suggesting that heterogeneous reactions should occur on the illuminated TiO_2. By comparison of Figs. 2 and 3 we see that the platinization of TiO_2 photocatalysts mainly effects the reduction process. Experiments were carried out by illuminating the non-platinized surface, the platinized surface not being illuminated. Illumination was carried out for 15 h under bubbling NO into 5 ml of 1 mol dm^{-3} $HClO_4$, and the solution was analyzed for NO_3^- as an oxidation product, and for ammonia and hydrazine as reduced ones. The results are given in Table 4.

The platinized photocatalysts give a lower amount of NO_3^- but higher amounts of ammonia and hydrazine than the non-platinized catalysts, in line with the results given in Table 2 when a comparison of results is made at the same potential.

Heterogeneous Reactions on Powder Photocatalysts. The formation of NO_3^- by oxidation and of NH_3 by reduction was investigated by using TiO_2 powder photocatalysts. As the photocatalysts, a commercially available powder, a partially reduced powder and a platinized powder subjected to no reduction were used. The degree of platinization was so low as to give a monolayer coverage, differing from the cases of single crystal catalysts. Photodeposition to give a much higher coverage was unsuccessful.

The results on the heterogeneous reactions on the powder photocatalysts are given in Table 5. The NO_3^- production was suppressed but NH_3 production seemed to increase with platinization as observed in single crystal photocatalysts. However, the effect of platinization was not so obvious as in the case of single crystal catalysts mainly due to the low coverage of deposited Pt. The effects of the partial reduction of the catalyst are not clear. The results obtained are greatly scattered, making it difficult to give conclusions on the effect of illumination time and the amount of catalyst loadings on the production of NO_3^- and NH_4^+. Since chemical reactions (Eqs. 11 to 13) are involved in the heterogeneous reaction, slight differences in bubbling conditions of NO might greatly influence the yield.

The results given in Figs. 4 and 5 indicate that the amount of ammonia produced is higher in the powder photocatalysts than in the single crystals. The ammonia production may require the adsorbed hydrogen on the catalysts surface. A large surface area of powder photocatalysts is advantageous. The attack

TABLE 5. HETEROGENEOUS REACTION OF NO ON TiO_2 POWDER PHOTOCATALYSTS[a)]

Catalyst	Sp. surface area / $m^2\ g^{-1}$	Amount of powder / g	Illumination time / h	NO_3^- / μmol	NH_3 / μmol
Unreduced TiO_2	14.2	0.2	8	40.7	5.91

a) Solution: 5 ml of 1 mol dm^{-3} $HClO_4$. b) H_2 reduction at 700 °C for 30 min. c) Amount of Pt: 21.8 mg Pt/g of TiO_2, corresponding roughly to a monolayer coverage.

of NO on the ammonia produced would not take place with the same rate in the powder and single crystal catalyst systems, since experimental conditions differ.

Summary of the Heterogeneous Reactions of NO. It was confirmed that NO dissolved in 1 mol dm^{-3} $HClO_4$ undergoes heterogeneous reactions on TiO_2 photocatalysts, the reaction schemes being complicated. From the current-potential curves of TiO_2 single crystal electrodes (Figs. 2 and 3), we see that heterogeneous reaction takes place on single crystal catalysts following electrochemical mechanism. This might be the case also for powder photocatalysts, since as regards ZnO[30)] and TiO_2[17,31)] there is close similarity in photoelectrochemical properties of semiconducting powders to those of single crystals. The reaction schemes can be estimated on the basis of anodic and cathodic reactions at TiO_2 electrodes.

The oxygen evolution occurs as the main anodic reaction (Table 1). The oxygen evolved would easily react with NO to give NO_2, and the resulting NO_2 would dissolve into solutions to give NO_3^- with a disproportionation reaction. The current efficiency for the oxygen evolution decreases in the presence of NO. This is partly attributable to the contribution of the chemical reaction with NO. The electrochemical oxidation of NO to finally give NO_3^- should also be taken into consideration. NO is oxidized to NO_3^- at high anodic potentials on Pt electrodes.[32)]

The oxidation processes are postulated on the basis of the electrolysis experiments. The main difference expected between the electrolysis experiments and photocatalytic experiments would result from the difference in the magnitude of the electric field built in the semiconductor surface, the magnitude being usually small in the cases of heterogeneous reaction systems. The weak electric field enhances the recombination of photo-generated positive holes with electrons as majority charge carriers, resulting in a low utilization efficiency of light quanta as demonstrated by Ohnishi *et al.*[33)] To our present knowledge this effect is the only one expected for the change of surface electric field. No change would be predicted in the nature of electrochemical reactions when variation arises in the electric field of semiconductor surfaces.

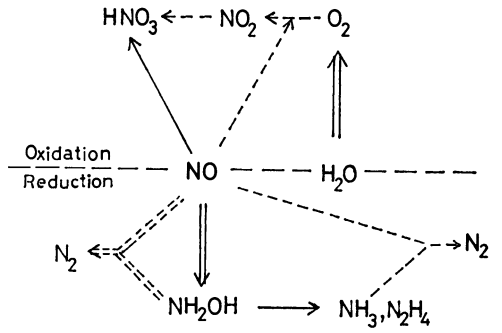

Fig. 5. Schematic illustrations of heterogeneous reactions of NO on illuminated TiO_2 in 1 mol dm^{-3} $HClO_4$.
Double lines stand for the main reaction path. Solid line: electrochemical reaction path, dashed line: chemical reaction path.

If there were any change the proposed reaction schemes would then become invalid.

As a cathodic process which should occur to keep the electrical neutrality of the photocatalysts, the reduction of NO to hydroxylamine would take place. A fraction of the hydroxylamine produced escapes from the chemical reaction with NO, and is subjected to further reduction to ammonia and hydrazine. A part of the produced ammonia and hydrazine would be decomposed into N_2 by the chemical reaction of NO. These routes are illustrated in Fig. 5.

In view of electrochemistry, the production of ammonia and hydrazine from NO seems promising in the heterogeneous reaction systems on illuminated TiO_2 if the entire processes are governed by electrochemical mechanisms. Actually, however, several chemical reactions are involved, and as a result N_2 is produced as the main substance.

The present study was supported by Grant-in-Aid for Scientific Research No. 505008 from the Ministry of Education, Science and Culture.

(Received September 5, 1980)

The structure factors $S_m(Q)$ over a wide range of Q (1.7—25 Å^{-1}) for aqueous solutions of DCl and DBr (*ca.* 1 M) at room temperature have been determined by means of LINAC-TOF neutron diffraction. The intramolecular structures of D_2O and D_3O^+ in the solutions are found to be identical with those in the "revised watery model" for water. Applying the subtraction method of analysis to diffraction data for the solutions, we have obtained the following results with respect to the structure of the nearest hydration shell around ions in the DCl and DBr solutions: (a) D_3O^+ is tetrahedrally coordinated with four water molecules and Cl^- and Br^- are octahedrally coordinated with six ones, (b) the O–O distances between the central oxygen atom and that of hydrated water molecules for D_3O^+ are 2.88±0.05 Å, (c) the anion-oxygen distances are 3.10±0.05 Å for Cl^- and 3.21±0.05 Å for Br^-, and (d) around cations (D_3O^+) water molecules take the configuration to orient the axis of one of the two lone-pair hybrids on a straight line joining an oxygen atom and the cation, while around anions (Cl^- and Br^-) those take the configuration to orient the vector which bisects the D–O–D angle on a straight line joining an oxygen atom and the cation.

With respect to the structural studies of aqueous ionic solutions, X-ray diffraction techniques have been widely used and a rather large amount of knowledge with respect to the structure of the hydration shell around ions have been accumulated. These X-ray results are summarized in recent review articles.[1,2] The results obtained, such as the coordination numbers, *etc.*, however, are diverse and no precise determination of the orientational configuration of hydrated water molecules has been made by the X-ray diffraction studies.

Then, the neutron diffraction method, which has a unique advantage for determination of the positions of light atoms such as hydrogen (deuterium) contained in the molecules within liquids,[3] has been applied to the study of aqueous solutions. Narten *et al.* carried out X-ray and neutron diffraction studies on aqueous LiCl[4] and DCl[5] solutions, and in the latter they used a well-known conventional method developed for steady state experiment at reactor. Enderby *et al.*, using the same reactor conventional method, investigated aqueous solutions of $NiCl_2$, NaCl, and $CaCl_2$.[2,6,7] The authors carried out studies on alkali chloride (LiCl, NaCl, KCl, and CsCl) solutions by the use of a TOF neutron diffraction method at LINAC.[8,9] These works have the following remarkable features. First, the resolving power of neutron diffraction in structural studies of aqueous solutions has turned out to be superior to that of X-ray diffraction.[1,2] The neutron studies are sufficiently effective to distinguish between various possible ion-water configurations. Second, for structural studies of liquids, the accuracy of a LINAC-TOF neutron diffraction method has been raised in comparison with that of the reactor conventional method.[8,9,10–14] Consequently, associated with the proposition of improved correction procedures for inelastic scattering, the authors' works for hydrogenous molecular liquids have made it possible to provide more detailed knowledge.[8,9,13,14]

Concerning neutron diffraction data of aqueous ionic solutions, there is no definite procedure for the analysis. Three procedures have been proposed recently: the near-neighbor model approach by Narten *et al.*,[4,5] the first- and second-order-difference spectroscopy by Enderby *et al.*,[2,6,7] and the subtraction method by the authors.[8,9] The subtraction method has been found to be useful in order to elucidate the structure of the nearest neighbor shell around ions in more dilute aqueous solutions,[8,9] while Enderby *et al.*'s method using isotopes is clearly restricted in its practical utility.[15] As regards the method of Narten *et al.* especially on the fundamental nature of the near-neighbor model itself, important criticism has been raised by several workers.[13,15,16]

In the present paper, the result of a neutron diffraction study on aqueous solutions of DCl and DBr at *ca.* 1 M is given. With respect to concentrated DCl solutions X-ray[17,18] and neutron[5] diffraction studies have been made recently. However, the diffraction study for its more dilute aqueous solutions has never been carried out, which is required for the elucidation of the fundamental structure of hydration. Then, in order to investigate the hydrated structures around ions in dilute solutions, we have made an experiment for *ca.* 1 M solutions of DCl and DBr.

Experimental

Procedures for Measurements. The experiment was performed by the TOF neutron diffraction method by LINAC at Hokkaido University. Details of the apparatus and procedures were reported.[13,19,20] Experimental accuracy has been raised to a more satisfactory level by recent improvements: the resolving powder $\Delta Q/Q$ of less than a few % and the statistical errors of smaller than 1% in the whole range of Q can be easily attained at present ($Q=(4\pi\sin\theta)/\lambda$)[19,20]

Measurements on the DCl and DBr solutions and pure

D_2O at room temperature (16 °C) were carried out at a scattering angle, $2\theta=90°$. Data for pure heavy water are required for analysis of the data of aqueous ionic solutions. The time-of-flight of neutrons was analyzed by a multichannel time analyzer with a channel width of 10 μs. Thin-walled cylindrical quartz vessels were used as a container of samples.

Samples. Two acid solutions were prepared by the addition of deuterated hydrochloric and hydrobromic acids with the purity of deuteration of 99% to heavy water. The concentration and density of the DCl solution at 25 °C were 1.097 M and 1.125 g cm^{-3}, and those of the DBr solution were 1.038 M and 1.160 g cm^{-3}.

Corrections and Calibrations of Raw Scattering Data. For the determination of the structure factor $S_m(Q)$, corrections for multiple scattering, absorption, background counting, and inelastic scattering are necessary and absolute normalization of data was performed by the use of the scattering data from a standard vanadium rod of the same shape and dimensions as those of the sample.[8,9,13,14] Above all the correction for the inelastic scattering of neutrons is the most important for hydrogenous molecular liquids including light nuclei like deuterium. In order to compensate for this effect, we can apply the correction method being used successfully in our recent studies on liquid D_2O and CD_3COCl.[13,14] In the present study the Placzek correction method[21] was used in a lower Q region and the Wick correction method[22] in a higher Q region.

Calibration of absolute values for high Q data was performed according to the limiting procedure that $S_m(Q)\rightarrow \sum b_n^2/(\sum b_n)^2$ as $Q\rightarrow\infty$, where n ranges over all the nuclei in a molecule. Calibration of low Q data was made by overlapping the $S_m(Q)$ curves in the range 6—10 Å^{-1} for the two corrected data.[14] Thus, combining the data sets, we obtained the final $S_m(Q)$ curve for a wide range of Q, 1.7—25 Å^{-1}. In Fig. 1, the $S_m(Q)$ curves of DCl and DBr solutions together with that of D_2O are given.

The resolving powder $\Delta Q/Q$ was 0.03 in the Q range 1—8 Å^{-1} and 0.04 in the range of Q greater than 10 Å^{-1}.

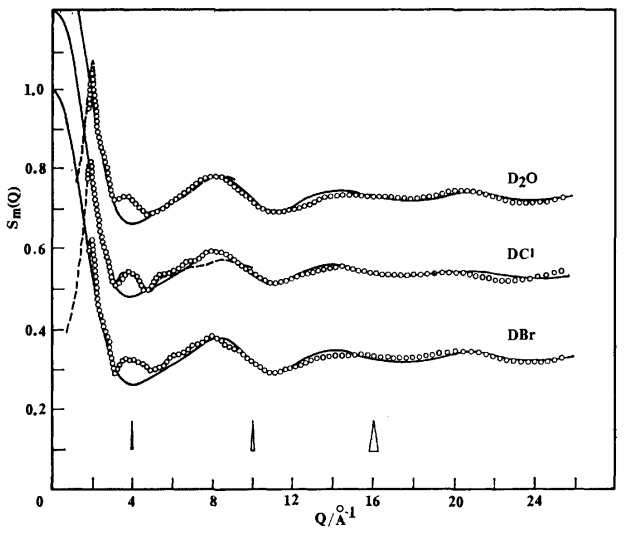

Fig. 1. Observed structure factors for DCl and DBr solutions at 1.10 M and 1.04 M, respectively, compared with the factor for D_2O.
○: $S_m(Q)$ observed, ----: $S_m(Q)$ observed previously (for D_2O by the authors[8,13] and for DCl solution by Triolo and Narten[5]), ——: $f_1^W(Q)$ for D_2O and $S_m^{(1)}(Q)$ for DCl and DBr solutions.

The magnitudes of resolution ΔQ are shown as triangles along the abscissa. The statistical error was found to be smaller than 1% in the whole range of Q.

Results. For the sake of comparison, the $S_m(Q)$ data for heavy water reported by the authors (dashed line)[8,13] are indicated in Fig. 1 overlapping the present data (open circles). Two sets of data agree fully with each other in the range of Q, 1.7—9 Å^{-1}, though slight differences in the main peak at 2 Å^{-1} and a broader peak at *ca.* 8 Å^{-1} are observed. Taking experimental uncertainties as well as the small difference in temperature into consideration, the $S_m(Q)$ data for D_2O are found to agree with other data (Page and Powles'[23] and Narten's[24] data at reactor, and the authors' at LINAC[8,13]). Thus, the reproducibility of the neutron data for D_2O is confirmed with sufficient accuracy.

Furthermore, the data for hydrochloric acid solution at *ca.* 1 M reported by Triolo and Narten (dashed line)[5] are indicated in Fig. 1 overlapping the present data (open circles). Their data in the figure are normalized to the value at the first peak of the structure factor obtained in the present work. A small deviation of Triolo and Narten's data from ours at 6—10 Å^{-1} is observed. Values of rms deviations for D_2O and D_3O^+ in their least-square analysis are, thus, supposed to be too large. Except for this point, their data are found to be essentially identical with our data in the range of Q, 1.7—6 Å^{-1}, and then the reproducibility of the data has been confirmed.

From the above-mentioned fact, reliability of the data required to elucidate the structure of the solutions is attained. Thus, with the help of the subtraction method in the analysis of lower Q data, the configurations of water molecules within the first hydration shell can be studied, and the molecular structure of D_2O and D_3O^+ within the solutions can be determined by the use of the $S_m(Q)$ data in a wide range of Q.[14]

Results and Discussion

Intramolecular Contribution to $S_m(Q)$. The structure factor $S_m(Q)$ for molecular liquids consists of an intramolecular contribution $S_m^{(1)}(Q)$ and an intermolecular one $S_m^{(2)}(Q)$, and is expressed as

$$S_m(Q) = S_m{}^{(1)}(Q) + S_m{}^{(2)}(Q). \quad (1)$$

Structure factors for higher Q region are dominated by the intramolecular contribution, *i.e.* $S_m(Q)\rightarrow S_m^{(1)}(Q)$. Then, the $S_m^{(1)}(Q)$ for the DCl and DBr solutions becomes

$$S_m{}^{(1)}(Q) = (1-x_+-x_-)f_1^W(Q)+x_+f_1^C(Q)+x_-f_1^A(Q). \quad (2)$$

$f_1^W(Q)$ is the intramolecular contribution from water molecules constituting a tetrahedral pentamer (the "revised watery model"[8,13]). $f_1^C(Q)$ and $f_1^A(Q)$ are the intramolecular contributions from the species constituting the first hydration shell around D_3O^+ and anions, respectively.[8] x_+ and x_- are mole fractions of D_2O molecules coordinated in the first shell around cations and anions.

The calculated curves $f_1^W(Q)$ for D_2O, $S_m^{(1)}(Q)$ for the DCl solution, and $S_m^{(1)}(Q)$ for the DBr solution are indicated in Fig. 1, in comparison with the observed data. The agreement between the calculated curves and the observed data at high Q region ($Q\gtrsim 8$ Å^{-1}) is satisfactory. The agreement in our results is found to be over a wider range of Q (8—25 Å^{-1})

than that in Triolo and Narten's work (8—13 Å^{-1}).[5] Thus, it has been confirmed that the intramolecular structures of D_2O within liquid heavy water are specified by those in the revised watery model.[8,13] Likewise, the structures of D_2O and D_3O^+ in the DCl and DBr solutions at 1 M have been found to be identical with those in the revised watery model.[8,13,25]

Significant differences between the $S_m(Q)$ data of D_2O and those of DCl and DBr solutions in the lower Q region (<7 Å^{-1}) can be ascribed mainly to contributions from the ion-water and water-water interactions within the structure of the first hydrated shell around ions.

Structure of the First Hydration Shell around Ions. A determination of the structure of the nearest hydration shell around ions has been made by comparing calculated values with observed data according to the subtraction method described in the preceding paper.[8,9] The method was proposed for the analysis of the data of comparatively dilute aqueous solutions, and its availability for the determination of the structure was demonstrated.[8,9] The outline of the subtraction method is as follows.

Determination of $\Delta S_m(Q)_{obsd}$: This factor is obtained by subtracting the structure factor $S_m(Q)_{D_2O}$ of D_2O multiplied by an appropriate fraction from the observed total structure factor $S_m(Q)_{total}$ for solution. Thus, in an aqueous solution as dilute as 1 M, the remaining factor for the hydrated structure $\Delta S_m(Q)_{obsd}$ becomes

$$\Delta S_m(Q)_{obsd} = S_m(Q)_{total} - (1-x)S_m(Q)_{D_2O} - axS_m(Q)_{D_2O}, \quad (3)$$

where x is the mole fraction of D_2O molecules coordinated in the first hydration shell, $x=c(n_+ + n_-)/55.3$: n_+ and n_- are the coordination numbers around cations and anions, respectively, and c is the concentration in M. The second term in Eq. 3 is the contribution from bulk water outside of the hydration shell, and the third one that from pairs between the molecules within the shell and bulk water molecules. The magnitude of a was estimated to be 1/2 in a preceding paper.[9]

Calculation of $\Delta S_m(Q)_{calcd}$: The structure of the hydration shell is specified by several parameters, such as coordination numbers, ion-oxygen distances, O–D···O distances, and orientational arrangements of water molecules around ions. Coordination numbers and ion-oxygen distances reported so far are given in Table 1 (see also Tables 1 and 2 in Ref. 8). As regards the configuration of water molecules around ions, two forms, "linear" and "bifurcated,"[8] are assumed for cations where lone-pair electrons are located in the vicinity of ions (Figs. 5(a) and (b) in Ref. 8), and also for anions where deuterium atoms in the vicinity of the ions (Figs. 5(c) and (d) in Ref. 8).

We calculated $\Delta S_m(Q)_{calcd}$ for a number of structure models in which the magnitudes of parameters were varied (Table 2). The expression for $\Delta S_m(Q)_{calcd}$ is given Eq. 4 of Ref. 9.

For each of the DCl and DBr solutions, 42 different types of structures with respect to varieties of coordination numbers and orientational configurations are assumed. In the case of D_3O^+, for the tetrahedral configuration three cases were taken into consideration: 1) all peripheral water molecules take the linear con-

Br^-	4 (Tetrahedral) 6 (Octahedral) 8 (Cubic)	3.15—3.50 (Interval of 0.05)	Linear, Bifurcated

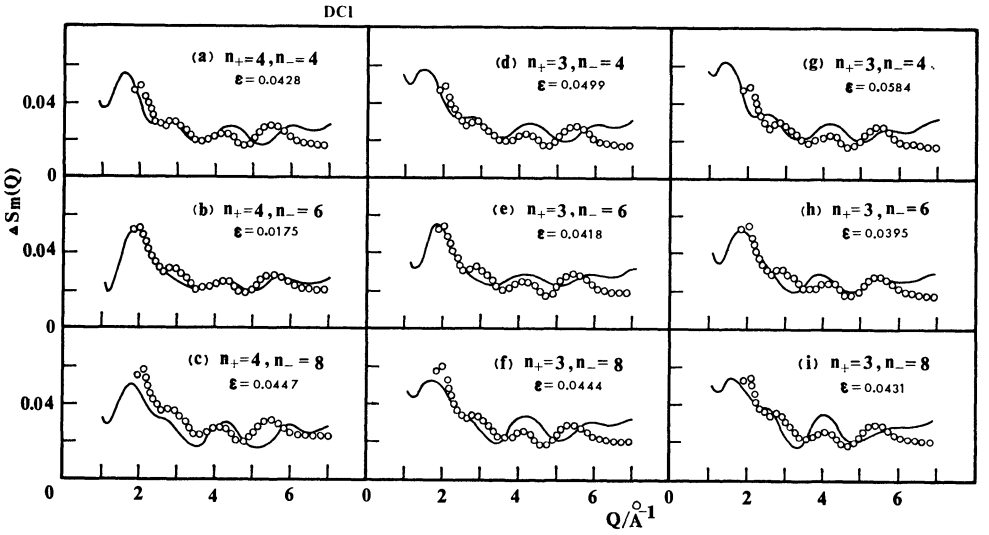

Fig. 2. Changes in the $\Delta S_m(Q)_{calcd}$ with variation of the coordination number for DCl solution. ○: $\Delta S_m(Q)_{obsd}$, ——: $\Delta S_m(Q)_{calcd}$, tetrahedral ($n_+=4$): (a) $n_-=4$, (b) $n_-=6$, and (c) $n_-=8$, pyramidal ($n_+=3$): (d) $n_-=4$, (e) $n_-=6$, and (f) $n_-=8$, planar ($n_+=3$): (g) $n_-=4$, (h) $n_-=6$, and (i) $n_-=8$.

figuration, 2) all those take the bifurcated one, and 3) one non-hydrogen-bonded molecule takes the bifurcated one and others the linear, and also for the pyramidal and/or planar configurations, two cases, 1) and 2), were taken. Distances were varied successively at intervals of 0.03 Å for the O–O distances and 0.05 Å for other ion-oxygen ones. As a whole, we calculated the $\Delta S_m(Q)_{calcd}$ curves for 516 different structure models of the first hydration shell in the DCl solution and those for 625 different models in the DBr solution, and then determined the best structure model by the comparison of $\Delta S_m(Q)_{calcd}$ with $\Delta S_m(Q)_{obsd}$ for both solutions.

Determination of the Best Fit Model: The procedure for determination of the best fit structure model is as follows. First the $\Delta S_m(Q)_{calcd}$ calculated by the above-mentioned procedures were compared by a rough estimation with the $\Delta S_m(Q)_{obsd}$ in the range of Q, 2—5 Å^{-1} and the models which gave appreciable deviations of the $\Delta S_m(Q)_{calcd}$ curves from the $\Delta S_m(Q)_{obsd}$ were excluded. Next, for the remaining $\Delta S_m(Q)_{calcd}$ curves, we calculated the deviations expressed as

$$\varepsilon = \{\sum_{i=1}^{N}[\Delta S_m(Q_i)_{obsd} - \Delta S_m(Q_i)_{calcd}]^2\}^{1/2} / \sum_{i=1}^{N}[\Delta S_m(Q_i)_{obsd}], \quad (4)$$

where N is the number of data points in the fitting region, and used ε as a measure for the fitness of the model. In the present study, the fitting region with respect to $\Delta S_m(Q)$ is taken to be Q=2—7 Å^{-1}.

In Figs. 2 and 3, the $\Delta S_m(Q)_{calcd}$ for different sets of coordination numbers are compared with the $\Delta S_m(Q)_{obsd}$ data for the DCl and DBr solutions. The values of ε calculated for each case are indicated. The ε_{min} is 0.0175 and 0.0347 for the DCl and DBr solutions, respectively. Thus, the best fit curve with $\Delta S_m(Q)_{obsd}$ is obtained in the case of $n_{D_3O^+}=4$ and $n_{Cl^-}=6$ for the DCl solution (Fig. 2(b)) and also obtained in the case of $n_{D_3O^+}=4$ and $n_{Br^-}=6$ for the DBr solution (Fig. 3(b)). The curves other than the best fit one deviate appreciably from the $\Delta S_m(Q)_{obsd}$ ($\varepsilon > \varepsilon_{min}$). In the case of $n_{D_3O^+}=3$, all curves are found to deviate from the observed ones ($\varepsilon > \varepsilon_{min}$) appreciably, and, thus, the structure models with

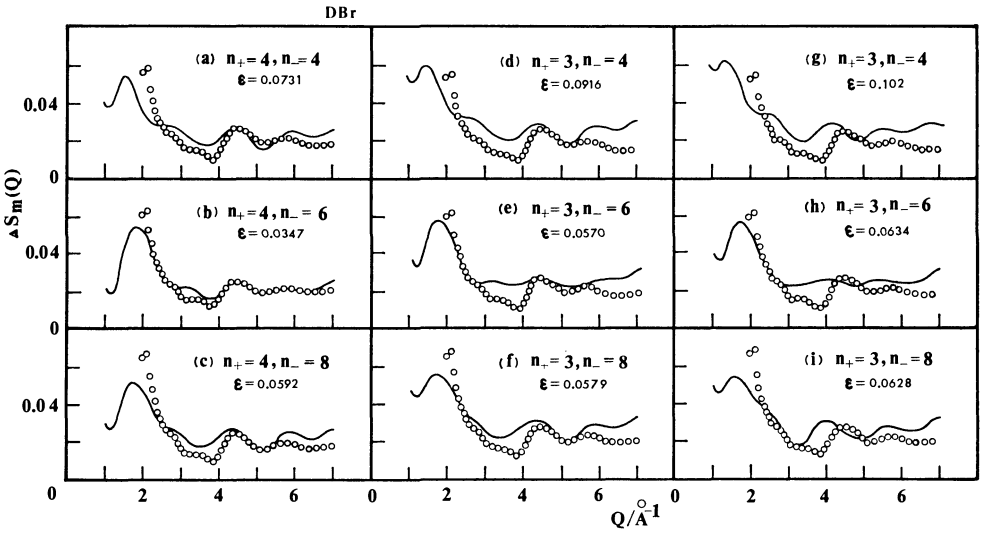

Fig. 3. Changes in the $\Delta S_m(Q)_{calcd}$ with variation of the coordination number for DBr solution. ○: $\Delta S_m(Q)_{obsd}$, ——: $\Delta S_m(Q)_{calcd}$, tetrahedral ($n_+=4$): (a) $n_-=4$, (b) $n_-=6$, and (c) $n_-=8$, pyramidal ($n_+=3$): (d) $n_-=4$, (e) $n_-=6$, and (f) $n_-=8$, planar ($n_+=3$): (g) $n_-=4$, (h) $n_-=6$, and (i) $n_-=8$.

$n_{D_3O^+}=3$ are rejected.

For $n_+=4$ and $n_-=6$, the $\Delta S_m(Q)_{calcd}$ curves with various magnitudes of the distances (r_{O-O}, r_{Cl^--O}, and r_{Br^--O}) are shown in Figs. 4(a)—(d), together with the parabolic curves in Figs. 4(a')—(d') required for locating the value of ε_{min}. For the distance r_{O-O} the ε_{min} exists at $r_0=2.88$ Å in both solutions, and that for r_{Cl^--O} and r_{Br^--O} exists at $r_0=3.10$ Å and $r_0=3.21$ Å in the DCl and DBr solutions, respectively. If we can introduce a range of allowance for ε, variations of distances can be determined. Then, taking account of the experimental errors, we set up the range, $\varepsilon<0.02$ for the DCl solution and $\varepsilon<0.035$ for the DBr solution. As a result, the deviations are found to be ±0.05 Å for all the distances.

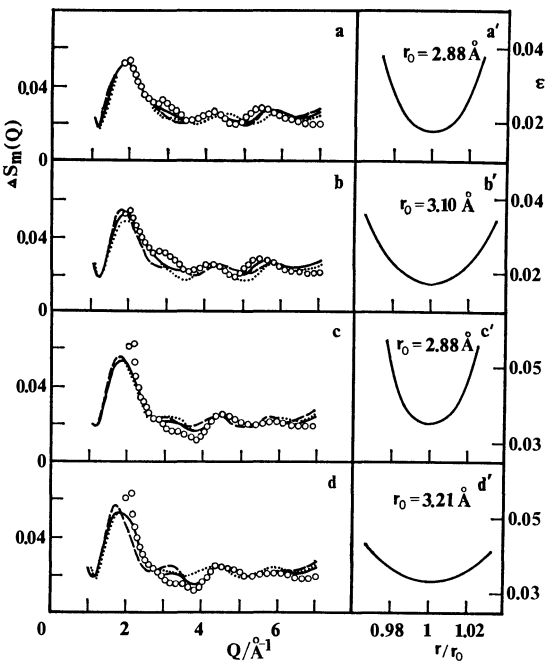

Fig. 4. Changes in the $\Delta S_m(Q)_{calcd}$ with variation of the O–O distance and the ion-oxygen distance for DCl (a, b) and DBr (c, d) solutions, and variation of ε with distances (a'—d').
○: $\Delta S_m(Q)_{obsd}$, (a), (c) r_{O-O} (all other parameters are identical with those given in Table 3), ……: 2.82 Å, ——: 2.88 Å, ----: 2.94 Å, (b) r_{Cl^--O} (all other parameters are identical with those given in Table 3), ……: 3.00 Å, ——: 3.10 Å, ----: 3.20 Å, (d) r_{Br^--O} (all other parameters are identical with those given in Table 3), ……; 3,15 Å, ——: 3.25 Å, ----: 3.35 Å.

In Figs. 5(a)—(d), the $\Delta S_m(Q)_{calcd}$ curves with various orientational configurations for the same set of coordination numbers ($n_+=4$ and $n_-=6$) are shown. Applying the same criterion ($\varepsilon<0.02$ for the DCl solution and $\varepsilon<0.035$ for the DBr solution) to these cases, linear configurations for D_3O^+ and bifurcated ones for anions are accepted as the best fit for both solutions.

The $\Delta S_m(Q)_{calcd}$ curves of the best models thus determined are given in Figs. 2(b) and 3(b) for the DCl and DBr solutions, respectively. The magnitudes of parameters and orientational configurations for the best fit models of the first hydration shell are given in Table 3.

Concerning the configurations of water molecules within the first hydration shell around D_3O^+, it is

TABLE 3. COORDINATION NUMBERS, O-O DISTANCES, ION-OXYGEN DISTANCES, AND ORIENTATIONAL CONFIGURATIONS AROUND IONS DETERMINED IN THE PRESENT STUDY

Ion	Coordination number	O-O and ion-oxygen distance/Å	Configuration around ion
D_3O^+	4	O-O: 2.88±0.05	Linear
Cl^-	6	Cl⁻-O: 3.10±0.05	Bifurcated
Br^-	6	Br⁻-O: 3.21±0.05	Bifurcated

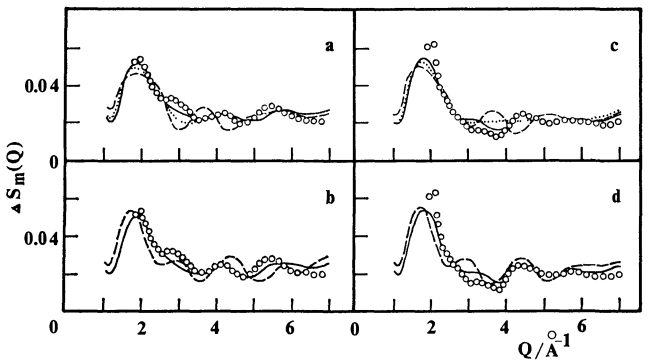

Fig. 5. Changes in the $\Delta S_m(Q)_{calcd}$ with variation of orientational configurations around ions for DCl (a, b) and DBr (c, d) solutions. ○: $\Delta S_m(Q)_{obsd}$, (a) confifurations around D_3O^+ (all other parameters are identical with those in Table 3), ……: one non-hydrogen-bonded water molecule takes the bifurcated configuration and others are the linear (ε=0.0252), ——: all peripheral water molecules take the linear configuration (ε=0.0175), ----: all peripheral water molecules take the bifurcated configuration (ε=0.0351), (b) configurations around Cl^- (all other parameters are identical with those given in Table 3), ——: bifurcated (ε=0.0175), ----: linear (ε=0.0432), (c) configurations around D_3O^+ (all other parameters are identical with those given in Table 3), ……: one non-hydrogen-bonded water molecule takes the bifurcated configuration and others are the linear (ε=0.0376), ——: all peripheral water molecules take the linear configuration (ε=0.0347), ----: all peripheral water molecules take the bifurcated configuration (ε=0.0507), (d) configurations around Br^- (all other parameters are identical with those given in Table 3), ——:bifurcated (ε=0.0347), ----: linear (ε=0.0554).

concluded that the "linear" type[8,9] of all water molecules is predominant for both solutions (Figs. 5(a) and (c)). On the other hand, with respect to the configurations around anions, it is concluded that the "bifurcated" type[8,9] is predominant for both solutions (Figs. 5(b) and (d)). The structure of the first shell around Cl^- in the DCl solution is found to be identical with those in aqueous alkali chloride solutions previously determined by the authors.[8,9] With respect to the coordination number around Cl^-, Triolo and Narten assigned the value of n_{Cl^-}=4 in their analysis (Ref. 5). However, as clearly seen in Figs. 2(a), (d), and (g), the tetrahedral coordination for Cl^- is rejected and n_{Cl^-}=6 is assigned. This difference between our results and those by Triolo and Narten is attributed to the difference in the concentration of solution.

In the present application of the "subtraction method" by using Eq. 3 we have taken the magnitude of

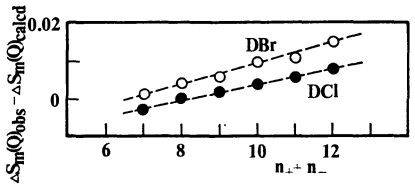

Fig. 6. $\Delta S_m(Q)_{obsd} - \Delta S_m(Q)_{calcd}$ plotted against $(n_+ + n_-)$.

a for 1/2 described above. In Fig. 6, the differences $\Delta S_m(Q)_{obsd} - \Delta S_m(Q)_{calcd}$[9] are plotted again against $(n_+ + n_-)$. The differences are substantially zero within the maximum range of 0.01. This supports the adequacy of the assignment of a as 1/2 (see Fig. 8 in Ref. 9).

A Theoretical Approach to the Dielectric Relaxation of Alcohol Solutions

Ryuichi MINAMI, Koichi ITOH,* Hiroshi SATO, Hiroaki TAKAHASHI, and Keniti HIGASI

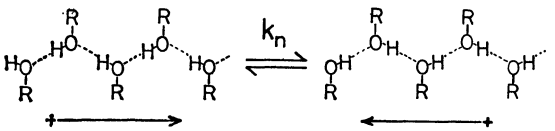
Department of Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160

(Received September 10, 1980)

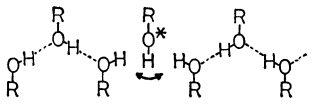
The dielectric relaxation mechanism of primary alcohols in solutions of various solvents with and without a hydrogen-bonding capacity was theoretically studied using the concept of the chemical equilibrium between hydrogen-bonded chain multimers and that between the multimers and solvents. The dipole-inversion processes originating from the successive rotation of the hydroxyl groups of the hydrogen-bonded multimers were considered to play the dominant role in the dielectric relaxation of alcohol solutions. By applying the one-dimensional random-walk process to the dipole inversion, we estimated the effect of dilution upon the dielectric relaxation times of primary alcohol in solution. The results of our calculation appear to explain the experimental data.

The dielectric relaxation of liquid alcohols was first studied by Mizushima[1] in 1926; since then, the theoretical explanation of its mechanism has become a long-standing problem which has never been solved clearly.[2-4] For the last decade some of the present authors have joined in examining the effect of dilution on the principal relaxation times of several alcohols, using inert solvents (*e.g.*, benzene) as well as those with functional groups (*e.g.*, pyridine and dioxane) as diluents.[5-8] In spite of these studies, it has still been difficult to give a simple molecular model for the dipole-inversion process of alcohol solutions in which various sorts of intermolecular hydrogen-bond interactions and steric hindrances are supposed to exist.[9] On the other hand, the theoretical explanation of the static dielectric constants of liquid alcohols has successfully been performed by several authors.[10-12] For example, Dannhauser[13] experimentally determined the values of the Kirkwood correlation factor,[11] g, for eight isomers of octanols and analyzed the data in terms of the thermodynamic equilibrium constants for cyclic-dimer and open-chain multimer formations.

Recently we ourselves proposed a new theoretical treatment of the dielectric relaxation process of pure liquid alcohols.[14] Following Dannhauser's treatment,[13] we assumed that liquid alcohol molecules exist in an association equilibrium involving both hydrogen-bonded cyclic dimers and open-chain n-mers, and, further, that each of the n-mers alters or reverses its dipole moment by the successive rotation of the indivisual hydroxyl group, as is shown in Scheme 1. This inversion process was assumed to be the main mechanism of the dipole relaxation of the hydrogen-bonded chain n-mers. Scheme 2 shows an intermediate state of the dipole inversion from the left multimer to the right one in Scheme 1. The hydroxyl group with an asterisk in Scheme 2 indicates a rotationally activated state. The dipole inversion of the n-mers is considered always to originate at the terminal molecules because, in order to activate one of the terminal segments, it needs to break only one



Scheme 1.



Scheme 2.

hydrogen bond, while two hydrogen bonds must be broken to activate an intermediate segment. Therefore, the inversion process can be regarded as the most probable process by which the activated state propagates from the left end to the right end, or from the right end to the left end. In our treatment, we applied the one-dimensional random-walk model with two absorption walls to these dipole inversion processes,[15] and concluded that the relaxation time, τ_n, of the n-mer is given by:

$$\tau_n = (n+1)\tau_H, \quad (1)$$

where τ_H is the reciprocal of k_H, the rate in which the terminal hydroxyl groups of the n-mer are activated rotationally. By using Eq. 1 and the values of the thermodynamic equilibrium constants for the cyclic dimer and chain n-mer formations, we calculated the complex permitivities as a function of the angular frequency, ω, of the field. The results are in fair agreement with the dielectric dispersion observed for liquid 1-heptanol.[16]

Sack also developed a theory for the relaxation process of a system containing linear chains of dipoles and applied it to explain the high dielectric constants and losses of long-chain alcohols in the solid state.[17] He assumed that there exists, at most, one discontinuity where two anti-parallel arrangements of the hydroxyl groups of alcohols face each other, and that the wandering of this discontinuity along each chain is the main mechanism of the dipole relaxation. It was concluded that the effective relaxation time of a linear chain n-mer is proportional to $(n+1)^2$. This mechanism, however, cannot be applied to the dielectric relaxation process of liquid alcohols because, immediately after a discontinuous point appears, a pair of anti-parallel chains should separate and move away from each other in the liquid state.

In this paper we extend the above-mentioned theory to include the effect of the addition of inert solvents as well as those with functional groups, which form hydrogen bonds, on the dielectric relaxation mechanism of alcohols. We also give a theoretical prediction regarding the dilution effect on the re-

laxation times of alcohol solutions. The results are compared with the experimental data.

Stoichiometry of Association Equilibria between Alcohol Monomers and Multimers and between Multimers and Solvents

The binary solutions of primary alcohols and solvents are assumed to consist of alcohol monomers, A_1; solvent molecules, B; hydrogen-bonded cyclic dimers,† A_c; hydrogen-bonded open-chain n-mers, A_n, and, if B has proton-acceptor groups, open-chain n-mers hydrogen-bonded with the solvent at one end, A_nB. As is the case with pure alcohols, the association equilibria can be expressed as follows:

i) Cyclic dimer: $A_1 + A_1 \overset{K_c}{\rightleftharpoons} A_c$,

ii) open-chain n-mer: $A_{n-1} + A_1 \overset{K_n}{\rightleftharpoons} A_n \quad (n \geqq 2)$,

where K_c and K_n are the equilibrium constants of the formation of the cyclic dimer and the open-chain n-mer respectively. When the solvent molecule, B, can form a hydrogen bond with the hydroxyl group of alcohols, we also assume the following equilibrium between A_n and B:

iii) addition compound: $A_n + B \overset{K_{nb}}{\rightleftharpoons} A_nB \quad (n \geqq 1)$,

where K_{nb} is the equilibrium constant of the association between A_n and B. As the mole fraction of the solvent molecules with the hydrogen-bond capacity is increased, the average degree of the association of alcohol multimers is decreased. This can be seen in the following stoichiometric calculations.

The stoichiometric relationships for the association equilibria mentioned above have been studied extensively,[13] and the volume fractions[18] of A_1, A_c, A_n, A_nB, and B, which are expressed as ϕ_1, ϕ_c, ϕ_n, ϕ_{nb}, and ϕ_b, are related to each other by the following equations:

$$\left.\begin{aligned} \phi_c &= K_c\phi_1^2, \\ \phi_n &= (K\phi_1)^{n-1}\phi_1, \\ \phi_{nb} &= (K\phi_1)^{n-1}\phi_1 K_b\phi_b, \end{aligned}\right\} \tag{2}$$

where we assumed that:[19]

$$K \equiv K_2 = K_3 \ldots = K_n = \ldots,$$

and

$$K_b \equiv K_{1b} = K_{2b} = \ldots = K_{nb} = \ldots .$$

The sum of the volume fractions is equal to one, giving this equation:

$$\sum_{n=1}^{\infty} \phi_n + \phi_c + \sum_{n=1}^{\infty} \phi_{nb} + \phi_b = 1. \tag{3}$$

The total mole fraction of the solvent B, x_B, can be expressed as follows:

$$\sum_{n=1}^{\infty} \phi_{nb}/(n+1) + \phi_b = x_B. \tag{4}$$

From Eqs. 2, 3, and 4, we derive the following transcendental equations:

$$(1+K_b\phi_b)\phi_1/(1-K\phi_1) + K_c\phi_1^2 + \phi_b = 1, \tag{5}$$

$$\phi_b - \{\ln(1-K\phi_1) + K\phi_1\}K_b\phi_b/K^2\phi_1 = x_B. \tag{6}$$

The numerical calculations[20] using Eqs. 5 and 6 give the ϕ_1 and ϕ_b values as functions of x_B for the assumed K, K_c, and K_b values. On the substitution of the ϕ_1 and ϕ_b values into Eq. 2 we can obtain the ϕ_c, ϕ_n, and ϕ_{nb} values as functions of x_B.

Dielectric Relaxation of Alcohol Solutions

The dielectric dispersion observed for alcohol solutions is the sum of the contributions from the dielectric relaxations of A_n, A_nB, and A_1 (and B, if it is a polar molecule.) The cyclic dimer A_c has no permanent dipole moment, and it does not contribute to the dielectric dispersion. The dielectric relaxation times of all the polar solvent molecules are, in general, very much smaller than those of the multimers. For this reason, the contribution from the solvent can also be neglected. We applied the one-dimensional random walk model also to the dipole inversion process of A_nB. The mechanism of its stochastic process, however, is a little different from that of the dipole inversion process of A_n. The reason for this is that activating the alcohol segment neighboring B requires a mechanism different from that required to activate one of the end segments in A_n. Therefore, we use the $\tau_{H'}$, symbol for the activation of the alcohol segments at the ends of A_nB instead of the symbol, τ_H, for the activation of the end segment of A_n. The relaxation time of the dipole inversion of A_nB, τ_{nb}, is expressed by:

$$\tau_{nb} = (n+1)\tau_{H'}. \tag{7}$$

The weights of the contributions of the multimers, A_n and A_nB, to the dielectric dispersion are proportional to the values of ϕ_n/n and $\phi_{nb}/(n+1)$, which represent the proportions of A_n and A_nB respectively, and are also proportional to the expected values of their squared dipole moments, $\langle\mu_n^2\rangle$ and $\langle\mu_{nb}^2\rangle$ respectively. In this paper we assume that μ_n is approximately equal to μ_{nb} and that $\langle\mu_n^2\rangle$ is proportional to n^2.†† On the basis of these considerations, we obtain the following equations:

$$\frac{\varepsilon^*-\varepsilon_\infty}{\varepsilon_0-\varepsilon_\infty} = Z^{-1}\left\{\frac{\phi_1}{1+i\omega\tau_1} + \sum_{n=2}^{\infty}\frac{n\phi_n}{1+i\omega(n+1)\tau_H} + \sum_{n=1}^{\infty}\frac{n^2\phi_{nb}/(n+1)}{1+i\omega(n+1)\tau_{H'}}\right\}, \tag{8a}$$

$$Z \equiv \sum_{n=1}^{\infty}(n\phi_n + n^2\phi_{nb}/(n+1)) = \phi_1/(1-K\phi_1)^2 + K_b\phi_b[K\phi_1^2/(1-K\phi_1)^2 - \{\ln(1-K\phi_1)+K\phi_1\}/K^2\phi_1], \tag{8b}$$

where ε^*, ε_0, and ε_∞ are the complex, static, and limiting high-frequency permitivities respectively.

† Cyclic trimers, cyclic tetramers, *etc.* are not considered here, after Dannhauser.[13]

†† For an extremely large n, $\langle\mu_n^2\rangle$ and $\langle\mu_{nb}^2\rangle$ would be proportional to n instead of n^2.[21] Our calculation, however, indicates that the average numbers $\langle n\rangle$, are 6.6, 8.7, and 10.8 for K=20, 30, and 40 respectively. For A_n and A_{nb} with these small n values, it is reasonable to assume that $\langle\mu_n^2\rangle$ and $\langle\mu_{nb}^2\rangle$ are proportional to n^2.

As is well known, the dielectric constants and losses of most of the liquid alcohols measured in the low-frequency region conform very well to the simple relaxation pattern of Debye. (This dispersion is often called "the principal dielectric dispersion", and the relaxation time corresponding to this dispersion, "the principal relaxation time".) On the other hand, some strong deviation from the simple Debye dispersion have been detected in the high-frequency region.[3] If we limit our discussion only to the low-frequency dispersions or the principal dispersions, we can express the measured complex permitivities of alcohol solutions by the well-known Debye equation:

$$(\varepsilon^*-\varepsilon_\infty)/(\varepsilon_0-\varepsilon_\infty) = 1/(1+i\omega\tau_p), \quad (9)$$

where τ_p is the principal relaxation time. By equating the right-hand side of Eq. 8a to that of Eq. 9, τ_p can be calculated as a function of ω. The results of calculation for several sets of the assumed values of K, K_b, K_c, and τ_H (assuming that τ_H is equal to $\tau_{H'}$) indicate that the calculated values of τ_p do not depend on ω so long as ω is less than $1/\tau_H$. On the basis of this result, we obtained the analytical equation of τ_p at the low-frequency limit(: $\omega\to 0$) as follows:

$$\tau_p = Z^{-1}\left\{\sum_{n=2}^{\infty} n(n+1)\tau_H\phi_n + \sum_{n=1}^{\infty} n^2\tau_H\phi_{nb}\right\}$$
$$= (\tau_H\phi_1/Z)[\{2+(1+K\phi_1)K_b\phi_b\}/(1-K\phi_1)^3-2], \quad (10)$$

where the contribution of alcohol monomers to the dielectric dispersion is neglected because τ_1 is much smaller than τ_n and τ_{nb} ($n\geqq 2$). This equation allows us to calculate the principal dielectric relaxation times of alcohol solutions for the assumed K, K_b, K_c, and τ_H values.

Effect of Dilution on Dielectric Relaxation Times of Alcohol Solutions

When an inert solvent is used as a diluent of alcohol solution, it can be assumed that K_b is equal to zero. Since primary alcohols associate strongly with each other, K is expected to be much larger than one, giving the condition $K\cdot x_A \gg 1$ (x_A denotes the total mole fraction of alcohol molecules, *viz.*, $x_A = 1-x_B$; its value is set so as to be always larger than 1/2.) A tentative assumption that K_c is equal to zero is also made because the K_c value of primary alcohol was experimentally found to be much smaller than the K value, and also because the cyclic dimers do not contribute to the dielectric dispersion of alcohol solutions.[13] Under these conditions, we can derive the analytical expression for ϕ_1 from Eqs. 5 and 6:

$$\phi_1 = x_A/(1+Kx_A). \quad (11)$$

On the substitution of Eq. 11 into Eq. 10, we obtain an approximate expression for τ_p defined by Eq. 9:

$$\tau_p = 2(1+Kx_A)\tau_H. \quad (12)$$

As can be seen from Fig. 1, the observed principal dielectric relaxation times of 1-propanol decrease linearly as the mole fractions of benzene are increased. From the variation in the observed principal dielectric relaxation times of 1-propanol and 1-butanol caused by the addition of benzene,[5,6] we can determine the values of K and τ_H. The results are summarized in Table 1.[22]

When the solvent has a functional group or groups which form a hydrogen bond or bonds with alcohols, K_b becomes much different from zero. In this case, we must use Eq. 10 in order to estimate the principal relaxation times of the solutions. Assuming that K is equal to 30 (*cf.* Table 1), we calculated the principal relaxation times of 1-propanol as functions of x_B, while varying the K_b from 0.5 to 30.0. The results are

Table 1. Experimental principal relaxation times, τ_p, for an alcohol/benzene mixture and estimated values of K and τ_H[a]

1-Propanol (25 °C)[b]		1-Butanol (25°C)[b]	
x_A[c]	τ_p/ps	x_A	τ_p/ps
1.0	338	1.0	504
0.920	324	0.899	472
0.886	294	0.806	422
0.788	279	0.670	353
0.691	235	0.620	314
K	τ_H/ps	K	τ_H/ps
30	5.5	41	6.1

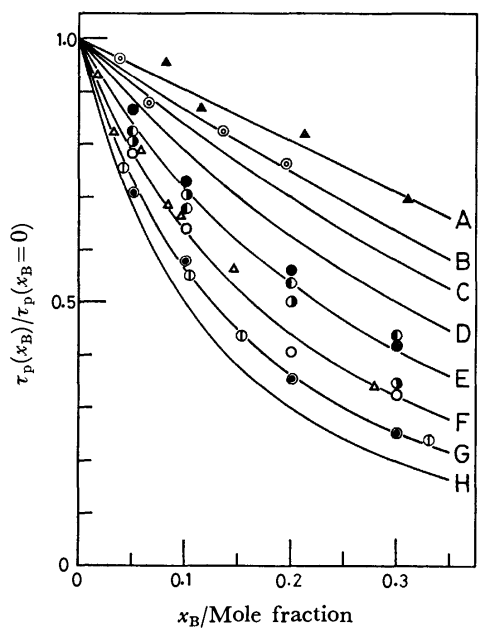

Fig. 1. Variation of principal dielectric relaxation times due to dilution with various solvents. Solid curves are theoretical results obtained from Eq. 10 with $K=30$ and $K_c=0$. The values of K_b for curves (A), (B),.., (H) are 0, 0.5, 1.0, 2.0, 4.0, 8.0, 15.0, and 30.0, respectively. The experimental data are for the 1-propanol solutions at 25 °C which are diluted with the following solvents.[5,6,8]
▲: Benzene, ◎: chlorobenzene, ●: water, ◐: camphor, ◑: cyclohexanone, △: pyridine, ○: 3-pentanone, ◉: acetone, ⓘ: dioxane.

shown by solid curves in Fig. 1. Into this figure we add also the result of calculation for the case when K_b is equal to zero. This theoretical curve (*i.e.*, (A)), which decreases linearly with the increase in x_B, compares well with the data of the principal relaxation time observed for the 1-propanol/benzene mixtures. Our previous papers[5-8] have shown that, when solutions are diluted with solvents having a hydrogen-bond capacity, the principal relaxation times of the solutions change in quite different manners from those in which the relaxation times of alcohol solutions change as they are diluted with inert solvents. As the results summerized in Fig. 1 show, the principal relaxation times of mixtures of 1-propanol and solvents with a hydrogen-bond capacity do not exibit a linear decrease with dilution, and this decrease is more pronounced than that observed for the 1-propanol/benzene system. The results of calculation for the K_b in the range from 4 to 15 correspond very well to the abovementioned observation.

Conclusion

Our mechanism, which was originally proposed to explain the anomalous dielectric relaxation behavior of pure primary alcohols, has now been extended to an examination of the effect of dilution upon the principal dielectric relaxation of 1-propanol using both inert and hydrogen-bonding solvents. The results obtained so far are in fair agreement with the experiments, confirming that our theory is valid for the dielectric relaxation of the liquid primary alcohols.

We are grateful to Dr. R. J. Meakins for providing us with valuable materials on his and Dr. Sack's work.

22) A maximum in τ_p *vs.* x_B curves was observed by Sagal[23] and Komooka[24] for alcohol–cyclohexane solutions. This suggests that the nature of benzene as a solvent is different from that of inert solvents, such as cyclohexane and hexane.[25] We can suspect that the properties of a solvent cause the dependency of τ_H in Eq. 12 upon the atmosphere surrounding alcohol molecules or, rather, surrounding the end OH group of the molecule. In this case, we can tentatively put $\tau_H=\tau_H(A)x_A+\tau_H(B)x_H$, where $\tau_H(A)$ is associated with the hydrogen-bonded chain in pure alcohols, and $\tau_H(B)$, with that isolated from each other with solvent molecules. On the basis of this assumption, we calculated τ_p *vs.* x_B while varying the $\tau_H(B)/\tau_H(A)$ ratio. The result of calculation shows a maximum in fair agreement with the observations of Sagal and Komooka.

(Received September 18, 1980)

A theory for the ion transport across liquid ion-exchange membrane was presented on the basis of nonequilibrium thermodynamics with the assumptions that the carrier ions and complexes were present only in the membrane phase, and that there was no volume flow and all chemical reactions were at equilibrium. The equations for "total" fluxes of membrane-permeable ions at steady state were derived from a set of the equations for "individual" fluxes of all mobile species present in the liquid membrane where the complexes were assumed to be partially dissociated. The "total" phenomenological coefficients were able to be expressed in terms of the "individual" coefficients. The diffusional and electroconductional membrane permeabilities to a selective ion in the liquid membrane–single electrolyte system were found to be in the same form as those in the fixed-site membrane–single electrolyte system, if the mean diffusion coefficient and mean mobility of the free species and its complex were used. The rate constants in the permeation process were also related to the diffusional membrane permeability. The experimental examination was made on a liquid cation-exchange membrane–aqueous single electrolyte system at 25 °C. The solution of calcium hexadecyl sulfate in 1-octanol and calcium chloride were used as the liquid membrane and the electrolyte, respectively. All the measured quantities were consistently interpreted by the presented theory.

Since the carrier model was introduced into the transport phenomena across cell membranes, liquid membranes having carrier species have been extensively studied by many investigators.[1,2] On the other hand, various ion-selective electrodes using liquid membranes have been devised and commercialized, because of their high selectivity to a particular ion.[3] Current research has been carried out to provide the underlying principle for the separation of metal ions by liquid membranes.[4,5]

In spite of numerous experimental works, theories proposed for the ion transport across liquid membrane are not as many as for the fixed-site membrane. The theory of Eisenman and his coworkers[6–9] has usually been applied to analyze the ion transport phenomena through liquid membranes, but it has been derived from the Nernst-Planck equation with some assumptions. A rigorous theory for the ion transport across fixed-site membrane has been presented in a previous paper on the basis of nonequilibrium thermodynamics without any assumptions concerning the distributions of concentration and potential within membrane.[10]

In the preceding paper,[11] an electrochemical study of the ion permeation has been made on a liquid membrane–aqueous single electrolyte system. The membrane permeabilities to the membrane-permeable ion p in the presence and absence of electric current, P_p and P_p^0, have been estimated according to the previous theory.[10] A remarkable discrepancy between P_p and P_p^0 has been observed and explained in terms of the permeability matrix. The theory of Eisenman *et al.* can not distinguish these two permeabilities since their theory is based on the Nernst-Planck equation which possesses only one transport coefficient for an ion.

In the preceding paper,[11] the theory of ion transport for the fixed-site membrane has been applied to estimate P_p and P_p^0 in the liquid membrane since the equation describing the ion transport can be deduced to have the same form for both systems.[12] However, the entities of physical representations for the membrane permeabilities, P_p and P_p^0, for the liquid membrane are supposed to be different from those for the fixed-site membrane, because the site ion as well as the complex is mobile in the liquid membrane.

Thus a theory for the liquid membrane was presented on the basis of nonequilibrium thermodynamics by taking into account the movements of the site ions and complexes in the liquid membrane. The experimental examination was also made with a liquid membrane–aqueous single electrolyte system.

Theoretical

System and Assumptions. We shall consider the ion transport phenomena in the system illustrated in Fig. 1. An aqueous phase I is separated by a liquid ion-exchange membrane from another aqueous phase II. The membrane phase is bounded by two planes normal to the x-axis at $x=0$ and $x=d$. There are stagnant layers on both sides of the membrane phase and their surfaces are in contact with the phase I at $x=-a$ and phase II at $x=b$, respectively. The two aqueous phases I and II are homogeneous be-

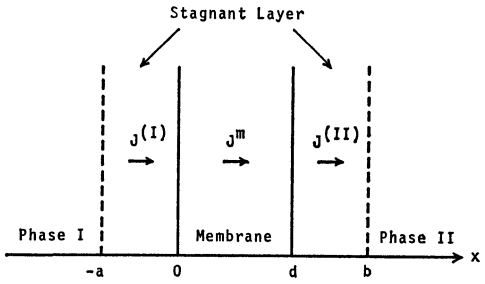

Fig. 1. Schematic diagram of the liquid membrane–aqueous electrolyte system.

cause of being well stirred. It is assumed that the system is isothermal and in a steady state in which there is no volume flow (Assumption 1), and the ion fluxes are constant. Moreover, all the chemical reactions are assumed to be at equilibrium anywhere within the membrane phase (Assumption 2) and a free carrier ion and its electrically neutral complexes are present only within the membrane phase (Assumption 3).

Flux Equation for Individual Species. Only counter- and co-ions can permeate across the liquid membrane, although all the species within membrane are mobile. The total flux of a permeable ion is the sum of the flux of free species and those of complexes. We shall first derive the flux equation for individual species in the membrane which will later be correlated with the total flux for the membrane-permeable species.

According to nonequilibrium thermodynamics, the flux of individual species, j_α, is given as a linear function of all forces that are negative gradients of the total chemical potentials

$$j_\alpha = -\sum_\beta l_{\alpha\beta}\nabla\bar{\mu}_\beta, \tag{1}$$

where α and β refer to all species in the membrane and $l_{\alpha\beta}$ indicates a phenomenological coefficient and satisfies the reciprocal relation of Onsager. Under the condition of chemical equilibrium, we have

$$\bar{\mu}_i = \sum_\gamma \nu_{\gamma i}\bar{\mu}_\gamma, \tag{2}$$

where the subscript i refers to the electrically neutral complex formed in the i-th reaction and $\nu_{\gamma i}$ denotes the stoichiometric coefficient of the free species γ in the i-th reaction. Since the complex is electrically neutral, we have

$$Z_i = \sum_\gamma Z_\gamma \nu_{\gamma i} = 0. \tag{3}$$

By substituting Eq. 2 into Eq. 1, the term for the force due to the complex can be eliminated, and the flux equations for all species can be written in terms of the forces for free species as follows:

$$j_\alpha = -\sum_\gamma l'_{\alpha\gamma}\nabla\bar{\mu}_\gamma, \tag{4}$$

where

$$l'_{\alpha\gamma} = l_{\alpha\gamma} + \sum_i \nu_{\gamma i} l_{\alpha i}. \tag{5}$$

The total chemical potential for species α, $\bar{\mu}_\alpha$, is expressed as[10]

$$\bar{\mu}_\alpha = \eta_\alpha + RT\ln a_\alpha + Z_\alpha F\psi = RT\ln\bar{\lambda}_\alpha, \tag{6}$$

where

$$\eta_\alpha = \mu_{\alpha,0} + p\bar{V}_\alpha + \xi_\alpha. \tag{7}$$

$\mu_{\alpha,0}$ denotes the standard chemical potential; a, the activity; ψ, the electric potential; p, the hydrostatic pressure; $\bar{V}$, the partial molar volume; ξ, the excess free energy; $\bar{\lambda}$, the absolute activity; and F, the Faraday constant.

By use of local electric potential, ψ, and equilibrium local electric potential for free ion γ, ψ_γ, the gradient of $\bar{\mu}_\gamma$ can be expressed alternatively as

$$\nabla\bar{\mu}_\gamma = Z_\gamma F\nabla(\psi-\psi_\gamma). \tag{8}$$

Using Eqs. 4 and 8, the individual ionic current for species α is given by

$$i_\alpha = Z_\alpha F j_\alpha = -\sum_\gamma \kappa'_{\alpha\gamma}\nabla(\psi-\psi_\gamma), \tag{9}$$

where $\kappa'_{\alpha\gamma}$ denotes a part of electric conductivity produced by the effective driving force of ion γ, $\nabla(\psi-\psi_\gamma)$ and given as

$$\kappa'_{\alpha\gamma} = Z_\alpha Z_\gamma F^2 l'_{\alpha\gamma}. \tag{10}$$

Electric Conductivity for Individual Species. According to Eq. 9, the electric conductivity of species α, κ'_α, is given by[13,14]

$$\kappa'_\alpha = \sum_\gamma \kappa'_{\alpha\gamma} = \sum_\gamma Z_\alpha Z_\gamma F^2 l_{\alpha\gamma} = (Z_\alpha F)^2 u_\alpha C_\alpha, \tag{11}$$

where u_α and C_α denote the absolute mobility and concentration of species α, respectively.

Now, the total flux for each free species in the membrane, J^m_γ, may be written as

$$J^m_\gamma = j_\gamma + \sum_i \nu_{\gamma i} j_i, \tag{12}$$

where the superscript m refers to the membrane phase. When the steady state is attained, the following relation can be realized:

$$J^m_\gamma = J^{(I)}_\gamma = J^{(II)}_\gamma \equiv J_\gamma, \tag{13}$$

where $J^{(I)}$ and $J^{(II)}$ denote the fluxes in the stagnant layers in phases I and II, respectively. According to Eqs. 12 and 13, the total ionic current for each free species, $I_\gamma = Z_\gamma F J_\gamma$, is seen to be expressed in terms of individual fluxes of the free species and of the complexes as follows:

$$I_\gamma = Z_\gamma F j_\gamma + Z_\gamma F\sum_i \nu_{\gamma i} j_i = i_\gamma + \sum_i i_i^{(\gamma)}, \tag{14}$$

where $i_i^{(\gamma)}$ represents the part of the ionic current of species γ carried by the form of complex i.

According to Eq. 14, it is seen that the flux of the complex contributes to the total ionic currents of free species from which the complex is formed even when the complex is electrically neutral. By using Eq. 4, $i_i^{(\gamma)}$ can be represented by

$$i_i^{(\gamma)} = Z_\gamma F\nu_{\gamma i} j_i = -\sum_\delta Z_\gamma Z_\delta F^2 \nu_{\gamma i} l'_{i\delta}\nabla(\psi-\psi_\delta), \tag{15}$$

where the subscript δ refers to the free species. According to Eqs. 14 and 15, the part of the electric conductivity of species γ due to the complex i, $\kappa_i^{(\gamma)}$, can be expressed as

$$\kappa_i^{(\gamma)} = \sum_\delta Z_\gamma Z_\delta F^2 \nu_{\gamma i} l_{i\delta} = (Z_\gamma F)^2 \nu_{\gamma i} u_i C_i. \tag{16}$$

It is evident from Eq. 16 that the contribution of the diagonal term l_{ii} to $\kappa_i^{(\gamma)}$ vanishes when the complex i is electrically neutral.[14] $\kappa_i^{(\gamma)}$ is correlated with the electric conductivity of the complex i, κ'_i, as follows:

$$\kappa'_i = \sum_\gamma \kappa_i^{(\gamma)} = 0, \tag{17}$$

where the superscript γ refers to the membrane-permeable ion as well as the carrier ion.

Total-Flux Equation for Free Species γ. Substituting Eq. 4 into Eq. 12, we have under the condition of the steady state

$$J_\gamma = -\sum_\delta l''_{\gamma\delta}\nabla\bar{\mu}_\delta, \tag{18}$$

where

$$l''_{\gamma\delta} = l'_{\gamma\delta} + \sum_1 \nu_{\gamma 1} l'_{1\delta}. \tag{19}$$

We see in Eq. 19 that the new phenomenological coefficient, $l''_{\gamma\delta}$, is expressed in terms of individual coefficients, $l_{\alpha\beta}$'s, and that the reciprocal relation for individual coefficients verifies that the $l''_{\gamma\delta}$'s also satisfy the reciprocal relation.

According to Eq. 18, the total ionic current for free species γ, I_γ, is expressed as

$$I_\gamma = -\sum_\delta \kappa''_{\gamma\delta}\nabla(\phi-\phi_\delta), \tag{20}$$

where

$$\kappa''_{\gamma\delta} = Z_\gamma Z_\delta F^2 l''_{\gamma\delta} = Z_\delta Z_\gamma F^2 l''_{\delta\gamma} = \kappa''_{\delta\gamma}. \tag{21}$$

Total Electric Conductivity for Free Species γ. According to Eq. 20, the total electric conductivity for ion γ, κ''_γ, is given by

$$\kappa''_\gamma = \sum_\delta \kappa''_{\gamma\delta}. \tag{22}$$

Substituting Eq. 19 into Eq. 21 and using Eqs. 11 and 16, Eq. 22 can be rewritten as

$$\kappa''_\gamma = \kappa'_\gamma + \sum_1 \kappa_1^{(\gamma)} = (Z_\gamma F)^2(u_\gamma C_\gamma + \sum_1 \nu_{\gamma 1} u_1 C_1). \tag{23}$$

Since the carrier species are completely trapped within the membrane phase, the total flux as well as total electric current of carrier species, J_s and I_s, should be zero at the steady state, *i.e.*,

$$J_s^m = J_s^{(I)} = J_s^{(II)} \equiv J_s = 0, \tag{24}$$

and

$$I_s = Z_s F J_s = 0, \tag{25}$$

where one kind of free carrier species, s, is assumed to be present in the membrane. According to Eq. 25, the total electric conductivity for the carrier species, κ''_s, is also zero. Using Eqs. 23 and 17, we obtain

$$\kappa''_s = \kappa'_s + \sum_1 \kappa_1^{(s)} = \kappa'_s - \sum_1\sum_\gamma \kappa_1^{(\gamma)} = 0 \quad (\gamma \neq s). \tag{26}$$

By means of Eq. 24, Eq. 18 can be reduced to a phenomenological relation

$$J_p = -\sum_q l^*_{pq}\nabla\bar{\mu}_q, \tag{27}$$

where

$$l^*_{pq} = l''_{pq} - \frac{l''_{ps} l''_{sq}}{l''_{ss}}, \tag{28}$$

and p and q refer to the membrane-permeable ions. The reciprocal relation of Onsager can be satisfied by l^*_{pq} as well as $l''_{\gamma\delta}$. According to Eq. 27, we have

$$I_p = -\sum_q \kappa^*_{pq}\nabla(\phi-\phi_q), \tag{29}$$

where

$$\kappa^*_{pq} = Z_p Z_q F^2 l^*_{pq} = Z_q Z_p F^2 l^*_{qp} = \kappa^*_{qp}. \tag{30}$$

The total electric conductivity for species p, κ''_p, given by Eq. 22 can also be expressed by using κ^*_{pq} as follows:

$$\kappa''_p = \sum_q \kappa^*_{pq}, \tag{31}$$

provided Eq. 26 holds.

Single Electrolyte System. Now, we shall apply our theory to the system in which only a single strong electrolyte, $M_{\nu'_M}A_{\nu'_A}$, is present in the aqueous phases. Moreover, the carrier ion is assumed to react only with counter ion to form a neutral complex in the membrane phase. As a result, the components present in the membrane phase are counter ion, M^{z_M+}, co-ion, $A^{|z_A|-}$, carrier ion, $S^{|z_s|-}$, and complex, C.

According to Eq. 29, the ionic current can be expressed as

$$I_p = -\sum_q \kappa^*_{pq}\nabla(\phi-\phi_q) \qquad (p, q; M, A). \tag{32}$$

Therefore, Eq. 23 can be written as

$$\kappa''_M = \kappa'_M + \kappa_c^{(M)} = (Z_M F)^2 \bar{u}_M C_M^{to}, \tag{33}$$

and

$$\kappa''_A = \kappa'_A, \tag{34}$$

where

$$\kappa'_M = (Z_M F)^2 u_M C_M, \quad \kappa_c^{(M)} = (Z_M F)^2 \nu_M u_c C_c, \tag{35}$$

and

$$\bar{u}_M \equiv f u_M + \nu_M(1-f)u_c. \tag{36}$$

C_M^{to} and f denote the total concentration and dissociated fraction of ion M ($f = C_M/C_M^{to}$), respectively, and the subscript c refers to the complex.

If κ^*_{pq} is independent of the externally applied field, Eq. 32 leads to

$$I_p - I_p^0 = -\kappa''_p\nabla(\phi-\phi^0) \qquad (p; M, A), \tag{37}$$

where the superscript 0 refers to the zero electric current. Under the condition of steady state, Eq. 37 can be integrated to give

$$(I_p - I_p^0)\int_{-a}^{b}\frac{dx}{\kappa''_p} = -(V-V^0), \tag{38}$$

where V^0 denotes the membrane potential at zero electric current. Therefore, the ionic membrane conductance of ion p, g_p, is expressed as

$$\frac{1}{g_p} = \int_{-a}^{b}\frac{1}{\kappa''_p}dx. \tag{39}$$

The contribution of carrier species to the ionic conductance vanishes outside the membrane.

At zero electric current, the following relation must hold

$$I_M^0 + I_A^0 = 0. \tag{40}$$

By means of Eq. 40, one of the forces in Eq. 32 can be eliminated to give

$$I_p^0 = -\kappa_p^0\nabla(\phi^0-\phi_p) \qquad (p; M, A), \tag{41}$$

where

$$\kappa_p^0 = \frac{\kappa^*_{pp}\kappa^*_{qq} - (\kappa^*_{pq})^2}{\kappa''_q} \qquad (p, q; M, A). \tag{42}$$

According to Eq. 41, the flux equation at zero electric current is given by

$$J_p^0 = -\frac{\kappa_p^0}{(Z_p F)^2}\nabla\bar{\mu}_p^0, \tag{43}$$

where $\bar{\mu}_p^0$ denotes the total chemical potential at zero electric current. Since Eq. 43 should be of the form of the Nernst-Planck equation, it can be written as

$$J_p^0 = -\frac{\bar{D}_p C_p^{to}}{RT}\nabla\bar{\mu}_p^0, \tag{44}$$

where $\bar{D}_p$ and C_p^{to} denote the diffusion coefficient and the total concentration of ion p, respectively, and

$$\frac{\kappa_p^0}{(Z_pF)^2} = \frac{\bar{D}_p C_p^{to}}{RT}. \tag{45}$$

Comparing Eq. 45 with Eqs. 33, 35, and 36, we have

$$\bar{D}_M = f(\kappa)\bar{u}_M RT = fD_M + (1-f)D_c, \tag{46}$$

and

$$D_A = f(\kappa)u_A RT, \tag{47}$$

where

$$f(\kappa) = 1 - \kappa_{MA}^*\left(\frac{1}{\kappa_M''} + \frac{1}{\kappa_A''}\right) = \frac{\kappa_p^0}{\kappa_p''}, \tag{48}$$

and D_M and D_c denote the diffusion coefficients of ion M, and of complex C, respectively. As seen in Eq. 48, the total electric conductivity at zero electric current, κ_p^0, is different from the total electric conductivity, κ_p'', unless the cross term κ_{pq}^* is zero. Under the condition of the steady state, Eq. 41 can also be integrated to give

$$I_p^0\int_{-a}^{b}\frac{dx}{\kappa_p^0} = -(V^0 - V_p), \tag{49}$$

where V_p denotes the equilibrium membrane potential of ion p. Therefore, κ_p^0, can be related to the ionic membrane conductance at zero electric current, g_p^0, as follows:

$$\frac{1}{g_p^0} = \int_{-a}^{b}\frac{1}{\kappa_p^0}dx. \tag{50}$$

Experimental

The materials, the apparatus and the procedures for measuring membrane potential, membrane conductance and salt flux were described in detail in the preceding paper.[11]

Partition of $CaCl_2$ between 1-Octanol and Aqueous Phases. The partition ratio, R^{wm}, was determined as the ratio of equilibrium concentration of $CaCl_2$ in 1-octanol phase to that in aqueous phase. The measurements were carried out both in the presence and absence of carrier species in 1-octanol phase. Preconditioned 1-octanol was layered on the aqueous $CaCl_2$, of which the initial concentration was 0.964 mol dm^{-3}. Whole system was vigorously shaken for thirty hours at 25 °C and allowed to stand until both phases became clear, then the sample was pipetted from 1-octanol phase for determining the equilibrium concentration of $CaCl_2$. The concentration was determined with a Nippon Jarrell-Ash atomic absorption spectrophotometer Model AA-8500. The partition ratio obtained for the system without carrier species was 1.7×10^{-4} which agreed well with the value obtained by the radiotracer method.[15] The partition ratio for the system with carrier species was 6.2×10^{-4}, where the concentration of calcium hexadecyl sulfate in 1-octanol phase was 2.5×10^{-3} mol dm^{-3}.

Molar Conductivity Measurement of Calcium Hexadecyl Sulfate in 1-Octanol. The electric conductivity of calcium hexadecyl sulfate in water-saturated 1-octanol was measured by use of a Yanagimoto conductivity outfit Model MY-7. The measurements were carried out with a pair of Pt–Pt electrodes immersed in 1-octanol solution of calcium hexadecyl sulfate at 25 °C. The cell constant, *ca.* 0.05, was determined by use of a standard solution of KCl. The molar conductivity is plotted against the square root of concentration in Fig. 2.

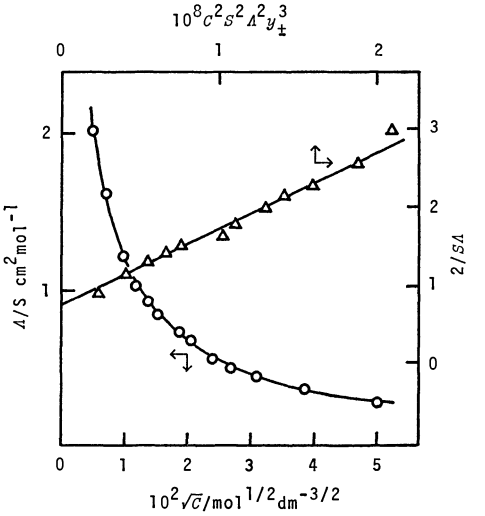

Fig. 2. Molar conductivity of calcium hexadecyl sulfate in 1-octanol as a function of square root of the concentration (○) and Shedlovsky's plot (△).

The limiting molar conductivity, Λ^∞, and the dissociation constant, K_1, were determined from Shedlovsky's plot,[16,17] $2/S\Lambda$ *vs.* $C^2S^2\Lambda^2y_\pm^3$, where

$$S = [z/2 + \{1 + (z/2)^2\}^{1/2}]^2, \tag{51}$$

and

$$z = \frac{2A'}{(\Lambda^\infty)^{3/2}}\sqrt{C\Lambda}. \tag{52}$$

A' is Onsager's coefficient; C, the concentration; $y_\pm$, the mean activity coefficient; and Λ, the molar conductivity. For the calculation of A', the values of viscosity[18] and relative permittivity[19] for pure solvent, *i.e.*, $\eta=0.0721$ P and $\varepsilon=9.85$, were used, respectively. The limiting transport number was assumed to be equal to that in water, $t_{Ca}^\infty=0.76$.[20] The mean activity coefficient was calculated by means of the Debye-Hückel equation in which the diameter of sodium hexadecyl sulfate, 9.9 Å, was used as an ion parameter. The diameter was estimated from its partial molar volume in water obtained by the extrapolation of the values for sodium alkyl sulfates of C_2–C_{12}.[21,22]

The Shedlovsky plot is also shown in Fig. 2. The values of Λ^∞ and K_1 obtained from the plot were 2.8 S cm^2 mol^{-1} and 4.1×10^{-9} mol^2 dm^{-6}, respectively. The degree of dissociation, θ, was 0.25 at 2.5×10^{-3} mol dm^{-3}, *i.e.*, the concentration of calcium hexadecyl sulfate in the liquid membrane studied.

Diffusion across Water–Octanol Interface. The kinetics of diffusion of $CaCl_2$ across the water–1-octanol interface was studied, where the concentration of carrier species in 1-octanol phase was 2.5×10^{-3} mol dm^{-3}. The modified apparatus of the type proposed by Davies[23], which is shown in Fig. 3, was used. The diffusion area was *ca.* 12.6 cm^2. Concentration change in aqueous phase was followed by measuring the electric conductance. A known amount of preconditioned 1-octanol was layered on the aqueous $CaCl_2$ solution with the initial concentration of 3.86×10^{-4} mol dm^{-3}. After the conductance of an aqueous phase became constant, 1-octanol solution of $CaCl_2$ was injected into the oil phase. The initial concentration of $CaCl_2$ in 1-octanol phase was 1.05×10^{-4} mol dm^{-3}. The measurement was carried out at 25 °C, and both phases were stirred at the

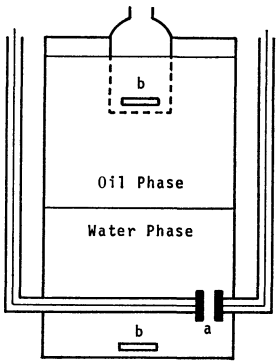

Fig. 3. Schematic diagram of the glass cell used for the measurement of diffusion across the oil–water interface. a: Pt–Pt electrodes, b: magnetic spin bar.

same rate as used for the salt flux measurements.

Results and Discussion

The membrane permeabilities evaluated from the electrical data, P_{Ca} and P_{Cl}, and those at zero electric current evaluated from the membrane potential and flux data, P^0_{Ca} and P^0_{Cl}, have already been reported in the preceding paper.[11] These values were again evaluated in the present study and are shown in Fig. 4. The general features of this figure are similar to those of the preceding paper, but somewhat lower values were obtained with P_{Ca} and P_{Cl}, being due to lower membrane conductance. After repeated measurements, it turned out to be essential for obtaining consistent membrane conductance that the liquid height of the membrane solution in the reservoir was kept constant. We shall, therefore, adopt the present results for analyzing the membrane permeability according to the presented theory.

Since the system is close to equilibrium with respect to calcium ion, we have[10]

$$P_{Ca} \approx \frac{RT}{(Z_{Ca}F)^2}\frac{g_{Ca}}{(a^{I}_{Ca}a^{II}_{Ca})^{1/2}}, \tag{53}$$

where superscripts I and II refer to the aqueous phases I and II, respectively. We shall assume that the ion transport is membrane-controlled. From Eqs. 33 and 39, the ionic conductance, g_{Ca}, can be expressed in terms of the absolute mobilities and concentrations of free calcium ion and its complex:

$$\frac{1}{g_{Ca}} = \int_0^d \frac{dx}{(Z_{Ca}F)^2(u_{Ca}C_{Ca} + \nu_{Ca}u_cC_c)}. \tag{54}$$

Combining Eq. 53 with Eq. 54, we have

$$\frac{1}{P_{Ca}} \approx \frac{(Z_{Ca}F)^2}{RT}(a^{I}_{Ca}a^{II}_{Ca})^{1/2}\int_0^d \frac{dx}{(Z_{Ca}F)^2(u_{Ca}C_{Ca} + \nu_{Ca}u_cC_c)}. \tag{55}$$

Since carrier species are completely trapped within membrane, we can obtain from Eq. 26

$$\kappa''_s = (Z_sF)^2u_sC_s - (Z_{Ca}F)^2\nu_{Ca}u_cC_c = 0. \tag{56}$$

Using Eq. 56, the term for the complex in Eq. 55 can be replaced by that for carrier ion, s,

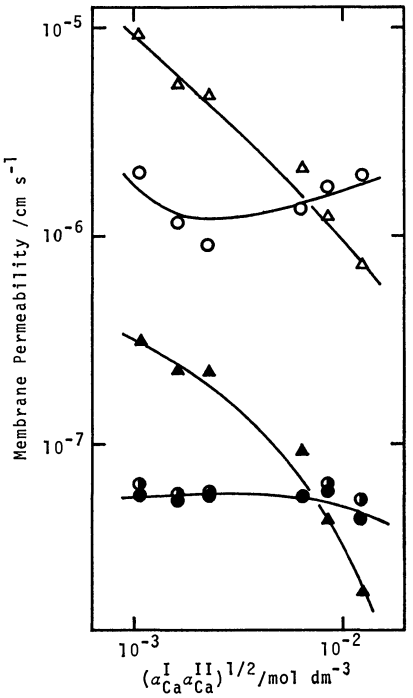

Fig. 4. The membrane permeabilities as a function of geometric mean of the activities of phases I and II. ○: P^0_{Ca}, ●: P^0_{Cl}, △: P_{Ca}, ▲: P_{Cl}. The membrane permeability to salt, P^0_{sa}, is also shown, ◑. The concentration of $CaCl_2$ in phase II was kept at 4×10^{-3} mol dm^{-3} and that in phase I being varied from 4×10^{-4} to 10^{-1} mol dm^{-3}. Solid lines indicate P^0_p and P_p calculated from P_{pq} according to Eqs. 6 and 7 in Ref. 11, respectively.

$$\frac{1}{P_{Ca}} \approx \frac{(Z_{Ca}F)^2}{RT}(a^{I}_{Ca}a^{II}_{Ca})^{1/2}\int_0^d \frac{dx}{(Z_{Ca}F)^2u_{Ca}C_{Ca} + (Z_sF)^2u_sC_s} \tag{57}$$

$$= \frac{(Z_{Ca}F)^2}{RT}\frac{(a^{I}_{Ca}a^{II}_{Ca})^{1/2}d}{(Z_{Ca}F)^2\tilde{u}_{Ca}\tilde{C}_{Ca} + (Z_sF)^2\tilde{u}_s\tilde{C}_s}, \tag{58}$$

where $\tilde{u}$ and $\tilde{C}$ denote the mean absolute mobility and mean concentration within membrane, respectively.

From the observed values of θ and R^{wm}, we see that the concentration of Donnan salt is negligible compared with that of free calcium ion. Under this condition, *i.e.*, $C_{Ca} \gg C_{Cl}$, Eq. 58 can be reduced to

$$P_{Ca} \approx \frac{RT}{(Z_{Ca}F)^2}\frac{\tilde{\Lambda}^1\tilde{\theta}\tilde{C}^{to}_{Ca}}{(a^{I}_{Ca}a^{II}_{Ca})^{1/2}d}, \tag{59}$$

$$\Lambda^1 = \nu_{Ca}\Lambda_{Ca} + \nu_s\Lambda_s, \tag{60}$$

where Λ_{Ca} and Λ_s denote the molar conductivity of calcium ion and of carrier ion, respectively, and Λ^1 is the hypothetical molar conductivity that the complex would have if it be completely dissociated and is related to the observed molar conductivity, Λ, as follows:[24]

$$\theta\Lambda^1 = \Lambda. \tag{61}$$

The molar conductivity within liquid membrane, $\tilde{\Lambda}$, must be independent of the external concentrations, because the total concentration of calcium ion within membrance is nearly constant, as stated above. Therefore, the dependence of P_{Ca} on the external

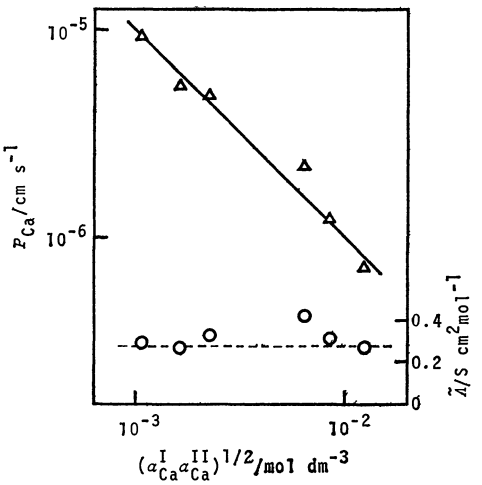

Fig. 5. The membrane permeability, P_{Ca} (△), and the molar conductivity in the liquid membrane estimated from P_{Ca}, $\tilde{\Lambda}$(○), as a function of the geometric mean of the activities of calcium ion in the aqueous phases I and II. Broken line indicates the molar conductivity of calcium hexadecyl sulfate measured in the bulk solution.

concentrations shown in Fig. 5 can well be described by Eq. 59. According to Eq. 59, $\tilde{\Lambda}$ was calculated from P_{Ca} and is compared with the molar conductivity measured in the 1-octanol solution of calcium hexadecyl sulfate in the same figure. We see from this figure that the agreement is satisfactory. This result implies that the electroconductional process of calcium ion is membrane-controlled and the effect of co-ion on this process is negligible.

From Eqs. 45 and 50, the diffusional ionic conductance at zero electric current, g^0_{Ca}, can be expressed as

$$\frac{1}{g^0_{Ca}} = \int_{-a}^{b} \frac{RT}{(Z_{Ca}F)^2 \bar{D}_{Ca} C^{to}_{Ca}} dx. \tag{62}$$

The membrane permeability of calcium ion at zero electric current is related to g^0_{Ca} as[10]

$$P^0_{Ca} \approx \frac{RT}{(Z_{Ca}F)^2} \frac{g^0_{Ca}}{(a^{I}_{Ca}a^{II}_{Ca})^{1/2}}, \tag{63}$$

when the system is close to equilibrium for calcium ion. Combining Eq. 63 with Eq. 62, P^0_{Ca} is expressed in terms of the mean diffusion coefficient, $\tilde{\tilde{D}}_{Ca}$, and mean total concentration, $\tilde{C}^{to}_{Ca}$, as

$$P^0_{Ca} \approx \frac{\tilde{\tilde{D}}_{Ca}\tilde{C}^{to}_{Ca}}{(a^{I}_{Ca}a^{II}_{Ca})^{1/2}d}, \tag{64}$$

provided the diffusion of calcium ion is membrane-controlled.

According to Eq. 64, $\tilde{\tilde{D}}_{Ca}$ was calculated from P^0_{Ca} and is shown in Fig. 6. We see from the small value of partitioning of $CaCl_2$, $R^{wm}=6.2\times10^{-4}$, and the concentrations of external $CaCl_2$ solutions less than 10^{-1} mol dm^{-3} that the concentration of Donnan salt is negligible. The mean total concentration of calcium ion in the membrane is nearly equal to 2.5×10^{-3} mol dm^{-3} which is a half of the concentration of membrane site and is almost independent of the external

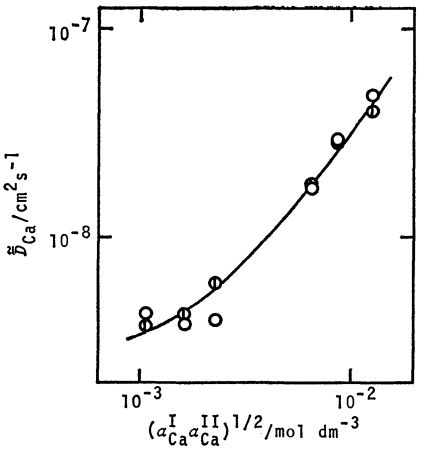

Fig. 6. Diffusion coefficient, $\tilde{\tilde{D}}_{Ca}$, as a function of the geometric mean of the activities in phases I and II. ○: Estimated from the observed P^0_{Ca}. ⓘ: Estimated from P^0_{Ca} calculated from P_{pq} according to Eq. 6 in Ref. 11.

electrolyte concentration. Therefore, the diffusion coefficient of calcium ion in the membrane phase would be almost independent of the external concentration of $CaCl_2$. Contrary to the expectation, a remarkable concentration dependence was found as shown in Fig. 6. A similar result has been obtained with an ion-exchange resin membrane and has been explained by assuming the energy barrier at the interface.[25] Thus the observed concentration dependence of $\tilde{\tilde{D}}_{Ca}$ may be attributed to the presence of energy barrier at the interface.

The diffusion of $CaCl_2$ across the interface was studied in the two-phase system of water and 1-octanol with carrier species. The flux of calcium ion at zero electric current can be expressed by Eq. 44. By substituting Eq. 6 into Eq. 44, we have

$$J^0_{Ca} = -\frac{\bar{D}_{Ca}C^{to}_{Ca}}{\bar{\lambda}_{Ca}} \nabla\bar{\lambda}_{Ca}. \tag{65}$$

Integrating Eq. 65 under the condition of steady state, we derive the equation for the flux across phase boundary as follows:

$$J^0_{Ca} = -P^{(b)}_{Ca}\{a^{w}_{Ca} \exp[(Z_{Ca}F\psi^{w} + \eta^{w}_{Ca} - Z_{Ca}F\psi^{m} - \eta^{m}_{Ca})/2RT] - a^{m}_{Ca} \exp[-(Z_{Ca}F\psi^{w} + \eta^{w}_{Ca} - Z_{Ca}F\psi^{m} - \eta^{m}_{Ca})/2RT]\}, \tag{66}$$

where

$$\frac{1}{P^{(b)}_{Ca}} = \left(\frac{a^{m}_{Ca}a^{w}_{Ca}}{\bar{\lambda}^{m}_{Ca}\bar{\lambda}^{w}_{Ca}}\right)^{1/2} \int \frac{\bar{\lambda}_{Ca}}{\bar{D}_{Ca}C^{to}_{Ca}} dx. \tag{67}$$

The integration extends over the boundary region interposing the interface. The superscript (b) refers to the boundary region, m and w, to the oil and aqueous phases, respectively. Equation 66 can be rewritten as[26]

$$J^0_{Ca} = -k_1C^{w}_{Ca} + k_2C^{m}_{Ca}, \tag{68}$$

where

$$k_1 = P^{(b)}_{Ca}y^{w}_{Ca} \exp\{[(Z_{Ca}F\psi^{w} + \eta^{w}_{Ca}) - (Z_{Ca}F\psi^{m} + \eta^{m}_{Ca})]/2RT\}, \tag{69}$$

and

$$k_2 = P_{Ca}^{(b)} y_{Ca}^{m} \exp\{[(Z_{Ca}F\psi^{m}+\eta_{Ca}^{m}) - (Z_{Ca}F\psi^{w}+\eta_{Ca}^{w})]/2RT\}. \quad (70)$$

y_{Ca} denotes the activity coefficient of calcium ion.

Assuming that the degree of dissociation of calcium hexadecyl sulfate in the membrane phase is not so much affected by the addition of a small amount of $CaCl_2$, the conservation law of mass holds for free calcium ion:

$$C_{Ca}^{m}v^{m} + C_{Ca}^{w}v^{w} = C_{Ca}^{m(e)}v^{m} + C_{Ca}^{w(e)}v^{w}, \quad (71)$$

where v denotes the volume of each phase and the superscript (e) refers to the equilibrium state. At the equilibrium state, we have from Eq. 68

$$\frac{k_2}{k_1} = \frac{C_{Ca}^{w(e)}}{C_{Ca}^{m(e)}}. \quad (72)$$

By means of Eqs. 71 and 72, Eq. 68 can be converted into a convenient form:[26,27]

$$\frac{dC_{Ca}^{w}}{dt} = k(C_{Ca}^{w(e)} - C_{Ca}^{w}), \quad (73)$$

where

$$k = A\left(\frac{k_1}{v^{w}} + \frac{k_2}{v^{m}}\right), \quad (74)$$

and t and A denote time and the diffusion area, respectively. By integrating Eq. 73 and replacing the concentration with the resistance of aqueous phase, R, we have

$$\ln\left(\frac{1}{R^{e}} - \frac{1}{R}\right) = -kt + \text{const.}, \quad (75)$$

where R^{e} denotes the resistance of aqueous phase at equilibrium. According to Eq. 75, k can be obtained from the slope of the logarithmic plot shown in Fig. 7. By using Eqs. 72 and 74, k_1 and k_2 were estimated and it was found that $k_1 = 2.8\times10^{-6}$ cm s^{-1}, and $k_2 = 2.3\times10^{-6}$ cm s^{-1}. In order to verify the relation of Eq. 72, the estimated values of k_1 and k_2 were substituted into Eq. 68 which was derived without the above assumption and J_{Ca}^{0} was calculated. The agreement between the calculated and observed J_{Ca}^{0}'s was excellent.

Combining Eq. 69 with Eq. 67, we have

$$\frac{y_{Ca}^{w}}{k_1} = \left[\exp\left(-\frac{Z_{Ca}F\psi^{w}+\eta_{Ca}^{w}}{2RT}\right)\right]\left(\frac{a_{Ca}^{w}}{\bar{\lambda}_{Ca}^{w}}\right)^{1/2}\int\frac{\bar{\lambda}_{Ca}}{\bar{D}_{Ca}C_{Ca}^{to}}dx, \quad (76)$$

$$= \int\frac{a_{Ca}\exp(U/RT)}{\bar{D}_{Ca}C_{Ca}^{to}}dx, \quad (77)$$

where U denotes the free energy of partition as

$$U \equiv Z_{Ca}F\psi + \eta_{Ca} - (Z_{Ca}F\psi^{w}+\eta_{Ca}^{w}). \quad (78)$$

According to a previous paper,[25] $\bar{D}_{Ca}$ can be expressed as

$$\bar{D}_{Ca} = \bar{D}_{Ca}^{0}\exp[(U-E)/RT], \quad (79)$$

where $\bar{D}_{Ca}^{0}$ and E denote the diffusion coefficient of calcium ion in bulk phase and the energy barrier at the interface, so that $E-U$ could be considered the apparent energy barrier for the diffusion of calcium ion. Substituting Eq. 79 into Eq. 77, we have

$$\frac{y_{Ca}^{w}}{k_1} = \int\frac{a_{Ca}/C_{Ca}^{to}}{D_{Ca}^{0}\exp(-E/RT)}dx. \quad (80)$$

We see from Eq. 80 that y_{Ca}^{w}/k_1 may almost be independent of the concentration of the external aqueous phase, since $\bar{D}_{Ca}^{0}$, E and a_{Ca}/C_{Ca}^{to} can be regarded as constant. This agrees well with the experimental observation[28] that k_1 is almost constant independent of the concentration of aqueous phase.

We shall compare k_1 with P_{Ca}^{0} determined from the salt flux across membrane. There are two interfaces in the liquid membrane–aqueous electrolyte system. Thus, the system may be regarded as that composed of the two o/w systems. The first consists of phase I and a half of the membrane, the second, phase II and another half of the membrane. According to Eq. 76, we find for the former system

$$\frac{y_{Ca}^{I}}{k_1^{(I)}} = \left[\exp\left(\frac{Z_{Ca}\Phi^{0}}{2}\right)\right]\left(\frac{a_{Ca}^{I}a_{Ca}^{II}}{\bar{\lambda}_{Ca}^{I}\bar{\lambda}_{Ca}^{II}}\right)^{1/2}\int_{-a}^{d/2}\frac{\bar{\lambda}_{Ca}}{\bar{D}_{Ca}C_{Ca}^{to}}dx, \quad (81)$$

where $-a$ and $d/2$ indicate the positions of the surface of the stagnant layer and of the middle of the membrane, respectively, and

$$\Phi^{0} = F(\phi^{II}-\phi^{I})RT. \quad (82)$$

Similarly we obtain

$$\frac{y_{Ca}^{II}}{k_1^{(II)}} = \left[\exp\left(-\frac{Z_{Ca}\Phi^{0}}{2}\right)\right]\left(\frac{a_{Ca}^{I}a_{Ca}^{II}}{\bar{\lambda}_{Ca}^{I}\bar{\lambda}_{Ca}^{II}}\right)^{1/2}\int_{d/2}^{b}\frac{\bar{\lambda}_{Ca}}{\bar{D}_{Ca}C_{Ca}^{to}}, \quad (83)$$

where b indicates the position of the surface of the stagnant layer in phase II. On the other hand, the

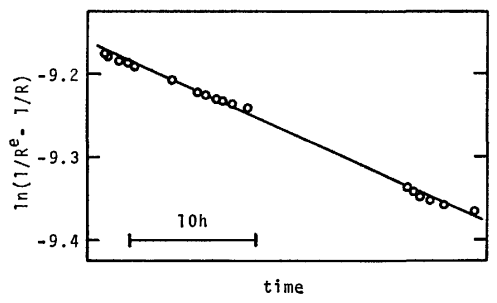

Fig. 7. Plot of $\ln(1/R^{e}-1/R)$ *versus* time.

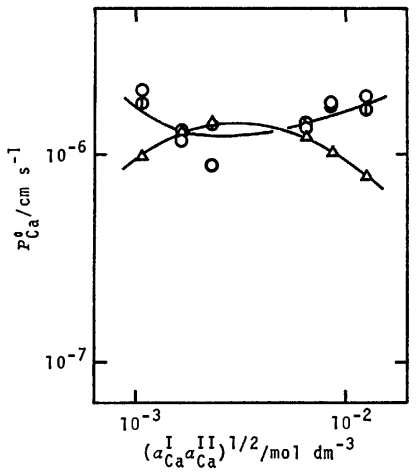

Fig. 8. Comparison of P_{Ca}^{0} estimated from k_1 according to Eq. 85 (△) with P_{Ca}^{0} observed in the liquid membrane–aqueous electrolyte system (○). P_{Ca}^{0} calculated from P_{pq} according to Eq. 6 in Ref. 11 (◫) is also shown.

diffusional membrane permeability to calcium ion can be obtained from Eq. 65 in a similar way to that described previously:[10]

$$\frac{1}{P^0_{Ca}} = \left(\frac{a^{I}_{Ca}a^{II}_{Ca}}{\bar{\lambda}^{I}_{Ca}\bar{\lambda}^{II}_{Ca}}\right)^{1/2}\int_{-a}^{b}\frac{\bar{\lambda}_{Ca}}{\bar{D}_{Ca}C^{to}_{Ca}}dx. \quad (84)$$

Comparing Eq. 84 with Eqs. 81 and 83, we have

$$\frac{1}{P^0_{Ca}} = \frac{y^{I}_{Ca}\exp(-Z_{Ca}\Phi^0/2)}{k_1^{(I)}} + \frac{y^{II}_{Ca}\exp(Z_{Ca}\Phi^0/2)}{k_1^{(II)}}. \quad (85)$$

According to Eq. 85, P^0_{Ca} can be estimated from k_1. The estimated P^0_{Ca} is compared with the observed P^0_{Ca} determined from the salt flux measurement on the membrane–electrolyte system in Fig. 8. We see from this figure that the estimated value agrees well with the observed one.

Thus the fact that the diffusional membrane permeability is less dependent on the external aqueous concentration can be attributed to the presence of an apparent energy barrier at interface. The diffusional fluxes of ions across liquid membranes have been measured by some workers.[15,29,30] However, they have not fully investigated the concentration dependence of the membrane permeability.

This research has been supported in part by a Grant-in-Aid for Scientific Research No. 247009 from the Ministry of Education, Science and Culture.

Reduction-Reoxidation Behavior of Silver(I) Ions in X-Type Zeolites

Masakazu IWAMOTO, Tsuneyasu HASHIMOTO, Toshikazu HAMANO, and Shuichi KAGAWA*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyomachi, Nagasaki 852

(Received September 27, 1980)

The reduction of Ag^+ ions in X zeolites by hydrogen, the reoxidation of Ag atoms by oxygen, and the formation of silver particles were studied kinetically. The reduction is suggested to be a catalyzed reaction requiring an activation of hydrogen at some specific sites on the basis of the influence of exchange levels and hydrogen pressures on the reduction rates. At elevated temperatures the reduction of Ag^+ ions proceeded quantitatively and resulted in formations of Ag particles with a diameter between 10 and 25 nm and of highly dispersed Ag clusters. The clusters were easy to be reoxidized by oxygen at 473 K or below, while the particles were difficult to revert into the zeolite matrix. The diameter of the Ag particles was dependent on the reduction temperature and ion-exchange level and independent on the reduction time. It is discussed that this is due to the slow nucleation and the fast nuclear growth of Ag particles.

Many efforts have been made to develop finely dispersed metal clusters or particles upon reduction of transition metal ions in zeolites.[1,2] These zeolites can be used as highly active and/or bifunctional catalysts for a wide range of chemical reactions. Interest was stirred when Rabo *et al.*[3] reported an active catalyst consisting of Pt metal supported in a Y-type zeolite. To date, X and Y zeolites containing several metals such as Ni,[4] Cu,[5] and Pt[3,6] have been well investigated. The following reaction stoichiometry has been suggested to the hydrogen reduction of a metal ion in the zeolite. Here, Me^{x+} represents a transition metal ion. It is also reported that variations of methods in preparing supported metal catalysts affect a dispersion of the metal particles and an activity of the catalyst.

$$Me^{x+} + {}^1/_2xH_2 \longrightarrow Me^0 + xH^+ \quad (1)$$

An endeavor to form small silver clusters or particles in or on zeolite framework is very interesting and desirable, since silver metal is a highly active catalyst for not only the epoxidation reaction of ethene but also oxidations of various organic compounds. In fact, Kagawa *et al.*[7] reported an active silver catalyst which was prepared by the reduction of Ag^+ ions in X zeolites followed by the dissolution of zeolite matrix with a concentrated alkali solution. Tsutsumi and Takahashi[8] found that Ag^+ ions in Y zeolites could be reduced to particles of Ag atoms with a diameter 15—30 nm upon a treatment with alkylbenzenes and alcohols. Riekert[9] reoxidized Ag–Y zeolites reduced with hydrogen and found the reproduction of the original Ag^+–Y zeolites. Beyer *et al.*[10] also performed a kinetic and physicochemical study on the reduction of Ag^+ ions in Y zeolites. Recently, Kimm and Seff[11] reported the formation of small silver clusters in A zeolites without reducing agents. Upon an evacuation and oxidation at elevated temperatures, Ag^+ ions were found to form Ag_6 clusters surrounded by 8 Ag^+ ions.

Since the number of metal ions exchangeable in a unit cell of X zeolites is greater than that of Y zeolites, the redox behavior of silver ions in X zeolites is of interest though the X-type lattices are less stable than the Y-type lattices. In the present paper, therefore, a systematic study has been carried out on various Ag^+–X zeolites to clarify the following problems: the kinetics of the reduction and reoxidation of Ag^+ ions in X zeolites, the mechanism of Ag particles formation, and the influence of an extent of exchange between Ag^+ and Na^+ ions on the reduction. This would serve to further progress in the standardization of methods of catalyst preparations.

Experimental

Materials. Eight AgNaX samples with different Ag^+ contents were prepared from Linde NaX zeolite of a composition $Na_{86}(AlO_2)_{86}(SiO_2)_{106}$. The zeolite was washed with diluted $NaNO_3$ solution in order to eliminate cation deficiency, ion-exchanged in aqueous silver nitrate solutions with adequate concentrations,[12] washed with water and dried at 473 K. The respective exchange levels of Ag^+ ions were analyzed by conventional analytical procedures. The compositions of the samples are summarized in Table 1. All the samples obtained were sieved to 30—60 mesh for use.

Hydrogen, oxygen, and nitrogen gases were of high purity grade (above 99.9% purity). Before use in reduction-reoxidation experiments, these gases were passed through a cold trap cooled at the liquid nitrogen temperature for removal of a trace amount of water.

Methods and Procedures. Reduction by hydrogen and reoxidation by oxygen were carried out in two ways of a static system and a flow system.

(a) Static System: An uptake of hydrogen could be followed accurately as a function of time by measuring the pressure drop in a static system. Reoxidation was also investigated by measuring the oxygen consumption in the same apparatus. The change of pressure was followed on a mercury manometer. A liquid nitrogen cold trap was

TABLE 1. THE AgNaX ZEOLITES USED

Sample	Exchange level (%)	Number of Ag^+ ions per unit cell	Amount of silver supported (g-Ag/g-AgNaX)
AgNaX- 6	5.6	4.8	0.038

99	98.6	84.8	0.444

equipped between a reactor and a vacuum pump to avoid a possibility of contamination due to vapors flowing backward from the pump. In the reactor, each zeolite sample was degassed at 673 K for more than 1 h, exposed to oxygen at the same temperature for more than 30 min, and then reevacuated for 5 min. This pretreatment[13] was always carried out for a fresh sample in order to remove water, carbon dioxide, and possible hydrocarbon impurities on the zeolite surface. Following the pretreatment, the sample was cooled to a chosen temperature in static vacuum and exposed to hydrogen at a desired pressure for a prescribed time. Subsequently, the sample was evacuated for 30 min and subjected to X-ray analysis or reoxidation. Reoxidation was carried out at a prescribed temperature, period, and pressure in the presence of oxygen. In this paper, the experiments were performed by this procedure unless otherwise specified.

(b) Flow System: After being mounted in a reactor, samples were purged with nitrogen at ambient temperature and an atmospheric pressure, and then heated to a chosen temperature. At that temperature a mixture of nitrogen and hydrogen diverted to flow through the reactor. A constant flow of the mixture, 30 cm^3/min, were maintained for a prescribed period. The reduced samples were cooled down to ambient temperature in a nitrogen atmosphere. This procedure was applied to the study on the formation of silver particles under severe reduction conditions.

Characterization of Samples. In order to ascertain the change of the zeolite framework and to determine the average size of Ag particles formed, a X-ray diffraction pattern was taken on each sample after the reduction or the reoxidation. The line width of (111) reflection of the Ag crystal was used to determine the average size of the Ag particles by a simplified Scherrer relation.

Results and Discussion

Kinetics of the Reduction. Amounts of hydrogen consumption over AgNaX-45 are shown in Fig. 1 as functions of the reaction temperature and time. A reduction level was evaluated from a theoretical uptake of hydrogen based on Eq. 1. Evidently the rate and the amount of hydrogen uptake increased at the higher temperatures. At 723 K the sample consumed an amount of hydrogen corresponding to complete reduction of the Ag^+ ions within a few minutes and there was no further consumption of hydrogen. In each case the catalyst turned black from white with a progress of the hydrogen consumption, indicating the reduction of Ag^+ ions to Ag atoms. The plots of the logarithm of initial rates of the reduction, calculated from the amount of hydrogen consumption for 10 s, versus reciprocal absolute temperatures between 273 and 471 K gave a straight line. This linearity would indicate that the mechanism is essentially unchanged in the initial stage of the reduction between 273 and 471 K; therefore, the apparent activation energy was evaluated to be 23.4±1.6 kJ/mol. This value seems to be reasonable because the activation energy of reduction of copper ions in X zeolites has been reported to be 49 kJ/mol[14] and silver ions are well known to be reduced more easily than copper ions. However, it should be noted that this value (23.4 kJ/mol) might be lower than the average value of activation energies for the whole

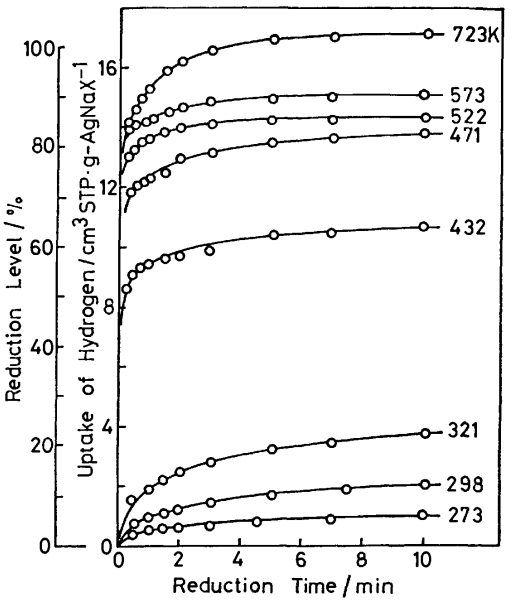

Fig. 1. Kinetic curves of the reduction of AgNaX-45 at various temperatures. The initial pressure of hydrogen was 13.3 kPa.

silver ions, since first the distribution of Ag^+ ions is somewhat heterogeneous as suggested by the dependence of the achievable degree of the reduction on the reaction temperature, and secondly the extent of reduction at 471 K for 10 s was about 50% which was too much to measure the initial reduction rate.

It was confirmed in a separate experiment that the rate of the reduction at 323 K did not depend on the partial pressure of hydrogen in the range 6.7—40.0 kPa. Beyer *et al.*[10] have reported that the reduction rate was proportional to the hydrogen pressure. However, it is very difficult to discuss the difference between these two results, since there was no description about the pressure range of hydrogen in their paper.

All samples reduced in the experiments of Fig. 1 were subjected to X-ray analyses. The reduction of AgNaX-45 at a temperature of 471 K or below did not give peaks in the diffraction pattern which are attributable to metallic silver particles. By contrast, the diffraction pattern of the sample reduced at a temperature higher than 522 K for 10 min showed a significant peak corresponding to the (111) reflection of metallic silver particles. These results lead to the conclusion that, under such mild reduction conditions as a treatment at 471 K for 10 min, the growth of silver particles should not proceed, or should stop below *ca.* 3.5 nm[15] in diameter.

The effect of an exchange level on the initial reduction rate of Ag^+ ions is depicted in Fig. 2. The reduction rate was calculated approximately from the amounts of hydrogen consumption during an initial short period, 10 sec, at 323 K. It was found that the reduction rate exhibited a characteristic correlation with the exchange level; the rate was very small for low-exchanged AgNaX zeolites until it increased rapidly above *ca.* 20% of the exchange level. This

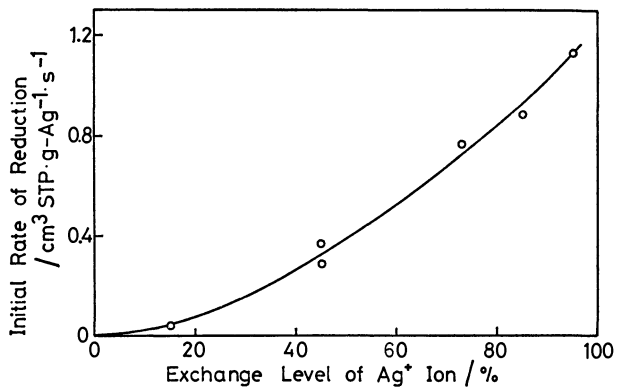

Fig. 2. Dependence of the initial rate of reduction at 323 K on the exchange level of silver(I) ions.

fact reflects that the reduction rate relates to the distribution of Ag^+ ions on several exchange sites in the zeolite framework. Ag^+ ions exhibit a tendency to occupy the interior sites (S_I or S_I') in dehydrated zeolites.[16] It is reasonable that the Ag^+ ions located at S_I and S_I' sites are difficult to be reduced with hydrogen. The influence of the exchange level and hydrogen pressure on the reduction rates at elevated temperatures could not be clarified, since the reduction rates were too fast to measure it accurately.

On the basis of the relation in Fig. 2, the activation energy of the reduction process, and the independency of the reduction rate on the hydrogen pressure, it is likely that the reduction is a catalyzed reaction in which the activation of hydrogen at some specific site S is required. This mechanism is acceptable

$$S + H_2 \rightleftharpoons S\text{-}H_2 \quad (2)$$

$$S\text{-}H_2 + Ag^+ \longrightarrow SH\text{-}Ag + H^+ \quad (3)$$

$$SH\text{-}Ag \longrightarrow SH + Ag \quad (4)$$

$$SH + Ag^+ \longrightarrow S\text{-}Ag + H^+ \quad (5)$$

$$S\text{-}Ag \longrightarrow S + Ag \quad (6)$$

if the exchange reaction of a Ag^+ ion with a H atom (Eq. 3) is a rate determining step. This cooperative exchange would be the reason for the lower activation energy of the process than that of a sole migration of univalent cations[17] (74.2 and 90.3 kJ/mol for Na^+ and Li^+ ions, respectively). This can explain the phenomenon shown in Fig. 2; that is, the reduction rate increased rapidly when Ag^+ ions began to situate inside or on the periphery of the supercage where Eq. 3 would become easy. The active species would be hydrogen atoms, since the hydrogen atoms have an average diameter small enough (0.1 nm)[18] to enter in the hexagonal or sodalite cavities through the hexagonal windows whose diameter is 0.22 nm,[19] while the diameter of hydrogen molecules is 0.24 nm.[20] Very recently, Che *et al.*[21] have reported that the reducing power of hydrogen atoms was higher than that of hydrogen molecules. In addition, in work on the equilibration of H_2–D_2 mixture over Y zeolites Heylen *et al.*[22] have shown that impurities such as iron ions are centers for the activation of hydrogen. These two findings support our assumption that the reduction is a catalyzed reaction requiring activation of the hydrogen at the site S. In the reduction process of Ag^+ ions located in S_I or S_I', it might be suggested that the generated Ag atoms are centeres for the activation of hydrogen and a spillover step of a hydrogen atom becomes significant.

Prior to the reduction experiments water vapor was introduced onto the sample which was dehydrated in the pretreatment. The reduction process was greatly inhibited in the presence of water, as shown in Fig. 3. This would result from the hydration of the active sites S or Ag^+ ions itself.

Kinetics of the Reoxidation. Reoxidation were performed on AgNaX reduced by a treatment with hydrogen at 573 K for 10 min. The uptakes of oxygen are illustrated in Fig. 4 as a function of time at dif-

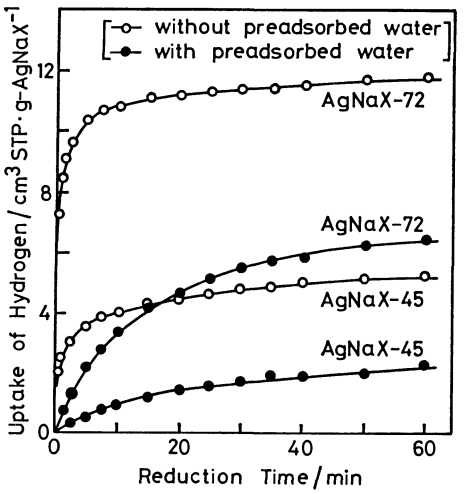

Fig. 3. Influence of the water addition on the reduction process of AgNaX-45 at 323 K. Water was introduced at 2.6 kPa into the system prior to the reduction and briefly evacuated at reaction temperature.

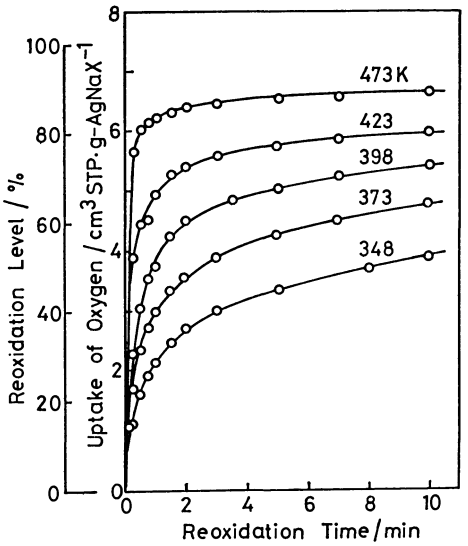

Fig. 4. Kinetic curves of the reoxidation of AgNaX-45 pre-reduced at 573 K for 10 min. The numerical values in the figure are the reoxidation temperatures. The initial pressure of oxygen was 13.3 kPa.

ferent temperatures. The reoxidation was slow at low temperatures. The achievable degree of reoxidation was nearly constant over the temperature range 348—473 K. For example, the uptake of oxygen in the reoxidation at 348 K for 2 h was 6.61 cm^3 STP/g-AgNaX-45, which was the same as that (6.65 cm^3 STP/g-AgNaX-45) at 473 K for 30 min within the experimental error. The apparent activation energy of the reoxidation, 20.1±2.0 kJ/mol, was calculated from the initial rates of Fig. 4 in the manner similar to that of the reduction. The extent of the reoxidation, evaluated from the amount of consumed oxygen on the basis of Eq. 7, was also graduated in Fig. 4. The

$$Ag + H^+ + {}^1/_4O_2 \longrightarrow Ag^+ + {}^1/_2H_2O \qquad (7)$$

reoxidation of the sample reduced at 573 K could not be achieved completely.

The stoichiometry of the reduction and reoxidation is quantitatively summarized in Table 2. Here, the reductions were carried out at two different temperatures for comparison. The amounts of reduced Ag^+ ions and reoxidized Ag atoms were determined by the quantities of the hydrogen and oxygen consumptions, respectively. The silver particles were defined here as the aggregates of silver metal which was detectable by X-ray analysis. Its quantities were measured by the method described in the following section. The remained Ag atoms were treated as silver clusters existing in the zeolites.

The hydrogen reduction of AgNaX-45 at 323 K for 30 min resulted in the production of 13.9 Ag atoms per unit cell. The formation of silver particles was not observed. Upon the treatment of this sample with oxygen at 473 K for 10 min, 3.01 cm^3 of oxygen was consumed and 14.0 Ag atoms were reoxidized to Ag^+ ions. This value is actually identical with the number of the produced Ag atoms. It is concluded that under these experimental conditions the reduction and reoxidation of Ag^+ ions in the zeolite are completely reversible. In contrast, among 34.8 Ag atoms generated by the reduction at 573 K 4.0 Ag atoms were found to form silver particles. Upon the reoxidation the amount of Ag^+ ions regenerated (30.9) is in fair agreement with that of silver clusters before the reoxidation (30.8). This is well interpreted by finding both amounts of silver particles before and after the reoxidation to be the same. These results lead to the conclusion that the silver particles remained unchanged even after the treatment of oxygen at 473 K and the reoxidation affected only the silver clusters presumably located inside the large cavities of the zeolite.

It is perhaps worthy of remark that there was no induction period in the reoxidation process and no effect of water addition on the reoxidation rate, in contrast to the observations for Ag–Y zeolites reported by Beyer *et al.*[10]

Formation of Metallic Silver Particles. The rates of particle formation during the reduction in the static system were evaluated from the increment of peak areas of Ag(111) diffraction pattern in the range 522—573 K. The apparent activation energy of the particle formation was 74.0±5.8 kJ/mol.

Next the reduction of Ag^+ ions was performed under severe conditions, *i.e.*, a treatment with hydrogen at 673 K and 101.3 kPa for 1 h in the flow system. The results were plotted in Fig. 5. The amounts of silver particles shown in Fig. 5A were essentially equal to those obtained when the reduction temperature and time were set to 773 K and 5 h. In addition, a good linear correlation evidently exists between the amounts of Ag^+ ions supported in the zeolite and the quantities

Table 2. Stoichiometry of reduction and reoxidation of AgNaX-45 sample

Run	A	B
Reduction		
Temperature/K	323	573
Time/min	30	10
Uptake of H_2/cm^3 STP	5.99	14.97
Reduced Ag^+ ions[a] /atoms per unit cell	13.9	34.8
Silver particles[b]	0	4.0
Silver clusters	13.9	30.8
Reoxidation		
Temperature/K	473	473
Time/min	10	30
Uptake of O_2/cm^3STP	3.01	6.65
Reoxidized Ag atoms[c] /atoms per unit cell	14.0	30.9
Silver particles[b] /atoms per unit cell	0	4.0

a) This value was evaluated from the amount of hydrogen consumption. b) This value was calculated from the peak area of a Ag(111) diffraction line. c) This value was evaluated from the amount of oxygen consumption.

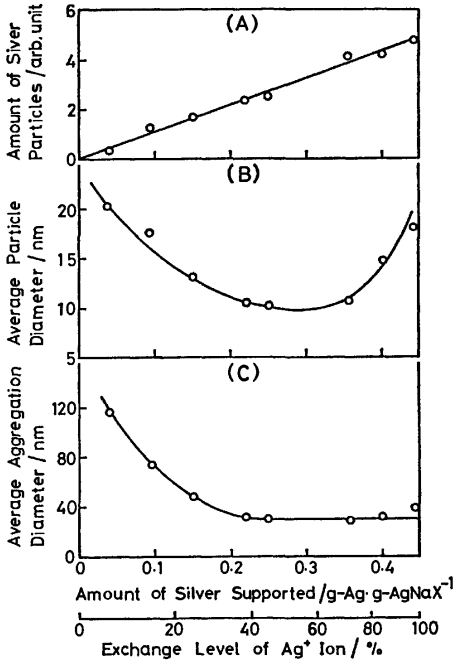

Fig. 5. Changes of amount of silver particles(A), particle diameter(B), and average aggregation diameter(C) with amount of silver supported. Reduction was performed at 673 K for 1 h by 101.3 kPa of hydrogen in the flow system.

of silver particles formed. Based on these facts, it was concluded that all Ag^+ ions were transferred into Ag particles. In Table 2, the amounts of Ag atoms converted into Ag particles were estimated by using this relation as a calibration.

In the experiments of Fig. 5, an irreversible destruction of the zeolite framework during the severe reduction was indicated by change in X-ray diffraction patterns. The diffraction patterns attributable to the zeolite structure were eliminated in proportion to the exchange level. After the reduction of AgNaX-99, for example, the diffraction patterns from the zeolites were completely disappeared and the formation of an amorphous phase was shown by the appearance of very broad and not intense peak. Under mild reduction conditions, however, the extent of the destruction was not so thorough, though the quantitative analysis concerning this phenomenon was not carried out.

The average diameters of the silver particles deduced from the line widths are shown in Fig. 5B. The diameter varied specifically with the Ag^+ ion-exchange level. It was approximately 20 nm for the low-exchanged AgNaX samples and decreased gradually with an increase in exchange level. The diameter increased after passing a minimum around 50% of the exchange level. The particle diameter were in the range 10—21 nm under these conditions. This value is in good agreement with 21 nm observed by Beyer *et al.*[10] and 15—30 nm by Tsutsumi and Takahashi.[8] Average aggregation diameters were evaluated by the following method from the results of Fig. 5B.

Since the crystal lattice of silver is of F. C. C., the number of Ag atoms included in a silver particles is given by $2\pi D_1^3/3A^3$ where D_1 represents the diameter of the silver particles and A is the lattice constant of silver crystal (0.4086 nm). On the other hand, the number of Ag^+ ions located in a unit cell of the X zeolite is $86E$, where E is an exchange level of Ag^+ ions. Therefore, writing the lattice constant of the zeolite (2.49 nm) as B, all silver ions situated in a volume of the zeolite given by $(2\pi D_1^3/3A^3)$ $(B^3/86E)$ were required to aggregate in order to form the silver particle. With an introduction of D_2 as a diameter of a sphere, whose volume is the same as that calculated above, Eq. 8 is

$$\frac{4}{3}\pi\left(\frac{D_2}{2}\right)^3=\left(\frac{2\pi D_1^3}{3A^3}\right)\left(\frac{B^3}{86E}\right) \tag{8}$$

$$D_2=\frac{D_1B}{A}\left(\frac{2}{43E}\right)^{1/3} \tag{9}$$

set up and then Eq. 9 is derived. Here, D_2 is named an average aggregation diameter. This value indicates a range of the migration and aggregation of silver in the reduction process to yield a silver particle.

The results of the calculation using Eq. 9 are shown in Fig. 5C. The aggregation diameter took a large value as 120 nm at the low exchange level and gradually decreased with increasing the exchange level. In order to understand this phenomenon and gather more informations about the process of particles formation, following experiments were performed. Amounts and

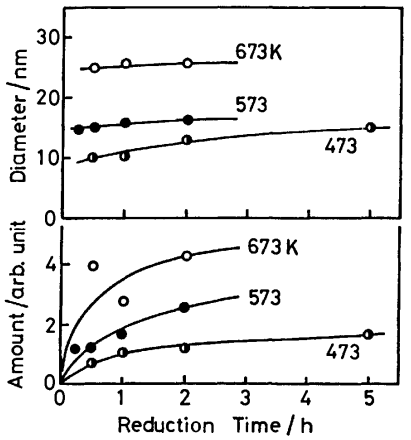

Fig. 6. Variations of amount and diameter of silver particles with reduction time at various temperatures. The reduction was performed by hydrogen at 10.1 kPa on AgNaX-99 in the flow system.

diameters of silver particles produced by the reduction of AgNaX-99 with 10.1 kPa of hydrogen in the flow system are plotted in Fig. 6 as functions of the reaction temperature and time. Clearly the amount of silver particles increased with the reaction time, while the particle diameters remained approximately constant irrespective of the reaction time. Moreover, the diameter showed a tendency to become larger at the higher temperatures.

The above observations suggest that in the formation of silver particles a step of nucleation is rate-determining and a process of subsequent nuclear growth is relatively fast. The constant particle diameters independent on the reduction time in Fig. 6 would be understood as a result of a phenomenon that once a nucleus generates, all silver ions located in the aggregation diameter are rapidly gather to its nucleus. At the higher reaction temperatures the nucleation becomes more difficult because of the unstability of nucleus and the rate of the nuclear growth is more facilitated. These result in the formation of larger particles at the higher reduction temperatures, as shown in Fig. 6. In a similar manner to the above, the low exchange level of the Ag^+ ions makes the nucleation more difficult. This is the reason why the average aggregation diameter changed with the extent of the Ag^+ ion-exchange in Fig. 5C.

Conclusions

The reduction of the Ag^+ ions and the reoxidation of Ag atoms in X zeolites are found to proceed with ease, while the silver particles with a diameter of 10—25 nm produced in the severe reduction are difficult to be reoxidized. The processes are summarized in Eq. 10, where E_a represents an activation energy

$$Ag^+ \underset{E_a=20.1\pm2.0}{\overset{E_a=23.4\pm1.6}{\rightleftarrows}} Ag^0 \xrightarrow{E_a=74.0\pm5.8} Ag(\text{particle}) \tag{10}$$

of each step (kJ/mol). The reduction requires a catalytic activation of hydrogen at specific sites in the zeolites. Upon mild reduction some of the reduced silver atoms would form clusters in the supercage of

the zeolites. The cluster might have a partial charge by the participation of unreacted silver ions, in a manner analogous to suggestions by Beyer *et al.*[10] or Kimm and Seff.[11] In the process of the particle formation it is suggested that the nucleation is rate-determining and its rate is varied with the reaction conditions. Che *et al.*[21] have recently found that Ni^{2+} ions in X zeolites were reduced to Ni atoms at very low temperatures (77—273 K) by hydrogen atoms and that the growth of clusters was achieved by gradually heating of the reduced sample above the reduction temperatures. These results indicate the possibility that the formations of Ag clusters and particles might be carried out by a migration of Ag atoms.

The authors wish to thank to Messrs. K. Kuroiwa and S. Miyazaki for carrying out some of the kinetic determination.

Crystal and Molecular Structure of Antibiotic Gilvocarcin M

Noriaki HIRAYAMA,* Keiichi TAKAHASHI, Kunikatsu SHIRAHATA,
Yuji OHASHI,† and Yoshio SASADA†

Tokyo Research Laboratory, Kyowa Hakko Kogyo Co., Ltd., 3-6-6 Asahimachi, Machida, Tokyo 194

†*Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received November 8, 1980)

The structure of gilvocarcin M, $C_{26}H_{26}O_9$, an antibiotic with a novel carbon skeleton, has been determined by single crystal X-ray analysis. The space group is $P2_1$ with $a=15.063(5)$, $b=16.162(4)$, $c=4.905(2)$ Å, $\beta=91.47(3)°$, and $Z=2$. The structure was solved by direct methods, and least-squares refinement using 1734 reflexions gave the final R value of 0.054. The title compound is composed of a unique aglycone and a fucofuranose, which are linked together through a C–C glycosyl linkage. The furanose ring takes the °E conformation.

Gilvocarcin M and V are antibiotics produced by *Streptomyces gilvotanareus* and *Streptomyces griseologilbus*.[1] They were called previously DC-38.[2] Their structures have been elucidated on the basis of their chemical nature and spectroscopic data.[3] The structural difference between M and V is that a methyl group at C(22) in the former is replaced by a vinyl group in the latter. The structure of gilvocarcin M and the numbering system is shown in Fig. 1. In spite of many efforts with various kinds of NMR techniques including proton-proton spin decoupling and ^{13}C-NMR with long range selective proton decoupling, there has still remained some ambiguity especially around the asymmetric carbons of the furanose. To determine the structure of gilvocarcins unequivocally, we have undertaken an X-ray analysis of gilvocarcin M. This paper will describe the crystal structure of the antibiotic.

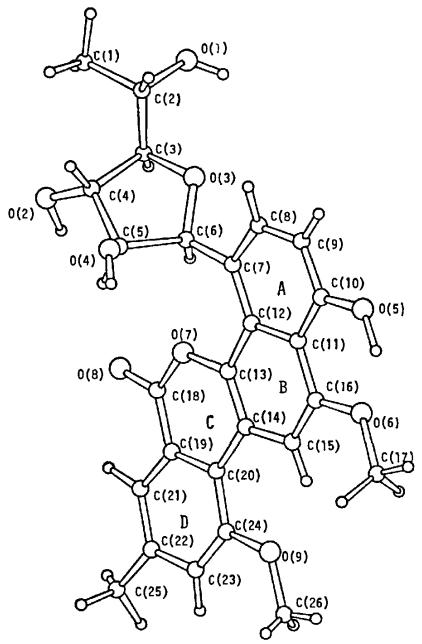

Fig. 1. The numbering system of gilvocarcin M.

Experimental and Structure Determination

Yellow prismatic crystals of gilvocarcin M were obtained from a DMSO–ethanol solution. A crystal, $0.5\times0.13\times0.05$ mm^3, was used for data collection on a Rigaku four-circle automated diffractometer with Ni-filtered Cu $K\alpha$ radiation. Preliminary unit cell dimensions and space group were obtained from oscillation and Weissenberg photographs. The space group was determined from systematic absences ($0k0$ for odd k). Accurate cell dimensions were determined by a least-squares calculation with 2θ values of 16 high-angle reflexions measured on the diffractometer. Crystal data are summarized in Table 1. All independent reflexions within the range $2\theta\leqq120°$ were collected by use of the ω-2θ scan mode with a scanning rate of $4°(2\theta)\text{min}^{-1}$. Stationary background counts were accumulated for 10 s before and after each scan. Periodic checks of the intensity values of three standard reflexions showed no significant X-ray damage. Corrections for absorption or extinction were not applied. Out of 1847 independent reflexions obtained, 1735 for which $|F_o|>3.0\sigma(|F_o|)$ were used.

TABLE 1.

$C_{26}H_{26}O_9\cdot0.4C_2H_6O$	$b=16.162(4)$ Å
$M.W.=500.9$	$c=4.905(2)$ Å
$P2_1$	$\beta=91.47(3)°$
$Z=2$	$D_x=1.393$ g cm^{-3}
$a=15.063(5)$Å	μ(Cu $K\alpha$)$=21.47$ cm^{-1}

The phases of 339 reflexions with $|E_o|\geqq1.2$ were assigned with MULTAN.[4] The best set of phases was used to calculate an E-map, which gave 21 chemically significant peaks. Other 15 non-hydrogen atoms were found by the successive Fourier syntheses. The structural parameters were refined by block-diagonal least-squares with a modified HBLS programme. All the hydrogen atoms and a molecule of the ethanol solvent without hydrogen atoms were found by the difference syntheses. Refinement gave the final R value 0.054 for 1734 reflexions. The atoms of the solvent molecules with the occupancy of 0.4 were refined isotropically. The weighting system used in the final stage was $w=0.3$ for $|F_o|<1.782$ and $|F_o|>17.82$, and $w=(0.00115(F_o)^2-0.12675|F_o|+4.48559)^{-1}$ for $1.782\leqq|F_o|\leqq17.82$. A strong reflexion, 020, was excluded because it seemed to suffer from secondary extinction. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[5] The final positional and thermal parameters are given in Table 2. The tables of anisotropic temperature factors and observed and calculated structure factors are kept as a Document No. 8132 at the Chemical Society of Japan.

Results and Discussion

Molecular Structure. Bond lengths and angles are tabulated in Table 3. A stereoscopic drawing of the molecule is shown in Fig. 2. The two bonds C(15)–C(16) and C(18)–O(7), which correspond to K region of phenantherene,[6] show rather high double bond character. There is an intramolecular hydrogen bond between O(5) and O(6) atoms; O(5)···O(6)= 2.547(6) Å, H(O(5))···O(6)=1.68(7) Å, and O(5)–H···O(6) angle is 141.2°. Although the reason is not clear, the C(24)–O(9) length is significantly shorter than the C(16)–O(16).

The C–C glycosyl bond length, C(6)–C(7), is somewhat longer than the corresponding values (1.492—1.501 Å) in formycin.[7] In usual nucleosides C(4')–O(1') is significantly longer than C(1')–O1(1'). In gilvocarcin M, however, C(6)–O(3) is significantly longer than C(3)–O(3). There are two short intramolecular non-bonded contacts; O(3)···C(8)=2.622(7) Å and O(7)···C(6)=2.682(6) Å.

The least-squares planes of interest and the dihedral angles between them are tabulated in Table 4. The aglycone part except the substituents is planar within ±0.1 Å. Although every six-membered rings are planar, the planarity of the D ring is best (±0.008 Å) and that of the C ring is worst (±0.035 Å). The dihedral angles between the rings A and B, between rings B and C, and between rings C and D are 1.9, 2.3, and 2.4°, respectively. These values show a smooth convex character of the aglycone part, as seen in Fig. 3, the side view of the molecule. The dihedral angles between the least-squares planes of furanose ring and the aglycone part is 53.5°.

The O(3) atom deviates by 0.531 Å from the plane determined by the C(3), C(4), C(5), and C(6) atoms, and the puckering parameters P and θ_m[8] are 94.8 and 39.9°, respectively. This indicates that the furanose ring takes an unusual $^{\circ}E$ conformation. It is probable that the $^{\circ}E$ conformation is related to the above-mentioned bond length reversion at the C(3)–O(3) and C(6)–O(3) bonds. The conformation around the C(2)–C(3) bond is *gauche-trans*, and the χ_{cc} angle of 19.7° is in the *anti* region. Torsional angles are listed in Table 5.

Crystal Structure. A stereoscopic drawing of the crystal structure viewed along the c axis is shown in Fig. 4. There are three intermolecular OH···O hydrogen bonds as listed in Table 6. Between the

molecules along the c axis, there are two hydrogen bonds; O(2)···O(4) and O(4)···O(8). The third hydrogen bond is formed between the O(1) atom and the oxygen atom of the solvent ethanol. In other part the molecules are stacked mainly by van der Waals interactions. The interplanar separation between the aglycone moieties along the c axis is 3.45 Å.

The solvent molecule of ethanol is disordered, which might be explained by the large cavity around it.

Structure Activity Relationship. It is assumed that the biological activity of gilvocarcins comes mainly from the interaction of the compounds with DNA.[1] It is conceivable from the stereochemical point of view, because gilvocarcins have geometrical prerequisites to interact with DNA. The dimensions and the planarity of the aglycone, and the delocalization of π electrons through the aglycone part are the common structural features found in most antibiotics which interact with DNA through the intercalation mode. It is interesting that gilvocarcins possess partial structures corresponding to K region and bay region[9]

in the aglycone.

In this connexion, it should be noted that when the methyl group at C(22) is replaced by a vinyl group (gilvocarcin V), the activity is enhanced.[1] The vinyl group is of less bulkiness than the methyl group to intercalate between the base pairs in DNA. In addition to the relief of the steric hindrance, the vinyl group would electronically increase the reactivity of the compound to DNA.

A hypothetical way of the intercalation of gilvocarcin M between the base pairs in DNA is shown in Fig. 5. The structure of the fragment of the unwound DNA is taken from the results of the X-ray analysis of ethidium/dinucleoside monophosphate complex.[10] This figure illustrates that gilvocarcin M has molecular dimensions suitable for intercalation between the base pairs in DNA.

Figures 2, 3, and 4 were drawn by TSD:XTAL, which is a computer-graphics interactive modelling programme for the NOVA3 computer.[11]

Intermolecular Potential, Vibrational Spectra, and Structures of Amino Acid Crystals. I. Distortion of Molecules and Equilibrium Crystal Structure

Katsunosuke MACHIDA* and Yoshihiro KURODA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 15, 1980)

A general method of the crystal packing optimization is developed for the molecular crystals consisting of non-rigid molecules. The intramolecular potential is described as a general harmonic force field in terms of a suitable set of internal symmetry coordinates, and the intermolecular potential as a sum of the pairwise atom-atom interaction terms. The adjustable structure parameters are those among the six cell constants, a, b, c, α, β, and γ, and the translations and the rotations of the molecules which maintain the crystal symmetry. The intermolecular force is separated into two parts, one of which determines the location of the center of mass and the orientation of the principal axes of each molecule and the other leads to a certain molecular distortion. The calculated distortion may be used, in addition to the difference between the calculated and the observed crystal structures, as a check point of the reliability of the model potential. The importance of this separation in the rigid molecule approximation is pointed out.

In order to search for the equilibrium structure of a given molecular crystal by taking account of all the degrees of freedom of atomic motions in the asymmetric unit, we should pay attention to both the intramolecular (internal) and the intermolecular (external) parts of the potential function. Any molecular crystals maintain their structures on the balance of the forces expressed as the gradients of these two parts. Confining the discussion to those crystals in which all the molecules are symmetrically equivalent, we shall denote the intramolecular and the intermolecular potentials per molecule as $V_{\rm in}$ and $V_{\rm ex}$, respectively. The contribution of $V_{\rm in}$ to the forces acting on the atoms may be estimated if the atomic displacements on the change from the gaseous state to the crystal are known experimentally and also the change of $V_{\rm in}$ on the change of state is assumed to be negligible. Warshel and Lifson carried out extensive calculations of this type for a number of hydrocarbons using the Cartesian coordinates of atoms as the working coordinates.[1] This method cannot be applied to amino acids for which the structures in the isolated zwitterionic form are unknown. Neither is the rigid molecule approximation applicable in this case, since the low-frequency intramolecular vibrations of amino acids couple appreciably with the lattice modes. The internal rotations around single bonds have been taken into account by several authors in the conformation analyses of molecular crystals.[2,3] In a series of studies on vibrational spectra of simple amino acids, however, we observed that some of the skeletal deformation frequencies were lower than the torsional frequencies of the NH_3^+ and the CH_3 groups.[4-7]

In this report, we propose a convenient procedure of the potential energy minimization for the crystals of amino acids and similar non-rigid molecules. General expressions for the increments of the structure parameters in the Newton-Raphson iteration are given by taking account of the effect of $V_{\rm in}$ without any knowledge on the structure of the isolated molecules. Application of the method to α-glycine, L-alanine and DL-alanine crystals will be given in the subsequent paper.

Theory

Molecular Distortion. The $3N$ degrees of freedom of motions of a non-linear N atomic molecule may be described by a set of $3N-6$ internal symmetry coordinates, denoted in a vector form as $\boldsymbol{S}_{\rm in}$, and 6 external coordinates, $\boldsymbol{S}_{\rm ex}$, representing the translation and the rotation of the whole molecule. These coordinates can be constructed from the Cartesian displacement coordinates $\boldsymbol{x}$ of the atoms through the transformations

$$\boldsymbol{S}_{\rm in} = \boldsymbol{B}_{\rm in}\boldsymbol{x} \quad \text{and} \quad \boldsymbol{S}_{\rm ex} = \boldsymbol{B}_{\rm ex}\boldsymbol{x}. \tag{1}$$

The matrix $\boldsymbol{B}_{\rm in}$ is related to the well known $\boldsymbol{G}$ matrix by

$$\boldsymbol{G} = \boldsymbol{B}_{\rm in}\boldsymbol{m}^{-1}\tilde{\boldsymbol{B}}_{\rm in}, \tag{2}$$

where $\boldsymbol{m}$ is a $3N\times 3N$ diagonal matrix consisting of the atomic masses.[8] Since $\boldsymbol{S}_{\rm ex}$ is so chosen as to fulfill the Eckart condition and is normalized,[9] it follows that

$$\boldsymbol{B}_{\rm in}\,\boldsymbol{m}^{-1}\,\tilde{\boldsymbol{B}}_{\rm ex} = \boldsymbol{0} \tag{3}$$

and

$$\boldsymbol{B}_{\rm ex}\,\boldsymbol{m}^{-1}\,\tilde{\boldsymbol{B}}_{\rm ex} = \boldsymbol{E}, \tag{4}$$

where $\boldsymbol{E}$ is a 6×6 identity matrix. Next we denote the vector of the external forces along the Cartesian coordinates by

$$\boldsymbol{f}_x^{\rm ex} = [-\partial V_{\rm ex}/\partial x_1 \; -\partial V_{\rm ex}/\partial y_1 \cdots -\partial V_{\rm ex}/\partial z_N]^{\rm T},$$

and introduce the vectors of generalized forces $\boldsymbol{f}_{\rm ex}^{\rm ex}$ and $\boldsymbol{f}_{\rm in}^{\rm ex}$ corresponding to the coordinates $\boldsymbol{S}_{\rm ex}$ and $\boldsymbol{S}_{\rm in}$, respectively. In accordance with Eq. 1, the transformation from the generalized forces to $\boldsymbol{f}_x^{\rm ex}$ is expressed as

$$\boldsymbol{f}_x^{\rm ex} = \tilde{\boldsymbol{B}}_{\rm in}\,\boldsymbol{f}_{\rm in}^{\rm ex} + \tilde{\boldsymbol{B}}_{\rm ex}\,\boldsymbol{f}_{\rm ex}^{\rm ex}. \tag{5}$$

Premultiplying Eq. 5 by $\boldsymbol{G}^{-1}\boldsymbol{B}_{\rm in}\,\boldsymbol{m}^{-1}$ and using Eqs. 2 and 3, we obtain

$$\boldsymbol{f}_{\rm in}^{\rm ex} = \boldsymbol{G}^{-1}\boldsymbol{B}_{\rm in}\,\boldsymbol{m}^{-1}\,\boldsymbol{f}_x^{\rm ex}. \tag{6}$$

Similarly, the use of Eqs. 3 and 4 after premultiplying by $\boldsymbol{B}_{\rm ex}\,\boldsymbol{m}^{-1}$ leads to

$$\boldsymbol{f}_{\rm ex}^{\rm ex} = \boldsymbol{B}_{\rm ex}\,\boldsymbol{m}^{-1}\,\boldsymbol{f}_x^{\rm ex}. \tag{7}$$

Equations 6 and 7 enable us to partition the external

force into two parts, one tending to distort the molecule and the other tending to displace and rotate it. At the equilibrium position, f_{ex}^{ex} should vanish while f_{in}^{ex} is not necessarily a zero vector since it can be offset by the internal force, f_{in}^{in}, which arises from a certain distortion of the molecule associated with the change of the environment from the isolated state into the crystal, *i.e.*,

$$f_{in}^{ex} = -f_{in}^{in}. \tag{8}$$

Kurittu and Pawley gave a general expression of this distortion in terms of the normal coordinates of the free molecule.[10] An alternative way, being applicable to the cases where the molecular structure in the free state is unknown, is to express the distortion in terms of the internal symmetry coordinates S_{in} of the molecules in the crystal. Denoting such a distortion by S_{in}^{c} and using Eqs. 6 and 8, we have

$$S_{in}^{c} = -F^{-1} f_{in}^{in} = F^{-1} G^{-1} B_{in} m^{-1} f_{x}^{ex}, \tag{9}$$

where F is the usual potential energy matrix for the internal vibrations defined by

$$2V_{in} = \tilde{S}_{in} F S_{in}.$$

The Cartesian components of the internal force are given by

$$f_{x}^{in} = \tilde{B}_{in} f_{in}^{in}, \tag{10}$$

since f_{ex}^{in} vanishes from the definition in contrast to the case of f_{ex}^{ex} in Eq. 5. When the F matrix does not change on going from the gaseous state to the crystal, S_{in}^{c} represents the structure change of the molecule on the change of state. In the procedure of Kurittu and Pawley,[10] one starts from the geometry of the undistorted molecule, and calculates the external force iteratively at the varying atomic positions until the final balance between V_{in} of the distorted molecule and V_{ex} is attained. On the other hand, the calculation in the present formulation is performed once for the distorted molecule, and the structure of the isolated molecule is inferred by subtracting S_{in}^{c} from the structure in the crystalline state. Obviously, our method is valid only for infinitesimal distortions while that of Kurittu and Pawley is applicable to larger ones. An advantage of our method is that we can incorporate all the degrees of freedom of atomic motions implicitly in the conformation analysis of molecular crystals, using the same number of adjustable parameters as the rigid molecule approximation, *viz.*, the lattice constants and the translations and the rotations of the whole molecule.

Changes of Lattice Constants and External Coordinates. The potential energy per unit cell of a uniformly deformed molecular crystal under a small strain may be expressed as

$$V = V_0 - \tilde{f}_{\sigma}\sigma - \tilde{f}_{x}x_{\rho} + (1/2)(\tilde{\sigma}F_{\sigma\sigma}\sigma + \tilde{x}_{\rho}F_{xx}x_{\rho}) + \tilde{\sigma}F_{\sigma x}x_{\rho}, \tag{11}$$

where σ is the strain vector,

$$\sigma = [\sigma_{xx}\ \sigma_{yy}\ \sigma_{zz}\ \sigma_{yz}\ \sigma_{zx}\ \sigma_{xy}]^{T},$$

which leads to the macroscopic deformation of the crystal, and x_{ρ} is the vector of the microscopic Cartesian displacements of the atoms in the unit cell.[11] We retain the linear terms in Eq. 11 considering the cases when no minima of the adopted model potential correspond to the experimentally determined structure. The vector f_x is the sum of the external and the internal forces, and is given by

$$f_{x} = f_{x}^{ex} + f_{x}^{in} = (E - \tilde{B}_{in} G^{-1} B_{in} m^{-1}) f_{x}^{ex} \tag{12}$$

from Eqs. 6, 8, and 10. The matrix F_{xx} is equivalent to the F matrix for the optical active crystal vibrations in terms of the Cartesian displacements, and can be diagonalized by the transformation into the normal coordinates,

$$x_{\rho} = L_{x} q_{\rho}. \tag{13}$$

In order to determine f_{σ}, $F_{\sigma\sigma}$, and $F_{\sigma x}$ in Eq. 11 and then to calculate the derivatives of V with respect to the lattice constants and the external coordinates, it is useful to follow the treatment of elastic constants of molecular crystals due to Shiro and Miyazawa in a slightly modified manner including the linear terms.[12]

Specifying each unit cell with an index vector L, we can express the Cartesian displacements of the ith atom in the cell L (denoted as the atom Li hereafter) of the uniformly deformed lattice as

$$x_{i}(L) = D^{i}(L)\sigma + E^{i} x_{\rho}, \tag{14}$$

where $D^{i}(L)$ consists of the Cartesian coordinates of the atom Li evaluated with reference to the origin of the cell $\mathbf{0}$ when $\sigma=\mathbf{0}$, $X_{i}^{0}(L)$, $Y_{i}^{0}(L)$, and $Z_{i}^{0}(L)$, *viz.*,

$$D^{i}(L) = \begin{bmatrix} X_{i}^{0}(L) & 0 & 0 & 0 & Z_{i}^{0}(L)/2 & Y_{i}^{0}(L)/2 \\ 0 & Y_{i}^{0}(L) & 0 & Z_{i}^{0}(L)/2 & 0 & X_{i}^{0}(L)/2 \\ 0 & 0 & Z_{i}^{0}(L) & Y_{i}^{0}(L)/2 & X_{i}^{0}(L)/2 & 0 \end{bmatrix},$$

and the elements of E^{i} are given in terms of Kronecker's delta as

$$(E^{i})_{jk} = \delta_{k-j,3(i-1)}.$$

The atomic displacement vector for the cell L is obtained by collecting $x_{i}(L)$ columnwise, and is written in the form

$$x(L) = D_{x}(L)\sigma + x_{\rho}, \tag{15}$$

where

$$D_{x}(L) = \Sigma_{i}\tilde{E}^{i}D^{i}(L).$$

The pairwise interaction potential between the atoms $\mathbf{0}i$ and Lj may be expanded as the power series of the relevant Cartesian displacements in the form

$$V^{ij}\{r_{ij}(L)\} = V^{ij}\{r_{ij}^{0}(L)\} - \tilde{f}_{ij}(L)\{x_{i}(\mathbf{0}) - x_{j}(L)\} + \frac{1}{2}\{\tilde{x}_{i}(\mathbf{0}) - \tilde{x}_{j}(L)\}F_{ij}(L)\{x_{i}(\mathbf{0}) - x_{j}(L)\}, \tag{16}$$

where $r_{ij}(L)$ is the distance between $\mathbf{0}i$ and Lj, and the superscript 0 denotes the value when $\sigma=\mathbf{0}$. The linear and the quadratic coefficients in Eq. 16 are given by

$$f_{ij}(L) = -\{\partial V^{ij}/\partial r_{ij}(L)\}e_{ij}^{0}(L)$$

and

$$\boldsymbol{F}_{ij}(\boldsymbol{L}) = \{\partial V^{ij}/\partial r_{ij}(\boldsymbol{L})\}\{\boldsymbol{E}-\boldsymbol{e}_{ij}{}^0(\boldsymbol{L})\tilde{\boldsymbol{e}}_{ij}{}^0(\boldsymbol{L})\}/r_{ij}{}^0(\boldsymbol{L}) + \{\partial^2 V^{ij}/\partial r_{ij}(\boldsymbol{L})^2\}\boldsymbol{e}_{ij}{}^0(\boldsymbol{L})\tilde{\boldsymbol{e}}_{ij}{}^0(\boldsymbol{L}),$$

respectively, where $\boldsymbol{e}_{ij}{}^0(\boldsymbol{L})$ denotes the unit vector along the direction from $\boldsymbol{L}j$ to $\boldsymbol{0}i$. Substituting Eq. 14 into Eq. 16, dividing by $1+\delta_{ij}$ and summing over all the intermolecular atom pairs $\boldsymbol{0}i$ and $\boldsymbol{L}j$ such that $i \leqq j$, we obtain the portion of the potential energy in Eq. 11 arising from V_{ex}. Since we are dealing with a homogeneous deformation, the contribution of V_{in} to Eq. 11 can be evaluated by writting down V_{in} for the cell $\boldsymbol{0}$ in terms of the Cartesian displacements as

$$V_{\text{in}} = -\tilde{\boldsymbol{f}}_x{}^{\text{in}}\boldsymbol{x}(\boldsymbol{0}) + (1/2)\tilde{\boldsymbol{x}}(\boldsymbol{0})\boldsymbol{F}_{xx}{}^{\text{in}}\boldsymbol{x}(\boldsymbol{0}),$$

and substituting Eq. 15. Carrying out these calculations, we have

$$\boldsymbol{f}_\sigma = \sum_{i\leqq j,\boldsymbol{L}}\sum (1+\delta_{ij})^{-1}\tilde{\boldsymbol{D}}^{ij}(\boldsymbol{L})\boldsymbol{f}_{ij}(\boldsymbol{L}) + \tilde{\boldsymbol{D}}_x(\boldsymbol{0})\boldsymbol{f}_x{}^{\text{in}}, \tag{17}$$

$$\boldsymbol{F}_{\sigma\sigma} = \sum_{i\leqq j,\boldsymbol{L}}\sum (1+\delta_{ij})^{-1}\tilde{\boldsymbol{D}}^{ij}(\boldsymbol{L})\boldsymbol{F}_{ij}(\boldsymbol{L})\boldsymbol{D}^{ij}(\boldsymbol{L}) + \tilde{\boldsymbol{D}}_x(\boldsymbol{0})\boldsymbol{F}_{xx}{}^{in}\boldsymbol{D}_x(\boldsymbol{0}) \tag{18}$$

and

$$\boldsymbol{F}_{\sigma x} = \sum_{i\leqq j,\boldsymbol{L}}\sum (1+\delta_{ij})^{-1}\tilde{\boldsymbol{D}}^{ij}(\boldsymbol{L})\boldsymbol{F}_{ij}(\boldsymbol{L})(\boldsymbol{E}^i-\boldsymbol{E}^j) + \tilde{\boldsymbol{D}}_x(\boldsymbol{0})\boldsymbol{F}_{xx}{}^{in}, \tag{19}$$

where

$$\boldsymbol{D}^{ij}(\boldsymbol{L}) = \boldsymbol{D}^i(\boldsymbol{0}) - \boldsymbol{D}^j(\boldsymbol{L}).$$

Substituting Eq. 13 into Eq. 11, and using the condition that the potential energy is stationary with respect to the microscopic deformation, we have

$$\boldsymbol{q}_\rho = \boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\boldsymbol{f}_x - \boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\tilde{\boldsymbol{F}}_{\sigma x}\boldsymbol{\sigma}, \tag{20}$$

where $\boldsymbol{\Lambda}$ is the diagonal matrix of the eigenvalues of $\boldsymbol{m}^{-1/2}\boldsymbol{F}_{xx}\boldsymbol{m}^{-1/2}$ corresponding to the genuine normal modes, and the eigenvectors for the translations of the whole crystal are excluded from $\boldsymbol{L}_x$. By eliminating $\boldsymbol{q}_\rho$ from Eqs. 13 and 20 and substituting the result into Eq. 11, the potential energy is rewritten as

$$V = V_0 - (\tilde{\boldsymbol{f}}_\sigma - \boldsymbol{L}_x\boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\tilde{\boldsymbol{F}}_{\sigma x})\boldsymbol{\sigma} + (1/2)\tilde{\boldsymbol{\sigma}}(\boldsymbol{F}_{\sigma\sigma} - \boldsymbol{F}_{\sigma x}\boldsymbol{L}_x\boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\tilde{\boldsymbol{F}}_{\sigma x})\boldsymbol{\sigma}. \tag{21}$$

The quadratic part of Eq. 21 divided by the volume of the unit cell gives the matrix of the elastic constants as derived by Shiro and Miyazawa.[12]

Let a set of infinitesimal changes of the cell dimensions be denoted in a vector form

$$\Delta\boldsymbol{a} = [\Delta a\ \Delta b\ \Delta c\ \Delta\alpha\ \Delta\beta\ \Delta\gamma]^{\text{T}},$$

and those required to eliminate the linear terms in Eq. 21 be $\Delta\boldsymbol{a}^*$. By differentiating Eq. 21 with respect to $\boldsymbol{\sigma}$ and using the transformation

$$\boldsymbol{\sigma} = \boldsymbol{A}\,\Delta\boldsymbol{a}, \tag{22}$$

the vector $\Delta\boldsymbol{a}^*$ is derived to be

$$\Delta\boldsymbol{a}^* = (\tilde{\boldsymbol{f}}_\sigma - \tilde{\boldsymbol{f}}_x\boldsymbol{L}_x\boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\tilde{\boldsymbol{F}}_{\sigma x})(\boldsymbol{F}_{\sigma\sigma} - \boldsymbol{F}_{\sigma x}\boldsymbol{L}_x\boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\tilde{\boldsymbol{F}}_{\sigma x})^{-1}\boldsymbol{A}^{-1} \tag{23}$$

Derivation of the transformation matrix $\boldsymbol{A}$ and its inverse is given in Appendix.

The first term of Eq. 20 represents those microscopic displacements of the atoms which are required to minimize the energy of a stress-free crystal in the first-order approximation. These displacements may also be expressed in terms of the internal symmetry and the external coordinates in the form

$$\boldsymbol{S}_{\text{in}}^* = -\boldsymbol{B}_{\text{in}}\boldsymbol{L}_x\boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\boldsymbol{f}_x \tag{24}$$

and

$$\boldsymbol{S}_{\text{ex}}^* = -\boldsymbol{B}_{\text{ex}}\boldsymbol{L}_x\boldsymbol{\Lambda}^{-1}\tilde{\boldsymbol{L}}_x\boldsymbol{f}_x. \tag{25}$$

Iterative minimization of the potential energy can now be carried out by the Newton-Raphson method in which $\Delta\boldsymbol{a}^*$ and $\boldsymbol{S}_{\text{ex}}^*$ are used as the correction vectors.[13] The normalized external coordinates are not so convenient to visualize the actual position and orientation of each molecule in the unit cell. Instead, we may use the translations along the principal axes of inertia, T_1^*, T_2^*, and T_3^*, and the rotations around those axes, R_1^*, R_2^*, and R_3^*. Denoting the vector of these quantities as $\boldsymbol{T}_{\text{ex}}^*$ and introducing a 6×6 diagonal matrix

$$\boldsymbol{M}^{-1/2} = \text{diag}[M^{-1/2}\ M^{-1/2}\ M^{-1/2}\ I_1^{-1/2}\ I_2^{-1/2}\ I_3^{-1/2}],$$

where M is the molecular mass and I_1, I_2, and I_3 are the principal moments of inertia of the molecule, we have

$$\tilde{\boldsymbol{T}}_{\text{ex}}^* = [T_1^*\ T_2^*\ T_3^*\ R_1^*\ R_2^*\ R_3^*] = \tilde{\boldsymbol{S}}_{\text{ex}}^*\boldsymbol{M}^{-1/2}. \tag{26}$$

When the unit cell has any symmetry elements, calculation of Eq. 25 for the non-totally symmetric species of the factor group can be avoided by using a set of properly chosen symmetry coordinates. If all the rotations R_i^* are small, the combined rotation is defined uniquely as their vector sum, the magnitude of which is

$$\theta = |R_1^{*2}+R_2^{*2}+R_3^{*2}|^{1/2},$$

and the direction cosine between the axis of the rotation and the ith principal axis is

$$l_i = R_i^*/\theta.$$

In the frame of the principal axes, the rotation is performed by using the transformation matrix familiar in crystallography[14] which consists of the diagonal elements

$$\theta_{ii} = \cos\theta + l_i^2(1-\cos\theta)$$

and the off-diagonal elements

$$\theta_{ij} = l_il_j(1-\cos\theta) + (j-i)(-1)^{i+j}l_{6-i-j}\sin\theta/|i-j|.$$

The Cartesian coordinates of the kth atom in the molecule after the correction of the structure according to $\Delta\boldsymbol{a}^*$ and $\boldsymbol{T}_{\text{ex}}^*$ are calculated from those before the correction, $x_k{}^0$, $y_k{}^0$, and $z_k{}^0$, by

$$x_k^* = \sum C_{xi}[\sum\theta_{ij}\{C_{xj}(x_k{}^0-x_g{}^0)+C_{yj}(y_k{}^0-y_g{}^0)+C_{zj}(z_k{}^0-z_g{}^0)\}+T_i^*]+(1+\sigma_{xx})x_g{}^0+\sigma_{xy}y_g{}^0+\sigma_{zx}z_g{}^0, \tag{27}$$

where C_{xi} is the direction cosine between the x axis and the ith principal axis, and $x_g{}^0$, $y_g{}^0$, and $z_g{}^0$ are the coordinates of the center of mass of the molecule before the correction, and similar expressions for the y and the z components.

Discussion

In the procedure described above, the internal correction vector S^*_{in} is excluded from the iteration and the internal structure of the molecules is accordingly kept unchanged throughout the energy minimization. If the matrix $L_x A^{-1} \tilde{L}_x$ is positive definite, the force f^{ex}_{ex} tends to vanish when the external correction vector S^*_{ex} diminishes according to Eq. 25, since

$$f_x = \tilde{B}_{ex} f^{ex}_{ex}$$

and the matrix $B_{ex} L_x A^{-1} \tilde{L}_x \tilde{B}_{ex}$ has an inverse, and S^*_{in} in Eq. 24 is made automatically a zero vector at a potential minimum. This condition is fulfilled by any model potential for which all the calculated lattice frequencies are real. In this respect, the present scheme of the crystal packing analysis resembles that based on the rigid molecule approximation in which the molecular structure can be chosen in the same way as that determined experimentally. The present method affords, however, a useful information not available from the rigid molecule approximation, *i.e.*, the molecular distortion vector S^c_{in}, which may be compared with the structure data in the gaseous state or the results of theoretical calculations on the electronic states of the isolated molecule.

The use of Eqs. 12 and 17 including f^{in}_x is essential in the calculation of Δa^* even when the rigid molecule approximation is adopted. In this case, the terms arising from V_{in} should be excluded from Eqs. 18 and 19, and the elements of A and L_x in Eq. 23 related to the internal modes should be absent. Since the rigid molecule approximation is the limiting case that the diagonal elements of F become infinite, the distortion S^c_{in} turns out to be infinitesimal but the product

$$f^{in}_{in} = -F S^c_{in}$$

remains undiminished because it is determined purely by the external force. This point has so far been overlooked and f^{ex}_x instead of f_x has been used as the net force acting on the atoms by many investigators who have adopted the rigid molecule approximation.

In contrast to the case of Δa^*, the effect of f^{in}_{in} on T^*_{ex} is expected to be important only for non-rigid molecules. If we use f^{ex}_x in place of f_x in Eq. 25, it follows from Eq. 5 that

$$S^*_{ex} = -B_{ex} L_x A^{-1} \tilde{L}_x (\tilde{B}_{in} f^{ex}_{in} + \tilde{B}_{ex} f^{ex}_{ex}). \quad (28)$$

If the internal and the external modes do not couple with each other, the matrix of the coefficients of f^{ex}_{in} in Eq. 28 vanishes and f^{ex}_x leads to the same T^*_{ex} as f_x does. This condition is approximately fulfilled when the crystal consists of nearly rigid molecules, whereas there are no simple conditions for the cancellation of the contributions of f^{in}_x to f_x and f_a in Eq. 23.

In order to check the effect of the internal force on the packing analysis of α-glycine, L-alanine, and DL-alanine crystals, the correction vectors Δa^* and T^*_{ex} were calculated from Eqs. 23 and 25, respectively, and also from the same equations in which f^{in}_x was set equal to zero. In this calculation, the atomic coordinates, the potential parameters and the ranges of the lattice sums were taken in the same way as those in our previous studies on the crystal vibrations of these amino acids.[5,7] As shown in Table 1, the correction vectors of each amino acid calculated for the cases $f^{in}_x \neq 0$ and $f^{in}_x = 0$ are roughly parallel to each other. As to the individual components of Δa^* and T^*_{ex}, however, there is no systematic trend in signs and relative magnitudes of the differences between the values obtained from the two calculations. Some of the components of T^*_{ex} change quite sensitively when f_x is replaced by f^{ex}_x, owing probably to the coupling between the internal and the external modes. These results suggest that we should take account of the internal force of non-rigid molecules correctly in searching for the crystal structure corresponding to the energy minimum for a given model potential. Similar consideration may be required when we try to adjust the potential parameters in such a way as to minimize the correction vectors.

We wish to express our sincere thanks to Prof. Kenji Osaki and Prof. Takeo Matsubara of Kyoto University for their valuable advices. The numerical calculations were carried out on FACOM 230-75 and M200 computers at the Data Processing Center of Kyoto University.

TABLE 1. COMPONENTS OF CORRECTION VECTORS Δa^* AND T^*_{ex}

f^{in}_x	α-Glycine		L-Alanine		DL-Alanine	
	$\neq 0$	$=0$	$\neq 0$	$=0$	$\neq 0$	$=0$
Δa^*	0.414	0.401	−0.353	−0.145	1.003	0.650
Δb^*	1.013	1.158	1.063	0.754	−0.388	−0.278

R_3^*	−0.036	−0.013	0.082	0.095	0.133	0.131

Δa^*, Δb^*, Δc^*, and T_i^* are in Å, and $\Delta \beta^*$ and R_i^* are in radian.

Appendix

Let the Cartesian coordinates of the atoms in a unit cell be defined in the framework where the x axis coincides with the a axis and the y axis lies on the ab plane. Then the matrix of the transformation from the fractional coordinates along the cell axes to the Cartesian coordinates is given by

$$\boldsymbol{C} = \begin{bmatrix} a & b\cos\gamma & c\cos\beta \\ 0 & b\sin\gamma & -c\sin\beta\cos\alpha^* \\ 0 & 0 & c\sin\beta\sin\alpha^* \end{bmatrix}, \tag{A1}$$

where the asterisk denotes the lattice constants of the reciprocal lattice.[14] By labelling the quantities at the equilibrium under vanishing stress with the subscript 0, the inverse of $\boldsymbol{C}$ at the equilibrium is expressed as

$$\boldsymbol{C}_0^{-1} = \begin{pmatrix} \dfrac{1}{a_0} & \dfrac{\cos\gamma_0}{a_0\sin\gamma_0} & \dfrac{\cos\beta_0^*}{a_0\sin\gamma_0\sin\beta_0^*} \\ 0 & \dfrac{1}{b_0\sin\gamma_0} & \dfrac{\cos\alpha_0^*}{b_0\sin\gamma_0\sin\alpha_0^*} \\ 0 & 0 & \dfrac{1}{c_0\sin\beta_0\sin\alpha_0^*} \end{pmatrix}. \tag{A2}$$

The elements of the matrix $\boldsymbol{C}\boldsymbol{C}_0^{-1}$ are related to the strain components by

$$(\boldsymbol{C}\boldsymbol{C}_0^{-1})_{ij} = \delta_{ij} + \sigma_{ij}, \tag{A3}$$

where δ_{ij} is Kronecker's delta and the subscripts 1, 2, and 3 for σ_{ij} represent x, y, and z, respectively.[15] Substituting Eqs. (A1) and (A2) into Eq. (A3), expanding each of the six independent elements of $\boldsymbol{C}\boldsymbol{C}_0^{-1}$ as a power series of the variations of the lattice constants and neglecting the higher-order terms, we obtain Eq. (22) in the text. The transformation matrix can be factored into two matrices

$$\boldsymbol{A}_1 = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & c \\ 0 & 0 & 1 & -r & -p & -pr \\ 0 & r & -r & -1 & c & cr-p \\ p & cr & b/s & 0 & -1 & -r \\ -c & c & 0 & 0 & 0 & -1 \end{pmatrix},$$

where

$$p = \cot\beta_0^*/\sin\gamma_0, \quad r = \cot\alpha_0^*, \quad s = \sin\alpha_0^*,$$
$$b = \cot\beta_0 \quad \text{and} \quad c = \cot\gamma_0$$

and

$$\boldsymbol{A}_2 = \mathrm{diag}[a_0^{-1}\, b_0^{-1}\, c_0^{-1}\ (\sin\gamma_0\sin\beta_0^*)^{-1}\ (\sin\alpha_0^*)^{-1}\ 1],$$

and is written as $\boldsymbol{A} = \boldsymbol{A}_1\boldsymbol{A}_2$. By a straightforward manipulation, an expression for the inverse of $\boldsymbol{A}_1$ was obtained as

$$\boldsymbol{A}_1^{-1} = \sin^2\gamma_0 \begin{pmatrix} 1+c^2 & 0 & 0 & 0 & 0 & 0 \\ c^2 & 1 & 0 & 0 & 0 & c \\ 0 & 0 & 0 & 0 & 0 & 0 \\ pc & -pc & 0 & 0 & 0 & p \\ 0 & 0 & 0 & 0 & 0 & 0 \\ -c & c & 0 & 0 & 0 & -1 \end{pmatrix}$$
$$+ \sin^2\beta_0 \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ b^2 & a^2 & s^2 & -as & bs & -ab \\ bq & a(s-bp) & ws & (bp-s)s & qs & -aq \\ -b/s & arb & bs & -ab & -1 & r \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix},$$

where

$$q = (pr-c)s = \cot\gamma_0^*/\sin\beta_0, \quad a = rs = \cos\alpha_0^*$$

and

$$w = bc - rs = \cos\alpha_0/\sin\beta_0\sin\gamma_0.$$

Since $\boldsymbol{A}_2$ is diagonal, it follows immediately that

$$\boldsymbol{A}_2^{-1} = \mathrm{diag}\,[a_0\ b_0\ c_0\ \sin\gamma_0\ \sin\beta_0^*\ \sin\alpha_0^*\ 1],$$

and we can express the inverse of $\boldsymbol{A}$ analytically as $\boldsymbol{A}^{-1} = \boldsymbol{A}_2^{-1}\boldsymbol{A}_1^{-1}$.

Intermolecular Potential, Vibrational Spectra, and Structures of Amino Acid Crystals. II. α-Glycine, L-Alanine, and DL-Alanine Crystals

Katsunosuke MACHIDA,* Akira KAGAYAMA, and Yoshihiro KURODA
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received November 15, 1980)

The lattice energies, the deviations of the structure parameters from the model equilibrium, the molecular distortions due to the intermolecular interaction and the vibrational frequencies of α-glycine, L-alanine and DL-alanine crystals were calculated from three sets of parameters for the pairwise atom-atom interaction potential functions. By comparing the calculated quantities with the observed ones, the combination of the exp-6 type non-bonded potential and the Lippincott type hydrogen bond stretching potential is shown to afford a better model of the intermolecular interaction in these crystals than the combination of the Lennard-Jones 6-12 potential and the general hydrogen bond 10-12 potential.

Evaluation of the intermolecular forces acting in amino acid crystals is an indispensable step for the conformational study of proteins. We have recently investigated the polarized Raman spectra of single crystals of glycine (α-form), L-alanine and DL-alanine,[1-4] and have obtained a common set of potential parameters with which the observed vibrational frequencies of these amino acids can be elucidated fairly well. The intermolecular potential of amino acid crystal is very complicated, however, owing to the presence of many terms due to the exchange repulsion and dispersion force, the hydrogen bonding and the Coulomb interaction between atomic charges. Even the simplest description of these forces requires too many parameters to be estimated from the vibrational spectra alone.

The present work has been undertaken to check if the potential parameters used in our previous analyses of the vibrational spectra are compatible with the crystal structure itself. By taking account of the non-rigidity of the molecule as described in the preceding paper,[5] the lattice energies, the equilibrium crystal structures, the molecular distortions due to the intermolecular force, the elastic constants and the vibrational frequencies have been calculated and a modification of a few potential parameters has been attempted. For the sake of comparison, the same calculations have been carried out by using the model potential proposed by Momany *et al.* on the basis of their extensive analyses of the conformations of amino acid crystals.[6]

Calculation

The potential energy per molecule was written in the same functional form as those used in our previous analyses of the vibrational spectra of α-glycine, L-alanine, and DL-alanine crystals.[1-4] The intramolecular part, $V_{\rm in}$, is the simple Urey-Bradley type quadratic force field supplemented with the diagonal terms in the CO_2^- out-of-plane deformation coordinate and the internal rotation coordinates around the N–C and the C–C bonds.[7] The intermolecular part, $V_{\rm ex}$, is the sum of the pairwise potential terms of the three types,

$$V_1 = \frac{1}{2}\sum_i\sum_j [-A_{ij}r_{ij}^{-6} + B_{ij}\exp(-C_{ij}r_{ij})]$$

$$V_2 = -\frac{1}{2}\sum_i\sum_j D_{ij}\exp[-k_{ij}r_{ij}^e(r_{ij}-r_{ij}^e)^2/2D_{ij}r_{ij}]$$

and

$$V_3 = \frac{1}{2}\sum_i\sum_j e_ie_j\,\mathrm{erfc}(\sqrt{\pi}Kr_{ij})/r_{ij},$$

where r_{ij} is the distance between the atoms i and j, the index i runs over a single molecule and j over the others. The potential V_1 represents the exchange-repulsion and dispersion interaction for the atom pairs H···H, C···H, C···C, O···H(C), and N···O. V_2 is the Lippincott type stretching potential[8] of the hydrogen bonds (N)H···O, and V_3 arises from the Coulomb interaction between the atomic charges e_i and e_j. The vector of the molecular distortion, $\boldsymbol{S}_{\rm in}^e$, the correction vector for the lattice constants, $\Delta\boldsymbol{a}^*$, and that for the molecular translation and rotation, $\boldsymbol{T}_{\rm ex}^*$, were calculated from Eqs. 9, 23, and 26, respectively, in the preceding paper,[5] and $V_{\rm in}$ from

$$V_{\rm in} = (1/2)\tilde{\boldsymbol{S}}_{\rm in}^e\boldsymbol{F}\boldsymbol{S}_{\rm in}^e,$$

where $\boldsymbol{F}$ is the potential energy matrix for the intramolecular vibrations. The lattice energy was then calculated from

$$V = V_{\rm in} + V_{\rm ex}.$$

An order-of-magnitude estimation of the zero point energy per molecule was made according to

$$V_0 = (1/2n)\sum_{i=1}^{6n-3}\nu_i^{\rm calcd},$$

where n is the number of molecules per primitive unit cell and $\nu_i^{\rm calcd}$ is the calculated value of the ith optical-active lattice frequency.

The calculation was carried out for two sets of potential parameters, Sets I and II. Both the sets consist of the same parameters as those used in our unified treatment of the vibrational spectra of α-glycine and DL-alanine crystals,[4] except that the parameters A_{ij} and C_{ij} for the N···O contact in Set II were taken as 3266.1 kJ mol^{-1} Å^6 and 37.11 Å^{-1}, respectively. The meaning of this adjustment will be given in the next section. The summation limit for V_1 was taken to be 8 Å. The limit of 6 Å used previously is sufficient for the convergence of the vibrational frequencies, but causes truncation errors up to 10% for the lattice energy. According to Williams,[9] the Coulomb potential V_3 was written in the form including the complementary error function as a con-

vergence factor. In a preliminary survey of the Coulombic lattice sum, we recognized little indication of the convergence of V_3 on extending the summation limit to 40 Å in the absence of the convergence factor. When the convergence constant K was taken to be 0.20 and 0.05, however, the energy converged with enough accuracy at the summation limits of 20 Å and 40 Å, respectively. We calculated the complete Coulomb energies for several representative choices of K by Bertaut's method,[10] and estimated the errors due to the neglect of the reciprocal lattice sum to be about 4 kJ mol^{-1} for α-glycine and L-alanine crystals and about 13 kJ mol^{-1} for DL-alanine crystal. The comparatively large error for DL-alanine may be ascribed to the residual dipole moment of the unit cell resulting from the polar structure of this crystal.[11]

In order to compare the behaviors of various types of the model potential functions, the same calculations as described above were carried out for the model potential proposed by Momany *et al.* in their conformation analysis of amino acid crystals.[6] In these authors' model, which will be abbreviated as MCS model hereafter, V_1 is given by the Lennard-Jones 6—12 potential, V_2 by the general hydrogen bond 10—12 potential and V_3 is written in the form including the reciprocal of the effective dielectric constant in place of the convergence factor. All the potential parameters and the atomic charges were taken from the original works.[6]

In the calculation with Sets I and II, the atomic coordinates were taken from the neutron diffraction study for α-glycine crystal[12] and the X-ray analyses for L-alanine[13] and DL-alanine[11,14] crystals. The positions of the hydrogen atoms of alanine were then adjusted by scaling the bond vectors in such a way that the averages of the C–H and the N–H bond lengths in each crystal became equal to those in α-glycine crystal, 1.09 Å and 1.039 Å, respectively. The same coordinates were used in our previous analyses of the crystal vibrations.[1-4] The atomic coordinates for MCS model were calculated from those for Sets I and II in the following two steps. First we shortened the N–H bondlengths of glycine and alanine and the C–H bondlengths of glycine to 1.00 Å without changing the valence angles and the internal rotation angles relevant to these bonds. The lattice constants of α-glycine and L-alanine crystals were next changed from the experimental values to those reported to give the minimum energy of the model potential according to the calculation of Momany *et al.*[6] In this adjustment of the lattice constants, the fractional coordinates of the center of mass of each molecule along the crystal axes were kept unchanged from the experimental values. No adjustment of the lattice constants were made for DL-alanine crystal.

Results and Discussion

The calculated values of the lattice energies, the components of the correction vectors $\boldsymbol{T}^*_{ex}$ and $\Delta\boldsymbol{a}^*$ and the diagonal elastic constants are listed in Tables 1 and 2 for the three sets of potential parameters investigated. The contributions of V_{in} and V_0 to the total energy are very small compared to those of V_{ex}, and may be disregarded at the present level of approximation. In support of the correctness of our

The summation limit for V_3 is 40 Å for Sets I and II, and 20 Å for MCS model. K for Sets I and II is 0.05 Å^{-1}. The units are the same as those in Table 1.

algorithm, the lattice energies calculated for MCS model are comparable with those reported by the original authors.[6] Recently, Gaffney *et al.* have estimated the heat of sublimation of glycine into the gaseous zwitterions by adding their mass-spectroscopic data of the heat of evaporation to the *ab initio* energy difference between the classical and the zwitterionic structures.[15] The value of *ca.* 218 kJ mol^{-1} obtained by these authors agrees very well with the lattice energy calculated for both Sets I and II.

The components of $\Delta\boldsymbol{a}^*$ of DL-alanine crystal calculated for MCS model were large because we used the lattice constants not adapted to this model. As to the components of $\boldsymbol{T}^*_{ex}$, MCS model seems to give an excellent result although these degrees of freedom have been left out of consideration by the original authors in determining the potential parameters.[6] MCS model were found, however, to give negative values of the elastic constant C_{44} of α-glycine and L-alanine crystals, failing to keep these crystals stable against the shearing stress along the bc (bc* for α-glycine crystal) plane. In such a case, the correction vectors $\Delta\boldsymbol{a}^*$ and $\boldsymbol{T}^*_{ex}$ indicate the direction of a pathway not toward a minimum but toward a saddle point on the potential supersurface. A large negative value of C_{66} was obtained for α-glycine crystal when the longest hydrogen bond, *i.e.*, one of the bifurcated hydrogen bonds with the bond distance 2.365 Å, was excluded from V_2 of Set I. This hydrogen bond is suggested accordingly to play an important role of stabilizing the crystal against the shearing stress along the ab plane. In a trial calculations without V_2 or V_3, some of C_{11}, C_{22} and C_{33} became negative, indicating that such a model cannot hold the crystal from expansion. The correction vector $\Delta\boldsymbol{a}^*$ of L-alanine calculated for MCS model has a fairly large component despite the use of the energy-minimizing lattice constants reported by Momany *et al.*[6] A possible origin of such a discrepancy between these authors' calculation and the present result is the effect of the microscopic deformation which partly relaxes the macroscopic stress. A slight difference in the assumed molecular geometry or in the scheme of taking the lattice sum may also result in different equilibrium structures.

For each of the three amino acid crystals, the largest of Δa^*, Δb^*, and Δc^* calculated for Set I is positive in sign and is associated with the axis along the longest edge of the unit cell. Since about half of the hydrogen bonds per unit cell of each crystal are roughly directed along this axis, the largest deviation is attributable to deficiency of the potential parameters for the hydrogen bonds. Only worse results were obtained, however, in various trials to adjust the parameters in V_2 or to replace the Lippincott potential by the 10-12 potential. Accordingly, we tried to modify the exp-6 type potential in V_1 related to the N···O contact, for which the original parameters had been estimated from those for the N···N and the O···O contacts involving no hydrogen bonds.[16] After the failure of several attempts to change the depth and the curvature of the potential curve, Set II was obtained by shifting the minimum to the same internuclear distance as that of the 10-12 potential used by Momany *et al.*[6] The revision was readily carried out by expressing the potential in terms of the parameters ε, ρ, and μ introduced by Taddei *et al.*,[17] and changing only ρ from 3.125 Å to 3.500 Å. As seen from Table 1, Set II was successful in confining all the elements

a) The change of the valence angle shown in the parentheses. b) $\rho=(1/2)[\delta(\text{C-C'-O}_t)-\delta(\text{C-C'-O}_c)]$, where O_t and O_c are the oxygen atoms at the trans and the cis positions, respectively, of the nitrogen atom. c) The definition is given in Ref. 7. t(C-C′O_2) is zero when O_c is at the exact cis position of the nitrogen atom. t(C-NH_3) and t(C-CH_3) are zero for the staggered conformations. d) The experimental (X-ray or neutron diffraction) value minus the *ab initio* value. e) The lattice sums for V_3 were taken as in Table 2.

of $\Delta\boldsymbol{a}^*$ and $\boldsymbol{T}^*_{ex}$ within the range between −0.27 Å and 0.16 Å.

Table 3 shows the calculated distortions of the skeletal deformation and the internal rotation coordinates brought about by the balance between the internal and the external forces. The distortions of the stretching coordinates are all smaller than the uncertainty in the corresponding bondlengths reported in the literature on the X-ray analyses,[11-14] and are not given here. For the deformation coordinates, an alternative set of $\boldsymbol{S}^c_{in}$ is available from the crystallographic data[11-14] by subtracting therefrom the theoretical values of the equilibrium structure parameters of the isolated zwitterionic glycine based on an *ab initio* LCMO-SCF method.[18] The signs of all the calculated distortions for Sets I and II agree with those predicted from the combination of the results of the crystallographic and the quantum-mechanical studies. As to the distortions of the internal rotation angles, all the signs calculated for Set I agree with those derived by assuming that the equilibrium structure of the isolated zwitterionic amino acids takes the staggered conformation around the N-C and the (CH_3)-C bonds and the planar conformation around the C-(CO_2) bond. Set II gave the wrong sign to the distortion of the internal rotation angle of the CO_2 group of α-glycine crystal, while MCS model predicted the sign of this distortion of the three amino acids correctly. At present, accuracy of this sort of calculation seems to be far from sufficient for discussing the difference in the molecular structure between L-alanine and DL-alanine crystals.

An iterative search for the minimum of the model potential according to the Newton-Raphson method[19] was carried out by taking the summation limit and the convergence constant for V_3 as 20 Å and 0.20, respectively. This limit was not large enough to disregard the effect of the neglected reciprocal sum, but was chosen in order to save computing time. Whenever the energy did not decrease in a single step, the correction vectors $\Delta\boldsymbol{a}^*$ and $\boldsymbol{T}^*_{ex}$ were multiplied by a damping factor 0.5. The iteration was repeated until all the elements of $\Delta\boldsymbol{a}^*$ and $\boldsymbol{T}^*_{ex}$ became less than 0.001 Å for the length and 0.001 radian for the angle. Set I failed to give any convergence of this procedure for L-alanine, leading to destruction of the crystal with negative infinite energy. Diverging results were obtained for the three amino acid crystals also by using MCS model. The success of this model for α-glycine and L-alanine crystals reported by Momany *et al.*[6] may be ascribed accordingly to the fixing of some degrees of freedom of molecular motions. The calculated equilibrium structures for the converging cases are described in Table 4 in terms of the lattice constants, the coordinates of the centers of masses and the Eulerian angles which define the principal axes of inertia of the molecules with reference to the unit cell axes. The maximum and the average distances between the calculated and the experimental atomic positions are also shown for the sake of comparison. Although the Eulerian angles seem to indicate that the calculated and the experimental orientations of the molecules are quite different from each other, the average deviations of the atomic positions are not too large, expecially for Set II, in comparison with the thermal motions of atoms in usual crystals. It is worth noting that these structures satisfy the equilibrium condition for all the degrees of freedom

The calculated frequencies to which the CO_2 torsional mode contributes dominantly are shown in italics.

of atomic motions under the influence of the internal and the external forces of the model. The numbers of iterations required to reach the energy minimum were 9 to 10 for Set I and 6 to 7 for Set II, being even smaller than the number of the adjustable parameters in the latter case.

The deviation of the calculated lattice constants from the observed values in Table 4 differs considerably from the initial guess of the corresponding elements of Δa^* in Tables 1 and 2. The inversion of signs is encountered in many cases and the structure of α-glycine crystal can be predicted by Sets I and II equally well after the iteration. Such discrepancies between the initial guess and the final result are attributable to the higher-order elastic constants as well as to the correlation between Δa^* and T^*_{ex}, both neglected in the present treatment.

The calculated and the observed frequencies of the lattice vibrational modes and the CO_2 torsional mode are shown in Table 5. In each symmetry species of the three amino acid crystals, the CO_2 torsional mode is the lowest-frequency internal mode and apts to couple appreciably with the lattice modes. Among the three sets of the potential parameters, Set I gave the closest fit between the calculated and the observed frequencies, and Set II ranks next. There are systematic deviations of the calculated frequencies for Sets I and II toward the lower- and the higher-frequency sides, respectively, of the observed values. For about half the data in Table 5, the observed frequency falls between the corresponding frequencies calculated from these two sets. On the other hand, MCS model failed to reproduce the observed frequencies between 200 and 140 cm^{-1} of L-alanine and DL-alanine crystals, and led to a vanishing frequency in the totally symmetric species of L-alanine. As to the factor group splittings of the deformation modes of the alkyl groups, the results for Sets I and II are essentially the same as those reported previously.[1-3] Compared to these sets, MCS model gave too large splittings of about 30 cm^{-1} for the CH_3 asymmetric deformation mode of DL-alanine crystal, and too small splittings of about 3 cm^{-1} for the CH_2 bending mode of α-glycine crystal. This result seems to reflect the difference in the dependence of $\partial^2 V/\partial^2 r$ on r between the 6-12 and the exp-6 potentials for the H···H contact. By substituting the potential parameters used in this work, we have confirmed that the former falls off more rapidly than the latter in the range between 2.3 and 3.0 Å in which the nearest-neighbor H···H distances of the alkyl groups of α-glycine, L-alanine and DL-alanine crystals are included.

According to the present calculation, the combination of the exp-6 type non-bonded atom-atom interaction potential and the Lippincott type hydrogen bond stretching potential gives more reasonable results with respect to the lattice energy, the crystal structure and the vibrational frequencies of the three amino acid crystals, than the combination of the Lennard-Jones 6-12 type and the 10-12 type general hydrogen bond potential. There is no assurance, however, as to whether the Lippincott potential is the best representation of the hydrogen bond stretching of amino acids in general. Furthermore, our choice of the parameter r^e_{ij}, which is the intrinsic equilibrium distance of the hydrogen bond, in V_2 (2.0 Å)[4] is very different from the original value of Lippincott and Schroeder (0.97 Å),[8b] and is rather similar to the equilibrium distance of the 10-12 general hydrogen bond potential given by Momany *et al.*[6] Further studies on the other amino acid crystals should be carried out extensively in order to settle this controversy.

The numerical calculations were carried out on a FACOM M200 computer at the Data Processing Center of Kyoto University.

Adsorption of Neutral α-Amino Acids at the Mercury–Aqueous Solution Interface and Hydrophobicity Scales of Amino Acid Side Chains at the Electrified Interfaces

Takashi KAKIUCHI and Mitsugi SENDA*

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 5, 1980)

The adsorption of glycine, DL-serine, L-threonine, L-asparagine, L-glutamine, L-valine, L-leucine, L-methionine, and L-tryptophan at the mercury-aqueous sodium fluoride solution interface has been studied by measuring differential capacities, potentials of zero charge, pzc, and surface tensions at the pzc. The standard adsorption free energies for these amino acids and for the amino acids previously studied have been used to deduce hydrophobicity scales of amino acid side chains at positively charged, negatively charged, and uncharged interfaces. The hydrophobicity scale at the uncharged interface was basically similar to that of Nozaki and Tanford. When the surface was charged positively, the positions of serine and alanine, and of threonine and α-aminobutyric acid, in the scale were reversed. This reversion was primarily ascribed to the difference in the positions of maximum adsorption potentials between the amino acids with an aliphatic side chain and those with a hydroxyl group in the side chain.

In previous papers we have reported the adsorption properties of four α-amino acids with normal hydrocarbon side chains[1] and of phenylalanines[2] at the mercury–aqueous solution interface. This paper is concerned with the adsorption behavior of nine neutral amino acids, *i.e.*, glycine, DL-serine, L-threonine, L-asparagine, L-glutamine, L-valine, L-leucine, L-methionine, and L-tryptophan, at the mercury–aqueous sodium fluoride solution interface.

The primary interest of this study is to find a hydrophobicity scale of amino acid side chains at the electrified interface. In recent years the electrochemical properties of proteins and enzymes at electrode interfaces have been a subject of intense studies.[3] Increasing attention has also been paid to the behavior of proteins and enzymes at the interfaces of two immiscible liquids. Since every interface is invariably electrified due to electric charges and/or oriented dipoles at the interface and the physicochemical properties of the interface largely depend on its electrical state, the hydrophobicity of amino acid side chains at electrified interface is expected to give important information for understanding electrochemical behavior of proteins and enzymes at such interfaces.

Nozaki and Tanford[5] have proposed a hydrophobicity scale of amino acid side chains based on the solubility measurements of amino acids in water and aqueous organic solvents. Aboderin[6] used the relative mobilities of amino acid derivatives in paper chromatography to estimate the hydrophobicity of amino acid side chains. These hydrophobicity scales resort to the physicochemical properties of amino acids in homogeneous bulk phases. On the other hand, the depression of the surface tension of the air–aqueous solution interface caused by the adsorption of amino acids was used by Bull and Breese[7] as a measure of the hydrophobicity. They found fairly good agreement between their hydrophobicity scale and that of Nozaki and Tanford. In the case of air–solution interfaces, however, it is not feasible to control its electrical state. In contrast, the mercury–aqueous solution interface behaves in a certain range of electrode potential as an ideally polarized electrode having an additional degree of freedom for an electrical variable,[8] which enables us to specify and control accurately its electrical state. In addition, the mercury in contact with aqueous solution provides an electrode surface of hydrophobic nature.[9,10] Therefore, the transfer free energies of amino acids from an aqueous bulk phase to the mercury–aqueous solution interface are expected to serve for a measure to estimate the hydrophobicity of amino acid side chains at electrified interfaces.

Experimental

Reagent grade glycine, DL-serine, L-threonine, L-asparagine, L-glutamine, L-valine, L-leucine, L-methionine, and L-tryptophan were obtained from Nakarai Chem. Co., Japan and were twice recrystallized from aqueous ethanol (for glycine, serine, and threonine) or from triple distilled water (for other amino acids). Sodium fluoride, a standard-reagent-for-analysis grade from Hashimoto Chem. Co., Japan, was used as the base electrolyte without further purification.

Test solutions were deaerated by bubbling purified nitrogen gas through the solution for 30 min and kept under nitrogen atmosphere during the measurement. Electrode potential was measured against a saturated calomel electrode (SCE). Procedures for measuring the potential of zero charge, surface tension at this potential, and double layer capacity for the amino acids at the dropping mercury electrode–aqueous solution interface are described elsewhere.[2] All measurements were made at 25±0.2 °C.

Results

The potentials of zero charge(pzc) and surface tensions at this potential for glycine, DL-serine, L-threonine, L-asparagine, L-glutamine, L-valine, L-leucine, L-methionine, and L-tryptophan in 0.500 mol l^{-1} sodium fluoride are summarized in Tables 1 and 2. The relative surface excesses of the amino acids at the pzc were calculated from the surface tension *vs.* logarithm of the amino acid concentration curves by using the basic electrocapillary equation.[11] Differentiation involved in the calculation was made numerically.[12] We assumed that the activity of sodi-

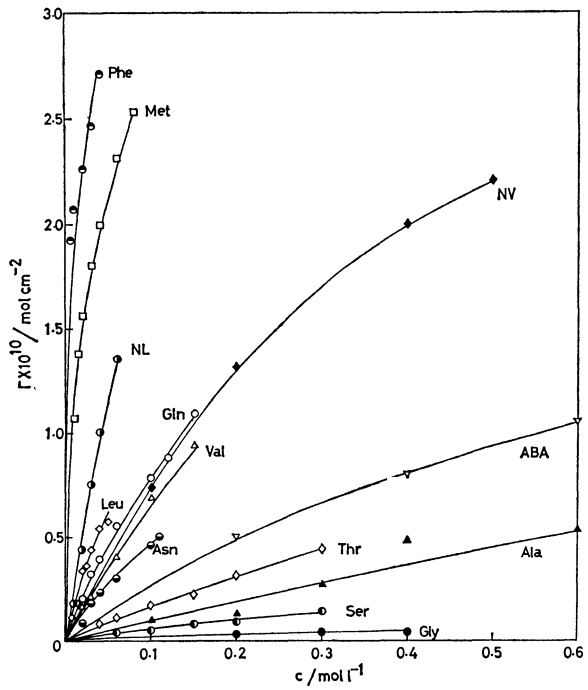

Fig. 1. Adsorption isotherms of amino acids at the mercury–aqueous 0.5 mol l^{-1} sodium fluoride solution interface at the potential of zero charge at 25 °C. See Table 3 for abbreviated name of the amino acids indicated by each line.

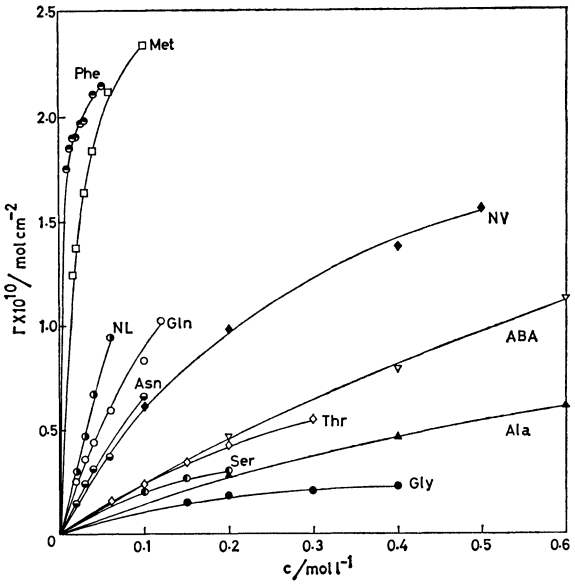

Fig. 2. Adsorption isotherms of amino acids at the positively charged mercury–aqueous 0.5 mol l^{-1} sodium fluoride solution interface (−0.1 V *vs.* SCE) at 25 °C.

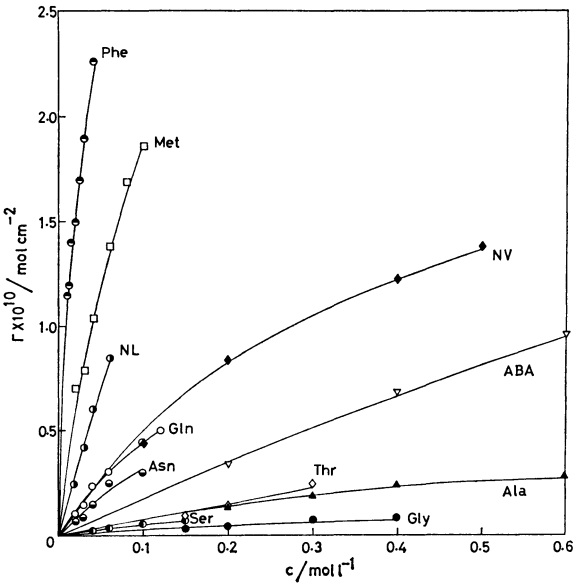

Fig. 3. Adsorption isotherms of amino acids at the negatively charged mercury–aqueous 0.5 mol l^{-1} sodium fluoride solution interface (−0.9 V *vs.* SCE) at 25 °C.

um fluoride and the activity coefficients of amino acids did not change over the experimental range of the amino acid concentration.[13] Figure 1 shows the relative surface excess of the amino acids, except tryptophan, plotted against their molar concentration. The relative surface excess of tryptophan seemed to reach a saturation value already at 0.005 mol l^{-1}, the lowest concentration studied; the surface tension *vs.* logarithm of tryptophan concentration plot was linear between 0.005 and 0.030 mol l^{-1}. The slope of this plot gave a relative surface excess of 2.4×10^{-10} mol cm^{-2} which was in agreement with the maximum surface concentration of 2.5×10^{-10} mol cm^{-2} calculated from a space filling model (CPK) of the tryptophan molecule adsorbed with its aromatic ring plane oriented parallel to the electrode surface. Figure 1 also includes the previous results for DL-alanine, DL-α-aminobutyric acid, DL-norvaline, DL-norleucine,[1] and L-phenylalanine.[2]

In order to obtain the surface excess of the amino acids at the electrically charged interfaces, differential capacities of the interface were measured for glycine, DL-serine, L-threonine, L-asparagine, L-glutamine, and L-methionine as functions of the electrode potential and amino acid concentration. Electrocapillary curves were obtained by numerical integration of the differential capacity *vs.* electrode potential curves and were used to calculate the surface excess of the amino acids at various electrode potentials. We chose for further analysis the electrode surfaces at −0.1 and −0.9 V (*vs.* SCE) as the representatives of positively charged and negatively charged interfaces, respectively. In 0.500 mol l^{-1} sodium fluoride base solution, the surface charge densities at −0.1 and −0.9 V were determined as 8.9 and −9.3 μC cm^{-2}, respectively. The relative surface excesses of the amino acids at −0.1 and −0.9 V are shown in Figs. 2 and 3 as a function of the amino acid concentration. These figures also include the previous results obtained for four aliphatic amino acids[1] and L-phenylalanine.[2]

Since the bulk concentrations of the amino acids used in this study are not high, as much as 1 mol l^{-1} for glycine at the highest, the relative surface excess of the amino acid may be regarded as the surface concentration of the adsorbed amino acid per unit area, Γ, without introducing significant error.[14] Then,

the relative surface excess *vs.* concentration curve shown in Figs. 1, 2, and 3 can be considered as the surface concentration *vs.* bulk concentration curves for the amino acids at the pzc, −0.1, and −0.9 V, respectively. In dilute concentration region the adsorption isotherm generally obeyes Henry's law[15]

$$Bc = \Gamma/\Gamma_m, \quad (1)$$

where B is the adsorption coefficient, c the bulk concentration of an adsorbate and Γ_m the maximum surface concentration of an adsorbate. The adsorption coefficient is related to the standard adsorption free energy, ΔG_a°, by

$$-\Delta G_a^\circ = RT \ln B, \quad (2)$$

where R is the gas constant and T the absolute temperature. The standard adsorption free energy in Eq. 2 is defined as the free energy change accompanied with the transfer of an adsorbate from a bulk phase at infinite dilution to an adsorption phase at infinite dilution. In this definition the adsorption free energy of an enantiomer and that of the correponding racemate must be the same[2] and, hence, will not be distinguished hereafter. We graphically evaluated the limiting slopes of the adsorption isotherms, $(\partial\Gamma/\partial c)_{c=0}$, in Figs. 1, 2, and 3 to obtain $B\Gamma_m$. The values are summarized in Table 3. The maximum surface concentrations of amino acids in the fifth column of Table 3 were calculated by using the CPK model of the amino acid molecules adsorbed with their side chains oriented parallel to the electrode surface. The ΔG_a° values evaluated from these data by using Eq. 2 are given in the last three columns in Table 3.

Discussion

The standard adsorption free energies for glycine and a series of aliphatic α-amino acids, alanine, α-aminobutyric acid, norvaline, and norleucine, at the pzc are plotted in Fig. 4 against the number of carbon atom in the side chain, n. The linear plot in Fig. 4 provides an experimental basis for dividing the standard adsorption free energy of an α-amino acid into two contributions, a contribution from a zwitterion group and that from a side chain group. The decrement of ΔG_a° per one methylene group in the side chain was found to be 2.9 kJ mol^{-1}. This may be comparable with 3.3 kJ mol^{-1} [16] obtained for the adsorption of normal aliphatic alcohols at the mercury–aqueous solution interface and 3.1 kJ mol^{-1} [17] for the adsorption of normal aliphatic acids at the copper–aqueous solution interface.

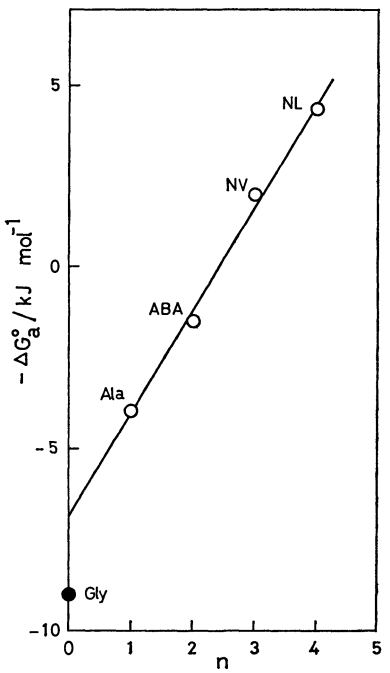

Fig. 4. Standard adsorption free energies of normal aliphatic α-amino acids and glycine as a function of the number of carbon atom, n, in the side chain.

TABLE 4. TRANSFER FREE ENERGY OF AMINO ACID SIDE CHAIN, $\Delta G^{\circ}_{a,s}$, FROM AQUEOUS BULK PHASE TO THE MERCURY–AQUEOUS SODIUM SULFATE SOLUTION INTERFACE AT 25 °C AS A HYDROPHOBICITY SCALE OF AMINO ACID SIDE CHAINS ON POSITIVELY CHARGED(−0.1 V), UNCHARGED(pzc), AND NEGATIVELY CHARGED(−0.9 V) INTERFACES

Amino acid side chains	$-\Delta G^{\circ}_{a,s}$/kJ mol^{-1}		
	−0.1 V	pzc	−0.9 V
Serine	1.8	3.2	2.0
Alanine	1.1	5.0	2.9
Threonine	3.3	6.9	3.6
α-Aminobutyric acid	2.6	7.5	5.4
Asparagine	6.3	7.8	8.0
Valine	—	11.0	—
Norvaline	5.6	11.1	8.0
Glutamine	7.9	12.5	9.4
Leucine	—	12.6	—
Norleucine	8.2	13.3	11.5
Methionine	12.3	17.8	13.6
Phenylalanine	15.1	20.9	17.1

The transfer free energy of an amino acid side chain from aqueous bulk phase to the interface, $\Delta G^{\circ}_{a,s}$, was calculated by subtracting ΔG°_{a} for glycine from ΔG°_{a} for each amino acid. Table 4 summarizes the $\Delta G^{\circ}_{a,s}$ values thus estimated at the pzc, −0.1 V and −0.9 V (*vs.* SCE). These series of the transfer free energies of the side chains may be regarded as interfacial hydrophobicity scales at electrified interfaces. The major trend in the series of $\Delta G^{\circ}_{a,s}$ at the uncharged interface (at the pzc) is essentially similar to that found by Nozaki and Tanford,[5] as illustrated in Fig. 5 in which $\Delta G^{\circ}_{a,s}$'s at the pzc are plotted against the transfer free energies of amino acid side chains from water to organic solvents, ΔG°_{tr}.[5] As seen in this figure serine, threonine, alanine, valine, leucine, and norleucine fall around the straight line of unit slope.

There are, however, a few facts in Table 4 and Fig. 5 which do not conform to the results by Nozaki and Tanford. In their scale, threonine is less hydrophobic than alanine whereas the converse is true in the interfacial hydrophobicity scale at the pzc. Introduction of a hydroxyl group into a hydrocarbon side chain decreases the hydrophobicity of the side chain by 1.8 kJ mol^{-1} (for an alanine and serine pair) and 0.6 kJ mol^{-1} (for an α-aminobutyric acid pair). These values are appreciably smaller than 3.4 kJ mol^{-1} estimated by Nozaki and Tanford[5] as a contribution of a hydroxyl group to the transfer free energy. At the interface the hydroxyl group of serine or threonine is probably only partially dehydrated because a part of the adsorbed molecule should be exposed to the aqueous phase, whereas on transfer of the molecule from water to nonaqueous solvent the hydroxyl group must completely be dehydrated and surrounded by nonaqueous medium. Table 4 also shows that glutamine is more hydrophobic than asparagine. This is contrary to the result obtained by Nozaki and Tanford who found that glutamine was apparently

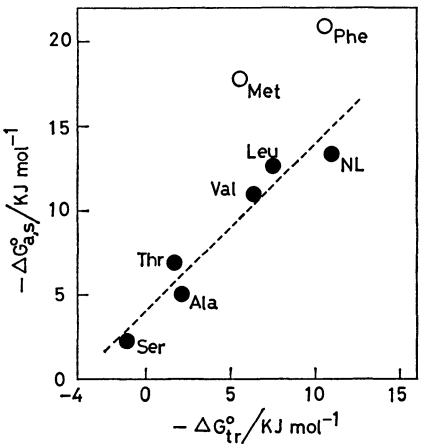

Fig. 5. Plot of the free energies of transfer of amino acid side chains from aqueous bulk phase to the uncharged mercury surface in contact with aqueous phase, $\Delta G^{\circ}_{a,s}$, against the free energies of transfer of amino acid side chain from aqueous bulk phase to pure organic solvents, ΔG°_{tr}, taken from Ref. 5.

less hydrophobic than asparagine. They have suggested that the formation of an intramolecular hydrogen bond in asparagine molecule in nonaqueous phase is responsible to the abnormal position of asparagine with respect to glutamine in their hydrophobicity scale. In adsorption layer asparagine molecules will not form an intramolecular hydrogen bond but remain to hold hydrogen bonding with adjacent water molecules. Figure 5 shows that methionine and phenylalanine have higher values of $\Delta G^{\circ}_{a,s}$ than those expected from the line of unit slope. Since sulfur atom has strong affinity with mercury,[18] such a chemical interaction should be involved in the observed high surface activity of methionine. Phenylalanine interacts with mercury surface through not only the hydrophobic interaction but also the charge transfer interaction due to π-electron in the aromatic ring.[2] Specific interaction also seems to exist between the amide group in asparagine and the mercury surface. Among the amino acid side chains studied only asparagine side chain showed higher surface activity at the negatively charged surface than at the pzc.

Table 4 shows that when the mercury surface is charged either positively or negatively, $\Delta G^{\circ}_{a,s}$'s for all the amino acid side chains but asparagine side chain at −0.9 V are increased; their surface activity becomes lower when the surface comes to bear excess charges. The change of $\Delta G^{\circ}_{a,s}$ with the change of the electrical state of the interface is illustrated in Fig. 6 for ten amino acid side chains. The effect of electrode charge on $\Delta G^{\circ}_{a,s}$ for alanine, α-aminobutyric acid, norvaline, and norlecuine, which we refer as group I, is appreciably asymmetrical with respect to the pzc, but the effect is almost symmetrical for serine and threonine (group II). This difference in the dependence of $\Delta G^{\circ}_{a,s}$ on electrode charge between groups I and II causes the reversion of the mutual positions of serine and α-alanine, and of threonine and α-aminobutyric acid in their interfacial hydrophobicity scale at the positively charged electrode surface.

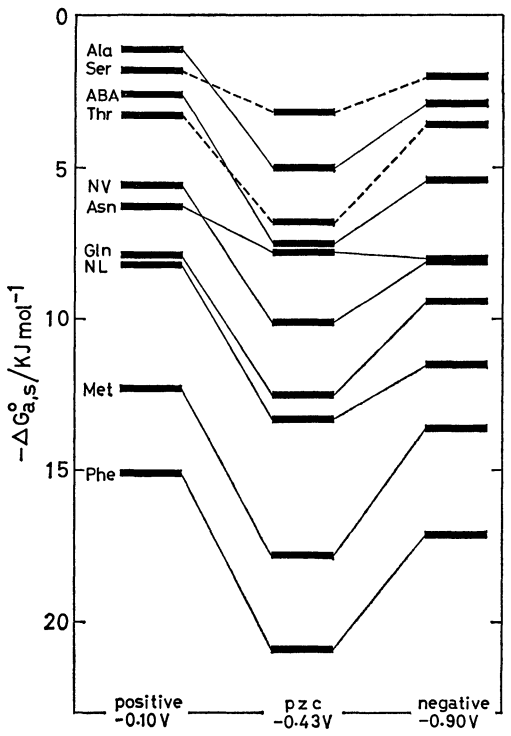

Fig. 6. Schematic representation of the change of the interfacial hydrophobicity of amino acid side chains with the change of the electrical state of the mercury–aqueous 0.5 mol l^{-1} sodium fluoride solution interface at 25 °C.

According to the theory of Frumkin[19] and Butler[20] on the adsorption of organic compounds at electrified interface, the dependence of the adsorption free energy, ΔG°_{a}, of an organic compound on electrode potential is described by

$$\Delta G^{\circ}_{a} = \Delta G^{\circ}_{a,max} + RT\alpha(E-E_{max})^2, \quad (3)$$

where $\Delta G^{\circ}_{a,max}$ is ΔG°_{a} at $E=E_{max}$, E the electrode potential, E_{max}, the electrode potential at which the adsorption maximum occurs, and α the constant represented by

$$\alpha = \frac{C_0-C_1}{2RT\Gamma_m}. \quad (4)$$

In Eq. 4 C_0 is the double layer capacity in the absence of adsorption ($\theta=0$) and C_1 is the double layer capacity at the full coverage of the electrode with adsorbate ($\theta=1$). The maximum adsorption potential in Eq. 3 is given by[21]

$$E_{max}-E^{\circ}_{pzc} = \frac{C_1(E^{\theta=1}_{pzc}-E^{\circ}_{pzc})}{C_1-C_0}, \quad (5)$$

where $E^{\theta=1}_{pzc}$ and E°_{pzc} are the potentials of zero charge at $\theta=1$ and $\theta=0$, respectively.

In view of Eqs. 3, 4, and 5, the difference in the effect of the electrode potential on $\Delta G^{\circ}_{a,s}$ between groups I and II is probably due primarily to the different values of E_{max} for groups I and II. Group II seems to have E_{max} values around the pzc, whereas the E_{max} values for group I seem to be located in more negative potential region with respect to E°_{pzc}. The presumption of $E_{max}-E^{\circ}_{pzc}<0$ for group I implies[1] that water dipoles are oriented with their negative end pointing toward the electrode surface,[9,10] because in this group the effective dipole moment of the side chain should be small, if any. The more positive E_{max} for group II compared with that of group I indicates the orientation of the hydroxyl group dipole with its negative end pointing toward the electrode surface.

According to Eqs. 3 and 4, the change of $\Delta G^{\circ}_{a,s}$ with the change of the electrical state of the interface depends also on the magnitude of the double layer capacities of the interface. The double layer capacities in the presence and absence of the adsorption are generally a function of the electrical state of the interface due to the change in the orientation mode of adsorbed molecules as well as solvent molecules in the compact layer of the double layer with the change of the electrical state.[22] Therefore, the change of the capacities may partly contribute to the observed dependence of $\Delta G^{\circ}_{a,s}$ on the electrical state of the interface.

The Effect of Iron(III) on the Cadmium Ion-selective Electrode

Sachiko SAKURA*,† and Rauno VIRTANEN

Chemical Laboratory, Technical Research Centre of Finland, Biologinkuja 7, SF-02150, Espoo 15, Finland

(Received March 7, 1980)

Iron(III) interferes with the operation of a cadmium, lead and copper ion-selective electrode. The cadmium ion-selective electrode (CdS/Ag_2S) showed a potential shift to the positive direction of more than 100 mV for a decade change of iron(III) concentration. However, the exact mechanism for this interference is not known, though it is expected to be the oxidation of sulfide ion by Fe(III). The mechanism of interference by iron(III) was studied by using the cadmium ion-selective electrode, flow-through cell, pH buffer solutions, potentiometric titrations, and atomic absorption spectrophotometry measurements. It was found that iron(III) promotes dissolution reaction of cadmium ions from the solid cadmium sulfide electrode and that flow conditions of samples have no effect on the iron(III) interference.

An important group of ion-selective electrodes is composed of metal sulfide membranes such as pure silver sulfide or silver sulfide mixed with other metal sulfides (*e.g.* CuS, PbS, CdS).[1] As a rule, these electrodes are interfered with by ions which can react with the membrane. For example, Ag^+ and Hg^{2+} interfere with the determination of Cu^{2+} with CuS/Ag_2S membrane electrode. Other interference is caused by the dissolution of the membrane to form a soluble complex with some ion in the membrane. For example, the cyanide ion interferes with all silver salt membranes. Actually, silver salt membranes can be used as cyanide ion selective electrode on the basis of this phenomenon. Another kind of interference is caused by oxidizers. For example, iron(III) oxidizes sulfide ions on the electrode membrane and thus affects the membrane potential.

The effect of oxidation by iron(III) on CdS/Ag_2S electrode has been noted by Brand *et al.*,[2] Mascini and Liberti,[3] and Kivalo *et al.*[4] In the case of PbS/Ag_2S electrode, the potential of PbS electrode changed about 59 mV by a decade change in the iron(III) concentration.[5] By the use of a reductant, iron(III) interference could be eliminated in low level analysis of copper(II) ion with CuS/Ag_2S electrode.[6] The effect of iron(III) on mixed sulfide electrode (CuS/Ag_2S) was used for quantitative determination of iron(III) in the range of (10^{-5}—10^{-2}) M (1 M=1 mol dm^{-3}) iron(III).[7] Kivalo *et al.* measured the interference of iron(III) on PbS/Ag_2S electrode,[8] and Bixler *et al.* found a large interference of iron(III) on Ag_2S electrode.[9]

Under different oxidizing conditions without iron(III), Johansson and Edström discussed corrosion of CuS/Ag_2S electrode.[10]

The purpose of this work is to study the mechanism of oxidation by iron(III) on the CdS/Ag_2S membrane, by measuring the rate of oxidation reaction by iron(III), the effect of pH buffer solution, the concentration of iron(III), and the amount of Cd(II) which was dissolved from CdS-membrane.

Experimental

Equipment. The electrodes used were Orion cadmium electrode 94-48A (CdS/Ag_2S) and Orion double junction reference electrode 90-02. Potentials were measured with an Orion 801A digital pH/mV-meter and recorded with a Goerz Servogor RE 511 strip chart recorder. The stabilization of electrode potential was followed with the aid of the chart recorder. Potential measurements were made either in a dip cell or in a thermostated flow-through cell (Fig. 1), both at 298 K.

Measurements in the Dip Cell: The dip cell was a polyethylene vessel with volume of 2000 cm^3. The solution was stirred at constant speed with a teflon propellor.

Measurements in the Flow-through Cell: The reference electrode was dipped in the outlet of the sample solution about 10 cm from the cadmium ion-selective electrode. Flow rate was from 0 $cm^3\ min^{-1}$ to 45.1 $cm^3\ min^{-1}$. Possible streaming potential was checked by using two calomel electrodes, one in the place of the indicator electrode and the other in the place of the reference electrode. No streaming potential developed in the flow-through cell, at any flow rate, in the solutions at pH 2, 3, or 5, either in the presence or in the absence of iron(III).

Cadmium ions dissolved from CdS was determined by an Hitachi model 518 atomic absorption spectrophotometer equipped with a cadmium hollow cathode lamp (229.0 nm).

Solutions. Chemicals used were of analytical purity. The ionic strength of solutions was adjusted to 0.1 M. The pH was adjusted with buffers (pH 2; potassium chloride

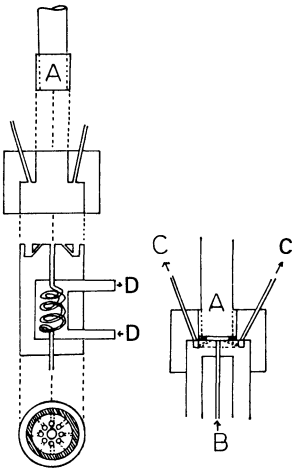

Fig. 1. The flow-through cell.

† Present address: Department of Chemistry, Faculty of Medicine, Hamamatsu University School of Medicine, Hamamatsu 431-31.

and hydrochloric acid, pH 3 and 5; potassium phthalate) or by nitric acid and potassium hydroxide (unbuffered solutions). The cadmium and iron(III) salts used were nitrates. Powder cadmium sulfide was the guaranteed reagent by Nakarai Co. Ltd.

Results

Figure 2 showed the results of the effect of iron(III) in the dip cell at buffered pH 2. The very severe effect of iron(III) is noticeable from the slope (115 mV for a decade change of iron(III) concentration). The selectivity coefficient for iron(III) of the cadmium electrode ($K=[Cd^{2+}]/[Fe^{3+}]^{2/3}$) was determined with the mixed solution method with constant activity of Cd^{2+} and varying activity of Fe^{3+} similar to the method recommended by IUPAC.[11] At pH 2, the value of K was 46 $mol^{1/3}\,dm^{-1}$. And iron(III) began to interfere at concentrations of about 10^{-6} M. Table 1 shows the numerical values of the dip cell measurements at pH 2, 3, and 5 (all were buffered solutions). As the pH decreased, the effect of iron(III) became more severe. This pH effect is attributed to the increase of the activity of free iron(III) ion with decreasing pH.

The interference of iron(III) still remained at pH 5 ($K=7.8$ $mol^{1/3}\,dm^{-1}$), although a large decrease in interference could be expected on the ground of pH change. At pH 5 the ratio of free iron(III) to the hydroxide complex is only $10^{-3.7}$ in the absence of other ligands except OH^-.[12]

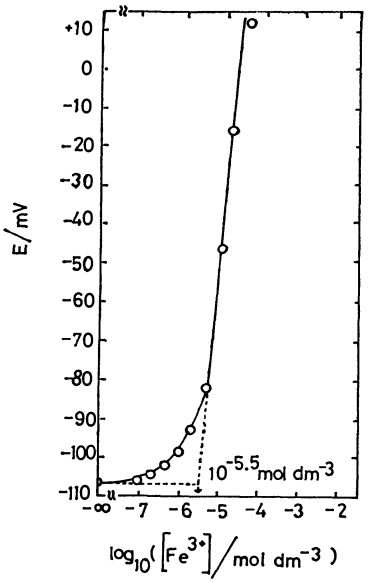

Fig. 2. The effect of iron (III) on the cadmium electrode in the dip cell in pH 2 buffered solution. Concentration of Cd^{2+} was 10^{-2} M.

Table 1. The effect of pH on the interference of iron(III) on the cadmium electrode potential in the dip cell (10^{-2} M Cd^{2+})

pH	Slope / mV	$[Fe^{3+}]$[a] / mol dm^{-3}	K[b] / $mol^{1/3}\,dm^{-1}$
5.0	37.5	4.57×10^{-5}	7.8
3.0	125.0	1.59×10^{-5}	16
2.0	115.0	3.16×10^{-6}	46

a) Concentration at the break point.[11] b) Selectivity coefficient, $K=[Cd^{2+}]/[Fe^{3+}]^{2/3}$.

In the dip cell measurement, if the electrode was dipped in the iron(III) solution for a short time, the response time[11] (the time until the change of potential is less than 1 mV min^{-1}) was short (about 1 or 2 s), although the change of the potential to the positive direction was large.

When the electrode was kept in 10^{-6} M iron(III) solution for a few seconds then rinsed by water, and the potential was measured in 10^{-2} M cadmium(II) solution, the potential was 10 mV lower than expected. When the electrode was polished with three successively finer grades of aluminium oxide (The German earth clay Nos. 1, 2, and 3, Jean Wirtz, Düsseldorf), it recovered.

If the electrode was kept some minutes in iron(III) solution (10^{-6} to 10^{-4} M), its potential in 10^{-2} M Cd^{2+} solution was found to have risen considerably, sometimes over 200 mV. And the response time[11] was very long (10 to 20 min). Slight polishing did not restore the potential to its original level. It was only after repeated polishing that the anomaly was removed. This result suggests that iron(II) has an interference effect on the deep interior of the CdS electrode membrane.

Measurements in the Flow-through Cell. The flow-through cell was used to study the effect of the flow conditions of the sample solution. Flow conditions are more easily and reproducibly effected in a flow-through cell than in the dip cell. The flow rate had no effect on the potential in the presence and absence of iron(III), either at buffered or unbuffered pH solution. The response time was as long as 120—150 min in the case of unbuffered pH 2 with 10^{-4} M iron(III). The response time at buffered pH 5 with 10^{-4} M iron(III) was also long (30—60 min). These results suggest that the oxidation of CdS is not controlled by the flow conditions in the solution, but by the reaction in the inside of solid CdS electrode.

The effect of iron(III) on the cadmium electrode was tested in buffered and unbuffered solutions at different pH at a fixed flow rate (5 cm^3/min). The concentration of Cd^{2+} was 10^{-3} M. Figure 3 shows that at pH 2, the effect of iron(III) on the potential was very pronounced both in buffered and unbuffered solutions, though in buffered solution the effect started at about 10 times lower concentration. At pH 5 there was no interference in unbuffered solution, but in buffered solution interference began at 10^{-5} M iron(III). The behaviour is the same as in the dip-cell experiments, *i.e.* buffering of solution preserves the attack by iron(III) on the membrane even at higher pH-values. It seems that by complex formation of phthalate ion with iron(III), iron(III) is still kept in solution even at pH 5 and the penetration of iron(III) into CdS electrode is easy. In fact, in unbuffered solution at pH 5 incipient precipitation of $Fe(OH)_3$ could be seen and no interference of iron(III) was observed.

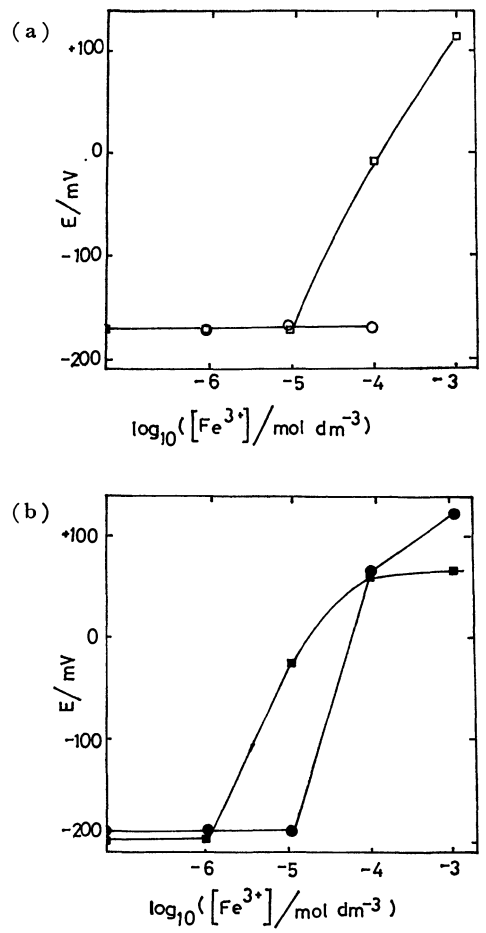

Fig. 3. The effect of iron(III) on the cadmium electrode in the flow-through cell, at pH 2 and pH 5. Concentration of Cd^{2+} was 10^{-3} M. Flow rate: 5 cm^3/min. (a): In unbuffered solution. □: pH 2, ○: pH 5. (b): In buffered solution. ■: pH 2, ●: pH 5.

Potentiometric Titrations and Atomic Absorption Spectrometry (AAS) Measurements. To determine whether the oxidation of CdS by iron(III) takes place, a suspension of CdS powder (guaranteed CdS was commercially obtained or wet CdS was obtained by freshly precipitation from equivalent $Cd(NO_3)_2$ and Na_2S) was titrated by iron(III) using platinum electrode. Titrations were performed in a nitrogen atomosphere. No noticeable oxidation of CdS took place, regardless of whether the CdS powder was dried or freshly precipitated. Obviously the oxidation of CdS by iron(III) is slow. On the other hand, the same titration curve of S^{2-} by iron(III) was obtained as was given in Ref. 13. Oxidation of S^{2-} by iron(III) takes place rapidly and quantitatively.

To measure the dissolution of Cd^{2+} from CdS, CdS powder was mixed with a deaerated solution; after one day the solution was filtered, and the concentration of cadmium in the filtrate was measured. If iron(III) was involved, fairly large amounts of Cd^{2+} were found in pH 2 solution (both for buffered and unbuffered solutions). Even in buffered pH 5 solution, a considerable amount of Cd^{2+} was found in the filtrate, though in unbuffered pH 5 solution, the dissolved Cd^{2+} in the presence of iron(III) was found to be just the same as in the absence of iron(III). The fact that a considerable amount of Cd^{2+} from CdS was found in buffered pH 5 solution in the presence of iron(III) supports the assertion that iron(III) and phthalate ion form stable complexes which remain in the solution.

Discussion

If oxidation of cadmium sulfide by iron(III) takes place according to the following reaction:

$$2Fe^{3+} + CdS \longrightarrow Cd^{2+} + S + 2Fe^{2+} \quad (1)$$

the equilibrium constant is obtained to be 2.1×10^{14}, by calculating from various standard potentials.[14] The reaction proceeds completely to the right. The equilibrium constants for the oxidation of different sulfides, calculated by reactions analogous to (1), are as follows: PbS, 5.5×10^{13}; CuS, 18; and Ag_2S, 7.1×10^{-9}. Ignoring kinetic aspects, one may thus deduce that interference of iron(III) is most pronounced at a CdS/Ag_2S electrode and least pronounced at a pure Ag_2S electrode.

From Table 1, the change of the potential for a decade change of iron(III) concentration at pH 2 was 115 mV in the case of cadmium electrode. The value of this slope is remarkably larger than those in the cases of lead or copper electrodes (59 mV for the lead electrode[5] and 25 mV for the copper electrode[7]).

In the case of a copper ion-selective electrode, it is reported that the potential drifts in the negative direction after prolonged use in high concentrations of iron(III).[7] When the cadmium electrode was dipped in lower concentrations of iron(III) for a short time, the potential drifted in the negative direction like a copper electrode. When the cadmium electrode was kept in high concentrations of iron(III) for a few minutes, the potential drifted in the positive direction; extended polishing was needed to remove the anomaly. These facts support the conclusions that reaction(1) takes place and suggest that the iron(III) exerts an influence on the deep interior of the electrode membrane, according to the dipping time and concentration of iron(III).

This oxidation reaction(1) was not controlled by the flow conditions of iron(III); the reaction rate was very slow and the reaction proceeded even with the complexed iron(III).

