Spectroscopic Measurements. A Bruker WH-90 FT and a Hitachi R-24B spectrometer were used to obtain ^{1}H NMR spectra in chloroform-*d* (>99.5%; E. Merck, Darmstadt) at room temperature. Chemical shifts are given in ppm from internal TMS and calibrated with a chloroform signal as the secondary external reference. ESR spectra were recorded on a JEOL JES-ME-3 X-band spectrometer equipped with a 100 kHz field modulation unit; a standard MgO/Mn(II) sample calibrated with a NMR magnetometer was employed for calibration of the magnetic field. Electronic spectra were taken on a Union Giken SM-401 high sensitive spectrophotometer at 25 °C.

Electrochemical Measurements. Cyclic voltammetry was carried out on a YANACO P-8 polarograph equipped with platinum wire of 0.5 mm diameter as working and auxiliary electrodes; the surface area of the former electrode being about 30 times smaller than that of the latter. A saturated calomel electrode (SCE) was served as a reference which was separated from a bulk electrolyte solution by a salt bridge prepared with benzyliden-D-glucitols[5] and a dichloromethane solution of TBAP. A dichloromethane solution containing a niobium complex (5.0×10^{-4} mol dm^{-3}) and TBAP (5.0×10^{-2} mol dm^{-3}) was deaerated prior to each measurement and the inside of the cell was maintained under argon atmosphere throughout each measurement. All the measurements were carried out at 25±2 °C. The scan rate was varied in a range from 5 to 500 mV s^{-1}. Half-wave potentials ($E_{1/2}$) and anodic (i_{pa}) and cathodic (i_{pc}) currents were evaluated by referring to the literature methods.[6]

Controlled potential electrolysis was carried out in a three-electrode cell, modified for ESR and electronic spectral

measurements, with platinum wire of 0.5 mm diameter as working and auxiliary electrodes. The reference electrode was the same as used for cyclic voltammetry. An applied potential between the working and auxiliary electrodes was maintained constant with a conventional potentiostat and monitored with a Takeda Riken TR-6656 digital multimeter.

Results

Coordination Behavior of Nb(O)(TPP)(AcO). In order to examine the further coordination ability of **1**, the interaction between **1** and pyridine was investigated by electronic and NMR spectroscopy. The electronic spectrum of **1** was measured by changing the concentration of pyridine in a range of 0 to 3.09 mol dm^{-3} while the concentration of **1** was maintained constant (3.7×10^{-6} mol dm^{-3}). The results are shown in Fig. 1, where

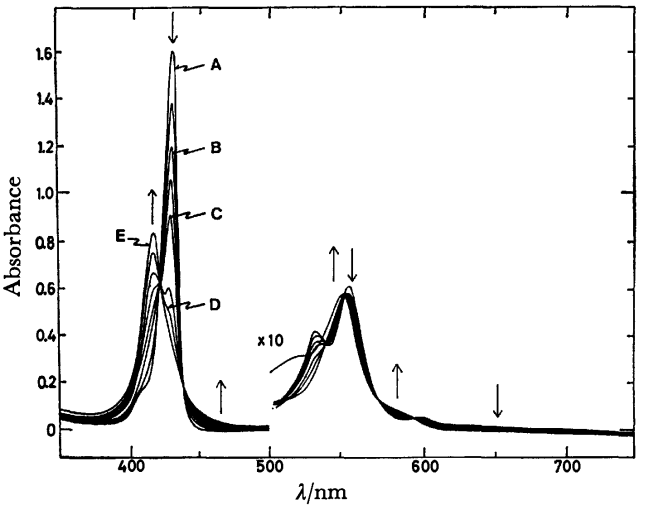

Fig. 1. Electronic spectra of Nb(O)(TPP)(AcO) (3.7×10^{-6} mol dm^{-3}) at 25.2 °C in the presence of pyridine at various concentrations (0—3.09 mol dm^{-3}): A, 0; B, 3.09×10^{-2}; C, 1.55×10^{-1}; D, 6.18×10^{-1}; E, 3.09 mol dm^{-3}. Trends of spectral change with increase in pyridine concentration are shown by arrows (↑ and ↓).

isosbestic points are observed at 420, 437, ≈510, 538, 550, 575, and 593 nm. The spectral behavior shows the formation of a single pyridine adduct of **1**. The NMR spectra clearly indicate the coordination of pyridine to **1**. A methyl signal of the coordinated acetate for **1** was observed at 1.27 ppm as shown in Fig. 2; appeared in a upper field range relative to the signal of acetic acid (2.20 ppm). This is attributed to a magnetic anisotropy effect provided by the macrocyclic ligand on the coordinated acetate group. This signal was, however, drastically shifted to a lower field range (5.28 ppm) in chloroform–pyridine (7 : 3 v/v) as shown in Fig. 2. This indicates that the methyl protons are displaced from a shielding to a deshielding zone of the porphyrin skeleton. Furthermore, signals due to the coordinated pyridine were observed in a range of 6 to 7 ppm, which are separated from those of the coordination-free pyridine appeared in the lower field range. By referring to the signal intensity of methyl protons

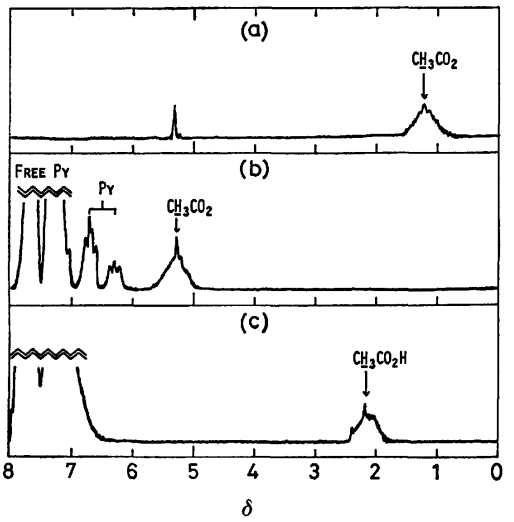

Fig. 2. NMR spectra of Nb(O)(TPP)(AcO) and acetic acid at room temperature: (a), Nb(O)(TPP)(AcO) in chloroform-*d* (a signal due to dichloromethane used as solvent for recrystallization appeared at 5.31 ppm); (b), Nb(O)(TPP)(AcO) in pyridine–chloroform-*d* (3 : 7 v/v); (c), acetic acid in pyridine–chloroform-*d* (3 : 7 v/v).

of the coordinated acetate, a number of pyridine molecules coordinated to **1** was evaluated to be one. Other signals observed in a low-field region below 7 ppm are: 7.78 (12H, m, *m*- and *p*-phenyl H's), 8.22 (8H, m, *o*-phenyl H's), and 9.04 (8H, s, pyrrole H's). The effect of pyridine coordination on the electronic and NMR spectra is consistent with the following solution equilibrium, where Py stands for pyridine.

$$\text{Nb(O)(TPP)(AcO)} + \text{Py} \overset{K}{\rightleftharpoons} \text{Nb(O)(TPP)(AcO)(Py)} \quad (1)$$

The equilibrium constant (K) was obtained from the intensity change at 427 nm by the aid of Benesi-Hildebrand equation[7] (Eq. 2), where $[Nb]_T$ and $[Py]_T$ stand for the total concentrations of **1** and pyridine, respectively; $\Delta\varepsilon$ is for the difference in molar absorption coefficient between **1** and its pyridine adduct, and ΔA represents the extent of absorbance change upon

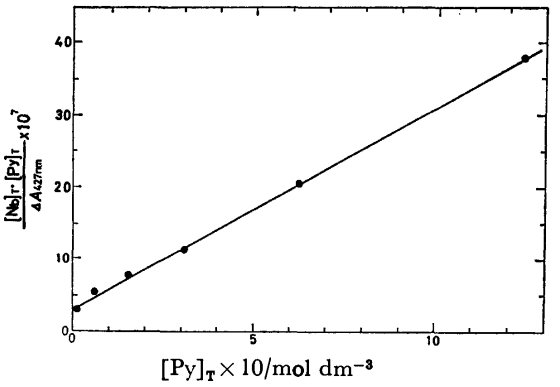

Fig. 3. Benesi-Hildebrand plot for the complex-forming equilibrium between Nb(O)(TPP)(AcO) and pyridine.

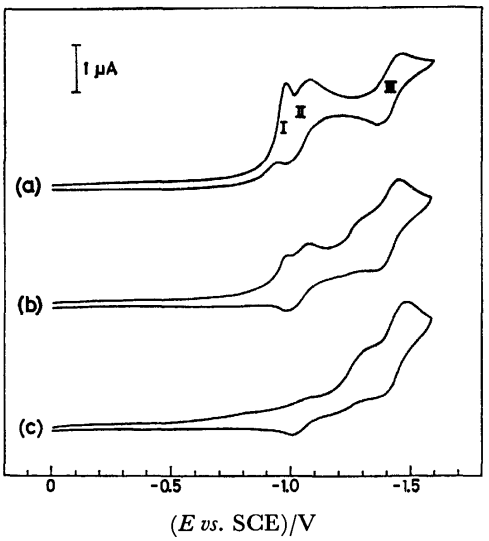

Fig. 4. Cyclic voltammograms of Nb(O)(TPP)(AcO) (5.0×10^{-4} mol dm^{-3}) in dichloromethane containing TBAP (5.0×10^{-2} mol dm^{-3}) at 25.2 °C in the presence of pyridine at various concentrations: (a), 0; (b), 0.8; (c), 3.5 mol dm^{-3}; scan rate 50 mV s^{-1}.

addition of pyridine. A good linear correlation based

$$\frac{[\mathrm{Nb}]_\mathrm{T}[\mathrm{Py}]_\mathrm{T}}{\Delta A}=\frac{1}{\Delta\varepsilon\cdot K}+\frac{[\mathrm{Py}]_\mathrm{T}}{\Delta\varepsilon} \qquad (2)$$

on Eq. 2 is observed as shown in Fig. 3: $K=9.6$ mol^{-1} dm^3; and $\Delta\varepsilon=3.48\times10^5$. The $\Delta\varepsilon$-value is in good agreement with that observed in the presence of a large excess of pyridine (3.44×10^5). The coordination of pyridine to **1** was also confirmed by cyclic voltammetry as shown in Fig. 4. Addition of pyridine to **1** resulted in marked cathodic shifts of reduction peaks I and II, from *ca.* −1 to −1.3 V *vs.* SCE, and the corresponding oxidation peaks appeared at −1.2 and −1.0 V *vs.* SCE. Redox peaks III, however, remained almost unchanged even in the presence of a large excess of pyridine.

Interaction of $Nb_2(O)_3(TPP)_2$ with Acetic Acid. The cyclic voltammogram of **2** for the range of 0 to −2.0 V *vs.* SCE in dichloromethane is shown in Fig. 5. The distinct cathodic peaks at −1.30, −1.56, and −1.80 V are coupled with anodic peaks at −1.23, −1.44, and −1.66 V, respectively, each being referred to one-electron transfer process. Redox peaks due to **1** appeared upon addition of acetic acid to a solution of **2**, and the cyclic voltammogram was completely converted to that of **1** in the presence of a 2-fold excess amount of acetic acid as shown in Fig. 5. Such conversion of **2** into **1** through reaction with acetic acid was also confirmed by electronic spectroscopy. The spectral change upon addition of acetic acid to **2** is shown in Fig. 6, where isosbestic points are observed at 421, 441, ≈500, 540, and 551 nm. Since the reaction was accelerated under anaerobic conditions, oxygen must participate in the reverse reaction as shown by Eq. 3.

$$\mathrm{Nb_2(O)_3(TPP)_2}+2\mathrm{AcOH}\underset{\mathrm{O_2}}{\rightleftharpoons}2\,\mathrm{Nb(O)(TPP)(AcO)}+\mathrm{H_2O} \qquad (3)$$

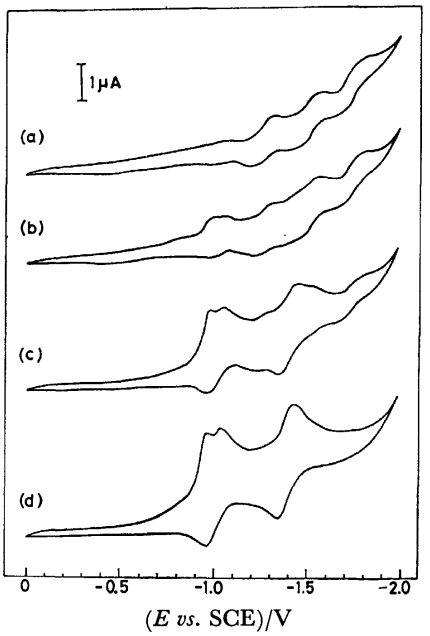

Fig. 5. Cylic voltammograms of $Nb_2(O)_3(TPP)_2$ (2.4×10^{-4} mol dm^{-3}) in dichloromethane containing TBAP (5.0×10^{-2} mol dm^{-3}) at 24 °C in the presence of acetic acid at various concentrations: (a), 0; (b), 1.24×10^{-4}; (c), 4.7×10^{-4}; (d), 9.7×10^{-4} mol dm^{-3}; scan rate 100 mV s^{-1}.

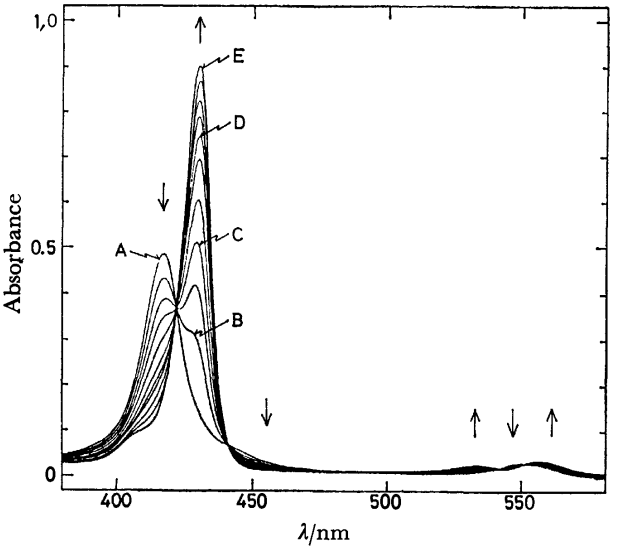

Fig. 6. Electronic spectral change during the reaction of $Nb_2(O)_3(TPP)_2$ (2.3×10^{-6} mol dm^{-3}) with acetic acid (7.1×10^{-5} mol dm^{-3}) in dichloromethane at 25 °C: A, 0; B, 0.5; C, 1.5; D, 3.0; E, 7.5 h. Trends of spectral change with time are shown by arrows (↑ and ↓).

Electrochemical Behavior of Nb(O)(TPP)(AcO). A typical cyclic voltammogram of **1** for the range of 0 to −1.6 V *vs.* SCE in dichloromethane is shown in Fig. 4. No other peak was observed in a cathodic range up to −2.0 V at any scan rate in a range from 10 to 200 mV s^{-1}. Two distinct cathodic peaks at −1.09 and −1.47 V are coupled with anodic peaks at −0.98 and −1.36 V, respectively. Although the anodic wave

coupled with the first cathodic peak at −0.97 V *vs.* SCE was obscure for faster scan rates, it became apparent by reducing the rate below 20 mV s^{-1}. We, therefore, evaluated three half-wave potentials for one-electron reduction steps, indicated by I, II, and III in Fig. 4(a), as −0.89, −1.05, and −1.41 V *vs.* SCE (within an accuracy of ±0.02 V), respectively. It has been generally realized that redox potentials of the central metal atom, incorporated into planar complexes formed with macrocyclic ligands, are quite sensitive to the nature of axial ligands, while those of the macrocyclic ligands are hardly affected by the variation of such ligands.[8] In the light of the coordination effect provided by pyridine on redox potentials, as described in a foregoing section, peaks I and II in Fig. 4(a) are attributed to the reductions of niobium, Nb^{V}/Nb^{IV} and Nb^{IV}/Nb^{III}, respectively, and peak III is due to that of the porphyrin ligand.

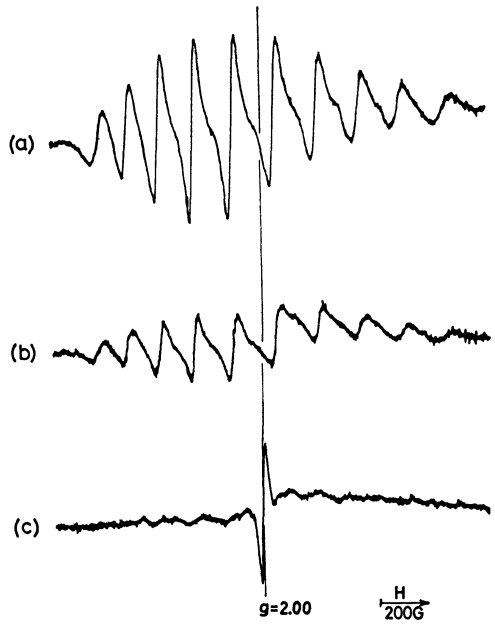

Fig. 7. ESR spectral change during the electrochemical reduction of Nb(O)(TPP)(AcO) at room temperature in dichloromethane containing TBAP (0.30 mol dm^{-3}) at potentials: (a), −0.92; (b), −1.1; (c), −1.46 V *vs.* SCE

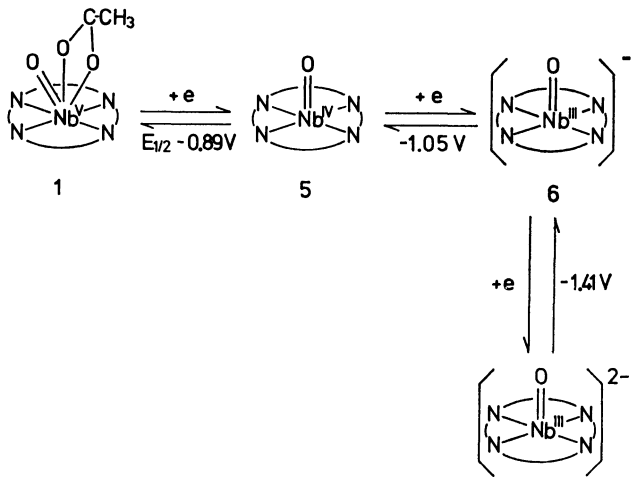
We carried out the controlled potential reduction of **1** at −0.92, −1.1, and −1.46 V *vs.* SCE in dichloromethane in the presence of TBAP; potentials sufficient for respective one-electron reductions of **1** as confirmed by voltammetric measurements. The parent complex is diamagnetic itself, so that no ESR signal was observed. When **1** was reduced at −0.92 V *vs.* SCE, ten intense lines caused through interaction with ^{93}Nb (I=9/2) nucleus were observed over a wide range of magnetic field as shown in Fig. 7(a); this indicates the formation of a paramagnetic niobium(IV) species. These lines, however, decreased their intensities to a large extent upon electrolysis at −1.1 V *vs.* SCE as shown in Fig. 7(b). This implies that the two-electron reduced species is either a diamagnetic niobium(III) complex or a paramagnetic spin-triplet species involving unpaired electrons in both metal and ligand sites, such as π-cation radical of copper(II)–porphyrin.[9] A considerable cathodic shift of peak II upon addition of pyridine to **1** as demonstrated by cyclic voltammetry as well as the ESR pattern for a species obtained by the following electrolysis at peak III range excludes the latter possibility. The controlled potential reduction at −1.46 V *vs.* SCE provided a new signal due to a radical species with concomitant disappearance of the lines due to ^{93}Nb nucleus as shown in Fig. 7(c). The third reduction step undoubtedly corresponds to reduction of the porphyrin ligand. Reversible oxidation reactions were observed after ceasing the respective electrolytic reductions. As a result, complete redox behavior of **1** is illustrated as in Scheme 1.



