde{q}) = A\int_V \langle \Delta\varepsilon(\tilde{r})\Delta\varepsilon(0)\rangle d^3r\left(1-\frac{1}{6}q^2R_c^2\right) \quad (7)$$

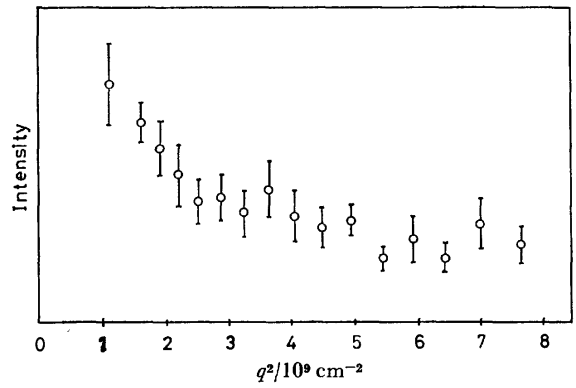

Fig. 2. The scattering intensity against q^2 for the 33 mmol dm^{-3} 12HOA–benzene gel at 24 °C.

with

$$R_c^2 = \int_V \langle \Delta\varepsilon(\tilde{r})\Delta\varepsilon(0)\rangle r^2 d^3r \Big/ \int_V \langle \Delta\varepsilon(\tilde{r})\Delta\varepsilon(0)\rangle d^3r. \quad (8)$$

R_c is called a correlation length of the fluctuation and corresponds to the mean size of the mesh of the gel network, made of 12HOA in the present system. R_c can be estimated by using Eq. 7 if we measure the intensity of the scattered light as a function of $\tilde{q}$.

The observed intensities are plotted against q^2 in Fig. 2. The scattered-light intensity is nearly constant in the range of $3.0\times10^9 < q^2 < 8.0\times10^9$ and then increases as q^2 increases in the range of $3.0\times10^9 > q^2$ (see Fig. 2). We have to put a large uncertainty in the final "correlation length" value because we could not measure $I(0) = A\int_V \langle \Delta\varepsilon(0)\Delta\varepsilon(\tilde{r})\rangle d^3r$ with sufficient accuracy. This arises from the existence of the stray light which is inevitable for small-angle measurements. In addition, the neglections of the higher-order terms of Eq. 7 can be a source of considerable uncertainty for the R_c value. However, it may be reasonable to conclude that the "correlation length of fluctuation" or the size of mesh in this gel is in the order of a few thousand angstroms.

Intensity Fluctuation Spectroscopy of the Scattered Light. The intensity fluctuation of the light scattered from the gel originates from various types of motions: (1) the relative motions between the solvent and the fiber-like crystallites which construct the gel network; (2) the relative motions of the 12HOA molecules in the crystallites, and (3) the relative motions of the solvent molecules. The correlation functions, $\gamma(\tilde{q},t)$, of the dielectric constant fluctuation caused by these relative motions can be expressed by this relation:[5]

$$\gamma(\tilde{q},\ t) \propto \exp(-q^2Dt), \quad (9)$$

where $\tilde{q}$ is the scattering vector and D is the parameter describing the rapidity of the motion, the dimension of which is $[L]^2/[T]$. In the case of the relative motion of Type (3), D is estimated from the thermal diffusivity of liquid benzene, to be in the order of 10^{-3} cm^2/s.[6] In the case of the relative motion of Type (2), D can be in the order of 10^{-6} cm^2/s, which is estimated from the elastic constant, K, and the

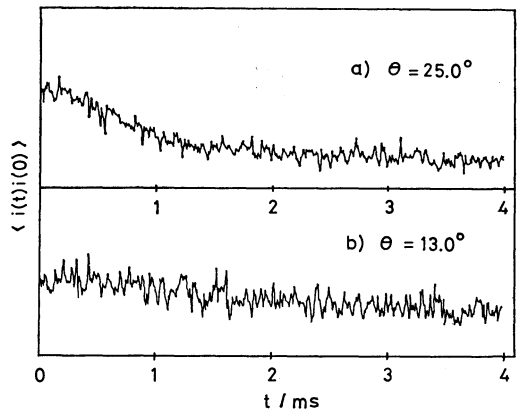

Fig. 3. The observed correlation function for the 33 mmol dm^{-3} 12HOA-benzene gel at 24 °C. The scattering angles are: a) 25° and b) 13°.

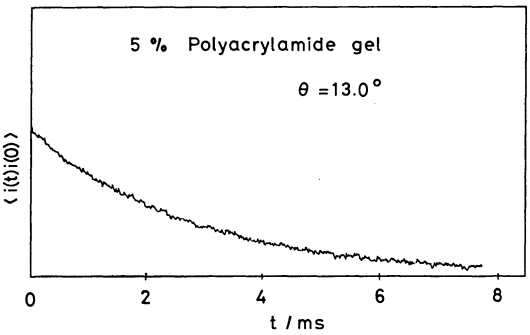

Fig. 4. The observed correlation function of the 5% w/w aqueous polyacrylamide gel at 24 °C with the scattering angle of 13°.

viscosity, η, for the ordinary smectic A-type liquid crystal through the relation: $D \simeq K/\eta$.[7] Furthermore, the scattered light strongly depolarized in this case, because this fluctuation is caused by the orientation of the mesophase molecules. On the other hand, the D-value for Type (1) has been known to be in the order of 10^{-7} cm^2/s, as estimated from the longitudinal compressional modulus, G, and the friction constant, f, observed for polyacrylamide gel through the relation: $D=G/f$.[2] Therefore, these three different modes can be observed separately if we adopt an appropriate experimental set-up for the actual measurement of the correlation function.

Figure 3 shows some typical examples of the actually observed current correlation function, which corresponds to the electrical field of the polarized component of the light scattered from the 12HOA-benzene gel. The correlation function of the depolarized component could not be observed in this case, because the intensity of the depolarized component was negligibly small in comparison with that of the correlation function in the aqueous polyacrylamide gel (5% w/w). One of the results is illustrated in Fig. 4. In the case of the aqueous polyacrylamide gel, we could observe the correlation function with a good reproducibity from any scattering volumes in the sample. From Eqs. 1, 6, and 9 it can be seen that the time-dependent part of the current correlation

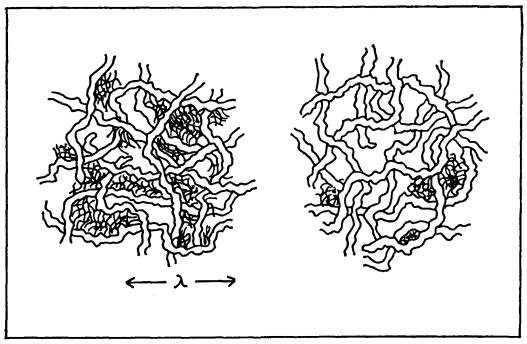

Fig. 5. The structure of the netweork constructed in the 12HOA-benzene gel (schematic). λ is several thousand Ångstroms which corresponds to the wavelength of the incident light.

function is related to the correlation function of the dielectric constant as:

$$\langle i(t)i(0)\rangle_t \propto \exp(-2q^2Dt). \quad (10)$$

The D-value was obtained for the polyacrylamide system as $(2.2\pm0.2)\times10^{-7}$ cm^2/s from the least-squares fitting to Eq. 9, which agrees well with the observation of Tanaka *et al.* ($D=(2.4\pm0.1)\times10^{-7}$ cm^2/s).

In the case of the 12HOA-benzene gel, D was obtained as $(0.97\pm0.24)\times10^{-7}$ cm^2/s. The relatively large uncertainty attached to the D-value arises from the poor S/N ratio of the observed correlation function. As the magnitude of D is as large as that of the polyacrylamide gel, we can conclude that the scattered light from the 12HOA-benzene gel reflects the relative motions of Type (1), that is, the relative motion between the solvent and the crystallites. The mesh of the network made from the crystallites should be much finer than the wavelength of the incident light. It must be emphasized that the correlation function was not always observed in the 12HOA-benzene gel; that is, the appearance of the correlation function was dependent on the position of the scattering volume. This may reflect the situation that the network with the fine mesh is not dispersed homogeneously in the sample, quite different the situation in the aqueous polyacrylamide gel.

Concluding Discussion. According to the results reported in the previous paragraphs, a network with rather complicated structures is formed in the 12HOA-benzene gel. The integrated intensity data and the current correlation function show that there are two kinds of networks in this gel. One is a network with a mesh of a few thousand angstroms (obtained from the intensity data), and the other is one with a much finer mesh (from the correlation function).

Tachibana *et al.* observed fiber-like crystallites whose thickness was 10—100 nm in the dried gel (the solvent being evaporated) under an electric microscope. The network with a mesh of a few thousand angstroms may be constructed from such fiber-like crystallites. As the thickness of the fiber-like crystallites is 10—100 nm, and as those crystallites contain no solvent,[3] the fiber might be very hard. Therefore, they cannot entangle themselves with each other densely, thus forming a rather coarse network. These fibers which

form the coarse network are linked together here and there by smaller networks with a fine mesh. These fine networks are dispersed inhomogeneously in the gel: that is, there might be some areas in which the fine networks are stretched densely and others in which the fine networks are not stretched. In Fig. 5 we visualize the structure of the network formed in the 12HOA–benzene gel schematically. The existence of the fine network has not been noticed before in the 12HOA–benzene gel. We believe the existence of this fine network is essential for the formation of the gel phase, because the solvent molecules can be trapped in this fine network much more easily than in the coarse network.

Incidentally, the present work has emphasized the importance of the light scattering study for the determination of complicated structures in materials, because we are able to choose appropriate regions of time and space for the measurements of the intensity and the correlation function of the electric field of the scattered light.

The authors of this report wish to express their thanks to Professor Taro Tachibana for suggesting to them this interesting system (12HOA).

Encapsulation of Krypton with (K, M^{II})-A Zeolites

Keiji ITABASHI,† Tetsuo TAKAISHI, and Tatsuo OHGUSHI*

School of Materials Science, Toyohashi University of Technology, Toyohashi 440

(Received January 20, 1981)

The encapsulation of krypton is realized with zeolite A, having compositions $(K_{12-2x}M^{II}_x)$-A with $1.11 \leqq x \leqq 3.78$, at temperatures lower than 300 °C and a pressure of 3.7×10^6 Pa. This encapsulation condition is much milder than the usual one, 350 °C and 4.2×10^8 Pa, which is adopted in industry. Such lowerings of the encapsulation temperature and pressure are caused by bivalent cations introduced through ion-exchanges. The result is an experimental evidence to the existence of the ion-loosening effect proposed in preceding papers.

Zeolite A has, at the center of its unit cell cube, a large cavity which is nearly spherical with a diameter of 1.14 nm and can accomodate sorbed molecules. This cavity is surrounded by six 8-membered oxygen rings, which are on {100} faces of the cube and constitute windows to the cavity. In commercial molecular sieves 3A and 4A, all of these windows are blocked by potassium and sodium ions, respectively.[1] The molecular sieving characters of these zeolites are primarily determined by the size of the aperture of the partially-blocked windows. The effective size of the aperture, however, depends upon temperature. At higher temperatures, a situation is realized that larger molecules, which are not sorbed at lower temperatures, are able to be sorbed. If the temperature is lowered after the large molecule being sorbed at higher temperature, the windows are closed and the sorbed molecules are encapsulated.[2]

An example of the practical use of the encapsulation is that of radio-active ^{85}Kr into 3A zeolite, for commercial distributions. It is a large merit that a lead container, required as a radiation shield, becomes very small for such a compactly encapsulated ^{85}Kr. Usually, krypton is encapsulated into 3A at 350 °C and a pressure of 4.2×10^8 Pa.[3,4]

It is expected that the encapsulation temperature and pressure are lowered by the ion-loosening techniques presented in the preceding papers.[5,6] The techniques consist in increasing the temperature dependence of the window size by introducing bivalent cations onto 6-membered oxygen rings. In the present paper, results of the krypton encapsulation are reported, which prove the ion-loosening effect.

Experimental

The starting material was commercial sodium-A zeolite of powder form, manufactured by Toyo Soda Co. or Union Carbide Co. Sodium-A zeolite was treated at 80 °C with an 1 mol dm^{-3} aqueous solution of KCl, repeatedly, to obtain K_{12}-A. Resultant K_{12}-A was further treated with a solution containing KCl and $M^{II}Cl_2$, of 0.2 total normality, where M^{II} is Ca, Co, Mn, or Zn. The composition of the zeolite was determined by the usual chemical analysis and atomic absorption spectrometry. The zeolite used contained M^{II} ions less than 4 per unit cell.

The dehydration process of the zeolite was studied with a quartz spring balance. The weight of the sample decreased to 75% of the initial one after vacuum baking-out for 2 h at 300 °C. After this treatment, no change was observed in the crystallinity of the sample with X-ray diffraction techniques. This degree of the dehydration, we judged, is appropriate to the practical use of the zeolite as an adsorbent. In the following experiments, the sample zeolite was dehydrated at 300 °C for 2 h under vacuum.

The sample zeolite (3—5 g) was packed in a conventional autoclave(300 cm^3) and dehydrated. Then, krypton gas at a pressure of 3.7×10^6 Pa was introduced into the autoclave, held at 300 °C, and sorbed into the zeolite. After a waiting time of 60 min, the system was slowly cooled under the pressure, to room temperature, and then a residual gas of a high pressure was evacuated from the dead space in the autoclave. The amount of gas encapsulated in the zeolite was measured by a thermal desorption method. The autoclave was heated at a rate of about 1.3 °C min^{-1}, and the amount of evolved gas was caught, through a flexible stainless steel tube, into a messcylinder placed upside-down in a water-filled vessel.

Results

Figuers 1 and 2 show the amount of krypton decapsulated as a function of temperature. The total amount encapsulated, $V_{tot.}$, depended sharply upon the content of calcium in the zeolite as shown in Fig.

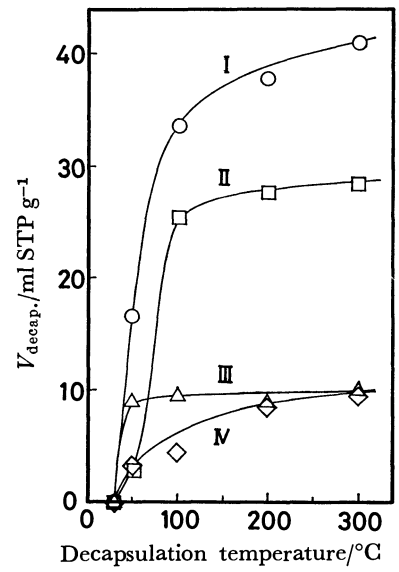

Fig. 1. Amount of Kr decapsulated as a function of temperature.
Curve I: $(K_{6.76}Ca_{2.62})$-A, Curve II: $(K_{7.84}Ca_{2.08})$-A, Curve III: Na_{12}-A, Curve IV: $(K_{5.81}Na_{6.19})$-A. Conditions of encapsulation: 300 °C, 3.7×10^6 Pa.

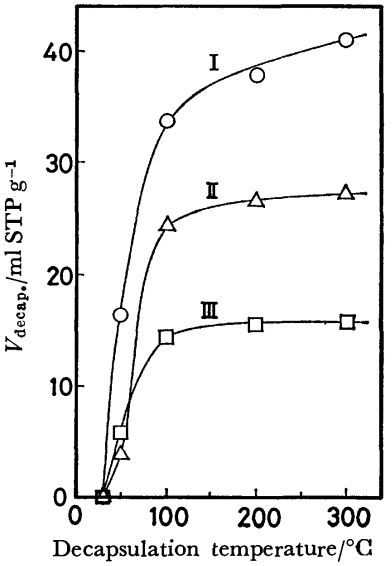

Fig. 2. Effect of encapsulation condition to the amount encapsulated with $(K_{6.76}Ca_{2.62})$-A.
Curve I: 300 °C, 3.7×10^6 Pa, Curve II: 150 °C 3.7×10^6 Pa, Curve III: 300 °C, 1.7×10^6 pa.

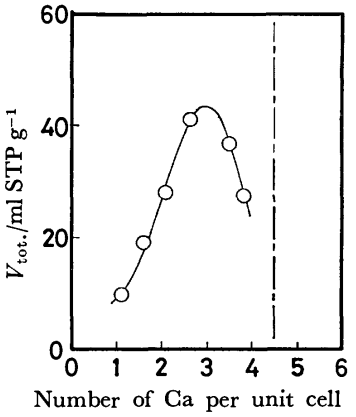

Fig. 3. Effect of calcium content to the total amount of encapsulation.

3. At a composition of 4.5 Ca per unit cell (represented by a chain line), the completely unblocked, say, open window starts to manifest itself.[7] Since krypton can freely pass through such an open window, V_{tot} should drastically decrease over this critical content. Experimentally, however, the value of $V_{tot.}$, starts to decrease when calcium content exceeds 3 per unit cell. To realize a maximum encapsulation, the content of calcium must be considerably smaller than 4.5 per unit cell.

Other bivalent cations, such as Co^{2+}, Mn^{2+}, and Zn^{2+}, have the effect as Ca^{2+}. Results are shown in Fig. 4.

Discussion

The diameter of krypton is slightly larger than that of the aperture in the K^+-blocked window. In order that a visiting krypton atom is sorbed into the large cavity, the blocking K^+ must be pushed aside to make

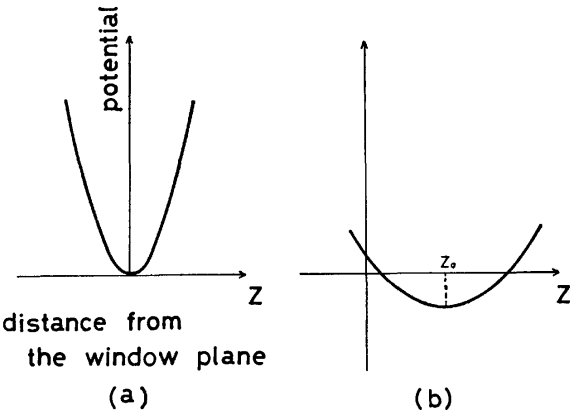

Fig. 5. Potential experienced by the window-blocking K^+.
(a) Potential in K_{12}-A zeolite. (b) Potential in (K,M^{II})-A zeolite.

a way for the visitor. In other words, an activation energy is required in krypton sorption. The magnitude of the activation energy is primarily determined by the potential experienced by the blocking K^+. The activation energy is large if the radius of curvature is small in the valley of the potential surface, while small if the radius is large. With this in view, we schematically represent the concerned potential forms for K_{12}-A and (K,M^{II})-A zeolites in Fig. 5. The abscissa, z, denotes the distance from the window plane, and z_o the position of the potential valley in (K,M^{II})-A. A permanent widening of the aperture results from a large value of z_o, while a temperature dependent one does from an increase in the radius of curvature. Such an aperture widening, due to bivalent cations, is named as an ion-loosening effect. The ion-loosening may increase with the increasing

content of M^{II}.[8] Thus, krypton can easily pass through K^+-blocked windows if the content of M^{II} exceeds 4 per unit cell, as shown in Fig. 3.

In the last place, let us discuss a problem of the storage of ^{85}Kr which is released in the reprocessing of nuclear fuel. The container tank must be air-tight and have a thick wall. (K,M^{II})-A zeolite cannot be used for such a purpose, since the zeolite will be destroyed by radiations from ^{85}Kr.†† However, it may be used as a transient storager. For instance, zeolites encapsulating ^{85}Kr are installed in an air-tight vessel of thin wall, and then vessel is concreted by cement before the zeolites are seriously damaged by the radiation. This packing process may considerably be economical than the usual direct containment with a thick vessel of corrosion-resistive metal.

†† Penzhorn and his coworkers are trying to encapsulate permanently.[9] In their case, zeolite A is structurally changed, and the situation is very different from ours.

The present paper was in part supported by a Grant-in-Aid for Research from the Ministry of Education, Science and Culture of the Japanese Goverment, Contract No. 443001.

Polarized Absorption and Reflection Spectra of the Single Crystals of 11,11,12,12-Tetracyano-2,6-naphthoquinodimethan (TNAP) Complexes

Kyuya YAKUSHI, Yoshiyuki SATO, Isao IKEMOTO,*,† and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-yu, Tokyo 113

† *Research Center for Spectrochemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received January 21, 1981)

The electronic absorption spectra of 2,6-bis(dicyanomethylene)-2,6-dihydronaphthalene (11,11,12,12-tetracyano-2,6-naphthoquinodimethan; TNAP) and its anion radical ($TNAP^-$) were studied. The absorption bands of the solution spectra of $TNAP^0$ and $TNAP^-$ were successfully assigned to the electronic transitions which were calculated by the use of molecular orbital method. The polarized absorption and reflection spectra were measured on the single crystals of Na·TNAP and (methyltriphenylphosphonium)$(TNAP)_2$ [(MTPP)$(TNAP)_2$]. The low-lying electronic excitations of these complexes are quite similar to those of the corresponding tetracyanoquinodimethan (TCNQ) salts.

The discovery of the low-dimensional metallic behavior of organic charge-transfer salts such as tetrathiafulvalene–tetracyanoquinodimethan (TTF–TCNQ)[1] strongly stimulated research concerning the physical properties of related organic charge-transfer salts and the synthesis of new organic electron donors and acceptors.

2,6-Bis(dicyanomethylene)-2,6-dihydronaphthalene (11,11,12,12-tetracyano-2,6-naphthoquinodimethan; TNAP) was synthesized by Diekmann *et al.* and shown to be a strong acceptor.[2] The simple salts of TNAP were found to have higher conductivities than the analogous TCNQ salts,[2] and HMTSF–TNAP (2,2′-bi[2,4-diselenabicyclo[3.3.0]octan-2-ylidene]–TNAP) was found to have very high electrical conductivity at room temperature.[3] For understanding the electronic behaviors of those TNAP complexes, it is necessary to accumulate the data concerning the electronic structures of TNAP complexes.

In the present study, we have investigated the polarized absorption and reflection spectra of the single crystals of the simple salt, Na·TNAP, and the complex salt, (methyltriphenylphosphonium)$(TNAP)_2$ [(MTPP)$(TNAP)_2$].

Experimental

TNAP was synthesized by the procedures described in the literature[2,4,5] and purified by recrystallization from an acetonitrile solution. The complexes, Na·TNAP and (MTPP)$(TNAP)_2$ were obtained according to the method described in the literature.[2,5]

Polarized absorption and reflection spectra were measured on very small single crystals by use of the microspectrophotometric apparatuses for the transmission and reflection spectroscopies. The details of those apparatuses and the procedure of measurement have been described elsewhere.[6,7] All spectra were obtained at room temperature.

Absorption spectra of solutions were measured using a Hitachi EPS-3 spectrometer.

Results and Discussion

Electronic Transitions of TNAP Molecule and $TNAP^-$ Ion. In order to interpret the crystal spectra of TNAP complexes, it is of essential significance to know the electronic transitions in TNAP molecule and $TNAP^-$ ion. In Fig. 1, we show the solution spectra of $TNAP^0$ and $TNAP^-$, obtained from acetonitrile solutions of TNAP and K·TNAP. The observed wave numbers, molar extinction coefficients, and oscillator strengths of absorption bands are listed in Table 1. To find out the assignments of the observed absorption bands, we carried out SCF-MO-CI calculations on the π electron systems of the molecule and ion of TNAP.[8] The results are also included in Table 1. The predicted transitions are indicated in Fig. 1, with the vertical lines, the length of which is proportional to the predicted oscillator strengths, the directions of transition moment being shown with an arrow.

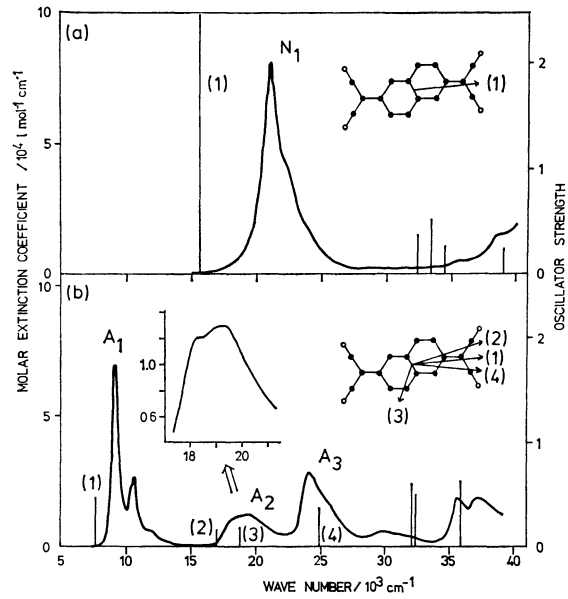

Fig. 1. The solution spectra of (a) TNAP molecule and (b) $TNAP^-$ ion in the acetonitrile solutions. The vertical lines represent the results of the SCF-MO-CI calculations. The arrows represent the directions of the transition moments.

In the solution spectrum of $TNAP^0$, there appears a strong absorption band at 21.1×10^3 cm^{-1} which is completely isolated from other weak absorption bands. The molecular orbital calculation predicted that the transition (1) had a strong oscillator strength (2.47) and was separated far from other transitions as shown in Fig. 1a. Therefore, the absorption band, N_1, is unambiguously assigned to the transition (1).

Table 1. Wave numbers, molar absorption coefficients, and oscillator strengths of local excitation bands of $TNAP^0$ and $TNAP^-$

	Obsd				Calcd			
	Transition	$\tilde{\nu}$[a] / 10^3 cm^{-1}	ε[b] / 1 mol^{-1} cm^{-1}	f[c]	Transition	$\tilde{\nu}$[d] / 10^3 cm^{-1}	f[e]	Dominant[f] configuration
$TNAP^0$	N_1	21.1	79600	0.94	(1)	16.6	0.82	$6a_u \leftarrow 5b_g$
$TNAP^-$	A_1	9.0	84400	0.38	(1)	7.7	0.16	$6a_u \leftarrow 5b_g$ and vibrational structures
		10.6	30400					
		11.8	7500					
	A_2	18.8	14200	0.18	(2)	17.0	0.12	$6b_g \leftarrow 6a_u$
		19.3	15000		(3)	18.8		$7b_g \leftarrow 6a_u$
	A_3	23.9	32800	0.32	(4)	25.0	0.12	$8b_g \leftarrow 6a_u$

a) Wave numbers. b) Molar absorption coefficients. c) Oscillator strengths. d) Wave numbers. e) Oscillator strengths which are divided by 3 in order to compare them with the experimentally obtained values from the solution spectrum. f) The dominant configuration of the wave functions of the ground states in $TNAP^0$ and $TNAP^-$ ion are represented as follows respectively;

$TNAP^0$: $\Psi_0 = (1a_u)^2(1b_g)^2(2a_u)^2(3a_u)^2(2b_g)^2(3b_g)^2(4b_g)^2(4a_u)^2(5a_u)^2(5b_g)^2(6a_u)^0$,

$TNAP^-$: $\Psi_0 = (1a_u)^2(1b_g)^2(2a_u)^2(3a_u)^2(2b_g)^2(3b_g)^2(4b_g)^2(4a_u)^2(5a_u)^2(5b_g)^2(6a_u)^1(6b_g)^0(7a_u)^0(7b_g)^0(8b_g)^0$.

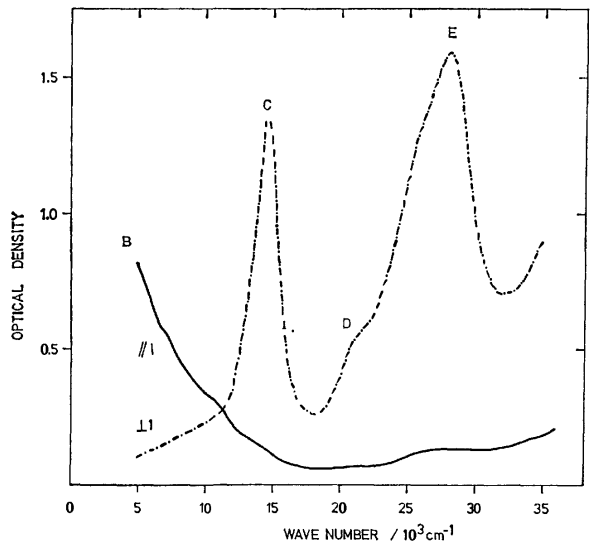

Fig. 2. Polarized absorption spectra of the single crystal of Na·TNAP.

The direction of the transition moment is almost parallel to the long axis of the molecule. The spectral features in this region are quite similar to those of $TCNQ^0$ except that the excitation energy of $TNAP^0$ is lower by about 3×10^3 cm^{-1} as compared with $TCNQ^0$.

The solution spectrum of $TNAP^-$ ion is more complicated than that of $TCNQ^-$ ion. We will denote the absorption bands as A_1, A_2, and A_3, respectively, in the order of increasing wave number, as shown in Fig. 1b. The structure of the band A_1 is similar to the vibrational structure of the absorption band of $TCNQ^-$ ion which has been assigned to the transition from the highest doubly occupied molecular orbital to the top-most singly-occupied molecular orbital. We can assign this band to the transition (1). The absorption band A_2 is broad and has a shoulder in the low wave number edge as shown in the inset of Fig. 1b. Probably it is composed of two electronic transitions. We will tentatively assign the band A_2 to the superimposition of the transitions (2) and (3). The band A_3 can be assigned to the transition (4) by comparing the observed energy and oscillator strength of this band with the calculated results.

Table 2. Wave numbers of absorption bands in the spectra of Na·TNAP

D	21.0	LE: A_2
E	28.0	LE: A_3

a) Wave numbers.

Na·TNAP. Na·TNAP is expected to be a salt composed of Na^+ and $TNAP^-$. Light-green plate-like crystals of this complex can be obtained from the acetonitrile solution. Since the crystal structure has not been known, the absorption spectra of the crystal were observed with the light polarized parallel and perpendicular to the elongated axis (*//l* and *⊥l*) of the crystal. The observed spectra are shown in Fig. 2. The wave numbers of the observed bands are listed in Table 2. The *//l* spectrum exhibits a strong absorption band below 5×10^3 cm^{-1} (B). There is no absorption band in this region in *⊥l* spectrum. Thus the absorption band (B) is completely polarized in the direction of the *l*-axis which is likely to be the stacking axis of $TNAP^-$. We cannot expect any local excitation band associated with an intramolecular transition of $TNAP^-$ in this region. Thus the observed absorption band (B) must be the one arising from the charge transfer (CT) between $TNAP^-$ ions.

In the region above 9×10^3 cm^{-1}, the *//l* spectrum shows no absorption band although the *⊥l* spectrum

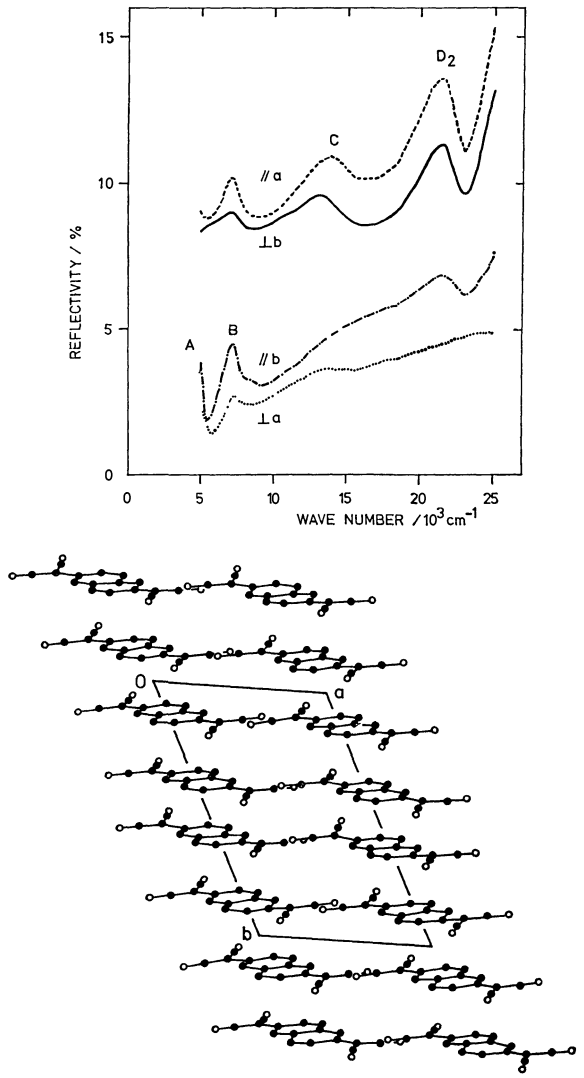

Fig. 3. Polarized reflection spectra of the single crystal of (MTPP)(TNAP)$_2$ measured on the (001) plane and the projection of TNAP molecules in the crystal onto (001) plane.

shows three absorption bands (C, D, and E). By comparing this $\perp l$ spectrum of Na·TNAP with the solution spectrum of TNAP$^-$, we can conclude that 14.5×10^3 (C), 21.0×10^3 (D), and 28.0×10^3 (E) cm^{-1} bands are the local-excitation bands corresponding to the 9—11.8×10^3 (A_1), 18.8—19.3×10^3 (A_2) and 23.9×10^3 (A_3) cm^{-1} bands in the solution spectrum of TNAP$^-$ ion, respectively. The relative intensity of the band D is very weak in comparison with the solution spectrum. It seems to be due to the difference of the direction of transition moment between the transition (2) and (3).

The local excitation bands C, D, and E are located at wave numbers higher by about 4—5×10^3 cm^{-1} as compared with the corresponding absorption bands of the solution spectrum of TNAP$^-$ ion. This is just the magnitude of the shift that is often found in the crystal where the intermolecular charge-transfer interaction is taking place between the constituent radical ions.[9]

(MTPP)(TNAP)$_2$. The crystal structure of this complex has been revealed by Sanz and Daly.[10] It is triclinic. In this crystal, TNAP molecules are arranged in groups of the four molecules which are almost parallel and equally spaced (3.30 Å) with each other. In other words, the crystal is composed of TNAP tetrads. The molecules between two consecutive tetrads are 3.46 Å apart. There is not significant difference in the molecular geometries of the four molecules in a tetrad.

The reflection spectra were measured on the (100) and (001) planes. On the (001) plane, the spectra were measured with the light polarizations, parallel to b and a axes (//b and //a) and perpendicular to b and a axes ($\perp$b and $\perp$a). On the (100) plane, the spectra were measured with the light polarizations parallel to b and c axes (//b and //c) and perpendicular to b and c axes ($\perp$b and $\perp$c). The observed reflection spectra are shown in Figs. 3 and 4 with the projections of TNAP molecules. The absorption spectra directly measured by the transmission method are shown in

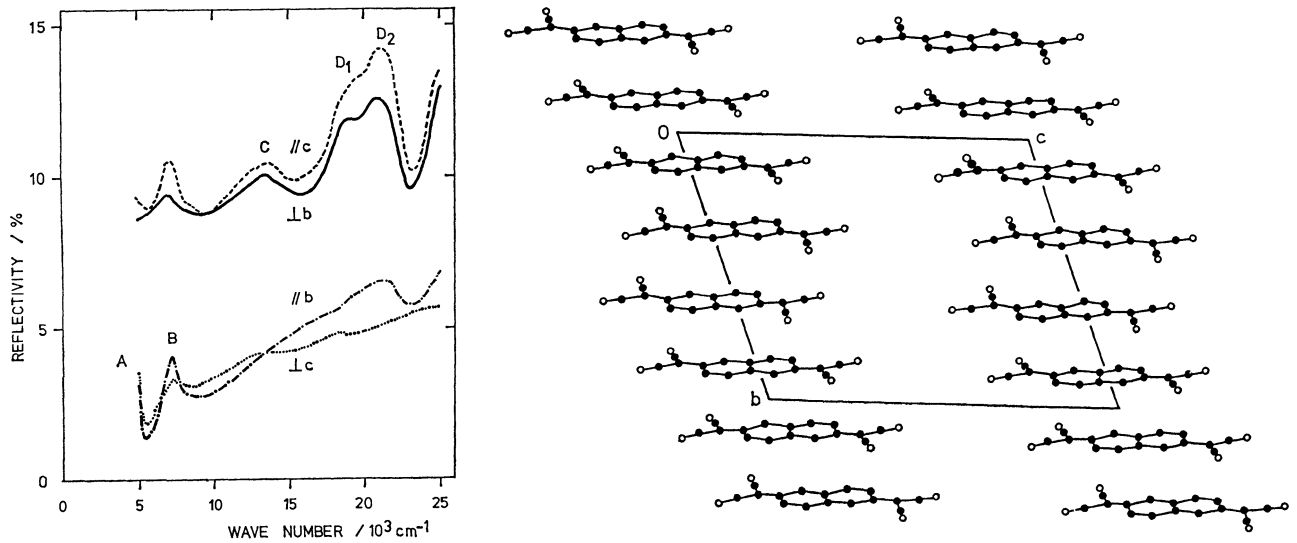

Fig. 4. Polarized reflection spectra of the single crystal of (MTPP)(TNAP)$_2$ measured on the (100) plane and the projection of TNAP molecules in the crystal onto (100) plane.

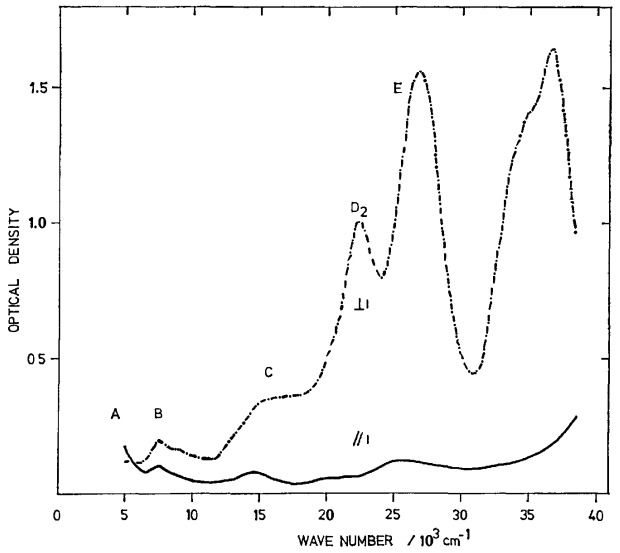

Fig. 5. Polarized absorption spectra of the single crystal of (MTPP)(TNAP)$_2$.

Fig. 5. Although we were not able to determine the observed crystallographic face directly, it is likely to be the (001) plane since it is in satisfactory agreement with the absorption spectra derived from the dispersion analysis of the reflection spectra obtained on the (001) crystal face. Therefore, we can consider that the spectra shown in Fig. 5 and the //a and ⊥a spectra. The wave numbers of the observed bands are listed in Table 3. The absorption spectra of this salt in the region lower than 17×10^3 cm^{-1} is quite similar to that of (MTPP)(TCNQ)$_2$ when we shift the spectrum of (MTPP)(TCNQ)$_2$ by about 3×10^3 cm^{-1} to higher wave number. The solution spectra of TNAP^0 and TNAP$^-$ are quite similar in nature with the spectra of TCNQ^0 and TCNQ$^-$, respectively, and the general feature of the crystal structure of (MTPP)(TNAP)$_2$ are almost the same as that of (MTPP)(TCNQ)$_2$. Therefore, we can interpret the electronic spectrum of (MTPP)(TNAP)$_2$ in analogy with that of (MTPP)-(TCNQ)$_2$. We have previously examined the temperature dependency of the reflection spectrum of (MTPP)(TCNQ)$_2$ and proposed an interpretation of the observed spectrum.[11] Using this result, we can assign the band A to the CT transition of the type TNAP^{0}TNAP$^-\rightarrow$TNAP$^-$TNAP^0, the band B mainly to the local excitation of TNAP$^-$ (A_1) and the band C to the CT transition from the second highest occupied molecular orbital of TNAP$^-$ to the lowest unoccupied molecular orbital of TNAP^0, which appears with an increased intensity by borrowing the intensity from the strong lowest transition of TNAP^0.

Let us examine the transition in the region about 20×10^3 cm^{-1}. The absorption spectrum measured on the (001) plane shows one absorption band in this region. The reflection spectra of the (001) crystal face also shows only one dispersion at the corresponding region. However, the c-polarized reflection spectra in the (100) crystal face shows that another dispersion (D_1) is superimposed on the dispersion D_2 as shown in Fig. 4. This result means that the direction of the transition moment of D_1 band is different from that of D_2 band. Since the direction of the transition moment of D_2 is almost parallel to those of C and E, D_1 must be attributable to the local excitation band associated with the transition (3) of TNAP$^-$, whose transition moment was predicted to be different from other transitions by the molecular orbital calculation as illustrated in Fig. 1b.

The absorption band E seems to correspond to the superimposition of the lowest transition of TNAP^0 and the transition (4) of TNAP$^-$.

Table 3. Wave numbers of absorption bands derived from the dispersion analysis of the reflection spectra of (MTPP)(TNAP)$_2$

Absorption bands	$\bar{\nu}$[a] / 10^3 cm^{-1}	Transition character
A	<5	(TNAP)^0(TNAP)$^-\rightarrow$ (TNAP)$^-$(TNAP)^0

TiO_2-supported Noble Metal Catalysts for the NO–CO and NO–CO–H_2O–H_2–O_2 Reactions

Ryuichi Nakamura, Shuichi Nakai, Kazuo Sugiyama, and Etsuro Echigoya*

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 8, 1980)

TiO_2-supported noble metal catalysts, such as Pt–, Pd–, and Rh–TiO_2, are much more active for the NO–CO reaction in the presence or absence of H_2O, H_2, and O_2 than the corresponding Al_2O_3– or other supported catalysts. They are effective even in an oxidative gas composition range for the NO–CO–(H_2O)–H_2–O_2 reaction, producing no NH_3 in the NO–CO–H_2O reaction. Comparison of the catalytic activity and properties of Pt–TiO_2 with those of other supported catalysts suggests that the higher activity of the TiO_2-supported catalysts could be attributed to their ability to activate NO molecules by the dissociative adsorption at lower temperatures.

The reduction of NO in automotive exhaust over supported Pt group catalysts has been extensively investigated by many workers, Al_2O_3 being commonly employed as the catalyst support.[1-3] However, few studies have been made on supports other than Al_2O_3 or Al_2O_3-based materials. As a result, no supports more effective for NO–CO reaction than Al_2O_3 are known. In the present investigation, a few types of TiO_2 were employed as a support for noble metals such as Pt, Rh, Pd, and Ru and their catalytic activities for the NO–CO reaction in the presence or absence of H_2O, H_2, and O_2 were determined and compared with those of the corresponding Al_2O_3-supported catalysts. Various supported Pt catalysts such as Pt–TiO_2, Pt–Al_2O_3, Pt–SiO_2, and Pt–SiO_2–Al_2O_3 were also employed, the catalytic activities and properties of the catalysts and supports being measured and compared with each other, and the role of the TiO_2 support in the catalytic activity was discussed.

Experimental

Catalyst Support. TiO_2(a) : TiO_2(anatase) was prepared by neutralization of HCl-acidic solution of $TiCl_4$ (Oosaka Titanium Co., Ltd., pH=0.1—0.2, 3.8 mol dm^{-3} $TiCl_4$) with ammonia water (1 mol dm^{-3}) up to a pH *ca.* 6, followed by washing of the precipitate obtained with water several times, drying at 393 K for 18 h, and calcination in air at 823 K for 4 h. TiO_2(a-s) : TiO_2(anatase) containing a very small amount of SO_4^{2-} was prepared from the $TiCl_4$ solution according to a procedure similar to that of Funaki and Saeki.[5] The resulting TiO_2 was calcined in the air at 823 K for 4 h. TiO_2(r-HSA) : TiO_2(rutile) with higher BET surface area as compared with the conventional rutile type TiO_2 was prepared from the $TiCl_4$-solution by evaporation followed by drying and air calcination. TiO_2(r-LSA) : TiO_2(rutile) with low BET surface area was prepared from TiO_2(a) by air calcination at 1273 K for 5 h. The BET surface area of TiO_2(a), TiO_2(a-s), TiO_2(r-HSA), and TiO_2(r-LSA) were 78, 73, 16, and 1 $m^2 g^{-1}$, respectively. $Al_2O_3(\gamma)$, SiO_2·Al_2O_3, SiO_2, MgO: These supports were prepared by the same procedure as reported[6]. Calcination was carried out in the air at 873 K for 4 h. The BET surface area of Al_2O_3, SiO_2, SiO_2·Al_2O_3, and MgO were 240, 150, 265, and 50 $m^2 g^{-1}$, respectively.

Catalyst. Supported noble metal catalysts (Tables 1—3) were prepared by impregnation of the support materials such as TiO_2(a), $Al_2O_3(\gamma)$ with a solution of $H_2PtCl_6 \cdot 6H_2O$, $RhCl_3 \cdot 3H_2O$, $RuCl_3 \cdot 3H_2O$, or $PdCl_2$, and subsequent evaporation and drying at 393 K for 18 h. Before the activity test, the catalysts were activated *in situ* by reduction with H_2 at 773 K for 1 h, followed by the purge of hydrogen in the reactor with oxygen-free dry helium at the same temperature for 1 h.

Reaction and Analysis. The reaction was carried out by use of the conventional flow system with a fixed bed of catalyst under gas compositions, NO(3*%), CO(3*%), H_2O(0*—6%), H_2(0*—6%), O_2(0*—6%), and He(balance*), where * denotes a standard gas composition. The flow rate of the reactant/helium gas mixture was kept at 100 cm^3 min^{-1}. The reaction temperature ranged from 423 to 673 K, being mostly fixed at 573 K. The composition of the product gas was determined by gas chromatography and mass spectrometry.

Measurement of Catalytic Properties. The structure of support materials was determined by an X-ray powder diffraction method. The BET surface areas of the supports or catalysts were measured by a high speed surface area analyzer (Shimadzu Micromeritics). The number of surface Pt atoms of the supported Pt catalysts was estimated by conventional H_2–O_2 pulse titration. Adsorption experiments for NO and CO were carried out in a gas adsorption heat analyzer (Tokyo Riko GAC-2) connected to a vacuum system equipped with mercury and oil manometers and a calibrated pirani vacuum gauge. Heat of adsorption and gas uptakes can be measured calorimetrically and volumetrically. Temperature programed desorption (TPD) experiments were carried out in a vacuum system equipped with a pirani gauge and a mass spectrometer under the following conditions. One gram of the sample was put in a quartz tube. After reduction of the sample with H_2 at 773 K for 1 h and subsequent outgassing at the same temperature for several hours (Activation Method I), NO was adsorbed to the sample at room temperature and 1.33×10^3 Pa, followed by evacuation at room temperature for 20 min. The temperature then rose *in vacuo* with a constant rate of 10 K min^{-1}. The total pressure response of the gas desorbed from the sample was measured with a pirani gauge, the composition of the gas being monitored periodically with a mass spectrometer. The following activation method (Activation Method II) was also employed. Before the NO-adsorption, the sample which had been activated by Activation method I was oxidized with O_2 at 773 K for 10 min, evacuated at the same temperature for 10 min, reduced with H_2 at 493 K for 15 min, followed by evacuation at 493 K for 5 min and then at 623 K for 20 min.

Results and Discussion

The catalytic activities of various supported Pt catalysts for the NO–CO reaction were measured and

a) Pt 1 wt%. b) At 573 K, NO, CO: 3%, He: 94%, 100 $cm^3\,min^{-1}$, catalyst: 0.3 g. c) The values were roughly estimated by the relation: Turn over frequency (s^{-1}) = apprant rate of NO consumption (mol s^{-1})/surface Pt (mol), after 10 min. d) After 60 min. e) From an H_2–O_2 pulse titration method. f) At 298 K. g) The values in ( ) correspond to those for the supports themselves. h) The decrease in the catalytic activity is due to the formation of surface NCO species.

Table 2. Comparison of activities of TiO-supported metal catalysts with those of Al_2O_3-supported ones[a]

Support	Promoter	NO conversion/% 523 K	573 K	623 K
TiO_2	Rh	9	76	100
	Pd	25	30	45
	Pt	≈2	9	21
	Ru	≈0	≈1	10
Al_2O_3(γ)	Rh	≈1	50	100
	Pd	≈3	17	40
	Pt	0	6	10
	Ru	0	≈1	6

a) NO, CO, 3%, He 94% flow rate 100 $cm^3\,min^{-1}$, catalyst: 0.01 g(1 wt%).

compared with each other. Conversion of NO distinctly depends on the support materials and decreases in the following order in the reaction temperature range 423—623 K: Pt-TiO_2(a-s)[100*, 98**]>Pt-TiO_2(a)[100*, 96**]>Pt-TiO_2(r-HSA)[100*, 87**]>Pt-Al_2O_3(γ)[100*, 25**] > Pt-SiO_2·Al_2O_3[16*] > Pt-MgO[10*] > Pt-SiO_2[9*] > Pt-TiO_2(r-LSA)[≈1*] > Pt-Al_2O_3(α)[0*]. The numeral in [ ] represents the % conversion of NO, after 10 min from the start of reaction, at 523 K and at $W/F=3\times10^{-3}$ g min cm^{-3} (*) or at $W/F=4\times10^{-4}$ g min cm^{-3}(**). The selectivity to N_2 also depends on the support meterials (Table 1). TiO_2, even a rutile type, unless its surface area is extremely small, gives better results. Similar carrier-effects were obtained when Rh, Pd, and Ru were employed instead of Pt. The catalytic activities of the TiO_2-supported noble metal catalysts are compared with those of the Al_2O_3-supported ones in Table 2.

Table 3. Activities of Pt-Al_2O_3(γ), Pt-TiO_2(a), and Pd-TiO_2(a) catalysts for NO-CO-H_2O or NO-CO-H_2-O_2 reaction

Catalyst	Reaction	% Conversion of NO or (NO+NO_2)	% Yield of (N_2+N_2O)	% Yield of NH_3
Pt-Al_2O_3(γ)	A	72	52	20
Pt-TiO_2(a)	A	100	100	0

Reaction conditions, temperature: 573 K, flow rate: 100 $cm^3\,min^{-1}$; A: NO, CO 3%, H_2O 1.7%, He 92.3%, $W/F=3\times10^{-3}$ g min cm^{-3}, after 150 min; B: NO, CO, O_2 3%, H_2 5%, He 86%, $W/F=1\times10^{-4}$ g min cm^{-3}, after 5 min; C: NO, CO 2%, H_2 3%, O_2 5%, He 88%, $W/F=2\times10^{-4}$ g min cm^{-3}. a) Conversion of NO including a non-catalytic reaction: $NO+(1/2)O_2\rightarrow NO_2$. b) Conversion of (NO+$NO_2$). c) The catalytic activity gradually decreased with increase in the time on stream.

TiO_2-supported noble metal catalysts show higher catalytic activity and selectivity to N_2. In addition they have the advantage of (a) producing very minor NH_3 in both NO-CO-H_2O and NO-CO-H_2O-H_2-O_2 reactions and (b) working effectively even in a rather oxidative gas composition range for the NO-CO-(H_2O)-H_2-O_2. Examples are given in Table 3. We see that Pt-TiO_2(a) gives no NH_3 when the NO-CO reaction is carried out in the presence of H_2O vapor. Pd-TiO_2, which has a significant catalytic activity for the NO-CO reaction even around 473 K, is a very active for the NO-CO-(H_2O)-H_2-O_2 reaction when the ratio of O_2 to H_2 is near 2, while Pt-Al_2O_3(γ), which is a conventional catalyst gives rise to high

concentration of NH_3 in the NO-CO-H_2O reaction under the same conditions, not working effectively in such an O_2-rich region.

Some catalytic properties of the supported Pt catalysts are summarized in Table 1. The surface area of Pt depends on the support. Pt on TiO_2(a) is less dispersed than that $Al_2O_3(\gamma)$ or $SiO_2 \cdot Al_2O_3$. Baker *et al.*, who studied the particle size of Pt on the thin film of titanium oxide, aluminium oxide, *etc.* by means of electron microscopy have shown that the mean particle size of Pt in the Pt-titanium oxide (Ti_4O_7) sample reduced with H_2 below 825 K is almost the same as that of Pt in the Pt-aluminium oxide sample[4]. The disagreement of the relative dispersion of Pt may fall in the difference in the method of preparation.

Comparison of the catalytic activities with the BET surface area of the catalyst and with the number of Pt surface atoms (corresponding to the surface area of Pt metal particles dispersed over the supports) or roughly estimated turn over frequencies for the consumption of NO (Table 1) led us to the conclusion that the surface area of Pt as well as that of the catalyst is not always a dominant factor in the catalytic activity. In other words, the catalyst with larger BET area or Pt surface area does not necessarily exhibit higher activity although the low catalytic activity of Pt-TiO_2(r-LSA) might be attributed to the low surface area of Pt. Table 1 indicates that the highly active catalysts, Pt-$Al_2O_3(\gamma)$ and Pt-TiO_2(a), are characterized by their higher heat of a adsorption for NO and also by both high NO and CO uptakes, while the other less active catalysts lack either one or both of the terms. For example, the lower activity of Pt-SiO_2 and Pt-$SiO_2 \cdot Al_2O_3$ might be due to their poor ability to activate NO molecules compared with Pt-$Al_2O_3(\gamma)$ and Pt-TiO_2(a), since they have lower heat of adsorption for NO.

In order to clarify why Pt-TiO_2(a) is more active than Pt-$Al_2O_3(\gamma)$, in particular at lower temperatures, temperature programmed desorption (TPD) experiments with respect to the NO-preadsorbed Pt-$Al_2O_3(\gamma)$ and Pt-TiO_2(a) were carried out. The results are shown in Figs. 1a and 1b, respectively. For Pt-$Al_2O_3(\gamma)$, there is a relatively sharp desorption peak of N_2 around 503 K, which was formed from the NO molecules adsorbed on the catalyst. The result closely agrees with that reported by Unland who concluded that the dissociation of NO on Pt-$Al_2O_3(\gamma)$ occurs above 503 K.[6-8] On the contrary, the TPD spectrum for Pt-TiO_2(a), in our case, was found to differ from that for Pt-$Al_2O_3(\gamma)$, the spectrum being characterized by the following two points: (a) N_2-desorption occurs at lower temperatures around 373 K, indicating that NO molecules dessociate on Pt-TiO_2(a) at much lower temperature on Pt-$Al_2O_3(\gamma)$, and (b) the spectrum of N_2-desorption spreads over a wide temperature range. This might be due to the heterogeneity of the active site on the Pt-TiO_2(a) catalyst.

It should be noted that N_2 and N_2O are formed not only by the reaction between the adsorbed NO molecules and Pt but also by the reaction between those and the TiO_2(a) support, since the support is probably reduced to some extent during the course of activation with H_2 at 773 K and adsorbs NO molecules. In fact an EPR experiment showed the presence of Ti^{3+} in the TiO_2(a) support activated by Activation Method I. NO-preadsorbed TiO_2(a) gave a TPD spectrum consisting of N_2, N_2O, and NO (Fig. 1c). A comparison of Figs. 1b and 1c, however, suggests that both N_2 and N_2O are formed mostly by the reaction between the adsorbed NO molecules and Pt, especially above 423 K. A TPD experiment for a Pt-TiO_2(a) catalyst which had been previously activated by Activation Method II was carried out (Fig. 1d). An EPR experiment revealed that the concentration of Ti^{3+} in Pt-TiO_2(a) activated by Activation Method II is negligible-less than one tenth of that in the Pt-TiO_2(a) sample activated by Activation Method I. This indicates that Activation Method II gives an almost fully oxidized TiO_2(a) support. In fact a TPD experiment showed that nither N_2 nor N_2O is liberated from NO-preadsorbed TiO_2(a) previously activated by Activation Method II. On the contrary, the Pt surface area of the Pt-TiO_2(a) catalyst activated by Activation Method II was close to that of Pt-TiO_2(a) activated by Activation Method I. These results indicate that the Pt-TiO_2(a) catalyst activated by Activation Method II consists of almost completely reduced Pt and almost fully oxidized TiO_2(a). No reaction between NO and the fully oxidized TiO_2(a)

support can be expected, the formation of N_2 and N_2O shown in Fig. 1d being ascribed to the reaction between NO and Pt on the TiO_2(a) support.

IR studies on the surface NCO species formed on the catalysts during the course of NO–CO reaction showed that the NCO species is formed on TiO_2-supported catalysts at lower temperatures than on the corresponding Al_2O_3-supported catalyst. The NCO species, for example, was observed not on Pt–$Al_2O_3(\gamma)$ at 473 K but on Pt–TiO_2(a) at the same temperature. The result suggests that the dissociation of NO occurs on the TiO_2-supported ones, since the NCO seems to be produced by the reaction between a CO molecule and an adsorbed N atom formed by the dissociation of an adsorbed NO molecule.

The big difference in catalytic activity between Pt–TiO_2(a) and the other suppored Pt catalysts is not attributed to the difference of the surface area of Pt but to that of the NO-dissociation ability of the catalysts. The reason why the TiO_2-supported catalysts easily dissociated NO at lower temperature than the others is still unknown. However, an explanation is that the NO-dissociation ability might be due to the high concentrations of free electrons of the TiO_2 support or Ti^{3+} ions having thermally emissive electrons; probably, the back donation of one of these electrons into a π^* (antibonding) orbital of the adsorbed NO molecule through the dispersed Pt metal on TiO_2 weakens the N–O bond.

In conclusion, TiO_2, either anatase or rutile unless its surface area is extremely low, was found to be a most effective support for different noble metal catalysts in the NO–CO reaction even in the presence of H_2O, H_2, and O_2. The high catalytic activity of the TiO_2-supported catalyst could be attributed, at least, to its ability to activate NO molecules by dissociative adsorption at lower temperatures.

This work was supported by Grant-in-Aid for Special Project Research.

(Received November 12, 1980)

The crystal structure of the α-cyclodextrin–benzaldehyde (1:1) complex hexahydrate, $C_{36}H_{60}O_{30}\cdot C_7H_6O\cdot 6H_2O$, was determined by the X-ray method. The crystal is monoclinic, the space group being $P2_1$ with $Z=2$. The cell dimensions are $a=7.932(1)$, $b=13.500(1)$, $c=24.704(2)$ Å, and $\beta=90.85(1)°$. The structure was solved by means of a Patterson map and a trial-and-error method combined with the rigid-body least-squares technique. Refinement was carried out by the block-diagonal least-squares method to the final R-value of 0.057 for 4565 reflections. α-Cyclodextrin molecules are stacked along the a axis in a head-to-tail fashion to form a channel-type structure. The α-cyclodextrin ring is tilted by an angle of 11.5° against the channel axis. Adjacent α-cyclodextrin molecules along the channel are linked by hydrogen bonds between the primary hydroxyl groups and the secondary hydroxyl groups, and O(2)···water···O(6) hydrogen-bond bridges. The guest benzaldehyde molecules are aligned inside the α-cyclodextrin column. The benzene ring is inserted into the α-cyclodextrin ring from the secondary hydroxyl side, while the carbonyl group is in the van der Waals contact with the primary hydroxyl side of the next α-cyclodextrin. The guest plane is nearly parallel to the channel axis, making an angle of 71.2° against the plane through six glycosidic oxygen atoms. Spaces between α-cyclodextrin columns are filled with water molecules. Many hydrogen bonds are observed among hydroxyl groups of α-cyclodextrin and water molecules, forming a hydrogen-bond network in the crystal.

Interaction of cyclodextrins with drugs has received considerable attention because the complexation may increase their solubility and chemical stability.[1] It was recently found that the photolysis and oxidation of benzaldehyde are significantly retarded by cyclodextrins,[2] several crystal structures of α-cyclodextrin complexes with benzene derivatives having been investigated by the X-ray method.[3–6] In this paper, the crystal structure of the benzaldehyde complex is discussed.

Experimental

α-Cyclodextrin and benzaldehyde in a 1:1 molar ratio were dissolved in degassed water at 80 °C. The solution was sealed under nitrogen and then cooled slowly to room temperature, colorless plate-like crystals being obtained. Experiments were carried out in the dark to avoid photolysis and oxidation of benzaldehyde. Measurements of lattice parameters and intensities were carried out on a Rigaku automatic four-circle diffractometer with graphite monochromated Cu $K\alpha$ radiation; 4565 independent reflections with $|F_o|>3\sigma(F)$ were collected up to 150° in 2θ by a θ-2θ scan technique. No corrections were made for absorption and extinction.

Crystal Data: $C_{36}H_{60}O_{30}\cdot C_7H_6O\cdot 6H_2O$, $F.W.=1187.1$, monoclinic, space group $P2_1$, $Z=2$, $a=7.932(1)$, $b=13.500(1)$, $c=24.704(2)$ Å, $\beta=90.85(1)°$, $V=2645.1$ Å^3, $D_x=1.490$, $D_m=1.495$ g·cm^{-3}.

Determination and Refinement of the Structure

The orientation of the α-cyclodextrin molecule in the crystal was easily deduced by inspection of a Patterson map. The position of the molecule was determined by the trial-and-error method. The positional and orientational parameters of each glucose residue were corrected by the rigid-body least-squares method. Benzaldehyde and water molecules were found on Fourier and difference-Fourier maps. A primary hydroxyl group (O(6,G1)) of α-cyclodextrin and a water molecule (W2) were statistically disordered. Their occupancy was estimated from an electron-density map, but the results were not refined. Seventy-three hydrogen atoms were found on a difference-Fourier map. The refinement of the structure was carried out by the block-diagonal least-squares method. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$, with $w=1.0$ for all the reflections, the final R-value being 0.057. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[7] The atomic coordinates are given in Table 1. Tables of anisotropic temperature factors of non-hydrogen atoms, atomic parameters of hydrogen atoms, observed and calculated structure factors, bond distances, angles, and conformation angles in α-cyclodextrin are kept at The Chemical Society of Japan (Document No. 8135).

Description of the Structure and Discussion

Outline of the Structure. The structure and numbering scheme of the complex are shown in Fig. 1, the atom numbering for α-cyclodextrin being the same as that used in the *m*-nitroaniline complex.[6] The α-cyclodextrin molecule is in the shape of a distorted hexagon, and is stacked along the a axis in the head-to-tail mode to form a typical channel-type structure (Fig. 2). The guest benzaldehyde molecule is linearly arranged in the channel, being fixed by the van der Waals force.

a) $B_{eq}=8\pi^2(U_1+U_2+U_3)/3$ where U_1, U_2, and U_3 are the principal components of U matrix. b) The occupancy factors for O(6A, G1), O(6B, G1), O(W2A), and O(W2B) are 0.5, 0.5, 0.6, and 0.4, respectively.

Conformation of α-Cyclodextrin. Average bond distances and angles in six glucose residues are shown in Fig. 3. The C–C bond distances are in the range 1.518—1.533 Å. The C(1)–C(2) and C(4)–C(5) bonds are somewhat longer than the C(2)–C(3) and C(3)–C(4) bonds. The anomeric C–O bonds (1.411 and 1.414 Å) are shorter than the other C–O bonds (1.421—1.437 Å). The C(3)–C(4)–O(4) and C(6)–C(5)–O(5) angles are relatively small, the C(4)–C(5)–C(6) angle (113.7°) being large. The same tendency has been observed in the uncomplexed α-cyclodextrin and in the α-cyclodextrin complexes with some other guests.[3,8] The larger C(4)–C(5)–C(6) angle may be ascribed to the repulsive interaction between the C(6) methylene group and the adjacent glucose residue. The C(4)–O(4)–C(1′) glycosidic oxygen angles are in the range 117.7—119.7° in good agreement with those of other α-cyclodextrin complexes.[3–6,8] Except for the G1 and G2 residues, the primary hydroxyl group is in the *gauche-gauche* conformation. The G2 residue has the hydroxyl group with the *gauche-trans* conformation, the primary hydroxyl group of the G1 residue being statistically disordered showing the *gauche-gauche* and *gauche-trans* conformations for O(6A,G1) and O(6B,G1), respectively (Fig. 1).

The hexagonal α-cyclodextrin ring is elliptically distorted owing to the inclusion of the planar molecule, as seen from the diagonal distances measured between

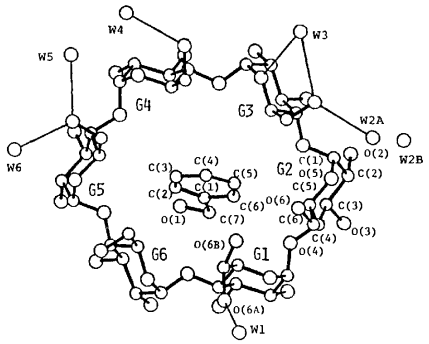

Fig. 1. Structure and numbering scheme of the α-cyclodextrin-benzaldehyde complex hexahydrate. The water molecules are shown by W1, W2A, W2B, W3, W4, W5, and W6, in which W2A and W2B denote the disordered W2 water. The disordered primary hydroxyl group of the G1 residue is denoted by O6A and O6B. Intermolecular contacts less than 3.1 Å are shown by thin lines.

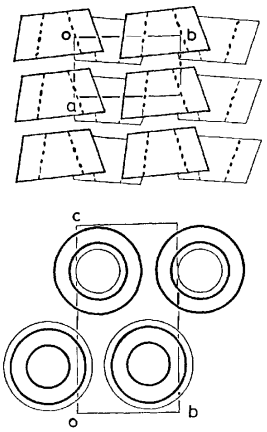

Fig. 2. Schematic drawings of the packing feature of α-cyclodextrin in the crystal.

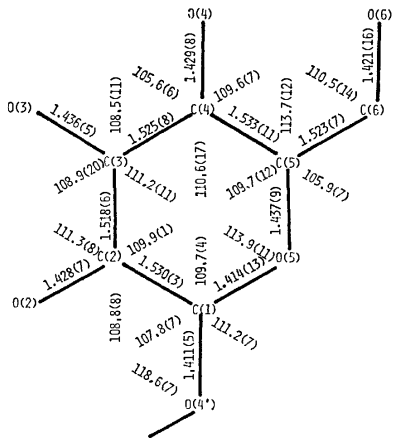

Fig. 3. Average bond distances (l/Å) and angles (ϕ/°) over six glucose residues. Standard deviations in parentheses were estimated according to the equation: $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x})^2/5]^{1/2}$, where x_i referes to the bond distance or angle in the i-th glucose residue, and $\bar{x}$ is the average value.

TABLE 2. GEOMETRICAL DATA FOR α-CYCLODEXTRIN RING

I. O(4)···O(4) distances

Distance (l/Å)		Distance (l/Å)	
O(4, G1)···O(4, G2)	4.466	O(4, G5)···O(4, G6)	4.126
O(4, G1)···O(4, G6)	4.328	O(4, G1)···O(4, G4)	8.047

C3	−0.015	C7	−0.040
C4	0.031	O1	0.078

the glycosidic oxygen atoms in Table 2. The conformation of each glucose residue is affected by such distortion. The distance between the adjacent glycosidic oxygen atoms is in the range 4.110—4.466 Å. The O(4)···O(4) distance is closely related to the conformation of pyranose ring characterized by the torsion-angle index.[3] The shorter O(4)···O(4) distance gives the large torsion-angle index. This is ascribed to the smaller conformation angles of C(2)–C(3)–C(4)–C(5) and C(3)–C(4)–C(5)–O(5) and the larger angles of O(5)–C(1)–C(2)–C(3) and C(5)–O(5)–C(1)–C(2).

A tilt-angle between the plane through six glycosidic oxygen atoms and the plane through O(4'), C(1), C(4), and O(4) atoms of each glucose residue was proposed as a convenient measure to describe the orientation of each glucose residue relative to the macro-cyclic ring.[9] In the benzaldehyde complex, the tilt-angles are in the range 10.9—19.9, the average value being 16.0°. These values are similar to those found in the *m*-nitroaniline complex,[6] but considerably larger than those of complexes with other aromatic

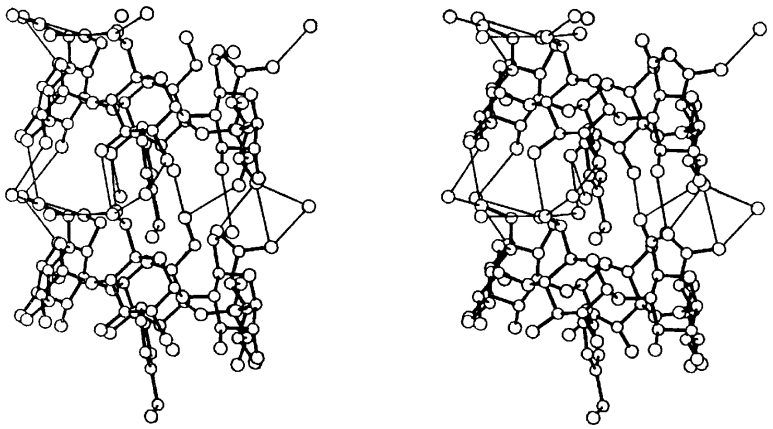

Fig. 4. A stereo-drawing of the packing feature of the complex with associated water molecules. Thin lines denote intermolecular contacts less than 3.1 Å.

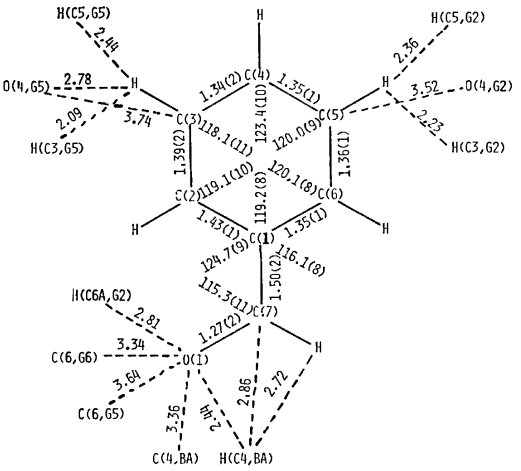

Fig. 5. Bond distances (l/Å) and angles (ϕ/°) in benzaldehyde and selected intermolecular distances (l/Å) between α-cyclodextrin and benzaldehyde. Estimated standard deviations in benzaldehyde are given in parentheses.

guests (average values of 10—12°).[9] Since the packing of α-cyclodextrin in the crystal is nearly the same in the complexes with *m*-nitroaniline and benzaldehyde, we propose another example to support the suggestion that the tilt-angle is largely determined by the packing of α-cyclodextrin in the crystal.

The O(2)···O(3) contact between the adjacent glucose residues is also important to interpret the α-cyclodextrin conformation. The greatest O(2)···O(3) distance is 3.695 Å observed between the G1 and G2 residues, while the other O(2)···O(3) distances are in the range 2.857—2.994 Å. We see from Table 2 that the C(4)–O(4)–C(1′) angle scarecely affects the O(2)···O(3) distance; the greatest O(2)···O(3) distance is observed between the most tilted residues, but the O(2,G2)···O(3,G3) distance is the smallest in spite of the large tilt of the G2 and G3 residues. The O(2)···O(3) distance is more sensitive to the angle made by two planes through O(4′), C(1), C(4), and O(4) of the corresponding glucose residues. The largest angle of 27.6° is found between the G1 and G2 residues, while the other values are in a relatively small region (12.2—15.4°) in accordance with the distribution of the O(2)···O(3) distances.

α-Cyclodextrin-Guest Interaction. Figure 5 shows bond distances and angles in benzaldehyde and intermolecular distances between α-cyclodextrin and benzaldehyde. There is no unusual value in bond distances and angles in benzaldehyde, the planarity of the molecule being fairly good (Table 3). The α-cyclodextrin ring includes about two-third of the benzene ring, while the carbonyl group protrudes from the secondary hydroxyl side and is inserted into the next α-cyclodextrin ring from the primary hydroxyl side (Fig. 4). The benzaldehyde molecule is tilted towards the G1 residue, making an angle of 71.2° against the O(4) plane. The value differs significantly from those found in the α-cyclodextrin complexes with benzene derivatives, in which the aromatic plane is nearly perpendicular to the O(4) plane.[3,5] In those complexes, the benzene ring is deeply inserted into the α-cyclodextrin ring. The benzaldehyde plane is nearly parallel to the C(3,G2)···C(3,G5) diagonal. The relatively short hydrogen···hydrogen contacts are observed between the benzene ring and the C(3) methine groups; H(C3,G5)···H(C3,BA) of 2.09 Å and H(C3,G2)···H(C5,BA) of 2.23 Å. Such a short intermolecular distance is also found between the benzaldehyde molecules; H(C4,BA)···O(1,BA) of 2.44 Å. It is noteworthy that the carbonyl group does not form a hydrogen bond with α-cyclodextrin, and the benzaldehyde molecule is fixed in the α-cyclodextrin ring by the van der Waals contact. In the α-cyclodextrin complexes with other aromatic guests, the guest molecule is hydrogen-bonded to the next α-cyclodextrin or adjacent water molecules. Although the inclusion geometry of the sodium benzenesulfonate complex is similar to the benzaldehyde complex, the sulfonato group of the guest is hydrogen-bonded to primary hydroxyl groups which are in the *gauche-trans* conformation.[4] In the benzaldehyde complex, the nearest primary hydroxyl group is in the *gauche-gauche* conformation, being oriented in the opposite direction. The carbonyl group is so deeply inserted into the α-cyclodextrin ring that it can not form a hydrogen bond with the primary hydroxyl group even when it is in the *gauche-trans* conformation.

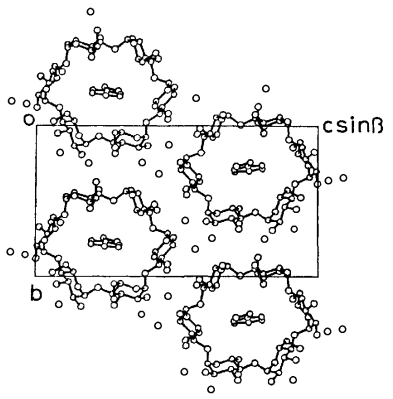

Fig. 6. Crystal structure viewed down the a axis.

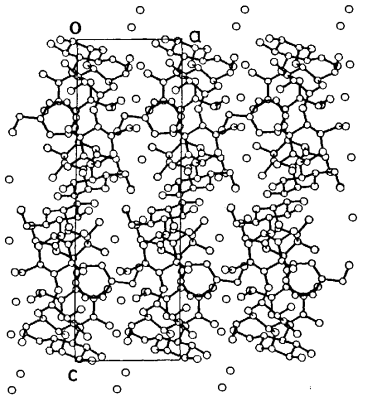

Fig. 7. Crystal structure viewed down the b axis.

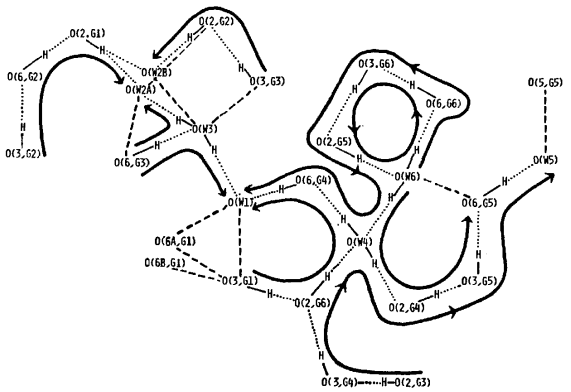

Fig. 8. A schematic drawing of the hydrogen-bond network in the crystal. Arrows indicate the direction of the O–H bond. Intermolecular O···O contacts less than 3.0 Å are shown by broken lines.

Molecular Packing and Hydrogen Bonds. Crystals of the α-cyclodextrin–benzaldehyde complex are built up of the stack of α-cyclodextrin molecules along the a axis to form endless columns. The projections of the crystal structure are shown in Figs. 6 and 7. The α-cyclodextrin molecule is nearly parallel to the a axis, being tilted by 11.5°. The guest benzaldehyde molecules are aligned inside the column with their planes parallel to the ac plane; the angle between these planes is 11.7°. The repetition unit along the column axis (7.932 Å) is almost the same as that of the *m*-nitroaniline complex (8.054 Å), but shorter by 0.3 Å than that of the sodium benzenesulfonate complex. Since the channel axis is perpendicular to the two-fold screw axis, the α-cyclodextrin molecule of the symmetry-related column is arranged up-side-down. These α-cyclodextrin columns are closely packed in the crystal, spaces between columns being filled with water molecules.

So far, no details of hydrogen-bond scheme have been described in the α-cyclodextrin complexes with the channel-type structure.[4,5] A number of hydrogen-bonding contacts were defined in the benzaldehyde complex since most of the hydrogen atoms were found. Five intramolecular hydrogen bonds are formed between the adjacent glucose residues: O(3,G1)–H···O(2,G6), O(3,G3)–H···O(2,G2), O(2,G3)–H···O(3,G4), O(2,G4)–H···O(3,G5), and O(3,G6)–H···O(2,G5). No hydrogen-bonding contact is observed between the G1 and G2 residues, but they are linked by the O(3,G2)–H···O(6,G2)–H···O(2,G1) hydrogen bonds. The adjacent α-cyclodextrin molecules along the channel are connected by the direct hydrogen bonds and hydrogen-bonding linkages involving water molecules. The G2, G4, G5, and G6

Table 4. Hydrogen-bond distances (*l*/Å) and angles (*φ*/°) and intermolecular distances (*l*/Å) less than 3.0 Å

Estimated standard deviations are in the ranges 0.006—0.008 Å for the distance, 0.06—0.10 Å for the distance involving the hydrogen atoms, and 1.0—4.0° for the O–H···O angle.

Code	Symmetry operator		
None	x,	y,	z
a	x	1+y,	z
b	-1+x,	y,	z
c	x,	-1+y,	z
d	-1+x,	-1+y,	z
e	-x,	-1/2+y,	-z
f	1-x,	1/2+y,	1-z
g	1-x,	-1/2+y,	-z
h	1-x.	-1/2+y,	1-z

residues are linked by the O(3)···O(6) hydrogen bond. In the G2, G4, and G5 residues, the O(3) hydroxyl group donates the hydrogen atom, while the O(6) hydroxyl group acts as a donor in the G6 residue. Although no hydrogen atom of the O(6A,G1) and O(6B,G1) hydroxyl group was found, the intermolecular distance (Table 4) indicates that they are hydrogen-bonded to the O(3,G1) hydroxyl group of the adjacent α-cyclodextrin. The O(2) hydroxyl groups are also involved in the hydrogen bonds connecting the adjacent α-cyclodextrins. The O(6,G2) hydroxyl group donates the hydrogen atom to O(2,G1). O(2, G4) and O(6,G4) are linked through the O(2,G4)···H–O(W4)–H···O(6,G4) hydrogen-bond bridge.

Water molecules are located in two intermolecular spaces. W1, W2A, W2B, and W3 fill the space encircled by the G1, G2, and G3 residues. W2 is statistically disordered, occupying two positions. The water molecules are linked by the O(W1)···H–O(W3)–H···O(W2A) hydrogen-bond bridge. Although no hydrogen atoms of the W2B water molecule were found, the O(W3)···O(W2B) distance of 2.680 Å suggests a hydrogen-bond formation. W4, W5, and W6 occupy the space encircled by the G4, G5, and G6 residues. W4 and W6 are connected by the O(W6)–H···O(W4) hydrogen bond, W5 being isolated and only hydrogen-bonded to O(6,G5).

In the crystal, a hydrogen-bond network is constructed by circles and chains of hydrogen bonds (Fig. 8). The four-membered hydrogen-bond circle is formed by O(2,G5), O(3,G6), O(6,G6), and W6. O(2,G4), O(3,G5), O(6,G5), O(W6), and O(W4) form a five-membered ring, but the circle is not closed since the O(W6) and O(6,G5) forms no hydrogen bond in spite of a suitable distance of 2.919 Å. In the five-membered ring composed of O(3,G1), O(2,G6), O(W4), O(6,G4) and O(W1), the O(W1)–H bond should be oriented to O(3,G1) to close the circle.

The α-cyclodextrin packing in the present crystal resembles that in the *m*-nitroaniline complex, but their crystal property is quite different; the crystal of the *m*-nitroaniline complex easily breaks up in the air. This may be mainly due to the conformation of G1, G2, and G3 residues and water molecules hydrogen-bonded to them. The primary hydroxyl group of the G1 residue in the benzaldehyde complex is disordered and that of the G2 residue is in the *gauche-trans* conformation. On the other hand, in the *m*-nitroaniline complex, the primary hydroxyl groups of the G2 and G3 residues are disordered, and the *gauche-gauche* conformation is found in the G1 residue. Four water molecules in the *m*-nitroaniline complex are located in the same positions as those of W3, W4, W5, and W6 in the benzaldehyde complex, but the other two water molecules occupy different sites.

Determination of Thermodynamic Properties of Gibbsite from Its Solubility Data in NaOH Solutions[1)]

Byong-Tae CHANG

Department of Chemistry, Faculty of Science, Korea University, Kodaira, Tokyo 187

(Received January 29, 1981)

A reasonable method for determination of thermodynamic properties of alumina hydrates from their solubility data in alkaline pH range was presented and applied to the solubility data of gibbsite in NaOH solutions with success. When $\log(K_s/a_w)$, where $K_s=m_H m_{Al}$ and a_w is the activity of water, was plotted against a Debye-Hückel function of the ionic strength I, $I^{1/2}/(1+B_t a_i I^{1/2})$, a linear relationship to moderately high ionic strengths was found over the range of temperatures from 40 to 110 °C, having the theoretical Debye-Hückel limiting slope and the intercept of $\log K_s^\circ$ at $I=0$. Assuming the same ionic size parameters, $a_1=a_2$, the solubility product (K_s°) of gibbsite was found to depend upon temperature up to 110 °C as follows: $\log K_s^\circ=-4064/T-1.54$ or $-4023/T-1.65$. At high ionic strengths above 1.0, $\log(K_s/a_w)$ showed positive deviations from the straight line, which may be attributed to the formation of complex ions, *e.g.*, $Al_2O(OH)_6^{2-}$, or the dehydration of $Al(OH)_4^-$ to $AlO(OH)_2^-$ and AlO_2^- ions.

The solubility of alumina hydrates such as gibbsite, boehmite, and diaspore in aqueous solutions is very important not only for alumina production by the alkaline or acid process, but also for quantitative understanding of aqueous geochemistry of aluminous minerals.[2-15)] Furthermore, the thermodynamics of Al-H_2O system is much useful in considering the corrosion and passivation of aluminium in water.[16)] A number of solubility data of gibbsite in alkaline solutions have been reported by many investigators.[2-13)] A purpose of most previous solubility studies is to determine precisely the standard thermodynamic properties of gibbsite and hydroxy-aluminium ions in aqueous solubtions. Unfortunately, these results do not agree well with each other; for example, as the ionic solubility product of gibbsite at 25 °C, Kittrick[6)] and May[10)] reported the values of 5.01×10^{-16} and 8.94×10^{-15}, respectively.

Russell, Edward and Taylor[2)] calculated an equilibrium constant (K_1) and its temperature dependancy from their solubility data of gibbsite in NaOH solutions from 40 to 170 °C, assuming that activity coefficients of OH^- and AlO_2^- ions are equal to each other, *i.e.*, $\gamma_{OH^-}=\gamma_{AlO_2^-}$;

$$Al(OH)_3(s) + OH^-(l) = AlO_2^-(l) + 2H_2O(l), \quad (1)$$

$$K_1 = C_{Al}a_w^2/C_{OH}, \quad (2)$$

$$\log K_1^\circ = -1605/T + 4.11, \quad (3)$$

where C_{Al} and C_{OH} are the equivalents per liter of aluminate and hydroxide ions, a_w is the activity of the water in the molar fraction unit, and K_1° is the value derived by extraporating K_1 to zero NaOH concentration at a given temperature. There are some doubtful problems in the Russell's method for determining K_1°; firstly, the differences in the ion size and interactions between the ions and water were neglected, assuming that the activity coefficients of AlO_2^- and OH^- ions are the same. Secondly, the values of a_w for NaOH solutions at 25 °C were used for sodium aluminate and hydroxide solutions at higher temperatures up to 170 °C without any correction. Finally the aluminate ion was expressed in the form of AlO_2^-.

The purpose of this work is to determine the thermodynamic properties of gibbsite in NaOH solution from its solubility data by a more reasonable method according to the Debye-Hückel theory.

Theoretical

According to various studies on the sodium aluminate and hydroxide solutions, the most probable structure of the aluminate ion is tetrahedral $Al(OH)_4^-$ ion at low aluminium concentrations, which, at higher concentrations, becomes dehydrated AlO_2^- ion.[17-19)] Therefore, it is reasonable to express the dissolution process of gibbsite as follows;

$$Al(OH)_3(s) + H_2O(l) = H^+(l) + Al(OH)_4^-, \quad (4)$$

$$K_s^\circ = a_H a_{Al}/a_w = K_s\cdot\gamma_1^2/a_w, \quad (5)$$

where $K_s=m_H m_{Al}$, $\gamma_1^2=\gamma_H\gamma_{Al}$, and m_i is the molality of species i. On the other hand, for the dissociation of water,

$$H_2O(l) = H^+(l) + OH^-(l), \quad (6)$$

$$K_w^\circ = a_H a_{OH}/a_w = K_w\gamma_2^2/a_w, \quad (7)$$

where $K_w=m_H m_{OH}$ and $\gamma_2^2=\gamma_H\gamma_{OH}$. From Eqs. 5 and 7 a general equation (8) for alumina trihydrates can be derived, introducing a new function, $f(I)$, of ionic strength (I).

$$f(I) = \log(m_{Al}/m_{OH}) + \log K_w^\circ = \log K_s^\circ + 2\log(\gamma_2/\gamma_1). \quad (8)$$

It should be noted that $f(I)$ is independent on the activity of water. Figure 1 gives relationships between $f(I)$ and I which were calculated from the solubility data of gibbsite reported by Russell *et al.*[2)] and K_w° values[20)] at a given temperature.

Using the extended Debye-Hückel equation with added terms, we can express the mean activity coefficient (γ_1) as follows;

$$\log\gamma_1 = -A_t I^{1/2}/(1+B_t a_i I^{1/2}) - c_i I - d_i I^2, \quad (9)$$

where A_t is the theoretical limiting Debye-Hückel slope, B_t a parameter depending upon temperature and dielectric constant of solvent, a_i an ion size parameter, and c_i and d_i are adjustable parameters. Substituting Eq. 9 into Eq. 8,

$$f(I) = \log K_s^\circ + 2A_t I^{1/2}[1/(1+B_t a_1 I^{1/2}) - 1/(1+B_t a_2 I^{1/2})] + CI + DI^2, \quad (10)$$

where $C=2(c_1-c_2)$ and $D=2(d_1-d_2)$. The problem is to decide the five parameters, K_s°, a_1, a_2, C, and

Results and Discussion

Most of solubility measurements of gibbsite in alkaline solutions presented up to date were carried out at 25 °C. Lyapunov reported interesting results showing an effect of NaCl addition on the solubility of gibbsite at 60 and 95 °C, but the range of conditions of solubility measurements was limited.[11] The Russel's data seems to be the most useful solubility data of gibbsite in the range of higher temperature and NaOH concentrations. The method presented here, therefore, was applied mainly to the Russel's data.

The Case of the Same Ion Size Parameters. Assuming the same ion size parameters, *i.e.*, $a_1=a_2$, as did May[10] or Smith,[21] Eq. 10 can be simplified into a following equation:

$$f(I) = \log K_s^\circ + CI + DI^2 \quad \text{(Case 1)}. \tag{11}$$

Table 1 gives log K_s°, C, and D obtained by the least square calculations for Eq. 11. Furthermore, Fig. 1 shows good straight line relationship between f(I) and I in the range of low ionic strengths, that is,

$$f(I) = \log K_s^\circ + CI \quad \text{(Case 2)}. \tag{12}$$

Table 1 also gives the values of log K_s° and C for Eq. 12.

Figures 2 and 3 show temperature dependency of the ionic solubility product of gibbsite for the case 1 and 2, respectively. Good linear relationships between log K_s° and $1/T$ can be observed in the range of 40—110 °C.

$$\log K_s^\circ = -4064/T - 1.54 \quad \text{(Case 1)}, \tag{13}$$

$$\log K_s^\circ = -4032/T - 1.65 \quad \text{(Case 2)}. \tag{14}$$

According to Eqs. 13 and 14, the values of log K_s° at 25 °C become the same value of −15.18, which is very close to the value of −15.30 reported by Kittrick,[6] being considerably lower than the value of −14.05 presented by May.[10] Based on the ΔG_f° value of −1151.9 kJ/mol selected for gibbsite by Parks,[8] the standard Gibbs free energy of formation (ΔG_f°) for $Al(OH)_4^-$ ion is calculated to be −1302.5 kJ/mol. The heat of reaction of Eq. 4 was found to be 77.4 −77.8 kJ between 40 and 110 °C, and to have a tendency to decrease at temperature above 110 °C.

For the following reaction of gibbsite with OH^- ion,

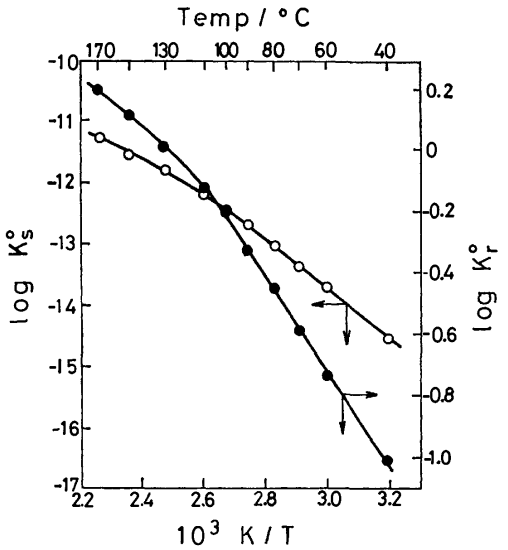

Fig. 3. Temperature dependencies of log K_s° and log K_r° from 40 to 170 °C for the case 2.

$$Al(OH)_3(s) + OH^-(l) = Al(OH)_4^-(l), \quad (15)$$

$$K_r^\circ = a_{Al}/a_{OH}, \quad (16)$$

using Eqs. 5 and 7, K_r° is given by

$$K_r^\circ = K_s^\circ/K_w^\circ. \quad (17)$$

Table 1, Figs. 2 and 3 also show the values of log K_r°, and its temperature dependency in the range from 40 to 110 °C is given as follows;

$$\log K_r^\circ = -1598/T + 4.10 \quad \text{(Case 1)}, \quad (18)$$

$$\log K_r^\circ = -1567/T + 3.98 \quad \text{(Case 2)}. \quad (19)$$

According to Eq. 18 or 19, the heat of reaction of Eq. 15 is 30.1—30.5 kJ.

The Case of Different Ion Size Parameters. In order to evaluate effects of the ion size parameters, a_1 and a_2, on log K_s°, we assumed conveniently $c_2=d_2=0$ for the dissociation of water. Then, from Eqs. 7 and 9.

$$\log (K_w/a_w) = \log K_w^\circ + 2A_tI^{1/2}/(1+B_ta_2I^{1/2}). \quad (20)$$

Using $K_s=m_Hm_{Al}=K_w(m_{Al}/m_{OH})$ and Eq. 20,

$$\log (K_s/a_w) = \log K_w^\circ + \log (m_{Al}/m_{OH}) + 2A_tI^{1/2}/(1+B_ta_2I^{1/2}). \quad (21)$$

At a given temperature, the value of log (K_s/a_w) depends upon the concentration ratio, (m_{Al}/m_{OH}), at equilibrium and the ion size parameter, a_2, for H^+ and OH^- ions. Figure 4 shows plots of log (K_s/a_w) and $I^{1/2}/(1+1.51I^{1/2})$ at 70 °C with a_1=4.5 Å and various values of a_2 from 3.5 to 6.0 Å. It is obvious from Fig. 4 that log (K_s/a_w) and slopes of curves increase with decrease in the a_2 value.

On the other hand, from Eqs. 5 and 9,

$$\log (K_s/a_w) = \log K_s^\circ + 2A_tI^{1/2}/(1+B_ta_1I^{1/2}) + 2c_1I + 2d_1I^2. \quad (22)$$

According to the Debye-Hückel theory, generally a plot of log (K_s/a_w) *vs.* $I^{1/2}/(1+B_ta_1I^{1/2})$ produces a straight line at low lonic strengths with the theoretical limiting slope, $2A_t$, and the intercept of log K_s° at I=0, and the last two terms becomes important only at higher ionic strengths. Figure 5 shows a plot of log (K_s/a_w) *vs.* $I^{1/2}/(1+B_ta_1I^{1/2})$ at 70, 80, 90, and 100 °C in the case of a_1=4.5 Å and a_2=5.0 Å.[24] Similarly, Fig. 6 shows a plot of log (K_s/a_w) *vs.* $I^{1/2}/(1+B_ta_1I^{1/2})$ at 60 °C, which were calculated from the Russell's data in NaOH solutions and the Lyapunov's data in both NaOH and (NaOH+NaCl) solutions. It is obvious from Figs. 5 and 6 that the straight line relationships hold at ionic strengths as high as 1.0, and that these slopes are very close to the theoretical values, $2A_t$, of 1.09, 1.11, 1.14, 1.16, and 1.19 at 60, 70, 80, 90, and 100 °C, respectively. The Lyapunov's data in NaOH and (NaOH+NaCl) solutions are able to be represented by the same curve as shown in Fig. 6, and gives log K_s°=−13.60 at I=0, which differs a little from a value of log K_s°=−13.73 for the Russell's data.

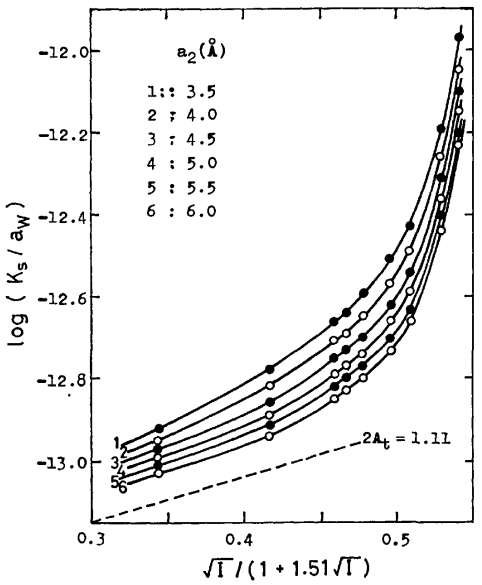

Fig. 4. Plots of $\log(K_s/a_w)$ *vs.* $I^{1/2}/(1+1.51I^{1/2})$ at various values of a_2 in the case of a_1=4.5 Å and 70 °C.

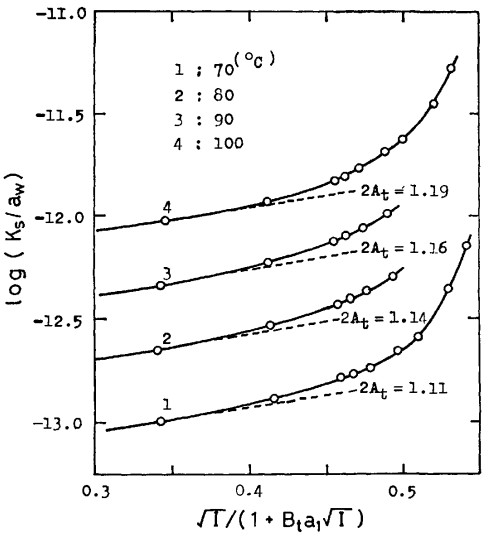

Fig. 5. Plots of $\log(K_s/a_w)$ *vs.* $I^{1/2}/(1+B_ta_1I^{1/2})$ at temperatures of 70, 80, 90, and 100 °C in the case of a_1= 4.5 Å and a_2=5.0 Å.

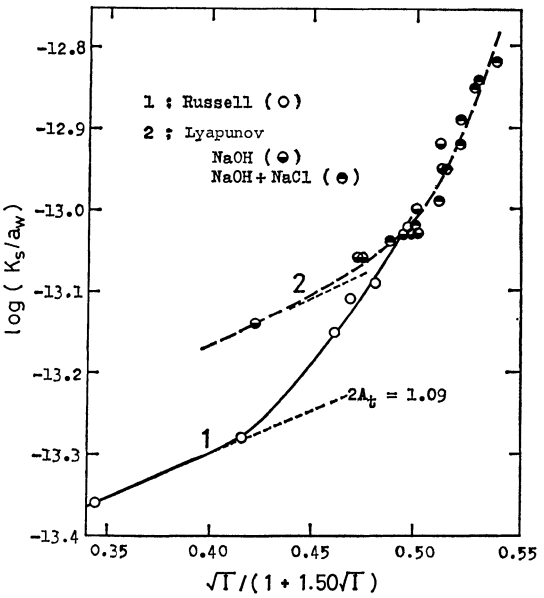

Fig. 6. Plots of $\log(K_s/a_w)$ *vs.* $I^{1/2}/(1+1.50I^{1/2})$ at 60 °C obtained from the Russell's data[2] and the Lyapnov's data[11] in the case of $a_1=4.5$ Å and $a_2=5.0$ Å.

At ionic strengths above 1.0, $\log(K_s/a_w)$ shows positive deviations from the straight line. Such positive deviation at high ionic strengths was also observed in $Ca(OH)_2$–$NaNO_3$–H_2O[22] or $NiSO_4$–$CoSO_4$–$(NH_4)_2SO_4$–H_2O[23] system, and was considered to be attributed to the formation of complexes. Moolnaar concluded from Infrared, Raman, and ^{23}Na and ^{27}Al NMR spectra of sodium aluminate solutions that at aluminium concentrations below 1.5 M, the tetrahedral $Al(OH)_4^-$ ions exist as the predominant aluminium-bearing species in the solution and that at aluminium concentrations of about 1.5 M and above, $Al(OH)_4^-$ condenses to form $Al_2O(OH)_6^{2-}$ ion.[19] In a detailed study of the saturated vapour pressures exerted by sodium hydroxide and aluminate solutions, Dibrov advanced evidence for the aluminate ion undergoing dehydration to the meta-aluminate ion AlO_2^- at high concentrations of 15% Na_2O and above:

$$Al(OH)_4^- \longrightarrow AlO(OH)_2^- + H_2O \longrightarrow AlO_2^- + 2H_2O. \quad (23)$$

From the above discussions it is reasonable to consider that the positive deviation from the straight line may be attributed to the formation of complex ion such as $Al_2O(OH)_6^{2-}$ and/or the dehydration of $Al(OH)_4^-$, leading to decrease in the activity coefficient of aluminate ion. This presents a striking contrast to increase in the activity coefficient designated by the salting-out effect.[20] The similar application of the method presented in this paper to alumina monohydrates is currently performed with success.

Quantitative Interpretation of Infrared Diffuse Reflectance Spectra over Whole Concentration Range

Tadashi HATTORI,* Kenji SHIRAI, Miki NIWA, and Yuichi MURAKAMI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received August 18, 1980)

The infrared diffuse reflectance spectra of $CaCO_3$ dispersed in KBr and Si were measured over a wide concentration range. The relation between relative reflectance and concentration varies with dispersing medium. The relation follows the Kubelka-Munk (K-M) equation only in the low concentration region. The deviation in the high concentration region from the K-M equation changes with wavelength and dispersing medium. The results over the whole concentration range can be interpreted by means of a modified K-M equation in which the difference in the scattering coefficients between the sample and the dispersing medium is taken into account. The tendency of scattering coefficients of $CaCO_3$, KBr, and Si calculated by the modified Kubelka-Munk equation agrees with that of refractive indexes.

The diffuse reflectance spectroscopy is widely used in the ultraviolet and visible regions.[1] The infrared diffuse reflectance spectroscopy would also be useful, several equipments having been succesfully developed.[2,3] We have constructed an emissionless infrared diffuse reflectance spectrometer (EDR) for *in situ* determination of reacting species on catalyst surface at elevated temperature.[4] Several theories have been proposed for the quantitative interpretation of the diffuse reflectance spectra.[5,6] The Kubelka-Munk equation is most widely used for analysis, but it should be regarded as a limiting law which holds only in a low concentration range.[6] A convenient equation is desirable for quantitative analysis over a wide concentration range.

We would like to show that the infrared diffuse reflectance spectra over the whole concentration range can be interpreted by means of a modified K-M equation, and that the factor determinig the intensity of absorption band is not only the absorption coefficient but also the scattering coefficient of the sample in the high concentration region.

Experimental

Fine powder of commercial calcium carbonate was used without further purification. Potassium bromide crystals for spectroscopy (Japan Spectroscopic Co.) and silicone wafers (99.9999%, Shin-Etsu Chem. Co. Ltd.) were ground to fine powder and used as dispersing media. Mixtures of the sample and a dispersing medium with predescribed ratios were packed in a sample holder, and the spectra were measured with an emissionless infrared diffuse reflectance spectrometer (Japan Spectroscopic Co., EDR-31) at an ambient temperature and at 200 °C. The details of the spectrometer were reported.[4]

Results

Figure 1 shows typical diffuse reflectance spectra of mixture of $CaCO_3$ and KBr. The absorption bands at 873 and 711 cm^{-1} can be ascribed to characteristic vibrations of carbonate ion, and the band at 2520 cm^{-1} to a combination band.[7] Even when the concentration of $CaCO_3$ was as low as 0.19%, the absorption bands were conspicuous. The band intensities increase with increase in concentration, but the relation between band intensity and concentration differs with wavelength. The band intensity of 100% $CaCO_3$ at 2520 cm^{-1} was much greater than that of 10% $CaCO_3$; the difference in band intensity at 873 cm^{-1} was not so great. On the other hand, the difference in band intensity between 0.19% and 1% $CaCO_3$ samples was greater at 873 cm^{-1} than that at 2520 cm^{-1}. The relation between band intensity

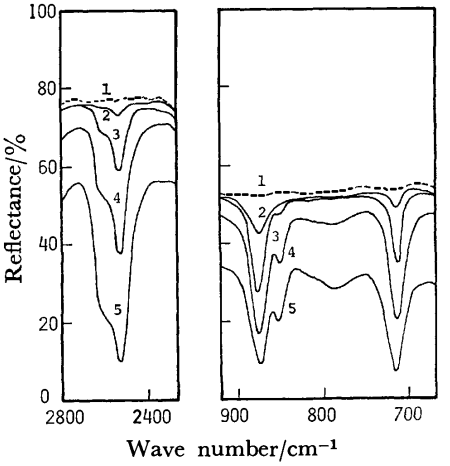

Fig. 2. IR diffuse reflectance spectra of $CaCO_3$ dispersed in Si. Wt fraction of $CaCO_3$: (1) 0%, (2) 1.0%, (3) 10%, (4) 40%, and (5) 100%.

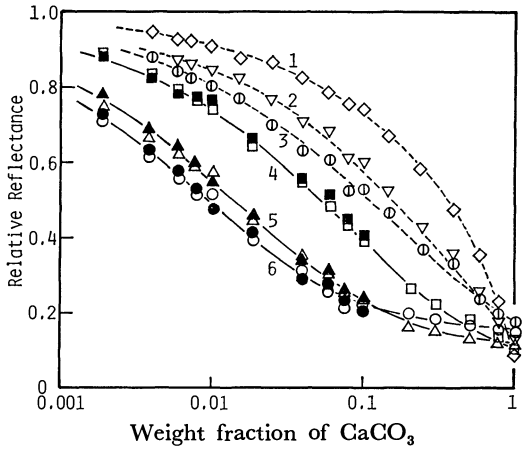

Fig. 3. Variation of relative reflectance with wt fraction of $CaCO_3$. Wavenumber and dispersing medium: (1) 2520 cm^{-1} in Si, (2) 711 cm^{-1} in Si, (3) 873 cm^{-1} in Si, (4) 2520 cm^{-1} in KBr, (5) 711 cm^{-1} in KBr, and (6) 873 cm^{-1} in KBr. Solid marks, at 200 °C; and empty marks, at ambient temp.

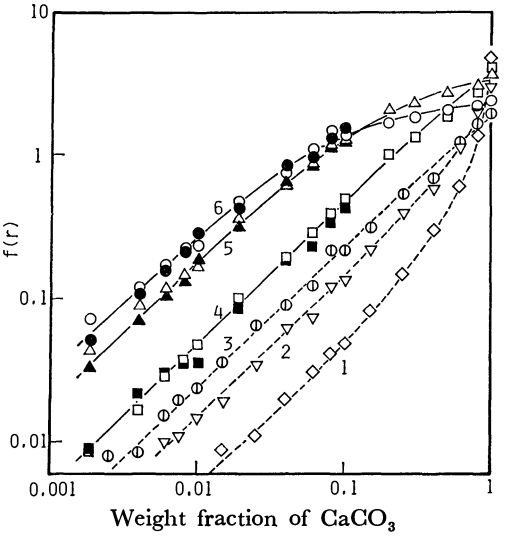

Fig. 4. Variation of K-M function with wt fraction of $CaCO_3$. For the symbols, see the legend of Fig. 3.

and concentration changes with dispersing medium. When Si was used as a dispersing medium, the band intensity changes a great deal with concentration in the high concentration region, as shown in Fig. 2. The difference in band intensity between 10% and 100% samples was much greater than that shown in Fig. 1. The band intensity does not change much with concentration in the low concentration region. The absorption bands of the 0.15% sample at 2520 and 711 cm^{-1} could not be observed.

The variation of band intensity with dispersing medium is shown in Fig. 3, in which the relative reflectance, defined as the ratio of reflectance at peak minimun to the reflectance of pure dispersing medium, is plotted against the weight fraction of $CaCO_3$ in a mixture of $CaCO_3$ and the dispersion medium. With increase in concentration the relative reflectance decreases remarkably in the low concentration region, when KBr is used as the disperison medium. In the case of Si, the relative reflectance decreases remarkably in a high concentration region. In both cases, the relative reflectance at 2520 cm^{-1} decreases in a higher concentration region as compared with that at 873 and 711 cm^{-1} (the results at ambient temperature ○, at 200 °C ●). Agreement between results indicates that the quantitative relation in the emissionless diffuse reflectance spectrometer does not change with temperature.

In the K-M theory, the reflectance is related to the absorption constant K and the scattering constant S of the mixture of the sample and dispersion medium:

$$f(R) = \frac{(1-R)^2}{2R} = \frac{K}{S}, \qquad (1)$$

where f(R) is the Kubelka-Munk function and R the absolute reflectance. In practice, the relative reflectance r defined as above is used in place of R. The following assumptions are usually made. The absorption constant K is equal to the product of the absorption coefficient ε_s and the concentration X of the sample, and the scattering constant S is equal to the scattering coefficient of the scattering medium σ_m. Thus, we have

$$f(r) = \frac{(1-r)^2}{2r} = \frac{\varepsilon_s X}{\sigma_m}. \qquad (2)$$

Figure 4 shows the relation between the logarithm of the K-M function and the logarithm of the sample concentration. In all cases, the plots give straight lines with the slope of unity only in the low concentration region. This is in line with the fact that the K-M equation is regarded as a limiting law which holds only in the low concentration region. The plots deviate from the straight lines in the high concentration region depending on the wavelength and dispersion medium.

Hecht[6] found that the reflectance in the ultraviolet and visible regions sometimes follows the Rozenberg equation, though a constant in the equation is too large to be physically interpreted. The results in the present study do not follow the Rozenberg equation, according to which the second derivarive of the reflectance with respect to the concentration should be positive. In the infrared diffuse reflectance spectra of $NaCO_3$, $NaNO_3$, and Na_2SO_4 dispersed in KI, Ishii *et al.*[2] found a linear relationship between the reflective absorbance and logarithm of the concentration in the low concentration region. The intensities of absorption bands at 711 and 873 cm^{-1} of $CaCO_3$ in KBr appeared to obey their relation in the low concentration region, but not the intensities of the other bands.

Discussion

In the K-M theory it is assumed that the absorption constants of a mixture of the sample and the dispersion medium is proportional to the concentration of the sample and the scattering constant is independent of concentration. However, both constants would depend on the concentrations of both sample

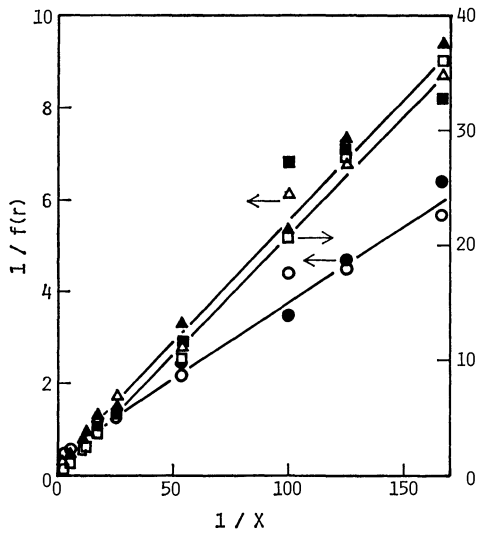

Fig. 5. Reciprocal plot of K-M function *vs.* wt fraction of $CaCO_3$ dispersed in KBr. (○,●) 873 cm^{-1}, (□,■) 2520 cm^{-1}, and (△,▲) 711 cm^{-1}.
Solid marks, at 200 °C; and empty marks, at ambient temp.

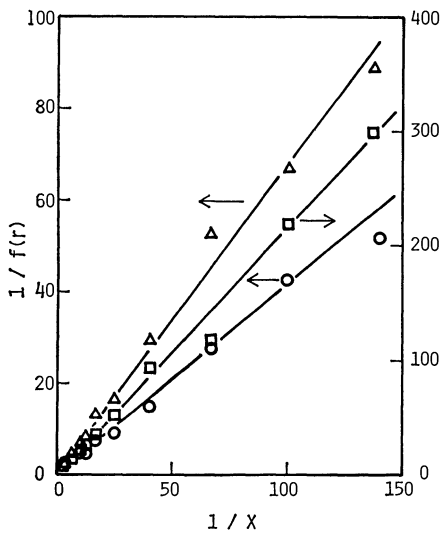

Fig. 6. Reciprocal plot of K-M function *vs.* wt fraction of $CaCO_3$ dispersed in Si. For the symbols, see the legend of Fig. 5.

and diepersion medium.[6,8] Thus, the K-M equation should be written as

$$f(r) = \frac{(1-r)^2}{2r} = \frac{\varepsilon_s X + \varepsilon_m(1-X)}{\sigma_s X + \sigma_m(1-X)}, \quad (3)$$

where σ_s and σ_m are the scattering coefficients and ε_s and ε_m the absorption coefficients of the sample and the dispersion medium, respectively. The absorption coefficient of the dispersion medium can be neglected, when the dispersion medium has no characteristic absorption. Thus we have

$$f(r) = \frac{(1-r)^2}{2r} = \frac{\gamma X}{1+(\delta-1)X}, \quad (4)$$

where δ is the ratio of the scattering coefficient of the sample to that of the dispersing medium, σ_s/σ_m, and γ is the ratio of the absorption coefficient of the sample to the scattering coefficient of the dispersion medium, ε_s/σ_m. Equation 4 indicates that the plot of the inverse K-M function against the inverse concentration would give a straight line.

$$\frac{1}{f(r)} = \frac{\delta-1}{\gamma} + \frac{1}{\gamma X} \quad (5)$$

Figures 5 and 6 show the relations between the inverse K-M function and the inverse weight fraction. We see that the plots give straight lines. Although the intercepts are not obvious, they can not be neglected; the scattering constant of the mixture changes with the concentration of sample.

The constants in Eq. 5 were calculated from the slopes and the intercepts (Figs. 5 and 6), and are given in Table 1. The curves (Fig. 4) calculated by substituting the constants into Eq. 4 agree with the experimental results over the whole concentration range. In the ratios of the scattering constant of KBr to that of Si (Table 1), two groups were calculated from the ratio of γ in the $CaCO_3$–Si mixture to that in the $CaCO_3$–KBr mixture and from the corresponding ratio of δ at each wavelength. The ratios thus obtained agree with each other, *i.e.*, $\sigma_{KBr}/\sigma_{Si}=0.086\pm 0.010$. The scattering coefficient varies with the refractive index, shape, size and the packing of the particles.[2,5] The refractive index of KBr is *ca.* 1.52 in the present wavelength region, and that of Si, *ca.* 3.42. The fact that the refractive index of KBr is smaller than that of Si is in line with the result that the scattering coefficient of KBr is smaller than that of Si. The effect of the shape and the size of particles also would be significant. The reflected light from the powder layer consists of the specularly reflected light at the surface of the powder layer as well as the diffusely reflected light.[9] The refractive index might have a predominant effect on the specular reflection and the shape and the size of powder on the diffuse reflection. The ratio of scattering coefficient of KBr to that of Si is fairly constant, but the ratio of the scattering coefficient of $CaCO_3$ to that of the dispersing medium varies with the wave length. This is in line with the fact that the refractive index of the substance which absorbs the light changes with wavelength in a complicated manner near the absorption band.[1]

In the K-M equation, the K-M function is proportional to the sample concentration (Eq. 2). Thus the Kubelka-Munk spectrum, or the plot of the K-M

Table 1. Ratio between absorption and scattering coefficients

Band position	711 cm^{-1}	873 cm^{-1}	2520 cm^{-1}
$\gamma(CaCO_3\text{-KBr})$[a]	9.5	15.0	2.40
$\delta(CaCO_3\text{-KBr})$[b]	6.0	13.5	1.30
$\gamma(CaCO_3\text{-Si})$	0.73	1.20	0.23
$\delta(CaCO_3\text{-Si})$	0.52	1.30	0.10
σ_{KBr}/σ_{Si}[c]	0.087	0.096	0.077
σ_{KBr}/σ_{Si}[d]	0.076	0.080	0.096

a) $\varepsilon_{CaCO_3}/\sigma_{KBr}$. b) $\sigma_{CaCO_3}/\sigma_{KBr}$. c) $\gamma(CaCO_3\text{-Si})/\gamma(CaCO_3\text{-KBr})$. d) $\delta(CaCO_3\text{-Si})/\delta(CaCO_3\text{-KBr})$.

function against wavenumber, would be the same as absorbance spectrum in transmission spectroscopy. Actually, however, discrepancy has been observed both in the ultra-violet and visible regions[6] and the infrared region.[3] Equation 4 indicates that the intensity of the absorption band in the diffuse reflectance spectrum also depends on the scattering coefficient of the sample, especially when the sample concentration is high. Since the scattering coefficient of the substance which absorbs the light appears to vary with the wavelength near the absorption band, the Kubelka-Munk spectrum is not always the same as the absorbance spectrum.

The modified K-M equation would also be useful in the ultraviolet and visible regions. The deviation of the K-M function from linearity appears to be greater in the ultraviolet and visible regions than in the infrared region. The variation of the scattering coefficient with the substance might be large in the ultraviolet and visible regions.

The Rapid Determination of Sulfide, Thiosulfate, and Polysulfide in the Lixiviation Water of Blast-furnace Slag by Means of Argentimetric Potentiometric Titration

Hiromu SATAKE, Takeo HISANO, and Sanae IKEDA*

Department of Applied Chemistry, Faculty of Engineering, Tokushima University, Minamijosanjima-cho, Tokushima 770

(Received September 27, 1980)

Sulfide, thiosulfate, and polysulfide ions in their mixtures were determined potentiometrically with a silver-nitrate standard solution. These three species can be precisely determined from two titrations for each sample with the coefficient of variation of 0.3% at the concentration level of 5×10^{-4} M (1 M=1 mol dm^{-3}). One aliquot is titrated, after making the titrand acidic with an acetate buffer (pH=4), to get the end points of the sulfide and thiosulfate ions respectively, in the presence of free sulfur. The other is titrated, after the sulfitolysis of the sample solution, to show the end points of the sulfide and thiosulfate(the original thiosulfate plus the thiosulfate which is formed from polysulfide) ions in the presence of excess sulfite. The addition of calcium nitrate is effective in making the end points clear and accurate. This method was applied to determine these species in lixiviation water of blast-furnace slag.

Elemental sulfur dissolves in an alkaline solution of sulfide to form polysulfides:[1)]

$$xS + S^{2-} \longrightarrow S_{x+1}^{2-}. \quad (1)$$

In addition, sulfur[2)] reacts with alkali hydroxide to produce sulfide, polysulfide, and thiosulfate through the following equation:

$$(4+2x)S + 6OH^- \longrightarrow 2S_{x+1}^{2-} + S_2O_3^{2-} + 3H_2O. \quad (2)$$

Therefore, there are many cases which involve these three species together, *e.g.*, sulfide, thiosulfate, and polysulfide, in such solutions as the lixiviation water of blast-furnace slag.[3,13)]

One sulfur atom in each polysulfide ion is denoted as sulfide sulfur(S^{2-}), while the rest of the ion(S_x) is denoted as polysulfide sulfur (or dissolved sulfur).[11)]

Various methods, such as potentiometric,[4,5)] biamperometric,[6)] and iodometric methods,[2)] to determine S^{2-}, $S_2O_3^{2-}$, and S_x in a polysulfide solution have already been presented. Blasius and his co-workers[3,14)] determined sulfur compounds in the lixiviation water of blast-furnace slag by photometric and titrimetric methods. Most of these methods are, however, rather complicated and time-consuming because of the necessity of separation, masking, and several titrations. Papp and Havas[7)] determined these three species potentiometrically by using a sulfide-ion-selective electrode as the indicator; they added an excess amount of sulfite to the sample solution, and the resultant $S_2O_3^{2-}$, equivalent to the S_x, was titrated with a mercury(II) chloride solution. Although this method is simple and useful, there are some problems, such as water pollution due to waste mercury and the necessity of masking the excess sulfite ions with formaldehyde. It was previously reported[8,9)] that $S_2O_3^{2-}$ in the presence of large amounts of SO_3^{2-} could be titrated with the silver ion by utilizing the formation of thiosulfatoargentate or silver sulfide in an acidic solution without masking SO_3^{2-} with formaldehyde. Sulfide, $S_2O_3^{2-}$, and SO_3^{2-} could also be determined[10)] directly by the three successive argentimetric titrations of the same sample solution in the presence of calcium nitrate. Sulfide and S_x in a polysulfide solution could be determined[11)] after the cyanolysis of the polysulfide, but the end points were affected by the presence of $S_2O_3^{2-}$. In these investigations, silver–silver sulfide, silver–silver iodide, and silver-ion-selective electrodes were used.

The present paper reports a method of determining S^{2-}, S_x, and $S_2O_3^{2-}$ in a synthetic polysulfide solution and the lixiviation water of blast-furnace slag by argentimetric potentiometric titration with silver–silver sulfide, silver–silver iodide, and saturated-calomel electrodes. The advantage of this method is that the contents of these three species can be determined from two titrations for each sample. One aliquot is titrated, after making the titrand acidic with an acetate buffer (pH=4), to give the end points of S^{2-} and $S_2O_3^{2-}$ in the presence of elemental sulfur. The other is titrated, after the sulfitolysis of the sample solution, to give the end point of S^{2-} and that of $S_2O_3^{2-}$ plus S_x in the presence of sulfite:

$$S_{x+1}^{2-} \xrightarrow{H^+} HS^- + S_x, \quad (3)$$

$$S_{x+1}^{2-} + xSO_3^{2-} \longrightarrow S^{2-} + xS_2O_3^{2-}, \quad (4)$$

$$S_2O_3^{2-} + Ag^+ \longrightarrow Ag(S_2O_3)^-. \quad (5)$$

Experimental

Reagent and Apparatus. All the chemicals used were of a reagent grade. Oxygen-free redistilled water was used for the preparation of all solutions. The stock solution of polysulfide was prepared and stored by a method described previously.[11)] Working solutions were prepared by the further dilution of the stock solution.

An automatic recording potentiometric titrator, Hiranuma RAT-101, with a silver–silver sulfide or a silver–silver iodide electrode, together with a saturated calomel electrode, was used.

Procedure. *Assay of S^{2-} and $S_2O_3^{2-}$ in S_{x+1}^{2-}*: Place a definite amount of a sample solution in a titration cell containing 10 ml of oxygen-free water and a 1-cm-thick liquid-paraffin layer. Add, successively, 2 ml of 1 M calcium nitrate, acetic acid, or acetate buffer to adjust the pH to 4 and oxygen-free water to make the volume up to about 100 ml, which should then be gently poured against the wall of the cell so that air bubbles are not entrained. Titrate this solution potentiometrically with 0.1 M silver nitrate solution using a silver–silver sulfide indicator electrode until the titration curve shows a sudden change, which corresponds to the end point for S^{2-} (Fig. 1, 1-A). Then replace the

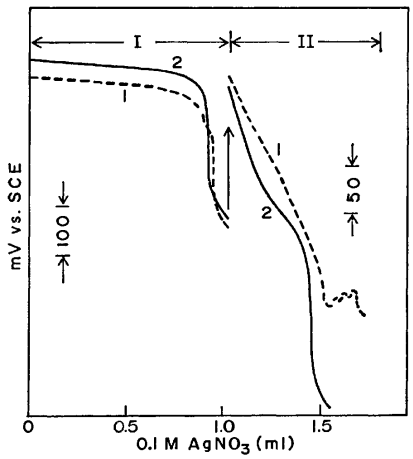

Fig. 2. Effect of calcium ion on the titration curves for sulfide and thiosulfate in polysulfide solution.
Sample solution: 100 ml of 5×10^{-4} M Na_2S_{x+1} (S^0= 1.6 mg), 5×10^{-4} M $Na_2S_2O_3$ and 2×10^{-2} M acetate buffer (pH=4).
1: Without $Ca(NO_3)_2$, 2: With 10^{-2} M $Ca(NO_3)_2$
I: Ag-Ag_2S electrode, II: Ag-AgI electrode.

indicator electrode by a silver-silver iodide and continue the titration until the end point for $S_2O_3^{2-}$ (Fig. 1, 1-B) is reached.

Assay of S^{2-} and S_x in S_{x+1}^{2-}: Add 10 ml of 0.5 M sodium sulfite and 30 ml of oxygen-free water to a sample solution which has been prepared in the manner described above. Heat this to about 50 °C and then allow it to stand for 3 min. Cool the solution below 15 °C. Add 10 ml of 1 M ammonia and 2 ml of 1 M calcium nitrate, and bring the total volume to about 100 ml with oxygen-free water. Titrate this solution with 0.1 M silver nitrate by using a silver-silver sulfide indicator electrode until the titration curve shows a sudden change for S^{2-} (Fig. 1, 2-A). Then adjust the pH to 1.5—3 with 0.5 M sulfuric acid and continue the titration until the end point for $S_2O_3^{2-}$ plus S_x is reached (Fig. 1, 2-C) by using a silver-silver iodide indicator electrode.

The S^{2-} (free sulfide plus the sulfide bound by polysulfide) content is obtained by the use of the end point(A). The original $S_2O_3^{2-}$ content is calculated from the difference between (A) and (B). The S_x content (measured as $S_2O_3^{2-}$) is estimated by (C) minus (B).

Results and Discussion

Determination of Sulfide, Thiosulfate, and Polysulfide-Sulfur in a Synthetic Polysulfide Solution. Figure 1 shows some typical titration curves. Acetate buffer (pH= 4) and calcium nitrate were added in order to isolate elemental sulfur and to get clear and accurate end points for S^{2-} and $S_2O_3^{2-}$. Calcium nitrate may be considered to have a coagulating action to the elemental sulfur isolated from the S_{x+1}^{2-} and silver sulfide produced during the titration. Figure 2 shows the effect of calcium nitrate on the titration of sulfide and thiosulfate ions in a polysulfide solution. The end point of $S_2O_3^{2-}$ was obtained by the formation of thiosulfatoargentate. The solution was protected from the evolution of hydrogen sulfide by covering it with a liquid-paraffin layer. Table 1 shows the results thus obtained from solutions with various concentrations. The S^{2-} and $S_2O_3^{2-}$ contents ranging from 10^{-4} to 5×10^{-4} M in the polysulfide solution could be determined with a good accuracy and reproducibility.

On the other hand, the S_x in polysulfide solution

I: Iodometric method[2,12]. II: Proposed method. a) Average of 4 titrations. b) Coefficient of variation. A sample solution was prepared by immersing 450 g of blast-furnace slag in 450 ml of demineralized water for 4 d.

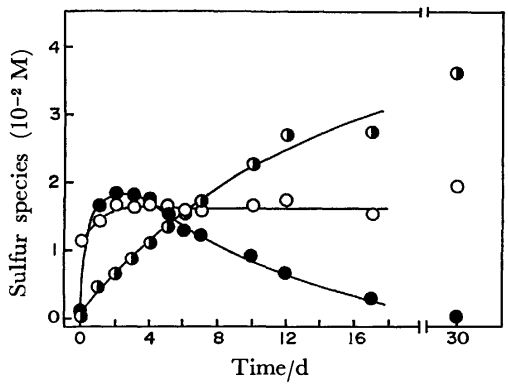

Fig. 3. Variation of sulfide, thiosulfate and polysulfide-sulfur in lixiviation water with the lapse of time.
Sample: Slag(700 g)+Demineralized water(300 ml).
Sample was placed in a dark room at 30 °C.
—◑—: S^{2-}, —○—: $S_2O_3^{2-}$, —●—: $S_x^{2-}(S^0)$.

was determined after converting it to $S_2O_3^{2-}$ through a reaction with SO_3^{2-}. An excess amount of SO_3^{2-} had no effect on the determination. The resulting solution was first titrated, after the addition of ammonia and calcium nitrate, to get the end point of S^{2-}, and then, after adjusting the titrand pH to 1.5—3, the titration was continued until the end point of $S_2O_3^{2-}$ (the original $S_2O_3^{2-}$ plus the $S_2O_3^{2-}$ produced from S_x) was attained. Any mixture containing each of the three species in various concentrations could be determined by the proposed method with a good accuracy and reproducibility, as is shown in Table 2. The analytical values for S_x in S_{x+1}^{2-} were identical to those determined by the mercury(II)–chloride method.[7]

The presence of sodium hydroxide, sodium carbonate, and sodium sulfate(the concentration of each being 2.5×10^{-2} M) did not disturb the determination.

Determination of Sulfide, Thiosulfate, and Polysulfide-Sulfur in Lixiviation Water of Blast-furnace Slag. The lixiviation waters were prepared by immersing 450-g portions of three different examples of blast-furnace slag (A, B, and C) in 450 ml of demineralized water for 4 d. Each lixiviation water was covered with a liquid-paraffin layer to prevent air oxidation. The contents of S^{2-}, $S_2O_3^{2-}$, and S_x in the lixiviation waters were then determined by the proposed method, and the values were compared with those obtained with other methods.[2,12] The results are shown in Table 3. When a 700-g portion of blast-furnace slag was immersed in 300 ml of water, the concentration variations of S^{2-}, $S_2O_3^{2-}$, and S_x in the lixiviation water with the lapse of time were as is shown in Fig. 3.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture. The authors wish to express their thanks to Mr. Masaru Hiraiwa of the Fukuyama Works of Nippon Kokan Co., Ltd., for his kind offer of the blast-furnace slag.

Chromatographic Behavior of Metalloporphyrins by Cellulose Thin-layer Chromatography

Yoshiaki ONOUE

Department of Chemistry, Faculty of Science and Technology, Kinki University, 3-4-1, Kowakae, Higashi-Osaka 577

(Received October 6, 1980)

Cellulose thin-layer chromatographic separation of chlorophyll a, b, and c, pheophytin a, b, and c, Zn(II)- and Cu(II)-complexes of protoporphyrin-IX dimethyl ester (PPDE) was studied by using a light petroleum–acetone developing solvent system. The hR_f values of metal–PPDE chelates were found to be virtually linearly related with the electronegativities-to-radius ratio (En/ri) of central-metal ions. The hR_f values of metalloporphyrins become progressively greater with increase in En/ri values of the central metal. This suggests that a dominant factor influencing the hR_f values of metal–porphyrins is the extent of electron transfer from the four nitrogens and/or the π-electron system of porphyrin to central metal.

Metalloporphyrins have been widely investigated because of their biological and chemical importance.[1,2] Recently porphyrins have also been used as a chelating agent for analysis of trace metals since free porphyrins and their metal chelate exhibit intense fluorescence and/or characteristic color.[3] Metal chelates could be further utilized for analysis by applying thin-layer chromatography (TLC). It is being widely used for the separation and purification of metalloporphyrins. In this paper, the chromatographic behavior of cobalt(II) and (III), nickel(II), copper(II), zinc(II), magnesium(II), and iron(III) complexes with PPDE, and magnesium(II) (=chlorophyll a), copper(II), and zinc(II) pheophytin a chelates on cellulose layer is described, considering the dominant factor controlling the mobility.