The authors would like to express their thanks to Prof. Dr. Pekka Kivalo, chief director of the Finnish Technical Inspectorate, former head of Chemical Laboratory of the Technical Research Centre of Finland, for his helpful suggestions and for arranging this work and to Mr. Tauno Mikkola for his kindly preparing the flow-through cell. The authors would also like to express their thanks to Prof. Dr. Norio Ichinose for his kind offer of the atomic absorption spectrophotometer. This work is supported in part by the Grant-in-Aid for Scientific Research from the Finnish Ministry of Education.

A Sensitive Atomic Absorption Spectrometric Method for Copper Employing the Direct Introduction of Chelating Resin into a Carbon Tube Atomizer

Akinori Isozaki,* Naoki Soeda, and Satori Utsumi

Department of Industrial Chemistry, College of Science and Technology, Nihon University, 1-8-14, Kanda-Surugadai, Chiyoda-ku, Tokyo 101

(Received May 14, 1980)

A new and simple method for the determination of ppb levels of copper by electrothermal atomic absorption spectrometry was established. The main feature of the proposed method is that chelating resin, a preconcentration agent for copper, is introduced directly as a "resin-suspension" into the carbon tube atomizer without drying and weighing of the resin. To a 250 cm^3 sample solution containing up to 1.0 μg of copper, 0.10 g of chelating resin (below 400 mesh) is added, and the mixture is stirred for about 20 min. After the separation of the resin from the aqueous phase through a membrane filter, 5.0 cm^3 of resin-suspension is prepared by adding water to the resin. Then, 10 μdm^3 (resin: 0.2 mg) of the suspension is introduced into an atomizer, and the copper peak-height is measured under the optimum operating conditions. The calibration graph was linear over the concentration range from 0.1 ppb to 4.0 ppb of copper. The relative standard deviation was 2.3% from 10 repeated measurements; a mean value of 1.08 ppb copper was obtained for a sea water sample.

Atomic absorption spectrometry with an electrothermal atomizer and a deuterium background corrector is today an useful analytical tool: the determinations of trace metal elements in both liquid and solid samples can be carried out rapidly and easily. The direct analysis of a solid sample has been applied to biological tissues[1,2] and plastic containers.[3]

Chitosan,[4] a natural chelating polymer with anion-exchange behavior, has been used for the separation of transition elements from alkali and alkaline-earth salts. By combining the concentration of vanadium (VO_3^-) on chitosan with the direct introduction of its powder into the atomizer, Muzzarelli *et al.*[5] proposed a sensitive method for the determination of vanadium in sea water; however, the method requires the drying and weighing of VO_3-adsorbed chitosan powder. Atomization methods which use direct heating of the metal-adsorbed ion-exchange resin have also been examined as ways to determine copper[6] and mercury[7] concentrations; these methods make it possible to analyze an extremely dilute solution, but the precisions are not satisfactory.

For the preconcentration and separation of trace metal ions in sample solution, the chelating resin[8] has been used because of its selectivity in forming stable chelates: for instance, Sato *et al.*[9] proposed a determination method for copper by Flameless A. A. S. which included preliminary treatment by the resin.

The present authors[10] have briefly reported a determination method for copper in which chelating resin was introduced as a "resin-suspension" into a carbon tube atomizer, after the adsorption of copper ions on it under a batchwise operation. Highly purified chelating resin contains no copper, and its smoke does not affect the value of the atomic absorption of copper or the base line. The method does not require drying and weighing of the resin, nor elution of copper from the resin. We did some experiments on the effect of foreign ions on the method: magnesium and calcium ions in as small an amount as 0.1 ppm caused lower results for the atomic absorption of copper. It was found that the interferences of these ions can be eliminated by adding cobalt nitrate to the sample solution; there will be no adsorptions of these ions on the resin.

The proposed method for the determination of copper in a matrix of chelating resin was studied in detail and applied to determine copper ion concentrations in water samples.

Experimental

Apparatus. A Nippon Jarrell-Ash FLA-100 carbon tube atomizer was used in conjunction with a Nippon Jarrell-Ash Model AA-8500 two channel atomic absorption spectrophotometer. A single-element copper hollow cathode lamp (Hamamatsu TV. Co. L-233) was employed as a light source, and peak-heights were recorded with a Rikadenki Co. B-34 recorder. Resin-suspension was injected into the atomizer by using a micropipette (Eppendorf Co. Model 3130) fitted with disposable plastic tips. A centrifuge tube (volume: 15 cm^3) with a glass stopper was used, and a 5.0 cm^3 mark was etched on the tube.

Reagents. All chemicals were of super-special grade. Deionized water was passed through a column packed with Chelex-100 (NH_4-form, 50—100 mesh) prior to use.

Standard Copper Solution: The copper stock solution (1000 ppm) was made by dissolving 0.5000 g of copper metal grain (99.99% purity) in nitric acid and then diluting to 500 cm^3 with water. The working solutions were prepared by diluting the stock solution properly.

Chelating Resin: Chelex-100 (Bio-Rad laboratories, Richmond, Calf., Na-form) prepared to grain size below 400 mesh was used. After the removal of fine particles in the resin by decantation, 500 cm^3 of 2 mol dm^{-3} hydrochloric acid was added to about 50 g of resin in a beaker. The mixture was stirred for about 30 min, and the resin was washed with water by decantation. Then, 500 cm^3 of 4 mol dm^{-3} ammonia water was added to the resin, and the mixture was stirred for 2 h. The resin was filtered through a glass filter (3G4), washed with water, and dried in vacuum for four hours at 60 °C.

Ammonium Tartrate Solution (10%): Ammonium tartrate was dissolved in water to give a 20% solution. The solution was passed through a column packed with Chelex-100 (NH_4-form), and diluted to 10%.

Buffer Solution: 0.8 mol dm^{-3} sodium acetate solution was purified by use of Chelex-100 (Na-form), and diluted to 0.4 mol dm^{-3}. 0.2 mol dm^{-3} acetic acid-sodium acetate solution was used as a buffer solution (pH: 4.7),

Cobalt Nitrate Solution (2.5%): 5.0% cobalt nitrate solution was purified by use of Chelex-100 (Co-form), and diluted to 2.5%.

Water Samples. Samples were acidified to about pH 2 with nitric acid, and stored in polyethylene bottles.

Analytical Procedure. To a sample solution (250 cm^3) containing less than 1.0 μg of copper, 5 cm^3 of 2.5% cobalt nitrate solution and 10 cm^3 of 10% ammonium tartrate solution are added. The solution is adjusted to about pH 5 with (1+10) ammonia water and acetic acid, and 5 cm^3 more of buffer solution is added to the solution. Then, 0.10 g of chelating resin is added to the solution, and the mixture is stirred for 20 min by a magnetic stirrer. After the resin has been separated from the mixture through a membrane filter (pore size: 2.0 μm) or glass filter (3G4), the resin is transferred into a centrifuge tube by using about 10 cm^3 of water and the tube is centrifuged. The supernatant liquid is decanted, being careful to leave the resin in the tube, and 5.0 cm^3 of "resin-suspension" is prepared by adding water to the resin in the tube. Then, 10 μdm^3 (resin: 0.2 mg) of the suspension, which has been mixed thoroughly to prepare a uniformly suspended solution, are introduced into a carbon tube atomizer. The atomic absorption of copper, its peak-height, is measured under the instrumental operating conditions shown in Table 1.

Table 1. Instrumental operating conditions

Operating step	Current A	Time s	Mode	Final temp °C
Drying	35	20	Ramp	*ca.* 300
Ashing	110	60	Ramp	*ca.* 1200
Atomization	250	10	Flash	*ca.* 2500

Wavelength: 324.75 nm, lamp current: 5 mA, argon gas flow rate: 3 dm^3/min, damping: 1, sensitivity: 0.

The calibration graph was linear over the concentration range from 0.1 ppb to 4.0 ppb of copper. It was confirmed by using standard copper solution that the copper ions in a sample solution (250 cm^3) are almost all adsorbed by the chelating resin (resin-suspension: 5.0 cm^3) under the conditions of this procedure; that is, the concentration ratio is found to be about 50:1.

Results and Discussion

Ashing of Chelating Resin. Figure 1 shows the typical profiles of absorption for copper-adsorbed resin and copper-free resin in a carbon tube under the instrumental operating conditions. In the case of copper-adsorbed resin, the first peak appeared in an ashing step owing to a smoke evolution of the resin, and then the second peak, which is based on the atomization of copper, was obtained. In copper-free resin, although the first peak appeared as before, there were neither the second peak nor any absorption by the deuterium lamp during the atomization step. Therefore, no correction is necessary for background absorption in measuring the second peak.

The Effect of Ashing Current. Figure 2 shows the effect of ashing current on the absorbance of copper. In the case of copper-adsorbed resin, the absorbance at an ashing current of 70 A was higher than those at the current range from 100 to 130 A, and the absorbance at 140 A was lower. The increase of absorbance at 70 A is due to an absorption by smoke evolution of the resin resulting from an incomplete ashing. This is seen by observing that the copper-free resin also has an absorption at the same current. On the other hand, the decrease of absorbance at 140 A is due to the loss of copper by its partial volatilization during the ashing step; in the case of an aqueous solution, the absorbance of copper also shows a similar decrease. As shown in Table 1, an ashing current of 110 A was adopted before the atomization step. It was observed that the resin acts as a sensitizer for copper during the atomization step; that is, the absorbance of copper-adsorbed resin at an ashing current of 110 A increases about 35% in comparison with that of copper in an aqueous solution. Similar sensitization was observed when a fine activated carbon was added instead of the resin to the aqueous solution. Yoshimura and Noda[11] have reported that an activated carbon is effective for the deoxidation of metal oxides (Cu_2O, CuO, PbO_2, ZnO, ZnO_2) in the direct atomization of these oxides during the flame A. A. S.

The Effect of the Amount of Chelating Resin and of the Stirring Time. We examined the effects of the

amount of chelating resin and of the stirring time in the procedure on the adsorption of copper on the resin. Since the absorbance of copper gave a constant value for amounts from 0.05 to 0.50 g, 0.10 g of the resin was added to a 250 cm^3 sample solution. Stirring for 20 min by a magnetic stirrer was sufficient to allow copper and cobalt ions to be adsorbed on the chelating resin from a sample solution. The resin transformed into NH_4-form was used in the procedure, because the rate of adsorption for copper ion on NH_4-form resin was faster than that on H-form resin.

The Effect of the Amount of Cobalt. Chelex-100[8] has a very strong attraction for transition metals. The selectivity series for cations in an acetate buffer system at pH 5 is:

$$Hg^{2+} > Cu^{2+} \gg Pb^{2+} > Ni^{2+} > Co^{2+} > Mn^{2+} \gg Mg^{2+} = Ca^{2+} \gg Na^{+} > NH_4^{+} > H^{+}.$$

In general, when a large amount of cobalt ion exists in a sample solution containing the resin, magnesium or calcium ions are not adsorbed by the resin, but a small amount of copper ion is quantitatively adsorbed by it. From some experiments, the addition of 5.0 cm^3 of 2.5% cobalt nitrate solution to a 250 cm^3 sample solution showed satisfactory results for copper ions in the presence of about 100 ppm of magnesium ions.

The Effect of PH on the Adsorption of Copper. As is seen in Fig. 3, the absorbance (△) decreased appreciably with the increase in pH, because of incomplete adsorption of copper due to the formation of hydrolysis products such as $Cu(OH)^+$ or $Cu(OH)_2$. The absorbance (●) also decreased as the pH increased from 4 to 7, but those at pH 9 and 10 increased again through the formation of ammine complexes such as $[Cu(NH_3)_4]^{2+}$. The absorbance (○) gave a constant value over the pH range from 2.5 to 10, because the hydrolysis of copper was prevented by the addition of 10 cm^3 of 10% ammonium tartrate solution. The effect of pH on the adsorption of cobalt ion was also examined: the amount of cobalt ion adsorbed by the chelating resin gave a maximum and constant value over the pH range from 4 to 7. Therefore, the buffer solution with pH 4.7 was used in the procedure.

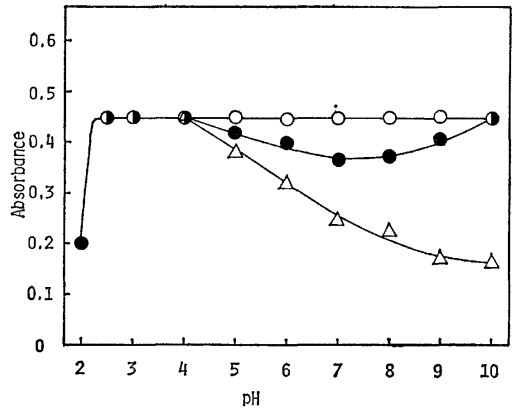

Fig. 3. Effect of pH on the adsorption of copper. Cu: 0.75 μg/250 cm^3, reagents used for pH adjustment; ○: CH_3COOH, NH_3–water, $(NH_4)_2C_4H_4O_6$, ●: CH_3COOH, NH_3–water, HNO_3, △: CH_3COOH, NaOH.

The Effect of Foreign Ions. The effect of foreign ions on the procedure were examined under the presence of 3.0 ppb copper ion, both in the case of the addition of a cobalt nitrate solution and in the case of no such addition. The experimental results are given in Table 2. When the cobalt nitrate solution was not added to a sample solution, strontium, iron(II) and chromium(III) ions in small amount such as 1 ppm gave lower results for the absorbance of copper. Further, magnesium and calcium ions interfered remarkably even at 0.1 ppm. On the other hand, the addition of a cobalt nitrate solution was found to be very effective in eliminating the interferences of these ions. Most anions did not interfere, even when 1000 ppm of them were present, regardless of the presence or absence of cobalt ion during the procedure.

Table 2. Effect of foreign ions

Ion	Proposed method		Without Co^{2+}	
	Amount/mg	Absorbance	Amount/mg	Absorbance
—	—	0.450	—	0.450
Na^+	2500	0.455	250	0.438
K^+	2500	0.445	250	0.439

a) Sample was taken about 2 km away from the coast.
b) Sample volume taken: 1000 cm^3.

The Determination of Copper in Various Water Samples. The results obtained by the procedure for water samples are shown in Table 3. The mean copper content of a sea water sample was 1.08 ppb from 10 repeated measurements and the relative standard deviation was 2.3%. The content was also confirmed by adding known amounts of copper to the sea water; good recovery of these amounts was achieved. Some experiments were performed on different volumes (100, 500, 1000 cm^3) of a sample solution containing 0.75 μg of copper ions; these absorbances of copper agreed, within the experimental error allowed, with that obtained by use of a sample volume of 250 cm^3. The proposed method is therefore applicable to the determination of copper ions in water samples over a wide concentration range. That is, the content of a deionized water used in this laboratory was determined to be 0.12 ppb by using a 1000 cm^3 sample volume instead of 250 cm^3 as in the standard procedure.

In addition, it is possible to increase the apparent sensitivity for the determination of copper by changing the volume (5.0 cm^3) of resin-suspension or the volume (10 μdm^3) injected into the atomizer. The procedure is relatively simple to use, and few chemicals are required. The proposed technique may be applied not only to the determination of copper, but also to that of other metals at ppb levels.

Sublimation Behavior of Tris(2,2,6,6-tetramethyl-3,5-heptanedionato)lanthanoid(III)

Ryohei Amano,* Akiko Sato,** and Shin Suzuki**

School of Paramedicine, Kanazawa University, Kodatsuno 5, Kanazawa 920

***The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2, Sendai 980*

(Received June 20, 1980)

Two fundamental experiments (to determine vapor pressures and vacuum sublimation-recrystallizing temperature zones) were undertaken on a series of remarkably volatile and thermally stable lanthanoid(III) chelates of 2,2,6,6-tetramethyl-3,5-heptanedione ($Ln(thd)_3$) in order to obtain information about their sublimation behavior. Vapor pressures of these chelates were measured from 100 to 150 °C by means of a modified Knudsen effusion technique. Vacuum sublimation-recrystallizing temperatures were determined by using a sublimation apparatus with a continuous temperature gradient along its sublimation tube. The obtained enthalpies of sublimation were classified into three groups (La to Gd, Tb and Dy, and Ho to Lu), and the vacuum sublimation-recrystallizing temperature zones were divided into two sets (La to Tb, and Dy to Lu). The Tb and Dy chelates were also found to change thermally from a dimeric form to a monomeric form at a definite temperature. These results are explained in terms of the two different crystallizing forms of $Ln(thd)_3$ chelates. Furthermore, the regularity in their sublimation behavior is discussed as a function of the atomic numbers of the lanthanoid metals, using thermochemical considerations.

The volatile lanthanoid chelates of 2,2,6,6-tetramethyl-3,5-heptanedione are very useful as gasoline antiknock additives and catalysts for the removal of carbon deposits,[1] and as sources of metal chelate vapors.[2] They are also useful in trace metal analysis by gas chromatography and sublimatography.[3–5] It is therefore important to study the thermal properties of these chelates over a wide temperature range. Sicre *et al.* have determined the vapor pressures of the $Ln(thd)_3$ chelates (Ln=lanthanoid ion, thd=2,2,6,6-tetramethyl-3,5-heptanedione) by means of the isoteniscope technique over the temperature range of 150 to 250 °C and have mentioned the regularity in their thermochemical behavior.[4] Radiochemical studies on the $Ln(thd)_3$ and $An(thd)_n$ (An=actinoid ion) have been carried out by vacuum sublimation method; their sublimation-recrystallizing temperature zones were found to be in the range of 70 to 150 °C.[6] These vacuum sublimatographic results prompted us to study the vapor pressures of these chelates over the temperature range lower than 150 °C.

A modified Knudsen effusion method has been chosen for the measurements of vapor pressures of $Eu(thd)_3$ and $^{243}Am(thd)_3$ chelates over a relatively low temperature range (100—150 °C).[7] This technique was found to be effective for a highly specific radioactive compound.

In the present study, the vapor pressure were determined as a function of temperature for 13 $Ln(thd)_3$ chelates by means of the Knudsen effusion technique, and their vacuum sublimation-recrystallizing temperatures were also determined by a sublimation apparatus with a continuous temperature gradient. Our purpose was to find what regularity might exist in the sublimation behavior. Some aspects of the sublimation behavior of $Ln(thd)_3$ chelates will be also discussed.

Experimental

Preparation of $Ln(thd)_3$ Chelates Labeled with Radioisotope. The purified lanthanoid oxides (99.9%) of La_2O_3, Pr_6O_{11}, Sm_2O_3, Eu_2O_3, Gd_2O_3, Tb_4O_7, Dy_2O_3, Ho_2O_3, Er_2O_3, Tm_2O_3, Lu_2O_3, and Y_2O_3 were each dissolved in a concentrated nitric acid solution. This was heated almost to dryness, then diluted with distilled water to make each stock solution. The gadolinium chloride of the radioisotope ^{153}Gd was purchased from The Radiochemical Centre (England). Other radioisotopes of ^{140}La, ^{142}Pr, ^{147}Nd, ^{153}Sm, ^{152}Eu, ^{160}Tb, ^{159}Dy, ^{166}Ho, ^{169}Er, ^{170}Tm, ^{169}Yb, and ^{177}Lu were produced from an (n,γ) nuclear reaction by irradiating each lanthanoid oxide with thermal neutrons in the reactor of Kyoto University. Yttrium radioisotope ^{88}Y was produced from a (γ,n) reaction by bremsstrahlung which was performed by using the LINAC of Tohoku University. Each radioisotope was dissolved in a minimum amount of concentrated nitric acid. Each radioisotope solution was added into the above stock solution of the same lanthanoid ion to make each solution be labeled with a radioisotope. The metal concentration and specific radioactivity of the solution were 10^{-2}—10^{-1} M and 10^{-3}—10^{2} μCi/μg of Ln, respectively.

The lanthanoid chelates, $Ln(thd)_3$, were prepared by the method of Eisentraut and Sievers[3] with a slight modification. The Ln nitrate solution (0.002 mol) labeled with radioisotopes was heated to dryness. The residue was dissolved in a minimum amount of 99% methanol, and pH of the resultant solution was adjusted between 3 and 5 by dropwise addition of 2 M NH_4OH solution. A solution of Hthd chelating agent (0.006 mol) in 10 ml of 99% methanol was then added to the above solution. The mixture was adjusted to the desired pH. The precipitate was filtered off, dried in a desiccator, then purified by recrystallization from chloroform and by two vacuum sublimations.

Vapor Pressure Measurements. Vapor pressures of the $Ln(thd)_3$ chelates were measured by a modified Knudsen effusion method. The major modifications from the normal Knudsen effusion method were as follows: (1) the $Ln(thd)_3$ chelate sublimated was collected stepwise at each temperature; (2) the amount of chelate on a collecting foil was determined by a radioactivity measurement. This method has the advantage that the spurous effluents caused by decomposition of the sample and/or volatile impurities have no corresponding lanthanoid metal and will not be counted. The relation between the amount of collected $Ln(thd)_3$ and the collecting time at a given temperature was linear

beyond 5 min, as previously described in a preliminary work on the vapor pressure measurement of Eu(thd)$_3$ chelate.[7] The effusion rate of each Ln(thd)$_3$ chelate was determined from more than 4 weight-time data points at each temperature. For example, a series of measurements at the intervals of 5, 15, 8, and 10 min was carried out at the same temperature.

The Knudsen cell was made of 18-8 stainless steel, nearly cylindrical, 1.3 cm high, and 1.2 cm in diameter. Orifice parameters were photographed and measured on a microscope. An orifice with an area of 0.0021 cm^2 and a height of 0.032 cm was used.[8] The cell was attached to the bottom of a molecular still of the cold-finger type. The glass still with the above effusion cell was connected to a vacuum system. The pressure inside the vacuum line, as measured by a penning gauge, Daia Vacuum Engineering Model CT-2P, fell below 1×10^{-3} Torr (1 Torr=133.3224 Pa) within 30 s. The cell containing each Ln(thd)$_3$ chelate sample was heated by an oil bath, whose temperature was measured by a standard thermometer. The difference in temperature between the oil bath and the cell was calibrated by simultaneous measurement of the temperature of another cell within an enclosed thermometer in the same oil bath.

The effusion cell was loaded with 50 mg of sample, transported into the still, and evacuated to a vacuum of 1×10^{-5} Torr. The cell containing the sample chelate was exposed to the argon atomosphere. After the cell was heated for 1 h at a constant temperature in an argon atomosphere, it was evacuated. The effusion chelate gas collected on a water-cooled Al foil for more than 5 min. Effusing of the chelate gas was stopped by introducing argon into the vacuum line. The temperature of the oil bath and the collecting time of chelate gas were recorded. The collecting foil was replaced with a new aluminum foil.

The above procedure was repeated for a series of collecting intervals at a given temperature; the same repetitions were applied to various temperatures.

The collecting foil was dissolved in diluted hydrochloric acid. Radioactivity of each lanthanoid solution was measured by a NaI(Tl) scintillation counter, or by a Ge(Li) semiconductor detector. By using the specific radioactivity of the sample, the total weight of the collected chelate on the foil, W, was calculated. The rate of sublimation, m, is obtained by dividing the total weight of the collected chelate by the area of the orifice, the collecting time, and the Clausing factor: *i.e.* $m=W/atK$, where a is the area of the orifice, t is the collecting time, and K is the Clausing factor.[8]

Measurements of Vacuum Sublimation-recrystallizing Temperatures. A schematic drawing of the vacuum sublimation apparatus for the measurement of the vacuum sublimation-recrystallizing temperatures of the Ln(thd)$_3$ chelates is shown in Fig. 1. The apparatus has the advantage that the continuous temperature gradient along the sublimation tube can be obtained by sliding a electric furnace gently (1 °C/cm) or steeply (10 °C/cm) along the outer porcelain tube (5.8 cm in outer diameter and 166 cm in length), which consists of a copper tube (1.6 cm in outer diameter and 180 cm in length) covered with air and aluminum. The sublimation tube for introducing Ln(thd)$_3$ sample (10 mg) was evacuated to 1—10×10^{-3} Torr, and placed in a definite position inside the sublimation apparatus. This had been heated and held at 180 °C before inserting the sublimation tube. The temperature gradients along the sublimation tube at various elapsed times are shown in Fig. 2. The sublimation of all Ln(thd)$_3$ chelates was carried out for 2 h under the above conditions. The radioactivity of the sublimate was

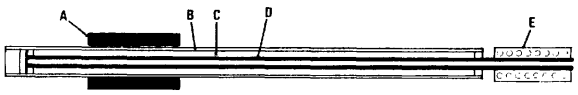

Fig. 1. Vacuum sublimation apparatus with continuous temperature gradient.
A: Electric furnace, B: outer porcelain tube, C: enclosed air and Al foil, D: copper tube, E: cooler.

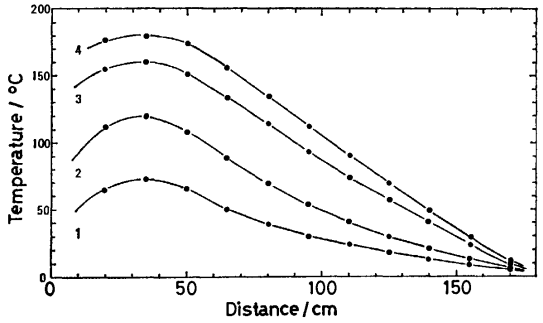

Fig. 2. Temperature gradient along vacuum sublimation tube at elapsed time.
1: 10 min, 2: 20 min, 3: 35 min, 4: 60—120 min.

scanned along the sublimation tube by sliding it on the lead slit of a NaI(Tl) scintillation detector. The highest temperature of the deposition zone on the wall of the sublimation tube was taken as a relative measure of the vacuum sublimation-recrystallizing temperature.

IR and X-Ray Powder Diffraction Measurements. IR spectra of the Ln(thd)$_3$ chelates were obtained with a JASCO Model DS-701G spectrometer in the range of 4000 to 400 cm^{-1} by using the KBr pellet technique. X-Ray powder diffraction data were taken with nickel-filtered Cu $K\alpha$ radiation and recorded with a Rigaku Denki Diffractometer.

Results and Discussion

The rate of sublimation of each Ln(thd)$_3$ chelate was constant for collecting times longer than 5 min at a given temperature. Figure 3 shows that the relationship in the Eu(thd)$_3$ chelate between the weight of the collected chelate and the collecting time is linear at each temperature, and the slope of the straight lines is given as the apparent rate of sublimation of the Eu chelate. A slight amount of the collected chelate was easily measured by the radioactive tracer technique.[7] The rate of sublimation of each Ln(thd)$_3$ chelate was obtained over the temperature range of 100 to 150 °C

Vapor pressure, P, is calculated from the rate of sublimation, m, according to the following equation:[8]

$$P = m\{(2\pi RT)/M\}^{1/2}, \quad (1)$$

where R is the gas constant; T, the absolute temperature of the sample; M, the molecular weight of the effusing gas. The units of m and P were chosen in g/(cm^2 s) and Torr, respectively (1 Torr=133.3224 Pa). The equation

$$P = 17.144\times m(T/M)^{1/2} \quad (2)$$

is obtained. The vapor pressures of each Ln(thd)$_3$ chelate were fitted to the following equation:

$$\log P = -(A/T) + B \quad (3)$$

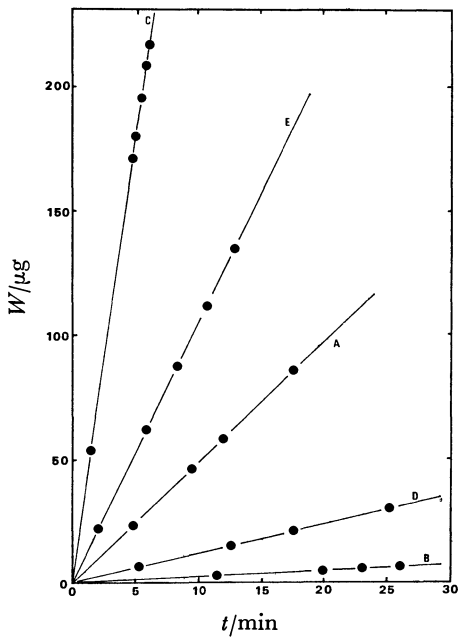

Fig. 3. Relation between amounts of collected Eu(thd)$_3$ chelate and collecting times at various temperatures.
A: 125.4 °C, B: 103.7 °C, C: 140.8 °C, D: 115.2 °C, E: 131.1 °C.

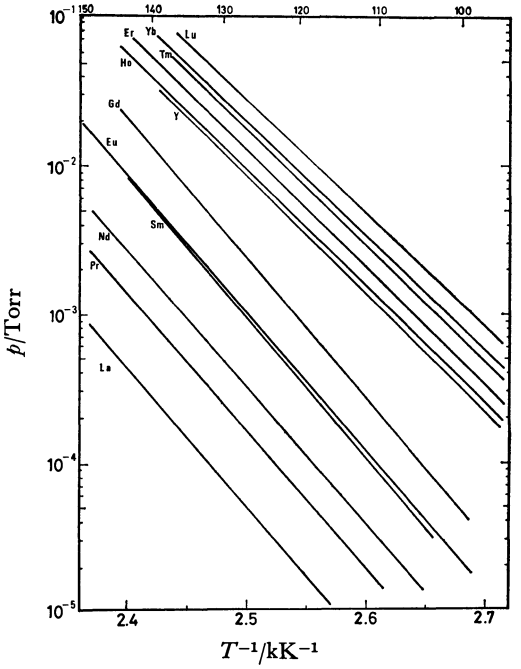

Fig. 4. Clausius-Clapeyron plots 11 Ln(thd)$_3$ and Y(thd)$_3$ chelates.

by a least square method. Heats of sublimation, ΔH_T, and entropies of sublimation, ΔS_T, were taken by equating the above experimental equation to the thermochemical equation

$$\ln(P/760) = (\Delta H_T - T\Delta S_T)/(-RT). \quad (4)$$

Thus, $\Delta H_T = 2.303 \times AR$ and $\Delta S_T = 2.303 \times R$(B-log 760) were obtained.

The Clausius-Clapeyron plots of a series of Ln(thd)$_3$ (expect Tb(thd)$_3$ and Dy(thd)$_3$) and Y(thd)$_3$ chelates are shown and compared in Fig. 4. Table 1 summarizes the thermochemical constants obtained. The plots of the Tb and Dy chelates were found to break at definite temperatures. The vapor pressures of these two chelates were measured in more detail in the temperature-descending process (160→100 °C), and the temperature-ascending process (100→160 °C). Figure 5 shows the Clausius-Clapeyron plots obtained in both processes for these chelates. Table 2 gives their thermochemical constants. The vapor pressures of the Ln(thd)$_3$ chelates have been found to increase with atomic number of lanthanoid ion, according to Sicre *et al.*[4] Figure 4 shows the same phenomena. The enthalpies of sublimation of the chelates of La to Gd, and Ho to Lu are slightly different from those of Sicre *et al.*

However, the Clausius-Clapeyron plots obtained in the temperature-ascending process of the Tb(thd)$_3$ chelate were found to break at 147 °C, where the crystal structure of this chelate changed thermally

from a monoclinic dimer to an orthorhombic monomer.[9] The enthalpy of sublimation of the Tb chelate in lower temperature range (100—147 °C) was similar to those of lighter lanthanoids (La to Gd), and the enthalpy in upper temperature range (147—160 °C) resembled those of heavier lanthanoids (Ho to Lu) and yttrium. On the other hand, the Clausius-Clapeyron plots in the temperature-descending procesess did not break at 147 °C and followed a straight line. The enthalpy of sublimation obtained from this line was the same as those in the upper temperature range (147—160 °C) of the ascending process, and almost equal to those of heavier lanthanoid chelates. The sublimation behavior of $Dy(thd)_3$ chelate is similar to that of the Tb chelate. The Dy chelate also changed its crystal structure at about 115 °C. The thermal transitions of the Tb and Dy chelates were found to be irreversible. The thermal behaviors of the $Ln(thd)_3$ chelates were found to be classified into three groups: La to Gd, Tb and Dy, and Ho to Lu. Figure 6 gives a relationship between the enthalpy of sublimation and the atomic number. The difference in enthalpy of sublimation between the lighter lanthanoids (La to Gd) and the heavier ones (Ho to Lu) is 6—8 kcal/mol (1 cal=4.184 J), which appears to correspond to the transition enthalpy of dimer to monomer of

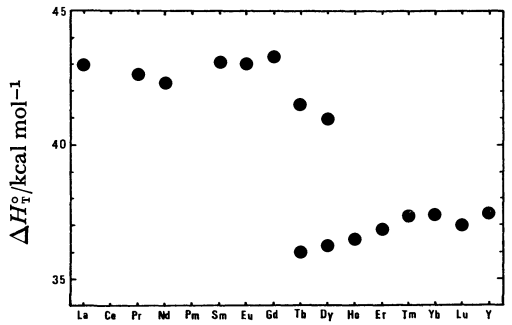

Fig. 6. Enthalpies of sublimation of $Ln(thd)_3$ as a function of atomic number.

the Tb and Dy chelates.

Partial X-ray powder patterns of the $Ln(thd)_3$ chelates are compared in Table 3. The patterns of the lighter lanthanoid chelates of La to Gd were different from those of heavier ones of Ho to Lu and yttrium. Erasmus and Boeyens reported the Pr chelate to be a monoclinic dimer.[10] The crystal structure of $Er(thd)_3$ and $Lu(thd)_3$ chelates have also been reported to be those of an orthorhombic monomer.[11,12] The crystal structure of the Tb chelate is the same as those of the lighter lanthanoid chelates. In the previous work,[9] the freshly sublimated Tb chelate has been found to change in crystallographic modification from a monoclinic dimer to an orthorhombic monomer at 147 °C, by means of differential scanning calorimetric technique and X-ray powder diffraction at elevated temperature. The breaking point on the Clausius-Clapeyron line of the Tb chelate corresponds to the temperature of its thermal transition. Fresh $Dy(thd)_3$ chelate was obtained in two different X-ray crystallographic systems by vacuum sublimation: a monoclinic dimer form and an orthorhombic monomer form. Vapor of the Dy chelate crystallizes in orthorhombic monomer form under the sublimation condition with a gentle temperature gradient, although it deposits in the monoclinic dimer form on the cooler of the molecular still if sublimed with a steep temperature gradient (100 °C/cm). Infra-red spectra of the freshly prepared lighter lanthanoid chelates were different from those of the heavier ones at 1300—1250 cm^{-1}, 1250—1100 cm^{-1}, 970—940 cm^{-1}, 810—770 cm^{-1}, and 510—450 cm^{-1}, as shown in Fig. 7. The spectral shape of the fresh Tb chelate was compared with those of lighter lanthanoid (La, Pr-Gd) chelates and found to be identical over the range of 4000 to 600 cm^{-1}. On the other hand, the IR spectra

$Y(thd)_3$	2.2	1.6×10^{-5}	1.4×10^{6}

a) $P_{180\,°C}$ indicates the pressure of chelate gas which is taken as the vapor pressure of the chelate at the temperature of heating site(180 °C). b) $P_{v.s.r.}$ is the saturated vapor pressure of the chelate at the highest site of vacuum sublimation-recrystallizing temperature. c) γ is the critical value calculated from the equation, $\gamma=P_{180\,°C}/P_{v.s.r.}$.

as a function of the atomic number of the corresponding lanthanoid. The plots can be classified in two distinct groups (La to Tb, and Dy to Lu) that coincided with the two different crystal structures observed from X-ray powder diffraction patterns. The $Dy(thd)_3$ chelate purified under the gentle temperature gradient belonged to a class of heavier lanthanoids. The lighter lanthanoids (La to Tb) form a monoclinic dimer system, and heavier ones (Dy to Lu) recrystallize in orthorhombic form on purification from the vapor phase. The vacuum sublimation-recrystallizing temperature can be explained on the basis of crystallization in the dimeric or monomeric system from the chelate vapor. Monomeric chelate gas of the lanthanoid will solidify to form a dimer system according to either of the following equations:

$$2Ln(thd)_3(gas) \rightarrow Ln_2(thd)_6(gas) \rightarrow Ln_2(thd)_6(solid), \quad (5)$$

or

$$2Ln(thd)_3(gas) \rightarrow 2Ln(thd)_3(solid) \rightarrow Ln_2(thd)_6(solid). \quad (6)$$

The enthalpies of the above two reactions are larger than that of the reaction of monomeric gas to monomeric solid. The enthalpy of sublimation of a monomeric $Ln(thd)_3$(solid) nearly equals 36 kcal/mol, and that of dimeric chelate is about 43 kcal/mol. From these results, the difference in the enthalpy of sublimation corresponds to the transition enthalpy of the following reaction:

$$Ln_2(thd)_6(soid) \rightarrow 2Ln(thd)_3(solid), \quad (7)$$

where the transition enthalpy of the reaction nearly equals 7 kcal/mol. In fact, the dimeric Tb and Dy chelates change to the monomeric chelates endothermically.[9] The enthalpies of both processes of (6)

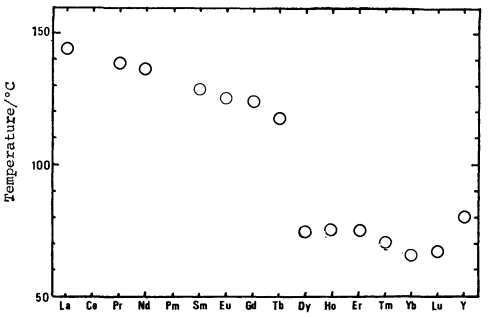

Fig. 8. Vacuum sublimation-recrystallizing temperatures of $Ln(thd)_3$ as a function of atomic number.

can be calculated from the thermochemical data obtained in this experiment. The volatilization process of the lighter lanthanoid chelate, $Ln_2(thd)_6$, is represented by the reverse of reaction (5) or (6). The lighter chelate thus requires more energy to vaporize than the heavier one. Deposition temperature is derived from overall sublimation-recrystallization processes. The lighter chelate deposits in a higher temperature zone than the heavier one. In general, the growth of crystals can be definitely observed at the "critical temperature."[13] Moreover, the ratio $\gamma=P_h/P_c$, where P_h is the pressure of vapor phase and P_c is the saturated vapor pressure at the critical temperature, have a characteristic value for each sample; this value is called the "critical value."[13] The vacuum sublimation-recrystallizing temperature in this paper corresponds to the critical temperature. The critical values have been calculated to the individual lanthanoid chelates to find out what regularity may exist in vacuum sublimation-recrystallization behavior; their values are given in Table 5. The critical values of the lanthanoid chelates were classified into two groups (La to Tb, and Dy to Lu) that coincided with the groupings of the vacuum sublimation-recrystallizing temperature. To estimate vacuum sublimation-recrystallizing temperatures of a variety of β-diketonato chelates, it would be necessary to collect the data of vapor pressures over the temperature range of deposition zone and critical values for these compounds.

The authors wish to express their thanks to Professor Eishin Kyuno of Hokuriku University for his kind permission to use the IR instruments. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 374189 and No. 574227 from the Ministry of Education, Science and Culture.

The Temperature Dependence of the Trapped and Averaged-valence State in Mono-oxidized Dialkylbiferrocenes

Sei'ichiro IIJIMA,† Ritsuko SAIDA, Izumi MOTOYAMA, and Hirotoshi SANO*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received August 4, 1980)

An interesting temperature dependence of the valence state was observed in the Mössbauer spectra of the mixed-valence salts of 1′,1‴-dialkylbiferrocenes, measured at various temperatures from 4.2 K to 300 K. A mechanistic consideration of the temperature dependence has been carried out assuming a conformational change of the monocation salts induced both by the variation in the temperature and by the kind of counter anion.

The monocation salts of binuclear ferrocenes are so-called "mixed-valence" compounds, in which, formally, two kinds of iron atoms, Fe(II) and Fe(III), are simultaneously contained. It is known that the monocation salts can be classified into two types, a trapped-valence type (or a mixed-valence type, in a narrow sense) and an averaged-valence one, by means of Mössbauer spectroscopy.[1-7] The former type gives two different states of irons, corresponding to bi- and tervalent irons, while the latter gives iron atoms in an equivalent state averaged between these two kinds of valence states. As for biferrocene derivatives, various monocation salts of biferrocene itself have been reported to be of the trapped-valence type,[1,4] while 1′,1‴-diiodobiferrocenium triiodide is of the averaged-valence type.[4]

In the present paper, results will be reported on the temperature dependence of valence states in mono-oxidized 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenes†† investigated by means of Mössbauer spectroscopy.

Results and Discussion

The biferrocene derivatives used in this study are listed in Table 1, all the compounds, **1**—**8**, were identified by means of elemental analyses (**1** and **5** were also identified by NMR), the results of which are summarized in Table 2. The Mössbauer data for the neutral species, 1′,1‴-diethylbiferrocene (**1**) and 1′,1‴-dipropylbiferrocene (**5**), are shown in Table 3, along with the data for unsubstituted biferrocene. The Mössbauer spectra of **1** and **5** at 78 K are shown in Fig. 1. The Mössbauer parameters of the substituted biferrocenes are actually identical to those of unsubstituted biferrocene at the same temperature, indicating that the replacement of hydrogens by alkyl groups does not affect the Mössbauer parameters of biferrocene.

The Mössbauer parameters for the dication salts, 1′,1‴-diethylbiferrocenium$^{2+}(BF_4^-)_2$ (**3**), 1′,1‴-diethylbiferrocenium$^{2+}(DDQH^-)_2$ (**4**), and 1′,1‴-dipropylbiferrocenium$^{2+}(BF_4^-)_2$ (**8**), are listed in Table 4, along with those for biferrocenium$^{2+}(BF_4^-)_2$. The Mössbauer spectra of these dication salts, **3**, **4**, and **8** show broad singlet peaks with very small quadrupole splittings, which are assignable to the ferrocenium-like tervalent iron, although generally no quadrupole splittings are found in the Mössbauer spectra of most mononuclear ferrocenium salts.[8] The 78 K spectra of **3** and **8** are shown in Fig. 2. The Mössbauer parameters of the dications of the diethylbiferrocene, **3** and **4**, with BF_4^- and $DDQH^-$ respectively as the counter ion, are essentially identical at the same temperature. Therefore, no effect of the counter anion was found on the parameters of these dication salts. These results agree with the fact that little difference can be detected in the Mössbauer parameters of mononuclear ferrocenium salts containing various anions as the counter ion.[8] Furthermore, the Mössbauer parameters of **3**, **4**, and **8** are quite similar to those of biferrocenium$^{2+}(BF_4^-)_2$ at the same temperature. Thus, no effect of the alkyl substitution was found on the Mössbauer parameters of the dications.

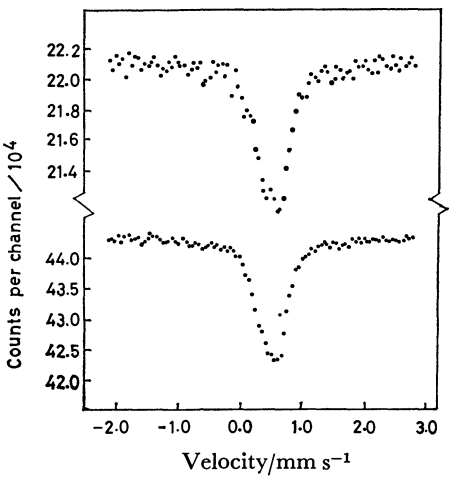

Fig. 2. Mössbauer spectra at 78 K of 1′,1‴-diethylbiferrocenium$^{2+}(BF_4^{-})_2$ (**3**) (top) and 1′,1‴-dipropylbiferrocenium$^{2+}(BF_4^{-})_2$ (**8**) (bottom).

Mössbauer measurements of the monocation salt, 1′,1‴-diethylbiferrocenium$^{+}I_3^{-}$ (**2**), were carried out at ten different temperatures between 4.2 to 300 K. The Mössbauer data for **2** are summarized in Table 5, along with those for the related compounds, while the spectrum at each temperature is shown in Figs. 3 and 4. As can be seen from Figs. 3 and 4, the shape of the spectrum greatly depends upon the temperature of the measurement. The spectrum at 4.2 K consists of inner and outer doublets in a nearly 1:1 ratio; these doublets are ascribed to the ferrocenium-like tervalent and ferrocene-like bivalent iron in **2** respectively. This spectrum is of the typical trapped-valence type. With an increase in the temperature, however, the quadrupole splitting of the inner doublet increases, while that of the outer doublet decreases gradually. Eventually, at 275 and 300 K, **2** shows typical averaged-valence spectra which consist of a single quadrupole doublet.

The Mössbauer data for 1′,1‴-dipropylbiferrocenium$^{+}I_3^{-}$ (**6**), are summarized in Table 6. The temperature dependence of the Mössbauer spectra of **6** was found to be very similar to that of **2**, but the typical averaged-valence spectrum appears at a temperature

about 25—30 degrees lower than that in the case of **2**, as is shown in Fig. 5.

As was mentioned in the Introduction, the Mössbauer spectra of biferrocenium$^+I_3^-$ and 1′,1‴-diiodobiferrocenium$^+I_3^-$ are of the trapped-valence and averaged-valence types respectively, neither of which is temperature-dependent. Consequently, it is obvious that these monocation salts of the dialkylbiferrocenes, **2** and **6**, are an additional type of "mixed-valence" compound, the valence state of which changes from the trapped-valence state to the averaged-valence one with the elevation of the temperature. Furthermore, from the Mössbauer spectroscopic behavior of the four monocation salts just discussed above, it can be said that the valence state of the mono-oxidized biferrocene system is greatly affected by the kind of substituent on the biferrocene system, while little effect of the substitution is found on the Mössbauer parameters of the neutral and dioxidized species.

In previous papers we reported that the monocation salt of *as*-indacenebis(cyclopentadienyliron) was the first example of a binuclear ferrocene salt which shows a remarkably temperature-dependent Mössbauer spectrum, that is, a trapped-valence-type spectrum at a lower temperature and an averaged-valence-type one at higher temperature.[9,10] This temperature dependence was interpreted successfully in terms of an electron-hopping process, in which the thermal electron-transfer takes place between two iron atoms and the electron-transfer increases with the increase in the temperature. However, the behavior of **2** and **6** observed in this study cannot be explained by using such an electron-hopping process, because the line-broadening of the Mössbauer spectrum at intermediate temperatures, which is characteristic of such a process,[9,11—13] was not found for **2** and **6**. It was previously suggested that the difference in valence state between biferrocenium$^+I_3^-$ and 1′,1‴-diiodobiferrocenium$^+I_3^-$ was attributable to the conformational difference between these monocations.[4] It was also suggested that the diiodo-monocation is in a *trans* or *cis* conformation with respect to the iron atoms, which would enhance the interaction between the two iron centers. The change in valence state observed for **2** and **6** seems to be understandable according to the following assumptions regarding the monocations:

that the conformation of the monocation of **2**, as well as that of **6**, at low temperatures (below about 200 K for **2**) differs from that at high temperatures (above about 270 K for **2**), and that the latter conformation, probably similar to that of the diiodo-monocation, causes strong interaction between the two iron atoms, that is, a full delocalization of electrons between the iron centers. At an intermediate temperature, it can be concluded that the conformation of the 1′,1‴-diethylbiferrocenium and 1′,1‴-dipropylbiferrocenium monocation varies gradually from the low-temperature-type conformation to the high-temperature-type one with an increase in the temperature.

a) Isomer-shift data are reported with respect to metallic iron foil.

As indicated by the data cited in Table 6, the anion-substituted monocation salt of 1′,1‴-dipropylbiferrocene, 1′,1‴-dipropylbiferrocenium$^+$(TCNQ)$_2^-$ (**7**), was found to give averaged-valence-type Mössbauer spectra, which are not temperature-dependent. As has been described above, we found little effect of anions on the Mössbauer parameters for the mononuclear ferrocenium salts; this was also demonstrated for the dioxidized 1′,1‴-diethylbiferrocene of Mössbauer spectra in the present work. The difference observed in the temperature dependence of the Mössbauer spectra between **6** and **7** may suggest that the conformation of the 1′,1‴-dipropylbiferrocenium mono-

cation in the crystalline state is considerably influenced by the counter ion and controls the extent of interaction between the metal centers.

Experimental

Mössbauer Measurements. As the radioactive source for Mössbauer measurements a $^{57}Co(Pt)$ moving in a constant-acceleration mode was used. The Mössbauer spectra of **2**, **5**, and **6** were obtained by using an Austin Science Associates Mössbauer spectrometer and a proportional counter. The other spectra were obtained by using a Shimadzu Mössbauer spectrometer and a NaI scintillator. The isomer shifts are determined relative to metallic iron foil. The experimental errors of the Mössbauer parameters are estimated to be ± 0.03 mm/s.

Materials. The 1′,1‴-diethylbiferrocene **1** was prepared by the Ullmann coupling of 1-ethyl-1′-bromoferrocene,[14] which had itself been obtained from the $LiAlH_4$-$AlCl_3$ reduction of 1-acetyl-1′-bromoferrocene.[15]

The 1′,1‴-dipropylbiferrocene **5** was prepared by the Ullmann coupling of 1-propyl-1′-bromoferrocene, which had itself been obtained from the reduction of 1-propionyl-1′-bromoferrocene. 1-Propyl-1′-bromoferrocene (2.5 g, 8.1 mmol) mixed with 10 g of copper powder was heated to 120—130 °C for 18 h in a sealed glass tube. **5** was rapidly separated from the starting materials by using column chromatography on alumina; it was then obtained as reddish needles upon recrystallization from hexane. Mp 67—68 °C. ^1H NMR δ 0.90 (6H, t), 1.46 (4H, m), 2.16 (4H, t), 3.90 (8H, s), 4.16 (4H, t), and 4.30 (4H, t).

The 1′,1‴-dipropylbiferrocenium$^+$(TCNQ)$_2^{\cdot-}$ (**7**) was synthesized according to the procedure used for the preparation of ferrocenium$^+$(TCNQ)$_2^{\cdot-}$,[16] as follows. To a refluxing solution of 82 mg (0.4 mmol) of TCNQ in 30 ml of acetonitrile, a 91 mg portion (0.2 mmol) of **5** was added. After the reaction mixture had been refluxed for 15 min, **7** was separated out as blue-black needles, but in a low yield, on cooling. **5** did not react with TCNQ in boiling dichloromethane in place of acetonitrile.

The 1′,1‴-diethylbiferrocenium$^+I_3^-$ (**2**), 1′,1‴-diethylbiferrocenium$^{2+}(BF_4^-)_2$ (**3**), 1′,1‴-diethylbiferrocenium^{2+}-$(DDQH^-)_2$ (**4**), and 1′,1‴-dipropylbiferrocenium$^{2+}(BF_4^-)_2$ (**8**) were synthesized according to the procedures previously reported for the preparation of the corresponding salts of unsubstituted biferrocene.[1,2,4]

The analytical data for all the compounds described above are listed in Table 2.

The Solution Chemistry of Organotin Compounds. I. A ^{1}H NMR Study of the Complex Formation between Methyltin Trichloride and 4-Substituted Pyridines

Hideaki FUJIWARA,* Fumihiko SAKAI, Miyoko TAKEYAMA, and Yoshio SASAKI

Faculty of Pharmaceutical Sciences, Osaka University, 133-1 Yamadakami, Suita, Osaka 565

(Received August 11, 1980)

The formation of donor-acceptor complexes between $MeSnCl_3$ and 4-substituted pyridines has been investigated by analyzing the concentration dependence of NMR parameters. The formation of 1($MeSnCl_3$):2(pyridine) and 1:1 complexes has been proved, and the equilibrium constants(K_1 and K_2) and complex formation shifts (Δ_{AB} and Δ_{AB_2}) are determined for the successive formation of these complexes. log K_1 and log K_2 are in a good linear correlation with each other, and they have a tendency parallel with that of pK_a of the pyridine derivative, suggesting a predominant contribution of σ-bonding in the donor-acceptor bond. Both Δ_{AB} and Δ_{AB_2} indicate a high-field shift on the formation of the complex, which is consistent with the expected electron transfer in the donor-acceptor bond. However, Δ_{AB} varies inversely to the basicity of the pyridines; the anisotropy effect of the pyridine ring is suggested as the reason for this. The results are also discussed in relation to Hammett's substituent constant.

Among a variety of organometallic compounds, organotins are particularly stable and so are widely used in industry and in pharmaceuticals. They are used, for example, as stabilizers and catalysts for synthetic polymers and such biocides as fungicides, bacteriostasis, and insecticides.[1,2] These facts have stimulated recent studies of the related compounds by means of modern physical techniques.[2,3] In these studies, the physico-chemical properties and geometries of the compounds as well as of their complexes with bases have been the main subject. However, studies from the standpoint of solution chemistry are equally inevitable for a full understanding of the nature of these substances. We are interested in the intermolecular interaction in solution and have, therefore, set about studying the equilibria and thermodynamics as well as the dynamics of the complex formation of organotin compounds.

In the present work the complex formation of methyltin trichloride ($MeSnCl_3$) with several 4-substituted pyridines is investigated by means of analyzing the concentration dependence of the NMR chemical shift, and the equilibrium constant and the complex-formation shift are determined for the 1($MeSnCl_3$):1(pyridine) and 1:2 complexes. The results are discussed in relation to the basicity of pyridines as well as to the substituent effect.

Experimental

The $MeSnCl_3$ and 4-nitropyridine were synthesized from Me_2SnCl_2[4] and 4-nitropyridine *N*-oxide[5] respectively. The other materials were from commercial sources. The $MeSnCl_3$ was purified by sublimation under reduced pressure at $\approx$30 °C. The NMR spectra showed an impurity of Me_2SnCl_2 of less than 1%. The pyridines were distilled over BaO under normal pressure (pyridine and 4-methylpyridine) and under reduced pressure (4-acetyl- and 4-(methoxycarbonyl)pyridines). The 4-cyanopyridine was sublimed at $\approx$70 °C, and the 4-nitropyridine was recrystallized several times from petroleum ether. The nitrobenzene was dried over BaO and distilled under reduced pressure. All the materials were stored in desiccators, and all operations of the above distillation and sample preparation for the NMR measurement were made in dry boxes under a relative humidity of <20%. The ^{1}H NMR spectra were observed with a Hitachi R-22 spectrometer operating at 90 MHz and 34.1 °C. The chemical shifts and coupling constants were measured by means of a frequency counter within an error of $\pm$0.1 Hz. As an internal reference, $\approx$0.02 vol% Me_4Si was added to the solvent. The calculations were done on a NEAC S-900 computer at the Computation Center, Osaka University.

Results and Discussion

$MeSnCl_3$ is known to form a 1:2 donor-acceptor complex with pyridine, as evidenced by the isolation of the complex from solution.[6,7] Therefore, in interpreting the equilibrium property of these systems, it is necessary to take into account the concurrent formation of 1:1 and 1:2 complexes. Although equilibrium studies have often been reported with regard to the complex formation of methyltin halides,[6] there have been very few analyses of the simultaneous formation of 1:1 and 1:2 complexes.[8] We have made a computer program, CONDEP,[9] which minimizes the standard deviation(σ) between the observed and calculated NMR parameters—such as the chemical shift and the coupling constant—on the basis of the equilibrium of 1) A+B=AB, 2) A+2B=AB_2, and 3) A+B=AB and AB+B=AB_2. In this program the NMR parameter can be measured on the side of either A or B, and several selections of the number of adjustable parameters are made possible. The calculations below are made through the use of this program.

Composition of the Complex Formed in Solution. Job plots are shown in Fig. 1 for the $MeSnCl_3$+4-methyl-, +4-acetyl-, and +4-cyanopyridine systems. In the $MeSnCl_3$+4-methylpyridine system, the errors are relatively large in the shift measurement and ^2J(SnH) is difficult to observe because of the signal broadening. The Job plots of this system are almost the same in pattern when the solvent is changed to CH_2Cl_2 from nitrobenzene. Job plots were not obtained for the $MeSnCl_3$+pyridine system because of precipitation during the sample preparation. The Job plots of the $MeSnCl_3$+4-methoxycarbonyl- and +4-nitropyridine systems are similar to those of the $MeSnCl_3$+4-acetyl- and +4-cyanopyridine systems (Figs. 1b and 1c) re-

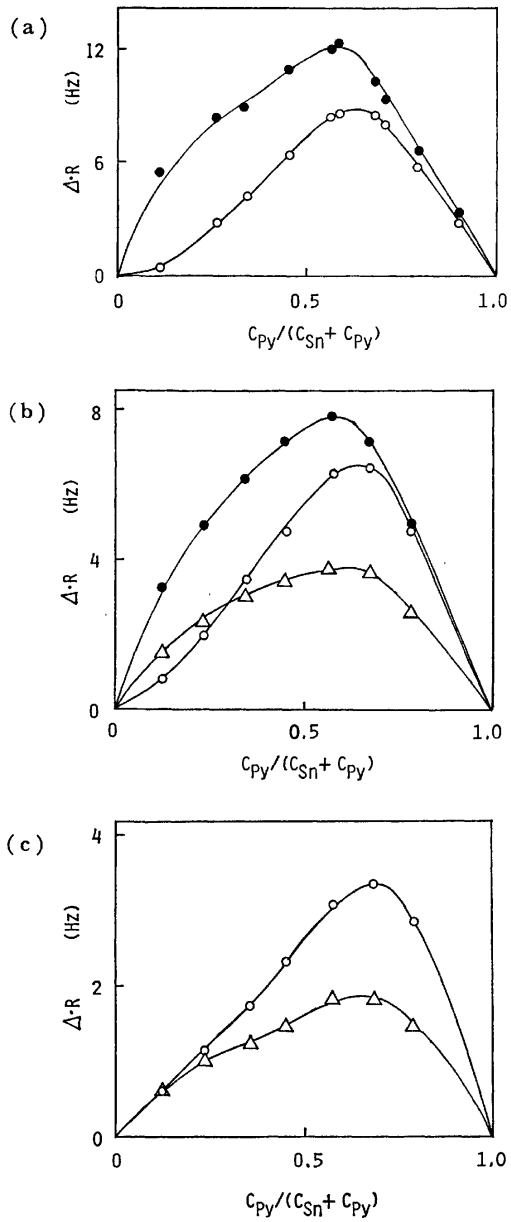

Fig. 1. Job plots for the a) $MeSnCl_3$+4-methylpyridine, b) $MeSnCl_3$+4-acetylpyridine, and c) $MeSnCl_3$+4-cyanopyridine systems.
C_{Sn} and C_{py} are molarities of $MeSnCl_3$ and the pyridines, respectively. $C_{Sn}+C_{py}\simeq 0.1$ mol dm^{-3}. Δ is equal to the variation in NMR parameters from a free state of the molecule under observation. R indicates mole fraction of the molecule under observation. $\Delta \cdot R$ is negative for δ (CH_3 in base) and $^2J(^{119}SnH)$, but absolute value is plotted. ●: Experimental point for $\delta_H(CH_3$ in base), △: experimental point for $^2J(^{119}SnH)$, ○: experimental point for $\delta_H(SnCH_3)$.

spectively. In all these systems, the plots show a plateau between 0.6—0.7 mole fraction of the base, irrespective of the NMR parameters observed, *i.e.*, $\delta_H(SnCH_3)$, δ_H(base), and ^2J(SnH), supporting the idea of the formation of a 1:2 complex in solution as well. On the other hand, the presence of a 1:1 complex is only inferred from the mole fraction corresponding to the plateau, which is a little smaller than 0.67. This is ascertained below from the simulation of the NMR concentration dependences based on several models of the equilibrium. Hitherto, little has been reported about the 1:1 complex.

Determination of the Equilibrium Constant and Complex-formation Shift. The equilibrium constant (K) and the complex-formation shift (Δ), the latter being equal to the variation in chemical shift when complex formation occurs, can be obtained from the simulation of the concentration dependence in the NMR shifts. For this purpose, the concentration of $MeSnCl_3$ is held constant at an appreciably low molarity ($\approx$0.005 M), while that of the base is varied. In this manner, the concentration dependence of δ ($SnCH_3$) is obtained as depicted in Fig. 2. This is analysed on the basis of the equilibrium of 1) $A+2B=AB_2$ and 2) $A+B=AB$ and $AB+B=AB_2$, considering the results of the above Job plots, which strongly support the 1:2 complex. The calculation based on the $A+2B=AB_2$ is shown in Table 1. In this table, the σ

a) K_1 and K_2 in a unit of $dm^3\,mol^{-1}$. b) In a unit of Hz. c) See footnote c) in Table 1.

amounts to 0.4—1.1 Hz. Furthermore, the deviation between the observed and calculated shifts is found to change systematically with the molarity of the base. These facts indicate the inadequacy of the model adopted. When the equilibrium of A+B=AB(K_1) and AB+B=AB_2(K_2) is assumed, four parameters have to be taken into account, *i.e.*, K_1, K_2, δ_{AB}, and δ_{AB_2}, the latter two being identified as the $\delta_H(SnCH_3)$ in the AB and AB_2 species respectively. Under these conditions, it proved necessary to obtain a rough estimate of the four parameters for the simultaneous determination of these parameters in the simulation. That is, the same final values were not always reached if the corresponding initial values were considerably changed. This is not the case in the above two-parameter calculation; it can be interpreted by saying that a small variation in one parameter is compensated for by that in others, with the σ almost unchanged, if the number of adjustable parameters is increased.[10] When the concentration of the base was increased further in Fig. 2, $\delta_H(SnCH_3)$ was found to level off. This ultimate value of $\delta_H(SnCH_3)$ should correspond to δ_{AB_2}, and so a three-parameter calculation becomes feasible, eliminating δ_{AB_2} from the variables. The values of the 4 parameters thus estimated are next used as the initial ones in the four-parameter calculation. Thus, a final set of all the parameters is obtained (Table 2). Errors are also estimated in the CONDEP program for each parameter as equal to the 95% confidence range, which makes the σ^2 larger by 1.96 times when a parameter under consideration is varied, whereas the others are held constant. The average of such errors was usually a little larger than the reproducibility of each parameter in several repeated experiments; it is also depicted in Table 2. The relatively large σ's in the $MeSnCl_3$+4-methylpyridine and +pyridine systems are due to signal broadening. The relatively large errors in log K_1 are caused by the experimental concentration conditions; that is, our experimental concentrations were rather suitable for the precise determination of small values of K_1 and K_2, but they were too high for the large value of K_1 to be determined more accurately.

Equilibrium Constant. A linear correlation is observable between the stability constants of the 1:1 and 1:2 complexes (Fig. 3). A least-squares fit by means of the $y=ax$ equation proves the satisfactory linearity between them:

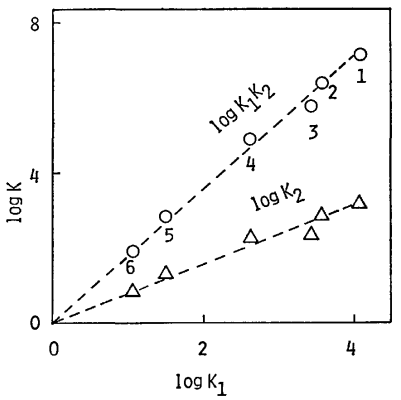

Fig. 3. Plots of log K_1K_2 and log K_2 against log K_1. The numbering corresponds to that in Fig. 2.

$$\log K_1K_2 = 1.78 \log K_1, \qquad \sigma = 0.20. \tag{1}$$

This equation also implies a linear relation between log K_1 and log K_2, a least-squares fit leading to log K_2=0.78 log K_1, and σ=0.20. These equations are reflections of the colinearity in the free-energy changes in the formation of 1:1 and 1:2 complexes; the latter equation also means that the absolute value of the free-energy change in the second step is decreased to *ca.* 3/4 of that in the first step. Such a simple relation may be understood as indicative of the absence of a particular derivative in the pyridines treated here, which exerts a specific steric effect or which behaves differently in the complex formation.

It may be seen from Fig. 4 that log K_1, log K_2, and log K_1K_2 change in parallel with pK_a.[12] The fact that they are not in a strictly linear relation is obvious from the plots of log K_2, for which the experimental accuracy is excellent. Such deviation is a little improved if log K_2 is plotted against the effective substituent constant($\bar{\sigma}$) determined from the Menschutkin reaction of pyridines with ethyl iodide in nitrobenzene[13] (Fig. 5). The Hammett ρ value can be determined from the log K/K_0 *vs.* $\bar{\sigma}$ plots and is 2.9, which is equal to the value for the Menschutkin reaction, *i.e.*, 2.94.[13] This indicates that the donor-acceptor bond formation is less sensitive to changes in electron density on the N atom than is the dissociation of pyridinium ions (ρ=6.01[12] and 6.24[14]). This is a reasonable result, because the ionicity in the present donor-acceptor bond should be smaller than that in the N^+–H bond of the pyridinium ion. As

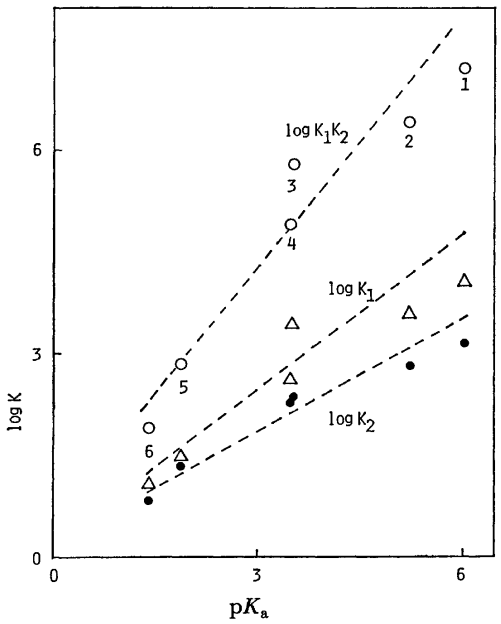

Fig. 4. Correlation between the equilibrium constant and basicity of the pyridine (pK_a).
The numbering corresponds to that in Fig. 2. pK_a's are cited from Ref. 12.

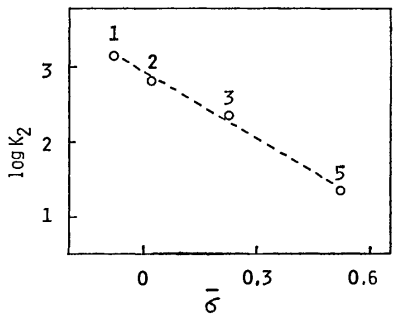

Fig. 5. Correlation between log K_1 and $\bar{\sigma}$ in nitrobenzene.
The numbering corresponds to that in Fig. 2. $\bar{\sigma}$ is cited from Ref. 13 and is available for the four derivatives among the ones treated here.

far as the electron-accepting group is concerned, the σ-effect is known to be a dominant factor in the substituent effect on the dissociation of the pyridinium ion[12,15] and on the above Menschutkin reaction.[13] Therefore, a parallel tendency between the log K's and pK_a as well as $\bar{\sigma}$ can be interpreted as indicating dominant σ-bonding in the formation of the present donor-acceptor complexes.

The distribution curve of $MeSnCl_3$ is shown in Fig. 6 for the $MeSnCl_3$+4-methylpyridine and +4-cyanopyridine systems. This figure clearly demonstrates that an appreciable amount of the 1:1 complex is formed in the solution. In Fig. 6a) the distribution to the free species of $MeSnCl_3$ rapidly falls off with the increase in the molar ratio, $C_{Py}/_{Sn}C$. This is responsible for the relatively large error in log K_1 in this system. If the initial concentration of $MeSnCl_3$ is reduced further, the fall-off will become slower, making the value of K_1 more accurate. However,

C_{Sn} and C_{Py} are molarities of $MeSnCl_3$ and the pyridines, respectively. C_{Sn} is held constant at $\approx$0.005 mol dm^{-3}. A=$MeSnCl_3$. B=Pyridine derivative.

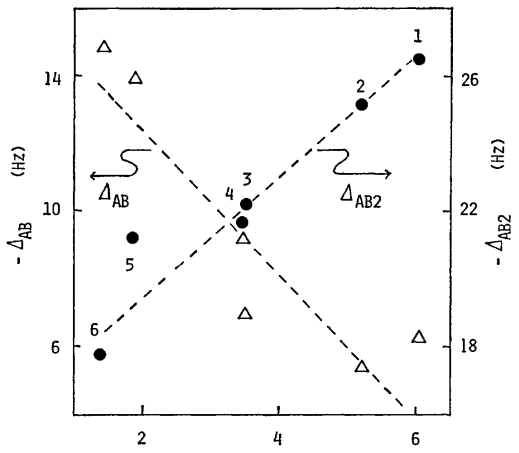

Fig. 7. Plots of Δ_{AB} and Δ_{AB2} against pK_a.
The numbering corresponds to that in Fig. 2. pK_a is cited from Ref. 12. See text for the definition of Δ_{AB} and Δ_{AB2}.

such an experiment is beyond the sensitivity of the spectrometer used here.

Complex-formation Shift. The complex-formation shifts, Δ_{AB} and Δ_{AB2}, which are defined as Δ_{AB}=

$\delta_{AB}-\delta_A$ and $\Delta_{AB2}=\delta_{AB2}-\delta_A$, are all negative, indicating a high-field shift on the formation of the complex. This is consistent with the expectation from the electron transfer in the donor-acceptor bond. When Δ_{AB} and Δ_{AB2} are plotted against pK_a, a nearly linear relation is obtained (Fig. 7). It is reasonable that Δ_{AB2} is varied to the high-field side by the more basic pyridine derivative. On the contrary, Δ_{AB} is seen to vary inversely with the basicity of the pyridine derivative, although the plots in Fig. 7 are scattered, reflecting the relatively large errors in $\log K_1$. As a reason for this inverse dependency, the anisotropy of the pyridine ring may be pointed out; it originates from the ring current effect. That the anisotropy effect really acts is also suggested by the variation of $\delta_H(SnCH_3)$ in Me_2SnCl_2, which moves toward the low-field side on the addition of pyridine, contrary to the case when DMSO or HMPA is added. A detailed analysis of this effect will be worthwhile for the elucidation of structural problems in solution; it will be the subject of further work.

The Thermal Decomposition of Sodium Nitrate and the Effects of Several Oxides on the Decomposition

Yoshio Hoshino,* Taizo Utsunomiya, and Osami Abe

Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received August 15, 1980)

The thermal decomposition of sodium nitrate and the effects of several oxides, such as silica, titania, zirconia, alumina, and magnesia, on the decomposition were studied up to 900 °C by means of the thermal analysis, gas analysis, and chemical analysis of the reaction products. The reaction of sodium nitrate and silica was especially investigated in some detail over a wide composition range. The thermal decomposition of sodium nitrate started at about 450 °C. The gases formed were O_2, NO, and N_2, the formation of N_2 being detected above 680 °C. The thermal decomposition of sodium nitrate was supposed to consist of the following three successive or concurrent reaction processes, according to the degree of the reaction: (I) the decomposition of sodium nitrate to nitrite and oxygen, (II) the first-order liquid-phase reaction, with some kind of quantitative relationship between nitrate and nitrite, and (III) the formation reaction of sodium oxide, expressed by the Avrami-Erofe'ef equation. The (II) and (III) reaction processes can be reasonably interpreted if the existence of the peroxide ion is assumed. Acidic oxides, such as silica and titania, were supposed to lower the activation energy of the (III) reaction process by forming stable salts with sodium nitrate and/or its intermediate reaction products. The effects of these oxides on the thermal decomposition of sodium nitrate could be interpreted by the relative scale of the acidity of oxides.

Sodium nitrate is one of the most important components used in the chemical industry. In recent years, it has been used as the source of the sodium used in multi-component glass fibers for optical waveguides.[1] This is because sodium nitrate has some advantages, such as oxidation and clarification effects, a low melting point, and a low decomposition temperature. However, few studies have been made of the reaction of sodium nitrate and several oxides. Furthermore, in the studies of the thermal decomposition of sodium nitrate,[2-6] there are some disagreement concerning the decomposition temperature and/or the kind of gas formed.

In the previous paper,[7] the following results were obtained with regard to the reaction of sodium nitrate and silica: (1) the formed gases in this system up to 800 °C were O_2 and NO; (2) 3 to 7 wt% sodium nitrite was present in the reaction system just before the formation of gas ceased; (3) the reaction products were sodium metasilicate (Na_2SiO_3) and disodium disilicate ($Na_2Si_2O_5$), depending on the silica content in the sample mixtures, and (4) the history of preparation and the relative surface area of the silica scarcely affect this reaction. However, the mechanism of the thermal decomposition of pure sodium nitrate was not investigated, since this decomposition appeared to be difficult to investigate in view of the creep-out of the melt of sodium nitrate from a platinum reaction vessel. In relation to the decomposition of sodium nitrate, disagreements among the other workers' paper[2-6] seem to be caused by not taking account of the possibility of the effect of the experimental conditions, such as the measuring atmosphere and the material of the reaction vessel, on the decomposition, and by not setting up precise conditions of gas analysis.

In this study, the thermal decomposition of sodium nitrate and the effects of silica, titania, zirconia, alumina, and magnesia on the decomposition were investigated by a simultaneous measurement of thermogravimetry (TG), differential thermal analysis (DTA), differential thermogravimetry (DTG), and gas chromatograpy (GC), by which the gas formed could be analysed directly in a short time. Furthermore, the effect of silica addition was investigated over a relatively wide range of silica compositions.

Experimental

Samples. Reagent-grade sodium nitrate, titania, zirconia, and magnesia from the Wako Chemical Industries, Ltd., and alumina from the Nishio Industries, Co., Ltd., were ground under 100 mesh in an agate mortar and dried in an oven at 100 °C. Commercially available α-quartz was also ground under 100 mesh by means of a ball mill, washed with acid and distilled water, and dried in the oven. Sodium nitrate was mixed with one of these oxides by dry-blending at each run. The composition of sample is indicated by the atomic ratio, X_i (=i/Na; i=Si, Ti, Zr, Al, or Mg), in each sample mixture.

Apparatus and Procedure. The TG-DTA measurement was carried out with a high-temperature thermobalance from the Rigaku Denki Co., Ltd. The DTG was carried out with a differentiator from the Rikadenki Kogyo Co., Ltd., in order to differetiate the TG curve. A GC-2C-type gas chromatograph from the Shimadzu Seisakusho, Ltd., was used for quantitative gas analysis, in which silica-gel and molecular-sieve 5A were used as the column-packing reagents after treatment by the method descrived by Sakaida *et al.*[8]

The simultaneous measurement of TG-DTA, DTG, and GC was carried out as follows. At first ,the sample mixture (less than 80 mg) was weighed in a reaction vessel (5 mm in diameter, 5 mm in depth), and this vessel was placed on a sample holder in the thermobalance; then, the ambient gas was introduced into the measuring system and adjusted to the desired flow rate (50 $cm^3\ min^{-1}$). Secondly, the sample was heated at 20 °C min^{-1} and then held at 250 °C for about one hour. By this procedure, a trace amount of adsorbed water could be removed. The sample was then heated up to the desired temperature at the rate of 5 °C or 20 °C per min. In gas chromatography, argon was used as the carrier gas, and the gas formed from the sample was introduced into the gas chromatograph every 2 min

It took less than one minute from gas formation to gas sampling.

On the other hand, the reaction products were identified by X-ray powder diffractometry with Cu $K\alpha$ radiation. These reaction products were also used for quatitative analysis. About 100 mg of the reaction products were dissolved in water for one hour and then filtered. The unreacted silica was determined from the amount of dissolution residue. The silicates and total sodium were determined by atomic absorption spectrometry and flame emission spectrometry respectively. The sodium nitrate and sodium nitrite were determined by using a nitrate-ion electrode from the Toa Electronics, Ltd., and by UV spectrometry with sulfanilic acid respectively.

Results and Discussion

Effect of Experimental Condition on the Thermal Decomposition of Sodium Nitrate. In order to investigate the thermal decomposition of sodium nitrate and the effects of several oxides on the reaction, various factors which seemed to affect the reaction were investigated. They are, for example, the amount of the sample mixture, the heating rate, the ambient gas and its flow rate, and the material of the reaction vessel. The use of a small amount of the sample would result in a better thermal response. Taking the accuracy of the measurement into consideration, a sample mixture containing 8.5, 10.0 or 17.0 mg of sodium nitrate was used. In the binary system of sodium nitrate and silica, the similar shapes of the TG and DTG curves, and also the similar behavior of gas formation, were shown for the sample with the same value of X_{Si} in the ranges from 14.5 mg to 58.0 mg ($X_{Si}=1.0$) and from 38.0 mg to 77.0 mg ($X_{Si}=5.0$). The heating rate and the flow rate of the ambient gas scarecely affected the decomposition in the range investigated here; therefore, they were not important experimental factors. It is well known that a quartz or Pyrex-glass reaction vessel affects the decomposition. The reason for this is that sodium nitrate reacts with these vessels to form stable salts. On the other hand, platinum and stainless steel vessels seldom affect the decomposition; however, a creep-out of the fused sample from the vessel sometimes occurs. The reactivity of the vessels and the creep-out of the sample were investigated with platinum, gold, and two kinds of sintered magnesia vessels (MgO-A vessel: pressed at 9.3×10^3 kg cm^{-2} and heated at 1000 °C for one day; MgO-B vessel: pressed at 1.85×10^4 kg cm^{-2} and heated at 1000 °C for two days). There are no appreciable difference among these reaction vessels. Figure 1 shows the DTG curves and the behavior of the gas formation when a platinum or MgO-B vessel was used. The rate of weight loss, $d\alpha/dt$, is the differential of the fraction of weight loss, α, with respect to the reaction time, t. R_{O_2}, R_{NO}, and R_{N_2} are the formation rates of O_2, NO, and N_2, respectively per mole of sodium nitrate. These results resemble each other below 700 °C. If the MgO-B vessel affected the decomposition, this behavior when a MgO-B vessel is used would be similar to that in the reaction of sodium nitrate and magnesia, which will be described later. When the sodium nitrate

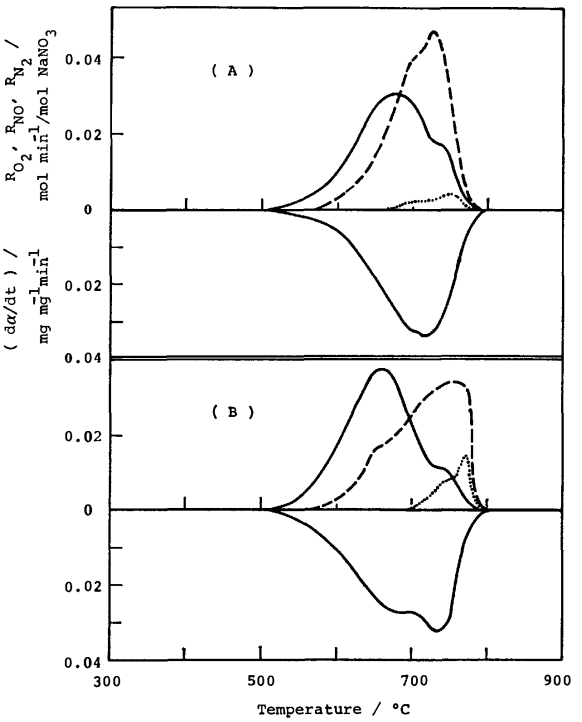

Fig. 1. DTC curves and the behavior of gas formation for the thermal decomposition of sodium nitrate with platinum (A) or MgO-B (B) reaction vessel in argon atmosphere. The solid line, the interrupted line and the dotted line indicate the formation rate of O_2 (R_{O_2}), NO (R_{NO}), and N_2 (R_{N_2}), respectively.

was held at a constant temperature, the MgO-B vessel, where no creep-out of the melt occurred, was used because it required a long time for measurement (for example, it took 260 min at 592 °C).

Then, the effect of the heating atmosphere, such as argon, nitrogen, oxygen and air on the reaction of the binary system of sodium nitrate and silica was investigated at the flow rate of 50 cm^3 min^{-1}. Figure 2 shows the TG curves and DTG curves for the reaction in argon (a) and oxygen (b). The TG and DTG curves for the reaction in nitrogen showed a shape similar to those obtained in argon. In air, they showed an intermediate shape between (a) and (b). The DTG curve of (b) showed peaks at 730 °C and 755 °C and shifted to a higher temperature than that of (a). From these results, it is evident that the partial pressure of oxygen (perhaps also nitrogen monoxide) affects the decomposition.

Thermal Decomposition of Sodium Nitrate. Figure 3 shows the results of the simultaneous measurement of TG-DTA, DTG, and GC on the thermal decomposition after heating at 5 °C min^{-1}. The DTA curves show the endothermic peaks at 278 °C and 308 °C which correspond to the transformation and melting. The TG and DTG curves indicate that the decomposition finished at 800 °C. It is found from the behavior of gas formation that, at first, sodium nitrate generates O_2, secondly, O_2 and NO, and then, over 680 °C, O_2 NO, and N_2. On the decomposition of sodium nitrite, the formation of N_2 was scarecely detected, so the formation must be caused by the reaction pro-

cess that sodium nitrate directly decomposes or reacts with its reaction products.

Furthermore, the decomposition was investigated at various constant temperatures in the range from 592 °C to 703 °C. Figure 4 and 5 show the TG curves

and the behavior of gas formation respectively.

The TG curves in Fig. 4 were analysed by the method described by Hancock and Sharp.[9] This method is based on the Avrami-Erofe'ef equation (Eq. 1):

$$(-\ln(1-\alpha))^{1/n} = kt, \quad (1)$$

where α is the fraction reacted, k is the kinetic constant, and t is the reaction time. The n value is a constant peculiar to this type of reaction; usually, it is an integer larger than 2. Hancock showed that, when $\ln(-\ln(1-\alpha))$ is plotted against ($\ln t$), an approximately linear relation is observed for many kinds of solid-state reactions and the first-order and zeroth-order reactions. For the first- and zeroth-order reactions, the n slopes equal unity and 1.24 respectively. Figure

6 illustrates the ln (−ln (1−α)) *vs.* (ln *t*) plots for the decomposition of sodium nitrate. Figure 6 shows the ranges in which the kinetic equation of the first-order reaction is valied ($\alpha \leqq 0.85$) and in which the Avrami-Erofe'ef equation with $n=3$ is valid ($\alpha \geqq 0.85$). In the α ranges mentioned above, the TG curves being

estimated with the kinetic equation of the first-order reaction and the Avrami-Erofe'ef equation, Fig. 7 obtained. They give approximately linear plot. The kinetic constants were obtained from these slopes. From their Arrhenius plot, the apparent activation energy was calculated to be 223 kJ mol^{-1} for the first-order reaction below 648 °C and 243 kJ mol^{-1} for the $n=3$ range above 672 °C.

The behavior of gas formation was analysed by the method of plotting the formation ratio of O_2 to NO *versus* α. They are illustrated in Fig. 8, which shows that the formation of O_2 is remarkable at the initial and final stages of the reaction. In the middle stage of the reaction, the R_{O_2}/R_{NO} value is nearly constant in the α range from 0.25 to 0.75. This strongly suggests that it is reasonable to divide the thermal decomposition of sodium nitrate into three successive or concurrent reaction processes. From the analysis of the solid-state reaction products, it was found that the amount of sodium nitrite in the melt increased at the initial stage of the reaction and decreased at the middle and final stages. The three predominant reaction processes in the initial, middle and final stages of the reaction may be summalized as follows:

Process I (predominant in the initial stage); the thermal decomposition of sodium nitrate to nitrite and oxygen (Eq. 2)

$$NaNO_3 = NaNO_2 + 1/2O_2. \quad (2)$$

This reaction process has been studied by several workers.[2-6]

Process II (predominant in the middle stage); the first-order liquid-phase reaction with some kind of quantitative relationship between nitrate and nitrite in the melt; the reverse reaction of sodium nitrite to form nitrate also occured. This can reasonably be interpreted if the existence of sodium peroxide or

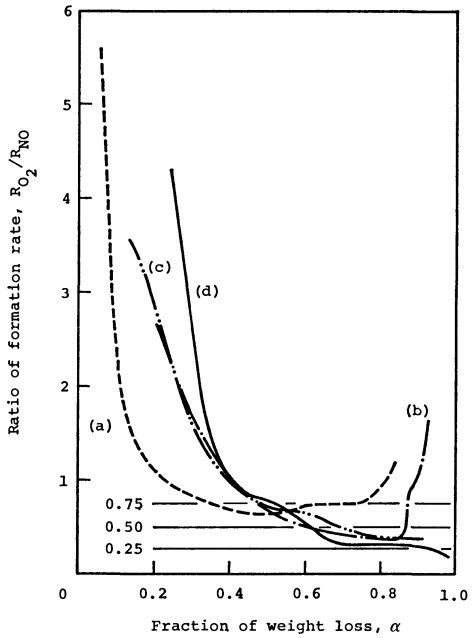

Fig. 8. The ratio of the formation rate of O_2 to NO, R_{O_2}/R_{NO} at various constant temperatures.
(a): 611 °C, (b): 648 °C, (c): 672 °C, (d): 703 °C.

hyperoxide as an intermediate during the decomposition of sodium nitrate is assumed. Paniccia *et al.*[10] reported that sodium peroxide was the main basic species in (sodium–potassium) nitrate eutectic *in vacuo*. Under the argon flow, peroxide is also considered to be the main basic species. This reaction process is expressed by the following equations:

$$NaNO_2 = 1/2Na_2O_2 + NO \quad (3)$$

$$Na_2O_2 = Na_2O + O \quad (4)$$

$$NaNO_2 + O = NaNO_3 \quad (5)$$

$$Na_2O_2 + O = NaO + O_2. \quad (6)$$

As the equilibrium constant of the I reaction process (Eq. 2) increases with an increase in the temperature, the R_{O_2}/R_{NO} value of the II precess will be close to 0.25, which is the formation ratio of O_2 to NO in Eq. 7:

$$NaNO_2 = 1/2Na_2O + NO + 1/4O_2 \quad (7)$$

Precess III (predominant in the final stage); the reaction process to form sodium oxide. Eq. 1 was applied to the solid-state reaction by taking account of the nucleation at various places in a crystal and the gradual piling up of these nuclei with the progress of the reaction. However, in the III process, it is reasonable to conclude that the reaction proceeds by means of a mechanism by which oxide precipitates are formed from the melt and the precipitate becomes the nuclei of the subsequent reaction. This process was remarkable at higher temperatures.

Effects of Several Oxides on the Decomposition. From the viewpoint of the Lux-Flood acid-base theory, sodium nitrate is considered to act as a base in the reaction with acidic oxides. Therefore, the effects of oxides with different acidities on the thermal decomposition of sodium nitrate was investigated at a constant heating rate. The results obtained are shown in Figs. 9 and 10.

The DTA curves in Fig. 9 show the relatively large endothermic peaks for the reactions at about 700 °C, 640 °C, and 690 °C in the systems containing silica (b), titania (c), and zirconia (d) respectively. In the (b) system, the endothermic peak at 575 °C indicates the transformation of α- to β-quartz.

To understand the effects of oxides in detail, the $2Z_i/r$ values were calculated as one of the scale of the acidity of oxides: here, Z_i is the charge of the metal ion, M^{Z_i+}, and r is the interatomic distance. The values of r were calculated from the data of Pauling.[11] The $2Z_i/r$ values express the relative bond strength between M^{Z_i+} and O^{2-}, the larger value indicating the stronger acidity. These values for several oxides are shown in Table 1. In Fig. 10, the behavior of the gas formation in the reaction of binary systems

containing silica (b), titania (c), zirconia (d), alumina (e), and magnesia (f), arranged in the order of acidity, is shown. The thermal decomposition of pure sodium nitrate (a) is also presented for the sake of comparison. Strong acidic oxides, such as silica and titania, remarkably accelerate the thermal decomposition of sodium nitrate ((b) and (c)). In the reaction of sodium nitrate and such basic oxides as magnesia (f), the formation of O_2 in the temperature range from 500 °C to 600 °C is characteristic. When the basic oxides are characterised by the formation rate of O_2 at 600 °C, this decreases in the order of: (f), (e), (d), and (c)≈(b). This trend agrees well with the order of acidities in Table 1. From the values in Table 1, the behavior of gas formation in the (c) system would be expected to show an appearance intermediate between (b) and (c), but Fig. 10 shows that the reaction in (c) is more accelerated than in (b). The reason for this is that the titania used in this experiment was very fine (the volume avarage particle size: 4 μm).

Reaction of Sodium Nitrate and Silica. Silica is an important material in the glass industry. Therefore, the reaction in the binary system of sodium nitrate (0.1 or 0.2 mmol) and silica was investigated at various constant temperatures from 570 °C to 700 °C and over a relatively wide range of silica composition. The results of the analysis of the reaction products (X_{Si}=0.5 to 5.0) were similar to those in the previous report.[7] Figure 11 shows the behavior of gas formation at 650 °C. When the X_{Si} value is 1.0, the range in which the R_{O_2} and R_{NO} values are both constant exists at the reaction times from 12 to 38 minutes. Even if the X_{Si} value is 0.5, the reaction is accelerated by silica, and when X_{Si} is 3.0 and 5.0, the reaction is more accelerated than the reaction with X_{Si}=1.0. In all cases, a range of nearly constant R_{NO} values was observed. Figure 12 shows the DTG curves of these systems. They also indicate the increase of the rate of weight loss with the increase in the X_{Si} value. The characteristic acceleration of the reaction was found at the final stage of the reaction. The peak based on this acceleration shifted to the shorter-reaction-time side with the increase in X_{Si} value, until it could not be detected at all at X_{Si}=5.0. When the $(d\alpha/dt)_{\alpha=0.25}$ values, which is the rate of weight loss at α=0.25, were plotted versus X_{Si} as a scale of the effect of silica, Fig. 13 was obtained. The larger X_{Si} value gives the larger $(d\alpha/dt)_{\alpha=0.25}$ value. Nearly constant $(d\alpha/dt)_{\alpha=0.25}$ values were obtained at $X_{Si}\geqq 5.0$ and $X_{Si}\leqq 1.0$. These results indicate that, at $X_{Si}\leqq 1.0$, the acceleration of the decomposition reaction of sodium nitrate by the addition of silica is scarcely observed in the first stage of the reaction ($\alpha\leqq 0.25$), but it becomes evident with the increase in the X_{Si} value, while at $X_{Si}\geqq 5.0$ the degree of acceleration is almost constant.

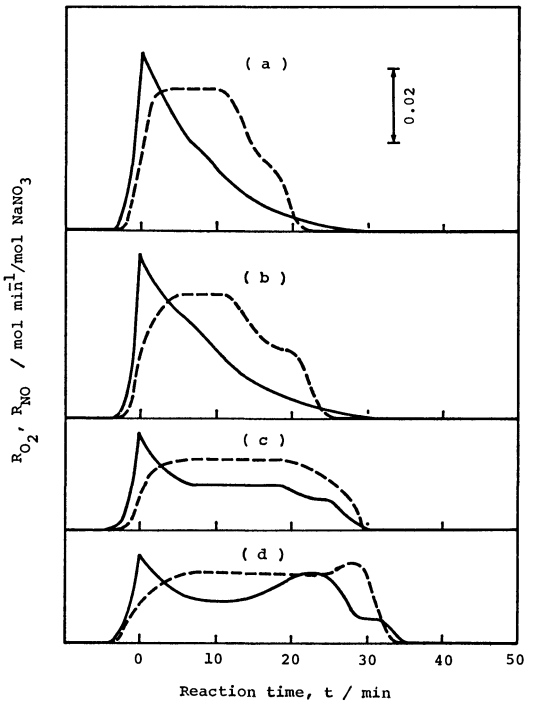

Fig. 11. Effect of silica on the behavior of gas formation at 650 °C.
(a): X_{Si}=5.0, (b): X_{Si}=3.0, (c): X_{Si}=1.0, (d): X_{Si}=0.5. The solid line and interrupted line indicate R_{O_2} and R_{NO}, respectively.

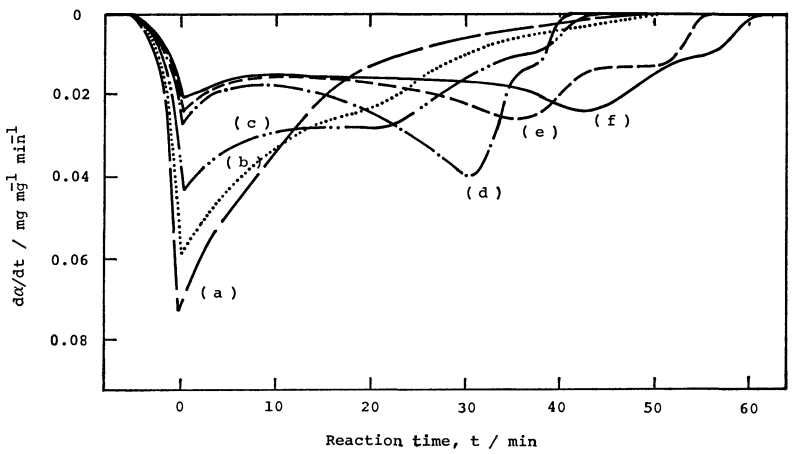

Fig. 12. Effect of silica on DTG curves at 650 °C. (a): X_{Si}=5.0, (b): X_{Si}=4.0, (c): X_{Si}=3.0, (d): X_{Si}=2.0, (e): X_{Si}=1.0, (f): X_{Si}=0.5.

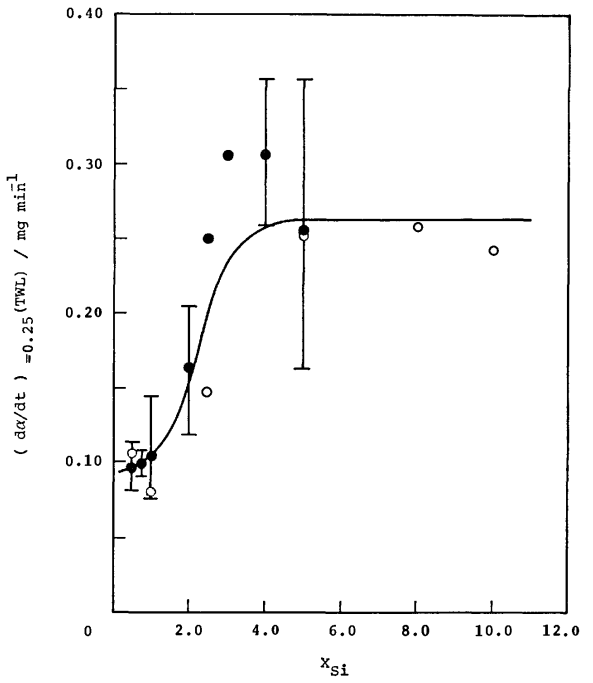

Fig. 13. $(d\alpha/dt)_{\alpha=0.25}$ (TWL) values for various X_{Si} values at 650 °C. (TWL) means the total amount of weight loss.
Open circle: 0.1 mmol $NaNO_3$, closed circle: 0.2 mmol $NaNO_3$.

By analysing TG curves by means of Hancock and Sharp's method, the n value was obtained as close to 3 at $\alpha \geqq 0.25$. This indicates that the reaction of sodium nitrate and silica is expressed by Avrami-Erofe'ef equation with $n=3$ and that the diffusion of Na^+ into silica ($n=0.54$ to 0.62) or the phase-boundary reaction ($n=1.07$, 1.11) is not a rate-determining step. Thus the mechanism of the reaction of this system is considered to be one in which the main basic species, sodium peroxide, reacts with a strong acidic oxide, silica, and forms the precipitate of silicate, and that they then grow in the melt. The apparent activation energy, ΔE, and the frequency factor, k_0, are shown in Table 2 for various X_{Si} values. The increase in k_0 supports the above-mentioned mechanism. ΔE is lower at $X_{Si}=1.0$ and 3.0 compared to that of the thermal decomposition of pure sodium nitrate. The reason for this is probably that silica, which is a strong acidic oxide, reacts with the basic species, such as sodium peroxide, and so lowers the activation energy of the reaction. Sodium metasilicate and disodium disilicate were identified as the reaction products. It is easily supporrted that these reaction products also affect the decomposition of sodium nitrate. At $X_{Si}=4.0$ and 5.0, a large amount of silicates would be formed and precipitated in the melt and at the boundary in the early stage on the reaction. These silicates are considered to cover a part of the surface of silica and to interfere with the effective contact of melt and silica. The increase in activation energy at $X=4.0$ and 5.0 might thus be caused. If so, about the same value of $(d\alpha/dt)_{\alpha=0.25}$ at $X_{Si} \geqq 5.0$ is considered to result from the competitive effects of covering and acceleration.

Table 2. Apparent activation energy, ΔE, and frequency factor, k_0, for the reaction of sodium nitrate and silica

X_{Si}		ΔE/kJ mol^{-1}		$\ln(k_0/\text{min}^{-1})$	
		a	b	a	b
0	$n=1$	—	223	—	25.5
	$n=3$	243	—	26.7	—
1.0		179	179	20.5	20.5
3.0		204	179	22.9	19.9
4.0		226	198	25.2	22.3
5.0		229	177	25.8	19.8

a: $\alpha \geqq 0.85$.
b: $0.25 \leqq \alpha \leqq 0.85$.

Sodium nitrate in this system may be supposed to decompose through the reactions expressed in Eqs. 2 to 6, but silica would react with sodium peroxide to form sodium metasilicate *via* disodium disilicate.

Structural Interpretation of Plasma-polymerized Tetrafluoroethylene

Keiichiro Hozumi,* Keisuke Kitamura, and Tatsuya Kitade

(Received September 4, 1980)

Structural interpretation of plasma-polymerized tetrafluoroethylene produced in a glow discharge chamber is given by referring to ^{19}F-NMR and IR spectroscopy, elemental analysis, and number-average molecular weight determination. The polymer is hardly soluble in the usual organic solvents because of its highly branched structure, making NMR spectroscopy and molecular weight determination impossible. However, the polymer is soluble in 1,2-dibromo-1,1,2,2-tetrafluoroethane and the following structural interpretation could be obtained. The number-average molecular weight is 3600 for the majority of the polymer, consisting of 96 carbon and 129 fluorine atoms within a unit molecule. The IR spectrum shows evidence of some C=C groups and the ^{19}F-NMR spectrum a highly branched and cross-linked structure in which a large number of quaternary carbons are involved in the polymer matrix as compared with CF_2 and CF carbons. The plasma-polymerized tetrafluoroethylene has been characterized in a somewhat different way from the plasma-polymerized ethylene, involving a small number of quaternary carbons.

Polymer thin films deposited on solid substrates by means of plasma polymerization in which monomer gases are exposed to glow discharge have a highly branched and cross-linked structure, uniform film thickness, and are pinhole free. By selective use of the monomer gases we can alter the physico-chemical properties of the polymer films, such as surface free energy, optical transmittance, and electric specificities.[1-3]

Plasma-polymerized fluorocarbons have an extraordinarily low surface free energy and a good optical transparency throughout the visible and infrared regions. Deposition of the plasma-polymer was successfully applied to the hydrophobic coating of ion-crystal windows installed in various infrared instruments and the anti-reflection coating of certain organic lenses.[4-6] We recently reported the use of tetrafluoroethylene (TFE) as a monomer gas by which solid materials of fine and complicated structure such as ashed residue of biological specimens were effectively coated by the hydrophobic plasma-polymer eliminating the initial hygroscopic nature and preserving the three-dimensional microstructures.[7] The results suggest further application of the plasma-polymer to the hydrophobic coating of porous surfaces or granular materials.

We have undertaken to obtain structural interpretation of plasma-polymerized tetrafluoroethylene (PPTFE) mainly by means of ^{19}F-NMR spectroscopy, also by infrared and ESR spectroscopy, elemental analysis, and number-average molecular weight determination. This paper reports a hypothetical model of the atom configration within the polymer molecule having average molecular weight.

Experimental

Monomer Gas. TFE was stored in a pressure tank and supplied to the plasma chamber through a flow meter and a needle valve. The purity was confirmed by a gas chromatograph incorporated with a Porapack column giving no signal of impurity.

Plasma System. A schematic diagram of the apparatus for the plasma polymerization, which is the same as reported[7] is shown in Fig. 1. A valve introducing air was incorporated with the system for occasional cleaning of the polymer film deposited on the inside wall of the plasma chamber by plasma oxidation. The gas pressure in the system was monitored by a MacLeod gauge attached to a three-way manifold located between the plasma chamber and a rotary pump. The plasma in the chamber was initiated and sustained by controlling high-frequency electric power supplied from a 100 W generator operating at 13.56 MHz. Typical operating conditions for the film deposition were 2—3 ml(1 atm)/min for the TFE flow, 20 W for the effective input power, and 0.2—0.4 Torr (13.322 Pa) for the gas pressure. Fig. 1. Schematic diagram of plasma-polymerization apparatus.

Results and Discussion

Solubility of PPTFE in Organic Solvents. TFE monomer gas was polymerized for 60 min in an empty chamber. Solid film was always deposited on the inside wall of the chamber under the plasma conditions employed without forming other types of polymer such as oil or powder. The solid film deposited in the chamber was scraped off and extracted with acetone. However, a large portion of the polymer, obviously of higher degree polymer, remained insoluble. Various other polar or nonpolar organic solvents were examined for removal of the insoluble substance. No usual organic solvent was found to be more effective than acetone.

1,2-Dibromo-1,1,2,2-tetrafluoroethane(DF114B$_2$) was found to be an effective solvent, supposedly because

of the chemical analogy within the two. TFE could be prepared simply by reacting sodium hydroxide with $DF114B_2$.

$DF114B_2$ still left a small fraction of insoluble substance which suggested an extremely high degree of cross-linking. The fraction was rejected from further application to NMR or molecular weight determination.

The acetone and $DF114B_2$ extracts were vacuum-evaporated at room temperature. The dried extracts together with the insoluble residue were weighed in order to determine the weight percent compositions of the initial polymer substance; acetone extract=15%, $DF114B_2$ extract=81%. Only 4% was left as insoluble residue. The acetone extract was dark brown, the $DF114B_2$ extract and the insoluble residue being amber colored.

The acetone and $DF114B_2$ dissolved the respective fractions of the polymer in high concentrations until forming viscous fluid, no quantitative solubility could be obtained. The solubility was therefore determined by use of organic solvents having much less solubility to the individual fractions. The powder sample was put in a centrifuge tube with an organic solvent. The mixture was stirred at room temperature and the resulting suspension was centrifuged (3500 rpm) for 5 min. 5 ml of the supernatant layer was transferred to a weighed beaker which was then vacuum-evaporated at room temperature. The beaker was weighed and the solubility calculated. The solubility data are given in Table 1.

The acetone extract was practically insoluble in nonpolar solvents, but somewhat soluble in polar solvents. On the other hand, the $DF114B_2$ extract was insoluble in all the solvents examined. The difference in behavior between the two extracts is probably due to the shape of the molecules, *i.e.*, the acetone extract consisting of smaller molecules is more or less polarized due to the branched structure of the plasma-polymer, while the $DF114B_2$ extract of larger molecules exhibits no orientation of the branching effects which were dispersed in all directions resulting in a perfectly nonpolar characteristic. It is understandable that the acetone extract is somewhat soluble in the polar solvents.

Thermal Property and Average Molecular Weight. Each of the three fractions of the polymer was powdered and the individual melting point was measured on a hot stage. Melting took place in a wide range of temperature, half-liquified point being taken as the melting point. The results are given in Table 2.

Table 1. Solubility data of two solvent extracts of PPTFE in different organic solvents

Solvent	Acetone extract (%)	$DF114B_2$ extract (%)
Petroleum ether	0.01	0.00
Carbon tetrachloride	0.01	0.00
Hexane	0.01	0.00
Toluene	0.01	0.00
Benzene	0.00	0.00
Chloroform	0.02	0.00
Diethyl ether	1.29	0.00
Ethanol	2.71	0.01
Methanol	1.23	0.00

Table 2. Physical and chemical properties of three fractions derived from PPTFE

Item of determination	Fractions: Acetone extract	$DF114B_2$ extract	Insoluble residue
Melting point/°C	80—105	141—150	190—225
Average molecular weight	900	3600	—
Elemental composition F (%)	56.4	67.8	64.0
Elemental composition C (%)	—	32.0	—

The insoluble residue showed the highest melting point but lower than that of the conventional Teflon resin by *ca.* 100 °C. This is understandable if we assume that the PPTFE we obtained has a lower molecular weight than that of the conventional Teflon and/or the intermolecular force was reduced by the three-dimensional molecular structure resulting from the high branching of carbon chain developed during the course of plasma polymerization.

Vapor pressure osmometry was carried out for the acetone and $DF114B_2$ solutions of respective extracts. The number-average molecular weight was calculated for the individual polymer extracts employing benzyl as a standard (Table 2). The molecular weight of the $DF114B_2$ extract was 3600, the majority of PPTFE thus not being polymerized as highly as expected.[8—10] The insoluble residue was polymerized and cross-linked to a greater extent.

Elemental Analysis. Elemental analysis was carried out with a carbon-hydrogen-nitrogen analyzer and fluorine determination with an oxygen flask. Mean values are given in Table 2. Fluorine content of PPTFE was significantly lower than that of Teflon, supporting the highly branched structure.

The result of elemental analysis made it possible to determine the number of carbon and fluorine atoms in a unit molecule when a hypothetical molecule having the average molecular weight was assumed. For acetone extract we have C:F=30:30, and for $DF114B_2$ extract C:F=96:129. It is of interest that the F/C ratios of the two extracts were both much smaller than the H/C ratio of plasma-polymerized ethylene evaluated by Tibbit *et al.*[10] Higher concentrations of quaternary or tertiary carbons should be assumed for the former molecules.

IR Spectrum. A pressed KBr tablet was placed in the plasma chamber and coated with PPTFE in 10000 Å thickness. Each of the two extracts and the insoluble residue were powdered and mixed with KBr to form a tablet. The IR spectrum of the PPTFE film (Fig. 2) shows a strong resemblance to that of the other three fractions, indicating that the structural characteristics of the three fractions of the polymer are essentially the same.

The wide absorption band at 950—1500 cm^{-1} was

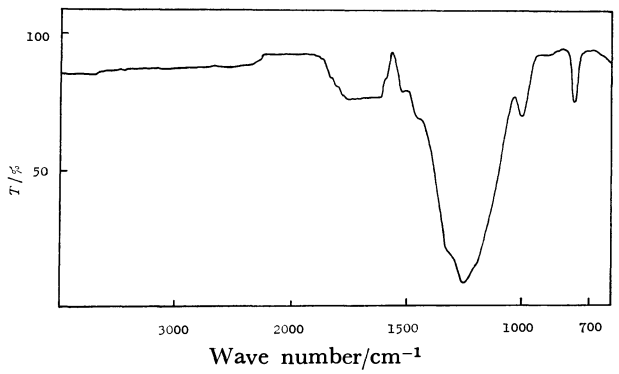

Fig. 2. IR spectrum of PPTFE.

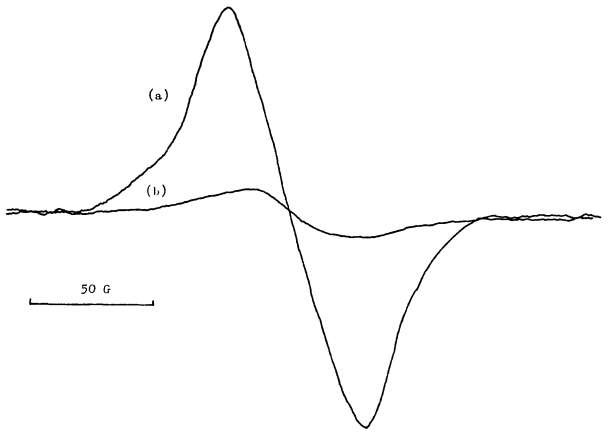

Fig. 3. Relative signal intensities of ESR spectra of freshly prepared PPTFE and its DF114B$_2$ extract.

assigned to C–F stretching vibration modified by various modes of neighboring atom groups. A weak absorption band at 1540—1800 cm^{-1} was tentatively assigned to C–C stretching vibration shifting considerably to higher wave number induced by the fluorinated carbon chain. Similarly the C=O absorption band appearing usually at *ca.* 1715 cm^{-1} is expected to shift towards much higher wave number for the same reason. The IR spectrum gave no signal of detectable C=O group. This is in line with the result of elemental analysis (Table 2). An intense and single band observed at 740 cm^{-1} is attributed to $-CF_2-$ bending vibration associated to adjacent $-CF_3$ terminal.

ESR Spectrum. Freshly prepared PPTFE was subjected to ESR spectroscopy. High concentration of unpaired spins, a characteristic of plasma-polymers, was observed as anticipated. The ESR spectrum of PPTFE was sealed in a standard 3.0 mm I.D. quartz tube filled with argon (Fig. 3(a)). The ESR signal showed a single and almost symmetrical wave form with a magnitude of 175 G having a *g*-value of 2.0038. The signal intensity decayed very slowly, reaching its half-intensity after 48 days at room temperature. A relative intensity of the ESR spectrum of the DF114B$_2$ extract is shown in Fig. 3-(b). A rough evaluation shows that the freshly prepared PPTFE contains *ca.* 20 folds higher concentration of free radicals than the DF114B$_2$ extract. This can be explained in terms of intense intermolecular collisions sustained during the course of extraction by the solvent DF114B$_2$ and

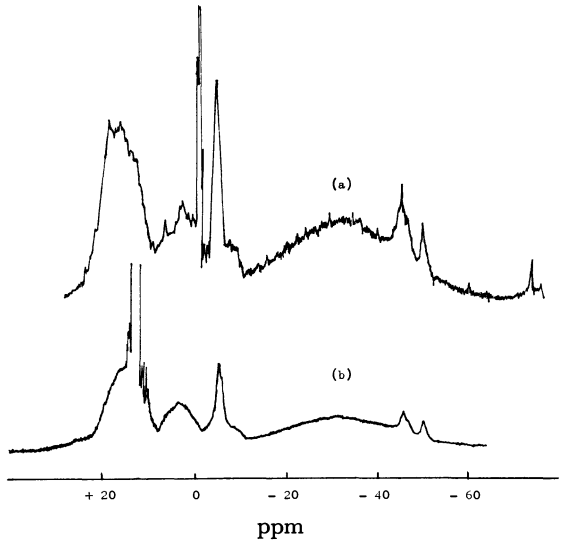

Fig. 4. ^{19}F-NMR spectra of PPTFE.

the resulting rapid termination of free radicals in the polymer. No quantitative determination was possible because of the lack of standard material. One free radical would be involved in a few plasma-polymer molecules.[11] In such a large molecule the radical site could be ignored for determining the chemical structure of the polymer molecule.

^{19}F-NMR Spectrum. ^{19}F-NMR spectra of the acetone extracts were measured with use of trifluoroacetic acid as an internal reference (Fig. 4(a)) and those of DF114B$_2$ extracts with the DF114B$_2$ itself (Fig. 4(b)).

The reference peaks are indicated at 0 and 16 ppm in the spectra (a) and (b), respectively. Eliminating these reference signals, the two spectra exhibit similar characteristics. It seems that the chemical structure of the two extracts are basically the same except for the difference in molecule size.

The individual signals were assigned from the lower magnetic field to the higher as follows:[6]

δ	30— 10 ppm	$\underline{CF_3}$-C
δ	10— 10 ppm	$\underline{CF_3}$-CF
δ	0——10 ppm	$\underline{CF_3}$-CF_2
δ	−10——60 ppm	CF_2 and CF_3
δ	−44 ppm	-$\underline{CF_2}$-CF_3
δ	−49 ppm	-$\underline{CF_2}$-CF_2-

Signal intensities of the CF_3 group derived from the DF114B$_2$ extract, the majority of PPTFE, were measured in order to calculate the relative abundance of different modes of adjacent carbon groups. From the result the following composition is obtained.

$$\underline{CF_3}\text{-C} : \underline{CF_3}\text{-CF} : \underline{CF_3}\text{-}CF_2 = 79 : 16 : 20$$

We see that the $\underline{CF_3}$–C group occupies a large majority of the overall CF_3 group within the polymer, in contrast to plasma-polymerized ethylene where the $\underline{CH_3}$–CH group is the major constituent, hardly any of the $\underline{CH_3}$–C group being found in the ^{13}C-NMR spectrum.[10] Thus it seems that the molecular structure of PPTFE consists of irregular sequences of very

highly branched aliphatic chains.

Hypothetical Model of Molecular Structure. If we assume that a polymer molecule has the average molecular weight derived from the DF114B$_2$ extract, an interpretation of its chemical structure can be given in reference to spectral data and the elemental analysis. Atom constitution of a unit molecule was calculated to be 96 carbon and 129 fluorine atoms, the existence of some C=C groups being presumed by IR spectrometry.

^{19}F-NMR spectroscopy clarified the constitution of fluorocarbon groups in the molecule. The signal intensities of the following underlined groups gave the ratio:

$$\underline{CF_3}\text{-C} : \underline{CF_3}\text{-CF} : \underline{CF_3}\text{-}\underline{CF_2} : \underline{CF_2} + \underline{CF} = 79 : 16 : 20 : 69$$

This indicates that equal numbers of CF_2 and CF groups are involved in one molecule. The signal intensity of CF_2+CF could be allocated to CF_2 and CF groups with 2/3 and 1/3 portions, respectively. If we denote the number of CF_3, CF_2, and CF groups within a unit molecule by x, y, and z, respectively, the relative abundance of these groups can be obtained.

$$x : y : z = \frac{79+16+20}{3} : \frac{69\times 2/3}{2} : \frac{69\times 1/3}{1}$$

$$= 38 : 23 : 23$$

Since the number of fluorine atoms in a unit molecule is 129, we have

$$3x + 2y + z = 129.$$

Solving the two equations, we get

$$x = 26.8, \quad y = 16.2, \quad z = 16.2.$$

The number of quaternary carbon is calculated by subtracting the number of carbons belonging to CF_3, CF_2, and CF groups from 96 the total number of carbon.

$$96 - (27+16+16) = 37$$

Rearranging the data, we get

$$CF_3 = 27, \quad CF_2 = 16, \quad CF = 16, \quad C = 37.$$

Signal intensities of CF_3 groups adjacent to different carbon groups were allocated in proportion to the numbers of adjacent carbon groups.

$$\underline{CF_3}\text{-}CF_2 = 4.5 \quad \underline{CF_3}\text{-CF} = 4.5 \quad \underline{CF_3}\text{-C} = 19$$

The composition of the atom groups within a unit molecule is as follws:

$$\underline{CF_3}\text{-}CF_2 = 4\text{—}5, \quad \underline{CF_3}\text{-CF} = 4\text{—}5, \quad \underline{CF_3}\text{-C} = 19,$$
$$CF_2 = 16, \quad CF = 16, \quad C = 37.$$

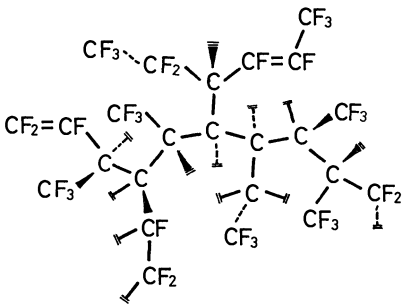

Fig. 5. Atom configuration of PPTFE depicted as 1/4 portion of unit molecule having average molecular weight.

A hypothetical model of a quarter of a unit molecule is shown in Fig. 5.

The structure is not yet established, since the abundance of the C–C group was roughly estimated by IR spectroscopy.

The authors wish to thank Dr. Y. Sugiura for carrying out ESR spectroscopy with PPTFE at the Department of Pharmaceutical Sciences, Kyoto University. They are indebted to Daikin Kogyo Co. Ltd. for the supply of TFE as a monomer gas and DF114B$_2$ as an effective solvent of PPTFE.

The Determination of Alkaline Phosphatase Activity in Serum by Means of Flow-through Analysis with an Ion-selective Electrode

Tadashi HARA,* Masakatsu IMAKI,** and Motohiro TORIYAMA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

***Horiba, Ltd., Kissyoin, Minami-ku, Kyoto 601*

(Received September 11, 1980)

In order to determine continuously the alkaline phosphatase activity in a serum sample, a potentiometric method using a newly prepared phosphate ion-selective electrode has been established by the authors for the first time. The alkaline phosphatase activity was determined by measuring the concentration of the phosphate ion which was liberated by the enzymatic hydrolysis of disodium phenyl phosphate in the presence of alkaline phosphatase. The measurement of the phosphate ion with an ion-selective electrode was seriously interfered with by protein and the halide ion, but the interference could be removed by covering the electrode surface with a cellulose acetate membrane and by separating the chloride ion from a serum sample by gel chromatography. The present method was applied to the determination of alkaline phosphatase activity in serum; the results obtained showed a satisfactory correlation with those obtained by the conventional method. The method was found to be useful for practical diagnosis based on the activity of alkaline phosphatase.

The present study was carried out with the object of establishing a simple, rapid, and economical method by which alkaline phosphatase activity(APA) in a transparent as well as an opaque sample solution could be determined continuously with a phosphate ion-selective electrode(PISE) by the use of an arbitrary substrate.

As can be seen from the following examples, the determination of APA is very important in various fields, such as biochemistry, analytical chemistry, clinical examination, and diagnosis: 1) APA in serum is significant for the diagnoses of cancer of the liver and malignant bone tumor, since there seems to be a close relationship between APA and the beforementioned diseases, and 2) the exact determination of APA is indispensable for the enzyme immunoassay, in which alkaline phosphatase is used as a labeling enzyme.

In the conventional determination of APA, the methods proposed by Bodansky,[1] Kind-King,[2] and Bessey-Lowry[3] have been used. All these methods are based on the absorptiometric determination of phosphoric acid,[1] phenol,[2] and *p*-nitrophenol,[3] which are formed by the enzymatic hydrolysis of the corresponding substrates in the presence of alkaline phosphatase. Nowadays, complicated autoanalyzers designed on the basis of these measurement principles are commercially available. These methods have, however, the following defects: 1) the measurement becomes complicated, since coloring and deproteinizing agents are added; 2) the fluctuation of the blank value is large, since the substrate is unstable; 3) the apparatus is complicated and expensive; 4) the method is not applicable to opaque samples, and 5) the concentration range suitable for the measurement is narrow, less than twenty times.

Though ion-selective electrodes have been used in several papers[4–11] for a simple and rapid estimation of enzyme activity, no reports have been published pertaining to the potentiometric determination of APA with a PISE. From this standpoint, the authors have newly made a PISE and applied it to the continuous determination of APA in serum with a simple and inexpensive apparatus; favorable results were obtained.

Experimental

Reagents. The buffers and the base solution were prepared from analytical-grade reagents without further purification. A substrate solution was prepared as a 1.0×10^{-2} mol/dm^3 disodium phenyl phosphate in a buffer solution (pH 10.15) consisting of disodium carbonate (3.18 g/dm^3) and sodium hydrogencarbonate (1.68 g/dm^3). The alkaline phosphatase was obtained from Sigma, and its standard solution was prepared by diluting 1.1 U/mg of alkaline phosphatase (Type 1) with distilled water. Sephadex G-25 was used as a packing agent in gel chromatography. Serum samples were offered by the Kyoto Prefectural University of Medicine; their APA values were certified to be around the normal values.

Apparatus. A PISE[12] in which trisilver phosphate was used as the active substance of a soild membrane was built up newly by the authors in order to estimate the amount of phosphate ions. A solid membrane composed of trisilver phosphate and disilver sulfide in the weight ratio of 4:1 was found to be the best with regard to the mechanical strength, the electromotive force of the electrode, the plasticity of the membrane, and the life of the electrode. The electrode responded to the phosphate-ion concentration in the range of 1.0×10^{-5}—1.0×10^{-1} mol/dm^3. The electrode has a serviceable life of at least six months. The determination of the phosphate ions was found to be seriously affected by chloride, thiocyanate, and sulfite. The other instrumental units used were as follows: 1) an Atto Perista mini-pump, type SJ 1211; 2) a thermostat manufactured by Netsudenshi Kogyo; 3) a Horiba 2535—05 T reference electrode, and 4) a model VP6521A recorder (Matsushita Communication Industrial Co., Ltd.).

Procedure. The determination of APA was done with the apparatus shown in Fig. 1. A 0.5-cm^3 serum sample is added with a pipette to the top(l) of a 290×8 mm i.d. column(a), which is then charged with Sephadex G-25 and cooled at 0 °C in a thermostat. By passing the substrate solution through the column at the rate of 0.5 cm^3/min, chloride and alkaline phosphatase are separated and eluted out of the column in the order shown in Fig. 3. The portion containing alkaline phosphatase is sent to a Teflon-made reaction tube by way of a four-way cock(c) at the rate of 0.5 cm^3/min by means of the pump(b_1). Since

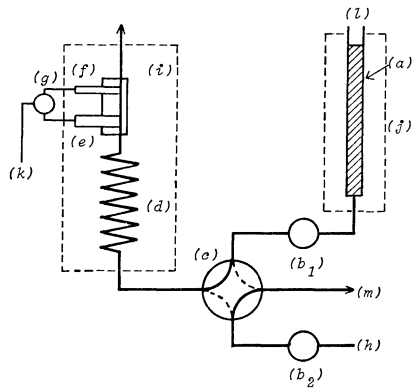

Fig. 1. Schematic flow diagram.
a: Gel column, b_1: pump, b_2: pump, *c*: four-way cock, *d*: reaction tube(Teflon), *e*: indicator electrode, *f*: reference electrode, *g*: voltmeter, *h*: inlet, *i*: thermostat (37.0 °C), *j*: thermostat (0 °C), *k*: recorder, *l*: sample, and *m*: exit.

the reaction tube, 10 m long and 1 mm i.d., is being held at 37.0±0.2 °C in a thermostat(*i*), the enzymatic hydrolysis of phenyl phosphate in the presence of alkaline phosphatase proceeds to form phosphate ions. The concentration of phosphate ions is measured with a voltmeter(*g*) as an electromotive force of a cell consisting of a PISE(*e*) and a reference electrode(*f*), and its value is recorded with a recorder (*k*). By turning a four-way cock(*c*) at a definite time after the addition of a serum sample, the portion containing chloride is removed by way of the exit(*m*), while the substrate solution is sent to the reaction tube by means of the pump(b_2) by way of the inlet(*h*) at the rate of 0.5 cm³/min. The APA in serum is estimated from the calibration curve on the basis of the peak height on a recorder chart.

Results and Discussion

Interference of Serum Proteins. Ion-selective electrodes for chloride and silver ions in which disilver sulfide is used as a constituent in an active solid membrane have been reported[13,14] to be interfered with by about 6% proteins consisting of albumin, globulin, and so on in serum. Since the present PISE is made of trisilver phosphate and disilver sulfide, it was expected to be interfered with by serum proteins. As can be seen from Fig. 2, the present PISE was interfered with by albumin in bovine serum (Fig. 2(d)). Therefore, the PISE is not applicable to the determination of APA in serum without removing the interference of protein.

It has been already reported[15] that the interference of protein can be removed by covering a electrode with a semi-permeable membrane. Several membranes were tested, but the best result was obtained when a cellulose acetate membrane (0.0203 mm thick, 2.4 nm pore size) was used; the interference of albumin was thus almost completely removed (Fig. 2(b)). In all the following experiments, the PISE covered with a cellulose acetate membrane was used.

Removal of Chloride. As can be foreseen from the solubility product of silver chloride and silver thiocyanate, the PISE is seriously interfered[12] with by chloride and thiocyanate ions. Since the concentration of chloride in serum is about 0.1 mol/dm³,

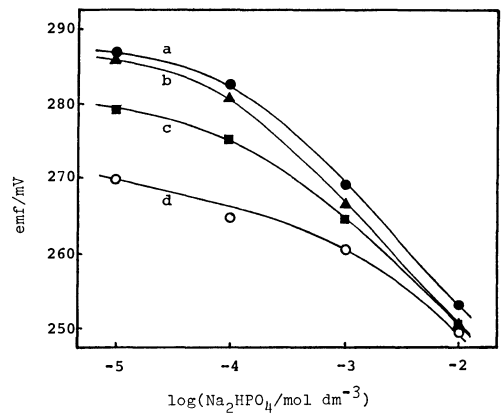

Fig. 2. Response of the PISE in sample solutions containing albumin.
a: Albumin free, b: covered with cellulose acetate, c: covered with nitrocellulose, and d: not covered with a membrane.

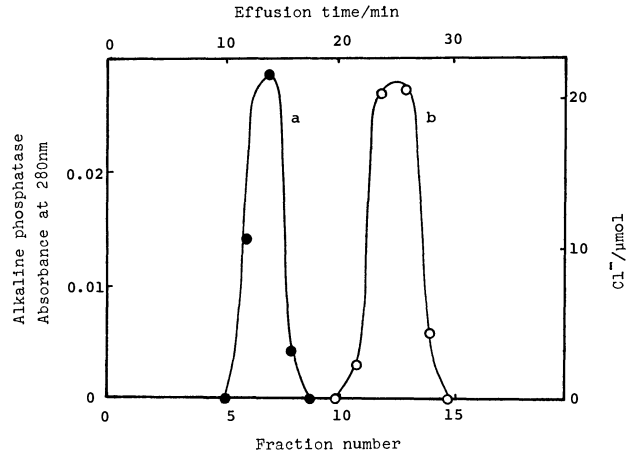

Fig. 3. Gel separation of alkaline phosphatase from a chloride ion on a Sephadex G-25 column.
a: Alkaline phosphatase, b: chloride ion.

the removal of chloride is indispensable for the determination of APA in serum.

The separation of alkaline phosphatase from chloride was examined by means of gel chromatography. A 0.5-cm³ sample solution containing sodium chloride (0.1 mol/dm³) and alkaline phosphatase (1 mg/cm³) was treated in order to separate its components by passing a buffer solution through the column at the rate of 0.5 cm³/min; the results are shown in Fig. 3. Here the flow rate of the buffer solution was chosen to be maximal so long as the gel particle was not crushed. The amounts of alkaline phosphatase and chloride in each 1-cm³ fraction were determined by the absorption at 280 nm and by the precipitation titration based on Mohr's procedure respectively. On the basis of Fig. 3, the following procedure is recommended for the separation of alkaline phosphatase from chloride: the eluent obtained from the column (Fig. 1(*a*)) in 0—16 min is introduced into the reaction tube(*d*), and the eluent obtained after 16 min is drawn out of the exit(*m*) by turning a four-way cock(*c*). By this procedure, the portion of chloride-free alkaline

phosphatase is sent to a measuring chamber equipped with a PISE.

Calibration Curve. The hydrolysis of disodium phenyl phosphate in the presence of alkaline phosphatase proceeds in accordance with Eq. 1:

$$C_6H_5OPO_3Na_2 + H_2O \xrightarrow{\text{phosphatase}} C_6H_5OH + Na_2HPO_4. \quad (1)$$

It is possible to estimate the APA by measuring the formation rate of phosphate ions, since the APA is generally represented by the reaction rate of Eq. 1. If the reaction of Eq. 1 proceeds as zero-order with respect to the concentration of disodium phenyl phosphate, the reaction rate of Eq. 1 is given by the concentration of phosphate ions at a definite time. To examine whether or not the reaction of Eq. 1 proceeds as a zero-order one, a PISE was dipped in a 1.0×10^{-2} mol/dm^3 disodium phenyl phosphate solution which contained 5.5—110 U/dm^3 alkaline phosphatase and was held at 37.0 °C in a thermostat; the relationship between the reaction time and the concentration of phosphate ions was thus obtained (Fig. 4). It may be concluded from Fig. 4 that the reaction of Eq. 1 proceeds as zero-order with respect to the concentration of disodium phenyl phosphate, since there is a linear relationship between the reaction time and the concentration of phosphate ions for the APA values of more than 20 U/dm^3. The present results, obtained at 10^{-2} mol/dm^3 disodium phenyl phosphate, seem to be quite reasonable considering that the Km value in the reaction of Eq. 1 is around 10^{-3} mol/dm^3.[16]

A calibration curve (Fig. 5) was obtained as a peak height against each standard solution of alkaline phosphatase. The curvature corresponding to 2.2—22 U/dm^3 alkaline phosphatase in the calibration curve is attributed to: 1) the deviation of an electrode potential from the Nernst equation at 10^{-4}—10^{-5} mol/dm^3 phosphate ion (Fig. 2(a)); 2) the deviation of the enzyme reaction rate from a zero-order one for the APA values less than 20 U/dm^3, 3) the broadening of a phosphate ion peak by the diffusion and/or mixing in a flowing solution, etc. For the practical determination of the APA, the part of the straight line in the calibration curve can be used satisfactorily, since the APA in serum is usually more than 20 U/dm^3.

Effect of Serum Matrix. To examine whether or not the present method can be applied to the determination of the APA in serum, different APAs were added to 0.5 cm^3 control serum and their APAs were estimated by the present method; the result thus obtained are shown in Fig. 6. Figure 6 shows that, there was a good relationship between the activities of the added alkaline phosphatase and the potentiometrically measured ones. The value at the intersection of the straight line on the abscissa in Fig. 6 corresponded exactly to the APA in the control serum. It became clear from the results that the present method could be satisfactorily applied to the determination of the APA in serum.

Serum Samples. The relationship between the APA values in serum samples measured by the present method and those measured by means of a Hitachi autoanalyzer, type 400, based on absorptiometry was examined (Fig. 7). As can be seen from Fig. 7, there was a fairly good correlation between them; the correlation factor was calculated to be 0.88.

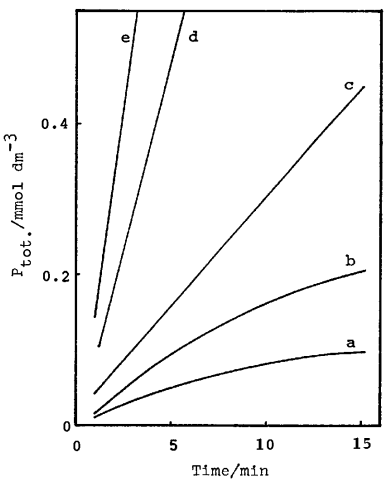

Fig. 4. Relationship between reaction time and $P_{tot.}$. Measured at 37.0 °C in a 1.0×10^{-2} mol/dm^3 disodium phenyl phosphate solution containing alkaline phosphatase.
a: 5.5 U/dm^3, b: 11 U/dm^3, c: 22 U/dm^3, d: 55 U/dm^3, e: 110 U/dm^3. $P_{tot.}=H_3PO_4+H_2PO_4^-+HPO_4^{2-}+PO_4^{3-}$.

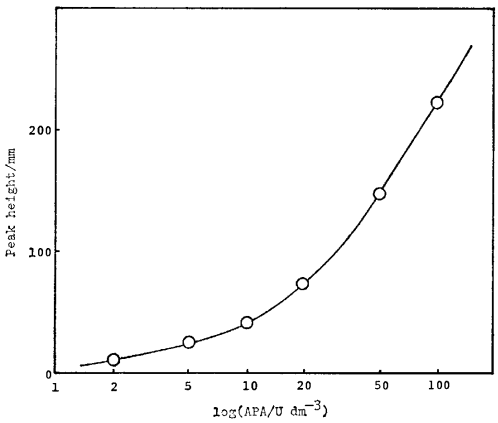

Fig. 5. Calibration curve.

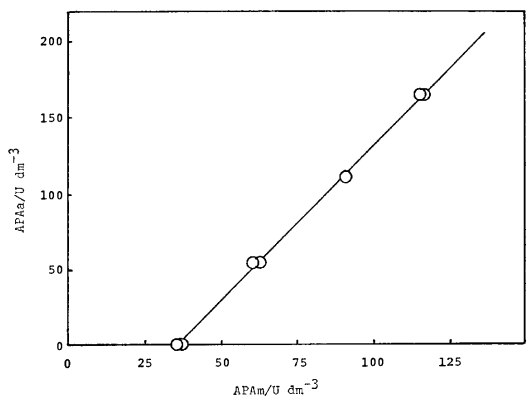

Fig. 6. Relationship between potentiometrically measured APA(APAm) and added APA(APAa).

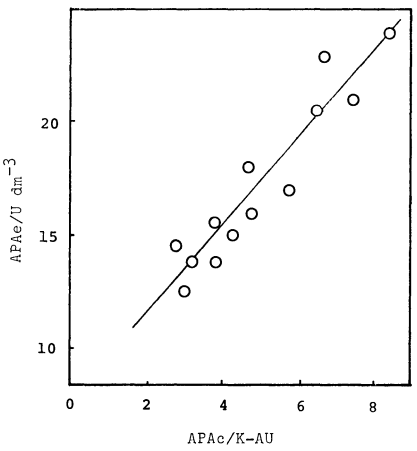

Fig. 7. Correlation between the APAs in serum samples measured by the PISE method(APAe) and by the conventional method(APAc).

Judging from the facts that: 1) the APA in serum sample used in this experiment corresponds to that of alkaline phosphatase in a healthy human, and 2) the APA in a liver patient is much larger than that value, the present method can be said to be sensitive enough for a practical diagnosis based on the APA.

According to the present method, it takes about 30 min for the analysis of one sample. However, many samples can be treated effectively and continuously by arranging a number of columns in parallel with column(*a*), because the time-consuming step in the present method is the separation of alkaline phosphatase from chloride ions. A system by which information concerning APA is obtained from a much smaller serum sample is now being developed.

Determination of Hyperoxide in Dimethyl Sulfoxide by Photometric Titration with Iodine

Katsumi KITAMURA, Koichi HASEGAWA, Katsura MOCHIZUKI,
Taira IMAMURA,* and Masatoshi FUJIMOTO*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received September 26, 1980)

The concentration of hyperoxide, O_2^-, in dimethyl sulfoxide (DMSO) was determined by photometric titration with iodine. The validity of the method was confirmed on the basis of stoichiometry by use of the standardized hyperoxide solution in the reaction of the complex, MoO(tpp)NCS, with methanol, where TPP denotes α,β,γ,δ-tetraphenylporphyrin.

Hyperoxide solutions prepared from potassium hyperoxide solubilized in aprotic solvents by crown ether[1] have been used for the syntheses of many organic compounds[2] and for reactions of metal complexes.[3] However, for determination of hyperoxide in aprotic solvents, only two reliable methods have been reported:[4] (1) determination of the dioxygen evolved first upon mixing a hyperoxide solution with water, then by the addition of catalase to the mixed solution,[6] and (2) measurement of the absorbance at 250 nm of the solution of potassium hyperoxide solubilized by 18-crown-6 ether in DMSO.[7]

In the kinetic study of the reaction of cobalt(III) complex with hyperoxide in aprotic solvents, we proposed a simple method for the determination of hyperoxide in DMSO according to the reaction[8]

$$I_2 + 2\,O_2^- \longrightarrow 2\,I^- + 2\,O_2. \qquad (1)$$

The reaction proceeds quantitatively[7] because of a large difference in the redox potential of iodine ($E^\circ = 0.54$ V)[9] and that of hyperoxide ion ($E^\circ = -0.5$—-0.6 V).[10] The validity of the proposed method was confirmed by applying the hyperoxide solution to the reaction between the complex, MoO(tpp)NCS, and CH_3OH in CH_2Cl_2.

Experimental

Materials. Potassium hyperoxide (KO_2, ICN Pharmaceuticals) and 18-crown-6 (Nippon Soda) were used without further purification. Potassium content in the hyperoxide specimen was determined to be 95.7% by the Kalibor-Zephiramine method.[11] The solution of hyperoxide was prepared in an argon atmosphere from potassium hyperoxide solubilized by 18-crown-6 in DMSO. About 10 h is required for the preparation of *ca.* 10^{-2} mol dm^{-3} solution.

Reagent grade iodine was purified by repeated sublimation. In order to avoid any loss of iodine in the preparation of the standard solution, the following procedure was adopted. A small amount of DMSO was taken in a well-stoppered volumetric flask, and weighed. A desired amount of iodine was carefully taken in the volumetric flask and completely dissolved. The amount of dissolved iodine was determined from the difference in weight. Then the solvent was added to a mark on the flask and mixed to prepare a standard solution. Since the absorbance at 365 nm, λ_{max} of the solution, gradually increases (*ca.* 10% for 2.0×10^{-3} mol dm^{-3} I_2 in 3 d), and decreases in the presence of 18-crown-6 (*ca.* 5% in 40 h), the standard DMSO solution of iodine should always be prepared immediately before use.

Dimethyl sulfoxide was kept with CaH_2 for several days, distilled under reduced pressure, and stored in an argon atmosphere. The water content in the purified DMSO was determined to be less than 0.03% by the Karl-Fischer method.

Dichloromethane was distilled and passed through an alumina column. The pre-purified solvent was distilled immediately before use. The complexes, MoO(tpp)NCS and MoO(tpp)Br, were synthesized.[12]

Results and Discussion

Photometric Titration with Iodine. The concentration of O_2^- in DMSO was determined as follows. A 3.00-cm^3 hyperoxide solution (2×10^{-5}—9×10^{-3} mol dm^{-3}) is taken into an optical cell in an argon atmosphere. The optical cell is sealed at once with a serum cap. A small amount of iodine solution (5×10^{-4}—1×10^{-1} mol dm^{-3}) is then injected into the optical cell with a 100 mm^3 microsyringe or a micropipet. The absorbance at 400 nm, λ_{sh} of the iodine solution, is measured and plotted against the volume of the iodine solution injected. A typical change in absorbance at 400 nm is shown in Fig. 1. The absorbance gradually decreases until the end point depicted by A in Fig. 1 is reached. After the point A, the absorbance is measured 15 min after each addition of the solution of iodine in order to complete the reaction. The concentration of hyperoxide, x, is calculated by $x=2VC/3$, where V is the volume of the iodine solution consumed and C the concentration of iodine. The 10-fold change in the concentration ratio of 18-crown-6 and weighed amount of KO_2 does not affect the

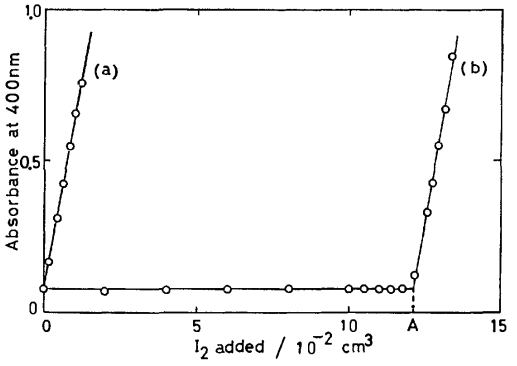

Fig. 1. Typical change in absorbance of hyperoxide solution at 400 nm by addition of an iodine solution. $[I_2]_0=3.98\times10^{-2}$ mol dm^{-3}. (a): $[O_2^-]_0=0$ and [18-crown-6]$_0=6.0\times10^{-3}$ mol dm^{-3}. (b): $[O_2^-]_0=3.12\times10^{-3}$ and [18-crown-6]$_0=6.0\times10^{-3}$ mol dm^{-3}.

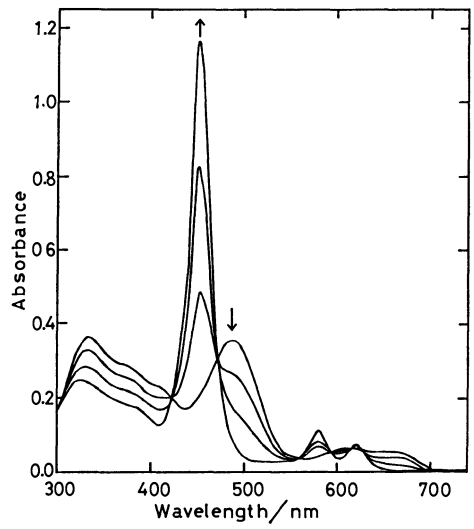

Fig. 2. Change in spectra for the reaction among MoO(tpp)NCS, CH_3OH, and O_2^- in CH_2Cl_2 containing 2%(v/v) CH_3OH, 1%(v/v) DMSO, and $[MoO(tpp)NCS]_0 = 7.54 \times 10^{-6}$ mol dm^{-3} at 25 °C.

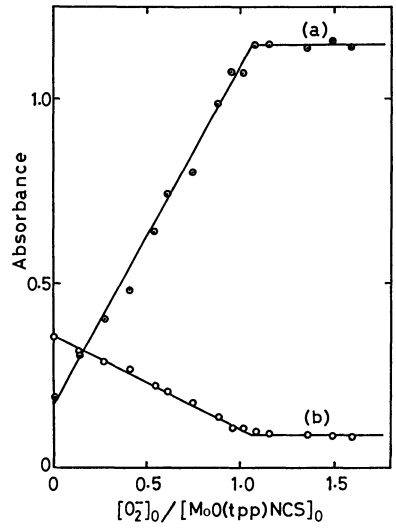

Fig. 3. Molar-ratio method for the reaction among MoO(tpp)NCS, CH_3OH, and O_2^- at 25 °C. (a): At 452 nm. (b): At 488 nm.

determination of O_2^-. Reproducibility of the data was estimated to be within ±1%.

Reaction among MoO(tpp)NCS, CH_3OH, and O_2^-. The solution of hyperoxide was applied to the reaction between the complex, MoO(tpp)NCS, and CH_3OH in order to confirm the validity of the proposed method. When the solution of hyperoxide is added to a dichloromethane solution of the complex, MoO(tpp)NCS, containing 2%(v/v) methanol, the spectrum changes with isosbestic points at 423 and 472 nm (Fig. 2).[13] The final spectrum agrees with the spectrum of the complex, $MoO(tpp)OCH_3$, synthesized from the complex, MoO(tpp)Br. The reaction should be written as follows.

$$Mo^{V}O(tpp)NCS + CH_3OH + O_2^- \longrightarrow Mo^{V}O(tpp)OCH_3 + HO_2 + NCS^- \quad (2)$$

The stoichiometry of the reaction was determined to

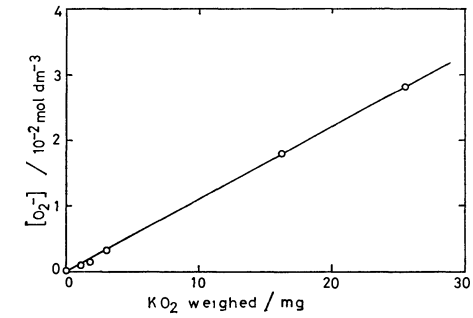

Fig. 4. Concentrations of O_2^- in DMSO *vs.* weighed amounts of KO_2. Two-fold excess of 18-crown-6 is contained over KO_2.

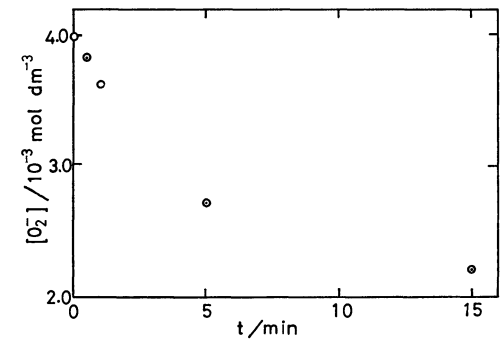

Fig. 5. Decomposition of hyperoxide solution in a flask placed in the ultrasonic cleaner (Bransonic, B-220, 45 kHz, 100 W).

be $MoO(tpp)NCS:O_2^- = 1:1.05$ by the molar-ratio method (Fig. 3). The absorbance at 452 nm, λ_{max} of the spectrum of the complex, $MoO(tpp)OCH_3$, increased in proportion to the concentration of O_2^- with an excess of the complex, MoO(tpp)NCS, and CH_3OH. This confirms the high accuracy of the determination of O_2^- in DMSO by means of the photometric titration with iodine.

Stability of O_2^- in DMSO. The concentration of hyperoxide in a stock solution was *ca.* 70% of that calculated from the weighed amount of KO_2, showing the decomposition of *ca.* 30% of O_2^- during the course of preparation of the solution (Fig. 4). The concentration gradually decreased *ca.* 2% a day.

When 1 volume of a 3.51×10^{-3} mol dm^{-3} hyperoxide solution was accurately diluted to 10 volumes with DMSO, a 3.19×10^{-4} mol dm^{-3} solution was obtained, which indicates partial decomposition of O_2^- by the addition of DMSO. Thus a hyperoxide solution should be standardized immediately before use.

A decrease in the concentration of O_2^- in DMSO was also observed when the solution was treated in an ultrasonic cleaner (Fig. 5).

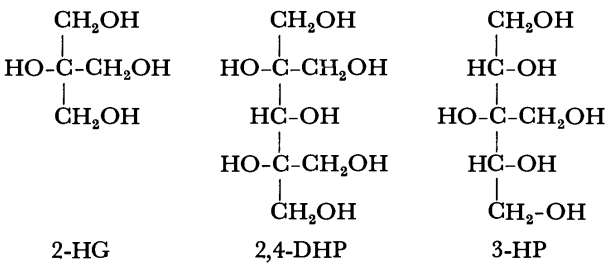
Formose Reactions. XIV. A Selective Formose Reaction in the Presence of a Slight Amount of Calcium Ions

Yoshihiro SHIGEMASA,* Tsuyoshi TAJI, Eiichi WAKI, and Ruka NAKASHIMA
Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Tottori 680
(Received July 4, 1980)

It was found that a formose reaction in the presence of small amounts of calcium and D-fructose gave rise to three products, 2-(hydroxymethyl)glycerol, 3-(hydroxymethyl)pentitol, and 2,4-bis(hydroxymethyl)pentitol, with a high selectivity. Various factors affecting the selectivity were also discussed: [Ca], pH, [D-fructose], the reaction temperature, co-catalysts, and metal hydroxides. The amount of formaldehyde relative to [Ca] is the most important factor in obtaining the selective formation of the three-branched sugar alcohols. Under these reaction conditions, the α,β-enediol structure is required in an effective co-catalyst for the formose reaction. 2-(Hydroxymethyl)glycerol, 3-(hydroxymethyl)pentitol, and 2,4-bis(hydroxymethyl)pentitol were formed with a high selectivity in the formose reactions catalyzed by KOH, $Mg(OH)_2$, $Fe(OH)_3$, and LiOH.

In the preceding papers,[1-3] which dealt with various factors affecting formose reactions catalyzed by $Ca(OH)_2$ in a batch reactor, the continuous measurement of the oxidation-reduction potential (ORP) of the reaction mixture has proven usefull for distinct discrimination among the induction, the sugar-forming, and the sugar-decomposing periods by means of an ORP minimum and maximum appearing at the end of the induction period and at the end of the sugar-forming period respectively. The T_{min} and T_{max} symbols correspond to the times of the end of the induction and the sugar-forming periods respectively.

In the course of our recent kinetic studies of $Ca(OH)_2$-catalyzed formose reactions, we found that three kinds of branched sugar alcohols, 2-(hydroxymethyl)glycerol (2-HG), 2,4-bis(hydroxymethyl)pentitol (2,4-DHP), and most probably a diastereomeric mixture of 3-(hydroxymethyl)pentitol (3-HP), are obtained with a high selectivity when most of the dissolved calcium ions are removed as hardly soluble salts or stable chelates at the end of the induction period (T_{min}).[4,5]



When the formose reaction was carried out in the presence of small amounts of calcium ions and D-fructose by adjusting the pH of the reaction mixture to 12.0 with potassium hydroxide, it was found to give rise to the same products. Under these reaction conditions, furthermore, the reaction mixture is homogeneous, so the analysis of the reaction is easier than in the heterogeneous system.

The purpose of this paper is to explore the reaction conditions which give a similar selective formation of the above three kinds of branched sugar alcohols. Particular attention is placed on the following factors: the calcium-ion concentration; the formaldehyde concentration; the kind of promoters, such as D-fructose and D-glucose; the D-fructose concentration; the pH of the reaction mixture; the reaction temperature, and the kind of metal hydroxide.

Experimental

The apparatus and the experimental procedure were virtually the same as those described previously.[1,2] The formaldehyde solutions were prepared from paraformaldehyde by refluxing for 4 h, followed by the filtration of the insoluble substances. The reaction was started by adding given amounts of $CaCl_2$ and D-fructose, immediately after which the pH of the reaction mixture was adjusted with concd KOH. The pH of the reaction mixture was maintained by adding concentrated aqueous KOH during the reaction.

The total saccharides were determined using the phenol-sulfuric acid method[6] and were calculated as glucose from a previously prepared calibration curve. The sugar yield was calculated according to the following equation: Sugar yield (%) = [sugars as glucose]/([HCHO]$_0$ + [D-fructose]) × 100. The formaldehyde was determined by the method of Bricker *et al.*;[7] only the optical density was measured at 579 nm, while the ORP was measured by the method described in a previous paper.[1]

The products were trimethylsilylated by Sweeley's method,[8] and the trimethylsilyl (TMS) derivatives were analyzed by gas chromatography, as has been described previously.[9] The products were numbered according to their retention time as GP-13, GP-18, *etc.* The yield of the products (GLC%) were given by measuring the peak areas.

The calcium salts and other reagents were of an analytical grade.

Results and Discussion

Effect of the Calcium-ion Concentration. In the previous papers,[4,5] it was suggested that the concentration of the dissolved calcium ions ([Ca]) at the formose-forming step was a very important factor in the selective product formation. It was found that the formose reaction in the presence of small amounts of calcium and D-fructose gave rise to similar selectivities (Table 1).

Table 1 shows the effects of [Ca] on formose reactions carried out at various pHs (9.5—12.0) of the reaction mixture. At any pH, the T_{max} value at which the consumption of formaldehyde reaches over 90% decreases, and the sugar yield increases with an increase in the amount of calcium. At [Ca] = 0.025 M, a similar relationship between T_{max} and the sugar yield with an increase in the pH of the reac-

a) [HCHO]=1.0 M; [D-fructose]=0.01 M; the pH was adjusted by concd KOH; temp=60 °C; total volume=200 ml. b) Total yield of 2-HG, 3-HP, and 2,4-DHP. c) GLC was below 1%. d) The number in parentheses is the HCHO consumption(%) at the time (min) shown by the subscript. e) 2-HG: 2-(hydroxymethyl)glycerol, 3-HP: 3-(hydroxymethyl)pentitol, 2,4-DHP: 2,4-bis(hydroxymethyl)pentitol; 18 and 25: products which were shown by the peak numbers of 18 and 25 respectively in a gas chromatogram of the TMS derivatives.

tion mixture is observed (Runs 1, 6, 12, and 18): the sugar yield increases as T_{max} decreases. These phenomena are in fairly good agreement with the results reported previously.[2,3] In this case, it could easily be considered that the sugar yield is affected by the amount of formaldehyde consumed by the Cannizzaro reaction. The sugar yield, however, is influenced by the product composition: the sugar yield decreases with an increase in the total yields of 2-HG, 3-HP, and 2,4-DHP, which are sugar alcohols. A sugar alcohol usually has little reducing power. Therefore, the sugar yield which is determined using the phenol-sulfuric acid method and calculated as glucose is useful only when the product composition is similar.

Here, the total yield (T_{3p}) of 2-HG, 3-HP, and 2,4-DHP is used as an indicator of the selectivity of the formose reaction. As is shown in Table 1, T_{3p} increases with a decrease in the pH of the reaction mixture and [Ca]. Although the yields of 2-HG and 3-HP are not affected by the pH of the reaction mixture, the yield of 2,4-DHP increases greatly with a decrease in the pH. The yield of 3-HP is not so much affected by [Ca]. The yields of 2,4-DHP and 2-HG increase with a decrease in [Ca], while the yield of GP-25, which is one of products shown by the peak number of 25 in a gas chromatogram of the TMS derivatives,[4,5] increases with an increase in [Ca]. These results led us to conclude that the formation of 2,4-DHP and GP-25 is competitive or that GP-25 is an intermediate of 2,4-DHP.

Figure 1 shows the effects of [Ca] on the sugar yield, T_{max}, and T_{3p} at given formaldehyde concentrations. The relationship between T_{max} and the sugar yield is quite similar to that shown in Table 1. Furthermore, the sugar yield increases with a decrease in the formaldehyde concentration at the same ratio of [Ca]/[HCHO]. This phenomenon is in fairly good agreement with the result reported previously.[2]

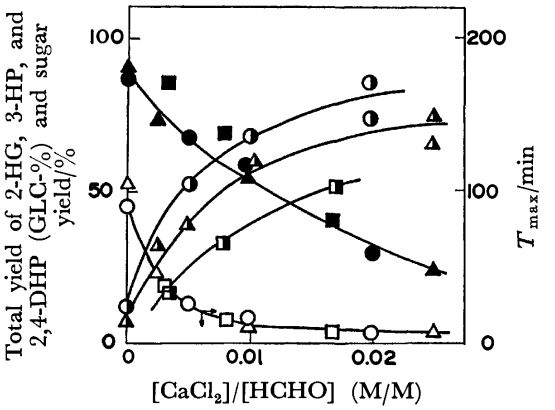

Fig. 1. Effects of $CaCl_2$ concentration on the selectivity, T_{max}, and sugar yield.
[D-Fructose]=0.01 M; pH=12.0 (adjusted by concd KOH); temp=60 °C; total volume=200 ml. T_{3p}, [HCHO](M): ●, 0.5; ▲, 1.0; ■, 3.0. T_{max}, [HCHO] (M): ○, 0.5; △, 1.0; □, 3.0. Sugar yield, [HCHO] (M): ◑, 0.5; ◭, 1.0; ◨, 3.0.

In Fig. 1, it is clear that the selectivity (T_{3p}) increases with a decrease in [Ca], and that at any formaldehyde concentrations the same [Ca]/[HCHO] ratios give similar total yields of 2-HG, 3-HP, and 2,4-DHP (T_{3p}). On the other hand, when the formaldehyde

concentration is varied at a given [Ca], the relationship between the ratio of [Ca]/[HCHO] and T_{3p} is also similar (Fig. 2) to that described above. These results suggest that these branched sugar alcohols of 2-HG, 3-HP, and 2,4-DHP are end products under these reaction conditions and that the ratio of the formaldehyde concentration to [Ca] is the most important factor in selective formation of these products. In this case, however, there is another important factor is the selective formation of the three branched sugar alcohols, namely, the role of D-fructose as a co-catalyst,

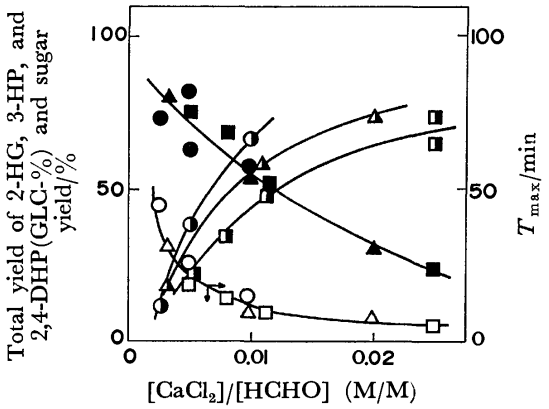

Fig. 2. Effects of HCHO concentration on T_{3p}, T_{max}, and sugar yield.
[D-Fructose]=0.01 M; pH=12.0 (adjusted by concd KOH); temp=60 °C; total volume=200 ml. T_{3p}, [$CaCl_2$] (M): ●, 0.005; ▲, 0.01; ■, 0.025. T_{max}, [$CaCl_2$] (M): ○, 0.005; △, 0.01; □, 0.025. Sugar yield, [$CaCl_2$] (M): ◑, 0.005; ◭, 0.01; ◨, 0.025.

for it diminishes the induction period and offers reaction conditions similar to those at T_{min}, which is the time of the beginning of the formose-forming step in the formose reaction catalyzed by calcium hydroxide.[4,5]

Therefore, large amounts of 2-HG, 3-HP, and 2,4-DHP can be easily obtained at one time by starting the reaction under the usual conditions ([$Ca(OH)_2$]= 0.1 M, [HCHO]=1.0 M, and temp=60 °C), followed by continuously adding a given amount of formaldehyde and adjusting the pH of the reaction mixture after T_{min}, at which the ORP curve shows a minimum. The details of these results will be presented in a subsequent paper.

Effect of the Fructose Concentration. In order to clarify the functions of D-fructose in the formose reaction, the relationship among the D-fructose concentration, [Ca], T_{max}, the sugar yield, and the product distribution was studied. The results are summarized in Table 2.

At the concentration of calcium ions ([Ca]) below 5×10^{-3} M, an increase in the D-fructose concentration led to decrease in T_{max} and to an increase in both the sugar yield and T_{3p}. At 25×10^{-3} M of [Ca], T_{3p} increases with an increase in the D-fructose concentration; however, the T_{max} and the sugar yield are little affected by the D-fructose concentration.

For a constant D-fructose concentration (10×10^{-3} or 50×10^{-3} M), an increase in [Ca] led to a decrease in both T_{max} and T_{3p} and to an increase in the sugar yield. These phenomena are the same as those described previously (Table 1). T_{3p} (2-HG, 3-HP, and 2,4-DHP) decreases, however, GP-25 increases with an increase in [Ca].

Table 2. Effects of fructose concentration[a]

[$CaCl_2$] mM	D-Fructose mM	T_{max} min	Sugar yield %	Products (GLC%)[d] 2-HG	3-HP	25	2,4-DHP	T_{3p}

a) [HCHO]=1.0 M; [$CaCl_2$]=0.005 M; [metal hydroxide]=0.1 M; [D-fructose]=0.01 M; pH=12.0 (adjusted by concd KOH); temp=60 °C; total volume=200 ml. b) pH=11.5, while the other reaction conditions were the same as in a). c) GLC was below 1%. d) See Table 1.

Furthermore, the TMS derivative of D-fructose was a minor one. In another experiment, *ca.* 50% of added D-fructose was found to decompose or change to other compounds in 10 min and *ca.* 70% of D-fructose in 20 min under these reaction conditions: [D-fructose] $=10\times10^{-3}$ M, [$CaCl_2$] $=5\times10^{-3}$ M, pH= 12.0 adjusted by concd potassium hydroxide, and temp=60 °C. These results led us to suggest that D-fructose added as a co-catalyst would react with formaldehyde or would decompose to some products, such as reductone,[10] which may then act effectively as co-catalysts.

Time Course of the Selective Formose Reaction in the Presense of a Small Amount of Calcium Ions. Figure 3 shows a typical time course of the formaldehyde consumption, the sugar yield, and ORP in the formose reaction which gives rise to 2-HG, 3-HP, and 2,4-DHP with a high selectivity when the reaction is catalyzed by potassium hydroxide and a small amount of calcium ions in the presence of D-fructose. Formaldehyde was consumed at a rather uniform rate,

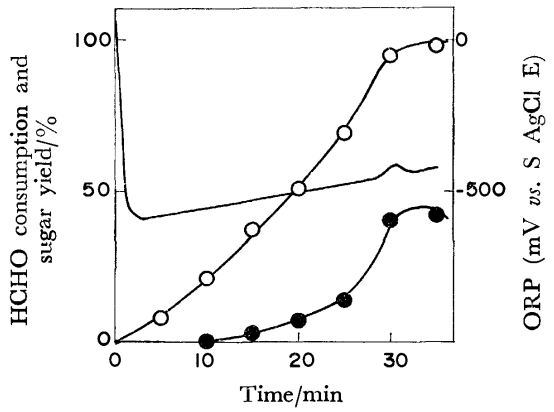

Fig. 3. Time course of HCHO consumption, sugar yield, and ORP.
[HCHO]=1.0 M; [$CaCl_2$]=0.005 M; [D-fructose]= 0.01 M; pH=12.0 (adjusted by concd KOH); temp= 60 °C; total volume=200 ml. ○: HCHO consumption, ●: sugar yield, —: ORP.

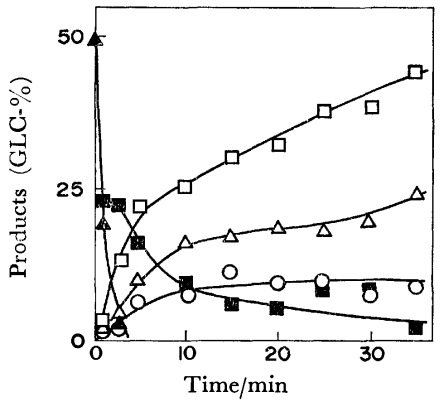

Fig. 4. Time course of selective formose reaction products.
[HCHO]=1.0 M; [$CaCl_2$]=0.005 M; [D-fructose]= 0.01 M; pH=12.0 (adjusted by concd KOH); temp= 60 °C; total volume=200 ml. ○, 2-HG, △, 3-HP, □, 2,4-DHP, ■, 25; ▲, fructose.

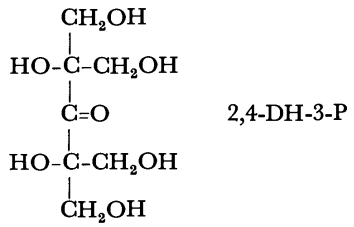
although the usual formose reaction catalyzed by calcium hydroxide consumed formaldehyde auto-catalytically.[1,11] This consumption curve is also different from that given by the formose reaction which is catalyzed by calcium oxide in the presence of various co-catalysts.[12]

In this reaction system, the maximum ORP is found to be useful for the indicator of the end point of the reaction (T_{max}) at which the sugar yield is at its maximum. The same relationship has been observed in the usual formose reaction catalyzed by calcium hydroxide alone.[1,11]

Figure 4 shows the time course of the main products; 2-HG, 3-HP, 2,4-DHP, GP-25, and D-fructose. The added D-fructose disappears rapidly and becomes of minor importance at the end of the reaction, as has been described above. 2,4-DHP, 3-HP, and 2-HG are formed selectively even at the initial stage. Although 2-HG early reaches a constant proportion (*ca.* 10 GLC%), 2,4-DHP and 3-HP increase continuously as the reaction proceeds.

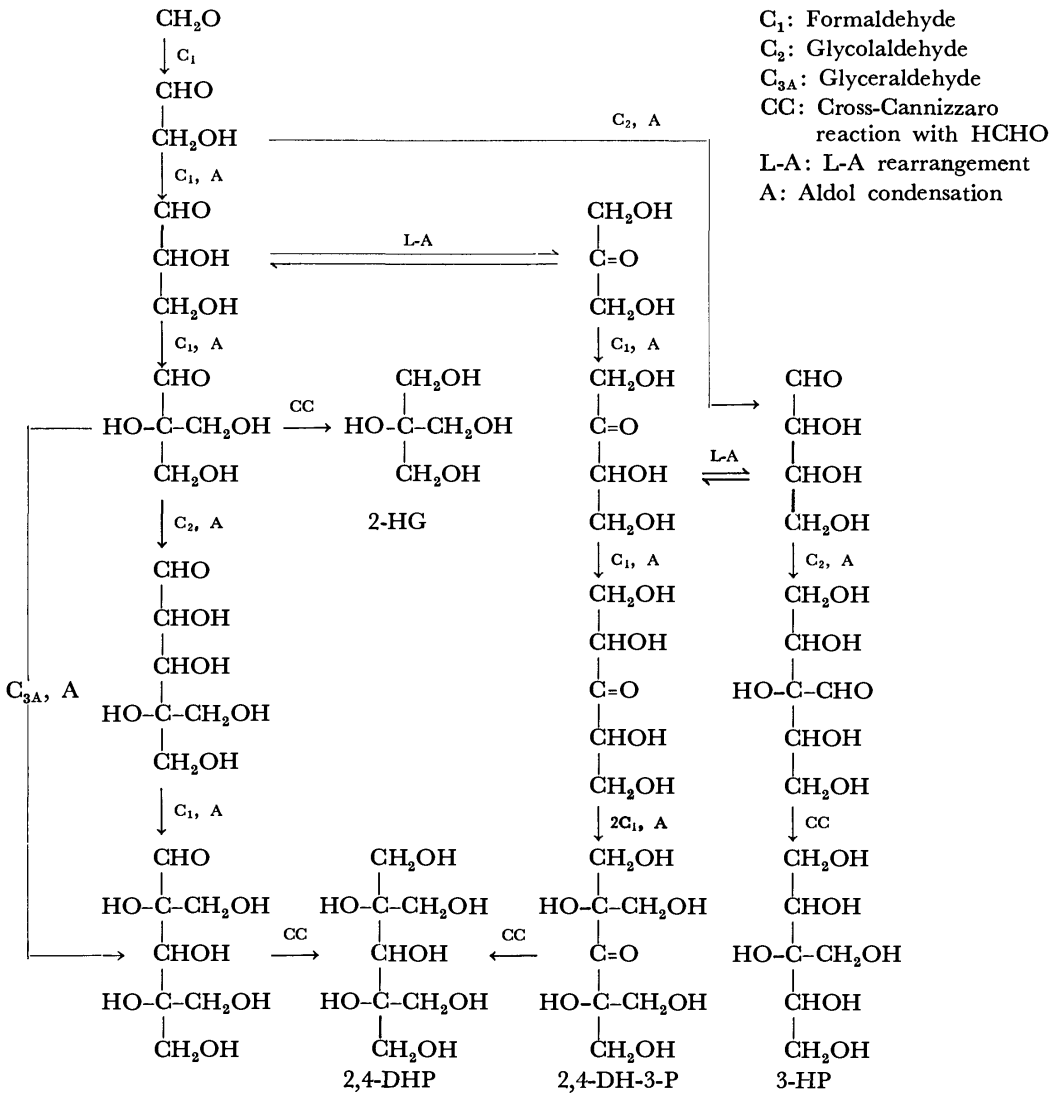
Quite importantly, GP-25 is formed with a high selectivity as one of the initial products; it then disappears with the simultaneous increase in both 2,4-DHP and 3-HP. These results suggest that GP-25 might be an intermediate of 2,4-DHP or 3-HP.

In our previous paper,[13] we have already proposed a scheme of possible pathways for the selective formation of these three branched sugar alcohols (2-HG, 3-HP, and 2,4-DHP), which may be explained by a conventional mechanism[14] involving cumulative aldol condensations, followed by the cross-Cannizzaro reaction of their aldose precursors. In addition, it has been already reported that the reduction of 2,4-bis(hydroxymethyl)-3-pentulose (2,4-DH-3-P) with sodium borohydride[15] or formaldehyde in the presence of a base[16] give 2,4-DHP. A modified scheme of possible pathways for the selective formose formation is proposed in Scheme 1. There has previously been no reasonable explanation for the occurrence of the selective formose reaction.



2,4-DH-3-P

Effect of Reaction Temperature. The formose reaction was carried out at various temperatures; the results are summarized in Table 3. T_{max} decreases with an increase in the reaction temperature, so with the decrease in T_{max} the sugar yield increases, as has been described previously.[2,3] At 80 °C, however, the sugar yield is not so high in spite of the short reaction time, because the resulting sugars easily decompose as a result of the high reaction temperature. Three branched sugar alcohols (T_{3p}) are formed with a high selectivity (*cf.* Table 3), although the increase in the reaction temperature leads to tendency for T_{3p} to decrease.



Scheme 1. Possible pathways for the selective formose formation.

Table 3. Effects of reaction temperature[a)]

Reaction temp °C	T_{max} min	Sugar yield %	Products (GLC%)[b)] 2-HG	3-HP	25	2,4-DHP	T_{3p}
50	334	33.5	16.8	27.4	16.2	31.0	75.2
60	45	42.1	13.1	18.9	5.8	45.5	77.5
70	6.3	49.3	7.7	27.7	1.0	30.4	65.8
80	1.0	45.6	11.7	18.9	1.8	22.3	52.9

a) [HCHO]=1.0 M; [$CaCl_2$]=0.005 M; [D-Fructose]=0.01 M; pH=11.5; total volume=200 ml. b) See Table 1.

On the other hand, Tambawala *et al.*[17)] reported that, at 50% and lower conversion levels, the C_4 and C_5 aldose and ketose products are practically pure straight chains at 40 °C and practically pure branched chains at 60 °C. At higher conversion levels as much as 40% branched chains are present at 40 °C. Furthermore, as has been mentioned above, the three branched sugar alcohols are formed selectively even at the initial stage, at which the formaldehyde consumption is only 10%. It would be supposed that these differences are mainly attributable to the amount of calcium ions. At any rate, there is a remarkable effect of the reaction temperature, that is, the formation of GP-25, which might be an intermediate of 2,4-DHP or 3-HP and which increases with a decrease in the reaction temperature. Efforts are under way to separate and identify GP-25. The formation of GP-25 under various reaction conditions is also under investigation in detail.

Effect of Various Co-catalysts on the Selectivity of Products. Since Kusin[18)] and Langenbeck[12)] reported that the induction period can be eliminated or shortened by the addition to the reaction mixture of small amounts of carbohydrates, the formose reaction in the presence

of carbohydrates or other compounds with an enediol form has been studied: the reaction is accelerated to a small extent, and the induction period is shortened greatly, by the addition of glycolaldehyde and glyceraldehyde; the catalytically active species is not the hydroxide of an alkaline earth metal, but its complex with a carbohydrate.[19-21]

However, there have been few reports which have discussed the effects of a formose-reaction-promoting-co-catalyst on the selectivity of products. Although we have already reported the effects of various co-catalysts on the formose reaction in the presence of a small amount of calcium ions,[22] a few other co-catalysts have been investigated in terms of how they affect the product distribution. The results are summarized in Table 4.

As has been described previously,[22] the formose reaction in the presence of acetoin or benzoin is found to give GP-13 and -14 or 1,2-diphenylglycerol respectively with a high selectivity and to give a low sugar yield as glucose. From these results, one can easily suppose that acetoin and benzoin do not act as co-catalysts, but only as substrates which are easily hydroxymethylated with formaldehyde to give a stable and unreactive compound.

On the other hand, other co-catalysts give rise to similar T_{max} values, sugar yields, and product distributions, although in the case of L-ascorbic acid the T_{max} is relatively long. In addition, phenacyl alcohol was found to form GP-16 (*ca.* 10 GLC%), which could not be detected without phenacyl alcohol. Hence, these co-catalysts would seem to function similarly to each other both as co-catalysts and substrates.

Furthermore, when DL-glyceraldehyde or dihydroxyacetone is used as a co-catalyst, the total yield of 2-HG, 3-HP, and 2,4-DHP (T_{3p}) is very high (*ca.* 80 GLC%). This results led us to assume that DL-glyceraldehyde and dihydroxyacetone would function both as co-catalysts and as substrates which especially act as intermediates of the above three branched sugar alcohols.

On the basis of the above results, we propose that the enediol form of a co-catalyst is very important in promoting the formose reaction: the $R-\overset{HO}{\overset{|}{C}}=\overset{OH}{\overset{|}{C}}-H$ type is effective, but the $R_1-\overset{HO}{\overset{|}{C}}=\overset{OH}{\overset{|}{C}}-R_2$ (R_1, $R_2 \neq H$) type is not effective in promoting the reaction. The same assumption has already been presented by Sakai *et al.*[23] The relatively long T_{max} with L-ascorbic acid is attributable to the time necessary to convert an enediol form of L-ascorbic acid, $R_1-\overset{HO}{\overset{|}{C}}=\overset{OH}{\overset{|}{C}}-R_2$, to the effective type, $R-\overset{HO}{\overset{|}{C}}=\overset{OH}{\overset{|}{C}}-H$.

Effect of Various Metal Hydroxides. In the presence of a slight amount of calcium ions, the formose reactions were carried out by various metal hydroxides in order to examine the effect of the kind of metal cation on the reaction. The results are summarized in Table 5. Judging from the results (T_{max} values, the sugar yields, and the product distributions), the catalytic activity of $Sr(OH)_2$ is very similar to that of $Ca(OH)_2$. The catalytic activity, furthermore, decreases in the following order: $Ca(OH)_2$, $Sr(OH)_2$> $Ba(OH)_2$>$Mg(OH)_2$. These results are the same as those reported by Partridge *et al.*,[24] who supposed that the intermediate complexes must contain a carbohydrate molecule in addition to formaldehyde molecules in the coordination sphere of the catalytically active cation. In Table 5, furthermore, $Mg(OH)_2$, $Fe(OH)_3$, and $Pb_2O(OH)_2$ have a longer T_{max} than that of the control experiment.

In the cases of $Cu(OH)_2$ and LiOH, in spite of their short T_{max} values, the sugar yield is low. Pfeil *et al.*[25] reported that LiOH catalyzes the Cannizzaro reaction rather than the formose reaction. In the presence of $Cu(OH)_2$, metal copper separated out from the reaction mixture, so one can easily suppose that $Cu(OH)_2$ would be reduced by formaldehyde to metal copper and that formaldehyde would be oxidized to formic acid. Hence, the low sugar yield in these formose reactions is attributable to the large consumption of formaldehyde to formic acid.

2-(Hydroxymethyl)glycerol (2-HG), 3-(hydroxy-

a) [HCHO]=1.0 M; [$CaCl_2$]=0.005 M; [metal hydroxide]=0.1 M; [D-fructose]=0.01 M; pH=12.0 (adjusted by concd KOH); temp=60 °C; total volume=200 ml. b) pH=11.5, while the other reaction conditions were the same as in a). c) GLC was below 1%. d) See Table 1.

methyl)pentitol (3-HP), and 2,4-bis(hydroxymethyl)-pentitol (2,4-DHP) are formed with a high selectivity (T_{3p}, 80 GLC%) in the formose reaction catalyzed by KOH, $Mg(OH)_2$, $Fe(OH)_3$, and LiOH in the presence of small amounts of calcium ions and D-fructose. Especially, $Fe(OH)_3$ is found to give 52 GLC% of 2,4-DHP only. $Pb_2O(OH)_2$, furthermore, give rise to an unknown product, GP-18; efforts are under way to isolate and identify this product. These results are in fair agreement with those results[5)] obtained from a modified formose reaction.

Under the same reaction conditions as in Table 5, but without calcium ions, furthermore, the formose reaction was found to give a longer T_{max} value than that in the presence of calcium ions, but the product distributions were quite similar to each other. For example, when no metal hydroxide was added, only adjusting the pH of the reaction mixture to 12.0 with concd KOH aq; the T_{max} was 182 min; at barium hydroxide, the T_{max} was 23 min.

(Received August 1, 1980)

The title compounds were prepared, and their ^{1}H- and ^{13}C-NMR spectra were examined. On the basis of the data for the benzene-solute collision complexes and the magnitudes of the γ shifts, five isomeric conformations of the compounds were discussed.

Recently, a number of conformational analyses of ethylene and trimethylene sulfites have been reported.[1-4] For example, Green and Hellier[1] have used the IR technique of the S=O stretching vibrations to study the conformation of trimethylene sulfites. They concluded that the higher wave number band (*ca.* 1195 cm^{-1}) is attributable to the chair form with an axial S=O function and/or flexible twist forms, while the lower wave number band (*ca.* 1234 cm^{-1}) is to be assigned to the chair form with an equatorial S=O group. Buchanan *et al.*[4] reported ^{13}C-NMR data on trimethylene sulfites and ten alkyl derivatives and concluded that these compounds exist in the chair form with an axial or equatorial S=O function and twist conformations.

In a previous paper,[5] we ourselves reported the reaction of *N*,*N*-bis(2-hydroxyethyl)anilines with thionyl chloride giving the 6-phenyl-5,6,7,8-tetrahydro-4*H*-1,3,2,6-dioxathiazocine 2-oxides, which had a structure similar to that of the trimethylene sulfite skeleton. In order to obtain more stereochemical information about the 1,3,2,6-dioxathiazocine 2-oxide system, it seems desirable to prepare 1,3,2,6-dioxathiazocine 2-oxides with a ortho-, meta-, para-substituent on the *N*-phenyl ring and methyl group on the C-4 and C-8. In this paper we wish to report the conformational analyses of 4,8-dimethyl-6-phenyl-5,6,7,8-tetrahydro-4*H*-1,3,2,6-dioxathiazocine 2-oxides (**1**—**7**) by means of NMR spectroscopy.

Experimental

Measurements. All the melting points are uncorrected. All the NMR spectra were determined at 100- and 60-MHz with JEOL JNM-PS-100 and JNM-PMX-60 spectrometers respectively. The ^{13}C-NMR spectra were obtained using a JNM-PS-100/EC-100 Fourier transform spectrometer operating at 25.15 MHz, with complete proton decoupling. The pulse width and repetition time were 10.2 μs for a 45° pulse and 6 s respectively. The spectra were observed as

a) Liquid.

2 mmol cm^{-3} solutions in $CDCl_3$ with a spectral width of 6250 Hz (data points : 8192). The chemical shifts were referred to the internal TMS as the standard. The IR spectra were recorded on a Shimadzu Model 27-G grating spectrophotometer on a KBr for the solid materials or on a NaCl plate for the liquid materials.

Compounds. The series of **1**—**7** was prepared by the reaction of the corresponding *N,N*-bis(2-hydroxypropyl)-anilines with thionyl chloride, as has been described in our previous paper.[5] The purification of the crude product by the use of a short silica gel column, with hexane or a hexane–benzene (1:1) mixture as an eluent, and subsequent recrystallization afforded two or three pure isomers as colorless crystals; these compounds gave satisfactory results for mass spectra and elemental analyses. The physical properties of the compounds of **1**—**7** are listed in Table 1.

Results and Discussion

S=O Frequencies. The IR spectra of **1**—**7** showed a characteristic band of the S=O function at 1190—1200 cm^{-1} (Table 1). Trimethylene sulfites prefer the chair form with an axial S=O group, and the same conformational preference is found for six-membered-ring sulfoxides.[6,7] In the case of trimethylene sulfites,[8] the S=O stretching band at 1190 cm^{-1} (CCl_4) to 1198 cm^{-1} (C_6H_{12}) indicates a axial S=O conformer, while 1233 (CS_2) to 1234 cm^{-1} (C_6H_{12}) is a equatorial conformer. Twist conformations apparently give intermediate values.

If this consideration can be extended to Compounds **1**—**7**, the position of the S=O stretching band of 1190—1120 cm^{-1} would indicate a predominance of the axial conformer or the twist conformer.

^{1}H-NMR Spectra. The NMR spectra of the heterocyclic protons of **5d**, **5e**, **7a**, **7b**, and **7c** are shown in Fig. 1. The NMR spectra of **7a** and **7b** consist of four distinct sets of multiplets, at *ca.* δ 4.7—4.9(m), 3.7—3.8(q), 3.1(q), and 1.3—1.4(d), for which a straightforward analysis was possible. In contrast, in Compounds **5d**, **5e**, and **7c**, the methylene protons for H-5 and H-7 gave complicated multiplets and were not easily analyzed. Striking differences in Compounds **5e** and **7c** compared with Compounds **5d**, **7a**, and **7b** are recognizable in the signals of the methine protons for H-4 and H-8. That is, two kinds of methine protons of H-4 and H-8 for **5e** and **7c** appeared at *ca.* δ 5.1 and 4.6 ppm. We subdivided the spectra into five types—A, B, C, D, and E, as can be seen in Fig. 1. The spectra of the compounds with an ortho-substituent may all be considered to belong to types A and B. Similarly, those without a substituent or with meta- and para-substituents belong to types C, D, and E. The methine proton for H-4 and/or H-8 of **5d**, **7a**, and **7b** shows one set of multiplets, while compounds of **5e** and **7c** show two sets of multiplets. We have, therefore, suggested that, in the case of Compounds **5d**, **7a**, and **7b**, the possible comformations are in the symmetric form, while, in contrast, Compounds **5e** and **7c** are asymmetric forms.

From the above considerations, the possible conformations of Types A, C, and D are illustrated in Scheme 1. For discussing the eight-membered-ring

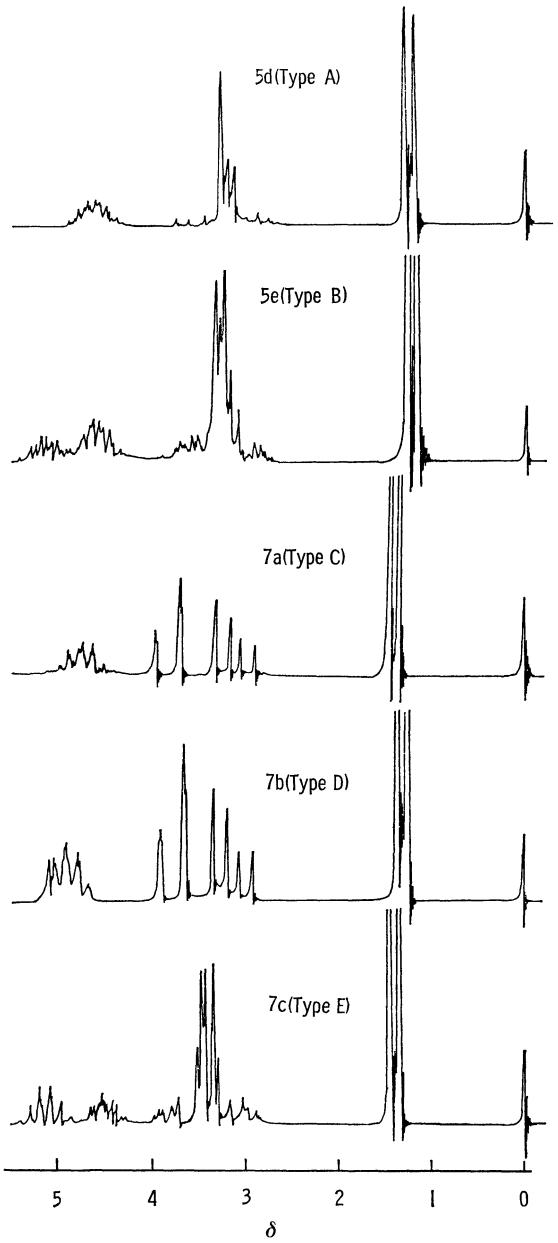

Fig. 1. NMR spectra of the heterocyclic and methyl protons of **5** and **7** in $CDCl_3$.

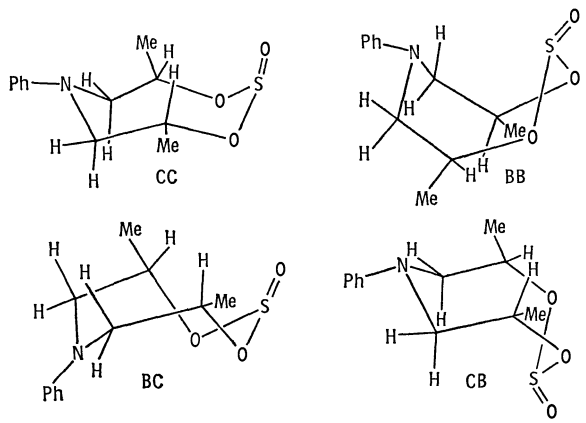

Scheme 1. Possible conformations of types A, C, and D.

stereochemistry, we used the nomenclature established for cyclooctane.[9]

For the geometry of solute-solvent collision complexes, Ledaal[10] proposed a common model with the dipole axis of the solute molecule located along the sixfold-symmetry axis of a benzene nucleus, with the positive end of the dipole nearest, and the negative end farthest away from, it. As for the aromatic solvent effect on the sulfoxides, our recent papers have also described the same type of collision complexes in connection with the stereochemistry of the 3-aryl-1,2,3-oxathiazolidine 2-oxides.[11,12]

Assuming that collision complexes of a similar geometry are formed between the benzene molecule (solvent) and the S=O bond in the compounds for chair-chair (CC), boat-boat (BB), boat-chair (BC), and chair-boat (CB) conformations, the following considerations are presented. For the CC conformation, benzene association should take place from the H-5 and H-7 axial protons of the solute molecule, *i.e.*, from the positively polarized end of the S=O bond. Consequently, the H-4 and H-8 axial protons are strongly deshielded. In the BB conformation, the benzene molecule should be formed from the H-4, H-5, H-7, and H-8 axial protons of the solute molecule; consequently, it is anticipated that all the protons of the heterocyclic ring will experience strong shielding effects in a benzene solution. Similar considerations are possible for the BC and CB conformations. That is, the axial protons of H-4, H-5, H-7, and H-8 are more deshielded than the remaining equatorial protons and methyl protons for the BC conformation. In the CB conformation, all the protons are shielded.

Table 2 shows the benzene-induced shift (Δ=

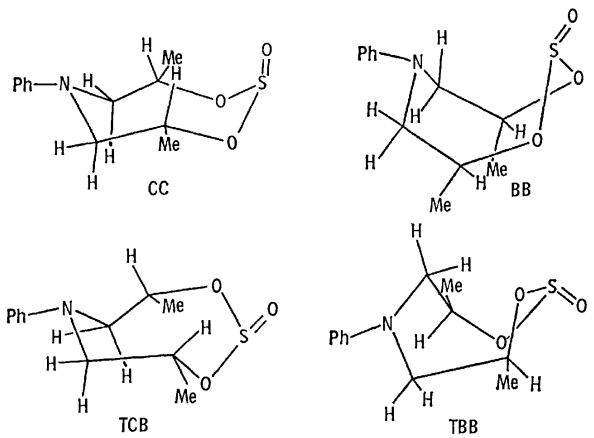
a) Coupling constants, Hz. b) Benzene-induced solvent shifts, $\Delta=(\delta_{CDCl_3}-\delta_{C_6D_6})$.

$\delta_{CDCl_3}-\delta_{C_6D_6}$) with the chemical shift of Compounds **1**—**7** in $CDCl_3$. As can be seen in Table 2, the 4,8-protons of Compound **7b** are deshielded (the mean value is *ca.* +0.13 ppm). Only the CC conformation in Scheme 1 is compatible with these observations; therefore, compounds of Type D are considered to take the CC conformation. The spectra of Compounds **1b**, **3b**, **4b**, **6b**, and **7b** may all be considered to belong to Type D. On the other hand, all the protons of Compounds **5d** and **7a** are strongly deshielded (the mean values are *ca.* +0.4 and +0.5 ppm, respectively). Therefore, the BB or CB conformation is compatible with the above observations discussed for Compounds **5d** and **7a**. The differences between the signal patterns of Types A and C may be due to the different conformations of Compounds **5d** and **7a**. We thought, therefore, that, in Type C, the most reasonable conformation is BB in Scheme 1. In contrast, in the case of Type A, the CB conformation is more suitable than the BB conformation because of the steric hindrance between the S=O group and the ortho-substituent. The spectra of Compounds **1a**, **3a**, **4a**, **6a**, and **7a** may all be considered to belong to Type C, and those of Compounds **2d** and **5d**, to Type A.

On the other hand, some possible conformations of Types B and E are illustrated in Scheme 2; that is, the CC and BB conformations are obtained by the replacement of *syn*-axial hydrogen by a methyl group in the CC and BB conformations in Scheme 1, while TCB and TBB are twist forms of CB and BB. If we consider that the CC or BB conformations in Scheme 2 are for Types B and E, the chemical shifts of the axial and equatorial methyl protons may be said to appear at different positions because of the anisotropy of the S=O bond. Nikander *et al.*,[2] in reporting on chemical shifts for methyl-substituted 1,3,2-dioxathiane 2-oxides in which the methyl group is *syn*-axial to the S=O bond, said that there is only a minor shielding effect relative to its equatorial counterpart. As can be seen in Fig. 1 or Table 2, the two methyl groups attached to C-4 and C-8 of Types B and E are almost equivalent magnetically in $CDCl_3$, while the two methine protons are not. Marked differences between compounds of Types B and E are shown in the benzene-induced shifts of the two methine protons and two methyl protons attached to C-4 and/or C-8. For the compounds of Type B, the methine and methyl protons attached to C-4 or C-8 are shielded, while the remaining methine and methyl protons are only marginally affected. Judging from the examination of the molecular model, the TCB conformation will give rise to severe nonbonded interactions between the ortho-substituent of the phenyl ring and the S=O group. Thus, we concluded that compounds of Type B exist in the TCB conformation. The spectra of Compounds **2e** and **5e** may all be considered to belong to Type B. On the other hand, in the case of compounds of Type E, two methine and methyl protons are shielded. Therefore, it can be considered that compounds of Type E exist in the TBB conformation. The spectra of Compounds **1c**, **3c**, **4c**, **6c**, and **7c** may all be considered to belong to Type E.



Scheme 2. Possible conformations of types B and E.

^{13}C-NMR Spectra. The conformations of Compounds **1**—**7** are further illustrated by means of ^{13}C-NMR. The ^{13}C-NMR chemical shifts for the Compounds, **1**—**7**, examined in $CDCl_3$ solutions are presented in Table 3. The assignments of the carbons were made on the basis of: (1) the relative signal intensity, (2) the off-resonance decoupling technique, and (3) a comparison with the published data for trimethylene sulfites and ethylene sulfites.

The upfield shifts of 6—9 ppm at C-4 and/or C-8 of the CC-conformation compared with those in the CB and BB conformations are due to the γ-relationship between the axial S=O and axial hydrogens at the C-4 and/or C-8 in Scheme 1. Nonbonded interactions between the axial oxygen in CC conformation and the axial hydrogens at C-4 and/or C-8 are probably sufficient to perturb the electron distribution about

C-4 and/or C-8 and increase their shieldings. These γ-shifts have already been reported for ethylene sulfites and propylene sulfites.[4,13] For example, Buchanan *et al.*[14] reported upfield shifts of 9.9 and 6.6 ppm at C-4 and C-6 of 4-phenyl-1,3,2-dioxathiane 2-oxide with an axial S=O bond relative to that of the equatorial S=O type. On the contrary, the chemical shifts of C-4 and C-8 in the TCB and TBB conformations appeared at different positions, as is shown in Table 3. The upfield shifts in C-4 indicate that the S=O function turned away to the axial hydrogen at C-4.

We concluded, in the light of all the available evidence, that Compounds **1**—**7** exist in five conformations, that is, CC, BB, CB, TCB, and TBB, as is shown in Schemes 1 and 2.

The Methylation of Nucleic Acids. The Analysis of Methylated Ribonucleosides by Means of High-performance Liquid ODS-Silica Gel[1] and Cation-exchange Chromatography

Toshizumi TANABE, Kiyoshi YAMAUCHI,* and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received August 2, 1980)

The quantitative determination of adenosine, guanosine, inosine, cytidine, uridine, and their methylated derivatives was studied by means of a high-performance liquid chromatographic method using ODS-silica gel, cation-exchange, and anion-exchange resins as column packings. The method was applied to the analysis of yeast-RNA, which was methylated by trimethyl phosphate at pH 7 and 9.

Nucleic acids, especially tRNA and mRNA, contain a variety of modified nucleosides.[2,3] A mutagenic study of the action of alkylating agents on nucleic acids has shown them to give polymers with various alkylated nucleosides.[4] The rapid and quantitative analysis of such rare nucleosides has, therefore, been actively sought. Although two-dimensional thin-layer chromatography and ion-exchange chromatography,[2,5-7] which are coupled with a scintillation-counting technique, have frequently been employed, the chromatographic procedures are complex and time-consuming. These drawbacks may be avoided by utilizing high-performance liquid chromatography (HPLC). There have been reports on the HPLC of such major nucleosides as Ado, Guo, Cyd, and Urd.[8-11] However, only a limited number of papers have dealt with the HPLC of rare nucleosides of nucleic acids.[9,12]

In this paper, we wish to report the HPLC of a variety of methylated ribonucleosides, *etc.*, using ODS-silica gel, cation-exchange, and anion-exchange resins as column packings. The application of the HPLC method to the analysis of the enzymatic hydrolysates of methylated RNA will also be described.

Results and Discussion

The following nucleosides were studied for the HPLC analysis: Ado, m^1Ado, m^6Ado, Guo, m^1Guo, m^6Guo, m^7Guo, Ino, m^1Ino, Cyd, m^3Cyd, Urd, and m^3Urd.[13] The methylated substances include not only the constituents of tRNA, but also the products furnished easily upon the treatment of RNA with methylating agents. In addition to these compounds, 7-methylguanine and the imidazole ring-opened m^7Guo[14] were examined, since m^7Guo has been known to give the former by a depurination reaction, and the latter, by hydrolysis under weakly alkaline conditions.[15]

Although previous HPLC studies of the rare nucleosides of RNA used ion-exchange columns exclusively,[9-12] we found that a ODS-silica gel column was most useful in fractionating these compounds. Of the various solvent systems investigated as the mobile phase, a buffer [triethylamine–acetic acid–water (0.3–0.3–100 v/v)] containing 2% acetonitrile gave the optimum results. Figure 1a shows a typical elution

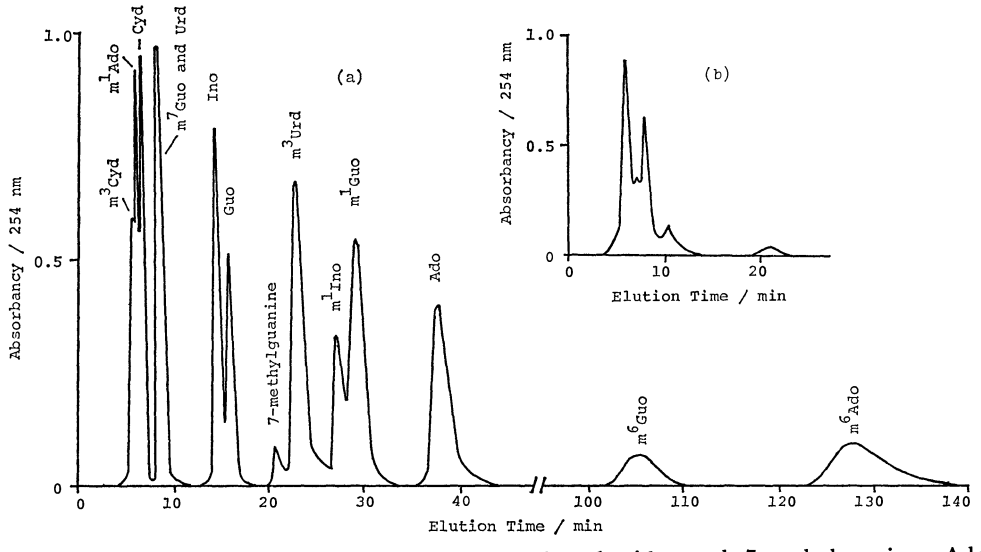

Fig. 1. (a): ODS silica gel HPLC of a mixture of nucleosides and 7-methylguanine; Ado; 3.33; m^1Ado, 2.10; m^6Ado, 1.81; Guo, 1.77; m^1Guo, 2.95; m^6Guo, 1.68; m^7Guo, 3.00; 7-methylguanine, 1.40; Ino, 3.33; m^1Ino, 1.94; Cyd, 3.33; m^3Cyd, 3.50; Urd, 3.33; m^3Urd, 4.36 (mmol/l). Injected volume, 15 μl. Solvent, triethylamine–acetic acid–water–acetonitrile= 0.3—0.3—100—2 v/v; pH 8.9; flow rate, 0.73 ml/min; column pressure, 40 kg/cm^2.
(b): ODS silica gel HPLC of imidazole ring opened m^7Guo (15 mmol/l). Injected volume, 15 μl. For chromatographic conditions see Fig. 1a.

pattern. The addition of acetonitrile to the buffer decreased the retention times considerably and resulted in a higher sensitivity (or height of the peaks) than the same solvent system without the organic solvent. The increase in the content of the amine in the solvent (for instance, triethylamine–acetic acid–water=0.5—0.8–0.3–100 v/v, 2% acetonitrile) resulted in a decreased resolution, especially for Urd, m^3Urd, m^1Guo, and Guo. The imidazole ring-opened m^7Guo may exist as a mixture of various compounds,[14] and its elution pattern overlaps with the peaks of Cyd, m^3Cyd, m^1Ado, m^7Guo, *etc.* (Fig. 1b).

This drawback in the silica gel column was, however, solved by the use of a cation-exchange column. The gradient chromatography achieved by changing the solvent was not employed here because of the time-consuming process needed for the reequilibration of the column after each sample application. As the mobile phase, an ammonium formate buffer (0.05 mol dm^{-3} with respect to the HCO_2^- concentration, pH 4.2) gave good results. A typical elution pattern furnished by the cation-exchange column is shown in Fig. 2a using the sample used in Fig. 1a. It is apparent that the ion-exchange column complemented

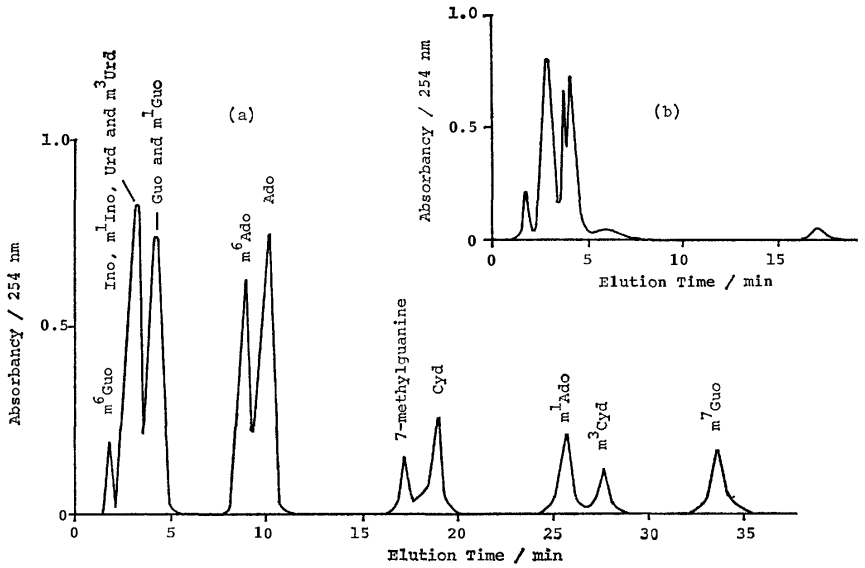

Fig. 2. (a): Cation-exchange HPLC of a mixture of nucleosides and 7-methylguanine. See Fig. 1a for the sample. Injected volume, 10 μl. Solvent, ammonium formate buffer (0.05 M, pH 4.2); flow rate, 0.67 ml/min; column pressure, 75 kg/cm².

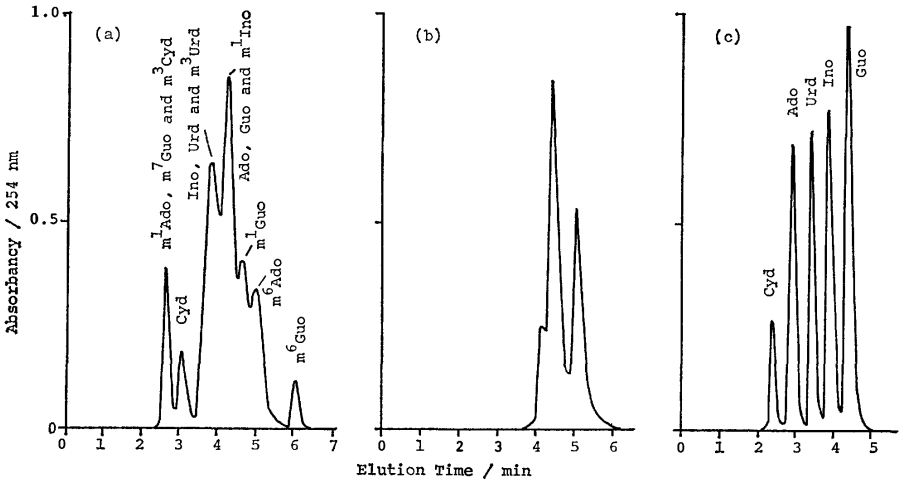

Fig. 3. (a): Anion-exchange HPLC of a mixture of nucleosides and 7-methylguanine. See Fig. 1a for the sample. Injected volume, 7 μl. Solvent, potassium phosphate buffer (0.03 M, pH 3.9); flow rate, 1.00/min; column pressure, 50 kg/cm².
(b): Anion-exchange HPLC of imidazole ring-opend m^7Guo (15 mmol/l). Injected volume, 5 μl. For chromatographic conditions see Fig. 3a.
(c): Anion-exchange HPLC of a mixture of Ado (0.83 mmol/l), Guo (1.37), Ino (0.95), Cyd (0.85) and Urd (1.00). Injected volume, 25 μl. Solvent, potassium phosphate buffer (0.03 M, pH 2.9); flow rate, 0.53 ml/min; column Pressure, 23 kg/cm².

Table 1. Retention data of nucleosides and 7-methylguanine[a)]

Compound	pK_a	Retention volume/ml (time/min)		
		Silica gel pH 8.9	Cation resin pH 4.2	Anion resin pH 3.9
Ado	3.5	27.9 (38.2)	6.4 (10.0)	4.2 (4.2)
m^{1}Ado	8.8	4.3 (5.9)	17.3 (25.8)	2.6 (2.6)
m^{6}Ado	4.0	93.4 (128)	5.9 (8.8)	5.0 (5.0)
Guo	1.6, 9.2	11.3 (15.5)	2.9 (4.4)	4.2 (4.2)
m^{1}Guo	2.4	21.3 (29.3)	2.9 (4.4)	4.6 (4.6)
m^{6}Guo	2.4	78.1 (107)	1.3 (2.0)	6.2 (6.2)
m^{7}Guo	7.0	5.7 (7.8)	22.5 (33.6)	2.6 (2.6)
Ring-opened m^{7}Guo	—	4.1—15.3 (5.6—21)	1.3—4.2, 11.7 (2.0—6.2, 17.4)	4.0—4.9 (4.0—4.9)
7-Methylguanine	3.5, 9.9	15.3 (21.0)	11.7 (17.4)	4.8 (4.8)
Ino	8.8, 1.2	10.2 (14.0)	2.1 (3.2)	3.9 (3.9)
m^{1}Ino	—	20.1 (27.6)	2.1 (3.2)	4.1 (4.1)
Cyd	4.2	4.5 (6.1)	12.1 (18.0)	3.1 (3.1)
m^{3}Cyd	8.7	3.9 (5.4)	18.5 (27.6)	2.6 (2.6)
Urd	9.2	5.7 (7.8)	2.1 (3.2)	3.6 (3.6)
m^{3}Urd	—	17.0 (23.3)	2.1 (3.2)	3.8 (3.8)

a) See the Experimental section for chromatographic conditions.

the silica gel column in separating characteristics. Thus, the group of compounds which eluted simultaneously with the imidazole ring-opened m^{7}Guo in the silica gel column (*vide supra*) were resolved fairly well by the cation-exchange column except for Urd. Although the peaks of m^{6}Guo, m^{1}Guo, Guo, and m^{3}Urd were overlapped by the complex peaks of the imidazole ring-opened m^{7}Guo, as is shown in Fig. 2b, the silica gel column separated these compounds well (Fig. 1a).

As is to be expected from the pK_a values (Table 1) of the nucleosides examined, the increase in the pH value of the buffer to 4.4—4.6 in the cation-exchange column resulted in the peak-coherence of m^{6}Ado with Ado, of Cyd with m^{7}Guo, and of m^{1}Ado with m^{3}Cyd.

An anion-exchange column, on the other hand, was not as useful as the silica-gel column and the cation-exchange column. The elution patterns of various nucleosides are shown in Figs. 3a—3c, using a potassium phosphate buffer (0.03 mol dm^{-3} with respect to the $H_2PO_4^-$ concentration). The retention volume (R_v)-difference between the initial peak and the last peak was small (*ca.* 3.7 ml) in comparison with the R_v of the initial peak (2.6 ml). It thus appeared that the anion-exchange column was suitable for the analysis of a mixture of major nucleosides of RNA (Fig. 3c).

The lowest concentration of samples for quantitative determination was found to be better than *ca.* 0.5 μmol/l (R_v 3—12 ml)—*ca.* 8 μmol/l (R_v 15—28 ml) for the ODS–silica gel column, *ca.* 0.5 μmol/l (R_v 1.3—7 ml)—5 μmol/l (R_v 11—23 ml) for the cation-exchange column, and *ca.* 0.5 μmol/l for the anion-exchange column. The retention data are summarized in Table 1.

As an application of the present HPLC method, yeast RNA was methylated with trimethyl phosphate at pH 7 and 9, and its enzymatic hydrolysates were analyzed. Table 2 shows the relative distribution of products against each major nucleosides.[16)] The values were obtained by dividing the peak areas by the respective molar extinction coefficients at 254 nm in the eluting buffer and by normalizing the data to 100% for each major nucleoside (see the Experimental section). Although the methylating conditions were vigorous, the distribution of the products agreed with

Table 2. Product distributions in the enzymatic hydrolysates of methylated yeast RNA[a,b)]

Compound	Buffer A[c)]		Buffer B[c)]

a) Anion-exchange HPLC showed that the starting yeast RNA contained Ado, Guo, Cyd and Urd in the molar ratio of 0.95 : 1.37 : 0.84 : 1. b) Percentages are based on the amounts of products against the respective major nucleosides in the starting RNA. Tr, nd, and nc indicate "a trace yield," "a compound was not detected," and "a yield was not calculated" respectively. c) The reaction media; buffer A, KH_2PO_4-NaOH (0.03 M); buffer B, Tris-HCl (0.05 M). d) See Ref. 16. e) See Ref. 18.

the general order of the increasing reactivity of the alkylation sites of the nucleoside residues in RNA:[4,17] *e.g.* at pH 7, $m^7Guo > m^3Cyd > m^1Ado$, m^6Ado[18] > m^3Urd, and at pH 9, $m^3Urd > m^1Guo > m^3Cyd > m^1Ado$, m^6Ado. It was found that the methylation of RNA in the phosphate buffer occurred more smoothly than the methylation in the tris buffer. Possibly, tris(hydroxymethyl)aminomethane (tris) in the buffer scavenged trimethyl phosphate by reacting the methylating agent at a rate faster than RNA. It is also noteworthy that the extent of the formation of m^6Guo, which may be an adequate measure of the mutagenic activity of the methylating agents,[3] was very small when trimethyl phosphate was used.

In conclusion, a variety of methylated nucleosides can be analyzed rapidly and easily by the HPLC method. ODS-silica gel and cation-exchange columns are especially useful for the study of methylated RNA.

Experimental

HPLC was run by means of a Toyo-Soda 803 liquid chromatograph with a 254-nm UV flow-cell detector and a Milton Roy model 396/2396 piston pump (Riviera Beach, Florida). All the measurements were carried out at the ambient temperature.

An ODS-silica gel column (stainless steel, 0.4 cm × 30 cm, LS-410-ODS), a cation-exchange column (stainless steel, 0.4 cm × 30 cm, IEX-510-SP), and an anion-exchange column (stainless steel, 0.4 cm × 30 cm, IEX-260) were purchased from the Toyo-Soda Co., Shinnanyo-shi, Hiroshima.

The most frequently employed solvent systems were as follows: triethylamine–acetic acid–water–acetonitrile (0.3–0.3–100–2 v/v), an ammonium formate buffer (0.05 mol dm^{-3} with respect to the HCO_2^- concentration, pH 4.2), and a potassium phosphate buffer (0.03 mol dm^{-3} with respect to the $H_2PO_4^-$ concentration, pH 4.5, 3.9, and 2.9).

The major nucleosides (Ado, Guo, Cyd, Urd, and Ino) were commercially available. The methylated nucleosides (m^1Ado, m^6Ado, m^1Guo, m^6Guo, m^7Guo, the imidazole ring-opened m^7Guo, m^1Ino, m^3Cyd, and m^3Urd) and 7-methylguanine were prepared in previous experiments[17] or according to the literature.[15] The yeast RNA was obtained from the Sigma (U.S.A.) Chemical Co. (lot R6750). The ribonuclease (bovine pancrease) was from Miles Laboratory (U.S.A.) (code 36-511, batch 228). The phosphodiesterase (P-6877, type II) and RNAse T_2 (lot 57c-9510) were obtained from the Sigma (U.S.A.) Chemical Co. The alkaline phosphatase (36—482) was purchased from Miles-Seravac (Cape Town, South Africa).

Methylation of Yeast RNA. RNA (6 mg) was dissolved in a KH_2PO_4–NaOH buffer (1.5 ml, pH 7.0 or 9.0, 0.05 mol dm^{-3} with respect to the $H_2PO_4^-$ concentration) or in a Tris-buffer (1.5 ml, pH 7.0 or 9.0, 0.05 mol dm^{-3}). The solution was mixed with trimethyl phosphate (0.2 g, 1.7 mmol) and kept at 37 or 55 °C for 12 h. The homogeneous solution was then concentrated under −10 °C to give a residue, which was subsequently washed with ether and dissolved in water (0.8 ml). Ethanol was poured into the solution until a cloudy, turbid solution appeared. Sometimes a few drops of sodium acetate (3 mol dm^{-3}) were added to the solution in order to make the precipitation complete. After repeating the precipitation procedure thrice, the precipitate was dried and subjected to an enzymatic hydrolysis, which was carried out in a manner similar to the method previously reported.[6]

Quantitative Analysis of the Enzymatic Hydrolysate. The hydrolysate was dissolved in 2 ml of water, and then 10—20 μl of the solution was injected into the chromatograph. The sample peaks of the HPLC chart were cut and weighed. They were then divided by the respective molar extinction coefficient at 254 nm in the eluting buffer in order to obtain the molar ratios of the methylated nucleosides against the respective major nucleosides. The yields of the products were calculated from the ratio; they are shown in Table 2.

Since the imidazole ring-opened m^7Guo showed a complex elution pattern, its content (%) in the mixture of products was estimated by means of the following equation: 100—[yields (%) of m^7Guo (cation-exchange column), of 7-methylguanine (cation-exchange column), of m^1Guo (ODS-silica gel column), of m^6Guo (ODS-silica gel column), and of unreacted Guo (ODS-silica gel column)].

The yield of m^3Urd could not be determined by the aforementioned method because neither the ODS-silica gel column nor the cation-exchange column gave an isolated peak for Urd. The yield of m^3Urd was, therefore, obtained by means of this equation: 100·a/the amount of Urd in the starting RNA, where a is the amount of m^3Urd in the hydrolysate. This last quantity was determined as follows. The ODS-silica gel HPLC was run before and after the addition of a known amount of m^3Urd to the hydrolysate; a = the added amount of m^3Urd × (the original area of m^3Urd/the increased area of m^3Urd).

Kinetic Study on the Reaction of (Arylthio)trimethylsilanes with Phenacyl Bromide Giving Aryl Phenacyl Sulfides and Bromotrimethylsilane

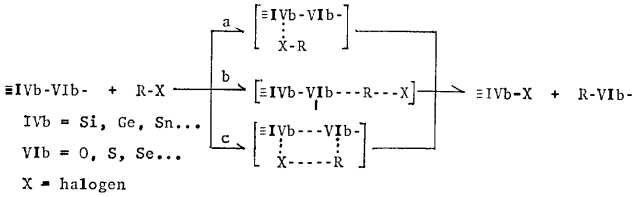
Seizi KOZUKA,* Tetsuji HIGASHINO, and Takuro KITAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka 558

(Received August 23, 1980)

A kinetic study has been conducted on the reactions of (arylthio)trimethylsilanes with phenacyl bromide giving aryl phenacyl sulfides and bromotrimethylsilane. Remarkably large positive substituent effect ($\rho = +2.2$) and large negative entropy of activation were observed for the reaction. A mechanism involving 5-coordinated silicon intermediate prior to the rate-determining heterolysis of the Si–S bond has been suggested for the reaction based on the kinetic results.

Three different mechanisms are conceivable for the cleavage reaction of the group IVb–VIb bond by the reaction with haloalkane. Assuming the coordination ability of the IVb element, a 5-coordinated complex would be formed as an intermediate of the reaction (path a). On the other hand, a nucleophilic reaction by the attack of the VIb element is also a possible route for the reaction (path b). A mechanism involving four-centered transition state is the third possibility if the paths a and b occurred simultaneously (path c) although this mechanism for a bimolecular reaction of this type has recently been suspected by us.[1]



The reactions of (alkylthio and arylthio)trimethylstannanes with haloalkanes have been known to be the nucleophilic reaction (path b) based on detailed kinetic and stereochemical studies.[2] Namely the reaction obeys a second order rate equation, apparently negative ρ value (-1.40) of the substituent effect of the arylthio moiety, solvent effect on the rate of the reaction, relative reactivity of haloalkanes, and inversion of the alkyl group of the haloalkane by the reaction.

$$Me_3Sn\text{–}SPh + R\text{–}X \longrightarrow [Me_3Sn\text{–}S^{+}(Ph)\text{–}R\ X^{-}] \quad (I)$$
$$I \longrightarrow PhS\text{–}R + Me_3Sn\text{–}X$$

An analogous reaction of thiosilane with haloalkane has been known to give halosilane and sulfide which then further react with excess haloalkane giving trialkylsulfonium salt.[3,4] A silicon analogue of the sulfonium salt of the type I had once been reported as an isolable product in the reaction of (butylthio)trimethylsilane with an equimolar amount of iodomethane.[3b] If the silylsulfonium salt was actually an isolable product, it would be a definite evidence in support of a nucleophilic reaction of the sulfur atom. It has been found, however, to be an erroneous result.[4]

$$R_3Si\text{–}SR' + R''\text{–}X \longrightarrow R_3Si\text{–}X + R'\text{–}S\text{–}R''$$
$$R'\text{–}S\text{–}R'' + R'' \longrightarrow R'R''_2S^{+}X^{-}$$

Kinetic and stereochemical studies of this reaction would be of interest, since if the reaction proceeded by the same mechanism with that of the tin analogue,[2] stereochemistry of the silicon atom may clarify the final step of the reaction *i.e.*, the mechanism of the step leading to the product from the intermediate I. Thus, we have extended our study to the reaction of (arylthio)trimethylsilane with haloalkane in order to clarify the mechanism and to compare the aspects of the reaction with those of the reaction of the tin analogue.

Results and Discussion

Iodomethane was chosen as a typical haloalkane for the kinetic study of the reaction with (arylthio)-trimethylsilane. Although this reaction without the use of a solvent gave aryl methyl sulfide and iodotrimethylsilane on heating as analogously to the reaction of (alkylthio)silanes,[3,4] the reaction in a solvent was found to be sluggish even at high temperature and gave mainly unexpected product. Namely, hydrolysis by moisture or decomposition of the substrate giving hexamethyldisiloxane took place faster than the reaction with iodomethane when the reaction was carried out in such a nonpolar solvent as carbon tetrachloride at 120 °C. In a polar solvent, acetonitrile, the consumption of the thiosilane was found to be much faster than that in nonpolar solvent, the reaction gave a similar complex products. The reaction of the thiosilane with benzyl bromide was tried since this compound is more reactive than iodomethane toward tin analogue of the thiosilane *i.e.*, trimethyl-(phenylthio)stannane.[2] The main product derived from the reaction of benzyl bromide was bromotrimethylsilane but still accompanied with substantial amounts of the disiloxane although milder reaction conditions gave a better result.

$$Me_3SiSPh \xrightarrow{RX} Me_3SiX + RSPh$$
$$\xrightarrow{\text{hyd. or decompn.}} Me_3SiOSiMe_3$$

Kinetic study of the reaction was thus found to be difficult due to instability of the thiosilane and our attempts were failed to compare the kinetic and stereochemical results of the reaction with those of

the tin analogue by using the same haloalkanes. These results, however, reveal that the possibility of a kinetic study on the reaction of the thiosilane with more reactive haloalkane in a polar solvent under mild reaction conditions.

Phenacyl bromide was chosen as one of the most reactive haloalkane. The reaction of phenacyl bromide with an equivalent of trimethyl(phenylthio)silane was carried out at 60 °C in acetonitrile solution. Although the formation of the disiloxane was detected, even at the beginning of the reaction, the amount was found to increase little during the reaction until all the starting thiosilane was converted to the bromosilane (5h). The products of the reaction were bromotrimethylsilane, phenacyl phenyl sulfide, and small amounts of hexamethyldisiloxane and diphenyl disulfide. The volatile products were identified by GLC and NMR analyses and sulfides were characterized by isolation.

$$PhSSiMe_3 + PhCOCH_2Br \xrightarrow[\text{in } CH_3CN]{60\,^\circ C,\ 5\,h} Me_3SiBr + PhCOCH_2SPH + (Me_3Si)_2O + Ph_2S_2$$

75% 82% 10% 8%

The rate of the reaction of trimethyl(phenylthio)-silane with two equivalents of phenacyl bromide in acetonitrile was measured by monitoring ^1H NMR trimethyl signals of the thiosilane (δ 0.26 ppm) and bromotrimethylsilane (δ 0.57 ppm) at time intervals. A good second order rate constant was obtained with tolerable reproducibility ($\approx\pm10\%$). In order to confirm the first order dependency of the rate on the concentration of phenacyl bromide, the rate of the reaction was measured with different concentrations of phenacyl bromide. A clear first order dependency was observed. Thus, the reaction was found to be second order. Rates of the reactions of several (arylthio)trimethylsilanes were measured similarly. Rates were also measured at various temperatures to obtain activation parameters. These results are given in Table 1.

An unexpectedly large negative entropy of activation was observed for the reaction. A similar large negative value was observed for the reaction of thiostannane with haloalkane in a nonpolar solvent ($CHCl_3$) but it was shown to fall in a smaller negative value when the reaction was carried out in a polar solvent (PhCN).[2] By an analogy, a smaller negative entropy value was expected in the present study since a much polar solvent (CH_3CN) was used. Therefore, the value may suggest that the reaction of (arylthio)trimethylstannane with haloalkane differs from that of (arylthio)-trimethylsilane with phenacyl bromide in the mechanism.

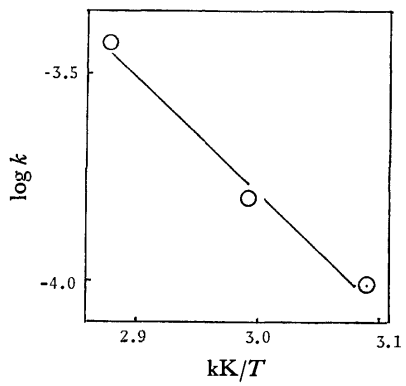


Fig. 1. Arrhenius plot of the rates of the reaction, $C_6H_5SSiMe_3 + C_6H_5COCH_2Br$ ($\gamma=0.984$).

Substituent effect also suggests that these two analogous reactions are quite different in their mechanisms. The results given in Table 1 are best correlated with σ constants giving a large positive ρ value (+2.2) with tolerable linearity as shown in Fig. 2. The deviation may be due to the instability of the thiosilanes.[5] The positive ρ value is consistent with a 5-coordination process and rules out the nucleophilic attack of the sulfur atom since the process would demand a negative ρ value as was observed for the reaction of the thiostannane with haloalkane.[2] The magnitude of the ρ value, however, appeared too large to be rationalized only by the formation of the 5-coordinated silicon intermediate.[6] A rate determining heterolysis of the Si–S bond of the coordinated intermediate would be involved in the reaction since

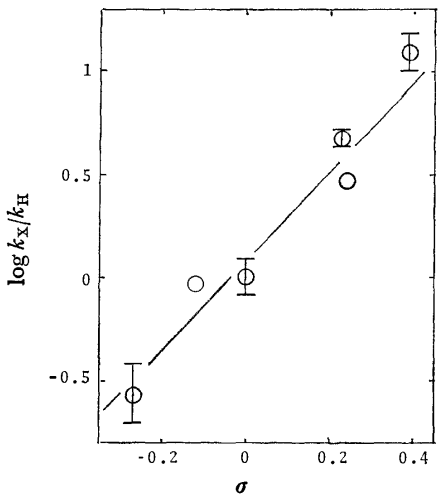

Fig. 2. Hammett plot of the rates of the reaction, $XC_6H_4SSiMe_3+C_6H_5COCH_2Br$ in CH_3CN at 51.5 °C.

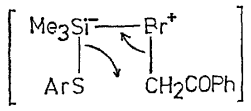
the value appeared in almost comparable magnitude to that of dissociation constants of arenethiols (+2.58).[7] Thus, the most plausible mechanism for the reaction can be formulated as follows:

$$Me_3SiSAr + PhCOCH_2Br \rightleftharpoons \underset{\text{II}}{\left[\begin{matrix} Me_3Si^{\delta-}\text{–}Br^{+}\text{–}CH_2CPh \\ | \qquad\qquad \| \\ ArS \qquad\quad O \end{matrix}\right]}$$

$$\xrightarrow{\text{slow}} \underset{\text{III}}{\left[\begin{matrix} Me_3Si\text{–}Br^{+}\text{–}CH_2CPh \\ | \qquad\qquad \| \\ ArS^{-} \qquad\quad O \end{matrix}\right]} \xrightarrow{\text{fast}}$$

$$Me_3SiBr + ArSCH_2\overset{\overset{O}{\|}}{C}Ph.$$

The large positive ρ value observed in the present study would be rationalized in terms of the sum of those of the first and the second steps *i.e.*, the formation of II and the heterolysis of II giving III. The intermediate III would be a short lived tight ion pair which collapsed rapidly into the product since a large negative entropy of activation was observed in the present study even the reaction was carried out in a polar solvent. An ionic four-centered transition state (IV) leading to the product from II is an attractive alter-



IV

native choice to account for the large negative entropy value since it has often been considered to suggest a cyclic transition state.[8] The large negative entropy value, however, could not be a definite evidence in support of a cyclic transition state since all the bimolecular reactions of this type which have been studied in detail, were found to proceed by non-cyclic process regardless of the large negative entropy values.[9]

The reaction of thiosilane with phenacyl bromide has thus appeared quite different in mechanism from that of thiostannane with haloalkane.[2] The reason for the difference is obscure at present but higher energy release by forming Si–X bond from Si–S bond (*ca.* 35 kcal/mol, X=Cl) than that of tin (23 kcal/mol, X=Cl)[10] may be one of the important factors to control the course of the reaction. The high reactivity of phenacyl bromide seems to play no important role to control the course of the reaction since the opposite substituent effects were also found for the reactions of benzoyl chloride with (arylthio)trimethylstannanes ($\rho=-1.6$)[11] and with (arylthio)trimethylsilanes ($\rho=+2.50$).[12]

Experimental

Materials. The (arylthio)trimethylsilanes were prepared by the same procedure described previously.[6] Phenacyl bromide was recrystallized from hexane–chloroform before use. Solvents were dried and distilled.

The Reaction of Trimethyl(phenylthio)silane with Iodomethane or Benzyl Bromide. The thiosilane (55 mg, 0.30 mmol) and iodomethane (426 mg, 3.0 mmol) were dissolved in carbon tetrachloride (total 5 cm^3). The solution was divided and sealed in glass tubes each containing *ca.* 0.5 cm^3. The tubes were heated in a constant temperature bath (120 °C) and subjected to NMR analysis at time intervals. After heating for 1 h, only a small amount of hexamethyldisiloxane (δ 0.07 ppm, 8%) was detected as the product. The formation of iodotrimethylsilane (δ 0.55 ppm) was detected after heating for 17 h (5%) accompanied with a large amount of the disiloxane (35%). The disiloxane would be formed by hydrolysis of the starting thiosilane and the product,

$$MeSiSAr \text{ and } Me_3SiI \xrightarrow{\text{moisture}} Me_3SiOH$$

$$2\,Me_3SiOH \longrightarrow Me_3SiOSiMe_3 + H_2O$$

iodotrimethylsilane or oxidation of them. All the materials and the apparatus were dried carefully but the results were not improved significantly. A similar result was also found by the reaction carried out in a polar solvent of acetonitrile. The consumption of the thiosilane was found to be faster in this solvent (within 1 h) but the detected product was manily the disiloxane. In separate experiments, both trimethyl(phenylthio)silane and iodotrimethylsilane were found to give substantial amounts of hexamethyldisiloxane by heating at 120 °C in these solvents.

The reaction of trimethyl(phenylthio)silane (0.06 mol dm^{-3}) with benzyl bromide (0.6 mol dm^{-3}) in acetonitrile was carried out similarly. The solution was heated at 80 °C until the thiosilane was consumed giving a mixture of bromotrimethylsilane (60%) and hexamethyldisiloxane (40%).

The Reaction of Trimethyl(phenylthio)silane with Phenacyl Bromide. The thiosilane (1 g, 5.5 mmol) and phenacyl bromide (1.1 g, 5.5 mmol) in acetonitrile (10 cm^3) were heated at 60 °C for 5 h. Solvent and volatile components were distilled off. Bromotrimethylsilane (75%) and hexamethyldisiloxane (10%) were identified by GLC and NMR analyses of the distillate. Identifications were done by comparing the NMR spectra and the GLC retention times with those of the authentic samples. The residue was separated by chromatography (silica gel, hexane–chloroform). Phenacyl phenyl sulfide (82%) and diphenyl disulfide (8%) were isolated and characterized. Phenacyl phenyl sulfide; Found: C, 73.42, H. 5.30%. Calcd for $C_{14}H_{12}OS$: C, 73.65, H, 5.30%.

Kinetics. The procedure is essentially the same with

that employed for the reaction of (arylthio)trimethylsilanes with carboxylic acids.[5] Concentrations of the substrates are recorded in Table 1. Temperatures were calibrated by measuring chemical shift of 1,2-ethanediol.

Asymmetric Reduction of Aromatic Ketones with Reagents Prepared from $NaBH_4$ and $ZnCl_2$ in the Presence of 1,2 : 5,6-Di-*O*-isopropylidene-α-D-glucofuranose

Akira HIRAO,* Masaki OHWA, Shinichi ITSUNO, Hidenori MOCHIZUKI, Seiichi NAKAHARA, and Noboru YAMAZAKI

Department of Polymer Science, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

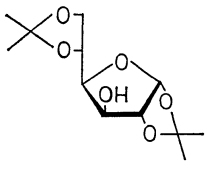
(Received August 29, 1980)

Asymmetric reduction of prochiral aromatic ketones using a freshly prepared complex derived from $NaBH_4$, 1/3 equiv of $ZnCl_2$, and 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**1**) gives an excess of the corresponding (*S*)-alcohols in substantial optical yields (28—68%). The effects of the $NaBH_4/ZnCl_2$/**1** ratio, temperature, solvent, structure of various monosaccharide derivatives, and the metal cation of the reagent on the optical yields were examined.

Asymmetric reduction of carbonyl compounds has recently been achieved by use of metal hydrides modified by chiral compounds such as chiral diols,[1] amines,[2] and α-pinene.[3,4] The hydrides would be of use for the synthesis of enantiomerically pure molecules of biological interest.

However, only a few reports have been made on the application of sodium borohydride($NaBH_4$) to the same type of asymmetric reduction, the reagent being found to be less effective with ketones,[5-8] though $NaBH_4$ is a mild and highly selective reducing agent.