Scheme 1.

Discussion

The tri-μ-oxo dimer (**2**) does not undergo coordination interaction with pyridine as confirmed by cyclic voltammetry. An overall feature as well as cathodic and anodic peak potentials of the voltammogram was not influenced by the presence of pyridine for its concentration range from 0 to 3.5 mol dm^{-3} under otherwise identical conditions as stated in Fig. 5. According to the X-ray crystallographic analysis of **2**,[3,4] each niobium atom is hepta-coordinate and displaced from the mean ligand plane toward the tri-μ-oxo group by 1.01 Å as shown in **3**. Thus, an additional ligand can not attack at the axial site *trans* to the tri-μ-oxo group due to geometrical reasons, and must approach from the site sandwiched in between the two porphyrin ligands. As a result, pyridine fails to interact with niobium(V) likely due to steric hindrance while acetic acid undergoes substitution reaction with **2** to yield **1**. The coordination geometry around niobium(V) for **1** bears a close

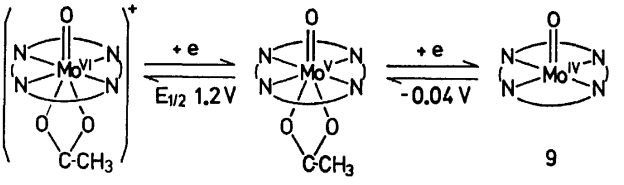
resemblance to that for **2** as depicted in **4** by referring to the X-ray crystallographic analysis of **1**.[2] On the basis of the same reasoning as mentioned for **2**, pyridine undergoes coordination with **1** at the same site that the oxo and acetato groups are placed even though the site becomes further sterically crowded. Such a profound effect and a strong affinity of niobium(V) for oxygen in part seem to be responsible for a weak coordination tendency of **1** toward pyridine, compared with other metalloporphyrins.[10]

Reduction and oxidation potentials for H_2TPP, **1**, and the corresponding molybdenum(V) complex, Mo(O)(TPP)(AcO) (**7**), are listed in Table 1. Table 2 summarizes the M=O stretching frequency for **1** and **7**, and spin Hamiltonian parameters for **7** and the one-electron reduced species of **1**. The one-electron reduced species of **1** shows ten intense lines over a wide range of magnetic field (1500—2000 G) due to hyperfine interaction with niobium nucleus (I=9/2). However, the superhyperfine structure due to four nitrogen nuclei was not detected for the present complex. Since both **7** and the one-electron reduced species of **1** provide ESR signals with remarkable intensity at room temperature, there is no excited d-orbital level placed close to the d-orbital of lowest energy for both species. Consequently, the second electron donated to the central metal atoms during the reductions, $Nb^{IV}\rightarrow Nb^{III}$ and $Mo^{V}\rightarrow Mo^{IV}$, must also be placed in the ground state orbital, which is then occupied with two electrons. The potential separation between first and second metal-reductions ($\Delta E_{1/2}$) for **1** is 0.16 V, while $\Delta E_{1/2}$ for **7** is 1.24 V since the corresponding processes for **7** are reductions of the Mo^{VI} and Mo^{V} species with reference to the number of d-electrons.

The acetato group seems to be released from the niobium(III) and molybdenum(IV) sites, as shown by structures **6** (Scheme 1) and **9** (Scheme 2) due to the reasons stated later, and both complexes may assume



8 7

Scheme 2.

a similar coordination geometry consequently. On this basis, Racah's interelectronic repulsion parameters (B) for d^2 configuration[11] are cited for comparison; 682 and 602 cm^{-1} for Mo^{IV} and Nb^{III}, respectively. Such a small difference in Racah parameter, however, does not explain the large difference in $\Delta E_{1/2}$ stated above. The odd electron density at the metal nucleus is strictly reflected on hyperfine splitting constant A_{metal} for the same metal species. A ρ-value, which is proportional in general to the odd electron density at a metal nucleus, is given by $A_{metal}/(\mu_I/I)$ where μ_I and I stand for nuclear magnetic moment and nuclear spin, respectively. ρ-Values for the molybdenum(V) and niobium(IV) complexes of d^1 configuration listed in Table 2 are comparable to each other, and again do not explain the large difference in $\Delta E_{1/2}$.

In order to elucidate the origin of such potential difference, the change of coordination structures in the course of redox reactions needs to be taken into consideration as shown in Schemes 1 and 2. We reported previously the plausible structures at various metal oxidation states for **7**; **7**, **8**, and **9** in Scheme 2 for the Mo^V, Mo^{VI}, and Mo^{IV} species, respectively.[1] The molybdenum species in d^0 and d^1 configurations retain the acetato group while it seems liberated in d^2 configuration. The marked structural change assigned to **9** is reflected in its redox reaction rate. When the Mo^{IV}

species was electrolytically re-oxidized at 0 V *vs.* SCE under anaerobic conditions, it took about 12 h to return to the Mo^{V} state. On the other hand, when the Nb^{III} species in d^2 configuration was re-oxidized under anaerobic conditions, the ESR signal due to the Nb^{IV} species appeared in 1—2 min. However, even the Nb^{IV} species underwent electrolytic re-oxidation to the Nb^{V} state at 0 V *vs.* SCE under anaerobic conditions, the ESR signal due to the Nb^{IV} species still remained even after *ca.* 12 h of oxidation. On the basis of these kinetic results, structures **5** and **6** are reasonably assigned to the Nb^{IV} and Nb^{III} complexes, respectively.

By referring to equilibrium data for substitution reaction of Mo(O)(TPP)(MeO) with acetate and chloride ions[1] as well as the X-ray crystallographic analysis of Mo(O)(TPP)Cl,[12] the acetato group involved in **7** is coordinated to the molybdenum atom with some ionic character. Such an ionic character of the axial bond tends to stabilize the lowest d-orbital due to the effective positive charge localized on the molybdenum atom. An additional energy is required to cleave the axial bond in reduction process from **7** to **9**. Such a bond-cleavage effect is more pronounced for the reduction of Mo(O)(TPP)(MeO). Since the Mo–OMe bond has a significant covalent character as reported previously,[1] the lowest d-orbital would not be so much stabilized as in the case of **7**. Nevertheless, the reduction potential for Mo^{V}/Mo^{IV} was shifted toward cathodic direction by 0.7 V relative to the same potential for **7**.[1] Consequently, the axial bond cleavage seems predominantly to control the reduction potential for Mo^{V}/Mo^{IV}. A large $\Delta E_{1/2}$ value (1.24 V) for **7** is presumably due to such a bond cleavage effect, while a small $\Delta E_{1/2}$ value (0.16 V) confirms the **5**→**6** process which does not require the axial bond cleavage.

Both H_2TPP and **7** have comparable values of first and second potentials for the ligand reduction, the separation between the potentials being 0.33—0.4 V. This is consistent with the situation that the lowest d-orbital of **7** undergoes little interaction with ligand orbitals. On the other hand, not only the first ligand reduction potential for **1** is a little shifted toward cathodic direction, but also the separation between first and second reduction potentials is much larger than those for H_2TPP and the molybdenum complex. We conclude, therefore, that a considerable cathodic shift of the second ligand reduction potential in particular is attributed to an increase in π-electron density provided by delocalization of added two electrons in the ground state d-orbital of niobium through d-π interactions.

This work provides the first example for the two-electron reduction of the central metal atom to occur prior to the two-electron reduction of the macrocyclic ligand among metalloporphyrins involving second and third transition metals. Now, we are at the gate of research toward developments of stacked complex polymers by using a novel niobium(III) complex obtained in this work.

New Application of Crown Ether. V.[1] The Effect of Crown Ethers on the Acid-Base Interaction between 2,4,4′,6-Tetranitrodiphenylamine and Primary Amines in Benzene

Fumio WADA,* Yoshiko WADA, Kiyoshi KIKUKAWA, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 22, 1980)

The effect of crown ethers on the acid-base interaction of 2,4,4′,6-tetranitrodiphenylamine (HA, λ_{max} 380 nm, $pK_a=8.88$ in water) with primary amines (RNH_2) in benzene was investigated spectrophotometrically. Crown ethers assisted strongly the formation of association complexes, $R\overset{+}{N}H_3\cdot$crown ether$\cdot A^-$, which existed as a single chemical species (λ_{max} 478 nm) assignable to "crown ether-separated ion pair." The effect of the steric factors of various primary amines on the equilibrium to form the association complex was discussed on the basis of the equilibrium constants and thermodynamic parameters of the systems involving 18-crown-6 and benzo-18-crown-6.

Macrocyclic polyethers (crown ethers) form stable complexes with mono-alkylammonium salts as well as alkali and alkaline earth metal salts. Structural effect of crown ethers on the ion-association extraction of an alkylammonium salt as crown ether complexes was investigated in detail by Cram and his collaborators[2] for t-$Bu\overset{+}{N}H_3\cdot\overset{-}{SCN}$, but structural effect of alkylamine moiety has not yet been studied. It is known that the formation of the crown ether complexes is dependent not only on the structure of crown ether itself, but also on the nature of the anion involved in the association complexes extracted in a non-polar solvent. In the case of the alkylammonium complexes, steric interactions between the substituent on the alkylamines and the crown ethers are presumed to be an important factor to affect the extent of the formation of the association complexes.

We recently showed that alkylamine–water–crown ether systems could be used as an effective hydroxide ion source in the reduction of unsaturated carbonyl compounds by hydridocarbonylferrate in a two-phase system (benzene–water).[3] The efficiency of the reduction was dependent not only on the nature of the crown ether added but also on the structure of the alkylamines.

The circumstances prompted us to study the association equilibrium between a weak acid and primary amines in a non-polar solvent (benzene) in the presence of crown ethers. Variation of the extent of the equilibrium (Eq. 1) with the structure of the amines and crown ethers (18-crown-6 and benzo-18-crown-6) is discussed in a quantitative manner in this paper.

Results and Discussion

Structure of the Association Complexes. Among several weak acids examined, 2,4,4′,6-tetranitrodiphenylamine (**1**; $pK_a=8.88$, $\lambda_{max}(Na^+\cdot A^-)$ 465 nm, ε_{max} 23800 in water[4]) was proved to be a suitable probe for spectroscopic study of the equilibrium. The acid (**1**) showed a strong absorption maximum at 380 nm in benzene. The reaction of **1** with RNH_2 to form $R\overset{+}{N}H_3\cdot A^-$ lies so far to the starting materials in a non-polar solvent such as benzene. Thus, the absorption spectra did not change even in the presence of excess amount of n-$BuNH_2$ (n-$BuNH_2$/**1**=10—500). When 18-crown-6 (18C6) was added to the benzene solution of **1** and n-$BuNH_2$ a strong bathochromic shift of the absorption maximum from 380 to 478 nm was observed (Fig. 1). The presence of an isosbestic point at 412.5 nm indicated that a single chemical species was formed by the addition of the crown ether. The increase in the intensity of the band at 478 nm ceased when the ratio of the crown ether to **1** reached around 1500 at 26.6 °C (150 at 6 °C) as shown in Fig. 1. Addition of an equimolar amount of DBU (1,8-diazabicyclo[5.4.0]undec-7-ene, a strong organic base) to a benzene solution of **1** produced a bathochromic shift of the absorption (380 nm) to 455

a) The amount of crown ether (in molar ratio to HA) necessary to reach equal concentration of HA (380 nm) and A^- (478 nm). HA=1.09×10^{-4} mol/dm^3, RNH_2=5.5×10^{-3} mol/dm^3, Temp 27.3 °C.
b) C: crown, DC: perhydrodibenzo, B: benzo.
c) Those to reach [A]/[HA]=1/9.

nm in the absence of the crown ether, and the absorption maximum moved up to 478 nm by further addition of DBU (≈100 fold excess). The latter bathochromic shift can be accounted for on the basis of the change in the structure of the resulting acid–base association complex, *i.e.* the change from a contact ion pair to a solvent-separated ion pair. It is to be noted that in *n*-$BuNH_2$–**1**–18C6 system, the position of the absorption maximum did not materially change with the variation of amine/**1** ratio from 10 to 500. The behavior of the crown ether complex of the alkylamine as well as that of the DBU-complex are noticeably compared with the observation that the absorption of $Na^+\cdot A^-$–benzo-15-crown-5 complex in benzene at 445 nm (Fig. 2) showed very little shift on further addition of B15C5 (≈50 fold excess). From these observations, it could be reasonably concluded that the ionic species with the absorption at 445 nm (and 455 nm for the DBU–**1** system) and the one absorbing at 478 nm are assigned to the contact ion pair and the crown ether-separated ion pair (or solvent-separated ion pair), respectively. Other crown ethers included in Table 1 as well as a bis(benzocrown ether), 1,7-bis[3,4-(1,4,7,10,13-pentaoxatridecane-1,13-diyl)phenyl]-1,4,7-trioxaheptane,[5] showed the behavior same as 18C6 forming complexes with an absorption maximum at 478 nm. It is to be added incidentally that in the absence of a crown ether the addition of a large amount of alkylamine (RNH_2/**1**≈1000) to the benzene solution of **1** caused a slow displacement of *p*-nitroanilino group in **1** by the amine giving *N*-alkylpicrylamine, which was characterized by the appearance of new absorptions at 338 and 417 nm.

Effect of the Structures of Alkylamines and Crown Ethers. Table 1 shows a qualitative comparison of the extent of the formation of the butylammonium ion complexes (**2**), where the values represent the amounts of a crown ether (molar basis) being necessary to reach to [**2**]/[**1**]=1 (for B15C5 see footnote in the Table). In line with the previous results,[2] 18C6 entered into the formation of the association complexes to a large extent, and B15C5 was much less efficient. With most of the crown ethers the increase in steric bulk of the alkyl group of

C–C– (C)	0.19_9	0.043_2

a) K_0 is the equilibrium constant of 18C6– *n*-$BuNH_2$ system at 26.6 °C.

the amines depressed the formation of the complex, but benzo-18-crown-6 (B18C6) showed an irregular order of the efficacy as *n*-$BuNH_2$>*t*-$BuNH_2$>*s*-$BuNH_2$. In order to inquire the factors which are related to the discrepancy, equilibrium constants for Eq. 1 were determined for various alkylamines with the use of 18C6 and B18C6, and the results are summarized in Table 2. Table 3 shows the relative ratios of the equilibrium constants at 26.6 °C which are derived by taking the 18C6–*n*-$BuNH_2$ system as a reference. The values for normal alkylamine–18C6 system were almost invariant with the chain length of the amines, while those in the B18C6 system showed some increase with the increase of the alkyl chain. A noticeable difference between the two systems was observed in the effect of α-alkyl substitution of the amines. The decrease of the ratio by the introduction of methyl group(s) was clearly smaller in the B18C6 system than in that of 18C6 as seen in the set involving *n*-$PrNH_2$, *i*-$PrNH_2$, and *t*-$BuNH_2$. The presence of α-ethyl group, however, caused larger steric effect in both systems, as is observed in the case of 3-aminopentane.

Thermodynamic parameters of the equilibrium in 18C6– and B18C6–*n*-$BuNH_2$ systems in benzene at 26.6 °C are shown in Table 4. The entropy change in the 18C6 system are almost constant ($\Delta S = -2.12$—-2.16×10^2 J/K mol), and the enthalpy term seems to mainly determine the extent of the complex formation decreasing in the order : *n*-$BuNH_2$>*s*-$BuNH_2$>*t*-$BuNH_2$. In the system of B18C6, however, the change of the two terms occurs in an opposite manner with the increase of the steric bulk of the amines to yield the orders, *t*-$BuNH_2$>*s*-$BuNH_2$>*n*-$BuNH_2$ for the enthalpy term and *n*-$BuNH_2$>*s*-$BuNH_2$>*t*-$BuNH_2$ for the entropy term, respectively. Thus, a subtle balance of the two terms would lead to the unexpected order of the stability among the alkylammonium complexes of B18C6 and also of 4′-acetylbenzo-18-crown-6, though the origin for the specificity of the B18C6 systems is not clear at present.

a) ΔG, ΔH, and ΔS at 26.6 °C.

Thermodynamic parameters for the complex-forming equilibria between crown ethers and various metal or ammonium salts have been reported mainly in a protic or a dipolar medium such as DMF. The entropy terms obtained[6] vary widely depending on the nature of the salts and crown ethers as well as the medium, but scarcely exceed −20 e.u. for the systems utilizing the crown ethers bearing 15- or 18-ring. The large loss of entropy (around -2.1×10^2 J/K mol or −50 e.u.) in the present equilibrium system suggests that several molecules of the medium, excess alkylamine (and/or benzene), are interacting with the alkylammonium complexes, in view of the result[7] that in the equilibrium of Eq. 2 in chloroform the entropy term much decreases from −23 to −40 e.u. by replacement of the crown ether with diglyme.

$$HBr + Br_2 + \text{di-Br-DBC} \rightleftharpoons H^+\cdot(\text{di-Br-DBC})\cdot Br_3^- \quad (2)$$

di-Br-DBC: 4,4′-dibromodibenzo-18-crown-6

Experimental

Materials. All crown ethers used were prepared according to the conventional methods;[8] 18C6: mp 39.9—40.2 °C, B18C6: mp 44.1—44.5 °C, 4′-acetylbenzo-18-crown-6: mp 77.9—78.2 °C,[5] and B15C5: mp 80.8—81.7 °C.

2,4,4′,6-Tetranitrodiphenylamine (HA, **1**) was prepared by the reaction of picryl chloride and *p*-nitroaniline in ethanol in the presence of sodium carbonate, and then recrystallized from ethanol (three times); yellow needles, mp 222.8—224.2 °C (uncorrected) (lit, 219 °C,[9] 220—220.6 °C[10]), Found: C, 41.20; H, 2.03; N, 19.98%. Calcd for $C_{12}H_7N_5O_8$: C, 41.27; H, 2.02; N, 20.06%. 1-Methylbutylamine and 1-ethylpropylamine were prepared by the methods described in the literature,[11] and other alkylamines (RNH_2) were of reagent grade. These amines were distilled over KOH and stored under nitrogen atmosphere prior to use. Benzene was dried over sodium metal and distilled under nitrogen atmosphere before use.

The complex of B15C5 with $Na^+\cdot A^-$ was prepared by the addition of a methanol solution of the crown ether to $Na^+\cdot A^-$ in methanol.

Absorption Spectra. The electronic spectra of the solutions were recorded on a Shimadzu UV-200 spectrophotometer over a temperature range from 6.0 to 35.0 °C (±0.1 °C).