Experimental

Materials. Chlorophyll a and b: Pigments were extracted from spinach with a methanol–acetone (1:1, v/v) mixed solvent. After partial purification according to the dioxane method,[4] the complexes were separated by chromatography of the crude chlorophyll extract on a glucose column.

Chlorophyll c_1 and c_2: The compounds were isolated from Undaria pinnatifida and Sargassum racemosum, respectively, according to the Jeffrey method.[5]

Pheophytin a, b, c_1, and c_2: The compounds were prepared[6] from their original chlorophylls by shaking an ethereal solution of the chlorophyll with 13% hydrochloric acid (w/w) for 5 min.

Cu and Zn Pheophytin a: These were prepared by heating pheophytin a and five-fold excess of zinc and copper acetate in ethanol at 40 °C, for 10 min.

PPDE and Its Metal Chelates: The carboxyl side chain of protoporphyrin IX (Midori Jūji Co., Ltd.) was esterified[7] with methanol containing 5% (w/v) concentrated sulfuric acid at 0 °C. After esterification, the ester was crystallized from methanol–chloroform solution.

Metal Insertion: Cobalt, nickel, and magnesium PPDE were prepared by the *N,N*-dimethylformamide method as described by Adler *et al.*,[8] using metal chloride. After reaction in *N,N*-dimethylformamide, the crude product was crystallized by addition of water and cooling. Insertion of zinc, copper, and iron to PPDE was carried out by heating the porphyrin with a metal salt [zinc acetate, copper acetate, and iron(II) chloride] in chloroform–ethanol, 40 °C for 30 min. After heating, the metalloporphyrin was crystallized by removing chloroform in a stream of nitrogen.

Purification of Metal Chelates: Purification of Ni, Co, and Zn chelates was carried out on a calcium carbonate column with chloroform eluent. After evaporation of the eluate to a small volume, the metalloporphyrins were crystallized by addition of ethanol. Crude Mg–PPDE was chromatographed on a cellulose column with a light-petroleum: acetone (20:3, v/v) eluent. Crystallization of Mg-chelate from benzene–chloroform solvent was then repeated three times.

Stationary Phase. Thin-layer chromatography was performed with commercial cellulose plates (Merck precoated cellulose plate Art. 5716, 5×20 cm).

Chromatographic Procedure. One μl solution of samples (PPDE and its metal chelates; 0.04 μg/ml in chloroform, chlorophylls, and their derivatives; *ca.* 0.05 μg/ml in diethyl ester) was spotted with a 10 μl micro-syringe at a point 3 cm from the lower edge of TLC. After air-drying, the chromatograms were developed (10 cm/*ca.* 14 min) in thin-layer chambers lined with filter paper, in which the atmosphere had been equilibrated with developing solvent for 15 min before the plates were inserted. Light-petroleum: acetone (20:3, v/v) was chosen as a developing solvent, in view of results obtained for (1) light-petroleum (bp 50—80 °C):acetone (20:3, v/v), (2) light-petroleum:1-propanol (24:1, v/v), and (3) light-petroleum:chloroform (7:3, v/v). After developing, the chromatograms were air dried and examined in daylight and under ultraviolet light (365 nm).

Results

A typical chromatogram of PPDE and its metal chelates on cellulose plate is shown in Fig. 1. The hR_f values obtained for seventeen porphyrins derivatives are given in Table 1. Porphyrins with carboxyl side chain, pheophytin c and Ni-protoporphyrin IX *etc.*, did not move from the origin of chromatogram with a light-petroleum:acetone (20:3, v/v) solvent system. More polar solvent systems such as light-petroleum:acetone (7:3, v/v) and dimethylpyridine:water system[9] should be used in order to separate the above compounds. However, porphyrin derivatives with carboxyl side chain showed extensive tailing and were not separated from each other on the chromatogram in the more polar solvent systems.

Free porphyrins are readily esterified with a alcohol[7] or diazomethane,[10] the esters being hydrolysed without degradation. The esters are more lipophilic than the free porphyrins, as indicated by their solubility in organic solvents. The ester of protoporphyrin IX was

1: Co–PPDE, 2: Ni–PPDE, 3: Cu–PPDE, 4: Zn–PPDE, 5: Mg–PPDE, 6: PPDE.

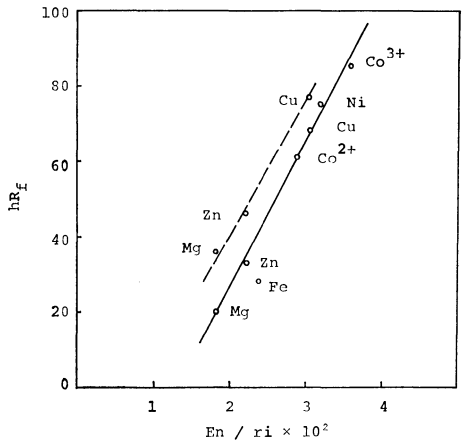

Fig. 2. Relationship between En/ri and TLC hR_f values of metalloporphyrins.
En: Pauling's electronegativity value, ri: Effective ionic radius, ——: Metal–PPDE chelate, ----: Metal–pheophytin-a chelate.

therefore used for the thin-layer chromatographic studies.

Since the hR_f values of the chromatogram were reproducible to about ±2 on repeated runs, porphyrins having hR_f values with a difference of over four were separated perfectly. Under ultraviolet light (365 nm) the separated spots exhibited either a characteristic, very intense red fluorescence (Zn, Mg–PPDE, and PPDE, chlorophylls, and their derivatives, except Cu–pheophytin a) or a dark one against the lighter background of the rest of the plate. The lower limits of detection were about 1 ng for the fluorescent substances, and 10 ng for non-fluorescent porphyrin metal complexes. As shown in Table 1, PPDE and Ni–PPDE were not separated completely, but they could be clearly distinguished by their different behavior under ultraviolet light (365 nm). The former (hR_f: 75) appeared as a black spot, the latter (hR_f: 74) showing red fluorescence.

Table 1. hR_f values and identification under ultraviolet light of porphyrins and their chelates

Compound	hR_f value[a)]	Identification[b)]
Pheophytin a	86	red-f
Pheophytin b	72	red-f
Pheophytin c	0	red-f
Protoporphyrin IX	0	red-f
Chlorophyll a	36	red-f
Chlorophyll b	21	red-f
Chlorophyll c	0	red-f
Cu–Pheophytin a	77	non-f
Zn–Pheophytin a	46	red-f
Protoporphyrin IX dimethyl ester	74	red-f
Co–Protoporphyrin IX dimethyl ester	85 61	non-f
Ni–Protoporphyrin IX dimethyl ester	75	non-f
Cu–Protoporphyrin IX dimethyl ester	68	non-f
Zn–Protoporphyrin IX dimethyl ester	33	red-f
Mg–Protoporphyrin IX dimethyl ester	20	red-f
Fe–Protoporphyrin IX dimethyl ester	28	non-f

a): Solvent system; light-petroleum: acetone (20 : 3, v/v). b): In ultraviolet light the separated zones exhibited either a red fluorescence or a dark one against the lighter background of the rest of the plate. TLC: Merck precoated cellulose plate (14 min/10 cm).

Co–PPDE has two varieties of hR_f values depending on the preservation time of the chloroform solution of Co–PPDE. The hR_f value of the freshly prepared solution of Co–PPDE was 85, but after being left to stand, it was 61, tailing being observed.

Discussion

The relationship between the individual metals of the porphyrin chelates and the hR_f values on cellulose TLC was studied. As shown in Fig. 2, the hR_f values of the metal chelates were proportional to the En/ri values of the central metals, where En is the Pauling electronegativity values[11] of the elements, irrespective of their oxidation state, and ri is the effective ionic radii cited from the recent compilation by Shannon and Prewitt.[12,13] Assuming that the En/ri value of the central atom is a measure of field strength, the extent of electric transfer from four nitrogens of porphyrin to central atom increased with increase in En/ri values. The charge transfer would make the metal atom nearly neutral, and the total positive charge of the central atom might be dispersed over the surrounding π-electron system of porphyrin.[14] The more delocalized bond between the metal and ligand of the chelates leads to less dipole-dipole interaction between the chelate to cellulose and higher solubility of the chelate in the developing solvent, and accordingly a larger hR_f value.

Co–PPDE shows two kinds of mobility (hR_f value). The hR_f values 61 and 85 could be assigned respectively to low(II) and high(III) oxidation state of cobalt ion for the following reasons. (1) The ionic radius of the cobalt in the two kinds of complexes is estimated to be 65 and 53 pm from the hR_f values 61 and 85, respectively. (2) Cobalt(II)–porphyrins are briefly oxidized to higher oxidation state(III) complex by air.[16] (3) The oxidation potentials of metalloporphyrins are Fe: −0.32, Co: +0.52, and Ni: +1.00.[17] Although the data could not be applied directly to this TLC condition, they indicate that the oxidation states of Co, Fe–porphyrins are easily changed by the change in the conditions. It should be expected that cobalt in the crystal of Co(II)–PPDE is air oxydized during storage, but reduced gradually in chloroform.

Fe–PPDE, which have a more sensitive oxidation-potential to the conditions than Co-porphyrin, moved more slowly than expected. The reason for the deviation from hR_f-En/ri relationship is not clear.

Conclusion

The mobility (hR_f values) of metalloporphyrin dimethyl esters on cellulose TLC is closely correlated to the En/ri values of central metal. The En/ri value determines the extent electron transfers from nitrogen to central metal, and it will be a dominant factor to control the mobility of metalloporphyrin. Thus the hR_f values of the metalloporphyrin dimethyl esters can be used for identification and also for metal determination of chelates with unknown central metal. These findings have prompted a study of chromatographic behavior of metalloporphyrin in non-aqueous developing solvent systems.

The author expresses his sincere thanks to Dr. Yasuharu Nishikawa and Dr. Keizō Hiraki, Faculty of Science and Technology, Kinki University, and Dr. Masayuki Tabushi, College of Medical Technology of Hirosaki University, for their advice and suggestions throughout the investigation.

The Depth Profiling of Glass Surfaces by Mass Spectrometry Using Neutral-particle Bombardment

Akira Iino and Atsushi Mizuike*

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received October 9, 1980)

Glass surfaces are bombarded by energetic neutral argon atoms or oxygen molecules, and the resulting sputtered ions are mass-analyzed. This technique has a higher depth resolution than conventional secondary-ion mass spectrometry. Quantitative depth-concentration profiles of sodium and potassium in the top layer of the surface (within several tens of nanometers of the surface) of Pyrex glass are obtained by the proposed technique.

Depth profiles of glass components, especially of univalent ions, in the glass surface layer are quite useful in studies of the physical chemistry of glass surfaces and glass technology. Recently, secondary-ion mass spectrometry (SIMS),[1-3] Auger electron spectrometry (AES) using ion beams for etching,[4] and ion-beam-induced radiation[5] have been applied to the depth profiling of glass surfaces. In the top layer of the surface (within several tens of nanometers of the glass surface), however, discrepancies[3-5] have been found among the profiles of the alkali ions obtained by these techniques. These facts suggest that all the techniques using ion bombardment are still qualitative in the top layer of the surface.

By the energetic ion or electron bombardment of glass, the surfaces become charged, and the resulting electric field may cause a migration of the univalent ions in the glass. Additionally, preferential sputtering, knock-on effects, and primary-ion implantation may be caused by ion bombardment within the top layer of the surface. These phenomena may distort the original depth-concentration profiles in glass and may change the secondary-ion yields, thus resulting in the discrepancies described above. McCaughan and Kushner[6] investigated the migration of sodium in thin silicon dioxide films on silicon by the radioactive-tracer technique. Neutral-particle bombardment gave less sodium migration than ion bombardment by at least four orders of magnitude, and less migration than ion bombardment with electron flooding (spraying) by at least two orders of magnitude. These results suggest that the migration of univalent ions in glass may be disregarded if mass spectrometry using neutral-particle bombardment[7] is used for depth profiling. Although the effects of preferential sputtering, knock-on effects, and primary-particle implantation cannot be reduced, it is shown in the present work that mass spectrometry using neutral-particle bombardment is more useful than conventional SIMS for obtaining quantitative depth-concentration profiles of sodium and potassium ions in the top layer of the surface of borosilicate glass.

Experimental

Apparatus. A Hitachi IMA-2 ion microanalyzer was modified for neutral-particle bombardment, as is shown in Fig. 1. The neutral-particle beam was obtained by removing ions by electrostatic deflection electrodes (515—530 V)[8] from the primary beam consisting of ions and neutral atoms or molecules probably produced by ion-neutral particle reactions and recombination. The spot diameters of the neutral atom or molecule beam were adjusted by means of apertures of 0.3, 0.5, 1, and 3 mm. The operating conditions of the microanalyzer are listed in Table 1. The ion intensities of boron, sodium, aluminium, silicon, and potassium were measured intermittently by means of manual magnetic scanning. For SIMS, electron flooding was started 10 s before the ion bombardment to eliminate the charge accumulation.

The depth of the craters formed on glass surfaces by sputtering was measured with a Mizojiri Kogaku Model II multiple-beam interferometer (Hg 546.1 nm, magnification

40X), with a maximum error of ±3 nm. An Olympus Model MF microscope (magnification 100—400X) with a Model MF-NIC Nomarski interference contrast attachment, and a Hitachi-Akashi Model MSM-2 scanning electron microscope (magnification 2000—10000X) were used for the observation of the glass surfaces.

Materials. Japanese standard-reference-material borosilicate glass R501 rods (79.9 SiO_2, 13.2 B_2O_3, 3.88 Na_2O, 2.17 Al_2O_3, 0.30 K_2O wt%, 6 mmϕ × 100 mm) were cut into *ca.* 8-mm lengths. The fracture-exposed surfaces were smooth under optical and electron microscopes. Pyrex glass sheets (81 SiO_2, 13 B_2O_3, 3.9 Na_2O, 2.2 Al_2O_3, 0.5 K_2O wt%, thickness; 1 mm) were annealed, etched *ca.* 1 μm with 1.4 M hydrofluoric acid-1.3 M sulfuric acid at 20±3 °C for 15 min, washed with water, and dried in a silica-gel desiccator.

Interdiffusion of Potassium and Sodium Ions. In a 50-ml silica glass beaker, 17.8 g of potassium nitrate and 6.4 g of sodium nitrate (70 KNO_3–30 $NaNO_3$ mol%) were melted and thoroughly mixed at 270±1 °C. A 30-mm-square piece of a Pyrex glass sheet was immersed in the molten salt to effect the interdiffusion of potassium and sodium ions in the glass. The piece was then withdrawn, cooled, washed in water, and dried in a silica-gel desiccator. After the interdiffusion no change was observed on the glass surfaces under optical and electron microscopes.

Results and Discussion

Bombardment by Neutral Atoms and Molecules. The fracture-exposed surfaces of borosilicate glass R501 were bombarded by the neutral atom (Ar^0), the neutral molecule (O_2^0), or the ion (Ar^+, O_2^+) beam, and the resulting sputtered ions were mass-analyzed. Figure 2 shows the depth profiles thus obtained. The concentrations of boron, sodium, aluminium, silicon, and potassium in the top layer of the fracture-exposed surfaces can be assumed to be constant.[9] The ion intensities of these elements, however, change with the increase in the depth in the top layer of the surface. The depth where the ion intensities reach steady values

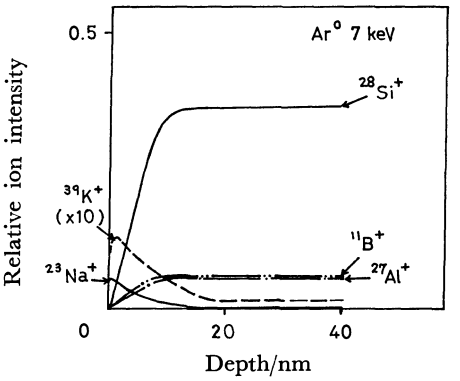

Fig. 3. Depth profiles of fracture-exposed surface of borosilicate glass R501 after electron flooding (1.5 keV, 25 μA) for 5 min.

is smaller in the neutral-atom or -molecule bombardment than in SIMS. This suggests a higher depth resolution in the former technique. In SIMS, primary ions with energies as low as 3 keV produced insufficient secondary ions for mass spectrometry, and lower primary-ion densities on the sample surface did not improve the depth resolution. Bombardment with neutral argon atoms is mainly used in the present work, because there is little difference in depth resolution between the argon-atom and the oxygen-molecule bombardment and because the sputtering rate is larger in the former.

In SIMS, in addition to ion bombardment, electron flooding may distort the depth profiles. The latter effects are shown in Fig. 3. Compared with Fig. 2(b), the ion intensities of sodium and potassium relative to silicon remarkably decreased upon electron flooding.

Calibration Graphs. To obtain quantitative depth-concentration profiles from the observed depth profiles in the top layer of the surface, calibration graphs were constructed by the use of the borosilicate

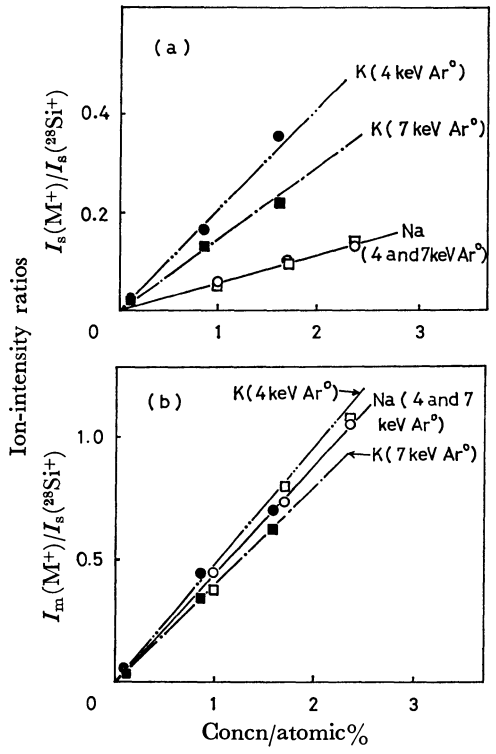

Fig. 4. Calibration graphs.
(a) For sodium and potassium concentrations at 10 nm (4 keV Ar^0) and 20—30 nm (7 keV Ar^0) from surfaces. (b) For surface sodium and potassium concentrations.

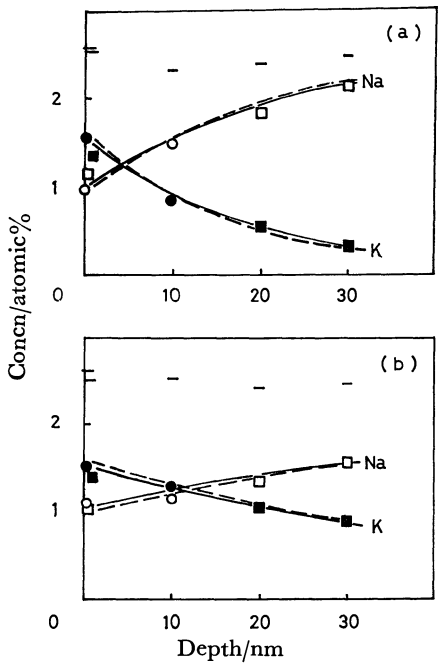

Fig. 5. Depth-concentration profiles after interdiffusion of potassium and sodium in Pyrex glass at 270 °C for (a) 1 min and (b) 7 min.
□■: 7 keV Ar^0, ○●: 4 keV Ar^0. Solid line: measured. Dashed line: calculated. —: Sum of K and Na (measured).

glass R501 and standard samples reported previously.[2] For obtaining sodium and potassium concentrations, at 10 and 20—30 nm from the surfaces, for 4 and 7 keV Ar^0 bombardments respectively, the steady values of the ion-intensity ratios, $I_s(^{23}Na^+)/I_s(^{28}Si^+)$ and $I_s(^{39}K^+)/I_s(^{28}Si^+)$, were plotted against the sodium and potassium concentrations {Fig. 4(a)}. For obtaining the sodium and potassium concentrations at the surfaces, the ratios of the maximum ion intensities of sodium and potassium to the steady values of the silicon-ion intensity, $I_m(^{23}Na^+)/I_s(^{28}Si^+)$ and $I_m(^{39}K^+)/I_s(^{28}Si^+)$, were plotted against the sodium and potassium concentrations {Fig. 4(b)}. All the calibration graphs were straight lines passing through the origin; the scattering of the points was less than ±10%. Also, no day-to-day variation in the calibration graphs was observed.

Depth-concentration Profiles. Figure 5 shows the quantitative depth-concentration profiles in the top layer of the surface of potassium-treated Pyrex glass sheets. The profiles obtained by the proposed technique (solid lines) are in good agreement with the calculated profiles (broken lines). The latter were calculated by using the interdiffusion coefficients reported previously[2] and the equilibrium surface concentrations of sodium and potassium as measured with a glass sheet immersed in a molten 70 KNO_3–30 $NaNO_3$ mol% bath at 270 °C for 1200 min.

(Received October 31, 1980)

Reactions of the bis(β-diketonato)palladium(II) complexes with various nitrogen bases (L) afforded [Pd(β-dik)L_2](β-dik), [PdL_4](β-dik)$_2$, or [Pd(β-dik)(β-dik-*C*)L] according to the natures of L and β-diketonate anions. Less basic ligands such as 1,1,1,5,5,5-hexafluoro- and 1,1,1-trifluoro-2,4-pentanedionates are readily removed by L to the outer sphere. Tendency of preferring the central-carbon-bonded state of the β-diketonate anion is related with the keto-favoring nature of its conjugate acid. Excess primary amines and pyridines can displace both of the β-diketonate ligands but secondary amines only one. These two types of compounds containing the 2,4-pentanedionate anion in the outer sphere undergo prompt deuteration of methine and amine protons by $CDCl_3$. Tribenzylamine and 2,6-diphenylpyridine react with bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)palladium(II) to afford orthometallated products.

β-Dicarbonyl compounds constitute a group of the most popular ligands and usually form the *O,O'*-chelate as a monoanion with almost all metal ions.[1] In recent years, reactions of the bis(β-diketonato)palladium(II) and -platinum(II) complexes with Lewis bases have been examined and found to give products involving the β-diketonate ligand of various bonding modes as shown in Fig. 1. Compounds **7** containing the central-carbon-bonded 2,4-pentanedionate anion (acac-C^3) were obtained by the reactions of [Pd(acac)$_2$] with bases such as pyridine, diethylamine, and triphenylphosphine,[2] but the kinetic and equilibrium studies of the reactions between [Pd(acac)$_2$] and alkylamines revealed that compounds **7** are produced *via* the outer-sphere complex **4**.[3] Primary amines give rise to **5**.[4] Complexes of type **6** were obtained by the reactions of [Pt(acac)$_2$] with piperidine[5] and triethylphosphine,[6] and the precursor complex of type **3** was isolated in the reaction of bis(1,1,1-trifluoro-2,4-pentanedionato)palladium(II), [Pd(tfac)$_2$], with tertiary phosphines.[7] The established examples of **2** are [M(hfac)$_2$L], where hfac stands for an *O,O'*-chelated 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate anion and L=tri-*o*-tolylphosphine for M=Pd(II) and Pt(II), and L=tricyclohexylphosphine for M=Pt(II).[8] Complexes **8** have been reported for [Pd(etac-C^2)$_2$L$_2$] (L=py, 2-Me-py, $PhCH_2NH_2$, $BuNH_2$, and 1/2bpy)[9] and [Pt(acac-C^3)$_2$(py)$_2$],[10] where etac represents anion of 1-ethoxy-1,3-butanedione (ethyl acetoacetate).

In a previous paper we reported preparation and characterization of the palladium(II) and platinum(II) complexes of various β-dicarbonyl compounds.[11] The present paper is concerned with the reactions of [Pd(β-dik)$_2$] (**1**) with a number of nitrogen bases (L) which are listed in Table 1. Various combinations of L(**a**—**u**) and bis-chelates (**1A**—**1I**) as well as a mixed-ligand chelate [Pd(acac)(tfac)] (**1M**) were examined and especially the reactions of **1A**—**1D** were investigated in detail.

Results and Discussion

Table 2 lists decomposition temperature and analytical data of complexes **4**, **5**, and **7** which were obtained by reactions of **1** either with neat liquid L or with L in appropriate solvents. The tendency of nitrogen bases to ligate palladium(II) is very strong and primary amines and pyridines displace both of the β-diketonate ligands to produce complexes **5**. It is difficult to isolate the intermediate products **4** in

these cases except **4Mb**. On the other hand secondary amines can not form complexes of type **5** because of their steric requirement, but result in **4**.

Transformation of the *O,O'*-chelated 2,4-pentanedionate ligand (acac) to the central-carbon-bonded state was first found by Baba *et al.*[2] for the reactions of $[Pd(acac)_2]$ with bases in dichloromethane. The equilibrium study of the $[Pd(acac)_2]$–Et_2NH system showed that the equilibrium is almost completely shifted to **4** in methanol, but is favorable to **7** in dichloromethane.[3] Preparation of complexes **7** in the present study was therefore carried out mainly in dichloromethane.

X-Ray analysis of $[Cu(dmed)_2(hfac)_2]$ (dmed=*N,N*-dimethylethylenediamine)[12] and $[Cu(en)_2](acac)_2 \cdot 2H_2O$[13] revealed that the β-diketonate anions occupy the apical positions though the Cu–O distances (2.79 Å) are too long to be considered as the coordination bond in either case. On the contrary, the X-ray crystal structure of $[Pd(acac)(Et_2NH)_2](acac)$ (**4Ah**) determined by Kasai and his collaborators at −170 °C showed that the acac anion does not lie on the

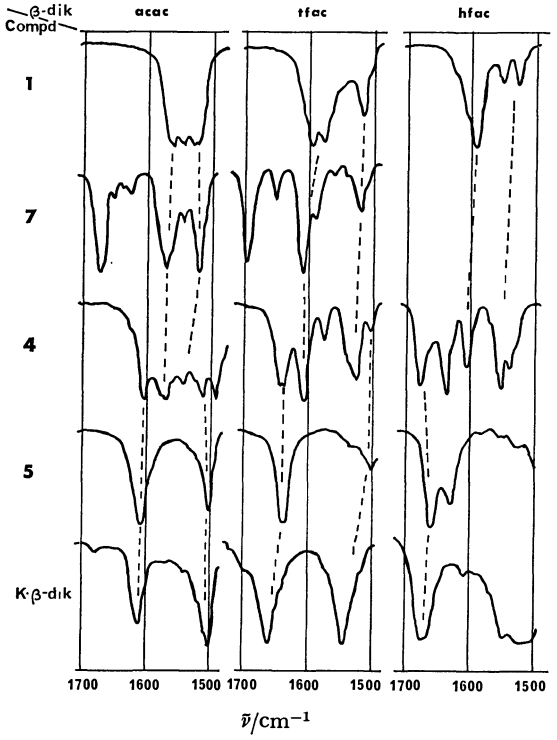

Fig. 2. IR spectra in Nujol of [Pd(β-dik)$_2$] (**1**), [Pd(β-dik)(β-dik-*C*^{3})(pip)] (**7**), [Pd(β-dik)(pip)$_2$](β-dik) (**4**), and [Pd(PrNH$_2$)$_4$](β-dik)$_2$ (**5**) together with those of K(β-dik) hydrate for comparison.

apical position, but stands aside of the coordination plane, forming hydrogen bonds with the ligated amine groups.[14] Compound **4Ah** is not stable at room temperature even in the solid state, but looses gradually the volatile amine ligand to convert into **7Ah**.

Infrared Spectra. Characteristic IR bands of some representative mixed-ligand complexes are listed in Table 3. The bands in the 1700—1500 cm^{-1} region which are assigned to the ν(C=O)+ν(C=C) vibrations are most useful for distinguishing the bonding mode of β-diketonate anions in metal complexes. Figure 2 exemplifies these IR bands for some acac, tfac, and hfac complexes. Substitution of the methyl group in acac with the electron-attracting trifluoromethyl group raises frequency of the ν(C=O) band in each type of complexes. Thus the highest-frequency band in this region is observed at 1595 and 1591 cm^{-1} for *trans*-[Pd(tfac)$_2$] (**1C**) and [Pd(hfac)$_2$] (**1D**), respectively, 30 cm^{-1} higher than 1563 cm^{-1} for [Pd(acac)$_2$] (**1A**). The central-carbon-bonded β-diketonate ligand in **7** has the keto structure,[2] and absorbs in the 1700—1650 cm^{-1} region. The absorption bands for the β-diketonate anions in the outer sphere appear in the frequency region lower than those for the carbon-bonded β-diketonate and higher than those for the chelated one. Thus the spectra of compounds **5** are quite similar to those of K(β-dik), although the spectra of **4** are more composite since the complexes contain β-diketonate anions in both the inner and outer spheres (Fig. 2).

In crystals of [Pd(acac)(Et$_2$NH)$_2$](acac) (**4Ah**), the C–O distance of the chelated acac anion is 1.277(5) Å, nearly the same as that in [Pd(acac)$_2$] (1.275(4) Å).[14] In accordance with this situation, the ν(C=O) frequency (1573 cm^{-1}) assignable to the former carbonyl bond is not so different from that (1563 cm^{-1}) for the latter. On the other hand the ν(C=O) frequency (1604 cm^{-1}) due to the acac anion in the outer sphere conforms with the shorter C–O distance (1.246(5) Å)[14] and is close to 1610 cm^{-1} of K(acac) hydrate in which the C–O distance is 1.25(2) Å.[15]

Secondary amines coordinated to palladium(II) in complexes **4** exhibit single ν(N–H) band in the 3180—3060 cm^{-1} region, whereas primary amines in complexes **5** and **4Mb** show two bands in the 3250—3030 cm^{-1} region.

^{1}H NMR Spectra. Table 4 lists the ^{1}H NMR data for complexes **5**. In the case of the platinum(II) complexes, for instance [Pt(py)$_4$](hfac)$_2$, absence of coupling to ^{195}Pt of ^{1}H, ^{13}C, and ^{19}F atoms in hfac confirms that the hfac anions are not coordinated to the metal ion but exist in the outer sphere as counter anions.[4] The β-diketonate anions involved in **5** exhibit only one set of ^{1}H signals, indicating that the two anions in each complex are environmentally equivalent. These data do not necessarily certify that they exist in the outer sphere. However, the methyl and methine protons of [Pd(NH$_3$)$_4$](tfac)$_2$ (**5Ca**) resonate at 2.22 and 5.38 ppm from internal DSS in D$_2$O (Table 4). The chemical shifts coincide with those of K(tfac), indicating that **5Ca** dissociates completely in D$_2$O. Proton signals from the ammine ligands were not observed because of rapid H-D exchange with D$_2$O.

In spite of their salt-like structures, most of complexes **4** and **5** are not soluble in water, but dissolve in organic solvents and the β-diketonate anions seem to be associated with the cation in solution. Thus, for instance, molecular weights determined in dichloromethane at 25 °C of **4Ch**, **4Ci**, and **5Dm** are 534, 551, and 811 in fair agreement with the calculated values 559, 583, and 837, respectively. The amine protons of complexes **4** and **5** resonate generally at substantially lower field than those of the corresponding neutral complexes **7**. The amine signal from **5Ad** for instance, is shifted downfield by 2.6 ppm compared with that from **7Ad** in C$_6$D$_6$. Similarly the amine protons of **4Ag**, **4Ai**, and **4Ci** resonate at lower field in C$_6$D$_6$ by 3.2, 3.2, and 3.4 ppm than the corresponding complexes **7**, respectively. Thus the hydrogen-bonding interaction between the coordinated amine and the β-diketonate anion in the outer sphere as revealed in crystals[14] persists in solution and is stronger in the case of compounds **4** than in **5**. The sequence of chemical shift (ppm) of the propylamine protons in CDCl$_3$, **5Bd**(5.8)>**5Ad**(5.6)>**5Cd**(5.3)>**5Dd**(4.9), reflects the relative strength of hydrogen bonding by the β-diketonate anions in accordance with the basicity sequence,[16] bzac~acac>tfac>hfac.

The methyl protons of β-diketonate anions in **5** resonate at about 0.3 ppm higher field than those in the corresponding parent bis-chelates,[11] reflecting the higher charge density in the former than in the latter. Complexes **5Ae**, **5Be**, and **5Ce** exhibit the methyl proton signals at extraordinarily high field. The phenyl ring of benzylamine in these complexes may exert the anisotropic shielding effect. It is strange that

a) Chemical shifts in ppm from internal Me_4Si in various solvents except D_2O in which sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as internal referrence. b) Solvent: i) $CDCl_3$, ii) C_6D_6, iii) $(CD_3)_2CO$, iv) $(CD_3)_2SO$, v) CD_3OD, vi) CD_2Cl_2, vii) py, viii) D_2O. c) Figures in parentheses and brackets give J(CH–CH) and J(CH–NH), respectively, in Hz. The NH_2-proton signals are usually broad. d) The H-D exchange reaction occurs with the solvent. e) Indiscernible due to overlapping with other signals.

compounds **5Cd** and **5Dd** give the molecular-weight values of 1330 and 1522, respectively, in dichloromethane at 25 °C which are equal to twice the calculated values. The molecular weight of **5Ad** also exceeds the value (665) calculated for monomer, depending substantially on concentration: 720—855 for 0.01—0.1 mol(monomer) dm^{-3}. The ^{19}F NMR spectrum (one signal at 77.7 ppm upfield from $CFCl_3$ in CH_2Cl_2) and the ^{13}C NMR data of **5Dd** which will be described later indicate that the two hfac anions are magnetically equivalent as was shown by the ^{1}H NMR spectrum. The dimeric structures of these compounds are very interesting and X-ray analysis of **5Dd** is now in progress.

Compounds **5Mb** and **5Mc** which were prepared by the reactions of [Pd(acac)(tfac)] (**1M**) with methylamine and ethylamine, respectively, exhibit two sets of methyl and methine signals assignable to the acac and tfac anions in the outer sphere. It is interesting that **5Mc** shows two amine-proton signals at 5.9 and 5.3 ppm in C_6D_6, presumably distinguishing the hydrogen-bonding with acac and tfac anions, although **5Mb** gives only one NH_2 signal in $CDCl_3$.

Table 5 lists the ^{1}H NMR data for complexes **4**. In accordance with the proposed structure, compounds **4A**, **4B**, **4C**, and **4M** exhibit two sets of proton signals from both β-diketonate anions in inner and outer spheres. The signal assignment was made by reference to data for the parent bis-chelates[11] and complexes **5** (Table 4). Results obtained for the related

a—e) Same as footnotes for Table 4. IS and OS abbreviate inner and outer spheres, respectively. f) Chemical shifts refer to $H^{2,6}$(equatorial), $H^{2,6}$(axial), and $H^{3,4,5}$(equatorial) in this sequence. Signals are all broad and those for $H^{3,4,5}$(axial) are indiscernible. g) The acac anion exists in IS and tfac in OS.

platinum(II) complexes such as [Pt(β-dik)(pip)$_2$](β-dik)[5)] were also helpful. Thus the methyl and methine protons resonating at higher field in $CDCl_3$ were assigned to the β-diketonate anion in the outer sphere.

It is noticed in Table 4 that the methyl and methine resonances from the acac (**5A**) and bzac (**5B**) compounds are shifted downfield by 0.14—0.26 ppm and 0.28—0.43 ppm, respectively, in C_6D_6 as compared with those in $CDCl_3$. In the case of the tfac compounds (**5C**), the methine protons are shifted in the same direction by 0.19—0.31 ppm but the methyl protons show slight upfield shifts by 0—0.15 ppm in C_6D_6. The same trend is observed for β-diketonate anions in the outer sphere of compounds **4** (Table 5). On the contrary, the methyl and methine resonances from the chelated β-diketonate ligands are shifted upfield by 0.32—0.42 ppm and 0.27—0.40 ppm for acac (**4A**) and by 0.57—0.93 and 0.45—0.51 ppm for tfac (**4C**), respectively.

Pinnavaia and Fay[17)] compared the methyl and methine chemical shifts for [M(acac)$_4$] and [M(tfac)$_4$] [M=Zr, Hf, Ce, and Th) as well as for free ligands in C_6D_6 with those in $CDCl_3$ and CCl_4. All signals were shifted upfield in C_6D_6; the methyl signals from enol tautomers of acacH and tfacH by 0.39 and 0.89 ppm, and the methine signals by 0.48 and 0.60 ppm, respectively. The metal chelates showed the same trend but the shifts were less pronounced. The authors ascribed the solvent effect to the diamagnetic anisotropy of the benzene ring and the especially large upfield shifts for the free ligands were supposed to result from a sandwiching of the planar enol molecules between the benzene molecules.

The present data are quite different from theirs, the upfield shifts for the chelated ligands being much pronounced and the effect on the counter anions being

a—e) Same as footnotes for Table 4. f) *cis* and *trans* mean *cis*(Me, L) and *trans*(Me, L), respectively. g) Chemical shifts refer to $H^{2,6}$ and $H^{3,4,5}$, respectively. Signals are all broad.

reversed. Benzene molecules may exert the diamagnetic anisotropic effect on the chelated β-diketonate ligand by sandwiching the coordination plane. The β-diketonate anion in the outer sphere is oblique to the coordination plane, forming hydrogen bonds with amine ligands.[14)] Thus the methyl and methine protons of the counter anion may experience the paramagnetic anisotropy of the benzene rings.

Since the tfac ligand is unsymmetric, two alkylamines in complexes **4C** are not environmentally equivalent. Thus two sets of the alkyl proton signals from the amine ligands are observed for **4Cg**, **4Ch**, and **4Cj**. In the reactions of [Pd(acac)(tfac)] (**1M**) with nitrogen bases, two types of products, [Pd(acac)L_2](tfac) and [Pd(tfac)L_2](acac) are conceivable. However ^{1}H NMR spectra indicate that the former type of products were obtained exclusively in each case (**4Mb**, **4Mh**, and **4Mi** in Table 5), reflecting the substantial difference in basicities of the acac and tfac anions.

Complex **4Dt** exhibits only one broad methine proton signal at 6.08 ppm in $CDCl_3$ at room temperature. The signal becomes sharper with increasing temperature probably by virtue of enhanced exchange between the two hfac anions in inner and outer spheres. The base L_2 (4,4'-Me_2-bpy) freed by reaction (1) may attack **4Dt** to give rise to **5Dt** in reaction (2).

$$[Pd(hfac)L_2](hfac) \rightleftharpoons [Pd(hfac)_2] + L_2 \quad (1)$$

$$[Pd(hfac)L_2](hfac) + L_2 \rightleftharpoons [PdL_4](hfac)_2 \quad (2)$$

Compound **5Dt** was isolated (Table 2) but its NMR spectrum is not determined because of poor solubility.

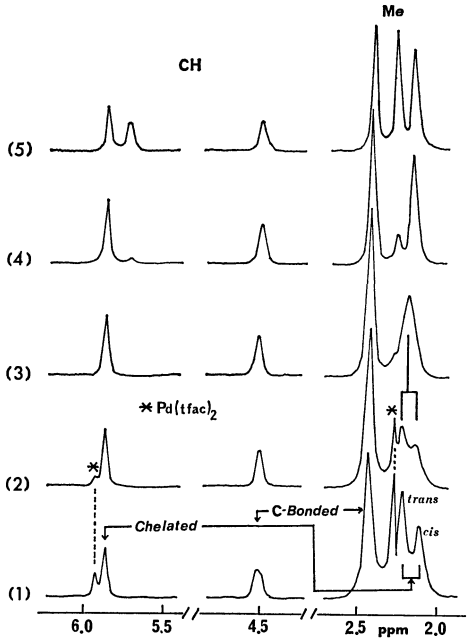

Fig. 3. ^{1}H NMR spectra of $CDCl_3$ solutions containing [Pd(tfac)$_2$] and various amounts of pyridine, the [pyridine]/[complex] molar ratio being 1.0(1), 1.5(2), 3.0(3), 6.0(4), and 11.0(5).

Averaging of the hfac anions in **4Dt** may be realized either by reaction (1) alone or by both of (1) and (2). A similar exchange of tfac anions in [Pd(tfac)(PPh$_3$)$_2$](tfac) was also noticed,[18] but the interrelation between the rate of exchange and the natures of β-diketonate and base ligands has not been studied.

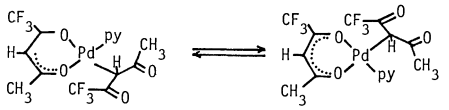
The ^{1}H NMR data for complexes **7** are collected in Table 6. Spectra in $CDCl_3$ of the acac complexes **7A** are similar to those reported for analogous complexes containing triphenylphosphine, pyridine, diethylamine, and *N*-methylbenzylamine as L[2] except that the chemical-shift difference for the two methyl groups of the chelated acac ligand is quite small in the present complexes **7**. By reference to the previous work[2] the signal at the highest field in $CDCl_3$ was assigned to the methyl group (a) located at the position cis to L and the lower-field signal to the methyl group (b) trans to L. The 6H signal around 2 ppm is easily assigned to methyl protons of the carbon-bonded acac ligand, of which the methine proton resonates at higher field than that of the chelated acac ligand.[2]

Since the bzac and tfac ligands are unsymmetric, two geometrical isomers, *cis*(Me,L) and *trans*(Me,L) are conceivable for **7B** and **7C**. In fact proton signals from these complexes exhibit splitting. The higher-field one of the two methyl signals from the chelated β-dik was assigned to the *cis*(Me,L) isomer based on the above consideration and the equilibrium quotient *cis*(Me,L)/*trans*(Me,L) was determined as the signal area ratio. Complexes **7B** except **7Bi** showed a single set of proton signals assignable to *cis*(Me,L) immediately after dissolution, but new signals ascribable to *trans*(Me,L) grew with time at the expense of the *cis*(Me,L) signals to attain an equilibrium. The rate of geometrical isomerization depends on the nature of L, **7Bm** and **7Bn** attaining equilibrium within 3 and 30 min, respectively, but **7Be** requiring *ca.* 10 h.

The [*cis*]/[*trans*] equilibrium quotient is 1 for **7Be** containing benzylamine as L and is larger than 1 for **7Bm**, **7Bn**, and **7Bq** containing pyridines, while the *trans*(Me,L) isomer is slightly more favorable for the piperidine complex, **7Bi**. In the case of **7C**, the *trans*(Me,L) isomers are favorable except for **7Ci** and **7Ck**. Complexes **7I** containing nitrogen bases as L also favor the *trans*(Me,L) form.[9]

Attainment of the isomerization equilibrium is accelerated by a free ligand L. Figure 3 shows ^{1}H NMR spectra of solutions containing [Pd(tfac)$_2$] (**1C**) and various amounts of pyridine. The spectrum in the presence of an equimolar amount of pyridine shows attainment of equilibria (3) and (4). About 80% of

$$[Pd(tfac)_2] + py \rightleftharpoons [Pd(tfac)(tfac\text{-}C^3)py] \quad (3)$$
1C **7Cm**

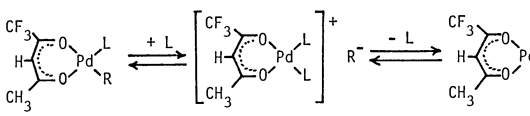


(4)

trans(Me,L)-**7Cm** *cis*(Me,L)-**7Cm**

1C is converted into **7Cm** and the *cis*(Me,L)/*trans*(Me,L) ratio is *ca.* 2/1. With increasing amount of pyridine, the methyl signals at 2.11 and 2.21 ppm become broader. When three times moles of pyridine is added, equilibrium (3) is almost completely shifted to right. The two methyl signals from the chelated tfac are also lost and instead a new signal is observed at 2.16 ppm, the chemical shift being close to the weighted mean of the values for two isomers. Thus the geometrical isomerization (exchange of the coordination sites) (Eq. 4) is assisted by free ligand and becomes fast on the NMR time scale at higher pyridine concentrations. Increased temperature also accelerates the isomerization, the *cis*- and *trans*(Me,L) signals in the presence of equimolar pyridine coalesce at higher temperatures.

Various mechanisms have been proposed for the cis-trans isomerization of square planar complexes.[19] The fact that the rapid isomerization occurs only in the presence of free pyridine does not accord with the dissociative mechanism *via* a three coordinate intermediate.[20] The double displacement mechanism[19] as is expressed by Eq. 5, where R represents the central-carbon-bonded β-diketonate ligand, is most widely accepted as the mechanism for the free-ligand catalyzed



(5)

trans(Me,L)-**7Cm** **4Cm** *cis*(Me,L)-**7Cm**

isomerization. The reactions of [Pd(acac)$_2$] with alkylamines to produce complexes **7A** were also found to proceed *via* the outer-sphere complex **4A**, the acac anion in turn replacing L as a carbanion.[3] If this mechanism is operative in the present case, that is, if the geometrical isomerization occurs rapidly on the NMR time scale *via* the forward and reverse reactions (5), environment of the carbon-bonded tfac and that

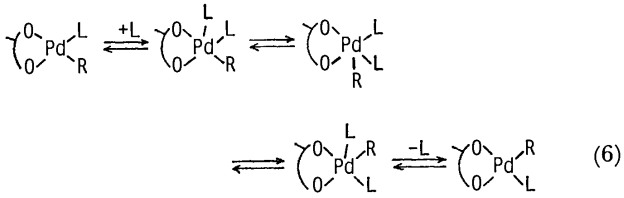
a) Chemical shifts in ppm from internal Me_4Si. Figures in parentheses and brackets give J(C–H) and J(C–F) in Hz, respectively. b) Symbols for carbon atoms are given referred to nitrogen. c) Resonances for the phenyl carbons are: quaternary C 144.7, *o*-C 127.4 (*ca.* 158), *m*-C 127.8 (*ca.* 158), and *p*-C 129.1 (159) ppm(Hz). d) [K] denotes a potassium ion surrounded by 18-crown-6, $[K(18\text{-crown-6})]^+$.

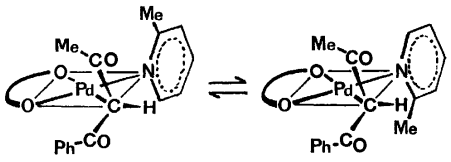
of the tfac anion in the outer sphere should be averaged. As is seen in Fig. 3, new signals grew at 2.26 and 5.69 ppm when increasing amount of pyridine was added to **7Cm**. These signals are assigned to the methyl and methine protons of the tfac anions in the outer sphere of $[Pd(py)_4](tfac)_2$ (**5Cm**). Compound **4Cm** is not so stable as to be detected spectroscopically, but converted into **5Cm**. The discrepancy in the ^1H chemical shifts in this reaction mixture from those (2.47 and 5.97 ppm, respectively) for pure **5Cm** in pyridine (Table 4) may be ascribed to the difference in the solution media. Thus the signals from the tfac anions both carbon bonded and in the outer sphere are separate and sharp, indicating that the exchange between these two types of tfac anions is not fast on the NMR time scale, even though the *cis*(Me,L) and *trans*(Me,L) configurations are rapidly averaged. Therefore the consecutive displacement mechanism is not realized in this case.

As an alternative mechanism for the geometrical isomerization (Eq. 4), we propose a rapid coordination site exchange of the five-coordinate square-pyramid intermediate as is exemplified in Eq. 6 by moving the unidentate ligands. Of course twisting of the chelate ring may be involved as well. This mechanism was first proposed in order to rationalize the dynamic behaviors in solution of $[M(hfac)_2P(o\text{-tolyl})_3]$ (M=Pd and Pt).[8] The exchange between apical and equatorial positions will occur *via* a trignal-bipyramid intermediate more easily than the Ray-Dutt twist in octahedral complexes.[21] Averaging of environments in solution of both halves of the 1,10-phenanthroline molecule in $[PtCN(phen)_2]NO_3$, which has a similar square-pyramid structure with a cyanide ligand in the basal plane, was also explained by virtue of an analogous mechanism.[22]



(6)

Complex **7Bn** containing 2-methylpyridine as L shows additional 1:1 splitting of each proton signal besides the splitting due to the geometrical isomerism (Table 6). This additional splitting is caused by hindered rotation of the bulky ligand around the Pd–N bond and the two sets of signals are assigned to the following two rotamers similar to those postulated for the central-carbon-bonded ester ligand in complexes **7I** containing 2-methylpyridine and 2,6-dimethylpyridine as L.[9] At higher temperatures, signals merge into one set for an equilibrium mixture of geometrical isomers.



^{13}C NMR Spectra. Table 7 lists the ^{13}C NMR data for some of complexes **5** containing propylamine or pyridine as L together with the data for [K(18-crown-6)](tfac) and [K(18-crown-6)](hfac) for comparison. The chemical shift of each carbon atom of the tfac and hfac anions involved in **5** is close to that of free anions separated from the potassium ion by virtue of the crown ether. The methyl carbons in **5** and free anions resonate at lower fields than those in the parent bis-chelates (25.4, 28.2, and 26.8 ppm for **1A**, **1B**, and **1C**), and the trifluoromethyl carbons than those in **1D** (114.7 ppm).[11] On the other hand, the methine carbons are shifted to upfield as compared with those in the corresponding bis-chelates (101.6,

a, b) Same as footnotes for Table 7. c) The phenyl-ring carbons except the quaternary carbon resonate in the 127.0—130.8 ppm region.

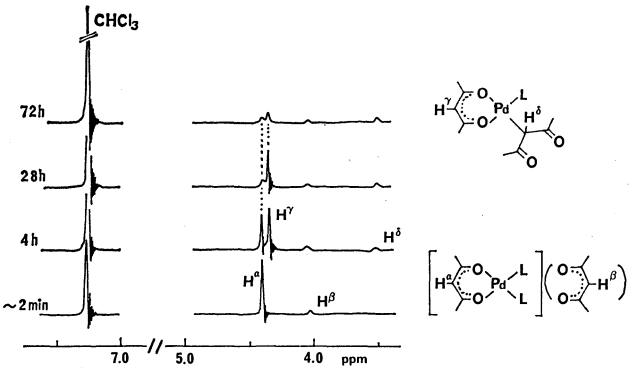

Fig. 4. Change with time of the methine proton signals from **4Ah** in $CDCl_3$ at room temperature.

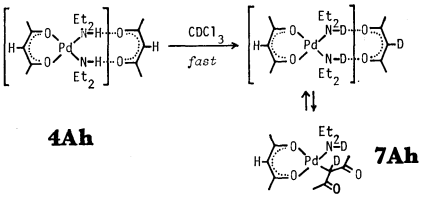
98.5, 97.8, and 93.8 ppm for **1A**, **1B**, **1C**, and **1D**).[11] It should be noted that the values of ^1J(C–F) for compounds **5** and the free hfac anion (290—292 Hz) are larger and the ^2J(C–F) values (30—33 Hz) are smaller than 284 and 37 Hz, respectively, for [Pd(hfac)$_2$]. In contrast to the case of ^{1}H NMR spectra, ^{13}C resonances of β-diketonate anions in C_6D_6 make no appreciable difference from those in $CDCl_3$ and CD_2Cl_2.

Similar ^{13}C NMR data for some of compounds **4** are collected in Table 8. Each complex except **4Dt** exhibits two sets of ^{13}C signals assignable to β-diketonate anions in the inner and outer spheres. Based on the above criteria, the upfield methyl and trifluoromethyl signals and the downfield methine signal for each complex are assigned to the coordinated β-diketonate ion. It is noteworthy that the ^1J(C–H) values for methine carbons of the coordinated β-diketonate are 5—10 Hz larger than those for the anion in the outer sphere. In the case of **4Ci** and **4Di**, the ^1J(C–F) values for the tfac and hfac ions in the outer sphere are larger than those for the coordinated anions. Then the CF_3CO carbons with lower ^2J(C–F) values are ascribed to the anion in the outer sphere. Compound **4Dt** shows dynamic behavior. The environments of two hfac anions are averaged on the NMR time scale as was evidenced by the ^{1}H NMR signal for the methine proton. Both of the chemical shifts and the J(C–F) values are intermediate for those for hfac anions in inner and outer spheres. It is not certain why the ^{13}C signals from the acac anion in the outer sphere of **4Ah** are broad. Various solvents were examined but the signals were always broad except in C_6D_6.

The ^{13}C NMR spectrum of [Pd(acac)(acac-C^3)-(Et_2NH)] (**7Ah**) resembles that of [Pt(acac)(acac-C^3)-(py)] reported by Ito *et al.*[10] Spectra of **7Ah** were recorded in several solvents (Table 9) and no appreciable solvent effect is noticed. Compounds **7Bq** and **7Ci** exhibit two sets of the β-diketonate signals caused by the unsymmetry of the bzac ligand. According to the ^{1}H NMR information, a set of more intense signals was assigned to the *cis*(Me,L) isomer.

The H-D Exchange Reactions of Complexes 4 and 5 with $CDCl_3$.[23] When complexes **4A** are dissolved in $CDCl_3$, the proton signals due to NH_2 and CH of the acac anion in the outer sphere become smaller, and instead the $CHCl_3$ signal grows with time. The H-D exchange reaction attains equilibrium within several minutes in the case of **4Ag** and **4Ah**, and after about 13 min for **4Ai**. The reaction is also detected by ^{13}C NMR spectroscopy. Besides the H-D exchange, complexes **4A** change spontaneously to **7A**, attaining equilibria during several days. Figure 4 exemplifies the change with time of the methine proton signals from complex **4Ah**. The spectrum at 4 h after dissolution involves signals attributable to **7Ah**, of which the one due to the methine group of the carbon-bonded acac ligand is much weaker than the other from that of the chelated acac. This fact indicates that the carbon-bonded acac originated from the counter anion of **4Ah** in accordance with the previous kinetic evidence (Eq. 7).[3] Deuteration of the methine group



(7)

in the chelated acac anion is much slower, requiring about three days for completion. It may be accomplished by the exchange of acac anions in the inner and outer spheres as shown by Eq. 8.

$$[Pd(acac)(Et_2NH)_2](acac^*) \rightleftharpoons [Pd(acac)(acac^*)] + 2Et_2NH \rightleftharpoons [Pd(acac^*)(Et_2NH)_2](acac) \quad (8)$$

A similar reaction of **4Cg** with $CDCl_3$ is much slower, attaining equilibrium after about ten days. Transformation to **7Cg** does not occur. Because of the unsymmetric tfac chelate, two dimethylamine molecules exhibit two separate doublets at 2.40 and 2.43 ppm with J(NH–CH_3)=5.$_5$ Hz (Table 5), which are transformed to singlets on deuteration of the NH proton. Amine ligands in other **4C** complexes are not deuterated by $CDCl_3$. The hfac complex **4Di** does not react either.

Complexes **5** react with $CDCl_3$ in a similar manner but the rate is slower than **4**. Necessary time for equilibrium attainment is about three days, two days, several hours, and less than 1 h for **5Ab**, **5Ac**, **5Ad**, and **5Ae**, respectively. Transformation to **7A** also occurs at the same time. Compounds **5Bd** and **5Be** attain the exchange equilibria within 16 and several hours, respectively, accompanied by the reactions to **7B**. Complex **5Cb** requires more than twenty days for completion of the reaction. Complexes **5Cc**, **5Cd**, **5Ce**, and **5Dd** are neither deuterated, nor transformed to **7**.

Amine protons and the methine proton of the tfac anion in the outer sphere of **4Mb** and **4Mh** attain the H-D exchange equilibria within several hours, but deuteration of the methine group of the chelated acac ligand requires more than four days. Substitution of the chelated acac ligand by the tfac anion *via* the pathway analogous to Eq. 8 seems more difficult than

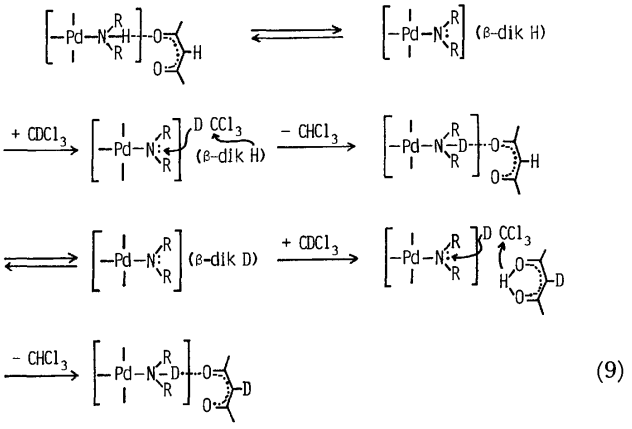
by the acac anion.

Deuteration of the coordinated amine and the β-diketonate anion in the outer sphere proceeds concurrently, and the rate seems to be greater for complexes containing stronger hydrogen bonds, since the reaction proceeds faster for **4** than for **5** and for more basic β-diketonate than for less basic anion. Kinetic study of deuteration by $CDCl_3$ of cationic palladium(II) alkylamine complexes containing various counter anions is now in progress and the following mechanism is tentatively proposed at present (Eq. 9).



(9)

Chloroform can be regarded as an acid and detritiation of C^3HCl_3 in aqueous solution by hydroxide ion[24)] and amines[25)] has been investigated. Dehalogenation of chloroform by ethylenediamine was also presumed to be initiated by proton abstraction from chloroform by the diamine.[26)] Although solutions of alkylamines in $CDCl_3$ show no sign of H-D exchange, complexes **4**, **5** or their precursors [Pd(β-dik)$_2$] can catalyze the reaction.[23)] Proton transfer from the coordinated amine to the β-diketonate anion in the outer sphere is presumed to reach equilibrium quickly and the concerted reaction among the amide center, $CDCl_3$ and β-dikH may be the rate-determining step. The deuterated amine molecule will be readily substituted by amine in solution to accomplish the catalytic cycle.

Anion Exchange of Compounds 4 and 5. In order to test validity of the proposed mechanism (9) for deuteration of compounds **4** and **5** by $CDCl_3$, substitution of the β-diketonate ions in the outer sphere with other appropriate anions is desirable. As a preliminary trial some anion exchange reactions have been examined. Addition of silver nitrate to a solution of **5Cm** in pyridine resulted in [Pd(py)$_4$](NO$_3$)$_2$ in a 62% yield, and **4Ah** reacted with equimolar K(tfac) in aqueous solution to give **4Mh** in a 72% yield. Thus the β-diketonate ion in the outer sphere is easily replaced by other anions. Table 10 lists the ^{1}H NMR data for some **4C** and **5C** compounds in trifluoroacetic acid. The methyl and methine proton signals assignable to tfacH are observed, indicating that the tfac anion in the outer sphere was completely protonated by the acid. The exact chemical shifts of CH_3 and CH are more or less different from those of authentic tfacH, but the identity was confirmed in each case by addition of the authentic sample. On being left in trifluoroacetic acid for a long time, compound **5Ce** decomposed gradually to give rise to the benzylammonium ion.

Relative Stabilities in Various Bonding Modes of β-Diketonate Anions. The reactions of [Pd(β-dik)$_2$] (**1**) with excess nitrogen bases are exothermic and it depends on the natures of both the β-diketonate ligand and base employed which of compounds **4**, **5**, **7**, and **8** is produced preferentially. When the chelating ligand is the acetylacetonate or other β-diketonate of weaker basicity, primary and secondary amines afford **5** and **4**, respectively. Basicities of both types of amines are not so different and the steric requirement of secondary amines seems to make **5** unfavorable. Although 2,2′-bipyridine reacts with **1D** to afford solely **4Ds**, 4,4′-dimethyl-2,2′-bipyridine produces either of **4Dt** and **5Dt** depending on the mole ratio of the reactants. Increased basicity of the latter ligand might overcome the steric disadvantage of the bis(bpy)-complexes **5**.

Tertiary amines do not react with **1** probably because their bulkiness is both kinetically and thermodynamically unfavorable for the ligand substitution. Tribenzylamine did react with **1D** not to afford a ligand-substituted product but to produce an orthometallated complex **9D*l***. 2,6-Diphenylpyridine also gave a similar product **9Dr**. The ^{1}H and ^{13}C NMR assay revealed that the hfac anion worked as a proton acceptor to result in hfacH (Eq. 10). In recent years a great many articles have appeared concerning orthometallated compounds, or "organometallic intramolecular-coordination compounds."[27)] Thus the reaction of lithium tetrachloropalladate(II) with *N,N*-dimethylbenzylamine in methanol gave di-μ-chlorobis-

Table 11. Equilibrium constants[a] estimated by ^{1}H NMR spectroscopy in $CDCl_3$ and C_6D_6 at room temperature:

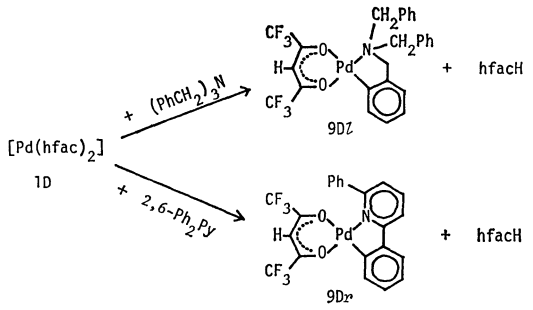
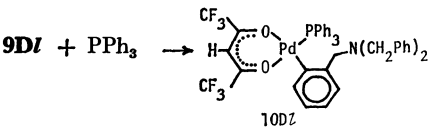
a) The figures in parentheses were determined in C_6D_6. The lower- and upper-limit values accompanied by the mark ≫ and ≪ were estimated by assuming concentration of the minor component as 1/10 of the initial concentration employed when it is detected but can not be determined quantitatively. The symbol ≈0 means that compound **7** can not be observed on the spectrum. b) The values of K_2 were tentatively calculated on the assumption that **5** exists as a monomer, although complexes of propylamine and presumably other alkylamines are dimeric in dichloromethane.



(10)

(*N*,*N*-dimethylbenzylamine-2*C*,*N*)dipalladium(II),[28] of which the bridge bond was cleaved by thallium(I) acetylacetonate to result in acetylacetonato(*N*,*N*-dimethylbenzylamine-2*C*,*N*)palladium(II)[29] analogous to **9D*l***. 2-Phenylpyridine also reacts with sodium tetrachloropalladate(II) to yield the chloro-bridged five-membered (*C*, *N*) chelate.[30] However, the reaction of [Pd(β-dik)$_2$] with a tertiary amine or a substituted pyridine to afford an orthometallated compound as expressed by Eq. 10 may be the first example. Furthermore it should be noted that triphenylphosphine can cleave the Pd–N coordination linkage in **9D*l*** to result in a phenylpalladium(II) complex **10D*l*** stable enough to be isolated (Eq. 11).



(11)

When a base reacts with complexes **1**, the β-diketonate ligand of weaker basicity is displaced more easily and the hfac and tfac ligands like to remove into the outer sphere. The acac ligand is also expelled from the coordination sphere by nitrogen bases, but the nature of solvent plays an important role in determining the most stable bonding mode. In polar solvents such as methanol compounds of type **4** and **5** are favorable, but dichloromethane stabilizes the carbon-bonded complexes.[3] The anion of ethyl acetoacetate is more basic than acac and complex **1I** readily reacts with pyridine to afford **8Im**,[9] while **1A** gives only **7Am** (Fig. 1). Thus the preference of bonding modes by β-dicarbonyl anions is related with the sequence of basicity as follows.

etac > acac ~ bzac > tfac > hfac

C-bonded——*O*,*O*′-chelate——Outer sphere

The relative tendency of β-dicarbonyl anions to form the central carbon bonding parallels with preference of the keto tautomer to enol. The percentage of enol in neat liquid at 33 °C was recorded as 8, 81, 97, and 100% for etacH, acacH, tfacH, and hfacH, respectively.[31] A β-dicarbonyl anion which prefers to accept a hydrogen ion at the central carbon atom rather than at an oxygen atom likes also to react with a metal ion as a carbanion. Ito and Yamamoto studied the reactions of [M(acac)(acac-*C*^{3})PPh_3] with several β-dikH and found that the keto-favoring β-dikH selectively replaces the carbon-bonded acac, while the enol-favoring β-dikH substitutes the chelated acac.[32]

Complexes **4**, **5**, and **8** gradually libcrate base to produce **7**. Table 11 lists the equilibrium constants estimated by the ^{1}H NMR spectroscopy and supports the above conclusion concerning the preference of bonding modes. Thus the stability of the outer-sphere complexes is in the sequence of hfac>tfac>bzac>acac and RNH_2>$BzNH_2$>py. The value (2.4) of K_1 for [Pd(acac)(Et_2NH)$_2$](acac) (**4Ah**) ⇄ **7Ah** + Et_2NH is not so different from the more accurate value (4.46) determined in dichloromethane at 25 °C by the spectrophotometric method.[3] When compounds **5** are converted to **7**, the reaction should proceed *via* **4**. However complexes **4** containing primary amines as L are usually unstable except **4Mb** and are not detected spectroscopically. Compound **4Mb**

as well as **4Mh** and **4Mi** is very stable in solution, showing no sign of transformation to **7**. The chelate-favoring acac and the outer sphere-favoring tfac may cooperate in stabilizing these compounds.

Experimental

Preparation of Compounds. The starting complexes, bis(β-diketonato)palladium(II) [Pd(β-dik)$_2$] (**1**) including [Pd(acac)(tfac)] (**1M**), were prepared by the methods described in a previous paper.[11] Methylamine, ethylamine, and dimethylamine were evolved by dissolving potassium or sodium hydroxide in aqueous solutions of these amines which are commercially available. Other amines, pyridines, and ammonia were purchased and used without purification. Most of the new compounds reported in this paper were prepared by one of the following two methods and the remaining compounds by other methods. (1) When the base is liquid at room temperature, compound **1** was dissolved or suspended in the neat liquid and the mixture was stirred. After reaction for appropriate time duration, the product was precipitated by cooling the solution, by adding another solvent such as diethyl ether, hexane, and petroleum ether to the reaction mixture, or by distilling away the excess base. (2) An appropriate amount of base was added to a solution of **1** in dichloromethane, benzene, or diethyl ether. The reaction mixture was worked up in a similar manner as above.

*[Pd(acac)(Me$_2$NH)$_2$](acac)·2H$_2$O (**4Ag**)*: Dimethylamine was distilled under nitrogen into a flask containing fine powder of [Pd(acac)$_2$] (**1A**) which was cooled with Dry Ice–methanol. The reaction mixture was then warmed to room temperature and stirred to result in a yellow solution. The amine was distilled away under reduced pressure to leave tiny yellow plates in a 90% yield.

*[Pd(acac)(Et$_2$NH)$_2$](acac) (**4Ah**)*: Pulverized **1A** (1.55 g, 5.09 mmol) was added to diethylamine (*ca.* 10 cm^3) and the mixture was warmed to result in a yellow solution, which was then cooled and kept at −5 °C in a refrigerator overnight to precipitate yellow columns. The product was filtered and washed several times with petroleum ether (boiling point<60 °C). The yield was 1.52 g (66%).

*[Pd(acac)(pip)$_2$](acac)·H$_2$O (**4Ai**)*: Complex **1A** (215 mg, 0.706 mmol) was dissolved in piperidine (*ca.* 0.8 cm^3) and diethyl ether (*ca.* 30 cm^3) was added to the solution. The solvent was then allowed to evaporate spontaneously to leave yellow needles on the wall of vessel. The product was gathered and washed with hexane. The yield was 156 mg (45%).

*[Pd(bzac)(pip)$_2$](bzac) (**4Bi**)*: Hexane was added to a solution of [Pd(bzac)$_2$] (**1B**, 59 mg, 0.14 mmol) in piperidine (0.9 cm^3) and the mixture was kept in a refrigerator to deposit yellow needles. The product was filtered and washed with a mixture of diethyl ether and petroleum ether (1:1 by volume). The yield was 77 mg (93%).

*[Pd(tfac)(Me$_2$NH)$_2$](tfac) (**4Cg**)*: In a similar manner as for **4Ag**, [Pd(tfac)$_2$] (**1C**, 300 mg, 0.727 mmol) was dissolved in dimethylamine. The amine was then distilled away to leave a yellow powder (331 mg) in a 91% yield.

*[Pd(tfac)(Et$_2$NH)$_2$](tfac) (**4Ch**)*: After **1C** (200 mg, 0.484 mmol) was dissolved in diethylamine, the excess amine was distilled away promptly under reduced pressure to leave a yellow crystalline solid (238 mg) in an 88% yield.

*[Pd(tfac)(pip)$_2$](tfac) (**4Ci**)*: Piperidine (*ca.* 0.2 cm^3) was added dropwise to a suspension of **1C** (413 mg, 1.00 mmol) in dichloromethane (0.5 cm^3) with stirring to result in a yellow solution. Hexane (20 cm^3) was added and the mixture was kept in a refrigerator overnight to deposit pale yellow plates (252 mg). The filtrate was concentrated and then cooled to precipitate another crop. The total yield was 392 mg (67%).

*[Pd(tfac)(BzNHMe)$_2$](tfac) (**4Cj**)*: A dichloromethane solution (2 cm^3) of *N*-methylbenzylamine (214 mg, 1.77 mmol) was added slowly to a solution of **1C** (511 mg, 1.24 mmol) in dichloromethane (5 cm^3) with stirring. After further addition of the amine (200 mg, 1.65 mmol), the solvent was allowed to evaporate spontaneously. Yellow crystals deposited on the wall of vessel were collected and washed with a mixture of diethyl ether and petroleum ether (1:1 by volume). The yield was 581 mg (72%).

*[Pd(tfac)(Bz$_2$NH)$_2$](tfac) (**4Ck**)*: Complex **1C** (100 mg, 0.242 mmol) was dissolved in hot dibenzylamine. Hexane was added to the solution to deposit a yellow precipitate, which was filtered and washed with hexane. The yield was 132 mg (67%).

*[Pd(tfac)(bpy)](tfac) (**4Cs**)*: A benzene solution (2 cm^3) of 2,2′-bipyridine (156 mg, 1.00 mmol) was added to a solution of **1C** (413 mg, 1.00 mmol) in benzene (10 cm^3) to precipitate a yellow crystalline solid immediately, which was filtered and washed with a mixture of benzene and hexane (1:1 by volume). The yield was 489 mg (86%).

*[Pd(hfac)(Me$_2$NH)$_2$](hfac) (**4Dg**)*: In a similar manner as the case of **4Ag**, [Pd(hfac)$_2$] (**1D**, 104 mg, 0.20 mmol) was dissolved in dimethylamine. On distilling away of the amine, white cubes and red oil were left, which were extracted with diethyl ether. The solvent was allowed to evaporate spontaneously to leave yellow plates of **4Dg** and a small amount of white columns. The yield of **4Dg** was 60 mg (49%). The latter was confirmed to be dimethylammonium 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate. Found: C, 33.02; H, 3.58; N, 5.54%. Calcd for C$_7$H$_9$NO$_2$F$_6$: C, 33.21; H, 3.58; N, 5.53%. IR: ν(NH) 3150s, ν(C=O) 1680vs.

*[Pd(hfac)(pip)$_2$](hfac) (**4Di**)*: Piperidine (98 mg, 1.2 mmol) was added to a solution of **1D** (300 mg, 0.576 mmol) in diethyl ether (3 cm^3). The solvent was allowed to evaporate spontaneously to leave yellow cubes in a 97% yield (387 mg).

*[Pd(hfac)(bpy)](hfac) (**4Ds**)*: A solution of 2,2′-bipyridine (71 mg, 0.45 mmol) in diethyl ether (1 cm^3) was added to a solution of **1D** (103 mg, 0.198 mmol) in diethyl ether (1 cm^3) to deposit a pale yellow precipitate immediately, which was filtered and washed with diethyl ether. The yield was 124 mg (93%).

*[Pd(hfac)(4,4′-Me$_2$-bpy)](hfac) (**4Dt**)*: In a similar manner as above, **1D** (208 mg, 0.400 mmol) reacted with 4,4′-dimethyl-2,2′-bipyridine (74 mg, 0.47 mmol) in diethyl ether (2 cm^3) to precipitate yellow needles immediately. The yield was 259 mg (92%).

*[Pd(hfac)(2,9-Me$_2$-phen)](hfac) (**4Du**)*: White crystals of compound **4Du** were prepared in a similar way as above. The yield was about 30%.

*[Pd(acac)(MeNH$_2$)$_2$](tfac) (**4Mb**)*: Methylamine (19 mg, 0.61 mmol) was kept in a small glass-stoppered bottle cooled with dry ice-methanol. Dichloromethane (1 cm^3) was poured into this bottle quickly and the solution was added to a dichloromethane solution (1 cm^3) of **1M** (114 mg, 0.318 mmol). The mixture was kept at room temperature for 1 h. Then petroleum ether (1 cm^3) was added to the solution and solvents were allowed to evaporate spontaneously to leave yellow plates (76 mg) in a 57% yield.

*[Pd(acac)(Et$_2$NH)$_2$](tfac) (**4Mh**)*: Compound **4Mh** was prepared *via* three alternative routes. (1) Immediately after dissolution of [Pd(acac)(tfac)] (**1M**, 100 mg, 0.279

mmol) in diethylamine (2 cm³), excess amine was distilled away at room temperature under reduced pressure to leave a yellow powder (136 mg) in a 97% yield. Recrystallization from dichloromethane–hexane gave yellow plates (yield: 80 mg, 57%). (2) Aqueous solution of potassium 1,1,1-trifluoro-2,4-pentanedionate (16 mg, *ca.* 0.1 mmol) was added to a fresh solution of [Pd(acac)(Et_2NH)$_2$](acac) (**4Ah**, 44 mg, 0.098 mmol) in water (1 cm³) with stirring to separate out a yellow precipitate (36 mg) in a 72% yield. After being dried *in vacuo*, the crude product was recrystallized from dichloromethane–hexane to give yellow hexagonal plates. The yield was 25 mg (51%). (3) A methanol solution of equimolar amount of potassium 2,4-pentanedionate was added to an acetone solution of [Pd(tfac)-(Et_2NH)$_2$](tfac) (**4Ch**) and the mixture was stirred for *ca.* 10 min. The solvents were distilled away under reduced pressure and the residue was extracted with diethyl ether. Then the solvent was allowed to evaporate spontaneously to leave yellow needles of **4Mh**, but the yield was very low.

*[Pd(acac)(pip)$_2$](tfac) (**4Mi**)*: Small portions of hexane and diethyl ether were added to a solution of **1M** (100 mg, 0.279 mmol) in piperidine (0.1 cm³) and the mixture was cooled to precipitate yellow plates, which were filtered and washed with hexane. The yield was 52 mg (35%).

*[Pd(NH_3)$_4$](acac)$_2$·2H_2O (**5Aa**)*: Gaseous ammonia from a cylinder was bubbled into a solution of **1A** (254 mg, 0.834 mmol) in dichloromethane (10 cm³) for *ca.* 15 min to deposit white crystallites, which were filtered, washed with diethyl ether. The yield was 280 mg (83%).

*[Pd($MeNH_2$)$_4$](acac)$_2$ (**5Ab**)*: A suspension of **1A** (270 mg, 0.886 mmol) in several cm³ of methylamine was stirred to produce a white precipitate on reaction. After distillation of the amine, a white powder was washed with a small portion of hexane. The yield was 357 mg (94%). Compound **5Ab** is not stable but turns yellow gradually on decomposition at room temperature.

*[Pd($EtNH_2$)$_4$](acac)$_2$·1/2H_2O (**5Ac**)*: On addition of **1A** (232 mg, 0.762 mmol) to *ca.* 3 cm³ of ethylamine, a white precipitate appeared immediately. The excess amine was distilled away slowly at −5 °C to leave a pale yellow crystalline solid, which was washed with hexane. The yield was 360 mg (96%). Compound **5Ac** was alternatively obtained by addition of an aqueous solution of ethylamine drop by drop to a suspension of **1A** in acetone. It is more stable than **5Ab** but decomposes slowly at room temperature.

*[Pd($PrNH_2$)$_4$](acac)$_2$ (**5Ad**)*: When **1A** was added to propylamine with stirring, the reaction occurred exothermically to deposit a white precipitate. The excess amine was distilled away and the residue was washed with diethyl ether. The yield was quantitative and recrystallization from diethyl ether–hexane gave colorless transparent columns. Compound **5Ad** also decomposes slowly at room temperature.

*[Pd($BzNH_2$)$_4$](acac)$_2$ (**5Ae**)*: Benzylamine (1.6 cm³) was added drop by drop to a solution of **1A** (400 mg, 1.31 mmol) in dichloromethane (5 cm³) and the solution was stirred for a while. Petroleum ether (6 cm³) was added to it and the mixture was kept in a refrigerator for three days to deposit white plates (840 mg) in an 87% yield, which decompose slowly to a white powder at room temperature.

*[Pd(en)$_2$](acac)$_2$·2H_2O (**5Af**)*: Six times as many moles of ethylenediamine was added dropwise to a solution of **1A** (294 mg, 0.97 mmol) in dichloromethane (10 cm³) with stirring to deposit a white precipitate (414 mg) in a 93% yield. The method is similar to that used for preparation of [Cu(en)$_2$](acac)$_2$·2H_2O.[13]

*[Pd(NH_3)$_4$](bzac)$_2$ (**5Ba**)*: Gascous ammonia was passed through a solution of [Pd(bzac)$_2$] (**1B**, 155 mg, 0.362 mmol) in dichloromethane at 0 °C for 10 min to separate out a yellowish white precipitate. On washing with diethyl ether a white powder of **5Ba** (164 mg) was obtained in a 91% yield.

*[Pd($MeNH_2$)$_4$](bzac)$_2$ (**5Bb**), [Pd($EtNH_2$)$_4$](bzac)$_2$ (**5Bc**), and [Pd($PrNH_2$)$_4$](bzac)$_2$ (**5Bd**)*: These compounds were obtained in similar manners as for the corresponding 2,4-pentanedionates in 90, 97, and 89% yields, respectively. Each complex decomposes gradually at room temperature.

*[Pd($BzNH_2$)$_4$](bzac)$_2$ (**5Be**)*: Cold benzylamine was added dropwise onto a fine powder of **1B** (327 mg, 0.763 mmol) with stirring at 0 °C to produce a white precipitate immediately, which was filtered and washed with hexane. The yield was 587 mg (90%).

*[Pd(en)$_2$](bzac)$_2$·2H_2O (**5Bf**)*: Five drops of ethylenediamine was added to a solution of **1B** (112 mg, 0.261 mmol) in dichloromethane to deposit a white precipitate immediately, which was filtered and washed with diethyl ether. The yield was 123 mg (81%).

*[Pd(NH_3)$_4$](tfac)$_2$ (**5Ca**), [Pd($MeNH_2$)$_4$](tfac)$_2$ (**5Cb**), [Pd($EtNH_2$)$_4$](tfac)$_2$ (**5Cc**), [Pd($PrNH_2$)$_4$](tfac)$_2$ (**5Cd**), [Pd-($BzNH_2$)$_4$](tfac)$_2$ (**5Ce**), and [Pd(en)$_2$](tfac)$_2$ (**5Cf**)*: These compounds were prepared by similar methods as those for the corresponding 2,4-pentanedionates in 90—99% yields. Recrystallization of **5Cf** from water gave colorless transparent needles of monohydrate.

*[Pd(py)$_4$](tfac)$_2$·3H_2O (**5Cm**)*: Compound **1C** (100 mg, 0.242 mmol) was dissolved in pyridine (*ca.* 0.3 cm³) and the mixture was allowed to stand overnight at room temperature. Large colorless plates were separated and washed with hexane. The yield was 144 mg (76%).

*[Pd(NH_3)$_4$](hfac)$_2$ (**5Da**):, [Pd($MeNH_2$)$_4$](hfac)$_2$ (**5Db**), [Pd($EtNH_2$)$_4$](hfac)$_2$ (**5Dc**), and [Pd($PrNH_2$)$_4$](hfac)$_2$ (**5Dd**)*: These compounds were obtained in similar manners as for the corresponding 2,4-pentanedionates in 90—99% yields. Compounds **5Db**—**5Dd** were able to be recrystallized from dichloromethane–hexane.

*[Pd(py)$_4$](hfac)$_2$ (**5Dm**)*: Compound **1D** dissolved in a small amount of pyridine exothermically. Diethyl ether and hexane were added to the solution and the mixture was cooled to deposit colorless plates in an 80% yield.

*[Pd(4,4′-Me_2-bpy)$_2$](hfac)$_2$ (**5Dt**)*: Compound **1D** (208 mg, 0.400 mmol) reacted with 4,4′-dimethyl-2,2′-bipyridine (147 mg, 0.800 mmol) in diethyl ether (4 cm³). Yellow crystallites were filtered and washed with diethyl ether. The yield was 332 mg (93%).

*[Pd($PrNH_2$)$_4$](Ph-acac)$_2$ (**5Ed**), [Pd($PrNH_2$)$_4$](dbm)$_2$ (**5Fd**), and [Pd($PrNH_2$)$_4$](dpm)$_2$ (**5Gd**)*: These compounds were obtained in 35—50% yields by dissolving [Pd(Ph-acac)$_2$] (**1E**), [Pd(dbm)$_2$] (**1F**), and [Pd(dpm)$_2$] (**1G**), respectively, in propylamine and distilling away the excess amine at −5 °C. Each product was washed with hexane.

*[Pd(py)$_4$](tta)$_2$ (**5Hm**)*: [Pd(tta)$_2$] (**1H**, 250 mg, 0.455 mmol) was dissolved in a mixture of dichloromethane (3 cm³) and pyridine (2 cm³) by stirring at 50 °C. The resulting clear solution was kept in a refrigerator overnight to give light yellow crystals, which were recrystallized from dichloromethane–petroleum ether. The yield was 350 mg (90%).

*[Pd(3-Me-py)$_4$](tta)$_2$ (**5Ho**) and* [Pd(4-Me-py)$_4$](tta)$_2$ *(**5Hp**)*: Both compounds were obtained in a similar manner as above in more than 90% yields.

*[Pd(en)$_2$](etac)$_2$ (**5If**)*: Ethylenediamine (0.5 cm³) was mixed with pulverized [Pd(etac)$_2$]·1/2H_2O[9] (277 mg, 0.741 mmol). A white precipitate deposited immediately, which was washed with large volumes of diethyl ether and acetone,

successively, and dried *in vacuo*. A gray powder of **5If** (311 mg) was obtained in an 86% yield. The compound does not dissolve in organic solvents other than alcohols, but is readily soluble in water and methanol and the ester anion in the outer sphere is solvolyzed. Thus recrystallization from a mixture of methanol, diethyl ether, and petroleum ether (2:2:1 by volume) resulted in colorless crystals of [Pd(en)$_2$](meac)$_2$·H$_2$O, where meac stands for the anion of methyl acetoacetate. Found: C, 35.99; H, 6.70; N: 11.96%. Calcd for $C_{14}H_{32}N_4O_7Pd$: C, 35.41; H, 6.79; N, 11.80%.

[Pd(MeNH$_2$)$_4$](acac)(tfac) (**5Mb**): Compound **1M** (100 mg, 0.279 mmol) was dissolved in several cm^3 of methylamine to result in a colorless solution. The excess amine was distilled away to leave white crystals (130 mg) in a 96% yield.

[Pd(EtNH$_2$)$_4$](acac)(tfac) (**5Mc**): In a similar manner as above white needles of **5Mc** were obtained in a quantitative yield. Recrystallization from petroleum ether gave pale yellow columns.

Dimethylamine(2,4-pentanedionato)(2,4-pentanedionato-C^3)palladium(II), *[Pd(acac)(acac-C^3)(Me$_2$NH)]* (**7Ag**): Compound **1A** (121 mg, 0.397 mmol) reacted with slightly excess dimethylamine (23 mg, 0.51 mmol) in dichloromethane (1 cm^3). Spontaneous evaporation of the solvent left a yellow mass and yellow liquid, which were washed with hexane to afford a yellow powder of **7Ag** (131 mg) in a 94% yield.

[Pd(acac)(acac-C^3)(Et$_2$NH)] (**7Ah**): This compound was previously prepared by the reaction of **1A** with diethylamine,[2] and now derived from **4Ah** (60 mg) by leaving its aqueous solution at room temperature. Yellow needles precipitated were filtered and dried *in vacuo*. The yield of **7Ah** from **4Ah** was 61% (31 mg).

[Pd(acac)(acac-C^3)(pip)] (**7Ai**): The compound was obtained in an 81% yield in a similar manner as **7Ag**, and recrystallized from diethyl ether–hexane. Compounds **7Ab**, **7Ad**, **7Ae**, and **7Ak** were also prepared in a similar manner.

Benzylamine(1-phenyl-1,3-butanedionato)(1-phenyl-1,3-butanedionato-C^2)palladium(II), *[Pd(bzac)(bzac-C^2)(BzNH$_2$)]* (**7Be**): Compound **1B** (179 mg, 0.418 mmol) reacted with benzylamine (71 mg, 0.66 mmol) in dichloromethane (3 cm^3) and the solvent was evaporated spontaneously to leave a yellow crystalline solid contaminated with oil. The product was washed with diethyl ether and dried *in vacuo*. The yield of a yellow powder of **7Be** was 196 mg (88%). The product was a mixture of *cis*(Me,L) and *trans*(Me,L) isomers. When it was dissolved in dichloromethane and the solvent was evaporated spontaneously after addition of a small amount of methyl iodide, a yellow crystalline solid left and washed with diethyl ether was pure *cis*(Me,L). The role of methyl iodide is not clear which was used in order to examine the possibility of substituting the carbon-bonded ligand.

[Pd(bzac)(bzac-C^2)(pip)] (**7Bi**): After the reaction of **1B** (123 mg, 0.287 mmol) with benzylamine (37 mg, 0.44 mmol) in dichloromethane (2 cm^3), the solvent was allowed to evaporate spontaneously to leave orange oil. A mixture (2 cm^3) of diethyl ether and hexane (1:2 by volume) was added to the vessel and the mixture was stirred. A yellow precipitate appeared, which was filtered, washed with diethyl ether and dried *in vacuo*. The yield was 92 mg (63%).

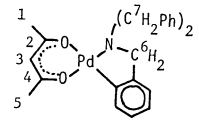
[Pd(bzac)(bzac-C^2)(py)] (**7Bm**): Compound **1B** (200 mg, 0.467 mmol) was dissolved in a small amount of pyridine by heating. Hexane was added to the solution and the mixture was cooled to deposit yellow crystals, which were filtered and washed with hexane. Compound **7Bm** (225 mg) thus obtained in a 95% yield is composed of the *cis*-(Me,L) isomer alone.

[Pd(bzac)(bzac-C^2)(2-Me-py)] (**7Bn**): Complex **7Bm** (100 mg, 0.196 mmol) was dissolved in a small amount of 2-methylpyridine by heating. Hexane was added to the solution and the mixture was cooled to separate out yellow needles (86 mg) in an 84% yield, which contain only the *cis*(Me,L) isomer.

[Pd(bzac)(bzac-C^2)(4-Me$_2$N-py)] (**7Bq**): Compound **1B** (100 mg, 0.233 mmol) reacted with 4-dimethylaminopyridine (28 mg, 0.23 mmol) in dichloromethane (2 cm^3) at room temperature. After 3 h, hexane (1 cm^3) was added to the solution and the mixture was cooled to deposit yellow needles (105 mg) in an 82% yield.

[Pd(tfac)(tfac-C^3)(Me$_2$NH)] (**7Cg**): Complex **1C** (268 mg, 0.650 mmol) reacted with twice molar dimethylamine (67 mg) in dichloromethane and the solvent was vaporized spontaneously to leave yellow plates, which were filtered and washed with hexane. The yield was 279 mg (94%). *[Pd(tfac)(tfac-C^3)(Et$_2$NH)]* (**7Ch**), *[Pd(tfac)(tfac-C^3)(pip)]* (**7Ci**), and *[Pd(tfac)(tfac-C^3)(Bz$_2$NH)]* (**7Ck**) were similarly obtained as a yellow powder, yellow needles, and yellow crystallites in 50, 80, and 50% yields, respectively.

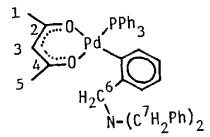
1,1,1,5,5,5-Hexafluoro-2,4-pentanedionato(tribenzylamine-2C,N)-palladium(II), *[Pd(hfac)(Bz$_3$N-2C,N)]* (**9Dl**): A mixture of **1D** (287 mg, 0.551 mmol) and tribenzylamine (316 mg, 1.10 mmol) were heated in toluene under reflux and the solvent was distilled away under reduced pressure to leave pale yellow needles. Recrystallization from dichloromethane–petroleum ether (1:1 by volume) gave **9Dl** (196 mg) in a 52% yield. Found: C, 51.98; H, 3.45; N, 2.37%; mol wt 574 in CH_2Cl_2. Calcd for $C_{26}H_{21}NO_2F_6Pd$: C, 52.06; H, 3.53; N, 2.34%; mol wt 600. Dec temp: 152—162 °C. IR in Nujol: ν(C=O)+ν(C=C), 1640vs, 1547s, 1515m cm^{-1}. ^{1}H NMR in $CDCl_3$, δ (ppm from internal Me_4Si): 3.97 (2H, s, 6CH$_2$); 3.9 and 4.3 (4H, AB-quartet, J=12 Hz,



7CH$_2$); 5.94 (1H, s, 3CH); 7.0—7.8 (*ca.* 15H, m, Ph). ^{13}C NMR in $CDCl_3$, δ(ppm from internal Me_4Si): C^2 and C^4, 174.7q and 174.9q (J(C–F)=34 Hz); C^3, 89.9; C^6, 65.7; C^7, 64.8. Signals from C^1 and C^5 are not discernible because of overlapping with other signals.

(2,6-Diphenylpyridine-2C,N)(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)palladium(II), *[Pd(hfac)(2,6-Ph$_2$-py-2C,N)]* (**9Dr**): The change with time of ^{1}H NMR spectrum in a $CDCl_3$ solution containing complex **1D** and equimolar 2,6-diphenylpyridine showed that the reaction to form **9Dr** and hfacH was completed after 16 h at 25 °C. Diethyl ether was added to the solution and the mixture was cooled to deposit yellow crystals of **9Dr** in *ca.* 80% yield. Found: C, 48.36; H, 2.38; N, 2.56%. Calcd for $C_{23}H_{13}NO_2F_6Pd$: C, 48.60; H, 2.41; N, 2.58%. Dec temp: 201—203 °C. IR in Nujol: ν(C=O)+ν(C=C), 1632vs, 1550s.

[2-(Dibenzylaminomethyl)phenyl](1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)(triphenylphosphine)palladium(II), *[Pd(hfac)(2-Bz$_2$NCH$_2$C$_6$H$_4$)(PPh$_3$)]* (**10Dl**): Complex **9Dl** (129 mg, 0.215 mmol) readily reacted with triphenylphosphine (56 mg, 0.214 mmol) in dichloromethane at room temperature. After concentration of the solution by evaporation under reduced pressure, haxane was added to the concentrate and the mixture was cooled to precipitate yellow crystals (61 mg) in a 33% yield. Found: C, 61.23; H, 4.18; N, 1.50%. Calcd for $C_{44}H_{36}NO_2F_6PPd$: C, 61.30; H, 4.21; N, 1.62%. Dec temp: 145—148 °C. IR in Nujol: ν(C=O)+ν(C=C), 1675vs, 1525vs cm^{-1}. ^{1}H NMR in $CDCl_3$, δ (ppm from



internal Me_4Si): 3.91 (4H, s, $7CH_2$); 4.10 (2H, s, $6CH_2$); 5.21 (1H, s, 3CH); 6.4—7.6 (*ca.* 30H, m, Ph). ^{13}C NMR in $CDCl_3$, δ (ppm from internal Me_4Si): C^1 and C^5, 117.6 q (J(C–F)=290 Hz): C^2 and C^4, 173.9 q (J(C–F)=32 Hz); C^3, 86.0; C^6, 63.3; C^7, 59.6.

*Reaction of $[Pd(py)_4](tfac)_2 \cdot 3H_2O$ (**5Cm**) with Silver Nitrate.* A solution of silver nitrate (48 mg, 0.28 mmol) in pyridine (0.3 cm^3) was added to a solution of complex **5Cm** (82 mg, 0.10 mmol) in pyridine (0.5 cm^3) to deposit a white precipitate immediately, which was filtered, washed with benzene, and dried *in vacuo*. The yield of $[Pd(py)_4](NO_3)_2$ was 35 mg (62%). It is not soluble in organic solvents, but dissolves in hot water and gives white needles on cooling. The compound coincides with the authentic sample which was prepared by the reaction among sodium tetrachloropalladate(II), silver nitrate, and pyridine. Found: C, 43.92; H, 3.68; N, 15.60%. Calcd for $C_{20}H_{20}N_6O_6Pd$: C, 43.93; H, 3.69; N, 15.37%. IR in Nujol: $\nu(NO_3)$, 1376vs, br, 1325vs, br. ^1H NMR in D_2O at 75 °C, δ (ppm from internal DSS): 8.77 (2H, d, J=5 Hz, H^2 and H^6), 8.0 (1H), m, H^4), 7.6 (2H, m, H^3 and H^5).

Measurements. IR spectra were recorded in Nujol on Hitachi EPI-S2 and 295 spectrophotometers. NMR spectra were measured with JEOL JNM-C60HL and JNM-MH 100 (for ^1H), FX60Q (for ^1H and ^{13}C), and PS-100 (for ^{19}F) spectrometers. The molecular weight was determined by vapor pressure osmometry with an instrument manufactured by Knauer in West Berline, West Germany.

We wish to thank Mr. Junichi Gohda for elemental analyses, and also Professor T. Tanaka and Dr. K. Kawakami of Osaka University for ^{19}F NMR measurements. B. K. M. thanks Japan Society for the Promotion of Science for the award of Fellowhsip. This work was partly supported by Grant-in-Aid for Scientific Research No. 243014 from the Ministry of Education, Science and Culture.

(Received December 3, 1980)

Paramagnetic tetraammine-5-nitrosalicylato cobalt complex, paramagnetic μ-hyperoxo-dicobalt complexes and related diamagnetic compounds have been studied by X-ray photoelectron spectroscopy. In all these compounds, the binding energies of Co 2p electrons and their spin-orbit separation were those of usual Co(III) complexes. In the spectrum of paramagnetic tetraammine-5-nitrosalicylatocobalt salt, satellites appeared near the Co 2p peaks showing certain spin density at the cobalt atoms. At the same time, the C 1s spectrum showed that considerable portion of carbon atoms has high binding energy suggesting delocalization of electron hole over the organic ligand. The O 1s peaks in μ-hyperoxo complexes were *ca.* 0.6 eV higher than those in μ-peroxo complexes. Deconvolution of the O 1s peak in the μ-OOH complex gave OH, =O–, and H_2O peaks at the 1:1:1 ratio, supporting the μ-OOH formulation.

Previous papers[1–5] described the preparation and properties of a series of deep green ammine 5-nitrosalicylato cobalt complexes formed from russet ammine salicylato cobalt(III) complexes.[6,7] Inasmuch as these deep green compounds have oxidizing power and are paramagnetic, the earlier papers formally denoted them as cobalt(IV) compounds. However, examination of electric resistivity,[3] ESR,[3] IR,[4] and NMR[4] spectra suggested that the electron deficiency is not centered at cobalt, but is delocalized over the system composed of the cobalt atom and the organic ligand. In this sense we have changed the series title to the present one.[5]

The situation is in a sense similar to the case of some paramagnetic μ-O_2 dicobalt complexes which were formerly described as Co(III)–Co(IV) complexes,[8] but which are now usually formulated as μ-hyperoxo-dicobalt(III) complexes on the basis of structural,[9] ESR,[10] vibrational,[11] and other studies.[12]

The present study has been intended to elucidate the valency and related problems in paramagnetic ammine 5-nitrosalicylato cobalt complexes and μ-O_2 dicobalt complexes by means of X-ray photoelectron spectroscopy (XPS), which is becoming to give useful information as to the state of the constituent atoms.

Experimental

Materials. Tetraammine-5-nitrosalicylatocobalt complexes were prepared after Yamamoto *et al.*,[1–5] whereas μ-O_2 dicobalt complexes were prepared according to the description by Mori *et al.*[13,14]

XPS Measurements. The spectra were obtained by irradiating the compounds with Mg $K\alpha$ X-rays (120 W) in a vacuum at a pressure of less than 3×10^{-7} Pa and at room temperature or around 220 K. The powdered compounds were uniformly mounted on Ni holders by using adhesive tape. The instrument used was a VG ESCA 3 electron spectrometer, and was calibrated with gold and copper, relative to the photoelectron peaks Au $4f_{7/2}$(84.0 eV), Cu $3s_{1/2}$(122.6 eV), and Cu $2p_{3/2}$(932.7 eV); FWHM (full width at half maximum) of the Au $4f_{7/2}$ peak was 1.18 eV, and C 1s peak due to the carbonaceous contamination formed on Au and Cu specimens in the instrument appeared at 284.8 eV. The peak shift caused by charge-up effect was corrected with the contamination C 1s peak.[15]

The spectra comprised of several components were deconvoluted with skewed Gaussian shape, where the same FWHM was assigned for components of the same element. The error of binding energy determination was estimated to be ±0.2 eV when the peaks were well-separated, whereas it was estimated to be ±0.4 eV when deconvolution was applied. The error of intensity estimation was around 5% in the former case while it was around 10% in the latter case.

Results and Discussion

XPS of Ammine 5-Nitrosalicylato Cobalt Complexes. The binding energies of C 1s, N 1s, O 1s, and Co 2p electrons of the cobalt complexes studied in this research are given in Table 1. The binding energies of Co 2p electrons as well as their spin-orbit separation ($\approx$15 eV) in the green paramagnetic complex $[Co(5\text{-}NO_2sal)(NH_3)_4]ClNO_3\cdot H_2O$ fell well within the range of those of cobalt(III) complexes[16] as of course did those of orange diamagnetic complexes $[Co(5\text{-}NO_2sal)(NH_3)_4]NO_3\cdot H_2O$ and $[Co(5\text{-}NO_2sal)(NH_3)_4]\text{-}Cl\cdot HCl\cdot H_2O$, the latter two being considered to be typical cobalt(III) complexes. This is consistent with the results of studies of electric conductivities, ESR,[3] IR, and NMR spectra[4] and suggests delocalization of the electron hole over the cobalt-ligand system in the former paramagnetic compound.

The following points, however, seem to be worth noting concerning the XPS of the paramagnetic $[Co(5\text{-}NO_2sal)(NH_3)_4]ClNO_3\cdot H_2O$: (1) Cobalt 2p peaks have satellites which show the presence of certain spin density at the cobalt atom (Fig. 1). Somewhat greater FWHM observed for the Co $2p_{3/2}$ peak (Table 1) may also be due to the presence of unpaired spin. (2) There are some carbon atoms (estimated to be 22.2% of the total carbon) that have high binding energies (Fig. 2). (1) is in apparent contradiction to the tervalence of cobalt as concluded from the binding energies and spin-orbit separation. These might be accommodated by assuming that although the unpaired spin is not centered at cobalt in the

a) In eV. The maximum of Cl $2p_{3/2}$ has been taken to be at 198.2 eV. b) The peak due to ring carbon admixed with that due to contaminating hydrocarbon from instrument.[15] c) Ring carbon of high binding energy.

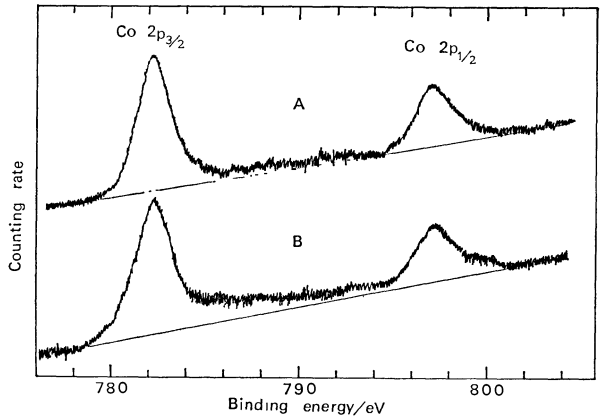

Fig. 1. XPS of $[(NH_3)_4Co(O-C(=O)-C_6H_3(NO_2)-O)]Cl\cdot HCl\cdot 2H_2O$ (A) and $[(NH_3)_4Co(O-C(=O)-C_6H_3(NO_2)-O)]Cl\cdot NO_3\cdot 2H_2O$ (B) in the Co 2p region at 220 K.

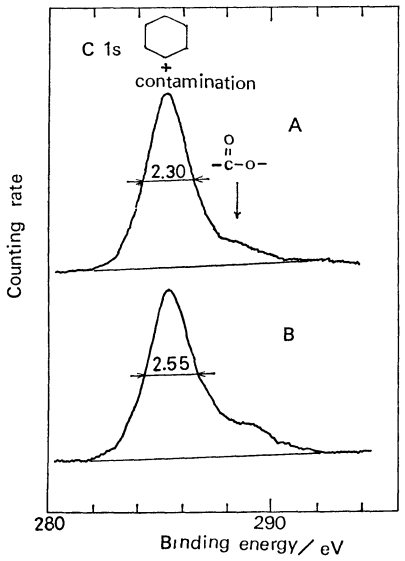

Fig. 2. XPS of $[(NH_3)_4Co(O-C(=O)-C_6H_3(NO_2)-O)]Cl\cdot HCl\cdot 2H_2O$ (A) and $[(NH_3)_4Co(O-C(=O)-C_6H_3(NO_2)-O)]Cl\cdot NO_3\cdot 2H_2O$ (B) in the C 1s region at 220 K.

sense that cobalt is quadrivalent, yet some fraction of the spin density remains on cobalt. However, a considerable part of the spin density or the electron deficiency seems to be also distributed over some carbon atoms of the 5-nitrosalicylato ligand as evidenced by (2), *i.e.* by the high binding energies observed for certain portion of the carbon atoms. In the case of orange diamagnetic $[Co(5\text{-}NO_2sal)(NH_3)_4](NO_3)\cdot H_2O$, a shoulder appeared at the high energy side of the main C 1s peak, and from its area (estimated to be 6.7% of the total carbon), it is considered to correspond to the carboxylato carbon.

In the green paramagnetic as well as the orange diamagnetic complexes the nitrogen 1s electrons appear as two peaks separated by 6.4—6.8 eV. The peak at *ca.* 400 eV was assigned to NH_3 nitrogen. The peak at higher energy could be deconvoluted to the one at 405—406 eV assignable to NO_2 nitrogen and to the one at *ca.* 407 eV assignable to NO_3 ni-

a) The C 1s peak due to hydrocarbon contamination from the instrument has been taken to be at 284.8 eV.[15] b) Green paramagnetic hyperoxo complex. c) Brown diamagnetic peroxo complex. d) Red diamagnetic hydroperoxo complex. e) I_{NH_2}/I_{NH_3}(or en) $\fallingdotseq$ 1/8. f) The above ratio is not equal to 1/8. The reason is not clear.

trogen. It has not so far been possible to deconvolute the peak of O 1s (half width=3.3 eV) into those of different types of atoms in the compound.

XPS of μ-NH_2-μ-O_2 Dicobalt Complexes. Okamoto *et al.* who studied the XPS of various cobalt compounds in connection with the catalytic activities reported that the Co 2p binding energies and their spin orbit separation of $[(NH_3)_5CoO_2Co(NH_3)_5](NO_3)_4$ (diamagnetic) and $[(NH_3)_5CoO_2Co(NH_3)_5]Cl_5$ (paramagnetic) were in the same range as those of usual cobalt(III) complexes.[17] Burness *et al.* studied the XPS of Shiff-base complexes and their O_2 adducts, found similar results,[18] and concluded that the oxygenated compounds contain tervalent cobalt, so that O_2 is a peroxo (diamagnetic) or a hyperoxo (paramagnetic) ligand. The peroxo compounds they studied included both mononuclear and dinuclear (*i.e.* μ-O_2) complexes, whereas the hyperoxo compounds they studied were all mononuclear. They also found that the O 1s binding energies of the hyperoxo complexes are *ca.* 1 eV higher than those of the peroxo complexes in conformity with the reduction of the charge on the O_2 moiety. The result of the present XPS study (Table 2) on the μ-NH_2-μ-O_2 dicobalt complexes also showed a similar trend. A slightly lower binding energies of Co 2p electrons in the peroxo as compared with those in the hyperoxo complex might be accounted for in terms of the donation of the extra antibonding π-electron of O_2 to cobalt in the former. Satellites were either inperceptible or very weak indicating low spin density on the cobalt atom (Fig. 3), again rationalizing the formulation of the paramagnetic compound as μ-hyperoxo-dicobalt(III) complex.

In $[(en)_2Co(NH_2)(OOH)Co(en)_2]Br_4\cdot H_2O$ spectrum, the O 1s band could be deconvoluted into three peaks at 531.4, 532.2, and 533.5 eV assigned to -OH, >O-, and H_2O oxygens, respectively, supporting the μ-OOH structure reported for the corresponding nitrate.[19] The higher binding energy of >O- in >O-OH as compared with that of usual peroxo oxygen might be due to the lower electron density caused by coordination of one peroxo oxygen to two cobalt ions in the former case. It has also been possible to dif-

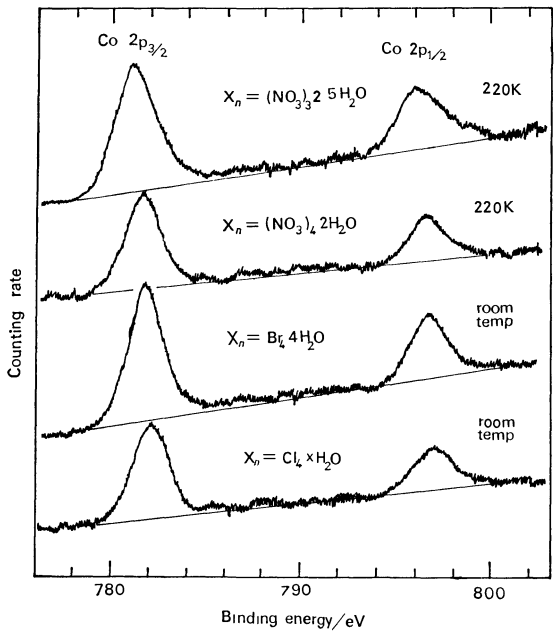

Fig. 3. XPS of $\left[(en)_2Co\begin{matrix}\diagup NH_2\diagdown \\ \diagdown OO\diagup\end{matrix}Co(en)_2\right]X_n$ in the Co 2p region.

ferentiate the nitrogen atom present as NH_2 from those present as NH_3 or en with the intensity ratio of 1:8 in most μ-NH_2-μ-O_2 complexes studied (*cf.* Table 2).

Comparison between the Two Series of Paramagnetic Cobalt Complexes. As discussed above, the deep green ammine-5-nitrosalicylatocobalt complex and the green μ-hyperoxo-dicobalt complex are in a sense similar in that one unpaired spin (an electron hole) has the probability of existence partly on the cobalt atom and partly on some of the ligand molecules. In the case of the paramagnetic μ-O_2 complex, the large hyperfine coupling constant due to ^{17}O nucleus in the ESR spectrum established that the spin density is much higher on the O_2 bridge,[10] rationalizing the μ-hyperoxo nomenclature. This seems to be in line with inperceptible or very weak satellites of Co 2p lines in the XPS of the μ-amido-μ-hyperoxo complex. On the other hand the appearance of satellites in the Co 2p lines in the XPS of the deep green tetraammine-5-nitrosalicylatocobalt complex seems to suggest a higher spin density on cobalt as compared with the μ-hyperoxo-dicobalt case. Yamamoto[3] observed eight hyperfine lines in the aqueous esr spectrum of deep green bis(ethylenediamine)-5-nitrosalicylatocobalt chloride nitrate in the narrow concentration range of ca. 10^{-2}—10^{-3} M, which may possibly be due to ^{59}Co nucleus, but simultaneous appearance of one sharp line leaves some ambiguity as to the state of the complex in aqueous solution. Thus, quantitative estimation of the spin density by use of more stable complex of this series containing isotopically labeled ligand seems to be very desirable.

Negative Ions Formed by Vacuum Spark Discharge. III.[1] Polyatomic Negative Ions of the Elements in A-Subgroups on the Periodic Table

Hiroshi KISHI†

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 15, 1980)

Polyatomic negative ions for almost all of the elements in A-subgroups on the periodic table were tested by the spark discharge type ion source mass spectroscopy. A large number of polyatomic negative ions such as "polymer" negative ions, hydride negative ions, oxide negative ions, and carbide negative ions, could be detected. The results are discussed with reference to the reported values of electron affinities of the molecules and to the reported results by other methods of formation.

A study on negative ion spark source mass spectroscopy using a Mattauch-Herzog type double focusing mass spectrograph has been carried out. Formation of atomic negative ions of 48 elements has previously been reported,[2] and the relative sensitivity coefficients for negative ions has also been reported.[1]

The significant features of the Mattauch-Herzog type double focusing mass spectroscopy[3] are (1) all ions of a given mass (m/z) range can be detected at the same time on a photographic emulsion plate, and (2) by the cumulative nature of the ion detection on the photographic emulsion plate, it is possible to detect ions of weak intensity: the exposure time is long and all ions formed during the exposure time are collected. In the experiment of atomic negative ions with the use of a spark discharge type ion source,[2] a large number of polyatomic negative ions were detected in addition to the atomic negative ions.

On the polyatomic negative ions detected by spark source mass spectroscopy, there are only a few reports in the literature.[4,5] This might reflect the difficulty of the formation of negative ions by spark discharge type ion sources, compared with the case of formation of positive ions. The probability of formation of negative ions versus the positive ions is 10^{-3} to 1, in an electron-impact type ion source.[6] In the spark discharge type ion source, the probability appears to be close to this value.

In the present experiment, the following testing materials were used: (1) elementary materials in the form of solid metals or powdered metals, (2) gases, (3) oxide compounds, (4) inter-elementary compounds such as GaAs or LiF, (5) other types of compounds, including almost all of the elements in A-subgroups (typical elements) on the periodic table, except for Po, At, Fr, and Ra.

In this report, the ionic species of polyatomic negative ions detected in the experiment are described, along with some polyatomic positive ions. The negative ions are classified into the following five types: (1) "polymer" negative ions, (2) hydride negative ions, (3) oxide negative ions, (4) carbide negative ions, and (5) other types of negative ions.

Electron affinity of molecules is important to the understanding of molecular phenomena. Reported values of electron affinities are available for some molecules in the literature;[7,57] however, the experimental determination and theoretical calculation both present great difficulties. The results given here present experimental evidence that molecular ions detected here have positive electron affinity values. The results are discussed with reference to the reported values of electron affinities.[32-56]

The results are also compared with those obtained from negative ion formation by means of the spark discharge, electron impact, surface ionization, and other methods.

Experimental

Apparatus. The instrument used was a Mattauch-Herzog type double focusing mass spectrograph, equipped with an r f spark discharge type ion source (Mitsubishi Denki Electric Co. Ltd.). Since details of the instrumentation were reported elsewhere,[8-10] only the operationing conditions are given here: spark voltage 20 kV, pulse width 200 μs, repetition rate 100 s^{-1}, ion accelerating voltage 15 kV for positive and negative ions.

Materials. Sample materials studied are (1) elementary materials in the form of solid metals or powdered metals, (2) gases, (3) oxide compounds, (4) binary compounds such as GaAs or LiF, (5) other types of compounds. They are listed in Table 1.

When the samples are solid materials, the discharge electrodes of the ion source, about 1 $mm^2 \times 5$ mm, are made from them. In this case, it is convenient to maintain a discharge between the electrodes, and to have a long exposure time. When the samples are fine powders, they are packed inside a small ($\approx$1 mm diameter) metal tube, made of gold or nickel, and a platinum counterelectrode is applied. When they are electrical insulators, some oxides for instance, powdered materials are mixed well with pure aluminium powder of equal weight, and pressed[11] to form rigid electrodes. Some insulators, lithium fluoride crystal for instance, can be ionized with a platinum counterelectrode.

When the samples are gaseous materials, they are introduced into the region of the spark discharge of Pt/Pt electrodes through a capillary leak. In "A/B spark discharge," A and B mean the electrode materials in the spark discharge ion source. This notation will be used throughout this report.

Vacuum discharge ionization is difficult to maintain when the melting point of the electrode is low. Gallium, for instance, is ionized using a gallium arsenide crystal.

† Present address: Oyama Technical College, Nakakuki, Oyama, Tochigi 323.

TABLE 1. SAMPLE MATERIALS FOR THE POLYATOMIC NEGATIVE IONS

Group	Element	Sample materials	Group	Element	Sample materials
IA	H	Hydrogen gas		Ge	Germanium, Crystal
	Li	Lithium fluoride, Crystal			Germanium dioxide, Powder
		Lithium carbonate, Powder		Sn	Tin metal

IVA	C	Graphite			Caesium bromide, Crystal
	Si	Silicon, Crystal			Silver bromide, Powder
		Silicon, Powder		I	Ammonium iodide, Powder

Results and Discussion

Method and procedure for the assignment of the mass spectral peaks obtained by the spark ion source mass spectroscopy are essentially the same as the experiment of the atomic negative ions.[2]

Experimental results for the polyatomic negative ions are tabulated in Table 2, along with the experimental results for atomic negative ions[2] and for polyatomic positive ions which were detected in the positive ion spark source mass spectra using the same samples.

Reported values of electron affinities of the molecules available in the literature[7] are tabulated in Table 3. In this table, the experimental or theoretical method used to determine the values of electron affinities are given in parentheses by an abbreviation.

Group IA Elements. By spark discharge of Pt/Pt electrodes in an atmosphere of H_2 gas, H^-, H_2^+, H_3^+ ions are detected, but H_2^- ion can not be detected. For the molecular ion of hydrogen, there are many reports in the literature. H_3^+ ion was detected by the parabola-type mass spectrograph, but H_2^- ion could not be detected.[12] The reported value of the electron affinity of H_2^- ion by the calculation is negative,[50,51] although H_2^- ion was detected by charge exchange of H_2^+ ion with H_2 gas,[13] and in a duoplasmatron ion source.[14] H_3^+, H_5^+, and H_5O^+ ions were detected by glow discharge.[15]

For the experiment of alkali-metal elements, alkali halide crystals are used as spark discharge electrodes. The polyatomic negative ions of $RbCl^-$, and the polyatomic positive ions of Li_2^+ and LiF^+ are detected in the spark discharge of LiF(crystal)/Pt electrodes.

For the polyatomic ions of alkali-metal elements, there are reports in the literature: MX^-, and MX_2^- ions (M=Li, Na, K, Rb, Cs; X=F, Cl, Br, I) are formed by surface ionization,[16] LiH_2^- ion by Penning discharge,[17] $LiCl^+$, $NaCl^+$, Na_2Cl^+, $Na_2Cl_2^+$, KCl^+, and $LiBH_2^+$ by spark discharge.[18]

Group IIA Elements. In the present experiment, only the Be^- ion is detected for negative ions. No polyatomic negative and positive ions are detected. The positives ions Be^+—Be_{25}^+, $Be_p(BeO)_q^+$,[19] and Mg^+—Mg_5^+ [4] are reported to form by spark discharge.

Group IIIA Elements. In this group, many polyatomic negative ions are detected. For the element Al, "polymer" negative ions of Al_2^-—Al_{13}^- are detected by Al/Al spark discharge. The results of detection of Al_2^-—Al_7^- and their relative intensities were already reported.[20] In addition to these ions, oxide negative ions AlO^-, and AlO_2^- are also detected.

⋮					⋮										
M_{15}^-					D										

For the element Ga, the diatomic negative ion Ga_2^- and the oxide negative ions GaO^- and GaO_2^- are detected by spark discharge of GaAs/GaAs. In this experiment, $GaAs^-$ and $GaAsH^-$ ions are also detected. For the element Tl, TlO^-, and TlC^- ions are detected.

For polyatomic positive ions of these elements, Al_2^+ and Ga_2^+ ions are detected; these results were already reported.[20]

Al_2^+—Al_{14}^+ ions were reported to form by spark discharge,[19] and BO^- and BO_2^- ions are reported to form by surface ionization.[21] Electron affinity values are available for AlO^- (2.60, 3.68 eV) and AlO_2^- (4.11 eV) (Table 3).

Group IVA Elements. In this group, many polyatomic negative ions are detected. For the element C, "polymer" negative ions C_2^-—C_{15}^-, and hydride negative ions CH^-—$C_{13}H^-$ are detected. For Si: Si_2^- and SiC^- and SiC_2^- ions are detected; for Ge: Ge_2^-, Ge_3^- and Ge_4^-; GeC^- and GeC_2^- ions; for Sn: SnC^- and SnC_2^- ions; and for Pb: PbC^- ions. The following positive ions are detected in these elements: C_2^+—C_{15}^+; Si_2^+—Si_4^+. Ge_2^+—Ge_4^+ "polymer" positive ions are also detected.

In the literature,[22,23] CS^-, CS_2^-, OCN^-, SCN^- ions are reported to form by ion-molecule reactions. SiO_2^- ions are reported by surface ionization.[24] Several positive "polymer" ions of C, C_2^+—C_{31}^+, are reported to form by spark discharge.[18,25,26,27]

The electron affinity values are available for the molecules C_2^-(2.9—4.0 eV), CH^-(0.74—4.1 eV), C_2H^-(2.3—3.73 eV) (Table 3).

Group VA Elements. In this group, for the element N, no atomic negative ion was detected,[2] and no polyatomic negative ion was detected. For the element P: PO^-, PO_2^-, PO_3^-, and PO_4^- are detected. For the element As: As_2^-; AsH^-, and As_2H^-; AsO^-; AsC^-, AsC_2^-, and AsC_3^- ions are detected. For the element Sb: Sb_2^- ion is detected. For the polyatomic positive ions of this group, As_2^+ and AsH^+ ions are detected.

The literature reports PH^- and PH_2^-, AsH^- and AsH_2^- ions by electron impact,[28] and N_3^-, CN^-, $C_2N_3^-$, C_3NO^-, $C_2N_4^-$, $C_2N_6^-$, $C_3N_2O^-$, $C_2N_5^-$, *etc.* ions by glow discharge.[29]

The electron affinity values are available for the molecules PO^- (<1.13 eV), and Sb_2^- (>0 eV) (Table 3).

Group VIA Elements. For the element O: O_2^-, O_2H^- and OH^- negative ions are detected. For the element S: S_2^- and S_3^-; for Se: Se_2^-, Se_3^-, and Se_4^-; and for Te, Te_2^-. These "polymer" negative ions are detected by the spark discharges of CdS(crystal)/Pt, CdSe(crystal)/Pt, and CdTe(crystal)/Pt, respectively. Positive ions of O_2^+, S_2^+, and Se_2^+ are also detected.

The literature reports O_3^-, OH^-, NO_2^-, SO_2^-, CS^-, CS_2^-, S_n^- (n=2—6) ions,[22] SF_6^-,[30] SCN^-, OCN^-, HS^-, NH_2S^- ions,[23] and S_{12}^+ ion.[31]

Electron affinity values are available for the molecules O_2^- (0.15—0.5 eV), OH^- (1.825—1.91 eV), O_2H^- (4.6 eV), S_2^- (2.0 eV), Se_n^- (n=2—4: >0 eV), and Te_2^- (>0 eV) (Table 3).

Group VIIA Elements. For Cl, Cl_2^-, and $RbCl^-$ ions are detected by spark discharge of RbCl/Pt. For Br, Br_2^-, Br_3^-, BrH^-, and Br_2O^- ions are detected

by AgBr/Pt spark discharge. Some polyatomic positive ions of the elements in this group are found: F_2^+, F_2H^+, and LiF^+ ions for the element F, and Br_2^+, Br_2O^+, $Br_2O_2^+$, and BrH^+ ions for the element Br. These are detected by the spark discharge of LiF/Pt and AgBr/Pt, respectively.

Electron affinity values are available for the molecules Cl_2^- (1.7—2.46 eV) and Br_2^- (>0—2.55 eV) (Table 3).

In summary, we have described the ionic species of polyatomic negative ions formed by the spark discharge type ion source for the elements in A-subgroups on the periodic table, along with the polyatomic positive ions. For the molecules that are detected as negative ions in this experiment, the reported values of the electron affinities are all positive. For the molecules having negative electron affinity values, available in the literature: (H_2^-: <0 eV,[50] −2.85 eV;[51] CO^-: −1.8 eV;[52] CO_2^-: >−0.9 eV;[53] N_2^-: −1.6 eV,[54] −11.345 eV;[55] HF^-: <0 eV[56]); no polyatomic negative ions can be detected in this experiment. Therefore, it seems that the electron affinity values are positive for the molecules which are detected as negative ions in this experiment, although there are many examples that the molecules can not be detected as negative ions in spite of the positive electron affinity values of them. This conclusion is in line with the case of atomic negative ions.[2] If this assumption is correct, the experimental results described in this report give experimental evidence that the ionic species that are detected as negative ions have the positive electron affinity values.

The polyatomic negative ions described in this report are classified into the following four types: (1) "polymer" negative ions, (2) hydride negative ions, (3) oxide negative ions, and (4) carbide negative ions. They are tabulated in Tables 4—7. Polyatomic positive ions detected can also be classified into the following four types: (1) "polymer" positive ions, (2) hydride positive ions, (3) oxide positive ions, and (4) other types of positive ions. They are tabulated in Tables 8—11. These tables indicate the following features for the formation of the polyatomic negative and positive ions by the spark discharge type ion source in the elements of A-subgroups on the periodic table.

(1) In the elements for which atomic negative ions can not be detected, no polyatomic negative ions can be detected.

(2) The elements, whose negative and positive "polymer" ions can easily be detected are identical, except for the elements H, Be, Sb, F, and Cl. They belong mostly to the IIIA, IVA, VA, VIA groups in the periodic table.

(3) Few hydride positive ions are detected, compared to the number of hydride negative ions; these are observed for the elements C, As, O, Cl, Br.

(4) Oxide negative ions are observed for the elements H, Al, Ga, Tl, P, As, and Br, whereas oxide positive ions are observed only for the element Br.

(5) Carbide negative ions are observed for the elements Si, Ge, Sn, Pb, As, and Sb. No carbide positive ions can be detected in this experiment.

The author would like to express his hearty thanks to Dr. K. Kodera and Dr. T. Makita, Kyoto University, for their encouragement and helpful suggestions throughout this work.

Negative Ions Formed by Vacuum Spark Discharge. IV.[1] Polyatomic Negative Ions of the Elements in B-Subgroups on the Periodic Table

Hiroshi KISHI†

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 15, 1980)

Polyatomic negative ions for almost all of the elements in B-subgroups on the periodic table were tested by the spark discharge type ion source mass spectroscopy. Polyatomic negative ions such as hydride negative ions, oxide negative ions, and carbide negative ions could be detected. The results are discussed with reference to the reported results by other methods of formation.

A study on negative ion spark source mass spectroscopy has been carried out using a Mattauch-Herzog type double focusing mass spectrograph. Formation of atomic negative ions of 48 elements,[2] relative sensitivity coefficients for negative ions,[3] and polyatomic negative ions of the elements in A-subgroups on the periodic table[1] have already been reported.

In the previous report,[1] polyatomic negative ions of the elements in A-subgroups on the periodic table were described; these were formed by the spark discharge type ion source and were detected with use of the Mattauch-Herzog type double focusing mass spectrograph. They were classified into five types: (1) "polymer" negative ions, (2) hydride negative ions, (3) oxide negative ions, (4) carbide negative ions and (5) other types of negative ions. The results were discussed with reference to the reported values of electron affinities and to the other methods of formation.

In the present report, polyatomic negative ions of the elements in B-subgroups on the periodic table which can be detected experimentally by a spark discharge type ion source are described, along with the polyatomic positive ions. Sample materials used were: (1) elementary materials in the form of solid metals or powdered metals, (2) oxide compounds, (3) binary compounds such as ZnSe or CdS, (4) various metal alloys, and (5) other types of compounds, including almost all of the elements in B-subgroups (transition metal elements) on the periodic table, except for the element Tc.

The detected polyatomic negative ions are classified into three types: (1) hydride negative ions, (2) oxide negative ions, and (3) carbide negative ions. No "polymer" negative ions can be detected for these elements in this experiment, in contrast to the case of the elements in A-subgroups (typical elements), in which many "polymer" negative ions were detected.[1]

Although there are fewer examples in the literature that describe the formation of polyatomic negative ions of the elements of B-subgroups by various methods of formation, as compared with the case of A-subgroups, the results obtained here are compared with such reports as do exist.

Few electron affinity values for the molecules containing transition metal elements are also available in the literature,[4,5] except for those of the molecular ions WO_3^-,[6] HWO_4^-,[6] and PtN^-.[7] This is just the opposite situation to the case of the molecular ions of the A-subgroups (typical elements), in which many examples of determination of the values of the electron affinities are reported. For example, experimental techniques for determining the electron affinity values include the following: photodetachment,[8,9] spectroscopy,[10] photoelectron spectroscopy,[11] photoionization,[12,13] charge exchange,[14] dissociative electron attachment,[15,16] thermochemistry,[17] surface ionization,[18,19] and electron impact.[20,21] Empirical techniques applied to the electron affinity values of molecular ions is the method of isoelectronic model (NO^- [22]).

Few theoretical calculations of the electron affinity values for the molecules containing transition metal elements are in the literature, though some for molecular ions containing the typical elements are reported.[4,5] Methods include variational calculation,[23] Hartree-Fock calculation,[24] configuration interactions,[25] and Rydberg-Klein-Rees calculations.[26]

The experimental results given here are thus considered to be very valuable from the standpoint of the study of electron affinity values for the molecular ions of the transition metal elements. They give experimental evidence that the molecular ions detected here have the positive electron affinity values. The results are also very valuable in the interpretation of negative ion mass spectra formed by the spark discharge type ion source.

Experimental

Apparatus. The instrument used was a Mattauch-Herzog type double focusing mass spectrograph equipped with an r. f. spark discharge type ion source (Mitsubishi Denki Electric Co., Ltd.). Since details of the instrumentation were reported elsewhere,[27-29] only the operationing conditions are given here: spark voltage 20 kV, pulse width 200 μs, repetition rate 100 s^{-1}, ion accelerating voltage 15 kV for both positive and negative ions.

Materials. Sample materials studied are (1) elementary materials in the form of solid metals or powdered metals, (2) oxide compounds, (3) binary compounds such as ZnSe or CdS, (4) various metal alloys, (5) other types of compounds. They are listed in Table 1.

Experimental procedures for measuring mass spectra o negative ions for these sample materials, and the method and procedure for the assignment of the mass spectral peaks obtained, are essentially the same as described in the previous report.[1,2]

† Present address: Oyama Technical College, Nakakuki, Oyama, Tochigi 323.

TABLE 1. SAMPLE MATERIALS FOR THE POLYATOMIC NEGATIVE IONS

Group	Element	Sample materials
IB	Cu	Copper metal
		Copper alloy
	Ag	Silver metal
		Silver alloy
		Silver(I) oxide, Powder
		Silver bromide, Powder
	Au	Gold metal
		Gold, powder
		Gold alloy
IIB	Zn	Zinc(II) selenide
		Zinc(II) oxide, Powder
	Cd	Cadmium(II) telluride, Crystal
		Cadmium(II) sulfide, Crystal
		Cadmium(II) oxide, Powder
	Hg	Mercury(I) chloride, Powder
		Mercury(II) oxide, Powder
IIIB	Sc	Scandium metal
		Scandium(III) oxide, Powder
	Y	Yttrium metal
		Yttrium(III) oxide, Powder
	La	Lanthanum metal
		Lanthanum(III) oxide, Powder
		Monazite
IVB	Ti	Titanium metal
		Titanium(IV) oxide, Powder
	Zr	Zirconium metal
		Zirconium (IV) oxide, Powder
		Monazite
	Hf	Hafnium metal
VB	V	Vanadium metal
		Vanadium(V) oxide, Powder
	Nb	Niobium metal
		Niobium(V) oxide, Powder
	Ta	Tantalum metal
		Tatalum(V) oxide, Powder
VIB	Cr	Chromium metal
		Chromium(III) oxide, Powder
	Mo	Molybdenum metal
		Ammonium molybdate, Powder
	W	Tungsten metal
		Tungsten(VI) oxide, Powder
VIB	Mn	Manganese metal
		Manganese(II) carbonate
	Re	Rhenium, Filament
		Rhenium, Powder
VIII	Fe	Iron metal
		Iron alloy
		Iron(III) oxide, Powder
		Meteorite
	Co	Cobalt alloy
		Meteorite
	Ni	Nickel metal
		Nickel alloy
		Meteorite
	Ru	Ruthenium, Powder
	Rh	Rhodium, Powder
		Rhodium-platinum alloy
	Pd	Palladium metal
		Palladium alloy
	Os	Osmium, Powder
	Ir	Iridium, Powder
	Pt	Platinum metal
		Platinum alloy

Results and Discussion

Experimental results for the polyatomic negative ions are tabulated in Table 2, along with the experimental results for atomic negative ions[2] and for polyatomic positive ions which were detected in the positive ion spark source mass spectra using the same samples.