It was found that aromatic ketones are asymmetrically reduced by $NaBH_4$ in the presence of monosaccharide derivatives, attempts for selectivity not being quite successful.[9] Stereoselectivities have been greatly enhanced by addition of Lewis acids. We reported on a test of modified reagents derived from $NaBH_4$ and Lewis acids such as zinc chloride and aluminium chloride in the presence of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**1**) for the asymmetric reduction of aromatic ketones.[10]



1

The results show that reaction of $NaBH_4$ with zinc chloride ($ZnCl_2$) affords a reagent, presumably a zinc borohydride or the related borohydride species, which give higher stereoselectivities than those achieved with $NaBH_4$ alone.

This paper describes a detailed study of asymmetric reduction of prochiral ketones with the reagents prepared from $NaBH_4$ and $ZnCl_2$ in the presence of **1** to establish the optimum conditions for maximum stereoselectivity. The species responsible for the maximum asymmetric induction (68%) has been discussed.

Results and Discussion

*Asymmetric Reduction of Ketones with the Reagents Derived from $NaBH_4$ and $ZnCl_2$ in the Presence of **1**.* Addition of 0.5 molar equiv of $ZnCl_2$ to the suspended $NaBH_4$ in tetrahydrofuran (THF) gave rise to quantitative precipitation of NaCl (1 mol) and the formation of soluble borohydride species in the solution. Subsequent addition of 2 equiv of monosaccharide **1** (R*OH) caused evolution of 2.0 mol of hydrogen, 2.0 equiv of hydride remaining in the reducing agents in the solution. No further hydrogen uptake took place after 24 h. The reaction of $NaBH_4$ with $ZnCl_2$ and subsequent addition of **1** seems to proceed according to the equation:

$$NaBH_4 + 1/2\,ZnCl_2 \rightleftarrows 1/2\,Zn(BH_4)_2 + NaCl\downarrow \quad (1)$$

$$1/2\,Zn(BH_4)_2 + 2\,R^*OH \longrightarrow 1/2\,Zn(BH_2(OR^*)_2)_2 + 2H_2\uparrow \quad (2)$$

Asymmetric reduction of propiophenone was carried out with suspension of $NaBH_4$ in THF to which $ZnCl_2$ in varying amounts and a fixed quantity (2 equiv to $NaBH_4$) of **1** had been added. The results are summarized in Table 1. We see that the stereoselectivity increases to a maximum and then decreases with addition of $ZnCl_2$. The reagent formed by adding 1/3 mol of $ZnCl_2$ per mole of $NaBH_4$ gives optimum induction; maximum selectivity as high as 68% was obtained. It was found that all the 1-phenyl-1-propanols produced with the reagents derived from $NaBH_4$ and $ZnCl_2$ have the (*S*)-configuration, while

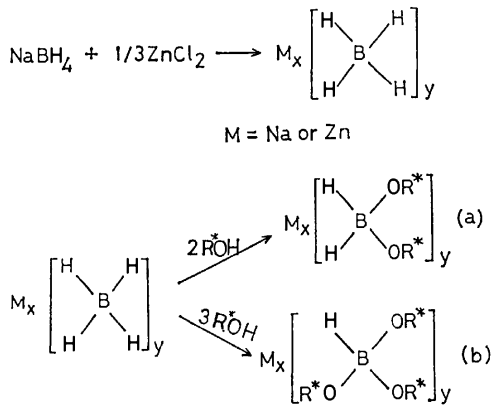
the reduction with $NaBH_4$ alone gives the same alcohol of the (*R*)-configuration in 18% of an optical yield.

The effect of the amount of **1** to the $NaBH_4$–1/3 $ZnCl_2$ reagent on optical yield was examined (Table 2). Optical yield increased with the increase in the ratio of **1** to the reagent based on $NaBH_4$. The maximum selectivity could be obtained at a *ca.* 2 molar ratio. A marked fall in selectivity took place by addition of 3 molar equiv of **1**. This is curious since the resulting monohydride (**b**) would be in a more steric and chiral environment than the corresponding dihydride (**a**):



Further addition of **1** (4 equiv) might remove all hydrides on the reagent giving tetrasubstituted alkoxyborate complex which can not react further. Addition of 4 equiv of **1** evolved 4.0 mol of hydrogen, giving rise to incomplete reduction of propiophenone. The stoichiometric quantities of $NaBH_4$, $ZnCl_2$, and **1** were found to be optimum at 1,/1/3,/ and 2.0, respectively.

We next examined the dependency of selectivity on chemical yield with the complex from $NaBH_4$, 1/3 equiv of $ZnCl_2$, and 2 equiv of **1** and found that selectivity is constant until less than one equiv of propiophenone to the reagent was used (Table 3). However, a significant decrease in the optical yield was observed when 1.5 equiv of ketone was used. This suggests that of two available hydrides on the complex (**a**) as described above, the first hydride would be more effective for the asymmetric induction.

Optical yields vary with solvent, THF being the best in stereoselectivity (Table 4).

−30	0	—	—	—

The temperature effect on asymmetric reduction of propiophenone appeared not to be critical in the range 0—50 °C (Table 5). Rise in temperature from 0 °C to 50 °C caused decrease in optical yield to some extent. No reduction took place at −30 °C even after 108 h.

The complex from $NaBH_4$, 1/3 equiv of $ZnCl_2$, and 2 equiv of **1**, reduced a variety of aromatic ketones in excellent chemical yields with substantial enantiomeric excesses (⩾50%) except for the case of isopropyl phenyl ketone. The same complex also reduced an alkyl ketone such as isobutyl methyl ketone with moderate selectivity. The six ketones were reduced with $NaBH_4$ in the presence of **1** (Table 6). It is apparent from a comparison of the results that the complex system is superior to the original system with use of $NaBH_4$ and **1**. In each case with the complex the (*S*)-configuration of the alcohols produced was opposite that of the alcohols obtained by $NaBH_4$ alone in which (*R*) isomer predominates.

In order to determine the structural effect of various

monosaccharide derivatives on the reaction, we have examined the asymmetric reduction of propiophenone with the complexes prepared from $NaBH_4$, 1/3 equiv of $ZnCl_2$, and 2 equiv of **2**, **3**, **4**, **5**, or 2/3 equiv of **6** (2 equiv for OH moiety) in THF at 30 °C. The reactions resulted in complete reduction in all cases. The enantiomeric excess from each reduction is given in Table 7. Selectivity was generally low as compared with that obtained by the complex from **1**. The order of asymmetric induction by the complexes from **1** to **6** is not the same as that by $NaBH_4$. An increase in the stereoselectivity of $NaBH_4$ by adding 1/3 equiv of $ZnCl_2$ occurred with **1**, but it is not as

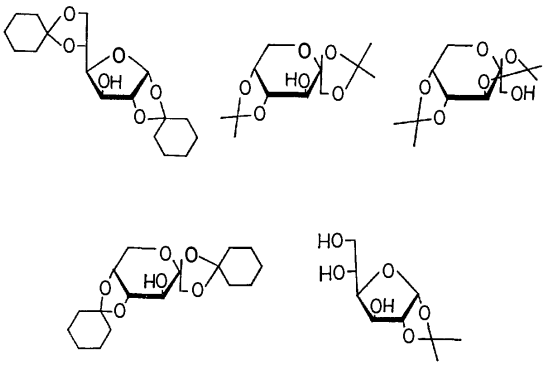

TABLE 8. ASYMMETRIC REDUCTION OF PROPIOPHENONE WITH REAGENTS FROM VARIOUS METAL BOROHYDRIDES AND 1/3 EQUIV OF $ZnCl_2$ IN THE PRESENCE OF **1** IN THF AT 30 °C (VALUES IN PARENTHESES WERE OBTAINED BY THE ASYMMETRIC REDUCTION WITH $LiBH_4$, $NaBH_4$, KBH_4, $RbBH_4$, OR $CsBH_4$ PLUS **1** IN THF AT 30 °C)

a) Chemical yields in both cases were less than 10% Optical rotations could not be measured.

pronounced as with other monosaccharides, **2**—**6**.

Four additional modified reagents were prepared from lithium, potassium, rubidium, or caesium borohydrides and 1/3 equiv of $ZnCl_2$ and were applied to the asymmetric reduction of propiophenone with subsequent addition of 2 equiv of **1** in THF at 30 °C. The results are summarized in Table 8. We see that the reagents from sodium, potassium, rubidium, and caesium borohydrides and 1/3 equiv of $ZnCl_2$ have emerged as more effective asymmetric reducing agents than the corresponding metal borohydrides and propiophenone can be reduced with these reagents in good chemical and optical yields, giving product mixtures in which the (*S*)-alcohol configuration predominates. Neither $LiBH_4$–1/3 $ZnCl_2$ nor $LiBH_4$ showed asymmetric induction, although the reducing yields were quantitative, the order of the influence of the metal cation on selectivity being Na>Rb>Cs≃K≫Li. The cause of the effect is not clear so far.

The rates of reduction by these reagents were much greater than those by the corresponding metal borohydrides except for the case when the metal was lithium: chemical yields: 100% with $NaBH_4$–1/3 $ZnCl_2$ *vs.* 20% with $NaBH_4$ for 2 h; 100% with KBH_4–1/3 $ZnCl_2$ *vs.* 25% with KBH_4 for 24 h; 100% with $RbBH_4$–1/3 $ZnCl_2$ *vs.* 10% with $RbBH_4$ for 72 h; 70% with $CsBH_4$–1/3 $ZnCl_2$ *vs.* 5% with $CsBH_4$ for 72 h. This can be, at least, attributed to the great increase in solubility of the metal borohydrides caused by the

addition of $ZnCl_2$. The order of reduction rate by the reagent, $LiBH_4$–1/3 $ZnCl_2$ > $NaBH_4$–1/3 $ZnCl_2$ > KBH_4–1/3 $ZnCl_2$ > $RbBH_4$–1/3 $ZnCl_2$ > $CsBH_4$–1/3 $ZnCl_2$, is in line with the order of the reducing strength of the metal borohydrides, $LiBH_4$ > $NaBH_4$ > KBH_4 > $RbBH_4$ > $CsBH_4$.[11]

Examination of the Reaction Species from $NaBH_4$ and $ZnCl_2$ in the Presence of **1**. The complex prepared from $NaBH_4$ and 1/3 equiv of $ZnCl_2$ with further addition of 2 equiv of **1** reduced propiophenone with the highest optical yield (68%). The complex responsible for the asymmetric induction was examined.

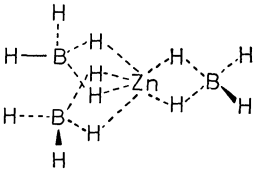
$ZnCl_2$ (7 mmol) in THF was added to a suspension of 21 mmol of $NaBH_4$ in THF at 30 °C. A solid was always present during the course of reaction. The resulting slurry was stirred at 30 °C for 3 h and then filtered. A very small amount of the starting zinc compound but no active hydride species was present in the solid product. From the result of analysis this seems to be sodium chloride, yield of which is nearly quantitative based on initial sodium amount. The filtrate contained *ca.* 100% of the initial amounts of zinc and the active hydrides. The analysis gave a Na:Zn: hydride (B-H): Cl of 1.0:1.0:12.3:0, indicating a physical mixture of $NaBH_4$ and $Zn(BH_4)_2$ at 1:1 molar ratio or a double hydride complex of $NaZn(BH_4)_3$. The reaction may be represented as follows.

$$NaBH_4 + 1/3\ ZnCl_2 \longrightarrow 1/3\ NaBH_4 + 1/3\ Zn(BH_4)_2 + 2/3\ NaCl\downarrow \quad (1)$$

$$NaBH_4 + 1/3\ ZnCl_2 \longrightarrow 1/3\ NaZn(BH_4)_3 + 2/3\ NaCl\downarrow \quad (2)$$

If the reaction of $NaBH_4$ and $ZnCl_2$ gives a physical mixture of $NaBH_4$ and $Zn(BH_4)_2$ (Eq. 1), the reaction might afford precipitates of $NaBH_4$ and NaCl, leaving $Zn(BH_4)_2$ in solution, since $NaBH_4$ is sparingly soluble in THF[12] and $Zn(BH_4)_2$ is soluble in THF. However, the reaction actually gave only a "soluble borohydride species" and a precipitate of sodium chloride. Thus, the product is not a physical mixture of the two simple borohydrides, but may be a soluble double borohydride complex, $NaZn(BH_4)_3$ (Eq. 2).

The double borohydride complex, first prepared by Nöth and his coworkers in 1971,[13] has been characterized by the ^{11}B-NMR, IR-spectra, and elemental analysis. The BH_4 groups in the reagent are bonded *via* double hydrogen bridges to the central Zn atom. The structure is as follows.



Further addition of 2 equiv of **1** evolved 2.2 moles of hydrogen, 1.8 equiv of hydrogen remaining in the complex. The reaction of the reagent with **1** seems to take place as follows.

$$NaBH_4 + 1/3\ ZnCl_2 \longrightarrow 1/3\ NaZn(BH_4)_3 + 2/3\ NaCl\downarrow$$

$$\downarrow 2\ R^*OH$$

$$1/3\ NaZn(BH_2(OR^*)_2)_3 + 2\ H_2\uparrow \quad (3)$$

The complex formed was soluble in THF and reduction with it was homogeneous, in contrast to $NaBH_4$ as reducing agent which was sparingly soluble in THF and gave reduction which was heterogeneous, at least in part.

Additional evidence for a homogeneous reduction was given when a suspension prepared from $NaBH_4$, 1/3 equiv of $ZnCl_2$, and 2 equiv of **1** was filtered under N_2 atomsphere. Addition of propiophenone to this clear filtrate resulted in the same asymmetric reduction obtained with the originally prepared complex.

Apart from the asymmetric induction, a comparison of the reagent from $NaBH_4$ and 1/3 equiv of $ZnCl_2$ with conventional hydridic reducing agents such as $NaBH_4$ demonstrates the potential utility of the reagent in organic reactions. (1) The reagent has a selectivity for functional groups similar to that of $NaBH_4$ but acts as a THF soluble analogue (*ca.* 4.5 g/100 mL at 25 °C) of $NaBH_4$ allowing selective reduction of carbonyl compounds in THF. Aldehydes and ketones are reduced in THF with much higher rates than those with $NaBH_4$ in the same solvent. For example, propiophenone was reduced to the corresponding alcohol quantitatively over a 2 h reaction period with the reagent in THF at 30 °C, whereas less than 20% of the alcohol was obtained with $NaBH_4$ under the same conditions. (2) The reagent can be easily modified in a stepwise fashion by various alcohols, *i.e.* even highly hindered alcohols such as **1**. No similar modification has been proposed for sodium borohydride. The highly hindered reagents thus formed indicate the possibility of developing a superior reducing agent with a high stereochemical selectivity.

Experimental

All reactions were carried out under an atmosphere of nitrogen. Tetrahydrofuran, diethyl ether, and benzene were heated under reflux over sodium metal and distilled from lithium aluminium hydride in a nitrogen atmosphere. Acetophenone, propiophenone, phenyl propyl ketone, and isopropyl phenyl ketone were dried and distilled over calcium hydride. Methyl 2-naphthyl ketone was purified by recrystallization. Sodium borohydride was purified by recrystallization from 2,5,8-trioxanonane. Zinc chloride was purified by sublimation and dried at 100 °C. The monosaccharide derivatives, 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose **1**, 1,2:5,6-di-*O*-cyclohexylidene-α-D-glucofuranose **2**, 1,2:4,5-di-*O*-isopropylidene-D-fructopyranose **3**, 2,3:4,5-di-*O*-isopropylidene-D-fructopyranose **4**, 1,2:4,5-di-*O*-cyclohexylidene-β-D-fructopyranose **5**, and 1,2-*O*-isopropylidene-D-glucofranose **6** were prepared according to the methods reported.[14–17] All the substances were stored under a nitrogen atmosphere prior to use. GLPC analyses were performed on a Shimadzu GC-6A instrument using a Silicone SE-30 prepared column. NMR spectra were measured on a Hitachi R-22, 90 MHz spectrometer. Optical rotations were taken on a Zeiss visual polarimeter with reading to ±0.02° using a 1 dm cell. IR spectra were measured with a JASCO IR-G instrument for nujol mulls. Na analysis by flame photometry was performed on a Hitachi 170-30 instrument. Hydrogen evolution was measured by Brown's method.[18] Zinc was determined by EDTA titration, halogens (chlorine) by Volhard procedure.

General Procedure for Asymmetric Reduction of Propiophenone with $NaBH_4$–$ZnCl_2$ Reagent in the Presence of **1** *in THF.* All experiments were carried out under a nitrogen atmosphere, transfer being made with a syringe through rubber septums. A typical experiment is as follows. THF suspension of $ZnCl_2$ (3 mmol) was added to a THF suspension of $NaBH_4$ (9 mmol) at 30 °C. After stirring for 3 h at 30 °C, THF solution of **1** (18 mmol) was added. On addition of **1**, hydrogen gas evolved slowly. After stirring at 30 °C for 24 h, hydrogen gas evolution was completed, propiopheone (7.2 mmol) then being added dropwise. The resulting mixture was decomposed by addition of 2 mol/l hydrochloric acid. The hydrolyzed mixture was filtered, the organic solvents being removed by evaporation under reduced pressure. The resulting aqueous layer was stirred for 1 h in order to decompose **1** completely. The aqueous mixture was extracted with three 10 mL portions of diethyl ether and the extract washed with saturated NaCl solution (2×10 mL). The etheral layer was dried over $MgSO_4$, and concentrated to give a crude product which was analyzed by GLPC. This was further purified by distillation under reduced pressure. The optical rotation was measured for this purified sample. Absolute configuration and optical yield were calculated from known values.

A number of other asymmetric reductions using different reagents such as ketones and sugar derivatives were performed under conditions similar to those described above.

Reaction of $NaBH_4$ with $ZnCl_2$. THF suspension of $ZnCl_2$ (10 mmol) was added to a suspension of $NaBH_4$ (30 mmol) at 30 °C. The resulting slurry was stirred at 30 °C for 3 h. The solid was separated by filtration under a nitrogen atmosphere and dried at room temperature *in vacuo*. The filtrate contained 33% and 100% of initial sodium and zinc concentrations, respectively. The solid product was found to be sodium chloride by analysis. The filtrate showed Na:Zn:hydridic hydrogen in the ratio 1:1.00:12.3, analyzed by flame photometry, EDTA titration, and hydrogen evolution measurement, but no chloride.

In the communication, we used $[\alpha]_{D\ max}^{20}$ +34.8° (in diethyl ether) as maximum rotation of 1-phenyl-1-propanol which was quoted in *J. Chem. Soc., Perkin Trans. 1*, **1978**, 371. However, the value was found to be erroneous, the true value being $[\alpha]_{D\ max}$ 52±1° (in diethyl ether). Revision of the data for 1-phenyl-1-propanol is being made. During this study, the optical rotations of 1-phenyl-1-propanol were measured in acetone and the optical yields calculated by the observed and known maximum rotations reported by H. Kwart and D. P. Hoster, *J. Org. Chem.*, **32**, 1867 (1967). The optical yields thus obtained were found to agree reasonably with those obtained in neat, ethanol, and chloroform.

The Cycloaddition of Nitrilimines with 1,2-Dibenzoylethylenes

Tatsuo OIDA,† Tomio SHIMIZU, Yoshiyuki HAYASHI,* and Kazuhiro TERAMURA

Department of Dyeing, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Kyoto 606

(Received September 29, 1980)

The cycloaddition of nitrilimines with 1,2-dibenzoylethylenes gave an unexpected 1,3-diaryl-4-benzoylpyrazole and benzoic acid, along with an expected cycloadduct, 1,3-diaryl-4,5-dibenzoyl-2-pyrazoline, and its dehydrogenated product, 1,3-diaryl-4,5-dibenzoylpyrazole. The elimination of the benzoyl group from the pyrazoline followed by dehydrogenation was shown to be the course of the unusual reaction.

The 1,3-dipolar cycloaddition of diarylnitrilimines with olefins is a versatile method for the stereoselective and regioselective synthesis of 2-pyrazolines or pyrazoles.[1-4] Diarylnitrilimines for the cycloaddition with dipolarophiles are usually prepared *in situ* by the dehydrochlorination of hydrazonoyl chlorides with triethylamine[4] and by the other method.[5,6] 1,2-Dibenzoylethylenes, with particular reference to their geometrical isomerism, have been intensively investigated by Lutz and his collaborator;[7] the ethylenes are good dipolarophiles for the investigation of the stereochemistry of the cycloaddition.[8]

This paper will report that the cycloaddition of nitrilimines with 1,2-dibenzoylethylenes gave 4-benzoylpyrazoles in high yields, along with the expected products. For example, the reaction of *cis*-1,2-dibenzoylethylene with *N*-(*p*-nitrophenyl)-*C*-phenylnitrilimine gave the unexpected 4-benzoyl-1-(*p*-nitrophenyl)-3-phenylpyrazole as the sole isolable product in a 48% yield, with the elimination of a benzoic acid, probably from the 4,5-dibenzoyl-2-pyrazoline. There is no precedent for the oxidative elimination of benzoic acid from 4,5-dibenzoyl-2-pyrazoline. We now wish to propose a scheme in which the nucleophilic attack of water on the 5-carbonyl carbon of the pyrazoline followed by the elimination of benzoic acid yielded the 4-benzoylpyrazoline, which then eliminated hydrogen of afford the unexpected pyrazole.

a) The reaction was carried out by Procedure A (see Experimental).

Results and Discussion

The cycloaddition between *trans*-1,2-dibenzoylethylenes and diarylnitrilimines prepared from hydrazonoyl chlorides in the presence of an excess of triethylamine was carried out in benzene at 80 °C for 5 h. The reaction products from the reaction mixture were shown to be *trans*-1,3-diaryl-4,5-dibenzoyl-2-pyrazolines (**1**), 1,3-diaryl-4,5-dibenzoylpyrazoles (**3**), and unexpected 1,3-diaryl-4-benzoylpyrazoles (**2**) (Scheme 1, Table 1. See Tables 2—4 for the notation of Ar^1, Ar^2, and Ar^3).

It is well-known that the reaction of nitrilimines with *cis*- and *trans*-olefins gives 2-pyrazolines stereospecifically in high yields.[4] With some *cis*-olefins in the presence of a base, however, two possible *cis*- and *trans*-pyrazolines can be formed by the base-catalyzed isomerization of the *cis*-product to the *trans*.[8,9] The pyrazole (**2a**) was isolated in a 48% yield from the reaction mixture of *N*-(*p*-nitrophenyl)-*C*-phenylnitrilimine and *cis*-1,2-dibenzoylethylene, while neither *cis*- nor *trans*-pyrazoline (*cis*- or *trans*-**1a**) was detected. The expected *cis*-pyrazoline (*cis*-**1a**) may be directly decomposed to **2a**, because some of the *trans*-pyrazoline (*trans*-**1a**) would remain in the reaction mixture under the conditions if the base-catalyzed isomerization product, *trans*-pyrazoline (*trans*-**1a**) were an intermediate to **2a**.

The NMR spectroscopy is a convenient method for establishing the stereochemistry of the adduct (**1**), since the coupling constants between 4- and 5-protons indicate whether the adduct is *trans* (J=6 Hz) or *cis* (J=12 Hz),[10] although some exceptions are known.[11] Thus, the *trans* structure of the expected 1,3-dipolar cycloadducts, (**1**) was confirmed on the basis of elemental analyses and NMR ($J_{4,5}$=6 Hz) and IR spectra.

2-Pyrazolines can be easily aromatized by autoxidation or thermal dehydrogenation, even in the absence of oxygen, or by some reagents such as a hydrogenation

† Present address: Institute for Chemical Research, Kyoto Universty, Uji, Kyoto 611.

catalyst, although little is known about these mechanisms[4,12] and only a small amount of hydrogen was identified.[18] The pyrazoles (**3**) were shown to be products dehydrogenated from **1** by the following experiment: the treatment of **1a** in a refluxing toluene solution with a suspension of active alumina gave **3a** in a 54% yield.

The structure of the pyrazole (**2b**) was established by elemental analysis ($C_{23}H_{20}N_2O$), NMR (two tolyl methyl at δ 2.34, H-5 at δ 8.19) and IR ($\nu_{C=O}$ 1635 cm^{-1}) spectra, and comparison with an authentic sample described below. Enamine is a regioselective dipolarophile,[13] and the reaction of nitrilimines with 3-dimethylamino-1-phenylpropen-1-one gave unstable intermediate pyrazolines, which eliminated dimethylamine to afford pyrazoles (**2**).[14,15] The regioselective cycloaddition of nitrilimines with ethynyl phenyl ketone[2,16,17] and phenyl vinyl ketone[13] gave pyrazoles (**4**) and pyrazolines (**5**) respectively. The alkaline–potassium hexacyanoferrate(III) oxidation of **5** also gave pyrazole (**4**), a regioisomer of the pyrazole (**2a**)[12] (Scheme 2). We could not find any trace amount of **4** in the reaction mixture of the *N*-(*p*-nitrophenyl)-*C*-phenylnitrilimine with dibenzoylethylenes.

If the reaction of the nitrilimines with *trans*-dibenzoylethylene was carried out at room temperature under nitrogen by the careful exclution of moisture and work-up below 30 °C the expected 1,3-dipolar cycloadducts **1** were isolated in high yields (Table 2). The isolated pure 4,5-dibenzoyl-2-pyrazolines (**1**) are

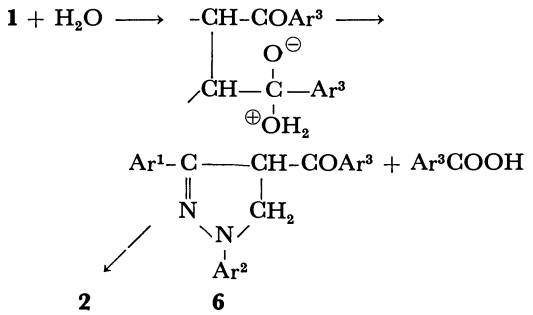
a) Pure **1c** could not be isolated.

thermally stable up to about 150 °C. However, the pyrolysis of **1** about 150 °C or the treatment of **1** with a base (and moisture) at about 80 °C gave **2** with appreciable rate.

To our knowledge, no pyrolysis of 4- or 5- (or 4,5-di-)benzoylpyrazolines which eliminates a benzoyl group to pyrazoles has yet been reported. The cycloadducts of the dibenzoylethylenes with nitrones[8a] and diazomethane[8b] are rather thermally stable. The pyrolysis of the pyrazolines (**1**) at 180 °C really gave the pyrazoles **2**) and benzoic acid. We tried to decompose several *trans*-2-pyrazolines (**1**) to **2** (3—75% yields) at 200 °C for 10 min (Table 3), although the reaction conditions used were not strictly the same.

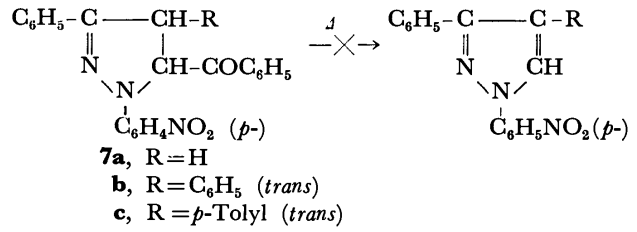
One can easily postulate the thermal elimination of benzaldehyde from **1** followed by the autoxidation of the benzaldehyde to produce the benzoic acid. However, all attempts to detect benzaldehyde, for example, by VPC, NMR, IR, and MS (the MS of **1a** was superimposable with that of an equimolar mixture of the **2a**, pyrazole, and benzoic acid), failed except for the one case to be described below. The careful exclusion of oxygen and moisture from the pyrolysis system under nitrogen decreased the yield of benzoic acid down to 35% along with a small amount of benzaldehyde (up to 10% yield), while the only decomposition products observed were the pyrazoles (**2**) and benzoic acid under usual conditions under nitrogen without strict drying over P_2O_5.

Benzaldehyde has been shown to react easily with aniline (or butylamine) to yield *N*-benzylideneaniline (or *N*-benzylidenebutylamine). No formation of any benzylideneamines in the pyrolysis products of **1a** in aniline (or butylamine) ruled out the formation of benzaldehyde as an intermediate. On the other hand, *N*-butylbenzamide (53% yield) and **2a** (62% yield) were isolated from the reaction mixture of **1a** in butylamine at 80 °C for 5 h, while benzoic acid is stable under the conditions. Furthermore, moisture and base enhanced the decomposition of **1** to **2**. The rate ratio of the decomposition of wet **1a** to that of dry **1a** was about 2. The decomposition of **1** to **2** in the presence of a small amount of water and triethyamine gave the pyrazole (**2**) in excellent yields (for example, **2a** in an 86% yield from **1a**) than the results shown in Table 3. Pyrazoline and pyrazole have some basic character; thus, the decomposition of **1** to **2** may be promoted by self-catalysis. Taking the results in butylamine into consideration, the acceleration of the pyrolysis rate by water can be explained if we assume that a reasonable first step involved the initial nucleophilic attack of water on 5-carbonyl carbon followed by the cleavage of the carbon-carbon bond to give 4-benzoylpyrazoline (**6**) (Scheme 3). Several attempts to prepare an authentic specimen of the intermediate, **6**, or to isolate it from the reaction mixture were fruitless; therefore, **6** may be thermally unstable and may undergo dehydrogenation to **2**. However, only a trace amount of hydrogen was detected in the pyrolysis products of **1a** by VPC (activated charcoal 5 m at 50 °C, carrier gas argon) and so far the fate of the hydrogen can not be identified.



Scheme 3.

Importance of two benzoyl groups at both 4- and 5-positions for the facile decomposition of **1** to **2** was shown by comparison with a series of 2-pyrazolines, where only the 5-position has a benzoyl group (Scheme 4). None of the compounds (**7a**—**c**) has a tendency to decompose thermally up to 250 °C under conditions where the pyrolysis of **1** occurs very easily. We have so far been able to find any definite explanations of the importance of the two benzoyl groups



Scheme 4.

on **1** in the facile transformation of **1** into **2**. One possible explanation is that the carbonyl-carbonyl interactions between the two benzoyl groups, along with steric hindrance, would facilitate the reactivity of the carbonyl carbon toward nucleophiles.

Experimental

All the melting points are uncorrected. The IR spectra were obtained on a Hitachi 215A Infrared Spectrophotometer. The ^{1}H-NMR spectra were measured of a Varian T-60A instrument in $CDCl_3$ unless otherwise stated, with TMS as an internal standerd. The column chromatography was carried over silica gel eluted with $CHCl_3$. All the new compounds reported here gave satisfactory elemental analyses.

Materials. The *N*-arylarenehydrazonoyl chlorides were prepared by the method of Huisgen *et al.*[4,9] The *trans*- and *cis*-1,2-dibenzoylethylenes were prepared by the method of Lutz et al.[7] The phenyl vinyl ketone and ethynyl phenyl ketone are commercially available (Nakarai Chem. Co.) and were used without further purification.

Reactions of Diarylnitrilimines with 1,2-Dibenzoylethylenes. General Procedure A: *N*-(*p*-Nitrophenyl)benzohydrazonoyl chloride (2.6 g, 9.5 mmol) as a precursor of the *N*-(*p*-nitrophenyl)-*C*-phenylnitrilimine was added, in small portions to a stirred solution of *trans*-1,2-dibenzoylethylene (2.3 g, 9.5 mmol) and triethylamine (2 ml) in benzene (50 ml) at 80 °C over a period of 30 min. The mixture was then stirred at 80 °C for 5 h. The precipitated triethylamine hydrochloride was filtered off, and the filtrate was evaporated *in vacuo*. The residue was crystallized from benzene to give the 2-pyrazoline (*trans*-**1a**; 0.96 g, 21%). The filtrate from the crystallization was chromatographed to give the pyrazole **2a** (1.6 g, 47%) and **3a** (0.45 g, 10%). The results are shown in Table 1. **1a**. Found: C, 73.48; H, 4.59; N, 8.58%. Calcd for $C_{29}H_{21}N_3O_4$: C, 73.25; H, 4.45; N, 8.84%. **2a**. Found: C, 71.89; H, 4.23; N, 11.11%. Calcd for $C_{22}H_{15}N_3O_3$: C, 71.53; H, 4.09; N, 11.38%. **3a**. Found: C, 73.47; H, 4.22; N, 8.91%. Calcd for $C_{29}H_{19}N_3O_4$: C, 73.56; H, 4.05; N, 8.88%.

General Procedure B: A solution of *N*-(*p*-nitrophenyl)benzohydrazonoyl chloride (1.1 g 4.0 mmol), *trans*-1,2-dibenzoylethylene (0.95 g, 4.0 mmol), and triethylamine (0.7 ml) in dry benzene (50 ml) was stirred at room temperature under nitrogen for 2 d. The triethylamine hydrochloride thus precipitated was filtered off, and the filtrate was evaporated *in vacuo* at below 30 °C. The residue was triturated with cold benzene to give the 2-pyrazoline (*trans*-**1a**, 1.5 g, 77%). **1** were recrystallized from DMF–H_2O without heating. The results are shown in Table 2.

Decomposition of 2-Pyrazolines (1). General Procedure: **1a** (0.57 g, 1.2 mmol) was heated in a sublimation apparatus at 200 °C for 10 min under reduced pressure (*ca.* 30 mmHg). Benzoic acid was thus isolated (0.088 g, 60%) as a sublimate. The residue was chromatographed to give **2a** (0.29 g, 65%) (and the recovered **1**). The results are shown in Table 3.

Detection of Benzaldehyde in the Pyrolysis products of 1a.

a) By NMR: **1a** was decomposed at 180 °C for 10 min in an NMR sample tube under N_2. The peak of benzaldehyde (δ 9.9, -CHO) was not detected, but the peak of benzoic acid (δ 12.7, -OH) was detected.

b) By MS: The strong peak of benzoic acid (m/e=122) appeared, while that of benzaldehyde (m/e=106) appeared very weak in the mass spectrum of **1a**.

c) By IR: A KBr pellet containing **1a** was heated at 180 °C for 10 min under N_2. The characteristic absorption of benzaldehyde (ν=2770 cm^{-1}) was not detected.

d) By VPC: When **1a** was analyzed by VPC (injection temperature 200—250 °C), only a trace amount of benzaldehyde was detected.

e) Decomposition of 1a after Thorough Drying: **1a** (0.81 g, 1.7 mmol) was dried over P_2O_5 under reduced pressure (2 mmHg) for 2 d; then the **1a** was decomposed at 200 °C for 10 min under 2 mmHg in a sealed vessel to give the sublimated benzoic acid (0.072 g, 35%) and the benzaldehyde (*ca.* 0.02 g, less then 10%). The residue was crystallized from $CHCl_3$–EtOH to give **2a** (0.33 g, 53%).

Decomposition of 1a in Aniline. A solution of **1a** (0.22 g, 0.46 mmol) and hydroquinone (0.1 g) in aniline (5 ml, distilled over KOH) was refluxed for 10 min under N_2. The reaction mixture was then poured into aq $NaHCO_3$ and extracted with benzene. The benzene layer was washed with aq $NaHCO_3$ several times. The water layer was separated, acidified with aq HCl, and extracted with ether. The ether was evaporated to give the benzoic acid (0.028 g, 50%). The benzene layer was washed with aq HCl several times and evaporated *in vacuo*. The residue was crystallized from $CHCl_3$–EtOH to give **2a** (0.14 g, 65%). Neither benzylideneaniline nor *N*-phenylbenzamide was detected in the reaction products by TLC.

Decomposition of 1a in butylamine. A solution of **1a** (0.52 g, 1.1 mmol) in butylamine (50 ml, distilled over CaH_2) was refluxed for 5 h under N_2. After the amine was evaporated under nitrogen and reduced pressure, the residue was distilled to give *N*-butylbenzamide (140—170 °C/0.1 mmHg, 0.10 g, 53%). The residue of the distillation was crystallized from $CHCl_3$–EtOH to give **2a** (0.23 g, 62%). Neither benzoic acid nor *N*-benzylidenebutylamine was detected in the reaction products by TLC.

Preparation of Pyrazole (2) from Enamine (Scheme 2a). General Procedure: A solution of *N*-(*p*-nitrophenyl)benzohy-

Table 4. Pyrazole (**3**)

	Ar^1	Ar^2	Ar^3	Yield / %	Mp / °C	IR (KBr) $\nu_{C=O}$/cm^{-1}

3c	C_6H_5	*p*-$NO_2C_6H_4$	*p*-Tolyl	51	143—148	1665
3e	C_6H_5	*p*-$NO_2C_6H_4$	Mesityl	38	150—155	1641
3f	C_6H_5	C_6H_5	C_6H_5	48	135—136	1668

drazonoyl chloride (1.4 g, 5.1 mmol), 3-dimethylamino-1-phenyl-2-propen-1-one (0.90 g, 5.2 mmol), and triethylamine (2 ml) in benzene (30 ml) was refluxed for 6 h. After a usual work-up, **2a** was recrystallized from $CHCl_3$–EtOH or DMF–H_2O in about a 30% yield.

Preparation of Pyrazole (3) from Pyrazoline (1). General Procedure: A solution of **1a** (0.44 g, 0.95 mmol) in toluene (50 ml) was refluxed with neutral aluminum oxide (5 g) until the solution was discolored (for about 5 h). The mixture was then filtered, and the filtrate was evaporated. The residue was crystallized from EtOH to give **3a** (0.23 g, 54%), which was then recrystallized from EtOH. The results are shown in Table 4.

Preparation of 2-Pyrazoline (7). General Procedure: A solution of *N*-(*p*-nitrophenyl)benzohydrazonoyl chloride (1.0 g, 3.7 mmol), phenyl vinyl ketone (0.57 g, 4.3 mmol), and triethylamine (2 ml) was stirred at room temperature for 2 d to give **7a** in a 88% yield; mp 242 °C (from EtOH). IR (KBr): 1698 cm^{-1} (C=O); NMR (DMSO-d_6) δ: 3.41 (dd, J=6 and 18 Hz, 1H, H-4), 4.17 (dd, J=12 and 18 Hz, 1H, H-4), 6.42 (dd, J=6 and 12 Hz, 1H, H-5). **7b** from *trans*-1,3-diphenyl-2-propen-1-one, 60% yield; mp 134—141 °C (from EtOH). IR (KBr): 1694 cm^{-1} (C=O); NMR ($CDCl_3$) δ: 4.66 (d, J=4 Hz, 1H, H-4), 5.71 (d, J=4 Hz, 1H, H-5). **7c** from *trans*-1-phenyl-3-*p*-tolyl-2-propen-1-one, 53% yield; mp 204—205 °C (from EtOH). IR (KBr): 1684 cm^{-1} (C=O); NMR ($CDCl_3$) δ: 4.61 (d, J=4 Hz, 1H, H-4), 5.67 (d, J=4 Hz, 1H, H-5).

Preparation of 5-Benzoyl-1-(p-nitrophenyl)-3-phenylpyrazole (4). Method A (Scheme 2b): A solution of *N*-(*p*-nitrophenyl)-benzohydrazonoyl chloride (0.69 g, 2.5 mmol), ethynyl phenyl ketone (0.33 g, 2.5 mmol), and triethylamine (1 ml) in benzene (50 ml) was stirred at room temperature for 20 h. After a usual work-up, the pyrazole was isolated in less than a 10% yield.

Method B (Scheme 2c): A solution of **7a** (0.26 g, 0.70 mmol) in EtOH (20 ml) was added to a solution of K_3-[Fe(CN)$_6$] (0.53 g, 1.6 mmol), and KOH (0.2 g) in aqueous EtOH (50 ml) at room temperature. The mixture was then stirred at room temperature for 10 h, poured into 200 ml of water, and extracted with benzene. The benzene layer was washed with water several times and concentrated. The residue was crystallized from EtOH to give the pyrazole (**4**) in a 28% yield; mp 164 °C (from EtOH). IR (KBr): 1670 cm^{-1} (C=O); NMR ($CDCl_3$); δ: 7.13 (s, 1H, 4-H). Found: C, 71.30; H, 4.04; N, 11.33%. Calcd for $C_{22}H_{15}N_3O_3$: C, 71.53; H, 4.09; N, 11.38%.

We would like to thank Professor Dr. Masaya Okano and Associate Professor Dr. Shigeo Tanimoto of Kyoto University for their valuable advice.

The Reaction of 2-Ethoxy-1,3-dithiolane with Carbonyl Compounds

Shigeo Jo,* Shigeo Tanimoto,* Tatsuo Oida, and Masaya Okano
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

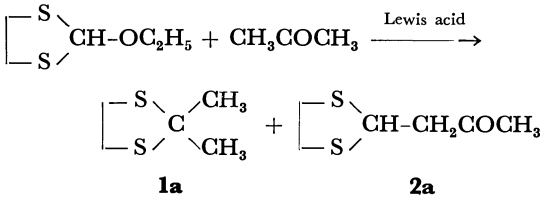
(Received October 4, 1980)

The reaction of 2-ethoxy-1,3-dithiolane with carbonyl compounds such as aldehydes and ketones was investigated. The reaction proceeded smoothly in the presence of the $HgCl_2$-catalyst to afford 2-substituted and 2,2-disubstituted 1,3-dithiolanes. The reaction also offers an interesting alternative to the previously reported methods of synthesizing 1,3-dithiolanes which involve the acid-catalyzed reaction of carbonyl compounds with 1,2-ethanedithiol.

Although the chemistry of 1,3-dithiolanes has been extensively studied, together with that of 1,3-dithianes,[1] little is known about the 2-alkoxy derivatives of these compounds, which have been described as five-membered cyclic orthodithioformates. This is mostly because the derivatives are sensitive to acidic reagents, especially to such inorganic acids as hydrochloric and sulfuric acids. For example, the addition of a trace amount of concd hydrochloric acid to 2-ethoxy-1,3-dithiolane resulted in an exothermic reaction leading to 2,2'-[1,2-ethanediylbis(thio)]bis-1,3-dithiolane.[2] A recent report[3] from this laboratory has described a new method for the introduction of the 1,3-dithiolan-2-yl group into some active methylene compounds. The reaction using 2-ethoxy-1,3-dithiolane proceeded smoothly without a solvent under the catalytic action of a metal halide, such as $ZnCl_2$ or $FeCl_3$, and 1,3-dithiolan-2-yl derivatives of the active methylene compounds could be isolated in moderately good yields. As a broadening of the synthetic scope of 2-ethoxy-1,3-dithiolane, we had chosen to react it with such carbonyl compounds as aldehydes and ketones. To date there has been no information on any reaction between one of the so-called cyclic orthodithioformates and carbonyl compounds.

Results and Discussion

It has been observed that the reaction of 2-ethoxy-1,3-dithiolane with aldehydes or ketones proceeds smoothly in the presence of a Lewis-acid catalyst to afford either 2-substituted or 2,2-disubstituted 1,3-dithiolane respectively. Thus, the successful utilization of the readily available 2-ethoxy-1,3-dithiolane in the synthetic reaction has been demonstrated. The first attempt was directed toward establishing the most effective Lewis-acid catalyst in the reaction. When 2-ethoxy-1,3-dithiolane was allowed to react with acetone in dichloromethane at room temperature for 16 h, in the presence of a Lewis-acid catalyst, the major product was 2,2-dimethyl-1,3-dithiolane (**1a**), accompanied by a comparatively small amount of 1-(1,3-dithiolan-2-yl)-2-propanone (**2a**). The results of the reaction with some different Lewis-acid catalysts are



1a **2a**

Table 1. Reaction of 2-ethoxy-1,3-dithiolane with acetone in the peesence of several different Lewis-acid catalysts

Run[a]	Catalyst (mmol)	Yield/%[b]	
		1a	**2a**[c]
1	$HgCl_2$(6)	60	0
2	$ZnCl_2$(30)	44	17
3	$BF_3 \cdot Et_2O$(15)	52	12
4	$FeCl_3$(6)	60	3
5	$AlCl_3$(6)	45	21

a) In all the reaction runs, 30 mmol of 2-ethoxy-1,3-dithiolane, 30 mmol of acetone, and 40—50 ml of dichloromethane were employed. Reaction conditions: room temperature, 16 h. b) Determined by gas-chromatographic analysis. c) Bp 100—101 °C/2 Torr (lit,[4] 143—145 °C/10 Torr), ^{1}H-NMR, δ (ppm from TMS, in $CDCl_3$), 4.77 (t, 1H, CH), 3.20 (s, 4H, SCH_2CH_2S), 3.00 (d, 2H, CH_2), 2.13 (s, 3H, CH_3). Found: C, 44.20; H, 5.99%. Calcd for $C_6H_{10}OS_2$: C, 44.41; H, 6.21%.

shown in Table 1.

As is evident from Table 1, the reaction using $HgCl_2$ as the catalyst resulted in the formation of **1a** in a 60% yield, while no **2a** was produced. Thus, we have studied the $HgCl_2$-catalyzed reaction of 2-ethoxy-1,3-dithiolane with a number of different aldehydes and ketones in the hope that the desired 2-substituted and 2,2-disubstituted 1,3-dithiolanes (**1**) could be exclusively made by the reaction with $HgCl_2$. The results are summarized in Table 2.

a) All yields refer to isolated products. Some starting 2-ethoxy-1,3-dithiolane was recovered in all runs. b) Carried out without any solvent. c) Carried out in a dichloromethane solvent.

As was originally anticipated, 2-substituted or 2,2-disubstituted 1,3-dithiolane (**1**), which is well known as a carbonyl-protective group,[5] was the sole product in the $HgCl_2$-catalyzed reaction. It was recognized by thin-layer chromatography that, even in the run involving a low yield of the product, the residue consists of the starting materials containing a small amount of an indefinite by-product. It should also be noted that the procedure is simple to carry out and applicable to a wide range of aldehydes and ketones.

It is obvious that an exclusive C–S bond fission occurred in the $HgCl_2$-catalyzed reaction of 2-ethoxy-1,3-dithiolane. Therefore, the first necessary step in the reaction would seem to be the coordination of $HgCl_2$ with one of the S atoms of the ring. Thus, a mechanism for the reaction was proposed involving, first, the formation of a resonance-stabilized sulfocarbonium ion, which would then combine with carbonyl carbon.

This seems probable on the basis of the information on the symbiotic effect on the HSAB principle presented by Pearson and Songstad.[6] In previous work on the reduction of 1,3-oxathiolanes with a mixture of $LiAlH_4$ and $AlCl_3$ in ether solution, Leggetter and

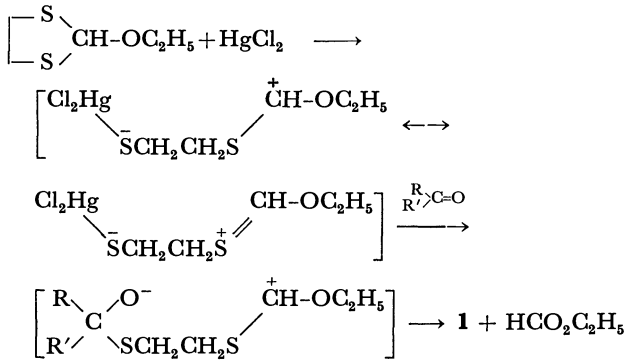
a) Purified by distillation. b) Purified by recrystallization (ethanol). c) Purified by recrystallization (hexane). d) Purified by both column chromatography and recrystallization (ethanol). e) Purified by both colume chromatography and distillation.



Brown[7] have found that the C–O, but not the C–S, bond is ruptured. This result suggests that the coordination of $AlCl_3$ with the O-atom is more favorable than the similar coordination of $AlCl_3$ with the S-atom. The formation of **2a** in the reaction of 2-ethoxy-1,3-dithiolane with acetone, using $AlCl_3$ as the catalyst, may be explained by a mechanism which involves the initial loss of the exocyclic ethoxyl group to give the 1,3-dithiolan-2-ium ion, and its subsequent attack on acetone. A similar coordination with the O-atom of 2-ethoxy-1,3-dithiolane leading to **2a** occurred in the end, but to a lesser extent, when $ZnCl_2$, $BF_3 \cdot Et_2O$, or $FeCl_3$ was used instead of the $AlCl_3$ catalyst. However, the major product formed in the reaction using these Lewis-acid catalysts is not **2a**, but **1a**, suggesting that the C–S bond fission in the starting 2-ethoxy-1,3-dithiolane is predominant. Because the only available evidence is that listed in Table 1, we are presently unable to establish a reasonable pathway to afford **1a** when these Lewis-acid catalysts are used. At least, as to the reaction with $AlCl_3$, which has a poor coordination ability with the S atom, **1a** might also be formed by another path involving the coordination[8] of $AlCl_3$ with acetone in the initial step of the reaction.

Such compounds as 2-substituted and 2,2-disubstituted 1,3-dithiolanes (**1**) can serve as protected aldehydes and ketones. They are commonly prepared by the acid-catalyzed reaction of carbonyl compounds with 1,2-ethanedithiol.[9] The present reaction offers an interesting alternative, because the protected carbonyl compounds are formed easily and under non-acidic conditions by the reaction of 2-ethoxy-1,3-dithiolane with carbonyl compounds.

Experimental

Preparation of 2-Substituted and 2,2-Disubstituted 1,3-Dithiolanes (1). General Procedure: To a mixture of 2-ethoxy-1,3-dithiolane (30 mmol) and an aldehyde (or ketone) (30 mmol) in dichloromethane (40—50 ml), was added $HgCl_2$ (6 mmol) at 0—5 °C. In some cases (Runs 1, 2, 3, 4, 5, 6, and 8) the dichloromethane solvent was omitted. The mixture was brought to room temperature, stirred for 24 h, and then poured into a mixture of ice water and ether. The ethereal layer was separated, and then it was combined with a dichloromethane extract of the aqueous phase. The organic layer was washed repeatedly with dilute aqueous $NaHCO_3$, and then with water, and dried ($MgSO_4$), a subsequent evaporation of the solvents gave a residue which was further purified by distillation, recrystallization or column chromatography on silica gel, using ether as the eluent.

Polarographic Studies on Oxygen Transport by Human Hemoglobin in Buffer Solutions

Katsumi HAYASHI and Masanosuke TAKAGI*

Department of Agricultural Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai, Osaka 591

(Received October 11, 1980)

Oxygen transport by human hemoglobin (Hb) to an electrode surface with hypo-oxygen partial pressure has been studied by the polarographic technique. The oxygen reduction current in Hb solution open to the atmosphere increased linearly with Hb concentration up to *ca.* 2 mM (1 M=1 mol dm^{-3}) heme. The current was ascribed to free and Hb bound oxygen. The increase in current with Hb concentration was attributed to the increasing oxygen supply to the electrode from oxygen bound Hb (oxyhemoglobin;oxyHb). Changes in temperature and pH largely affected the current, corresponding to the change in dissociation rate of oxygen from oxyHb. The relation between the current due to oxyHb and the apparent first order rate constant of the dissociation (k) measured by the stopped-flow method implies two different rate-determining steps of oxygen transport by Hb. When k exceeded *ca.* 60 s^{-1}, the limiting step altered from the dissociation of oxygen to the diffusion of Hb molecules. It is concluded that the oxygen transport by Hb on physiological conditions is controlled by the diffusion of Hb. The diffusion coefficient of Hb in 20 mM heme as found in erythrocytes was estimated to be 5.8×10^{-8} cm^2 s^{-1} at 25 °C and pH 7.4.

For better understanding of the oxygen transporting capacity of erythrocytes, it is important to clarify rate-determining factors of uptake or release of oxygen by erythrocytes. Hartridge and Roughton[1] reported that the observed half-time of the oxygen uptake by erythrocytes was 40 times greater than that by free hemoglobin (Hb) in a rapid mixing continuous flow apparatus. Since then, investigators[2-4] have suggested that the behavior of oxygen in Hb solution, particularly in concentrated solutions corresponding to those in erythrocytes, should be investigated. The mechanisms of the association of oxygen with Hb and also the dissociation, were extensively studied by static or kinetic methods.[5-8] However, few quantitative studies have been carried out on the oxygen transport by Hb, further by erythrocytes to the region with hypo-oxygen partial pressure, *viz.* the transport phenomena involving diffusion process. Spectrophotometric methods which have been used for studying various problems of oxygen binding to Hb, do not seem very effective for the transport phenomena.

Scholander,[9] and Wittenberg[10-12] proposed the idea of "facilitated oxygen diffusion" for describing the oxygen transport by Hb in solution. They measured the flux of oxygen passing through a millipore filter holding Hb by gas-liquid chromatography and suggested that the rate-determining factor is the translational diffusion of Hb molecules. Wyman[13] gave the theoretical explanation for the facilitated diffusion. However, the conditions for the clear demonstration of the diffusion-controlled oxygen transport have not so far been established.

We tried an electrochemical method for covering the shortcomings of the previous investigations. In our method, an electrode, to which an appropriate potential is applied, works as a model of biological surface on which oxygen is consumed immediately on its arrival, that is, the electrode generates a region with hypo-oxygen partial pressure. The diffusion of oxyhemoglobin (oxyHb) to the electrode surface may result in the dissociation of oxygen from oxyHb and the electrochemical reduction of the oxygen. The oxygen reduction current due to oxyHb (I_{Hb}) corresponds to the rate of oxygen transport by Hb to the electrode surface. Thus, by analyzing the current, it is possible to clarify the rate-determining factor of oxygen transport in Hb solution. The electrochemical method is also applicable to a relatively concentrated solution corresponding to that in erythrocytes, since the result obtained by the electrochemical method is not restricted by the concentration of Hb in the system. The optical measurements can not be applied to a solution of high concentration of Hb, without any modification of the conventional method.

In this study, we have applied the d.c.-polarographic method with a dropping mercury electrode to Hb solution. The rate-determining steps of oxygen transport to the electrode surface by Hb are discussed as regards the behavior of the reduction current of oxygen in Hb solution.

Experimental

Materials. Human Hb was prepared from fresh blood of donors. Erythrocytes were washed four times with 0.9% sodium chloride and hemolyzed by addition of an equal volume of distilled water and 0.4 volume of toluene and by vigorous shaking for 3 min. A clear Hb solution was obtained by centrifuging the mixture at 12000 rpm for 10 min. The resulting Hb solution was dialyzed for 20 h with renewal of a large volume of distilled water several times followed by centrifuging at 12000 rpm for 30 min. All the operations were carried out at 4 °C. The Hb concentration was measured with a Hitachi 323 recording spectrophotometer in term of the absorbance of oxyHb at 576 nm. Concentrated Hb solutions were obtained by centrifugal filtration through Amicon CF 25 membrane cones (Amicon Co., Lexington Mass.). Methemoglobin (metHb) was prepared by adding a slight excess of potassium ferricyanide to the dialyzed oxyHb and was again dialyzed for 20 h with renewal of a large volume of distilled water several times. Experiments were performed within a week from the completion of preparation. Reagents of analytical grade were used.

Polarographic Measurements. Polarograms were record-

ed with a Yanagimoto Polarograph Model PA 101. The dropping mercury electrode had the following characteristics: $m=1.91$ mg s^{-1}, $t=5.87$ s at open circuit in distilled water with 60 cm height of mercury reservoir. Saturated calomel electrode (SCE) was used as a reference electrode. All measurements were carried out in test solutions thermostated and under the oxygen partial pressure equilibrated with open atmosphere.

Kinetic Measurements. Over-all first order rate constants of oxygen dissociation from oxyHb were measured with a Yanagimoto SPU-1S stopped-flow spectrophotometer with a memoriscope. The light path of the cell was 10 mm. The dissociation of oxygen from oxyHb was forced by mixing Hb solution equilibrated with atmospheric oxygen with a sodium dithionite solution. The time course was followed by measuring absorbance at 576 nm. In most cases, the concentrations of Hb and dithionite after mixing were 50 μM (1 M=1 mol dm^{-3}) heme and 30 mM, respectively. The dithionite solution was freshly prepared for each run of experiments.

Results and Discussion

Oxygen Reduction Current in Hb Solution. Oxygen gives two reduction waves at dropping mercury electrode in supporting electrolyte solutions, corresponding to the following equations.[14]

$$O_2 + 2e + 2H^+ \longrightarrow H_2O_2 \quad (1)$$

$$H_2O_2 + 2e + 2H^+ \longrightarrow 2H_2O \quad (2)$$

The reduction current increased largely with addition of the Hb in electrolyte solution open to the atmosphere (Fig. 1). The increase of the current gives rise to a wave newly appearing between the lst and 2nd waves. This may be due to the catalytic reduction of O_2 to H_2O involving the dismutation of H_2O_2 to O_2 and H_2O by some catalase or peroxidase action of Hb itself or a trace amount of a contaminant having a catalytic activity,[15,16] at this potential, at which only the reduction (1) is expected electrochemically. The catalytic activities can not alter the value of the total reduction current of O_2 to H_2O (at -1.45 to -1.50 V *vs.* SCE), unless the total oxygen supply to the electrode changes. On addition of metHb which has no oxygen binding capacity, the total reduction current of oxygen was practically constant, though a catalytic phenomenon similar to that of Hb was observed. Thus, the increase of the total current (I) can be attributed to the reduction of oxygen transported by Hb, since the concentration of free oxygen in Hb solution should be constant, equilibrated with atmospheric oxygen. Considering the oxygen transport by Hb to the electrode with the above observations, we can utilize the potential at which the 2nd wave reaches its limiting current, *i.e.* from -1.45 to -1.50 V *vs.* SCE. The following description deals with the 4 electron transfer current of oxygen.

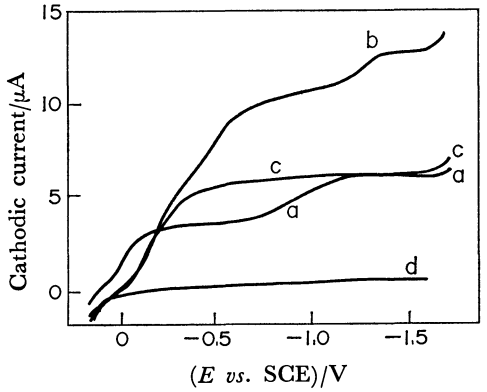

Fig. 1. Polarograms of oxygen reduction waves in electrolyte solutions open to the atmosphere.
a: Phosphate buffer (0.1 M, pH 7.4), b: a+Hb (2.3 mM heme), c: a+metHb (2.0 mM heme), d: b without oxygen. 25 °C.

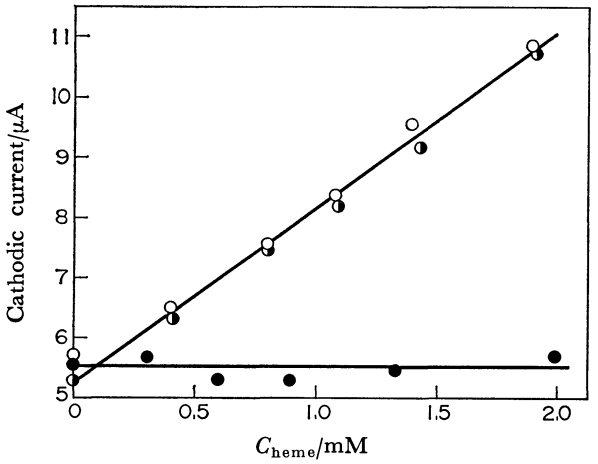

Fig. 2. Dependence of the reduction current of oxygen on the concentration of Hb without removing organic phosphates (○), stripped Hb (◐) and metHb (●) in phosphate buffer (0.1 M, pH 7.4) open to the atmosphere at 25 °C.

The dependence of I on the concentration of Hb is shown in Fig. 2. I is seen to increase linearly with Hb concentration. No appreciable difference between Hb prepared for the present study and stripped Hb prepared according to Benesch *et al.*,[17] could be observed. Thus, the subsequent experiments were carried out without removing organic phosphates from the Hb preparation. Since the current in metHb solution was almost constant, the increase of I in Hb solution might be due to the increasing supply of oxygen to the electrode by Hb. It seems that a flux of oxygen in Hb solution consists of the contributions from both free and Hb bound oxygen.[9-13] The current I might consist of the reduction currents of both:

$$I = I_{O_2} + I_{Hb}, \quad (3)$$

where I_{O_2} is diffusion current of free oxygen, and I_{Hb} the oxygen reduction current due to oxyHb. From Ilkovic equation,[18,19] we have

$$I_{O_2} = \kappa D_{O_2}^{1/2} C_{O_2}, \quad (4)$$

where $\kappa=607$ $nm^{2/3}$ $t^{1/6}$ with $n=4$, D_{O_2} and C_{O_2} being the diffusion coefficient and the concentration of free oxygen in the solution equilibrated with the atmospheric oxygen, respectively. In relatively dilute Hb solution, D_{O_2} and I_{O_2} might be nearly equal to those in the medium without Hb ($^*D_{O_2}$ and $^*I_{O_2}$, respectively). They can be regarded as constant under given conditions. The increase of I is due to only the increase of I_{Hb}, being directly proportional to the

concentration of Hb presented in heme (C_{heme}). Thus, I_{Hb} can be written as

$$I_{Hb} = \alpha C_{heme} Y, \quad (5)$$

where Y is fractional oxygen saturation of Hb. Under the present conditions we might put Y=1, since Hb solutions are equilibrated with the atmospheric oxygen partial pressure. α is a factor characterized by the rate-determining step of oxygen transport by Hb.

We can postulate two steps for α, (a) the diffusion process of Hb molecules bound oxygen to the electrode and (b) the oxygen dissociation from oxyHb in the vicinity of the electrode with hypo-oxygen partial pressure. When (a) is predominant, α might be proportional to the diffusion coefficient of Hb (D_{Hb}) and I_{Hb} might be the diffusion-controlled current. In (b) where the rate constant of oxygen dissociation (k) is included in α, I_{Hb} might be the kinetic current.[20,21] It seems that the alteration of the rate-determining step is practically caused by change in the rate of dissociation, since the D_{Hb} value does not change a great deal with temperature of pH, as compared with the dissociation step.

For the sake of confirmation we examined the effect of temperature and pH on I_{Hb}, since the oxygen dissociation rate is strongly dependent on the above two factors,[22,23] in contrast to the rate of oxygen combination with Hb which is little affected.[22]

Effects of Temperature and pH on I_{Hb}. Figure 3 shows the linear relationship between I_{Hb} (Eq. 3) and C_{heme} at various temperatures open to the atmospheric oxygen. The slope of the curve, I_{Hb}/C_{heme} *i.e.* α (Eq. 5) increases with temperature. The plot of α (slope of the curve, Fig. 3) against temperature indicates that α depends on the oxygen dissociation rate which changes with temperature (Fig. 4-a). The relation between the reciprocal temperature and logarithms of α obtained is shown in Fig. 4-b. When the rate-determining step of I_{Hb} is single, a straight line should be obtained. However, a bending curve with two different slopes was obtained indicating that I_{Hb} is controlled by at least two different steps. The apparent activation energy of each step was found to be 83.7 and 29.7 K J mol^{-1} for the lower and higher temperature ranges, respectively. Since the value of the former is in line with that of oxygen dissociation reported by Gibson[23] and Dalziel and O'Brien,[24] and our Arrhenius plot of stopped-flow data also gave 79.1 K J mol^{-1} as the activation energy, one of these steps might be oxygen dissociation, which turns to another step at the inflection point on the curve *i.e.* about 22 °C (at pH 7.4).

The change in pH also resulted in the variation in α (Fig. 5). The pattern of the variation is similar to that of the Bohr effect[25] which reflects the change in the dissociation rate of oxygen from oxyHb, and gives a symmetrical curve with pK'=7.0, when k is plotted against pH.[24] The change in I_{Hb} with pH can be ascribed to that in the rate of dissociation of oxygen from oxyHb. In order to clarify the rate-determining step for I_{Hb}, effects of temperature and pH were examined on the basis of the dissociation rate of oxygen at various temperatures or pH.

Figure 6 shows the relation between α and k obtained by the stopped-flow method, carried out by

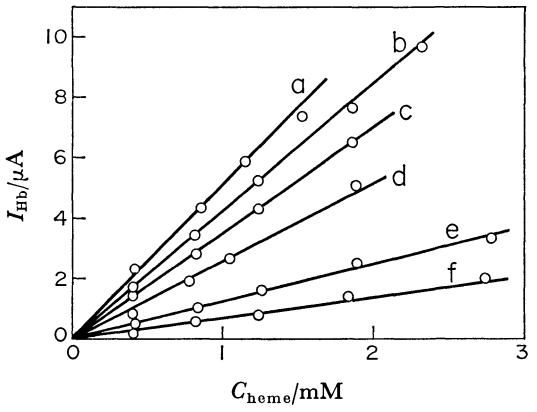

Fig. 3. Relation between I_{Hb} and relatively low concentration of Hb at various temperatures open to the atmosphere.
a: 40 °C, b: 35 °C, c: 30 °C, d: 25 °C, e: 15 °C, f: 12.5 °C. Other conditions are the same as in Fig. 2. I_{Hb} was obtained by subtracting $*I_{O_2}$ from I.

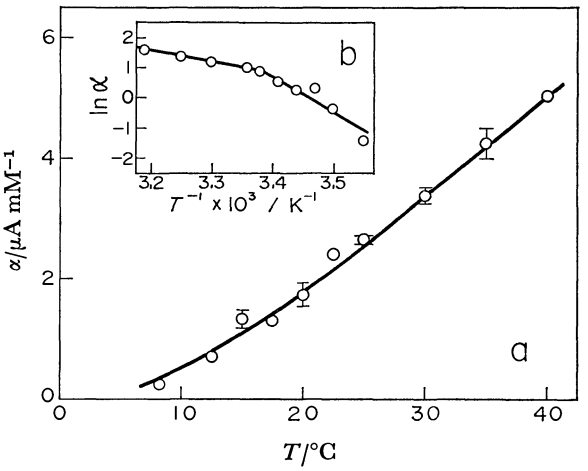

Fig. 4. Effect of temperature on α (a) and plots of logarithms of α against the reciprocal temperature (b).
α is I_{Hb}/C_{heme} or $(I-*I_{O_2})/C_{heme}$, and was obtained as the slope of the curve in Fig. 3.

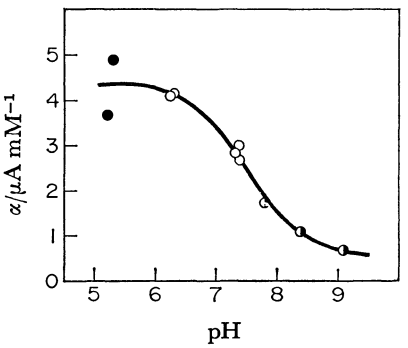

Fig. 5. Effect of pH on α.

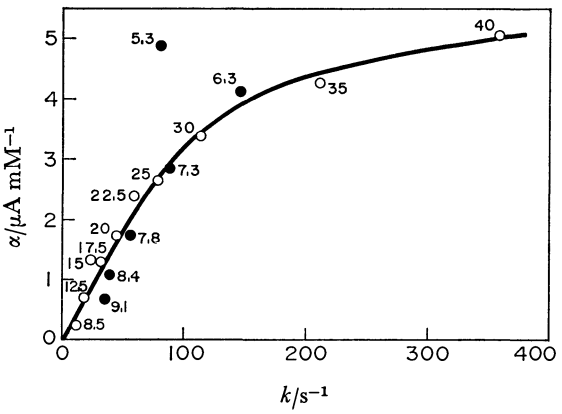

Fig. 6. Plot of α against apparent first order rate constant of oxygen dissociation from oxyHb (k). ○: Temperature effect at pH 7.4 (see Fig. 4-a), ●: pH effect at 25 °C (see Fig. 5). Numbers with experimental points are temperature (°C) (○) or pH (●) at which α and k were measured by polarography and by stopped-flow method, respectively.

TABLE 1. DIFFUSION COEFFICIENTS OF Hb(D_{Hb}) OBTAINED POLAROGRAPHICALLY AND APPARENT FRST ORDER RATE CONSTANTS OF OXYGEN DISSOCIATION FROM oxyHb (k) OBTAINED BY STOPPED-FLOW METHOD

k/s^{-1} (T/°C, pH)[a]	$D_{Hb}/10^{-7}$ cm² s⁻¹
78.4 (25, 7.4[b])	2.8
81.6 (25, 5.3[c])	9.4
114.0 (30, 7.4[b])	4.4
148.4 (25, 6.3[b])	7.0
209.1 (35, 7.4[b])	6.2
357.8 (40, 7.4[b])	7.6

a) Conditions for kinetic measurements. b) 0.1 M phosphate buffer. c) 0.1 M acetate buffer.
Values of k (Fig. 6) are given in increasing order, irrespective of experimental conditions. D_{Hb} is the value corrected for 25 °C, though each actual measurement was carried out at the temperature for the corresponding k measurement.

changing temperature at a fixed pH or changing pH at a constant temperature. A satisfactory coincidence could be obtained for the results of two series of different kinds of experiments. The curve obtained implies two rate-determining factors for oxygen transport by Hb to the electrode surface. At relatively small k values, where I_{Hb} is proportional to k, the rate-determining step is the dissociation of oxygen. When k value exceeds *ca.* 60 s^{-1}, where I_{Hb} is not appreciably affected by k, the dissociation is no longer rate-determining, and is replaced by the diffusion of Hb to the electrode. This can be supported by the following observation: current I is almost a diffusion current in the range beyond the k around 60 s^{-1}, while it obviously contains characteristics of kinetic current[20,21] up to the k value. This is in line with the idea of Wittenberg[11] and Wyman[13] who treated the oxygen transport by Hb in terms of translational diffusion of Hb and the oxygen dissociation from oxyHb. A slight increase in α with k in the diffusion-controlled region can be understood as due to the increase in D_{Hb} with temperature. The diffusion-controlled transport of oxygen should be confirmed by comparing the D_{Hb} value estimated from I_{Hb} with the published data.

In the diffusion-controlled region, D_{Hb} is involved in α. I_{Hb} can be expressed from Ilkovic equation,[18,19] by

$$I_{Hb} = \kappa D_{Hb}^{1/2} C_{heme}. \quad (6)$$

I_{O_2} can not be measured directly, but it can be estimated by

$$I_{O_2} = (D_{O_2}/{}^*D_{O_2})^{1/2} {}^*I_{O_2}, \quad (7)$$

where ${}^*I_{O_2}$ is I measured in the medium without Hb, and is given by

$${}^*I_{O_2} = \kappa {}^*D_{O_2}^{1/2} C_{O_2}. \quad (8)$$

Combining Eqs. 3, 6, 7, and 8, we obtain

$$I/{}^*I_{O_2} = (D_{O_2}/{}^*D_{O_2})^{1/2} + C_{O_2}^{-1}(D_{Hb}/{}^*D_{O_2})^{1/2} C_{heme}. \quad (9)$$

The value D_{Hb} at a given concentration can be estimated by means of the equation, substituting D_{O_2} value for given Hb concentration and other measured values. In practice, the value D_{Hb} in relatively dilute concentration range was obtained using α obtained experimentally for diffusion-controlled region under the assumption of $D_{O_2} = {}^*D_{O_2}$†. The value D_{Hb} obtained experimentally agrees with the reported values $6-7\times10^{-7}$ cm² s^{-1}, irrespective of the increase of k with either temperature or with pH (Table 1). The result might support the validity of the assumption that the rate-determining step for I_{Hb} changes from the dissociation of oxygen to the diffusion of Hb with increase in k.

A relatively large deviation of the experimental point at pH 5.3 and 25 °C in acetate buffer from the curve drawn through other experimental points (Fig. 6) can be explained by the contribution of an apparent increase of D_{Hb} with the dissociation of tetramer to dimer or further monomer of Hb (Table 1), since such dissociation was observed more readily in acetate buffer than in other buffer at pH 5.3.[28,29]

Under the physiological conditions (pH 7.4, 37 °C), the oxygen transport by Hb is restricted by the diffusion rate of Hb molecules (Fig. 6). It is of interest to examine whether the relation (Fig. 6) is also applicable to a relatively concentrated solution of Hb. Figure 7 shows the relation between k and α at 18 mM heme of Hb concentration. A similar relation to that in Fig. 6 was obtained, the same k values being used,

† Equation 9 is simplified as
$$I/{}^*I_{O_2} = 1 + C_{O_2}^{-1}(D_{Hb}/{}^*D_{O_2})^{1/2} C_{heme}.$$
Further modification gives
$$C_{O_2}(I - {}^*I_{O_2})/(C_{heme}\,{}^*I_{O_2}) = (D_{Hb}/{}^*D_{O_2})^{1/2}.$$
Since $(I - {}^*I_{O_2})/C_{heme}$ is α (Fig. 4), we have
$$\alpha C_{O_2}/{}^*I_{O_2} = (D_{Hb}/{}^*D_{O_2})^{1/2}.$$
Thus
$$D_{Hb} = {}^*D_{O_2}(\alpha C_{O_2}/{}^*I_{O_2})^2.$$
The value 2.0×10^{-5} cm² s^{-1} was used for ${}^*D_{O_2}$ at 25 °C in the present study, since similar values were reported for various electrolyte solutions at 20—25 °C.[26,27] The C_{O_2} value was taken from International Critical Tables. ${}^*I_{O_2}$ was obtained experimentally.

since the oxygen affinity of Hb is little affected by the variation of Hb concentration.[30] The observation enables us to consider that the behavior of oxygen in a relatively concentrated solution of Hb such as in erythrocytes is also restricted by the diffusion of Hb and not by the dissociation of oxygen from oxyHb.

In the following we examine the behavior of oxygen in concentrated solution of Hb corresponding to that in erythrocytes in term of D_{Hb}, since the value D_{Hb} in various concentrations can be calculated by Eq. 9, when I is diffusion-controlled.

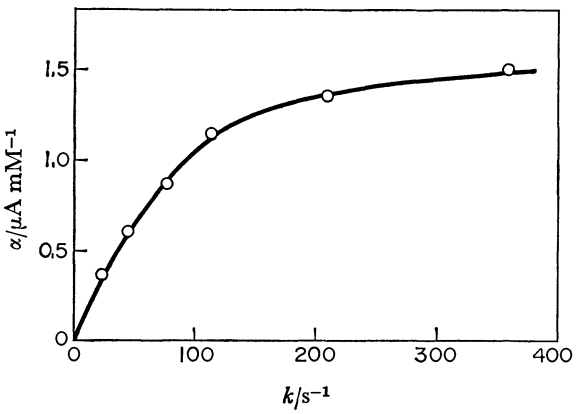

Fig. 7. Relation between apparent first order rate constant of oxygen dissociation from oxyHb (k) and α in a relatively concentrated Hb solution.
Hb concentration: 18 mM heme. α was obtained from the measurements at various temperatures at pH 7.4. The k values are the same as in Fig. 6. Other conditions are the same as in Fig. 2.

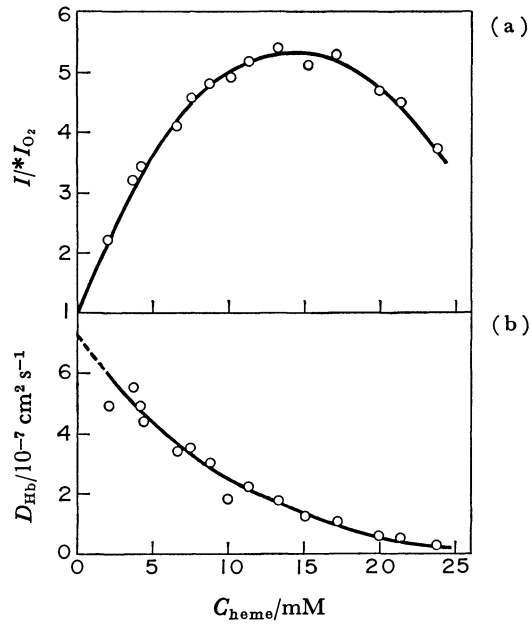

Fig. 8. Hb concentration dependence of $I/{}^*I_{O_2}$ (a), and diffusion coefficient of Hb (D_{Hb}) (b), in a relatively wide concentration range. D_{Hb} values were calculated by using Eq. 8 with $C_{O_2}=0.26$ mM and ${}^*D_{O_2}=2.0\times10^{-5}$ cm^2 s^{-1}. See the text for detail of estimation of D_{Hb}. Other conditions are the same as in Fig. 2.

D_{Hb} *in Concentrated Solution of Hb.* Figure 8-a shows the relation between $I/{}^*I_{O_2}$ and C_{heme} over a wide concentration range at pH 7.4 and 25 °C. The linear current increase with C_{heme} (Fig. 2 or 3) was observed only up to *ca.* 2 mM of C_{heme}, beyond which the current increase, whose maximum was around 14 mM, was lowered. This can not be attributed to the change in oxygen affinity of Hb, but to the decrease of D_{Hb} due to the increase of viscosity of the solution with C_{heme}. A similar observation has been reported by Wittenberg[11] by means of millipore filter method. However, no estimation was given on D_{Hb} in various concentration of Hb necessary for the demonstration of the diffusion-controlled oxygen transport. We can calculate D_{Hb} by substituting the $I/{}^*I_{O_2}$ value (Fig. 8-a) into Eq. 9, since we can expect diffusion current for oxygen reduction. In a relatively concentrated solution of Hb, D_{O_2} can not be identical with ${}^*D_{O_2}$. Hence, we employed the D_{O_2} value used by Roughton,[2] who estimated it in Hb solution, by comparison with D of nitrogen in a similar Hb solution. The relation between D_{Hb} obtained and C_{heme} in the present experiments is shown in Fig. 8-b. The increase of C_{heme} gave rise to a large decrease in D_{Hb}. The intercept on the ordinate of the curve passing through points experimentally obtained gave *ca.* 7×10^{-7} cm^2 s^{-1}, corresponding to the value known as D_{Hb} in dilute solution. In 20 mM Hb solution, *viz.*, equivalent concentration in erythrocytes, D_{Hb} is *ca.* 5.8×10^{-8} cm^2 s^{-1}. This is in agreement with 6.4×10^{-8} cm^2 s^{-1} obtained by Kreuzer.[31] The fact that the D_{Hb} obtained is 300 times smaller than ${}^*D_{O_2}$, suggests that oxygen in erythrocytes can move only with about one-three hundredth mobility of oxygen outside erythrocytes.

Selective Oxidation of Unsymmetrical Thiosulfinic S-Esters to the Corresponding Thiosulfonic S-Esters with $NaIO_4$[1]

Toshikazu TAKATA, Yong Hae KIM,[2] and Shigeru OAE*
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305

(Received October 17, 1980)

Unsymmetrical thiosulfinic S-esters were oxidized with sodium metaperiodate in aqueous media to the corresponding unsymmetrical thiosulfonic S-esters nearly quantitatively. The oxidation was accelerated by addition of a catalytic amount of inorganic and organic acids or halogen. Sulfinic esters were produced competitively along with the thiosulfonic S-esters in the oxidation of thiosulfinic S-esters in aqueous alcohol. However, unsymmetrical disulfides were not oxidized selectively to the corresponding unsymmetrical thiosulfonic S-esters but a mixture of both symmetrical and unsymmetrical thiosulfonic S-esters was obtained.

We have recently reported that oxidations of unsymmetrical thiosulfinic S-esters with peroxy acid[3] or dinitrogen tetraoxide[4] afforded the corresponding symmetrical thiosulfonic S-esters which were undoubtedly derived by the cleavage of sulfur-sulfur bond. A few previous studies[3,5] on the oxidations of thiosulfinic S-esters with some peroxy acids or peroxides revealed that none of these oxidations resulted in the selective oxidation of unsymmetrical thiosulfinic S-ester to the corresponding unsymmetrical thiosulfonic S-ester with no apparent cleavage of sulfur-sulfur bond. The oxidation of linear unsymmetrical thiosulfinic S-ester generally afforded both symmetrical and unsymmetrical thiosulfonic S-esters (Eq. 1). Only the oxidation of a six-membered cyclic thiosulfinic S-ester with peroxy acid was found to proceed without any apparent cleavage of sulfur-sulfur linkage to afford two unsymmetrical thiosulfonic S-esters in good yields.[6a]

$$\mathrm{RSSR'} \xrightarrow{[O]} \mathrm{RS(O)SR'} + \mathrm{RSS(O)R'} + \mathrm{RS(O)SR} + \mathrm{R'S(O)SR'} \quad (1)$$

In attempts to detect imaginary "α-disulfoxide (RS(O)S(O)R')" which is considered to be formed initially in the oxidation of thiosulfinic S-ester but too unstable to be observed, Barnard[5a] and Kice *et al.*[5c] have carried out the oxidation of unsymmetrical thiosulfinic S-esters and obtained a mixture of thiosulfonic S-esters, resulting from the initial oxidation, subsequent cleavage of the disulfide linkage, and the recombination.

However, surprisingly, when sodium metaperiodate ($NaIO_4$) was used as an oxidant, many unsymmetrical thiosulfinic S-esters were found to be oxidized selectively to the corresponding unsymmetrical thiosulfonic S-esters in aqueous media such as dioxane–water under mild conditions, with no apparent cleavage of sulfur-sulfur bond. This paper describes this new selective oxidation in detail.

Results and Discussion

$NaIO_4$ Oxidation. When an unsymmetrical thiosulfinic S-ester **1** was treated with an equimolar amount of sodium metaperiodate, only one product, *i. e.* the corresponding unsymmetrical thiosulfonic S-ester **2**, was found to be obtained. The reaction was also found to be accelerated by addition of a catalytic amount of inorganic or organic acid as well as iodine. Selected results are listed in Table 1.

$$\mathrm{R\text{-}S(O)\text{-}S\text{-}R'} \xrightarrow[\text{aqueous solvent, r.t., Cat.}]{NaIO_4} \mathrm{R\text{-}S(O)_2\text{-}S\text{-}R'} \quad (2)$$

1 → **2** ≈100%

1a	R=Ph, R'=Ph	**1f**	R=Et, R'=Ph
1b	R=Ph, R'=*p*-Tol	**1g**	R=Ph, R'=Pr
1c	R=*p*-Tol, R'=Ph	**1h**	R=Me, R'= 
1d	R=Ph, R'=Me	**1i**	*p*-Tol, R'=Me
1e	R=Me, R'=Ph	**1j**	*p*-ClC_6H_4, R'=Me

Following is a typical run. A solution of $NaIO_4$ (1.2 mmol) in water (2.0 ml) was added into a dioxane solution (3.5 ml) containing thiosulfinic S-ester (**1**, 1.0 mmol) at room temperature. To the resulting mixture a small amount of a catalyst (*e. g.* concd HCl, 1 or 2 drop) was added. After stirring the mixture for *ca.* 30 min at the room temperature or until the solution turned to dark brown, the highly pure unsymmetrical thiosulfonic S-ester **2** was obtained nearly quantitatively by extraction of the reaction mixture. The product generally showed only one component on GC, LC, TLC, or NMR. The yield of the product was determined by isolation through column chromatography or GC. New products were identified by comparing their IR and NMR spectra with those of authentic samples prepared by a known method[7] which is the condensation of sulfinic acids and sulfenyl chlorides in the presence of a tertiary amine. The starting thiosulfinic S-ester **1** were prepared by the condensation of the corresponding sulfinyl chlorides and thiols in the presence of pyridine in carbon tetrachloride at a temperature lower than 0 °C, according to the method of Backer *et al.*[8] The purification of **1** was carried out by recrystallization or column chromatography, while the identification was performed by several spectra and elemental analysis, as described in "Experimental Section."

As shown in Table 1, thiosulfinic S-esters of various types were oxidized to the corresponding thiosulfonic S-esters without cleavage of sulfur-sulfur linkage. Electrophilic catalysts highly accelerated the reaction while the reaction usually had a long induction period without any catalyst. Yields of the unsymmetrical thiosulfonic S-esters were nearly quantitative regardless

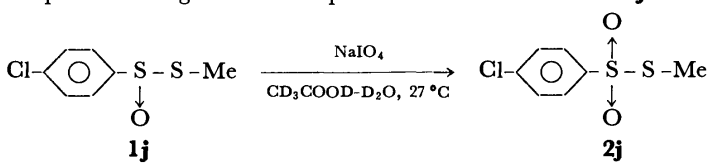
Fig. 1. Spectral change in NMR spectra in the oxidation of **1j** with $NaIO_4$.



1j **2j**

of the substituent.

No detectable intermediate was observed in the NMR study of the oxidation of thiosulfinic *S*-ester **1j** with $NaIO_4$ in CD_3COOD–D_2O as shown in the following Fig. 1. Methyl signal at 2.33 ppm (from external TMS) of **1j** gradually changed to the signal at 2.26 ppm which is identical to that of **2j**. No other peak of methyl group was observed in the NMR spectra throughout the reaction. An interesting relationship found between the two unusual chemical shifts of **1** and **2** in which the chemical shift of **1j** is lower than that of **2j**, has been re-confirmed.[9]

Effects of Catalyst and Solvent. The oxidation was found to be accelerated by addition of a catalytic amount of organic or inorganic acid or halogen. While weaker acids such as acetic and formic acids than trifluoroacetic acid (pK_a 1.0) did show little catalytic ability, the oxidation was accelerated in acetic acid as solvent even without catalyst. Catalysts effective in the oxidation are the following: CF_3COOH, H_2SO_4, HIO_4, $HClO_4$, HCl, I_2, and Br_2, as shown partially in Table 2. The catalytic activity of iodine found in this reaction was already noticed in the oxidation of cyclic disulfide to the corresponding thiosulfonic *S*-ester with KIO_4 by Field and Kim.[10] Solvents used were dioxane, acetonitrile, and acetone, all of which can mix freely with water. Acetic acid was effective not only as a solvent but also as a catalyst and hence the best system for the oxidation. Alcohols were not effective because the competitive reaction of **1** with the alcohols took place, as described later.

If no catalyst was used, the reaction occurred suddenly with coloring by iodine derived from $NaIO_4$ after a long induction period (5—10 h) and finished within 1 h as in the case with catalyst, due mainly to the catalytic action of iodine accumulated. Figure 2 indicates the rate of disappearance of **1c** in the oxidation with $NaIO_4$ as monitored by LC. Appearance of color of iodine was in accordance with the initiation of the reaction. The reaction is presumed to be an auto-catalyzed reaction with iodine formed since iodine increases as the reaction proceeds.

Table 2. Effects of catalyst and solvent (20 °C)

Substrate	Solvent	Catalyst	Time/h	Yield of products/%[a]

2c

Reaction in Aqueous Alcohol. The oxidation of **1d** with $NaIO_4$ in aqueous alcohol resulted in the competitive formation of the sulfinic ester of the alcohol along with that of the usual oxidation product of thiosulfonic *S*-ester **2d** (Eq. 3). When three different alcohols of varying bulkiness, *i.e.* ethanol, isopropyl alcohol and *t*-butyl alcohol were used as solvents, the amount of the sulfinic ester **3** produced was found

* Reaction catalyzed by concd HCl within 1 h.

to decrease in the following order: ethanol>isopropyl alcohol>*t*-butyl alcohol, which is the order of bulkiness as well as the nucleophilicity of the alcohols used. The distribution of products changed little in the acid-catalyzed reaction (parentheses). Sulfinic esters (**3**) were not oxidized at all under these conditions. GC analysis confirmed that the symmetrical disulfide is derived only from the sulfenyl part. The disulfide was considered to be produced from the thiol formed during the reaction involving nucleophilic attack of alcohol to **1**. The thiol thus formed should be oxidized immediately to the corresponding disulfide under the conditions.

Reaction of Disulfide with $NaIO_4$. When an unsymmetrical disulfide, methyl phenyl disulfide **5**, was treated with two molar amount of $NaIO_4$ under the same conditions, the following two symmetrical thiosulfonic *S*-esters (**6** and **7**) were obtained as major products which are undoubtedly derived by the cleavage of sulfur-sulfur bond, along with $PhSSO_2Me$ (**8**) (Eq. 4). By direct observation of NMR spectral change in the reaction of **5** with 2 equiv. $NaIO_4$ in CD_3COOD-D_2O at 27 °C, the cleavage of sulfur-sulfur bond was found to occur at the beginning of the reaction and is competitive with the oxidation

$$\underset{\mathbf{5}}{\text{Ph-S-S-Me}} \xrightarrow[\text{dioxane-}H_2O,\ \text{r.t.}]{\text{2 equiv. } NaIO_4} \underset{\mathbf{6}\ 27\%}{PhSSO_2Ph} + \underset{\mathbf{7}\ 25\%}{MeSSO_2Me} + \underset{\mathbf{8}\ 31\%}{PhSSO_2Me} \quad (4)$$

of sulfur atom, since all the methyl signals of dimethyl disulfide and the starting disulfide and those attached to sulfinyl and sulfonyl groups were observed simultaneously during the reaction. Meanwhile, oxidation of a mixture of diphenyl disulfide and dimethyl disulfide with $NaIO_4$ under the same conditions as in the above NMR study, also afforded an unsymmetrical and two symmetrical thiosulfonic *S*-esters (Eq. 5).

$$\left.\begin{matrix}\text{PhSSPh}\ \ \mathbf{9}\\ \text{MeSSMe}\ \ \mathbf{10}\end{matrix}\right\} \xrightarrow[\substack{CD_3COOD\text{-}D_2O\\ 27\,^\circ C\ (NMR)}]{\text{4 equiv. } NaIO_4} \underset{\mathbf{8}}{PhSSO_2Me} + \underset{\mathbf{7}}{MeSSO_2Me} (+ \underset{\mathbf{6}}{PhSSO_2Ph}) \quad (5)$$

Thus, any unsymmetrical thiosulfinic *S*-ester can be selectively oxidized to the corresponding unsymmetrical thiosulfonic *S*-ester nearly quantitatively in this oxidation with $NaIO_4$.

Obviously the oxidation of thiosulfinic *S*-ester with $NaIO_4$ is entirely different from that with peracetic acid which proceeds *via* formation of "α-disulfoxide,"[3] which is so unstable to collapse immediately yielding the corresponding four symmetrical and unsymmetrical thiosulfonic *S*-esters by the cleavage of sulfur-sulfur bond. In fact, in order to confirm the difference, the oxidations of 3-methyl-1,2-dithiane 1-oxide, a six-membered unsymmetrical thiosulfinic *S*-ester, were carried out with both $NaIO_4$ and peroxy acid, and the clear difference between products of two oxidations was confirmed.[6] This new selective oxidation of thiosulfinic *S*-ester with $NaIO_4$ appears to proceed by the nucleophilic attack of the periodate on the sulfinyl sulfur atom to form the corresponding thiosulfonic *S*-ester.

Experimental

General. Chemicals were of reagent grade unless otherwise specified. All melting points were measured by Yanaco instrument and were uncorrected. IR spectra were taken on a Hitachi 215 spectrophotometer. NMR spectra of the compounds were taken with a Hitachi Perkin-Elmer R-20 spectrometer in $CDCl_3$ using TMS as an internal standard. Mass spectra were taken with a Hitachi RMU-6MG mass spectrometer. Shimadzu GC-6A instrument was used for gas chromatography using N_2 gas as a carrier gas. High pressure liquid chromatography was carried out with Yanaco L-1030 instrument using methanol as an eluent. Elemental analyses were carried out by the Chemical Analysis Center at this university.

Preparation of Thiosulfinic S-*Ester.* Both symmetrical and unsymmetrical thiosulfinic *S*-esters were prepared by the method reported by Backer and Kloosterziel[8] with rather little modification. Namely, addition of a thiol into a distilled sulfinyl chloride in CCl_4 under cooling at a temperature lower than 0 °C gave thiosulfinic *S*-ester (85—90%). The thiosulfinic *S*-ester was identified by comparing melting point with that reported previously, IR spectrum, and NMR spectrum, and elemental analysis.

S-*Phenyl Benzenethiosulfinate* **1a**: Pale yellow crystals; mp 69—70 °C (lit,[11] 69—70 °C); IR ($CHCl_3$, cm^{-1}) 3055, 1577, 1475, 1093, and 1060 (S=O).

S-p-*Tolyl Benzenethiosulfinate* **1b**: Pale yellow crystals; mp 70—71 °C (lit,[11] 68 °C); IR ($CHCl_3$, cm^{-1}) 3050, 1590, 1470, 1095, and 1055 (S=O).

S-*Phenyl* p-*Toluenethiosulfinate* **1c**: Pale yellow crystals; mp 82 °C (lit,[11] 83—84 °C); IR ($CHCl_3$, cm^{-1}) 3050, 1590, 1470, 1095, and 1065 (S=O).

S-*Methyl Benzenethiosulfinate* **1d**: Colorless crystals; mp 26—28 °C; IR (neat, cm^{-1}) 3050, 2975, 2900, 1570, 1470, 1095, and 1060 (S=O) (lit,[12] 1104 (in CCl_4)).

S-*Phenyl Methanethiosulfinate* **1e**: Colorless oil; IR (neat, cm^{-1}) 3050, 2980, 2900, 1570, 1470, and 1090 (S=O), (lit,[12] 1101 (in CCl_4)).

S-*Phenyl Ethanethiosulfinate* **1f**: Pale yellow oil; IR (neat, cm^{-1}) 3050, 1575, 1473, 1440, and 1085 (S=O); NMR ($CDCl_3$, δ) 1.41 (3H, t, $-CH_3$, J=7.5 Hz), 3.10 (2H, q, $-CH_2-$, J=7.5 Hz), 7.20—7.73 (5H, m, arom.). Found: C, 51.53; H, 5.50%. Calcd for $C_8H_{10}OS_2$: C, 51.58; H, 5.41%.

S-*Propyl Benzenethiosulfinate* **1g**: Colorless oil; IR (neat, cm^{-1}) 3050, 2950, 1575, 1470, 1090, and 1060 (S=O); NMR ($CDCl_3$, δ) 1.03 (6H, t, $-CH_3$, J=7.5 Hz), 1.80 (2H, m, $-C\underline{H}_2-CH_3$), 3.09 (1H, t, $-S-CH_2-$, H_A or H_B, J=6.0 Hz), 3.12 (1H, t, H_A or H_B, J=7.4 Hz), 7.33—7.75 (5H, m, arom.). Found: C, 54.08; H, 5.98%. Calcd for $C_9H_{12}OS_2$: C, 53.96; H, 6.03%.

S-*Cyclohexyl Methanethiosulfinate* **1h**: Colorless oil; IR (neat, cm^{-1}) 2970, 2905, 2840, 1440, and 1080 (S=O); NMR ($CDCl_3$, δ) 1.05—2.35 (10H, m, ring protons), 2.95 (3H, s, $-CH_3$), 3.28 (1H, broad s, $-S-CH\langle$). Found: C, 47.15; H, 7.85%. Calcd for $C_7H_{14}OS_2$: C, 47.15; H, 7.91%.

S-*Methyl* p-*Toluenethiosulfinate* **1i**: Pale yellow oil; IR (neat, cm^{-1}) 3000, 2900, 1590, 1490, 1085, and 1062 (S=O); NMR ($CDCl_3$, δ) 2.38 (3H, s, Ar–$C\underline{H}_3$), 2.52 (3H, s, $-S-CH_3$), 7.23 (2H, d, arom., J=8.3 Hz), 7.54 (2H, d, arom., J=8.3 Hz). Found: C, 51.60; H, 5.35%. Calcd for $C_8H_{10}OS_2$: C, 51.58; H, 5.41%.

S-*Methyl* p-*Chlorobenzenethiosulfinate* **1j**: Colorless oil; IR (neat, cm^{-1}) 3070, 2970, 1573, 1470, and 1080 (S=O); NMR ($CDCl_3$, δ) 2.53 (3H, s, $-CH_3$), 7.41 (2H, d, arom., J=8.9 Hz), 7.63 (2H, d, arom., J=8.9 Hz). Found: C, 41.03; H, 3.19%. Calcd for $C_7H_7ClOS_2$: C, 40.67; H, 3.41%.

Oxidation of Thiosulfinic S-*Ester* **1** *with* $NaIO_4$. All the reactions were carried out at room temperature (*ca.* 20 °C).

To a stirred solution of thiosulfinic *S*-ester (**1**, 1.0 mmol) in organic solvent (acetone, acetonitrile, or dioxane, 3.5 ml) a solution of sodium metaperiodate ($NaIO_4$, 1.2 mmol) in 2.0 ml of water was added. A small amount of one of catalysts (H_2SO_4, HCl, HIO_4, CF_3COOH, I_2, or Br_2, one or two drop(s) of liquid catalyst, or 3—10 mg of solid catalyst) was added to the mixture. Within 1.0 h the solution turned to light yellow and gradually changed to dark brown. The solution became usually homogeneous but sometimes remained heterogeneous. After disappearance of the starting material was confirmed by TLC, the reaction mixture was poured into water and extracted three times with chloroform (*ca.* 100 ml) and then organic layer was washed with an aqueous sodium thiosulfate solution (sat. 10 ml) and water. When chloroform was removed *in vacuo* after drying the organic layer with $MgSO_4$, the residue was highly pure thiosulfonic *S*-ester. Usually GC, LC, and NMR spectra showed only one component. Products were identified by comparing their IR and NMR spectra with those of authentic samples prepared by another method and the structures

of new compounds were confirmed by elemental analyses besides IR and NMR spectra.

If no catalyst was used, the oxidation was very slow and had a long induction period (*ca.* 5—10 h). However, the reaction after the long induction period was nearly as fast as the reaction with catalyst and completed within 1.0 h after the start of the reaction.

When acetic acid was used as a solvent, the oxidation proceeded as fast as the reaction with catalyst, although the catalytic amount of acetic acid did not accelerated the oxidation. In order to remove acetic acid from organic extract, the solution was washed with $NaHCO_3$ solution before washing with a sodium thiosulfate solution.

The reaction in alcohol as solvent was performed as in the above-mentioned oxidation procedure. The whole feature of the reaction was similar to the ordinary oxidation and the reaction was also accelerated by addition of catalyst. However, the distribution of products, *i. e.* thiosulfonic *S*-ester (**2**) and sulfinate (**3**), was affected rather little. Yields of both **2** and **3** were easily determined by measuring NMR spectra of the reaction mixture. The structures of the sulfinates obtained as side products were identified by comparison of their IR (S=O) and NMR spectra[13] with those of authentic samples which were prepared by the reaction of sulfinyl chloride and excess alcohol according to the known method.[14]

The reaction of disulfide with $NaIO_4$ was carried out using acetic acid as a solvent. The reaction procedure was also the same as the usual oxidation method mentioned above. The amount of $NaIO_4$ used was two equivalent to disulfide. After the disappearance of unsymmetrical disulfide **5** or the mixture of symmetrical disulfides **9** and **10** was confirmed, the usual work-up gave a mixture of both symmetrical and unsymmetrical thiosulfonic *S*-esters which were identified by comparing their retention times in GC charts and chemical shifts of methyl groups in NMR spectra with those of authentic samples.

S-*Phenyl Benzenethiosulfonate* **2a**: Pink crystals; mp 44—45 °C (lit,[15] 44—45 °C); IR (KBr, cm^{-1}) 3050, 1578, 1471, 1440, 1325, and 1310 (SO_2), 1147 (S=O); MS (70 eV) *m/e* 250 (M^+, 39%), 125 (M^+-PhSO, 100%).

S-p-*Tolyl Benzenethiosulfonate* **2b**: Colorless crystal; mp 52 °C (lit,[15] 54 °C); IR ($CHCl_3$, cm^{-1}) 3030, 1598, 1450, and 1330 (SO_2), 1145 (S=O); MS (70 eV) *m/e* 264 (M^+, 39%), 139 (M^+-PhSO, 100%).

S-*Phenyl* p-*Toluenethiosulfonate* **2c**: Colorless crystals; mp 78—80 °C (lit,[15] 78 °C); IR ($CHCl_3$, cm^{-1}) 3025, 1597, 1443, 1335 (SO_2), 1145 (S=O); MS (70 eV) *m/e* 264 (M^+, 68%), 155 (M^+-PhS, 100%).

S-*Methyl Benzenethiosulfonate* **2d**: Colorless oil; IR (neat, cm^{-1}) 3050, 3000, 2920, 1580, 1475, 1445, 1330, and 1302 (SO_2), 1142 (S=O); NMR ($CDCl_3$, δ) 2.48 (3H, s, $-CH_3$), 7.21—8.08 (5H, m, arom.). Found: C, 44.92; H, 4.18%. Calcd for $C_7H_8O_2S_2$: C, 44.66; H, 4.28%.

S-*Phenyl Methanethiosulfonate* **2e**: Colorless crystals; mp 85—86.5 °C, IR (KBr, cm^{-1}) 3050, 3000, 2905, 1565, 1465, and 1310 (SO_2), 1130 (S=O); NMR ($CDCl_3$, δ) 3.12 (3H, s, $-CH_3$), 7.30—7.83 (5H, m, arom.). Found: C, 44.87; H, 4.25%. Calcd for $C_7H_8O_2S_2$: C, 44.66; H, 4.28%.

S-*Phenyl Ethanethiosulfonate* **2f**: Colorless crystals; mp 52 °C (lit,[16] 50—52 °C); IR ($CHCl_3$, cm^{-1}) 3055, 2975, 2930, 1575, 1472, and 1326 (SO_2), 1128 (S=O); NMR ($CDCl_3$, δ) 1.41 (3H, t, $-CH_3$, J=7.4 Hz), 3.16 (2H, q, $-CH_2-$, J=7.4 Hz), 7.18—7.75 (5H, m, arom.).

S-*Propyl Benzenethiosulfonate* **2g**: Colorless oil; IR (neat, cm^{-1}) 3065, 2970, 2930, 2875, 1580, 1330, and (SO_2), 1150 (S=O); NMR ($CDCl_3$, δ) 0.90 (3H, t, $-CH_3$, J=6.6 Hz), 1.62 (2H, m, $-CH_2-CH_3$), 2.97 (2H, t, $-S-CH_2-$, J=6.4 Hz), 7.26—8.00 (5H, m, arom.). Found: C, 49.69; H, 5.38%. Calcd for $C_9H_{12}O_2S_2$: C, 49.97; H, 5.59%.

S-*Cyclohexyl Methanethiosulfonate* **2h**: Colorless oil; IR (neat, cm^{-1}) 2925, 2850, and 1321 (SO_2), 1132 (S=O); NMR ($CDCl_3$, δ) 1.10—2.35 (10H, m, ring protons), 3.32 (3H, s, $-CH_3$), 3.48 (1H, broad s, $-CH<$). Found: C, 43.10; H, 7.31%. Calcd for $C_7H_{14}O_2S_2$: C, 43.27; H, 7.26%.

S-*Methyl* p-*Toluenethiosulfonate* **2i**: Colorless crystals; mp 59—61 °C; IR ($CHCl_3$, cm^{-1}) 3050, 2915, 1592, 1493, 1335, and 1305 (SO_2), 1142 (S=O); NMR ($CD_3COOD-D_2O$ (3:1), δ, external TMS) 2.13 (3H, s, $Ar-CH_3$), 2.21 (3H, s, $-S-CH_3$), 7.08 (2H, d, arom.), 7.48 (2H, d, arom.). Found: C, 47.80; H, 4.99%. Calcd for $C_7H_{10}O_2S_2$: C, 47.50; H, 4.98%.

S-*Methyl* p-*Chlorobenzenethiosulfonate* **2j**: Colorless crystals; mp 35—37 °C; IR ($CHCl_3$, cm^{-1}) 3080, 3020, 2920, 1578, 1475, and 1335 (SO_2), 1145 (S=O); NMR ($CD_3COOD-D_2O$ (3:1), δ, external TMS) 2.32 (3H, s, $-CH_3$), 7.40 (2H, d, arom.), 7.70 (2H, d, arom.). Found: C, 38.01; H, 3.15%. Calcd for $C_7H_7ClO_2S_2$: C, 37.75; H, 3.16%.

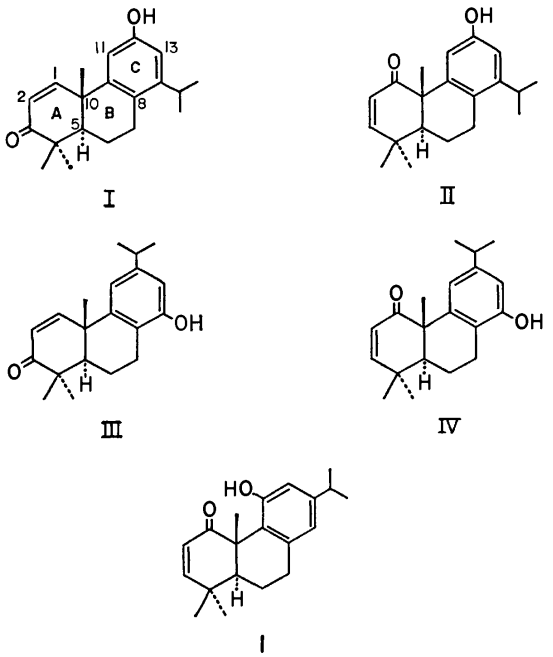
(Received October 21, 1980)

Treatment of methyl (+)-11-oxo-13β-abieta-8-en-18-oate with copper(II) bromide and lithium bromide afforded the corresponding phenol derivative, which was methylated to methyl 11-methoxyabieta-8,11,13-trien-18-oate (**7**). The same compound was also prepared from methyl (+)-7,11-dioxo-13β-abieta-8-en-18-oate *via* methyl 11-hydroxy-7-oxoabieta-8,11,13-trien-18-oate, its methyl ether, and methyl 11-methoxyabieta-6,8,11,13-tetraen-18-oate. The Grignard reaction of **7** with phenylmagnesium bromide followed by treatment with lead tetraacetate and subsequent oxidation with selenium dioxide afforded 11-methoxy-19-norabieta-4(18),8,11,13-tetraen-3α-ol (**12**), which was converted to 11-methoxy-19-norabieta-8,11,13-trien-3-one (**20**) by catalytic hydrogenation, Jones oxidation, and isomerization. The compound **20** was also obtained by Birch reduction of 11-methoxy-19-norabieta-4,8,11,13-tetraen-3-one prepared from **12** *via* 11-methoxy-19-norabieta-4,8,11,13-tetraen-3α-ol. Subsequently, the compound **20** was transformed to 11-methoxyabieta-1,8,11,13-tetraen-3-one (**27**) by a series of reactions: acetalization, demethylation, hydrolysis, acetylation, bromination, dehydrobromination, and methylation. Finally, the compound **27** was converted to the title compound, (+)-11-hydroxyabieta-2,8,11,13-tetraen-1-one (**1**), by oxidation with alkaline hydrogen peroxide, heating with hydrazine hydrate, Jones oxidation, and demethylation. Although the synthetic (+)-**1** was shown to be different from natural shonanol, the spectral analyses of the synthetic structural isomers showed the structure of shonanol to be 12-hydroxyabieta-2,8,11,13-tetraen-1-one.

Shonanol is a tricyclic diterpene phenol isolated from *Libocedrus formosana* by Lin and Liu.[1] On the basis of spectroscopic studies, they deduced the structure of shonanol to be 12-hydroxytotara-1,8,11,13-tetraen-3-one (I). This structure is unique among the naturally-occurring tricyclic diterpenes, in that it contains an α,β-unsaturated carbonyl group in the A ring and a hydroxyl group at the position meta to an isopropyl group in the C ring. To make the structural confirmation, (±)-I had been synthesized in our laboratory.[2] However, the synthetic (±)-I had been shown to be different from natural shonanol by spectral comparison. Further studies[3] on the syntheses of (±)-12-hydroxytotara-2,8,11,13-tetraen-1-one (II), (±)-14-hydroxy-12-isopropylpodocarpa-1,8,11,13-tetraen-3-one (III), and (±)-14-hydroxy-12-isopropylpodocarpa-2,8,11,13-tetraen-1-one (IV) led to the same result, whereas the chemical shifts of vinyl protons in the NMR spectra of these synthetic I—IV suggested that shonanol (δ 5.91 and 6.47 ppm) must have a Δ^2-1-oxo moiety (δ 5.95, 5.90 and 6.53, 6.48 ppm in those of II and IV) rather than the proposed Δ^1-3-oxo one (δ 5.99, 5.94, and 7.54, 7.55 ppm in those of I and III) in the A ring of the tricyclic skeleton. In this study, (+)-11-hydroxyabieta-2,8,11,13-tetraen-1-one (**1**) possessing a hydroxyl group at the position meta to an isopropyl group was synthesized starting from methyl (+)-11-oxo-13β-abieta-8-en-18-oate (**2**)[4] and methyl (+)-7,11-dioxo-13β-abieta-8-en-18-oate (**3**),[4] to allow a comparison of the physical and spectral data with those of natural shonanol.



The 11-oxo compound (**2**) was refluxed with copper(II) bromide and lithium bromide in acetonitrile[5] to give methyl 11-hydroxyabieta-8,11,13-trien-18-oate (**4**) and a small amount of methyl 11-hydroxyabieta-6,8,11,13-tetraen-18-oate (**5**), which was also prepared from the 7,11-dioxo compound **3** by the following route. Similar treatment of **3** with copper(II) bromide and lithium bromide, followed by heating at 100 °C with lithium carbonate and lithium chloride in *N,N*-dimethylformamide and then at 45 °C with zinc in acetic acid, produced methyl 11-hydroxy-7-oxoabieta-8,11,13-trien-18-oate (**6**). This 7-oxo compound **6** was reduced with sodium borohydride in methanol and the resulting alcohol was immediately dehydrated with *p*-toluenesulfonic acid monohydrate in refluxing benzene to give **5**, which was easily converted to **4** by catalytic hydrogenation over PtO_2. **4** and **6** were each methylated at 35—40 °C with methyl iodide and sodium hydride in *N,N*-dimethylformamide under a stream of nitrogen to give the corresponding methyl ether, **7**[6] and **8**.[6,7] The compound **7** was also obtained by catalytic hydrogenation of methyl 11-methoxyabieta-6,8,11,13-tetraen-18-oate (**9**), which was prepared by reduction of **8** with sodium borohydride, followed by dehydration with *p*-toluenesulfonic acid monohydrate. The Grignard reaction of **7** with phen-

ylmagnesium bromide at 100—110 °C afforded a *gem*-diphenyl alcohol (**10**), which was treated with lead tetraacetate and calcium carbonate in refluxing benzene to give a mixture of Δ^3-, Δ^4-, and $\Delta^{4(18)}$-19-nor compounds (**11**) in a ratio of *ca.* 1:1:8. The mixture was oxidized at room temperature with selenium dioxide and *t*-butyl hydroperoxide in dichloromethane in the presence of salicylic acid[8] or with selenium dioxide in refluxing aqueous ethanol to yield 11-methoxy-19-norabieta-4(18),8,11,13-tetraen-3α-ol (**12**). The α-configuration of the hydroxyl group at the C-3 position in **12** was supported by a signal at δ 4.14 ppm with half-height width of 5 Hz in the NMR spectrum, suggesting the presence of an equatorial β hydrogen. The 3α-ol (**12**) was isomerized at 100 °C with lithium in ethylenediamine under a stream of nitrogen to 11-methoxy-19-norabieta-4,8,11,13-tetraen-3α-ol (**13**), which was immediately oxidized with Jones reagent to 11-methoxy-19-norabieta-4,8,11,13-tetraen-3-one (**14**). Methylation of this conjugated ketone **14** with methyl iodide and potassium *t*-pentyl oxide in refluxing benzene under a stream of nitrogen gave the corresponding 4,4-dimethyl ketone (**15**), which was reduced with lithium aluminium hydride in ether to give 11-methoxyabieta-5,8,11,13-tetraen-3β-ol (**16**). The stereochemistry of the hydroxyl group in **16**, which was expected to be β-configuration from previously published results,[2,3,9,10] was confirmed by conversion to the corresponding acetate (**17**), whose NMR spectrum showed a double doublet signal at δ 4.44 ppm (J=6.5 and 9 Hz), suggesting the presence of an α hydrogen at the C-3 position. The 3β-ol **16** was so unstable that it was gradually transformed to a naphthalene derivative (**18**). The structure of **18** was also supported by its NMR spectrum. Since catalytic hydrogenation of C-5 double bond in **16** proved to be more difficult than expected, this synthetic route was discontinued. Thus, another synthetic route was attempted.

Catalytic hydrogenation of **12** in ethanol over Raney Ni, followed by oxidation with Jones reagent, gave 11-methoxy-18-norabieta-8,11,13-trien-3-one (**19**) and its 19-nor isomer (**20**) in a ratio of 69:2. The former **19** was easily isomerized with sodium methoxide in refluxing methanol to the thermodynamically-stable latter **20** in an almost quantitative yield. The stable

isomer **20** was also obtained by Birch reduction of **14** with lithium in liquid ammonia and tetrahydrofuran. Acetalization of **20** with ethylene glycol in the presence of *p*-toluenesulfonic acid monohydrate in refluxing benzene, followed by demethylation of the crude acetal (**21**) with sodium ethanethiolate in refluxing *N,N*-dimethylformamide, yielded a phenol derivative (**22**). This compound, without purification, was converted to 11-acetoxy-19-norabieta-8,11,13-trien-3-one (**24**) by hydrolysis with hydrochloric acid in acetone and subsequent acetylation of the resulting ketone (**23**) with acetic anhydride in pyridine. Bromination[11] of **24** in chloroform with bromine in carbon tetrachloride at 0 °C, followed by dehydrobromination of the crude 2-bromo derivative (**25**) with lithium carbonate and lithium bromide in *N,N*-dimethylformamide at 120—125 °C, afforded an α,β-unsaturated ketone (**26**) which was converted to 11-methoxyabieta-1,8,11,13-tetraen-3-one (**27**) by refluxing with methyl iodide and potassium *t*-pentyl oxide in benzene under a stream of nitrogen. Demethylation of **27** with sodium ethanethiolate in refluxing *N,N*-dimethylformamide produced 11-hydroxyabieta-1,8,11,13-tetraen-3-one (**28**), whose physical and spectral data were different from those of natural shonanol. Subsequently, 1,3-carbonyl transposition[3,12] of the α,β-unsaturated carbonyl group in **27** was carried out as follows. Oxidation of **27** with alkaline hydrogen peroxide in methanol at −10 °C, followed by treatment of the resulting epoxy ketone (**29**)[13] with hydrazine hydrate in refluxing methanol containing a small amount of acetic acid, led to 11-methoxyabieta-2,8,11,13-tetraen-1α-ol (**30**), which was immediately oxidized at 0 °C with Jones reagent to afford 11-methoxyabieta-2,8,11,13-tetraen-1-one (**31**). The 1-oxo compound **31** was finally demethylated at 0 °C with boron tribromide in dichloromethane to give the title compound, 11-hydroxyabieta-2,8,11,13-tetraen-1-one (**1**), and 3β-bromo-11-hydroxyabieta-8,11,13-trien-1-one (**32**) in a ratio of *ca.* 1:1. Dehydrobromination of **32** with lithium carbonate and lithium bromide in *N,N*-dimethylformamide at 120—125 °C produced **1** in an almost quantitative yield. The structure of **32** was supported by the NMR spectrum, which showed signals at δ 2.91 (1H, dd, J=12 and 4.5 Hz) and 3.60 ppm (1H, dd, J=13 and 12 Hz) due to the methylene protons at the C-2 position, and at δ 4.04 ppm (1H, dd, J=13 and 4.5 Hz) due to the methine proton at the C-3 position. The physical and spectral data of the synthetic **1** were also different from those of natural shonanol.

Another structural isomer possessing a hydroxyl group at the position meta to an isopropyl group is 13-hydroxy-11-isopropylpodocarpa-2,8,11,13-tetraen-1-one (V), whose isopropyl group should be sterically hindered by a methyl group at the C-10 position and a carbonyl group at the C-1 position. Therefore, the chemical shifts and coupling pattern of the isopropyl group in V might be expected to be different from those of sempervirol (VI) or ferruginol (VII), which possess an isopropyl group at the less hindered C-12 or C-13 position. However, since the reported chemical shifts of two methyl groups (6H, d, δ 1.15—1.20 ppm) and a methine proton (1H, hept, δ 3.03—3.30 ppm) of the isopropyl group in shonanol were very similar to those[14] in VI (δ 1.19 and 3.10 ppm) or VII (δ 1.19 and 3.09 ppm), the possibility of V could also be ruled out. In the NMR spectrum of natural shonanol, Lin and Liu[1] assigned two singlet signals at δ 6.67 (2H) and 7.30 ppm (1H) to two aromatic protons and a hydroxyl proton, respectively. However, we favored an alternative assignment, in which the signal at δ 6.67 ppm was due to an aromatic proton and a hydroxyl proton and that at δ 7.30 ppm was due to another aromatic proton, because II and IV showed a signal at δ 7.21 ppm[3] corresponding to an aromatic proton at the C-11 position. Consideration of these NMR spectral data suggested that shonanol is either 13-hydroxy-12-isopropyl or a 12-hydroxy-13-isopropyl derivative. Moreover, it is known[14] that VI shows a singlet signal at δ 6.18 ppm due to an aromatic proton at the C-14 position, while VII shows the corresponding signal at δ 6.68 ppm.

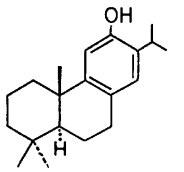
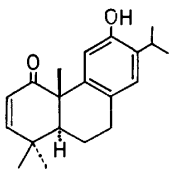
VI



VII



VIII

From these NMR analyses we now propose the structure of shonanol to be 12-hydroxyabieta-2,8,11,13-tetraen-1-one (VIII).

Experimental

All melting points are uncorrected. The IR and optical rotations were measured in chloroform. The NMR spectra (90 MHz) were taken in carbon tetrachloride on a Hitachi Model R-22 NMR spectrometer using tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. Column chromatography was performed using Merck silica gel (0.063 mm).

Methyl 11-Hydroxy-7-oxoabieta-8,11,13-trien-18-oate (6). A mixture of methyl 7,11-dioxo-13β-abieta-8-en-18-oate (**3**: 3.46 g)[4] (mp 87—89.5 °C, $[\alpha]_D$ +78°), copper(II) bromide (4.24 g), and lithium bromide (0.82 g) in freshly distilled acetonitrile (170 ml) was refluxed for 5 h and then evaporated *in vacuo*. After the addition of a mixture of ether and brine, the reaction mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated to give a brown oil (4.00 g).

A mixture of the brown oil (4.00 g), lithium carbonate (3.70 g), and lithium chloride (3.40 g) in *N,N*-dimethyl-

formamide (200 ml) was heated at 100 °C for 8 h in a stream of nitrogen. After cooling, the mixture was diluted with ether, acidified with dilute sulfuric acid, and then extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated to give a dark brown oil (3.81 g).

A mixture of the dark brown oil (3.81 g) and zinc dust (15.2 g) in acetic acid (95 ml) was stirred at 45 °C for 4 h. The reaction mixture was filtered and the filtrate was diluted with water, neutralized with sodium hydrogencarbonate, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue (3.58 g) was purified by column chromatography on silica gel (380 g), using ether–benzene (5:95) as the eluent, to give **6** (2.50 g: 73%), which was recrystallized from ethanol; mp 154—155 °C, mp 180—181 °C after drying at 140—145 °C; $[\alpha]_D$ +38° (*c* 1.17); IR: 3600, 3330br, 1725, 1680, 1610, 1577 cm^{-1}; NMR (DMSO-d_6); 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.27 and 1.37 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 3.61 (3H, s, $-CO_2CH_3$), 6.92 (1H, d, J=2 Hz, C_{12}–H), 7.28 (1H, d, J=2 Hz, C_{14}–H). Found: C, 72.93; H, 8.20%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

Methyl 11-Hydroxyabieta-6,8,11,13-tetraen-18-oate (5). A mixture of **6** (1.03 g) and sodium borohydride (170 mg) in methanol (25 ml) was allowed to stand overnight at room temperature. After the addition of acetone (1.0 ml), the solvent was removed *in vacuo* and the residue was acidified with dilute hydrochloric acid. The mixture was then extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated to give a curde alcohol (1.07 g) as a pale brown solid.

A mixture of the crude alcohol (1.07 g) and *p*-toluenesulfonic acid monohydrate (20 mg) in benzene (100 ml) was refluxed for 2 h. After cooling, the mixture was diluted with ether, washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was recrystallized from methanol to afford **5** (0.87 g: 89%); mp 173.5—175 °C; $[\alpha]_D$ −35° (*c* 1.93); IR: 3600, 3400br, 1720 cm^{-1}; NMR ($CDCl_3$): 1.18 and 1.39 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.03 (1H, t, J=3 Hz, C_5–H), 3.65 (3H, s, $-CO_2CH_3$), 4.86 (1H, bs, –OH, disappeared on deutration), 5.64 and 6.43 (each 1H, dd, and J=10 and 3 Hz, C_6–H and C_7–H), 6.40 and 6.49 (each 1H and bs, C_{12}–H and C_{14}–H). Found: C, 76.78; H, 8.80%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (15 g), using benzene as the eluent, to give some additional **5** (0.11 g: 11%).

Methyl 11-Hydroxyabieta-8,11,13-trien-18-oate (4). a): A mixture of methyl 11-oxo-13β-abieta-8-en-18-oate (**2**: 9.49 g)[4] (mp 108—110 °C, $[\alpha]_D$ +104° (EtOH)), copper(II) bromide (11.50 g), and lithium bromide (2.23 g) in freshly distilled acetonitrile (470 ml) was refluxed for 5 h and then evaporated *in vacuo*. After the addition of a mixture of ether and brine, the mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residual solid (10.37 g) was recrystallized from ethanol to give **4** (5.30 g: mp 201—203 °C). A pure sample for analysis was obtained by repeated crystallization; mp 203—205 °C; $[\alpha]_D$ +77° (*c* 1.22); IR: 3600, 3370br, 1720, 1617, 1575 cm^{-1}; NMR ($CDCl_3$): 1.19 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.29 and 1.35 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 3.14 (1H, bd, J=12.5 Hz, $C_{1\beta}$–H), 3.68 (3H, s, $-CO_2CH_3$), 4.82 (1H, s, –OH, disappeared on deutration), 6.32 and 6.51 (each 1H and bs, C_{12}–H and C_{14}–H). Found: C, 76.20; H, 9.16%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (300 g), using benzene as the eluent, to give a colorless solid (**4**: 1.85 g) containing a small amount of **5**. Further elution with ether–benzene (1:99) afforded the recovered **2** (1.73 g: 18%).

b): A mixture of **5** (651 mg) and PtO_2 (100 mg) in ethanol (30 ml) was subjected to catalytic hydrogenation at room temperature. After the usual work-up, the crude product was recrystallized from ethanol to give **4** (600 mg: 90%), mp 201—203.5 °C, whose IR and NMR spectra were identical with those of the sample prepared in *a)*. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel to give some additional **4** (61 mg: 9%).

Methyl 11-Methoxy-7-oxoabieta-8,11,13-trien-18-oate (8). A mixture of **6** (344 mg) and 50% sodium hydride (72 mg) in *N,N*-dimethylformamide (6.5 ml) was stirred at room temperature for 45 min under a stream of nitrogen. After the addition of methyl iodide (0.06 ml), the mixture was stirred at 35—40 °C for 3 h, cooled, and some additional methyl iodide (0.02 ml) was added. The mixture was further stirred at 35—40 °C for 5 h, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (40 g), using ether–benzene (1:99) as the eluent, to give **8** (309 mg: 86%), which was recrystallized from hexane; mp 113—114 °C; $[\alpha]_D$ +60° (*c* 1.15); IR: 1727, 1680 cm^{-1}; NMR: ($CDCl_3$): 1.25 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 and 1.38 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 3.64 (3H, s, $-CO_2CH_3$), 3.82 (3H, s, C_{11}–OCH_3), 6.94 (1H, d, J=2 Hz, C_{12}–H), 7.59 (1H, d, J=2 Hz, C_{14}–H). Found: C, 73.44; H, 8.39%. Calcd for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44%. The IR and NMR spectra of **8** were identical with those of an authentic sample.[7]

Methyl 11-Methoxyabieta-6,8,11,13-tetraen-18-oate (9). A solution of **8** (270 mg) and sodium borohydride (43 mg) in methanol (7.0 ml) was allowed to stand overnight at room temperature. The crude alcohol was then dehydrated with *p*-toluenesulfonic acid monohydrate in refluxing benzene, as described for the preparation of **5**. The crude product was chromatographed on silica gel (25 g), using hexane–benzene (1:1) as the eluent, to give **9** (244 mg: 95%); $[\alpha]_D$ −15° (*c* 1.45); IR: 1717 cm^{-1}; NMR: 1.10 and 1.33 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.89 (1H, t, J=3 Hz, C_5–H), 3.58 (3H, s, $-CO_2CH_3$), 3.73 (3H, s, C_{11}–OCH_3), 5.55 and 6.32 (each 1H, dd, J=10 and 3 Hz, C_6–H and C_7–H), 6.42 and 6.48 (each 1H, d, and J=2 Hz, C_{12}–H and C_{14}–H). Found: C, 77.45; H, 9.02%. Calcd for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83%.

Methyl 11-Methoxyabieta-8,11,13-trien-18-oate (7). a): A mixture of **9** (190 mg) and PtO_2 (19 mg) in ethanol (20 ml) was submitted to catalytic hydrogenation at room temperature. After the usual work-up, the crude product was purified by column chromatography on silica gel (20 g), using hexane–benzene (1:1) as the eluent, to give **7**[6] (181 mg: 95%); $[\alpha]_D$ +89° (*c* 1.35); IR: 1718, 1610, 1568 cm^{-1}; NMR ($CDCl_3$): 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.27 and 1.31 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 3.65 (3H, s, $-CO_2CH_3$), 3.77 (3H, s, C_{11}–OCH_3), 6.50 (2H, bs, C_{12}–H and C_{14}–H). Found: C, 76.84; H, 9.50%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

b): A mixture of **4** (7.15 g) containing a small amount

of **5**, 50% sodium hydride (5.20 g), and *N,N*-dimethylformamide (200 ml) was methylated with methyl iodide (4.0 ml) as described for the preparation of **8**. The crude product was purified by column chromatography on silica gel (350 g), using hexane–benzene (1:1) as the eluent, to give **7** (3.98 g) and a mixture (2.42 g) of **7** and a small amount of **9**.

The above mixture (2.42 g) in ethanol (14 ml) was hydrogenated over PtO_2 and then purified by column chromatography to give **7** (2.14 g), whose IR and NMR spectra were identical with those of the sample prepared in *a)*.

Grignard Reaction of 7 with Phenylmagnesium Bromide. A solution of **7** (344 mg) in dry ether (3.4 ml) was added dropwise to a refluxing ethereal solution of phenylmagnesium bromide prepared from magnesium turnings (194 mg) and bromobenzene (1.26 g) in dry ether (3.4 ml). The mixture was further refluxed for 2 h and the ether was removed in a stream of nitrogen. The viscous residue was heated at 100—110 °C for 5 h, allowed to stand overnight at room temperature, carefully hydrolyzed with a mixture of ice and dilute sulfuric acid, and then extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (65 g), using hexane–benzene (1:1) as the eluent, to give a *gem*-diphenyl alcohol (**10**) (373 mg: 80%) as a colorless solid, which was recrystallized from methanol; mp 191.5—193 °C; $[\alpha]_D$ +101° (*c* 1.65); IR: 3580, 1610, 1568, 700 cm^{-1}; NMR: 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 and 1.30 (each 3H and s, C_4-CH_3 and $C_{10}-CH_3$), 2.34 (1H, s, –OH, disappeared on deutration), 3.69 (3H, s, $C_{11}-OCH_3$), 6.17 and 6.31 (each 1H and bs, $C_{12}-H$ and $C_{14}-H$), 6.9—7.9 (10H, m, 2-C_6H_5). Found: C, 84.84; H, 8.68%. Calcd for $C_{33}H_{40}O_2$: C, 84.57; H, 8.60%.

Fragmentation of 10 with Lead Tetraacetate. A mixture of lead tetraacetate (1.06 g) and calcium carbonate (1.20 g) in dry benzene (60 ml) was refluxed for 5 min. To this mixture was added a solution of **10** (937 mg) in dry benzene (30 ml). The mixture was refluxed for 8 h, cooled, and then filtered. The filtrate was diluted with ether and the solution was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. After drying over sodium sulfate, the solution was evaporated *in vacuo* and the residue was chromatographed on silica gel (100 g), using hexane–benzene (95:5) as the eluent, to give a mixture of Δ^3-, Δ^4-, and $\Delta^{4(18)}$-19-nor isomers (**11**) (508 mg: 89%). The NMR spectrum of the mixture indicated that it was composed of approximately 10% of Δ^3- (δ 5.34 ppm, C_3-H), 10% of Δ^4- (δ 1.42 ppm, $C_{10}-CH_3$), and 80% of $\Delta^{4(18)}$-19-nor compound (δ 4.48 and 4.74 ppm, $CH_2=\overset{|}{C}-$). Found: C, 84.74; H, 10.18%. Calcd for $C_{20}H_{28}O$: C, 84.45; H, 9.92%. The above olefinic mixture (**11**) was recrystallized from methanol to afford the pure $\Delta^{4(18)}$-19-nor compound; mp 81—82 °C; $[\alpha]_D$ +242° (*c* 1.23); NMR: 1.17 (3H, s, $C_{10}-CH_3$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.01 (1H, bd, J=12 Hz, $C_{1\beta}-H$), 3.75 (3H, s, $C_{11}-OCH_3$), 4.48 and 4.74 (each 1H, bs, and $W_{1/2}$=4 Hz, $CH_2=\overset{|}{C}-$), 6.39 (2H, bs, $C_{12}-H$ and $C_{14}-H$). Found: C, 84.32; H, 10.15%. Calcd for $C_{20}H_{28}O$: C, 84.45; H, 9.92%.

11-Methoxy-19-norabieta-4(18),8,11,13-tetraen-3α-ol (12).

a): The olefinic mixture (**11**: 142 mg) was added to a stirred mixture of 70% *t*-butyl hydroperoxide (0.26 ml), selenium dioxide (1 mg), and salicylic acid (7 mg) in dichloromethane (0.3 ml). The mixture was further stirred at room temperature for 28 h, diluted with benzene (5.0 ml), and then evaporated. The residue was dissolved in ether and the ether solution was washed successively with aqueous potassium hydroxide and brine. After the solution had been evaporated *in vacuo*, the residue was dissolved in cold acetic acid (1.0 ml) and dimethyl sulfide (0.25 ml) was added slowly with stirring and cooling in a water bath. The mixture was then stirred at room temperature for 3 h, neutralized with aqueous potassium carbonate at 0—5 °C, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (17 g), using ether–benzene (1:99) as the eluent, to give **12** (95 mg: 63%), which was recrystallized from hexane; mp 68—69.5 °C; $[\alpha]_D$ +186° (*c* 2.59); IR: 3600, 3420br, 1648, 1610, 1568 cm^{-1}; NMR: 1.01 (3H, s, $C_{10}-CH_3$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.92 (1H, bs, –OH, disappeared on deutration), 3.73 (3H, s, $C_{11}-OCH_3$), 4.14 (1H, bs, $W_{1/2}$=5 Hz, C_3-H), 4.55 and 4.90 (each 1H and bs, $CH_2=\overset{|}{C}-$), 6.39 (2H, bs, $C_{12}-H$ and $C_{14}-H$). Found: C, 80.20; H, 9.56%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

b): A solution of selenium dioxide (566 mg) in ethanol (29 ml) and water (0.08 ml) was added dropwise to a stirred solution of the olefinic mixture (**11**: 2.88 g) in ethanol (29 ml) at room temperature over a 20 min period. The mixture was further stirred at room temperature for 30 min, refluxed for 8 h, cooled, and then filtered. The filtrate was diluted with ether and the ether solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (320 g), using ether–benzene (1:99) as the eluent, to give **12** (1.68 g: 55%) as a pale brown solid, whose IR and NMR spectra were identical with those of the sample prepared in *a)*.

11-Methoxy-19-norabieta-4,8,11,13-tetraen-3-one (14). A solution of **12** (1.01 g) in ethylenediamine (70 ml) was added to lithium (1.18 g) in ethylenediamine (70 ml). The mixture was heated at 100 °C for 1 h under a stream of nitrogen, poured into brine, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated to give a crude 11-methoxy-19-norabieta-4,8,11,13-tetraen-3α-ol (**13**) as an oil (1.00 g); NMR (60 MHz): 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.38 (3H, s, $C_{10}-CH_3$), 1.74 (3H, s, C_4-CH_3), 3.65 (1H, bs, $W_{1/2}$=6 Hz, C_3-H), 3.76 (3H, s, $C_{11}-OCH_3$), 6.42 (2H, bs, $C_{12}-H$ and $C_{14}-H$).

A solution of the crude **13** (1.00 g) in acetone (60 ml) was oxidized with Jones reagent (2.5 M: 3.37 ml) at 0 °C for 30 min. After the usual work-up, the crude product was purified by column chromatography on silica gel (50 g), using ether–benzene (1:99) as the eluent, to give **14** (830 mg: 83%) as an oil; $[\alpha]_D$ +362° (*c* 1.71); IR: 1650, 1613, 1570 cm^{-1}; NMR: 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.61 (3H, s, $C_{10}-CH_3$), 1.78 (3H, s, C_4-CH_3), 3.80 (3H, s, $C_{11}-OCH_3$), 6.44 and 6.48 (each 1H and bs, $C_{12}-H$ and $C_{14}-H$). Found: C, 80.25; H, 8.96%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

11-Methoxyabieta-5,8,11,13-tetraen-3-one (15). A solution of potassium *t*-pentyl oxide in *t*-pentyl alcohol prepared from potassium (141 mg) and *t*-pentyl alcohol (7.8 ml) was evaporated to dryness and the residual potassium *t*-pentyl oxide was suspended in dry benzene (7.0 ml). After a solution of **14** (596 mg) in dry benzene (18 ml) had been added over a 10 min period under a stream of nitrogen, the stirred mixture was refluxed for 30 min, cooled, and a solution of methyl iodide (0.37 ml) in dry benzene (5.0

ml) was added. The stirred mixture was further refluxed for 2 h, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (60 g), using benzene as the eluent, to give **15** (447 mg: 72%) as a colorless solid; IR: 1700, 1612, 1573 cm^{-1}; NMR: 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.25 (6H, s) and 1.28 (3H, s) ($-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 3.36 (2H, bd, J=4 Hz, $=CHC\underline{H}_2-$), 3.80 (3H, s, $C_{11}-OCH_3$), 5.67 (1H, t, J=4 Hz, C_6–H), 6.46 (2H, bs, C_{12}–H and C_{14}–H). The compound (**15**) was labile and it was immediately subjected to the next reaction.

*11-Methoxyabieta-5,8,11,13-tetraen-3β-ol (**16**).* A solution of **15** (99 mg) in dry ether (4.0 ml) was added to a stirred suspension of lithium aluminium hydride (24.3 mg) in dry ether (1.5 ml). The mixture was refluxed for 1.5 h, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (1:99) as the eluent, to give **16** (70 mg: 70%) as an oil; IR: 3610, 3400br, 1610, 1572 cm^{-1}; NMR: 1.13, 1.18, and 1.41 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), *ca.* 3.1 (2H, m, $C_{1\beta}$–H and C_3–H), 3.28 (2H, bd, J=4 Hz, $=CHC\underline{H}_2-$), 3.75 (3H, s, $C_{11}-OCH_3$), 5.78 (1H, t, J=4 Hz, C_6–H), 6.42 (2H, bs, C_{12}–H and C_{14}–H).

The compound (**16**) was labile and it gradually transformed into a naphthalene derivative (**18**); IR: 1705, 1627, 1572 cm^{-1}; NMR: 1.06 and 1.30 (each 6H, d, and J=7 Hz, 2-$CH(C\underline{H}_3)_2$), 2.38 (3H, s, $-CH_3$), 3.82 (3H, s, $-OCH_3$), 6.57 (1H, d, J=2 Hz), 7.01 (1H, d, J=2 Hz,) 7.05 (1H, d, J=8 Hz), and 7.30 (1H, d, J=8 Hz) (aromatic protons). Found: C, 80.76; H, 9.24%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

*3β-Acetoxy-11-methoxyabieta-5,8,11,13-tetraene (**17**).* A mixture of **16** (107 mg) and acetic anhydride (0.5 ml) in pyridine (0.5 ml) was allowed to stand overnight at room temperature. After the usual work-up, the crude product was chromatographed on silica gel (10 g). Elution with benzene gave **17** (77 mg), which was recrystallized from hexane; mp 122—122.5 °C; $[\alpha]_D$ +24° (*c* 0.37); IR: 1725, 1614, 1577 cm^{-1}; NMR: 1.11, 1.22, and 1.44 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.98 (3H, s, $-OCOCH_3$), 3.30 (2H, bd, J=4 Hz, $=CHC\underline{H}_2-$), 3.78 (3H, s, $C_{11}-OCH_3$), 4.44 (1H, dd, J=9 and 6.5 Hz, C_3–H), 5.84 (1H, t, J=4 Hz, C_6–H), 6.42 and 6.44 (each 1H and bs, C_{12}–H and C_{14}–H). Found: C, 77.30; H, 9.19%. Calcd for $C_{23}H_{32}O_3$: C, 77.49; H, 9.05%.

*11-Methoxy-18-norabieta-8,11,13-trien-3-one (**19**) and 11-Methoxy-19-norabieta-8,11,13-trien-3-one (**20**).* *a)*: A solution of **12** (365 mg) in ethanol (8.0 ml) was hydrogenated using Raney Ni (W-2: 750 mg) at room temperature in an atmosphere of hydrogen. The crude dihydro compound, without purification, was oxidized with Jones reagent (2.5 M: 1.2 ml) in acetone (20 ml) at 0 °C for 30 min. After the usual work-up, the crude product was purified by column chromatography on silica gel (40 g), using ether–benzene (0.5:99.5) as the eluent, to give **20** (9 mg: 2%) as an oil. Further elution gave **19** (250 mg: 69%) as an oil; $[\alpha]_D$ +188° (*c* 2.07); IR: 1700, 1610, 1570 cm^{-1}; NMR: 1.16 (3H, d, J=7.5 Hz, C_4-CH_3), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.24 (3H, s, $C_{10}-CH_3$), 3.77 (3H, s, $C_{11}-OCH_3$), 6.42 (2H, bs, C_{12}–H and C_{14}–H). Found: C, 80.05; H, 9.65%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

b): A mixture of **19** (172 mg) and sodium methoxide (154 mg) in methanol (10 ml) was refluxed for 1 h, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (15 g), using ether–benzene (1:99) as the eluent, to give **20** (168 mg: 98%) as an oil; $[\alpha]_D$ +138° (*c* 0.665); IR: 1698, 1610, 1570 cm^{-1}; NMR: 1.05 (3H, d, J=7 Hz, C_4-CH_3), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.36 (3H, s, $C_{10}-CH_3$), 3.77 (3H, s, $C_{11}-OCH_3$), 6.42 (2H, bs, C_{12}–H and C_{14}–H). Found: C, 80.09; H, 9.39%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

c): A solution of **14** (121 mg) in tetrahydrofuran (2.5 ml) was added to a solution of lithium (28 mg) in liquid ammonia (12 ml) at −33 °C. The mixture was stirred at this temperature for 1 h, and ammonium chloride (321 mg) was added. After removal of the ammonia, the residue was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (12 g), using ether–benzene (0.5: 99.5) as the eluent, to give **20** (60 mg: 48%) as an oil; its IR and NMR spectra were identical with those of the sample prepared in *a)* and *b)*.

*11-Acetoxy-19-norabieta-8,11,13-trien-3-one (**24**).* A mixture of **20** (170 mg), ethylene glycol (0.32 ml), and *p*-toluenesulfonic acid monohydrate (17 mg) in benzene (15 ml) was refluxed for 4 h. The mixture was cooled, diluted with ether, and then washed successively with aqueous sodium hydrogencarbonate and brine. After drying over sodium sulfate, the solution was evaporated *in vacuo* to give a crude acetal (**21**) as an oil.

A solution of the above crude acetal (**21**) in *N*,*N*-dimethylformamide (10 ml) was added to sodium ethanethiolate prepared from sodium (92 mg) and ethanethiol (2.0 ml). The stirred mixture was refluxed for 2.5 h under a stream of nitrogen, cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated to give a crude phenol (**22**) as an oil.

A solution of the above crude phenol (**22**) in acetone (15 ml) was stirred with dilute hydrochloric acid (6 M: 2.0 ml) at room temperature for 1 h. The mixture was diluted with ether, washed with brine, and dried over sodium sulfate. Evaporation of the solution gave a crude keto phenol (**23**) as an oil, which was then acetylated with acetic anhydride (1.0 ml) in pyridine (1.0 ml) at room temperature for *ca.* 15 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (20 g). Elution with ether–benzene (3:97) afforded **24** (173 mg: 92%), which was recrystallized from hexane; mp 105—106 °C; $[\alpha]_D$ +141° (*c* 1.37); IR: 1750, 1705, 1620, 1567 cm^{-1}; NMR: 1.07 (3H, d, J=6.5 Hz, C_4-CH_3), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.31 (3H, s, $C_{10}-CH_3$), 2.23 (3H, s, $-OCOCH_3$), 6.53 and 6.71 (each 1H, d, and J=2 Hz, C_{12}–H and C_{14}–H). Found: C, 76.65; H, 8.70%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

*11-Acetoxy-19-norabieta-1,8,11,13-tetraen-3-one (**26**).* A solution of bromine (1 M: 1.25 ml) in carbon tetrachloride was added at 0 °C to a stirred solution of **24** (373 mg) in chloroform (13 ml). The mixture was further stirred at this temperature for 45 min, diluted with ether, and the ether solution was washed successively with aqueous sodium thiosulfate and brine. Evaporation of the dried solution gave a crude 2-bromo derivative (**25**) as an oil.

A stirred mixture of the crude 2-bromo compound (**25**), lithium carbonate (211 mg), and lithium bromide (158 mg)

in *N,N*-dimethylformamide (15 ml) was heated at 120—125 °C for 75 min under a stream of nitrogen. The mixture was cooled, poured into dilute sulfuric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (40 g). Elution with ether–benzene (2:98) afforded **26** (205 mg: 55%) as an oil; $[\alpha]_D$ +199° (*c* 2.05); IR: 1760, 1670, 1620, 1570 cm^{-1}; NMR: 1.19 (3H, d, J=6.5 Hz, C_4–CH_3), 1.22 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.34 (3H, s, C_{10}–CH_3), 2.27 (3H, s, –OCOCH_3), 5.77 (1H, d, J=10 Hz, C_2–H), 6.65 and 6.76 (each 1H, bd, and J=2 Hz, C_{12}–H and C_{14}–H), 7.78 (1H, d, J=10 Hz, C_1–H). Found: C, 77.07; H, 8.01%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%.

11-Methoxyabieta-1,8,11,13-tetraen-3-one (27). A solution of **26** (129 mg) in dry benzene (5.0 ml) was added to a stirred suspension of potassium *t*-pentyl oxide (prepared from potassium (139 mg) and *t*-pentyl alcohol (3.0 ml) in dry benzene (3.0 ml) over a 5 min period under a stream of nitrogen. The mixture was gently refluxed for 30 min, cooled, and a solution of methyl iodide (0.15 ml) in dry benzene (1.0 ml) was added. The mixture was refluxed for 2 h, cooled, and some additional solution of methyl iodide (0.15 ml) in dry benzene (1.0 ml) was added. The mixture was further refluxed for 2 h, cooled, poured into water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (20 g). Elution with ether–benzene (1:99) gave **27** (84 mg: 68%), which was recrystallized from methanol; mp 84.5—85 °C; $[\alpha]_D$ +206° (*c* 0.670); IR: 1660, 1612, 1577 cm^{-1}; NMR: 1.11, 1.16, and 1.43 (each 3H and s, –$\underset{|}{C}(CH_3)_2$ and C_{10}–CH_3), 1.21 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 3.86 (3H, s, C_{11}–OCH_3), 5.77 (1H, d, J=10 Hz, C_2–H), 6.49 (2H, bs, C_{12}–H and C_{14}–H), 7.96 (1H, d, J=10 Hz, C_1–H). Found: C, 80.71; H, 9.18%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

11-Hydroxyabieta-1,8,11,13-tetraen-3-one (28). A stirred mixture of **27** (28 mg) and sodium ethanethiolate (prepared from sodium (21 mg) and ethanethiol (1.5 ml)) in *N,N*-dimethylformamide (3.0 ml) was refluxed for 3 h under a stream of nitrogen. The mixture was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (5.0 g), using ether–benzene (3:97) as the eluent, to give **28** (16 mg: 60%), which was recrystallized from methanol; mp 199—200 °C; $[\alpha]_D$ +190° (*c* 0.075); IR: 3580, 3280br, 1655, 1610, 1572 cm^{-1}; UV (λ_{max}^{EtOH}): 225 nm (ε 18900), 283 (2490); NMR ($CDCl_3$): 1.22 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.22, 1.25, and 1.53 (each 3H and s, –$\underset{|}{C}(CH_3)_2$ and C_{10}–CH_3), 5.53 (1H, bs, –OH, disappeared on deutration), 5.96 (1H, d, J=10.5 Hz, C_2–H), 6.45 (1H, bd, J=2 Hz) and 6.59 (1H, bs) (C_{12}–H and C_{14}–H), 8.34 (1H, d, J=10.5 Hz, C_1–H). Found: C, 80.26; H, 8.98%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

11-Methoxyabieta-2,8,11,13-tetraen-1-one (31). A solution of **27** (35 mg) in methanol (10.5 ml) was cooled to −10 °C under a stream of nitrogen; then 30% hydrogen peroxide (0.064 ml) was added, followed by 5% aqueous sodium hydroxide (0.5 ml). The mixture was stirred at −12—−8 °C for 4.5 h, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated to give an epoxy ketone (**29**) as an oil (37 mg). Without purification, this was immediately submitted to the next reaction.

A mixture of the crude **29** (37 mg), hydrazine hydrate (0.17 ml), acetic acid (0.04 ml), and methanol (3.7 ml) was refluxed for 13.5 h under a stream of nitrogen. After the methanol had been evaporated *in vacuo*, the residue was extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and then evaporated to give a crude 1α-ol (**30**: 37 mg). The crude **30** (37 mg) was oxidized with Jones reagent (2.5 M: 0.112 ml) at 0 °C for 15 min. After the usual work-up, the crude product was purified by column chromatography on silica gel (5.0 g). Elution with benzene gave **31** (15 mg: 43%) as an oil; $[\alpha]_D$ +266° (*c* 1.02); IR: 1695, 1618, 1580 cm^{-1}; NMR: 1.13, 1.19, and 1.60 (each 3H and s, –$\underset{|}{C}(CH_3)_2$ and C_{10}–CH_3), 1.24 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 3.73 (3H, s, C_{11}–OCH_3), 5.77 and 6.16 (each 1H, d, and J=10 Hz, C_2–H and C_3–H), 6.43 and 6.54 (each 1H and bs, C_{12}–H and C_{14}–H). Found: C, 80.55; H, 9.19%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

Demethylation of 31. A solution of **31** (10.0 mg) and boron tribromide (0.015 ml) in dichloromethane (0.50 ml) was stirred at 0 °C for 30 min, poured into a mixture of ice and water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (5.0 g), using benzene as the eluent, to give 11-hydroxyabieta-2,8,11,13-tetraen-1-one (**1**) (4.7 mg: 49%) as an oil; $[\alpha]_D$ +470° (*c* 0.35); IR: 3200br, 1657, 1615, 1567 cm^{-1}; UV (λ_{max}^{EtOH}): 222.5 nm (ε 15500), 281.5 (2220); NMR: 1.21 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.22 (6H, s, –$\underset{|}{C}(CH_3)_2$), 1.58 (3H, s, C_{10}–CH_3), 5.88 and 6.56 (each 1H, d, and J=10 Hz, C_2–H and C_3–H), 6.37 and 6.60 (each 1H and bs, C_{12}–H and C_{14}–H). Found: C, 80.28; H, 8.93%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

Further elution with benzene gave 3β-bromo-11-hydroxyabieta-8,11,13-trien-1-one (**32**) (6.0 mg: 50%) as an oil; IR: 3320br, 1690 cm^{-1}; NMR: 1.18 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.22 and 1.24 (each 3H and s, –$\underset{|}{C}(CH_3)_2$), 1.64 (3H, s, C_{10}–CH_3), 2.91 (1H, dd, J=12 and 4.5 Hz, $C_{2\alpha}$–H), 3.60 (1H, dd, J=13 and 12 Hz, $C_{2\beta}$–H), 4.04 (1H, dd, J=13 and 4.5 Hz, $C_{3\alpha}$–H), 5.63 (1H, bs, –OH), 6.41 and 6.52 (each 1H and bs, C_{12}–H and C_{14}–H).

A mixture of **32** (6.0 mg), lithium carbonate (8.0 mg), and lithium bromide (6.0 mg) in *N,N*-dimethylformamide (1.0 ml) was heated at 120—125 °C for 3 h under a stream of nitrogen. After the same work-up as described for the preparation of **26**, the crude product was chromatographed on silica gel (5.0 g). Elution with benzene gave a colorless oil (4.9 mg: 96%), whose IR and NMR spectra were identical with those of **1**.

The authors are grateful to Arakawa Chemical Co. Ltd. for the generous gift of (+)-13β-abieta-8-en-18-oic acid.

Intramolecular Cyclization of Nerol and the Related Attack of (*Z*)-Allylic Alcohol Moiety on the Terminal Olefin Linkage as Induced by $TiCl_4$-PhNHMe Complex. Synthesis of Nezukone

Akira Itoh, Tadashi Saito, Koichiro Oshima,* and Hitosi Nozaki

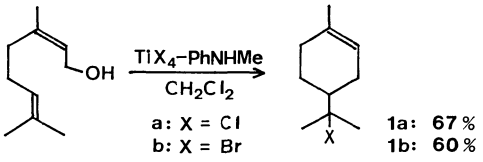
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received November 10, 1980)

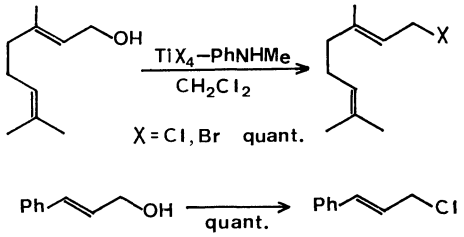
Nerol was cyclized to terpinyl chloride or bromide in the presence of TiX_4–PhNHMe (1:1) complex (I, X= Cl, Br) in dichloromethane at −23 °C, geraniol being converted into geranyl halide by simple halogenation. Terminally modified derivatives $YCH_2C(Me)=CHCH_2CH_2CMe=CHCH_2OH$ (Y=$SiMe_3$, $SnBu_3$) of (2*Z*,6*E*) configuration were cyclized by treatment with I to afford limonene in high yields and 100% selectivity. Cyclization of (2*Z*) isomers of $CH_2=CR-CH_2CH_2CMe=CHCH_2OH$ (R=H, Me, Cl) produced seven-membered carbocyclic products in fair yields. The novel procedure has been utilized in the synthesis of nezukone from (2*E*)-3-isopropyl-2,6-heptadien-1-ol involving five steps.

The reaction of diethyl neryl phosphate with organoaluminium reagents R_2AlX (X=OR, NHR, *etc.*) has led to the stereospecific synthesis of limonene and similar cyclic terpenes.[1] The smooth cyclization is ascribed to the combined Lewis acid-base character of the reagents.[2] We wish to report on the cyclization technique of this type which is more efficient and much simpler.[3]

Addition of *N*-methylaniline (1.0 mmol) to a solution of TiX_4 (X=Cl or Br, 1.0 mmol) in dichloromethane at 0 °C gave a complex.[4] Both the chloride and bromide complexes reacted smoothly at −23 °C with nerol itself,[5] providing terpinyl halides **1a** and **1b**, respectively, in fair yields. In contrast to the previous organoaluminium reactions[1] or acid catalyzed solvolytic reactions,[6] formal carbocation is thus stabilized by halide ion-uptake rather than by proton-loss.[7]



Analogous treatment of geraniol with TiX_4–PhNHMe complex gave the corresponding geranyl halides in good yields. The drastic alteration in the course of the reaction demonstrates that the steric integrity of the allylic double bond is strictly preserved in a possible intermediate, allylic carbocation.[2] The results are similar to those obtained in the reactions of diethyl neryl phosphate or diethyl geranyl phosphate with organoaluminium reagents R_2AlX or R_3Al.[1a,1b] The TiX_4–PhNHMe complex provides an efficient method for the transformation of allylic alcohols into allylic halides as shown below.[8]



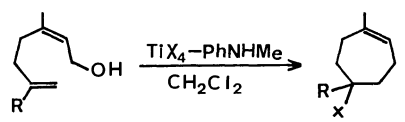
Reaction of nerol with $TiCl_4$ alone afforded a complex mixture not containing terpinyl chloride. It is apparent that the 1:1 complex behaves differently. The 1:1 molar ratio of $TiCl_4$ and PhNHMe gave the best result.[9] Several amines were examined for the reaction of nerol with $TiCl_4$–amine complex with reaction conditions and yield of terpinyl chloride as follows: *N*-methylaniline, 20 min at −23 °C, 67%; 2,2,6,6-tetramethylpiperidine, 20 min at −23 °C, 65%; triethylamine, 1 h at 25 °C, 52%; 1,4-diazabicyclo-[2.2.2]octane, 12 h at 25 °C, 40%; diethylamine, 20 min at −23 °C, 32%; α-methylbenzylamine, 20 min at −23 °C, 28%; pyridine, 3 h at 25 °C, 0%. Several other metal chlorides similar to $TiCl_4$ were also examined. A complex VCl_4–PhNHMe gave **1a** in 50% yield and $AlCl_3$–PhNHMe (38%) was found to be marginal. Halides such as $ZrCl_4$, WCl_6, and $SnCl_4$ gave no sign of cyclized products with or without an amine.

The halides **1a** and **1b** are slowly decomposed on treatment with silica gel in dichloromethane at room temperature to give a complex mixture of hydrocarbons mainly consisting of limonene and terpinolene. Selective synthesis of limonene was achieved in the following way.[10] Treatment of **2a** and **2b** with $TiCl_4$–PhNHMe complex resulted in the exclusive formation of limonene ascribed to the expected selective elimination of $SiMe_3$ or $SnBu_3$ groups from terpinyl carbocation.[11] This method is superior to the previously

	X	R	Reagent	Yield of **3**/%
2a	$SiMe_3$	H	$TiCl_4$-PhNHMe/CH_2Cl_2	79
2a′	$SiMe_3$	$COCH_3$	$MeAl(OCOCF_3)_2$/hexane	29[a]
2b	$SnBu_3$	H	$TiCl_4$-PhNHMe/CH_2Cl_2	73
2b′	$SnBu_3$	$COCH_3$	$MeAl(OCOCF_3)_2$/hexane	51

a) Polymeric products were obtained.

Table 1. Seven-membered ring formation by means of TiX_4–PhNHMe complexes



R	X	Y/%
H	Cl	65
H	Br	56
Me	Cl	66
Cl	Cl	18[a]

a) The corresponding allylic chloride was obtained in a 54% yield.

reported one[1c] using organoaluminium reagent $MeAl(OCOCF_3)_2$ as far as cyclization yields are concerned.

Treatment of (*Z*)-allylic alcohols $CH_2{=}CR{-}CH_2CH_2{-}CMe{=}CHCH_2OH$ (R=H, Me, Cl) with the complex $TiCl_4$–PhNHMe gave seven-membered ring products carrying X on the R-substituted carbon. The novel route to cycloheptenes gives satisfactory yields (Table 1). The (*E*)-alcohols produce the corresponding allylic halides as in the geraniol case.

The present method has provided us with a simple route to troponoid derivatives, which has been exemplified by the synthesis of nezukone. The transformation of allylic alcohol **4** into the cycloheptenyl chloride **5** was easily performed in 60% yield by means of $TiCl_4$–PhNHMe complex. None of the conceivable S_N2 type reactions worked at all with the C–Cl bond of **5**, which was always recovered intact.[12] The difficulty was solved by trapping the Grignard reagent derived from **5** with Bu_3SnCl and successive oxidation by Still's method,[13] which provided cycloheptenone **6** (65%). Nezukone was obtained by simple bromination-debromination procedure (60%).[14]

Experimental

Infrared spectra were determined on a Shimadzu IR 27-G spectrometer, mass spectra on a Hitachi RMU 6-L machine, GLPC analyses on a Yanagimoto GCG 550-F, and NMR spectra on a JEOL C-60H or Varian EM 390H spectrometer. The chemical shifts are given in δ in ppm with TMS as an internal standard. Splitting patterns are denoted by s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. Microanalysis was carried out at the Elemental Analyses Center of Kyoto University. All the experiments were carried out under an atmosphere of dry argon. Tetrahydrofuran was dried by distillation from sodium-benzophenone. Thin and thick layer plates were made of E. Merck PF-254, and preparative columns silica gel E. Merck Art. 7734.

Reaction between Nerol and $TiCl_4$–PhNHMe Complex. A solution of titanium tetrachloride in dichloromethane (1.0 M, 4.5 ml) was added to a solution of *N*-methylaniline (0.48 g, 4.5 mmol) in dichloromethane (5 ml) at 0 °C. No evolution of HCl took place. After 20 min, the resulting dark red solution was cooled to −23 °C, treated with nerol (0.46 g, 3.0 mmol), and allowed to stand at −23 °C for 1 h. Water and ether were added and the organic layer was washed with 1 M HCl, saturated aqueous solution of sodium hydrogencarbonate, and brine, dried, and concentrated. Purification by pre-cooled column chromatography on silica gel afforded terpinyl chloride **1a** (0.29 g, 57% yield) as a colorless oil: bp 108—109 °C (15 Torr, 1 Torr= 133.322 Pa); IR (neat) 2930, 1438, 1385, 1368, 1118 cm^{-1}; NMR (CCl_4) δ 1.50 (s, 3H), 1.55 (s, 3H), 1.63—2.20 (m, 10H), 5.33 (m, 1H); MS *m/e* (%) 174 (3), 172 (10), 136 (47), 121 (61), 95 (59), 93 (100). Found: C, 69.33; H, 10.14%. Calcd for $C_{10}H_{17}Cl$: C. 69.55; H, 9.92%.

Similarly, the reaction between nerol and $TiBr_4$–PhNHMe complex afforded terpinyl bromide **1b** (60% yiled): IR (neat) 2950, 1460, 1375, 1358, 1100 cm^{-1}; NMR (CCl_4) δ 1.50—1.80 (m, 3H), 1.63 (s, 3H), 1.71 (s, 3H), 1.77 (s, 3H), 1.90—2.10 (m, 4H), 5.28 (m, 1H); MS *m/e* (%) 218 (6), 216 (6), 186 (12), 137 (45), 136 (32), 121 (32), 95 (38), 93 (52), 81 (100).

(2Z)-3-Methyl-2,6-heptadien-1-ol and (2Z)-3,6-Dimethyl-2,6-heptadien-1-ol. These compounds were obtained according to a procedure similar to that for the preparation of (2*Z*)-6-chloro-3-methyl-2,6-heptadien-1-ol (**7**). Separation of *E* and *Z* isomers was performed prior to aluminium hydride reduction.

5-Chloro-1-methylcycloheptene: Bp 90 °C (20 Torr); IR (neat) 2950, 1450, 1235, 820 cm^{-1}; NMR (CCl_4) δ 1.70—2.50 (m, 11H), 4.17 (m, 1H), 5.50 (m, 1H); MS *m/e* (%) 146 (10), 144 (27), 109 (33), 95 (33), 93 (100), 91 (27). Found: C, 66.42; H, 9.35%. Calcd for $C_8H_{13}Cl$: C, 66.43; H, 9.06%.

5-Chloro-1,5-dimethylcycloheptene: Bp 96—97 °C (21 Torr); IR (neat) 2940, 1440, 1365, 1190, 1070, 770 cm^{-1}; NMR (CCl_4) δ 1.60 (s, 3H), 1.70 (s, 3H), 1.65—2.63 (m, 8H), 5.47 (m, 1H); MS *m/e* (%) 160 (12), 158 (29), 123 (30), 122 (30), 107 (84), 94 (63), 93 (100). Found: *m/e* 158.0874. Calcd for $C_9H_{15}Cl$: M, 158.0863.

(2Z)-6-Chloro-3-methyl-2,6-heptadien-1-ol (7). A solution of methyl acetoacetate (7.5 ml, 70 mmol) in THF (250 ml) was successively treated with sodium hydride (70 mmol) and butyllithium (1.8 M solution in hexane, 40 ml, 72 mmol) at 0 °C.[15] A solution of 2,3-dichloropropene (5.5 ml, 60 mmol) in THF (20 ml) was added to the resulting orange solution at −78 °C. After 3 h at −78 °C and 30 min at 0 °C, the mixture was poured into water and extracted with ethyl acetate. The crude product was dissolved in aqueous sodium hydroxide solution (0.9 M, 200 ml) and heated at reflux for 70 min. Extractive work-up (ether) gave essentially pure 5-chloro-5-hexen-2-one (6.4 g, 49 mmol) in 81% yield. Treatment of the hexenone (2.9 g, 22 mmol) with lithiated ethyl trimethylsilylacetate[16] (20 mmol, pre-

pared *in situ* from lithium dicyclohexylamide and ethyl trimethylsilylacetate) in THF (125 ml) at −78 °C for 30 min and at 25 °C for 30 min gave an *E* and *Z* mixture of ethyl 6-chloro-3-methyl-2,6-heptadienoate (**8**) in nearly quantitative yield. Pure samples of *E* and *Z* isomer were obtained by preparative TLC (hexane:ether=2:1) and the stereochemistry was assingned by the examination of their NMR spectra in CCl_4.

E-Isomer: δ 1.25 (t, J=6.9 Hz, 3H), 2.14 (s, 3H), 2.43 (bs, 4H), 4.06 (q, J=6.9 Hz, 2H), 5.12 (s, 2H), 5.60 (s, 1H).

Z-Isomer: δ 1.25 (t, J=6.9 Hz, 3H), 1.91 (s, 3H), 2.56 (m, 2H), 2.83 (m, 2H), 4.06 (q, J=6.9 Hz, 2H), 5.12 (s, 2H), 5.60 (s, 1H).

A solution of **8** (4.4 g, 22 mmol, mixture of stereoisomers) in ether (25 ml) was added to a mixture of lithium aluminium hydride (2.1 g, 55 mmol) and aluminium chloride (1.9 g, 14 mmol) in ether (200 ml) at 0 °C and the mixture was stirred for 80 min. Purification by silica gel column chromatography (hexane: ether=2:1) gave the title compound **7** (1.7 g, 11 mmol) in 48% yield along with the *E* isomer (0.86 g, 5.4 mmol, 24% yield). The (*Z*) compound (**7**): bp 118 °C (bath temp, 21 Torr); IR (neat) 3326, 1660, 1632, 878 cm^{-1}; NMR (CCl_4) δ 1.74 (s, 3H), 2.36 (bs, 5H), 4.03 (d, J=6.6 Hz, 2H), 5.11 (s, 2H), 5.41 (t, J=6.6 Hz, 1H); MS *m/e* (%) 144 (2), 142 (6), 129 (26), 107 (41), 91 (52), 84 (58), 79 (47), 71 (100). Found: C, 59.68; H, 8.10%. Calcd for $C_8H_{13}ClO$: C, 59.81; H, 8.16%.

E-Isomer of **7**: NMR (CCl_4) δ 1.69 (s, 3H), 2.19—2.57 (m, 4H), 4.03 (q, J=6.6 Hz, 2H), 5.17 (s, 2H), 5.45 (t, J=6.6 Hz, 1H).

5,5-Dichloro-1-methylcycloheptene. The compound was obtained in 18% yield by treatment of **7** with $TiCl_4$–PhNHMe complex: bp 60 °C (bath temp, 1 Torr); IR (neat) 2950, 1445, 1190, 1025, 980, 940, 835, 755, 700 cm^{-1}; NMR (CCl_4) δ 1.70 (s, 3H), 2.10—2.50 (m, 8H), 5.50 (t, J=6.0 Hz, 1H); MS *m/e* (%) 182 (2), 180 (10), 178 (15), 119 (20), 117 (25), 107 (100). Found: C, 53.36; H, 6.97%. Calcd for $C_8H_{12}Cl_2$: C, 53.65; H, 6.75%.

(2Z)-1,6-Dichloro-3-methyl-2,6-heptadiene: IR (neat) 1662, 1632, 1254, 883 cm^{-1}; NMR (CCl_4) δ 1.81 (s, 3H), 2.45 (bs, 4H), 4.03 (d, J=7.8 Hz, 2H), 5.19 (s, 2H), 5.53 (t, J=7.8 Hz, 1H); MS *m/e* (%) 182 (0.3), 180 (2), 178 (3), 142 (7), 107 (41), 91 (99), 79 (57), 77 (100).

Reaction between Geraniol and $TiCl_4$–PhNHMe Complex. A solution of geraniol (0.31 g, 2.0 mmol) in dichloromethane (2 ml) was added to the $TiCl_4$–PhNHMe complex derived from $TiCl_4$ (2.2 mmol) and PhNHMe (2.2 mmol) in dichloromethane (5 ml) at −23 °C. After 1 h, the mixture was diluted with hexane and washed with water and brine. Essentially pure geranyl chloride (NMR analysis) was obtained in quantitative yield after removal of the solvent.

*(2Z,6E)-3,7-Dimethyl-8-trimethylsilyl-2,6-octadien-1-ol (**2a**).* Treatment of (2*E*,6*Z*)-8-acetoxyl-1-bromo-2,6-dimethyl-2,6-octadiene **9**[17] (1.3 g, 4.6 mmol) with sodium benzenethiolate (13.5 mmol) in methanol (20 ml) at 65 °C for 2 h gave (2*Z*,6*E*)-3,7-dimethyl-8-phenylthio-2,6-octadien-1-ol quantitatively. The sulfide (1.0 g, 4.0 mmol) was dissolved in THF (18 ml) and successively treated with butyllithium (1.7 M solution in hexane, 2.8 ml, 4.8 mmol) and *s*-butyllithium (0.85 M solution in hexane, 5.6 ml, 4.8 mmol) at −78 °C. After 15 min, chlorotrimethylsilane (1.5 ml, 12 mmol) was added and the mixture was stirred for 45 min at −78 °C and for 15 min at 25 °C. Hydrochloric acid (1.0 M, 4.0 ml) was added and the mixture was stirred for an additional 30 min at 25 °C. The crude trimethylsilylated sulfide was added to a solution of lithium (0.16 g, 23 mg-atoms) in ethylamine (5 ml) at −70 °C. After 40 min, ether and methanol were added and the mixture was poured into ice–water. Purification by silica gel column chromatography afforded **2a** (0.49 g, 2.2 mmol, 55% yield based on the sulfide) as a colorless oil: bp 122 °C (bath temp, 0.5 Torr); IR (neat) 3350, 1665, 1252, 995 cm^{-1}; NMR (CCl_4) δ 0.00 (s, 9H), 1.41 (s, 2H), 1.54 (s, 3H), 1.66 (s, 3H), 2.00 (m, 4H), 3.95 (d, J=7.2 Hz, 2H), 4.91 (m, 1H), 5.35 (t, J=7.2 Hz, 1H); MS *m/e* (%) 147 (4), 143 (3), 141 (4), 134 (3), 121 (5), 105 (3), 75 (27), 73 (100). Found: C, 69.03; H, 11.51%. Calcd for $C_{13}H_{26}OSi$: C, 68.96; H, 11.57%.

*(2Z,6E)-3,7-Dimethyl-8-tributylstannyl-2,6-octadien-1-ol (**2b**).* A solution of butyllithium in hexane (1.5 M, 6.0 ml, 9.0 mmol) was added to a solution of hexabutyldistannane (5.0 ml, 9.8 mmol) in THF (30 ml) at −23 °C.[18] After 15 min, the resulting reddish yellow solution was cooled to −78 °C and treated with the bromide **9** (0.63 g, 2.3 mmol) dissolved in THF (2 ml). After 20 min at −78 °C and 20 min at 0 °C, the mixture was poured into water and extracted with ether. Purification by pre-cooled silica gel column chromatography (hexane: ether=2:1) gave **2b** (0.28 g, 27% yield) as a colorless oil: IR (neat) 3340, 1650, 1364, 1001 cm^{-1}; NMR (CCl_4) δ 0.77—0.95 (m, 15H), 1.08—1.60 (m, 15H), 1.54 (s, 3H), 1.71 (s, 3H), 2.02 (m, 4H), 3.95 (d, J=7.2 Hz, 2H), 4.87 (m, 1H), 5.35 (t, J=7.2 Hz, 1H); MS *m/e* (%) 365 (5), 363 (50), 361 (25), 360 (9), 359 (19), 358 (8), 357 (12), 69 (100).

*Reaction between **2a** and $TiCl_4$–PhNHMe Complex.* A solution of **2a** (0.20 g, 0.88 mmol) in dichloromethane (2 ml) was treated with the $TiCl_4$–PhNHMe complex (1.3 mmol) in dichloromethane (5 ml) at −23 °C. After 1 h, 1-dodecene (internal standard, 84 mg) was added and the mixture was worked up in the usual way. The yield of limonene (77%) was determined by GLPC analysis (Apiezone L 5% and KOH 1% on Chromosorb WMW dmcs, 2 m, 85 °C). Reaction between **2b** and the $TiCl_4$–PhNHMe complex was similarly performed (−23 °C, 2 h), the yield being determined by GLPC.

*Reaction between the Acetate of **2a** and Methylaluminium Bis(trifluoroacetate).* A solution of the acetate of **2a** (0.25 g, 0.94 mmol) in hexane (1 ml) was added to methylaluminium bis(trifluoroacetate)[11] (1.9 mmol, prepared *in situ*) in hexane (2 ml) and the mixture was stirred at 25 °C for 17 h. The yield (28%) was determined by GLPC. The reaction between the acetate of **2b** and the aluminium reagent was similarly performed (25 °C, 21 h).

*(2Z)-3-Isopropyl-2,6-heptadien-1-ol (**4**).* Allylation of 3-methyl-2-butanone dimethylhydrazone and subsequent hydrolysis[19] afforded 2-methyl-6-hepten-3-one in 51% yield based on the hydrazone. The allylic alcohol **4** was obtained from this ketone in the usual way.

*5-Chloro-1-isopropylcycloheptene (**5**).* A solution of **4** (0.80 g, 5.3 mmol) in dichloromethane (3.5 ml) was added to the $TiCl_4$–PhNHMe complex (8.0 mmol) in dichloromethane (15 ml) at 0 °C. After 15 min at 0 °C and 10 min at 25 °C, the mixture was worked up. The crude product was subjected to silica gel column chromatography to give **5** (0.55 g, 3.2 mmol) in 60% yield as a colorless oil: bp 120 °C (bath temp, 10 Torr); IR (neat) 1650, 1245, 830, 790, 735 cm^{-1}; NMR (CCl_4) δ 0.93 (d, J=7.0 Hz, 6H), 1.5—2.6 (m, 9H), 4.10 (m, 1H), 5.53 (t, J=6.3 Hz, 1H). Found: C, 69.77; H, 9.70%. Calcd for $C_{10}H_{17}Cl$: C, 69.55; H, 9.92%.

*4-Isopropyl-4-cycloheptenone (**6**).* A mixture of the chloride **5** (1.0 g, 6.0 mmol), granular magnesium (0.43 g, 18 mg-atoms), and ether (8.5 ml) was refluxed for 20 min, a solution of tributylstannyl chloride (3.3 g, 10 mmol) in

ether (3 ml) being added. After 20 min at reflux, the mixture was poured into saturated aqueous ammonium chloride and extracted with ether. The crude product was dissolved in dichloromethane (25 ml) and added to a mixture of pyridine (19 ml, 0.24 mol) and chromium(VI) oxide (12 g, 0.12 mol) in dichloromethane (300 ml). After 12 h at 25 °C, the mixture was filtered through a pad of Celite 545, the filtrate being washed with 5% sodium hydroxide solution (three times), 1 M HCl (three times), and brine. Purification by silica gel column chromatography gave **6** (0.60 g, 3.9 mmol, 65% yield based on the chloride **5**): bp 80 °C (bath temp, 3 Torr); IR (neat) 1705, 1660, 1460, 1260 cm^{-1}; NMR (CCl_4) δ 1.00 (d, J=7.0 Hz, 6H), 2.0—2.6 (m, 9H), 5.57 (t, J=5.7 Hz, 1H); MS *m/e* (%) 152 (M^+, 94), 137 (34), 124 (28), 119 (27), 110 (36), 109 (76), 95 (100). Found: *m/e* 152.1189. Calcd for $C_{10}H_{16}O$: M, 152.1200.

Nezukone. Pyrrolidone hydrotribromide (0.20 g, 0.40 mmol) was added to a solution of the cycloheptenone **6** (20 mg, 0.13 mmol) in THF (5 ml) and the mixture was stirred in the dark at 25 °C for 24 h. The solvent was removed under reduced pressure and the residue was diluted with water (25 ml) and chloroform (10 ml). The aqueous layer was extracted with chloroform (10 ml, four times). The crude product was dissolved in DMF (5 ml) and the solution heated at 150 °C for 1 h in the presence of anhydrous lithium chloride (0.10 g). Water was added and the product was extracted with chloroform. Purification by preparative TLC (benzene: ether=2:1) gave nezukone (12 mg, 0.08 mmol) in 62% yield whose spectral characteristics (IR, NMR, MS) were identical with those reported.[20]

Tellurium-catalyzed Carbonylation of Amines with Carbon Monoxide[1)]

Nobuaki KAMBE, Kiyoshi KONDO, Hideo ISHII, and Noboru SONODA*

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received November 10, 1980)

Carbonylation of amines with carbon monoxide was catalyzed by tellurium to produce corresponding urea derivatives, formamides, and molecular hydrogen. The urea formation proceeds according to the equation; $2RNH_2+CO \rightarrow (RNH)_2CO+H_2$. The successful achievement of the catalytic formation of urea derivatives would be due to the thermal instability of hydrogen telluride which decomposes to generate elemental tellurium and hydrogen. The formation of formamides and hydrogen was found to be suppressed by the addition of nitrobenzene which did not affect the urea formation. Effects of the reaction time, temperature, pressure of carbon monoxide, and additives on this carbonylation reaction are discussed.

Carbonylation of amines with carbon monoxide to produce urea derivatives by the use of S,[2)] Se,[3)] $Fe(CO)_5$,[4)] AgOAc,[5)] and inorganic oxidizing agents[6)] has been known to proceed as stoichiometric reaction. On the other hand, in order to carry out this carbonylation catalytically many studies have been done to show the effectiveness of Se,[3)] transition metals, and their complexes of Hg,[7)] Mn,[8)] Fe,[9)], Co,[10)] Ni,[11)] Rh,[12)] Pd,[13)] W,[14)] Pt.[15)]

The reaction of primary amines with carbon monoxide in the presence of sulfur gave corresponding urea derivatives and hydrogen sulfide[2)] (Reaction 1).

$$2\,RNH_2 + CO + S \longrightarrow (RNH)_2CO + H_2S \qquad (1)$$

This reaction gave moderate yields of ureas based on sulfur used, and it required high temperature and high pressure of carbon monoxide.

In contrast to the above sulfur dependent reaction, under mild reaction conditions selenium[3)] catalyzed the carbonylation of various amines with carbon monoxide and oxygen to afford quantitative yields of urea derivatives with high selectivity (Reaction 2). This

$$2\,RR'NH + CO + \frac{1}{2}O_2 \xrightarrow[\text{r. t., 1 atm}]{\text{Se}} (RR'N)_2CO + H_2O \qquad (2)$$

reaction was shown to consist of the carbonylation reaction (Reaction 3), and the oxidative regeneration of the catalyst (Reaction 4).

$$2\,RR'NH + CO + Se \longrightarrow (RR'N)_2CO + H_2Se \qquad (3)$$

$$H_2Se + \frac{1}{2}O_2 \longrightarrow Se + H_2O \qquad (4)$$

In the periodic table, tellurium belongs to the same VIa group as oxygen, sulfur, and selenium. The present paper describes the novel carbonylation of amines with carbon monoxide catalyzed by elemental tellurium. The tellurium-catalyzed carbonylation is shown characteristically in the simplest mode to form the equimolar amounts of ureas and molecular hydrogen (Reaction 5). In this reaction, the formation

$$2\,RNH_2 + CO \xrightarrow{\text{Te}} (RNH)_2CO + H_2 \qquad (5)$$

of formamide derivatives was found to occur (Reaction 6).

$$RNH_2 + CO \longrightarrow RNHCHO \qquad (6)$$

Results and Discussion

General Reactions. Butylamine, octylamine, cyclohexylamine, and benzylamine were examined for this carbonylation reaction. The results are shown in Table 1. The equimolar amounts of ureas and molecular hydrogen were obtained (Reaction 5). Un-

Table 1. Tellurium-catalyzed carbonylation[a)] of amines with CO

Run	Amine (100 mmol)	Te (mmol)	Time h	Urea (mmol)	H_2 (mmol)	Formamide (mmol)

a) Temp: 140 °C, CO: 30 kg/cm². b) Cyclohexylamine: 85.1 mmol (10 ml). c) Octylamine: 60.2 mmol (10 ml).
d) Not determined.

less otherwise noted, 1 mmol of tellurium was always used, and thus the yields of products (in mmol) correspond to the turnover numbers. For all amines, the carbonylation reaction proceeded catalytically. The turnover number for the urea formation in Run 5 in Table 1, for example, corresponded to 5.8 per hour.

The reaction of butylamine with carbon monoxide in the presence of tellurium catalyst was carried out four times under the identical reaction conditions. The reproducibility of the formation of 1,3-dibutylurea and hydrogen was satisfactory (Runs 1—4). The reproducibility using octylamine and cyclohexylamine was also confirmed fairly good by duplicated experiments. In regard to the reproducibility of formamide formation, the yields varied much more than those of the urea derivatives and hydrogen.

In the reaction performed for 72 h, almost all butylamine was consumed to give urea and formamide derivatives (Run 6). The mass balance in the carbonylation of octylamine was confirmed nearly 100% (Run 11).

Dialkylamines such as diethylamine and dimethylamine failed to react resulting in the recovery of the starting materials. Ammonia and aniline were also unreactive under similar conditions.

Effects of Temperature and CO Pressure. The yields of 1,3-dibutylurea increased as the temperature was elevated, whereas plots of the yields of hydrogen and *N*-butylformamide showed the maxima around at 160 °C (Fig. 1). The temperature higher than 100 °C was required for the effective performance of the catalytic reaction. The change of the reaction temperature caused the similar effects both on the hydrogen formation and the formamide formation. This fact seemed very suggestive. That is, in both reactions the same species would play important roles; which was hydrogen telluride we tentatively considered.

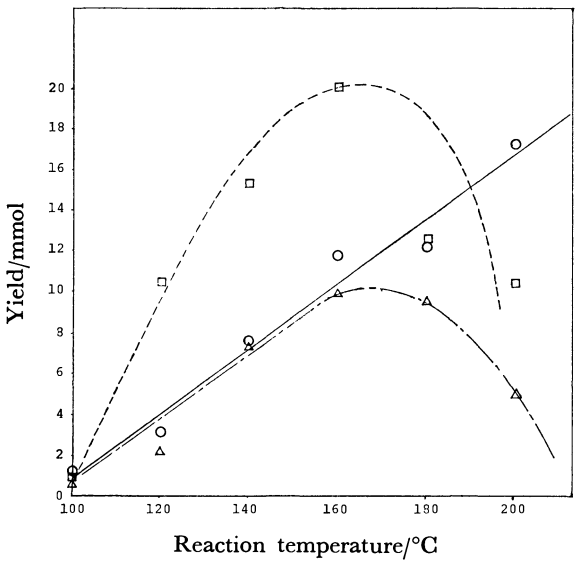

Fig. 1. Effect of temperature on tellurium-catalyzed carbonylation of amines with carbon monoxide. Tellurium: 1 mmol, butylamine: 100 mmol, carbon monoxide: 30 kg/cm², time: 10 h. —○—: 1,3-Dibutylurea, —△—: hydrogen, —□—: *N*-butylformamide.

The higher pressure of carbon monoxide was advantageous for all the formation of 1,3-dibutylurea, hydrogen, and *N*-butylformamide (Fig. 2). But it should be noted that the formamide formation was more sensitive to the pressure than the others.

Effects of Additives. We have reported that nitrobenzene was reduced with hydrogen telluride generated *in situ* from aluminum telluride and water.[16] Evidently, the addition of nitrobenzene to the present tellurium-catalyzed carbonylation system gave aniline in good yield, resulting in the drastic suppression of the formation of hydrogen and *N*-butylformamide (Run 2 in Table 2). The value of the reaction constant, ρ, of the Hammett equation for the concurrent reduction of nitrobenzenes in the tellurium-catalyzed carbonylation system was obtained as +0.8. These results might suggest the presence of hydrogen telluride in this carbonylation. The reaction would proceed as shown in Scheme 1.

Comparison of the Catalyses by Se and Te in the Urea Formation Reaction. We have reported[3] that carbonylation reaction of amines in the presence of selenium afforded stoichiometric amounts of urea derivatives and hydrogen selenide (Reaction 3). By use of selenium under the typical reaction conditions at 140 °C for 10 h, the carbonylation was carried out in a glass

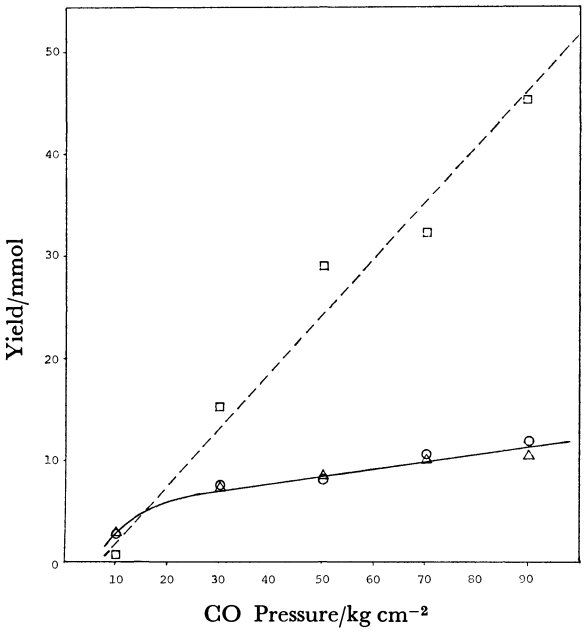

Fig. 2. Effect of CO pressure on tellurium-catalyzed carbonylation of amines with carbon monoxide. Tellurium: 1 mmol, butylamine: 100 mmol, temperature: 140 °C, time: 10 h. —○—: 1,3-Dibutylurea, —△—: hydrogen, —□—: *N*-butylformamide.

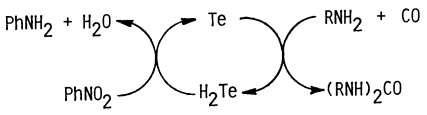


Scheme 1. Tellurium-catalyzed carbonylation of amines with carbon monoxide in the presence of nitrobenzene.

TABLE 2. CONTROLLED EXPERIMENTS[a]

Run	Te (mmol)	Additive (mmol)	Time h	Urea (mmol)	H_2 (mmol)	Formamide (mmol)	$PhNH_2$ (mmol)
1	1	—	72	22.0	21.0	51.8	—
2[b]	1	$PhNO_2$: 10	72	15.9	1.3	2.0	9.0
3	1	—	10	7.6	7.1	10.1	—
4	1	Se : 1	10	19.1	14.5	28.7	—
5	0	Se : 1	10	1.2	0.8	10.6	—

a) *n*-$BuNH_2$: 100 mmol (10 ml), Temp: 140 °C, CO: 30 kg/cm². b) Unreacted nitrobenzene was not detected after the reaction.

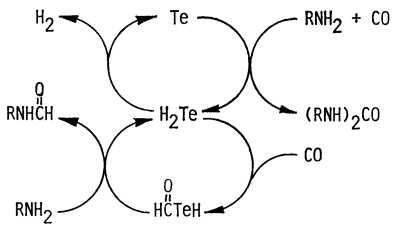
tube inserted in an autoclave. This reaction gave the stoichiometric amount of 1,3-dibutylurea to the used selenium with little formation of hydrogen. When this inserted glass tube was not used, more than equimolar amount of urea to selenium catalyst was produced (Run 5 in Table 2). This result would be attributed to the wall effect of the autoclave. In the tellurium-catalyzed carbonylation, no wall effect was observed on the contrary. These results show the similarity and the difference in the catalyses by selenium and tellurium; both non-transition metal elements, selenium and tellurium, catalyze the carbonylation of amines with carbon monoxide, where the former requires suitable oxidizing agents such as oxygen to give water, while the latter does not with the production of hydrogen. With regard to the reaction conditions, the selenium-catalyzed urea synthesis was achieved under much milder conditions than the other.

A Plausible Reaction Path. At present, we don't have enough evidence to propose the precise reaction mechanism. But some of the results mentioned above may help us to describe the plausible carbonylation path by tellurium catalyst, referring to the accumulated knowledge on selenium catalyzed carbonylation. From a close analogy to the selenium chemistry,[3] tellurium catalyzed urea formation (Reaction 5) would be best explained by the assumption that it consists of two reactions: one, the stoichiometric reaction of amines, carbon monoxide, and tellurium to produce ureas and hydrogen telluride (Reaction 7); the other, the dehydrogenative decomposition of hydrogen telluride to molecular hydrogen and activated tellurium (Reaction 8). The assumption of the intermediacy of hydrogen telluride in this reaction does not contradict the following evidences. i) Pure hydrogen telluride was prepared by the reaction of aluminum telluride and water. Thus prepared hydrogen telluride was found to decompose quite readily to its components, molecular hydrogen and tellurium (Reaction 8). This may be due to the weak bond energy between hydrogen and tellurium reported as 64 kcal/mol.[17] Therefore hydrogen telluride may well be the precursor of hydrogen and tellurium catalyst. ii) The equimolar formation of ureas and hydrogen should be well accounted for by the Reaction 5. iii) The formylation of nitrogen-hydrogen bond with carbon monoxide was also mentioned in the catalysis by the triethylammonium salt of hydrogen selenide at elevated temperature under CO pressure similar to the present reaction conditions.[18] The formation of formamides was observed in the tellurium catalyst system (see Table 1 and Reaction 6). These results might be also due to the catalysis of hydrogen telluride. iv) There was found a similar tendency in the temperature effects on the yields of hydrogen and formamides (Fig. 1). The same species, which we suppose is hydrogen telluride, might be responsible for it. v) The addition of nitrobenzene into the tellurium catalyzed carbonylation system gave important results as mentioned already; a) no effect on the urea formation, b) the drastic suppression on the formation of molecular hydrogen and formamides, c) the production of aniline, as the reduced form of nitrobenzene.

$$2\,RNH_2 + CO + Te \longrightarrow (RNH_2)CO + H_2Te \quad (7)$$

$$H_2Te \longrightarrow H_2 + Te \quad (8)$$

In conclusion a probable reaction path could be represented as shown in Scheme 2.



Scheme 2. A plausible reaction path for the tellurium-catalyzed carbonylation of amines with carbon monoxide.

The intermediacy of tellurol formic acid, $HC(=O)TeH$,[19] in the formamide formation reaction is still a subject to be solved.

Experimental

Instruments. Melting points were measured with a Yanagimoto Micro Melting Point apparatus. IR spectra were taken with a Shimadzu IR-400. NMR spectra (60 MHz) were recorded on a Hitachi R-24 B. Mass spectra were recorded on a Hitachi mass spectrometer, Model RMU-6E. Analytical gas chromatography was performed with a Shimadzu 3BT with thermal conductivity detector, Shimadzu 3BF and GC-6A both with flame ionization detector.

Apparatus. All carbonylations were carried out using 50 ml stainless steel autoclaves (SUS-304) purchased from Taiatsu Glass Kogyo. In order to eliminate the wall effect, the reaction was carried out in a glass tube inserted in the

autoclave.

Materials. Butylamine, cyclohexylamine, octylamine, and benzylamine were purchased from Nakarai Kagaku, and purified by distillation from KOH just before use. Tellurium lump (99.999%) was obtained from Wako Junyaku. Tellurium was powdered by use of agate mortar and pestle and stored under dry nitrogen in the absence of light. The reactive gray tellurium had to be used within a few weeks, since it gradually turned black becoming inactive for the carbonylation under similar conditions. Carbon monoxide (99.99%) was purchased from Neriki Gas in a cylinder and used without any purification. CO pressure mentioned in this paper refers to that at room temperature.

Product Analysis. The analysis of the gas phase after the reaction was performed with a Shimadzu 3BT gas chromatograph using a 3.3 m × 3 mm stainless steel column packed with 30—60 mesh molecular sieves 5A and nitrogen effluent gas at 150 °C of the oven temperature. The analytical error of hydrogen was less than 2%. 1,3-Dibutylurea was analyzed on a Shimadzu GC-6A using a 70 cm × 3 mm glass column packed with 3% DEGS on acid-washed, base-treated, DMCS-treated, 80—100 mesh Shimalite W at 150 °C of the oven temperature, and diethyl phthalate was used as an internal standard. Formamides, nitrobenzenes, and anilines were analyzed using a 3.3 m × 3 mm stainless steel column packed with 25% PEG-20M on acid-washed, 60—80 mesh Shimalite W at 200 °C of the oven temperature, and dodecane was used as an internal standard. 1,3-Dicyclohexylurea, 1,3-dioctylurea, and 1,3-dibenzylurea were obtained after the removal of unreacted amines and formed formamides from the reaction mixtures under reduced pressure. Identifications were made based on spectroscopic data (IR, NMR, and Mass measurements). Melting points were in good agreement with those[20] of authentic samples.

Carbonylation of Butylamine (Run 1 Table 1). In the autoclave were placed tellurium (1 mmol, 128 mg), butylamine (100 mmol, 10 ml), and a magnetic stirring bar. The autoclave was flushed with carbon monoxide three times and charged at 30 kg/cm². The autoclave was sunk in an oil bath maintained at 140 °C, and the reaction was conducted for 10 h with magnetic stirring. After the reaction, the autoclave was immediately cooled to room temperature with cold water. Then the resulting gas was collected in a gas sampler. The VPC analysis of the gas revealed to contain 7.1 mmol of molecular hydrogen. The reaction mixture was transferred into a 100 ml flask and was allowed to contact with air for 30 min with magnetic stirring in order to precipitate tellurium. Products were obtained after the removal of deposited tellurium followed by the evaporation of the unreacted butylamine. From GLPC analyses, 1,3-dibutylurea and *N*-butylformamide were found to be produced in the yields of 7.6 mmol and 10.1 mmol, respectively. 1,3-Dibutylurea was recrystallized from hexane.

Carbonylation of Octylamine (Run 11 in Table 1). Similarly, the carbonylation of octylamine (60.2 mmol, 10 ml) was carried out. 1,3-Dioctylurea was produced as crystals (2.48 g, 10.0 mmol). *N*-Octylformamide (114—120 °C/4 mmHg, 3.90 g, 24.8 mmol) and unreacted octylamine (54—57 °C/10 mmHg, 1.68 g 13.0 mmol) were obtained after fractionation.

Carbonylation of Butylamine by Te in the Presence of Nitrobenzene. In the autoclave tellurium (1 mmol, 128 mg), butylamine (100 mmol, 10 ml), and nitrobenzene (10 mmol, 123 mg) were placed with a magnetic stirring bar. The autoclave was then flushed with carbon monoxide three times and charged at 30 kg/cm². The reaction was conducted at 140 °C for 72 h with vigorous stirring. After the reaction, resulting gas was analyzed by VPC, and 1.3 mmol of hydrogen was found to be formed. GLPC analyses of the reaction mixture, after the removal of tellurium, showed the formation of 15.9 mmol of 1,3-dibutylurea and 2.0 mmol of *N*-butylformamide. Neither 1-butyl-3-phenylurea nor 1,3-diphenylurea was detected.

Competitive Reduction of Nitrobenzene and p-*Nitrotoluene in This Carbonylation System.* The autoclave was charged with tellurium (1 mmol, 128 mg), butylamine (100 mmol, 10 ml), nitrobenzene (5 mmol, 615 mg), *p*-nitrotoluene (5 mmol, 685 mg), and carbon monoxide (30 kg/cm²). After the reaction at 140 °C for 72 h, deposited tellurium was removed by filtration. GLPC analyses of the filtrate revealed that 2.48 mmol of aniline and 1.81 mmol of *p*-toluidine were formed.

Carbonylation of Butylamine by Selenium Using a Glass Tube. Into a glass tube inserted in the autoclave were placed selenium (1 mmol, 79 mg), butylamine (100 mmol, 10 ml), and a magnetic stirring bar. The apparatus was charged with carbon monoxide at 30 kg/cm². After the reaction at 140 °C for 10 h, the resulting gas was collected in a gas sampler, and little amount of hydrogen was detected by VPC analysis. The resulting mixture was transferred into a 100 ml flask and the oxidation with air at room temperature for 1 h precipitated selenium. Products were obtained by the removal of selenium followed by the evaporation of the solvent. GLPC analyses of the products showed the formation of 1.0 mmol of 1,3-dibutylurea and 1.5 mmol of *N*-butylformamide.

Generation of Pure Hydrogen Telluride. In a 100 ml three-necked glass vessel equipped with a 10 ml dropping funnel, a stopper, and a connection tube to a trapping vessel maintained at −196 °C, was placed powdered aluminum telluride (29 g, 66 mmol) under nitrogen atmosphere. All the apparatus was covered with aluminum foil to eliminate the effect of light. Then, 10 ml of water was dropped very slowly into the reaction vessel over a period of 1 h. The reaction was exothermic, so the reaction vessel should be cooled with ice. Hydrogen telluride was trapped at −196 °C as a white solid. When warmed to −78 °C, hydrogen telluride began to decompose. As the temperature was slowly elevated, hydrogen telluride decomposed below its melting point of −51 °C and gray tellurium remained.

The present work was partially supported by a Grant-in-Aid for Developmental Scientific Research (No. 485215) and by a Grant-in-Aid for Encouragement of Young Scientist (No. 575561) from the Ministry of Education, Science and Culture.

Reactivities of Stable Rotamers. VI. Manifestation of Differential Reactivities of the Methyls in a *t*-Butyl Group in Radical Halogenations[1,2]

(Received November 22, 1980)

The methyls in a *t*-butyl group are shown to exhibit different reactivities in radical halogenations, if rotation about a $(CH_3)_3C$–CXY_2 bond is frozen. Barriers to rotation of halogenated 9-*t*-butyl-1,2,3,4-tetrachlorotriptycenes are obtained as ΔH^* *ca.* 32 kcal/mol. The cause of the selectivity in chlorination with sulfuryl chloride was discussed by obtaining reactivity data with a variety of compounds and halogenating reagents. It is concluded that the neighboring group participation of the peri-halo substituent is responsible for the observed selectivity.

Reactivities of rotamers drew attention of some investigators. Curtin and Hammett[3] discussed the problem from the product ratio and Winstein and Holness[4] from the reaction rates, when the reaction and the equilibration of rotamers are represented by Eq. 1.

$$A_1 \xleftarrow{k_{21}} A_2 \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} A_3 \xrightarrow{k_{34}} A_4 \qquad (1)$$

Eliel and Ro discussed the matter from the similar stand point[5] and Zefirov *et al.* elaborated further.[6] Although the scheme was mathematically treated by Seeman and Farone,[7] the solution gives some ambiguities because the rate constants, k_{21} and k_{34}, are both arbitrary. As far as the reactivity of a single rotamer is not known, this arbitrariness is always involved in the discussion. Winstein and Holness used a diastereomeric pair of 4-*t*-butylcyclohexyl derivatives as models of rotamers.[4] It may be assumed that a remote *t*-butyl group should not affect the reaction rate to a large extent. The assumption will succeed, if we are discussing the rule of thumb, but will fail in discussion with quantitative aspects. Therefore, in understanding the reactivities of rotamers, which are so often present in nonrigid organic molecules, the knowledge on the reactivities of respective rotamers is absolutely necessary.

Since we have been able to isolate stable rotamers of triptycene and 9-arylfluorene derivatives,[8] we have felt that comparison of the reactivities will produce useful information about those of rapidly exchanging systems. Furthermore, the merit of using these systems instead of using 1-substituted 4-*t*-butylcyclohexanes is the possibility of introducing a wide variety of substituents. Under these expectations, we decided to launch a project of studying the reactivities of triptycene and 9-arylfluorene systems.

As the beginning of the study in the triptycene system, we focussed our attention to the reactivities of the methyls in a *t*-butyl group. Chemically idential ligands in a group of local C_{3v} symmetry, such as the methyls in a *t*-butyl group, are usually treated nondistinguishable in organic chemistry, because they are usually interchanged rapidly on the laboratory time scale by rotation. However, if the rotation of a *t*-butyl group is frozen on the laboratory time scale, three methyls in a molecule of $(CH_3)_3C$–$CXYZ$ type are all diastereomeric. In a molecule of $(CH_3)_3C$–CXY_2 type, two methyls are enantiotopic and another is diastereotopic with any of the enantiotopic pair of methyls. In principle, the diastereomeric and diastereotopic methyls should show different reactivities if the rotation is frozen. This paper reports the manifestation of the differential reactivities of the diastereotopic methyls in 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene (**1**) and related compounds in radical halogenation reactions.

Experimental

Spectral Measurement. ^{1}H NMR spectra were obtained on a Hitachi R-20B spectrometer operating at 60 MHz or a Varian EM 390 spectrometer operating at 90 MHz.

9-t-Butyl-1,2,3,4-tetrachlorotriptycene (1). (a): To a suspension of hexachlorobenzene (5.7 g or 20 mmol) in 350 mL of dry ether was added a hexane solution of butyllithium (20 mmol) under a dry nitrogen atmosphere below −30 °C. To the mixture, which was stirred for 2 h at −30——20 °C, was added 2.34 g (10 mmol) of crystalline 9-*t*-butylanthracene[9] and the whole was heated under reflux for 3 h. Lithium chloride was filtered off and the filtrate was evaporated. Chromatography of the residue on alumina, using hexane–benzene (10:1) as an eluent, gave 3.3 g (72%) of the desired compound, mp 283.5—284.5 °C. Found: C, 64.07; H, 4.03; Cl, 31.83%. Calcd for $C_{24}H_{18}Cl_4$: C, 64.31; H, 4.05; Cl, 31.64%. ^{1}H NMR ($CDCl_3$, δ): 2.20 (3H, s), 2.31 (6H, s), 6.09 (1H, s), 6.90—7.15 (4H, m), 7.30—7.45 (2H, m), 7.82—8.15 (2H, m).

(b): To a boiling mixture of 1.0 g (4.3 mmol) of 9-*t*-butylanthracene and 1 mL of isopentyl nitrite in 50 mL of dichloromethane was added a solution of 2.5 g (5.0 mmol) of tetrachloroanthranilic acid[10] in 20 mL of acetone over a period of 2 h. Additional 1.0 mL of isopentyl nitrite was added in 2 portions with intervals of 30 min. The mixture was heated for further 30 min and evaporated. Chromatography of the residue on alumina with 10:1 hexane–benzene as an eluent afforded 700 mg (36%) of the desired compound.

9-t-Butyltriptycene (5), mp 241—241.5 °C, was prepared similarly from 9-*t*-butylanthracene and anthranilic acid in 76% yield. Found: C, 93.07; H, 7.24%. Calcd for $C_{24}H_{22}$: C, 92.86; H, 7.14%. ^{1}H NMR ($CDCl_3$, δ): 2.06 (9H,

s), 5.23 (1H, s), 6.85—7.10 (6H, m), 7.27—7.48 (3H, m), 7.70—8.93 (3H, m).

1,2,3,4-Tetrabromo-9-t-butyltriptycene (2), mp 287—288 °C, was similarly prepared from 9-*t*-butylanthracene and tetrabromoanthranilic acid[11] in 8% yield. Found: C, 46.23; H, 2.83; Br, 50.78%. Calcd for $C_{24}H_{18}Br_4$: C, 46.05; H, 2.90; Br, 51.06%. ^{1}H NMR ($CDCl_3$, δ): 1.98 (3H, s), 2.46 (6H, s), 6.22 (1H, s), 6.97—7.20 (4H, m), 7.37—7.58 (2H, m), 7.92—8.15 (2H, m).

9-t-Butyl-2,3-dichlorotriptycene (3), mp 184.5—185.5 °C, was similarly prepared from 9-*t*-butylanthracene and 4,5-dichloroanthranilic acid[12] in 39.7% yield. Found: C, 76.28; H, 4.77; Cl, 19.20%. Calcd for $C_{24}H_{20}Cl_2$: C, 75.99; H, 5.31; Cl, 18.69%. ^{1}H NMR ($CDCl_3$, δ): 1.99 (9H, s), 5.05 (1H, s), 6.65—7.03 (4H, m), 7.03—7.35 (2H, m), 7.39 (1H, s), 7.78 (1H, s), 7.46—7.90 (2H, m).

Reaction between 9-t-Butylanthracene and Lithiated m-Dichlorobenzene. To a solution of 3.54 g (24.1 mmol) of *m*-dichlorobenzene in dry ether was added 25.6 mmol of butyllithium in hexane at −40 °C in 40 min and the mixture was stirred for 1 h. 9-*t*-Butylanthracene (15.2 mmol) was added and the temperature was allowed to rise. After the mixture was refluxed for 2 h, it was treated as usual and the product was separated by careful chromatography. The following compounds were obtained (given by the order of elution from an alumina column by hexane).

9-t-Butyl-4-chlorotriptycene: Mp 273 °C, yield 21%. Found: C, 83.76; H, 6.08; Cl, 10.40%. Calcd for $C_{24}H_{21}Cl$: C, 83.58; H, 6.14; Cl, 10.28%. ^{1}H NMR (CCl_4, δ): 2.06 (3H, s), 2.08 (6H, s), 5.76 (1H, s), 6.7—7.1 (6H, m), 7.1—7.5 (2H, m), 7.5—7.8 (3H, m).

9-t-Butyl-2(and/or 3)-chlorotriptycene: Mp 258—268 °C, yield 11%. ^{1}H NMR (CCl_4, δ): 2.07 (9H, s), 5.43 (1H, s), 6.7—7.1 (3H, m), 7.1—7.4 (2H, m), 7.4—7.9 (6H, m).

9-t-Butyl-1-chlorotriptycene (4): Mp 260.0—260.5 °C, yield 47%. Found: C, 83.54; H, 6.50; Cl, 10.96%. Calcd for $C_{24}H_{21}Cl$: C, 83.58; H, 6.14; Cl, 10.28%. ^{1}H NMR (CCl_4, δ): 2.03 (3H, s), 2.29 (6H, s), 5.05 (1H, s), 6.6—7.05 (6H, m), 7.05—7.4 (3H, m), 7.6—8.0 (2H, m).

The assignment of the structures bases on the NMR spectral data and the consideration that the lithiation of *m*-dichlorobenzene should be preferred in 2-position. Namely, 3-chlorobenzyne should be the main intermediate in this reaction to lead to 1-chloro- and 4-chlorotriptycene derivatives. Of these major products, the chemical shift difference between the methyls of the *t*-butyl group should be larger in the 1-chloro derivative than in the 4-chloro derivative.

Chlorination of 9-t-Butyl-1,2,3,4-tetrachlorotriptycene (1) with Sulfuryl Chloride. A solution of 200 mg (0.45 mmol) of **1** and 1.2 mL (14 mmol) of sulfuryl chloride in 20 mL of chlorobenzene containing 10 mg of dibenzoyl peroxide was heated under reflux for 1 h. The solvent was evaporated and the residue was subjected to dry-column chromatography on silica gel, using hexane–dichloromethane (20:1) as an eluent, to give fractions containing the starting material (R_f 0.4), a $\pm sc$-*ap* mixture of monochlorinated compounds (R_f 0.3), *ap* isomer of dichlorinated compound (R_f 0.25), and $\pm sc$ isomer of the dichlorinated compound (R_f 0.2). The yields were 5, 28, 27, and 26%, respectively in a typical run. These compounds were purified by recrystallization from tetrahydrofuran–ethanol.

1,2,3,4-Tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene. It was not possible to obtain pure isomers by chromatography on silica gel. Chromatography on alumina partially decomposed the $\pm sc$ form and the *ap* fraction afforded pure *ap* form, mp 251.5—252.5 °C, on recrystallization from chloroform–ethanol. Found: C, 60.02; H, 3.41; Cl, 36.89%. Calcd for $C_{24}H_{17}Cl_5$: C, 59.72; H, 3.55; Cl, 36.73%. ^{1}H NMR ($CDCl_3$, δ): 2.42 (6H, s), 4.58 (2H, s), 6.12 (1H, s), 7.00—7.21 (4H, m), 7.35—7.63 (2H, m), 7.77—8.13 (2H, m).

By subtracting the NMR signals of the *ap* form, the following ^{1}H NMR data ($CDCl_3$, δ) were obtained for the $\pm sc$ form: 2.14 (3H, s), 2.33 (3H, s), 4.97 (2H, br. s), 6.12 (1H, s), 7.00—7.21 (4H, m), 7.35—7.63 (2H, m), 7.77—8.13 (2H, m).

1,2,3,4-Tetrachloro-9-(2-chloro-1-chloromethyl-1-methylethyl)-triptycene. *ap* form, mp 210.5—211.5 °C. Found: C, 55.51; H, 2.97; Cl, 40.89%. Calcd for $C_{24}H_{16}Cl_6$: C, 55.75; H, 3.12; Cl, 41.14%. ^{1}H NMR ($CDCl_3$, 60 MHz, δ): 2.19 (3H, s), 5.01 (4H, q, $\Delta\delta_{AB}$=50.0 Hz, J_{AB}=12.4 Hz), 6.12 (1H, s), 7.03—7.22 (4H, m), 7.35—7.63 (2H, m), 7.82—8.17 (2H, m).

$\pm sc$ form, mp 221.0—221.5 °C. Found: C, 55.87; H, 2.97; Cl, 41.43%. Calcd for $C_{24}H_{16}Cl_6$: C, 55.75; H, 3.12; Cl, 41.14%. ^{1}H NMR ($CDCl_3$, 60 MHz, δ): 2.48 (3H, s), 4.65 (2H, q, $\Delta\delta_{AB}$=12.2 Hz, J_{AB}=12.4 Hz), 5.00 (2H, q, $\Delta\delta_{AB}$=15.2 Hz, J_{AB}=12.2 Hz), 6.12 (1H, s), 7.03—7.22 (4H, m), 7.35—7.63 (2H, m), 7.76—8.03 (2H, m).

Chlorination of Other 9-t-Butyltriptycenes with Sulfuryl Chloride. The reaction was carried out similarly and the following results were obtained.

(a): Chlorination of 9-*t*-butyl-1-chlorotriptycene (**4**) gave a mixture of *ap* and $\pm sc$ forms of monochlorinated compounds, of which separation was tedious. However, assignment of the structure and determination of the ratio of the products were straightforward because the ^{1}H NMR spectroscopic features of the rotamers were similar with others. The following ^{1}H NMR data (CCl_4, 60 MHz, δ) were obtained. *ap*: 2.37 (6H, s), 4.55 (2H, s). $\pm sc$: 2.13 (3H, br. s), 2.28 (3H, s), 4.97 (2H, q, $\Delta\delta_{AB}$=16.6 Hz, J_{AB}=11.9 Hz).

(b): Chlorination of 9-*t*-butyl-2,3-dichlorotriptycene (**3**) gave a 1:2 mixture of *ap* and $\pm sc$ forms. Chromatography of the product showed some enrichment of the respective forms but the final separation was not possible. The following ^{1}H NMR data were obtained at 60 MHz. *ap* (CCl_4, δ): 2.12 (6H, s). *ap* (C_6D_6, δ): 1.82 (6H, s). $\pm sc$ (CCl_4, δ): 2.12 (6H, s), 4.65 (2H, q, $\Delta\delta_{AB}$=14 Hz, J_{AB}=12 Hz). $\pm sc$ (C_6D_6, δ): 1.92 (3H, s), 1.85 (3H, s).

(c): Chlorination of 9-*t*-butyltriptycene (**5**) afforded a mixture of the starting material, 9-(2-chloro-1,1-dimethylethyl)triptycene and a dichlorinated compound in a 9:70:21 ratio. The mixture was chromatographed on a TLC plate using hexane–benzene (20:1) as a developing solvent. The chromatography afforded a mixture of *ca.* 10:1 monochlorinated compound and the starting material. Recrystallization of the mixture from acetone–hexane yielded pure 9-(2-chloro-1,1-dimethylethyl)triptycene, mp 201—202 °C. Found: C, 83.54; H, 5.88; Cl, 10.63%. Calcd for $C_{24}H_{21}Cl$: C, 83.58; H, 6.14; Cl, 10.28%. ^{1}H NMR ($CDCl_3$, δ): 2.15 (6H, s), 4.70 (2H, s), 5.22 (1H, s), 6.85—7.10 (6H, m), 7.25—7.48 (3H, m), 7.56—7.80 (3H, m). The following ^{1}H NMR data at 60 MHz were obtained for 9-(2-chloro-1-chloromethyl-1-methylethyl)triptycene from the spectrum of a mixture of mono- and dichlorinated compounds ($CDCl_3$, δ): 2.27 (3H, s), 4.71 (4H, q, $\Delta\delta_{AB}$=15.7 Hz, J_{AB}=12.2 Hz), 5.22 (1H, s).

(d): Chlorination of 9-*t*-butyl-1,2,3,4-tetrabromotriptycene (**2**) afforded a mixture of various products. It was not possible to isolate the desired product.

Bromination of 9-t-butyl-1,2,3,4-tetrachlorotriptycene (1). A solution of 100 mg (0.22 mmol) of the triptycene and 160 mg (1.0 mmol) of bromine in 50 mL of carbon tetra-

chloride was irradiated with tungsten lamps at room temperature. The reaction mixture was worked up as usual and the products were submitted to dry-column chromatography on silica gel or TLC. Elution with 20:1 hexane–dichloromethane afforded a mixture of *ap*- and ±*sc*-9-(2-bromo-1,1-dimethylethyl)-1,2,3,4-tetrachlorotriptycene (R_f 0.3), *ap*-9-(2-bromo-1-bromomethyl-1-methylethyl)-1,2,3,4-tetrachlorotriptycene (R_f 0.2), and the ±*sc* isomer (R_f 0.15) of the latter. The ±*sc* form of the monobrominated compound was concentrated up to 90% (as judged by ^{1}H NMR spectra) by the chromatography and the following ^{1}H NMR data ($CDCl_3$, δ) were obtained for the two forms. *ap*: 2.40 (6H, s), 4.53 (2H, s), 6.10 (1H, s), 6.95—7.16 (4H, m), 7.35—7.60 (2H, m), 7.80—8.15 (2H, m). ±*sc*: 2.14 (3H, s), 2.36 (3H, s), 4.93 (2H, br. s), 6.10 (1H, s), 6.95—7.16 (4H, m), 7.36—7.60 (2H, m), 7.80—8.15 (2H, m). Elemental analyses of the 10:1 mixture, mp 168—169 °C, gave the following data: C, 54.51; H, 3.08; Br, 15.02; Cl, 26.65%. Calcd for $C_{24}H_{17}BrCl_4$: C, 54.69; H, 3.25; Br, 15.16; Cl, 26.90%.

The following ^{1}H NMR data were obtained for the dibrominated compounds ($CDCl_3$, 60 MHz, δ). *ap*: 2.23 (3H, s), 4.97 (4H, q, $\Delta\delta_{AB}$=43.0 Hz, J_{AB}=11.9 Hz), 6.12 (1H, s), 7.02—7.23 (4H, m), 7.36—7.60 (2H, m), 7.85—8.10 (2H, m). ±*sc*: 2.53 (3H, s), 4.58 (2H, q, $\Delta\delta_{AB}$=14.1 Hz, J_{AB}=11.9 Hz), 4.96 (2H, q, $\Delta\delta_{AB}$=14.0 Hz, J_{AB}=12.0 Hz), 6.11 (1H, s), 7.02—7.23 (4H, m), 7.36—7.60 (2H, m), 7.75—7.99 (2H, m).

Bromination of 9-*t*-butyltriptycene afforded *9-(2-bromo-1,1-dimethylethyl)triptycene*, mp 212—213 °C. Found: C, 74.24; H, 5.34; Br, 20.88%. Calcd for $C_{24}H_{21}Br$: C, 74.04; H, 5.44; Br, 20.52%. ^{1}H NMR ($CDCl_3$, δ): 2.18 (6H, s) 4.67 (2H, s), 5.23 (1H, s), 6.83—7.10 (6H, m), 7.27—7.48 (3H, m), 7.55—7.90 (3H, m).

Bromination with Bromine-N-Bromosuccinimide. This reaction was carried out similarly with the photobromination except that the equimolar *N*-bromosuccinimide to bromine was added. The reaction was faster than that in the absence of *N*-bromosuccinimide but the products were the same as the photobromination.

Bromination of 9-*t*-butyl-1,2,3,4-tetrabromotriptycene with bromine–*N*-bromosuccinimide gave a *ca.* 10:1 mixture of ±*sc* and *ap* forms of a monobrominated compound of which separation was not possible. The compound was very labile, being decomposed even in chromatography on Florisil, and decomposed on standing at room temperature. The following ^{1}H NMR data ($CDCl_3$, 60 MHz, δ) were obtained. *ap*: 2.51 (6H, s), 4.48 (2H, s), 6.22 (1H, s). ±*sc*: 2.08 (3H, s), 2.48 (3H, s), 5.03 (2H, q, $\Delta\delta_{AB}$=15.0 Hz, J_{AB}=11.1 Hz), 6.22 (1H, s).

Photochlorination was carried out by irradiating a solution of 50 mg of a substrate in 50 mL of carbon tetrachloride containing 0.1 mmol of chlorine by tungsten lamps for 10—15 min. The products were identical with those obtained by chlorination with sulfuryl chloride.

Competitive Halogenation. It was carried out using the same conditions as described in the foregoing paragraphs except that equimolar amounts of *t*-butyltriptycene and a halotriptycene were dissolved in carbon tetrachloride or chlorobenzene. Analyses of the products were performed by ^{1}H NMR spectra.

Determination of the Rotational Barrier. (a): A solution was prepared by dissolving 50 mg of 9-(2-chloro-1,1-dimethylethyl)triptycene (±*sc*/*ap*=*ca.* 3) in 0.5 mL of 1-chloronaphthalene. The solution was placed in an NMR sample tube and the tube was sealed after purging the air by nitrogen. The tube was immersed in a boiling solvent bath and the ±*sc*/*ap* ratio was checked by ^{1}H NMR spectra at appropriate intervals. The solvents (boiling points) used for the study were naphthalene (218.5 °C), nitrobenzene (208.0 °C), ethylene glycol (197.0 °C), and *trans*-decalin (187.0 °C). The data were treated as the first order reversible reaction: consideration of Eqs. 2 and 3 gave rate constants given in Table 1.

Table 1. Rate constants for the exchange between and equilibrium constants of ±*sc* and *ap* isomers of 1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene

T/°C	$k_{sc\rightarrow ap}/10^{-4}\,s^{-1}$	K(±*sc*/*ap*)
218.5	2.39	0.96
208.0	1.27	0.96
197.0	0.589	0.96
187.0	0.259	0.96

Table 2. Rate constants for the exchange between and equilibrium constants of ±*sc* and *ap* isomers of 1,2,3,4-tetrachloro-9-(2-chloro-1-chloromethyl-1-methylethyl)triptycene

T/°C	$k_{sc\rightarrow ap}/10^{-4}\,s^{-1}$	K(±*sc*/*ap*)
218.5	2.20	1.84
208.0	0.939	1.80
197.0	0.434	1.80
187.0	0.202	1.80

$$K = \frac{2\,k_{ap\rightarrow sc}}{k_{sc\rightarrow ap}} \tag{2}$$

$$\log\left[1-\left(1+\frac{1}{K}\right)\frac{x}{a}\right] = -\frac{k}{2.303}\left(1+\frac{1}{K}\right)t, \tag{3}$$

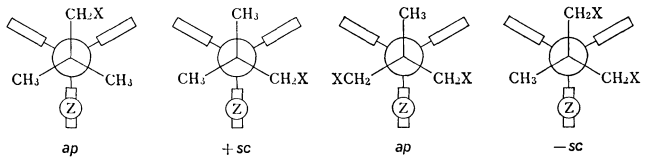
where a and x are the molar concentrations at time 0 and t, respectively. From the results shown in Table 1, the Eyring plot produced $\Delta H^*_{sc\rightarrow ap}$=32±5 kcal/mol (1 cal=4.18 J) and ΔS^*=−10±13 e. u. $\Delta H^*_{ap\rightarrow sc}$ and ΔS^* were obtained as 32±5 kcal/mol and −12±13 e. u., respectively. The compound tended to decompose at high temperatures on prolonged heating. This seems to cause errors to some extent.

(b): Similarly the rates of isomerization of 9-(2-chloro-1-chloromethyl-1-methylethyl)-1,2,3,4-tetrachlorotriptycene were determined and the data shown in Table 2 were obtained. These data produced $\Delta H^*_{ap\rightarrow sc}$ 31±0 kcal/mol and ΔS^* −13±0 e. u., respectively. We may have to admit errors as large as those for the monochlorinated compound, although the errors in the least squares treatment were small. Decomposition of the substrate on prolonged heating occurred to some extent.

Results and Discussion

Assignment of the Stereochemistry of the Halogenation Products. The assignment is straightforward because, if it is an *ap* isomer of the monohalogenated compound, the signal due to two methyl groups appears as a singlet and the methylene protons give a singlet as well, as can be seen from the Newman projections. In contrast, ±*sc* forms give two signals for the methyl protons and an AB quartet for the methylene protons, if it is a monohalogenated compound. Sim-

ilarly, in dihalogenated compounds, *ap* forms give a set of AB quartet because the methylene protons are diastereotopic, whereas the $\pm sc$ 2 sets of AB quartet for the methylene protons.



monohalogenated dihalogenated

Barriers to Rotation and Population Ratios. From the enthalpies and entropies of activation for rotation, we can calculate the life times of the respective rotamers at a given temperature. At the highest temperature, boiling point of chlorobenzene, we have used, it takes about two weeks for effecting the conversion of 5% of one conformer to another, the amount being considered as the error limit for detection of the change by integration of the NMR spectra. Thus we may neglect the isomerization, since the reaction is over within 1 h. Although not determined, other rotamers must also be stable since even 9-(2-phenyl-1,1-dimethylethyl)-2,3-dichlorotriptycene, a model for compound **2**, has a high barrier to rotation.[12] This assures that we are directly observing the reactivities of respective methyls by comparing the product ratios.

Population ratios of the rotamers are also interesting. At the equilibrium, the population ratio of 9-(2-chloro-1,1-dimethylethyl)-1,2,3,4-tetrachlorotriptycene is very close to unity. Since the statistical value must be $\pm sc/ap=2.0$, the $\pm sc$ form is disfavored to some extent. Probably the steric factor dominates. In contrast, 9-(2-chloro-1-chloromethyl-1-methylethyl)-1,2,3,4-tetrachlorotriptycene gives $\pm sc/ap$ values of *ca.* 1.80 which are very close to the statistical value. This is probably caused by the fact that at least one chloromethyl group always flanks the peri-chloro group irrespective of the conformation.

Comparison of the Reactivities of Methyl Groups. The following results are the mean values of 3—5 runs. Reproducibility of the results was good.

At the outset, we looked at the reactivities of methyls in 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene (**1**) with sulfuryl chloride. The $\pm sc/ap$ ratio was 3.2 ± 0.2. Since there are two $\pm sc$ methyls and one *ap* methyl, the relative reactivity of the $\pm sc$ methyl is 1.6 if we take the *ap* methyl as a standard. The formation ratio $ap/\pm sc$ of dichlorinated product is in conformity with this relative reactivity also: if we assume the relative reactivities of 1.6 and 1.0 for the remaining $\pm sc$ and *ap* methyls in the monochlorinated compounds, the calculated ratio of $ap/\pm sc$ for the dichlorinated compounds is 0.8, which is in good agreement with the observed. The difference in reactivity must be caused by the presence of the peri-chloro group, because chlorination of 9-*t*-butyl-2,3-dichlorotriptycene gave a 2:1 mixture of $\pm sc$ and *ap* isomers.

Two reasons may be considered for the apparent enhancement of the reactivity of the $\pm sc$ methyls. Since the molecular structure of 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene (**1**) studied by X-ray crystallography[13] reveals that the peri-chloro and the *t*-butyl groups are tilted away from each other, the *ap* methyl may be pushed into the triptycene skeleton to make it less exposed to the external attack of radicals. Or else, the peri-chloro group may stabilize the transition state for abstraction of hydrogen by radicals. Although the extent of neighboring participation of the chloro group in radical reactions is not large, yet it definitely exists.[14] In order to establish the cause for the selectivity, we took advantage of three techniques: changing halogenation reagents to examine the change in selectivity, changing the peri-substituent to change the extent of neighboring group participation, and competitive halogenation between 9-*t*-butyltriptycene (**5**) and a halogen-substituted 9-*t*-butyltriptycene.

Table 3. Effects of the halogenating reagent on the $\pm sc/ap$ ratios of 9-(2-halo-1,1-dimethylethyl)-1,2,3,4-tetrachlorotriptycenes

Reagent	$1/2(\pm sc/ap)$
SO_2Cl_2	1.6 ± 0.1
Cl_2	1.0 ± 0.05
Br_2	3.1 ± 0.06
Br_2–NBS	1.5 ± 0.1

The effects of changing the halogenation reagent on the $\pm sc/ap$ ratio are summarized in Table 3. The rate determining step in radical halogenations is the hydrogen abstraction.[15] Chlorination with sulfuryl chloride is known to be a little more selective than that with chlorine.[15,16] The product ratio in the chlorination with chlorine indicates that the $\pm sc$ and *ap* forms are formed almost statistically. If the steric reason had dominated, even chlorine would have given some selectivity, because the *ap* methyl should be protected sterically. Thus the results favor the chloro-participation. The neighboring group participation is further supported by the fact that bromination with bromine gives a very large $\pm sc/ap$ ratio, since the bromination is known to proceed with high selectivity.[17] The large $\pm sc/ap$ ratio suggests lowering the energy of the transition state because of the chloro-participation. If it were the steric reasons that preferred the $\pm sc$ form in the SO_2Cl_2-chlorination, the ratio should not have changed to a large extent. *N*-Bromosuccinimide is often used to trap hydrogen bromide in photobromination of hydrocarbons.[16] Usually *N*-bromosuccinimide is assumed to not participate in the halogenation reaction but in trapping hydrogen bromide. However, the present results suggest that succinimido radicals participate in hydrogen abstraction because the selectivity is inferior to the photobromination in the absence of *N*-bromosuccinimide. Skell reported recently that succinimido radicals sometimes participate in hydrogen abstraction,[18] and this is another example of such a kind. It is also interesting to note that sulfuryl chloride does give selectivity to some extent, although Russel observed that the difference in selectivity between chlorine and sulfuryl chloride chlorinations vanished in aromatic solvents and suggested that a complex be-

tween the aromatic molecule and the chlorine atom was a true attacking species.[19] It seems that chlorosulfonyl radicals participate in hydrogen abstraction in this case.

Now that the bromo group is known to give better assistance in radical formation,[17] if we introduce a bromo substituent in the peri-position, the reactivity of the $\pm sc$ methyls should be enhanced. In fact, the $\pm sc/ap$ ratio of 9-(2-bromo-1,1-dimethylethyl)-1,2,3,4-tetrabromotriptycene rose to >10 in bromine–*N*-bromosuccinimide bromination. Thus the results support again that the enhancement of the reactivity of the $\pm sc$ methyls must be attributed to the neighboring group participation of the peri-substituent.

The results of competitive halogenations are given in Table 4. The $\pm sc/ap$ ratios observed in the individual halogenations of the respective compounds were reproduced in these reactions. The results suggest that, while the reactivities of the *ap* methyls are uniformly suppressed to some extent, those of the $\pm sc$ methyls vary widely: while chlorination gives generally smaller values than unity, bromination gives larger values than that. It is especially noteworthy that the 1,2,3,4-tetrabromo compound (**2**) gives a value as high as 4. This is again the indication that the participation of the peri-substituent is important.

The less reactivity of the tetrachloro compound (**1**) in chlorination is confusing if one simply assumes the neighboring group participation. This phenomenon together with the suppressed reactivity of the *ap* methyls in all halogenations may be attributed to the inductive effect: since the halogenating radicals are known to be electron-demanding,[20] the tetrachloro substituents on a benzeno bridge should suppress the reactivity. We have had such an experience in bromination of 9-allyl-1,2,3,4-tetrachlorotriptycene.[21]

To give further support to this discussion, we have carried out halogenations of 9-*t*-butyl-1-chlorotriptycene (**4**) which should give less electron-withdrawing effect than the tetrahalo compounds. The results are given in Table 5, where $\pm sc/ap$ ratios are taken from the reactions carried out individually. Apparently the reactivity of the *ap* methyl is raised relative to the tetrahalo compounds. The results suggest that the inductive effect is important. It is also interesting to note that the $\pm sc/ap$ ratios are raised relative to the tetrachloro compound (**1**) except the chlorination with chlorine. Probably the higher electron-donating ability of the monochlorobenzeno bridge than the tetrachlorobenzo moiety[22] is responsible for the phenomenon.

Table 4. Relative reactivities of methyls in *t*-butyltriptycenes relative to one of the methyls in 9-*t*-butyltriptycene

Halogenating reagent	Substituents	Relative reactivities	
		$\pm sc$	*ap*
SO_2Cl_2	1,2,3,4-Cl_4	0.95±0.05	0.60±0.03
Cl_2	1,2,3,4-Cl_4	0.84±0.02	0.83±0.05
Br_2	1,2,3,4-Cl_4	2.78±0.3	0.89±0.04
Br_2-NBS	1,2,3,4-Cl_4	1.16±0.08	0.82±0.04
Br_2-NBS	1,2,3,4-Br_4	4.1±0.8	0.8±0.2

Table 5. $\pm sc/ap$ ratios and relative reactivities of methyls in 9-*t*-butyl-1-chlorotriptycene relative to one of the methyls in 9-*t*-butyltriptycene

Halogenation reagent	$\pm sc/ap$	Relative reactivities	
		$\pm sc$	*ap*
Cl_2	2.1±0.1	0.94±0.03	0.92±0.03
Br_2	7.8±0.3	4.2±0.2	1.05±0.02
SO_2Cl_2	3.80±0.04	—	—

Esterification of Carboxylic Acids by Alcohols with 2-Chloro-1,3,5-trinitrobenzene as Condensing Agent[1)]

Seiji TAKIMOTO,[2)] Junji INANAGA, Tsutomu KATSUKI, and Masaru YAMAGUCHI*
Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812
(Received November 28, 1980)

When mixtures of carboxylic acids or their sodium salts and alcohols were treated with 2-chloro-1,3,5-trinitrobenzene in the presence of pyridine under mild conditions, the corresponding carboxylic esters were formed. The yields and the rates of the ester formation depended on the types of the acids and the alcohols used.