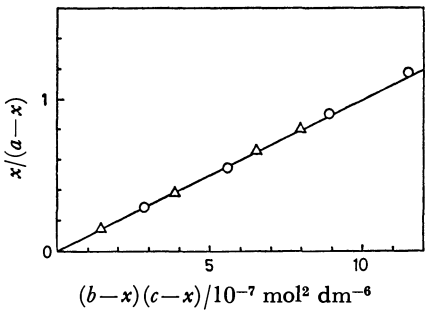

Fig. 3. Determination of formation constant according to Eq. 4.
○: [*n*-BuNH$_2$]/[HA]=25, [HA]=3×10^{-5} M (M=mol·dm^{-3}), [18C6]/[HA]=11—75 at 35.0 °C.
△: [18C6]/[HA]=1.8, [HA]=5×10^{-5} M, [*n*-BuNH$_2$]/[HA]=33—266 at 35.0 °C.
Both systems gave the same formation constant (K=(0.976±0.08)×10^4 M^{-2}) within the experimental error.

A quartz cell with a silicone rubber stopper was used in all determinations. A constant temperature of ±0.1 °C was maintained by circulating water from a thermostated bath. The temperature inside the cell compartment was monitored with a thermocouple. In benzene solution, the absorption maxima and absorption coefficients of **1** and Na$^+$·A$^-$–B15C5 were 380 nm (ε_{max}: 1.64×10^4) and 445 nm (ε_{max}: 1.72×10^4), respectively. The absorption maxima and absorption coefficient of crown separated ion pair, $\overset{+}{R}NH_3\cdot CR\cdot A^-$, in benzene were obtained from the RNH$_2$–**1**–18C6 system containing such amount of the crown ether that the absorbance of the system did not increase by its further addition. Concentration change of **1** was corrected. The resulting absorption coefficient for *n*-BuNH$_2$– and *n*-pentylamine–**1**–18C6 (and B18C6) systems was the same value (λ_{max}: 478 nm, ε_{max}: 3.41×10^4). The conductance of these solutions was negligible.

Calculations. The formation constants of the complexes were calculated from the measured concentration of $\overset{+}{R}NH_3\cdot CR\cdot A^-$ by considering the following equilibrium.

$$\underset{(a-x)}{HA} + \underset{(b-x)}{CR} + \underset{(c-x)}{RNH_2} \overset{K}{\rightleftharpoons} \underset{x}{\overset{+}{R}NH_3\cdot CR\cdot A^-} \qquad (3)$$

CR : A crown ether
a, b, and c : Initial concentrations of **1**, CR, and RNH$_2$, respectively.
K : Formation constant

The constant K may be represented by

$$K = x/(a-x)(b-x)(c-x) = \frac{d-d_{HA}}{d_A-d} \times \frac{1}{\left(b-\frac{d-d_{HA}}{\varepsilon_A-\varepsilon_{HA}}\right)\left(c-\frac{d-d_{HA}}{\varepsilon_A-\varepsilon_{HA}}\right)}, \qquad (4)$$

where the symbols have the following significance, x: the fraction of ionized HA, ε_{HA}, and ε_A: the absorption coefficients of HA and $\overset{+}{R}NH_3\cdot CR\cdot A^-$ at 478 nm, respectively; $d_{HA}=a\cdot\varepsilon_{HA}$ and $d_A=a\cdot\varepsilon_A$. On the basis of the absorbance at 478 nm ($=d$) concentrations of HA and $\overset{+}{R}NH_3\cdot CR\cdot A^-$ are given by $x=(d-d_{HA})(\varepsilon_A-\varepsilon_{HA})^{-1}$ and $(a-x)=(d-d_A)(\varepsilon_{HA}-\varepsilon_A)^{-1}$. Substitution of the values of x and $(a-x)$ into Eq. 4 leads to Eq. 5.

$$\frac{d-d_{HA}}{d_A-d} = K\cdot\left(b-\frac{d-d_{HA}}{\varepsilon_A-\varepsilon_{HA}}\right)\cdot\left(c-\frac{d-d_{HA}}{\varepsilon_A-\varepsilon_{HA}}\right) \qquad (5)$$

A plot of $(d-d_{HA})(d_A-d)^{-1}$ *vs.* $[b-(d-d_{HA})(\varepsilon_A-\varepsilon_{HA})^{-1}]\times[c-(d-d_{HA})\times(\varepsilon_A-\varepsilon_{HA})^{-1}]$ gives a straight line, and hence K can be obtained from its slope. Figure 3 shows the validity of this method. Initial concentrations of HA and RNH$_2$ used were 3×10^{-5} and 7.5×10^{-4} mol/dm^3, respectively.

Photoinduced Intramolecular Aromatic Nucleophilic Substitution (the Photo-Smiles Rearrangement) in Amino Ethers[1]

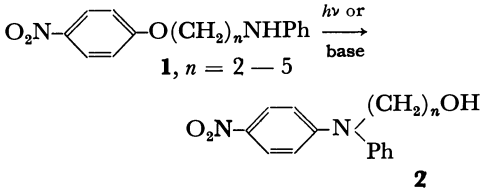
Kiyoshi MUTAI* and Keiji KOBAYASHI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received May 20, 1980)

Intramolecular rearrangement was induced by light as well as base in a homologous series of 1-(*p*-nitrophenoxy)-ω-anilinoalkanes, p-$O_2NC_6H_4O(CH_2)_nNHPh$(n=2—5), yielding *N*-(*p*-nitrophenyl)-ω-anilino-1-alkanols, p-$O_2NC_6H_4N(Ph)(CH_2)_nOH$. The reaction rate in acetonitrile showed abnormal order, $n=4>5>3>2$, which was reversed by the addition of triethylamine. The mechanism of this photorearrangement through a radical ion pair and a spiro type Meisenheimer complex was proposed. The anomaly in the reaction rate order was discussed on the basis of this mechanism.

The intramolecular nucleophilic aromatic substitution is generally called the Smiles rearrangement,[2] which is in most cases induced by base. The reaction of the same type induced by light may be called the photo-Smiles rearrangement. A homologous series of 1-(*p*-nitrophenoxy)-ω-anilinoalkane (**1**) gave *N*-(*p*-nitrophenyl)-ω-anilino-1-alkanol (**2**) on irradiation of light (>300 nm). The product **2** was also obtained by the reaction with strong base such as sodium hydride or sodium ethoxide, undoubtedly through nucleophilic attack of the corresponding anilide type anion at the ring carbon atom attached to the ether oxygen, followed by formation of a Meisenheimer type complex. Thus the photorearrangement of **1** to **2** is a photo-Smiles rearrangement.



There is only one precedent[3] for this type of photorearrangement so far as we know. We report here the effects of the chain length in **1** on reaction kinetics and some mechanistic aspects of this photoreaction.

Results and Discussion

Photorearrangement. Solutions of a homologous series of **1** are almost colorless, but become yellow when irradiated with a high-pressure Hg lamp. As an example, the change of the ultraviolet-visible region of the spectrum of p-$ON_2C_6H_4O(CH_2)_4NHPh$ (**1**, n=4) in acetonitrile is shown in Fig. 1. The spectral maximum at *ca.* 305 nm, characteristic of *p*-nitrophenoxyl group, disappears with time and a new peak appears at *ca.* 395 nm. This photoreaction was observed in polar solvents such as acetonitrile, alcohols, and tetrahydrofuran, but not in cyclohexane or hexane.

The structure of the products (**2**) was confirmed by spectral and elemental analysis. Their spectral features agreed well with those of the rearranged products obtained by base-induced reaction.[4] One of the most striking characteristics is the absorption peak at *ca.* 395 nm suggesting the presence of nitroaniline type chromophore. As seen in Fig. 1, the increase of the

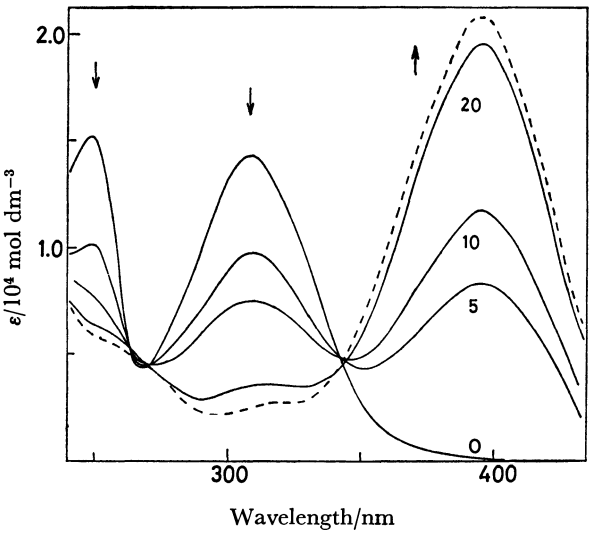


Fig. 1. Absorption spectra of p-$O_2NC_6H_4O(CH_2)_4NHPh$ in acetonitrile (0.8×10^{-4} mol/dm^3), irradiated with a high-pressure Hg lamp. Numerals attached to the curves denote time of irradiation in min. The curve in broken line is the absorption spectrum of the product.

product (**2**, n=4) can be easily followed with ultraviolet spectroscopy. It also shows isosbestic points, suggesting one-to-one correspondent conversion of **1** to **2**. Since the starting materials showed no appreciable absorption at visible region, the reaction rate was determined simply by the measurement of the time dependence of the intensity at *ca.* 395 nm. Close examination of the Fig. 1 shows that the absorption curves irradiated for a long time deviate slightly from the isosbestic points. This phenomenon is due to the formation of polymeric substances probably produced by the photodecomposition of **2**.

In order to avoid the further reaction of **2** which absorbs mainly at longer wavelength region (>330 nm), a filter of an aqueous $NiSO_4$ solution as well as Pyrex was used as the standard conditions for the determination of the rate constants.[5] Employing acetonitrile as representing aprotic solvent, the photoreaction rates were determined and the relative rate constants (first order reaction) are summarized in Table 1. These are relative values because they are variable with photolysis conditions such as concentration of the solution, intensity of the light, form of the reaction vessel, *etc.*

Table 1. Relative initial rate constants (k_{rel}) for the photorearrangement of **1** in CH_3CN

	n=2	3	4	5
k^0_{rel} a)	1.0	2.0	420	120
k^{TEA}_{rel} a,b)	710	400	110	8.6
k^{TEA}_{rel}/k^0_{rel}	710	200	0.25	0.072

a) $k^0_{rel}(n=2)=1.0$. b) Values in the presence of triethylamine (2.84×10^{-2} mol/dm^3).

A notable fact in Table 1 is low reactivity of the lower homologs (n=2 and 3) in comparison with the higher ones. It is generally accepted that lower homologs are favored (*i.e.*, react faster or give products in higher yields) in intramolecular reaction. In fact, the Smiles rearrangement of **1** in the presence of sodium hydride in DMF showed the rate order, $n=2\gg3>4>5$.[4] The anomaly in the photoreaction is closely connected with the reaction mechanism and will be discussed in the later part of this paper.

Addition of triethylamine or pyridine to the solution accelerated the reaction remarkably. The amines are weak bases unable to catalyze the rearrangement of **1** in the dark. The results for triethylamine are summarized in Table 1. The resulting reactivity order with regard to n is the same as that observed in the base-catalyzed reaction. In the third row of Table 1, the ratios of the rate constants in the presence *vs.* in the absence of the amine are shown. The rate increase in the lower homologs is in the order of 10^2, but the higher homologs showed a slight decrease. This rather unexpected behavior of the higher homologs is a result of a concomitant photoreaction of **1** with the added amine. The electronic spectrum of the solution containing triethylamine showed a new peak at *ca.* 290 nm in addition to those of **2** on irradiation. This side reaction, which apparently retarded the rate, was also observed in the lower homologs but to a far less extent. Since irradiation under the same conditions of an acetonitrile solution of *p*-nitrophenetole containing the amine induced a similar spectroscopic behavior, the side reaction observed in **1** is probably due to a reaction between *p*-nitrophenoxyl moiety and triethylamine whose photoreductive capability is well known.[6]

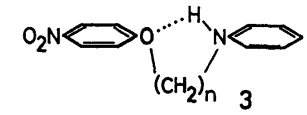
In order to see the effect of protic solvent, the rate constants in methanol were determined and summarized in Table 2.

Table 2. Relative initial rate constants (k_{rel}) for the photorearrangement of **1** in CH_3OH

	n=2	3	4
k_{rel} a)	1.0	0.5	1.0
k^{TEA}_{rel} a,b)	75	30	4.0
k^{TEA}_{rel}/k_{rel}	75	60	4.0

a) $k_{rel}(n=2)=1.0$. b) Values in the presence of triethylamine (2.84×10^{-2} mol/dm^3).

It is interesting that there is little difference in the rate of three homologs studied, though considering the distance of the two reacting centers, the rate of n=4 should be regarded still as unusually large. Comparison of the absolute values of k^0 in methanol with those in acetonitrile shows acceleration by a factor of 10 and 2 in methanol for n=2 and 3, respectively, and reduction by 0.02 for n=4. The observed rate acceleration may be due to the destruction of intramolecular N-H···O hydrogen bond which is present in these lower homologs[7] and arranges the molecule in conformation with two π-electron systems far apart, unfavorable situation for exciplex formation (**3**). Different solvating



3

manner of methanol from acetonitrile for **1** in the ground and excited states and for reaction intermediates is also an important factor, though the details are yet unknown.

In the presence of triethylamine, the absolute k^{TEA}'s of the n=2 homolog in these two solvents are nearly the same, implying the upper limit of the reaction rate of this homolog. The smaller accelerating effect of the base in n=3 (one order less than in acetonitrile) may be due to lower activity of triethylamine in this protic solvent. It is notable that a small but definite rate acceleration by the amine is observed for the n=4 homolog. In contrast to the reaction in acetonitrile, no reaction of **1** with the amine was observed in methanol.

Some Mechanistic Aspects. The effect of the amine suggests ionic character of the photoreaction. The most probable ionic process is abstraction of the N-H proton by the amine, thus producing an anilide type anion, *p*-$O_2NC_6H_4O(CH_2)_n\overset{\ominus}{N}Ph$, which then takes the same course as in the Smiles rearrangement. The same reactivity order with regard to n in both cases supports this possibility. The key step in this mechanism is the increase of the acidity of the N-H group on absorption of ultraviolet light. There are two possibilities: (i) The acidity of the anilino moiety increases on excitation[1] as is the case in naphthylamine[8] and phenols;[9] (ii) Intramolecular exciplex or excited state of intramolecular charge-transfer interaction may facilitate proton release from the N-H group. Of these, the mechanism (ii) has been proved to be valid by Yokoyama *et al.*[10] They confirmed the presence of a radical ion pair (**4**)

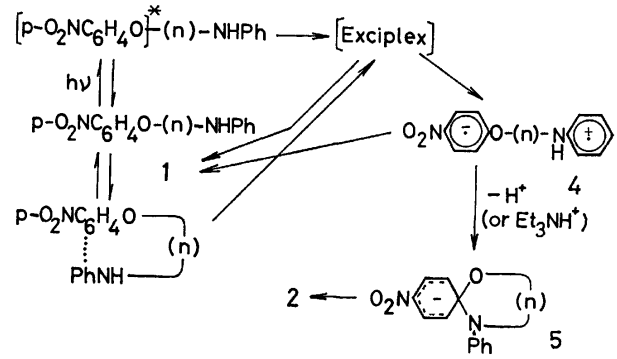


Fig. 2. Photolysis mechanism of **1**, where (n) denotes $(CH_2)_n$ group.

and a spiro type Meisenheimer complex (**5**) by means of time dependent transient absorption spectral measurement of solutions irradiated with N_2-laser pulse. Therefore a probable photorearrangement mechanism is as depicted in Fig. 2.

One of the possible processes which lead to the ion pair may start with the excitation of the *p*-nitrophenoxyl chromophore absorbing at *ca.* 305 nm, followed by formation of an intramolecular exciplex. Another one leading to a similar exciplex may be the excitation of the molecule in the state of intramolecular charge-transfer interaction.[11] Since the charge-transfer interaction in the ground state is very weak, the ionic character of the exciplex is large and the electron transfer to form the radical ion-pair (**4**) is probably a smooth process. In the step following the exciplex formation, an electron from the anilino group in **1** is transferred to the nitrophenoxyl group, and the resulting radical cation moiety has an N–H group with sufficiently strong acidity to release its proton. Here, the role of triethylamine is evident, because the basicity of the amine is far stronger than acetonitrile. The failure of the photo-Smiles rearrangement in cyclohexane or hexane is also apparent, as these solvents are poor acceptors of proton and have meager solvating power for ions. In fact, the formation of the ion pair (**4**) has not been detected in these solvents.[10]

There remains a question why the reactivity of the lower homologs in acetonitrile is abnormally low in the absence of bases. The anomaly is in the lower homologs (n=2 and 3), and not in the higher ones (n=4 and 5). Since the process subsequent to the release of the N–H proton should be the same as the Smiles rearrangement, the step where the reaction rates in question are mainly determined is after the excitation of **1** and before the proton release. Therefore, the factors governing the reactivity may be concerned with the fate of excited chromophores and/or of the radical ion pair.

It should be mentioned here that the lifetimes of the ion pair, **4**, for n=2, 3, and 4 are 65, 73, and 98 ns, respectively.[10] Similar effect of chain length on the process of intramolecular fluorescence quenching has been reported.[12] Since the electron return process and conformational change to form a sandwich type form is far faster than proton transfer,[13] the reason of the low reactivity in the absence of the amine is probably due to the presence of effective quenching routes for the ion pairs of the homologs with short chain length.

Experimental

Reaction Kinetics of Photolysis. A 200-cm^3 solution was irradiated with a 100 W high-pressure Hg lamp equipped with a Pyrex cooling jacket, through which a solution of nickel sulfate (500 g $NiSO_4$/dm^3 aqueous solution) was passed. The lamp was immersed in a vessel containing the solution of $0.8—0.9\times10^{-4}$ mol/dm^3. For the determination of the reaction rate, the solution was circulated through a flow-cell set in a Hitachi 100-50 spectrophotometer. Time dependence of the increase of the characteristic absorbance of the product at *ca.* 395 nm was recorded and the initial rate constant calculated, assuming first-order reaction.

Solvents. Acetonitrile (Wako, G. R. grade) was distilled from the mixture with phosphorus pentaoxide (5 g/dm^3 CH_3CN). Methanol (Wako, G. R. grade) was used after distillation.

Preparation of 2. General Procedure: A 250-cm^3 acetonitrile solution containing *ca.* 50 mg of **1**[10] is irradiated with a 100 W high-pressure Hg lamp through Pyrex and aqueous $NiSO_4$ filters. For the solutions of n=2 and 3 homologs of **1**, 2 cm^3 of triethylamine was added. After removing the solvent, the residue was dissolved in dichloromethane, and the solution was passed through a column packed with silica gel using benzene–dichloromethane (1 : 1) and dichloromethane as eluents.

N-*(p-Nitrophenyl)-2-anilinoethanol (2, n=2)*: This compound was obtained in 87% isolated yield as dark red liquid; 3,5-dinitrobenzoate, mp 172—173 °C; UV_{max} (95% EtOH), 392 nm (ε 19200); NMR ($CDCl_3$) δ=2.72 (1H s, OH), 3.8 (4H, m, CH_2CH_2), 6.57 and 7.82 (4H, two d, J=9 Hz, *p*-$O_2NC_6H_4$), and 7.2 (5H, m, C_6H_5); MS (70 eV), *m/e* 258 (M^+), 227 ($O_2NC_6H_4(Ph)NCH_2^+$), and 181 (227−NO_2).