Group IB Elements. In this group, for the elements Cu, the oxide ion CuO^- and the carbide ions CuC^- and CuC_2^- are detected. For the element Ag, the carbide negative ion AgC^-; for the element Au, oxide negative ions AuO^- and AuO_2^-, and carbide negative ions AuC^-, AuC_2^-, AuC_3^-, and AuC_4^- are detected. The positive ion Ag_2^+ is detected.

In the literature,[30] Cu^+—Cu_5^+ ions were detected by spark source mass spectroscopy. NO electron affinity values for the molecules that are detected in this experiment are available in the literature.

Group IIB Elements. For all of the elements in this group, no polyatomic negative or positive ions are detected by the experiment. Spark electrodes in this experiment were ZnSe(crystal)/Pt, or ZnO(powder)/Pt, Zn-alloy/Pt; CdS(crystal)/Pt, CdTe(crystal)/Pt, CdO(powder)/Pt; Hg_2Cl_2(powder)/Pt, HgO(powder)/Pt.

In the literature,[31] CdO^-, CdO_3^-, CdO_6^-, and CdO_7^- ions are reported to form by surface ionization. No electron affinity values are available for the molecules in this group.

Group IIIB Elements. In this group, negative ions of YO^-, LaO^-, LaO_2^-, LaO_3^-, $LaOH_2^-$, and $LaO_2H_2^-$ are detected. Positive ions of YO^+, YOH_3^+, and LaO^+ are also detected. When the pure metals of Y/Y and La/La electrodes are used as sample materials, these ions are detected. The oxygen and hydrogen atoms in these detected ions may derive from the contamination on the electrodes or from the background gas molecules. Carbide negative ions for these elements can not be detected. There are no reports on polyatomic negative ions or electron affinity values

Table 2. Polyatomic negative ions and positive ions

Group	Element	Atomic	Polyatomic negative ions	Polyatomic positive ions
IB	Cu	D[a]	CuO^-; CuC^-, CuC_2^-

	Pd	D	PdH^-	
	Pt	D	PtO^-, PtO_2^-; PtC^-—PtC_4^-; PtH^-; $PtCH^-$—PtC_3H^-	

a) Detected. b) Not detected.

of these elements.

Group IVB Elements. In this group, ZrO^- and ZrO^+ are detected by this experiment, For the elements Ti and Hf, no polyatomic negative and positive ions are detected.

In the literature,[30] Ti^+—Ti_5^+ ions were reported to form by the spark discharge ion source. No electron affinity values are available in the literature.

Group VB Elements. For the element Nb, we detected in the Nb/Pt spark discharge oxide negative ions, NbO^-, NbO_2^-, and NbO_3^-; hydride oxide negative ions NbO_2H^- and NbO_3H^-; and carbide ions NbC^-, and NbC_2^-. For the elements V and Ta, no atomic or polyatomic negative ions are detected. The positive ions TaO^+, TaO_2^+, and TaO_3^+ ions are detected.

There are no reports on the polyatomic negative ions for these elements and their electron affinity values.

Group VIB Elements. For the element Cr, oxide negative ions CrO^-, CrO_2^-, and CrO_3^- are detected by Cr/Cr spark discharge, for Mo, we detected oxide negative ions MoO^-, MoO_2^-, MoO_3^-, and MoO_4^-; hydride oxide negative ions $MoOH^-$, MoO_2H^-, and MoO_3H^-; carbide negative ions MoC^-, MoC_2^-, MoC_3^-, and MoC_4^-; and hydride negative ions MoH^- by Mo/Mo spark discharge. For the element W, oxide negative ions WO^-, WO_2^-, WO_3^-, and WO_4^- and carbide negative ions WC^-, WC_2^-, WC_3^- are detected by W/W spark discharge. No polyatomic positive ions for these elements are detected.

Table 3. Hydride negative ions

Group	VIB	VIII		
Element	Mo	Rh	Pd	Pt
M^-	D	D	D	D
MH^-	D	D	D	D

The literature reports detection of WO_6^- and WO_8^- ions by surface ionization,[31] and WO^+, WO_2^+, and WO_3^+ ions by the reaction of incandescent W-filament with oxygen gas followed by the electron-impact.[32] Electron affinity values for the molecular ions WO_3^- and HWO_4^- are reported to be 3.6 eV and 4.4 eV respectively from a thermochemical measurement,[6] but HWO_4^- ion could not be detected in this experiment.

Group VIIB Elements. For this group, no atomic or polyatomic negative ions are detected, nor are any

positive polyatomic ions.

In the literature,[31] ReO_2^- and ReO_4^- ions were reported to form by surface ionization. No electron affinity values are available here.

Group VIII Elements. For the element Rh, hydride RhH^-, oxide RhO^-, and carbide negative ions RhC^- and RhC_2^- are detected by Pt–Rh/Pt–Rh spark discharge. For Pd, the hydride negative ion PdH^- is detected by Pd/Pd spark discharge. For the element Pt, we detected hydride negative ion PtH^-, oxide negative ions PtO^- and PtO_2^-, carbide negative ions PtC^-, PtC_2^-, PtC_3^-, and PtC_4^-; and carbide hydride negative ions $PtCH^-$, PtC_2H^-, and PtC_3H^-, by Pt/Pt spark discharge. For the other elements in this group, no polyatomic negative or positive ions are detected.

Fe_2^+—Fe_6^+ ions were detected by spark discharge.[30] The electron affinity value for PtN^- ion was reported to be >0 eV.[7]

In summary, we described the ionic species of polyatomic negative ions for the elements in B-subgroups on the periodic table, in addition to the polyatomic positive ions which are detected in this experiment. The polyatomic negative ions described here are classified into the following three types: (1) hydride negative ions, (2) oxide negative ions, and (3) carbide negative ions. They are tabulated in Tables 3, 4, and 5. Polyatomic positive ions are classified into (1) "polymer" positive ions, and (2) hydride positive ions. They are shown in Tables 6 and 7. From these tables, the following features are observed concerning the formation of polyatomic negative and positive ions by the spark discharge type ion source in the elements of B-subgroups on the periodic table.

(1) No polyatomic negative ions can be detected for the elements in which atomic negative ions can not be detected. (Zn, Cd, Hg, Sc, Ti, V, Ta, Re).

(2) No "polymer" negative ions can be detected for the elements of the B-subgroups, in contrast to the case of the elements of A-subgroups, in which many "polymer" negative and positive ions are detected. The only "polymer" positive ion detected in an element of B-subgroup is Ag_2^+.

(3) Hydride negative ions can be detected for the elements Mo, Rh, Pd, and Pt. No hydride positive ion can be detected.

(4) Oxide negative ions are detected in a large number of the ionic species, than in the case of the elements of A-subgroups.[1] Oxide positive ions are detected for the elements Y, La, Zr, and Ta.

(5) Carbide negative ions are also detected in a large number of ionic species than in the elements of A-subgroups.[1] No carbide positive ions can be detected in the elements of B-subgroups.

The electron affinity values for the molecular ions detected here are not available in the literature, except for the molecular ion of WO_3^- (3.6 eV[6]). Therefore, the comparison between the experimental results given here and the reported values of electron affinities is impossible. However, in the case of atomic negative ions,[2] and in the polyatomic negative ions of the elements of A-subgroups,[1] there were no exceptions to the assumption that the ionic species detected in these experiments had positive electron affinity

values in the literature. If this assumption is correct also in the case of the polyatomic negative ions of the elements of B-subgroups on the periodic table, the results presented here give experimental evidence that the ionic species described in this report have positive electron affinity values.

The author would like to express his hearty thanks to Dr. K. Kodera and Dr. T. Makita, of Kyoto University, for their encouragement and helpful suggestions throughout this work.

Preparation and Properties of Monoalkylnickel(II) Complexes Having a Phenoxo, Benzenethiolato, Oximato, β-Diketonato, or Halo Ligand

Takakazu YAMAMOTO,* Teiji KOHARA, and Akio YAMAMOTO
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received January 22, 1981)

Thirteen complexes of a type $NiR(Y)L_n$ (R=CH_3 (Me), C_2H_5 (Et); Y=OC_6H_5, *p*-cyanophenoxo, *p*-phenylphenoxo, 8-quinolinolato, OCOEt, OCOPh, acetophenone oximato, acetylacetonato, benzoylacetonato, Cl; L=triethylphosphine (PEt_3), 2,2′-bipyridine (bpy)) have been prepared by reactions of dialkylnickel(II) complexes NiR_2L_2 (**1**) with the corresponding active hydrogen compounds HY. Reactions of **1** with R′COY (Y=OC_6H_5, $OCOC_6H_5$, Cl) also afford the $NiR(Y)L_n$ type complexes with formation of unsymmetrical ketones RCOR′. Reactions of **1** with alcohols lead to dehydrogenation of alcohols to afford aldehydes or ketones. The $NiR(Y)L_n$ type complexes have been characterized by elemental analysis and spectroscopies (IR, NMR, visible). NMR spectra of *trans*-NiMe(OCOPh)(PEt_3)$_2$, NiMe(acetophenone oximato)(PEt_3) (**11**), NiMe(benzoylacetonato)(PEt_3) show temperature dependence, indicating occurrence of rapid dynamic reactions on NMR time scale in these complexes. The acetophenone oximato ligand in **11** is proposed to serve as an oxa-, aza-π-allylic ligand on the bases of IR and NMR spectroscopies. NiEt($OCOC_2H_5$)(bpy) (**8**), NiEt($OCOC_6H_5$)(bpy), and NiEt(Cl)(bpy) (**14**) undergo disproportionation reaction to give $NiEt_2$(bpy) and NiY_2(bpy) type complexes. Diethyl ketone is also produced during the disproportionation of **8**. Reactions of **14** with olefins having electron-withdrawing substituents afford $NiCl_2$(bpy) and Ni(olefin)$_2$(bpy).

Nickel complexes of a type $NiR(Y)L_n$, where R is an alkyl, alkenyl, or aryl group and Y is an anionic ligand such as Cl, OPh, or NR^1R^2, are often assumed as key intermediates in various Ni-catalyzed reactions such as isomerization of olefin and polymerization or oligomerization of olefins and dienes.[1-4] However, only a few papers[5-7] have reported on the isolation and chemical properties of the $NiR(Y)L_n$ type complexes except for monoaryl(halo)nickel(II) complexes such as Ni(aryl)X(PR_3)$_2$[8,9] and Ni(aryl)X(bpy).[10]

In our preceding paper[11] we reported preparation of monoalkyl(amido)nickel(II) complexes, $NiR(NR^1R^2)L_2$, by reactions of dialkylnickel(II) complexes, NiR_2L_2, with corresponding N–H compounds. As an extention of the work we have carried out reactions of NiR_2L_2 with phenols, alcohols, benzenethiol, carboxylic acids, oximes, β-diketones, and hydrogen halides and isolated several new $NiR(Y)L_n$ type complexes from the reaction mixtures. This paper deals with the preparation and chemical properties of the complexes. In some cases the $NiR(Y)L_n$ type complexes can be prepared also by reactions of NiR_2L_2 with carbonyl compounds such as CH_3COCl, $CH_3COOC_6H_5$, and $(C_6H_5CO)_2O$, and the results are included in this paper.

Results and Discussion

Preparation of NiR(Y)L$_n$. Reactions of NiR$_2$L$_2$ with Active Hydrogen Compounds HY: Dialkylnickel(II) complexes, NiR_2L_2, react with equimolar amounts of active hydrogen compounds to give monoalkylnickel(II) complexes of the type $NiR(Y)L_n$:

$$NiR_2L_2 + HY \longrightarrow NiR(Y)L_n + RH \quad (1)$$

a) At room temperature. Reaction time: *ca.* 10 min for Runs 1—3, 1 d for Runs 4 and 5.

Preparation of $NiEt(OC_6H_5)(bpy)$ and $NiMe(OC_6H_5)$-(dpe) (dpe=1,2-bis(diphenylphosphino)ethane) by a similar method has been reported.[5,6)]

The reactions proceed more rapidly than the reactions of NiR_2L_2 with N–H compounds[11)] due to the higher acidity of the HY compounds than the N–H compounds. Addition of an excess HY afforded the same product as in the 1:1 reactions when the acidity of the HY was not so high (*e.g.*, phenols and benzenethiol), whereas addition of an excess of a highly acidic HY (carboxylic acids and HCl) led to a further reaction to give NiY_2L_2.

Table 1 shows preparative conditions, yield, melting points and analytical data of the complexes **2**—**14**. Coordination of two PEt_3 to Ni in the phenoxo complex **5** indicates that the phenoxo group bonds to Ni through oxygen serving as a monodentate ligand, although it sometimes coordinates to transition metal through the aromatic ring.[12)] The SC_6H_5 group in **7** also seems to coordinate to Ni through sulfur. The coordination of only one PEt_3 ligand to Ni in **6** and **11** suggests that the 8-quinolinolato and acetophenone oximato ligands serve as 3-electron ligands. As for the 8-quinolinolato ligand it is reasonable to assume intramolecular coordination of nitrogen to nickel to form a stable 5-membered chelate ring as observed in many such known complexes. As for the acetophenone oximato ligand we propose that it serves as an oxa-, aza-π-allylic ligand in the mononuclear (for Mw, see Table 1) complex **11**, whose IR and NMR data are consistent with the π-allylic coordinating mode of the acetophenone oximato ligand (*vide infra*). A THF solution of **14** shows only a minor electric conductivity indicating that the complex does not have an ionic structure. $NiMe(OC_6H_5)(PEt_3)_2$ **15** and NiEt-(Br)(bpy) **16** were also obtained by similar reactions as expressed by Eq. 1. However, isolation of analytically pure samples was not feasible due to instability in solutions (for **15**) or lack of a suitable solvent for recrystallization (for **16**).

In contrast to the reactions of phenols, reactions of alcohols with NiR_2L_2 do not give monoalkylnickel-(II) complexes but they lead to dehydrogenation of alcohols to yield aldehydes or ketones as shown in Table 2. The reaction most probably proceeds through abstraction of β-hydrogen by R group in an intermediate species formulated as $NiR(alkoxo)L_2$:

$$NiR_2L_2 + R^1R^2CHOH \xrightarrow{-RH} \left[L_2Ni\begin{matrix}OCHR^1R^2\\ \diagdown\\ R\end{matrix}\right] \quad \textbf{17}$$

$$\longrightarrow \begin{matrix}R^1\\ \diagdown\\ R^2\end{matrix}\!\!>C{=}O + RH. \qquad (2)$$

Among the reactions examined, treatment of **1c** with *i*-C_3H_7OH (No. 4 in Table 2) gave quantitative yields of methane and acetone. The other reactions may follow the similar course but they were not pursued further.

Reactions of NiR_2L_2 with Organic Acyl Compounds R'COY: The monoalkylnickel(II) complexes, NiR-(Y)L_2, can be prepared also by reactions of NiR_2L_2 with organic acyl compounds with simultaneous formation of unsymmetrical ketone.

$$NiR_2L_2 + R'COY \longrightarrow NiR(Y)L_n + RCOR' \qquad (3)$$

R'COY: phenyl carboxylate (Y=OC_6H_5)
carboxylic anhydride (Y=OCOR')
acyl chloride (Y=Cl)

The results suggest a four-centered mechanism,

$$NiR_2L_2 + R'COY \longrightarrow \begin{matrix}O\\ \|\\ \overset{\delta-}{Y}-\overset{\delta+}{C}-R'\\ \vdots\quad\vdots\\ L_2\overset{\delta+}{Ni}-\overset{\delta-}{R}\\ |\\ R\end{matrix} \longrightarrow NiR(Y)L_2 + RCOR'. \qquad (4)$$

a) Strongest three peakes are given. The peak with * mark is assigned to ν(C=O). b) s=singlet, d=doublet, t=triplet, q=quartet, qui=quintet, m=multiplet, br=broad. c) From external H_3PO_4 (downfield positive). Measured at r.t. in C_6D_6. d) In CD_2Cl_2 at r.t. e) In C_6D_6 at r.t. f) In acetone-d_6 at −60 °C. g) In pyridine-d_5 at r.t. ^{1}H-NMR spectrum of **11** in acetone-d_6 at r.t. shows almost the same pattern as that in pyridine-d_5. h) In pyridine-d_5 at 86 °C. i) Two signals are overlapped with each other. j) Good spectrum was not obtained due to instability of the complex in solutions (see text). k) IR spectrum was not taken due to the low melting point and high sensitivity of **12** to air.

Preparation of the $NiR(Y)L_n$ type complex by the method expressed by Eq. 3 has no precedent.

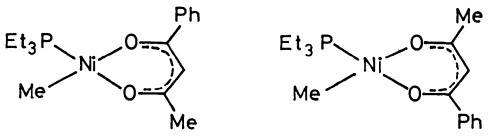
Characterization of the Complexes by Means of Spectroscopy. IR, NMR, and visible spectroscopic data are summarized in Table 4.

IR Spectra: All of the IR spectra of the complexes are consistent with the formulation of the complexes given in Table 1, showing bands due to R, Y, and L ligands. IR spectra of the bpy-coordinated compounds show δ(C–H) bands of bpy at 750—780 cm^{-1}, and those of the PEt_3-coordinated complexes do strong ν(C–H) bands of the PEt_3 ligand in a region of 2850—3000 cm^{-1}. IR spectra of the phenoxo type complexes **2**—**6** shows strong ν(C–O) at about 1300 cm^{-1} characteristic of transition metal phenoxides. ν(C≡N) bands of **3** and **4** are observed at about 2200 cm^{-1}.

The benzoato complexes **9** and **10** give rise to ν(C=O) bands in a region where the ν(C=O)| bands of unidentate carboxylato complexes appear.[13] The ν(C=O) band of the propionato complex **8** appears at a somewhat lower frequency, suggesting the presence of some interaction between Ni and the carbonyl oxygen of the propionato ligand. The benzoylacetonato complex **13** shows ν(C=O) band at 1565 cm^{-1}, indicating the formation of an *O,O'*-bonded six-membered chelate ring.[13] The IR spectrum of the oximato complex shows no ν(O–H) band, excluding the possibility that the oxime bonds to nickel as a neutral base through nitrogen[14] or as a chelating ligand through *ortho*-metalated carbon of the aromatic ring and nitrogen.[15]

NMR Spectra: In ^{1}H-NMR spectra of the methylnickel complexes **2**, **3**, **5**—**7**, and **10**—**13** the CH_3 signals are observed at normal regions where CH_3 signals of methylnickel(II) complexes are expected.[1,11] Similarly to ^{1}H-NMR spectra of the monoethyl(amido)nickel complexes the ^{1}H-NMR spectra of **4**, **9**, and **14** show CH_2 signals of the ethyl ligand at lower field than CH_3 signals, indicating the electronegativity of nickel is increased through replacement of one of the Et ligands of **1b** by the electron-withdrawing Y ligand.[11]

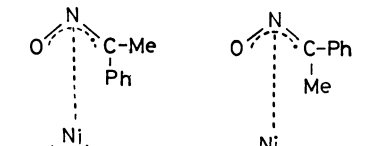
Coupling patterns of the Ni–CH_3 signals of $NiMe(Y)(PEt_3)_n$ also reflect the increase in the electronegativity of nickel through the replacement of one of the two Me ligands of **1c**, whose ^{1}H-NMR shows no coupling between ^{31}P of PEt_3 and ^{1}H of CH_3 even at −60 °C due to a rapid exchange reaction between the coordinated PEt_3 and free PEt_3 in solution partly liberated from **1c**. Similarly to the ^{1}H-NMR spectra of the complexes of the type $NiMe(amido)(PEt_3)_2$,[11] the ^{1}H-NMR spectra of **5**, **7**, **11**, and **12** at room temperature clearly show the coupling between ^{1}H of the CH_3 ligand and ^{31}P of the PEt_3 ligand, indicating that the Ni–PEt_3 bonding becomes stronger due to the increase in the electronegativity of Ni through the replacement of the Et ligand by the Y ligand. In contrast to the ^{1}H-NMR spectra of **5**, **7**, **11**, and **12**, the ^{1}H-NMR spectra of **6**, **10**, and **13** do not show the ^{1}H–^{31}P coupling at room temperature. In the case of **6** the weak bonding between Ni and PEt_3 is attributable to an increase in the basicity of Ni through the intramolecular coordination of N of the 8-quinolinolato ligand. The CPK molecular model shows steric repulsion between the OCOPh ligand and PEt_3 ligands in **10**, accounting for the rapid dissociation of PEt_3 from **10** on NMR time scale. In the case of the benzoylacetonato complex **13**, however, the molecular model shows no special steric repulsion between the Ph group of the bzac ligand and PEt_3, and therefore the difference in the dynamic behavior of the PEt_3 ligand between **12** and **13** at room temperature seems to be attributable to a difference in an electronic effect between the acac and bzac ligands. In cases of **10** and **13** the rapid exchange of the PEt_3 ligand is frozen on lowering the temperature to −60 °C where the NMR spectra show the ^{31}P–^{1}H coupling. The NMR spectrum of **13** at −60 °C reveals that **13** is composed of a 1:1 mixture of the following isomers



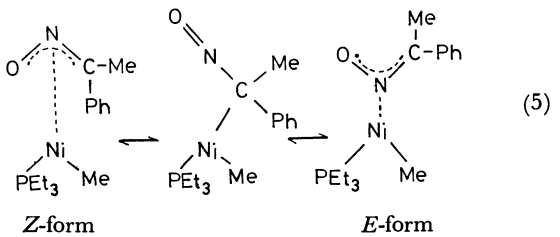
13a **13b**

at the temperature. The exchange of the PEt_3 ligand in **6** is not frozen even at −60 °C.

The ^{1}H-NMR spectrum of **11** at room temperature shows two sets of signals with a peak area ratio of 1.2:1.8, suggesting that there exist the following two stereoisomers in the solution,[16] The fairly large difference in chemical shifts of the Ni–CH_3 signal between the two steroisomers may be due to a large difference in the anisotropic magnetic effect of the phenyl ring of the oxa, aza-π-allyl ligand. On raising temperature to 86 °C, the ^{1}H-NMR spectrum shows averaged somewhat broad signals, demonstrating occurrence of a rapid exchange reaction between the two stereoisomers. Such a dynamic exchange reaction is often observed for nickel π-allyl complexes[1,17] and the following exchange process involving formation of an 1-nitrosoalkylnickel intermediate is suggested for the present complex,



Z-form *E*-form



(5)

Z-form *E*-form

Visible Spectra: Similarly to visible spectra of NiR(imido)(bpy) type complexes,[11] those of **2**, **3**, **4**, **9**, and **14** show Ni→bpy CT bands at about 500 nm ($\varepsilon = 3 \times 10^3$), which are shifted to shorter wavelength by about 150 nm from the position of Ni→bpy CT

bands of $NiR_2(bpy)$,[18] demonstrating that the highest occupied level of Ni is lowered by the replacement of the R ligand by the Y ligand.

Chemical Properties. Thermolysis, Acidolysis, and Degradation in Air: Although complexes **2**—**14** have higher thermal stabilities than the original dialkylnickel complexes, their thermal stabilities are not so high as the $NiR(NR^1R^2)L_n$ type complexes[11] presumably due to lower stability of the Ni–Y bond than the Ni–NR^1R^2 bond against the thermolysis. The ethyl complex evolves a *ca.* 1:1 mixture of C_2H_4 and C_2H_6 on the thermolysis, and the methyl complex does a mixture of CH_4 and C_2H_6, the CH_4/C_2H_6 ratio varying from *ca.* 2.0 to 0.5 depending on the complex. Acidolysis of $NiR(Y)L_n$ by HCl gives RH and HY (Y=OC_6H_5, OCOR) with formation of $NiCl_2L_n$. The complexes with bpy have moderate stabilities to air in solid, whereas those with PEt_3 are very sensitive to air even in the solid state. All of the complexes are very sensitive to air in solutions. On exposure of an ethereal solution of **14** to air C_2H_4 (0.2 mol/Ni) was evolved exclusively as a gaseous product, suggesting β-hydrogen elimination promoted by oxygen.

Disproportionation: On standing a THF solution of **14** at room temperature the color gradually changes from purple to deep green with eventual formation of a light green precipitate of $NiCl_2(bpy)$, indicating that a disproportionation reaction proceeds in the solution,

$$\underset{\text{purple}}{2\,NiEt(Cl)(bpy)} \longrightarrow \underset{\text{deep green}}{NiCl_2(bpy)} + \mathbf{1b}. \qquad (6)$$

The disproportionation reaction is greatly accelerated by adding π-acids such as acrylonitrile and maleic anhydride, although in these cases the products are $NiCl_2(bpy)$, butane, ethane, ethylene, and $Ni(\pi\text{-acid})_n(bpy)$ (n=1 or 2), since **1b** once formed reacts with the π-acid to afford $Ni(\pi\text{-acid})_n(bpy)$ with evolution of a gas mainly composed of butane.[18] The carboxylato complexes **8** and **9** also undergo similar disproportionation reactions to give Ni(carboxylato)$_2$(bpy) and **1b**. In the case of **8** formation of diethyl ketone (*ca.* 50%/Ni) takes place besides the disproportionation reaction, the result suggesting occurrence of a coupling reaction between the COR group in the OCOR ligand and the Et ligand.[19]

Reactions with Other Reagents: Complex **10** reacts with excess EtBr to afford PhCOOEt (0.73 mol/Ni). Acetylene is trimerized to benzene by **13** and aldehydes (CH_3CHO, C_2H_5CHO) are dimerized by **2** or **3**. A reaction between **14** and i-C_3H_7ONa affords acetone (0.72 mol/Ni) with evolution of C_2H_6. Acetone seems to be formed through a metathesis reaction between the two reactants to produce an intermediate ethyl(propoxo)nickel species **18** and β-hydrogen elimination from **18**.

$$\mathbf{14} + i\text{-}C_3H_7ONa \xrightarrow{-NaCl} \underset{\mathbf{18}}{\left[(bpy)Ni\begin{matrix}C_2H_5\\OC_3H_7\end{matrix}\right]} \longrightarrow \text{acetone} + C_2H_6 \qquad (7)$$

Experimental

General, Materials, Analysis, and Spectroscopic Measurements. Reactions, analysis, and spectroscopic measurements were carried out as reported in the preceding paper.[11] Complexes **1a**—**1c** were prepared according to literature.[18,20]

Preparation of Complexes. Phenoxo and Benzenethiolato Complexes 2—7 and 15 (cf. *Table 1*): THF (0.5 cm^3) containing 53 mg (0.57 mmol) of phenol was added to 140 mg (0.57 mmol) of **1a** and the mixture was stirred for 24 h at room temperature to obtain a purple solution. Hexane (10 cm^3) was added to the solution to obtain a purple solid, which was recrystallized from acetone to yield 160 mg (89%) of **2**. The other phenoxo and benzenethiolato complexes were prepared in similar ways under conditions shown in Table 1 (phenol:**1**=1:1). Solvents for recrystallization were actone for **3** and **4** and diethyl ether for **5**—**7**. A reaction between **1c** (150 mg, 0.47 mmol) and phenol (45 mg, 0.47 mmol) at room temperature in 1.4 cm^3 of benzene afforded **15**, whose NMR shows a Ni–CH_3 signal at δ −1.08 (3H, t, 8.5 Hz) and PEt_3 signals around δ 1 ppm (30H, m). However, isolation of the complex failed.

Carboxylato Complexes 8—10: Propionic acid (0.062 cm^3, 0.84 mmol) was added to a THF (10 cm^3) solution of **1b** (230 mg, 0.84 mmol) at −78 °C. The mixture was warmed to room temperature and stirring the solution at the temperature for 20 min gave 0.75 mmol of C_2H_6 and a deep red solution, which was condensed to 2 cm^3 to obtain a dark red solid of **8** (170 mg, 62%). Longer reaction time led to the disproportionation reaction (see text) and the complex obtained was not recrystallized due to the instabilities of **8** in solutions.

Toluene (5 cm^3) containing 180 mg (1.5 mmol) of benzoic acid was added to a toluene (20 cm^3) solution of **1b** (400 mg, 1.5 mmol) and the mixture was stirred at room temperature. The color of the solution instantly changed from deep green to purple. Hexane (10 cm^3) was added to the solution immediately after changing of the color to obtain a purple solid (430 mg, 80%). The disproportionation of **9** is not so fast as that of **8** and a sample for analysis could be obtained by recrystallization from acetone. Complex **10** was prepared analogously and crystallized from ether.

Acetophenone Oximato Complex 11: Diethyl ether (5 cm^3) was added to a mixture of **1c** (600 mg, 1.9 mmol) and acetophenone oxime (250 mg, 1.9 mmol) at −10 °C. Stirring the mixture for 10 min at room temperature led to formation of a yellow precipitate, which was recrystallized from THF to yield 450 mg (75%) of **11**.

β-Diketonato Complexes 12 and 13: Acetylacetone (0.042 cm^3, 0.41 mmol) was added to an ethereal solution of **1c** (130 mg, 0.41 mmol) and the mixture was stirred at room temperature for 24 h to obtain a brown solution. Cooling the solution to −78 °C gave yellowish brown crystals of **12** (74 mg, 45%). Complex **13** was prepared analogously.

Chloro Complex 14: Diethyl ether (19 cm^3) containing 3.4 mmol of dry HCl was added to a THF (20 cm^3) solution of **1b** (940 mg, 3.4 mmol). Color of the solution changed instantly from deep green to dark purple and then excess hexane was added to the solution to yield a dark purple precipitate, which was recrystallized from THF–hexane to yield 350 mg (36%) of **14**.

Reactions of Dialkylnickel(II) Complexes with R'COY (cf. *Table 3*). Propionyl chloride (0.46 cm^3, 5.3 mmol) was added to a THF (60 cm^3) solution of **1b** (1.4 g, 5.2 mmol). The color of the solution instantly changed from deep green to dark purple. Addition of hexane (50 cm^3) gave a yellow

precipitate (1.0 g, 68%) whose IR spectrum was identical to that of **14**. GLC analysis of the solution revealed formation of 4.2 mmol (80%) of diethyl ketone. A similar reaction between **1b** (200 mg, 0.74 mmol) and acetyl bromide (0.059 cm^3, 0.74 mmol) in toluene (10 cm^3) gave a purple powder of **16** (220 mg, 90%) with formation of ethyl methyl ketone (76%). IR spectrum of the purple powder showed almost a similar absorption pattern to that of **14** and the analytical data (Found: C, 42.1; H, 3.0; N, 8.2; Br, 24.6%. Calcd for: C, 44.5; H, 4.0; N, 8.7; Br, 24.7%) roughly agreed with the composition of NiEt(Br)(bpy). The reaction of dialkylnickel(II) complexes with $CH_3COOC_6H_5$ and $(C_6H_5CO)_2O$ were carried out analogously.

Reactions of Dialkylnickel(II) Complexes with Alcohol (cf. Table 2). Benzyl alcohol (0.073 cm^3, 0.71 mmol) was added to an ethereal (1 cm^3) solution of **1c** (110 mg, 0.35 mmol). Although no apparent change was observed after stirring the mixture for 12 h, GLC analysis and measurement of the amount of gas evolved with a Toepler pump showed formation of 0.40 mmol of CH_4 and 0.28 mmol of benzaldehyde. The other reactions listed in Table 2 were carried out analogously.

Disproportionation Reaction. A mixture of acrylonitrile (1.0 cm^3) and THF (1.5 cm^3) was added to **14** (140 mg, 0.51 mmol) to obtain a deep reddish purple homogeneous solution. A light green solid started to precipitate after stirring the mixture for 40 min at room temperature. After 1.5 h GLC analysis of the gas phase indicated evolution of 0.11 mmol of C_2H_4 and 0.03 mmol of n-C_4H_{10}.[21] On adding 20 ml of THF to the reaction mixture, the solid precipitated (54 mg, 37%) was separated by filtration and characterized as $NiCl_2$(bpy) by its IR spectrum.[18] The filtrate was condensed to 2 ml and then 20 ml of hexane was added to obtain 26 mg (19%) of a precipitate whose IR spectrum coincides with that of Ni(acrylonitrile)(bpy).[18]

Benzene (4 cm^3) was added to 140 mg (0.44 mmol) of **8** and the mixture was stirred for 20 h at 70 °C. GLC analysis of the solution showed formation of 0.20 mmol of diethyl ketone. A light yellow solid precipitated was $Ni(OCOC_2H_5)_2$(bpy) as proved by its IR spectrum.

16) It is also conceivable that the observation of the two sets of peaks is due to the presence of two stereoisomers according to the difference in a relative position of the oxa, aza-π-allylic ligand to the PEt_3 and Me ligands. However, the rotation of π-allylic ligands around metal–π-allyl bonds is generally a more rapid process compared with the *Z*-form-*E*-form isomerization,[1,17] and therefore in the text we ignore the isomerism according to the difference in a relative position of the π-allylic ligand.

Digitally Controlled Automatic Coulometric Karl Fischer Titrator

Kisaburo UMEMOTO

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received October 22, 1980)

An automatic coulometric Karl Fischer titrator capable of direct readout of the water titrated and the background of titration was constructed. Control of the generation of reagent was carried out by a digital counting method. The over- and under-titration was minimized by holding the level of reagent at the start and the end of titration as close as possible. Details of the circuit configuration were presented. The precision of determination was *ca.* ±2 μg and ±1—±2 μg for the automatic titration of 1 mg and 10—500 μg of water, respectively. Water of less than 20 μg was titrated within a precision of 1 μg by watching the drift and subsequent recovery of the blank level.

Karl Fischer determination of water is based on a reaction in which 1 mol of iodine is consumed in the titration of 1 mol of water in a methanolic solution of pyridine, sulfur dioxide and iodine. In the coulometric determination of water, iodine is generated by electrolysis and the amount of water is determined by measuring the quantity of the current consumed during titration, since 10.71 mC is required for each microgram of water.[1] At the end point of titration excess iodine is generated, which is detected by the depolarization of platinum indicator electrodes. The coulometric Karl Fischer titration was found to be suitable for the determination of a trace of water.[1–12] For the purpose to automate the titration, Kelly *et al.* designed an automatic cutoff attachment to a pH meter[2] but the current for compensating the background of titration was set manually. Hoyt constructed an automatic end point indicator[7] but no care was taken for compensation of the background of titration. Miyake and Sudo constructed an instrument capable of automatic control of the generation of iodine and also capable of automatic elimination of the blank,[12] but compensation of the background of titration was not performed. Recently, automatic coulometric Karl Fischer titrators capable of automatic compensation of the background of titration have appeared.[17,18] The electrolysis current of Mitsubishi Kasei Model CA-02 titrator is controlled to be proportional to the drift of the potential of the indicator electrodes, the titration being terminated when the electrolysis current substantially returns to the blank level. However, insufficient period of time for anticipation of the end point restricts the accuracy of determination of a micro amount of water, since the Karl Fischer reaction is not fast enough to assure the instant completion of reaction.[14–16] Hiranuma Sangyo Model AQ-3B titrator was constructed on the basis of constant current coulometry; near the end of titration the current is periodically interrupted with subsequent anticipation of the end point. In the method of anticipation of the end point, some overshoot at the end point is present since the end point is determined when the potential of the indicator electrodes lasts above the cutoff potential over a given anticipated period of time. No care has been taken for minimizing this type of over-titration except for restricting the generation of iodine near the end point. Moreover, in constant current coulometry, inaccuracy in the count of current was caused by the switching time delay in each on-off operation of the electrolysis current.[12]

The automatic coulometric Karl Fischer titrator presented in this paper was designed with the following improvements. (i) The electrolysis current is so adjusted that 100% current efficiency is guaranteed for any size of working electrode and concentration of the reagent. The current was measured by current-to-frequency conversion with subsequent counting for integration. (ii) The method of anticipation of end point is preferred in order to avoid the risk of under-titration since the Karl Fischer reaction is not instantaneous in spite of much improvement in the reagents.[13–16] Care was taken to minimize the overshoot at the end point not only by restricting the rate of generation of iodine near the end point but also by holding the potential of the indicator electrodes at the start and the end of titration as close as possible. (iii) With the use of digitally controlled counting method of the blank, the waving drift in the level of iodine during the standby state[12] is minimized by controlling the generation of iodine to one count for each detection of the blank. (iv) The background of titration is directly read out by integrating the level of the blank instead of compensating it. This method is more simple than the method of compensation since no extra precise control of the constant current power supply is required. (v) The blank level is directly read out so that micro amount of water can be accurately determined by watching the drift and the subsequent recovery of the blank level.

Apparatus

A block diagram of the instrument is shown in Fig. 1. The blank level is held prior to introduction of the sample in order to integrate it for counting the background of titration. After introduction of the sample, electrolysis is started by opening the gate of the transistor switching circuit. The electrolysis current is fed into the current measuring circuit and converted into the frequency of one count equivalent to one microgram of water, the count being read out on the display unit. The background counting circuit integrates the blank level until the end of titration is reached, the count being read out on another display unit. The monitoring circuit detects any excess or

deficiency of iodine, giving out "on" and "off" signals for controlling the electrolysis. The end point determining circuit detects the approach of end of titration; near the end point the amount of generating iodine is restricted by the controlling circuit. At the end point of titration, the controlling circuit starts to control the counting of the blank and holding of the blank level. During this standby state for subsequent titration, the blank level can be read out on the diplay unit with the operation of the selection switch. Details of the circuit configurations are given below, where all the TTL logic gates are composed of SN74LS series and the power supplies are regulated by the standard method.

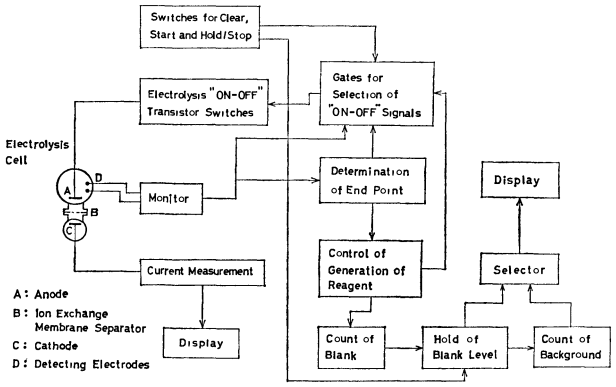

Fig. 1. Block diagram of the functional construction of the instrument.

Operation for Start, Hold/Stop, and Clear. The circuit is shown in Fig. 2. The whole circuit is reset by signal *a* from gate G_1; automatically by a delay circuit when power is switched on or manually by pushing spring switch S_1. When spring switch S_2 is pushed to "Hold/Stop" position, latch L_1 is reset to stop the electrolysis. This operation is performed prior to introduction of the sample. In order to start titration, switch S_2 is pushed to "Start" position, triggering timer T_1 to give a pulse *c* which resets the results of the previous titration. At the end of pulse *c*, latch L_1 is set to activate gate G_3 to start electrolysis. The electrolysis current power supply is adjustable in the range 5—25 V.

Monitoring Circuit. A potential difference of a few millivolts is given between the detecting electrodes (Fig. 2). When excess water is present in the cell, the cathode of the detecting electrodes is polarized, no current flowing. However, when iodine is in excess the cathode is depolarized and a small current flows, resulting in a voltage drop across a resistor of 1 kΩ. The voltage drop is fed into operational amplifier A_1. The noise involved in the voltage due to the turbulent mixing of the solution is substantially filtered off by placing a capacitor in the feedback loop of A_1. A_1 is balanced *ab initio* so that its output is nega-

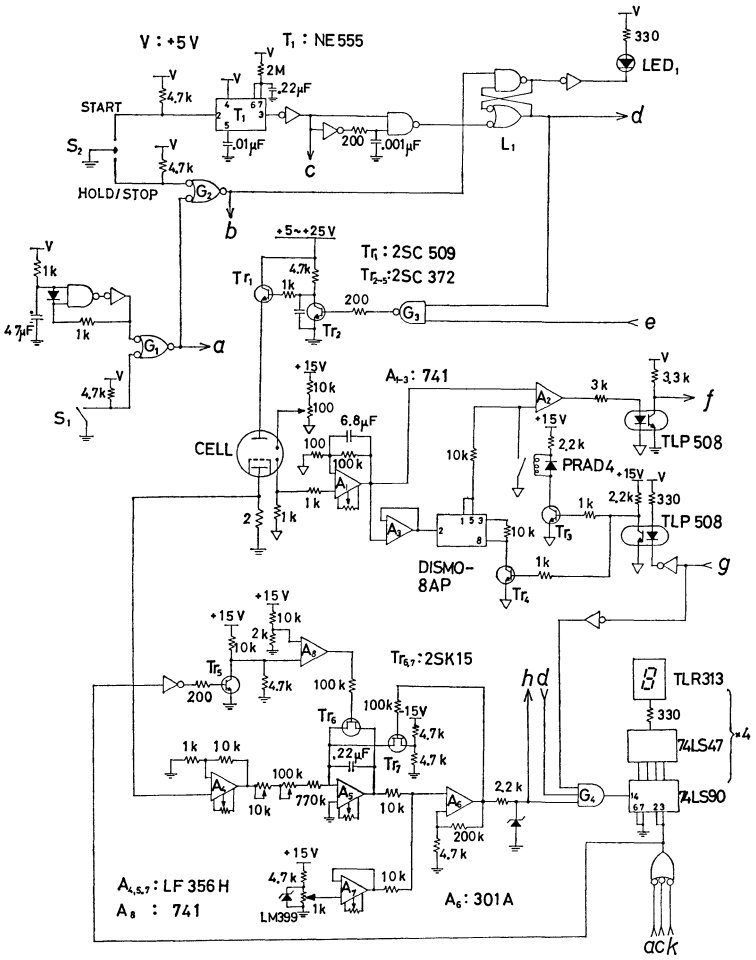

Fig. 2. Operational, monitoring, and current measuring circuits.

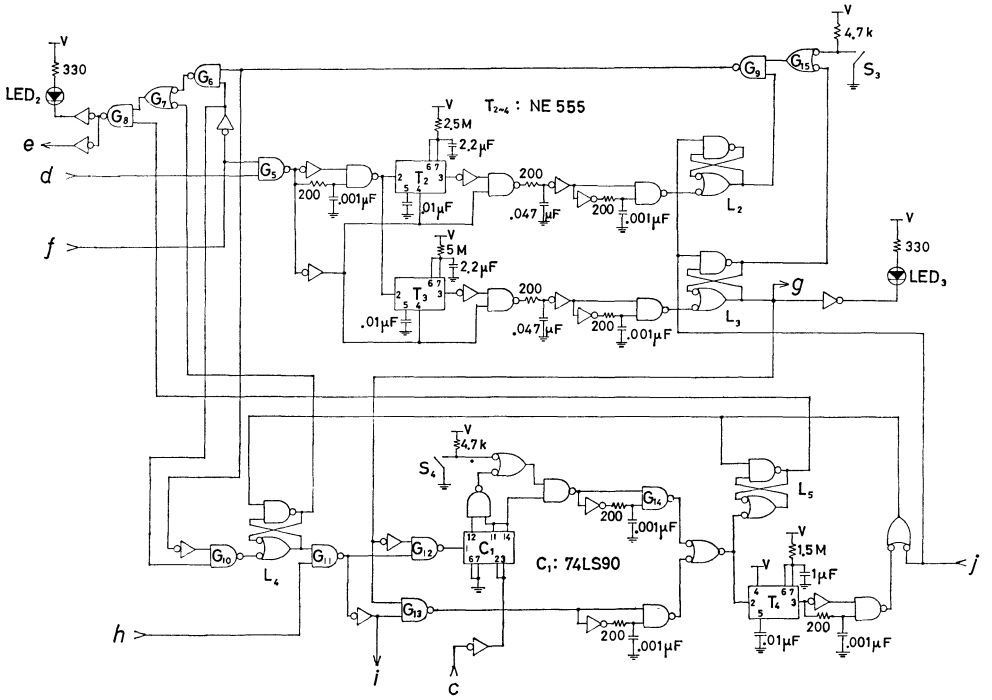

Fig. 3. End point determining and controlling circuits.

tive when excess water is present in the cell. The output of A_1 increases as the titration approaches the end point, turning to positive when excess iodine is detected. The output of A_1 is fed into comparator A_2 which is used as a zero cross detector during the course of titration. The output of A_2 is fed into a photocoupler whose output signal *f* controls the "on" or "off" of the electrolysis depending on whether iodine is deficient or excess in the cell. Isolation of the monitoring circuit is necessary for the electrolysis cell current not to flow into it. The monitoring circuit is operated with an isolated power supply.

The sample-hold circuit DISMO 8AP(Xebec) was used to minimize the overshoot at the end point. At the end point of each titration, the potential of the detecting electrodes was found to concentrate around a potential which is a little higher than zero, indicating that the amount of excess iodine present at the end point of titration is about the same for each titration. The overshoot at the end point is minimized by starting subsequent titration from this level of excess iodine to make the level of iodine at the start and the end of titration as close as possible. In order to maintain this level of excess iodine constant during the standby state, the cutoff potential of the monitoring circuit is switched from zero to a potential which is held by the sample-hold circuit DISMO 8AP at the end point of titration.

Current Measuring Circuit. The current through the cell is measured with a voltage drop across a high quality precision resistor of 2 Ω and converted into frequency with a V-F converting circuit (Fig. 2). High quality metal film resistors and a polycarbonate capacitor were used to ensure the accuracy and stability of this circuit. The time required for resetting the integrator was *ca.* 15 μs. The integrator was so adjusted that the V-F converter advances one count within an accuracy of 0.1% on flowing a current of 10.71 mC through the current measuring resistor and the amount of water titrated is directly read out in microgram unit. The output of the V-F converter is fed into the counter of the display unit *via* gate G_4 which is opened by the start signal *d* and closed by the end point signal *g* to register the result of the titration.

End Point Determining and Controlling Circuit. The end point determining circuit and the controlling circuit are shown in Fig. 3. At an early stage of titration, the signal *f* passes through gates G_6, G_7, and G_8, and controls the "on-off" of the electrolysis. On approaching the end point, the rate of generation of iodine exceeds that of consumption and the electrolysis stops temporarily. The excess iodine is soon consumed by the residual water, electrolysis starting again. This procedure is repeated, the interval of "on" being elongated with approach to the end point. Titration has been completed to 98—99% and to 100% when the electrolysis "off" continues for 8 and 20 s, respectively. Timers T_2 and T_3 are used to detect the approach or reach of the end point, each delay time being determined as 8 and 20 s, respectively. Both timers are triggered at the instant the signal *f* turns to "off" and reset when *f* turns to "on" before each delay time is over. When the electrolysis "off" begins to last over 8 s, latch L_2 is set and signal *f* is introduced into the controlling circuit *via* gate G_{10} so that the subsequent electrolysis is controlled at gates G_7 and G_8 by latches L_4 and L_5. When signal *f* turns to "on," L_4 is set to make the electrolysis "on," and the current counting pulse *h* is fed into the counter C_1 *via* gates G_{11} and G_{12}. The outputs of C_1 are wired into a scaler so that L_5 is set to stop the electrolysis at 5 or 10 counts advance depending on whether preset switch S_4 is open or closed. Timer T_4 is used

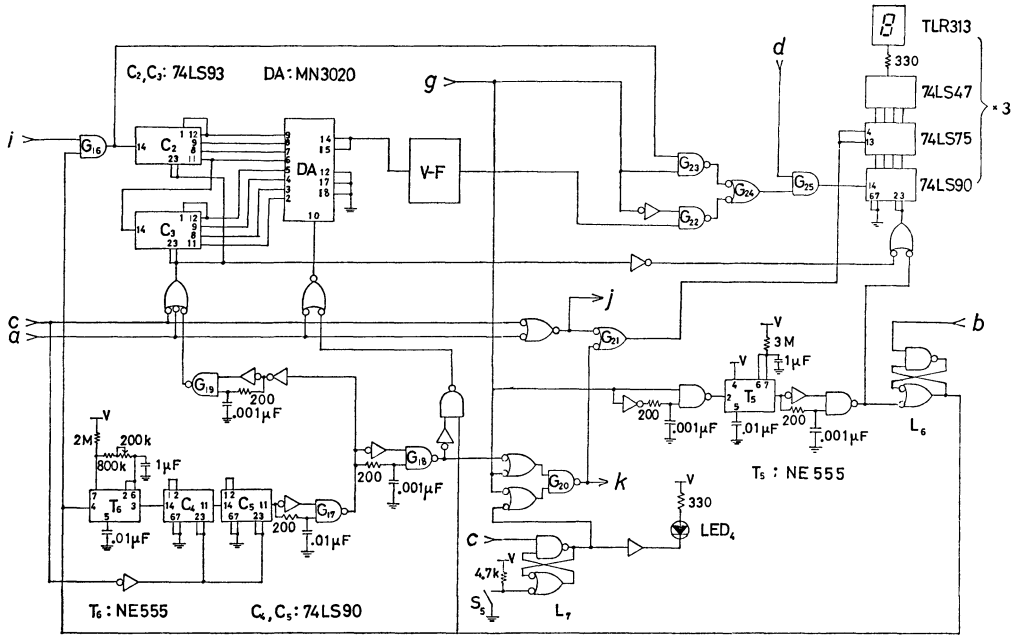

Fig. 4. Circuits for counting the blank, holding the blank level, and counting the background of the titration.

to provide a time delay of about 1.2 s before the reset of L_4 and L_5 to ensure the generated iodine to reach the detecting electrodes. Generation of a preset amount of iodine and subsequent waiting is repeated whenever the signal *f* turns to "on" until the end point of titration is reached. When the electrolysis "off" lasts over 20 s, latch L_3 is set to stop titration. With the signal *g*, gates for counting the electrolysis current and the background of titration are closed, DISMO being switched to "hold" mode and counting of the blank is started.

Circuits for Counting the Blank and Holding the Blank Level. The circuit for compensating the blank is shown in Fig. 3. The signal *g* closes gate G_{12} and opens gate G_{13} at the end of titration, the rate of generating iodine being restricted to one count whenever the blank is detected. The waving drift in the level of iodine[12] is minimized at most to one count during the standby state.

The blank level is defined as the number of blank for 30 s and determined by counting the blank current counting pulse *i* by a controlling method as shown in Fig. 4. The pulse *i* is fed into gate G_{16} which is activated at 5 s after the end of titration with latch L_6 and timer T_5. The delay is required for waiting for the cutoff operation of the monitoring circuit to settle at a voltage held by DISMO 8AP. When L_6 is set, G_{16} is opened for introducing *i* into counters C_2 and C_3, oscillator T_6 being activated simultaneously. T_6 is *ab initio* adjusted so that pulses with 30 s interval are obtained from G_{17}. From the leading and trailing edge of this pulse, non-overlapping pulses are obtained from gates G_{18} and G_{19}. The pulse from G_{18} registers the count of C_2 and C_3 into the D/A converter, and the pulse from G_{19} clears the counters. In this manner, the counters count the numbers of the blank and transfer it to the D/A converter before being cleared at every 30 s to hold the latest blank level.

In parallel with these operation, the blank is also counted with the BCD counters of the display unit. When the blank level is required to be displayed, spring switch S_5 is pushed to set latch L_7, which opens gate G_{20} so that the pulse from G_{18} is given to the shift registers as a strobe to show the blank level.

Circuit for Counting the Background of Titration. The background of titration is counted by integrating the blank level held just before the start of titration. The circuit for counting the background of titration is shown in Fig. 4. By pushing switch S_2 to "Hold/Stop" position (Fig. 2), latch L_6 is reset by signal *b* to make gate G_{16} and oscillator T_6 inactive so that the D/A converter continues to hold the last blank level until the end of titration is reached. The output of the D/A converter is fed into a V-F converter consisting of the same circuit configuration as that used in the electrolysis current measuring circuit. The time constant of the V-F converter is *ab initio* adjusted so that the counting rate coincides with the blank level. The output of the V-F converter is fed into BCD counters through gates G_{22}, G_{24}, and G_{25}. The shift registers of the display unit are kept active while titration proceeds, but made inactive by signal *g* to keep the counted background of titration on the display unit after the end of titration. The count of the background of titration is subtracted from the reading of the electrolysis current to obtain the net amount of water titrated.

Experimental

Aqualyte G (generator electrolyte) and aqualyte C (counter electrolyte) from Hiranuma Sangyo were used as Karl Fischer reagent. The water–methanol solution was prepared by diluting 247.0 mg of water with dehydrated methanol in a measuring flask of 25.00 ml calibrated by weighing pure

water. The density of pure water was taken into consideration for calibration. The water content in the methanol taken in the measuring flask was determined to be 0.440 mg/ml. The water content in the water–methanol solution was calculated to be 10.32 mg/ml. The solution was transferred into a sample bottle in a dry bag and sealed with a serum-type rubber stopper. The water–methanol solution was taken with a 100 μl(# 710) or 10 μl(# 701) Hamilton micro syringe which has an accuracy of 1% full scale. The titration vessel was a separable H-type cell with an assembly similar to that reported.[1,13]

Results and Discussion

In order to examine the effect of the rate of iodine generation, the voltage applied to electrolysis was changed in the range 5—25 V. The corresponding rate of iodine generation was 3—18 counts/s, for which the titration of a given amount of water gave an identical result. This indicates that the condition of 100% current efficiency is preserved in this range of applied voltage. The voltage for the routine use was adjusted to approximately 15 V in order to limit the rate of iodine generation to *ca.* 10 counts/s, sufficiently lower than the safety limit. Incomplete titration was avoided by confirming that the blank level returned to the original level at the end of titration.

Accuracy and precision of titration is affected by the stability of the blank level. If the blank level is not settled, error is caused in the counting of the background of titration. When a fine porosity glass filter was used as a separator of the two compartments of the titration vessel, the blank level was high and unstable. The blank level increases after each titration unless the level of the counter electrolyte is kept lower than that of the generating electrolyte. This indicates that use of this type of separator is restricted by the leakage of counter electrolyte. When an ion-exchange membrane[12] was used as separator, the blank level was kept low and stable. The following determinations were carried out with an ion-exchange membrane as separator.

The results of titration of the standard water-methanol solution are given in Table 1. The precision was *ca.* ±2 μg and ±1—±2 μg for automatic titration of 1 mg and 10—500 μg of water, respectively. The time needed for the titration of 1 mg of water was *ca.* 150 s. The precision is better than that reported for the automatic coulometric Karl Fischer titrator.

The over- and under-titration was minimized by holding the level of iodine at the start and the end of titration as close as possible by using a sample-hold circuit (Fig. 2). The waving drift in the level of iodine during the standby state was minimized by restricting the rate of iodine generation to one count for each detection of the blank level by digitally controlled counting method (Fig. 3). The effect of these circuit devices was examined as follows.

When a small amount of water is introduced into the cell, the reading of the blank level increases but it soon returns to the original level. The amount of water is determined by taking the summation of the differences obtained by subtracting the original blank level from those read out at 30 s intervals. Over- or under-titration is thus completely avoided. The results are given in Table 2. The amount of water less than 50 μg was determined with a precision of ±1 μg. By comparing the results shown in Tables 1b) and 2, the average values were found to agree within an accuracy of 1 μg, indicating that the error due to over- or under-titration does not exceed 1 μg.

An example showing absolute accuracy of the method of determination of water by watching the drift and subsequent recovery of the blank level was given for the determination of atmospheric humidity. Air was taken with a 1 ml tuberculin syringe. The results are given in Table 3. The experimentally obtained values agree with the values calculated from the relative humidity within an accuracy of 1 μg with a preci-

Table 1. Repeadability of titration of water–methal solution (10.32 mg H_2O/ml)

Amount of sample / μl	No. of runs	Found / μg
a) Sample taken with 100 μl micro syringe.		
100	7	1035.6±1.9
50	7	520.4±1.7
10	5	109.6±1.0
b) Sample taken with 10 μl micro syringe.		
10	5	104.2±1.9
5	6	52.0±1.7
2	5	22.2±1.5
1	5	11.2±1.5

Table 2. Repeadability of titration of water–methanol solution (10.32 mg H_2O/ml)[a]

Amount of sample / μl	No. of runs	Found / μg
5	6	52.1±1.0
2	6	22.2±1.0
1	6	11.4±0.8

a) The end point of titration was determined by watching the drift and subsequent recovery of the blank level. Sample was taken with 10 μl micro syringe.

Table 3. Determination of water content in 1.0 ml of atmospheric air

Temperature / °C	Relative humidity / %	No. of runs	Found / μg	Calculated / μg
23.8	53	12	11.1±0.4	11.7
24.0	70	10	15.7±0.8	15.3
23.0	23	8	5.9±0.7	5.4

sion of less than ± 1 μg. The discrepancy observed in the titration of 10 μl of the standard water–methanol solution taken with different micro syringes (Table 1) is due to the inaccuracy in the scale of the micro syringe.

In conclusion, the circuit devices presented in this work are useful for improving the accuracy and precision of the automatic coulometric Karl Fischer titration of water.

The author wishes to thank Dr. Tadashi Aoki for his advice in the construction of the V-F converter.

The Study of Transition-metal Complexes with Ethylenediamine and Cyano Ligands by Means of the X-Ray Photoelectron Spectra

Mitsuru SANO and Hideo YAMATERA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received November 12, 1980)

The X-ray photoelectron spectra (XPS) were measured in order to obtain the N1s and C1s core-orbital energies of ten ethylenediamine and 21 cyano complexes of transition metals. The difference between the N1s and C1s energies, ΔE, which was found to be hardly affected by the counter ion or by charging, was accurately determined for each complex. The trends observed in the ΔE values for these series of complexes are correlated with the electronic structures of the complexes by the use of Siegbahn's equation. For the ethylenediamine complexes, the ΔE values are shown to be related to the σ donation. For the cyano complexes, the ΔE values are mainly controlled by the nitrogen charge, which is itself closely connected with the π back-donation. Demonstrative of the importance of the π back-donation are the cases of $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$, where the decrease in the negative charge from the former to the latter is found to occur dominantly (76%) in the nitrogen atoms. Molecular orbital (MO) calculations in the discrete variational Xα (DV-Xα) scheme were performed for a few series of the cyano complexes, giving results consistent with the XPS results.

The X-ray photoelectron spectrum (XPS) gives information about the charge distribution in a molecule and, accordingly, can be expected to provide a clue to clarifying the electronic structure. However, the chemical shifts of the inner-shell electrons of the metal and ligand atoms of transition-metal complexes have not been well related to the electronic structures because of several difficulties. One is the phenomenon of sample charging, which is serious for insulators. This phenomenon hinders one from making accurate measurements of electron binding energies. In order to overcome this difficulty, the 4f peaks of sputtered gold are usually used as a reference. This is not satisfactory, however, for measuring small chemical-shift differences, since the Au4f levels are influenced by the quantity of the gold and sometimes also by the chemical reaction of the gold with the sample, as is the case with cyanides. Another problem is that the electron binding energies of a complex ion to be measured may be influenced by the counter ion. These difficulties can be removed by the use of an internal reference or by the observation of the difference between the binding energies of different electrons in the same complex.

We investigated how the difference between two core binding energies of ligand atoms is related to the electronic structure of the complex. Transition-metal complexes coordinated with ethylenediamine and cyano ligands were selected for the investigation for the following reasons. Firstly, they are stable enough under a high vacuum and against X-ray irradiation to show reproducible results at −50 °C or below. Secondly, they contain carbon and nitrogen atoms in the ligand, and their coordination bonds show a striking contrast between the mainly σ character in the ethylenediamine complexes and both σ and π characters in the cyano complexes.

The XPS studies of some cyano complexes have been reported on the valence-region spectra by Calabrase and Hayes[1] and on the chemical shifts of the ligand core orbital by Vannerberg.[2]

In this paper, the XPS experimental results are presented for the N1s and C1s binding energies in ethylenediamine and cyano complexes of various transition-metal ions, and trends observed for the differences between the N1s and C1s energies are discussed in relation to the electronic structures of the complexes.

Experimental

The spectra were recorded on a JEOL Model JESCA-3A spectrometer. Aluminium $K\alpha_{1,2}$ radiation (1486.6 eV) was used as the X-ray excitation source, and the measurements were carried out at 5×10^{-8} Torr (1 Torr = 133.3 Pa) or below. For the calibration of the electron binding energies, we used both $Au4f_{7/2}$ (83.8 eV) and $Ag3d_{5/2}$ (368.2 eV) peaks[3] from a thin layer of gold and/or silver deposited onto an aluminium plate. Commercially available potassium salts of cyanide complexes, $K_3[Mn(CN)_6]$, $K_3[Fe(CN)_6]$, $K_3[Co(CN)_6]$, $K[Cu(CN)_2]$, $K[Ag(CN)_2]$, and $K[Au(CN)_2]$, were used without further purification. Other compounds were prepared according to standard methods. A small amount of each sample was ground in ethanol, and a droplet of this ethanolic suspension was placed on a gold plate and dried, or the crystals were ground without solvent and were deposited on an adhesive tape. Care was taken to make sure that the spectra did not contain any features due to contaminants. Carbon contaiminations were examined by comparing the integrated intensities of the carbon 1s and nitrogen 1s peaks. All the spectra reported here were proved to be free from any appreciable contamination. In order to avoid any significant decomposition of the sample by high-vacuum and X-ray irradiation, the sample was cooled at about −50 °C or below. We obtained the difference between the C1s and N1s binding energies by measuring them at the same time. This procedure was repeated several times for each sample, yielding consistent results. The average binding-energy difference was determined with an accuracy of about ±0.1 eV in several runs on a given compound.

We tried to obtain the absolute binding energies by calibrating the nitrogen 1s and carbon 1s peaks against the $4f_{7/2}$ peak of the gold sputtered onto the sample. This method was not, however, satisfactory for giving the absolute values of the binding energies, because the measured chemical shifts of the N1s and C1s binding energies were dependent upon the quantity of the sputtered gold[4] and it is not certain that the Fermi level in the gold should coincide with that in the sample. However, the uncertainty associated with the binding energies can, for the most part, be eliminated

TABLE 1. THE ELECTRON BINDING ENERGIES OF N1s AND Cl s AND THEIR DIFFERENCES FOR VARIOUS TRIS(ETHYLENEDIAMINE)COBALT(III) SALTS ($Au4f_{7/2}$=83.8 eV)

Compound $[Co(en)_3]X_3$	Binding energy/eV		
	N1s	Cl s	ΔE(N1s−Cl s)
X=Cl	399.4	285.3	114.1
Br	399.5	285.4	114.1
NO_3	399.6	285.5	114.1
ClO_4	399.7	285.5	114.2

TABLE 2. THE ELECTRON BINDING ENERGIES OF N1s AND Cl s AND THEIR DIFFERENCES FOR VARIOUS ETHYLENEDIAMINE COMPLEXES ($Au4f_{7/2}$=83.8 eV)

Compound	Binding energy/eV		
	N1s	Cl s	ΔE(N1s−Cl s)
$[Cr(en)_3]Cl_3$	400.4	286.5	113.9
$[Co(en)_3]Cl_3$	399.4	285.3	114.1
$[Ni(en)_3]Cl_2$	399.4	285.7	113.7
$[Cu(en)_3]SO_4$	399.4	285.4	114.0
$[Zn(en)_3]Cl_2$	400.0	285.9	114.1
$[Pd(en)_2]Cl_2$	399.7	285.7	114.0
$[Pt(en)_2]Cl_2$	400.2	285.9	114.4

by making use of their difference. For the convenience of comparison, the binding energies in ethylenediamine complexes were standardized against the sputtered-gold $4f_{7/2}$ peak (83.8 eV), and those in cyanide complexes, against the internal-potassium $2p_{3/2}$ peak (293.5 eV).[2)]

Results

In order for us to correlate the chemical shift of the electron binding energy from XPS with the electronic structure of the complex, an accurate determination of the chemical shift is needed. The chemical shift is, however, influenced considerably by the charging effect and also by the counter-ion effect. We first investigated these two effects on the chemical shift using Λ-$[Co(en)_3]X_3$ (X=Cl^-, Br^-, NO_3^-, and ClO_4^-) as the samples. The Cl s and N1s electron binding energies, as measured for the complex salts, are shown in Table 1, along with the energy difference (ΔE) between N1s and Cl s. Both the N1s and Cl s energies increase in the order of Cl^-, Br^-, NO_3^-, and ClO_4^- salts, but the ΔE value remains almost unchanged (114.1—114.2 eV), suggesting that ΔE is hardly affected by the counter ion. In addition, the ΔE value is not influenced by sample charging. Thus, the ΔE values can be used with advantage for the discussion of the electronic structures of the metal complexes. The Cl s and N1s energies were measured on various ethylenediamine complexes; the meaningful and reproducible data are listed in Table 2 in the order of the increasing atomic number of the metal. The N1s and Cl s binding energies listed in Columns 2 and 3 of this table show scattered values, without any apparent trend, but their differences, ΔE, given in Column 4, clearly show the following trends:

TABLE 3. THE ELECTRON BINDING ENERGIES OF N1s AND Cl s AND THEIR DIFFERENCES FOR VARIOUS CYANO COMPLEXES ($K2p_{3/2}$=293.5 eV)

Compound	Binding energy/eV		
	N1s	Cl s	ΔE(N1s−Cl s)

KCN	399.0	285.4	113.6

a) Uncalibrated value.

(1) The ΔE value increases in going from left to right, or from top to bottom, of the periodic table in each series of bi- and tervalent metal complexes: 113.9→114.1 eV for Cr^{3+}→Co^{3+}, 113.7→114.1 eV for Ni^{2+}→Zn^{2+}, and 113.7→114.4 eV for Ni^{2+}→Pt^{2+}.

(2) The ΔE value is larger for tervalent metal complexes than for bivalent ones if a comparison is made between complexes of the metals near to each other in the periodic table: $Ni^{2+}<Cr^{3+}<Cu^{2+}<Co^{3+}$, Zn^{2+}.

Measurements were also made of various cyanide complexes, for which the N1s and Cl s binding energies and the ΔE values are given in Table 3. The following trends are observed:

(3) The ΔE values for $[M(CN)_6]^{3-}$ and $[M(CN)_6]^{4-}$ decrease with an increase in the atomic number of the metal of the first transition series: 113.6→113.2 eV for Cr^{3+}→Co^{3+} and 113.2→113.1 eV for Mn^{2+}→Fe^{2+}.

(4) The ΔE value is greater for a tervalent-metal complex than for the complex of the same metal of a bivalent state: Fe^{3+} (113.3)>Fe^{2+} (113.1), and Mn^{3+} (113.4)>Mn^{2+}(113.2).

(5) The ΔE value is also greater for the higher oxidation number of the metal if a comparison is made between complexes of different metals with the same structure and the same electronic configuration: Hg^{2+}(113.5)>Au^{+}(113.2) for $[M(CN)_2]^{(2-n)-}$, and Co^{3+}(113.2)>Fe^{2+}(113.1) and Fe^{3+}(113.3)>Mn^{2+} (113.2) for $[M(CN)_6]^{(6-n)-}$.

(6) The ΔE value decreases with an increase in the atomic number of the metal in the same family: $Fe^{2+}(113.1)>Os^{2+}(112.7)$, $Ni^{2+}(113.4)>Pd^{2+}(113.3)>Pt^{2+}(113.2)$, $Ag^{+}(113.4)>Au^{+}(113.2)$, and $Zn^{2+}(113.7)>Cd^{2+}(113.6)>Hg^{2+}(113.5)$.

(7) In contradistinction to the trend described under (3), ΔE shows an increase with an increase in the atomic number in the series: $[Fe(CN)_6]^{4-}(113.1)<[Ni(CN)_4]^{2-}(113.4)<[Zn(CN)_4]^{2-}(113.7)$, $[Pd(CN)_4]^{2-}(113.3)<[Cd(CN)_4]^{2-}(113.6)$, and $[Os(CN)_6]^{4-}(112.7)<[Pt(CN)_4]^{2-}(113.2)<[Hg(CN)_4]^{2-}(113.5)$. This may be due to different symmetries of the complexes. The order of increasing ΔE is $O_h<D_{4h}<T_d$.

(8) The ΔE values for cyanide complexes are smaller than that for KCN; AgCN and $K_2[Zn(CN)_4]$ are exceptions, however.

These trends (1)—(8) will be discussed in more detail in the following section.

Discussion

The trends observed for ethylenediamine and cyanide complexes will be discussed in order to correlate them with the electronic structure. The charge-potential model developed by Siegbahn and his co-workers[5] is used to relate the shift in the core-electron binding energy to the charge distribution in a molecule. According to the model, the binding energy of the relevant electron of the i atom can be given by:

$$E_i = E_i^\circ + k_i q_i + \sum_{j\neq i} q_j/r_{ij}. \quad (1)$$

In this equation, E_i° is the energy of a reference level; q_i and q_j, the charges on the i and j atoms respectively, and r_{ij}, the internuclear distance between the i and j atoms. The last term of Eq. 1 represents an intramolecular Madelung-type potential. The value of the k parameter depends on the atomic species and can be obtained experimentally from the chemical-shift data in small molecules. Using Eq. 1, the difference between N1s and C1s can be expressed as follows:

$$\Delta E = k_N q_{N^*} - k_C q_{C^*} + \left(\sum_{i\neq N^*} q_i/r_{iN^*} - \sum_{j\neq C^*} q_j/r_{jC^*}\right) + E_{N^*}^\circ - E_{C^*}^\circ, \quad (2)$$

where the subscripts, N* and C*, denote, respectively, the particular nitrogen and carbon atoms under consideration and where r_{iN^*} and r_{jC^*} are the distances of the i and j atoms from the particular nitrogen and carbon atoms. The k_N and k_C values are taken as 21.5 and 21.9 for N1s and C1s respectively. (The units of the charge and the potential are e and V respectively.)[5]

The Trends (1) and (2) Observed for Ethylenediamine Complexes. The trends will be discussed by using Eq. 2. For the sake of simplicity, all the bond lengths and the charges on the carbon and hydrogen atoms are assumed to remain unchanged when the central metal is changed. Then, the difference in ΔE between two complexes can be obtained as follows:

$$\Delta(\Delta E) = \Delta E' - \Delta E = k_N(q_{N^*}' - q_{N^*}) + (q_M' - q_M)/r_{MN^*} + (q_N' - q_N)(1+4\sqrt{2})/2r_{MN^*}, \quad (3)$$

where M refers to metal atoms, and N to nitrogen atoms different from N*, although $q_N=q_{N^*}$, $q_N'=q_{N^*}'$, and $r_{MN}=r_{MN^*}$. In this and the following equations, the primed symbols refer to the complex containing the metal of higher atomic number. From the conservation of the charge, one obtains:

$$q_M' - q_M = -6(q_N' - q_N). \quad (4)$$

By substituting Eq. 4 in Eq. 3, one obtains:

$$\Delta(\Delta E) = (q_N' - q_N)(k_N - 6/r_{MN} + (1+4\sqrt{2})/2r_{MN}). \quad (5)$$

If the bond length, r_{MN}, is taken to be 2.0 Å, then the term, $(k_N - 6/r_{MN} + (1+4\sqrt{2})/2r_{MN})$, has a positive value of 2.3 V.

The trend (1) shows that the $\Delta(\Delta E)$ values are positive for the sequence of Cr^{3+} and Co^{3+} ($\Delta E_{Co} - \Delta E_{Cr} = 0.2$ eV) and for Ni^{2+} and Zn^{2+} ($\Delta E_{Zn} - \Delta E_{Ni} = 0.4$ eV). Therefore, the term of $(q_N' - q_N)$ is positive and the negative nitrogen charge decreases in going from Cr^{3+} to Co^{3+} and from Ni^{2+} to Zn^{2+}. This change in the nitrogen charge results from an increase in the nitrogen-to-metal σ donation with an increase in the atomic number, that is, with an increase in the effective nuclear charge.

For square-planar bis ethylenediamine complexes of Pd^{2+} and Pt^{2+}, Eq. 2 leads to the following equation instead of Eq. 5:

$$\Delta(\Delta E) = (q_N' - q_N)(k_N - 4/r_{MN} + (1+2\sqrt{2})/2r_{MN}). \quad (5')$$

The substitution of parameter values in Eq. 5′ gives:

$$\Delta E_{Pt} - \Delta E_{Pd} = 6.5(q_N' - q_N).$$

The corresponding experimental $\Delta(\Delta E)$ value is 0.4 eV; thus, $(q_N' - q_N)$ is positive. This means a greater σ donation in the Pt^{2+} complex, which is consistent with the general tendency for the electronegativity to increase in going down the periodic table in its middle part, where the noble metals appear.

The same argument applies to the trend described under (2) for a tervalent-metal complex to show a larger ΔE value when compared with the complex of a bivalent metal of a similar atomic number. A metal ion of a higher oxidation state is usually more electronegative and usually accepts a larger amount of negative charge from the coordinated nitrogen atoms. Thus, the trends observed in the ΔE values of ethylenediamine complexes can be well explained on the basis of Eq. 3 and correlated with the extent of the σ donation.

The Trends (3) Observed for the Octahedral Cyanide Complexes. Now, we shall turn to the cyanide complexes, $[M(CN)_6]^{3-}$ (M=Cr, Mn, Fe, and Co) and $[M(CN)_6]^{4-}$ (M=Mn and Fe). For these complexes, Eq. 2 leads to:

$$\Delta E = k_N q_N + q_C/r_{CN} + q_M/r_{MN} + 4q_C/\sqrt{r_{MC}^2 + r_{MN}^2} + 4q_N/\sqrt{2}\,r_{MN} + q_C/(r_{MN}+r_{MC}) + q_N/2r_{MN} - (k_C q_C + q_N/r_{NC} + q_M/r_{MC} + 4q_C/\sqrt{2}\,r_{MC} + 4q_N/\sqrt{r_{MC}^2 + r_{MN}^2} + q_C/2r_{MC} + q_N/(r_{MN}+r_{MC})),$$

which gives the following equation for $\Delta(\Delta E)$ with the metal–carbon and carbon–nitrogen bond lengths of 2.0 and 1.15 Å respectively:

$$\Delta(\Delta E) = \Delta E' - \Delta E = 6.0(q_N' - q_N) - 15.1(q_C' - q_C) - 2.6(q_M' - q_M). \quad (6)$$

Table 4. The Mulliken charges (in e) and core-orbital energy differences (in eV) for $[M(CN)_6]^{3-}$ (M=Cr, Mn, Fe, and Co) and $[Fe(CN)_6]^{4-}$, as estimated by DV-Xα MO calculations

	Cr^{3+}	Mn^{3+}	Fe^{3+}	Fe^{2+}	Co^{3+}
Metal	+1.21	+1.13	+0.98	+0.83	+0.84
Carbon	−0.17	−0.14	−0.05	−0.06	−0.04
Nitrogen	−0.53	−0.55	−0.61	−0.74	−0.60
ΔE(N1s−C1s)	110.0	109.9	109.9	109.8	109.6

With the relation between the charges given by:

$$6(q_N'-q_N) + 6(q_C'-q_C) = -(q_M'-q_M), \quad (7)$$

Eq. 6 can be written as:

$$\Delta(\Delta E) = 21.6(q_N'-q_N) + 0.5(q_C'-q_C). \quad (8)$$

On the basis of this equation, the relation between the atomic charges and $\Delta(\Delta E)$ will be discussed in this and the following sections.

Since the coefficient of $(q_C'-q_C)$ is much smaller than that of $(q_N'-q_N)$ in Eq. 8, we shall, for the present, ignore the $(q_C'-q_C)$ term. With the XPS result, $\Delta(\Delta E)=-0.4$ eV, for Cr^{3+} and Co^{3+}, Eq. 8 gives $q_N'-q_N=-0.02$. The negative value is to be expected from the qualitative consideration that the cobalt complex with a larger number of $d\pi$ electrons will show a greater π back-donation, which increases the electron density at the nitrogen atom; this tendency is, however, partially compensated for by the greater effective nuclear charge of Co^{3+}. This may explain why the charge on nitrogen is slightly more negative in the cobalt complex than in the chromium complex. Consistent results are obtained from the infrared spectroscopy, which shows that the force constant of the M–C vibration is greater for Co^{3+} than for Cr^{3+}, while that of C–N remains nearly constant.[6] Table 4 shows the results of our DV-Xα MO calculation,[7] which are in qualitative agreement with the above findings, although the $(q_N'-q_N)$ value (−0.07) and the $\Delta(\Delta E)$ value (1.5 eV) derived from the calculated atomic charges are greater (in absolute values) than those obtained from the experimental results. The $(q_C'-q_C)$ value is positive and greater than $-(q_N'-q_N)$, showing that the σ donation increases in going from the Cr^{3+} to the Co^{3+} complex by a larger amount than the increase in the π back-donation. The $\Delta(\Delta E)$ value (0.4 eV) obtained as the difference of calculated N1s and C1s energies showed a good agreement with the XPS result (0.4 eV).

The Trend (4) Observed between $[M(CN)_6]^{4-}$ and $[M(CN)_6]^{3-}$ (M=Mn and Fe). The relation of the charges between bivalent and tervalent complexes is:

$$q_M' + 6q_C' + 6q_N' = q_M + 6q_C + 6q_N + 1.0, \quad (9)$$

where the prime refers to the tervalent complexes. If the geometry of complexes is the same as has been described above, the equation for $\Delta(\Delta E)$ can be obtained as follows:

$$\Delta(\Delta E) = \Delta E(M^{3+}) - \Delta E(M^{2+}) = 21.6(q_N'-q_N) + 0.5(q_C'-q_C) - 2.6. \quad (10)$$

Experimentally, the $\Delta(\Delta E)$ value was found to be about 0.2 eV, so that we may write;

$$0.2 + 2.6 = 21.6(q_N'-q_N) + 0.5(q_C'-q_C). \quad (11)$$

Disregarding $0.5(q_C'-q_C)$, we obtain $q_N'-q_N=0.13$. According to the orbital mixing rule,[8,9] a π back-donation from metal to ligand will result in an increased population at the nitrogen atom, but in an almost unchanged or even decreased population at the carbon atom. Thus, the XPS result can be taken as showing the effect of π back-donation; the extent of π back-donation is greater in the Fe^{2+} than in the Fe^{3+} complex. This is also shown by the force constants reported for the M–C and C–N vibrations. Thus, the M–C force constant is greater for Fe^{2+} than for Fe^{3+}, while the C–N force constant is smaller for the Fe^{2+} complex.[10] The results of our MO calculations (given in Table 4) are also in good agreement with the XPS results. Thus, the charges at the nitrogen atom of the complexes are −0.74 (Fe^{2+}) and −0.61 (Fe^{3+}), which give $q_N'-q_N=0.13$. This agrees excellently with the result (0.13) derived from the XPS data by disregarding the $q_C'-q_C$ term. Therefore, $q_C'-q_C$ can be expected to be small, and a consistent result of $q_C'-q_C=0.01$ is shown by the MO calculation. Thus, the positive $\Delta(\Delta E)$ shows that the major part (more than 72%) of the decreased negative charge of the complex has been lost from the nitrogen atoms; for $\Delta(\Delta E)=0.2$ in the case under consideration, the loss from the nitrogen atoms amounts to 76%. This means that the π back-donation greatly decreases in going from the Fe^{2+} to the Fe^{3+} complex.

The Trend (5) Observed for the Isoelectronic Cyanide Complexes. The trend (5) will be discussed in the case of the octahedral complexes, *e.g.*, $[Fe(CN)_6]^{4-}$ and $[Co(CN)_6]^{3-}$. If $0.5(q_C'-q_C)$ is ignored in comparison with $21.6(q_N'-q_N)$ in Eq. 8, we obtain:

$$0.1 + 2.6 = 21.6(q_N'-q_N), \quad (12)$$

where the prime refers to tervalent complexes. Equation 12 gives 0.13 for the value of $(q_N'-q_N)$, which is in good agreement with the value of 0.14 obtained from the DV-Xα MO calculation for the Fe^{2+} and Co^{3+} complexes.[10] The above argument on the basis of XPS results is also supported by the small value of $(q_C'-q_C)$ (=0.02) from DV-Xα.

In the cases of $[Au(CN)_2]^-$ and $[Hg(CN)_2]$ with $D_{\infty h}$ symmetry (N–C–M–C–N), the metal–carbon and carbon–nitrogen bond lengths are taken to be 2.0 and 1.15 Å respectively, and the relation between the charges is given by:

$$2q_N' + 2q_C' + q_M' = 2q_N + 2q_C + q_M + 1.0, \quad (13)$$

where the prime refers to $[Hg(CN)_2]$. Then, the following equation can be obtained:

$$\Delta(\Delta E) = 13.7(q_N'-q_N) - 4.9(q_C'-q_C) - 2.6. \quad (14)$$

As a first approximation, $(q_C'-q_C)$ is disregarded, as

Table 5. The Mulliken charges (in e) and core-orbital energy differences (in eV) for $D_{\infty h}$ symmetry complexes, as estimated by DV-Xα MO calculation

	$[Ag(CN)_2]^-$	$[Au(CN)_2]^-$	$[Hg(CN)_2]$
Metal	+0.42	+0.33	+1.11
Carbon	−0.22	−0.17	−0.26
Nitrogen	−0.50	−0.49	−0.30
ΔE(N1s−C1s)	110.2	109.7	110.5

in the above cases. Then, with the observed $\Delta(\Delta E)$ value of 0.3 eV, we obtain $q_N'-q_N=0.21$, which means a smaller π back-donation in $[Hg(CN)_2]$ than in $[Au(CN)_2]^-$. This can be expected from the higher nuclear charge of the central ion for the former. The MO calculation gave a consistent result, $q_N'-q_N=0.19$.[11] However, the MO calculation showed that $(q_C'-q_C)$ $(=-0.09)$ is not so small (in absolute value) as to be neglected.[12] The negative value means that the carbon atom has a more negative charge when it is coordinated to Hg^{2+} than when linked to Au^+. This might seem to contradict the higher electronegativity of Hg^{2+}; however, it can be understood electrostatically by considering the higher polarizing power of Hg^{2+}. It is also consistent with the molecular orbital consideration that the greater π back-donation in the Au^+ complex will cause a more extensive mixing of the antibonding CN^- π orbital into the bonding CN^- π, in-phase at N and out-of-phase at C. The importance of the change in π back-donation has also been demonstrated in this case. Calculating $\Delta(\Delta E)$ with the atomic charges from the MO calculation, we obtain 0.4 eV for $\Delta(\Delta E)$, which is nearly equal to the XPS result (0.3 eV). (The ΔE(N1s−C1s) values directly obtained from the MO calculation (Table 5) also show a consistent trend, although the $\Delta(\Delta E)$ value is twice as large.)

The Trend (6) Observed for Complexes of the Metals of the Same Family. The ΔE value slightly decreased in going down the periodic table in each family. A discussion of $\Delta(\Delta E)$ similar to those made above cannot be made here, because the differences in the M–C distance are appreciable in the present case. With the calculated atomic charges for the Ag^+ and Au^+ complexes (Table 5), however, Siegbahn's equation gave a $\Delta(\Delta E)$ value (−0.1 eV) consistent with the XPS result (−0.2 eV).

The Trend (7) Observed between Complexes of Different Symmetries. The coordination of cyanide ions to a metal ion results in a shift of the negative charge from the ligands to the metal ion. When the oxidation number of the metal ion remains the same, the total charge received by the metal ion will not remarkably change from one metal ion to another. Thus, the donation per ligand will be less in $[Fe(CN)_6]^{4-}$ than in $[Ni(CN)_4]^{2-}$, for example. The smaller net donation can be attributed to a smaller σ donation or to a larger π back-donation; the former leaves more negative charge on C, and the latter increases the electronic density on N. The observed tendency for the ΔE value to be smaller for a hexacyano than for a tetracyano complex implies the importance of the effect of the π back-donation. Among the tetracyano complexes, the observed ΔE value is smaller for a planar than for a tetrahedral coordination. This may also indicate a greater π back-donation in the planar complexes.

The Trend (8) Observed for Most of the Cyano Complexes. As has been described above, the electronic density of the cyanide ion is decreased on C, and increased on N, by the ligation of the cyanide ion to a metal ion. Thus, compared with the free cyanide ion, the ΔE value can be expected to be smaller in a complex. This is demonstrated by the XPS results (Table 3). The exceptionally high ΔE value for $[Zn(CN)_4]^{2-}$ may be attributed to the poor π back-donation and/or the polarization of the CN^- ligand. Though less pronounced, a similar situation is also found in other tetrahedral complexes. The Cr^{3+} ion is the hardest of the metal ions listed in Table 3 and has only three $d\pi$ electrons. Thus, a large ΔE value can be expected for $[Cr(CN)_6]^{3-}$, in agreement with the XPS results.

Conclusion

The ΔE value, the difference between the N1s and C1s orbital energies, was measured for various ethylenediamine complexes and cyano complexes. The following trends were observed.

1) The ΔE value was not influenced by the counter ion or by the charging-up of the sample, and the observed trends could be related to the trends in the charge distribution of the complex and the character of the coordinate bond by making use of Siegbahn's equation and also by means of the DV-Xα MO calculation.

2) For ethylenediamine complexes, the ΔE value increased in the following orders: $Cr^{3+}<Co^{3+}$, $Ni^{2+}<Cu^{2+}<Zn^{2+}$, and $Ni^{2+}<Pd^{2+}<Pt^{2+}$. These indicate the sequences of the decreasing negative charge of the nitrogen atom or the increasing donation of electrons from ligand to metal.

3) For cyanide complexes, the following trends are found and explained. The ΔE value increased in the following orders: $Cr^{3+}<Mn^{3+}<Fe^{3+}<Co^{3+}$, $Mn^{2+}<Fe^{2+}$, $Mn^{2+}<Mn^{3+}$, $Fe^{2+}<Fe^{3+}$, $Mn^{2+}<Fe^{3+}$, $Fe^{2+}<Co^{3+}$, $Au^+<Hg^{2+}$, $Os^{2+}<Fe^{2+}$, $Pt^{2+}<Pd^{2+}<Ni^{2+}$, $Au^+<Ag^+$, $Hg^{2+}<Cd^{2+}<Zn^{2+}$ (for complexes of the same symmetries), and $O_h<D_{4h}<T_d$ (for those of different symmetries). In the $[M(CN)_6]^{3-}$ (M: Cr→Co) and $[M(CN)_6]^{4-}$ (M: Mn→Fe) series, Siegbahn's equation shows that the tendency observed in ΔE reflects mainly the change in the nitrogen charge. The greater change in the carbon charge, as shown by the DV-Xα calculation, has a minor effect on the ΔE value. In $[M(CN)_6]^{n-}$ (M=Mn and Fe), the nitrogen charge becomes less negative by about 0.1 in going from the M^{2+} to the M^{3+} complex with a decreasing π back-donation, whereas the carbon charge remains almost unchanged. For complexes of different metal ions with the same electronic configuration, the ΔE value is controlled by the nitrogen charge, whose difference is about 0.2 between Hg^{2+} and Au^+ and 0.13 between Mn^{2+} and Fe^{3+} and between Fe^{2+}

and Co^{3+}. The π back-donation is shown to be also important in accounting for the trend observed in the ΔE values of complexes of different geometries and of free CN^-.

4) The DV-Xα MO calculation gave results consistent with the XPS results, thus showing its usefulness for the interpretation of the XPS results.

(Received November 14, 1980)

Cobalt(III) complexes containing *N*-alkyl-L-alanine and a Schiff base ligand, β_2-[Co(α-Me-sal$_2$en)(*N*-R-L-ala)] (where α-Me-sal$_2$en represents the dianion of *N,N'*-ethylenebis(α-methylsalicylideneamine) and *N*-R-L-ala denotes the anion of titled amino acids), have been prepared. They were characterized by the use of the absorption, circular dichroism, and ^{1}H NMR spectra of the complexes. They showed quite high stereoselectivity for Λ_{RS}-β_2-configuration: 93% for *N*-methyl-L-alanine, and almost 100% for *N*-benzyl-L-alanine and *N*-benzyl-*N*-methyl-L-alanine. The similar β_2-Co(sal$_2$-(*S,S*)-chxn) complexes with *N*-benzyl-L- and *N*-benzyl-D-alanines, where sal$_2$-(*S,S*)-chxn represents the dianion of (1*S*,2*S*)-*N,N'*-1,2-cyclohexylenebis(salicylideneamine), have been synthesized to investigate the stereospecificity of the complex toward *N*-benzyl-L-alanine. It was found that Co(sal$_2$-(*S,S*)-chxn) complex reacts with *N*-benzyl-L-alanine in a high stereospecificity (93—94% at the 1:2 reaction molar ratio between the complex and racemic *N*-benzylalanine, and almost 100% at the 1:100 molar ratio). The above phenomena were explained in terms of the thermodynamic selectivity of the complexes.

The steric control of the diastereoisomers of metal complexes is one of the interesting subjects in the stereochemistry of coordination compounds. Many studies have been directed toward the stereoselectivity or stereospecificity of Co(N$_4$) complexes with a chiral amino acid,[1] where (N$_4$) denotes a tetramine ligand such as (en)$_2$ or trien. However, the stereoselectivity of the [Co(N$_4$)(aa)]$^{2+}$ complexes is not so high. For examples, the isomeric ratio of the diastereoisomers, Λ/Δ, at the equilibrium conditions is about 50/50 in [Co(en)$_2$(L-ala)]$^{2+}$,[2] 37/63 in [Co(en)$_2$(L-val)]$^{2+}$,[2] 33/67 in β_2-[Co(trien)(L-pro)]$^{2+}$,[3] and 18/82 in β_2-[Co(pyht)(L-ala)]$^{2+}$.[4] In the case of Co(N$_4$) complexes with *N*-alkyl-L-amino acid, the stereoselectivity is higher than the corresponding L-amino acidato complex; but the Λ/Δ ratio is 80/20, 60/40, or 90/10 in [Co(en)$_2$(*N*-Me-L-ala)]$^{2+}$,[5] β_2-[Co(trien)(*N*-Me-L-ala)]$^{2+}$,[6] or β_2-[Co(2(*S*)10(*S*)-Me$_2$-2,3,2-tet)(*N*-Me-L-ala)]$^{2+}$ [7] respectively.[8]

We have recently found that the stereoselectivity of cobalt(III)–Schiff base complexes with a chiral amino acid, β_2-[Co(Schiff base)(L-aa)], is much higher than that of the corresponding Co(N$_4$) complexes: Λ/Δ is 67/33 in the L-ala complex, 90/10 in the L-phe complex, and about 0/100 in the L-pro complex.[9,10] It is most interesting that the stereoselectivity of the L-pro complex reaches almost 100%. This quite high stereoselectivity of the L-pro complex comes from the strong intramolecular steric repulsion between the Schiff base ligand and the pyrrolidine ring, a kind of *N*-alkyl group, of L-proline. Therefore, in the Co(III)–Schiff base system, it can be expected that the *N*-alkyl amino acidato complex may show quite high stereoselectivity.

In this paper, the preparation and the stereoselectivity of Co(α-Me-sal$_2$en) complexes with *N*-methyl-L-alanine, *N*-benzyl-L-alanine, and *N*-benzyl-*N*-methyl-L-alanine will be studied to establish a quite high steric control of the diastereoisomers of amino acidato cobalt(III) complexes. The optical resolution of amino acids[11] will be used to study the stereospecificity of Co(sal$_2$-(*S,S*)-chxn) complex toward *N*-benzyl-L-alanine.

Experimental

Preparation of the Complexes. [Co(α-Me-sal$_2$en)] was prepared by the method of Bigotto *et al.*[12] [Co(sal$_2$-(*S,S*)-chxn)] was prepared by the method described in Ref. 13. (1*S*,2*S*)-1,2-Cyclohexanediamine was resolved by the method reported in Ref. 13. *N*-Alkyl amino acids were prepared by the method of Quitt *et al.*[14]

[Co(α-Me-sal$_2$en)(N-Bz-L-ala)]. 1:1 Mixture of Λ_{RS}- and Δ_{SS}-β_2-Isomers (Complex I): *N*-Benzyl-L-alanine (2.1 g, 1.2×10^{-2} mol) in a mixed solvent of water (20 cm^3) and methanol (130 cm^3) was added to a slurry of [Co(α-Me-sal$_2$en)] (3.8 g, 1.1×10^{-2} mol) in chloroform (250 cm^3). The mixture was stirred vigorously in the open air for about 7 min until the color of the solution became green. After a trace amount of unreacted [Co(α-Me-sal$_2$en)] had then been filtered off, water (about 500 cm^3) was added to the filtrate; then the water-soluble component was extracted into water (twice). The chloroform layer was filtered, and petroleum ether (about 2 dm^3) was added to the filtrate to give a green powder. Since the reaction product is labile in isomerization in solution, the above procedure should be carried out as quickly as possible. When the procedure took about 15 min, the green precipitate thus obtained showed the molar rotation at 435 nm of -1.95×10^4° ($c=1.0\times10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution), which corresponds to a 1:2 mixture of Δ_{SS}- and Λ_{RS}-β_2-isomers of [Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)]. Yield, about 4.0 g. Found: C, 62.27; H, 5.61; N, 7.77%. Calcd for $CoC_{28}H_{30}N_3O_4\cdot0.5H_2O$: C, 62.22; H, 5.78; N, 7.77%. The 1:1 mixture was obtained by treating the 1:2 mixture as follows. The 1:2 mixture (0.4 g) was dissolved in chloroform (20 cm^3), and acetone (30 cm^3) was added to it. The solution was concentrated to a small volume with a rotary vacuum evaporator at about 40 °C. The green powder thus obtained was washed with acetone and dried under vacuum. Yield, about 0.2 g. Found: C, 59.30; H,

5.36; N, 7.36%. Calcd for $CoC_{28}H_{30}N_3O_4 \cdot 0.5H_2O \cdot 0.5 CHCl_3$: C, 59.49; H, 5.52; N, 7.37%. $[M]_{435} = -2.50 \times 10^3°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution).

Λ_{RS}-β_2-Isomer (Complex II): Method A. One gram of the green powder ($[M]_{435} = -1.95 \times 10^4°$) obtained above was dissolved in the mixed solvent of chloroform (30 cm^3) and methanol (30 cm^3). The solution was slowly concentrated to a small volume at room temperature to give green crystals in about an 85% yield. Found: C, 51.48; H, 5.13; N, 6.26%. Calcd for $CoC_{28}H_{30}N_3O_4 \cdot 1.5H_2O \cdot CHCl_3$: C, 51.38; H, 5.05; N, 6.20%. $[M]_{435} = -4.38 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform soon after dissolution).

Method B. *N*-Benzyl-L-alanine (2.1 g, 1.2×10^{-2} mol) in a mixed solvent of water (20 cm^3) and methanol (130 cm^3) was added to the slurry of [Co(α-Me-sal$_2$en)] (3.8 g, 1.1×10^{-2} mol) in chloroform (175 cm^3). The mixture was stirred vigorously in the open air for 2 h. After a trace amount of brownish by-product had been filtered off, the filtrate was slowly concentrated to a small volume. The green crystals thus obtained were recrystallized from a mixed solvent of chloroform and methanol (1:1 in volume). Yield, about 4.2 g. Found: C, 51.67; H, 5.06; N, 6.32%. Calcd for $CoC_{28}H_{30}N_3O_4 \cdot 1.5H_2O \cdot CHCl_3$: C, 51.38; H, 5.06; N, 6.20%. $[M]_{435} = -4.38 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution). When the complex was recrystallized from methanol and water, green crystals without any crystalline chloroform were obtained. Found: C, 58.36; H, 6.10; N, 7.29%. Calcd for $CoC_{28}H_{30}N_3O_4 \cdot 2.5H_2O$: C, 58.33; H, 6.12; N, 7.29%. $[M]_{435} = -4.38 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution).

[Co(α-Me-sal$_2$en)(N-Me-L-ala)]. 1:1 Mixture of Λ_{RS}-β_2-Isomer and Δ-β_2-Isomers (Complex III): *N*-Methyl-L-alanine (1.3 g, 1.2×10^{-2} mol) in a mixed solvent of water (10 cm^3) and methanol (100 cm^3) was added to the slurry of [Co(α-Me-sal$_2$en)] (3.7 g, 1.1×10^{-2} mol) in chloroform (250 cm^3). The mixture was stirred vigorously in the open air for about 10 min, until the solution became green. After a trace amount of unreacted [Co(α-Me-sal$_2$en)] had been filtered off, water (500 cm^3) was added to the filtrate to extract the water-soluble component into water (twice). The chloroform layer thus obtained was filtered, and petroleum ether (about 2 dm^3) was added to the filtrate to give green powder in about a 3.5 g yield. It was dried under vacuum. When this procedure took about 20 min, the green product thus obtained showed $[M]_{435}$ of $-1.44 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution), which corresponds to the 1:2 mixture of Δ- and Λ_{RS}-β_2-isomers. The 1:1 mixture was obtained by the following procedure. The green powder (0.8 g) obtained above was dissolved in chloroform (20 cm^3), and acetone (20 cm^3) was added to it. When the solution was concentrated to a small volume with a rotary vacuum evaporator at about 40 °C, the 1:1 mixture was precipitated as a green powder in about a 40% yield. Found: C, 56.47; H, 5.82; N, 8.95%. Calcd for $CoC_{22}H_{26}N_3O_4 \cdot 0.5H_2O$: C, 56.90; H, 5.86; N, 9.05%. $[M]_{435} = -6.1 \times 10^3°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution).

Λ_{RS}-β_2-Isomer (Complex IV): One gram of the green powder obtained above (the 1:2 mixture of Δ- and Λ_{RS}-β_2-isomers) was dissolved in a mixed solvent of chloroform (10 cm^3) and methanol (30 cm^3), and the solution was warmed at about 50 °C for 7 h. When petroleum ether (about 300 cm^3) was added to the solution, the Λ_{RS}-β_2-isomer was precipitated as a green powder in about an 80% yield. It was dried under vacuum. Found: C, 56.64; H, 5.91; N, 8.82%. Calcd for $CoC_{22}H_{26}N_3O_4 \cdot 0.5H_2O$: C, 56.90; H, 5.86; N, 9.05%. $[M]_{435} = -4.15 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution).

When the 1:2 mixture obtained above was recrystallized from a mixed solvent of methanol and water, green crystals with $[M]_{435}$ of $-2.40 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform, soon after dissolution) were isolated in an 85% yield. The product corresponds to the 1:4 mixture of Δ- and Λ_{RS}-β_2-isomers. Found: C, 56.72; H, 5.99; N, 8.93%. Calcd for $CoC_{22}H_{26}N_3O_4 \cdot 0.5H_2O$: C, 56.90; H, 5.86; N, 9.05%.

Λ_{RS}-β_2-[Co(α-Me-sal$_2$en)(N-Bz,Me-L-ala)] (Complex V). This complex was prepared by a method similar to that employed for the preparation of Λ_{RS}-β_2-[Co(α-Me-sal$_2$en)-(*N*-Bz-L-ala)] (Complex II), as mentioned above (Method B). When the complex was recrystallized from methanol and water, it was obtained as a green powder in about a 70% yield. Found: C, 60.61; H, 6.22; N, 7.15%. Calcd for $CoC_{29}H_{32}N_3O_4 \cdot 1.5H_2O$: C, 60.84; H, 6.16; N, 7.34%. $[M]_{435} = -4.12 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; chloroform).

Λ_{RS}-β_2-[Co(sal$_2$-(S,S)-chxn)(N-Bz-L-ala)] (Complex VI). *N*-Benzyl-L-alanine (0.27 g, 1.5×10^{-3} mol) in a mixed solvent of water (10 cm^3) and methanol (20 cm^3) was added to a slurry of [Co(sal$_2$-(*S,S*)-chxn)] (0.5 g, 1.3×10^{-3} mol) in methanol (40 cm^3). The mixture was stirred vigorously in the open air for about 1 h to give a green solution. When the green solution was concentrated to a small volume, green crystals were obtained in about an 0.6 g yield. They were recrystallized from methanol. Found: C, 60.70; H, 6.21; N, 7.18%. Calcd for $CoC_{30}H_{32}N_3O_4 \cdot 2H_2O$: C, 60.71; H, 6.11; N, 7.08%. $[M]_{435} = -3.94 \times 10^4°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; methanol).

1:1.5 Mixture of Δ-$_{RS}$ and Λ_{RR}-β_2-[Co(sal$_2$-(S,S)-chxn)(N-Bz-D-ala)] (Complex VII). This complex was prepared by a method similar to that employed for the preparation of Complex VI. It was obtained as a green powder in about a 70% yield. Found: C, 60.56; H, 6.18; N, 7.27%. Calcd for $CoC_{30}H_{32}N_3O_4 \cdot 2H_2O$: C, 60.71; H, 6.18; N, 7.08%. $[M]_{435} = -8.6 \times 10^3°$ ($c = 1.0 \times 10^{-3}$ mol dm^{-3}; methanol).

The Optical Resolution of N-Benzylalanine with [Co(sal$_2$-(S,S)-chxn)]. Racemic *N*-benzylalanine (0.47 g, 2.64×10^{-3} mol) in water (20 cm^3) was added to the slurry of [Co(sal$_2$-(*S,S*)-chxn)] (0.5 g, 1.32×10^{-3} mol) in methanol (100 cm^3). The mixture was stirred in the open air for about 1 h. To the resulting green solution, chloroform (250 cm^3) and water (250 cm^3) were added, and the mixture was shaken for about 5 min. The chloroform layer (A) and the water layer (B) were separated with a separatory funnel. Water (150 cm^3) was added to the chloroform layer (A), and a residual trace amount of *N*-benzylalanine was extracted into the water layer (C). Then, chloroform (150 cm^3) was added to the water layer (B), and a residual trace amount of green complex was extracted into chloroform layer (D). The water solutions (B) and (C) were mixed together, and the resulting mixture was evaporated to dryness. A white precipitate was obtained in about an 0.23 g (98%) yield. The precipitate was confirmed to be *N*-benzylalanine from its ^{1}H NMR spectrum and the elemental analysis. The optical purity of the *N*-benzylalanine was determined to be 93% (D-form) by the method of Ref. 15.

The chloroform solutions (A) and (D) were combined and the mixture was evaporated to dryness. The green powder thus obtained was washed with water. This green powder was then partially dissolved in a mixed solvent of methanol (50 cm^3) and water (100 cm^3), $NaBH_4$ (0.05 g, 1.32×10^{-3} mol) was added to the mixture. The mixture

was stirred vigorously for about 15 min until an orange precipitate of [Co(sal$_2$-(*S*,*S*)-chxn)] appeared. The precipitate was filtered, and water (250 cm^3) and chloroform (250 cm^3) were then added to the filtrate to extract a trace amount of orange complex into the chloroform. The pH of the water solution was adjusted to about 7 with dil HCl, and then the solution was evaporated to dryness to give a white powder. Methanol (150 cm^3) was added to the white precipitate to extract *N*-benzylalanine into methanol. When the methanol solution was concentrated to a small volume, a white precipitate was obtained in about an 0.24 g yield. The precipitate was confirmed to be *N*-benzylalanine, contaminated by a small amount of H_3BO_3 from the ^{1}H NMR spectrum and the elemental analysis. No further purification was attempted. The optical purity of the *N*-benzylalanine was 94% (L-form).[15]

Measurements. The electronic absorption spectra were recorded with a Hitachi EPS-3 Spectrophotometer at 23 °C. The CD spectra were measured with a JASCO J-20 Automatic Recording Spectropolarimeter at room temperature. The optical rotation at 435 nm was measured with a JASCO DIP-140 Digital Polarimeter. The ^{1}H NMR spectra were recorded with a Hitachi R-20 Spectrometer (60 MHz) using TMS as the internal reference at 35 °C.

Results and Discussion

The Reaction of [Co(α-Me-sal$_2$en)] with N-*Alkyl*-L-*alanine, and the Preparation and Properties of β$_2$-[Co(α-Me-sal$_2$en)(*N*-*R*-L-ala)] Complexes.* *1) β$_2$-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)]*: Figure 1 shows the absorption spectrum of [Co(α-Me-sal$_2$en)] and that of the reaction solution of [Co(α-Me-sal$_2$en)] and *N*-benzyl-L-alanine under air-oxidation conditions. Figure 2 shows the time dependences of the absorbance at 600 nm and the rotation at 435 nm for the reaction solution. The absorbance at 600 nm becomes almost constant within a few minutes after the initiation of the reaction, and the absorption spectrum soon after reaction closely resembles that at the equilibrium conditions. Further, the absorption spectra are very similar to those of the β$_2$-[Co(α-Me-sal$_2$en)(L-aa)].[8,9,16] Accordingly, it seems that the complexation between [Co(α-Me-sal$_2$en)] and *N*-benzyl-L-alanine proceeds quite rapidly to form β$_2$-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)]. On the other hand, the rotation at 435 nm of the reaction solution shows a small plus value soon after reaction, but it changes gradually to show a large minus value at the equilibrium conditions. The plot of $\ln|\alpha_\infty-\alpha_t|$ *vs.* the time for the mutarotation gives a straight line, as is shown in Fig. 2. These facts indicate that the reaction produces a mixture of two species: $(+)_{435}$- and $(-)_{435}$-isomers of β$_2$-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)] complex, and then the $(+)_{435}$-isomer thus formed isomerizes slowly to the $(-)_{435}$-isomer. In fact, as has been mentioned in the Experimental section, from the initial reaction solution, a green powder with a small minus rotation at 435 nm (represented as Complex I) was isolated. From the equilibrium solution, green crystals with a large minus rotation at 435 nm (Complex II) were isolated. Both complexes had the same composition that corresponding to [Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)], and their absorption spectra resemble not only each other but also those of the reaction solution mentioned above. Further, the mutarotation curve for Complex I was very similar to that for the reaction solution: the slopes of the plots of $\ln|\alpha_\infty-\alpha_t|$ *vs.* the time for both mutarotations were the same. Therefore, it can be concluded that [Co(α-Me-sal$_2$en)] reacts with *N*-benzyl-L-alanine quite rapidly to form a mixture of the $(+)_{435}$- and $(-)_{435}$-isomers of β$_2$-[Co(α-Me-sal$_2$en)-

(*N*-Bz-L-ala)] complex, and the $(+)_{435}$-isomer thus formed isomerizes slowly to the $(-)_{435}$-isomer. It has already been shown that β_2-Co(α-Me-sal$_2$en) complexes with L-amino acids are labile in isomerization between Δ- and Λ-configurations.[8,9] On the other hand, no mutarotation was observed for Complex II.

Figure 3 shows the ^{1}H NMR spectra of the *N*-Bz-L-ala complexes. The numerical data are listed in Table 1. The ^{1}H NMR spectrum of Complex I exhibited a time dependence in its methyl signal of the coordinated *N*-benzyl-L-alaninato ligand, and that of the complex at the equilibrium conditions coincided with that of Complex II. The methyl signal of Complex I soon after dissolution consists of two doublets at 0.77 and 1.35 ppm (center of the doublet) with the relative intensity ratio of about 1:1. Complex II shows only one doublet at 0.77 ppm. No other peaks or shoulders were observed for the methyl signal. These facts strongly support the assertion that only two species, the $(+)_{435}$- and $(-)_{435}$-isomers, are involved in the mutarotation of Complex I. From the ^{1}H NMR spectra, it can be concluded that 1) Complex I is the 1:1 mixture of the $(+)_{435}$- and $(-)_{435}$-isomers of β_2-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)], 2) Complex II is the pure $(-)_{435}$-isomer of the *N*-Bz-L-ala complex, and 3) the stereoselectivity at the equilibrium conditions of the *N*-Bz-L-ala complex is almost 100%. As will be mentioned later, the Λ_{RS}-β_2-structure is assigned to the $(-)_{435}$-isomer, and the Δ_{SS}-β_2-structure to the $(+)_{435}$-isomer. Here, it should be noted that 1) the formation of both $(+)_{435}$- and $(-)_{435}$-isomers in the initial reaction between [Co(α-Me-sal$_2$en)] and *N*-benzyl-L-alanine can be regarded as kinetic in origin,[9] 2) the isolation of the 1:1 mixture of $(+)_{435}$- and $(-)_{435}$-isomers from the solution of the 1:2 mixture may be due to the lower solubility

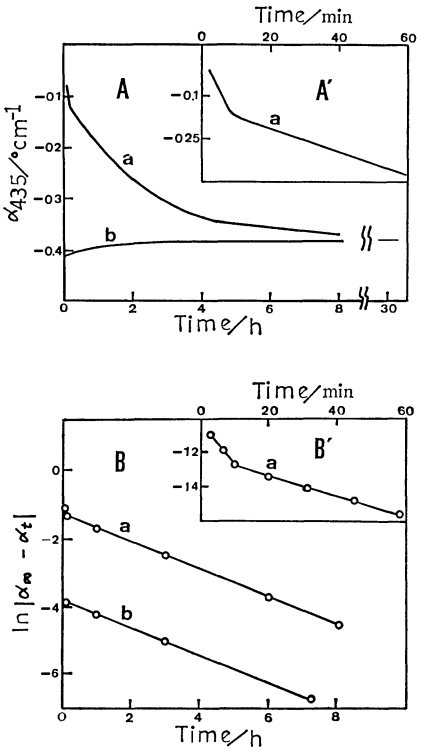

Fig. 4. The mutarotation (A) and the plot of ln$|\alpha_\infty - \alpha_t|$ *vs.* the time (B).
A′ and B′ show those of the initial reaction solution.
a: The reaction solution of [Co(α-Me-sal$_2$en)] (1.0×10^{-3} mol dm^{-3}) with *N*-methyl-L-alanine (1.1×10^{-3} mol dm^{-3}) in a mixed solvent of $CHCl_3$ and CH_3OH (4:1) under the air-oxidation conditions at 35 °C,
b: Complex IV (Δ_{RS}-β_2-[Co(α-Me-sal$_2$en)(*N*-Me-L-ala)]) (1.0×10^{-3} mol dm^{-3}) in the same conditions as a.

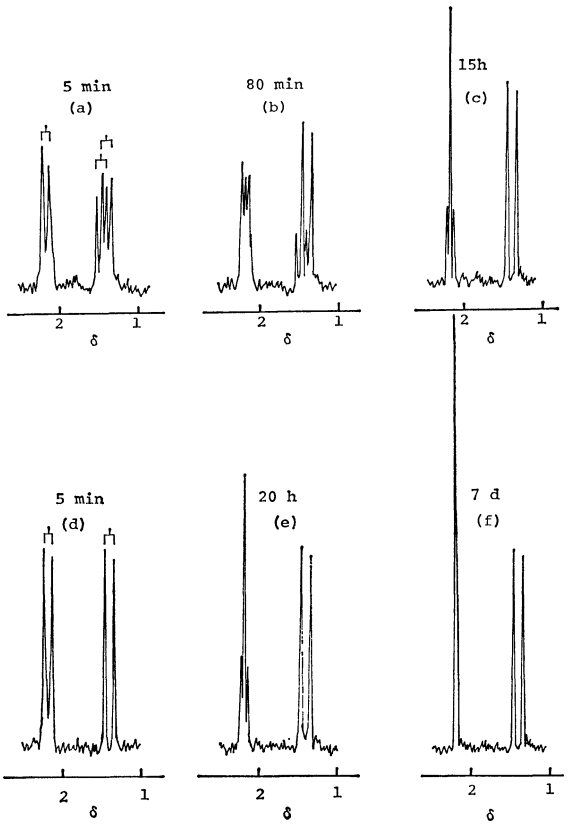

Fig. 5. The ^{1}H NMR spectra of β_2-[Co(α-Me-sal$_2$en)-(*N*-Me-L-ala)] complexes in a mixed solvent of $CDCl_3$ and CD_3OD (4:1).

of the 1:1 mixture as compared with the solubility of the 1:2 mixture, and 3) the preference of the $(-)_{435}$-isomer at the equilibrium conditions should come from a thermodynamic origin. The thermodynamic stereoselectivity of the *N*-Bz-L-ala complex will be mentioned later in detail.

*2) β_2-[Co(α-Me-sal$_2$en)(*N*-Me-L-ala)]*: In the reaction for [Co(α-Me-sal$_2$en)] and *N*-methyl-L-alanine, the absorption spectra of the reaction solution soon after reaction and at the equilibrium conditions resembled each other quite closely, and they were very similar to those for β_2-[Co(α-Me-sal$_2$en)(L-aa)]. The absorbance at 600 nm of the reaction solution became almost a constant within a few minutes after initiation of the reaction: the complexation is very fast. The rotation at 435 nm of the reaction solution changed gradually to show a large minus rotation at the equilibrium conditions. These spectral and rotational properties of the *N*-Me-L-ala complex are very similar to those of the *N*-Bz-L-ala complex. However, as is shown in Fig. 4, the plot of ln$|\alpha_\infty - \alpha_t|$ *vs.* the time for the mutarotation gives two straight lines crossing at about $t=10$ min. A quite similar mutarotation was observed for Complex III, which was isolated from the initial reaction solution between [Co(α-Me-sal$_2$en)] and *N*-methyl-L-alanine. These facts indicate that three species at least, two $(+)_{435}$-isomers and one $(-)_{435}$-isomer of β_2-[Co(α-Me-sal$_2$en)(*N*-Me-L-ala)] complex, are involved in the mutarotation, and one of the two $(+)_{435}$-isomers isomerizes much faster to the $(-)_{435}$-isomer than the other $(+)_{435}$-isomer does. As mentioned later, four diastereoisomers are thought to be available for the β_2-[Co(α-Me-sal$_2$en)(*N*-Me-L-ala)] complex; their relative stability is as follows: Δ_{RS}->Δ_{SS}->Δ_{RS}->Δ_{SS}-isomers. Therefore, the $(+)_{435}$-isomer, which isomerizes first, may correspond to the less stable Δ_{RS}-isomer, and the other $(+)_{435}$-isomer may correspond to the Δ_{SS}-isomer.

As is shown in Fig. 4, Complex IV also exhibits a mutarotation; it has a smaller minus rotation at the equilibrium conditions than that soon after dissolution, although the degree of the mutarotation is very small. This fact indicates that the stereoselectivity of the *N*-Me-L-ala complex is less than 100%.

Figure 5 shows the ^{1}H NMR spectra of Complexes III and IV. The ^{1}H NMR spectrum of Complex III exhibited a time dependence in the *C*-methyl signal of the coordinated *N*-methyl-L-alaninato ligand. The methyl signal of Complex III soon after dissolution consists of two doublets at 1.34 and 1.55 ppm (center of the doublet) with the relative intensity of about 1:1. At the equilibrium conditions, only one doublet at 1.34 ppm is observed, and the ^{1}H NMR

Table 2. The isomeric ratio of β_2-[Co(α-Me-sal$_2$en)(*N*-R-L-ala)] at the equilibrium conditions[a)]

N-R-L-ala	Λ_{RS}-Isomer/Λ_{SS}-Isomer	Stereoselectivity
N-Bz-L-ala	≈100/≈0	≈100%
N-Me-L-ala	96.5/3.5	93%
N-Bz,Me-L-ala	≈100/0	≈100%

a) Solvent=$CH_3OH+CHCl_3$(1 : 4 in volume), Temp=35 °C.

spectrum is identical with that for Complex IV. Complex IV showed no observable time dependence in its ^{1}H NMR spectrum, except that the *N*-methyl signal became a singlet due to the H-D exchange of N–H proton on the *N*-methyl-L-alaninato ligand with deuterium of the solvent. Such ^{1}H NMR spectral behavior suggests that 1) Complex III is the 1:1 mixture of two species of isomer of [Co(α-Me-sal$_2$en)(*N*-Me-L-ala)] complex, 2) Complex IV is the pure $(-)_{435}$-isomer of the *N*-Me-L-ala complex, and 3) the stereoselectivity at the equilibrium conditions of the *N*-Me-L-ala complex is almost 100%. However, the above suggestions 1) and 3) somewhat disagree with the results obtained from the rotational measurements for the *N*-Me-L-ala complexes mentioned above. The disagreement in suggestion 1) may come from the overlap of peaks in the ^{1}H NMR spectrum, low sensitivity of the ^{1}H NMR spectrum as compared with the rotational measurement, or the rapid isomerization of one of the two $(+)_{435}$-isomers to the $(-)_{435}$-isomer in the course of the ^{1}H NMR spectral measurement for Complex III. The discrepancy in suggestion 3) should come from the low sensitivity of the ^{1}H NMR spectrum as compared with that of the rotational measurement. Here, the stereoselectivity at the equilibrium conditions of the *N*-Me-L-ala complex was estimated by the use of the following equation:

$$\text{Stereoselectivity (\%)} = [M]^B_{435}/[M]^A_{435} \times 100,$$

where $[M]^A_{435}$ and $[M]^B_{435}$ denote the molar rotations at 435 nm of Complex IV soon after dissolution (A) and at the equilibrium conditions (B) respectively. The estimated stereoselectivity is listed in Table 2.

3) β_2-[Co(α-Me-sal$_2$en)(N-Bz,Me-L-ala)]: The absorbance at 600 nm of the reaction solution between [Co(α-Me-sal$_2$en)] and *N*-benzyl-*N*-methyl-L-alanine became a constant value within a few minutes after the start of the reaction: the complexation of *N*-benzyl-*N*-methyl-L-alanine is quite fast, as are those of *N*-benzyl-L-alanine and *N*-methyl-L-alanine. Unlike the above two amino acids, however, the reaction solution of *N*-benzyl-*N*-methyl-L-alanine showed a large minus rotation at 435 nm from the beginning of the reaction, and no mutarotation was observed. The rotation of free *N*-benzyl-*N*-methyl-L-alanine itself is negligibly small at 435 nm under the experimental conditions employed ($c=1.0\times10^{-3}$ mol dm^{-3}). These facts indicate that only the $(-)_{435}$-isomer of β_2-[Co(α-Me-sal$_2$en)(*N*-Bz,Me-L-ala)] complex is produced by the formation reaction, and that the other isomers are not produced. As mentioned later, the other isomers may be too unstable to be produced. In fact, only the $(-)_{435}$-isomer (Complex V) was isolated from the reaction solution. Complex V itself is not so stable; thus, it decomposes at a higher temperature in methanol.

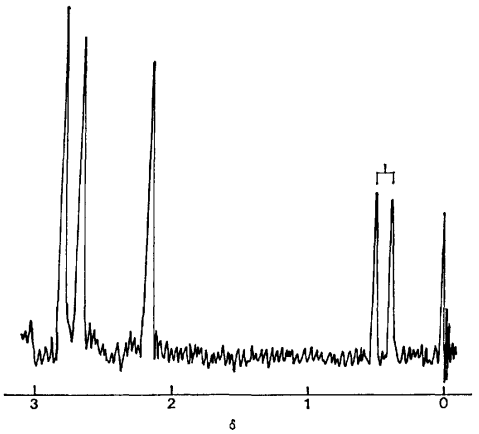

Fig. 6. The ^{1}H NMR spectrum of Λ_{RS}-β_2-[Co(α-Me-sal$_2$en)(*N*-Bz,Me-L-ala)] in $CDCl_3+CD_3OD$ (4:1).

Figure 6 shows the ^{1}H NMR spectrum of Complex V. The ^{1}H NMR spectrum corresponds to that of the only species of isomer, and no time dependence is observed. Since Complex V exhibits no mutarotation at 435 nm and no time dependence in its ^{1}H NMR spectrum, the stereoselectivity under the equilibrium conditions is estimated to be almost 100%.

The Structure and the Stereoselectivity of β_2-[Co(α-Me-sal$_2$en)(N-R-L-ala)] Complexes. 1) The Structure of the Complexes: The electronic absorption (AB) and the circular dichroism (CD) spectra of the isolated Complexes I—V are shown in Fig. 7. The CD spectra of Complexes I, III, and IV exhibited mutarotations The CD spectrum of Complex I gradually increased in its intensity, and that of Complex I at the equilibrium conditions corresponded to that of Complex II. The CD spectrum of Complex III gradually increased in its intensity, whereas that of Complex IV slowly decreased in its intensity, and the CD spectra of both Complexes at the equilibrium conditions coincided with each other. Further, the AB spectrum of Complex I soon after dissolution was very similar to that at the equilibrium conditions, and the AB spectrum at the equilibrium conditions coincided with that of Complex II. For Complexes III and IV, each AB spectrum soon after dissolution was very similar to that at the equilibrium conditions; AB spectra of both Complexes at the equilibrium conditions were the same.

Since the AB spectra of all the complexes isolated here resemble each other quite closely, it can be assumed that the geometrical structure with respect to the coordinated atoms is the same for all the complexes. The CD spectra of Complexes II, IV, and V, which correspond to the pure $(-)_{435}$-isomer of each *N*-R-L-ala complex, are very similar to that of $(-)_{435}$-Λ-β_2-[Co(α-Me-sal$_2$en)(L-ileu)].[8,16] Therefore, the Λ-β_2-structure can be assigned to the $(-)_{435}$-isomers. Figure 8 shows the vicinal effect of the coordinated *N*-R-L-ala in Complexes II, IV, and V. The vicinal effect was calculated by the use of the

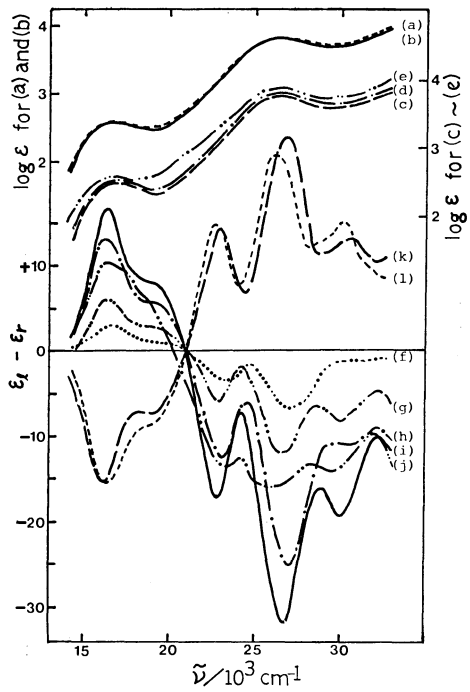

Fig. 7. AB and CD spectra of the complexes in a mixed solvent of $CHCl_3$ and CH_3OH (4:1).
(a): Complex I soon after dissolution, (b): Complex II, (c): Complex III soon after dissolution, (d): Complex IV soon after dissolution, (e) Complex V, (f): CD spectrum of Complex III at the isomeric ratio of 1:2 (Δ_{SS}-:Δ_{RS}-isomers), (g): Complex I at the isomeric ratio of 1:2 (Δ_{SS}-:Δ_{RS}-isomers), (h): Complex IV soon after dissolution, (i): Complex II, (j): Complex V, (k): the estimated CD spectrum of Δ_{SS}-β_2-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)], and (l): the estimated CD spectrum of Δ_{SS}-β_2-[Co(α-Me-sal$_2$en)(*N*-Me-L-ala)].

following equation:[17]

$$\text{CD(vicinal) in } (-)_{435}\text{-isomer} = \text{CD}^{\text{A}} - 3(\text{CD}^{\text{B}} - \text{CD}^{\text{C}}), \quad (1)$$

where CD^A represents the CD for the pure $(-)_{435}$-isomer of β_2-[Co(α-Me-sal$_2$en)(*N*-R-L-ala)], and CD^B and CD^C represent the CD's of the 1:2 (B) and 1:1 (C) mixtures of Δ- and Δ-β_2-[Co(α-Me-sal$_2$en)(L-ala)][8,16] respectively. The vicinal effects of all the *N*-R-L-ala closely resemble each other; they are very similar to that of the L-pro complex,[9] except for the reversed CD sign. It is well known that L-proline can chelate to metal ion with *N(S)C(S)*-configuration, and that the vicinal effect of the asymmetric coordinated atom is much larger than that of the asymmetric atom far from the metal ion. Thus, *N(R)C(S)*-configuration can safely be assigned to the coordinated *N*-R-L-ala in Complexes II, IV, and V. The X-ray study for Complex II is now going on, and we have recently confirmed that Complex II takes the Δ_{RS}-β_2-structure.[18]

The estimated CD curves for the $(+)_{435}$-isomers of the *N*-Me-L-ala and *N*-Bz-L-ala complexes, which exist in the course of the isomerization of Complexes I and III, are shown in Fig. 7. These CD curves were calculated by the use of the following equation:

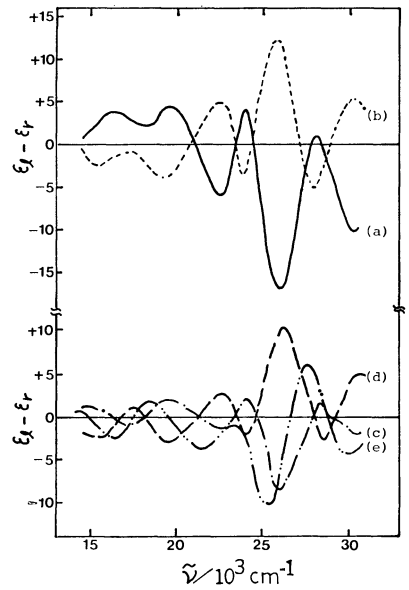

Fig. 8. The vicinal CD of the complexes.
(a) and (b) are those for Δ_{RS}- and Δ_{SS}-β_2-isomers of *N*-Bz-L-ala-complex respectively, (c) and (d) are those for Δ_{RS}- and Δ_{SS}-β_2-isomers of *N*-Me-L-ala-complex respectively, and (e) is the vicinal CD for Δ_{RS}-β_2-isomer of *N*-Bz,Me-L-ala-complex.

$$\text{CD}((+)_{435}\text{-isomer}) = 3\text{CD}^{\text{D}} - 2\text{CD}^{\text{A}}, \quad (2)$$

where CD^D represents the CD of the 1:2 mixture of the $(+)_{435}$- and $(-)_{435}$-isomers of the *N*-R-L-ala complex. The CD spectra could be measured in the course of the isomerization of the 1:1 mixture (Complexes I and III).[19] CD^A denotes the CD of the pure $(-)_{435}$-isomer of the *N*-R-L-ala complex. It is observed that the estimated CD curves for the $(+)_{435}$-isomers are almost mirror images of the CD spectra of the $(-)_{435}$-isomers. Thus, the Δ-β_2-structure can be assigned to the $(+)_{435}$-isomers. The vicinal effect of the *N*-R-L-ala in the $(+)_{435}$-isomers is shown in Fig. 8. The vicinal CD was calculated by the use of the following equation:

$$\text{CD(vicinal) in } (+)_{435}\text{-isomer} = \text{CD}^{\text{E}} - 3(\text{CD}^{\text{B}} - \text{CD}^{\text{C}}), \quad (3)$$

where CD^B and CD^C have been described above, and CD^E denotes the CD of the pure $(+)_{435}$-isomer. Since the vicinal effect is almost a mirror image of that of the corresponding *N*-R-L-ala in the $(-)_{435}$-isomers, the *N(S)C(S)*-configuration can be assigned to the *N*-R-L-ala in the $(+)_{435}$-isomers.

From these results and discussion, it can be concluded that the $(-)_{435}$-isomers of *N*-R-L-ala complex (Complexes II, IV, and V) take the Δ_{RS}-β_2-structure, whereas the $(+)_{435}$-isomer of the *N*-Bz-L-ala complex and one of the two $(+)_{435}$-isomers of the *N*-Me-L-ala complex, which isomerizes more slowly, take the Δ_{SS}-β_2-structure.