Though the high reactivity of 2,4,6-trinitrophenyl carboxylates (**2**) in substitution reactions has been well recognized,[3)] the applications of these active esters to synthetic reactions are not many because few good methods for the general preparation of **2** under mild conditions are known.[4)] The kinetic parameters for the formation of chloride ion in the aqueous methanolic solutions of 2-chloro-1,3,5-trinitrobenzene (**1**) and sodium carboxylates,[5)] indicate that **1** reacts with carboxylates fairly rapidly and that the intermediate thus formed, in situ, may be used for the synthetic reactions. Wittmann utilized **1** in this way for the preparation of phosphoric acid esters[6)] and recently Inomate *et al.* 2-fluoro-1,3,5-trinitrobenzene (FTNB) for the preparation of *N*-phenyl amides, carboxylic esters, and thiocarboxylic *S*-esters.[7)] Several studies on the use of other polynitrohalobenzenes are also known.[8)] The present paper describes that **1** is particularly useful for the synthesis of esters of aromatic and aliphatic carboxylic acids.

Results and Discussion

Preliminarily, mixtures of sodium carboxylates and 2-butanol were treated with **1** at room temperature in ether, benzene, dichloromethane, acetonitrile, dimethyl sulfoxide, or hexamethylphosphoric triamide. In all cases, the formation of *s*-butyl carboxylates was observed but the esters were always contaminated with varied amounts of acid anhydrides. Alternatively, when **1**, carboxylic acids, and triethylamine were mixed in a 0.5:1:1 molar ratio under the absense of alcohols, acid anhydrides (**4**) were formed in good yields, as exemplified in Table 1.

On the other hand, however, when carboxylic acids or their sodium salts, alcohols, and **1** were mixed in pyridine used as the solvent, the corresponding esters (**5**) were formed in good yields, except for the esterification of carboxylic acids not branched at the α-carbon atom, where the use of a limited amount of pyridine in dichloromethane was preferable. Other bases such as triethylamine or 1,8-diazabicyclo[5.4.0]-undec-7-ene did not give the good yield and the products were contaminated with deep red substance. 4-Dimethylaminopyridine, known as an excellent acyl transfer reagent,[9)] was not effective and even retarded the reaction. In agreement with the trend in the nucleophilic aromatic substitution, the corresponding iodo- or bromotrinitrobenzene was less reactive than **1** and 2,4-dinitrochlorobenzene was almost useless.

The mechanism of this esterification is not clear at present. Inomata *et al.* described that the esteri-

Mp 100.5—101.5 °C. Found: C, 77.16; H, 7.08%. Calcd for $C_{20}H_{22}O_3$: C, 77.39; H, 7.14%.

fication using FTNB proceeds through the acyl fluorides as the intermediates which undergo the nucleophilic attack.[7b] On the other hand, in the esterification using **1** the main reaction seems to proceed through the acid anhydrides presumably formed from the other more reactive intermediates, the active esters (**2**) and/or acyl chlorides, by the attack of carboxylate anions remaining in the mixture. However, the direct attack of alcohols on **2** or on acyl chlorides are also considered to participate to a varied extent. For example, the formation of *t*-butyl pivalate (entry 7, Table 3) can not be explained by the anhydride route alone because the reaction between 2-methyl-2-propanol and pivalic anhydride in pyridine is extremely slow.[10] The difference between the two reagents, **1** and FTNB, in the esterification reaction can be easily understood when we consider the fact that fluorine atom attached to aromatic nucleous is much more reactive than chlorine atom in nucleophilic aromatic substitution, but that the acyl fluorides are, in turn, comparatively sluggish in nucleophilic displacements. In fact, the esterifications with FTNB are much slower than those with **1**.[11]

Aromatic Acids. Common aromatic acids were smoothly esterified in pyridine by the procedure exemplified in experimental part (Method A). They are summarized in Table 2. The esterification of 2,3,6-trimethylbenzoic acid by secondary or tertiary alcohol was difficult and a considerable amount of the acid anhydride was formed (entry 14 and 15, Table 2). An alcohol (**6**)[12] having an acid-sensitive acetal group could also be benzoylated in good yield.

Aliphatic Acids Branched at the α-Carbon Atom. The esters of primary, secondary, and tertiary alcohols were prepared by the same procedure as used in the above aromatic acid esters. The results are summarized in Table 3. Sterically crowded *t*-butyl pivalate was formed only in poor yield and a large amount of pivalic anhydride was detected. In order to examine the stability of the epimerizable α-carbon atom during the reaction, methyl hydrogen *meso*-2,4-dimethylglutarate was esterified with 2-methyl-2-propanol (entry 9, Table 3). The ester was obtained in good yield but the product was partly epimerized (*dl*:*meso*=1:10). On the other hand, the ester of secondary alcohol was obtained without any epimerization (entry 8, Table 3), presumably because of the rapidness of the reaction.

Aliphatic Acid Not Branched at the α-Carbon Atom. When aliphatic carboxylic acids which do not bear alkyl substituents on the carbon atom α to the carboxyl group, were esterified by the same procedure as described above (Method A), the products were contaminated by reddish brown substance and by some unchanged **1**. The yield of the esters was accordingly not satisfactory (50—60%). Various modifications were made to improve the yield, and the best result was obtained by conducting the reaction in dichloromethane using a limited amount of pyridine as catalyst (2—3 mole equiv. per 1 mole of **1**; Method B).[13] This procedure required much longer reaction time and the rate of esterification decreased in the order of primary alcohols>secondary alcohols>tertiary alcohols. They are summarized in Table 4.

Phenol Esters. The present method was not suitable for the preparation of phenol esters because of the concomitant formation of phenyl 2,4,6-trinitrophenyl ether (Table 5). Alternatively, the same ether

was obtained in 73% yield by mixing **1** and phenol in the presence of pyridine. Similar preparation of unsymmetrical diphenyl ethers has already been reported.[14]

Experimental

All reagents employed were dried by appropriate methods. Commercial 2-chloro-1,3,5-trinitrobenzene (**1**) was recrystallized from chloroform to a constant mp 81—82 °C. The whole procedures were carried out under the exclusion of moisture. The progresses of the reactions were followed by GLPC and the esters formed were identified by comparing their NMR spectra with those of the authentic specimens.

Acid Anhydrides (Table 1). A mixture of **1** (1 mmol, 245 mg), carboxylic acid (2 mmol), and triethylamine (2 mmol, 276 μl) in benzene (3 ml) was stirred at room temperature. The products were identified by the comparison of the retention time in GLPC with the authentic specimens, and the yields were determined by comparison with appropriate internal standards.

Esters of Aromatic Acids and Esters of Aliphatic Acids Branched at the α-Carbon Atom (Method A) (Tables 2 and 3). The typical example is as follows. **1** (2 mmol, 490 mg) was added to a stirred mixture of benzoic acid (2 mmol, 244 mg) and 2-butanol (2.4 mmol, 220 μl) in pyridine (2 ml). After stirring for 3 h, an 8% aqueous sodium hydrogencarbonate solution (20 ml), water (10 ml), and ether (20 ml) were added and the whole mixture was stirred until the precipitate of pyridine picrate dissolved in the aqueous layer. The ether layer was separated and combined with the second extract (ether, 20 ml). The ether extract was washed with water until the yellow color of the solution was removed, then twice with 2% aqueous hydrochloric acid (20 ml) and water, and dried with sodium sulfate. Distillation of the residue gave *s*-butyl benzoate in 93% yield.

Crystalline esters (entries 4—13, Table 2) were filtered after treating with sodium hydrogencarbonate solution and washed well with water. All these crude crystalline esters showed correct mp and NMR spectra without further purification.

dl-erythro-*2,3-Isopropylidenedioxy-2-methylpentyl Benzoate.* It was prepared by the method A by stirring the corresponding isopropylidenedioxy alcohol (**6**)[12] (1.05 mmol, 186 mg), sodium benzoate (1.05 mmol, 152 mg), and **1** (1.05 mmol,

260 mg) in pyridine (1 ml) at room temperature for 3 h in 86% yield. Mp 70.5—71 °C. Found: C, 69.05; H, 7.97%. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.

Esters of Aliphatic Acids Not Branched at the α-Carbon Atom (Method B) (Table 4). A typical example is as follows. Pyridine (2.1 mmol, 170 μl) was slowly added over a period of five minutes to a stirred mixture of propionic acid (1 mmol, 75.5 μl), benzyl alcohol (1.1 mmol, 114.4 μl), and **1** (1 mmol, 245 mg) in dichloromethane (2 ml). The mixture was stirred for 20 h at room temperature. The reaction mixture was worked up as described in method A, giving benzyl propionate in 96% yield.

Phenol Esters. Carboxylic acid, phenol, and **1** (1 mmol each) reacted according to the method B (3.5 mmol of pyridine). Results were shown in Table 5. In an experiment without the carboxylic acid (40 h), 2,4,6-trinitrophenyl phenyl ether was obtained in 73% yield.

Synthesis and Properties of Bridgehead-substituted Bicyclo[*n*.2.2] Bridgehead Alkenes

Yasuo SAKAI,* Shingo TOYOTANI, Masaru OHTANI, Masaharu MATSUMOTO, Yoshito TOBE, and Yoshinobu ODAIRA

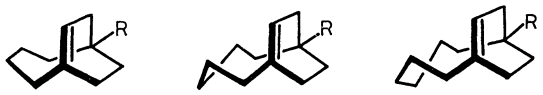
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received November 28, 1980)

The bridgehead-substituted bicyclo[*n*.2.2] bridgehead alkenes (**1b—3b**) (**1**, $n=4$; **2**, $n=5$; **3**, $n=6$; **b**, R=OAc) were synthesized based on the oxidative decarboxylation of [*n*.2.2]propellanecarboxylic acids with lead tetraacetate. The parent alkene (**1a—3a**) (**a**, R=H) and other bridgehead-substituted derivatives (**1c—3c** and **1d—3d**) (**c**, R=OH; **d**, R=Cl) were prepared from **1b—3b**. The examination of the ^{13}C NMR chemical shifts of **1a—c**, **2a—c**, and **3a—c** indicates the presence of electronic interaction between the bridgehead double bond (C_γ) and the opposite bridgehead carbon (C_α), being the homoallylic position of the double bond. From the product study and the kinetic results of the solvolysis of the bridgehead chlorides **1d—3d**, it is indicated that the homoallylic participation of the strained bridgehead double bond to the carbonium ion center located at the opposite bridgehead position operates in the solvolysis of **1d** and **2d**. It may be, therefore, concluded that highly strained bridgehead alkenes, especially, bicyclo[4.2.2]decene system, show remarkable homoallylic type α,γ-interaction both in the ground state and in the transition state (carbonium ion).

There has been considerable interest in the chemistry of strained bridgehead olefins, especially with regard to the development of new efficient methods providing an entry to the highly strained molecules and the examination of specific physical properties and chemical reactivities associated with the distortion imposed on the double bond.[1] In a continuation of the study on the transformation of readily available [*n*.3.2]propellanones into other important carbocyclic ring systems,[2] we have recently developed a synthetic entry to the bicyclo[*n*.2.2]bridgehead alkenes (**1b—3b**) having an acetoxyl group at the opposite bridgehead position based on the oxidative decarboxylation of [*n*.2.2]propellanecarboxylic acids (**4a—6a**) with lead tetraacetate.[3a] In this connection, we wish to report here on the synthesis of bicyclo[*n*.2.2] bridgehead alkenes (**1a—3a**) and the bridgehead-substituted derivatives (**1c—3c**) and (**1d—3d**) from **1b—3b**, on the physical properties, that is, ^{13}C NMR spectra of **1a—3a**, **1b—3b**, and **1c—3c**, and on the chemical reactivities in the solvolysis of the bridgehead chlorides **1d—3d**.[3]

Although the ^{13}C NMR spectra of conformationally rigid polycarbocyclic compounds possessing bridgehead substituents have been extensively studied,[4] little is known concerning those of highly strained bridgehead olefins.[5] It is, therefore, of particular interest to examine the ^{13}C NMR chemical shifts of a series of the bridgehead-substituted bridgehead alkenes **1a—c**, **2a—c**, **3a—c** in connection with the effect of both oxygen substituents at the bridgehead position and the ring size (*n*) on the chemical shifts. The examination of the chemical shifts of **1a—c**, **2a—c**, and **3a—c** obviously indicated the presence of electronic interaction between the bridgehead double bond and the opposite bridgehead carbon, being the homoallylic position of the double bond. These results prompted us to investigate the homoallylic interaction between the bridgehead double bond and the carbonium ion center located at the opposite bridgehead position in the solvolysis of the bridgehead chlorides **1d—3d**.[6] As a result, the product study and the kinetic results of the solvolysis demonstrated the presence of the



1a—d **2a—d** **3a—d**

a, R=H; **b**, R=OAc; **c**, R=OH; **d**, R=Cl

homoallylic participation of the strained double bond to the carbonium ion center, especially in the case of the most strained bicyclo[4.2.2]decene system (**1**).

Results and Discussion

Synthesis. The entry into the bridgehead-substituted bicyclo[*n*.2.2] bridgehead alkene systems was based on the oxidative decarboxylation of [*n*.2.2]-propellanecarboxylic acids **4a—6a** with lead tetraacetate, which were prepared from [*n*.3.2]propellanones[7] by the ring contraction involving the photochemical Wolff rearrangement. The reaction of **4a—6a** with lead tetraacetate was carried out in the presence of pyridine in benzene solution at 80 °C for 1 h. The [6.2.2]propellane **6a** gave the intended allylcarbinyl type bicyclic acetate **3b**, having a bridgehead double bond, in 81% yield. In the case of the [5.2.2]propellane **5a**, the cyclopropylcarbinyl type tricyclic acetate (**8b**), however, was obtained as the major product in 60% yield along with 13% of the desired bridgehead olefin **2b** and small amounts (3%) of [5.2.2]propellene (**10**). Moreover, the [4.2.2]propellane **4a** afforded the tricyclic acetate (**7b**) exclusively in 68% yield together with 5% of [4.2.2]propellene (**9**), but the intended olefin **1b** was not produced at all. These products may be derived from the rearrangement of the initially formed cyclobutyl cation to allylcarbinyl and/or cyclopropylcarbinyl ones. In order to transform the tricyclic acetates **7b** and **8b** into the corresponding bridgehead alkenes **1b** and **2b**, we first examined the

9 **10**

vapor phase thermolysis of **7b** and **8b** at 350 °C under nitrogen stream. Although the thermolysis proceeded in high efficiency to give **1b** and **2b**, this process seems to be not suited for large-scale preparation of **1b** and **2b**. We next tried, therefore, the acid catalyzed rearrangement of **7b** and **8b**. After many trials, it appeared that simple treatment of **7b** and **8b** with acetic acid was the best way for this purpose. The bridgehead alcohols **1c**—**3c** were prepared by the lithium aluminum hydride reduction of **1b**—**3b**, and the bridgehead chlorides **1d**—**3d**, being the substrates required for solvolysis experiments, were derived from the reaction of **1c**—**3c** with thionyl chloride or phosphoryl chloride. The preparation of the unsubstituted hydrocarbons **1a**—**3a** was not straightforward. Thus **1a** was prepared by the elimination of acetic acid by means of the vapor phase thermolysis of the saturated acetate (**11b**) (76%) or by the dehydration through treating the saturated alcohol (**11c**) with thionyl chloride/pyridine (74%), which were derived by the diimide reduction of **1b** and **1c**, respectively.[8] Although the similar reduction of **2c** afforded **12c**, those of **2b**, **3b**, and **3c**, however, were unsuccessful.[9,10] The bridgehead alkene **2a** was prepared, therefore, by the dehydration of **12c** (80%) or by the thermolysis of **12b** (82%) which was obtained by the acetylation of **12c** using 4-dimethylaminopyridine/acetic anhydride.[11] On the other hand, **3a** was prepared by the reduction of the chloride **3d** with lithium/*t*-butyl alcohol in 67% yield. All the synthetic scheme is summarized in Scheme 1.

^{13}C NMR Spectra. The ^{13}C NMR chemical shifts for the bridgehead-substituted bridgehead alkenes **1a**—**c**, **2a**—**c**, and **3a**—**c** are listed in Table 1. Though it was impossible to assign all the carbons, α carbon, olefinic γ carbon, and olefinic δ carbon (Fig. 1) were unequivocally assigned on the basis of

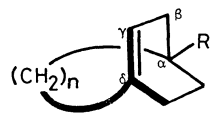


Fig. 1.

the multiplicities of the off-resonance decoupled spectra. Therefore, the discussion should be focused on the chemical shifts of the above three carbons. The substituent effects in each ring system, *i.e.*, the chemical shift differences between the alkenes having same ring system and different bridgehead substituents taking the hydrocarbons **1a**—**3a** as standard, are listed in Table 2, and the ring size effects, *i.e.*, the chemical shift differences between the alkenes having same substituent and different ring systems taking bicyclo[6.2.2]-dodecene systems **3a**—**3c** as standard, are in Table 3. As shown in Table 2, the magnitude of the substituent effects on each carbon is in the order α effects> γ effects>δ effects, as might be expected from the distance from the substituents to each carbon. The magnitude of α substituent effects, which are directly related to the electronegativity of oxygen, as well as the small degree of δ effects observed for **1b**—**c**, **2b**—**c**, and **3b**—**c** are in accord with the cases of other bridgehead substituted alkanes.[4] However, by contrast to the small downfield shifts for γ carbons in the bridgehead substituted alkanes,[4] the remarkable upfield shift was observed for the γ carbons in the present bridgehead alkenes. Thus, for example, the γ carbon resonances of **1b** and **1c** appeared 4.99 and 3.98 ppm higher field than that of **1a**. As can be seen in Table 3, most of α, γ, and δ carbons of **1a**—**c** and **2a**—**c**, except for γ carbons of **2a**—**c**, were deshielded compared with those of **3a**—**c**, which indicated the increase of steric strain with decrease in the ring size (n).

2b	OAc	0.54	−0.83	2.11
2c	OH	1.35	−0.69	1.54

a) Values refer to the differences between the chemical shifts of a given compound and those of **3a—3c** having the same bridgehead substituent. Positive shifts are to lower field and negative shifts are to higher field.

The most significant feature in the ^{13}C NMR spectra of the bicyclo[n.2.2] bridgehead alkenes is the remarkable shielding γ effects observed in **1b—c**, **2b—c**, and **3b—c**. The γ anti shielding effects is well known for some alicyclic systems and several possible mechanisms have been posturated for interpretation of the effect such as electrostatic field effect,[12)] back-lobe interaction of sp^3 orbitals on C_γ with that of C_α-hetero atom bond,[13)] and α,γ-hyperconjugative type interaction of free-electron pairs on hetero atom.[14)] The present γ effect may also be accounted by one or more

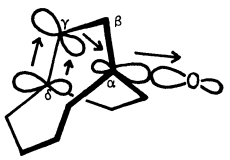

Fig. 2.

of the above explanations, because the molecular framework of the bridgehead alkenes are considerably deformed so that C_α and C_γ are in close proximity compared with unstrained saturated bicyclic systems. However, in view of the solvolysis behavior of the bridgehead chlorides **1d** and **2d** described later, we think it more attractive to ascribe the present γ effect to the interaction of the back-lobe of sp^3 orbital of C_α-oxygen bond with C_γ p orbital of the distorted bridgehead double bond, as shown in Fig. 2. Moreover, inspection of molecular models suggests that, in agreement with the observed effects, such interaction may be most pronounced in bicyclo[4.2.2]decene system (**1**) because of favorable geometry of the two orbitals for the interaction.

*Solvolysis of the Bridgehead Chlorides **1d—3d**.* From the standpoint of facility in the identification of the solvolysis products, the hydrolysis of the bridgehead chlorides **1d—3d** was attempted, because the expected hydrolysis products, that is, the bridgehead alcohols **1c—3c** and **7c—8c** should be readily available. The product study of the solvolysis of **1d—3d** was, therefore, carried out in 80% (v/v) acetone–water containing 2,6-lutidine buffer. Whereas the solvolysis of **3d** gave only the unrearranged alcohol **3c**, **1d** afforded the rearranged cyclopropylcarbinyl type alcohol **7c** as a sole product, and, in addition, **2d** gave 87% of the rearranged alcohol **8c** and 13% of the unrearranged one **2c**. The solvolysis rates of **1d—3d** were determined in ethanol solvent, because, unfortunately,

a) ^{1}H NMR spectra of **1a—3a** were measured in $CDCl_3$ solutions and those of the other compounds were in C_6D_6 solutions. b) Since **1a** was highly sensitive to oxygen, correct analytical data could not be obtained. c) Mp 33—35 °C. d) Mp 30—32 °C. e) Bp 50—60 °C (bath temp)/20 mmHg. f) Bp 75—78 °C/0.5 mmHg. g) Bp 80—83 °C/0.2 mmHg. h) Bp 85—87 °C/0.3 mmHg. i) Semisolid. j) Mp 84—85 °C. k) Bp 55—65 °C (bath temp)/1 mmHg; ^{13}C NMR ($CDCl_3$) δ 141.46 (s), 123.31 (d), 76.73 (s), 46.55 (t), 41.64 (t), 38.23 (t), 36.40 (t), 28.97 (t), 27.24 (t), 26.79 (t). l) Bp 75—85 °C (bath temp)/2 mmHg; ^{13}C NMR ($CDCl_3$) δ 139.53 (s), 121.25 (d), 75.37 (s), 47.67 (t), 43.82 (t), 36.34 (t), 35.21 (t), 29.44 (t), 28.79 (t), 26.80 (t), 26.44 (t). m) Bp 102—105 °C/4 mmHg; ^{13}C NMR ($CDCl_3$) δ 138.07 (s), 122.27 (d), 75.49 (s), 46.50 (t, 2C), 37.36 (t, 3C), 28.55 (t), 27.13 (t), 26.92 (t, 2C). n) Mp 87—89 °C. o) Mp 90—92 °C.

the hydrolysis rates of **1d—3d** were too rapid to measure.[15] The rates of ethanolysis of **1d—3d** buffered with 10% (v/v) of 2,6-lutidine were listed in Table 4.[16] For comparison, the ethanolysis rates of the saturated chloride (**11d**) were also determined. As shown in Table 4, **1d** was most reactive and was solvolyzed at a rate 214 times faster than the corresponding saturated chloride **11d**. The solvolysis rate of **2d** was about a half of that of **1d** but was still considerably greater than those of **3d** and **11d**. The product study and the kinetic results indicate clearly the presence of the homoallylic participation of the strained bridgehead double bond to the carbonium ion center located at the opposite bridgehead position in bicyclo[4.2.2]decene and bicyclo[5.2.2]undecene systems, although it may be conceivable that relief of large strain in the ground state of **1d** and **2d** may partially contribute to the observed rate enhancement. Examination of molecular models suggests that, in analogy with the case of the ^{13}C NMR study, more favorable geometry, both in distance and in orientation, can be attained for the homoallylic interaction between the vacant p orbital at the bridgehead position and the p orbital of the distorted bridgehead double bond with decrease in the size (n) of the bicyclo[n.2.2] framework. Thus, it may be concluded that the highly strained bridgehead alkenes, especially bicyclo[4.2.2]-decene system, show remarkable homoallylic type α,γ-interaction both in the ground state and in the transition state (carbonium ion).

Experimental

All the melting and boiling points are uncorrected. IR spectra were recorded on a JASCO IR-G spectrometer. Mass spectra were taken by using a Hitachi RMU-6E spectrometer. ^1H NMR spectra were obtained on a JEOL JNM-PS-100 spectrometer and ^{13}C NMR spectra were on a JEOL JNM-FX-60S spectrometer. Analytical GLC was carried out on a Hitachi 163 gas chromatograph (10% FFAP or 5% SE-30 column) and preparative GLC separation was undertaken on a Varian Aerograph 920 gas chromatograph. The spectral and analytical data for the bridgehead alkenes **1a—3a**, **1b—3b**, **1c—3c**, and **1d—3d** and those for the cyclopropylcarbinyl type tricyclic compounds **7b**, **8b**, **7c**, and **8c** were listed in Table 5.

Preparation of [n.*2.2*]*Propellanecarboxylic Acids* ***4a—6a***. The ring contraction of [n.3.2]propellanones[7] were carried out by the usual procedure involving the photochemical Wolff rearrangement.[17] Namely, the condensation of [n.3.2]propellanones with ethyl formate using sodium hydride in ether[18] gave the corresponding hydroxymethylene derivatives (IR 1670, 1600, 1520, 1180 cm^{-1}) in 80—87% yields and subsequent diazo transfer with tosyl azide[19] gave the corresponding diazo ketones (IR 2050, 1650 cm^{-1}) in quantitative yield. The crude diazo ketones were dissolved in methanol and the solutions were irradiated in a Pyrex vessel with a 500 W high pressure mercury lamp for 16—20 h. The solvent was removed under reduced pressure and the residue distilled to afford the methyl esters (**4b—6b**) of [n.2.2]propellanecarboxylic acids **4a—6a** in 65—85% yields. GLC analysis showed that **4b—6b** were the mixtures of epimers in about 1:2 ratio. **4b**: bp 103—105 °C/10 mmHg; IR 1720, 1165 cm^{-1}; MS m/e 194 (M^+); ^1H NMR (CCl_4) δ 1.00—2.72 (m, 14H), 3.04, 3.16 (t, J=8 Hz, 1H), 3.58 (s, 3H). Found: C, 74.17; H, 9.43%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%. **5b**: bp 110—112 °C/5 mmHg; IR 1720, 1165 cm^{-1}; MS m/e 208 (M^+); ^1H NMR (CCl_4) δ 1.10—2.55 (m, 16H), 3.02, 3.04 (t, J=8 Hz, 1H), 3.59 (s, 3H). Found: C, 74.77; H, 9.79%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%. **6b**: bp 124—128 °C/8 mmHg; IR 1720, 1165 cm^{-1}; MS m/e 222 (M^+); ^1H NMR (CCl_4) δ 1.10—2.56 (m, 18H), 3.08 (t, J=8 Hz, 1H), 3.60 (s, 3H). Found: C, 75.35; H, 10.11%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

The solutions of the esters **4b—6b** and 2 equiv. of potassium hydroxide in methanol were heated at reflux for 3 h. The solvent was concentrated and the residue was diluted with water and washed with ether. The aqueous layer was acidified with 6 mol dm^{-3} hydrochloric acid and extracted with ether. Evaporation of the ether gave **4a—6a** (92—93% yield) as colorless viscous oil which solidified on standing. IR 3500—2500, 1690, 1220 cm^{-1}. The treatment of **4a—6a** with ethereal diazomethane gave **4b—6b** having the similar ratio of epimers to that of the original ester mixtures.[20]

Oxidative Decarboxylation of ***4a—6a*** *with Lead Tetraacetate.* The solution of **4a—6a**, 1.1 equiv. of lead tetraacetate, and 0.6 equiv. of pyridine in benzene was heated under nitrogen at 80 °C for 1 h. After filtration, the solution was washed successively with dilute hydrochloric acid, sodium hydrogencarbonate solution, and water and then dried over anhydrous sodium sulfate (Na_2SO_4). After evaporation of the solvent, the products were analyzed by GLC and the yields determined: **4a**; **7b** (68%), **9** (5%). **5a**; **2b** (13%), **8b** (60%), **10** (3%). **6a**; **3b** (81%). The products were separated by preparative GLC. **9**: IR 3030 cm^{-1}; MS m/e 134 (M^+); ^1H NMR (CCl_4) δ 1.20—2.00 (m, 12H), 6.17 (s, 2H). Found: C, 89.20; H, 10.64%. Calcd for $C_{10}H_{14}$: C, 89.49; H, 10.51%. **10**: IR 3030 cm^{-1}; MS m/e 148 (M^+); ^1H NMR (CCl_4) δ 1.10—2.20 (m, 14H), 6.14 (s, 2H). Found: C, 89.06; H, 10.92%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%.

Preparation of ***1b*** *and* ***2b*** *by the Rearrangement of* ***7b*** *and* ***8b*** *in Acetic Acid.* The solution of **7b** and **8b** in acetic acid was stirred under nitrogen at room temperature for 5 and 22 h, respectively, and the progress of the reaction was monitored by GLC. The solution was cooled with ice and carefully neutralized with aqueous sodium hydroxide solution and extracted with ether. The ether extract was washed with water and dried over Na_2SO_4. Evaporation of the solvent followed by distillation afforded **1b** and **2b** in 90 and 97% yields, respectively. Analytical sample of **1b** was obtained by preparative GLC.

Preparation of the Bridgehead Alcohols ***1c—3c*** *and* ***7c—8c*** *by Lithium Aluminum Hydride Reduction of* ***1b—3b*** *and* ***7b—8b***. The solution of the acetates **1b—3b** and **7b—8b** in ether was added dropwise to the suspension of lithium aluminum hydride (1 equiv.) in the same solvent and the mixture was stirred at room temperature for 1 h. Water was added dropwise followed by dilute hydrochloric acid. The organic layer was separated and washed with sodium hydrogencarbonate solution and water and then dried (Na_2SO_4). Evaporation of the solvent gave the alcohols **1c—3c** and **7c—8c** in 68—80% yields which were purified by preparative GLC.

Preparation of the Bridgehead Chlorides ***1d—3d***. To the solution of **1c—3c** and 5 equiv. of pyridine in benzene was added 2 equiv. of thionyl chloride (phosphoryl chloride was used in the case of **1c**) and the solution was stirred at room temperature for 2 h. Water was added carefully and the organic layer was washed with dilute hydrochloric acid,

sodium hydrogencarbonate solution, and water. After drying over Na_2SO_4, the solvent was evaporated to give **1d—3d** as light brown oil (45—87% yields). Pure samples of **1d—3d** were obtained by preparative GLC.

*Preparation of **11b**, **11c**, and **12c** by the Diimide Reduction of **1b**, **1c**, and **2c**.* The solution of **1b**, **1c**, and **2c**, 20 equiv. of 90% hydrazine hydrate, and 0.1 equiv. of copper (II) sulfate in ethanol was stirred at room temperature while air was bubbled through a syringe. The course of the reaction was monitored by GLC and the reaction times required for completion were within 1 h for **1b** and **1c** and 20 h for **2c**. However, the similar reaction of **2b**, **3b**, and **3c** was unsuccessful.[10] The solution was diluted with water and extracted with ether. The ether extract was washed with water and dried (Na_2SO_4). After evaporation of the solvent, the products were purified by passing through a silica-gel column. Yields of the isolated products were 71—79%. **11b**: IR 1720, 1255, 1230 cm^{-1}; MS *m/e* 136 (M^+-AcOH); ^1H NMR (CCl_4) δ 1.32—2.40 (m, s at 1.84). Found: C, 73.45; H, 10.37%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%. **11c**: mp 73—74 °C; IR 3350, 1020 cm^{-1}; MS *m/e* 154 (M^+, trace), 136 (M^+-H_2O); ^1H NMR (CCl_4) δ 1.40—2.30 (m). Found: C, 77.49; H, 11.86%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%. **12c**: mp 79—80 °C; IR 3350, 1060, 1050 cm^{-1}; MS *m/e* 150 (M^+-H_2O); ^1H NMR (CCl_4) δ 1.35—2.30 (m). Found: C, 78.50; H, 11.63%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

*Preparation of **12b**.* To the solution of 80 mg of **12c** and 120 mg of 4-dimethylaminopyridine in 2 ml of dichloromethane was added with stirring the solution of 100 mg of acetic anhydride in 0.5 ml of dichloromethane and the solution was stirred at room temperature for 6 h. The solution was diluted with ether and washed successively with dilute hydrochloric acid, sodium hydrogencarbonate solution, and water and dried over Na_2SO_4. Evaporation of the solvent gave **12b** as a clear oil (80% yield). IR 1720, 1240 cm^{-1}; MS *m/e* 150 (M^+-AcOH); ^1H NMR (CCl_4) δ 1.10—2.40 (m, s at 1.84).[22]

*Preparation of the Alkenes **1a** and **2a**.* *(a) By the Vapor Phase Thermolysis of **11b** and **12b**:* The 3% solution of **11b** and **12b** in hexane was passed through a Pyrex column which was heated at 350 °C under nitrogen stream (15 ml/min) and the end of the column was connected to a trap containing powdered potassium carbonate cooled at −78 °C. The trapped solution was filtered and concentrated to give **1a** and **2a** as semisolid in 76—82% yields.

*(b) By the Dehydration of **11c** and **12c**:* The treatment of **11c** and **12c** with thionyl chloride/pyridine in the similar manner to the chlorination of **2c** and **3c** afforded **1a** and **2a** in 74—80% yields.

*Preparation of the Alkene **3a**.* The solution of 900 mg of **3d** and 3.3 g of *t*-butyl alcohol in 30 ml of tetrahydrofuran was heated at reflux with stirring and to this solution was added portionwise 315 mg of lithium cut in small pieces. The mixture was heated for 3 h and then poured into water. The organic layer was separated and the aqueous layer was extracted with ether. The combined extracts was washed with saturated sodium chloride solution and dried over Na_2SO_4. Evaporation of the solvent followed by distillation gave **3a** as a colorless oil in 67% yield.

*Preparation of the Bridgehead Chloride **11d**.* 138 mg of the alcohol **11c** was added portionwise to 1.0 g of thionyl chloride and the solution was stirred at room temperature for 1 h. Crashed ice was added followed by water and the mixture was extracted with ether. The extract was washed with sodium hydrogencarbonate solution and water and dried over Na_2SO_4. After evaporation of the solvent, **11d** was purified by sublimation (70 °C/20 mmHg): mp 70—71 °C; IR 850 cm^{-1}; MS *m/e* 172 (M^+, trace), 137 (M^+-HCl); ^1H NMR (CCl_4) δ 1.15—2.60 (m). Found: C, 69.94; H, 9.96%. Calcd for $C_{10}H_{17}Cl$: C, 70.14; H, 9.96%.

*Kinetic Measurements of the Ethanolysis of **1d—3d** and **11d**.* The solution (0.1 M) of the chlorides and the internal standard (octadecane or nonadecane) in ethanol containing 10% (v/v) of 2,6-lutidine was set in a constant temperature bath and at appropriate intervals aliquots were removed by a syringe and the decrease of the chlorides was determined by GLC. The products of the ethanolysis were isolated by preparative GLC and the ^1H NMR spectra of them were taken. **1d** gave a single ether which showed a multiplet (2H) at δ 0.52—0.98, a triplet at δ 1.21, and a quartet (2H) at δ 3.48 ppm. **2d** gave two ethers in a ratio of 3:1; the former exhibited a multiplet (2H) at δ 0.37—0.88, a triplet at δ 1.24, and a quartet (2H) at δ 3.52 ppm, and the latter a triplet at δ 1.11, a quartet (2H) at δ 3.28, and a multiplet (1H) at δ 5.36—5.52 ppm. **3d** afforded a single ether which showed a triplet at δ 1.15, a quartet (2H) at δ 3.31, and a broad doublet (1H) at δ 5.54 ppm.

*Preparative Hydrolysis of **1d—3d**.* The solution of **1d—3d** in 80% aqueous acetone containing 5 equiv. of 2,6-lutidine was stand at room temperature over night. The solvent was concentrated and extracted with ether. The products were identified by the comparison in GLC retention times and IR spectra with those of the authentic samples: **1d**; **7c** (96%). **2d**; **8c** (80%), **2c** (12%). **3d**; **3c** (99%).

15) It was deduced that the products of the ethanolysis were similar to those of the hydrolysis in acetone-water based on the ^1H NMR analysis of the ethanolysis products (see Experimental).

16) Since the bridgehead chlorides, especially **1d**, were unstable in acidic media, the ethanolysis rate measurements were carried out in the presence of large excess of 2,6-lutidine. Considerable rate decrease was observed for the ethanolysis in this solvent system compared with that in ethanol solvent. For example, the ethanolysis rates of **11d** in ethanol solvent were about five times of those in the lutidine containing solvent; $k_{40\,^\circ C}=3.05\times10^{-5}$, $k_{55\,^\circ C}=2.00\times10^{-4}\ s^{-1}$.

(Received December 4, 1980)

The configurational analysis of a series of alkyl substituted pentadienyl anions in THF was examined by trimethylsilylation and from the variable temperature ^{1}H- and ^{13}C-NMR spectra. Potassium pentadienide, -2-methylpentadienide or -2,4-dimethylpentadienide produced preferentially (*Z*)-2,4-pentadienyltrimethylsilane or its methyl substituted analogues to indicate that these compounds have the "U"-shaped structure in solution. By contrast, trimethylsilylation of potassium pentadienide and -2-methylpentadienide in the crystalline state produced the (*E*)- and the (*E*),(*Z*)-isomers, respectively, suggesting that the geometry is drastically changed to the "W"- or "S"-shaped by the medium effect. The W-shaped structure of potassium 3-methylpentadienide in THF and in the solid state is exceptional. Geometry of trapped products of potassium cycloheptadienide and -cyclooctadienide is also (*Z*) but the silylation occurred on the central carbon in contrast to the terminal silylation seen for the open-chain pentadienides. Geometry of these dienyl anions determined by NMR below −30 °C was consistent with the result obtained from trimethylsilylation. Superficial conflict between MINDO/3 prediction and the experimental evidence was reasonably reconciled by considering contact ion pairs for potassium pentadienide in THF and more strongly-solvated ion pairs for the lithium analogues.

A study of structures and configurational stabilities of a series of pentadienyl anions is of particular importance since such carbanions are crucial intermediates for base-catalyzed equilibration[1] of diolefins and are valuable organometallic reagents for syntheses.[2] Several theoretical studies on the geometry of open-chain pentadienyl anions are now available. Extended Hückel calculations by Hoffmann and Olofson[3] and CNDO/2 by Bushby *et al.*[4] predict that the horseshoe-like "U"-shaped anion should be preferred over the zigzag-like "W"- or sickle-like "S"-shaped anions. However, Dewar *et al.*[5] recently reported on the basis of MINDO/3 and MNDO calculations that the W-shaped structure is more stable than the U- or S-shaped structure by 2.5—15.5 kJ/mol for pentadienyl, 3-methyl- or 1,3-dimethylhexadienyl anions. Dewar's prediction is in accord with the experimental evidence obtained by NMR which indicates that lithium pentadienide,[6] hexadienide[7] and 2-methylpentadienide in THF, and potassium pentadienide[8] and hexadienide[9] in liquid ammonia exist preferentially as W-shaped anions. However, Schlosser *et al.* recently reported evidence for the U-shaped structure for the first time in the cases of potassium 2-methyl- and 2,4-dimethylpentadienide in THF based on the geometry of 2,4-pentadien-1-ol chemically derived from the anions.[10] Such predominance of the U-shaped structure has also been confirmed by us independently for the parent potassium pentadienide in THF from the hydrolysis data.[11]

This paper is concerned with 1) the regioselective trimethylsilylation of a series of potassium pentadienide in THF to determine the geometry of the pentadienyl moiety to confirm Dewar's MO prediction and the geometry suggested by Schlosser *et al.*, 2) the direct measurement of the geometry in solution by variable temperature ^{1}H- and ^{13}C-NMR, and 3) the medium (solution *vs.* the solid state) and counter-cation dependence of the geometry of a series of pentadienyl anions. All the experiments were conducted with use of isolated crystalline pentadienyl anions.

Results and Discussion

Chemical Trapping in Solution and in the Solid State. Trimethylsilylation of pentadienyl anions with an equimolar amount of chlorotrimethylsilane can be accomplished with extreme regioselectivity as has been shown in the trimethylsilylation of some nucleophiles.[12] Potassium pentadienide **1**, rubidium pentadienide **2**, and caesium pentadienide **3** in THF at 20 °C gave (*Z*)-2,4-pentadienyltrimethylsilane in 88, 90, and 92% regioselectivity in 95—98% yield and at −40 °C in 96—98% regioselectivity as evidenced by high resolution GC, ^{1}H-NMR (Table 1), IR, MS, and the analytical data (Table 5 in experimental section). Such high regioselectivity has also been found in the protolysis of **1** at 5 °C giving 92—95% of (*Z*)-1,3-pentadiene.[11] No product derived from the electrophilic attack on the central atom is formed in either case. In contrast, lithium pentadienide **4** in THF gave the (*E*)-isomer exclusively (98% yield) at −40 °C. The *Z*/*E* ratio for **1**—**3** (98:2) was determined with a high resolution gas chromatograph equipped with a 45 m capillary column. The resulting products are thermally stable and no isomerization of (*Z*)- to (*E*)-2,4-pentadienyltrimethylsilane or of the (*E*)- to the (*Z*)-isomer occurred by heating to 80 °C for 1 h in THF. The thermal stability permits the isolation of the respective pure isomers (Fig. 1) by distillation or with preparative GC. Sodium pentadienide gave a 7:3 mixture of (*Z*)- and (*E*)-isomers at 30 °C and a 6:4 mixture at −20 °C. Thus, the geometry of trapped products was successfully controlled by changing the counter cation.

If above anions are present as a single torsional isomer and trimethylsilylation occurs equally at both termini (C_1 and C_5), it would yield just one pair of products as shown in Schemes 1 and 2. Based on this postulate, the above results are readily explained

TABLE 1. ^{1}H-NMR CHEMICAL SHIFTS(δ-VALUES) AND COUPLING CONSTANTS(Hz) FOR PENTADIENYLTRIMETHYLSILANES IN $CDCl_3$ AT 30 °C[a)]

a) $CHCl_3$ was used as an internal standard(assuming to be 7.20 ppm downfield from TMS).

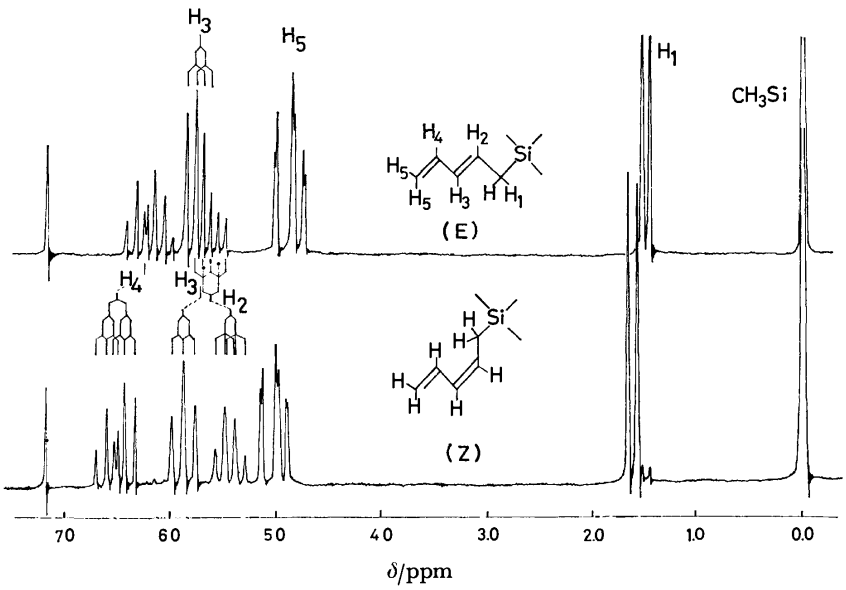

Fig. 1. ^{1}H-NMR spectra (100 MHz, in $CDCl_3$) of (*Z*)- and (*E*)-2,4-pentadienyltrimethylsilane prepared from **1** in THF and in the solid state.

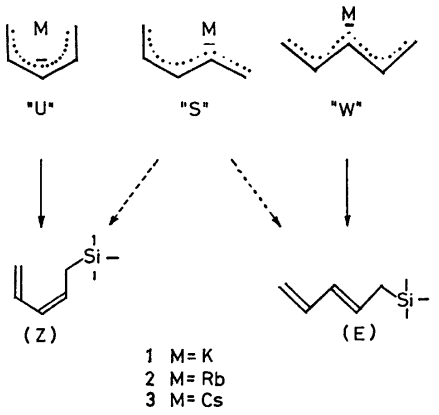
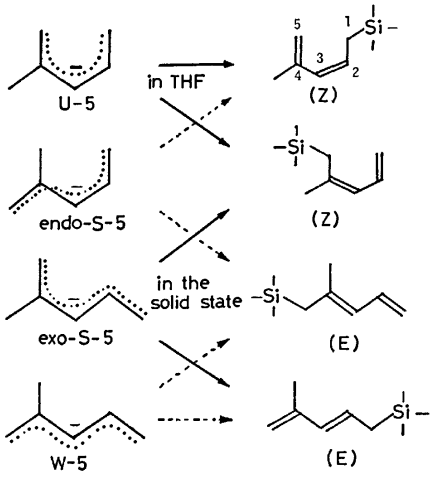
by regarding the U-shaped structure for **1**—**3** in solution and the W-shaped structure for **4**. The S-shaped anion should produce a *Z*/*E* mixture. To rationalize this assumption, the chemical trapping of an unsymmetrical pentadienyl anion, potassium 2-methylpentadienide **5**, was examined in THF at −20 °C using pure single crystals of **5**. Indeed, a 11:9 mixture of (*Z*)-4-methyl-2,4-pentadienyltrimethylsilane and (*Z*)-2-methyl-2,4-pentadienyltrimethylsilane was obtained to indicate the presence of a single torsional isomer with the U-shaped structure. The configuration of the former was determined from the proton-proton coupling constant (described later) observed in the ^{1}H-NMR spectrum (100 MHz) and by the measurement of NOE for the latter. This behavior corresponds well to dimethoxyboration-oxidation sequence of **5** in THF at −78 °C reported by Schlosser which gave (*Z*)-4-methyl-2,4-pentadien-1-ol (41%) and (*Z*)-2-methyl-2,4-pentadien-1-ol (22%) implying the U-shaped structure in THF.[10a)] If the anion **5** assumes the *endo-S*-, *exo-S*-, or W-structure, (*E*)-2-methyl- or (*E*)-4-methyl-2,4-pentadienyltrimethylsilane should be accompanied. Ex-



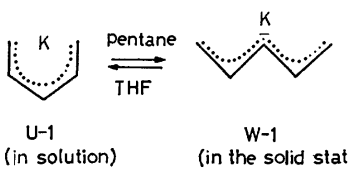
Scheme 1.



Scheme 2.

change of the counter cation to lithium changed the geometry of the product; *i.e.*, successive treatment of 2-methyl-1,4-pentadiene with *s*-butyllithium in THF, fluorodimethoxyborane and alkaline hydrogen peroxide has been reported to produce both 4-methyl- and 2-methyl-2,4-pentadien-1-ol.[13] The formation of (*E*)-isomer favored over (*Z*)-isomer consistent with the trimethylsilylation of **4**. Based on these facts, one can conclude the structure of **1**, **2**, **3**, and **5** in solution to be the U-shaped and **4** to be the W-shaped structure in solution. The S-shape may be, thus, excluded for **1**—**5**.

A drastic change in geometry of the trapped products was found when the medium was changed from solution to the solid state. The solubility of **1** in THF at 40 °C is 135 g/dm^3 and that of **2** and **3** is lower than that. Hence the addition of excess pentane or octane (10 ml) to the saturated THF solution (1 ml) at 40 °C brought about quantitative precipitation of **1**—**3** (90%) by cooling to −40 °C. Trimethylsilylation of the resulting suspension of **1**, **2**, and **3** in pentane

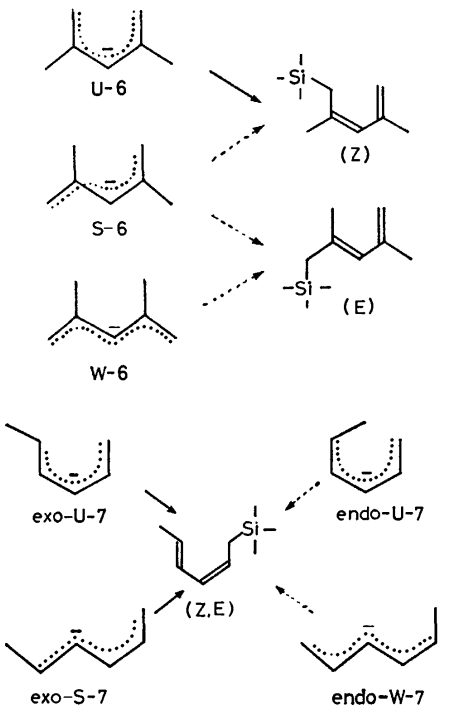


surprisingly produced (*E*)-2,4-pentadienyltrimethylsilane exclusively (98% GC yield) in 84, 90, and 92% regioselectivity at 0 °C and in 93—95% regioselectivity (~95% yield) at −70 °C in sharp contrast to the reaction in solution which gave the (*Z*)-isomer. THF-free pentadienyl anions of **1** and **2**, which were prepared by heating crystals to 80 °C *in vacuo*,[11a] are sparingly soluble in hydrocarbons and showed an extreme regioselectivity in silylation (99% in pentane at 0 °C). Lithium compound **4** or its TMEDA complex **4'** suspended in pentane at 0 °C also produced the (*E*)-isomer exclusively (97%) in line with the reaction in solution. No medium effect was observed for the lithium analogue. These results clearly indicate the W-shaped structure for **1**—**4** and **4'** in the crystalline state but the S-shape can not be ruled out distinctly from this experiment. Dialkoxyboration-oxidation of **1** in hexane (in the solid state reaction) also produced (*E*)-pentadien-1-ol exclusively,[10b] whereas it was recently found to give (*Z*)-isomer in good yield by reaction in THF solution in agreement with our result.[15c] Thus, the frequently experienced poor reproducibility on the (*Z*)/(*E*)-ratio has now solved by introducing the concept of the medium effect.

The similar medium effect was found also for **5**, which gave (*E*)-4-methyl-2,4-pentadienyltrimethylsilane (48%), (*Z*)-4-methyl-2,4-pentadienyltrimethylsilane (12%), and (*Z*)-2-methyl-2,4-pentadienyltrimethylsilane (40%) in the solid state reaction in pentane (THF coordinated to **5** was removed previously at 80 °C *in vacuo*). No contamination of (*E*)-2-methyl-2,4-pentadienyltrimethylsilane was detected in each isolated products. This shows that **5** has predominantly the *exo*-S-shaped structure in the crystalline state. The *exo*-S/U-ratio is calculated to be 78/22 if the U-**5** species in the solid state is postulated to give (*Z*)-4-methyl- and (*Z*)-2-methyl-2,4-pentadienyltrimethylsilane in 11/9 ratio as was observed in trimethylsilylation in solution. Protolysis of **5** with water producing a *ca.* 1:1 mixture of (*Z*)-2-methyl- and 4-methylpentadiene in both media[11] gave little information on the configuration.

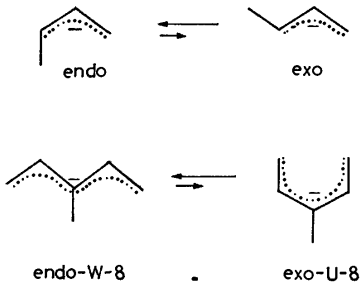
The steric repulsion between the two methyl groups on the 2,4-dimethylpentadienyl anions will lead to the U- or S-shaped structure since planar W-form is sterically hindered for this anion. Indeed, (*Z*)-2,4-dimethyl-2,4-pentadienyltrimethylsilane was identified as the almost exclusive product (97% regioselectivity, 96% yield) from potassium 2,4-dimethylpentadienide **6** both in solution and in the solid state suggesting the presence of the U-shaped single torsional isomer. The geometry was determined by the NOE experiment. The U-shaped structure have recently been confirmed also by Schlosser *et al.* by dialkoxyboration-oxidation of **6** in THF which results in the exclusive production of (*Z*)-2,4-dimethylpentadien-1-ol.[10]

The trapped product of potassium hexadienide **7** also comprises one isomer, (2*Z*,4*E*)-2,4-hexadienyltrimethylsilane (92%) independent of the medium (solution and the solid state) and hexadiene precursor [1,3-hexadiene, 1,4-hexadiene, (*E*,*E*)-2,4-hexadiene and (*E*,*Z*)-2,4-hexadiene]. This result suggests the con-

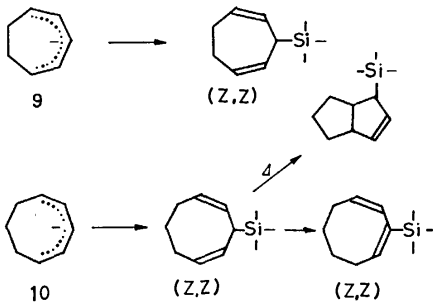


figuration of **7** to be either *exo*-U- or *exo*-S-shaped or their mixture. The value of the proton-proton coupling constant of J_{45}, 14.5 Hz, observed in ^{1}H-NMR (described later) evidently excludes the endo-W-form which had been considered for lithium derivative[7] or **7** in liquid ammonia.[9] The planar *endo*-U-shape seems implausible for steric reasons. The most striking feature of this reaction lies in the predominant attack of chlorotrimethylsilane on the primary carbon end (at C_1). Electrophilic attack on the secondary carbon (C_5 attached to CH_3 group) which should give 1-methyl-2,4-pentadienyltrimethylsilane was absent. This regioselectivity is valuable for organic syntheses[33a] and an insect pheromone was recently prepared utilizing this type of reagent.[14]

The geometry of 3-alkylpentadienyl anions seems exceptional. For example, potassium 3-methylpentadienide **8** in solution and in the solid state gave (*E*)-3-methylpentadienyltrimethylsilane (in 92—95% regioselectivity) by trimethylsilylation and (*E*)-3-methyl-1,3-pentadiene exclusively (97—99%) by hydrolysis in THF at −30 °C. Their structures were confirmed by the lack of NOE and the reaction with maleic anhydride.[11] Thus, only **8** gave the (*E*)-isomer contrary to the behavior of other open-chain dienyl anions (**1**—**3**, **5**—**7**) in solution. The difference in geometry may be correlated to the strong preference of allylic potassium for the endo configuration over the exo configuration.[15]



The mode of reaction of pentadienyl anions in a cyclic skeleton, *e.g.*, cycloheptadienyl or cyclooctadienyl anions, is known to be different from that of linear pentadienyl anions.[11,16] The former showed a clear predominance of the electrophilic attack on the central carbon while the latter underwent attack on the terminal carbons reflecting higher charge on C_3-atom as confirmed by the ^{1}H-NMR (described later). Trimethylsilylation of potassium cycloheptadienide **9** in solution occurred only at the central carbon as expected and pure (*Z*,*Z*)-2,6-cycloheptadienyltrimethylsilane was obtained in high yield (99%). Potassium cyclooctadienide **10** behaved similarly to **9** but the isomerization of (*Z*,*Z*)-2,7-cyclooctadienyltrimethylsilane into (*Z*,*Z*)-1,7-cyclooctadienyl derivative was rapid in THF at 40 °C presumably due to the base catalysis. Isomerization of isolated (*Z*,*Z*)-2,7-cyclooctadienyltrimethylsilane to (*Z*)-bicyclo[3.3.0]-oct-3-en-2-yltrimethylsilane by electrocyclization[17] was also observed by heating to 200 °C in a column of gas chromatograph (typical percent conversion, 30—40%).



Determination of geometry of **1** in liquid ammonia by trimethylsilylation was unsuccessful due to the predominant production of 1,1,1,3,3,3-hexamethyldisilazane. To confirm the geometry of pentadienyldimethoxyborane, which was postulated by Schlosser *et al.* as the intermediate in dialkoxyboration-oxidation of **1**, we attempted its isolation by distillation but the borane compounds were thermally too unstable to permit the isolation and were converted to polymeric substances above 0 °C.

Direct Measurement of the Geometry in Solution by ^{1}H-NMR. The variable ^{1}H-NMR spectra (Table 2) were measured in THF-d_8 to obtain direct evidence for the configuration of above-mentioned anions and to confirm the geometry determined by the regioselective trimethylsilylation and hydrolysis. Lithium pentadienide **4** and its TMEDA complex, which were obtained by direct metalation of 1,4-pentadiene with metallic Li[11] or butyllithium[7] in THF, are fluxional at room temperature but the rotation around the C_1–C_2(C_4–C_5) and C_2–C_3(C_3–C_4) bonds was frozen by lowering the temperature below −70 °C (Fig. 2). The proton-proton coupling constant of J_{23}(J_{34}), 11.9—12.0 Hz observed for **4** (THF complex) and the TMEDA complex at −90 °C is essentialy the same as that reported by Bates *et al.*[6] indicating the presence of the W-shaped single torsional isomer. The coupling constant for allylic lithium compounds

a) In ppm downfield from external TMS in THF-d_8(calibrated using the downfield THF peak, assumed to be 3.75 ppm). Data were collected at 100 MHz from the decoupled spectra. b) Data in liquid ammonia by Kloosterziel *et al.* (Refs. 8, 9, and 20).

is known to be 6.5—7.5 Hz for cis-inner bond,[16] 11.5—12.0 Hz for trans-inner bond, 9—10 Hz for cis-outer bond, and 16—17 Hz for trans-outer bonds. The values increased by exchanging the cation to potassium; cis-inner bond 8.3—9.1 Hz,[18] trans-inner bond 13 Hz,[18] cis-outer bond 9—10 Hz, and trans-outer bond 16—17 Hz. The increased value may be due to the increased C_1–C_2–C_3 angle derived from the electrostatic effect of the larger ionic radius of potassium.

Based on these data, the geometry of a series of potassium dienides was analyzed. The NMR signals of the protons on C_1(C_5) and C_3 of parent anion **1** heavily overlapped with each other and therefore the correct coupling constant was measured utilizing potassium 1,1,5,5-tetradeuterated pentadienide[2b] in THF-d_8 (Fig. 3). The value of J_{23} was found for the first time to be 9.1 Hz at 60 °C and was frozen out to give 8.7 Hz below -30 °C. This value clearly shows the cis-relationship of the two protons on the C_2–C_3 and C_3–C_4 bonds. The geometry of **1** in ethereal solution was thus shown to be U-shaped in accord with the chemical trapping experiment. The rotation around the outer bonds, C_1–C_2(C_4–C_5), is very slow even at 60 °C as evidenced by the coupling constant, J_{12}(trans)=15.9 Hz, J_{12}(cis)=10.0 Hz. The values are 16.1 and 9.9 Hz at -30 °C. The high barrier for rotation around the C_1–C_2 (estimated to be >25 kcal/mol by Schlosser[10c]) and C_2–C_3 bonds may account for the small temperature dependence of the coupling constant variation ΔJ_{12} (0.2 Hz) and ΔJ_{23} (0.4 Hz). Such high rotational barriers have recently been reported also for allylic potassium compounds.[18] The behavior of rubidium and caesium derivatives is similar to **1** but their coupling constants at 38 °C are a little smaller; J_{23}=8.9 Hz for **2** and 8.7 Hz for **3**. Therefore the rotational barrier around the C_2–C_3 bond in the pentadienyl anion was estimated to increase with the ionic radius of the alkali counter ion, Li<Na$\ll$K<Rb$\simeq$Cs in line with the order observed for allylic anion system,[19] though the line-shape analysis is required to obtain the exact value, ΔG. The spectra of **1** obtained from (*Z*)-, (*E*)-1,3-pentadiene or 1,4-pentadiene were the same with each other irrespective of the geometry of starting dienes.

Potassium hexadienide **7** was prepared from (*E*,*E*)-2,4-hexadiene, (*E*)-1,4-hexadiene, (*E*)-1,3-hexadiene and/or (*Z*)-1,3-hexadiene. All of these were heated to 70 °C for 30 min. The ^{1}H-NMR spectra of resulting anions **7** were the same independent of the geometry of the starting dienes and show the presence of two isomers in every cases; *exo*-U-shaped and presumably *exo*-S-shaped anions in 4:1 ratio. The predominant species was readily assigned to be *exo*-U-shaped from the chemical shift and the coupling constant obtained from the decoupled spectra (Table 2). The proton signals of minor species was too weak to make an assignment. However, the extreme stereoselec-

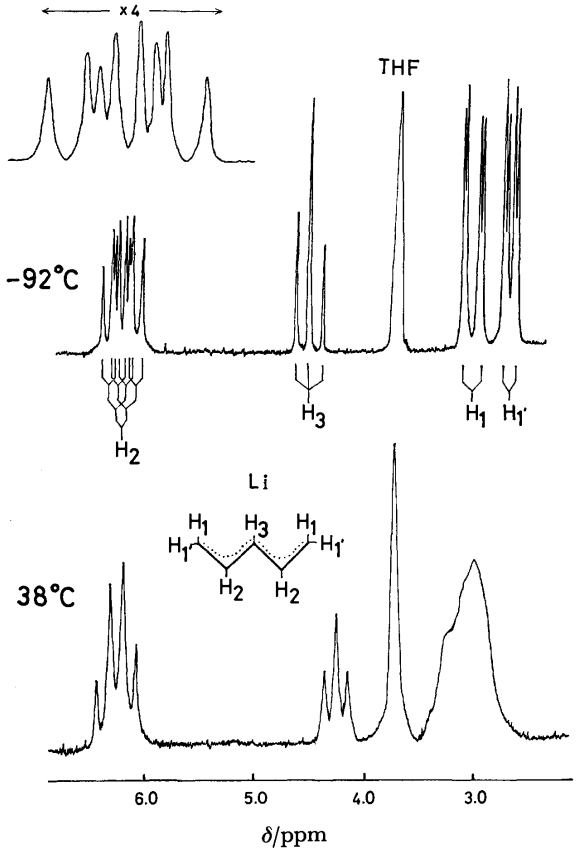

Fig. 2. Variable temperature ^{1}H-NMR spectra (100 MHz) of lithium pentadienide **4** in THF-d_8.

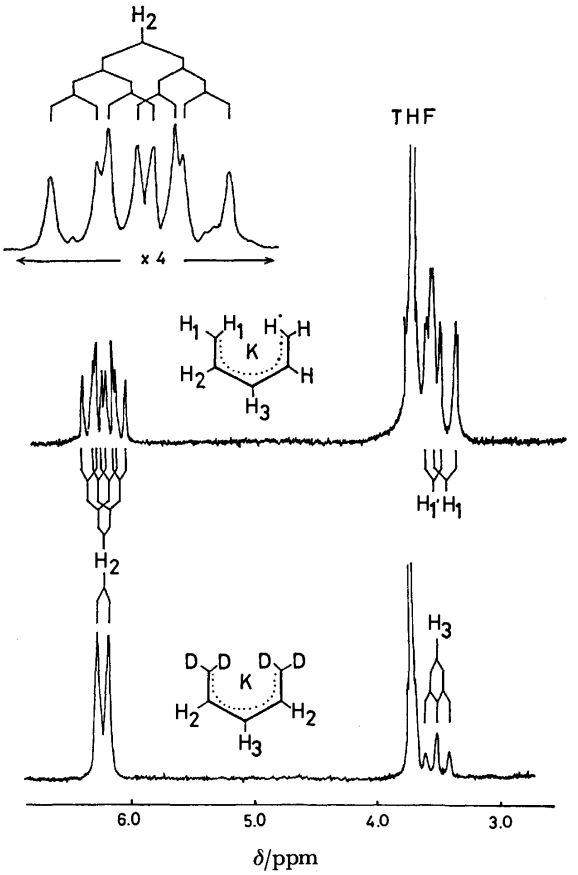

Fig. 3. ^{1}H-NMR spectra (100 MHz) of potassium pentadienide **1** and potassium 1,1,5,5-tetradeuterated pentadienide in THF-d_8 at −60 °C.

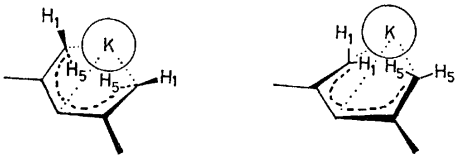
tivity observed in trapped products strongly suggests the presence of the *exo*-S-shaped anion as the minor species because only this isomer (except for the above *exo*-U) can provide (*Z,E*)-2,4-hexadienyltrimethylsilane. The ^{1}H-NMR spectrum of 2-methylpentadienyl anion **5** gave only partial information on the geometry. That is, J_{34} is 8.7 Hz below −30 °C. This value suggests the U- or *endo*-S-shaped structure for **5** and excludes the W- and *exo*-S-shape. However, we can reasonably suggest the U-shaped structure for **5** because of the result of chemical trapping experiments.

The chemical trapping of potassium 2,4-dimethylpentadienide **6** clearly shows the presence of the U-shaped single torsinal isomer in solution. However, the chemical shift difference was observed between the two terminal proton signals in ^{1}H-NMR below 10 °C (Fig. 4). The double doublet assigned to H-3 is caused by the H_1–H_3 coupling and H_5–H_3 coupling, not the CH_3–H_3 coupling, as evidenced from the decoupled spectrum. Supposition of the S-shaped structure which may explain the NMR data is in conflict with chemical trapping data. Hence, the deformed out-of-plane U-shaped or the following helicene-like U-shaped structure[15c] is suggested by Schlosser for



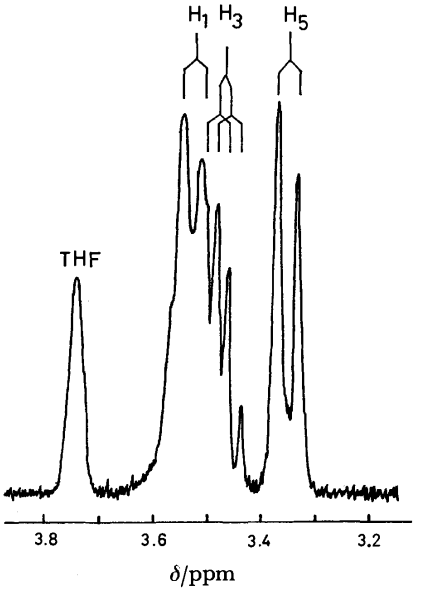


Fig. 4. ^{1}H-NMR spectra (100 MHz) of potassium 2,4-dimethylpentadienide **6** in THF-d_8 at −40 °C.

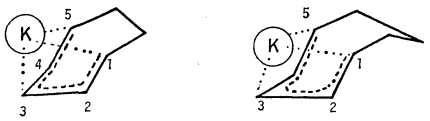
this observation, although they are indistinguishable by ^{1}H-NMR or chemical trapping experiments. The spectra simulation with a high resolution spectrometer will be required for further discussions.

The ^{1}H-NMR spectrum of **8** also gave little infor-

mation on the geometry but the presence of the single torsional isomer with the W-shaped structure is proposed based on the excellent stereospecificity observed in trimethylsilylation and hydrolysis in addition to the chemical shift values. The proton-proton coupling for the outer bonds (C_1–C_2 and C_4–C_5) is frozen below −30 °C and the spectral pattern was unchanged within 2 Hz on lowering the temperature to −90 °C. The ^{13}C-NMR spectral data at −40 °C (Table 3) also supports the presence of **8** as the single torsional isomer, W- or U-shaped anion. If rapid 1,3-rearrangement occurs exceeding the NMR time scale, a mixture of the (*Z*)- and the (*E*)-isomer should be formed chemically contrary to the fact. Thus, the extreme preference of the endo-W form is considered for **8**.

The coupling constants observed for **9** and **10** in THF-d_8 are essentially the same as those in liquid ammonia reported by Kloosterziel.[20] The plane defined by C_2–C_3–C_4 should never be coplanar to the plane made by C_1–C_2–C_4 or C_2–C_4–C_5 to relieve the ring strain.[21] Therefore, the decreased coupling constant of $J_{2,3}$ (6.8—7.0 Hz) for **9** and **10** compared to the value of $J_{2,3}$ (8.3—9.1 Hz) for open-chain dienylpotassium compounds may be rationalized in terms of the deviation of dihedral angle H_2–C_2–C_3–H_3 from zero to *ca.* 20° calculated by the Karplus equation. The smaller δ-values of H_3 of **9** and **10** as compared with that of **1**—**8** of the open-chain structure might be ascribed to both a larger electron-repelling effect of the CH_2 group bound to pentadienide termini and a larger torsion around the C_2–C_3 (and C_3–C_4) bond



of **9** and **10** as Kloosterziel already suggested.[20]

Configurational Studies on Potassium Pentadienides by ^{13}C-NMR. ^{13}C-NMR chemical shifts provide the best measure of the electron density in many delocalized carbanions[22] and have been successfully employed to distinguish the geometry of the isomers considered for some lithium pentadienides.[5,23] ^{13}C-NMR parameters will be useful for configurational analysis of the present potassium derivatives since their rotational barriers around terminal- and inner-bonds is higher than those for lithium derivatives as mentioned above. The spectra of **1**—**3**, **6**, **8**—**10** (Table 3) clearly shows the presence of a single torsional isomer with a symmetric structure, U- or W-form, because the chemical shift value of C-1 or C-2 are equal to that of C-5 or C-4, respectively. The W-shaped structure can be ruled out from the chemical trapping experiments and the ^{1}H-NMR spectral data. The chemical shift of C-1 of **6** is equal to that of C-5 and hence the deformed out-of-plane U-shaped structure seems more probable than the helicene-like U-shaped one. In the case of **7**, two species were detected in agreement with ^{1}H-NMR measurement and the major species is assigned to the *exo*-U-shaped anion.

It is noteworthy that sodium pentadienide show a simple averaged NMR spectrum with three signals assignable to $C_1(C_5)$, $C_2(C_4)$, and C_3 (half-width of the signal is 1.1 ppm) at 20—50 °C but those were split into several peaks (the half-width, 0.2 ppm) by lowering the temperature below −40 °C. One of the best explanation for this is to consider the presence of a 4:1 mixture of S- and U-shaped anions at −40 °C, because this ratio is consistent to the *Z*/*E* ratio (42/58) of 1,3-pentadiene obtained by hydrolysis of sodium pentadienide in THF at −40 °C.

On the basis of the chemical shift data, one can conclude that the electron density on C-3 of potassium

a) In ppm downfield from external TMS in THF-d_8(calibrated using the high-field THF peak, assumed to be 25.8 ppm). Peak assignments were made in part from an off-resonance decoupled spectrum. b) Major species (*exo*-U). c) Data of W. T. Ford *et al.*(Ref. 7). d) Data of R. B. Bates *et al.*(Ref. 16).

pentadienides (**1**, **5**, **6**, **9**, and **10**) is close to or higher than those on C-1 and C-5, while higher electron density lies on C-1 and C-5 for lithium derivatives (**4**, **8'**). That is, the latter has stronger sp^3 character on the terminal carbons than the former in THF.

Electronic Spectral Studies on Pentadienyl Anions. Acyclic and cyclic potassium pentadienides (except 3-alkylpentadienyl anions) have, thus, been revealed to assume the "U"-shaped structure in THF. The remaining problems to be solved are why potassium pentadienide **1** in liquid ammonia and lithium pentadienide **4** in THF assume the "W"-shape whereas **1** in THF assumes the "U"-shape. The geometry of potassium hexadienide **7** in liquid ammonia and lithium hexadienide (*exo*-W) is also different from **7** in THF (*exo*-U).

One of the key factors controlling the geometry is the solvation. It is generally accepted that organolithium compounds having carbanion with extensive charge delocalization exist as solvent-separated ion pairs in THF as evidenced by the strong bathochromic shift (24—44 nm) of the absorption maximum in polar solvents.[23-27] The sodium and higher analogues exist as contact ion pairs even in the polar solvents (the absorption maximum appears at shorter wavelength compared to that of the solvent-separated lithium compounds). Similar red shifts are also known for sodium naphthalenide and sodium benzophenone ketyl.[28] However, such cation dependence is observable only when the anion species have extensive π-electron systems; *e.g.*, diphenyl- and triphenylmethyl anions,[23] 1,1-diphenylhexyllithium,[24] diphenyl- and triphenylallylic anions,[25] 9-fluorenyl and the substituted fluorenyl anions.[26] The electronic spectra of organoalkali compounds without extensive negative charge delocalization are less sensitive to solvent polarity as was found for benzylic-,[22] allylic metals,[23] mono- or dianions of polystyrene, polybutadiene and polyisoprene.[29] Kinetic studies are sometimes more useful for these systems to detect the solvent-separated ion pairs.[30] Higher negative charge delocalization seems possible on the pentadienyl moiety compared to the allylic moiety mentioned above. If the π-electron system existing in pentadienyl group is sufficient for the extensive charge delocalization, lithium pentadienide **4** should show the bathochromic shift. The absorption maxima for **1**—**4** and the sodium analogue in THF (Table 4), indeed, appeared at longer wavelength than that of allylic anions (310—320 nm in THF and benzene).[31] However, the absorption maximum of **4** was observed at shorter wavelength than that of **1**—**3**, in line with the spectra of solvent less-sensitive allylic systems in which the wavelength for the absorption maxima increased with an increase of the radius of counter cations. The absorption maximum (355 nm) for **4** in hexane at 20 °C is nearly equal to that in THF. Therefore, the π-electron system existing in the pentadienyl group is concluded to be insufficient to compose the stable solvent-separated ion pairs. Other methods are required to evaluate the solvent-affinity by THF.

Table 4. Electronic absorption spectral data for **1**—**4** in THF

Dienyl anions	λ_{max}/nm (ε)
4 (Li)	358 (5400)
(Na)[a]	365 (5700)
1 (K)	376 (6200)
2 (Rb)	377 (6000)
3 (Cs)	379 (5800)

a) Sodium pentadienide. All the spectra were measured at 20 °C.

Effect of Solvent-affinity on the Geometry of Pentadienyl Anions. To estimate the approximate strength of the solvation by THF to pentadienyl metals, the ease in dissociation of THF was examined on heating the respective 1:1 THF complexes[11] *in vacuo*. The Rb and Cs complexes readily release the THF molecule (>90%) on heating the crystals at 60 °C/1 mm Hg† for 15 min, K complex at 80 °C/1 mmHg for 30 min (80% of THF was released as evidenced by GC of the hydrolyzate of octane suspension) while lithium and sodium complexes give off no THF even heating them at 120 °C/0.1 mmHg for 2 h. The weak interaction of THF to **1**, **2**, and **3** was also confirmed by washing the crystals of *ca.* 1:1 THF complexes of **1**—**3** (1 g) in excess of pentane (40 ml) four times at 30 °C, which resulted in the release of 70, 90, and 93% of THF, respectively. Lithium derivative **4** gives off no THF again and sodium derivative 10—20% of THF under the same conditions. This behavior clearly indicates that the solvent-affinity increases as size of the cation decreases, Li>Na$\gg$K>Rb$\simeq$Cs. Therefore, we can reasonably explain the solution structure of lithium pentadienide by strongly-solvated ion pairs and potassium and higher alkali metal analogues by contact ion pairs. This inference was also supported by ^{1}H-NMR of **1**—**3** which show the significant low-field shift of the $C_1(C_5)$-proton signals by 0.4—0.9 ppm and high-field shift of C_3-proton by 0.8 ppm compared to the corresponding signals of lithium derivative **4** in THF. A similar high-field shifts (0.18 ppm) of the terminal proton signals caused by the solvation is known for lithium 1,3-diphenylpropenide.[25] The anion **1** in liquid ammonia should also exist as strongly solvated or solvent-separated ion pairs because its ^{1}H-NMR data (chemical shifts and coupling constants, see Table 2) correspond well to that of **4** in THF. Thus, combination of chemical trapping, NMR data and the solvent-affinity will lead to the very important conclusion; *i.e.*, pentadienyl anions which exist as strongly-solvated ion pairs assume the "W"-shaped structure consistent to the MNDO prediction,[5] whereas potassium and the higher alkali metal pentadienides, which will exist as contact ion pairs, favor the "U"-shaped structure. Geometry of the pentadienyl anion in the solid state is probably controlled by the mode of packing in the crystal lattice rather than the solvation effect. The lattice energy would cancel the small difference in net stabilization energy calculated for the three geometries. The X-ray analysis of **1** and **2** with good single crystals confirmed absence of the solvation and the presence of THF molecule at the interstitial po-

† 1 mm Hg$\approx$133.322 Pa.

sition but the intensity data were insufficient to warrant definite conclusion on the geometry in the crystalline state.[32]

In contrast to pentadienyl anion, bis(2,4-pentadienyl)metal compounds of Be, Mg, and Zn prefer the (*E*)- over the (*Z*)-structure.[2] This behavior is ascribable to their fluxional properties which permit the rearrangement of (*Z*)- to thermally more stable (*E*)-configuration by 1,3- or 1,5-shift. The facile control of the geometry by changing the medium or exchanging the cation will be valuable for organic synthesis. For example, the Lewis acid catalyzed regioselective addition of carbonyl compounds to 2,4-pentadienyltrimethylsilane has been recently reported.[33] The reaction of 2,4-pentadienyltrimethylsilane with lithium amide is also useful for introduction of substituents to the pentadienyl group.[34]

Experimental

Potassium pentadienide used at the present work were prepared by the procedure previously reported.[11] Metallic rubidium (99.9% purity) and caesium (99.9%) used for the direct metalation of 1,3-dienes were purchased from Mitsuwa Pure Chem. Tetrahydrofuran-d_8 (99%, Merck Co.) and chloroform-d_1 (99.8%, Merck Co.) were dried over Na/K alloy and calcium hydride, respectively, and distilled before use. Starting dienes were purchased from Aldrich Chemicals or prepared using the reactions previously described.[2,11] Potassium pentadienide-1,1,5,5-d_4 was prepared starting from 1,4-pentadiene-1,1,5,5-d_4.[2b] GC analysis was made with a Hitachi Model 163 gas chromatograph using a capillary column (45 m) OV-1, CW-45, or HB-2000 and the separation of the reaction products was done with a Varian-Aerograph Model 700 gas chromatograph using a column (4 m) packed with Silicone DC-550. ^{1}H- and ^{13}C-NMR spectra were recorded on a Varian XL-100 instrument with a VFT-100-620L pulse Fourier transform accessory with the use of a sealed tube. NOE was measured using the tube sealed at 10^{-1} mmHg at 63 K after the solution was degassed (15—20% of NOE was observed in $CDCl_3$ and 20—25% in acetone-d_6). IR spectra were recorded on a Hitachi EPI-2 spectrometer. The absorption spectra were run on a JASCO Model UVIDEC-5A spectrometer. Elemental analysis for trimethylsilyl derivatives were carried out using a capillary with a Yanagimoto Model MT-2-CHN analyzer. The mass spectrum was recorded on a JEOL JNS-01SG-2 spectrometer. All the procedures were carried out in an argon atmosphere using the high vacuum technique.

Trimethylsilylation of Pentadienyl Anions in THF. A typical experiment is as follows. To a THF solution (100 ml) of **1** (0.5 g, 4.7 mmol) in a Schlenk tube was added dropwise a THF solution (5 ml) of chlorotrimethylsilane (0.6 ml, 4.9 mmol) over a 30 min period under the magnetic

a) Relative intensity assuming the fragment of $(CH_3)_3Si$ as 100. Spectrum was recorded at 70 eV.

stirring at −40 °C). A rapid addition of chlorotrimethylsilane should be avoided or it causes the production of 3-trimethylsilyl-1,4-pentadiene in <20% yield. The solution changes from orange to colorless near the equivalence point precipitating the salt. The mixture was stirred at −40 °C for 30 min and then at 0 °C for 1 h. After condensing the solution to 10 ml by evaporation, pentane (20 ml) was added for the complete precipitation of the salt. The resulting salt was separated by centrifugation with the use of a two-necked glass tube fitted with rubber stoppers protected with a plastic cover. The precipitate was washed with two portions of pentane (20 ml) for extraction of the products. After the removal of pentane and THF from the combined solution by evaporation, the remaining (*Z*)-pentadienyltrimethylsilane was separated by distillation (143 °C/760 mmHg. GC yield 98% and isolated yield 70—75%). A series of trimethylsilylated compounds was isolated in the similar manner. Trimethylsilylated products from **5**, **6**, and **9** were distilled at 45 °C/6 mmHg, 55 °C/4 mmHg and 75 °C/0.5 mmHg, respectively. When the product comprises isomers, they were separated into the respective isomers with a preparative GC. The geometries and structures of the isolated isomers were analyzed by ^{1}H-NMR (Table 1) and IR, MS, and the elemental analysis (Table 5).

Trimethylsilylation of Pentadienyl Anions in the Solid State. Solubility of potassium pentadienide **1** for THF is relatively small; 135 g/dm^3 at 40 °C, 27 g/dm^3 at 0 °C and that of rubidium and caesium derivatives, **2** and **3**, at 40 °C are 10.5 and 18.5 g/dm^3, respectively. Lithium and sodium derivatives are freely soluble in THF at 0 °C. The addition of pentane or octane (40 ml) to the THF solution (5 ml) of **1**, **2**, and **3** (7.5 mmol for **1**) saturated at 60 °C resulted in the quantitative precipitation (90—92%) of the crystals by cooling the mixture below −40 °C. To the resulting suspension of **1**, **2** or **3** (7.5 mmol) was added dropwise chlorotrimethylsilane (1 ml, 7.7 mmol) in pentane (5 ml) at −70 °C for undergoing the solid state reaction. After continuing the vigorous magnetic stirring for 1 h, the salt was removed by centrifugation at room temperature and trimethylsilylated compounds were isolated by distillation. A typical isolated yield, 85% (GC Yield, 99%). The regioselectivity in reactions of **1**, **2**, and **3** to give the (*E*)-isomer was 93, 95, and 95% respectively. THF-free pentadienyl anions **1**—**3** which were prepared by heating their THF complexes at 80 °C/0.1 mmHg for 40 min were completely insoluble in pentane, benzene or diethyl ether. To a suspension of THF-free compounds **1**—**3** (10 mmol) in pentane (40 ml) was added at −40 °C chlorotrimethylsilane (1.3 ml, 11 mmol) dissolved in pentane (5 ml). The mixture was stirred for 2 h at 0 °C. Thus, (*E*)-2,4-pentadienyltrimethylsilane was produced quantitatively (GC Yield, >98%) and was isolated by distillation (Yield, 90%, regioselectivity, 99%). Great care is necessary in handling the THF-free pentadienyl anions because of their flammability in the air. THF complexes of sodium- and lithium pentadienide **4** were also insoluble in pentane below −40 °C and the solid state reactions were carried out in the same procedure as described for **1**—**3**. The regioselectivity in trimethylsilylation of a series of pentadienyl anions in solution and in the solid state, the (*Z*)/(*E*) ratio of the major products and total yields were summarized in Table 6.

The Use of Grignard Reagents in the Synthesis of Carbohydrates. III.[1] The One-way Anomerization of Methyl Glycofuranosides and the Opening of Their Furanose Rings

Masajiro KAWANA,* Hiroyoshi KUZUHARA, and Sakae EMOTO
The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received October 14, 1980)

The anomerization of methyl glycofuranoside derivatives with methylmagnesium iodide or *t*-butylmagnesium bromide occurred in a one-way manner. For example, methyl 5-*O*-benzyl-β-D-ribofuranoside (**3β**) was converted into the corresponding α-anomer (**3α**) in a 95% yield when a mixture of **3β** and *t*-butylmagnesium bromide in benzene–ether was heated at about 75 °C to remove the ether; the reverse reaction (from **3α** to **3β**) did not proceed. The reaction of **3β** with methylmagnesium iodide gave open-chain products (33%), besides **3α** (30%). Twenty kinds of anomers were tested, and the mechanisms of the reactions were discussed. The cleavage of a benzyl- or trityl-protecting group with the Grignard reagent was also observed during the reaction.

Glycosidic linkages and furanose rings of methyl glycofuranosides are generally stable under neutral or mild alkaline reaction conditions, whereas, in the presence of an acid, these furanosides are hydrolyzed, anomerized, or converted into the corresponding pyranosides, depending upon the conditions used.[2] In this paper we would like to report the first example of the anomerization and furanose-ring opening of methyl glycofuranosides using Grignard reagents; two preliminary reports of this work have been published.[3]

Mallory *et al.*[4] have reported that the cyclic acetal protecting groups in steroids were cleaved by Grignard reagents. Recently, Fischer and Horton[5] and also two of the present authors have found similar reactions in the carbohydrate field. For example,[1a] when methyl 5,6-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-β-D-*arabino*-hexofuranoside (**1a-β**) was treated with 4 molar equiv. of methylmagnesium iodide (MeMgI) in a benzene–ether solution under reflux for 3 h, the 5,6-*O*-cyclohexylidene ring of **1a-β** was cleaved and the methyl group was introduced to form the corresponding 6-*O*-(1-methylcyclohexyl) derivative (**2a-β**) in a 73% yield (Fig. 1). We applied this reaction to the corresponding C-2 epimer (**1b-β**) to obtain an expected 6-*O*-(1-methylcyclohexyl) derivative (**2b-β**), besides two additional products which had relatively large values of the specific rotations with a positive sign. This suggested that these two compounds had α-D-glycoside structures. On the basis of a comparison of their spectroscopic data with those for authentic samples, the one was identified as methyl 5,6-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-α-D-*ribo*-hexofuranoside (**1α**),[6] while the other was found to be the corresponding 6-*O*-(1-methylcyclohexyl) derivative (**2α**).[1a] The latter could also be obtained by the treatment of **1α** with MeMgI. These results clearly indicated that the stereocontrolled anomerization occurred under strong conditions with the Grignard reagent.

In order to clarify the scope and mechanism of this new anomerization, simple sugar derivatives, methyl mono-, di-, or tri-*O*-benzylated α- and β-D-pentofuranosides, were subjected to similar Grignard anomerizations. The preparations of the starting materials will be described in the Experimental section. The anomeric configurations of pairs of the new methyl α- and β-D-pentofuranosides were determined by the comparison of their coupling constants[7] of anomeric protons (Table 2) and of their optical rotations[8] (Table 4).

Results

The results are summarized in Table 1.

The Reaction of Methyl D-*Ribofuranoside Derivatives.* When methyl 5-*O*-benzyl-β-D-ribofuranoside (**3β**) was treated with 5 molar equiv. of MeMgI in a benzene–ether solution under forcing conditions,[1a] in which the ether was distilled out from the reaction mixture, an expected α-anomer (**3α**) was obtained in a 30% yield, along with a 7:3 diastereomeric mixture of open-chain products (**4**) in a 33% yield (Fig. 2). As the reaction went on, undissolved materials were deposited in a solution rich in benzene, and the reaction mixture became heterogeneous. Under similar conditions, **3α** gave neither **3β** nor **4**. Therefore,

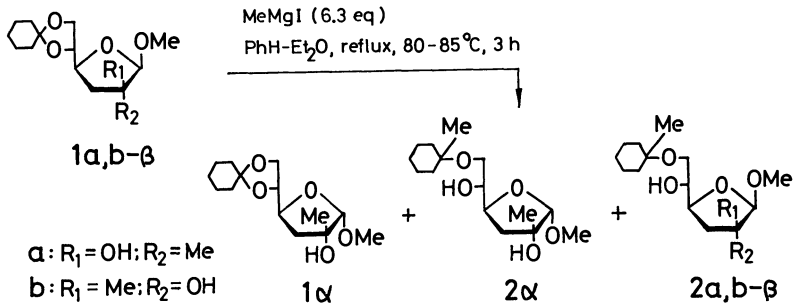

Fig. 1. The acetal ring-opening reaction and stereocontrolled anomerization of branched-chain deoxy sugars.

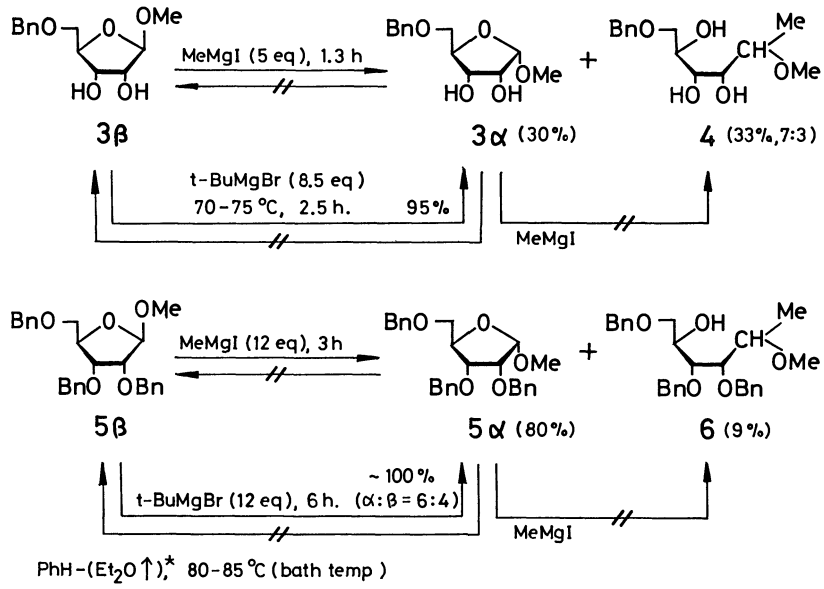

* The ether was allowed to evaporate.

Fig. 2. The reaction of methyl D-ribofuranoside derivatives with Grignard reagents.

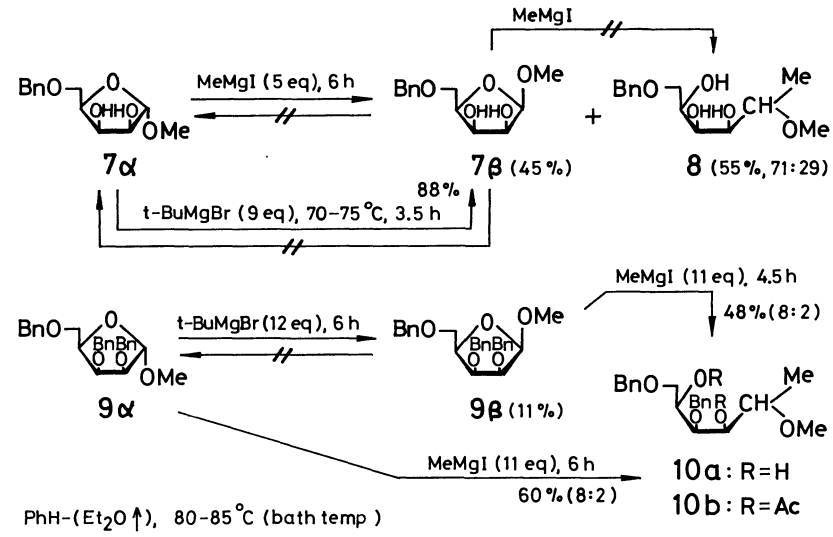

Fig. 3. The reaction of methyl D-lyxofuranoside derivatives with Griganrd reagents.

the anomerization took place in a one-way manner.

In order to obtain **3α** exclusively in the present reaction, we attempted to use *t*-butylmagnesium bromide (*t*-BuMgBr) instead of MeMgI, because the former reagent was sterically bulky, so that the formation of the open-chain products would be prevented. As expected, the reaction of **3β** with *t*-BuMgBr proceeded smoothly to give **3α** (95%) as the sole product, although it also contained a trace of the starting material, judging from TLC analyses and ^{1}H NMR spectroscopy.

Similarly, methyl 2,3,5-tri-*O*-benzyl-β-D-ribofuranoside (**5β**) reacted with MeMgI to give the corresponding α-anomer (**5α**, 80%) and open-chain products (**6**, 9%). The reverse reaction (from **5α** to **5β**) did not proceed. It should be noted here that, although the anomerization with MeMgI took place slower on the perbenzylated anomer (**5β**) than on the monobenzylated one (**3β**), the yield of **5α** was much better than that of **3α**. Some explanations for these phenomena will be presented later on. When *t*-BuMgBr was used in this reaction in place of MeMgI, the anomerization occurred very slowly and many precipitates were deposited during the reaction; after 6 h, we could not detect any anomers in the organic phase. The usual work-up gave a 6:4 mixture of **5α** and **5β**. Under the same reaction conditions, **5α** did not anomerize.

The Reaction of Methyl D-*Lyxofuranosides.* The behavior of MeMgI upon methyl 5-*O*-benzyl-α- and β-D-lyxofuranosides (**7α** and **7β**) was almost the same as that on the corresponding ribose derivatives (Fig. 3). Thus, **7α** was converted into **7β** by the use of MeMgI (yield, 45%) and *t*-BuMgBr (yield, 88%); the reaction with the former reagent also gave open-chain products (**8**, 55%). On the other hand, **7β**

did not react with these reagents under conditions similar to those used for the conversion of **7α**. However, the reaction of methyl 2,3,5-tri-*O*-benzyl-α-D-lyxofuranoside (**9α**) with MeMgI provided a 8:2 diastereomeric mixture of open-chain products (**10a**, 60%) as the main products; here the benzyloxy group originally attached to the C-2 position of **9α** was lacking. Starting from **9β**, we also obtained **10a** (48%) in the same diastereomeric ratio as that from **9α**.

When *t*-BuMgBr was used instead of MeMgI, only an 11% conversion of **9α** to **9β** was accomplished; many precipitates were deposited during this reaction, and no anomers survived in the organic phase after 6 h. The reverse reaction (from **9β** to **9α**) did not proceed under the same reaction conditions.

The Reaction of Methyl D-*Xylofuranosides.* The anomerization of methyl 5-*O*-benzyl-β-D-xylofuranoside (**11β**) with MeMgI occurred in a one-way manner to give an inseparable mixture of the anomers (**11α** and **11β**, *ca.* 19%, 1:1) and open-chain products (**12a**), which were isolated as their acetates (**12b**, 37%) (Fig. 4). With *t*-BuMgBr, only a small percentage of the **11β** was converted into **11α**.

When a 3,5-di-*O*-benzylated derivative (**13β**) was treated with MeMgI, the reaction smoothly proceeded in a one-way manner to provide the corresponding α-anomer (**13α**, 16%) and open-chain products (**14**, 38%). Similarly, *t*-BuMgBr was effective for the conversion of **13β** to **13α** (37%). However, in this case, we also obtained an unexpected crystalline ketone (**15a**) in a 52% yield. This compound was further converted into its acetate (**15b**). The structures of both compounds were tentatively assigned as depicted in Fig. 4.

The behavior of MeMgI or *t*-BuMgBr upon methyl-perbenzylated xylofuranosides (**16α** and **16β**) was somewhat different from that for **11** and **13** (Fig. 5). Thus, **16β** reacted with MeMgI to afford a 6:4 diastereomeric mixture of open-chain products (**17**, 19%), but 63% of the starting β-anomer was recovered. On the other hand, **16α** was easily converted into the corresponding β-anomer (**16β**, 32%), along with **17** (54%, 83:17), the main diastereomer being identical with that from **16β**. Both anomers reacted with *t*-BuMgBr to afford an anomeric mixture.

The Reaction of Methyl D-*Arabinofuranosides.* Only

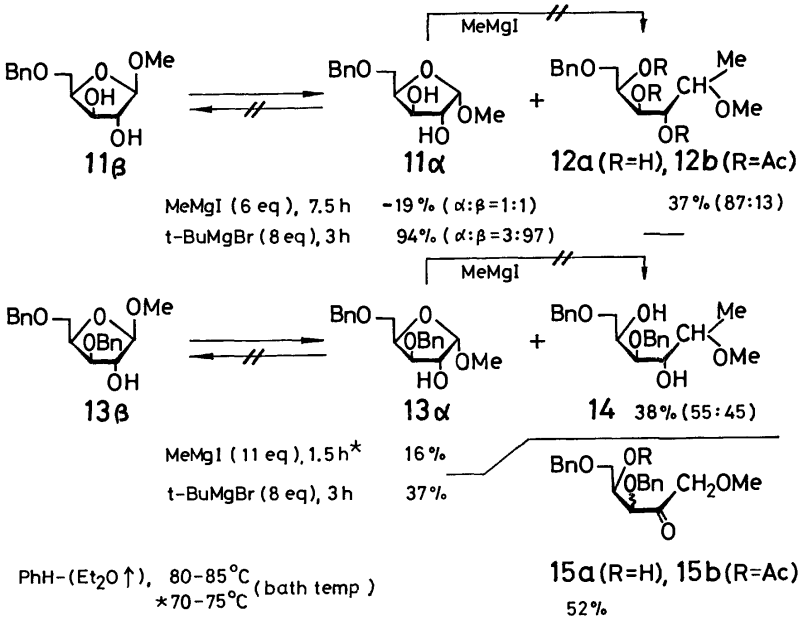

Fig. 4. The reaction of methyl D-xylofuranoside derivatives with Grignard reagents.

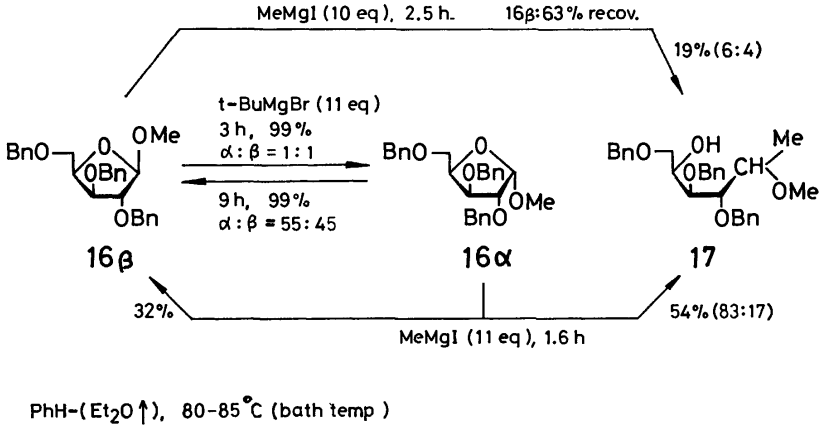

Fig. 5. The reaction of methyl 2,3,5-tri-*O*-benzyl-D-xylofuranosides with Grignard reagents.

perbenzylated anomers, methyl 2,3,5-tri-*O*-benzyl-α- and β-D-arabinofuranosides (**18α** and **18β**), were examined (Fig. 6). Upon treatment with MeMgI, both anomers were converted into a diastereomeric mixture of open-chain products (**19a** and **19b**), which were subsequently separated by silica-gel column chromatography. The selectivity of these reactions was higher on **18β** than on **18α**. The anomerization was also observed by means of TLC analyses, but neither anomer accumulated because of its consumption in the ring-opening reaction. Both anomers were anomerized with *t*-BuMgBr to give an anomeric mixture, the results being similar to those for the anomerization of **16**.

The Reaction of Other Methyl D-*Ribofuranosides.* Methyl 5-*O*-trityl-β-D-ribofuranoside (**20a-β**) also reacted with *t*-BuMgBr to produce the corresponding α-anomer (**20a-α**) in a 57% yield (Fig. 7). Since the trityl group was labile under the present Grignard reaction conditions, some of this group was removed from the α-anomer which had been formed during the reaction.

Similarly, methyl 5-deoxy-β-D-ribofuranoside (**20b-β**) was found to be converted into the corresponding α-anomer (**20b-α**) in a 59% yield; this yield was improved to 94% when a small amount of *t*-butyl alcohol was added to a Grignard solution prior to the addition of **20b-β**.[9]

Discussion

The formation of the 7:3 diastereomeric open-chain products, **4**, from **3β** suggested that the anomerization of this anomer proceeded through the opening of the furanose ring. A possible mechanism of the reactions for the ribose series is illustrated in Fig. 8. The magnesium atom of the Grignard reagnet is coordinated with the ring oxygen of the furanoside (**A** or **B**),[1a,10] resulting in a weakening of the C_1–O bond of the furan ring. Furthermore, either the oxygen at C-5 or the methoxyl one may participate in this coordination.[1a] When a large amount of the ether is distilled out from the reaction mixture, the complexation of the sugar with the Grignard reagent comes to be more favorable.[4] The cleavage of the C_1–O bond is thus accelerated to form an open-chain intermediate (**C**), which reacts with a methyl anion of MeMgI to yield the diastereomeric products (**D**). When the sterically bulky *t*-BuMgBr is used, the Grignard addition to **C** is prevented, presumably because for a steric reason. It is not clear whether or not there is another pathway to form **D** by the direct attack of MeMgI on the anomeric carbon of **A** or **B**.

The ring closure of **C** gives either the α- or β-anomer, although the presence of a **C**→**A** or **B** path has not been proved in this case. However, once the α-anomer (**E**) is produced, it may attain a high stability, probably by the appropriate coordination of the oxygens of the sugar to the Grignard reagent. At the end of the anomerization reaction, we observed many undissolved materials in the reaction mixture; the Grignard complex of the α-anomer precipitated out more easily than that of the respective β-anomer. The α-anomers, **3α** and **5α**, did not react with either MeMgI or *t*-BuMgBr, but were recovered. Therefore, the anomerization of **3β** and **5β** occurs in a one-way manner, the *trans*-1,2-anomers being preferably transformed into the respective *cis*-1,2-anomers. In a preliminary report,[3a] the selective ring closure of **C** to **E** has been proposed, but the present mechanism, based on these experimental results, dose not necessarily involve this selectivity. Recently, a catalytic anomerization of alkyl per-*O*-benzyl-β-D-glucopyranosides with titanium tetrachloride has been found by Morishima *et al.*,[11] who have also proposed a ring-opening, reclosure mechanism for the anomerization.

The perbenzylated anomer (**5β**) gave a better yield for the anomerization with MeMgI than the monobenzylated one (**3β**). This finding can be explained as follows. We have postulated the presence of a complex (**C'** in Fig. 8) as an intermediate for the reaction of **5β** with MeMgI. Ohrui *et al.*[12] have reported the base-catalyzed epimerization of *C*-glycosides (Fig. 9); for example, 2,3,-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosylacetonitrile is epimerized to the corresponding α-*C*-glycoside via an open-chain intermediate (**F**), the latter epimer being thermodynamically more stable than the former one. They have also pointed out that the presence of one five-membered ring such as an isopropylidene group in **F** strongly favors the formation of a second, fused five-membered

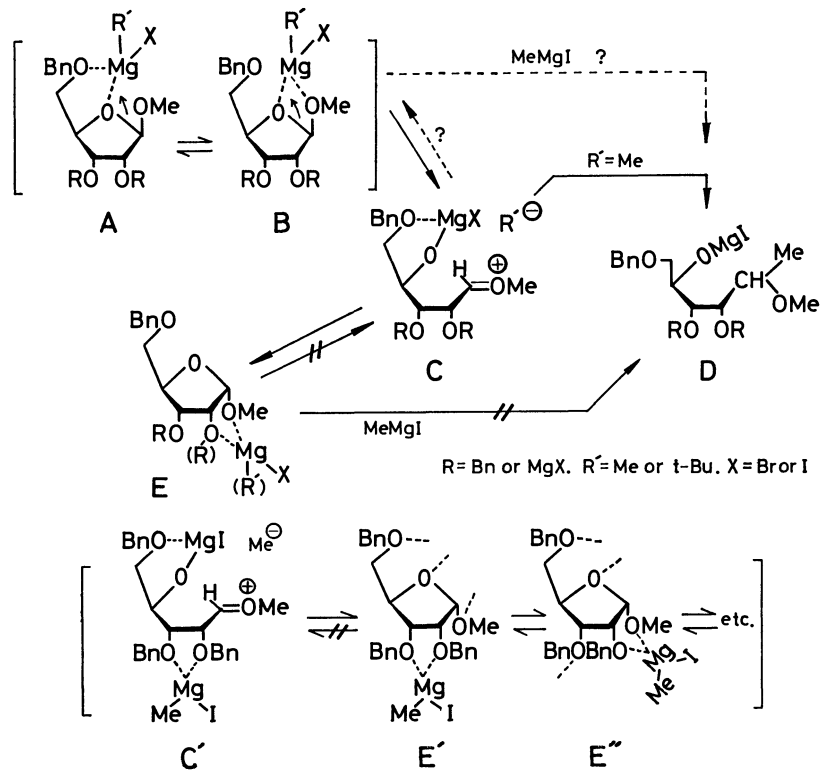

Fig. 8. The possible mechanisms of the one-way anomerization and of the formation of open-chain products.

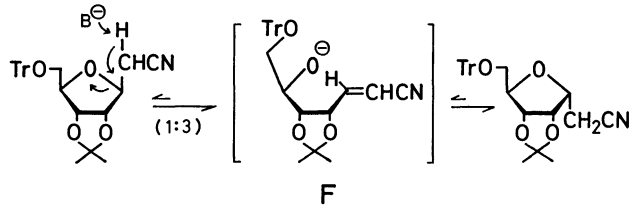

Fig. 9. The base-catalyzed epimerization of a *C*-glycoside reported by Ohrui *et al.*

ring.[12a] The two intermediates, **C'** and **F**, are quite similar in shape. Therefore, it seems likely that the structure of **C'** also fits a cyclization, resulting in the preferred formation of complexes (**E'**, **E''**,..*etc.*). On the other hand, it is rather difficult for **3β** to form an intermediate similar to **C'**.

The equilibrium between **3α** and **3β** in a boiling methanolic solution in the presence of an acid was found to be largely on the side of **3β** in a ratio of 20:80. Similarly, in the case of **5**, the ratio of **5α** to **5β** was 15:85. Therefore, the present one-way anomerization is a "contrathermodynamic" interconversion[13] of more stable isomers into less stable ones.

The reaction of all the lyxose and xylose derivatives except **16** resulted in the one-way anomerization and/or the formation of the open-chain products according to a mechanism similar to that for the ribose series. However, the extent of the one-way anomerization depended on the structure of the starting furanoside and on the reagent. For example, the reactions of **5β**, **9α**, and **11β** with *t*-BuMgBr proceeded very slowly and were incomplete; many precipitates appeared during these reactions.

The perbenzylated xylose derivative (**16α**), which had a *cis*-1,2 relationship, was predominantly transformed, with MeMgI, into the *trans*-1,2-anomer (**16β**), while it was apparent that the latter anomer did not anomerize. The direction of this transformation is in contrast with that for the other furanosides, but this phenomenon can be explained in terms of the difference in reaction rates. The reaction of **16α** with MeMgI is much faster than that of **16β**. In this reaction, **16β** may also anomerize to **16α** (we could observe the presence of a trace of **16α** on a TLC plate), but the latter anomer is consumed rapidly to form the former one and **17**. Both anomers, **16** and **18**, could be anomerized with *t*-BuMgBr. However, before the equilibrium of the anomerization was reached, these anomers had been precipitated out from the reaction mixture.

When the one-way anomerization did not occur, no, or only a small amount of, precipitates were observed at the early stage of the reaction, except that the reaction of **16α** with *t*-BuMgBr gave many precipitates like gels after a few minutes. There may be a relationship between the reactivity and the solubility of the Grignard complex of the sugar.

The newly formed chiral centers in the open-chain products have not been determined in the present work. In the case of the formation of the open-chain products from **16** and **18**, the *cis*-1,2-anomers showed a higher selectivity than did the *trans*-1,2-anomers; the reaction rates for the former anomers were also faster than those for the latter. These results suggest that the reactions involve the pathways of the direct attack of MeMgI on the anomeric carbons of **16α**

a) During the reaction, the ether was allowed to evaporate from the reaction mixture. b) H: 80—85 °C (bath temperature). L: 70—75 °C (bath temperature). c) The ratios of the diastereomers or anomers were estimated by ^{1}H NMR spectroscopy and TLC analyses. d) Each product was isolated by chromatography on a silica-gel column with the following solvent systems: A, benzene-ethyl acetate; B, chloroform-methanol; C, hexane-ether. D: The crude products were identified by ^{1}H NMR spectroscopy and TLC analyses. e) A reaction mixture was refluxed in a flask equipped with a condenser. f) Contained a trace amount of **3β**. g) Contained a small amount of by-products. h) Diastereomerically almost pure. i) A main diastereomer was crystallized. j) The ^{1}H NMR spectrum of the **10a** prepared from **9α** was identical with that prepared from **9β**. This product (**10a**) was characterized as its acetate (**10b**). k) **11α,β**:**12a**=4:6. The product (**12a**) was isolated as its diastereomeric acetate (**12b**, 87:13); see Experimental. l) A large amount of the starting material was decomposed under these conditions. m) The ^{1}H NMR spectrum of the main isomer obtained from **16α** was identical with that of the major isomer prepared from **16β**. n) Some of the trityl groups in **20a-α** were deblocked. o) An unknown by-product (10 mg) was isolated; see Ref. 9. p) Before the addition of **20b-β**, a solution of *t*-butyl alcohol (170 mg, 2.3 mmol) in dry benzene (1 ml) was added to a Grignard solution.

and **18β**, besides the pathways via common intermediates similar to **C** in Fig. 8. It seems likely that the *cis*-1,2 structure is desirable for the direct attack, presumably because of steric reasons, thus giving a high selectivity.

The crystalline ketone, **15a**, was the only open-chain product produced by the use of *t*-BuMgBr. The formation of this product results from the elimination of a proton on the carbon adjacent to the C–OMe group of an intermediate similar to **C** in Fig. 8, followed by the ketonization of the resulting enol in the work-up step. Although the configuration of the benzyloxy group next to the keto function of **15a** had not been determined, this compound was proved to be diastereomerically pure, judging from ^{1}H NMR spectroscopy and TLC analyses.

The present anomerization reaction was found to be applicable to 5-*O*-trityl- and 5-deoxy-ribose derivatives (**20a-β** and **20b-β**). Under the Grignard reaction conditions, however, some of the trityl groups of **20a-α** were removed. Debenzylation was also observed during the formation of **10a**. These findings suggest the posibility that the trityl and benzyl protecting groups in sugars may be selectively deblocked under appropriate reaction conditions with the Grignard reagents.

Experimental

The melting points were determined with a Yamato capillary-melting point apparatus and are uncorrected. The IR spectra were recorded on a Shimadzu IR-27 instrument. The ^{1}H NMR spectra were recorded on a Varian HA-100D apparatus, with tetramethylsilane as the internal standard. The optical rotations were measured on a Perkin-Elmer Model 241MC polarimeter.

Merck silica gel GF_{254} was used for the TLC, and the compounds were detected by heating after spraying them with a methanol-sulfuric acid-*p*-methoxybenzaldehyde (85:15:5, v/v) mixture. Merck silica gel 60 (0.063—0.29 mm) was utilized for the column chromatography. The elemental analyses were performed by this Institute.

The ^{1}H NMR spectral data of the compounds are listed in Tables 2 and 3, while their physical properties and the results of their elemental analyses are summarized in Table 4.

Materials. In order to obtain new methyl pentofuranosides, the following sugar derivatives were prepared by the conventional methods. The oxidation of methyl 2,3-*O*-isopropylidene-α-D-mannofuranoside[14] with sodium metaperiodate, followed by reduction with sodium borohydride, gave methyl 2,3-*O*-isopropylidene-α-D-lyxofuranoside (**21**), which was then treated with sodium hydride-benzyl chloride to yield methyl 5-*O*-benzyl-2,3-*O*-isopropylidene-α-D-lyxofuranoside (**22**). The deprotection of **22** with an acid afforded **7α**. Starting from 1,2-*O*-cyclohexylidene-α-D-xylofuranose,[15] the corresponding 5-*O*-tosyl (**23**) and 3,5-di-*O*-benzyl (**26**) derivatives were prepared. An anhydro compound (**24**) was synthesized by the reaction of **23** with sodium methoxide. The treatment of **24** with sodium benzylate yielded 5-*O*-benzyl-1,2-*O*-cyclohexylidene-α-D-xylofuranose (**25**), which was then converted into an anomeric mixture of **11** by methanolysis. Similarly, an anomeric mixture of **13** was obtained from **26**.

General Procedure for the Anomerization and Ring-opening Reactions. Some of the reaction conditions and the results are summarized in Table 1. A solution of a Grignard reagent in ether was prepared from magnesium and an alkyl halide in a three-necked flask, and was then diluted with dry benzene. A solution of a sugar derivative (*ca.* 0.7 mmol) in dry benzene (2—3 ml) was added to the stirred Grignard

9β	4.81 (1H, d, J=4.8 Hz)	3.41 (3H, s, CH_3), 3.57—3.89 (3H, m), 3.98—4.29 (2H, m), 4.48—4.89 (6H, m, CH_2Ph×3), 7.26 and 7.28 (15H, s, phenyl protons).
11α	4.94 (1H, d, J=4.6 Hz)	3.44 (3H, s, CH_3), 3.74 (2H, m, H-5,5′), 3.96—4.40 (3H, m), 4.55 (2H, s, CH_2Ph), 7.27 (5H, s, phenyl protons).
11β	4.81 (1H, s)	3.33 (3H, s, CH_3), 3.51—3.93 (2H, m, H-5,5′), 3.93—4.20 (2H, m), 4.35—4.57 (1H, m), 4.58 (2H, s, CH_2Ph), 7.29 (5H, s, phenyl protons).
13α	4.95 (1H, d, J=4.6 Hz)	2.74 (1H, d, J=7.2 Hz, OH), 3.44 (3H, s, CH_3), 3.66 (2H, m, H-5,5′), 3.98 (1H, m), 4.14—4.48 (2H, m), 4.50—4.79 (4H, m, CH_2Ph×2), 7.1—7.5 (10H, m, phenyl protons).
13β	4.76 (1H, d, J=2.0 Hz)	2.36 (1H, d, J=5.0 Hz, OH), 3.36 (3H, s, CH_3), 3.7 (2H, m, H-5,5′), 3.9 (1H, m), 4.2 (1H, m), 4.4 (1H, m), 4.54 (4H, m, CH_2Ph×2), 7.1—7.4 (10H, m, phenyl protons).
16α	4.72 (1H, d, J=4.0 Hz)	3.38 (3H, s, CH_3), 3.44—3.82 (2H, m, H-5,5′), 4.0 (1H, m), 4.20—4.46 (2H, m), 4.46—4.72 (6H, m, CH_2Ph×3), 7.1—7.4 (15H, m, phenyl protons).
16β	4.89 (1H, d, J=1.3 Hz)	3.38 (3H, s, CH_3), 3.68—3.82 (2H, m, H-5,5′), 3.92—4.12 (2H, m), 4.34—4.46 (1H, m), 4.46—4.70 (6H, m, CH_2Ph×3), 7.1—7.5 (15H, m, phenyl protons).
18α	4.93 (1H, br s)	3.37 (3H, s, CH_3), 3.60 (2H, d, J=4.7 Hz, H-5,5′), 3.80—4.08 (2H, m), 4.08—4.33 (1H, m), 4.33—4.65 (6H, m, CH_2Ph×3), 7.22 and 7.26 (15H, s, phenyl protons).
18β	4.72 (1H, br d, J=4 Hz)	3.30 (3H, s, CH_3), 3.44—3.66 (2H, m, H-5,5′), 3.96—4.26 (3H, m), 4.53 (2H, s, CH_2Ph), 4.60 (4H, s, CH_2Ph×2), 7.24, 7.26, and 7.28 (15H, s, phenyl protons).
20a-α	4.97 (1H, d, J=4.0 Hz)	2.53 (1H, d, J=8.0 Hz, OH), 2.88 (1H, d, J=9.4 Hz, OH), 3.03—3.43 (2H, q, H-5,5′), 3.46 (3H, s, CH_3), 3.83—4.37 (3H, m), 7.1—7.5 (15H, m, phenyl protons).

TABLE 2. (Continued)

Compound	Anomeric proton δ	Other protons δ
20a-β	4.82 (1H, s)	2.31 (1H, br d, J=6 Hz, OH), 2.60 (1H, br d, J=4 Hz, OH), 3.28 (2H, m, H-5,5′), 3.30 (3H, s, CH_3), 3.9—4.32 (3H, m). 7.1—7.6 (15H, m, phenyl protons).
20b-α	4.88 (1H, d, J=4.4 Hz)	1.28 (3H, d, J=6.4 Hz, C-CH_3), 3.13 (1H, br d, J=8 Hz, OH), 3.32 (1H, br d, J=9 Hz, OH), 3.44 (3H, s, OCH_3), 3.5—3.7 (1H, m), 3.9—4.2 (2H, m).
20b-β	4.78 (1H, s)	1.35 (3H, d, J=6.0 Hz, C-CH_3), 3.36 (3H, s, OCH_3), 3.7 (2H, br s, OH×2), 3.9—4.1 (3H, m).
20c-α	4.75—5.10[b]	1.36 (3H, d, J=6.6 Hz, C-CH_3), 2.10 (6H, s, acetyl protons), 3.41 (3H, s, OCH_3), 4.16 (1H, dd, J=6.6, 4.3 Hz, H-4), 4.75—5.10 (3H, m, H-1,2, and 3).
21	4.91 (1H, s, H-1)	1.30 and 1.45 (6H, s, isopropylidene protons), 2.65 (1H, t, J=6.6 Hz, OH), 3.32 (3H, s, OCH_3), 3.8—4.2 (3H, m), 4.56 (1H, d, J=6.4 Hz, H-2), 4.76 (1H, dd, J=6.4, 3.6 Hz, H-3).
22	4.90 (1H, s, H-1)	1.29 and 1.42 (6H, s, isopropylidene protons), 3.32 (3H, s, OCH_3), 3.58—3.94 (2H, m), 4.04—4.26 (1H, m), 4.44—4.78 (4H, m), 7.2—7.4 (5H, m, phenyl protons).
23	5.84 (1H, d, J=3.6 Hz)	1.2—2.0 (10H, cyclohexylidene protons), 2.42 (3H, s, CH_3), 2.54 (1H, d, J=5.6 Hz, OH), 4.1—4.4 (4H, m), 4.46 (1H, d, J=3.6 Hz, H-2), 7.75 and 7.31 (4H, ABq, J=8.8 Hz, phenyl protons).
24	6.26 (1H, d, J=3.6 Hz)	1.2—1.9 (10H, m, cyclohexylidene protons), 4.24 (1H, dd, J=7.4, 2.0 Hz, H-5), 4.72 (1H, dd, J=7.4, 4.4 Hz, H-5′), 4.72 (1H, d, J=3.6 Hz, H-2), 5.08 (1H, dt, J=4.0, 2.0 Hz, H-4), 5.20 (1H, d, J=4.4 Hz, H-3).
25	5.96 (1H, d, J=3.8 Hz)	1.2—1.8 (10H, m, cyclohexylidene protons), 3.45 (1H, d, J=3.4 Hz, OH), 3.91 (2H, d, J=4.0 Hz, H-5,5′), 4.10—4.40 (2H, m), 4.49 (1H, d, J=3.8 Hz, H-2), 4.60 (2H, d, J=2 Hz, CH_2Ph), 7.29 (5H, s, phenyl protons).
26	5.91 (1H, d, J=4.0 Hz)	1.2—1.8 (10H, m, cyclohexylidene protons), 3.75 (2H, d, J=6.0 Hz, H-5,5′), 3.97 (1H, d, J=3.2 Hz), 4.3—4.7 (6H, m), 7.24 and 7.26 (10H, s, phenyl protons).

a) Measured in DMSO-d_6. b) Did not resolve.

solution in the flask without a refluxing condenser[3b] at room temperature under an atmosphere of dry nitrogen, and the mixture was heated at a given temperature for a given period to remove the ether. After cooling, aqueous ammonium chloride was added; the mixture was then extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated. The crude products were purified by silica gel column chromatography with a given solvent system.

*Methyl 5-O-Benzyl-α-D-ribofuranoside (**3α**) and Its β-Anomer (**3β**).* The method of Tener and Khorana[16] was modified. To a solution of methyl 5-*O*-benzyl-2,3-*O*-isopropylidene-β-D-ribofuranoside[16] (970 mg, 3.3 mmol) in methanol (20 ml) and water (4 ml), we added concd sulfuric acid (0.2 ml) after which the mixture was heated at 75—80 °C (bath temperature) for 1.5 h with stirring. After cooling, the acid was neutralized with calcium hydroxide (500 mg). The undissolved materials were filtered through a Celite pad and washed with methanol. The combined filtrate and washings were concentrated. The residue was chromatographed on a silica-gel column with chloroform–methanol (98:2) to give **3α** (160 mg, 19%) and **3β** (550 mg, 66%).

*Methyl 2,3,5-Tri-O-benzyl-α-D-ribofuranoside (**5α**) and Its β-Anomer (**5β**).*[17] To a stirred solution of **3α** (350 mg, 1.4 mmol) in dry benzene (5 ml) and *N,N*-dimethylformamide (2 ml) we added sodium hydride (*ca.* 60% in oil, 300 mg) at room temperature under an atmosphere of dry nitrogen. After 5 min, benzyl chloride (0.6 ml) was added, and the mixture was heated at 75—80 °C (bath temperature) for 30 min. After cooling, methanol was carefully added to decompose the excess sodium hydride. The mixture was then extracted with ether, and the extract was washed with water, dried ($MgSO_4$), and concentrated. The residue was chromatographed on a silica-gel column with benzene–ethyl acetate (95:5) to give **5α** (510 mg, 85%).

A solution of **3β** (460 mg, 1.8 mmol) in dry benzene (25 ml) and *N,N*-dimethylformamide (5 ml) was treated with sodium hydride (*ca.* 60% in oil, 850 mg) and benzyl chloride (0.8 ml) under conditions similar to those described above to give, after chromatography, **5β** in a quantitative yield.

*Methyl 5-O-Benzyl-α-D-lyxofuranoside (**7α**).* The method of Shunk *et al.*[18] was slightly modified. To a solution of **22** (4.0 g, 13.6 mmol) in methanol (75 ml), we added a solution of concd sulfuric acid (0.35 ml) in water (30 ml). The mixture was refluxed at 85—90 °C (bath temperature) for 5 h. After cooling, calcium hydroxide (2 g) was added.

Table 3. The ^{1}H NMR spectral data of the open-chain products

Compound[a)]	δ (in $CDCl_3$)
4	1.21 and 1.24 (3H, d, J=6.0 Hz, 7:3, C-CH_3), 3.35 (3H, s, OCH_3), 3.4—4.0 (6H, m), 4.55 (2H, s, CH_2Ph), 7.30 (5H, s, phenyl protons).
6	1.19 (3H, br d, J=5.8 Hz, C-CH_3), 3.15 (1H, br d, J=3 Hz, OH), 3.32 (3H, s, OCH_3), 3.5—3.8 (5H, m), 4.04 (1H, br s), 4.50 (2H, s, CH_2Ph), 4.59 (2H, d, J=2 Hz, CH_2Ph), 4.65 (2H, s, CH_2Ph), 7.23 and 7.26 (15H, s, phenyl protons).
8[b)]	1.19 (3H, d, J=6.4 Hz, C-CH_3), 3.00, 3.15, and 3.22 (3H, d, J=4.7, 5.6, 5.2 Hz, OH×3), 3.32 (3H, s, OCH_3), 3.38—3.88 (5H, m), 4.10 (1H, m), 4.54 (2H, s, CH_2Ph), 7.28 (5H, s, phenyl protons).
10a	1.13 and 1.16 (3H, d, J=6.4 Hz, 8:2, C-CH_3), 2.7—3.2 (2H, br m, OH×2), 3.25 (3H, s, OCH_3), 3.3—3.7 (4H, m), 3.9 (1H, m), 4.1 (1H, m), 4.35—4.70 (4H, m, CH_2Ph×2), 3.22 and 3.24 (10H, s, phenyl protons).
10b[c)]	1.09 (3H, d, J=6.4 Hz, C-CH_3), 2.00, 2.02, and 2.06 (6H, s, acetyl protons), 3.30 (3H, s, OCH_3), 3.46—3.80 (3H, m, -CH(OMe)- and CH_2OBn), 2.89 and 4.17 (1H, dd, J=7.5, 3.8 Hz, J=9.8, 2 Hz, 75:25, -CH(OBn)-), 4.46 and 4.48 (2H, s, 25:75, CH_2Ph), 4.60 (2H, s, CH_2Ph), 4.96—5.38 (2H, m, -CH(OAc)-×2), 7.24 (10H, s, phenyl protons).
12b[d)]	1.11 (3H, d, J=6.0 Hz, C-CH_3), 2.03, 2.04, and 2.06 (9H, s, acetyl protons), 3.26 (3H, s, OCH_3), 3.40 (2H, m), 3.55 (2H, d, J=5.0 Hz, CH_2Ph), 4.50 (2H, s, CH_2Ph), 5.04—5.26 (2H, m), 5.57 (1H, m), 7.28 (5H, s, phenyl protons).
14	1.10 and 1.20 (3H, d, J=6.0 Hz, 45:55, C-CH_3), 2.9 (2H, br m, OH×2), 3.26 and 3.32 (3H, s, 45:55, OCH_3), 3.3—3.7 (4H, m), 3.8—4.2 (2H, m), 4.49 (2H, d, J=2.0 Hz, CH_2Ph), 4.65 (2H, s, CH_2Ph), 7.26 (10H, s, phenyl protons).
15a	3.0 (1H, br s, OH), 3.33 (3H, s, OCH_3), 3.4—3.6 (2H, m, CH_2OBn), 4.0—4.2 (2H, m), 4.26 (2H, d, J=2.0 Hz, CH_2Ph), 4.46 and 4.61 (2H, ABq, J=12.0 Hz, $COCH_2$), 4.47 (2H, s, CH_2Ph), 7.26 (10H, s, phenyl protons).
15b	2.01 (3H, s, acetyl protons), 3.32 (3H, s, OCH_3), 3.63 (2H, d, J=6.4 Hz, CH_2OBn), 4.17 (2H, d, J=2.0 Hz, CH_2Ph), 4.34 (1H, d, J=4.0 Hz, -CH(OBn)-), 4.48 (2H, s, CH_2Ph), 4.3—4.9 (2H, m, $COCH_2$), 5.40 (1H, dt, J=6.4, 4.0 Hz, -CH(OAc)-), 7.26 and 7.27 (10H, s, phenyl protons).
17[e)]	1.16 and 1.26 (3H, d, J=6.0 Hz, 83:17, C-CH_3), 2.89 (1H, d, J=6.0 Hz, OH), 3.30 (3H, s, OCH_3), 3.40—3.70 (4H, m), 3.76—4.08 (2H, m), 4.42—4.82 (6H, m, CH_2Ph×3), 7.22, 7.24, and 7.25 (15H, s, phenyl protons).
19a	1.10 (3H, d, J=6.0 Hz, C-CH_3), 3.22 (1H, br m, OH), 3.32 (3H, s, OCH_3), 3.44—3.86 (5H, m), 4.0 (1H, br s), 4.53 (4H, s, CH_2Ph×2), 4.67 (2H, s, CH_2Ph), 7.22, 7.26, and 7.28 (15H, s, phenyl protons).
19b	1.25 (3H, d, J=6.0 Hz, C-CH_3), 2.73 (1H, br d, J=6 Hz, OH), 3.24 (3H, s, OCH_3), 3.44—4.10 (6H, m), 4.48 (2H, s, CH_2Ph), 4.55 (2H, d, J=2 Hz, CH_2Ph), 4.67 (2H, s, CH_2Ph), 7.22, 7.25, and 7.26 (15H, s, phenyl protons).

a) The values of the diastereomeric ratios for the open-chain products refer to Table 1. b) A crystalline isomer. c) Decoupling experiments showed that one proton (δ 5.26) on the carbon bearing an acetoxyl group coupled with a proton (δ 3.75) on the carbon bearing the methyl and methoxyl groups. d) The major isomer. e) A diastereomeric mixture from **16α**.

The undissolved materials were filtered through a Celite pad and washed with methanol. The combined filtrate and washings were concentrated to dryness. The residue was dissolved in methanol (100 ml), and concd sulfuric acid (0.7 ml) was added. The mixture was then refluxed at 80 °C (bath temperature) for 1 h. The acid was neutralized with calcium hydroxide (3 g). The work-up gave a syrupy product, which was chromatographed on a silica-gel column with benzene–ethyl acetate (7:3) to provide **7α** (2.1 g, 61%).

Methyl 5-O-Benzyl-β-D-lyxofuranoside (7β). A solution of **7α** (220 mg, 0.78 mmol) in dry benzene (2 ml) was added to a solution of *t*-BuMgBr (7.9 mmol) in dry benzene (15 ml) and ether (10 ml) at room temperature with stirring under an atmosphere of dry nitrogen. The mixture was heated at 70—75 °C for 3.5 h to remove the ether. The usual work-up gave a crystalline product (**7β**, 194 mg, 88%). Its TLC and ^{1}H NMR spectral analyses showed that the product was almost pure. Recrystallization from benzene–hexane afforded an analytically pure sample.

Methyl 2,3,5-Tri-O-benzyl-α-D-lyxofuranoside (9α) and Its β-Anomer (9β). To a stirred solution of **7α** (590 mg, 2.3 mmol) in dry benzene (10 ml) and *N,N*-dimethylformamide (4 ml) we added sodium hydride (*ca.* 60% in oil, 600 mg) at 0—5 °C (bath temperature) under an atmosphere of dry nitrogen, after which the mixture was stirred at room temperature for 30 min. Benzyl chloride (0.8 ml) was then added, and the mixture was heated at 75—80 °C (bath

temperature) for 30 min. A work-up similar to that used for the synthesis of **5α** gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (95:5) to afford **9α** in a quantitative yield.

The sugar derivative (**7β**, 280 mg, 1.1 mmol) was treated in a manner similar to that described above to yield **9β** (365 mg, 76%).

*Acetylation of the Open-chain Products (**10α**).* Acetic anhydride (0.4 ml) was added to a cold (0—5 °C) solution of **10a** (116 mg, 0.32 mmol) in dry pyridine (2 ml), after which the mixture was allowed to stand at room temperature overnight. The usual work-up gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (96:4) to afford **10b** (130 mg, 91%). IR (neat): 1735 (C=O) cm^{-1}. The ^1H NMR spectrum of **10b** showed that it consisted of a 75:25 diastereomeric mixture.

*Methyl 5-O-Benzyl-α-D-xylofuranoside (**11α**) and Its β-Anomer (**11β**).* A mixture of **25** (1.5 g, 4.7 mmol) and concd sulfuric acid (0.2 ml) in methanol (40 ml) was heated at 65 °C (bath temperature) for 3 h with stirring. After cooling, calcium hydroxide (2 g) was added and the mixture was vigorously stirred. The undissolved material were filtered through a Celite pad and washed with methanol. The combined filtrate and washings were concentrated, and the residue was chromatographed on a silica-gel column with chloroform–methanol (99:1) to give **11α** (350 mg, 29%) and **11β** (580 mg, 49%).

*Acetylation of the Open-chain Products (**12α**).* The sugar derivative (**11β**, 470 mg, 1.85 mmol) was treated with MeMgI according to the conditions described in Table 1 and according to the general procedure for the anomerization to yield a syrupy mixture, which consisted mainly of **11α**, **11β**, and **12a** in a ratio of 1:1:8, judging from the ^1H NMR spectroscopy. This mixture (340 mg) was dissolved in dry pyridine (5 ml). To this solution we then added acetic anhydride (2 ml) at 0—5 °C (bath temperature), after which the mixture was allowed to stand at room temperature overnight. The excess acetic anhydride was decomposed by iced water, and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated. The pyridine was removed by co-evaporation with xylene. The residue was chromatographed on a silica-gel column with hexane–ether (6:4) to give an anomeric mixture of methyl 2,3-di-*O*-acetyl-5-*O*-benzyl-D-xylofuranoside (120 mg, 19% based on the starting material), and **12b** (239 mg, 37% based on the starting material). IR (neat): 1735 (C=O) cm^{-1}.

*Methyl 3,5-Di-O-benzyl-α-D-xylofuranoside (**13α**) and Its β-Anomer (**13β**).* To a stirred suspension of **26** (2.3 g, 5.6 mmol) in methanol (80 ml) we added concd sulfuric acid (0.25 ml), after which the mixture was heated at 60—65 °C (bath temperature) for 6 h. After cooling, calcium hydroxide (2.5 g) was added. After the mixture had been vigorously stirred, the undissolved materials were filtered through a Celite pad and washed with methanol. The combined filtrate and washings were concentrated, and the residue was chromatographed on a silica-gel column with benzene–ethyl acetate (9:1) to give **13α** (930 mg, 48%) and **13β** (1.0 g, 52%).

*Acetylation of the Open-chain Product (**15α**).* A mixture of **15a** (200 mg, 0.58 mmol) and acetic anhydride (0.8 ml) in dry pyridine (3 ml) was stirred at room temperature for 4 h. The usual work-up gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (8:2) to give **15b** (188 mg, 84%). IR (neat): 1735 (C=O) cm^{-1}.

*Methyl 2,3,5-Tri-O-benzyl-α-D-xylofuranoside (**16α**) and Its β-Anomer (**16β**).* *From Methyl D-Xylofuranoside*: Sodium hydride (*ca.* 60% in oil, 3.0 g) was added to a stirred solution of methyl D-xylofuranoside[19] (3.2 g, 19.5 mmol) in dry benzene (60 ml) and *N,N*-dimethylformamide (35 ml) at 0—5 °C (bath temperature) under an atmosphere of dry nitrogen, after which the mixture was stirred for 10 min. Benzyl chloride (10 ml) was added, and the mixture was then heated at 75—80 °C (bath temperature) for 2 h. A work-up similar to that described in the synthesis of **5α** gave a syrup, which was chromatographed on a silica-gel column with hexane–ether (7:3) to afford **16β** (2.8 g, 33%) and **16α** (2.3 g, 27%).

*From **13α***: A solution of **13α** (80 mg, 0.23 mmol) in dry benzene (1 ml) and *N,N*-dimethylformamide (0.4 ml) was treated with sodium hydride (*ca.* 60% in oil, 60 mg) and benzyl chloride (0.1 ml), in a manner similar to that described for the synthesis of **16α** from methyl D-xylofuranoside, to give pure **16α** (55 mg, 54%) after chromatography. The physical properties of this product was identical with those of the sample prepared from methyl D-xylofuranoside.

*Methyl 2,3,5-Tri-O-benzyl-α-D-arabinofuranoside (**18α**) and Its β-Anomer (**18β**).* To a stirred solution of methyl D-arabinofuranoside[19] (1.6 g, 0.01 mol) in dry benzene (40 ml) and *N,N*-dimethylformamide (20 ml) we added sodium hydride (*ca.* 60% in oil, 1.8 g) at 0—5 °C (bath temperature) under an atmosphere of dry nitrogen. After the mixture had been stirred at this temperature for 5 min, benzyl chloride (5 ml) was added. The mixture was stirred at room temperature for 30 min and then heated at 75—80 °C for 1 h. After cooling, the mixture was treated in a manner similar to that described for the synthesis of **5α** to give a syrup, which was subsequently chromatographed on a silica-gel column with hexane–ether (8:2) to afford **18α** (1.8 g, 42%) and **18β** (1.1 g, 26%).

*Methyl 5-O-Trityl-α-D-ribofuranoside (**20a-α**) and Its β-Anomer (**20a-β**).* The method of Leonard *et al.*[20] was modified. To a cold (0—5 °C) solution of methyl D-ribofuranoside[21] (5.5 g, 34 mmol) in dry pyridine (70 ml) we added trityl chloride (15 g, 54 mmol), after which the mixture was stirred at room temperature for 2 d. After cooling, iced water was added and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated. The pyridine was removed by co-evaporation with xylene. The residue was chromatographed on a silica-gel column with chloroform–methanol (99:1) to give **20a-α** (1.8 g, 13%) and **20a-β** (9.4 g, 69%).

*Methyl 5-Deoxy-α-D-ribofuranoside (**20b-α**) and Its β-Anomer (**20b-β**).* The method of Shunk *et al.*[18,22] was modified. A solution of methyl 5-deoxy-2,3-*O*-isopropylidene-β-D-ribofuranoside[23] (1.7 g, 9 mmol) in a mixture of methanol (10 ml) and aqueous sulfuric acid (0.2 mol dm^{-3}, 4 ml) was refluxed at 85—90 °C (bath temperature) for 85 min. After cooling, the acid was neutralized with calcium hydroxide. The undissolved materials were filtered through a Celite pad and washed with methanol. The combined filtrate and washings were concentrated to give a syrup, which was subsequently chromatographed on a silica-gel column with chloroform–methanol (95:5) to afford **20b-α** (240 mg, 18%) and **20b-β** (780 mg, 58%).

*Methyl 2,3-Di-O-acetyl-5-deoxy-α-D-ribofuranoside (**20c-α**).* To a solution of **20b-α** (60 mg, 0.41 mmol) in dry pyridine (2 ml) we added acetic anhydride (0.4 ml), after which the mixture was allowed to stand at room temperature overnight. The usual work-up gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (85:15) to give **20c-α** (85 mg, 90%). IR (neat): 1740 (C=O) cm^{-1}.

TABLE 4. THE PHYSICAL PROPERTIES AND ELEMENTAL ANALYSES OF THE SUGAR DERIVATIYES AND OPEN-CHAIN PRODUCTS

Methyl 2,3-O-Isopropylidene-α-D-lyxofuranoside (21). A solution of sodium metaperiodate (20 g) in water (150 ml) was stirred into a solution of methyl 2,3-*O*-isopropylidene-α-D-mannofuranoside[14] (10 g, 43 mmol) in dioxane (250 ml) and water (20 ml) at room temperature. After the mixture had been stirred for 2 h, it was extracted with ether (750 ml) and the extract was washed with water. Sodium borohydride (3 g) was added to the extract. The mixture was stirred at room temperature for 1.5 h; then it was washed with water and dried ($MgSO_4$). The evaporation of the solvent gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (8:2) to afford **21** (3.6 g, 41%).

Methyl 5-O-Benzyl-2,3-O-isopropylidene-α-D-lyxofuranoside (22). To a solution of **21** (3 g, 15 mmol) in dry benzene (50 ml) and *N,N*-dimethylformamide (8 ml) we added sodium hydride (*ca.* 60% in oil, 900 mg) at room temperature under an atmosphere of dry nitrogen, after which the mixture was stirred for 1 h. Benzyl chloride (2.6 ml) was added, and the mixture was stirred at room temperature overnight. A work-up similar to that described for the synthesis of **5α** gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (95:5) to provide **22** (4.0 g, 93%).

1,2-O-Cyclohexylidene-5-O-tosyl-α-D-xylofuranose (23). Tosyl chloride (1.42 g, 5.1 mmol) was added to a stirred solution of 1,2-*O*-cyclohexylidene-α-D-xylofuranose[15] (1.15 g, 5 mmol) in dry pyridine (9 ml) at 0—5 °C (bath temperature). The mixture was stirred at this temperature for 1 h and then at room temperature for another 1.5 h. The

usual work-up gave a solid, which was chromatographed on a silica-gel column with benzene–ethyl acetate (9:1) to afford crystalline **23** (1.59 g, 83%). An analytically pure sample was obtained by recrystallization from ether–hexane. IR (KBr): 3440 (OH), 1365 (S=O), 1176 (S=O) cm^{-1}.

*3,5-Anhydro-1,2-O-cyclohexylidene-α-D-xylofuranose (**24**).* This compound was prepared according to the method used for the synthesis of the corresponding isopropylidene derivative reported by Levene *et al.*[24] To a solution of sodium methoxide (65 mmol) in methanol (50 ml) we added **23** (5.0 g, 13 mmol) at 0—5 °C (bath temperature), after which the mixture was stirred at room temperature for 17 h. After cooling, iced water was added, and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated to give a syrup, which was subsequently chromatographed on a silica-gel column with benzene–ethyl acetate (95:5) to afford **24** (2.6 g, 94%).

*5-O-Benzyl-1,2-O-cyclohexylidene-α-D-xylofuranose (**25**).* The method of Kuzuhara and Emoto[25] was modified. A mixture of sodium (2 g) and benzyl alcohol (30 ml) was stirred at room temperature until the exothermic reaction had finished; the mixture was then heated at 120—125 °C (bath temperature) for 4 h. After the mixture had been cooled to room temperature, **24** (2.5 g, 12 mmol) was added. The mixture was heated at 120—125 °C (bath temperature) for 3 h. After cooling, iced water was added, and the mixture was extracted with ether, dried ($MgSO_4$), and concentrated. The benzyl alcohol was removed by co-evaporation with xylene. The resulting syrup was chromatographed on a silica-gel column with benzene–ethyl acetate (95:5) to give **25** (3.1 g, 82%).

*3,5-Di-O-benzyl-1,2-O-cyclohexylidene-α-D-xylofuranose (**26**).* To a stirred solution of 1,2-*O*-cyclohexylidene-α-D-xylofuranose[15] (2.3 g, 0.01 mol) in dry benzene (40 ml) and *N,N*-dimethylformamide (5 ml) we added sodium hydride (*ca.* 60% in oil, 1.1 g) at 0—5 °C (bath temperature) under an atmosphere of dry nitrogen, after which the stirring was continued for 30 min. Benzyl chloride (3.2 ml) was then added, and the mixture was heated at 70 °C (bath temperature) for 4 h and subsequently treated in a manner similar to that described for the synthesis of **5α** to give **26** as a syrup, which was then crystallized from benzene–hexane: 3.7 g (90%).

*Anomerization of **3β** and **5β** with an Acid.* A mixture of **3β** (75 mg) and concd sulfuric acid (30 mg) in methanol (5 ml) was refluxed at 80—85 °C (bath temperature) for 6 h. Aliquots were analyzed by ^1H NMR spectroscopy after the usual work-up. An equilibrium was reached within 3 h, the ratio of **3α** to **3β** being 20:80.

In a similar way, a mixture of **5β** (99 mg) and concd sulfuric acid (30 mg) in methanol (4 ml) was treated for 24 h. An equilibrium was reached within 6 h (**5α**:**5β**= 15:85).

We wish to thank Dr. Haruo Homma and his staff for the elemental analyses, and Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for measuring the NMR spectra. We are also grateful to Dr. Hiroshi Ohrui for his valuable discussion.

Catalysis by Alkaline Earth Metal Oxides. III. X-Ray Photoelectron Spectroscopic Study of Catalytically Active MgO, CaO, and BaO Surfaces

Yasunobu INOUE* and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 24, 1980)

X-Ray photoelectron spectroscopy was used to reveal the surface states of MgO, CaO, and BaO oxides, which are catalytically active for ethylene hydrogenation. The catalytic activity of CaO exposed to H_2O changed with an increase in the temperature of evacuation in a way similar to that of $Ca(OH)_2$ decomposed by heat treatment. The photoelectron spectrum of CaO evacuated at 1223 K showed a peak of O 1s at 529.6 eV, while those of Ca $2p_{3/2}$ were at 346.3 eV and Ca $2p_{1/2}$ at 349.8 eV. The adsorption of H_2O at room temperature gave rise to an additional peak of O 1s at 532.4 eV and one of Ca $2p_{3/2}$ at 348.6 eV, which were attributed to a Ca–O–H structure. With an increase in the temperature of evacuation from 553 to 1053 K, at which the catalytic activity attained a maximum, the latter O 1s peak shifted to the lower binding-energy side by 0.4 eV, and the corresponding Ca 2p peak became broader. These spectral variations were ascribable to the formation of O^- species. Evacuation above 1273 K destroyed both the catalytic activity and characteristic peaks. BaO provided three O 1s peaks, at 528.5, 530.6, and 532.1 eV, after evacuation at 1373 K; these peaks were assigned to lattice oxygen of the oxide, O^-, and OH^- species respectively. The Ba 4d spectra showed correspondingly superposed peaks. The XPS peak due to O^- was observed only when BaO was evacuated at temperatures high enough to generate the catalytic activity. Such spectral features were less pronounced in the case of MgO. The structural analysis of CaO showed that the coordinatively unsaturated cations also play a role in the catalytic hydrogenation. On the basis of these findings, it was concluded that a combined structure of O^- and the cations is responsible for the hydrogenation activity.

It has been recently established that alkaline earth metal oxides became catalytically active for the hydrogenation of olefins and dienes when the oxides are subjected to heat treatment *in vacuo* within definite ranges of temperature;[1] in the case of olefin hydrogenations, the temperature ranges for activation were 1200—1400 K for MgO, 850—1200 K for CaO and 1200—1400 K for BaO. In our previous studies,[2,3] the mechanism of ethylene hydrogenation on such thermally activated CaO[2] and MgO[3] was analyzed on the basis of the detailed kinetics as well as the deuterium distributions in the reaction with D_2. In view of the similarities in the kinetic behavior of the reactions on the two oxides, we predicted the presence of active sites possessing common features in their structures and nature.

The surface states of alkaline earth metal oxides, especially MgO, and their changes upon the adsorption of electron-donor or acceptor molecules have been extensively studied by means of ESR and IR techniques,[4] but the information so far accumulated is not necessarily definitive in elucidating the catalytic behavior of the oxides described above. Thus, the present study was undertaken in order to characterize the surface states of catalytically active MgO, CaO, and BaO oxides by X-ray photoelectron spectroscopy (XPS), which is capable of revealing the electronic state of metals and oxides. A few experiments using XPS have so far been done on alkaline earth metal oxides in connection with their catalytic properties.[5] The most interesting aspect of the catalytic behavior of these metal oxides is that the activity is lost by heat treatment at temperatures higher than the activation range, but can be recovered by exposing the oxides to water vapor and by then re-evacuating at temperatures in the activation range. Since these phenomena well reflect the characteristics of the active sites present on the oxides, it is important to investigate the changes in the surface states of the oxides with H_2O-adsorption and subsequent evacuation at various temperatures. The present work was mainly concentrated on CaO because its catalytic properties were well clarified in a previous study.[2] Scanning-electron microscopic observation and X-ray diffraction were also employed for the structure analysis.

Experimental

The X-ray photoelectron spectra were recorded at room temperature on a Hewlett-Packard 5950A ESCA spectrometer, using monochromatic Al $K\alpha$ exciting radiation. The magnesium, calcium, and barium oxides were prepared from the respective hydroxides. The magnesium and calcium hydroxides of an extra pure grade were the same as those used in the previous kinetic studies.[2,3] Barium hydroxide and barium oxide of an extra pure grade were purchased from Wako Chemical Ind. and the Rare Metallic Co. respectively. The hydroxides, after being pressed into discs and placed on a recessed quartz plate, were transferred into the preparation chamber of the spectrometer and subsequently subjected to *in situ* decomposition into the respective oxides and then to prolonged evacuation at various temperatures up to 1400 K in a vacuum below 3×10^{-7} Torr (1 Torr=133.3 Pa). For H_2O adsorption, the vapor was admitted to the preparation chamber through a leak valve. The samples were heated with a halogen infrared lamp, Osram 25, which had been placed inside the chamber at a distance of 2.5 cm from the sample surface. The irradiation permitted a rapid and fine control of heating over a wide temperature range, 400—1400 K. The temperature of the smaple surface was monitored by means of a calibrated Pt–Pt/13%Rh thermocouple which was brought into contact with the samples on the occasion of measurement. The experimental conditions of the heat treatment were analogous to those used previously in the kinetic studies.[2,3]

The shift of X-ray photoelectron peaks caused by the

positive charging of the surface was compensated for, or at least minimized, by showering electron beams from a "flood gun." The electric current and accelerating voltage of the beam were adjusted in the ranges of 0.1—0.5 mA and 0—4 eV so as to yield peaks with the narrowest full width at half maximum(fwhm) as optimum. The C 1s level of a trace of contaminant carbons, 285.0 eV, was taken as a reference. During XPS measurements, the background pressure was maintained below 2×10^{-9} Torr. For X-ray diffraction and scanning-electron microscopic observation, the calcium hydroxide was decomposed and subjected to heat treatment *in vacuo* at various temperatures. The pretreated samples were stored *in vacuo* in a quartz vessel until just before measurement. The procedures and apparatus used for the measurement of the catalytic activity of the oxides were the same as those reported previously.[2,3]

Results

Figure 1 compares the variations in the catalytic activity of MgO,[1] CaO,[2] and BaO[1] for olefin hydrogenations when the oxides were subjected to heat treatment *in vacuo* at various temperatures. These oxides possess different temperature ranges for the generation of the activity. The figure also shows the effect of pretreatment upon the recovery of the catalytic activity of CaO, which was almost completely deactivated by evacuation at 1273 K. The subsequent evacuation of the oxide at 1073 K had no effect at all. However, when the oxide was exposed to water vapor at room temperature to such a extent that its surface was nearly covered by a monolayer, followed by evacuation at high temperatures, the activity was regained at around 800 K and attained a maximum at around 1073 K. It should be noted that the H_2O-exposed oxide exhibits a similar pattern of the catalytic activity *vs.* the evacuation temperature, although the highest activity at 273 K was about a half of the original level, 3.6×10^{18} molecules m^{-2} min^{-1}.

Calcium Oxide. Figures 2 and 3 show the X-ray photoelectron spectra in the O 1s and Ca 2p regions respectively for CaO subjected to various treatments. The spectra of CaO evacuated at 1223 K gave a single peak of the O 1s, A, at 529.6 eV and a pair of Ca $2p_{3/2}$ and $2p_{1/2}$ peaks, A, at 346.3 and 349.8 eV respectively (Spectrum 6 in Figs. 2 and 3). The subsequent adsorption of H_2O on the oxide surface at room temperature produced a new O 1s peak, B, with a larger fwhm value of 3.0 eV at around 532.4 eV, in addition to the original A peak, the fwhm of which was 1.9 eV. In the Ca 2p region, the adsorption of H_2O gave rise to three peaks, the central one of which was apparently derived from a superposition of two peaks; the substraction of the original A peak from the superposed spectrum provided a pair of new peaks, B, *i.e.*, Ca $2p_{3/2}$ at 348.6 and $2p_{1/2}$ at 352.0 eV, which were similar in fwhm to those of $Ca(OH)_2$, 2.0 eV. Upon the evacuation of the catalyst at 553 K for 30 min, the intensity of the higher-binding-energy side of the O 1s B peak diminished; from the difference between Spectra 1 and 2, this was regarded as reflecting the disappearance of the B_h peak, whereas the Ca 2p spectra remained almost unchanged. The evacua-

Simple dashed line: 1-butene hydrogenation on BaO. See Ref. 1.

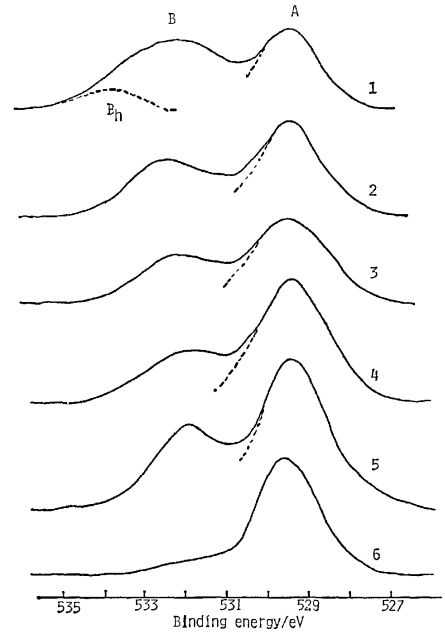

Fig. 2. X-Ray photoelectron spectra in the O 1s region of CaO.
1: After being evacuated at 1223 K for 30 min, CaO was exposed to 5 Torr of H_2O at room temperature and evacuated at the same temperature, 2: evacuated at 553 K for 30 min, 3: evacuated at 883 K for 30 min, 4: evacuated at 1053 K for 30 min, 5: $Ca(OH)_2$ was decomposed and evacuated at 1063 K for 30 min, 6: evacuated at 1223 K for 30 min.

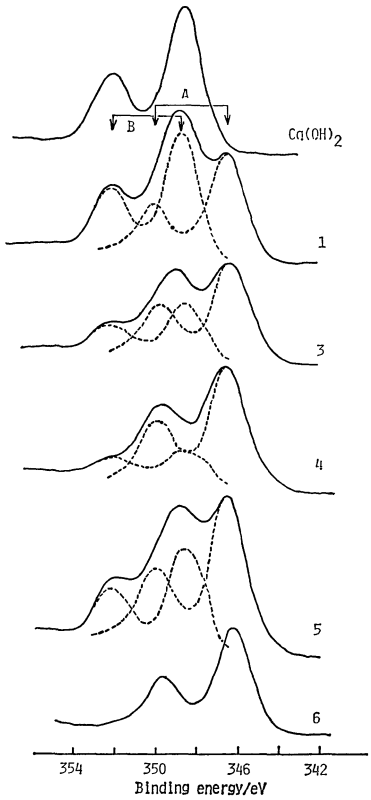

Fig. 3. X-Ray photoelectron spectra in the Ca 2p region. The pretreatments of CaO with respect to spectrum 1 to 6 are the same as those described in Fig. 2 except for the absence of a spectrum corresponding to No. 2.

tion of the sample at 883 K for 30 min, caused significant changes in both O 1s and Ca 2p spectra; the A peak of O 1s became broader by 0.4 eV, and the position of the O 1s-B peak shifted by 0.3 eV to the lower-binding-energy side. In the Ca 2p region, the substraction of the A peak from the observed spectra gave a pair of peaks, the fwhm values of which were broader by 0.2 eV than those of $Ca(OH)_2$ (Spectrum 3 in Fig. 3). Further evacuation at 1053 K considerably enhanced the intensity of the O 1s-A peak, decreasing its fwhm value by 0.2 eV. The B peak of Ca 2p became broader. For evacuation at 1273 K, these characteristic structures in the O 1s and Ca 2p regions vanished, and Spectra 6 in Figs. 2 and 3 were regained. In another experiment in which $Ca(OH)_2$ was decomposed *in vacuo* at various temperatures up to 1273 K, the spectral features of the activated CaO were quite similar to those of the above-mentioned CaO (cf. Spectra 5 in Figs. 2 and 3).

The X-ray diffraction of CaO showed that the relative intensities of lines from such index plane as (111), (220), and (200) remained nearly unchanged on heating *in vacuo* from 873 to 1073 K, but evacuation at 1273 K caused a considerable enhancement of the diffraction intensity from the (111) plane, compared to that from the (220) and (200) planes. Scanning-electron microscopic observation also indicated the preferential growth of particles, probably related to the (111) orientation, upon pretreatment at 1273 K.

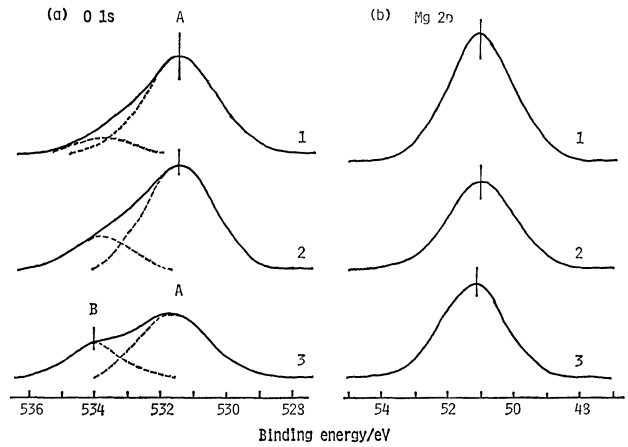

Fig. 4. X-Ray photoelectron spectra in the O 1s (a) and Mg 2p (b) regions of MgO. 1: $Mg(OH)_2$ was evacuated at 1373 K for 30 min, 2: exposed to 5 Torr of H_2O at room temperature for 30 min and evacuated at the same temperature, 3: $Mg(OH)_2$ was evacuated at 873 K for 30 min.

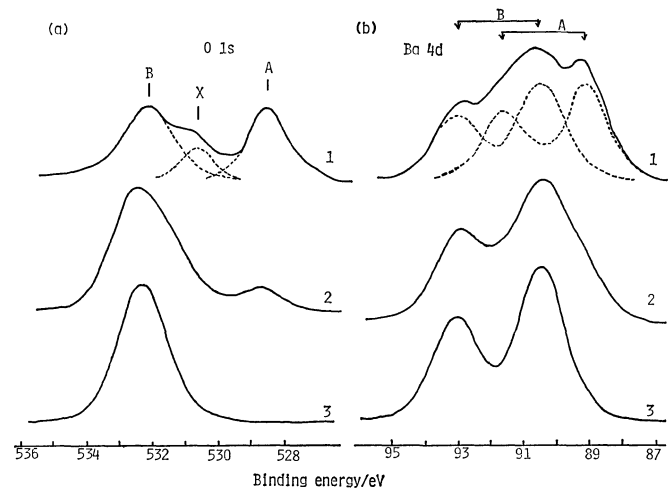

Fig. 5. X-Ray photoelectron spectra in the O 1s (a) and Ba 4d (b) regions of BaO. 1: evacuated at 1373 K for 40 min; the observed peak was roughly deconvoluted by assuming that the intensity ratio of the A to B peak in the Ba 4d line was the same as that in the O 1s line, 2: exposed to 3 Torr of H_2O at room temperature and evacuated at 853 K for 40 min, 3: exposed to air for a long time.

Magnesium Oxide. Figure 4 shows the X-ray photoelectron spectra of MgO pretreated in various ways. The heat treatment of $Mg(OH)_2$ *in vacuo* at 873 K gave rise to two peaks in the O 1s region, *i.e.*, A at 531.6 and B at 534.0 eV. Further treatment at 1373 K caused an appreciable development of the A peak at 531.4 eV and changed the B peak to a small one appearing at around 533.7 eV. The exposure of the oxide to 4 Torr of H_2O at room temperature for 30 min resulted in the appearance of a broad peak at almost the same position as that of the B peak, but its intensity was low. The temperature of H_2O adsorption was raised to 373 K, but no drastic development of the peak occurred. With the Mg 2p photo-

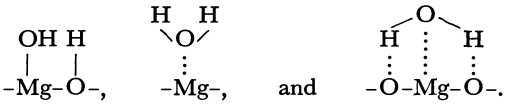
electron peak, no appreciable change was observed upon such treatment except for the broadening of the peak upon the H_2O adsorption.

Barium Oxide. Figure 5 shows the O 1s and Ba 4d spectra of BaO evacuated at 1373 K for 40 min. In the O 1s region, there existed three peaks, *i.e.*, A at 528.5 eV, X at 530.6 eV, and B at 532.1 eV. The corresponding Ba 4d spectra also consisted of superposed peaks. The adsorption of H_2O on the oxide at room temperature and the following evacuation at 853 K led to a drastic decrease in the intensity of the A peak and the development of a broad B peak at 532.4 eV in the O 1s region. With the Ba 4d spectra, the corresponding peaks due to $4d_{5/2}$ and $4d_{3/2}$ were still broad, but the doublets were considerably separated. For comparison, the figure also involves the spectra of BaO exposed to air at room temperature; the O 1s level gave a single peak at 532.3 eV, whereas the Ba 4d levels showed well-separated peaks of Ba $4d_{5/2}$ at 90.5 eV and $4d_{3/2}$ at 93.0 eV. These spectra were substantially identical with those of $Ba(OH)_2$.

Table 1 summarizes the values of the binding energies and fwhm of the photoelectron peaks described above.

Discussion

The adsorption of H_2O on the three oxides and subsequent evacuation caused similar variations in their X-ray photoelectron spectra. Deane *et al.* studied the adsorption of H_2O at room temperature on MgO by IR spectroscopy and classified the produced surface species into several kinds of groups,[6] such as



Similar situations are likely to hold for the other alkaline earth metal oxides. In Spectrum 1 in Fig. 2, the close similarities in the binding energy and fwhm to those of anhydrated CaO permit us to assign the A peak of O 1s to the lattice oxygen of the oxide. The broad B peak is evidently composed of more than one kind of peak and is attributable to the oxygen atoms in the hydroxyl groups and adsorbed water, by analogy with the above-mentioned IR results, since these species are substantially associated with a common unit structure, Ca–O–H, but with slightly different binding energies in their O 1s levels. The peak on the higher-binding-energy side of the B peak is attributable to the oxygen of the adsorbed water, because the value of the binding energy was close to that of condensed water (534—535 eV); the peak readily disappeared upon heat treatment at temperatures as low as 553 K. In the Ca 2p region, the three peaks were well resolved into the Ca 2p peaks due to CaO and $Ca(OH)_2$; the A peak is evidently to be assigned to the Ca ion of the oxide, whereas the B

C 1s=285.0 eV as reference.

peak was considered to combine with hydroxyl groups (and presumably involves Ca ions combining with adsorbed water). The intensity of the i peak, I_i, was evaluated from each peak area and the I_A/I_B ratios were calculated to be 0.7 ± 0.1 for the O 1s peak and 0.8 ± 0.1 for Ca 2p peak. From these intensity ratios and the escape depth of the electrons ejected, the thickness of the hydroxide layer was estimated to correspond to several monolayers.

The most significant changes caused by evacuation at 883 K were the broadening of the O 1s-A and Ca 2p-B peaks and the shift of the O 1s-B peak toward the lower-binding-energy side. The findings that these characteristic variations proceeded further upon evacuation at temperatures up to 1073 K, while the heat treatment at 1273 K destroyed the resulting spectral fine structures, strongly suggest that a new oxygen species is formed on the surface treated in this definite range of temperature, *viz.*, 900—1073 K.

The O 1s A and B peaks which were observed after the evacuation of $Mg(OH)_2$ at 873 K were assinged to oxygen of the oxide and hydroxides respectively. The separation between the two peaks, 2.4 eV, was consistent with the value, 2.5 eV, obtained by Fuggle *et al.* in the case of H_2O[7a] or O_2[7b] adsorbed on evaporated magnesium films. Upon evacuation at 1373 K, the A peak developed whereas the B peak changed to a small one and merged into the tail of the main A peak. The spectral features of the produced oxygen species were not so clear as in the case of CaO, but it is not unreasonable to ex ect that these variations in the O 1s peak upon heating are correlated with the process of the catalytic activation.

The most striking features of BaO treated at 1373 K, which gives a maximum activity for 1-butene hydrogenation,[1] were clearly observed in the O 1s region where three oxygen peaks appeared; from a comparison with Spectra 2 and 3, the A and B peaks were assigned to oxygen of the oxide and hydroxides respectively, whereas the X peak was assigned to a new oxygen species. As for the cation, the corresponding Ba 4d photoelectron spectra provided superposed peaks similar to those observed in the Ca 2p region of the activated CaO. An additional peak due to anhydrated BaO was not obtained under the present heating conditions; the superposed peaks were analyzed by substracting the peaks of hydrated BaO (Fig. 5b, 3). This procedure gave rise to a pair peak which shifted by 1.4 eV to the lower-binding-energy side and was assigned to anhydrated BaO. Since neither broadening nor shoulder peaks were appreciably observed, the resulting peak appears to be insensitive to the influence of the newly-produced oxygen species.

It should be noted that there existed a similarity in the photoelectron spectra of these oxides when they were subjected to the heat treatment by which their catalytic activities were generated, in spite of the difference in the optimum temperature for activation. A recent mass-spectrometric analysis of gases evolved during the thermal decomposition of $Mg(OH)_2$ showed that hydrogen and water molecules are released in the temperature range, 570—970 K, and oxygen atoms above 770 K.[8] The following processes were proposed to occur:

$$2\,OH^- \rightarrow O^-\cdots O^- + H_2 \text{ and } 2\,OH^- \rightarrow O^{2-} + H_2O$$

at a lower temperature, and:

$$OH^- \rightarrow O^- + 1/2\,H_2 \text{ and } 2\,O^- \rightarrow O^{2-} + O$$

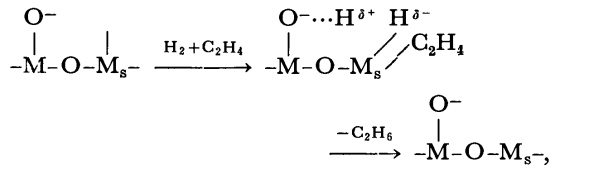
at a higher temperature. The formation of O^- species on CaO[9] and MgO[10] upon heat treatment *in vacuo* was also confirmed by ESR studies. The change in surface structures due to this process is not clearly reflected in the XPS spectra of MgO, probably because of the low concentration of the species formed. This view is in line with the fact that the density of O^- species was estimated to be less than $1\times10^{17}\,m^{-2}$ from the quantitative analysis of the hydrogen evolved.[8] The processes described above are likely to take place on CaO and BaO to a greater extent, since the formation of peroxide is more favored in both oxides. Accordingly, the broadening of the O 1s-A peak of CaO after evacuation at 883 K seems to result from a contribution of the surface O^{2-} species thus formed, the binding energy of which is probably not far from that of lattice oxygen. The variation in the OH-band intensity of $Ca(OH)_2$ with an increase in the evacuation temperature showed that most of the OH groups were removed by evacuation up to 773 K, but still remained as isolated OH groups even after evacuation at 1173 K.[11] By taking the charge distribuitons into account, the B peak of O 1s appears to be derived from the O^- species and the residual OH^- groups. The splitting in energy between O^{2-} and O^- levels is not clear in the present case, but falls within the range of 1.9—2.2 eV, as was also observed in the adsorption of oxygen on NiO and Cu_2O surfaces.[12] The broadening of the Ca 2p-B peak by evacuation at temperatures between 883 and 1053 K appears to be brought about as a result of the partial conversion of OH^- species to O^- (and surface O^{2-}) species; it is likely that the broadening of the B peak toward the lower-binding-energy side is due to a contribution from the Ca ions, which combine with these oxygen species in place of the hydroxyl group, since the binding energies of O 1s were in this order; $O^{2-}<O^-<OH^-$ and since the Ca 2p level was lower in CaO than in $Ca(OH)_2$.

A similar consideration of the activated BaO leads to the conclusion that the O 1s X peak is associated with the O^- species. This assignment is supported by the results of the XPS study of H_2O adsorbed on the Fe surface;[13] the O 1s peak at 530 eV was assigned to the chemisorbed oxygen, $O^{\delta-}$, and the peak at 532 eV to the $OH^{\delta-}$ species. The findings described above for the oxides evidently show that the conditions necessary for the catalytic activation are also effective in producing the common oxygen species, which are coordinatively unsaturated O^- and O^{2-}. The O^- species appears to be more responsible for the catalysis as a part of the active sites for the hydrogenation, since the density of the surface O^{2-} was attenuated with an increase in the catalytic activity of CaO, as is shown in the narrowing of the O 1s-A peak upon evacuation at temperatures from 883 to 1053 K, and since the active BaO surface provided

exclusively the X peak associated with the O^- species. Besides, there is evidence that the species is able to contribute to the H_2-D_2 equilibration reaction.[14]

As was shown in a previous study,[2] evacuation following the calcination of $Ca(OH)_2$ in air gave rise to a low catalytic activity. This implies that the cations in specific positions also play an important role in the catalytic hydrogenation, because the UV reflectance spectra revealed that the sintering of CaO in O_2 at 1073 K preferentially decreased the intensities of the lower frequency bands which relate to ions with lower coordinations, indicating the preferential destruction of high-index faces and local imperfections.[15] The X-ray diffraction and electron microscopic results for the decomposition of $Ca(OH)_2$ demonstrated that the CaO produced by evacuation at temperatures between 873 and 1073 K was still in a crystallographically transient state, retaining many cations with a lower coordination, *e.g.*, those located at edges and corners, but it changed to an oxide with a well-developed (111) orientation upon heat treatment above 1273 K. These findings give support to the above view. Furthermore, the contribution of incompletely coordinated cations or oxygen-deficient sites of CaO to the exchange reaction of butene with D_2 has been pointed out.[16] Therefore, the consolidation of these findings leads to the conclusion that the active sites of the oxides are composed of the O^- species adjacent to the specific cations. This model apparently explains the fact that the fraction of the active sites was as small as 0.5% of the total surface ions.[2]

Evidence for the adsorption of H_2 and C_2H_4 on these sites was shown in the ESR study; the ESR signal of oxygen adsorbed on MgO and CaO was remarkably enhanced by the pre-exposure of MgO to H_2, C_2H_4, or CO[17] and by that of CaO to H_2,[9] and it was concluded that such effects were due to the adsorption of these reducing molecules on the coordinatively unsaturated ions. These considerations, as well as the above-mentioned conclusion as to the structure of the active sites, confirm the following pathway of ethylene hydrogenation, which was previously proposed on the basis of the kinetic results:[2]



where M_s denotes a metal cation with a lower coordination on such specific sites as edges or corners. It appears likely that this structure of the isolated active sites produces heterolytically split hydrogen, thus leading to the formation of a π-allyl carbanion proposed as an intermediate in the 1,3-butadiene hydrogenation on MgO.[18] A comparison of the intensities of the O 1s peaks attributable to O^- shows that its concentration relative to lattice oxygen becomes higher in the order of: BaO>CaO>MgO. The above-mentioned structure of the active sites predicts that the catalytic activity also increases in this order, provided that the contribution of M_s is similar in the three oxides. This prediction is in line with the observed results.[1] An XPS study by Vinek *et al.* revealed that the hydroxide layer on MgO catalysts is enhanced with the storage time, causing a change in selectivity from the dehydrogenation of buta-2-ol to dehydration.[5] We have at present no evidence confirming the contribution of the OH groups to the hydrogenation; further study of their role is needed.

The authors are indebted to K. Kasama for his assistance in measuring the catalytic activity of CaO.

The Magnetic Circular Dichroism of the Conjugated *O*- and *S*-Heterocycles

Nobuko IGARASHI, Akio TAJIRI, and Masahiro HATANO*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received September 20, 1980)

The MCD spectra of the monobenzo and dibenzo derivatives of thiophene and furan are reported; especially in dibenzofuran, two electronic origins are revealed in its lowest energy absorption band. The quantum-mechanical calculations of the transition energies and the Faraday parameters elucidate the experimental data to a fair extent, suggesting similarities in the electronic structures of the lower-lying excited states of furan and thiophen derivatives.

The oxygen (sulfur) atom is incorporated into a conjugated system so as to form ether (thioether) or ketone (thioketone). Sulfur heterocycles of the former type have attracted the attention of many authors because of their characteristic chemical and physical properties.

Johnstone *et al.*[1] have measured the UV and photoelectron spectra of molecules containing several sulfur atoms located in the five-membered ring part of the structure, and have tried to elucidate the observed spectra within the framework of semi-empirical SCF–MO–CI calculations, retaining both the one-center and two-center core integral terms as variable parameters. They have found reasonable values which reproduce the observed electronic spectra. The photoelectron spectra of planar sulfur heterocycles, such as benzothiophene, thienothiophene, and benzothiadiazole have been reported by Clark *et al.*[2] The ionization potentials calculated by the extended Hückel and the PPP method, without 3d atomic orbitals in the basis set, give good agreement with the experimental data; this suggests that sulfur 3d-orbital participation must be very small. The singlet-singlet absorption spectra of six-membered heterocyclic compounds were studied by the use of the PPP method in order to make spectroscopic assignments in the UV region.[3]

The UV spectra of thiophenes seem to have thus far been discussed in conjunction with those of furans, leading to a similarity and correspondence between their electronic transitions. Recently, however, Bree *et al.*[4] have measured the single-crystal absorption spectra of dibenzofuran and shown that the lowest absorption band, which seems to correspond to that of dibenzothiophene, consists of two electronic transitions; one is polarized along the short axis, and the other, along the long axis. Although this point has been further investigated by Tanaka,[5] the vibrational structure has complicated the resolution of the band into its two electronic components.

On the other hand, the magnetic circular dichroism (MCD) technique[6] has been recognized to be a powerful tool for investigating the electronic structures of molecules and their ions in their ground and excited states.[7] In addition, the MCD technique often reveals hidden transitions or resolves heavily overlapping bands into their components. However, although simple organic compounds and their ions have been extensively studied,[8] the MCD technique has not been applied to organic sulfur compounds except for thiophene.[9,10] Håkansson and Nordén[9,10] have demonstrated the existence of two transitions with opposite MCD in the UV-spectral region of thiophene.

In this paper, the electronic structures of thiophene, furan, and their benzo derivatives are investigated from the viewpoint of MCD spectroscopy. On the basis of the UV and MCD spectral data and the results of the PPP calculation, the electronic states of these compounds will be discussed.

Experimental

The thiophene, furan, benzo[*b*]thiophene, benzofuran, dibenzothiophene, and dibenzofuran were purified by repeated distillation or sublimation after recrystallization. Cyclohexane, ethanol, and heptane were used as solvents; all were of a spectral grade.

The MCD spectra were measured with a JASCO J-500C recording spectropolarimeter using an electromagnet, while the UV spectra were recorded on a HITACHI EPS-3T recording spectrophotometer. The magnetic-field strength was calibrated with freshly prepared potassium hexacyanoferrate(III) and was 1.169T.

The observed spectrum was resolved into its components according to the curve-fitting procedure assuming a Gaussian function. The error in estimating the area under the curve was less than ±5%. The experimental oscillator strengths, f, and Faraday B terms, B, were extracted according to the following equations:

$$f = 4.3792\times10^{-9}\times\tilde{\nu}_0\times\int\frac{\varepsilon(\tilde{\nu})}{\tilde{\nu}}d\tilde{\nu}, \quad (1)$$

$$B = \frac{1}{33.5294}\times\int\frac{[\theta]_M(\tilde{\nu})}{\tilde{\nu}}d\tilde{\nu}, \quad (2)$$

where f and B were expressed in units of cgs and (debye)$^2\beta$/cm^{-1} (β=Bohr magneton) respectively.

Theoretical Calculations

The excitation energies, the oscillator strengths, and the Faraday B values of the furans and thiophenes have been calculated within the framework of the PPP approximation,[11] including configuration interaction (CI) among the 28 singly excited configurations. The one-center core and repulsion integrals have been evaluated from the valence-state ionization potentials and electron affinities using the table of Hinze and Jaffé.[12] For the sulfur atom, the one-center core and repulsion integrals are −16.27 eV and 10.78 eV respectively. The two-center core and repulsion integrals have been evaluated by the use of the Wolfsberg-Helmholz[13] and Nishimoto-Mataga[14] equations respectively. The proportionality constant, κ, in the

Wolfsberg-Helmholz equation has been chosen to be 0.7602 so as to reproduce the observed extrema of the MCD spectra of thiophene.

In the absence of degeneracy, a quantum mechanical expression for the Faraday B value associated with an electronic transition a←0 is:

$$B_{0a} = \frac{1}{3} Im \left\{ \sum_{b \neq 0} \frac{\hat{\mu}_{b0}}{\nu_{b0}} \cdot \hat{m}_{0a} \times \hat{m}_{ab} + \sum_{b \neq a} \frac{\hat{\mu}_{ab}}{\nu_{ab}} \cdot \hat{m}_{0a} \times \hat{m}_{b0} \right\}, \quad (3)$$

where $\hat{\mu}_{ij}$ and $\hat{m}_{ij}$ represent the off-diagonal matrix elements of the magnetic- and electric-moment operators respectively, whereas *Im* stands for taking the imaginary part of the bracketed expression of the above equation. The denominator ν_{ij} is the energy difference between the i and j states. The atomic orbitals used in the calculation are the Slater AO's χ, with which the basis set, χ^{λ}, in the PPP procedure is expanded in terms of the overlap integral, S, according to this equation:[15]

$$\chi^{\lambda} = \chi S^{-1/2}. \quad (4)$$

The molecular geometries of furan and thiophene were taken from microwave results,[16,17] and those of dibenzofuran and dibenzothiophene, from the X-ray diffraction data.[18,19] In benzofuran and benzo[*b*]-thiophene, the nuclear arrangements were assumed to be those of furan and thiophene for the five-membered ring, while the bondlengths in the six-membered ring were taken to be equal, 1.40 Å.

Results and Discussion

The UV and MCD spectra of furans and thiophenes are reproduced in Figs. 1—5. In each figure, the full line shows the observed spectrum, while the broken lines stand for the curves after the curve-fitting procedure.

Thiophene and Furan. In the spectral region corresponding to the lowest energy-absorption band of thiophene, there have been observed two MCD bands; one is negative at a higher energy, while the other is positive, as is shown in Fig. 1. It is clear that there are at least two π-π^* electronic origins in this region, as has already been pointed out by Håkansson and Nordén.[9,10] In their calculation, based on the PPP method, these two oppositely directed MCD bands have nearly equal transition energies and Faraday B values which are too large to reproduce the experimental values. This comes from the small energy gap between the lowest two excited states predicted in their calculation. On the contrary, it should be noted that the experimental B values are larger for the higher-energy band than for the lower-energy band, even though cancellation is taken into account.

In Table 1 the theoretical results for thiophene are summarized and listed along with the experimental data. The lowest energy transition is predicted to be B_2←A_1, with its transition moment directed along the long axis, while the second is A_1←A_1, with its transition moment directed along the short axis. The theoretical oscillator strengths and Faraday B values seem to reproduce well the relative magnitudes of the experimental data. Especially the splitting of the first and second excited states is calculated to be 3500 cm^{-1}, in fairly good agreement with the observed

value, 3000 cm^{-1}.

Nordén *et al.* observed a negative MCD band at 47000 cm^{-1} and also an onset of the positive MCD band in the energy region higher than 50000 cm^{-1} for the broad absorption spectrum of furan, which suggests that there are two electronic transitions.[10]

Our calculated results for furan are included in Table 1. In the lower-energy region two π-π^* transitions assigned to $B_2 \leftarrow A_1$ and $A_1 \leftarrow A_1$ are predicted. The sign of the *B* value associated with the first transition is positive, in agreement with the experimental results. As for the excitation energies, however, the theoretical values are in disagreement with the experimental values.

Benzo[b]thiophene and Benzofuran. The UV and MCD spectra of benzo[*b*]thiophene are illustrated in Fig. 2. In the highest energy region, two negative peaks are observed at *ca.* 44000 cm^{-1} and *ca.* 46000 cm^{-1} in the MCD spectrum. It seems to be interesting to consider whether they are due to the vibrational structure or to different electronic origins. We ascribed these bands to the latter, because the PPP method calculation indicates that there are two π-π^* electronic transitions in this energy region. Accordingly, the MCD and UV spectra are resolved into four components, assuming Gaussian functions. Then, corresponding to four absorption bands of benzo[b]thiophene, four MCD bands are observed; their signs are all negative except that of the lowest energy band, at 34500 cm^{-1}.

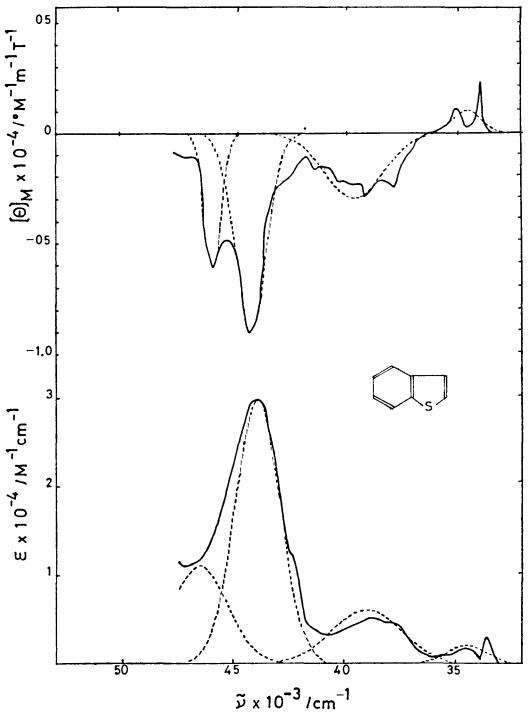

Fig. 2. The MCD (upper) and absorption (lower) spectra of benzo[b]thiophene in ethanol at room temperature.

The theoretical results for benzo[b]thiophene are listed in Table 2, along with the experimental data. Calculation gives the transition energies at 33000, 38600, 45300, and 47200 cm^{-1}, in good agreement with the observed values of 34500, 39000, 43900, and 46500 cm^{-1} respectively. Benzo[*b*]thiophene belongs to the point group C_s, and these four transitions are assigned to A′←A′ polarized on the molecular plane. The predicted *B* values seem to agree well with the extracted values both in sign and magnitude. Unfortunately, however, the calculation gives a negative *B* value associated with the fourth transition, while the experiment gives a positive value. The further inclusion of the CI neglected in this calculation may improve this disagreement.

As is shown in Fig. 3, the UV and MCD bands are blue-shifted in benzofuran. Only two bands are observed for benzofuran in the UV region, although there are four bands for benzo[*b*]thiophene. These two bands, however, in the lower-energy region are similar to those of benzo[*b*]thiophene with respect to the spectral-band shape and the absorption coefficient. At energies higher than 46000 cm^{-1}, a strong absorption band with a negative MCD is observed. As a result, it is expected that the MCD sign sequence of benzofuran is +, −, −, which is the same as that of benzo[*b*]thiophene, and benzofuran seems to show a band system similar to that of benzo[*b*]thiophene in the whole UV spectral region.

The calculation predicts that benzofuran has positive and negative MCD bands for the first and the second transitions respectively. The absolute values of the Faraday B term and the oscillator strength associated

with the first transition are smaller than those associated with the second one, which is in good agreement with the experimental values. For the second and the third transitions, it is found that the relative magnitude of the theoretical values for benzofuran is similar to that for benzo[*b*]thiophene. The calculation seems to show the similarity between benzofuran and benzo[*b*]thiophene, as does the experiment.

Dibenzothiophene and Dibenzofuran. Figure 4 shows the observed and resolved spectra for dibenzothiophene. The MCD spectrum is considered to consist of five main bands, with extrema at 32000, 35500, 38800, 42100, and 44000 cm^{-1}. Accordingly, the observed UV spectrum is resolved into three components in the spectral range of 37000—46000 cm^{-1}, so as to give five absorption bands as a whole. In both the UV and MCD spectra the lowest energy band is assumed to be single.

The UV and MCD spectra of dibenzofuran are reproduced in Fig. 5. Apart from the blue-shifts of the bands, the observed UV spectrum of dibenzofuran seems to have the same profile as that of dibenzothiophene, provided that a shoulder at 43700 cm^{-1} in Fig. 5 corresponds to the third absorption band in dibenzothiophene.

On the other hand, the MCD spectrum of dibenzofuran shows a complicated band system different from that of dibenzothiophene; especially in the lowest energy absorption region, the MCD spectrum shows a fine structure with an alternating sign. These positive and negative MCD bands may be ascribed to either electronic or vibrational origins. In general, prominent sign-alternation is observed in the MCD

a) "UV Atlas of Organic Compounds," Verlag Chemie, Weinheim, Butterworths, London (1967).

spectra for symmetry-forbidden but vibronically-allowed transitions, such as the $B_{2u}\leftarrow A_{1g}$ transition of benzene.[20] In order to examine the existence of symmetry-forbidden transitions, the INDO/S calculations[21] were carried out for dibenzofuran. However, neither n-π^*, σ-π^* nor π-σ^* electronic transitions were predicted in the energy region lower than 40000 cm^{-1}. The possibilities of the electronic origins due to n-π^*, σ-π^*, and π-σ^* transitions, and, in turn, the possibility of the vibrational origin, seem to be quite small. The positive and negative MCD bands in the lowest energy region are ascribed to two π-π^* electronic transitions. Considering this in conjunction with the positive onset of the MCD spectrum in the highest energy region, dibenzofuran can be said to show a band system consisting of six main bands (see the resolved UV and MCD spectrum in Fig. 5).

The PPP method predicts two π-π^* electronic transitions in the lowest energy region for dibenzofuran. The $A_1\leftarrow A_1$ and $B_2\leftarrow A_1$ transitions are encountered at 33600 cm^{-1} and 35600 cm^{-1}; they are assigned to the first and second MCD bands at 33800 cm^{-1} and 35700 cm^{-1} respectively. The calculation gives the same results as for the single-crystal absorption spectra with regard to the polarization of these transitions.[4,5] For the remaining four transitions, the assignments are given in Table 3.

The theoretical results for dibenzothiophene are summarized and listed in Table 3, which shows that two π-π^* transitions are predicted in the lowest energy region; one is at 32600 cm^{-1} and the other, at 34100 cm^{-1}. For comparison, a schematic diagram of the states for dibenzothiophene and dibenzofuran is given in Fig. 6. A very close similarity is found for the predominant configuration which contributes to the excited state in question. In conclusion, six π-π^* electronic transitions are theoretically predicted in the UV spectral region of dibenzothiophene.

It seems reasonable to consider that there exists a similarity between dibenzofuran and dibenzothiophene as to the π-π^* electronic transitions, because

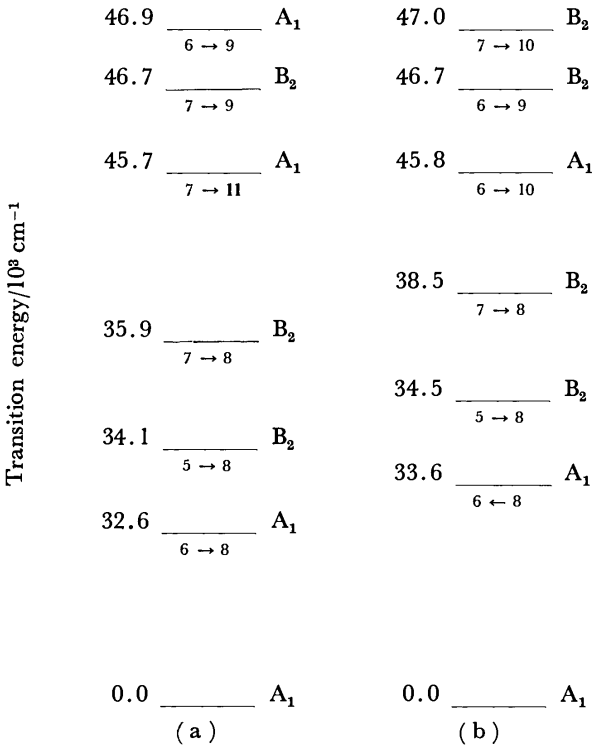

Fig. 6. The calculated lower lying excited states in dibenzothiophene(a) and dibenzofuran(b). The numbers under the bars stand for the main singly excited configuration contributing to the CI state.

both the molecules are iso-π-electronic; nevertheless, the observed UV and MCD spectra of the former consist of six main bands while those of the latter consist of five main bands.

Accordingly, it appears that there is one more transition in the lowest spectral region of dibenzothiophene as well as of dibenzofuran. This may be partially verified by the PPP calculation, which predicts two closely separated π-π^* transitions in dibenzothiophene. One of the two transitions in dibenzothio-

phene, however, is considered to be so weak as not to be observed or as to be hidden by the neighbouring transition, which was difficult to resolve even in the present MCD work.

Concluding Remarks

The lowest absorption band of dibenzofuran is confirmed, by the analysis of the MCD spectra and the PPP calculation, to be a super position of the two π-π^* electronic transitions, which is consistent with the results of the single-crystal experiments by Bree *et al.*[4] and Tanaka.[5] For dibenzothiophene, the lowest absorption band is expected to consist of two transitions, although the present work was not successful in resolving these transitions.

Singlet-excitation Migration in Pure Liquid Methyl- and Ethylnaphthalenes

Takeshi Ohno* and Shunji Kato

College of General Education, Osaka University, Toyonaka, Osaka 560

(Received September 24, 1980)

The fluorescence quenching of solvent molecules and solute molecules was studied in the alkylnaphthalene solvents. The singlet-excited states of the solvent molecules were quenched by 1,4-bis(trichloromethyl)benzene with the rate parameter of 2.8×10^{10} mol^{-1} dm^3 s^{-1} at 45 °C. This rate parameter is twelve times as great as that of the solute, dibenz[*a,c*]anthracene, in the solvent, 1-methylnaphthalene. The diffusion constant of the excitation migration of the solvent molecule is calculated to be larger (0.35×10^{-4} cm^2 s^{-1} at 45 °C) than that (0.03×10^{-4} cm^2 s^{-1}) of the solute. The temperature coefficient (22 kJ/mol) of the excitation migration is too small to explain the migration mechanism on the hypothesis of the "successive association-dissociation reaction of excimer" proposed by Birks. The presence of a short-range exciton in the liquid is likely.

Since pure liquid aromatic hydrocarbons do not have such long-range periodicity as molecular crystals, it seems difficult to predict, from the point of view of exciton diffusion, the migration rate of the electronic-excitation energy in the molecular liquids,[1] while Lipsky and Burton suggested exciton diffusion in toluene.[2]

The solvent-solvent excitation migration in the liquid scintillator of toluene–2,5-diphenyloxazole has been attributed to multipole-multipole resonance interaction between the solvent molecules, which have been considered to be free from any kind of aggregation.[1]

However, since the singlet-excited states of many aromatic hydrocarbons form excimers which may be shallow traps and/or excitons with the shortest possible length, the role of the excimer in the excitation migration can not be neglected. Birks *et al.*[3] proposed that a sequence of the rapid association and dissociation of an excimer in the singlet-excited state brought about the solvent-solvent excitation migration. Though the excimer dissociation process (detrapping) should be the rate determing step of the excitation migration according to their mechanism, it has not yet been examined.

In this work, the singlet-excitation migration rates of several liquid naphthalenes are examined in the range from 5 to 75 °C. Two mechanisms of the excitation migration, exciton diffusion and the rapid association and dissociation of the excimer will be discussed.

Experimental

Materials. The 1-methylnaphthalene(1-MN, mp: −34 °C) was purified through a 30-cm column of Al_2O_3 followed by distillation using a Widmer column under reduced pressure. The 2-methylnaphthalene(2-MN, mp: 35.2 °C) was purified by two different methods. The purified sample(A) was obtained by three recystallizations from methanol and by subsequent simple distillation under reduced pressure. The other sample(B) was obtained by distillation using a 30-cm Widmer column in place of the simple distillation under reduced pressure. G. R. grade 1-ethylnaphthalene(1-EN, mp: −3.7 °C) and 2-ethylnaphthalene(2-EN, mp: −7.4 °C) were used without further purification.

The dibenz[*a,c*]anthracene(DBA) and pyrene were recrystallized three times from an ethanol solution, followed by sublimation. The 1,4-bis(trichloromethyl)benzene-(TCB), benzophenone, and CBr_4 were purified by two times recrystallizations from an ethanol solution, and *p*-phenylenediamine, from a benzene solution. After the CCl_4 had been refluxed with NaOH, washed with water, and dried by $CaCl_2$, it was distilled. G. R. grade diphenylamine was used without further purification.

Measurements. Quenching constant(K_{SV}): The intensities of the fluorescence were measured by using a Hitachi MPF-2A spectrofluorometer. In the measurement of the emission intensity from a sample of a high optical density such as neat liquids, a triangular cell was used so that we could see a small illuminated part of the sample cell. In order to exclude any error in the measurement, a slit was inserted between the cell and the condenser lens for emission. A N_2-substituted sample in the cell was set in a small thermostat (0—80 °C, ±0.5 °C).

The lifetime of the fluorescence was measured by means of laser excitation. One of the lasers was a compact, high-power N_2-laser with a Blumlein circuit (10 kV, pressure of N_2: 40 mmHg (1 mmHg=133.3 Pa), 2 mJ), which consists of two stainless steel electrodes (3 mmϕ) 20 mm apart, barium titanate capacitors (Taiyo Yuden, 750×14 pF, 25 kV), and a triggered spark gap. The other one was a compact, low-power N_2-laser (10 kV, 10 μJ) containg a coaxial cable as a capacitor.[4] The high-power laser was used for almost allthe samples. The dibenz[*a,c*]anthracene solution was excited by the dye laser (0.02 mol dm^{-3} 2,5-diphenyloxazole benzene solution, 368 nm). The fluorescence decay was recorded by using a Tektronix oscilloscope 475 and Fuji X-ray film or Kodak Recording Film 2475. As for 2-EN with the shortest life the low-power laser was used while a Tektronix sampling scope 661, and Yokogawa 3083 X-Y recorder were used for the detection.

Results and Discussion

Determination of the Molar Enthalpy of Excimer Formation. Each fluorescence spectrum from 280 K to 350 K of liquid naphthalene derivatives consists of a monomer band and an excimer band. At temperatures close to the melting point of the naphthalenes, the strong excimer emission with a peak at 400 nm is the most evident (see Fig. 1). As the temperature is raised, however, the monomer emission without a fine structure becomes stronger than the excimer emission. This situation is very similar to the spectral changes in 1-MN and 2-MN reported by Stevens and Dickinson.[5]

Because both the excimer-formation rate (k_{DM}[M]: 3.5×10^{11} s^{-1}) and the excimer-dissociation rate (k_{MD}: 10^8 s^{-1})[6] are more rapid than the decay rate (k_d: 1.8×10^7 s^{-1}) in the case of 1-MN, an equilibrium between the monomer and the excimer in the excited singlet state exists. The monomer-excimer equilibrium

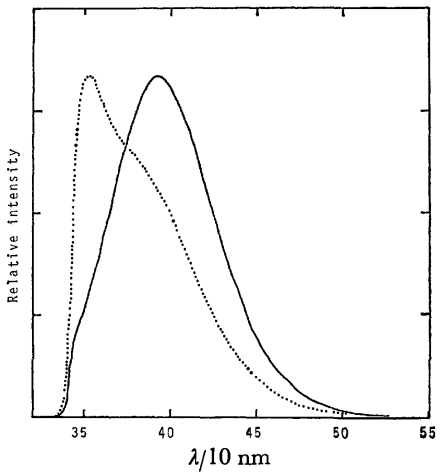

Fig. 1. Fluorescence spectra of liquid 1-MN on excitation at 316 nm.
Solid line: 12 °C, dotted line: 75 °C. The maximum intensity of fluorescence is normalized.

in the excited state is supported by the fact that the Stern-Volmer quenching constant (K_{SV}) obtained by using the excimer band is the same as that obtained by using the monomer band. Further, it is assumed that the intensity of the monomer band (or the excimer band) is proportional to the product of the excited-monomer (or the excimer) concentration and the radiative-rate parameter of the excited monomer (or the excimer), k_{FM} (or k_{FD}). From their dependence on the temperature, one can obtain the molar enthalpy of the excimer formation (ΔH) by using Eq. 1;

$$\ln\frac{I_{352}}{I_{440}} = \ln\frac{\alpha k_{FM}}{k_{FD}[M]} - \frac{\Delta S}{R} + \frac{\Delta H}{RT} \quad (1)$$

where I_{352} and I_{440} are the intensity of the monomer emission measured at 352 nm and that of the excimer measured at 440 nm respectively; α, the apparatus constant; [M], the concentration of the ground-state naphthalene, and ΔS, the molar entropy of the excimer formation. Plotting the left term of Eq. 1 against reciprocal of the temperature (see Fig. 2) gives a linear relation with the slope of $\Delta H/R$ in all cases; the values are shown in Table 1.

The values of ΔH for 1-MN and 2-MN seem similar to the reported values in the ethanol solution,[6] and the ΔH value for 1-EN is close to the value measured by Christophorou and Carter in the neat liquid,[7] though smaller values have been reported in a diluted heptane solution.[8]

Determination of Excitation-migration Coefficient. When the fluorescence of DBA or pyrene is quenched by an adequate quencher in liquid naphthalenes, the quenching-reaction-rate parameter is given by Eq. 2, according to Birks,[3] where N_0 is Avogadro's number; p, the quenching probability; R_{AQ}, the interaction distance, and D_A and D_Q, the diffusion coefficients of DBA (or pyrene) and the quencher respectively;

$$k_q = p4\times10^3 N_0(D_A+D_Q)R_{AQ}. \quad (2)$$

When the solvent fluorescence is quenched by the quencher, a term based on the excitation migration is added to Eq. 2, as Eq. 3 shows;

$$k_q' = p4\times10^3 N_0(D_N+D_Q+\Lambda)R_{NQ} \quad (3)$$

where D_N and Λ are the diffusion coefficients of the solvent naphthalene and the excitation-migration coefficient of the solvent respectively.

Assuming (i) the values of R_{AQ} and R_{NQ} to be the same, and (ii) the values of D_A and D_N to be the same, one can obtain the value of Λ from the difference between the values of k_q and k_q' when an efficient quencher is chosen ($p=1$). The values of k_q and k_q' are calculated in the usual manner from the Stern-Volmer quenching constant and the fluorescence-decay-rate parameter(k_d).

A Stern-Volmer plot is linear in all cases using TCB as a quencher (see Fig. 3). The slopes (the quenching constants in Table 4) become a little steeper as the temperature is increased. While p-phenylenediamine quenches the fluorescence of 2-MN with the same efficiency as TCB, diphenylamine, CCl_4, and benzophenone are inefficient quenchers and the quenching constants are a little smaller (see Table 2).

The values of K_{SV} are sensitive to impurities in the

samples. The carefully purified samples, 2-MN(B), have larger K_{SV} values than 2-MN(A). In the case of 1-MN, the quenching constants obtained by the use of TCB as a quencher are dependent on the temperature in a way similar to those in the case of 2-MN (see Table 3). For 1-EN and 2-EN, TCB is used as a quencher; the measured quenching constants are listed in Tables 5 and 6.

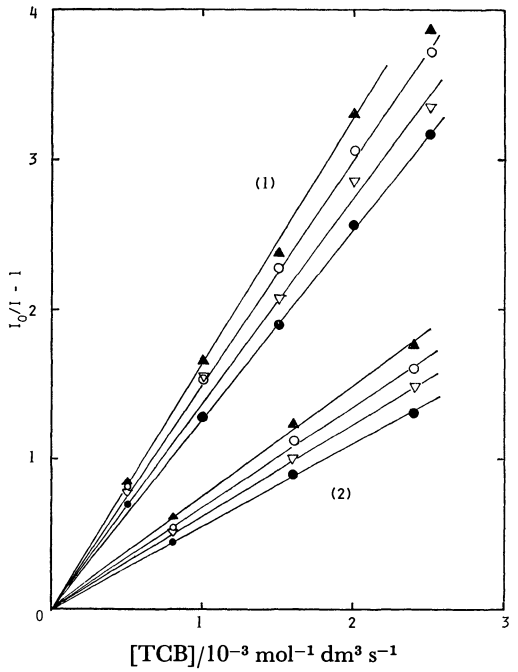

Fig. 3. Stern-Volmer plot for the fluorescence quenching of liquid 2-MN by TCB(1) and diphenylamine(2). ●: 36 °C, ▽: 45 °C, ○: 60 °C, and ▲: 70 °C.

In order to ascertain the product of the molecular diffusion constant (D_A+D_Q) and the interaction distance (R_{AQ}), the quenching constants for one solute in the several liquid naphthalenes are necessary at the same temperatures. DBA was used as a solute for 1-MN and 2-MN, and pyrene, for 1-EN and 2-EN. The values of K_{SV} are shown in Tables 3,4,5, and 6.

Determination of the Fluorescence-decay-rate Parameter. The sampling method and single-pulse method gave the same value of the first-order decay-rate parameter(k_d). As the temperature rises, k_d increases in all cases (see the fourth column of Tables 3,4,5, and 6). The value of k_d is sensitive to impurities in the sample, as is K_{SV}. The fluorescence lifetime of 2-MN(A) is 1/3 as long as that of 2-MN(B). All the k_d values measured are very close to or smaller than those previously reported: 1.7×10^7 s^{-1} for 1-MN at 20 °C, 5×10^7 s^{-1} for 2-MN at 40 °C,[9] and 2.5×10^7 s^{-1} for 1-EN at 20 °C.[8]

k_q, k_q', D, and A. Both quenching-rate parameters for the solute (k_q) and the naphthalenes (k_q') in the liquid naphthalenes are calculated from K_{SV} and k_d. The values shown in the fifth column of Tables 3—6 are based on the K_{SV}, using TCB as a quencher; which give the largest values of K_{SV}. The k_q values are in the order of 10^9 mol^{-1} dm^3 s^{-1} in all cases and are assumed to be diffusion-controlled. This is supported by the fact that they are similar to those (2×10^9 mol^{-1} dm^3 s^{-1}) for the triplet-excited state of DBA in liquid 1-MN,[10] which were obtained by using the most efficient quencher of ferrocene.[11]

and DBA at 45 °C, the values of D_A+D_Q are calculated, by using Eq. 1, to be 3×10^{-6} cm^2 s^{-1}. On the same assumption, the values of $D_N+D_Q+\Lambda$ are calculated to be 32×10^{-6} cm^2 s^{-1}. Therefore, it is concluded that Λ is 29×10^{-6} cm^2 s^{-1}, or about 19 times as great as the molecular diffusion constant in liquid 2-MN. This procedure also gives the Λ values in the other cases; they are shown in the last column of Tables 3—6. Though the better-purified sample, 2-MN(B), has a longer fluorescence lifetime than that of 2-MN(A), the Λ values are quite close to those of 2-MN(A). It can be expected that the calculated Λ values for the unpurified samples, 1-EN and 2-EN, will be close to the real values.

These present values of Λ are similar to those obtained in liquid benzene and alkylbenzenes, in which the molecular diffusion constants are of the same order as Λ,[3] so that a difference between the unknown diffusion constant of benzene in the singlet-excited state and that of some solute seems to result in a relatively larger error in the calculation of Λ. It is also noted that Λ is one-fifth as great as that (10^{-4} cm^2 s^{-1}) in the molecular crystal of naphthalene.[13] Eastman, Smutny, and Coppinger reported a little larger value (4.5×10^{10} mol^{-1} dm^3 s^{-1}) of the k_q' of 1-EN by using an aromatic quencher, such as sub-

stituted *p*-quinone, benzophenone, *p*-nitrophenol, and *p*-nitrosophenol.[12] However, it is very difficult to extract the contribution of the excitation migration from them because the Förster-type energy transfer between 1-EN and the quencher must increase the value of k'_q.

The Λ gradually increases with the temperature, as does D. Plotting $\log \Lambda$ against the reciprocal of the temperature, we obtain a curved line, as Figs. 4 and 5 show. Taking the best-fitting straight line through these points, an excitation-migration activation energy of about 17—22 kJ/mol is obtained.

Effect of Dilution on the Value of k'_q. The dilution of 1-MN with hydrogenated naphthalene (*cis*-decaline) makes the quenching reaction parameter smaller. Figure 6 shows the change in the rate parameter with the mole fraction of 1-MN at 20 °C. It should be noted that the rate-parameter increases in the very concentrated region, where some of the nearest neighbours are naphthalene itself. Because a collisional singlet-excitation transfer reaction is very efficient, the dilution effect suggests a collapse of the large molecular assembly responsible for excitation migration with dilution. This will be discussed further in the next section.

○: 1-MN, ●: 2-MN.

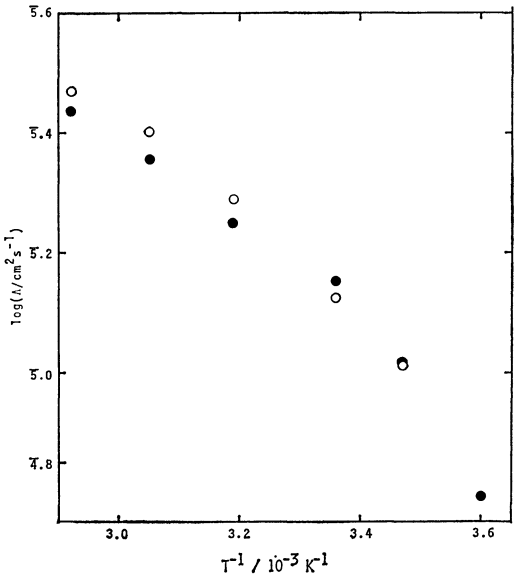

Fig. 5. Temperature dependence of the excitation migration in 1-EN and 2-EN.
○: 1-EN, ●: 2-EN.

Mechanism of Excitation Migration. With respect to the singlet-excitation migration in neat alkylbenzene, two mechanisms of excitation-migration have been proposed; the "association-dissociation reaction of an excimer"[3] and "exciton motion."[2] The "association-dissociation reaction of an excimer"—The formation of an excimer between the excited-singlet state of Molecule A and the neighbouring molecule, B, is followed by its dissociation, resulting in a 50% probability of Molecule B being in the monomer-excited state. The rapidty of the association-dissociation may create a large excitation-migration without any molecular displacement. In this case, Λ is described by Eq. 4[3], where β is the root-mean-square displacement of excitation, and K_e, the equilibrium constant of excimer formation:

$$\Lambda = \beta^2 \frac{k_{DM}[M]}{6(1+K_e[M])} \tag{4}$$

$$\approx \beta^2 \frac{k_{DM}}{6K_e} = (\beta^2/6)\exp(-\Delta E_{MD}/RT). \tag{5}$$

If the product of K_e and [M] is much larger than unity, Eq. 4 can be approximated to Eq. 5. Because K_e is 5.2—20.5 mol^{-1} dm^3 [6] and [M] is about 7 mol dm^{-3} for 1-MN and 2-MN, the value of Λ can be estimated by Eq. 5 and rewritten using the activation energy of the excimer-dissociation process (ΔE_{MD}).

"Exciton motion"—In neat liquid, there is a kind of singlet-exciton assumed whose length is shorter than that of the molecular crystal because (i) a periodicity in the radial and orientational distributions has been

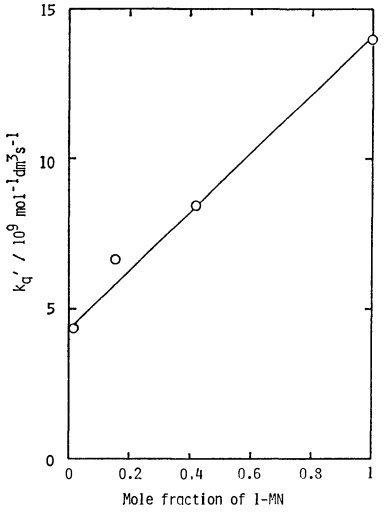

Fig. 6. Change of rate parameter for the fluorescence quenching of 1-MN diluted by *cis*-decaline at 20 °C. The quencher is TCB.

TABLE 7. ACTIVATION ENERGIES OF EXCITATION MIGRATION

Liquid	E_{ex} kJ mol^{-1}	ΔH kJ mol^{-1}	$\Delta E'_{MD}$ kJ mol^{-1}	$\Delta H'$ [a] kJ mol^{-1}
1-MN	22	−19	32	−20
2-MN	18	−19	33	−21
1-EN	17	−24	—	—
2-EN	16	−20	—	—

a) These values were obtained for the ethanol solution by B. K. Selinger (Ref. 6).

recognized for liquid benzene;[14,15] (ii) the absorption spectrum of liquid benzene has a crystal field K-band like that of crystal benzene;[15] and (iii) the band shifts of liquid benzene and 1-EN in the higher-energy region from those of the diluted solution have been explained in terms of excitonic interaction, as have those of the crystal sample.[16,17] Therefore, the excitation energy in neat liquid migrates through the small exciton, while the length of the exciton is shorter than that for the molecular crystal. Though the monomer-excited state is reproduced from a trap of the excimer with a certain temperature, the periodical structure of the liquid is destroyed by thermal motion, so that the excitation migration may not increase monotonically with the temperature. The migration constant of excitation is described by Eq. 6:

$$\Lambda = \Lambda_0(T) \exp\frac{-\Delta E_{MD}}{RT}, \quad (6)$$

where $\Lambda_0(T)$ is intrinsic to the exciton and is as dependent on the temperature as is the length of the exciton.

An experimentally determined value of the activation energy of the migration process is useful for the diagnosis of the migration mechanism. Since a curved line is drawn between log Λ and the reciprocal of the temperature, and since the activation energy gets a little smaller in the higher-temperature region, "exciton motion" is the more reasonable mechanism. It is based on the inference that the migration rate is dependent on both the detrapping and the intrisic exciton length, the latter of which gets smaller with a rise in the temperature. The values of the apparent activation energies are smaller than those of the excimer dissociation process ($\Delta E'_{MD}$) reported in the case of a diluted ethanol solution, as Table 7 shows. Even when taking account of the difference between ΔH in the pure liquid and $\Delta H'$ in the ethanol solution, ΔE_{MD} is considered to be approximately equal to $\Delta E'_{MD}-(\Delta H'-\Delta H)$, whose values are 31 kJ/mol in the cases of both 1-MN and 2-MN, higher than the observed values.

The smaller activation energy may be caused by a decrease in the intrinsic exciton length with a rise in the temperature. However, the collapse of such a liquid exciton at higher temperatures allows excitation transfer through the association-dissociation reaction mechanism at higher temperatures.

It seems that the dilution effect on excitation migration can be understood on the bases of the exciton mechanism. It is reasonable that the gradual increase in k'_q with the mole fraction of 1-MN comes from a concurrent increase in its exciton length. Alternatively, the "association-dissociation reaction of the excimer" mechanism predicts that the value of k'_q will be independent of the concentration of 1-MN for a concentrated solution (0.2 mol dm^{-3}) because of rapid excimer formation.

We wish to thank Dr. T. Okada for permission to use the low-power N_2-laser and the detection system.

(Received August 14, 1980)

Ab initio LCAO MO SCF calculations were carried out on $[Co(CN)_6]^{3-}$. The character of the wave-functions was discussed in terms of the orbital-mixing rule. The radial distribution of electron density obtained from molecular orbital (MO) calculation was compared with that obtained from X-ray experiments. On the ionization from a metal d-orbital, a significant electronic relaxation was shown to occur, which makes Koopmans' theorem invalid. The calculated excitation energies without a configuration interaction showed a qualitative correspondence with the absorption spectrum.

The electronic structure of the hexacyanocobaltate (III) ion, $[Co(CN)_6]^{3-}$, is of interest from both experimental and theoretical points of view, because this ion is the simplest of the typical symmetrical complexes in which the back-donation of electrons from the metal $d\pi$ to the ligand $p\pi$ orbitals possibly takes place.[1] This complex has been the subject of extensive experimental studies in relation to the electronic structures in the ground and excited states; these studies have included studies of the absorption,[2] infrared (IR),[3,4] Raman,[5] photoelectron,[6,7] and NMR[8,9] spectra, and X-ray analysis.[10,11] A comprehensive review of the chemistry of cyano complexes has been published.[12]

Recently, a precise X-ray crystallographic study of hexamminecobalt(III) hexacyanocobaltate(III) has been made by Iwata and Saito,[13] who have shown the deformation of electron density distribution and calculated the electronic charge on the cobalt atom to be 26.8 ± 0.3 for the cyano complex. Previous theoretical calculations were done for the electronic state of this compound by Kida *et al.*[14] and by Alexander and Gray[2] using the Wolfsberg-Helmholz approach. The energy-level scheme for the octahedral cyanide complexes given by the latter authors have shown the following orbital energy sequence:

$$\sigma(CN^-) < \pi(CN^-) < \sigma(CN^-) < d\pi.$$

The cobalt charge was estimated to be $+0.18$ by Kida *et al.* and $+0.41$ by Alexander and Gray. The aim of the present work is to investigate the cobalt-ligand interaction, the mechanism of π back-donation, and the validity of the application of the Hartree-Fock method to transition-metal complexes. Results are reported for the ground, excited, and ionized states of $[Co(CN)_6]^{3-}$.

Computational Method

The present calculation is of the LCAO MO SCF type, using a basis set of Gaussian functions. The basis set for Co was chosen as follows. The primitive GTF (Gaussian-type function) set, [12s, 6p, 4d], which had been optimized for the ^4F state of the neutral Co atom,[15] was modified by replacing the two most diffuse s functions by tighter functions with the exponents of 0.26 and 0.10 and by adding two supplementary p functions with the same exponents. The resulting [12s, 8p, 4d] functions were contracted to [8s, 6p, 2d]. For C and N, [9s, 5p] sets[16] were contracted to [4s, 2p]. Thus, 348 GTF's were contracted to 158 GTO's (Gaussian-type orbitals). The ion was assumed to be octahedral, and the interatomic distances were taken as:[13]

$$Co\text{-}C = 1.894\,\text{Å}, \qquad C\text{-}N = 1.157\,\text{Å}$$

The calculations were carried out by using a program package called JAMOL2 written by Kashiwagi *et al.*[17] In order to make the integral calculations more tractable, an integral approximation scheme based on semi-orthogonalized orbitals[18,19] was utilized; the threshold value for the degree of overlap was set at 0.0007.

Open-shell calculations for the ionized and excited states have been performed in the restricted Hartree-Fock formalism as given by Roothaan.[20] The corresponding vector coupling coefficients for the various states were calculated according to the reference.[21] The electron-density map was prepared by using the program written by Sano and Miyoshi.[22]

Results and Discussion

The results for the orbital energies and populations of the ground state of the $[Co(CN)_6]^{3-}$ ion have been reported in previous papers.[23–25]

The Electron Density Associated with the Ground States of $[Co(CN)_6]^{3-}$ and CN^-. The charge distribution of the cyanide ion will first be discussed in order to give a basis for the discussion of the electronic structure of the complex. The cyanide ion is isoelectronic with N_2 and CO, and the molecular orbitals of CN^- can be expected to be similar to those of CO. The calculated wave-function contours for the valence shell of the CN^- ion are shown in Fig. 1.[26]

The CN^- 3σ MO consists of the nitrogen 2s and carbon 2s orbitals. The high amplitude in the region midway between the atoms is indicative of substantial σ bonding. In the 4σ MO, a node appears near the nitrogen nucleus; this shows that the nitrogen 2p orbital makes a significant contribution. This MO is derived from the nitrogen sp-hybrid orbital mixed with the predominantly 2s orbital of carbon, and it has approximately the character of the nitrogen lone-pair orbital. The 1π MO shows a higher density at the more electronegative nitrogen. The highest occupied MO (HOMO), 5σ, is strongly polarized towards carbon. This MO is mostly a carbon sp-

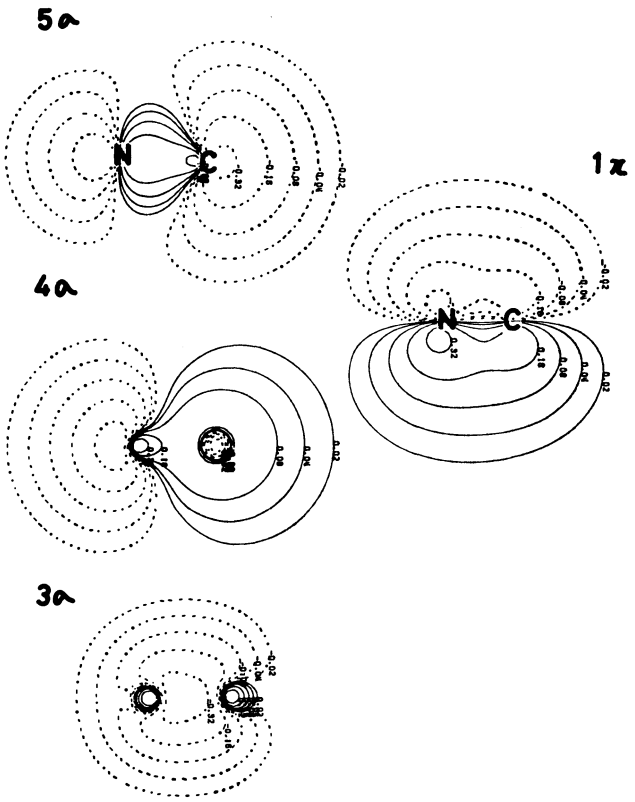

Fig. 1. The wave-function contours for valence shell MO's of the free CN^- ion. The first solid and dotted contours show ± 0.02, respectively, and neighboring contours differ by a factor of two.

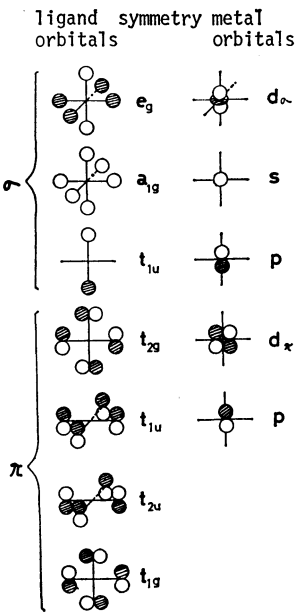

Fig. 2. Octahedral symmetry-adapted combinations of ligand orbitals (left), and the metal-atom orbitals with which they may interact (right). Only one orbital or orbital combination is shown from each degenerate set.

TABLE 1. THE ORBITAL MIXING RULE[27,28]

Case	Energy level	Perturbed |a'> orbital
(a)	$\varepsilon_b > \varepsilon_a$, $\varepsilon_c > \varepsilon_a$	$\|a> + \|b> + \|c>$
(b)	$\varepsilon_b < \varepsilon_a$, $\varepsilon_c > \varepsilon_a$	$\|a> - \|b> + \|c>$
(c)	$\varepsilon_b > \varepsilon_a$, $\varepsilon_c < \varepsilon_a$	$\|a> - \|b> - \|c>$

hybrid lone-pair orbital, slightly mixed with the nitrogen p orbital. These MO features explain why the cyanide ion is coordinated to the metal ion not at the nitrogen end, but at the carbon end. The 5σ MO, HOMO of the free CN^- ion, is primarily of the carbon lone-pair, and thus the theory predicts that the coordination of the cyanide ion to the cobalt ion will occur at the carbon end.

The symmetry-allowed interaction between $(CN^-)_6$ and Co^{3+} orbitals in $[Co(CN)_6]^{3-}$ is shown in Fig. 2. Selected wave-function contours for $[Co(CN)_6]^{3-}$ are shown in Fig. 3. In the formation of $[Co(CN)_6]^{3-}$, the σ-type metal 4s (a_{1g}), $3d\sigma$ (e_g), and $4p\sigma$ (t_{1u}) orbitals interact with the CN^- 4σ and 5σ orbitals, while the π-type metal $3d\pi$ (t_{2g}) and $4p\pi$ (t_{1u}) orbitals interact with the CN^- 1π and 2π orbitals. According to the orbital-mixing rule presented by Inagaki *et al.*,[27,28] the interaction of the |a> and |b> orbitals of one system with the |c> orbital of another system will result in a perturbed |a'> orbital consisting of the three orbitals with the signs given in Table 1.

This orbital-mixing rule will now be applied to the interactions between the $Co\sigma$ and the CN^- 4σ and 5σ orbitals and between the $Co\pi$ and the CN^- 1π and 2π orbitals. The σ interaction system will be considered first. The order of orbital energies in the σ system is $4\sigma < 5\sigma < Co\sigma$. The new orbital of the lowest energy resulting from the interaction of $Co\sigma$ with 4σ and 5σ is of the $4\sigma + 5\sigma + Co\sigma$ type (Case (a)), and the second lowest, of the $5\sigma - 4\sigma +$ $Co\sigma$ type (Case (b)). The $7a_{1g}$, $6t_{1u}$, and $4e_g$ MO's correspond to the MO's of the $4\sigma + 5\sigma + Co\sigma$ type. The amplitude of the carbon lone-pair increases through the in-phase mixing of 5σ into 4σ, while the amplitude decreases at the nitrogen atom. The ligand parts of $6t_{1u}$ and $4e_g$ are very similar to CN^- 4σ because of the small mixing of CN^- 5σ. In the $7a_{1g}$, however, CN^- 4σ is appreciably modified by CN^- 5σ. The $8a_{1g}$, $5e_g$ and $7t_{1u}$ MO's correspond to the $5\sigma - 4\sigma + Co\sigma$ type. This linear combination of 5σ and 4σ with the opposite sign means that the amplitudes are more or less compensated for at the carbon atom and intensified at the nitrogen atom. In the π interaction system, the energies of the orbitals of the t_{2g} symmetry are in the order: Co $d\pi$ < CN^- 1π < CN^- 2π. The 1π MO is bonding, and the 2π MO is antibonding, with respect to C–N. The $1t_{2g}$ MO consists mainly of Co $d\pi$. The $2t_{2g}$ MO of the $1\pi - 2\pi - d\pi$ type results from the 1π ligand orbital through mixing with Co $d\pi$ and 2π orbitals according to the orbital-mixing rule (Case (c) of Table 1). The $2t_{2g}$ MO in Fig. 3 has a node between the cobalt and carbon nuclei. This shows that the $2t_{2g}$ MO consists of a minus combination of $d\pi$ and the dominant CN^- 1π. According to the orbital-mixing rule, the combination of CN^- 2π with $d\pi$ in the $2t_{2g}$ MO is bonding; however, the extent of the mixing of CN^- 2π is small because of its high energy in com-

Fig. 3.

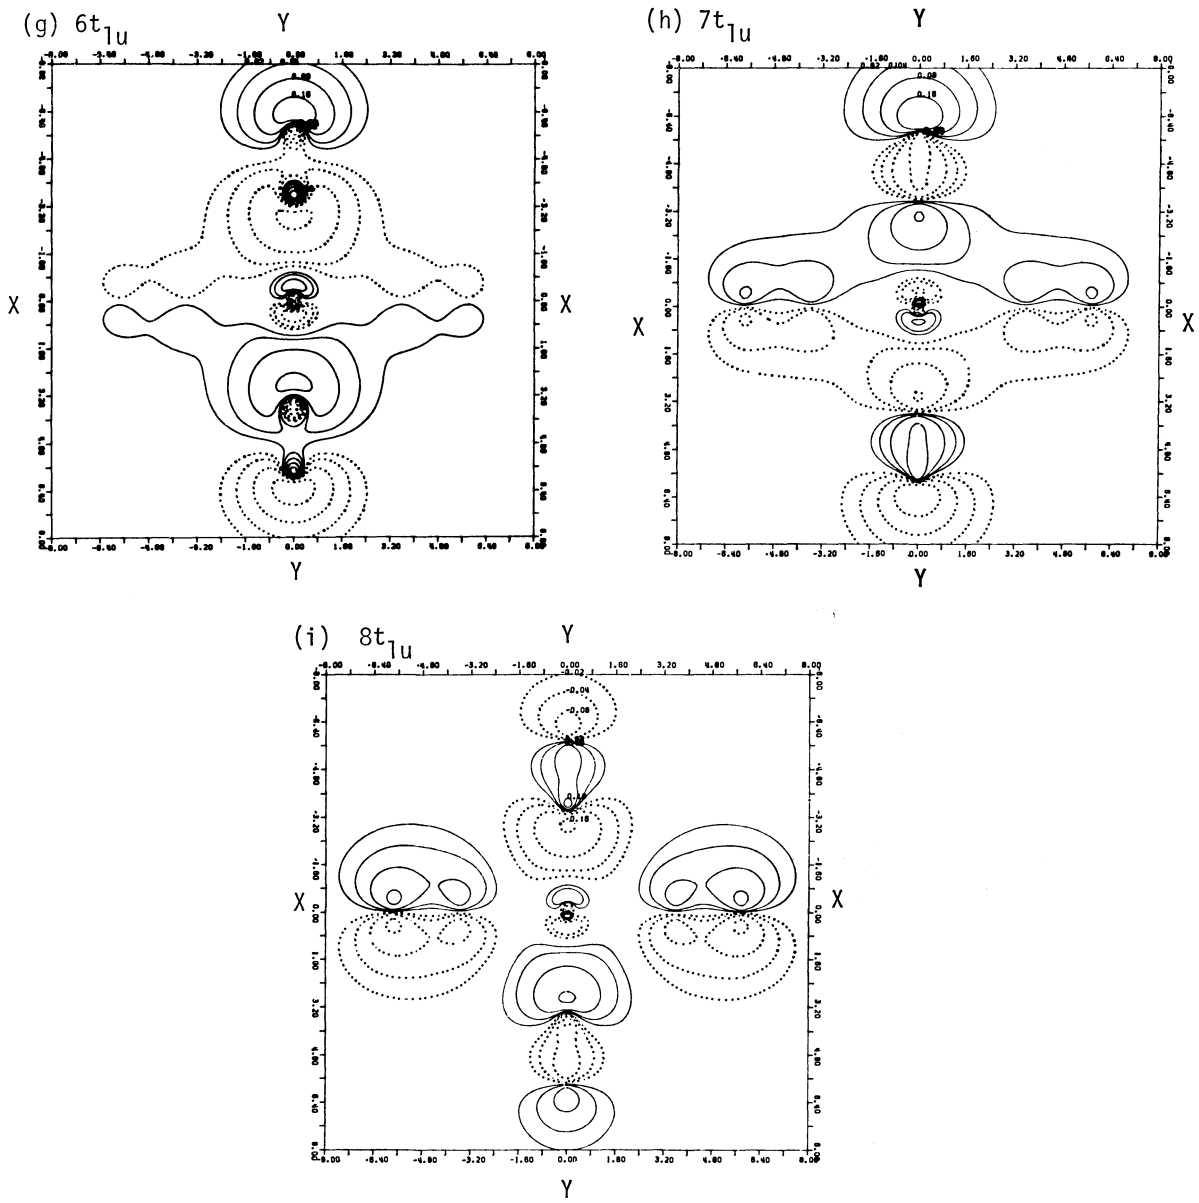

Fig. 3. Selected wave-function contours for valence shell MO's of $[Co(CN)_6]^{3-}$ on the plane containing Co and four CN^-. Each set of contours is drawn in a frame of 16 a.u.×16 a.u. (1 a.u.=0.529 Å= 52.9 pm). The Co atom is located at the center of the frame, and four C and four N atoms at the distances of 3.58 and 5.77 a.u. from the center, respectively. The first solid and dotted contours show ±0.02, respectively, and neighboring contours differ by a factor of two.

parison with CN^- 1π. This interaction scheme of cobalt cyanide is different from that of $d\pi$-π^* assumed by Alexander and Gray.[2] A small contribution of π back-donation still exist in $[Co(CN)_6]^{3-}$.