Found: C, 64.97; H, 5.43; N, 10.68%. Calcd for $C_{14}H_{14}N_2O_3$: C, 65.10; H, 5.46; N, 10.85%.

N-*(p-Nitrophenyl)-3-anilino-1-propanol (2, n=3)*: This compound was obtained in 74% isolated yield as red liquid, 3,5-dinitrobenzoate, mp 124—125 °C; UV_{max} (95% EtOH), 391 nm (ε 18900); NMR ($CDCl_3$)δ=1.94 (2H, m, C-CH_2-C), 2.91 (1H, s, OH), 3.71 and 3.88 (4H, two t, NCH_2 and OCH_2), 6.57 and 7.87 (4H, two d, J=9 Hz, *p*-$O_2NC_6H_4$), and 7.2 (5H, m, C_6H_5); MS (70 eV), *m/e*, 272 (M^+), 227, and 181.

Found: C, 66.27; H, 5.84; N, 10.37%. Calcd for $C_{15}H_{16}N_2O_3$: C, 66.15; H, 5.92; N, 10.29%.

N-*(p-Nitrophenyl)-4-anilino-1-butanol (2, n=4)*: This compound was obtained in 82% isolated yield as yellow needles: mp 75—76 °C; UV_{max} (95% EtOH), 391 nm (ε 19400); NMR ($CDCl_3$) δ=1.7 (5H, m, C-CH_2-CH_2-C and OH), 3.7 (4H, m, NCH_2 and OCH_2), 6.50 and 7.87 (4H, two d, J=9 Hz, *p*-$O_2NC_6H_4$), and 7.2 (5H, m, C_6H_5); MS (70 eV), *m/e*, 286 (M^+), 227, and 181.

Found: C, 67.27; H, 6.43; N, 9.59%. Calcd for $C_{16}H_{18}N_2O_3$: C, 67.11; H, 6.34; N, 9.78%.

N-*(p-Nitrophenyl)-5-anilino-1-pentanol (2, n=5)*: This compound was obtained in 61% isolated yield as dark red liquid; UV_{max} (95% EtOH), 389 nm (ε 19400); NMR ($CDCl_3$) δ= 1.55 (7H, m, C-CH_2-CH_2-CH_2-C and OH), 3.8 (4H, m, NCH_2 and OCH_2), 6.79 and 8.28 (4H, two d, J=10 Hz, *p*-$O_2NC_6H_4$), and 7.5 (5H, m, C_6H_5); MS (70 eV), *m/e*, 300 (M^+), 227, and 181.

Found: C, 67.74; H, 6.93; N, 9.42%. Calcd for $C_{17}H_{20}N_2O_3$: C, 67.98; H, 6.71; N, 9.33%.

Hydration of Aza-aromatic Aldehydes. II. Solvent Effect on the Equilibrium Constants of the Hydration

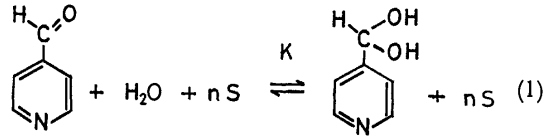
Kazuhisa ABE, Hiroko ENDO, and Minoru HIROTA*

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received May 24, 1980)

The equilibrium constants for the hydration reaction of 4-pyridinecarbaldehyde were determined in several solvents by ^{1}H-NMR spectroscopic measurements. The hydration reactions were sensitive to the nature of the solvents. In strong donor solvents such as hexamethylphosphoric triamide, pyridine, and dimethyl sulfoxide, formation of the hydrate is far more favorable than in water or other poor donor solvents. Thus the stabilization of the product by hydrogen bond formation is assumed to favor the reaction. Polarity of the solvent alone does not explain the solvent effect, even if it is supposed to affect the equilibria secondarily.

The hydration reaction to form geminal diols is known on several aliphatic aldehydes carrying electronegative groups.[1-5] The present authors have reported in a previous paper[6] that the corresponding geminal diols were produced when the six-membered aza-aromatic aldehydes carrying a formyl group at 2 or 4-position were submitted to the reaction with water. The enthalpies of hydration were determined from the temperature dependence of their ^{1}H-NMR spectra. In this report, equilibrium constants (K) of the hydration of 4-pyridinecarbaldehyde (given by Eq. 1) were determined in several organic solvents by means of ^{1}H-NMR spectroscopy.[7] The advantage of NMR



(1)

spectroscopy in the determination of free and hydrated species of aldehydes in mixtures has been described by several authors.[8-12] In the case of 4-pyridinecarbaldehyde, it is possible to observe two sets of resonance lines assigned to the hydrated and the free species in its ^{1}H-NMR spectrum.[6] The methine proton signal of the hydrated species appears at *ca.* 4 ppm upfield relative to the formyl proton signal of the unhydrated species. Similarly, ring proton signals of the hydrated species shift *ca.* 0.5 ppm upfield relative to those of the unhydrated species.

The hydration of aza-aromatic aldehydes is an addition reaction initiated by the nucleophilic attack of water molecule on the positively-charged carbonyl carbon atom. In an aldehyde–water–solvent ternary system, the hydration reaction is supposed to be affected considerably by the nature of solvent because of the difference in polarity and in hydrogen-acceptability, or electron-donability, in hydrogen bond formation. Thus the equilibrium constants were determined in various solvents and with various proportions of reactant system in order to study the specific interaction between the solvent and the solute molecules, and to elucidate how the solvent participates in the reaction mechanism.

Experimental

Preparation of Materials. 4-Pyridinecarbaldehyde was distilled prior to use. Deuterium oxide was used as the nucleophilic reagent in place of H_2O in most runs. No remarkable difference in equilibrium constant was observed in comparison with the results using H_2O.[13] Deuterated solvents were used without further purification. Other solvents were purified by the usual procedures.

Measurement of ^{1}H-NMR Spectra. ^{1}H-NMR experiments were performed with a JEOL JNM C-60H NMR spectrometer. In cases of very dilute solutions, the spectra were measured with a JEOL JNM FX-60 or an FX-100 NMR spectrometer, accumulations carried out hereby in order to get a high signal-to-noise ratios. Equilibrium constants of the hydration in various solvents were determined from the ratios of integrated intensities of the free and the hydrated species of the aldehyde. The relative integrated intensity was obtained as a mean of the observed values by several (at least 3) times of scans in the integration mode. Chemical shifts are given in terms of part per million (ppm) downfield from TMS. The probe temperature was kept at 34.5 °C in all measurements except otherwise stated.

Table 1. The enthalpy of hydrogen bond formation between 4-(hydroxymethyl)pyridine and dimethyl sulfoxide

$C=4.42\times10^{-3}$ mol/l $H=21.1$ KJ/mol

292.5	39.5	58.5
297.7	40.6	52.7
303.7	42.5	46.5
309.3	44.8	41.4
316.2	46.1	35.1

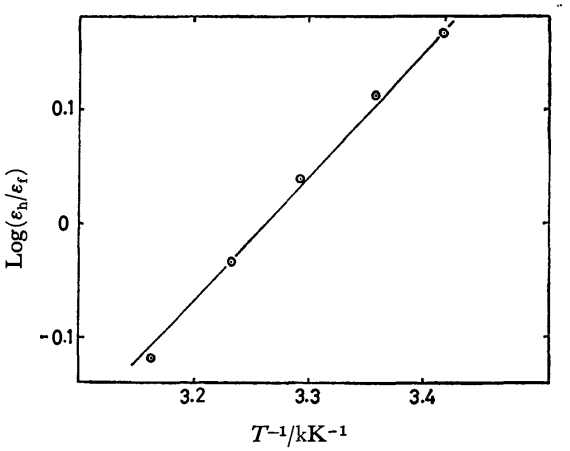

Fig. 1. The log ($\varepsilon_h/\varepsilon_f$) *vs.* $1/T$ of 4-(hydroxymethyl)-pyridine–dimethyl sulfoxide hydrogen bond system.

Determination of $\Delta\nu_{OD}$ and the Enthalpy of Hydrogen Bond Formation by Infrared Spectroscopic Measurements. Infrared O–D stretching absorptions of methanol-*d* were measured with a Hitachi Model 225 grating infrared spectrometer. The reference O–D absorption in benzene was also measured under the same conditions.

The enthalpy of hydrogen bond formation of 4-(hydroxymethyl)pyridine was obtained by measuring the O–H absorption intensities of free and hydrogen-bonded species (ε_f and ε_h, respectively) at several temperatures. The slope and the abscissa of the ($\varepsilon_h/\varepsilon_f$) *vs.* $1/T$ plot gave the enthalpy and the entropy, respectively. The results are given in Table 1 and Fig. 1.

Results and Discussion

Formation Constants of the Hydrate in Several Organic Solvents. Equilibrium constants of the hydration in various solvents are given together with some indices for the solvent polarity and the hydrogen acceptability in Table 2. The $\Delta\nu_D$ value is defined as the solvent induced shift (in cm^{-1}) of the O–D stretching band of methanol-*d* (CH_3OD) in a solvent with reference to that in benzene (2688 cm^{-1}) and used as a measure for the electron donating power of solvent. Most $\Delta\nu_D$ values were cited from reference,[14] some of them being determined in the present investigation. From the above definition, the $\Delta\nu_D$ value increases with the increasing order of the electron donating power in the hydrogen bond formation. The log K *vs.* $\Delta\nu_D$ plot gives a straight line with $r=0.982$ representing a very good linear relation. A good correlation is also observed between ln K and the donor number (Dn) defined by Gutaman ($r=0.984$).[15] From the results, it is supposed that strong donor solvents facilitate hydrogen bond formation of the produced geminal diol with water, playing an important role in the hydration reaction.

In the reactant system (consisting of the aldehyde, water, and solvent), water molecules form hydrogen bonds with solvent molecules preferably when the solvent is a stronger donor than water. This is estimated from the hydrogen bond energies obtained by NMR and infrared spectroscopic measurements.[16,17] Thus the energy of formation of water–dimethyl sulfoxide hydrogen bond (4.6 kcal/mol) is shown to be larger than that for the self-association of water (4.4 kcal/mol). The water–solvent hydrogen bond stabilizes the aldehyde, disfavoring the formation of geminal diol in the equilibrium. The strong hydrogen bond between the solvent and water molecules tends to destroy the cluster structure of liquid water by breaking the O–H···O hydrogen bond constructing the structure. The destruction of the cluster is especially remarkable in the range of larger mole fractions of the strongly donable solvents, being proved by the measurement of neutron inelastic scattering and X-ray diffraction studies.[18] Hydrogen bond formation between the carbonyl oxygen atom and water is also possible in the reactant system. However the hydrogen bond of this type is supposed to be a little weaker than the O–H···O hydrogen bond in water-donable solvent and the O–H···N hydrogen bond in water–aza-aromatic aldehyde pairs, the difference in the enthaplies of hydrogen bond formations being very small in these two cases. Hence this interaction might affect less remarkably the equilibrium of the hydration reaction.

Similar stabilization may occur in the product system consisting of the geminal diol, water, and the solvent. Contrary to the case of reactant system, the stabilization by forming hydrogen bonds will favor the hydration reaction. As the geminal diol has two O–H functions, it can attain considerably large stabilization in strong donor solvents. In order to estimate the energies of hydrogen bond formation in the product system, 4-(hydroxymethyl)pyridine was used as a model compound and the enthalpy of association with dimethyl sulfoxide was determined by the infrared spectroscopic method. Ternary 4-(hydroxymethyl)pyridine–dimethyl sulfoxide–carbon tetrachloride system shows two O–H absorptions at 3637 and 3380 cm^{-1}, which are assigned to the free and the hydrogen-bonded species, respectively. Then the temperature dependence measurement of their intensities gives the enthalpy of hydrogen bond formation to be 5.03 kcal/mol. As 4-(hydroxymethyl)-pyridine has a similar structure to the geminal diol and the additional α-hydroxyl group is expected to favor the hydrogen bond by its electronic effect, the hydrogen bond in the geminal diol is assumed to be stronger than that in the reactant. The geminal diol can exist as the two types of associated species given by (A) and (B).

Table 2. Thermodynamic quantities for the hydration of 4-pyridinecarbaldehyde in several organic solvents

Solvent	K(34.5 °C)	δ:ppm (formyl proton) aldehyde	*gem*-diol	ΔH / K J mol^{-1}	ΔS / J mol^{-1} K^{-1}	ε	$\Delta\nu_D$ / cm^{-1}	D_n

(A) (B)

The second hydrogen bonds in these species might be a little weaker. Thus, the stabilization caused by the hydrogen bond in the 1 : 2 associated species, (A) or (B), is expected to overcome that in the reactant system.

The solvent polarity can be another factor which controls the hydration reaction. If a polar molecule (dipole moment μ, radius r) is transferred from the vaccum ($\varepsilon=1$) to a medium of which dielectric constant is ε, the energy change ($\Delta\Delta G$) is given by the Kirkwood Eq. 2.

$$\Delta\Delta G = -\frac{\mu^2}{r^3}\frac{\varepsilon-1}{2\varepsilon+1} \qquad (2)$$

Therefore, the contribution of the solvent polarity to $\Delta G°$(hydration) should be proportional to $(\varepsilon-1)/(2\varepsilon+1)$. In practice, no definite correlation is observed between log K and $(\varepsilon-1)/(2\varepsilon+1)$, implying that the polar effect of solvent is not a predominant factor to affect the equilibrium of hydration. However, by comparison of the results in deuterium oxide with those in acetonitrile-d_3 and acetone-d_6 it is probable that the polarity of solvent favors the hydration secondarily. Since acetone and acetonitrile are less donable than water, effect of the polarity which is masked by the effect of hydrogen bonding in cases of more strongly donable solvents becomes apparent in cases of acetone and acetonitrile solutions.

Influence of the Composition of Reaction Medium on the Equilibrium Constant. In the experiments discussed above, the mole fractions (x) of the solvents were kept approximately 0.30, which is the most convenient concentration to observe NMR signals of the hydrated and the unhydrated species accurately. However, the eqilibrium constant (K) is dependent upon the composition of the reaction medium, *i.e.* the mole fractions of the components. Thus the equilibrium constants were determined as a function of the mole fraction of solvent in the ternary aldehyde–water–solvent mixture. Results are given in Table 3 and Fig. 2. The solvents can be classified into two groups from the shape of their concentration *vs.* log K plots. The first group consists of strongly donable solvents such as hexamethylphosphoric triamide, pyridine, and dimethyl sulfoxide. The other consists of less donable solvents such as acetone and acetonitrile. In a solvent more donable than water, K increases almost linearly with the mole fraction of solvent in the region of $x \lesssim ca.$ 0.5. This phenomenon is explained by the formation of stronger hydrogen

bond between geminal diol and solvent in the product system than those in the reactant system. As the hydrogen bonded species of the geminal diol is supposed to increase in proportion to x, K becomes larger than that in water. The increase in log K becomes gradually less when the mole fraction of donable solvent is larger than 0.5. In some instances, the log K *vs.* x plots become flat or turn to decrease in a higher mole fraction range of the solvent. In this range of mole fraction, polarity of the medium seems to be decreased in comparison with that of water, since all solvents employed in the experiments have dielectric constants lower than water (Table 2). Therefore the equilibrium of the hydration reaction is not so favorable as expected from the solvent donicity alone.

Another factor suspected to affect the equilibrium constants is the decrease of the number of the O–H···N hydrogen bonds between water and 4-pyridinecarbaldehyde molecules during the process of hydration, since one molecule of water is consumed in this process. The produced geminal diol molecule can form two hydrogen bonds alternatively. If the solvent is a stronger donor than pyridine, the effect is less predominant because O–H···D (where D refers to a donable solvent molecule) hydrogen bond might be more favorable than O–H···N hydrogen bond both in the reactant and the product systems. In case when the solvent is less donable than pyridine, the O–H(in water)···N hydrogen bond in the reactant is replaced by the O–H(in the geminal diol) ···D hydrogen bond during the hydration, disfavoring the equilibrium to a certain extent. Another O–H···N hydrogen bond can be formed by the self-association of the aza-aromatic geminal diol. However, the concentration of the aldehyde is kept to be relatively low, preventing the produced geminal diol from self-associating to a measurable extent. The former case is the reaction in hexamethylphosphoric triamide, the typical examples of the latter case being those in dimethyl sulfoxide and in *N*,*N*-dimethylformamide.

In contrast to the results in strongly donable solvents, the dependence of the equilibrium constants on x was not remarkable in several less donable solvents which does not perturb the hydrogen-bonded structure of water considerably. As shown in Fig. 2, the equilibrium constants in acetone and acetonitrile tend to decrease monotonously in the wide range of X. The lowering of K values in these solvents are due to the decrease in polarity of the solvent, because the molecules of such solvents are unable to interact strongly with water and geminal diol molecules. It is deduced from the results in these less donable solvents that the effect of polarity which is masked by the effect of hydrogen bonding in cases of strongly donable solvents will also contribute to the hydration reaction apparently.

The authors are grateful to Prof. M. Ōki, the University of Tokyo, for his generously allowing us to use the FT-NMR spectrometer. They are also grateful to Mr. M. Ohuchi, Japan Electron Optics Laboratories Ltd., for his technical assistance in the measurement of NMR spectra with a JNM-FX 100 spectrometer. This research was partly supported by a Grant-in-Aid for Special Project Research from the Ministry of Education, Science and Culture.

Synthesis of Four Stereoisomers of γ-Hydroxyarginine *via* the Corresponding Isomers of γ-Hydroxyornithine

Koichi MIZUSAKI and Satoru MAKISUMI*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 29, 1980)

Diastereomeric γ-hydroxy-L- and D-ornithines were prepared by reduction of the corresponding γ-oxoornithines synthesized from L- and D-histidines with sodium borohydride. The isomeric composition of the product obtained from L-histidine was estimated to be 68% *erythro* and 32% *threo* isomers and that of the product from D-histidine 65% *erythro* and 35% *threo* isomers by automatic amino acid analysis after conversion of the basic amino acids into neutral N^{δ}-acetyl derivatives. The diastereoisomers of each γ-hydroxyornithine were separated by chromatography on a Dowex 50 column, four optically active isomers being isolated as their hydrochlorides in crystalline state. Guanidination of these isomers with 1-amidino-3,5-dimethylpyrazole nitrate (ADPN) gave the corresponding optically active isomers of γ-hydroxyarginine which were isolated as crystalline hydrochlorides. *Erythro*-γ-hydroxy-L-arginine hydrochloride shows a specific rotation which agrees very closely with that of natural product of γ-hydroxyarginine.