2) The Stereoselectivity: The stereoselectivity at the equilibrium conditions of *N*-R-L-ala complex is listed in Table 2. A quite high stereoselectivity can be established in the Co(Schiff base) complexes of *N*-R-L-ala, and the stereoselectivity is much higher than

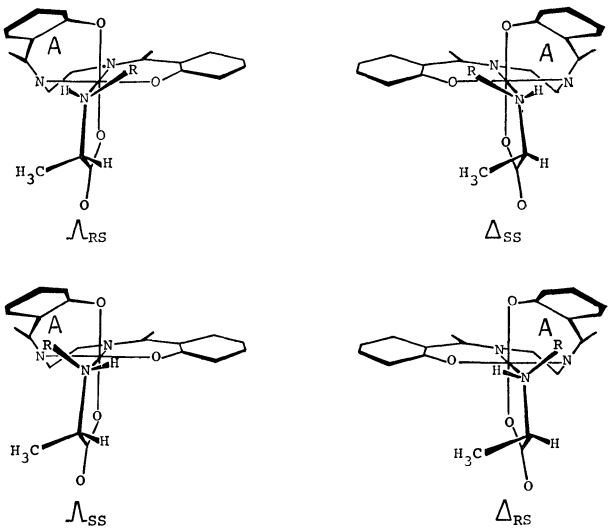

Fig. 9. Structure of four diastereoisomers of β_2-[Co(α-Me-sal$_2$en)(*N*-R-L-ala)].

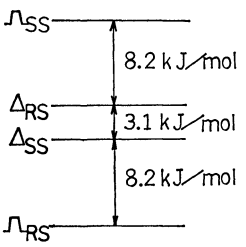

Fig.10. The relative energy difference among four diastereoisomers of *N*-Me-L-ala-complex.

that of Co(trien) complexes. Since the stereoselectivity under the equilibrium conditions can be regarded as thermodynamic in origin, the sterochemical reason why there is a large difference in the thermodynamic stability among the diastereoisomers of Co(Schiff base) complexes is developed as follows.

(a) N-*Me*-L-*ala Complex*: The possible four β_2-isomers are shown in Fig. 9. It is characteristic of a tetradentate Schiff base ligand with β-configuration that the chelate ring (A) in Fig. 9 inclines toward the side of the coordinated amino acid about 30° from the N–Co–O plane of (A). In the cases of Λ_{RS}- and Λ_{SS}-β_2-isomers, the molecular models indicate that the inclination of the chelate ring (A) brings about an extreme steric closeness (1.2—1.4 Å) between the distored chelate ring (A) and the *N*-methyl group of the coordinated amino acid. However, in the cases of Λ_{RS}- and Δ_{SS}-β_2-isomers, there is no abnormal steric closeness between them. In the cases of Λ_{RS}- and Δ_{SS}-β_2-isomers, the *N*-methyl group somewhat approaches to the two phenolic oxygen atoms of α-Me-sal$_2$en ligand (about 2.3 Å), but the steric repulsion seems to be much weaker than that between the chelate ring (A) and the *N*-methyl group in the Δ_{RS}- and Λ_{SS}-β_2-isomers. Thus, it can be assumed that Λ_{RS}- and Δ_{SS}-β_2-isomers are much more stable than Δ_{RS}- and Λ_{SS}-β_2-isomers. In the case of L-pro complex, it has been reported that the Δ_{SS}-β_2-isomer is more stable than the Λ_{SS}-β_2-isomer at about 11.3 kJ mol^{-1} or more.[9]

On the other hand, the conformational relationship between the *N*-methyl and *C*-methyl groups of the *N*-methyl-L-alaninato ligand is staggered (*trans*) in the Λ_{RS}- and Λ_{RS}-β_2-isomers, but it is nearly eclipsed (*cis*) in the Λ_{SS}- and Δ_{SS}-β_2-isomers. And, staggered is more stable than eclipsed. In the case of Co(α-Me-sal$_2$en) complex with *N*-methyl-L-alanine, the energy difference is estimated to be about 8.2 kJ mol^{-1} from the isomeric ratio, Λ_{RS}-isomer/Λ_{SS}-isomer, at the equilibrium conditions, and it is clearly smaller than the steric repulsion energy difference, 11.3 kJ mol^{-1}, between the Schiff base ligand and the *N*-methyl group mentioned above.

Consideration of the above two factors, which are though to contribute greatly to the stability of the diastereoisomers, allows the relative stability among the four isomers to be estimated to be Λ_{RS}->Δ_{SS}->Λ_{RS}->Λ_{SS}-β_2-isomers. The estimated energy differences among the four isomers are shown in Fig. 10.

In the cases of Co(trien) and Co((3*S*,8*S*)-dimetrien) complexes with *N*-methyl-L-alanine,[1,6] the isomeric ratio at the equilibrium conditions is Λ_{RS}-:Δ_{SS}-:Λ_{RS}-isomers=about 60:20:20 and about 85:11:4 respectively. On the other hand, in the case of the Co(α-Me-sal$_2$en) complex, the isomeric ratio at the equilibrium conditions is Λ_{RS}-:Λ_{SS}-isomers=96.5:3.5. The difference in the stereoselectivity between the Co(N$_4$) and Co(Schiff base) complexes seems to come from the following steric reasons: 1) the steric interaction between *N*-methyl group and the tetradentate ligand is much stronger in a Co(Schiff base) complex than a Co(N$_4$) complex, so that Λ_{RS}- and Λ_{SS}-isomers are too unstable to exist at the equilibrium conditions in the case of the Co(Schiff base)-system. 2) In order to decrease the steric closeness between *N*-methyl and *C*-methyl groups in the *N(S)C(S)*-configuration, the chelate ring of *N*-methyl-L-alanine in Co(trien) complex takes a nearly puckered conformation.[20] However, in the case of Co(Schiff base) complex, when the chelate ring takes this nearly puckered conformation, the *N*-methyl group comes close to one of the phenolic oxygen atoms of the Schiff base ligand. Thus, the energy difference between Λ_{RS}- and Λ_{SS}-isomers is much larger in the Co(Schiff base)-system than in the Co(N$_4$)-system.

(b) N-*Bz*-L-*ala Complex*: The steric crowding brough about by a *N*-benzyl group is much larger than that by a *N*-methyl group. Accordingly, the steric interaction between the *N*-alkyl group and the chelate ring (A) in Fig. 9 is much stronger in the *N*-Bz-L-ala complex than in the *N*-Me-L-ala complex, when they take Δ_{RS}- and Λ_{SS}-β_2-configurations. The Δ_{RS}- and Λ_{SS}-isomers of the *N*-Bz-L-ala complex are thus thought to be more unstable than those of the *N*-Me-L-ala complex. Further, the *cis* interaction between the *N*-alkyl group and the *C*-methyl group of the chelated amino acid in the *N(S)C(S)*-configuration is also much stronger in the *N*-Bz-L-ala complex than in the *N*-Me-L-ala complex. Thus, in the case of *N*-Bz-L-ala complex, only the Λ_{RS}-β_2-isomer is favored stereoselectively under the equilibrium conditions.

(c) N-*Bz,Me*-L-*ala Complex*: From the strong steric

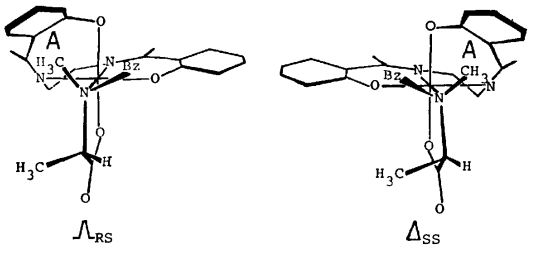

Fig. 11. The steric structure of Λ_{RS}- and Λ_{SS}-β_2-isomers of *N*-Bz,Me-L-ala-complex.

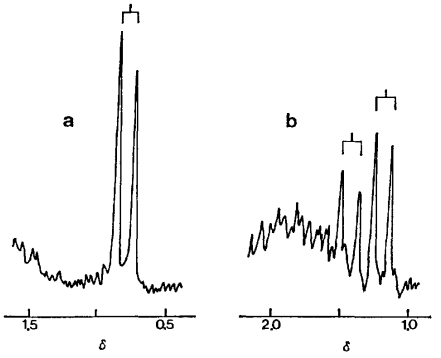

Fig. 12. The ^{1}H NMR spectra of Co(sal$_2$-(*S*,*S*)-chxn)-complexes in a mixed solvent of $CDCl_3$ and CD_3OD (4:1).
a: Λ_{RS}-β_2-[Co(sal$_2$-(*S*,*S*)-chxn)(*N*-Bz-L-ala)], b: a mixture of Λ_{RR}- and Δ_{SR}-β_2-isomers of [Co(sal$_2$-(*S*,*S*)-chxn)(*N*-Bz-D-ala)].

intereaction between the *N*-benzyl group and the distored chelate ring (A), the Λ_{RS}- and Λ_{SS}-β_2-isomers of the *N*-Bz,Me-L-ala complex are though to be relatively unstable as compared with the Λ_{RS}- and Δ_{SS}-isomers of the complex. Further, as shown in Fig. 11, even when the complex takes Λ_{RS}- and Δ_{SS}-configurations, the strong steric repulsion between the *N*-methyl group and the chelate ring (A) is inevitable: the *N*-Bz,Me-L-ala complex is thought to be more unstable than the *N*-Me-L-ala and *N*-Bz-L-ala complexes. In fact, Complex V decomposes at a higher temperature. The *cis* interaction between *N*-alkyl group and *C*-methyl group is also inevitable in the case of the *N*-Bz,Me-L-ala complex. However, the *cis* interaction between *N*-methyl group and *C*-methyl group in the Λ_{RS}-configuration is weaker than that between *N*-benzyl group and *C*-methyl group in the Δ_{SS}-configuration. Thus, the *N*-Bz,Me-L-ala complex takes the Λ_{RS}-β_2-structure stereoselectively.

Stereospecificity of Co(sal$_2$-(S,S)-chxn) Complex. It has been reported that a Co(sal$_2$-(*S*,*S*)-chxn) complex assumes the Λ-β_2-structure excusively when it reacts with amino acids such as L- and D-alanines and L- and D-valines.[11] Accordingly, it can be expected that the Co(sal$_2$-(*S*,*S*)-chxn) complex produces a complex containing *N*-benxyl-L-alanine stereospecifically, when it is allowed to react with racemic *N*-benzylalanine, because the Co(α-Me-sal$_2$en) complex with *N*-benzyl-L-alanine, which is similar, shows almost 100% stereoselectivity for the Λ_{RS}-β_2-configuration, as has been mentioned above.

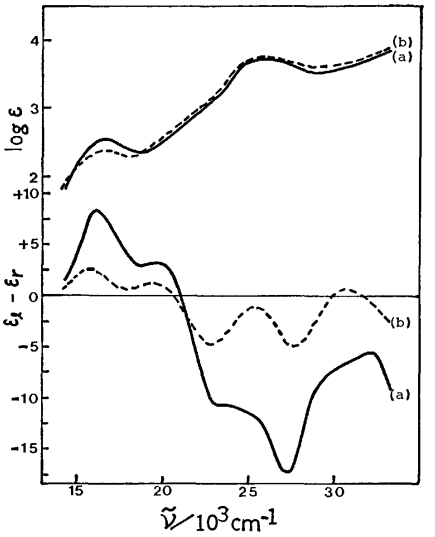

Fig. 13. AB and CD spectra of Co(sal$_2$-(*S*,*S*)-chxn)-complexes in the same solvent as that in Fig. 7.
a: *N*-Bz-L-ala, b: *N*-Bz-D-ala.

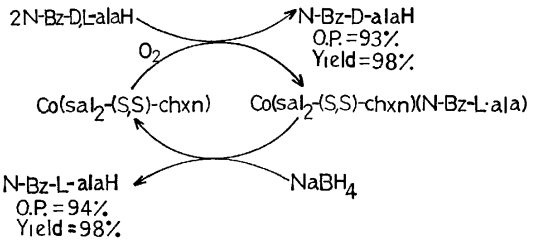

Fig. 14. The scheme for the optical resolution of *N*-benzylalanine with Co(sal$_2$-(*S*,*S*)-chxn)-complex.
The optical purity shown in this figure is the value when the reaction molar ratio between [Co(sal$_2$-(*S*,*S*)-chxn)] and racemic *N*-benzylalanine is 1:2.

Figure 12 shows the ^{1}H NMR spectra of the Co(sal$_2$-(*S*,*S*)-chxn) complexes with *N*-Bz-L-ala and *N*-Bz-D-ala. From the *C*-methyl signals of the coordinated *N*-benzyl amino acids, it is clear that the *N*-Bz-L-ala complex (Complex VI) exists as only one species of isomer but the *N*-Bz-D-ala complex (Complex VII) exists as a mixture of two species of isomer at about 1:1.5 isomeric ratio.

Figure 13 shows the AB and CD spectra of the complexes. Since the AB and CD spectra of the *N*-Bz-L-ala complex are very similar to those of $(-)_{435}$-Λ-β_2-[Co(α-Me-sal$_2$en)(L-ileu)],[8,16] the Λ_{RS}-β_2-structure can be assigned to it. In the case of the *N*-Bz-D-ala complex, the AB and CD spectra are also similar to those of $(-)_{435}$-Λ-β_2-[Co(α-Me-sal$_2$en)(L-ileu)]; however, the CD intensity is much smaller than that of the *N*-Bz-L-ala complex. The molecular model of Co(sal$_2$-(*S*,*S*)-chxn) complexes suggests that the sal$_2$-(*S*,*S*)-chxn moiety can take Λ-β-configuration as well as Λ-β-form, although the strain energy is much larger in Λ-β-configuration. Therefore, the *N*-Bz-D-ala complex may be a mixture of Λ_{RR}-β_2- and Δ_{SR}-β_2-isomers with the isomeric ratio of about 1.5:1.

The formation of the Δ_{SR}-β_2-isomer was not expected. It is expected that the Δ_{SR}-β_2-isomer will be more unstable than the Λ_{RR}-β_2-isomer and the Λ_{RR}-

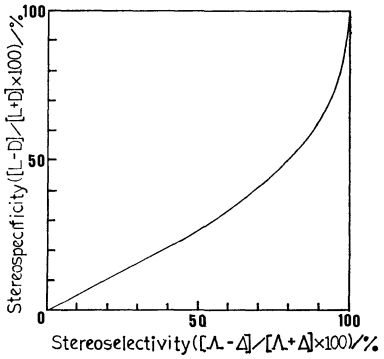

Fig.15. The estimated relationship between stereoselectivity of Co(α-Me-sal$_2$en)-complex and stereospecificity in the reaction of [Co(sal$_2$-(*S*,*S*)-chxn)] with racemic amino acid (the molar ratio=1:2).

β_2-isomer will be much more unstable than the Λ_{RS}-β_2-isomer of *N*-Bz-L-ala complex. Thus, our initial expectations may still be satisfied.

In order to estimate the stereospecificity of the Co(sal$_2$-(*S*,*S*)-chxn) complex toward *N*-benzyl-L-alanine, we examined the reaction of [Co(sal$_2$-(*S*,*S*)-chxn)] and racemic *N*-benzylalanine at 1:2 reaction molar ratio under the air-oxidation conditions. The reaction scheme is shown in Fig. 14. The detailed experimental procedure is described in the Experimental section. Two points should be noted; 1) no racemization of *N*-benzylalanine is observed in the employed experimental conditions, and 2) the recovered [Co(sal$_2$-(*S*,*S*)-chxn)] can be used repeatedly.

From the optical purity of the isolated *N*-benzylalanine, it can be concluded that *N*-benzyl-L-alanine coordinates to the Co(sal$_2$-(*S*,*S*)-chxn) complex in a high stereospecificity (93—94%). However, the stereospecificity did not reach 100%. Figure 15 shows the relationship between the stereoselectivity for Δ- and Λ-isomers in the Co(α-Me-sal$_2$en) complex and the stereospecificity in the reaction of similar Co(sal$_2$-(*S*,*S*)-chxn) complex with a racemic amino acid at 1:2 reaction molar ratio. The relationship was calculated by the use of Equations (3) and (4) in Ref. 11. This figure indicates that the higher the stereoselectivity, the higher the stereospecificity, but their values are not the same. For example, when the stereoselectivity is 98%, the stereosepecificity is 82%. and when it is 99.7%, the stereospecificity is 93%. From these calculations, it is estimated that the stereoselectivity of β_2-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)] is not complete but it may reach about 99.7%.

It should be noted that when the reaction molar ratio between [Co(sal$_2$-(*S*,*S*)-chxn)] and racemic *N*-benzylalanine was 1:100, the optical purity of the *N*-benzylalanine recovered from the produced complex was almost 100% (L-form).

The authors whish to express their deep thanks to Professor J. Hidaka of Tsukuba University and to Professor K. Sone and Dr. Y. Fukuda of Ochanomizu University for their kind assistance with the CD spectral measurements. This work was partly supported by a Grant-in-Aid for Scientific Research No. 547038 from the Ministry of Education, Science and Culture.

18) Will be published elsewhere.
19) In the case of the *N*-Me-L-ala complex, Complex I contains three isomers: two $(+)_{435}$-isomers and one $(-)_{435}$-isomer. However, one of the two $(+)_{435}$-isomers isomerizes quite rapidly. Thus, the contribution of one of the two $(+)_{435}$-isomers to the CD intensity at the isomeric ratio of 1:2 between $(+)_{435}$- and $(-)_{435}$-isomers can be neglected.

Substituent and Solvent Effects in the Reactions of Diaryldiazomethanes with 2,3-Dichloro-5,6-dicyanobenzoquinone

Takumi Oshima and Toshikazu Nagai*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received August 18, 1980)

Kinetic studies have been made of the reactions of fifteen *meta*- and *para*-substituted diphenyldiazomethanes(DDMs) with 2,3-dichloro-5,6-dicyanobenzoquinone(DDQ) in benzene. The second-order rate constants, k, increased with the electron-donability of the substituents, and the value could be correlated with the Yukawa-Tsuno equation: $\log k/k_0 = -2.33(\sigma^0 + 0.47\Delta\bar{\sigma}_R^+) + 0.017$, ($r$=0.996,30 °C). The ρ value, −2.33, indicates the development of a positive charge at the diazo carbon in the transition state, while the R value, 0.47, confirms the moderate stabilization of the positive charge by the π-electronic contribution of the para substituents. The rate constants have also been determined for the reaction of diphenyldiazomethane(DDM) with DDQ in 28 aprotic solvents. The effects of solvents can be interpreted in terms of the basicity and the steric nature of the solvents. The products of these reactions were poly(2,3-dichloro-5,6-dicyanohydroquinone benzhydryl ether)s, which were easily convertible into benzophenones and α,α-dimethoxydiphenylmethane, together with 2,3-dichloro-5,6-dicyanohydroquinone, under the influence of water and methanol. These solvolysis products were also obtained in excellent yields in the initial presence of these additives.

In view of the general interest in reactions of diazoalkanes with quinones, most of the synthetic and mechanistic works have been carried out by use of the simplest diazoalkane, *e.g.*, diazomethane.[1] However, little is known of the reactions of aryl- and diaryldiazomethanes[2] with quinones or of kinetic studies of these systems.

We previously reported that chloranil decomposed a variety of substituted diphenyldiazomethanes(DDMs) to produce poly(2,3,5,6-tetrachlorohydroquinone benzhydryl ether)s and that the second-order rate constants were very dependent on the substituents and the solvents.[3] In this paper, we extend our studies of substituent and solvent effects to the kinetics of the reactions of DDMs with 2,3-dichloro-5,6-dicyanobenzoquinone(DDQ).

Results and Discussion

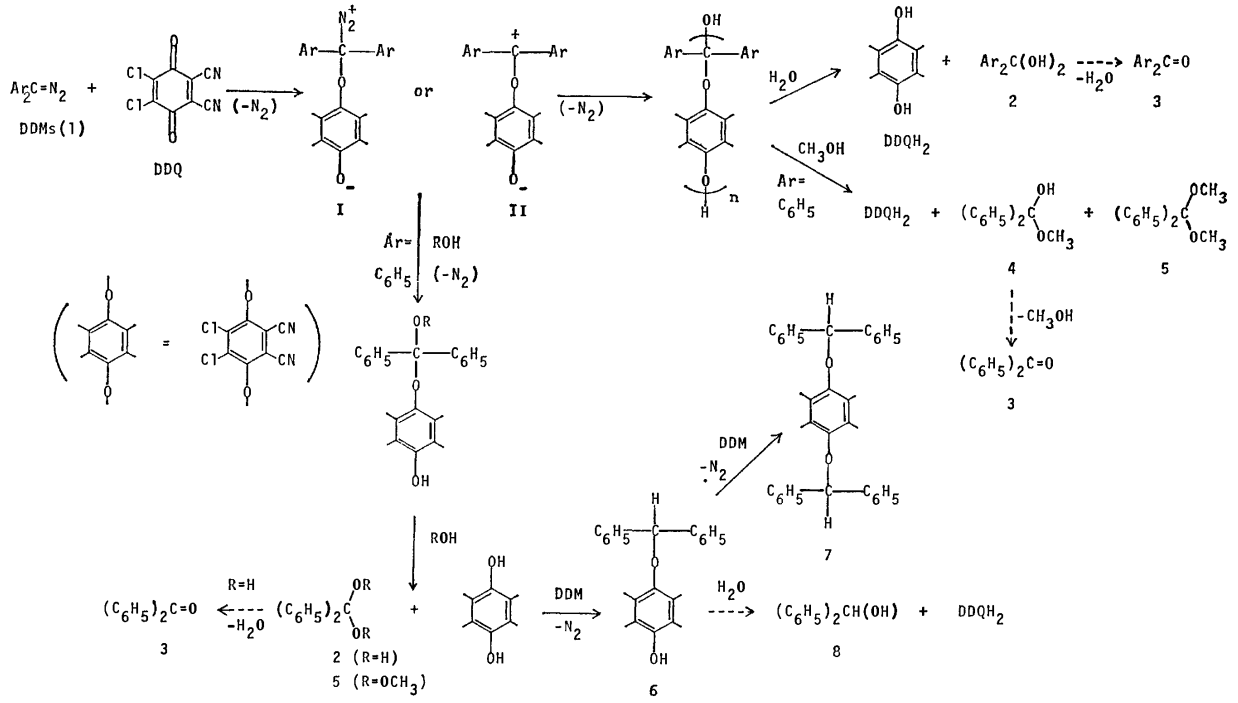
Product Studies. As well as in the case of chloranil,[3] the reactions of fifteen *meta*- and *para*-substituted DDMs with an equimolar amount of DDQ in benzene at 30 °C were much more accelerated with the increase in the electron-donating abilities of the substituents. All these reactions, more or less accompanied by an evolution of N_2, gave resinous products which were highly sensitive to hydroxylic solvents. When these products were hydrolyzed, corresponding benzophenones (**3**) and 2,3-dichloro-5,6-dicyanohydroquinone($DDQH_2$) were isolated in most cases greater than 95%. Moreover, the methanolysis of the product in the case of diphenyldiazomethane(DDM) afforded α,α-dimethoxydiphenylmethane (**5**) in an 81% yield, together with **3** (15%) and $DDQH_2$ (96%). These chemical findings strongly suggest the structure of the 1:1 reaction products to be a hydroquinone polyether linkage similar to that previously considered for the chloranil–DDMs systems.[3] This suggestion is also supported by the representative IR spectrum of the DDM–DDQ system, which exhibited a complete loss of the characteristic carbonyl absorption of DDQ.

The ether linkage may be made up by the successive combination of intermediary diazonium betaines(I) or carbonium betaines(II), as is predicted in Scheme 1. The propagation may be terminated by the action of the residual water present in the solvent. Further action of water and methanol can cause the hydrolytic and methanolytic cleavage of the ether bonds to give *gem*-diols (**2**) and **5**, together with $DDQH_2$; the *gem*-diols are transformed into **3**. In the case of methanolysis, the formation of **3** as a by-product is attributable to the terminal benzhydrol moiety, which primarily degrades into α-methoxy-α-phenylbenzyl alcohol (**4**), which is itself easily convertible into **3**. Therefore, it is possible to estimate the average polymerization degree (n) from the ratio of **5** (81%) to **3** (15%); the value over 5 corresponds to n=6—7.

On the other hand, the initial presence of water and methanol as additives induced solvolysis reactions giving, respectively, **3** and **5**, along with $DDQH_2$. These products are thought to be yielded by the successive nucleophilic attack of these additives on the betaine intermediate, as is also depicted in Scheme 1. These reactions were accompanied by trace amounts of benzhydrol (**8**) and 2,3-dichloro-5,6-dicyanohydroquinone dibenzhydryl ether (**7**) arising from the acid-induced decomposition of DDM by the resulting $DDQH_2$; **8** seems to be afforded by the hydrolysis of 2,3-dichloro-5,6-dicyanohydroquinone benzhydryl ether (**6**).

Apparently, the susceptibility of rates to the substituents, the stoichiometry of the reactions, and the solvolysis evidence all confirm that the present diaryldiazomethanes(DDMs)–DDQ systems proceed through a reaction course similar to that of chloranil systems.[3]

Kinetic Studies. Substituent Effects: The reactions of DDMs with DDQ in benzene can be followed spectrophotometrically by monitoring the disappearance of the absorption of DDQ at 408 nm or that of the combined absorptions of both components at 500 nm in the case of nitro-substituted DDMs. These reactions have been found to obey a second-order kinetic law. The rate constants, k, determined for the fifteen *meta*- and *para*-substituted DDMs at various temperatures are listed in Table 1, together



Scheme 1.

a) The values in parentheses are the second-order rate constants for the reactions of DDMs with chloranil in benzene.

with the activation parameters. This table also includes the comparable kinetic data of the reactions of DDMs with chloranil in benzene at 30 °C. It is noteworthy that the present reactions were much more accelerated with an increase in the electron-releasing abilities of the substituents; the *p,p'*-dimethoxy substituents caused a *ca.* 9000-fold increase in the rates compared with the *p*-nitro substituent, though the chloranil system showed only a 960-fold increase.

The dependency of log k/k_0 on the Hammett σ[4] and Brown σ^+[5] constants is shown in Fig. 1. As may be noticed, the additivity of the substituent constants holds for the disubstituted DDMs. Four *meta*-substituted DDMs gave a sufficient linear dependence ($\rho=-2.19$), $r=0.990$ (correlation coefficient) when the simple Hammett equation and normal σ values were used. When correlating all the DDMs and using the normal σ values, we obtained slighlty worse results ($\rho=-2.65$, $r=0.983$). The correlation line curved somewhat upward from the meta line. The replacement of σ by σ^+ displayed a significant curvature with a ρ value of −1.67 ($r=0.976$), wherein the meth-

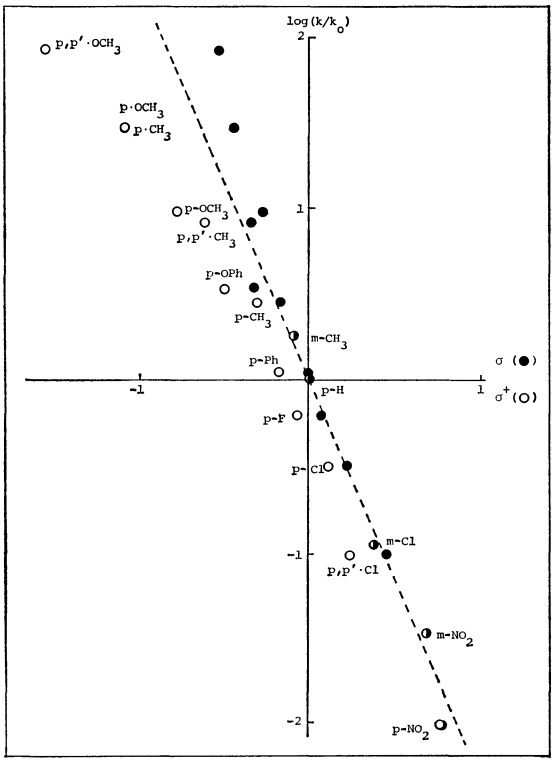

Fig. 1. Plot of $\log k/k_0$ against the Hammett σ(●) and Brown σ^+(○) constants.

oxy substituents induced the marked deviation from the meta line. Thus, the one-parameter equation did not well fit the correlation of *para*-substituted DDMs. We used, therefore, the two-parameter Yukawa-Tsuno equation,[6] $\log k/k_0 = \rho(\sigma^0 + R\Delta\bar{\sigma}_R^+)$, where σ^0, R, and $\Delta\bar{\sigma}_R^+$ are the normal substituent constant, the resonance reaction constant, and the resonance substituent constant respectively. The two-parameter treatment provided a better correlation (Eq. 1):

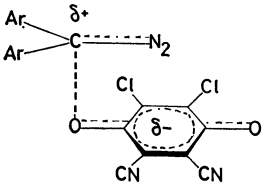
$$\log k/k_0 = -2.33(\sigma^0 + 0.47\Delta\bar{\sigma}_R^+) + 0.017(r=0.996,\ s=0.09,\ n=15). \quad (1)$$

The ρ value of -2.33 is consistent with the development of a positive charge at the diazo carbon in the transition state, while the R value of 0.47 indicates an almost equivalent stabilization of the positive charge by both the inductive and the resonance contributions of the *para* substituents.

When a similar regression analysis was applied to the chloranil–DDMs reactions in benzene (Table 1), a sufficient correlation (Eq. 2) was also obtained with a ρ value of -1.39 and an R value of 0.69:†

$$\log k/k_0 = -1.39(\sigma^0 + 0.69\Delta\bar{\sigma}_R^+) + 0.0314(r=0.989,\ s=0.12,\ n=14). \quad (2)$$

A comparison of the Hammett parameters in the two systems is of usefulness in obtaining some information about the transition state. As well as the chloranil–DDMs reactions[3] the present DDQ reactions are postulated to proceed through the polar transition state depicted below, though the polar transition state of 1,3-dipolar addition can not be ruled out. The negatively larger ρ value for DDQ reactions implies that DDQ induces a more positive charge in the diazo carbon, probably because its electron acceptability is stronger than that of chloranil.[7] How-



ever, the extent of the resonance stabilization of the positive charge is somewhat lower in DDQ reactions (0.47) than in chloranil reactions (0.69). This discrepancy can be explained by speculating that the higher electron-acceptor ability of DDQ tends to develop more the bond between the diazo carbon and the quinone oxygen. That is, the sp^2 hybridization of the diazo carbon is reduced, and the effect of resonance contribution is thereby lessened, compared to the case of chloranil.

Solvent Effects: In a previous paper, we discussed the kinetics of the reaction of DDM with chloranil in several aprotic solvents.[3] The kinetic solvent effects were tentatively interpreted in terms of the stabilization of the initial state relative to the transition state. We have now extended these studies of solvent effects to the kinetics of the present reaction. As is shown in Table 2, the rates were much more accelerated in the halogenated solvents, while they were decelerated in tetrahydrofuran or toluene; the k values for chloroform and carbon tetrachloride are *ca.* 110—160 times greater than for toluene. Nonpolar carbon tetrachloride is also noticiable for bringing about a 10—50-fold increase in the rate compared to the polar acetonitrile and acetone. These kinetic results imply that the reaction rate is primarily influenced by the solvation of the initial state rather than by that of the transition state for which the polar-activated complex was deduced from the kinetic substituent effects. This situation is represented in the free-energy profile, where the stronger solvation of initial reactants overcomes the accelerating solvation of the present polar-activated complex, consequently increasing the free activation energy (Fig. 2).

Since DDQ is a strong electron-acceptor, like chloranil and TCNE,[7] such specific solute-solvent interactions as the formation of a charge-transfer complex may be expected, especially in the solvents with a high basicity.[8] Therefore, we attempted to correlate $\log k$ with some of the solvent-basicity parameters, *e.g.*, $\Delta\nu_D$,[9] β,[10] and DN.[11] The symbols have the following meanings: $\Delta\nu_D$ is defined as the relative difference between the O–D absorption band of methanol-*d* observed in a given solvent and that in benzene; β, as the hydrogen-bonding acceptor basicity, and DN (donor number), as the negative ΔH values for 1:1 adduct formation between antimony pentachloride and electron-pair donor solvents in 1,2-dichloroethane.

† We have reported in our previous paper[3] that in the THF medium the chloranil systems also gave an excellent correlation with a somewhat large negative ρ value of -1.67 and a substantially equal R value of 0.66.

Table 2. Rate constants and activation parameters for the reaction between DDM and DDQ in aprotic solvents, with solvent basicity parameters

	Solvents	k/l mol^{-1} s^{-1} 30 °C	40 °C	50 °C	$\Delta H^{\ddagger}$ kJ mol^{-1}	$\Delta S^{\ddagger}$ J mol^{-1} K^{-1}	$\Delta\nu_D$	β	DN

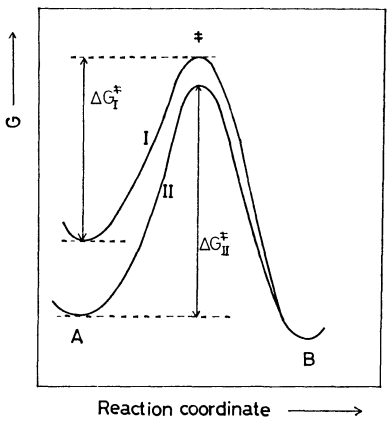

Fig. 2. Schematic free energy profiles for the reaction with non-solvated(I) and solvated(II) reactants (preferential solvation of the initial reactants).
$\Delta G^{\ddagger}_{I}$, $\Delta G^{\ddagger}_{II}$=Free activation energy in nonpolar(I) and polar solvents(II) respectively. A=Initial reactants; ‡=activated complex; B=products.

The values of $\Delta\nu_D$, β, and DN are available for 23, 15, and 13 of our solvents respecitvely, and inspection (Table 2) shows that the reaction tends to be fast in weakly basic solvents and slow in strongly basic solvents.

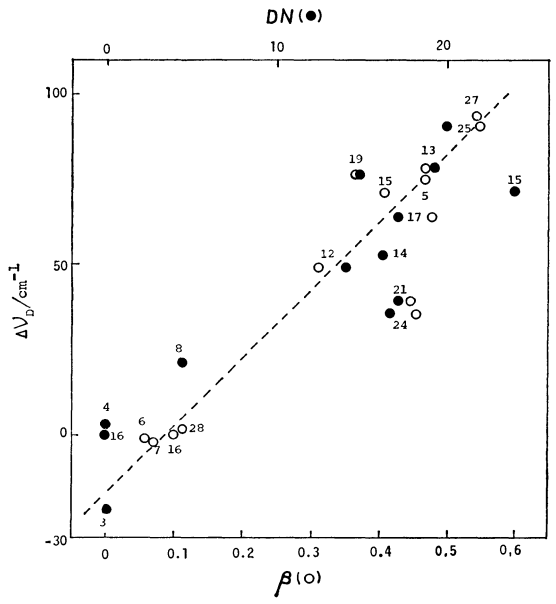

Fig. 3. Relationships between $\Delta\nu_D$ and β, and DN; for point numbers, see Table 2.

A comparison of these parameters substantially presented the linear relationship shown in Fig. 3. We adopted the widely available $\Delta\nu_D$ values as the solvent

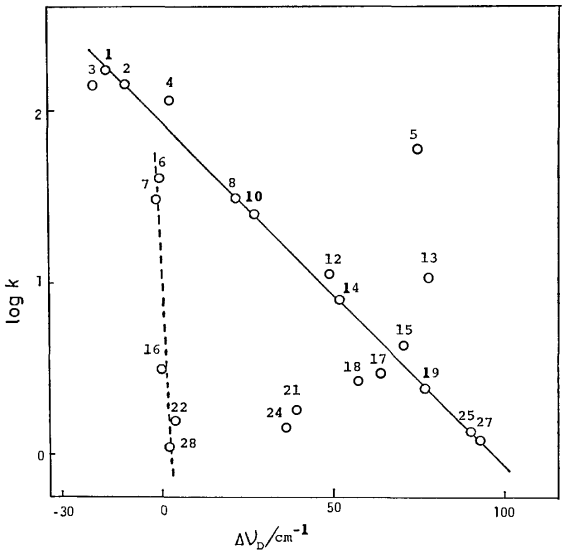

Fig. 4. Plot of log k against $\Delta\nu_D$; for point numbers, see Table 2.

basic parameter. As is shown in Fig. 4, a plot of log k against the $\Delta\nu_D$ values provided two correlation groups, excluding six solvents (Solv. Nos. 5, 13, 17, 18, 21, 24). The first solvent group, including aliphatic chlorinated solvents, nitriles, and cyclic ethers, moderately decreased the logarithmic rate with the increase in the solvent basicities. The regression analysis gave an excellent correlation (Eq. 3, solid line). The second group, consisting of five aromatic solvents, brought about a steeper decrease (slope −0.259, broken line). The correlation equation (r= 0.848), however, is not so good, probably because the $\Delta\nu_D$ values of these aromatic solvents are too narrow (ranging from −2 to 4 cm^{-1}) to avoid the uncertainty due to the error (±1 cm^{-1}) in the measured shift of O–D stretching.

$$\log k = -0.0196\Delta\nu_D + 1.92 \quad (r=0.991,\ s=0.005,\ n=12) \qquad (3)$$

These phenomena confirm that the present reaction is essentially governed by the extent of the interaction between solvents and DDQ in the initial state. Two solvent groups are given because of the difference in the solvent basic nature. Of the solvents, alkyl halides are σ-donors; ethers, nitriles, and ketones are n-donors, and aromatic hydrocarbons are π-donors.[12] According to the HSAB concept,[13] DDQ is a soft acid π-acceptor and prefers to bind soft bases, such as benzene and toluene. Therefore, the specific stability of the π-donor–π-acceptor complexes between the aromatic solvents and DDQ seems to give a separate correlation line from the first solvent group. These aromatic solvents are strong bases toward such π-acceptors as DDQ, while they are weak toward a typical hard acid methanol, as judged by the small $\Delta\nu_D$ values. However, nitrobenzene was an exceptional aromatic solvent, probably because the negatively charged nitro group acts overwhelmingly as an associating site.

It can also be seen in Fig. 4 that the log k values for the solvents containing carbonyl groups (Nos. 17, 18, 21, 24) and for diethyl ether (No. 13) and diisopropyl ether (No. 5) are smaller and larger respectively than called for by Eq. 3. We assume that these carbonyl solvents possess, to some extent, a softness toward DDQ, the property of which can not be evaluated by the interaction with hard acid methanol-*d*. Methyl chloroacetate, however, belongs to the first solvent group because the chlorine substituent weakens the basicity. The upper deviation of diethyl and diisopropyl ethers is attributable to the steric hindrance, which is of some importance in estimating the strength of the solvent-DDQ interaction. A bulky substituent adjacent to the oxygen atom undoubtedly causes an increase in the rate, probably because of the poor solvation of DDQ. This phenomenon can be understood in terms of the Taft steric constants,[14] E_S, which predict the present increase in k in the series of diisopropyl ether (E_S=−0.47)>dibutyl ether (−0.39)>diethyl ether (−0.07).

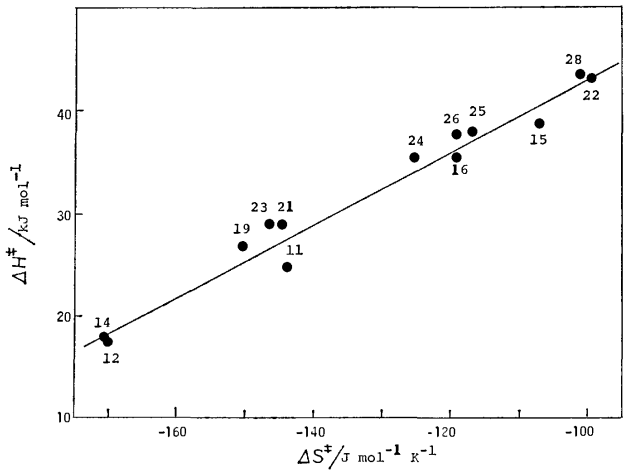

Fig. 5. Plot of ΔH^* *vs.* ΔS^*; for point numbers, see Table 2.

With regard to the enthalpies and entropies of activation, a plot of ΔH^* against ΔS^* displayed a linear correlation (r=0.98, Fig. 5). The ΔH^* values vary from 17.2 to 43.6 kJ mol^{-1} in going from acetonitrile to toluene, while the ΔS^* values vary from −99.5 to −170 J mol^{-1} K^{-1} in going from ethylbenzene to acetonitrile. The larger ΔH^* values for toluene and ethylbenzene are indicative of the high stabilization of the DDQ molecule, consistent with the favorable π-π donor acceptor interaction in the initial state, by which the negatively smaller ΔS^* values of these solvents can be explained.

Experimental

The IR and NMR spectra were recorded on Hitachi 215 and Varian EM-360 spectrometers respectively. The UV spectra were observed with Hitachi 323 and JASCO UVIDEC 505 instruments.

Materials. All the diaryldiazomethanes were made by the oxidation of the corresponding hydrazones with yellow mercury(II) oxide, as has previously been described.[15] The physical properties of these diazoalkanes were listed in previous papers.[3,16] The 2,3-dichloro-5,6-dicyanobenzoquinone(DDQ) was of commercial origin and was recrystal-

lized from dichloromethane; orange yellow needles, mp 213 °C. All the solvents were dried and purified according to the standard procedures.[17]

Kinetic Measurements. The kinetic data were obtained according to the standard spectrophotometric methods. Solutions for kinetic experiments were prepared separately just before use in a volumetric flask equipped with a stopper. The DDQ solution (10^{-5}—10^{-3} mol dm^{-3}) was introduced into a stoppered quartz optical cell (10 mm) and kept at the given temperature within ±0.1 °C in a thermostat-controlled cell-holder of a Hitachi 323 spectrophotometer. The reaction was initiated by the quick addition of the requisite volume of a DDM slution(10^{-5}—10^{-3} mol dm^{-3}), which had been preheated in a water bath to the same temperature as the above cell-holder. The change in the maximum absorption (408 nm, ε=2750) of DDQ in benzene was conveniently monitored over at least two half-lives in the cases of the DDMs (**1a**—**m**), for these diazoalkanes and the products are essentially transparent at this wavelength. In the cases of nitrosubstituted DDMs(**1n**—**o**), the additive absorption of these diazoalkanes(**1n**; ε=122, **1o**; ε=290) and DDQ(ε=361) at 500 nm in benzene was followed. The measurements in the other solvents were made by following the appropriate absorption of DDQ in the regions of 380—410 nm. The second-order rate constants, k, were determined graphically from the plots of $\ln\{b(a-x)/a(b-x)\}/(a-b)$ against the time, where a and b are the initial concentrations of the DDMs or DDQ respectively, x being the consumed DDMs or DDQ. The rate constants were reproducible within ±3%(usually two determinations).

Reactions of Diaryldiazomethanes(DDMs) with DDQ in Benzene. General Procedures: A benzene solution (10 ml) of diphenyldiazomethane(DDM) (0.50 g, 2.58 mmol) was added, all at once, to a solution of DDQ (0.59 g, 2.60 mmol) in benzene (20 ml). The purple color of DDM suddenly disappeared with the vigorous evolution of N_2. After stirring for 1 h (one overnight standing for the nitro-substituted DDMs), the solvent was evaporated *in vacuo* to give an essentially colorless, resinous product, the IR spectrum of which showed no absorption in the C=O region. The product was then treated with a ten-fold excess of water or methanol for 10 min, with occasional shaking and dried under reduced pressure. The pasty residue thus obtained was triturated with 50 ml of benzene. Filtration gave $DDQH_2$ (0.56—0.57 g, 94—96%). The filtrate was washed with aqueous sodium carbonate and dried over anhydrous sodium sulfate. The subsequent evaporation of benzene gave benzophenone (0.45 g, 96%) in the case of treatment with water or α,α-dimethoxydiphenylmethane(**5**) (0.48 g, 81%) and benzophenone (70 mg, 15%) in the case of treatment with methanol. The relative yields of **5** and benzophenone were determined by means of the NMR spectrum of the product mixture, while pure **5** was obtained by fractional crystallization from pentane. The benzophenones and **5** were identified by a comparison of the IR and NMR spectra with those of authentic samples.[3]

Reaction of Diphenyldiazomethane(DDM) with DDQ in H_2O–Benzene. A benzene solution (10 ml) of DDM (0.50 g, 2.58 mmol) and H_2O (0.23 g, 13 mmol) was added, all at once, to a solution of DDQ (0.59 g, 2.60 mmol) in benzene (20 ml). After stirring for 1 h, the removal of the solvent, followed by column chromatography(silica gel), gave 2,3-dichloro-5,6-dicyanohydroquinone dibenzhydryl ether(**7**) (35 mg, 5% based on the DDM used), and benzophenone (0.40 g, 85%) with a petroleum ether–benzene mixture, and then $DDQH_2$ (0.49 g, 83%) and benzhydrol(**8**) (30 mg, 6%) with a benzene–ether mixture. The product, **7**, had a mp of 190—191 °C (from benzene) (lit,[18] mp 189—190 °C), IR(KBr): 2235, 1412, 993, 928, and 695 cm^{-1}; NMR (δ, $CDCl_3$): 6.67(2H, s) and 7.33(20H, s); Found: C; 72.94, H; 4.15, N; 4.94%. Calcd for $C_{34}H_{22}Cl_2N_2O_2$: C; 72.72, H; 3.95, N; 4.99%. Compound **8** was identified by a comparison of its IR and NMR spectra with those of a commercial sample.

Reaction of DDM with DDQ in CH_3OH–Benzene. A benzene solution (10 ml) of DDM (0.50 g, 2.58 mmol) and CH_3OH (0.42 g, 13 mmol) was added, all at once, to a solution of DDQ (0.59 g, 2.60 mmol) in benzene (20 ml). After stirring for 1 h, the reaction mixture was evaporated *in vacuo* and the pasty residue was triturated with benzene (50 ml). Filtration gave pure crystalline $DDQH_2$ (0.54 g, 91%). The filtrate part was divided in equal parts and was examined by two different methods. One part was washed with aqueous sodium carbonate (5%), dried over sodium sulfate, and evaporated to dryness to give crystalline **5** (0.26 g, 87%). The other part was evaporated, followed by column chromatography(silica gel) to give **7** (30 mg, 4%) and benzophenone (0.20 g, 85%) with a petroleum ether–benzene mixture, and **8** (15 mg, 6%) with a benzene–ether mixture. Thus, acetal **5** was completely changed into benzophenone on silica-gel-column chromatography.

Acetylenic and Polyacetylenic Compounds Derived from Thiophene, Furan, and *p*-Dibromobenzene Using 1,1-Dichloro-2,2-difluoroethene

Kunio Okuhara

Government Industrial Research Institute, Nagoya, Hirate Machi, Kita-ku, Nagoya 462

(Received September 1, 1980)

Compounds of the type AZCF=CCl_2, prepared from AZA (thiophene, furan, and *p*-dibromobenzene; Z= 2,5-thiophenediyl, 2,5-furandiyl, and *p*-phenylene; A=H or Br), were converted into CCl_2=CFZC≡CH, CCl_2=CFZC≡CCF=CCl_2, and CCl_2=CFZC≡C$Si(CH_3)_3$ in a one-flask procedure *via* LiZC≡CLi. The products were further converted into acetylenic compounds such as $(CH_3)_3$SiC≡CZC≡C$Si(CH_3)_3$ and $(CH_3)_3$SiC≡CZC≡C–C≡C$Si(CH_3)_3$. 1-Ethynyl-4-(1,3-butadiynyl)benzene was isolated. 2,5-Diethynylthiophene and -furan were prepared in two steps from thiophene and furan, respectively, *via* CCl_2=CFZCF=CCl_2. By treatment with copper (II) acetate hydrate in pyridine, (CCl_2=CFZC≡C–)$_2$ were obtained not only from CCl_2=CFZC≡CH but also from CCl_2=CFZC≡C$Si(CH_3)_3$.

For introduction of the ethynyl group, the method using CF_2=CCl_2 (**1**)[1] is useful where R is aryl[2,3] and the organolithium and/or magnesium compounds are available. The method is particularly attractive when

$$RLi \longrightarrow RCF{=}CCl_2 \longrightarrow RC{\equiv}CLi$$

an appropriate lithium compound is easily obtained by lithiation[4] rather than by halogen-lithium exchange.[5] Lithium compounds easily obtained by lithiation are also expected to give rise to the desired substitution in high proportion (undesirable Cl-Li exchange in low proportion) in the reaction with **1**, since the partial negative charge is considerably delocalized in such compounds.[6] A typical example is the preparation of 2-ethynylthiophene from thiophene.[1] A good overall yield is also expected for the preparation of 2-ethynylfuran from furan *via* 2-(2,2-dichloro-1-fluoroethenyl)furan (**4b**).[7]

In the previous study,[1] however, only one position in each compound[8] was used for introduction of Li followed by reaction with **1** and subsequent transformations even where more than one position are available. In the present study two positions in each compound have been used in order to expand the synthetic possibility of the proposed method. 2,5-Diethynylthiophene (**23a**) and 2,5-diethynylfuran (**23b**) were prepared from thiophene and furan by this method. For the synthesis of these new diethynyl compounds, other methods used for the synthesis of 2-ethynylthiophene[9–13] and 2-ethynylfuran[14–16] do not seem to be feasible.[17] *p*-Dibromobenzene was also subjected to similar conversions, though preparation of *p*-diethynylbenzene was not attempted because of its known preparation from divinylbenzene (isomeric mixture),[18] diethylbenzene,[19] and *p*-diacetylbenzene.[20]

Results and Discussion

Treatment of 2-(2,2-dichloro-1-fluoroethenyl)thiophene (**4a**) and 2-(2,2-dichloro-1-fluoroethenyl)furan (**4b**) with two equivalents of butyllithium affords lithium acetylides **5**[1] (Scheme 1). Further addition of butyllithium lithiated the 5-position of the heterocycles to give dilithium compounds (**6a** and **6b**). A similar dilithium compound (**6c**) was formed, together with butyl bromide, from **4c** *via* Li-Br exchange between **5c** and butyllithium. When a portion of a mixture obtained in this way was left standing in the absence of **1**, 1-butyl-4-lithioethynylbenzene (**18**) was formed by the reaction of **6c** with butyl bromide.

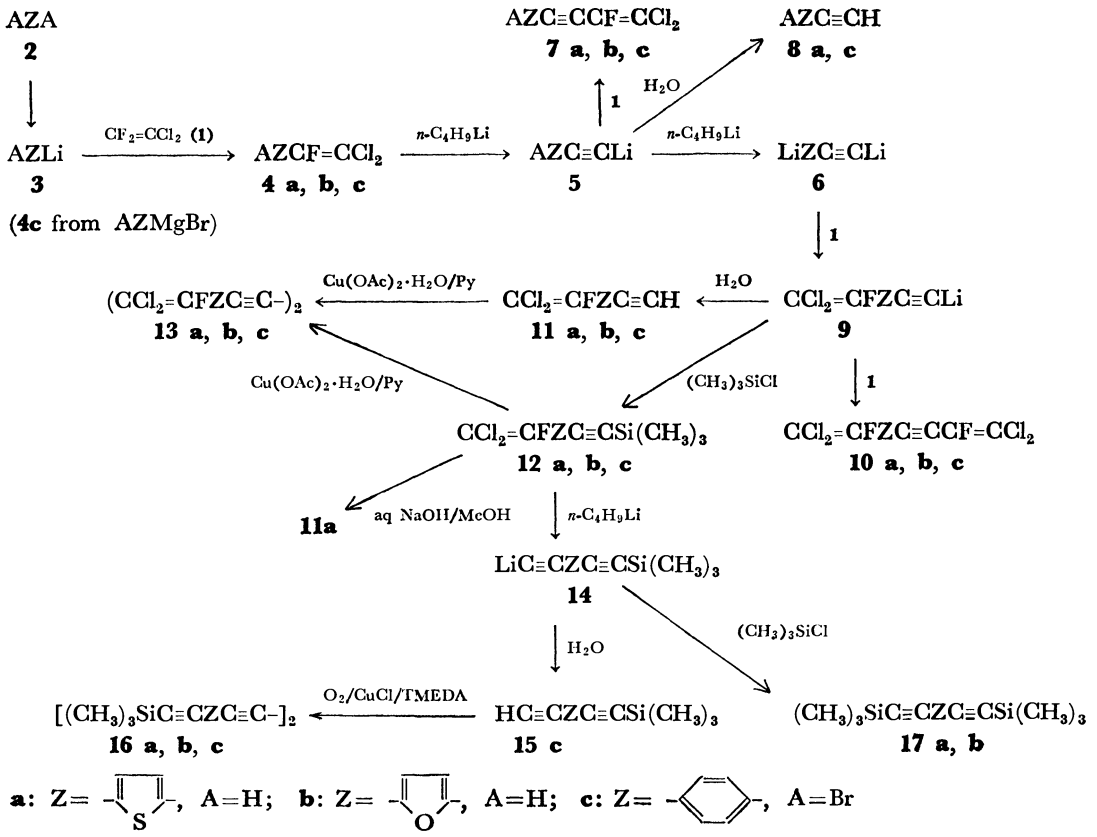
$$p\text{-}BrC_6H_4CF{=}CCl_2 + 2\,n\text{-}C_4H_9Li \quad (\mathbf{4c})$$
$$\longrightarrow p\text{-}BrC_6H_4C{\equiv}CLi + 2\,n\text{-}C_4H_9Cl + LiF \quad (\mathbf{5c})$$

$$\mathbf{5c} + n\text{-}C_4H_9Li \longrightarrow p\text{-}LiC_6H_4C{\equiv}CLi + n\text{-}C_4H_9Br \quad (\mathbf{6c})$$
$$\longrightarrow p\text{-}(n\text{-}C_4H_9)C_6H_4C{\equiv}CLi + LiBr \quad (\mathbf{18})$$

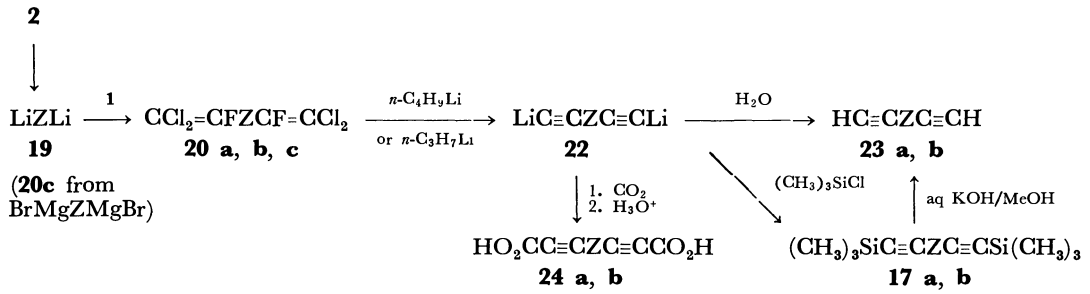
Compounds **6** serve as key intermediate in the transformations shown in Scheme 1. Treatment with **1** under refluxing conditions afforded compounds (**10**) having two –CF=CCl_2 groups. As the nucleophilicity of the acetylide carbanion is much smaller than that of the ring carbanion, the reaction can be carried out in such a way that only the latter takes part in the reaction. Thus the reaction of **6** with **1** at about 15 °C for a short time or at 0 °C for 1—2 h led to the formation of lithium acetylides **9** as the predominant product. Hydrolytic work-up afforded terminal acetylenes **11**, and quenching with chlorotrimethylsilane gave **12**. Compound **11a** was relatively unstable,[21] no procedure for its isolation in satisfactory yield being found. Thus the isolated yield of **11a** from **4a** was only 29%, whereas **12a** (a silylated acetylene)[22] was obtained in 78% yield together with 7% crude yield of **10a**. (At present the best way to prepare **11a** is the hydrolysis of **12a** by alkali.) Compounds **11b** and **11c** were much more stable than **11a**.

The 2,2-dichloro-1-fluoroethenyl group in **12** can also be converted into the lithioethynyl group by treatment with butyllithium. The conversion *via* **12** thus illustrates a method for the preparation of compounds of the type $A_1C{\equiv}CZC{\equiv}CA_2$, though there are limitations regarding the types of A_1 and A_2 for the conversion to be applicable. The conversions of **4** into **10**, **11**, and **12**, *via* several steps each, were conveniently carried out by a one-flask procedure.

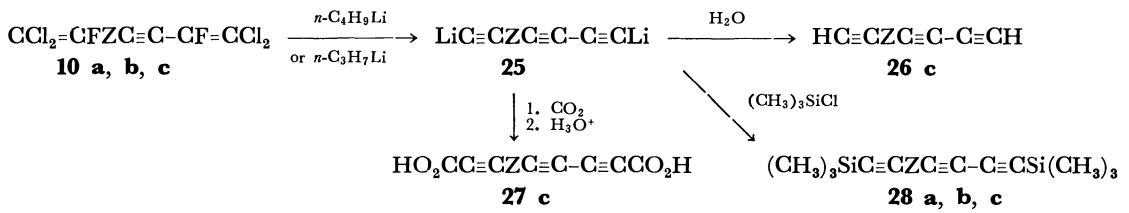
Terminal acetylenes were oxidatively coupled in order to obtain more stable crystalline "derivatives." Compounds **11a**, **11b**, and **11c** were satisfactorily converted into the symmetrically substituted butadiynes **13** by Eglinton coupling.[23,24] However, the use of



Scheme 1.



Scheme 2.



Scheme 3.

this method in the case of **15b** (curde product obtained from **12b**) resulted in the formation of a black, insoluble substance instead of **16b**, suggesting the cleavage of the Si–C (acetylenic) bond followed by a coupling reaction. Thus **12b** was subjected to the conditions for Eglinton coupling of **11b**, formation of **13b** being expected. Compound **13b** was indeed obtained in 77% isolated yield, higher than the yield (58%) of this compound obtained from **11b**. Likewise **13c** was obtained in an excellent yield from **12c** as well as from **11c**. On the other hand, the yield of **13a** obtained from **12a** was considerably lower than that obtained from **11a**. Under the reaction conditions compound **12a** (or a compound derived therefrom) probably undergoes a side reaction, such as ring cleavage, whereas compound **11a** is rapidly converted into the coupling product (**13a**). The coupling product formed from **11a** soon crystallizes, remaining mostly intact. The conversion of **15** into **16** was effected by use of Hay's procedure.[25]

Scheme 2 shows the conversion of thiophene and furan into 2,5-diethynylthiophene (**23a**) and 2,5-di-

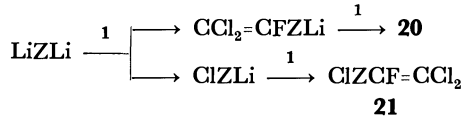
a) Isolated yield, calculation being based on the starting compound indicated in parentheses. b) 20% Solution in $CDCl_3$ unless otherwise stated. ^1H and ^{19}F chemical shifts measured downfield relative to internal tetramethylsilane and upfield relative to external CF_3CO_2H, respectively. Splitting pattern and (apparent) coupling constant (Hz) indicated in parentheses. c) ^{19}F chemical shift for $-C\equiv C-CF=CCl_2$ indicated by bold face; broad signals at expanded scale (half-height width of roughly 1 Hz) denoted by br. ^{19}F chemical shifts and splitting patterns (in parentheses) not given in the Table are as follows: **4a**, 20.7(d 2.8)(t 1.1); **7a**, 23.9(d 0.6); **4b**, 34.1(t 1.4)(t 0.5); **7b**, 25.2 br; **4** (Z=*p*-phenylene, A=H), 15.6 br; **7** (Z=*p*-phenylene, A=H), 23.6; **4c**, 18.8 br; **7c**, 24.2 br. d) $Si(CH_3)_3$ (0.22—0.26 ppm), CO_2H (4.90—5.30 ppm), and C≡CH (2.52—3.48 ppm, in italics). e) Aromatic ring proton. Data for (gross) AB pattern: chemical shift of A+chemical shift of B (coupling constant: J_{AB} in Hz). Further splittings indicated under the respective chemical shifts. f) νC=C of $-CF=CCl_2$, νC≡C (in bold face), and νC-H of -C≡CH (in italics) are given. Neat for liquid and in KBr pellet for crystals. w, weak; sh, shoulder; br, broad. g) Crude yield. h) Saturated solution in thiophene. This compound is sparingly soluble in organic solvents. i) Concentration smaller than 10%. j) Obtained in *ca.* 7% crude yield as by-product of **20a** or **20b**. k) Melting point *ca.* 15 °C. l) No melting point observed; turning dark with rise in temperature. m) CD_3OD used as solvent. n) Chemical shift probably concentration-dependent due to the equilibrium: $-COOH+CD_3OD \rightleftharpoons -COOD+CD_3OH$. o) The three bands of νC≡C of comparable strength. p) 2-(Trimethylsilylethynyl)furan obtained in 17% yield. q) Approximate value of J_{AB} of AA'BB' (or AA'BB'X) system. Since J_{AB} is the coupling constant between protons in mutually ortho positions and is expected to be much larger than other coupling constants, the spectrum has been treated as a (gross) AB pattern. r) νC≡C not observed: apparently IR-inactive. s) A stronger band, probably not due to the $-CF=CCl_2$ group, present at 1608 cm^{-1}. t) Previously reported (Ref. 23). u) Obtained in 9% yield together with 52% yield of **4c** when excess **1** was refluxed for a total of 19 h (in 3 days) in a Grignard reagent mixture prepared from *p*-dibromobenzene (0.5 mol) and magnesium (0.62 g-atom: Ventron chips).

ethynylfuran (**23b**), as well as their derivatives. The yields of 2,5-bis(2,2-dichloro-1-fluoroethenyl)thiophene (**20a**) and -furan (**20b**) obtained *via* lithiation of thiophene and furan followed by treatment with **1** were 64 and 37%, respectively. The low yields are apparently due to incomplete dilithiation of the heterocycles (and to possible decomposition of the dilithium compounds), particularly in the case of furan,[26] rather than to the yield of the reaction of the dilithium compounds with **1**. In the lithiation an increase in the proportion of butyllithium is expected to increase the extent of conversion of the heterocycles into dilithium compounds. However, the use of a large excess of butyllithium is undesirable since remaining butyllithium reacts with **20** as well as with **1**. In the present experiments a 50% excess of butyllithium (a total of three equivalents) was used for the dilithiation of thiophene and furan with a refluxing time of 9.5—11 h. In the reaction with **1**, the inverse addition method was not used since a significant portion of the butyllithium was considered to remain and to offset the advantage of use of this less convenient method.

The by-products of these reactions are 2-chloro-5-(2,2-dichloro-1-fluoroethenyl)thiophene (**21a**) and

-furan (**21b**) besides **4a** and **4b**, which were formed from the monolithiated compounds (**3a** and **3b**). Compounds **21a** and **21b** were isolated by preparative GC for identification. The formation of $ClZCF{=}CCl_2$ (**21**) from LiZLi seems to proceed *via* ClZLi rather than *via* $LiZCF{=}CCl_2$ since LiZLi is expected to give much higher proportion of the Li-Cl exchange to the substitution than $LiZCF{=}CCl_2$, in view of stabilization to a much smaller extent of the negative charge[6] in LiZLi than in $CCl_2{=}CFZLi$.



Treatment of **20a** and **20b** with excess butyllithium (or propyllithium) followed by work-up and rotary evaporation of the solvent and butyl chloride (or propyl chloride) afforded crude 2,5-diethynylthiophene (**23a**) and 2,5-diethynylfuran (**23b**), respectively. The yields were high, but the samples contained hydrocarbon impurities, apparently originating from lithium reagent solutions and not effectively removable by rotary evaporation. 2,5-Diethynylthiophene (**23a**) was not sufficiently stable to be purified by preparative GC; purification was successfully performed through conversion into the disilver diacetylide. 2,5-Diethynylfuran (**23b**) was more stable, pure samples being obtained by careful preparative GC as well as through conversion into its disilver diacetylide.

Alkali hydrolysis of the bis(trimethylsilyl) derivatives (**17**), obtained by treatment of the dilithium diacetylides (**22**) with chlorotrimethylsilane as well as by a one-flask procedure from **12** (Scheme 1), also afforded 2,5-diethynylthiophene (**23a**) and -furan (**23b**). However, the crude samples obtained from **17** contained $(CH_3)_3SiOSi(CH_3)_3$, and its removal required the use of the methods by which the samples obtained from **20** were purified.

The conversion of 1,4-bis(2,2-dichloro-1-fluoroethenyl)benzene (**20c**) into 1,4-diethynylbenzene (**23c**) was not undertaken. 1-Ethynyl-4-(1,3-butadiynyl)benzene (**26c**) was, however, prepared for the first time by treatment of **10c** with butyllithium (or propyllithium) as shown in Scheme 3. This is probably the easiest route for preparation of **26c**. The dicarboxylic acid (**27c**) and the bis(trimethylsilyl) derivative (**28c**) were also obtained. The corresponding bis(trimethylsilyl) derivatives (**28a** and **28b**) of thiophene and furan were similarly obtained. Compound **28a** remained as a viscous oil even after being purified by preparative GC.

Each of the compounds **28** obtained from **10** was accompanied by a by-product resulting from addition of butyllithium to **25** and subsequent replacement of three lithium atoms by trimethylsilyl groups. Propyllithium was not used for the preparation of **28**. On the basis of the infrared spectrum (ν C≡C 2122 and 2158 cm^{-1} for **30a** as compared with ν C≡C 2090, 2135, and 2180 cm^{-1} for **28a**) and from the fact that no addition of butyllithium to **22** takes place in the treatment of **20** with excess butyllithium, as confirmed by GC-mass spectroscopic examination of crude **17** obtained from the route given in Scheme 2, the by-product is considered as formed *via* 1,2-addition of butyllithium to one of the triple bonds in the lithiobutadiynyl group of **25**. Structure **29** is most likely for the adduct, structure **30** being tentatively assigned to the trisilylated compound. The addition of butyllithium to **25** was particularly conspicuous in the case of the thiophene derivative.

$LiC{\equiv}CZC(C_4H_9\text{-}n){=}C(Li)C{\equiv}CLi$ (**29**)

$(CH_3)_3SiC{\equiv}CZC(C_4H_9\text{-}n){=}C[Si(CH_3)_3]C{\equiv}CSi(CH_3)_3$ (**30**)

The following remarks are given on the NMR data summarized in Table 1: (1) The unusually high ^{19}F NMR chemical shifts of the $-CF{=}CCl_2$ group of furan derivatives are clearly associated with a similar trend of the ^1H NMR chemical shifts of the ring protons. Note that the ^{19}F NMR and ^1H NMR chemical shifts are measured in mutually opposite directions. (2) The coupling patterns in ^1H NMR spectra of thiophene and furan derivatives are much simpler than those of benzene derivatives. In many cases, the coupling constant between the fluorine of the $-CF{=}CCl_2$ group (attached to the 2-position of the ring) and the proton at the 3-position is comparable to the one between the fluorine and the proton at the 4-position. However, of the two coupling constants or of the two ^1H chemical shifts, it is not clear which one is for the proton at the 3-position.

Experimental

Caution should be taken in the handling of acetylenic compounds. Some terminal acetylenes are liable to exothermic decompostion upon heating (*cf.* descriptions for **11a** and **23a**).

Temperature readings are uncorrected. Pressure readings are given in terms of mmHg (1 mmHg=133.322 Pa). ^{19}F NMR and ^1H NMR spectra were recorded on a Hitachi R-20BK operated at 56.451 MHz and on a Hitachi R-22 operated at 90 MHz, respectively. IR spectra were recorded on a Hitachi EPI-G3, and mass spectra[27] on a Shimadzu GCMS-7000. All reactions of butyllithium and propyllithium were conducted under an atmosphere of nitrogen with use of sodium-dried ether. Butyllithium and propyllithium were prepared from butyl bromide and propyl bromide, respectively, by the reaction with cut pieces of lithium in ether and stored at −20 °C. The amounts of these reagents are calculated from nominal concentration.

*2-Ethynyl-5-(2,2-dichloro-1-fluoroethenyl)thiophene (**11a**).* Compound **4a**[1] (19.06 g, 96.7 mmol) was treated with butyllitium, **1** being added as described in the section for **12a**. The resulting mixture was allowed to warm to 0 °C, at which it was stirred for 1.3 h. The worked-up mixture was crystallized by cooling to −20 °C, crystals of **11a** (4.32 g) remaining unmelted at room temperature being filtered off. Vacuum distillation of the mother liquor afforded an additional amount of **11a** (1.95 g, bp 96—98 °C/6 mmHg), increasing the total isolated yield to 29%. A large amount (11.86 g) of distillation residue remained. The experiment was repeated, and the total worked-up mixture was subjected to vaccum distillation. A few minutes after air[28] had been admitted into the apparatus in order to replace the condenser, in which the first portion of **11a** had crystallized, the content of the still pot decomposed with ignition. The analytical sample (mp 42—43 °C) of **11a** was obtained by

recrystallization (from methanol) of a sample obtained by alkaline hydrolysis of **12a**. MS *m/e*, 220 (M).

2-(2,2-Dichloro-1-fluoroethenyl)-5-(trimethylsilylethynyl) thiophene (12a). Ethereal butyllithium (322 mmol, 192 ml) was added to a stirred solution of **4a** (19.70 g, 100 mmol) in ether (100 ml) cooled with Dry Ice–acetone below −50 °C. The resulting mixture was stirred for 1.5 h at *ca.* 20 °C and re-cooled with Dry Ice–acetone. After addition of **1** (36 g, 270 mmol) in one portion, the Dry Ice–acetone bath was replaced by an ice–water bath. The internal temperature rose rapidly to reach a maximum of 20 °C and then began to fall. The resulting mixture was stirred at 13—17 °C for 16 min after that moment, re-cooled with Dry Ice–acetone, and chlorotrimethylsilane (24.5 g, 225 mmol) was added. After the cooling bath had been removed, the whole mixture was stirred for 2 h and poured onto a mixture of crushed ice and concd hydrochloric acid. Distillation of 94% of the worked-up mixture afforded 21.47 g (78% yield) of **12a**, bp 126—128 °C/2.5 mmHg. The distillation residue (2.2 g, corresponding to 7% yield) was found to be mainly **10a** by IR and ^{19}F NMR spectroscopy. No crystallization of **12a** took place in the condenser during the course of distillation, though crystallization was easily induced by seeding. The analytical sample (mp 76.5—78 °C) was obtained by recrystallization from ethanol. MS *m/e* (rel intensity), 292 (M, 46), 277 (M−CH_3, 100).

Bis[5-(2,2-dichloro-1-fluoroethenyl)-2-thienyl]butadiyne (13a). Compound **11a** (2.00 g, 9.0 mmol) and copper(II) acetate hydrate (3.00 g) was stirred in pyridine (30 ml) in a bath at 50 °C. The solution turned into a bright brown slurry in a few minutes. After being stirred for 30 min, the resulting mixture was poured onto water (*ca.* 500 ml) with agitation. The precipitate was collected by filtration and dried (mp 195—199 °C; 1.93 g, corresponding to 97% yield of **13a**). The first crop of recrystallization of **13a** from dioxane was 1.54 g, (77%; mp 197—198 °C with decomposition as judged from formation of a black melt). MS *m/e* (rel intensity), 438 (M, 100), 368 (M−2Cl, 22).

When compound **12a** (2.00 g, 6.8 mmol) was subjected to essentially the same treatment as described above, the crude product obtained by pouring the reaction mixture onto water amounted to 1.44 g, corresponding to 96% yield of **13a**. However, only 38% yield (0.57 g) of **13a** was obtained from this. The rest of the material was more strongly adsorbed on alumina and is suggested to be a mixture by its elution behavior.

2,5-Bis(trimethylsilylethynyl) thiophene (17a). Ethereal butyllithium (31 mmol, 19 ml) was added to a cooled stirred suspension of **12a** (3.36 g, 11.5 mmol) in ether (60 ml) over a period of 12 min below −58 °C. After addition of chlorotrimethylsilane (6 g, 55 mmol) at −5 °C, the resulting mixture was stirred for 1.5 h without cooling. Hydrolysis, workup, and solvent evaporation afforded a crystalline residue, from which 2.65 g (mp 82.5—83.5 °C) of **17a** was obtained by digestion with ethanol followed by filtration. From the filtrate, less pure **17a** (mp 79—81 °C. 0.36 g; total 95%) was recovered. Recrystallization from ethanol afforded the analytical sample (mp 82.5—83.5 °C). MS *m/e* (rel intensity), 276 (M, 100), 261 (M−CH_3, 51).

The same compound was obtained in 95% yield from **20a** by the same procedure, its identity being confirmed by undepressed mixed melting point.

1,4-Bis[p-*(trimethylsilylethynyl)phenyl*]*-1,3-butadiyne (16c).* An acetone (10 ml) solution of crude **15c**[29] obtained from **12c** (2.00 g, 7.0 mmol) by treatment with butyllithium (19 mmol) was added to an oxygen-bubbled solution of *N,N,N′,N′*-tetramethylethylenediamine (0.12 g) and copper(I) chloride (0.10 g) in acetone (20 ml). The resulting mixture, which became a crystalline slurry in a few minutes, was stirred for 39 min with continued oxygen bubbling and treated with a mixture of ether (*ca.* 150 ml) and aqueous hydrochloric acid. Crystals of **16c** remaining insoluble even after addition of benzene (50 ml) followed by shaking of the total mixture were filtered off (dried 0.28 g, mp 231—232 °C). An additional amount (0.79 g) of crystals of **16c** was obtained from the organic layer after washing (with aqueous hydrochloric acid and then with water), drying, and concentration, with increase in the total isolated yield of **16c** to 78% (based on **12a**). A mixture (0.20 g, 15%) of **15c** and **16c** recovered from the mother liquor is excluded from the above yield. Recrystallization from benzene afforded the analytical sample (mp 231—232 °C). MS *m/e* (rel intensity), 394 (M, 100), 279 (M−CH_3, 94). The corresponding thiophene and furan derivatives (**16a** and **16b**) were much more soluble in organic solvents than **16c**; most of the acetone was removed by evaporation before similar work-up.

2,5-Bis(2,2-dichloro-1-fluoroethenyl)thiophene (20a). Ethereal butyllithium (300 mmol, 180 ml) was added (exothermic) to a stirred solution of thiophene (8.41 g, 100 mmol) in ether (100 ml) in a 500 ml four-necked flask equipped with a thermometer, a dropping funnel, and a Dimroth condenser. The solution was refluxed for 12 h to give a slurry. Compound **1** (51 g, 380 mmol) was added over a period of 43 min, during which time the internal temperature was kept below −50 °C by cooling with Dry Ice–acetone. Circulation of ice water through the Dimroth condenser was initiated, and the dropping funnel was replaced by an additional condenser, two condensers being necessary to control the excessive exothermicity. The cooling bath was replaced with a vacant bath vessel, which was filled with ice water to the necks of the flask as soon as the internal temperature reached 0 °C. The temperature rose slowly up to 20 °C but very rapidly to refluxing temperature (30—32 °C) from 20 °C. After vigorous boiling subsided, the cooling bath and the additional condenser were removed, the mixture was heated to reflux for 2 h, and poured onto a mixture of crushed ice and concd hydrochloric acid (30 ml). The ether layer was separated, washed (with water and with aq $NaHCO_3$), dried, and 95% of the solution was evaporated to leave a crystalline residue. Digestion with ethanol followed by filtration afforded **20a** (14.50 g). Fractional distillation of the filtrate with a short Vigreux column gave an additional amount (4.51 g) of **20a** (bp 130—132 °C/2 mmHg), increasing its total yield to 64%, besides an approximately 1:1 mixture (3.02 g, in three fractions) of **4a** (7% yield) and **21a** (7% yield). The analytical sample of **20a**, mp 85—86 °C, obtained from a distilled sample by recrystallization from ethanol, was colorless. MS *m/e* (rel intensity), 308 (M, 100), 273 (M−Cl, 6), 238 (M−2Cl, 32). A pure sample of **21a** was obtained by preparative GC. MS *m/e* (rel intensity), 230 (M, 100), 195 (M−Cl, 30), 160 (M−2Cl, 42). By a similar procedure with an externally heated refluxing time of 2 h for lithiation of thiophene using 2.4 equivalents of butyllithium, **4a** and **20a** were isolated 31 and 35% yields, respectively.

2,5-Diethynylthiophene (23a). Ethereal butyllithium (20 mmol, 12 ml) was added below −58 °C over a period of 10 min to a cooled stirred slurry of **20a** (1.00 g, 3.2 mmol) in ether (50 ml). The resulting mixture was allowed to warm to −10 °C and poured onto a mixture of concd hydrochloric acid (4 ml) and crushed ice. The whole mixture was shaken, the ether layer separated, washed (with water and with aq sodium hydrogencarbonate), and dried (Na_2-

SO_4). The oil (0.57 g; *caution*[30]) obtained after brief rotary evaporation was dissolved in ethanol (20 ml), and a solution of silver nitrate (2.00 g) in water (2 ml) was added giving a bright yellow precipitate, which was filtered off and washed with ethanol and with ether. The precipitate was stirred in ether (100 ml). An aqueous solution (15 ml) containing 3 ml of concd hydrochloric acid was added, the ether layer separated (after complete conversion of the precipitate), then washed (aq hydrochloric acid, water, and aq sodium hydrogencarbonate), dried and evaporated (up to 45 °C bath temp) to give **23a** as an oil (0.37 g, 87%). IR and ^{1}H NMR examination indicated the presence of ether (2%), the yield of **23a** being 85%. Pure **23a** was obtained by further evaporation.

Aqueous potassium hydroxide (a 0.08g pellet dissolved in 2 ml of water) was added to a solution of **17a** (1.00 g, 3.6 mmol) in methanol (50 ml) stirred in a bath kept at 20 °C. After 20 min, the resulting solution was shaken with a mixture of ether (100 ml) and water (100 ml). Crude **23a** was obtained from the ether layer and purified by conversion *via* the disilver diacetylide. Regenerated **23a** (0.42 g) contained 3% of ether (yield of **23a**: 85%). A 0.20 g portion of this sample was further evaporated to give 0.18 g of pure **23a** (79% from **17a**). MS *m/e* (rel intensity), 132 (M, 100), 82 (M−C_4H_2, 16), 69 (M−C_5H_3, 23), 63 (C_5H_3, 11); IR (neat),[31] 3290 [1], 3100 [2], 3090 sh [2], 2590 w, 2106 [3], 1784 [4], 1620 [5], 1518 [6], 1513 sh [6], 1442 [7], 1340 br [8], 1235 sh, 1219, 1152, 1138, 1034 [9], 813 [10], 705, 676 sh [11], 670 [11], 608 [12], 548, 495, 442 cm^{-1} [13].

*2,5-Diethynylfuran (**23b**).* MS *m/e* (rel intensity), 116 (M, 100), 88 (M−CO, 12), 63 (C_5H_3, 13), 62 (C_5H_2, 13), 53 (M−C_5H_3, 10); IR (neat),[31] 3290 [1], 3146 [2], 3110 w [2], 2692 w, 2107 [3], 1730 [4], 1600 [5], 1570 [6], 1565 sh [6], 1497 [7], 1380 br [8], 1347, 1310, 1214, 1200, 1022 [9], 965, 800 [10], 688 [11], 670 sh [11], 604 [12], 453 cm^{-1} [13].

*1-Ethynyl-4-(1,3-butadiynyl)benzene (**26c**).* Compound **10c** (1.00 g, 3.1 mmol each time) was treated with butyllithium or propyllithium (20 mmol) below −50 °C in order to find an appropriate isolation procedure for **26c**, an unstable compound. The ether solution obtained after work-up from each run was dried (Na_2SO_4) and subjected to rotary evaporation to leave a crystalline residue (0.5—0.6 g, corresponding to 109—130% yield of **26c**). All samples showed ^{1}H NMR signals at the alkyl hydrogen region, impurities not being completely removable by continued evaporation. Digestion with cold ethanol (or methanol) followed by filtration afforded pure **26c**, the yields being less than 50% even after combining the crystals obtained by cooling the filtrates to −20 °C. Conversion into the disilver diacetylide led to the highest isolated yield of pure **26c**. Thus the crude sample obtained from a butyllithium run was dissolved in ethanol (25 ml), and a solution of silver nitrate (2.00 g) in water (2 ml) was added to give a pale yellow precipitate, which was filtered off, washed, and treated with aqueous hydrochloric acid as in the case of **23a**. The sample of regenerated **26c** (0.36 g, 79%) showed no ^{1}H NMR signal other than three single peaks (2.52, 3.20, 7.47 ppm) in 1:1:4 relative intensities. The crystals of **26c** first appearing on the inside wall of the flask upon evaporation of every worked-up solution were nearly white, indicating that **26c** is stable in ether. However, the crystals turned rapidly to beige and to brown black. The compound showed no melting point and turned dark with rise in temperature. Cooling to or below −20 °C was neccessary for storage even for a short time (*e.g.* 2 h). The spectroscopic data of freshly prepared samples are as follows. MS *m/e* (rel intensity), 150 (M, 100), all other peaks (<7); IR (KBr), 3295 sh(w), 3275 sh, 3270, 2205, 1920, 1670, 1505 sh, 1497, 1403, 1378 w, 1269, 1258, 1109, 1020, 838, 711, 679, 668, 641, 636 sh, 548, 508, 451 cm^{-1}. The KBr discs of IR measurement turned black in one day upon standing in the dark at room temperature. The IR spectrum at this stage was nearly the same as the spectrum obtained after several months. Notable spectral changes were: (1) broadening and decrease in intensity of the 3270, 1403, 1109, 1020, 838, 668, 641, and 548 cm^{-1} bands, (2) disappearance of 2205, 1920, 1670, 1378, 1269, 1258, 711, 679, 508, and 451 cm^{-1} bands, and (3) replacement of the bands at 711—636 cm^{-1} by two broad bands (of decreased intensity) at 650 and 618 cm^{-1}.

*5-[p-(Carboxyethynyl)phenyl]-2,4-pentadiynoic Acid (**27c**).* Compound **10c** (1.00 g, 3.1 mmol) was treated with butyllithium as above, several pieces of Dry Ice (*ca.* 10 g) being added to the resulting active mixture. After stirring for 1.5 h water was added, the whole mixture shaken, filtered, the aqueous layer separated, washed with ether, and acidified with aqueous hydrochloric acid. The resulting faintly yellow crystalline precipitate was filtered off and dried (0.62 g, 85% yield of **27c**) over calcium chloride in a vacuum desiccator. Recrystallization of a portion of the sample from a small amount of methanol by cooling to −20 °C gave a colorless analytical sample showing no melting point and turning dark above *ca.* 190 °C. Recrystallization from water was inappropriate. Heating the compound in boiling water appeared to induce decarboxylation, the product (not purely isolated) suspected to be $HO_2CC{\equiv}CC_6H_4C{\equiv}C{-}C{\equiv}CH$. (The analytical samples of **24a** and **24b** were obtained by recrystallization from acetone and from water, respectively.)

*1-(Trimethylsilylethynyl)-4-(4-trimethylsilyl-1,3-butadiynyl)-benzene (**28c**).* Compound **10c** (2.00 g, 6.1 mmol) was treated with butyllithium (40 mmol), and the resulting active mixture with chlorotrimethylsilane. From the crystalline mixture obtained after work-up, **28c** (1.45 g, 81%; mp 107.5—108.5 °C) was obtained by digestion with methanol followed by filtration. The filtrate upon standing for one week, precipitated crystals (0.21 g, mp *ca.* 75—97 °C), which were found to be a mixture (*ca.* 3:2) of **28c** and a compound whose mass spectroscopic molecular weight is greater than that of **28c** by 130 [$(CH_3)_3SiC_4H_9$]. The latter seems to have the structure **30c**.

pp. 51—65.

6) In the reaction of **1** with organolithium compounds (RLi), the proportion of the Cl-Li exchange to the sum of the exchange and substitution varies widely depending on the nature of R. It is suggested that the smaller the extent of delocalization of the negative charge in the reagent, the higher the proportion of the exchange (Ref. 1). The word "delocalization" may be replaced by "stabilization."

7) The isolated yield of **4b** was improved to 76% from the yield (53%) reported in Ref. 1. The major difference in reaction conditions is that the refluxing time for lithiation of furan with butyllithium was extended from 1 h (used after standing overnight) to 4 h (used at once). Compound **4b**, though turning intensely colored and then darkend on exposure to air, remained colorless when stored at −20 °C in an ampule filled with nitrogen.

8) Ferrocene was an exception, where 1,1′-disubstituted as well as monosubstituted derivatives were obtained.

24) G. Eglinton and A. R. Galbraith, *J. Chem. Soc.*, **1959**, 889.

25) A. S. Hay, *J. Org. Chem.*, **27**, 3320 (1962).

26) Treatment of furan with a three-fold excess of butyllithium in refluxing ether for 4 h followed by quenching with D_2O gave furan-2,5-d_2: G. R. Ziegler and G. S. Hammond, *J. Am. Chem. Soc.*, **90**, 513 (1968). The material is reported to be 80% dideuterated. However, the absolute yield of furan-2,5-d_2 may be considerably lower than 80%.

27) None of the peaks due to ^{37}Cl-containing species is given. Such a peak is not taken as a base peak (intensity 100) even if it is the strongest (*e.g.*, *m/e* 310 in the case of **20a**).

28) Admission of nitrogen is instructed after termination of distillation of acetylenic compounds *in vacuo*: Ref. 10, p. 13.

29) This compound was previously reported: V. D. Ermakova, M. G. Chauser, J. S. Nesterova, and M. I. Cherkoshin, *Tesisy Dokl. Vses, Konf. Khim. Stsetilena*, 5th, 1975, 505; *Chem. Abstr.*, **88**, 153350r (1978).

30) In an earlier experiment of the same scale, such an oil (crude **23a**) was further evaporated, and GC examination of the resulting oil (0.30 g, not pure according to IR) was attempted. As soon as the needle of the microsyringe was inserted into the injection port (*ca.* 250 °C), the content (1 μl+needle volume) decomposed with ignition. Although crude samples of lower **23a** content (and solutions of **23a** in ether) were injectable, a considerable decomposition of **23a** was apparent in its low sensitivity.

31) The figures in square brackets indicate the correspondence of frequencies of **23a** and **23b** suggested from comparative inspection of the two spectra (aside from rigorous assignments of frequencies).

Specific Catalysis by α-Cyclodextrin on the Dichlorocarbene Attack at Phenolate

Makoto KOMIYAMA* and Hidefumi HIRAI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 14, 1980)

A selective attack of dichlorocarbene at the para-position of phenolate has been achieved by using α-cyclodextrin and the reaction mechanism has been studied by the ^{13}C-NMR and ^{1}H-NMR spectroscopy. The attack of the carbene at the para-position of phenolate (82%) is dominant over the attack at the ortho-position (18%) in the presence of 0.15 mol dm^{-3} of α-cyclodextrin, which is in contrast with the predominance of the ortho-attack (59%) over the para-attack (41%) in the absence of α-cyclodextrin.

Specificity is one of the important characteristics of the cyclodextrin catalyses.[1] This specificity has been attributed to the complex formation of the substrate with cyclodextrin prior to the chemical transformation. However, detailed analysis on the origin of the specificity has been scant, mainly because of poor information on the structures of the inclusion complexes of cyclodextrin in solution.

In previous papers, the time-averaged conformations of the inclusion complexes were determined by use of the ^{1}H-NMR[2,3] and ^{13}C-NMR[4] spectroscopy. Furthermore, a much larger magnitude of the catalysis of α-cyclodextrin in the cleavage of *m*-nitrophenyl acetate than that in the cleavage of *p*-nitrophenyl acetate was satisfactorily interpreted in terms of the structures of the inclusion complexes of the substrates and α-cyclodextrin.[5]

In the present paper, the α-cyclodextrin-catalyzed para-selective attack of dichlorocarbene at phenolate is shown. Furthermore, the origin of the selectivity is clarified by using the time-averaged structure of the α-cyclodextrin-phenolate complex, determined by the ^{13}C-NMR and ^{1}H-NMR spectroscopy.

Experimental

Determination of the Para-Ortho Selectivity in the Dichlorocarbene Attack at Phonolate. Dichlorocarbene, prepared *in situ* from chloroform and sodium hydroxide, was allowed to react with phenolate as shown in Eqs. 1—3 (Reimer-Tiemann reaction).[6] The reactions were carried out in 0.2 mol dm^{-3} NaOH solution at 30 °C, and the initial concentrations of phenolate, chloroform, and α-cyclodextrin, respectively, were in the regions of 5×10^{-3}—2×10^{-2}, 1×10^{-2}—4×10^{-2}, and 0—1.5×10^{-1} mol dm^{-3}. The rate and the selectivity in the attack at phenolate were determined by the absorption spectroscopy on the hydrolysis products, hydroxybenzaldehydes, of the adducts of dichlorocarbene with phenolate.[7] The concentrations of *p*- and *o*-hydroxybenzaldehydes were determined by using the absorptions at 330 and 378 nm, respectively.

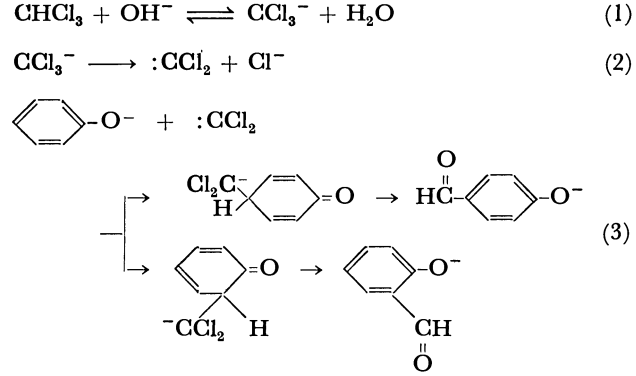

Table 1. The para : ortho selectivity in the dichlorocarbene attack at phenolate in the presence of α-cyclodextrin[a,b]

[α-Cyclodextrin]$_0$ / 10^{-1} mol dm^{-3}	Conversion of phenolate / %	Products: Para : Ortho molar ratio	Products: Para selectivity/%
0	12	0.71	41
0.071	9.7	0.77	44
0.15	8.1	0.85	46
0.25	6.0	0.99	50
0.35	4.3	1.11	53
0.60	2.3	1.71	63
1.0	1.5	3.55	78
1.5	0.95	4.65	82

a) In 0.2 mol dm^{-3} NaOH solution; [phenolate]$_0=10^{-2}$ and [chloroform]$_0=3\times10^{-2}$ mol dm^{-3}; the reaction time is two days. b) The subscript 0 refers to the initial concentration.

Determination of the Time-averaged Position of Phenolate in the Cavity of α-Cyclodextrin. The time-averaged position of phenolate was determined by use of the position of each of the carbon atoms of phenolate in the cavity of α-cyclodextrin, estimated by the ^{13}C-NMR spectrsocopy. The depths of the penetration of the carbon atoms of phenolate were estimated from the observed ^{13}C-NMR chemical shift changes by using the relationship between the depth of the penetration and the ^{13}C-NMR chemical shift changes reported in the previous paper.[5] As shown previously,[5] the change of the ^{13}C-NMR chemical shift of the aromatic carbon atom of the guest compound on the complex formation with α-cyclodextrin is governed by the depth of the penetration of the carbon atom in the cavity, irrespective of the substituents of the benzene moieties of the guest compounds.

The ^{13}C-NMR spectrometry was run in 0.2 mol dm^{-3} NaOD solution on a JEOL PFT-100 spectrometer operating at 25.03 MHz, connected with JEOL EC-100 computer. The ^{13}C-NMR chemical shifts were determined by use of sodium formate as the internal standard. The ^{1}H-NMR spectra were taken on a JEOL PS-100 spectrometer in 0.2 mol dm^{-3} NaOD solution. The signal of HOD was used as the internal reference.

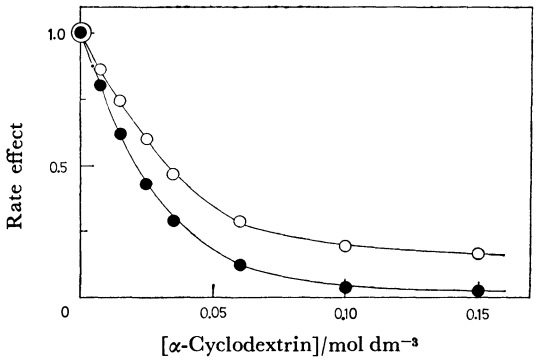

Fig. 1. Effects of α-cyclodextrin on the rates of the para-attack (○) and the ortho-attack (●) of dichlorocarbene at phenolate; the rates of the para-attack and the ortho-attack in the absence of α-cyclodextrin are taken as unity.

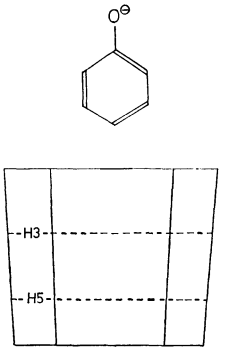

Fig. 2. Time-averaged conformation of the α-cyclodextrin–phenolate complex; ---H3--- and ---H5--- show the planes comprised of the corresponding six atoms of α-cyclodextrin.

Results

Effect of α-Cyclodextrin on the Orientation of the Dichlorocarbene Attack at Phenolate. Table 1 shows the dependence of the para-ortho ratio in the dichlorocarbene attack at phenolate on the concentration of α-cyclodextrin. In the absence of α-cyclodextrin, the attack at the ortho-carbon atom (59%) was dominant over the attack at the para-carbon atom (41%). However, α-cyclodextrin changed the specificity of this reaction from the ortho-selectivity to the para-selectivity. The ratio of the para-attack to the ortho-attack increased with the increase of the concentration of α-cyclodextrin. At the concentration of 0.15 mol dm^{-3}, the ratio was 4.65, which corresponded to 82% para-selectivity.

The variations of the initial concentrations of phenolate and chloroform in the regions of 5×10^{-3}—2×10^{-2} and 1×10^{-2}—4×10^{-2} mol dm^{-3}, respectively, showed little effect on the para-ortho ratio at a fixed initial concentration of α-cyclodextrin.

The para-selectivity in the presence of α-cyclodextrin came from the larger magnitude of the suppression of the ortho-attack by α-cyclodextrin than that of the para-attack as shown in Fig. 1. For example, 0.15 mol dm^{-3} of α-cyclodextrin decreased the rate of the ortho-attack and that of the para-attack, respectively, by 41 and 6.3 fold with respect to the rates in the absence of α-cyclodextrin, which resulted in the para-ortho ratio of 4.65. The ratio in the absence of α-cyclodextrin was 0.71.

No reaction product between α-cyclodextrin and dichlorocarbene was detected in the present reactions. Thus, the reaction mixture with the initial concentrations of phenolate, chloroform, and α-cyclodextrin, respectively, of 10^{-2}, 4×10^{-2}, and 5×10^{-2} mol dm^{-3} was acidified with hydrochloric acid after 2 d at 30 °C, and was then vigorously extracted with chloroform. The ^{1}H-NMR and IR spectroscopy on the white powder, obtained after the evaporation of the aqueous layer, showed that all α-cyclodextrin remained intact during the reaction.

Time-averaged Position of Phenolate in the Cavity of α-Cyclodextrin. Figure 2 depicts the time-averaged position of phenolate in the cavity of α-cyclodextrin determined by the ^{13}C-NMR spectroscopy. The depths of the penetration of the carbon atoms of phenolate in the cavity, determined from the changes of the ^{13}C-NMR chemical shifts on the complex formation (see Experimental Section) and listed in Table 2, were used here. The agreements between the observed changes of the ^{13}C-NMR chemical shifts and the calculated ones are fair as shown in Table 2.

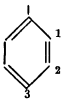
In the time-averaged conformation of Fig. 2, phenolate penetrates in the cavity with the hydrogen atom on the para-carbon atom as a head from the secondary hydroxyl side of α-cyclodextrin.

The validity of this conformation of the complex was further supported by the ^{1}H-NMR spectroscopy. In this conformation, the anisotropic shielding effects of the aromatic ring of phenolate on the H-3 and H-5 atoms of α-cyclodextrin (see Fig. 2), estimated by using the table of Johnson and Bovey[8] as described previously,[2] are −0.07 and −0.07 ppm, respectively.

TABLE 2. OBSERVED AND CALCULATED VALUES OF THE ^{13}C-NMR CHEMICAL SHIFT CHANGES OF PHENOLATE ON THE COMPLEX FORMATION WITH α-CYCLODEXTRIN, AND THE DEPTHS OF THE PENETRATION OF THE CARBON ATOMS IN THE CAVITY

Carbon atoms[a]	^{13}C-NMR chemical shift change/ppm[b]		Depth of the penetration/Å[c]
	Obsd	Calcd	
1	+0.33	—[d]	−3.7
2	+0.54	+0.55	−2.3
3	+0.12	+0.07	−1.6

a) The numbering system is as follows;



b) The positive sign shows the increase of the shielding. c) The depth from the plane comprised of the six H-3 atoms (see Fig. 2) of α-cyclodextrin. The negative sign refers to the region in the side of the secondary hydroxyl groups. d) The position of the carbon atom was so far away from the region examined previously (Ref. 4) that the calculation was not made.

Table 3. Effect of chloroform on the ^{13}C-NMR chemical shift changes due to the complex formation of α-cyclodextrin with phenolate

System[a]	Changes of ^{13}C-NMR chemical shifts of phenolate/ppm[b]		
	C-1	C-2	C-3
α-Cyclodextrin(10^{-1}) -phenolate(3×10^{-2})	+0.28	+0.43	+0.10
α-Cyclodextrin(10^{-1}) -phenolate(3×10^{-2}) -chloroform(3×10^{-2})	+0.02	+0.02	0.00

a) The numbers in parentheses are the concentrations in mol dm^{-3} unit in 0.2 mol dm^{-3} NaOD solution. b) The numbering system of the carbon atoms is shown in the footnote a) of Table 2. The positive sign shows the increase of the shielding.

Here the negative sign refers to the decrease of the shielding. These values show fair agreements with the corresponding observed changes of the ^{1}H-chemical shifts (−0.07 and −0.08 ppm, respectively, for the H-3 and H-5 atoms).

Effect of Chloroform on the Complex Formation between α-Cyclodextrin and Phenolate. The changes of the ^{13}C-NMR chemical shifts of phenolate on the complex formation with α-cyclodextrin were highly suppressed by the addition of chloroform (Table 3). The changes of the chemical shifts of all the carbon atoms of phenolate were virtually none in the presence of 3×10^{-2} mol dm^{-3} of chloroform. This result indicates that the complex formation between chloroform and α-cyclodextrin takes place competitively with that between phenolate and α-cyclodextrin. Almost all of phenolate are free from the complex formation with α-cyclodextrin in the reaction mixtures used in the present study.

Discussion

The reaction between dichlorocarbene and phenolate in the presence of α-cyclodextrin proceeds as the one between the carbene complexed with α-cyclodextrin and free phenolate. The complex formation of chloroform with α-cyclodextrin almost completely inhibits the complex formation of phenolate with α-cyclodextrin in the reaction mixture as shown in Table 3. Chloroform, complexed with α-cyclodextrin, is converted to dichlorocarbene according to Eqs. 1 and 2. Alternative pathway of the formation of the complex between α-cyclodextrin and the carbene, where the carbene is formed in solution followed by complexation with α-cyclodextrin, is unlikely, since the carbene in solution is so unstable that its life-time is short.

Figure 3 schematically depicts the mechanism of the para-selectivity of the catalysis by α-cyclodextrin in the dichlorocarbene attack at phenolate. Toward the carbene, formed inside the cavity of α-cyclodextrin, phenolate can approach in two ways such as A and B, which should predominantly result in the para-attack and the ortho-attack, respectively, because of a sterical reason. The para-selectivity observed in

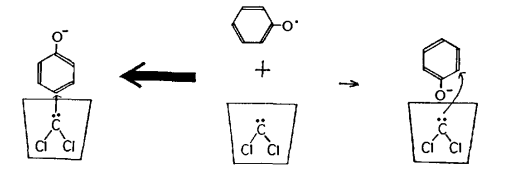


Fig. 3. Proposed mechanism of the α-cyclodextrin-catalyzed selective para attack of dichlorocarbene at phenolate.

the present study is attributable to the predominant occurrence of the approach of the phenolate in the type A, which is due to the fact that the penetration of the hydrogen atom on the para-carbon atom of the phenolate in the cavity as a head is more favorable than the penetration of the phenoxide oxygen atom as a head. The approach in the type A should be easier than that in the type B, since the penetration of the apolar aromatic moiety of phenolate in the apolar cavity of α-cyclodextrin is more stable than the penetration of the polar phenoxide oxygen atom in the apolar cavity.

The above argument is definitely supported by the time-averaged conformation of the α-cyclodextrin–phenolate inclusion complex shown in Fig. 2. Penetration of phenolate in the cavity with the side of the para-carbon as a head in the complex strongly indicates the predominant formation of the transition state involving the penetration of the para-carbon of phenolate in the cavity (type A).

The mechanism involving the dichlorocarbene formed inside the cavity is consistent with the suppression of the rates of the reactions between phenolate and dichlorocarbene by α-cyclodextrin (Fig. 1). Since the carbene is formed *via* anion of chloroform as shown in Eq. 1, the negative charges of the secondary hydroxyl groups electrostatically prevent the formation of the carbene. The secondary hydroxyl groups of α-cyclodextrin exist mostly in the anionic forms in the reaction mixture, since their pK_a is around 12.[1] Steric hindrance by α-cyclodextrin should also reduce the reactivity of the carbene. The suppression of the reaction by α-cyclodextrin also indicates that the formation of dichlorocarbene by the reaction of chloroform with the alkoxide ion of α-cyclodextrin (in place of hydroxide ion in Eq. 1) is less important.

The para-selectivity in the present reaction is consistent with those in the β-cyclodextrin-catalyzed Reimer-Tiemann reaction of phenolate[9] and the α-cyclodextrin-catalyzed chlorination of anisole.[10]

In conclusion, a selective attack of dichlorocarbene at the para-position of phenolate was achieved by using α-cyclodextrin. α-Cyclodextrin regulated the orientation of phenolate with respect to the carbene on the mutual access, resulting in the specific catalysis.

Photo-promoted Hypochlorite Oxidation of α-Amino Acids. Kinetics and Irradiation Effect for the Strecker Degradation[1)]

Yoshiro OGATA,* Makoto KIMURA, and Yoshinori KONDO

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received July 9, 1980)

Hypochlorite oxidation of simple α-amino acids (the Strecker degradation) in aqueous solutions has been studied in the dark and under UV-irradiation. UV-spectra, iodometry, and amino acid determination (2,4-dinitrofluorobenzene method) suggest that the intermediate *N*-chloro amino acid is formed quickly at an initial stage, then its slow oxidative decomposition takes place to give aldehyde, carbon dioxide, and ammonia. The mechanism is also supported by the fact that the oxidation follows the first-order rate expression; $-d[RCH(NH_2)CO_2H]/dt = k_1[RCH(NHCl)CO_2H]$. UV-irradiation was found to promote remarkably the degradation of *N*-chloro amino acid. When equimolar amounts of amino acid and hypochlorite were used, the products such as unreacted amino acid, ammonia, and aldehyde were analogous to those of the dark reaction. The use of a large excess of hypochlorite under irradiation enables complete oxidative degradation of amino acid to carbon dioxide, water, and nitrogen. Its application to waste water treatment is discussed.

Simple α-amino acids often present in municipal waste water may be one of the major organic pollutants causing serious eutrophication in seas and lakes. Treatment of α-amino acids with sodium hypochlorite in the dark is known to cause the Strecker degradation leading to carbon dioxide, ammonia, and aldehydes possessing one less carbon atom.[2)] Langheld postulated a mechanism involving *N*-chloro amino acid (Eq. 1),[3)] but only limited information is available as to the kinetics and mechanism.[4,5)]

$$RCHCO_2H \xrightarrow[NH_2]{NaOCl} RCHCO_2Na \xrightarrow[NHCl]{-HCl} RCCO_2Na \xrightarrow[NH]{} \xrightarrow{-CO_2}$$

$$RCH{=}NH \xrightarrow{H_2O} RCHO + NH_3 \qquad (1)$$

Sodium hypochlorite exhibits under UV-irradiation a high oxidation power, decomposing effectively organic compounds and ammonia.[6)] It has been reported that irradiated hypochlorite effectively oxidizes some sulfonic acids,[7)] ethers,[8)] and aliphatic acids,[9)] which are fairly stable against hypochlorite in the dark. Hypochlorite oxidation of ammonia to nitrogen is greatly accelerated by irradiation.[10)] This photo-oxidation method might be important for waste water treatment, in which pollutants should be eliminated completely.

The present paper describes the kinetic behavior of the Strecker degradation in order to clarify the rate-determining step and also the effect of irradiation. We have found that on irradiation in the presence of large excess of NaOCl amino acids are decomposed rapidly into carbon dioxide and nitrogen.

Results and Discussion

Dark Reaction and Its Kinetics. The dark reactions of 5—10 mM (1 mM=10^{-3} mol dm^{-3}) glycine, alanine, and valine with NaOCl were examined in various buffer solutions at room temperature by monitoring the concentration of amino acid and oxidant. Analysis was based on (A) iodometry which gives concentration of hypochlorite and even *N*-chloro amino acids, and (B) determination of amino acids by 2,4-dinitrofluorobenzene method after converting *N*-chloro amino acids into amino acids. When hypochlorite was used in a 5—10-fold amount to amino acid at various pH, degradation of amino acid at pH 3—11 was too fast to determine the accurate rate of oxidation.

Table 1. First-order rate constants (k_1)[a)] for the dark reaction of α-amino acids with NaOCl at 20 °C

Amino acid	pH	$k_1 \times 10^5$/s^{-1}
Glycine	7.0	0.74
Alanine	6.0	7.5
	7.0	8.0 (9.8)
	9.0	8.5 (9.0)
Valine	7.0	10.3 (12.0)

a) Determined by iodometry (method A). Figures in parentheses are based on consumed amino acid (method B).

When equimolar (1:1 mol) amounts of hypochlorite and amino acid were used, oxidation became slow enough to be followed by spectrophotometry, iodometry, and amino acid determination. The UV spectroscopy of the equimolar solution indicated the instantaneous and quantitative formation of *N*-monochloro amino acid at pH 5—11. Each *N*-chloro amino acid was assigned by its absorption maximum at *ca.* 250 nm and its observed molar absorption coefficient (see Experimental). In acidic solutions at pH 2—4, *N*,*N*-dichloro amino acids were detected.

For the reaction of one mole of amino acid with one mole of hypochlorite, the change in amino acid concentration (c) was measured from time to time by methods (A) and (B). The observed values were found to fit the first-order rate expression ($\ln c_0/c = k_1 t$), though an apparent deviation from the first-order was observed at conversion higher than 70%. The first-order rate constants (k_1) analogous in methods (A) and (B) are given in Table 1.

The observed first-order rate suggests that the Strecker degradation with hypochlorite involves the decomposition of *N*-chloro amino acids at a rate-determining step. Thus the rate is first-order with respect to *N*-chloro amino acid:

$-d[RCH(NH_2)CO_2H]/dt = k_1[RCH(NHCl)CO_2H]$.

TABLE 2. PHOTOLYSIS AND DARK REACTION OF AMINO ACID WITH HYPOCHLORITE[a]

Light	Substrate	Amino acid		Ammonia		Aldehyde	
		Unreacted (mM)	Consumed (%)	Produced (mM)	Yield[b] (%)	Produced (mM)	Yield[b] (%)
>290 nm	Glycine	1.50	70	3.57	102	1.35	39
	Alanine	1.07	78	3.53	90	c)	
	Valine	0.85	83	4.28	97	c)	
None	Glycine	1.90	62	2.30	74	0.50	17
	Alanine	0.96	81	4.11	102	c)	
	Valine	0.75	85	4.61	108	c)	

a) Initial concentration; amino acid 5.0 mM; NaOCl 5.02 mM. Photolysis at 22 °C for 2.0 h, dark reaction at 25±2°C for 52 h. b) Yield based on consumed amino acid. c) Unsuccessful in quantitative determination, but positive to 2,4-dinitrophenylhydrazine reagent.

This is in accord with the UV spectroscopic measurements indicative of rapid and quantitative *N*-chlorination of amino acid. Though monochlorination of amino acid with chloramine T giving nitrile is slow,[5] the *N*-chlorination with hypochlorite leading to Strecker degradation is very rapid as is seen in ammonia and alkylamines.[11]

Chloramine NH_2Cl is in equilibrium with ammonia and hypochlorite.[12] Thus, the following mechanism is proposed:

$$\underset{\underset{NH_2}{|}}{RCHCO_2H} + HOCl \underset{\text{fast}}{\overset{\text{very fast}}{\rightleftharpoons}} \underset{\underset{NHCl}{|}}{RCHCO_2H} + H_2O \quad (2a)$$

$$\underset{\underset{NHCl}{|}}{RCHCO_2H} \xrightarrow{\text{slow}} RCHO + NH_3 + CO_2. \quad (2b)$$

Fast *N*-chlorination takes place with the equilibration of Eq. 2a (the equilibrium is extremely shifted to the right), followed by slow decomposition of *N*-chloro amino acid (Eq. 2b), indicating that the reverse process in pre-equilibrium (Eq. 2a) should be faster than decomposition (Eq. 2b). Otherwise, the second-order rate instead of first-order would have been observed.

The oxidation rate at pH 7 increases in the order glycine<alanine<valine (Table 1). The order might indicate that the electron-releasing group (CH_3) accelerates the reaction by stabilizing the developing positive charge during the course of oxidation. The effect of pH on the rate is not significant.

Photo-oxidation. Equimolar solutions (5—10 mM) of hypochlorite and amino acid were irradiated with light of wavelength>290 nm at pH 2—11. By means of iodometry and UV spectroscopy, *N*-chlorinated amino acids were found to decompose quite readily at any pH. To attain 95% consumption of *N*-chloro amino acid (oxidant), only 15 min was sufficient with an internal irradiation (see Experimental), whereas a period of over two days was necessary with the dark reaction. In spite of the presence of *N,N*-dichloro amino acid at pH 2—4, the decomposition rate was the same as that at pH 5—11; the effect of pH on decomposition rate of *N*-chlorinated amino acids was negligible. This may be due to the rapid interconversion between *N,N*-dichloro amino acid and *N*-chloro amino acid.

$$\underset{\underset{NCl_2}{|}}{RCHCO_2H} + \underset{\underset{NH_2}{|}}{RCHCO_2H} \longrightarrow 2\underset{\underset{NHCl}{|}}{RCHCO_2H} \quad (3)$$

Aldehydes, ammonia, carbon dioxide, and nitrogen were identified as products of the equimolar reaction together with unchanged amino acids. These products are the same as those of the corresponding dark reaction. A parallel experiment between irradiated and dark reactions was conducted with an equimolar solution at pH 7.0 in order to examine their product distribution. The results are summarized in Table 2.

The consumption extent of amino acid is in the order glycine<alanine<valine, irrespective of irradiated and dark reactions. In irradiated and dark reactions (Table 2), each case of amino acid shows similar amounts of unreacted amino acid and produced ammonia. UV irradiation might essentially affect the rate of decomposition of *N*-chlorinated amino acid, accelerating the Strecker degradation. This is energetically possible since light energy supplied as high as 400 kJ/mol surpassed the N–Cl bond energy (about 190 kJ/mol) in *N*-chloro amino acid. Formation of formaldehyde resulted in a lower yield than expected from the stoichiometry (Eq. 1), though high yield was observed for ammonia (Table 2). Reactions of amino acid with one mole of hypochlorite were carried out in the presence of five moles of aldehyde. Increase in the amount of recovered amino acid was observed. Aldehydes produced should reduce *N*-chloro amino acid to the original amino acid.

Another kind of irradiation was carried out in order to attain complete oxidation of amino acid in water. According to the theoretical equation (*e.g.* Eq. 4), 5, 8, and 15 equivalent amounts (only slight excess) of hypochlorite were irradiated (>290 nm) with glycine, alanine, and valine, respectively.

$$2H_2NCH_2CO_2H + 9NaOCl \longrightarrow 4CO_2 + 5H_2O + N_2 + 9NaCl \quad (4)$$

Iodometry showed rapid comsumption of oxidants such as OCl^- (alkaline solution) or HOCl (in acidic solution). After completion of the reaction, no significant amount of starting amino acids nor their primary products (ammonia and aldehydes) was detected. Estimation of carbon dioxide produced gave 60, 43, and 23% yields for glycine, alanine, and valine, respectively, based on the complete oxidation stoichiometry. Attempts to detect formic acid as a pos-

sible oxidation product of glycine were unsuccesful. However, acetic acid for alanine, and 2-methylpropanoic acid for valine could be detected by analysis of their crude reaction mixtures. Carboxylic acids can be completely oxidized with a large excess of hypochlorite under irradiation,[9] the oxidation of ammonia to nitrogen being considerably accelerated under irradiation.[10] Photochemical oxidation of sulfonic acids,[7] ethers,[8] and carboxylic acids[9] has been attributed to active oxygen species derived from hypochlorite ion. The oxygen atom might take part in the complete oxidation of aldehyde and carboxylic acid. It is evident that the initial stage for amino acid oxidation involves the formation and subsequent decomposition of *N*-chloro amino acid.

Experimental

General. Aqueous sodium hypochlorite (1 M) was prepared by introducing gaseous chlorine to aqueous NaOH (2.1 M) at 0 °C, the concentration of which was determined by iodometry. All amino acids (guaranteed grade) were DL-compounds. A buffer solution of pH 7 for the reactions was prepared with 0.2 M KH_2PO_4 added to NaOH. Commercial reagents (guaranteed grade) were used for analysis. Visible and UV absorption spectra were measured on a Hitachi 124 spectrophotometer in 1 cm cells. The internal irradiation was carried out in a vessel equipped with a Halos 100 W high-pressure mercury lamp, and external irradiation with a merry-go-round apparatus equipped with a Halos 300 W high-pressure mercury lamp.

Analysis. The 2,4-dinitrofluorobenzene (DNFB) method[13] was selected for the determination of amino acid. To a sample adjusted at pH 10 (1+1 ml) was added 1 w/v % 2,4-dinitrofluorobenzene in 2-propanol (1 ml). After being kept at 40 °C for 15 min, 1 M HCl solution (2 ml) of 2-propanol (1:1) was added. The resulting coloration was determined spectrophotometrically at 460 nm. The presence of equal mol of ammonia was found to increase the estimation of glycine, alanine, and valine by 29, 22, or 17±2%, respectively. Hence, we corrected the apparent values of amino acid by substracting the contribution due to eventual amount of ammonia.

The estimation of ammonia was based on the Nessler method[14] according to the procedure of JIS K 0101-1976. Chloramine, which is formed from ammonia and hypochlorite, disturbed the colorimetry at 450 nm. No interference was observed in the presence of amino acids. The presence of equimolar formaldehyde in an ammonia solution gave positive 28±3% error, acetaldehyde and 2-methylpropanal giving only *ca.* 5% error. No correction was made in the reactions of alanine and valine.

As regards aldehydes, 2,4-dinitrophenylhydrazine method was restricted only to qualitative analysis because of low sensitivity for quantitative analysis. Chromotropic acid reagent[15] was used for determination of formaldehyde, which was confirmed to be specific for formaldehyde. Colorimetry was carried out at 570 nm.

Dark Reaction. An equimolar amount of aqueous sodium hypochlorite was added to buffered solution of amino acid. Immediate iodometry showed a slight decrease in oxidant concentration, the concentration of amino acid based on DNFB method decreasing to 5—10% of the initial concentration. UV inspection of the solution showed a new absorption instead of HOCl (at 235 nm) and OCl^- (at 292 nm). After reduction with sodium thiosulfate solution, the DNFB method gave the expected value. This shows that since *N*-chloro amino acid is formed quickly, it is determined by iodometry but not by the DNFB method. The UV absorption data for *N*-chloro amino acid are as follows: absorption maximum (molar coefficient), *N*-chloroglycine 254 nm (342) (lit,[16] 256 nm (350)), *N*-chloroalanine 252 nm (349) (lit,[16] 253 nm (385)), and *N*-chlorovaline 254 nm (338). Each acidic (pH 2—4) solution of glycine, alanine, and valine containing an equimolar amount of hypochlorite showed an absorption at 302, 293, and 295 nm, respectively. These absorptions were assigned to the corresponding *N,N*-dichloro amino acid, based on lit.[16]

Kinetic runs were conducted with an equimolar solution of amino acid (7.0 mM) and sodium hypochlorite (7.0 mM) in buffer solutions at 20±1 °C. The change of concentration of *N*-chloro amino acid with time was followed by iodometry (method A). In order to know the true consumption of amino acid, determination by the DNFB method was applied after reduction of *N*-chlorinated amino acid with aqueous thiosulfate (method B). The results are given in Table 1.

Photo-oxidation. Internal irradiation was started immediately after addition of aqueous sodium hypochlorite to a buffer solution of glycine, alanine, and valine. Progress of each reaction was followed by iodometry together with UV spectroscopy. The irradiation was continued for 15—20 min. In order to detect aldehydes, the irradiated solution was treated with 2,4-dinitrophenylhydrazine dissolved in sulfuric acid and ethanol. 2,4-Dinitrophenylhydrazones of aldehydes (recrystallized from ethanol), obtained from glycine, alanine, and valine, respectively, showed following mps (mixed mps) and ^{1}H-NMR spectra: formaldehyde 168—169 °C (lit,[17] 166 °C), δ (d_6-DMSO) ppm 6.90 (d, J=12 Hz, N=$\underset{|}{\text{C}}$–H) 7.71 (d, J=12 Hz, N=$\underset{|}{\text{C}}$–H) 8.03 (d, J=10 Hz, arom. H^6) 8.44 (d, d, J=10 Hz, J'=2 Hz, H^5) 9.02 (d, J'=2 Hz, H^3) 11.7 (broad s, N–H); acetaldehyde 168—170 °C (lit,[18] 168 °C) δ ($CDCl_3$) 2.15 (d, J=6 Hz, CH_3) 7.63 (q, J=6 Hz, =$\underset{|}{\text{C}}$H); 2-methylpropanal 180—182 °C (lit,[19] 182 °C) δ ($CDCl_3$) 1.20 (d, J=6 Hz, CH_3) 2.68 (m, >CH). Carbon dioxide was trapped on acidification of the solution with $Ba(OH)_2$ solution as $BaCO_3$. Nitrogen was ascertained by GLC with a column packed with Molecular Sieve 5A.

A solution of amino acid and sodium hypochlorite (50 mM, 5-fold equivalent to glycine, 8-fold to alanine and 15-fold to valine) was irradiated internally at pH 4, 7, and 10 until over 99% hypochlorite was consumed (for 15—20 min), 100% amino acid was consumed with negligible formation of ammonia and aldehydes. By titration using $Ba(OH)_2$, the yield of carbon dioxide was 60, 43, and 23% (average values) for glycine, alanine, and valine, respectively. Several kinds of detection of formic acid (reduction with magnesium in acidic solution followed by coloration of resulting formaldehyde with chromotropic acid; IR spectroscopy of the dried-up material) were attempted, but were unsuccessful. Acetic acid and 2-methylpropanoic acid were detected successfully by GLC method (with a column packed Chromosorb WAW).

Comparison of Products between Photo Reaction and Dark Reactions. To a 10.0 mM amino acid solution prepared in a buffer solution of 7.0 was added in one portion 50 ml of a buffered 10.3 mM NaOCl (existing as HOCl). Two samples of the solution (each 25 ml) were subjected to external irradiation at 22 °C until iodometry showed zero titer (for 2.0 h). The other two quarters were kept in the dark at 25±2 °C for 52 h. In the case of glycine, the oxidant

remained 6% after 52 h. All determinations were performed within 1 d. The results are given in Table 2.

Decomposition of N-*Chloro Amino Acid in the Presence of Aldehydes.* Solutions containing 5.0 mM amino acid, 5.0 mM hypochlorite, and 12.5 mM aldehyde were kept standing in the dark for 2 d. Addition of aldehyde increased the recovery yield of starting amino acid from 19% to 36% in the case of alanine and from 15% to 34% in the case of valine.

Reactivity of Peroxomonophosphoric Acid in the Oxidation of Benzaldehydes and Dimethyl Sulfoxide in Aqueous Ethanol[1)]

Yoshiro OGATA,* Yasuhiko SAWAKI, and Yasuyuki TSUKAMOTO
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received October 14, 1980)

Oxidation of benzaldehydes and dimethyl sulfoxide with peroxomonophosphoric acid (PMPA) has been studied in 40% aqueous EtOH in order to examine the reactivity of undissociated and dissociated PMPA in comparison with that of peroxycarboxylic acid. The reactivity for DMSO was in the order $RCO_3^- > H_3PO_5 > H_2PO_5^- > RCO_3H > HPO_5^{2-}$. As in the peroxycarboxylic acid oxidation, PMPA oxidation of substituted benzaldehydes afforded phenols by aryl migration and benzoic acids by hydride migration. The product ratio changed with substituents and pH; salicylaldehyde (*o*-HO) gave only catechol by aryl migration, while *p*-chloro- and unsubstituted benzaldehydes afforded benzoic acids predominantly. The oxidation of aldehydes bearing *p*-MeO and *p*-Me was a borderline case and the migratory ratio of Ar~/H~ was higher at lower pH, *i.e.*, the order being $H_3PO_5 > H_2PO_5^- > HPO_5^{2-}$. The substituent effect in the apparent k_{obsd} values was very small (*i.e.*, $\rho \approx 0$), but the effect for aryl migration ($k_{Ar\sim}$) estimated from product selectivity gave $\rho = -2.88$ (σ). The rate for hydride migration ($k_{H\sim}$) resulted in $\rho = 1.7$ and 2.0 (σ). Reactivity of PMPA in each dissociated form was compared with that of RCO_3H.

Peroxomonophosphoric acid (PMPA) has been known for a long time,[2)] but its reactivity has not been clarified. Its decomposition[3)] and reactions with bromide[4)] and iodide ions[5)] were studied kinetically. Reports have been given on PMPA oxidation of organic substances, including the hydroxylation of aromatic rings,[6)] the Baeyer-Villiger(B-V) reaction of acetophenones,[7)] the epoxidation of *trans*-stilbene,[8)] and the oxidation of tertiary amines.[9)]

PMPA is a tribasic acid having three dissociated forms.[10)] We were interested in the reactivity of each form of PMPA as well as in their possibility as an oxidant with bifunctional catalysis since phosphoric acid is known as such a catalyst.[11)] The reaction of PMPA is also of interest from a biochemical standpoint, since PMPA might be produced by perhydrolysis of pyrophosphoric acids[12)] with oxygen species such as H_2O_2 or $O_2^{\cdot-}$.[13)] When we had almost completed our experiment a kinetic study on the PMPA oxidation of benzaldehydes was reported,[14)] the conclusion of which differing from ours.

Results and Discussion

Peroxomonophosphoric acid (PMPA) dissociates into three forms, affording $pK_1 = 1.1$, $pK_2 = 5.2$, and $pK_3 = 12.7$ in water.[10)] Oxidation of dimethyl sulfoxide (DMSO) and benzaldehydes with PMPA was carried out in the presence of 0.4 mM EDTA in 40% aqueous ethanol at 25 °C. The decrease of PMPA was monitored by iodometric titration in 5% AcOH; its spontaneous decompositition was very slow in the absence of added substrates. Products were determined by GLC directly or after methylation with dimethyl sulfate for phenols or with diazomethane for carboxylic acids.

$$H_3PO_5 \overset{K_1}{\rightleftharpoons} H_2PO_5^- + H^+ \quad (1)$$

$$H_2PO_5^- \overset{K_2}{\rightleftharpoons} HPO_5^{2-} + H^+ \quad (2)$$

$$HPO_5^{2-} \overset{K_3}{\rightleftharpoons} PO_5^{3-} + H^+ \quad (3)$$

Oxidation of DMSO. Dimethyl sulfoxide was easily oxidized to sulfone in over 90% yield based on PMPA consumed. The oxidation follows the second-order rate equation (Eq. 4). The pH-rate profile

$$v = k_{obsd}[\text{PMPA}][\text{Substrate}] \quad (4)$$

is shown in Fig. 1. The resulting second-order rate constant are 210, 45, and 1.2 $M^{-1} s^{-1}$ for H_3PO_5, $H_2PO_5^-$, and HPO_5^{2-}, respectively. The kinetically determined pK_1 and pK_2 values for PMPA in 40% EtOH are 1.6 and 4.6, respectively, close to the reported pK_a values 1.1 and 5.2, respectively, in water.[10)] The difference of *ca.* 0.5 might be partly due to the solvent effect on pK_a of PMPA.

The Baeyer-Villiger Oxidation of Benzaldehydes. Products. Products from the B-V oxidation of benzaldehydes with PMPA vary with substituents and pH (Table 1). Salicylaldehyde with strong electron-releasing *o*-HO afforded only catechol by aryl migration. The relatively low yields (*i.e.*, 65—75%) of catechol can be ascribed to further oxidation by PMPA. The other aldehydes resulted in the simultaneous formation of phenols by aryl migration and benzoic acids by hydride migration.

$$\text{ArCHO} \xrightarrow{\text{PMPA}} \begin{cases} \xrightarrow{Ar\sim} \text{ArOCHO} \xrightarrow{H_2O} \text{ArOH} & (5a) \\ \xrightarrow{H\sim} \text{ArCO}_2\text{H} & (5b) \end{cases}$$

We see from Table 1 that the aryl migration is facilitated by an increase in electron-releasing power of ring substituents and by a decrease of pH. Higher pH and electron-attracting groups favor the hydride

a) Reaction with 0.04 M each of H_3PO_5 and ArCHO in 40% EtOH at 25 °C. % Yields are based on the aldehyde consumed and determined by GLC after methylation with dimethyl sulfate for phenols or with diazomethane for carboxylic acids.

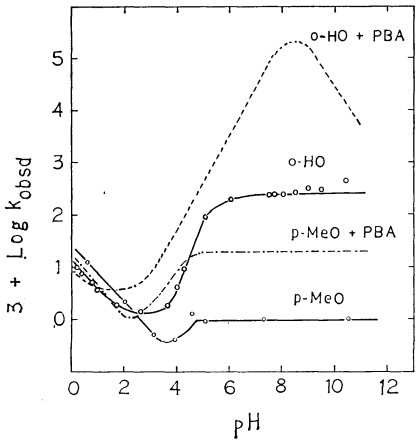

Fig. 2. pH-rate profiles for the PMPA oxidation of substituted benzaldehydes in 40% EtOH at 25.0 °C. The dotted lines are plots for perbenzoic acid (PBA) oxidation from Ref. 15. The solid line for *o*-HO is calculated according to the rate data in Table 3.

migration leading to carboxylic acids. The trend is similar to that of the B-V oxidation with perbenzoic acid (PBA).[15]

Mechanism. In case of the PBA oxidation of salicylaldehyde the rate-determining step is the addition of PBA to C=O.[15] Since the pK_a values of the aldehydes and PBA are 8.45 and 8.5, respectively, in 40% EtOH,[15] the pH-rate profile gives a bell-shaped curve (dotted line, Fig. 2). The oxidation with PMPA afforded a similar profile (Fig. 2); the observed slopes of *ca.* −0.5 at pH<2 suggest an acid-catalysis, while horizontal lines at pH 5—10 indicate no catalysis by H^+ or HO^-. If the addition of PMPA to C=O were rate-limiting, the rate should slow down at pH above 9 on the basis of the dissociation of salicylaldehyde, which was not the case. This is in contrast to the PBA case, suggesting that the addition to C=O is not rate-determining. The rate is determined by the migration step (Eq. 7). Here, YOOH

$$ArCHO + YOOH \overset{K_6}{\rightleftharpoons} \underset{\underset{OOY}{|}}{\overset{OH}{|}}{ArCH} \quad (6)$$

1

$$\mathbf{1} \xrightarrow{k_7} \text{Products} + YOH \quad (7)$$

is H_3PO_5, $H_2PO_5^-$, or HPO_5^{2-}. In the neutral region, the most prevalent species is $H_2PO_5^-$, so that the

a) Reaction with 0.01—0.05 M each of benzaldehyde and PMPA. b) Observed rate constant determined iodometrically. c) For comparison, the k_{obsd} values for PBA (Ref. 17) are shown in parentheses. d) Rate constants for aryl or hydride migration obtained by dividing k_{obsd} values by product selectivities in Table 1. e) Numbers of data were too small, the correlation being poor.

departing group YOH from **1** is $H_2PO_4^-$ (pK_a= 7.2), which is significantly less potent as a departing group than benzoic acid (pK_a=4.2) in the PBA oxidation. The rate of rearrangement of **1** (*i.e.*, k_7) is then substantially lowered, leading to the establishment of preequilibrium 6 for the PMPA case.