Figure 4 shows the map of the electron-density difference between $[Co(CN)_6]^{3-}$ and $Co^{3+}(d\pi^6)$ plus six free CN^- ions. The electron density for Co^{3+} was calculated like that of the t_{2g}^6 electron configuration in octahedral symmetry. The C–N bond length for the free CN^- was assumed to be the same as that in the complex. The CN^- ions were placed along three axes (x, y, z, −x, −y, −z) with the same geometry as in $[Co(CN)_6]^{3-}$. The solid and broken lines denote, respectively, an increase and a decrease in the electron density upon complexation. As can be seen from the increased electron density around the cobalt atom and the decreased density around the ligands, the electron flows from the ligands into cobalt. The positive region corresponding to the cobalt σ orbitals represents an increased electron density attributable to σ donation from the ligands. The decreased electron density in the $d\pi$ orbital indicates π back-donation. The increase in the cobalt charge accompanied by σ donation is larger than the decrease accompanied by π back-donation; thus, the positive charge of the cobalt atom is decreased. The orbital populations ($3d\sigma$, 1.040; 4s, 0.242; 4p, 0.667; and $3d\pi$, 5.885) obtained from the Mulliken population analysis of the semi-double-zeta basis set are consistent with the map. The electron density in the cyanide ligand decreases in the vicinity of the carbon nucleus, increases in the outer region of the carbon atom, and

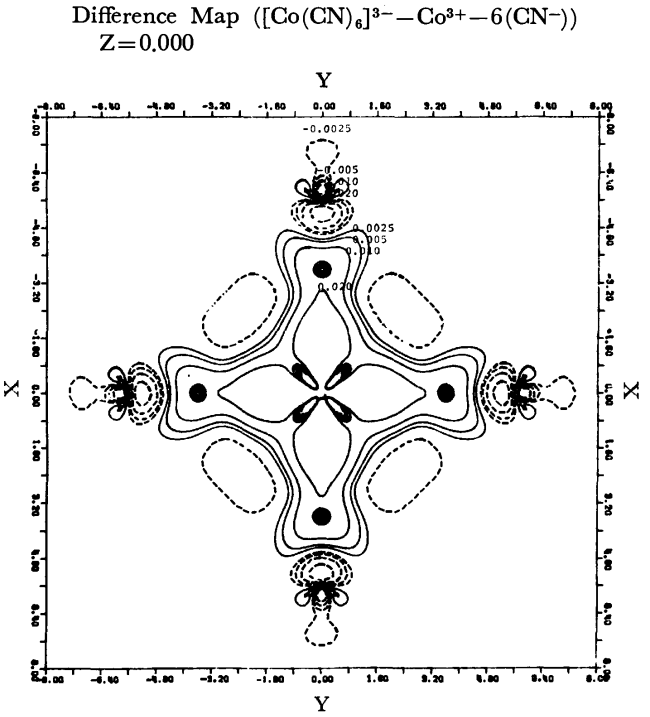

Fig. 4. The electron density difference between $[Co(CN)_6]^{3-}$ and Co^{3+} (with $d\pi^6$ configuration) plus six free CN^- ions. The first solid and dotted contours show ± 0.0025 e(a.u.)$^{-3}$, respectively, and neighboring contours differ by a factor of two.

decreases around the nitrogen nucleus. This shows that the cyanide ion is polarized by the positive charge of cobalt and that, in the carbon atom, the 2s population is decreased and the 2p population is increased. In effect, the nitrogen atom donates an electron density to the cobalt atom through the carbon atom; only slight π back-donation takes place from cobalt to nitrogen.

Comparison with X-Ray Results. In this section, the results of our calculation will be compared with those of the precise X-ray crystallographic study performed by Iwata and Saito,[13] who obtained 26.8 ± 0.3 e as the positive charge on the cobalt atom by directly integrating the electron density of the cobalt atom. They also showed the asphericity of the distribution of Co 3d electrons by difference Fourier synthesis.

The results of the present calculation are shown in Fig. 5, in which the radial distribution of the electron density around the central cobalt nucleus and the integrated number of electrons are plotted against the radius of the sphere, r. It is shown that the calculated radial electron density has a minimum value at 0.95 Å from the cobalt nucleus and that the number of electrons contained in a sphere of the 0.95 Å radius is 24.7. Both of these values are considerably lower than the corresponding experimental values of 1.22 Å and 26.8 ± 0.3. However, the integration of the electron density up to 1.22 Å gives 26.7 electrons, in good agreement with the experimental results. A fine structure which has not been reported by Iwata and Saito is observed: a minimum at 0.3 Å and a

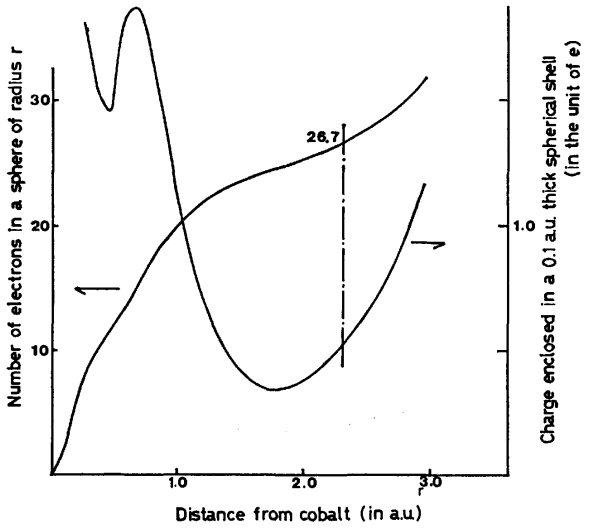

Fig. 5. The radial distribution and integrated number of electrons around the central cobalt atom.

maximum at 0.4 Å from the cobalt nucleus. Thermal vibrations in the experimental system may blur the fine structure and make the effective radii of orbitals greater than those for the frozen system assumed in the calculation.

Orbital Energies and Ionization Potentials. The sequence of orbital energies for the $[Co(CN)_6]^{3-}$ ion has already been reported.[23] The important finding was that the ordering:

$$\sigma(CN^-) < 3d\pi < \sigma(CN^-) < \pi(CN^-)$$

is different from that:

$$\sigma(CN^-) < \pi(CN^-) < 3d\pi$$

which has usually been assumed.

According to Koopmans' theorem,[29] the ionization potential (I.P.) associated with the removal of one electron from a given orbital of a closed-shell system is equal to the corresponding orbital energy with the sign inverted. Veillard and Demuynck[30] reported that Koopmans' theorem is not always valid and that it is not possible to rely on Koopmans' theorem to establish the spectral sequence. The most consistent way to compute ionization potentials is to calculate and compare two total energies at the same level of approximation for the molecule with N electrons and the ion with $N-1$ electrons. This is called the ΔSCF method. The ΔSCF calculation has been carried out in the following way. The energies of the electronic state with a hole in a given orbital and of the ground state are independently calculated in the SCF procedure; then the difference between them gives the ionization potential. The calculation has been carried out for the electronic states resulting from the removal of an electron from the orbitals, $8a_{1g}$, $5e_g$, $1t_{1g}$, $1t_{2g}$, $8t_{1u}$, and $1t_{2u}$. The geometry in these electronic states has been kept the same as that of the N-electron state; hence, the computed ionization energies may be compared with the vertical I.P.

The ΔSCF results are given in Table 2, together with the orbital energies in the ground state, $^1A_{1g}$.

TABLE 2. COMPUTED IONIZATION ENERGIES OF $[Co(CN)_6]^{3-}$

Species	Orbital from which an electron is removed	State	Energy[a]	Computed I.P.[b]	Koopmans' I. P.
$[Co(CN)_6]^{3-}$		$^1A_{1g}$	−1934.402		
$[Co(CN)_6]^{2-}$	$8t_{1u}$	$^2T_{1u}$	−1934.379	0.023	0.029
	$1t_{1g}$	$^2T_{1g}$	−1934.378	0.024	0.035
	$1t_{2u}$	$^2T_{2u}$	−1934.361	0.041	0.052
	$5e_g$	^2E_g	−1934.336	0.066	0.103
	$8a_{1g}$	$^2A_{1g}$	−1934.280	0.122	0.133
	$1t_{2g}$	$^2T_{2g}$	−1934.472	−0.070	0.250

a) Values in a.u. b) I.P. computed as the difference in the energy values for the ionized and ground states. (For the negative value, see the text and Ref. 31.)

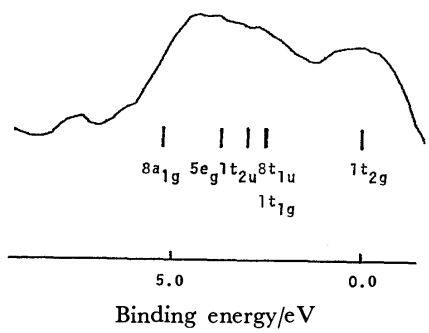

Fig. 6. Valence shell XPS and ΔSCF orbital energies.

The ΔSCF orbital energies decreased in the order:

$$3d\pi(1t_{2g}) > \pi(CN^-) > \sigma(CN^-)$$

which is similar to those in previous reports.[2,14] The computed I.P. corresponding to the removal of one electron from the $1t_{2g}(d\pi)$ orbital is negative; that is, the $[Co(CN)_6]^{2-}$ ion in its $^2T_{2g}$ state is shown to be more stable than the $[Co(CN)_6]^{3-}$ ion in its ground state, $^1A_{1g}$. However, $[Co(CN)_6]^{3-}$ is stable in actual systems, since the trinegative ion is stabilized to a greater extent than the dinegative ions by the electrostatic interaction with surrounding cations.[31] The experimental and calculated ionization potentials are compared in Fig. 6, in which the energy of the $d\pi$ orbital is taken as the reference in the comparison of the calculated I.P. with the X-ray photoelectron spectrum. The computed values show a good correspondence with the spectrum. This may support a previously proposed assignment for the valence-level peaks of XPS.[6,7] Koopmans' theorem may be valid when the electronic relaxation upon ionization and the change in correlation energy between the initial and the ionized states are sufficiently small to be ignored. The following discussion will attempt to clarify the importance of the electronic relaxation upon the ionization of a d-orbital electron. Figure 7 shows a map of the electron-density difference between the $8a_{1g}$ (located dominantly in the ligands) hole state and the $^1A_{1g}$ ground state, while Fig. 8 is a similar difference map for the $1t_{2g}$ (dominantly metal $d\pi$) hole state and the ground state. In these maps, the solid and broken lines denote, respectively, decreased and increased electron density upon ionization. The density map of $8a_{1g}$ MO is shown in Fig. 9; it resembles the difference map for the $8a_{1g}$ hole state (Fig. 7).

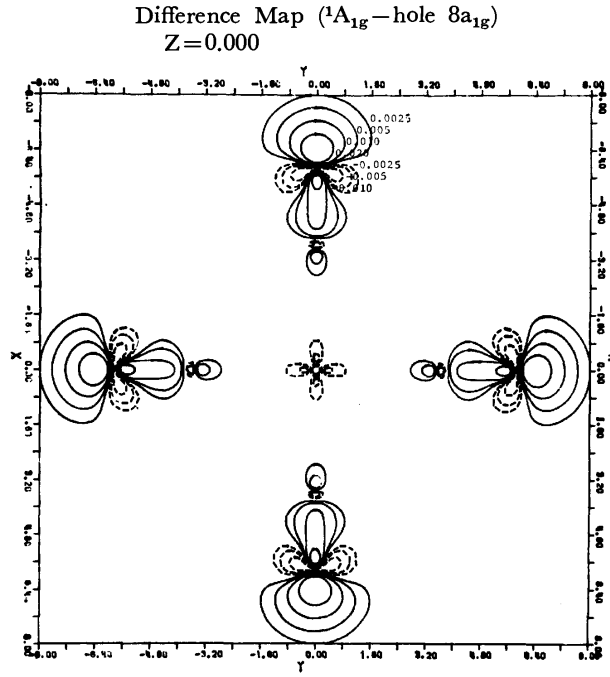

Fig. 7. The electron density difference between the $^1A_{1g}$ ground state and the $8a_{1g}$ hole state. The first contours show ± 0.0025 e(a.u.)$^{-3}$, neighboring contours differing by a factor of two. The positive and negative values represented by the solid and dotted curves correspond to decrease and increase in electron density upon the ionization, respectively.

This means that ionization from the $8a_{1g}$ orbital is accompanied by only a slight relaxation. Thus, Koopmans' theorem is valid for $8a_{1g}$ MO, which is essentially a ligand orbital. The map of the $1t_{2g}$ MO function (Fig. 3-e) is significantly different from the map of the difference between $^1A_{1g}$ and $^2T_{2g}$ states (Fig. 8). The latter shows that a decrease in $3d\pi$ electron density is accompanied by an increase in the $3d\sigma$ density, indicating an extensive relaxation upon ionization. The situation is more clearly demonstrated by Table 3, which shows the orbital population differences between the ground and ionized states on the semi-double-zeta basis set. The positive value shows an increase, and the negative value, a decrease, in the electron population caused by ionization. The Mulliken orbital populations for $8a_{1g}$ and $1t_{2g}$ are also given for the sake of comparison. It should be

TABLE 3. CHANGE IN ORBITAL POPULATION UPON IONIZATION

noted that the Co atomic charge is scarcely changed by $8a_{1g}$ ionization or even by the ionization of the $1t_{2g}$ electron, which is dominantly the Co 3dπ electron. The $1t_{2g}$ ionization in effect removes an electron from the nitrogen atoms, not from the cobalt atom. This orbital relaxation explains why the low-lying $1t_{2g}$ electron is most easily ionized and why Koopmans' theorem becomes invalid.

The Excited States of the d-d Transition. In this section we will present some results relative to the excited states resulting from d-d transitions. As found in many other studies of transition metal complexes,[30,32] the excitation energy is not merely the difference between the energies of the occupied and virtual orbitals in the ground state. A rigorous way to calculate the transition energy is to achieve separately energy minimization for the ground and excited states and to equate the difference in their energies with the transition energy, E_{ij}:

$$E_{ij} = E_j - E_i,$$

where the subscripts i and j refer to the ground and excited states respectively. Restricted Hartree-Fock-type calculations have been performed on the two lowest triplet and the two lowest singlet excited states derived from d-d transitions, as is shown in Table 4. All the calculations were performed on the full octahedral space group. The ordering of the excited levels is in good agreement with that predicted by ligand-field theory with empirical parameters.[33] However,

TABLE 4. TOTAL ENERGIES AND RELATIVE ENERGIES OF VARIOUS *d*-STATES

State	Configration	Total energy/a.u.	Relative energy/eV
$^1A_{1g}$	t_{2g}^6	−1934.4016	0.0
$^3T_{1g}$	$t_{2g}^5e_g^1$	−1934.3325	1.88
$^3T_{2g}$	$t_{2g}^5e_g^1$	−1934.2928	2.96
$^1T_{1g}$	$t_{2g}^5e_g^1$	−1934.2745	3.46 (3.97)[a]
$^1T_{2g}$	$t_{2g}^5e_g^1$	−1934.2478	4.19 (4.77)[a]

a) In the parentheses the experimental values are shown.

the energies calculated for the $^1T_{1g}$ and $^1T_{2g}$ states are smaller than the spectroscopic data[2] by about 0.5 eV. Although the Hartree-Foock calculations without configuration interactions gave a qualitative correspondence with the spectrum, a more elaborate treatment is necessary for a quantitative agreement.

Conclusions

The electronic structure of the $[Co(CN)_6]^{3-}$ ion has been investigated by the LCAO MO SCF method, using a double-zeta basis set of Gaussian orbitals. The following results were obtained;

(1) The interaction of cobalt and cyanide ions can be satisfactorily explained in terms of the orbital-mixing rule.

(2) The σ donation from cyanide to cobalt is the dominant interaction, while the π back-donation is weak in $[Co(CN)_6]^{3-}$.

(3) Koopmans' theorem holds approximately for the ligand orbitals, but not for the metal 3d orbitals.

(4) An extensive electronic relaxation occurs during the ionization from a metal d orbital.

(5) The calculated value for the number of electrons around the cobalt atom is in good agreement with the experimental values.

(6) The d-d transition energies obtained by the Hartree-Fock calculation show a qualitative correspondence with the spectrum.

The work was partly supported by the Joint Studies Program (1979—1980) of the Institute for Molecular Science. The computations reported in this paper have been carried out on FACOM 230-75 computers of the Nagoya University Computation Center and the Hokkaido University Computing Center, while the calculation of the electron-density map has been carried out on the HITAC M-180 computer of the Institute for Molecular Science.

The CD Spectra of Carbonato Complexes of the $[Co(CO_3)(O,O)(N)_2]^-$ and $[Co(CO_3)(N)_4]^+$ Types and Related Diaqua Complexes[1)]

Kenshi Tsuji, Shuhei Fujinami, and Muraji Shibata*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received August 16, 1980)

Five carbonato complexes, $[Co(CO_3)(ox)(tn)]^-$, *cis*-$[Co(CO_3)(ox)(py)_2]^-$, *cis*·*cis*-$[Co(CO_3)(NH_3)_2(py)_2]^+$, *cis*-$[Co(CO_3)(en)(py)_2]^+$, *cis*-$[Co(CO_3)(NH_3)_2(bpy)]^+$, and two related complexes, *cis*-$[Co(ox)(NH_3)_2(en)]^+$ and *cis*-$[Co(mal)(NH_3)_2(en)]^+$, have been prepared and resolved. The solution CD spectra of these resolved complexes and those of diaqua complexes derived from the carbonato complexes have been measured. The CD spectral comparison in the first absorption band (T_{1g}-band) region has suggested a relation in the sign of the Cotton peak between each of the carbonato complexes and the corresponding diaqua complex. Based on this relation, the assignments of the absolute configurations for the present complexes have been established.

It is known[2,3)] that the CD spectra of $(-)_{589}[Co(CO_3)(ox)(en)]^-$ and $(+)_{546}[Co(CO_3)(en)_2]^+$ exhibit a (+) Cotton peak in the first absorption band (T_{1g}-band) region, while the spectra for $(+)_{589}[Co(ox)(en)(H_2O)_2]^+$ and $(+)_{546}[Co(en)_2(H_2O)_2]^{3+}$, which are derived from the above carbonato complexes by acid-hydrolysis, show two peaks, (−) and (+), in the T_{1g}-band region. The absolute configurations of these carbonato complexes have been assigned to *Λ* based on a suggestion[2,3)] that the observed (+) peak is due to the $A_{1g}\rightarrow E_g$ (D_{4h}) transition component, while the absolute configurations of the corresponding diaqua complexes are also assigned to *Λ* based on the fact that acid-hydrolysis proceeds with retention of configuration. However, the (−) peak for $(+)_{589}[Co(ox)(en)(H_2O)_2]^+$ with CoN_2O_4 chromophore and the (+) peak for $(+)_{546}[Co(en)_2(H_2O)_2]^{3+}$ with CoN_4O_2 chromophore seem to be assignable to the $A_{1g}\rightarrow E_g$ transition component, when the ligand-field strengths of N and O are considered. In comparison of the CD signs due to the $A_{1g}\rightarrow E_g$ transition component, the sign of the $(-)_{589}$ carbonato complex is opposite to that of the $(+)_{589}$ diaqua complex, while the sign of the $(+)_{546}$ carbonato complex is the same as that of the $(+)_{546}$ diaqua complex. These different results come from the above-mentioned assignments of Cotton peaks, suggesting that the assignments are inconsistent.

In this work, the preparation and resolution of some new complexes of the $[Co(CO_3)(O,O)(N)_2]^-$ and $[Co(CO_3)(N)_4]^+$ types have been carried out. Optically active diaqua complexes have been also derived from the resolved carbonato complexes by acid-hydrolysis. In addition, this work has been extended to derive optically active oxalato complexes from the resolved carbonato complexes by a substitution reaction. The CD spectra of these active complexes have been measured and compared.

Experimental

Synthesis and Resolution. *a)* cis-*Diamminecarbonatoethylenediaminecobalt(III) Chloride Monohydrate*, cis-$[Co(CO_3)(NH_3)_2(en)]Cl\cdot H_2O$: This complex had been prepared by Bailar and Peppard,[4)] but we found another convenient method: to a solution of *cis*-$K[Co(CO_3)_2(en)]\cdot H_2O$ (35 g, 0.1 mol, in 150 cm³ H_2O) were added concd aqueous ammonia (14 cm³, 0.2 mol) and ammonium chloride (5.35 g, 0.1 mol); the mixture was then stirred at 50 °C until a red solution was obtained. The resulting solution, once filtered, was charged on a column containing Dowex 50W-X8 resin in Na^+ form (100—200 mesh, 7×8 cm). When the elution was carried out with a 0.15 M (1 M=1 mol/dm³) NaCl aqueous solution, one red band descended. The effluent was concentrated to a small volume under reduced pressure; after being filtered once, the filtrate was kept in a refrigerator overnight. The deposited crystals were recrystallized from warm water. The yield was about 10 g. Found: C, 13.34; H, 6.12; N, 20.71%. Calcd for $[Co(CO_3)(NH_3)_2(C_2H_8N_2)]Cl\cdot H_2O$: C, 13.52; H, 6.00; N, 21.02%.

Though Hawkins *et al.* had resolved this complex using $[Co(SO_3)_2(NH_3)_2(R\text{-pn})]^-$ as the resolving agent,[5)] we resolved it with $(-)_{546}[Co(ox)_2(en)]^-$: the racemate (2 g, 0.008 mol) was dissolved in warm water (5 cm³, *ca.* 35 °C), and $(-)_{546}Na[Co(ox)_2(en)]$ (1.3 g, 0.004 mol) was added to the solution. On cooling the whole solution in an ice-bath, a less soluble diastereoisomer containing the $(+)_{589}$ carbonato complex deposited. Recrystallization from water was repeated three times. The final yield was about 0.5 g. Found: C, 19.02; H, 4.86; N, 14.13%. Calcd for $[Co(CO_3)(NH_3)_2(C_2H_8N_2)][Co(C_2O_4)_2(C_2H_8N_2)]\cdot 2.5H_2O$: C, 18.92; H, 5.08; N, 14.72%.

b) cis-*Diammine(2,2′-bipyridine)carbonatocobalt(III) Chloride Dihydrate*, cis-$[Co(CO_3)(NH_3)_2(bpy)]Cl\cdot 2H_2O$: A solution of 2,2′-bipyridine (7.8 g, 0.05 mol) in 20 cm³ CH_3OH was mixed with a solution of *cis*-$K[Co(CO_3)_2(NH_3)_2]\cdot H_2O$ (12.5 g, 0.05 mol) in 20 cm³ H_2O, and perchloric acid (30%) was then added dropwise to the mixture until the pH reached 5.5, with stirring in an ice-bath. After filtering off potassium perchlorate which precipitated, the filtrate was stirred at room temperature overnight. The resulting solution, filtered once, was poured into a column containing Dowex 50W-X8 in Na^+ form (100—200 mesh, 5×20 cm). Upon elution with a 0.2 M NaCl solution, only one red band descended. The eluate was concentrated to a small volume (*ca.* 20 cm³). After removal of the sodium chloride by filtration, the filtrate was kept in a refrigerator to precipitate powdery crystals. The crystals were recrystallized from a minimum amount of warm water (*ca.* 30 °C). The yield was about 1.5 g. Found: C, 37.39; H, 4.08; N, 15.35%. Calcd for $[Co(CO_3)(NH_3)_2(C_{10}H_8N_2)]Cl\cdot 2H_2O$: C, 37.36; H, 4.24; N, 15.84%.

The $(+)_{546}Na[Co(edta)]$ complex (1.2 g, 0.0029 mol) was dissolved in a warm solution of the above racemate (2 g, 0.0058 mol, in 10 cm³ H_2O). When the mixture was cooled in an ice-bath and the sides of the vessel were scratched with a glass rod, one diastereoisomeric salt of the $(+)_{589}$ carbonato complex precipitated. The recrystallization was repeated four times from water. The final yield was about

0.5 g. Found: C, 36.64; H, 4.16; N, 11.68%. Calcd for $[Co(CO_3)(NH_3)_2(C_{10}H_8N_2)][Co(C_{10}H_{12}N_2O_8)]\cdot 2H_2O$: C, 36.41; H, 4.33; N, 12.14%.

c) cis·cis-*Diamminecarbonatobis(pyridine)cobalt(III) Chloride Monohydrate*, cis·cis-$[Co(CO_3)(NH_3)_2(py)_2]Cl\cdot 2H_2O$: An appropriate amount of 60% $HClO_4$ was added dropwise to a mixture of $K[Co(CO_3)_2(NH_3)_2]\cdot H_2O$ (10 g, 0.036 mol, in 20 cm³ H_2O) and pyridine (6 cm³, 0.072 mol) in an ice-bath in order to adjust the pH to 5.5. After filtration, the filtrate was stirred at room temperature for some time. Some pink crystals deposited. A solution of the crude product was poured into a column of Dowex 50W-X8 resin in Na^+ form. The effluent obtained by elution with a 0.3 M NaCl was concentrated to a small volume (*ca.* 10 cm³). When the solution was kept in a refrigerator, red crystals deposited. These were recrystallized from warm water (*ca.* 35 °C). The yield was about 1.0 g. Found: C, 36.07; H, 4.93; N, 15.55%. Calcd for $[Co(CO_3)(C_5H_5N)_2(NH_3)_2]\text{-}Cl\cdot H_2O$: C, 36.23; H, 4.98; N, 15.36%.

Into a solution of this racemate (3.3 g, 0.009 mol, in 10 cm³ H_2O) was poured a resolving agent, $(-)_{546}Na[Co(ox)_2\text{-}(en)]\cdot H_2O$ (1.2 g, 0.0038 mol), with stirring. The less soluble diastereoisomer containing the $(-)_{589}$-isomer of the carbonato complex crystallized out when the solution was allowed to stand in an ice-bath. This was recrystallized from water. The final yield was about 0.3 g. Found: C, 31.37; H, 4.67; N, 12.82%. Calcd for $[Co(CO_3)(NH_3)_2\text{-}(C_5H_5N)_2][Co(C_2O_4)_2(C_2H_8N_2)]\cdot 2.5H_2O$: C, 31.35; H, 4.49; N, 12.90%.

d) cis-*Carbonatoethylenediaminebis(pyridine)cobalt(III) Chloride Monohydrate*, cis-$[Co(CO_3)(py)_2(en)]Cl\cdot H_2O$: This complex was prepared in the same way as described in c) except for the use of $K[Co(CO_3)_2(en)]\cdot H_2O$ (10 g, 0.034 mol, in 20 cm³ H_2O). The reacted solution, filtered once, was chromatographed on a column of Dowex 50W-X8 resin in Na^+ form (100—200 mesh, 5×25 cm) using 0.1 M NaCl as the eluting solution. Two bands colored pink and red descended. The eluate of the red band was collected in a fraction, and concentrated to a small volume (*ca.* 10 cm³). After filtration, the filtrate was kept in a refrigerator (*ca.* 4 h). The crude precipitates thus obtained were recrystallized from warm water. The yield was about 2 g. Found: C, 39.72; H, 5.02; N, 14.01%. Calcd for $[Co(CO_3)\text{-}(C_2H_8N_2)(C_5H_5N)_2]Cl\cdot H_2O$: C, 39.95; H, 5.12; N, 14.24%.

$(-)_{546}Na[Co(ox)_2(en)]\cdot H_2O$ (1.6 g, 0.005 mol) was dissolved in a hot solution of the racemate (3.9 g, 0.01 mol, in 10 cm³ H_2O), followed by addition of ethanol (*ca.* 2 cm³). The mixture was cooled in an ice-bath and the sides of the vessel were scratched with a glass rod, whereupon the diastereoisomeric salt of the $(-)_{589}$ carbonato complex deposited. The salt was collected and recrystallized four times from warm water (*ca.* 35 °C). The final yield was about 0.7 g. Found: C, 34.24; H, 4.40; N, 12.52%. Calcd for $[Co(CO_3)\text{-}(C_2H_8N_2)(C_5H_5N)_2][Co(C_2O_4)_2(C_2H_8N_2)]\cdot 2H_2O$: C, 34.16; H, 4.52; N, 12.57%.

e) *Sodium Carbonatooxalatotrimethylenediaminecobaltate(III)*, *Na[Co(CO₃)(ox)(tn)]*: Trimethylenediamine (7.4 g, 0.1 mol) and oxalic acid (12.6 g, 0.1 mol) were mixed with stirring in an ice-bath, and then ethanol was added until trimethylenediammonium oxalate deposited. This product (6.7 g, 0.05 mol) was added to a green solution of $[Co(CO_3)_3]^{3-}$ ($Co(NO_3)_2\cdot 6H_2O$ 15 g, 0.05 mol scale). The mixture was stirred at 45 °C until the color of the solution became blue-violet, and then the resulting solution was concentrated to a small volume under reduced pressure. After filtration, the filtrate was chromatographed using a column containing Dowex 1X-8 resin in Cl^- form (5× 20 cm) and 0.1 M NaCl as the eluent; one blue-violet band came out. The eluate was concentrated to a small volume under reduced pressure, and after being filtered once, was kept in a refrigerator (*ca.* 1 h). The crude product thus obtained was recrystallized from warm water. The yield was about 3 g. Found: C, 23.52; H, 3.20; N, 9.03%. Calcd for $Na[Co(CO_3)(C_2O_4)(C_3H_{10}N_2)]$: C, 23.68; H, 3.29; N, 9.21%.

A mixture of the racemate (2 g, 0.006 mol) and $(-)_{589}\text{-}[Co(ox)(en)_2](C_2H_3O_2)$ (0.9 g, 0.003 mol) in water (10 cm³) was cooled in an ice-bath. Immediately a less soluble diastereoisomeric salt of the $(-)_{589}$ carbonato complex deposited. The recrystallization was repeated five times from water. The final yield was about 0.4 g. Found: C, 24.10; H, 5.09; N, 13.40%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2][Co\text{-}(CO_3)(C_2O_4)(C_3H_{10}N_2)]\cdot 3H_2O$: C, 23.93; H, 5.32; N, 13.95%.

f) cis-*Bis(ethylenediamine)dinitrocobalt(III)* cis-*Carbonatooxalatobis(pyridine)cobaltate(III) Dihydrate*, cis-$[Co(NO_2)_2(en)_2]\text{-}$cis-$[Co(CO_3)(ox)(py)_2]\cdot 2H_2O$: To a concentrated solution of *cis*-$[Co(CO_3)(ox)(py)_2]^-$, which was prepared by the literature method[6] ($Co(NO_3)_2\cdot 6H_2O$, 15 g scale, 0.05 mol), was added *cis*-$[Co(NO_2)_2(en)_2](C_2H_3O_2)$ (8.25 g, 0.025 mol). The mixture was kept in a refrigerator until a less soluble salt deposited; this was then recrystallized from warm water. Found: C, 30.33; H, 4.34; N, 16.24%. Calcd for $[Co(NO_2)_2(C_2H_8N_2)_2][Co(CO_3)(C_2O_4)(C_5H_5N)_2]\cdot 2H_2O$: C, 30.36; H, 4.46; N, 16.67%.

The resolving agent $(-)_{589}[Co(NO_2)_2(en)_2]I$ (1 g, 0.0025 mol) was converted into the acetate with silver acetate (0.4 g, 0.0025 mol). The compound, $[Co(NO_2)_2(en)_2][Co(CO_3)\text{-}(ox)(py)_2]\cdot 2H_2O$ (3 g, 0.005 mol), was dissolved in water (30 cm³) and converted into sodium salt by passing the solution through a column of Dowex 50W-X8 resin in Na^+ form. After the column had been rinsed thoroughly with water, the whole effluent was concentrated to a small volume (*ca.* 10 cm³). The concentrate was added to the solution of the above resolving agent. When the mixed solution was kept in a refrigerator, the precipitates obtained soon were optically inactive, and subsequently the desired diastereoisomer containing the $(+)_{589}$ carbonato complex was obtained. The yield was about 0.05 g. Found: C, 30.33; H, 4.34; N, 16.24%. Calcd for $[Co(NO_2)_2(C_2H_8N_2)_2]\text{-}[Co(CO_3)(C_2O_4)(C_5H_5N)_2]\cdot 2H_2O$: C, 30.36; H, 4.46; N, 16.67%.

g) cis-*Diammineethylenediamineoxalatocobalt(III) Chloride Monohydrate*, cis-$[Co(ox)(NH_3)_2(en)]Cl\cdot H_2O$: The preparation of this complex from trans(NH_3)-$[Co(Cl)_2(NH_3)_2(en)]Cl$ has been reported.[4] In our work, *cis*-$[Co(CO_3)(NH_3)_2(en)]Cl\cdot H_2O$ was used as the starting material. To a mixture of *cis*-$[Co(CO_3)(NH_3)_2(en)]Cl\cdot H_2O$ (10 g, 0.04 mol) and $K_2C_2O_4\cdot H_2O$ (7 g, 0.04 mol) in water (20 cm³), was added a solution of $H_2C_2O_4\cdot 2H_2O$ (5 g, 0.04 mol, in 10 cm³ H_2O) dropwise in an ice-bath. The solution was further stirred at 40 °C for 3 h. After filtering the solution, the filtrate was charged on a column containing Dowex 50W-X8 resin Na^+ form (4×20 cm). By elution with a 0.1 M NaCl solution, one band descended. The effluent was concentrated to a small volume, and this concentrated solution was filtered and then kept in a refrigerator. The red crystals which deposited were recrystallized from warm water (*ca.* 35 °C). The yield was about 7 g. Found: C, 16.26; H, 5.48; N, 19.15%. Calcd for $[Co(C_2O_4)(NH_3)_2(C_2H_8N_2)]Cl\cdot H_2O$: C, 16.30; H, 5.43; N, 19.02%.

The $[Co(ox)(NH_3)_2(en)]Cl\cdot H_2O$ complex (2 g, 0.007 mol) was converted to the acetate with silver acetate (1.2 g, 0.007 mol). On adding $(-)_{546}Na[Co(ox)_2(en)]\cdot H_2O$ (1.12 g,

0.0035 mol) to a solution of the acetate in 20 cm^3 water, a less soluble diastereoisomer containing the $(+)_{589}$ isomer of the cation separated out. The salt was recrystallized five times from warm water (*ca.* 35 °C). The final yield was about 0.4 g. Found: C, 21.49; H, 4.39; N, 14.86%. Calcd for $[Co(C_2O_4)(NH_3)_2(C_2H_8N_2)][Co(C_2O_4)_2(C_2H_8N_2)]\cdot H_2O$: C, 21.66; H, 4.34; N, 15.16%.

h) cis-Diammineethylenediaminemalonatocobalt(III) Chloride 0.5-Hydrate, cis-$[Co(mal)(NH_3)_2(en)]Cl\cdot 0.5H_2O$: An aqueous solution of *cis*-$[Co(CO_3)(NH_3)_2(en)]Cl\cdot H_2O$ (10 g, 0.004 mol, in 20 cm^3 H_2O) was treated in the same way as described in g) except for the use of potassium malonate (7 g, 0.04 mol) and malonic acid (4 g, 0.04 mol). The yield was about 4 g. Found: C, 20.16; H, 5.75; N, 19.07%. Calcd for $[Co(C_3H_2O_4)(NH_3)_2(C_2H_8N_2)]Cl\cdot 0.5H_2O$: C, 20.04; H, 5.67; N, 18.70%.

This complex was resolved by column chromatography: a solution of the racemic chloride complex was charged on a column containing Dowex 50W-X8 resin in Na^+ form (2×40 cm). Elution with a 0.1 M $K_2[Sb_2(d\text{-tart})_2]$ aqueous solution resulted in a partial resolution. The specific rotation of the later effluent was positive at 589 nm.

Derivation from Optically Active Complex *a)* $(+)_{546}[Co(ox)(en)_2]^+$: The compound, $(+)_{546}[Co(CO_3)(en)_2](+)_{546}[Co(ox)_2(en)]$ was dissolved in water and converted into the chloride by passing the solution through a column (5×2 cm) of Dowex 1-X8 resin in Cl^- form. After being washed with water, the whole effluent was concentrated to a small volume. To the concentrated solution was added a solution of $H_2C_2O_4\cdot 2H_2O$ dropwise in an ice-bath, and then the solution was stirred at 40 °C for 3 h. The resulting solution was charged on a column of Dowex 50W-X8 resin in Na^+ form. The elution was carried out with a 0.1 M NaCl solution, whereby one band descended. The absorption and CD spectral data of this effluent were identical with those of $(+)_{546}[Co(ox)(en)_2]^+$.[3]

b) $(+)_{589}[Co(ox)(NH_3)_2(en)]^+$: This complex was prepared in the same way as described in a) except for the use of $(+)_{589}[Co(CO_3)(NH_3)_2(en)]^+$ instead of $(+)_{546}[Co(CO_3)(en)_2]Cl$. The effluent showed the same absorption and CD spectra as those of $(+)_{589}[Co(ox)(NH_3)_2(en)]^+$.

c) $(-)_{546}[Co(ox)_2(en)]^-$: A solution of $H_2C_2O_4\cdot 2H_2O$ was added to a solution of $(-)_{589}[Co(CO_3)(ox)(en)]^-$ little by little with stirring in an ice-bath. After the resulting solution was stirred at 50 °C for a while, the solution was chromatographed on a column of Dowex 1-X8 resin in Cl^- form using a 0.1 M NaCl solution. Only one band descended. The absorption and CD spectra of this effluent was identical to those of $(-)_{546}[Co(ox)_2(en)]^-$.

Measurement. The absorption spectra in aqueous solution were recorded with a Hitachi 323 recording spectrophotometer. In the case of the *cis*-$[Co(CO_3)(ox)(py)_2]^-$ complex, the spectrum was measured with a solution passed through a cation exchange resin in Na^+ form in order to remove the counter ion, $[Co(NO_2)_2(en)_2]^+$. For the CD spectral measurements, a JASCO J-40CS automatic recording spectropolarimeter with a JASCO Model J-DPZ data processor was used; a JASCO Model DIP-SL automatic polarimeter was used for optical rotation measurements. In both cases, samples were converted into the same cations and anions as those of the corresponding racemates by means of ion-exchange techniques.

The absorption and CD spectra of the diaqua complex species were measured with solutions of the carbonato complexes acidified with 10% $HClO_4$. The absorption and CD spectra of the acidified solutions were reformed into the spectra of the parent carbonato complexes when potassium hydrogencarbonate was added to the acidified solutions. This result suggests that the acid hydrolyses proceed with retention of the configurations.

Results and Discussion

CD Spectra. The absorption spectra of the new complexes are shown in Figs. 1 and 2. The CD spectra for the complexes of the types $[Co(O,O)_2(N)_2]^-$, $[Co(O,O)(N)_4]^+$, $[Co(O,O)(N)_2(H_2O)_2]^+$, and $[Co(N)_4(H_2O)_2]^{3+}$ ($O,O=CO_3^{2-}$, ox^{2-}, and mal^{2-}; $(N)_2=2NH_3$, 2py, en, tn, and bpy) are shown in Figs. 3—7, while the numerical data are summarized in Tables 1 and 2. We are interested in the comparison of the CD spectra in the T_{1g}-band region; hereafter, only the spectra observed in the region are discussed.

The CD spectra of $(+)_{546}[Co(CO_3)(en)_2]^+$, $(+)_{589}$-

the above carbonato complexes show (−) and (+) peaks from the lower frequncy side. The CD spectrum of $(-)_{589}[Co(CO_3)(NH_3)_2(py)_2]^+$ shows (−) and (+) peaks from the lower frequency side and the (+) peak is dominant. The CD spectrum of $(+)_{589}[Co(CO_3)(en)(py)_2]^+$ shows one (+) peak. The CD spectra of the diaqua complexes, $(-)_{589}[Co(NH_3)_2(py)_2(H_2O)_2]^{3+}$ and $(-)_{589}[Co(en)(py)_2(H_2O)_2]^{3+}$, derived from the above bis(pyridine) complexes by the acid hydrolyses show (+) and (−) peaks from the lower frequency side. The CD spectra of the carbonato complexes suggest that the above five carbonato complexes have the same absolute configuration. On the other hand, the CD spectra of the diaqua complexes suggest that the absolute configurations of the first three carbonato complexes are opposite to those of the last two carbonato complexes, since the acid hydrolyses proceed with retention of the configurations. Thus, the relative configurations based on the CD spectra of the carbonato complexes don't agree with those based on the CD spectra of the corresponding diaqua complexes in the bis(pyridine) complexes.

The CD spectra of $(-)_{589}[Co(CO_3)(ox)(en)]^+$,

a) $\tilde{\nu}_{max}$ values in 10^3 cm^{-1}. b) Spectral data are in Ref. 3.

$(+)_{589}[Co(CO_3)(ox)(NH_3)_2]^-$,[2] $(+)_{589}[Co(CO_3)(ox)(tn)]^-$ and $(+)_{589}[Co(CO_3)(ox)(py)_2]^-$ have all one (+) peak, and those of the diaqua complexes derived from the above carbonato complexes have (−) and (+) peaks from the lower frequency side. The CD spectrum of $(-)_{589}[Co(CO_3)(mal)(NH_3)_2]^-$ [2] shows (+) and (−) peaks, in which the (+) peak at the lower frequency side is dominant. The CD spectrum of $(-)_{589}[Co(mal)(NH_3)_2(H_2O)_2]^+$ derived from the above malonato complex shows (−) and (+) peaks from the lower frequency side. The CD spectra of these carbonato complexes suggest that the above five carbonato complexes have the same absolute configuration. The CD spectra of the corresponding diaqua complexes also suggest that the above five carbonato complexes have the same absolute configuration.

Assignment of Transition Component. In order to understand the various CD patterns in the T_{1g}-band region for a series of the $[Co(O,O)_2(N)]^-$-type complexes, Muramoto *et al.* attempted to analyze the observed patterns into Gaussian curves.[2] In this analysis, the CD curve was resolved into two components of opposite sign. The results showed that every pattern was a curve which resulted from the mutual cancellation of a component at a lower frequency and a component at a higher frequency, and that the component at the lower frequency never changed its CD sign due to the mutual cancellation. With the $[Co(O,O)_2(N)_2]^-$-type complexes, since the $A_{1g}\rightarrow A_{2g}$ (D_{4h}) transition lies at a higher frequency than the $A_{1g}\rightarrow E_g$ transition, the CD peak at the lower

frequency is assigned to the component corresponding to the latter transition (*i.e.* E_g component). From this assignment, the dominant peak in the spectrum of a $[Co(CO_3)(O,O)(N)_2]^-$-type complex is assignable to the E_g component. Since the CD spectrum of a $[Co(O,O)(N)_2(H_2O)_2]^+$-type complex shows two Cotton peaks with opposite sign, the peak at a lower frequency is assignable to the E_g component. From these assignments, the Cotton peak of the $A_{1g}\rightarrow E_g$ transition component for a $[Co(CO_3)(O,O)(N)_2]^-$-type complex has the opposite sign to that for the corresponding diaqua complex.

The CD spectrum of $(-)_{589}[Co(CO_3)(NH_3)_2(py)_2]^+$ and that of $(-)_{589}[Co(NH_3)_2(py)_2(H_2O)_2]^{3+}$ show (−) and (+) peaks and (+) and (−) peaks, respectively. Since the $A_{1g}\rightarrow E_g$ transition lies at a higher frequency than the $A_{1g}\rightarrow A_{2g}$ one in the case of the $[Co(O)_2(N)_4]^+$-type complexes, the (−) peak of the former complex and the (+) peak of the latter complex are both assignable to the $A_{1g}\rightarrow A_{2g}$ transition component (*i.e.* A_{2g} component).

The CD spectra of $(+)_{589}[Co(mal)(NH_3)_2(en)]^+$ and $(+)_{589}[Co(mal)(en)_2]^+$ [7] show two peaks of the same sign. On the other hand, the CD spectrum of $(-)_{589}[Co(ox)_2(NH_3)_2]^-$ [2] shows also (+) and (+) peaks and the dominant peak lies at the lower frequency side in the T_{1g}-band region. In the Gaussian analysis, the CD spectrum of $(-)_{589}[Co(ox)_2(NH_3)_2]^-$ was resolved into a (+) component at a lower frequency and a (−) component at a higher frequency. Since the major peaks for the above malonato complexs with CoN_4O_2 chromophore lie at a lower frequency than the minor peaks, if the observed CD spectra are resultant curves from the mutual cancellation of two components, which have opposite signs and correspond to the $A_{1g}\rightarrow A_{2g}$ and $A_{1g}\rightarrow E_g$ transitions, the two CD peaks of both malonato complexes are residues of the peak corresponding to the A_{2g} component.

A comparison of the CD spectra of $(+)_{546}[Co(CO_3)(en)_2]^+$, $(+)_{546}[Co(ox)(en)_2]^+$,[7] and $(+)_{589}[Co(mal)(en)_2]^+$ shows that the intensities of their dominant Cotton peaks decrease in the order of the carbonato, oxalato, and malonato complexes. Since the (+) Cotton peak of $(+)_{589}[Co(mal)(en)_2]^+$ has been assigned to the A_{2g} component, this change can be explained by considering that the intensity of the E_g component, which has a negative sign, increases according to the change in the O,O ligands. Therefore, the dominant CD peak of $(+)_{546}[Co(CO_3)(en)_2]^+$ is also assigned to the A_{2g} component.

Since the CD spectra of $(+)_{589}[Co(CO_3)(NH_3)_2(en)]^+$, $(+)_{589}[Co(ox)(NH_3)_2(en)]^+$ and $(+)_{589}[Co(mal)(NH_3)_2(en)]^+$ have the same CD patterns as those of $(+)_{546}[Co(CO_3)(en)_2]^+$, $(+)_{546}[Co(ox)(en)_2]^+$ and $(+)_{589}[Co(mal)(en)_2]^+$, respectively, the dominant peaks of these diammine-type complexes can be assigned to the A_{2g} component. On the other hand, since the CD spectra of $(+)_{546}[Co(en)_2(H_2O)_2]^{3+}$ and $(+)_{589}[Co(NH_3)_2(en)(H_2O)_2]^{3+}$ show (−) and (+) peaks from the lower frequency side, the Cotton peak at the lower frequency side in the T_{1g}-band region for $(+)_{546}[Co(en)_2(H_2O)_2]^{3+}$ or $(+)_{589}[Co(NH_3)_2(en)(H_2O)_2]^{3+}$ is also assignable to the A_{2g} component.

From these discussions, it may be concluded that the dominant Cotton peaks for the $[Co(O,O)(N)_4]^+$-type complexes are not always assignable to the E_g component and that the sign of the Cotton peak corresponding to the $A_{1g}\rightarrow A_{2g}$ for a complex of the $[Co(CO_3)(N)_4]^+$-type is opposite to that for the $[Co(N)_4(H_2O)_2]^{3+}$ complex derived from the acid-hydrolysis of the carbonato complex.

Since the CD spectrum of $(+)_{589}[Co(CO_3)(en)(py)_2]^+$ shows one (+) peak in the T_{1g}-band region and that of the corresponding diaqua complex shows (+) and (−) peaks from the lower frequency side, the (+) peak for $(+)_{589}$ carbonato complex can be assigned to the E_g component from the above conclusion. On the other hand, since the CD spectrum of $(+)_{589}[Co(CO_3)(NH_3)_2(bpy)]^+$ shows one (+) peak and that of the corresponding diaqua complex shows (−) and (+) peaks form the lower frequency side, the (+) peak for the $(+)_{589}$ carbonato complex is assignable to the A_{2g} component.

These assignments are supported by comparison of extrema of the dominant Cotton peaks with the corresponding absorption maxima. As given in Table 2, the extrema of the dominant peaks for the $[Co(CO_3)(NH_3)_2(bpy)]^+$, $[Co(O,O)(en)_2]^+$ and $[Co(O,O)(NH_3)_2(en)]^+$ complexes shift to lower frequencies compared with the corresponding absorption maxima, and the extremum for the $[Co(CO_3)(en)(py)_2]^+$ complex to a higher frequency than its absorption maximum. In the case of the $[Co(O,O)(N)_4]^+$-type complexes, the mutual cancellation of the two components, which have opposite sign and correspond to the $A_{1g}\rightarrow A_{2g}$ and $A_{1g}\rightarrow E_g$ transitions, would tend to shift the observed extremum for the former component to lower energies than the absorption maximum. On this basis, the dominant peaks of the $[Co(CO_3)(NH_3)_2(bpy)]^+$, $[Co(O,O)(en)_2]^+$, and $[Co(O,O)(NH_3)_2(en)]^+$ complexes are assignable to the A_{2g} component, and the dominant peak of the $[Co(CO_3)(en)(py)_2]^+$ complex to the E_g component.

Absolute Configuration. The (+) peak of $(+)_{546}[Co(ox)(en)_2]^+$ is assignable to the A_{2g} component and the absolute configuration has been known as Λ.[8] Since the (+) peaks of $(+)_{546}[Co(CO_3)(en)_2]^+$, $(+)_{589}[Co(CO_3)(NH_3)_2(en)]^+$, $(+)_{589}[Co(CO_3)(NH_3)_2(bpy)]^+$, $(+)_{589}[Co(ox)(NH_3)_2(en)]^+$, $(+)_{589}[Co(mal)(en)_2]^+$ and $(+)_{589}[Co(mal)(NH_3)_2(en)]^+$ are assignable to the A_{2g} component, the absolute configurations of the above six complexes are assignable to Λ. The facts that $(+)_{546}[Co(ox)(en)_2]^+$ and $(+)_{589}[Co(ox)(NH_3)_2(en)]^+$ are derived from $(+)_{546}[Co(CO_3)(en)_2]^+$ and $(+)_{589}[Co(CO_3)(NH_3)_2(en)]^+$ support the above assignments. Since the (+) peaks of $(+)_{589}[Co(CO_3)(en)(py)_2]^+$ and $(-)_{589}[Co(CO_3)(NH_3)_2(py)_2]^+$ are assignable to the E_g component, the $(+)_{589}$ complex has a Δ configuration and the $(-)_{589}$ one a S configuration, which is equivalent to a Δ configuration for the bis(chelate) complex. There is a question about the assignment of the absolute configurations of these pyridine complexes, because the dominant peak for the pyridine complexes arises from the E_g component, and that for other

complexes, which contain no pyridine, from the A_{2g} component. Such a difference makes it possible that the relationship between the sign of the Cotton peak and the absolute configuration differs between a $[Co(N)_4(O)_2]$-type complex containing pyridine and that containing no pyridine ligand.

Of the $[Co(O,O)_2(N)_2]^-$-type complexes, $(-)_{546}[Co(ox)_2(en)]^-$ has been known to have a *Λ* configuration.[9] Since the (+) peak for this complex is assigned to the E_g component, the peak corresponding to the E_g component for this type of complex in *Λ* configuration may have (+) sign. The (+) peak of $(-)_{589}[Co(CO_3)(ox)(en)]^-$ is assigned to the E_g component. Therefore, the absolute configuration of this $(-)_{589}$ complex is assignable to *Λ*. The fact that $(-)_{546}[Co(ox)_2(en)]^-$ is derived from $(-)_{589}[Co(CO_3)(ox)(en)]^-$ supports the above assignment. In the same way, since the (+) peaks of $(+)_{589}[Co(CO_3)(ox)(tn)]^-$ and $(+)_{589}[Co(CO_3)(ox)(py)_2]^-$ are both assigned to the E_g component, the absolute configurations of these two complexes are also assignable to *Λ*.

Structural Study of Optical Resolution. IX. The Crystal Structure of $(-)_{589}$-Tris(biguanide)cobalt(III) Chloride *d*-Tartrate Pentahydrate

Toshiji TADA, Yoshihiko KUSHI, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730

(Received September 11, 1980)

The crystal structure of the less-soluble diastereomeric salt, $(-)_{589}$-[Co(Hbg)$_3$]Cl(*d*-tart)·5H$_2$O, has been determined by X-ray analysis (R=0.056, 1277 reflections). The crystals are orthorhombic, with the space group of C222, Z=4, a=24.846(5), b=12.970(2), and c=8.645(2) Å. The main features of the crystal structure are as follows: (1) The complex cation and Cl$^-$ anion are arranged alternately along the b-axis to form an infinite spiral chain. The distances between N(Hbg) and Cl are 3.452 and 3.376 Å. (2) The tartrate ions exist as a dimeric unit whose structure closely resembles that of [Sb$_2$(d-tart)$_2$]$^{2-}$. Through the center of this dimeric unit pass three mutually orthogonal twofold axes. (3) There are short contacts between the Hbg ligands and the tartrate ions along the twofold axis of the complex; N(A2)···OT3 2.862, N(B2)···OT2 3.116, N(B3)···OT2 2.754, and N(B4)···OT1 2.963 Å. On the basis of these features, the chiral discrimination mechanism is discussed.

In the previous papers of this series,[1-3] the crystal structures of the diastereomeric salts composed of *Λ*-[M(en)$_3$]$^{3+}$ and *d*-tartrate ions (*d*-C$_4$H$_4$O$_6^{2-}$, abbreviated as *d*-tart), $(+)_{589}$-[Co(en)$_3$]Br(*d*-tart)·5H$_2$O,[1] Li{$(+)_{589}$-[Cr(en)$_3$]}(*d*-tart)$_2$·3H$_2$O,[2] and H{$(+)_{589}$-[Co(en)$_3$]}(*d*-tart)$_2$·3H$_2$O,[3] were determined. In all these crystals there exists a unique face-to-face ion-pair between the complex and *d*-tart; four carbon atoms of *d*-tart make a plane which is perpendicular to the threefold axis of the complex, and four oxygen atoms of *d*-tart are projecting toward the complex and facing the triangular face formed by three NH$_2$ groups of the complex. From these observations, we assumed that such a one-to-one ion-pair formation plays a dominant role in the chiral discrimination.[3] Our presumption was strongly supported by chromatographic separation of enantiomers using the *d*-tart solution as the eluent. The complete separation of the enantiomers was accomplished not only for [Co(en)$_3$]$^{3+}$,[4] but also for many octahedral complexes with three NH$_2$ groups in their triangular face,[5,6] including electrically neutral fac-[Co(*β*-alaninato)$_3$].[7] Consistently with the chromatographic results, the ion-association constant of *d*-tart proved to be greater for the *Λ* complex than for the *Δ* complex.[8-12]

On the other hand, it was reported that tris(biguanide)cobalt(III), [Co(Hbg)$_3$]$^{3+}$ (C$_2$H$_7$N$_5$, abbr. Hbg) could be separated into enantiomers *via* a diastereomeric salt containing both chloride and *d*-tart anions.[13] Here, it is interesting to note that the less-soluble diastereomeric salt has the [Co(Hbg)$_3$]Cl(*d*-tart)·5H$_2$O composition, which is quite analogous to that of [Co(en)$_3$]Br(*d*-tart)·5H$_2$O. Moreover, in both cases, the *Λ* complex forms the less-soluble diastereomeric salt with *d*-tart. The crystal structure of the optically active chloride salt, $(+)_{589}$-[Co(Hbg)$_3$]Cl$_3$·H$_2$O, has been determined by Snow;[14] in it biguanide ligands form almost planar chelate rings. The N–H bonds in the Hbg ligand are presumed to be different in nature from those in the ethylenediamine ligand. Thus, the chiral discrimination by *d*-tart in the [Co(Hbg)$_3$]$^{3+}$ complex is expected to be different from that in the [Co(en)$_3$]$^{3+}$ complex. We also attempted to determine the crystal structure of the less-soluble diastereomeric salt, $(-)_{589}$-[Co(Hbg)$_3$]Cl(*d*-tart)·5H$_2$O, in order to obtain the mode of chiral discrimination effected by the *d*-tart.

Experimental

Preparation of Compound. Biguanide sulfate and [Co(Hbg)$_3$]Cl$_3$ were prepared by the method given in the literature.[15,16] The less-soluble diastereomeric salt, $(-)_{589}$-[Co(Hbg)$_3$]Cl(*d*-tart)·5H$_2$O, was prepared by the procedure of Ray and Dutt.[13] The crystals thus obtained are thin, brownish orange plates. The optical purity of the crystals was checked by the CD measurement ($\Delta\varepsilon_{510}=-3.52$ and $\Delta\varepsilon_{452}=+4.76$).[17] Found: C, 19.15; H, 4.94; N, 33.33%. Calcd for $(-)_{589}$-[Co(Hbg)$_3$]Cl(*d*-tart)·5H$_2$O (4H$_2$O): C, 18.89 (19.44); H, 5.55 (5.38); N, 33.04 (34.01)%.

Crystallographic-data Collection. The unit-cell dimensions and crystal symmetry were initially checked from Weissenberg photographs taken with Ni $K\alpha$ radiation (λ=1.6591 Å). The results indicated an orthorhombic mmm Laue Symmetry. The systematic absence of *hkl* reflections when $h+k=2n+1$ suggested the following possible space groups: C222, Cmm2 (Cm2m), and Cmmm. Since the sample is optically active, the space group C222 was chosen; the later success of the structure determination confirmed the wisdom of this selection.

The intensities and cell dimensions were measured on a Rigaku AFC-5 automated four-circle diffractometer with Mo $K\alpha_1$ radiation (λ=0.70926 Å) monochromated by a graphite plate. The crystal size used was 0.39×0.19×0.08 mm. The unit-cell dimensions were refined by a least-squares treatment of the setting of 22 reflections. The crystal data were as follows: orthorhombic, space group C222, a=24.846(5), b=12.970(2), c=8.645(2) Å, D_m=1.51 g cm^{-3} (by flotation in a chloroform–bromoform mixture), Z=4, and D_c=1.52 g cm^{-3}. The intensity data were collected in the ω-2θ scan mode up to 2θ=55° with the scan rate of 16°/min (50 kV, 170 mA). The ω scan range was $(1.0+0.45\tan\theta)$°. Of the 1443 unique observed reflections, 1277 reflections with $|F_o| \geq 3\sigma(F_o)$ were used for the structure determination. Corrections for the absorption effect were neglected (μ(Mo $K\alpha$)=7.83 cm^{-1}).

Determination and Refinement of Crystal Structure

Since the number of formula units per unit-cell is four and the space group is C222, the central cobalt

atom, one nitrogen atom of the $[Co(Hbg)_3]^{3+}$ cation, and the Cl^- anion should lie on a twofold axis. The position of the Co atom was determined from a three-dimensional Patterson map. Subsequent electron density maps calculated with the phase of the Co atom revealed the positions of the remaining non-hydrogen atoms. Several cycles of the block-diagonal least-squares refinement reduced the R value (defined as $\Sigma||F_o|-|F_c||/\Sigma|F_o|$) to 0.070. At this stage, all the hydrogen atoms were located from a difference Fourier map. The final refinement including these H atoms with isotropic temperature factors converged the R value to 0.056. The final difference map showed no peaks higher than 0.4 electron/Å^3, and the highest peak (*ca.* 0.4 electron/Å^3) remained around the OW2 water molecule.

In the refinement, the quantity minimized was $w(|F_o|-k|F_c|)^2$. The weighting scheme used was $w=(\sigma_{cs}^2+a|F_o|+b|F_o|^2)^{-1}$, where σ_{cs} is the standard deviation obtained from the counting statistics for each reflection; the values of a and b were 0.2 and 0.0009 respectively. All the atomic scattering factors, with corrections for the anomalous dispersion of Co and Cl, were taken from the International Tables for X-Ray Crystallography, Vol. IV.[18]

All the computations were carried out by a HITAC 8700 computer at the Hiroshima University Information Processing Center. The computer programs used were FOUR-MMM[19] and HBLS-IV, with a slight modification.[20] An ORTEP drawing was carried out by the use of a computer system, XTL, in a Syntex R3 automated four-circle diffractometer.[21] The final atomic parameters are listed in Table 1. The anisotropic thermal parameters and complete lists of the $|F_o|$ and $|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 8121).

Results and Discussion

The projections of the crystal structure along the c- and b-axes are shown in Figs. 1 and 2 respectively. The thermal ellipsoids in these figures are illustrated with a 50% probability. The crystallographic twofold axes of the space group C222 pass through the complex, *d*-tart, Cl^-, and three kinds of water molecules (OW1, OW2, and OW3).

Cation Geometry. The bond distances and angles for the complex cation are listed in Table 2. These values are in good agreement with those reported in previous works.[14,22] However, there is a small but siginificant difference in geometry between the present results and those for $(+)_{589}$-$[Co(Hbg)_3]Cl_3\cdot H_2O$.[14] In both crystals, the planarity of biguanide itself is nearly kept, but that of the chelate ring as a whole (including the metal atom) is lost. The dihedral angles between the plane of the biguanide ligand and the plane of Co and two donor nitrogen atoms are 6.9, 6.0, and 12.8° for the $(+)_{589}$-$[Co(Hbg)_3]Cl_3\cdot H_2O$. The mean value is 8.6°.

In contrast, in the present crystal, a crystallographic twofold axis passes through the chelate ring A along the direction Co···N(A3), and the dihedral angle is only 3.0°. The chelate ring A is approximately planar, as is shown in Table 3. On the other hand, the planarity of the chelate ring B is definitely broken (Table 3). The corresponding dihedral angle is 16.4°. This fairly large difference between their dihedral angles suggests that the *d*-tart interacts more strongly

Table 1. Positional and thermal Parameters for $(-)_{589}$-$[Co(Hbg)_3]Cl(d\text{-tart})\cdot 5H_2O$

$B_{eq}=(8/3)\pi^2(U_{11}+U_{22}+U_{33})$. The anisotropic thermal parameters bave been preserved by the Chemical Society of Japan.

with the Hbg B ligand than with the Hbg A ligand. Indeed, the atoms in the chelate ring B and the α-hydroxy carboxylate moiety of *d*-tart lie on nearly the same plane, as is shown in Fig. 3.

Anion Geometry. A crystallographic twofold axis passes through the middle point of *d*-tart. The bond distances and angles for *d*-tart are listed in Table 2. These values coincide with those reported in previous works.[23] The five non-hydrogen atoms of each α-hydroxy carboxylate moiety lie approximately on a plane, as is shown in Fig. 3. The dihedral agnle between the planes of two moieties is 50.8°. This value is within the range of hitherto reported values, which show a wide variation in many crystals: *ca.* 50—75° (av. 66°) for $[Sb_2(d\text{-tart})_n(l\text{-tart})_{2-n}]^{2-}$ ($n=1$ or 2) and analogous compounds, and *ca.* 44—89° (av. 54°) for *d*- and *l*-tartrates.[24]

In addition, a unique dimeric structure of two *d*-tart anions is formed in the present crystal. The structure of this dimeric unit and that of $[Sb_2(d\text{-tart})_2]^{2-}$ [25] are compared in Fig. 4. Three mutually orthogonal crystallographic twofold axes pass through the center of this dimeric unit ($x=0$, $y=1/2$, $z=1/2$). The structure of this dimeric unit closely resembles that of $[Sb_2(d\text{-tart})_2]^{2-}$ if two Sb atoms are left out of consideration. However, the distances between the two hydroxyl oxygen atoms, 3.13 and 3.63 Å, in the dimeric unit differ from the corresponding distances, 3.69 and 3.08 Å, in $[Sb_2(d\text{-tart})_2]^{2-}$, as is shown by

Roman numerals as superscripts refer to the following equivalent positions, relative to the reference atom at x, y, z: ii (x, 1−y, 1−z).

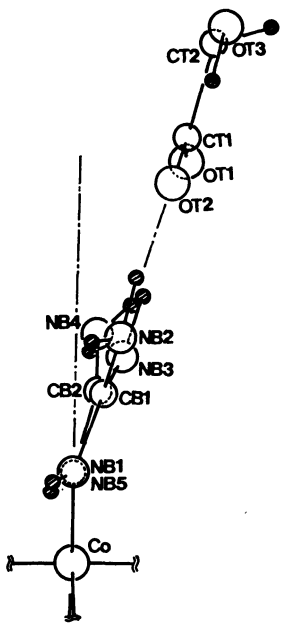

Fig. 3. Projecting of Hbg(B) ligand and α-hydroxycarboxylate moiety of *d*-tartrate viewed down the direction of N(B1)···N(B5).

Short contacts are formed between the N atoms of the Hbg A ligand and the Cl^- anion. The arrangement of the complex cation, $(-)_{589}$-$[Co(Hbg)_3]^{3+}$, and Cl^- can be regarded as an infinite spiral chain along the twofold screw, which is parallel to the b-axis through the ($x=1/4$, $z=1/2$) position, as is clearly shown in Fig. 2. Figure 5 shows the schematic illustration of the present crystal structure. If the complex cation and the Cl^- anion are linked alternately, as is shown by arrows in Fig. 5, the spiral is left-handed. Here, it should be noted that such a spiral arrangement of the complex cation, $(+)_{589}$-$[Co(Hbg)_3]^{3+}$, and the Cl^- anion is also found in the crystal structure of $(+)_{589}$-$[Co(Hbg)_3]Cl_3\cdot H_2O$,[14] but the spiral is the opposite, that is, right-handed.

There are short contacts between the Hbg ligands and the dimeric unit $(d\text{-tart})_2^{4-}$, as is shown in Table 4. It is worth noting that, while the hydroxyl oxygen atom of the *d*-tart forms a short contact with the Hbg

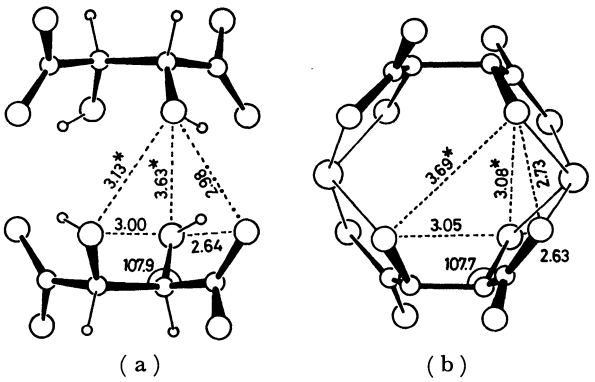

Fig. 4. (a) Structure of the $(d\text{-tart})_2^{4-}$ dimeric unit. (b) Structure of $[Sb_2(d\text{-tart})_2]^{2-}$. Short contacts are indicated by broken lines and their values are in Å.

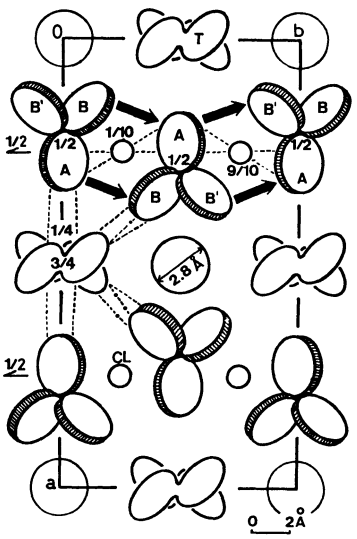

Fig. 5. A schematic drawing of the crystal structure viewed down the c-axis. A, B, and B′ are biguanide ligands. T and CL mean *d*-tartrate and chloride anions respectively. The numerals represent the fractional z-coordinates for the center of each molecule. Big open circles indicated empty channels. Water molecules are omitted for clarity.

Roman numerals as superscripts refer to the following equivalent positions, relative to the reference atom at x, y, z:
i ($-x$, $1-y$, z), ii (x, $1-y$, $1-z$), iii ($1/2-x$, $-1/2+y$, $1-z$),
iv ($1/2+x$, $-1/2+y$, z), v (x, y, $1+z$), vi ($-x$, y, $1-z$),
vii ($1/2-x$, $-1/2+y$, $-z$), viii (x, $1-y$, $-z$), ix ($1-x$, y, $-z$).
D, Hydrogen donor; A, Hydrogen acceptor.

A ligand, the carboxylate oxygen atoms of the *d*-tart form short contacts with the Hbg B ligand. All short contacts are formed along the twofold axes of the complex.

The positions of the water molecules are also shown in Fig. 2. There are four kinds of crystallographically independent water molecules. Three of them, OW1, OW2, and OW3, lie on a twofold axis parallel to the a-axis at the ($y=1/2$, $z=0$) position. The fourth water molecule, OW4, occupies the general position, but its z-coordinate ($z=0.0269$) is nearly equal to zero. Therefore, all the water molecules form a sheet on the ab plane at $z=0$.

The most remarkable feature of the present crystal is that a large empty channel with a diameter of *ca.* 2.8 Å passes through the ($x=1/2$, $y=1/2$) position along the c-axis, as is shown in Fig. 5. The size of the diameter is estimated from the van der Waals radii of the N(B2) and OW4 atoms[26] which surround this channel. The overall crystal-packing mode is highly symmetrical in comparison with those of the diastereomeric salts of $[Co(en)_3]^{3+}$–*d*-tart systems.

Chiral Discrimination Mode. As has been descrived above, there is no one-to-one intimate ion-pair of the complex cation and *d*-tart anion in the present crystal. This is a remarkable difference as compared with the case of the corresponding $(+)_{589}$-$[Co(en)_3]Br(d\text{-tart})\cdot 5H_2O$ crystal,[1] in which a unique one-to-one ion-pair, called "face-to-face" close contact, has been found. It has been proposed, on the basis of the CD change on the addition of *d*-tart, that *d*-tart probably discriminates the Λ- and Δ-forms of $[Co(en)_3]^{3+}$ through the formation of such a unique face-to-face close contact.[27]

An attempt was then made to see if any change in the CD spectrum of the optically active $[Co(Hbg)_3]^{3+}$ in solution is observed upon the addition of *d*-tart. No appreciable change was detected.[28] Another attempt was also made to see if the CD spectrum was induced for the racemic complex salt by the addition of *d*-tart, but no CD spectrum was observed. We also tried to separate the racemic $[Co(Hbg)_3]^{3+}$ ions into enantiomers through an SP-Sephadex ion-exchange column, using the *d*-tart solution as the eluent, but no separation was achieved. These facts suggest that the individual *d*-tart ion can not discriminate the chirality of the individual $[Co(Hbg)_3]^{3+}$ complex ion.

Therefore, it should be considered that the crystal-packing mode as a whole is responsible for the chiral discrimination in the present $[Co(Hbg)_3]^{3+}$–*d*-tart system. Figure 5 shows the schematic illustration of the left-handed spiral chain $\{\Lambda\text{-}[Co(Hbg)_3]Cl\}_\infty$. A similar but right-handed spiral chain is also found in the crystal of $(+)_{589}$-$[Co(Hbg)_3]Cl_3\cdot H_2O$. Therefore, it is reasonable to presume that $[Co(Hbg)_3]^{3+}$ ions have a strong tendency toward the formation of an infinite spiral chain in the presence of Cl^- ions. The questions are why such spiral chains of the same chirality come together to form a crystal, and why the crystal is less-soluble in the present case. In relation to those points, it must be noted that a layer

is formed on the ab plane, linked by hydrogen bonds between $\{\Lambda\text{-}[Co(Hbg)_3]Cl\}_\infty$ and $(d\text{-tart})_2^{4-}$, as is shown in Figs. 2 and 5. Between these layers, a sheet composed of water molecules is stacked along the c-axis; this prevents a strong interaction between these layers along the c-axis. Therefore, it can be considered that a strong interaction is present only in a layer structure of $\{\Lambda\text{-}[Co(Hbg)_3]Cl\}_\infty$ and $(d\text{-tart})_2^{4-}$ on the ab plane. The strong interaction in this layer is probably attributable to the hydrogen bonding. If the absolute configuration of the complex changes from Λ to Δ, the spiral chain would change from left-handed to right-handed, and a discrepancy would take place on the N–H···O hydrogen bonding between the right-handed spiral chains, $\{\Lambda\text{-}[Co(Hbg)_3]Cl\}_\infty$, and the dimeric unit, $(d\text{-tart})_2^{4-}$, so that a reasonable crystal packing could not be formed in this layer. In other words, the *d*-tart is locked by the left-handed spiral chains, $\{\Lambda\text{-}[Co(Hbg)_3]Cl\}_\infty$, formed along the b-axis. Therefore, it seems that the discrimination of optical isomers in this crystal originates in the formation of such a "lock-in-column" structure through the strong hydrogen-bond network on the ab plane. The crystal structures of several less-soluble diastereomeric salts, $(+)_{589}$-$[Ni(bpy)_3]_2Cl_2(d\text{-tart})\cdot nH_2O$,[29] $(+)_{589}$-$[Ru(bpy)_3]_2Cl_2(d\text{-tart})\cdot nH_2O$,[30] Λ-$[Co(bpy)_3]d\text{-tart}\cdot nH_2O$,[30] and $(+)_{589}$-$[Co(tame)_2]Cl(d\text{-tart})\cdot 5.4H_2O$,[31] have been determined. In these crystals, the dimeric unit of *d*-tart anions is not found. Thus, it is probable that, between the $\{\Lambda\text{-}[Co(Hbg)_3]Cl\}_\infty$ spiral chain and *d*-tart anions, there is a stereospecific interaction which stabilizes the dimeric unit of *d*-tart anions, and the formation of the dimeric unit, $(d\text{-tart})_2^{4-}$, plays a dominant part in the optical resolution of $[Co(Hbg)_3]^{3+}$, using *d*-tart as a resolving agent *via* the diastereomeric salt.

We wish to thank the Hiroshima University Information Processing Center for its generous allocation of computer time and wish to acknowledge a Grant-in-Aid for Scientific Research from the Ministry of Education.

Spectrophotometric Determination of Iron(III) with *N,N'*-Bis(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetic Acid

Tetsuo KATSUYAMA* and Toshihiko KUMAI

Department of Basic Technology, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received September 26, 1980)

N,N'-Bis(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetic acid (hbed) reacts with iron(III) to form a red complex having an absorption maximum at 485 nm. The iron(III) complex is so stable that the maximum absorbance of the solution is constant over the pH range from 2.5 to 13.2 and a large excess of reagent is not necessary. Beer's law is obeyed up to 1.6×10^{-4} mol dm^{-3} (9 μg cm^{-3}) of iron(III). The molar absorption coefficient is 3.95×10^{3} l cm^{-1} mol^{-1}, and the relative standard deviation for determination of 3.5 μg cm^{-3} of iron was 0.29%. The molar ratio of iron(III) to hbed was found to be 1:1. The effect of 32 diverse ions was examined; only colored aqua metal ions interfere. The present method was applied to the determination of iron in aluminium alloys.

Spectrophotometric determination of iron(III) has been extensively studied by many authors.[1-9] In these studies, the method[6-8] using the reagent ethylenediamine-*N,N'*-di(2-hydroxyphenylacetic acid) (eddha) is peculiar: the reagent reacts with iron(III) to form a very stable complex (stability constant *ca.* 10^{34}); hence the color development is maximal over a wide pH range, and a large excess of the reagent is not necessary in the determination. These features are desirable in spectrophotometric determinations.

The reagent *N,N'*-bis(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetic acid (hbed) gives a red color with iron(III) through the formation of a very stable complex whose stability constant is *ca.* 10^{40}. The constant is the highest of those of iron(III) complexes. Further, the constant is particularly large among metal–hbed complexes. So, in this study, hbed has been examined for the spectrophotometric determination of iron(III). The present method gives accurate results for iron(III) ranging from 1×10^{-5} to 16×10^{-5} M (1 M=1 mol dm^{-3}) (0.6—9 μg cm^{-3}), and has high selectivity.

Experimental

Reagents. *hbed Solution*: Material hbed·2HCl·2H$_2$O was prepared by the literature method.[10] Found: C, 48.75; H, 5.92; N, 5.65; Cl, 14.11%. Calcd for $C_{20}H_{24}N_2O_6\cdot2HCl\cdot2H_2O$: C, 48.30; H, 6.04; N, 5.64; Cl, 14.25%.

A 1×10^{-3} M hbed solution was prepared by dissolving a weighed amount of the prepared reagent in water.[11]

Iron(III) Solution: A 0.01 M iron(III) solution was prepared by dissolving guaranteed reagent grade iron(III) nitrate in 0.02 M nitric acid. The solution was standardized by edta titration using Variamine Blue B as indicator. This solution was diluted with 0.02 M nitric acid as required.

Iron(II) Solution: A 0.01 M iron(II) solution was prepared by dissolving GR grade iron(II) sulfate in 0.02 M nitric acid. The solution was standardized by the following procedure. Hydrogen peroxide was first added to the iron(II) solution. After the iron(II) was oxidized to iron(III), the excess hydrogen peroxide was expelled completely by warming the solution. Then the solution was titrated with edta, using Variamine Blue B as indicator.

Water: The ion-exchanged water was distilled with an allquartz distillation apparatus.

Apparatus. Absorbance and absorption spectra were measured with a Hitachi Perkin Elmer 139 spectrophotometer using 10 mm quartz cells. The pH values were measured with a Toa Electronics Model HM-15A digital pH-meter.

Standard Procedure. A sample solution containing up to 4 μmol (230 μg) of iron(III) is taken into a 50 cm^3 Erlenmeyer flask. Then 6 cm^3 of 1×10^{-3} M hbed, 1 cm^3 of 1 M acetic acid, and 2.5 cm^3 of 1 M sodium acetate are added. After being kept for about three minutes in a boiling water bath, the solution is cooled with running water. Next, the solution is transferred to a 25 cm^3 volumetric flask, and diluted to the mark with water (final pH: 5.1). The absorbance of the solution is measured at 485 nm against water.

Results and Discussion

Absorption Spectra. The red solution of Fe(III)–hbed complex had an absorption maximum at 485 nm. The reagent solution did not absorb light in the visible region.

Effect of pH. The pH of the Fe(III)–hbed complex solution was altered by the addition of nitric acid, acetic acid, acetic acid–sodium acetate, mannitol–boric acid–sodium borate, or sodium borate–sodium hydroxide buffer system. The absorbance of the solution at 485 nm remained constant over a wide pH range 2.5—13.2, as is shown in Fig. 1.

Stability of the Color. The color reaction of hbed with iron(III) seemed to take place rapidly, but the absorbance of the resultant colored solution increased very slowly. However, when the resultant solution was heated in a boiling water bath for about a few

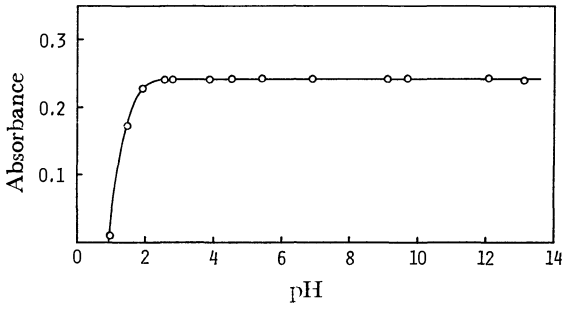

Fig. 1. Effect of pH on formation of Fe(III)–hbed complex.
Fe(III): 6.29×10^{-5} M (3.51 μg cm^{-3}), hbed: 1.03×10^{-4} M, wavelength 485 nm, reference: water, I= 0.1 M.

minutes, the maximum color development was obtained. The color, once developed, was very stable; the absorbance remained constant over a period of 72 h, and the absorbance was not affected by the measurement temperature (10—35 °C). Further, the reagent solution itself was stable; the concentration was unchanged for at least 40 d.

Effect of hbed Concentration. A constant absorbance was obtained over a [hbed]/[Fe(III)] ratio range 1.0—6.0. This fact shows that a large excess of reagent is not needed for full color development.

Effects of the Amount of Buffer Solution and Ionic Strength. A buffer solution was prepared by mixing 1 M acetic acid solution with 1 M sodium acetate solution in 1:2.5 ratio. The addition of from 1 to 10 cm^3 of the buffer solution (for 1.5 μmol of iron(III) in 25 cm^3 solution) had no effect on the color intensity of the iron(III) complex. The effect of ionic strength was also examined. The color intensity of the iron(III) complex did not change in ionic strengths from 0.1 to 0.4 M.

Calibration Curve. The calibration curve under the conditions described in the standard procedure was linear at least up to 1.6×10^{-4} M (9 μg cm^{-3}) of iron(III). The molar absorption coefficient of Fe(III)–hbed complex was 3.95×10^3 l mol^{-1} cm^{-1}, and the Sandell sensitivity for the absorbance of 0.001 was 1.41×10^{-2} μg cm^{-2}. The relative standard deviation of the absorbance was 0.29% for 6.3×10^{-5} M (3.5 μg cm^{-3}) of iron(III) (12 determinations).

Effect of Diverse Ions. The effect of diverse ions was investigated, as is shown in Table 1. It was seen that a large excess of colored metal ions interfered to some extent, and other metal ions did not interfere even if they were present at a concentration of 2000 times that of iron(III). The interferences from the metal ions such as chromium(III), cobalt(II), nickel(II), and uranyl(II) are considered to be attributed to the absorption of light by the colored aqua metal ions, since positive error occurs.

Composition of the Complex. The results obtained by the molar ratio study are shown in Fig. 2. It is seen that iron(III) forms a 1:1 complex with hbed. The same results were also obtained by the continuous variation method.

Determination of Iron(II). It seemed that hbed reacted with iron(II) and the Fe(II)–hbed complex formed was oxidized instantly to the red complex Fe(III)–hbed. Thus, the determination of iron(II) was run by use of the present method. The results of the three repeated determinations for 1.54 μmol/25 cm^3 of iron(II) were 1.53, 1.54, and 1.53 μmol/25 cm^3; iron(II) could be determined without addition of any oxidizing agent. Consequently, the total iron content, iron(II) and iron(III), is determined by the present method.

Determination of Iron in an Aluminium Alloy. Aluminium alloys were furnished by the National Bureau of Standards. 85b wrought: Fe, 0.24; Cu, 3.99; Si, 0.18; Mn, 0.61; Ni, 0.084; Cr, 0.21; Ti, 0.022; Pb, 0.021; Mg, 1.49; Zn, 0.03%. 87a Al-Si: Fe, 0.61; Cu, 0.30; Si, 6.24; Mn, 0.26; Ni, 0.57; Cr, 0.11; Ti, 0.18; Pb, 0.10; Mg, 0.37; Zn, 0.16%.

A weighed amount of the alloy (85b wrought: 0.5 g, 87a Al–Si: 1.2 g) was taken in a 50 cm^3 Erlenmeyer flask, and concentrated hydrochloric acid

TABLE 2. ANALYTICAL RESULTS OF IRON IN ALUMINUM ALLOYS

Sample	Certified (%)	Found (%)
NBS 85, Wrought	0.24	0.23 0.24 0.24
NBS 87a, Al-Si	0.61	0.61 0.61 0.61

was added drop by drop. After the dissolving was complete, a small amount of concentrated nitric acid was added and the solution was boiled gently for several minutes. Next, the solution was transferred to a 100 cm^3 volumetric flask and diluted to the mark with water. Then, 3 cm^3 of the solution prepared was used for determination of iron. In the determination, the pH was adjusted to 3.2. The analyses were run three times, starting from the weighing of the sample. As shown in Table 2, satisfactory results were obtained.

Conditional Stability Constants. The stability constants for the hbed complexes of iron(III), copper(II), nickel(II), manganese(II), cadmium(II), lead(II), magnesium(II), calcium(II), cobalt(II), and zinc(II) are known.[10] Thus, the conditional stability constants[12] ($K_{M'L'(ML)'}$) for the hbed complexes were calculated from Eq. 1[13] with the aid of an electronic computer (OKITAC 50).

$$K_{M'L'(ML)'} = \frac{[(ML)']}{[M'][L']} = \frac{\alpha_{ML(H)}}{\alpha_{M(OH)}\alpha_{L(H)}} K_{ML}, \quad (1)$$

where

$$\alpha_{M(OH)} = 1 + \sum_{m=1}^{m} \beta_{M(OH)_m}[OH^-]^m,$$

$$\alpha_{L(H)} = 1 + \sum_{n=1}^{n} \beta_{H_nL}[H^+]^n,$$

$$\alpha_{ML(H)} = 1 + \sum_{i=1}^{i} \beta_{MH_iL}[H^+]^i.$$

Here, K_{ML} refers to the stability constant of the complex ML, $\beta_{M(OH)_m}$ and β_{H_nL} are the over-all stability constant of the metal complex with hydroxide ion and the over-all protonation constant of the ligand, respectively, and β_{MH_iL} is the over-all protolytic stability constant of the acid complex MH_iL $\left(\prod_{i=1}^{i} \frac{[MH_iL]}{[MH_{i-1}L][H^+]}\right)$. The formation of an acid complex with known constant was taken into consideration. In Fig. 3, the conditional constants calculated at various pH values are plotted. Figure 3 shows that the value of the conditional constant of Fe(III)–hbed complex is considerably higher than those of the hbed complexes of other metals.

Conditional stability constants of metal–eddha complexes were also calculated from the stability constants[14,15] of the related complexes, and compared with those of the metal–hbed complexes. The conditional constant of Fe(III)–hbed complex is higher than that of Fe(III)–eddha complex, as shown in Fig. 3. For other metals, however, the consitional

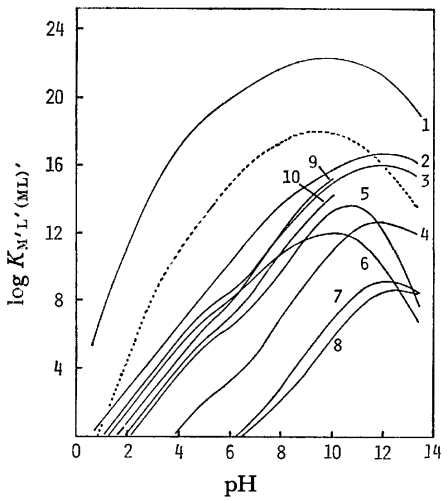

Fig. 3. Conditional stability constants, $K_{M'L'(ML)'}$, of various metal–hbed complexes as functions of pH. Metal: 1, Fe(III); 2, Cu(II); 3, Ni(II); 4, Mn(II); 5, Cd(II); 6, Pb(II); 7, Mg(II); 8, Ca(II); 9, Co(II); 10, Zn(II). The dotted line shows the conditional stability constant of Fe(III)–eddha complex.

constant of the hbed complex is similar in magnitude to that of eddha complex. Consequently, it may be seen that reagent hbed is superior to reagent eddha in the determination of iron(III).

Characteristics of the Present Method. The present method has high selectively without masking agents (Table 1). This is attributable to the following reasons: (1) the stability constant of Fe(III)–hbed complex is particularly large among those of metal–hbed complexes; (2) the absorption spectrum of Fe(III)–hbed complex in the visible region differs from those of other metal–hbed complexes, whose spectra are similar in shape and magnitude to those of aqua metal ions. The precision is relatively high (relative standard deviation: 0.29%); this seems to be attributable to the high stability of the developed color. On the other hand, the sensitivity is small. In selectivity the present reagent hbed is superior to other reagents, *e.g.*, eddha,[6] 5-sulfosalicylic acid,[16] tiron,[17] edta,[18] and salicylic acid,[19] whose sensitivities are also small.

(Received September 19, 1980)

Wet oxidation of various water-soluble polymers was carried out with particular attention given to the reactivity of polyethylene glycol. Polymers with high molecular weight were more reactive than their low molecular weight analogues or monomer models. It is suggested that the high reactivity of the polymers can be attributed to the ease of an intramolecular hydrogen abstraction in the propagation step of oxidation. Bio-degradability of the polymers was highly improved by wet oxidation. Wet oxidation is especially effective for the treatment of waste water containing water-soluble polymers.

Wet oxidation of organic compounds is carried out under a high pressure of air and at an elevated temperature between 100 °C and a critical temperature of water, 372 °C. This method has been successfully applied to the treatment of various sludges,[1,2] waste water from organic chemicals manufacturing process,[3] and pulp and paper mill waste matters.[4] Under appropriate conditions, organic pollutants can be completely removed. However, the severe reaction conditions require higher running and installation costs than other processes, and practical application of this method is limited.

The reaction mechanism of the process has not been clarified as yet. Mitigation of the conditions is desirable by the development of effective catalysts or improvement of the process of the operation.[5] Previously investigation was carried out on the wet oxidation of various low molecular weight organic compounds including dyes and amides.[6-8] The reactivity of these compounds is correlated with the carbon content in a molecule. Compounds with higher carbon content seem to lose carbon monoxide or carbon dioxide more easily in the course of their degradation to refractory lower carboxylic acids, giving rise to faster decrease in total organic carbon. If this reactivity-carbon content relationship can be applied to the wet oxidation of polymers, the reactivity of homologous polymers would be independent of their molecular weight.

We have investigated the wet oxidation of water-soluble polymers with an emphasis on polyethylene glycol. Water-soluble polymers are widely used as water treatment agents, food additives, antifreeze, and in cosmetics. Their discharge into environment might cause serious water pollution because some of them are inert to biological degradation and accumulate in the environment.[9] Their complete removal is difficult when ordinary physicochemical treatment such as adsorption or reverse osmosis is carried out. Improvement of the bio-degradability of the polymers by the treatment has also been examined.

Experimental

Material. Commercial reagents were used without further purification. Polyethylene glycol (PEG), polypropylene glycol (PPG), poly(vinyl alcohol) (PVA), polyacrylamide (PAM), pol(acrylic acid) (PAA), carboxymethylcellulose (CMC), 2-hydroxyethylcellulose (HEC), and methylcellulose (MC) were used as the water-soluble polymers. Their molecular weights, except for PEG and PPG, were determined from the corresponding molecular weight-viscosity relationship.[10] The results are given in Table 1.

TABLE 1. MOLECULAR WEIGHT OF POLYMERS

Polymer	Molecular weight
PEG-200	190—210
PEG-400	380—420
PEG-1000	950—1050
PEG-2000	1800—2200
PEG-4000	3000—3700
PEG-6000	7800—9000
PEG-20000	24900
PPG	1000
PVA	21500
PAM	485000
PAA	38000
CMC	17500
HEC	82600
MC	58200

Apparatus and Procedure. Deionized water, nitrogen (0.98 MPa), and Oxygen (1.96 MPa) were placed in the reaction vessel, a 1—1 autoclave equipped with a sample injector and a valve for sampling. The vessel was heated with an electric furnace. A polymer solution was injected through the injector under pressure, the solution being stirred magnetically. It was confirmed that the reactions were not controlled by the diffusion of oxygen into the liquid phase. At appropriate time intervals, an aliquot of the solution was withdrawn through a cooling jacket and subjected to analysis.

The reactivity of polymers was determined on the basis of the decrease in total organic carbon during the course of reaction.

Analysis. Total organic carbon (TOC) analysis was carried out with a Sumitomo Model GCT-12N TOC analyzer and gas chromatographic (GPC) analysis with a Shimadzu GC-6A gas chromatograph equipped with a flame ionization detector using nitrogen as the carrier gas. Polyester FF 10% on Neosorb NFH, 3 mm × 2 m, was used for the GPC analysis of ethylene glycol (EG), diethylene glycol (DEG), triethylene glycol (TEG) and formaldehyde, and chromosorb 101, 3 mm × 2 m, for ethanol and propionamide. Ion chromatographic analysis was performed on a Dionex Model 10 ion chromatograph using an anion separating column and 2.5×10^{-3} mol dm^{-3} Na_2CO_3 plus 3.0×10^{-3}

mol dm^{-3} $NaHCO_3$ as an eluent. Proton NMR spectra were taken on a Varian Model T-60A spectrometer using tetramethylsilane as a standard and deuteriochloroform as solvent, and infrared spectra on a Hitachi Model 215 grating spectrophotometer. Molecular weight of PEG was determined on a Toyo Soda Model HLC-802 UR gel permiation chromatograph using commercial PEG samples as standard.

Results and Discussion

Effect of Molecular Weight on the Wet Oxidation of PEG. Figure 1 shows the time courses of the TOC decrease in the wet oxidation of PEG-20000 at various temperature. The temperature dependency is remarkable as in the oxidation of benzyl alcohol reported previously.[6] The rate of the reaction was found to be independent of the oxygen pressure above 0.98 MPa.

The reactivity of PEG depends upon the molecular weight (Fig. 2). Ethylene glycol does not react under the conditions, but the reactivity of PEG increases with an increase in molecular weight. Although there is a maximum in the rate of TOC decrease at a molecular weight around 2000, PEG with higher molecular weight is more reactive as compared with its low molecular weight analogues. Thus, successive reaction was carried out with PEG-200 and PEG-20000.

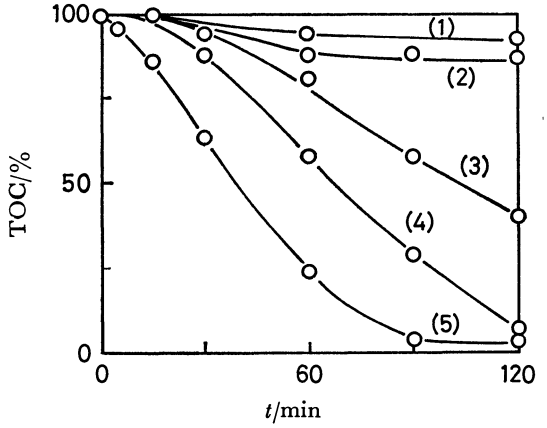

Fig. 1. Wet oxidation of PEG-20000. Effect of temperature.
$[PEG]_0$=5000 ppm, $P(O_2)$=1.96 PMa. (1): 160 °C, (2): 180 °C, (3): 200 °C, (4): 210 °C, (5) 220 °C.

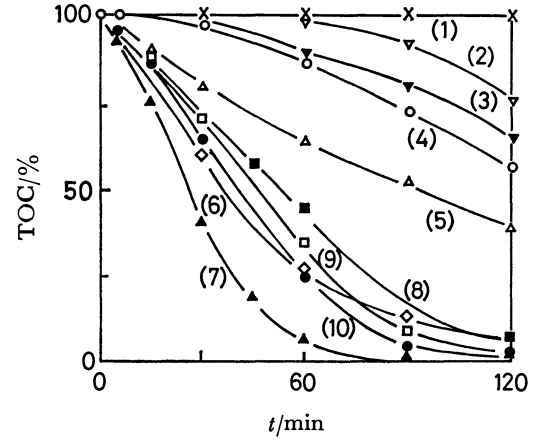

Fig. 2. Wet oxidation of PEG. Effect of molecular weight.

Accumulation of Acids during the Course of Reaction. Figure 3 shows the changes in pH and acid accumulation during the course of wet oxidation of PEG-200 and PEG-20000. The pH decreases at the initial stage of the reaction, recovering gradually. In the case of PEG-20000, the change in pH is more rapid as compared with PEG-200. The amount of acid increases at an early stage of the reaction, then decreasing. Both accumulation and decrease of acids were faster with PEG-20000 than with PEG-200, which can be explained in terms of the difference in molecular weight. Acids formed from PEG-20000 should have higher molecular weight than those from PEG-200, and should be more reactive. The molecular weight determined in the course of oxidation of PEG-20000 was *ca.* 600 after 5 min, and *ca.* 300 even after 30 min.

Product Analysis. Gas chromatographic analysis of the reaction mixture of the wet oxidation of PEG-200 and PEG-20000 showed formation of formaldehyde, EG, DEG, and TEG during the course of oxidation. The amount of these products, shown as functions of the reaction time in Figs. 4 and 5, increased with the progress of reaction in the case of PEG-200. Oxidation of PEG-20000 gave a large

a) Accumulation of EG, DEG, and formaldehyde is expressed by TOC contained in these compounds.

amount of formaldehyde at an early stage of the reaction, decreasing with the progress of reaction. Only trace amount of EG and DEG were detected in this case.

Ion chromatographic analysis of the reaction mixture in the oxidation of PEG-20000 showed the formation of formic acid and acetic acid. Proton NMR spectra of the oxidation products of PEG-20000 showed unresolved signals at δ 4.4—4.7 and 3.6. A signal observed at δ 8.1 was assigned to formyl protons. The results indicate the formation of formic acid and/or formic esters. Infrared spectra of these products indicate the presence of carboxylic acids.

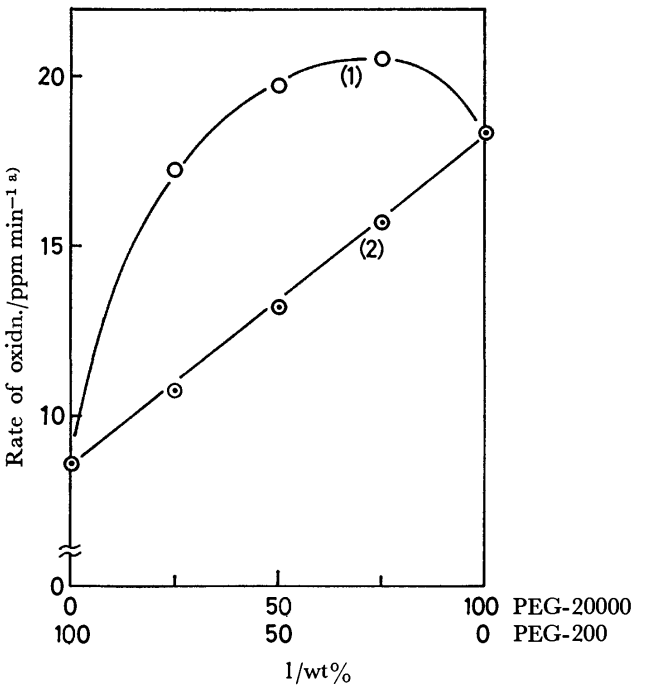

Fig. 6. Co-oxidation of PEG-200 and PEG-20000.
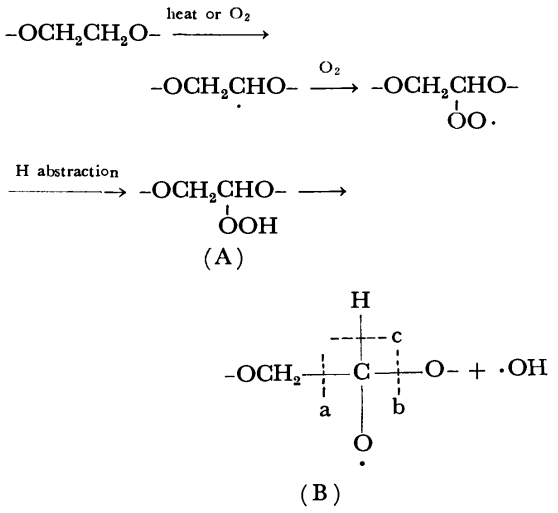
$P(O_2)=1.96$ MPa, Total $[TOC]_0=2500$ ppm, 220 °C. (1): obsd, (2): calcd.
a) The rate was calculated from TOC decrease.

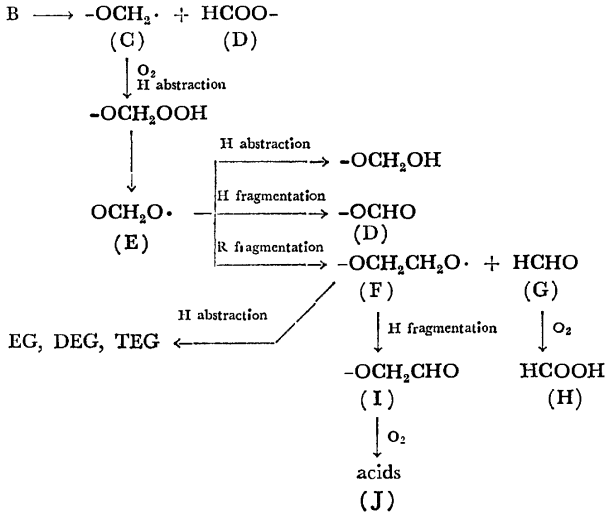
Co-oxidation of PEG-200 with PEG-20000. First, the effect of the concentration of the polymers on the rate of oxidation was examined. The curves of TOC decrease show an induction period (Fig. 2), the rate of oxidation being expressed by the mean velocity of TOC decrease at the reaction time of 60 min. The apparent reaction orders with respect to TOC were found to be 1.0 and 0.75 for PEG-20000 and PEG-200 respectively.

Figure 6 shows the dependence of the rate of oxidation on the ratio of the concentrations of PEG-200 and PEG-20000. The calculated line was obtained by taking the reaction order into consideration. The experimental data lie far above this line, suggesting that the reaction proceeds in a radical mechanism, where active species produced from PEG-20000 attack PEG-200. Co-oxidation of reactive compounds with less reactive reactants would thus be useful in practical waste water treatment. The apparent activation energy for the oxidation of PEG-20000 was 97.9 kJ/mol in the temperature range 180—220 °C.

Mechanism of Product Formation in Wet Oxidation of PEG. The following scheme is proposed for an explanation of the formation of the identified products. A radical mechanism seems to support the result. Goglev and Neiman reported that the thermal oxidation of PEG proceeds in a radical mechanism in which the first step is the formation of hydroperoxide of PEG.[11] The first step would be the formation of a hydroperoxide A, which undergoes thermal decomposition to produce an alkoxyl radical B and a hydroxyl radical. The hydroxyl radical is highly reactive and would give rise to further degradation of PEG.



Hydrogen atom fragmentation at bond c or hydrogen abstraction of the intermediate B might lead to the formation of an alcohol or an ester, although they were not characterized.



Fragementation at bond a of the radical B might produce formic ester D. The radical C is converted into an alkoxyl radical E, which undergoes an alkoxyl radical fragmentation (R fragmentation) to give another alkoxyl radical F and formaldehyde G. The latter might undergo further oxidation to produce formic acid H. Alkoxyl radical F would give EG, DEG, or TEG by hydrogen abstraction. Radical F might also produce aldehyde I, from which carboxylic acid J would be formed.

Fragmentation at bond b of the radical B can explain the formation of aldehyde and alkoxyl radical; their behaviour would be the same as discussed above.

$$B \longrightarrow -OCH_2CHO + \cdot OCH_2CH_2O-$$

Consideration on the Effect of Molecular Weight on the Reactivity of PEG. The reactivity of a hydrocarbon in the autoxidation depends upon the rate of the propagation step.

$$ROO\cdot + RH \longrightarrow ROOH + R\cdot$$

This step generally occurs intermolecularly, although intramolecular reaction is also possible. Intramolecular hydrogen abstraction *via* cyclic intermediate occurs easily in the oxidation of acyclic ethers.[11,12] It is assumed that intramolecular process plays an important role when the concentration of PEG is low. Ease of cyclization depends upon the stability of the ring formed and on the activation entropy of cyclization. In the lactone formation from hydroxy acid, five to seven membered rings are easily produced, rings with more than fourteen atoms being also possible.[13] In the oxidation of PEG, cyclic transition state with five, six, and more than fourteen membered rings including peroxy oxygen atoms seems favorable. However, in the oxidation of PEG with a low molecular weight, *e.g.* PEG-200, intramolecular hydrogen abstraction would be difficult after several chain scissions. On the other hand, PEG with a high molecular weight holds a long chain during the course of oxidation (Fig. 3) and would undergo further intramolecular reaction.

Although the above explanation is possible for the effect of molecular weight on the wet oxidation of PEG, it does not necessarily follow that the higher the molecular weight, the higher the reactivity. A maximum in the reactivity was observed for PEG with a molecular weight *ca.* 2000, further increase in molecular weight showing little effect (Fig. 2). This suggests that the propagation step is a competition between intra- and intermolecular hydrogen abstraction as Goglev and Neiman indicated.[11] Intermolecular reaction should decrease with the increase in the molecular weight of PEG as a result of the reduced rate in the diffusion of the molecule.

Wet Oxidation of Other Polymers. Reactivity of other polymers in the wet oxidation was also investigated. In the case of CMC, HEC, and MC, viscosity of the aqueous solution of these polymers was very high, making the use of the sample injector impossible. Thus, reactions were carried out by heating a sample solution under a nitrogen atmosphere followed by injecting oxygen into the vessel. Viscosity and pH of the solution decreased during the course of pre-heating, indicating that thermal degradation occurred during this period. As shown in Fig. 7, all polymers were equally or even more reactive than PEG-20000. The reactivities of PVA, PPG, PAM, and PAA and their respective monomer models, ethanol, 1,2-propanediol, propionamide, and propionic acid were compared (Figs. 8 and 9), the sample injector being used. The reactivity of PVA was high, but TOC decrease in the oxidation of ethanol was slow, the amount of residual TOC being in line with the residual amount of ethanol determined by gas chromatography. Propionamide gradually decomposed, but TOC remained unchanged. On the other hand, PAM oxidized rapidly. Similar results were observed for PPG and PAA.

The results indicate that the polymers are reactive to a greater extent than the corresponding low molecular weight analogues due to a significant polymer effect, and that wet oxidation is particularly effective for the treatment of these water-soluble polymers. The reactivity-carbon content relationship, observed in the

oxidation of low molecular weight compounds, is not applicable to the wet oxidation of polymers.

Improvement of Bio-degradability of Polymers. Synthetic polymers are generally inert to biological treatment. Although PEG can be degraded by some microorganism, the rate of degradation is low.[9]

We have examined the improvement of bio-degradability of the polymers by wet oxidation. The results are given in Table 2. The bio-degradability is expressed by $(BOD_5/COD_{Cr})\times 100$ of the sample solution. Although all the polymers examined were inert to biological degradation, their bio-degradability was remarkably improved by wet oxidation. Treatment for only 5 min considerably improved the reactivity. After 2 h of oxidation, complete reactivity in the biological treatment was attained with PEG-1000 and PEG-2000. The effects of atmosphere and temperature of wet oxidation on the improvement of the bio-degradability of PEG-20000 are given in Table 3. Although degradation of the polymer chain occurs under a nitrogen atmosphere, scarcely any improvement in bio-degradability was observed. Incorporation of oxygen atoms into the reactant is inevitable. The bio-degradability was considerably improved by the wet oxidation at 160 °C, although there

was scarcely any decrease in TOC. Moreover, the oxidation at as low as 100 °C was still effective when sufficient reaction time as 2 h was employed. This shows that wet oxidation under mild conditions is sufficient for the improvement of bio-degradability. Thus wet oxidation is an effective pre-treatment for the biological purification of waste water containing those water-soluble polymers.

We thank Dr. J. Yoshida and Dr. S. Kojiya, Kyoto Institute of Technology, for their helpful advice and discussions.

Peroxomonophosphoric Acid Oxidation. V.[1] A Kinetic and Mechanistic Study of Oxidation of Aminobenzoic Acids in Acid Medium. Double Bell Shaped pH Rate Profile

Ganesh Prasad PANIGRAHI* and Abhina Kumar PANDA
Department of Chemistry, Berhampur University, Berhampur 760007, India
(Received April 28, 1980)

Anthranilic acid and *p*-aminobenzoic acid were oxidized with peroxomonophosphoric acid in aqueous acid medium to the corresponding azoxy derivatives. Suitable rate laws for the double bell shaped pH rate profile were derived and rationalized on the basis of protonation of the amino group and ionization of the carboxyl group. The mechanism of oxidation involves the nucleophilic attack of nitrogen on the electrophilic peroxo oxygen. The reactivity of different peroxomonophosphoric acid species has been estimated.

Reports have been given on the oxidation of 3-aminopyridine,[1] dimethyl sulfide,[2] dimethyl sulfoxide,[3] and benzaldehyde[4] by peroxomonophosphoric acid (PMPA). In the oxidation of sulfide, the sulfur functions as a nucleophile. While the dimethyl sulfoxide oxidation presents dualistic behavior, sulfur acts as a nucleophile in the acid medium, becoming an electrophile in alkaline medium. It is of interest to see whether amines which are good nucleophiles act by a mechanism similar to that of sulfides. There seems to be no kinetic and mechanistic study on the oxidation of aromatic amines except for a preliminary work by Boyland and Manson[5] who screened a number of amines towards their reactivity to PMPA to see whether they involve oxidative phosphorylation. Recently, Ogata and co-workers[6] studied the oxidation of *N,N*-dimethylaniline to *N,N*-dimethylaniline *N*-oxide and determined the relative reactivity of the various species of PMPA. We felt it necessary to extend the kinetic studies to aromatic amines such as anthranilic acid (OAB) and *p*-aminobenzoic acid (PAB). We wish to report some of the salient kinetic features of the reaction.

Experimental

All the chemicals were of analytical grade. Conductivity water was used in the preparation of the solutions and as a reaction medium. PMPA was prepared by acid hydrolysis of $K_4P_2O_8$.[7] The concentration was checked frequently by iodometry, the self-decomposition being negligible in the pH region examined. The acidity was adjusted by adding appropriate amounts of perchloric acid or standard buffers[8] and measured with a Systronics digital pH-meter 335. Sodium perchlorate was used for adjusting the ionic strength. Whenever necessary sodium perchlorate was generated by neutralizing the perchloric acid with carbonate free sodium hydroxide. Both the aminobenzoic acids were purified by recrystallization from water, their melting points (OAB-144 °C, PAB-191 °C) agreeing with those in literature (OAB-145 °C, PAB-192 °C). The kinetics was followed by measuring the rate of disappearance of PMPA, the estimation of which was made by iodometry in an acetic acid–acetate buffer of pH 4—5 with a drop of ammonium molybdate solution.[4] The rate constants were computed by the usual method and were found in duplicate runs to be reproducible within ±5%. Computations were carried out with a DCM minicomputer Microsystem 1121. The IR absorption spectra were recorded on a Perkin Elmer 137 spectrophotometer.

Product Study. PMPA=0.04 mol dm^{-3} (50 ml) and anthranilic acid 0.008 mol dm^{-3} (50 ml) were mixed at pH 1.3 and 45 °C and kept for 48 h. The product azoxybenzene-2,2′-dicarboxylic acid was extracted with diethyl ether (dark brown solid, yield 75%), checked for its purity by TLC and identified by its mp 225 °C (uncorrected) and IR (Nujol): 1690(s) (ArCOOH) and 1290(s) (N=N→O) cm^{-1}. Under similar conditions the product azoxybenzene-4,4′-dicarboxylic acid isolated from *p*-aminobenzoic acid (a yellow solid, yield 80%) was identified by its mp 238 °C (uncorrected) and IR (Nujol): 1710(s) (ArCOOH) and 1300(s) (N=N→O) cm^{-1}.

Results

The kinetics of oxidation of OAB and PAB by PMPA in aqueous medium was investigated at 308 K. The rate data for both OAB and PAB suggest second order kinetics at constant acidity, the rate law being

$$V = k'[\text{Aminobenzoic acid}]_t[\text{PMPA}]_t, \quad (1)$$

where subscript t stands for total concentration and k' the observed second order rate constant.

Effect of Acidity. The kinetics was investigated over the pH range 0—7. The rate data are summarized in Table 1. The plots of log k' *vs.* pH (Figs. 1 and 2) have two bell shaped regions, 0—3 and 3—7. This indicates participation of different species of PMPA resulting from dissociation (Eqs. 4 and 16) as well as different aminobenzoic acid species either resulting from protonation of the amino group or dissociation of the carboxyl group (Eqs. 3 and 15).

It appears that the rate law has to include complex H^+ dependence for each of the pH regions. It is possible to write the rate law in a general form as

$$V = k'[\text{substrate}]_t[\text{PMPA}]_t[H^+]^n, \quad (2)$$

where $-1<n<+1$.

Effect of Added Substances. At pH 1 ionic strength has little influence on the rate. A marginal influence is observed at pH 4.17 (Table 1). The reaction rate was found to be insensitive to the addition of radical trapping agents such as acrylamide. No influence was observed on rate by variation of solvents such as acetic acid.

Temperature Variation. Activation parameters have been evaluated from the linear Arrhenius plots of log k' *vs.* T^{-1} by measuring the rates of oxidation at four temperatures in the range 308—323 K (Table 2).

1.0	OAB	66.6	−52.4
4.85	OAB	55.2	−89.2
1.0	PAB	66.0	−55.6

Discussion

In view of the rate-pH profile the following equilibria seem to be likely in the pH region 0—1.

$$BH^+ \overset{K_H}{\rightleftharpoons} B + H^+ \quad (3)$$

where B stands for aminobenzoic acid and BH^+ for N-protonated aminobenzoic acid.

$$H_3PO_5 \overset{K_1}{\rightleftharpoons} H_2PO_5^- + H^+ \quad (4)$$

The magnitude of $K_1(=8.0\times10^{-2})$ suggests that the peracid exists in a neutral form[9] as H_3PO_5 below pH 1. Similarly the protonation equilibria for the aminobenzoic acids suggest that it may exist both as BH^+ and B in the pH range 0—1. The inverse first order acid dependence in the region indicates the participation of free aminobenzoic acid but not the protonated species. The step may involve reaction between the neutral species of the substrate molecule and H_3PO_5 only.

The steps of the reaction below pH 1 may be as follows.

$$BH^+ \overset{K_H}{\rightleftharpoons} B + H^+ \quad (5)$$

and

$$B + H_3PO_5 \overset{k_1}{\longrightarrow} \text{Products.} \quad (6)$$

The total concentration of the base can be expressed as

$$[B]_t = [B] + [BH^+].$$

Hence

$$[B]_t = [B] + \frac{[B][H^+]}{K_H}$$

or

$$[B]_t = [B]\{1+[H^+]/K_H\} = \frac{B(K_H+[H^+])}{K_H}$$

or

$$[B] = \frac{[B]_t K_H}{(K_H+[H^+])}. \quad (7)$$

Hence the rate is expressed by

$$V = k_1[B][H_3PO_5]_t \quad (8)$$

$$= k_1\frac{K_H}{K_H+[H^+]}[B]_t[H_3PO_5]_t$$

$$= k'[B]_t[H_3PO_5]_t, \quad (9)$$

where

$$k' = \frac{k_1K_H}{K_H+[H^+]}, \quad (10)$$

which can be rearranged to

$$\frac{1}{k'} = \frac{1}{k_1} + \frac{[H^+]}{k_1K_H}. \quad (11)$$

Plot of $1/k'$ *vs.* $[H^+]$ was found to be linear (corr. coeff= 0.988 and 0.99) in both cases, confirming the rate law. The plot gives K_H values of 0.53 and 0.16 and value of $k_1=0.071$ and 0.054 dm^3 mol^{-1} s^{-1} for OAB and PAB, respectively.

In order to interpret the bell shaped nature of log k' *vs.* pH plot in the pH region 0—3, it seems necessary to consider the dissociation of both protonated OAB and PAB and that of H_3PO_5 to $H_2PO_5^-$ as well.

The other species of peracid, *viz.* HPO_5^{2-} and PO_5^{3-}, are not relevant in the pH region under consideration since the second and third dissociation constants of PMPA are of the order of 10^{-6} and 10^{-13}, respectively.[9] The probable steps of the reaction might be as follows.

$$BH^+ \overset{K_H}{\rightleftharpoons} B + H^+ \quad (5)$$

$$B + H_3PO_5 \overset{k_1}{\longrightarrow} \text{Products} \quad (6)$$

$$B + H_2PO_5^- \overset{k_2}{\longrightarrow} \text{Products} \quad (12)$$

which lead to the rate expression,

$$-\frac{d[PMPA]_t}{dt} = \frac{k_1K_H[H^+]+k_2K_1K_H}{K_1K_H+(K_1+K_H)[H^+]+[H^+]^2}[B]_t[PMPA]_t$$

$$= k'[B]_t[PMPA]_t, \quad (13)$$

where

$$k' = \frac{k_1K_H[H^+]+k_2K_1K_H}{K_1K_H+(K_1+K_H)[H^+]+[H^+]^2}. \quad (14)$$

A least-squares solution of Eq. 14 was attempted using the reported value of K_1. The K_H value obtained kinetically from $1/k'$ *vs.* $[H^+]$ plot (Eq. 11) in the region of pH 0—1 was used. k_1 and k_2 values are estimated from Eq. 14, the results being summarized in Table 3. These values are in line with the order of reactivity between peracid species[6] ($H_3PO_5>H_2PO_5^-$). In order to check the validity of the rate law, the computed k_1 and k_2 values were employed to calculate the pH-log k' profile (Figs. 1 and 2). Agreement between the experimental points and theoretical line is satisfactory.

TABLE 3. RATE CONSTANTS OF DIFFERENT PMPA SPECIES IN dm^3 mol^{-1} s$^{-1}\times10^2$

Substrate	k_1	k_2	k_3	$\left(k_4\frac{K_a}{K_2}+k_5\right)$	k_6
OAB	8.1	4.1	4.02	24.7	1.20
PAB	6.3	3.5	2.83	23.5	0.88

k_1 values from the composite rate law (Eq. 13) compare well with those obtained from the k'^{-1} *vs.* $[H^+]$ plot in the pH region 0—1 where the neutral species of PMPA alone was assumed to be effective. Indifference of rate to added salt at pH 1 can also be rationalized by the steps postulated above.

To account for the pH dependence of rate in the pH region 3—7, it is reasonable to assume that both the substrate as well as PMPA species are dissociated and all species resulting from dissociation are involved in controlling the rate.

$$B \overset{K_a}{\rightleftharpoons} B^- + H^+ \quad (15)$$

$$H_2PO_5^- \overset{K_2}{\rightleftharpoons} HPO_5^{2-} + H^+, \quad K_2 = 4.2\times10^{-6}, \quad (16)$$

where B has the same meaning as before and B^- is

$NH_2C_6H_4COO^-$.

In the pH region under discussion, the major oxidant species[9] are $H_2PO_5^-$ and HPO_5^{2-}. The total PMPA concentration $[PMPA]_t$ can therefore be assumed to consist of $H_2PO_5^-$ and HPO_5^{2-}. Similarly, total substrate concentration $[B]_t$ can be assumed to be due to B and B^-:

$$[B]_t = [B] + [B^-] \quad (17)$$

and

$$[PMPA]_t = [H_2PO_5^-] + [HPO_5^{2-}]. \quad (18)$$

In view of the overall second order dependence at constant pH, the steps of the reaction in the pH region may be described as

$$B + H_2PO_5^- \xrightarrow{k_3} \text{Products} \quad (19)$$

$$B^- + H_2PO_5^- \xrightarrow{k_4} \text{Products} \quad (20)$$

$$B + HPO_5^{2-} \xrightarrow{k_5} \text{Products} \quad (21)$$

$$B^- + HPO_5^{2-} \xrightarrow{k_6} \text{Products}. \quad (22)$$

These steps also explain the marginal salt effect on the rate at pH 4.17 (Table 1). From Eqs. 19—22, the rate law can be written as

$$-\frac{d[PMPA]_t}{dt} = k_3[B][H_2PO_5^-] + k_4[B^-][H_2PO_5^-] + k_5[B][HPO_5^{2-}] + k_6[B^-][HPO_5^{2-}]. \quad (23)$$

Equation 23 can be rearranged to give the rate expression

$$-\frac{d[PMPA]_t}{dt} = \frac{k_3[H^+]^2 + \left(k_4\frac{K_a}{K_2} + k_5\right)K_2[H^+] + k_6K_aK_2}{(K_a + [H^+])(K_2 + [H^+])} \times [PMPA]_t[B]_t = k'[PMPA]_t[B]_t, \quad (24)$$

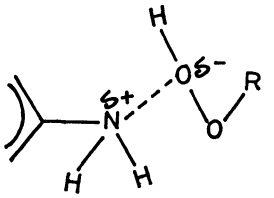
where

$$k' = \frac{k_3[H^+]^2 + \left(k_4\frac{K_a}{K_2} + k_5\right)K_2[H^+] + k_6K_aK_2}{(K_a + [H^+])(K_2 + [H^+])}. \quad (25)$$

Using the reported values[10] of K_a for OAB or PAB, the least-squares solution of Eq. 24 yields values of k_3, $\left(k_4\frac{K_a}{K_2} + k_5\right)$ and k_6 (Table 3). Substituting these least square values of k_3, $\left(k_4\frac{K_a}{K_2} + k_5\right)$ and k_6 in Eq. 25, log k'-pH profile was calculated (Figs. 1 and 2). The agreement between the experimental points and the theoretical line (Figs. 1 and 2) justifies the rate law.

The values of k_3, $\left(k_4 \cdot \frac{K_a}{K_2} + k\right)$ and k_6 suggest minimum reactivity for the reaction with HPO_5^{2-} species compared with $H_2PO_5^-$ which is in agreement with the decreasing electrophilicity of HPO_5^{2-} over $H_2PO_5^-$. We see fair agreement between k_3 (reaction between B and $H_2PO_5^-$ in the pH range 3—7) and k_2 (reaction between B and $H_2PO_5^-$ in the pH range 0—3) for both the substrates. This is in favour of the rate laws postulated to account for the rate variation over the entire pH range.

Mechanism. Polar mechanisms in peroxide reactions have been advanced on the basis[11] of a) bimolecular kinetics, b) negative entropy of activation, and c) insensitivity to radical trapping agents.



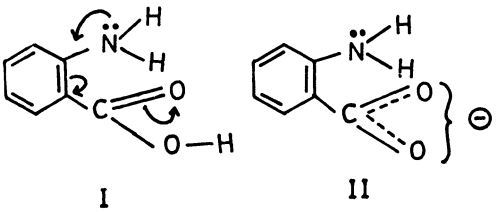
The present reactions confirm the above requirements and most probably involve polar transition states as shown in the following.

where $R = H_2PO_3$, HPO_3^-, or PO_3^{2-}.

Another question of importance is the nature of the peroxide attack, electrophilic *vs.* nucleophilic as dual character having been observed earlier[12,13] depending on the electronic environment. The species of PMPA namely H_3PO_5, $H_2PO_5^-$, HPO_5^{2-}, and PO_5^{3-} are in the decreasing order of electrophilicity. The fact that these aminobenzoic acids are not oxidized above pH 7 is strong evidence that the nucleophilic PMPA species are ineffective and the reaction essentially involves nucleophilic attack by the unprotonated amine on the electrophilic peroxo oxygen of the PMPA species. The rate should decrease with increase in pH.

The decrease in rate with increase in pH was not monotonic; there are two rate maxima-pH profiles, one at pH≈1, and the other at pH≈5, near the pK_a of the aminobenzoic acid. The rate maximum at pH 1 presents a situation where the concentration of the free base becomes maximum, the estimated K_H value being≈0.53. The amine is about 80% unprotonated at pH 1. The statistical distribution of H_3PO_5 and $H_2PO_5^-$ is 55 and 45% respectively. Even when the more electrophilic H_3PO_5 predominates at still lower pH, there is a marked decrease in rate because of the decrease in the unprotonated amine.

The second rate maximum around pH≈5 is unusual and the fact that this occurs near the pK_a of the carboxylic acid dissociation is of interest. The mesomeric effect taking place in the undissociated acid seems to cause a reduced nucleophilicity of nitrogen in I. In II, the carboxylate anion opposes the conjugation of amine lone pair and thus most probably increases the nucleophilicity of nitrogen.



I II

The formation of azoxybenzene-2,2′-dicarboxylic acid from anthranilic acid is of interest. The abnormal course of oxidation was recognized in the oxidation of 3-aminopyridine by H_2O_2/fuming H_2SO_4,[14] Caro's acid,[15] and PMPA.[1] Anthranilic acid is oxidized to the phenylhydroxylamine derivative in the rate limiting step and its oxidation to the nitroso derivative is fast as in the case of aniline, the rate of oxidation of aniline to phenylhydroxylamine being about five times lower than that of the oxidation of phenylhydroxylamine to

nitrosobenzene.[16] The formation of azoxybenzene-2,2′-dicarboxylic acid involves the rapid condensation[17] between the nitroso and phenylhydroxylamine derivatives which are the reactive intermediates.

The authors wish to thank Drs. S. N. Mahapatro and R. K. Panda of this department for helpful discussions and Mr. B. Dash for product study. Financial assistance from C.S.I.R. by way of award of fellowship to A.K.P. is gratefully acknowledged.

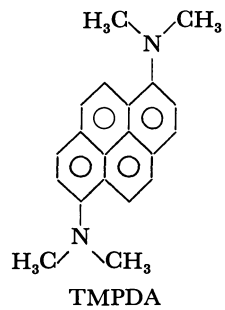
(Received July 7, 1980)

Synopsis. Monophotonic ionization of *N,N,N',N'*-tetramethyl-1,6-pyrenediamine (TMPDA) in acetonitrile was studied by means of ns laser photolysis and transient photocurrent measurement. The time dependences of the absorption of TMPDA cation radical and of the photocurrent were different. Photoionization thus occurs through an ion-pair state.

Photoionization of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in organic solvent has been extensively studied in order to clarify the primary process of the photoionization.[1] These studies showed that biphotonic ionization occurs through excited singlet and triplet states as the intermediates in non- or less-polar solvents. On the other hand, monophotonic ionization was observed in polar solvents such as acetonitrile.[2] However, the mechanism of the monophotonic ionization in such a solvent as acetonitrile has not yet been clarified. The difficulty encountered in the photolysis of TMPD in organic solvent is that the triplet-triplet (T-T) absorption of TMPD and the absorption of TMPD cation radical are observed in the same wavelength region, which makes kinetic treatment difficult.[1] We noticed that *N,N,N',N'*-tetramethyl-1,6-pyrenediamine (TMPDA) has a low ionization potential compared to TMPD,[3] and that the absorptions of the T-T transition and of the TMPDA cation radical are well separated. In order to clarify the mechanism of the monophotonic ionization, we studied the photoionization of TMPDA in acetonitrile by ns laser photolysis and transient photocurrent measurements.



TMPDA

Experimental

TMPDA was synthesized according to the reported procedure.[4] Acetonitrile was distilled four times in the presence of phosphorus pentoxide, followed by distillation in the presence of potassium carbonate. It was finally distilled without any additives. In the case of ns photolysis, we used a nitrogen laser (peak power of 400 kW and pulse width of 5 ns) as an excitation light source, and a Xe-flash lamp (3CP-3, EG & G Co., Ltd) as a monitor light. In the transient photocurrent measurements, we also used the nitrogen laser as an excitation light source. The sample cell has two stainless steel electrodes (1.45 cm×0.95 cm) with a spacing of 0.8 cm: 110 V was applied between them. Special care was taken not to irradiate the electrodes. A load resistance of 1 kΩ was used: this results in the time constant of 0.4 μs. The sample solution was always degassed several times by a freeze-pump-thaw method.

Results and Discussion

Figure 1 (a) shows the change of the electronic absorption spectra of the acetonitrile solution of TMPDA after N_2 laser excitation ([TMPDA]=3.5×10^{-4} mol/l). We can assign the absorption bands at 510 and 560 nm as the T-T absorption and that at 595 nm as the TMPDA cation radical.[5] The absorption band longer than 600 nm is probably due to the solvated electron.[6] Figure 1 (b) shows the change of the absorption of $TMPDA^+$ at 590 nm with time in the ns time range. Although we could not measure

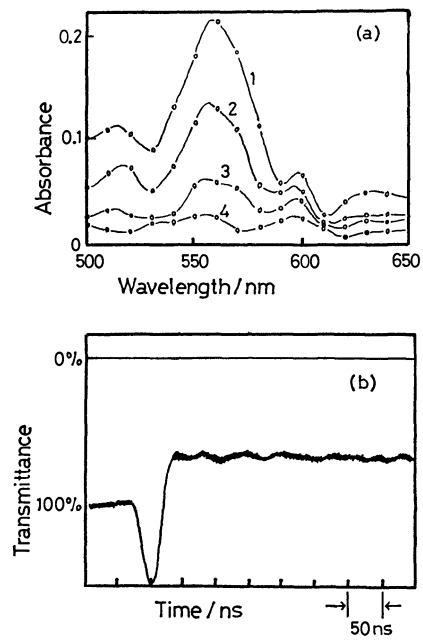


Fig. 1. (a) Time dependence of the absorption spectra of TMPDA in acetonitrile after N_2 laser excitation. 1, 0.4 μs; 2, 3 μs; 3, 10 μs; 4, 18 μs. (b) The change of the absorption of $TMPDA^+$ at 590 nm with time.

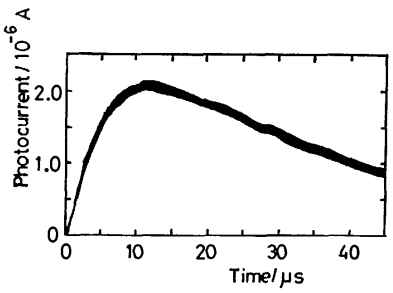

Fig. 2. Transient photocurrent of TMPDA in acetonitrile after N_2 laser excitation at 20 °C.

the absorption spectra of $TMPDA^+$ during the initial 50 ns after the laser pulse excitation because of the interference of the fluorescence of TMPDA, we assume that a TMPDA cation radical be produced immediately after the laser excitation. Figure 2 shows the transient photocurrent of the acetonitrile solution of TMPDA excited by the nitrogen laser at 20 °C ([TMPDA] $= 1.4 \times 10^{-4}$ mol/l). The curve showed gradual increase of the photocurrent during the initial 10 μs, and then the gradual decay of the current.[7] The plot of the peak photocurrent against the laser light intensity showed a linear relation, thus verifying the one-photon ionization of the present system.[8] In order to see whether photoionization occurs through the triplet state or not, we did the photocurrent measurement using a POPOP dye laser[10] ($\lambda_{max} = 418$ nm) as an excitation light source and anthracene as a triplet quencher of TMPDA.[11] The photocurrent measurement of the mixture of the acetonitrile solution of TMPDA and anthracene ([TMPDA] $= 1.04 \times 10^{-4}$ mol/l, [anthracene] $= 1.04 \times 10^{-3}$ mol/l) showed no obvious reduction of the photocurrent. On the other hand, the flash photolysis in the same system showed complete quenching of the T-T absorption. Thus, photoionization does not occur through the lowest triplet state of TMPDA.

If the electron were ejected directly by the laser pulse excitation in the one-photon ionization, the time-dependence of the absorption of $TMPDA^+$ and photocurrent should coincide. Figures 1 and 2 clearly show that this is not the case in the present system. The observed difference between the absorption and current may be ascribed to a cationic transient, which gives no current but shows an absorption similar to that of $TMPDA^+$. This transient seems to be an ion-pair of $TMPDA^+$ and an electron ($TMPDA^+e^-$). The ion-pair is produced by the laser pulse excitation

$$TMPDA \xrightarrow{h\nu} TMPDA^* \xrightarrow{\text{fast}} \underset{\text{ion-pair}}{TMPDA^+e^-} \xrightarrow{\Delta} TMPDA^+ + e^-$$

(probably through the singlet excited state) and dissociates thermally into free ions or recombines to give neutral TMPDA. One may ask whether an ion-pair can exist as long as 10 μs. It is noteworthy that the absorption of the solvated electron is observed for about 10 μs after the laser pulse excitation (Fig. 1 (a)). One possibility is that the TMPDA cation radical and a solvated electron form an ion-pair.

We are grateful to Dr. Masaaki Yokoyama, Faculty of Engineering, Osaka University, for constructing the nitrogen laser.

3) The half-wave oxidation potentials of TMPDA and TMPD are 0.49 and 0.1 V (*vs.* SCE), respectively (see Ref. 4).

4) H. Vollman, H. Becker, M. Correll, and H. Streek, *Ann.*, **531**, 1 (1937); A. Zweig, A. H. Maurer, and B. G. Roberts, *J. Org. Chem.*, **32**, 1322 (1967); TMPDA was purified by column chromatography (silica gel) using benzene as an eluent, and purified finally by two vacuum sublimations.

5) The 510 and 560 nm bands are assigned as the T-T absorption because of the following reasons. These bands decay exponentially with a life time of 11 μs, and they disappear completely by the addition of the triplet quencher, anthracene. The 595 nm band is assigned as the TMPDA cation radical because of the following reason. The same absorption spectrum is obtained by the one-electron oxidation of TMPDA with ferric nitrate, and by thermal ionic dissociation reaction of TMPDA with chloranil in acetonitrile.

6) A. Singh, H. D. Gesser, and A. R. Scott, *Chem. Phys. Lett.*, **2**, 271 (1968).

7) Similar curves are also obtained at 11, 30, and 40 °C.

8) When we compare the dependence of the photocurrent with the excitation laser intensity, we must consider the saturation effect. This effect is significant when the value *EH* exceeds 1 (see Ref. 9). Here *E* and *H* denote the absorption cross section of the molecule and photon number per unit area. In the present experimental condition, the maximum value of *EH* is 0.05. Thus, we need not worry about the saturation effect.

10) A dioxane solution of 1,4-bis(5-phenyl-2-oxazolyl)-benzene was excited by N_2 laser light to obtain the POPOP dye laser light.

11) The lowest singlet (S_1) and triplet (T_1) states o TMPDA and anthracene are as follows. TMPDA: S_1 2.91 eV, T_1 1.97 eV (estimated from the phosphorescence spectrum); anthracene: S_1 3.31 eV, T_1 1.85 eV.

Anomalous Solvatochromism of Charge-transfer Absorption Bands

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 15, 1980)

Synopsis. When n-donor solvents are employed, charge-tansfer absorption bands become broader on the low-energy side, the absorption peaks shifting toward the high-energy side. This type of solvatochromism has an analogy with that of the n-π^* transitions.

Despite continued interest in the charge-transfer (CT) complexes in the solution phase, various aspects of the electronic spectra remain unclarified.[1-3] As Offen and Abidi pointed out,[1] no current theory of solvatochromism can be applied assuredly to the CT absorption bands. In order to solve the problem, the absorption spectra of weak CT complexes were reexamined in various solvents. It was found that the CT absorption band changes with solvent. An attempt was made to interpret this phenomenon in terms of specific solvation.

In general, unsubstituted aromatic hydrocarbons are suitable as donor components for the study of solvent effects on binary CT complexes. Bulky substituents of the donor molecule suppress solvatochromism to some extent.[4] Naphthalene and tetracyanoethylene (TCNE) best illustrate the donor-acceptor pair for the present purpose. Figure 1 shows the electronic absorption spectra of the naphthalene–TCNE complex in four solvents. The first two absorption bands appear in the visible region, and have been assigned to the CT transitions from naphthalene to TCNE.[5] These CT bands are usually asymmetric in appearance.[6]

The peak of the first CT band moves in a wide range when the solvent is changed. There is an absorption peak at 17670 cm^{-1} in carbon disulfide while it shifts to 19800 cm^{-1} in acetonitrile. The difference in energy amounts to 2100 cm^{-1}. The peaks in the 1,2-dichloroethane and bromoethane solutions are located halfway at 18170 and 18940 cm^{-1}, respectively. Despite such a large displacement of the peak position, the absorption edge remains in almost the same position, light absorption beginning at *ca.* 14500 cm^{-1} in each solution. All solutions of the complex do not exhibit the absorption edge here; in solvents, such as hexane, cyclohexane, ethyl acetate, and methanol, the absorption edge shifts to *ca.* 15500 cm^{-1}. However, such a displacement of the edge is small as compared with that of the absorption peak. The first absorption peaks are located at 18980 cm^{-1} in hexane, at 18520 cm^{-1} in cyclohexane, at 20200 cm^{-1} in ethyl acetate, and at 20530 cm^{-1} in methanol. Consequently, broadening of the entire absorption band occurs as the peak position is displaced to the higher-energy side.

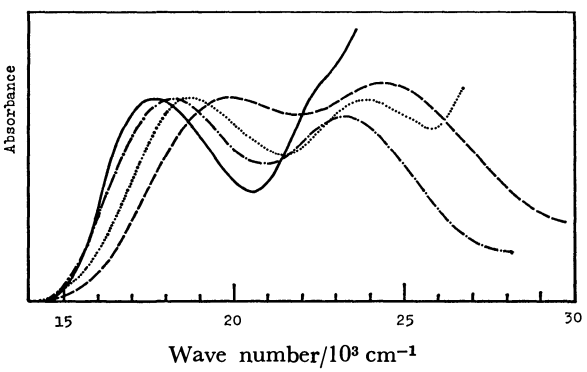

Fig. 1. Absorption spectra of the naphthalene–TCNE complex in carbon disulfide (——), 1,2-dichloroethane (—·—), bromethane (·····), and acetonitrile (– – –).

When hydrocarbon solvents, such as hexane and cyclohexane, are used, the absorption peak apparently follows the dielectric theory of solvatochromism.[2,7] However, most other solvents affect the CT band in quite a different manner. Even when a solvent has a large dielectric constant, it often gives rise to a large blue shift of the CT absorption band.[1-3] If we consider that a weak CT complex has a larger dipole moment in the excited state than in the ground state,[5] this is obviously inconsistent with the theory of solvatochromism described in terms of the refractive index and the dielectric constant of the solvent.[8] It is evident that the solvent dependence of the CT absorption band cannot be applied to the determination of the dipole moment of the excited-state complex by means of the dielectric theory.[9]

The absorption edge is closely related to the 0–0 vibronic level of the electronic transition. The first absorption band of the naphthalene–TCNE complex in the gas phase begins at 16900 cm^{-1} with a peak at 21100 cm^{-1}.[2] The edge shifts to the low-energy side by 2400 cm^{-1} when the complex is dissolved in the solvents given in Fig. 1; this indicates that both the 0-0 and higher vibronic levels move to the red in these solvents. The solvent shift caused by the dielectric effect, if any, should thus be evaluated as an energy shift of a certain (*i.e.*, fixed) vibronic level.

In principle, the absorption peak is related to the Franck-Condon (*i.e.*, vertical) transition. The shift of the CT absorption maximum along with the deformation of the band shape is determined mainly by the variation of the Franck-Condon transition level. It is evident that the first band maximum of the naphthalene–TCNE complex does not always represent a fixed vibronic level (Fig. 1). It is likely that the 0-1 vibronic level is the strongest in saturated-hydrocarbon solvents.[10] However, it seems that the higher vibronic levels are more intense in the other solvents although they are blurred. A plausible vibrational mode taking part in the first CT band of the naphthalene–TCNE complex is an intramolecular vibration with a frequency of about 1300 cm^{-1} in the excited state. The frequency was estimated from the fine structure in the CT bands of the saturated-hydrocarbon solutions.[10]

The systematic study so far carried out on weak CT complexes has enabled us to distinguish n-donor

solvents from other ones. Nagy *et al.* found that the n-donor solvents markedly shift the CT absorption band to the blue, and that the electron-donating power of the solvent is primarily responsible for the anomalous blue shift.[3] In line with this, the present observation revealed that the broadening of the CT band is conspicuous in such n-donor solvents as acetonitrile, ethyl acetate, and methanol. Therefore, it seems that the variation of the Franck-Condon envelope is substantially due to the coordination of n-donor-solvent molecules to the CT complex in the ground state.[3]

For example, acetonitrile is highly polar, and the molecular dynamics is highly anisotropic in the neat liquid.[11] An antiparallel arrangement seems to be the most probable orientational arrangement in acetonitrile. The acetonitrile molecules would, likewise, tend to be coordinated selectively to TCNE, since the C≡N bond moment of TCNE (3.6 D)[12] is comparable to the overall dipole moment of acetonitrile (3.92 D),[13] and acetonitrile has a large n-donor ability.[3,14] This suggests that the variation of the Franck-Condon envelope can be induced essentially by the solvation of the acceptor part (*i.e.*, TCNE). Thus, the vibrational mode which contributes to the first CT band of the naphthalene–TCNE complex might be ascribed to TCNE.

The above explanation is in line with that of McConnell[15,16] given to the blue shift of the n-π^* transitions, in which he states that the blue shift originates from the solvent molecules orienting themselves around the solute molecule to fit in with the ground-state charge distribution of the solute molecule. On excitation, if the charge distribution of the solute changes drastically (as in the case of n-π^* transitions and CT transitions alike), the solvent molecules would not have the position and orientation to bind most strongly with the excited-state charge distribution. This would give rise to the blue-shift phenomenon, since (relative to a saturated-hydrocarbon solvent) an n-donor solvent would give a greater solvation energy for the ground state of the solute than for the excited state. The resulting absorption peak would become much higher in energy than the relaxed excited state. This would give rise to the broadening of the absorption band on the low-energy side.

In conclusion, the anomalous blue shift, accompanied by band broadening, is commonly observed in the absorption spectra of weak CT complexes in solution. This blue-shift phenomenon seems to have caused great confusion in the analysis of solvent shifts.[1-3,9]

The Separation of Solutes with Different Diffusion-coefficients by Two-layer Convection

Katsuyoshi KAMAKURA

Department of Industrial Chemistry, Toyama Technical College, Hongo-cho, Toyama 930-11

(Received July 18, 1980)

Synopsis. When a two-layer system which consists of water (upper layer) and an aqueous solution (lower layer) is heated from one side and cooled from the opposite side, a convection starts in each layer. The empirical formula for mass transfer between the convections was studied for a system of water containing a mixture of solutes; the flux of a solute in the mixture was found to be proportional to the square root of the diffusion coefficient of the solute. Therefore, solutes with different diffusion-coefficients can be separated by two-layer convection.

When a two-layer system which consists of water (upper layer) and an aqueous solution (lower layer) is heated from one side and cooled from the opposite side, a convection starts in each layer. We have already studied the system of a solution of one solute and have presented an empirical formula for mass transfer between convections.[1] From this formula, the flux of a solute in a mixture of solutes can be presumed, under certain conditions, to be proportional to the square root of the diffusion coefficient of the solute. Therefore, the separation of solutes may be done by the two-layer convection for a mixture of solutes. The purpose of this investigation is to discuss the possibility of the separation of solutes by this method.

Theoretical

In a previous paper[1] the empirical formula of mass transfer was presented for the two-layer convection in the case of a solution of one solute. Then, the flux, W_A, of a solute, A, was expressed by

$$W_A = a_1(\Delta\rho_1 - \Delta\rho_0)D^{0.5}(\Delta c_I/\Delta\rho_2). \quad (1)$$

Here, a_1 is the mass-transfer coefficient; $\Delta\rho_1$, the density difference between the liquid on the heated wall and that on the cooled wall; $\Delta\rho_0$, a constant; D, the diffusion coefficient of a solute; and Δc_I and $\Delta\rho_2$, the concentration difference and the density difference respectively between the solution of the upper layer and that of the lower layer.

In this paper we will discuss the mass transfer in the case of a mixture of two solutes. If the temperatures of cooling and heating are constant, $(\Delta\rho_1 - \Delta\rho_0)$ is approximately constant for a solution of different solutes. Then, the flux, W_x, of a solute, x, in a mixture may be expressed as follows:

$$W_x = a_2 D_x^{0.5}(\Delta c_x/\Delta\rho_2), \quad (2)$$

where a_2 is the mass transfer coefficient. The D_x[2] and the Δc_x are the values for a solute, x, while the $\Delta\rho_2$ is the density difference between the solutions. The $\Delta c_I/\Delta\rho_2$ was constant for the system of a solution of one solute. For that of two solutes, the $\Delta c_x/\Delta\rho_2$ will also be constant if the ratio of the amounts of solutes in a layer is constant while the two-layer convection is occurring, or if the amount of a solute, x, is very much larger than that of the other solute. Generally, the $\Delta c_x/\Delta\rho_2$ will be roughly constant for a small change of $\Delta\rho_2$. The ratio, W_x/W_y, of the fluxes of the two solutes is, then, expressed as follows:

$$W_x/W_y = (D_x D_y)^{0.5}(\Delta c_x/\Delta c_y). \quad (3)$$

When the Δc_x is equal to Δc_y, the W_x/W_y is expressed as follows:

$$W_x/W_y = (D_x/D_y)^{0.5}. \quad (4)$$

Experimental

The materials and apparatus used in this study were similar to those described in a previous paper.[1] The nitrates were used for the system of a solution of two electrolytes, while the chlorides were used for the other system (electrolyte-organic compound). The soluble starch was obtained from the Wako Pure Chem. Co. and was used without further purification. The temperatures of the heating and cooling water were 30 and 20 °C respectively, and the flow speed of those waters was 1.6 $dm^3\ min^{-1}$. The concentration of the electrolyte was determined by atomic absorption spectrometry, while that of the organic compound was determined by colorimetry as reported by Dubois *et al.*[3] The samples (30—50 mm^3) for the determination of the solute concentration were taken out from the solution in the middle of the upper layer.

Results and Discussion

We examined the system of a solution of two solutes (mass ratio; 1:1) in order to separate the solutes, and investigated the relation between W_x/W_y and $(D_x/D_y)^{0.5}$. Figure 1 shows a case in which the concentrations in the lower layer are low, while the

relation between the concentration in the upper layer and the time is nonlinear. Figure 2 shows a case in which the concentrations in the lower layer are high and the relation is linear. If the relation is linear, the W_x or W_y can easily be evaluated. Therefore, subsequent experiments were carried out on the systems with the high concentrations.

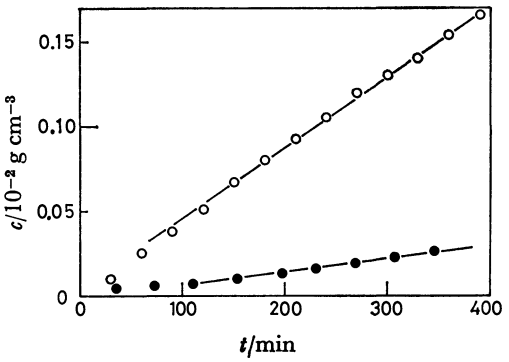

Fig. 4. Variation of concns in upper layer.
○: KCl, ●: starch.
Concns in lower layer at the start of convections; KCl: 1×10^{-2} g cm^{-3}, starch: 1×10^{-2} g cm^{-3}.

As Fig. 3 shows, W_x/W_y is equal to $(D_x/D_y)^{0.5}$.[2] Therefore, Eq. 4 seems to be proper and the separation of solutes is possible.

Figure 4 is the plot for the system of a solution containing an electrolyte (low molecular weight) and a starch. The electrolyte mainly moves from the lower layer to the upper layer. Nevertheless, the starch gradually moves to the upper layer. The diffusion coefficient of the starch was calculated by means of Eq. 4 from the two slopes for each solute. The value thus obtained, 0.72×10^{-6} cm^2/s, agreed with the order of the data (0.8×10^{-6} cm^2/s) in the literature.[4]

In view of the above results, we conclude that the separation of solutes is possible by this method.

Spin Densities in the Radical Anion of 3,3′-Bipyridine

Hideo FUJITA* and Yasuo DEGUCHI

Department of Chemistry, College of Liberal Arts and Sciences, Kyoto University, Kyoto 606

(Received September 1, 1980)

Synopsis. The ESR spectrum of the radical anion of 3,3′-bipyridine has been measured. The hfs constants agree with the calculated values based on the spin densities using the McLachlan method.

Although the ESR spectra of the radical anion of 2,2′-[1-4] and 4,4′-bipyridines[5-7] are known, the radical anion of 3,3′-bipyridine has not been investigated by ESR tecniques. Therefore, it is of interest to measure the ESR spectrum of the radical anion of 3,3′-bipyridine in order to compare the spin distribution of this radical anion with those of 2,2′- and 4,4′-bipyridine. We wish to report here an ESR study of the radical anion of 3,3′-bipyridine.

The radical anion was generated by the reduction of 3,3′-bipyridine, which had been prepared from 3,3′-bipyridine-2,2′-dicarboxylic acids by the method of Smith,[8] with potassium metal in 1,2-dimethoxyethane (DME). This solution was investigated by ESR spectroscopy in the temperature range from 85 to −85 °C.

The intense well-resolved ESR spectrum measured at 80 °C of the radical anion of 3,3′-bipyridine is shown in Fig. 1a (g=2.0024). Figure 1a consists of hyperfine splitting (hfs) constants due to the equivalent protons, a_H=0.626, 0.582, and 0.115 mT and the nitrogens, a_N=0.094 mT (see Table 1). Using these parameters, the computer-simulated spectrum shown in Fig. 1b was obtained; it agreed well with the observed spectrum. On the other hand, we could not obtain the well-resolved ESR spectra at temperature lower than room temperature. Probably, this is due to the overlap of the hfs constants, because these spectra have a slight different values from the above hfs constants. In consequence, we can not yet analyze these spectra.

In order to assign the hfs constants, we have carried out MO calculations.[9] The results are summarised, together with the observed hfs constants, in Table 1. The most interesting features are the approximately equal and large hfs constants of the γ- and ε-protons, and the hfs constant of the α-protons, which is smaller than the simulated linewidth, 0.007 mT.

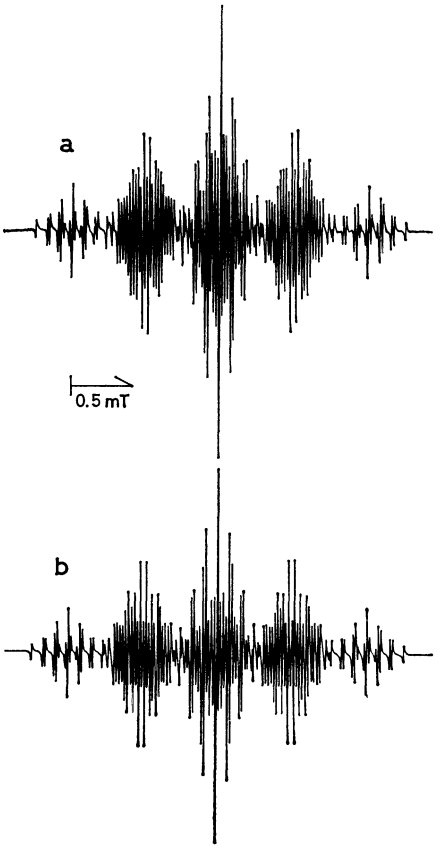

Fig. 1. (a) The observed ESR spectrum of the radical anion of 3,3′-bipyridine: solvent, DME; counterion, K^+; at 80 °C. (b) The spectrum simulated by means of the hfs constants listed in Table 1: lineshape, Lorentzian; linewidth, 0.007 mT.

TABLE 2. THE hfs CONSTANTS OF THE RADICAL ANIONS OF BIPHENYL, BIPYRIDINES, AND BIPYRIMIDINE

Radical anion	hfs constants/mT				
	$a_{H\alpha}$	$\alpha_{H\beta}$	$a_{H\gamma}$	$a_{H\delta}$	$a_{H\varepsilon}$
Biphenyl[a]	0.266	0.041	0.531	0.041	0.266
4,4′-Bipyridine[b]	0.235	0.043	0.364[e]	0.043	0.235
2,2′-Bipyridine[c]	0.258[e]	0.057	0.470	0.120	0.106
2,2′-Bipyrimidine[d]	0.141[e]	0.015	0.498	0.015	0.141[e]

a), b), c), and d) Values reported in Refs. 10, 6, 4, and 11. e) These are the hfs constants of the nitrogen atoms.

We can recognize the suitability of the assignments for the hfs constants (see Table 1) of the radical anion of 3,3′-bipyridine, which are compared with the hfs constants of various radical anions of biphenyl,[10] 2,2′- and 4,4′-bipyridines,[4,6] and 2,2′-bipyrimidine[11] in Table 2. That is, the hfs constant of the nitrogens for the radical anion of 3,3′-bipyridine is a usual value, while the $a_{H_\alpha} \simeq 0$ and $a_{H_\epsilon} = 0.582$ mT values are unsual in comparison with the hfs constants of other bipyridines. However, the hfs constants agree well with the MO calculated values, as is shown in Table 1. Therefore, as an example to facilitate comparison with the a_{H_α} and $a_{H_\epsilon} = 0.235$ mT of the radical anion of biaxial symmetric 4,4′-bipyridine,[6] the computed average value of the hfs constant for the radical anion of 3,3′-bipyridine is about 0.29 mT and is normal. All thing considered, each of the three radical anions of bipyridine isomers has a proper hfs constant and a different MO calculated spin-density distribution[3,6] because each molecule containing two nitrogen atoms has a different space-coordination.[12,13] In conclusion, we have found that the ESR spectrum of the radical anion of 3,3′-bipyridine consists of the hfs constants shown in Table 1, and the spin densities calculated using the McLachlan method[9] satisfy the experimental values.

Structure of the Complex of Neodymium Nitrate with Pentaethylene Glycol

Yoshiyuki HIRASHIMA,* Koji KANETSUKI, Jiro SHIOKAWA, and Nobuo TANAKA**

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received September 12, 1980)

Synopsis. Crystals of the complex, $Nd(NO_3)_3$–$HO(CH_2CH_2O)_5H$, are monoclinic. The Nd atom is coordinated by ten oxygen atoms, four from two bidentate nitrate ions and six from a pentaethylene glycol. The pentaethylene glycol forms a ring-like structure similar to that of crown compounds.

The preparation of the solid complexes of lanthanoid ions with macrocyclic polyethers was reported,[1-4] some structures being determined by X-ray crystallography.[5-7] It was found that some noncyclic polyethers form solid complexes with lanthanoid nitrates, their stability appearing to decrease with increasing atomic number of the lanthanoid in contrast to the lanthanoid complexes of most ligands.[8] This behavior is similar to that of the complexes of 18-crown-6,[9] and might be related to the structures of the complexes. X-Ray diffraction studies were carried out on the structure of the complex of pentaethylene glycol (denoted by EO5) with neodymium nitrate, the results of which are given in this report.

Crystals suitable for X-ray study were obtained by adding a dilute ethyl acetate solution of neodymium nitrate to an ethyl acetate solution of EO5 and then standing the resulting solution for crystal deposit.

Crystal data: $Nd(NO_3)_3\cdot(C_{10}H_{22}O_6)$, F.W.=568.5, monoclinic, space group $P2_1/n$, a=8.220(2) Å, b=15.072(3) Å, c=17.089(4) Å, β=110.80(2)°, V=1979.2(6) Å^3, D_{calcd}=1.91 g cm^{-3} for Z=4, D_{obsd}=1.90 g cm^{-3}, μ(Mo $K\alpha$)=27.2 cm^{-1}.

A crystal was sealed in a 1 mm diam. glass capillary because of its deliquescence. Intensity data were collected with a Rigaku automated four-circle diffractometer using β-filtered Mo $K\alpha$ radiation. The 2θ-ω scan technique was employed with a scan speed 4°/min on 2θ. A scan range of 1.4° plus θ-dependent dispersion term was used. A total of 4189 reflections were obtained. Net intensities of 1354 reflections were observed as zero. Lorentz and polarization corrections, but no absorption correction, were made.

The structure was solved by the heavy atom method, the atomic parameters except for the hydrogen atoms being refined by the block diagonal least squares method.[10] The weighting scheme applied was as follows, w=1 if $|F_o|>2.5$; w=0.3 if $|F_o|<2.5$. After several cycles of the calculation with anisotropic temperature factors, the R factor was converged to 0.11.

Figure 1 shows the structure of the complex $Nd(NO_3)_3\cdot HO(CH_2CH_2O)_5H$. The bond lengths and bond angles are given in Table 1.†

† The complete F_o-F_c data and the table of atomic parameters are deposited as Document No. 8122 at the Chemical Society of Japan.

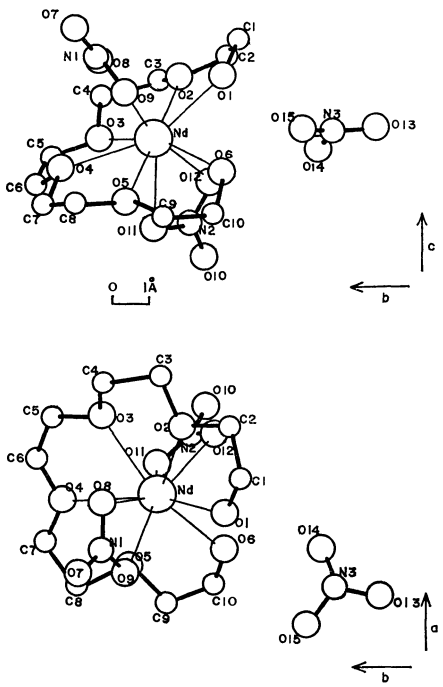

Fig. 1. Structure of $Nd(NO_3)_3\cdot EO5$.
Top: Projection along [001]. Bottom: Projection onto [001].

The Nd atom is coordinated by ten oxygen atoms, four from two nitrate ions and six from a pentaethylene glycol (EO5). The coordination polyhedron is similar to that based on bicapped-dodecahedron,[11] though it is irregular. The pentaethylene glycol acts as a hexadentate ligand forming a ring-like structure with its oxygen atoms. The ring-like structure is similar to the structure of so-called crown compounds. The six oxygen atoms of EO5 are not quite coplanar, their shifts from the mean plane being in the range 0.03—0.83 Å. The Nd atom is located near the center of the hexagon of the oxygen atoms of EO5. The angles of O_i–Nd–O_{i+1} (i=1—5) are close to 60° (60—63°), while the angle of O_1–Nd–O_6 is 67° a little higher than the others. This can be attributed to the large shifts of the two terminal oxygen atoms from the mean plane (0.64 and 0.83 Å). Above and below this mean plane two nitrate ions coordinate to a Nd atom as a bidentate ligands. The angle of N_1–Nd–N_2 is 169°, the bi-capped units being slightly distorted from the ideal form. A third nitrate ion does not coordinate to a Nd atom (the nearest Nd–O distance: 4.6 Å).

The average Nd–O bond length is 2.54 Å, which is between the bond lengths of La–O and Tb–O (2.6

and 2.47 Å, respectively) reported for bis(bipyridyl)-trinitratolanthanoids which are decacoordinate complexes.[11,12] The sequence of the bond lengths is reasonable in view of the expected contraction in radius for the lanthanoid series.

The tortion angles in EO5 are given in Table 2. The conformation around the CH_2–CH_2 bonds are all nearly gauche, while those around the CH_2–O bonds are all approximately trans. The conformation for CH_2–CH_2–O–CH_2–CH_2–O–CH_2 is GTT$\bar{G}$TT, which was reported by Iwamoto[13] to be the most stable conformation, where T, G, $\bar{G}$ denote trans, gauche, and minus gauche, respectively. Some of the angles around the CH_2–CH_2 bonds are considerably lower than 60°. The deviation can be attributed to the deformation of the EO5 molecule from the ideal form in order to maintain the Nd–O distances at suitable lengths for coordination.

The Methylation of Ribonucleosides by Trimethyl Phosphate or Dimethyl Sulfate in the Presence of Boric Acid

Yorisato HISANAGA, Toshizumi TANABE, Kiyoshi YAMAUCHI,* and Masayoshi KINOSHITA

Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 13, 1980)

Synopsis. Uridine, inosine, adenosine, and thymidine were methylated selectively at the base moieties by the use of trimethyl phosphate or dimethyl sulfate in the presence of boric acid. A suppressing effect of boric acid on the methylation of the ribose-hydroxyl groups was discussed briefly.

Alkylation reactions of nucleosides have been carried out in various ways in the search for useful physiological activity of the products.[1,2] The study has been also stimulated by the discovery of a variety of alkylated nucleosides from RNA.[3] The direct alkylation of nucleosides, however, frequently provides a mixture of mono- and multialkylated nucleosides, giving a desired product in a small yield.

In this paper we wish to report the selective methylation of ribonucleosides at the base moieties by the use of trimethyl phosphate (TMP) and dimethyl sulfate (DMS) in the presence of boric acid.

The reactions were carried out by stirring mixtures of a nucleoside, TMP or DMS, and boric acid at pH>12 and at 25 or 50 °C. The reaction sizes and results are summarized in Table 1. It was found generally that methylation at the base moieties of nucleosides was hardly affected at all by boric acid, whereas methylation on hydroxyl groups of the ribose moieties (*O'*-methylation) was suppressed with an increase in the amount of boric acid, the effect reaching its maximum when the amount of boric acid used was approximately equivalent to that of the nucleosides. For instance, the treatment of uridine with TMP in the absence of boric acid produced 3-methyl-, 3,$O^{2'}$-dimethyl-, and 3,$O^{3'}$-dimethyluridines in 51, 25, and 10% yields respectively; by contrast, the reaction in the presence of the acid afforded 3-methyluridine in a 78% yield and the dimethyluridines in combined yields of only 9% (Run 1 of the Table 1). Although DMS was more reactive than TMP, methylation by DMS gave results similar to those obtained with TMP.

The selective methylation at the base moieties of ribonucleosides is attributable to the decreased *O'*-methylation by boric acid. Possibly, the ribose hydroxyl groups were deactivated by complex formation with the acid (Fig. 1). A similar complex formation has been suggested in the phosphorylation of ribonucleosides,[4] the acylation of carbohydrates,[5] *etc.*[6] The NMR spectra of mixtures of ribonucleosides and boric acid also indicated a complex structure. Thus, the addition of the acid to an aqueous solution of a nucleoside considerably shifted the absorption signals of the ribose-protons, especially 2'-H and 3'-H. Figure 2 shows the NMR spectra of the ribose moiety of uridine as an example.

After the reactions, the boric acid was removed easily as the methyl ester from the reaction mixtures by coevaporation with anhydrous methanol.

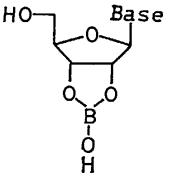

Fig. 1.

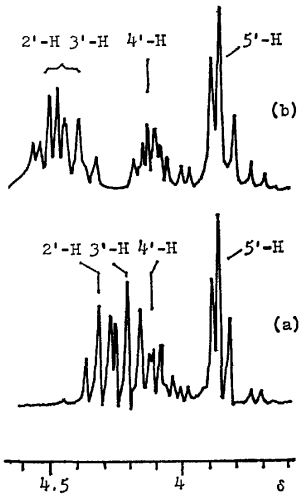

Fig. 2. ^{1}H-NMR (100 MHz) spectra of the ribose moiety of uridine (0.25 mol/l): (a) in the absence of boric acid: (b) in the presence of the acid (0.25 mol/l).
Solvent: D_2O, temperature: 25 °C, pH: *ca.* 12, spectrometer: JEOL PS 100. 3-(Trimethylsilyl)propionic acid-d^4 sodium salt was used as the internal standard.

Experimental

General Methylation Procedure. The reaction sizes and conditions are described in Table 1. A mixture of a nucleoside, a methylating agent, and boric acid in water was heated at 25 or 50 °C and at pH>12. The pH value of the solution was maintained by the occasional addition of 1 mol dm^{-3} sodium hydroxide. The progress of the methylation reactions was checked by silica-gel thin-layer chromatography (TLC) using the solvents employed previously.[2,7]

The reaction mixture was concentrated and washed with benzene or diethyl ether to remove the methylating agent unreacted. Anhydrous methanol was then added to the residue, and the solution was concentrated under reduced pressure. This coevaporation procedure was repeated several times to remove the boric acid completely. The resulting reaction mixtures were placed in a silica-gel column (Merck, 7734, 100—200 mesh) using the solvents indicated in Footnote c of Table 1. The yields and mp's of the prin-

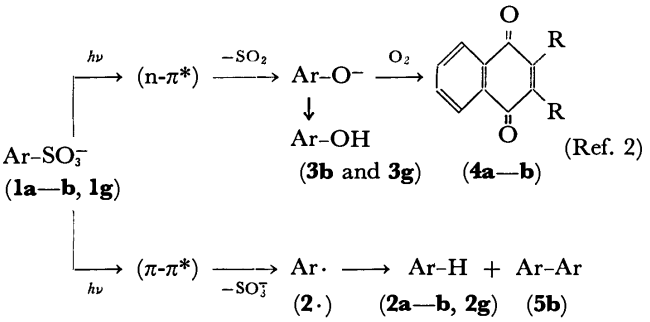
Photolysis of Sodium Arenesulfonates in Alkaline Dimethyl Sulfoxide Solutions[1,2]

Nobutaka Suzuki,* Kinya Ito, and Yasuji Izawa
Chemistry Department, Faculty of Engineering, Mie University, Tsu, Mie 514
(Received April 21, 1980)

Synopsis. Photolysis of arenesulfonates in alkaline DMSO under air gave the corresponding desulfonation products, arenes, presumably *via* the π-π^* excited triplet state.

With respect to the relationship between the photochemical behavior and electronic configuration (n-π^* or π-π^*) of the excited states of the arenesulfonates, a report was given on a new photoelimination of SO_2 (desulfonylation) of sodium 9-anthracene-, 1-naphthalene-, and mesitylene-sulfonates (**1a—b** and **1g**) *via* n-π^* excited states, along with photoelimination of SO_3 (desulfonation) *via* π-π^* excited states.[2] This seems to be the first example of the photodesulfonylation of sulfonic acids. Ogata *et al.*[3] reported on a photochemical reaction of benzenesulfonic acid in an aqueous alkaline solution, giving benzene (16%) and biphenyl (1%) and assumed to involve an initial radical fission of C–S bond giving Ph· and $\cdot SO_3H$ radicals. In this report we describe the photolysis of arenesulfonates (**1a—f**) in alkaline DMSO to give the corresponding arenes (**2**) by desulfonation almost as the sole product, presumably *via* the π-π^* excited state.



a: Ar=g-Anthryl, **b**: Ar=1-Naphthyl, **g**: Ar=Mesityl

Solutions of the sulfonic acids (**1a—f**: *ca.* 5 mmol/l) in DMSO with aqueous 1 mol/l NaOH were irradiated with a low-pressure mercury lamp (30W) in quartz cells at tap-water temperature. The photoreactions were monitored by GLC. The results are summarized in Table 1. It was found that the photolysis of **1d—f** gives the parent hydrocarbons (**2**), photodesulfonation products, whereas **1a—c** yielded traces of a quinone (**4a**), or 1- or 2-naphthol (**3b** or **3c**) besides the parent hydrocarbons (**2a—b**) as main products. The results significantly differ from those obtained by the experiments in aqueous medium. In aqueous solutions, photodesulfonylation was distinctly

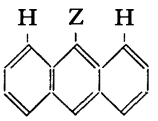
$$\underset{\textbf{1a—f}}{Ar\text{-}SO_3^-} \xrightarrow[DMSO/H_2O]{h\nu} (\pi\text{-}\pi^*) \longrightarrow \underset{\textbf{2a—f}}{Ar\text{-}H}$$

a: Ar=9-anthryl; **b**: Ar=1-naphthyl;
c: Ar=2-naphthyl; **d**: Ar=*o*-tolyl;
e: Ar=*p*-tolyl; and **f**: Ar=phenyl

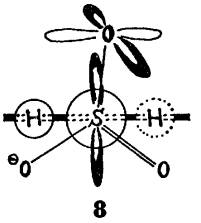
observed for **1a—b**.[2]

DMSO accelerates reactions of anions in contrast with the reduced activity of hydrogen-bonded anions in protic solvents of comparative dielectric constants.[4] A (π-π^*) excited state is more ionic than an appropriate (n-π^*) excited state considered to be biradical. Hence, in DMSO, preference of the desulfonation ($-SO_3$) to the desulfonylation ($-SO_2$) can be expected.

Steric effect of the sulfonyl group on the peri H atom(s) (**1a—b**) or the *o*-methyl group (**1d**) can be expected for the present reactions by the analogy of a similar photoelimination of 9-nitro- and 9-carboxy-anthracene (**6** and **7**),[5] whose nitro and carboxyl functional groups are not coplanar, not being able to resonate with aromatic rings[5] due to the steric hindrance with the peri H atoms. In contrast to **6** and **7**, the sulfonyl group is tetrahedral and the hindrance with the peri H atoms would not inhibit the coplanarity between one of the three S–O bonds and the aromatic nucleus as shown in formula **8**.



6: Z=NO_2
7: Z=CO_2H



8

The data showing absence or presence of a trace of desulfonylation, obtained by changing the arene moieties attached to the sulfonyl groups for the purpose of differentiating the effect of peri H atom on the sulfonyl groups (*i.e.*, **1a**, **1b**, **1d**, and **1f**: also **1c** and **1e** were employed) supported the above interpretation on the steric effect.

It seems that the arene moieties determine the electronic configurations (n-π^* or π-π^*) of the S_1 and T_1 excited states of the arenesulfonates and also the reaction course. In contrast to the results in aqueous solution where desulfonylation and desulfonation of **1a** proceed *via* T_1 (n-π^*) and T_2 (π-π^*), respectively,[2] quenching experiments of **1a—c** in DMSO with 1,3-pentadiene on the fluorescence (not quenched), desulfonation (quenched), and desulfonylation (not quenched) revealed that desulfonation occurs *via* T and not S_1, and that desulfonylation might proceed *via* S_1 in DMSO. The results could be explained if the desulfonation and desulfonylation in DMSO proceed *via* T_1 (π-π^*) and S_1 (n-π^*), respectively. The relative stability of n-π^* and π-π^* excited states of **1a** might be inverted in water and in DMSO. Stern-Volmer plots of the other sulfonates with 1,3-pentadiene to the reaction products suggest that the desulfonation proceeds *via* T_1 excited states. Large viscosity of DMSO might cause relatively small rates of diffusion

of 1,3-pentadiene, and no quenching of the fluorescence and desulfonylation. Measurement of viscosity of DMSO, however, eliminated the possibility, the observed diffusion constant, $k_{dif.}$ being 3.80×10^9 l/mol, which is in the range of that of the other organic solvents ($k^{25}_{dif.}=10^9$—10^{10}).[6]

Experimental

Fluorescence and phosphorescence spectra were recorded on a Hitachi MPF-2A spectrometer and GLC on a Yanagimoto Yanaco G-1800F gas chromatograph.

Materials. Sodium anthracene-9-sulfonate (**1a**) was prepared according to the method worked out by Yura and Oda.[7] Commercial sodium naphthalene-1- and -2-, *o*- and *p*-toluene-, and benzene-sulfonates (**1b**—**1f**), and commercial authenitic samples (**2a**—**f**, **3b**—**f**, **4a**—**b**, **4f**, and **5b**) were used. DMSO was distilled *in vacuo* from CaH_2. 1,3-Pentadiene was distilled before use in quenching experiments.

General Method for Photolyses of 1a—f. A solution of compound **1** (*ca.* 5 mmol/l) in DMSO (3 ml) and aqueous 1 mol/l NaOH (100 μl) was irradiated with a low pressure mercury lamp (30 W, Eikosha; P1L-30) in a quartz cell (ϕ 10 mm) at tap-water temperature (*ca.* 15 °C). The reaction was monitored at intervals by GLC. The product(s) was identified and the yields were determined by comparison with the corresponding authentic sample(s) on GLC (Table 1). GLC were afforded on 10% Silicone SE-GE-31 on Diasolid L (60—80 mesh) for **1a**, **1d**—**e**, and **1f**, and on Apiezon L on Diasolid L, 2.2 m for **1b**—**c**.

Solvent Effect of 1 on Fluorescence and Phosphorescence Spectra. The 0-0 bands of fluorescence and phosphorescence spectra of **1a**—**f** were measured in various solvents at 77 K in a quartz cell. The results showed the electronic configurations (π-π^* or n-π^*) of the S_1 and T_1 excited states of **1a**—**f** to be n-π^* for S_1 and π-π^* for T_1.

a) Yields based on the starting material used. b) Not detected. c) Photolysis in aqueous solution (Ref. 2).

Quenching with 1,3-Pentadiene. (a) Quenching on fluorescence of **1** in DMSO (5.0 mmol/l) with various concentrations of 1,3-pentadiene (1.3, 2.9, 5.2, 10.3, and 20.7 mmol/l) was observed by means of the MPF-2A spectrometer at 25 °C. (b) Quenching on the products of desulfonation and/or desulfonylation from **1** in DMSO (5.0 mmol/l) with various concentrations of 1,3-pentadiene in air was observed by GLC. The $k_q\tau$ values were calculated from the slopes of the Stern-Volmer plots.[8] The fluorescence and desulfonylation of **1a**—**c** were not quenched, while desulfonation of **1a**—**c** was quenched, the $k_q\tau$ values being 2.6×10, 7.4×10, and 5.8×10, respectively.

Viscosity of DMSO. The viscosity of DMSO used was calculated from the equation

$$\eta_{DMSO} = \eta_{H_2O}\cdot(\rho_{DMSO}\cdot t_{DMSO})/(\rho_{H_2O}\cdot t_{H_2O})$$
$$= 8.004^{9)}\times1.1014^{10)}\times122.3/(0.9956756^{9)}\times61.0)$$
$$= 17.751 \text{ (mpoise)},$$

the values of $t^{30°}_{H_2O}$ and $t^{30°}_{DMSO}$ being measured with an Ostwald viscometer. From the results the diffusion constant $k_{dif.}$ in DMSO was estimated by

$$k_{dif.} = 8RT/3000\eta \text{ (l/mol s)} = 3.80\times10^9 \text{ (l/mol s)},^{11)}$$

where

$$R = 8.314\times10^7 \text{ erg K}^{-1}\text{ mol}^{-1}.$$

11) An upper limit to the magnitude of the bimolecular quenching constant k_q of $k_q\tau$ calculated from the slope of Stern-Volmer plots is usually set by the rate of diffusion ($k_{dif.}$) of the excited state and quencher (1,3-pentadiene) into a solvent cage; see Ref. 6, p. 260.

A New Route to Vitispiranes

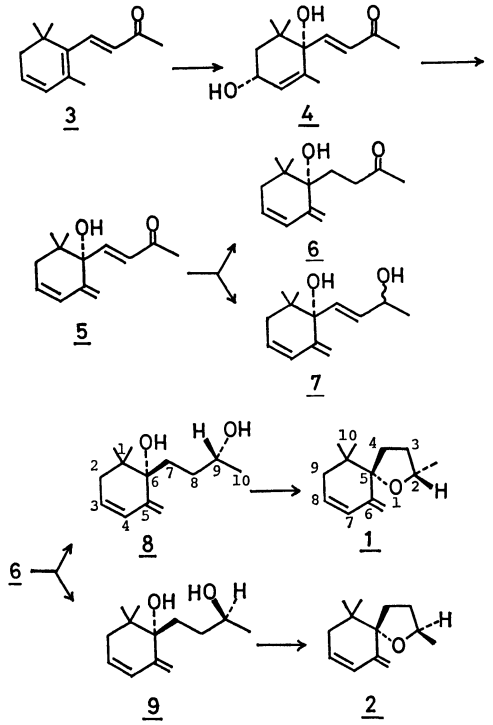
Tetsuya KATO* and Hisao KONDO

Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura 248

(Received April 26, 1980)

Synopsis. Diastereoisomeric vitispiranes have been synthesized from 2,6,6-trimethyl-1-(3-oxo-1-butenyl)-1,3-cyclohexadiene by five-step reactions including photooxygenation.

Vitispirane, an odoriferous C_{13} spiro-ether, was initially found in the aroma volatiles of grape juice (vine sp. *Vitis vinifera*), as well as in table and fortified wines and in distilled spirits.[1] Recently Ohloff *et al.* have also isolated vitispirane from the volatiles of a vanilla extract and have shown the presence of (2*RS*,5*RS*)- and (2*RS*,5*SR*)-vitispiranes (**1** and **2**) in the vanilla extract; their relative configurations were established by stereoselective synthesis.[2] In relation to our own interest in devising simplified approaches to the synthesis of ionone-related flavorants, we have developed an alternative synthesis of vitispiranes (**1** and **2**) from an easily accessible dehydroionone **3**.[3] Our synthetic route is outlined in the following scheme.



The photosensitized oxygenation of the dehydroionone **3**,[4] followed by the reduction of the resulting peroxide with thiourea,[5] provided the *cis*-diol **4**.[6] The subsequent treatment of **4** with dimethyl sulfoxide[7] at 140 °C for 8 h afforded the crystalline triene ketone **5** in a 47% yield. The conjugate reduction of the α,β-unsaturated ketone of **5** with $LiAlH(OMe)_3$–CuBr[8] in tetrahydrofuran at −20 °C provided the diene ketone **6** in a 48% yield. Although a high selectivity for 1,4-addition was reported by Semmelhack *et al.* with a variety of cyclic and acyclic α,β-unsaturated ketones,[8] the formation of a 1,2-adduct **7** in a moderate yield was also observed in the reduction of **5**. When the reagent prepared from $LiAlH_4$–CuI[9] was employed, the 1,2-adduct **7** was obtained as the major product.

The reduction of **6** with sodium borohydride in ethanol gave the diastereoisomeric diene diols, **8** and **9**, in a ratio of *ca.* 7:1. The pure **8** was obtained by the recrystallization of the mixture. The diene diol **8** was stereospecifically cyclized[10] to (2*RS*,5*RS*)-vitispirane **1** by heating with *p*-toluenesulfonyl chloride in pyridine, the relative configurations at C-6 and C-9 of **8** being established as (6*RS*,9*SR*). The filtrate fraction was chromatographed to afford a mixture containing **8** and **9** in a ratio of *ca.* 1:1. The ^{1}H-NMR spectrum of this mixture is practically identical with that of the pure **8** except for a pair of singlets at 5.18 and 5.20 ppm due to one of the *exo*-methylene protons of **8** and **9** respectively. The treatment of this mixture with *p*-toluenesulfonyl chloride afforded (2*RS*,5*RS*)- and (2*RS*,5*SR*)-vitispiranes (**1** and **2**) in a ratio of *ca* 1:1.

Experimental

The melting points are uncorrected. The following spectrometers were used: IR, Hitachi 215; NMR, Varian XL-100 or JOEL FX-100 (tetramethylsilane as the internal standard); mass spectra, JEOL D-300. The thin-layer chromatography (TLC) was performed on 0.25 mm precoated silica gel PF_{254} (Merck). Silica gel (70—230 mesh, Merck) was used for the column chromatography.

cis-2,6,6-Trimethyl-1-(3-oxo-1-butenyl)-2-cyclohexene-1,4-diol (4). A solution of dehydroionone **3** (3.00 g, 15.8 mmol, purity 85%) and Rose Bengal (30 mg) in methanol (50 ml) was irradiated externally with a high-pressure mercury vapor lamp (Toshiba HT-400PL) in a water-cooled (0—5 °C) apparatus, while oxygen was being bubbled through the solution (*ca.* 30 ml/min). The reaction was essentially complete after 25 min. After the addition of thiourea (1.37 g, 18.0 mmol), the mixture was stirred at 25 °C for 7 h. After the subsequent removal of the solvent, the residue was chromatographed (benzene–ethyl acetate, 1:1) on silica gel to give the *cis*-diol **4** (0.80 g, 28%). **4**: IR (neat) 3400, 1672, 1620, 1098, 1015, 988 cm^{-1}; NMR ($CDCl_3$) δ 0.97 (s, 3H), 0.99 (s, 3H), 1.65 (t, J=2 Hz, 3H), 1.60—2.16 (m, 4H), 2.88 (s, 3H), 4.25 (m, 1H), 5.65 (m, 1H), 6.43 (d, J=16 Hz, 1H), 6.74 (d, J=16 Hz, 1H): MS, *m/e* 224 (M^+), 191, 150, 108, 43. Found: *m/e* 224.1418. Calcd for $C_{13}H_{20}O_3$: M, 224.1412.

6,6-Dimethyl-2-methylene-1-(3-oxo-1-butenyl)-3-cyclohexen-1-ol (5). A solution of the *cis*-diol **4** (1.50 g, 6.70 mmol) in dimethyl sulfoxide (6.5 g) was heated at 140 °C for 8 h. The reaction mixture was then cooled, poured into water, and extracted with ethyl acetate. The ethyl acetate extracts were washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was chromatographed (benzene– ethyl acetate, 7:1) on silica gel to give the triene ketone **5** (0.65 g, 47%). **5**: mp 81—82 °C; IR (Nujol) 3490, 1785, 1682, 1655, 1595, 1140, 995, 978, 892 cm^{-1}; NMR ($CDCl_3$) δ 0.92 (s, 3H), 0.96 (s, 3H), 1.69 (s, 1H), 2.06—2.20 (m, 2H), 2.25 (s, 3H), 5.02 (s, 1H), 5.16 (s, 1H), 5.62—5.86 (m, 1H), 6.08—6.26

(m, 1H), 6.43 (d, J=16 Hz, 1H), 6.89 (d, J=16 Hz, 1H); MS, *m/e* 206 (M^+), 191, 163, 121, 43. Found: *m/e* 206.1270. Calcd for $C_{13}H_{18}O_2$: M, 206.1305.

*6,6-Dimethyl-2-methylene-1-(3-oxobutyl)-3-cyclohexen-1-ol (**6**).* A solution of lithium trimethoxyaluminium hydride in tetrahydrofuran (0.659 mol/l, 60.7 ml, 40.0 mmol) was added, drop by drop, to a suspension of copper(I) bromide (2.86 g, 20.0 mmol) in tetrahydrofuran (15 ml) at −20 to −10 °C. After 30 min, the resulting dark brown suspension was cooled to −20 °C. A solution of the triene ketone **5** (1.03 g, 5.00 mmol) in tetrahydrofuran (10 ml) was added (*ca.* 5 min). The mixture was then stirred at −20 °C for 50 min, poured into cold water, and extracted with ethyl acetate. The ethyl acetate extracts were washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was chromatographed (hexane–ethyl acetate, 5:4) on silica gel to give the diene ketone **6** (490 mg, 48%) and the triene diol **7** (499 mg, 49%). **6**: mp 60—62 °C; IR (Nujol) 3320, 3025, 1782, 1715 (weak), 1642, 1600, 1106, 1042, 892 cm^{-1}; NMR ($CDCl_3$) δ 0.8—1.2 (m, 6H, with two s at 0.88 and 1.06), 1.4—2.6 (m, 10H, with a d at 1.62 and a s at 2.14), 4.80—5.16 (m, 2H), 5.32—5.68 (m, 1H), 5.90—6.12 (m, 1H); MS *m/e* 208 (M^+), 190, 185, 150, 131, 99, 43. Found: *m/e* 208.1458. Calcd for $C_{13}H_{20}O_2$: M, 208.1461.

*1-(3-Hydroxybutyl)-6,6-dimethyl-2-methylene-3-cyclohexen-1-ols (**8** and **9**).* A solution of the diene ketone **6** (439 mg, 2.11 mmol) and sodium borohydride (300 mg, 7.93 mmol) in ethanol (15 ml) was stirred at 25 °C for 1 h. The reaction mixture was then poured into water and extracted with ethyl acetate. The ethyl acetate extracts were washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent, the crystalline residue was recrystallized from hexane–ethyl acetate to yield **8** (179 mg). The filtrate was concentrated and crystallized again from hexane–ethyl acetate to yield **8** (90 mg). The filtrate was concentrated and chromatographed (hexane–ethyl acetate, 2:5) on silica gel to give a mixture containing **8** and **9** in a ratio *ca.* 1:1 (91 mg). The total yield of **8** and **9** was 81%. **8**: mp 141—142 °C; IR (Nujol) 3300, 3020, 1780, 1640, 1598, 1048, 988, 890 cm^{-1}; NMR ($CDCl_3$) δ 0.88 (s, 3H), 1.06 (s, 3H), 1.16 (d, J=6 Hz, 3H), 1.26—2.46 (m, 8H), 3.56—3.92 (m, 1H), 5.04 (s, 1H), 5.02 (s, 1H), 5.50—5.72 (m, 1H), 6.00—6.18 (m, 1H); MS, *m/e* 210 (M^+), 192 177, 126, 43. Found: *m/e* 210.1672. Calcd for $C_{13}H_{22}O_2$: M, 210.1620.

*Vitispiranes (**1** and **2**).* To a solution of the diene diol **8** (1.007 g, 4.79 mmol) in pyridine (13 ml), was added *p*-toluenesulfonyl chloride (1.57 g, 8.24 mmol). The mixture was then stirred at 0 °C for 18 h, heated at 80 °C for 4 h, and cooled to 0 °C. After the addition of water (6 ml), the mixture was stirred at 0 °C for 1 h, poured into water, and extracted with ether–pentane. The organic layers were washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was distilled (oil bath 100 °C/1 Torr) to give (2*RS*,5*RS*)-vitispirane **1** (812 mg, 88%). The mixture of **8** and **9** from the previous experiment, upon treatment under the same conditions, afforded (2*RS*,5*RS*)- and (2*RS*,5*SR*)-vitispiranes (**1** and **2**) in a ratio of *ca.* 1:1. The IR, NMR, and mass spectral data of **1** and **2** were identical with those of authentic samples.[2]

Synthesis and Reactions of Perylenecarboxylic Acid Derivatives. X. Synthesis of *N*-Alkyl-3,4-perylenedicarboximide

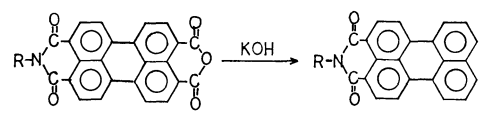
Yukinori NAGAO* and Takahisa MISONO

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda 278

(Received August 14, 1980)

Synopsis. *N*-Alkyl-3,4-perylenedicarboximides (alkyl=methyl, ethyl, propyl, butyl, isobutyl, pentyl, hexyl, and octyl) were prepared by the decarboxylation of *N*-alkyl-3,4:9,10-perylenetetracarboxylic monoanhydride monoimides (same alkyls) in potassium hydroxide solution.

In a previous publication we reported that the 3,4-perylenedicarboximide was sulfonated, and that the *N*-substituted perylene-3,4-dicarboximides could be prepared from the sulfonic acid *via* sulfoperylene-3,4-dicarboxylic anhydride and *N*-substituted sulfoperylene-3,4-dicarboximide.[1] This method may be applicable to many kinds of *N*-substituted perylene-3,4-dicarboximide preparations, but it includes too many reaction steps. 3,4-Perylenedicarboximide was prepared by decarboxylation of 3,4:9,10-perylenetetracarboxylic monoanhydride monoimide in potassium hydroxide solution.[2] The present work was undertaken to apply the decarboxylation to *N*-substituted 3,4:9,10-perylenetetracarboxylic monoanhydride monoimides to prepare *N*-alkyl-3,4-perylenedicarboximide(**2a**—**h**) (alkyl=**a**, methyl; **b**, ethyl; **c**, propyl; **d**, butyl; **e**, isobutyl; **f**, pentyl; **g**, hexyl; **h**, octyl) from *N*-alkyl-3,4:9,10-perylenetetracarboxylic monoanhydride monoimide[3,4] (**1a**—**h**) (same alkyls).



1a—h **2a—h**

R=**a**, methyl; **b**, ethyl; **c**, propyl; **d**, butyl; **e**, isobutyl; **f**, pentyl; **g**, hexyl; **h**, octyl.

Results and Discussion

The *N*-alkyl-3,4-perylenedicarboximides(**2a**—**h**) prepared by the decarboxylation of *N*-alkyl-3,4:9,10-perylenetetracarboxylic monoanhydride monoimides (**1a**—**h**) in potassium hydroxide solution are listed in Table 1. Their structures were confirmed by elemental analyses, absorption spectra, and IR and MS spectra. These are given in Table 2. All compounds could be prepared in 60—80% yield. The raw products of **2a**—**h** were given in good yields. The differences of yield are due to the difficulties of recrystallization from solvent.

All λ_{max} in the visible spectra of sulfuric acid solutions are 612—614 nm, and no different λ_{max} values due to alkyl group were found. All IR spectra indicate $\nu_{C=O}$ of imide on 1637—1647 cm^{-1} and 1680—1687 cm^{-1}, and no different $\nu_{C=O}$ due to alkyl group were found either. Mass spectra show the corresponding molecular ion peak. Table 3 shows the color, tinting strength, and light-fastness obtained by a similar method in previous work.[4] Colors were all reddish, and the colors of **2b**,**2c**,**2e**, and **2f** were very clear. Tinting strengths of **2b**,**2e**, and **2f** were high, and that of **2a** was the lowest. Light-fastness of *N*-butyl compound (**2d**) was the highest and *N*-pentyl compound(**2f**) was the lowest.

Table 1. Reaction conditions for the preparation of 3,4-perylenedicarboximide(**2a**—**h**)
Reaction temp: 220—230 °C; Time: 18 h.

1a—**h**(g)		12% KOH(ml)	Yield of **2a**—**h**/%	
1a	5.0	100	**2a**	74
1b	6.0	120	**2b**	62
1c	6.1	123	**2c**	64
1d	10.0	200	**2d**	67
1e	5.0	100	**2e**	71
1f	5.0	100	**2f**	81
1g	5.0	100	**2g**	70
1h	5.0	100	**2h**	76

Experimental

Material. **1a**—**h** were prepared by the previous methods.[3,4]

Preparation of 2a—h. For example, **2a** was prepared as follows. **1a** (5.0 g) and 12% potassium hydroxide solution (100 ml) were heated in an autoclave at 220—230 °C for 18 h with stirring. The cooled reaction mixture was filtered, and the precipitate was washed with water and dried to yield 3.7 g (89%) of crude reddish brown powder of **2a**. The crude **2a** was recrystallized from nitrobenzene–methanol to obtain 3.0 g (74%) of **2a** (mp>300 °C). **2b**—**h** were prepared with the same treatment under the conditions given in Table 1. The obtained crude yield of **2b**—**h** was: **2b**, 89%; **2c**, 81%; **2d**, 88%; **2e**, 77%; **2f**, 85%; **2g**, 90%; **2h**, 90%. The crude **2b**—**h** were recrystallized from benzene–methanol: **2b**, **2c**, **2d**, and acetic anhydride–methanol: **2e**, **2f**, **2g**, **2h**, respectively. The yields of **2b**—**h** were: **2b**, 62% (mp 292 °C); **2c**, 64% (mp 250 °C); **2d**, 67% (mp 267 °C); **2e**, 71% (mp 293 °C); **2f**, 81% (mp 249 °C); **2g**, 70% (mp 206 °C); **2h**, 76% (mp 190 °C).

Measurement. Mass spectra were recorded on a Hitachi RMU-7M mass spectrometer. Visible spectra were measured using a Hitachi 124 spectrometer for solutions in concd sulfuric acid (95.0%), and IR spectra on a Nippon Bunko IR-E spectrometer.

The prepared pigment (1.00 g) and 20.0 g of sodium sulfate were milled with a lab mill for 5 h. The mixture was added to water to remove sodium sulfate and then filtered. The residue was dried under vacuum at room temperature. The sample (100 mg), titanium dioxide (2.0 g), and boiled oil (1.2 ml) were mixed by a muller for three hundred revolutions. The mixture was painted on paper, then the tests were carried by the previous methods.[5]

1,3-Dioxolane Bearing Perfume and Herbicide Aldehyde Residues

Hiroyoshi KAMOGAWA,* Yuichiro HARAMOTO, Terumi NAKAZAWA, Harumitsu SUGIURA, and Masato NANASAWA

Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400

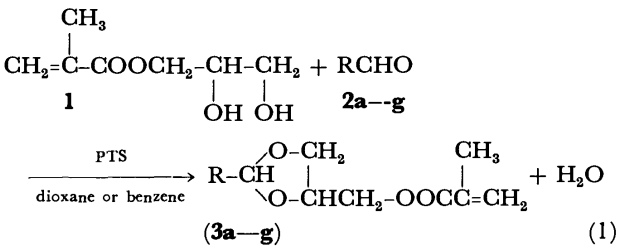
(Received October 17, 1980)

Synopsis. 4-Methacryloyloxymethyl-1,3-dioxolanes substituted at the 2 position with perfume and herbicide aldehyde residues were synthesized either by acetalization or by transacetalization involving 2,3-dihydroxypropyl methacrylate. The effect of the 2-substituent of the dioxolane ring on the rate of hydrolysis was remarkable.

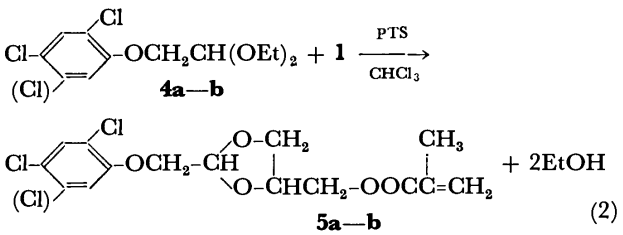
In the course of studies to synthesize polymerizable acetals bearing various functions capable of being released by hydrolysis, those from perfume and vitamin alcohols have been reported.[1,2] In the meantime, polyurethanes containing the acetal linkage in the principal chain[3] and polyamide attached with acetal side chains,[4] both containing a herbicide function, have also been reported.

In this note, we wish to report on novel acetals containing the 1,3-dioxolane unit composed of the perfume or herbicide aldehyde and 2,3-dihydroxypropyl methacrylate residues.

Acetals **3a—g** were synthesized by the acid-catalyzed acetalization of **1** and **2a—g** (Eq. 1), where R represents a perfume or herbicide residue in Table 1.



(1)



(2)

4a, **5a**: 2,4-Dichloro; **4b**, **5b**: 2,4,5-Trichloro

Diethyl acetals (**4a—b**) were also employed to conduct the *p*-toluenesulfonic acid (PTS)-catalyzed transacetalization as indicated in Eq. 2. A Soxhlet extractor, the thimble of which contained 4A or 5A molecular sieves for the removal of the ethanol produced, was employed in this case. Although the repetition of column chromatography decreased the yields of isolated products (9 and 11% for **5a** and **5b**, respectively), acetal conversions, calculated from the ^{1}H-NMR data for crude product **5a**, were 47 and 59% with 4A and 5A molecular sieves, respectively, on the basis of the starting **4a**, indicating advantage of the latter molecular sieves with larger micropores. The conversion for **5b** was 55% with 5A molecular sieves, also a much higher value than the yield (11%) of the purified product.

TABLE 1. ACETALS SYNTHESIZED ACCORDING TO Eq. 1

Abbreviation		Acetalization: Yield of 3a—g/%[a]	Acetalization: Solvent	Acetalization: Means of dehydration
2a, 3a		28	Dioxane	3A molecular sieves
2b, 3b		39	Dioxane	3A molecular sieves
2c, 3c		23	Dioxane	3A molecular sieves
2d, 3d		25	Dioxane	3A molecular sieves
2e, 3e		21	Dioxane	3A molecular sieves
2f, 3f		8	Benzene	Dean-Stark trap
2g, 3g		10	Benzene	Dean-Stark trap

a) Values for purified products.

TABLE 2. HYDROLYTIC RELEASE OF FUNCTIONAL ALDEHYDES FROM ACETALS

Acetals	Aldehyde released in: 2 h	Aldehyde released in: 24 h, %
3a	44	—
3d	Trace	—
3f	25	77
3g	27	—
5a	9	—

Novel 1,3-dioxolanes thus synthesized were subjected to acid hydrolysis, as exemplified in Table 2. The results indicate that the kind of 2-substituent of the dioxolane ring, *i.e.*, aldehyde residue, exerts a remarkable influence on the rate of hydrolysis: acetal **3a** bearing *p*-methoxyphenyl group as R which stabilizes the intermediate carbocation produced during the hydrolysis provides the highest rate, whereas, for **3d** and **5a** with aliphatic R, rates are much lower

than that for **3a** and even considerably lower than those for **3f** and **3g** with essentially the same release components as that in **5a**. This fact indicates that the release rate of the functional portion can be controlled here over a wide range by choosing the group neighboring to the C-2 atom of the 1,3-dioxolane ring.

Experimental

2,3-Dihydroxypropyl Methacrylate (**1**). A mixture of glycidyl methacrylate (14.2 g, 100 mmol), 4-*t*-butylcatechol (0.1 g), H_2SO_4 (concd, 0.2 ml), and water (100 ml) was stirred vigorously at room temperature for 24 h. The resulting clear solution was neutralized with an anion-exchange

resin (Diaion SA-10A) and freeze-dried to leave a liquid, which was distilled under reduced pressure to afford pure **1** as a colorless liquid (bp 115—120 °C/1.0 mmHg) in 60—70% yield. Found: C, 52.41; H, 7.74%. Calcd for $C_7H_{10}O_3$: C, 52.49; H, 7.55%. IR(CCl_4) 3500, 1720 cm^{-1}; NMR (D_2O) δ 2.0 (s, 3H, CH_3), 3.5—4.5 (m, 5 H, $-CH_2-CHCH_2$), 5.7 (s, 1H, $CH_2=$), 6.2 (s, 1H, $CH_2=$) ppm.

*2-(p-Methoxyphenyl)-4-methacryloyloxymethyl-1,3-dioxolane (**3a**).* A solution of **1** (1.3 g, 8.1 mmol), *p*-anisaldehyde (**2a**; 1.1 g, 8.1 mmol), PTS (0.3 g), and phenothiazine (0.05 g) in dioxane (50 ml) was stirred at room temperature for 24 h under nitrogen in the presence of 3A molecular sieves. The reaction mixture was diluted with chloroform and neutralized with aq $NaHCO_3$ by shaking. The organic layer was dried over anhyd. Na_2SO_4 and evaporated *in vacuo* to leave an oil, which was chromatographed on alumina (Wako, 300 mesh, neutral). Methanol elution provided an oily product. Found: C, 64.26; H, 7.01%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%. IR ($CHCl_3$) 1710 cm^{-1}; NMR (CCl_4) δ 1.9 (s, 3H, CH_3), 3.3—4.5 (m, 5H, $-CH_2-CHCH_2$), 3.7 (s, 3H, OCH_3), 5.1—5.8 (m, 1H, acetal CH), 5.6 (s, 1H, $CH_2=$), 6.1 (s, 1H, $CH_2=$), 6.6—7.4 (m, 4H, ArH) ppm; Mass (*m/e*) 278 (M^+).

Products **3b**, **3c**, **3d**, and **3e**, each oily compound, were synthesized in the same manner.

*2-(3,4-Methylenedioxyphenyl)-4-methacryloyloxymethyl-1,3-dioxolane (**3b**).* Found: C, 61.24; H, 5.92%. Calcd for $C_{15}H_{16}O_6$: C, 61.64; H 5.52%. IR (CCl_4) 1710 cm^{-1}; NMR (CCl_4) δ 1.9 (s, 3H), 3.4—4.5 (m, 5H), 5.1—5.8 (m, 1H), 5.5 (s, 1H), 5.9 (s, 2H), 6.0 (s, 1H), 6.5—6.9 (m, 3H) ppm; Mass (*m/e*) 292 (M^+).

*2-Styryl-4-methacryloyloxymethyl-1,3-dioxolane (**3c**).* Found: C, 69.65; H, 7.02%. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%. IR ($CHCl_3$) 1710 cm^{-1}; NMR (CCl_4) δ 1.9 (s, 3H), 3.3—4.3 (m, 5H), 4.8—5.3 (b, 1H), 5.5 (s, 1H), 6.1 (s, 1H), 6.6—6.8 (d, 2H), 7.0—7.4 (s, 5H) ppm; Mass (*m/e*) 274 (M^+).

*2-(2,6-Dimethyl-5-heptenyl)-4-methacryloyloxymethyl-1,3-dioxolane (**3d**).* Found: C, 68.65; H, 8.67%. Calcd for $C_{17}H_{28}O_4$: C, 68.89; H, 8.86%. IR (CCl_4) 1720 cm^{-1}; NMR (CCl_4) δ 0.8—2.4 (m, 19H), 3.1—4.5 (m, 5H), 4.7—5.5 (m, 2H), 5.6 (s, 1H), 6.2 (s, 1H) ppm.

*2-(2,6-Dimethyl-1,5-heptadienyl)-4-methacryloyloxymethyl-1,3-dioxolane (**3e**).* Found: C, 69.75; H, 8.48%. Calcd for $C_{17}H_{26}O_4$: C, 69.35; H, 8.90%. IR (CCl_4) 1730 cm^{-1}; NMR (CCl_4) δ 0.8—3.0 (m, 16H), 3.1—4.2 (m, 5H), 4.5—6.1 (m, 3H), 5.5 (s, 1H) 6.0 (s, 1H) ppm.

*2-(2,6-Dichlorophenyl)-4-methacryloyloxymethyl-1,3-dioxolane (**3f**).* A mixture of **1** (1.6 g, 10 mmol), 2,6-dichlorobenzaldehyde (**2f**; 1.7 g, 10 mmol), hydroquinone (0.5 g), PTS (0.5 g), and benzene (100 ml) was refluxed for 2 h with a Dean-Stark trap fitted. The reaction mixture was washed with 5% aq K_2CO_3 (200 ml) and dried over anhyd. Na_2SO_4, followed by evaporation *in vacuo*. Silica gel (Wakogel C-300) column chromatography conducted on the crude product afforded pure **3f** as a viscous colorless oil (benzene eluate). Found: C, 52.61; H, 4.50%. Calcd for $C_{14}H_{14}O_4Cl_2$: C, 53.02; H, 4.45%. IR ($CHCl_3$) 1720 cm^{-1}; NMR ($CDCl_3$) δ 2.0 (s, 3H, CH_3), 3.8—4.9 (m, 5H, $-CH_2-CHCH_2$), 5.7 (s, 1H, $CH_2=$), 6.2 (s, 1H, $CH_2=$), 6.3, 6.6, 6.7 (t, 1H, acetal CH), 7.2—7.5 (t, 3H, ArH) ppm; Mass (*m/e*) 317 (M^+).

*2-(2,4-Dichlorophenyl)-4-methacryloyloxymethyl-1,3-dioxolane (**3g**).* A viscous oil [hexane–benzene (1:4 v/v) eluate]. Found: C, 52.83; H, 4.41%. Calcd for $C_{14}H_{14}O_4Cl_2$: C, 53.02; H, 4.45%. IR ($CHCl_3$) 1720 cm^{-1}; NMR ($CDCl_3$) δ 2.0 (s, 3H), 3.8—4.9 (m, 5H), 5.6 (s, 1H), 6.2 (s, 1H), 5.9, 6.2, 6.3 (t, 1H), 7.2—7.9 (m, 3H) ppm; Mass(*m/e*) 317 (M^+).

*(2,4-Dichlorophenoxy)acetaldehyde Diethyl Acetal (**4a**).* A solution of 2,4-dichlorophenol (16 g, 0.1 mmol) and potassium hydroxide (8 g) in methanol (100 ml) was evaporated *in vacuo* at 50—60 °C almost to dryness. The residue was dissolved in DMF (100 ml) and equimolar bromoacetaldehyde diethyl acetal (0.1 mol) was added, followed by stirring at 100 °C for 5 h under nitrogen. The reaction mixture was poured into excess aq $NaHCO_3$ (500 ml) and the oil thus separated was extracted with ether (200 ml). The ether extract was washed first with dil aq NaOH, then with water, dried over anhyd. Na_2SO_4, and concentrated *in vacuo*, followed by distillation under reduced pressure to afford **4a** as a light yellow oil (bp 121—122 °C/0.1 mmHg) in 33% yield. Found: C, 51.82; H, 5.70%. Calcd for $C_{12}H_{16}O_3Cl_2$: C, 51.79; H, 5.75%. NMR ($CDCl_3$) δ 1.2 (t, 6H, $2CH_3$), 3.2—4.2 (m, 6H, $3CH_2$), 4.8 (q, 1H, CH), 6.7—7.5 (m, 3H, ArH) ppm; Mass (*m/e*) 278 (M^+).

*(2,4,5-Trichlorophenoxy)acetaldehyde Diethyl Acetal (**4b**).* A light yellow oil of bp 135—137 °C/0.1 mmHg (30% yield). Found: C, 46.02; H, 4.94%. Calcd for $C_{12}H_{15}O_3Cl_3$: C, 46.15; H, 4.81%. NMR ($CDCl_3$) δ 1.3 (t, 6H), 3.5—4.2 (m, 6H), 4.9 (q, 1H), 7.3 (d, 2H) ppm; Mass (*m/e*) 312 (M^+).

*2-(2,4-Dichlorophenoxymethyl)-4-methacryloyloxymethyl-1,3-dioxolane (**5a**).* In a Soxhlet flask were placed **4a** (3.1 g, 10 mmol), **1** (3.2 g, 20 mmol), PTS (0.1 g), hydroquione (0.1 g), and chloroform (100 ml). The flask, fitted with a thimble containing 4A or 5A molecular sieves, was heated with stirring to reflux for 7 h. The reaction mixture was diluted with chloroform (50 ml), washed with aq Na_2CO_3, dried over anhyd. Na_2SO_4, and evaporated *in vacuo* to leave the crude product, which was chromatographed on silica gel (Wakogel C-300) to afford a viscous oil in 9% yield [benzene–ether (1:4 v/v) eluate]. Found: C, 51.94; H, 4.85%. Calcd for $C_{15}H_{16}O_5Cl_2$: C, 52.02; H, 4.62%. IR (CCl_4) 1720 cm^{-1}; NMR ($CDCl_3$+DMSO-d_6) δ 1.9 (s, 3H, CH_3), 3.1—4.3 (m, 7H, $3CH_2$+CH), 4.5—5.2 (b, 1H, acetal CH), 5.5 (s, 1H, $CH_2=$), 6.1 (s, 1H, $CH_2=$), 6.5—7.4 (m, 3H, ArH) ppm.

*2-(2,4,5-Trichlorophenoxymethyl)-4-methacryloyloxymethyl-1,3-dioxolane (**5b**).* A light yellow viscous oil [benzene–ether (4:1 v/v) eluate; 11% yield]. Found: C, 46.67; H, 4.12%. Calcd for $C_{15}H_{15}O_5Cl_3$: C, 47.18; H, 3.94%. IR (CCl_4) 1730 cm^{-1}; NMR ($CDCl_3$) δ 2.0 (s, 3H), 3.5—4.3 (m, 7H), 4.6—5.2 (b, 1H), 5.6 (s, 1H), 6.2 (s, 1H), 6.6—7.5 (m, 2H) ppm; Mass (*m/e*) 381 (M^+).

Hydrolysis of the Acetals Synthesized. A solution of an acetal (1 mmol), PTS (0.05 g), and 4-*t*-butylcatechol (0.01 g) in THF–water (2:1 v/v; 30 ml) was let stand at 20 °C for 2 h. The solution was neutralized with solid Na_2CO_3, filtered, and evaporated *in vacuo*. The residue was extracted with $CHCl_3$– aq $NaHCO_3$. The organic layer was dried over anhyd. Na_2SO_4 and evaporated *in vacuo* to dryness. The relative strength of either the aldehyde signal produced or the remaining acetal CH in the ^{1}H-NMR ($CDCl_3$) was determined for the residue to calculate the value of % hydrolysis. Time of hydrolysis was also prolonged to 24 h.

N-Trifluoroacetylimidazoles as a Reagent for Converting Aldoximes into Nitriles under Mild Conditions

Takashi KEUMI,* Takayoshi YAMAMOTO, Hiroshi SAGA, and Hidehiko KITAJIMA

Department of Fiber and Color Chemistry, Faculty of Engineering, Fukui University, Bunkyo, Fukui 910

(Received October 29, 1980)

Synopsis. It was found that *N*-trifluoroacetylimidazole was an excellent reagent for the intramolecular dehydration of aldoximes to give nitriles uner mold conditions.

There are only a few examples of the use of *N*-trifluoroacetylimidazole (TFAI) as an organic synthetic reagent, though it seems to have a great potential. Thus far, it has only been used as trifluoroacetylating agent of amines or alcohols[1] and as condensation agent of amino acids with *p*-nitrophenol.[2] We have previously shown that TFAI is useful for the condensation of carboxylic acids with aromatic hydrocarbons to give aromatic ketones.[3] In this paper, we wish to report that TFAI is also an excellent reagent for the intramolecular dehydration of aldoximes (**1**) to give nitriles (**4**).

Many methods are known for converting **1** into **4**, but some of them have disadvantages, such as needing vigorous reaction conditions or tedious work-up procedures, having unsatisfactory yields, or needing unusual reagents.[4-6] For example, recently reported trifluoroacetic anhydride is very useful as the reagent;[4] however, it requires at least two equivalents of a base to catalyze the reaction and to remove the acid generated.

TFAI converted **1** into **4** under practically neutral and mild conditions without any additives. The reac-

a) The isolated yield of **4**. b) Obtained by GLC. c) Ether was used as the solvent for this reaction. In the other reactions, THF was used as the solvent.

tion is carried out by heating a solution of **1** and TFAI (in a molar ratio of 1:1.1) in ether or tetrahydrofuran under reflux for 2—3.5 h. The results are summarized in Table 1. A wide variety of **1** substances, from the aliphatic or aromatic to the olefinic, are dehydrated by TFAI to give the corresponding **4** substances in satisfactory yields.

The dehydration of **1** is generally considered to proceed by means of a base-promoted bimolecular mechanism.[4] TFAI has a powerful trifluoroacetylating ability; in addition, as a result of the trifluoroacetylation, the reagent generates imidazole (**3**), which can act as a base. Therefore, in the above reaction it seems that the trifluoroacetylation of **1** by TFAI takes place first to give *O*-trifluoroacetyl aldoxime (**2**) and **3**, followed by the elimination of trifluoroacetic acid by the **3** thus yielded to afford **4** and imidazolium trifluoroacetate (**5**). Thus, the reaction system should be kept constantly neutral during the reaction. Further, conveniently, the by-product, **5**, can be easily removed from the product, **4**, by filtration, because it is hardly soluble in cold ether and tetrahydrofuran. TFAI is familiar in the field of the peptides chemistry[2] and is commercially available. Consequently, TFAI seems to be an efficient reagent for converting **1** into **4**.

Experimental

Materials and Measurements. TFAI was prepared from imidazole and trifluoroacetic anhydride accoridng to the procedure described in the literature.[1] The aldoximes were prepared by a general method. The solvents used for the reactions were dried and distillated over lithium aluminium hydride. The IR spectra were recorded on a Hitachi EPI-S2 Model spectrophotometer. The NMR spectra were measured as carbon tetrachloride solutions at 100 MHz with a JEOL Model PS-100 spectrometer, using tetramethylsilane as the internal standard.

General Procedure. A typical procedure will be described for the preparation of benzonitrile (**4f**): To a solution of benzaldehyde oxime (0.500 g, 4.1 mmol) in dried tetrahydrofuran (6 ml), TFAI (0.745 g, 4.5 mmol) in tetrahydrofuran (4 ml) was added, after which the mixture was heated under reflux for 3 h. After cooling, the resultant precipitates of imidazolium trifluoroacetate were removed off by filtration and washed with ether (about 30 ml). The combined filtrate was washed with water (about 30 ml×2) and dried over anhydrous sodium sulfate. The solvent was then evaporated to obtain **4f** (0.400 g, 94%). Bp 190 °C (lit,[7] Bp 191 °C).

Thermal Rearrangement of *N*-(Substituted allyl)-1-naphthylamines

Seisaku INADA* and Ryu-ichiro KURATA

Department of Chemical Engineering, Faculty of Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received November 14, 1980)

Synopsis. The title reaction was examined and the results were compared with those of the thermal reaction of the corresponding *N*-tosyl derivatives.

In the previous papers,[1] we have reported the *amido*-Claisen rearrangement of *N*-tosyl and *N*-mesyl derivatives of aromatic *N*-allylamines which proceeds almost quantitatively in *N*,*N*-dialkylaniline solvent containing a small amount of triphenylphosphine. In the course of our studies, it was found that the thermal reaction of *N*-(substituted allyl)-*N*-tosyl-1-naphthylamines (**1f—h**) forms para-rearranged products (**3d—f**) as well as ortho-rearranged ones (**2g**, **2h**) respectively, when the allyl group contains substituents in γ-position.[2] So we were interested to confirm whether the thermal reaction of the corresponding *N*-(substituted allyl)-1-naphthylamines was accompanied by the para-rearrangement. About *N*-allyl-1- (**1a**) and 2-naphthylamine themselves, Marcinkiewicz *et al.* reported the formation of ortho rearranged product as sole one,[3] which have formed the only successful example of the aromatic *amino*-Claisen rearrangement.

4

The amines (**1a—1e**) neat were heated at 260±0.3 °C under nitrogen. In general, the thermal reaction of these amines gave complicated products, together with some amount of tarry matters.[4] The reaction mixtures from **1a—1e** were converted to the ones of *N*-tosylamines by treating them with tosyl chloride in pyridine immediately after the reaction and analyzed according to the method previously described. The results are shown in Table.

The main products were the ortho rearranged ones throughout the reactions except for **1d** from which the deallylated product **2f** was formed as the only confirmable one. The formation of para-rearranged products was not observed except **3c** formed from **1e**.[5] It may be reasonably considered that **3c** should be formed partially at least *via* a dissociation-recombination process, since the formation of **2e** involving a sterically retained cinnamyl group in ortho position was also observed. In general, the ortho-rearrangement apparently proceeds *via* a [3,3]-sigmatropic reaction as denoted by the examples of the amines containing an asymmetrically-substituted allyl group (**1c**, **1e**). The results accorded with what we deduced about the para-rearrangement in the corresponding *amido*-Claisen rearrangement; a steric repulsion between a tosyl group and α-substituents in an inverted allyl group which is involved in the intermediate such as **4** formed by the first [3,3]-shift promotes the second one to para rearranged products.

Experimental

IR spectra were determined on a Shimadzu IR-27G spectrometer and NMR spectra on a Hitachi R-24 spectrometer; chemical shifts are given in δ with TMS as an internal standard. *N*-(Substituted allyl)-1-naphthylamines were obtained in excellent yields by the corresponding *N*-allylations of *N*-trifluoroacetyl-1-naphthylamine and the subsequent hydrolysis.

N-*(Substituted allyl)*-N-*trifluoroacetyl-1-naphthylamines.* To a stirred mixture of *N*-trifluoroacetyl-1-naphthylamine[6] (80 g, 0.33 mol) and K_2CO_3 (46.2 g, 0.33 mol) in DMF (100 ml) was added the corresponding allyl bromide (0.40 mol) at room temperature. Then the mixture was stirred for 2 h at 60 °C. The usual work up gave the following *N*-(substituted allyl) derivatives in 88—99% yields.

Table 1. Thermal rearrangement of *N*-(substituted allyl)-1-naphthylamines (260 °C, neat)

*Thermal Rearrangement of **1a—1e***. A test-tube containing *N*-(substituted allyl)-1-naphthylamines (2—3 g) under nitrogen was immersed for an appropriate period of time in an oil bath, the temperature of which was maintained at 260.0±0.3 °C. The chilled reaction mixture was dissolved in pyridine (25 ml) and tosyl chloride (1.2 equivalents to **1**) was added. The whole solution was stirred at 60—70 °C for 6 h and poured into diluted hydrochloric acid (1:3). The resulting precipitate was filtered, washed with diluted hydrochloric acid and water, and dried. The samples thus obtained were analyzed by the method described previously.[2]

Substituent Effect on the N-H Stretching Absorptions of 2-(Substituted anilino)pyridines

Minoru HIROTA* and Kunio KOBAYASHI

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received November 21, 1980)

Synopsis. The N-H stretching frequencies of the title compounds were determined precisely. These amines have two absorption bands in the N-H stretching region owing to the existence of the rotational isomers. Their frequencies were plotted against the Hammett σ-constants of the substituents, giving a negative ρ-value. The results gave support to the planar (sp^2) conformation of the *exo*-cyclic nitrogen atom.

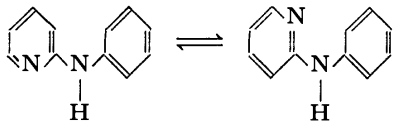
The substituent effect on the N-H stretching (ν_{NH}) frequencies have been reported for anilines,[1,2] *N*-methylanilines,[1] anilides,[3] and diphenylamines.[4] In these investigations, the frequencies were plotted against the Hammett σ or similar substituent parameters standing for their electronic effect. The results are rather contradictory giving ρ-values of different signs depending on the substituent (R) on the nitrogen atom (Table 1).

TABLE 1. SUBSTITUENT(X) EFFECT ON THE ν_{NH} FREQUENCIES OF VARIOUS *N*-SUBSTITUTED(R) ANILINES XC_6H_4NHR

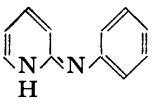
R	Sign of ρ	Ref.
H	+	1, 2
CH_3	+	1
$COCH_3$	−	3
C_6H_5	borderline	4
2-C_5H_4N	−	this work
Cf. XC_6H_4OH	−	5

In our previous report, the contradiction was interpreted by assuming the participation of the two competing factors of the opposite direction. The electron attracting nature of a substituent would decrease the electron density on the amino nitrogen atom, causing the increase in the s-character of its N-H bonding orbital. The increase in the s-character, in turn, shortens and strengthens the N-H bond, giving rise to a high frequency shift of the ν_{NH} absorption. Alternatively, the decrease in electron density of the amino nitrogen atom weakens the N-H bond when the change in the hybridization is absent.

On the other hand, 2-anilinopyridines have been shown to have two absorption bands in the ν_{NH} region. They were assigned to the two planar rotational isomers I and II.[6] An alternative assignment of these two bands to the amino and the imino tautomers (I and III, respectively) were excluded by the spectroscopic evidences.[7,8]



(I) (II)



(III)

In this report, the hybridization of the *exo*-cyclic nitrogen atom will be discussed from the substituent effect on the ν_{NH} bands of 2-anilinopyridines.

Experimental

Infrared spectra were recorded with a Hitachi 225 infrared spectrophotometer. The frequencies were calibrated by the absorption bands of gaseous water at 3447.09 and 3442.41 cm^{-1} in order to keep the accuracy of the location of the band maxima within 0.2 cm^{-1}. The anilinopyridines were prepared by the usual procedures.

Results and Discussion

The frequencies and the intensities of the ν_{NH} bands are given in Table 2. The absorption bands were tentatively assigned to the rotamers I and II, respectively, according to the conclusion in our previous report.[6] The ν_{NH} frequencies, as well as the intensity ratios of the two bands, were plotted against the Hammett σ-constants.[9] In case when the substituent is mesomerically electron-attracting (+M), the σ^--constant is used instead. The ν_{NH} frequencies of both rotamers tend to decrease as the increase of σ-values, showing negative ρ-values. A negative ρ-value has been observed with a series of substituted benzamides,[3] of which nitrogen atoms have been proved to be sp^2-hybridized from other evidences. The results suggest that the *exo*-cyclic nitrogen atom in 2-anilinopyridine is sp^2 hybridized. Since the 2-pyridyl group in these

amines is more electronegative than the phenyl groups in diphenylamines which shows the borderline ρ-alue,[4] the negative ρ-values are reasonable.

The $\varepsilon_I/\varepsilon_{II}$ ratios are also correlated with the σ-constants, the rotamer I (giving rise to the lower ν_{NH} band) becoming less favorable than the rotamer II when the substituent is electron-attracting. The results can be explained as follows. In the rotamer I, a weak attractive interaction[10] keeps the N–H···N system nearly coplanar. As a result, the anilinopyridine molecule is twisted around the C_{Ph}–N bond because of the steric hindrance between 3- and 2′ (or 6′)-hydrogen atoms. On the other hand, the *exo*-cyclic nitrogen atom and the phenyl group can be coplanar in the rotamer II. In the latter case, the phenyl group with an electron-attracting substituent is stabilized by conjugating with the planarly attached amino group. Hence, the rotamer II is more favorable than the rotamer I when the substituent is electron-attracting.

10) The low ν_{NH} frequency in the rotamer I suggests the participation of a weak hydrogen bond-like interaction, the N–H bond being weakened considerably by this interaction. However, the predominant force might be of dipolar nature.

A Selective Monodehydration of C_{4-14}-α,ω-Alkanediols with Stearic and/or Palmitic Acids

Tohr YAMANAKA* and TAKASHI IMAI

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received November 26, 1980)

Synopsis. The formation of monoesters of the C_{4-14}-α,ω-alkanediol(**1**) with stearic and/or palmitic acids and the consecutive pyrolysis of the monoesters to an ω-alken-1-ol(**2**) were effected at 320—350 °C under 260—760 mmHg** in a backmix flow reactor of a constant volume equipped with a fractionating column, through which the unchanged **1** was partially recycled. The selectivity in the preparations of **2**(C_6, C_{10}, and C_{14}) was greater than 79%.

We found a useful synthetic method to prepare a C_{4-14}-ω-alken-1-ol(**2**) from the corresponding α,ω-alkanediol(**1**). Acid catalyzed dehydrations of an

$$\underset{\mathbf{1}}{HOCH_2(CH_2)_nCH_2OH} \longrightarrow \underset{\mathbf{2}}{CH_2{=}CH(CH_2)_{n-1}CH_2OH} + H_2O \quad (1)$$

alkanol to form the corresponding alkene are generally accompanied by migration of the double bond and the intermolecular and/or the intramolecular ether formations.[1] These reactions can not be applied to **1** in the substantial yield, without the formations of alkadienes, the double bond-isomers of **2**, and the polyethers.

The vapor phase pyrolysis of acetates at 300—600 °C is known to be effective for the preparation of alkenes from the corresponding alkanols without migration of the double bond.[2] Preparation of any ω-alken-1-ol *via* the esters of alkanediols has not been reported. The selective preparation of the monoacetate of **1** without accompanying the formation of the diacetate will be difficult. We used high boiling saturated fatty acids **3** *i.e.*, palmitic acid, stearic acid, or the mixture of them so that the ester formation (Eq. 2) and the subsequent pyrolysis (Eq. 3) to give the ω-alken-1-ols might be induced concurrently at 320—350 °C. These steps were operated by means

$$\mathbf{1} + \underset{\mathbf{3}}{RCOOH} \longrightarrow RCOOCH_2(CH_2)_nCH_2OH + H_2O \quad (2)$$

$$RCOOCH_2(CH_2)_nCH_2OH \longrightarrow \mathbf{3} + \mathbf{2} \quad (3)$$

of a backmix[3] flow reactor of a constant volume of a liquid phase. While H_2O and **2** are being taken out through the rectification column, **1** is continuously supplied to the reactor. Compound **3** initially introduced into the reactor steadily functions like a catalyst throughout the operation period.

Experimental

A mixture of 24.3 g of stearic acid and 30.9 g of palmitic acid, and 61.5 g of 1,10-decanediol(purity 98.2 wt%) were placed in a 200-ml flask equipped with a 20 mmϕ × 200 mm-Vigreux fractionating column of *ca.* three theoretical plates connected with a reflux condenser, and refluxed at 330—350 °C, under 700 mmHg.** The temperature at the top of the column initially indicated 295 °C and gradually lowered to 265 °C. Then the effluent vapor was started to be taken out from the column at a rate of 10 g/h. Concurrently, 1,10-decanediol was started to be fed to the flask at the same rate. The temperature of the effluent vapor was maintained by regulating the temperature in the flask between 330 and 350 °C as well as by regulating the feed rate. From 1500 g of 1,10-decanediol, 126 g of the H_2O layer and 1372 g of the oily part were obtained as the distillate.

n=12 910, 995, 1643, 3060	4.74—6.05(ABX, 3H, C<u>H</u>$_2$=C<u>H</u>-), 3.46 (t, J=6 Hz, 2H, -CH$_2$-C<u>H</u>$_2$OH), 2.01 (t, d, J=6 Hz, 2H, =CH-C<u>H</u>$_2$-CH$_2$-), 1.27(b, s, 20H, -CH$_2$-(C<u>H</u>$_2$)$_{n-2}$-CH$_2$-), 4.13(s, 1H, CH$_2$O<u>H</u>)

The oily part was analyzed by gas chromatography using a Shimadzu GC 6A apparatus on a 2 mmϕ × 3 m column packed with 5 wt% of FFAP on Chromosorb W, AW-DMCS (80—100 mesh). The column temperature was elevated from 100 to 230 °C by 10 °C/min, N_2 was used as the carrier at 50 ml/min, and the injection temperature was 280 °C.

The oily part was fractionated by a further distillation. The main fraction of 869 g was identified to be 9-decen-1-ol; IR and NMR data are shown in Table 1. Each fraction was characterized by its boiling point and the main components were distinguished by their retention times in its gas chromatogram by comparison with those of the corresponding authentic samples.

In the same way as above, we prepared 3-buten-1-ol, 5-hexen-1-ol, and 13-tetradecen-1-ol from the corresponding 1,4-butanediol(purity 96.9 wt%), 1,6-hexanediol (99.0 wt%), and 1,14-tetradecanediol(81.3 wt%) in the presence of

**1 mmHg≈133.3 Pa.

This value denotes twice the amount of dimers of butadiene.

palmitic acid.

Results and Discussion

Results are shown in Tables 1 and 2. By means of increasing the mole ratio **1**/**3** in the reactions of C_6- and C_{10}-alkanediol, the formation of the by-products such as double bond isomers of ω-alken-1-ol and the alkadienes were suppressed, although the conversions of **1** were decreased. However, the ratio should be reduced to the range 0.8—1.0 in order to maintain the reaction temperature at 320—350 °C in the reactions of 1,4-butanediol and 1,6-hexanediol, because boiling points of them were 230 and 250 °C respectively at an ordinary pressure. On the whole, the decrease of the carbon number of the alkanediol increased the difficulty in the application of this reaction.

In the case of 1,4-butanediol, the selectivity was exceptionally low. There tetrahydrofuran was formed as the smaller part of the by-products. However, it should be noticed that this result stands in contrast to the fact that tetrahydrofuran was a primary product in the dehydration of 1,4-butanediol catalyzed by HCl.[4]

ω-Alken-1-ols thus produced are important in perfumery; *e.g.*, 1-decen-1-ol has been used as the component of a rosy odor and 5-hexen-1-ol has a verdurous odor.

Regiospecific Synthesis of 3-Alkylfurans and 3-Alkylthiophenes *via* Organoboranes

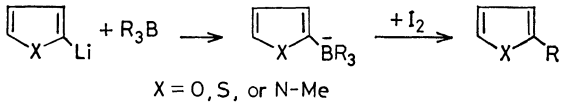
Itaru Akimoto, Masahiro Sano, and Akira Suzuki*

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received November 5, 1980)

Synopsis. The reaction of bromine or iodine with ate-complexes obtained from trialkylboranes and 3-lithiofuran or 3-lithiothiophene gives the corresponding 3-alkylfurans or 3-alkylthiophenes in good yields, respectively.

Heterocyclic compounds with one hetero atom have been recognized to be useful precursors and reagents for the syntheses of functionalized organic compounds.[1] Many synthetic procedures of such heterocycles through the alkylation of heterocyclic nuclei have been recently reported.[2-9] Especially, novel syntheses by the aromatic substitution *via* organoboranes readily obtainable from olefins are being watched with interest.[5-9] In connection with the synthesis, we reported that the reaction of iodine with ate-complexes prepared from trialkylboranes and 2-lithiofuran,[8] 2-lithiothiophene[9] or 1-methyl-2-lithiopyrrole[9] gave regiospecifically the corresponding 2-alkyl heterocycles in good yields (Scheme 1). One may wonder if the reaction is applicable for the preparation of 3-alkyl heterocycles from organoboranes and the corresponding 3-lithio derivatives. On the other hand, it was reported that there was a large difference of chemical properties between C_2 and C_3 atoms of furans and thiophenes.[10]



Scheme 1.

For instance, in the reaction of butyllithium with 3-bromobenzo[*b*]thiophene,[11] the following carboxylation even at −70 °C gives a mixture of 3-bromobenzo[*b*]thiophene-2-carboxylic acid, benzo[*b*]thiophene-2-carboxylic acid, benzo[*b*]thiophene-3-carboxylic acid, 3-bromobenzo[*b*]thiophene and benzo[*b*]thiophene, indicating that the reaction gives not only the straightforward metal-halogen exchange product but also 3-lithio derivatives as the intermediates. In the course of our studies on the aromatic substitution of heterocycles *via* organoboranes, we attempted the reaction of iodine or bromine with the ate-complexes prepared from trialkylboranes, butyllithium and 3-bromofuran or 3-bromothiophene, and found that the reaction proceeds smoothly without any difficulty to give regiospecifically the corresponding 3-alkylfurans or 3-alkylthiophenes in good yields. The results of reactions with representative trialkylboranes are summarized in Table 1.

In the present reaction, trialkylboranes with bulky alkyl groups such as isobutyl, *s*-butyl, and cyclopentyl seem to give high yields of corresponding 3-alkyl heterocycles. One of the possible procedures for the synthesis of such 3-substituted heterocycles may involve the reaction of 3-lithio derivatives with alkyl halides. Our experiment on the reaction of propyl bromide with 3-lithiothiophene formed from 3-bromothiophene and butyllithium, gave only a trace amount of 3-propylthiophene. Moreover, the synthesis of 3-*s*-alkyl heterocycles by the same method should be hopeless, because secondary alkyl halides readily undergo competitive elimination reactions.[12] On the other hand, the present reaction is free of this limitation. Secondary groups appear to be introduced more readily than primary groups, as indicated in Table 1. In the case of 3-alkylthiophene synthesis, bromine was found to be more effective as the electrophile than iodine.