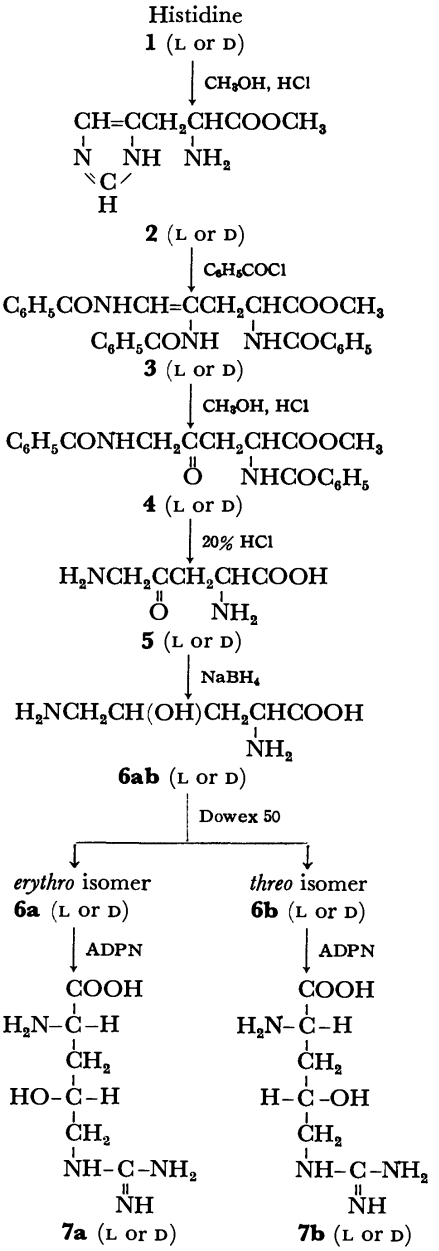
γ-Hydroxyarginine was first isolated from the sea cucumber *Polycheira rufescens* by Fujita[1] and subsequently from the sea anemone *Anthopleura japonica* Verrill by Makisumi.[2] In plants, this amino acid has been detected in the seeds of many species of *Vicia*[3] and isolated as its lactone from the seeds of *Vicia sativa* by Bell and Tirimanna.[4] Although little is known concerning the significance of the presence of this amino acid in animals and plants, the compound is known to participate in several enzymatic reactions.[1,2,5-7] An assumption that this amino acid exists as an intermediate in the metabolic pathway of L-arginine to 2-nitroimidazole in *Streptomyces eurocidicus* has been proposed by Nakane *et al.*[8]

γ-Hydroxyarginine contains two asymmetric carbon atoms (α and γ) and should thus exist theoretically in four stereoisomeric forms. The whole configuration of the natural γ-hydroxyarginine was confirmed to be *erythro*-γ-hydroxy-L-arginine by Fujita.[9] Synthetic attempts leading to an epimeric mixture of γ-hydroxyarginine have been reported.[1,10] However, none of the optically active isomers, other than the natural product, has hitherto been isolated and characterized.

In the present study the four stereoisomers of γ-hydroxyarginine were prepared by guanidination of the corresponding isomers of γ-hydroxyornithine synthesized from optically active histidines (Scheme 1).

Results and Discussion

γ-Oxoornithine (**5**) was synthesized from optically active histidine by the method of Heath *et al.*[12] Histidine (**1**) was first converted into the methyl ester (**2**) dihydrochloride by the conventional method and then transformed into methyl 2,4,5-tribenzamido-4-pentenoate (**3**) by Bamberger cleavage.[13] α,δ-Dibenzoyl-γ-oxoornithine methyl ester (**4**) was formed on heating the tribenzoyl compound (**3**) in methanolic hydrogen chloride. Acid hydrolysis of the ester **4** with 20% hydrochloric acid afforded the keto amino acid (**5**) dihydrochloride as oily residues. Owing to the instability of the acid hydrochloride, the oily product was used for further reduction without crystallization. Treatment of the aqueous solution of **5** dihydrochloride with sodium



Scheme 1. Synthesis of stereoisomers of γ-hydroxyornithine (**6**) and γ-hydroxyarginine (**7**).

borohydride gave diastereoisomeric γ-hydroxyornithine (**6ab**), which was isolated as a crystalline hydrochloride. The diastereoisomeric composition of **6ab** thus obtained was estimated by amino acid analysis of its N^{δ}-acetylated derivative.[11] The amino acid L-**6ab** was composed of 68% *erythro* and 32% *threo*, the D-enantiomorph (D-**6ab**) of 65% *erythro* and 35% *threo* isomers.

Witkop and Beiler[14] pointed out the significance of their failure to esterify or reduce with sodium borohydride γ-oxo-L-ornithine and its derivatives. However, the keto amino acid **5** was hydrogenated smoothly to the hydroxy amino acid **6ab** with the same reducing agent in the present study. With regard to the racemization of α-carbon atom of **5**, no racemization took place during the course of synthesis of mercaptohistidine *via* L-**5** from L-histidine.[12,15,16] The optical purity of L-**5** obtained in this study was ascertained by the conversion of γ-hydroxy-L-ornithine (L-**6ab**) prepared from the compound L-**5** into γ-hydroxy-L-arginine and the digestion of the resulting arginine derivative with the L-directed arginase. The approach described abov seems to be useful for the synthesis of γ-hydroxyornithine which retains the configuration of α-carbon atom, starting from readily available histidine through simple and relatively high-yield operations.

Diastereoisomeric γ-hydroxyornithines (L-**6ab** and D-**6ab**) were separated into the two diastereoisomers by chromatography using a column (3.8×275 cm) of Dowex 50 (Na^+ form).[11] The separated diastereoisomers of γ-hydroxyornithine were isolated as their crystalline hydrochlorides, their stereochemical purities being ascertained by assay using an amino acid analyzer.[11] The specific rotations of natural γ-hydroxyornithine obtained enzymatically from natural γ-hydroxyarginine and the four stereoisomers obtained are given in Table 1. The value for *erythro* L-isomer attained by synthesis is close to that of natural γ-hydroxyornithine. This suggests that surprisingly little racemization or epimerization occurred during the series of reactions and, consequently, the synthetic isomers of γ-hydroxy-L-ornithine were almost optically pure.

The four stereoisomers of γ-hydroxyornithine were separately guanidinated with 1-amidino-3,5-dimethylpyrazole nitrate (ADPN) and the products, the corresponding γ-hydroxyarginines, were isolated as their hydrochlorides.[11] The data of specific rotation for natural and synthetic preparation of γ-hydroxyarginine measured in alkaline medium are given in Table 1. The value for *erythro* L-isomer agrees very closely with that for natural γ-hydroxyarginine. The specific rotations of D-antipodes are expected to be equal but opposite to those of L-antipodes. The value for *erythro* D-isomer is also in good agreement with the value expected. It is evident that the synthetic *erythro* L- and D-isomers are optically pure. On the other hand, *threo* isomers seem to be optically pure.

Table 1. Specific rotations of γ-hydroxyornithine and γ-hydroxyarginine hydrochlorides

Isomer	γ-Hdyroxyornithine hydrochloride $[\alpha]_D^{20}$ (*c* 2, H_2O)	γ-Hydroxyarginine hydrochloride $[\alpha]_D^{20}$ (*c* 1, 0.5 M NaOH)
Natural		
erythro L	+10.5°[a]	− 8.5°
Synthetic		
erythro L	+ 9.4°[b]	− 8.4°
D	− 9.8°	+ 8.5°
threo L	− 6.3°[c]	+11.0°
D	+ 6.4°	−11.0°

a) Ref. 9, $[\alpha]_D^{20}$ +10.6° (*c* 5, H_2O). b) Ref. 11, $[\alpha]_D^{20}$ +10.5° (*c* 2, H_2O). c) Ref. 11, $[\alpha]_D^{20}$ −7.0° (*c* 2, H_2O).

Two different values measured in 5 M (1 M=1 mol dm^{-3}) hydrochloric acid were reported with regard to the specific rotation of natural preparations of γ-hydroxyarginine. We also measured the specific rotation of natural γ-hydroxyarginine in 5 M hydrochloric acid, but obtained no such values as reported.[1,2] We found that the solution had at first $[\alpha]_D$ +17.6° which dropped to +7.5° in 10 min, to −5.6° in 3 h, and then remained constant. Partial transformation of γ-hydroxyarginine into a compound more basic than the original amino acid was ascertained by paper electrophoresis. The mutarotation may be ascribed to the formation of the lactone[4] of γ-hydroxyarginine. The above-cited authors[1,2] overlooked this mutarotative nature of γ-hydroxyarginine.

Experimental

All melting points are uncorrected. Amino acid analyses were carried out using a JEOL-6AS amino acid analyzer. The optical rotations were measured with a Union high sensitivity polarimeter PM-71. Paper chromatography was carried out by the ascending technique on Toyo Roshi No. 52 paper with 1-butanol–acetic acid–pyridine–water(4 : 1 : 1 : 2,v/v). Paper electrophoresis was carried out at 300 V for 2.5 h on Toyo Roshi No. 52 paper in a buffer solution of pyridine–acetic acid–water (20 : 10 : 970, v/v). Spots were made visible with ninhydrin and Sakaguchi reagents.

Methyl 2,4,5-Tribenzamido-4-pentenoate (3). Compound **3** was prepared from the ester **2**·2HCl by Bamberger cleavage[13] according to the procedure of Heath *et al.*[12] The product was recrystallized from Methyl Cellosolve. The yield of L-**3** from L-**2**·2HCl (24.1 g, 0.1 mol) was 34.3 g (73%); mp 215—216 °C.

Compound D-**3** was obtained from D-**2**·2HCl (14.5 g, 60 mmol); yield, 21.8 g (77%); mp 214—215 °C.

Found (L-**3**): C, 68.59; H, 5.33; N, 9.00%. Found (D-**3**): C, 68.54; H, 5.28; N, 8.70%. Calcd for $C_{27}H_{25}O_5N_3$: C, 68.73; H, 5.34; N, 8.91%.

α,δ-Dibenzoyl-γ-oxoornithine Methyl Ester (4). Compound **4** was obtained from the parent tribenzoyl compound **3** by boiling for 30 min with 10% methanolic hydrogen chloride.[12] Recrystallization of the crude product was performed from hot ethanol. The yield of L-**4** from L-**3** (22 g, 47 mmol) was 7.1 g (42%); mp 168—170 °C.

The yield of D-**4** from D-**3** (21.2 g, 45 mmol) was 6.5 g (40%); mp 168—170 °C.

Found (L-**4**): C, 65.01; H, 5.45; N, 7.55%. Found (D-**4**): C, 65.11; H, 5.43; N, 7.50%. Calcd for $C_{20}H_{20}O_5N_2$: C, 65.20; H, 5.47; N, 7.61%.

γ-Oxoornithine (5) Dihydrochloride. Compound **5**·2HCl was prepared from the dibenzoyl ester **4** (5.5 g, 15 mmol) by

refluxing with 20% hydrochloric acid (54 ml) for 7 h. The oily product could not be crystallized by treatment with ethanol. Paper electrophoretic analysis showed that it was almost pure. Owing to the instability of the acid dihydrochloride the oily product was used directly.

*Diastereoisomeric γ-Hydroxyornithine (**6ab**) Hydrochloride.* γ-Oxoornithine (**5**) dihydrochloride obtained as above was dissolved in water (30 ml) and cooled in an ice-water bath. To the solution was added 2 equivalents of sodium borohydride (0.57 g, 15 mmol) in small portions with continuous stirring over a period of 30 min. The cold mixture was stirred for 2 h and neutralized with 2 M hydrochloric acid. The progress of the reaction was checked by paper electrophoresis. The solution containing γ-hydroxyornithine was applied to a column (3.6×9 cm) of Dowex 50 (H^+ form). After the column had been washed with water and 2.5 M pyridine (300 ml), the amino acid was eluted with 2 M aqueous ammonia (350 ml) and the pooled eluate was evaporated to dryness *in vacuo*. The residue, taken up in water, was adjusted to pH 5 with 1 M hydrochloric acid, decolorized with charcoal and concentrated to a syrup *in vacuo*. The syrup was dissolved in a small amount of 50% ethanol, γ-hydroxyornithine being crystallized as its hydrochloride with the addition of absolute ethanol. Yield of L-**6ab**·HCl, 2.5 g (90%); mp 167—168 °C (dec). Yield of D-**6ab**·HCl, 2.4 g (88%); mp 169 °C (dec).

Found (L-**6ab**·HCl): C, 32.21; H, 7.01; N, 14.83%. Found (D-**6ab**·HCl): C, 31.92; H, 7.16; 14.93%. Calcd for $C_5H_{12}O_3N_2$·HCl: C, 32.53; H, 7.10; N, 15.17%.

*Separation of the Diastereoisomers of γ-Hydroxyornithine (**6ab**).* A diastereoisomeric compound **6ab**·HCl (600 mg) was separated into its two diastereoisomers by chromatography using a column (3.8×275 cm) of Dowex 50 (Na^+ form).[11] Two ninhydrin positive peaks were obtained. The component of the forepeak was confirmed to be *threo* isomer and that of the afterpeak *erythro* isomer by the assay using an amino acid analyzer.

erythro-*γ-Hydroxy*-L-*ornithine* (L-*6a*) *Hydrochloride.* The diastereoisomers of γ-hydroxy-L-ornithine were separated chromatographically as described above. The combined eluate containing *erythro* L-isomer was treated as described for L-**6ab**. The *erythro* isomer was obtained as its hydrochloride. It was recrystallized from water–ethanol; yield, 272 mg (67%); mp 176—177 °C (dec); $[\alpha]_D^{20}$ +9.4° (*c* 2, H_2O). [lit,[9] $[\alpha]_D^{20}$ +10.6° (*c* 5, H_2O), lit,[11] $[\alpha]_D^{20}$ +10.5° (*c* 2, H_2O)].

threo-*γ-Hydroxy*-L-*ornithine* (L-*6b*) *Hydrochloride.* From the pooled forepeak fractions of the eluate, the *threo* isomer was obtained as its hydrochloride. It was recrystallized from water–ethanol; yield, 146 mg (76%); mp 193—194 °C (dec); $[\alpha]_D^{20}$ −6.3° (*c* 2, H_2O). [lit,[11] $[\alpha]_D^{20}$ −7.0° (*c* 2, H_2O)].

erythro-*γ-Hydroxy*-D-*ornithine* (D-*6a*) *Hydrochloride.* The diastereoisomers of γ-hydroxy-D-ornithine were separated as described above. From the combined afterpeak fractions of the eluate, the *erythro* isomer was obtained as its hydrochloride. It was recrystallized from water–ethanol; yield, 260 mg (67%); mp 174—175 °C (dec); $[\alpha]_D^{20}$ −9.8° (*c* 2, H_2O).

threo-*γ-Hydroxy*-D-*ornithine* (D-*6b*) *Hydrochloride.* From the pooled forepeak fractions of the eluate, the *threo* isomer was obtained as its hydrochloride. It was recrystallized from water–ethanol; yield, 132 mg (63%); mp 189—190 °C (dec); $[\alpha]_D^{20}$ +6.4° (*c* 2, H_2O).

Found (L-**6a**·HCl): C, 32.05; H, 7.12; N, 14.81%. Found (L-**6b**·HCl): C, 32.44; H, 7.12; N, 14.91%. Found (D-**6a**·HCl): C, 31.97; H, 7.11; N, 14.87%. Found (D-**6b**·HCl): C, 32.32; H, 7.10; N, 14.71%. Calcd for $C_5H_{12}O_3N_2$·HCl: C, 32.53; H, 7.10; N, 15.17%.

Guanidination of Four Stereoisomers of γ-Hydroxyornithine. Each isomer of γ-hydroxyornithine (184.5 mg) was converted into the corresponding γ-hydroxyarginine by treatment with 1-amidino-3,5-dimethylpyrazole nitrate (ADPN), the unchanged material and the product being separated by chromatography using a column (1.6×16 cm) of Dowex 50 (pyridinium form).[11]

erythro-*γ-Hydroxy*-L-*arginine* (L-*7a*) *Hydrochloride.* Compound L-**6a**·HCl was guanidinated with ADPN and the reaction mixture subjected to column chromatography, as described above. From the pooled afterpeak fractions of the eluate, *erythro* L-isomer (L-**7a**) was crystallized as its hydrochloride. It was recrystallized from water–ethanol; yield, 95 mg (42%); mp 188—189 °C (dec); $[\alpha]_D^{20}$ −8.4° (*c* 1, 0.5 M NaOH).

erythro-*γ-Hydroxy*-D-*arginine* (D-*7a*) *Hydrochloride.* Compound D-**7a**·HCl was obtained from D-**6a**·HCl in the same manner as described above. It was recrystallized from water–ethanol; yield, 115 mg (51%); mp 188—189 °C (dec); $[\alpha]_D^{20}$ +8.5° (*c* 1, 0.5 M NaOH).

threo-*γ-Hydroxy*-L-*arginine* (L-*7b*) *Hydrochloride.* Compound L-**6b**·HCl was treated in the same manner as above. *threo* L-Isomer L-**7b** was obtained as a hygroscopic crystalline hydrochloride; yield, 90 mg (40%); $[\alpha]_D^{20}$ +11.0° (*c* 1, 0.5 M NaOH).

threo-*γ-Hydroxy*-D-*arginine* (D-*7b*) *Hydrochloride.* Compound D-**7b**·HCl was obtained from D-**6b**·HCl in the same manner as described above. It was obtained as a hygroscopic crystalline hydrochloride; yield, 105 mg (46%); $[\alpha]_D^{20}$ −11.0° (*c* 1, 0.5 M NaOH).

Found (L-**7a**·HCl): C, 31.76; H, 6.75; N, 24.65%. Found (D-**7a**·HCl): C, 31.86; H. 6.69; N, 24.77%. Found (L-**7b**·HCl): C, 31.70; H, 6.72; N, 24.20%. Found (D-**7b**·HCl): C, 31.39; H, 6.85; N, 24.40%. Calcd for $C_6H_{14}O_3N_4$·HCl: C, 31.79; H, 6.67; N, 24.72%.

Restricted Rotation Involving the Tetrahedral Carbon. XXXV.[1] Stereodynamics of 9-(3,5-Dimethylbenzyl)triptycene Derivatives

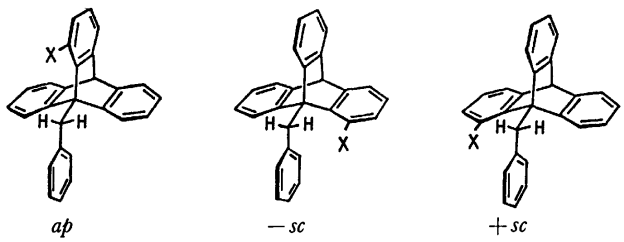
Gaku YAMAMOTO and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 31, 1980)

Stereodynamics of a variety of 9-(3,5-dimethylbenzyl)triptycene derivatives was studied. Atropisomerism about the bridgehead-to-methylene bond was realized in a triply *peri*-substituted derivative, 8,13-dichloro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene: the activation enthalpy for the *ap*→±*sc* conversion was 26.4 kcal/mol. Barriers to rotation about the bridgehead-to-methylene bond in a variety of triply, doubly, and singly *peri*-substituted derivatives were obtained by DNMR method. DNMR behavior of the diastereotopic *m*-methyl groups in the benzyl moiety revealed the dual mechanisms of the methyl exchange process: rotation about the methylene-to-aryl bond by 180° without rotation about the bridgehead-to-methylene bond ("isolated rotation (IR)") and rotation about the methylene-to-aryl bond by 180° synchronous with rotation about the bridgehead-to-methylene bond by 120° ("gear motion (GM)"). The GM process predominates in *peri*-unsubstituted derivatives, while the IR process predominates in triply *peri*-substituted ones.