The PMPA oxidation of *p*-anisaldehyde (*p*-MeO) is substantially slower than that of salicylaldehyde at pH>3, but slightly faster at pH<2 (Fig. 2). The rates for the other aldehydes are similar to that of anisaldehyde, the k_{obsd} values not varying with substituent, *i.e.*, $\rho \approx 0$ (Table 2-A). It can be assumed that the ρ value for K_6 is close to the ρ value of 1.6

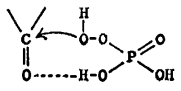
(σ) for the H_2O_2 addition (Y=H, Eq. 6).[15] The apparent zero value of ρ for k_{obsd} might be due to the cancellation, since $k_{obsd}=k_7K_6$, between a positive ρ value for K_6 and a negative ρ value for k_7. Negative ρ values for aryl and hydride migration are well known.[15–17] Such a cancellation is often observed in reactions involving carbonyl addition.[18]

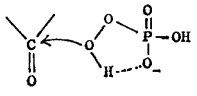
A mechanism was postulated for the PMPA oxidation of benzaldehydes, which involves a rate-determining attack of PMPA on benzaldehyde hydrates, $ArCH(OH)_2$.[14] However, the scheme is questionable. (i) No reaction is known in which the nucleophilic attack on tetrahedral carbons such as aldehyde hydrate is much faster than that on free aldehyde ArCHO. (ii) Benzaldehydes exist essentially as free aldehydes ArCHO under these conditions of aqueous EtOH; an exception is *p*-nitrobenzaldehyde, where 20% of the aldehyde exists as its hydrated form.[19] Likewise, the addition equilibrium of HO^- instead of H_2O shifts to the free ArCHO rather than to the adduct $ArCH(OH)O^-$ at pH<14.[20] Thus the C=O addition scheme is favorable, since both concentration and reactivity of the free aldehydes are much higher than those of the hydrates.

Polybasic acids such as phosphoric acid are sometimes effective as a bifunctional catalyst.[11] We intended to examine such a possibility in the addition to C=O, *e.g.*, an intermolecular acid-catalysis (**2a**) or an intramolecular base-catalysis (**2b**). However,



2a

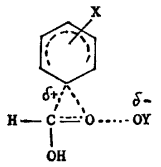
or



2b

the addition to C=O was not rate-determining even in the case of salicylaldehyde with the most facile migratory aptitude; no such catalysis could be examined.

Aryl and Hydride Migration. Although the k_{obsd} values in Table 2-A are little affected by substituents (*i.e.*, $\rho\approx0$), interesting results for the relative migratory aptitudes were obtained by multiplying the k_{obsd} values by products selectivities in Table 1. The aryl migration ($k_{Ar\sim}$) at pH 1.3 affords $\rho=-2.88$ (σ) (Table 2-B). Similar results ($\rho=-2.55$ *vs.* σ) are known for the PMPA oxidation of acetophenones.[7] These correlations are in contrast to the σ^+ correlation for the B-V reaction with PBA.[15,16] The difference might be due to the fact that in the rearrangement of **1** at pH<2 the departing phosphoric acid (pK_a=2.1) is a much stronger acid than benzoic acid (pK_a=4.2). The loosening of O–O bond in the PMPA oxidation is relatively weak, and hence the developing cationic charge (δ^+) in **3** is much lower than in the



3

PBA case. The interpretation seems to be in line with the observed high rate ratios of *p*-MeO/*p*-Me for the reaction at pH 4 (*i.e.*, $H_2PO_5^-$) and pH 7 or 10 (*i.e.*, HPO_5^{2-}), suggesting a σ^+ correlation. Since $H_2PO_4^-$ (pK_a=7.2) and HPO_4^{2-} (pK_a=12.7) are much less potent departing groups as compared with H_3PO_4, the cationic charge in **3** increases leading to the σ^+ correlation at pH>4. High rate ratios of *p*-MeO/*p*-Me correspond to a σ^+ correlation, small ratios giving rise to σ correlation.

On the other hand, Hammett's equation for the hydride shift gives $\rho=1.74$ (pH 4) and 2.0 (pH 7.3) with σ correlation (Table 2-C). The same reaction with PMPA in the presence of 0.2 M NaOH gives a ρ value 1.27 (σ) in water.[14] These ρ values are close to 1.6 (σ) for the addition equilibrium of H_2O_2 (Eq. 6).[15] Since $k_{obsd}=k_7K_6$, the net ρ value for the hydride shift (*i.e.*, k_7) might be close to zero. Similar ρ values of 1.1—1.8 were obtained at pH 1—12 in the PBA oxidation of benzaldehydes affording hydride shift,[17] which is rather insensitive to acid and base catalysis.[15] The same might be the case for the PMPA oxidation.

Comparison with Peroxycarboxylic Acid. The reac-

tivity of PMPA was compared with that of peroxycarboxylic acids (Table 3). In one-step electrophilic oxidation, relative reactivities of PMPA and RCO_3H change with substrate. For example, the relative reactivity in the oxidation of bromide ion differs from the corresponding order for iodide ion. The rate order for olefin epoxidation is $RCO_3H \gtrsim H_3PO_5$,[8] that for the oxidation of DMSO, $H_3PO_5 > H_2PO_5^- > RCO_3H > HPO_5^{2-}$. The DMSO oxidation with RCO_3^- is of a different mechanism and excluded from the comparison; the alkaline reaction involves two steps, a nucleophilic addition to sulfoxide and its decomposition to sulfone and carboxylate ion,[21] just as the B-V reaction.

The relative reactivity for the B-V reaction also changes with substrates and pH (Fig. 2, Table 2-A, and Table 3). The rate order for the B-V reaction of benzaldehydes at pH 3—10 is $RCO_3H > PMPA$, but changes to the order $PMPA > RCO_3H$ at the lower pH. This is due to the higher sensitivity of PMPA to acid-catalysis as compared with that of RCO_3H.

Experimental

GLC analysis was performed with a Yanagimoto 550F gas chromatograph using a column of PEG 20 M on Chromosorb (1 m).

Materials. Peroxomonophosphoric acid (PMPA) was prepared from P_2O_5 and 90% H_2O_2.[9] Commercial benzaldehydes were used.

Typical Procedure. The reaction with 0.04 M each of PMPA and benzaldehyde was carried out in 40 vol % EtOH at 25.0 °C. EDTA (0.4 mM) was added to minimize a metallic ion-catalyzed decomposition of PMPA. The pH of solution was maintained with perchloric acid ($pH < 1$), 0.5 M acetate (pH 2.5—4.4), 0.5 M phosphate (pH 3.7—6.1), and 0.5 M carbonate buffers (pH 7.5—10). The pH values were determined with a glass electrode before and after the reaction. The decrease of PMPA was monitored by iodometric titration in 5% aqueous AcOH. The spontaneous decomposition of PMPA was very slow in the absence of substrate added. Reproducibility of the oxidation kinetics was ascertained to be adequate (*i.e.*, within ±5%).

Reaction products were determined by means of GLC directly or after methylation with diazomethane using biphenyl or propiophenone as an internal standard. Catechol was determined after methylation with dimethyl sulfate.

The Reactions of Phenylmagnesium Halides with Seleninyl Chloride, Diphenyl Selenoxide, and Dibromodiphenylselenium

Yasunori Iwama, Masashi Aragi, Motohide Sugiyama, Kasumi Matsui, Yasutaka Ishii, and Masaya Ogawa*

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received October 21, 1980)

Triphenylselenonium halides were readily prepared in good yields by the one-step reaction of seleninyl chloride with phenylmagnesium halides, followed by treatment with hydrogen halides. The yields of triphenylselenonium halides are markedly affected by the molar ratio of seleninyl chloride to the phenylmagnesium halides. In order to interpret the above results, some probable intermediates, such as diphenyl selenoxide, dibromodiphenylselenium, and diphenyl selenide, were investigated by allowing them to react with the phenylmagnesium halides. A pathway which consists of competitive and successive reactions is discussed.

Trimethylselenonium hydroxide ($(CH_3)_3Se^+OH^-$) is a very useful methylation reagent for carboxylic, thiol, and aromatic hydoroxyl groups.[1] Hampton[2] has reported on the use of diphenyliodonium chloride ($Ph_2I^+Cl^-$) for terminal phenylation. Triarylselenonium halides ($Ar_3Se^+X^-$), which may be expected as arylation reagents, could be prepared by a convenient one-step synthesis.[3] Strecker and Willing[4] have obtained only diphenyl selenide (Ph_2Se) and diphenyl (Ph_2) by the reaction of seleninyl chloride ($SeOCl_2$) with phenylmagnesium bromide (PhMgBr); they have not described the formation of selenonium salt. However, the addition of about three moles of arylmagnesium halides to one mole of $SeOCl_2$ afforded the corresponding triarylselenonium salts, together with Ph_2Se and Ph_2.[3] This method is useful for the preparation of selenonium salts, since the usual methods require several steps.[5,6]

In order to clarify the formation path of triphenylselenonium halides ($Ph_3Se^+X^-$), the reaction of phenylmagnesium halides (PhMgX) with such probable intermediates as diphenyl selenoxide (Ph_2SeO), dibromodiphenylselenium (Ph_2SeBr_2), and diphenyl selenide (Ph_2Se) were investigated.

Results and Discussion

Reaction of PhMgX with $SeOCl_2$. After the addition of 3.5-fold mole of various PhMgX's to $SeOCl_2$ in THF or ether, the solution was maintained at the reflux temperature for 2 h.[7] The hydrolysis of the reaction mixtures with aqueous hydrobromic acid (HBr *ca.* 1 mol dm^{-3}) gave $Ph_3Se^+X^-$, Ph_2Se, and Ph_2, as is shown in Table 1. It is of interest that $Ph_3Se^+Br^-$ appeared in the reaction of $SeOCl_2$ with the PhMgCl was afforded by the treatment of the resulting reaction mixtures with HBr. In the case of PhMgI, $Ph_3Se^+I^-$ was produced, even though the mixtures were similarly treated with HBr.[8]

The reaction with PhMgCl, followed by treatment with HBr, gave $Ph_3Se^+Br^-$ in a 56% yield, but the yield of selenonium salt in the same reaction in the presence of $MgBr_2$ fell to 39%, which is comparable to the yield of the reaction with PhMgBr,[9] as is shown in Table 1. These findings indicate the occurrence of halogen exchange in the reaction system during the period of reaction and the treatment with HBr. It is considered that the lower yield of selenonium salt in the reaction with PhMgBr results from the formation of more reactive, but less selective, $SeOBr_2$ by halogen exchange between $SeOCl_2$ and the resulting $MgBr_2$ during the reaction. The considerable lowering in the yield in the case of PhMgI is thought to be due to the decomposition of the unstable $SeOI_2$.[10]

These results indicate that the seleninyl halides ($SeOX_2$) generated by halogen exchange react with three moles of PhMgX to give triphenylselenonium halogenomagnesium oxide ($Ph_3Se^+OMgX^-$), which then affords $Ph_3Se^+X^-$ upon subsequent hydrolysis with HBr.

The product distributions of $Ph_3Se^+Br^-$, Ph_2Se, and Ph_2 varied with the ratio of PhMgX to $SeOCl_2$. Figure 1 shows a typical curve for the yield of each product obtained by the addition of PhMgBr to $SeOCl_2$ in ether. The production of Ph_2SeBr_2 was at its maximum at the molar ratio of 1.5; thereafter, it decreased rapidly to zero at the ratio of 2.5, in contrast to the increase in Ph_2Se and Ph_2. The amount of selenonium salt increased gradually with the increase in PhMgBr until the molar ratio of 3.5. At more than 3.5, a rapid decrease in the selenonium salt led to the formation of Ph_2Se and Ph_2. Thus, the present reaction is considered to be a complicated successive reaction.

Reaction of PhMgBr with Ph_2SeBr_2. A solution of PhMgBr in ether was added to equimolar amounts of Ph_2SeBr_2, and then the mixture was worked-up as above. The selenonium salt which was expected as the primary product was not obtained at all, but

Table 1. Addition of PhMgX to a solution of $SeOCl_2$[a] (Followed by HBr work-up)

X PhMgX	MgX_2	Yield[b]/mmol		
		$Ph_3Se^+Br^-$	Ph_2Se	Ph_2[c]
Cl	—	16.9(56.2)	11.7(39.0)	4.2(14.3)
Br	—	11.2(37.3)	14.9(49.5)	7.9(26.3)
I[d]	—	0.8(2.5)[e]	10.6(35.2)	9.9(33.1)
Cl	$MgCl_2$	16.4(54.5)	12.1(40.2)	5.4(18.1)
Cl	$MgBr_2$	11.7(39.0)	15.1(50.5)	9.6(32.0)

a) PhMgX (105 mmol) was added to a solution of $SeOCl_2$ (30 mmol) in THF (100 ml). b) Yields given in parentheses indicate the mol% based on $SeOCl_2$. c) Formation from Ph_4Se was assumed. d) Ether was used as the solvent. e) $Ph_3Se^+I^-$.

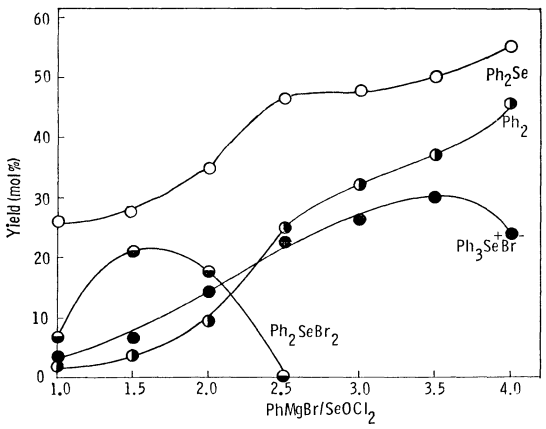

Fig. 1. Dependence of the yield of each product on the molar ratio of PhMgBr to $SeOCl_2$.

equimolar amounts of Ph_2Se and Ph_2 were.[11] This fact shows that Ph_2SeBr_2 reacts with PhMgBr to give, probably, an unstable tetraphenylselenium (Ph_4Se), which then immediately decomposed to Ph_2Se and Ph_2. It was found that Ph_2SeBr_2 is not connected with the production of selenonium salt.

On the other hand, no product was furnished by the reaction of Ph_2Se with PhMgBr.

Reaction of PhMgBr with Ph_2SeO. Ph_2SeO could not be isolated in the reaction of $SeOCl_2$ with PhMgBr, but it appeared to be one of the most probable intermediates. Wildi[12] has reported the production of triphenylsulfonium bromide ($Ph_3S^+Br^-$) by the reaction of diphenyl sulfoxide (Ph_2SO) with PhMgBr.

The reaction of Ph_2SeO with PhMgBr, followed by hydrolysis with HBr, gave $Ph_3Se^+Br^-$, Ph_2Se, and Ph_2 in yields of 25, 63, and 10% respectively. It seems that selenonium salt was produced through triphenylselenonium bromomagnesium oxide (Ph_3Se^+-$OMgBr^-$) according to the following equation.

$$Ph_2SeO + PhMgBr \longrightarrow Ph_3Se^+OMgBr^-$$

$$Ph_3Se^+OMgBr^- + HBr \longrightarrow Ph_3Se^+Br^- + MgBr(OH)$$

Some of the $Ph_3Se^+OMgBr^-$ reacts further with PhMgBr to afford Ph_2Se and Ph_2 *via* Ph_4Se:

$$Ph_3Se^+OMgBr^- + PhMgBr \longrightarrow Ph_4Se + (MgBr)_2O$$

$$Ph_4Se \longrightarrow Ph_2Se + Ph_2$$

However, the significant formation of Ph_2Se can not be interpreted by considering only the above reaction. It may be supposed that Ph_2Se is produced by the elimination of oxygen from Ph_2SeO, which is liable to be reduced, but the detailed process has not been ascertained.[13]

Consequently, the reaction proceeds first through halogen exchange between $SeOCl_2$ and PhMgX, as well as, the MgX_2 which is generated during the period of reaction, and the resulting $SeOX_2$ reacts with PhMgBr to give Ph_2SeO and Ph_2SeBr_2. Selenonium salts are chiefly derived from Ph_2SeO, and Ph_2Se and Ph_2, from Ph_2SeBr_2. From these results, it seems reasonable that the maximum yield of selenonium salts is at the molar ratio of PhMgX to $SeOCl_2$ of 3.5, and that the reaction proceeds through competitive and successive paths which are complicated by halogen exchange.

Experimental

The melting points, determined on a Yanagimoto micro-melting-point apparatus (MP-J3), are uncorrected. The IR spectra were obtained with a Shimadzu IR-27G spectrophotometer. The mass spectra were measured with a JEOL JMS-01SG apparatus. The general procedure for the reaction of PhMgX with $SeOCl_2$ was the same as in a previous paper.[3] The yields of $Ph_3Se^+X^-$ and Ph_2Se, based on the $SeOCl_2$ used, and of Ph_2 were estimated and considered to result from the decomposition of Ph_4Se to Ph_2Se and Ph_2.

Reaction of PhMgCl with $SeOCl_2$ in the Presence of $MgBr_2$. Anhydrous $MgBr_2$ (5.5 g, 30 mmol) was added to a solution of $SeOCl_2$ (5.0 g, 30 mmol) in THF (100 ml). The mixture gradually became brownish and was then allowed to react with PhMgCl (105 mmol) in THF under reflux for 2 h. After the THF had been evaporated *in vacuo*, the mixture was hydrolyzed with HBr (*ca.* 1 mol dm^{-3}) and extracted with benzene; the remaining aqueous solution was further extracted with chloroform. The benzene extract was dried over sodium sulfate, and the benzene was evaporated *in vacuo*. The residue was distilled under reduced pressure to give Ph_2 (1.5 g; 32%) and Ph_2Se (3.6 g; 50.5%).

Ph_2: mp 69—70 °C; IR 3055, 3025, 1473, 1423, 902, 725, 690 cm^{-1}. These values were identical with those of an authentic sample.

Ph_2Se: bp 106 °C/2 mmHg; IR 3060, 1575, 1475, 1440, 1000, 735 cm^{-1}; MS *m/e* 234 (M^+), 154 (M^+—Se). Found: C, 61.77; H, 4.42%. Calcd for $C_{12}H_{10}Se$; C, 61.81; H, 4.32%.

The chloroform extract afforded $Ph_3Se^+Br^-$ (4.6 g; 37%) upon recrystallization from chloroform–acetone(1:5): mp 236 °C decomposed; IR 3050, 1580, 1430, 990, 765, 745, 734 cm^{-1}; MS *m/e* 234 (M^+—PhBr), 157 (M^+—Ph_2). Found; C, 55.32; H, 3.79%. Calcd for $C_{16}H_{15}SeBr$: C, 55.42; H, 3.88%.

Reaction of PhMgBr with Ph_2SeBr_2. $SeOCl_2$ (5.0 g; 30 mmol) was added to PhMgBr (45 mmol) in ether (100 ml), and the mixture was stirred under reflux for 1 h. After the removal of the ether, the reaction mixtures were treated with HBr (*ca.* 1 mol dm^{-3}), and then crude Ph_2SeBr_2 was precipitated. The crystals were collected and recrystallized from ether to afford Ph_2SeBr_2 (2.4 g; 21.6%): mp 147.5 °C decomposed; IR 1600, 1460, 1150, 990, 738, 681 cm^{-1}. Found: C, 36.62; H, 2.61%. Calcd for $C_{12}H_{10}Br_2Se$: C, 36.67; H, 2.57%.

Ph_2SeBr_2 (12.3 g; 31 mmol) was added to a solution of PhMgBr (31 mmol) in ether (50 ml) at 34 °C, and the mixture was hydrolyzed with HBr (*ca.* 1 mol dm^{-3}) and extracted with benzene and then with chloroform. Ph_2Se (3.5 g; 47.9%), Ph_2 (1.9 g; 42.4%), and unreacted Ph_2SeBr_2 (4.9 g; 40%) were obtained from the benzene extracts. From the chloroform extract, though, no product was obtained.

Reaction of PhMgBr with Ph_2SeO. Ph_2SeO was prepared by the method of Rheinboldt.[14] PhMgBr (60 mmol) was added, drop by drop, over a period of 1 h at 34 °C to an equimolar amount of Ph_2SeO (60 mmol) in ether (50 ml). After the addition, the ether was removed and the residue was hydrolyzed with HBr (*ca.* 1 mol dm^{-3}), and then extracted with benzene and subsequently with chloroform, as has been described above. From the extracts, Ph_2Se (6.2 g; 63.5%), $Ph_3Se^+Br^-$ (5.9 g; 25.2%), and Ph_2 (0.86 g; 10.0%) were afforded.

Effects of Chelated and Non-chelated Transition Metal Ions on the Photoreactions of Pyridinecarboxylic Acids in Aqueous Solutions

Akira SUGIMORI,* Kōtarō TAKADA, Tsutomu KIMURA, and Junji KAMIMURA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102

(Received October 23, 1980)

Iron(III) and copper(II) chelated by 2-pyridinecarboxylate bring about the photochemical decarboxylation of the ligand *via* the electron transfer from carboxylate to metal ions to give pyridine and 2,2′-bipyridine (for Fe(III)) or 2-pyridinol (for Cu(II)). In the presence of iron(III), ruthenium(III), and copper(II), 3-pyridinecarboxylic acid gives photochemically 2,2′-bipyridine-3,5′-dicarboxylic acid without decarboxylation. 4-Pyridinecarboxylic acid is photo-resistant both in the presence and in the absence of iron(III) and copper(II).

Metal ions, especially transition metal ions, have profound effects on the photoreactions of organic compounds.[1] Recently, long range electron transfer mechanism has been proposed for the metal ion-catalyzed photo-oxidation of olefins.[2] Effects of metal ions on the photoreactions of carboxylic acids have extensively been studied,[3] together with their photoreactions in the absence of metal ions.[4] A metal ion may have different effects on the photoreaction depending on whether it is coordinated by an organic ligand or not. Pyridinecarboxylic acids afford a good system to investigate the differences between the coordinated and the non-coordinated metal ions: 2-pyridinecarboxylic acid forms very stable chelate bonds with many metal ions, whereas 3- and 4-pyridinecarboxylic acid form no such stable chelate bonds.[5]

We have reported some results on the photoreactions of 2- and 3-pyridinecarboxylic acid in the absence of metal ions. The irradiation of 3-pyridinecarboxylic acid in an aqueous solution with 254 nm light gives 2-hydroxy-3-pyridinecarboxylic acid in the pH range of 0—2 and 2,3′-bipyridine-5-carboxylic acid in the pH range of 4—6.[6] 2-Pyridinecarboxylic acid gives photochemically 6-hydroxy-2-pyridinecarboxylic acid in an acidic aqueous solution.[7]

Results and Discussion

The photoreactions of pyridinecarboxylic acids in the presence of several metal ions are summarized in Tables 1 and 2. Among the metal ions, iron(III) and copper(II) have remarkable effects on the photochemical processes of the acids. The metal ion effects on 2-pyridinecarboxylic acid (**1**) are different from those on 3-pyridinecarboxylic acid (**2**). In the case of **1**, which forms stable chelate bonds with metal ions,[8] the products *via* decarboxylation are significant. The 254 nm light irradiation of 2-pyridinecarboxylatoiron(III) complex gives pyridine (**3**), 2,2′-bipyridine (**4**) and a trace of 2-pyridinol. The photoreaction

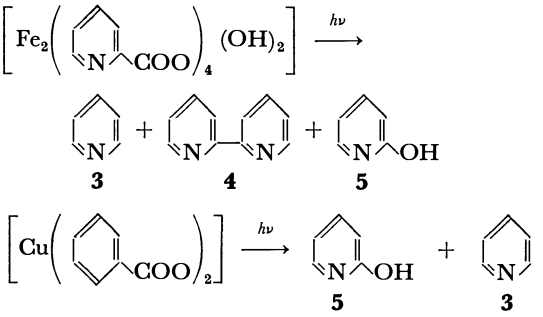
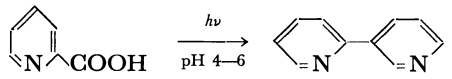
of 2-pyridinecarboxylatocopper(II) complex gives 2-pyridinol and a trace of pyridine.



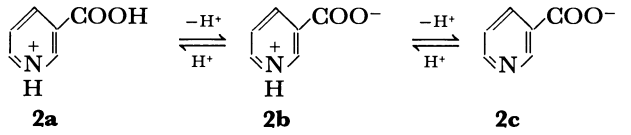
In the absence of metal ions, the UV-irradiation of 2-pyridinecarboxylic acid in the pH range of 4—6 gives 2,3′-bipyridine in 20% yield.



The addition of hydroquinone, a radical scavenger, to the iron(III) complex solution inhibits the formation of 2,2′-bipyridine and increases the yield of pyridine.

The coordinated cobalt(II) and magnesium(II), the lower oxidation states of which are unstable, stabilyze the coordinating 2-pyridinecarboxylate under illumination.

The photoreaction of 3-pyridinecarboxylic acid, which forms no stable chelate bond with metal ions, is affected by iron(III) ions differently from that of 2-pyridinecarboxylic acid. 3-Pyridinecarboxylic acid exists in three forms depending on the pH of the solutions. The effects of iron(III) on the photoreaction of 3-pyridinecarboxylic acid is pH dependent (Fig. 1). At pH 4—6, where the form of 3-pyridinecarboxylic

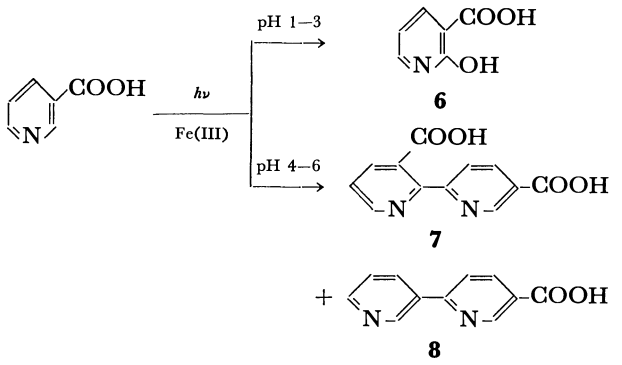


2a pK_a at 25 °C, 2.07[9] **2b** pK_a at 25 °C, 4.81[9] **2c**

acid is a mixture of **2b** and **2c**, the UV-irradiation in the presence of Fe(III) gives 2,2′-bipyridine-3,5′-dicarboxylic acid (**7**), which is obtained as an iron(II) complex, in addition to 2,3′-bipyridine-5-carboxylic acid (**8**), which is the main product in the absence of Fe(III).[6]

At pH 1—3, where the form of 3-pyridinecarboxylic acid is **2a**, the irradiation in the presence of Fe(III) gives 2-hydroxy-3-pyridinecarboxylic acid (**6**), the same product as in the photoreaction in the absence of Fe(III).[6]

In higher pH range, iron(III) is precipitated as hydroxide or oxide, and hence the effect of iron(III) can not be studied.



The effects of ruthenium(III) and copper(II) are practically the same as those of iron(III). The UV-irradiation of **2** in the presence of Ru(III) or Cu(II) in the pH range of 4—5 gives **7** and **8**.

Figure 2 shows the effects of iron(III) as a function of iron(III) concentration. Here the efficiency of Fe(III) effect (Q) on the photoreaction is expressed on the basis of the light absorbed by 3-pyridinecarboxylic acid according to the following equation.

$$Q = \frac{[\text{Product}] \text{ or } -[\mathbf{2}]}{\dfrac{\text{Light absorbed by } \mathbf{2}}{\text{Light absorbed by } \mathbf{2} \text{ and } FeCl_3}}$$

(The Q-value is a relative quantum yield calculated for the light absorbed by 3-pyridinecarboxylic acid.)

The saturation of the effect of Fe(III) at relatively low concentration and the constant Q-values over the wide range of Fe(III) concentration suggest that the photoreaction originates from the excited **2** not from the excited Fe(III), and the reaction between the excited **2** and Fe(III) should be rapid.

For the photoreaction of 4-pyridinecarboxylic acid, iron(III) and copper(II) have practically no effects. Four hours' irradiation of 5×10^{-4} mol dm^{-3} solutions of 4-pyridinecarboxylic acid at pH 4.7 gave slight UV-spectral changes both in the presence and in the absence of iron(III) and copper(II).

The photochemical decarboxylation of 2-pyridinecarboxylate attached to iron(III) and copper(II) under

Table 3. Composition of 2-pyridinecarboxylatometal complexes

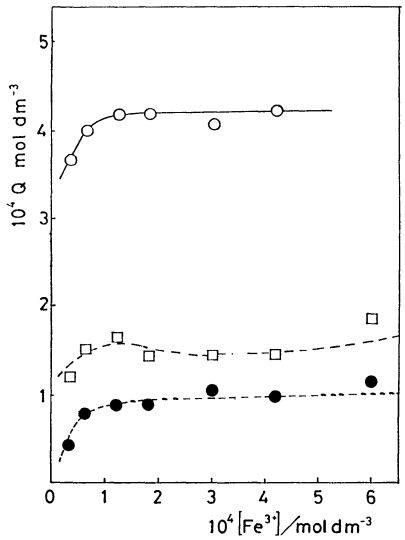

Fig. 2. Dependence of photoreactions of 3-pyridinecarboxylic acid on Fe(III) concentration ([2]=6×10^{-4} mol dm^{-3}, pH≈4.4).
The efficiency of the photoreaction is defined as,

$$Q = \frac{[\text{Product}] \text{ or } -[\mathbf{2}]}{\text{Light absorbed by } \mathbf{2}} \Big/ \frac{\text{Light absorbed by } \mathbf{2} \text{ and } FeCl_3}{\text{Light absorbed by } \mathbf{2}}$$

--●--: **7**, —·—□—·—: **8**, —○—: **2** reacted.

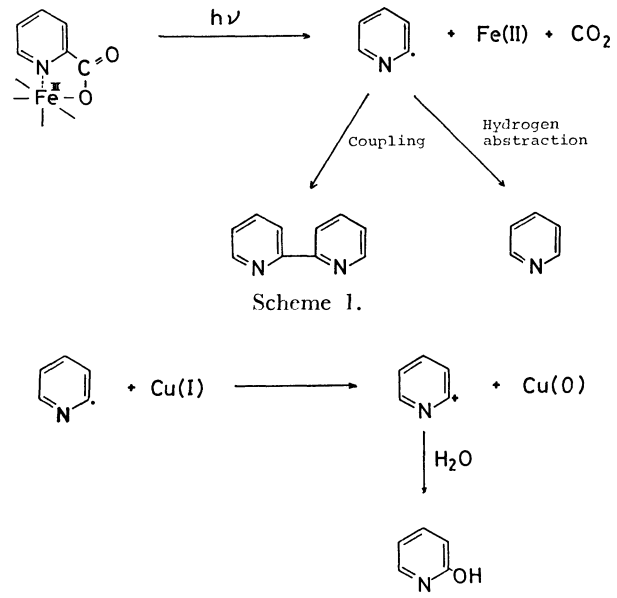
illumination can be explained by the effective electron transfer from the carboxylate to the coordinated metal ions to give carbonyloxy radicals which easily decarboxylate to form 2-pyridyl radicals.

2,2′-Bipyridine is considered to be a coupling product of 2-pyridyl radicals. The fact that the addition of hydroquinone, an effective hydrogen donor, inhibits the photochemical formation of 2,2′-bipyridine and promotes that of pyridine supports the suggested mechanism (Scheme 1).

The promotion of radical coupling in the presence of transition metal ions has been reported,[10] and a long lived free radical-metal complex has been proposed.[11]

The formation of 2-pyridinol in the photoreaction of 2-pyridinecarboxylatocopper(II) complex can be explained by the subsequent oxidation of 2-pyridyl radicals by copper(I). The formation of a copper mirror on the reaction vessel was observed during the irradiation (Scheme 2).

The process of the formation of 2,2′-bipyridine-3,5′-dicarboxylic acid in the photoreaction of the 3-pyridinecarboxylic acid–iron(III) system is different from that



Scheme 1.

Scheme 2.

of the formation of 2,2′-bipyridine in the photoreaction of 2-pyridinecarboxylatoiron(III) complex.

The formation of a bipyridine derivative and iron(II) indicates the electron transfer from 3-pyridinecarboxylic acid to iron(III). At pH=5, no evidence for the complex formation between 3-pyridinecarboxylic acid and iron(III) in the ground state, because the UV-absorption spectrum of the mixture of 3-pyridinecarboxylic acid and iron(III) is almost the same as the sum of those of the components. As is shown earlier, only the light absorbed by 3-pyridinecarboxylic acid is effective for the formation of **7**. These facts suggest that the formation of **7** occurs *via* charge transfer interaction between an excited 3-pyridinecarboxylic acid and a ground state iron(III) ion.

Thermal oxidation of pyridine by iron(III) at high temperature is an example in which the oxidation of pyridine gives bipyridine.[12]

Experimental

Materials. Commercial 2-, 3-, and 4-pyridinecarboxylic acid (G.R. grade reagents of Tokyo Kasei Co. or Wako Junyaku Co.) were used without further purification. 2-Pyridinecarboxylatometal complexes were prepared in the crystalline form by refluxing the metal salt and sodium 2-pyridinecarboxylate in water. The composition of the metal complexes were determined by elemental analysis (Table 3).

UV-irradiation. The solutions of 2-pyridinecarboxylatometal complexes were prepared by dissolving the complexes in water. The sample solutions of 3- and 4-pyridinecarboxylic acid–transition metal salt systems were prepared by adding the metal salts to the solutions of sodium pyridinecarboxylates. The pH of the solution was adjusted with hydrochloric acid or sodium hydrogencarbonate.

For the identification of the photoproducts 2—3 dm^3 of the solution were irradiated with a low pressure mercury lamp under the bubbling of nitrogen. For the quantitative analysis 50—100 cm^3 of the solution deaerated by bubbling nitrogen or argon for at least 30 min were irradiated with a low pressure mercury lamp under magnetic stirring.

Separation, Identification, and Quantitative Analysis of the Photoproducts. Photoproducts from 2-Pyridinecarboxylatometal Complexes: Pyridine was extracted with dichloromethane from the irradiated solutions and identified by means of UV-spectra. Other products were separated by anion exchange chromatography (column, Dowex-1 formate; eluent, formic acid).

2,2′-Bipyridine was obtained as tris(2,2′-bipyridine)iron-(II). 2,2′-Bipyridine liberated by refluxing it in a sodium hydroxide solution was steam-distilled. By comparing its NMR spectra with those of the authentic 2,2′-bipyridine, 2,2′-bipyridine in the photoproducts was identified. The UV- and visible spectra of the iron(II) complex supports this conclusion.

2-Pyridinol and 2,3′-bipyridine were identified by the comparison of UV-, IR-, and NMR spectra with those of the authentic samples.

Quantitative analysis was done by means of the ion exchange chromatography and spectroscopy.

Photoproducts from the 3-Pyridinecarboxylic Acid–$FeCl_3$ System: After the irradiated solution was concentrated under reduced pressure, iron(II) and iron(III) were precipitated with hydrogen sulfide. The photoproducts were separated by means of the anion exchange chromatography (column, Dowex-1 formate; eluent, formic acid) and by means of gel-filtration with Sephadex G-10. Two photoproducts were identified.

Iron(II) Complex of 2,2′-Bipyridine-3,5′-dicarboxylic Acid. In order to liberate the ligand the complex was refluxed with aqueous sodium hydroxide. After the evaporation of the solvent the residue was extracted in a Soxhlet's extractor with dry 1,4-dioxane. The crystalline product thus obtained was converted to the methyl ester by diazomethane. The compound was identified as dimethyl 2,2′-bipyridine-3,5′-dicarboxylate from the following data; mp 115—116 °C; IR (KBr disk) 2900 (CH_3), 1735, 1730, 1720 (C=O), and 1295 cm^{-1} (ester C–O); NMR ($CDCl_3$) δ=9.25 (1H, dd, J=2.1 and 0.9 Hz, H at the 6′-position), 8.82 (1H, dd, J=4.9 and 1.6 Hz, H at the 6-position), 8.49 (1H, dd, J=8.0 and 2.1 Hz, H at the 4′-position), 8.27 (1H, dd, J=8.0 and 0.9 Hz, H at the 3′-position), 8.10 (1H, dd, J=7.8 and 1.6 Hz, H at the 4-position), 7.44 (1H, dd, J=7.8 and 4.9 Hz, H at the 5-position), 4.00 (3H, s, CH_3), and 3.82 (3H, s, CH_3); The above assignment is based on the decoupling experiment; MS (70 V) *m/e*(relative intensity), 272(20), 257(54), 242(19), 241(100), 214(10), 213(8), 198 (7), 183(11), 105(12), 91(12), 78(10), 77(10). Found: C, 61.62; H, 4.41; N, 10.43%; M^+, 272. Calcd for $C_{14}H_{12}N_2O_4$: C, 61.76; H, 4.44; N, 10.29%; M, 272.

UV spectra of the iron(II) complex, λ_{max}=515 (shoulder) and 550 nm.

2,3′-Bipyridine-5-carboxylic Acid. The product eluted by 0.5 mol dm^{-3} formic acid was identified as 2,3′-bipyridine-5-carboxylic acid by comparing its spectra with those reported previously.[6]

Determination of the Yields of Products. The quantitative analyses of the photoproducts from 3-pyridinecarboxylic acid–metal salt systems were carried out spectrophotometrically after the separation with anion exchange chromatography.

The authors are grateful to Mr. Susumu Kumon of Shinnihon Jitsugyo Co. for MS measurement. 8) Considering the following equilibria,
$Fe(III)+2L+OH^- \rightleftarrows [Fe(III)L_2(OH)]$ $K_1=10^{23.84}$ mol^{-3} dm^9
$2[Fe(III)L_2(OH)] \rightleftarrows [Fe(III)_2L_4(OH)_2]$ $K_2=10^{3.06}$ mol^{-1} dm^3
$[Fe(III)L_2(OH)]+H^+ \rightleftarrows [Fe(III)L_2]+H_2O$ $K_3=10^{2.96}$
where L represents 2-pyridinecarboxylate, it was found that 30% of iron(III) is in the form of $[Fe(III)_2L_4(OH)_2]$ and 70% of iron(III) is in the form of $[Fe(III)L_2(OH)]$ in 1.3×10^{-4} mol dm^{-3} solution of $[Fe(III)_2L_4(OH)_2]$ at pH=6. Almost all the iron(III) ions are coordinated by 2-pyridinecarboxylate (G. Anderegg, *Helv. Chim. Acta*, **43**, 1530 (1960)).

A similar calculation on the following equilibria:
$Cu(II)+L \rightleftarrows [Cu(II)L]$ $K_1=10^{7.95}$ mol^{-1} dm^3
$[Cu(II)L]+L \rightleftarrows [Cu(II)L_2]$ $K_2=10^{7.00}$ mol^{-1} dm^3
showed that 98% of copper(II) is in the form of $[Cu(II)L_2]$ in 2.0×10^{-4} mol dm^{-3} solution of $[Cu(II)L_2]$ at pH=6 (G. Anderegg, *Helv. Chim. Acta*, **43**, 414 (1960)).

Nucleophilic Cleavage of Phosphate Triesters in Dialkylammonium Bilayer Membranes[1)]

Yoshio Okahata, Hirotaka Ihara, and Toyoki Kunitake*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812

(Received October 27, 1980)

A study was carried out on the reaction of *p*-nitrophenyl phosphates with hydroxamate nucleophiles in water in the presence of dialkylammonium bilayer membranes. With ethyl bis(*p*-nitrophenyl) phosphate, clean second-order kinetics was observed for all the hydroxamate nucleophiles, two equivalents of *p*-nitrophenol being released in most cases. In contrast, a complex kinetics was observed for octadecylbis(*p*-nitrophenyl)phosphate. The second cleavage process of this long-chain substrate by a long-chain hydroxamate was affected by the fluidity of the matrix membrane, an inflection region being present in the Arrhenius plots near the phase transition temperature(T_c) of the $2C_{16}N^+2C_1$ membrane. The activation energy was 14 and 21 kcal/mol at temperatures above and below T_c, respectively. Similar changes in the activation energy had been observed for decarboxylation and proton abstraction.

Since it was first found that bilayer membranes are formed from dialkylammonium salts,[2,3)] physicochemical characterization of the dialkylammonium bilayer has been extensively carried out. One important characteristic is the occurrence of the crystal-to-liquid crystal phase transition similar to that of biolipid bilayers, as confirmed by differential scanning calorimetry,[4,5)] NMR spectroscopy,[6)] fluorescence depolarization,[6,7)] and positron annihilation.[7)]

The unique organization of the dialkylammonium bilayer was subsequently used as site for several kinds of organic reaction. A large rate difference was observed between the intra-vesicle and inter-vesicle reactions of nucleophiles and a phenyl ester.[8)] A cholesteryl nucleophile was specifically activated in the ammonium membrane,[9)] and the reaction rate was influenced by the phase transition in acyl transfer,[10)] proton abstraction,[11)] and decarboxylation.[12)]

In this article we report on the hydrolysis of activated phosphoric triesters by hydrophobic hydroxamate nucleophiles in the presence of hexadecyltrimethylammonium bromide (CTAB) micelle and dialkylammonium ($2C_nN^+2C_1$) bilayer membranes.[13)] The hydrolysis of phosphoric triesters proceeds *via* general-base or nucleophilic pathways. The relative ease of these pathways is determined by structural combinations of substrates and bases, the relative basicity of leaving group and nucleophile and steric crowding in the transition state being concluded to be the two most important factors.[14—16)]

The micellar effect on the cleavage of phosphoric triesters was studied by Bunton and Ihara[17)] and Epstein *et al.*[18)] for oximate nucleophiles and by Tagaki *et al.*[19)] for imidazole nucleophiles. It was found that cationic micelles accelerate the reaction and change the mechanism. It is of particular interest to see how the peculiar molecular organization of the bilayer membrane affects the cleavage of phosphoric esters.

The structures of nucleophiles, substrates and membrane-forming ammonium salts used in this study are given below together with their abbreviations.

Experimental

Nucleophiles. Octadecanehydroxamic acid (C_{18}-HA), *N*-methyloctadecanehydroxamic acid (C_{18}-MHA), and *N*-phenyloctadecanehydroxamic acid (C_{18}-PHA) were prepared from octadecanoyl chloride and the corresponding hydroxylamines, and identified by NMR and IR spectroscopy and elemental analysis. C_{18}-HA: mp 102—104 °C. Found: C, 71.86; H, 12.46; N, 4.65%. Calcd for $C_{18}H_{37}NO_2$: C, 72.19; H, 12.45; N, 4.68%. C_{18}-MHA: mp 60—62 °C. Found: C, 72.59; H, 12.39; N, 4.40%. Calcd for $C_{19}H_{37}NO_2$: C, 72.79; H, 12.54; N, 4.47%. C_{18}-PHA: mp 88—89 °C. Found: C, 76.33; H, 10.97; N, 3.70%. Calcd for $C_{24}H_{41}NO_2$: C, 76.74; H, 11.00; N, 3.73%.

Mono-*N*,*N*-dioctadecylamide of succinic acid (9.3 g, 15 mmol) as prepared from dioctadecylamine and succinic anhydride, and 2 g (18 mmol) of *N*-hydroxysuccinimide were dissolved in 70 ml of tetrahydrofuran (THF), 3.7 g (18 mmol) of dicyclohexylcarbodiimide being added with stirring at ice-bath temperature. The reaction mixture was warmed to room temperature after 1 h and stirred for 24 h. *N*,*N*'-Dicyclohexylurea was filtered. After the solvent had been removed, the residue was recrystallized from 1:10 ether–methanol to give colorless powder: yield 9.3 g (86%), mp 64—67 °C. The succinimide ester obtained (5 g, 8 mmol) was dissolved in 30 ml of $CHCl_3$, and 2.5 g (30 mmol) of *N*-methylhydroxylamine and 3 g (30 mmol) of triethylamine in 60 ml of $CHCl_3$ were slowly added with stirring. After the mixture had been stirred for 6 h at room temperature, the solvents were evaporated and the residue was dissolved in ether, washed with dilute hydrochloric acid and water, and dried over Na_2SO_4. The solution was concentrated and 3 g of solids was recovered by addition of methanol. Colorless powder was obtained by repeated recrystalliza-

tion from 1:1 acetone–ether: yield 1.4 g (30%), mp 50—52 °C. The product, *N*-methyl-3-(dioctadecylcarbamoyl)propanehydroxamic acid, ($2C_{18}$-suc-MHA) was confirmed by IR and NMR spectroscopy and by elemental analysis. Found: C, 75.62; H, 12.80; N, 4.20%. Calcd for $C_{41}H_{82}N_2O_3$: C, 75.63; H, 12.69; N, 4.30%.

Preparation and purification of *N*-dodecylbenzohydroxamic acid (C_{12}-BHA),[20] and *N*-benzylbenzohydroxamic acid (BBHA)[21] were reported. $C_{12}N^+C_2$-MHA was supplied by T. Sakamoto.[22]

Substrates. Tris(*p*-nitrophenyl) phosphate (1 g, 2.2 mmol) was refluxed for 1 d in 10 ml of dry ethanol, coloreless needles of C_2-BNPP being obtained on cooling: yield 0.7 g (90%), mp 134—135 °C (lit,[23] mp 133 °C). The purity was confirmed by NMR spectroscopy and elemental analysis. Found: C, 45.50; H, 3.57; N, 7.68%. Calcd for $C_{14}H_{13}N_2O_8P$: C, 45.67; H, 3.56; N, 7.61%.

Triethylamine (3.7 g, 37 mmol) and 10.0 g (37 mmol) of octadecyl alcohol were dissolved in 100 ml of dry ether, 21 g (137 mmol) of $POCl_3$ being added with stirring at ice-bath temperature. The mixture was then stirred for 3 h at room temperature and precipitates were removed. The solvent was evaporated and the residual white solid was recrystallized from acetonitrile: yield 15 g, mp<30 °C. The acid chloride obtained and 21.5 g (155 mmol) of *p*-nitrophenol were dissolved in 100 ml of dry ether, 15.5 g (155 mmol) of triethylamine being added dropwise with stirring at ice-bath temperature. After stirring for one day at room temperature, precipitates were removed and the solution was concentrated to give a waxy product. Recrystallization twice from acetone and methanol gave colorless needles of C_{18}-BNPP: yield 3 g (13%), mp 59—60 °C. The NMR spectrum was consistent with the expected structure. Found: C, 60.80; H, 7.68; N, 4.89%. Calcd for $C_{10}H_{45}N_2O_8P$: C, 60.79; H, 7.65; N, 4.83%.

Other Materials. Commercial CTAB was recrystallized twice from ethanol. Dialkyldimethylammonium bromides ($2C_nN^+2C_1$) were prepared by stepwise alkylation.[3,9]

Kinetics. Hydrolysis was initiated by injecting substrate solutions (in ethanol or acetonitrile) into aqueous solutions of surfactants containing given amounts of catalyst. The progress of the reaction was followed by the appearance of *p*-nitrophenolate anion (λ_{max}=400 nm in CTAB micelles and 390 nm in ammonium membranes, ε=18100) with a Hitachi 124 spectrophotometer. The surfactant concentration was 1×10^{-3} M (1 M=1 mol dm^{-3}), which is larger than the cmc of CTAB and $2C_nN^+2C_1$. The reaction conditions were 3 v/v% organic solvent–H_2O, μ=0.01 (KCl), 0.01—0.02 M borate buffer (pH 7—10), unless stated otherwise. The pH measurement was carried out with a Toa Digital pH meter (Type HM-10A), the pH variation of the reaction medium being smaller than 0.05.

Results

Course of Phosphoric Ester Cleavage. Ethyl bis(*p*-nitrophenyl) phosphate (C_2·BNPP) undergoes slow hydrolysis in alkaline CTAB solutions (pH 8—10). The UV absorption of C_2·BNPP (λ_{max}=270 nm) diminishes with time, new absorptions appearing at 400 and 290 nm (Fig. 1). The 400-nm band is attributable to *p*-nitrophenolate anion, one equivalent of which is formed eventually. The 290-nm band is ascribable to ethyl *p*-nitrophenyl phosphate anion (ε=9500)(C_2·MNPP$^-$) which is stable under these conditions. Tagaki *et al.*[19] confirmed that phenyl *p*-nitrophenyl phosphate anion is hydrolyzed very slowly even at 55 °C, pH 12.5. Brass and Bender[16] similarly observed the formation of *p*-nitrophenyl methylphosphonate anion at 288 nm (ε=9560) in the alkaline hydrolysis of bis(*p*-nitrophenyl) methylphosphonate.

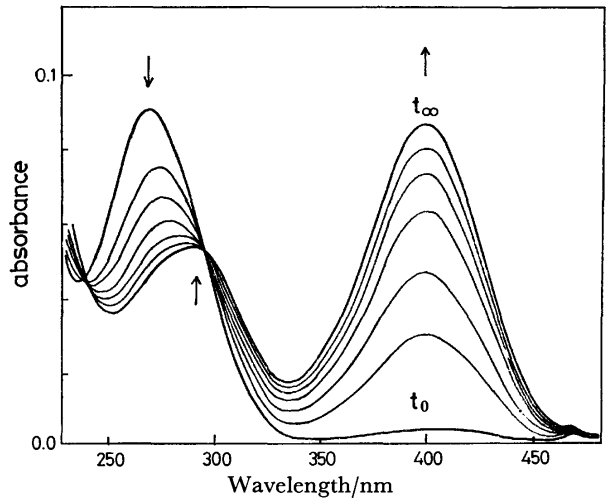

Fig. 1. Spontaneous hydrolysis of C_2-BNPP in the CTAB micelle.
pH 9.6, 30 °C, 0.01 M borate buffer, μ=0.01(KCl), 3 v/v%EtOH–H_2O. [CTAB]=1.00×10^{-3} M, [C_2-BNPP]=5.00×10^{-6} M.

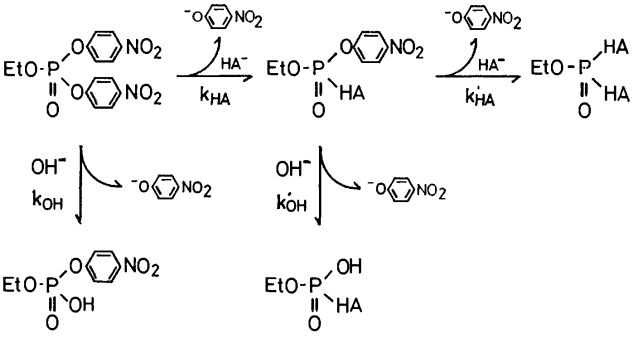

Fig. 2. The course of the ester cleavage of C_2-BNPP.

In the presence of excess hydroxamate nucleophiles, the predominant course of reaction is the release of two equivalents of *p*-nitrophenol without formation of ethyl *p*-nitrophenyl phosphate anion.

The courses of the phosphoric ester cleavage are summarized in Fig. 2. The alkaline hydrolysis (k_{OH} process) is negligible in the presence of excess of most hydroxamates, since the UV peak (λ_{max} 290 nm) characteristic of diester product C_2-MNPP$^-$ (Fig. 1) cannot be detected in the reaction mixture.

On the other hand, if equimolar amounts of substrate and nucleophile (C_{18}·MHA) are present, we observe, upon correction for the alkaline hydrolysis, rapid formation of one equivalent of *p*-nitrophenol followed by much slower *p*-nitrophenol release. These steps correspond to the k_{HA} and k'_{OH} processes (Fig. 2). Introduction of additional C_{18}·MHA during the second stage induces rapid *p*-nitrophenol release of the k'_{HA} process.

Behavior of Different Hydroxamate Nucleophiles toward C_2·BNPP. Figure 3 shows the time course of

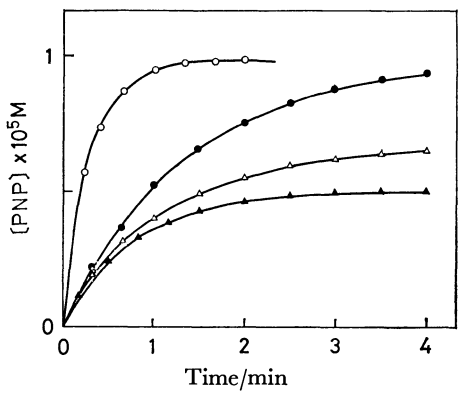

Fig. 3. The time course of the *p*-nitrophenol (PNP) release from C_2-BNPP by several hydroxamates in the presence of the CTAB micelle.
30 °C, pH 8.8, 0.02 M borate buffer, $\mu=0.01$ (KCl), [CTAB] $=1.00\times10^{-3}$ M, [hydroxamate] $=5.00\times10^{-5}$ M, [C_2-BNPP] $=5.00\times10^{-6}$ M. *p*-Nitrophenolate anion: λ_{max} 400 nm, $\varepsilon=1.81\times10^4$. p-nitrophenol release from C_2-BNPP by a series of long-chain hydroxamate nucleophiles in the CTAB micelle.

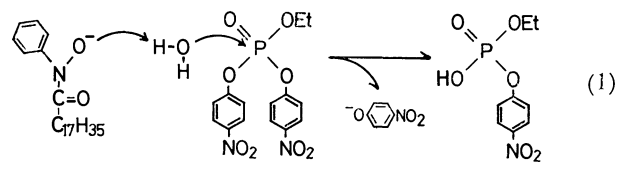
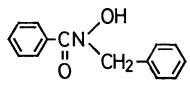
$C_{12}N^+C_2$-MHA

The ultimate *p*-nitrophenol release varies considerably with nucleophile. Excess of C_{18}-HA, C_{18}-MHA, and $2C_{18}$-MHA (not shown in Fig. 3) releases two equivalents of *p*-nitrophenol due to k_{HA} and k'_{HA} processes of Fig. 2. However, C_{18}-PHA produces 1.4—1.6 equivalents, the release by $C_{12}N^+C_2$-MHA being one equivalent. In the reaction with C_{18}-PHA, the difference spectrum indicates increases in absorbance at 245 and 300 nm (shoulder). The 245-nm absorption can be attributed to the monosubstitution product, the shoulder at 300 nm suggesting the formation of C_2-MNPP$^-$ (λ_{max} 290 nm, see above). The simple alkaline hydrolysis is too slow to explain the results. General base catalysis (Eq. 1) might become com-

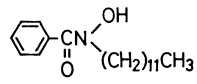


(1)

petitive with the nucleophilic process, since the latter process is rendered less efficient due to steric hindrance of the phenyl substituent near the nucleophilic center. Similarly, less than two equivalents of *p*-nitrophenol were released with related nucleophiles, BBHA and C_{12}-BHA. The release of one equivalent of *p*-ni-



BBHA



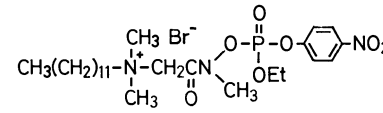
C_{12}-BHA

Table 1. Values of k_1 for *p*-nitrophenol release from C_2-BNPP with hydroxamate nucleophiles

Nucleophile	$10^3 k_1/s^{-1}$		
	CTAB	$2C_{12}N^+2C_1$	$2C_{16}N^+2C_1$
None(OH^-)	1.0	1.8	1.4
C_{18}-HA	9.1	35	28
C_{18}-MHA	88	100	74
C_{18}-PHA	8.3	45	50
$2C_{18}$-MHA	45	40	28

30 °C, pH 8.8, 0.02 M borate buffer, $\mu=0.01$(KCl), [Ammonium] $=1.00\times10^{-3}$ M, [hydroxamate] $=5.00\times10^{-5}$ M, [C_2-BNPP] $=5.00\times10^{-6}$ M.

trophenol by $C_{12}N^+C_2$-MHA is ascribed to the very low reactivity of the first substitution product **1** in the subsequent nucleophilic attack. There is no indication of the general base catalysis (formation of C_2-MNPP$^-$) in this case.



1

The presence of the $C_{12}N^+C_2$-MHA moiety in the intermediate and/or nucleophile appears to interfere with the second nucleophilic attack. This presumption is supported by the following experiments: (a) no *p*-nitrophenol release was observed when C_{18}-MHA was added to an equimolar reaction mixture (1:1 adduct formed) of C_2-BNPP and $C_{12}N^+C_2$-MHA, (b) addition of $C_{12}N^+C_2$-MHA did not promote *p*-nitrophenol release from an equimolar reaction mixture (1:1 adduct formed) of C_{18}-MHA and C_2-BNPP.

In spite of the varying extent of *p*-nitrophenol release, all the time courses of Fig. 3 obeyed the pseudo first-order kinetics (Eq. 2) for up to 80% conversion.

$$k\cdot t = -\ln\frac{A_\infty - A_t}{A_\infty}, \qquad (2)$$

where A_∞ and A_t are absorbances at the infinite time and at time t, respectively. The results indicate that the second nucleophilic attack is not slower than the first one ($k_{HA}\leqq k'_{HA}$) in the two-step nucleophilic attack toward C_2-BNPP, except in the case of $C_{12}N^+$-C_2-MHA.

The kinetic pattern of the C_2-BNPP cleavage was the same in the CTAB micelle as well as in the dialkylammonium membrane for given nucleophilics. The pseudo first-order rate constants with various hydroxamates in micellar and membrane systems are summarized in Table 1. The effective nucleophile is the hydroxamate anion. The true nucleophilic reactivity of the anion cannot be compared, since the pK_a value and consequently the fraction of the dissociated species was not determined.

Cleavage of C_{18}-BNPP. The reaction scheme for the cleavage of long-chain substrate C_{18}-BNPP is fundamentally the same as that for C_2-BNPP (Fig. 2). However, the kinetic patterns are quite different. In the reaction with excess C_{18}-HA, the first-order

kinetics holds only approximately, two equivalents of *p*-nitrophenol being released. The reaction with C_{18}-PHA was very slow ($k_{HA} \ll k_{OH}$), no further kinetic examination being performed.

In the reaction with excess C_{18}-MHA, the first-order plots in the CTAB micelle consist of two lines (Fig. 4). Since the ultimate *p*-nitrophenol release is two equivalents per mole of C_{18}-BNPP, the result

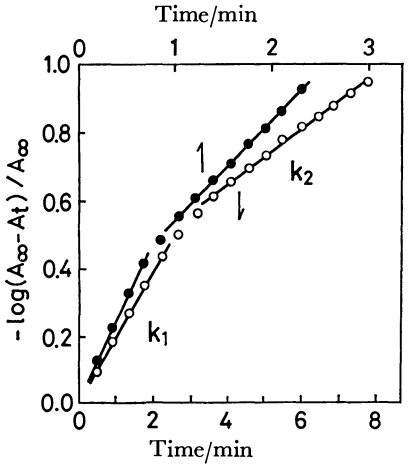


Fig. 4. Pseudo first order plots of the reaction of C_{18}-BNPP with C_{18}-MHA in the presence of the CTAB micelle.
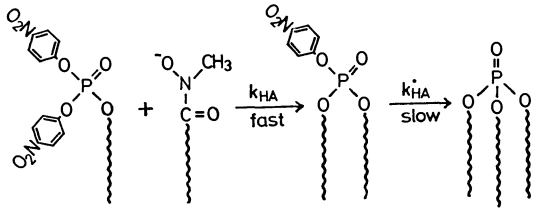
pH 8.7, 0.02 M borate buffer, μ=0.01 (KCl), [CTAB] = 1.00×10^{-3} M, [C_{18}-MHA] = 1.00×10^{-4} M, [C_{18}-BNPP] = 1.00×10^{-5} M. 30 °C: —○—, 43 °C: —●—.

indicates that the second stage of the nucleophilic displacement (k'_{HA} process) is appreciably slower than the first stage (k_{HA} process). Similar kinetic results were obtained in the membrane system. Figure 5a shows the first order plots obtained at 30 °C. The slopes for the initial release do not vary much with the membrane. On the other hand, the slope for the second stage is suppressed increasingly with increasing lengths of the alkyl chain of the membrane. At a higher reaction temperature of 43 °C, the changes in slope are smaller except for the $2C_{18}N^+2C_1$ membrane (Fig. 5b). The apparent rate constants of the first and second steps of the reaction, k_1 and k_2, respectively, are given in Table 2. The k_1 value was determined from the initial linear portion of the first-order plots, k_2 being obtained from the second linear portions corresponding to 60—90% conversion. These two steps approximately correspond to the k_{HA} and k'_{HA} processes. The k_1 value is $(7.8\pm1.0)\times10^{-3}$



(3)

s^{-1} at 30 °C and $(18\pm3)\times10^{-3}$ s^{-1} at 43 °C, indicating that the magnitude of k_1 is not influenced by the membrane (or micelle) used.[24] In contrast, k_2 is dependent

$2C_{14}N^+2C_1$	6.9	1.7	1/4.1	15	6.8	1/2.2
$2C_{16}N^+2C_1$	8.6	1.0	1/8.6	21	9.8	1/2.2
$2C_{18}N^+2C_1$	8.3	0.52	1/15.8	20	1.4	1/13.8

pH 8.7 (30 °C), pH 8.8 (43 °C), 0.02 M borate buffer (μ=0.01), [Ammonium] = 1.00×10^{-3} M, [C_{18}-MHA] = 1.00×10^{-4} M, [C_{18}-BNPP] = 1.00×10^{-5} M.

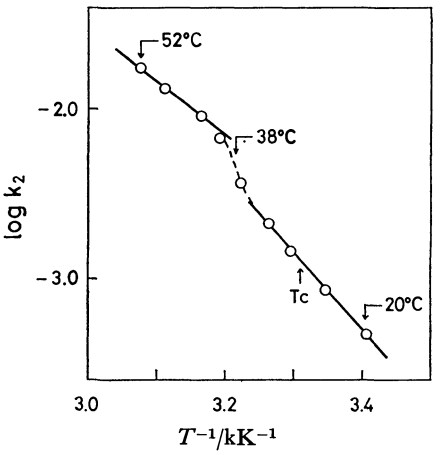

Fig. 6. Arrhenius plots for $k_{2,obsd}$ for the reaction of C_{18}-BNPP with C_{18}-MHA in the $2C_{16}N^+2C_1$ membrane.
pH 9.4, 0.02 M borate buffer, $\mu=0.01$(KCl), $[2C_{16}N^+2C_1]=1.00\times10^{-3}$ M, $[C_{18}$-MHA$]=1.00\times10^{-4}$ M, $[C_{18}$-BNPP$]=1.00\times10^{-5}$ M.

of the ammonium membrane used, decreasing with increasing alkyl chain lengths of the dialkylammonium membrane at 30 °C but not necessarily at 43 °C. A smaller k_2 value was obtained only for the $2C_{18}N^+2C_1$ membrane at higher temperature. The rate depressing effect for k_2 can be seen more clearly by comparing the ratio of the rate constants k_2/k_1. The ratio is *ca.* 1/3 for the CTAB system at both temperatures, the temperature effect being similarly small for the $2C_{12}N^+2C_1$ system. It is smaller at 30 °C than at 43 °C for the $2C_{14}N^+2C_1$ and $2C_{16}N^+2C_1$ systems, but small and constant at the two temperatures for the $2C_{18}N^+2C_1$ membrane. Since the change in k_2/k_1 due to temperature is the largest for the $2C_{16}N^+2C_1$ system, the temperature effect was studied carefully in this system. Figure 6 shows the Arrhenius plots for k_2. The plots are represented by two lines with inflection at 35 to 40 °C.

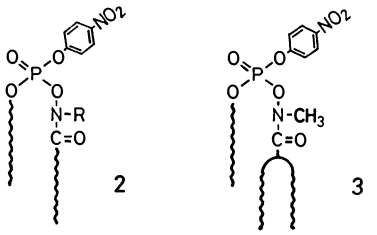
Discussion

The kinetic behavior of the nucleophilic attack of a series of long-chain hydroxamates toward phosphoric esters is summarized in Table 3. Clean second-order kinetics was observed for all the hydroxamates in the case of C_2-BNPP. This indicates that the first substitution is not faster than the second: $k_{HA}\leqq k'_{HA}$ in Fig. 1. A C_{18} alkyl chain is introduced in the first substitution. The resulting monosubstitution product is hydrophobic and the second substitution would be accelerated more efficiently in the micelles and membranes. Micellar acceleration is greater with hydrophobic substrates.

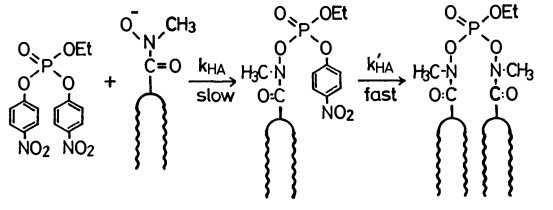
In sharp contrast with C_2-BNPP, no clean second-order kinetics could be found for C_{18}-BNPP. It appears that the steric constraint considerably retards the reaction with C_{18}-PHA and $2C_{18}$-MHA. The monosubstitution products of C_{18}-BNPP possess structures **2** and **3**. The CPK molecular model shows that the steric interference due to *N*-substituents (R)

Table 3. Kinetic behavior of various combinations of nucleophile and substrate

Nucleophile	Substrate: C_2-BNPP	Substrate: C_{18}-BNPP
C_{18}-HA	Clean second order: $k_{HA}\ll k'_{HA}$. 2 equiv. PNP released.	Approximate pseudo first order: $k_1\leqq k_2$. 2 equiv. PNP released.
C_{18}-MHA	Clean second order: $k_{HA}\ll k'_{HA}$. 2 equiv. PNP released.	Two steps in the first order plots: $k_1>k_2$. Membrane fluidity influential. 2 equiv. PNP released.
C_{18}-PHA	Clean second order: 1.4—1.6 equiv. PNP released.	PNP release very slow.
$2C_{18}$-MHA	Clean second order: $k_{HA}\ll k'_{HA}$. 2 equiv. PNP released.	Two steps in the first order plots: $k_1\gg k_2$. k_2 very small. More than equiv. PNP released.



is appreciable in **2**. Thus, when R=H, mono- and disubstitutions proceed smoothly, but when R=phenyl, even the monosubstitution virtually does not proceed. When R=methyl, the monosubstitution is smooth but the disubstitution is slower. When the attacking nucleophile is a double-chain compound, even the monosubstitution is extremely slow with a *N*-methylhydroxamate ($2C_{18}$-MHA). Disubstitution proceeds faster than monosubstitution for the combination of C_2-BNPP and $2C_{18}$-MHA (Eq. 4). The double alkyl chain in $2C_{18}$-MHA may be not very demanding sterically since the double chain is removed from the phosphorus center.



(4)

The rate constant for the pair of C_{18}-BNPP and C_{18}-MHA shows a characteristic variation with the membrane matrix. k_2 (*i.e.*, k'_{HA}) appears to be sensitive to membrane fluidity (Table 2).

The phase transition temperature (T_c) of the dialkylammonium bilayer membrane has been determined by various physicochemical means. The results determined by differential scanning calorimetry

Table 4. Phase transition temperature of dialkylammonium ($2C_nN^+2C_1Br^-$) membranes

n	12	14	16	18
T_c °C	0—5	18	28	45

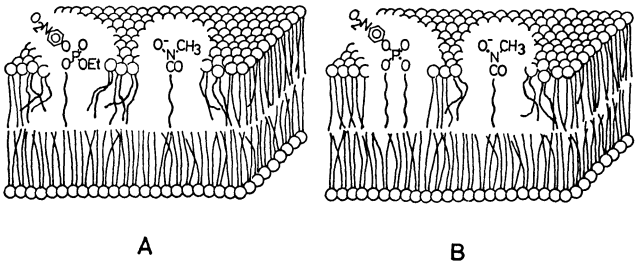


Fig. 7. Schematic illustration of nucleophiles and substrates in the membrane matrix.
Note that the double-chain substrate in B perturbs the neighboring membrane less than the single-chain substrate in A.

seems to be most reliable. The T_c data are given in Table 4. At reaction temperature 30 °C, the $2C_{16}N^+2C_1$ and $2C_{18}N^+2C_1$ membranes are in the crystalline phase, their k_2 values being smaller than those in the other membranes. At reaction temperature 43 °C, only the $2C_{18}N^+2C_1$ membrane is in the crystalline state, giving a small k_2 value. The influence of the membrane fluidity is more apparent when k_2/k_1 values are compared. The membranes in the liquid crystalline state (above T_c) give k_2/k_1 ratios of 1/2—1/4, but the rigid membranes at temperatures below T_c give smaller ratios.

It may be asked why the k'_{HA} process and not the k_{HA} process is affected by membrane fluidity. The k_{HA} process is a reaction between a single-chain nucleophile and a single-chain substrate. The same type of reaction between a single-chain imidazole and a single-chain phenyl ester is influenced by phase transition.[10] The presence or absence of the influence of the membrane fluidity might depend on particular combinations of the single-chain reagents.

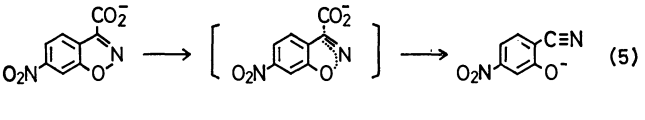
The k'_{HA} process is a reaction between a single-chain nucleophile and a double-chain monosubstitution product. Since the reactivity of the nucleophile (C_{18}-MHA) is not affected by membrane fluidity (k_{HA} invariant), the dependence of k'_{HA} on the membrane fluidity should arise from the varying reactivity of the double-chain intermediate. If we assume that the double-chain compound does not destroy the neighboring dialkylammonium membrane matrix, its reactivity would be affected by membrane fluidity more than the reactivity of the single-chain substrate. That is, the dialkyl species can be a part of the membrane matrix but the single-chain species should act as an impurity for the membrane. The situation is illustrated in Fig. 7.

The inflection of the Arrhenius plots (Fig. 5) is similarly associated with the phase transition, although the inflecting temperature region centered at 38 °C is 10 °C higher than T_c of the $2C_{16}N^+2C_1$ membrane (28 °C).

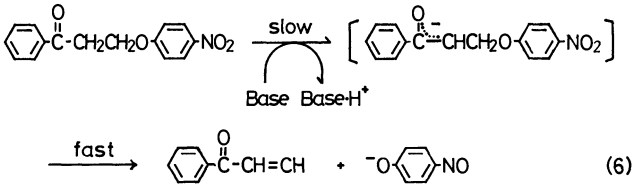
Table 5. Activation energy in $2C_{16}N^+2C_1$ membrane

Reaction	E_a/kcal mol^{-1} Below T_c	E_a/kcal mol^{-1} Above T_c	Remark
Nucleophilic displacement (k_{HA}' process)	21	14	This study
Decarboxylation (Eq. 5)	25	19	Ref. 12
Proton abstraction (Eq. 6)	46	20	Ref. 11

The presence of two sets of the activation energy in the membrane system has been detected in the cleavage of a phenyl ester,[10] in decarboxylation (Eq. 5),[12] and in the proton abstraction (Eq. 6).[11]



(5)



fast

(6)

The E_a value determined from Fig. 6 is 14 kcal/mol at temperatures above T_c and 21 kcal/mol at temperatures below T_c. E_a values obtained in the temperature ranges above and below T_c for different types of reaction are compared in Table 5. In all cases, E_a below T_c is appreciably larger than E_a above T_c. It becomes more difficult for these reactions to proceed at low temperatures due to increased rigidity of the $2C_{16}N^+2C_1$ membrane matrix.

Conclusion

Phase transition is associated with the regulation of physiological functions of the biomembrane. For example, the activity of succinic acid oxidase of sheep liver mitochondria membrane changes with phase transition, the activation energy being 2 and 12 kcal/mol at temperatures above and below T_c, respectively.[25] These biochemical results are very similar to those observed for some common organic reactions: nucleophilic displacement, base-catalyzed proton abstraction, and unimolecular decarboxylation (Table 5). It is presumed that the regulation of the reaction rate by phase transition becomes possible for a large variety of organic reactions.

24) The k_1 and k_2 values in the $2C_{14}N^+2C_1$ membrane are slightly smaller than expected. Small deviations from the first-order plot were observed in the initial stage of the *p*-nitrophenol release, the reaction mixture becoming turbid in some cases. These observations suggest that the reacting species are not entirely miscible with the $2C_{14}N^+2C_1$ membrane, and explain the small, negative deviations of k_1 and k_2.

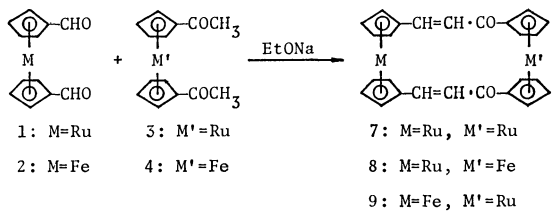
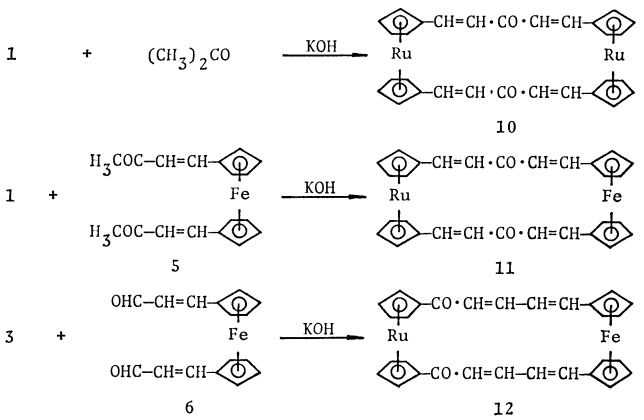
(Received October 27, 1980)

[3.3](1,1′)Ruthenocenophane-2,14-diene-1,16-dione, [5.5](1,1′)ruthenocenophane-2,14,17,29-tetraene-1,16-dione and their ferrocenoruthenocenophane homologs were synthesized by using an intermolecular base-catalyzed condensation.

A variety of layered compounds have been synthesized and their physical and chemical properties have been studied.[1-4] Cyclophanes in which aromatic rings are mutually stratified have been well investigated from a viewpoint of transannular π-electronic interactions. In contrast to the active interest in cyclophanes, little attention has been focused on [2.2](1,1′)ferrocenophane-1,13-diyne,[5] [2.2](1,1′)ferrocenophane-1,13-diene,[6] [2]paracyclo[2]paracyclo[2](1,1′)-ferrocenophane derivatives,[7] [3.3](1,1′)ferrocenophane-1,15-diene-3,14-dione,[8] [5.5](1,1′)ferrocenophane1,4,-16,19-tetraene-3,18-dione,[8] and [0]metacyclo[2]-metacyclo[0](1,1′)ferrocenophan-7-ene.[9] In addition, there are only a few synthetic investigations of [5]-ruthenocenophane derivatives[10] and [3]- and [4]-ruthenocenophane derivatives.[11] This paper is concerned with the synthesis of [3.3](1,1′)- and [5.5]-(1,1′)ruthenocenophanes and their ferrocenoruthenocenophane homologs, including olefinic and carbonyl groups between metallocene systems, in order to examine the transannular π-electronic interactions of the chromophores.



Scheme 1.



Scheme 2.

Results and Discussion

Synthesis of [3.3](1,1′)Ruthenocenophane. In the presence of sodium ethoxide, the reaction of 1,1′-ruthenocenedicarbaldehyde (**1**) with 1,1′-diacetylruthenocene (**3**)[12] in ethanol gave a good yield of [3.3]-(1,1′)ruthenocenophane-2,14-diene-1,16-dione (**7**).[13] Under the same conditions, the internal base-catalyzed condensations of **1** with 1,1′-diacetylferrocene (**4**)[17] and 1,1′-ferrocenedicarbaldehyde (**2**)[16] with **3** gave rise to the formation of [3.3](1,1′)ferrocenoruthenocenophane-13,25-diene-1,12-dione (**8**)[13] and [3.3](1,1′)-ferrocenoruthenocenophane-2,14-diene-1,16-dione (**9**),[13] respectively (Scheme 1).

Synthesis of [5.5](1,1′)Ruthenocenophane. In the presence of KOH, the base-catalyzed condensation of **1** with acetone led to the formation of [5.5]-(1,1′)ruthenocenophane-2,14,17,29-tetraene-1,16-dione (**10**).[13] In the same manner, the reactions of **1** with 1,1′-bis(2-acetylvinyl)ferrocene (**5**)[18] and of **3** with 1,1′-bis(2-formylvinyl)ferrocene (**6**)[18] also gave [5.5](1,1′)-ferrocenoruthenocenophane-2,14,17,29-tetraene-1,16-dione (**11**)[13] and [5.5](1,1′)ferrocenoruthenocenophane-2,4,16,18-tetraene-1,20-dione (**12**),[13] respectively (Sceheme 2).

Characterization and Spectral Data. The structures of the phane compounds **7**—**12** and the other compounds were determined on the basis of IR, ^{1}H NMR, and mass spectra and elemental analyses. The ^{1}H NMR spectral data of the phane compounds **7**—**12** are summarized in Table 1. The coupling constants of doublets for olefinic protons in **7**—**12** are 15 or 16 Hz, except for the case of **12**. On the other hand, the IR spectral data of olefinic linkages in **7**—**12** exhibit two bands at *ca.* 1600 and 960 cm^{-1} (Table 2). The J values in the ^{1}H NMR spectra and the IR spectral data support the conclusion that the olefinic protons occupy a *trans* position relative to each other. The ^{1}H NMR signal of the olefinic protons in **7** (δ, 6.34 and 6.91 ppm) is shifted upfield by about 0.37 ppm, as compared with that of the reference compound, 1,3-diruthenocenyl-2-propen-1-one (**13**) (δ, 6.71 and 7.29 ppm) (Fig. 1). The upfield shift of the olefinic protons in **7** should be due to the magnetic anisotropy of the other olefinic bond. Similarly, the protons of the olefinic bonds in **8**, **9**, **10**, **11**, and **12** are shifted somewhat upfield, as compared with the positions of the reference compounds, 1-ferrocenyl-3-ruthenocenyl-2-propen-1-one (**14**), 3-ferrocenyl-1-ruthenocenyl-2-propen-1-one (**15**), 1,5-diruthenocenyl-1,4-pentadien-3-one (**16**), 1-ferrocenyl-5-ruthenocenyl-1,4-

pentadien-3-one (**17**), and 5-ferrocenyl-1-ruthenocenyl-2,4-pentadien-1-one (**18**), respectively (see Table 1). These upfield shifts may also be caused by the magnetic anisotropy of the other olefinic group.

The electronic spectra of phane compounds **7**, **10**, and **12** and the reference compounds **13**, **16**, and **18** in chloroform are shown in Figs. 2—4. The electronic

Fig. 1.

spectra of d^6 metallocenes have been thoroughly studied.[14] It is well known that the bathochromic and hyperchromic shifts of absorption bands of metallocenes are caused by the conjugations of the olefinic and carbonyl groups with cyclopentadienyl rings.[15] Thus, the absorption bands of **13**, **16**, and **18** in the 400 and 500 nm regions correspond to the spin-allowed d-d transitions of ruthenocene and ferrocene, respectively. The intense bands of **13**, **16**, and **18** at *ca.* 300 nm are associated with the charge transfer

transitions between metal and ligand. The electronic spectra of **7** and **10** show new shoulder bands at longer wavelengths and the broadening of absorption curves, and the absorption bands of charge transfer and d-d transitions are located at shorter wavelengths and the intensity increases, as compared with the spectra of **13** and **16**. On the other hand, three bands of **12** are located at similar positions to the bands of **18**, and the intensity of **12** is much higher than those of **18**.

Experimental

Measurements. The ^{1}H NMR spectra were obtained with a JEOL JNM-FX 100 spectrometer (100 MHz) at 26 °C. All the chemical shifts are expressed in δ (ppm: downfield from internal Me_4Si). The IR spectra were measured in KBr pellets with a Hitachi Model 285 infrared spectrometer. The electronic spectra were recorded with a Shimadzu Double 40-R spectrophotometer at room temperature.

Materials. All the melting points are uncorrected. The following compounds were synthesized by the methods described in the literature: 1,1′-ruthenocenedicarboxylic acid,[12] 1,1′-ferrocenedicarbaldehyde (**2**),[16] 1,1′-diacetylruthenocene (**3**),[12] 1,1′-diacetylferrocene (**4**),[17] 1,1′-bis(2-acetylvinyl)ferrocene (**5**),[18] and 1,1′-bis(2-formylvinyl)ferrocene (**6**).[18]

Dimethyl 1,1′-Ruthenocenedicarboxylate. A methanol solution (120 ml) containing 1,1′-ruthenocenedicarboxylic acid (3.8 g, 11.9 mmol) and concentrated sulfuric acid (0.30 ml) was refluxed for 20 h under a nitrogen atmosphere. After the mixture was poured into water, the solution was extracted by chloroform. The chloroform extract was washed by saturated sodium hydrogencarbonate, water and brine, and then dried over anhydrous sodium sulfate. After purification by column-chromatography (silica gel–chloroform), 4.0 g (98%) of this compound was obtained; mp 165—167 °C (chloroform). ^{1}H NMR ($CDCl_3$): δ 3.74 (6H, s, $-COOCH_3$), 4.73 (4H, t, J=1.8 Hz, Rc ring protons), 5.17 ppm (4H, t, J=1.8 Hz, Rc ring protons). IR (KBr): 1709 cm^{-1} ($-COOCH_3$). MS: *m/e* 347 (M^+) and 101 (Ru^+). Found: C, 48.59; H, 4.32%. Calcd for $C_{14}H_{14}O_4Ru$: C, 48.41; H, 4.06%.

1,1′-Bis(hydroxymethyl)ruthenocene. A solution of dimethyl 1,1′-ruthenocenedicarboxylate (2.7 g, 7.78 mmol) in benzene (150 ml) was added dropwise to a mixture of lithium aluminum hydride (0.65 g) in ether (150 ml). After the solution was refluxed for 4 h under a nitrogen atmosphere, the excess lithium aluminum hydride was decomposed with a small amount of cold water. The resulting mixture was extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate. The removal of chloroform yielded 2.2 g (98%) of this compound; mp 125—127 °C (chloroform). ^{1}H NMR ($CDCl_3$): δ 1.80 (4H, br-s, $-CH_2-$), 4.16 (2H, br-s, –OH), 4.58 (4H, t, J=1.8 Hz, Rc ring protons), and 4.71 ppm (4H, t, J=1.8 Hz, Rc ring protons). IR (KBr): 3176 cm^{-1} (–OH). MS: *m/e* 291 (M^+) and 101 (Ru^+). Found: C, 49.99; H, 4.42%. Calcd for $C_{12}H_{14}O_2Ru$: C, 49.48; H, 4.84%.

*1,1′-Ruthenocenedicarbaldehyde (**1**).* A solution of 1,1′-bis(hydroxymethyl)ruthenocene (1.5 g, 5.15 mmol) and active manganese dioxide (12 g) in chloroform (100 ml) was shaken for 24 h at room temperature. After filtration of active manganese dioxide, the removal of chloroform left 1.0 g (70%) of **1**; mp 235 °C (dec) (hexane–dichloromethane). ^{1}H NMR ($CDCl_3$): δ 4.94 (4H, t, J=1.8 Hz, Rc ring protons), 5.18 (4H, t, J=1.8 Hz, Rc ring protons), and 9.71 ppm (2H, s, –CHO). IR (KBr): 1655 cm^{-1} (–CHO). MS: *m/e* 287 (M^+) and 101 (Ru^+). Found: C, 50.44; H, 3.28%. Calcd for $C_{12}H_{10}O_2Ru$: C, 50.17; H, 3.51%.

General Procedure for an Intermolecular Base-catalyzed Condensation.

*[3.3](1,1′)Ruthenocenophane-2,14-diene-1,16-dione (**7**).* A mixture of **1** (1.0 g, 3.48 mmol), **3** (1.1 g, 3.48 mmol), and sodium (0.5 g) in ethanol (100 ml) was stirred at 60 °C for 6 h under a nitrogen atmosphere. After the crude product was filtered off, washed with water, ethanol, and

Prerequisites for the Enhancement of Formose Formation in the Presence of Hydroxy Oxo Compounds

Tomoya Sakai,* Masahiko Ishizaki, Katsuaki Kobayashi, and Masafumi Goto

Department of Chemical Reaction Engineering, Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467

(Received October 28, 1980)

The enhancement of formose formation in the presence of several hydroxy oxo compounds was examined in an aqueous $Ca(OH)_2$ solution. Four terminal hydroxy oxo compounds, 2-hydroxyacetophenone, 1,3-dihydroxyacetone, DL-glyceraldehyde, and D-glucose, were confirmed to accelerate the reaction, but two internal hydroxy oxo compounds, 2-hydroxypropiophenone and acetoin, were found not to be effective. The acceleration efficiency was larger for a system in which hydroxy oxo compounds were introduced to an aqueous mixture of $Ca(OH)_2$ and formaldehyde than for a system in which formaldehyde was introduced to an aqueous mixture of $Ca(OH)_2$ and the hydroxy oxo compounds. The difference in the acceleration efficiencies between the two procedures of reagent introduction was large for 2-hydroxyacetophenone and 1,3-dihydroxyacetone. This is accounted for by the rapid conversions of the added hydroxy oxo compounds in an aqueous $Ca(OH)_2$ solution.

The typical formose formation in the absence of accelerators takes place in an aqueous mixture of $Ca(OH)_2$ and formaldehyde(C_{1A}) at about 50 °C. The initial heterogenous suspension of $Ca(OH)_2$ turns into a homogeneous solution as the reaction proceeds. The consumption rate of C_{1A} for the formose formation shows a characteristic feature of an auto-catalysis, accompanied by a long induction period. After the maximum rate of C_{1A} consumption, the reaction mixture is tinged with pale yellow. At this "yellowing point," the yield of formose sugars reaches its maximum; after that the dehydration of sugars proceeds gradually. The main products at the "yellowing point" have been reported to be C_2—C_8 sugars centering around C_6, including reducing sugars and sugar alcohols.[1] The reaction scheme proposed by Mizuno and Weiss[1] is summarized in a series of reactions: (1) the slow dimerization of C_{1A} to glyceraldehyde (C_{2A}), (2) the rapid aldol addition of C_{1A} to C_{2A} and higher carbohydrates, (3) Lobry de Bruyn-Alberda van Ekenstein(L·V) transformation, and (4) Cannizzaro and cross-Cannizzaro reactions among the products and C_{1A}.

The presence of such hydroxy oxo compounds as C_{2A} and D-glucose (Glu) in the reaction system has been known to shorten or to eliminate the induction period and to cause the reaction to proceed rapidly through C–C chain growth. Most of the hydroxy oxo compounds so far examined have the terminal 1-hydroxy-2-oxo structure: the order of the acceleration efficiency has been reported by Kusin[2] as D-fructose (Fru) > Glu > maltose; by Langenbeck,[3] as 1,3-dihydroxyacetone (C_{3K}) > C_{2A} > Fru, and by Langenbeck[4] and Monozov and Lavanevskii,[5] as will be described in a later section.

This study deals with the efficiencies of seven hydroxy oxo compounds, 2-hydroxyacetophenone (HAP), C_{3K}, DL-glyceraldehyde (C_{3A}), Glu, 2-hydroxypropiophenone (HPP), and acetoin, as accelerators of the formose formation. Among them, C_{3A} and C_{3K} represent the initial products of the typical formose formation. Glu was used because the major products at the "yellowing point" are hexoses. One of the most efficient accelerators, HAP, is unique because it is not involved in the typical formose formation. HPP and acetoin have the internal hydroxy oxo structure and are employed to examine whether or not these compounds show the acceleration effect.

The accelerators with terminal 1-hydroxy-2-oxo structure all shared large acceleration efficiencies with regard to the formose formation. It was also noted that the procedure of reagent introduction, *i.e.*, either the reaction was started with the introduction of accelerators into an aqueous mixture of $Ca(OH)_2$ and C_{1A} or it was started with the introduction of C_{1A} into an aqueous mixture of $Ca(OH)_2$ and hydrox oxo compounds, affected the efficiency of each accelerator. The phenomenon was attributed to the rapid transformation of the hydroxy oxo compounds in an aqueous $Ca(OH)_2$ solution in the absence of C_{1A}.

Experimental

Materials. A commercially available 37% C_{1A} solution (Wako) was used for the C_{1A} stock solution without further purification. This contained 3 to 4% methanol as a stabilizer. Commercially available guaranteed-reagent-grade calcium hydroxide (Katayama), C_{3K} (Wako), and C_{3A} (Tokyo Kasei) were used without further treatment. The C_{3K} and C_{3A} are dimers, but these have been known to dissociate to the respective monomers immediately in an aqueous $Ca(OH)_2$ solution.[6]

HAP was prepared according to the method of Cebrian:[7] mp 76—78 °C (lit, 75—76 °C). HPP was prepared according to the method of Temnikowa;[8] the material thus obtained was found by GLC measurements to contain an isomer, 1-hydroxy-1-phenyl-acetone, in a 27% amount, but it was used without further purification: bp 115—120 °C/12 Torr (lit,[8] for HPP 123—124 °C/13 Torr) (1 Torr= 133.322 Pa).

Product Analysis. The products of formose formation have been reported to consist of formose sugars, including reducing sugars, sugar alcohols, and formic acid, produced by the side Cannizzaro reaction.[1] The amounts of remaining C_{1A} and formic acid were measured on a Kyowa K-880 high-performance liquid (HPL) chromatograph, using a column of Shodex Ionpak C-811 and an aqueous eluent of 0.1% phosphoric acid under a pressure of 50 bar at room temperature, and with an UV monitor (Kyowa KUV-254)

at 254 nm and a refractive index monitor (Shodex RISE-11) connected in series. The accuracy of the quantitative measurement of C_{1A} was confirmed to be in agreement with the photometric method with chromotropic acid[9] within a 2—3% error. Higher formose sugars, such as C_5 and C_6, were not fully separated in this HPL chromatogram, though.

The spectral change between 210—300 nm of an aqueous HAP and $Ca(OH)_2$ solution was recorded at 5-min interval with a Shimadzu UV-210A spectrophotometer with a Shimadzu WP-1 wavelength programmer and an X-Y recorder (Rika Denki) attached. The amounts of HPP and its isomer were measured with a postulation of equal molar sensitivities for the two isomers on an Ohkura Model 802 gas-liquid chromatograph, with FID by means of a silicone grease (SE-30) column at 150 °C.

Formose-formation Procedures. In a three-necked, round-bottomed flask, either an aqueous or a 40% methanol aqueous solution of $Ca(OH)_2$ was placed and thermostated at 35—50 °C. The reaction was initiated with two different procedures. In the normal procedure, first a thermostated C_{1A} solution was mixed with the $Ca(OH)_2$ solution; then after 1 or 3 min, a reaction was initiated by the introduction of a thermostated aqueous accelerator solution. In the reverse procedure, first, a thermostated aqueous accelerator solution was mixed with the $Ca(OH)_2$ solution; then, after 1 or 3 min, a reaction was initiated with the introduction of a thermostated C_{1A} solution. The reaction mixture was stirred magnetically and thermostated in a water bath. Aliquots of the reaction mixture were pipetted out at appropriate time intervals and were then dissolved in a dilute hydrochloric acid to quench the reaction (litmus). The amounts of remaining C_{1A} and formic acid were determined with the HPL chromatograph. The conversion of C_{1A} to formose was calculated by Eq. 1, where the formation of formic acid was assumed to be caused through the cross-Cannizzaro reaction between C_{1A} and aldoses.

$$C_{1A} \text{ conversion to formose} = 1 - \frac{[C_{1A}]_{remained} - [HCOOH]}{[C_{1A}]_{initial}} \quad (1)$$

Deactivation of Accelerators. An aqueous solution of an accelerator was added to a $Ca(OH)_2$ solution in the absence of C_{1A}. At appropriate time intervals, aliquots of the reaction mixture were pipetted out and examined by means of an HPL chromatograph after acid treatment.

Results and Discussion

Essential Structure for Acceleration. C_{1A} consumption in a typical formose formation in the absence of accelerators is shown in Fig. 1. This shows the autocatalytic nature of the formose formation. The change in the HPL chromatogram with reaction periods is illustrated in Fig. 2. The arrow indicates the retention time of each authentic sample, measured separately under the same conditions of HPL chromatography. C_{4A} and C_{5A} denote D-erythrose and D-arabinose respectively. The final chart at 60 min shows product peaks distributing between C_{5A} and Glu, suggesting that they are mostly aldo- and ketohexoses including sugar alcohols, in accordance with the literature.[1] Figure 3 shows a change in the HPL chromatogram in the presence of an accelerator, C_{3A} (0.01 mmol cm^{-3}), with the normal procedure. The products of formose formation gave similar HPL chromatograms irrespective of the introduction of a small amount of C_{3A} (compare Figs. 2 and 3), although the consumption of C_{1A} was rapid for the reaction with added C_{3A}. The reaction shown in Fig. 3 was carried out in an aqueous solution.

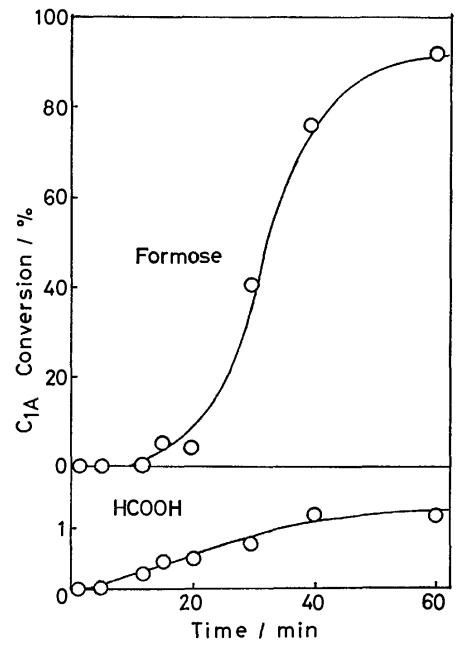

Fig. 1. Autocatalytic nature of formose formation in the absence of accelerators.

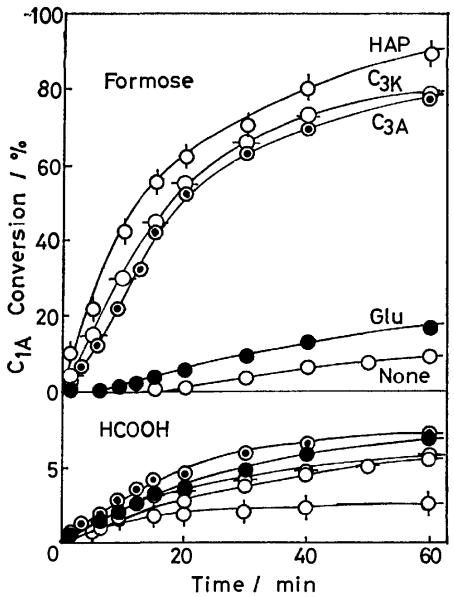

Fig. 4. Acceleration efficiencies of HAP, C_{3K}, C_{3A}, and Glu.
50 °C, H_2O, $Ca(OH)_2$: 0.10 mmol cm^{-3}, C_{1A}: 2.45 mmol cm^{-3}, accelerator: 0.01 mmol cm^{-3}.

The efficiencies of the acceleration of various hydroxy oxo compounds, HAP, C_{3K}, C_{3A}, or Glu, are compared in Fig. 4 with the normal procedure. The concentration of each accelerator is 0.01 mmol cm^{-3}, while that of C_{1A} is 2.45 mmol cm^{-3}. The conversion of C_{1A} amounted to 80% at 60 min for HAP, C_{3K}, and C_{3A}, so that the molar amounts of the converted C_{1A} are more than 200 times those of the introduced accelerators. A comparison of the results shown in Fig. 4 with those in Fig. 1 suggests that the steep rising of the conversion of C_{1A} in the middle and the leveling off in the later stage of the reaction periods in Fig. 1 correspond to the rapid C_{1A} additions to lower carbohydrates, such as C_{3A} and C_{3K}, and to the slow C_{1A} additions to higher carbohydrates, such as Glu, respectively, based on the different acceleration efficiencies of the compounds shown in Fig. 4.

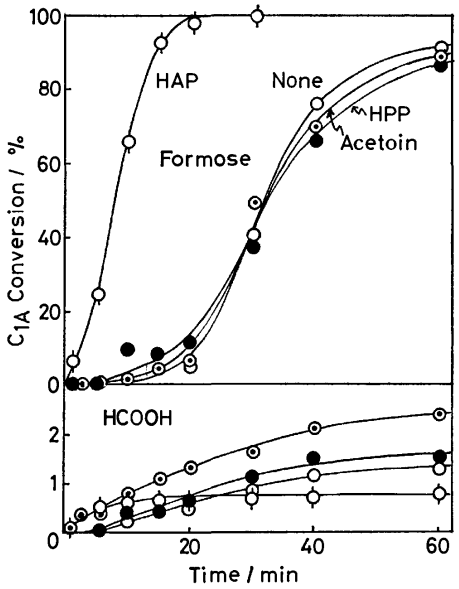

Fig. 5. Non-effectiveness of internal hydroxy oxo compounds, HPP and acetoin, as accelerator.
50 °C, 20 vol% methanol–H_2O, $Ca(OH)_2$: 0.10 mmol cm^{-3}, C_{1A}: 2.45 mmol cm^{-3}, accelerator: 0.01 mmol cm^{-3}.

HAP is a unique compound in that it belongs to the most effective class of accelerators for the formose formation and in that it is not formed in a typical formose reaction. Langenbeck[4] has reported that the efficiency of the acceleration of hydroxy oxo compounds decreases in the following order; HAP > 2-hydroxyacetonaphthone > 1-hydroxy-2-propanone > C_{3K} > C_{2A} > 5-(2-hydroxyacetyl)acenaphthene > Fru > Glu. Further, Monozov and Levanevskii[5] have reported that the efficiencies of HAP derivatives follow a Hammett-type LFER; *i.e.*, 2′,5′-dichloro-HAP>4′-chloro-HAP=3′-chloro-HAP>HAP>4′-methyl-HAP>4′-methoxy-HAP. These compounds have, without exception, terminal 1-hydroxy-2-oxo structure. The accelerations by internal hydroxy oxo compounds deserve to be examined. Langenbeck[3] reported the acceleration efficiencies of benzoin, anisoin, and acetoin to be smaller than that of Glu. The present results with HPP and acetoin as internal hydroxy oxo compounds are shown in Fig. 5. A mixture of methanol and water (2:8 in volume) was employed in this case because of the poor solubility of these substances in water. It is concluded that internal hydroxy oxo compounds have no acceleration efficiency.

Influence of the Procedures of Reagent Introduction. The procedures of the reagent introduction for starting

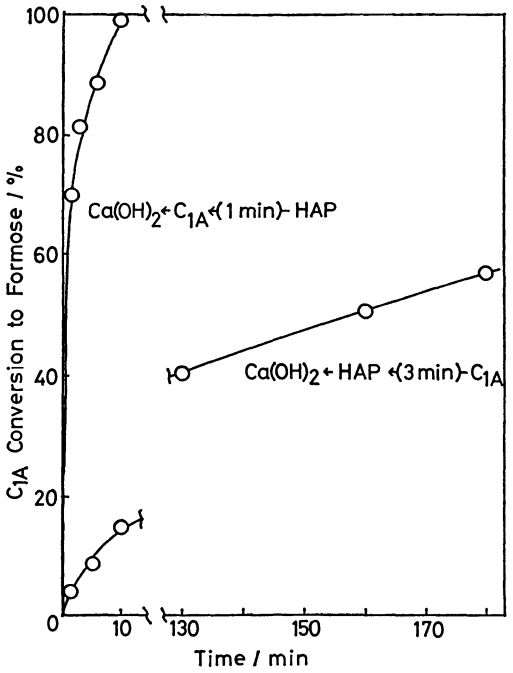

Fig. 6. Difference in acceleration efficiency of HAP with normal or reverse procedure.
35 °C, 40 vol% methanol–H_2O, $Ca(OH)_2$: 0.10 mmol cm^{-3}, C_{1A}: 1.0 mmol cm^{-3}, HAP: 0.20 mmol cm^{-3}.

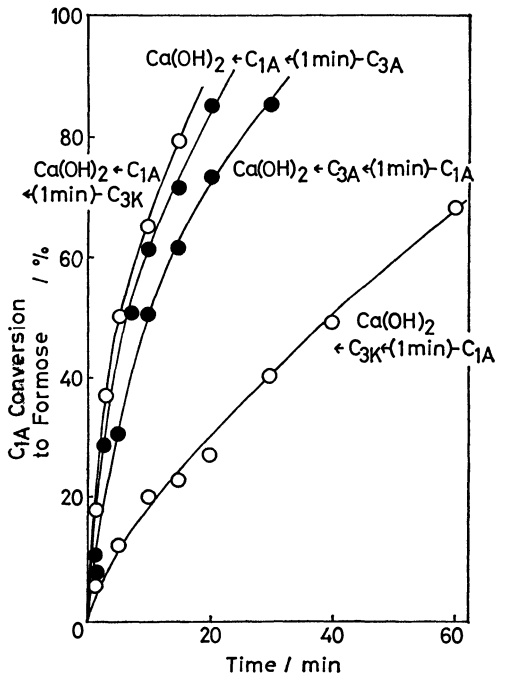

Fig. 7. Differences in acceleration efficiencies of C_{3K} and C_{3A} with normal or reverse procedure.
35 °C, H_2O, $Ca(OH)_2$: 0.10 mmol cm^{-3}, C_{1A}: 0.98 mmol cm^{-3}, C_{3A}: 0.20 mmol cm^{-3}, C_{3K}: 0.20 mmol cm^{-3}.

formose formation greatly influenced the efficiency of acceleration, whether by the normal procedure, $Ca(OH)_2$←C_{1A}←accelerator, or by the reverse procedure, $Ca(OH)_2$←accelerator←C_{1A}. A large difference in the acceleration efficiencies was observed for

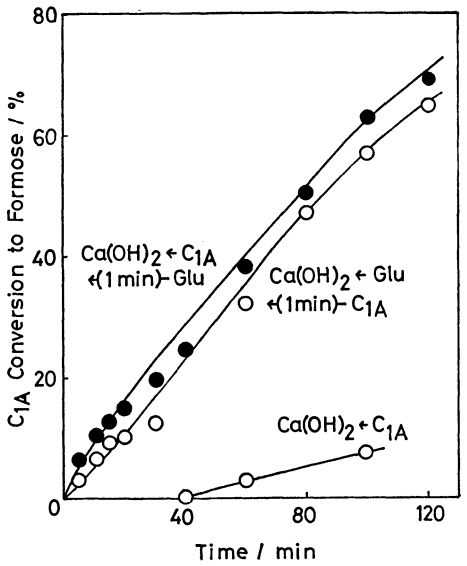

Fig. 8. Difference in acceleration efficiency of Glu with normal or reverse procedure.
35 °C, 40 vol% methanol–H_2O, $Ca(OH)_2$: 0.10 mmol cm^{-3}, C_{1A}: 1.0 mmol cm^{-3}, Glu: 0.20 mmol cm^{-3}.

35 °C, H_2O, $Ca(OH)_2$: 0.10 mmol cm^{-3}, C_{3A}: 0.20 mmol cm^{-3}, C_{1A}: 1.0 mmol cm^{-3}.

HAP, as is shown in Fig. 6. The results for C_{3A} and C_{3K} are shown in Fig. 7. The difference is larger for C_{3K} than for C_{3A}. The difference for Glu was small, as shown in Fig. 8.

To investigate the difference in the acceleration efficiencies between the two procedures, the HPL chromatographic change of the accelerator with a duration time of 1 min was examined for the case of C_{3K} in Fig. 9. The chromatogram of the mixture of C_{3K} and $Ca(OH)_2$ solution, 1 min after the mixing, showed a complete consumption of C_{3K} and the formation of C_6 sugars (C_{6AK}) containing DL-dendroketose, Fru, and D-sorbose.[10] A chromatogram obtained with the normal procedure (a C_{3K} solution was mixed 1 min

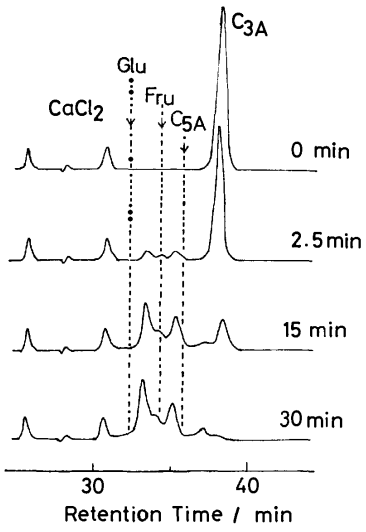

Fig.10. HPL chromatographic change of C_{3A} in an aqueous $Ca(OH)_2$ solution.
20 °C, H_2O, $Ca(OH)_2$: 0.05 mmol cm^{-3}, C_{3A}: 0.20 mmol cm^{-3}.

after the preparation of an aqueous mixture of C_{1A} and $Ca(OH)_2$) exhibited few dimerization products, but a peak corresponding to C_{4A} (D-erythrose), presumably a mixture of tetroses (C_{4AK}), appeared. On the other hand, the chromatogram of the reaction mixture with the reverse procedure (a C_{1A} solution was mixed 1 min after the preparation of an aqueous mixture of C_{3K} and $Ca(OH)_2$) showed that C_{3K} had already been converted to dimerization products and that no tetrose peak had appeared. Thus, the high efficiency of C_{3K} with a normal procedure, as is shown in Fig. 7, corresponds to the process which involves C_{1A} addition to C_{3K}, where the dimerization of C_{3K} is excluded. With the reverse procedure, however, the dimerization takes place prior to the addition of C_{1A} to C_{3K} and the weak acceleration efficiencies of such dimerization products, like that of Glu, govern

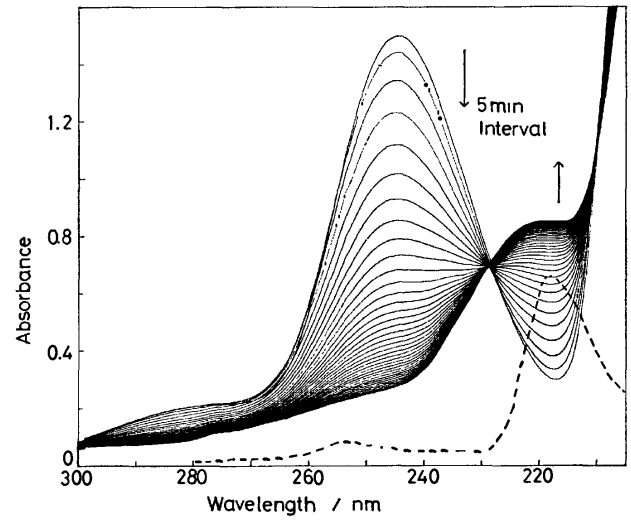

Fig. 12. UV spectral change of HAP in an aqueous $Ca(OH)_2$ solution.
25 °C, H_2O, $Ca(OH)_2$: 2.0×10^{-3} mmol cm^{-3}, HAP: 1.3×10^{-4} mmol cm^{-3}.

the formose formation. For C_{3A}, the dimerization in the presence of $Ca(OH)_2$ is slower than for C_{3K}, as is shown in Fig. 10. The difference with different procedures for reagent introduction is not significant for this accelerator, as is shown in Fig. 7. The dimerization of either C_{3A} or C_{3K} has been reported by Gutche *et al.*[10] and Berl and Feazel.[11] Glu changed little in a $Ca(OH)_2$ solution, as is shown in Fig. 11; consequently, no apparent difference between the two procedures was observed.

The significant difference observed for HAP with the procedure of reagent introduction *cf.* Fig. 6 is not fully understood. A spectral change in the ultraviolet spectrum of HAP in an aqueous $Ca(OH)_2$ solution (shown in Fig. 12) exhibits a decrease in absorbance at the absorption maximum, 246 nm, and an increase in the region of wavelength shorter than the isosbestic point at 227 nm. This suggests a loss of absorption due to the carbonyl group conjugated with the phenyl group of HAP by the reaction below. However, the HPL chromatographic separation of these compounds was not attained.

This postulation is in agreement with the facts that no significant absorption appears around 246 nm for phenylethylene glycol, as is shown by the broken curve in Fig. 12, and that 2-hydroxybutyrophenone forms an equilibrium mixture with 1-hydroxy-1-phenyl-2-butanone in the presence of OH^-.[12] The addition of one molecule of C_{1A} to the isomerized product of HAP, *i.e.*, 2-hydroxy-2-phenylacetaldehyde (HPA), would yield 2-phenylglyceraldehyde, which has saturated α-carbon next to carbonyl group, and thus is not susceptible to the addition of further C_{1A}. Although HPA has not yet been isolated from the reaction mixture with HAP, the isomerization of HAP in a $Ca(OH)_2$ solution is a plausible reason why the

large difference was observed between the different procedures of HAP introduction.

On the Mechanism of Formose Reaction. The finding of the present study, that the acceleration does not originate from the internal hydroxy oxo structure, but from the terminal hydroxy oxo structure of the accelerator, indicates that the C–C chain growth in formose formation is attained by successive additions of C_{1A} to the α-carbon to the carbonyl group, accompanied by the successive L-V transformation of the carbonyl group to the terminal position. The internal hydroxy oxo compound exhausts the hydrogen attached to α-carbon by the addition of one molecule of C_{1A} and then terminates, provided that there is no cleavage of the C–C bond of the accelerator during the reaction. Another finding, that the procedures of reagent introduction considerably influence the efficiencies of the accelerators, also suggests the aldol addition mechanism for the C–C chain growth of formose formation, because the acceleration by the hydroxy oxo compound occurs through the reaction between the hydroxy oxo compound and C_{1A}, as is shown in Fig. 9 for C_{3K}.

Moreover, the findings, that the acceleration efficiencies of Glu and Fru are small compared with those of C_{3A} and C_{3K}[4] and that the molar amounts of the consumption of C_{1A} are more than 200 times those of the introduced accelerators, as is shown in Fig. 4, suggest a degradation by a retro aldol reaction in order to account for the high activity being retained throughout the reaction until most of the C_{1A} is consumed.

Applications of Homogeneous Water-gas Shift Reaction. III. A Further Study of the Hydrocarbonylation. A Highly Selective Formation of Diethyl Ketone from Ethene, CO, and H_2O

Kazuhisa MURATA* and Akio MATSUDA

National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Tsukuba, Ibaraki 305

(Received November 12, 1980)

The hydrocarbonylation of ethene with CO and H_2O produces diethyl ketone with a high selectivity of 99±1%(propanal 1±1%); a $Co_2(CO)_8$–phosphine system is used as an efficient catalyst, which is also active for the homogeneous water-gas shift reaction. The effects of the reaction parameters(CO pressure, temperature, and ethene and H_2O concentrations) on the selectivity and activity are examined for the $Co_2(CO)_8$–1,2-bis(diphenylphosphino)ethane (diphos) system; the selectivity to yield the ketone is fairly high under the variety of conditions studied here. Evidence suggests that the active species which catalyze the water-gas shift reaction participate in the hydrocarbonylation of ethene.

Diethyl ketone(3-pentanone) is produced under normal oxo conditions using a transition-metal catalyst;[1] it was previously reported that a maximum molar ratio of the ketone to propanal up to *ca.* 3 was achieved using $Co_2(CO)_8$ as the catalyst.[2,3]

In preceding papers[4,5] we described the hydrocarbonylation of propene with CO and H_2O, using a $Co_2(CO)_8$-phosphine catalyst system, to yield a mixture of dipropyl ketones(4-heptanone+2-methyl-3-hexanone+2,4-dimethyl-3-pentanone) as primary products.[6] Therefore, the hydrocarbonylation of ethene has become of great interest to us, because a selective and efficient industrial route to obtain diethyl ketone may be realized.

In the present study, optimum conditions are explored for the ketone formation and the catalytic behavior of hydrocarbonylation is discussed further.

Experimental

Materials. The ethene (Research Grade), phosphine, dioxane, and acetone were obtained commercially and used without further purification.

Reaction Procedure. The hydrocarbonylation reactions were carried out in a 100-ml stainless-steel autoclave in which $Co_2(CO)_8$, phosphine, H_2O, and solvent had been placed. The vessel was sealed and degassed by three 10 kg/cm² pressurization/depressurization cycles with CO. Into the vessel both ethene and CO were introduced. The vessel was heated with stirring to a definite reaction temperature for a certain reaction period and then cooled down to room temperature.

Analytical Methods. The liquid products were analyzed at 100 °C by means of a gas chromatograph equipped with FID using a 6-m column packed with polyethylene glycol adipate. The infrared and ^{1}H-NMR spectra of the catalyst solutions were recorded on a Hitachi type 215 spectrometer and a Hitachi type R-40 spectrometer respectively.

Results and Discussion

Time Course of Diethyl Ketone Formation. A typical example of the reaction is shown in Fig. 1, where the molar ratio ethene/$Co_2(CO)_8$ of 150/2 was used. At 165 °C, the selectivity of the ketone was as high as 97±1% (propanal 3±1%, 32:1 ratio). An induction period of about 1 h preceded the onset of catalysis; this is roughly the same as that observed in the formation of dipropyl ketones.[4]

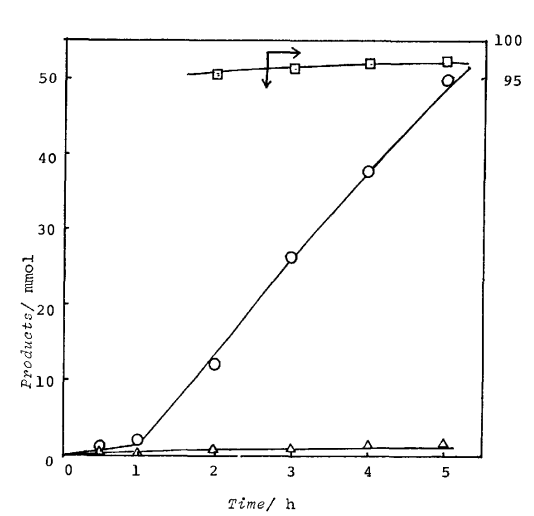

Fig. 1. Cobalt-catalyzed hydrocarbonylation as a function of time.
$Co_2(CO)_8$ 2 mmol, diphos 2 mmol, dioxane 50 ml, H_2O 60 mmol, CO 70 kg/cm²(const.), temp. 165 °C, ethene 150 mmol.
—○— Diethyl ketone, —△— propanal, —□— selectivity; [diethyl ketone]$_t$/([diethyl ketone]$_t$+[propanal]$_t$), t: time.

No trace of propanoic acid was detected under the conditions described here. Moreover, neither the hydrogenation of propanal to 1-propanol[7] nor aldol condensation occurred, partly because the amount of propanal formed was too small.

The extremely high selectivity suggests that the cobalt-catalyzed hydrocarbonylation of ethene may have some industrial importance. Thus, the optimum conditions were explored in detail in the hope of developing a feasible industrial process.

Effect of Reaction Parameters. Table 1 shows the effect of the phosphorus ligand on the selectivity(S) and activity(r^{max}). The S value was slightly affected by both the phosphine structure(Runs 1—6) and the ratio of diphos to $Co_2(CO)_8$(Runs 7—10), although excess amounts of diphos decreased the S value (Run 7). The use of an equimolar amount of H_2 (60 mmol) instead of H_2O drastically decreased the S value (Run 12). The use of MeOH (60 mmol) resulted in a

decrease in the activity r^{max} (Run 13).

The selectivity and activity were examined as a function of the ethene([C_2']) and H_2O([H_2O]) concentration as well as of the CO pressure (Table 2). The S value slightly increased with the increase in ethene from 75 to 190 mmol. The r^{max} value increased with the initial increase in [C_2'], but reached a maximum at *ca.* 150 mmol and decreased thereafter (Runs 1—4). The S value slightly increased with the increase in CO pressure(P_{CO}), while r^{max} reached a maximum at *ca.* 100 kg/cm² of P_{CO}. Excess water reduced the S value (Run 9). The S value decreased with the increase in reaction temperature, but it was still high at 180 °C (Fig. 2). The use of acetone as a solvent resulted in a decrease in the activity, especially at 135 °C.

Thus, the selectivity to diethyl ketone is fairly high under the variety of conditions studied here. However, the mode of the influence of these parameters on the activity r^{max} is similar to that observed in the case of propene.[4]

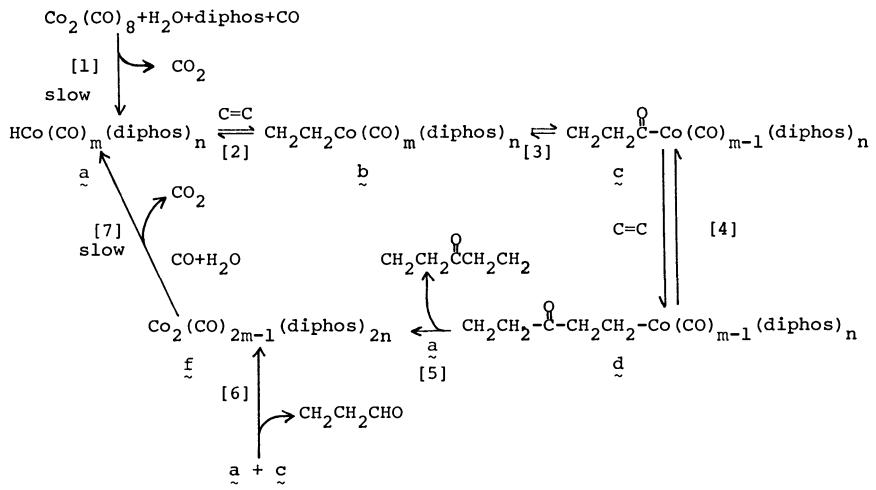

Scheme 1. A possible reaction scheme of the hydrocarbonylation of ethene with CO and H_2O.

The Nature of Catalytically Active Species. The active species responsible for the hydrocarbonylation of ethene may be assumed to be $HCo(CO)_m(diphos)_n$, as in the case of propene.[4,8] In fact, an induction period of *ca.* 1 h was also observed for the diethyl ketone formation (Fig. 1) and the catalytic behavior was generally similar (Tables 1 and 2 and Fig. 2).

A catalyst solution[8] consisting of $Co_2(CO)_8$, diphos, H_2O, and dioxane, which is active in the water-gas shift reaction, has a characteristic ^{1}H-NMR resonance at δ −17.2.[9,10] Some experiments were performed in order to elucidate the NMR behavior in connection with the catalytic properties. The results may be summarized as follows.

(1) In the absence of CO, a stoichiometric reaction of the water-gas shift catalyst solution with ethene occurred, even at room temperature, to give diethyl ketone[11] selectively. The intensity of the ^{1}H-NMR resonance of the solution decreased significantly after the 3 h-reaction.[12]

(2) The NMR spectrum exhibited no resonance on a short-time (5 min) treatment of a solution ($Co_2(CO)_8$ (4 mmol), diphos (4 mmol), and dioxane (5 ml) with both CO (70 kg/cm^2) and H_2O (60 mmol) at 165 °C; this is in contrast to the reaction of a matured solution[8] (see Fig. 1).

(3) No NMR resonance could be observed during the catalytic hydrocarbonylation of ethene at 165 °C under a CO pressure of 80 kg/cm^2, indicating a rapid consumption of the active species.

(4) The NMR spectrum of a solution in the absence of diphos or H_2O showed no resonance in either case.

(5) When an acetone solution consisting $Co_2(CO)_8$, diphos, and H_2O was treated at 135 °C for 3 h under CO(70 kg/cm^2), its ^{1}H-NMR spectrum exhibited a resonance at δ −17.2, although it was weak in comparison with that of the dioxane solution prepared under the same conditions[13] (see Fig. 2).

Thus, the active species which catalyze the water-gas shift reaction can be expected to participate in the hydrocarbonylation of ethene and to exhibit the ^{1}H-NMR resonance at δ −17.2.

A possible reaction scheme is illustrated in Scheme 1:[14,15] The species, **a**, formed during the course of the water-gas shift reaction[1] is trapped by ethene to form a alkyl cobalt complex, **b**, [2]; CO insertion [3] and succeeding ethene addition to **c**[4] give a 2-propyonylethyl cobalt complex, **d**, and the reaction of **a** with **d** produces diethyl ketone[5].[16] Step [6] accounts for the aldehyde formation, though it may be disregarded because of the high selectivities of the ketone formation. (Figs. 1 and 2 and Tables 1 and 2). The resulting complex, **f**, is converted into **a** by the WGSR pathway[7] again, and thus the catalytic cycle is completed.

Reactions 2—6 proceed rapidly, even under mild conditions, as has been mentioned above((1) and (2)). Reactions 1 and 7, on the other hand, proceed only at a relatively high temperature (120 °C or above (2), Figs. 1 and 2).

Although there is no direct evidence that the ^{1}H-NMR peak is due to $HCo(CO)_m(diphos)_n$, the present reaction scheme of the cobalt-catalyzed hydrocarbonylation using CO and H_2O seems to be probable.

7) Under the conditions given in Fig. 1, propanal (10 mmol) introduced independently can be hydrogenated to yield 1-propanol (2 mmol) in a 4 h-reaction.

8) A standard sample of the catalyst solution which is subjected to the ^{1}H-NMR analysis was prepared as follows: in a stainless-steel autoclave (50 ml volume) were mixed 4 mmol of $Co_2(CO)_8$, 4 mmol of diphos, 30 mmol of H_2O, and 5 ml of dioxane. The vessel was then sealed, and CO (70 kg/cm^2, room temp) was introduced. After the vessel had been heated to 165 °C with stirring for 3 h, an aliquot sample was quickly withdrawn from the vessel at 0 °C.

Intramolecular Hydrogen Bonding and Conformations of α,α-Dialkyl- and α-Alkyl-o-methoxybenzyl Alcohols. II. Enthalpies of Hydrogen Bond Formation and Molecular Force Field Calculations on α-Alkyl-substituted Benzyl Alcohols

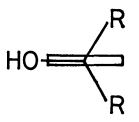
Masayuki Ito and Minoru Hirota*

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

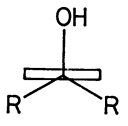
(Received November 17, 1980)

Enthalpies of intramolecular hydrogen bond formation (ΔH) were determined for a series of α-mono- and α,α-dialkyl-o-methoxybenzyl alcohols and related compounds. The $-\Delta H$ values of the unsubstituted and α,α-dialkyl-o-methoxybenzyl alcohols are more than 2.5 kJ mol^{-1}, while those for the corresponding α-monoalkyl derivatives are at most 1 kJ mol^{-1}. This tendency is in accordance with the results on their $\Delta\nu_{OH}$ and $\varepsilon_b/\varepsilon_f$ values, showing the hydrogen bonded conformations of the α-monoalkyl derivatives are less favorable than those of the other alcohols in discussion. Molecular force field calculations on α-alkyl- and α,α-dialkylbenzyl alcohols were also carried out. The results shows that the hydroxyl/aryl coplanar conformation ($\omega=0°$) is the most stable for the unsubstituted and α,α-dialkylbenzyl alcohols and the hydroxyl/aryl non-coplanar conformation ($\omega=30°$) for α-alkylbenzyl alcohols. Since the OH···O distance might be farther and, hence, the overlap between the unshared electron pairs on the methoxyl oxygen and the anti-bonding OH orbital might be less in the non-coplanar conformation, α-monoalkyl-o-methoxybenzyl alcohols are less favorable than the corresponding α,α-dialkyl derivatives in the intramolecular hydrogen bond formation.

The conformations of several benzyl alcohols have been discussed by the measurement of infrared and NMR spectra. Thus Ōki and Iwamura have concluded the existence of weak attractive interaction similar to hydrogen bonding between hydroxyl group and aromatic π-electron system.[1] The OH···π interaction might be favored when the hydroxyl group approached from upright the plane of aromatic nucleus, taking conformation II. On the other hand, α,α-di-



I



II

t-butylbenzyl alcohol is a highly crowded molecule, the rotation around the C(benzyl)–C(aromatic) bond being so slow as to make it possible to observe the signals of 2- and 6-protons separately by ^{1}H-NMR measurement.[2,3] This fact strongly suggests that conformer I or a similar one predominates over conformer II. We have also measured the infrared OH stretching absorptions and ^{1}H-NMR of α-alkyl-o-methoxybenzyl alcohols and discussed on their conformations.[4] A remarkable difference in the preference of hydrogen-bonded conformer has been observed between the α-monoalkyl and α,α-dialkyl-substituted derivatives.

In order to study further on this point, the enthalpies of the intramolecular hydrogen bond formation are determined with these alcohols. The most favorable conformers are also estimated theoretically by the molecular force field approaches.

Experimental

Preparation of Materials. Unsubstituted and α,α-dialkylbenzyl alcohols were prepared by the known procedures.[5,6] α-Monoalkylbenzyl alcohols were obtained by the Grignard reactions of o-methoxybenzaldehyde with the corresponding alkylmagnesium bromides. 2-Methoxy-α,α,3,5-tetramethylbenzyl alcohol was prepared similarly by the addition reaction to acetone of 2-methoxy-3,5-dimethylphenylmagnesium bromide, which was derived from 2,4-xylenol. Bp 89.0—90.0 °C/2 mmHg; MS (70 eV) *m/e*, 194.

Measurement of Infrared Spectra. Infrared OH stretching absorptions were recorded with a Hitachi Model 225 grating infrared spectrophotometer. The temperature dependence measurements were carried out on the dilute carbon tetrachloride solutions at the temperature ranging from 290 to 312 K. Throughout each measurement, temperature of the solution was kept sufficiently constant (The temperature variation was kept within 0.5 K). The results are given in Table 1. The enthalpies of the hydrogen bond formation was obtained as the gradients of the $\log_{10}(\varepsilon_b/\varepsilon_f)$ *vs.* $1/T$ plot by the least squares calculations.

The measurements were carried out within a relatively narrow range of temperature. Since the influence of temperature dependent broadening were shown to be negligible with some typicals of the absorption bands in this range of temperature, the peak heights (absorbance) of the bands were used to evaluate the relative equilibrium constants instead of integrated intensities. Fortunately the free and the hydrogen-bonded bands were rather well resolved, which made possible to use the peak intensities without any correction for the effect of the overlapping bands in most instances.

Molecular Force Field Calculations. We have employed the empirical force field proposed by Allinger and coworkers[7] to calculate steric energies and geometries of the benzyl alcohols. The geometries corresponding to the potential minima were obtained by the full optimization calculations, while the other labile conformations were calculated by restricting the torsional angle around C(aryl)–C(benzyl) bond.

Results and Discussion

The infrared OH absorptions of some newly prepared α,α-dialkylbenzyl alcohols, 1-(o-methoxyphenyl)cycloalkanols and 2-(8-chromanyl)-2-propanol are given in Table 2. The strength of hydrogen bond can be evaluated by the hydrogen bond shift ($\Delta\nu_{OH}$) of the

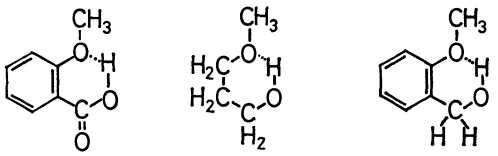
OH stretching band, which is defined as the difference in the OH frequencies of the free and the hydrogen bonded species. The $\Delta\nu_{OH}$ is often related with the OH···O distance of hydrogen bond system.[8] Thus it can be a measure for the strength of the hydrogen bond. The enthalpy of hydrogen bond formation serves as another scale for the strength of the hydrogen bond, being determined from the temperature dependence measurement of the OH absorption intensities of free and hydrogen bonded species.[9] Results are given in Table 3 together with the $\Delta\nu_{OH}$ and $\varepsilon_b/\varepsilon_f$ values.

Enthalpies of Hydrogen Bond Formation and the Hydrogen Bond Shifts of OH Stretching Bands. Enthalpies of intramolecular hydrogen bond formation is generally smaller than those of intermolecular hydrogen bond formation when hydrogen donating and accepting groups are similar. The hydrogen bond enthalpies for the benzyl alcohols are rather small even when compared with those of similar six-membered hydrogen-bonded chelates. The enthalpies of intramolecular hydrogen bond formation (ΔH) for *o*-methoxybenzoic acid (**1**)[10] and 3-methoxy-1-propanol (**2**)[11] have been determined to be −13.8 and −8.8 kJ/mol, respectively.