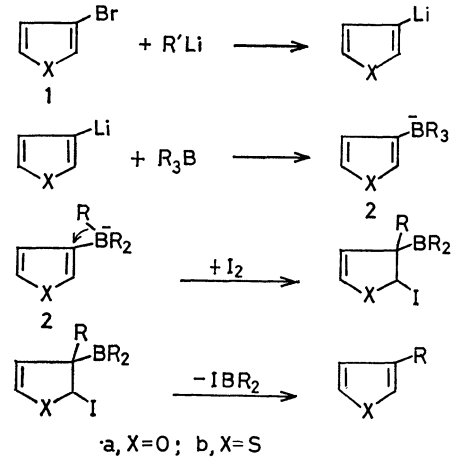
a) All products were either compared with authentic samples or exhibited analytical data and spectra in accodance with the assigned structures. b) Based on the organoborane used and determined by VPC.



Scheme 2.

The reaction mechanism, although not explored in detail, could be considered to proceed through the following pathway (Scheme 2).

Experimental

Materials. All the chemicals and solvents were purified by distillation before use. Trialkylboranes were prepared by the usual procedure.[13] 3-Bromofuran was prepared by the Nazarova's method.[14]

The IR and NMR spectra were taken on a Hitachi-Perkin-Elmer Model 125 spectrophotometer and Hitachi R-22 spectrometer at 90 MHz using tetramethylsilane as an internal standard.

General Procedure. A representative procedure for the preparation of 3-*s*-butylfuran is as follows. A dry 50 ml round-bottomed flask equipped with a condenser, a septum inlet and a magnetic stirring bar was flushed with nitrogen. In the flask was placed 3-bromofuran (3 mmol, 0.27 ml) and anhydrous ether (5 ml) under nitrogen gas. Then butyllithium (3 mmol, 1.54 ml of a 1.95 M solution in ether) was added dropwise at −78 °C to form 3-lithiofuran.[15] The mixture was stirred for 30 min. After metallation was complete, tri-*s*-butylborane (3 mmol, 1.5 ml of a 2 M solution in THF) was added to the mixture at −78 °C, followed by stirring for 30 min. The solution was allowed to warm to 0 °C and then stirred again for 30 min. Finally, a solution of iodine (3 mmol, 0.726 g in 10 ml of ether) was fed in at −78 °C. The reaction mixture was allowed again to warm to room temperature and stirred for 2 h. In order to remove the residual organoborane, the mixture was treated with 3 M aqueous sodium hydroxide (2 ml), followed by a dropwise addition of 30% hydrogen peroxide (1 ml). The product thus obtained was extracted three times with ether and the combined organic layer was dried over magnesium sulfate. VPC analysis (15% Silicone DC-550 on Uniport B, 120 °C) indicated that 2.73 mmol (91%, based on tri-*s*-butylborane) of 3-*s*-butylfuran had been obtained. An analytically pure material was obtained by preparative VPC (15% Silicone DC-550 on Uniport B, 3 m) with Varian Autoprep Model-2800.

Identification of the Products. *3-Butylfuran*: n_D^{20} 1.4705. Found: C, 77.02: H, 9.85%. Calcd for $C_8H_{12}O$: C, 77.37; H, 9.74%. Mass; *m/e*=124 (M^+). IR(neat); 3150, 1520, 885, 780 cm^{-1}. NMR(CCl_4): δ, 0.95 (3H, t, J=7.0 Hz), 1.50 (4H, m), 2.42 (2H, t, J=7.0 Hz), 6.20—7.30 (3H, m).

Transmission of Low-energy Electrons through Thin-films of Benzene and Hexane at 80 K

Kenzo HIRAOKA* and Masaji NARA
Faculty of Engineering, Yamanashi University, Takeda-4, Kofu 400
(Received May 6, 1980)

Transmission spectra of low-energy electrons (0—15 eV) for 10—100 Å films of benzene and hexane have been measured at 80 K. Resonances are clearly indicated by electron current I_t transmitted through the dielectric as a function of the incident electron energy V_1, displayed as dI_t/dV_1 *vs.* V_t. When the film thickness of hexane was increased, the height of the first peak (due to injection of electrons in the film) decreased drastically and a second peak appeared and grew strongly. From the energy of the second peak, the bulk electron affinity ($-V_0$) of thin film was estimated. The V_0 values for hexane and octane are 0.9 and 1.0 eV, respectively.

The excitation of gas-phase molecules by electron impact has often been studied by a variety of techniques ranging from low-energy threshold excitation[1,2] to energy loss spectroscopy,[3-5] using both high- and medium-energy electrons. Threshold excitation techniques of Schulz[1] and Compton *et al.*[2] are similar in that the yields of low-energy electrons produced by resonant electron impact processes are measured either by the trapped electron method or by the SF_6 scavenger technique.[2]

Applications of electron impact techniques to thin organic films have previously been restricted to the measurements of energy loss spectra of high-energy electrons transmitted through thin films of polymers.[6,7] Since the optical selection rules are relaxed for excitation by low-energy electrons,[8] it is not possible to extrapolate results from energy loss spectra involving high-energy electrons to processes involving low-energy electrons.

Recently, Hiraoka and Hamill[9-14] and Sanche[15,16] reported a simple method for measuring the electronic levels of molecules supported as ultrathin films on a metal surface at 77 K.[9-14] The film was bombarded by a beam of low-energy electrons, and the current transmitted through the film(I_t) was measured as a function of the incident electron energy(V_i). This method was found particularly useful for detecting optically forbidden electronic transitions.

A similar apparatus was constructed. The main objective of this work is to relate the energy dependence of the transmission features to specific interactions occuring in films of benzene and hexane.

Experimental

A schematic diagram of a prototype spectrometer housed in a stainless steel high-vacuum system (ULVAC, EBD-50M) maintained at $\lesssim 2\times10^{-7}$ Pa appears in Fig. 1. An electron gun used is a commercial TV gun (The Japan Lamp Industrial Co., LTD.) consisted of an einzel lense and an indirectly heated oxide-coated cathode. The gun is mounted in a grounded stainless steel cylinder. The angle of incidence of the electron beam to a metal target is normal.

A schematic diagram of the spectrometer system used for the measurement of electrons transmitted through thin solid films is shown in Fig. 2. Differentiation of the transmitted current I_t with respect to the incident electron energy V_1 is accomplished electronically by superimposing a small a.c. voltage (0.3 V peak-to-peak at 78 Hz) on the base cathode voltage and synchronously detecting the resulting a.c. signal

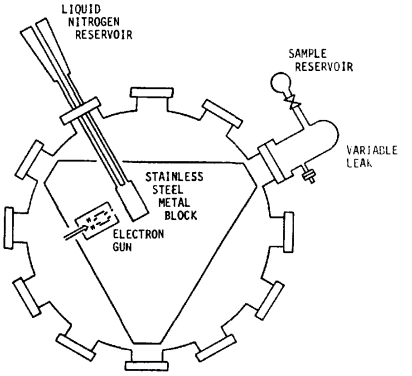

Fig. 1. Schematic diagram of the spectrometer.

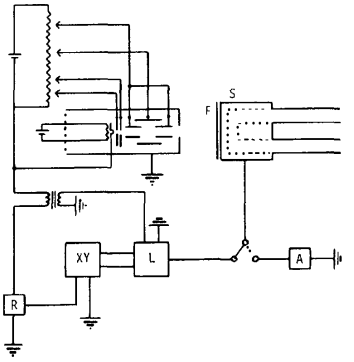

Fig. 2. Schematic arrangement of the apparatus used for measuring the electron current transmitted through the dielectric film F to the stainless steel support S at ≈80 K. Other components include a lock-in amplifier L, a ramp function generator R, a recorder XY, and an electrometer A.

at the target with a lock-in amplifier (NF Circuit Design Block Co., LTD. model LI-573). An X-Y recorder plot of the magnitude of the a.c. signal *vs.* the the cathode potential provides the transmission spectrum, dI_t/dV_1 *vs.* V_1.

The sample was deposited as a thin film on the stainless steel block (face 3.6×2.0 cm^2) cooled by circulating liquid nitrogen. The temperature of the metal block was measured by an iron-constantan thermocouple which was spot-welded on the metal block. A sample was admitted to the vacuum chamber through a variable leak valve. The film thickness was estimated by establishing a given partial pressure of a sample vapor in the vacuum chamber for a specific time, assuming a sticking probability of unity. The pressure gauge, which reads the ion current of an ion pump, was calibrated

for nitrogen. Because almost all of organic compounds have larger ionization cross sections than nitrogen, the reading of the pressure gauge must be higher than the actual pressure of an introduced organic compound at the ion pump. However, the position of the pressure gauge was far from the metal block, and the effective pressure at the metal block could be higher than the pressure at the ion pump. Thus the value of the film thickness given in this work should be considered as only a roughly estimated one. The film thickness was changed by changing the deposition time with the constant vapor pressure at 10^{-5} Pa. It has not been known whether films are crystalline or amorphous, but the randomness in the solid was suggested for benzene film at 77 K.[17]

In the previous works,[9-14,17] the incident electron current of 10^{-9}—10^{-8} A with a beam spot of $\approx$1 mm in diameter was used, where it was found that the condensed films of organic compounds were very sensitive to electron bombardment. The spectrum dI_t/dV_i *vs.* V_i for the bare metal block often showed apparent difference before and after the measurement of an aromatic sample, indicating that a metal surface was contaminated by the radiolytic products. The metal block had to be cleaned every time after the measurement of an aromatic sample. Saturated molecules gave less radiolytic products than aromatic compounds under the same experimental conditions.

In this experiment, the incident electron current of $\leq 2\times 10^{-9}$ A with a larger beam spot was used in order to reduce the radiation damage of a film. The diameter of the aperture for electrons in the end wall of the cylinder was 5 mm. The size of the beam spot could be roughly estimated by observing weak blue luminescence from thin-film benzene bombarded by electrons with the energy of 15—20 eV. The observed faint luminous lobe was about 13 mm in diameter. Thus the current density should be at most 2×10^{-9} A/cm^2. Matsushige and Hamill measured the yields of decomposition products from multilayer films of cyclohexane and hexane caused by low-energy electron irradiation.[18] They found the G values† to be $\approx$0.5 for electron energies of 10—20 eV. With decomposition yields of this magnitude, a monolayer of the hydrocarbons could be decomposed in 100 h under the conditions of our study. The spectrum for bare metal block did not change under repeated measurements for aliphatic and aromatic compounds, in agreement with the results of Matsushige and Hamill.[18]

Results and Discussion

Benzene. The transmission spectra dI_t/dV_i *vs.* V_i for benzene are shown in Fig. 3. The film thickness was changed from 2 to 10 L.†† The spectrum of the metal block is also shown in the Figure, which was measured before the organic sample was deposited. The temperature of the metal block was $\approx$80 K.

The spectra of benzene are in excellent agreement with the result obtained by Hiraoka and Hamill,[10] indicating a good reproducibility of the present method. In Fig. 3 are also shown the trapped electron spectrum[19] and the energy loss spectrum of 300 eV electrons[20] for comparison. These spectra serve to establish the energy

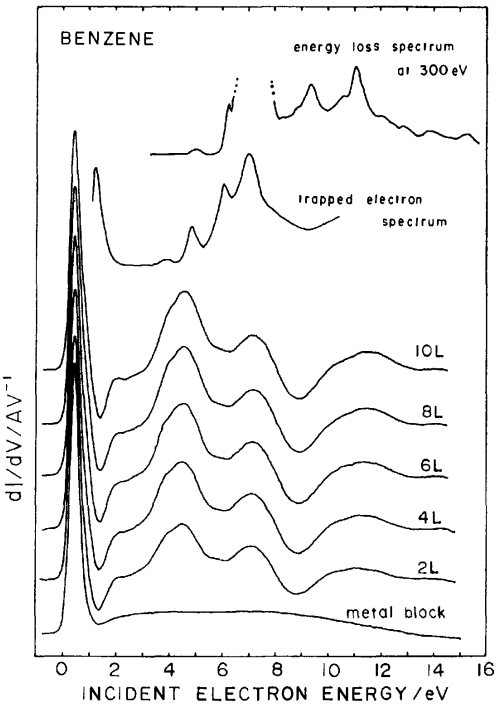

Fig. 3. The dependence of dI_t/dV_i *vs.* V_i for metal block and benzene. The film thickness was changed from 2 to 10 L. The trapped electron spectrum[19] and the energy loss spectrum of 300 eV electrons[20] are also shown for comparison.

shift of the spectrum dI_t/dV_i *vs.* V_i. The best fit locates the zero of the incident electron energy at the onset of the first peak.

The strong bands appear in the spectrum dI_t/dV_i *vs.* V_i at 3.9 and 4.6 eV in Fig. 3 which correspond to energies lost by exciting benzene to the $^3B_{1u}$ and $^1B_{2u}$ states, respectively. These optically forbidden transition bands are even larger than the optically allowed $^1E_{1u}\leftarrow{}^1A_{1g}$ transition band at 7 eV, indicating the major advantage of the electron impact over the photon spectroscopy for its ability to induce optically forbidden transitions.

Another weak events are also observed as a shoulder of the first peak and two small peaks in the range 1.5—3.0 eV. Although the shoulder peak corresponds approximately to the peak at 1 eV in the trapped electron spectrum which is due to the transient negative ion formation, the relative intensity of the shoulder peak is much smaller than the peak at 1 eV in the trapped electron spectrum, and the assignment of this peak would not be so straightforward. The origins of events in the range 1.5—3.0 eV were not well understood either. A further investigation for the detailed analysis of the spectra is now in progress.

It is evident from Fig. 3 that the 2 L film is thick enough to give a characteristic transmission spectrum of benzene and the spectra of thicker films did not show any marked dependence on the film thickness up to 10 L. This suggests that the interaction of low-energy electrons with only a few monolayers from the surface of benzene film gives the characteristic transmission spectrum. In addition, the onset of the first peak and the positions

† The *G* value refers to the number of molecules of a product formed on irradiation per 100 eV of energy absorbed.

†† The amount of the gas admitted in the vaccum chamber is expressed in Langmuir units (1 L$=1\times 10^{-6}$ Torr s). When the sticking probability is unity, the surface will be covered by approximately one monolayer with 1 L gas admission.

of peaks in transmission spectra appear at almost the same energies with increasing the film-thickness from 2 to 10 L. This indicates that the charging of electrons in the film is negligible for the present experimental conditions.

Since the first peak of the spectrum for the metal block describes a crude electron energy distribution function with the high-energy tail at the onset, the detailed examination of the change of the first peak after the dielectric film is deposited on the metal surface would be helpful for understanding the interaction of low-energy electrons (0—2 eV) with dielectrics. As shown in Fig. 3, there is almost no difference in shape (height and half-width) between the first peak for the metal block and those for benzene for 2—10 L. It is noteworthy that the acceptance coefficients for electrons at low energies are nearly the same for benzene and the stainless steel metal block. Only the difference is the appearance of a small shoulder peak at $\approx$1 eV and the sharp negative peak at $\approx$1.3 eV in the benzene spectra which are not observed for the stainless steel metal block.

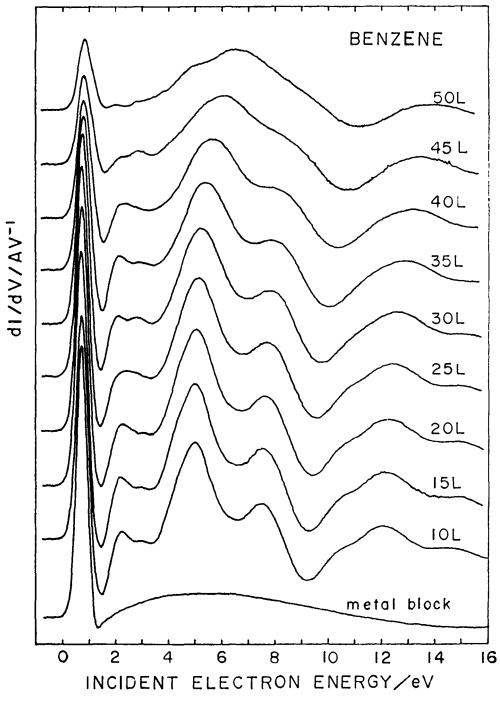

Fig. 4. The dependence of dI_t/dV_1 *vs.* V_1 for benzene. The film thickness was changed from 10 to 50 L.

In Fig. 4 is shown the change of spectra when the film thickness was increased from 10 to 50 L. The height of the first peak decreases only gradually with increasing the film thickness. The peaks of the spectra show only very small positive shifts with increasing the film thickness up to 25 L. Above 30 L, the positive shifts become more evident possibly due to the charging of the film.

Hexane. The transmission spectra are shown in Fig. 5. The film thickness was changed from 2 to 30 L. The zero of the energy scale is arbitrary. Contrary to the spectra of benzene, the first peak decreases drastically and the second peak at $\approx$1.4 eV grows strongly as the

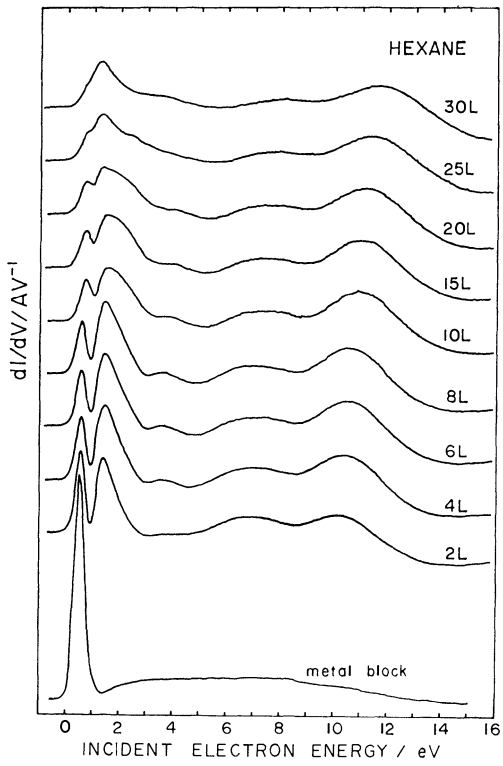

Fig. 5. The dependence of dI_t/dV_1 *vs.* V_1 for metal block and hexane. The film thickness was changed from 2 to 30 L.

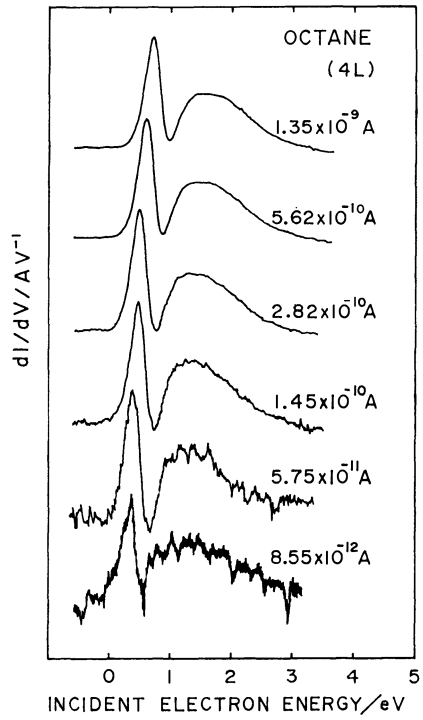

Fig. 6. Spectra of octane in the energy range 0—3 eV with the incident electron current changed from 8.55×10^{-12} to 1.33×10^{-9} A.

film thickness is increased. At 30 L, the first peak shows up as only a small shoulder peak of the second peak. Such a marked change of the spectra with an

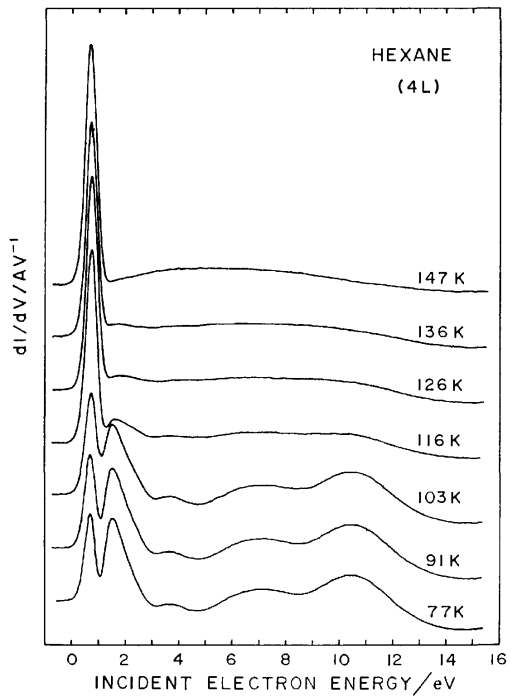

Fig. 7. Temperature programmed spectra following the adsorption of hexane on the stainless steel metal block at 77 K. The heating rate is 10 K/min.

increase of the film-thickness was also observed for octane (Fig. 6), but not for benzene and other aromatic compounds. These characteristic low-energy events of hexane may be related to the interaction of electrons with the bulk of the solid film, *i.e.*, the cluster of molecules.

Figure 7 shows spectra of the temperature dependence following the adsorption of hexane (4 L) on the metal block at 77 K. The heating rate is 10 K/min. As the temperature is increased, the intensity of first peak increases gradually with an expense of the second peak. The spectrum at 147 K coincides with that of the metal block, indicating that all samples are desorbed from the metal block at this temperature. The observed rapid desorption suggests the weak adsorption of hexane on the stainless steel substrate. Madey and Yates observed two peaks at 150—175 K and 277 K in the temperature programmed desorption spectra following the adsorption of cyclohexane on Ru(001) at 80 K.[21] They concluded that the state at 150—175 K is due to a condensed multilayer and that at 227 K is due to C_6H_{12} adsorbed in the first monolayer in contact with the Ru(001) substrate. In Fig. 7, the rapid change of spectra is observed from 77 to 126 K, but the spectra at 126 and 136 K are almost exactly the same, suggesting that these spectra are those for the monolayer of hexane on the metal substrate. The multilayer should be exhausted in this temperature range because the vapor pressure of hexane at 126 and 136 K are about 1×10^{-4} and 1×10^{-3} Pa, respectively. The second peak of spectra for 126 and 136 K is still observed but it shows the positive shift by 0.3—0.4 eV with respect to the peak of multilayer films. The coverage of hexane monolayer at these temperatures could not be estimated under the present experimental conditions.

Bulk Electron Affinity. As shown in Figs. 3 and 5, the low-energy events of benzene are very different from those of hexane in the range 0.5—2.0 eV. In the case of benzene, the first peak does not show a marked film-thickness dependence and a sharp negative peak is observed at $\approx$1.3 eV. On the contrary, a rapid decrease of the first peak accompanied by a strong growth of the second peak is observed for hexane as the film-thickness is increased. These experimental results suggest the existence of the positive energy barrier in hexane thin film and the negative one in benzene thin film for the injection of electrons from the vacuum into the film. If the positive energy barrier for hexane is due to the temporal charging of the film, the spectra should be dependent on the amount of the incident electron current at least to some extent. Figure 6 shows the spectra of octane in the energy range 0—3 eV with the incident electron current changed from 8.55×10^{-12} to 1.35×10^{-9} A. It is apparent from the Figure that the shape of the spectra does not change with an increase of the incident electron current more than two orders of magnitude. Thus the energy barrier for the incident electrons can not be attributed to the one generated by charging in the film. We would like to conclude that energy barrier is an intrinsic one for each compound, *i.e.*, the bulk electron affinity.

In Fig. 6, the gradual positive shifts of the spectra are observed with the increase of the incident electron current. This is *not* due to the charging of the film. When the film thickness is $\leq$10 L, the spectra of organic compounds generally do not show any observable peak shifts under repeated and prolonged irradiation of the electron beam of $\approx10^{-9}$ A. The shifts observed in Fig. 6 is a manifestation of the positive shifts of the current-voltage characteristic curve of the electron gun. The positive shift is always observed when the voltage of the draw-out electrode in front of the cathode is increased in order to get more electron current.

For an electron of energy E in the condensed medium, the Schrödinger equation is

$$\left[-\frac{\hbar^2}{2m}\nabla^2+V\right]\Psi=E\Psi, \tag{1}$$

where V is the one-electron potential exerted by the unperturbed medium. When the potential V is periodic from one sphere to another and spherically symmetric inside the sphere, only one radial equation needs to be solved, so that the ground state eigenvalue E of Eq. 1 can be uniquely defined. Springett *et al.*[22] calculated the energy levels of an excess electron in multiatom system by using a Wigner-Seitz model to obtain a spherically symmetric potential. In the Wigner-Seitz model each atom is replaced by a sphere of radius r_s given by

$$r_s=\left(\frac{3}{4\pi n}\right)^{1/3}, \tag{2}$$

where n is the number density. The wave function ψ is smooth inside r_s, and V is the pseudopotential approximated as ∞ for $r<\bar{a}$ and U_p for $r>\bar{a}$. This pseudopotential excludes the excess electron from the hard core radius $\bar{a}$ of the atom. U_p is the polarization potential from the atom inside and the atoms outside r_s which is approxi-

mated by

$$U_p = \frac{-3\alpha e^2}{2r_s^4}\left[\frac{8}{7}+\left(1+\frac{8}{3}\pi\alpha n\right)^{-1}\right], \quad (3)$$

where α is the isotropic polarizability. Then, Eq. 1 may be solved to yield

$$E = U_0 + \frac{\hbar^2 k_0}{2m} = U_0 + T_0, \quad (4)$$

where the electron wave vector k_0 is obtained from the Wigner-Seitz boundary condition $(d\psi/dr)_{r=r_s}=0$, which gives the equation

$$\tan k_0 (r_s-\bar{a}) = k_0 r_s, \quad (5)$$

and T_0 is the zero point energy which arises because the excess electron is excluded from the hard core region of radius in each Wigner-Seitz sphere. The lowest energy eigenvalue E of Eq. 1 is the ground state energy of an excess electron in the medium (V_0), *i.e.*, an energy required for injection of an electron from the vacuum into the medium. The bulk electron affinity of the medium corresponds to $-V_0$.

The positive bulk electron affinity may be assigned for benzene film. When the bulk electron affinity of the film is positive, the energy level of an excess electron (V_0) in the film is lower than that of the vacuum. In such a case, the electrons see the "negative" energy barrier when they enter the film from the vacuum, and the injection peak of electrons (the first peak) should not be very different from that of the bare metal block, in good agreement with the experiment. On the other hand, the excess electron in the film see the "positive" energy barrier for escaping into the vacuum. For a spherically-asymmetric distribution of elastically scattered electrons in a film, with a negative V_0, the quantum mechanical reflection coefficient at the film-vacuum interface may be given by $R=\{|V_0|/(|V_0|+E_i)\}^{1/2}$, where E_i is the energy of electrons.[16] According to this theory, the backscattered current will show an increase as the energy of incident electrons increases because it is easier for injected electrons in the film to overcome the positive energy barrier ($-V_0$) and escape the film into the vacuum at higher incident electron energy (E_i), *i.e.*, the effective reflection coefficient at the film-vacuum interface will decrease with an increase of the energy of electrons. This might explain the observed negative peak at $\approx$1.3 eV in the benzene spectrum.

The low-energy events observed for hexane and octane can be explained reasonably if the negative bulk electron affinity is assigned for these compounds. Figure 8 shows the schematic potential distribution along the axis of the spectrometer and the spectrum, dI_t/dV_i *vs.* V_i, for a film whose bulk electron affinity is negative ($0<V_0$). Because of the positive energy barrier of the film for the incident electrons, the injection peak of electrons (the first peak) should be much smaller than that of the metal block, and the transmitted electron current should show a sharp increase as a second peak in the spectrum, dI_t/dV_i *vs.* V_i, when the energy of the incident electrons exceeds the positive energy barrier, in all good agreement with the experimental results.

If the observed low-energy events are manifested by the bulk electron affinity of the films, it might be

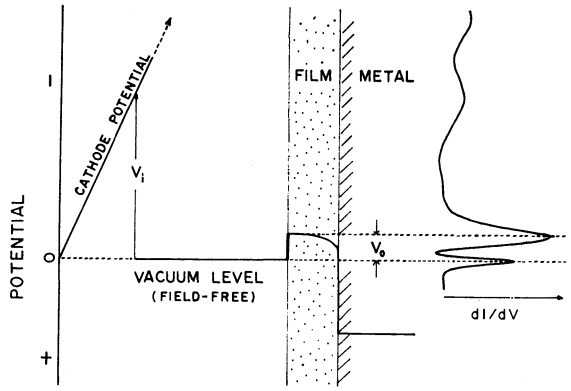

Fig. 8. The schematic diagram of the potential distribution along the axis of the spectrometer. The space between the electron gun and the metal block is field-free. The bulk electron affinity of the film shown in the figure is negative. The spectrum of hexane, dI_t/dV_i *vs.* V_i, is shown along the potential axis in the right part of the figure. V_i is the accelerating voltage. V_0 represents the ground state energy of excess-electrons in the film. The value of the bulk electron affinity corresponds to $-V_0$.

possible to estimate the bulk electron affinities from the spectra dI_t/dV_i *vs.* V_i. The spectrum is a convolution of the current-voltage characteristics of an electron gun $I(V)$, and the energy dependent acceptance coefficient of electrons for the film $F(V)$. $F(V)$ may be affected by many factors such as the bulk electron affinity, the density and the structure of the film, density of trapping sites and the distribution of the well-depth of trapping sites, *etc.* Because so many factors are involved in the low-energy events of the spectra, it would be difficult to determine the bulk electron affinity unequivocally. Here the bulk electron affinity ($-V_0$) is tentatively estimated by the energy difference of the first peak for the metal block and the second peak of the spectra for hexane and octane, which are -0.9 and -1.0 eV, respectively.

The positive bulk electron affinity could be estimated by the amount of the positive shift of the spectrum if the reference peak is available for the determination of the energy scale. For benzene, the horizontal axis of Fig. 3 is the energy for the trapped electron spectrum[19] and the energy loss spectrum of 300 eV electrons.[20] With this scale, the energy of the transmission spectrum is increased by 0.3 eV to establish a coincidence between structures present in these spectra. Thus the bulk electron affinity of benzene film could be estimated as about 0.3 eV (V_0 is -0.3 eV).

For solid hydrocarbons, no direct experimental V_0 determinations have been reported so far. Jortner's calculations[22,23] give nearly equivalent V_0 values for solid and liquid argon. On the other hand, recent experiments by Noda *et al.* have shown that V_0 increases with decreasing temperature in liquid ethane.[24] Recently Grand and Bernas[25,26] measured V_0 for solid hydrocarbons indirectly by measuring the ionization potential of a solute in various polar and nonpolar rigid solvents. Their indirectly measured V_0 for rigid hexane is 0.98 eV, in good agreement with our value (0.9 eV).

The Springett, Jortner and Cohen model for calculat-

ing V_0 (Eq. 4) was originally developed for rare gas liquids[22] but has been applied to hydrocarbons.[24,27] For liquid hexane, U_0 and T_0 can be calculated as -2.4 and 1.77 eV, respectively, and thus V_0 is -0.63 eV. The experimental value of V_0 in liquid hexane by photoelectric work function measurements is 0.04 eV,[28] which is much smaller than the value in rigid hexane. Grand and Bernas[26] also found that the 77 K V_0 values appear significantly greater than the ones measured at 298 K (liquid) by 0.7—1.0 eV.

The author would like to thank Professor W. H. Hamill of the University of Notre Dame for his encouragement and Professors E. Hayashi and K. Sakai and Mr. S. Takeuchi of Yamanashi University for valuable discussions. The financial supports of the Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 354135, 1978) and of 1978 RCA Research Grant are gratefully acknowledged.

The Adsorption of Basic α-Amino Acids in an Aqueous Solution by Titanium(IV) Oxide

Susumu Okazaki,* Teruaki Aoki, and Koichi Tani

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi 316

(Received June 5, 1980)

TiO_2 showed a pronounced activity in the adsorption of basic α-amino acids, such as L-lysine and L-arginine, in an aqueous solution. The adsorptive activity of TiO_2 containing sulfate ions was lower than that of the sulfate ion-free TiO_2, and it was suppressed by phosphate ions. The pH of the aqueous solution hardly affected the adsorption, while the heat-treatment of TiO_2 above 500 °C noticeably lowered the adsorption. The Langmuir equation was applicable to the adsorption of L-lysine, showing that the amount of saturated adsorption was about 0.7 mmol/g TiO_2 heat-treated at 500 °C. The heat of adsorption of L-lysine, as determined from the adsorption isotherms at 10, 30, and 50 °C, was 2257 J/mol. A linear relationship was observed between the amount of L-lysine adsorbed and that of the surface OH groups.

The removal of excess α-amino acids in the blood is required for the treatment of certain kidney diseases.[1] The use of activated carbon has been an important removal method. Ito[2] has observed a marked adsorption of the basic amino acids, such as lysine, histidine, and arginine, by animal charcoals, and Wunderly[3] has obtained adsorption isotherms for phenylalanine, leucine, serine, and aspartic acid on animal and sugar charcoals. However, a systematic investigation of the adsorption of amino acids on Darco G-60 lignite charcoal by Cherdelin *et al.*[4] indicated that activated carbon was not effective for the adsorption of all kinds of α-amino acid, for the absence of the aromatic group in amino acids decreased the adsorption. Aliphatic amino acids, having a high solubility in water, can be expected to be better adsorbed by an adsorbent which is more polar than activated carbon.

In recent years, TiO_2 and its hydrate have been extensively used as catalysis,[5] catalyst-carriers,[6] and ion-exchangers.[7] They have also been observed to be excellent adsorbents for uranium in sea water.[8] However, no studies dealing with the adsorptions of α-amino acids by TiO_2 have been reported. The use of TiO_2 as an adsorbent for α-amino acids is, though, a matter of considerable interest because of its extremely low solubility in water, its nontoxicity, and its amphoteric nature.

In this paper, we wish to report our results concerning the activity of TiO_2 in the adsorption of basic α-amino acids in aqueous solutions. The adsorptive activities of alumina and activated carbon for α-amino acids were also examined for reference.

Experimental

Preparation of the Samples. Two TiO_2 samples were prepared: one by the hydrolysis of titanium tetraisoproxide (Wako Chemical Co.) at room temperature (designated as S-1), and the other, by the hydrolysis of titanium oxide sulfate (Nakarai Chemical Co.) at the temperature of boiling water (designated as S-2). After repeated washings and decantations, both samples were dried in air at 120 °C for 10 h. Although the complete removal of the sulfate ion was confirmed by the use of a $BaCl_2$ aqueous solution, S-2 contained a considerable amount of bound sulfate ion (for example, 0.5 mmol/g after heat-treatment at 400 °C). Therefore, in most experiments, S-1 was employed. Only in experiments relating to the effects of the heat-treatment temperature was S-2 used.

The alumina was prepared by the hydrolysis of aluminum isopropoxide (Wako Chemical Co.), followed by washing with water and drying at 120 °C. The activated carbons used were the commercial products of the Kureha Chemical Co. (MU and MU-E).

The various amino acids used in this study were commercial reagents of a special grade prepared by the Kokusan Kagaku Co.

Determination of the Amount of Surface OH Groups. The amount of surface OH groups was determined by a modification of Boehm's method.[9] The amount of OH on S-1 sample, which was heat-treated at 500 °C, was 0.7 mmol/g TiO_2.

Method of Adsorption. One or 2 g of the adsorbent were added to 50 or 200 ml of an amino solution of 400 or 200 mg dm^{-3}, and then the mixture was continuously shaken for 3 h at 30 °C using a shaker. Prior to the adsorption, the TiO_2 and Al_2O_3 were ground so as to pass through a 150-mesh sieve and then fabricated to granules of a 14—20 mesh size under a pressure of 40 MPa. The solutions were buffured at pH 7.3 by using KH_2PO_4 and Na_2HPO_4. To ascertain the effect of pH, KH_2PO_4/Na_2HPO_4 ratio was adjusted to give the solution pH values of 5.2 and 8.3. On the other hand, to find the effect of the phosphate-ion concentration on the adsorption, its concentration was adjusted to 0.025, 0.050, and 0.083 mol dm^{-3}. The adsorption isotherm was determined in deionized water, since phosphate ions affected the adsorption of amino acid.

Analysis. The analysis of the amino acids was carried out by using a Total Carbon Detector (Toshiba-Beckmann Co., Type 915) or the ninhydrin method.[10]

Results and Discussion

Comparisons of Adsorptive Activities of Adsorbents for Amino Acids. The results obtained for the adsorption of various types of α-amino acid are listed in Table 1. The adsorptive activities of other metal oxides, such as ZrO_2, MgO, and SiO_2, were also examined, but their activities appeared to be considerably less than that of TiO_2.

As is shown in Table 1, TiO_2 exhibited the highest activity for the adsorption of all the basic amino acids except L-tryptophan. Its activity for the neutral or acidic α-amino acids was far less than those of activated carbons. The high activities of TiO_2 in the adsorption of L-lysine·HCl and L-ornithine·HCl may be due to the high degree of hydrolysis of these salts in solution.

Effects of Phosphate Ion and pH on Adsorption. A

Table 1. Effect of acid-base property of amino acid on adsorption

Adsorbate	Degree of adsorption/%[a]			
			Activated carbon	
	Al_2O_3[b]	S-1[b]	MU-LE	MU-L
Neutral				
Glysine	18.5	22.9	24.4	23.3
L-Alanine	22.2	21.5	25.0	16.5
L-Valine	12.9	16.9	50.6	46.0
α-Amino-isobutyric acid	0	0	18.1	15.8
DL-Leucine	0	0	84.1	79.5
L-Isoleucine	20.6	0	81.6	84.8
Acidic				
DL-Glutamic acid	0	0	20.8	22.6
DL-Aspartic acid	0	0	18.1	12.2
Basic				
L-Lysine	12.0	83.4	20.5	15.1
L-Arginine	1.8	72.6	73.5	71.1
L-Histidine	8.6	86.2	92.2	94.3
L-Tryptophan	7.8	18.1	100	99.5
Salt				
L-Lysine·HCl	1.1	73.4	24.9	20.7
L-Citrulline·HCl	0	11.9	83.9	80.4
L-Ornithine·HCl	15.3	87.1	26.1	14.2

a) Adsorption temperature: 30 °C; time: 3 h; initial concentration of amino acid: 400 mg/l; phosphate buffer: pH 7.3 (0.033 mol/l). b) Heat-treated at 150 °C for 3 h immediately before use.

considerable change in the pH of the solutions was observed during the course of adsorption. The adsorption experiments in phosphate buffer solutions were carried out at pH values close to that of the blood. However, since the phosphate ion is adsorbed on TiO_2,[11] the effect of the phosphate ion on the adsorption of amino acid was examined, together with the effect of the pH of the solutions. L-Lysine was selected as representative of aliphatic and basic α-amino acids because of the ease of analyzing.

As is shown in Fig. 1, both the rate of adsorption and the amount of L-lysine adsorbed at the equilibrium were reduced by the presence of the phosphate ion. In

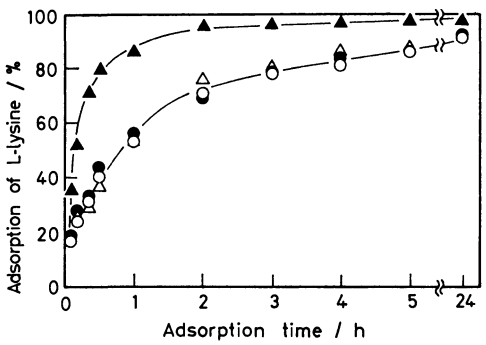

Fig. 1. Effect of pH on adsorption.
L-Lysine (20 mg) and S-1 (2 g) were added to 50 ml of the solntions buffered at pH 5.2 (○), 7.3 (●), and 8.3 (△). ▲ Denotes the result of the adsorption carried out in deionized water.

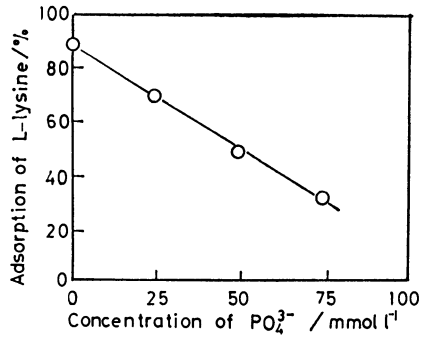

Fig. 2. Effect of concentration of phosphate ion on adsorption. S-1 (1 g) was added to 50 ml of the solution buffered at pH 7.3, and the adsorption was carried out 5 h. Other conditions were the same as those in Fig. 1.

the absence of the phosphate ion, the pH of the solution dropped from the initial value of 9.7 to 7.4 after 24 h. However, the effect of the pH on the adsorption of the amino acid was slight in the pH range of 5.2—8.3 when the concentration of phosphate ion was kept constant. The amount of L-lysine adsorbed at the equilibrium decreased linearly with the increase in the phosphate concentration as is shown in Fig. 2. This fact suggests that the α-amino acid and the phosphate would be adsorbed on identical sites. Thus, it appeared that the adsorption of the α-amino acids proceeded in competition with the phosphate ion. However, a preferential adsorption of the amino acid on TiO_2 was observed at higher phosphate concentrations (0.0033 mol dm^{-3}) and at dilute amino acid concentrations (0.0027 mol dm^{-3}).

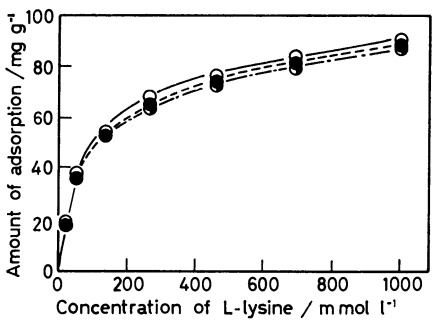

Fig. 3. Adsorption isotherm of L-lysine in deionized water. Adsorption were carried out for 70 h at 10 °C (○), 30 °C (●), and 50 °C (◑). Other conditions were the same as those Fig. 2.

Adsorption Isotherms in Deionized Water. Figure 3 shows the adsorption of L-lysine at 10, 30, and 50 °C. The effect of the temperature on the adsorption was slight. As is shown in Fig. 4, a linear relation was obtained between the logarithm of the equilibrium constant of adsorption, K_c, and $1/T$. Here, the equilibrium constant was calculated by dividing the amount of the amino acid adsorbed by that in the solution at the equilibrium (*i.e.*, about 1000 mg dm^{-3}). At this concentration, the surface of TiO_2 appeared to be saturated almost completely with the amino acid at

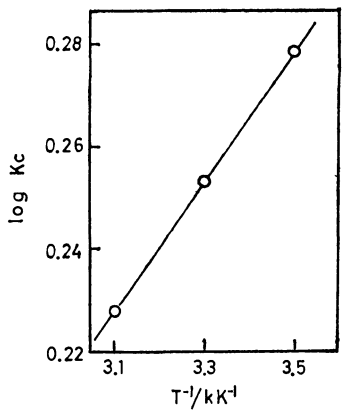

Fig. 4. Linear relationship between $1/T$ and log K_c.
K_c denotes the equilibrium constant of adsorption of L-lysine.

these temperatures. The heat of adsorption, H_a, was calculated to be 2257 J/mol by using the van't Hoff equation; this value indicates a weak interaction of the amino acid with the TiO_2 surface.

The linear relation between the concentration of L-lysine and the value of the concentration divided by the amount of adsorption at the equilibrium (Fig. 5) indicates that the Langmuir adsorption equation is applicable. The values of the monomolecular adsorption, V_m, were calculated to be 0.70 (at 10 °C), 0.67 (at 30 °C), and 0.65 (at 50 °C) mmol/g from the reciprocal of the slope, namely, $\Delta C/\Delta(C/V)$, shown in Fig. 5.

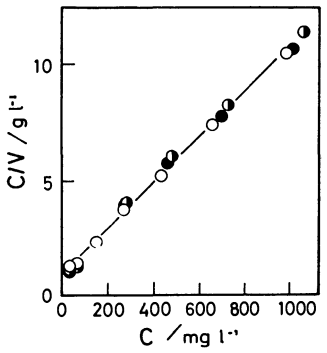

Fig. 5. Application of Langmuir equation to the adsorption shown in Fig. 3.

Effects of Heat-treatment Temperature of TiO_2 and the Amount of Surface OH Groups on the Adsorptive Activity. Figure 6 shows the effects of the heat-treatment temperature of S-1 and S-2 on the adsorption of L-lysine. The adsorptive activity of S-1 showed a maximum at 150 °C, which is close to the dehydration temperature (160 °C) of titanium hydroxide or $TiO_2 \cdot H_2O$.[12] Almost all the adsorptive activity was lost upon heat-treatment at 700 °C, which is the temperature of the conversion from anatase to rutile.[12]

The adsorptive activity of S-2, which contains sulfate ions, also decreased with the increase in the heat-treatment temperature. However, the adsorptive activity of S-2 was less than that of S-1, and it was lost

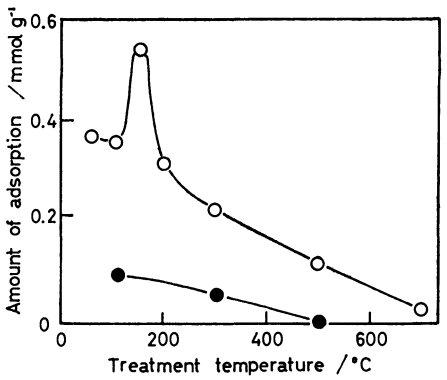

Fig. 6. Effect of heat-treatment temperature of TiO_2 on adsorption.
One gram of S-1 (○) or S-2 (●) was added to 50 ml of the buffered solution containing 2000 mg of L-lysine per litter, and the adsorption were carried out for 50 h at 30 °C.

upon heat-treatment at 500 °C. Since it has been established that TiO_2 containing sulfate ions has acid sites,[13] the adsorptive activity of TiO_2 toward α-amino acid is not related merely to the surface acidity. If the sulfate ions in TiO_2 diffuse to the surface at higher temperature and are lost as SO_3 at about 600 °C,[14] the surface of S-2 treated at temperatures near 600 °C may be covered by sulfate ions, which are then decomposed to SO_3 at slightly higher temperatures (about 600 °C). These sulfate ions on the TiO_2 surface possibly depress the adsorptive ability due to Ti^{4+} ions, O^{2-} ions, and/or OH groups on the surface, resulting in the observed decrease in the adsorptive activity. Since it is known that the Brönsted acid sites due to OH groups on the TiO_2 surface are able to interact with NH_3 and pyridine,[15] the OH groups may react also with amino acids through the interaction with lone-pair electrons of the N atom. The amount of surface OH groups was determined, therefore, to find the correlation between OH and the adsorptive activity.

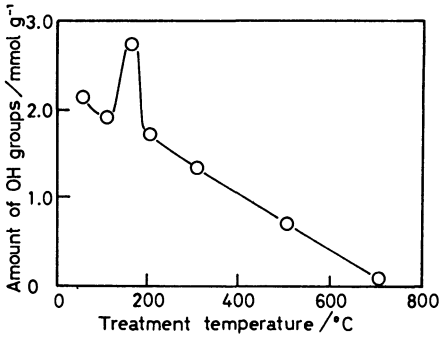

Fig. 7. Effect of heat-treatment temperature of TiO_2 on the amount of surface OH groups.

Figure 7 shows that the amount of surface OH groups was at its maximum when the sample was heat-treated at 150 °C, as was the activity of adsorption (Fig. 6). The linear relation between the amount of adsorption and the amount of surface OH groups shown in Fig. 8 indicates that the adsorptive activity of TiO_2 is largely dependent on the amount of surface OH

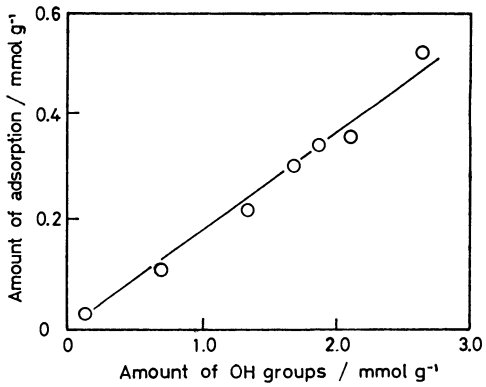

Fig. 8. Amount of L-lysine adsorbed *vs.* amount of surface OH groups for S-1.

groups. The amount of monomolecular adsorption of amino acid on TiO_2 was calculated as 0.65—0.70 mmol/g TiO_2 in the preceding section. This value almost coincides with the amount of surface OH groups on TiO_2 treated at 500 °C; the amount is shown to be 0.72 mmol/g TiO_2 in Fig. 7. This fact further supports the view that the adsorptive activity depends on the surface OH groups.

According to Kobayashi *et al.*,[11] TiO_2 heat-treated at 160 °C showed a maximum activity for the adsorption of phosphate ions. This temperature (160 °C) almost coincides with that at which the amount of OH was at its maximum, suggesting that the phosphate ions also may be adsorbed on the surface OH groups. The suppression of the adsorption of L-lysine by phosphate ions is possibly due to the competition between the phosphate ions and the amino acid for the interaction with surface OH groups.

Table 2. Comparison of adsorptions of various amino acids

Adsorbate	Degree of adsorption/%[a]			
	Al_2O_3[b]	S-1[b]	Activated carbon	
			MU-LE	MU-L
α-Aminoisobutyric acid	1.4	10.9	21.8	22.9
DL-α-Aminobutyric acid	0	15.7	32.1	33.2
γ-Aminobutyric acid	8.7	38.2	26.8	29.1
L-Lysil-L-lysine·2HCl	5.3	7.9	45.3	47.9

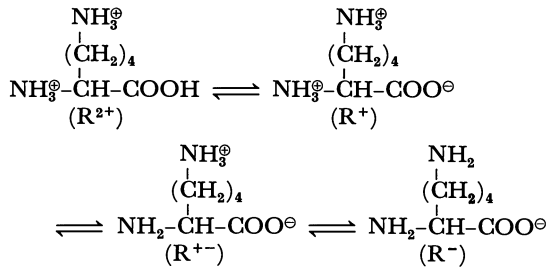
a) The adsorptions were carried out in deionized water. Adsorption temperature: 30 °C; time: 5 h; initial concentration of amino acid: 400 mg/l. b) Heat-treated at 150°C for 3h immediately before use.

Effect of Structure of Amino Acid on the Adsorption. In order to obtain some structural interpretation of the adsorption, the adsorption of three kinds of amino butyric acid were carried out under the same conditions. Table 2 shows the results, including also those of the dimer of L-lysine. γ-Amino acid is preferably adsorbed over α-amino acid, indicating that the end position is more favored for the interaction than is the α-position. The difference in the activity for the interaction between the α and γ position may be ascribed, at least in part, to steric factors. Also, the fact that the iso-type isomer and the dimer were adsorbed by less butyric acid than normal would seem to support this explanation.

Table 3. Acid-base parameters of some basic amino acids in an aqueous solution[16]

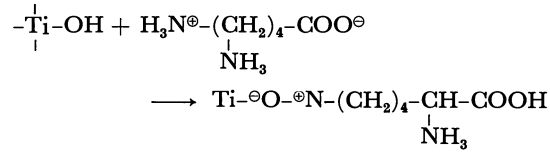
Amino acid	pK_{a1}	pK_{a2}	pK_{a3}	pH_I
Lysine	2.18	8.95 (α-Amino)	10.53 (ε-Amino)	9.74
Arginine	2.17	9.04 (α-Amino)	12.48 (Guanigino)	10.76
Histidine	1.82	6.00 (Imidazol)	9.17	7.58
Tryptophane	2.38	9.39		5.88

Behavior of Lysine on the TiO_2 Surface. In aqueous solutions, most amino acid molecules take one of these forms, NH_3^+RCOOH, $NH_3^+RCOO^-$, or NH_2RCOO^-, depending on the pH of the solution. The dissociation constants of the carboxyl group (pK_{a1}) and amino groups (pK_{a2}, pK_{a3}) in various basic amino acids listed in Table 3, together with the isoelectric points (pH_I). The pH_I values show that lysine and arginine should exist as cations in the pH range (5.2—8.3) of this study. For example, lysine should exist in the form of R^+, as is shown below.



As is generally known, basic amino acids, which exist as cations in a neutral solutions, are selectively adsorbed by weakly acidic ion-exchange resins.[17] Accordingly, TiO_2 may show a high adsorptive activity for lysine and arginine, for the surface OH groups on TiO_2 show weak Brönsted acidity.[5] On the other hand, Al_2O_3, which has only Lewis acidity,[18] did not show a high adsorptive activity for the basic amino acids.

The fact that γ-aminobutyric acid was preferably adsorbed over a α-type isomer (Table 2) suggests that the activity of ω-NH_3^+ is higher than that of α-NH_3^+. Thus, the adsorption of lysine on TiO_2 is considered to proceed as follows:



The authors wish to thank the Tokyo Laboratory of the Kureha Chemical Co. for the supply and analysis of some amino acids; they are also grateful to Mr. Atsumu Nishimura for helpful discussions of the experimental results.

The Equilibrium and the Vibrational Spectra of the *t*-Butylamine-Chloroform System

Isao KANESAKA,* Mitsue IZUMI, Misaki MITSUISHI, and Kiyoyasu KAWAI
Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received June 17, 1980)

The thermodynamic constants, $\Delta H°$ and $\Delta S°$, of the *t*-butylamine (TBA)–chloroform-*d* system in carbon tetrachloride are obtained from the analysis of the Raman intensities observed in the C–D stretching region of chloroform-*d*, while the $\Delta H°$ on the associated species of $TBA \cdot CDCl_3$ and $(TBA)_2 \cdot CDCl_3$ are evaluated to be −14.2 and −22.6 kJ/mol respectively. The IR or Raman spectrum of a solid sample, adjusted by the rapid cooling of a gaseous or liquid one respectively, with the TBA: chloroform ratio of ≈1 is compared with that of TBA in the gaseous, liquid, or solid state; it is confirmed, on the basis of the assignments of the observed frequencies, that the solid sample consists almost entirely of the associated species of $TBA \cdot CHCl_3$. Only one associated species of $(TBA)_2 \cdot CHCl_3$ is also obtained by the crystallization of the gaseous sample with the molar ratio of 2.0. The NH_2 group vibrations in $TBA \cdot CHCl_3$ or $(TBA)_2 \cdot CHCl_3$ are related intimately in their frequencies and band shapes to those in gaseous or solid TBA respectively.

t-Butylamine (TBA) associates itself[1] and forms a weak hydrogen bond with chloroform. On account of those properties of TBA, we are interested in the thermodynamic properties of the present system. Here, we try to evaluate the thermodynamic constants, $\Delta H°$ and $\Delta S°$, by means of an analysis of the Raman intensities of the C–D stretching region of the system, using carbon tetrachloride as a solvent; hereafter, we will denote an associated species $(TBA)_m \cdot (CHCl_3)_n$ as a m : n species.

There are many studies of the vibrational spectra of self-associated species in the solid state by using the matrix-isolation technique, but no spectrum of a solid composed of two kinds of molecules capable of the formation of a weak hydrogen bond has yet been reported, as far as we know. We report here, on the basis of assignments of the vibrational spectra, that the solid sample made by the rapid cooling of a liquid or gaseous sample with a TBA : chloroform ratio of ≈1 or ≈2 consists almost entirely of the 1 : 1 or 2 : 1 species respectively. Although partial information on the structure or the bonding of associated species is obtained from the vibrational spectra of an equilibrium system in the liquid state, it is, of course, apparent that more definite information is obtained from those of a solid consisting of the associated species.

We here assign the IR and Raman spectra of the 1 : 1 species and the IR spectrum of the 2 : 1 species, by referring to those of the related compounds $(CX_3)_3CY$, where X refers to H or D, and Y to OH,[2] CN,[3] or halogen,[4-6] and compare the NH_2 group vibrations of the two species with those of gaseous or solid TBA.

Experimental

TBA or carbon tetrachloride was purified by distillation after drying with anhydrous calcium oxide or calcium chloride respectively. Chloroform was also purified by distillation after removing the ethanol, while commercially obtained chloroform-*d* was used as it was. The liquid Raman samples were adjusted *in vacuo*, so the molarity was determined by assuming that $n=PV/RT$ and by the volumetry of a liquid sample adjusted at 233 K by Hg; the molarities of TBA and chloroform-*d* in the carbon tetrachloride solution were, respectively, for three samples: (i) 3.72 and 1.93, (ii) 2.87 and 2.73, and (iii) 1.99 and 3.83. The Raman spectra were observed in the range from 223 to 244 K by adjusting them within±0.5 K by the use of ethanol and liquid nitrogen.

The solid IR sample was obtained by the deposit of a gaseous sample with a molar ratio of $R=P_{TBA}/P_{CHCl_3}$ on a KRS-5 plate cooled at 77 K in a cryostat; the spectrum was then observed without any annealing. The solid Raman sample was obtained by the rapid cooling of a liquid sample with an adequate *R*, and the Raman spectrum was observed at 113±2 K. The IR or Raman spectrum of solid TBA was also observed in the same way.

The IR spectrum was observed by using a JASCO-IRA spectrometer in the range of 4000—330 cm^{-1}, and the Raman one, by using a JASCO-R800 spectrometer and a 514.5 nm line of the Ar^+ ion laser with the power of 200 mW. The observed frequencies were calibrated by those of a polystyrene film or indene for the IR or Raman spectrum respectively; they are believed to be accurate within±2 cm^{-1}.

The Equilibrium of the TBA-Chloroform-*d* System in Carbon Tetrachloride

The polarized Raman spectrum of the C–D stretching region of Sample (i) at 223 K is given in Fig. 1, together with the one analyzed by two Foight functions[7,8] by means of the least-squares method. The higher and lower frequency components in Fig. 1 are assinged to the C–D stretching mode of the $CDCl_3$ monomer (hereafter,

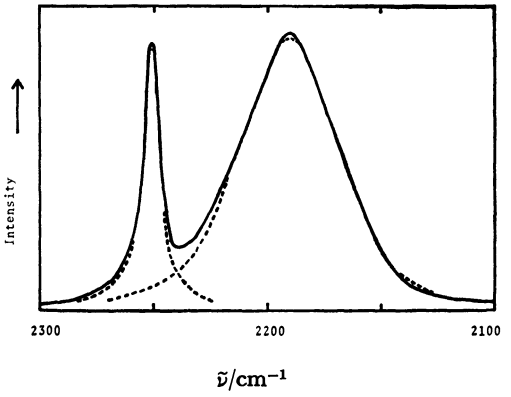

Fig. 1. The observed Raman spectrum (solid line) of the C–D stretching region of Sample (i) at 223 K. Two Foight functions analyzed are given by the broken lines.

$CDCl_3$) and the associated species respectively. The peak shift $\Delta\nu_{C-D}$ obtained from the analyzed band origins is 61.5—57.0 cm^{-1} in the order of the increase in temperature for Sample (ii). The observed relative intensity, $I_{R,O}$, is defined by S_{mn}/S_M, where S_{mn} and S_M are the band areas obtained from the parameters of the Foight functions for the associated species and $CDCl_3$ respectively; it is summarized in Table 1, where $I_{R,O}$ is found to be distributed over the sufficiently wide region of 5.69—0.73.

Under the assumption that some associated species give the lower frequency band, we analyze $I_{R,O}$ as follows: The equilibrium constant is defined by:

$$K_{mn} = \frac{C_{mn}}{C_t^m C_M^n}, \quad (1)$$

where C_t, C_M, and C_{mn} are the molarities of TBA, $CDCl_3$, and the m : n species respectively in the equilibrium state. K_{mn} relates to $\Delta H°$ and $\Delta S°$ as follows:

$$\ln K_{nm} = -\Delta H°_{mn}/RT + \Delta S°_{mn}/R. \quad (2)$$

The molarity of each species in the equilibrium state in the presence of some associated species is determined by using an iterative Newton method.[9] The calculated relative intensity, $I_{R,C}$, is defined by:

$$I_{R,C} = \sum \beta_{mn} C_{mn}/C_M, \quad (3)$$

where β_{mn} is the intensity ratio of each m : n species to $CDCl_3$, and the summation is carried out for all the associated species with chloroform.

The values of $\Delta H°$, $\Delta S°$, and β are adjusted by the least-squares method on the assumption that these parameters are constant in the range of temperature and concentration used here. The results obtained by taking K_{11} and K_{21} into consideration are given in Table 1. If only K_{11} is used, $I_{R,C}$ disagrees as a whole with $I_{R,O}$. The results obtained using K_{11}, K_{21}, and K_{20} are not better than those in Table 1. The NH_2 proton chemical shift of TBA[1] in cyclohexane at 24.5 °C has been analyzed by using only K_{30}, whose value is 2.3. An attempt to take K_{30} into consideration results, however, in less convergence. Since there should be small amounts of the species other than the 1 : 1 and 2 : 1 species under such high molarities of TBA and chloroform as are used here, the disagreement of about 5% found between $I_{R,O}$ and $I_{R,C}$ may, thus, be caused by not taking them into account.

Table 1. The observed and calculated relative intensities

Sample	T/K	$I_{R,O}$	$I_{R,C}$
(i)	244	3.72	3.56
	238	3.92	4.06
	233	4.47	4.47
	229	4.99	4.91
	223	5.69	5.62
(ii)	244	1.41	1.50
	238	1.52	1.62
	233	1.56	1.70
	229	1.66	1.79
	223	1.80	1.91
(iii)	244	0.73	0.69
	238	0.75	0.72
	233	0.78	0.75
	229	0.82	0.77
	223	0.85	0.80

Table 2. The values obtained for $\Delta H°$, $\Delta S°$, and β

$\Delta H°_{11}$	−14.2
$\Delta S°_{11}$	−58.5
$\Delta H°_{21}$	−22.6
$\Delta S°_{21}$	−90.3
β_{11}	1.78
β_{21}	0.62

$\Delta H°_{mn}$/kJ mol^{-1}, $\Delta S°_{mn}$/J K^{-1} mol^{-1}

The adjusted values for the parameters are given in Table 2, where $\Delta H°_{11}$ is −14.2 kJ/mol, larger than the −17.0[10] or −19[11] kJ/mol reported for the 1 : 1 species of triethylamine with chloroform. $\Delta\nu_{C-D}$ observed here is smaller than the 79 cm^{-1} [11] reported for the 1 : 1 species of triethylamine with chloroform. These facts reflect well the basicities of the two amines. $\Delta H°_{21}$ suggests that $\Delta H°_{20}$ is about −8.4 kJ/mol if the dimer has such an open-chain structure as is found in the 2 : 1 species to be shown later. The values of β indicate that the intensity of the C–D stretching in the 1 : 1 or 2 : 1 species is, respectively, stronger or weaker than that in $CDCl_3$. This means that the intensity depends on the spatial structures of the associated species; the C–D stretching frequencies of these species are nearly the same as those treated here.

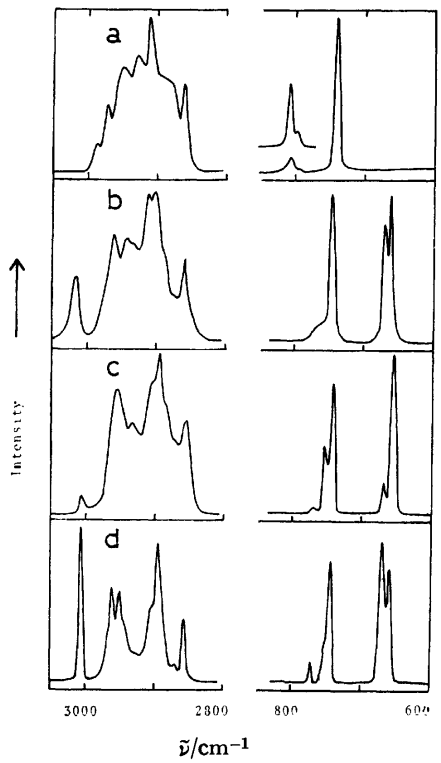

Fig. 2. The Raman spectra of the C–H and CCl_3 stretching regions of TBA and the TBA–chloroform system. (a) Gaseous TBA, (b) the liquid sample with R=0.66 at 212 K, (c) the solid sample with R=0.97 at 113 K, and (d) the solid sample with R=0.50 at 113 K.

The Vibrational Assignment of the 1 : 1 Species

The Confirmation of the 1 : 1 Species in $R \approx 1$. In Fig. 2 the Raman spectra of the C–H and CCl_3 stretching regions of the TBA–chloroform system in the solid and liquid states are compared with those of TBA in the gaseous state. By a comparison of Fig. 2-c (R=0.97) with 2-a (gas) or the spectrum of solid chloroform,[12-14] the weak bands at 3008 and 667 cm^{-1} in Fig. 2-c are assigned to the C–H stretching mode and the CCl_3 symmetric stretching mode of excess chloroform respectively (hereafter, H* denotes the hydrogen atom of chloroform), and the strong bands at 2895 and 657 cm^{-1}, to those of chloroform in the associated species. This assignment for excess chloroform is further confirmed by comparing the spectra in Fig. 2-c with those in Fig. 2-d (R=0.50), where the bands at 3005 and 669 cm^{-1} are relatively intensified. Similarly, by an examination of the Raman bands in the 1200—1280 cm^{-1} region, the two weak bands at 1211 and 1202 cm^{-1} observed for the sample with R=0.50 are assigned to the C–H* bending of excess chloroform, and the band near 1277 cm^{-1} observed for the samples with R=0.97 and 0.50, to that of chloroform in the associated species. The fact that bands due to excess chloroform are weak in the sample with R=0.97 is, thus, explained by the relation of $0.97TBA+CHCl_3 \rightarrow 0.97TBA \cdot CHCl_3 + 0.03CHCl_3$, with reference made also to the fact that there is no appearance of the bands characteristic of the 2 : 1 species, which will be discussed later. Thus, the solid sample with R=0.97 is found to consist mostly of the 1 : 1 species.

Most of the bands observed in the IR spectrum for the solid sample with R=1.03 are nearly consistent in their frequencies with those in the Raman spectrum with R=0.97, as is shown in Table 3, which indicates that the solid IR sample also consists mostly of the 1 : 1 species. Thus, the bands observed in both spectra for the solid samples with $R \approx 1$ are to be assigned on the basis of the 1 : 1 species, except for several weak ones regarded as other species.

The Band Due to Chloroform. From the assignment of the bands due to chloroform described above and given in Table 3, it is found that the C–H* stretching mode shifts to frequencies lower by 113 cm^{-1} than that of the isolated molecule, and the C–H* bending mode to ones higher by about 70 cm^{-1}, while, of the vibrations of the CCl_3 group, only the CCl_3 symmetric stretching mode shifts lower by about 10 cm^{-1}. These shifts can be explained reasonably by the interaction of chloroform with TBA through the hydrogen atom of the former with the nitrogen atom of the latter. Of the degenerate vibrations of chloroform in the 1 : 1 species, only the C–H* bending splits into two bands, whose separation is 13 cm^{-1}. On the other hand, the observed site splittings of excess chloroform in R=0.50 are nearly the same as the respective ones of solid chloroform.[12,13]

The Bands Due to the NH_2 Group. If chloroform interacts with TBA in the way described above, one can expect that the spectral features on TBA in the 1 : 1 species will differ from those on solid TBA, especial-

a) Excess chloroform.

ly in the regions characteristic of the NH_2 group. The strong and medium Raman bands at 3287 and 3351 cm^{-1} are assigned to the NH_2 symmetric and asymmetric stretching modes respectively. They are the frequencies characteristic of the non-hydrogen bonded NH_2 group and are in a frequency region lower by 28 cm^{-1} than those of gaseous TBA.

The weak Raman band at 1589 cm^{-1} and the medium one at 893 cm^{-1} have their IR counterparts at 1589 and 894 cm^{-1} respectively; the former is assigned to the NH_2 bending mode, and the latter, to the wagging mode. In Fig. 2-a, the band at 811 cm^{-1}, which is a highly polarized one without any rotational structures,[15] is assigned to the NH_2 wagging mode, and the weak one at 799 cm^{-1}, to a combination band, 345+458=803 cm^{-1}. The weak Raman band at 1112 cm^{-1} in Table 3, whose IR counterpart is at 1110 cm^{-1}, is probably to be assigned to the NH_2 twisting mode rather than to be regarded as a combination band, because this band is considerably influenced by circumstances; it shifts to higher frequencies in solid TBA or the 2 : 1 species, as is shown in Table 4, though the NH_2 twisting mode of methylamine[16] or hydroxylamine[17] has been estimated from *ab initio* calculations to be about 1250 cm^{-1}. The NH_2 torsion of gaseous TBA has been assigned to the strong IR band at 245 cm^{-1}.[18] For the 1 : 1 species, there is no Raman band in this region, but a weak one at 320 cm^{-1}, which is not attributable to any of the skeletal bending modes. We assign this band to the NH_2 torsion of the 1 : 1 species. The NH_2-group frequencies thus assigned to the 1 : 1 species are summarized in Table 4, along with those for TBA and the 2 : 1 species.

a) From Ref. 18.

The Bands Due to CH_3 Groups. By referring to the theoretical[19,20] and experimental[2,3] studies of the P-R separation, some typical bands observed with P-R separations of about 23 and 20 cm^{-1} for TBA can be regarded as the parallel and perpendicular ones respectively. These separations indicate that TBA has a slightly asymmetric oblate top, as would be expected for this molecule.

The vibrational modes of the methyl groups of the 1 : 1 species can be approximately interpreted as referring to the normal modes of such molecules with three methyl groups as trimethylacetonitrile[3] or $[(CH_3)_3AlCl]^-$.[21]

The medium band at 2936 cm^{-1} (Fig. 2-c) corresponds to the medium band at 2945 cm^{-1} (Fig. 2-b), which is a polarized band, and the very strong band at 2955 cm^{-1} (Fig. 2-c) splits into two sharp bands, at 2961 and 2951 cm^{-1} (Fig. 2-d). The former is assigned to the CH_3 asymmetric stretching mode (A_1), and the latter, to the CH_3 asymmetric stretching modes (E) accidentally degenerated from two more bands. There is no Raman band in the CH_3 symmetric bending region of the 1 : 1 species, but there are three IR bands whose spectral features correspond well to those of the IR-nitrogen-matrix spectrum of *t*-butyl alcohol.[2] The assignment of the bands due to the CH_3 rocking can be confirmed by examining the spectra for gaseous TBA in Fig. 3, where the IR or Raman band at 941 cm^{-1}

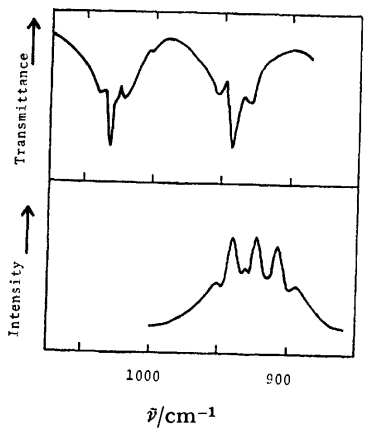

Fig. 3. The IR (upper) and Raman (lower) spectra of the CH_3 rocking region of gaseous TBA.

has a parallel-type envelope or a sharp Q branch respectively and is assigned to the symmetric rocking mode (A_1). This assignment correlates well with that in *t*-butyl alcohol[2] or trimethylacetonitrile,[3] but not to that in *t*-butyl chloride.[4] The A_1 mode of *t*-butyl chloride has been assigned to the band at 1155 cm^{-1} on the basis of the normal coordinate analysis; it is noticeably higher than those of the three related compounds. This fact may be explained in terms of the vibrational coupling between the CH_3-rocking and the C-X-stretching mode (X=Cl, NH_2, OH, or CN).

The Band Due to the Skeleton of TBA and the Lattice Modes. The CC_3 symmetric stretching mode is assigned to the strong Raman band at 744 cm^{-1}, and the CC_3 asymmetric ones, to two medium Raman bands at 1222 and 1248 cm^{-1}. The C–N stretching mode is assigned to the Raman band at 1323 cm^{-1}, which is a polarized band in liquid TBA. These stretching frequencies correlate well with those in *t*-butyl alcohol[2] or trimethylacetonitrile,[3] but not with those in *t*-butyl chloride.[4] The CC_3 asymmetric deformation and CCN bending

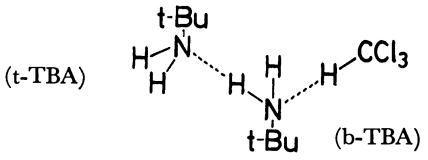
vibrations are assigned to two medium Raman bands, at 345 and 458 cm^{-1} respectively, by comparing them with the IR or Raman bands in gaseous TBA; two bands with strong rotational structures[15] are observed at 351 and 450 cm^{-1} in the Raman spectrum, and also two band with a perpendicular-type envelope at 347 and 447 cm^{-1} in the IR one.

A weak Raman band is observed at 428 or 429 cm^{-1} in liquid or solid TBA respectively; it may be assigned to the CC_3 symmetric bending mode. However, we could observe no band in this region of either the IR or Raman spectrum in the 1 : 1 species.

There are five Raman bands in the region of lattice vibrations of the 1 : 1 species. The strong band at 65 cm^{-1} can reasonably be assigned to the hydrogen-bonded N···H stretching mode, because there is no band in that region of solid TBA and chloroform.[12,13] The IR bands denoted by D in Table 3 are attributably to the species with excess TBA.

The 2 : 1 Species

One can expect, by analogy with the previous section, that the solid sample with $R \approx 2$ consists mainly of the 2 : 1 species. The IR spectrum of the solid sample with $R=2.0$ is given for the stretching, wagging, and torsion regions of the NH_2 group in Fig. 4, in which the stretching region has nearly the same spectral features as those observed for solid TBA in Fig. 5. A sharp band at about 3330 cm^{-1} in Fig. 4 or 5 lies almost in the middle of the two NH_2 stretching frequencies of the 1 : 1 species; it is assigned to the non-hydrogen-bonded N–H stretching mode. The other two bands have band shapes characteristic of the hydrogen-bonded stretching modes. We assign them to the two components of the Fermi resonance of the hydrogen-bonded N–H stretching mode, with an overtone of the NH_2 bending mode, and propose that solid TBA has a polymeric chain structure consisting of bridged TBA, which has both hydrogen-bonded and non-hydrogen-bonded N–H groups, and that the 2 : 1 species has bridged and terminal TBA, b-TBA, and t-TBA, such as:



The IR bands due to the NH_2 stretching modes of t-TBA are still expected to be as weak as those of TBA in the gaseous state or the 1 : 1 species.

A strong band at 877 cm^{-1} is assigned to the NH_2 wagging mode, which is observed at 894 cm^{-1} for the 1 : 1 species. From this fact, it is concluded that this sample consists almost entirely of the 2 : 1 species as expected.

There are some bands characteristic of the 2 : 1 species, including the band mentioned above. Two bands, at 1609(b) and 1584(t), 1130(b) and 1109(t), or 963(b) and 877(t) cm^{-1}, are assigned to the bending, twisting or wagging modes respectively of the NH_2 groups, while the bands indicated by b in parentheses can be attributed to b-TBA, and those by t, to t-TBA, with reference to the bands observed for solid TBA or the 1 : 1 species. Of the two bands at 498 and 415 cm^{-1}, the former is assigned to the NH_2 torsion of b-TBA, while the latter may be a component of the Fermi resonance of the NH_2 torsion of b-TBA with the other mode, because this frequency is too high to be assigned to the NH_2 torsion of t-TBA as against 320 cm^{-1} in the 1 : 1 species. The two C–N stretching modes are at 1332 and 1316 cm^{-1}.

From the fact that the frequencies due to chloroform of the 2 : 1 species are nearly in accord with those of the 1 : 1 species, the basicity of an open-chain dimeric TBA is found to be almost equal to that of the monomeric one. The TBA in the present study is classified into non-bridged and bridged types. The wagging mode in non-bridged TBA shifts to the higher-frequency region in the order of gaseous TBA, the 2 : 1 species, and the 1 : 1 species; a similar shift can be expected for the torsion, though it is not observed for the 2 : 1 species. On the other hand, the NH_2-group frequencies of bridged-TBA of the 2 : 1 species correlate well with those of solid TBA.

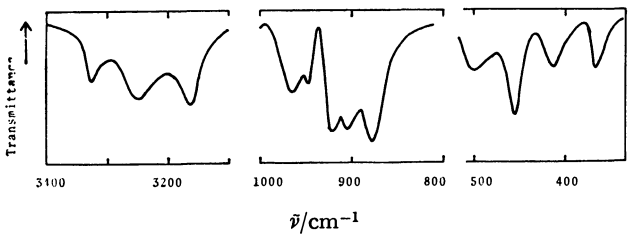


Fig. 4. The IR spectrum of the NH_2 stretching, wagging, and torsional regions of the solid sample with $R=2.0$ at 77 K.

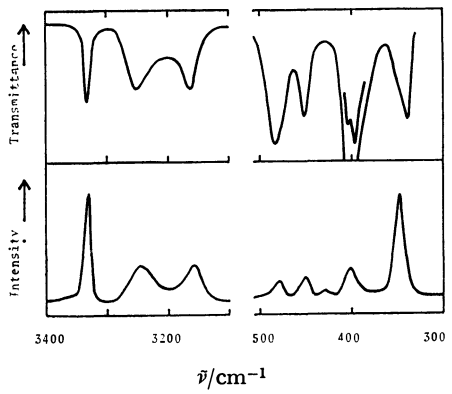

Fig. 5. The IR (upper) and Raman (lower) spectra of the NH_2 stretching and torsional regions of solid TBA at 77 and 113 K respectively.

High Resolution Proton Nuclear Magnetic Resonance Studies of Solute Molecules in the Poly(vinylalcohol) Gel Medium

Shizuo FUJIWARA,† Ryo FUJIKURA, Takashi OGINO, Michiko TANAKA, and Yoji ARATA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 7, 1980)

It was shown that a pair of spectra is observed for each solute in the medium of poly(vinylalcohol) gels swollen in water. Each of the spectra was assigned as originating from the solute in the PVA gel itself and that in the bulk solution surrounding the gel. It was concluded that the chemical shift difference is primarily explained in terms of the difference in the volume susceptibility of the PVA gel and the bulk solution. It was observed in the case of nicotinamide adenine dinucleotide (NAD) that the chemical shift differences are different for different functional groups. We suggest that this observation reflects a contribution from intermolecular interaction between PVA gel and the NAD molecule.

In a previous work from this laboratory we have shown that in poly(vinylalcohol) (PVA) gels rotational diffusion of nitroxide radicals is strongly dependent upon the pore size of the gels.[1] In order to characterize in detail the PVA gel as a medium we have measured ^{1}H NMR spectra of a various kinds of solute molecules. The present paper reports an analysis of ^{1}H NMR spectra which are given by solute molecules in the PVA gels. Interactions between solute molecules and the PVA gel will briefly be described using nicotinamide adenine dinucleotide (NAD) which is flexible in shape and is expected to exhibit a pH dependent interaction with the PVA gel.

Experimental

PVA Gels. When an aqueous solution of PVA is irradiated with γ-rays at sufficient dose, the polymer molecules interlink each other, and insoluble gels are formed. It is known that a degradation process rather than cross-linking occurs predominantly when PVA solution is subject to ionizing radiation. When it is irradiated in the presence of water, however, a cross-linking type of reaction occurs, and a gel is formed in the following manner.[2] Upon γ-ray irradiation, water molecules are turned into free radicals, which react with the protons of PVA. This reaction occurs above the critical concentration; the gel formation does not occur below the critical concentration even upon prolongated irradiation. The critical concentration is approximately 0.36 g/100 ml for PVA with an initial degree of polymerization of 1740.[2] The gel prepared by a total dose of irradiation below 1×10^6 rads was like a paste. When the total dose was above that level, a rubber-like substance was formed; the gels formed with higher doses of irradiation were of higher density and more elastic. The gels sometimes contain small bubbles, which are mainly H_2 gas developed during the gel formation. The gel was usually colorless, sometimes pale yellow. It is chemically stable. It is stable even when it is heated with boiled water in an autoclave at 150 °C for one hour, and retains its original shape on boiling in 0.1 M HCl solution or in 0.1 M NaOH solution at 100 °C for 3 h.[2] When it was dried, it shrinked remarkably and turned into a hard colorless or pale yellow substance. When the dried gel is immersed in water, it is swollen back and the original color and shape were restored. However, the color was changed into yellow or light brown when it was swollen in alkaline solution (pH>11) or in DMSO. In the gel form, the size of the average diameter of the holes in the network can be calculated using

$$\langle l \rangle = 2.5 \times \left(\frac{5.1 \times 10^8 \pm 1.37 \times 10^8 \times C}{R} \right),$$

where R is the amount of the total dose in Rads and C is the concentration of PVA (g/100 ml).[2] It should be noted that the diameter is represented by a distribution function and that $\langle l \rangle$ does not represent any definite size of the hole. It should rather be, therefore, regarded as only one of the variables which describe the density of the gel. We also defined C_{GEL}, which is the gel concentration

$$C_{GEL} = \frac{w_{DRY}}{w_{ORIG}},$$

where W_{ORIG} is the weight of the original gel and W_{DRY} is that of the dried gel.

Preparation of PVA Gel. PVA, with an average degree of polymerization of 2000, was purchased from Wako Pure Chemicals. Twenty grams of the PVA powder were suspended in 1 L water and stirred while heating until dissolved. Then the solution was stirred another 10 h to be homogenized. Glass tubes filled with the aqueous solution were fixed on a brass stand and were irradiated by γ-ray. The γ-irradiation was performed using three different furnaces A, B, and C at Japan Atomic Energy Institute, Tokai, Japan Atomic institute, Takasaki and institute for Atomic Energy, The University of Tokyo, respectively. Because the gel contracts during formation. as mentioned above, the diameter of glass cylinder must be chosen according to the total dose of irradiation fitting the prepared gel to a 5 mm OD NMR sample tube.

Although all of the glass tubes and the aqueous solution became brown after the irradiation, the gels remained colorless. The gels were washed with distilled water several times, immersed in distilled water and left there overnight to exchange the colored water in the gels for distilled water. Then a 3—4 cm cylinder was cut out from the prepared gel and dried at 50—60 °C *in vacuo* for 20 h. If the temperature is above 70 °C, dried gels become yellow. The dried gel was soaked in sample solutions in 5-mm OD NMR tubes and kept at least for one night at room temperature. Then they swelled back to their original size. The time, which is necessary for PVA gels to be swollen back to the original size, depends strongly on temperature and solvent. In aqueous solution, it took a few hours in hot water, 10 h at 23 °C, 3 d at 10 °C, more than a week in the refrigerator and about a week in DMSO at room temperature. Although the gels which were irradiated using furnaces A and B were homogeneous for NMR measurements, the gels prepared using furnaces C were not suitable for NMR. They often tore to small pieces. Even when they did not, they contained a number of bubbles. In the case of furnace C, homogeneous gels finally could not be

† Present address: Department of Chemistry, Faculty of Science, Chiba University, Chiba 260.

prepared at any PVA concentration, any degree of polymerization and any dose rate examined. Degassing before irradiation also did not work. A possible reason for the difference between the gels prepared using furnaces A and B and that by furnace C is a difference in the temperature at which irradiation was made. In the case C, the temperature was at 30—50 °C, whereas in the cases of A and B the temperature was maintained at 10—30 °C. Therefore, it may be concluded that the temperature below 30 °C is a necessary condition for obtaining homogeneous gels that are suitable for NMR measurements.

Reagents. NAD was purchased from Kojin (Lot No. 2113) and used without further purification. All other chemicals were of reagent grade.

NMR Measurements. The concentration of NAD was 10—100 mM. The pH was adjusted by DCl or NaOD. All pH values reported are uncorrected meter readings of D_2O solution made with an electrode standardized by using H_2O buffers. PVA gels were prepared by 30 MRads irradiation and C_{GEL}=23.7%. A 3-cm cylinder was cut out from the prepared gels and dried *in vacuo*. The dried gels were immersed in 5-mm OD NMR tubes and kept at least one night at room temperature until they were swollen back to their original size. When the pH was above 8, NAD decomposed within 10 h, and the color of the solution turned into brown. NMR spectra were obtained at 100 MHz with a JEOL PS-100 spectrometer in the correlation mode.[3] Typically 100 transients (409.6 Hz/3.0 s) were accumulated to improve the signal to noise ratio. A Bruker HXS-360 spectrometer was used to apply the magnetic field to the direction which is perpendicular to that in the case of a conventional electromagnet. All chemical shifts are given in ppm relative to internal DSS. The probe temperature was 29 °C.

Results and Discussion

An NAD–PVA gel system gives a spectrum as shown in Fig. 1. Beside a broad signal of the methylene protons of the PVA molecule, all the signals consist of doublets; in each pair, the signal at lower field is broader than that at higher field. For the assignment of each of these signals, a small amount of Fe^{3+} ion was added from the top of the gel in an NMR tube. After addition of Fe^{3+}, each higher field signal instantaneously broadened and became unobservable. In contrast to this, the lower field signals started to show some broadening only after several hours. This result indicates that the signals at higher field arise from the molecules in the solution surrounding the PVA gel (Hereafter the solution will be referred to as the *surrounding solution*) and that the signals at lower field arise from those in the PVA gel.

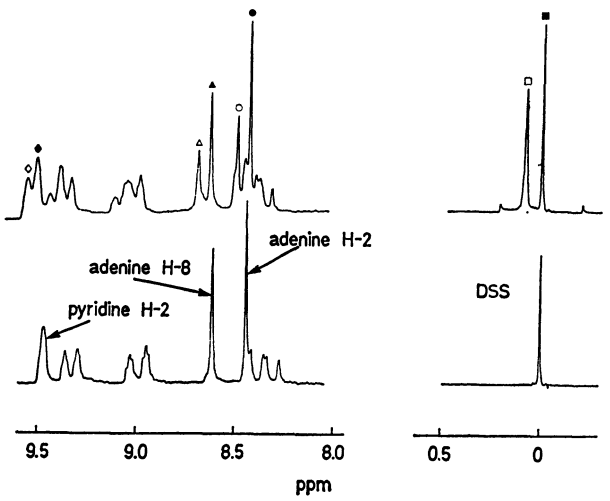

Fig. 1. 100 MHz ^1H NMR spectrum of NAD. The upper and lower spectra correspond to NAD in the PVA gel medium and aqueous solution, respectively. Open and closed symbols indicate signals due to the solutes in the PVA gel and in the surrounding solution, respectively.

Hereafter, the chemical shift for a signal due to the solutes in the PVA gel relative to the corresponding signal of that in the surrounding solution will be simply referred to as a *chemical shift difference*.

It was conformed that with an NMR spectrometer using a superconducting magnet signals due to solutes in PVA gel appear at higher field relative to those of the surrounding solution. The direction of the magnetic field of a superconducting magnet is perpendicular to that of a conventional magnet. It may be concluded, therefore, that the chemical shift difference is primarily due to the difference in the volume susceptibility of the PVA gel and the surrounding solution.[4]

It was observed that the chemical shift differences for each doublet were clearly different. This fact suggests that, in addition to the volume susceptibility effect, a contribution to the observed shift due to an intermolecular interaction between PVA gel and solutes exists at least to some extent. The chemical shift difference ($\Delta\delta$) will be written as

$$\Delta\delta = \Delta\delta_0 + \Delta\delta_1, \quad (1)$$

where $\Delta\delta_0$ is the chemical shift difference which would be given only by the difference in the volume susceptibility of two media, $\Delta\chi_v$, and $\Delta\delta_1$ is the deviation of the observed chemical shift difference from $\Delta\delta_0$.

Two independent methods can be used to estimate $\Delta\delta_0$ and $\Delta\delta_1$. The magnetic field H_n experienced by a nucleus may be given by[5]

$$H_n = H_0 + h_1 + h_2 + h_3 + h_4, \quad (2)$$

where H_0 is the applied external magnetic field; h_1 is dependent upon the shape of the sample tube and the bulk susceptibility of the sample and the sample tube. h_2 is the contribution due to magnetization external to the Lorentz sphere, *i.e.*,

$$h_2 = \frac{4}{3}\pi\chi_v H_0, \quad (3)$$

where χ_v is the volume susceptibility of the molecule. In the case of spherical samples, the contribution $(h_1 + h_2)$ is given for a conventional electromagnet (4) and a superconducting magnet (5), respectively, by [4]

$$h_1 + h_2 = +\frac{2}{3}\pi\chi_v H_0, \quad (4)$$

$$h_1 + h_2 = -\frac{4}{3}\pi\chi_v H_0. \quad (5)$$

h_3 is an intermolecular interaction effect, and h_4 is the intramolecular chemical shift in an isolated molecule. From Eqs. 4 and 5 the observed chemical shift differences $\Delta\delta_{obs}$ for an electromagnet and a superconducting magnet, respectively, are given by

$$\Delta\delta_{obsd} = \frac{2}{3}\pi\Delta\chi + \Delta\delta_1 \quad (6)$$

$$\Delta\delta_{obsd} = -\frac{4}{3}\pi\Delta\chi + \Delta\delta_1, \quad (7)$$

where $\Delta\chi = \chi_v^{in} - \chi_v^{out}$ is the difference in the bulk susceptibility between in and outside the PVA gel and $\Delta\delta_1$ is the chemical shift induced by the intermolecular interactions. Equations 6 and 7 can be solved simultaneously to give $\Delta\chi$ and $\Delta\delta_1$.

Alternatively, $\Delta\chi$ and $\Delta\delta_1$ can be evaluated by using only one kind of magnet.[5] In this case we assume a mathematically idealized system, *i.e.*, one regards the PVA gel and sample tube as an infinitely long perfect coaxial cylinder. In the absence of sample spinning, the observed NMR spectrum gives two maxima. The separation of the maxima ($\Delta\nu$ (Hz)) is a linear function of the difference in the volume susceptibility of both media which is given by[5]

$$\Delta\chi = 4\pi\nu_0\Delta\chi(a/r)^2, \quad (8)$$

where r is the radius of inner boundary of the tube, a is that of the PVA gel and ν_0 is a fixed radiofrequency (100 MHz in the present case). With sample spinning, the NMR spectrum of the surrounding solution collapses to a single line. Figure 2 is a spectrum of H_2O in the PVA gel. Spectra A and B are obtained without and with spinning, respectively. The difference in volume susceptibility of a sample can be obtained from this separation. The shape of signals were found to depend strongly on the mapping of heterogeneity in the magnetic field due to imperfections in the PVA gel system. If measurements are carefully performed in the same manner, the values of $\Delta\chi$ obtained in this way become quite reproducible within 0.005 ppm.

In Fig. 3, the chemical shift differences are shown for H_2O, DSS, and glycylglycylglycylglycine(Gly_4) as a function of C_{GEL}. In the case of DSS, $\Delta\delta$ was in excellent agreement with $\Delta\delta_0$ throughout the entire range of C_{GEL} examined. $\Delta\delta$ of DSS depends slightly upon temperature. As the temperature rose, $\Delta\delta_0$ increased; the slope of $\Delta\delta_0/(1/T)$ was quite similar for any sample and for any pH. This fact suggests that $\Delta\delta_0$ depends on temperature but not on pH.

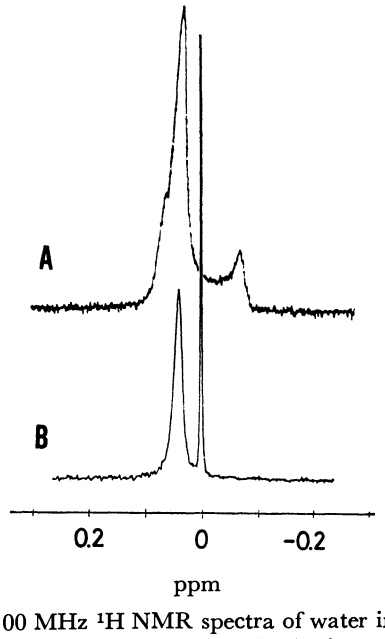

Fig. 2. 100 MHz ^1H NMR spectra of water in the PVA gel system. A and B are obtained without and with spinning, respectively.

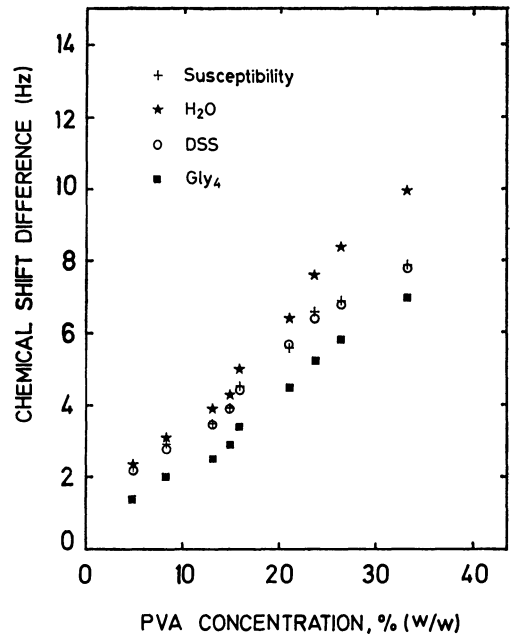

Fig. 3. Chemical shift differences for H_2O, DSS, and Gly_4 *versus* PVA concentration C_{GEL}.

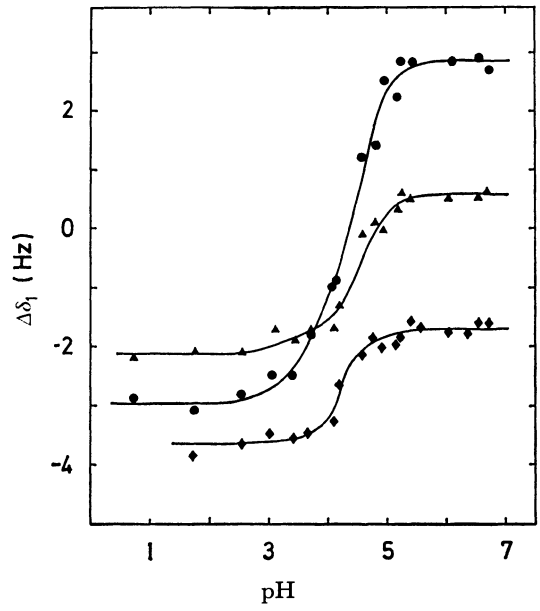

Fig. 4. Titration curves of $\Delta\delta_1$ of NAD.
●: Adenine H-2, ▲: adenine H-8, ◆: pyridine H-2.

As Fig. 4 shows, $\Delta\delta_1$ of the three protons of NAD are dependent upon pH. Each curve gives a quite similar pK_a of approximately 4. The chemical shifts of the adenine signals presumably reflect protonation of *N*-1 at pK_a 3.8.[6] This result may be interpreted in terms of an intermolecular interaction between NAD and PVA gel.

We are grateful to Prof. Michael Rode for his helpful comments and discussion.

The Thermal and Hydrothermal Behavior of Silica-adsorbed Magnesium Hydroxide

Haruto MURAISHI

Department of Chemistry, Fukuoka University of Education, Munakata-cho, Fukuoka 811-41

(Received July 14, 1980)

Silica-adsorbed $Mg(OH)_2$ was treated thermally and hydrothermally. The resulting change in the adsorption layer was followed, and the effects of the adsorbed silica on the change in the bulk ($Mg(OH)_2$, MgO) were examined. (1) Thermal treatment: The dehydration temperature of $Mg(OH)_2$ increased with an increase in the amount of silica adsorbed, and it was higher by 25 °C for $Mg(OH)_2$ adsorbing silica above 0.4 mmol/g than for pure $Mg(OH)_2$. The amorphous silicate of the adsorption layer on the $Mg(OH)_2$ surface was transformed into forsterite (Mg_2SiO_4) and chain or sheet-like silicate over the temperature range of 870—1100 °C, and the presence of the silica inhibited the sintering and crystallite growth of the MgO grains. At 1400 °C, these products were all transformed into forsterite, and the presence of the silica had little effect on the crystallite growth. (2) Hydrothermal treatment: Below 360 °C, the amorphous silicate on the surface crystallized as serpentine ($Mg_3Si_2O_5(OH)_4$), and the crystallite growth of $Mg(OH)_2$ was inhibited. Above 420 °C, on the other hand, the silicate was transformed into forsterite through serpentine-like silicate, and the crystallite growth of $Mg(OH)_2$ was promoted. The change in the crystallite size of the bulk by the treatment was interpreted mainly in terms of the behavior of the silicate on the surface.

Our previous works[1,2] have shown that soluble silica was chemisorbed at temperatures under 100 °C, forming –Mg–O–Si– bonds on the $Mg(OH)_2$ surface, and that the resulting surface had properties like magnesium silicate gels, *e.g.*, a relatively large amount of acidity and adsorptive properties for Methylene Blue and Methyl Red. The behavior of the silica-adsorbed $Mg(OH)_2$ upon the thermal and hydrothermal treatment is interesting from the viewpoint of the process of the formation of ceramics and the mechanism of producing magnesium silicate minerals.

In this work, the transformation of the magnesium silicate on the $Mg(OH)_2$ surface by thermal and hydrothermal treatment was observed. In addition, the effects of adsorbed silica were investigated on: (1) the dehydration temperature of $Mg(OH)_2$, (2) the crystallite growth of the dehydration product, MgO, upon the thermal treatment, and (3) the crystallite growth of the $Mg(OH)_2$ upon the hydrothermal treatment.

In some of the earlier works the effect of impurities on the dehydration temperature of $Mg(OH)_2$[3,4] and the effects of the addition of foreign materials on the sintering of MgO[5–8] have been investigated. However, there has been no investigation placing emphasis on the behavior of the silicate.

Experimental

Samples. The silica-adsorbed $Mg(OH)_2$ used as the starting material was prepared in a previously reported way.[2] The silica gel used for chromatography (Wako Pure Chemicals) was dissolved in hot water, and then the silica solution was adjusted to a concentration of about 100 ppm. $Mg(OH)_2$ powder (Kanto Kagaku) was suspended in this solution and was allowed to adsorb the soluble silica while being stirred at 500 rpm at 80 °C. The amount of silica adsorbed was determined by the decrease in the silica concentration in the solution. The silica concentration was determined colorimetrically by the usual molibdate yellow method. The aqueous silica was soluble in monomeric unit form, $Si(OH)_4$, since the value of the silica concentration did not vary when the solution was treated with a 0.1 mol/l NaOH solution. The non-adsorbed $Mg(OH)_2$ which was used as a reference standerd was immersed in distilled water at 80 °C for 8 h before use in order to have the same history as the silica-adsorbed $Mg(OH)_2$. Its surface area was about 30 m^2/g.

Experimental Procedures and Apparatus. The thermal treatment were carried out by the use of an electric furnace in the air at 430 °C for 4 h, 870 °C for 3 h, 1000 °C for 2 h, 1200 °C for 1 h, and 1400 °C for 1 h respectively. The hydrothermal treatment was carried out using a modified Morey-type autoclave with a fill ratio of water of 50% and a heating rate up to a fixed temperature of 75 °C/h.

The dehydration temperatures of the samples was measured by differential thermal analysis (DTA). The DTA was carried out using a Rigaku 8002 Thermal Analyser with a thermobalance. The sample (about 10 mg) was packed in a platinium dish, while the same weight of Al_2O_3 was packed in a reference dish; the heating rate was 10 °C/min.

The crystallite size of MgO and $Mg(OH)_2$ obtained was determined by the X-ray line-broadening method,[9] using diffraction peaks from the (110) and the (0001) planes respectively. The aspect of the samples was observed by means of an Hitachi S-430 scanning electron microscope (SEM). The samples submitted to treatment were examined by IR spectroscopy and X-ray diffractometry. The IR spectra were observed by the KBr tablet method; the tablet was made up of 2 mg of the sample and 150 mg of KBr. A Hitachi EPI-G IR Spectrometer and a Rigaku XGC-20 X-ray Diffractometer were used for the measurement.

The specific surface area of the sample was determined by applying the BET method to the nitrogen-adsorption data obtained at the temperature of liquid nitrogen, assuming the cross-sectional area of a nitrogen molecule to be 16.2 $Å^2$.

Results and Discussion

Part 1. Thermal Behavior

The Effect of Adsorbed Silica on the Dehydration of $Mg(OH)_2$. Figure 1 shows DTA and TG curves for pure $Mg(OH)_2$ and a typical silica-adsorbed $Mg(OH)_2$. The position of the endothermic peaks shows that the dehydration of the latter takes place at a higher temperature than that of the former. In addition to the rise of the dehydration temperature, the DTA curve for the silica-adsorbed sample had a small exothermic peak at about 850 °C which was assigned to the reaction of MgO with silica. Both the TG curves

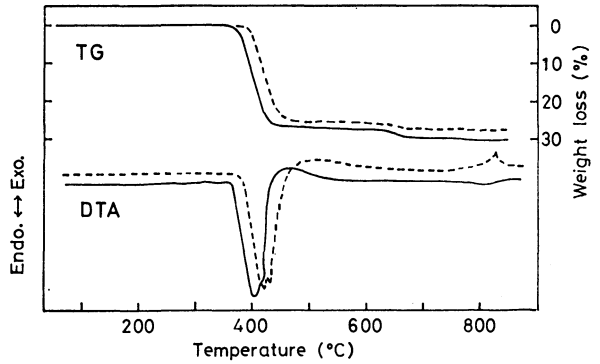

Fig. 1. TG and DTA curves for pure $Mg(OH)_2$ (——) and silica-adsorbed $Mg(OH)_2$ (------).

gradually declined with an increase in the temperature after the dehydration occurred at about 400 °C. Such a phenomenon has often been observed in various hydroxides and minerals containing water; it can be attributed to residual essential water or OH groups.

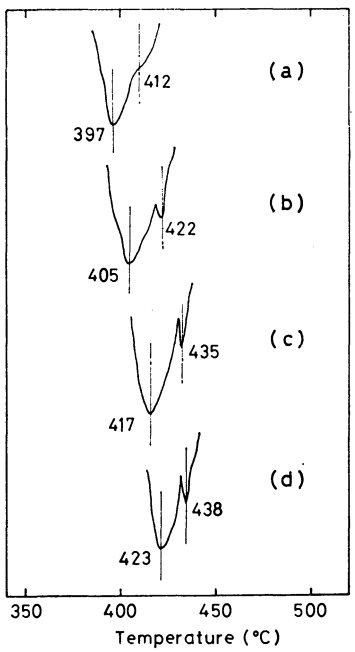

Fig. 2. DTA curves for pure $Mg(OH)_2$ and $Mg(OH)_2$ with various amount of adsorbed silica. Amount of adsorbed silica (mmol/g): (a), Non adsorption; (b), 0.097; (c), 0.34; (d), 1.26.

Figure 2 shows the change in the position and shape of the endothermic peak with a variation in the amount of silica adsorbed. The dehydration temperature increased with the increase in the amount of silica adsorbed, and the shape of the endothermic peak apparently varied from singlet to doublet for these silica-adsorbed $Mg(OH)_2$. This peak separation suggests that the two-step dehydration of $Mg(OH)_2$ was induced by the adsorption of silica. Weber and Rustum Roy[10] have observed a two-step dehydration of $Mg(OH)_2$ and presumed it to result from the formation of an intermediate phase in the dehydration process. Ball and Taylor[11] asserted the formation of an intermediate phase with a spinel-like structure (*e.g.*, $(MgO)_3 \cdot H_2O$) resulting from cation migration during dehydration. In this study, the intermediate phase was not observed by means of X-ray diffractometry. This bimordal DTA curve, therefore, is not ascribed to the structure change, but it indicates that the dehydration process following the release of the resulting H_2O from the $Mg(OH)_2$ particle is surely affected by the adsorbed silica.

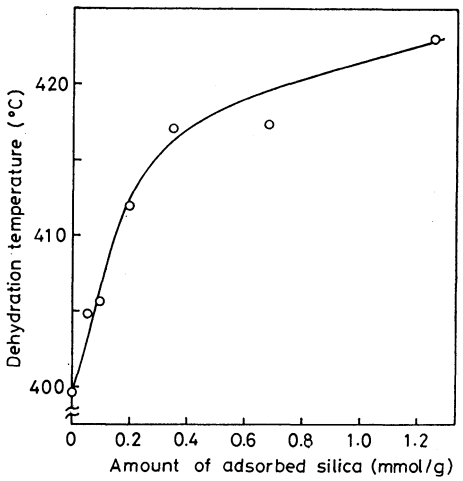

Fig. 3. Effect of amount of adsorbed silica on dehydration temperature of $Mg(OH)_2$.

Figure 3 shows the relation between the amount of silica adsorbed and the dehydration temperature. The dehydration temperature rose greatly with the increase in the amount of silica up to about 0.4 mmol/g, although above this amount it rose only slightly. The $Mg(OH)_2$ particles used were observed microscopically to be disk-like crystals with a well-developed (0001) plane. Consequently, it may be said that the crystal consists only of an approximate (0001) plane with respect to the estimate of its surface area. The number of Mg atoms exposed on the surface can, therefore, be calculated from the specific surface area and the array of Mg atoms on the (0001) plane.[12] On the other hand, it can reasonably be considered from the structure of the (0001) plane that two silica molecules combine with three Mg atoms on the surface of $Mg(OH)_2$. Thus, the amount of silica adsorbed required to form a monolayer on 1 g of the used $Mg(OH)_2$ is calculated to be 0.34 mmol/g. This amount corresponds to the quantity of about 0.4 mmol g^{-1} observed as a characteristic amount in the relation between the dehydration temperature and the amount of silica adsorbed. In other words, it can be said that the dehydration temperature of silica-adsorbed $Mg(OH)_2$ rose appreciably until the surface was completely covered with a monolayer of silicate, while it rose only slightly when the surface had an excess of silica. The rise in the dehydration temperature may be accounted for as follows. The dehydration of $Mg(OH)_2$ has been interpreted as an inhomogeneous mechanism in which the reaction takes place through the two steps of nucleus formation and growth.[13] The nucleus formation is known to be mainly initiated at such sites as grain boundaries or defects on the surface (*i.e.*, step, kink, and pit).[14] Since these sites are also atcive in the adsorption of silica, some of them are occupied by the

silica molecules in the case of silica-adsorbed $Mg(OH)_2$. The decrease in the active sites forces a delay in the rate of nucleus formation. In addition, the grain surface covered with the silica obstructs the release of the H_2O molecules formed by the decomposition. This effect may be compared with the rise in the decomposition temperature of $Mg(OH)_2$ due to an increase in the water-vapor pressure.[15]

The Change in Surface Products. In a previous study,[2] it has been found that the silica-adsorbed $Mg(OH)_2$ has surface properties and a structure similar to those of magnesium silicate gel. In addition, when magnesium silicate gels were calcined above 870 °C, forsterite (Mg_2SiO_4) and a small amount of enstatite ($MgSiO_3$) were produced in the case of a SiO_2/MgO ratio below 1, while mainly enstatite was produced in the case of a ratio above 1. Since the silica-adsorbed samples have a large excess of MgO, the silicate layer on the surface is presumed to be transformed into forsterite by thermal treatment.

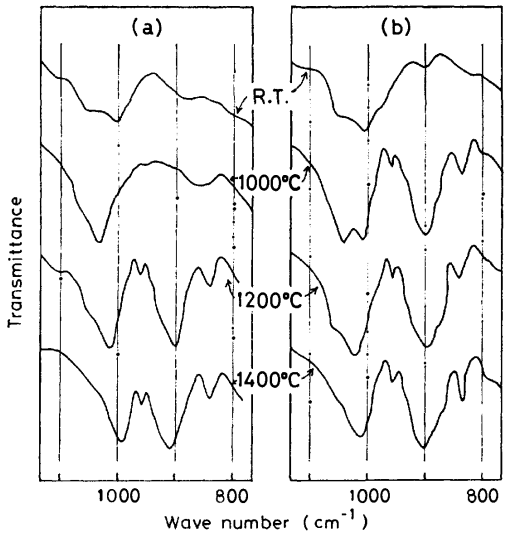

Fig. 4. The changes of IR spectra of silica-adsorbed $Mg(OH)_2$ by thermal treatment. Amount of adsorbed silica (mmol/g): (a), 0.19; (b), 1.26.

Figure 4 shows the change in the IR spectra by thermal treatment for $Mg(OH)_2$ with a different amount of the silica. It was found from the IR spectra that, when the samples were heated at 1000 °C, forsterite, which is composed of nesosilicates, was formed. In addition to the absorption spectrum for forsterite, some additional bands were observed in the region from 1000 to 1100 cm^{-1}. It is known that nesosilicates with a three-dimensional structure of single SiO_4^{4-} usually exhibit their absorption in the region of 800—1000 cm^{-1},[16] while chain silicates (*i.e.*, enstatite) or sheet silicates (*i.e.*, talc ($Mg_3Si_4O_{10}(OH)_2$)) do so in the region of 1000—1100 cm^{-1}. In order to examine the route of the appearance of the additional bands in the region of 1000—1100 cm^{-1}, the following procedure was carried out. The silica-adsorbed samples heated above 1000 °C were treated with a 5% NH_4Cl solution until the bulk MgO had been removed completely. This treatment is based on the fact that an amorphous material consisting of a –Mg–O–Si– bond, forsterite, and enstatite is insoluble in a NH_4Cl solution, but MgO is soluble.[17] The residue in the solution was filtered and dried. The residue was identified by IR spectroscopy and X-ray diffractometry. When the spectrum for the residue is compared with that for the parent sample, the absorption pattern in the region of 800—1000 cm^{-1} which was assigned to forsterite did not change; the slight absorption peaks in the region of 1000—1100 cm^{-1}, however, changed to larger, broad absorption bands ranging from 1010 to 1090 cm^{-1}. On the other hand, the X-ray diffraction pattern of the residue was assigned to forsterite and an amorphous material. Therefore, it is reasonable to assume that the additional bands are due to an amorphous material, which is an incomplete chain or sheet-like silicate.

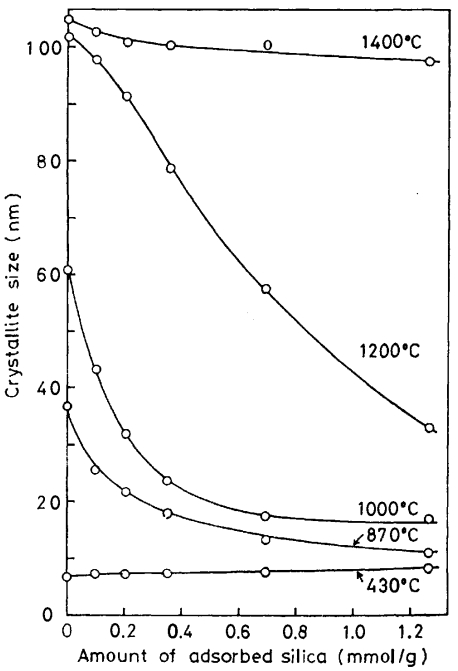

Fig. 5. Effect of amount of adsorbed silica on crystallite size of bulk MgO at various treatment temperatures.

The Effect of Adsorbed Silica on the Crystallite Growth of the Dehydration Product MgO. Figure 5 shows the crystallite size of MgO at various treatment temperatures. The crystallite size of MgO was not influenced by the adsorbed silica at a little above the dehydration temperature of $Mg(OH)_2$, but over the temperature range of 870 to 1200 °C it became smaller with an increase in the amount of silica adsorbed. At a temperature of 1400 °C, at which sintering evidently begins,[18] it became independent of the adsorbed silica.

Moreover, the thermal changes in pure $Mg(OH)_2$ and silica-adsorbed $Mg(OH)_2$ were observed comparatively by the use of the SEM. As may be seen from the photographs in Fig. 6, there was no difference between pure $Mg(OH)_2$ and silica-adsorbed $Mg(OH)_2$ before heat treatment (Figs. 6(a) and 6(d)). After the treatment at 1000 and 1400 °C, the apparent grain of MgO from pure $Mg(OH)_2$ grew; it was much larger than

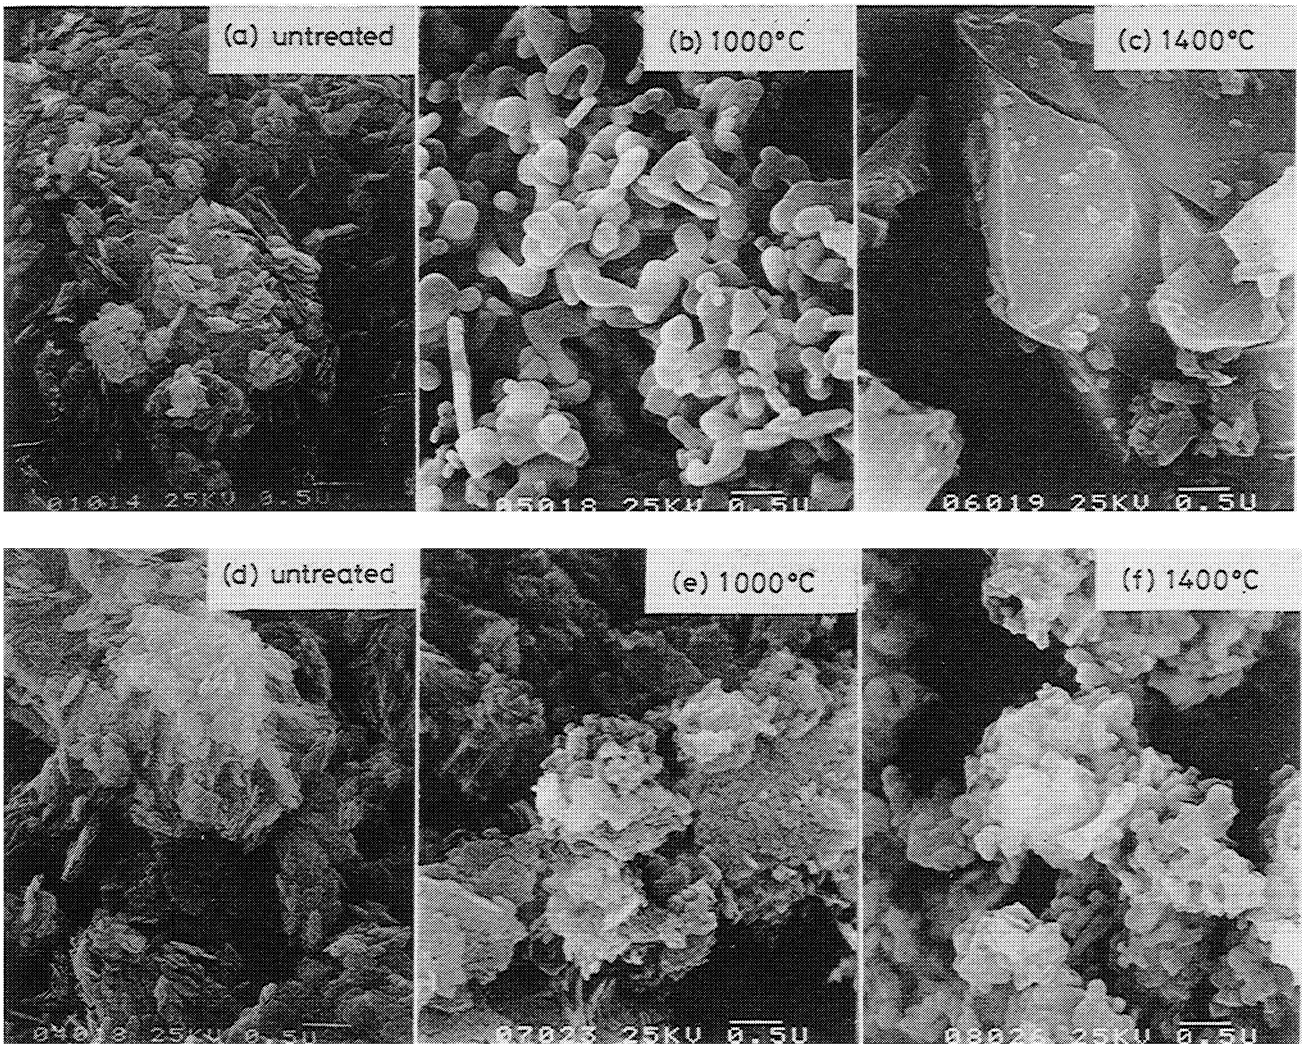

Fig. 6. SEM microphotographs of the samples treated thermally at 1000 and 1400 °C. (a), (b), (c): Non-adsorbed $Mg(OH)_2$. (d), (e), (f): Silica-adsorbed $Mg(OH)_2$.

the crystallite measured by the X-ray method. Therefore, the apparent grain seems to be an aggregate of crystallites formed by their sintering. On the other hand, the size of MgO from silica-adsorbed $Mg(OH)_2$ (amount of silica adsorbed; 1.26 mmol/g) was relatively similar to the crystallite size, as is shown in Fig. 5.

From these results, the thermal behavior of $Mg(OH)_2$ and MgO can be explained as follows. An untreated pure $Mg(OH)_2$ powder was observed by means of the SEM as a layered aggregate of disk-like grains 20 to 50 nm thick in the direction of the c-axis. The thickness of a single grain observed was in good agreement with the crystallite size as measured by the use of the X-ray line broadening method. Therefore, the single grain observed seems to be a single crystal of $Mg(OH)_2$. The dehydration product of the aggregate is also considered to be an aggregate of single crystals keeping the same crystallographic orientation with each other, since the dehydration of $Mg(OH)_2$ is a topotactic reaction.[11,19] The rise in the temperature leads to a grain growth resulting from the disappearance of the grain boundary upon the sintering of these single crystals. This grain growth may be limited to the size of the aggregate consisting of single grains with the same crystallographic orientation. The presence of a silicate layer on the grain surface will result in lowering the motion of the grain boundary because of its hindrance to the surface diffusion and the grain boundary diffusion. This hindrance will depress the grain growth and the formation of a polycrystal by sintering. At temperatures above 1300 °C (the so-called Tamman temperature of MgO (melting point, 2800 °C)), atoms or ions on the surface and in the bulk MgO are easy to diffuse. In addition, the silicate layer has been transformed into a forsterite crystal with a three-dimensional construction. It is, therefore, considered that the grain growth of the silica-adsorbed samples is not distinguishable from that of pure sample, since the silicate can no longer inhibit the motion of the grain boundary.

Part 2. Hydrothermal Behavior

The Change in the Surface Product. The silica-adsorbed $Mg(OH)_2$ indicated the IR absorption spectra of magnesium silicate gels-like material to be as has been described in the previous paper.[2] The hydrothermal treatment at 250 °C for 72 h changed them into absorption bands near 960, 1010, and 1080 cm^{-1}, which are

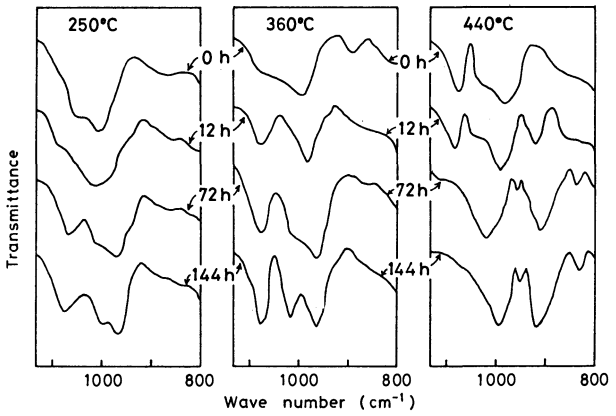

Fig. 7. IR spectra of silica-adsorbed $Mg(OH)_2$ treated hydrothermally at 250—440 °C for 0—144 h.

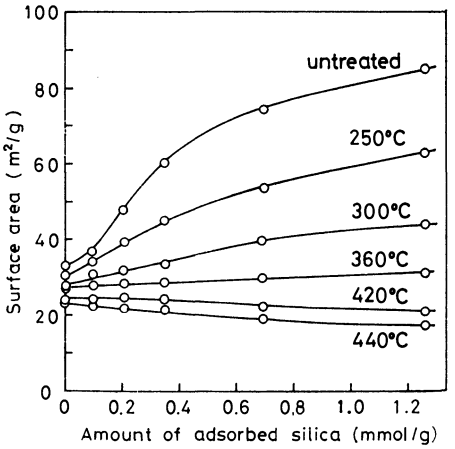

Fig. 8. The change of surface area by hydrothermal treatment for 72 h.

assigned to a compound having the sheet silicate group. The absorption bands became sharp upon treatment at 360 °C for 144 h. The results are shown in Fig. 7. On the basis of the data proposed by Brindley *et al.*[20] and the spectrum of serpentine synthesized in our laboratory, these IR spectra were assigned to serpentine. Above 420 °C, a serpentine-like spectrum was observed in the beginning of the treatment, but it was transformed into the absorption spectra of forsterite, which was characterized by four absorption peaks in the 800—1000 cm^{-1} region, upon subsequent treatment. The surface products obtained below 360 °C were easily isolated by dissolving the bulk $Mg(OH)_2$ with a 5% NH_4Cl solution or a dilute acid solution. The isolated silicate was identified by the use of X-ray diffractometry and IR spectroscopy. The IR spectra of surface products were hardly changed by isolation; therefore, the serpentine-like spectra are attributable to a poor crystalline serpentine.

The phase diagram of the SiO_2–MgO–H_2O system described by Bowen *et al.*[21] shows that, under relatively low water-vapor pressures, serpentine is stable below 380 °C, while above that point forsterite is stable. The phase boundary of the serpentine and forsterite formed hydrothermally from the silica-adsorbed $Mg(OH)_2$ was comparable to the phase boundary presented by Bowen *et al.* Talc was not formed, even if the ratio of the silica molecules and Mg^{2+} ions in the surface layer had the stoichiometric relationship of talc. It was found that the kind of magnesium silicate produced by hydrothermal treatment does not depend upon the composition of the silicate layer on the surface, but upon the composition of the sum of the silicate layer and the bulk.

The Change in the Surface Area. The effects of the amount of silica adsorbed and the treatment temperature on the surface area of silica-adsorbed $Mg(OH)_2$ are shown in Fig. 8. As has been described in the previous paper,[2] the chemisorption of soluble silica on the surface of $Mg(OH)_2$ led to an increase in the surface area; the increase was attributed to the formation of micro pores on the surface (see the "Untreated" curve in Fig. 8). The surface area was more or less decreased by hydrothermal treatment over the temperature range from 250 to 440 °C. It was found, from the measurement of the N_2-adsorption isotherms of the samples and the t-plots[22] derived from this isotherm, that the decrease in the surface area by the treatment is mainly attributable to the disappearance of the micro pores. However, on treatment above 420 °C, the surface area of the silica-adsorbed samples became smaller than that of the non-adsorbed sample. This reduction in the surface area cannot be interpreted only in terms of the disappearance of the micro pores. It will be discussed in the following section.

The Growth of the Crystallite of $Mg(OH)_2$. The change in the crystallite size of the bulk $Mg(OH)_2$ by the treatment was followed as a function of the time at various temperatures. The crystallite size of pure $Mg(OH)_2$ was not appreciably affected by the treatment, while that of silica-adsorbed $Mg(OH)_2$ was dependent on the treatment temperature. The growth of the crystallite of silica-adsorbed $Mg(OH)_2$ did not proceed below 300 °C, but above 360 °C it proceeded with the treatment time. Moreover, the crystallite

growth at various temperatures was investigated with respect to the effects of the amount of adsorbed silica, as is shown in Fig. 9. The crystallite size at a temperature below 300 °C decreased with an increase in the amount of silica adsorbed, while above 360 °C, on the contrary, the size increased with the amount of silica adsorbed. In other words, the adsorbed silica contributes to inhibiting the growth of the crystallite of $Mg(OH)_2$ up to 300 °C, while above 360 °C it serves to promote it.

The non-adsorbed and the silica-adsorbed $Mg(OH)_2$ treated at various temperatures were observed comparatively by the use of the SEM. The microphotographs are shown in Fig. 10. As may be seen from the photographs, the grain of non-adsorbed $Mg(OH)_2$ did not grow throughout the treatment from 250 to 440 °C, while the grain of silica-adsorbed $Mg(OH)_2$ grew in thickness at the temperature of 440 °C. This increase in grain size corresponds to the change in the crystallite size of $Mg(OH)_2$ shown in Fig. 10, and also to the change in the surface area shown in Fig. 8. Therefore, the grain is considered to be a single crystal.

These phenomena may be explained as follows. The surface of the $Mg(OH)_2$ grain will still be covered by the silicate layer under treatment at temperatures below 300 °C. It was found, from the determination of the Mg^{2+} ion in the hydrothermal solutions, that the presence of the silicate layer tends to decrease the rates of the dissolution and solubility of $Mg(OH)_2$. This decrease seems to have resulted in the slower crystal growth of $Mg(OH)_2$, since its growth is considered to be a solution growth based on the dissolution and recrystallization of $Mg(OH)_2$. However, at temperatures above 360 °C, the silicate layer changed into a crystalline silicate (serpentine or forsterite), with a three-dimensional growth. The silicate may exist in the isolated state, and so may no longer coat the surface of $Mg(OH)_2$ grain. In order to confirm whether or not the characteristic crystal growth of silica-adsorbed $Mg(OH)_2$ is due to the presence of the isolated silicate, a mixture of pure $Mg(OH)_2$ and a synthesized serpentine (or forsterite) was treated hydrothermally above 360 °C. It was found that the $Mg(OH)_2$ crystal hardly grows at all under these conditions. Therefore, the growth is

not due to the presence of the silicate crystal, but the process of the crystallization of the silicate layer makes some contribution to the growth. Unfortunately, it is difficult to make this phenomenon clearer using our limited experimental procedure.

The author would like to express his hearty thanks to Professor Shigeo Kitahara for his valuable guidance and for his critical reading of this manuscript. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 474205 from the Ministry of Education, Science and Culture.

The Crystal and Molecular Structure of the Photodimer of Biphenylene

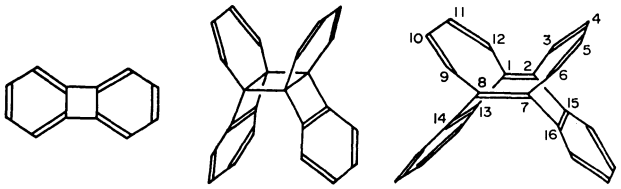
Akio Furusaki,* Nobuhiro Hashiba, Takeshi Matsumoto, Tomoji Aotsuka, and Shinya Nishida

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 25, 1980)

The molecular structure of the photodimer of biphenylene has been determined by X-ray crystal analysis. The crystals are triclinic, with eight molecules in a unit cell with dimensions of $a=15.061$, $b=17.687$, $c=13.091$ Å, $\alpha=108.91$, $\beta=98.52$, and $\gamma=89.71°$; the space group is $P\bar{1}$. 6625 unique intensity data were collected on a four-circle diffractometer with LiF-monochromated Cu $K\alpha$ radiation. The structure was solved by the symbolic-addition method using 8 symbols, and refined by the block-diagonal least-squares method. The final R value was 0.101. The molecular structure thus obtained corresponds to *syn*-13,14 : 15,16-dibenzotricyclo[6.4.2.$2^{2,7}$]hexadeca-1,3,5,7,9,11,13,15-octaene. Of the four crystallographically-independent molecules, two have approximately the C_{2v} symmetry, while the remaining two are somewhat deformed, their symmetry being nearly C_2. The molecules are held together mainly by van der Waals interactions.

In 1968, Goldman and Ruden reported that, on ultraviolet irradiation, biphenylene (**1**) in refluxing hexane affords a dimer to which they assigned the **2** structure.[1] However, an X-ray study of the octahydrodimer[2] showed that this photodimer might correspond to **3**, not **2**. In order to determine the structure unambiguously, we have now undertaken an X-ray crystal analysis of the photodimer itself.



1 **2** **3**

Experimental

The biphenylene dimer (mp 257—267 °C (dec) (lit,[1] mp 255—265 °C (dec))) was prepared by the reported method.[1] The size of the sample used for the X-ray measurement was about $0.5\times0.5\times0.25$ mm^3. The crystal data are summarized in Table 1. The cell dimensions and reflection intensities were measured on a Rigaku four-circle diffractometer using Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) monochromated with an LiF crystal. The intensity measurement was made by the θ-2θ continuous-scan technique at a 2θ scan rate of 2° min^{-1}; the background was measured for 20—30 s at each end of the scan range. Three standard reflections, measured at intervals of every 62 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 140°, 6625 unique structure factor magnitudes above the $3\sigma(F)$ level were selected for the structure determination.

	$\beta=98.52(3)°$
	$\gamma=89.71(3)°$
V	3259.2 Å^3
Z	8
D_x	1.241 g cm^{-3}
μ(Cu $K\alpha$)	4.98 cm^{-1}

Structure Determination

The structure was solved by the symbolic-addition method.[3] The space group was assumed to be $P\bar{1}$; this choice was later confirmed by a successful refinement. Of the phases of the 1016 reflections with $|E|$ values above 1.70, 408 were expressed in terms of 8 symbols. Since one of the 2^8 possible combinations of the symbol values led to a phase set showing a low R_K value of 0.240 ($R_K=\sum||E_o|-k|E_c||/\sum|E_o|$) and a nonzero q value[4] of 0.368 ($q=1-\sum_h|E_h|(|\sum_k E_kE_{h-k}|/\sum_k|E_kE_{h-k}|)/\sum_h|E_h|$), this phase set was further extended by the use of 1827 $|E|$ values above 1.40; the R_k and q values thus became 0.288 and 0.496 respectively. An E-map based on 1632 phases afforded two superimposed molecular arrangements which were related to each other by the center of symmetry, and each of which might be taken as centrosymmetric. These molecular arrangements could be easily resolved from a consideration of the molecular packing.

The structure thus obtained was refined by the block-diagonal-matrix least-squares method. After all the 64 hydrogen atoms had been located in a difference Fourier map, a further least-squares refinement was done including the hydrogen atoms with isotropic temperature factors. The weighting scheme used was as follows: $w=1/\{\sigma(F)^2\exp(AX^2+BY^2+CXY+DX+EY)\}$, where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients are constants which were determined from the $(\Delta F)^2$ values; $A=0.2254\times10^{-4}$, $B=8.219$, $C=0.05559$, $D=-0.01387$, and $E=-7.770$. The final R value was 0.101. The final atomic parameters are listed in Table 2. The tables of the anisotropic temperature factors and hydrogen parameters, and those of the observed and calculated structure factors, are kept at the Chemical Society of Japan (Document No. 8126).

The calculations were performed on a FACOM 230-75 computer at the Hokkaido University Computing

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid.

Center, using our own programs. The atomic scattering factors were taken from the International Tables.[5)]

Results and Discussion

The molecular framework thus obtained is shown in Fig. 1. The bond distances and angles are listed in Table 3, while the torsion angles are given in Fig. 2. From these results, it is concluded that the biphenylene dimer has the **3** structure. As may be seen in Fig. 2, of the four crystallographically-independent molecules, the A and C molecules have approximately the C_{2v} symmetry, while the B and D molecules are somewhat deformed, their symmetry being nearly C_2. The mean

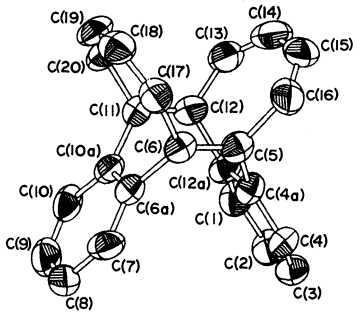

Fig. 1. A perspective view of the A molecule, and the numbering system of atoms. Carbon atoms are represented as thermal ellipsoids enclosing 50% probabilities. For the sake of clarity, hydrogen atoms are omitted.

values of the equivalent bond distances and angles for the four molecules are given in the last column of Table 3, the C_{2v} symmetry being assumed for all these molecules.

The mean lengths for the C(4a)–C(5) and C(5)–C(16) bonds, 1.499 and 1.500 Å, show that there is no appreciable conjugation between the C(5)=C(6) double bond and the benzene ring or the C(13)=C(14)–C(15)=C(16) diene part.[6] This can be explained by the fact that the mean magnitudes for the C(12a)–C(4a)–C(5)–C(6) and C(6)–C(5)–C(16)–C(15) torsion angles are 74 and 101° respectively. On the other hand, the mean length for C(14)–C(15), 1.450 Å, indicates that the C(13)=C(14) and C(15)=C(16) double bonds are thoroughly conjugated.

The central cyclooctatetraene ring takes a tub form. The bridging by the conjugated diene systems causes a close approach between the C(5)=C(6) and C(11)=C(12) double bonds; the average distance between the midpoints of these bonds is 2.67 Å, while the corresponding average for the C(4a)–C(12a) and C(6a)–C(10a) bonds is 2.85 Å. Because of this approach, the C(5)–C(4a)–C(12a) bond angle is somewhat shrunk, its mean value being 115.2°. The conjugated diene system further brings about a remarkable out-of-plane bending deformation[7] of the C(5)=C(6) and C(11)=C(12)

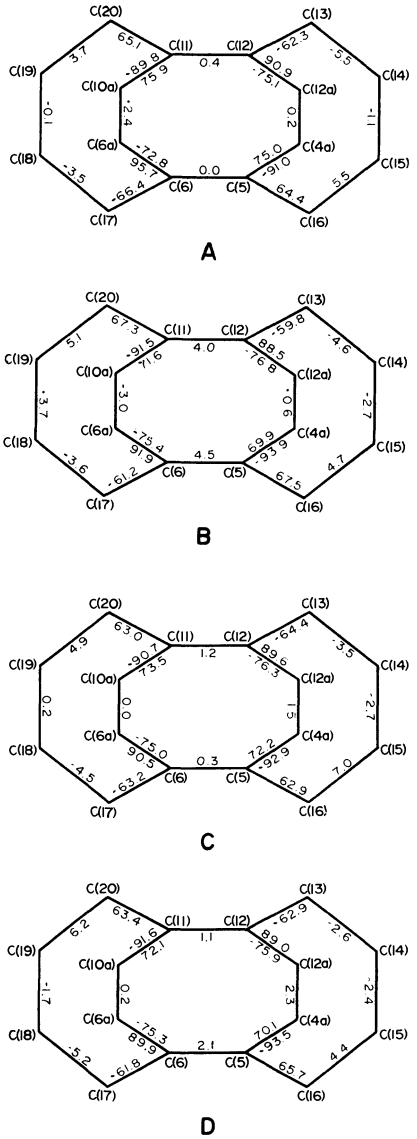

Fig. 2. The torsion angles (ϕ/°) for the tricyclo [6.4.-2.2^{2,7}]hexadeca-1,3,5,7,9,11,13,15-octaene skeletons. Only the torsion angles relevant to atoms which form the same ring are given in the ring.

Table 3. The bond distances (l/Å) and angles (ϕ/°), with their standard deviations
The standard deviations given in parentheses refer to the last decimal position.

TABLE 4. THE PROJECTIONS (ϕ/°) OF THE BOND ANGLES ALONG THE C(5)=C(6) OR C(11)=C(12) BOND

	A	B	C	D
(1) Along C(5)=C(6)				
C(4a)–C(5)–C(16)	164.2	162.2	163.9	161.9
C(6a)–C(6)–C(17)	167.5	166.6	164.0	164.3
(2) Along C(11)=C(12)				
C(10a)–C(11)–C(20)	164.4	161.6	162.6	162.3
C(12a)–C(12)–C(13)	164.6	164.4	165.1	163.9

ethylenic groups (see Table 4); the average for the projected angle of C(4a)–C(5)–C(16) along the C(5)=C(6) double bond is 164°.

On the other hand, the restricted approach between the C(5)=C(6) and C(11)=C(12) double bonds results in an enlargement of the C(12)–C(13)=C(14) and C(13)=C(14)–C(15) bond angles; the averages for these bond angles are 125.4 and 133.1° respectively. Such a way of deformation of the two bond angles can be reproduced by the following simple calculation. If one assumes that the C(12)–C(13)=C(14)–C(15)=C(16)–C(5) moiety has the C_{2v} symmetry, the C(5)···C(12) distance, l, is expressed by:

$$l = l_1 - 2l_2 \cos\theta_1 + 2l_3 \cos(\theta_1+\theta_2), \quad (1)$$

where l_1, l_2, and l_3 are the C(14)–C(15), C(13)=C(14), and C(12)–C(13) distances respectively, and where θ_1 and θ_2 are the C(13)=C(14)–C(15) and C(12)–C(13)=C(14) angles respectively. If, as a first approximation, the change in the bond distortion of the C(5) and C(12) terminal atoms is neglected, the variable part of the strain energy due to the bond-angle deformation, ΔE, is given by:

$$\Delta E = k\{(\theta_1-\theta_0)^2 + (\theta_2-\theta_0)^2\}, \quad (2)$$

where k is the force constant for the deformation of the C=C–C bond angle and where θ_0 is the strainless C=C–C bond angle, for which 120° is assumed in the present calculation. When the average observed values of 1.450, 1.329, 1.500, and 2.675 Å are used for l_1, l_2, l_3, and l respectively, ΔE is minimized at $\theta_1=132°$ and $\theta_2=127°$ under the conditions of Eq. 1. These θ_1 and θ_2 values are in good agreement with their respective observed values. For $\theta_1=\theta_2=120°$, $(\partial l/\partial\theta_1)$ is greater than $(\partial l/\partial\theta_2)$ by a factor of 1.886, while $(\partial\Delta E/\partial\theta_1)$ is equal to $(\partial\Delta E/\partial\theta_2)$; that is, the enlargement of θ_1 can separate the C(5) and C(12) atoms more effectively than that of θ_2. This explains why, in both the observed and calculated geometries, θ_1 is greater than θ_2.

In all four molecules, the C(14) and C(15) atoms deviate slightly from the least-squares plane for the C(5), C(12), C(13), and C(16) atoms onto the side of the benzene ring (C(1), C(2), C(3), C(4), C(4a), and C(12a)); the average for the dihedral angle between this plane and the least-squares plane of the C(13)=C(14)–C(15)=C(16) part is 3.9°.

The crystal structure viewed along the c axis is shown in Fig. 3. The orientations of the four independent molecules are somewhat different from one another. All the intermolecular contacts correspond to the normal van der Waals interactions.

(Received September 30, 1980)

The molecular structure of grayanotoxin XIX, $C_{20}H_{30}O_3$, has been determined by means of X-ray crystal analysis. The crystals are triclinic, with two molecules in a unit cell with dimensions of $a=10.406$, $b=10.648$, $c=8.003$ Å, $\alpha=90.00$, $\beta=94.25$, and $\gamma=102.76°$; the space group is P1. 2671 unique intensity data were collected on a four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The structure was elucidated by the Monte Carlo direct method, using the 50 strongest reflections as the starting set. The block-diagonal least-squares refinement reduced the R value to 0.038. The structure obtained corresponds to 14-deoxygrayanotoxin VII. The two independent molecules exist in different conformations: one has a half-chair A-ring, and the other, an envelope A-ring. In both molecules, the B-ring takes a conformation intermediate between the chair and twist-chair forms, and the C-ring adopts a boat conformation. The crystal consists of infinite hydrogen-bonded molecular chains along the c axis.

A number of diterpenoids, such as grayanotoxins,[1,2] leucothols,[3] and grayathols,[4] have thus far been isolated from *Leucothoe grayana Max.* In this paper, we wish to report on the X-ray structure determination and molecular geometry of grayanotoxin (hereafter G) XIX, a new minor constituent from the same plant.

Experimental

Isolation of G XIX. Grayathol A was crystallized from a diethyl ether solution of the unknown-compound-containing fraction (81 mg)[5] obtained from the crude extract of *Leucothoe grayana Max.* The chromatography of the filtrate on silica gel (1 g) afforded G XIX (21 mg) in a 5×10^{-7} % yield from dried leaves; mp 132—133 °C (recrystallized from diethyl ether), $[\alpha]_D$ −12° (*c* 1, MeOH); IR (Nujol) 3496, 3370^{sh}, 1658, 1637 cm^{-1}; ^{1}H-NMR ($CDCl_3$) 1.05, 1.29 (each 3H, s), 1.69 (3H, d, $J=2$ Hz), 3.00 (1H, q, $J_{AX+BX}=8+11$ Hz), 3.60 (1H, q, $J_{AX+BX}=2+7$ Hz), 3.73 (1H, q, $J_{AX+BX}=4+11$ Hz), 4.91, 5.04 (each 1H, s), 5.18 (1H, bs); MS *m/e* 318 (M^+). Found: C, 74.91; H, 9.37%. Calcd for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50%. The ^{1}H-NMR spectrum was recorded on a Hitachi R-20B spectrometer, using TMS as the internal reference. The chemical shifts are given on the δ scale (s=singlet, d=doublet, q=quartet, bs=broad singlet). The IR spectrum was obtained on a JASCO Model IR-S spectrophotometer.

X-Ray Measurement. A colorless single crystal cut into a cube with an edge of about 0.3 mm was used. The crystal data are summarized in Table 1. The cell dimensions and reflection intensities were measured on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation (40 kV, 60 mA, $\lambda=1.5418$ Å). The θ-2θ continuous-scan technique was applied at a θ scan rate of 8° min^{-1}; the background was measured for 5 s at each end of the scan range. Three standard reflections, measured at intervals of every 60 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 125°, 2671 unique structure factor amplitudes above the $\sigma(F)$ level were selected for the structure determination.

Table 1. The crystal data

$C_{20}H_{30}O_3$	M.W.=318.46

	$c=8.003(2)$ Å
	$\alpha=90.00(7)°$
	$\beta=94.25(3)°$
	$\gamma=102.76(2)°$
V	862.4 Å^3
Z	2
D_x	1.226 g cm^{-3}
μ(Cu $K\alpha$)	5.99 cm^{-1}

Structure Determination

The structure was elucidated by the Monte Carlo direct method,[6] using the 50 strongest reflections as the starting set. In order to extend the tentative phase set derived from successively-generated random numbers, 10 cycles of the tangent procedure were performed by the use of 556 $|E|$ values above 1.30. Since the 208th phase set gave a low R_K value of 0.296 ($R_K=\sum||E_o|-k|E_c||/\sum|E_o|$) and a moderate q value of 0.424 ($q=\sum_h|E_h|(|\sum_k|E_kE_{h-k}|\exp\{2\pi i(\phi_k+\phi_{h-k})\}|/\sum_k|E_kE_{h-k}|)/\sum_h|E_h|$), 6 additional cycles of the tangent procedure were carried out using 604 $|E|$ values above 1.25; the R_k and q values were 0.299 and 0.356 respectively. An E-map based on 560 phases afforded all the 46 non-hydrogen atoms.

The structure thus obtained was refined by the block-diagonal-matrix least-squares method, first with isotropic and then with anisotropic temperature factors. After 57 of the 60 independent hydrogen atoms had been located in a difference Fourier map, further least-squares refinement including these hydrogen atoms with isotropic temperature factors was carried out. The weighting scheme used was as follows: $w=1/\{\sigma(F)^2\exp(AX^2+BY^2+CXY+DX+EY)\}$, where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients are constants which were determined from the $(\Delta F)^2$ values. In this manner, the R value reached 0.038. The final atomic parameters are listed in Table 2. The table of

TABLE 2. THE FINAL ATOMIC PARAMETERS AND ESTIMATED STANDARD DEVIATIONS

The coordinates of the non-hydrogen and hydrogen atoms are multiplied by 10^4 and 10^3 respectively.

(1) The non-hydrogen atoms.

a) The hydrogen atoms are denoted by the number of the non-hydrogen atom to which they are attached, suffixed by a, b, or c where necessary.

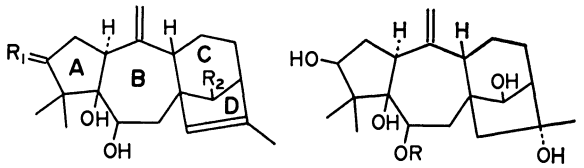
the anisotropic thermal parameters and that of the observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8128).

The calculations were performed on an ACOS 700 computer at the Institute for Protein Research, Osaka University, and on a FACOM 230-75 computer at the Hokkaido University Computing Center. The atomic scattering factors were taken from the International Tables.[7]

Results and Discussion

Molecular Structure. The skeletons of the two independent G XIX molecules, **A** and **B**, are illustrated in Fig. 1. The bond distances and angles and the torsion angles are given in Table 3 and Fig. 2 respectively. From these results, it is concluded that G XIX has the **1** structure.

The five-membered A-ring in the **A** molecule takes a half-chair form with an approximate two-fold rotation axis through the C(A2) atom, while that in the **B**



1 (GXIX): $R_1 = <^{OH}_{H}$ $R_2 = H$ 3 (GII): R = H

2 (GXVIII): $R_1 = O$ $R_2 = OH$ 4 (GXVI): R = Ac

Table 3. The bond distances (l/Å) and angles (ϕ/°), with their standard deviations

The standard deviations given in parentheses refer to the last decimal position.

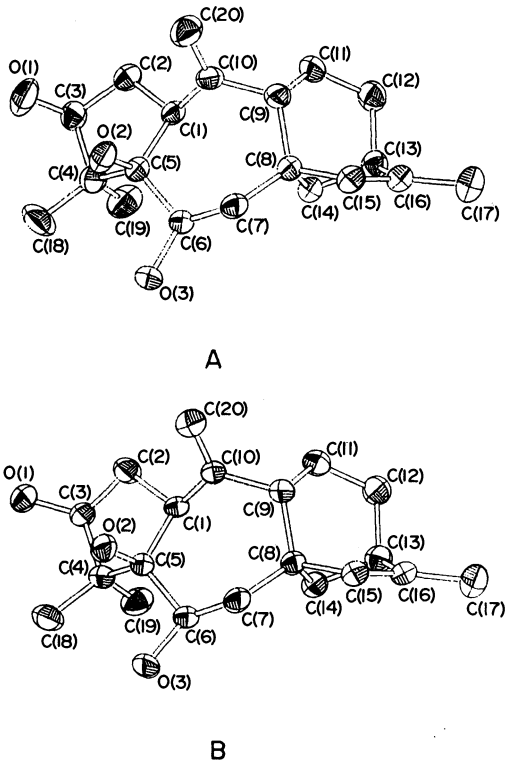

Fig. 1. Perspective views of the A and B molecules. Each non-hydrogen atom is represented as a thermal ellipsoid enclosing a 50% probability.

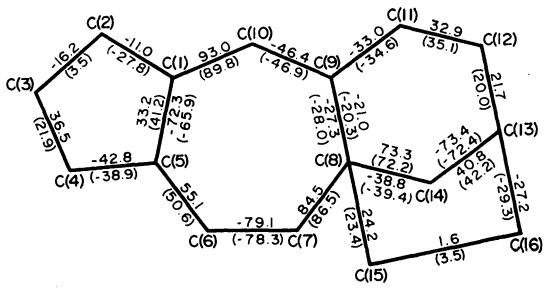

Fig. 2. The torsion angles (ϕ/°) of the A-, B-, C-, and D-rings. Only the torsion angles relevant to atoms which form the same ring are given in the ring. The values for the B molecule are given in parentheses.

molecule has an envelope form with an approximate mirror plane through the C(B5) atom. Although the former conformation permits the formation of the intramolecular hydrogen bond, O(2)–H···O(1) (see Table 4), the latter is unfavorable for this hydrogen bonding, the O(B1)···O(B2) distance being 3.248(3) Å. Consequently, the O(B2)H hydroxyl group forms a considerably bent hydrogen bond with the O(B3) atom of the same molecule; the O(B2)–H···O(B3) angle is 121°. Since, in the G XVIII (**2**) molecule[8] having almost the same ring conformation as the **B** molecule, the O(2)H hydroxyl group donates its proton to the exocyclic double bond, C(10)=C(20), the present O(B2)–H···O(B3) interaction will be nearly as weak as the O–H···π hydrogen bonding.[9] The O(1)–C(3)–C(4)–C(18) torsion angles in the **A** and **B** molecules are 38.9 and 20.4° respectively; the resulting difference in torsional strain results in a difference of 6.0° between the O(1)–C(3)–C(4) bond angles in the two molecules.

As is found also in other grayanotoxins, **2**—**4**,[8,10,11] the C(4)–C(5) bonds in the **A** and **B** molecules are somewhat lengthened. This bond lengthening is probably due to the steric repulsions between the C(18)H_3 and O(2)H groups and between the C(19)H_3 and C(6)H groups: C(A18)···O(A2), 2.871(7); C(A19)···C(A6), 3.061(6); C(B18)···O(B2), 2.872(6); C(B19)···C(B6), 3.034(5) Å. These steric repulsions further result in a distortion of the C(4)–C(18) and C(4)–C(19) bonds; the C(5)–C(4)–C(18) and C(5)–C(4)–C(19) bond angles are larger than the C(3)–C(4)–C(18) and C(3)–C(4)–C(19) bond angles by 1.6 and 4.5° respectively for the **A** molecule, and by 2.6 and 3.8° respectively for the **B** molecule.

In both molecules, the seven-membered B-rings adopt conformations intermediate between the chair form

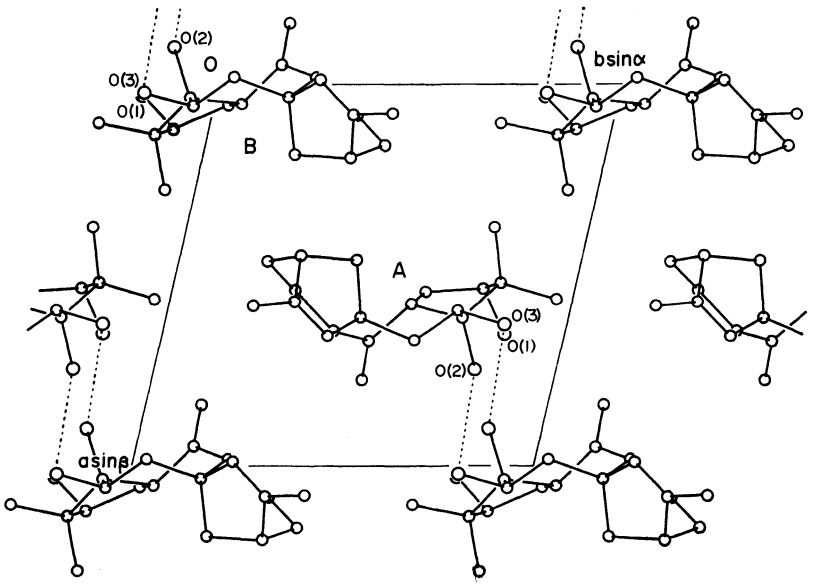

Fig. 3. The crystal structure viewed along the c axis.

characterized by the mirror plane through the C(5) atom and the twist-chair form characterized by the two-fold rotation axis through the C(9) atom. The corresponding torsion angles of these two B-rings are in good agreement with each other except for the three bonds associated with the A-ring atoms. If the present B-rings are considered to be of the chair form, the interaction between axial groups at the C(7) and C(10) atoms corresponds to the severe 3a-3'a repulsion in the chair cycloheptane.[12] However, since the C(10) atom forms a double bond with the C(20), the conformations of these B-rings are free from the 3a-3'a repulsion; hence, they are probably more stable than the B-ring conformations in G II[10] and XVI.[11]

The six-membered C-rings in both **A** and **B** molecules take boat conformations similar to that of the C-ring in G XVIII.[8] On the other hand, it has been found that, in all of the G I,[13] II, and XVI molecules where the C(15)–C(16) bond is a single bond, the C-rings possess the chair conformation. These facts suggest that the C-ring conformation depends largely on the nature of the C(15)–C(16) bond. Force-field calculations[14] for 6-methylbicyclo[3.2.1]octane and 6-methylbicyclo[3.2.1]oct-6-ene showed that, if the influence of the B-ring is neglected, the transformation of the C(15)–C(16) single bond into the double bond can reduce the chair-boat enthalpy difference of the C-ring by 1.8 kcal/mol, but that it cannot reverse the relative stabilities of the two C-ring conformations.[8] Accordingly, in order fully to understand the conformational behavior of the C-ring, the force-field calculations including the B-ring are now in progress.

Table 4. The hydrogen bonds, X–H···Y

	X	Y	X···Y l/Å	H···Y l/Å	X–H···Y ϕ/°
(1)	Intramolecular				
	O(A2)	O(A1)	2.863(4)	2.19(4)	145(4)
	O(B2)	O(B3)	2.676(3)	2.13(3)	121(3)
(2)	Intermolecular				
	O(A1)	O(A3)[a)]	3.034(3)	2.23(6)	171(5)
	O(A3)	O(B2)[b)]	2.938(4)	2.03(5)	165(5)
	O(B1)	O(A2)[c)]	2.950(3)	2.24(5)	140(4)
	O(B3)	O(B1)[d)]	2.894(3)	2.03(4)	171(4)

The symmetry codes are as follows: a) $x, y, -1+z$; b) $1+x, 1+y, 1+z$; c) $-1+x, -1+y, -1+z$; d) $x, y, 1+z$.

Crystal Structure. The crystal structure viewed along the c axis is shown in Fig. 3. The details of hydrogen bonding are given in Table 4. The **A** and **B** molecules are connected by the O(A3)–H···O(B2) and O(B1)–H···O(A2) hydrogen bonds, forming a dimer. These hydrogen-bonded dimers are further held together by the intermolecular hydrogen bonds, O(A1)–H···O(A3) and O(B3)–H···O(B1), to form a double molecular chain. The present crystal consists of such infinite hydrogen-bonded molecular chains along the c axis.

(Received October 21, 1980)

The behavior of recoil tririum atoms in solid neopentane containing a small amount of alkane has been studied at 77 K by means of ESR spectroscopy and radio-gas chromatography. Though it was reported that the H (or D) atoms produced in the radiolysis and photolysis of solid neopentane react selectively with the solute alkane, the T atoms neither diffuse into the matrix at 77 K nor react selectively with the solute alkane. Most of the recoil T atoms react in their own track. The results are explained by a hot-zone model. The radius and the duration time of the hot zone are estimated to be ≈60 Å and ≈10^{-10} s respectively.

Tritium-technology in fusion reactors requires the elucidation of the behavior of hot tritium atoms in solid materials, which involve the integrity of the constructing materials as well as a tritium inventory. So far many studies have been undertaken on the hot tritium reaction in the gas phase, and the fundamental reaction modes have well been established,[1] but many fewer studies have been reported for the solid phase. In the condensed phases, there exist two important factors controlling the final product-distributions. One is the rapid collisional stabilization of excited primary products, and the other is a cage effect. The latter effect, due to the confinements of both radicals and a thermalized atom, constitutes one of the central interests in the condensed phases. However, it has been verified experimentally that the cage effect is much less important in the hot tritium atom because of its small size and because of the high probability of diffusing out from the cage wall.[2] For example, the change from the high-pressure gas phase to the liquid leaves the H substitution reaction by T in 1,2-dichloro-1,2-difluoroethane almost unaffected.[3] Furthermore, the increase in the yield of c-C_4H_7T, found in the phase change of deuterated cyclobutane from gas to a liquid or to a solid was well interpreted by the rapid collisional stabilization of excited c-$C_4D_7T^*$ molecules in the condensed phase.[4]

Recently, the behavior of H (or D) atoms, produced by the photolysis of hydrogen iodide or by the γ-radiolysis of alkane, have been studied in the solid alkane at 77 K.[5] When hydrogen atoms with an initial kinetic energy of 2—3 eV are produced in solid neopentane containing a small amount of alkane at 77 K, they migrate through the solid matrix and abstract hydrogen atoms selectively from the solute alkane. The selective hydrogen-atom abstraction has the following characteristic features: (1) The ratio of the rate constant for the hydrogen atom abstraction from the solute to that from the solvent ($k_{solute}/k_{solvent}$) is 700 for neopentane–alkane mixtures at 77 K. (2) The selective hydrogen-atom-abstraction reaction by H or D atoms in the neopentane-alkane mixtures at 77 K becomes more favored with a decrease in the initial energy of the H or D atoms. (3) The selective hydrogen atom abstraction is suppressed above a certain temperature (140 K). (4) The selective hydrogen-atom abstraction is effectively caused by both H and D atoms: there exists no definite isotope effect between them. Thus, it can be expected that the T atom in the energy range of the photolysis and the radiolysis also reacts selectively with solute alkanes at 77 K if the T atom migrates through the matrix at that temperature.

The recoil tritium atoms produced by the $^6Li(n,\alpha)T$ reaction have an initial energy of 2.7 MeV. After the consequences of collisional energy losses, they enter the reaction-energy range and react there. However, certain fractions of them continue to escape reactions and finally become thermalized T atoms. In the cooling processes down to thermalization, the T atoms must pass through the energy range of 2—3 eV, which is equal to the initial energies of the hydrogen atoms formed in the photolysis. The effects of scavengers, such as O_2 and Br_2, on the recoil T-atom reaction in CH_4,[6] C_2H_6,[7] and i-C_4H_{10}[1a] systems indicated that 30—40% of the total recoil T atoms are thermalized in the gas phase.

The question raised here is whether or not such T atoms can migrate through the solid alkane at 77 K, as the hydrogen atoms formed in the photolysis can. Here, in order to solve this problem, the reactions of T atoms were studied in neopentane–alkane mixtures. Although the preliminary experiments[8] provided no evidence for the selective H abstraction reaction of recoil T atoms, the failure in the observation might have been because the sample temperature was raised during the neutron irradiations. In the present experiments, the sample temperature during the irradiation was checked through the ESR measurements of radicals formed concomitantly. The results obtained were analyzed by comparison with the characteristic features of the behavior of the H (or D) atoms formed in the photolysis and radiolysis.

Experimental

The LiF, used as the target for $^6Li(n,\alpha)T$, was purchased from the Johnson Mathey Chemicals. The mass-spectroscopic analysis showed that the $^6Li/^7Li$ ratio in the LiF is 0.04. The neopentane and propane were more than 99.9 mol % and 99.7 mol % respectively in purity. At least 95% of the isobutane-2-d_1 (i-C_4H_9D) was correctly labeled with the deuterium at the tetriary position. The 2-methyl-d_3-propane-1,1,1,3,3,3-d_6 (i-C_4D_9H), supplied by Merck Sharp and Dohm, Canada, Ltd., has a listed isotopic purity of 98 mol %.

In order to make solid neopentane–alkane–LiF mixtures, the liquid mixtures were immersed rapidly in liquid nitrogen.

H atoms, produced by the radiolysis of neopentane, react effectively with the alkane solute to form alkyl radicals. The yields of the alkyl radicals increase with an increase in the concentration of the solute alkane.[5c] Thus, most of the alkane solute may be dissolved uniformly in the neopentane matrix at 77 K. A part of the LiF may be dissolved in the neopentane matrix, while the rest is precipitated in the solvent. Thus, T atoms may be produced from the dissolved LiF as well as the precipitated LiF.

The reagents were sealed into a quartz cell. The sealed cell was inserted into a polyethylene capsule packed with powered dry ice. Subsequently, the capsule was immersed in liquid N_2 until it reached an equilibrium and was then immediately irradiated in the pneumatic tube of the JRR-4 reactor of the Japan Atomic Energy Research Institute. The neutron flux and the dose rate of γ-rays from the reactor were 3×10^{13} n cm^{-2} s^{-1} and 2×10^{8} rad h^{-1} respectively.[9] At the end of the irradiation, some capsules were immersed in liquid N_2 to make them ready for the subsequent ESR measurements.

The free radicals of the irradiated samples were measured at 77 K with a JEOL-PE3X ESR spectrometer at a microwave power level of 0.2 mW, which did not result in a saturation of the signals of the alkyl radicals. The tritiated products were analyzed by means of radio-gas chromatography. A 5-m ferric oxide γ-alumina column at 77 K was used for the separation of HT and DT, and a 3-m Parapak Q column at 380 K, for the organic products. The two columns were combined by means of a double-column technique,[10] in which a whole sample can be injected at a time.

Results and Discussion

ESR Spectra of Irradiated Sample. Figure 1a shows the ESR spectrum of a *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %)–LiF mixture irradiated at 77 K in the reactor. The spectrum of eight lines, indicated by arrows (↓), is ascribed to the *t*-C_4H_9 radical.[11] The spectrum of three broad lines, indicated by arrows (⇩), is ascribed to the *neo*-C_5H_{11} radical.[11] The unsymmetrical spectrum, indicated by arrows (⇣), is due to a color center of irradiated quartz. Figure 1b shows the ESR spectrum of a *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %) mixture γ-irradiated at 77 K with Co-60. The spectrum consists of spectra of *neo*-C_5H_{11} and *t*-C_4H_9 radicals. The amount of the *t*-C_4H_9 radical is about 30% of the total radical yield. Similarly, C_3H_7 or *t*-C_4D_9 radicals are remarkably produced in the γ-radiolysis of *neo*-C_5H_{12} containing C_3H_8(2 mol %) or *i*-C_4D_9H(2 mol %) at 77 K.

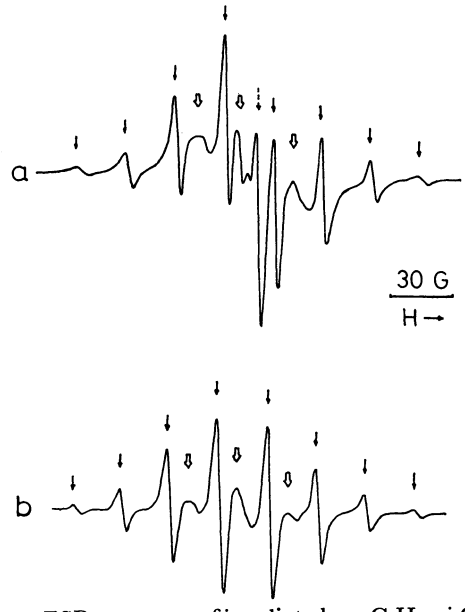

Fig. 1a. ESR spectrum of irradiated *neo*-C_5H_{12}–*i*-C_4H_9D-(2 mol %)–LiF mixture at 77 K with a reactor for 15 s at a dose of 0.8 Mrad. b. ESR spectrum of irradiated *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %) mixture at 77 K with γ-rays of Co-60 at a dose of 0.1 Mrad.

A comparison of Fig. 1a with Fig. 1b makes it obvious that the neutron-irradiation of the *neo*-C_5H_{12}–*i*-C_4H_9D-(2 mol %)–LiF mixture gives approximately the same ESR spectra of *neo*-C_5H_{11} and *t*-C_4H_9 radicals as in the γ-irradiation. This is reasonable since, during the neutron-irradiation in the reactor, the sample is also exposed to a high dose of γ-rays. The chemical damage caused by the recoil T and ^{3}He atoms amounts to only 1—2% of that caused by γ-rays.

According to the previous studies,[5] the *t*-C_4H_9 radicals are produced by the selective hydrogen-atom-abstraction reaction by H atoms produced from the radiolysis of neopentane (Reactions 1 and 2):

$$\textit{neo}\text{-}C_5H_{12} \rightsquigarrow \textit{neo}\text{-}C_5H_{11} + H \quad (1)$$

$$H + \textit{i}\text{-}C_4H_9D \longrightarrow HD + \textit{t}\text{-}C_4H_9. \quad (2)$$

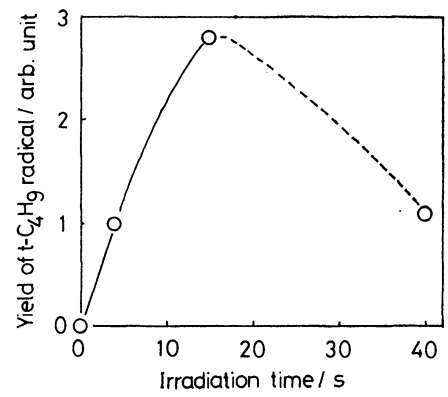

Fig. 2. Yield of *t*-C_4H_9 radical in the irradiation of *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %)–LiF mixture with a reactor against irradiation time.

Figure 2 shows the effect of the irradiation time in the reactor on the amount of the *t*-C_4H_9 radical produced in the irradiated *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %)–LiF mixture. The amount of the *t*-C_4H_9 radical increases almost linearly up to an irradiation time of 15 s, while the amount decreases drastically at 40 s. In the case of an irradiation time of 40 s, most of the *t*-C_4H_9 radicals may disappear as a result of the elevation of the temperature of the sample during the irradiation.[12] Thus, a sample temperature of near 77 K is assured within the irradiation time of 15 s, during which time the selective hydrogen-atom-abstraction reaction by T atoms can proceed. Therefore, the irradiation of the samples in the reactor was restricted to within 15 s.

Recoil T Atoms in Neopentane–Alkane Mixtures at 77 K. Table 1 shows the yields of tritiated products in the neopentane–alkane mixtures at 77 K. The DT/HT ratio in the *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %) system is only

TABLE 1. YIELDS OF TRITIATED PRODUCTS OF THE RECOIL TRITIUM REACTION IN NEOPENTANE AT 77 K

Sample[a]	Irradiation time / s	Relative yield/% HT	DT	CH_3T	RT[b]	P[c]	*neo*-$C_5H_{11}T$	DT/HT
neo-C_5H_{12}–*i*-C_4H_9D(2)	40	42	1	14	2	4	37	0.020
neo-C_5H_{12}–*i*-C_4H_9D(2)	15	37	2	16	2	4	39	0.055
neo-C_5H_{12}–*i*-C_4H_9D(2)	4	37	2	—	—	—	—	0.056
neo-C_5H_{12}–*i*-C_4D_9H(2)	15	38	1	15	3	4	39	0.029
neo-C_5H_{12}–C_3H_8(2)	15	40		14	2	6	38	
neo-C_5H_{12}–*i*-C_4H_{10}(2)–DI(0.5)	15	45	1	14	3	—	37	0.022
neo-C_5H_{12}	15	36		15		7	42	

a) The unit of concentration in mol% is shown in parentheses. LiF (0.05 g/l g of solvent) is added to all the samples. The yields at the irradiation time of 15 s are the mean values of three or four runs, and the errors are about 10%. b) RT represents a tritiated solute, such as *i*-C_4H_9T, *i*-C_4D_9T, or C_3H_7T. c) P may be *i*-C_4H_7T. d) Since not all the tritiated products were analyzed in this sample, it is assumed that the yield of hydrogen (HT+DT) is equal to that of *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol%) at the irradiation time of 15 s.

0.055 for the irradiation time of 15 s.

Now, we will try to estimate the DT/HT ratio from the previously accepted mechanisms. Though the recoil T atoms have an initial energy of 2.7 MeV, a part of them may continue to lose energy through a series of collisional deactivations to the energy range of the H (or D) atoms produced by the photolysis. The scavenger study showed that about one-third of the total recoil T atoms are deactivated.[1a,6,7] If the deactivated T atoms (T_t)[13] behave in a manner similar to that of H (or D) atoms in the photolysis, they should migrate through the *neo*-C_5H_{12}–*i*-C_4H_9D mixture and react selectively with the isobutane solute (Reaction 3):[5]

$$T_t + CH_3\text{–}\underset{\displaystyle D}{\overset{\displaystyle CH_3}{\underset{|}{\overset{|}{C}}}}\text{–}CH_3 \longrightarrow DT + CH_3\text{–}\overset{\displaystyle CH_3}{\underset{\displaystyle \cdot}{\overset{|}{C}}}\text{–}CH_3 \qquad (3)$$

Furthermore, the possibility of the occurrence of Reactions 4 and 5 can be dismissed on the basis of the following results of H-atom reactions in the photolysis:

$$T_t + CH_3\text{–}\underset{\displaystyle D}{\overset{\displaystyle CH_3}{\underset{|}{\overset{|}{C}}}}\text{–}CH_3 \longrightarrow HT + CH_3\text{–}\overset{\displaystyle CH_3}{\underset{\displaystyle D}{\overset{|}{C}}}\text{–}CH_2\cdot \qquad (4)$$

$$\searrow \quad CH_3T + C_3H_6D\cdot \qquad (5)$$

When H atoms are produced by the photolysis of HI in the *neo*-C_5H_{12}–*i*-C_4H_9D mixtures at 77 K, only *t*-C_4H_9 radicals are produced by Reaction 3.[5b] The isobutyl or propyl radicals, which should be formed in Reactions 4 and 5, were not observed by ESR spectroscopy in the reaction of H atoms with *i*-C_4H_9D at 77 K. Thus, most of the T_t atoms can be expected to react with *i*-C_4H_9D to form DT by means of Reaction 3.

The amounts of hot T atoms with a high energy (T_h) are about 60—70% of the total-recoil T-atom reactions in alkanes.[1a,6,7] These T atoms react with alkane by means of abstraction, replacement, and fragmentation reactions. Since the ratio of the D atom to the H atom in the *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %) mixture is only 0.002, the hot T_h atoms in the abstraction reaction react virtually with the H atom to form HT by means of Reaction 6:

$$\underset{(i\text{-}C_4H_9D)}{T_h + \textit{neo}\text{-}C_5H_{12}} \longrightarrow HT + \underset{(C_4H_8D)}{C_5H_{11}\cdot} \qquad (6)$$

Thus, the maximun yield of HT is less than 60—70% of the total tritiated products. The T_t atoms, the amounts of which are about 40—30% of the total recoil T atoms, form DT by means of Reaction 3.

Therefore, the ratio of DT to HT can be expected to be higher than 0.4:

$$\frac{DT}{HT} = \frac{40 - 30\%}{\leqq 60 - 70\%} \geqq 0.4. \qquad (7)$$

The expected ratio (DT/HT) dose not coincide at all with the experimental value (0.055) in Table 1. The quite low value of the experimental DT yield indicates that most of the T_t atoms neither diffuse into the neopentane matrix at 77 K nor abstract D atoms selectively from *i*-C_4H_9D.

Hot-zone Model for Recoil-T-atom Reactions. If the thermalization process of recoil-T atoms in the solid phase is approximately the same as that in the gas phase, the question arises of why the thermalized recoil T_t atoms do not diffuse into the neopentane matrix at 77 K. The hot-zone model, proposed previously by Seitz *et al.*,[14] Harbottle *et al.*,[15] and others,[16] gives a hypothetical explanation for this question. The ratios of the rate constants ($k_{i\text{-}C_4H_9D}/k_{neo\text{-}C_5H_{12}}$) for hydrogen-atom

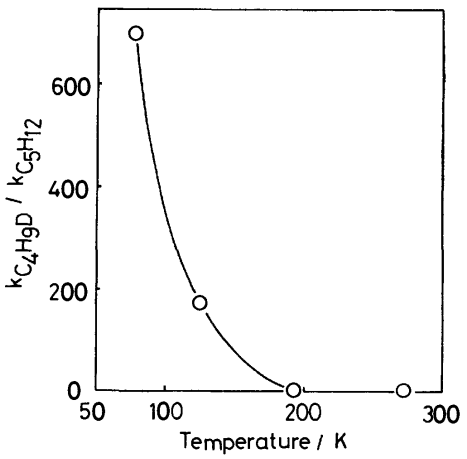

Fig. 3. Temperature effect of rate constants($k_{solute}/k_{solvent}$) for hydrogen atom abstraction by hydrogen atom produced by the UV-photolysis of *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %)–HI(0.5 mol %) mixture. The values are estimated from the results of previous papers.[5b,5d]

abstraction by H atoms in the photolysis of *neo*-C_5H_{12}–*i*-C_4H_9D-HI mixtures were determined previously,[5b,5d] and they are summarized in Fig. 3. The ratio of the rate constants, which represents the selectivity of the abstraction reaction, decreases drastically with an increase in the temperature. The selective hydrogen-atom-abstraction reaction in a neopentane matrix is suppressed at temperatures higher than 140 K, which is the transition point of solid neopentane.

A recoil-T-atom produces a "track," *i.e.* "continuous spurs," around its trajectory. If the temperature of the track is much higher than 77 K and the T atom reacts in its track, the T_t atom does not abstract a D atom selectively from solute *i*-C_4H_9D, but it may react with solvent *neo*-C_5H_{12} and free radicals in the track.

We can estimate the size of a hot zone from the negative temperature effect on the selective hydrogen-atom-abstraction reaction. A cylindrical hot-zone model is used for a high-LET track produced by a recoil T atom. The excess temperature distribution (T_{ex}) in space (r) and time (t) is given for this geometry by:

$$T_{ex} = T_0(1+4\delta t/r_0^2)^{-1} \exp[-r^2/(r_0^2+4\delta t)], \quad (8)$$

where T_0 is the initial temperature excess on the track axis and where r is the distance from it.[17] The quantity r_0 denotes the size parameter of the track cylinder, where 0.56 r_0 corresponds to the mean radius of the track. If S denotes the energy loss per unit length, then T_0 is given by the equation $T_0=S/(\pi\rho c\, r_0^2)$, where ρ and c are the density and the specific heat of the solid. Equation 8 is, in principle, the same as that proposed by Seitz *et al.*[14] except that the size of the initial track is considered according to the method of Mozumder.[17] The quantity δ, called the thermal diffusivity, equals $\kappa/\rho c$, where κ denotes the heat conductivity.

Recently the experimental and theoretical results on the stopping powers and path lengths of hydrogen and helium have been summarized by Ziegler.[18] The path lengths of the D atom and the ^{4}He atom with 1 keV through carbon are 160 Å and 100 Å respectively. It is assumed here that the length of the T atom with 1 keV through hydrocarbon is 130 Å. Thus, the average stopping power (S) is 7.7 eV Å^{-1}. The heat conductivity (κ), the specific heat (c), and the density (ρ) of solid neopentane at 77 K are 1.4×10^{-3} J s^{-1} cm^{-1} deg^{-1},[19] 0.80 J g^{-1} deg^{-1},[20] and 0.72 g cm^{-3} respectively. According to the experimental and theoretical studies of radiation chemistry, the radii of the track produced by β-rays are about 15 Å in water[17] and 25 Å in methanol[21] respectively. Thus, two values of 20 and 40 Å are tentatively taken here for the size parameters of the track (r_0). Since the selective hydrogen-atom-abstraction reaction in the *neo*-C_5H_{12}–*i*-C_4H_9D mixture is suppressed at 140 K (*cf.* Fig. 3), the lower limit of the temperature of the hot zone is assumed to be 140 K. Then, $T_{ex}=140-77=63$ K. If the excess temperature (T_{ex}) at the boundary of the hot zone is 63 K, the radius (r) of the hot zone can be calculated by Eq. 8 as a function of the duration time (t).

Figure 4 shows the size of the hot zone. The maximum radius and the duration time of the hot zone are found to be $\approx$60 Å and $\approx10^{-10}$ s respectively, both of which values are roughly independent of the initial size

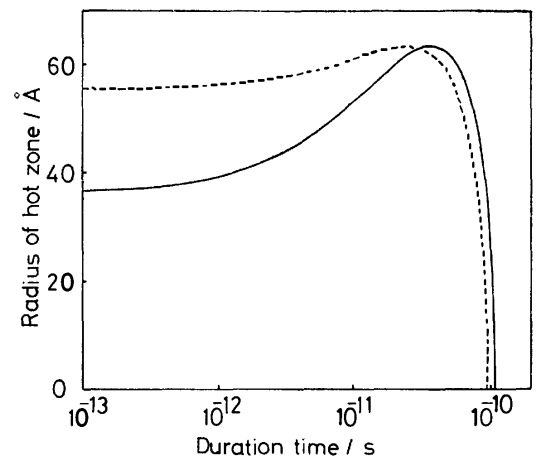

Fig. 4. Time dependence of hot zone produced by recoil T atom in solid neopentane.
——, A size parameter (r_0) of a track is 20 Å.
·····, A size parameter (r_0) of a track is 40 Å.

parameter (r_0) of the track. The radius increases with an increase in the duration time from 10^{-13} s to 3×10^{-11} s, and then decreases drastically at 10^{-10} s. The increase in the radius is caused by the diffusion of the initial energy deposited by a recoil T atom. The subsequent drastic decrease in the radius is due to the cooling of the hot zone. Most of the recoil T atoms may react in this hot zone within $\approx10^{-10}$ s, while only a few of them diffuse out of the zone.

Amount of T Atoms Leaking out of the Hot Zone. Though most of the recoil T atoms react in the hot zone, some of them may diffuse out of the zone. Now, we will attempt to estimate the upper limit of T_t atoms which may leak out of the zone. Table 1 shows the volatile tritiated products in the neopentane system. As no polymeric products are produced in a butane system,[2] most of the activity in the neopentane system may also appear in a volatile form. Thus, the yields in Table 1 represent roughly the overall reaction products.

The most possible reaction of the T_t atoms which diffuse out of the hot zone is a selective hydrogen-atom-abstraction reaction with the alkane solute in the neopentane matrix at 77 K. For example, the T_t atom reacts with *i*-C_4H_9D in the *neo*-C_5H_{12}–*i*-C_4H_9D(2 mol %) mixture to form DT (Reaction 3). The DT yield, however, amounts to only 2% of the total tritiated products.

There is a possibility that T_t atoms may migrate through the matrix and recombine with trapped radicals produced by the radiolysis of the sample. In order to examine this possibility, the reaction of T atoms has been studied in the *neo*-C_5H_{12}–C_3H_8(2 mol %) system. The ESR measurements of this mixture, after it has been γ-irradiated at 77 K, verified the production of a large amount of C_3H_7 radicals. If the C_3H_7 radicals are also produced by reactor-irradiation, the T_t atoms would recombine with the trapped C_3H_7 radicals.

$$T_t + C_3H_7 \longrightarrow C_3H_7T. \quad (9)$$

The yield of C_3H_7T is only 2% of the total tritiated products (*cf.* Table 1). Since C_3H_7T may also be formed by the substitution reaction of hot T atoms with

C_3H_8, the amount of T atoms which recombine with the trapped C_3H_7 radicals is much less than 2%.

There is also the additional possibility that the T_t atoms react with the trapped radicals by means of a disproportionation reaction. The disproportionation reaction between an H atom and a butyl radical occurs at such a low temperature as 90 K.[22] The ESR measurement of the γ-irradiated *neo*-C_5H_{12}–*i*-C_4D_9H(2 mol %) mixture shows the predominant formation of C_4D_9 radicals. It is expected that the C_4D_9 radicals are also produced by the reactor-irradiation. If the T_t atoms migrate through the *neo*-C_5H_{12}–*i*-C_4D_9H mixtures at 77 K and react with the trapped C_4D_9 radicals by means of the disproportionation reaction, DT should be formed by Reaction 10:

$$T_t + C_4D_9 \longrightarrow DT + C_4D_8. \quad (10)$$

Table 1 shows that the yield of DT is only 1% of the total tritiated products.

The effect of a radical scavenger, such as DI, has also been studied in the *neo*-C_5H_{12}–*i*-C_4H_{10}–DI mixtures at 77 K. It is expected that the T_t atoms may react with DI, with the resultant formation of DT:

$$T_t + DI \longrightarrow DT + I. \quad (11)$$

Table 1 shows that the yield of DT is only 1% of the total tritiated yield. This result also indicates that the amount of the diffusively mobile T atoms may be quite small.

The authors wish to thank Prof. Noriaki Ito of Nagoya University for his fruitful discussion. The authors wish also to thank Dr. Shigeo Tsujimura of the Japan Atomic Energy Research Institute for his encouragement throughout the work and Dr. Yasuo Ito of the University of Tokyo for his helpful advice concerning the ESR measurement. This work was done under the Collaboration Program between Japan Atomic Energy Research Institute and Nagoya University. It was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Brillouin Scattering Study of Clathrate Hydrate Formation in Acetone-Water Solution

Tadashi KATO, Masako YUDASAKA, and Tsunetake FUJIYAMA*
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received October 28, 1980)

Light scattering spectra have been observed for binary solutions of acetone and water at 24, 34, and 44 °C in the concentration range of $0 \leq x_{AC} \leq 0.25$, where x_{AC} is the mole fraction of acetone. The hypersonic velocities and the adiabatic compressibilities at 4.5 GHz were obtained from the observed values of Brillouin shifts. The observed concentration and temperature dependencies of the adiabatic compressibility were interpreted by assuming the existence of clathrate hydrate-like local structures in the solutions. The adiabatic compressibilities for binary solutions of *t*-butyl alcohol (TBA) and water were used as reference data. A comparison is made between the local structure formed in the acetone–water solution and that in the TBA–water solution.

Molecules such as tetrahydrofuran, *t*-butyl alcohol (TBA), and acetone are known to form solid clathrate hydrates.[1,2] Recently, Iwasaki *et al.* have observed the concentration and temperature dependencies of the mean-square concentration fluctuations for the binary solutions of TBA–water by means of light scattering.[3] In their study, the existence of local structures of the type $(H_2O)_l$TBA ($l \simeq 20$) has been suggested. The results of the X-ray diffraction analyses for the structure of solid clathrate hydrate have contributed to the following picture for the mixing state of the TBA–water mixtures. In the concentration range of $0 < x_{TBA} < 0.05$, a TBA molecule forms a polyhedron which is surrounded by water molecules; the polyhedra are dispersed in water (x_{TBA} is the mole fraction of TBA). In the concentration range of $0.05 < x_{TBA} < 0.15$, aggregates of several polyhedra are dispersed in TBA. At $x_{TBA} \simeq 0.05$, the number of molecules which take part in the clathrate hydrate formation becomes a maximum.

We believe that the above picture can be applied to the other aqueous solutions of non-electrolytes which are known to form solid clathrate hydrates. In the present study, the mixing state for the acetone–water system will be discussed through the observation of hypersonic velocity obtained from the Brillouin scattering measurements. Hypersonic velocity affords information about the structuring of a solution. For the TBA–water system, Stone *et al.* have shown that the hypersonic velocity takes a maximum value at $x_{TBA} \simeq 0.05$.[4] As the number of molecules which take part in the clathrate hydrate formation becomes maximum at this concentration for the TBA–water system, the characteristic concentration dependence of the hypersonic velocity seems to originate from the formation of the local structure of the type suggested by Iwasaki *et al.* An acetone molecule also forms a solid clathrate hydrate at about −35 °C.[5] We will interpret the concentration dependence of the hypersonic velocity or the adiabatic compressibility of the acetone–water solution based on the assumption that clathrate hydrate-like local structures exist in the solution. The mean-square concentration fluctuations could not be obtained accurately for the present system because the Rayleigh intensity arising from the concentration fluctuation is not so strong as that arising from the entropy fluctuation.

Experimental

The light scattering spectrometer used in the present study was designed and constructed in our laboratoly. Figure 1 shows the schematic diagram of the spectrometer. The light source is a He–Ne laser (NEC GLG 5800) which produces 50 mW power at 632.8 nm. The laser beam is irradiated on a sample cell made of quartz. The scattered light at 90° is directed into a piezoelectrically driven Fabry-Perot interferometer (Burleigh RC 110). After being passed through the interferomer, the light is focussed by a telemeter lens into a pinhole. The central spot of the interferometer ring system is then detected by a photomultiplier (HTV R-649). The photomultiplier signal is amplified, discriminated, and then put into a multichannel analyzer (Camberra Series 30) by which the spectra are averaged over many times. A stabilization system (Burleigh DAS 10, RC 43) was used for the elimination of the axial drift of the interferometer cavity and for maintaining the parallelism of the etalon. The free spectral range was 0.625 cm^{-1} and the finesse was about 20.

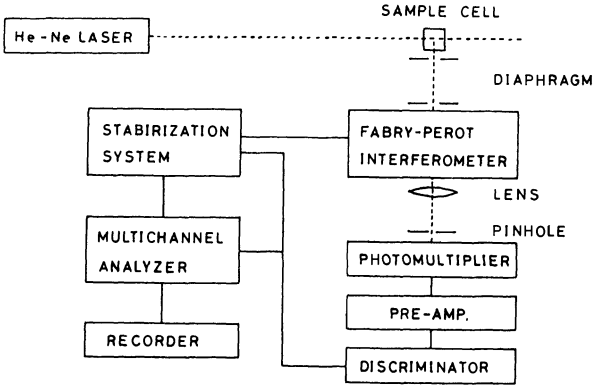

Fig. 1. Block diagram of the light scattering spectrometer.

Acetone was purchased from Wako Pure Chemical Industries, Ltd., and used after distillations. Water was distilled after being passed through an ion exchange resin. The binary mixtures of acetone–water were made dust-free by the use of Millipore filter FG with a pore size of 0.2 μm. The temperature of the sample was controlled by a high temperature cell. A temperature constancy of ±0.5 °C was obtained with the apparatus. The light scattering spectra were observed at 24, 34, and 44 °C. The refractive index of the sample was measured by means of an Atago Abbe refractometer; the results are shown in Table 1.

Results and Discussion

Hypersonic Velocity and Adiabatic Compressibility. The sound velocity, v_S, and the adiabatic compressibility, κ_S, at 4.56 GHz were obtained from the observed Brillouin shifts, $\Delta\nu$, by the relations[6)]

$$v_S = \frac{c\lambda_0}{2n\sin(\theta/2)}$$

and

$$\kappa_S = (v_S^2\rho)^{-1},$$

where c is the velocity of light, λ_0 the wavelength of the incident light in a vacuum, n the reftactive index of the sample, θ the scattering angle, and ρ the density.[9)] In Figs. 2 and 3, the observed v_S and κ_S are plotted against the mole fraction of acetone, x_{AC}, for different temperatures. It is seen from these figures that v_S (or κ_S) takes a maximum (or minimum) value at $x_{AC}\simeq 0.1$ for 24 °C and $x_{AC}\simeq 0.05$ for 44 °C. These results suggest that some sort of long-range structures are formed in the binary solution of acetone–water, especially in the concentration range around $x_{AC}=0.1$.

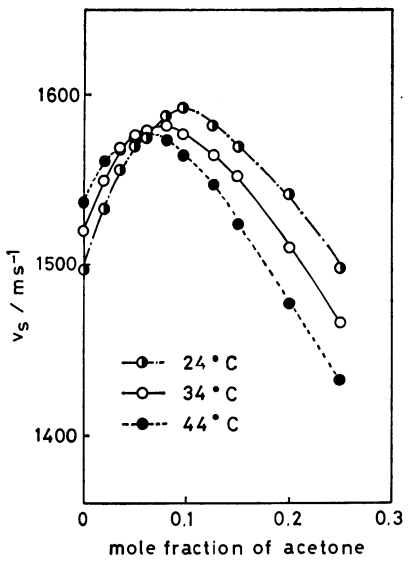

Fig. 2. Concentration dependence of hypersonic velocity for acetone–water system at 24, 34, and 44 °C.

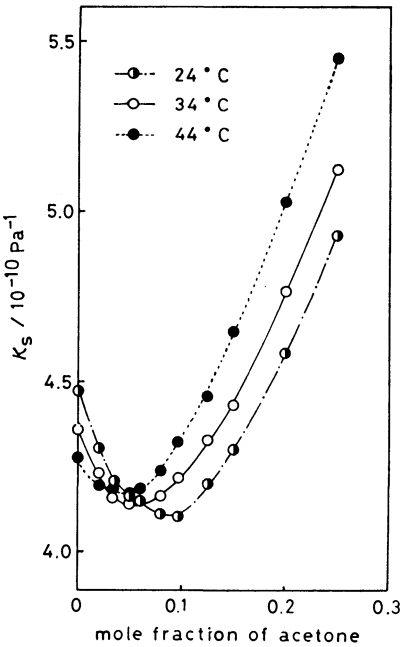

Fig. 3. Concentration dependence of adiabatic compressibility for acetone–water system at 24, 34, and 44 °C.

Mixing State of Acetone–Water Solution. X-Ray diffraction analysis has shown that an acetone molecule forms a solid clathrate hydrate with several water molecules at about −35 °C.[5)] The chatacterstic concentration dependence of v_S or κ_S may arise from the clathrate hydrate-like local structure formation in the solution. If the composition of such a structure is of the type $A(H_2O)_l$ where A is acetone, κ_S is expected to take a minimum value at $x_{AC}=1/(l+1)$, because the number of the molecules which do not take part in the clathrate formation becomes minimum at $x_{AC}=1/(l+1)$. Figs. 2 and 3 show that the number ratio of water molecules to acetone molecules in the local structure (we will call this ratio R, from now on) is about 10 at 24 °C and about 20 at 44 °C.

It has been established that water molecules in a solid clathrate hydrate form polyhedra, each of which encages a guest molecule.[1,2)] More than 24 water molecules are necessary to form a polyhedron which can encage a molecule as large as an acetone molecule. In the case of a solid hydrate, however, several polyhedra share one of their faces (we will call this "association of polyhedra") and, therefore, R can become less than 24. For example, R is 7⅔ or 5¾ for "structure I" and 17 for "Structure II."[1,2)] As R obtained from the observed κ_S is 10 at 24 °C, it may be concluded that polyhedra associate to some extent in the solution at this temperature.

If the concentration of acetone is very low, however, association of polyhedra cannot be expected. Therefore, R may be 24 or more. As the concentration increases, it is expected that the polyhedra begin to associate with each other near $x_{AC}\simeq 0.04$ because almost all the water molecules form polyhedra at this concentration. The slowing down of the gradient change of κ_S near

$x_{AC} \simeq 0.05$ at 24 °C may reflect this situation.

In the concentration range of $0.05 < x_{AC} < 0.1$, κ_s continues to decrease with the increase of x_{AC}. This fact suggests the growth of the local structures with the increase of the concentration. With the increase of x_{AC} up to 0.1, the association degree of the polyhedra increases and, therefore, R decreases down to 10. Since an acetone molecule is known to form a solid clathrate hydrate of the Structure II ($R=17$), at least 17 water molecules are thought to be necessary to form a stable local structure of a clathrate hydrate type. Therefore, the local structure formed at $x_{AC} \simeq 0.1$ ($R=10$) may be more unstable than the local structure formed at $x_{AC} \simeq 0.05$ ($R=20$). In fact, κ_s increases as the temperature increases near $x_{AC} \simeq 0.1$, while κ_s is almost independent of the temperature near $x_{AC} \simeq 0.05$.

In the concentration range of $x_{AC} > 0.1$, κ_s increases rapidly with the increase of the concentration. This suggests that the number of acetone molecules which are not encaged by water molecules increases with the increase of x_{AC}. Thus, it can be imagined that the associated polyhedra begin to be separated by acetone molecules at $x_{AC} \simeq 0.1$.

Burton has measured the ultrasonic velocity at 1 MHz for the acetone–water solution at 27 °C and found that v_s takes a maximum value at $x_{AC} \simeq 0.05$.[7] However, our results at 4.5 GHz show that v_s takes a maximum value at $x_{AC} \simeq 0.1$ at room temperature. This difference is considered to come from the fact that the life-time of the local structure, τ, is dependent of concentration. τ at $x_{AC} \simeq 0.1$ may be much shorter than the period of the ultrasonic wave, but may be longer than that of the hypersonic one. On the other hand, τ at $x_{AC} \simeq 0.05$ may be longer than the period of the ultrasonic wave.

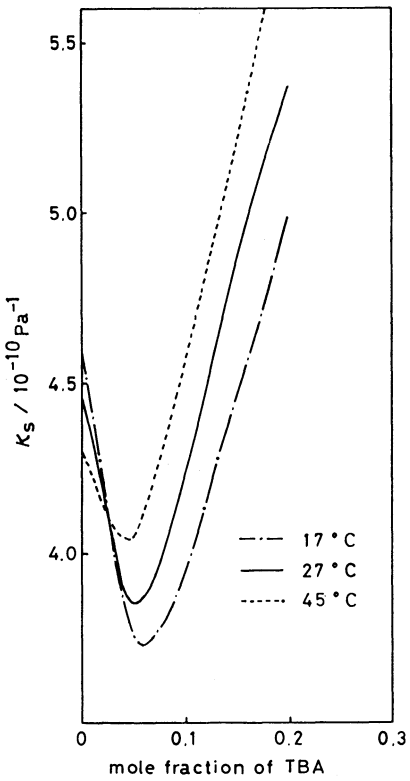

Fig. 4. Concentration dependence of adiabatic compressibility for *t*-butyl alcohol (TBA)–water system at 17, 27, and 45 °C calculated from the hypersonic velocity data of Stone *et al.*[4]

Comparison with TBA–Water System. Stone *et al.* have measured the hypersonic velocity for the TBA–water system at 6 GHz. Figure 4 shows the adiabatic compressibility for the system calculated from their sound velocity data. It is seen from the figure that κ_s takes a minimum value at x_{TBA} is about 0.06 (at 17 °C), 0.05 (at 27 °C), or 0.045 (at 45 °C). These data can be reduced to the R values of 16 (at 17 °C), 19 (at 27 °C), and 21 (at 45 °C). Iwasaki *et al.* have obtained the R values of 17 ± 2 at 17 °C and 21 ± 2 at 65 °C from the analyses of the concentration dependence of the concentration fluctuation.[3] The R value at 17 °C obtained from the adiabatic compressibility is in agreement with that obtained from concentration fluctuation at the same temperature. Moreover, those R values obtained from the measurements of the adiabatic compressibility and the concentration fluctuation have similar temperature dependences. These facts confirm the R values obtained for the acetone–water system in our present study. The R value for the acetone–water system at room temperature is smaller than that for the TBA–water system. This difference seems to come from the difference between acetone and TBA in the size of the hydrophobic group of the molecule. The number of molecules which can encage an acetone molecule may be smaller than that for a TBA molecule.[8]

Figures 3 and 4 also show that the minimum values of κ_s for the acetone system are larger than those for the TBA system. This difference may also originate from the difference in hydrophobicity between acetone and TBA. The more hydrophobic a solute molecule is, the more stabilization energy is required for dissolution. Thus, the hydrate-like structure for the TBA system becomes more stiff than that for the acetone system.

The authors wish to express their sincere thanks to Mr. Nobuyuki Ito for his helpful advice on the construction of the light scattering spectrometer.

Elementary Patterns in Protein-Nucleic Acid Interactions. II.† Crystal Structure of 3-(Adenin-9-yl)propionamide

Midori TAKIMOTO,* Akio TAKENAKA, and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received November 8, 1980)

In order to study adenine-amide interactions, 3-(adenin-9-yl)propionamide has been synthesized and its crystal structure examined. The crystals are monoclinic, the space group being $P2_1/a$, with unit-cell dimensions of $a=25.668$ (1), $b=8.025$ (1), $c=4.684$ (1) Å, $\beta=103.54$ (1)°, and $Z=4$. The adenine bases are linked along the two-fold screw axis through the hydrogen bonds, N(6)H···N(1) and N(6)H···N(7). The amide group is hydrogen-bonded to N(3) of adjacent adenine moiety, the distance NH···N(3) being 3.055 Å. The model fitting by computer graphics indicates that this binding scheme could be an elementary interaction pattern between the amide group in protein and adenine in the minor groove of double helical DNA.

Studies have been carried out on elementary patterns in protein-nucleic acid interactions using model crystals with the anticipation that their specificity might arise from the interaction between purine-pyrimidine bases and amino acid residues supported sterically and electronically by their three-dimensional structures. Several elementary patterns due to hydrogen bonds have been found in the following combinations: cytosine-carboxyl,[1-4] adenine-indole,[5,6] and adenine-carboxyl group.[7]

Attempts were made to extend the study to the adenine-glutamine or asparagine system. These amino acids contain an amide group in the side chain and significance of their interaction with nucleic acid base was proposed.[8,9] In order to examine the intermolecular hydrogen bonds between adenine and amide moieties, we have synthesized a new compound, 3-(adenin-9-yl)-propionamide and examined its crystal structure.

Experimental and Structure Determination

3-(Adenin-9-yl)propionic acid, synthesized from adenine and β-propiolactone by the method of Kondo *et al.*,[10] was converted into ester in CH_3OH solution saturated with HCl and then into amide in NH_3/CH_3OH. The amide formation was confirmed by elemental analysis and IR spectrum (δ_{N-H} 1600 cm^{-1}, amide group). By slow evaporation, prism crystals were obtained from water-methanol (1 : 1) solution at room temperature. Oscillation and Weissenberg photographs showed the space group to be $P2_1/a$. Density was measured by flotation in a mixture of cyclohexane and carbon tetrachloride. A crystal, $0.3\times0.5\times0.1$ mm in size, was mounted on a Rigaku automated four-circle diffractometer. Nickel-filtered Cu $K\alpha$ radiation ($\lambda=1.54178$ Å) was used. The accurate unit-cell dimensions were determined by least-squares calculation with 2θ values of 40 high-angle reflexions.

TABLE 1. CRYSTAL DATA

Space group: $P2_1/a$	
$a=25.668(1)$ Å	$U=938.1(1)$ Å^3
$b=8.025(1)$ Å	$Z=4$
$c=4.684(1)$ Å	$D_x=1.46$ g cm^{-3}
$\beta=103.54(1)°$	$D_m=1.46$ g cm^{-3}

† Part I of this series is Ref. 5.

Crystallographic data are summarized in Table 1.

Intensity data were collected on the diffractometer by means of $\omega/2\theta$ scanning ($8°<2\theta<115°$), the scan speed being 4° (in 2θ) min^{-1} and scan width 0.9° (in ω) plus α_1-α_2 divergence. Five reference reflexions monitored periodically showed no significant intensity deterioration. Corrections were made for Lorentz and polarization factors, but not for absorption effects. A total of 1280 independent reflexions were obtained, 175 of which had no net intensities: the observational threshold value, F_{11m}, was 1.69. The standard deviations were estimated

TABLE 2. FRACTIONAL COORDINATES AND ISOTROPIC TEMPERATURE FACTORS

The B values with ⟨ ⟩ are the equivalent isotropic temperature factors calculated from anisotropic thermal parameters using the equation $B=8\pi^2\Sigma(U_1+U_2+U_3)/3$, where U_1, U_2, and U_3 are the principal components of mean square displacement matrix $\boldsymbol{U}$. Values in ⟨ ⟩ are anisotropicity defined by $(\Sigma(B-8\pi^2U_i)^2/3)^{1/2}$. The e.s.d.'s in ( ) refer to last decimal places.

by the equation $\sigma^2(F_o)=\sigma_p^2(F_o)+qF_o^2$, where $\sigma_p(F_o)$ was evaluated by counting statistics and q (6.8×10^{-6}) was derived from the variations of the monitored reflexions.[11]

The structure was solved by the symbolic addition procedure, the parameters being refined by the block-diagonal leasts-quares method. The quantity minimized was $\sum w(|F_o|-|F_o|)^2$, where $w=1/(\sigma^2(F_o))$. All the hydrogen atoms, found on a difference map, were included. The zero-reflexions, for which $|F_c|>F_{lim}$, were included in the least-squares calculation by assuming $F_o=F_{lim}$ and $w=w(F_{lim})$, The final R value was 0.049 for 1170 reflexions with $F_o\geq3\sigma(F_o)$; the maximum shift of parameters in the last cycle was 0.02σ for C, N, and O, and 0.1σ for H. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography".[12] Atomic parameters are given in Table 2, and the observed and calculated structure factors in Table 3.[13]

Results and Discussion

Molecular Structure. Bond distances and angles are shown in Fig. 1. Bond angles involving hydrogen atoms are given in Table 4, and the least-squares planes of adenine and amide moieties in Table 5. Figure 2 shows a stereoscopic view of the 3-(adenin-9-yl)-propionamide molecule. The bond lengths and angles of the adenine ring are in good agreement with those found in 9-methyladenine[14] and other related compounds.[15] The adenine moiety is planar with maximum shift of 0.009 Å for C(5) and C(8) from the least-squares plane.

The dimensions of the amide group is similar to those in L-asparagine monohydrate (neutron study),[16] and L-glutamine (neutron study).[17] Small differences might be related to the strengths of the hydrogen bondings. A comparison of the dimensions of amide group is given in Table 6.

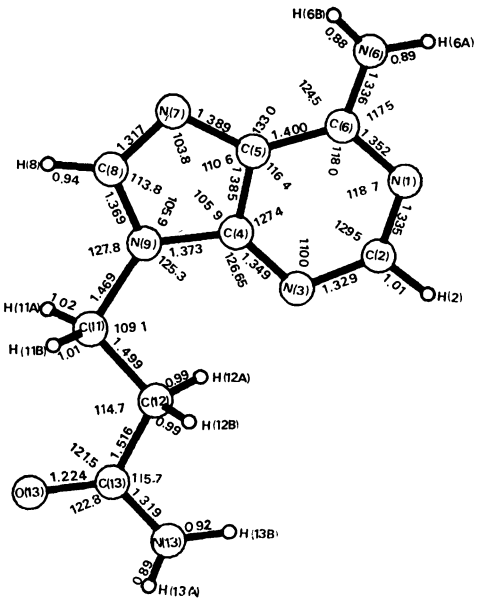

Fig. 1. Atomic numbering of 3-(adenin-9-yl)propionamide with bond lengths (l/Å) and angles (ϕ/°). E.s.d.'s are 0.006 Å and 0.3° for C, N, and O atoms, and 0.04 Å for H atoms. Bond angles involving H atoms are given in Table 4.

two-fold screw axis through the hydrogen bonds, N(6)H···N(1) and N(6)H···N(7). The arrangement is the same as that found in 3-(adenin-9-yl)propionic acid[7] and 5′-*O*-acetyladenosine.[18]

The amino group in amide is hydrogen-bonded to N(3) of the adenine moiety in the molecule related by inversion. The same kind of hydrogen bonding is found in 3-(adenin-9-yl)tryptamide crystal, in which the secondary amide of the peptide bond is a donor of hydrogen bond to N(3) of adenine moiety.

In the present crystal, the N(13)H···N(3) hydrogen bond links adenine ribbons in an anti-parallel mode to each other to form a sheet. The molecular sheet resembles that found in the 3-(adenin-9-yl)propionic acid crystal, though in the latter the linkage is the O–H···N(3) hydrogen bond, the adenine ribbons being parallel to each other.

The remaining hydrogen atom of the amide group participates in the hydrogen bond N(13)H···O(13) between the amide groups to link the molecular sheets (Fig. 4).

Elementary Pattern of Interaction between Adenine and Amide Group. In order to see if the binding mode between adenine N(3) and amide group N(13) is an elementary pattern of protein–nucleic acid interactions, we have tried to fit the binding geometry into a minor groove of the double helical DNA by an interactive computer graphics; atomic coordinates of DNA were taken from the work of Arnott and Hukins.[19]

In DNA (A form), the amide side chain of amino acid fitting into adenine N(3) with the observed binding geometry (Table 8)[3] is free from any steric hindrance as shown in Fig. 5. However, the groove is not very large and the rotation of the amide group about the N(13)H···N(3) hydrogen bond (60°) gives rise to a close contact between O(13) and the ribose ring of the neighbouring nucleotide.

On the other hand, in DNA (B form) with a much narrower minor groove the amide side chain fitting into adenine N(3) gives rise to an abnormal contact between N(13) and oxygen atom of the ribose ring of the neighbouring nucleotide. Even after considerable adjustments of torsional angles and bond angles a close contact of 2.5 Å still remains. Conformational change of DNA should be introduced.

Energy Conversion and Storage in Solid-state Photogalvanic Cells

Hiroshi HADA,* Kazuchiyo TAKAOKA, Masahiko SAIKAWA, and Yoshiro YONEZAWA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received November 22, 1980)

The solid-state photogalvanic cells involving photochemically deposited metals as active materials are presented. As these cells have many excellent features as compared with usual photogalvanic cells in which both the cathodic and anodic materials are dissolved in solution, they will promise a novel storage system for the conversion of solar energy to electrical energy. A typical two-compartment cell: TiO_2, aqueous $Ce(SO_4)_2$–$Ce_2(SO_4)_3$||aqueous $AgNO_3$, Pt could be charged by the irradiation of 300—400 nm light on TiO_2. The deposited silver on a platinum black storage electrode has almost the same electrochemical properties as the silver metal electrode and is capable of recharging after a nearly complete discharge.

Although good efficiencies in solar energy conversion have been achieved with solid-state devices, especially with a *pn*-junction solar cell, energy conversion of light in electrochemical cells based on the photovoltaic effect at the semiconductor-liquid interface has still attracted considerable attention.[1,2] Fujishima and Honda have shown that water photolysis occurs in a photoelectrochemical cell using TiO_2 as a photosensitive electrode, together with taking out the electrical energy through an external load (photoelectrolysis cell).[3] When a suitable redox couple is dissolved in the electrolyte solution, the chemistry occurring in the cell having a n-type semiconductor electrode can be represented by the two half-cell reactions: oxidation of the reduced form at the photoelectrode and reduction of the oxidized form at the dark electrode, respectively. Light energy is thus converted to electrical energy with no net chemical changes in the whole cell (photovoltaic cell).[4] Since Becquerel first discovered the photogalvanic effect,[5] a number of papers on the subject appeared in the scientific literature.[6–8] However, the energy conversion efficiency in the conventional photogalvanic cells which make use of the photochemically generated species in an electrolyte solution as active materials is not so high due mostly to wasteful recombination reactions. The photoelectrolysis cell of Fujishima and Honda can produce hydrogen and oxygen from water, which are both useful active materials of the fuel cell. On the practical aspect, it seems to be most convenient to store the light energy as solid-state active materials at the electrode surface. We want to call such cells as solid-state photogalvanic cell in a sense that light energy is stored in solid state and *in situ* before taking out electrical energy at any time. We expect that these cells will show more excellent properties of the conversion and storage of light energy than the conventional photogalvanic cells because of their relatively compact size and ease to prevent wasteful reactions of active materials. There have been only few reports on such cells until now. Zaromb *et al.* proposed the cyclic photogalvanic silver halide cells: Pt, Ag–AgX, aqueous FeX_3–FeX_2, Pt (X=Cl, Br).[9] Recently, Hodes *et al.* have investigated the photoelectrochemical storage cell: CdSe; S/S^{2-} couple, Ag_2S–Ag.[10]

We have investigated the photoreduction of Ag^+ at the surface of either ZnO or TiO_2 by means of 365 nm light which belongs to the fundamental absorption band of them and observed that the quantum yield of the reaction is about 10^{-1} and that general feature of the reaction is elucidable by a local cell model.[11] While ZnO suffers irreversible decomposition by positive holes in the course of the reaction, TiO_2 is fairly stable and decomposes water into oxygen. Therefore, the photochemical reaction at TiO_2 surface may be regarded as conversion of light energy to the chemical energies represented by Ag^+/Ag couple (0.80 V *vs.* NHE) and $O_2,H^+/H_2O$ couple (1.23 V at pH=1). If we construct a photocell so as to separate the photochemical reaction at TiO_2 surface; an anodic reaction at TiO_2 photoelectrode (O_2 evolution) and a cathodic reaction (Ag deposition) at a storage electrode, we can indeed store the light energy *in situ* as active materials of the galvanic cell ready to convert to electrical energy any time. Cyclic discharge and photoelectrochemical recharging of the cell are easily accessible by switching the TiO_2 electrode to an inert counter electrode and *vice versa*. One of the merits of this cell is a decreased internal resistance as the electrodes are not made of non-metallic materials such as AgX and Ag_2S which were used by Zaromb *et al.* and Hodes *et al.*, respectively. If we make use of anion specific membrane to separate the solutions of two half cells, we can employ various combinations of cathodic and anodic materials. The present study is aimed at a preliminary examination of the possibility of various solid-state photogalvanic cells by using TiO_2 as a photoelectrode.

Experimental

TiO_2 film electrode was prepared by heating a plate of titanium in a fire of town gas at about 1600 K for 300 s according to Fujishima *et al.*[12] Titanium oxide of *ca.* 2 μm in thickness and more than 10 cm^2 area could be easily formed on titanium metal. Photoelectrochemical behavior of the oxide film electrode was somewhat inferior to TiO_2 single crystal electrode. The maximum photocurrent of the former electrode in UV-region was less than the latter one. An experimental cell is schematically indicated in Fig. 1. A storage electrode (A) and a counter electrode(C) are both made of platinum black disc. Anion specific membrane ACH-45T (Tokuyama Soda Co. Ltd.) separated the solutions of two half cells. A TiO_2 electrode (P) was connected with A-electrode directly or through an external load under photoelectrochemical charging, and then exchanged to C-electrode on discharge by two switch terminals. The electrolyte solution in the compartment of P- and C-electrodes consisted of aqueous solutions of KNO_3 plus HNO_3, Ce^{4+}/Ce^{3+} couple, or Fe^{3+}/Fe^{2+} couple.

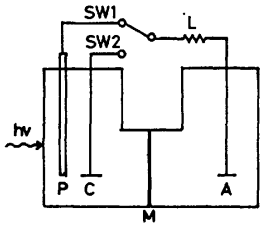

Fig. 1. Schematic representation of the solid-state photogalvanic cell with three electrodes.
P: TiO_2 electrode, A: Pt–Pt electrode (5.5 cm^2), C: Pt–Pt electrode (1.0 cm^2), M: Anion specific membrane, L: External load composed of variable resistance box, SW1, SW2: switches.

That in the A-electrode compartment ordinarily comprised KNO_3 plus either Ag^+ or Cu^{2+}. When we examined an applicability of AgCl/Ag, Cl^- couples as a storage electrode, AgCl electrode of *ca.* 0.1 cm^2 area was prepared according to Zaromb *et al.*[9] All potentials given in this paper are measured *versus* a normal hydrogen electrode (NHE).

As the light source, a high pressure 500-W mercury lamp (Ushio Denki Co. Ltd.) was used in combination with an interference filter UV-D2 (Toshiba Co. Ltd.) and water filter to select 300—400 nm light. The number of photons incident on the cell was 1.9×10^{17} cm^{-2} s^{-1} according to the trioxalatoferrate(III) actinometry.[13] Photoelectrochemical charging was achieved by irradiating on about 3 cm^2 area of TiO_2 electrode through the electrolyte solution. The photocurrent was measured by the voltage across a resistance box, which was recorded on an electrometer TR-84M (Takeda Riken Co. Ltd.) or a recorder EPR-100A (Toa Electronics Co. Ltd.). The current-voltage characteristics of the cells before and after charging were determined in a similar manner at 298 K in the darkness. The amounts of electricity passed through the circuit on the photoelectrochemical charging and discharge were obtained by the integration of the current monitored continuously as the voltage across a constant resistance. The amount of silver atoms deposited on a storage electrode was determined with an aid of a Jarrel-Ash AA-780 atomic absorption spectrophotometer. The optical density measurement of the solutions containing Ce^{4+}/Ce^{3+} couple has been carried out by using a MPS-5000 spectrophotometer (Shimadzu Seisakusho Co. Ltd.). All solutions were prepared from reagent grade chemicals purchased from Nakarai Chemicals Co. Ltd.

Results

Possibility of Solid-state Photogalvanic Cell. We have searched for a possibility of several combination of active materials which can be charged photoelectrochemically. With a reference of our former study on the photoreduction of Ag^+ at the semiconductor surface,[11] we at first examined the solid-state photogalvanic cell involving oxygen and silver as active materials: TiO_2, $HNO_3||Ag^+$, Pt (cell I). The electrolyte solutions comprised 1 M HNO_3 plus 1 M KNO_3 for a compartment of TiO_2 electrode and 1 M $AgNO_3$ plus 1 M KNO_3 for a compartment of the storage electrode, respectively. Figure 2 shows the curve of photocurrent against photovoltage in light. Photocurrent flowed from a storage electrode to TiO_2 electrode. The net electrochemical reactions will be as follows:

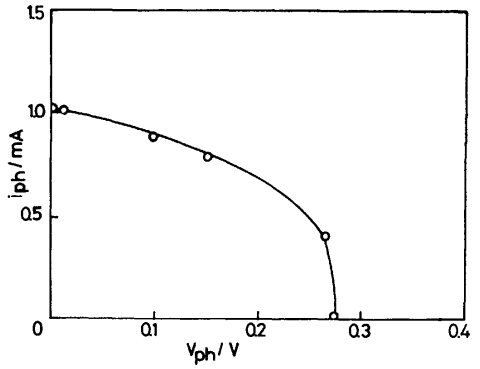

Fig. 2. Curve of photocurrent, i_{ph}, against photovoltage, V_{ph}, for the TiO_2 photocell: TiO_2, $HNO_3||Ag^+$, Pt.

$$TiO_2 + h\nu \longrightarrow e^- + p^+ \quad (1)$$

$$Ag^+ + e^- \longrightarrow Ag \quad (2)$$

$$2H_2O + 4p^+ \longrightarrow 4H^+ + O_2, \quad (3)$$

where e^- and p^+ denote an electron and positive hole, respectively. The photocurrent under a short-circuit condition was *ca.* 1 mA, which corresponds to an apparent quantum efficiency of about 1% (The number of electrons passed per s divided by the number of incident photons for 300—400 nm region per s). The open-circuit photovoltage was about 0.28 V. After illuminating the cell for 7200 s (the electricity flowed was 7.2 C), the discharge current from the counter electrode to the storage electrode was measured. The current-voltage curve of this cell was compared with that of a reference cell having a silver metal electrode of nearly equal surface area (Fig. 3). Except for some-

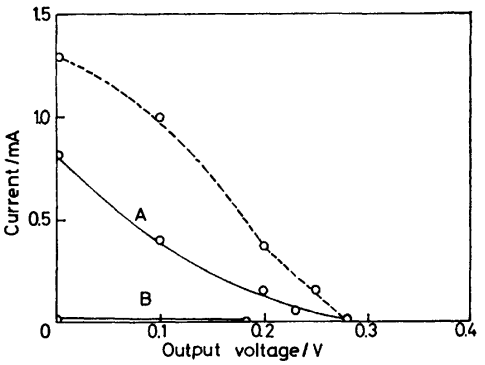

Fig. 3. The current-voltage characteristics for cells; Pt, $HNO_3||Ag^+$, Pt, ○—○, and Pt, $HNO_3||Ag^+$, Ag, ○···○. A: After charging, B: after nearly complete discharge.

what smaller short-circuit current, the current-voltage characteristics of the photogalvanic cell is not so inferior to the reference cell. Furthermore, we could hardly take out electrical energy from the cell either before the charging or after a nearly complete discharge. Therefore, we confirmed that this cell can be photoelectrochemically charged and that the contribution of a different hydrogen ion concentrations in the two cell compartments will be negligible.

In order to employ an active material more positive than O_2,H^+/H_2O couple, we next examined a photo-

galvanic cell: TiO_2, Ce^{4+}/Ce^{3+} couple ||Ag^+, Pt (cell II). The electrolyte solutions comprised 5×10^{-2} M $Ce_2(SO_4)_3$, 0.1 M $Ce(SO_4)_2$ plus 1 M HNO_3 for a compartment of P-electrode and 0.1 M $AgNO_3$ plus 1 M KNO_3 for A-electrode, respectively. The current flowed from a storage electrode to TiO_2 on irradiation. Silver atom was deposited at platinum black according to Eq. 2. Positive hole at the TiO_2 can oxidize Ce^{3+} according to Frank and Bard.[14] After illuminating the cell for 3600 s

$$Ce^{3+} + p^+ \longrightarrow Ce^{4+} \quad (4)$$

(2.6 C), the current-voltage curve of the cell was measured and compared with that of a reference cell having the same silver electrode as mentioned before (Fig. 4). Two cells show almost the same features. The open-circuit voltage nearly coincides with a difference of the standard electrode potentials of Ag^+/Ag and Ce^{4+}/Ce^{3+} (1.61 V) couples.

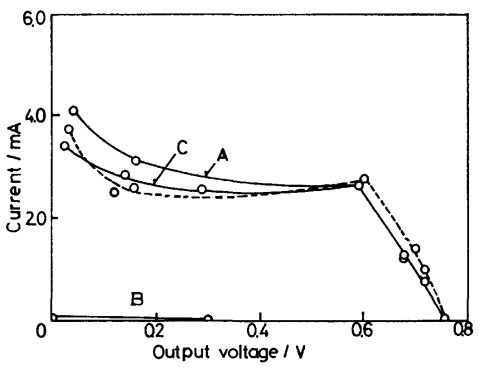

Fig. 4. The current-voltage characteristics for cells; Pt, Ce^{4+}/Ce^{3+} couple||Ag^+, Pt, ○—○, and Pt, Ce^{4+}/Ce^{3+} couple||Ag^+, Ag, ○···○.
A: After charging, B: after nearly complete discharge, C: after recharging.

With an aim to employ an active material more negative than Ag^+/Ag couple, we constructed a cell: TiO_2, Fe^{3+}/Fe^{2+} couple ||Cu^{2+}, Pt (cell III). Electrolyte solutions comprised 1.0×10^{-2} M $FeSO_4$ plus 1.09 M KNO_3 for P-electrode and 2.5×10^{-2} M $CuSO_4$ plus 1.1 M KNO_3 for A-electrode, respectively. This cell was capable of photoelectrochemical charging in agreement with an induction from the former work of Wrighton *et al.*[15] We charged the cell for 6600 s (2.3 C)

$$Cu^{2+} + 2e^- \longrightarrow Cu \quad (5)$$

$$Fe^{2+} + p^+ \longrightarrow Fe^{3+} \quad (6)$$

and then measured the current-voltage curve. Figure 5 gives a comparison of a deposited copper electrode with copper metal electrode of 2.2 cm^2 area. The current-voltage curves of the two cells resembled each other but the open-circuit voltage of them was somewhat smaller than the difference of the standard electrode potentials of Cu^{2+}/Cu (0.34 V) and Fe^{3+}/Fe^{2+} (0.77 V) couples.

We finally intended to employ a AgCl/Ag,Cl^- couple (0.22 V) and constructed a cell: TiO_2, Fe^{3+}/Fe^{2+} couple ||KCl, AgCl,Pt (cell IV) with a reference of the former study of Zaromb *et al.*[9] The electrolyte solutions contained 1.0×10^{-2} M $FeCl_2$ plus 0.2 M KCl for P-electrode and only 0.2 M KCl for A-electrode, respectively. Irradiation of TiO_2 extended the photocurrent to induce cathodic decomposition of AgCl:

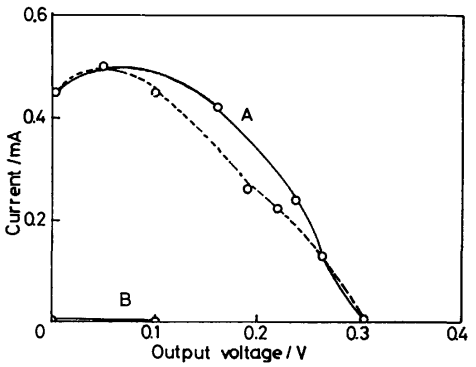

Fig. 5. The current-voltage characteristics for cells; Pt, Fe^{3+}/Fe^{2+} couple||Cu^{2+}, Pt, ○—○, and Pt, Fe^{3+}/Fe^{2+} couple||Cu^{2+}, Cu, ○···○.
A: After charging, B: after nearly complete discharge.

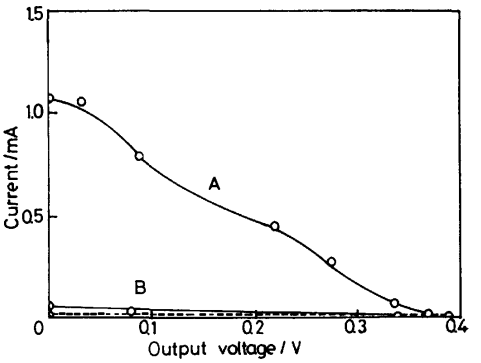

Fig. 6. The current-voltage characteristics for cells; Pt, Fe^{3+}/Fe^{2+} couple||KCl, AgCl, Pt, ○—○, and Pt, Fe^{3+}/Fe^{2+} couple||KCl, Ag/AgCl, ○···○.
A: After charging, B: after nearly complete discharge.

$$AgCl + e^- \longrightarrow Ag + Cl^- \quad (7)$$

accompanied with reaction (6). After illumination for 4200 s (0.21 C), we measured the current-voltage characteristics. Figure 6 gives a comparison of the Ag/AgCl electrode established in this manner with a commercial Ag/AgCl reference electrode HS-305D (Toa Electronics Co. Ltd.). The current-voltage curve of the former cell seems to be superior to the latter, although a direct comparison of the discharge current may be difficult because of a different surface area of them.

Energy Storage in the Cell II Using Ce^{4+}/Ce^{3+} Redox Couple. In order to obtain a most convincing proof of the true photoelectrochemical charging with a typical photogalvanic cell, we illuminated the cell II for varying irradiation time over a 110 Ω resistance. The electrolyte solution of the compartment of A-electrode was the same as in Fig. 4 throughout this item. That of a TiO_2 compartment contained 5×10^{-3} M $Ce_2(SO_4)_3$, 0.6 M HNO_3 plus 0.5 M KNO_3. The magnitude of silver atom deposited at the A-electrode was compared with the net charge stored which was determined by integrating the total photocurrent on irradiation (Fig. 7). A linear plot obtained is in agreement with the charging reaction of Eq. 2. It is observed that the greater part

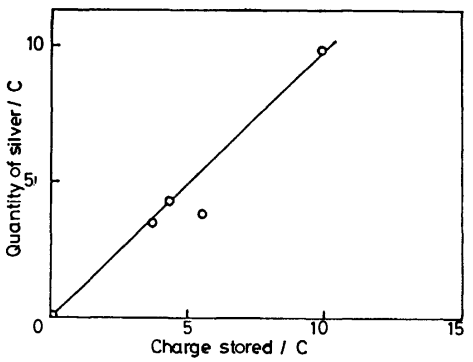

Fig. 7. Relation between the net charge stored in and the quantity of silver deposited on a Pt–Pt electrode for a cell: Pt, Ce^{4+}/Ce^{3+} couple||Ag^+, Pt.

of the photocurrent was consumed for the silver reduction at the A-electrode, because a slope of the straight line in this Figure is 0.94. The apparent quantum efficiency of silver deposition was about 1%. The power efficiency of this cell for 300—400 nm light was roughly estimated from the product of the apparent quantum efficiency of charging current and the ratio of energy level difference of Ag^+/Ag and Ce^{4+}/Ce^{3+} couples (0.81 eV) to the band-gap energy of TiO_2 (3.05 eV). It was about 0.3%. We next tried to detect an increase of Ce^{4+} in the TiO_2 compartment. The concentration of Ce^{4+} was determined spectrophotometrically by measuring the optical density at 375 nm corresponding to the absorption tail of this ion. The solutions in the cell were the same as those in Fig. 7. Ce^{4+} initially increased with time and then reached some stationary value after a prolonged irradiation. For example, the amount of oxidized Ce^{3+} corresponded initially to 98% of the net charge at 3.7 C charging but only to 22% after 10 C charging.

The relation between the charge stored on illumination and withdrawn in the darkness was examined by using two electrolyte solutions in the TiO_2 compartment, either the same as in Fig. 4 or 2.5×10^{-3} M $Ce_2(SO_4)_3$, 0.6 M HNO_3 plus 0.5 M KNO_3. It is observed that although a discharge current over a 1 kΩ resistance had initially a constant value of *ca.* 0.7 mA, it then successively decreased without stirring of a Ce^{4+}/Ce^{3+} half cell by a suitable stirrer. Such tendency was more evident for the cell containing smaller initial concentration of this couple. Figure 8 gives a plot between the net charge stored and withdrawn determined by integrating the total current before an above-mentioned fall-off region of the discharge current. From the slope, it is found that *ca.* 18% of the charge stored could be withdrawn as a nearly constant discharge current from cell A even without stirring. Furthermore, even from cell B which had smaller initial Ce^{4+}/Ce^{3+} concentration than cell A, up to 78% of the charge stored could be extracted only with a stirring by a magnetic stirrer.

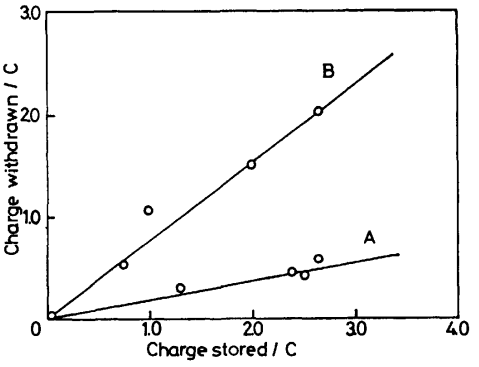

Fig. 8. Dependence of the net charge withdrawn on the charge stored in the two different Pt, Ce^{4+}/Ce^{3+} couple|| Ag^+, Pt cells.
A: 5×10^{-2} M $Ce_2(SO_4)_3$+0.1 M $Ce(SO_4)_2$ without stirring, B: 2.5×10^{-3} M $Ce_2(SO_4)_3$ with stirring.

We finally confirmed that the cell with the same electrolyte solution as in Fig. 4 could be recharged by many times after nearly complete discharge. A typical result is included in the same Figure.

Discussion

Photoelectrochemical charging of the solid-state photogalvanic cells having a TiO_2 photoelectrode was achieved with four different storage modes. According to an energetic consideration, it seems to be promising at sight to employ a combination of active materials: those which have as negative electrode potentials as the conduction-band edge and those which have as positive electrode potentials as the valence-band edge of the surface of the photoelectrode. In this respect, Ag^+/Ag–Ce^{4+}/Ce^{3+} combination is superior to Ag^+/Ag–O_2,H^+/H_2O one. Moreover, Cu^{2+}/Cu–Fe^{3+}/Fe^{2+} and AgCl/Ag,Cl^-–Fe^{3+}/Fe^{2+} combinations may also treasure up some possibilities. However, H_2 evolution at the cathode and O_2 evolution at the anode during photoelectrochemical charging strongly limit the choice of arbitrary redox couples in aqueous solution. A decreased charging current, as expected from a local cell consideration, may give an additional criterion for the choice.