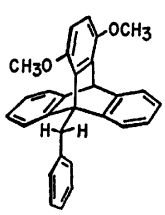
Ample examples of restricted rotation about the bridgehead-to-substituent bond in 9-substituted triptycene derivatives have been reported.[2] Among them, 9-benzyltriptycenes have drawn much attention because of several interesting aspects in their conformational behavior. One is the apparently anomalous conformational preference for the ±*sc* rotamers on the basis of the steric consideration, especially when the *peri*-substituent X is a methoxyl (Scheme 1).[3,4] This



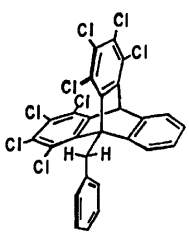
ap −*sc* +*sc*

Scheme 1.

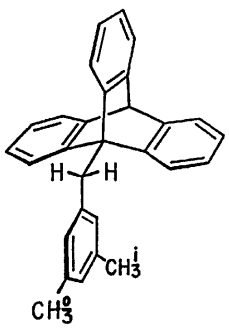
phenomenon suggests the existence of some kind of attractive interaction between the methoxyl and the phenyl groups.[3] Another interesting aspect is about the energy barriers to the conformational interconversion among these rotamers. In case of singly *peri*-substituted derivatives, the barrier to interconversion between *ap* and ±*sc* rotamers is dependent on the nature of the *peri*-substituent X. Interconversion between the +*sc* and −*sc* rotamers may occur either directly by passing of the aryl group over the *peri*-substituent or stepwise by way of the *ap* rotamer. DNMR studies on this aspect have been made revealing that the stepwise process is energetically more favored.[4] In addition, the rotational barriers are highly dependent on the number of *peri*-substituents. For instance, the $\Delta G^{\ddagger}$ for the *ap*→±*sc* process in compound **1** with one *peri*-substituent was 11.9 kcal/mol at −15 °C,[5] while that for the +*sc*⇌−*sc* interconversion in **2** with two *peri*-substituents rose up to 18.1 kcal/mol at 100 °C.[3c] These data make one expect that the triply *peri*-substituted derivatives might have an even higher barrier, which is possibly so high that atropisomerism can be realized. We found this was actually the case in one of the derivatives and the detail is described in this paper.[6] Third aspect of interest is the conformational behavior of the benzylic phenyl group. Several lines of evidence suggest that the stable conformation with respect to the phenyl group is the one in which the benzene ring is coplanar with the bridgehead-to-methylene bond as shown in Scheme 1.[3] Molecular model consideration indicated that the rotation of the phenyl group might be considerably hindered, but hithertofore NMR studies have given no definite information on this point because the benzylic aromatic signals are overshadowed by the triptycyl aromatic signals. We therefore planned to introduce two *m*-methyl groups into the benzylic benzene ring as an NMR probe in order to have a deeper insight into the conformational behavior of the aryl group.



1



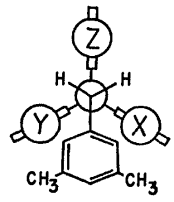
2



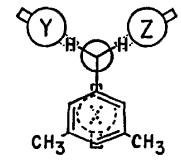
3

If conformation **3** has a sufficiently long lifetime on the NMR time scale, two methyl groups should be diastereotopic and anisochronous. Two processes that exchange the magnetic environments of the two methyl groups can be *a priori* deduced. One is a simple rotation

of the aryl group by 180°, without rotation about the bridgehead-to-methylene bond, by way of the transition state shown by **4**. We call this process "isolated rotation (IR)." Another process is a correlated rotation of the aryl and the triptycyl groups in which rotation about the methylene-to-aryl bond by 180° occurs synchronously with rotation about the bridgehead-to-methylene bond by 120° by way of the transition state shown by **5**.



4



5

We refer to this process as "gear motion (GM)." Strictly speaking, exchange of the methyl groups by this process occurs only when the rotamers before and after the process are homomeric or enantiomeric to each other, namely X=Y=Z or at least Y=Z. We report here the stereodynamics of the aryl groups as revealed by DNMR behavior of the *m*-methyl groups in some detail.[7]

Results and Discussion

Atropisomerism. In order to investigate the possibility of atropisomerism, several triply *peri*-substituted 9-(3,5-dimethylbenzyl)triptycenes (**6**—**9**) were synthesized.

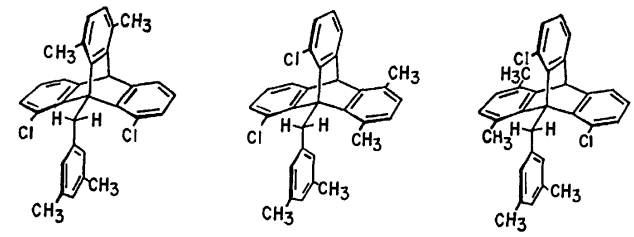
Reactions of 3,6-dimethylbenzyne, generated *in situ* from the corresponding anthranilic acid, with **10a** and with **10b** gave the triptycene skeletons of **6** and **8**, while Diels-Alder reactions of *p*-benzoquinone with **10a** and with **10b** followed by treatment with dimethyl sulfate and potassium hydroxide gave the skeletons of **7** and **9**. Among the compounds obtained only **6** afforded atropisomers.

Anthracene **10a** reacted with 3,6-dimethylbenzyne to give a mixture of *ap* and ±*sc* rotamers of the triptycene **6**. NMR spectral investigation of the mixture revealed that the interconversion between the rotamers was considerably slow at room temperature in the classical sense, and that the formation ratio of the two rotamers was dependent on the reaction temperature. The reaction in boiling dichloromethane at *ca.* 40 °C gave the highest *ap*/±*sc* ratio of *ca.* 9 and the higher reaction



ap −*sc* +*sc*

temperature caused the decrease of the rotamer ratio because of the probable decrease in the stereoselectivity and the partial isomerization of the *ap* to the ±*sc* rotamer at the reaction temperature. The high stereoselectivity shown in the reaction is consistent with our previous finding that the Diels-Alder addition of a dienophile to a 9-substituted anthracene preferentially gives an atropisomer in which the bulkiest α-group in the 9-substituent ocuppies the antiperiplanar position to the entering dienophile.[8,9]

Recrystallization from chloroform–ethanol of the rotamer mixture thus obtained gave the pure *ap*-**6**. ±*sc*-**6** was isolated in a pure state by column chromatography of the equilibrated mixture of the two rotamers (*vide infra*) followed by recrystallization from chloroform–ethanol. Rotamer assignment was clearly made from the ^{1}H NMR spectral pattern of the methylene protons: a singlet for the *ap* and an AB-quartet for the ±*sc* rotamer. Although these rotamers are quite stable at room temperature both in solution and in the crystalline state, elevation of the temperature caused the isomerization of the rotamers in solution. Detailed kinetic study was made by following the change of the relative intensities of the 1-methyl signals in ^{1}H NMR spectra at 48—69 °C with chloroform-*d* solution. The data agreed with the rate law for a first order reversible reaction, and the first order rate constants were obtained at four temperatures, and the activation parameters were calculated as shown in Table 1. The equilibrium constant ±*sc*/*ap* for **6** was 2.0 throughout the temperature range examined and this value may reflect the same degree of interaction of the methyl and the chloro groups as exerted to the flanking aryl group.

DNMR Study on Rotation about the Bridgehead-to-Methylene Bond. The other triply *peri*-substituted derivatives **7**—**9** carrying the smaller *peri*-groups than those of **6** were shown to be too labile to give rise to atropisomers and their stereodynamics was studied by DNMR.

a) Obtained by DNMR method except for **6**. b) Obtained by classical kinetics. See Table 1. c) See Experimental. d) With errors of ±0.1 kcal/mol due mainly to the errors in T_c of ±2 °C.

^{1}H NMR spectrum of the thermodynamically equilibrated sample of **7** showed the sole existence of the $\pm sc$ rotamer at room temperature, as indicated by an AB-quartet signal for the methylene protons and only one pair of the methoxyl signals. Smaller bulkiness of the methoxyl group compared with that of the chloro group should be responsible for this phenomenon, as the oxygen atom with the van der Waals radius of 1.40 Å mainly interacts with the aryl group. Attractive interaction between the aryl and the methoxyl groups may contribute to the rotamer equilibrium.[3)] The AB-quartet signal due to the methylene protons coalesced into a singlet on elevation of the temperature and this DNMR behavior gave the $+sc \rightleftarrows -sc$ interconversion barrier shown in Table 2. In fluorinated compounds **8** and **9**, both the *ap* and the $\pm sc$ rotamers were present at equilibrium. DNMR of the 4-methyl signals of **8** and the 1-methoxyl signals of **9** afforded the $ap \rightleftarrows \pm sc$ interconversion barrier as shown in Table 2. Interesting is the large rotamer ratio ($\pm sc/ap$) of 3.0 shown by **9**. As the fluoro group is thought to be smaller than the methoxyl group, the ratio smaller than the statistical value of 2.0 would be expected on the steric ground. This result suggests that the methoxyl group exerts some attractive interaction with the aryl group as suggested before,[3)] while the fluoro group does not exert such an interaction.

16

Although stereodynamics of some doubly and singly *peri*-substituted 9-benzyltriptycenes has been studied,[3-5)] several additional compounds **11**—**15** carrying two *m*-methyl groups in the benzyl moiety were now synthesized and their DNMR behaviors were examined. Energy barriers to the $+sc \rightleftarrows -sc$ process for **11** and to the $ap \rightleftarrows \pm sc$ processes for **12** and **14** were obtained as shown in Table 2

Table 2 indicates the significant dependence of the barrier upon the number and the size of the *peri*-substituents. The transition state for these processes must be best represented by **5**, and the nature of the *peri*-group X over which the aryl group passes should have the largest effect on the barrier, but the *peri*-groups Y and Z which eclipse the benzylic hydrogens also exert a large effect (**8** *vs.* **9** and **11** *vs.* **12**).

1,8-Dichloro-9-benzyltriptycene (**16**) was synthesized in order to check the effect of the *m*-methyl groups on the energy barrier by comparing the DNMR data with those of **11**. Compound **16** existed solely in the $\pm sc$ rotamer and the AB-quartet signal due to the methylene protons coalesced into a singlet at 60 °C corresponding to the $+sc \rightleftarrows -sc$ barrier of 16.1 kcal/mol. This barrier has a small but significant difference from that in **11**. The difference might be attributed to the buttressing

effect of the *m*-methyl groups against the ortho protons, which operates to destabilize the ground state resulting in the decrease of the barrier.

Stereodynamics of the Aryl Group. Low temperature ^{1}H NMR spectra of the above mentioned compounds **6**—**9** and **11**—**15** showed equally intense singlets for the *m*-methyl groups, indicating the freezing of the conformation **3** on the NMR time scale. The higher field singlet may be assigned to the inner methyl group (CH_3^i) and the lower field one to the outer methyl (CH_3^o), if one considers the ring current effect of the triptycyl benzene rings. Similarly, the signal ascribed to the proton at the inner ortho position appeared at the higher field of the aromatic region (δ 6.0—6.4), while the outer *o*-proton appeared around δ 7.2 although it could not be definitely assigned as it was overshadowed by the other aromatic signals.

Two *m*-methyl singlets coalesced into a singlet at higher temperatures to indicate the presence of rate process(es) exchanging the magnetic environments of the two methyl groups. The rate constants for the methyl exchange process at the coalescence temperatures were calculated and are shown in Table 3 together with the free energies of activation therefrom.

As for $\pm sc$-**6**, the DNMR study was made on the equilibrium mixture of *ap*- and $\pm sc$-**6**, because the isomerization of the $\pm sc$ rotamer to the *ap* occurred with considerable rates at around the coalescence temperature of the methyl signals of $\pm sc$-**6**. In compounds **8** and **9** which existed as a mixture of *ap* and $\pm sc$ rotamers, low temperature chemical shifts of the *m*-methyl groups of the two rotamers coincided, but the coalescence temperatures could be separately determined for each rotamer; the overlap of the signals somewhat decreased the accuracy of $\Delta\delta$ and T_c determination affording the errors of *ca.* $\pm$0.2 kcal/mol for ΔG^* values. In **12** and **14**, the coalescence temperatures could not be separately determined for each rotamer; this would cause rather large errors in ΔG^* values.

As discussed in the introductory section, magnetic exchange of the two *m*-methyl groups can occur by two processes: IR and GM. Rotation about the bridgehead-to-methylene bond can be naturally assumed to occur exclusively by the GM process, and therefore the barrier data in Table 2 correspond to the GM barriers of these compounds. Thus we can discuss on the contribution of these two mechanisms on the methyl exchange process for each compound.

Judging from the observation that the GM barrier sharply dropped as the number of *peri*-substituents decreased, while the methyl exchange barrier was not so sensitive to the *peri*-groups, we expect that the GM process can be a main contributor to the methyl exchange in *peri*-unsubstituted derivatives. The IR barrier in the *peri*-unsubstituted derivatives was estimated as follows. Compound **15** with a methyl group in the benzyl methylene position showed broadening of the signals in the aromatic region at 80—100 °C reflecting that the rotation about the bridgehead-to-methylene bond became fast on the NMR time scale at this temperature region. The barrier to rotation was roughly estimated to be about 18—20 kcal/mol, which may be reasonable if one takes it into account that 2,4-dimethyl-9-isopropyltriptycene has the $ap \rightleftharpoons \pm sc$ barrier of 19.9 kcal/mol.[10] DNMR behavior of the *m*-methyl groups in this compound suggests that the methyl exchange with ΔG_c^* of 13.3 kcal/mol occurs by the IR process. It can be assumed that the introduction of a methyl group into the benzylic position does not significantly affect the IR barrier, and therefore compounds **13** and **14** which do not carry *peri*-groups have similar IR barrier to **15**. One may argue that the presence of a methyl group in the benzylic position considerably modifies the potential curve of the IR process. But the methyl group cannot significantly affect the rate determining transition state (**4**) in which

Table 3. DNMR data for the methyl exchange

Compound and rotamer	Solvent	$\delta^i_{CH_3}$ [a]	$\delta^o_{CH_3}$ [a]	$\Delta\delta$ [b] / Hz	T_c [d] / °C	ΔG_c^* [f] / kcal/mol

a) Obtained at the lowest temperature examined (*ca.* −35 °C for **6**—**9**, **11**, and **15**, and *ca.* −90 °C for **12**—**14**). b) Independent of the temperature within the experimental errors. c) Coincident between the *ap* and $\pm sc$ rotamers. d) With errors of $\pm$2 °C unless otherwise stated. e) With uncertainty of *ca.* $\pm$5 °C because of the impossibility of determining T_c's separately for each rotamer. f) With errors of $\pm$0.1 kcal/mol unless otherwise stated. g) With uncertainty of $\pm$0.2 kcal/mol. h) With uncertainty of *ca.* $\pm$0.5 kcal/mol.

the largest steric interaction occurs between the *o*-hydrogens of the aryl group and the *peri*-substituents, as is suggested by inspection of molecular models. Nor can the methyl group significantly affect the ground state (**3**) of the molecule. Therefore we believe that the assumption is reasonable. Then it is the GM process that showed the barrier of *ca.* 10 kcal/mol for the methyl exchange. The GM barrier obtained from the DNMR of 2-methoxyl signals in **14**, 11.0 kcal/mol, agrees well, if one takes the probable large error into account. Thus, the GM barrier is lower than that of the IR in *peri*-unsubstituted compounds and the exchange of the *m*-methyl groups is concluded to occur preferentially by the GM process.

In the ^{1}H NMR spectrum at −90 °C of compound **12**, the signal assigned to the inner *m*-methyl group appeared as two slightly shifted singlets of the relative intensity of 3.3 : 1 corresponding to the ±*sc* and the *ap* rotamers, respectively, while only one singlet was observed for the outer methyl group. These peaks coalesced into a singlet at −20 °C and the analysis using the approximate method for coalescing two equally intense peaks gave a rough estimate of the methyl exchange barrier of 12.6 kcal/mol. The GM barrier obtained from the DNMR of the 1-methoxyl peaks was 12.4 kcal/mol for the *ap*→±*sc* conversion at −28 °C (Table 2). The IR barrier in the *ap* rotamer of this compound should also be similar to that in **15**, around 13 kcal/mol. It can therefore be deduced that both the IR and the GM processes contribute to the methyl exchange in this singly *peri*-substituted derivative.

Compound **11**, a sole doubly *peri*-substituted derivative examined, showed the barrier of 15.7 kcal/mol for the GM process and 15.2 kcal/mol for the methyl exchange process. The IR barrier in this compound should not exceed 15.6 kcal/mol, the IR barrier in **7**, because the latter compound has a chloro and a methyl groups as the *peri*-substituents flanking the aryl group while the former has a hydrogen and a chloro groups. Thus the IR and the GM processes in this compound should have almost the same barrier and comparably contribute to the methyl exchange.

From the above discussion it has been demonstrated that the actual mechanism of the methyl exchange detected by DNMR vary on successive substitution in the *peri*-positions, from the GM process in *peri*-unsubstituted compounds to the IR process in the triply *peri*-substituted ones. This must come from the fact that the GM barrier sharply increased on substitution in the *peri*-positions, from 11.0 kcal/mol of *peri*-unsubstituted compound **14** to 25.2 kcal/mol of the triply *peri*-substituted one **6**, while the change in the IR barrier was relatively small, from 13.3 kcal/mol in **15** to 17.9 kcal/mol in ±*sc*-**8**.

Table 4 lists the energy barriers definitely assigned to the IR process. The IR barrier increases with the increasing size of the *sc*-substituents X and Y if the *ap*-substituent Z is the same (±*sc*-**8** *vs.* ±*sc*-**9**, ±*sc*-**6** *vs.* ±*sc*-**7**, and *ap*-**6** *vs.* *ap*-**8**), indicating the destabilization of the transition state **4** to a greater extent than the ground state **3**. Interesting is the effect of the *ap*-substituent Z; the larger the *ap*-group is, the lower the IR barrier becomes if the *sc*-substituents are unaltered (*ap*-**8** *vs.* *ap*-**9**). This clearly suggests that the buttressing effect of the *ap*-substituent causes the destabilization of the ground state rather than the transition state of the IR process. Similar barriers of *ap*-**8** and **15** can be ascribed to the compensating effects of the *ap*- and the *sc*-substituents: destabilization of the transition state by the *sc*-fluoro groups and that of the ground state by the *ap*-methyl group of *ap*-**8** relative to the hydrogens of **15**. Another similarity in the IR barriers of *ap*-**6** and ±*sc*-**7** may be ascribed to the effect of the *sc*-substituents, the transition-state-destabilizing chloro group in *ap*-**6** and the ground-state-stabilizing methoxyl group in ±*sc*-**7**, if one takes the similar size of the *ap*-groups into account.

Table 4. Energy barriers to the IR process[a)]

a) Extracted from Table 3.

Experimental

Melting points are not corrected. ^{1}H NMR spectra at ambient temperature (*ca.* 35 °C) were recorded on either a Hitachi R-20B (60 MHz) or a Varian EM-390 (90 MHz) spectrometer with tetramethylsilane as an internal standard. ^{19}F NMR spectra were obtained on a Varian EM-390 spectrometer operating at 84.67 MHz with *ca.* 10% (w/v) solutions in $CDCl_3$ containing 2% of hexafluorobenzene. Chemical shifts were read with a Hewlett-Packard 5381A frequency counter relative to C_6F_6 as an internal lock signal and expressed in ppm downfield from it.