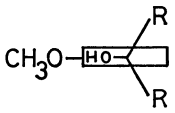


1 **2** **3**

On the other hands, the $-\Delta H$ values for the *o*-methoxybenzyl alcohols in Table 3 are at most 8 kJ/mol, most of them being less than 6 kJ/mol. This is due to the fact that the alcoholic hydroxyl group is a weak hydrogen donor and the oxygen atom of aromatic ether is a weak hydrogen acceptor in forming hydrogen bonds. In compound **1**, the carboxylic OH group is a very strong donor, while the aliphatic ether group in **2** is a stronger hydrogen acceptor than the aromatic ether group in **3**.

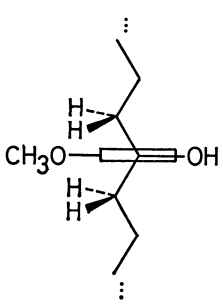
When compared among the benzyl alcohols, α-monoalkyl alcohols **4**—**7** have shown to have smaller $\Delta\nu_{OH}$ and $\varepsilon_b/\varepsilon_f$ values than the alcohols in other series, having been supposed to be less favorable in forming hydrogen bonds.[4] This tendency is again obvious with the $-\Delta H$ values in Table 3. The intramolecularly hydrogen bonded conformers of the α-monoalkyl alcohols are at most only 1 kJ/mol more stable than the free conformers, in contrast to the unsubstituted and α,α-dialkyl benzyl alcohols of which hydrogen-bonded conformers are more than 2.5 kJ/mol more stable than the free conformers.

In the series of α,α-dialkylbenzyl alcohols, α,α-diethyl and higher homologous α,α-di(*n*-alkyl) derivatives have considerably low $-\Delta H$ values around 2.5 kJ/mol. The anomalous behavior was first suspected when the $\varepsilon_b/\varepsilon_f$ and $-\Delta H$ values were compared among a series of dialkyl derivatives carrying $CH_{3-n}(CH_3)_n$ groups, where *n* is 0, 1, 2, and 3. To investigate further on this point, infrared OH stretching absorptions of homologous di(*n*-alkyl) derivatives with propyl, butyl, and pentyl groups were measured, giving very similar ν_f, ν_b, $\Delta\nu_{OH}$, $\varepsilon_b/\varepsilon_f$, and $-\Delta H$ values as shown in Tables 2 and 3. The Hydrogen bond shifts ($\Delta\nu_{OH}$) of dialkyl derivatives increase in the order of the bulkiness of alkyl substituent [$CH_3<C_2H_5<CH(CH_3)_2<C(CH_3)_3$], revealing no indication of anomaly. The $\Delta\nu_{OH}$ value has been correlated to be nearly inversely proportional to the OH···O distance, giving a measure to the strength of intramolecular hydrogen bond. Thus, the order is rationalized by taking the buttressing effect of the alkyl groups in the intramolecularly hydrogen-bonded conformation (III) into consideration. A



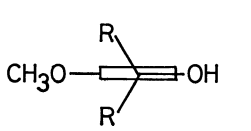
III

strong hydrogen bond is not necessary to be favorable in the equilibrium of its formation reaction, however. The hydrogen bonded conformation can be unfavorable when the steric hindrance and other unfavorable entropy effects in other parts of molecule is serious. Thus the lower $-\Delta H$, as well as the lower $\varepsilon_b/\varepsilon_f$, for **9** and its homologs should be related either to the unfavorable steric effect in other part of the intramolecularly hydrogen bonded conformation or to the favorable steric circumstances in the free conformation. The possible free conformation with extended chain (IV) of α,α-di-*n*-alkylbenzyl alcohols are presumably more stable than those for α,α-diisopropyl- and α,α-di-*t*-butylbenzyl alcohols, because the alkyl-methoxyl repulsion is less in the former. An evidence in support of this explanation was obtained from the measurements on 1-(2-methoxyphenyl)cycloalkanols. Anomalously low ΔH and $\varepsilon_b/\varepsilon_f$ values were not observed with these cyclic alcohols the end of whose alkyl chain are connected to each other. These compounds cannot take the extended chain conformation IV. 1-(2-Methoxyphenyl)cycloalkanols **15**—**17** have the ν_f bands considerably lower than those of other open chain alcohols investigated. They are located between 3604 and 3600 cm^{-1}, assignable to OH···π interacted hydroxyl groups according to the extensive works by Ōki and Iwamura[1b] who attributed the bands at 3620.5 and 3605.2 cm^{-1} of 1-phenylcyclohexanol to the free and the OH···π interacted forms, respectively. The higher ν_{OH} bands of the open chain alcohols **3**—**14**, on the contrary, lies in the frequency region higher than 3616 cm^{-1}. They were assigned to the free OH absorptions according to the fact that the free ν_{OH} bands of 2-phenyl-2-propanol and 3-phenyl-3-pentanol were shown to appear at 3620.6 and 3618.2 cm^{-1}, respectively.[1a]

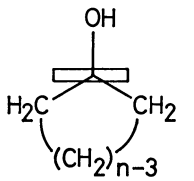


IV

From the results in molecular force field calculations, the free conformers of the dialkyl alcohols without ring structures are estimated to take the OH periplanar conformation V which is unfavorable to have the OH···π interaction. The methoxycycloalkanols **15**—**17**, on the contrary, takes preferably the free conformation (VI) in which the hydroxyl group is clinal to the plane of aromatic ring because of steric hindrance between the alicyclic ring and the *ortho*-methoxyl group expected in conformation V. The conformer VI is supposed to be sterically more crowded than the conformer V of the open chain series. This should be a reason for the larger $-\Delta H$ of the alcohols **15**—**17**. The clinal conformation VI is very favorable to have the OH···π interaction to which the low frequency shifts of the ν_f bands of **15**—**17** is due.



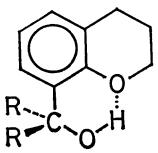
V



$n=5$, 6, and 7

VI

In order to investigate the effect of the conformation of hydrogen-accepting alkoxyl group upon the hydrogen bonding, 2-(8-chromanyl)-2-propanol (**18**) and 2-methoxy-α,α,3,5-tetramethylbenzyl alcohol (**19**) were prepared and their behavior in intramolecular hydrogen bond formation was examined. The intramolecularly hydrogen bonded conformer of **18** is supposed to take conformation VII, which is very similar to



VII

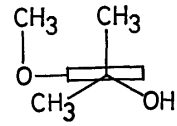
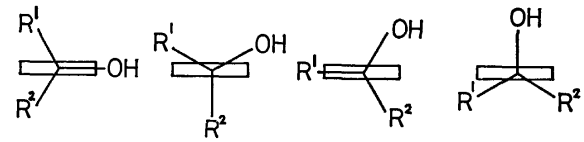
a) The relative values with reference to the most stable conformers are given in parentheses. b) The bond angles and the bond lengths for the most stable conformers are given.

that of **8**. In line with this consequence, the $\Delta\nu_{OH}$ and the $-\Delta H$ values of **18** are very close to those of **8**. The $\varepsilon_b/\varepsilon_f$ value of **18** is significantly larger than the corresponding ratio of **8**, however. The alkoxyl group in **18** is fixed antiperiplanar to the 2-hydroxy-2-propyl moiety by the condensed dihydropyran ring and is favorable entropically to the intramolecular hydrogen bond formation, causing the larger $\varepsilon_b/\varepsilon_f$. Introduction of the 3-methyl group onto the hydrogen bonded molecule as in **19** prevents the antiperiplanar conformation favorable for the hydrogen bonding. Thus, the $-\Delta H$ and $\varepsilon_b/\varepsilon_f$ values of **19** are considerably lower than the corresponding quantities of **8** due to the increase in steric energy and the restriction of the conformation in the hydrogen bonded conformer. In contrast, the $\Delta\nu_{OH}$ increases remarkably because the OH···O distance becomes closer due to the buttresing effect caused by the 3-methyl group. Thus, it is probable that the intramolecular hydrogen bonds can be persistent even in cases when the alkoxyl group is not coplanar to the chelate ring formed by the hydrogen bonding. Similar tendency has been observed with the hydrogen bond chelates containing carboxyl groups as hydrogen donors.[12] The ethereal oxygen atom can interact with hydroxyl and other hydrogen donating groups in various conformations because it has two pairs of unshared electrons. The alcohol **19** has a low frequency ν_f band locating at 3607 cm^{-1}. Since the 3-methyl group in **19** enforces the methoxyl group to take nonplanar conformation and to approach nearer to the 2-hydroxy-2-propyl moiety, the most favorable conformation of the free species tends to have a nonplanar hydroxyl group favorable to interact with the aromatic π-electrons (just illustrated schematically by VIII).



VIII

Estimation of the Most Stable Conformations by Molecular Force Field Approach. The probable conformations of these alcohols were then discussed on the basis of the molecular force field calculations carried out by use of the MMI version of the computer program developed by Allinger and co-workers.[7] As the force field involving hydrogen bond system has not yet been available, the calculations were carried out on benzyl alcohol and its α-substituted derivatives void of methoxyl group. The results are given in Table 4. Here, in this Table, the torsional angle ω refers to the dihedral angle between the aromatic ring and the hydroxyl group (as illustrated in IX—XII). The



ω = 0° 30° 60° 90°

IX X XI XII

results show that the most stable conformation of α-monoalkylbenzyl alcohols are X in which ω is around 30° and that those of α,α-dialkylbenzyl alcohols are IX with $\omega=0°$.[13] The optimized torsional angles were calculated to be 31.3°, 32.2°, 33.1°, and 34.4° for the most stable conformers of α-methyl, α-ethyl, α-isopropyl, and α-*t*-butylbenzyl alcohols, respectively.

As expected from the repulsive force operating between the alkyl and the hydroxyl groups, the torsional angles increase in the same order. Since the methoxyl group on the aromatic ring is ignored in calculations, the results should be applied on the methoxy alcohols **3**—**14** with care. Nevertheless the hydrogen bonded conformations might be rather properly estimated since the methoxyl group lies far from the alkyl group(s).

The results which conclude the conformation X of **4**—**7** with non-coplanar hydroxyl group to be the most stable coincide with the fact that the hydrogen bonded conformers of these alcohols are less favorable than those of the α,α-dialkylbenzyl alcohols as revealed by both the $\varepsilon_b/\varepsilon_f$ and the ΔH values in Table 3. The OH···O distance might become farther and, moreover, the overlap between the unshared electron pairs and the anti-bonding OH orbital might be less in conformation X than in conformation IX. The OH proton signals of **4**—**7** have shown to appear at higher fields than those of the corresponding dialkylbenzyl alcohols. This can be ascribed to the magnetic anisotropy effect on the hydroxyl protons lying above the aromatic rings to induce the high field shifts.

The introduction of α-alkyl groups causes considerable C_α–C_{ipso} bond stretching and O–C_α–C_{ipso} bond angle decrease but little C_α–C_{ipso}–C_2 bond angle alteration. As a result, the estimated distance between the hydroxyl and the methoxyl oxygen atoms decreases from 2.34 to 2.14 Å when the two benzylic hydrogen atoms are replaced with *t*-butyl groups.[14] This explains the $\Delta\nu_{OH}$ increase caused by the introduction of α,α-dialkyl groups. The consequences from the calculations on α,α-di-*t*-butylbenzyl alcohol (**20**) agrees with the fact that the protons at 2- and 6-positions of **20** are not isochronous because of the very high rotational barrier around C_{ipso}–C_{benzyl} bond.[2,3] The conformation IX which is estimated to be the most stable explains the unisochronous ^{1}H-NMR spectrum of **20** together with the rotational barrier supposed to be a little higher than 110 kJ/mol. The extended conformation IV of **9** was also confirmed by the calculation giving the torsional angle near 180° (177.1 and 177.9° exactly) for both of the C_α–$CH_2(CH_3)$ bonds.

We wish to thank Prof. Eiji Osawa, Hokkaido University, for his valuable advice and kind permission to use their MMI program. We are also grateful to Prof. Hiizu Iwamura, the Institute of Molecular Sciences, for his valuable advice and facilitation in using the HITAC M-200H computer. The molecular force field calculations were carried out by using a HITAC 8800/8700 computer of the University of Tokyo and a HITAC M-200H computer of the Institute of Molecular Sciences.

13) It cannot be deduced straightforwardly from this conclusion that the OH···π interacted conformer is unfavorable in α,α-dialkylbenzyl alcohols. The OH..π interacted conformation is known to be rather flexible, the torsional angle varying in a considerably wide range. As the torsional barriers of benzyl alcohol and its α-methyl-substituted derivatives are rather low, the interacted conformer may become the most stable owing to the additional stabilization due to attractive OH···π interaction.

14) The OH···O(CH_3) distance was calculated by assuming that the coordinates of *ortho*-methoxyl group is exactly the same as those of anisole. Similar calculations on α,α-dimethyl, α,α-diethyl, and α,α-diisopropyl derivatives gave 2.28, 2.28, and 2.23 Å (=10^{-1} nm), respectively, as O···O distances.

Structure and Synthesis of (+)-Shonanol

Takashi MATSUMOTO,* Sachihiko IMAI, Hiroyuki KAWASHIMA, and Masanori MITSUKI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received November 17, 1980)

The structure of shonanol was restudied and found to be 12-hydroxyabieta-2,8,11,13-tetraen-1-one (**1**) by the following synthesis. A Grignard reaction of methyl (+)-12-methoxyabieta-8,11,13-trien-18-oate with phenylmagnesium bromide, followed by treatment with lead tetraacetate and calcium carbonate afforded a mixture of Δ^3-, Δ^4-, and $\Delta^{4(18)}$-19-nor compounds. This was oxidized with selenium dioxide to give (+)-12-methoxy-19-norabieta-4(18),8,11,13-tetraen-3α-ol. This alcohol was converted to (+)-12-methoxyabieta-5,8,11,13-tetraen-3-one (**6**) by the known procedure. Reduction of **6** with lithium aluminium hydride, followed by catalytic hydrogenation, yielded (+)-12-methoxyabieta-8,11,13-trien-3β-ol (**8**) and a small amount of its *cis* isomer. The compound (**8**) was then converted to (+)-12-methoxyabieta-1,8,11,13-tetraen-3-one (**12**) by a series of reactions: oxidation with pyridinium chlorochromate, bromination with pyridinium tribromide, and dehydrobromination with lithium carbonate and lithium bromide. Demethylation of **12** with boron tribromide gave (+)-12-hydroxyabieta-1,8,11,13-tetraen-3-one. Oxidation of **12** with alkaline hydrogen peroxide, followed by treatment with hydrazine hydrate, gave (+)-12-methoxyabieta-2,8,11,13-tetraen-1α-ol; this was oxidized with Jones reagent to give the corresponding 1-oxo compound. The 1-oxo compound was finally demethylated with boron tribromide to yield (+)-**1**, whose spectra were identical with those of natural shonanol.

The structure of shonanol, a tricyclic diterpene phenol isolated from the sawdust of *Libocedrus formosana* by Lin and Liu[1] in 1965, has been tentatively assigned as 12-hydroxytotara-1,8,11,13-tetraen-3-one (I) on the basis of spectroscopic studies. To confirm this structure we synthesized (±)-I in our laboratory.[2] However, this synthetic (±)-I was shown to be different from natural shonanol by spectral comparison. Further synthetic studies on the structural isomers[3,4] possessing a hydroxyl group at the position meta to an isopropyl group in the C ring: (±)-12-hydroxytotara-2,8,11,13-tetraen-1-one (II), (±)-14-hydroxy-12-isopropylpodocarpa-1,8,11,13-tetraen-3-one (III), (±)-14-hydroxy-12-isopropylpodocarpa-2,8,11,13-tetraen-1-one (IV), (+)-11-hydroxyabieta-1,8,11,13-tetraen-3-one (V), and (+)-11-hydroxyabieta-2,8,11,13-tetraen-1-one (VI), led to the same result, whereas the spectral analyses of these synthetic materials I—VI and natural shonanol suggested that the structure of shonanol is 12-hydroxyabieta-2,8,11,13-tetraen-1-one (**1**).[4] To confirm the validity of our proposed structure, we now attempted the synthesis of **1**. This paper will describe the structural confirmation of natural shonanol by the synthesis of (+)-**1** starting from methyl (+)-12-methoxyabieta-8,11,13-trien-18-oate (**2**).[5,6]

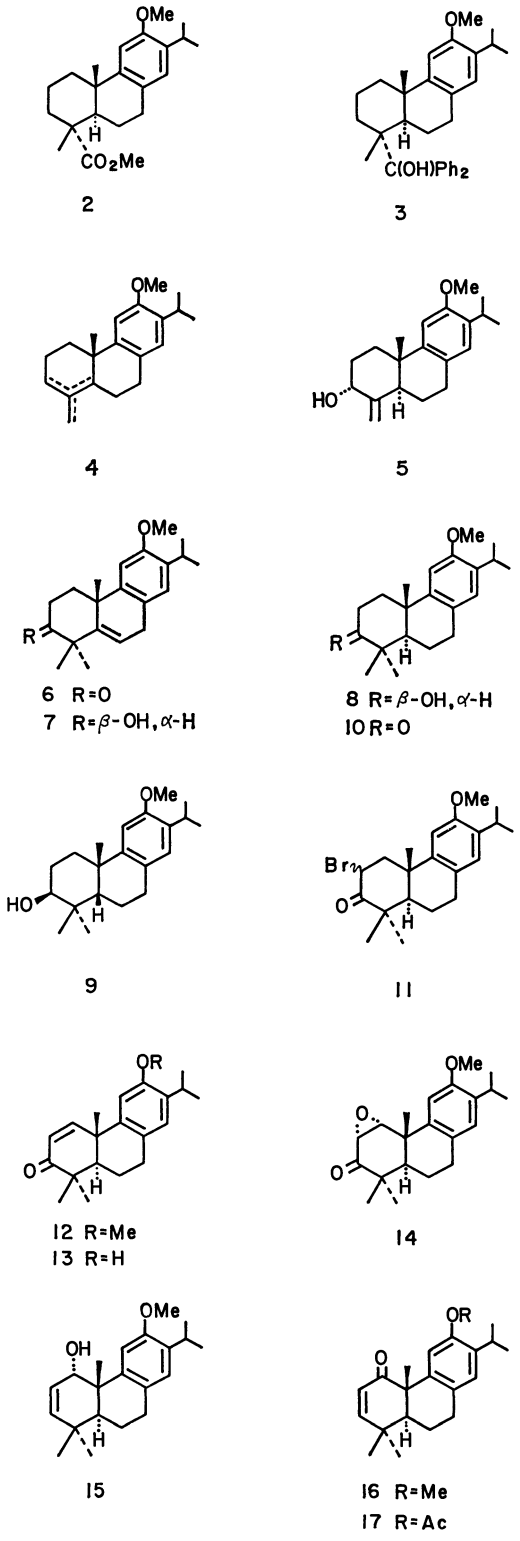
I

The Grignard reaction of **2** with phenylmagnesium bromide at 95—100 °C afforded a diphenylmethanol derivative (**3**: 80%). This was treated with lead tetraacetate and calcium carbonate in refluxing benzene to give a mixture (**4**: 78%) of Δ^3-, Δ^4-, and $\Delta^{4(18)}$-19-nor compounds in a ratio of *ca.* 1:2:7. The mixture was then oxidized with selenium dioxide in refluxing aqueous ethanol to yield (+)-12-methoxy-19-norabieta-4(18), 8,11,13-tetraen-3α-ol (**5**: 51%).[7,8] This alcohol (**5**) was subsequently converted to (+)-12-methoxyabieta-5,8,11,13-tetraen-3-one (**6**) by a series of known procedures:[7] isomerization with lithium in ethylenediamine to 12-methoxy-19-norabieta-4,8,11,13-tetraen-3α-ol, Jones oxidation, and methylation with methyl iodide in the presence of potassium *t*-butoxide. Reduction of **6** with lithium aluminium hydride in ether afforded (−)-12-methoxyabieta-5,8,11,13-tetraen-3β-ol (**7**: 90%), which was submitted to catalytic hydrogenation over 5% Pd–C in methanol to yield (+)-12-methoxyabieta-8,11,13-trien-3β-ol (**8**: 68%)[9,10] as a major product and its *cis* isomer (**9**: 11%) as a minor one. The stereochemistry of the hydroxyl group at the C-3 position in **7**, which was expected to be β-configuration from many literature precedents,[2,3,10,11] was confirmed by the conversion to the known compound (**8**).[9,10] The *cis*-configuration of the A/B ring junction in **9** was supported by the appearance of a signal due to one of the *gem*-dimethyl groups at the C-4 position in very high field (δ 0.42 ppm) owing to the shielding effect of the aromatic C ring. The β-configuration of the hydroxyl group at the C-3 position was also supported by a signal at δ 3.22 ppm with half-height width of 9 Hz, suggesting the presence



of an equatorial α hydrogen. Oxidation of the *trans*-compound (**8**) with pyridinium chlorochromate in dichloromethane afforded (+)-12-methoxyabieta-8,11,13-trien-3-one (**10**: 73%).[7,9,10] On bromination with pyridinium tribromide in ethanol and chloroform, this was converted to a mixture of the epimeric 2-bromo derivatives (**11**: 69%). The mixture (**11**), without purification, was immediately treated with lithium carbonate and lithium bromide in *N*,*N*-dimethylformamide at 120—125 °C to produce (+)-12-methoxyabieta-1,8,11,13-tetraen-3-one (**12**: 63%), which was demethylated with boron tribromide in dichloromethane to give (+)-12-hydroxyabieta-1,8,11,13-tetraen-3-one (**13**: 82%).[12] The physical and spectral data of **13** were different from those of natural shonanol.

Subsequently, 1,3-carbonyl transposition[3,4,13] of the α,β-unsaturated carbonyl group in **12** was carried out as follows. Oxidation of **12** with alkaline hydrogen peroxide in methanol and dichloromethane at −10—−5 °C, followed by treatment of the resulting epoxy ketone (**14**)[14] with hydrazine hydrate in refluxing methanol containing a small amount of acetic acid, yielded (+)-12-methoxyabieta-2,8,11,13-tetraen-1α-ol (**15**: 49% from **12**). This alcohol (**15**) was then oxidized with Jones reagent. The resulting (+)-12-methoxyabieta-2,8,11,13-tetraen-1-one (**16**: 78%) was demethylated with boron tribromide to give (+)-12-hydroxyabieta-2,8,11,13-tetraen-1-one (**1**: 74%), whose melting point and spectra (IR and ^{1}H NMR) were identical with those of natural shonanol. The synthetic **1** was further characterized as its acetate (**17**).

From the present study, the structure of shonanol was conclusively assigned as **1**.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, t: triplet, m: multiplet. Column chromatography was performed using Merck silica gel (0.063 mm).

Grignard Reaction of Methyl 12-Methoxyabieta-8,11,13-trien-18-oate (2) with Phenylmagnesium Bromide. A solution of **2**[5,6] (43.985 g) in dry ether (90 ml) was added to a refluxing ethereal solution of phenylmagnesium bromide prepared from magnesium turnings (12.4 g) and bromobenzene (80.2 g) in dry ether (180 ml). The mixture was refluxed for 1 h, the ether was removed, and the viscous residue was heated at 95—100 °C for 8 h. After standing overnight at room temperature, the mass was carefully hydrolyzed with a mixture of dilute hydrochloric acid and ice, and then extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated. The residue was recrystallized from acetone–hexane to give a diphenylmethanol derivative (**3**) (34.796 g), mp 205—207.5 °C, $[\alpha]_D$ +97.4° (*c* 2.73), IR: 3591 cm^{-1}; NMR: 1.10 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.22 and 1.34 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 2.33 (1H, s, –OH, disappeared on deuteration), 3.14 (1H, m, $-C\underline{H}(CH_3)_2$), 3.69 (3H, s, $-OCH_3$), 6.53 (2H, s, C_{11}–H and C_{14}–H), 7.0—7.9 (10H, m, 2-C_6H_5). Found: C, 84.79; H, 8.86%. Calcd for $C_{33}H_{40}O_2$: C, 84.57; H, 8.60%.

The mother liquor of recrystallization was evaporated *in vacuo* and the residue was purified by column chromatography on silica gel (300 g), using hexane–benzene (6:4 and then 4:6) as the eluent, to give an additional alcohol (**3**: 10.047 g).

Fragmentation of 3 with Lead Tetraacetate. A solution of **3** (18.383 g) in dry benzene (100 ml) was added to a stirred suspension of 87% lead tetraacetate (24.0 g) and

calcium carbonate (23.5 g) in dry benzene (150 ml). The mixture was refluxed for 8 h, cooled, and then filtered. The filtrate was diluted with ether and the solution was washed successively with 10% aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo* and the residue was purified by column chromatography on silica gel (200 g), using hexane as the eluent, to give a mixture of Δ^3-, Δ^4-, and $\Delta^{4(18)}$-19-nor compounds (**4**) (8.654 g: 77.6%). The NMR spectrum of the mixture indicated that it was composed of approximately 7% of Δ^3- (δ 1.02 ppm, C_{10}–CH_3; 5.38 ppm, C_3–H), 21% of Δ^4- (δ 1.36 ppm, C_{10}–CH_3), and 72% of $\Delta^{4(18)}$-19-nor compound (δ 0.99 ppm, C_{10}–CH_3; 4.57 and 4.81 ppm, CH_2=C–).

*12-Methoxy-19-norabieta-4(18),8,11,13-tetraen-3α-ol (**5**).* A solution of selenium dioxide (1.494 g) in ethanol (48 ml) and water (2.0 ml) was added dropwise to a stirred suspension of **4** (7.661 g) in ethanol (50 ml). The mixture was refluxed for 4 h, cooled, and then filtered. The filtrate was diluted with chloroform, evaporated *in vacuo*, and the residue was chromatographed on aluminium oxide (Merck activ. II—III: 150 g), using ether–benzene (1:9 and then 4:6) as the eluent, to give **5**[7,8] (4.097 g: 50.6%) which was recrystallized from hexane, mp 59—61 °C, $[\alpha]_D$ +159° (*c* 5.80); IR: 3610, 3415 cm^{-1}; NMR: 0.91 (3H, s, C_{10}–CH_3), 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.58 (1H, s, –OH, disappeared on deuteration), 3.22 (1H, m, $-C\underline{H}(CH_3)_2$), 3.73 (3H, s, $-OCH_3$), 4.17 (1H, bs, $W_{1/2}$=5 Hz, C_3–H), 4.60 and 4.92 (each 1H and bs, CH_2=C–), 6.63 and 6.77 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.86; H, 9.55%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

*12-Methoxyabieta-5,8,11,13-tetraen-3-one (**6**).* The 3α-ol (**5**) was converted to **6** by the known procedure.[7] The crude product was purified by column chromatography on silica gel, using ether–benzene (1.5:98.5) as the eluent, to give **6** which was recrystallized from hexane, mp 92.5—93.5 °C, $[\alpha]_D$ +41.3° (*c* 3.25), IR: 1705 cm^{-1}; NMR: 1.18 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.18, 1.24, and 1.32 (each 3H and s, $-C(CH_3)_2$ and C_{10}–CH_3), 3.32 (2H, d, J=4 Hz, $=CHC\underline{H}_2$–), 3.78 (3H, s, $-OCH_3$), 5.90 (1H, t, J=4 Hz, C_6–H), 6.72 and 6.85 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 80.77; H, 9.14%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

*12-Methoxyabieta-5,8,11,13-tetraen-3β-ol (**7**).* A mixture of **6** (502 mg) and lithium aluminium hydride (61 mg) in dry ether (15 ml) was stirred at room temperature for 80 min, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was purified by column chromatography on silica gel (15 g), using ether–benzene (2:98) as the eluent, to give **7** (457 mg: 90.5%), which was recrystallized from hexane, mp 69—71 °C, $[\alpha]_D$ −53.5° (*c* 3.10); IR: 3616, 3454 cm^{-1}, NMR: 1.13, 1.21, and 1.28 (each 3H and s, $-C(CH_3)_2$ and C_{10}–CH_3), 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.17 (1H, s, –OH, disappeared on deuteration), 3.26 (2H, d, J=4 Hz, $=CHC\underline{H}_2$–), 3.75 (3H, s, $-OCH_3$), 5.97 (1H, t, J=4 Hz, C_6–H), 6.68 and 6.80 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.92; H, 9.91%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

*Catalytic Hydrogenation of **7**.* A mixture of **7** (456 mg) and 5% Pd–C (450 mg) in methanol (10 ml) was subjected to catalytic hydrogenation at room temperature for *ca.* 24 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (40 g), using ether–benzene (1:99) as the eluent, to give 12-methoxy-5β*H*-abieta-8,11,13-trien-3β-ol (**9**) (51 mg: 11.1%) $[\alpha]_D$ +41.2° (*c* 1.68); IR: 3630, 3455 cm^{-1}; NMR: 0.42, 0.99, and 1.18 (each 3H and s, $-C(CH_3)_2$ and C_{10}–CH_3), 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.60 (1H, s, –OH, disappeared on deuteration), 3.22 (1H, m, $W_{1/2}$=9 Hz, C_3–H), 3.75 (3H, s, $-OCH_3$), 6.67 and 6.70 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.42; H, 10.33%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

Further elution with ether–benzene (5:95) afforded 12-methoxyabieta-8,11,13-trien-3β-ol (**8**)[9,10] (314 mg: 68.4%) which was recrystallized from hexane, mp 104—105 °C (softened at *ca.* 95 °C), $[\alpha]_D$ +60.7° (*c* 2.39); IR: 3625, 3455 cm^{-1}; NMR: 0.85, 1.04, and 1.19 (each 3H and s, $-C(CH_3)_2$ and C_{10}–CH_3), 1.16 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.95 (1H, s, –OH, disappeared on deuteration), 3.20 (1H, m, $W_{1/2}$=15 Hz, C_3–H), 3.74 (3H, s, $-OCH_3$), 6.58 and 6.72 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.94; H, 10.30%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

*12-Methoxyabieta-8,11,13-trien-3-one (**10**).* Pyridinium chlorochromate (2.74 g) was added at 0—5 °C to a stirred solution of **8** (2.649 g) in dry dichloromethane (30 ml) over a 5 min period. The mixture was stirred at room temperature for 2 more hours and then diluted with ether. After the addition of water, the mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (80 g), using ether–benzene (1:99) as the eluent, to give **10** (1.911 g: 72.6%), whose IR and NMR spectra were identical with those of authentic hinokione methyl ether.[10]

*12-Methoxyabieta-1,8,11,13-tetraen-3-one (**12**).* A mixture of **10** (1.295 g) and 80% pyridinium tribromide (1.482 g) in ethanol (13.3 ml) and chloroform (26.6 ml) was stirred at room temperature for 30 min. After the addition of aqueous sodium thiosulfate, the mixture was extracted with ether. The ether extract was washed with dilute hydrochloric acid and brine, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was chromatographed on silica gel (100 g), using hexane–benzene (1:1) as the eluent, to give a mixture of epimeric 2-bromo derivatives (**11**) (1.115 g: 68.9%), which was immediately submitted to dehydrobromination.

A mixture of **11** (1.009 g), lithium carbonate (570 mg), and lithium bromide (446 mg) in *N*,*N*-dimethylformamide (16 ml) was stirred at 120—125 °C for 3 h in a stream of nitrogen. The reaction mixture was cooled, poured into dilute sulfuric acid, and extracted with ether. The ether extract was washed with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (30 g), using benzene as the eluent, to give **12** (505 mg: 62.9%), which was recrystallized from hexane, mp 145.5—146.5 °C, $[\alpha]_D$ +158° (*c* 0.505), IR: 1665 cm^{-1}; NMR: 1.14, 1.17, and 1.39 (each 3H and s, $-C(CH_3)_2$ and C_{10}–CH_3), 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.19 (1H, m, $-C\underline{H}(CH_3)_2$), 3.73 (3H, s, $-OCH_3$), 5.89 (1H, d, J=10 Hz, C_2–H), 6.72 and 6.77 (each 1H and s, C_{11}–H and C_{14}–H), 7.46 (1H, d, J=10 Hz, C_1–H). Found: C, 80.70; H, 9.16%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

*12-Hydroxyabieta-1,8,11,13-tetraen-3-one (**13**).* A solution of **12** (58.4 mg) and boron tribromide (0.05 ml) in dichloromethane (1.5 ml) was allowed to stand at 0—5 °C for 30 min, poured into a mixture of ice and water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and water, dried over sodium sulfate, and then evaporated *in vacuo*. The

crude product was chromatographed on silica gel (3.0 g), using ether–benzene (3:97) as the eluent, to give **13** (45.9 mg: 82.3%), which was recrystallized from acetone–hexane, mp 175.5—176.5 °C, $[\alpha]_D$ +162° (*c* 0.500, EtOH) (lit,[12] mp 175—178 °C, $[\alpha]_D$ +163° (EtOH)); IR: 3607, 3357, 1665 cm^{-1}; NMR (90 MHz): 1.16, 1.18, and 1.36 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}–CH_3), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.15 (1H, m, $-C\underline{H}(CH_3)_2$), 5.73 (1H, s, –OH), 5.94 (1H, d, J=10 Hz, C_2–H), 6.69 and 6.78 (each 1H and s, C_{11}–H and C_{14}–H), 7.43 (1H, d, J=10 Hz, C_1–H). Found: C, 80.21; H, 8.92%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

*12-Methoxyabieta-2,8,11,13-tetraen-1α-ol (**15**).* A solution of **12** (500 mg) in methanol (75 ml) and dichloromethane (25 ml) was cooled to −15 °C and over *ca.* 6 min was added dropwise 30% hydrogen peroxide (0.92 ml), followed by 10% aqueous sodium hydroxide (3.24 ml), in a stream of nitrogen. The solution was stirred at −10——5 °C for 2 h, poured into water (50 ml), and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated to give the corresponding epoxy ketone (**14**) (525 mg).

A solution of the crude epoxy ketone (**14**: 140 mg) in methanol (10 ml) was cooled to 0 °C in a stream of nitrogen and a mixture of hydrazine hydrate (0.65 ml) and acetic acid (0.13 ml) was added dropwise over a 3 min period. The reaction mixture was stirred at 0—5 °C for an additional 15 min, at room temperature for 15 min, and then refluxed for 13.5 h. After the methanol had been evaporated *in vacuo*, the residue was extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was chromatographed on silica gel (10 g), using ether–benzene (1:99) as the eluent, to give **15** (65.6 mg: 48.9% from **12**) as an oil, $[\alpha]_D$ +251° (*c* 3.49), IR: 3550 cm^{-1}; NMR: 0.98, 1.08, and 1.17 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}–CH_3), 1.19) (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.41 (1H, s, –OH, disappeared on deuteration), 3.21 (1H, m, $-C\underline{H}(CH_3)_2$), 3.78 (3H, s, $-OCH_3$), 4.23 (1H, d, J=5 Hz, C_1–H), 5.64 (2H, m, C_2–H and C_3–H), 6.59 and 6.77 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 80.16; H, 9.90%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

*12-Methoxyabieta-2,8,11,13-tetraen-1-one (**16**).* A solution of **15** (170 mg) in acetone (3.0 ml) was oxidized at −12——6 °C for 5 min with Jones reagent (2.5 M: 0.2 ml) and then diluted with ether. The ether solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (10 g), using benzene as the eluent, to give **16** (133 mg: 78.2%), which was recrystallized from hexane, mp 106.5—107 °C, $[\alpha]_D$ +333° (*c* 4.60), IR: 1677 cm^{-1}; NMR: 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.19 (6H, s, $-\dot{C}(CH_3)_2$), 1.47 (3H, s, C_{10}–CH_3), 3.21 (1H, m, $-C\underline{H}(CH_3)_2$), 3.74 (3H, s, $-OCH_3$), 5.78 (1H, d, J=10 Hz, C_3–H), 6.38 (1H, d, J=10 Hz, C_2–H), 6.66 and 7.22 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 80.77; H, 9.13%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

*12-Hydroxyabieta-2,8,11,13-tetraen-1-one (Shonanol) (**1**).* A solution of **16** (108.2 mg) and boron tribromide (0.10 ml) in dichloromethane (3.0 ml) was allowed to stand at 0—5 °C for 1 h. After the same work-up as described for the preparation of **13**, the crude product was chromatographed on silica gel (10 g), using ether–benzene (1:99 and then 3:97) as the eluent, to give **1** (76.9 mg: 74.4%) which was recrystallized from ether–hexane, mp 188—189 °C, $[\alpha]_D$ +326° (*c* 0.500, EtOH) (natural shonanol,[1] mp 187—188 °C, $[\alpha]_D$ +3.01 (EtOH)[15]); IR (KBr): 3375, 2960, 1670, 1618, 1515, 1470, 1425, 1376, 1362, 1265, 1205, 1177, 1053, 1020, 947, 883, 825, 816, 750, 715 cm^{-1}; NMR (90 MHz): 1.16 and 1.18 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.19 (6H, s, $-\dot{C}(CH_3)_2$), 1.49 (3H, s, C_{10}–CH_3), 3.18 (1H, m, $-C\underline{H}(CH_3)_2$), 5.95 (1H, d, J=10 Hz, C_3–H), 6.50 (1H, d, J=10 Hz, C_2–H), 6.67 (1H, s, C_{14}–H), 6.74 (1H, s, C_{12}–OH, disappeared on deuteration), 7.33 (1H, s, C_{11}–H). Found: C, 80.42; H, 8.91%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%. The IR and NMR spectra of the synthetic **1** were identical with those of natural shonanol.

*12-Acetoxyabieta-2,8,11,13-tetraen-1-one (**17**).* A solution of **1** (39.4 mg) and acetic anhydride (0.3 ml) in pyridine (1.0 ml) was heated at 80—85 °C for 1.5 h. After the usual work-up, the crude product was chromatographed on silica gel (5.0 g), using ether–benzene (1:99) as the eluent, to give **17** (37.0 mg: 82.3%) as an oil, $[\alpha]_D$ +295° (*c* 0.285); IR: 1752, 1678 cm^{-1}; NMR (90 MHz): 1.17 (6H, s, $-\dot{C}(CH_3)_2$), 1.18 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.47 (3H, s, C_{10}–CH_3), 2.25 (3H, s, $-OCOCH_3$), 5.80 (1H, d, J=10 Hz, C_3–H), 6.40 (1H, d, J=10 Hz, C_2–H), 6.82 (1H, s, C_{14}–H), 7.31 (1H, s, C_{11}–H). Found: C, 77.71; H, 8.48%. Calcd for $C_{22}H_{28}O_3$: C, 77.61; H, 8.29%.

The authors are grateful to Arakawa Chemical Co. Ltd. for a generous gift of rosin. Thanks are also due to Professor Y. T. Lin for kindly supplying the spectral data of natural shonanol.

Improvement of Furan Yield in Oxidation of Crotonaldehyde by Modifying 12-Molybdophosphoric Acid Catalysts

Tian-hsi Tsai, Mamoru Ai,* and Atsumu Ozaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received December 1, 1980)

12-Molybdophosphoric acid effective for oxidation of crotonaldehyde to furan was modified in two ways; by adding various cations and by replacing Mo with V or W. Among cations caesium was proved to be most effective in improving the furan yield, by decreasing reactivity of product furan relative to crotonaldehyde, thus minimizing the secondary oxidation of furan to maleic anhydride. The highest efficiency of caesium is associated with its high basicity, while the active catalyst species responsible for the furan formation is acidic in nature. The replacement of Mo by V or W gave rise to decreased activity, in contrast to other oxidations on the same catalyst. The unique character of crotonaldehyde oxidation is discussed.

It is known that acrylaldehyde and methacrylaldehyde are oxidized to acrylic acid and methacrylic acid, respectively, over V_2O_5- or MoO_3-based catalysts, while crotonaldehyde is oxidized to furan, instead of crotonic acid on the same catalyst.[1] Recently, it was found that heteropoly compounds such as 12-molybdophosphoric acid are effective as catalyst for the furan formation from crotonaldehyde and that an acidic caesium salt of 12-molybdophosphoric acid gives a higher yield than the 12-molybdophosphoric acid.[2]

It would be of interest to see how the yield of furan is affected by modification of the 12-molybdophosphoric acid catalyst. The present paper deals with the effect of partial relpacement of the catalyst protons by various cations and that of the catalyst molybdenum by vanadium or tungsten on the catalytic performance.

Experimental

Catalysts. Two series of supported heteropoly compounds were used: (i) The first series of catalysts are represented by a general equation of $M_{x/n}H_{3-x}PMo_{12}O_{40}$ where M represent an n valent cation and $O \leqslant x \leqslant 3$ is the extent of proton replacement. The cation M was introduced by adding carbonate (alkali, Ag, and Ba), acetate (Mn, Co, Cu, and Ni), or nitrate (Fe and Bi) to aqueous solution of $H_3PMo_{12}O_{40}$ followed by deposition on pumice by evaporation to dryness. Other procedures were the same as previously reported.[2] (ii) The second series of catalysts are $H_3PMo_6W_6O_{40}$, $H_4PMo_{11}VO_{40}$, and $H_5PMo_{10}V_2O_{40}$. The $H_3PMo_6W_6O_{40}$ catalyst was prepared by mixing aqueous solutions of $H_3PMo_{12}O_{40}$ and $H_3PW_{12}O_{40}$ (Kanto Chemical Co. Inc.). $H_5PMo_{10}V_2O_{40}$ was synthesized following a procedure reported by Tsigdinos.[3] The $H_4PMo_{11}VO_{40}$ catalyst was prepared by mixing aqueous solutions of $H_5PMo_{10}V_2O_{40}$ and $H_3PMo_{12}O_{40}$. Other procedures were the same as those for the series (i).

Reaction Procedures. The vapor-phase oxidation of crotonaldehyde was carried out in an ordinary continuous-flow system. The reactor and the experimental procedures were the same as those employed in the preceding work.[2]

Results

Effect of Cs^+. The oxidation of crotonaldehyde was carried out over a series of $Cs_xH_{3-x}PMo_{12}O_{40}$ catalysts with $x=0$, 0.5, 1.0, 1.5, and 2.0 (amount of catalyst used=20 g), using a fixed concentration of reaction mixture: $C_4H_6O/O_2/H_2O/N_2=1.66/6.6/7.6/84.1$ mol% and a total flow rate of 1.0 l/min. Variation of furan yield with reaction temperature are shown for the Cs-exchanged catalysts in Fig. 1. The catalytic activity to give furan clearly decreases with increase in the caesium content at a fixed temperature, while the maximum yield of furan attained at a different temperatures increases with increase in caesium content up to $x=1.0$, and remains constant at about 40 mol% in the range of $x=1$ to 2.

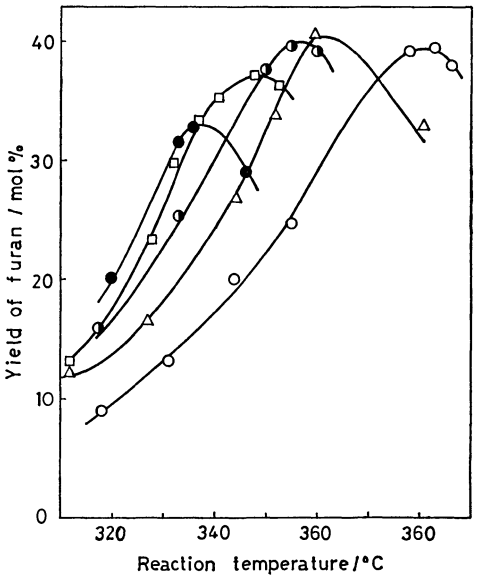

Fig. 1. Variation of furan yield with reaction temperature.
Catalysts=$Cs_xH_{3-x}PMo_{12}O_{40}$. Caesium content($x$): (●)=0, (□)=0.5, (◑)=1.0, (△)=1.5, (○)=2.0.

The yield of furan is plotted as a function of the overall conversion of crotonaldehyde in Fig. 2. The furan yield increases with increase in the conversion and passes a maximum. The conversion of crotonaldehyde to give the maximum yield of furan increases from 83 to 92% with the addition of caesium up to $x=1.0$ and remains almost constant at 92 to 95% in the range of $X=1.0$ to 2.0. As demonstrated in the preceding papers the product furan is consecutively oxidized to maleic anhydride on the heteropoly-acid catalyst so that the maximum yield of furan is determined by reactivity of furan relative to crotonaldehyde

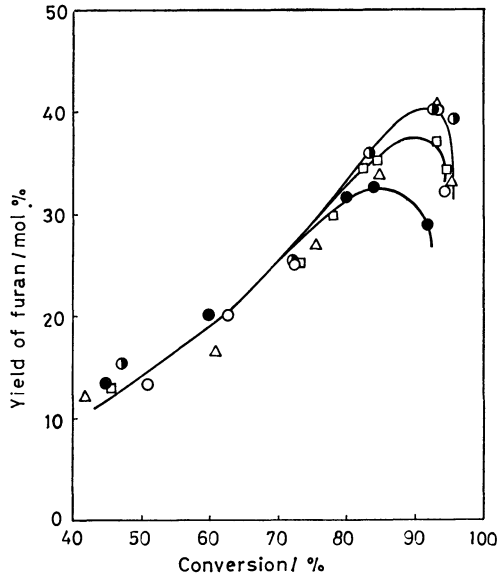

Fig. 2. Yield of furan as a function of the overall conversion of crotonaldehyde.
Catalysts=$Cs_xH_{3-x}PMo_{12}O_{40}$. Casesium content($x$): (●)=0, (□)=0.5, (◑)=1.0, (△)=1.5, (○)=2.0.

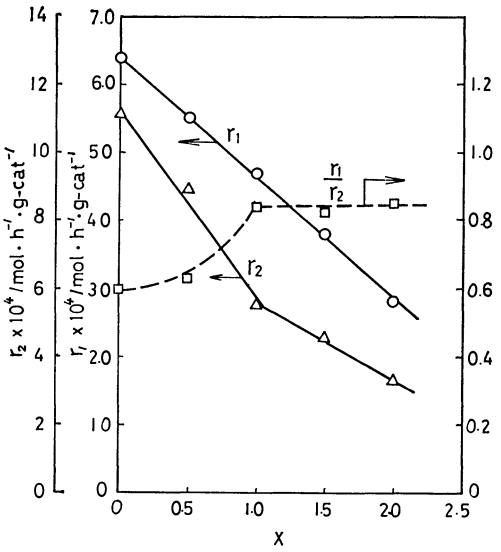

Fig. 3. Effect of the caesium content on the rate of furan formation and that of furan consumption. r_1=Rate of furan formation from crotonaldehyde, r_2=rate of furan consumption, catalysts=$Cs_xH_{3-x}PMo_{12}O_{40}$.

on the catalyst. The observed increase in the maximum yield of furan suggests that the reactivity ratio of furan to crotonaldehyde decreases with the caesium addition up to $x=1.0$.

In order to examine the relative reactivity of furan, initial rate of furan formation from crotonaldehyde (concentration=1.66 mol%), r_1, and that of furan consumption (concentration=0.96 mol%), r_2, were determined at 330 °C over the Cs-exchanged catalysts. The results are shown in Fig. 3. The ratio r_1/r_2 really increases with x up to $x=1.0$ and remains constant in the range of $x=1.0$ to 2.0 in agreement with the above suggestion.

The yield of furan, maleic anhydride, CO, and CO_2 obtained at a conversion of 85 to 90% are shown in Fig. 4 as a function of x. It is seen that the product distribution is much less affected by the caesium content up to $x=2.0$ than in the range $x>2$. It is clear that the x value should be kept below 2 to give higher yield of furan.

Effect of Univalent Cations. Analogous effect of other univalent cations was examined with Li^+, Na^+, K^+, Rb^+, and NH_4^+. Figure 5 shows variation of the maximum yield of furan as a function of x. The maximum yield was mostly attained at the aldehyde conversion of about 90 to 95%. It is seen that the maximum yield of furan generally increases with x

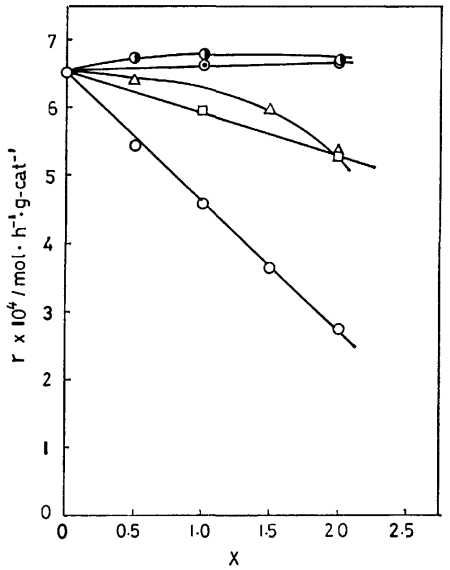

Fig. 6. Effect of the content of univalent cations on the rate of furan formation.
Temperature=330 °C. Catalysts=$M_xH_{3-x}PMo_{12}O_{40}$, (○)=Cs^+, (□)=K^+, (⊙)=Na^+, (◑)=Li^+, (△)=NH_4^+.

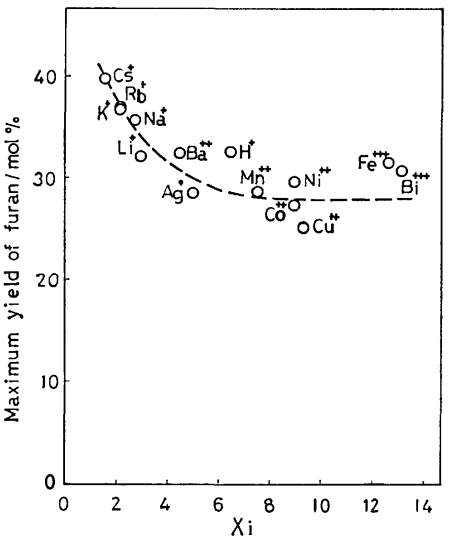

Fig. 7. Maximum yield of furan obtained with the $M_{2/n}HPMo_{12}O_{40}$ catalysts as a function of the electronegativity of metal cation, X_i.

value up to respective maximum, while the yield of furan at the maximum decreases in the order of $Cs^+ > NH_4^+ > Rb^+ > K^+ > Na^+$. It is clear that caesium is the most effective in improving the furan yield.

Thus, the effect of alkali substitution on the initial rate of furan formation was examined at 330 °C. As shown in Fig. 6 as a function of x value, the inhibitive effect of cation is largest with Cs^+, less marked with K^+ and NH_4^+, and nondetectable with Li^+ and Na^+. The large inhibitive effect of Cs^+ seems to be associated with the favorable results on Cs-catalyst.

Effect of Other Cations. Analogous effect of other cations was studied with Fe^{3+}, Bi^{3+}, Cu^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, Ba^{2+}, and Ag^+. No clear improvement in the oxidation activity was observed by the addition of

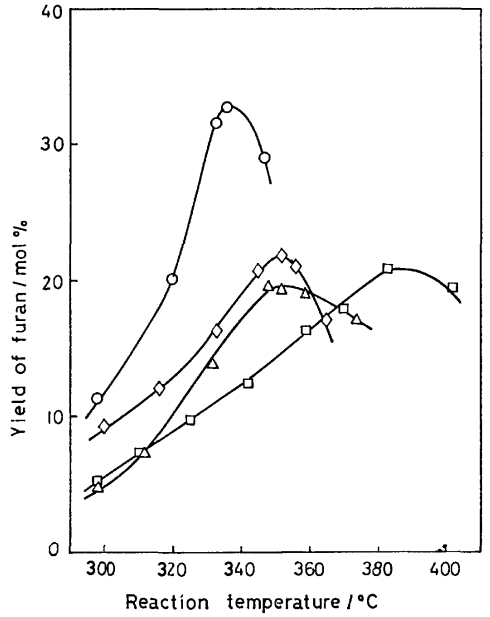

Fig. 8. Yield of furan obtained on $H_3PMo_{12}O_{40}$, $H_3PMo_6W_6O_{40}$, $H_4PMo_{11}VO_{40}$, and $H_5PMo_{10}V_2O_{40}$ catalysts.
(○)=$H_3PMo_{12}O_{40}$, (△)=$H_3PMo_6W_6O_{40}$, (◇)=$H_4PMo_{11}VO_{40}$, (□)=$H_5PMo_{10}V_2O_{40}$.

these cations up to $x=2$. Summarizing the effect of metal cations examined above, imporvement in furan yield is generally made by more basic elements. Thus, the maximum yield of furan obtained on the series (i) catalysts with $x=2$ are plotted against the electronegativity of metal cation, X_i, which can be regarded a parameter of acidity of cation. Although the reaction temperature to give the maximum yields were different from each other, it is apparent from Fig. 7 that the maximum furan yield decreases with increase in the acidity of metal cation added, in agreement with the above generalization.

Replacement of Mo Atom in $H_3PMo_{12}O_{40}$ by W or V. The oxidation of crotonaldehyde was carried out on the series (ii) catalysts under the same reaction conditions as adopted for the series (i) catalysts. The results obtained on $H_3PMo_6W_6O_{40}$, $H_4PMo_{11}VO_{40}$, and $H_5PMo_{10}V_2O_{40}$ catalysts are compared with those of $H_3PMo_{12}O_{40}$ catalyst in Fig. 8. It is clear that the replacement of Mo atom of $H_3PMo_{12}O_{40}$ by W or V results in decreases in the oxidation activity as well as in the maximum yield of furan.

Discussion

As demonstrated by the above results, the attainable furan yield in the oxidation of crotonaldehyde on the heteropoly acid catalysts is improved by adding basic element to the catalyst. Since complete replacement of the acidic proton results in loss of the catalytic activity, the improvement is likely caused by a partial neutralization of the acid. The result shown in Fig. 3 clearly demonstrated that the high furan yield is realized by increase in stability or decrease in reactivity of furan relative to crotonaldehyde on the catalyst surface. The reactivity decrease by the incorpora-

tion of caesium ion is associated with a decrease in acidity,[4] in conformity with the partial neutralization suggested above. The results shown in Fig. 7 suggest that the highest yield obtained with the Cs–HPA catalyst is ascribed to the highest basicity of caesium. Indeed other elements of less basicity are less efficient in reducing reactivity of crotonaldehyde as shown in Fig. 6.

On the other hand, the reactivity decrease caused by the incorporation of basic element indicates an active site acidic in nature. It is reported in the preceding paper that the rate of furan formation increases with partial pressure of water vapor.[2] In connection with this, it is known that enolization of crotonaldehyde requires water, *i.e.*[5]

$$CH_3\text{-}CH{=}CHCHO \overset{H^+,\ H_2O}{\rightleftharpoons} CH_3\text{-}\underset{OH}{CH}\text{-}CH{=}CHOH.$$

Since the trans-form predominates in crotonaldehyde, it is required to take a cis-form before cyclization to furan. The water-enhanced enolization would provide a chance for cyclization. Thus the water-promoted furan formation can be understood in terms of acid catalysis as suggested by the inhibitive effect of caesium. The enhancement of enolization would be another role of water in addition to the enhancement of furan desorption as suggested in the previous paper.[2]

The effect of caesium addition to heteropoly acid catalyst is also known with oxidation of methacrylaldehyde,[4] isobutyraldehyde,[6] butadiene,[7] and ethyl methyl ketone.[4] It is commonly observed that the catalytic activity increases with the caesium addition up to $x=2$, in a striking contrast to the present result. It is accordingly suggested that the nature of present oxidation of crotonaldehyde is quite different from others. Indeed, the oxidation of crotonaldehyde is unique in the kinetic behavior. The rate of furan formation is nearly zero order with respect to oxygen pressure,[2] whereas the rates of other oxidations are 0.5 to 1.0 order in oxygen.[4] This would be reasonable in view of the difference in the oxidation reaction to be undertaken. Methacryladehyde is oxidized to methacrylic acid, while crotonaldehyde is oxidized to furan, on the same catalyst. Since no furan formation was found in the oxidation of crotonic acid on the heteropoly-acid catalyst, crotonic acid cannot be the intermediate from crotonaldehyde to furan. Thus it is clear that the oxidation of crotonaldehyde is completely different from that of methacrylaldehyde although they are structural isomers. This difference in the nature of oxidation reaction should give rise to difference in the type of activation of reactant molecule.[4]

The last results shown in Fig. 8 may be understood on the ground of above concept. Partial replacement of Mo in $H_3PMo_{12}O_{40}$ with V is reported to enhance the oxidation of methacrylaldehyde[8] or isobutyraldehyde,[9] while it results in decrease in the activity to form furan from crotonaldehyde. It is likely that the replacement with V increases oxidizing activity which is essential for those oxidations, while modifies the acidic nature which is essential for the furan formation.

Stereospecific and Stereoselective Reactions. V.[1] Alkylation of Active Methylene Compounds by the Use of Alcohols, Diethyl Azodicarboxylate, and Triphenylphosphine[2]

Toshio KURIHARA, Masaru SUGIZAKI, Itaru KIME, Makoto WADA, and Oyo MITSUNOBU*

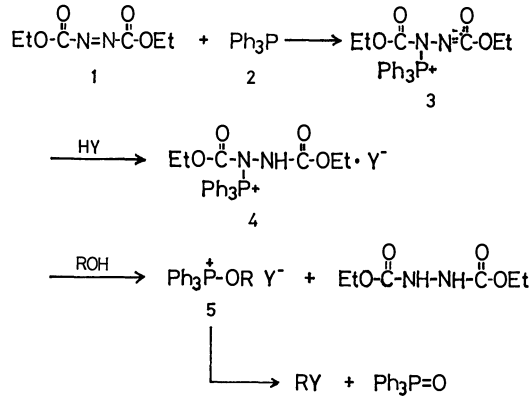
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received December 4, 1980)

The reagent formed by the reaction of diethyl azodicarboxylate (**1**) and triphenylphosphine (**2**) reacted with alcohols and ethyl cyanoacetate (**6**) to give alkylated products in 30—80% yields. When ethyl acetoacetate, 1,3-cyclopentanedione, or 1,3-cyclohexanedione was used in place of **6**, the corresponding *O*-alkylated products were obtained. The reaction of either (*S*)-(−)-ethyl lactate or (*S*)-(−)-ethyl 2-hydroxy-3-phenylpropionate with **1**, **2**, and **6**, followed by hydrolysis resulted in the formation of (*S*)-(−)-methylsuccinic acid or (*S*)-(−)-benzylsuccinic acid. The results indicate that nearly complete inversion of the configuration takes place in the alkylation step.

Alkylation of anions derived from active methylene compounds furnishes a synthetically useful reaction producing carbon to carbon bonds. A number of bases are effective for removing a proton from the carbon atom alpha to an electron-withdrawing group, but only a few alkylating reagents are utilized in the alkylation of the carbanions.[3]

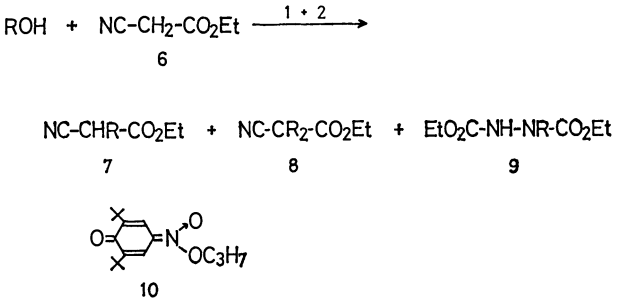
It was reported that the reaction of diethyl azodicarboxylate (**1**) and triphenylphosphine (**2**) in the presence of an alcohol and an acidic component gives an alkoxyphosphonium salt intermediate (**5**) which functions as a versatile alkylating reagent.[4] The reaction seems to proceed through (a) addition of **2** to **1** giving a quaternary phosphonium salt (**3**),[5] (b) protonation of **3**, (c) formation of an alkoxyphosphonium salt (**5**), and (d) S_N2 type displacement of the resulting species **5** as shown in Scheme 1.



Scheme 1.

Acidic components (Scheme 1; YH) alkylated by this method include phosphoric mono- and diesters, carboxylic acids, imides, phenols, and oximes. Not only simple alcohols but also complex hydroxy compounds such as nucleosides, carbohydrates, and steroids can be used.[4] This paper deals with the alkylation of acyclic and cyclic active methylene compounds by the above reaction.

Alkylation of Ethyl Cyanoacetate. The alkylation of ethyl cyanoacetate (**6**) was carried out under the same conditions as for the preparation of carboxylic esters.[6] Thus, **1** was added to a solution of 1-propanol, **2**, and **6** in tetrahydrofuran (THF) at room temperature (Procedure A). No alkylation of **6** took place, 45% of **6** being recovered. Similarly, no alkylated product was obtained when the reaction was carried out at −10——15 °C. On the other hand, when **1** was added to **2** in THF at −10——15 °C, followed by the addition of **6** and 1-propanol (Procedure B) and the reaction was continued for 1 h, ethyl 2-cyanopentanoate (**7**; R=C_3H_7) was isolated in 29% yield along with dialkylated product, ethyl 2-cyano-2-propylpentanoate (**8**; R=C_3H_7; 3—4%). A small amount of diethyl *N*-propylhydrazine-*N*,*N*′-dicarboxylate (**9**; R=C_3H_7) was also obtained (Scheme 2).



Scheme 2.

In Procedure B, a white fine precipitate is sometimes observed in the initial 5—10 min (1—2 mmol each of **1** and **2**/2—3 ml of THF). Complete disolution takes place on addition of alcohol and **6**, **7** (R=C_3H_7) being obtained in a comparable yield as above. No identification has yet been made but the precipitate seems to be an intermediate in the reaction. Since stirring of the slurry of the adduct is difficult, the alcoholic and acidic components are added preferably before the precipitation of adduct.

It was found that various alcohols can also enter into the reaction under similar conditions. The results are summarized in Table 1.

The formation of **9** suggests that both ethyl cyanoacetate anion and diethyl hydrazinedicarboxylate anion exist in the reaction mixture at equiliblium, the product ratio (**7**/**9**) depending on relative acidity of **6** and diethyl hydrazinedicarboxylate as well as the nucleophilicity of their anions (Scheme 3).[7]

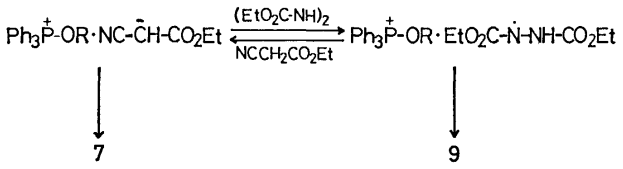
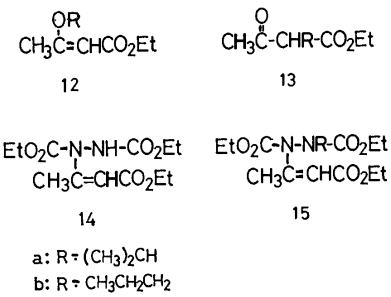
a) 12 and 17% yields of **8**($R=C_3H_7$) and **9**($R=C_3H_7$), respectively, 23% of **6** recovered. b) Procedure C. c) 3—4% yield of **8**($R=C_3H_7$). d) 7% yield of **8**($R=C_3H_7$). e) 10% yield of **8**($R=CH_2=CHCH_2$-). f) 21% yield of **8**($R=CH_2=CHCH_2$-), 29% of **6** recovered. g) 10% yield of **9**($R=EtO_2C(CH_3)CH$).



Scheme 3.

The yields of the alkylated products are not so high as compared with those obtained in the alkylation of relatively strong acid such as phosphoric diesters,[8] carboxylic acids,[6] or imides.[9] A possible explanation of the difference is obtained if a protonated phosphonium salt (**4**) is assumed to be an active intermediate for the formation of an alkoxyphosphonium salt (**5**). In the reaction of **6**, equilibrium is not favorable to protonated form (**4**; $Y=CH(CN)CO_2Et$) because of its low acidity. In order to increase the concentration of the protonated form in equilibrium, alkylation of **6** by various alcohols was examined in the presence of 2,6-di-*t*-butylphenol as a proton source. The yields of alkylated products increased to some extent, but no marked effect of the proton source was observed (Table 1). When 2,6-di-*t*-butyl-4-nitrophenol was used in place of 2,6-di-*t*-butylphenol, an *aci*-nitro ester (**10**)[10] was obtained in 70% yield with a 67% recovery of **6**.

Alkylation of Ethyl Acetoacetate. The reaction of ethyl acetoacetate (**11**) with **1**, **2**, and 2-propanol was carried out by Procedure B giving ethyl 3-isopropoxy-2-butenoate (**12a**), 3-[1,2-bis(ethoxycarbonyl)hydrazino]-2-butenoate (**14**), and 3-[2-isopropyl-1,2-bis(ethoxycarbonyl)hydrazino]-2-butenoate (**15a**) in 17, 16, and 12% yields, respectively. Contrary to the case of alkylation of **6**, that of **11** took place even at room temperature by Procedure A giving **12a**, **14**, and **15a** in 6, 40, and 8% yields, respectively (Scheme 4). No *C*-alkylated product (**13a**) could be isolated in these reactions.



Scheme 4.

The side product **14** would be formed *via* a vinyloxyphosphonium salt (**16**) which arises from the reaction of **3** with **11** (enol form). Collapse of **16** by an addition-elimination process gave rise to **14** and triphenylphosphine oxide (Scheme 5). The assumption is supported by the reaction of **11** with **1** and **2** in

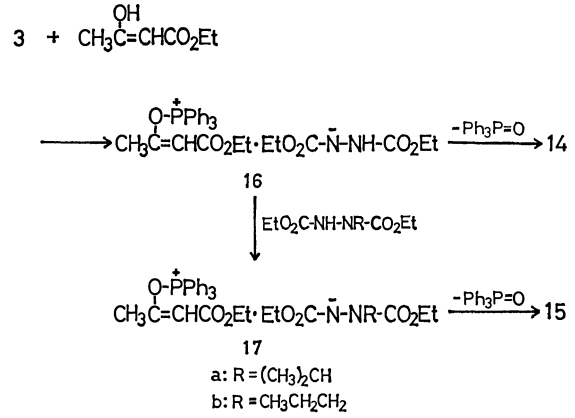
the absence of an alcoholic component where **14** was obtained in 68% yield. Compound **15** would be produced through a similar intermediate **17**.

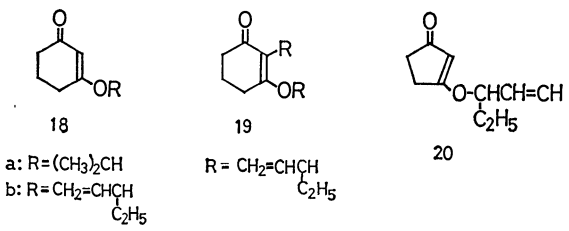


Scheme 5.

In order to suppress the formation of undesirable **14** and **15a**, 2-propanol (2 equivalents) and **11** were successively added to the reaction mixture of **1** with **2** at −10——20 °C (Procedure C). By this procedure, the yield of **12a** increased to 35%.

Similarly, the reaction of 1-propanol with **11** by Procedure A or B resulted in the formation of *O*-alkylated product (**12b**) in 18% yield, the yield increasing to 37% by Procedure C. When 1-propanol was used in large excess (10 equivalents), the *C*-alkylated product (**13b**) was formed in 6—10% yield along with **12b** (30%). The results are summarized in Table 2.

Alkylation of Cyclic 1,3-Diketone. In contrast to the case of acyclic active methylene compounds, the alkylation of cyclic 1,3-diketones proceeded smoothly in a perior of 0.5—1 h, giving *O*-alkylated products in good yields. Thus, when 1,3-cyclohexanedione was allowed to react with 2-propanol, **1**, and **2**, 3-isopropoxy-2-cyclohexenone (**18a**) was isolated by Procedures A and B in 74% and 81% yields, respectively. When 1-penten-3-ol was used in this reaction (Procedure B), 3-(1-ethyl-2-propenyloxy)-2-cyclohexenone (**18b**) and 3-(1-ethyl-2-propenyloxy)-2-(1-ethyl-2-propenyl)-2-cyclohexenone (**19**) were obtained in 40 and 13% yields, respectively (Scheme 6; Table 3). The reaction of 1,3-cyclopentanedione with 1-penten-3-ol by Procedure A resulted in the formation of 3-(1-ethyl-2-propenyloxy)-2-cyclopentenone (**20**) in nearly quantitative yield.

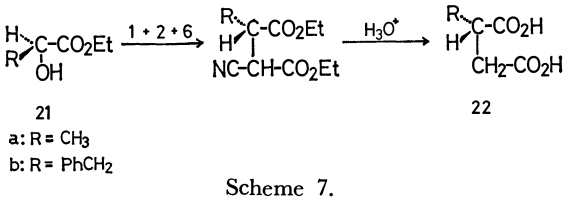


Scheme 6.

Stereochemistry. Intermolecular dehydration between an optically active alcohol and active hydrogen compounds by the use of **1** and **2** proceeds through the inversion of the configuration at the carbon atom bonded to hydroxyl group.[4]

The inversion of configuration was observed in the alkylation of **6**. Thus, (*S*)-(−)-ethyl lactate (**21a**) reacted with **6** in the presence of **1** and **2** to give diethyl 2-cyano-3-methylsuccinate in 61% yield. On hydrolysis, methylsuccinic acid (**22a**) with $[\alpha]_D$ −15.1° was obtained. This indicates that complete or nearly complete inversion of the configuration at the reaction site takes place in the alkylation step. Similarly, (*S*)-

(−)-ethyl 2-hydroxy-3-phenylpropionate (**21b**) was converted into opticcally pure (*S*)-(−)-benzylsuccinic acid (**22b**) (Scheme 7).



Scheme 7.

Concluding Remarks. The reagent formed by the reaction of **1** and **2** could be utilized in direct condensation between alcohols and active methylene compounds. The reaction proceeds under mild neutral conditions with inversion of configuration at the reaction site. In spite of some reduced yields, a high degree of stereospecificity is observed. The reaction might provide an effective procedure for the synthesis and transformation of natural products.

The fact that the alkylation of 1,3-dicarbonyl compounds mainly gives *O*-alkylated products suggests that the alkoxyphosphonium salt intermediate is a harder alkylating reagent than alkyl halides and alkyl sulfonates.[11] Steric interaction between alkoxyphosphonium salt having three bulky phenyl groups and ambident anion derived from the dicarbonyl compound would also favor *O*-alkylation.

Diethyl malonate can not enter into the alkylation reaction,[2b] suggesting that an active methylene compound to be alkylated should be more acidic than diethyl hydrazinedicarboxylate for achievement of the reaction.

Experimental

The reaction was carried out under anhydrous conditions. Anhydrous tetrahydrofuran (THF) was obtained by distillation from sodium benzophenone ketyl. Unless otherwise stated, the products were isolated by preparative layer chromatography (PLC) carried out on Kieselgel 60 PF_{254} (Merck) or Wakogel-B5 plates (20 cm × 20 cm or 20 cm × 30 cm), visualization being made by UV light or iodine vapor. Nuclear magnetic resonance spectra were measured on a Hitachi R-20 spectrometer (60 MHz) using tetramethylsilane as an internal standard.

Alkylation of Ethyl Cyanoacetate. Procedure A: A solution of **1** (522 mg, 3 mmol) in THF (2 ml) was added dropwise to a solution of **2** (787 mg, 3 mmol), **6** (226 mg, 2 mmol), and 1-propanol (240 mg, 4 mmol) in THF (6 ml) at room temperature. The solution was stirred at room temperature for 2 d. No alkylated product could be obtained, 45% of **6** being recovered.

Procedure B: A solution of **1** (1.3—1.5 mmol) in THF (0.5 ml) was added dropwise to a solution of an equimolar amount of **2** in THF (3 ml) stirred in an ice–salt bath. The intermediate formed in solution by this procedure will be referred to as "adduct." A few min after mixing the components, a solution of **6** (1 mmol) and an alcohol (1—2 mmol) in THF (3 ml) was added at this temperature. Stirring was continued under the conditions shown in Table 1.

Reaction in the Presence of 2,6-Di-t-butylphenol. To the adduct was added a solution of 1 mmol each of **6**, 2,6-di-*t*-butylphenol, and an alcohol in THF (3 ml) at −20 °C. The solution was stirred for appropriate periods of time (Table 1).

Reaction in the Presence of 2,6-Di-t-butyl-4-nitrophenol. To the adduct prepared from 3 mmol each of **1** and **2** in THF (4.5 ml) was added all at once a solution of 1-propanol (4 mmol) and 2,6-di-*t*-butyl-4-nitrophenol (754 mg, 3 mmol) in THF (3 ml). A solution of **6** (2 mmol) in THF (2.5 ml) was then immediately added over a period of 20 min and the resulting solution was kept standing at −20 °C for 10 h. The products were separated by PLC (benzene) giving **10** in 70% (617 mg) yield and recovered **6** (67%). Compound **10** was again applied to silica-gel plates and developed with ether–petroleum ether (1:5) to give semicrystalline sirup which crystallized on trituration with petroleum ether, subliming at 138—141 °C. NMR (CCl_4) δ 1.8—2 (m, $C\underline{H}_3C\underline{H}_2$), 1.13 (s, *t*-$C_4H_9$), 4.25 (t, CH_2O), 7.28 and 7.5 (AB q, J=3 Hz, 2H, vinyl H).

Preparative Scale Experiment. Reaction with Ethyl 2-Hydroxyheptanoate. A solution of **6** (54 mmol) and ethyl 2-hydroxyheptanoate (9.387 g, 54 mmol) in THF (25 ml) was added dropwise at −20——30 °C to a solution of the adduct prepared from 70 mmol each of **1** and **2** in THF (20 ml). After the solution had been stirred at −30——20 °C for 5 h, −10 °C for 12 h, at 0 °C for 10 h, and then at room temperature for 5 d, the solvent was removed under reduced pressure. Ether (30 ml) was added to the residue and precipitate was filtered off. The filtrate was evaporated and the residue was applied to a silica-gel column (Wakogel C-200, 4 cm × 30 cm) and eluted with benzene. Diethyl 2-cyano-3-pentylsuccinate was obtained in 83% yield and purified by distillation; 64%, bp 119—122 °C/0.25 Torr (1 Torr = 133.322 Pa).

The ester was treated with concd HCl under reflux for 15 h. The mixture was extracted with ether and organic layer was evaporated giving pentylsuccinic acid which was recrystallized from hexane; 84% yield, mp 82—83 °C (lit,[12] mp 82.5—83.5 °C) (*R*-(+)-form). NMR (acetone-d_6) δ 1.6—2.0 (m, 11H, C_5H_{11}), 2.3—3.2 (m, 3H, $CHCH_2$), 9.51 (s, 2H, COOH).

Alkylation of Ethyl Acetoacetate. Procedure A: A solution of **1** (3 mmol) in THF (3 ml) was added dropwise to a solution of **2** (3 mmol), **11** (260 mg, 2 mmol), and 2-propanol (4 mmol) in THF (7 ml) at room temperature, and the solution was stirred at room temperature for 2 d. After removal of the solvent *in vacuo*, the residue was applied to silica-gel plates, developed with benzene giving **12a** in 6% (20 mg) yield. The zone containing **14** and **15a** was rechromatographed (AcOEt–CCl_4 = 1:3) affording chromatographically homogeneous **14** and **15a** in 40% (231 mg) and 8% (55 mg) yields, respectively. NMR, **12a** (CCl_4) δ 1.20 (t, $C\underline{H}_3C\underline{H}_2$) and 1.25 (d, $(CH_3)_2CH$); total 9H, 2.15 (s, $C\underline{H}_3$–$\underline{C}$=C<), 3.9 (q, $CH_3C\underline{H}_2$) and 4.3 (septet, $(CH_3)_2C\underline{H}$); total 3H, 4.7 (s, >C=C$\underline{H}$). **14** ($CDCl_3$) δ 1.25 (superimposed t, 9H, three $C\underline{H}_3CH_2$), 2.45 (s, $C\underline{H}_3$–$\underline{C}$=C<), 3.84—4.4 (superimposed q, 6H, $CH_3C\underline{H}_2$), 5.85 (s, >C=C$\underline{H}$–), 7.2—7.5 (br s, NH). **15a** (CCl_4) δ 1.1 (d, $(C\underline{H}_3)_2CH$) and 1.25 (superimposed t, three $C\underline{H}_3CH_2$); total 15H, 2.35 (s, $C\underline{H}_3$–C=C<), 3.7—4.35 (septet and superimposed q, total 7H, three $CH_3C\underline{H}_2$ and $(CH_3)_2C\underline{H}$), 5.5 (s, >C=CH–).

Procedure B: A solution of **1** (3 mmol) in THF (3 ml) was added dropwise to a solution of **2** (3 mmol) in THF (3 ml) stirred in an ice–salt bath. A few min after the components had been mixed, a solution of **11** (2 mmol) and 2-propanol (4 mmol) in THF (4 ml) was added and stirring was continued for 5 h. After the solution had been kept standing for 2 d at *ca.* −20 °C, **12a** **14**, and **15a** were obtained in 17, 16, and 12% yields, respectively.

Procedure C: A solution of 2-propanol (4 mmol) in THF (2 ml) was added all at once at −20 °C to a solution of the adduct prepared from 3 mmol each of **1** and **2** in THF (4 ml). Immediately after the addition of 2-propanol, a solution of **11** (2 mmol) in THF (2 ml) was added dropwise over a period of 15 min at −20 °C. The reaction mixture was stirred for 1.5 h and then kept standing at −20 °C for 2 d. The products were separated by PLC giving **12a** in 35% yield. Small amounts of **14** and **15a** were also formed as indicated by thin layer chromatography of the crude reaction mixture, no attempt being made to isolate them.

When 1-propanol was used in large excess (10 equivalents), a mixture of *C*-alkylated and *O*-alkylated products were obtained. The ratio was estimated from integration of the signal of NMR spectrum.

*Preparation of **14***. Compound **1** (3 mmol) in THF (2 ml) and **11** (2 mmol) in THF (2 ml) were successively added to a solution of **2** (3 mmol) in THF (3.5 ml) at −20 °C, and the mixture was kept standing at −20 °C for 2 d. Compound **14** was isolated by PLC (AcOEt–CCl_4=1:3) in 68% (390 mg) yield.

Alkylation of 1,3-Cyclohexanedione. Procedure A: A solution of **1** (2 mmol) in THF (3 ml) was added dropwise over a period of 10 min to a solution of **2** (2 mmol), 2-propanol (2 mmol), and 1,3-cyclohexanedione (1.5 mmol) in THF (6 ml) at room temperature. After the solution had been stirred at room temperature for 35 min, water (4 ml) was added, and extracted with $CHCl_3$. The organic layer was evaporated and the residue was separated by PLC (AcOEt–petroleum ether=1:1) giving **18a** which was contaminated with a small amount of diethyl hydrazinedicarboxylate. The crude product was suspended in CCl_4, stirred, and filtered in order to remove undissolved diethyl hydrazinedicarboxylate to give practically pure **18a**, 188 mg (81%). A pure sample was obtained by distillation, bp (oven temperature) 58—68 °C/35 Torr. NMR (CCl_4) δ 1.25 (d, $(C\underline{H}_3)_2CH$), 1.6—2.5 (m, $-(CH_2)_3-$), 4.4 (septet, $(CH_3)_2C\underline{H}$), 5.13 (s, $>C{=}C\underline{H}-$).

Procedure B: A solution of 1-penten-3-ol (258 mg, 3 mmol) and 1,3-cyclohexanedione (168 mg, 1.5 mmol) in THF (3 ml) was added over a period of 15 min to a solution of the adduct prepared from 3 mmol each of **1** and **2** in THF (7 ml) cooled in an ice–salt bath. Thin layer chromatography of the reaction mixture revealed that the cyclohexanedione disappeared in 10 min after the addition. The reaction mixture was stirred for 1 h and water was added. The mixture was extracted with $CHCl_3$ and the organic layer was evaporated. The residue was applied to silica-gel plates and developed with ether–petroleum ether=3:1 giving **18b** (108 mg, 40%) and **19** (48 mg, 13%). NMR; **18b** (CCl_4) δ 0.9 (t, CH_3), 1.25—2.55 (m, CH_3CH_2 and $-(CH_2)_3-$), 4.37 (q, CH–O), 4.85—5.95 (m, 4H, vinyl H). **19** (CCl_4) δ 0.75 (t, CH_3), 0.95 (t, CH_3), 0.9—2.6 (m, two $CH_3C\underline{H}_2$ and $-(CH_2)_3-$), 3.35 (q, $\equiv C-C\underline{H}(C_2H_5)CH{=}CH_2$), 4.4 (q, CH–O), 4.5—6.2 (m, 6H, vinyl H).

Alkylation of 1,3-Cyclopentanedione. A solution of 1,3-cyclopentanedione (147 mg, 1.5 mmol) and 1-penten-3-ol (172 mg, 2 mmol) in *N,N*-dimethylformamide (1 ml) was added at −17 °C to the adduct prepared by the reaction of 2 mmol each of **1** and **2** in THF (2 ml). The solution was stirred at −17——12 °C for 1.5 h and then at room temperature overnight. The products were separated by PLC (ether) to give **20** in 93% yield. NMR (CCl_4) δ 1.0 (t, CH_3), 1.7 (m, $CH_3C\underline{H}_2$), 2.1—2.8 (A_2B_2, $-CH_2CH_2-$), 4.5 (q, CH–O), 5—6.15 (m, 5H, vinyl H).

Preparation of (S)-(−)-*Methylsuccinic Acid*. A solution of (*S*)-(−)-ethyl lactate [1.53 g, 13 mmol, $[\alpha]_D^{19}$ −10.9° (neat)], **6** (1.13 g, 10 mmol), and 2,6-di-*t*-butylphenol (2.06 g, 10 mmol) in THF (17 ml) was added dropwise to a solution of the adduct prepared from 15 mmol each of **1** and **2** in THF (5 ml) at −20 °C. After the solution had been stirred at −20 °C for 3 h and then at room temperature for 1 d the solvent was removed *in vacuo*. Ether was added and the precipitate was filtered off. The filtrate was concentrated and the products were separated by PLC ($CHCl_3$) giving diethyl 2-cyano-3-methylsuccinate in 61% (1.29 g) yield, $[\alpha]_D^{20}$ −2.76° (*c* 6.03, CCl_4). The product was contaminated by small amounts of two side products as indicated by gas chromatography (OV-1, 1 m, column temperature was 140 °C in initial 6 min and then raised at a rate of 5 °C/min, retention time; the succinate, 2.3 min, unknown side products, 4 and 12.5 min, respectively).

The succinate (1.13 g, 5.3 mmol) was treated with acetic acid (1 ml) and concd HCl (4 ml) under reflux for 6 h and then 4 ml of concd HCl was added. After the mixture had been refluxed for 10 h, ether was added. Organic layer was concentrated to dryness giving crude methylsuccinic acid (502 mg, mp 80—85 °C). Recrystallization from hexane–CH_2Cl_2 (1:1) caused a rise in the melting point to 100—103 °C, $[\alpha]_D^{20}$ −12.5° (*c* 1.82, EtOH). Recrystallization for the second time from the same solvent system gave a pure sample, mp 109—109.5 °C, $[\alpha]_D^{19}$ −15.1° (*c* 0.818, EtOH) [lit,[13] mp 111—113 °C, $[\alpha]_D^{24.2}$ −15.0 (*c* 1.89, EtOH)].

Preparation of (S)-(−)-Benzylsuccinic Acid. (*S*)-(−)-Ethyl 2-hydroxy-3-phenylpropionate [1.94 g, 10 mmol, $[\alpha]_D$ −22.7° (*c* 0.852, benzene), lit [14] $[\alpha]_D$ −22.6° (*c* 4.33, benzene)] was allowed to react with 10 mmol each of **1**, **2**, and **6** by Procedure B. After the addition of the hydroxy ester and **6**, the solution was stirred at room temperature for 2 h. Diethyl 2-benzyl-3-cyanosuccinate was isolated by distillation (250 mg, 8.7%, bp 130 °C/0.25 Torr). The succinate was treated with a mixture of acetic acid (2.5 ml) and concd HCl (11.3 ml) under reflux for 10 h giving (*S*)-(−)-benzylsuccinic acid (159 mg, 88%) which was recrystallized from water, mp 153—154 °C, $[\alpha]_D^{21}$ −28.9° (*c* 0.665, AcOEt) [lit,[14] mp 159—161 °C, $[\alpha]_D^{26}$ −26° (*c* 1.5, AcOEt)].

An Occurrence of Attractive Alkyl-Phenyl Interaction. The Conformations of Several 1-Phenyl-2-alkanols

Shoji Zushi, Yoshio Kodama, Yoshimasa Fukuda, Ken Nishihata, Motohiro Nishio,* Minoru Hirota†, and Jun Uzawa††

†† *The Institute of Physical and Chemical Research, Wako 351*

(Received December 5, 1980)

The conformations have been studied, by means of NMR spectroscopy, for a series of 1-alkyl-substituted 2-phenylethyl alcohols with the structure $C_6H_5CH_2CH(OH)$-R, where R=CH_3 (**1**), C_2H_5 (**2**), i-C_3H_7 (**3**), and t-C_4H_9 (**4**). It has been suggested that a rotamer in which the phenyl group is oriented *gauche* to the alkyl (R) and *anti* to the hydroxyl group is most populated in the conformational equilibria of **1**—**3**. Another rotamer (in which Ph is *anti* to R) has, on the other hand, been suggested to be preferred in the conformational equilibrium of **4**. The results have been discussed in the light of the presence of an attractive alkyl-phenyl interaction (CH-π interaction).

In connection with the general interest in the conformational problems of acyclic compounds, we have now studied the conformations of a series of benzylic alcohols with the following structures:

$C_6H_5CH_2CH(OH)$-R

R=CH_3 (**1**), C_2H_5 (**2**), i-C_3H_7 (**3**), and t-C_4H_9 (**4**).

Results

Tables 1 and 2 list the proton and carbon NMR parameters, respectively, for a series of 1-alkyl-substituted 2-phenylethyl alcohols: 1-phenyl-2-propanol (**1**), 1-phenyl-2-butanol (**2**), 3-methyl-1-phenyl-2-butanol (**3**), 3,3-dimethyl-1-phenyl-2-butanol (**4**). Parts of the ^{1}H NMR spectra are reproduced in Fig. 1.

An inspection of the tables and figures reveals several interesting facts. First, the signal attributed to the OH proton moves progressively to a higher magnetic field as the alkyl group, R, goes from the methyl group through the ethyl and isopropyl groups and then to the t-butyl group. The shape of the OH peak is a sharp singlet for **1**, **2**, and **3**; this suggests that the OH group is largely free from the OH-π complexation in these alcohols.[1] For the t-butyl homologues (**4**), the signals ascribed to the OH and the proton adjacent to this (labeled H_x) are a little bit broader than those in the lower alkyl compounds. Second, the benzylic protons are magnetically nonequivalent, except for **1**, giving rise to a pair of quartets. The spin-coupling constants[2] with the vicinal proton (H_x) are larger for the higher part (H_a) of the double quartets than for the lower one (H_b). The coupling constant,

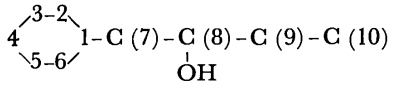
a) Ppm downfield from internal TMS in $CDCl_3$.



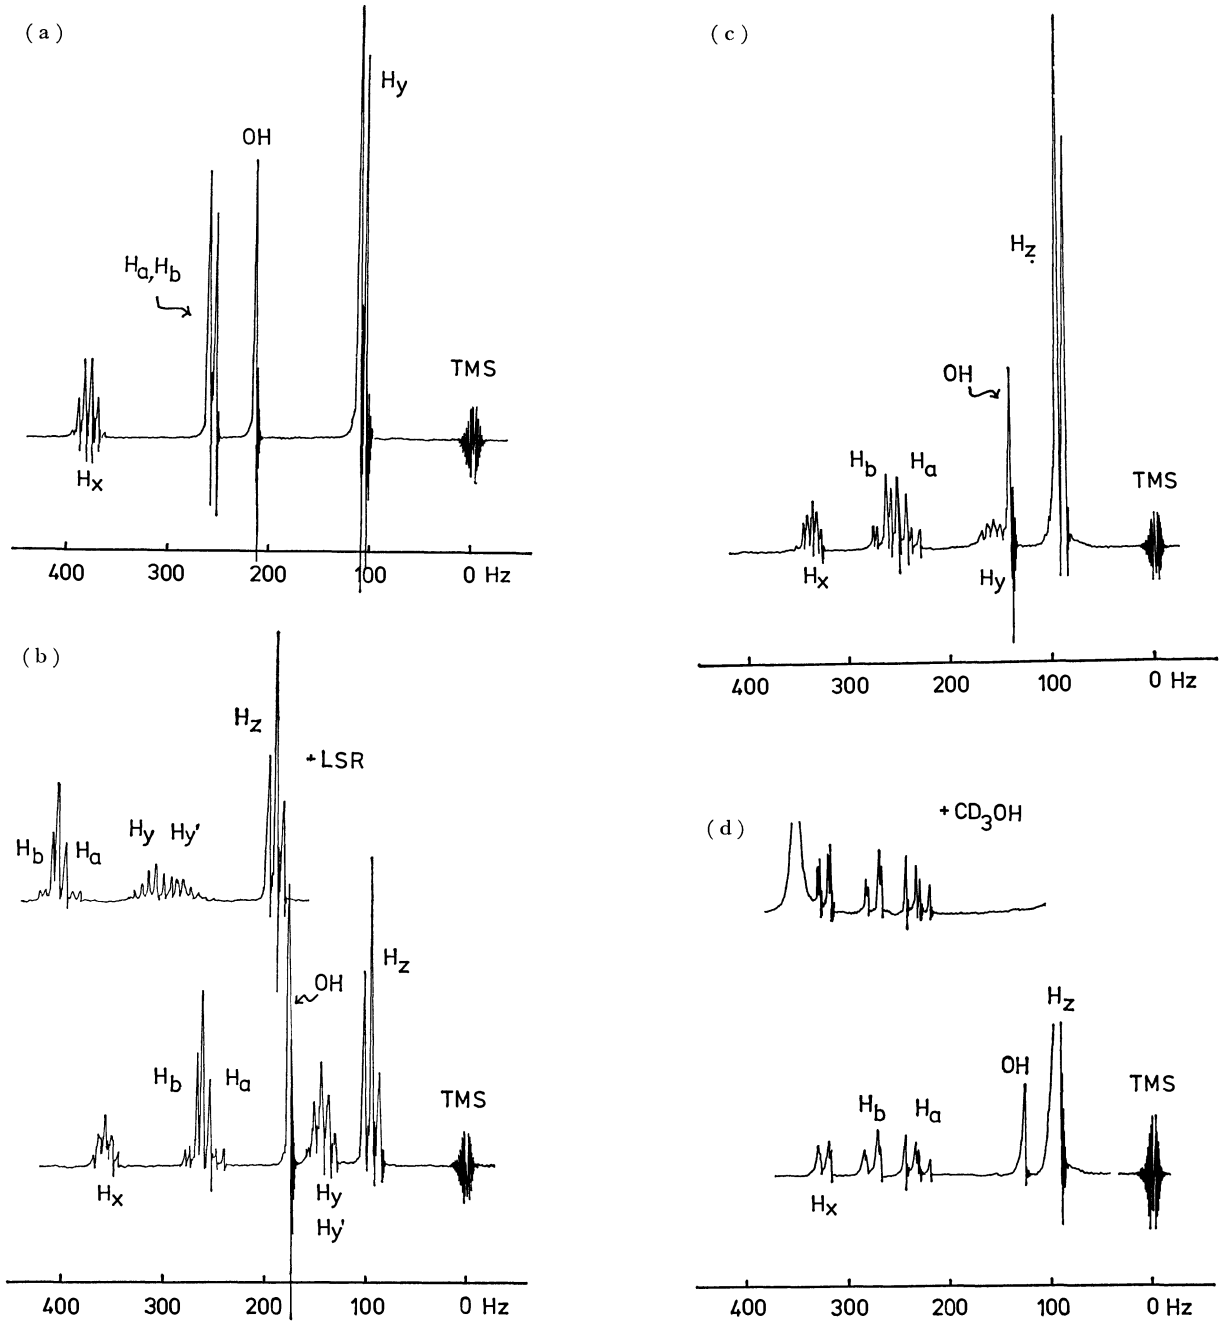


Fig. 1. Proton NMR spectra of (a) 1-phenyl-2-propanol (**1**); (b) 1-phenyl-2-butanol (**2**), insert shows the effect of LSR; (c) 3-methyl-1-phenyl-2-butanol (**3**); and (d) 3,3-dimethyl-1-phenyl-2-butanol (**4**), insert shows the effect of added CD_3OH.

$^3J_{HaHx}$, becomes progressively larger as the methyl group in **1** is replaced by the ethyl, isopropyl, and then *t*-butyl groups; the reverse is true for $^3J_{HbHx}$. Third, the lanthanoid shift-reagent[3] (LSR) induced shift[4] (LIS, Table 3) is greater for H_a than for H_b, the difference in the LIS is most remarkable for **4** (R=Bu^t). The LIS values for the benzylic protons are virtually the same in the cases of **1** and **2**. A signal assignment is possible for the diastereotopic protons if the LIS data are combined with information obtained by the coupling constants. These points will be discussed later.

The conformations of **1**—**4** were then studied by means of a computer simulation[5] of the LIS. Ac-

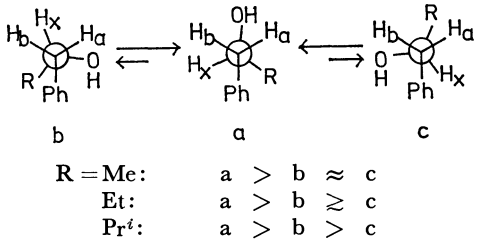

Fig. 4. Relative stabilities of the rotamers **a**, **b**, and **c**, suggested for the conformational equilibria of **1**, **2**, and **3**.

cording to the procedure described in an earlier paper,[1b] the positions of the LSR and the geometry of the substrate were varied, step by step, in the search for a reasonable agreement of the computed LIS's with the observed values.[6]

Figure 2 plots the Hamilton reliability factors (AF)[7] against the O–C(8)–C(7)–Ph dihedral angle, ϕ, for a representative case of Compound **1**. Here, the Ln–O distance, R, is fixed at 0.32 nm,[8] while the LSR-distribution index A,[6] is varied from 0.0 to 1.2. A good fit is obtained at ϕ *ca.* 180° in every case. The agreement is worst at ϕ around 0°, but it becomes better with a larger value of A; this is reasonable, since the rotation of the LSR will be hindered if OH (the LSR-complexation site) comes close to the phenyl group. The values of ϕ at the AF-minima do not vary significantly with the change in A; however, the presence of the second (or third) minimum becomes more apparent with a higher value of A.

Figure 3 summarizes the results obtained for **1**, **2**, and **3**. (A and R are fixed at 0.8 and 0.32 nm respectively). A notable feature of these profiles is the presence of three minima in every case. The AF at these ϕ-values are not necessarily good enough to be acceptable, except for the best-fit position. It should be kept in mind that the value of AF represents the plausibility for a single, hypothetical conformation and by no means corresponds to the potential energy or the population of the respective rotamer. However, for reasons previously cited,[1,9] we believe it likely that the appearance of the second and third minima reflects the contribution from other, less populated rotamers. The values of ϕ and AF might thus reflect, though in an indirect manner, the geometry and the relative stability of the respective rotamers.

An inspection of Fig. 3 suggests that the rotamer with the hydroxyl group *anti* to the phenyl group (ϕ *ca.* 170°, rotamer **a**) is the most populated one in the rotameric mixture of these alcohols. The **b** (ϕ *ca.* 80°) and **c** (ϕ *ca.* 280°) rotamers seem to be of about the same importance for **1** and **2**; the **b** rotamer appears to be more stable than the **c** rotamer in the case of the isopropyl-substituted alcohol (**3**).

A configuration assignment is given in Fig. 4 for the benzylic hydrogens in alcohol **3** (R=Pr^i). With this assignment, the coupling data ($J_{HaHx} > J_{HbHx}$) and the LIS data (larger for H_a) are consistent with the suggested geometries and the equilibrium; a conflict occurs, however, with the alternative assignment. The same conclusion can be reached for **2** and **1**; in the latter case, the chemical shifts of the diastereotopic protons are virtually equivalent.

For the *t*-butyl homologue (**4**), however, a paradoxical result is obtained. With the same signal assignment, the simulation indicates the coexistence of rotamers with ϕ *ca.* 90° and 140° (Figs. 5 and 6a). This conclusion is unacceptable in view of the coupling data (Table 1: 10.5 Hz for H_a and 2.5 Hz for H_b).

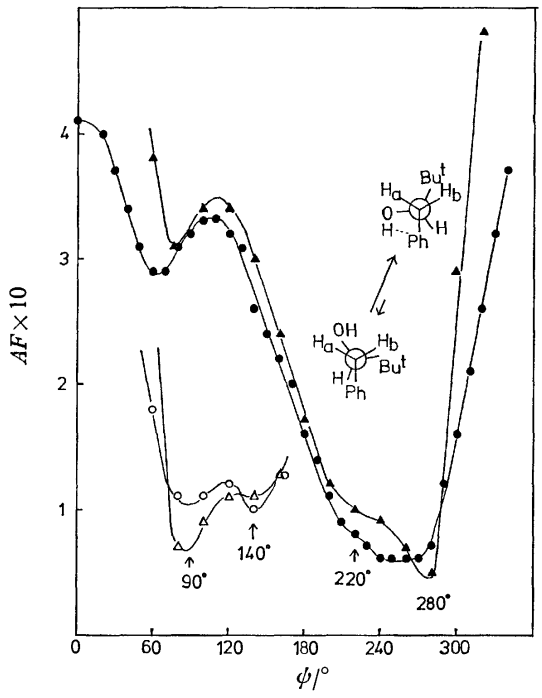

Fig. 5. Plots of AF *vs.* ϕ for **4**. Assignment for the benzylic protons is made as indicated. ▲: A=0.4, ●: A=0.8. Insert shows the profiles obtained with the reversed assignment; this equals to the assignment given for the lower alkyl homologues. △: A=0.4, ○: A=0.8. R is kept constant at 0.32 nm.

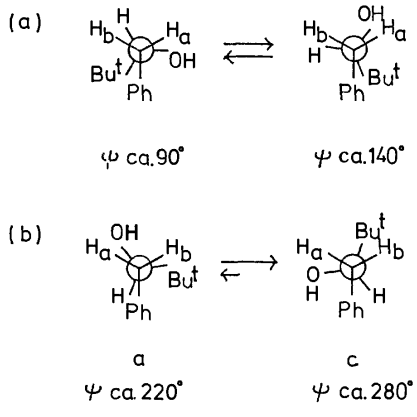

Fig. 6.

A more reasonable conclusion is reached with the alternative assignment. Thus, with an inversed signal assignment, the concomitant presence of rotamers corresponding to the **c** rotamer (ϕ *ca.* 280°) and the **a** rotamer (ϕ *ca.* 220°) is suggested, the former being likely to be predominant (Figs. 5 and 6b). In this case, the conclusion is compatible with the coupling data.

Support for the above suggestions regarding the rotameric equilibria of **1**—**4** is provided by an inspection of the NMR data. In the **c** rotamer (and **b**), the hydroxyl group is *gauche* to Ph and is expected to participate in the OH–π complexation.[10] The hydroxyl group in the **a** rotamer, in contrast, lies *anti* to the phenyl group. The OH proton in the **c** rotamer can, therefore, be expected to be magnetically more

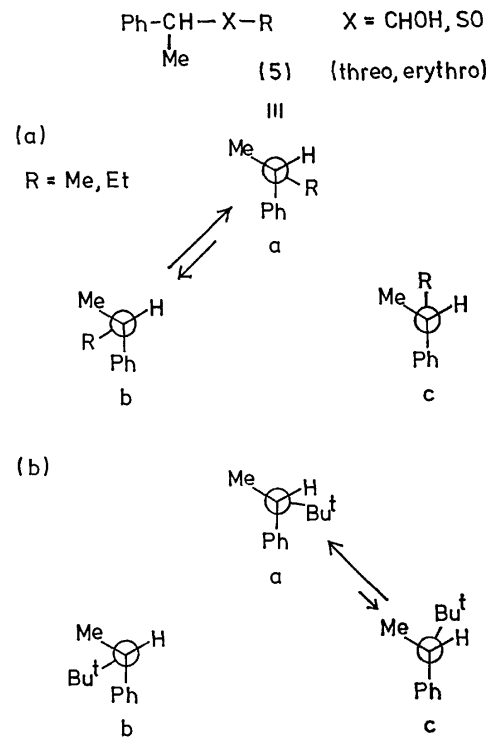

Fig. 7. Rotameric equilibria suggested for the diastereoisomeric pairs of sulfoxides (**5**, X=SO) and alcohols (X=CHOH).

shielded and free from proton exchange, than that in the **a** rotamer.[1] In fact, the hydroxyl proton of **4** gives rise to the highest peak in the series, and it is broader (due to the slow exchange) than that in the lower alkyl homologues. This can be understood by considering the important contribution of the **c** rotamer to **4** and the relative non-importance of this rotamer (and the **b** rotamer) for the other alcohols.

In the **a** rotamer, whereby the OH group is flanked by the two benzylic hydrogens, H_a and H_b, the LIS is anticipated to be about the same for these nuclei. The LIS for H_a and H_b should be very different in the **b** and **c** rotamers, but the effect will be cancelled if these rotamers are populated at an approximately equal concentration. This is what we observed in the proton NMR spectra of **1** and **2**; the trend is reflected in the simulated results. The tendencies observed for the coupling constants as well as the shift data are compatible with the computed results, judging from the assignments given in Figs. 4 and 6b.

Discussion

A remarkable feature of the present result is the finding that the **a** rotamer (Fig. 4) is most populated in the rotameric mixtures of **1**, **2**, and **3**. In the **a** rotamer, the alkyl group lies close to the phenyl group. Note that the benzylic methyl group, which is present in compounds previously studied (Fig. 7), is absent in these molecules. We believe that the above finding can be accommodated only in terms of an attractive force operating between an alkyl and a phenyl group (the CH/π interaction).[1,11]

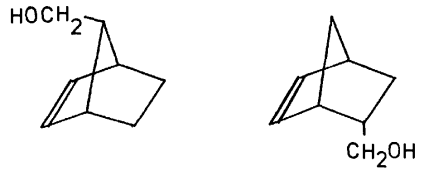
With regard to the *t*-butyl homologue (**4**), the most populated rotamer has been suggested to be the **c** rotamer (Fig. 6b). In this conformation, the *t*-butyl group is oriented *anti* (Bu^t–Ph torsional angle *ca.* 160°) to the phenyl group. The geometry corresponding to the **a** rotamer (Bu^t–Ph torsional angle *ca.* 100°) is found to be the second most stable one in this case. A comment is required on the apparent discrepancy that the **a** rotamer is most stable for **1**, **2**, and **3**, while the **c** rotamer is more important than **a** in the case of **4**. This result is in contrast to the earlier finding that in compounds such as **5** (Fig. 7) the most stable rotamer always has its alkyl group *gauche* to Ph, irrespective of the nature of Groups R and X. The conformational equilibria suggested for sulfoxides (**5**, X=SO)[9a] and alcohols (**5**, X=CHOH)[1b] are illustrated in Fig. 7. In both of these cases, the rotameric mixtures have been shown to consist, principally, of the **a** and **b** rotamers for the lower alkyl homologues and of the **a** and **c** rotamers for the *t*-butyl derivatives, the more stable one being the **a** rotamer in every case.[12] The position of the alkyl group in the most stable geometries has been found to be shifted (slightly, but distinctly) to give a larger R–Ph torsional angle for the *t*-butyl compounds (compare the **a** rotamers in Figs. 7a and 7b) as compared with the lower alkyl homologues.

The conformation of a molecule is, indeed, a consequence of a compromise of a number of interactions. In compounds such as **5**, where a methyl group is present in the benzylic position, the geometry of a molecule is controlled, primarily, by the balance of two interactions: R *vs.* CH_3, and R *vs.* Ph. These interactions may be attractive at an appropriate distance (the dispersion force[13] and/or the CH–π interaction[11]) or repulsive if the relevant groups come too close.

The suggestion that the **c** rotamer (ψ *ca.* 280°) represents the most stable conformation for **4** is understood in view of the absence of the benzylic methyl; the **a** rotamer might have become energetically less favorable than **c** in the present molecular environment. The **a** rotamer may be destabilized by the unfavorable (repulsive van der Waals) interaction between Bu^t and a benzylic hydrogen (H_b). This situation might occur when a methyl group in Bu^t takes a suitable position for the CH–π bonding.

Other possible factors which may contribute to controlling the rotameric equilibria of these compounds are the OH–π hydrogen bonding and the O–Ph dipole-quadrupole and *gauche*-vicinal H–H interactions. Some speculations will be made, on the basis of the suggested geometries of the preferred conformations, as to the factors influencing the molecular geometries of these alcohols.

The operation of the attractive CH–π interaction is possible in both the **a** and **b** rotamers (Fig. 4). However, the **a** rotamer has been found to be more stable than **b** in all cases. To accommodate this, it may be pointed out that there are two vicinal H–H interactions in the **b** rotamer. According to Wertz and Allinger, this interaction is very destabilizing.[14] The O–Ph dipole-quadrupole interaction[15] may also destabilize the **b** rotamer (and **c**).[16] The OH–π interaction[10,17] is undoubtedly attractive, but the other unfavorable interactions might override its effect. In this respect, it should be noted that OH–π bonding has not been observed in such compounds as **6** and **7**[18] even though these molecules appear to be ideally

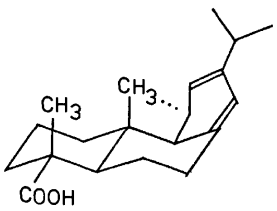


6 7

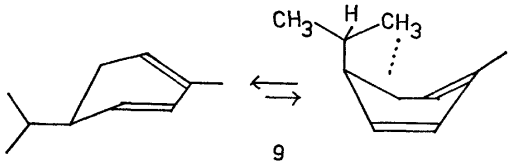
constituted for such interactions to take place. The observance of the OH–π hydrogen bonding might, therefore, be merely a consequence of a given (somewhat compelled) geometry of a molecule.

To conclude, we suggest that the attractive CH–π interaction is very important in the consideration of the conformational problems of flexible molecules. It may be more important than the OH–π hydrogen bonding. The stabilization energy is probably very small for a single CH–π interaction. In some molecular dispositions, however, the sum total of the stabilization energy may become sufficiently large to ensure a low-entropy structure of a complex molecule.

The recognition of the above facts would be of help in elucidating certain well-known, but poorly understood phenomena. Possible examples have been given in earlier papers,[9b,19] so here we will confine ourselves to illustrating a probable case from terpene chemistry. It has been established that levopimaric acid (**8**) exists in a folded conformation.[20,21] It is also well known that a considerable fraction of the folded conformer (with an axially oriented isopropyl group) contributes to conformational equilibrium of α-phellandrene (**9**).[20,22] These results were once at-



8



9

tributed, by Burgstahler *et al.*[20] to the presence of some type of attractive interaction which stabilizes an otherwise unfavorable conformation. The above interpretation was later replaced by alternative ones based principally on repulsive steric effects.[21,23]

The well-known diene chirality rule, in its original form,[24] states that the long wavelength π→π*-transition Cotton effect is mainly controlled by the helicity and the amount of twist of a conjugated diene. Re-

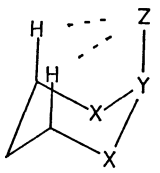


Fig. 8. A possible explanation (in terms of the CH–π or CH–n[9b]) interactions) for the axial preference of the Group Z.
Z: unsaturated groups or hetero atoms. X: O, S, CH_2 *etc.* Y: CH, S, or P.

cently, Burgstahler and his associates presented evidence[25] that the Cotton effects of 1,3-cyclohexadienes are primarily determined by the chirality contributions of allylic axial substituents according to the size or polarizability of the group. The suggestion has gained rapid acceptance and has been followed by quantum mechanical studies[26] and the proposal of an empirical quadrant rule.[27] In particular, Rosenfield and Charney presented evidence,[26a] obtained by MO calculations, that an axially oriented allylic hydrogen and methyl group contribute significantly to the rotatory strength of cisoid diene, a methyl group being *ca.* twice as effective as a hydrogen atom.

We suggest that these results are better accommodated in terms of the CH–π interaction. In our view, the folded conformations of **8** and **9** are consequences of an attractive interaction.[28] Also, it seems reasonable to suggest that the axial allylic (or homoallylic[29]) effect[25] operates mainly through the dissymmetric perturbation of the π^* orbital of the chromophore by virtue of the C–H groups,[30] which are oriented suitably for this interaction to take place. Inspections of Dreiding models suggest, in fact, that such an interaction is possible between CH groups and conjugated π-systems whenever a significant contribution of axial allylic or homoallylic (or even remoter) groups is present.[25,27,29] The same kind of argument will perhaps apply to the theoretical background, at least in part, of the Octant rules of ketones[31] and olefins,[32] and to the genesis of the 2-axial ketone effect.[33] Also noteworthy in this regard is the tendency for a group which bears π- or unshared-electrons to adopt the axial conformation (configuration) in saturated six-membered heterocycles (Fig. 8).[34] It is tempting to speculate about the possibility that the above effect (the generalized anomeric effect) is ascribable, at least in part, to the CH–π (and CH–n[9b]) interaction.[35]

Experimental

Materials. The alcohols (**1**—**4**) were prepared by treating phenylacetaldehyde with an appropriate Grignard reagent, RMgCl. The samples were purified as usual and shown gas-chromatographically to be pure.

NMR Spectra. ^{1}H NMR spectra were recorded at 30 °C on a JEOL MH-100 spectrometer (100 MHz) for *ca.* 0.2 M solutions in CCl_4 (locked to internal TMS; sweep-rate, 4 Hz s^{-1}). The calibrations of the chemical shifts (reported in ppm relative to internal TMS) were made by referring to the signals of standard samples. The coupling constants were determined by an inspection of the spectra and are accurate to $\pm$0.5 Hz. The ^{13}C NMR spectra were obtained at 27 °C on a JEOL FX-100 instrument (25.05 MHz) for $CDCl_3$ solutions in 10 mm ϕ-sample tubes (FT-conditions: data points, 8 K; spectral width, 4 kHz; flip angle, 45°; repetition time, 1.2 s). The signal assignments were made by the use of selective and gated decoupling techniques. The chemical shifts are reported in ppm downfield from internal TMS (δ=0) and are accurate to $\pm$0.04 ppm.

LIS Measurements. Weighted LSR [Eu(fod)$_3$] was added, step by step, to a solution containing a known amount of a substrate, and the signals were followed in the spectra. A least-squares fit of the experimental points was used to obtain the observed LIS's used in the computations. In all cases straight lines were obtained with correlation coefficients of $r>0.998$.

We wish to thank Professor Naoya Nakagawa (The University of Electro-communications) for his useful discussions, and Drs. Teiichiro Ito and Koshiro Umemura (Meiji Seika Kaisha) for their encouragement.

The Formylation of an Aromatic Nucleus by the Use of 2-Ethoxy-1,3-dithiolane

Shigeo Jo, Shigeo Tanimoto,* Toyonari Sugimoto, and Masaya Okano
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received December 8, 1980)

The reaction of various phenols with 2-ethoxy-1,3-dithiolane proceeded smoothly in the presence of $BF_3 \cdot Et_2O$ to afford 1,3-dithiolan-2-ylated phenols, which were readily hydrolyzed to the corresponding aldehydes. This process was also extended to *N,N*-dimethylaniline and indole.

Considerable efforts have been devoted towards the discovery of methods for the introduction of a formyl moiety onto an aromatic nucleus. The Gattermann-Koch reaction,[1] the Reimer-Tiemann reaction,[2] the Vilsmeier reaction,[3] the Duff reaction,[4] the Friedel-Crafts reaction with dichloromethyl alkyl ether or with trialkyl orthoformate,[5] *etc.* are well known and widely used. Recently, Gassman and Amick have reported a process which involves the reaction of phenols with a salt formed through the mixing of *N*-chlorosuccinimide and dithiane.[6] However, all these reactions give relatively poor yields or can be used only with electron-rich aromatic compounds. It is proper to say that no reaction for formylating aromatic compounds which would not be subjected to either one of the above limitations has been found.

We have now found that 2-ethoxy-1,3-dithiolane in dichloromethane with a Lewis acid catalyst is an efficient reagent for the introduction of the 1,3-dithiolan-2-yl group to some phenols and that the resulting cyclic thioacetal derivatives (protected formylated phenols) are easily hydrolyzed to the corresponding aldehydes. This process for the formylation of phenols could also be extended to *N,N*-dimethylaniline and indole. Although this formylation process is also subject to limitations similar to those of the earlier methods, that is, it is applicable only to electron-rich aromatic compounds, such as phenols, *N,N*-dimethylaniline, and indole, and the yields of the obtained aldehydes are roughly the same as those in the previously reported reactions, it has such advantages that the starting 2-ethoxy-1,3-dithiolane is readily available, and can be stored for a long time, and the reaction smoothly proceeds under relatively mild conditions.

Results and Discussion

The first attempt was directed toward establishing the most effective Lewis acid catalyst for the reaction of *p*-cresol (**1d**) with 2-ethoxy-1,3-dithiolane in dichloromethane. The yields of 2-(1,3-dithiolan-2-yl)-*p*-cresol (**2d**) formed in the reaction with various Lewis acid catalysts are shown in Table 1.

As is evident from Table 1, the best yield (55%) was achieved in a run involving a 1.5 molar ratio of 2-ethoxy-1,3-dithiolane and a 0.75 molar ratio of $BF_3 \cdot Et_2O$ for **1d**. The $BF_3 \cdot Et_2O$ catalyst, therefore, would be a very effective catalyst for the 1,3-dithiolan-2-ylation of phenols other than **1d**. Thus, we have studied the $BF_3 \cdot Et_2O$-catalyzed reaction of 2-ethoxy-1,3-dithiolane with several phenols in dichloromethane at room temperature. The results are summarized in Table 2.

It seems plausible that the reaction path involves the coordination of $BF_3 \cdot Et_2O$ with 2-ethoxy-1,3-dithiolane to give the 1,3-dithiolan-2-ium ion and the subsequent attack on the aromatic nucleus. As can be seen from Table 2, the exclusive attack occurs in the 2- and 3-positions of **1d** and *p*-hydroxyanisole (**1f**) respectively and also in the 4-positions of *o*-cresol (**1b**) and guaiacol (**1e**). Phenol (**1a**) was 1,3-dithiolan-

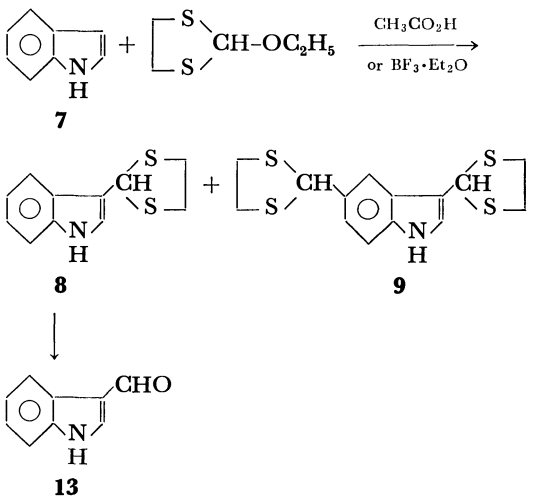
a) Yield is based upon **5** or **7**. b) 0.75 molar ratio of $BF_3 \cdot Et_2O$ for **7**.



The 1,3-dithiolan-2-ylation of indole (**7**) was also promoted by using acetic acid as both catalyst and solvent. When the reaction was carried out at 110 °C, the products were 3-(1,3-dithiolan-2-yl)indole (**8**) (64%) and 3,5-bis(1,3-dithiolan-2-yl)indole (**9**) (8%), a hitherto unknown compound; only the former was produced in a good yield (81%) in the reaction conducted at room temperature.

Most of the 1,3-dithiolan-2-ylated aromatics obtained in this work were hydrolyzed to the correspond-

ing aldehydes. The procedure used to accomplished the hydrolysis involved the treatment of the aromatic thioacetals with HgO and $BF_3 \cdot Et_2O$, followed by neutralization with aqueous Na_2CO_3.[11] As can be seen from Table 6, the overall yields of the aldehydes from the starting aromatics (**1**, **5**, and **7**) ranged from 15 to 77%.

Experimental

Reaction of Phenols (1) with 2-Ethoxy-1,3-dithiolane. General Procedure: To a mixture of **1** (20 mmol) and 2-ethoxy-1,3-dithiolane (4.5 g, 30 mmol) in dichloromethane (40 ml), we added, drop by drop, $BF_3 \cdot Et_2O$ (2.1 g, 15 mmol) at 0 °C. The mixture was brought to room temperature, stirred for 14 h, and then poured into about 200 ml of water. The organic layer was separated, and the aqueous phase was thoroughly extracted with dichloromethane. The combined dichloromethane solution was washed successively with water, 5% aqueous $NaHCO_3$, and again with water, dried over anhydrous $MgSO_4$, filtered, and concentrated *in vacuo* to give the crude product. The crude 1,3-dithiolan-2-ylated phenols thus obtained were purified by distillation under reduced pressure or by column chromatography on silica gel (see footnote to Table 2).

Reaction of N,N-*Dimethylaniline (**5**) with 2-Ethoxy-1,3-dithiolane in Acetic Acid.* To a solution of **5** (1.6 g, 13 mmol) in acetic acid (30 ml) we added, drop by drop, 2-ethoxy-1,3-dithiolane (3.0 g, 20 mmol) at 110 °C. The mixture was stirred for 5 h at the same temperature, cooled, and then poured into about 150 ml of saturated brine. The resulting acidic solution was thoroughly extracted with ether and backwashed repeatedly with saturated brine containing Na_2CO_3, saturated brine, and a small amount of water, dried over anhydrous $MgSO_4$, filtered, and concentrated *in vacuo* to give a residue. It was chromatographed on silica gel, using 15% ether–hexane as eluent, to provide 2.3 g (77%) of **6**.

*Reaction of Indole (**7**) with 2-Ethoxy-1,3-dithiolane in Acetic Acid.* To a solution of **7** (1.5 g, 13 mmol) in acetic acid (30 ml) we added, drop by drop, 2-ethoxy-1,3-dithiolane (3.0 g, 20 mmol) at 110 °C. The mixture was stirred for 5 h at the same temperature and then worked up as described in the above experiment using **5**. Subsequent column chromatography on silica gel, using 50% chloroform–hexane as the eluent, gave two products, **8** (1.8 g, 64%) and **9** (0.34 g, 8%). When the reaction temperature was varied from 110 °C to room temperature, only the former, **8**, was obtained in an 81% yield.

Preparation of Aldehydes from 1,3-Dithiolan-2-ylated Aromatics. To a suspension of red HgO (3.9 g, 18 mmol) in 20 ml of 15% aqueous tetrahydrofuran, maintained under N_2 at 0 °C, we added, drop by drop, $BF_3 \cdot Et_2O$ (2.6 g, 18 mmol). The mixture was then allowed to warm to room temperature. A 1,3-dithiolan-2-ylated aromatic (9 mmol) was added over a period of 20 min, after which the mixture was stirred for 1 h. The resulting insoluble precipitate was filtered and washed thoroughly with a large amount of ether. The foregoing filtrate was extracted repeatedly with the washings and once with ether. The combined ethereal extracts were washed successively with saturated brine containing Na_2CO_3 (pH 10), saturated brine, and a small amount of water, dried over anhydrous $MgSO_4$, filtered, and concentrated *in vacuo* to give the crude aldehyde, which was then purified.

Asymmetric Reactions. X. Asymmetric Hydrogenation Catalyzed by Bis(dimethylglyoximato)cobalt(II)–Chiral Cocatalyst (Amino Alcohol) System

Yoshiaki Ohgo,* Seiji Takeuchi, Yukikazu Natori, and Juji Yoshimura†

Niigata College of Pharmacy, 5829 Kamishin'ei-cho, Niigata 950-21

† *Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received December 16, 1980)

The catalytic asymmetric hydrogenations of α-diketones, α-keto carboxylates, α-(acylamino)acrylates, α-phenylacrylophenone, and α-phenylacrylate were examined with bis(dimethylglyoximato)cobalt(II)–chiral cocatalyst (amino alcohol) and with simple achiral base coordinated bis(dimethylglyoximato)cobalt(II)–chiral cocatalyst (amino alcohol) systems. These gave corresponding optically active reduction products, and in some cases, optically active reductive dimerization products. High degrees of enantioselectivities (≈78%) are achieved in the hydrogenation of α-diketones. Evidence for non-binding of chiral base to cobalt complexes was presented in the case of latter system, *i.e.*, it was shown that the catalytic site and the enantioselectivity-determining site are separated in this system, as in enzymes. The importance of protonated chiral bases for enantioselection was also shown. Based on these results and the stereochemical correlations between structures of the chiral bases and those of the products, a mechanism for this asymmetric hydrogenation was proposed.

Considerable attention has recently been paid to metal complex-catalyzed asymmetric hydrogenation.[1,2] Most of the researches in this area concentrate on the chiral phosphine rhodium complexes which have given successful results in the asymmetric hydrogenation of olefinic compounds.[1,2] In spite of the obvious advantages of being easily accessible and versatile, catalytic asymmetric hydrogenation using cobalt complexes and/or chiral cocatalysts has scarcely been studied.[3–6]

From the viewpoint of chemical evolution, the authors began to study asymmetric hydrogenation with one of the simplest catalysts, cyanocobalt–chiral amine systems.[3,4] The limitations of these systems suggested that we should use a complex whose framework is stable during the reaction. On the other hand, bis(dimethylglyoximato)cobalt(II) complex (Fig. 1)[7]

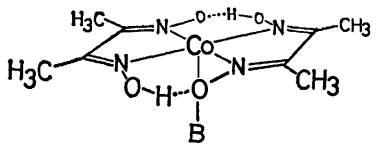

Fig. 1. Bis(dimethylglyoximato)cobalt(II).

was shown to be an effective catalyst for hydrogenation of activated olefinic compounds, α-diketones, α-keto carboxylates, and unsaturated nitrogen compounds.[8,9] We expected that a polyfunctional asymmetric substance bound weakly to cobalt or dimethylglyoxime ligand could draw a substrate into the reaction center with an attractive interaction and should bring about asymmetric induction. Thus, we have found two unique and excellent catalyst systems, bis(dimethylglyoximato)cobalt(II)–chiral amino alcohol and achiral base coordinated bis(dimethylglyoximato)-cobalt(II)–chiral amino alcohol, which catalyze asymmetric hydrogenation of α-diketones, α-keto carboxylates, and olefinic compounds. These have, in part, been communicated previously.[5]

The purpose of this paper is to describe more detailed results and the mechanism of this asymmetric hydrogenation which revealed the unique characteristic of these systems: the catalytic site and the enantioselectivity-determining site are separated, as in enzymes.

Results and Discussion

Catalytic Asymmetric Hydrogenation of α-Keto Carbonyl Compounds and Olefinic Compounds with Bis(dimethylglyoximato)cobalt(II)–Chiral Base System. (a) Substrate Study: Catalytic hydrogenations of various keto carbonyl compounds were examined using bis(dimethylglyoximato)cobalt(II)–quinine under an atmospheric pressure of hydrogen in benzene solution. α-Diketones and α-keto carboxylates were catalytically hydrogenated with this catalyst system to give the corresponding optically active reduction products as shown in Table 1. However, β-keto carboxylates, α-keto carboxamides, and 1,4-dibenzoylbenzene resisted reduction under the given conditions.

Asymmetric hydrogenation of benzil gave *S*(+)-benzoin almost quantitatively with 71% optical yield at 10 °C. The carbonyl group adjacent to the phenyl group of methyl phenyl diketone was preferentially reduced to give *S*(+)-α-hydroxy-α-phenylacetone in 56% optical yield. This compound was shown to racemize under the reaction conditions, and the true enantioselectivity (about 67%) was obtained by extrapolation of the linear log $[\alpha]_D$ *vs.* reaction time to $t=0$. The hydrogenation of biacetyl gave not only the simple reduction product, but also reductive dimerization products. The simple reduction product, acetoin, and reductive dimerization products, 3,4-dihydroxy-3,4-dimethyl-2,5-hexanedione, were separated by silica gel column chromatography. The ratio of *erythro* isomer (78%) and *threo* isomer (22%) in the dimerization products was determined from the intensities of NMR signals of C–CH_3 [δ 1.25 (*erythro*) and δ 1.30 (*threo*)] and CH_3CO [δ 2.36 (*erythro*) and δ 2.23 (*threo*)].[10] Reduction of 1,2-cyclohexanedione gave 2-hydroxycyclohexanone with $[\alpha]_D$ −2.44° in 54% chemical yield. The optical yield can not be

a) Catalytic hydrogenation was carried out in benzene under the atmospheric pressure of hydrogen. In every experiment, equimolar amounts of quinine (Q*) and its HCl salt (Q*HCl) were used (Q*/Co=Q*HCl/Co=1). b) Specific rotation of pure *R*(−)-α-hydroxy-α-phenylacetone, $[\alpha]_D^{20}$ −158.3° (*c* 2.5, ethanol).[11] c) Specific rotation of pure (*R*(−)-acetoin, $[\alpha]_D$ −82° (*c* 0.844, water)[12] d) This value was based upon the concentration of *threo* derivative calculated from the ratio of *threo* to *erythro*. e) Specific rotation of pure ethyl *S*(+)-mandelate, $[\alpha]_D^{20}$ +205.1° (*c* 0.7, carbon disulfide).[13] f) Specific rotation of mandelic acid derived by hydrolysis of the product (isopropyl mandelate); Specific rotation of pure *S*(+)-mandelic acid, $[\alpha]_D^{20}$ +157.5 (*c* 2.1875, water)[14] g) S/Co: molar ratio of substrate to cobalt. h) Specific rotation of pure benzoin, $[\alpha]_D$ ±118.5 (*c* 1, acetone).[15]

determined because the optically pure enantiomer is unknown. Hydrogenation of ethyl phenylglyoxylate and isopropyl phenylglyoxylate gave ethyl *S*(+)-mandelate and isopropyl *S*(+)-mandelate in optical yields of 19.5 and 11.4%, respectively. In these cases, reductive dimerization products which had positive rotation were also obtained. The yields of reductive dimerization products increase with increasing molar ratio of substrate to cobalt. The details of these reductive dimerizations will be published separately.

Catalytic asymmetric hydrogenations of olefinic compounds were also carried out in benzene solution. The reaction products were purified by distillation, except for the case of methyl (*S*)-*N*-(phenylacetyl)-alaninate (**23**). All these samples were checked by ^{1}H NMR. Optical yields were calculated from the specific rotations of the products by reference to the maximum optical rotation reported in the literature, except for **23** which was obtained by methylation of (*S*)-*N*-(phenylacetyl)alanine ($[\alpha]_D$ −30°)[19] with diazomethane, $[\alpha]_D$ −56.9° (*c* 2, methanol) (see experimental part). The results are shown in Table 2. Olefinic double bonds of both the olefinic ketone and olefinic carboxylates are chemospecifically hydrogenated with this catalyst system to give the corresponding saturated optically active ketone and carboxylates.

In general, the optical yields with the substrates carrying acyl groups were much higher than those with the substrates carrying alkoxycarbonyl groups (Tables 1 and 2).

(b) Effect of Solvent: Catalytic hydrogenation of benzil was examined in several solvent systems (Table

3). As is seen from Table 3, the optical yield increases with decreasing polarity of the solvent used. The reaction in benzene gave maximum optical yield under the given conditions. The carbonyl and hydroxyl groups in the solvent molecules decrease the enantioselectivity considerably, suggesting that these groups are concerned with the enantioselection mechanism.