So far as our experiments, solid-state photogalvanic cell of type II seems to be most excellent with regard to the short-circuit current and open-circuit voltage. Moreover, almost all the photocurrent could be stored as deposited silver. In the darkness, an active material Ce^{4+} could be stored over a long time at the open-circuit condition, because thermal reduction of Ce^{4+} by water is rather slow at room temperature.[16] In this respect, Ce^{4+}/Ce^{3+} couple seems to be superior to, say, Co^{3+}/Co^{2+} one, as Co^{3+} is reduced by water in the darkness.[17] Indeed, there are several problems to be solved with this cell. The power efficiency of the cell seems to be not so large at present. However, it will be due mostly to the reduced quantum efficiency of anodic photocurrent of TiO_2 film electrode employed here. So that, we may expect a considerable improvement if we operate a refined electrode under an optimum condition. Appearance of a stationary concentration of Ce^{4+} with irradiation time suggests an existence of competition processes of the formation and disappearance of this ion. It may be due at least in part to both the bulk photochemical reactions of Ce^{4+} and Ce^{3+} even in 300—400 nm region[18,19] and to the filter effect of

incident light on TiO_2 by Ce^{4+}. The effect of stirring of Ce^{3+},Ce^{4+}/Pt half cell in Fig. 8 suggests that discharge current will be limited by some reasons at this part of the photogalvanic cell. To overcome these difficulties, several efforts are undertaken at present.

In the silver halide cell of Zaromb *et al.*,[9] the energy of light absorbed by, say, AgCl was converted to the chemical energy by the following reaction:

$$AgCl + Fe^{2+} \longrightarrow Ag + Cl^- + Fe^{3+}. \quad (8)$$

A serious drawback of this cell was that it could operate satisfactorily only in light because there exist several self-discharge reactions in the darkness. With regard to this, cell IV may be an extension of their cell.

Though TiO_2 electrode is photochemically stable, spectral response of it is mostly in the ultraviolet. With regard to this point, the photoelectrochemical storage cell of Hodes *et al.*[10] using CdSe photoelectrode seems to be superior to ours. However, as CdSe suffers the irreversible decomposition reaction unless operated in the alkaline solution containing a suitable redox couple such as S/S^{2-}, the choice of active materials stable in alkaline solution will inevitably be reduced in consequence. Apart from an application of some other photoelectrode having smaller band-gap energy, the design of the solid-state photogalvanic cells which are capable of *in situ* storage of both anodic and cathodic materials is under way.

Use of Propagators in the Hückel Model. II. Propagators in Terms of Trigonometrical Functions

Shigeyuki Aono,* Takayuki Ohmae, and Kiyoshi Nishikawa

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920

(Received November 22, 1980)

The propagators of the chain molecules with and without the bond alternation are expressed in terms of trigonometrical functions. These expressions are convenient to practical manipulations. For exercises, the total energy, charge density and bond order are calculated.

In the previous paper,[1] we have developed a propagator theory for the Hückel model or in the tight-binding approximation. Useful methods to obtain the propagators of general networks have been presented, and propagators have been finally expressed as polynomials in terms of the energy parameter z. This analytical form being convincing from the theoretical viewpoints, is not so convenient for various application. As has been done in the simple examples of I, the actual calculations always need the contour integrals around the poles. If we use the polynomial expressions for propagators, it is difficult for us to find poles except the simplest cases. Therefore we give the compact analytical forms to the propagators in terms of trigonometrical functions. Then we calculate the charge density, bond order and total energy of the systems under consideration. Mathematical tools are almost due to the Coulson's old paper,[2] which is not so far in spirit from the present modern treatment.

Propagators of Linear Chain Molecules with Equal Bond Distance

In this section, the propagator of the linear chain molecule with same atoms and with equal bond length is investigated. The transfer integral between the nearest sites is scaled to be unity and if necessary it will be recovered by the dimensional analysis. The linear chain molecule with n sites are numbered as Fig. 1. The propagator of this system has been given in I as

$$G_n(0)^{-1} = z - \cfrac{1}{z - \cfrac{1}{z - \cfrac{1}{z - \cfrac{1}{\vdots}}}} = z + \frac{-1}{z} + \frac{-1}{z} + \frac{-1}{z} + \cdots, \tag{1}$$

where $G_n(0)$ is the (0,0) matrix element of the Green's function operator of this chain.

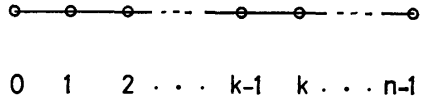

Fig. 1. Linear chain molecule.

The continued fraction more general than Eq. 1

$$S_n = b_0 + \frac{a_1}{b_1} + \frac{a_2}{b_2} + \cdots + \frac{a_{n-1}}{b_{n-1}} \tag{2}$$

is expressed as[3]

$$S_n = A_{n-1}/B_{n-1}. \tag{3}$$

Here A_k and B_k satisfy the recurrance formula

$$\begin{pmatrix} A_k \\ B_k \end{pmatrix} = \begin{pmatrix} A_{k-1} & A_{k-2} \\ B_{k-1} & B_{k-2} \end{pmatrix} \begin{pmatrix} b_k \\ a_k \end{pmatrix} \tag{4}$$

with

$$\begin{pmatrix} A_{-1} \\ A_0 \end{pmatrix} = \begin{pmatrix} 1 \\ b_0 \end{pmatrix}, \quad \begin{pmatrix} B_{-1} \\ B_0 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}. \tag{5}$$

In our case, b_k and a_k in Eq. 2 are simply

$$\begin{aligned} b_0 &= b_1 = b_2 = \cdots = z, \\ a_1 &= a_2 = a_3 = \cdots = -1, \end{aligned} \tag{6}$$

and then

$$\begin{aligned} A_k &= zA_{k-1} - A_{k-2}, \\ B_k &= zB_{k-1} - B_{k-2}, \end{aligned} \tag{7}$$

with the initial conditions

$$\begin{aligned} A_0 &= z, \quad A_1 = z^2 - 1, \\ B_0 &= 1, \quad B_1 = z. \end{aligned} \tag{8}$$

We have a theorem: If it holds that

$$S_k = bS_{k-1} + aS_{k-2}, \ (S_1 \text{ and } S_2 \text{ are given}) \tag{9}$$

the polynomial defined by

$$S(x) \equiv 1 + S_1x + S_2x^2 + \cdots \tag{10}$$

is calculated as

$$S(x) = \frac{1}{1-(bx+ax^2)}\{1+(S_1-b)x+(S_2-bS_1-a)x^2\}. \tag{11}$$

The proof is very easy and omitted.

Applying this theorem to A_k and B_k, we can find

$$\begin{aligned} A(x) &= 1 + A_0x + A_1x^2 + \cdots = \sum_{n=0}^{\infty} A_{n-1}x^n \\ &= \frac{1}{1-zx+x^2} = \sum_{n=0}^{\infty} \frac{\sin(n+1)\theta}{\sin\theta} x^n, \end{aligned} \tag{12}$$

$$z = 2\cos\theta \tag{13}$$

and

$$\begin{aligned} B(x) &= 1 + B_1x + B_2x^2 + \cdots = \sum_{n=0}^{\infty} B_nx^n \\ &= \frac{1}{1-zx+x^2} = \sum_{n=0}^{\infty} \frac{\sin(n+1)\theta}{\sin\theta} x^n. \end{aligned} \tag{14}$$

From Eq. 12 and Eq. 14 we can obtain

$$\begin{aligned} A_{k-1} &= \sin(k+1)\theta/\sin\theta \\ B_{k-1} &= \sin k\theta/\sin\theta \end{aligned} \tag{15}$$

and

$$G_n^{-1}(0) = A_{n-1}/B_{n-1} = \sin(n+1)\theta/\sin n\theta. \tag{16}$$

It should be mentioned that the replacement of Eq. 13 is safely permitted, because any site of this chain is

connected only to two nearest neighbors, and the value of z does not exceed 2.

The next problem is to obtain any diagonal element of the propagator, $G_n(k)$. If we employ a method composing the propagator,[1] it yields that

$$G_n^{-1}(k) = G_{n-k}^{-1}(0) - G_k(0) \tag{17a}$$

$$= \frac{\sin(n+1)\theta \sin\theta}{\sin(n-k)\theta \sin(k+1)\theta}. \tag{17b}$$

The relation (17a) is nothing but the Dyson equation in the site representation.

The off-diagonal element of propagator, $G_n(k,k+l)$ is expressed as

$$G_n(k,k+l) = G_n(k)G_n(k+1,[k]) \cdots G_n(k+l[k+l-1])$$
$$= G_n(k)G_{n-k-1}(0) \cdots G_{n-k-l}(0), \tag{18}$$

where $G_n(p[q])$ is the p-th diagonal element, when the q-th site is omitted. Note that the transfer integral is scaled to be unity. Using Eq. 17b in Eq. 18, we can easily obtain

$$G_n(k,k+l) = \frac{\sin(n-k-l)\theta \sin(k+1)\theta}{\sin(n+1)\theta \sin\theta}. \tag{19}$$

We now turn to evaluation of the charge density, bond order and total energy.

The charge density at k-th site is written as

$$q_n(k) = \frac{1}{2\pi i}\int_C dz G_n(k;z), \tag{20}$$

where integration is carried out along the so-called Coulson contour shown in Fig. 2a. In evaluating Eq. 20, we want to use the expression (17b) for G_n. Then we have to examine how the contour and poles are mapped onto the θ-plane by the relation (13). Let

$$z = x + iy, \quad \theta = \varphi + i\psi, \tag{21}$$

so that

$$x + iy = 2(\cos\varphi \cosh\psi - i \sin\varphi \sinh\psi). \tag{22}$$

The results obtained are displayed by Fig. 2b. The corresponding positions on the contours between two are indicated by ①. How the poles are mapped is also explained in the figure caption in the case of the six members ring. We note first of all that while the contour turns round once in the z-plane, it goes round twice in the θ-plane, so that we need the additional multiplicative factor, 1/2. Second, every pole in the z-plane splits into two except ones of values $\theta=0$ and π. However we need not worry about this behavior since the pole strength at any pole correctly produces the result.

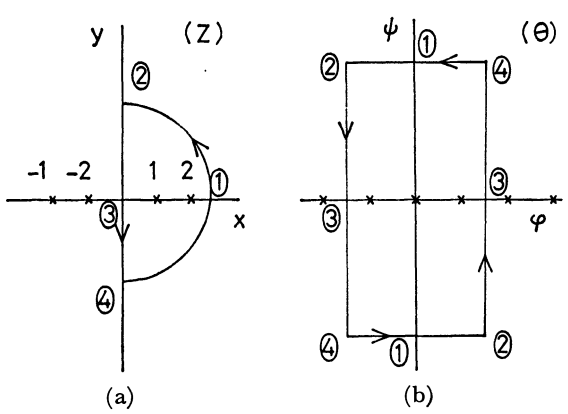

Fig. 2. (a) Contour in z-plane; Poles are those of the six member ring. (b) Contour in θ-plane; Poles are transfered as $2\to 0$; $1\to\pi/3$, $-\pi/3$; $-1\to 2\pi/3$, $-2\pi/3$; $-2\to\pi$.

Using Eq. 17b and Eq. 20, we obtain

$$q_n(k) = \frac{-1}{2\pi i}\int_C d\theta \frac{\sin(n-k)\theta \sin(k+1)\theta}{\sin(n+1)\theta}, \tag{23}$$

where poles are

$$\theta_r = \pi r/(n+1), \quad r = \pm 1, \pm 2, \cdots, \pm n. \tag{24}$$

Hereafter we confine ourselves to the simplest case of the so-called half-filled band, *i.e.*, the levels with $|n| \leq n/2$ being occupied. The contour integral in Eq. 23 yields (the spin factor, 2 is included)

$$q_n(k) = -2\sum_{r=-n/2}^{n/2} \frac{\sin(n-k)\theta_r \sin(k+1)\theta_r}{(n+1)\cos(n+1)\theta_r}$$
$$= \frac{n}{n+1} - \frac{2}{n+1}\sum_{r=1}^{n/2}(-1)^r \cos\left(\frac{n-2k-1}{n+1}\right)\pi r$$
$$= 1. \tag{25}$$

Here we have used the relation

$$\sum_{r=1}^{k}(-1)^{r-1}\cos xr$$
$$= \frac{1}{2} + (-1)^r \cos\frac{(k+1)}{2}x/2 \cos\frac{x}{2} \tag{26}$$

and see that in the second term of Eq. 25, the terms except with $r=1$ vanish. Note that $q_n(k)$ is independent of k.

The bond order, $q_n(k,k+1)$ is given by Eq. 19 as

$$q_n(k,k+l) = \frac{1}{2\pi i}\int_C dz G_n(k,k+l;z)$$
$$= \frac{-1}{2\pi i}\int_C d\theta \frac{\sin(k+1)\theta \sin(n-k-l)\theta}{\sin(n+1)\theta}. \tag{27}$$

In the similar way but a little tedious calculations lead to

$$q_n(k,k+l) = \frac{1}{n+1}\left\{\frac{\sin l\pi/2}{\sin l\pi/2(n+1)} - \frac{\sin(2k+l+2)\pi/2}{\sin(2k+l+2)\pi/2(n+1)}\right\}. \tag{28a}$$

If we here put

$$k = S-1, \quad k+l = t-1,$$

the above becomes

$$q_n(s-1,t-1) = \frac{1}{n+1}\left\{\frac{\sin(t-s)\pi/2}{\sin(t-s)\pi/2(n+1)} - \frac{\sin(t+s)\pi/2}{\sin(t+s)\pi/2(n+1)}\right\} \tag{28b}$$

as usual. From this expression, we can clearly conclude that $q_n(s-l, t-l)$ vanishes for the cases that $(t-s)$ is even, *i.e.*, between the starred atoms, or between the unstarred atoms.

The total energy of the present system, E is

$$E_n = \mathrm{Tr}\frac{1}{2\pi i}\int_C dz\, z\mathbf{G}_n(z) \tag{29}$$
$$= \sum_{k=0}^{n-1}\frac{-1}{\pi i}\int_C d\theta \frac{\cos\theta \sin(n-k)\theta \sin(k+1)\theta}{\sin(n+1)\theta}$$

$$= 4\sum_{r=1}^{n/2}\cos\theta_r$$

$$= 2\sum_{r=1}^{n/2} z(\theta_r). \tag{30}$$

In obtaining this result, we have made the k-summation at the beginning, using the relations,

$$\sum_{k=1}^{n}\sin xk = \sin\frac{(n+1)x}{2}\sin\frac{nx}{2}\Big/\sin\frac{x}{2}$$

$$\sum_{k=1}^{n}\cos xk = \cos\frac{(n+1)x}{2}\sin\frac{nx}{2}\Big/\sin\frac{x}{2}. \tag{31}$$

Propagator of Ring Molecule with Equal Bond Distance

We shall obtain the propagator of the ring molecule shown in Fig. 3. For simplicity, the number of atoms, n is assumed to be $4m+2$, $m=1,2,\cdots$ Employing the method[1] to build up the ring propagator from the chain propagator, we get

$$\begin{aligned} R_n^{-1}(0) &= G_1^{-1}(0) - G_n(1[0]) - G_n(1,n[0]) \\ &\quad - G_n(n[0]) - G_n(n,1[0]) \\ &= G_1^{-1}(0) - 2G_{n-1}(0) - 2G_{n-1}(0,n-2) \\ &= \frac{\sin 2\theta}{\sin\theta} - 2\left\{\frac{\sin(n-1)\theta}{\sin n\theta} + \frac{\sin\theta}{\sin n\theta}\right\} \\ &= -\frac{2\sin(n\theta/2)\sin\theta}{\cos(n\theta/2)}. \end{aligned} \tag{32}$$

The poles of R_n are

$$\theta_r = \frac{2\pi r}{n},\ r = 0,\ \pm 1,\ \cdots,\ \pm\left(\frac{n}{2}-1\right),\ \frac{n}{2} \tag{33}$$

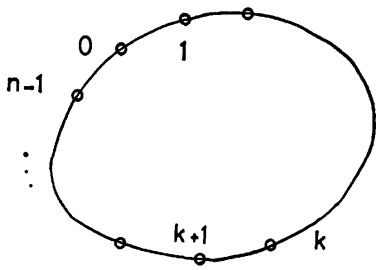

Fig. 3. Ring molecule.

Now we calculate the charge density, bond order and total energy for the case of the half-filled band. The charge density at any site is given by

$$\begin{aligned} q_n^R(0) &= \frac{1}{2\pi i}\int_C dz\, R_n(0;z) \\ &= \frac{1}{4\pi i}\int_C d\theta\,\frac{\cos(n\theta/2)}{\sin(n\theta/2)}. \end{aligned} \tag{34}$$

The integration along the contour shown in Fig. 2b is easily carried out as

$$q_n^R(0) = \frac{2}{n}\sum_{\text{Poles}} 1 = 1, \tag{35}$$

where the fact has been used that the number of poles corresponding occupied levels, *i.e.*$|\theta_r|<\pi/2$ is $n/2$. The spin summation is also done.

In order to estimate the bond order, $q_n(0,k)$, we need the off-diagonal element of the ring propagator, which is

$$\begin{aligned} R_n(0,k) &= R_n(0)R_n(1,k[0]) + R_n(0)R_n(n-1,k[0]) \\ &= R_n(0)G_{n-1}(0,k) + R_n(0)G_{n-1}(0,n-k-1), \end{aligned} \tag{36}$$

where the first and second terms correspond to the clockwise and anticlockwise propagations in Fig. 3, respectively. Using Eq. 32 and Eq. 19 in Eq. 36, we get

$$R_n(0,k) = \frac{-1}{4\sin^2\dfrac{n\theta}{2}\sin\theta}\{\sin(n-k)\theta + \sin k\theta\}. \tag{37}$$

Thus a little tedious but straightforward calculations yield

$$\begin{aligned} q_n^R(0,k) &= \frac{1}{4\pi i}\int_C d\theta\,\frac{1}{2\sin^2\dfrac{n\theta}{2}}\{\sin(n-k)\theta + \sin k\theta\} \\ &= \frac{2}{n^2}\{(n-k)+k\}\frac{\sin k\pi/2}{\sin k\pi/n} \\ &= \frac{2}{n}\frac{\sin k\pi/2}{\sin k\pi/n}, \end{aligned} \tag{38}$$

where, in the second line, the first and second terms are contributions from the clockwise and anticlockwise pathes, respectively. The final result clearly shows that in the alternant hydrocarbons the bond order vanishes between the starred atoms or between the unstarred atoms, *i.e.*, k is even. In the case of $k=1$,

$$q_n^R(0,1) = \frac{2}{n}\operatorname{cosec}\frac{\pi}{n}. \tag{39}$$

The total energy is given as

$$\begin{aligned} E &= \mathrm{Tr}\,\frac{1}{2\pi i}\int_C dz\, z\mathbf{R}_n(z) \\ &= n\frac{1}{4\pi i}\int_C d\theta\,\frac{\cos\theta\sin n\theta}{\sin^2(n\theta/2)} \\ &= 4\operatorname{cosec}\frac{\pi}{n}. \end{aligned} \tag{40}$$

Linear Chains with Bond Alternation

Linear polyenes actually show the bond alternation. If we consider phenomena concerning with linear polyene, it is natural to start with systems with the bond alternation. In this sense, it seems instructive to investigate the propagators for these molecules. Those which we are now considering are shown in Fig. 4.

The propagator of the chain molecule and chain radical are denoted G_{2n} and F_{2n+1}, respectively, where

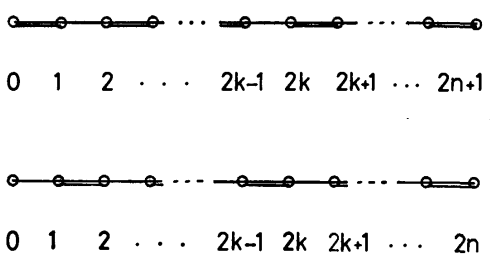

Fig. 4. Chain molecule $C_{2n}H_{2n+2}$ and chain radical $C_{2n+1}H_{2n+3}$.

indices give the number of the carbon atoms. The resonance integrals corresponding to the double and single bonds are written as β^* and β.

As has been done in Eq. 1, $G_{2n}(0)$ is given as

$$G_{2n}^{-1}(0) = z - \cfrac{\beta^{*2}}{z - \cfrac{\beta^2}{z - \cfrac{\beta^{*2}}{\ddots}}}$$

$$= z + \frac{-\beta^{*2}}{z} + \frac{-\beta^2}{z} + \cdots . \tag{41}$$

If we divide both sides by $\sqrt{\beta\beta^*}$, it yields that

$$\bar{G}_{2n}^{-1}(0) = \bar{z} + \frac{-\gamma}{\bar{z}} + \frac{-\gamma^{-1}}{\bar{z}} + \cdots , \tag{42}$$

where

$$\gamma = \beta^*/\beta , \tag{43}$$

and

$$\bar{G}_{2n} = G_{2n}/\sqrt{\beta\beta^*}, \quad \bar{z} = z/\sqrt{\beta\beta^*}. \tag{44}$$

Hereafter the dimensionless $\bar{G}_{2n}$ and $\bar{z}$ are rewritten as G_{2n} and z. Namely, instead of Eq. 42

$$G_{2n}^{-1}(0) = z + \frac{-\gamma}{z} + \frac{-\gamma^{-1}}{z} + \cdots . \tag{45}$$

Similarly, for the radical

$$F_{2n+1}^{-1}(0) = z + \frac{-\gamma^{-1}}{z} + \frac{-\gamma}{z} + \cdots . \tag{46}$$

If we write $G_k^{-1}(0)$ and $F_k^{-1}(0)$ as

$$G_k^{-1}(0) = \frac{A_{k-1}^*}{B_{k-1}^*}, \quad F_{k+1}^{-1}(0) = \frac{A_k}{B_k}. \tag{47}$$

The same treatments as has been done from Eq. 2 to Eq. 7 yield,

$$\begin{aligned}
A_0^* &= z \\
A_1^* &= z^2 - \gamma \\
A_2^* &= z^3 - z(\gamma+\gamma^{-1}) \\
A_3^* &= z^4 - z^2(2\gamma+\gamma^{-1}) + \gamma^2 \\
A_4^* &= z^5 - 2z^3(\gamma+\gamma^{-1}) + z(\gamma^2+1+\gamma^{-2}) \\
A_5^* &= z^6 - z^4(3\gamma+\gamma^{-1}) + z^2(3\gamma^2+\gamma^{-2}) - \gamma^3 \\
&\vdots
\end{aligned} \tag{48a}$$

$$\begin{aligned}
B_0^* &= 1 \\
B_1^* &= z \\
B_2^* &= z^2 - \gamma^{-1} \\
B_3^* &= z^3 - z(\gamma+\gamma^{-1}) \\
B_4^* &= z^4 - z^2(\gamma+2\gamma^{-1}) + \gamma^{-2} \\
B_5^* &= z^5 - 2z^3(\gamma+\gamma^{-1}) + z(\gamma^2+1+\gamma^{-2}) \\
&\vdots
\end{aligned} \tag{48b}$$

In the above interchanging γ and γ^{-1}, we can obtain the similar expressions for A_k and B_k,

$$\begin{aligned}
A_k &= A_k^*(\gamma \leftrightarrow \gamma^{-1}) \\
B_k &= B_k^*(\gamma \leftrightarrow \gamma^{-1}).
\end{aligned} \tag{49}$$

Also we can observe

$$\begin{aligned}
A_k &= B_{k+1}^* \\
B_k &= A_{k-1}^*.
\end{aligned} \tag{50}$$

From relations, Eqs. 48 and 49, we can immediately obtain the recurrance formulae:

$$\begin{aligned}
A_k^* &= zA_{k-1} - \gamma A_{k-2}^* \\
A_k &= zA_{k-1}^* - \gamma^{-1}A_{k-2}
\end{aligned} \tag{51}$$

and

$$\begin{aligned}
B_k^* &= zB_{k-1} - \gamma^{-1}B_{k-2}^* \\
B_k &= zB_{k-1}^* - \gamma B_{k-2}.
\end{aligned} \tag{52}$$

If we eliminate A in Eq. 51, we obtain

$$A_k^* + A_{k-2}^*(\gamma+\gamma^{-1}-z^2) + A_{k-4}^* = 0. \tag{53}$$

Entirely same relations hold for A_k, B_k^*, and B_k.

Now we can use the theorem given by Eq. 9 and Eq. 11. Let

$$A^*(x) = 1 + A_1^*x + A_2^*x^2 + \cdots + A_{2n-1}^*x^n + \cdots \tag{54}$$

and put

$$b = z^2 - \gamma - \gamma^{-1}, \quad a = -1 \tag{55}$$

in Eq. 9, it yields that

$$A^*(x) = \frac{1+\gamma^{-1}x}{1-(z^2-\gamma-\gamma^{-1})\,x + x^2}. \tag{56}$$

Here we put

$$z^2 = \gamma + \gamma^{-1} + 2\cos\theta \tag{57}$$

and obtain

$$\begin{aligned}
A^*(x) &= \sum_{n=0}^{\infty} \frac{\sin(n+1)\theta}{\sin\theta} x^n (1+\gamma^{-1}x) \\
&= \sum_{n=0}^{\infty} \left\{ \frac{\sin(n+1)\theta}{\sin\theta} + \gamma^{-1}\frac{\sin n\theta}{\sin\theta} \right\} x^n.
\end{aligned} \tag{58}$$

Combining this and Eq. 54, we get

$$A_{2n-1}^* = \left\{ \frac{\sin(n+1)\theta}{\sin\theta} + \gamma^{-1}\frac{\sin n\theta}{\sin\theta} \right\}. \tag{59a}$$

Similar analysis for B_{2n-1}^* enables us to get

$$B_{2n-1}^* = z\frac{\sin n\theta}{\sin\theta}. \tag{59b}$$

Remembering relations in Eq. 50, we obtain

$$A_{2n} = B_{2n+1}^* = z\frac{\sin(n+1)\theta}{\sin\theta}, \tag{60a}$$

$$B_{2n} = A_{2n-1}^* = \frac{\sin(n+1)\theta}{\sin\theta} + \gamma^{-1}\frac{\sin n\theta}{\sin\theta}. \tag{60b}$$

Consequently, the propagators of systems shown in Fig. 4 are

$$G_{2n}^{-1}(0) = \{\sin(n+1)\theta + \gamma^{-1}\sin n\theta\}/z\sin n\theta, \tag{61}$$

$$F_{2n+1}^{-1}(0) = z\sin(n+1)\theta/\{\sin(n+1)\theta + \gamma^{-1}\sin n\theta\}. \tag{62}$$

It is noted that once $G_{2n}^{-1}(0)$ is given, we can immediately obtain $F_{2n+1}^{-1}(0)$ by the following relation

$$F_{2n+1}^{-1}(0) = F_1^{-1}(0) - \gamma^{-1}G_{2n}(0), \tag{63}$$

and *vice versa*. Note that $F_1^{-1}(0) = z$.

Some Properties of Linear Chains with Bond Alternation

Since we have written the propagators of linear chains with bond alternation in the previous section, we now move to get some physical properties by use of them. The poles of propagators give the single particle energies: for example in the case of the chain with $2n$ members the relation

$$\sin(n+1)\theta_r + \gamma^{-1}\sin\theta_r = 0, \tag{64}$$

determines the single particle energies. The roots of Eq. 64 cannot be obtained easily, but if γ is not so far from unity, the solution has been approximately

obtained as[2,4]

$$\theta_r = \frac{2\pi r}{2n+1} - \frac{1}{2n+1}(1-\gamma^{-1}) + \tan\frac{\pi r}{2n+1}, \quad r=1,2,\cdots,2n, \tag{65}$$

where the first term stands for the case with equal bond distance, and the second for the correction in this case.

For further steps, we need the expressions of $G_{2n}(2k)$, $G_{2n}(2k+1)$, $F_{2n+1}(2k)$ and $F_{2n+1}(2k-1)$. For example, $G_{2n}(2k)$ is given as (see Fig. 4)

$$G_{2n}^{-1}(2k) = G_{2(n-k)}^{-1}(0) - \gamma^{-1} G_{2k}(0). \tag{66}$$

From this and similar equations for others, we obtain

$$G_{2n}^{-1}(2k) = \frac{\sin\theta\{\sin(n+1)\theta+\gamma^{-1}\sin n\theta\}}{z\sin(n-k)\theta\{\sin(k+1)\theta+\gamma^{-1}\sin k\theta\}}, \tag{67a}$$

$$G_{2n}^{-1}(2k-1) = \frac{\sin\theta\{\sin(n+1)\theta+\gamma^{-1}\sin n\theta\}}{z\sin k\theta\{\sin(n-k+1)\theta+\gamma^{-1}\sin(n-k)\theta\}}, \tag{67b}$$

$$F_{2n+1}^{-1}(2k) = \frac{z\sin(n+1)\theta\sin\theta}{\{\sin(k+1)\theta+\gamma\sin k\theta\}\{\sin(n-k+1)\theta+\gamma^{-1}\sin(n-k)\theta\}}, \tag{68a}$$

$$F_{2n+1}^{-1}(2k-1) = \frac{\sin(n+1)\theta\sin\theta}{z\sin(n-k+1)\theta\sin k\theta}, \tag{68b}$$

where $z=z(\theta)$ is shown in Eq. 57.

The Total Energy of the 2n *Chain.* This is given by

$$E_{2n} = \mathrm{Tr}\frac{1}{2\pi i}\int_C dz\, zG_{2n}(z) = 2\sum_{k=1}^{n-1}\frac{-1}{4\pi i}\int_C d\theta\frac{z\sin(n-k)\theta\{\sin(k+1)\theta+\gamma^{-1}\sin k\theta\}}{\sin(n+1)\theta+\gamma^{-1}\sin n\theta}. \tag{69}$$

The integration contour in this case is the same as Fig. 2b, if the two points $\pi/2$ and $-\pi/2$ are replaced by π and $-\pi$, respectively. Also note that the integration in Eq. 69 includes the spin sum. The summation with respect to k is made and then followed by the contour integration:

$$E_{2n} = 2\sum_{r=-n}^{n} \frac{z(\theta_r)\left[\frac{n}{2}\{\cos(n+1)\theta_r+\gamma^{-1}\cos n\theta_r\}-\frac{1}{2}\frac{\sin n\theta_r}{\sin\theta_r}\{1+\gamma^{-1}\cos\theta_r\}\right]}{(n+1)\cos(n+1)\theta_r+\gamma^{-1}\cos n\theta_r}. \tag{70}$$

Then using the relation (64), we can get

$$E_{2n} = \sum_{r=-n}^{n} z(\theta_r) = 2\sum_{r=1}^{n} z(\theta_r), \tag{71}$$

namely, we find the usual description that the levels with $r=1\sim n$ are doubly occupied. For numerical estimation, Eq. 65 should be invoked.

In the case of the $2n$ chain, we have been unable to give the simple and compact expressions for the poles of the propagator, which enable us difficult to carry out the contour integration. Therefore in the following we confine ourselves to treat the $2n+1$ chain, or radicals.

*The Charge Density at the (*2k−1*)-th Site of the* 2n+1 *Chain.* This is given simply by

$$q_{2n+1}(2k-1) = \frac{1}{2\pi i}\int_C dz\, F_{2n+1}(2k-1;z) = \frac{-1}{4\pi i}\int_C d\theta\frac{\sin(n-k+1)\theta\sin k\theta}{\sin(n+1)\theta}, \tag{72}$$

where poles are

$$\theta_r = \pi r/(n+1), \tag{73}$$

and those with $r=\pm1,\pm2,\cdots,\pm n$ are doubly occupied and $r=\pm(n+1)$ are singly occupied. In the course of the contour integration, we can observe that the contribution from the terms with $r=\pm(n+1)$ vanishes, and that from others exactly gives

$$q_{2n+1}(2k-1) = 1, \tag{74}$$

which is independent of k. Here we have also used the relation (26).

It is naturally expected to be

$$q_{2n+1}(2k) = 1, \tag{75}$$

but the proof seems tedious because of the rather complicated expression of Eq. 68a, and the z^2 term which appears in the denominator of the contour integrand. Briefly speaking, our proof is as follows: we separate the numerator into two parts, the first with z^2 as a common factor and the second not. We can show the contribution from the second to the integration vanishes. Concerning the first, the integration is carried out as well as in the case of $q_{2n+1}(2k-1)$, and yields the result (75). We expect a simpler proof.

The Bond Orders of the 2n+1 *Chain.* We investigate the bond order between the sites $2k-1$ and $2k$, which concerns with the double bond as indicated in Fig. 4. This is given by

$$q_{2n+1}(2k-1,2k) = \frac{1}{2\pi i}\int_C dz\, F_{2n+1}(2k-1,2k;z), \tag{76}$$

in which

$$F_{2n+1}(2k-1,2k) = F_{2n+1}(2k)\gamma^{-1/2}G_{2(n-k)}(0) = \frac{\sin k\theta\{\gamma^{1/2}\sin(n-k+1)\theta+\gamma^{-1/2}\sin(n-k)\theta\}}{\sin\theta\sin(n+1)\theta}. \tag{77}$$

Accordingly it follows that

$$q_{2n+1}(2k-1,2k) = \frac{-1}{4\pi i}\int_C \frac{d\theta}{z(\theta)}\frac{\sin k\theta\{\gamma^{1/2}\sin(n-k+1)\theta+\gamma^{-1/2}\sin(n-k)\theta\}}{\sin(n+1)\theta}. \tag{78}$$

Since the term, $z(\theta)$ is regular at the poles,

$$\theta_r=\pi r/(n+1),\ r=1,2,\cdots,(n+1). \tag{79}$$

The integration is easily carried out to yield,

$$q_{2n+1}(2k-1,2k) = \frac{2}{n+1}\sum_{r=1}^{n}\frac{\sin k\theta_r}{z(\theta_r)}\{\gamma^{1/2}\sin\theta_r+\gamma^{-1/2}\sin(k+1)\theta_r\}. \tag{80}$$

The similar result is also obtained for $q_{2n+1}(2k,2k+1)$ which concerns with the single bond:

$$q_{2n+1}(2k,2k+1) = \frac{2}{n+1}\sum_{r=1}^{n}\frac{\sin(k+1)\theta_r}{z(\theta_r)}\{\gamma^{1/2}\sin k\theta_r+\gamma^{-1/2}\sin(k+1)\theta_r\}. \tag{81}$$

In deriving these, we ignore the cut arisings from $z(\theta)=0$. If one worrys about this, the partial integration with respect to z should be done at the beginning. This

procedure moves $z(\theta)$ from the denominator to the numerator. Then tedious but straightforward calculations leads to the same results. For the case of $\gamma=1$, namely, with the equal bond length, it is simple task to get

$$q_{2n+1}(r, r+1) = \frac{1}{n+1}\left\{\cot\frac{\pi}{2n+2}+(-1)^{r-1}\cot\frac{(2r+1)\pi}{2n+2}\right\} \quad (85)^{5)}$$

from Eq. 80 or Eq. 81.

Concluding Remarks

We have presented some expressions for propagators of the chain molecules in the Hückel approximations. One may say that in deriving the physical quantity, *e.g.*, the charge density, the usual quantum chemical method is much simpler. However we can expect that in the future application, the propagator approach enables us to treat many problems in a quite general aspects and provide powerful devices to quantum chemical problems.

Dynamic Properties of the Phosphorescent Triplet State of 9*H*-Thioxanthen-9-one (Thioxanthone) from Optically Detected Magnetic Resonance Spectroscopy

Kazuhiko SUGA and Minoru KINOSHITA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received December 10, 1980)

A variety of optically detected magnetic resonance (ODMR) experiments have been performed on the lowest excited triplet state of 9*H*-thioxanthen-9-one at 1.4 K. The absorption and phosphorescence excitation spectra were also measured to supplement the ODMR studies. The results were analyzed to determine the mechanisms responsible for the radiative decay and intersystem crossing processes. The z sublevel has large activity in vibronic bands due to non-totally symmetric vibrations. The intensity mainly comes from mechanisms involving vibronic coupling between $^1n,\pi^*$ and $^1\pi,\pi^*$ states. The y sublevel is selectively affected by the introduction of the sulfur atom, because of the increased importance of spin orbit coupling with $^1\sigma',\pi^*$ state which is largely localized on the thioether group.

Detailed information about the magnetic and spectroscopic properties of the lowest triplet states of aromatic carbonyls[1-13] has been accumulated in recent years, particularly by means of optically detected magnetic resonance (ODMR) spectroscopy. In the case of aromatic carbonyls having the lowest triplet states of π,π^* type, these properties have been shown to vary markedly depending on the molecular structure, the nature of environments, and the energy separations between the $^3\pi,\pi^*$ state and $^3n,\pi^*$ state (ΔE_{TT}) or the $^1n,\pi^*$ state (ΔE_{ST}). However, in the case of 9*H*-xanthen-9-one (we shall use the popular name, xanthone, hereafter) where ΔE_{TT} is rather large and the carbonyl group is rigidly held to the planar π-electron system, Chakrabarti and Hirota[17] have shown that the radiative and non-radiative properties are very different from those found in other carbonyls such as benzaldehydes and acetophenones.

The aims of the present paper are to study dynamic properties of the lowest triplet state of 9*H*-thioxanthen-9-one (we shall use the popular name, thioxanthone, hereafter) in comparison with those of xanthone[14-19] and to elucidate the mechanism of dynamical processes of the state.

Experimental

Xanthone, thioxanthone, and bis(4-bromophenyl) ether (DDE) were purified by recrystallization followed by extensive zone refining under vacuum. Hexane, heptane, and octane of spectroscopic grade (Tokyo Kasei Co., Ltd.) were used without further purification. Crystals were grown by the Bridgman method from the melts.

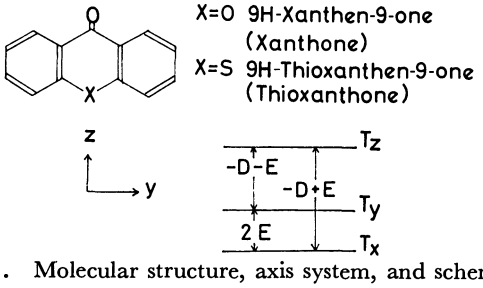

Fig. 1. Molecular structure, axis system, and scheme of zero field splitting.

The experimental set up for optical and magnetic resonance spectroscopic experiments was essentially the same as that reported previously.[20,21] The absorption spectra were measured on solutions in 1 cm path quartz cells by a Hitachi type 556 spectrophotometer at room temperature.

The molecular structures of xanthone and thioxanthone are shown in Fig. 1 together with the axis system used in this study and the zero-field(zf) splitting pattern which will be described below.

Results

Absorption Spectra. Figure 2 shows the absorption spectrum of thioxanthone observed in hexane at room temperature in comparison with that of xanthone. The intensity of the whole spectrum of thioxanthone is approximately halved as compared with that of xanthone, and each band shifts by about 3000 cm^{-1} to the red, showing that the excited π,π^* states lower their energy by sulfur substitution.

Phosphorescence Excitation Spectra. The phosphor-

a) and b) neat crystal, c) in DDE, and d) in xanthone.

escence excitation spectra of thioxanthone in several host crystals are shown in Fig. 3. The excitation spectrum of the thioxanthone neat crystal starts at 22340 cm^{-1}, which is about 60 cm^{-1} higher than that of the origin of the phosphorescence spectrum. This indicates that the phosphorescence of the neat crystal, to be discussed below, originates from traps. There are a strong absorption band at 24980 cm^{-1} and a shoulder at about 24740 cm^{-1}. In the DDE and xanthone host crystals, the absorption at 22340 cm^{-1} is not observable, but other two absorption bands are clear.[22] The absorption at 24980 cm^{-1} is assigned to the $^1A_1(\pi,\pi^*)\leftarrow S_0$ absorption by considering the position of the first band in Fig. 2 and the excitation spectrum in heptane shown in Fig. 4. The absorptions starting at 24740 and 22340 cm^{-1} are assigned to the transitions of $^3A_2(n,\pi^*)\leftarrow S_0$ and $^3A_1(\pi,\pi^*)\leftarrow S_0$, respectively.

The excitation spectra of thioxanthone obtained in normal alkanes are complicated because of superposition of the spectra coming from multiple sites. The spectra coming from the sites are separated by using site selective monitoring technique. As an example, the spectra of the two major sites in heptane are shown in Fig. 4. The site higher in energy is referred to as site I, and the site lower as site II.

The phosphorescence excitation spectrum obtained in hexane is also shown in Fig. 5. Table 1 compares

the locations of the lower lying excited states of xanthone and thioxanthone determined from the excitation spectra. The energy levels for xanthone are essentially identical with those reported.[14,17] Most results for thioxanthone are new.

ODMR Experiments. Two strong MIDP signals at 3.088 and 1.098 GHz were observed for the emission of the traps in the thioxanthone neat crystal. Third zf transition at about 1.99 GHz could be observed by monitoring the emission at the 0,0 band. In view of the results of the other $^3\pi,\pi^*$ aromatic carbonyls so far studied,[1-9] the ordering of the sublevels is reasonably assigned as $T_z > T_y > T_x$ in energy. The x sublevel is the slowest decaying one. This assignment will be verified further by the unique behavior of the middle sublevel. Therefore, the zf transitions at 3.088 and 1.098 GHz are assigned as the $T_z \leftrightarrow T_x$ and $T_y \leftrightarrow T_x$ transitions, respectively. The ODMR transitions of thioxanthone observed in the DDE and xanthone host crystals are also assigned in a like manner. It is worthy to note that in the case of these three crystal systems, the total decay rates of the y and z sublevels are almost similar and large.

In the case of thioxanthone in hexane, on the other hand, only two positive PMDR signals were observed at 1.179 and 1.373 GHz. The third transition could be observed only slightly by the MIDP method at about 2.6 GHz. Since there is a strong likelihood that the x sublevel is the slowest decaying one, the signal at 1.179 GHz is attributed to the $T_y \leftrightarrow T_x$ transition and the signal at 1.373 GHz to $T_y \leftrightarrow T_z$. Two different sets of the zf ODMR transitions were observed for thioxanthone in heptane. The site selective experiment leads to the conclusion that site I is associated with the transitions at 1.186 and 1.376 GHz, and site II at 1.176 and 1.373 GHz.

The two sets of the ODMR signals corresponding to two distinct emitting species were observed for xanthone in the DDE host. The properties of these emitting species in the DDE host are very similar to those of the two traps observed in the xanthone neat crystal.[17]

The total decay rates k_i, relative steady state populations N_i^0, and relative populating rates P_i of the spin sublevels (i=x, y, z) were measured by the MIDP method. The relative radiative decay rates k_i^r were obtained for the 0,0 and vibronic bands at 0—670 cm^{-1}. The results are summarized in Table 2.

Phosphorescence and Sublevel Emission Spectra. The phosphorescence spectra of thioxanthone in alkanes were obtained under steady state excitation conditions. The spectrum obtained in hexane is shown in Fig. 6 in comparison with that of xanthone. The latter is resolved much better than the spectrum in the literature.[18] Unlike in hexane, where only one major site is evident, the phosphorescence spectra in heptane and octane appear as no less than two-site emission.

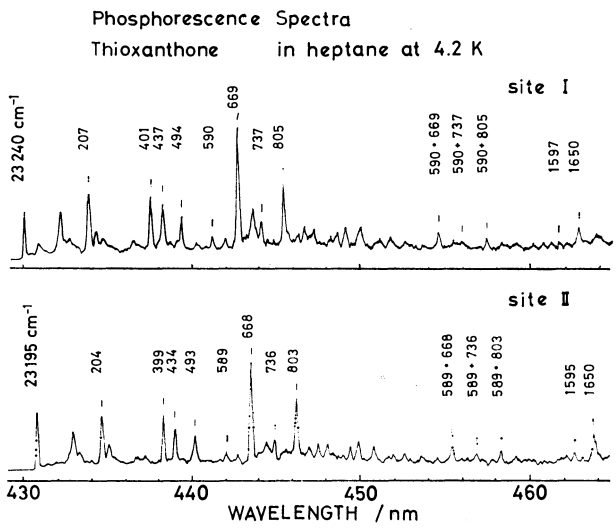

Fig. 7. The single site phosphorescence spectra of thioxanthone in heptane at 4.2 K.
Site I (upper) and site II (lower).

As an example, the emission spectra of sites I and II in heptane obtained by using the site selective excitation technique are shown in Fig. 7.

Much clear information can be obtained through separated sublevel emission spectra measured by means of the MIDP spectrum method reported previously.[20] Figure 8 shows the sublevel emission spectra of thioxanthone in hexane. Vibrational analysis of the spectrum is made by reference to the vibrational data for the compounds with related structure.[26-28] The vibronic bands found at 0—1650 and 0—1598 cm^{-1} are due to the C=O and C=C stretching modes of a_1 symmetry, respectively. The band at 0—590 cm^{-1} is also due to the totally symmetric mode, the combinations of which with the other modes have a certain intensity in the phosphorescence spectrum.

By considering the intensity behavior, the rest of bands of a considerable intensity may be attributed to the non-totally symmetric modes. The vibrations such as 670 and 810 cm^{-1} are considered as the same

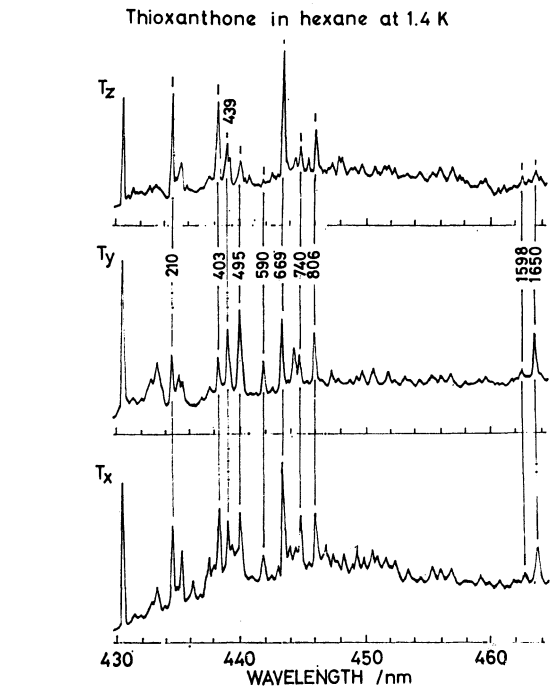

Fig. 8. The sublevel phosphorescence spectra of thioxanthone in hexane at 1.4 K.

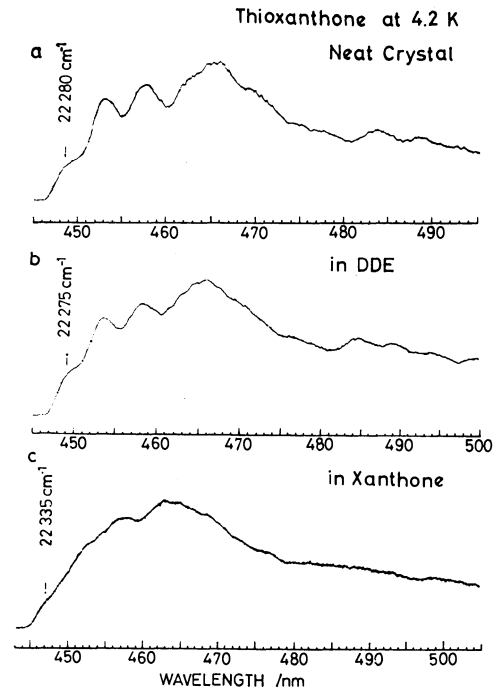

Fig. 9. The phosphorescence spectra at 4.2 K.

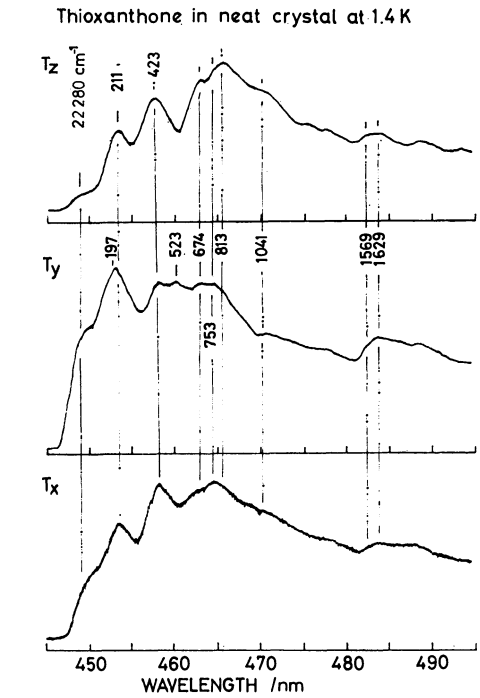

Fig. 10. The sublevel phosphorescence spectra of thioxanthone traps in the neat crystal at 1.4 K.

vibrations appearing in the spectrum of xanthone. In view of the infrared activity,[28] these vibrations are surely assigned to the out of plane vibrations of b_1 symmetry in the case of xanthone. The vibrational modes such as 430 and 720 cm^{-1}, more intense in the y sublevel spectrum than z, may be considered also as the out of plane vibrations probably of a_2 symmetry.

The phosphorescence spectra of thioxanthone also obtained in various crystals are shown in Fig. 9. The sublevel emission spectra obtained for traps in the neat crystal are shown in Fig. 10. The vibrational modes of 211, 423, 674, and 813 cm^{-1}, corresponding to frequencies 210, 403, 669, and 813 cm^{-1} observed in hexane, also appear in the z sublevel spectrum.

The phosphorescence spectra of xanthone are measured in alkanes and in the DDE host crystal. Although the spectra in heptane and octane appear as multi-site emission, the vibrational feature is very similar to that in hexane, shown in Fig. 6. As in the case of the xanthone neat crystal,[17] the phosphorescence spectrum in DDE appears to consist of the superposition of the spectra with different origins, one at 25023 cm^{-1} and the other at 24890 cm^{-1}.

Discussion

Total Decay Rate and Zero Field Splitting. The decay rate of the y sublevel, $k_y=12.1\ s^{-1}$, for traps in the thioxanthone neat crystal is larger by a factor of about six than that for traps in the xanthone neat crystal.[17] Such a remarkable change in the decay rate of the y sublevel must be due to the heavier nucleus S instead of O. In fact, the effective one electron spin orbit coupling constant for the 3p electrons of a S atom is expected to be much larger than that for the 2p electrons of an O atom.[25] Accordingly, the mixing with a $^1B_1(\sigma',\pi^*)$ state which is largely localized on the ether or thioether group may play a considerable role in determining k_y's of both compounds in addition to the mixing with the $^1B_1(\sigma,\pi^*)$ state, largely localized on the carbonyl group. This conclusion may be supported by the fact that the value of k_y of xanthone is considerably larger than the decay rates due to the mixing with $^1\sigma,\pi^*$ state commonly found in other systems such as quinoxaline[23] and naphthalene.[24] Furthermore, the above consideration confirms the assignment of the middle sublevel to y and verifies the zf splitting pattern of Fig. 1.

In the systems of thioxanthone traps in the neat, DDE, and xanthone crystals, the decay rates of the x sublevel are considerably smaller as compared with those of substituted benzaldehydes.[1,7,8] This seems to indicate that neither the $^3n,\pi^*$ admixture into the lowest $^3\pi,\pi^*$ state *via* vibronic coupling nor the deviation from the planarity contributes to k_x. A similar conclusion has been obtained for xanthone in crystalline hosts.[17] In the systems of thioxanthone in alkanes, however, relatively large values of k_x are obtained. The reason for this is not clear at present, but a possible contribution from spin-lattice relaxation is not completely eliminated in the alkane systems.

In xanthone it was shown that spin orbit mixing with $^1n,\pi^*$ state is mainly responsible for the decay from the z sublevel, because rather large ΔE_{TT} is unfavorable for mixing with $^3n,\pi^*$ state.[17] This is also true for thioxanthone. Both ΔE_{TT} and ΔE_{ST} become large by introduction of sulfur instead of oxygen. However, the decrease in k_z observed in the thioxanthone neat crystal is not so large as that expected from the increase in ΔE_{TT} and rather seems to reflect the increase in ΔE_{ST}. Therefore, rather small difference in k_z between xanthone and thioxanthone observed in the neat crystals seems to confirm the above inference.

It is notable that the total decay rates of the z sublevel of thioxanthone in alkanes are much smaller than those obtained in the crystal systems, clearly indicating that the mixing with $^1n,\pi^*$ state is reduced largely in hexane. This may be a consequence of larger value of ΔE_{ST} and/or smaller value of spin orbit matrix element, $G=\langle\pi,\pi^*|H_{SO}|n,\pi^*\rangle$, than in crystal system.

The $|D|$ values of thioxanthone traps in the neat crystal and in the DDE and xanthone hosts are small compared with that of xanthone.[17] By assuming that the value of the spin orbit coupling matrix element, G, is similar to that estimated for a series of benzaldehydes; $G^2=90\ cm^{-2}$,[5,8] the difference in the spin orbit contribution to D of xanthone and thioxanthone is predicted to be about 0.037 cm^{-1}. This value seems to be in agreement with the observed difference in D. Thus, the change in the spin orbit contribution is responsible, at least partly, for the change in D. Further reduction in $|D|$ observed when the environment is changed to alkanes suggests that the energy difference, ΔE_{TT}, becomes much larger in these matrices.

Intersystem Crossing. There is a distinct difference in the populating rates between the systems of thioxanthone in alkanes and in the other host crystals. Since the lowest excited triplet and singlet states of thioxanthone are π,π^* states of A_1 orbital symmetry, all the three sublevels require vibronic spin orbit mechanisms, when the intersystem crossing is assumed to proceed directly from S_1 to T_1. However, if the $T_2(n,\pi^*)$ state lies lower than S_1, it is necessary to consider an indirect process, namely $S_1\rightarrow T_2\rightarrow T_1$, which may make a contribution toward populating of the z sublevel.

In the case of thioxanthone traps in the neat crystal and in the DDE and xanthone hosts, the populating pattern of the sublevels is characterized by high selectivity for the y and z sublevels, relative to the x sublevel. In these host crystals, the $T_2(n,\pi^*)$ state is located lower than S_1. The high selectivity for the z sublevel, therefore, indicates clearly that the indirect process plays a role in the populating process of the z sublevel.

In the case of thioxanthone in hexane and heptane, on the other hand, ΔE_{TT} is much larger than in the DDE and xanthone host crystals, as described in the preceding section. As a result, the T_2 and S_1 states are expected to interchange position. If this is the case, the significant decrease in the relative populating rate of the z sublevel on going from in the host crystals to in alkanes is surely ascribed to the vanishment of the indirect process and also to the decrease of the vibronic interaction between the n,π^* and π,π^* states in singlet and/or triplet manifolds resulting from the increase of the energy separations.

As discussed in the preceding section, there is a good reason to expect that the mixing between the $^3A_1$ and $^1B_1(\sigma',\pi^*)$ states is effective. In addition, there is also evidence for considerably large b_1 vibration band activity in the y sublevel emission (Table 2). Thus, the large activity of the y sublevel with respect to the intersystem crossing process can be interpreted as a consequence of, for the main, large spin orbit coupling terms between the $^3A_1$ and $^1B_1(\sigma',\pi^*)$ states and also vibronic coupling matrix element between the $^1A_1$ and $^1B_1$ states.

Radiative Processes. Radiative Decay from the z Sublevel: The mechanisms governing the radiative decay from the z sublevel of $^3\pi,\pi^*$ aromatic carbonyls so far studied[7,8,10-13] may be classified as follows.

(1) Direct spin orbit mixing with the $^1n,\pi^*$ state

$$T_z(^3\pi,\pi^*) \leftarrow H_{so} \rightarrow {}^1n,\pi^*$$

(2) Direct configurational mixing with the $^3n,\pi^*$ state

$$T_z(^3\pi,\pi^*) \leftarrow H_{el} \rightarrow T_z(^3n,\pi^*) \leftarrow H_{so} \rightarrow {}^1\pi,\pi^*$$

(3) Herzberg-Teller type vibronic spin orbit mixing

(a) $T_z(^3\pi,\pi^*) \leftarrow H_v \rightarrow T_z(^3n,\pi^*) \leftarrow H_{so} \rightarrow {}^1\pi,\pi^*$

(b) $T_z(^3\pi,\pi^*) \leftarrow H_{so} \rightarrow {}^1n,\pi^* \leftarrow H_v \rightarrow {}^1\pi,\pi^*$

It has been shown that the relative importance of these is much dependent on the systems chosen.

In xanthone, Chakrabarti and Hirota[17] have shown that mechanisms (1), (2), and (3a) are not main ones and that only mechanism (3b) may be considered to be important for the emission of the z sublevel. A similar conclusion holds commonly for thioxanthone, but some more detailed information can be obtained by comparing the results with those of xanthone.

Mechanism (1) is important rather than mechanism (2) in the 0,0 band emission from the z sublevel. This inference can be derived from the facts that the relative intensity of the 0,0 band in the z sublevel emission is insensitive to the change in ΔE_{TT} from 1461 cm^{-1} for xanthone to 2400 cm^{-1} for thioxanthone and that the z sublevel emits only weakly at the 0,0 band even in the system of xanthone in hexane where ΔE_{TT} is relatively small.

With respect to xanthone, Chakrabarti and Hirota have suggested, on the basis of the phosphorescence polarization data by Pownall and Huber,[14] that such strong bands as found at 0—670 cm^{-1} likely gain intensity by the following mechanism.[17]

$$T_z(^3\pi,\pi^*) \leftarrow H_{so} \rightarrow {}^1n,\pi^*(A_2) \leftarrow H_v(b_1) \rightarrow {}^1\pi,\pi^*(B_2)$$

As mentioned above, the out of plane vibrational modes such as 670 and 810 cm^{-1} of thioxanthone can be assigned to the vibrations of b_1 symmetry. The observation that these vibrations appear strongly in the z sublevel spectra of thioxanthone seems to give a good proof of the validity of the mechanism suggested by Chakrabarti and Hirota.

The a_2 vibrational modes such as 430 and 730 cm^{-1} appear only weakly in the z sublevel spectrum of thioxanthone. These vibrations are still of quite low intensity in the case of xanthone where ΔE_{TT} is much smaller than that of thioxanthone. This indicates that also the vibronic bands involving the a_2 vibrations should gain intensity by mechanism (3b) rather than (3a).

Radiative Decay from the y Sublevel: In the case of $^3\pi,\pi^*$ aromatic carbonyls, the y sublevel emission was ascribed to the direct mixing with the $^1\sigma,\pi^*$ state, largely localized on the carbonyl group[7,12]

$$T_y(^3\pi,\pi^*) \leftarrow H_{so} \rightarrow {}^1\sigma,\pi^*(B_1).$$

The y sublevel emission of xanthone has also been explained with this mechanism.[17]

In xanthone, however, the ether group participates in the π-conjugation. It is therefore necessary to consider the importance of one center terms on the O atom of the ether group in spin orbit coupling matrix element in addition to the above mechanism. The y sublevel is expected to couple with $^1B_1(\sigma',\pi^*)$, where σ' orbital has a large contribution from in-plane non-bonding orbital of sp^2 hybrid type in the ether group. Since the effective one electron spin orbit coupling constant for sulfur is much larger than for oxygen,[25] the contribution of the mixing with $^1B_1(\sigma',\pi^*)$ state is more important in thioxanthone than in xanthone. In fact, there is evidence that the radiative activity of the y sublevel increases dramatically in going from xanthone to thioxanthone as given in Table 2. In addition, the vibronic bands involving non-totally symmetric vibrations appear with some intensity in the y sublevel spectrum. It is likely that the vibronic interaction in singlet manifolds involving the $^1B_1(\sigma',\pi^*)$ and $^1\pi,\pi^*$ states is the main source for the emission in these bands, rather than the vibronic interaction in triplet manifolds.

The authors wish to thank Prof. Saburo Nagakura of the University of Tokyo and Prof. Nobuyuki Nishi of Institute for Molecular Science for their valuable discussions. The present work was in part supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (Nos. 334026, 410401).

(Received December 10, 1980)

A new method for molecular conformational analysis using photoelectron spectral data was developed and applied to alkyl-substituted styrenes as an example. The dihedral angle between the phenyl ring and the olefinic group planes, θ, in each molecule is evaluated by comparing the observed difference between the first and the third vertical ionization energies, $\Delta E_{iv}^{1,3}$, with the empirically estimated $\Delta E_{iv}^{1,3}$ *vs.* θ curve, the alkyl substituent effect being taken into account by the first order perturbation theory. The new method gives reasonable results consistent qualitatively with those given by other former methods.

As a part of our program to investigate the steric hindrance effect on molecular photoelectron spectra and the application of photoelectron spectroscopy to molecular conformational analysis,[1] in this paper a new method for conformational analysis by photoelectron spectroscopy is presented and applied to some β-alkylstyrenes and related compounds as an example.

The simplest method for molecular conformational analysis by photoelectron spectroscopy is at present that by Maier and Turner.[2] They estimated empirically the dihedral angles in molecules by the composite molecule type consideration on the HMO level taking into account the interaction between two group orbitals only, that is, in their method the conjugative interaction of these two group orbitals with other group orbitals are completely neglected throughout the calculations. The new method presented in this paper is devised to be applicable even to the cases where this type of interaction is not negligible.

The relations between the molecular conformations and photoelectron spectra of some styrenes have formerly been studied by us[1c] and Maier and Turner.[2b] During the course of our photochemical study of β-alkylstyrenes[3] it was found that the accurate conformational data of these molecules useful for the interpretation of photochemistry are still completely lacking. This is the reason why alkylstyrenes are revisited here.

Experimental

Measurements. The photoelectron spectra were recorded with the He I resonance line as the excitation source in the same way as described formerly.[1c]

Materials. *cis*-β-Methylstyrene[4] and *cis*-β-ethylstyrene[4] were obtained by hydrogenation of 1-phenylpropyne and 1-phenylbutyne, respectively, on Pd/C in ethyl alcohol and purified by column chromatography. *trans*-β-Methylstyrene[4] and *trans*-β-ethylstyrene[4] were prepared by dehydration of the alcohols obtained through the reaction of acetaldehyde and benzaldehyde, respectively, with the appropriate Grignard reagents. A mixture of *cis*- and *trans*-β-*t*-butylstyrene was synthesized according to Ref. 5 and the *cis*- and *trans*-isomer were isolated by column chromatography. The purities of the samples were checked by gas chromatography and their molecular structures were identified by NMR spectroscopy. These styrenes were distilled under reduced pressure just before use.

Computational

The CNDO/S[6] calculations of styrene, *s-trans*-butadiene, and naphthalene were carried out with a FACOM 230-75 computer at the Institute of Physical and Chemical Research. All the necessary atomic integrals and parameters were taken from or estimated according to Ref. 6.

The structural parameters of *s-trans*-butadiene and naphthalene were taken from Ref. 7 and those of styrene were assumed as follows:

The C=C and the C–H bond lengths of the phenyl group were assumed to be 1.397 Å and 1.084 Å, respectively, on the basis of the data for benzene.[7] The C=C, the C–H bond lengths of the vinyl group, and the C–C bond length between the phenyl and the vinyl groups were assumed to be 1.337 Å, 1.08 Å, and 1.483 Å, respectively, by consulting the data for *s-trans*-butadiene.[7] All the C–C–C and the C–C–H bond angles were assumed to be 120°.

Results and Discussion

Photoelectron Spectra. The photoelectron spectra of *cis*- and *trans*-β-methyl-, ethyl-, and *t*-butylstyrene measured in this study are shown in Figs. 1, 2, and 3. The vertical ionization energies of the lower energy bands of these compounds obtained from the spectra are summarized in Table 1 with those of the related compounds.

The first three bands of β-methyl-, β-ethylstyrenes, or *trans*-β-*t*-butylstyrene are well separated from one another, their vertical ionization energies being rather close to those of styrene, and are safely correlated with the first three bands of styrene,[1c] from the top respectively. The first and the third bands of styrene,[1c] respectively, correspond to the ionizations from the two molecular orbitals approximately expressed as the anti-bonding and the bonding types of combinations of the benzene ring $e_{1g}(S)$-like group orbital with the vinyl group occupied π orbital. Here $e_{1g}(S)$ denotes one of the doubly degenerate e_{1g} π orbitals of benzene, and is symmetrical with respect to the mirror plane passing the 1- and the 4-position and perpendicular to the benzene ring. On the other hand, the second

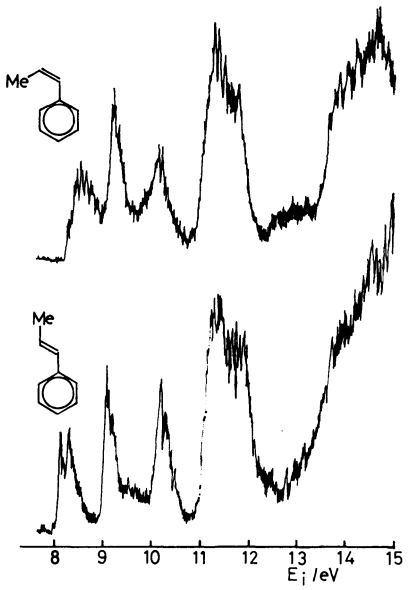

Fig. 1. Photoelectron spectra of *cis*-β-methylstyrene and *trans*-β-methylstyrene.

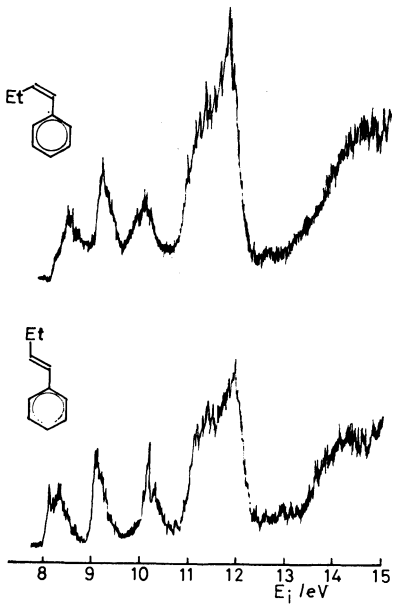

Fig. 2. Photoelectron spectra of *cis*-β-ethylstyrene and *trans*-β-ethylstyrene.

band corresponds to the ionization from the orbital composed almost completely of the benzene ring e_{1g}(A)-like orbital. Here e_{1g}(A) denotes the other e_{1g} orbital of benzene which is antisymmetrical with respect to the mirror plane mentioned above. The ionization energies of and the splitting between the first and the third bands of styrene are, therefore, quite sensitive to the dihedral angle, θ, between the vinyl group and the benzene ring planes, while the second ionization energy is almost indifferent to the change in θ because of its completely localized nature on the benzene ring as visualized in Fig. 4 of Ref. 1c.

In the case of *cis*-β-*t*-butylstyrene the second and the third bands are evidently highly overlapping with each other, and it is quite natural to consider that this has been caused by the heavy steric hindrance effect of the bulky *t*-butyl group. But one should be careful in the point that the electronic effect of *t*-butyl group is also contributing to the lower ionization energy shift of the third band of *cis*-β-*t*-butylstyrene when compared to styrene. Similar care is more or less important for the other bands and for the other alkyl-substituted styrenes also.

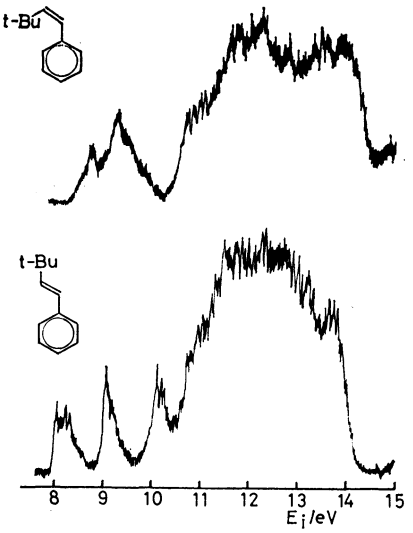

Fig. 3. Photoelectron spectra of *cis*-β-*t*-butylstyrene and *trans*-β-*t*-butylstyrene.

Table 1. Vertical ionization energies, E_{iv}, of styrenes and related compounds

Compound	E_{iv}/eV			
	Band 1	2	3	4
Styrene[a]	8.49	9.27	10.55	11.52
2-Methylstyrene[a]	8.53	8.99	10.37	11.22
3-Methylstyrene[a]	8.37	8.98	10.34	11.27
4-Methylstyrene[a]	8.20	9.11	10.24	11.29
α-Methylstyrene[a]	8.52	9.18	10.12	11.26
cis-β-Methylstyrene	8.48	9.18	10.26	11.30
trans-β-Methylstyrene	8.34	9.09	10.25	11.46
cis-β-Ethylstyrene	8.54	9.16	10.02	11.24
trans-β-Ethylstyrene	8.30	9.09	10.19	11.37
cis-β-*t*-Butylstyrene	8.85	9.27	9.5[c]	10.91
trans-β-*t*-Butylstyrene	8.18	9.05	10.10	11.02
2,4-Dimethylstyrene[a]	8.22	8.80	10.11	11.06
2,6-Dimethylstyrene[a]	8.48	8.62	10.04	11.04
Propylene[b]	9.744			
Ethylbenzene[a]	8.78	9.27		

a) Ref. 1c. b) Ref. 8. c) This value is the approximate one because of the heavy overlapping between the second and the third bands of *cis*-β-*t*-butylstyrene.

In the following we use the observed differences between the first and the third vertical ionization energies of alkyl-substituted styrenes, $\Delta E_{iv}^{1,3}$, for the estimation of the dihedral angles, taking into account the electronic effect of the alkyl groups.

Conformational Analysis by Photoelectron Spectroscopy. The calculational steps of the new method for conformational analysis by photoelectron spectroscopy are described in the following.

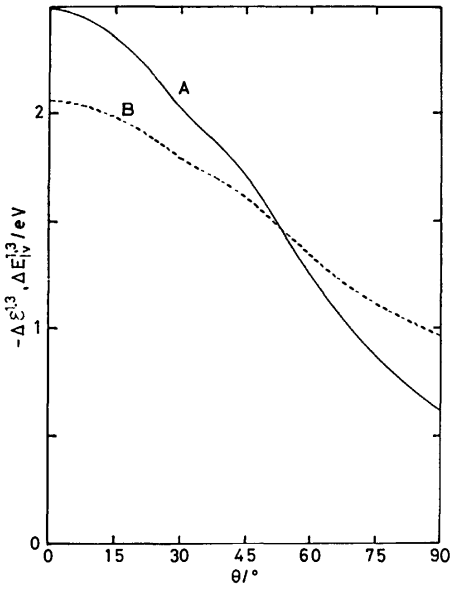

Fig. 4. Twist angle, θ, dependence of calculated orbital energy difference between the highest and the third highest occupied π orbitals for styrene, $\Delta\varepsilon^{1,3}$, (curve A) and that of difference between the first and the third vertical ionization energies of styrene, $\Delta E_{iv}^{1,3}$, estimated using curve A and formula (1) (curve B).

At first SCFMO calculations including all valence electrons are carried out for various twist angles of the parent compound. In this study we carried out CNDO/S[6] calculations of styrene itself for the twist angle from 0° to 90° at the intervals of 15°.

The calculated energy difference between the highest and the third highest occupied π orbitals of styrene, $\Delta\varepsilon^{1,3}$, is plotted against θ. Thus we get the $\Delta\varepsilon(\theta)^{1,3}$ *vs.* θ curve (curve A in Fig. 4).

In most cases this type of curve deviates more or less from the corresponding $\Delta E_{iv}(\theta)^{1,3}$ *vs.* θ curve. To estimate the realistic $\Delta E_{iv}(\theta)^{1,3}$ *vs.* θ curve, in this paper we transform curve A in Fig. 4 by the following simple formula:

$$\Delta E_{iv}(\theta)^{1,3} = a\Delta\varepsilon(\theta)^{1,3} + b \qquad (1)$$

Here a and b are constants and are evaluated by using the experimental $\Delta E_{iv}^{1,3}$ of styrene as $\Delta E_{iv}(0°)^{1,3}$ and the difference between the first ionization energies of propene[8] and ethylbenzene[1c] as $\Delta E_{iv}(90°)^{1,3}$. Styrene itself is planar in the ground state according to the Raman spectral study.[9] The a and b values thus evaluated are −0.586 and 0.603 eV, respectively. Now we get curve B in Fig. 4.

The $\Delta E_{iv}(\theta)^{1,3}$ *vs.* θ curve obtained above takes into account effectively the effect of the interactions of the two molecular orbitals under consideration with other orbitals. This curve B is expected to simulate rather well the real $\Delta E_{iv}(\theta)^{1,3}$ *vs.* θ curve, especially in the small θ region because styrene, which is known to be planar in the ground state as mentioned before, was used as the reference compound for $\theta=0°$.

By the way, the following equation can simulate well curve B in Fig. 4 if we adopt the same $\Delta E_{iv}(0°)^{1,3}$ and $\Delta E_{iv}(90°)^{1,3}$ values as in the case of formula (1):

$$\Delta E_{iv}(\theta)^{1,3} = \sqrt{\{\Delta E_{iv}(90°)^{1,3}\}^2 + [\{\Delta E_{iv}(0°)^{1,3}\}^2 - \{\Delta E_{iv}(90°)^{1,3}\}^2]\cos^2\theta} \qquad (2)$$

This equation can easily be derived by the composite molecule type consideration on the HMO level taking into account the interaction between two group orbitals only. This means that in the case of styrene the two-orbital model is not bad approximation.

Returning to the main story, for the conformational analysis of alkyl-substituted styrenes, we must correct curve B by taking into account the alkyl substituent electronic effect. This effect on the ionization energies can be estimated by the following formula according to the first order perturbation theory:[10,11]

$$-\Delta E_{ivj} = g\{\sum_{\alpha} C_{j\alpha}^2 + m\sum_{\beta} C_{j\beta}^2\} + h \qquad (3)$$

Here ΔE_{ivj} denotes the j-th vertical ionization energy change caused by alkyl substitution, C_{jk} the pπ atomic orbital coefficient of the atom k in the j-th molecular orbital, being calculated by the CNDO/S method in this study, α the alkyl-substituted carbon atom(s) and β the carbon atom(s) adjacent to the atom α. The parameter m is a kind of damping factor and is put equal to 1/3 by consulting the result in Ref. 10. Though the g and h values for methyl and t-butyl groups have already been given in Ref. 11, we reevaluated these parameter values by the least square method using the recent ionization energy data with those for ethyl group.

The compounds and the vertical ionization energy data used for the evaluation of g and h are as follows:

For methyl group, the first ionization energies of ethylene,[8] its methyl,[8] *cis*- and *trans*-1,2-dimethyl derivatives,[8] *s-trans*-butadiene,[12] its 1-methyl[12] and 1,4-dimethyl derivatives,[12] benzene,[13] toluene,[1d] and *m*-xylene.[1d]

For ethyl group, the first ionization energies of ethylene,[8] its ethyl derivative,[8] *s-trans*-butadiene,[12] its 4-ethyl derivative,[12] benzene,[13] ethylbenzene,[1c] and the first three ionization energies of naphthalene, 8.15, 8.88, 10.00 eV,[10] those of 1-ethylnaphthalene, 7.91, 8.72, 9.68 eV, and those of 2-ethylnaphthalene, 7.94, 8.63, 9.83 eV.

For t-butyl group, the first ionization energies of ethylene,[8] its t-butyl derivative,[8] propylene,[8] its *cis*- and *trans*-t-butyl derivatives,[8] three isomers of di-t-butylethylenes,[8] benzene,[13] and the first two ionization energies of t-butylbenzene.[11]

The g and h values with the mean square errors, and the mean square error for ΔE_{ivj} thus obtained are for methyl group, $1.04^0\pm0.04^2$ eV, $-0.00^7\pm0.03^1$ eV, $\pm0.06^4$ eV; for ethyl group, $1.30^0\pm0.03^1$ eV, $0.00^3\pm0.00^8$ eV, $\pm0.02^3$ eV; for t-butyl group, $1.33^8\pm0.04^6$ eV, $0.00^2\pm0.03^5$ eV, $\pm0.08^4$ eV, respectively.

Thus we can estimate the $\Delta E_{iv}(\theta)^{1,3}$ *vs.* θ curve for each alkyl-substituted styrene by correcting curve B in Fig. 4 for alkyl substituent effect by applying formula (3) to the highest and the third highest occupied π orbitals of styrene. For example, we get the curve shown in Fig. 5 in the case of 2-methylstyrene.

Now it is quite easy to estimate the twist angle θ. By comparing the observed $\Delta E_{iv}^{1,3}$ value of 2-methylstyrene, for example, with the curve shown in Fig. 5

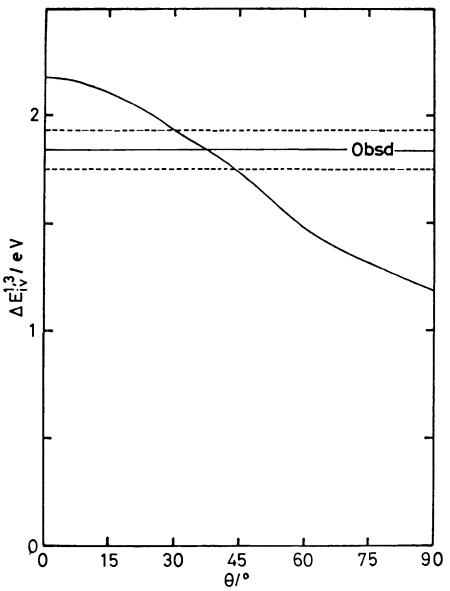

Fig. 5. Estimated twist angle, θ, dependence of difference between the first and the third vertical ionization energies of 2-methylstyrene, $\Delta E_{iv}^{1,3}$ with observed $\Delta E_{iv}^{1,3}$. Broken lines denote the mean square error.

TABLE 2. DIHEDRAL ANGLES, θ, IN STYRENES

Compound	θ/° UPS: This work	UPS: M.-T.[a]	UVS: S.[b]	UVS: B.-S.[c]

a) Ref. 2b. b) Ref. 14. c) Ref. 15. d) The values in the parentheses are the assumed ones. e) This value is the approximate one. See footnote c) for Table 1.

the twist angle θ of 2-methylstyrene is estimated to be $38°\pm{}^{7°}_{8°}$. The error limits for θ were approximately estimated from the mean square error for ΔE_{ivj} multiplied by $\sqrt{2}$. The dihedral angles of the other molecules were also estimated in the same way and are summarized in Table 2.

In the case of 3-methyl-, 4-methyl-, *trans*-β-methyl-, and *trans*-β-*t*-butylstyrene, the error ranges for θ include 0° as shown in Table 2, and in the case of *trans*-β-ethylstyrene the lower error limit is not so far from 0°. These results are reasonable because *trans*-β-alkyl substitution can not be considered to cause any steric hindrance effect upon the benzene ring parts in these cases. These reasonable results support the validity of the method developed here.

The θ value for *cis*-β-ethylstyrene given in Table 2 is slightly larger than that for *cis*-β-methylstyrene, and that for *cis*-β-*t*-butylstyrene is far larger than that for *cis*-β-ethylstyrene. These tendencies are also reasonable.

Suzuki[14] estimated the twist angles of some styrenes from the UV absorption band energies in solution by the HMO level consideration. Braude and Sondheimer[15] estimated the angles from the UV absorption spectral intensities on the assumption of $\varepsilon/\varepsilon_0=\cos^2\theta$ where ε and ε_0 are the molar absorptivity of the conjugation band of the alkylstyrene in question and that of the corresponding planar reference system, respectively. Maier and Turner[2b] estimated the twist angles for 2-methyl-, α-methyl-, and 2,6-dimethylstyrene by the two-orbital model consideration on the HMO level mentioned before. The twist angles of some styrenes estimated by these authors are also summarized in Table 2. The general tendency of the calculated twist angles in this paper seems to correspond roughly to those by the other methods mentioned above.

To our regret there are at present no accurate data on the conformations for these alkyl-substituted styrenes as yet. The θ values predicted here may be useful as guiding data until accurate conformational data become available.

Raman Scattering and Phase Transition of Ammonium Nitrates

Kenji AKIYAMA,† Yoshiyuki MORIOKA, and Ichiro NAKAGAWA*
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980
(Received December 15, 1980)

Polarized Raman spectra of single crystals are observed for the room-temperature phase NH_4NO_3(IV). The spectra in the low-frequency lattice vibration region as well as in the internal vibration region are well interpreted based on D_{2h}^{13} structure. Raman spectra of powdered samples are measured at various temperatures covering whole phases NH_4NO_3 I—V. A characteristic feature of Raman spectrum is clarified for each phase. An abrupt spectral change occurs in the phase transition, indicating a first order transition. The splitting of A_g and B_{1g} components of ν_3 (asymmetric stretching mode of NO_3^- ion) in NH_4NO_3 is quite large, due to the strong interionic interaction between NH_4^+ and NO_3^- ions.

In our previous paper we discussed the lattice vibrations and phase transitions of KNO_3 and $NaNO_3$ crystals.[1] In relation to the study on a series of alkali nitrates, the investigation on NH_4NO_3 is significant, from the viewpoint of the behavior of NO_3^- ion in the crystal as well as that of NH_4^+ ion. There have been several reports on the phase transition of NH_4NO_3 and it has been shown that the phase transition at high temperature is caused by the order-disorder on the rotational motion of NO_3^- ion and the following crystalline modifications exist:[2-5]

Phase I	cubic	169°C—126°C
Phase II	tetragonal	126°C— 80°C
Phase III	orthorhombic	80°C— 32°C
Phase IV	orthorhombic	32°C——18°C
Phase V	tetragonal	below −18°C

Tang and Torrie measured polycrystalline Raman spectra from room temperature down to 11 K and discussed IV⇌V phase transition.[6] James *et al.* also discussed IV⇌V phase transition as well as III⇌IV phase transition,[7] based on their Raman data measured in the temperature range 210 K—320 K. Iqbal seemed to suggest the existence of an additional phase VII,[8] for which no evidence was found by Tang and Torrie.[6] The study on the high-temperature phases by Raman measurement was made by Österlund and Rosen,[5] whose spectra seem however insufficient. Théorêt and Sandorfy measured the infrared spectra of solid crystalline films in the temperature range 169 °C——190 °C and obtained four different spectra corresponding to the I, II, IV, and VII phases.[9] In all of these studies polycrystalline samples were used for the spectral measurement and thus a definite assignment of the observed bands to the symmetry species could not be done by the polarization measurement.

We attempted a thorough spectroscopic study at various temperatures covering whole phases and clarified a characteristic feature of Raman spectrum in the low-frequency lattice vibration region for each phase. Polarized Raman spectra of single crystals were measured for the room temperature phase IV to give a characterization of the lattice vibrations. A supplementary far infrared transmission measurement was also made. We present here these results and specify how the successive phase transitions in NH_4NO_3 are reflected on the vibrational spectra.

† Present address: Shin-Etsu Handotai Co., Ltd., Isobe, Annaka, Gunma 379-01.

Experimental

Single crystals of NH_4NO_3 were grown by slow evaporation of saturated aqueous solution at room temperature. Needle-like crystals of ≈5 mm length along a-axis of NH_4NO_3(IV) were obtained.

Raman spectra were recorded with a JRS 400 T triple monochromator using a standard 90° scattering configuration. The 514.5 nm line from Ar ion laser (Lexel, model 95) was used for excitation. For the measurement of polarized spectra, the natural shaped crystals were used without any polishing. At the transition temperatures these crystals cracked, probably due to the change in crystal structure, and therefore in the measurement for the high and low-temperature phases the powdered samples were employed.

Far infrared spectra were measured by a Hitachi 070 far infrared interferometer.

Crystal Structure and Factor Group Analysis

The room temperature phase IV is orthorhombic with the space group D_{2h}^{13} and two formula units per unit cell ($z=2$). The phase III is also orthorhombic but it has four formula units per unit cell and its space group is D_{2h}^{16}. The structures of these phases III and IV are sketched in Fig. 1. The low-temperature phase V is non-centric tetragonal with the space group C_4^3 and $z=8$. The high-temperature phase II is also tetragonal with the space group C_{4v}^2 and $z=2$. The phase I has a CsCl-type structure with $z=1$ in a cubic unit cell. The results of factor group analysis based on the space groups mentioned above are summarized in

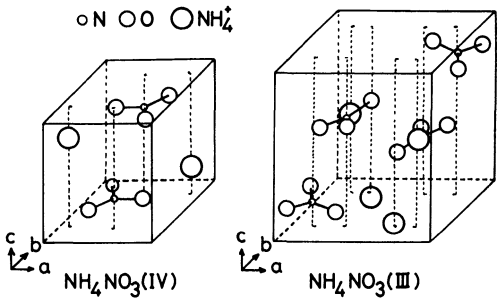

Fig. 1. Structures of NH_4NO_3(IV) and (III) crystals.

Table 1. No Raman active mode exists for the structure of the phase I.

Results and Discussion

Low frequency Lattice Vibration. In this region we may expect primarily the rotational and translational lattice modes of NO_3^- ion. The rotational modes of NH_4^+ ion are expected in the region higher than 300 cm^{-1}.[10] The polarized Raman spectra below 300 cm^{-1} at room temperature are shown in Fig. 2, which arise from the phase IV. The observed frequencies and assignments to the symmetry species based on D_{2h}^{13} structure are listed in Table 2. In the spectra of powdered sample shown in Fig. 3, three bands around 90 cm^{-1}, 140 cm^{-1}, and 170 cm^{-1} are observed at 29 °C, which correspond to the three intense bands at 85 cm^{-1} (B_{2g}), 139 cm^{-1} (B_{2g}), and 170 cm^{-1} (B_{3g}), respectively, observed in the polarized spectra. On referring to Table 1, the 170 cm^{-1} band (B_{3g}) is unambiguously

a) T and R denote translational and rotational lattice modes, respectively. ν_1—ν_4: internal modes of NO_3^- ion. ν_4': internal mode of NH_4^+ ion. b) Observed values by Tang and Torrie.[6)]

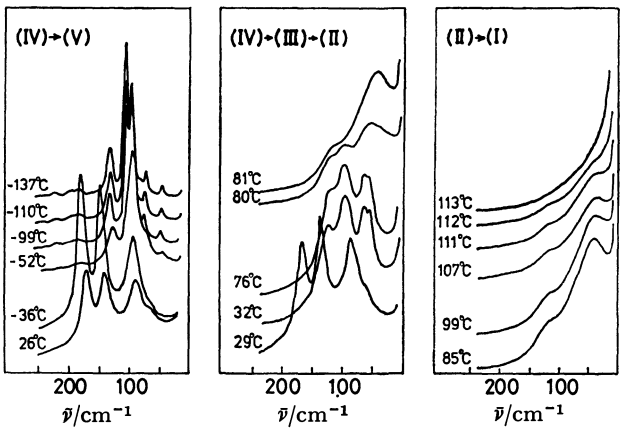

Fig. 3. Raman spectra of powdered samples at various temperatures in the low-frequency region.

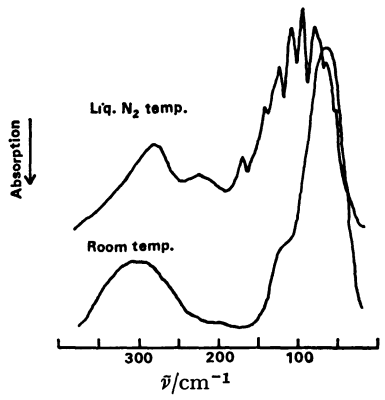

Fig. 4. Far infrared transmission spectrum of NH_4NO_3-(IV) (Nujol mull). This spectrum is recorded by the single-beam operation. The low transmissivity around 0 and 400 cm^{-1} is due to the efficiency of the beam-splitter.

assigned to the rotational lattice mode of NO_3^- ion about a-axis, while the 85 cm^{-1} (B_{2g}) and 139 cm^{-1} (B_{2g}) bands are assigned to the translational mode along c-axis and the rotational mode about b-axis, which are more or less coupled with each other. The B_{1g} rotational lattice mode about c-axis might be very weak since the polarizability does not change singnificantly for the rotation about an axis perpendicular to the NO_3 plane.

Other four weak bands 58 cm^{-1} (B_{1g}), 60 cm^{-1} (A_g), 90 cm^{-1} (A_g), and 220 cm^{-1} (B_{1g}) observed in the polarized spectra are assigned to the translational lattice modes. Among them the 220 cm^{-1} (B_{1g}) band is associated with the NH_4^+ translational mode, since in the Raman spectrum of KNO_3 no band is observed

around 200 cm^{-1}. Furthermore in the far infrared transmission spectrum shown in Fig. 4 a broad band around 200 cm^{-1} is observed, which also exists in the far infrared spectrum of NH_4Cl.

The Raman spectra at various temperatures in Fig. 3 reveal an abrupt spectral change in the phase transition as expected for a first order transition. This can be seen more clearly in the frequency change with temperature shown in Fig. 5.

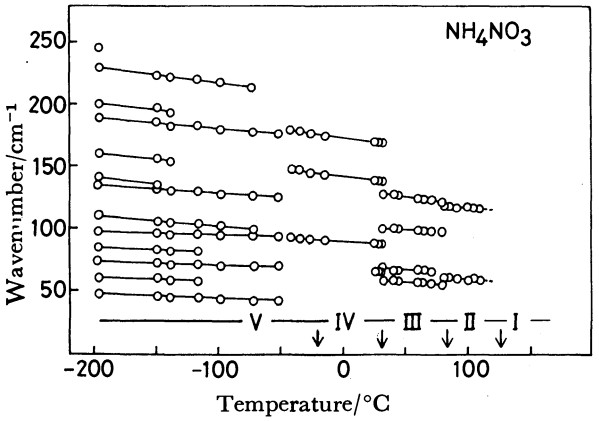

Fig. 5. Temperature dependence of Raman frequencies in NH_4NO_3.

First we discuss the spectra of high-temperature phases. Österlund and Rosen showed in their Raman spectra the phase III was not observed but the phase IV was converted directly to the phase II at 50 °C.[5] In our measurement the spectrum at 81 °C in Fig. 3(b) is considered to arise from the phase II. However, in the temperature range 32 °C—80 °C we have the spectrum which is different from those of both phase II and IV and this corresponds to the spectrum of phase III. The spectrum of phase III is also confirmed by the single crystal spectrum of NH_4NO_3–KNO_3 mixed crystal which takes the same structure as NH_4NO_3-(III).[11]

In the spectrum of phase II two bands are observed. As the temperature is raised these bands shift to lower frequency and show no anomalous behavior as the II→I transition is approached. Actually at 113 °C no band is observed. In the phase I, NO_3^-, and NH_4^+ groups are freely rotating and are described to have a spherical symmetry, resulting in the CsCl-type structure of NH_4NO_3(I). No Raman band is observed as expected from this structure.

Next we discuss the spectra of the low-temperature phase V. As seen in Figs. 3 and 5, an abrupt spectral change corresponding to the phase transition IV⇌V is observed around −50 °C, which is lower than the generally accepted temperature −18 °C. Probably a supercooling state is produced. The cooling rate in our measurement is ≈0.5 K/min. Our measurement is made down to 77 K but no evidence is found for another low-temperature phase VII. Our result at 77 K is in agreement with that at 11 K by Tang and Torrie,[6] who also could not find phase VII.

Table 2 summarizes the observed frequencies in various phases.

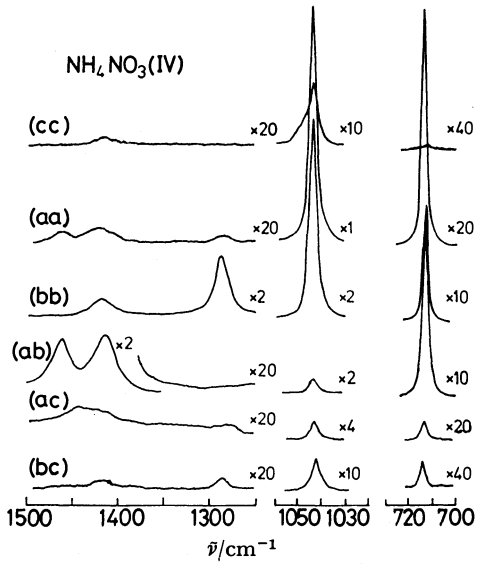

Fig. 6. Polarized Raman spectra of NH_4NO_3(IV) crystal in the internal vibration region.

Internal Vibrations of NO_3^- and NH_4^+ Ions. The polarized Raman spectra in the internal vibration region at room temperature are shown in Fig. 6, which can be interpreted based on D_{2h}[13] crystal symmetry. The correlation between the D_{3h} (NO_3^- free ion) and the D_{2h}[13] (NH_4NO_3 crystal) is as follows:

	$D_{3h}(NO_3^-$ ion)	C_{2v}(site sym.)	$D_{2h}^{13}(NH_4NO_3)$
A_1'	ν_1(≈1050 cm^{-1})	A_1	A_g+B_{3u}
A_2''	ν_2(≈ 830 cm^{-1})	B_2	$B_{2g}+B_{1u}$
E'	ν_3(≈1350 cm^{-1})	A_1	A_g+B_{3u}
	ν_4(≈ 720 cm^{-1})	B_1	$B_{1g}+B_{2u}$

As for NH_4^+ ion the following correlation exists:

	$T_d(NH_4^+$ ion)	C_{2v}(site sym.)	$D_{2h}^{13}(NH_4NO_3)$
A_1	ν_1'	A_1	A_g+B_{3u}
E	ν_2'	A_1	A_g+B_{3u}
		A_2	$B_{3g}+A_u$
F_2	ν_3'	A_1	A_g+B_{3u}
		B_1	$B_{1g}+B_{2u}$
	ν_4'(≈1450 cm^{-1})	B_2	$B_{2g}+B_{1u}$

In the spectra of Fig. 6, the 1043 cm^{-1} band (ν_1 : A_g) and the 715 cm^{-1} band (ν_4 : A_g) are observed as expected from the correlation diagram. The 715 cm^{-1} band is also observed in the (ab) scattering configuration, which corresponds to the $\nu_4(B_{1g})$.

In the region 1250 cm^{-1}—1500 cm^{-1}, the ν_3 of NO_3^- ion and ν_4' of NH_4^+ ion are expected. On referring to the correlation diagram, the 1289 cm^{-1} and 1418 cm^{-1} bands observed in the (bb) configuration are assigned to the $\nu_3(A_g)$ and $\nu_4'(A_g)$ respectively, and the 1415 cm^{-1} and 1461 cm^{-1} bands observed in the (ab) configuration are assigned to the $\nu_3(B_{1g})$ and $\nu_4'(B_{1g})$ respectively.

The splitting of the A_g and B_{1g} components of the ν_3 (asymmetric stretching mode of NO_3^- ion) in NH_4NO_3-(IV) is 126 cm^{-1}, which seems abnormally large

compared with $\approx 10\ cm^{-1}$ in KNO_3(II). In NH_4NO_3-(III) this splitting is $\approx 35\ cm^{-1}$ (see Table 2). In the NH_4NO_3–KNO_3 mixed crystals $(NH_4)_xK_{1-x}NO_3$ which will be discussed in the following paper, the ν_3 splitting is $\approx 40\ cm^{-1}$. The large splitting of ν_3 may be caused by the strong interionic interaction between NH_4^+ and NO_3^- ions. The neutron diffraction measurement by Choi *et al.* showed that in NH_4NO_3(IV) the hydrogen bond is formed between the hydrogen in NH_4^+ ion and one of the oxygens in NO_3^- ion.[12] This kind of hydrogen bond also exists in NH_4NO_3(V), which gives rise to the large splitting of ν_3 in the low-temperature phase V as observed by Tong and Torrie.[6] A crystallographic study suggests that the phase transition III⇌IV is related to the hydrogen bonding, which is reflected on the splitting of ν_3. James *et al.* suggested that the bands at $1289\ cm^{-1}$ and $1415\ cm^{-1}$ are the transverse and longitudinal components of ν_3 and the structure of phase IV is non-centric due to the observation of such a polar mode in the Raman spectrum.[7] However, their interpretation is highly unlikely since as seen in Fig. 6 polarized Raman spectra of single crystals for various scattering configurations do not reveal any TO/LO character and they can be interpreted based on D_{2h}^{13} structure as mentioned before.

In conclusion, the structural change can be sensitively probed by studying the Raman active lattice modes in the low-frequency region. An abrupt spectral change occurs in the phase transition, indicating a first order transition. The spectra of single crystals for the room-temperature phase IV, in the low-frequency region as well as in the internal vibration region, are reasonably interpreted based on D_{2h}^{13} structure.

A part of this investigation was supported by a grant of Yamada Science Foundation.

(Received December 15, 1980)

NH_4NO_3–KNO_3 mixed crystals, $(NH_4)_xK_{1-x}NO_3$ (x=0.88, 0.75, and 0.61), are prepared by evaporation of aqueous solutions of ammonium nitrate and potassium nitrate. Polarized Raman spectra of single crystals of mixed crystals are observed at room temperature and are interpreted based on the NH_4NO_3(III) type D_{2h}^{16} structure. Raman spectra of powdered samples are examined at various temperatures and it is shown that the NH_4NO_3-(IV) type phase which is a room-temperature phase of NH_4NO_3 is not realized in the mixed crystals. In $(NH_4)_{0.88}K_{0.12}NO_3$, NH_4NO_3(III) type is converted to NH_4NO_3(V) type around −120 °C. In the spectra of high-temperature phase of mixed crystals, only one broad band in the region 100 cm^{-1}—120 cm^{-1} is observed, which corresponds to KNO_3(I) or KNO_3(III) type structure.

In alkali nitrates, Rb and Cs salts, where the ionic radii of the cations are larger than that of K^+ ion, take the CsCl type structure at high temperatures as in NH_4NO_3, while Li and Na salts consisting of smaller cations take the distorted NaCl type structure. KNO_3 is ferroelectric in its phase III, which has not been known in other univalent nitrates. The ionic radius of NH_4^+ ion is slightly larger than that of K^+ ion, and the effect of the substitution of NH_4^+ ion for K^+ ion and the phase transition of NH_4NO_3–KNO_3 mixed crystals have been studied in relation to ferroelectricity.[1-4] It is considered that at high temperatures mixed crystals take the KNO_3(III) type structure, which is ferroelectric, as well as KNO_3(I) type, from the study on the temperature dependence of the lattice constant.[2,3] An X-ray crystallographic study showed that the room-temperature structure of mixed crystals is the NH_4NO_3-(III) type.[5] As for the low-temperature structure no crystallographic study has been reported.

On these backgrounds we attempted spectroscopic studies on the phase transition of NH_4NO_3–KNO_3 mixed crystals. In the preceding paper we studied Raman scattering and phase transition of NH_4NO_3 and clarified a characteristic spectral feature for each phase.[6] In the present investigation Raman spectra of single crystals of NH_4NO_3–KNO_3 mixed crystals at room temperature are studied and the structural changes at high temperatures are examined spectroscopically. Furthermore an elaborate measurement of temperature dependence of Raman spectra at low temperatures is made to find whether an abrupt spectral change associated with the phase transition exists, since so far no study has been done as to the phase transition at low temperatures.

Another objective of this study is to make a definite vibrational assignment of NH_4NO_3(III) for which single crystal spectra could not be obtained, by using the results of NH_4NO_3–KNO_3 mixed crystals of NH_4NO_3(III) type structure.

Experimental

$(NH_4)_xK_{1-x}NO_3$ mixed crystals were prepared by evaporation of aqueous solutions of ammonium nitrate and potassium nitrate of appropriate molar ratio in a desiccator at room temperature. The initial crops in each solution which precipitate in microcrystalline form were removed from this solution and subsequently single crystals began to grow. Thus uniform solid solutions of NH_4NO_3 and KNO_3 were obtained. All these crystals grew as a long needle whose axis coincides with the b-axis of the NH_4NO_3(III) type crystal. It was confirmed from the X-ray powder diffraction measurement that these mixed crystals have the same structure as that of NH_4NO_3(III). The molar ratio of mixed crystals was determined by chemical analysis.

In the preparation of $(NH_4)_xK_{1-x}NO_3$ mixed crystals by evaporation of aqueous solutions, the molar ratio (x) of NH_4NO_3 amounts to the value in the range $0.96>x>0.60$ for the produced crystals. The mixed crystals with the x value in the range $0.60>x>0.04$ are not produced from aqueous solutions at room temperature. (It is reported that the crystal with $x<0.04$ is isomorphous with KNO_3 (II)[1,5]).

We prepared the following three kinds of mixed crystals:

Molar ratio of NH_4NO_3 in aqueous solution	Molar ratio of NH_4NO_3 in mixed crystal
0.9	0.88
0.8	0.75
0.7	0.61

Spectral measurements were performed in the procedure described in the preceding paper.[6]

Results and Discussion

Temperature Dependence of Raman Spectra of Polycrystalline Samples. Figure 1 shows the Raman spectra of powdered samples of $(NH_4)_xK_{1-x}NO_3$ mixed crystals (x=0.88, 0.75, and 0.61) at room temperature, compared with those of NH_4NO_3 at 32°C, which corresponds to the spectrum of NH_4NO_3(III) as discussed in the preceding paper.[6] The spectra of the above three kinds of mixed crystals are similar to that of NH_4NO_3-(III), confirming the crystallographic conclusion that $(NH_4)_xK_{1-x}NO_3$ ($x>0.6$) at room temperature takes the NH_4NO_3(III) type structure with the space group D_{2h}^{16} (z=4).[5] Raman frequencies of $(NH_4)_{0.88}K_{0.12}NO_3$ at various temperatures in the process of cooling and heating from room temperature are shown in Fig. 2.

In the low-temperature spectra, a phase transition is found around −120 °C for $(NH_4)_{0.88}K_{0.12}NO_3$, while for the other two kinds of mixed crystals no sudden change in the spectra is found. Figure 3 shows the

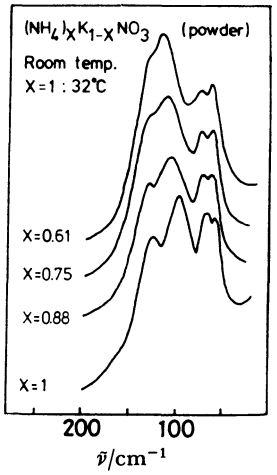

Fig. 1. Raman spectra of powdered samples of $(NH_4)_x$-$K_{1-x}NO_3$ mixed crystals at room temperature. For NH_4NO_3 ($x=1$) the spectrum at 32 °C is given.

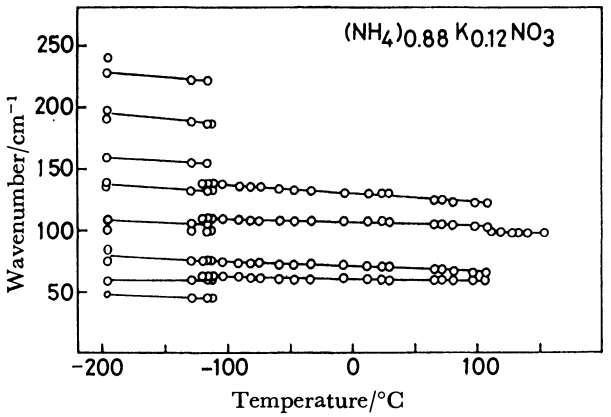

Fig. 2. Raman frequencies at various temperatures for $(NH_4)_{0.88}K_{0.12}NO_3$ mixed crystal.

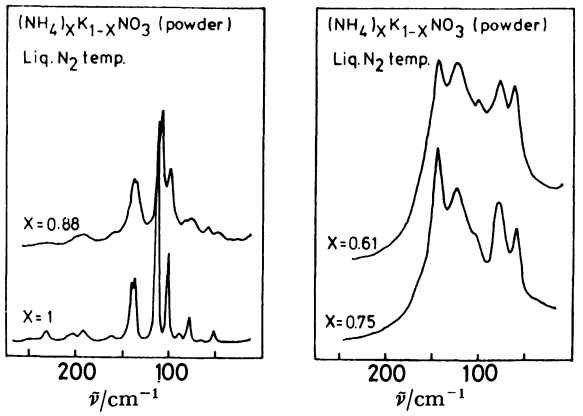

Fig. 3. Raman spectra of powdered samples of $(NH_4)_x$-$K_{1-x}NO_3$ mixed crystals at liquid-N_2 temperature.

Raman spectra at liquid-N_2 temperature. From Fig. 3(a), it is shown that the low-temperature phase of $(NH_4)_{0.88}K_{0.12}NO_3$ takes the NH_4NO_3(V) type structure (low-temperature phase of NH_4NO_3). It should be noted that in this mixed crystal NH_4NO_3(III) type→ NH_4NO_3(V) type phase transition occurs without passing through NH_4NO_3(IV) type structure unlike NH_4NO_3 crystal. As seen in Fig. 3(b), for the mixed crystals with $x=0.75$ and $x=0.61$, the room-temperature structure of NH_4NO_3(III) type is still retained at liquid-N_2 temperature. However, it might be possible that a supercooling state is produced in these mixed crystals.

Next we see the spectra of high-temperature phase. It is generally accepted that the following phase transitions exist in the mixed crystals at high temperature:[3]

$$NH_4NO_3(III)\ \text{type} \underset{75°C—115°C}{\overset{105°C—125°C}{\rightleftharpoons}}$$

$$KNO_3(III)\ \text{type} \underset{\approx 120°C}{\overset{\approx 130°C}{\rightleftharpoons}} KNO_3(I)\ \text{type}$$

The spectra of high-temperature phase are shown in Fig. 4. In the high-temperature spectra, only one broad band with the peak around 100 cm^{-1}—120 cm^{-1} is observed, which is assigned to the NO_3^- ion rotational lattice mode of C_{3v}^5 ($z=1$) or D_{3d}^5 ($z=1$) structure. KNO_3(I) type⇌KNO_3(III) type phase transition is not revealed in the spectra markedly.

Polarized Raman Spectra of Single Crystals. Figure 5 shows polarized Raman spectra of single crystals for $(NH_4)_xK_{1-x}NO_3$ mixed crystals at room-temperature in the low-frequency lattice vibration region. As the ratio of NH_4NO_3 decreases, the observed bands shift

to the higher frequency, which reflects the crystallographic result that the lattice constants become smaller. Table 1 summarizes the vibrational frequencies together with the mode assignments.

In NH_4NO_3(IV) crystal reported in the preceding paper, it was found that the lattice mode about a-axis of NO_3^- ion (R_a) is observed as a single band while that about b-axis (R_b) is accompanied by a band due to the translational lattice mode which is coupled with the rotational mode and strengthens its intensity. In the NH_4NO_3(III) type crystal a similar feature is seen, but somewhat in an approximate description. One of the oxygen atoms (O_1) in NO_3^- ion is located in the mirror plane in NH_4NO_3(III) crystal (refer to Fig. 1 of the preceding paper[6]). Although NO_1 is not exactly parallel to the a-axis of crystal, we designate approximately the rotational mode about the NO_1-axis, R_a, and that about the axis perpendicular to the NO_1-axis and in the NO_3^- plane, R_b. In the NH_4NO_3(III) type D_{2h}^{16} structure, R_a belongs to the B_{1g} and B_{3g} species and R_b to the A_g and B_{2g} species. As seen in Fig. 5, in the spectrum of the a scattering configuration (A_g), two strong bands are observed, while in the spectra of the ab (B_{1g}) and bc (B_{3g}) configurations one strong band is observed with a very weak band around 60 cm^{-1}. The spectral feature revealed in NH_4NO_3(IV) crystal and $(NH_4)_xK_{1-x}NO_3$ crystal of the NH_4NO_3(III) type, that the rotational lattice mode about a-axis is observed as a single band while that about b-axis coupled with the translational mode as two bands, is characteristic of the orthorhombic structure. In the crystals possessing C_3-axis perpendicular to NO_3^- plane, such as KNO_3(I), KNO_3(III), and $NaNO_3$(I) types, the rotational modes about a- and b-axes are degenerate

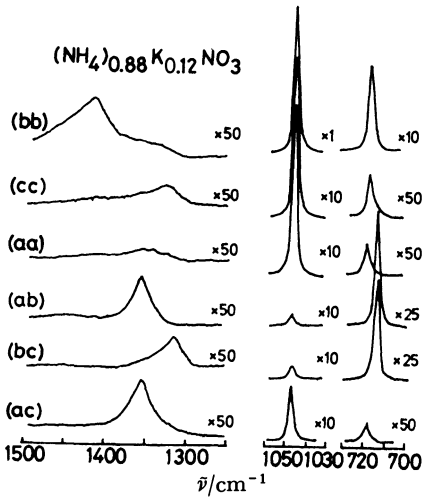

Fig. 6. Polarized Raman spectra of single crystals of $(NH_4)_{0.88}K_{0.12}NO_3$ mixed crystal (Internal vibration region).

and a single band corresponding to E_g species is observed, as seen in the high-temperature phase of mixed crystal.

Next we discuss briefly the polarized Raman spectra in the internal vibration region in Fig. 6. Based on the spectra of six kinds of scattering configurations, the observed bands are assigned straightforwardly to the symmetry species of D_{2h}^{16} factor group as shown in Table 1. The splitting of ν_3 (NO_3 asymmetric stretching mode) in mixed crystals is within $\approx$40 cm^{-1}, comparable with 35 cm^{-1} in NH_4NO_3(III), which indicates that in the NH_4NO_3(III) type structure no strong hydrogen bond is formed between NH_4^+ and NO_3^- ions unlike in the case of NH_4NO_3(IV) and NH_4NO_3(V) type structures.

To sum up, polarized Raman spectra of single crystals of mixed crystals at room temperature are interpreted based on the NH_4NO_3(III) type D_{2h}^{16} structure. In NH_4NO_3(III) itself single crystal spectra could not be obtained due to the crack of crystals at phase transition NH_4NO_3 IV→III. Therefore it is significant that a vibrational assignment of the spectra of powdered sample for NH_4NO_3(III) can be done on comparing with the single crystal spectra of mixed crystals at room temperature. The NH_4NO_3(IV) type phase which is a room-temperature phase of NH_4NO_3 is not realized in the mixed crystals. In some mixed crystals, the NH_4NO_3(III) type is converted directly to the NH_4NO_3-(V) type around −120 °C, without passing through the NH_4NO_3(IV) type. At high temperatures, only one broad band in the region 100 cm^{-1}—120 cm^{-1} is observed, which corresponds to KNO_3(I) or KNO_3(III) type structure.

The authors wish to express their sincere thanks to Prof. Takei, The Research Institute for Iron, Steel and Other Metals, Tohoku University, for permitting us to use X-ray diffractometer.

A part of this study is supported by a grant of Yamada Science Foundation.

(Received December 18, 1980)

Current doubling mechanism of the photoanodic reaction of sodium formate at the ZnO electrode is re-examined. Quantitative analysis of the reaction products revealed that ZnO electrode corroded during the current doubling reaction, which has not been previously reported. However, zinc ions were formed with about 50% of current efficiency. Carbon dioxide, instead of oxygen, was formed during the reaction. These experimental observations strongly suggested mechanism proposed by earlier workers were incorrect. A new mechanism is proposed.

The anodic photoreaction of a ZnO electrode in an inert electrolyte solution is known[1,2] as a dissolution reaction ($ZnO+2p^+ \rightarrow Zn^{2+}+1/2O_2$), in which the current efficiencies of Zn^{2+} dissolution and oxygen evolution are each 100%.

However, when formic acid, aldehydes or alcohols are added to the electrolyte solution, Morrison *et al.*[3-6] found that the anodic photocurrent of a ZnO single crystal doubled, and they proposed a current doubling mechanism. Subsequently, similar effects were reported on other semiconductor electrodes. Gerischer *et al.* observed[7,8] current doubling behavior on a single crystal CdS electrode when aldehydes or alcohols were added to the electrolyte. Tamura *et al.*[9,10] found that the photooxidation current for a TiO_2 single crystal electrode increased with the addition of alcohols. Bard *et al.*[11-15] studied the oxidation of acetate ions, both on an irradiated TiO_2 electrode and on TiO_2 powders, and they named the reaction the Photo-Kolbe Reaction. Using irradiated p-type GaP electrode, Memming showed[16,17] that $S_2O_8^{2-}$, H_2O_2, or *p*-benzoquinone were current-doubling agents under cathodic polarization.

According to the mechanism proposed by Morrison *et al.*,[3-6] holes formed by photoirradiation of an n-type semiconductor react with a current doubling agent R to give R^+, which then donates an electron to the conduction band and becomes R^{2+}. In this case, the dissolution reaction of ZnO is suppressed.

However, our preliminary study[18] with the ZnO electrode shows that while typical current doubling agents such as formate ion or ethyl alcohol made the photoanodic current increase, oxygen evolution could not be observed and zinc ions were detected in the electrolyte solution after photoelectrolysis. The quantity of zinc ions dissolved was almost equivalent to the quantity of holes flowing to the ZnO surface. These facts indicate that the current doubling effect may not always follow Morrison's mechanism.

In this paper we re-examine the mechanism of current doubling. Using a polycrystalline ZnO electrode and $HCOO^-$ as the current doubling agent, we present quantitative data on the magnitude of photocurrent, the amount of zinc ions dissolved, and the amount of oxygen and CO_2 formed.

Experimental

Polycrystalline ZnO Electrode. A polycrystalline ZnO pellet was made by pressing the powder (reagent grade) with a pressure of 0.5 t/cm^2 and then heating it for 3 h at 1300 °C in air.[19] Its diameter was 17 mm and the thickness about 2 mm. After an ohmic contact was made with an In–Ga alloy, a lead wire was connected with Silver Epoxy, and then all surfaces except one were covered with an epoxy resin.

Electrochemical Reaction on Illuminated Polycrystalline ZnO Electrode. Current-potential and photocurrent-time behavior of the ZnO electrode were measured with a potentiostat (Nikko Keisoku NPG 301), with a saturated calomel electrode as the reference electrode and platinum as the counter electrode. Irradiation was carried out with the light from a 500 W high pressure mercury lamp with a quartz lens and a filter (Toshiba Kasei UVD2) to pass wavelengths around 360±30 nm. The electrolyte contained Na_2SO_4 or KNO_3, and HCOONa was employed as a current doubling agent. A potassium nitrate agar salt bridge separated the cell compartments containing the ZnO and the Pt electrodes. All chemicals. were reagent grade. The experimental setup is shown in Fig. 1.

To elucidate the reaction mechanism, quantitative analyses of the products (Zn^{2+}, O_2, H_2O_2, and CO_2), which could be predicted by the photoanodic reactions on the ZnO electrode, were carried out, as follows: Zn^{2+} ions, which were formed as the result of photoanodic reaction of ZnO electrode, were quantitatively analysed photometrically[20] using the absorp-

tion peak (λ=570 nm) of complex between Zn^{2+} and Xylenol Orange at pH 6.0. The amount of dissolved oxygen was measured with an oxygen meter (Ishikawa Seisakusho DG) and a gas-chromatography (Ohkura Denki). The amount of CO_2 formed after photoelectrolysis was determined by making the electrolyte solution pH 12 with highly purified NaOH, then adding an aqueous $BaCl_2$ solution, and finally weighing the $BaCO_3$. For this measurement we used KNO_3 as the electrolyte. Hydrogen peroxide was quantitatively analyzed with permanganate.[21]

Results

The current-potential curves obtained using a polycrystalline ZnO electrode were almost the same as those obtained previously using a single crystal ZnO, as shown in Fig. 2. With addition of formate ions to the supporting electrolyte solution, a saturated photoanodic current increased.

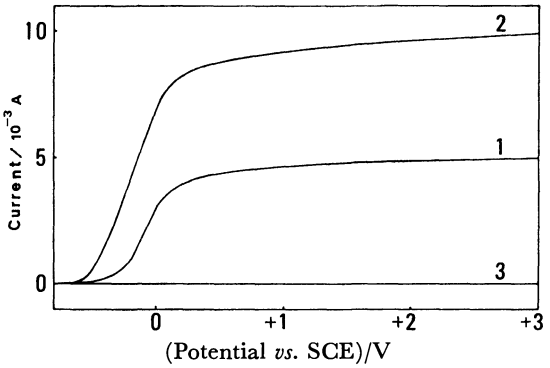

Fig. 2. The current-potential curves of a polycrystalline photoanode.
1: 0.4 M KNO_3, 2: 0.4 M HCOONa+0.4 M KNO_3 (1 M=1 mol dm^{-3}), 3: in dark.

Table 1 shows the results of photocurrent densities, current efficiencies of Zn^{2+}, oxygen, H_2O_2, and CO_2 formation. With addition of HCOONa, photocurrent increased up to almost twice. However, the amounts of dissolved Zn^{2+} were almost the same, that was, the current efficiencies of dissolution of Zn^{2+} were the half. Figure 3 shows amounts of dissolved Zn^{2+} and current efficiencies of Zn^{2+} against time. At any irradiation time current efficiencies were almost the half. This indicates that Zn^{2+} ions were dissolved in the equivalent

and without the presence of HCOONa, even photocurrent increased with it. On the other hand, with addition of concentrated HCOONa increase of oxygen was not observed, as shown in Table 1. The results of the quantitative analysis of dissolved oxygen versus time are shown in Fig. 4. The quantity of oxygen produced versus time upon irradiating the ZnO in 0.4 M KNO_3 and with a photocurrent $i=4.1\times10^{-3}$ A/cm^2 is shown in Curve 1. About the same oxygen versus time relationship was obtained without irradiation by substituting the ZnO electrode with a Pt electrode and with an oxidation current of 4.1×10^{-3} A/cm^2 (Curve 2). The latter conditions correspond to electrolysis of water. With the addition of HCOONa the photocurrent increased, and at a high enough concentration ($>10^{-2}$ M) the photocurrent was almost double the value obtained with the inert electrolyte alone. This addition of HCOONa decreased the rate of oxygen during photolysis to essentially zero as shown in Curve 3. Finally, a blank run was made without electrolysis but with irradiation of the ZnO electrode in an electrolyte, with or without HCOONa, and the results show essentially a zero oxygen evolution rate (Curve 4).

Formation of H_2O_2, which was reported by Hauffe and Range[22] during the photooxidation of ZnO electrode, was not detected with and without HCOONa, as shown in Table 1.

The amount of the formation of CO_2 was almost the half compared with the charge flowed, but nearly close to that calculated by the charge based on the increased part of photocurrent in the presence of HCOONa.

As shown in the last column in Table 1, we analyzed the products when iodide ions were added to the electrolyte solution. The photocurrent decreased to less than the value only in the supporting electrolyte, because iodine formed absorbed light quanta. Both current efficiencies of Zn^{2+} dissolved and CO_2 formation became to zero, and also increase of O_2 dissolved was not detected. The behavior can easily be understood[6] that holes formed in the valence band reacted preferentially with I^- ions, resulting in suppression of dissolution ZnO.

Discussion

According to Morrison's current doubling mechanism,[3-6] the holes formed by irradiation of a semiconductor react with $HCOO^-$, to give $H^\cdot$ and CO_2;

$$HCOO^- + p^+ \longrightarrow H^\cdot + CO_2. \quad (1)$$

The $H^\cdot$ formed as an intermediate donates an electron to the conduction band:

$$H^\cdot \longrightarrow H^+ + e^-. \quad (2)$$

Therefore, the net current doubling reaction is

$$HCOO^- + p^+ \longrightarrow H^+ + CO_2 + e^-. \quad (3)$$

Recently, Harbour and Hair,[23] using the spin trapping technique, detected $COO^\cdot$ as an intermediate of the photocatalytic reaction occurring on ZnO powder irradiated in an aqueous solution containing formate or oxalate ions. They proposed a new mechanism in which $COO^\cdot$ donated an electron to the conduction band as follows,

$$HCOO^- + p^+ \longrightarrow H^+ + COO^\cdot \quad (4)$$

$$COO^\cdot \longrightarrow CO_2 + e^-. \quad (5)$$

In this case the net reaction is the same as Eq. 3.

The above mechanisms assume that ZnO is not photooxidized to Zn^{2+}. However, the results in Table 1 show that we observed Zn^{2+} in the electrolyte solution after photoirradiation when the photocurrents was increased, even in the presence of $HCOO^-$. When $HCOO^-$ was present, the current efficiency of Zn^{2+} formation was about 0.5, but the current efficiency would be almost 1.0 if we used the same value of photocurrent observed without $HCOO^-$ addition.

Can we explain these facts from the Morrison's mechanism? One possibility is that the H^+ formed by Eq. 3 reacts chemically with the ZnO,

$$ZnO + 2H^+ \longrightarrow Zn^{2+}(aq) + H_2O. \quad (6)$$

However, it may be very difficult for H^+ formed on the ZnO surface to attack the ZnO lattice. In an alternative and more probable mechanism, an intermediate oxygen species, O*, which is assumed to be one of the intermediates of the simple dissolution reaction of ZnO, reacts with $HCOO^-$ to produce an active $\cdot COO^-$ radical;

$$ZnO + 2p^+ \longrightarrow Zn^{2+} + O^* \quad (7)$$

$$O^* + 2HCOO^- \longrightarrow 2COO^\cdot + H_2O. \quad (8)$$

Then, $COO^\cdot$ can donate an electron to the conduction band, as in Eq. 5,

$$2COO^\cdot \longrightarrow 2CO_2 + 2e^-. \quad (9)$$

By combining Eqs. 7, 8, and 9 we obtain the net reaction,

$$ZnO + 2p^+ + 2HCOO^- \longrightarrow Zn^{2+} + H_2O + 2CO_2 + 2e^-. \quad (10)$$

The experimental results shown in Table 1, *e.g.* the current efficiencies of the products Zn^{2+}, O_2, and CO_2, can be explained if Eq. 10 is valid for the current doubling effect. For example, with HCOONa present in solution, the current efficiencies for Zn^{2+} and CO_2 are observed to be almost 0.5, in accordance with the stoichiometry of Eq. 10.

Conclusion

Mechanism of current doubling reaction of formate ion was re-examined by using a polycrystalline ZnO photoanode. From the quantitative analyses of the products of the current doubling reaction, a new mechanism is proposed;

$$ZnO + 2p^+ + 2HCOO^- \longrightarrow Zn^{2+} + H_2O + 2CO_2 + 2e^-.$$

The ZnO electrode corrodes during the current doubling reaction.

Temperature Dependence of Thermal Positive Ion Production through Dissociation of Polyatomic Molecules

Hiroyuki KAWANO,* Yoshiaki HIDAKA, and Masao SUGA

Department of Chemistry, Faculty of Science, Ehime University, 2-5, Bunkyo-cho, Matsuyama 790

(Received August 6, 1980)

The production of a thermal positive ion (M^+) from a polyatomic molecule (MX) incident upon a heated metal surface is investigated theoretically as a function of surface temperature (T). The quantitative expression of the ion emission current (i^+) of M^+ at a constant incident flux (N) of MX is found to change according to the condition whether the work function (ϕ) of the surface is higher or lower than the first ionization energy (I) of M and also to the degree of dissociation (γ) of MX on the surface. Namely,

(1) When $\phi - I > 0$,

$$i^+ \approx \begin{cases} K_1 \text{ for } \gamma \approx 1. \\ K_2\, T^{-1/4} \exp\left[\dfrac{\phi - I - D}{2\,R\,T}\right] \text{ for } \gamma \ll 1. \end{cases}$$

(2) When $\phi - I < 0$,

$$i^+ \approx \begin{cases} K_3 \exp\left[\dfrac{\phi - I}{R\,T}\right] \text{ for } \gamma \approx 1. \\ K_4\, T^{-1/4} \exp\left[\dfrac{\phi - I - D/2}{R\,T}\right] \text{ for } \gamma \ll 1. \end{cases}$$

Here D is the bond dissociation energy of MX and K's are virtually independent of T. In any other cases i^+ cannot be expressed in such a simple form. The particular temperature regions corresponding to $\gamma \approx 1$ or $\gamma \ll 1$ are evaluated for given sets of N, D, I, and ϕ.

When a beam of an atom (M) with a small value of the first ionization energy (I(M)) is impinged upon a positively biased metal surface at a high temperature, a positive ion (M^+) is emitted after attaining the following equilibrium on the surface.

$$M \rightleftharpoons M^+ + e^-. \tag{1}$$

This phenomenon is usually called thermal positive ion emission or positive surface ionization, and has long been investigated both experimentally and theoretically by great many workers. Nowadays, in consequence, it is generally accepted that the ionization coefficient (α^+(M)) of M is described by Saha-Langmuir's equation.[1,2]

$$\alpha^+(M) \equiv \frac{n(M^+)}{n(M)} = \frac{w^+}{w^0} \exp\left[\frac{\phi - I(M)}{R\,T}\right]. \tag{2}$$

Here $n(M^+)$ and $n(M)$ are the numbers of M^+ and M emitted per unit time from unit surface area, respectively, w^+/w^0 the statistical weight ratio of M^+ to M, ϕ the work function of the surface, R the gas constant, and T the absolute temperature of the surface. The enthalpy change (ΔH_1) due to the surface reaction ($M \rightarrow M^+ + e^-$) is equal to $-(\phi - I(M))$, which is naturally included in Eq. 2. The ionization efficiency is usually given by

$$\beta^+(M) \equiv \frac{n(M^+)}{N(M)} = \sigma(M) \frac{n(M^+)}{n(M) + n(M^+)}$$

$$= \sigma(M) \frac{\alpha^+(M)}{1 + \alpha^+(M)}, \tag{3}$$

where N(M) and σ(M) are the incident flux per unit time per unit surface area and the accommodation coefficient of M, respectively.

The ion current collected with a Faraday cage is generally expressed by

$$i^+(M) = e\,S\,\eta(M^+)\,N(M)\,\beta^+(M). \tag{4}$$

Here e, S, and $\eta(M^+)$ are the elementary electric charge, the area of the ionizing surface, and the collection efficiency of M^+, respectively. Substitution of Eqs. 3 and 2 in Eq. 4 yields

$$i^+(M) \approx \begin{cases} C_1 \text{ for } \alpha^+(M) \gg 1. & (5) \\ C_1 \left[1 + \dfrac{w^0}{w^+} \exp\left[\dfrac{\Delta H_1}{R\,T}\right]\right]^{-1} \text{ for neither} \\ \quad \alpha^+(M) \gg 1 \text{ nor } \alpha^+(M) \ll 1. & (6) \\ C_1 \dfrac{w^+}{w^0} \exp\left[\dfrac{-\Delta H_1}{R\,T}\right] \text{ for } \alpha^+(M) \ll 1. & (7) \end{cases}$$

Here C_1 is given by

$$C_1 \equiv e\,S\,\eta(M^+)\,\sigma(M)\,N(M). \tag{8}$$

Clearly the quantitative expression of i^+(M) changes according to the value of α^+(M), and it is ΔH_1, of course, that is included in the Boltzmann factor governing the thermal positive ion production from the incident atom M. When $\alpha^+(M) \gg 1$, however, i^+(M) is virtually independent of both ΔH_1 and T, as shown by Eq. 5. When α^+(M) is neither much larger nor much smaller than unity, Eq. 6 indicates that the slope of an emission plot ($\log i^+(M)$ *vs.* $1/T$) is not constant. On the other hand, such a plot as is based on Eq. 7 yields a straight line, the gradient (G) of which is equal to $-(0.434/R)\,\Delta H_1$. Only when $\alpha^+(M) \ll 1$, therefore, it is possible to determine I(M)[3-5] or ϕ[6-9] from G.

Such emission of the positive ion M^+ is observed also when a beam of a molecule (MX) including the same element M impinges upon the surface. In the case of this molecular beam incidence, however, M^+ is emitted after attaining Equilibria (9) and (1) on the ionizing surface, and the ion production processes are more complicated than those in the case of the atomic beam incidence described above.

$$MX \rightleftharpoons M + X. \tag{9}$$

The enthalpy change (ΔH_2) due to the surface reaction

($MX \rightarrow M^+ + X + e^-$) is equal to $-(\phi - I(M) - D(MX))$, where $D(MX)$ is the bond dissociation energy of MX. The temperature dependence of the collected ion current ($i^+(MX)$) of M^+ thus produced from MX has long been investigated experimentally by many workers.[1,2] The theoretical investigation of the dependence, however, has not yet fully been made, and a quantitative expression of $i^+(MX)$ as a function of T seems not to be derived theoretically or empirically by any workers. Consequently, the quantitative relation between $i^+(MX)$ and ΔH_2 also seems to be left unknown, in contrast to the case of the atomic beam incidence described above. From analogy with Eqs. 6 and 7, it may possibly be inferred that none other than ΔH_2 can be included in the Boltzmann factor governing the production of M^+ from MX. The validity of this inference, however, should be checked rigorously on the basis of thermochemistry. Previously one of the present authors made a theoretical study of thermal negative ion production from incident molecules.[10,11] A theoretical model developed in the previous work may probably be useful for solving the above problems, too.

From the viewpoints described above, the present authors have applied the theoretical model to the thermal positive ion production from polyatomic molecules. In consequence, they have found that $i^+(MX)$ is expressed as a function of T by seven different equations according to the ionization coefficient and to the degree of dissociation of MX, and also that the Boltzmann factors in some of the equations include ΔH_1, $\Delta H_2/2$, or $(\Delta H_1 + \Delta H_2)/2$, as opposed to the above inference that ΔH_2 alone is included.

This paper describes the theoretical investigation leading to the above findings and also illustrates an application of the present theory to several sample–surface systems.

Theoretical

Expression of the Ionization Coefficient. In a similar way as in the previous work,[10,11] let us consider an isothermal airtight metal vessel, inside of which Equilibria (9) and (1) exist. If the density of the charged particles is so small that the space-charge effect may be neglected, then Eqs. 10—12 are derived from thermochemical considerations.

$$\frac{P(M)\,P(X)}{P(MX)} = \frac{f(M)\,f(X)}{f(MX)} \exp\left[\frac{-D(MX)}{R\,T}\right]. \quad (10)$$

$$\frac{P(M^+)\,P(e^-)}{P(M)} = \frac{f(M^+)f(e^-)}{f(M)} \exp\left[\frac{-I(M)}{R\,T}\right]. \quad (11)$$

$$P(e^-) = f(e^-) \exp\left[\frac{-\phi}{R\,T}\right]. \quad (12)$$

Here $P(Y)$ and $f(Y)$ are the equilibrium vapor pressure and the partition function, respectively, of the particle Y, and ϕ is the work function of the surface of the vessel.

The flux of Y evaporating per unit time from a unit area of the surface is given by

$$J(Y) = \frac{N_A P(Y)}{\{2\pi M(Y)\,R\,T\}^{1/2}}, \quad (13)$$

where N_A and $M(Y)$ are Avogadro's number and the molecular (or atomic) weight of Y, respectively. In surface ionization, however, free evaporation occurs in a vacuum. Strictly speaking, therefore, $P(Y)$ should be corrected with a factor of the evaporation coefficient ($\varepsilon(Y)$).[12] Consequently, the flux of Y emitted from an ionizing surface is

$$n(Y) = \varepsilon(Y)\,J(Y). \quad (14)$$

From Eqs. 10—14 we obtain Eqs. 15—17.

$$\frac{n(M)\,n(X)}{n(MX)} = \frac{N_A \rho(MX)}{\{2\pi\mu R\,T\}^{1/2}} \exp\left[\frac{\Delta S^\circ(MX)}{R}\right] \times \exp\left[\frac{-D(MX)}{R\,T}\right]. \quad (15)$$

$$\alpha^+(MX) \equiv \frac{n(M^+)}{n(M)} = C_2 \exp\left[\frac{\phi - I(M)}{R\,T}\right]. \quad (16)$$

$$C_2 \equiv \rho(M) \exp\left[\frac{\Delta S^\circ(M)}{R}\right]. \quad (17)$$

Here $\Delta S^\circ(MX)$ and $\Delta S^\circ(M)$ are the standard entropy changes due to the dissociation and the positive ion production, respectively; and $\rho(MX)$, $\rho(M)$, and μ are given by $\varepsilon(M)\,\varepsilon(X)/\varepsilon(MX)$, $\varepsilon(M^+)/\varepsilon(M)$, and $M(M) \times M(X)/M(MX)$, respectively. Essentially C_2 is equal to w^+/w^0 because Eq. 2 is derived on the implicit assumption $\rho(M)=1$. If the flux of MX or M impinging separately upon the same ionizing surface is so small that ϕ may be regarded essentially constant without being affected by adsorption of MX or M, then the ionization coefficient $\alpha^+(MX)$ given by Eq. 16 is equal to $\alpha^+(M)$ by Eq. 2.

Under such a steady-state condition that all of the particles evaporate from the ionizing surface immediately after attaining Equilibria (9) and (1) on the surface, the following relations hold.

$$n(M) + n(M^+) = n(X) = \sigma(MX)\,\gamma(MX)\,N(MX). \quad (18)$$

$$n(MX) = \{1-\gamma(MX)\}\,\sigma(MX)\,N(MX). \quad (19)$$

Here $\sigma(MX)$ is the accommodation coefficient of MX incident upon the ionizing surface, and represents the fraction of the MX molecules attaining Equilibria (9) and (1) on the surface. Namely,

$$\sigma(MX) \equiv \frac{n(MX) + n(M) + n(M^+)}{N(MX)}. \quad (20)$$

The ionization efficiency is given by

$$\beta^+(MX) \equiv \frac{n(M^+)}{N(MX)} = \sigma(MX)\,\gamma(MX)\,\frac{\alpha^+(MX)}{1+\alpha^+(MX)}. \quad (21)$$

Eqs. 16 and 18 yield

$$n(M) = \frac{\sigma(MX)\,\gamma(MX)\,N(MX)}{1+\alpha^+(MX)}. \quad (22)$$

By substituting Eqs. 18, 19, and 22 in Eq. 15, we obtain

$$\frac{\gamma(MX)^2}{1-\gamma(MX)} = \{1+\alpha^+(MX)\}\,B, \quad (23)$$

or

$$\gamma(MX) = \frac{\{1+\alpha^+(MX)\}B}{2} \times \left[\left\{1 + \frac{4}{\{1+\alpha^+(MX)\}B}\right\}^{1/2} - 1\right]. \quad (24)$$

Here

$$\begin{cases} B \equiv b\ T^{-1/2} \exp\left[\dfrac{-D(\mathrm{MX})}{R\ T}\right]. & (25) \\ b \equiv \dfrac{N_{\mathrm{A}}\ \rho(\mathrm{MX})}{\sigma(\mathrm{MX})\ N(\mathrm{MX})\{2\pi\mu R\}^{1/2}} \exp\left[\dfrac{\Delta S^{\circ}(\mathrm{MX})}{R}\right]. & (26) \end{cases}$$

Again, it should be noted that Eq. 2 is based upon simplifying assumptions such as $\rho(\mathrm{M})=1$ and $\sigma(\mathrm{M})=1$ but is nevertheless approved widely as a quantitative expression of $\alpha^{+}(\mathrm{M})$ in usual surface ionization, where the electric field drawing out M^{+} from the surface is so weak that Schottky effect may be neglected. When potassium halide molecules impinge upon a rhenium surface, for example, $\beta^{+}(\mathrm{KX})$ is virtually unity in the range 1200—1900 K.[13] This result may give evidence that both $\sigma(\mathrm{KX})$ and $\rho(\mathrm{KX})$ are essentially unity in the above cases. In addition, cesium chloride molecules are completely accommodated on both iridium and carburized iridium surfaces.[14]

Judging from the experimental results described just above, it may be reasonable at least with alkali halide molecules to regard that both $\sigma(\mathrm{MX})$ and $\rho(\mathrm{MX})$ are virtually unity in usual surface ionization. In a narrow temperature range usually covered in positive surface ionization, therefore, b given by Eq. 26 may be regarded essentially constant for a constant value of $N(\mathrm{MX})$.

Expression of the Ion Emission Current. The ion current collected with a Faraday cage is expressed by Eq. 27, which is derived from Eq. 21.

$$\begin{aligned} i^{+}(\mathrm{MX}) &= e\,S\,\eta(\mathrm{M}^{+})\ N(\mathrm{MX})\ \beta^{+}(\mathrm{MX}) \\ &= C_3\,\gamma(\mathrm{MX})\,\frac{\alpha^{+}(\mathrm{MX})}{1+\alpha^{+}(\mathrm{MX})}, \end{aligned} \quad (27)$$

where C_3 is

$$C_3 \equiv e\,S\,\eta(\mathrm{M}^{+})\ \sigma(\mathrm{MX})\ N(\mathrm{MX}). \quad (28)$$

Since C_3 may be regarded constant for a fixed value of $N(\mathrm{MX})$, it is essentially upon $\gamma(\mathrm{MX})$ and $\alpha^{+}(\mathrm{MX})$ that $i^{+}(\mathrm{MX})$ depends. First, therefore, Eq. 27 will be treated as a function of $\gamma(\mathrm{MX})$.

(A) Equation 24 indicates that $\gamma(\mathrm{MX})\approx 1$ when $\{1+\alpha^{+}(\mathrm{MX})\}B \gg 4$. In this case Eq. 27 becomes

$$i^{+}(\mathrm{MX}) \approx C_3\,\frac{\alpha^{+}(\mathrm{MX})}{1+\alpha^{+}(\mathrm{MX})}. \quad (29)$$

In usual surface ionization the measurement of $i^{+}(\mathrm{MX})$ is accompanied with an error of about $\pm 5\%$, and hence a prerequisite for Eq. 29 may be written down

$$\gamma(\mathrm{MX}) \gtrsim 0.95 \text{ or } \{1+\alpha^{+}(\mathrm{MX})\}\,B \gtrsim 18. \quad (30)$$

(B) When $\gamma(\mathrm{MX}) \ll 1$, Eq. 23 reduces to

$$\gamma(\mathrm{MX}) \approx [\{1+\alpha^{+}(\mathrm{MX})\}\,B]^{1/2}. \quad (31)$$

Substitution of Eq. 31 in Eq. 27 yields

$$i^{+}(\mathrm{MX}) \approx C_3\,B^{1/2}\,\frac{\alpha^{+}(\mathrm{MX})}{\{1+\alpha^{+}(\mathrm{MX})\}^{1/2}}. \quad (32)$$

Consideration of the experimental error mentioned above leads to the conclusion that a prerequisite for Eq. 32 may be set up

$$\gamma(\mathrm{MX}) \approx [\{1+\alpha^{+}(\mathrm{MX})\}\,B]^{1/2} \lesssim 0.098. \quad (33)$$

(C) When $\gamma(\mathrm{MX})$ is intermediate, namely,

$$0.95 > \gamma(\mathrm{MX}) > 0.098 \text{ or}$$
$$18 > \{1+\alpha^{+}(\mathrm{MX})\}\,B > 0.0095, \quad (34)$$

$i^{+}(\mathrm{MX})$ cannot be approximated adequately in such a simple form as in Eq. 29 or 32. In this case, $i^{+}(\mathrm{MX})$ is expressed in a complex form by Eq. 35, which is obtained by substituting Eqs. 16 and 24 in Eq. 27.

$$i^{+}(\mathrm{MX}) = C_4 T^{-1/2}\,\mathrm{F}(T) \exp\left[\frac{\phi - I(\mathrm{M}) - D(\mathrm{MX})}{R\ T}\right]. \quad (35)$$

Here

$$\begin{cases} C_4 \equiv \dfrac{e\,S\,\eta(\mathrm{M}^{+})\ N_{\mathrm{A}}\,\rho(\mathrm{M})\ \rho(\mathrm{MX})}{2\{2\pi\ \mu\ R\}^{1/2}} \\ \qquad \times \exp\left[\dfrac{\Delta S^{\circ}(\mathrm{M}) + \Delta S^{\circ}(\mathrm{MX})}{R}\right], & (36) \\ \mathrm{F}(T) \equiv \left[1 + \dfrac{4}{\{1+\alpha^{+}(\mathrm{MX})\}\,B}\right]^{1/2} - 1. & (37) \end{cases}$$

It should be noted that Eq. 35 holds not approximately but exactly for any values of $\gamma(\mathrm{MX})$ and $\alpha^{+}(\mathrm{MX})$.

Consideration of the Ionization Coefficient. Secondly, let us treat $i^{+}(\mathrm{MX})$ as a function of $\alpha^{+}(\mathrm{MX})$.

(A) Equation 16 indicates that $\alpha^{+}(\mathrm{MX})$ is much larger than unity when $\phi - I(\mathrm{M}) \gtrsim 10$ kcal mol^{-1}. Because $R\ T$ is less than about 3 kcal mol^{-1} in a temperature range (1100—1800 K) usually covered in positive surface ionization, and also because C_2 is about 1/2 for alkali metal or its salt, which is the most typical sample material in positive surface ionization. Under the above condition we obtain Eqs. 38 and 39 from Eqs. 29 and 32, respectively, while no simple equation other than Eq. 35 holds for the intermediate values of $\gamma(\mathrm{MX})$.

$$i^{+}(\mathrm{MX}) \approx \begin{cases} C_3 \text{ for } \gamma(\mathrm{MX}) \gtrsim 0.95. & (38) \\ C_4\ T^{-1/2}\,\mathrm{F}(T) \exp\left[\dfrac{\phi - I(\mathrm{M}) - D(\mathrm{MX})}{R\ T}\right] \\ \quad \text{for } 0.95 > \gamma(\mathrm{MX}) > 0.098. & (35) \\ C_5\ T^{-1/4} \exp\left[\dfrac{\phi - I(\mathrm{M}) - D(\mathrm{MX})}{2\ R\ T}\right] \\ \quad \text{for } \gamma(\mathrm{MX}) \lesssim 0.098. & (39) \end{cases}$$

Here C_5 is

$$C_5 \equiv \frac{e\,S\,\eta(\mathrm{M}^{+})\,\{N_{\mathrm{A}}\,\sigma(\mathrm{MX})\ N(\mathrm{MX})\ \rho(\mathrm{M})\ \rho(\mathrm{MX})\}^{1/2}}{\{2\ \pi\ \mu\ R\}^{1/4}} \times \exp\left[\frac{\Delta S^{\circ}(\mathrm{M}) + \Delta S^{\circ}(\mathrm{MX})}{2\ R}\right]. \quad (40)$$

(B) Under the condition that $\phi - I(\mathrm{M}) \lesssim -10$ kcal mol^{-1}, $\alpha^{+}(\mathrm{MX})$ in the usual temperature range is negligibly small compared with unity, and hence Eqs. 41 and 42 are obtained from Eqs. 29 and 32, respectively. Similarly as in the case (A) described just above, it is only Eq. 35 that holds for the intermediate values of $\gamma(\mathrm{MX})$.

$$i^{+}(\mathrm{MX}) \approx \begin{cases} C_6 \exp\left[\dfrac{\phi - I(\mathrm{M})}{R\ T}\right] \text{ for } \gamma(\mathrm{MX}) \gtrsim 0.95. & (41) \\ C_4\ T^{-1/2}\,\mathrm{F}(T) \exp\left[\dfrac{\phi - I(\mathrm{M}) - D(\mathrm{MX})}{R\ T}\right] \\ \quad \text{for } 0.95 > \gamma(\mathrm{MX}) > 0.098. & (35) \\ C_7\ T^{-1/4} \exp\left[\dfrac{\phi - I(\mathrm{M}) - D(\mathrm{MX})/2}{R\ T}\right] \\ \quad \text{for } \gamma(\mathrm{MX}) \lesssim 0.098. & (42) \end{cases}$$

Here C_6 and C_7 are given by Eqs. 43 and 44, respectively.

$$C_6 \equiv e\,S\,\eta(\mathrm{M}^{+})\ \sigma(\mathrm{MX})\ N(\mathrm{MX})\ \rho(\mathrm{M}) \exp\left[\frac{\Delta S^{\circ}(\mathrm{M})}{R}\right]. \quad (43)$$

$$C_7 \equiv \frac{e S \eta(M^+) \rho(M) \{N_A \rho(MX) \sigma(MX) N(MX)\}^{1/2}}{\{2 \pi \mu R\}^{1/4}} \times \exp\left[\frac{\Delta S^\circ(M) + \Delta S^\circ(MX)/2}{R}\right]. \quad (44)$$

(C) When $|\phi - I(M)| < 10$ kcal mol^{-1}, the condition that neither $\alpha^+(MX) \gg 1$ nor $\alpha^+(MX) \ll 1$ holds in the usual temperature range so long as the allowable error due to approximation is restricted to less than about $\pm 5\%$. In this case, $i^+(MX)$ is expressed as follows:

$$i^+(MX) \approx \begin{cases} C_6\, G(T) \exp\left[\dfrac{\phi - I(M)}{R\,T}\right] \\ \quad \text{for } \gamma(MX) \gtrsim 0.95. \quad (45) \\ C_4\, T^{-1/2}\, F(T) \exp\left[\dfrac{\phi - I(M) - D(MX)}{R\,T}\right] \\ \quad \text{for } 0.95 > \gamma(MX) > 0.098. \quad (35) \\ C_7\, T^{-1/4}\, G(T)^{1/2} \exp\left[\dfrac{\phi - I(M) - D(MX)/2}{R\,T}\right] \\ \quad \text{for } \gamma(MX) \lesssim 0.098. \quad (46) \end{cases}$$

Here $G(T)$ is given by

$$G(T) \equiv \left[1 + C_2 \exp\left[\frac{\phi - I(M)}{R\,T}\right]\right]^{-1}. \quad (47)$$

Equations 45 and 46 are derived from Eqs. 29 and 32, respectively. So long as $|\phi - I(M)| < 10$ kcal mol^{-1}, therefore, $i^+(MX)$ cannot be expressed in such a simple form as in Eq. 38, 39, 41, or 42.

Evaluation of the Degree of Dissociation. For the reasons described just below Eq. 26, the factors $\sigma(MX)$, $\rho(M)$, and $\rho(MX)$ may be assumed to be unity, and hence Eqs. 48—50 may be obtained from Eqs. 23—26.

$$\frac{\gamma(MX)^2}{1 - \gamma(MX)} \approx \frac{2.67 \times 10^{25}}{N(MX)\{\mu T\}^{1/2}} \times \exp\left[\frac{\Delta S^\circ(MX)}{R}\right] \exp\left[\frac{-D(MX)}{R\,T}\right] \times \begin{cases} 1 \text{ for } \alpha^+(MX) \ll 1. \quad (48) \\ \left\{1 + \exp\left[\dfrac{\Delta S^\circ(M)}{R}\right] \exp\left[\dfrac{\phi - I(M)}{R\,T}\right]\right\} \\ \quad \text{for neither } \alpha^+(MX) \ll 1 \text{ nor } \alpha^+(MX) \gg 1. \quad (49) \\ \exp\left[\dfrac{\Delta S^\circ(M)}{R}\right] \exp\left[\dfrac{\phi - I(M)}{R\,T}\right] \text{ for } \alpha^+(MX) \gg 1. \quad (50) \end{cases}$$

Here the first figure on the right hand side includes the factor 1.013×10^6, which is necessary because the entropy changes refer to a standard gaseous state for $P(Y) = 1$ atm. At $\alpha^+(MX) \gg 1$, $\gamma(MX)$ depends strongly upon ϕ in contrast to the other cases, as may be easily understood from Eqs. 48—50. Obviously Eq. 50 is $\exp[\{\phi - I(M) + \Delta S^\circ(M)\, T\}/R\, T]$ times as large as Eq. 48, thereby indicating that the dissociation of MX is promoted at $\alpha^+(MX) \gg 1$. In a high temperature range where $\gamma(MX)$ is close to unity, of course, $\gamma(MX)$ is virtually independent of the factors such as $N(MX)$, $D(MX)$, $I(M)$, and ϕ included in Eqs. 48—50, as will be illustrated below (see Fig. 1).

To take concrete examples, let us consider that a beam of NaF strikes single crystal surfaces of Mo(100), W(100), W(110), and Ir(111), the work functions of which are

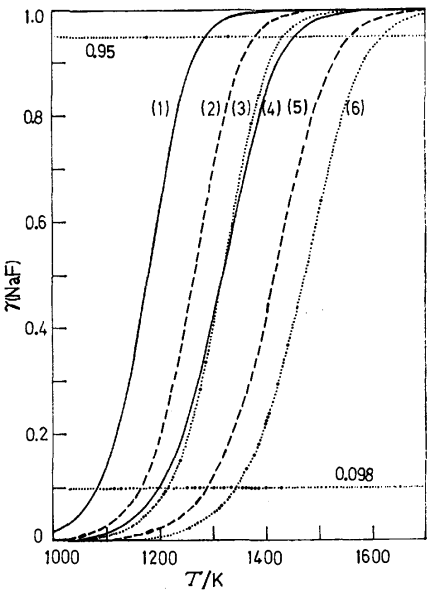

Fig. 1. Temperature dependence of the degree of dissociation of NaF on several surfaces.

a) The values of $\alpha^+(NaF)$ calculated for 1100—1800 K by using Eq. 16. b) The equation employed to evaluate the boundary temperatures.

100,[15] 105,[15] 124,[16] and 132[17] kcal mol^{-1}, respectively. Since I(Na) is 118 kcal mol^{-1}, it is concluded from Eq. 16 in the usual temperature range (1100—1800 K) that α^+(NaF)$\ll$1 for both Mo(100) and W(100), that α^+(NaF)$\gg$1 for Ir(111), and that α^+(NaF) is intermediate for W(110). The values of γ(NaF) at various temperatures are calculated with the above surfaces by using Eqs. 48—50. The thermochemical data for $\Delta S°$(Na), $\Delta S°$(NaF), and D(NaF) are cited from Refs. 18 and 19. The results thus obtained for γ(NaF) are shown in Fig. 1. The boundary temperatures ($T_{0.098}$ and $T_{0.95}$) corresponding to γ(NaF)=0.098 and 0.95, respectively, at N(NaF)=10^{10} or 10^{12} molecules cm^{-2} s^{-1} may be read off in Fig. 1. The temperatures thus evaluated are summarized in Table 1, which shows that both $T_{0.098}$ and $T_{0.95}$ depend upon N(NaF) and also upon α^+(NaF) unless α^+(NaF) is much smaller than unity. The three temperature regions ($T\lesssim T_{0.098}$, $T_{0.098}<T<T_{0.95}$, and $T\gtrsim T_{0.95}$) are hereafter referred to as T_L, T_M, and T_H, respectively. As may be seen in Fig. 1, γ(NaF) at $T\gtrsim$1700 K is essentially constant at about unity without depending upon both N(NaF) and the nature (ϕ) of the ionizing surface employed. In the temperature range below about 1600 K, however, γ(NaF) at N(NaF)=constant depends upon ϕ unless α^+(NaF)$\ll$1, as already stated above.

Therefore, the following results (A)—(C) are obtained when the present theory as to molecular beam surface ionization is applied to the above sample-surface systems at N(NaF)=10^{12} molecules cm^{-2} s^{-1}.

(A) For the NaF-Ir(111) system where α^+(NaF)$\gg$1,

$$i^+(\mathrm{NaF})\approx\begin{cases} C_3 \text{ at } T_H\gtrsim 1450 \text{ K.} & (38)\\ C_4\,T^{-1/2}\,F(T)\exp\left[\dfrac{-\Delta H_2}{RT}\right] & \\ \quad \text{at } 1450>T_M>1200 \text{ K.} & (35)\\ C_5\,T^{-1/4}\exp\left[\dfrac{-\Delta H_2}{2RT}\right] \text{ at } T_L\lesssim 1200 \text{ K.} & (39)\end{cases}$$

(B) For the NaF-Mo(100) or NaF-W(100) system where α^+(NaF)$\ll$1,

$$i^+(\mathrm{NaF})\approx\begin{cases} C_6\exp\left[\dfrac{-\Delta H_1}{RT}\right] \text{ at } T_H\gtrsim 1620 \text{ K.} & (41)\\ C_4\,T^{-1/2}\,F(T)\exp\left[\dfrac{-\Delta H_2}{RT}\right] & \\ \quad \text{at } 1620>T_M>1340 \text{ K.} & (35)\\ C_7\,T^{-1/4}\exp\left[\dfrac{-\Delta H_1-\Delta H_2}{2RT}\right] & \\ \quad \text{at } T_L\lesssim 1340 \text{ K.} & (42)\end{cases}$$

(C) For the NaF-W(110) system where neither α^+(NaF)$\gg$1 nor α^+(NaF)$\ll$1,

$$i^+(\mathrm{NaF})\approx\begin{cases} C_6\,G(T)\exp\left[\dfrac{-\Delta H_1}{RT}\right] \text{ at } T_H\gtrsim 1560 \text{ K.} & (45)\\ C_4\,T^{-1/2}\,F(T)\exp\left[\dfrac{-\Delta H_2}{RT}\right] & \\ \quad \text{at } 1560>T_M>1290 \text{ K.} & (35)\\ C_7\,T^{-1/4}\,G(T)^{1/2}\exp\left[\dfrac{-\Delta H_1-\Delta H_2}{2RT}\right] & \\ \quad \text{at } T_L\lesssim 1290 \text{ K.} & (46)\end{cases}$$

Characteristics of the Emission Plots. All of the factors C_1—C_7 in the above equations are virtually independent of T because, σ, ρ, and $\Delta S°$ may be regarded constant in a narrow temperature range usually covered in positive surface ionization and also because N is usually kept constant throughout the course of a run. On the other hand, both $F(T)$ and $G(T)$ depend upon T. The characteristics of an emission plot ($\log i^+$(M) *vs.* $1/T$) for atomic beam surface ionization is already outlined below Eq. 8. Similarly those for molecular beam surface ionization will be summarized in this section.

Equation 35 indicates that an emission plot of $\log[i^+(\mathrm{MX})\,T^{1/2}]$ *vs.* $1/T$ does not yield a straight line in the region T_M, irrespectively of the value of α^+(MX). Also when α^+(MX) is neither much smaller nor much larger than unity, no straight line is obtained in any temperature range if $\log i^+$(MX) or $\log[i^+(\mathrm{MX})\,T^{1/4}]$ is plotted against $1/T$, as may readily be understood from Eq. 45 or 46. In the case of α^+(MX)$\ll$1, on the other hand, the emission plots ($\log i^+$(MX) *vs.* $1/T$ and $\log[i^+(\mathrm{MX})\,T^{1/4}]$ *vs.* $1/T$) owing to Eqs. 41 and 42, respectively, yield straight lines except in T_M so long as ϕ is constant in the temperature range covered in a run. The gradients of the plots are equal to $-(0.434/R)\times\Delta H_1$ and $-(0.434/R)(\Delta H_1+\Delta H_2)/2$ in the ranges T_H and T_L, respectively. Similarly the gradients in the case α^+(MX)$\gg$1 are constant for a constant value of ϕ and are equal to null and $-(0.434/R)\,\Delta H_2/2$ in T_H and T_L, as may be proved from Eqs. 38 and 39, respectively. In any case, therefore, the gradient of an emission plot ($\log[i^+(\mathrm{MX})\,T^n]$ *vs.* $1/T$ where n=0, 1/4, or 1/2) is never equal to $-(0.434/R)\,\Delta H_2$ in any temperature range. If $\log[i^+(\mathrm{MX})\,T^{1/2}/F(T)]$ instead of $\log[i^+(\mathrm{MX})\times T^{1/2}]$ is plotted against $1/T$, on the other hand, a straight line is obtained even in T_M when ϕ is constant, and its gradient is equal to $-(0.434/R)\,\Delta H_2$, as may readily be concluded from Eq. 35. In a similar way, straight lines with a different slope are obtained in T_H and T_L if $\log[i^+(\mathrm{MX})/G(T)]$ and $\log[i^+(\mathrm{MX})\,T^{1/4}/G(T)^{1/2}]$ are plotted against $1/T$ according to Eqs. 45 and 46, respectively. For making the plots, however, the accurate values of N(MX), ΔH_2, $\Delta S°$(MX), and $\Delta S°$(M) and of ΔH_1 and $\Delta S°$(M) are required to evaluate $F(T)$ and $G(T)$, respectively.

These characteristics of the above various emission plots should be taken into consideration when an experiment of molecular beam surface ionization is made to confirm the present theory or to determine ϕ, I(M), or D(MX).

Experimental Confirmation of the Present Theory. In this section the conclusions derived theoretically in this work will be compared with experimental results obtained by other workers in order to verify the present theory.

When α^+(MX) is much larger than unity and also γ(MX) is essentially unity, β^+(MX) defined by Eq. 21 is virtually unity and hence i^+(MX) is independent of T, just as concluded by Eq. 38. This conclusion may be supported strongly by the experimental result that i^+(MX) is essentially constant in a high temperature region when a molecular beam of alkali halide (KCl,

KBr, KI, or CsCl) impinges upon a surface of Re[13] or Pt.[20]

In the cases other than both $\alpha^+(MX)\gg1$ and $\gamma(MX)\approx1$, the characteristics of the plots described in the preceding section may afford a quite simple method to experimentally confirm the present theory. Namely, the gradient determined experimentally under a certain condition (*e.g.*, $\alpha^+(MX)\gg1$ and $\gamma(MX)\ll1$) may be expected virtually equal to the value (*e.g.*, $-(0.434/R)\,\Delta H_2/2$) predicted by the corresponding theoretical conclusion (*e.g.*, Eq. 39).

When atomic and molecular beams including a common alkali element (Li, Na, or K) impinges separately upon the same polycrystalline surface (Re, Ir, or Pt), the temperature dependence of $i^+(MX)$ shows a strong resemblance to that of $i^+(M)$ in a region above a certain temperature (T_C).[20-22] A similar result is obtained with potassium halide–tungsten systems.[23] These results may suggest with the region that (a) $\gamma(MX)$ is approximately unity, (b) the temperature dependence of both $i^+(MX)$ and $i^+(M)$ is governed by the common Boltzmann factor including ΔH_1, and hence (c) $i^+(MX)$ is expressed by Eq. 41 or 45 at $T\gtrsim T_C$. Below T_C, on the other hand, a large difference in temperature dependence appears between $i^+(MX)$ and $i^+(M)$, and this difference is concluded to arise from incomplete dissociation of MX.[21,22] Unfortunately the experimental data reported in Refs. 20—23 are not available enough to obtain a definite answer to the question whether the gradient of the emission plot such as $\log[i^+(MX)\ T^{1/2}/F(T)]$ *vs.* $1/T$ or $\log[i^+(MX)\ T^{1/4}]$ *vs.* $1/T$ is equal to that predicted by the present theory. Firstly because the accurate value of ϕ below T_C is unknown, and secondly because the quantitative relation between $i^+(MX)$ and T in each run is not described in detail but is shown roughly in a figure where a relative value of $i^+(MX)$ is plotted against T. In addition, the comparison of T_C with $T_{0.95}$ is not useful for confirming experimentally the present theory because there is no evidence that the value of ϕ in the ranges both above and below T_C is constant and also identical between the atomic and molecular beam surface ionizations. The workers[20-23] have neither employed single crystal surfaces nor tried to plot $\log[i^+(MX)\ T^n]$ against $1/T$ for each of the sample–surface systems under study. Accordingly, they seem to have eliminated the possibility of finding the following consequences (a)—(c); when ϕ remains unchanged in the whole temperature range investigated in a run, (a) the plot shows a line having constant, inconstant, and constant gradients in the high, middle, and low temperature regions (T_H, T_M, and T_L), respectively, and hence (b) the quantitative expression of $i^+(MX)$ changes according to the condition $\gamma(MX)\gtrsim0.95$, $0.95>\gamma(MX)>0.098$, or $\gamma(MX)\lesssim0.098$, and also (c) the boundary temperatures ($T_{0.95}$ and $T_{0.098}$) depend largely upon $D(MX)$ and $N(MX)$ in the case $\alpha^+(MX)\ll1$ but strongly upon ΔH_2 and $N(MX)$ in the case $\alpha^+(MX)\gg1$.

It should be emphasized that a clean surface of single crystal is homogeneous with respect to ϕ and that the value of ϕ effective for thermal positive ion emission is equal to that for thermal electron emission, in contrast to a polycrystalline surface.[8,12,17,24] Therefore, the possible dependence of ϕ upon T during sample beam incidence upon the single crystal surface under study may be checked definitely by monitoring electron emission current soon after and/or before running positive surface ionization. In other words, the value of ϕ or its change may be determined from a Richardson plot without depending upon any datum obtainable from a Saha-Langmuir plot. This merit of single crystal over polycrystal may be quite helpful for confirming experimentally the theoretical predictions made in this work.

In conclusion, none of the published experimental data that are known to the present authors is available for confirming sufficiently the present theory as to the temperature dependence of $i^+(MX)$ especially in the region $T<T_{0.95}$.

Conclusions

The theoretical investigation described above may be summarized as follows:

(1) In usual positive surface ionization where $N(MX)$ is kept constant during the study of temperature dependence, the quantitative expression of $i^+(MX)$ varies according to the values of both $\gamma(MX)$ and $\alpha^+(MX)$, and hence to the temperature region T_L, T_M, or T_H.

(2) When $\alpha^+(MX)\gg1$ and also $\gamma(MX)\ll1$, $i^+(MX)$ is a function of both $T^{-1/4}$ and the Boltzmann factor, the numerator of which is not $-\Delta H_2$ but $-\Delta H_2/2$. Consequently, the gradient of an emission plot ($\log[i^+(MX)\ T^{1/4}]$ *vs.* $1/T$) in the region T_L is equal to $(0.434/R)\{\phi - I(M) - D(MX)\}/2$.

(3) In such a high temperature region that $\gamma(MX)$ may be estimated to be essentially unity, it is not ΔH_2 but ΔH_1 that is included in the Boltzmann factor governing the production of M^+ from MX, and hence temperature dependence of $i^+(MX)$ is essentially the same to that of $i^+(M)$ when ϕ is virtually identical between the atomic and molecular beam surface ionizations under study.

(4) When both $\alpha^+(MX)\ll1$ and $\gamma(MX)\ll1$, $i^+(MX)$ is proportional to both $T^{-1/4}$ and the Boltzmann factor, the numerator of which is neither $-\Delta H_1$ nor $-\Delta H_2$ but is $-(\Delta H_1+\Delta H_2)/2$. In consequence, the gradient of a plot ($\log[i^+(MX)\ T^{1/4}]$ *vs.* $1/T$) is equal to $(0.434/R)\times\{\phi - I(M) - D(MX)/2\}$.

(5) When neither $\gamma(MX)\approx1$ nor $\gamma(MX)\ll1$, $i^+(MX)$ cannot be expressed by a simple equation, and a plot ($\log[i^+(MX)\ T^{1/2}]$ *vs.* $1/T$) does not show a straight line in the region T_M even if $\alpha^+(MX)\gg1$ or $\alpha^+(MX)\ll1$.

(6) When neither $\alpha^+(MX)\gg1$ nor $\alpha^+(MX)\ll1$, $i^+(MX)$ is not expressed in a simple form, and hence the gradient of a plot ($\log[i^+(MX)\ T^n]$ *vs.* $1/T$ where $n=0$, 1/2, or 1/4) is not constant in any temperature region (T_H, T_M, or T_L).

(7) Under any condition the gradient of a plot ($\log[i^+(MX)\ T^n]$ *vs.* $1/T$) is never equal to $-(0.434/R)\times\Delta H_2$.

(8) Under the condition that (a) $\alpha^+(MX)\gg1$ and

$\gamma(MX) \ll 1$, (b) $\alpha^+(MX) \ll 1$ and $\gamma(MX) \approx 1$, or (c) $\alpha^+(MX) \ll 1$ and $\gamma(MX) \ll 1$, either ϕ or $I(M)$ can be determined from the gradient (G) of a plot ($\log[i^+(MX) \times T^n]$ *vs.* $1/T$) while such a determination in atomic beam surface ionization is available only at $\alpha^+(M) \ll 1$. Determination of $D(MX)$ from G, however, can be made under the condition (a) or (c) alone.

(9) For $\alpha^+(MX) \ll 1$, $\gamma(MX)$ is essentially independent of the value of $\alpha^+(MX)$. In any other cases, however, $\gamma(MX)$ increases with increase in $\alpha^+(MX)$.

To the best of the present authors' knowledge, neither theoretical nor experimental investigation arriving at the above conclusions (1)—(9) except (3) has yet been carried out.

Electrochemical Fixation of Molecular Nitrogen on p-Type Gallium Phosphide Photocathode

Masashi KOIZUMI, Hiroshi YONEYAMA,* and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received September 11, 1980)

Electrochemical fixation of molecular nitrogen to ammonia and hydrazine at p-type GaP photocathodes was studied in nonaqueous electrolytes containing either one of titanium tetraisopropoxide, titanium trichloride, vanadium trichloride, or chromium trichloride and a trace amount of water. Positive evidences for the nitrogen fixation were obtained in these electrolytes, but the current efficiency was quite low, and usually less than 1%. It is suggested from the present study that there are a variety of choices of electrolyte systems for the nitrogen fixation.

The fixation of molecular nitrogen to ammonia and hydrazine under mild ambient conditions has been an important subject in chemical research fields. The most intensive studies have been done on nitrogen fixation *via* nitrogen complexes, which are summarized in a recent review.[1]

The fixation of N_2 by a photoelectrochemical process was reported in 1978 by Dickson and Nozik,[2] who used an electrolyte system reported by Van Tamelen and his coworkers,[3-5] *i.e.*, titanium tetraisopropoxide in 1,2-dimethoxyethane(glyme) which was originated from previous studies on nitrogen fixation *via* nitrogen metallo-organic complexes.[3] An essential component of the electrolyte is judged to be titanium tetraisopropoxide which can bind and ionize N_2 when reduced to a divalent species in the course of the electrolysis. Electrochemical fixation of N_2 was also reported to be possible if N_2 is subjected to a silent discharge prior to bubbling into aqueous electrolytes of sulfuric acid or potassium hydroxide,[6] but this approach should be excluded from nitrogen fixation under mild conditions.

It is known from redox potentials of $Ti^{3+/4+}$ and $Ti^{2+/0}$ in aqueous solutions[7] that Ti(II) is a strong reducing agent. The Ti(II) species originated from titanium tetraisopropoxide in glyme must also have a high reducing power. The idea has then developed that from an electrochemical point of view the chemical species having a reducing power comparable to that of the Ti(II) species may work effectively to fix N_2. We tested Cr(II), V(II) as well as Ti(II), and found that nitrogen fixation is possible on illuminated p-type GaP cathodes with assistance of these reducing agents. Although obtained current efficiencies for the nitrogen fixation were very low, the results obtained in the present study suggested that there are a variety of choices of solvent–electrolyte systems to fix N_2 by the photoelectrochemical process.

Experimental

1,2-Dimethoxyethane (glyme), propyrene carbonate (PC), methanol, acetonitrile, and *N,N*-dimethylformide (DMF) were chosen as the solvent of electrolytes into which $AlCl_3$ as an indifferent electrolyte and either one of the redox agents, $Ti[OCH(CH_3)_2]_4$, $TiCl_3$, VCl_3, or $CrCl_3$ were dissolved. In the case $CrCl_3$, $CrCl_2$ was also dissolved in a small amount to raise its solubility. We arbitrarily chose the concentration of the redox agent to be 10 mmol per 50 ml of the solvent. However, the solubility was often found to be too low to satisfy this standard, necessitating the use of a much lower concentration. The solubility of $AlCl_3$ was also often too low in the presence of the redox agents of the chloride form to dissolve 15 mmol to 50 ml of the redox solutions. Among the solvents used, PC, with which major experiments of the present study were carried out, was purified first by passing through molecular sieve 3A columns, then by twice distillation under 5—10 mmHg (1 mmHg=133.332 Pa). Methanol and acetonitrile were distilled before use. The other solvents were used without purification of commercially available reagent grade chemicals.

An Al plate and a p-type GaP wafer were used as an anode and a cathode, respectively. The preparation of the GaP cathode, the area of which was *ca.* 0.5 cm^2, was already reported.[8] The electrolytic cell made of quartz was equipped with a water cooled jacket, gas inlet and outlet. The electrode was set in a sealed cell with a silicone rubber stopper which positioned *ca.* 2 cm above the electrolyte. An electrolyte bridge was inserted into the electrolytic cell through the stopper from an air-tight another cell which was filled with the same electrolyte. An electrical connection between the latter cell and an SCE reference was made by using a salt bridge. By placing the one more cell between the electrolytic cell and the reference electrode, probable contamination from the reference electrode was believed to decrease.

All the insertion points of the stopper were sealed with silicone rubber cement to keep the cell assembly air-tight. N_2 was bubbled into the electrolyte after purification with a flow rate of *ca.* 5 ml/min. The purification was done by successively passing N_2 through an alkaline pyrogallol solution, sulfuric acid, water, a column packed with $CaCl_2$ and a column packed with silica gel. Prior to flowing into the electrolyte, the nitrogen gas was pre-saturated with the same solvent as used in the electrolyte. The effluent gas from the cell was passed through a 0.05 mmol dm^{-3} H_2SO_4 trap before exiting to atmospheres. Light from an 1 kW xenon lamp was focused to a diameter of *ca.* 15 mm by using a glass lenz, by which light of wavelengths longer than 350 nm struck on the electrolytic cell. The intensity of the beam was *ca.* 2 W, as determined by a power meter (Coherent Radiation, model 201), and water at room temperatures was flowed through the water-cooled jacket to prevent evaporation of the electrolyte.

Ammonia was analyzed by the method of Kruse and Mellon.[9] Both the electrolyte and the acid trap was analyzed. For this purpose, the electrolyte was protonated with 20 ml of 0.05 mol dm^{-3} H_2SO_4 under air-tight conditions. A known portion of the solution was subjected to distillation in a micro-Kjeldahl apparatus after adding 10 ml of 30% NaOH to the acidified solution. The ammonia in the distillates was collected in 0.05 mol dm^{-3} H_2SO_4, and its amount was determined. The solution in the acid trap was also subjected to the almost same distillation. Hydrazine was determined for the protonated electrolyte solutions. By adding 30% NaOH

to the acidified solution, metal salts in the solution precipitated. After the filtration, the hydrazine in the filtrate was determined with *p*-dimethylaminobenzaldehyde.[10]

The current efficiency η for the formation of NH_3 and N_2H_4 was determined by using Eq. 1;

$$\eta = \frac{\text{Moles of } NH_3(N_2H_4) \text{ produced}}{\dfrac{\text{Coulombs consumed in the electrolysis}}{69480 \times 3\,(4)}}. \quad (1)$$

Results and Discussion

Ammonia Production in Glyme Containing Three Different Redox Agents. In order to investigate whether or not the combination of glyme and titanium tetraisopropoxide is essential as the electrolyte solution to fix N_2 to NH_3, glyme solutions containing $TiCl_3$ and VCl_3 were tested. Current-potential curves of the Al anode and the p-type GaP cathode are shown in Fig. 1, from which it is shown that the onset potential of the anode was negative of that of the illuminated cathode, indicating that photoelectrochemical cells can be constructed. The principal anodic reaction is the dissolution of Al, and the oxidation of the reduced form of the redox electrolyte, which is produced at the illuminated cathode as its main reaction, must be superposed on the dissolution reaction of the anode. The main reaction at the individual electrode is then given by Eqs. 2 and 3;

$$\text{Al anode: } Al = Al^{3+} + 3e^- \quad (2)$$

$$\text{p-type Gap cathode: } 3Ox + 3e^- = 3R \quad (3)$$

where Ox and R represent an oxidant and a reductant of a redox couple, respectively. When the photoelectrochemical cell was operated under short-circuited conditions, the initial photocurrent usually decreased with illumination time, suggesting that the electrode potential of the p-type GaP cathode varied under the short-circuited conditions. In order to eliminate ambiguities introduced by such a nonsteady behavior of photocurrents, experiments were carried out under potentiostatic control.

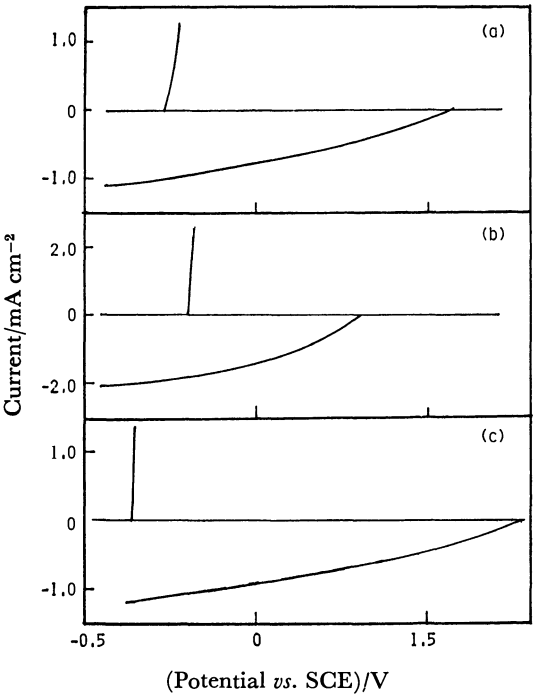

Fig. 1. Current-potential curves for photoelectrochemical cells using an Al anode and a p-type GaP cathode in three kinds of glyme solutions. Electrolyte; (a): 0.5 mol dm^{-3} $Ti[OCH(CH_3)_2]_4$ and 0.75 mol dm^{-3} $AlCl_3$, (b): 0.2 mol dm^{-3} $TiCl_3$ and 0.3 mol dm^{-3} $AlCl_3$, and (c): 0.07 mol dm^{-3} VCl_3 and 0.06 mol dm^{-3} $AlCl_3$.

Table 1 shows results obtained in glyme solutions. In the first row of the table, the results for titanium tetraisopropoxide are given. This electrolyte was already used by Dickson and Nozik.[2] The results for $TiCl_3$ and VCl_3 electrolytes are shown in the second and third rows, from which it is known that ammonia is produced in these electrolytes with a rate almost comparable to that in the titanium tetraisopropoxide electrolyte. Since there is no doubt concerning nitrogen fixation with the electrolyte of glyme–titanium tetraisopropoxide,[2] the glyme–$TiCl_3$ and glyme–VCl_3 electrolytes must also be effective for nitrogen fixation, even though the produced amount was very tiny.

The current efficiency for the formation of ammonia was quite low for all the glyme solutions used. A large fraction of the charge given in the table must have been consumed to reduce the oxidizing agents of the redox couples, *i.e.*, Ti(III) to Ti(II) for $TiCl_3$, V(III) to V(II) for VCl_3, and Ti(IV) to Ti(II) *via* Ti(III) for titanium tetraisopropoxide. If a Pt cathode was used instead of the p-type GaP, no fixation of N_2 was found to occur, as shown in the fourth row of Table 1, suggesting that photosensitization seems to be important for nitrogen fixation.

Nitrogen Fixation Using a Variety of Redox Solutions. In order to catch information on whether or not glyme is essential as the solvent of electrolytes, $TiCl_3$ solutions in different media were tested. As the media, aqueous 0.05 mol dm^{-3} H_2SO_4, methanol and PC were chosen. Results obtained for these electrolytes are shown from the second to fourth rows of Table 2. In the case of the aqueous electrolyte, the hydrogen evolution preferen-

tially took place, as judged from occurring no color change of the electrolyte, resulting in no nitrogen fixation. On the other hand, methanol and PC solutions containing $TiCl_3$ were found to be effective for nitrogen fixation, although the current efficiencies of these electrolytes were very low. In these electrolytes, the color of electrolytes which are characteristics of dissolved Ti(III) were gradually changed in the course of electrolysis. Then, the suggestion was given that the divalent state of the redox agents is necessary for nitrogen fixation to occur. When analyses of hydrazine were made for a $TiCl_3$–PC solution, a positive result for its formation was obtained, as shown in Table 2. It is known from positive results on nitrogen fixation in glyme, methanol and PC solutions that the nature of the solvent does not play a primarily important role in determining whether or not nitrogen fixation takes place.

The results mentioned above give the suggestion that there are a variety of choices for combinations of solvents and electrolytes to fix N_2 in photoelectrochemical processes at p-type GaP cathodes. In order to have experimental evidences for this, additional experiments were performed. Results obtained are summarized from the fifth to eighth rows of Table 2. In the cases of DMF and acetonitrile solutions, it was found that these solvents brought about errors in the determined amounts of NH_3 in the distillates due to contribution of nitrogen originated from the solvent molecules. By this reason, the results for these solutions were obtained only for the acid trap. It is noticed from the obtained results that nitrogen fixation is possible in all the nonaqueous electrolytes tested.

Effects of the Concentration of Electrolyte on Nitrogen Fixation. The current efficiency for the formation of ammonia was investigated as a function of the electrolyte concentration. PC was chosen as the solvent and $TiCl_3$ and $AlCl_3$ as the electrolytes. The molar ratio of $TiCl_3$ to $AlCl_3$ was arbitarily fixed to 2/3. The electrolysis was conducted for 2 d at potentials almost equal to those obtained under short-circuited conditions of the photoelectrochemical cells, which were influenced by the electrolyte concentration as suggested in the captions of Fig. 2. Figure 2 shows the current efficiency for ammonia production (the ordinate in the left hand side) and photocurrents obtained in the initial stage of the electrolysis (the ordinate in the right hand side) as a function of the electrolyte concentration. The magnitude of the cathodic photocurrent in the initial stage of electrolysis was affected by the electrolyte concentration. The current value decreased gradually from those shown in this figure with polarization time probably due to some change in surface conditions of the electrode, as already mentioned. Nevertheless, Fig. 2 gives a strong suggestion that the current efficiency for ammonia production increases with decreasing the cathodic photocurrent.

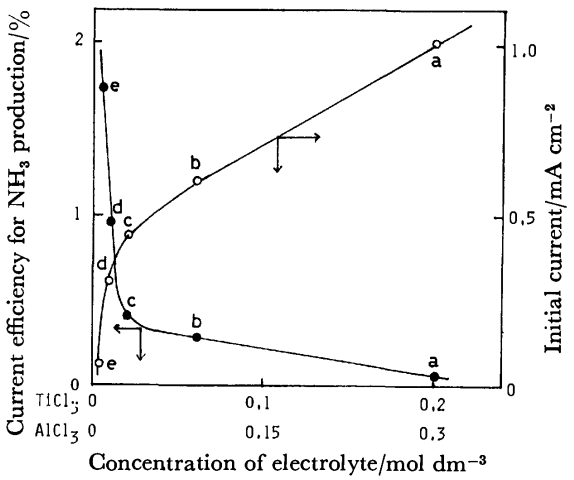

Fig. 2. Effects of the electrolyte concentration in PC solutions on the current efficiency for NH_3 production and initial photocurrent at the p-type GaP cathode at potentials close to those obtained under short-circuited conditions. The potential (V *vs.* SCE); a: −0.3 V, b: −0.3 V, c: −0.2 V, d: −0.2 V, and e: −0.5 V.

Such a dependency of the current efficiency for ammonia production on the magnitude of cathodic photocurrent will be obtained if either one of the following conditions is fulfilled. (1) N_2 is easily reduced but its solubility is so low that the rate of N_2 reduction is determined by mass transport control of N_2. Since the photocurrent is increased with an increase in the electrolyte concentration due to high reducibility of the redox agents, the current efficiency is decreased with

increasing the electrolyte concentration. (2) The concentration of N_2 in the electrolyte is relatively high, but the amount of reducible N_2, which may be bound to the reduced form of the redox agents, is quite low so that the supply of the reducible N_2 to the electrode is limited. In this case, the current efficiency depends on the electrolyte concentration as in the case (1). (3) The rate of the electrochemical reduction of N_2 is quite low and hence almost fixed at a fixed polarization potential regardless of the electrolyte concentration. Since the photocurrent is increased with increasing the electrolyte concentration, the current efficiency decreases in the electrolyte concentration.

No one will believe that the first case is valid. It is well known that nitrogen molecuoes are very stable. Furthermore, it was ascertained that the concentration of dissolved N_2 in the electrolyte was in a range of that usually chosen in kinetic studies of electroactive species. For example, a gas chromatographic analysis of N_2-saturated PC, which was carried out by using a molecular sieve 5A column at 180 °C, showed that the solubility of N_2 is 5.6 mmol dm^{-3}. Such a solubility will be high enough to give an photocurrent of an order of mA cm^{-2} if N_2 were easily reduced, as judged from the reduction of oxygen in aqueous solution which has a comparable solubility, *i.e.*, *ca.* 12 mmol dm^{-3}. As a result, if the case (1) is valid, a much larger current efficiency should be obtained.

As already shown above, V(II), Ti(II), and Cr(II) can assist the reduction of N_2 at illuminated GaP cathodes. This seems to imply that there is some interaction of N_2 with the reduced form of the redox agents. However, the interaction will not be so high as to destroy the N–N bond in a nitrogen molecule, because if the bond breaking would occur, no photosensitization at the GaP cathode would be required for nitrogen fixation. In order to investigate whether or not the case (2) is the most important rate controlling factor, experiments were carried out in electrolytes containing a relatively high amount of the reducing agents. The amount of N_2 bound to the reduced form of the redox agents, if any, must be proportional to the concentration of the reducing agent. If the case (2) is valid, therefore, the current efficiency will be high for an electrolyte rich in the reductant. The experiments were carried out in $AlCl_3$–PC solutions into which either $TiCl_3$ or VCl_3 was dissolved, and the solutions were pre-electrolyzed by using an Al anode and a Pt or an illuminated p-type GaP cathode to prepare Ti(II) or V(II) in the solutions. When the GaP cathode was used, the pre-electrolysis was conducted under Ar atmospheres. By the pre-electrolysis, the electrolytes changed their color, indicating that the reduced form of the redox agents became rich. At this stage, the p-type GaP cathode was polarized under illumination in the prepared electrolytes into which N_2 was continuously bubbled. Results obtained in these experiments are shown in Table 3. According to this table, the current efficiency for production of ammonia was not increased by the pre-electrolysis of the electrolytes, suggesting that the concentration of N_2 bound to the reductant, if any, does not affect significantly on the reduction of N_2. It follows then that the case (3) seems to be most probable as the rate controlling factor for the electrochemical reduction of N_2.

Effects of Water as an Impurity in the Electrolyte on the Production of Ammonia. As a proton source of the ammonia formation, attention was focused to water dissolved in the electrolytes. It was shown by the Karl-Fischer titration method that $TiCl_3$–PC solutions contained 0.29 mg of water for 1 ml of 0.02 mol dm^{-3} $TiCl_3$ and 0.20 mg for the same volume of 0.01 mol dm^{-3} $TiCl_3$. These contents correspond to the water concentration of 0.016 and 0.011 mol dm^{-3}, respectively. If 1 ml of water was intentionally added to 50 ml of the solution, the water concentration increased to 1.1 mol dm^{-3}. According to results obtained by using these aquated PC solutions, the current efficiency was found to be influenced by the water content and was high for solutions of high concentrations, as Table 4 shows. However, it was found that by adding water to PC solutions, the chloride salts in the electrolyte were hydrolyzed, giving rise to precipitates. As a result, the conductivity of solutions decreased. By this reason, more negative potentials were chosen for the electrolysis of the intentionally aquated solutions. Nevertheless, the initial current for the electrolysis was still small compared to that obtained for solutions of no intentional water. As already shown in Fig. 2, the current efficiency for nitrogen fixation was increased by decreasing the current density for electrolysis. Therefore, the enhancement of the current efficiency by introducing water into PC solutions may be ascribable at least in part to the decreasing effect of the current density. Although a simple conclusion may not be drawn from the results given in Table 4, it will be of no doubt that a trace amount of water in the electrolyte can act as a proton source for nitrogen fixation.

Table 3. Fixation of N_2 in electrolytes containing relatively high amount of reducing agents[a)]

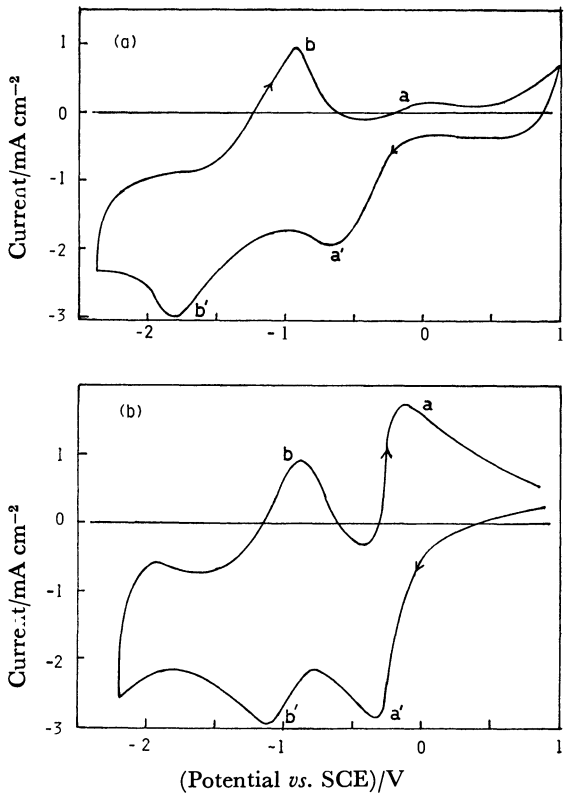

Fig. 3. Voltammograms at a Pt electrode at 0.2 V/s for two kinds of redox electrolytes. (a): PC containing 0.1 mol dm^{-3} VCl_3 and 0.5 mol dm^{-3} $LiClO_4$, (b): PC containing 0.05 mol dm^{-3} $TiCl_3$ and 0.05 mol dm^{-3} $LiClO_4$. The couple of waves a and a' are related to the redox reaction of M(III)/M(II), and those of b and b' to the reaction of M(II)/M(0).

Peak Potentials of Redox Agents. Qualitative information on the reducing power of the redox agents used were compared by measuring peak potentials of voltammograms for the redox reactions at a Pt electrode. The electrolytes used contained not $AlCl_3$ but $LiClO_4$ as an indifferent electrolyte, being different from those used in the experiments of nitrogen fixation. If $AlCl_3$ was used, obtained voltammograms were ill-defined compared to those obtained in $LiClO_4$. By using $LiClO_4$ as the indifferent electrolyte, the obtained results may not directly be applicable to the electrolyte systems used for the experiments of nitrogen fixation, but qualitative information is believed to be still useful.

Two examples of voltammograms are shown in Figs. 3(a) and (b), which were obtained in VCl_3–PC and $TiCl_3$–PC solutions, respectively. The waves a and a' in these figures are connected to the redox reactions between the trivalent and divalent states, b' to the deposition of the metal ions of the divalent state, and b to the re-oxidation of the depositied metal to give dissolution. The voltammograms were also obtained for other electrolytes used in the experiments for nitrogen fixation at 0.2 V/s, and obtained results of peak potentials for individual redox reaction are collected in Table 5.

According to the obtained results, the separation between E_{pc} and E_{pa} is larger than that expected theoretically for a reversible system, which is 0.057 V,[12] suggesting that the value of the peak potentials are varied by the sweep rate chosen for all the electrolytes given in this table. Therefore, rigid comparison of the peak potentials with each other will be of no significance. However, if one assumes that the redox potentials will be obtained as average values of E_{pc} and E_{pa}, it becomes then possible to compare these values with

Table 5. Peak potentials of voltammograms for redox reactions used for nitrogen fixation experiments

Solvent	Redox agent	Its concn / M	(Peak potentials *vs.* SCE)/V[a)]: M(III)/M(II) E_{pc}	M(III)/M(II) E_{pa}	M(II)/M(0) E_{pc}	M(II)/M(0) E_{pa}

PC	$TiCl_3$	0.05	−0.3	−0.1	−1.1	−0.8
Glyme	VCl_3	0.1	−0.7	−0.1	−1.45	−1.05
PC	VCl_3	0.1	−0.65	0	−1.8	−0.94
PC	$CrCl_3$	0.02	−0.45	−0.4	−1.4	n.d.

a) The electrolytes contained 0.5 mol dm^{-3} $LiClO_4$ except for glyme–$TiCl_3$ and glyme–VCl_3 where its concentration was 0.3 mol dm^{-3}. Sweep rate: 0.2 V/s. b) Not determined due to no appearence of the peak in the voltammogram. The cathodic current increased monotonically with increasing cathodic polarization in these cases.

one another. By such comparisons, it can be roughly said that the redox potential of Ti(III)/Ti(II) are not greately different among the kind of solvents chosen and that the reducing power of vanadium and chromium ions are also comparable to that of titanium ions. This observation seems to give a basis on the finding that nitrogen fixation occurs with almost the same degree in all the redox electrolytes given in Table 5.

Conclusion. It has been revealed from the present study that nitrogen fixation occurs when the following conditions are fulfilled. (1) Titanium, vanadium and chromium ions are in the divalent state. (2) The electrolytes contain a trace amount of water as an proton source. (3) The cathode can photosensitize the reduction reaction. The fact that the redox agent of a high reducing power is essential for nitrogen fixation seems to suggest that there is some interaction between the redox agent and nitrogen molecules before nitrogen is reduced, as already discussed above. Then the following schemes are evolved as the most probable path for nitrogen fixation.

$$M(III)(solv)_n \xrightarrow{+e^-} M(II)(solv)_n$$

$$M(II)(solv)_n \xrightarrow{+N_2} M(II)(solv)_n\cdots N_2$$

$$M(II)(solv)_n\cdots N_2 + 6H_2O \xrightarrow[\text{photosensitization}]{+6e^-,\ -6OH^-} M(II)(solv)_n + 2NH_3$$

where $M(III)(solv)_n$ and $M(II)(solv)_n$ represent solvated redox agents having trivalent and divalent states, respectively. The experimental results obtained in the present study were rather scattered, as noticed from comparison of the current efficiency for a variety of redox agents, but the scatters are believed to have been brought about partly by different experimental conditions such as different electrolyte and water concentrations and partly by errors in determination of the amounts of ammonia and hydrazine due to very small amounts of production of these substances. If these are taken into consideration, the results obtained in the present study will be much enough to suggest that there are a variety of choices of electrolyte systems for nitrogen fixation at illuminated p-type GaP cathodes.

The present study was supported by Grant-in-Aid for Scientific Research Nos. 412212 and 505008 from the Ministry of Education, Science and Culture.

Studies on Electrode Processes of Stabilized Zirconia Cell System by Complex Impedance Method

Jun SASAKI,* Junichiro MIZUSAKI, Shigeru YAMAUCHI, and Kazuo FUEKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 20, 1980)

Three kinds of materials, Pt, Ag, and $La_{0.5}Sr_{0.5}CoO_3$, were applied to stabilized zirconia as electrodes and the electrode behavior was investigated by means of the complex impedance method. The impedance arc due to the electrode/stabilized zirconia interface was always depressed semi-circles. Impedance behavior was strongly dependent on the electrode materials. Assuming that the impedance arc could be interpreted by a parallel *R-C* circuit, the interface resistance R_i and the interface capacitance C_i were determined. The apparent activation energy determined from the slope of the plots of log R_i *vs.* $1/T$ was nearly the same for the same electrode material. (Ag electrode: 92 kJ/mol and Pt electrode: 201 kJ/mol). The oxygen pressure dependence of C_i and R_i was also investigated. Although C_i was virtually independent of the oxygen partial pressure P_{O_2}, R_i was proportional to $P_{O_2}^{-2/3}$ for Ag electrodes and $P_{O_2}^{-1/4}$ for Pt electrodes. The rate-determining step was supposed to be the dissociation of oxygen molecules into atoms for Ag electrodes, and the dissociation of oxygen molecules or one of the subsequent steps for Pt electrodes.

The complex impedance method has been widely used to study the solid state cell systems.[1-8] This method provides an important tool for separating the impedance due to interfacial phenomena from that due to bulk properties of solid state cells.

So far, a lot of works have been carried out by this method to investigate the polarization processes at the stabilized zirconia/electrode interface.[1-7] However, results by different investigators were often inconsistent. This would be partly due to the scarcity of experimental evidence on the relationship between the interface behavior and electrode materials.

The purpose of the present study is to elucidate the influences of the nature of electrode materials on the polarization process by the complex impedance method.

Experimental

The electrolyte used in the experiments was 8 m/o yttria-stabilized zirconia disks supplied by Toray Industries, Inc. The diameter of the sample was 10 mm. Three different thickness, 1, 5, and 10 mm, were used in order to separate bulk properties from the interfacial ones of the stabilized zirconia cell. Both faces of stabilized zirconia disk were polished with No. 2000 emery paper and rinsed with alkaline cleaning solution.

The electrodes were prepared in various ways. Three kinds of electrode materials, Pt, Ag, and $La_{0.5}Sr_{0.5}CoO_3$ were applied to both faces of stabilized zirconia disks. The methods of preparation are listed in Table 1. Sputtered electrodes were prepared by means of RF sputtering (1500 V, 5×10^{-2} Torr† argon, 10—180 min) from a nominally pure foil of Pt or Ag. Evaporation was carried out by means of the electron beam melting furnace. Pt electrodes from H_2PtCl_6 were obtained by repeated application of H_2PtCl_6 aqueous solution subsequently followed by firing to drive off H_2O and Cl_2 gas. Pastes with glass flux were commercial materials from Tanaka-Matthey (Pt paste: 760A, Ag paste: FSP-306). Platinum paste without glass flux were prepared using Pt powder and an organic suspending medium. $La_{0.5}Sr_{0.5}CoO_3$ was prepared by mixing $La_2(CO_3)_3$, $SrCO_3$ and $CoCO_3$, and firing the mixture at 1100 °C for 8 h. $La_{0.5}Sr_{0.5}CoO_3$ thus obtained was then ground into powder and mixed with organic suspending medium. Then the paste of $La_{0.5}Sr_{0.5}CoO_3$ was applied on both faces of stabilized zirconia. Platinum gauze (200 mesh-cm^{-1}) connected with a Pt lead wire was dipped into the $La_{0.5}Sr_{0.5}CoO_3$ paste. Then, the paste was dried and fired at 1200 °C for 12 h. As current collectors, Ag gauze was used for Ag electrodes and Pt gauze for other electrodes. The gauze was pressed to electrodes by two very porous alumina disks to make sure the good contact.

Table 1. Electrode materials and method of preparation

Electrode material	Method of preparation
Platinum	Sputtering
	Evaporation
	Decomposition of H_2PtCl_6
	Paste with glass flux
	Paste without glass flux
Silver	Paste with glass flux
	Sputtering
$La_{0.5}Sr_{0.5}CoO_3$	Paste without glass flux

Measurements were made in the temperature ranges, 500—900 °C for the cells with Pt electrodes, 350—800 °C for those with Ag electrodes and 400—1200 °C for those with $La_{0.5}Sr_{0.5}CoO_3$ electrodes.

The complex impedance measurements were performed over the frequency range of 20 kHz to 5 Hz by means of a phase sensitive detector (Complex Impedance Meter 7010, Toho Technical Research Co.). In the frequency range from 1 Hz to 0.001 Hz Lissajous figure method was used. In this method the sine wave voltage was applied to the combination of the cell and a standard resistance in series by a sine wave generator (WAVETEK Model 184). The input and output signals were displayed simultaniously on an X-Y recorder, and the impedance of the cell was determined from the dimensions of Lissajous figures. The oxygen partial pressure (1—10^{-4} atm) was controlled by mixing oxygen and pure argon gas.

Results and Discussion

Effects of Electrode Materials on Interface Impedance.

Pt Electrode: Figure 1 gives the impedance plots of the specimens with various types of Pt electrodes measured

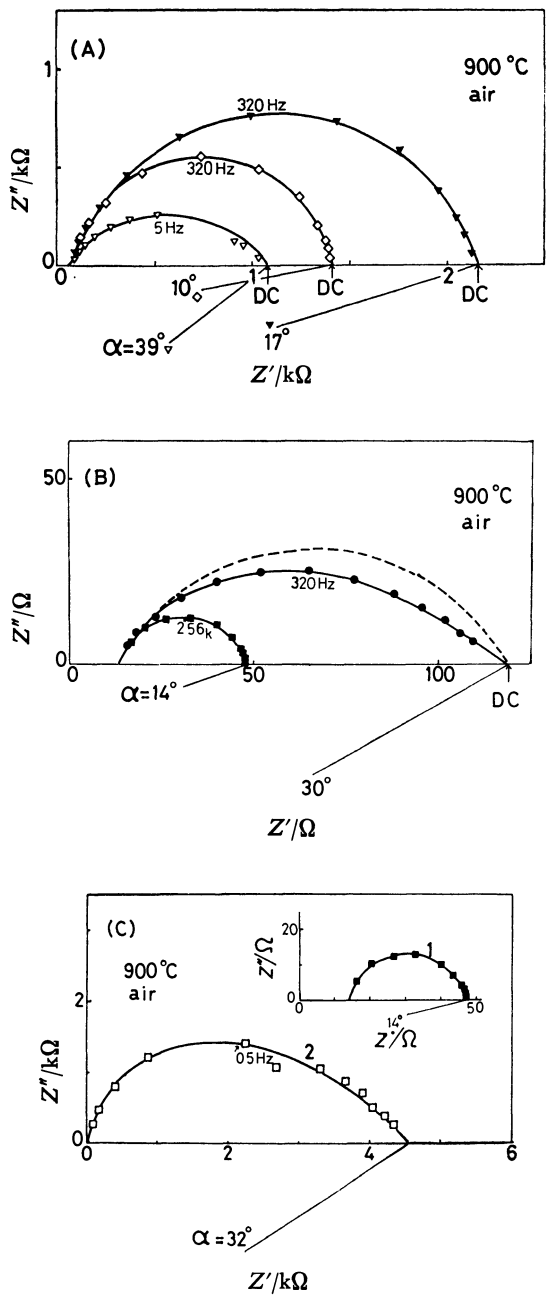

Fig. 1. Impedance plots of the cell with Pt electrodes. (A): ▼; evaporated Pt, ◇; sputtered Pt, ▽; Pt from H_2PtCl_6. (B): ●; Pt paste with glass flux, ■; Pt paste without glass flux. (C): Pt paste without glass flux, ■; before annealing at 1300 °C for 72 h, □; after annealing at 1300 °C for 72 h.

in air. Stabilized zirconia disks used were 5 mm in thickness. The semi-circular arc corresponds to the impedance at the electrode/stabilized zirconia interface. Figure 1(A) shows the impedance plots of specimens with Pt electrodes from evaporation, sputtering or decomposition of H_2PtCl_6. The centers of semi-circles are not on the real axis. Therefore, the results cannot be fully interpreted by an equivalent circuit of a parallel *R-C* combination. The depression angle α represents the deviation of the center of circle from the real axis. Two intercepts of the arc with the real axis give the resistivity of the equivalent circuit of the interface impedance.[1,2,10] The difference R_i between these intercepts is the sum of the interface resistances at cathode and anode. In the present study, the voltage applied to the electrode was kept below 10 mV in order to avoid non-linearity between the current and the overvoltage, and the polarization resistances at both electrodes are therefore supposed to be equal.

Figure 1(B) gives the impedance plots of specimens with Pt paste electrodes with or without glass flux. It is evident that glass flux depresses the impedance arc, especially in the right side of arc, which means that the curvature of arc in the low frequency region is smaller than that in the high frequency region.

Figure 1 (C) shows the effects of the annealing on the impedance plots for the specimen with Pt paste electrode without glass flux. Platinum paste without glass flux was applied on the faces of stabilized zirconia and fired at 900 °C for 3 h and then at 1300 °C for 72 h. Curves 1 and 2 in the figure were impedance arcs measured before and after the annealing at 1300 °C respectively. It is apparent from the figure that the long period annealing has resulted in a noticeable increase in interface resistance and a depression of semi-circle. This may be due to the decrease in the three phase boundary (lines where the electrode, electrolyte and gas phase meet) and the decrease in the interconnected gas channels in the Pt electrode. So far, the depression of impedance arc has been accounted for by the contribution of Warburg impedance.[2] The decrease in the volume of open pores in electrode accompanies the decrease in diffusion flux of gaseous species. Accordingly, the contribution of Warburg impedance to the interface impedance increases. Likewise, the addition of glass flux is supposed to decrease the diffusion flux and to cause the increase in the depression angle.

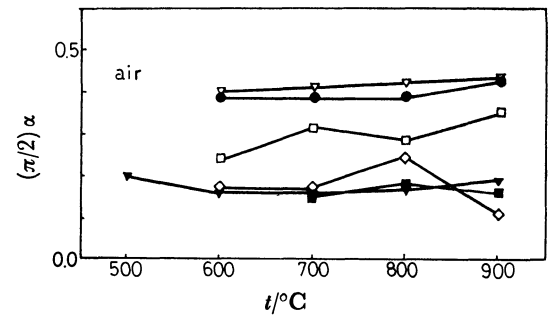

Fig. 2. Temperature dependence of α.
▽: Pt from H_2PtCl_6, ●: Pt paste with glass flux, □: Pt paste without glass flux annealed at 1300 °C for 72 h, ◇: sputtered Pt, ▼: evaporated Pt, ■: Pt paste without glass flux.

Figure 2 shows the depression angle α against temperature for various types of Pt electrodes in air. The electrodes with relatively thin films, for example the sputtered or evaporated electrodes, seem to have somewhat small depression angle. But in the case of Pt paste electrodes with glass flux, correlation was not observed between the electrode thickness and the depression angle.

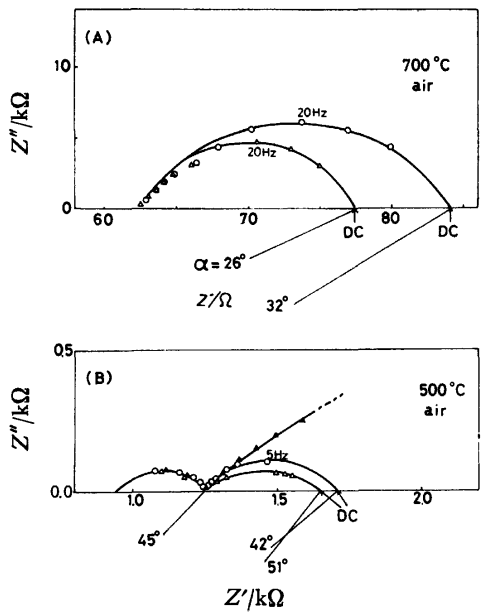

Fig. 3. Impedance plots of the cell with Ag and $La_{0.5}Sr_{0.5}CoO_3$ electrodes.
○: Ag paste with glass flux, △: sputtered Ag, ▲: $La_{0.5}Sr_{0.5}CoO_3$.

Ag Electrode: Figure 3 shows the impedance plots of the cells with Ag electrodes and $La_{0.5}Sr_{0.5}CoO_3$ electrode measured in air. Stabilized zirconia disks used were 5 mm in thickness. Although only one arc was observed at high temperature (above 550 °C), below 550 °C the second arc appeared in the high frequency region for both Ag and $La_{0.5}Sr_{0.5}CoO_3$ electrodes. Impedance measurements on specimens with different thickness of electrolyte showed that the high frequency dispersion is dependent on the electrolyte thickness but independent of the method of preparation of Ag electrodes. Accordingly, the arc of high frequency region would corresponds to the impedance of grain boundary.[1-8]

The arc in the low frequency region would corresponds to the interface impedance. Silver electrodes prepared from Ag paste with glass flux gave a more depressed arc in the low frequency region than the sputtered one at temperatures below 500 °C. In the case of Ag and $La_{0.5}Sr_{0.5}CoO_3$ electrodes, the interface resistance R_i is given from the two intercepts of impedance arc with the real axis in the low frequency region.

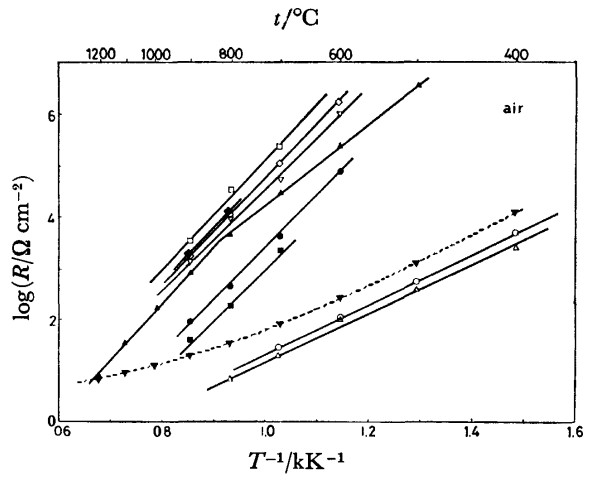

Fig. 4. Plots of log R_i *vs.* $1/T$.
□: Pt paste without glass flux annealed at 1300 °C for 72 h, ◇: sputtered Pt, ◆: evaporated Pt, ▽: Pt from H_2PtCl_6, ▲: $La_{0.5}Sr_{0.5}CoO_3$, ●: Pt paste with glass flux, ■: Pt paste without glass flux, ○: Ag paste with glass flux, △: sputtered Ag.

Figure 4 shows the plots of log R_i against $1/T$ for various kinds of electrodes. The broken line indicates the bulk resistance of stabilized zirconia measured in this study. Since the grain boundary impedance is negligible above 550 °C, the bulk resistance is determined from the intercept of the impedance arc with the real axis at high frequency region. When the grain boundary impedance arc appears below 550 °C, the bulk resistance is determined from the extrapolation to high frequency in the grain boundary region.[2] As can be seen from the figure, Ag electrodes have relatively low interface resistance. $La_{0.5}Sr_{0.5}CoO_3$ is a mixed conductor which has high ionic conductivity as well as high electronic conductivity.[9] So, it is expected that oxygen dissolves into the oxide electrode and is ionized at the electrode/electrolyte interface. This means that the reaction area is much larger than that of three phase boundary. But, the experimental results did not show any evidence of low interface resistance.

From Fig. 4, it is evident that the same metal has nearly the same activation energy. This fact suggests that the rate-determining step of the electrode processes is the same for the same metal in a temperature range studied. It was found that the activation energy for Pt electrodes is about 201 kJ/mol and that for Ag electrodes is about 92 kJ/mol.

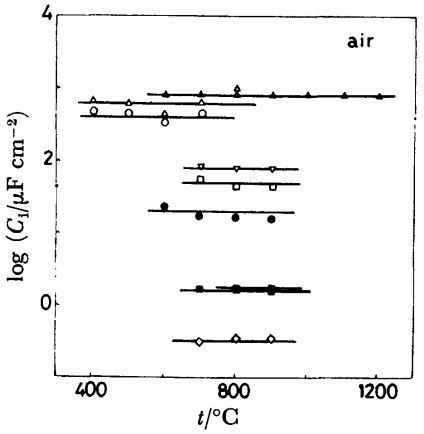

Fig. 5. Temperature dependence of log C_i.
▲: $La_{0.5}Sr_{0.5}CoO_3$, △: sputtered Ag, ○: Ag paste with glass flux, ▽: Pt from H_2PtCl_6, □: Pt paste without glass flux annealed at 1300 °C for 72 h, ●: Pt paste with glass flux, ▼: evaporated Pt, ■: Pt paste without glass flux, ◇: sputtered Pt.

Figure 5 shows log C_i against temperature for various kinds of electrode materials, where C_i is the interface capacitance calculated from the impedance plots assuming that the interface impedance is approximated by *R-C* parallel circuit. It is obvious that the interface capacitance is independent of the temperature and strongly dependent on the preparation of electrode.

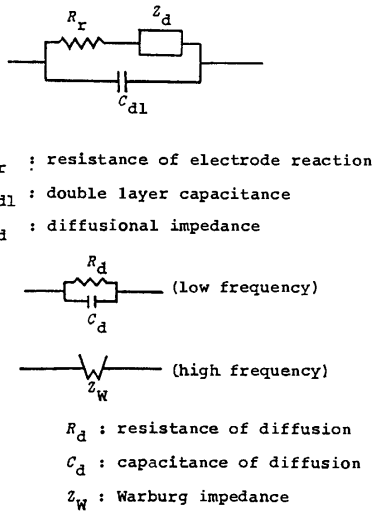

Fig. 6. Equivalent circuit of interface impedance.

Sputtered or evaporated Pt electrodes show small capacitance. Since C_i is considered to be proportional to the contact area at the electrode material/electrolyte interface, the small capacitance would be explained as the low contact area.

Equivalent Circuit and Oxygen Pressure Dependence of the Interface Impedance. As shown in Figs. 1 and 3, the impedance arcs for various kinds of electrodes are depressed. Therefore they cannot be accounted for by a parallel R-C combination.

According to Franklin,[10] when the gas diffusion in pores of electrode is slow, the equivalent circuit is as shown in Fig. 6. In this equivalent circuit, Z_d expresses the impedance due to diffusional process of gaseous oxygen in pores, which is approximated by Warburg impedance in the high frequency region and by a parallel R_d-C_d circuit in the low frequency region. Accordingly, the interface resistance is represented by the sum of the diffusional resistance R_d and the electrode reaction resistance R_r. Therefore, the higher one of R_d and R_r determines the interface resistance. Since R_d is proportional to $1/P_{O_2}$ and C_d is proportional to P_{O_2}, the P_{O_2} dependence of the impedance plots elucidate the contribution of R_d and C_d.

Figure 7 gives the change in the impedance plots with oxygen pressure for specimens with Pt electrode from H_2PtCl_6 and sputtered Ag electrode. The interface resistance R_i increases as the P_{O_2} decreases. However, the capacitance obtained by assuming the parallel R-C circuit was found to be independent of the P_{O_2} as shown in Fig. 8. Probably, the capacitance would correspond to the double layer capacitance in Fig. 6.

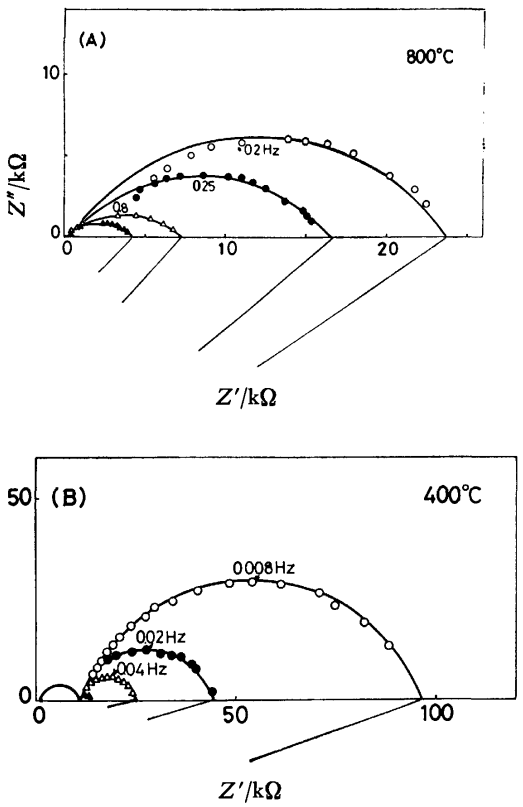

Fig. 7. P_{O_2} dependence of impedance plot.
(A): Pt from H_2PtCl_6. P_{O_2}/atm ▲; 1.0, △; 2.0×10^{-1}, ●; 1.1×10^{-2}, ○; 8.5×10^{-4}. (B): sputtered Ag P_{O_2}/atm ▲; 3.0×10^{-2}, △; 1.1×10^{-2}, ●; 2.1×10^{-3}, ○; 6.5×10^{-4}.

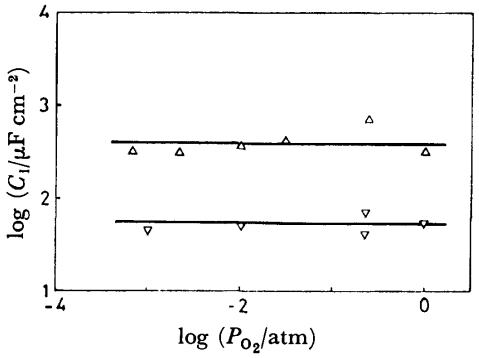

Fig. 8. P_{O_2} dependence of log C_i.
△: Sputtered Ag (400 °C), ▽: Pt from H_2PtCl_6 (800 °C).

Figure 9 (A) shows the P_{O_2} dependence of the interface resistance of Pt electrodes. The interface resistance is proportional to $P_{O_2}^{-1/4}$, irrespective of electrode preparation. Bauerle's[1] results on sputtered Pt electrodes show a tendency of saturation with the increase in P_{O_2}.

Figure 9 (B) shows the same plot for the sputtered Ag electrode. The interface resistance is proportional to $P_{O_2}^{-2/3}$.

From the results shown in Fig. 9, under low overvoltages the interface resistance of both Pt and Ag electrode is attributed to the resistance of electrode reaction R_r in Fig. 6.

Electrode Reaction. As indicated in the preceding section, the interface impedance can be approximated by the parallel R_r(resistance of electrode reaction)-C_{dl} (double layer capacitance) circuit in spite of the depression of the impedance arcs. Unlike C_{dl}, R_r was found to be sensitive to temperature and oxygen pressure. One may consider $1/R_r$ to be a measure of the rate of over-all electrode reaction. The over-all electrode reaction consists of several elementary steps given in Table 2. The value of n in the form of $1/R_r \propto P_{O_2}^n$,

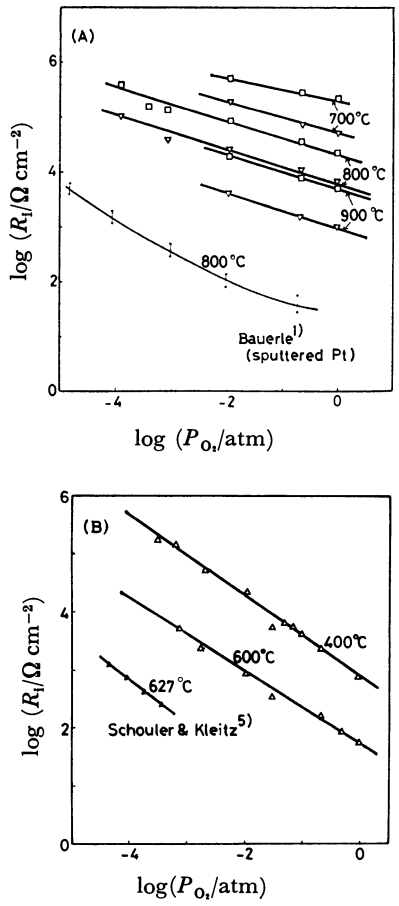

Fig. 9. P_{O_2} dependence of log R_i.
(A): □; Pt paste without glass flux annealed at 1300 °C for 72 h, ▽; Pt from H_2PtCl_6. (B): Sputtered Ag.

characteristic of each rate-determining step is also given in Table 2. If step (I) is rate-determining, $1/R_r$ should be proportional to P_{O_2} ($n=1$). From the results obtained in this work, $1/R_r$ is not proportional to P_{O_2}. So, this adsorption process is considered to be not rate-determining. When the step (II) is rate-determining and the adsorption of oxygen obeys Langmuir isotherm, n is supposed to take values from 1 to 0. Similarly, n would take values from 1/2 to 0, when step (III) or (IV) is rate-determining. Results of the present work indicate that n is 2/3 for Ag electrodes. Moreover, Buttner and his co-investigators[11)] have found that

TABLE 2. ELEMENTARY REACTION STEPS AND THE VALUE OF n, CHARACTERISTIC OF RATE-DETERMINING STEP

	Elementary step	n in $1/R_r \propto P_{O_2}^n$
I	$O_2(g) \rightleftarrows O_2$ (ad)	1
II	O_2(ad) $\rightleftarrows$ 2O (ad)	1—0
III	Surface diffusion of O(ad)	1/2—0
IV	O(ad)+2e $\rightleftarrows$ O^{2-}	1/2—0

oxygen is strongly adsorbed on the surface of Ag. From these results, the rate-determining step of the electrode processes on Ag electrodes is supposed to be the dissociation of adsorbed oxygen molecules into atoms.

For Pt electrodes, n was found to be 1/4. According to Fryburg and Petrus,[12)] at temperatures and oxygen pressure studied, the surface of Pt would be completely covered with a tightly bound monolayer of oxygen atoms. So, we could assume the weakly adsorbed molecular oxygen. If the adsorption is Langmuir type, the rate-determining step would be the dissociation of oxygen molecules into atoms or either one of the subsequent steps.

The IR Spectra of $Cs_xV_2O_5$ ($x=0-0.66$)

Yoshiya KERA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 23, 1980)

The IR spectra of Cs-vanadates (C=[Cs]/[V]=0—0.332) were recorded in the 650—1200 cm^{-1} region. In the V_2O_5, which had cautiously been purified, the V=O stretching band was found at 1022 cm^{-1}, and the V–O–V stretching band, at 815 cm^{-1}. Upon the addition of Cs, sharp new bands began to appear at 965 cm^{-1} at C=0.0042 and also at 1000 cm^{-1} at C=0.0120, and a shift in the 815-cm^{-1} band was found. Finally, at C=0.332 the original 1022-cm^{-1} band was replaced by the 965 and 1000 cm^{-1} bands, the intensity ratio (I_{965}/I_{1000}) of which was 2.0. The X-ray diffraction pattern of the last sample was in agreement with that of CsV_3O_8. The IR and the X-ray results suggest that the CsV_3O_8 phase appears at around C=0.004. Based on the band shifts of 1022→965 and 1000 cm^{-1}, the force constant and the bond strength of V=O in CsV_3O_8 were discussed. With respect to the band shift in the 815-cm^{-1} region with the increase in the Cs content, the corretion of $\Delta\bar{\nu}$ to $C^{1/3}$ is shown in $C<0.020$.

V_2O_5 has a layer structure and has large channels along the b- and c-axes,[1-3] through which oxygen ions can be easily taken into and/or out of the lattice.[4] The property of the vanadium oxide as a catalyst has been discussed in relation to such a structural feature and behaviour of the oxygen ion.[4-8] V_2O_5 can also take many kinds of metal ion into the channels to form "vanadium bronzes;" the physico-chemical properties vary delicately and complicatedly depending upon the kind and the concentration of metal ions.[9] Recently, a big change was found in the catalytic properties of V_2O_5 when a commercial V_2O_5 (guaranteed grade) was cautiously purified.[10] This finding forces us to think that it is very important to control a small amount of impurities for a clear study of the catalytic activity and the catalytic property of vanadium oxide.

Now a series of studies of the effects of alkali metal-addition (Li–Cs) on the physico-chemical and the catalytic properties in V_2O_5 has been started. Upon the addition of Cs, the largest effects were found on the catalytic activity leading to ethanol decomposition and on the band shift in the V–O–V stretching in the IR spectrum.[11] These results could easily be expected because the Cs atom has the lowest ionization potential and the largest ionic radius of the alkali metals. However, the details of the structural change of V_2O_5 upon alkali-metal addition have not yet been made clear. In the present paper, the changes in the V=O and the V–O–V bonding properties in the original V_2O_5 lattice upon the addition of Cs are examined in especial detail. The IR spectra of the Cs–vanadates, the Cs content of which was controlled over a wide range, were measured for the purpose.

Experimental

The Cs–vanadates were prepared from Cs_2CO_3 (guaranteed grade) and NH_4VO_3 which had been purified cautiously[12] by the following procedures. The NH_4VO_3 was immersed into a aq. soln. of Cs_2CO_3, dried at 120° C, and calcined in air at 600 °C for 16—20 h. The Cs-contents of the samples are summarized in Table 1. The Cs-5 sample was prepared by grinding Cs-1 and Cs-7 well in an agate mortar, followed by heat treatment at 623 °C for 12 h and then by fusing at 700 °C for 6 h. The Cs-6 sample was prepared by grinding Cs-1 and Cs-7 well followed by heat treatment at 610 °C for 24 h; it was then fused at 623 °C for 12 h.

TABLE 1. Cs-CONTENT OF Cs-VANADATES

Sample	Cs-content([Cs]/[V])
Pure-V_2O_5	0.0000
Cs-1	0.0013
Cs-2	0.0042
Cs-3	0.0120
Cs-4	0.0203
Cs-5	0.100
Cs-6	0.168
Cs-7	0.332

The IR spectra of the Cs–vanadates were recorded in the frequency range from 650 to 1200 cm^{-1} by the normal KBr-disk method. The IR spectrometer used was JASCO, Model DS-402 G. The X-ray powder diffraction was checked on five samples: pure-V_2O_5 and Cs-4—Cs-7. The X-ray diffractmeter used was Rigaku Denki, Model 2001; Cu $K\alpha$-radiation (at 35 kV) and an Ni-filter were used.

Results

The IR spectra of the pure-V_2O_5 and the Cs–vanadates are shown in Fig. 1. In the spectrum of the pure-V_2O_5[8,13] a sharp band assigned to the V=O stretching vibration and a broad band assigned to V–O–V stretching are seen at 1022 and 815 cm^{-1} respectively (Fig. 1-a). The spectrum changes with the increase in the Cs–content (C=[Cs]/[V]): with C=0.0042 a new sharp band begins to appear at 965 cm^{-1} (Fig. 1-c) and with C=0.0203, one also appears at 1000 cm^{-1} (Fig. 1-e). In the samples with contents higher than C=0.0203, the bands at 965 and 1000 cm^{-1} were intensified with the Cs-content without any change in the frequencies. With C=0.332, finally, the original band at 1022 cm^{-1} disappeared and was completely replaced by the bands at 965 and 1000 cm^{-1} (Fig. 1-h).

On the other hand, the broad band at 815 cm^{-1} became broader and shifted toward the low frequencies from C=0.0013 to 0.0203 with the addition of Cs ions. In the samples with contents higher than C=0.100, the band split further into two peaks. With C=0.332,

* Present address: Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Higashi-Osaka, Osaka 577.

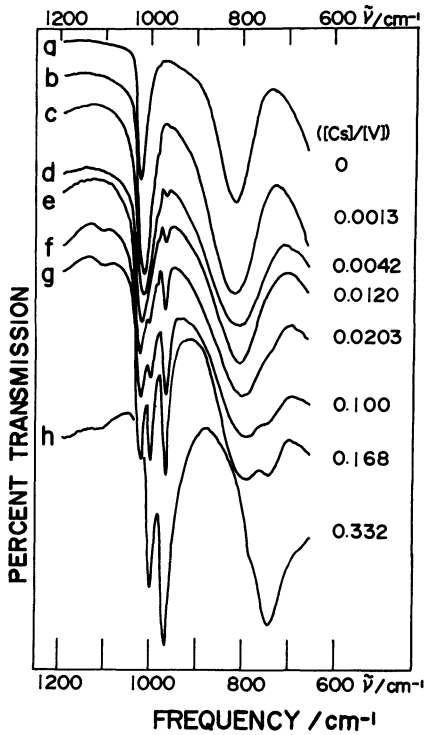

Fig. 1. IR spectra of $Cs_xV_2O_5$ (x=0—0.664), recorded in the frequency range of 1200—650 cm^{-1}. Spectrum a shows IR spectrum of the original V_2O_5, which was cautiously purified:[12] the bands at 1022 and 815 cm^{-1} have been assigned to the V=O and the V–O–V stretching, respectively.[8] The frequencies of the bands in the spectra b—h are summarized in Table 2.

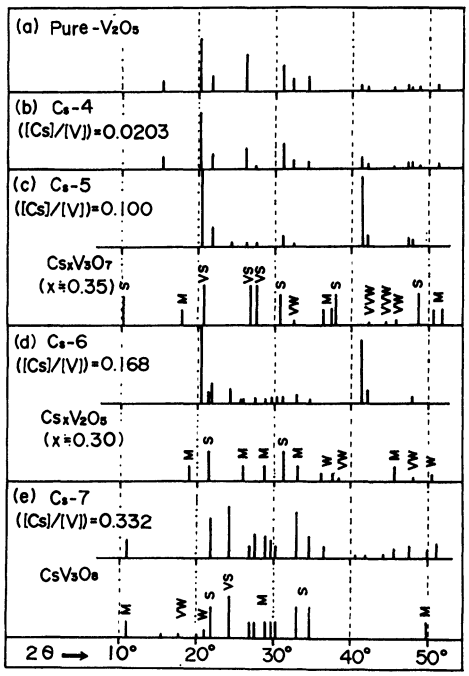

Fig. 2. The X-ray powder diffraction patterns of the pure-V_2O_5 and $Cs_xV_2O_5$ (x=0—0.664). For comparison the X-ray powder patterns of Cs–vanadates, already reported,[14–16] were added in Figs. 2-c, d, and e. In Cs-4 the patterns is almost agreement with that of the pure-V_2O_5 except for a little difference in the relative intensities. In Cs-7 the main lines of the pattern is agreement with that of Cs–hexavanadate. In Cs-5 and Cs-6 the very strong lines were seen at 20.4 and 41.2°, which have not been reported yet.

finally, the band at 815 cm^{-1} seems to be replaced by the bands at 742 and 780 cm^{-1}. The frequencies of all the bands in the spectra shown in Fig. 1 are summarized in the third column of Table 2.

The X-ray diffraction patterns of the pure-V_2O_5 and the Cs-4—Cs-7 samples are shown in Figs. 2-a—e. The pattern of Cs-4 (at C=0.0203) is almost the same as that of the pure-V_2O_5,[3] except for a very weak line appearing at 27.4° and a small change in the intensities between the corresponding peaks (Figs. 2-a and b). Strong lines appear at 20.3 and 41.3° in the diffraction patterns of Cs-5 and Cs-6. Both samples were prepared by mixing pure-V_2O_5 with Cs-7, followed by fusing and recrystallizing. Thus, the "preferred orientation" toward the (010) plane may be expected in the samples. The lines at 20.3 and 41.3° shifted just a little bit from those at 20.2 and 41.2°, which are ascribed to the diffraction from the (010) and the (020) planes respectively in pure-V_2O_5. These shifts might be caused by the formation of a non-stoichiometric phase of $Cs_xV_2O_5$ (x: too small).

In Cs-5, besides the lines at 20.3 and 41.3°, the very weak lines at 21.7, 26.2, 31.0, 32.4, and 47.3° correspond to the diffraction from pure-V_2O_5. The weak lines at

TABLE 2. THE FREQUENCIES OF THE V=O AND THE V–O–V STRETCHING BANDS IN THE IR-SPECTRA OF PURE-V_2O_5 AND Cs-VANADATES, AND THE BAND SHIFT ($\Delta\tilde{\nu}$) OF THE V–O–V STRETCHING UPON Cs-ADDITION

Samples	Cs-content ([Cs]/[V])	Frequencies/cm^{-1}					$\Delta\tilde{\nu}$/cm^{-1}
		V=O stretching			V–O–V stretching		
Pure-V_2O_5	0	1022	—	—	815		0
Cs-1	0.0013	1017	—	—	818		—3
Cs-2	0.0042	1017	—	966	808		7
Cs-3	0.0120	1020	—	965	806		9
Cs-4	0.0203	1023	1000	965	797		18
Cs-4	0.0203	1021	1001	965	803		12
Cs-5	0.100	1022	1000	965	795	750	—
Cs-6	0.168	1020	999	965	790	743	—
Cs-7	0.332	—	1000	965	780	742	—

27.5 and 24.2° correspond well to the strong lines in Cs-7, which are ascribed to the diffractions from the (021) and the (210) planes in CsV_3O_8 respectively. However, no lines accord with the diffraction from $Cs_xV_3O_7$ (x: 0.35), given for comparison in Fig. 2. Thus, Cs-5 may be regarded as a composite phase of V_2O_5 and CsV_3O_8 or $Cs_xV_2O_5$ (x: too small) and CsV_3O_8. In Cs-6, the lines other than those at 20.3 and 41.3° which correspond to the diffraction from V_2O_5, appear at 21.7, 31.0, and 47.8°. The lines at 24.1, 27.4, 32.8, and 34.5° accord with the main lines of Cs-7. However, unknown lines appear at 25.5 and 25.8° in this samples, although they are very weak. No lines correspond to the diffraction from $Cs_xV_2O_5$ (x=0.3), given also for comparison in Fig. 2-d. This evidence suggests the formation of a new phase other than a mixed phase of V_2O_5 and CsV_3O_8 or $Cs_xV_2O_5$ (x: too small) and CsV_3O_8.