DNMR Studies. Sample solutions were prepared by dissolving *ca.* 10% (w/v) of the compounds in appropriate solvents containing 0.5% of tetramethylsilane (in case of $CDCl_3$ and CS_2) or hexamethyldisiloxane (in case of hexachloro-1,3-butadiene and chlorobenzene) as an internal standard. Variable temperature ^{1}H NMR spectra were obtained on a Hitachi R-20B spectrometer at 60 MHz and the temperatures were calibrated using methanol or ethylene glycol.[11] Because the unreliability of the enthalpies and entropies of activation obtained from DNMR analysis of relatively simple patterns ($AB \rightleftharpoons A_2$ with or without mutual coupling) is often questioned in detailed discussions, we have not attempted the computer-assisted total lineshape analysis: only the first order rate constants at the coalescence temperatures and the free energies of activation therefrom were calculated and used in discussion. Rate constants at T_c were obtained from Eq. 1 in case of two singlets of equal intensity and Eq. 2 in case of an AB-quartet,[12] and the graphical method by Shanan-Atidi and Bar-Eli in case of two singlets of unequal intensity.[13] Validity of the use of Eqs. 1 and 2 was discussed by Kost *et al.*[14]

$$k_c = \frac{\pi}{\sqrt{2}} \Delta\delta \quad (1)$$

$$k_c = \frac{\pi}{\sqrt{2}} \sqrt{(\Delta\delta)^2 + 6J^2} \quad (2)$$

1,8-Difluoroanthraquinone. A mixture of 10 g of thoroughly dried 1,8-dichloroanthraquinone and 20 g of completely anhydrous caesium fluoride in 50 mL of anhydrous dimethyl sulfoxide was heated with efficient stirring at 130—135 °C for 8 h. The mixture was cooled and poured into 300 mL of water. The solid mass was collected by filtration, dried in air, and submitted to column chromatography on alumina with hexane–dichloromethane (4 : 1) as an eluent. 1,8-Dichloro-, 1-chloro-8-fluoro-, and 1,8-difluoroanthraquinones were eluted successively in this order. 1,8-Difluoroanthraquinone was recrystallized from tetrahydrofuran–ethanol to give 3.0 g (34%) of yellow crystals, mp 227—228 °C. Found: C, 69.07; H, 2.19%. Calcd for $C_{14}H_6F_2O_2$: C, 68.86; H, 2.48%. ^{19}F NMR ($CDCl_3$): 50.5 ppm.

1,8-Difluoroanthrone. To a solution of 3.47 g (14.2 mmol) of 1,8-difluoroanthraquinone in 35 mL of concentrated sulfuric acid was added portionwise 1.0 g of aluminium powder and the mixture was stirred for 15 h at room temperature. The reaction mixture was poured onto ice. The solid formed was filtered, washed with water and dried in air. ^{19}F NMR of the crude reaction products revealed the presence of *ca.* 10% of 4,5-difluoroanthrone (44.3 ppm) as well as the desired 1,8-difluoroanthrone (49.1 ppm), which was purely isolated upon recrystallization of the mixture from benzene–hexane in the yield of 2.06 g (63%), mp 167—168 °C (dec). Found: C, 73.34; H, 3.24%. Calcd for $C_{14}H_8F_2O$: C, 73.04; H, 3.50%. ^{1}H NMR ($CDCl_3$, δ): 4.27 (2H, s), 6.8—7.7 (6H, m). ^{19}F NMR ($CDCl_3$): 49.1 ppm.

4-Methoxyanthrone. Simple and high-yield synthesis of the compound was developed. A mixture of 24.3 g (0.1 mol) of 1-chloroanthraquinone in 500 mL of sodium methoxide solution prepared from 6.0 g of sodium metal was heated under reflux for 40 h. The mixture was evaporated and diluted with water. The residual solid was filtered, washed with water, dried in air and recrystallized from tetrahydrofuran–hexane to give 20.5 g (86%) of 1-methoxyanthraquinone, mp 164—165 °C (lit,[15] 169.5 °C). The mixture of 7.14 g (30 mmol) of 1-methoxyanthraquinone and 18 g of sodium dithionite in 200 mL of 1 mol/L aqueous sodium hydroxide was heated under reflux for 3 h. The solid formed was filtered, washed with water, dried in air, and recrystallized from tetrahydrofuran–hexane to give 5.54 g (82%) of 4-methoxyanthrone, mp 134—135 °C (lit,[16] 142—143 °C).

General Procedure for the Synthesis of Anthracene Derivatives by Grignard Reaction. To an ethereal solution of two-fold excess of a Grignard reagent prepared from benzyl chloride, 3,5-dimethylbenzyl chloride,[17] or 1-(3,5-dimethylphenyl)ethyl chloride, which was prepared from the corresponding alcohol[18] and thionyl chloride, was added portionwise an appropriate anthrone in a powdery form and the mixture was stirred at room temperature for 1 h and then heated under reflux for 1 h. The reaction mixture was decomposed with aqueous ammonium chloride to give a 9-benzyl-9,10-dihydro-9-anthrol derivative, which, without further purification, was dissolved in benzene and treated with thionyl chloride and pyridine at 50 °C for 1 h. Column chromatography on alumina of the reaction products followed by recrystallization from tetrahydrofuran–hexane gave the desired anthracene.

9-(3,5-Dimethylbenzyl)anthracene, mp 134—135 °C, was prepared from 3,5-dimethylbenzyl magnesium chloride and anthrone in 97% yield. Found: C, 93.43; H, 6.58%. Calcd for $C_{23}H_{20}$: C, 93.20; H, 6.80%. ^{1}H NMR ($CDCl_3$, δ): 2.14 (6H, s), 4.91 (2H, s), 6.73 (3H, s), 7.1—7.6 (4H, m), 7.8—8.4 (4H, m), 8.39 (1H, s).

1,8-Dichloro-9-(3,5-dimethylbenzyl)anthracene, mp 196—197 °C, was prepared from 3,5-dimethylbenzylmagnesium chloride and 1,8-dichloroanthrone[19] in 88% yield. Found: C, 75.55; H, 4.88; Cl, 19.40%. Calcd for $C_{23}H_{18}Cl_2$: C, 75.62; H, 4.97; Cl, 19.41%. ^{1}H NMR ($CDCl_3$, δ): 2.08 (6H, s), 5.61 (2H, s), 6.23 (2H, s), 6.63 (1H, s), 7.1—8.0 (6H, m), 8.33 (1H, s).

1,8-Difluoro-9-(3,5-dimethylbenzyl)anthracene, mp 189—190 °C, was prepared from 3,5-dimethylbenzylmagnesium chloride and 1,8-difluroanthrone in 53% yield. Found: C, 83.24; H, 5.36%. Calcd for $C_{23}H_{18}F_2$: C, 83.11; H, 5.46%. ^{1}H NMR ($CDCl_3$, δ): 2.18 (6H, s), 5.13 (2H, br s), 6.70 (3H, s), 6.8—7.9 (6H, m), 8.32 (1H, br t, J_{HF}=1.8 Hz). ^{19}F NMR ($CDCl_3$): 54.2 ppm.

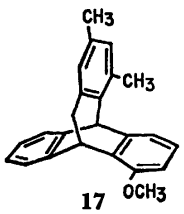
2-Methoxy-9-(3,5-dimethylbenzyl)anthracene, mp 87—89 °C, was prepared from 3,5-dimethylbenzylmagnesium chloride and 2-methoxyanthrone[20] in 59% yield. Found: C, 88.53; H, 6.60%. Calcd for $C_{24}H_{22}O$: C, 88.31; H, 6.79%. ^{1}H NMR ($CDCl_3$, δ): 2.03 (6H, s), 3.64 (3H, s), 4.68 (2H, s), 6.72 (3H, s), 6.9—8.2 (5H, m), 8.10 (1H, s).

9-[1-(3,5-Dimethylphenyl)ethyl]anthracene, mp 153—155 °C, was prepared from 1-(3,5-dimethylphenyl)ethylmagnesium chloride and anthrone in 34% yield. Found: C, 93.07; H, 6.99%. Calcd for $C_{24}H_{22}$: C, 92.86; H, 7.14%. ^{1}H NMR ($CDCl_3$, δ): 1.96 (3H, d, J=7.2 Hz), 2.20 (6H, s), 5.70 (1H, q, J=7.2 Hz), 6.81 (1H, s), 6.89 (2H, s), 7.2—7.6 (4H, m), 7.8—8.4 (4H, m), 8.38 (1H, s).

4-Methoxy-10-(3,5-dimethylbenzyl)anthrone. To a mixture of 1.7 mL (*ca.* 11 mmol) of 3,5-dimethylbenzyl chloride

and 2.24 g (10 mmol) of 4-methoxyanthrone in 60 mL of methanol was added dropwise under nitrogen a solution of 0.6 g of potassium hydroxide in 15 mL of methanol in the course of 1 h. The mixture was stirred at room temperature for 2 h, evaporated, diluted with water and extracted with benzene. The benzene solution was washed with water, dried over magnesium sulfate, and evaporated. The residue was recrystallized from benzene–hexane to give 4-methoxy-10-(3,5-dimethylbenzyl)anthrone in the yield of 1.72 g (50%), mp 108—109 °C. Found: C, 83.97; H, 6.29%. Calcd for $C_{24}H_{22}O_2$: C, 84.17; H, 6.47%. ^{1}H NMR ($CDCl_3$, δ): 2.05 (6H, s), 2.87 (1H, dd, J=12.7 and 6.4 Hz), 3.13 (1H, dd, J=12.7 and 4.4 Hz), 3.97 (3H, s), 4.78 (1H, dd, J=6.4 and 4.4 Hz), 5.99 (2H, s), 6.72 (1H, s), 7.0—7.6 (5H, m), 7.78 (1H, dd), 8.13 (1H, s).

1-Methoxy-9-(3,5-dimethylbenzyl)anthracene. To a boiling solution of 685 mg (2.0 mmol) of 4-methoxy-10-(3,5-dimethylbenzyl)anthrone in 20 mL of ethanol was added dropwise a solution of 756 mg (20 mmol) of sodium borohydride in 20 mL of 10% aqueous ethanol. The mixture was heated under reflux for 1 h, evaporated, poured into water, and extracted with chloroform. Evaporation of the solvent gave 4-methoxy-9,10-dihydro-10-(3,5-dimethylbenzyl)-9-anthrol as a pale yellow solid, which was shown to be of a single isomer by ^{1}H NMR. The alcohol was immediately treated with 10 g of phosphorus pentaoxide in 50 mL of carbon tetrachloride under reflux for 2 h. Removal of the solid and evaporation of the solvent gave 506 mg of a yellow oil, which was shown to be a 5 : 1 mixture of the desired anthracene and a by-product which was spectrally assigned to a homotriptycene derivative **17** [^{1}H NMR (CCl_4, δ): 2.00 (3H, s), 2.54 (3H, s), 3.08 (2H, d, J= 4 Hz), 3.72 (3H, s), 4.63 (1H, t, J=4 Hz), 5.17 (1H, s).] Recrystallization of the mixture from hexane gave a pure sample of the anthracene, mp 112—113 °C. Found: C, 88.38; H, 6.79%. Calcd for $C_{24}H_{22}O$: C, 88.31; H, 6.79%. ^{1}H NMR ($CDCl_3$, δ): 2.17 (6H, s), 3.72 (3H, s), 5.20 (2H, s), 6.65 (1H, m), 6.72 (3H, s), 7.1—8.3 (6H, m), 8.30 (1H, s).



17

1,8-Dichloro-9-benzylanthracene, mp 110—112 °C, was prepared from 1,8-dichloroanthrone and benzylmagnesium chloride in 67% yield. Found: C, 74.92; H, 3.91; Cl, 21.35%. Calcd for $C_{21}H_{14}Cl_2$: C, 74.79; H, 4.18; Cl, 21.03%. ^{1}H NMR ($CDCl_3$, δ): 5.63 (2H, s), 6.4—7.9 (11H, m), 8.28 (1H, s).

General Procedure for the Synthesis of Triptycenes by Benzyne Reaction. To a boiling solution of 1 mmol of an anthracene and 1 mL of isopentyl nitrite in 30 mL of dichloromethane was added a solution of 2—3 mmol of an anthranilic acid in 10 mL of tetrahydrofuran in the course of 1 h and the mixture was heated under reflux for further 1 h. The desired triptycene was obtained after evaporation of the solvent, column chromatography of the residue on alumina with dichloromethane–hexane as an eluent, and recrystallization of the elute from dichloromethane–hexane.

ap-*8,13-Dichloro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene* (ap-**6**). Reaction of 578 mg (1.58 mmol) of 1,8-dichloro-9-(3,5-dimethylbenzyl)anthracene with the benzyne from 3,6-dimethylanthranilic acid[21] gave 355 mg (48%) of a rotameric mixture of the triptycene ($ap/\pm sc$=9) upon column chromatography on alumina. Recrystallization from chloroform–ethanol gave 242 mg (33%) of the pure *ap* rotamer: mp 305—307 °C. Found: C, 79.30; H, 5.42; Cl ,15.02%. Calcd for $C_{31}H_{26}Cl_2$: C, 79.31; H, 5.58; Cl, 15.11%. ^{1}H NMR ($CDCl_3$, δ): 1.6—2.5 (6H, br d), 2.40 (3H, s), 2.84 (3H, s), 5.44 (2H, s), 5.58 (1H, s), 6.68 (2H, s), 6.7—7.5 (9H, m).

$\pm$sc-*8,13-Dichloro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene* ($\pm$sc-**6**). The equilibrated mixture of *ap*- and $\pm sc$-**6** was chromatographed through an alumina column with benzene–hexane (15 : 85) as an eluent. The $\pm sc$ rotamer eluted slightly faster than the *ap*. Fractions consisting of more than 85% of the $\pm sc$ rotamer were collected and recrystallized from chloroform–ethanol to give the pure $\pm sc$-**6**, mp 305—306 °C. Found: C, 79.10; H, 5.30%. Calcd for $C_{31}H_{26}Cl_2$: C, 79.31; H 5.58%. ^{1}H NMR ($CDCl_3$, δ): 1.82 (3H, br s), 2.16 (3H, s), 2.37 (3H, br s), 2.56 (3H, s), 5.20 and 5.67 (2H, AB-q, J=18 Hz), 5.56 (1H, s), 6.04 (1H, br s), 6.4—7.5 (10H, m).

8,13-Difluoro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene (**8**), mp 252—253 °C, was prepared from 1,8-difluoro-9-(3,5-dimethylbenzyl)anthracene and 3,6-dimethylanthranilic acid in 70% yield. Found: C, 85.58; H, 6.05%. Calcd for $C_{31}H_{26}F_2$: C, 85.29; H, 6.00%. NMR spectra showed that the compound existed as a 7 : 3 mixture of the *ap* and $\pm sc$ rotamers. ^{1}H NMR ($CDCl_3$, δ): 1.90 and 2.37 (br s, $\pm sc$), 2.13 (br s, *ap*), *ca.* 2.1 (s, $\pm sc$), 2.42 (s, *ap*), 2.53 (s, $\pm sc$), 2.79 (s, *ap*), 4.88 (br s, $ap/\pm sc$), 5.66 (t, J_{HF}=2.0 Hz, $ap/\pm sc$), 6.3—7.4 (m, $ap/\pm sc$). ^{19}F NMR ($CDCl_3$): 44.8 and 54.2 ppm ($\pm sc$), and 50.9 ppm (*ap*).

1,8-Dichloro-9-(3,5-dimethylbenzyl)triptycene (**11**), mp 270—271 °C, was prepared from 1,8-dichloro-9-(3,5-dimethylbenzyl)anthracene and anthranilic acid in 47% yield. Found: C, 78.96; H, 4.90; Cl, 16.09%. Calcd for $C_{29}H_{22}Cl_2$: C, 78.91; H, 5.02; Cl, 16.06%. ^{1}H NMR ($CDCl_3$, δ): 1.7—2.6 (6H, br s), 4.75 and 5.90 (2H, AB-q, J=18 Hz), 5.35 (1H, s), 6.7—7.6 (13H, m).

1-Methoxy-9-(3,5-dimethylbenzyl)triptycene (**12**), mp 239—240 °C, was prepared from 1-methoxy-9-(3,5-dimethylbenzyl)-anthracene and anthranilic acid in 29% yield. Found: C, 89.60; H, 6.49%. Calcd for $C_{30}H_{26}O$: C, 89.51; H, 6.51%. ^{1}H NMR ($CDCl_3$, δ): 2.18 (6H, s), 3.27 (3H, s), 4.62 (2H, s), 5.38 (1H, s), 6.4—7.6 (14H, m).

9-(3,5-Dimethylbenzyl)triptycene (**13**), mp 215—217 °C, was prepared from 9-(3,5-dimethylbenzyl)anthracene and anthranilic acid in 46% yield. Found: C, 93.81; H, 6.37%. Calcd for $C_{29}H_{24}$: C, 93.51; H, 6.49%. ^{1}H NMR ($CDCl_3$, δ): 2.19 (6H, s), 4.41 (2H, s), 5.42 (1H, s), 6.7—7.6 (15H, m).

2-Methoxy-9-(3,5-dimethylbenzyl)triptycene (**14**), mp 196—197 °C, was prepared from 2-methoxy-9-(3,5-dimethylbenzyl)-anthracene and anthranilic acid in 19% yield. Found: C, 89.59; H, 6.39%. Calcd for $C_{30}H_{26}O$: C, 89.52; H, 6.51%. ^{1}H NMR ($CDCl_3$ δ): 2.19 (6H, s), 3.56 (3H, s), 4.37 (2H, s), 5.34 (1H, s), 6.48 (1H, dd, J=8 and 3 Hz), 6.7—7.5 (13H, m).

9-[1-(3,5-Dimethylphenyl)ethyl]triptycene (**15**), mp 179—180 °C, was prepared from 9-[1-(3,5-dimethylphenyl)ethyl]-anthracene and anthranilic acid in 62% yield. Found: C, 93.00; H, 6.81%. Calcd for $C_{30}H_{26}$: C, 93.22; H, 6.78%. ^{1}H NMR ($CDCl_3$, δ): 2.07 (3H, d, J=7.2 Hz), 2.19 (6H, s), 4.71 (1H, q, J=7.2 Hz), 5.37 (1H, s), 6.5—7.9 (15H, m).

1,8-Dichloro-9-benzyltriptycene (**16**), mp 239—241 °C, was prepared from 1,8-dichloro-9-benzylanthracene and anthranilic acid in 52% yield. Found: C, 78.42; H, 4.18; Cl, 17.07%. Calcd for $C_{27}H_{18}Cl_2$: C, 78.46; H, 4.39; Cl, 17.15%. ^{1}H NMR ($CDCl_3$, δ): 4.80 and 5.98 (2H, AB-q, J=18 Hz), 5.33 (1H, s), 6.5—7.6 (15H, m).

General Procedure for the Synthesis of Triptycenes by p-*Benzoquinone Addition.* A mixture of 2 mmol of an anthracene and 10 mmol of *p*-benzoquinone in 30 mL of acetonitrile was heated under reflux for 40 h. After evaporation of the solvent and removal of most of the unreacted *p*-benzoquinone by sublimation, the residue was dissolved in 20 mL of 1,4-dioxane and stirred with an aqueous solution of 0.5 g of potassium hydroxide and 1 mL of dimethyl sulfate overnight at room temperature and then at 90 °C for 1 h. The reaction mixture was extracted with diethyl ether, and the ether layer was washed with water and dried over magnesium sulfate. Evaporation and column chromatography on alumina followed by recrystallization from dichloromethane–hexane gave the desired triptycene.