(c) Effect of Temperature and Activation Parameters: The enantioselectivities and pseudo-first-order rate constants were determined at 10°, 20°, and 30 °C in the Co(dmg)$_2$–quinine catalyzed hydrogenation of benzil. The results are summarized in Table 4. From the Arrhenius plot of the rate constants, the apparent activation energy (ΔE_a^*) and the activation entropy (ΔS^*) were estimated to be 8.3 kcal/mol and −50 eu, respectively. Plotting logarithms of the enantiomeric ratio (*S*-isomer/*R*-isomer) *vs.* $1/T$ gave fairly good linearity. From the slope and the intercept at $1/T=0$, the difference between the activation enthalpies for the formation of *R*-isomer and that of

S-isomer ($\Delta\Delta H^{*}_{R\text{-}S}$), and the corresponding entropy difference of activation ($\Delta\Delta S^{*}_{R\text{-}S}$) were estimated to be 2.9 kcal/mol and 6.5 eu, respectively. It should be mentioned that in spite of the rather large difference in activation enthalpies, activation free energy difference became rather small ($\Delta\Delta G^{*}_{R\text{-}S}$=1.1 kcal/mol at 10 °C) since the contribution of the activation entropy term of the same sign is also large ($T\cdot\Delta\Delta S^{*}_{R\text{-}S}$=1.8 kcal/mol).

(d) Effect of Structure of Chiral Amines: In order to obtain some information on the structural parts which have effective interactions in enantioselection, several amines were tested for this catalytic asymmetric hydrogenation of benzil. Only free bases were used in this series of experiments. The results are shown in Table 5; the structures of chiral amines needed for this explanation are shown in Fig. 2. Quinine, quinidine, and cinchonidine have the same configuration at C_3 and C_4 (3*R*,4*S*).[20] The configuration at C_8 and C_9 of quinine and cinchonidine is (8*S*,9*R*), while that of quinidine is (8*R*,9*S*).[20] (−)-Ephedrine,[21] (−)-*N*-methylephedrine,[22] (1*R*,2*S*)-2-amino-1,2-diphenylethanol[23] have the same configurations as quinine at carbon atoms which are attached to amino and hydroxyl groups, *i.e.*, (C_N–*S*,C_{OH}–*R*). *Ψ*-Ephedrine,[24] and (1*S*,2*S*)-2-amino-1,2-diphenylethanol[23] have the (C_N–*S*,C_{OH}–*S*) configuration.

The results indicate that the chiral structure at C_3 and C_4 of quinine, quinidine, and cinchonidine does not affect enantioselectivity (runs 1—4), and that the configuration of predominant isomer is unequivocally determined by those of the vicinal carbons which are attached to amino and hydroxyl groups, *i.e.*, (C_N–*S*,C_{OH}–*R*) and (C_N–*R*,C_{OH}–*S*) give *S*(+)- and *R*(−)-benzoin, respectively. Brucine and *O*-acetylquinine gave extremely low enantioselectivity and moreover, *S*(−)-α-methylbenzylamine could not bring about asymmetric hydrogenation. These facts show again that the hydroxyl group of chiral amines plays an extremely important role in the enantioselection, as already pointed out in a previous section (b). The enantioselectivity of chiral amino alcohol seems to increase in the order of primary, secondary, and tertiary amines.

Asymmetric Hydrogenation Catalyzed by a Conjugated System Composed of Achiral Base Coordinated Bis(dimethylglyoximato)cobalt(II) and Chiral Amino Alcohols (Cocata-

lysts). (a) Evidence for Non-binding of Chiral Base to Cobalt Complexes: Our primary concern is to disclose the mechanism by which chiral amine brings about asymmetric induction. Two dimethylglyoxime monoanions are in planar coordination to cobalt. If chiral amine would coordinate to cobalt, the catalytically active site must be at the site trans to the chiral amine which can not interact with the substrate directly. All attempts to isolate a quinine or quinidine coordinated complex were unsuccessful. However, (1*R*, 2*S*)-2-amino-1,2-diphenylethanol coordinated (2-cyanoethyl)bis(dimethylglyoximato)cobalt(III) (**25**) was isolated. From NMR and circular dichroism spectra of the complex and from the importance of the hydroxyl group of chiral amine, asymmetric induction had, first, been assumed to be brought about by an asymmetric field induced at the site trans to chiral axial base through hydrogen bonding between the oxygen of the dimethylglyoxime ligand and the hydroxyl group of chiral amino alcohol. However, X-ray analysis of the complex (**25**) revealed that the amino nitrogen and the hydroxyl group of amino alcohol are fully transoid; there exists no hydrogen bonding between the oxygen of the inplane ligand and the hydroxyl group of amino alcohol and also no significant asymmetric distortion of the inplane ligand (Fig. 3).[25] The optical yields increase in the order of primary, secondary, and tertiary amines. This order is consistent with that of the difficulty in coordination of the amine. Such results suggested the possibility that asymmetric induction was brought about by an amino alcohol molecule other than that coordinated to the cobalt atom. Thus, asymmetric hydrogenation was examined in the presence of both chiral amino alcohol and an achiral simple base such as benzylamine, pyridine, and triphenylphosphine. The results are summarized in Table 6. A comparison of runs 4 and 6 (or 1 and 2) shows the optical yields did not decrease, while the reaction rates were extremely enhanced on addition of benzylamine to bis(dimethylglyoximato)cobalt(II)–quinine or –quinidine system. The reaction rates increase in the order of increasing electron donor ability of the achiral simple base added. This seems to suggest that the achiral simple base is coordinated to a cobalt atom. The rate acceleration made it easy to react at a lower temperature. At −10 °C in mesitylene the optical yield reached 78%.

In order to obtain more precise information on the coordinated base, the circular dichroism was examined. If an optically active amine is coordinated to a cobalt atom, the CD band due to vicinal effect[26] of the amine should be observed in the d-d transition region of cobalt. The CD spectra of mixtures of methylbis(dimethylglyoximato)cobalt(III) and quinidine were measured for various molar ratios (Fig. 4). The CD Cotton effect in the d-d transition region of cobalt increased with the increasing molar ratio of quinidine to cobalt complex, showing an equilibrium between the states of quinidine coordinated and non-coordi-

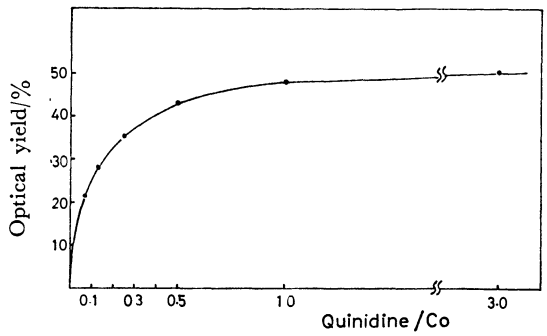

Fig. 5. Non-linear correlation between optical yields and molar ratio of quinidine to $Co(dmg)_2$ in the hydrogenation of benzil catalyzed by $Co(dmg)_2$·benzylamine-quinidine.

nated to the cobalt complex. Addition of an equimolar amount of benzylamine to the above system erased the Cotton effect. This clearly indicates that benzylamine coordinates selectively to cobalt in the system:

$$[CH_3Co(dmg)_2\cdot Q^* \rightleftarrows CH_3Co(dmg)_2 + Q^*] \xrightarrow{PhCH_2NH_2} CH_3Co(dmg)_2\cdot NH_2CH_2Ph + Q^*$$

However, the results still do not rule out the possibility that the amino alcohol have some interaction with some part of the ligands. In order to check this possibility, we studied the change in optical yield with variation of molar ratio of quinidine to cobalt complex in the hydrogenation of benzil by this system. If chiral amine and cobalt complex have a 1:1 interaction or binding, then the optical yields will increase linearly up to the ratio of Q*/Co=1. However, the results do not show a linear correlation (Fig. 5). These results clearly indicate that this enantioselection is brought about by chiral amino alcohol which does not bind firmly to any part of the complex. This fact is quite surprising in view of how asymmetric induction is brought about.

(b) Importance of Protonated Chiral Base for Enantioselection, and Mechanism of Asymmetric Hydrogenation: As is seen from Table 7, when free quinine only is used as the chiral substance in the hydrogenation of benzil, the optical yield is only 46%. However, when the hydrochloride of quinine is used, the optical yield becomes much higher. The optical yield increases a little more when both free quinine and its hydrochloride salt are used. Moreover, the addition of hydrochloride of achiral quinuclidine caused a remarkable decrease in enantioselectivity. A similar effect of hydrochloride salt was also observed in the hydrogenation of α-phenylacrylophenone (Table 8). These facts suggest that protonated chiral amino alcohol plays a decisive role in this enantioselection and also that the proton pulled out of the hydridobis(dimethylglyoxi-

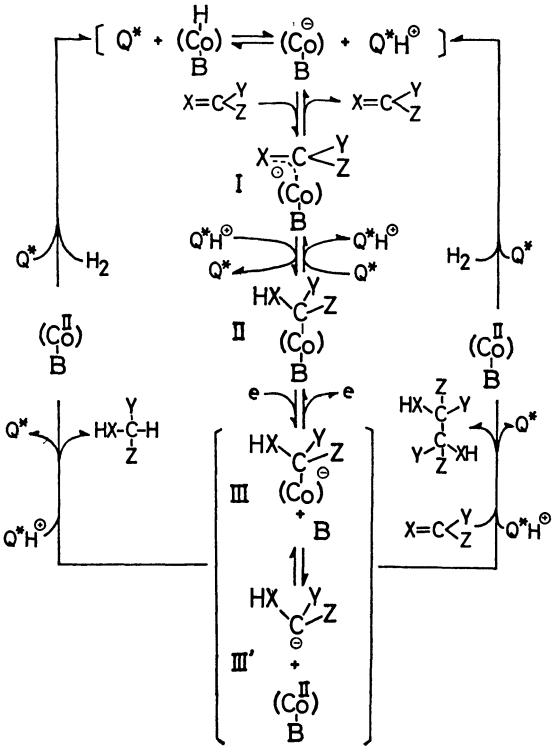
mato)cobalt complex by the amine reacts with substrate or substrate-bound complexes in a bound state. Addition of an achiral base stronger than the chiral base gives a protonated achiral base (t-BH^+), in competition with the formation of a protonated chiral base (B^*H^+). This is expected to cause a decrease in enantioselectivity. As expected, addition of a

$$[B^* + t\text{-}B + HCo(dmg)_2 \cdot B \rightleftharpoons Co(dmg)_2 \cdot B^- + B^*H^+ + t\text{-}B \rightleftharpoons Co(dmg)_2 \cdot B^- + B^* + t\text{-}BH^+]$$

stronger base to the system caused a remarkable decrease in enantioselectivity (Table 9). Even though these tertiary amines have almost the same basicity, their effects on the enantioselectivities are considerably different. The differences can be understood in terms of steric hinderances which prevent these protonated bases from approaching the reaction center. The same kind of steric effect is observed in cases of sterically hindered chiral amine (Table 10). On using quinine or quinidine, whose effective bulk around nitrogen atom is relatively small owing to the cage structure, optical yields did not vary with achiral weak bases such as benzylamine, pyridine, and triphenylphosphine. However, when *N*-methylephedrine was used as the chiral base, optical yields varied remarkably with variation of the above achiral bases. In this case, even a small amount of a protonated simple base (for example, dissociated benzylamine) or hydride complex seems to compete seriously. Thus, a fairly good result is obtained using triphenylphosphine as the axial base which has very low basicity toward protons.

Thus, protonated chiral amino alcohol must recognize enantiotopic face on giving its proton to the substrate or substrate-bound complexes. This, in turn, requires an electron donor at some stages. The species must be a Co(I) anion which is released by abstraction of H^+ from a hydride complex. The rate accelerations with increasing basicity and with addition of proton sources are in accord with the mechanism comprised of an electron donor [Co(I) anion] and a proton donor. In addition, the catalytic hydrogenation by this system has been shown to proceed through an α-alkyl complex, followed by the reductive cleavage of Co–C bond with a Co(I) anion.[9,28] The mechanism of this hydrogenation is schematically delineated in Scheme 1.

A hydridobis(dimethylglyoximato)cobalt complex is produced by the reaction of bis(dimethylglyoximato)-cobalt(II)–base and molecular hydrogen. The hydride complex dissociates into proton and Co(I) anion with an aid of a basic solute in equilibrium. The proton is captured by bases in this system. The substrate



Scheme 1. Catalytic cycle in the hydrogenation with $Co(dmg)_2$·B-Q*.
Electron (e) is supplied from hydrogen probably *via* $(Co^{I})\cdot B^{-}$. (Co), B, and Q* represent bis(dimethylglyoximato)cobalt, axial base and chiral cocatalyst (chiral amino alcohol), respectively.

gains an electron from the Co(I) anion to give an intermediate (anionic alkyl complex or radical anion) which undergoes the attack of the protonated base to give an alkyl complex (II). The reaction of the alkyl complex (II) with the electron donor, Co(I) anion, will form the reduced state of the alkyl complex, III, and/or carbanion, III'. The subsequent attack of the protonated base, Q^*H^+, and/or the protonated basic solute including the hydridobis(dimethylglyoximato)cobalt complex will give the simple reduction product. But if the reduced state of the alkyl complex or carbanion (III or III') undergoes the attack of another substrate followed by protonation, the reductive dimerization product may be formed. Enantioselection will take place in two stages when Q^*H^+ gives its proton to the intermediates I and III and/or III'. The latter stage of enantioselection will be more important for the following reasons. The former stage was shown to be in an equilibrium;[9] also, deuterium cleavage of optically pure [(*R*)-1-(methoxycarbonyl)ethyl](pyridine)bis(dimethylglyoximato)cobalt(III), which was easily derived by displacement of the axial base of [(*R*)-1-(methoxycarbonyl)ethyl] [*R*(+)-methylbenzylamine]bis(dimethylglyoximato)cobalt(III)[29] with pyridine, gave the inversion product predominantly, but the stereoselectivity was extremely low (lower than 1%).[30] This result implies that the reduced state of alkyl complex III is also in an equilibrium with carbanion III'.

Before presenting the mechanism of chiral recognition it is necessary to discuss the conformations of alkyl complexes or carbanions ejected from the reduced state of alkyl complexes. They will be able to exist in two forms of rotamers with respect to the rotating axis of C_α–COR' bond:

Transoid (*T*) Cisoid (*C*)

One is the rotamer in which substituents, R and R' are transoid, and the other is one in which they are cisoid. The stability of each form will be determined by the balance of the attractive interaction between O and HX, and the repulsive interaction between R and R'. Considering that Q^*H^+ selects the favored chirality of two enantiomers (or the favored prochiral face of carbanion) in the more stable rotamer (*T* or *C*) to furnish its proton, we can predict the configuration of the predominant enantiomer in all the cases examined.

In cases of substrates having large substituents such as benzil and α-phenylacrylophenone, two substituents have to situate in trans form, because of the large steric repulsion between these groups. Protonated quinine will approach the reduced alkyl complex (III) or carbanion (III') with an attractive interaction between the OH group of quinine and carbonyl group of substrate and also between the positive charge of protonated quinine and the negative charge of reduced alkyl complexes or carbanion (Fig. 6). The assumption of the attractive interaction between the hydroxyl group of amino alcohol and the carbonyl group of the substrate may be substantiated by solvent

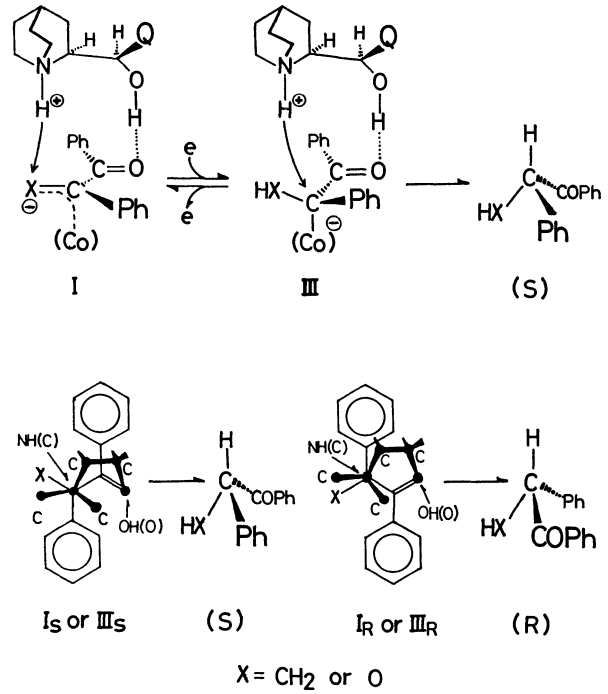


Fig. 6. A proposed mechanism for enantioselection in the hydrogenation of benzil, α-phenylacrylophenone, and methyl phenyl diketone.

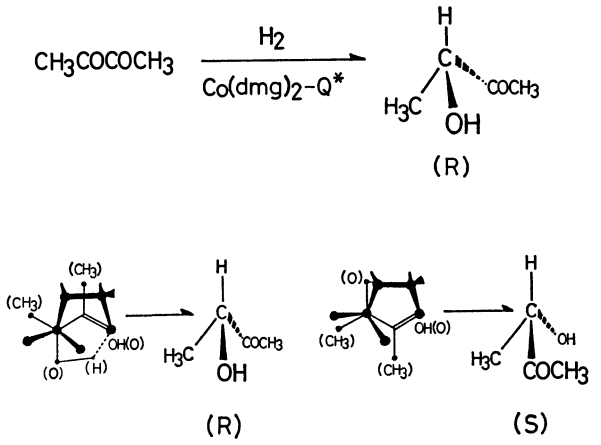

Fig. 7. A proposed mechanism for enantioselection in the hydrogenation of biacetyl.

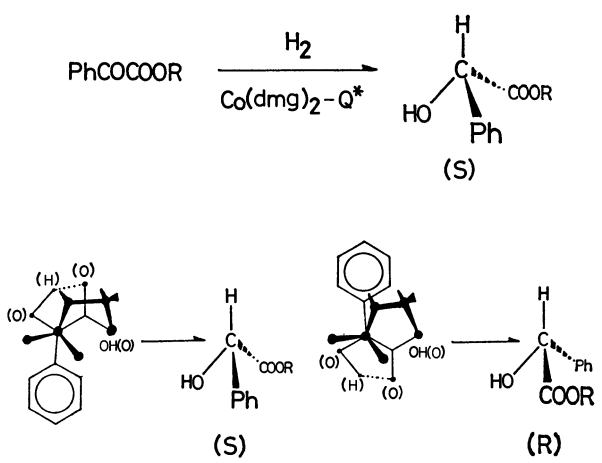

Fig. 8. A proposed mechanism for enantioselection in the hydrogenation of phenylglyoxylates.

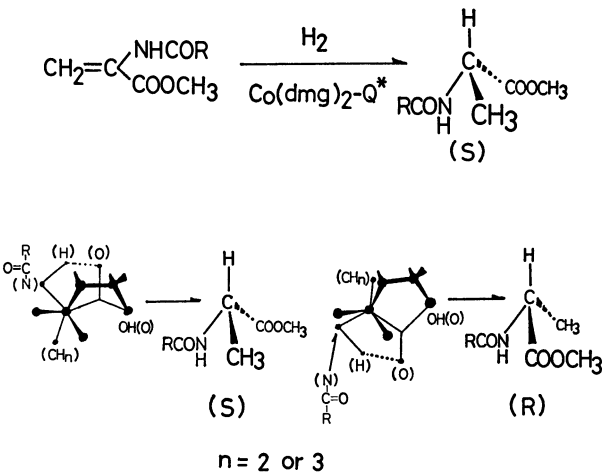

Fig. 9. A proposed mechanism for enantioselection in the hydrogenation of dehydroalanine derivatives.

effect: that solvents having hydroxyl and carbonyl groups decrease enantioselectivity, and also by the importance of hydroxyl group of chiral amine for the enantioselection. Is (or IIIs) and Ir (or IIIr) are the projections which are obtained by viewing I (or III) from above. As is seen, an approach like Is (or IIIs) which gives the predominant enantiomer (*S*) is well fitting and has no substantial repulsion, while the other (*R*) will result in a serious repulsion because the substituents around the reaction site are nearly eclipsed. In cases of the substrates having small substituents or substituents compelled to be in cisoid form, such as biacetyl and 1,2-cyclohexanedione, hydrogen bonded cis form will be favored. Thus, the attack of protonated quinine to the cis form (***C***) will reasonably be assumed in cases of substrates having small substituents or substituents compelled to be in cis form. The transition state which gives *R* isomer is more stable than that giving *S* isomer (Fig. 7). The same explanation will be made in the cases of α-keto carboxylates and α-(acylamino)acrylates (Figs. 8 and 9). Although only quinine was used for the explanation of the enantioselection mechanism, the enantioselectivity of other chiral amino alcohols can also be explained in the same way.

Features and Limitations of This Catalyst System. Thus, the attempt to overcome the shortcomings of the previously studied catalyst system, the cyanocobalt–chiral amine system, have led us to explore a unique catalyst system, bis(dimethylglyoximato)cobalt(II)·B–chiral amino alcohol system, which resembles enzymes. The catalytic site and the enantioselectivity-determining site of this catalytic system are separated: bis(dimethylglyoximato)cobalt complex and chiral amino alcohol are considered to correspond to NAD (or NADP) and apoenzyme, respectively. This makes it possible to improve these two catalytic features almost independently. In fact, catalytic activity was enhanced by increasing electron density on cobalt atom without decreasing enantioselectivity, when the chiral base used was the same.

On the other hand, enantioselection of this catalytic system is performed when the chiral proton carrier gives the proton. In consequence, the existence of achiral proton carrier makes enantioselectivity lower. This is an inherent shortcoming of this catalytic system. However, this is not one which is impossible to overcome: Directed proton transfer with complete enantioselectivity seems to be involved in biological redox systems.

Another aspect is concerned with kinetic parameters. As described in a previous section, in spite of the rather large difference of activation enthalpies ($\Delta\Delta H^{*}_{R\text{-}S}=2.9$ kcal/mol), the activation free energy difference becomes rather small ($\Delta\Delta G^{*}_{R\text{-}S}=1.1$ kcal/mol at 10 °C) because of large difference in activation entropy term which has the same sign. If it would be possible to make the entropy term zero, almost complete enantioselectivity (99%) should be achieved. Thus, controlling the entropy term is an essential problem to be solved.

Experimental

Melting points were measured by a Yanagimoto micro-melting point apparatus and are uncorrected. Nuclear magnetic resonance spectra were recorded on a JEOL JNM-4H-100 spectrometer, using TMS as the internal standard.

Gas liquid chromatography was performed on a Shimadzu GC-4CM using 10% PEG 4000-Celite column. Optical rotations were measured on a Carl Zeiss photoelectric precision polarimeter. Circular dichroism spectra were measured by JASCO ORD/UV-5 spectrometer. Infrared spectra were taken on a Hitachi EPI-G2 spectrophotometer.

General Procedure for Asymmetric Hydrogenation Catalyzed by Bis(dimethylglyoximato)cobalt(II)-Puinine. A 200 ml flask which have a side neck with a rubber cap was used as the reaction vessel. To a methanol (10 ml) solution of $CoCl_2 \cdot 6H_2O$ (0.25 g) was added a hot solution of dimethylglyoxime (0.244 g) in methanol (14 ml) under nitrogen atmosphere with stirring. The solution was stirred for 5—10 min and then 1 ml of 2.35 mol dm^{-3} sodium methoxide solution was added to this solution. After 1—2 min, a degassed methanol solution of an equimolar mixture of quinine and quinine hydrochloride (which is prepared by adding 0.46 ml of 2.35 mol dm^{-3}-sodium methoxide solution to a solution of quinine $HCl \cdot 2H_2O$ (0.84 g) in methanol (5 ml)) was added to the above reaction vessel. The reaction vessel was connected to a gas burret and a vacuum system through a three-way tap. Methanol in the resulting catalyst solution was evaporated under a reduced pressure with warming and stirring to a wet paste (in this case, caution should be taken not to dry the catalyst). To this paste 10 ml of degassed benzene was added by a syringe under atmospheric pressure of hydrogen, and the mixture was then evaporated again to a wet paste under a reduced pressure in order to eliminate the residual methanol (the above caution should be repeated). To the resulting catalyst was added a degassed benzene solution of substrate with a syringe under atmospheric pressure of hydrogen; hydrogenation was then initiated with vigorous stirring. After the theoretical amount of hydrogen was absorbed, about 300 ml of benzene or ether was added to the reaction mixture, and then successively washed with water (several times), 6 mol dm^{-3} or dilute hydrochloric acid (several times), and water. The organic layer was dried over anhydrous sodium sulfate, and concentrated under a reduced pressure to give the corresponding reduction products.

Asymmetric Hydrogenation of Benzil. In this case, the crude product obtained according to the general procedure was shown to contain substantially no impurity by TLC and GLPC; optical rotation was therefore measured without further purification. The IR and NMR spectra were identical with those of the authentic sample (benzoin). Yields were almost quantitative (Tables 1 and 3).

Asymmetric Hydrogenation of Methyl Phenyl Diketone. After carrying out the usual workup (general procedure) described above, 1.4 g of a syrupy product was obtained from 1.48 g of methyl phenyl diketone. The reaction products were adsorbed on a silica-gel column (Kiesel gel H, Merck) and successively eluted by hexane, benzene, and ethyl acetate. α-Hydroxy-α-phenylacetone (**8**) and α-hydroxypropiophenone (**9**) were thus isolated and characterized by NMR as follows. **8**: NMR ($CDCl_3$) δ 7.20 [s, 5H, phenyl], 5.05 [s, 1H, α-CH–], 3.70 [s, 1H, OH], 2.05 [s, 3H, $COCH_3$]. $[\alpha]_D^{22}$ +88.8° (*c* 2.3, ethanol). TLC R_f 0.27 (benzene/hexane/ethyl acetate=4.5/4.5/1). **9**: NMR ($CDCl_3$) δ7.85 [2H, ortho H of phenyl], 7.20 [mc, 3H, metha and para H of phenyl], 5.00 [q, 1H α-CH–], 1.45 [d, 3H, methyl). TLC R_f 0.41 (benzene/hexane/ethyl acetate=4.5/4.5/1). The ratio of **8** and **9** was determined by NMR of the crude products.

Asymmetric Hydrogenation of Biacetyl. The catalyst was prepared according to the general procedure, except for using twice the amounts of the reagents. To the catalyst was added a solution of 1.81 g of biacetyl in 50 ml of benzene. The mixture was stirred under the atmospheric pressure of hydrogen. The reaction was stopped when 97 ml of hydrogen was absorbed (this took 2 h). The reaction mixture was adsorbed on a silica-gel column (40 g of Wako gel C-200) and eluted by ether/petroleum ether (2/1). The eluate was checked by thin layer chromatography. The first fraction contained biacetyl; the next ones contained *erythro*- and *threo*-3,4-dihydroxy-3,4-dimethyl-2,5-hexanedione (**11**-E and **11**-T). The fractions containing reductive dimerization products were combined and concentrated under a reduced pressure to give 1.0 g of a syrup. The syrup was dissolved in benzene and the optical rotation was measured. The ratio of *threo* and *erythro* products was determined from the intensities of NMR signals of C–CH_3 and CH_3CO to be 22/78. From the ratio and the optical rotation of the mixture (**11**-E and **11**-T), the specific rotation of **11**-T produced was determined: $[\alpha]_D$ −33° (*c* 2.02, benzene). The fractions containing only acetoin were combined. The solvent was evaporated by bubbling N_2 gas into the eluate. The residue was distilled at 25—25.5 °C/29 mmHg (1 mmHg=133.322 Pa.) $[\alpha]_D$ −2° (*c* 0.8, water). From the optical rotation, the optical yield was calculated by reference to that of the optically pure acetoin.[12] Optical yield, 2.5%.

Asymmetric Hydrogenation of 1,2-Cyclohexanedione. The reaction was performed according to the general procedure, except for using benzene/methanol (4/1) as a solvent. After a theoretical amount of hydrogen was absorbed, the reaction mixture was extracted with chloroform and the chloroform layer was washed with NaCl-saturated water, dil HCl and water, successively. The chloroform layer was dried over anhydrous sodium sulfate, and concentrated under a reduced pressure to give a syrup which crystallized gradually. $[\alpha]_D$ −2.44° (*c* 0.35, chloroform).

Asymmetric Hydrogenation of Ethyl Phenylglyoxylate. After carrying out the general procedure, 1.6 g of a syrupy product was obtained from 1.78 g of ethyl phenylglyoxylate. The yields of ethyl mandelate and reductive dimerization products were calculated by ^1H NMR spectra and yield of the crude product. The crude product crystallized partially (about 0.31 g), mp 118—121 °C; it was recrystallized by hexane to give cubic crystals, mp 124 °C. Found: C, 67.02; H, 6.10; MS *m/e* 359[$(M+1)^+$]. Calcd for $C_{20}H_{22}O_6$: C, 67.02; H, 6.15. ^1H NMR ($CDCl_3$) δ 7.15 [10H, phenyl], 5.07 [s, 2H, OH], 4.30 [q, 4H, $-CH_2-$], 1.27 [t, 6H, methyl]. The syrup obtained after removal of crystals (by filtration) was chromatographed on a silica-gel column using hexane–benzene (with increasing polarity of the solvent) as the solvent, giving ethyl phenylglyoxylate (0.3 g), dimerization products (0.06 g), and ethyl mandelate (0.42 g). The specific rotations of ethyl mandelate are given in Table 1.

Asymmetric Hydrogenation of Isopropyl Phenylglyoxylate. After carrying out the general procedure, the crude products were adsorbed on a silica-gel column (Kiesel gel H, Merck) and eluted by hexane/benzene; the polarity of the solvent was gradually increased. Diisopropyl α,α′-diphenyltartrate and isopropyl mandelate were thus isolated and characterized by ^1H NMR spectra. ^1H NMR of diisopropyl α,α′-diphenyltartrate ($CDCl_3$) δ 7.02 [m, 10H, phenyl], 5.1 [q, 2H, methine H of isopropyl], 4.9 [s, 2H, OH], 1.14 [t, 12H, methyl]. ^1H NMR of isopropyl mandelate ($CDCl_3$) δ 7.35 [m, 5H, phenyl], 5.09 [s, 1H, methine H of α-carbon], 5.02 [m, 1H, methine H of isopropyl], 3.4 [broad s, 1H, OH], 1.28 [d, 3H, methyl], 1.11 [d, 3H, methyl].

Isopropyl mandelate thus isolated was hydrolyzed by refluxing with 4 mol dm^{-3}-sulfuric acid for 24 h. The reaction mixture was made alkaline and washed with benzene.

The aqueous layer was acidified and extracted with benzene. The organic layer was washed with water, and concentrated *in vacuo* to give 0.1 g of mandelic acid, $[\alpha]_D$ +18° (*c* 2.0, water).

Asymmetric Hydrogenation of Methyl α-(Acetylamino)acrylate. After carrying out the usual workup (general procedure), an oily product was obtained which was chromatographed on a silica-gel column using ether as a solvent. 0.8 g of an oily substance (*N*-acetylalanine methyl ester) was obtained starting from 1.2 g of the substrate; this was further purified by distillation at 70—82 °C/1—2 mmHg, 0.4 g, $[\alpha]_D$ −17.2° (*c* 1.2, water).

Asymmetric Hydrogenation of Methyl α-(Phenylacetylamino)acrylate. 187 ml of hydrogen was absorbed for 2.2 h. The reaction mixture was treated as usual (general procedure) to give 1 g of *N*-(phenylacetyl)alanine methyl ester (starting from 1.67 g of substrate), $[\alpha]_D$ −4° (*c* 2, methanol). The IR and ^{1}H NMR spectra of the product were identical with those of the authentic sample prepared by the reaction of (*S*)-*N*-(phenylacetyl)alanine with diazomethane.

(S)-N-(Phenylacetyl)alanine Methyl Ester. (*S*)-*N*-(Phenylacetyl)alanine was esterified with diazomethane. The crude product was purified by recrystallization from ether–petroleum ether, mp 68.5—70.5 °C, $[\alpha]_D$ −56.9° (*c* 2, methanol). ^{1}H NMR ($CDCl_3$) δ 7.30 [s, 5H, phenyl], 6.32 [broad d, 1H, NH], 4.57 [qt, 1H, CH], 3.68 [s, 3H, OCH_3], 3.57 [s, 2H, CH_2], 1.34 [d, 3H, C–CH_3]. IR (KBr), 3340 cm^{-1} (NH), 1745 cm^{-1} (ester), 1640 cm^{-1} (amide).

Asymmetric Hydrogenation of Methyl 2-Phenyl-2-propenoate. After carrying out the usual workup (general procedure), 2.5 g of a syrup was obtained from 2.7 g of substrate, $[\alpha]_D$ +7.7° (*c* 6.2, toluene). This was distilled at 67—68 °C/2 mmHg and 0.9 g of purified product (methyl 2-phenylpropanoate) was obtained, $[\alpha]_D$ +11.5° (*c* 6.2, toluene).

Asymmetric Hydrogenation of α-Phenylacrylophenone. After carrying out the usual workup (general procedure) 1.9 g of a syrup (crude α-phenylpropiophenone) was obtained from 2 g of substrate, $[\alpha]_D$ +88.6° (*c* 3.5, chloroform). The syrup was distilled at 115—116 °C/1 mmHg, 1.0 g $[\alpha]_D$ +99.4° (*c* 3.57, chloroform).

Reaction Rate. A 200 ml Erlenmeyer flask which has a side neck with a rubber cap was used as the reaction vessel. The catalyst was prepared according to the general procedure using $CoCl_2 \cdot 6H_2O$ (0.25 g), dimethylglyoxime (0.244 g), and quinine $HCl \cdot 2H_2O$ (0.84 g) (a half of which was neutralized with sodium methoxide). To the reaction vessel containing the catalyst was added a degassed benzene solution (50 ml) of benzil (2.24 g) by a syringe. The reaction was initiated with vigorous stirring. The reaction temperature was maintained constant within ±0.2 °C. The quantity of hydrogen absorbed was measured by a gas burret. The pseudo-first-order rate constants are listed in Table 4.

General Procedure for Asymmetric Hydrogenation Catalyzed by a Conjugated System Composed of Achiral Base Coordinated Bis-(dimethylglyoximato)cobalt(II) and Chiral Amino Alcohols. To a methanol solution (10 ml) of $CoCl_2 \cdot 6H_2O$ (0.25 g) was added a hot solution of dimethylglyoxime (0.244 g) in methanol (14 ml) under nitrogen atmosphere with stirring. The solution was stirred for 5—10 min and then 1 ml of 2.35 mol dm^{-3}-sodium methoxide solution was added to this solution. After 1—2 min, achiral base, additives, and a degassed methanol solution of equimolar mixture of quinine and quinine hydrochloride (which is prepared by adding 0.46 ml of 2.35 mol dm^{-3}-sodium methoxide solution to a solution of quinine $HCl \cdot 2H_2O$ (0.84 g) in methanol (5 ml)) were added to the above reaction vessel, one by one. The procedure hereafter was the same as in the "General Procedure for Asymmetric Hydrogenation Catalyzed by Bis-(dimethylglyoximato)cobalt(II)–Quinine."

Circular Dichroism Study. To each methanol solution of 9.15 g of methyl(dimethyl sulfide)bis(dimethylglyoximato)-cobalt(III)[31] 8.1 mg (1 molar equivalent), 12.1 mg (1.5 molar equivalent), 32.4 mg (4 molar equivalent), or 64.8 mg (8 molar equivalent) of quinidine was added. The resulting solution was evaporated *in vacuo* to dryness. The residue was dissolved in methanol and the resulting solution was again evaporated *in vacuo* to dryness. The procedure was repeated several times, during which dimethyl sulfide was completely expelled. Circular dichroism spectrum of 25 ml dichloromethane solution of each sample thus prepared was measured by JASCO ORD/UV-5 Spectrometer. The results are shown in Fig. 4.

The authors are grateful to Dr. Yuji Ohashi and Professor Yoshio Sasada, Tokyo Institute of Technology, for their valuable discussions. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (Japan) and by the Kawakami Foundation. The authors are also indebted to Professor Hiroshi Kobayashi, Tokyo Institute of Technology, for CD measurements, and Mr. Hitoshi Matsumoto for NMR measurements.

Asymmetric Hydrogenation Catalyzed by the (Achiral Base)bis(dimethylglyoximato)cobalt(II)-Chiral Cocatalyst System. The Preparation of a New Type of Chiral Cocatalyst and Its Application to the Asymmetric Hydrogenation of Methyl *N*-(Acetylamino)acrylate and Benzil[1)]

Seiji Takeuchi* and Yoshiaki Ohgo

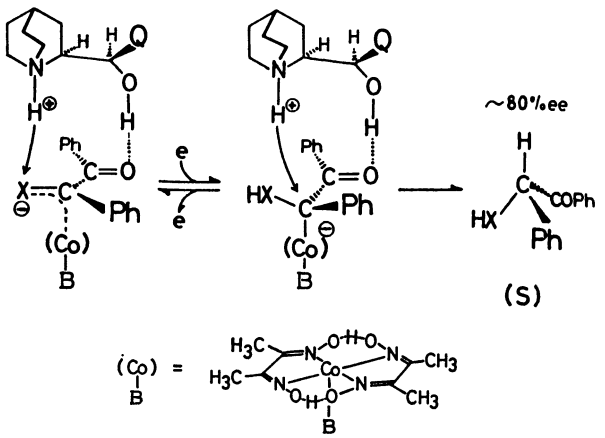
Niigata College of Pharmacy, 5829 Kamishinei-cho, Niigata 950-21

(Received December 16, 1980)

As a new type of chiral cocatalyst in the achiral base-coordinated bis(dimethylglyoximato)cobalt(II)–chiral cocatalyst system, tertiary amines with an amide group at α- or β-carbon were prepared, and asymmetric hydrogenation was examined by using them. The optical yield reached 34.5% enantiomeric excess(ee) by using *N*-[(2*S*,3*S*)-2-acetoxy-3-dimethylamino-3-phenylpropionyl]-(*R*)-α-methylbenzylamine; this is the highest value attained so far in the asymmetric hydrogenation of methyl *N*-(acetylamino)acrylate with this system. The enantioselectivity in the hydrogenation of methyl *N*-(acetylamino)acrylate was reversed with a configurational alteration of the α-methylbenzylamine moiety of *N*-[*N*,*N*-dimethyl-(*S*)-phenylalanyl]-α-methylbenzylamine, while it was not reversed in the hydrogenation of benzil by the configurational alteration. From these facts, it is deduced that the hydrogen bond between amide groups of the chiral amino carboxamides and methyl *N*-(acetylamino)acrylate may act as an attractive force to enhance the enantioselectivity of the asymmetric hydrogenation.

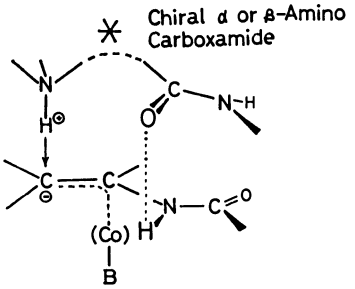
The authors have previously reported the asymmetric hydrogenation of α-diketones, α-keto carboxylates, and olefinic compounds catalyzed by an achiral base-coordinated bis(dimethylglyoximato)cobalt(II)–chiral base system (hereafter abbreviated as $Co(dmg)_2$·B–B*: B and B* are achiral and chiral bases respectively). This system resulted in high optical yields (up to 78%ee) and high reactivities for such α-diketone as benzil, but in low optical yields (up to 19%ee) and low reactivities for dehydro amino acid derivatives.[2)]

The catalytic system comprises two independent elementary processes, *i.e.*, electron-donation to a substrate by $[Co(dmg)_2 \cdot B]^-$ and proton-donation to a reduced state of the substrate by a protonated chiral base, of which only the proton-donation by the protonated chiral base is responsible for the asymmetric induction. Another important characteristic of this catalytic system is that the hydrogen bond between the hydroxyl group of the chiral base (chiral amino alcohol) and the carbonyl group of the substrate extremely enhances the enantioselectivity of the proton-donation reaction (Scheme 1).[1,2)]



Scheme 1.

Therefore, the chiral base can be modified arbitrarily so long as the characteristics are retained. If the hydrogen bond between amide groups of a chiral amine having a secondary amide group and a dehydro amino acid derivative will act as an effective attractive force in the enantioselective proton-donation steps, the chiral amine can be expected to afford better results for the enantioselective hydrogenation of dehydro amino acid derivatives (Scheme 2).



Scheme 2.

Here, we would like to describe the preparation of chiral tertiary amines bearing an alkylcarbamoyl group at the α- or β-carbon and the enantioselective hydrogenation of benzil and methyl *N*-(acetylamino)acrylate by their use of as cocatalysts.

Results and Discussion

Tertiary amines with an alkylcarbamoyl group at the α-carbon were prepared by the condensation of *N*-benzyloxycarbonyl derivatives of α-amino acids (L-phenylalanine, D-phenylglycine, L-isoleucine, and L-proline) with the corresponding amines (benzylamine, (*R*)- and (*S*)-α-methylbenzylamine), followed by reductive methylation. *N*-[(2*S*,3*S*)-3-dimethylamino-2-hydroxy-3-phenylpropionyl]-(*R*)-α-methylbenzylamine and its antipode were prepared by the condensation of (2*S*,3*R*)-2,3-epoxy-3-phenylpropionic acid and the (2*R*,3*S*)-isomer with (*R*)- and (*S*)-α-methylbenzylamine

respectively (using the DCC method), followed by opening the epoxide ring by the use of dimethylamine (see Experimental section).

The structures and abbreviations of these amino carboxamides are listed in Table 1.

The asymmetric hydrogenation of benzil and methyl *N*-(acetylamino)acrylate with $Co(dmg)_2$·B–B* was carried out in benzene under an atmospheric pressure of hydrogen at room temperature by using these amino carboxamides as chiral cocatalysts (B*). The hydrogenation rate with $Co(dmg)_2$·BA is much faster than that with $Co(dmg)_2$·PPh_3 (BA and PPh_3 are abbreviations of benzylamine and triphenylphosphine respectively). However, triphenylphosphine was used as B when B* was the chiral α-amino carboxamides, since the optical yield of benzoin with benzylamine (5.7%ee) was considerably lower than that with triphenylphosphine (15.7%ee). The amine released in some stage of the catalytic cycle competes with chiral α-amino carboxamides in catching and in transferring the proton to a reduced state of the substrate. Because of the lower basicity of α-amino carboxamides, the competition is rather more serious when benzylamine is used as B than when triphenylphosphine[1,2] (which has a very low basicity toward proton) is so used. Both benzylamine and triphenylphosphine were employed when B* was the chiral β-amino carboxamides.

The results are summarized in Tables 2 and 3.

As the chemical yield of methyl *N*-acetylalaninate was lowered during isolation, and as the amount of the enantiomeric excess did not exceed that of the loss in chemical yield, the possibility of enantiomer enrichment during the isolation procedure was checked. The methyl *N*-acetylalaninate had no optical rotation such as was isolated after the treatment of the racemic one under the same conditions as in the catalytic hydrogenation. Therefore, it is evident that the optical activities of methyl *N*-acetylalaninate shown in Tables 2 and 3 are those brought about only by the asymmetric hydrogenation.

As may be seen in Table 2, the optical yields of methyl *N*-acetylalaninate were up to 17.2%ee and did not exceed that attained with the $Co(dmg)_2$–quinine system, but an interesting difference in the direction of stereoselectivities for benzil and methyl *N*-(acetylamino)acrylate was observed. The reaction using *S*-amino acid derivatives as the chiral cocatalysts gave *S*-benzoin predominantly, irrespective of the configuration of the α-methylbenzylamine moiety (Runs 1,2, 3,6, and 7), but the enantioselectivity of methyl *N*-acetylalaninate was reversed with a configurational change in the α-methylbenzylamine moiety (Runs 2 and 3). Furthermore, methyl *N*-acetylalaninate with the same configuration as that of the α-carbon of the α-amino carboxamides used as chiral cocatalysts was produced predominantly, except for Run 3.

The reversal of enantioselectivity by changing the configuration of α-methylbenzylamine (Runs 2 and 3 of methyl *N*-acetylalaninate) makes us imagine that the hydrogen bond between the amide groups of Pha-*S*,*R* and methyl *N*-(acetylamino)acrylate may be formed in the proton-donation steps; such a phenomenon may be brought about only when chiral α-amino carboxamides are able to be in a conformation suitable

for hydrogen bonding between the amide groups of the chiral α-amino carboxamides and the substrates.

If the above consideration is reasonable, it is possible to explain the enantioselectivities (the configurations and optical yields of products) in terms of the following factors: I) the bulkiness and arrangement of substituents around the α-carbon atom of the α-amino acid moiety, II) the conformation of the chiral α-amino carboxamides, and III) the hydrogen bonding between the amide groups of the chiral α-amino carboxamides and the substrates. The configurations and optical yields of the products are determined by the I) and II) factors, while the reversal enantioselectivity and/or the relatively high optical yields are obtained when the III) factor brought about by the II) factor becomes predominant.

It is impossible here to infer what conformation of the chiral α-amino carboxamide, Pha-*S*,*R*, is most effective and suitable for hydrogen bonding between the amide groups of Pha-*S*,*R* and methyl *N*-(acetylamino)acrylate in the proton-donation steps.

As may be seen in Table 3, the optical yield of methyl *N*-acetylalaninate rose to 34.5%ee, which is the highest value attained so far in the asymmetric hydrogenation of methyl *N*-(acetylamino)acrylate with the $Co(dmg)_2$·B–B* system, and a marked difference in the enantioselectivities for benzil and for methyl *N*-(acetylamino)acrylate was observed. The optical yield of benzoin was 22.2%ee (Run 1), but that of methyl *N*-acetylalaninate was 6.2%ee at most (Runs 1 and 4) when chiral β-amino carboxamides used had a hydroxyl group. On the other hand, the optical yield of methyl *N*-acetylalaninate rose to 34.5%ee (Run 6), while that of benzoin was lowered to 1.1%ee (Run 5), when the chiral β-amino carboxamide used had no free hydroxyl group, but an acetoxyl group.

From these results it may be deduced that the hydroxyl group of DHP-(*R*,*R*)*S* and DHP-(*S*,*S*)*R* in Runs 1 and 4, and the amide group of DHP-*OAc*-(*S*,*S*)*R* in Runs 5 and 6, are operative in forming the hydrogen bond to the carbonyl group of benzil and to the amide group of methyl *N*-(acetylamino)acrylate respectively,

in their enantioselectivity-determining step.

The findings that the optical yield of benzoin was considerably lowered (Run 4) when triphenylphosphine was used as the achiral base, as compared with that using benzylamine (Run 1), and that the enantioselectivity was reversed by change from the presence of the hydrochloride of DHP-(*R,R*)*S* to its absence (Runs 1 and 3), differ from those observed when a simple chiral amino alcohol such as *N*-methylephedrine was employed as the chiral base of the $Co(dmg)_2$·B–B* system, although it is not evident why these differences are brought about.

In conclusion, new type of chiral cocatalysts, α- and β-amino carboxamides, were explored; of them, DHP-*OAc*-(*S,S*)*R* is one of the most promising chiral bases of the $Co(dmg)_2$·B–B*-catalyzed asymmetric hydrogenation of methyl *N*-(acetylamino)acryrate. It can also be mentioned that the hydrogen bond between the amide groups of DHP-*OAc*-(*S,S*)*R* and methyl *N*-(acetylamino)acrylate may play an important role in the asymmetric hydrogenation.

Experimental

The melting points were determined by a Yanagimoto micro-melting-point apparatus and were uncorrected. The IR spectra were recorded on a JASCO A-3 spectrometer. The NMR spectra were obtained on JEOL JNM-PMX60 and JNM-PS-100 spectrometers. The optical rotations were measured with a Perkin Elmer 241 polarimeter.

Preparation of Chiral α-Amino Carboxamides. The chiral α-amino carboxamides (Pha-*S,0*, Pha-*S,S* Pha-*S,R*; Phg-*R,S*; Il-*S,S* and Pr-*S,S* Pr-*S,R*) were prepared by essentially the same procedure. Benzylamide and (*R*)- or (*S*)-α-methylbenzylamides of *N*-benzyloxycarbonylated α-amino acids (purchased from the Peptide Institute, Osaka) were prepared from the corresponding amines and α-amino acid derivatives by a modified DCC method,[3] and then the reductive *N,N*-dimethylation or *N*-methylation of them with formalin[4] was carried out.

The preparation of Pha-*S,R* as a typical procedure and that of Phg-*R,S* as an exceptional one are shown below.

N-[N-*Benzyloxycarbonyl-(S)-phenylalanyl*]-(R)-*α-methylbenzylamine.* To a solution of *N*-benzyloxycarbonyl-(*S*)-phenylalanine (15.0 g, 50 mmol) and (*R*)-α-methylbenzylamine (purchased from Aldrich: $[\alpha]_D^{23}$ +38° (neat); 6.47 ml, 50 mmol) in DMF (100 ml) was added a solution of DCC (10.73 g, 52 mmol) and 1-hydroxybenzotriazole (7.43 g, 55 mmol) in DMF (100 ml) during 1 h on ice-cooling with stirring. The reaction mixture was then allowed to stand overnight at room temperature. The dicyclohexylurea separated out was filtered off, and the filtrate was concentrated *in vacuo* at 30—40 °C. The residue was dissolved in ethyl acetate (*ca.* 500 ml), and the solution was washed successively with a 1 mol dm^{-3}-hydrochloric acid (100 ml), a 1 mol dm^{-3}-sodium hydrogencarbonate solution (100 ml), and a sodium chloride solution (100 ml) and then dried over anhydrous sodium sulfate. The solution was concentrated to a half, and the crystals separated out were thoroughly dissolved on heating. To the solution was added petroleum ether carefully. 13.1 g of a first crop (needles) and from the filtrate after similar recrystallization, 3.15 g of a second crop (needles) were obtained: first crop, mp 135.0—146.0 °C, $[\alpha]_D^{22.0}$ +24.9° (*c* 1.018, $CHCl_3$) and second crop, mp 134.0—135.0 °C, $[\alpha]_D^{22.0}$ +24.1° (*c* 1.045, $CHCl_3$); IR (KBr) 3340 (NH), 1690 (carbamate C=O) and 1650 cm^{-1} (amide C=O); NMR ($CDCl_3$) δ=1.26 (3H, d, *J*=7 Hz, $C\underline{H}_3$–CH), 3.10 (2H, dd, Ph–$C\underline{H}_2$–CH), 4.40 (1H, q, Ph–CH_2–$C\underline{H}$), 5.00 (1H, quintet, *J*=7 Hz, CH_3–$C\underline{H}$), 5.08 (2H, s, Ph–$C\underline{H}_2$–O), 5.46 (1H, d, N$\underline{H}$), 5.90 (1H, d, N$\underline{H}$), 7.30 (15H, d, Ph).

N-[N,N-*Dimethyl-(S)-phenylalanyl*]-(R)-*α-methylbenzylamine, (Pha-S,R).* *N*-[*N*-Benzyloxycarbonyl-(*S*)-phenylalanyl]-(*R*)-α-methylbenzylamine (6.0 g, 15 mmol: the first crop obtained above) was dissolved in methanol (*ca.* 200 ml) on heating, and to the solution glacial acetic acid (0.85 ml, 15 mmol) was then added. Under a weak nitrogen-gas flow, the solution was poured into an Erlenmeyer flask (with a special neck stoppered with a silicone gum cap) in which a 10% palladium charcoal catalyst (1.0 g) has been placed. Setting up the equipment for hydrogenation, the flask was degassed and charged with hydrogen gas, and then hydrogenation was carried out under atmospheric pressure at room temperature with stirring. About a theoretical amount of hydrogen was absorbed during 1 h; then, after degassing and the introduction of hydrogen, 37% formalin (2.4 ml, 32 mmol) was injected through the silicone gum cap and the hydrogenation was continued overnight. About two equivalents of hydrogen were absorbed. The reaction mixture was then filtered through celite, and the filtrate was concentrated *in vacuo*. The residue was dissolved in ether (*ca.* 200 ml) and washed twice with sodium hydrogencarbonate solution, and then the ether layer was dried over anhydrous sodium sulfate. The solution was concentrated *in vacuo* to afford 4.26 g of crystalline materials. This was recrystallized from ether–petroleum ether to yield 2.90 g of a first crop (needles) and 0.98 g of a second crop (needles): first crop, mp 79.5—80.5 °C, $[\alpha]_D^{12.5}$ +72.0° (*c* 1.005, $CHCl_3$) and second crop, mp 78.0—79.0 °C, $[\alpha]_D^{22.0}$ +70.8° (*c* 1.016, $CHCl_3$); IR (KBr) 3300 (NH) and 1630 cm^{-1} (amide C=O); NMR ($CDCl_3$) δ=1.38 (3H, d, *J*=7 Hz, $C\underline{H}_3$–CH), 2.28 (6H, s, $N(C\underline{H}_3)_2$), 3.13 (3H, m, Ph–$C\underline{H}_2$–CH), 5.10 (1H, quintet, *J*=7 Hz, CH_3–$C\underline{H}$), 7.03 (1H, d, N$\underline{H}$), 7.28 (10H, d, Ph).

N-[N,N-*Dimethyl-(R)-phenylglycyl*]-(S)-*α-methylbenzylamine, (Phg-R,S).* The reductive *N,N*-dimethylation of *N*-[*N*-benzyloxycarbonyl-(*R*)-phenylglycyl]-(*S*)-α-methylbenzylamine gave *N,N*-dimethylated, *N*-monomethylated and deaminated products; the yield of the *N,N*-dimethylated product, Phg-*R,S*, among them was very low. Therefore, *N*-[*N*-methyl-(*R*)-phenylglycyl]-(*S*)-α-methylbenzylamine was prepared in a 75% yield by using an equimolar amount of formardehyde and stopping the reductive methylation when equimolar amount of hydrogen had been absorbed. The isolated *N*-methylated product was further *N*-methylated by the following procedure.

A solution of *N*-[*N*-methyl-(*R*)-phenylglycyl]-(*S*)-α-methylbenzylamine (6.5 g, 24 mmol), 37% formalin (2.17 ml, 29 mmol) and 88% formic acid (3.7 g, 71 mmol) was refluxed for 3.5 h. After cooling, the solution was acidified with conc hydrochloric acid and extracted with ether (*ca.* 50 ml). By making the water layer basic with sodium hydroxide, an oily material was separated out and then crystallized. The crystalline products were extracted with ether (100 ml), and the solution was dried over sodium sulfate. The solution was concentrated *in vacuo* to afford 5.82 g of crystalline products. This was recrystallized from ether-petroleum ether to yield 4.27 g of white needles: mp 92.5—93.5 °C, $[\alpha]_D^{12.5}$ −146.6° (*c* 1.006, $CHCl_3$); IR (KBr) 3300 (NH) and 1660 cm^{-1} (amide C=O); NMR ($CDCl_3$) δ=1.56 (3H, d, *J*=7 Hz, $C\underline{H}_3$–CH), 2.20 (6H, s, $N(C\underline{H}_3)_2$), 3.72 (1H, s, Ph–$C\underline{H}$–CONH), 5.15 (1H, quintet, *J*=7 Hz, CH_3–$C\underline{H}$), 7.24 (11H, m, N$\underline{H}$ and Ph).

The hydrochlorides of the α-amino carboxamides were

prepared by bubling dry hydrogen chloride gas into an ether solution of α-amino carboxamides and recrystallized from methanol–ethyl acetate or methanol–ether–ethyl acetate.

The physical constants and data of the elemental analyses of the chiral α-amino carboxamides and their hydrochlorides are summarized in Table 4.

Preparation of Chiral β-Amino Carboxamides.

N-[(2S,3R)-2,3-Epoxy-3-phenylpropionyl]-(R)-α-methylbenzylamine and Its Antipode. (*R*)-α-methylbenzylammonium (2*S*,3*R*)-2,3-epoxy-3-phenylpropionate and its antipode were prepared by Harada's method.[5]

To a suspension of (*R*)-α-methylbenzylammonium (2*S*, 3*R*)-2,3-epoxy-3-phenylpropionate ($[\alpha]_D^{24.0}$ +126.3° (*c* 1.001, 99% ethanol), lit,[5] $[\alpha]_D$ +125.5° (*c* 0.96, abs ethanol); 15.3 g, 54 mmol) in DMF (300 ml) was added a solution of DCC (11.2 g, 54 mmol) and 1-hydroxybenzotriazole (7.3 g, 54 mmol) in DMF (100 ml) during 1.5 h on ice-cooling with stirring. The reaction mixture gradually became homogeneous and then heterogeneous again. Stirring was continued overnight at room temperature. After the filtration of the precipitates, the filtrate was concentrated *in vacuo* at 30—40 °C. The residue was dissolved in ethyl acetate (*ca.* 800 ml), after which the solution was washed successively with a 10% citric acid solution (200 ml), a 4% sodium hydrogencarbonate solution (200 ml), and a sodium chloride solution (200 ml) and then dried over anhydrous sodium sulfate. The solution was subsequently concentrated to 500—600 ml, and the crystals separated out were dissolved thoroughly on heating. To the solution was added petroleum ether carefully. 10.2 g of a first crop (needles) and, from the filtrate, 3.3 g of a second crop (needles) were obtained: first crop, mp 168.0—169.0 °C, $[\alpha]_D^{23.0}$ +143.1° (*c* 0.997, $CHCl_3$) and second crop, mp 167.0—168.0 °C, $[\alpha]_D^{23.0}$ +143.2° (*c* 0.997, $CHCl_3$): IR (KBr) 3300 (NH) and 1660 cm^{-1} (amide C=O); NMR ($CDCl_3$) δ=1.50 (3H, d, *J*=6.5 Hz, $C\underline{H}_3$–CH), 3.50 (1H, d, *J*=2 Hz, Ph–C<u>H</u>–O), 3.68 (1H, d, *J*=2 Hz, C<u>H</u>–CONH), 5.07 (1H, quintet, *J*=6.5 Hz, CH_3–C<u>H</u>), 6.43 (1H, d, N<u>H</u>), 7.17 (10H, Ph).

Its antipode was likewise prepared from (*S*)-α-methylbenzylammonium (2*R*,3*S*)-2,3-epoxy-3-phenylpropionate (18.0 g, 63 mmol) to afford 14.4 g of a first crop (needles) and 2.3 g of a second crop (needles): first crop, mp 169.0—170.0 °C, $[\alpha]_D^{22.0}$ −144.5° (*c* 0.996, $CHCl_3$) and second crop, mp 167.0—168.0 °C, $[\alpha]_D^{22.0}$ −138.7° (*c* 0.990, $CHCl_3$).

N-[(2S,3S)-3-Dimethylamino-2-hydroxy-3-phenylpropionyl]-(R)-α-methylbenzylamine, (DHP-(S,S)R) and Its Antipode (DHP-(R,R)S). A suspension of the first and second crops of *N*-[(2*S*,3*R*)-2,3-epoxy-3-phenylpropionyl]-(*R*)-α-methylbenzylamine (13.1 g, 49 mmol) prepared above in a 50% dimethylamine aqueous solution (250 ml) was stirred for 4 h at room temperature. The undissolved crystals were then filtered off, and the filtrate was evaporated *in vacuo*. A crystalline mass was separated out when the water began to evaporate and was then filtered off. After drying, the crystals were recrystallized from benzene to yield 7.4 g of a first crop (needles): mp 157.0—157.5° C, $[\alpha]_D^{26.5}$ +52.7° (*c* 1.028, $CHCl_3$); IR (KBr) 3400 (NH), 3200 (OH) and 1660 cm^{-1} (amide C=O); NMR ($CDCl_3$) δ=1.40 (3H, d, *J*=7 Hz, $C\underline{H}_3$–CH), 2.26 (6H, s, $N(C\underline{H}_3)_2$), 3.59 (1H, d, *J*=5 Hz, N–C<u>H</u>–CH–CONH), 4.20 (1H, s, OH), 4.60 (1H, d, *J*=5 Hz, C<u>H</u>–CONH), 4.90 (1H, quintet, *J*=7 Hz, CH_3–C<u>H</u>), 6.75 and 7.20 (11H, m, N<u>H</u> and Ph); Found: C, 73.23; H, 7.76; N, 9.03%; Calcd for $C_{19}H_{24}N_2O_2$: C, 73.04; H, 7.74; N, 8.97% and 1.43 g of a second crop (needles): mp 157.0—157.5 °C, $[\alpha]_D^{26.0}$ +53.1° (*c* 1.018, $CHCl_3$). The crystals obtained above by the filtration of the reaction mixture were also recrystallized from benzene to yield 2.7 g of a third crop (needles): mp 156.5—157.5 °C, $[\alpha]_D^{26.0}$ +51.3° (*c* 1.082, $CHCl_3$).

Its antipode, DHP-(*R*,*R*)*S*, was likewise prepared from *N*-[(2*R*,3*S*)-2,3-epoxy-3-phenylpropionyl]-(*S*)-α-methylbenzylamine (14.0 g, 52 mmol) to afford 7.82 g of a first crop: mp 156.5—157.5 °C, $[\alpha]^{26.5}$ −52.7° (*c* 1.007, $CHCl_3$); Found: C, 72.32; H, 7.74; N, 8.88%, a second crop (1.37 g): mp 156.5—157.5 °C, $[\alpha]_D^{26.5}$ −52.9° (*c* 1.007, $CHCl_3$) and a third crop (3.18 g): mp 156.0—157.0 °C, $[\alpha]_D^{26.5}$ −51.1° (*c* 1.101, $CHCl_3$).

The hydrochloride of DHP-(*R*,*R*)*S* was prepared by the procedure described above from the first crop of DHP-(*R*, *R*)*S*: mp 211.5—212.5 °C, $[\alpha]_D^{20.0}$ −38.7° (*c* 1.004, CH_3OH).

N-[*(2S,3S)-2-Acetoxy-3-dimethylamino-3-phenylpropionyl*]-*(R)*-*α-methylbenzylamine, (DHP*-OAc-*(S,S)R)*. To a solution of the first crop of DHP-*(S,S)R* prepared above (2.0 g, 64 mmol) in dry ethyl acetate (150 ml) was added acetyl chloride (0.54 g, 64 mmol). The solution was allowed to stand for 2 d at room temperature and then concentrated *in vacuo*. The residue was solidified by scratching the flask with ether. The solids were filtered off and dissolved in water. The solution was washed with ether, and the aqueous layer was made basic with a sodium hydrogencarbonate solution. The solution was extracted with ether, and the ether layer was dried over anhydrous sodium sulfate. The solution was concentrated *in vacuo* to afford 1.8 g of a crystalline material. This was recrystallized from ether–petroleum ether to yield 1.35 g of needles: mp 83.0—84.0 °C, $[\alpha]_D^{23.0}$ +21.6° (*c* 1.008, $CHCl_3$); IR (KBr) 3400 (NH), 1725 (ester C=O) and 1675 cm^{-1} (amide C=O); NMR ($CDCl_3$) δ=1.46 (3H, d, *J*=7 Hz, $C\underline{H}_3$-CH), 2.03 (3H, s, $C\underline{H}_3COO$), 2.23 (6H, s, N-($C\underline{H}_3$)$_2$), 3.89 (1H, d, *J*=7 Hz, N-C$\underline{H}$-CH-CONH), 5.03 (1H, quintet, *J*=7 Hz, CH_3-C$\underline{H}$), 5.78 (1H, d, *J*=7 Hz, C$\underline{H}$-CONH), 7.00 and 7.22 (10H, m, Ph), 7.62 (1H, d, N$\underline{H}$); Found: C, 70.28; H, 7.61; N, 7.78%; Cacld for $C_{21}H_{26}N_2O_3$: C, 71.16; H, 7.39; N, 7.90%.

Its hydrochloride was prepared by the procedure described above: mp 212.0—213.0 °C (dec), $[\alpha]_D^{20.0}$ +48.6° (*c* 0.693, CH_3OH).

Hydrogenation of Benzil and Methyl N-*(Acetylamino)acrylate with the Co(dmg)*$_2$·*B-Chiral Amino Carboxamide System.* The preparation of the catalyst system and the hydrogenation of the two substrates with it were identical to those described in the previous paper[1] except for using the chiral amino carboxamide as the chiral base; hence, only the typical procedure of the isolation of methyl *N*-acetylalaninate in Run 2 of Table 2 is given below.

After theoretical amounts of hydrogen (1.5 g, 10.5 mmol of methyl *N*-(acetylamino)acrylate was used) had been absorbed, the benzene solution was filtered through a short (*ca.* 10 cm×1.5ϕ) silica-gel column (Wako gel C-300), and then the column was washed with ethyl acetate (*ca.* 300 ml). The filtrate was concentrated *in vacuo*, and the residue was dissolved in ether (*ca.* 100 ml). Into the ether solution dry hydrogen chloride gas was bubbled until the solution became acidic. The amorphous solid which separated out was filtered off, and the filtrate was concentrated *in vacuo* to 5—10 ml. The residual ether solution was again filtered through a short silica-gel column (similar to the one above), and the column was washed with ethyl acetate (*ca.* 300 ml). The filtrate was neutralized and dried over anhydrous sodium carbonate and sodium sulfate. The solution was concentrated *in vacuo*, and to the residue was added water (100 ml). The crystalline materials which separated out were filtered off through celite and washed with water (150 ml). The filtrate was concentrated *in vacuo*, the residue was dissolved in ether (100 ml), and the ether solution was dried over anhydrous sodium sulfate. After the concentration of the solution, 1.13 g (75.3% yield) of an oily product, $[\alpha]_D^{25.0}$ −12.0° (*c* 2.121, water) was obtained. This was distilled at 98—99 °C/3 mmHg to give 0.49 g of a colorless liquid: $[\alpha]_D^{25.0}$ −13.1° (*c* 2.091, water).

No contamination of the chiral α-amino carboxamide, Pha-*S,S*, in the distilled product was observed in the NMR spectra.

Examination of Enantiomer Enrichment during Isolation. 2.0 g of racemic methyl *N*-acethylalaninate were treated under the same conditions as were used for the hydrogenation in Run 2 of Table 2 and were then isolated by the procedure described above. 1.1 g of an oily material was thus obtained: $[\alpha]_D^{13.0}$ −0.1° (*c* 2.108, water). This was subsequently distilled at 99—101 °C/3 mmHg to give 0.4 g of a colorless liquid: $[\alpha]_D^{15.6}$ 0.0° (*c* 2.010, water).

The NMR spectra of the colorless liquid was identical to that observed above.

The authors wish to express their thanks to Professor Juji Yoshimura, Dr. Ken'ichi Sato, and Mr. Yuzuru Ishida of the Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, for their NMR measurements and elemental analyses. The present work was partially supported by two Grants-in-Aid for Scientific Research (No. 264149 and No. 454159) from the Ministry of Education, Science and Culture.

(Received December 12, 1980)

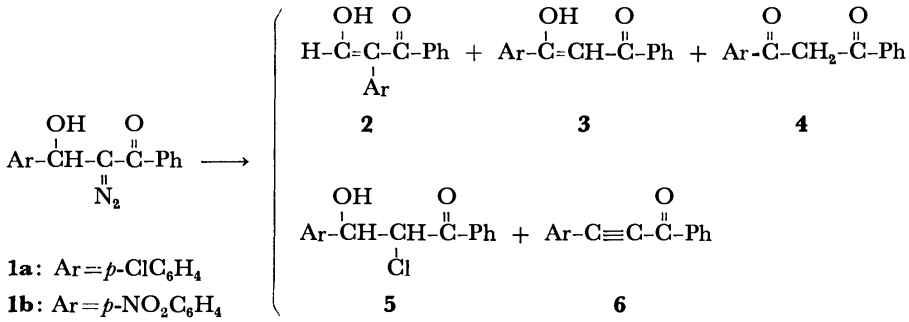
The proton acid-catalyzed decomposition of 3-aryl-2-diazo-3-hydroxy-1-phenylpropanone (**1**) gave aryl and hydrogen migration products. The former was the enol-form (**2**) of 2-aryl-3-phenyl-1,3-propanedione and the latter was the enol- (**3**) and keto-form (**4**) of 1-aryl-3-phenyl-1,3-propanedione. The product ratios, **2**/(**3**+**4**), were affected by the catalysts and solvents used. More polar solvents favored the formation of aryl migration products (**2**). On the other hand, the BF_3-catalyzed decomposition of **1** gave acetylenic ketones as main products along with **2**, **3**, and **4**. The TsOH-catalyzed decomposition of 2-diazo-3-hydroxy-3-phenyl-1-indanone, (cyclic α-diazo β-hydroxy ketone), gave 2-phenyl-1,3-indandione quantitatively through phenyl migration.

The acid-catalyzed decomposition of diazo compounds has been studied extensively from the synthetic and mechanistic view points.[1] However, only a few papers have been published on the acid-catalyzed decomposition of diazo carbonyl compounds bearing a hydroxyl group on the carbon atom adjacent to the diazomethyl-carbon. Wenkert and McPherson have reported the BF_3-catalyzed decomposition of α-diazo β-hydroxy esters and ketones to give the corresponding acetylenic esters and ketones.[2] Schöllkopf and his co-workers obtained ethyl 2-methyl-3-oxobutanoate as a methyl migration product in the HCl-catalyzed reaction of ethyl 2-diazo-3-hydroxy-3-methylbutanoate.[3] Similar observations were also reported by Disteldorf and Regitz in the BF_3- or HCl-catalyzed decomposition of 1-diazo-2-hydroxyethyldiphenylphosphine oxide.[4]

As an extension on the acid-catalyzed reaction of diazo carbonyl compounds,[5] we describe here the protonic or Lewis acids-catalyzed decomposition of 3-aryl-2-diazo-3-hydroxy-1-phenyl-1-propanones (**1**) to give aryl and hydrogen migration products and acetylenic ketones depending on the catalysts used.

Results and Discussion

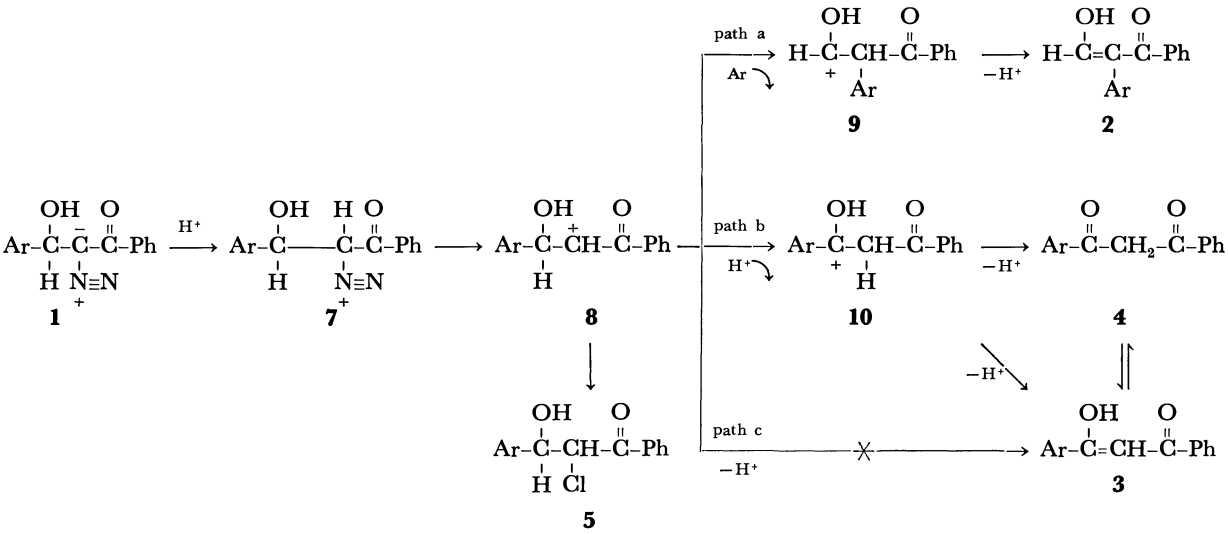
An acetonitrile solution of 3-(*p*-chlorophenyl)-2-diazo-3-hydroxy-1-phenyl-1-propanone (**1a**) was treated with a catalytic amount of acid at 30 °C. In the proton acid-catalyzed reaction, the major product was the enol-form (**2a**) of 2-(*p*-chlorophenyl)-1,3-propanedione accompanying the enol- (**3a**) and keto-form (**4a**) of 1-(*p*-chlorophenyl)-3-phenyl-1,3-propanedione. In the BF_3-catalyzed reaction, however, 3-(*p*-chlorophenyl)-1-phenyl-2-propyn-1-one (**6a**) was obtained as a major product along with **2a**, **3a**, and **4a**. 3-(*p*-Nitrophenyl)-2-diazo-3-hydroxy-1-phenyl-1-propanone (**1b**) also gave similar products, with a few differences in the product ratios. The main difference is that **2b** is still the main product in the BF_3-catalyzed reaction of **1b** contrary to the case of **1a**. The other point is that the yield of the chlorinated product (**5b**) is much higher than that of **5a** in the HCl- and $AlCl_3$-catalyzed reactions of **1b**. The results are summarized in Table 1.



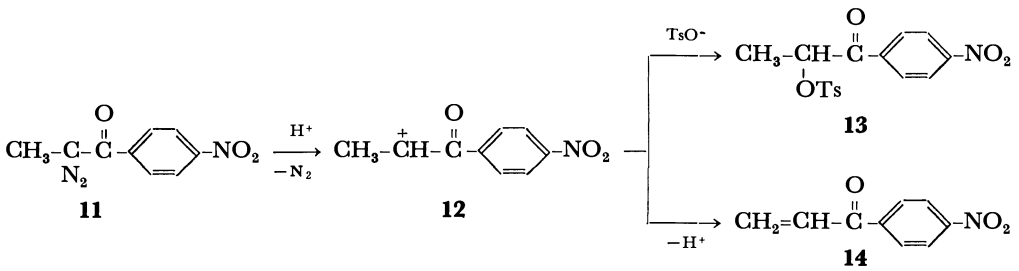
Scheme 1.

Table 1. Yields of products in the acid-catalyzed decomposition of **1** in acetonitrile at 30 °C

	Acid	**2**	**3**	**4**	**5**	**6**	**2**/(**3**+**4**)
1a	TsOH	84.3	3.0	8.0	—	—	7.7
	aq.HCl	76.1	5.5	2.6	14.5	—	9.4
	$AlCl_3$	68.8	8.0	3.1	18.8	—	6.2
	$BF_3(OEt_2)$	11.9	1.2	—	—	75.2	9.9
1b	TsOH	64.1	23.3	10.9	—	—	1.9
	aq.HCl	38.0	16.7	5.7	34.6	—	1.7
	$AlCl_3$	24.6	22.2	trace	47.1	—	1.1
	$BF_3(OEt)_2$	50.8	4.1	4.8	—	29.8	5.7



Scheme 2.



Scheme 3.

The difference between the behavior of proton acid and that of BF_3 may be attributed to the difference of the catalytic actions on the starting diazo ketones (**1**) as is described below.

In the proton acid-catalyzed reaction, the reaction may be initiated by protonation on the diazomethyl-carbon of **1** to give diazonium ion (**7**).[3,4] Successive elimination of nitrogen, aryl migration, and deprotonation lead to the enol ketone (**2**) through carbonium ion intermediate (**8** and **9**) (path a in Scheme 2). The hydrogen migration of **8** will afford diaroylmethane (**4**) and its enol-isomer (**3**) *via* deprotonation of intermediate (**10**) (path b in Scheme 2). Although direct deprotonation from the carbon attached by the hydroxyl group of **8** seems to give the enol-isomer (**3**) directly (path c in Scheme 2), this process can be excluded based on the results of the pinacol rearrangement of 1,1,2-triphenylethane-2-*d*-1,2-diol.[6]

The HCl-catalyzed reaction of **1** gave 3-aryl-2-chloro-3-hydroxypropiophenone (**5**) along with **2**, **3**, and **4**. This chlorinated compound may be produced by the attack of chloride ion with its high nucleophilicity on the carbonium ion intermediate (**8**) in competition with the aryl and hydrogen migrations. The higher yield of chlorinated product (**5b**) in the reaction of **1b** than that of **5a** may be explained by the high positive charge density on carbonium carbon in **8b** caused by the electron attracting nitro group on the phenyl ring. The behavior of $AlCl_3$ was quite similar to that of hydrochloric acid. This may be due to hydrogen chloride produced by the reaction with moisture in the reaction system. However, no tosylate[7] corresponding to **5** was obtained in the reaction when *p*-toluenesulfonic acid was used as a catalyst. And neither oxazoles[5a] nor oxazolium salts,[8] which might be produced by the reaction of **8** with acetonitrile used as a solvent, were recognized in the reaction products.

When α-diazo-*p*-nitropropiophenone (**11**), instead of **1**, was treated with an equivalent amount of TsOH in acetonitrile at 0—5 °C, the reaction gave 1-(*p*-nitrobenzoyl)ethyl tosylate (**13**) as a main product in 69% yield accompanying a small amount (13%) of *p*-nitrophenyl vinyl ketone (**14**) without formation of the corresponding oxazoles (Scheme 3). Therefore, the preference of the migration of aryl group or hydrogen atom to the intermolecular nucleophilic attack of tosylate ions or the nitrogen atom of acetonitrile to the carbonium ion intermediate (**8**), as has been observed in the decomposition of **1**, seems to be attributable to the effect of hydroxyl group attached to the carbon atom adjacent to the diazo carbon.

As listed in Table 1, the yields of aryl migration products (**2**) were larger than those of hydrogen migration products (**3**+**4**). The results may be due to the difference of resonance stabilities in the transition states of aryl- and hydrogen-migrations. Moreover the product ratios, **2**/(**3**+**4**), in the reaction of **1b** (Ar=*p*-$NO_2C_6H_4$) were observed to be smaller than those in the reaction of **1a** (Ar=*p*-ClC_6H_4), suggesting that the migratory aptitude of *p*-nitrophenyl group is smaller than that of *p*-chlorophenyl group. The

Table 2. Solvent effect on the yields of products in the TsOH-catalyzed decomposition of **1a** at 30 °C

Solvent	μ(D)	ε	Products yield/% 2	3	4	2/(2+4)
Cyclohexane	0.00	2.02	46	38	14	0.9
CCl_4	0.00	2.24	44	22	16	1.2
Benzene	0.00	2.28	54	24	17	1.3
Dioxane	0.45	2.21	66	25	8	2.0
$C_2H_5OC_2H_5$	1.15	4.81	68	9	11	3.3
$CHCl_3$	1.15	4.81	68	9	11	3.4
$CH_3OCH_2CH_2OCH_3$	1.71	7.20	67	9	9	3.7

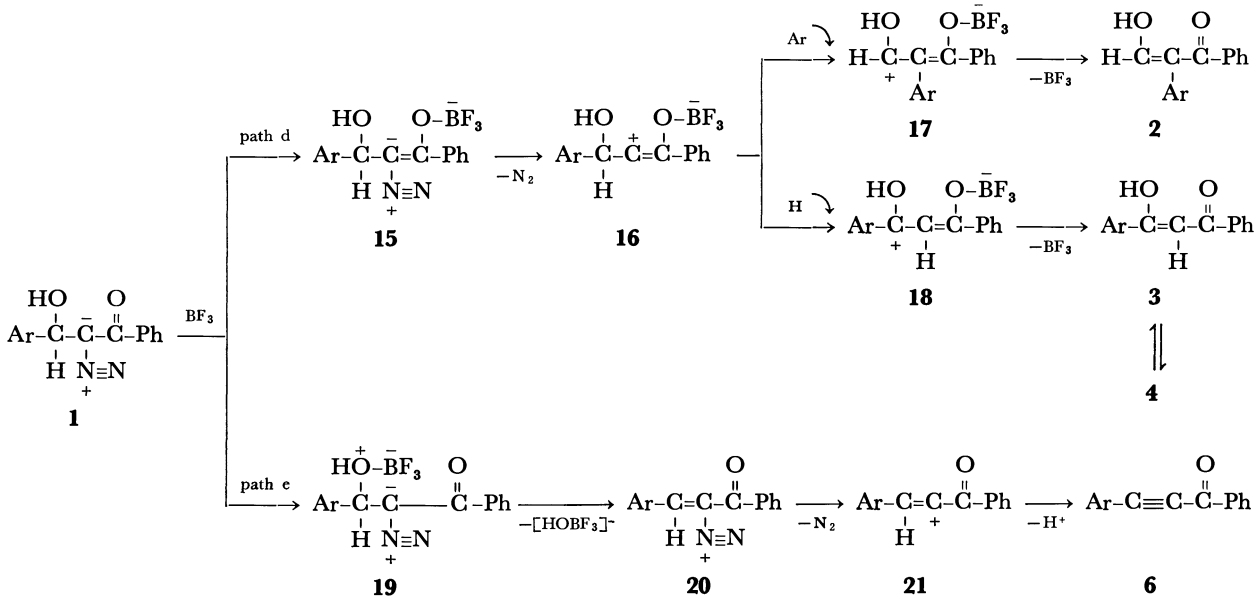
CH_3CN	3.44	33.0	84	3	8	7.7

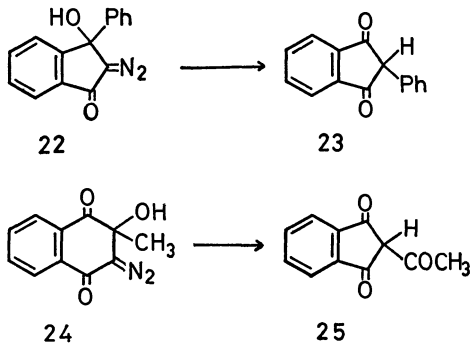


Scheme 4.

results further seem to accord with the view that the electron-withdrawing substituents reduce the migratory aptitude of aryl groups in the pinacol rearrangement.[9]

When the TsOH-catalyzed decomposition of **1a** was carried out in various solvents at 30 °C, it was recognized that the more polar solvents favored the migration of *p*-chlorophenyl group. In this case, the tendency of the migration of *p*-chlorophenyl in comparison to that of hydrogen, **2**/(**3**+**4**), seems to fit better to dielectric constant (ε) than to dipole moment (μ) (Table 2). The large migratory aptitude of aryl groups in polar solvent may be explained by the "principle of reactivity and selectivity relationship."[10] In other words, solvation stabilization of the carbonium ion intermediate (**8**) in polar solvents increases the amount of aryl migration products (**2**), owing to the large selectivity of **8** to the reaction paths (a and b).

In the BF_3-catalyzed reaction, two kinds of initial attack of BF_3 are expected. When the initial attack of BF_3 occured on the carbonyl-oxygen atom of **1**, the reaction will proceed to give diazonium ion intermediate (**15**),[5,11] from which two kinds of enol ketones (**2** and **3**) and β-diketone (**4**) may be derived *via* carbonium ion intermediates (**16**, **17**, and **18**) in a similar manner as described above (path d in Scheme 4). If the initial attack of BF_3 took place on hydroxyl-oxygen atom of **1** to afford oxonium ion intermediate (**19**), diarylpropynones (**6**)[2,12] will be given via intermediates (**20** and **21**) (path e in Scheme 4). Although the path e is the main path of the reaction of **1a**, the electron attracting nitro group retards the path e in the reaction of **1b** to give the small amount of **6b**.



Scheme 5.

In another experiment, the TsOH-catalyzed decomposition of 2-diazo-3-hydroxy-3-phenyl-1-indanone (**22**) was carried out in order to compare with that of acyclic α-diazo β-hydroxy ketones. The reaction led to 2-phenyl-1,3-indandione (**23**) quantitatively without formation of the corresponding tosylate. In this reaction, the phenyl migration was observed also. However, Moore and his co-workers showed that the acid-catalyzed decomposition of 2-diazo-3-hydroxy-3-methyl-1,4-(2*H*,3*H*)-naphthalenedione (**24**) gave 2-acetyl-1,3-indandione (**25**) caused by ring contraction in a quantitative yield without methyl migration products.[13] The ring size seems to exert an influence on the course of the acid-catalyzed decomposition of cyclic α-diazo β-hydroxy ketones.

Experimental

All melting points were measured with a Yanagimoto Melting Point Apparatus and are not corrected. The IR spectra were measured on a JASCO IR Spectrometer model IR-G. NMR spectra were recorded in $CDCl_3$ solution at 60 MHz on a Varian Spectrometer model EM-360 using TMS as an internal standard.

Materials. *3-Aryl-2-diazo-3-hydroxy-1-phenyl-1-propanones (**1**)* were prepared by the reaction of α-diazoacetophenone and corresponding benzaldehydes according to the method described by Wenkert.[14] The obtained α-diazo β-hydroxy ketones were purified by recrystallization from benzene-heptane.

1a (Ar=*p*-ClC_6H_4): mp 126—127 °C; IR (KBr) 3350 (OH), 2070 (diazo), 1600 cm^{-1} (diazo C=O); ^{1}H-NMR ($CDCl_3$) δ 3.97 (d, 1H, OH, J=3.6 Hz), 6.14 (d, 1H, CH, J=3.6 Hz), 7.23—7.73 (m, 9H, arom). Found: C, 63.01; H, 3.82; N, 9.77%. Calcd for $C_{15}H_{11}O_2N_2Cl$: C, 62.84; H, 3.87; N, 9.77%.

1b (Ar=*p*-$NO_2C_6H_4$): mp 120—121 °C; IR (KBr) 3360 (OH), 2060 (diazo), 1600 (diazo C=O), 1515, 1340 cm^{-1} (NO_2); ^{1}H-NMR ($CDCl_3$) δ 4.15 (d, 1H, OH, J=3.8 Hz), 6.30 (d, 1H, CH, J=3.8 Hz), 7.38—7.95 (m, 9H, arom). Found: C, 60.63; H, 3.83; N, 13.91%. Calcd for $C_{15}H_{11}O_4N_3$: C, 60.60; H, 3.73; N, 14.14%.

*α-Diazo-*p*-nitropropiophenone (**11**)* was synthesized by the reaction of *p*-nitrobenzoyl chloride with an excess of diazoethane in the presence of an equimolar amount of triethylamine at 0 °C under vigorous stirring.[15] Mp 106—107 °C; IR (KBr) 2070 (diazo), 1610 (diazo C=O), 1510, 1340 cm^{-1} (NO_2). Found: C, 52.47; H, 3.47; N, 20.75%. Calcd for $C_9H_7O_3N$: C, 52.68; H, 3.44; N, 20.48%.

*2-Diazo-3-hydroxy-3-phenylindanone (**22**)* was synthesized by the triethylamine-catalyzed isomerization of 2-benzoyl-α-diazoacetophenone, which was prepared by the reaction of DCC-complex of 2-benzoylbenzoic acid with an excess of diazomethane,[16] according to the method of Burkoth.[17] Mp 179—180 °C; IR (KBr) 3280 (OH), 2090 (diazo), and 1662 cm^{-1} (diazo C=O). Found: C, 71.71; H, 3.60; N, 11.26%. Calcd for $C_{15}H_{10}O_2N_2$: C, 71.99; H, 4.03; N, 11.20%.

Acid Catalysts. Reagent grade chemicals were used as catalyst without further purification.

All solvents were purified by distillation over appropriate drying reagents just before use.

General Procedure of the Acid-catalyzed Decomposition of α-Diazo β-Hydroxy Ketones. To a solution of diazo ketone (**1**; 2 mmol) in an appropriate solvent (30 ml) were added an acid catalyst (0.2—0.4 mmol) under vigorous magnetic stirring at 30 °C. After evolution of N_2 ceased the reaction mixture was poured into 50 ml of water and the products were extracted with ether (20 ml) three times. The ether extract was column-chromatographed on silica gel after usual work-up.

2a (Ar=*p*-ClC_6H_4): mp 132—133 °C; $FeCl_3$ test, positive; IR (KBr) 3054 (OH), 1584 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ 7.12 (ABq, 4H, arom), 7.32 (s, 5H, Ph), 8.59 (d, 1H, =CH, J=4.8 Hz), and 16.93 (d, 1H, enol-OH); Found: C, 69.59; H, 4.24%. Calcd for $C_{15}H_{11}O_2Cl$: C, 69.64; H, 4.29%.

6b (Ar=*p*-$NO_2C_6H_4$): mp 154—156 °C; IR (KBr) 2210 (C≡C), 1630 (C=O), 1528, 1352 cm^{-1} (NO_2); ^{1}H-NMR ($CDCl_3$) δ 7.50—8.54 (m, arom). Found: C, 71.61; H, 3.67; N, 5.58%. Calcd for $C_{15}H_9O_3N$: C, 71.71; H, 3.61: N, 5.57%.

*p-Toluenesulfonic Acid-catalyzed Decomposition of α-Diazo-*p*-nitropropiophenone (**11**).* To a solution of **11** (0.41 g, 2 mmol) in an acetonitrile (10 ml) was added an equimolar amount of TsOH·H_2O (0.38 g, 2 mmol) in small portions at 0—5 °C under vigorous stirring. After evolution of N_2 ceased the reaction mixture was poured into 50 ml of cold water and the organic layer was extracted with each 30 ml of ether three times. Combined ether solution was dried over $MgSO_4$ and separated with silica gel column chromatography. Major product was characterized to 1-(*p*-nitrobenzoyl)ethyl tosylate (**13**); white crystals; 0.48 g, 69%;

mp 146—147.5 °C; IR (KBr) 1685 (C=O), 1520, 1345 (NO_2), 1365, 1195 cm^{-1} (SO_2); ^{1}H-NMR ($CDCl_3$) δ 1.60 (d, 3H, CH_3 J=6.6 Hz) 2.43 (s, 3H, CH_3), 5.68 (q, 1H, CH, J=6.6 Hz), and 7.2—8.4 (two pairs of ABq, 8H, arom). Found: C, 54.95; H, 4.27; N, 4.12%. Calcd for $C_{16}H_{15}O_6NS$: C, 55.01; H, 4.33; N, 4.01%. The minor product was determined to *p*-nitrophenylvinylketone (**14**): 0.046 g, 13%; mp 87—87.5 °C; IR (KBr) 1645 (enone), 1490, 1320 cm^{-1} (NO_2); ^{1}H-NMR ($CDCl_3$) δ 6.03 (dd, 1H, Hx), 6.42 (dd, 1H, Hb (*cis* to Hx), 9.13 (dd, 1H Ha (*trans* to Hx)) and 8.0—8.4 (ABq, 4H, arom), (Jab=16.0, Jax=10.0, and Jbx=2.0 Hz). Found: C, 60.95; H, 4.07; N, 7.59%. Calcd for $C_9H_7O_3$: C, 61.01; H, 3.98; N, 7.91%.

p-*Toluenesulfonic Acid-catalyzed Decomposition of 2-Diazo-3-hydroxy-3-phenyl-1-indandione (**22**).* To an acetonitrile solution (10 ml) of **22** (0.500 g, 2 mmol) was added a catalytic amount of $TsOH \cdot H_2O$ at room temperature. Pouring the reaction mixture into 50 ml of water gave a white crystalline product (**23**) in quantitative yields. The structure was determined by the comparison of its IR spectra with that of authentic sample prepared by the alkali-catalyzed reaction of 3-benzylidenephthalide.[18]

Structure of Octa-*O*-acetyl-tris(*N*-ethoxycarbonyl)destomycin A

Shigeomi Horito, Yuji Ohashi, Nobert Gassner, Juji Yoshimura,* and Yoshio Sasada

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received January 16, 1981)

The molecular and crystal structure of octa-*O*-acetyl-tris(*N*-ethoxycarbonyl)destomycin A tetrahydrate, $C_{45}H_{65}N_3O_{27}\cdot 4H_2O$, has been determined by X-ray analysis. The space group is $P2_1$ with $a=14.738(4)$, $b=17.391(4)$, $c=12.171(4)$ Å, $\beta=105.58(4)°$, and $Z=2$. The structure was solved by the direct method, and the least-squares refinement using 4008 reflections led to the final R value of 0.12. The configuration of the ortho ester carbon atom is (*R*). The D-talose moiety has the boat conformation whereas the other rings are in the chair form.

A group of antibiotics such as everninomicins, flambamycin, curamycin, avilamycins, destomycins, hygromycin B, the antibiotics A-396-I and SS-56C was recently named as the orthosomycin family,[1] because they commonly include a very unique ortho ester linkage of a glyconic acid lactone to an α-diol function of an aldose in their molecules. This interlinkage provides two possible stereoisomers depending on the (*R*) or (*S*) configuration at the ortho ester carbon atom; however, no absolute configuration has been determined except for one of the two orthoester linkages in everninomicin D.[2] The difficulties in the elucidation of the configuration is attributed to that only X-ray analysis is applicable for this purpose at the present stage and that these sugar derivatives are not easily crystallizable.

In this paper, we intended to confirm the proposed structure and to determine the absolute configuration of the ortho ester linkage of destomycin A (Fig. 1),[3] which is the main aminoglycoside antibiotic produced by a strain of *Streptomyces rimofaciens*. By the examination of several derivatives, octa-*O*-acetyl-tris(*N*-ethoxycarbonyl)destomycin A (**1**) was obtained as crystals, and its X-ray analysis disclosed the structure to be 4,6-di-*O*-acetyl-3-ethoxycarbonylamino-1-[*N*-(ethoxycarbonyl)methylamino]-5-*O*-[4,6-di-*O*-acetyl-2,3-*O*-(2,3,7-tri-*O*-acetyl-6-deoxy-6-ethoxycarbonylamino-L-*glycero*-D-*galacto*-(*R*)-heptopyranosylidene)-β-D-talopyranosyl]-1D-1,2,3-trideoxy-*myo*-inositol.

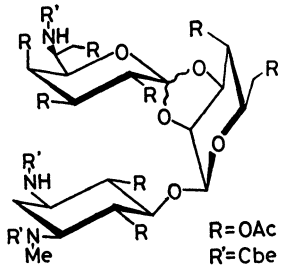

Fig. 1. The chemical structure.

Experimental and Structural Determination

Preparation of Octa-O-acetyl-tris(N-ethoxycarbonyl)destomycin A (1). To an ice-chilled aqueous solution of destomycin A (0.53 g, 1.0 mmol) and sodium carbonate (0.42 g, 4.0 mmol) was added ethoxycarbonyl chloride (0.35 g, 3.2 mmol) with stirring, and the resulting mixture was stirred overnight at room temperature, neutralized with dilute hydrochloric acid, and evaporated. The residue was fractionated on a silica gel column (1-butanol–methanol–water 3:2:1), and evaporation of the fractions showing one spot on TLC gave pure tri-*N*-ethoxycarbonyl derivative as a light yellow, hygroscopic hard syrup. Yield, 0.53 g (70.9%); $[\alpha]_D$ −17.0° (*c* 0.4, ethanol).

A solution of the above tri-*N*-ethoxycarbonyl derivative (0.74 g, 1 mmol) and acetic anhydride (1 ml, 10.6 mmol) in chloroform (10 ml) and pyridine (1 ml) was allowed to stand overnight at room temperature, diluted with water, and the organic layer was washed with aqueous sodium hydrogencarbonate and three time with water. The organic layer was evaporated, and the residual sirup was purified on a silica gel column with ethyl acetate as an eluent to give crystalline (**1**) which was recrystallized twice from ethanol–water (1:1). Single crystals suitable for X-ray studies were obtained as well-formed parallelepipeds. Yield, 0.75 g (69.8%), mp 143—145 °C, $[\alpha]_D$ +20.4°, (*c* 1.07, pyridine); NMR (δ): *ca.* 1.22 (3×C–CH_3, t), 1.98, 2.30, 2.08, 2.10, 2.12, 2.14 (8×Ac, each s), 2.74 (N–CH_3, s). Found: C, 50.01; H, 6.14; N, 4.01%. Calcd for $C_{45}H_{65}N_3O_{27}$: C, 50.04; H, 6.07; N, 3.89%.

X-Ray Analysis. Preliminary unit-cell dimensions and space group were obtained from photographs. The space group was determined as $P2_1$ from the systematic absences of reflections for $0k0$ with odd k. A crystal with dimensions of $0.5\times0.4\times0.2$ mm³ was used for data collection on a Rigaku automated four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation ($\lambda=1.54184$ Å). Accurate cell dimensions were determined by least-squares calculation with 2θ values of 16 high-angle reflections measured on the diffractometer. Crystal data are summarized in Table 1. Intensity data

a) $B_{eq}=\frac{4}{3}\sum_i\sum_j \beta_{ij}\boldsymbol{a}_i\cdot\boldsymbol{a}_j$, where $\boldsymbol{a}_i$ and $\boldsymbol{a}_j$ are the base vectors in real space, and β_{ij}'s are anisotropic thermal parameters.

within the range of $3° \leq 2\theta \leq 125°$ were collected in the ω-2θ scan mode at a scanning rate of 8° (2θ) min^{-1}. Stationary background counts were accumulated for 5 s before and after each scan. The periodic check of the intensity values of three standard reflections revealed a slight change. The intensities decreased by 5—6% during the data collection. The cell dimensions also changed appreciably; the values after the data collection are also listed in Table 1. This is probably due to the dehydration of the crystal. As this change did not seem to be serious, it was ignored in the structure determination. A total of 4957 independent reflections was obtained, of which 4008 $[|F_o| \geq 3\sigma(|F_o|)]$ were used for the structure determination. Any correction for absorption or extinction was not applied.

Structure Determination. The structure was solved by direct methods with the MULTAN 78 program.[4] At the first stage, only 40 chemically significant peaks were found on the *E*-map. The other non-hydrogen atoms were obtained by the subsequent Karle recycling procedure. The structure was refined by the block-diagonal least-squares method with the modified HBLS program. The difference synthesis revealed that several substituents were disordered. This is probably due to the rearrangement of the substituents after the dehydration. Since the volume of the disordered portion, however, was probably less than 20%, the disordered model was not taken into account. All the hydrogen atoms except for those of the methyl groups and water molecules were located geometrically. Refinement using the anisotropic and isotropic temperature factors for the non-hydrogen and hydrogen atoms, respectively, gave the final *R* value of 0.12 for 4008 reflections. The weighting scheme used in the final stage was $w=[(|F_o|)^2+(0.015|F_o|)^2]^{-1}$. Atomic scattering factors were taken from "International Table for X-Ray Crystallography."[5] The final positional and thermal parameters are given in Table 2.†

The stereoscopic drawing of the molecular structure is shown in Fig. 2. The numbering of the atoms and the bond distances and angles are illustrated in Fig. 3.

Results and Discussion

The structure of destomycin A was previously elucidated as 5-*O*-[2,3-(6-amino-6-deoxy-L-*glycero*-D-*galacto*-heptopyranosylidene)-β-D-talopyranosyl]-1D-3-amino-1-methylamino-1,2,3-trideoxy-*myo*-inositol by chemical and spectroscopic studies[6] as shown in Fig. 1. The structure of aminocyclitol[7] and 6-aminoheptonic acid[8] (destomic acid) moieties were also proved by syntheses. The analyzed structure confirmed the above-mentioned spectroscopic and chemical elucidations. From the spatial interrelation of the destomic acid and D-talose moieties, the absolute configuration of the orthoester carbon atom was determined to be (*R*). The torsional angles around several bonds are listed in Table 3.

Surprisingly, the D-talopyranose moiety has $B_{1,4}$ conformation. In the case of everninomicin D in which a pentono-1,5-lactone makes a spiro cyclic ortho ester with the *trans*-diequatorial 3,4-diol function of L-lyxopyranose moiety,[2] the pyranose ring exists in $^1C_4$ conformation, because $B_{1,4}$ conformation causes an additional distortion to the five-membered ortho ester

† The table of the observed and calculated structure factors and the list of the anisotropic temperature factors are kept as Document No. 8140 at the office of the Chemical Society of Japan.

ring.[9] Besides, in the case of (**1**) in which the 6-aminoheptono-1,5-lactone links to the *cis*-2,3-diol function of D-talopyranose moiety, $B_{1,4}$ conformation assists the formation of five-membered ortho ester ring, and erases the non-bonded interactions caused by C4′-hydroxyl group previously in axial orientation. In fact, the dihedral angle of C(2′)–O(2′) and C(3′)–O(3′) is 15°. These facts must also be true in the natural destomycin A itself.

From the synthetic studies,[10] it was suggested that the five-membered ring has a twist or envelope conformation to avoid the non-bonded interactions. The determined structure proved that the ring takes an envelope conformation in which the O(3′) atom of D-talopyranose moiety deviated significantly from the average plane of other four atoms. The equation of the plane and the deviation of each atom from the plane in the five-membered ring are shown in Table 4.

It is characteristic that the both C–O bonds in the five-membered ring concerned with ortho ester carbon is slightly short as was observed in the anomeric C–O bond in the usual aldopyranosides.[11] Other bond distances and angles show the values common in carbohydrate derivatives.

The crystal structure viewed along the b axis is shown in Fig. 4. The hydrogen bonds, listed in Table 5, make a three-dimensional network through the water molecules.

One of the authors (J.Y.) is grateful to Meiji Seika Co. Ltd. for the gift of destomycin A.

Reaction of Organoaluminium Reagents with Cyclopropylmethyl Acetates and 2-Vinylcyclopropane-1,1-dicarboxylate Esters

Tamejiro HIYAMA,* Yoshitomi MORIZAWA, Hajime YAMAMOTO, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

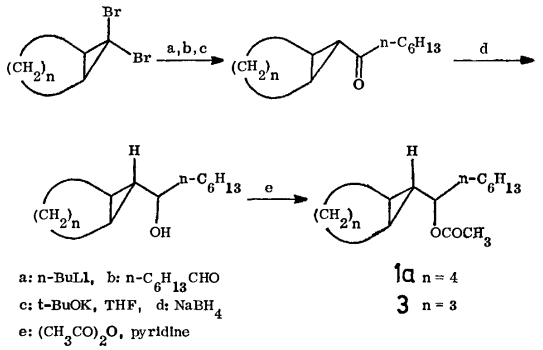
(Received January 20, 1981)

Ring-opening alkylation of cyclopropylmethyl acetates was studied. The acetoxyl group of 7-(1-acetoxyheptyl)norcarane is substituted by the alkyl group upon treatment with trialkylaluminium, but alkylation of *trans*-1-(1-acetoxyethyl)-2-phenylcyclopropane with trialkylaluminium gives rise to *trans*-5-phenyl-2-alkenes. The reaction of (1*S*,2*S*)-2-phenylcyclopropylmethyl acetate with trimethylaluminium resulted in the complete loss of optical activity to give racemic 4-phenyl-1-pentene. Alkylation of *trans*-1-(1-acetoxy-3-phenylpropyl)-2-vinylcyclopropane with trialkylaluminium proceeds under regioselective ring-opening to give 3-alkylated *trans*-8-phenyl-1,5-octadiene (selectivity 73—83%). The regio- and stereochemistry of homoconjugate addition to activated vinylcyclopropanes having a doubly carbonyl substituted ring carbon was studied. Trialkylaluminium on addition to diethyl 2-vinylcyclopropane-1,1-dicarboxylate in a 1,5-manner afford diethyl (2-alkyl-3-butenyl)-propanedioate (over 96% selectivity). In contrast, the reaction of this cyclopropane with tetraalkylaluminiumlithium takes place in a 1,7-manner to give diethyl (*trans*-4-alkyl-2-butenyl)propanedioate with 88—92% selectivity. Clean regiocontrol of the reaction is observed in the methylation of ethyl *exo*-6-(*trans*-1-propenyl)-2-oxobicyclo[3.1.0]hexane-1-carboxylate with trimethylaluminium or tetramethylaluminiumlithium. Alkylation with trimethylaluminium proceeds with 86% inversion of the configuration at C(6) of the substrate, affording (2*R**,3*R**)-2-ethoxycarbonyl-3-[(*S**)-*trans*-1-methyl-2-butenyl]cyclopentanone which is transformed into neonepetalactone.

Reagents of main group elements have furnished manifold synthetic methodologies.[1] The reaction of organolithium and -magnesium compounds provides a basic C–C bond forming process. The organometallics of electron-deficient elements such as boron and aluminium have intrinsic Lewis acidity and thus show to some extent Lewis acid catalysis. Examples are found in oxirane-allyl alcohol rearrangement, cyclization of neryl phosphate and alkylation of geranyl phosphate with the aid of organoaluminium reagents.[2] We have studied the reaction of organoaluminium reagents with cyclopropanes and found that (a) cyclopropylmethyl acetates undergo alkylation with or without ring-opening depending on the substituent on the cyclopropane ring and (b) regiochemistry in the homoconjugate addition of an alkyl group to 2-vinylcyclopropane-1,1-dicarboxylate esters is controlled by means of appropriate organoaluminium reagents.

Alkylation of Cyclopropylmethyl Acetates. The transformation of cyclopropylmethyl alcohols into (*E*)-homoallyl bromides is important for the stereoselective synthesis of olefins.[3,6] Strong Lewis acid such as hydrobromic acid or zinc bromide (plus phosphorus tribromide) is essential for the generation of homoallyl cations which react with bromide anion. The resulting homoallyl bromides should be treated with organometallics for the sake of carbon skeleton extention. We have found trialkylaluminium reagents can produce homoallylic cations in the presence of carbanionic species, attaining the C–C bond formation in a single step.

The cyclopropylmethyl esters **1a**, **1b**, and **3** were prepared starting with 7,7-dibromonorcarane (Scheme 1).[7] 7,7-Dibromonorcarane was treated with butyllithium at −95 °C, the lithium carbenoid generated being allowed to react with heptanal. The adduct was then treated with potassium *t*-butoxide to give *exo*-7-heptanoylnorcarane which was subsequently reduced with sodium borohydride to an alcohol, the acetylation and benzoylation of which gave **1a** and

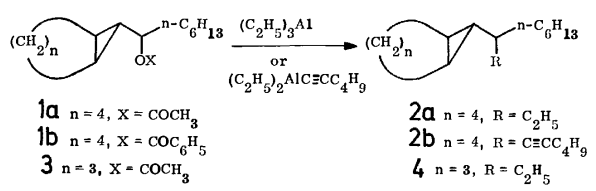


Scheme 1.

1b, respectively. **3** was prepared from 6,6-dibromobicyclo[3.1.0]hexane in a similar way.

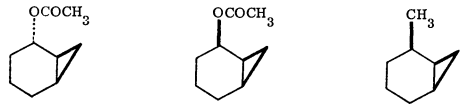
When the acetate **1a** was treated with 2.8 mol of triethylaluminium at room temperature, the acetoxyl group was substituted by ethyl group without ring-opening, giving **2a** in 91% yield.[8] The reaction took place likewise in benzene (98% yield) or hexane (93%) and even in dichloromethane at −78 °C (93%).

The benzoate **1b** was also converted into **2a** in 68% yield. Alkylation of **3** was somewhat less effective to give **4** in 57% yield. A mixed aluminium reagent $Et_2AlC{\equiv}CC_4H_9$, prepared by treatment of diethylaluminium chloride with an equimolar amount of 1-lithio-1-hexyne, afforded **2b** only upon reaction with **1a** (56% yield). Thus, ethynyl group is more reactive than the ethyl group.[9]



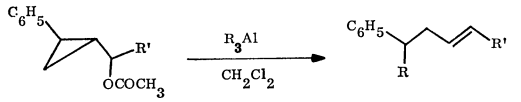
The reaction can be explained in terms of cyclopropylmethyl cation intermediates, since both *exo*- and

endo-2-acetoxynorcarane (**5a** and **5b** respectively) give *endo*-2-methylnorcarane **6** almost exclusively.[10]



5a **5b** **6**

In contrast to the alkylation of **1a**, **1b**, **3**, or **5a,b**, the phenyl substituted cyclopropylmethyl acetates underwent alkylation under ring-opening. The cyclopropylmethyl acetate **7** was prepared by the reaction of *trans*-2-phenylcyclopropanecarbaldehyde with methylmagnesium iodide followed by acetylation. When **7** (45:55 diastereomeric mixture) was treated with 3 mol of trimethylaluminium, *trans*-5-phenyl-2-hexene (**8a**) was produced in 86% yield. The newly produced C=C bond was found to be *trans* (over 97% purity). By a similar reaction **8a** (>94% *trans*) and **8c** (>96% *trans*) were produced as the sole products from **7** upon treatment with triethylaluminium and triisobutylaluminium, respectively. For the sake of stereochemical confirmation, both diastereomers of **7** were isolated and subjected to the alkylation with triethylaluminium. The sole product was found to be **8b** resulting from each diastereomer (75, 63% yield respectively). Similarly both the diastereomers of the *cis* isomer of **7** gave **8b** (53% and 67% yields from each diastereomer). The reaction was entirely independent of the stereochemistry of the starting material. The primary acetate **9a** was less reactive than the secondary one, **7**, giving **10a** in 59% yield.



7 R' = CH_3
9a R' = H
9b R' = H (1S, 2S)

8a R' = CH_3, R = CH_3
8b R' = CH_3, R = C_2H_5
8c R' = CH_3, R = n-C_4H_9
10a R' = H, R = C_2H_5
10b R' = H, R = CH_3

In order to study the stereochemical aspect of alkylation, we prepared (1*S*,2*S*)-2-phenylcyclopropylmethyl acetate **9b** (optical purity >98%) by lithium aluminium hydride reduction of (1*S*,2*S*)-2-phenylcyclopropanecarboxylic acid followed by acetylation with acetic anhydride and pyridine. When **9b** was treated with trimethylaluminium, 4-phenyl-1-pentene (**10b**) having no optical activity was obtained. Since the carboxylic acid derived from **10b** by potassium permanganate-sodium periodate oxidation also showed no optical rotation, we can conclude that alkylation proceeds through a planar cationic intermediate.

Alkylation of 7-acetoxymethyl-1-phenylnorcarane **11a,b** showed a similar stereochemical feature. The starting materials were prepared by bromine-lithium exchange of 7,7-dibromonorcarane with butyllithium, carbonation with carbon dioxide gas, lithium aluminium hydride reduction, and the final acetylation (Scheme 2). First, a 1:3 mixture of **11a** and **11b** thus prepared was treated with trimethylaluminium in dichloromethane to produce an inseparable mixture (35:65) of **12** and **13**. The stereochemical assignment is based on the observation that isomer **13** should give a methyl singlet signal at higher field due to the shielding effect of C=C bond.[11] When the stereoisomer of the starting acetate was separated and subjected to the alkylation reaction with trimethylaluminium, the same mixture was obtained. Thus, the aluminium-mediated alkylation proceeds through a common intermediate irrespective of the stereochemistry of the starting material.

Scheme 3.

2-Vinylcyclopropylmethanol was obtained by the reaction of 1,5-hexadiene monoepoxide with lithium diethylamide in ether-hexamethylphosphoric triamide.[12] Subsequent oxidation with pyridinium chlorochromate and Grignard reaction with 2-phenylethylmagnesium bromide gave an alcohol the acetylation of which gave **14** as a 55:45 diastereomeric mixture (two epimers at the acetoxyl group-bearing carbon). Both diastereomers were isolated and subjected to alkylation with trimethylaluminium at 0 °C. Isomers as well as their mixture gave almost the same mixture of **15a** and **16a** (Table 1, run 11). Methylation takes place predominantly at the cyclopropane carbon rather than the terminal methylene carbon, the newly pro-

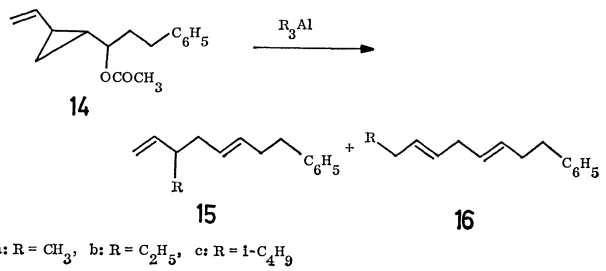
a) D: dichloromethane, C: dichloroethane, B: benzene, E: ether. b) A hexane solution (1.84 M) used. c) Prepared from 1-hexyne (0.45 g, 5.5 mmol), butyllithium (5.0 mmol), and diethylaluminium chloride (5.0 mmol) in hexane. d) A hexane solution (1.0 M) used. e) A by-product, *trans*-2-phenylcyclopropylmethanol (43 mg, 25%), also formed. f) α_D^{18} −0.002 to −0.005° in 5 ml of $CHCl_3$, 5 cm cell. g) One diastereomer used. The same product was invariably produced from the other diastereomer of **7** and the two diastereomers derived from the *cis*-**7**. In another experiment with the diastereomeric mixture of **7**, **8b** was produced in 89% yield. h) GLC analysis (Apiezon L, 5%, on Chromosorb WAW DMCS, KOH 1%, 2 m, 110 °C) revealed over 94% purity. i) Diastereomeric mixture of **7** used. j) A hexane solution of reagent (0.76 M) used. k) GLC analysis of the crude product showed the presence of a trace amount of 5-phenyl-2-pentene. l) A 24:76 mixture of **11a** and **11b** used. With the stereochemically pure starting material of **11a** and **11b**, the following results were obtained: yield of **12** and **13**, **12** to **13** ratio; 75%, 38:62; 86%, 36:64 respectively. m) GLC assay (PEG 20 M, 20%, on Celite 545, 2 m, 142 °C) showed the R_t of **12**, 15.8 min and the R_t of **13**, 16.8 min. n) A diastereomeric mixture (55:45) used. Both diastereomers of **14** gave nearly identical results, or the total yield of 59% or 63%, and the ratio of **15a** to **16a**, 83:17, or 83:16. When $NiCl_2(PPh_3)_2$ (10 mol% or 100 mol% was added, the total yield and the ratio of **15a** to **16a** changed to 79%, 69:31 for one isomer and 63%, 52:48 for the other. o) GLC analysis (PEG 20 M, 5% on Cellite 545, 1.5 m, 160 °C). p) The substrate **17** added to the trialkylaluminium reagent solution. q) GLC yield. r) The following results were obtained under different conditions: solvent, temperature, total yield of **18a** and **19a** (ratio); benzene, r.t., 74% (92:8); dichloromethane, 0 °C, 62% (86:14). In dichloromethane a dimeric by-product (24%) was also produced. In ether or THF at 0 °C or r.t. no trace of the product was formed, **17** being recovered unchanged. s) Reagent prepared from butyllithium (0.71 mmol), phenylacetylane (0.71 mmol) and diethylaluminium chloride (0.71 mmol) in hexane at 0 °C. t) Under other conditions, the following results were obtained: solvent, temperature, total yield of **21** and **22** (ratio); dichloromethane, 0 °C, 55% (79:21); hexane, 0 °C, 66% (86:14), toluene, 0 °C, 63% (85:15). In ether or THF no trace of the product was produced. u) GLC (PEG 20 M, 5%, on Celite 545, 1.5 m, 143 °C) showed 87% purity, the major product assumed to be **30**, the minor one being its epimer.

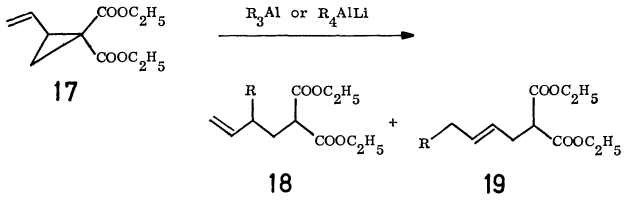
duced C=C bond being deduced to be *trans* (see Experimental). The regioselective alkylation takes place also with triethyl- and triisobutylaluminum. An attempt to change the regioselectivity by adding transition metal complexes failed except $NiCl_2(PPh_3)_2$ which accelerated the formation of **16a**.



a: R = CH_3, b: R = C_2H_5, c: R = 1-C_4H_9

Regio- and Stereochemistry of Homoconjugate Addition to Activated Vinylcyclopropanes. Introduction of an alkyl group into 2-vinylcyclopropane-1,1-dicarboxylate esters or related compounds would control the regioselectivity, *i.e.* 1,5- or 1,7-homoconjugate addition.[13] Dialkylcopperlithium[14] would be a suitable reagent for 1,7-alkyl addition. However, none is known for 1,5-alkyl introduction. We have found that trialkylaluminium performs 1,5-homoconjugate addition and tetraalkylaluminiumlithium prepared from equimolar amounts of trialkylaluminium and alkyllithium effects 1,7-homoconjugate addition.

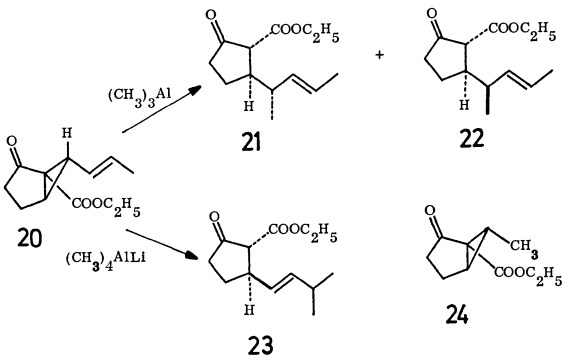
The vinylcyclopropane **17** was allowed to react with 3 mol of trimethylaluminium. The reaction took place immediately and ended usually in 10 min at 0 °C. Quenching with aq satd. sodium citrate solution, followed by work-up and isolation, gave a 96:4 mixture of **18a** and **19a**[14a] (Table 1, run 14). Among the solvents tested benzene gave best results as regards yield and selectivity. In dichloromethane a dimeric by-product was obtained. In a coordinating solvent such as ether the starting material was recovered unchanged. In order to accelerate the conversion of **17** into the products, use of 2.5 to 3 mol of trialkylaluminium is preferable, with less than 2 mol the reaction being extremely slow. Regioselectivity with triethylaluminium was almost perfect to give **18b** exclusively. Using the reagent of $Et_2AlC{\equiv}CPh$, **18c** only was produced. Thus, ethynyl carbon reacts in preference to ethyl group.[9]



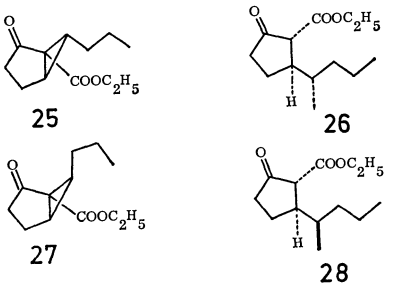
a: R = CH_3, b: R = C_2H_5, c: R = $C{\equiv}CC_6H_5$

The regioselectivity was reversed when tetramethylaluminiumlithium was used, the **18a**/**19a** ratio being 8:92 comparable to the cuprate reaction.[14] In a similar way tetraethylaluminiumlithium gave mainly **19b**. In these alanate reactions ether solvent was found to give the highest regioselectivity. Dilution with hexane gives rise to a decrease in the formation of 1,7-adduct **19**.

The regio-control of the homoconjugate addition was also attained in the reaction of a bicyclic β-keto ester **20** prepared according to the procedure shown in Scheme 4. With trimethylaluminium, **20** gave 1,5-homoconjugate adducts **21** and **22** as the sole products (Table 1, run 19). The reaction carried out in dichloromethane at −20 °C gave the adduct with the best yield. The product ratio **21**:**22** was almost independent of solvent except ether or tetrahydrofuran (THF) in which no reaction took place. The amount of trimethylaluminium necessary for alkylation was found to be more than 2 mol, 2.5 mol being usually employed.

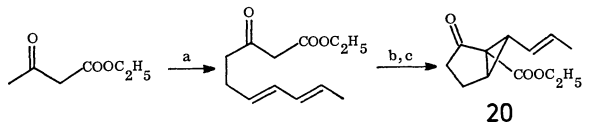


The stereochemistry of the products was determined by hydrogenating **21** and **22** and by comparing the spectral properties of the dihydro derivatives **26** and **28**, respectively. Each authentic sample was obtained by the reaction of **25** or **27** with dimethylcopperlithium.[15] We conclude that the 1,5-homoconjugate addition proceeds with *ca.* 86% inversion of the configuration at the cyclopropane carbon. This is in sharp contrast to the alkylation of **9** or **11a,b** in which complete loss of stereochemical integrity took place.



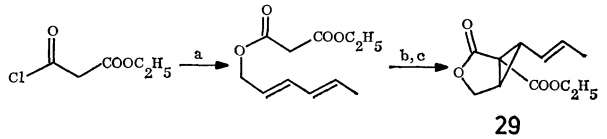
For successful homoconjugate addition, two necessary factors are (a) two activating carbonyl groups since ethyl chrysanthemate does not undergo conjugate addition, and (b) a vinyl group on the cyclopropane ring since compound **24** was recovered unchanged. Prolonged reaction of **24** with trimethylaluminium gave rise only to 1,2-methyl addition to the ketonic carbonyl.[16]

A similar regio- and stereochemical control was realized with **29** prepared according to Scheme 5. Using trimethylaluminium we obtained a 1,5-adduct of over 87% purity in 81% yield. We may assume



a: NaH, n-BuLi, $ClCH_2CH{=}CHCH{=}CHCH_3$, b: p-$CH_3C_6H_4SO_2N_3$, $(C_2H_5)_3N$
c: $Cu(acac)_2$, $C_6H_5CH_3$ reflux

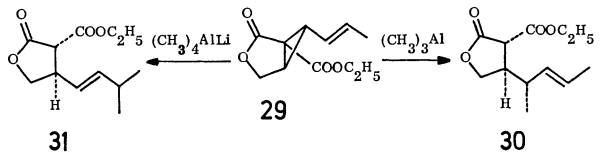
Scheme 4.



a: $HOCH_2CH{=}CHCH{=}CHCH_3$, pyridine, b: p-$CH_3C_6H_4SO_2N_3$, $(C_2H_5)_3N$
c: $Cu(acac)_2$, $C_6H_5CH_3$ reflux

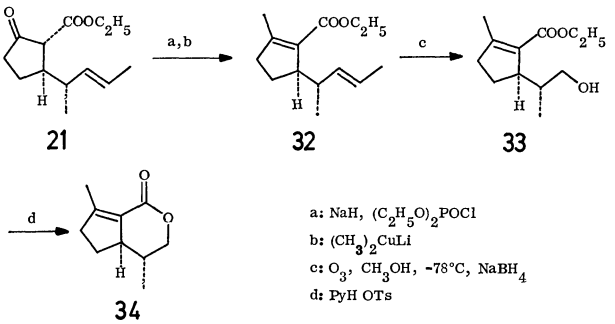
Scheme 5.

the reaction proceeded mainly with inversion in analogy to the case of **20**. The present major product would have the structure shown in the formula **30**. In contrast, the reaction of **29** with tetramethylaluminiumlithium gave **31** only in 80% yield.



Thus we control the stereochemistry of the α-carbon of a side chain (*e.g. cf.* structure **21**). This is particularly useful for the synthesis of neonepetalactone,[17] and should be extended to the preparation of such terpenes having the same structural unit as chrysomelidial[18] and juvabione.[19]

The synthesis of neonepetalactone **34** (Scheme 6) was carried out as follows. The β-keto ester **21** was freed from its epimer **22** by preparative TLC and converted into an enol phosphate which was then allowed to react with dimethylcopperlithium to give **32**. The two C=C bonds in **32** may be differentially cleaved. Ozonolysis of **32** at −78 °C followed by reductive work-up gave a hydroxy ester **33** whose lactonization gave neonepetalactone **32** exhibiting consistent spectral properties.[17]



Scheme 6.

Experimental

Temperatures are uncorrected. Distillation of small amount of samples (less than 1 g) was carried out with Kugelrohr. ^{1}H-NMR spectra (tetramethylsilane as an internal standard) were taken on a Varian EM 390 spectrometer or JEOL PMX-60 spectrometer, chemical shifts being given in ppm unit. IR spectra were obtained on a Shimadzu IR-27G spectrometer, MS on a Hitachi RMU-6L spectrometer. Trialkylaluminium (Nippon Alkyl Aluminium Co., Ethyl Corp., or Alfa Division of Ventron Corp., a neat liquid) was diluted with specified solvents. All the reactions with organometallics were carried out under an argon atmosphere. Preparative TLC plates (20 cm×20 cm) were prepared by use of Merck Kiesel-gel PF_{254}. Column chromatography was carried out with silica gel at atmosphereic pressure (Wacogel C-100) or under pressure of 4—6×10^5 N/m^2 (Wacogel C-300).

Synthesis of exo-*7-(1-Acetoxyheptyl)norcarane (**1a**) and* exo-*7-(1-Benzoyloxyheptyl)norcarane (**1b**).* Butyllithium (1.80 M hexane solution, 19.0 ml, 34 mmol) was added to a THF (50 ml) solution of 7,7-dibromonorcarane (7.2 g, 28 mmol) at −95 °C over a period of 7 min. After stirring for 10 min heptanal (4.6 ml, 34 mmol) was added at −95 °C and the reaction mixture was stirred at −95 °C for 30 min, at −78 °C for 1 h, then at room temperature for 15 min. Work-up gave a crude β-bromo alcohol which was dissolved in THF (20 ml) and the mixture was stirred overnight with potassium *t*-butoxide (4.0 g, 35 mmol). Work-up followed by column chromatography (hexane–ether 10:1) gave *exo*-7-heptanoylnorcarane (4.7 g, 73% yield), which was dissovled in ethanol (10 ml) and treated under a nitrogen atmosphere at 0 °C with sodium borohydride (0.43 g, 11.2 mmol). Work-up and column chromatography (hexane–ether 10:1) gave *exo*-7-(1-hydroxyheptyl)norcarane (3.7 g, 57% yield from 7,7-dibromonorcarane), bp 83—85 °C (bath temp)/1 Torr; IR (neat): 3350, 1065, 1024 cm^{-1}; MS: *m/e* 192 (M^+-18). Found: C, 80.10; H, 12.58%. Calcd for $C_{14}H_{24}O$: C, 79.93; H, 12.46%.

The alcohol (0.22 g, 1.10 mmol) was mixed with pyridine (1 ml), and acetic anhydride (0.8 ml), and allowed to react at room temperature overnight. All the volatile material was then evaporated under reduced pressure and the residue was purified with short silica-gel column to give **1a** (0.26 g, 96% yield), bp 98—100 °C (bath temp)/1 Torr. ^{1}H-NMR (CCl_4): δ 1.4—2.1 (m+s (δ 1.92), 27H), 4.12 (dt, J=8, 5 Hz, 1H); IR (neat): 2940, 2870, 1730, 1450, 1365, 1235, 1020 cm^{-1}; MS: *m/e* (rel intensity) 210 (M^+-CH_2CO, 7), 192 (15), 135 (18), 125 (32), 121 (34), 79 (43), 67 (44), 43 (100). Found: C, 76.36; H, 11.38%. Calcd for $C_{16}H_{28}O_2$: C, 76.14; H, 11.18%.

The benzoate (**1b**) (1.22 g, 96% yield) was obtained by treating the alcohol (0.85 g, 4.0 mmol) with benzoyl chloride (0.49 ml, 4.2 mmol) and pyridine (2 ml) in dichloromethane (3 ml) at 0 °C for 1 h. Work-up and column chromatography (hexane–ether 10:1) gave **1b** as a colorless viscous oil, bp 165—170 °C (bath temp)/1 Torr. ^{1}H-NMR (CCl_4): δ 0.5—2.1 (m, 24H), 4.2—4.7 (m, 1H, CHOBz), 7.1—7.5 (m, 3H), 7.7—8.1 (m, 2H); IR (neat): 1715, 1605, 1587, 1110, 1025, 718 cm^{-1}; MS: *m/e* (rel intensity) 192 ($M^+-C_6H_5COOH$, 25), 135 (20), 122 (22), 105 (100), 94 (33), 79 (47), 77 (45), 41 (32). Found: C, 80.46; H, 9.74%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

Preparation of exo-*7-(1-Ethylheptyl)norcarane (**2a**). A Typical Procedure for the Reaction with Trialkylaluminium.* A hexane solution of triethylaluminium (1.84 M, 1.5 ml, 2.8 mmol) was added to a dichloromethane (3 ml) solution of **1a** (0.25 g, 1.0 mmol) at room temperature. The reaction mixture was stirred for 2 h and then quenched with satd. aq sodium sulfate solution (few drops). This was stirred vigorously, diluted with dichloromethane and filtered through a short column of anhydrous sodium sulfate. Concentration followed by column chromatography gave **2a** (0.20 g, 91% yield), bp 160—168 °C/16 Torr; ^{1}H-NMR (CCl_4): δ 0.0—2.1 (m); IR (neat): 3020, 1370, 1070, 968 cm^{-1}; MS: *m/e* (rel intensity) 222 (M^+, 10), 193 (12), 137 (24), 110 (53), 95 (82), 81 (91), 70 (98), 68 (100), 55 (85), 40 (86). Found: C, 86.37; H, 13.62%. Calcd for $C_{16}H_{30}$: C, 86.40; H, 13.60%.