Finally, it is noteworthy that the diffraction at 27.5° was found in Cs-4 (at C=0.020), which is ascribed to the diffraction from the (021) plane in CsV_3O_8. This suggests that CsV_3O_8 phase can be already formed in such a low concentration as C=0.020 with Cs-addition to pure-V_2O_5.

The main lines of the diffraction in Cs-7 are completely in agreement with the pattern of CsV_3O_8, but none of the minor lines correspond to that of the Cs–vanadates reported hitherto. Thus, the Cs-7 sample consists of the Cs–trivanadate (CsV_3O_8), accompanied by a small quantity of an unknown compound.

Discussion

The V=O Stretching Bands. The peak intensities of the bands at 1022, 1000, and 965 cm^{-1} (I_{1022}, I_{1000}, and I_{965}) were estimated by drawing a base line smoothly under the bands in the spectra of Fig. 1. The intensities of the bands and the intensities normarized by the use of I_t ($I_{1022}+I_{1000}+I_{965}$) are summarized in Table 3.

Table 3. Intensity changes in the V=O stretching bands upon Cs-addition

Samples	C	I_{1022}	I_{1000}	I_{965}	$\frac{I_{1022}}{I_t}$	$\frac{I_{1000}}{I_t}$	$\frac{I_{965}}{I_t}$
Cs-2	0.0042	0.639	—	0.037	0.946	—	0.054
Cs-3	0.0120	0.397	—	0.042	0.904	—	0.096
Cs-4	0.0203	0.487	0.054	0.136	0.719	0.080	0.201
		0.549	0.059	0.103	0.772	0.083	0.145
Cs-5	0.100	0.492	0.124	0.301	0.536	0.135	0.328
Cs-6	0.168	0.677	0.405	0.672	0.386	0.231	0.383
Cs-7	0.332	0	0.514	1.095	0	0.319	0.681

The normalized intensities are plotted against the Cs-content in Fig. 3. The (I_{965}/I_t) and (I_{1000}/I_t) grow linearly with the Cs-content, but the ratio of I_{965} to I_{1000} remains constant at about 2 in the range of C= 0.020—0.332. When the curves of (I_{965}/I_t) and (I_{1000}/I_t) *vs.* C are extrapolated to C=0, they cut the vertical axis while keeping the ratio constant at about 2. On the other hand, at contents lower than C=0.020, the curve of (I_{965}/I_t) *vs.* C cuts the point of origin. Figure 3

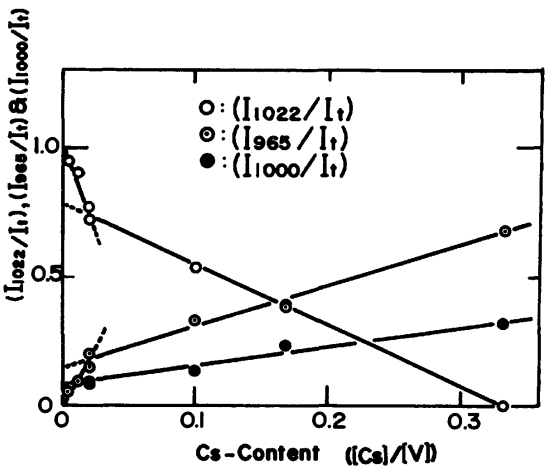

Fig. 3. The changes in the intensities of the original band at 1022 and the new bands at 1000 and 965 cm^{-1} with the increase in the Cs-content. In the Cs-content higher than C=0.020 the ratio of (I_{965}/I_t) to (I_{1000}/I_t) is kept constant at about 2.0.

indicates that the fashion of the Cs-insertion in the range of C=0—0.012 differs from that in C=0.020—0.332.

According to the X-ray analysis described above, Cs-5 and Cs-6 were regarded as mixtures of V_2O_5 and CsV_3O_8, while the CsV_3O_8 phase seems to co-exist with the V_2O_5 phase in Cs-4. That is, the CsV_3O_8-content in the V_2O_5 increases with the Cs-addition in the range of C=0.020—0.332, until finally the unified CsV_3O_8 is formed at C=0.332. The X-ray results correspond completely to the IR results that the intensities of the bands at 1000 and 965 cm^{-1} increase linearly with the Cs-content without any changes in the frequencies. Therefore, the bands at 1000 and 965 cm^{-1} can be ascribed to the characteristic bands of CsV_3O_8.

The results of the X-ray analysis by Walterson *et al.*[14,15] showed that the Cs ion occupies one kind of site in $Cs_xV_3O_7$ ($x\simeq0.35$), but in $Cs_xV_2O_5$ ($x\simeq0.3$) it occupies two kinds of sites, the ratio of which is 2 : 1. Evans *et al.*[17] also showed, in CsV_3O_8, two kinds of Cs-occupation, the ratio of which was 2 : 1. The ratio of the Cs-occupation corresponds well to the intensity ratio of the bands at 965 and at 1000 cm^{-1} (I_{965}/I_{1000}) in the samples of Cs-4—Cs-7. Thus, the bands at 965 and 1000 cm^{-1} could be ascribed to the stretching bands of V=O groups, affected by the nearest-neighbored Cs ions, which are placed in two kinds of sites.

An application of the Bond-Strength-Bond-Length-Parameters of Brown an Shannon to the band shifts from 1022 to 1000 and to 965 cm^{-1} will now be tried. The bond strength, S, is defined as Eq. 1;

$$S = S_0(R/R_0)^{-N}. \quad (1)$$

The bond strength is evaluated as S=1.848 for the V=O bond in pure-V_2O_5 by the use of the values in Table 3 of Ref. 18 : S_0=1.25, R_0=1.700, and N=4.8. The V=O bond length, R, was regarded as 1.567 Å, which is the average of the values given by Ketelaar,[1] Byström,[2] and Bachmann.[3] The bond strength, S, is assumed to be proportional to the force constant, k. Thus, the IR-frequency, f, is proportional to $S^{1/2}$

because the $f=(k/\mu)^{1/2}$ relation, holds, where μ denotes a reduced mass. From the isotope shift of the V=O stretching band with the replacement of ^{16}O for ^{18}O, the reduced mass for the band has been regarded exactly as 16.[18] This means that the oxygen ion bonds to a large body with an infinite mass. For this reason, the V=O stretching mode is prevented from the interuption of the other modes, thus giving a very sharp band. The same situation could remain in the V=O groups of such Cs–vanadates as Cs-3—Cs-7 because the bands at 965 and 1000 cm^{-1} of the samples are also very sharp, as is the original band at 1022 cm^{-1}.

The changes in the bond strength and the subsequent changes in the V=O bond length with the Cs-addition, therefore, can be estimated exactly from the band shifts from 1022 to 1000 and 965 cm^{-1} based on the relation, $f \propto S^{1/2}$. For the shift from 1022 to 1000 cm^{-1},

$$(1000/1022) = \{S(1000)/1.848\}^{1/2},$$

where the 1.848 value is $S(1022)$, which was evaluated above for the V=O bond in pure-V_2O_5; thus, the bond strength corresponding to the band at 1000 cm^{-1}, $S(1000)$, became 1.769. For the shift from 1022 to 965 cm^{-1},

$$(965/1022) = \{S(965)/1.848\}^{1/2}.$$

Thus, the bond strength corresponding to the band at 965 cm^{-1}, $S(965)$, became 1.648. By substituting the values of $S(1000)$ and $S(965)$ into Eq. 1, the V=O bond lengths corresponding to the bands at 1000 and 965 cm^{-1}, $R(1000)$ and $R(965)$, were estimated as 1.581 and 1.605 Å respectively. These values are consistent with the V=O bond distances in the CsV_3O_8, 1.575 and 1.624 Å, as deduced from X-ray analysis by Evans *et al.*[17] This agreement confirms that, in CsV_3O_8, the V=O stretching band is subjected to shifts from 1022 to 1000 and 965 cm^{-1} by the Cs ions in two different sites.

Recently, Blasse[19] found a linear correlation between the Ti–O symmetric stretching frequencies in titanates of several metals and the bond strength, P, as estimated by Pauling's Electrostatic Valence Rule. The linear correlation means that the bond strength, P, is proportional to the square root of the force constant, because the $P \propto f=(k/\mu)^{1/2}$ relation holds. Under the assumption of $f \propto S$ according to Blasse, the bond lengths of the V=O are estimated as 1.574 and 1.586 Å by a procedure similar to that described above. The values are less consistent with those in CsV_3O_8 than those estimated above under the assumption of $f \propto S^{1/2}$. From a physical analogy, the bond strength seems to correspond directly to the force constant itself rather than the square root of the force constant. In Fig. 1 in Ref. 19 by Blasse, the plots of $P^{1/2}$ against f seem, in fact, to give a better linearity than that of P against f.

The crystal structure of the Cs–vanadates (C= 0.100—0.50) has been determined by X-ray diffraction;[14–17,20,21] the V=O bond length has also been estimated. The bond length expands linearly with the Cs-content, as is indicated by the open circles in Fig. 4. The bond lengths estimated above at C=0.332 are shown by the closed circles. They are located near the linear line.

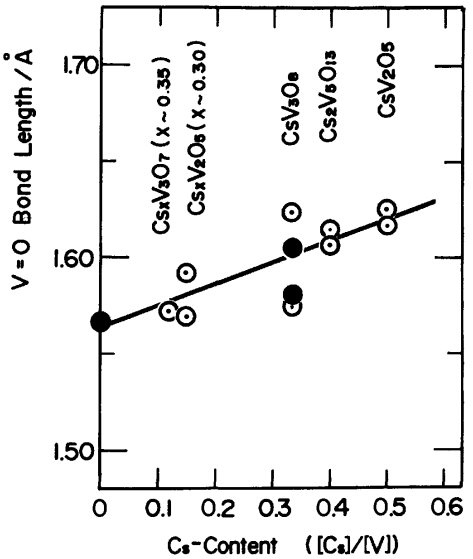

Fig. 4. The expansion of the V=O bond with the Cs-addition to V_2O_5. The open circles indicate the V=O bond lengths for the Cs–vanadates: $Cs_xV_3O_7$ ($x \approx 0.35$),[14] $Cs_xV_2O_5$ ($x \approx 0.3$),[16] CsV_3O_8,[17] $Cs_2V_5O_{13}$,[20] and CsV_2O_5,[21] which have been determined by the X-ray analysis. The closed circles at C=0.332 indicates the V=O bond lengths, estimated by the application of the Bond-Strength-Bond-Length parameters by Brown and Sahnnon to the band shifts from 1022 to 1000 and to 965 cm^{-1}. The closed circle at C=0 indicates the reference for the estimation of the V=O bond length mentioned above and the values (1.567 Å) is the average of the values determined by Ketelaar,[1] Byström *et al.*,[2] and Backmann *et al.*[3]

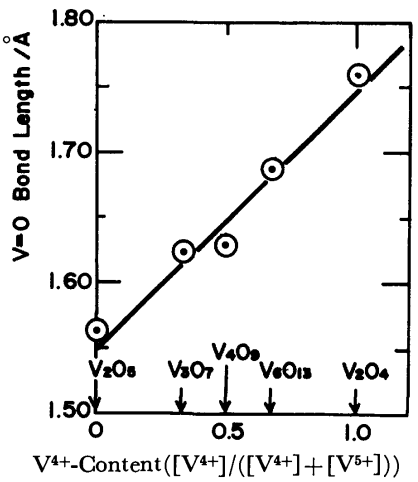

Fig. 5. The expansion of the V=O bond with the reduction of V_2O_5. In V_2O_5 the average of the values by Ketelaar,[1] Byström *et al.*,[2] and Backmann *et al.*,[3] and in V_2O_4 the value by Anderson[25] were given. In the intermediate phases, V_3O_7,[22] V_4O_9,[23] and V_6O_{13},[24] the V^{4+}-content was evaluated under the assumption that the V-ions take a mixed valency of V^{4+} and V^{5+}. In the phases there are two or three kinds of the V=O group and thus the averages of the V=O bond length were given.

Therefore, it is confirmed that Cs-ions occupy two kinds of sites, which are close to the V=O groups in

the CsV_3O_8 crystalline lattice, and that the bond strengths of the V=O groups are weakened by the Cs ions inserted; thus, the stretching frequency decreases from 1022 to 1000 cm^{-1} and to 965 cm^{-1}.

With the reduction in V_2O_5, the VO_6 polyhedral unit changes in symmetry from a distorted trigonal bipyramid toward an octahedron.[12] The V=O bond expands linearly with the reduction, as is shown in Fig. 5; the expansion in the V=O bond is accompanied by a decrease in the valence state of the vanadium ion and then by a change in the symmetry around the vanadium ion. In other words, the bond expansion is caused by the formation of the V^{4+} ion, that is, V^{4+}=O. The curve of the V=O bond length *vs.* the V^{4+}-content in Fig. 5 corresponds well to that of the V=O bond length *vs.* the Cs-content in Fig. 4. The complete transfer of electrons from alkali metals such as Li and Na to vanadium ions has, in fact, been observed in alkali-vanadates by NMR and ESR spectrometry.[26] With Cs–vanadates, electron transfer could occur more favorably because Cs atom has the lowest ionization potential of all the alkali metals. Therefore, it can be concluded that the expansion in the V=O bond by the Cs-addition is caused not only by its steric effect, but also by the electron transfer from Cs to the vanadium ion to form the V^{4+}=O group.

The V–O–V Stretching Bands. With respect to the V–O–V stretching vibration in pure-V_2O_5, the original band itself was too broad. The band broadened further and also shifted toward the low frequencies upon the Cs-addition. The band shifts from 815 cm^{-1}, $\Delta\tilde{\nu}$, are summarized in the last column of Table 2. In the three samples of C=0.100—0.332, in which the band is split into two peaks, the band shift could not be estimated. The plot of $\Delta\tilde{\nu}$ *vs.* C is shown in Fig. 6-a. In the range of C=0—0.020, there is a good correlation between the band shift, $\Delta\tilde{\nu}$, and the cubic root of the Cs-content, $C^{1/3}$, as is shown in Fig. 6-b.

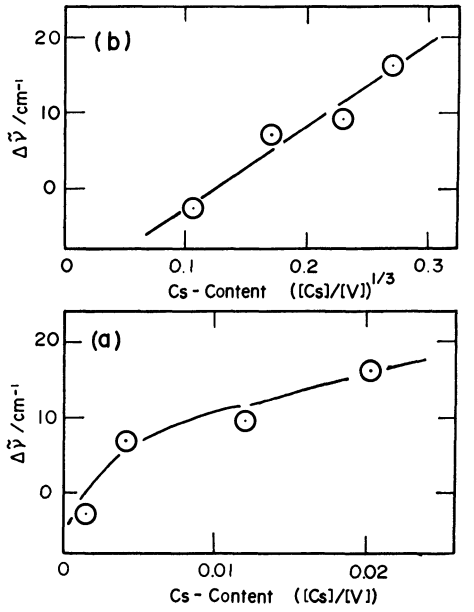

Fig. 6. The band shift of the V–O–V stretching ($\Delta\tilde{\nu}$) with the Cs-content (C) in the region of C=0—0.020; a) the plot of $\Delta\tilde{\nu}$ *vs.* C, b) the plot of $\Delta\tilde{\nu}$ *vs.* $C^{1/3}$.

In samples of Cs-4—Cs-6, the phases of V_2O_5 or $Cs_xV_2O_5$ and CsV_3O_8 co-exist, as was clearly shown above in the discussion of the V=O stretching band. In Cs-3 (C=0.012) the characteristic bands of CsV_3O_8 appear at 965 and 1000 cm^{-1}. In Cs-2 (C=0.0042), the 965 cm^{-1} band appeared, but the 1000 cm^{-1} band did not appear; it might have been masked under the steep part of the 1022 cm^{-1} band of pure-V_2O_5. If so, CsV_3O_8 would already be formed in such a low concentration as C=0.0042. In such a situation, the broadening and the shifts in the 815 cm^{-1} band might arise for the mixing of the 815 cm^{-1} by V_2O_5 with the 780 and the 742 cm^{-1} by CsV_3O_8 even though it is very weak. Furthermore, the intensities of the 780 and the 742 cm^{-1} bands grow relatively with the increase in the Cs-content; thus, the band shifts may be expected to become larger.

In fact, the region where the non-stoichiometric phase of $Cs_xV_2O_5$ (x=too small) can exist stably and the Cs-content, at which the CsV_3O_8 phase begins to appear, can not be exactly determined in the present paper. Therefore, even in the region of C=0—0.020, where the linear correlation of $\Delta\tilde{\nu}$ to $C^{1/3}$ holds as is shown in Fig. 6-b, the x in the $Cs_xV_2O_5$ could not be simply regarded as varying with the changes in the Cs-content. The physical meanings of the correlation can not be discussed further.

The author wishes to express his appreciation to Mr. Shinichi Ishikawa and Mr. Tetuo Yamamoto for their measurements of the IR spectra, and to Professor Keiji Kuwata for his continued interest in this work and for his valuable suggestions.

(Received September 11, 1980)

Kinetic studies of the oxidation of *o*-, *m*-, and *p*-benzenediols (H_2A) by tris(1,10-phenanthroline)iron(III) were made in dilute perchloric acid solution at an ionic strength of 1.0 mol dm^{-3} at four temperatures between 10 and 30 °C. The second-order rate constants (k_0) which follow the observed rate law of $-d[Fe(phen)_3^{3+}]/dt = k_0[Fe(phen)_3^{3+}][H_2A]$ were determined under varied conditions. The order of the rate constants was *m*-<*o*-<*p*-benzenediols, with the ratio being approximately $1 : 10^3 : 10^4$. By the application of the Marcus theory to the kinetic parameters obtained, the standard redox potentials of the dihydroxyphenyl radicals (H_2A^+) were estimated in 0.11 mol dm^{-3} perchloric acid solution to be 1.41, 1.10, and 0.97 V for *m*-, *o*-, and *p*-benzenediols, respectively. The energies of the highest occupied molecular orbitals for the H_2A molecules (ε_{HOMO}) were calculated to be −0.4468, −0.4332, and −0.4224 a.u. for *m*-, *o*-, and *p*-benzenediols, respectively. The differences of the total electronic energies between H_2A^+ and H_2A molecules (ΔE_T) were calculated to be 0.4183, 0.4033, and 0.3957 a.u. for *m*-, *o*-, and *p*-benzenediols, respectively. Thus, the standard redox potentials of the free-radicals estimated are found to be well correlated with the HOMO energies and also with the differences of the total electronic energies between the cation radicals and the parent molecules.

The application of the Marcus theory[1] to kinetics of the reactions involving organic and inorganic substrates has given satisfactory results in the explanation of the observed kinetic parameters. An application of Marcus theory to the investigation of the kinetic data in the outer-sphere electron transfer reactions allows an estimation of the redox potentials of the unstable free-radicals of organic molecules.[2,3] The present paper demonstrates the kinetics of the outer-sphere electron transfer reactions of *o*-, *m*-, and *p*-benzenediols with tris(1,10-phenanthroline)iron(III), and explains the estimation of the standard redox potentials of those free-radicals by means of the application of Marcus theory to the kinetic parameters obtained. We calculated the energy of the highest occupied molecular orbitals (HOMO) of each benzenediol and the difference in the total electronic energy between the cation radical and the parent molecule, by using CNDO/2 MO.[5] The correlation between the theoretically calculated energies and the standard redox potentials estimated by the application of Marcus theory to the kinetic parameters is discussed in the present paper.

Experimental

Chemicals. Reagent-grade *o*-, *m*-, and *p*-benzenediols from Wako Pure Chemical Co. Inc., were used without further purification. The solution of each reagent was prepared just before use. Tris(1,10-phenanthroline)iron(III) perchlorate was prepared by oxidizing tris(1,10-phenanthroline)iron(II) with lead(IV) dioxide in dilute sulfuric acid solution; after removal of lead(IV) dioxide and lead(II) sulfate, the perchlorate salt of the tris(1,10-phenanthroline)-iron(III) was precipitated by the addition of sodium perchlorate solution. The solid obtained was recrystallized from aqueous perchlorate solution. A stock solution of tris(1,10-phenanthroline)iron(III) was prepared by dissolving the perchlorate salt in 70% (v/v) perchloric acid. The stock solution of the blue solution having an absorption maximum at 600 nm was very stable in perchloric acid and no appreciable decomposition occurred for at least 3 months at room temperature in the dark. Sodium perchlorate, used for adjusting ionic strength, was recrystallized twice from aqueous solution. Deionized water was distilled with and without addition of some permanganate in a glass still.

Kinetic Measurements. The kinetic experiments were carried out with a Union Stopped Flow Spectrophotometer RA-401 by following the increase of the absorbance at 510 nm due to the tris(1,10-phenanthroline)iron(II) of a reaction product. The concentrations of *m*-benzenediol were kept at least 10-fold larger than those of tris(1,10-phenanthroline)iron-(III) in order to ensure pseudo-first-order conditions. In most of the reactions of *o*- and *p*-benzenediols with tris(1,10-phenanthroline)iron(III), second-order conditions were adopted because these reactions were extremely fast under the conditions of excess benzenediols with respect to tris(1,10-phenanthroline)iron(III). The rate constants were evaluated by treating an average-kinetic curve for 10 runs, the Stopped-Flow apparatus being equipped with a micro-computer system for memorizing and averaging the multiple runs. The acidity was kept constant at 0.055, 0.11, or 1.0 mol dm^{-3} in perchloric acid. The ionic strength was adjusted to be 1.0 mol dm^{-3} by the addition of sodium perchlorate solution. The temperature (with ±0.1 °C) of the cell housing was regulated by circulating the thermostated water.

Results

Stoichiometry. By the titration of 2.6×10^{-5} mol dm^{-3} tris(1,10-phenanthroline)iron(III) with *o*- or *p*-benzenediol monitoring the absorbance at 510 nm due to tris(1,10-phenanthroline)iron(II), the stoichiometry was determined to be 2 : 1 for $[Fe(phen)_3^{3+}]$: [bezenediol]. Thus, the stoichiometric equation is written as Eq. 1:

$$2\,Fe(phen)_3^{3+} + H_2A \longrightarrow 2\,Fe(phen)_3^{2+} + A + 2H^+, \quad (1)$$

where H_2A indicates a benzenediol and A, a quinone. The stoichiometry for the reaction between *m*-benzenediol and tris(1,10-phenanthroline)iron(III) was not determined by the titrimetric method due to the slow reaction. A large excess of *m*-benzenediol was necessary for the reaction to proceed completely.

Kinetics of Reaction. The kinetic runs were carried out in the acid solutions so that the acid dissociation of benzenediols could be completely neglected.[4] For the reactions of *o*- and *p*-benzenediols with tris(1,10-phenanthroline)iron(III), when pseudo-first-order conditions were adopted, plots of ln $(A_\infty - A_t)$ *vs.* t were linear for at least 80% of a whole reaction. Moreover, when the reaction was started at a second-order condition of $[Fe(phen)_3^{3+}] = 2[H_2A]$, plots of $1/(A_\infty - A_t)$ *vs.* t were also linear for at least 60% of a whole reaction. This confirms the first-order dependence of each reactant and the stoichiometry given in Eq. 1. Thus, the following empirical rate law can be written:

$$-d[Fe(phen)_3^{3+}]/dt = k_0[Fe(phen)_3^{3+}][H_2A], \quad (2)$$

where k_0 is the observed second-order rate constant. In case of the reaction between *m*-benzenediol and tris(1,10-phenanthroline)iron(III), plots of ln $(A_\infty - A_t)$ *vs.* t were linear for the initial periods of about 20% of a whole reaction and gradually deviated from the straight line under a pseudo-first-order condition. Thus, the rate constants in this case were evaluated by using the initial slope. The second-order rate constants obtained were, within the experimental error, constant irrespective of the reactants over the wide ranges of 5.0×10^{-5} to 5.0×10^{-2} mol dm^{-3} *m*-benzenediol and of 1.2×10^{-6} to 2.0×10^{-5} mol dm^{-3} tris(1,10-phenanthroline)iron(III). However, when tris(1,10-phenanthroline)iron(II) was added to the reaction solution before starting the reaction, the rate of reaction decreased according to the amounts of tris(1,10-phenanthroline)iron(II) added. Unless the amounts of tris(1,10-phenanthroline)iron(II) exceeded about 10% of the tris(1,10-phenanthroline)-iron(III) concentrations, the rate constants obtained from the initial slope of ln $(A_\infty - A_t)$ *vs.* t were not influenced.

Temperature Dependence. The observed second-order rate constants k_0 at varied temperatures were determined under given conditions. The forward rate constants k_1 in Reaction 3 (and Eq. 5) are tabulated in

a) $r_1=4.0\times10^{-10}$ m for benzenediols; $r_2=7.0\times10^{-10}$ m for $Fe(phen)_3^{3+/2+}$; $\lambda_{12}=80.8$ kJ mol^{-1}; the potentials estimated for the reaction $H_2A^+ + e^- \rightleftarrows H_2A$; the error of E° is ±0.01 V. b) The error is $\pm$ 1 kJ mol^{-1}. c) The error is ±4 J K^{-1} mol^{-1}. d), e), and f) indicate the results in 0.055, 0.11, and 1.0 mol dm^{-3} perchloric acid at an ionic strength of 1.0 mol dm^{-3}. g) Evaluated by using $\Delta G^{*}_{11}=23$ and $\Delta G^{*}_{22}=20$ kJ mol^{-1} (see Text).

Table 1, where the observed rate constants k_0 are equal to $2k_1$ (*v. i.*).

Calculation of ε_{HOMO} *and* ΔE_T. To evaluate the oxidation potential theoretically, a CNDO/2 MO[5] calculation was made for *o*-, *m*-, and *p*-benzenediols and the corresponding dihydroxyphenyl radicals. The following two energies may be compared to the redox potentials determined experimentally. One is the energy level of the highest occupied molecular orbital of the neutral species (ε_{HOMO}). This gives the ionization potential of benzenediols of H_2A species. The other is ΔE_T, the difference of the total electronic energies between the neutral molecule and its cation radical of H_2A^+. The ΔE_T corresponds to the energy required to cause $H_2A \rightarrow H_2A^+ + e^-$, and is described as $\Delta E_T = E_T(H_2A^+) - E_T(H_2A)$. The value of E_T of the radical was computed by using the UHF MO. For the calculation of ε_{HOMO} and E_T, the geometries of the molecules were determined through the optimization of the functional group (-OH part). The structure of the benzene ring was fixed throughout this work. The geometries determined in this way are exhibited in Fig. 1, together with the pictures of ε_{HOMO} and ΔE_T.

Discussion

Tris(1,10-phenanthroline)iron(III) is an one-electron oxidizing agent. Thus, the non-complementary oxidation reactions are expected to occur through two successive one-electron transfer reactions, as follows:

$$H_2A + Fe(phen)_3^{3+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_2A^+ + Fe(phen)_3^{2+}, \quad (3)$$

$$H_2A^+ + Fe(phen)_3^{3+} \xrightarrow{k_2} Fe(phen)_3^{2+} + 2H^+ + A. \quad (4)$$

Assuming the steady state conditions for the concentrations of H_2A^+ species, the following rate equation can be derived:

$$-d[Fe(phen)_3^{3+}]/dt = \left\{1 + \frac{k_2[Fe(phen)_3^{3+}]}{k_{-1}[Fe(phen)_3^{2+}] + k_2[Fe(phen)_3^{3+}]}\right\} \times k_1[H_2A][Fe(phen)_3^{3+}]. \quad (5)$$

When the condition of $k_2[Fe(phen)_3^{3+}] \gg k_{-1}[Fe(phen)_3^{2+}]$ is satisfied, Eq. 5 can be represented by the empirical rate law of Eq. 2 with relationship of $k_0=2k_1$. These conditions were fulfilled for the reactions of *o*- and *p*-benzenediols with tris(1,10-phenanthroline)iron(III) for at least 80% of a whole reaction, and for the reactions of *m*-benzenediol with tris(1,10-phenanthroline)iron(III) for about 20% of a whole reaction. In the reaction of *m*-benzenediol, the rate of reaction decreased with increasing the ratios of $[Fe(phen)_3^{2+}]_i/[Fe(phen)_3^{3+}]_i$, and the value of k_{-1}/k_2 was approximately 0.7. According to the Marcus theory[1] for the outer-sphere electron transfer reaction, the excess free energy of activation for a cross reaction (ΔG^{*}_{12}) varies with the standard free energy change (ΔG°_{12}) for the redox step, as shown in Eqs. 6 and 7:

$$\Delta G^{*}_{12} = \omega_{12} + \lambda_{12}(1+\Delta G^{\circ}_{12}/\lambda_{12})^2/4, \quad (6)$$

$$\lambda_{12} = 2(\Delta G^{*}_{11} - \omega_{11} + \Delta G^{*}_{22} - \omega_{22}), \quad (7)$$

where ΔG^{*}_{11} and ΔG^{*}_{22} are the activation free energies for the self-exchange electron-transfer reactions, and ω_{11} and ω_{22} represent the work terms involved in the same reactions; ω_{12} is the work term required to bring the reactants onto the activated complex. The work terms can be evaluated from Eq. 8:

$$\omega_{ij} = \frac{Z_1 Z_2 e^2}{D_s r_{ij}} \exp[-\kappa r_{ij}], \quad (8)$$

where Z_1 and Z_2 are the formal charges of reactants, e is the electron charge, D_s is the static dielectric constant, r_{ij} is the distance of the closest approach of the reactants in the activated complex, and κ is the reciprocal Debye radius. According to the Marcus theory,[1] the parameter λ_{12} is equal to $\lambda_o+\lambda_i$, where λ_o is the solvent reorientation term and λ_i is the contribution term from the inner-sphere change in bond lengths and angles in the molecules. When λ_i is negligible, then λ_{12} is set to be λ_0, which is represented as Eq. 9:

$$\lambda_0 = \left(\frac{1}{2r_1} + \frac{1}{2r_2} - \frac{1}{r_{12}}\right)\left(\frac{1}{n^2} - \frac{1}{D_s}\right)(\Delta e)^2, \quad (9)$$

where r_1 and r_2 are the radii of the reactants, r_{12} is the distance between the reacting centers in the activated state and can be approximately set as (r_1+r_2), n is the

refractive index of the medium, D_s the static dielectric constant, and Δe the charge transferred. By assuming $r_1=4.0\times10^{-10}$ m for *o*-, *m*-, and *p*-benzenediols[6,7] and $r_2=7.0\times10^{-10}$ m for tris(1,10-phenanthroline)iron(III),[8] $n=1.342$,[9] and $D_s=78.5$,[10] the value of λ_0 is calculated to be 80.8 kJ mol^{-1}. The work terms for the forward reaction of Eq. 3 are evaluated to be zero for ω_{12} and ω_{11}, and 0.08 kJ mol^{-1} for ω_{22} at an ionic strength of 1.0 mol dm^{-3} at 25 °C. The activation free energy ΔG^*_{12} is described as follows:

$$k_{12} = Z \exp\left[-\Delta G^*_{12}/RT\right], \qquad (10)$$

where Z is the collision frequency in solution and is usually taken as 10^{11} at 25 °C. Thus, the ΔG^*_{12} for the forward reaction of Eq. 3 are determined by using the data in Table 1. By using the parameters obtained, the value of ΔG°_{12} can be evaluated by Eq. 6. The ΔG°_{12} allows the estimation of the standard redox potentials of the cation radicals of *o*-, *m*-, and *p*-benzenediols. By using $E^\circ(\mathrm{Fe(phen)_3^{3+/2+}})=1.06$ V,[11] the values of the standard reduction potentials of the cation radicals were estimated; these are shown in Table 2. The potentials of the radicals could be estimated without knowledge of the contributions of ΔG^*_{11}, ΔG^*_{22}, ω_{11}, and ω_{22}. The rate constant for the self-exchange reaction of tris(1,10-phenanthroline)iron(III) and -(II) has been reported to be larger than 3×10^7 dm^3 mol^{-1} s^{-1} at 25 °C.[12] Meisel[13] has reported that the observed self-exchange rate constants for a series of reactions between the organic radicals and the parent molecules fall in the range of 1×10^7 to 1×10^9 dm^3 mol^{-1} s^{-1}. If we adopt the values of 3×10^7 dm^3 mol^{-1} s^{-1} for k_{22} of $\mathrm{Fe(phen)_3^{3+/2+}}$ and 1×10^7 dm^3 mol^{-1} s^{-1} for k_{11} of $\mathrm{H_2A^+/H_2A}$, the activation free energies of ΔG^*_{22} and ΔG^*_{11} are evaluated to be 20 and 23 kJ mol^{-1} for $\mathrm{Fe(phen)_3^{3+/2+}}$ and $\mathrm{H_2A^+/H_2A}$ from Eq. 10, respectively.[14] This leads to the value of 86 kJ mol^{-1} for λ_{12}. Therefore, we can determine the values of $E^\circ(\mathrm{H_2A^+/H_2A})$ to be 1.39, 1.07, and 0.94 V in 0.11 mol dm^{-3} perchloric acid solution for *m*-, *o*-, and *p*-benzenediols, respectively. These values are in good agreement with the corresponding ones which are estimated without using ΔG^*_{11} and ΔG^*_{22} and neglecting λ_i (refer to Table 2). The values of $E^\circ(\mathrm{H_2A^+/H_2A})$ increased slightly with increasing acidity in *m*- and *p*-benzenediols. This may indicate some contributions of Reaction 11, which involves a simultaneous transfer of an electron and a proton:

$$\mathrm{HA^\cdot + H^+ + e^- \rightleftharpoons H_2A.} \qquad (11)$$

The Marcus theory[1] holds for a reaction which occurs adiabaticly by the outer-sphere electron transfer reaction, and thus, the activation entropy is expected to be close to zero. Although the collision frequency (Z) is generally assumed to be 10^{11} dm^3 mol^{-1} s^{-1} in solution, the pre-exponential factor deviates sometimes from the value, indicating some contribution of a non-adiabatic reaction. The activation enthalpy and entropy ΔH^* and ΔS^* can be determined by assuming $\kappa=1$ in Eyring's absolute rate equation:

$$k = \kappa \frac{kT}{h} \exp\left[\Delta S^*/R\right] \exp\left[-\Delta H^*/RT\right], \qquad (12)$$

where κ is the probability of the electron-transfer within the activated complex. The values of ΔH^* and ΔS^* were estimated by assuming $\kappa=1$; they are listed in Table 2 together with the other parameters.

It is of interest to interpret theoretically the order of the redox potentials of *o*-, *m*-, and *p*-benzenediols and to compare them to those estimated experimentally. Since the environment effect such as the solvent effect on the potentials is expected to be almost the same among these isomers, the differences of the genuine electronic properties must be related to the order of the redox potentials. According to the results in Fig. 1, both ε_{HOMO} and ΔE_T indicate that the ease for the oxidation is in the order of *m*-<*o*-<*p*-. This trend is well correlated with that obtained experimentally by the application of Marcus theory to the kinetic parameters. The order of these potentials is ascribed to the positional difference of the O–H group. To apply the orbital interaction scheme to this analysis, benzenediol is regarded as a system of phenol and O–H group. In this respect, the HOMO of benzenediols is mainly composed of the highest occupied MO of phenol (*homo*) and the p_π atomic orbital on the oxygen of the O–H group. Thus, ε_{HOMO} is determined by the extent of this orbital interaction. Examining the shape of *homo* in

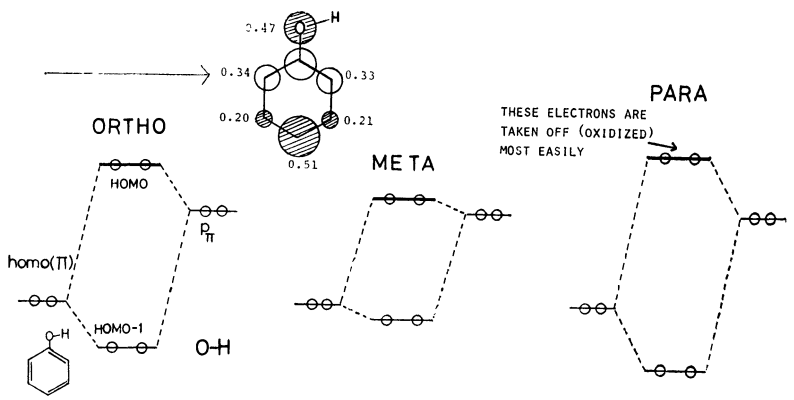

Fig. 2. Schematic sketch of the orbital interaction between homo of phenol and the pπ atomic orbital of the O–H group. The HOMO levels of benzenediols (ε_{HOMO}) are determined by the extent of this orbital interaction. The degree of the interaction is ascribed to the coefficient attached to the atomic orbital of homo, the coefficient being shown by the absolute value in this figure.

Fig. 2, one may find that the *para* position has the largest coefficient (0.51), the *ortho* is of the second (0.33 or 0.34) and the *meta* is of the smallest one (0.21 or 0.20). Since the position with the large coefficient undergoes the large extent of the orbital interaction (the bigger energy splitting in Fig. 2), the order of the coefficients should be reflected in that of ε_{HOMO}. This prediction is confirmed by the comparison of the values of ε_{HOMO} in Fig. 1. Thus, the order of the ease of oxidation may be interpreted in terms of the orbital interaction and the origin of the difference of ε_{HOMO} is basically the same as the *ortho, para orientation* for the nucleophilic substitution onto the benzene ring of phenol.

Kinetics and Equilibrium of the Reaction between Bis(trifluoroacetylacetonato)palladium(II) and Tri-*o*-tolylphosphine

Shinichi MATSUMOTO and Shinichi KAWAGUCHI*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received October 2, 1980)

Tri-*o*-tolylphosphine reacts with bis(trifluoroacetylacetonato)palladium(II), $Pd(tfac)_2$, to convert one of the chelating ligands into the unidentate state, resulting in $Pd(tfac)(tfac\text{-}O)P(o\text{-tolyl})_3$. The reaction was studied by a spectrophotometric method. The equilibrium constant was determined at several temperatures, K being 1.38×10^3, 4.35×10^3 dm^3 mol^{-1} and more than 10^9 dm^3 mol^{-1} in benzene, dichloromethane, and methanol, respectively, at 25 °C. In the presence of excess phosphine, the reaction proceeds as a pseudo first order reaction to attain equilibrium. The forward and reverse rate constants, k_1 and k_{-1}, were obtained as 0.172 dm^3 mol^{-1} s^{-1} and 1.22×10^{-4} s^{-1} in benzene and 2.28 dm^3 mol^{-1} s^{-1} and 4.9×10^{-4} s^{-1} in dichloromethane at 25 °C, respectively. In methanol the forward rate was measured under irreversible pseudo first order conditions and conforms with the usual two term rate law, $k_{obsd}/s^{-1}=2\times10^{-3}+56.6[P(o\text{-tolyl})_3]$. The remarkable dependence of K and k_1 on the nature of solvent is related to the hydrogen bonding interaction between the carbonyl group of the coordinated tfac anion and a solvent molecule.

The kinetic study in a previous paper[1] of the reactions between bis(acetylacetonato)palladium(II) and alkylamines (L) to afford the mixed-ligand cationic complexes of the $[Pd(acac)L_2](acac)$ type revealed that $Pd(acac)(acac\text{-}C^3)L$ is not an intermediate in this reaction but is formed *via* the above outer-sphere complex.** A complex such as $Pd(acac)(acac\text{-}O)L$ containing an *O*-unidentate acetylacetonate anion is then supposed to be involved as an intermediate in the reaction pathway, although it is not sufficiently accumulated to be detected spectrophotometrically.

Mercury(II)[2,3] and silicon(IV)[4,5] complexes containing an oxygen-bonded β-diketonate anion as a unidentate ligand have been reported. Recently the reactions of bis(acetylacetonato)platinum(II) with triethylphosphine[6] at low temperature (<-10 °C) and with piperidine[7] at 70 °C were found to give the $Pt(acac\text{-}O)_2L_2$ complexes. Similarly the reaction of dimethyl(acetylacetonato)gold(III) with tricyclohexylphosphine[8] and reactions of bis(trifluoroacetylacetonato)-platinum(II) and -palladium(II) with tri-*o*-tolylphosphine[9] also gave the *O*-bonded β-diketonato complexes. The present paper reports on the kinetic and equilibrium studies of the reaction between bis(trifluoroacetylacetonato)palladium(II) and tri-*o*-tolylphosphine.

Experimental

Materials. Tri-*o*-tolylphosphine was recrystallized from ethanol and stored under nitrogen. Methanol and benzene were dried with Linde Molecular Sieves 3A and 4A, respectively, and distilled before use. Dichloromethane was stored over sodium carbonate, dried with Linde Molecular Sieve 4A, and distilled. Water contents of these solvents were determined with an MCI digital water microanalyzer CA-01 to be $3—4\times10^{-3}$ mol dm^{-3} for methanol and $1—2\times10^{-3}$ mol dm^{-3} for benzene and dichloromethane.

Bis(trifluoroacetylacetonato)palladium(II), $Pd(tfac)_2$, was prepared according to Okeya *et al.*[10] by reacting sodium hexachlorodipalladate(II) with trifluoroacetylacetone in methanol containing sodium carbonate. Found: C, 29.13; H, 1.94%. Calcd for $C_{10}H_8O_4F_6Pd$: C, 29.11; H, 1.95%.

Trifluoroacetylacetonato(trifluoroacetylacetonato-*O*) (tri-*o*-tolylphosphine)palladium(II), $Pd(tfac)(tfac\text{-}O)P(o\text{-tolyl})_3$, was also prepared by the method of Okeya *et al.*[9] A solution in benzene (20 cm^3) of $Pd(tfac)_2$ (0.602 g, 1.46 mmol) and $P(o\text{-tolyl})_3$ (0.456 g, 1.50 mmol) was stirred for 1 h and then concentrated to *ca.* 3 cm^3 by evaporation under reduced pressure. Petroleum ether (bp *ca.* 40 °C) was added dropwise to the concentrate to deposit an orange precipitate in an 85% yield, which was recrystallized from benzene–petroleum ether. Found: C, 52.07; H, 4.11%. Calcd for $C_{31}H_{29}O_4PF_6Pd$: C, 51.92; H, 4.08%.

Measurements. For the kinetic and equilibrium studies, absorbance at 380 nm was used which involves negligible contribution by uncoordinated $P(o\text{-tolyl})_3$. In benzene and dichloromethane, $Pd(tfac)_2$ ($8—24\times10^{-5}$ mol dm^{-3}) was allowed to react with excess $P(o\text{-tolyl})_3$ ($8—21\times10^{-4}$ mol dm^{-3}) and the pseudo first order rate to attain the equilibrium was determined. In methanol, the equilibrium shifts further to right and a large excess of the phosphine ($1—4\times10^{-3}$ mol dm^{-3}) was used to measure the irreversible first order rate. The reverse reaction of $Pd(tfac)(tfac\text{-}O)P(o\text{-tolyl})_3$ in benzene to produce $Pd(tfac)_2$ was also followed spectrophotometrically, and the first order rate constant was obtained by analyzing the initial stage of reaction. Spectral measurements were carried out with a Hitachi EPS-3T recording spectrophotometer and a Union stopped-flow rapid-scan spectrophotometer RA-1300.

Results and Discussion

Equilibria of the Reaction. When a mixture of $Pd(tfac)_2$ and $P(o\text{-tolyl})_3$ was stirred in benzene or dichloromethane for 24 h, the following reaction attained equilibrium. Concentrations of both the palladium(II) complexes were calculated from their absorption spectra shown in Fig. 1. Values of the equilibrium constant K thus obtained in both solvents

$$Pd(tfac)_2 + P(o\text{-tolyl})_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Pd(tfac)(tfac\text{-}O)P(o\text{-tolyl})_3,\ K \qquad (1)$$

** In this paper, acac and tfac represent the acetylacetonate and trifluoroacetylacetonate anions, respectively, chelating a metal ion through two oxygen atoms, while acac-*O*, tfac-*O*, and acac-C^3 refer to the oxygen-bonded and central-carbon-bonded states, respectively.

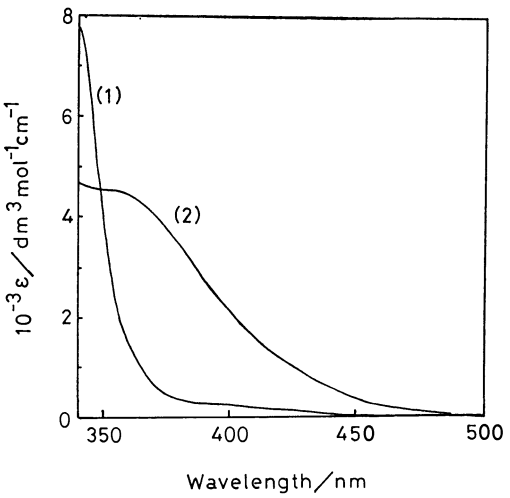

Fig. 1. Absorption spectra of $Pd(tfac)_2$ (curve 1) and Pd(tfac) (tfac-*O*) $P(o\text{-tolyl})_3$ (curve 2) in benzene.

Table 1. Equilibrium constants of the reaction between $Pd(tfac)_2$ and $P(o\text{-tolyl})_3$ (Eq. 1)

Solvent	Temp / K	$10^{-3}K$ / dm^3 mol^{-1}	$\Delta H°$ / kJ mol^{-1}	$\Delta S°$ / J K^{-1} mol^{-1}

at several temperatures are listed in Table 1. The plot of ln K against $1/T$ gave good straight lines (Fig. 2), from which the thermodynamic parameters were calculated and included in Table 1. Similar experiments in methanol were not successful for determining the equilibrium constant because of its too large value. Conversely, a methanol solution of Pd(tfac)(tfac-*O*)$P(o\text{-tolyl})_3$ was kept in a 5-cm cell and degree of the phosphine dissociation was determined. In this way the value of K in methanol at 25 °C was estimated to be larger than 10^9 dm^3 mol^{-1}.

As is seen in Table 1, reaction (1) is exothermic and the K value depends remarkably on the nature of solvent, increasing in the sequence, benzene<dichloromethane≪methanol. The dangling carbonyl group of the unidentate tfac ligand might be stabilized by interaction with the hydrogen-bonding solvent. Even in the presence of a large excess of the phosphine, however, the product complex shows no sign of further substitution, whereas tricyclohexylphosphine (PCy_3) reacts with $Pd(tfac)_2$ to afford not only Pd(tfac)(tfac-*O*)-PCy_3 but also $[Pd(tfac)(PCy_3)_2](tfac)$.[9] The large steric requirement of $P(o\text{-tolyl})_3$ seems to make the bisphosphine complex thermodynamically unfavorable.

Kinetics of the Reaction in Benzene and Dichloromethane. When $Pd(tfac)_2$ reacts with $P(o\text{-tolyl})_3$ in benzene or dichloromethane, absorption spectrum of the solution changes with time, exhibiting an isosbestic point at 348 nm, to reach a final spectrum corresponding to an equilibrium mixture of the two complexes. The plot of $\ln(A_t - A_\infty)$ against time gave a straight line covering

more than three half-lives. Here A_t and A_∞ represent The forward and reverse rate constants, k_1 and k_{-1} obtained from the slope and intercept of the straight line, respectively, are given in Table 3. Both the forward and the reverse reactions are faster in dichloromethane than in benzene. The values of $K=k_1/k_{-1}$ calculated from these rate constants in benzene and dichloromethane are 1410 and 4650 $dm^3\ mol^{-1}$, respectively, at 25 °C, showing satisfactory coincidence with those obtained from the equilibrium measurements (Table 1).

When a solution of Pd(tfac)(tfac-*O*)$P(o\text{-tolyl})_3$ in benzene (*ca.* 10^{-4} mol dm^{-3}) is left to stand, the phosphine molecule is expelled from the coordination sphere to produce $Pd(tfac)_2$. The reaction attains equilibrium after decomposition of *ca.* 90% of the mixed-ligand complex (Fig. 4). Values of the first order rate constant k_{-1} obtained by analyzing the early stage of the reaction at a few temperatures are given in Table 4. The k_1 values at each temperature were calculated by combining the value of k_{-1} with that of K. The values of k_1 and k_{-1} at 25 °C thus obtained coincide with those

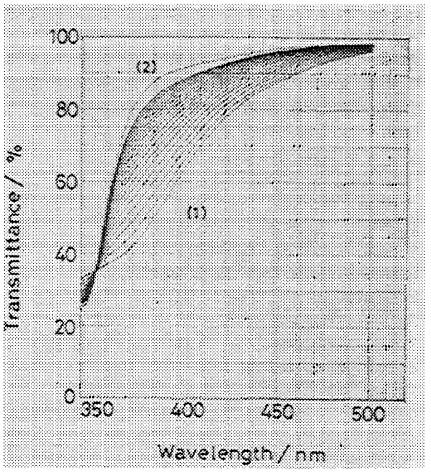

Fig. 4. Change with time of the absorption spectrum of a solution of Pd(tfac)(tfac-*O*)$P(o\text{-tolyl})_3$ in benzene at 25 °C, curves 1 and 2 representing the spectra 5 min and 24 h after commencement of the reaction, respectively. The initial concentration of the starting complex was 1.360×10^{-4} mol dm^{-1}.

TABLE 4. THE RATE CONSTANTS AND ACTIVATION PARAMETERS IN BENZENE

Temp / K	$10\,k_1$ / $dm^3\ mol^{-1}\ s^{-1}$	$10^4\,k_{-1}$ / s^{-1}
298	1.71[a]	1.24±0.01[b]
	1.72±0.02[c]	1.22±0.02[c]

ΔH^*/kJ mol^{-1}	14±3	42±3
ΔS^*/J K^{-1} mol^{-1}	−210±10	−180±10

a) Calculated by combining the values of k_{-1} and K at each temperature. b) Determined directly by following the reverse reaction of (1). c) Determined by following the equilibrium attainment of (1).

determined under the reversible reaction conditions. The activation parameters related to k_1 and k_{-1} in benzene were obtained from the Eyring plot and are included in Table 4. The data used for calculations are insufficient to allow detailed discussion, but the small values of ΔH^* associated with k_1 accords with the fast rate of reaction (1), ΔS^* being largely negative as is expected for the associative mechanism. Even ΔS^* for the reverse k_{-1} reaction is largely negative and might be related with the intramolecular nucleophilic attack of the dangling trifluoroacetyl group on the central metal atom. The differences between the kinetic parameters, $\Delta(\Delta H^*)$ and $\Delta(\Delta S^*)$, for the forward and reverse processes of reaction (1) coincide with $\Delta H°$ and $\Delta S°$ determined by equilibrium studies.

Kinetics of the Reaction in Methanol. The reaction in methanol was carried out under the irreversible pseudo first order conditions employing a large excess of $P(o\text{-tolyl})_3$. The plot of k_{obsd} thus obtained (Table 2) against the concentration of $P(o\text{-tolyl})_3$ gives a straight line (Fig. 5). The intercept of the straight line can not be the reverse rate contrary to the case for the reaction in benzene and dichloromethane (Fig. 3), since the

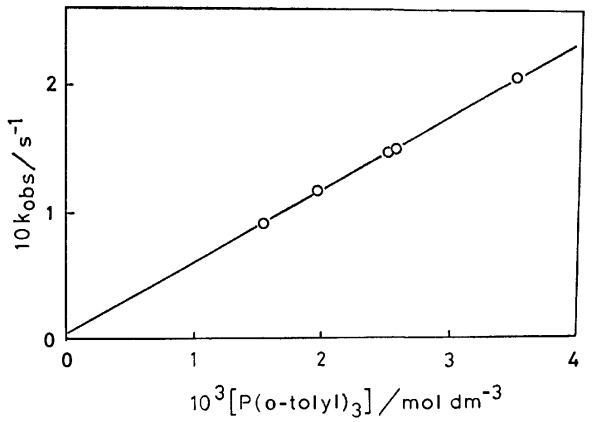

Fig. 5. Plot of the pseudo first order rate constant for the forward reaction of (1) in methanol at 25 °C against the concentration of $P(o\text{-tolyl})_3$.

equilibrium constant in methanol was estimated to be greater than 10^9 dm^3 mol^{-1}. The rate thus follows the two term rate law:

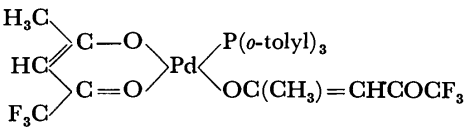
$$k_{obsd} = k_0 + k_1[P(o\text{-tolyl})_3]. \quad (4)$$

This type of rate equation is widely applicable to the ligand substitution reactions of square planar complexes,[11] the first term being attributed to the nucleophilic attack of a solvent molecule on the complex. In the case of Fig. 3, the intercept was entirely ascribed to the reverse rate, giving a consistent value of equilibrium constant. Thus the solvent path is not involved in the forward reaction in benzene and dichloromethane, but contributes a little to the reaction in methanol which has higher coordination ability.

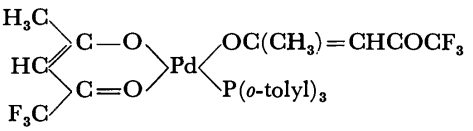
The rate constant k_1 for the reagent path also depends remarkably on the nature of solvent, decreasing in the sequence $CH_3OH \gg CH_2Cl_2 > C_6H_6$ (Table 3). The ratio of rates in methanol and benzene, 330 : 1, is larger than that (180 : 1) observed for the reaction of $Pd(acac)_2$ with dipropylamine.[1] Such a solvent effect might be related to the difference in hydrogen-bonding ability. A solvent molecule might interact with a carbonyl group of the coordinated tfac anion, enhancing the one bond cleavage of the chelated ligand. Of the three kinds of solvents, methanol has the highest tendency of hydrogen bonding and dichloromethane possesses weak hydrogen donating ability.[12]

The change of spectrum during the course of reaction (1) in each solvent shows a distinct isosbestic point, indicating that the five-coordinate intermediate is not accumulated enough to be detected spectrophotometrically. Bis(hexafluoroacetylacetonato)palladium(II) reacts with $P(o\text{-tolyl})_3$ to afford $Pd(hfac)_2P(o\text{-tolyl})_3$, which was confirmed by X-ray analysis to have a squarepyramid structure with the phosphine at a basal position.[13] On the other hand, $Pd(acac)_2$ does not react with $P(o\text{-tolyl})_3$ at all.[9] The three related Pd-(β-dik)$_2$ complexes show substantially different tendency of reaction with $P(o\text{-tolyl})_3$.

The starting complex $Pd(tfac)_2$ was reported to have the *trans* configuration in solid but exist as a mixture of *cis* and *trans* (1 : 3) in C_6D_6.[10] As to the structure of the reaction product, there exist the following two possibilities and the ^1H NMR spectrum in $CDCl_3$ showed that the isomer ratio *cis*(Me, L)/*trans*(Me, L) in equilibrium is 1/5.[9]



cis(Me, L)



trans(Me, L)

Reaction Process between Zinc Oxide and Sulfur Dioxide in the Presence of Carbon

Akimasa YAJIMA, Ryoko MATSUZAKI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received October 21, 1980)

The reaction products obtained by heating a mixture of ZnO and carbon in a SO_2 stream at various temperatures were examined. The possible reactions during the above process were also examined. When a mixture of ZnO and carbon was heated in a SO_2 stream, the formation of ZnS was observed above 600 °C. At 800 °C, all the ZnO used was converted to ZnS. Sulfur was also obtained outside the heating zone, and its amount increased markedly above *ca.* 750 °C. The ZnS formed was a mixture of α-ZnS and β-ZnS regardless of the reaction temperature. The process of formation of ZnS can be represented as follows: the reaction between carbon and SO_2 occurs at first to form sulfur. Above *ca.* 600 °C, the reaction between ZnO and the sulfur occurs to form ZnS. In addition to these reactions, the reduction of ZnO with carbon occurs slightly to form zinc, which then reacts with sulfur to form ZnS.

The chemical process for synthesizing metal sulfides from the oxides using sulfur dioxide(SO_2) as a sulfidizing agent is not only interesting from the viewpoint of the synthesis itself, but also important for the development of SO_2 utilization. In this work, the reaction process between zinc oxide (ZnO) and SO_2 in the presence of carbon was examined in order to understand the above chemical process.

Regarding the reaction between ZnO and SO_2 in the presence of carbon, little information has been available apart from the work of Pechkovskii,[1] who reports that zinc sulfide (ZnS) is formed at 650—800 °C by heating a mixture of ZnO and carbon in a SO_2 stream and that 91.8% of the charged ZnO is sulfidized at 800 °C by using a 4 : 1 mixture of carbon and ZnO (molar ratio). The formation process of ZnS and the modification of ZnS formed have not been described.

In this work, the reaction products between ZnO and SO_2 in the presence of carbon at various temperatures were examined. The reactions between ZnO and carbon, between ZnO and gaseous sulfur in a SO_2 stream, and between zinc and gaseous sulfur in a SO_2 stream were also examined in order to elucidate the reaction process between ZnO and SO_2 in the presence of carbon.

Experimental

The ZnO used was prepared by the thermal decomposition of tetrazinc monocarbonate hexahydroxide monohydrate ($Zn_4CO_3(OH)_6 \cdot H_2O$), which was prepared by adding ammonium carbonate solution to zinc nitrate solution, at 600 °C.[2] The carbon was prepared by the thermal decomposition of the guaranteed reagent D-glucose. The above materials were used as powders under 150 mesh. Zinc (guaranteed reagent, sandy form) was used after washing with acetone and with dilute hydrochloric acid. Gaseous SO_2 was dried by passing it through concd H_2SO_4 and over P_2O_5.

A mixture of ZnO and carbon at a specified ratio in a quartz boat (length: 72 mm, width: 16 mm, depth: 9 mm) was placed in a transparent quartz reaction tube (inner diameter: 28 mm, length: 1000 mm). Gaseous SO_2 was then introduced into the reaction tube. The sample part was positioned in the middle of a tubular electric furnace (heating length: 300 mm) maintained at a specified temperature for 1 h. The temperature of the sample part was controlled within ±2 °C. After heating, the sample was held at 100 °C for 1 h in an argon stream in order to release the adsorbed SO_2 on unreacted carbon.[3] The reactions between ZnO and carbon in an argon stream, between ZnO and gaseous sulfur in a SO_2 stream, and between zinc and gaseous sulfur in a SO_2 stream were examined in a similar manner.

The X-ray analysis of the sample was performed with an X-ray powder diffractometer equipped with a proportional counter using Ni filtered Cu radiation.

Results and Discussion

Reaction Products between ZnO and SO_2 in the Presence of Carbon. Prior to the examination of the reaction products between ZnO and SO_2 in the presence of carbon, the thermogravimetry of ZnO in a SO_2 stream was carried out in the temperature range up to 900 °C. The sample of ZnO (0.3 g) was heated at a rate of 2.5 °C/min and the flow-rate of SO_2 was maintained at 50 cm³/min. The sensitivity of the quartz helix used was approximately 72 mm/g. No weight change was observed, and the sample after the heating was found by X-ray analysis[4] to be unreacted ZnO. These results indicate that ZnO does not react with SO_2.

The products obtained by heating a mixture of 2.00 g of ZnO and 1.20 g of carbon at various temperatures for 1 h in a SO_2 stream at a flow-rate of 100 cm³/min were examined. The results are shown in Table 1, together with the weight changes in the samples. The

Table 1. Products obtained by heating a mixture of ZnO and carbon in a SO_2 stream at various temperatures

Temp /°C	Weight change/%	Sample in the boat	Amount of sulfur obtained outside the heating zone/g
550	+ 0.1	ZnO	Trace
600	+ 1.5	ZnO>>ZnS[α>β]	Trace
650	+ 2.1	ZnO>>ZnS[α>β]	<0.01
700	+ 2.7	ZnO>ZnS[α>β]	<0.01
750	− 3.0	ZnS[α>β]>ZnO	0.24
800	−24.9	ZnS[α>β]	1.59

Note; α=α-ZnS, β=β-ZnS.

sample in the boat was identified by X-ray analysis.[4-6] The modification of the ZnS formed is represented in the brackets.

The formation of ZnS was observed above 600 °C, and no unreacted ZnO was observed at 800 °C. Sulfur was obtained outside the heating zone throughout the temperature range in this experiment, and the amount of sulfur markedly increased above *ca.* 750 °C. The sample weight also markedly decreased above *ca.* 750 °C. The slight increase in the sample weight at 550 °C was due to the adsorption of the sulfur formed by the reaction on the unreacted carbon.[3]

The ZnS formed was a mixture of α-ZnS (high-temperature form, hexagonal) and β-ZnS (low-temperature form, cubic) at all temperatures.

Chemical analysis of the sample in the boat at 800 °C showed that the atomic ratio of zinc to sulfur[3] to be 1.0_0. From this result, it is confirmed that all the ZnO used was sulfidized at 800 °C.

Reaction Process between ZnO and SO_2 in the Presence of Carbon. To elucidate the reaction process between ZnO and SO_2 in the presence of carbon, the following experiments were carried out under conditions similar to those described in the preceding paragraph.

Reaction between ZnO and Carbon: The experimental results obtained by heating a mixture of ZnO (2.00 g) and carbon (1.20 g) in an argon stream (100 cm^3/min) for 1 h at various temperatures are shown in Table 2.

Table 2. Experimental results for the reaction between ZnO and carbon in an argon stream

Temp /°C	Weight loss/%	Amount of Zn obtained outside the heating zone/g	Conversion of ZnO to Zn/%
600	0.1	Detectable	Not calculated
650	0.2	0.001	<0.1
700	0.3	0.003	0.2
800	1.1	0.021	1.3

The samples after heating at all the temperatures were found to be unreacted ZnO by X-ray analysis. Zinc deposited outside the heating zone above 600 °C was dissolved in dilute nitric acid, and was determined by chelatometric titration.[7] The percentages of ZnO converted to zinc were calculated from the amounts of the zinc deposited.

These results indicate that a slight reduction of ZnO with carbon to zinc occurs above *ca.* 600 °C under the conditions in this experiment.

Reaction between ZnO and Sulfur in a SO_2 Stream: As seen from Table 1, when the mixture of ZnO and carbon was heated in a SO_2 stream, sulfur was formed. The reaction between carbon and SO_2 occurs even at 350 °C to form sulfur. This reaction proceeds markedly above *ca.* 700 °C, as reported by the present authors.[3] Therefore, the reaction between ZnO and sulfur was examined in a SO_2 stream.

ZnO (2.00 g) was heated in a stream of SO_2 containing a specified amount of gaseous sulfur at various temperatures for 1 h. The gaseous sulfur was formed by heating liquid sulfur and was carried by a stream of SO_2 (100 cm^3/min). Based on the experimental results for the reaction between carbon and SO_2, reported by the present authors,[3] the amounts of sulfur introduced at various temperatures were controlled to be 0.01 g for the experiments below 550 °C, 0.03 g at 600 °C, 0.25 g at 700 °C, and 1.90 g at 800 °C, since the experimental conditions (the amount of carbon, the flow-rate of SO_2, *etc.*) in this work were identical to those for the experiment on the reaction between carbon and SO_2. The results are shown in Table 3. The percentages of ZnO converted to ZnS shown in Table 3 were calculated from the weight gains in the samples.

Table 3. Products obtained by heating ZnO in a stream of SO_2 containing gaseous sulfur

Temp /°C	Sample in the boat	Conversion of ZnO to ZnS/%
550	ZnO	—
600	ZnO>>ZnS[α>β]	2
700	ZnO>ZnS[α>β]	12
800	ZnS[α>β]>ZnO	74

These results and the fact that ZnO does not react with SO_2 as described above show that the reaction between ZnO and sulfur proceeds above *ca.* 600 °C to form ZnS under the conditions in this experiment. The ZnS formed was a mixture of α-ZnS and β-ZnS, similar to the ZnS obtained by the reaction between ZnO and SO_2 in the presence of carbon as described above.

Reaction between Zinc and Sulfur in a SO_2 Stream: As mentioned in the previous paragraph, on heating ZnO and carbon, ZnO was slightly reduced with carbon to form zinc above *ca.* 600 °C. It has been briefly reported in the early literature[8] that zinc powder vigorously reacts with sulfur in a SO_2 atmosphere. But no details of the reaction were given.

The products obtained by heating zinc (1.00 g) at various temperatures for 1 h in a stream of SO_2 (100 cm^3/min) containing a specified amount of sulfur were examined. The amounts of sulfur introduced were controlled so as to be the same as those in the experiment on the reaction between ZnO and sulfur in a SO_2 stream described above. The experimental results are shown in Table 4.

Table 4. Products obtained by heating zinc in a stream of SO_2 containing gaseous sulfur

Temp /°C	Sample in the boat	Conversion of Zn to ZnS/%
350	Zn	—
400	Zn>>ZnS[β]	<1
500	Zn>>ZnS[β]	1
600	Zn > ZnS[β]	2
700	Zn > ZnS[β]	3
800	Zn > ZnS[β]	6

These results show that on heating zinc in a stream of SO_2 containing gaseous sulfur, the reaction between zinc and sulfur proceeds above *ca.* 400 °C to form β-ZnS.

Although there has been a report[9] which describes that ZnO, ZnS, $ZnSO_4$, and $ZnSO_4 \cdot ZnO$ are formed on heating zinc and SO_2 in a sealed tube at 500—800 °C, the formation of these compounds except ZnS is not observed in this experiment.

From the above-mentioned experimental results, the reaction process between ZnO and SO_2 in the presence of carbon can be represented as follows: On heating a mixture of ZnO and carbon in a SO_2 stream, the reaction between carbon and SO_2 occurs at first to form sulfur. Above *ca.* 600 °C, the reaction between ZnO and the sulfur occurs to form ZnS. In addition to these reactions, the reduction of ZnO with carbon occurs slightly to form zinc, which then reacts with sulfur to form ZnS.

It has been reported that the $\beta \rightleftharpoons \alpha$ transition temperature of ZnS is 1020 °C.[10] The temperature range in this work was below the transition temperature, and β-ZnS was only formed by the reaction between zinc and sulfur in a SO_2 stream, as shown in Table 4. While, the ZnS formed by heating the mixture of ZnO and carbon in a SO_2 stream was found to be a mixture of α-ZnS and β-ZnS, as shown in Table 1. The percentages of α-ZnS and β-ZnS were calculated to be α-ZnS 75% and β-ZnS 25% at 700 °C, and α-ZnS 70% and β-ZnS 30% at 750 and 800 °C, by the method reported by Bansagi *et al.* (the reproducibility: *ca.* ±2.5%).[11] Also, the ZnS formed by the reaction between ZnO and sulfur in a SO_2 stream was found to be a mixture of α-ZnS and β-ZnS, as shown in Table 3. And the percentages of α-ZnS and β-ZnS were calculated to be α-ZnS 70% and β-ZnS 30% at 700 and 800 °C.

The variation of the modification of ZnS, formed by heating the mixture of ZnO and carbon in a SO_2 stream or by the reaction between ZnO and gaseous sulfur in a SO_2 stream, with the reaction time (0.5—3 h) was examined. The ZnS formed by both processes was a mixture of α-ZnS and β-ZnS, and the wide variation in the percentages of α-ZnS and β-ZnS with the reaction time was not observed.

Regarding the formation of α-ZnS in the temperature range at which β-ZnS is stable, it has been reported that when ZnO having the wurtzite (α-ZnS) structure is present in ZnS, the metastable growth of α-ZnS can be promoted below the $\beta \rightleftharpoons \alpha$ transition temperature,[12] and that on heating β-ZnS mixed with a small amount of ZnO[12] or CdS,[13] both having the wurtzite structure, a part of the β-ZnS is transformed into α-ZnS even below the $\beta \rightleftharpoons \alpha$ transition temperature. Considering the above reports, the formation of a mixture of α-ZnS and β-ZnS observed in this work is due to the presence of ZnO during the formation of ZnS.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 555306 from the Ministry of Education, Science and Culture.

The σ-Bonded Palladium(II) Complexes of 2-Aryl-4,4-dimethyl-2-oxazolines

Takeo Izumi, Hiroyuki Watabe, and Akira Kasahara*

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received October 27, 1980)

Reactions of 2-phenyl-4,4-dimethyl-2-oxazoline with lithium tetrachloropalladate(II) and palladium(II) acetate give dichlorobis(2-phenyl-4,4-dimethyl-2-oxazoline,3-*N*)palladium(II) and a cyclopalladated binuclear complex, di-μ-acetato-bis[2-(4′,4′-dimethyl-2′-oxazolinyl)phenyl,1-*C*,3′-*N*]dipalladium(II), respectively. The latter complex is readily converted by a metathetical reaction with lithium chloride into its chloro-bridged analogue. The chloro-bridged complex reacts with triphenylphosphine to give the corresponding mononuclear σ-bonding palladium complex. All the complexes prepared in this study were characterized by means of IR and NMR spectroscopies.

Following the first report of the intramolecular cyclopalladation of azobenzene and *N*,*N*-dimethylbenzylamine,[1] there has been considerable interest in the intramolecular cyclometalation of nitrogen, phosphorus, and sulfur donor ligands by transition metals.[2] The cyclometalation reaction of 2-aryloxazolines with butyllithium proceeds regiospecifically and nearly quantitatively to the formation of an ortho-lithiation product.[3,4] One might, therefore, expect 2-aryloxazolines to undergo cyclopalladation. In this paper, we wish to report on the intramolecular cyclopalladation reaction of 2-phenyl-4,4-dimethyl-2-oxazoline (**1**) and 2-(3,4-dimethoxyphenyl)-4,4-dimethyl-2-oxazoline (**2**) in the formation of acetato-bridged binuclear complexes.

Results and Discussion

In the presence of sodium acetate, the reaction of **1** with lithium tetrachloropalladate(II) in methanol at room temperature gave dichloro-bis(2-phenyl-4,4-dimethyl-2-oxazoline)palladium(II) (**3**), which has no palladium-carbon σ-bonding. The NMR spectrum could not be measured because of the low solubility of **3** in all common solvents. However, the structure of **3** was consistent with the results of the elemental analysis and the IR spectrum of the compound. The IR bands of the aromatic ring C–H out-of-plane deformation vibrations suggest the modes of ring substitution.[5] The bands of the starting material **1** are observed at 745 and 695 cm^{-1}, corresponding to five adjacent ring hydrogens. The bands of complex **3** are observed at 750 and 690 cm^{-1}. This indicates the presence of monosubstituted benzene ring. Furthermore, complex **3** also shows ν(Pd–Cl) at 350 cm^{-1}, the position characteristic of *trans*-$[PdCl_2L_2]$,[6] and ν(C=N) was shifted to lower frequencies (1630 cm^{-1}) compared with **1** (ν(C=N)= 1650 cm^{-1}). Judging from these results, complex **3** contains two moles of **1** as ligands coordinated only with

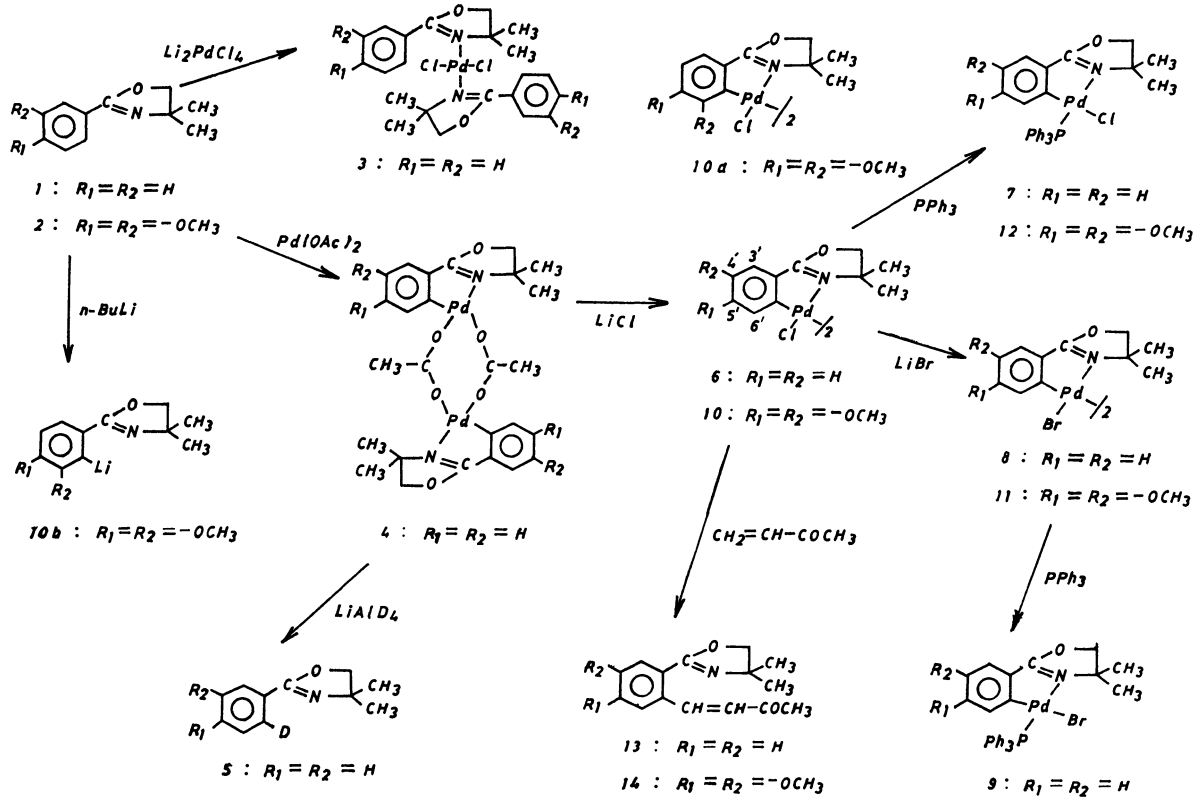

Fig. 1.

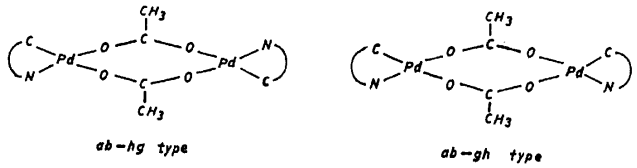
a nitrogen donor site, but does not contain a cyclopalladation moiety, and may have a trans-configuration with **1** as a N-donor.

On the other hand, the reaction of **1** with equimolar quantities of palladium(II) acetate in acetic acid at reflux produced the desired σ-bonded palladium complex (**4**), whose IR spectrum exhibited two strong absorption bands due to bridging acetato ligand at 1570 and 1410 cm^{-1}.[7] Moreover, the IR spectrum in **4** exhibits a band about 725 cm^{-1} which is characteristic of ortho-disubstituted benzene ring. The lithium aluminum hydride reduction of **4** gave **1**, whose mass spectrum was identical with that of an authentic sample, while the lithium aluminum deuteride reduction of **4** gave 2-(phenyl-2-*d*)-4,4-dimethyl-2-oxazoline (**5**). On the basis of elementary analysis and the characterization of the derivatives from **4**, the complex was assigned to a binuclear cyclopalladated complex, di-μ-acetato-bis[2-(4′,4′-dimethyl-2′-oxazolinyl)phenyl, 1-*C*, 3′-*N*]-dipalladium(II). It is noteworthy that even in the presence of acetate ion, **1** reacted with tetrachloropalladate(II) ion to give only the addition product **3** and with palladium(II) acetate to produce the cyclopalladated complex **4**, similar to the case of 1-ethyl-2-phenylimidazole.[8] The NMR spectrum of **4** was also in good agreement with the proposed structure, and the methyl resonance of bridging acetato ligand showed a sharp singlet at δ 2.22 together with two weak resonances at 2.15 and 2.28 ppm. These resonances were ascribed to two geometrical isomers, as shown in Fig. 2;[9] the former was due to two magnetically equivalent methyl protons in an ab-hg type and the latter were due to non-equivalent methyl protons in an ab-gh type (the isomer ratio ab-hg : ab-gh=4 : 1, approximately).



(C, N) =2-[4′,4′-Dimethyl-2′-oxazolinyl]phenyl,1-*C*, 3′-*N*-

Fig. 2. Geometrical isomers of **4**.

The complex **4** was smoothly converted by metathetical reaction with lithium chloride in acetone into its chloro-bridged analogue, di-μ-chloro-bis[2-(4′,4′-dimethyl-2′-oxazolinyl)phenyl,1-*C*,3′-*N*]dipalladium(II) (**6**). The IR spectrum in **6** exhibits a band at 730 cm^{-1} which can be assigned to the C–H deformation mode of an ortho-disubstituted benzene derivative. In the far-IR spectrum of **6**, there are two bridged Pd–Cl stretching absorptions at 270 and 245 cm^{-1}. The NMR spectrum of the complex was also in agreement with the proposed structure. The singlet at 1.51 ppm corresponds to the methyl group, the singlet at 4.36 ppm corresponds to the methylene group, and a typical ABCD system at 6.86—7.56 ppm corresponds to the *o*-phenyl group in 2-(4,4-dimethyl-2-oxazolin-2-yl)phenyl moiety. The 4′- or 5′-H was observed at δ 6.98 (2H) and 7.31 ppm (2H) as a double triplet due to coupling with other ring protons. The 6′-H and 3′-H appeared at 6.86 (2H) and 7.56 ppm (2H) as a double doublet due to coupling with 4′- and 5′-H, respectively. The coupling constants were $3'J_{HH}=7.0$ Hz and $4'J_{HH}=1.5$ Hz. Moreover, the complex **6** underwent a typical bridge-splitting reaction with triphenylphosphine to give a monomeric triphenylphosphine derivative (**7**). These results indicate unambiguously that the complex **4** has the cyclopalladated structure of **1**. In the far-IR spectrum of **7**, a band at 295 cm^{-1} was assigned as the ν(Pd–Cl) frequency, by comparison with the corresponding bromo derivative (**9**) which was derived from the bromo-bridged complex (**8**). Crociani *et al.* reported that the ν(Pd–Cl) frequencies trans to an aromatic nitrogen atom and an ary-carbon one fell in the range of 353—321 and 299—280 cm^{-1}, respectively.[10] The chloride ligands in **7**, therefore, are located trans to a carbon donor.

On the other hand, the reaction of **2** with equimolar amounts of palladium(II) acetate in acetic acid at reflux, followed by treatment with lithium chloride, gave di-μ-chloro-bis[2-(4′,4′-dimethyl-2′-oxazolinyl)-4,5-dimethoxyphenyl, 1-*C*, 3′-*N*]dipalladium(II) (**10**). The IR spectrum in the complex **10** exhibits a band near 860 cm^{-1} which is characteristic of 1,2,4,5-tetrasubstituted benzene ring. In addition, the NMR spectrum in the region of aromatic absorption displays two singlets at 6.73 and 6.98 ppm. The infrared frequencies and the coupling constants in the NMR spectrum are all in agreement with the proposed structure **10** rather than with $\mathbf{10}_a$. Meyers and Mihelich[4] had reported that ortho-lithiation of **2** with butyllithium led to the formation of 1,2,3,4-tetrasubstituted phenyllithium derivative ($\mathbf{10}_b$). It is noteworthy that **2** reacted with palladium(II) acetate to produce the 1,2,4,5-tetrasubstituted benzene derivative (**10**). The complex **10** also shows a quite low ν(Pd–Cl) frequency at 240 cm^{-1}; this band disappears on metathesis with lithium bromide, and yields the bromo analogue product (**11**). Furthermore, the complex **10** underwent the typical bridge-splitting reaction with triphenylphosphine to afford **12**.

The reactions of cyclopalladation products from σ-aryl-nitrogen derivatives with numerous reagents have been reported.[2] In the presence of triethylamine, complexes **6** and **10** reacted with methyl vinyl ketone in toluene at 100 °C, leading to the formation of 1-(2-acetylvinyl)-2-(4,4-dimethyl-2-oxazolin-2-yl)benzene (**13**) and 1-(2-acetylvinyl)-2-(4,4-dimethyl-2-oxazolin-2-yl)-4,5-dimethoxybenzene (**14**), respectively.

Experimental

Materials. All the melting points are uncorrected. 2-Phenyl-4,4-dimethyl-2-oxazoline (**1**) and 2-(3,4-dimethoxyphenyl)-4,4-dimethyl-2-oxazoline (**2**) were prepared according to the method described by A. I. Meyers *et al.*[11]

Measurements. The IR spectra were measured on KBr disks (4000—650 cm^{-1}) and nujol mulls mounted on thin polyethene windows (700—200 cm^{-1}) with Hitachi 215 and EPI-L spectrometers. The NMR spectra were determined in $CDCl_3$ with a Hitachi R-22 spectrometer (90 MHz), using TMS as the internal standard (δ, ppm). The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer, using a direct insertion probe at an ionization energy of 70 eV.

The molecular weight was determined in $CHCl_3$ with a Hitachi 115 vapor pressure osmometer.

Dichlorobis(2-phenyl-4,4-dimethyl-2-oxazoline)palladium(II) (3). A solution of **1** (2.0 g, 11.4 mmol) in 50 cm³ of methanol was added to a solution of lithium tetrachloropalladate (II) (1.31 g, 5 mmol) in 50 cm³ of methanol at room temperature for 15 h. The yellow precipitate which formed immediately was filtered and washed with several portions of methanol. The solid (2.3 g, 88% yield based on Li_2PdCl_4) was insoluble in all common solvents: mp 245—248 °C (dec). IR: 1630 (coordinated C=N), 750, 690 (monosubstituted benzene ring), and 350 cm^{-1} (ν Pd–Cl). Found: C, 49.75; H, 4.79; N, 5.16%. Calcd for $C_{22}H_{26}Cl_2N_2O_2Pd$: C, 49.97; H, 4.95:; N, 5.29%.

Di-μ-acetato-bis[2-(4',4'-dimethyl-2'-oxazolinyl)phenyl, 1-C, 3'-N]dipalladium(II) (4). To a solution of palladium(II) acetate (1.3 g, 5.7 mmol) in acetic acid (30 cm³) was added **1** (1.0 g, 5.1 mmol) in acetic acid (30 cm³) at room temperature. After refluxing for 1.5 h, the resulting mixture was diluted with water and extracted with chloroform. The chloroform extracts were concentrated and chromatographed on silica gel. A yellow band eluted by chloroform was collected and the solvent was evaporated. Recrystallization from benzene gave 0.8 g of **4** as yellow crystals: yield 46% based on **1**, mp 135—137 °C (dec). IR: 1625 (coordinated C=N), 1570, 1410 (bridging acetate), and 720 cm^{-1} (*o*-disubstituted benzene ring). NMR: δ 1.55 (s, 12H, CH_3–C), 2.15, 2.22, and 2.28 (each s, 6H, CH_3 of acetato group), 4.38 (s, 4H, $-CH_2-$), 6.96—7.55 ppm (m, 8H, Ar–H). Found: C, 45.74; H, 4.34; N, 3.97%; mol wt (in $CHCl_3$), 665. Calcd for $C_{26}H_{30}N_2O_6Pd_2$: C, 45.82; H, 4.43; N, 4.12%; mol wt 679.

Reduction of 4 with Lithium Aluminium Hydride. Lithium aluminium hydride (0.02 g, 0.5 mmol) in anhydrous ether (50 cm³) was slowly added to a suspended solution of **4** (0.66 g, 1 mmol) in anhydrous ether (100 cm³). The resulting black mixture was stirred at room temperature for 6 h; then water (10 cm³) was added with cooling. The ether layer was washed with water and dried over anhydrous $MgSO_4$. After removal of the solvent, **1** was obtained as a pale yellow oil and the IR, NMR, and MS spectra were identical with those of the authentic sample.[12] IR: 1650 cm^{-1} (C=N). NMR: δ 1.24 (s, 6H, CH_3–), 3.95 (s, 2H, $-CH_2-$), 7.31 (m, 3H, Ar–H), and 7.89 ppm (m, 2H, Ar–H). MS: 175 (M^+). Calcd for $C_{11}H_{13}NO$: M, 175.

Reduction of 4 with Lithium Aluminium Deuteride. The reduction of **4** (0.66 g) in anhydrous ether with lithium aluminium deuteride (0.02 g) was carried out as in the preceding experiment; this gave a pale yellow oily product which can be identified as 2-(phenyl-2-d)-4,4-dimethyl-2-oxazoline (**5**) on the basis on the following evidence: IR: 1650 cm^{-1} (C=N). NMR: δ 1.24 (s, 6H, CH_3–), 3.95 (s, 2H, $-CH_2-$), 7.31 (m, 3H, Ar–H). 7.89 ppm (m 1H, Ar–H). Found: C, 74.31; H, 7.94; N, 7.88%; M^+, 176. Calcd for $C_{11}H_{12}DNO$: C, 74.40; H, 7.99; N, 7.94%; M, 176.

Di-μ-chloro-bis[2-(4',4'-dimethyl-2'-oxazolinyl)phenyl, 1-C, 3'-N]dipalladium(II) (6). A mixture of lithium chloride (0.10 g, 2.4 mmol) and **4** (0.78 g, 1.16 mmol) in acetone (50 cm³) was stirred at room temperature for 10 h. The evaporation of the solvent gave a pale yellow solid, which was washed with water and diethyl ether. The solid was purified by passing through a short silica gel column with chloroform, and 0.72 g of **6** was obtained as pale yellow crystals; yield 98% based on **4**, mp 175—178 °C (dec.) IR: 1620 (coordinated C=N), 730 (*o*-disubstituted benzene ring), 270, and 245 cm^{-1} (bridged Pd–Cl). NMR: δ 1.51 (s, 12H, CH_3–), 4.36 (s, 4H, $-CH_2-$), 6.86 (d-d, 2H, 6'-H), 6.98 (d-t, 2H, 4'- or 5'-H), 7.31 (d-t, 2H, 5'- or 4'-H), and 7.56 ppm (d-d, 2H, 3'-H). Found: C, 41.69; H, 3.73; N, 4.27%; mol wt (in $CHCl_3$), 624. Calcd for $C_{22}H_{24}Cl_2N_2O_2Pd_2$: C, 41.80; H, 3.82; N, 4.43%; M, 632.

Reaction of 6 with Triphenylphosphine. Triphenylphosphine (0.24 g, 0.92 mmol) was added to a suspension of **6** (0.29 g, 0.46 mmol) in 30 cm³ of benzene. A clear solution formed immediately; this was concentrated after stirring for 10 h at room temperature. The evaporation of the solvent gave a pale yellow solid, which was purified by passing through a silica gel column with chloroform. 0.52 g of chloro-[2-(4',4'-dimethyl-2'-oxazolinyl)phenyl, 1-*C*, 3'-*N*](triphenylphosphine)palladium(II) (**7**) was obtained as pale yellow crystals: yield 98%, mp 181—183 °C (dec). IR: 1630 (coordinated C=N), 740 (*o*-disubstituted benzene ring), 750, 690 (mono-substituted benzene ring), and 295 cm^{-1} (terminal Pd–Cl). NMR: δ 1.67 (s, 6H, CH_3–), 4.34 (s, 2H, $-CH_2-$), 6.72—7.11 (m, 4H, Ar–H), and 7.24—7.75 ppm (m, 15H, Ar–H). Found: C, 60.11; H, 4.57; N, 2.33%; mol wt (in $CHCl_3$), 565. Calcd for $C_{29}H_{27}ClNOPPd$: C, 60.22; H, 4.70; N, 2.42%; M, 578.

Di-μ-bromo-bis[2-(4',4'-dimethyl-2'-oxazolinyl)phenyl, 1-C, 3'-N]dipalladium(II) (8). The complex **6** (0.2 g) suspended in acetone (50 cm³) was treated with lithium bromide (0.2 g), and the mixture was warmed at reflux for 6 h. The resulting orange red solution was evaporated to dryness under reduced pressure. After silica gel column chromatography with chloroform, recrystallization from benzene–hexane gave pale yellow crystals of **8**; yield 60% based on **6**, mp 186—188 °C (dec). IR: 1620 (coordinated C=N) and 730 cm^{-1} (*o*-disubstituted benzene ring). NMR: δ 1.52 (s, 12H, CH_3–), 4.36 (s, 4H, $-CH_2-$), and 6.90—7.54 ppm (m, 8H, Ar–H). Found: C, 36.89; H, 3.31; N, 3.85%; mol wt (in $CHCl_3$), 695. Calcd for $C_{22}H_{24}Br_2N_2O_2Pd_2$: C, 37.05; H, 3.39; N, 3.92%; M, 713.

Bromo[2-(4',4'-dimethyl-2'-oxazolinyl)phenyl, 1-C, 3'-N](triphenylphosphine)palladium(II) (9). The reaction of **8** with triphenylphosphine was carried out in the same way as described for **7**, and pale yellow crystals of **9**, mp 198—200 °C (dec), were produced in 57% yield. IR: 1625 (coordinated C=N), 740 (*o*-disubstituted benzene ring), 750, and 690 cm^{-1} (mono-substituted benzene ring). NMR: δ 1.67 (s, 6H, $-CH_3$), 4.35 (s, 2H, $-CH_2-$), 6.75—7.13 (m, 4H, Ar–H), and 7.26—7.73 ppm (m, 15H, Ar–H). Found: C, 55.81; H, 4.30; N, 2.17%; mol wt (in $CHCl_3$), 615. Calcd for $C_{29}H_{27}BrNOPPd$: C, 55.92; H, 4.36; N, 2.24; M, 622.

Di-μ-chloro-bis[2-(4',4'-dimethyl-2'-oxazolinyl)-4,5-dimethoxyphenyl, 1-C, 3'-N]dipalladium(II) (10). To a solution of palladium(II) acetate (1.23 g, 5.5 mmol) in acetic acid (20 cm³) was added the compound **2** (1.15 g, 5.0 mmol) in acetic acid (15 cm³) at room temperature. After refluxing for 1 h, the resulting mixture was treated with an aqueous solution of lithium chloride (5.0 g) in water (20 cm³) for 10 h at room temperature. The reaction mixture was diluted with water and extracted with several portions of chloroform. The combined extracts were washed with water, dried over anhydrous $MgSO_4$, concentrated, and chromatographed on silica gel. The product **10** (0.90 g, 45% yield based on **2**) was obtained as pale yellow crystals from benzene–hexane: mp 245—248 °C (dec). IR: 1620 (coordinated C=N), 860 (1,2,4,5-tetra-substituted benzene ring), 270, and 240 cm^{-1} (bridged Pd–Cl). NMR: δ 1.62 (s, 12H, $-CH_3$), 3.82 (s, 6H, $-OCH_3$), 3.91 (s, 6H, $-OCH_3$), 4.37 (s, 4H, $-CH_2-$), 6.73 (s, 2H, Ar–H), and 6.98 ppm (s, 2H, Ar–H), Found: C, 41.44; H, 4.21; N, 3.63%; mol wt (in $CHCl_3$), 746. Calcd for $C_{26}H_{32}Cl_2N_2O_6Pd_2$: C, 41.51; H, 4.28; N, 3.72%; M, 752.

Di-μ-bromo-bis[2-(4',4'-dimethyl-2'-oxazolinyl)-4,5-dimethoxyphenyl, 1-C, 3'-N]dipalladium(II) (11). The reaction of **10** with lithium bromide in acetone was carried out in the same way as described for **8**, and pale yellow crystals of **11**, mp

242—245 °C (dec), were produced in 65% yield. IR: 1620 (coordinated C=N) and 860 cm^{-1} (1,2,3,5-tetra-substituted benzene ring). NMR: δ 1.64 (s, 12H, $-CH_3$), 3.82 (s, 6H, $-OCH_3$), 3.93 (s, 6H, $-OCH_3$), 4.38 (s, 4H, $-CH_2-$), 6.75 (s, 2H, Ar–H), and 6.99 ppm (s, 2H, Ar–H), Found: C, 37.06; H, 3.77; N, 3.28%; mol (in $CHCl_3$), 810. Calcd for $C_{26}H_{32}Br_2N_2O_6Pd_2$: C, 37.12; H, 3.83; N, 3.33%; M, 821.

Chloro[2-(4',4'-dimethyl-2'-oxazolinyl)-4,5-dimethoxyphenyl, 1-C, 3'-N](triphenylphosphine)palladium(II) (12). The reaction of **10** with triphenylphosphine was carried out in the same way as described for **7**, and pale yellow crystals of **12** were obtained; mp 225—227 °C (dec). IR: 1620 (coordinated C=N), 860 (1,2,4,5-tetrasubstituted benzene ring), 750, 690 (monosubstituted benzene ring), and 290 cm^{-1} (terminal Pd–Cl). NMR: δ 1.65 (s, 6H, $-CH_3$), 3.80 (s, 3H, $-OCH_3$), 3.89 (s, 3H, $-OCH_3$), 4.36 (s, 2H, $-CH_2-$), 6.75 (s, 1H, Ar–H), 7.01 (s, 1H, Ar–H), and 7.25—7.73 ppm (m, 15H, Ar–H). Found: C, 58.19; H, 4.81; N, 2.05%; mol wt (in $CHCl_3$) 626. Calcd for $C_{31}H_{31}ClNO_3PPd$: C, 58.32; H, 4.89; N, 2.19; M, 638.

Reaction of 6 with Methyl Vinyl Ketone. In a closed vessel, a mixture of the complex **6** (1.26 g, 2 mmol) and methyl vinyl ketone (6 mmol) and triethylamine (0.60 g, 6 mmol) in toluene (50 cm^3) was stirred for 5 h at 80 °C under a nitrogen atomsphere. The reaction mixture was cooled and filtered to remove precipitated palladium, and the filtrate was evaporated *in vacuo*. The residue was dissolved in ether, which had been washed with water and dried over anhydrous $MgSO_4$. After removal of the solvent, purification of the crude product by column chromatography (silica gel–hexane) gave 1-(2-acetylvinyl)-2-(4,4-dimethyl-2-oxazolin-2-yl)benzene (**13**), a pale yellow oil, in 45% yield based on **6**. IR (oil film): 1680 (C=O), 1650 (C=N), 1620 and 950 cm^{-1} (trans –CH=CH–). NMR: δ 1.33 (s, 9H, $-CH_3$), 4.10 (s, 2H, $-CH_2-$), 6.94—7.40 (m, 5H, Ar–H+–C=CH–CO–), and 7.55 ppm (d, 1H, –CH=C–CO–). Found: C, 74.96; H, 6.91; N, 5.70%; M^+, 243. Calcd for $C_{15}H_{17}NO_2$: C, 75.05; H, 7.04; N, 5.76%; M, 243.

Reaction of 10 with Methyl Vinyl Ketone. The reaction of **10** with methyl vinyl ketone was carried out in the same way as above, and 1-(2-acetylvinyl)2-(4,4-dimethyl-2-oxazolin-2-yl)-4,5-dimethoxybenzene (**14**), a pale yellow oil, was obtained in 38% yield. IR (oil film): 1675 (–C=O), 1650 (–C=N), 1620, and 950 cm^{-1} (trans –CH=CH–). NMR: δ 1.31 (s, 9H, $-CH_3$), 3.89 (s, 3H, $-OCH_3$), 3.91 (s, 3H, $-OCH_3$), 4.07 (s, 2H, $-CH_2-$), 6.85 (d, 1H, –C=CH–CO–), 7.27 (s, 1H, Ar–H), 7.47 (s, 1H, Ar–H), and 7.53 ppm (d, 1H, –CH=C–CO–). Found: C, 67.19; H, 6.88; N, 4.53; M^+, 303 Calcd for $C_{17}H_{21}NO_4$: C, 67.31; H, 6.98; N, 4.62%; M, 303.

Catalytic Polarographic Wave of Fe(II) in Neutral Thiocyanate Solutions at Dropping Mercury Electrode

Sadayuki HIMENO* and Atsuyoshi SAITO

Department of Chemistry, College of General Education, Kobe University, Nada-ku, Kobe 657

(Received October 27, 1980)

The electrochemical behavior of Fe(II) in neutral thiocyanate solutions has been investigated at a dropping mercury electrode (DME). It was found that Fe(II) in neutral thiocyanate solutions gave a catalytic polarographic wave at potentials prior to the main Fe(II) reduction wave. The mechanism of the catalytic process involves the chemical reduction of thiocyanate ions with $Fe(OH)_{2,aq}$ at the electrode surface. Controlled potential electrolysis suggests that the reduction of thiocyanate ions proceeds with the formation of sulfide and cyanide ions. Sulfide ions produced at the electrode surface can react with Fe(II) diffusing to the electrode to form FeS. The discharge of this is responsible for the catalytic current, while cyanide ions have no essential role in the catalytic process. The effects of surface active substances and iodate ions on the catalytic wave are also discussed.

A number of papers have been devoted to the study of the electrode reactions of the iron group metal ions occurring in thiocyanate solutions.[1-4] Electrode reactions of these systems at a mercury electrode are quite complex, due to the low solubility of these metals in mercury.[5-8]

In the electroreduction of Ni(II) or Co(II) from thiocyanate solutions, catalytic polarographic currents are observed at DME. There are, however, conflicting ideas concerning the origin of the catalytic wave. Itabashi *et al.* proposed a mechanism involving the cyclic regeneration of Ni(II) or Co(II) by the oxidation of electrodeposited metals with thiocyanate ions.[9-11] On the other hand, Krogulec *et al.* explained the catalytic current of the Ni(II)–thiocyanate system in terms of the discharge of hydrogen ions on metallic nickel.[12] However, there seems to be agreement that, with Ni(II) or Co(II) present, the reduction of thiocyanate ions proceeds with the formation of sulfide and cyanide ions at the mercury surface.

The formation of sulfide ions was also observed during the electroreduction of Co(II) in thiosulfate solutions.[13] According to Baranski and Galus,[14] the reduction of transition metal ions in solutions containing sulfur-containing organic compounds resulted in the formation of sulfide ions at the mercury surface.

Stojek and Kublik investigated the process of the reduction and reoxidation of Fe(II) in neutral thiocyanate solutions at a stationary mercury electrode.[15] During the course of the investigation, they observed a small prewave preceding the usual Fe(II) reduction wave. However, they have given no detailed discussion about the reaction mechanism.

In the present paper we report the characteristics of the catalytic current of Fe(II) in neutral thiocyanate solutions. A possible explanation for the catalytic process is proposed.

Experimental

Apparatus. All polarographic measurements were performed with a Princeton Applied Research polarographic analyzer, model 174, and were recorded with a Riken Denshi X-Y recorder, model D-8CP. The controlled potential electrolysis was carried out with a Yanagimoto potentiostat, model V-8. The working electrode for the controlled potential electrolysis was a mercury pool with a surface area of approximately 7 cm^2. Potentials were measured against a saturated calomel electrode (SCE) with the use of a Kikusui Electronics digital voltmeter, model 156-A. The dropping mercury electrode (DME) had a flow rate of 1.95 mg s^{-1} and a drop time of 4.32 s in a 0.1 M KCl solution with an open circuit. The pH of the solutions was measured with a Hitachi-Horiba pH meter, model M-7. Dissolved oxygen was removed from the solution with nitrogen. The cell was immersed in a water bath maintained at (25±0.1) °C.

Reagents. All chemicals were of analytical reagent grade and were used without further purification. All solutions were prepared from redistilled water.

Results

Prewave of Fe(II)–Thiocyanate System. A d. c. polarogram of 1.0 mM† Fe(II) in 0.1 M NaSCN (pH 5.5) is shown in curve a of Fig. 1. A prewave appears at about 0.2 V more positive than the main Fe(II) reduction wave. The current of the prewave was independent of the height of the mercury reservoir, indicating that the electrode process was kinetically controlled.

The relationship between the catalytic wave height and pH of the solution is shown in curve a of Fig. 2. The catalytic wave was obtained in the pH range 4.8—8.2 under the above conditions. By buffering the solution, however, the catalytic wave disappeared completely without any surfactant. With an Fe(II) concentration of 1 mM, the catalytic wave first increased with thiocyanate concentration up to 0.1 M and then decreased above this thiocyanate concentration.

Effect of Iodate Ions on the Catalytic Wave. With iodate ions present, there appeared an increase of the catalytic current in unbuffered thiocyanate solutions. The reduction of iodate ions proceeds as follows:

$$IO_3^- + 3H_2O + 6e = I^- + 6OH^-$$

The iodate reduction process was a source of hydroxide ions, and buffering of the solution caused the catalytic wave to disappear under these conditions.

The effect of iodate concentration on the catalytic current is shown in Fig. 3. For iodate concentrations

† 1 M=1 mol dm^{-3}.

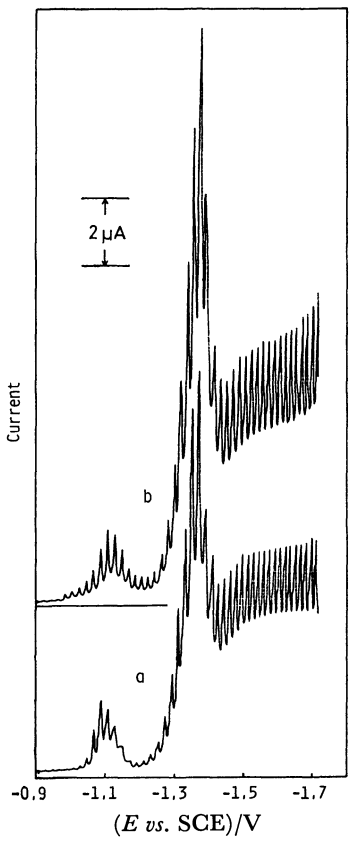

Fig. 1. D. c. polarograms of 1.0 mM Fe(II) in (a) 0.1 M NaSCN (pH 5.5), (b) 0.1 M acetate buffer (pH 5.9) containing 0.2 mM Na_2S.

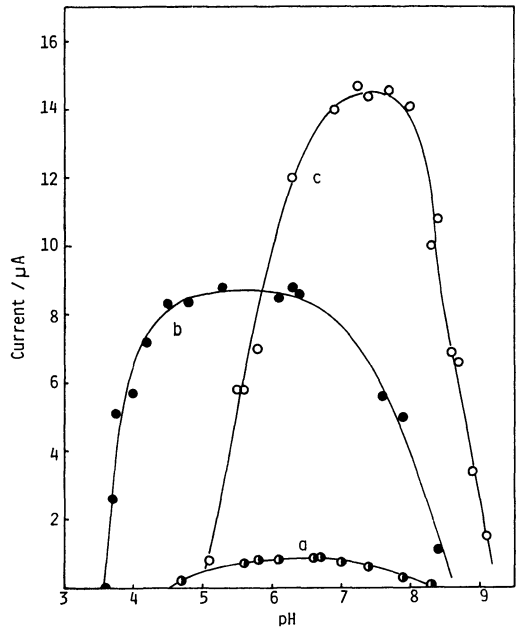

Fig. 2. Relationship between pH and catalytic current of 1.0 mM Fe(II) in (a) 0.1 M NaSCN, (b) solution (a) with 0.01% decylamine, (c) solution (a) with barbital buffer and 0.01% decylamine.

exceeding 0.04 mM, the catalytic current obtained in a 0.5 M NaSCN solution became practically equal to that obtained in a 0.1 M NaSCN solution. The result in

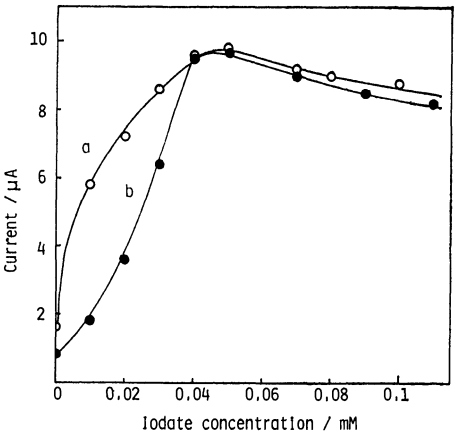

Fig. 3. Catalytic currents of 1.0 mM Fe(II) as a function of iodate concentration in (a) 0.1 M NaSCN (pH 5.6), (b) 0.5 M NaSCN (pH 6.1).

Fig. 3 suggests that the increase in pH in the vicinity of the electrode leads to the increase of the rate of the catalytic reaction.

Effect of Surfactant on the Catalytic Wave. The catalytic wave was practically unaffected by the presence of an anionic surfactant such as sodium dodecyl sulfate. However, the presence of a cationic surfactant like decylamine resulted in the appearance of the catalytic wave even in buffered solutions, and caused the current increase in unbuffered media.

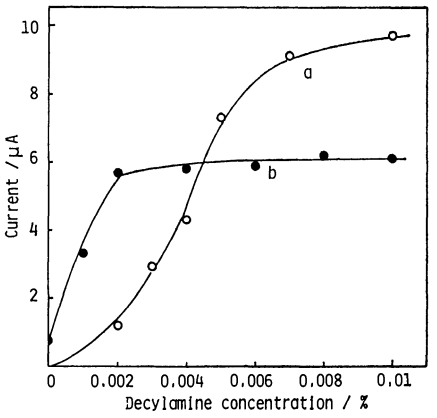

Fig. 4. Catalytic currents of 1.0 mM Fe(II) as a function of decylamine amount in (a) 0.1 M acetate buffer and 0.1 M NaSCN (pH 5.9), (b) 0.1 M NaSCN (pH 6.0).

The effect of the amount of decylamine on the catalytic current is given in Fig. 4. In the solution containing 0.1 M acetate buffer and 0.1 M NaSCN, the current increased gradually on increasing the amount of decylamine up to 0.01%, while it reached a limiting value when 0.002% decylamine was present in the 0.1 M NaSCN solution. Hence, most of the following experiments were carried out in a solution containing 0.01% decylamine.

In the presence of 0.01% decylamine, the catalytic wave was observed in the pH range of 3.6—8.5 and 5.1—9.1 in unbuffered and barbital buffer solutions, respectively (curves b and c in Fig. 2).

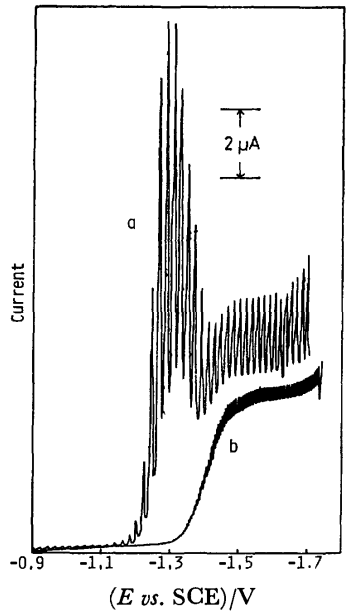

Fig. 5. D. c. polarograms of 1.0 mM Fe(II) in 0.1 M acetate buffer (pH 5.9), 0.1 M NaSCN and 0.01% decylamine with (a) natural drop, (b) a drop time of 0.5 s.

Figure 5 shows d. c. polarograms of 1.0 mM Fe(II) in the solution containing 0.1 M acetate buffer (pH 5.9), 0.1 M NaSCN, and 0.01% decylamine, using natural drop and forced drop (t=0.5 s) methods. No catalytic wave was observed with a drop time of 0.5 s. It is well known that catalytic and kinetic currents can be minimized or eliminated with rapid DME.[16,17] From comparison of a with b in Fig. 5, it follows that the catalytic wave was obtained at potentials before the reduction of aquairon(II) ions reached its limiting plateau. This result clearly shows that the catalytic reaction takes place under the conditions where aquairon(II) ions exist at the electrode surface.

Effect of Thiocyanate and Fe(II) Concentrations on the Catalytic Wave. Figure 6 presents the relationship between the catalytic current and thiocyanate concentrations. In buffered solutions, the catalytic current increased with thiocyanate concentrations up to 0.1 M. Above this concentration, the current went through a maximum and then decreased. In unbuffered solutions, however, the current increased over the thiocyanate concentration range studied.

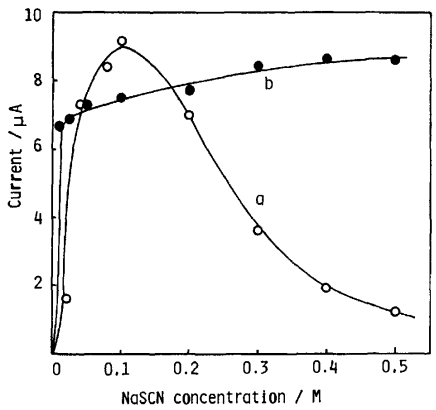

Fig. 6. Catalytic currents of 1.0 mM Fe(II) as a function of thiocyanate concentration in (a) 0.1 M acetate buffer (pH 5.9), (b) 0.1 M $NaClO_4$ (pH 6.0). Each solution contains 0.01% decylamine.

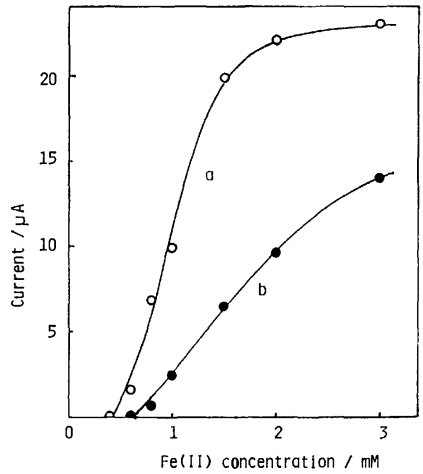

Fig. 7. Catalytic currents as a function of Fe(II) concentration in 0.1 M acetate buffer (pH 5.9) and 0.01% decylamine containing (a) 0.1 M NaSCN, (b) 0.5 M NaSCN.

Figure 7 shows the catalytic currents as a function of Fe(II) concentration. As can be seen, the wave height was dependent on Fe(II) concentration, although it was not a linear function.

D.c. Polarography of Fe(II) in an Acetate Buffer Containing Na_2S. To identify the Fe(II) species responsible for the catalytic current, d. c. polarograms of Fe(II) in neutral solutions containing sodium sulfide were also recorded. As an example, curve b in Fig. 1 shows a d. c. polarogram of 1.0 mM Fe(II) in 0.1 M acetate buffer (pH 5.9) containing 0.2 mM Na_2S. There appeared a prewave preceding the main Fe(II) reduction wave. The kinetic character of the prewave was verified by its dependence of the height of the mercury reservoir. Both catalytic waves of Fe(II) obtained in thiocyanate and sulfide solutions are very similar in appearance in d. c. polarography, suggesting that the same species of Fe(II) is responsible for the catalytic currents. In this case, however, an addition of decylamine had no effect on the catalytic current.

In cyclic voltammetry at a hanging mercury drop electrode (HMDE), Itabashi recently found a similar prewave of Fe(II) in unbuffered perchlorate solutions containing Na_2S; he ascribed the prewave to the reduction of FeS.[18]

Pulse Polarography for an Anodic Scan. Normal pulse polarograms for anodic scans of 1.0 mM Fe(II) in 0.1 M NaSCN (pH 6.0) are shown in Fig. 8. When the initial potential was set at −1.5 V, no oxidation current of iron was obtained, as shown in curve a. However, when the initial potential was chosen at a potential where the catalytic wave appeared (at −1.15 V), an oxidation current was observed with a half-wave potential of −0.53 V.

On the basis of cyclic voltammetry, Stojek and Kublik

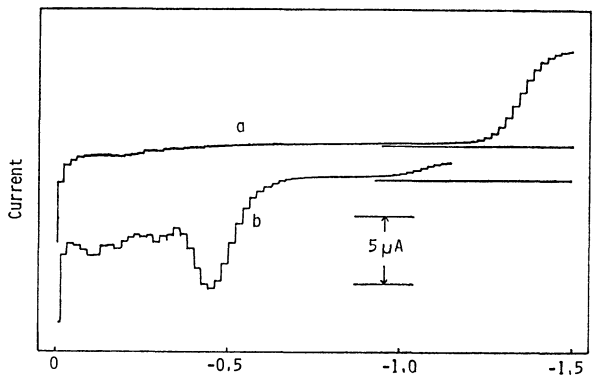

Fig. 8. Normal pulse polarograms for anodic scans of 1.0 mM Fe(II) in 0.1 M NaSCN (pH 6.0). Initial potential, (a) −1.50 V, (b) −1.15 V. Drop time, 2 s.

suggested that metallic iron electrodeposited at potentials of the catalytic wave stayed on the mercury surface, while iron deposited in the main reduction wave penetrated into the electrode.[15] The result obtained by pulse polarography seems to be in line with their observations and shows that, in the potential region of the catalytic wave, Fe(II) is reduced to metal which stays on the electrode surface.

Controlled Potential Electrolysis. For the purpose of elucidating the reaction mechanism, controlled potential electrolysis experiments were carried out with 25 ml of a 2.0 mM Fe(II) solution in 0.5 M NaSCN (pH 5.3) containing 0.01% decylamine at a potential of −1.25 V. After the solution was carefully deoxygenated, the electrode potential was held at −0.9 V to remove any remaining traces of oxygen dissolved in the solution. The pH of the solution increased during the electrolysis and the precipitation of Fe(II) as the hydroxide was observed. This result is in accord with the work of Stojek and Kublik, who explained this behavior in terms of the decomposition of water on an electrodeposited metallic iron. Hence, the following experiments were performed in acetate buffer solutions.

Electrolysis was carried out with a 25 ml solution containing 2.0 mM Fe(II), 0.1 M acetate buffer (pH 5.9), 0.5 M NaSCN, and 0.01% decylamine at −1.25 V. During the course of the electrolysis, gas evolution was observed on the mercury surface. The gas was introduced into a 0.25 M NaOH solution and was analyzed by d. c. polarography. The polarogram obtained showed a single anodic wave with a half-wave potential of −0.36 V, which corresponded to that of cyanide ions. A black solid was obtained on the mercury surface after the progress of the electrolysis. After the black solid was washed carefully with distilled water, it was dissolved in a 5 M H_2SO_4 solution. Bubbles of gas were observed. The polarographic analysis revealed the presence of sulfide ions in the solutions. The sulfuric acid solution was treated with thiocyanate ions and the solution turned red on the addition of hydrogen peroxide. This result indicates that the black solid is FeS.

The electrolysis of 1.0 mM Fe(II) in a 0.1 M acetate buffer (pH 5.9) containing 0.8 mM Na_2S was also performed at a potential of −1.20 V. There appeared a black solid on the mercury surface. Analysis of the black compound according to the procedure mentioned above showed the presence of FeS, suggesting that the prewave was due to the reduction of FeS.

Discussion

The catalytic current can not be ascribed to the formation of Fe(II)–thiocyanate complexes, since Fe(II) and thiocyanate ions form only a weak complex, $FeSCN^+$,[19] and the increase of thiocyanate concentrations is not necessarily related to the increase of the catalytic current. As shown in Fig. 7, on the other hand, the catalytic current is closely related to the Fe(II) concentration.

Wells and Salam investigated the hydrolysis of Fe(II) in perchlorate media.[20] According to them, $Fe(OH)^+$ exists in equilibrium with Fe^{2+} at about pH 3. Above pH 4, the predominant species is $Fe(OH)_{2,aq}$, which is converted slowly to a hydrated dimer. Since such polymerization reactions are known to be slow,[21] we can assume that the predominant species of Fe(II) in the pH range where the catalytic wave appears is $Fe(OH)_{2,aq}$ which has a much stronger reducing ability than Fe^{2+}.[22]

Controlled potential electrolysis shows that thiocyanate ions are reduced to sulfide and cyanide ions in the presence of Fe(II). The formation of these ions by the reduction of thiocyanate ions has also been observed in the solution of either Ni(II) or Co(II).[4,9-12] Taking account of the resemblance of the catalytic wave of Fe(II) in thiocyanate solutions to that in sulfide media, we can ascribe the current to the discharge of FeS formed at the electrode surface. In an attempt to check the effect of cyanide ions on the catalytic reaction, sodium cyanide was added to the thiocyanate-free Fe(II) solution. The presence of cyanide ions only caused the decrease of the main Fe(II) reduction wave and no contribution of Fe(II)–cyanide complexes in the catalytic process could be observed.

Wroblowa *et al.* observed that the adsorption of thiocyanate ions on the mercury electrode occurred in the potential region of the catalytic wave.[23]

On the basis of these observations, the reaction mechanism of the Fe(II)–thiocyanate system can be written as the following sequence of reactions:

$$SCN^-_{bulk} \longrightarrow SCN^-_{ads}$$

$$2Fe(OH)_{2,aq} + SCN^-_{ads} + 2OH^- \longrightarrow 2Fe(OH)_3 + CN^- + S^{2-}$$

$$Fe^{2+} + S^{2-} \longrightarrow FeS \xrightarrow{2e} Fe(0)_{metal} + S^{2-}.$$

The fact that the catalytic current is greatly enhanced by the presence of iodate ions can be accounted for by the increase of $Fe(OH)_{2,aq}$ in the vicinity of the electrode. In the absence of iodate ions, hydroxide ions produced by the decomposition of water on the metallic iron are available for the formation of $Fe(OH)_{2,aq}$ at the electrode surface. As shown in Fig. 2, therefore, no catalytic wave may be observed in buffered media below pH 5. However, we cannot fully explain why we can obtain greater catalytic currents in buffered media

than in unbuffered media.

As long as the electrode potential is more positive than the main Fe(II) reduction potentials, aquairon(II) ions are continuously supplied at the electrode surface and can react with hydroxide ions and sulfide ions. At the limiting plateau of the main Fe(II) reduction wave, on the other hand, the formation of either $Fe(OH)_{2,aq}$ or FeS becomes impossible because of the direct reduction of aquairon(II) ions to the metal. As shown in Figs. 1 and 5, therefore, no catalytic current is observed in the limiting region of the main Fe(II) reduction wave.

It is possible to assume that, in the potential region of the catalytic wave, $FeSCN^+$ adsorbs on the electrode surface, and in the adsorbed state it stimulates the catalytic reaction. On the basis of this adsorption process, however, we cannot explain the effect of the surfactants on the catalytic wave. Thus we excluded the participation of this process in the overall electrode reaction.

The effect of decylamine on the catalytic current may be attributed to the formation of a bridge between thiocyanate ions, the positively charged surfactant, and the negatively charged mercury surface. The adsorption of thiocyanate ions onto the mercury surface may thus take place more easily.

The present investigation was partially supported by a Grant-in-Aid for Scientific Research No. 554170 from the Ministry of Education, Science and Culture.

Preparation and Properties of Monoalkylnickel(II) Complexes $NiR(NR^1R^2)L_2$ Having Imido, Imidazolato, or Methyl Phenylcarbamato-*N* Ligand

Takakazu YAMAMOTO,* Teiji KOHARA, and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received November 26, 1980)

Reactions of dialkylnickel(II) complexes NiR_2L_2 **1** ($R=CH_3$, C_2H_5; $L=1/2$ bpy(2,2'-bipyridine), 1/2 dpe (1,2-bis(diphenylphosphino)ethane), PEt_3) with compounds having acidic N–H bonds (succinimide, phthalimide, diacetamide, pyromellitimide (1,2 : 4,5-benzenebis(dicarboximide)), imidazole) gave corresponding monoalkylnickel(II) complexes having Ni–N bond formulated as $NiR(NR^1R^2)L_2$. A reaction of $NiMe_2(PEt_3)_2$ with CH_3OH and phenyl isocyanate gives $NiMe(N(Ph)COOMe)(PEt_3)_2$. The IR, NMR, and visible spectroscopic studies of the complexes indicate that the electronegativity of Ni is enhanced by the replacement of one of the two R groups in **1** with the NR^1R^2 ligand. NMR spectra of complexes of a type $NiMe(NR^1R^2)(PEt_3)_2$ show that they have *trans*-configurations. Thermolyses of the monoalkylnickel(II) complexes start at temperatures higher by 80—100 °C than those of **1**, liberating RH, R–R, and olefin R(–H). Exposure of monoethylnickel(II) complexes to air releases ethylene as the main gaseous product. Reactions of the complexes of a type NiR(phthalimido)L_2 with R'X ($R'=C_6H_5$, $C_6H_5CH_2$) and C_6H_5COCl produce *N*-alkyl- or *N*-arylphthalimide and ketone C_6H_5COR, respectively.

Although a number of compounds having metal-nitrogen (M–N) covalent bonds have been prepared with various transition metals such as Ti, V, and Mo,[1,2] only a few reports[3–5] have appeared on the preparation of compounds having Ni–N covalent bonds. We previously reported in preliminary form the preparation and some chemical properties of monoalkylnickel(II) complexes with a succinimido or phthalimido ligand by reactions of dialkylnickel(II) complexes with the imides:[6]

$$NiR_2L_2 + HN(COR^1)_2 \longrightarrow RNi[N(COR^1)_2]L_2 + RH. \quad (1)$$

We have expanded the work by using other several active N–H compounds such as pyromellitimide (1,2 : 4,5-benzenebis(dicarboximide)) and imidazole to obtain the corresponding monoalkylnickel(II) complexes with the covalent Ni–N bond.

This paper deals with details of the preparation, characterization, spectroscopic data, and chemical properties of the monoalkylnickel(II) complexes with succinimido, phthalimido, or the other *N*-ligands. In connection with the preparation of the monoalkylnickel-(II) complexes having the *N*-anionic ligands, we also report the preparation of a monoalkylnickel(II) complex with a methyl phenylcarbamato-*N* ligand by treating $NiMe_2(PEt_3)_2$ with CH_3OH and Ph–N=C=O.

Results and Discussion

Preparation of Complexes. Dialkylnickel(II) complexes, NiR_2L_2 ($R=CH_3$, C_2H_5; $L=1/2$ bpy (2,2'-bipyridine), PEt_3, 1/2 dpe (1,2-bis(diphenylphosphino)-ethane)), react smoothly at room temperature with imides including succinimide ($pK_a=9.6$[7,8]), phthalimide ($pK_a=9.9$[8]), diacetamide, and pyromellitimide to give monoalkylnickel(II) complexes with covalent Ni–N bonds in medium to high yields (52—94%) with evolution of 1 mol of RH per NiR_2L_2:

$$NiR_2L_2 + HN(COR^1)_2 \longrightarrow L_2Ni(R)[N(COR^1)_2] + RH. \quad (1)$$

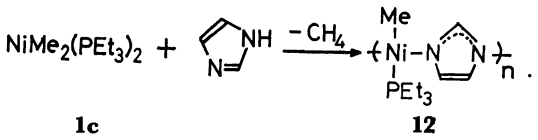
suc = Succinimido. pht = Phthalimido.
Me = Methyl. Et = Ethyl.

Addition of excess imides afforded the same products and further replacement of the R ligand in NiR-$[N(COR^1)_2]L_2$ by the $-N(COR^1)_2$ ligand did not proceed. A reaction of **1c** with *N*-phenylbenzamide also led to liberation of 1 mol of CH_4 per **1c** with formation of a pale brown complex whose IR spectrum suggests the formation of a complex of a type $NiR(NR^1R^2)L_2$. However, isolation of the complex was not feasible.

The reaction expressed by Eq. 1 generally proceeds more rapidly with **1c** than with the other dialkylnickel-(II) complexes with bidentate ligands (see Table 1). NMR spectroscopic studies of **1c** indicate that the PEt_3 ligand in **1c** rapidly exchanges with free PEt_3, partly liberated from **1c** into solution, presumably through a dissociative mechanism involving formation of a three coordinate intermediate. The formation of the three coordinate species in solution seems to account for the high reactivities of **1c** toward the imides.

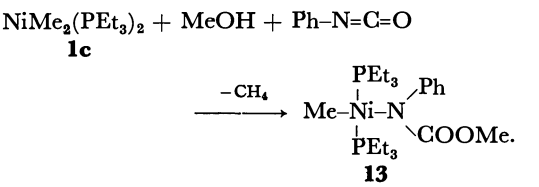
Employment of compounds with less acidic N–H bonds such as benzimide (pK_a=13—14[8]), diphenylamine (pK_a=23[7]), and methyl phenylcarbamate did not lead to the formation of $NiR(NR^1R^2)L_2$, but addition of imidazole with a pK_a value of 14.5[8] leads to the formation of a polymeric monoalkylnickel(II) complex:



1c **12** (2)

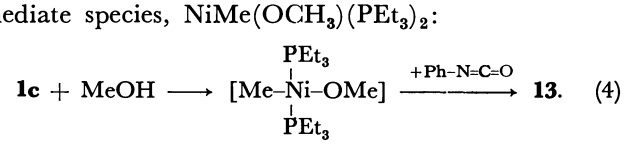
It is known that the N–H bond in imidazole ring has high reactivities toward metals such as Hg,[10] Cu,[3] and Ni[3] to form complexes of a type $M(C_3H_3N_2)_mX_n$, in spite of its weak acidity.

Although methyl phenylcarbamate did not react with NiR_2L_2 to give a complex with the –N(Ph)COOMe ligand, the complex with the –N(Ph)COOMe ligand can be prepared through a different reaction pathway:



1c **13** (3)

The reaction most probably proceeds through insertion of phenyl isocyanate into a Ni–O bond in an intermediate species, $NiMe(OCH_3)(PEt_3)_2$:



(4)

Several examples of insertion of isocyanates into metal-alkoxy bonds to form the M–N compounds are known.[11,12]

Table 1 shows preparative conditions, yields, melting points, and analytical data of the complexes **2**—**13**.

The bpy-coordinated complexes are reddish brown and PEt_3 or dpe-coordinated complexes are yellow or yellowish. The complexes with the bidentate neutral ligand (bpy, dpe) have moderate stabilities to air in solid, whereas those with the PEt_3 ligand are very sensitive to air even in the solid state. All of the complexes are very sensitive to air in solutions.

Characterization of the Complexes. IR, NMR, and visible spectroscopic data are summarized in Table 2.

IR Spectra: The ν(C=O) bands of succinimide (1700 cm^{-1}), phthalimide (1755 cm^{-1}), diacetamide (1965 cm^{-1}), and pyromellitimide (1700 cm^{-1}) are shifted to lower frequencies by 50—130 cm^{-1} on complex formation, and the shift is accounted for by asumming electron migration from Ni to the imido ligands. The magnitudes of the shifts are comparable to those observed with Pd,[13] Pt,[13] and Cu[14] imido complexes which have

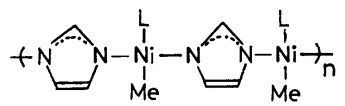
a) Strongest three peaks are given. The absorption peaks with an asterisk are assigned to ν(C=O). b) Measured at r.t. s=singlet, d=doublet, t=triplet, q=quartet, qui=quintet. Solvent: CD_2Cl_2 for **2**, **3**, **4**, **5**, **8**, and **9**; C_6D_6 for **6**, **7**, **10**, and **13**; THF-d_8 for **11**. c) From external H_3PO_4 (downfield positive). d) In acetone-d_6 at −60 °C. e) Signals of the PEt_3 ligand are overlapped with signals of impurities of THF-d_8.

covalent M–N bonds. The covalency of the Ni–N bonds in **2**—**9** is supported by negligible electric conductivities (Λ=0.17−0.80 S cm^2) of CH_2Cl_2 solutions of the complexes. The possibility that one of the two N–H bonds in pyromellitimide remains intact is excluded not only on the basis of the analytical data given in Table 1 but also by the absence of ν(N–H) bands in the IR spectrum.

The IR spectrum of **12** resembles those of polymeric Hg(II)[10] and Tl(III)[15] complexes with the imidazolato ligand, showing bands characteristic of the imidazole ring at 1480 and 1080 cm^{-1} and no band associated with an NH group. The insolubility of **12** in common organic solvents suggests a polymeric structure which has been proposed for the Hg(II) and Tl(III) complexes:



Coordination of only one PEt_3 ligand to Ni in **12** is consistent with the polymeric structure.

The IR spectrum of **13** shows a similar pattern to that of methyl phenylcarbamate except for the N–H region, showing ν(C=O) and ν(C–O) bands at 1650 and 1330 cm^{-1}, respectively, and no ν(N–H) band. The IR data together with NMR data given in Table 1 support the formation of **13**.

NMR Spectra: Patterns of ^{1}H-NMR spectra of complexes **2**—**11** and **13** are consistent with the formulation of the complexes as given in Table 1. The CH_3 signals of **2**, **3**, **6**—**11**, and **13** appear at normal positions

where CH_3 signals of methylnickel(II) complexes appear.[4,16,17] ^1H-NMR spectra of **4** and **5** show CH_2 signals of the ethyl ligand at lower field than CH_3 signals, in contrast to the NMR spectrum of $NiEt_2(bpy)$ **1b** which shows the CH_2 signal (δ 0.8 ppm) at higher field than the CH_3 signal (δ 1.1 ppm).[17] Since it is known[18] that the chemical shift difference between the CH_2 and CH_3 signals ($\Delta=\delta_{CH_2}-\delta_{CH_3}$) increases linearly with the increase in the electronegativity of the atom to which the ethyl group is attached, the appearance of the CH_2 signal at the lower magnetic field can be taken as an indication of an increase in electronegativity of nickel through replacement of the Et ligand of **1b** by the electron-withdrawing imido ligand.

As described above the PEt_3 ligand of $NiMe_2(PEt_3)_2$ **1c** rapidly exchanges at room temperature with free PEt_3 in solutions partly liberated from **1c** and therefore the ^{31}P–^1H coupling is not observable for the Ni–CH_3 signal of **1c**, whereas the Ni–CH_3 signals of **6**, **7**, **11**, and **13** clearly show the ^{31}P–^1H coupling, indicating that the PEt_3 ligand in the complexes is bonded to Ni on NMR time scale. The difference in the dynamic behavior between **1c** and complexes of the type $NiR(NR^1R^2)(PEt_3)_2$ is accounted for by the increase in the electronegativity of nickel through the replacement of the Me ligand by the NR^1R^2 ligand, since electron-donating ligands such as PEt_3 are expected to bond to the central atom more strongly when the electronegativity of the central atom increases. Triplet patterns of the Ni–CH_3 signals in the $NiR(NR^1R^2)L_2$-type complexes indicate not only that the complexes have a trans configuration but also that the complexes have monomeric structures, since if the complexes have multi-nuclear structures, the coupling patterns will become more complex. For **6** the monomeric structure has been established by cryoscopic measurement of the molecular weight (Table 1).

The methylene protons of the succinimido ligand in *cis*-complexes **2**, **4**, and **8** appear as a sharp singlet, indicating that the four hydrogens in the succinimido ligand are magnetically equivalent either due to rapid rotation of the imido ligand around the Ni–N bond or due to accidental coincidence of chemical shifts. The CH_2-signal of **4** appears as a sharp singlet even at -30 °C.

Each of $^{31}P\{^1H\}$-NMR spectra of **7** and **13** shows only one sharp signal and this also supports that the two PEt_3 ligands bonds tightly to Ni occupying the trans position to each other.

Visible Spectra: Solutions of the monoalkylnickel(II) complexes with the bpy ligand have very strong ($\varepsilon \fallingdotseq 3\times10^3$) adsorption bands at about 500 nm, which are assignable to Ni→bpy CT-bands. The dialkyl complexes **1a** and **1b**, show the Ni→bpy CT-bands of lowest transition energy at about 650 nm. The blue shift of the CT-band from 650 nm to 500 nm on the replacement of the Et ligand by the imido ligand is associated with the lowering of the highest occupied level of Ni due to the electron-withdrawing imido ligand.[21]

Chemical Properties. Thermolysis, Acidolysis, and Degradation in Air: Complexes $NiR(NR^1R^2)L_2$ have remarkably high thermal stabilities as shown in Table 1. Their thermolyses start at temperatures by 80—100 °C higher than those of the starting dialkylnickel(II) complexes NiR_2L_2.[17a,19,20] For example, **3** begins to decompose at 230 °C, the temperature being one of the highest decomposition temperatures among dialkyl- and monoalkylnickel(II) complexes reported to date.[4] Even if the alkyl group has β-hydrogens as in **4** and **5**, the complexes is thermally stable up to 175 and 190 °C, respectively.

In cases of Ni–bpy complexes the starting dimethyl- and diethylnickel(II) complexes decomposes mainly through unimolecular reductive elimination process,[21]

$$NiR_2(bpy) \longrightarrow R\text{-}R. \quad (5)$$
$$R = Me, Et$$

The marked enhancement of the thermal stability by the replacement of one of the ethyl ligands by the imido ligand may be attributed to the lack of the low energy intramolecular reductive elimination pathway with NiR(imido)(bpy). Thermolyses of **2** and **3** give C_2H_6 as the main product (Table 3), suggesting a bimolecular process in the thermolyses. Thermolyses of **4** and **5** afford disproportionation products, C_2H_4 and C_2H_6, which are considered to be formed through a β-elimination process,

$$NiEt(imido)(bpy) \longrightarrow [NiH(imido)(bpy)] + C_2H_4. \quad (6)$$
$$[\mathbf{14}]$$
$$\downarrow + NiEt(imido)(bpy)$$
$$C_2H_6$$

Mechanisms involving coupling between metal hydrides and metal alkyls have been proposed for thermolyses of a few transition alkylmetals.[22] Evolution of CH_4 and C_2H_4 as main products together with some ethane (Table 3) in the thermolysis of a mixture of **2** and **4** (*ca.* 1 : 1) supports the β-elimination mechanism shown above and suggests further that the hydride intermediate [**14**] reacts with the methyl **2** and the ethyl complex **4** to form methane and ethane. In thermolysis of com-

$$[\mathbf{14}] \begin{cases} \xrightarrow{\mathbf{2}} CH_4 \\ \xrightarrow[\mathbf{4}]{} C_2H_6 \end{cases} \quad (7)$$

Table 3. Products of thermolysis of $NiR(imido)(bpy)$[a]

Complex	Gaseous products (mol/Ni)			ΣR/Ni[b]
	CH_4	C_2H_6	C_2H_4	
R=Methyl				
2	0.19	0.35	—	0.89
3	0.09	0.39	Trace	0.87
R=Ethyl				
4	—	0.40	0.53	0.93

2 (0.16 mmol) + **4** (0.19 mmol)	0.11 mmol	0.07 mmol	0.14 mmol	

a) At 220—230 °C, in solid in a vacuum. b) $\Sigma R = CH_4+2(C_2H_6+C_2H_4)$ for methyl complexes, $=C_2H_6+C_2H_4$ for ethyl complexes.

TABLE 4. PRODUCTS OF THE REACTIONS OF NiR(imido)L_2 WITH ORGANIC HALIDES (R'X AND R'COX)[a]

No	Complex	Organic halide	Temp °C	Time h	Products (%-yield/Ni) R'-Imide	R-R'	Others
1	**3**	$C_6H_5CH_2Br$[b]	100	1	83	74	
2	**4**	$C_6H_5CH_2Br$[b]	50—60	6	51	51	C_2H_4 (6)
3	**6**	$C_6H_5CH_2Br$[b]	30	0.8	29	66	Bibenzyl (26)
4	**7**	C_6H_5Br[b]	120	1	95	30	
					RCOR'		
6	**7**	C_6H_5COCl[c]	r.t.	12	71		

a) 0.2—0.4 mmol of the complex was used. b) In *N,N*-dimethylacetamide (1 ml). c) In THF (0.5 ml).

plexes containing the PEt_3 ligand, the amount of C_2H_4 evolved sometimes exceeded 1 mol/Ni. The evolution of excess C_2H_4 seems to be due to thermal degradation of the PEt_3 ligand on Ni. Evolution of more than 1 mol of C_2H_4 per Ni was observed also in the thermolysis of complexes with the dpe ligand.

As described above complexes **2**—**13** do not react with excess HNR^1R^2, although a complex having a composition of Ni(phthalimido)$_2$(bpy) is known.[5] The poor reactivities of the monoalkylnickel complexes seem to be attributable to decrease in nucleophilicity of nickel or the Ni-bound alkyl group by bonding of the electron-withdrawing NR^1R^2 ligand. Treatment of the monoalkylnickel(II) complexes with stronger acids such as CH_3COOH, HCl, and H_2SO_4, however, leads to acidolysis of the Ni–R bond to liberate RH quantitatively (Table 1). Imides are also released from complexes of a type NiR(imido)L_2 on the acidolysis by dry HCl.

Complexes **2**—**13** are decomposed on exposure to air as described above. In cases of the ethylnickel complexes, **4** and **5**, they generate C_2H_4 as the main gaseous product on exposure to dry air,

e.g., **4**(solid) + dry air
$$\longrightarrow C_2H_4(40\%/Ni) + C_2H_6(\text{trace}). \quad (8)$$

The fact suggests that β-hydrogen elimination process is promoted by interaction of the complex with dioxygen or by direct interaction of β-hydrogens with oxygen. IR spectrum of the residue shows strong ν(O–H) absorption band, implying the presence of an Ni–OH or Ni–OOH bond in the residual substance.

Reactions with Organic Halides: Reactions of complexes NiR(imido)L_2 with alkyl or aryl halides R'X give *N*-alkyl or -aryl imides with formation of alkanes R–R' (Table 4). Relative reactivities of Ni–N and Ni–R bonds toward R'X varies with the complex and R'X employed. For example, the Ni–CH_3 bond in **6** reacts smoothly with $C_6H_5CH_2Br$ to liberate ethylbenzene in a 66% yield, whereas only 29% of the imido ligand is alkylated. An opposite trend is observed for the reaction of **7** with C_6H_5Br, whereas both the Ni–C and Ni–N bonds in **3** are reactive toward $C_6H_5CH_2Br$. Occurrence of the reaction of **7** with C_6H_5Br to liberate *N*-phenyl phthalimide stands in contrast to the known poor reactivity of potassium phthalimide against aryl halides in Gabriel synthesis of amines, and the reaction may be applied to prepare arylamines from phthalimide and aryl halides. A reaction of **7** with C_6H_5COCl affords ketone $CH_3COC_6H_5$ in 71% yield, accompanied by decarbonylation from C_6H_5COCl to afford benzene and biphenyl. A similar reaction of **9** also affords the same ketone with a lower yield (18%/Ni).

Reactions of NiR(imido)(bpy) with dihalomethanes afford RCH_2CH_2R, RCH_2R, RCH_3, and olefin R(–H)=CH_2 (*e.g.*, propylene from ethyl complexes) besides normal degradation products (R–R, RH, and R(–H)).[23] The formation of the unusual products can be accounted for by assuming insertion of CH_2 carbene formed from CH_2X_2 into the Ni–R bonds.

Reactions with Unsaturated Compounds: Complexes of the type NiR(imido)L_2 (**2**, **4**, **7**, **8**) initiate polymerization of acrylonitrile to yield polyacrylonitrile in high yields (>70%). Attempts to yield a copolymer from butadiene and acrylonitrile were not successful and only homopolymers of acrylonitrile were obtained. Methyl methacrylate is polymerized by **4** to give syndiotactic poly(methyl methacrylate) (Bovey's σ value[24]=0.17) in a 35% yield. Vinyl monomers with less electron-withdrawing substituents such as styrene and vinyl acetate were not polymerized by NiR(imido)L_2. The trend is similar to the polymerization of vinyl monomers initiated by isolated transition metal alkyls and hydrides.[25] Acetylene was trimerized by **7** to benzene and propionaldehyde was dimerized to EtCH=CMeCHO by **2**.

Experimental

General and Materials. All reactions were carried out under nitrogen or argon or in vacuum by using Schlenk type tubes. Complexes **1a**—**1d** were prepared according to literature.[17,19,21] The compounds with N–H bonds were used as purchased from Tokyo Kasei Co. Ltd. Solvents were dried over Na wires or CaH_2, distilled under N_2, and stored under an atmosphere of N_2.

Analyses and Spectroscopic Measurements. Microanalysis of C, H, and N was performed by Mr. T. Saito in our laboratory with a Yanagimoto CHN Autocorder Type MT-2. The melting point was measured in a sealed glass capillary. Amounts of gases evolved during reactions or thremolysis were measured with a Toepler pump and analyzed by GLC using a Shimadzu GC-3BT gas chromatograph. Identification and quantitative analysis of organic compounds were carried out by NMR spectroscopy and GLC.

IR and NMR spectra were recorded on a Hitachi Model 295 infrared spectrophotometer and a JEOL JNM-PS-100 spectrometer, respectively. Visible spectra were obtained by using a Hitachi Model 200-20 spectrophotometer. Electric conductivities of the CH_2Cl_2 solutions of complexes were measured by a Toa Model CM-5B conduct meter.

Preparation of Complexes. NiMe(suc)(bpy) 2 and NiMe(pht)(bpy) 3: THF (2 cm³) was added to a mixture of **1a** (91 mg, 0.37 mmol) and succinimide (38 mg, 0.38 mmol). Stirring the solution for 1 d at room temperature gave a reddish brown precipitate, which was recrystallized from CH_2Cl_2–hexane to give 109 mg (89%) of **2**. Evolution of CH_4 (0.94 mol/Ni) was observed during the reaction.

A similar reaction of **1a** (500 mg, 2.1 mmol) with phthalimide (300 mg, 2.1 mmol) in THF (4 cm³) and recrystallization from CH_2Cl_2–hexane yielded 670 mg (87%) of **3**.

NiEt(suc)(bpy) 4 and Other Complexes with suc or pht Ligand 5—9: THF (4 cm³) was added to a mixture of **1b** (350 mg, 1.3 mmol) and succinimide (130 mg, 1.3 mmol). Stirring the solution at room temperature for 1 d gave a reddish brown precipitate with evolution of C_2H_6 (0.92 mol/Ni). The reddish brown precipitate was recrystallized from CH_2Cl_2–hexane to yield 344 mg (79%) of **4**.

The other complexes were prepared in similar manners under conditions listed in Table 1. Solvents for recrystallization were diethyl ether for **6** and **7** and a mixture of CH_2Cl_2 and hexane for **5**, **8**, and **9**.

trans-*NiMe(diacetamido)*$(PEt_3)_2$ *10*: Diethyl ether (5 cm³) was added to a mixture of **1c** (580 mg, 1.8 mmol)and diacetamide (180 mg, 1.8 mmol) at −10 °C. On warming the solution to room temperature, a smooth reaction occurred with vigorous evolution of CH_4. A red solution was obtained after 30 min and cooling the solution to Dry Ice temperature gave 520 mg of yellow crystals. Recrystallization from diethyl ether gave 270 mg (52%) of **10**.

trans, trans-Ni_2Me_2*(pyromellitimido)*$(PEt_3)_2$ *11*: Diethyl ether (10 cm³) was added to a mixture of **1c** (740 mg, 2.3 mmol) and pyromellitic diimide (240 mg, 1.2 mmol) at −20 °C and then the mixture was warmed to room temperature. Stirring the mixture for 3 h at room temperature afforded a yellow precipitate, which was collected by filtration and recrystallized from THF to yield 760 mg (80%) of **11**.

$[NiMe(imidozolato)(PEt_3)]_n$ *12*: Diethyl ether (5 cm³) was added to a mixture of **1c** (230 mg, 0.71 mmol) and imidazole (49 mg, 0.72 mmol). Stirring the solution at room temperature caused precipitation of a yellow solid with evolution of CH_4. The precipitate was washed thoroughly with diethyl ether, THF, and toluene to yield 170 mg (93%) of **12**. The complex was insoluble in diethyl ether, benzene, toluene, THF, ethyl alcohol, acetone, and *N,N*-dimethylformamide.

NiMe(methyl phenylcarbamato-N*)*$(PEt_3)_2$ *13*: A diethyl ether (3 cm³) solution of **1c** (330 mg, 1.0 mmol) was solidified by cooling to −196 °C and then phenyl isocyanate (0.11 cm³, 1.0 mmol) and methyl alcohol (0.041 cm³, 1.0 mmol) were added by microsyringe at −196 °C. The mixture was warmed to 0 °C and the solution was stirred for 18 h at the temperature to give a homogeneous yellow solution. Evolution of CH_4 (0.86 mmol) during the reaction was observed. Cooling the yellow solution to −78 °C afforded yellow crystals, which were separated by filtration and recrystallized from diethyl ether to yield 260 mg (55%) of **13**.

Thermolysis, Acidolysis, and Degradation in Air. A Schlenk type tube containing 44 mg (0.13 mmol) of **2** was connected to a vacuum line and evacuated. The tube was immersed in an oil bath and the temperature of the oil bath was raised to 210 °C. After 2 h, evolution of 0.025 mmol (0.19/Ni) of CH_4 and 0.048 mmol (0.35/Ni) of C_2H_6 was observed. Thermolyses of other complexes were carried out in similar manners.

A Schlenk type tube containing a diethyl ether (0.5 cm³) solution of **3** (30 mg, 0.080 mmol) was connected to a vacuum line and evacuated. Dry HCl (excess) was introduced to the vessel and the mixture was stirred for 1 d at room temperature to obtained 0.074 mmol of CH_4 and 0.080 mmol of phthalimide. Acidolyses of other complexes were carried similarly.

A Schlenk type tube (25 cm³) containing **4** (120 mg, 0.35 mmol) was evacuated, and then dry air (1 atm) was introduced. After 11 h a brown powder (120 mg) was obtained with evolution of 0.14 mmol of C_2H_4. IR spectrum of the brown powder showed strong ν(O–H) and ν(C=O) bands at 3400 and 1590 cm^{-1}, respectively. Elemental analysis of the brown powder roughly agrees with a composition of Ni(OOH)–(succinimido)(bpy) (Found: C, 46.7; H, 3.9; N, 11.2%. Calcd: C, 48.6; H, 3.8; N, 12.1%). A reaction of **4** with dry air in diethyl ether and those of **5** in solid and in solution afforded similar results.

Reactions with Organic Halides. Benzyl bromide (0.063 cm³, 0.53 mmol) was added to a *N,N*-dimethylacetamide solution of **3** (79 mg, 0.21 mmol). Stirring the solution at 100 °C for 1 h gave a green precipitate with formation of *N*-benzylphthalimide (0.17 mmol, 83%/Ni). Reactions of the Ni–phthalimido complexes with benzyl bromide or bromobenzene were carried out similarly under conditions listed in Table 4.

Benzoyl chloride (0.059 cm³. 0.51 mmol) was added to a THF (0.5 cm³) solution of **7** (46 mg, 0.10 mmol). Stirring the solution for 12 h at room temperature produced 0.071 mmol of acetophenone, 0.031 mmol of benzene, and 0.008 mmol of of biphenyl.

Reactions with Unsaturated Compounds. Acrylonitrile (3.3 g) was added to a vessel containing **2** (33 mg) by trap-to-trap distillation in a vacuum. Almost all of acrylonitrile was polymerized on standing the mixture for 40 min at room temperature. After 2 h the polymer was dissolved in *N,N*-dimethylformamide and precipitated by pouring the solution into HCl–methyl alcohol to yield 2.5 g (74%) of polyacrylonitrile. Other polymerizations were carried out similarly.

Acetylene (500 cm³, 1 atm) was introduced into a vessel containing a THF (1 cm³) solution of **7** (24 mg, 0.052 mmol). Stirring the solution for 30 min at room temperature gave a black precipitate. After 2 d formation of benzene (0.72 mmol) was observed.

Propionaldehyde (3.0 g, 51 mmol) was added to a vessel containing **2** (76 mg, 0.23 mmol). Stirring the solution for 12 h at room temperature gave a viscous pale green solution, in which 0.65 g (6.6 mmol) of $EtCH{=}C(CH_3)CHO$ was contained as determined by GLC.

Oxidized Rubredoxin Models. Iron(III) Complexes of Z-Cys-Ala-Ala-Cys-OMe and Z-Ala-Cys-OMe

Norikazu UEYAMA, Michio NAKATA, and Akira NAKAMURA*

Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received November 29, 1980)

Oxidized rubredoxin models using Fe(III) ion and cysteine-containing peptide as Z-Cys-Ala-Ala-Cys-OMe were synthesized in solution and characterized by the absorption, CD, MCD, and EPR spectra. The Fe(III)/Z-Cys-Ala-Ala-Cys-OMe complex exhibits similar CD spectra as well as absorption, MCD, EPR spectra to native oxidized rubredoxin. Thus, the model complex has a similar electronic configuration and core structure to that of native protein. From the comparison with the result of Fe(III)/Z-Ala-Cys-OMe complex, the tetrapeptide complex probably has a relatively stable chelate structure with the hairpin turn conformation of the tetrapeptide.

Iron-sulfur proteins play important roles in biological electron-transfer and oxygenation reactions.[1,2] These proteins have two major classes. One is a rubredoxin type, $[Fe(SR)_4]^{-,2-}$ (SR denotes cysteine thiolate), which has one or two independent active sites per molecule. Its active site is constructed by one iron atom with four cysteine thiolate groups but without inorganic sulfide. The X-ray crystallographic studies on oxidized rubredoxin from *Clostridium pasteurianum* revealed that the iron atom is coordinated by the four cysteine thiolates with distorted tetrahedral geometry.[3] The other is ferredoxin type, which has also one or two active sites per molecule. Each active site consists of two or four iron atoms with the same number of inorganic sulfide (S^{2-}) to form $[Fe_2S^*_2(SR)_4]^{n-}$(n=2 or 3) or $[Fe_4S^*_4(SR)_4]^{n-}$(n=1, 2, or 3) cluster, respectively (S* denotes inorganic sulfide), and each cluster is coordinated by four cysteine thiolates. Very recently the existence of new type ferredoxin, [3Fe3S*], was suggested.[4]

It is interesting that amino acid sequence, -Cys-A-B-Cys-, exists at the metal binding site of many iron-sulfur proteins. In such cases, it is supposed that conformational restriction due to the steric effects caused by side chains of the two amino acid residues, A and B, interposed between the two cysteine residues may contribute to the stabilities of chelate rings, the determination of the geometries around the metal ion, and the revelation of the enzymatic activities. Although many model studies for iron-sulfur proteins have been reported,[5-10] the roles of the protein or chelating units as ligands in controlling metal ion activities still remain ambiguous. It is presumed that the model studies by the use of peptide complexes possessing partial amino acid sequences of native metalloenzymes give significant informations about the roles of proteins. The preparation of cysteine-containing peptide-iron complexes so far investigated,[6,8,10] however, has employed sequencial oligopeptides such as $\{Gly-Cys-Gly\}_n$ which possess no sterical restriction by the side chains of two amino acids interposed between two terminal cysteine residues. For example, Rydon *et al.*[8] reported the rubredoxin-like complex formation between Fe(III) and $Ac\{Gly-Cys-Gly\}_nNH_2$ (n=1—4) but these complexes were very unstable to result in the oxidation of thiols by Fe(III) ion under strictly unaerobic conditions whereas native rubredoxin is stable under such conditions. Denatured rubredoxin[11,12] in 80 or 90% aqueous dimethyl sulfoxide (DMSO) exhibits a similar absorption spectra to that of native protein and it is stable under unaerobic conditions. These informations indicate that the stability of $[Fe(SR)_4]^-$ chromophore is dependent on the amino acid sequence of the active site as well as the whole protein environment. In native rubredoxin,[1] two well-separated tetrapeptide units at the binding site, Cys(6)-Thr-Val-Cys(9) and Cys(39)-Pro-Leu-Cys(42) for *C. pasteurianum* rubredoxin, should take specific conformations by interactions of side chains of the two amino acid residues interposed between two terminal cysteine residues, of course with the aid of the other peptide sequence, to form a stable chelate complex and to prevent the oxidation of thiols by Fe(III) ion. In view of importance of identity of amino acid residues in native metalloenzymes, these simple models such as Rydon's models are not sufficient in discussion of the role of amino acids in the structures and functions of iron-sulfur proteins. Thus we took the tetrapeptide such as Z-Cys-Ala-Ala-Cys-OMe in order to establish basic informations about the points mentioned above.

In this report, we describe the formation of $[Fe(SR)_4]^-$ moiety with cysteine-containing peptides. In particular, spectroscopic properties of Fe(III)/Z-Cys-Ala-Ala-Cys-OMe complex are discussed on the basis of its relevance to rubredoxin.

Experimental

Peptide Syntheses. The syntheses of peptides were carried out by mixed anhydride method using isobutyl chloroformate as a coupling reagent by stepwise elongation from C-terminus and cysteine thiolate group was protected by acetamidomethyl group. The detail will be reported separately. The SH-free peptides, Z-Ala-Cys-OMe and Z-Cys-Ala-Ala-Cys-OMe, were prepared by the reaction of the corresponding S-blocked peptides with Hg(II) and H_2S.

Complex Formation. All operations were carried out under argon atmosphere. Dimethyl sulfoxide and triethylamine were degassed and distilled before use. Iron(III) chloride hexahydrate was of commercial grade.

The metal salt and 4 molar equivalents of SH-groups based on the cysteine contents of cysteine-containing peptide were dissolved in DMSO. The addition of an equimolar amount of triethylamine for one SH-group to the solution gave a deep red-violet solution. The color faded gradually in the absence of air, especially for Fe(III)/Z-Ala-Cys-OMe complex.

Physical Measurements. Absorption and circular dichroism (CD) spectra were measured on a JASCO UVIDEC-5A and a JASCO J-40 spectrometer, respectively. Magnetic circular dichroism (MCD) spectra were measured on a JASCO J-20 spectrometer equipped with an electromagnet in field strength of 1.5 T and corrected for the zero-field circular dichroism. Electron paramagnetic resonance (EPR) spectra were recorded on a JEOL JESFE 1X with 100 kHz magnetic field modulation using Mn(II) as *g*-marker ($g=1.981$). Absorption, CD, and MCD spectra were recorded at room temperature whereas EPR spectra at 77 K. The values of ε, $\Delta\varepsilon$, and $\Delta\varepsilon_M$ were based on the molar concentration of Fe(III).

Results and Discussion

Addition of triethylamine to a DMSO solution of cysteine-containing peptide and iron(III) chloride gave a deep red-violet solution. The resulting Fe(III) complex of cysteine-containing peptide were characterized with absorption, CD, MCD, and EPR spectra in solution. Figures 1 and 2 show the absorption and CD spectra of Fe(III)/peptide complex, respectively, together with those of native oxidized rubredoxin from *C. pasteurianum*[13,14] for comparison. The CD spectrum of native rubredoxin[14] was converted from wave-number-linear scale in the original paper to wavelength-linear scale and was reproduced in Fig. 2. The CD spectra of other rubredoxins from different organisms show similar spectral pattern to *C. pasteurianum* rubredoxin.[15]

The Fe(III)/Cys-containing peptide complexes showed absorption maxima at 355 and 495 nm, which are typical for the oxidized rubredoxin. These spectral

The spectrum of the native protein (W. A. Lovenberg and B. E. Sobel, *Proc. Natl. Acad. Sci. U.S.A.*, **54**, 193 (1965)) was inserted together with our spectra for comparison.

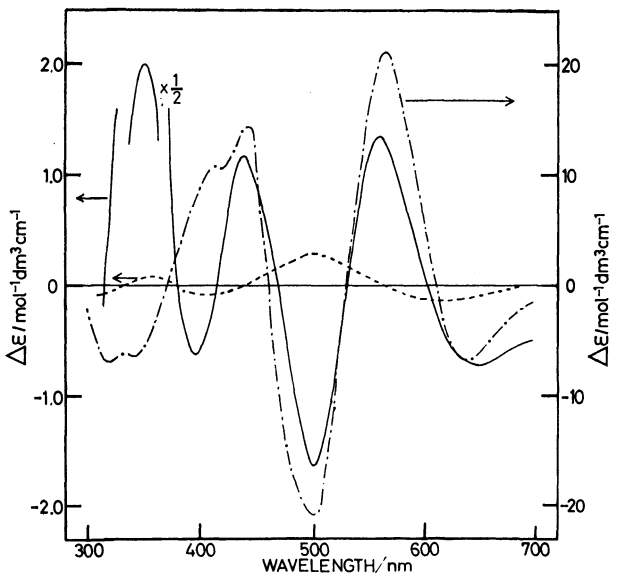

Fig. 2. CD spectra of Fe(III)/Cys-containing peptide complexes.
——: Fe(III)/Z–Cys–Ala–Ala–Cys–OMe complex in DMSO, ------: Fe(III)/Z–Ala–Cys–OMe complex in DMSO, -·-·-: oxidized rubredoxin (*C. pasteurianum*) in Tris buffer. The spectrum of the native protein (W. A. Eaton and W. Lovenberg, "Iron-Sulfur Proteins," ed by W. Lovenberg, Academic Press, New York and London (1973), Vol. II) was converted to wavelength-linear scale and was inserted together with our spectra for comparison.

patterns disappeared gradually due to the oxidation of thiols by the Fe(III) ion. Rydon *et al.*[8] reported that the rubredoxin-like spectra of Fe(III)/Ac{Gly–Cys–Gly}$_n$NH$_2$ ($n=1$—4) complex disappeared rapidly and after 5 min no typical spectra were observed in visible region under strictly unaerobic conditions. In our study, Fe(III)/Z–Ala–Cys–OMe complex was more unstable toward the autoxidation of thiols than Fe(III)/Z–Cys–Ala–Ala–Cys–OMe. The half-life times of absorbance at 495 nm of Fe(III)/peptide complexes were about 22 and 10 min for the Z–Cys–Ala–Ala–Cys–OMe complex and the Z–Ala–Cys–OMe complex, respectively.

The EPR spectra at 77 K showed signals at $g=4.0$ and 4.2 for Fe(III)/Z–Cys–Ala–Ala–Cys–OMe complex and Fe(III)/Z–Ala–Cys–OMe complex, respectively, whereas oxidized rubredoxin at $g=4.3$.[1] It is clear that these peptide complexes have high-spin d^5 Fe(III) structure under an approximately tetrahedral environment surrounded by four cysteine thiolates identical with the core structure of the active site of oxidized rubredoxin.

The MCD spectra also supported the conclusion but there was a little difference between dipeptide and tetrapeptide complex. The MCD spectrum of oxidized rubredoxin in the visible region has two dispersion type bands with crossover points at 382 and 495 nm, and a positive and negative bell-shaped bands at 565 and 357 nm, respectively.[14] Both dispersion type bands were assigned to the Faraday *A* terms, while the bell-shaped bands were assigned to the Faraday *B* terms.[14]

Hatano *et al.*[9] investigated the MCD spectra of Fe(III) complexes of various simple dithiols such as 1,2-ethanedithiol, 1,4-butanedithiol, 1,6-hexanedithiol, and *o*-xylene-α,α'-dithiol. They reported that Fe(III)/1,6-hexanedithiol complex has very similar MCD spectral pattern to that of oxidized rubredoxin and, consequently, a similar core structure, whereas Fe(III)/1,2-ethanedithiol complex has very different spectral pattern from that of oxidized rubredoxin. The complex of 1,2-ethanedithiol was reported to exhibit no dispersion type band at around 490 nm but a positive bell-shaped band at 590 nm ascribed to the Faraday *B* terms, and this indicates that this complex had a binuclear form, $[Fe(SCH_2CH_2S)_2]_2^{2-}$, with five sulfur atoms coordinated to each Fe(III) ion, and its geometry was distorted trigonal bipyramidal around the high-spin Fe(III) ion with coupling interaction between iron atoms confirmed with X-ray crystallographic study.[16]

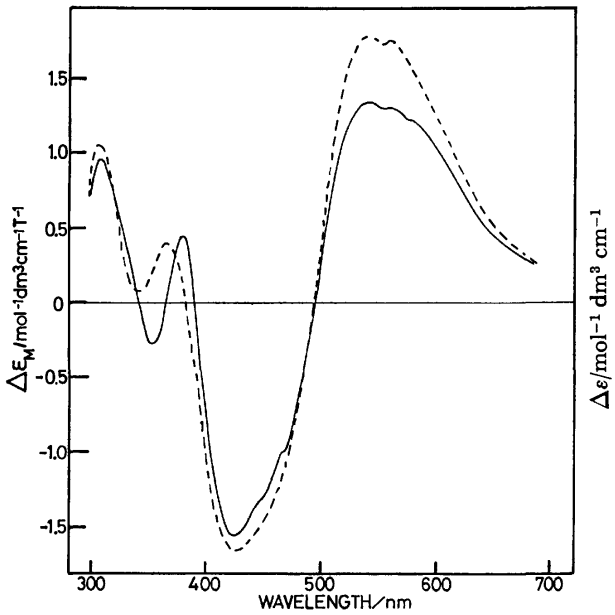

Fig. 3. MCD spectra of Fe(III)/Cys-containing peptide complexes.
——: Fe(III)/Z-Cys-Ala-Ala-Cys-OMe complex in DMSO, ------: Fe(III)/Z-Ala-Cys-OMe complex in DMSO.

Figure 3 shows the MCD spectra of the Fe(III)/peptide complexes. The MCD spectra of the di- and the tetrapeptide complexes in 400—700 nm region have similar spectral pattern. The dispersion type bands with crossover points at around 380 and 490 nm were assigned to the Faraday *A* terms and the positive bell-shaped band at around 540 nm to the Faraday *B* term tentatively. In the shorter wavelength below 400 nm, however, the complex of Fe(III)/Z-Cys-Ala-Ala-Cys-OMe had a negative bell-shaped band at 355 nm which was assignable to the Faraday *B* term. Similar MCD was observed for oxidized rubredoxin. On the other hand, Fe(III)/Z-Ala-Cys-OMe had a positive MCD band. Such difference has also been reported between Fe(III)/1,6-hexanedithiol and Fe(III)/1,4-butanedithiol or *o*-xylene-α,α'-dithiol complexes by Hatano *et al.*[9] They suggested that the MCD spectra of the dithiol Fe(III) complexes at around 350 nm reflect the chelate ring size.

In our case, the potential difference between Z-Cys-Ala-Ala-Cys-OMe and Z-Ala-Cys-OMe, affects the geometry of $[FeS_4]$ core (S denotes cysteinyl sulfur atom). The fact that Z-Cys-Ala-Ala-Cys-OMe can coordinate to Fe(III) ion as a chelating dithiolate ligand should be considered. The Fe(III)/peptide complexes have monomeric $[FeS_4]$ core structure as inferred from the MCD measurements and the core structure of Fe(III)/Z-Cys-Ala-Ala-Cys-OMe complex thus resembles to that of oxidized rubredoxin more closely than Fe(III)/Z-Ala-Cys-OMe complex.

Although the absorption, MCD, and EPR spectra of Fe(III)/peptide complexes did not show so large differences between the dipeptide and the tetrapeptide complexes, the CD spectra exhibited very different spectral pattern between them (Fig. 2). The CD spectrum of Fe(III)/Z-Cys-Ala-Ala-Cys-OMe complex was very similar to that of oxidized rubredoxin in visible region while the intensity was *ca.* 1/10. For oxidized rubredoxin the transitions at 565 and 494 nm have been assigned by MO treatments to the charge transfer transitions from occupied ligand π-orbitals to Fe d-orbitals.[17] The similarity in the CD spectra between oxidized rubredoxin and Fe(III)/Z-Cys-Ala-Ala-Cys-OMe complex in these transitions suggests that not only geometry of the $[FeS_4]$ core but also the major parts of the orientations of Fe–S–C_β (C_β denotes cysteine β carbon) groups resembles each other. The differences in the CD patterns and the CD strength between Fe(III)/Z-Cys-Ala-Ala-Cys-OMe and Fe(III)/Z-Ala-Cys-OMe complexes suggest that the $[FeS_4]$ core is formed for the dipeptide complex similar to the tetrapeptide complex but the orientations of the Fe–S–C_β groups largely differ from the tetrapeptide complex because the CD spectra are generally very sensitive to both the identity of asymmetric ligands and their orientations relative to the metal.

Bair *et al.*[18] studied the electronic properties of the active site of rubredoxin by *ab initio* methods. They used $[Fe(SH)_4]^{-/2-}$ as a model complex for the rubredoxin active site and examined several different sets of S–Fe–S–H dihedral angles. They found that energy separation of the d-d transitions is sensitive to the dihedral angle of the S–H bonds, and that the orientations of the S lone pairs pointing toward Fe ion, which are strongly influenced by the positions of the S–H bonds, directly affect the splitting energies of the Fe d-orbitals and thus play important roles in determining the redox properties of the Fe site. So it is expected that the tetrapeptide complex has different redox properties and also catalytic activities from the dipeptide complex.

We have studied Pd(II)/Z-Cys-Ala-Ala-Cys-OMe complex and revealed that the tetrapeptide coordinates to Pd(II) at two cysteine thiolate groups as a *cis*-chelate ligand from the conformational analyses of the peptide using ^{1}H-NMR spectra.[19] Other related di-cysteine peptides that we have also examined, Z-Cys-Ala-Cys-OMe, Z-Cys-Val-Val-Cys-OMe, and Z-Cys-Gly-Pro-Cys-OMe, were not able to take such stable chelate structure. These results allow us to conclude

that the tetrapeptide, Z–Cys–Ala–Ala–Cys–OMe, prefers a folded structure like a hairpin turn to form a stable *S,S-cis*-chelate Pd(II) structure which has rigid square planar geometry. Stability of such chelate structures should be influenced by the identity and sequence of amino acids intervening the two terminal cysteine residues. It is reasonable to think that the conformational restriction toward chelate ligand caused by tetrahedral metal ion as Fe(III) is looser than by square planar metal ion as Pd(II). Thus, a macro ring chelate structure probably exists for Fe(III)/Z–Cys–Ala–Ala–Cys–OMe system although direct evidences such as X-ray structure are lacking.

In conclusion, the CD spectrum as well as the absorption, MCD, and EPR spectra of Fe(III)/Z–Cys–Ala–Ala–Cys–OMe complex is similar to those of oxidized rubredoxin. The tetrapeptide complex has the mononuclear $[Fe(S\text{–}C_\beta)_4]^-$ structure similar to the rubredoxin active site and probably has the chelate structure although the amino acid sequence is different from the native protein except for two terminal cysteines. The tetrapeptide complex was more stable than the dipeptide complex. This is interesting in connection with the fact that mononuclear Fe(III) complex with monodentate thiolate ligand such as benzenethiolate anion has not been isolated whereas corresponding bidentate chelate complex, $[Fe(o\text{-xylene-}\alpha,\alpha'\text{-dithiolate})_2]^-$, is isolated.[7] Conceivably, Z–Cys–Ala–Ala–Cys–OMe chelated to Fe(III) ion takes a relatively stable conformation by the interaction between side chains of the alanyl residues to resist the oxidation of thiols. It is presumed that a tetrapeptide unit such as Cys–Gly–Gly–Cys lacking such interaction takes more flexible conformation and consequently the stability of the complex will decrease even if a chelate structure exists.

The roles of amino acid residues intervening the two terminal cysteine residues on the geometry and stability of active site of native enzyme is now being investigated using oligopeptides having the same sequence as the native enzyme active site.

The authors wish to express their thanks to Assistant Professor Mikiharu Kamachi of Osaka University for measuring the EPR spectra and Professor Yoichi Shimura, Osaka University, for his kindly offering the MCD equipment.

Reaction of Dimeric Copper(II) Acetate with Pyridine and Quinoline Bases in Dioxane

Kazuo HASEGAWA,† Noriyuki NAKASUKA, and Motoharu TANAKA*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 15, 1980)

Copper(II) acetate reacts with pyridine and quinoline bases in dioxane giving rise to adduct compounds, which were characterized by UV and EPR techniques. The reaction is formulated as follows:

$$Cu_2(OAc)_4 + L \overset{K_{21}}{\rightleftharpoons} Cu_2(OAc)_4L,$$

where L denotes a free base and K_{21} is an adduct formation constant. Values of K_{21} range from 12 for quinoline or 2-picoline to 146 $mol^{-1}\,dm^{-3}$ for 4-ethylpyridine. A linear free energy relationship is observed between the adduct formation and the protonation of bases in water except for sterically crowded bases.

Considerable interest has been shown in synthesis and physical properties of copper(II) carboxylates and of their adduct compounds with Lewis bases.[1-3] Usually copper(II) carboxylates and their adducts with pyridine bases have absorption maxima at about 370 nm, and the effective magnetic moments of these compounds are less than the spin-only value at room temperature. This has been taken as an indication of a dimeric structure, which is well established by X-ray diffraction studies for copper(II) acetate monohydrate[4] and its pyridine adducts in a solid state.[5]

Copper(II) carboxylate retains the dimeric structure also in solvents with weak solvating power and low dielectric constant, such as ethanol,[6,7] dioxane,[7,8] acetic acid,[9] benzene,[8,10] and chloroform.[10] On the other hand it dissociates into monomers in strongly solvating solvents such as water and pyridine. The latter solvent, having strong coordinating ability, breaks the dimeric structure despite a rather low dielectric constant ($\varepsilon=12$). At any rate dielectric properties may play an important role in the dissociation of the dimer.[11] Few quantitative investigations have, however, been carried out on reactions of these compounds in solution,[10-12] as compared with a number of works on their physical properties in a solid state.[1-3]

In this paper we report the reaction of copper(II) acetate with pyridine and quinoline bases in dioxane ($\varepsilon=2.2$).

Experimental

Reagents. *Dioxane*: Anhydrous tin(II) chloride was added to dioxane (G. R., Wako Pure Chemical Ind. Ltd.) to remove peroxides and the solution was distilled after refluxing for about 10 h. The distillate was then refluxed over sodium for about 10 h, followed by distillation. The water content of the dioxane thus purified was found to be 3.2×10^{-3} to 2.1×10^{-2} M†† by the Karl-Fischer method.

Copper(II) Acetate Solution in Dioxane: G. R. anhydrous copper(II) acetate (Wako Pure Chemical Ind. Ltd.) was washed with dioxane several times before use. The solution was standardized complexiметrically with 4-(2-thiazolylazo)-resorcinol as an indicator.[13]

Pyridine and Quinoline Bases: All bases were distilled under atmospheric or reduced pressure over sodium or potassium hydroxide.

Measurements. All measurements were made at 25±1 °C unless otherwise noted.

Absorbance was measured on a Union Giken spectrophotometer Model SM-401 (absorption curve) or on a Carl Zeiss spectrophotometer Model PMQ II (at 650 nm).

Electron paramagnetic resonance spectra were obtained with a JEOL ES-SCXA X-band spectrometer.

Results and Discussion

An apparent molar extinction coefficient remained constant at 650 nm for a solution containing copper(II) acetate alone over the concentration range from 3.7×10^{-4} to 4.6×10^{-3} M ($\varepsilon_0=220\pm5$ $M^{-1}\,cm^{-1}$†††). This indicates retention of the dimeric structure. Absorption spectra are shown in Fig. 1 for a copper(II) acetate–pyridine system, and similar ones are observed for the other bases employed. Addition of a base gives rise to a considerable change in absorption in the visible region, in contrast to virtual invariance of the shoulder discernible at about 370 nm. Since all the bases used in the present study do not absorb in these regions, this spectral behavior may be accounted for by coordination of the base to an apical position of a copper(II) dimer without dissociation into monomers.[10]

This argument is substantiated by the fact that the red shift of the band I in solution corresponds well to that in a solid state on addition of pyridine,[8] which is summarized in Table 1.

Presence of isosbestic points in Fig. 1 suggests only

$C_{Cu}=1.993\times10^{-3}$ M. $C_L/C_{Cu}=$(1) 0, (2) 0.614, (3) 2.47, (4) 6.16, (5) 8.65, (6) 10.5, (7) 14.8, (8) 24.7.
The figure at right is diminished in scale on the abscissa by a factor of 2.5.

one chemical equilibrium between a base and the dimeric acetate. Therefore the main reaction may be formulated as follows:

$$Cu_2(OAc)_4 + nL \overset{K_{2n}}{\rightleftharpoons} Cu_2(OAc)_4L_n, \quad (1)$$

where L denotes a free base and K_{2n} is the constant for the equilibrium (1). Unless the base concentration is considerably high, a 1 : 1 complex will predominate ($n=1$). Let D and DL stand for $Cu_2(OAc)_4$ and $Cu_2(OAc)_4L$ respectively, then consideration of stoichiometric relations gives the following expressions:

$$A = 2\varepsilon_0[D] + 2\varepsilon_{21}[DL] \quad (2)$$

$$A_0 = \varepsilon_0 C_{Cu} \quad (3)$$

$$C_{Cu} = 2[D] + 2[DL] \quad (4)$$

$$C_L = [L] + [DL], \quad (5)$$

where A and A_0 are the absorbances at 650 nm in the presence and in the absence of a base, ε_0 and ε_{21} the molar extinction coefficients of D and DL. C_{Cu} and C_L represent the total concentrations of copper and a base, respectively.

Combination of these equations leads to:

$$\frac{C_{Cu}C_L}{A-A_0} = \frac{1}{\varepsilon_{21}-\varepsilon_0}\left[C_L+\frac{C_M}{2}-\frac{A-A_0}{2(\varepsilon_{21}-\varepsilon_0)}\right] + \frac{1}{K_{21}(\varepsilon_{21}-\varepsilon_0)}. \quad (6)$$

Plots of the left-hand side against $[C_L+C_M/2-(A-A_0)/2(\varepsilon_{21}-\varepsilon_0)]$ yielded a family of straight lines as was expected, with ε_{21} roughly chosen. A better extinction coefficient ε_{21} and an adduct formation constant K_{21} were obtained from the gradient and the intercept of the straight line (Fig. 2).

Formation of the 1 : 1 adduct DL was confirmed in a more general fashion.

An apparent molar extinction coefficient may be expressed in the following way:

$$\varepsilon = \frac{A}{C_M} = \frac{\varepsilon_0+\varepsilon_{2n}K_{2n}[L]^n}{1+K_{2n}[L]^n}. \quad (7)$$

Transformation of Eq. 7 gives

$$\log(\varepsilon_0-\varepsilon) = \log(\varepsilon_0-\varepsilon_{2n}) + \log\left(\frac{K_{2n}[L]^n}{1+K_{2n}[L]^n}\right). \quad (8)$$

A plot of $\log(\varepsilon_0-\varepsilon)$ against $\log[L]$ may be compared

determined by the curve-fitting method.

These values were further refined by the least squares method with an electronic computer FACOM 230-75 at Computation Center of Nagoya University. The final results are summarized in Table 2.

The experimental data were also treated by plotting graphically the spectral change at 650 nm as well as by refining with the computer, dissociation of the dimer being assumed as the main reaction. Then the predominant reaction might be written as follows:

$$Cu_2(OAc)_4 + 2nL \overset{K_{1n}}{\rightleftharpoons} 2Cu(OAc)_2L_n. \quad (9)$$

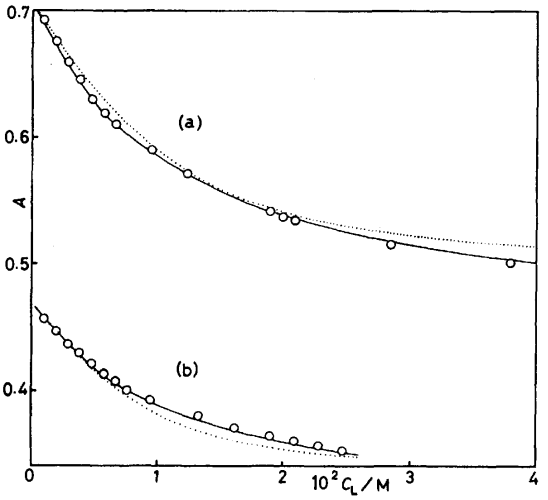

Fig. 4. Change in absorbance at 650 nm with the concentration of 3-ethylpyridine.
a) $C_{Cu}=3.22_1\times10^{-3}$ M. b) $C_{Cu}=2.14_8\times10^{-3}$ M.
○ refers to the experimental value. ——: Calculated curve assuming DL alone, ……: calculated curve assuming ML alone. It was drawn with tentative values of $K'_{11}=78.8\ M^{-1}$ and $\varepsilon'_{11}=156\ M^{-1}\,cm^{-1}$ (see text).

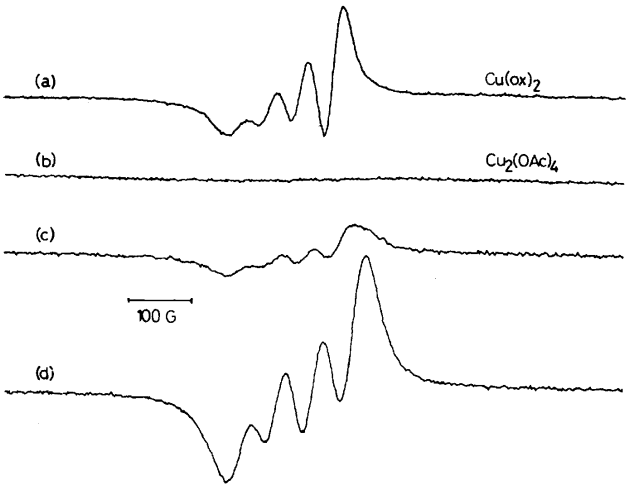

Fig. 5. EPR spectra of dioxane solutions at room temperature (about 20 °C).
a): Copper(II) 8-quinolinolate ($C_{Cu}=6.10\times10^{-5}$ M), b): $C_{py}=0$ M, c): $C_{py}=2.62\times10^{-2}$ M, d) $C_{py}=2.47_2\times10^{-1}$ M.
The concentration was $2.39_2\times10^{-3}$ M in copper(II) acetate except for a).

The assumption of a monomer formation alone results in a systematic deviation of the calculated curves from the experimental data for 3-ethylpyridine as shown in Fig. 4. The dotted lines are drawn with tentative values of K'_{11} and ε'_{11}[14] that gave the best fit to the data on assuming only the Eq. 9. In the case of pyridine, however, the dissociation reaction also accounts for the spectral change satisfactorily when $n=1$.

This finding prompted us to an electron paramagnetic resonance study. A solution containing copper(II) acetate alone did not exhibit any EPR spectra other than ones characteristic of the dimeric structure, while typical copper(II) spectra began to appear on addition of pyridine at concentrations higher than those used in the UV study (Fig. 5). Analysis of spin concentration was carried out for a monomeric form by double integration of the spectra.[15] Copper(II) 8-quinolinolate in dioxane was selected as a standard, since the shape of EPR spectra is similar to those of monomeric copper(II) acetate. Table 3 indicates that the monomeric concentration [ML] thus determined experimentally is much lower than the value of [ML]', which was tentatively estimated with $K'_{11}=11.3\ M^{-1}$ (*cf.* Eq. 9).

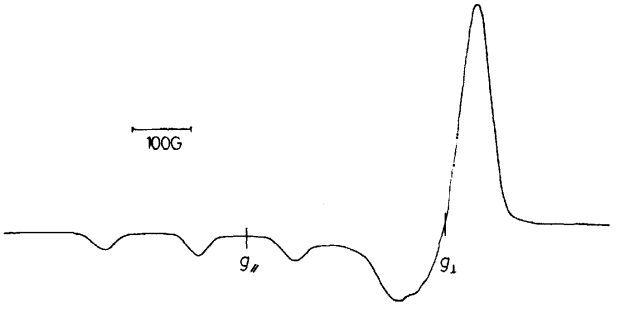

Fig. 6. EPR spectra of copper(II) acetate monopyridine adduct in dioxane at 99.3 K.
$C_{py}=2.47_2\times10^{-1}$ M and $C_{Cu}=2\times10^{-3}$ M.

Table 3. Comparison of monomeric and dimeric species [a)]

No.	10 C_L/M	10^3[ML]′/M[b)]	10^4[ML]/M	10^3[DL]/M	[L]/M	log (K_{11}/M^{-1})
1	0.131	1.05	0.24	0.609	0.0125	−2.20
2	0.262	1.62	0.35	0.811	0.0254	−2.31

a) L, ML, and DL denote pyridine, $Cu(OAc)_2L$, and $Cu_2(OAc)_4L$, respectively. The concentration of copper(II) acetate was maintained at $2.39_2 \times 10^{-3}$ M. b) [ML]′ was calculated using a tentative value of K'_{22}= 11.3 M^{-1} (see text).

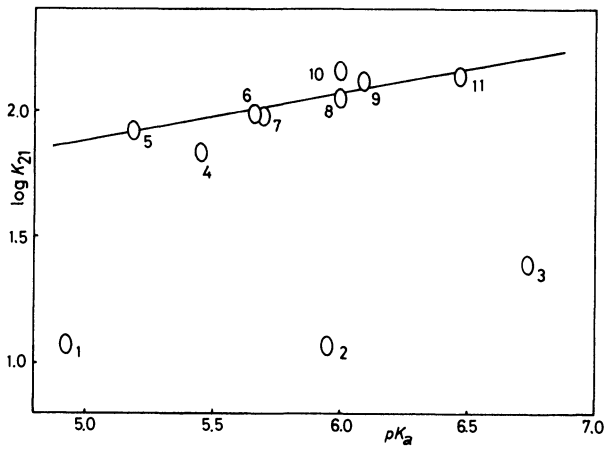

Fig. 7. Linear free energy relationship between the addition of bases to dimeric copper acetate and the protonation of bases.
1): Quinoline, 2): 2-picoline, 3): 2,4-lutidine, 4): isoquinoline, 5): pyridine, 6): 3-picoline, 7): 3-ethylpyridine, 8): 4-picoline, 9): 3,5-lutidine, 10): 4-ethylpyridine, 11): 3,4-lutidine.

In brief, monomeric species appear appreciably only when a base concentration becomes much higher. The last column in Table 3 shows experimental quotients $K_{11}=[ML]^2/[D][L]^2$, which are roughly constant (log $K_{11}=-2.1\pm0.1$).

The EPR spectra at room temperature (about 20 °C) gave merely an average value of g, which was determined as $\bar{g}=2.142$ from Fig. 5. Therefore spectra were also measured at 99.3 K for a dioxane solution, and $g_\perp=2.063$ and $g_{//}=2.309$ were obtained (Fig. 6). These values give $g=2.148$ in a fair accord with the above value found at room temperature, and are compared with the values $g_x=2.065$, $g_y=2.070$, and $g_z=2.362$ for the crystal of $Cu_2(OAc)_4Py_2$.[16] Distortion from the O_h symmetry with an elongation along the z axis is expected in the monomeric $Cu(OAc)_2Py$, because $g_{//}>g_\perp>2$.[17]

For most bases the formation constant of the 1 : 1 adduct log K_{21} increases linearly with pK_a of a base as illustrated in Fig. 7. Among the pyridine bases examined, however, 2-picoline and 2,4-lutidine have abnormally low formation constants, possibly because of the steric hindrance of 2-methyl group. More crowded 2,6-lutidine and collidine hardly react with copper(II) acetate. The steric effect of an adjacent benzene ring is also observed with quinoline.

Similar relations are also observed in other systems, such as copper(II)–β-diketone,[18–20] oxovanadium(IV)–β-diketone,[21] and 2,3-butanedionebis(benzoylhydrazonato)nickel(II)[22] complexes with pyridine or quinoline bases. A linear free energy relationship is also found between the adduct formation constant for copper(II) acetate (log K_{21}) and that for bis(acetylacetonato)oxovanadium(IV) (log K_x) with pyridine or quinoline bases. Linearity holds, however, for all bases including the sterically crowded ones, as shown in Fig. 8.

Contrary to exclusive formation of a 1 : 2 adduct DL_2 in a solid state, a 1 : 1 species DL predominates in

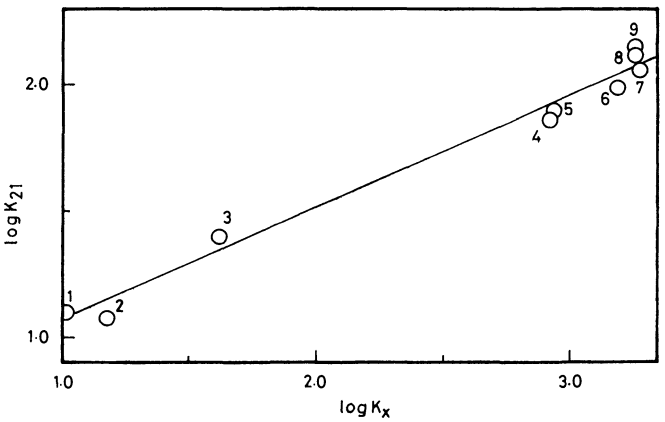

Fig. 8. Linear free energy relationship for the addition reactions of bases.
K_{21} refers to dimeric copper(II) acetate and K_x to bis(acetylacetonato)oxovanadium(IV).
1): 2-Picoline, 2): quinoline, 3): 2,4-lutidine, 4): isoquinoline, 5): pyridine, 6): 3-picoline, 7): 4-picoline, 8): 3,5-lutidine, 9): 4-ethylpyridine.

dioxane. This is rather unusual when compared with the reactions in other solvents. In anhydrous acetic acid, for example, copper acetate dissociates into monomer at early stage on addition of lithium acetate[9] and pyridine,[23] with rapid dissappearance of the shoulder at 370 nm. Extraction of copper(II) with an aliphatic long chain carboxylic acid also revealed existence of a monomer ML as well as a dimer DL in the presence of pyridine in benzene.[12]

Adduct formation may be interpreted in terms of substitution of a solvent molecule, bound to an apical site of the dimeric copper(II), by a base which has stronger coordination power than dioxane.

The authors are greatly indebted to Dr. W. Mori, Osaka University, for helpful discussions in interpreting the EPR data, and also to Mr. T. Seto, Nagoya University, for performing the EPR measurement. This research was financially supported by a Grant-in-Aid for Scientific Research No. 347029 from the Ministry of Education, Science and Culture (Japan).

Syntheses and Characterizations of μ-Dicarboxylato-bis[pentaamminecobalt(III)] Complexes

Hiroshi OGINO,* Keiichi TSUKAHARA,† Yoshiyuki MORIOKA, and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 22, 1980)

Five new complexes, $[(NH_3)_5Co(dicarboxylate)Co(NH_3)_5]X_4$ (dicarboxylate=oxalate, succinate, pimelate, fumarate, and maleate; $X=ClO_4^-$ or Cl^-), were synthesized by the reactions of $[Co(hydrogen\ dicarboxylate)(NH_3)_5](ClO_4)_2$ with $[Co(NH_3)_5(H_2O)](ClO_4)_3$ and characterized by chromatographic behavior and electronic and NMR techniques. When maleate was used as the dicarboxylate, the formation of $[(NH_3)_5Co(fumarate)Co(NH_3)_5]^{4+}$ as well as $[(NH_3)_5Co(maleate)Co(NH_3)_5]^{4+}$ was observed. The IR and Raman spectra of $[(NH_3)_5Co(oxalate)Co(NH_3)_5]^{4+}$ indicate that the symmetry of the oxalate ion in the complex may be approximated by D_{2h}.

The syntheses of a series of μ-dicarboxylato-bis[pentaamminecobalt(III)] complexes were reported by Duff,[1] where malonic, glutaric, adipic, malic, phthalic, citraconic, and itaconic acids were used as the μ-bridging ligands. However, the synthetic procedure of Duff is time consuming, that is, it takes a week or more. Our attempt to prepare μ-malonato-bis[pentaamminecobalt(III)] complex using Duff's procedure failed. Furthermore, synthesis of the simplest complex of this series, $[(NH_3)_5Co(O_2CCO_2)Co(NH_3)_5]X_4$, has not been reported.

This paper reports the syntheses and characterizations of the bis[pentaamminecobalt(III)] complexes containing μ-oxalate, malonate, succinate, pimelate, fumarate, and maleate ligands.[2] Some observations on the products of the reaction of $[Co(Hdic)(NH_3)_5]^{2+}$ with $[Co(NH_3)_5(H_2O)]^{3+}$ are also described.

Experimental

Materials. The complexes $[Co(NH_3)_5(H_2O)](ClO_4)_3$ and $[Co(Hox)(NH_3)_5](ClO_4)_2$ were prepared by the published methods.[3,4] The other complexes containing Hdic, $[Co(Hdic)(NH_3)_5](ClO_4)_2$, were prepared by the published method with slight modifications:[5,6] The H_2dic (0.2 mol) was dissolved into 200 cm^3 of water containing NaOH (0.2 mol). After the addition of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (0.02 mol), the temperature of the solution was kept at 70—75 °C for 3 h, and then the solution was cooled, and diluted to 3 dm^3 with water. The solution was poured into an SP-Sephadex C-25 column (4.5 cm × 35 cm). The desired species was eluted out with a 0.1 M $NaClO_4$ solution of pH 2—3 adjusted with $HClO_4$ (1 M=1 mol dm^{-3}).[7] Small amounts of $[Co(NH_3)_5(H_2O)]^{3+}$ and $[(NH_3)_5Co(dic)Co(NH_3)_5]^{4+}$ (yield=2—3%) remained in the column. The eluate was evaporated to a small volume with a rotary evaporator whereupon red crystals of $[Co(Hdic)(NH_3)_5](ClO_4)_2$ were obtained; yield 80—90%.

Syntheses of μ-Dicarboxylato-bis[pentaamminecobalt(III)] Perchlorates. The complex $[Co(Hdic)(NH_3)_5](ClO_4)_2$ (0.01 mol) was dissolved into 150 cm^3 of water. The pH of the solution was adjusted to 4 with $NaHCO_3$. To this solution was added 0.01 mol of $[Co(NH_3)_5(H_2O)](ClO_4)_3$. The solution was kept at 70—75 °C for 2—3 h and then cooled to room temperature. After diluting the solution to 1.5 dm^3 with water, the pH was adjusted to 3 with $HClO_4$. This was poured into the SP-Sephadex C-25 column. The adsorbed species were eluted with $NaClO_4$ solutions of pH 2—3 adjusted with $HClO_4$. Major species on the column were identified as $[Co(Hdic)(NH_3)_5]^{2+}$,[7] $[Co(NH_3)_5(H_2O)]^{3+}$, and $[(NH_3)_5Co(dic)Co(NH_3)_5]^{4+}$. Detailed product distribution will be given in Results and Discussion. The $[(NH_3)_5Co(dic)Co(NH_3)_5]^{4+}$ was eluted with a 0.4 M $NaClO_4$ solution,[9] after the species less charged than 4+ had been eluted out. The eluate was evaporated to a small volume with a rotary evaporator whereupon red crystals of the perchlorate salt were obtained. The recrystallizations were made from water. The chloride salt of $[(NH_3)_5Co(ox)Co(NH_3)_5]^{4+}$ was obtained when 0.4 M KCl solution was used in place of the 0.4 M $NaClO_4$ eluant.

The analytical data for the complexes are given in Table 1.

Apparatus. Electronic spectra of the complexes in aqueous solutions were recorded on a Union-Giken SM-401 spectrophotometer. ^1H-NMR spectra (in D_2O containing 0.1 M D_2SO_4, with sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal standard) were obtained by the use of a Varian A 60 spectrometer and a JEOL MH-100 spectrometer. ^{13}C-NMR spectra were recorded on a Varian XL-200 at a frequency of 50 MHz (D_2O lock) in the proton noise decoupled mode. The solubility of the perchlorate salts of

a) sh=Shoulder.

the μ-dicarboxylato complexes into D_2O was found to be too low for the measurement of the NMR spectra. These complexes converted to the chloride salts with the aid of Dowex 1 X-4 resin in the chloride form, because the chlorides were found to be much more soluble than the perchlorates. The IR spectra (KBr disks) were recorded on a Hitachi EPI-S2 spectrometer. Raman spectra of $[(NH_3)_5Co(ox)Co(NH_3)_5](ClO_4)_4$ were recorded on a JEOL JRS-400T spectrometer. The 488 nm line of an Ar-ion laser (150 and 250 mW of power) was used as a light source. The spectra were measured in the solid state with KBr as a support. The rotating sample technique was employed to avoid decomposition.

Results and Discussion

Formulation of the Complexes. The analytical results of the $[(NH_3)_5Co(dic)Co(NH_3)_5]X_4$ shown in Table 1 are compatible with the assigned formulation. The positions of the absorption maxima due to the d-d transitions are characteristic for the $[CoN_5O]$ chromophores (Table 2) and the molar absorption coefficients (ε/M^{-1} cm^{-1}) are approximately 2 times larger than those of the corresponding $[Co(Hdic)(NH_3)_5]^{2+}$ complexes. The dimeric complex ions showed flow rates on a Sephadex column such that the ions must be the 4+ charged species.[14]

The ^{1}H-NMR spectra of $[(NH_3)_5Co(dic)Co(NH_3)_5]^{4+}$ showed only two NH_3 peaks at 2.90—2.94 ppm (6H) and 3.86—3.93 ppm (24H) (Table 3). This result also supports the μ-dicarboxylato-bis[pentaamminecobalt(III)] formulation, because the two peaks can be assigned to *trans*-NH_3 and *cis*-NH_3 to the μ-dicarboxylate ion, respectively, on the basis of the assignment reported for the spectra of $[CoX(NH_3)_5]^{n+}$ complexes.[15,16] The ^{1}H-NMR spectra of $[Co(Hmale)(NH_3)_5]^{2+}$ and $[Co(Hfum)(NH_3)_5]^{2+}$ showed AB splitting patterns due to the presence of CH=CH protons. Chemical shifts (coupling constants) were 6.10 and 6.43 ppm (J_{H-H}= 12.0 Hz) for the Hmale complex and 6.53 and 6.75 ppm (J_{H-H}=16.0 Hz) for the Hfum complex. In the spectra of $[(NH_3)_5Co(male)Co(NH_3)_5]^{4+}$ and $[(NH_3)_5Co(fum)Co(NH_3)_5]^{4+}$, each complex showed a singlet signal for the CH=CH protons which is compatible with the assigned formulation.

Table 3. Numerical data for the ^{1}H-NMR spectra of $[(NH_3)_5Co(dic)Co(NH_3)_5]^{4+}$ complexes

dic	Chemical shift δ/ppm		
	trans-NH_3	*cis*-NH_3	C–H_n
ox	2.93	3.93	—
malo	2.90	3.90	3.33(CH_2)
suc	2.90	3.86	2.46(CH_2CH_2)
pim	2.92	3.89	2.19, 2.26, 2.34 triplet (CH_2COO) 1.12—1.64 multiplet ($CH_2CH_2CH_2$)
fum	2.94	3.92	6.45 (CH=CH)
male	2.94	3.92	6.11 (CH=CH)

Table 4. Numerical data for the ^{13}C-NMR spectra of $[(NH_3)_5Co(dic)Co(NH_3)_5]^{4+}$ complexes[a]

dic	ox	malo	suc	pim	fum	male
$O_2\underline{C}$–	165.8	181.3	186.8	188.5	178.3	179.3
$O_2C\underline{C}$–	—	49.1	34.5	38.7	135.2	130.4
$O_2CC\underline{C}$–	—	—	—	25.8	—	—
$O_2CCC\underline{C}$–	—	—	—	29.0	—	—

a) Dioxane (δ=67.4 ppm *vs.* tetramethylsilane) was used as the internal standard. Chemical shifts were referenced to tetramethyl silane, downfield shifts having positive values.

As expected from the symmetric nature of the complexes, the ^{13}C-NMR spectra showed only one signal for the μ-ox complex, two signals for the μ-malo, μ-suc, μ-fum, and μ-male complexes, and four signals for the μ-pim complex (Table 4).

Product Distribution of the Reaction of $[Co(Hdic)(NH_3)_5](ClO_4)_2$ with $[Co(NH_3)_5(H_2O)](ClO_4)_3$. Figure 1 shows a chromatogram for the solution produced in the reaction between $[Co(Hox)(NH_3)_5]^{2+}$ and $[Co(NH_3)_5(H_2O)]^{3+}$. The distribution of the species formed in the reaction of $[Co(Hdic)(NH_3)_5](ClO_4)_2$ with $[Co(NH_3)_5$-

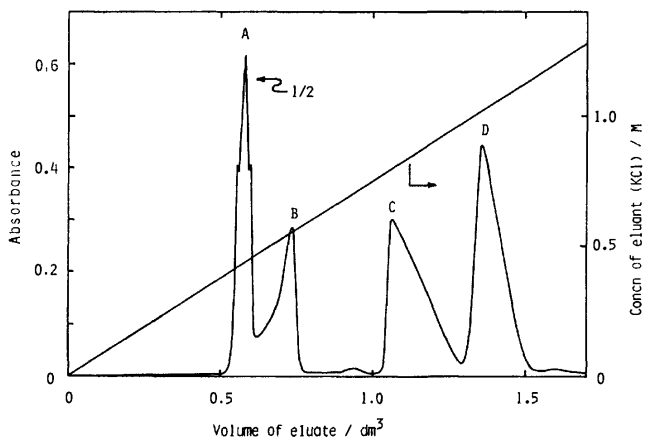

Fig. 1. Chromatogram for the solution produced in the reaction between $[Co(Hox)(NH_3)_5](ClO_4)_2$ and $[Co(NH_3)_5(H_2O)](ClO_4)_3$. The bands A, B, C, and D correspond to $[Co(ox)(NH_3)_5]^+$, $[Co(Hox)(NH_3)_5]^{2+}$, $[Co(NH_3)_5(H_2O)]^{3+}$, and $[(NH_3)_5Co(ox)Co(NH_3)_5]^{4+}$, respectively. The preparative scale was one-fourth of that given in Experimental. Heating time of the mixture was 4 h. The chromatography was made with an SP-Sephadex C-25 column ($\phi 2.6 \times 40$ cm). The pH of the eluant was asjusted to 3 with HCl. Absorbance was measured at 505 nm with a flow-cell of 0.5 cm optical length.

$(H_2O)](ClO_4)_3$ was determined semi-quantitatively. The results are shown in Table 5. In the case of ox, malo, male, or pim system, a small amount of a violet species was detected at the lowest band. The species could be eluted out very easily with a 0.1 M $NaClO_4$ solution and hence the charge of the species was considered to be 1+. For the ox and malo systems, the species were characterized as chelated complexes $[Co(dic)(NH_3)_4]^+$ from a comparison of the electronic spectra with published data.[17,18]

In most systems, the amounts of $[Co(Hdic)(NH_3)_5]^{2+}$ which remained unreacted were less than those of $[Co(NH_3)_5(H_2O)]^{3+}$ unreacted. This suggests the simultaneous occurrence of the dimerization reaction with $[Co(NH_3)_5(H_2O)]^{3+}$ and the aquation reaction of the $[Co(Hdic)(NH_3)_5]^{2+}$.

The ^1H-NMR spectra of the starting material pentaamminemaleatocobalt(III) complex did not show a detectable amount of pentaamminefumaratocobalt(III) complex (<2%). However, the formation of $[(NH_3)_5Co(fum)Co(NH_3)_5]^{4+}$ was observed in the male system. Therefore, the μ-fum complex is thought to be formed by the isomerization of $[(NH_3)_5Co(male)Co(NH_3)_5]^{4+}$.

IR and Raman Spectra. IR spectra of all the dimeric complexes show intense bands in the regions of 1300—1400 cm^{-1} and 1600—1650 cm^{-1}, which can be assigned to the CO stretching vibrations, though these bands are obscured by the overlap of the NH_3 deformation vibrations.[19] The deuterated μ-ox complex exhibits three CO stretching absorptions, *i.e.*, at 1625 (strong), 1435 (weak), and 1302 cm^{-1} (strong). Table 6 shows the IR and Raman spectral data of $[(NH_3)_5Co(ox)Co(NH_3)_5](ClO_4)_4$ and related compounds. The IR spectral pattern of $[(NH_3)_5Co(ox)Co(NH_3)_5]^{4+}$ is quite similar to that of free $C_2O_4^{2-}$ whose symmetry is known to be D_{2h} and hence the symmetry of the oxalate ion in the complex may be approximated by D_{2h}. A strong Raman band at 1438 cm^{-1} can be assigned to vibration of a_g mode. A weak IR band at 1435 cm^{-1} may be also assigned to the vibration of a_g mode which appears by the lowering of symmetry in a crystal.

The complexes $[(NH_3)_5Cr(ox)Cr(NH_3)_5]^{4+}$ and $[(NH_3)_5Co(ox)Co(NH_3)_4(H_2O)]^{4+}$ have been prepared

7) Under the present experimental conditions, the pentaaminecobalt(III)–ox complex shows two bands on the Sephadex column (see Fig. 1). This may arise from the fact that $[Co(Hox)(NH_3)_5]^{2+}$ is rather strongly acidic ($pK_a=2.06$)[8] and the complex is present as the equilibrium mixture of $[Co(Hox)(NH_3)_5]^{2+}$ and its conjugate base form, $[Co(ox)(NH_3)_5]^{+}$. Restricted supply of acid during the elution prevents interconversion between these two forms.

Electron-transfer Reaction from Sodium Benzenethiolate to Acceptors Assisted by Photo-excited Tris(2,2′-bipyridine)ruthenium(II)

Tokuji MIYASHITA and Minoru MATSUDA*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980

(Received May 12, 1980)

The photo-excited tris(2,2′-bipyridine)ruthenium(II) ($Ru(bpy)_3^{2+*}$) was effectively quenched by sodium benzenethiolate in acetonitrile (Stern-Volmer constant=4860 $dm^3\ mol^{-1}$). The flash photolysis of a solution containing $Ru(bpy)_3^{2+}$ and benzenethiolate (excitation wavelength (λ)>480 nm) produced transient species absorbing *ca.* 510 nm; this species was identified as $Ru(bpy)_3^{+}$ and decayed with first-order kinetics with $k=3.0\ s^{-1}$. This slow decay of $Ru(bpy)_3^{+}$ implies that the back-electron-transfer reaction was suppressed. The decay of $Ru(bpy)_3^{+}$ was accelerated by the addition of water, suggesting the possibility of the reaction between $Ru(bpy)_3^{+}$ and water, though no H_2 was detected. The steady irradiation of a solution containing $Ru(bpy)_3^{2+}$, benzenethiolate, and an electron-acceptor produced the radical anion of the added acceptor, which was detected with ESR spectroscopy.

Recently there has been considerable interest in photo-induced electron-transfer reactions in a solution containing $Ru(bpy)_3^{2+}$ from the viewpoint of solar energy conversion.[1-6] $Ru(bpy)_3^{3+}$ and $Ru(bpy)_3^{+}$ generated by the electron-transfer quenching of photo-excited tris(2,2′-bipyridine)ruthenium ($Ru(bpy)_3^{2+*}$) (Eqs. 1 and 2) are thermodynamically capable of

$$Ru(bpy)_3^{2+*} + Q \rightleftharpoons Ru(bpy)_3^{3+} + Q^{-} \quad (1)$$

$$Ru(bpy)_3^{2+*} + Q \rightleftharpoons Ru(bpy)_3^{+} + Q^{+} \quad (2)$$

oxidizing water to O_2 and of reducing water to H_2, respectively. However, the practical utility of these

$$Ru(bpy)_3^{2+} + e^{-} \rightleftharpoons Ru(bpy)_3^{+} \qquad E_{1/2} = -1.33\ V^{7)}$$

$$Ru(bpy)_3^{3+} + e^{-} \rightleftharpoons Ru(bpy)_3^{2+} \qquad E_{1/2} = +1.29\ V^{8)}$$

reactions is limited by the energy-wasting back-electron-transfer of Eqs. 1 and 2.[8-10] One approach to suppressing the back-electron-transfer reaction is to remove the quenching products by rapid irreversible reactions coupled with quenching processes.

We have found that the life-time of $Ru(bpy)_3^{+}$ can be elongated when benzenethiolate is used as the electron-donor for the quenching of $Ru(bpy)_3^{2+*}$. The thiyl radical formed in the electron-transfer from benzenethiolate to $Ru(bpy)_3^{2+*}$ can disappear upon rapid dimerization into disulfide,[11] which has a high redox (more negative) potential,[12] leading to the result that the back-electron-transfer can be suppressed. This paper reports the photo-induced reduction of $Ru(bpy)_3^{2+}$ in the presence of sodium benzenethiolate and the electron-transfer reaction from the $Ru(bpy)_3^{+}$ generated to some organic electron-acceptors.

Results and Discussion

The quenching experiments of the luminescence of $Ru(bpy)_3^{2+*}$ by sodium benzenethiolate were carried out in a highly degassed acetonitrile solution. The emission maximum of $Ru(bpy)_3^{2+*}$ was not shifted by the addition of benzenethiolate, and only the intensity of emission (I) decreased. The plot of I_0/I *vs.* the concentration of benzenethiolate (Stern-Volmer plot) is shown in Fig. 1. The Stern-Volmer quenching constant, $K_{sv}=4860\ dm^3\ mol^{-1}$, was obtained from the slope in Fig. 1. The quenching-rate constant (k_q) was calculated to be $5.7\times10^9\ dm^3\ mol^{-1}\ s^{-1}$ from the Stern-Volmer constant,

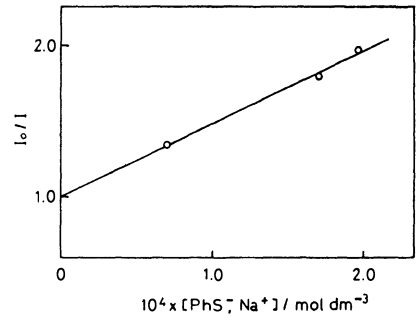

Fig. 1. Stern-Volmer plots for the quenching of the $Ru(bpy)_3^{2+*}$ luminescence (610 nm) by sodium benzenethiolate in acetonitrile. [$Ru(bpy)_3^{2+}=1.4\times10^{-5}$ mol dm^{-3}, excitation at 450 nm.

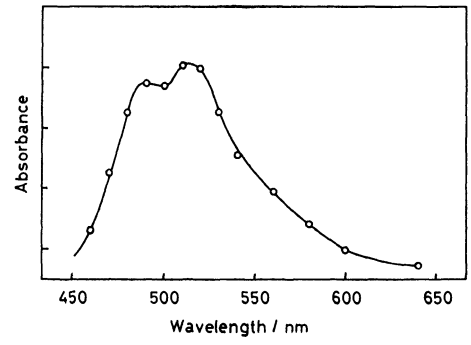

Fig. 2. Transient absorption spectrum in flash photolysis of acetonitrile solution containing $Ru(bpy)_3^{2+}$ (1×10^{-5} mol dm^{-3}) and sodium benzenethiolate (1×10^{-4} mol dm^{-3}).

assuming that the rate constant for the natural deactivation of $Ru(bpy)_3^{2+*}$ (k_0) is $1.18\times10^6\ s^{-1}$ in acetonitrile.[13]

The flash photolysis of acetonitrile solutions containing $Ru(bpy)_3^{2+}$ ($1—4\times10^{-5}$ mol dm^{-3}) and benzenethiolate ($1—5\times10^{-4}$ mol dm^{-3}) gave the transient absorption spectrum shown in Fig. 2, which was assigned to $Ru(bpy)_3^{+}$. Similar spectra have been reported in pulse-radiolysis,[14] laser-photolysis,[15] and electrochemical studies.[7] The absorbance of transient species at a given wavelength was not changed on repetitive flashing (up to 20 flashes were tested). The photoanation reaction of $Ru(bpy)_3^{2+}$ by thiocyanate has been reported,

although the quantum yield is low.[16] Our above results concerning repetitive flashing and both the absorption and emission spectra showed that such a photoanation reaction did not occur. The transient species decayed with first-order kinetics and had a long life-time ($\tau=1/k=333$ ms). These results imply that the back-electron-transfer reaction was effectively suppressed, because the decay of $Ru(bpy)_3^+$ by the back-electron-transfer reaction should obey second-order, equal-concentration kinetics.[13] When Eu(II) or aromatic amine was used as a quencher, the decays of $Ru(bpy)_3^+$ obeyed second-order kinetics, and the rate constants were 2.7×10^7 for Eu(II)[17] and 10^7—10^{10} $dm^3\ mol^{-1}\ s^{-1}$ for amines.[13] Whitten *et al.*[18] have found the very long-lived $Ru(bpy)_3^+$, which was generated by the quenching of $Ru(bpy)_3^{2+*}$ with triethylamine in dry acetonitrile. Since the triethylamine cation radical formed in the quenching as a counterpart of $Ru(bpy)_3^+$ was removed by an irreversible reaction with a solvent (CH_3CN), the back-electron-transfer reaction was almost entirely avoided. The irreversible reactions and their products were complex, whereas the irreversible product in our system was diphenyl disulfide, which could reproduce benzenethiolate (see below).

The results obtained here can be explained by a mechanism (Eqs. 3—6) in which the $Ru(bpy)_3^+$ formed in the reductive quenching of $Ru(bpy)_3^{2+*}$ (Eq. 4) may transfer an electron to disulfide, not to thiyl radicals (back-electron-transfer reaction), which dimerize each other to disulfide with $k_d=10^9$ $dm^3\ mol^{-1}\ s^{-1}$ (Eq. 5):[11]

$$Ru(bpy)_3^{2+} \underset{k_0}{\overset{h\nu}{\rightleftharpoons}} Ru(bpy)_3^{2+*} \quad (3)$$

$$Ru(bpy)_3^{2+*} + PhS^- \xrightarrow{k_q} Ru(bpy)_3^+ + PhS\cdot \quad (4)$$

$$PhS\cdot + PhS\cdot \xrightarrow{k_d} PhSSPh \quad (5)$$

$$Ru(bpy)_3^+ + PhSSPh \xrightarrow{k_{et}} Ru(bpy)_3^{2+} + PhS^- + PhS\cdot \quad (6)$$

The pseudo-first-order rate constant for the decay of $Ru(bpy)_3^+$ varied upon an added concentration of diphenyl disulfide (Fig. 3), showing the occurrence of an electron-transfer reaction, as is shown in Eq. 6. The rate constant (k_{et}) for the electron-transfer reaction

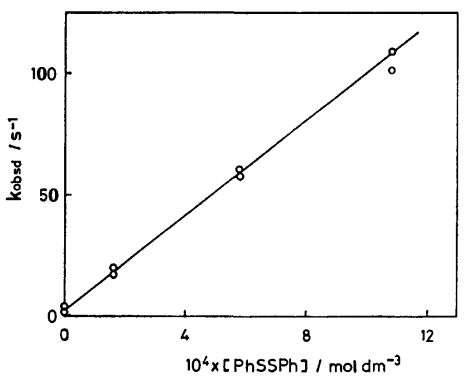

Fig. 3. Dependence of first-order rate constants for the decay of $Ru(bpy)_3^+$ (510 nm) on the concentration of added diphenyl disulfide.

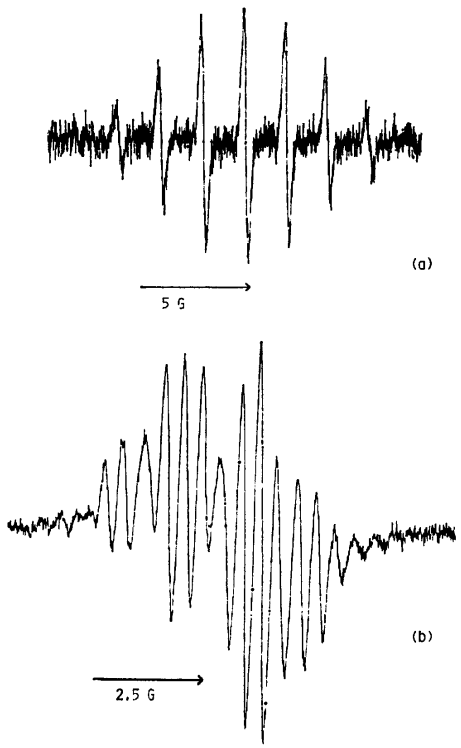

Fig. 4. ESR spectra of duroquinone radical anion (a) and benzil radical anion (b) in acetonitrile.

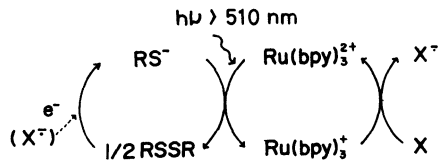
Table 1. Photo-induced electron-transfer from sodium benzenethiolate in the presence of $Ru(bpy)_3^{2+}$ in acetonitrile

Acceptor(X)	$E_{1/2}$/V[a]	Formation of X^-
Duroquinone	−0.69[23]	Yes, $a_H=1.88$ G (Septet)
Acenaphthene-quinone	−0.96	Yes, $g=2.0045$(Multiplet)
Benzil	−1.21	Yes, $g=2.0048$(Multiplet)[24]
9-Fluorenone	−1.26	Very small
Azobenzene	−1.36	No

a) *vs.* SCE and used $(n\text{-}C_4H_9)_4NClO_4$ as a supporting electrolyte in acetonitrile.

was found to be 9.6×10^4 $dm^3\ mol^{-1}\ s^{-1}$. This slow electron-transfer reaction is due to the high redox potential of diphenyl disulfide ($E_{peak}=-1.6$ V *vs.* 10^{-3} mol dm^{-3} Ag^+/Ag).[12]

The steady irradiation (wavelengths longer than 510 nm) of an acetonitrile solution containing $Ru(bpy)_3^{2+}$, benzenethiolate, and an electron-acceptor produced the radical anion of the added acceptor, which was detected with ESR spectroscopy (Table 1) (*e.g.*, the ESR spectra of duroquinone and benzil radical anions are shown in Fig. 4). As can be seen from Table 1, acceptors with a potential more positive than the $E_{1/2}$ of the $Ru(bpy)_3^{2+}/Ru(bpy)_3^+$ couple ($E_{1/2}=-1.33$ V *vs.* SCE) were reduced to radical anions. The irradiation in the absence of either $Ru(bpy)_3^{2+}$ or benzenethiolate produced no acceptor's radical anion, and the mixing of $Ru(bpy)_3^{2+}$, benzenethiolate, and acceptor in the dark produced no radical anion, either. The results suggest the following electron-transfer cycle:



where X is an electron-acceptor. Benzenethiolate could be reproduced with the reduction of disulfide.[19] The RS^-/RSSR redox couple is known to be biologically important in an electron-transport system in ferredoxin or other iron-sulfur proteins.[20]

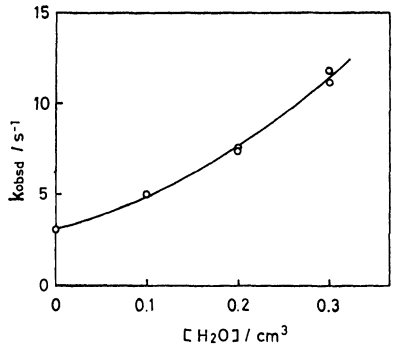


Fig. 5. Effect of added water on the rate constants for the decay of $Ru(bpy)_3^+$ (510 nm); total volume was 10 cm^3.

Although the decay of $Ru(bpy)_3^+$ was accelerated by the addition of water (Fig. 5), the formation of H_2 could not be detected.[21] Meyer *et al.*[6] have reported that there was no production of H_2 in the reaction of water with $Ru(bpy)_3^+$, whereas the reaction with $Ru(bpy)_3^0$ could produce H_2. This has been explained by the difference in two-electron reducing capability between $Ru(bpy)_3^+$ and $Ru(bpy)_3^0$:

$$Ru(bpy)_3^+ \rightleftharpoons Ru(bpy)_3^{3+} + 2e^- \qquad E = 0.00 \text{ V } vs. \text{ NHE}$$

$$Ru(bpy)_3^0 \rightleftharpoons Ru(bpy)_3^{2+} + 2e^- \qquad E = -1.42 \text{ V } vs. \text{ NHE}.$$

Although our system could not succeed in the formation of H_2, the electron-transport cycle described above shows the possibility of applying this system to other reduction reactions. An experiment for the application to the photo-galvanic cell of this system using the $Ru(bpy)_3^+/Ru(bpy)_3^{2+}$ couple is also undertaken.

Experimental

$Ru(bpy)_3Cl_26H_2O$ was synthesized according to published procedures.[22] Commercially available (reagent-grade) acceptors (duroquinone, acenaphthenequinone, benzil, 9-fluorenone, and azobenzene) were recrystallized twice from ethanol and sublimed under high vacuum (about 10^{-3} Pa). The preparation of sodium benzenethiolate was described previously.[19] The concentration of benzenethiolate in acetonitrile was determined from the absorbance at 298 nm ($\varepsilon = 1.8 \times 10^4$ dm^3 mol^{-1} cm^{-1}). The solutions for the experiments of the flash photolysis, the quenching, and the ESR measurement were prepared by a high-vacuum-line technique.[19] The prepared sodium benzenethiolate solution was introduced through a breakseal to a solution containing $Ru(bpy)_3^{2+}$ and acceptor which had been degassed by the freeze-thaw-cycle method.

The quenching experiment of $Ru(bpy)_3^{2+*}$ by benzenethiolate was carried out with a Shimadzu RF 501 fluorescence spectrophotometer. The FSR measurements were carried out with a Varian E-4 ESR spectrometer. The steady irradiation for the photo-ESR study was obtained using a 500-W xenon lamp. The light shorter than 510 nm was cut off with a filter (Toshiba L-51).

The flash apparatus delivered a flash with an energy of 98 J and a half-peak duration of 10 μs from xenon lamps. The filter was used to cut off flash light shorter than 480 nm.

Synthetic Studies of Rifamycins. III.[1] The Partial Synthesis of Rifamycin Ansa-chain Compounds from Their Degradation Products†

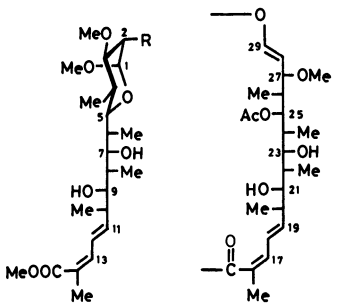
Masaya NAKATA, Toshiya SAKAI, Kuniaki TATSUTA, and Mitsuhiro KINOSHITA*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received July 29, 1980)

The ansa-chain compound methyl [methyl 2,4,6,8,10,11,12,13,14-nonadeoxy-4,6,8,10,14-penta-*C*-methyl-3-*O*-methyl-L-*manno*-β-D-*galacto*-(11*E*,13*Z*)-11,13-pentadecadienopyranosid]uronate (**1a**) and its (*R*)-2-bromo derivative, **1b**, were transformed into the corresponding 7,9-diacetate **3a** and **3b** or the 7,9-acetonide **7a** and **7b**. The ozonolysis of **3a** or **3b** gave methyl 7,9-di-*O*-acetyl-2,4,6,8,10-pentadeoxy-4,6,8,10-tetra-*C*-methyl-3-*O*-methyl-L-*manno*-β-D-*galacto*-undecodialdopyranoside-(1,5) (**4a**) or its (*R*)-2-bromo derivative (**4b**) respectively. The Wittig condensation of **4b** with (methoxycarbonylmethylene)triphenylphosphorane, followed by debromination with tributylstannane, afforded methyl [methyl-7,9-di-*O*-acetyl-2,4,6,8,10,11,12-heptadeoxy-4,6,8,10-tetra-*C*-methyl-3-*O*-methyl-L-*manno*-β-D-*galacto*-(*E*)-11-tridecenopyranosid]uronate (**6a**). The diisobutylaluminium hydride reduction of **6a**, followed by acetonation, gave methyl 2,4,6,8,10,11,12-heptadeoxy-7,9-*O*-isopropylidene-4,6,8,10-tetra-*C*-methyl-3-*O*-methyl-L-*manno*-β-D-*galacto*-(*E*)-11-tridecenopyranoside-(1,5) (**10a**). The allylic alcohol, **10a**, was converted into the allylic bromide, **12a**, which then yielded the triphenylphosphonium bromide, **13a**. The Wittig condensation of the reactive ylide generated from **13a** with methyl pyruvate afforded a 4 : 5 mixture of **7a** and its 13*E*-isomer. The partial synthesis of **1a** was accomplished by the selective hydrolysis of the **7a** isolated from the mixture.

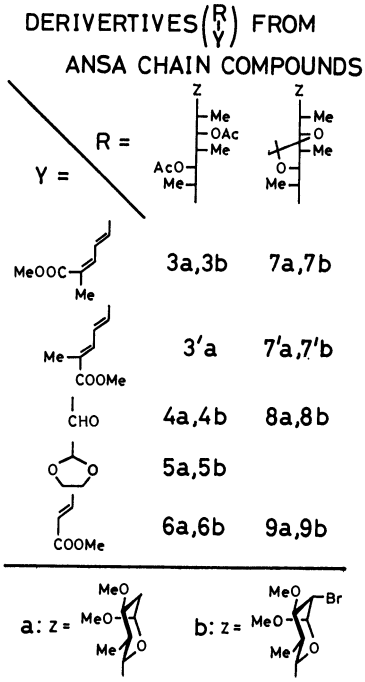
The ansa-chain compound **1a**,[2] corresponding to the 25-deacetylated ansa-bridge portion, **2**, of rifamycin B, O, S, and SV, has recently been obtained *via* its (*R*)-2-bromo derivative, **1b**, itself produced by the novel degradation of 25-deacetylrifampicin. During the course of our studies of the synthesis of **1a**,[1] a degradation-reconstruction program of **1a** and **1b** has been under-



1a R=H **1b** R=Br **2**

taken to secure materials for establishing the structure of the synthetic intermediate, **4a** or **6a**, and to survey the practical methods for the construction of **1a** starting with **4a** or **6a**. This paper will describe the partial degradation of **1a** or **1b** to their synthetic intermediates, **4a**, **4b**, **8a**, and **8b**, and the partial synthesis of **1a** or **1b** from the degradation products *via* the intermediates, **6a**, **9a** or **9b**, and **10a** or **10b**, by Wittig reaction.

The acetylation of **1a** with acetic anhydride in pyridine afforded a mixture of the diacetate, **3a** (15%), and its 13*E*-isomer, **3'a** (22%), and a mixture of the monoacetate of **1a** (20%) and its 13*E*-isomer (18%). The structures of the isomeric products were confirmed by the ^{1}H-NMR data. On the contrary, the acetylation of **1b** with acetic anhydride and 4-dimethylaminopyridine (DMAP) in ethyl acetate gave the diacetate, **3b**, as the sole product in a 90% yield.[3] Both **1a** and **1b** were smoothly acetonated with 2,2-dimethoxypropane (DMP) in acetone containing a small amount of sulfuric acid to afford the 7,9-acetonides, **7a** and **7b**, in 99% and 76% yields respectively. Although it is unclear why the bromine atom situated far from the unsaturated system of the molecule of **1b** prevents its 13 *Z*-geometry from geometrical isomerization during acetylation, the unsaturated system of a free ansa-chain compound such as **1a** seems to be less stable than that of the intact ansa-chain in rifamycins.

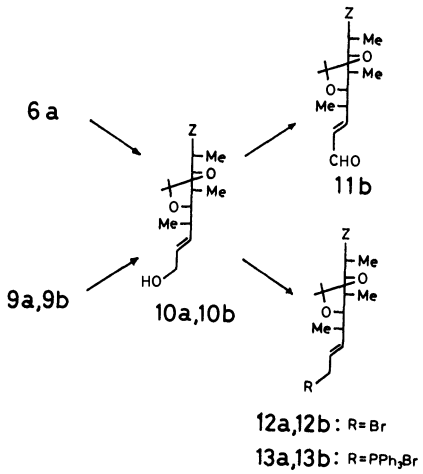


The ozonolysis of a mixture of **3a** and **3'a** with ozone and dimethyl sulfide in dichloromethane[4] gave the aldehyde, **4a**, in a 77% yield: this is a strategic intermediate in the synthesis of **1a**. The direct treatment of **4a** with ethylene glycol and *p*-toluenesulfonic acid in

† Presented at the ACS/CSJ Chemical Congress, Honolulu, Hawaii, April 6, 1979; Organic Abstract No. 481.

acetonitrile failed, however, to afford the ethylene acetal, **5a**, because of the simultaneous hydrolysis of the cyclic methyl acetal moiety of **4a**, and so the following alternative process was necessary. The ozonolysis of **3b**, followed by the treatment of the resulting aldehyde, **4b**, with ethylene glycol, gave the crystalline ethylene acetal, **5b**, in a 53% yield; on selective hydrolysis with 70% trifluoroacetic acid (TFA), this then provided **4b** in a quantitative yield. The debromination of **5b** with tributylstannane afforded plates of **5a** in a 64% yield after recrystallization. Attempts to obtain **4a** by the selective hydrolysis of the ethylene acetal group of **5a** were all unsuccessful. From these results, it was found that **5a** was not a synthetic precursor suitable for **4a**, while **5b** was a useful precursor for **4b**. The useful derivative, **6a**,[5] was obtained in a 95% yield by the debromination of **6b**, which had itself prepared by the Wittig condensation of **4b** with (methoxycarbonylmethylene)triphenylphosphorane in an 84% yield. The ozonolysis of **7a** or **7b**, followed by the Wittig condensation of the resulting aldehyde, **8a** or **8b** with the phosphorane, gave **9a** or **9b** in an 88 or 70% yield respectively.

We examined the possibility of the formation of **7a** *via* the allylic alcohol, **10a**, from **6a** or **9a**. At the same time, the transformation of **9b** into **7b** *via* **10b** was also examined, taking into account the fact that **7b** might be more stable than **7a** in the geometrical isomerization of an unsaturated system. The treatment of **6a** with diisobutylaluminium hydride (DIBAL) in toluene led to the corresponding triol, which, without purification, was acetonated with DMP in DMF containing *p*-toluenesulfonic acid to afford **10a** in a 73% yield. The reduction of **9a** or **9b** with DIBAL in toluene gave **10a** or **10b** in a 70 or 96% yield respectively. At first, the



condensation of the phosphonate anion generated from dimethyl [1-(methoxycarbonyl)ethyl]phosphonate (**14**) with the α,β-unsaturated aldehyde, **11b**, which had been obtained in a 62% yield by the oxidation of **10b** with chromium trioxide in hexamethylphosphoric triamide (HMPA),[6] was examined. The reaction was carried out in THF at −75——60 °C to afford, predominantly, the undesired 11*E*,13*E*-isomer **7'b** in an 83% yield, accompanied by a small amount of **7b** (1.5%) [Reaction 1]. The structure of **7'b** was confirmed by the ^{1}H-NMR data. This reaction was highly stereoselective, and similar results have been reported in a recent paper;[7] therefore, it was conclusively disadvantageous for the formation of the desired 11*E*,13*Z*-isomer **7b**.