Reaction with Diethyl(1-Alkynyl)aluminium. Butyllithium (1 mol) hexane solution was added to 1-alkyne (slightly more than 1 mol) at 0 °C. After 10 min diethylaluminium chloride (1 mol) hexane solution was added, stirring being carried out for 15 min at 0 °C. The reaction mixture was concentrated *in vacuo* below room temperature. The residue was dissolved in a specified solvent, and a substrate was added.

Tetraalkylaluminiumlithium. This reagent was prepared by mixing equimolar amounts of trialkylaluminium (hexane solution) and alkyllithium (ether solution) at 0 °C for 20 min. Substrate dissolved in ether was added to the solution.

exo-*7-(1-Hexyl-2-heptynyl)norcarane* (**2b**): Bp 135—139 °C (bath temp)/2 Torr; ^{1}H-NMR (CCl_4): δ 0.2—2.3 (m); IR (neat): 2950, 2880, 1450 cm^{-1}; MS: *m/e* (rel intensity) 274 (M^+, 1.4), 217 (23), 189 (32), 147 (32), 133 (46), 107 (54), 91 (79), 79 (79), 43 (60), 41 (100). Found: C, 87.54; H, 12.76%. Calcd for $C_{20}H_{34}$: C, 87.51; H, 12.49%.

Synthesis of exo-*6-(1-Acetoxyheptyl)bicyclo[3.1.0]hexane* (**3**). The procedure for the synthesis of **1a** was applied to the one of *exo*-6-heptanoylbicyclo[3.1.0]hexane, bp 80—83 °C (bath temp)/0.04 Torr. Found: C, 80.51; H, 11.73%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

Sodium borohydride reduction of this ketone followed by acetylation gave **3** quantitatively. Bp 87—91 °C (bath temp)/0.04 Torr; ^{1}H-NMR (CCl_4): δ 0.5—2.5 (m+S (δ 1.92), 25H), 3.9—4.3 (m, 1H); IR (neat): 3030, 1728, 1235, 1018 cm^{-1}; MS: *m/e* (rel intensity) 196 (M^+-CH_2CO, 4), 178 (9), 135 (9), 121 (20), 111 (22), 93 (33), 79 (42), 67 (38), 55 (24), 43 (100). Found: C, 75.63; H, 11.29%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

exo-*6-(1-Ethylheptyl)bicyclo[3.1.0]hexane* (**4**): ^{1}H-NMR (CCl_4): δ 0.1—1.9 (m); MS: *m/e* (rel intensity) 208 (M^+, 3), 189 (4), 140 (10), 123 (14), 111 (22), 95 (33), 81 (54), 70 (100), 55 (65), 41 (81). Due to the lack of sample confirmation of the structure was not carried out.

Preparation of (1S,2S)-2-Phenylcyclopropylmethyl Acetate (**9b**). Optical resolution of *trans*-2-phenylcyclopropanecarboxylic acid with quinine[20] gave a sample of $[\alpha]_D^{16}$ +375° (*c* 2.3, $CHCl_3$), estimated to be 98% optically pure based on the reported value $[\alpha]_D^{14}$ +381° ($CHCl_3$),[20] $[\alpha]_D^{20}$ +376° ($CHCl_3$).[21] The carboxylic acid was reduced with lithium aluminium hydride and acetylated with acetic anhydride to give **9b**, $[\alpha]_D^{19}$ +87.6° (*c* 2.0, $CHCl_3$) quantitatively. Bp 75—79 °C (bath temp)/0.03 Torr; ^{1}H-NMR (CCl_4): δ 1.0—2.0 (m, 4H), 2.04 (s, 3H), 4.04 (d, J=6.4 Hz, 2H), 7.0—7.4 (m, 5H); IR (neat): 3035, 1743, 1608, 1500, 1237, 1030, 757, 698 cm^{-1}; MS: *m/e* (rel intensity) 190 (M^+, 10), 149 (15), 130 (100), 115 (48). Found: C, 75.87; H, 7.42%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

trans-*7-(1-Acetoxyethyl)-2-phenylcyclopropane* (**7**). Methylmagnesium iodide (0.88 M ethereal solution, 0.99 ml, 0.87 mmol) was added to *trans*-2-phenylcyclopropanecarbaldehyde[22] (84 mg, 0.58 mmol) dissolved in ether (5 ml) at 0 °C, and the reaction mixture was stirred for 3 h, quenched with aq satd. ammonium chloride solution (10 ml) and extracted with dichloromethane. The combined dried organic phase was concentrated and the residue chromatographed with preparative TLC (dichloromethane) to give two diastereomers of *trans*-1-(1-hydroxyethyl)-2-phenylcyclopropane (R_f 0.4, 30 mg; R_f 0.3, 36 mg, 75% total yield). The more polar diastereomer gave ^{1}H-NMR (CCl_4): δ 0.7—1.4 (m, 3H), 1.26 (d, J=6.2 Hz, 3H), 1.5—2.0 (m, 1H), 2.08 (s, 1H), 3.1—3.7 (m, 1H), 6.7—7.4 (m, 5H). The less polar alcohol was acetylated with acetic anhydride (0.2 ml) and pyridine (0.2 ml) (r.t., 5 h) to give one diastereomer of **7** (38 mg, 95% yield). ^{1}H-NMR (CCl_4): δ 0.7—1.5 (m+d (δ 1.31, J=6.4 Hz, 6H), 1.8—2.2 (m+s (δ 1.97), 4H), 4.50 (quintet, J=6.4 Hz, 1H), 6.8—7.3 (m, 5H); IR (neat): 1735, 1605, 1503, 1372, 1242 cm^{-1}. The more polar alcohol was acetylated to give the other diastereomer of **7** (38 mg, 79% yield), bp 84—87 °C (bath temp)/0.05 Torr. ^{1}H-NMR (CCl_4): δ 0.8—1.6 (m+d(δ 1.33, J=6.4 Hz), 6H), 1.6—2.1 (m+s(δ 1.99), 4H), 4.99 (quintet, J=6.4 Hz, 1H), 6.8—7.3 (m, 5H); IR (neat): 1737, 1610, 1507, 1377, 1245 cm^{-1}; MS: *m/e* 204 (M^+). Found: C, 76.41; H, 8.01%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

Physical properties of the *cis* isomers of **7** (prepared from *cis*-2-phenylcyclopropanecarboxylic acid): bp 102—104 °C (bath temp)/0.09 Torr. Found: C, 76.71; H, 8.00%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

Each diastereomer was separated at the stage of alcohol (dichloromethane, R_f 0.6 and 0.4). The acetate of the less polar alcohol showed following spectra. ^{1}H-NMR (CCl_4): δ 0.7—1.6 (m+d (δ 1.23, J=6.2 Hz), 6H), 1.67 (s, 3H), 1.9—2.5 (m, 1H), 3.6—4.2 (m, 1H), 7.16 (s, 5H). IR (neat): 1733, 1605, 1503, 1370, 1245 cm^{-1}. The acetate of the more polar alcohol exhibited ^{1}H-NMR (CCl_4): δ 0.8—1.1 (m+d (δ 0.98, J=6.2 Hz), 6H), 1.9—2.4 (m+s (δ 1.92), 4H), 4.1—4.5 (m, 1H), 7.15 (s, 5H); IR (neat): 1730, 1605, 1503, 1370, 1245 cm^{-1}; MS: *m/e* (rel intensity) 204 (M^+, 4), 149 (34), 129 (100), 107 (70).

trans-*5-Phenyl-2-hexane* (**8a**): Bp 68—75 °C (bath temp)/1 Torr; ^{1}H-NMR (CCl_4): δ 1.22 (d, J=6.9 Hz, 1H), 1.60 (d, J=3.9 Hz, 3H), 2.1—2.4 (m, 2H), 2.67 (sextet, J=6.9 Hz, 1H), 5.2—5.4 (m, 2H), 7.0—7.3 (m, 5H); IR (neat): 3045, 1610, 1502, 968, 760, 704 cm^{-1}; MS: *m/e* (rel intensity) 160 (M^+, 6), 144 (2), 105 (100), 91 (5), 79 (5), 77 (5). Found: C, 90.17; H, 10.30%. Calcd for $C_{12}H_{16}$: C, 89.94; H, 10.06%.

trans-*5-Phenyl-2-heptene* (**8b**): Bp 81—88 °C (bath temp)/1 Torr; ^{1}H-NMR (CCl_4): δ 0.77 (t, J=7.5 Hz, 3H), 1.3—2.1 (m+d (δ 1.56, J=4 Hz), 5H), 2.1—2.7 (m, 3H), 5.2—5.5 (m, 2H), 6.9—7.3 (m, 5H); IR (neat): 3030, 1604, 1497, 966, 756, 698 cm^{-1}; MS: *m/e* (rel intensity) 174 (M^+, 3), 145 (1), 119 (56), 91 (100), 77 (5). Found: C, 89.58; H, 10.53%. Calcd for $C_{13}H_{18}$: C, 89.59; H, 10.41%.

trans-*7-Methyl-5-phenyl-2-octene* (**8c**): Bp 89—96 °C (bath temp)/1 Torr; ^{1}H-NMR (CCl_4): δ 0.7—1.0 (m, 6H), 1.1—1.7 (m+d (δ 1.52, J=4 Hz), 5H), 2.1—2.4 (m, 2H), 2.5—2.8 (m, 1H), 5.2—5.5 (m, 2H), 6.9—7.3 (m, 5H); IR (neat): 3040, 1606, 1500, 1468, 1456, 968, 760, 701 cm^{-1}; MS: *m/e* (rel intensity) 202 (M^+, 1), 147 (27), 105 (28), 91 (100), 77 (4). Found: C, 89.28; H, 10.81%. Calcd for $C_{15}H_{22}$: C, 89.04; H, 10.96%.

Preparation of endo- *and* exo-*7-Acetoxymethyl-1-phenylnorcarane* (**11a** *and* **11b**). Bromoform (0.36 ml, 4.1 mmol) was added to a mixture of 1-phenylcyclohexane (0.55 g, 3.5 mmol), potassium *t*-butoxide (4.3 mmol), and hexane (5 ml) at ice–salt temperature over a period of 30 min. After the addition was completed, the reaction mixture was warmed to room temperature, stirred for 1.5 h, then poured into water (20 ml). Extraction with dichloromethane (10 ml× 3 times) followed by the usual work-up and column chromatography gave 7,7-dibromo-1-phenylnorcarane (0.67 g, 58% yield; 79% yield based on the consumed olefin) as a viscous oil, bp 98—100 °C (bath temp)/0.03 Torr. ^{1}H-NMR (CCl_4): δ 1.2—1.7 (m, 5H), 1.9—2.5 (m, 4H), 7.24 (s, 5H); IR (neat): 3035, 1603, 1496, 1449, 753, 747, 697 cm^{-1}; MS: *m/e* (rel intensity) 264 (1.2), 262 (2.2), 260 (1.2), 251 (24), 249 (24), 169 (100), 141 (80), 126 (52), 115 (53), 91 (68). Found: C, 47.46; H, 4.20%. Calcd for $C_{13}H_{14}Br_2$: C, 47.31; H, 4.28%.

To a THF (10 ml) solution of the dibromonorcarane (0.33 g, 1.0 mmol) was added butyllithium (1.60 M hexane solution, 0.69 ml, 1.1 mmol) at −95 °C over a period of 5 min and the reaction mixture stirred for 20 min. Dry carbon dioxide gas was bubbled at −95 °C for 25 min into the reaction mixture which was then warmed to room temperature and acidified with dil hydrochloric acid. Work-up gave a crude bromo carboxylic acid (0.30 g, quantitative yield). ^{1}H-NMR ($CDCl_3$): δ 1.1—2.5 (m, 9H), 7.3—7.7 (m, 5H), 9.3—10.1 (br s, 1H); IR (neat): 3400, 2500, 1737, 1704, 1603, 1496, 1266, 760, 698 cm^{-1}; MS: *m/e* (rel intensity) 256 (1), 214 (77), 187 (28), 169 (79), 142 (83), 141

(77), 129 (60), 115 (70), 91 (100).

The bromocarboxylic acid (0.83 g, 2.8 mmol) was dissolved in THF (10 ml) and to this solution was added butyllithium (1.53 M hexane solution, 3.8 ml, 5.9 mmol) at −78 °C over a period of 8 min. The reaction mixture was stirred for 25 min, then treated with ethanol (1 ml) and warmed to room temperature. Acidification with dil hydrochloric acid followed by the work-up gave a crude carboxylic acid (0.50 g). Preparative TLC (hexane–ethyl acetate 2:1 double development) of the crude product (0.10 g) gave *endo*-carboxylic acid (R_f 0.6—0.7, 72 mg) and its *exo* isomer (R_f 0.5—0.6, 25 mg) in 80% total yield.

The *endo* isomer, 1-phenylnorcarane-*endo*-7-carboxylic acid (colorless prisms, mp 75—76 °C (hexane)), gave ^{1}H-NMR ($CDCl_3$): δ 1.1—2.4 (m, 10H), 7.41 (br s, 5H), 8.6—9.5 (m, 1H); IR (neat): 3400—2500, 3040, 1698, 1604, 760, 700 cm^{-1}; MS: *m/e* (rel intensity) 217 (4), 216 (M^+, 36), 198 (14), 171 (80), 129 (83), 115 (57), 91 (100). Found: C, 77.78; H, 7.44%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

The *exo* isomer, 1-phenylnorcarane-*exo*-7-carboxylic acid (colorless prisms, mp 139—140 °C (benzene)); ^{1}H-NMR ($CDCl_3$): δ 1.1—2.4 (m, 10H), 7.35 (br s, 5H), 8.0—9.0 (m, 1H); IR ($CHCl_3$): 3450—2500, 3060, 1693, 1604, 694 cm^{-1}; MS: *m/e* (rel intensity) 217 (M^+ +1, 7), 216 (M^+, 36), 198 (14), 171 (80), 129 (83), 115 (57), 91 (100). Found: C, 78.00; H, 7.37%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

The *exo* carboxylic acid (23 mg, 0.11 mmol) was reduced with lithium aluminium hydride (8.0 mg, 0.22 mmol) in ether (1 ml) to give *exo*-7-hydroxymethyl-1-phenylnorcarane, bp 93—98 °C (bath temp)/0.03 Torr; ^{1}H-NMR (CCl_4): δ 1.0—2.3 (m, 11H), 3.12 (dd, J=6.6, 3.0 Hz, 2H), 7.2 (br s, 5H); IR (neat): 3320, 2930, 1603, 1497, 1447, 1018, 759, 700 cm^{-1}; MS: *m/e* (rel intensity) 202 (M^+, 4), 184 (40), 171 (69), 141 (57), 129 (82), 115 (65), 91 (100). Found: C, 83.25; H, 9.20%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

The alcohol was acetylated with acetic anhydride (0.2 ml) and pyridine (0.2 ml) (r.t., 13 h) to give **11a** (27 mg, 97% yield for 2 steps). bp 108—110 °C (bath temp)/0.04 Torr; ^{1}H-NMR (CCl_4): δ 1.0—2.3 (m+s (δ 1.94), 13H), 3.56 (d, J=6.6 Hz, 2H), 7.17 (s, 5H); IR (neat): 3035, 1738, 1603, 1252, 1028, 960, 701 cm^{-1}; MS: *m/e* (rel intensity) 244 (M^+, 2), 184 (85), 141 (100), 129 (49), 115 (41), 91 (78). Found: C, 78.72; H, 8.24%. Calcd for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25%.

The *endo* acetate **11b** was prepared similarly. *endo*-7-Hydroxymethyl-1-phenylnorcarane: bp 114—116 °C (bath temp)/0.06 Torr; ^{1}H-NMR (CCl_4): δ 1.1—2.3 (m, 11H), 3.8 (d, J=6.9 Hz, 2H), 6.9—7.3 (m, 5H); IR (neat): 3350, 3030, 1603, 1494, 1449, 1018, 749, 700 cm^{-1}; MS: *m/e* (rel intensity) 203 (0.8), 202 (M^+, 4), 184 (37), 171 (77), 141 (51), 129 (83), 91 (100). Found: C, 82.91; H, 8.93%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

Acetylation of the alcohol gave **11b**, bp 90—93 °C (bath temp)/0.04 Torr; ^{1}H-NMR (CCl_4): δ 1.2—2.1 (m+s (δ 2.06), 13H), 4.27 (d, J=5.4 Hz, 2H), 7.16 (br s, 5H); IR (neat): 3035, 1739, 1604, 1494, 1242, 1028, 759, 700 cm^{-1}; MS: *m/e* (rel intensity) 244 (M^+, 1), 184 (82), 141 (100), 91 (82). Found: C, 78.89; H, 8.47%. Calcd for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25%.

1-Methyl-1-phenyl-2-vinylcyclohexane. This was obtained as a *ca.* 2:3 mixture of **12** and **13**: bp 117—123 °C (bath temp)/5 Torr; ^{1}H-NMR (CCl_4): δ 1.21 (s, 1.05 H, CH_3 for **12**), 1.32 (s, 1.95 H, CH_3 for **13**), 1.7—2.3 (m, 8H), 2.3—2.7 (m, 1H), 4.6—5.0 (m, 2H), 5.2—6.0 (m, 1H), 7.0—7.5 (m, 5H); IR (neat): 3070, 3040, 1638, 1602, 1497, 990, 908, 762, 697 cm^{-1}; MS: *m/e* (rel intensity) 200 (M^+, 29), 184 (45), 131 (56), 118 (100), 105 (64), 91 (45). Found: C, 89.67; H, 10.08%. Calcd for $C_{15}H_{20}$: C, 89.94; H, 10.06%.

Synthesis of trans-*1-(1-Acetoxy-3-phenylpropyl)-2-vinylcyclopropane (**14**).* The major isomer of 2-vinylcyclopropylmethanol[12] (93:7 isomeric mixture based on GLC (PEG 20 M, 5%, on Celite 545, 1.5 m, 72 °C)) was assigned to be *trans* on the basis of ^{13}C-NMR (CCl_4): chemical shift (δ from TMS) (intensity), 112.25 (100) and 115.36 (8), 140.76 (64) and 136.72 (5), 66.00 (100) and 62.88 (7). Pyridinium chlorochromate (0.63 g) oxidation (0 °C, 16 h) of this alcohol (0.100 g, 2.0 mmol) followed by the reaction (0 °C, 2.5 h) with 2-phenylethylmagnesium bromide (2.4 mmol) and preparative TLC (hexane–ether 5:1) gave two diastereomers of (1*R**,2*S**)-1-(1-hydroxy-3-phenylpropyl)-2-vinylcyclopropane (R_f 0.3, 136 mg; R_f 0.2, 131 mg) totally in 65% yield. The less polar alcohol showed ^{1}H-NMR (CCl_4): δ 0.5—0.7 (m, 2H), 0.8—1.1 (m, 1H), 1.2—1.5 (m, 1H), 1.7—2.1 (m, 3H), 2.72 (dt, J=8.7, 3.0 Hz, 2H), 3.00 (q, J=6.6 Hz, 1H), 4.7—5.6 (m, 3H), 7.13 (s, 5H). The more polar alcohol gave ^{1}H-NMR (CCl_4) spectrum: δ 0.4—1.0 (m, 3H), 1.1—1.4 (m, 1H), 1.7—2.0 (m, 3H), 2.70 (dt, J=8.1. 2.6 Hz, 2H), 2.98 (q, J=6.6 Hz, 1H), 4.7—5.6 (m, 3H), 7.14 (s, 5H).

Acetylation of the less polar alcohol gave one diastereomer of **14**, ^{1}H-NMR (CCl_4): δ 0.5—1.7 (m, 3H), 1.8—2.1 (m+s (δ 1.95), 5H), 2.4—2.7 (m, 2H), 4.2—4.5 (m, 1H), 4.7—5.6 (m, 3H), 7.0—7.3 (m, 5H). The more polar alcohol afforded the other diastereomer of **14**, ^{1}H-NMR (CCl_4): δ 0.4—1.4 (m, 3H), 1.8—2.1 (m+s (δ 1.95), 5H), 2.5—2.7 (m, 2H), 4.2—4.5 (m, 1H), 4.8—5.6 (m, 3H), 7.0—7.3 (m, 5H). Physical properties of the diastereomeric mixture of **17** were as follows: bp 124—127 °C (bath tem)/0.1 Torr; IR (neat): 3080, 3040, 1730, 1638, 1605, 1497, 1240, 1020, 700 cm^{-1}; MS: *m/e* (rel intensity) 224 (M^+, 4), 184 (11), 160 (8), 130 (52), 117 (34), 104 (35), 91 (100), 77 (25), 65 (20). Found: C, 78.44; H, 8.41%. Calcd for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25%.

*(E)-3-Methyl-8-phenyl-1,5-octadiene (**15a**) and (E,E)-1-Phenyl-3,6-nonadiene (**16a**).* The reaction product formed an 83:17 mixture of **15a** and **16a**, bp 83—93 °C (bath temp)/1 Torr; ^{1}H-NMR (CCl_4): δ 0.93 (d, J=6.6 Hz, 3H), 1.8—2.4 (m, 5H), 2.5—2.8 (m, 2H), 4.7—5.1 (m, 2H), 5.3—5.9 (m, 3H), 7.0—7.3 (m, 5H). Preparative GLC separation (PEG 20 M, 30%, on celite 545, 3 m, 180 °C) gave pure components. The product **15a** showed practically the same ^{1}H-NMR spectrum and IR (994, 969, 910 cm^{-1}) as those of the mixture. MS: *m/e* 200 (M^+). Found: C, 89.86; H, 10.30%. Calcd for $C_{15}H_{20}$: C, 89.94; H, 10.06%. The geometry of the newly produced carbon-carbon double bond was inferred to be *trans* based on the IR absorptions at 969 cm^{-1}. The other product **16a** was characterized spectrometrically. MS: *m/e* 200 (M^+); IR (neat): 969 cm^{-1}; ^{1}H-NMR: (CCl_4): δ 0.97 (t, 3H), 1.7—2.5 (m, 6H), 2.5—2.8 (m, 2H), 5.2—5.6 (m, 4H), 7.10 (s, 5H). The IR absorption at 969 cm^{-1} was almost twice as intense as that of **16a** (based on the intensity of the phenyl absorptions), no absorptions near 800—750 cm^{-1} being detected. Consequently both of the C=C bonds in **16a** were assigned to be *trans*.

*(E)-3-Ethyl-8-phenyl-1,5-octadiene (**15b**) and (E,E)-1-Phenyl-3,6-decadiene (**16b**).* The reaction product formed an 83:17 mixture of **15b** and **16b**, bp 105—110 °C (bath temp)/1 Torr. Found: C, 89.49; H, 10.40%. Calcd for $C_{16}H_{22}$: C, 89.65; H, 10.35%. Each product was separated by

preparative GLC. The product **15b** showed IR (neat): 995, 970, 910, 745, 700 cm^{-1}; ^1H-NMR (CCl_4): δ 0.80 (t, J=7 Hz, 3H), 1.0—1.5 (m, 2H), 1.5—2.1 (m, 3H), 2.1—2.4 (m, 2H), 2.5—2.7 (distorted t, 2H), 4.7—5.0 (m, 2H), 5.2—5.7 (m, 3H), 7.0—7.3 (m, 5H); MS: *m/e* 214 (M^+). The isomer **16b** exhibited ^1H-NMR (CCl_4): δ 0.90 (t, J=6 Hz, 3H), 1.1—1.7 (m, 2H), 1.7—2.1 (m, 2H), 2.1—2.5 (m, 2H), 2.5—2.8 (m, 4H), 5.2—5.6 (m, 4H), 7.0—7.3 (m, 5H).

*(E)-3-Isobutyl-8-phenyl-1,5-octadiene (**15c**) and (E,E)-10-Methyl-1-phenyl-3,6-undecadiene (**16c**)*: Bp 89—93 °C (bath temp)/0.05 Torr; IR (neat): 3030, 1641, 1607, 1497, 994, 966, 909, 745, 700 cm^{-1}. Found: C, 89.16; H, 11.03%. Calcd for $C_{18}H_{26}$: C, 89.19; H, 10.81%. Preparative GLC separation gave pure **15c**: ^1H-NMR (CCl_4): δ 0.80 (d, J=6 Hz, 3H), 0.83 (d, J=6 Hz, 3H), 1.0—1.4 (m, 2H), 1.4—1.7 (m, 1H), 1.7—2.4 (m, 5H), 2.5—2.8 (m, 2H), 4.7—5.0 (m, 2H), 5.2—5.6 (m, 3H), 7.0—7.3 (m, 5H).

*Diethyl (2-Methyl-3-butenyl)propanedioate (**18a**)*: Bp 75—77 °C (bath temp)/0.05 Torr; ^1H-NMR (CCl_4): δ 1.04 (d, J=6.6 Hz, 3H), 1.29 (t, J=6.9 Hz, 6H), 1.7—1.9 (m, 2H), 1.9—2.2 (m, 1H), 3.21 (dd, J=8.4, 2.4 Hz, 1H), 4.10 and 4.12 (2q, J=6.9 Hz each, 4H), 4.8—5.1 (m, 2H), 5.4—5.8 (m, 1H); IR (neat): 3090, 1756, 1737, 1645, 1373, 1270, 1240, 1180, 1150, 1031, 998, 917 cm^{-1}; MS: *m/e* (rel intensity) 228 (M^+, 2), 183 (11), 160 (100), 137 (55), 109 (59), 81 (58), 68 (55). Found: C, 63.29; H, 8.95%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

Spectral data of **19a**[14a] are as follows. ^1H-NMR (CCl_4): δ 0.95 (t, J=7.8 Hz, 3H), 1.27 (t, J=6.9 Hz, 6H), 1.8—2.2 (m, 2H), 2.43 (dd, J=7.5, 6.3 Hz, 2H), 3.19 (t, J=7.5 Hz, 1H), 4.12 (q, J=6.9 Hz, 4H), 5.1—5.6 (m, 2H); IR (neat): 1755, 1739, 1372, 1152, 1024, 969 cm^{-1}; MS: *m/e* 228 (M^+).

*Diethyl(2-Ethyl-3-butenyl)propanedioate (**18b**)*: Bp 123—126 °C (bath temp)/0.2 Torr. ^1H-NMR (CCl_4): δ 0.87 (t, J=7.8 Hz, 3H), 1.29 (t, J=6.9 Hz, 6H), 1.2—2.2 (m, 5H), 3.1—3.4 (m, 1H), 4.11 and 4.13 (2q, J=6.9 Hz each, 4H), 4.9—5.1 (m, 2H), 5.2—5.7 (m, 1H); IR (neat): 3080, 1752, 1736, 1645, 1252, 1225, 1178, 1145, 1031, 998, 917 cm^{-1}; MS: *m/e* (rel intensity) 242 (M^+, 1), 213 (2), 197 (15), 160 (100), 151 (38), 132 (48), 123 (48), 95 (55), 67 (57). Found: C, 64.26; H, 9.30%. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%.

Alternative Synthesis of Diethyl trans-*2-Hexenylpropanedioate (**19b**)*. Diethylcopperlithium (0.71 mmol) was allowed to react with **17** (50 mg, 0.24 mmol) in ether (2 ml) at −23 °C. Work-up and preparative TLC (hexane–ethyl acetate 5:1, R_f 0.4—0.5) gave a mixture (5:95 by GLC) of **18b** and **19b** (40 mg, 70% yield), bp 114—116 °C (bath temp)/0.1 Torr; ^1H-NMR (CCl_4): δ 0.87 (t, J=7.8 Hz, 3H), 1.2—1.5 (m+t (δ 1.29, J=6.9 Hz), 8H), 1.8—2.1 (m, 2H), 2.4—2.6 (distorted t, 2H), 3.21 (t, J=7.8 Hz, 1H), 4.13 (q, J=6.9 Hz, 4H), 5.3—5.5 (m, 2H); IR (neat); 1753, 1738, 1230, 1174, 1150, 1034, 969 cm^{-1}; MS: *m/e* (rel intensity) 242 (M^+, 7), 197 (11), 160 (75), 125 (100), 95 (69), 67 (55). Found: C, 64.37; H. 9.30%. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%.

*Diethyl [2-(Phenylethynyl)-3-butenyl]propanedioate (**18c**)*. Bp 163—167 °C (bath temp)/0.15 Torr; ^1H-NMR (CCl_4): δ 1.28 (t, J=6.9 Hz, 6H), 1.9—2.3 (m, 2H), 4.2—4.5 (m, 1H), 4.51 (dd, J=8.4, 2.1 Hz, 1H), 4.13 and 4.16 (2q, J=6.9 Hz each, 4H), 5.1—5.5 (m, 2H), 5.6—6.0 (m, 1H), 7.2—7.5 (m, 5H); IR (neat): 2220, 1734, 1643, 1602, 1494, 1260, 1230, 1178, 1156, 1030, 990, 925, 759, 693 cm^{-1}; MS: *m/e* (rel intensity) 314 (M^+, 6), 285 (1), 241 (10), 240 (11), 213 (11), 211 (11), 195 (34), 167 (39), 154 (100), 141 (32), 115 (69). Found: C, 72.35; H, 7.10%. Calcd for $C_{19}H_{22}O_4$: C, 72.59; H, 7.05%.

*Synthesis of Ethyl 2-Oxo-*exo*-6-(*trans*-1-propenyl)bicyclo[3.1.0]hexane-1-carboxylate (**20**)*. Ethyl (*E,E*)-3-oxo-6,8-decadienoate (1.32 g, 6.3 mmol)[23] was treated with *p*-toluenesulfonyl azide (TsN_3) (1.26 g, 6.4 mmol) and triethylamine (0.88 ml, 6.4 mmol) in acetonitrile (25 ml) (r.t., 7 h). Work-up gave the α-diazo β-keto ester (IR: 2140, 1723, 1662 cm^{-1}). The diazo compound was dissolved in benzene (27 ml) and heated to reflux in the presence of copper(II) acetylacetonate (0.18 g) for 7 h. Work-up followed by column chromatography (hexane–ethyl acetate 10:1 to 5:1) gave **20** (1.13 g, 86% yield); bp 132—134 °C (bath temp)/0.09 Torr; ^1H-NMR (CCl_4): δ 1.29 (t, J=6.9 Hz, 3H, $COOCH_2C\underline{H}_3$), 1.70 (dd, J=6.3, 1.8 Hz, 3H, $=CH-C\underline{H}_3$), 1.9—2.3 (m, 5H), 2.4—2.5 (m, 1H), 4.14 (q, J=6.9 Hz, 2H, $COOC\underline{H}_2CH_3$); IR (neat): 3000, 1750, 1730, 1374, 1296, 1184, 1033, 967 cm^{-1}; MS: *m/e* (rel intensity) 208 (M^+, 22), 179 (27), 162 (68), 151 (40), 91 (73), 79 (100). Found: C, 69.32; H, 7.80%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

(2R,3R*)-2-Ethoxycarbonyl-3-[(S*)-*trans*-1-methyl-2-butenyl]-cyclopentanone (**21**) and Its Epimer (**22**)*: Bp 70—78 °C (bath temp)/0.15 Torr; ^1H-NMR (CCl_4): δ 1.03 and 0.98 (d, J=7.2 Hz, totally 3H, $CH-C\underline{H}_3$), 1.29 (t, J=6.9 Hz, 3H, $COOCH_2C\underline{H}_3$), 1.60 (d, J=5.4 Hz, 3H, $=CHC\underline{H}_3$), 1.8—2.6 (m, 6H), 2.71 and 2.76 (d, J=10.8 Hz, totally 1H), 4.08 and 4.10 (2q, J=6.9 Hz, totally 2H, $OC\underline{H}_2CH_3$), 5.0—5.4 (m, 2H); IR (neat): 3060, 1760, 1726, 1460, 1370, 1276, 1180, 970 cm^{-1}; MS: *m/e* (rel intensity) 224 (M^+, 2), 206 (9), 178 (18), 155 (42), 109 (55), 95 (36), 83 (40), 69 (100). Found: C, 69.34; H, 9.10%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

(2R,3R*)-2-Ethoxycarbonyl-3-(*trans*-3-methyl-1-butenyl)cyclopentanone (**23**)*: Bp 109—112 °C (bath temp)/0.03 Torr; ^1H-NMR (CCl_4): δ 0.99 (d, J=7.2 Hz, 6H, $CH(C\underline{H}_3)_2$), 1.27 (t, J=6.9 Hz, 3H, $OCH_2C\underline{H}_3$), 1.5—1.8 (m, 1H), 1.9—2.5 (m, 5H), 2.75 (d, J=11.1 Hz, 1H), 4.14 (q, J=6.9 Hz, 2H, $OC\underline{H}_2CH_3$), 5.1—5.5 (m, 2H); IR (neat): 1753, 1726, 1630, 1370, 967 cm^{-1}; MS: *m/e* (rel intensity) 224 (M^+, 1), 223 (1), 205 (1), 152 (30), 109 (24), 96 (56), 81 (71), 69 (100), 55 (55). Found: C, 69.67; H, 9.17%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

Synthesis of Ethyl exo-*6-Propyl-2-oxobicyclo[3.1.0]hexane-*1*-carboxylate (**25**)*. Ethyl acetoacetate (0.39 g, 3.0 mmol) dissolved in THF (5 ml) was added to sodium hydride (50% in oil, 0.16 g, 3.3 mmol) suspended in THF (10 ml) at 0 °C. After 15 min butyllithium hexane solution (1.70 M, 1.88 ml, 3.2 mmol) was added and the reaction mixture was stirred for 15 min at 0 °C. *Trans*-1-bromo-2-hexene (0.60 g, 3.7 mmol) dissolved in THF (4 ml) was then added and the reaction mixture was stirred for 50 min. Column chromatography (ethyl acetate–hexane 1:10) gave ethyl 3-oxo-trans-6-decenoate (0.34 g, 53% yield). IR (neat): 1750, 1723, 970 cm^{-1}; ^1H-NMR (CCl_4): δ 0.88 (t, J=6.9 Hz, 3H), 1.2—1.7 (m+t (δ 1.28 J=6.9 Hz, 5H), 1.8—2.6 (m, 6H), 3.28 (s, 2H), 4.16 (q, J=6.9 Hz, 2H), 5.3—5.5 (m, 2H).

The compound (0.34 g, 1.6 mmol) was converted into the diazo compound with TsN_3 (0.31 g, 1.6 mmol) and triethylamine (0.24 ml, 1.75 mmol) in acetonitrile (10 ml) (r.t., 15 h). The diazo compound was then heated in benzene (10 ml) with $Cu(acac)_2$ (49 mg) at reflux for 2.5 h. Concentration and column chromatography gave **25** (0.25 g, 74% yield), bp 124—127 °C (bath temp)/0.07 Torr; ^1H-NMR (CCl_4): δ 0.94 (t, J=6.3 Hz, 3H), 1.1—2.5 (m+t (δ 1.31, J=6.9 Hz), 13H), 4.16 (q, J=6.9 Hz, 2H); IR (neat): 3060, 1738, 1183, 1037 cm^{-1}. Found: C, 68.36; H, 8.69%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

*Reaction of **25** with Dimethylcopperlithium.* Compound **25** (27 mg, 0.13 mmol) was allowed to react at 0 °C for 30 min with dimethylcopperlithium generated from CuI (122 mg, 0.64 mmol), methyllithium (1.41 M ethereal solution, 0.64 ml, 1.28 mmol) and ether (3 ml). Preparative TLC (hexane–ethyl acetate 5:1, R_f 0.4—0.5) gave (2*R**,3*R**)-2-ethoxycarbonyl-3-[(*S**)-1-methylbutyl]cyclopentanone (**26**) (23 mg, 83% yield), bp 98—103 °C (bath temp)/1 Torr; ^{1}H-NMR (CCl_4): δ 0.75—1.8 (m+d (δ 0.91, J=7.2 Hz) +t (δ 1.28, J=6.9 Hz), totally 14H), 1.8—2.6 (m, 5H), 2.75 (d, J=11.1 Hz, 1H), 4.13 (q, J=6.9 Hz, 2H); IR (neat): 1757, 1726, 1184, 1116, 1024 cm^{-1}; MS: *m/e* (rel intensity) 226 (M^+, 3), 208 (3), 181 (6), 180 (6), 155 (19), 109 (44), 83 (100), 55 (96). Found: C, 69.14; H, 9.88%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

(2R,3R*)-2-Ethoxycarbonyl-3-[(R*)-1-methylbutyl]cyclopentanone (**28**).* This compound was prepared similarly starting with *cis*-1-bromo-2-hexene and characterized spectrometrically. ^{1}H-NMR (CCl_4): δ 0.8—2.5 (m+d (δ 0.89, J=6.3 Hz) +t (δ 1.30, J=6.9 Hz), totally 19H), 2.75 (d, J=11.1 Hz, 1H), 4.15 (q, J=6.9 Hz, 2H); IR (neat): 1757, 1727, 1249, 1180, 1113 cm^{-1}; MS: *m/e* (rel intensity) 226 (M^+, 5), 208 (3), 181 (14), 155 (41), 137 (40), 109 (100), 83 (45), 55 (70).

*Hydrogenation of a Mixture of **21** and **22**.* A mixture of **21** and **22** (56 mg, 0.25 mmol) dissolved in ethanol (5 ml) was stirred in the presence of 10% palladium on charcoal (*ca.* 10 mg) under a hydrogen atmosphere for 2 h. Removal of the catalyst by filtration, concentration, and preparative TLC (hexane–ethyl acetate 5:1, R_f 0.5) gave a mixture of dihydro derivatives of **26** and **28** (49 mg, 87% yield). The ^{1}H-NMR (CCl_4) was practically the same as that of the authentic specimen of **26** except for two doublets at δ 0.89 (attributable to that of **28**) and δ 0.91 (identical with the doublet of **26**). MS: *m/e* 226 (M^+).

Synthesis of Ethyl exo-*6-Methyl-2-oxobicyclo[3.1.0]hexane-1-carboxylate (**24**).* This compound was prepared from ethyl *trans*-3-oxo-6-octenoate[24] (0.62 g, 3.4 mmol) *via* diazotization (TsN_3 0.66 g, 3.4 mmol), Et_3N (0.47 ml, 3.4 mmol, CH_3CN (18 ml), r.t., 3 h) and decomposition (Cu(acac)$_2$ (34 mg), toluene (7 ml), reflux, 3 h) in 84% yield. Bp 99—103 °C/0.06 Torr; ^{1}H-NMR (CCl_4): δ 1.22 (d, J=6.3 Hz, 3H), 1.31 (t, J=6.9 Hz, 3H), 1.62 (dq, J=4.0, 6.3 Hz, 1H), 1.8—2.5 (m, 5H), 4.15 (q, J=6.9 Hz, 2H); IR (neat): 1732, 1193, 1034 cm^{-1}; MS: *m/e* (rel intensity) 182 (M^+, 28), 155 (42), 137 (92), 112 (89), 67 (100). Found: C, 65.72; H, 7.87%. Calcd for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74%.

*Reaction of **24** with Trimethylaluminium.* A hexane solution of trimethylaluminium (1.0 M, 0.32 ml, 0.32 mmol) was added to a hexane (4 ml) solution of **24** (23 mg, 0.13 mmol) at 0 °C and the mixture was stirred for 1.5 h. Preparative TLC (hexane–ethyl acetate 2:1, double development, R_f 0.5—0.6) gave ethyl 2-hydroxy-2-*exo*-6-dimethylbicyclo[3.1.0]-hexane-1-carboxylate (18 mg, 72% yield), bp 88—90 °C (bath temp)/1 Torr; ^{1}H-NMR (CCl_4): δ 1.03 (d, J=5.9 Hz, 3H), 1.1—1.9 (m+t (δ 1.28, J=6.9 Hz) +s (δ 1.30), 12H), 2.2 (br s, 1H), 4.15 (q, J=6.9 Hz, 2H); IR (neat): 3500, 1714, 1117, 1050, 1010, 948 cm^{-1}; MS: *m/e* (rel intensity) 198 (M^+, 19), 183 (33), 137 (100), 124 (58). Found: C, 66.41; H, 9.14%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

Synthesis of Ethyl exo-*6-(*trans-*1-Propenyl)-3-oxa-2-oxo-bicyclo-[3.1.0]hexane-1-carboxylate (**29**).* Ethoxycarbonylacetyl chloride (1.82 g, 12.1 mmol) dissolved in ether (15 ml) was added at 0 °C to a mixture of (2*E*,4*E*)-2,4-hexadien-1-ol (0.99 g, 10.1 mmol) and pyridine (0.98 ml, 12.1 mmol) and the reaction mixture was stirred for 1.5 h. Work-up followed by column chromatography (hexane–ethyl acetate 10:1) gave ethyl (2*E*,4*E*)-2,4-hexadienyl propanedioate (1.96 g, 92% yield).

The mixed malonate (1.96 g, 9.3 mmol) was converted (Et_3N (1.42 ml), TsN_3 (1.82 g), CH_3CN (15 ml), r.t., 22 h) into the corresponding diazo compound which decomposed (Cu(acac)$_2$ (0.13 g), toluene (20 ml), reflux, 7 h). Work-up and column chromatography gave **29** (0.57 g, 63% yield), bp 154—157 °C (bath temp)/0.1 Torr; ^{1}H-NMR (CCl_4): δ 1.35 (t, J=6.9 Hz, 3H), 1.77 (dd, J=6.6, 2.1 Hz 3H) 2.21 (dd, J=8.7, 5.1 Hz, 1H), 2.61 (t, J=4.6 Hz, 1H), 4.1—4.4 (m+q (δ 4.23, J=6.9 Hz), 4H), 5.31 (dd, J=9.0, 15.6 Hz, 1H), 5.80 (dq, J=6.6, 15.6 Hz, 1H); IR (neat): 1785, 1723, 1184, 1051, 962 cm^{-1}; MS: *m/e* (rel intensity) 210 (M^+, 5), 164 (34), 137 (86), 93 (100), 79 (95). Found: C, 62.83; H. 6.67%. Calcd for $C_{11}H_{14}O_4$: C, 62.84; H, 6.71%.

(3R,4R*)-3-(Ethoxycarbonyl-4-[(S*)-*trans*-1-methyl-2-butenyl]oxolan-2-one (**30**)*: Bp 150—152 °C (bath temp)/0.09 Torr; ^{1}H-NMR (CCl_4): δ 1.00 (d, J=6.3 Hz, 3H), 1.30 (t, J=6.6 Hz, 3H), 1.63 (d, J=6.0 Hz, 3H), 1.9—2.4 (m, 1H), 2.6—3.1 (m, 1H), 3.13 (d, J=9.3 Hz, 1H), 3.87 (t, J=8.4 Hz, 1H), 4.1—4.6 (m+q (δ 4.18, J=6.6 Hz), 3H), 5.0—5.8 (m, 2H); IR (neat): 1782, 1736, 1146, 1017, 973 cm^{-1}; MS: *m/e* (rel intensity) 226 (M^+, 2), 181 (8), 180 (8), 157 (17), 107 (21), 69 (100). Found: C, 63.41; H, 8.13%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*3-Ethoxycarbonyl-4-(*trans*-3-methyl-1-butenyl)oxolan-2-one (**31**)*: Bp 134—136 °C (bath temp)/0.1 Torr; ^{1}H-NMR (CCl_4): δ 1.01 (d, J=6.6 Hz, 3H), 1.31 (t, J=6.5 Hz, 3H), 2.24 (heptet, J=6.4 Hz, 1H), 3.20 (d, J=9.6 Hz, 1H), 3.2—3.7 (m, 1H), 3.89 (t, J=8.4 Hz, 1H), 4.1—4.5 (m, 1H), 4.23 (q, J=6.5 Hz, 2H), 5.28 (dd, J=15.8, 7.1 Hz, 1H), 5.65 (dd, J=15.8, 6.4 Hz, 1H); IR (neat): 1787, 1738, 1150, 1020, 973 cm^{-1}; MS: *m/e* (rel intensity) 226 (M^+, 5), 182 (22), 139 (56), 107 (89), 95 (100), 81 (77), 79 (79). Found: C, 63.45; H, 7.86%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*Transformation of **21** into **32**.* The β-keto ester **21** (142 mg, 0.63 mmol) dissolved in THF (5 ml) was added at 0 °C to sodium hydride (50% in oil, 33 mg, 0.70 mmol) suspended in THF (2 ml) and the reaction mixture was stirred for 15 min. Diethyl phosphorochloridate (101 μl, 0.70 mmol) was added and the mixture was stirred for 30 min. Work-up and preparative TLC (hexane–ethyl acetate 10:1, R_f 0.6—0.7) gave ethyl (5*R**)-2-methyl-5-[(*S**)-*trans*-1-methyl-2-butenyl]cyclopentene-1-carboxylate (**32**) (96 mg, 69% yield), bp 107—110 °C (bath temp)/0.08 Torr; ^{1}H-NMR (CCl_4): δ 0.81 (d, J=7.8 Hz, 3H), 1.30 (t, J=6.9 Hz, 3H), 1.6—2.0 (m+d (δ 1.65, J=3.9 Hz), 5H), 2.04 (br s, 3H), 2.2—2.8 (m, 3H), 2.8—3.2 (m, 1H), 4.12 (q, J=6.9 Hz, 2H), 5.2—5.4 (m, 2H); IR (neat): 1714, 1648, 1632, 1098, 970 cm^{-1}; MS: *m/e* (rel intensity) 222 (M^+, 6), 179 (14), 177 (15), 153 (70), 107 (74), 69 (100). Found: C, 75.42; H, 10.04%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

*Transformation of **32** into Neonepetalactone (**34**).* Ozone was bubbled into a methanol (1 ml) solution of **32** (40 mg, 0.18 mmol) at −78 °C under monitoring by TLC. When all the starting material was consumed, sodium borohydride (*ca.* 20 mg) was added to the reaction mixture, which was then allowed to react at room temperature. After most of the methanol was removed *in vacuo*, the residue was treated with brine and extracted with dichloromethane. Concentration of the extract followed by preparative TLC (hexane–ethyl acetate 2:1, R_f 0.3) gave an alcohol **33** (8 mg, 21%

yield). ^{1}H-NMR (CCl_4): δ 0.80 (d, J=6.3 Hz, 3H), 1.33 (t, J=6.9 Hz, 3H), 1.5—2.2 (m+br s (δ 2.09), 7H), 2.2—2.6 (m, 2H), 2.9—3.3 (m, 1H), 3.36 (d, J=6.0 Hz, 2H), 4.17 (q, J=6.9 Hz, 2H); IR (neat): 3450, 1705, 1108, 1054 cm^{-1}; MS: *m/e* (rel intensity) 212 (M^+, 2), 194 (4), 166 (30), 107 (44), 79 (100).

The alcohol (8 mg) was mixed with pyridinium *p*-toluenesulfonate (3 mg) in dichloromethane (1 ml) and the mixture heated to reflux for 7 h. Concentration and preparative TLC (hexane–ethyl acetate 2:1, R_f 0.7) gave neonepetalactone (**34**) (2 mg, 35% yield) having spectra consistent with the recorded ones. ^{1}H-NMR (CCl_4): δ 0.96 (d, J=6.9 Hz, 3H), 1.2—1.8 (m, 4H), 2.9 (br s, 3H), 2.3—2.7 (m, 2H), 3.78 (dd, J=12.4, 10.7 Hz, 1H), 4.17 (dd, J=4.7, 10.7 Hz, 1H); IR (CCl_4): 1722, 1645, 1244, 1197, 1105, 1056 cm^{-1}; MS: *m/e* (rel intensity) 166 (M^+, 46), 151 (16), 124 (61), 79 (100).

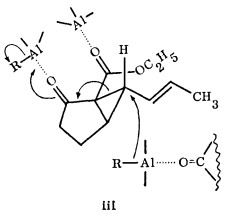
16) The reaction of **7**, **9**, **11a,b**, and **14** with trialkylaluminium can be understood in terms of the tight ion pairs shown in the bracket below. Trialkylaluminum dimer interacts with the leaving acetoxyl group of i to form fairly less nucleophilic complex ii whose R group on aluminium atom is in turn activated to some extent to attack an electron-deficient center. The cyclopropylmethyl cation generated undergoes rearrangement to the homoallyl cation stabilized by a phenyl or vinyl group. Thus, the overall reaction is reminiscent of an S_N1 type reaction[10] which proceeds in the absence of a polarizing solvent.

In contrast, the homoconjugate 1,5-addition to activated vinylcyclopropanes is explained by an S_N2-like mechanism illustrated in iii. Use of more than two mol of trialkylaluminium reagent as well as the presence of two activating carbonyls and a vinyl group in the substrate is essential for the reaction. Trialkylaluminium acid should possibly coordinate both of the carbonyls. The cyclopropane C–C bond is thus loosened and cleaved by the attack of an alkyl anion liberated from the third molecule of trialkylaluminium possibly coordinated on another substrate molecule.



The 1,7-homoconjugate addition may be explained by an electron-transfer mechanism as discussed in the conjugate addition of lithium organocuprate.[25]

Insertion of Carbon Monoxide into Nickel-Alkyl Bonds of Monoalkyl- and Dialkylnickel(II) Complexes, $NiR(Y)L_2$ and NiR_2L_2. Preparation of $Ni(COR)(Y)L_2$ from $NiR(Y)L_2$ and Selective Formation of Ketone, Diketone, and Aldehyde from NiR_2L_2

(Received January 22, 1981)

Reactions of monoalkylnickel(II) complexes, $NiR(Y)L_2$ (R=CH_3, C_2H_5; Y=Cl, suc(succinimido), pht-(phthalimido), OC_6H_4-*p*-CN; L=1/2 bpy (2,2′-bipyridine), PEt_3 (triethylphosphine)), with CO afford monoacylnickel(II) complexes, $Ni(COR)(Y)L_2$, which are characterized by elemental analysis and spectroscopies (IR and NMR). Reactions of the acylnickel(II) complexes with alcohols and aniline give the corresponding esters and amides, respectively. Exposure of $Ni(COR)(Y)L_2$ to dry air leads to oxidation of RCO to a RCOO ligand giving a complex formulated as $Ni(OCOR)(Y)L_2$. Reactions of dimethylnickel(II) complexes, $Ni(CH_3)_2L_2$ (L=1/2 bpy, PEt_3, 1/2 dpe (1,2-bis(diphenylphosphino)ethane, 1/2 dpp (1,3-bis(diphenylphosphino)propane), with carbon monoxide afford acetone and/or 2,3-butanedione in medium to high yields, the acetone/2,3-butanedione ratio varying with the ligand L, reaction temperature, and additives such as maleic anhydride and triphenylphosphine. Generally the acetone/2,3-butanedione ratio decreases with increase in thermal stabilities of $Ni(CH_3)_2L_2$. $Ni(C_2H_5)_2$(bpy) and $Ni(n\text{-}C_3H_7)_2$(bpy) give 3-pentanone and 4-heptanone, respectively, on treating them with CO, whereas $Ni(C_2H_5)_2$(dpe) produces C_2H_5CHO and C_2H_4.

Insertion of carbon monoxide into transition metal-carbon bond constitutes a crucial step in industrially important processes.[1] It is known that transition metal (Ni, Pd, *etc.*) compounds catalyze carbonylation of unsaturated compounds and organic halides in the presence of alcohols and amines to afford esters and amides, respectively,[1,2] and a mechanism involving nucleophilic attack of alcohol or amine to an acyltransition metal intermediate is sometimes proposed for the reactions. However, in contrast to the well explored catalytic reactions, fundamental studies of the carbonylation process dealing with well characterized transition metal alkyl compounds are still limited[3] and chemical reactivities of acyltransition metal complexes prepared by the CO insertion reaction have not been well explored.

We have carried out reactions of isolated monoalkyl- and dialkylnickel(II) complexes, $NiR(Y)L_2$ and NiR_2L_2, with CO to find out that several isolable acylnickel(II) complexes are obtained in the reactions of the monoalkylnickel complexes with CO, whereas the reaction of NiR_2L_2 with CO gives ketone, diketone, and/or aldehyde. The paper deals with the results of the reactions of $NiR(Y)L_2$ and NiR_2L_2 with CO and chemical behavior of $Ni(COR)(Y)L_2$ with compounds such as alcohols and amines. A part of the results given in this paper has been reported in a communication form.[4]

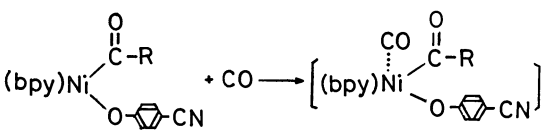
Results and Discussion

I. Preparation of Acylnickel(II) Complexes. The following five acylnickel complexes can be prepared by reactions of the $NiR(Y)L_2$ type complexes[5] with CO. Although several acetylnickel(II) complexes have been prepared by several groups of researchers,[6,7] the propionylnickel complex has only one precedent.[7a] The acylnickel(II) complexes having the Cl, suc, or pht ligand can be prepared under a wide range of reaction conditions, whereas the complexes with the OC_6H_4-*p*-CN ligand can be prepared only by 1:1 reactions of $NiR(OC_6H_4\text{-}p\text{-}CN)$(bpy) with CO at low temperature (−78 °C). Carrying out the reaction of $NiR(OC_6H_4\text{-}p\text{-}CN)$(bpy) at −78 °C or above in the presence of excess CO leads to the formation of $RCOOC_6H_4$-*p*-CN and $Ni(CO)_2$(bpy), suggesting that coordination of CO to **3** and **4** enhances reductive coupling of the RCO and OC_6H_4-*p*-CN groups. In fact, **3** and **4** once isolated have considerably high stabilities in organic solvents even at room temperature, whereas addition of CO to the solution of **3** or **4** leads to rapid formation of $RCOOC_6H_4$-*p*-CN and $Ni(CO)_2$(bpy) almost quantitatively even at −78 °C,

$$NiR(Y)L_2 + CO \longrightarrow Ni(COR)(Y)L_2 \quad (1)$$

	R	Y	L
1	Et	Cl	1/2 bpy
2	Et	suc	1/2 bpy
3	Et	OC_6H_4-*p*-CN	1/2 bpy
4	Me	OC_6H_4-*p*-CN	1/2 bpy
5	Me	pht	PEt_3

Me=CH_3, Et=C_2H_5, suc=succinimido, pht=phthalimido, bpy=2,2′-bipyridine



$$\xrightarrow{+CO} RCOOC_6H_4\text{-}p\text{-}CN + Ni(CO)_2(bpy). \quad (2)$$

Complexes **1**, **2**, and **5** are stable in solutions and do not undergo the reductive coupling to produce RCOY even in the presence of excess CO, presumably due to high stabilities of the Ni–Cl, Ni–suc, and Ni–pht bonds.

The reductive coupling is considered to proceed through a concerted mecahnism involving simultaneous loosening of the Ni–COR and Ni–Y bonds and overlapping of bonding orbitals of the COR and Y groups. When there is a difference in bond energies

a) In KBr. The band with an asterisk is assigned to ν(C=O) of the RCO ligand. b) s=singlet, d=doublet, dd=double doublet, qui=quintet, m=multiplet. Chemical shifts of ^{31}P- and ^{13}C{^{1}H}-NMR spectra are referred to external PEt_3 and internal TMS, respectively (downfield positive). Solvents for ^{1}H-NMR: CD_2Cl_2 for **1** and **2**, acetone-d_6 for **3** and **4**, and C_6D_6 for **5**. The solvent for ^{13}C{^{1}H}-NMR: THF-d_8. c) Measured in THF. d) The CH_3 and CH_2 groups of COEt give rise to a triplet and a quartet, respectively, with the J value of 7—8 Hz.

between the Ni–COR and Ni–Y bonds, however, the ease of reductive elimination may be critically dependent on the ease of activation of the stronger bond, Ni–Y in this case. If the Ni–Y bond is too stable, the complex may be decomposed by other route than reductive elimination.

Reactions of NiMe(OC_6H_5)(bpy),[5] NiEt(OC_6H_5)(bpy),[8] and NiMe(OC_6H_4-*p*-C_6H_5)(PEt_3)$_2$[5] with an equimolar amount of CO at −78 °C gave nickel carbonyl complexes, Ni(CO)$_2L_2$, and the corresponding esters, $CH_3COOC_6H_5$, $C_2H_5COOC_6H_5$, and $CH_3COOC_6H_4$-*p*-C_6H_5, respectively, but the acylnickel(II) complexes were not obtained in these reactions. The Ni–OC_6H_5 and Ni–OC_6H_4-*p*-C_6H_5 bonds in these complexes are expected to have lower stabilities than the Ni–OC_6H_4-*p*-CN bonds in NiR(OC_6H_4-*p*-CN)(bpy) since an OR group generally binds to metals more strongly when the electron-withdrawing ability of the OR group increases. This effect may account for the successful isolation of the *p*-cyanophenoxo(acyl)-nickel complexes **3** and **4** and failure of isolation of the supposed intermediates Ni(acyl)(OC_6H_5)L_2 and Ni(acyl)(OC_6H_4-*p*-C_6H_5)L_2 which may reductively eliminate esters even in the absence of excess CO and at −78 °C.

The isolated acylnickel(II) complexes **1**—**5** have relatively high thermal stabilities but are sensitive to air to give carboxylatonickel(II) complexes (*vide infra*).

IR, NMR, and Visible Spectroscopic Data. Table 1 summarizes spectroscopic data of the complexes. IR spectra of the acylnickel(II) complexes show ν(C=O) bands at about 1650 cm^{-1} which may be compared with the ν(C=O) bands of reported acylnickel(II) complexes observed in the region of 1680 to 1625 cm^{-1}.[6,7]

In the ^{1}H-NMR spectrum, the CH_3 signal of the Et ligands in the ethyl complexes NiEt(Y)L_2[5] is only slightly shifted by the CO insertion into the Ni–Et bond, whereas the CH_2 signals of the Et ligand is considerably shifted to lower field. The acetyl complexes, **4** and **5**, give rise to signals of $COCH_3$ in a region where the signal of $COCH_3$ of acetyltransition metal complexes is usually observed.[1,3,6,7] The complexes are stable in solutions and signals of decarbonylated complexes (NiR(Y)L_2) are not observed at room temperature.

^{13}C{^{1}H}-NMR spectrum of **5** shows a triplet (J=

a) ex=excess, Me=CH_3, Et=C_2H_5, Ph=C_6H_5, Pr=C_3H_7, MAH=maleic anhydride, EMA=ethyl methacrylate. b) The reaction was carried out under an atmosphere of CO. c) Dry air (not pure O_2) was added. The last column shows compounds recovered after treating the produced complex with dry HCl. d) Followed by NMR. e) Formation of the complex was confirmed by IR but the amount not measured.

22 Hz) at 258.31 ppm assignable to the CO carbon of the $COCH_3$ ligand, the triplet pattern indicating that **5** has a *trans* configuration. The *trans* configuration is consistent with an observation of an only one sharp singlet in ^{31}P-NMR spectrum of **5**.

Visible spectra of the bpy-coordinated complexes, **1**—**4**, in THF show Ni→bpy CT-band ($\varepsilon \fallingdotseq 3\times10^3$) at 480—503 nm, the λ_{max} values being shifted to shorter wave length by 20—30 nm from the starting NiR(Y)-(bpy) type complexes.[5] The shift suggests that the electronegativity of Ni is increased by replacing the R ligand with the COR ligand.[9]

Chemical Reactivities of Ni(COR)(Y)L_2. Products of thermolysis and reactions of NiR(Y)L_2 with various compounds are summarized in Table 2.

Thermolysis: Although the acylnickel(II) complexes have fairly high thermal stabilities, they undergo decarbonylation reaction at 100—150 °C in solid to liberate CO and a mixture of C_2H_4 and C_2H_6 from the propionyl complexes or CH_4 from the acetyl complex (Nos. 1—6 in Table 2). Formation of ester in the thermolysis of **3** and **4** indicates occurrence of the reductive coupling of the RCO and OC_6H_4-*p*-CN groups at the elevated temperature. Thermolyses of **1**, **2**, and **5** which have stronger Ni–Y bonds, on the other hand, do not give the reductive coupling product RCOY even at the elevated temperature, but they afford ketone RCOR presumably through a coupling reaction between Ni(COR)(Y)L_2 and NiR(Y)L_n formed in the thermolysis. The thermolysis of Ni(COR)-

a) Reactions are carried out in the presence of excess (more than 3 mol/Ni) CO. b) Decomposition temperature of the complex (see Refs. 9, 12, and 13). c) Evolution of C_2H_4 was confirmed by GLC, but measurement of its amount was not feasible due to high solubility of C_2H_4 in the solvent at the temperature.

$$Ni(COR)(Y)L_2 \rightleftarrows NiR(Y)L_2 + CO \quad (3)$$
$$\downarrow +Ni(COR)(Y)L_2$$
$$RCOR$$

$(Y)L_2$ proceeds at lower temperature in solutions.

Reactions with Alcohols and Aniline: $Ni(COR)(Y)L_2$ reacts with alcohols and aniline to afford esters and amides, respectively,

$$Ni(COR)(Y)L_2 + R'OH \longrightarrow RCOOR', \quad (4)$$
$$Ni(COR)(Y)L_2 + C_6H_5NH_2 \longrightarrow RCOONHC_6H_5. \quad (5)$$

Carrying out the reaction with R'OH in the absence of excess CO gives RCOOR' only in a low yield presumably due to a partial decarbonylation of $Ni(COR)(Y)L_2$ in the presence of R'OH, and the yield increases considerably when the reaction is carried out in the presence of excess CO. In the reaction with aniline,

$$Ni(COR)(Y)L_2 \rightleftarrows NiR(Y)L_2 + CO \quad (6)$$
$$\downarrow +R'OH$$
$$RCOOR'$$

on the contrary, the yield of amide is virtually independent of the presence or absence of excess CO. These reactions which may be regarded as nucleophilic attack of alcohol or amine on the acyl ligand are relevant to the transition metal-catalyzed synthesis of esters or amides from organic halide, CO, and alcohols

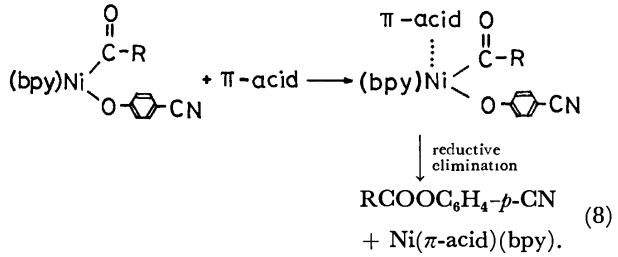
or amines.[1,2]

Oxidation of the RCO Ligand: $Ni(COR)(Y)L_2$ absorbs O_2 (about 0.5 mol/Ni) in dry air. Acidolysis of the paramagnetic product by dry HCl gives RCOOH in 56—100% yield, indicating that oxidation of the acyl to a carboxylato ligand takes place on exposure of $Ni(COR)(Y)L_2$ to dry air,

$$Ni(COR)(Y)L_2 + O_2 \longrightarrow [Ni(OCOR)(Y)L_n] \xrightarrow{+HCl} RCOOH \quad (7)$$

Isolation of $Ni(OCOR)(Y)L_n$ was not feasible due to the lack of suitable solvents for recrystallization, but IR spectrum of a complex formed by the reaction of **2** with dry air is identical to that of a product formed by an 1:1 reaction of NiEt(suc)(bpy) with C_2H_5-COOH, supporting the occurrence of the reaction expressed by Eq. 7.

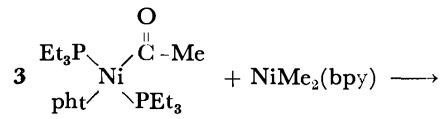
π-Acid Induced Reductive Elimination of Ester from 3 and 4: As described above, reductive elimination of $RCOOC_6H_4$-*p*-CN from $Ni(COR)(OC_6H_4$-*p*-CN)-(bpy) is enhanced by addition of CO, which is regarded as a typical π-acid. Addition of other π-acids such as maleic anhydride (MAH) and ethyl methacrylate (EMA) also enhances the reductive elimination (No. 24—26). The Ni–COR and/or Ni–OC_6H_4-*p*-CN bond seems to be activated by coordination of the π-acid to cause the reductive elimination,



$$RCOOC_6H_4\text{-}p\text{-}CN + Ni(\pi\text{-acid})(bpy). \quad (8)$$

Similar enhancement of reductive elimination of R–R from $NiR_2(bpy)$ by coordination of π-acid to Ni has been reported.[9] A stronger π-acid, MAH, affords the ester in a higher yield than a weaker π-acid, EMA. The reaction (8) can be regarded as a reverse process of oxidative addition of ester to a Ni(0) complex.[10] Addition of MAH does not induce such a reductive elimination of RCOY from complexes **1**, **2**, and **5** having stronger Ni–Y bonds.

Reactions with Ni(0)- and Dialkylnickel(II) Complexes: Addition of $Ni(PPh_3)_4$ (PPh_3=triphenylphosphine) to a solution of **4** leads to formation of a mixture of NiMe-$(OC_6H_4$-*p*-CN)(bpy) and $Ni(CO)(PPh_3)_3$. The reaction is considered to proceed through partial decarbonylation of **4** and trapping of CO by $Ni(PPh_3)_4$. A similar decarbonylation of an acetylnickel(II) complex enhanced by Ni(0) complexes has been observed.[6a] The acylnickel(II) complexes are also decarbonylated on treatment with dialkylnickel(II) complexes. For example, a reaction of **5** with $NiMe_2(bpy)$ **6** (1:1) at 40 °C (No. 28) gives acetone (33%, determined by ^{1}H-NMR), the decarbonylated product NiMe(pht)-$(PEt_3)_2$ (100%), $Ni(CO)_2(bpy)$,[11] and intact **6** (67%), suggesting CO partly liberated from **5** is trapped by **6** to release acetone and $Ni(CO)_2(bpy)$ according to the following stoichiometry,



$$MeCOMe + 3NiMe(pht)(PEt_3)_2 + Ni(CO)_2(bpy). \quad (9)$$

When $NiEt_2(bpy)$ is added to a solution of **5**, a cross coupling reaction to give MeCOEt takes place (No. 29) besides the simple CO trapping reaction by $NiEt_2$-(bpy) to give EtCOEt. The results suggest the occurrence of intermolecular alkyl or acyl transfer reactions.

II. Reactions of NiR_2L_2 with CO. In contrast to the reactions of monoalkylnickel(II) complexes with CO, reactions of dialkylnickel(II) NiR_2L_2 with CO did not afford any isolable acylnickel complexes, but they produced carbonylated compounds of the alkyl ligands, ketone, diketone, and/or aldehyde:

$$NiR_2L_2 + CO \longrightarrow RCOR, RCOCOR, \text{and/or } RCHO. \quad (10)$$

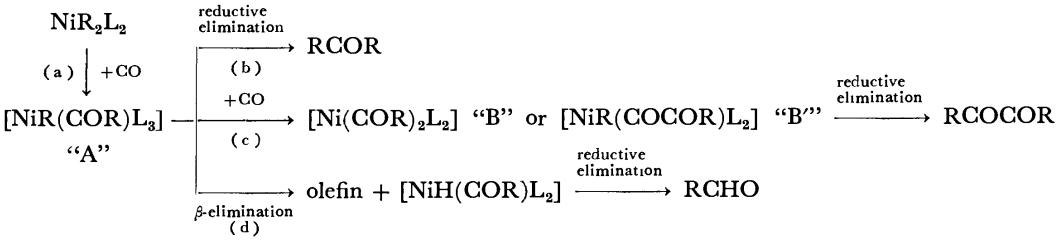
6 $NiMe_2(bpy)$
7 $NiMe_2(dpe)$
8 $NiMe_2(dpp)$ dpe=1,2-bis(diphenylphosphino)-ethane
9 $NiMe_2(PEt_3)_2$
10 $NiEt_2(bpy)$ dpp=1,3-bis(diphenylphosphino)-propane
11 $Ni(n\text{-}C_3H_7)_2(bpy)$
12 $NiEt_2(dpe)$

Table 3 summarizes results of the reactions. It is seen in Table 3 that the product of the reaction (10) varies with changes in the R and L ligands and reaction conditions. Following is details of effects of the ligands and reaction conditions on the product.

Effects of R and L: Reactions of dimethylnickel complexes **6**—**9** with CO give 2,3-butanedione and acetone and the ratio of the two products varies with the nature of L and the reaction temperature. At −78 °C the fraction of the diketone increases in an increasing order of a thermal stability of $NiMe_2L_2$, **9**<**8**<**7**<**6**.[9,12,13]

Among the complexes of a type $NiR_2(bpy)$ examined, only the methyl complex which has the higher thermal stability than the ethyl and propyl homologs gives diketone at −78 °C, and less stable complexes **10** and **11** afford ketones exclusively at −78 °C. These results suggest that the ketone/diketone ratio at −78 °C may be related to the thermal stability of NiR_2L_2 (or the strength of the Ni–R bond). The reaction of **12** with CO gives a different type of product, propanal, with evolution of ethylene.

Effect of Temperature: On raising the reaction temperature, the fraction of acetone formed in the reaction of **6** with CO increases and at 13 °C or above acetone becomes a sole liquid product. Similar increases in the proportion of acetone on raising the reaction temperature to room temperature are observed in the reactions of diphosphine-containing complexes **7** and **8** with CO. Complexes **9**, **10**, and **11** which give ketones as the sole liquid products at −78



Scheme 1.

°C afford the same products at room temperature.

Effect of Additive: Addition of maleic anhydride increases the fraction of acetone formed in the reactions of **6** and **7** with CO at −78 °C presumably due to the activating effect of the alkyl and/or acyl ligands by coordination of the π-acid. Addition of bpy and PEt_3 in the reactions of the dimethyl complexes **6** and **9** with CO, respectively, seems to affect neither the product nor the rate of the reaction.

Other Factors: Table 3 shows results of the reactions carried out in the presence of excess CO (more than 3 mol/Ni) which left no intact NiR_2L_2. When the reaction is carried out in the presence of a less amount of CO, however, the yield of the product decreases. For example, reactions of **9** in the presence of 1.0 and 2.0 mol of CO per **9** at −78 °C afford acetone in 21 and 68% yields, respectively. Since $Ni(CO)_2(PEt_3)_2$ is isolated from the reaction mixture, the stoichiometry of the reaction of **9** with CO can be written as follows,

$$NiMe_2(PEt_3)_2 + 3CO \longrightarrow MeCOMe + Ni(CO)_2(PEt_3)_2 \quad (11)$$

and the yields obtained in the presence of 1.0 and 2.0 mol of CO per **9** roughly agree with the stoichiometry. $Ni(CO)_2(dpe)$[14] (isolated yield=76%), $Ni(CO)_2(dpp)$[14] (81%), and $Ni(CO)_2(bpy)$[11] (50%) are obtained in the reaction Nos. 3, 5, and 20 (see Table 3), respectively.

Although detailed examination has not been made concerning rates of the reactions, among the phosphine-coordinated complexes the monodentate PEt_3-coordinated complex **9** seems to react with CO at a faster reaction rate than the bidentate phosphine coordinated complexes **7** and **8**.

Among the complexes of the type $NiR_2(bpy)$, the dimethyl complex **6** reacts with CO most slowly. At −78 °C the reaction of **6** with CO requires more than 10 h to be completed, whereas the reactions of **10** and **11** with CO are completed in few minutes even at the temperature. A competitive reaction between the dimethyl and diethyl complexes, **6** and **10**, (1:1) in the presence of 1 mol of CO per Ni (**6**+**10**) at room temperature produces 3-pentanone (30%/**10**) exclusively and all of **6** remains intact, indicating **10** reacts with CO much faster than **6**. The difference in the rate may be related to the difference in relative strength of the Ni–C bond of the complex and/or to the difference in relative affinity of the complex to CO. It is known that the Ni–CH_3 bond in **6** is stronger than the Ni–C_2H_5 and Ni–C_3H_7 bonds in **10** and **11** and that **6** has a weaker affinity toward π-acids than **10** and **11** due to its weaker Lewis basicity.[9]

Reaction Scheme and Factors Controlling the Distribution of Products. These results of the reactions of NiR_2L_2 with CO can be reasonably explained by a scheme involving formation of a monoalkyl(acyl)nickel(II) complex "A" as the key reaction intermediate (Scheme 1). In the reaction scheme CO inserts into one of the Ni–R bonds of NiR_2L_2 (step (a)) to form an intermediate monoalkyl(acyl)nickel(II) complex "A". The intermediate "A" undergoes reductive elimination to give ketone (step (b)). Further CO-insertion reaction may give a diacylnickel(II) complex "B" or alkyl(pyruvoyl)nickel(II) complex "B'" from which diketone is produced (step (c)). When the ethyl group is employed, β-elimination reaction from "A" may produce olefin (R(−H)) and aldehyde. Formation of acetone from isolated platinum (IV) complexes having both methyl and acetyl groups have been reported.[15] In the case of the reaction of **6** with CO, the intermediacy of "A" is supported by production of 2-butanone on carrying out the reaction in the presence of C_2H_5Br. Attempts to isolate NiMe(COMe)(bpy), however, have not been successful presumably due to instability of the complex.

As described above, $CH_3COC_2H_5$ is produced in the reaction of **6** with CO at −78 °C in the presence of C_2H_5Br, whereas no $CH_3COCOC_2H_5$ was detected in the product. This suggests that 2,3-butanedione is produced through the intermediate diacyl species "B" rather than "B'". However, at present it is not possible to exclude the possibility for the intermediacy of the doubly CO-inserted species, since a transition metal complex having a CH_3COCO ligand is known[16] and evidence for the double CO-insertion has been obtained for carbonylation of a dimethylpalladium complex.[17]

According to Scheme 1, the distribution of the products is determined by relative rates of the elemental reactions (b)—(d), and the results described above indicate that the relative rates depend on the R and L ligands, reaction temperature, and additives in following ways.

(i) Effect of R and L: The relative rate of the reaction (b) at −78 °C to that of the reaction (c) increases when the thermal stability of the starting dialkylnickel(II) complex NiR_2L_2 decreases. If the strength of either or both of the Ni–R and Ni–COR bonds in "A" is controlled by the nature of the R and L ligands in a similar way to that of the Ni–R bonds in NiR_2L_2, these results indicate that the reductive elimination of RCOR from "A" takes place prior

to the further attack of CO at "A" (step (c) in Scheme 1) when the Ni–R and/or Ni–COR bond is weak. On the contrary, when the bonds are stronger, the intermediate "A" can wait for the further attack of CO to form "B" or "B‴" and diketone is formed in this case.

(ii) Effect of Temperature: When the reaction temperature is raised, the Ni–R and Ni–COR bonds in "A" will be activated to cause the reductive elimination and the proportion of ketone will thus increase.

(iii) Effect of Additive: The effect of MAH to increase the proportion of ketone may be related to the MAH-induced reductive elimination of $RCOOC_6H_4$-*p*-CN from **3** and **4**. Namely, coordination of MAH to "A" may lead to activation of the Ni–R and Ni–COR bonds as in the case of **3** and **4**, and therefore the fraction of ketone will increase on the addition of MAH. An alternative explanation of the effect of MAH is that MAH coordinates to "A" to block the coordination site to prevent the further attack of CO at "A". We consider that the former explanation is more reasonable since the effect of MAH on the reductive elimination of esters and R–R from the acyl(phenoxo)-type complexes and $NiR_2(bpy)$ (R=Me, Et),[9] respectively, is so pronounced.

*(iv) Difference between **10** and **12***: The difference in the products of the reaction of **10** with CO and that of **12** with CO may be related to the difference of thermolysis between **10** and **12**; the former gives mainly the coupling product C_4H_{10} on the thermolysis,[9] whereas the latter exclusively affords the disproportionation products, C_2H_6 and C_2H_4,[12] indicating that the β-elimination in **12** proceeds more easily than that in **10**. If coordination of dpe to Ni having ethyl ligand(s) makes the abstraction of the β-hydrogen in the Et ligand by Ni easier, the formation of C_2H_5CHO and C_2H_4 through the path (d) in Scheme 1 can be reasonably explained. Lower yield of C_2H_5CHO than that of C_2H_4 seems to be due to partial polymerization of C_2H_5CHO catalyzed by Ni complexes.[18]

Conclusion and Scope

Carbon monoxide inserts into Ni–R bonds of monoalkyl- and dialkylnickel(II) complexes, $NiR(Y)L_2$ and NiR_2L_2, to give complexes of a type $Ni(COR)(X)L_n$ (X=R, Cl, phenoxo, imido). When the X ligand has a moderate or strong bonding ability to Ni as in Cl, OC_6H_4-*p*-CN, and imido ligands, the acylnickel(II) complex can be isolated. On the contrary, when X has only a weak bonding ability as R, OC_6H_5, and OC_6H_4-*p*-C_6H_5, the reductive elimination of RCOX takes place under the reaction conditions and the acylnickel(II) complex could not be isolated. In the case of $NiR(COR)L_n$, other types of reactions, namely, further insertion of CO to form "B" (or "B‴") and β-elimination of C_2H_5CHO and C_2H_4, can also take place depending on nature of the R and L ligands and the reaction conditions. The acylnickel(II) complexes having a moderately strong bonding ligand, OC_6H_4-*p*-CN, are activated by coordination of π-acids (CO, MAH, EMA) to cause the reductive elimination of $RCOOC_6H_4$-*p*-CN. Such a reductive elimination, however, is not induced on adding the π-acids to complexes having stronger Ni–X bonds such as Ni–Cl and Ni–imido. The isolated acylnickel(II) complexes afford esters, amides, and carboxylato complexes in the reactions with alcohols, aniline, and O_2, respectively.

These results obtained in this work may be useful in planning carbonylation of organic compounds by CO. The formation of ketone from NiR_2L_2 has been actually applied to nickel-catalyzed synthesis of ketone from RMgX, RX, and CO.[4a]

Experimental

General. Manipulation of nickel complexes was carried out under deoxygenated nitrogen or argon or in a vacuum. IR spectra were taken on a Hitachi Model 295 spectrometer using KBr discs under nitrogen. NMR spectra were taken by using a Japan Electron Optics Lab. JNM-PS-100 spectrometer. Microanalysis of C, H, and N was performed by T. Saito in our laboratory with a Yanagimoto CHN Autocorder Type MT-2. High sensitivities of the nickel complexes to air should be taken into account concerning the microanalysis. Nickel contents of the complexes were measured by volumetric titration after acidolysis of the complexes. Gases evolved were analyzed with a Hitachi RMU 5B mass-spectrometer and a Shimadzu GC-5B gas chromatograph, their volumes being measured with a Toepler pump. Liquid products were analyzed with a Shimadzu GC-5B gas chromatograph.

Material. The monoalkyl-[5] and dialkylnickel(II)[9,12,13] complexes were prepared as described in literature. Solvents were dried over Na wires or CaH_2, distilled under N_2, and stored under N_2. CO gas was dried by bubbling through concd H_2SO_4.

*Preparation of the Acylnickel Complexes. Propionyl(chloro)(2,2′-bipyridine)nickel(II) **1***: A reaction vessel (60 cm³) containing a THF (10 cm³) solution of NiEt(Cl)(bpy) (420 mg, 1.5 mmol) was evacuated and then CO (50 cm³, 1 atm) was introduced into the vessel. Stirring the solution for 10 min at room temperature gave a reddish brown solution, into which 40 cm³ of hexane was added to obtain 440 mg of a reddish brown solid. The reddish brown solid was recrystallized from THF–hexane to yield brown crystals of **1** (220 mg, 48%); mp 130 °C (dec). Found: C, 51.2; H, 4.2; N, 9.1; Cl, 11.2%. Calcd for $C_{13}H_{13}ClN_2NiO$: C, 50.8; N, 4.3; N, 9.1; Cl, 11.5%.

*Propionyl(succinimido)(2,2′-bipyridine)nickel(II) **2***: A reaction vessel (60 cm³) containing a CH_2Cl_2 (10 cm³) solution of NiEt(suc)(bpy) (630 mg, 1.8 mmol) was evacuated and CO (50 cm³, 1 atm) was introduced into the vessel. Stirring the solution for 30 min at room temperature gave a red solution and a small amount of a precipitate. The solution was separated by filtration and hexane was added to the filtrate to obtain a dark brown precipitate, which was recrystallized from THF–hexane to yield a reddish brown microcrystals of **2** (450 mg, 73%); mp 150 °C (dec). Found: C, 54.1; H, 4.9; N, 10.0%. Calcd for $C_{17}H_{17}N_3NiO_3$: C, 55.2; H, 4.6; N, 11.2%.

*Propionyl(p-cyanophenoxo)(2,2′-bipyridine)nickel(II) **3***: A reaction vessel containing a THF (7 cm³) solution of NiEt(OC_6H_4-*p*-CN)(bpy) (420 mg, 1.2 mmol) was connected to a vacuum line and the vessel was evacuated. After cooling the solution to −78 °C, CO gas (1.2 mmol) whose amount was measured by a manometer was introduced and the solu-

tion was stirred for 3 h at −78 °C to obtain a reddish purple homogeneous solution. An excess amount of hexane was added to the solution to yield 430 mg (94%) of reddish purple crystals of **3**. A sample for the microanalysis was obtained by recrystallization from acetone–hexane; mp 120 °C (dec). Found: C, 60.8; H, 3.9; N, 11.1; Ni, 14.7%. Calcd for $C_{20}H_{17}N_3NiO_2$: C, 61.6; H, 4.4; N, 10.8; Ni, 15.1.

Acetyl(p-cyanophenoxo)(2,2'-bipyridine)nickel(II) **4**: A vessel containing a THF (20 cm³) solution of NiMe(OC_6H_4-*p*-CN)(bpy) (1.0 g, 2.8 mmol) was connected to a vacuum line and the vessel was evacuated. After cooling the solution to −78 °C, a measured amount of CO (2.8 mmol) was introduced into the vessel and the solution was stirred at −78 °C for 5 h. Hexane (excess) was added to the solution to obtain a brown powder, which was recrystallized from acetone to yield reddish brown crystals of **4** (380 mg, 36%); mp 140 °C (dec). Found: C, 59.5; H, 4.1; N, 10.5; Ni, 15.6. Calcd for $C_{19}H_{15}N_3NiO_3$: C, 60.7; H, 4.0; N, 11.2; Ni, 15.6%.

Acetyl(phthalimido)bis(triethylphosphine)nickel(II) **5**: A vessel containing an ethereal solution (20 cm³) of NiMe(pht)(PEt_3)$_2$ was evacuated and then CO (100 cm³, 1 atm) was introduced into the vessel. Stirring the solution for 10 min at room temperature gave a yellow solution and a small amount of a precipitate. The yellow solution was separated by filtration and cooling the solution to −78 °C gave yellow crystals of **5** (470 mg, 83%); mp 100 °C (dec). Found: C, 54.0; H, 7.8; N, 2.9; Ni, 12.4%. Calcd for $C_{22}H_{37}NNiO_3P_2$: C, 54.6; H, 7.7; N, 2.9; Ni, 12.1%.

Reactions of NiR_2L_2 with CO (cf. Table 3). *No. 1*: Carbon monoxide (3.2 mmol) was introduced at −78 °C into an evacuated vessel containing 130 mg (0.53 mmol) of **6** in 6.5 ml of diethyl ether. The dimethylnickel(II) complex was partly soluble in diethyl ether at −78 °C and the solution was colored deep green (color of **6**) at the initial stage of the reaction. On stirring the mixture at −78 °C, the color of the solution gradually turned to red. After 1 d, a homogeneous red solution was obtained and GLC analysis of the solution indicated formation of 0.48 mmol of 2,3-butanedione. Drying up the solution in vacuum at −78 °C gave almost pure bpy, whereas drying up the solution after warming the solution to room temperature gave a mixture of bpy and Ni(CO)$_2$(bpy),[11] indicating that there exists an equilibrium, Ni(CO)$_4$+bpy$\rightleftharpoons$Ni(CO)$_2$(bpy)+2CO, and the equilibrium lies to the left at −78 °C.

Other Reactions of NiR_2L_2 with CO: Other reactions listed in Table 3, except for reactions in the presence of MAH, were carried out in similar ways to the reaction of **6** at −78 °C. Reactions of NiR_2(bpy) with CO at room temperature gave Ni(CO)$_2$(bpy) in high yields. Nickel carbonyl complexes, Ni(CO)$_2$(bpy),[11] Ni(CO)$_2$(PEt_3)$_2$,[14] Ni(CO)$_2$(dpe),[14] and Ni(CO)$_2$(dpp)[14] were identified by their IR spectra. Reactions in the presence of MAH require the following special attention to prevent NiR_2L_2 to decompose before the reaction with CO since MAH strongly activates the Ni–R bond of NiR_2L_2. A solution of NiR_2L_2 in THF was solidified by cooling to −196 °C and then MAH was added to the reaction system. CO was added immediately after the solution melted on raising temperature.

(Received February 2, 1981)

The title compounds were synthesized from L-arabinose and D-glucose as intermediates to a few naturally occuring branched-chain sugars. Oxidation conditions of precursors to the corresponding 4-uloses were examined.

In previous papers of this series, stereoselectivities in nucleophilic reactions of hexopyranosid-2-uloses[2] and 3-uloses[3] have been extensively examined, from the views of non-bonded interactions, electrostatic interaction in the transition state,[4] and kinetic or thermodynamic control in reversible reactions.[5] In order to examine the stereoselectivities in similar reactions of 4-uloses and to utilize the results for the stereoselective synthesis of 2,3-*O*-methylene-4-*C*-substituted aldono-1,5-lactones found in everninomicins,[6] flambamycin,[7] and avilamycins,[8] benzyl 2,3-*O*-benzyl-(**1**) and 2,3-*O*-methylene-β-L-*threo*-pentopyranosid-4-uloses (**2**), benzyl 2,3-*O*-benzyl-6-deoxy-(**3**) and 6-deoxy-2,3-*O*-methylene-α-D-*xylo*-hexopyranosid-4-uloses (**4**), together with benzyl 2,3-di-*O*-benzyl-6-*O*-trityl-α-D-*xylo*-hexopyranosid-4-ulose (**5**) and methyl 6-deoxy-2,3-*O*-methylene-α-D-*ribo*-hexopyranosid-4-ulose (**6**), were synthesized in this paper.

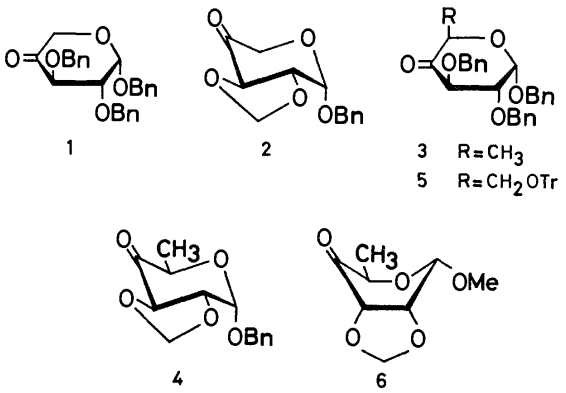

Fig. 1.

Results and Discussion

Treatment of benzyl 2,3-di-*O*-benzoyl-α-L-arabinopyranoside[9] in acetic acid with dimethyl sulfoxide and acetic anhydride[10] at room temperature for 2 days gave the corresponding 4-*O*-methylthiomethyl derivative (**7**) in 88% yield, which was converted into de-*O*-benzoylated derivative (**8**) by treatment with sodium methoxide in 57% yield. Treatment of **8** in *N*,*N*-dimethylformamide with sodium hydride and benzyl chloride or dichloromethane[11] gave the corresponding 2,3-di-*O*-benzyl (**9**) and 2,3-*O*-methylene derivatives (**10**) in 81% and 46% yields, respectively. In the case of **10**, a small amount of dimers were formed, however, they could not be characterized. Treatment of **9** and **10** in aqueous acetonitrile with mercury(II) chloride and calcium carbonate gave the corresponding de-*O*-methylthiomethyl derivatives (**11** and **12**) in quantitative and 62% yields, respectively.

On the other hand, treatment of benzyl 4,6-*O*-benzylidene-α-D-glucopyranoside[12] in *N*,*N*-dimethylformamide with sodium hydride and dichloromethane gave the corresponding 2,3-*O*-methylene derivative (**13**)[11] and two dimers (**14** and **15**) in 43%, 6.2%, 7.2% yields, respectively. The dimers showed no absorption of a hydroxyl group in IR spectra, and the parent ion peak of *m/e* 741 in MS spectra. Configurations of 2,3′:2′,3-bis-*O*-methylenedi(benzyl 4,6-*O*-benzylidene-α-D-glucopyranoside) (**14**) and the corresponding 2,2′:3,3′-bis-*O*-methylene isomer (**15**) were assigned from the *O*-methylene proton signals in NMR spectra. Compound **14** showed AB quartet indicating two magnetically nonequivalent protons in equivalent two methylene groups, whereas **15** two singlets indicating each two equivalent protons in non-equivalent two methylene groups. Analogous two dimers were also obtained by the reaction of the corresponding methyl glucoside with dibromomethane in each 22% yield, together with 2,3-*O*-methylene derivative (**16**),[11,13] but their structures were not assigned. While, similar reaction of methyl 4,6-*O*-benzylidene-α-D-allopyranoside[14] gave the corresponding 2,3-*O*-methylene derivative (**17**) in 65% yield.

For the deoxygenation of *C*-6 position, **13** was treated with 80% acetic acid at room temperature for one day to give de-*O*-benzylidenated product (**18**) in 64% yield. Selective tosylation of **18** in pyridine at 0 °C with 1.4 equivalent *p*-toluenesulfonyl chloride gave 6-*O*-tosyl (**19**) and 4,6-di-*O*-tosyl (**20**) derivatives in 80% and 8% yields, respectively. Reduction of **19** in *N*,*N*-dimethylformamide with lithium aluminium hydride gave the corresponding 6-deoxy derivative (**21**) in 81% yield. For the preparation of **21**, oxidative ring-opening of the 4,6-*O*-benzylidene group of **13** with *N*-bromosuccinimide was unsuccessful, probably due to the reaction of the strained 2,3-*O*-methylene group. By the same route, **16** and **17** were also converted into methyl 6-deoxy-2,3-*O*-methylene-α-D-glucopyranoside (**22**) and -allopyranoside (**23**), respectively. While, monotosylation of benzyl 2,3-di-*O*-ben-

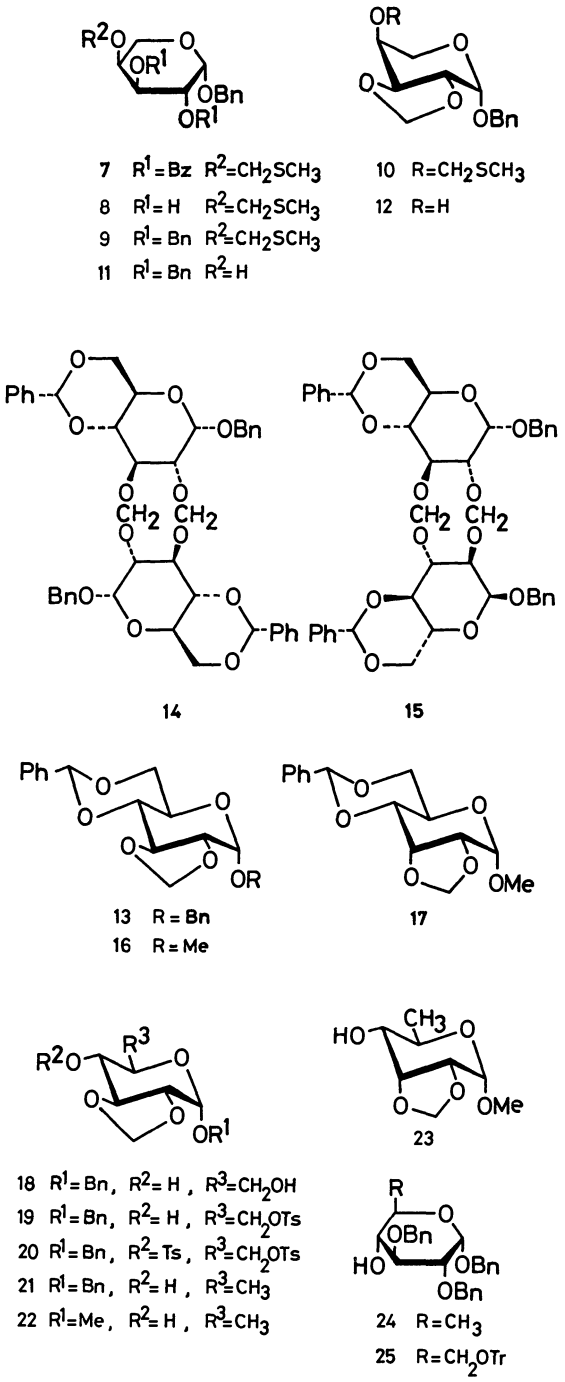

Fig. 2.

zyl-α-D-glucopyranoside[10] and successive reduction of the product with lithium aluminium hydride gave benzyl 2,3-di-*O*-benzyl-6-deoxy-α-D-glucopyranoside (**24**) in 38% overall yield.

Oxidation of **11**, **12**, **21**—**24**, and benzyl 2,3-di-*O*-benzyl-6-*O*-trityl-α-D-glucopyranoside (**25**)[12] into the corresponding 4-uloses was examined by a few methods, and the results were summarized in Table 1. The chromium trioxide-pyridine oxidation of 2,3-di-*O*-benzyl derivatives, (**11**, **24**, and **25**) was unsuccessful, probably due to the oxidation of the benzyl groups as was reported by Stevens and Czernecki[15] in the case of oxidation of methyl 6-deoxy-2,3-di-*O*-benzyl-α-D-galactopyranoside with ruthenium tetraoxide. A similar oxidation of **22** was accompanied by the epimerisation at *C*-3 position to give **6** in 45% yield. The epimerization of equatorial C–O bond to axial configuration implies that the 2,3-*O*-methylene ring from *trans*-diequatorial hydroxyl groups contains a fairly large steric strain. Configuration of 6 obtained above was confirmed by the comparison with that obtained by the oxidation of **23** with chromium trioxide in 63% yield. Oxidation of **11** with dimethyl sulfoxide (DMSO)–acetic anhydride gave the corresponding 4-ulose in 60% yield, together with a small amount of 4-*O*-methylthiomethyl derivative (**9**), however, similar oxidation of 2,3-*O*-methylene derivatives (**12** and **22**) gave only a small amount of 4-*O*-methylthiomethyl derivative. Although DMSO–acetic anhydride oxidation of the corresponding methyl glucoside of **24** was reported to be unsuccessful,[15] DMSO–trifluoroacetic anhydride oxidation[16] gave commonly good results. Thus 4-uloses, **1**—**6**, could be obtained from **11**, **12**, **24**, **21**, **25**, and **23**, respectively.

Table 1. Preparation of 4-uloses

Substrates	Oxidation methods[a]	Products (%)	
		4-Uloses	4-*O*-Methylthiomethyl derivatives
11	B	**1** (60)	**9** (7.8)
	C	**1** (82)	
24	C	**3** (72)	
25	C	**5** (98)	
12	B		**10** (10)
	C	**2** (quant)	
21	C	**4** (quant)	
22	B		(10)
	A	**6** (45)	
23	A	**6** (63)	

a) Method A, B, and C indicate the oxidation with CrO_3–pyridine, DMSO–Ac_2O, and DMSO–$(CF_3CO)_2O$, respectively.

^{1}H NMR parameters of 4-uloses thus obtained were shown in Table 2. The results indicate that **1**—**5** exist in *C*1 conformation, and **6** in ^{1,4}B. Because **23** takes *C*1 conformation (see Experimental), the conformational difference between **6** and **23** will be attributed to the larger bond angle of sp^2-carbon than that of sp^3-carbon at *C*-4, and the trend of coplanarity of 2,3-*O*-methylene ring.

Experimental

General Methods. Melting points were determined with a Mel-Temp melting point apparatus and not corrected. Optical rotations were measured with Carl Zeiss LEP-Al or JASCO DIP-4 polarimeter, using a 0.5 dm tube. IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. NMR spectra were recorded with a JEOL JNM PS-100 spectrometer in chloroform-*d* containing tetramethylsilane as the internal reference. Chemical shifts and coupling constants were recorded in δ(ppm) and Hz units, and IR frequencies in cm^{-1}. Evaporations were conducted under diminished pressure.

Benzyl 2,3-Di-O-benzoyl-4-O-methylthiomethyl-β-L-arabinopyranoside (7). A solution of benzyl 2,3-di-*O*-benzoyl-β-L-

a) $J_{1,2}$ and $J_{2,3}$ were observed by the use of a shift reagent, Pr(FOD)$_3$.

arabinopyranoside[9] (50 g, 0.109 mol) in dimethyl sulfoxide (DMSO, 400 ml), acetic anhydride (240 ml) and acetic acid (80 ml) was kept at room temperature for 2 d, then poured into saturated sodium hydrogencarbonate, and the resulting solution was extracted with ether. The extract was evaporated and the residue was purified on a silica gel column to give **7** (50 g, 88%) as a syrup. $[\alpha]_D$ +176.8° (c 1.24, $CHCl_3$), NMR: 8.2—7.94 and 7.60—7.10 (Ph; m), 5.82 (H-3; q, $J_{2,3}$=10.8, $J_{3,4}$=2.0), 5.71 H-2; q, $J_{1,2}$=3.0), 5.31 (H-1; d), 4.74 (SCH_2O; s), 4.68 ($PhCH_2$; ABq, J=13.0), 4.46 (H-4; m, $J_{4,5e}$=1.8, $J_{4,5a}$=2.0), 4.00 (H-5e; q, $J_{5e,5a}$=13.2), 3.84 (H-5e; q), 1.98 (CH_3S, s). Found: C, 65.59; H, 5.66; S, 6.98%. Calcd for $C_{28}H_{28}O_7S$: C, 66.12; H, 5.55; S, 6.31%.

Benzyl 4-O-Methylthiomethyl-β-L-arabinopyranoside (8). A solution of **7** (600 mg, 1.18 mmol) in methanol (8 ml) containing sodium (60 mg, 2.6 mmol) was kept at room temperature for 6 h, evaporated, and the residue was purified on a silica gel column (benzene–ethyl acetate–ethanol 6:1:1) to give pure crystals in 57% (200 mg) yield. Mp 72—73 °C ($CHCl_3$–hexane), $[\alpha]_D$ +193.9° (c 0.72, $CHCl_3$), NMR: 7.34 (Ph; s), 5.00 (H-1; d, $J_{1,2}$=3.0), 4.73 and 4.85 (SCH_2O, ABq, J=11.3), 4.52 and 4.75 ($PhCH_2$; ABq, J=12.0), 4.02 (H-4; m, $J_{3,4}$=2.0), 3.84—3.70 (H-2, H-3, H-5e, and H-5a; m), 2.18 (CH_3S, s). Found: C, 55.53; H, 6.69; S, 10.73%. Calcd for $C_{14}H_{20}O_5S$: C, 55.98; H, 6.71; S, 10.68%.

Benzyl 2,3-Di-O-benzyl-4-O-methylthiomethyl-β-L-arabinopyranoside (9). To a solution of **8** (1 g, 3.3 mmol) in *N*,*N*-dimethylformamide (DMF, 10 ml) was added with stirring sodium hydride (0.35 g, 14.5 mmol) washed with hexane and then benzyl chloride (1.01 g, 7.9 mmol). After stirring one day at room temperature, the reaction mixture was poured into water, and the resulting solution was extracted with chloroform. The extract was evaporated, and the residue was purified on a silica gel column (hexane–ethyl acetate 10:1) to give a syrup (1.3 g) in 81.3% yield. $[\alpha]_D$ +91.4° (c 1.1, $CHCl_3$), NMR: 7.6—7.2 (Ph; m), 4.96—4.47 (4×$PhCH_2$, m), 4.91 (H-1; d, $J_{1,2}$=3.0), 4.18 (H-4; m, $J_{4,5e}$=1.6, $J_{4,5a}$=2.8), 4.01 (H-3; dd, $J_{2,3}$=10.3, $J_{3,4}$=2.5), 3.90 (H-2; dd), 3.80 (H-5e; dd, $J_{5e,5a}$=13.0), 3.66 (H-5a; dd), 2.13 (CH_3S; s). Found: C, 69.65; H, 6.81; S, 6.34%. Calcd for $C_{28}H_{32}O_5S$: C, 69.97; H, 6.71; S, 6.67%.

Benzyl 2,3-O-Methylene-4-O-methylthiomethyl-β-L-arabinopyranoside (10). To a solution of **8** (0.5 g, 1.66 mmol) in DMSO (30 ml) was added with stirring sodium hydride (170 mg, 7.1 mmol) washed with hexane, and then excess dichloromethane (1 ml). The usual work-up of the reaction mixture as **13** gave a syrup (0.4 g) which was purified on a silica gel column (benzene–acetone 4:1) to give pure **10** (240 mg, 46%). $[\alpha]_D$ +110.1° (c 1.0, $CHCl_3$), NMR: 7.33 (Ph, s), 5.36 (H-1; d, $J_{1,2}$=2.8), 5.06 and 5.09 (OCH_2O; ABq, J=1.0), 4.82 (SCH_2O; s), 4.66 and 4.73 ($PhCH_2$; ABq, J=13.0), 4.48 (H-4; m), 3.95 (H-3; dd, $J_{3,4}$=2.0), 3.87 (H-2; dd, $J_{2,3}$=10.0), 3.78 (H-5e; dd, $J_{4,5e}$=1.5, $J_{5e,5a}$=13.0), 3.65 (H-5a; dd, $J_{4,5a}$=1.0), 2.16 (CH_3S). Found: C, 57.47; H, 6.62; S, 9.97%. Calcd for $C_{15}H_{20}O_5S$: C, 57.67; H, 6.45; S, 10.27%.

Benzyl 2,3-Di-O-benzyl-β-L-arabinopyranoside (11). A supension of **9** (1.2 g, 2.5 mmol), mercury(II) chloride (1.36 g, 5.0 mmol), and calcium carbonate (0.75 g, 7.5 mmol) in aqueous acetonitrile (75%, 30 ml) was refluxed for 7 h, filtered, and the filtrate was evaporated. A dichloromethane solution of the residue was washed twice with aqueous sodium iodide (10%), and then evaporated to give a syrup (1.0 g) quantitatively. $[\alpha]_D$ +105.9° (c 3.2, $CHCl_3$). Found: C, 74.28; H, 6.37%. Calcd for $C_{26}H_{28}O_5$: C, 74.26; H, 6.71%.

Benzyl 2,3-O-Methylene-β-L-arabinopyranoside (12). A similar work up of **10** (240 mg, 0.77 mmol) as above and purification of syrupy product on a silica gel column (benzene–acetone 4:1) gave pure **12** (120 mg, 62%). $[\alpha]_D$ +212.2° (c 1.6, $CHCl_3$); NMR: 7.28—7.40 (Ph; m), 5.36 (H-1; d, $J_{1,2}$=1.0), 5.04 and 5.11 (OCH_2O, ABq, J=1.0), 4.64 and 4.75 (CH_2Ph; ABq, J=12.5), 4.30 (H-4; m), 3.89 (H-3; dd, $J_{3,4}$=1.0), 3.79 (H-2; dd, $J_{2,3}$=10.0), 3.73 (H-5e; dd, $J_{4,5e}$=2.0), 3.58 (H-5a; dd, $J_{4,5a}$=1.8, $J_{5e,5a}$=13.2). Found: C, 61.83; H, 6.39%. Calcd for $C_{13}H_{16}O_5$: C, 61.89; H, 6.39%.

Benzyl 4,6-O-Benzylidene-2,3-O-methylene-α-D-glucopyranoside (13). To a solution of benzyl 4,6-*O*-benzylidene-α-D-glucopyranoside[11] (50 g, 150 mmol) in DMF (500 ml) was added with stirring sodium hydride (21.6 g, 450 mmol) and then dichloromethane (28.6 ml, 450 mmol) dropwise, and the resulting suspension was stirred overnight at room temperature. A mixture of ethyl acetate and water was added to the reaction mixture, and the resulting solution was extracted with chloroform. The extract was washed

with water, dried, and evaporated. The residue was separated on a silica gel column (hexane–ethyl acetate 8:1) to give **13** (22.4 g, 43.3%) and a mixture of two dimers (7.2 g, 13.9%). The dimers were separated on a preparative TLC (developed three times with hexane–ethyl acetate 3:1) to give 2,3′:2′,3-bis-*O*-methylenedi(benzyl 4,6-*O*-benzylidene-α-D-glucopyranoside) (**14**) and the corresponding 2,2′:3,3′-bis-*O*-methylene isomer (**15**) in 6.2% and 7.2% yields, respectively.

13: Mp 107—108 °C, $[\alpha]_D$ +123° (*c* 1.0, $CHCl_3$); NMR: 7.6—7.2 (Ph; m), 5.58 (PhCH; s), 5.35 (H-1; d, $J_{1,2}=3.5$), 5.17 (OCH_2O, s), 4.64 and 4.67 (CH_2Ph, ABq, $J=12.8$), 3.45 (H-2; dd, $J_{2,3}=9.0$), 3.68—4.30 (H-3, H-4, H-5, H-6, and H-6′, m). Found: C, 67.99; H, 5.86%. Calcd for $C_{21}H_{22}O_6$: C, 68.09; H, 5.99%.

14: Mp 111—113 °C, $[\alpha]_D$ +171° (*c* 0.98, $CHCl_3$); NMR: 7.14—7.53 (Ph; m), 4.75 and 4.96 (OCH_2O, ABq, $J=7.0$), 4.90 (H-1; d, $J_{1,2}=4.0$), 4.63 and 4.74 ($PhCH_2$; ABq, $J=12.0$), 4.18 (H-6e; dd, $J_{6e,6a}=9.5$, $J_{5,6a}=4.0$), 4.12 (H-3; t, $J_{2,3}=J_{3,4}=9.0$), 3.87 (H-5; dd, $J_{4,5}=9.0$), 3.71 (H-6e; d), 3.49 (H-4; t), 2.57 (H-2; dd); MS (70 eV): *m/e* 741. Found: C, 68.00; H, 5.87%. Calcd for $C_{42}H_{44}O_{12}$: C, 68.09; H, 5.99%.

15: Mp 114—116 °C, $[\alpha]_D$ +196° (*c* 0.8, $CHCl_3$); NMR: 7.10—7.60 (Ph; m), 4.92 (H-1; d, $J_{1,2}=3.5$), 3.71 and 4.90 (OCH_2O; each s), 5.49 (PhCH, s), 4.58 and 4.76 ($PhCH_2$; ABq, $J=12.0$), 4.17 (H-6e; dd, $J_{5,6e}=4.0$, $J_{6e,6a}=9.5$), 4.00 (H-3; t, $J_{2,3}=J_{3,4}=9.5$), 3.80 (H-5; dt, $J_{4,5}=J_{5,6a}=9.5$), 3.68 (H-6a; t), 3.66 (H-2; dd), 3.49 (H-4; t); MS (70 eV): *m/e* 740. *Methyl 4,6-O-Benzylidene-2,3-O-methylene-α-D-glucopyranoside (**16**) and -α-D-allopyranoside (**17**).* *(A)*: Reaction of 4,6-*O*-benzylidene-α-D-glucopyranoside (1 g, 3.5 mmol) in DMF (50 ml) with sodium hydride (0.27 g, 10.6 mmol) and dibromomethane (1.85 g, 10.6 mmol) as above, and the usual work up of the reaction mixture gave **16** [mp 103—104 °C, $[\alpha]_D$ +124.1° (*c* 1.0, $CHCl_3$); MS: *m/e* 294; lit,[11] mp 104—105 °C, $[\alpha]_D$ +122.9° (*c* 0.21, $CHCl_3$); Found: C, 61.03; H, 6.07%. Calcd for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17%], and two dimers [mp 209—212 °C and 225—229 °C; each MS: *m/e* 588. Found: C, 61.69; H, 6.20%. Calcd for $C_{30}H_{36}O_{12}$: C, 61.21; H, 6.17%] in 28% (290 mg), 22% (230 mg), and 13% (140 mg) yields, respectively.

(B): A similar reaction of methyl 4,6-*O*-benzylidene-α-D-allopyranoside[14] (3.7 g, 13.1 mmol) gave the corresponding 2,3-*O*-methylene derivative (**17**) in 50% (1.93 g) yield. Mp 162—164 °C, $[\alpha]_D$ +102.8° (*c* 1.0, $CHCl_3$); NMR: 7.5—7.2 (Ph; m), 5.54 (PhCH; s), 5.32 and 5.06 (OCH_2O; ABq, $J=1.8$), 4.74 (H-1; dd, $J_{1,2}=4.0$, $J_{1,3}=1.6$), 4.44—4.20 (H-2, H-5, H-6e; m, $J_{5,6e}=5.2$, $J_{6e,6a}=10.5$), 4.12 (H-4; dd, $J_{4,5}=10.0$, $J_{3,4}=5.0$), 3.80 (H-3; m, $J_{2,3}=8.4$), 3.68 (H-6a; t, $J_{5,6a}=10.0$), 3.40 (OMe).

*Benzyl 2,3-O-Methylene-α-D-glucopyranoside (**18**).* A solution of **13** (22.4 g, 60.5 mmol) in 80% acetic acid (400 ml) was stirred 1 d at room temperature. The solution was extracted with petroleum ether to remove benzaldehyde, and the water layer was evaporated to give crystals which were recrystallized from ethanol–hexane. From the mother liquor, the second crop was obtained by separation on a silica gel column (hexane–ethyl acetate 3:1). The combined yield was 63.7% (10.8 g). Mp 108—110 °C, $[\alpha]_D$ +176° (*c* 1.0, $CHCl_3$). Found: C, 59.17; H, 6.38%. Calcd for $C_{14}H_{18}O_6$: C, 59.56; H, 6.43%.

*Benzyl 2,3-O-Methylene-6-O-(p-tolylsulfonyl)-α-D-glucopyranoside (**19**).* To an ice-cooled solutions of **18** (10 g, 35.4 mmol) in pyridine (150 ml) was added portionwise with stirring *p*-toluenesulfonyl chloride (9.9 g, 50 mmol). After keeping at room temperature overnight, the reaction mixture was poured into ice–water and extracted with chloroform. Evaporation of the chloroform solution gave a syrup which was separated on a silica gel column (hexane–ethyl acetate 8:1) to give **19** (12.3 g, 80%) and the corresponding di-*O*-tosylate (**20**: 1.7 g, 8%).

19: Mp 80—82 °C, $[\alpha]_D$ +78.9° (*c* 1.2, $CHCl_3$), NMR: 7.84—6.70 (Ph; m), 5.02 (H-1; d, $J_{1,2}=3.0$), 4.90 and 4.88 (OCH_2O; ABq, $J=0.8$), 4.81 (H-4; t, $J_{4,5}=9.0$), 4.50 and 4.48 (CH_2Ph; ABq, $J=12.0$), *ca.* 4.32 (H-6a and H-6e; m), 4.00 (H-3; t, $J_{3,4}=9.0$), 3.62 (H-5; m), 3.10 (H-2; dd, $J_{2,3}=9.0$), 2.94 (OH; s), 2.44 (CH_3Ph; s). Found: C, 58.14; H, 5.60; S, 7.59%. Calcd for $C_{21}H_{24}O_8S$; C, 57.79; H, 5.54; S, 7.35%.

20: Mp 144—145 °C, $[\alpha]_D$ +87.6° (*c* 1.1, $CHCl_3$), NMR: 7.15—7.85 (Ph; m), 5.21 (H-1; d, $J_{1,2}=3.0$), 5.04 (OCH_2O; s), 4.72 (H-4; t, $J_{3,4}=J_{4,5}=10.0$), 4.57 and 4.70 (CH_2Ph; ABq, $J=11.0$), 4.25 (H-6e; dd, $J_{5,6e}=2.5$, $J_{6e,6a}=11.0$), 4.03 (H-6a; dd, $J_{5,6a}=5.5$), 3.95 (H-3; t, $J_{2,3}=10.0$), 3.70 (H-5; sex), 3.30 (H-2; dd), 2.45 ($2\times CH_3Ph$). Found: C, 57.54; H, 5.16; S, 10.7%. Calcd for $C_{28}H_{30}O_{10}S_2$: C, 56.93; H, 5.12; S, 10.7%.

*Benzyl 6-Deoxy-2,3-O-methylene-α-D-glucopyranoside (**21**).* A mixed solution of **19** (8 g, 18.4 mmol) and sodium borohydride (1.7 g, 45.7 mmol) in DMSO (100 ml) was heated at 80 °C for 3 h, and then poured into ice–water. The resulting solution was extracted with ether, and the extract was evaporated. The residual syrup was purified on a silica gel column (hexane–ethyl acetate 8:1) to give **21** (6.1 g, 81%) as a syrup. $[\alpha]_D$ +154° (*c* 0.85, $CHCl_3$), NMR: 7.50—7.20 (Ph; m), 5.24 (H-1; d, $J_{1,2}=3.0$), 5.13 (OCH_2O; s), 4.63 and 4.80 (CH_2Ph; ABq, $J=10.5$), 3.87 (H-3; t, $J_{2,3}=J_{3,4}=9.5$), 3.56 (H-5; dq, $J_{4,5}=9.5$, $J_{5,6}=6.5$), 3.45 (H-4; t), 3.35 (H-2; dd), 1.30 (H-6; d). Found: C, 62.64; H, 6.95%. Calcd for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81%.

*Methyl 6-Deoxy-2,3-O-methylene-α-D-glucopyranoside (**22**).* Compound **16** was converted into **22** in a similar manner to that of **13** into **21**. Partial hydroxysis of **16** (24 gr, 8.16 mmol) in aqueous acetic acid (80%, 500 ml) at 35 °C for 1 d gave methyl 2,3-*O*-methylene-α-D-glucopyranoside (12 g, 68.5%) as a syrup. Monotosylation of the syrup (9.4 gr, 45.6 mmol) in pyridine (200 ml) with *p*-toluenesulfonyl chloride (9.9 g, 52 mmol) and purification of the products on a silica gel column (benzene–acetone 50:1) gave the 6-*O*-tosylate (12.6 g, 77%) as a syrup. NMR: 7.80 and 7.34 (Ph; each d, $J=8.0$), 5.13 (OCH_2O; s), 5.05 (H-1; d, $J_{1,2}=3.2$), 4.36 (H-6; dd, $J_{5,6}=4.0$, $J_{6,6'}=11.0$), 4.30 (H-6′; dd, $J_{5,6'}=2.4$), 3.9—3.4 (H-3, H-4, and H-5; m), 3.44 (OMe; s), 3.28 (H-2; dd, $J_{2,3}=9.5$), 2.44 (CMe; s). Found: C, 50.00; H, 5.60; S, 8.88%. Calcd for $C_{15}H_{20}O_8S$: C, 49.99; H, 5.59; S, 8.90%.

Reduction of 6-*O*-tosylate (9.18 g, 25.5 mmol) in THF (400 ml) with lithium aluminium hydride (LAH) (1.94 g, 50 mmol) and the purification of the product on a silica gel column gave pure **24** (2.0 g, 41.3%) as a syrup. $[\alpha]_D$ +202.3° (*c* 1.0, $CHCl_3$). Found: C, 50.21; H, 7.71%. Calcd for $C_8H_{14}O_5$: C, 50.52; H, 7.42%.

*Methyl 6-Deoxy-2,3-O-methylene-α-D-allopyranoside (**23**).* Compound **17** was converted into **23** as above. Partial hydrolysis of **17** and successive monotosylation of the product gave methyl 2,3-*O*-methylene-6-*O*-tosylsulfonyl-α-D-allopyranoside as a syrup in 62% yield. $[\alpha]_D$ +65.3° (*c* 1.0, $CHCl_3$). NMR: 7.79 and 7.36 (Ph; each d, $J=8.0$), 5.02 and 4.80 (OCH_2O; ABq, $J=2.0$), 4.58 (H-1; d, $J_{1,2}=5.0$), 4.4—4.1 (H-6 and H-6′; $J_{5,6}=2.4$, $J_{5,6'}=5.0$, $J_{6,6'}=10.8$), 4.06 (H-2; t, $J_{2,3}=5.0$), 3.95—3.65 (H-3 and H-5;

m, $J_{3,4}=3.0$, $J_{4,5}=10.0$), 3.50 (H-4; m), 3.34 (OMe; s), 3.24 (OH; s), 2.47 (CMe; s). Found: C, 49.76; H, 5.65; S, 8.75%. Calcd for $C_{15}H_{20}O_8S$: C, 49.99; H, 5.59; S, 8.90%.

Reduction of the above 6-*O*-tosylate with LAH gave **23** as a syrup in 83% yield. $[\alpha]_D$ +88.4° (*c* 2.75, $CHCl_3$); NMR: 5.27 and 5.03 (OCH_2O; ABq, $J=2.0$), 4.69 (H-1; d, $J_{1,2}=5.0$), 4.35—4.10 (H-3 and H-4; m), 3.64 (H-5; dq, $J_{5,6}=6.3$, $J_{4,5}=10.0$), 3.25 (H-4; dd, $J_{3,4}=3.5$), 3.40 (OMe; s), 2.56 (OH; s), 1.29 (H-6; d). Found: C, 50.41; H, 7.56%. Calcd for $C_8H_{14}O_5$: C, 50.52; H, 7.42%.

The coupling constants mentioned above indicate that **23** and the precursor exist in a flattened *C*1 conformation.

*Benzyl 2,3-Di-*O*-benzyl-6-deoxy-α-*D*-glucopyranoside (**24**).* To an ice-cooled solution of benzyl 2,3-di-*O*-benzyl-α-D-glucopyranoside[10] (28 g, 62 mmol) in pyridine (400 ml) was added *p*-toluenesulfonyl chloride (15.7 g, 82 mmol) portionwise for 4 h with stirring. After keeping overnight at room temperature, the reaction mixture was poured into ice-water and extracted with chloroform. The chloroform solution was evaporated, and the residual syrup was dried and dissolved in THF, and LAH (2.8 g, 74 mmol) was added to THF solution with stirring. After stirring for 3 h at room temperature, a mixture of ethyl acetate and water was added to the reaction mixture and the precipitates deposited were filtered off. The filtrate was extracted with chloroform, and evaporation of the extract gave a syrup (13.2 g) which was purified on a silica gel column (hexane–ethyl acetate 10:1) to give **24** as a syrup (10.2 g, 38%). $[\alpha]_D$ +51.5° (*c* 0.84, $CHCl_3$), NMR: 7.44—7.22 (Ph; m), 4.79 (H-1; d, $J_{1,2}=3.0$), 4.42—5.09 (CH_2Ph; m), 3.81 (H-4; t, $J_{3,4}=J_{4,5}=9.5$), 3.75 (H-5; dq, $J_{5,6}=5.5$), 3.50 (H-2; dd, $J_{2,3}=9.5$), 3.17 (H-3; t), 1.23 (H-6; d). Found: C, 71.60; H, 6.98%. Calcd for $C_{27}H_{30}O_6$: C, 71.98; H, 6.71%.

Preparation of 4-Uloses. Method A: Oxidation with chromium oxide-pyridine is illustrated by the preparation of methyl 6-deoxy-2,3-*O*-methylene-α-D-*ribo*-hexopyranosid-4-ulose (**6**). To a mixture of pyridine (1.79 g, 22.6 mmol) and dichloromethane (40 ml) was added chromium trioxide (1.81 g, 18.1 mmol) in two portions, and the mixture was stirred for 20 min. To the mixture was added a solution of **22** (860 mg, 45 mmol) in dichloromethane (10 ml) and it was stirred for 20 min until **22** had disappeared on TLC. The mixture was poured into saturated sodium hydrogencarbonate, and the organic layer was processed conventionally to give a syrup which was purified on a silica gel column (benzene–acetone 5:1) to give **6** (382 mg, 45%). This fact implies the epimerrization at *C*-3 during the oxidation. IR: 1745 (C=O). Found: C, 50.82; H, 6.21%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%.

Method B: The DMSO–acetic anhydride oxidation is typically shown by the preparation of benzyl 2,3-di-*O*-benzyl-β-L-*threo*-pentopyranosid-4-ulose (**1**). A solution of **11** (0.5 g, 1.19 mmol) in DMSO (8 ml) and acetic anhydride (4 ml) was kept overnight at room temperature, poured into ice–water, and extracted with ether. The usual work up of the extract gave **1** as a syrup in 60% (0.3 g) yield. $[\alpha]_D$ +98.3° (*c* 1.25, $CHCl_3$), IR: 1740 (C=O). Found: C, 74.08; H, 6.51%. Calcd for $C_{26}H_{26}O_5$: C, 74.62; H, 6.26%.

Method C: The DMSO–trifluoroacetic anhydride oxidation is illustrated by the preparation of benzyl 2,3-di-*O*-benzyl-6-*O*-trityl-α-D-*xylo*-hexopyranosid-4-ulose (**5**). To a chilled solution of DMSO (143 mg, 2.01 mmol) and dichloromethane (2 ml) at −78 °C was added trifluoroacetic anhydride (318 mg, 1.51 mmol) in dichloromethane (2 ml) with stirring, and after 10 min, subsequently a solution of benzyl 2,3-di-*O*-benzyl-6-*O*-trityl-α-D-glucopyranosid (**25**)[12] (349 mg, 0.58 mmol) in dichloromethane (4 ml) dropwise. After stirring for 1 h, the reaction mixture was carefully neutralized at −78 °C with triethylamine, and then poured into ice-water. The resulting solution was extracted with chloroform, and the usual work up of the extract and purification of the product on a silica gel column gave pure **5** in 98% (341 mg) yield, which was crystallized from ethanol. Mp 131—136 °C; $[\alpha]_D$ +41.5° (*c* 1.42, $CHCl_3$). Found: C, 79.50; H, 6.01%. Calcd for $C_{46}H_{42}O_6$: C, 79.98; H, 6.13%.

In a similar manner, benzyl 2,3-*O*-methylene-β-L-*threo*-pentopyranosid-4-ulose (**2**), benzyl 2,3-*O*-benzyl-6-deoxy-α-D-*xylo*-hexopyranosid-4-ulose (**3**), benzyl 2,3-*O*-methylene-6-deoxy-α-D-*xylo*-hexopyranosid-4-ulose (**4**) were also obtained as syrups from **12**, **24**, and **21**, respectively. These compounds showed the correct analytical values, and the structures were confirmed by the NMR and IR spectra. However, the rotational values were not measured, because a small amount of impurities could not be removed, and they were directly used to the next reaction.

The present work was partially supported by a Grand-in-Aid for Scientific Research No. 347023 from Ministry of Education, Science and Culture.

Determination of the Non-stoichiometry of Zeolite A

Tatsuo OHGUSHI

School of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440

(Received September 29, 1980)

Zeolite A was synthesized in the sodium form with the composition $Na_{12}(AlO_2 \cdot SiO_2)_{12}(NaAlO_2)_\delta \cdot nH_2O$, $0 \leqq \delta \leqq 1$. A new method was developed for the determination of the δ-value of the non-stoichiometric part in the product. It consists of repeated ion exchanges of zeolite with $TlNO_3$ (or $BaCl_2$), and determination of the residual amount of Na^+ in the zeolite as a function of the number of treatments. The K_δ/δ value was determined from a linear plot, where K_δ is a selectivity coefficient of the ion exchange reaction between Tl^+ (or Ba^{2+}) and Na^+ in the non-stoichiometric part. The K_δ value was taken from the observed K_δ/δ value, the δ-value being obtained by chemical analysis. The δ-value of a sample can be determined by introducing the K_δ-value into K_δ/δ. An approximate δ-value can be estimated from a break point of the curve, log(residual amount of Na^+) *vs.* the number of times of treatment.

Zeolite A was synthesized in the sodium form, having the composition $Na_{12}(AlO_2 \cdot SiO_2)_{12}(NaAlO_2)_\delta \cdot nH_2O$, with $0 \leqq \delta \leqq 1$.[1,2] The $(AlO_2 \cdot SiO_2)_{12}$ constitutes the framework of the crystal, twelve Na^+ undergoing ion exchange with other cations.[1-4] The non-stoichiometric part, $NaAlO_2$, abbreviated as the δ-part, is occluded in the β-cage of sodalite unit.[2,5] This model for the δ-part, however, has not been confirmed as yet by X-ray analysis, since the structural studies have usually been carried out with single crystals synthesized by Charnell's method,[6] which are said to contain no non-stoichiometric part.[7,8] On the other hand, most studies on ion exchange, thermal measurement, gas sorption, and catalysis are carried out with commercial zeolite (hydrothermally synthesized), and their non-stoichiometry cannot be ignored. The physical and chemical properties of zeolite A, which might be influenced by the δ-value are as follows. In entirely Ca-exchanged zeolite A, $(1+\delta)Ca^{2+}$ ions are located on the 8-membered oxygen ring,[9] Ca^{2+} acting as a highly active center for the isomerization reaction of 1-butene.[10] In (K,Zn)–A systems, discrepancy was found between the conclusions obtained by X-ray analysis[11] and ion exchange isotherm.[12] This was explained by a difference in δ-values of samples.[9] Recently Rees analyzed ion exchange isotherms on (Na,Ca)–A systems and found that there is considerable divergence in data obtained by different authors.[13] He suggested that such divergence is partly attributable to the difference in δ-values.[14]

It is desirable to work out a reliable method to determine the δ-value. The one proposed by Barrer and Meier is too laborious.[15] In the present paper new methods are proposed.

Experimental

Pretreatment. Commercial molecular sieves 4A powder (Shōwa-Unox Co., Lot No. 410713) was used as the starting material. The powder, which was passed through a 200-mesh sieve, contained some sodium hydroxide and iron oxide. In order to remove these impurities, the powder was shaken with a vibrator washer fifteen times in 0.2—0.02 mol dm^{-3} sodium acetate and then washed with distilled water three times. The residual iron impurity was less than 50 ppm as checked by spectrophotometry.

Chemical Analysis. The pretreated zeolite (*ca.* 0.6 g) was dehydrated at 400 °C in a vacuum of 10^{-3} Pa for 4 h and weighed *in situ* with a quartz spring balance. The sensitivity and sensibility of the balance were 0.5 mm/mg and 0.2 mg, respectively. The sample was dissolved in 2 mol dm^{-3} HCl with sodium impurity less than 0.65 ppm in 37% concentration. The amount of silicon, aluminum, and sodium in the dissolved solution was analyzed by gravimetry. Silicon was precipitated as silica, and the filtrate, free from silica, was analyzed. Aluminum and sodium were precipitated as complexes with oxine and zinc uranyl acetate, respectively, and weighed after filtration.[16]

Activation Analysis. Residual amounts of sodium, in ion exchanged Tl–A, Ba–A, and Sr–A zeolite, were determined by neutron activation analysis. Dehydrated samples weighed were irradiated in a TRIGA MARK II REACTOR of Rikkyo (St. Paul's) University for 1—5 h. After a cooling time of 20 h, 1368.4 and 2753.6 keV γ-rays from ^{24}Na in the sample were measured with a γ-ray spectrometer (CANBERRA Ge(Li)-4K-PHA). The absolute amount of ^{24}Na in the sample was determined by comparison with a standard sample. Dehydrated Na_{12}–A zeolite was used as a standard since neutrons are absorbed and reflected by it in a way similar to that of the sample concerned. The sodium content of the standard was determined by chemical analysis.[16]

Results

Chemical Analysis. Results of the chemical analysis of Na–A are given in Table 1. The δ-value was determined from the ratio [Si]/[Al] but not from [Si]/[Na]. When zeolite A is washed a certain amount of Na^+'s is replaced by proton,[17-19] and hence the ratio [Si]/[Na] cannot be used as a means to determine the δ-value. The unfavorable proton exchange is estimated to be 0.5 protons per unit cell from the ratio [Na]/[Al] (Table 1), since [Na]/[Al] would have been unity if no hydrolysis took place.† The observed value for the ratio [Si]/[Al] is 0.988 ± 0.05, giving $\delta = 0.15 \pm 0.05$.

Ion Exchange. (a) Na_{12}–A zeolite (2 g) was subjected to ion exchange in 30 ml of a 0.2 mol dm^{-3} $TlNO_3$ or $BaCl_2$ solution at 82 ± 2 °C. (b) The same amount of zeolite was treated in 50 ml of a 0.05 mol dm^{-3} $BaCl_2$, $SrCl_2$, or $TlNO_3$ solution at 82 ± 2 °C.