8,13-Dichloro-1,4-dimethoxy-9-(3,5-dimethylbenzyl)triptycene(7), mp 277—278 °C, was prepared from 1,8-dichloro-9-(3,5-dimethylbenzyl)anthracene in 52% yield. Found: C, 74.38; H, 5.11; Cl, 14.02%. Calcd for $C_{31}H_{26}Cl_2O_2$: C, 74.25; H, 5.23; Cl, 14.14%. ^{1}H NMR ($CDCl_3$, δ): 1.5—2.5 (6H, br d), 2.89 (3H, s), 3.85 (3H, s), 5.29 and 5.54 (2H, AB-q, J=18 Hz), 6.38 and 6.62 (2H, AB-q, J=9 Hz), 6.6—7.5 (9H, m).

8,13-Difluoro-1,4-dimethoxy-9-(3,5-dimethylbenzyl)triptycene (9), mp 265—266 °C, was prepared from 1,8-difluoro-9-(3,5-dimethylbenzyl)anthracene in 25% yield. Found: C, 79.36; H, 5.54%. Calcd for $C_{31}H_{26}F_2O_2$: C, 79.47; H, 5.59%. NMR spectra showed the existence of the *ap* and $\pm sc$ rotamers in the ratio of 1 : 3. ^{1}H NMR ($CDCl_3$, δ): 1.93 and 2.34 (br s, $\pm sc$), 2.13 (br s, *ap*), 2.90 (s, $\pm sc$), 3.75 (s, *ap*), 3.78 (s, *ap*), 3.82 (s, $\pm sc$), 4.6—5.1 (br m, *ap*/$\pm sc$), 5.91 (t, J_{HF}= 2 Hz, *ap*/$\pm sc$), 6.2—7.4 (m, *ap*/$\pm sc$). ^{19}F NMR ($CDCl_3$): 45.7 and 52.6 ppm ($\pm sc$), and 51.4 ppm (*ap*).

Kinetics of Isomerization of ap-**6**. A solution of *ap*-**6** in $CDCl_3$ (*ca.* 10%(w/v)) in an NMR sample tube was inserted to the NMR probe heated at constant temperature which was calibrated using ethylene glycol, and the change in the relative intensity of the singlets at δ 2.84 (*ap*) and 2.54 ($\pm sc$) was followed. The rate law for a first order reversible reaction is given by Eq. 3,

$$\log\left[1-\left(1+\frac{1}{K}\right)\frac{x}{a}\right]=-\frac{2k_1}{2.303}\left(1+\frac{1}{K}\right)t, \qquad (3)$$

where a is the initial quantity of the *ap*-**6**, x the quantity of $\pm sc$-**6** at time t and K the equilibrium constant $[\pm sc]/[ap]$. The left side of the Equation was obtained from the NMR measurement and plotted against t to afford a good straight line, the slope of which gave the rate constant k_1, from which $\Delta G^{\ddagger}$ was calculated. Determination of the rate constants was made at four temperatures between 48 and 69 °C and the Eyring plot gave $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values.

Restricted Rotation Involving the Tetrahedral Carbon. XXXVI.[1] Stereodynamics of 9-(2-Methylbenzyl)triptycene Derivatives

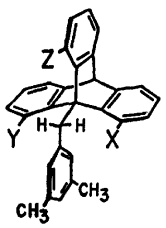
Gaku YAMAMOTO and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 19, 1980)

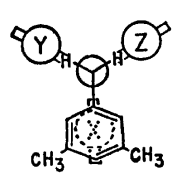
DNMR study of a series of singly *peri*-substituted 9-(2-methylbenzyl)triptycene derivatives showed that the interconversion among the *ap* and $\pm sc$ rotamers with the *o*-methyl group pointing outside the triptycyl skeleton occurs by two consecutive gear motion steps by way of the unstable rotamers with the *o*-methyl group pointing inside. The $+sc \rightleftharpoons -sc$ interconversion barriers (13.2—14.1 kcal/mol) are lower than the $ap \rightleftharpoons \pm sc$ ones (17.7—20.8 kcal/mol). The aryl group passes over a *peri*-hydrogen at the transition state of the former process and over the *peri*-substituent in the latter.

Our recent DNMR study on 9-(3,5-dimethylbenzyl)-triptycene derivatives[2] has revealed the freezing of the conformation **1** at low temperatures rendering the two *m*-methyl groups in the benzyl moiety diastereotopic and anisochronous. The coalescence of the two *m*-methyl

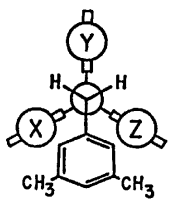


1

groups caused by the temperature rise indicates the occurence of rate processes which exchange the magnetic environments of the two methyl groups. In order to understand the stereodynamic behavior, two degrees of freedom of internal rotation should be considered: rotation about the bridgehead-to-methylene bond and that about the methylene-to-aryl bond. Rotation about the bridgehead-to-methylene bond by 120° is assumed to occur by way of the transition state shown by **2**, being always accompanied by the rotation about the methylene-to-aryl bond by 180°, thus exchanging the magnetic environments of the two methyl groups if the conformations before and after the process are homomeric (X=Y=Z) or enantiomeric (Y=Z) to each other. We refer to this process as "gear motion (GM)." Exchange of the methyl groups can occur not only by GM but also by a process in which the methylene-to-aryl bond rotates by 180° without rotating the bridgehead-to-methylene bond, by way of the transition state **3**. We refer to this process as "isolated rotation (IR)." It was shown[2] that the two processes actually participate in the methyl exchange in compounds **1** as detected by DNMR and the relative contribution of the processes is dependent on the number and size of the *peri*-substituents; IR is the main process in triply *peri*-substituted derivatives, GM predominating in the *peri*-unsubstituted ones. This comes from the fact that the GM barrier sharply drops with decrease in the number of the *peri*-substituents while the IR barrier is less sensitive to the *peri*-substitution.

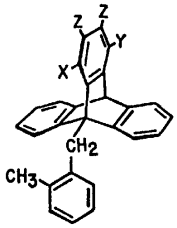


2



3

The structural modification which raises the IR barrier is expected to make GM the sole process rendering the rotations about the bridgehead-to-methylene and the methylene-to-aryl bonds completely correlated. In order to attain this situation we planned to introduce a methyl group in one of the ortho positions of the benzylic phenyl group. We have synthesized a series of singly *peri*-substituted 9-(2-methylbenzyl)triptycene derivatives (**4**—**8**) and examined their DNMR behavior to find that the observed process can best be explained in terms of correlated motion of the bonds under consideration.[3]

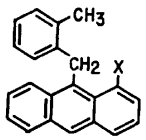


4: X=OCH_3, Y=Z=H
5: X=Y=CH_3, Z=H
6: X=CH_3, Y=Z=H
7: X=Cl, Y=Z=H
8: X=Y=Z=Cl

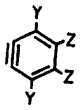
Ample examples have been reported on correlated rotation of two or more sp^3-sp^2 or sp^2-sp^2 bonds in triarylmethanes,[4] tetraarylethanes,[5] triarylboranes,[4] and triarylamines[6] and other systems. The present results constitute the first example of correlated rotation of an sp^3-sp^2 and an sp^3-sp^3 bonds.

Results and Discussion

Syntheses. Triptycenes **4**—**8** were synthesized by the reaction of 9-(2-methylbenzyl)anthracene derivatives **9a**—**d** with benzynes **10a**—**c** generated *in situ* from the corresponding anthranilic acids (**9c**+**10a**→**4**, **9a**+**10b**→**5**, **9d**+**10a**→**6**, **9b**+**10a**→**7**, and **9a**+**10c**→**8**). Anthracenes **9a** and **9b** were prepared by the Grignard reaction of 2-methylbenzyl chloride with 1-substituted anthrones **11**, followed by dehydration with thionyl chloride–pyridine. Synthesis of anthracene **9c**



9a: X=H
9b: X=Cl
9c: X=OCH_3
9d: X=CH_3



10a: Y=Z=H
10b: Y=CH_3, Z=H
10c: Y=Z=Cl

by the Grignard reaction of 1-methoxyanthrone (**11**: X=OCH_3) was abandoned because preliminary examination of the anthrone suggested that it existed not as a keto form but as an enol form. 4-Methoxyanthrone (**13a**) was condensed with 2-methylbenzyl chloride to give 4-methoxy-10-(2-methylbenzyl)anthrone (**14a**). Reduction with sodium borohydride followed by dehydration with either phosphorus pentaoxide or thionyl chloride–pyridine gave **9c**. Anthracene **9d** was also prepared by 2-methylbenzylation of 4-methylanthrone (**13b**) followed by reduction and dehydration because of the easier availability of the anthrone **13b** as compared with 1-methylanthrone (**11**: X=CH_3).

Rotamer Equilibrium. ^{1}H NMR data at low temperatures (*ca.* −30 °C) are given in Tables 1 and 2. Both of the *ap* and ±*sc* rotamers with respect to the bridgehead-to-methylene bond were present in each compound. Methylene protons of the *ap* rotamer appeared as a singlet, while those of the ±*sc* rotamer did as an AB-quartet. *o*-Methyl protons appeared as two singlets of the relative intensity corresponding to the *ap*/±*sc* ratio with the exception of **4** in $CDCl_3$

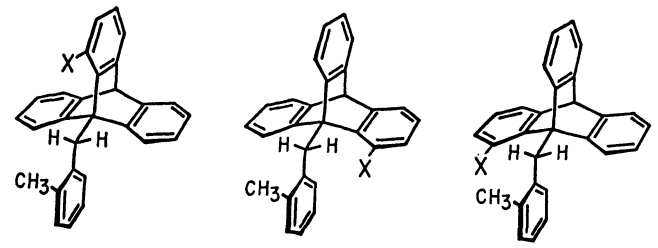
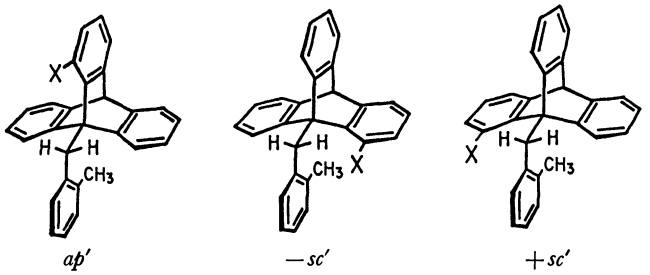
where coincidence of the chemical shifts occurred. 1-Methoxyl protons in **4**, 1- and 4-methyls in **5**, and 1-methyl in **6** also appeared as two singlets reflecting the presence of two rotamers.



ap *−sc* *+sc*



ap′ *−sc′* *+sc′*

Scheme 1.

It is assumed that the benzylic moiety adopts a conformation in which the benzene ring is coplanar with the bridgehead-to-methylene bond as decuced for 9-benzyl-[7] and 9-(3,5-dimethylbenzyl)triptycenes,[2] and that the *o*-methyl group points toward outside the triptycyl skeleton as shown in Scheme 1. This is supported by ^{1}H NMR spectra. The *o*-methyl signal resonated at δ 2.6—2.7 (Table 1), considerably lower field than the methyl signal of toluene (δ 2.32) or *o*-xylene (δ 2.25),[8] suggesting that the methyl group is located in the deshielding region of the ring current effect of the triptycyl benzene rings in line with the conformations. A multiplet signal assigned to the 6-proton of the 2-methylbenzyl group appeared at higher field of the aromatic region of δ 6.2—6.4 which is also consistent with the suggested conformations. Molecular model consideration indicates that the conformers with the *o*-methyl group pointing inside (*ap′* and $\pm sc'$ in Scheme 1) would be highly unstable because of the severe steric interaction between the methyl group and the triptycyl moiety. If these rotamers could exist in a detectable amount, the *o*-methyl group would show a definite signal at a considerably higher field, since the rotamers should have lifetimes long enough for detection on the NMR time scale at these low temperatures. No such signals were detected at δ 0—2 region, and these rotamers were concluded to be at least 2.0 kcal/mol (1 kcal/mol=4.18 kJ/mol) less stable than the rotamers with *o*-methyl group outside.

No significant temperature dependence of the equilibrium constants ($\pm sc/ap$) was detected except for **5** and **6**, which showed a slight increase of the $\pm sc$ rotamers at higher temperatures. The equilibrium constants of **4**—**8** were similar to those of the corresponding 9-benzyltriptycenes,[7,9] suggesting that the interaction between the aryl and the triptycyl moieties do not largely differ in these two systems.

DNMR Behavior. Upon gradual elevation of the temperature the AB-quartet signal due to the methylene protons of the $\pm sc$ rotamer broadened and then coalesced into a singlet in the range of −1 to 17 °C depending on the compound, while the other part of the spectrum except for the aromatic region showed no noticiable change. This indicates that the interconversion between the $+sc$ and $-sc$ rotamers becomes fast on the NMR time scale in the temperature range. The rate constants and the free energies of activation at the coalescence temperatures for the $+sc \rightleftharpoons -sc$ interconversion were calculated; the results are given in Table 3.

The $\pm sc$-methylene signal sharpened on further elevation of temperature until the half-width of the signal became *ca.* 2.5 Hz, almost the same as that of

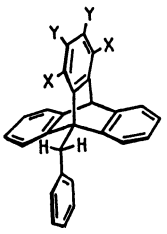
a) Extrapolated to T_c.

the *ap*-methylene singlet, and then began to broaden together with the *ap*-methylene signal. Finally these two signals coalesced into a singlet in the temperature region 66—112 °C.

These coalescence phenomena of the singlets of unequal intensity were analyzed according to the method of Jaeschke *et al.*,[10] affording the rate data for the $ap \rightleftharpoons \pm sc$ interconversion. The rate constants thus obtained and the free energies of activation at the coalescence temperatures are given in Table 4.

The other pairs of signals due to the two rotamers, *i.e.*, *o*-methyls of **4**—**8**, 1-methoxyl of **4**, 1-methyls of **5** and **6**, and 4-methyl of **5** also showed similar coalescence phenomena. DNMR data from some of these signals are also included in Table 4. Free energies of activation obtained from the analysis of different signals agree with each other to support the validity of the approximation in deriving these values if we consider that the entropies of activation would be small for internal rotation.

The observation that, while the signals due to the *ap* rotamer remained completely intact, the coalescence of the AB-quartet signal due to the $\pm sc$-methylene protons occurred suggests that the $+sc \rightleftharpoons -sc$ interconversion takes place without intervention of the *ap* rotamer. An explanation for this is that the interconversion occurs by two consecutive gear motion steps by way of the unstable *ap'* rotamer with the *o*-methyl group pointing inside. The two transition states lying between the *ap'* and $\pm sc$ rotamers, where the aryl group passes over a *peri*-hydrogen, are enantiomeric to each other. The energy barriers to this process can be compared with those to the $ap \rightleftharpoons \pm sc$ process of the corresponding non-*o*-methylated analogs since the two processes have similar transition states. Thus the free energies of activation for the $\pm sc \rightarrow ap$ process of **16a** to **16c** are 12.2,[9a] 13.6,[7b] and 13.5 kcal/mol,[9b] respectively, calculated for 0 °C from the available data. They are 0.6—1.1 kcal/mol lower than those of the corresponding *o*-methylated analogs. This is understandable if we consider that the presence of the *o*-methyl group should raise the transition state to some extent.



16a: X=OCH_3, Y=H
16b: X=CH_4, Y=H
16c: X=Y=Cl

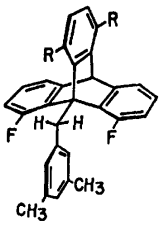
The IR process of $ap' \rightleftharpoons ap$ should have a higher barrier than the $ap' \rightleftharpoons \pm sc$ step, otherwise the coalescence of the *ap*-methylene signal with those of the $\pm sc$-methylene should have occurred at the same time as the coalescence of the AB-quartet signal of the $\pm sc$-methylene.

Interconversion between the *ap* and $\pm sc$ rotamers can occur by two types of pathways. One consisting of two consecutive gear motion steps ($ap \rightleftharpoons \mp sc' \rightleftharpoons \pm sc$) and the other consisting of a gear motion (GM) step and an isolated rotation (IR) step ($ap \rightleftharpoons \pm sc' \rightleftharpoons \pm sc$ with IR in the $\pm sc$ sites or $ap \rightleftharpoons ap' \rightleftharpoons \pm sc$ with IR in the *ap* site). Of these two possible pathways, the former (2GM) seems more reasonable than the latter (GM-IR) as a process actually occurring. The feasibility is discussed from the *peri*-substituent effects on the barrier in the following sections.

If the $ap \rightleftharpoons \pm sc$ interconversion takes place by the GM-IR pathways, the rate determining step should be IR since the barrier to the GM steps should be *ca.* 14 kcal/mol as was actually observed for the $\pm sc \rightleftharpoons ap'$ step (Table 3), while the barriers observed for the process in question are much higher (Table 4). Studies on 9-(3,5-dimethylbenzyl)triptycenes revealed that the bulkier *peri*-substituent flanking the aryl group raises the IR barrier as a result of destabilization of the transition state to a greater extent than the ground state.[2] Considering that the presence of the *o*-methyl group in the present case would increase the dependence of the IR barrier on the flanking *peri*-groups, we can reasonably assume that the $\pm sc \rightleftharpoons \pm sc'$ barrier should be larger than the $ap \rightleftharpoons ap'$ barrier. Even though we may have to take the difference of the *ap*-substituent into account (*vide infra*), the effect of the *ap*-substituent

is not large enough to revert the circumstance. The GM-IR process should occur by the $ap \rightleftharpoons ap' \rightleftharpoons \pm sc$ pathway rather than the $ap \rightleftharpoons \pm sc' \rightleftharpoons \pm sc$ pathway, if at all.

The energy barrier to the IR process in 9-(3,5-dimethylbenzyl)triptycene derivatives was found to decrease with a larger *peri*-substituent at the *ap*-position to the aryl group,[2] *e.g.*, the IR barrier in the *ap* rotamer of compound **17a** (13.5 kcal/mol) is lower by 1.0 kcal/



17a: R=CH_3
17b: R=OCH_3

mol than that in the *ap* rotamer of compound **17b** (14.5 kcal/mol). This was explained by assuming that the ground state was destabilized due to the buttressing effect of a bulky *ap*-substituent pushing the aryl moiety into the triptycyl skeleton, while the transition state for the IR was not appreciably affected. In 9-(2-methylbenzyl)triptycenes, the steric situation of the ground state is similar to that of 9-(3,5-dimethylbenzyl)-triptycenes, destabilization of the ground state by the bulkier *ap*-substituent being expected. Although it is difficult to estimate the effect of the *ap*-substituent on the transition state of the IR process, molecular model consideration suggests that the effects should be small if any. Thus replacement of the *ap*-substituent with a bulkier one is expected to lower the $ap \rightleftharpoons ap'$ IR barrier to a small extent, and to lower the $ap \rightleftharpoons \pm sc$ barrier observed by DNMR.

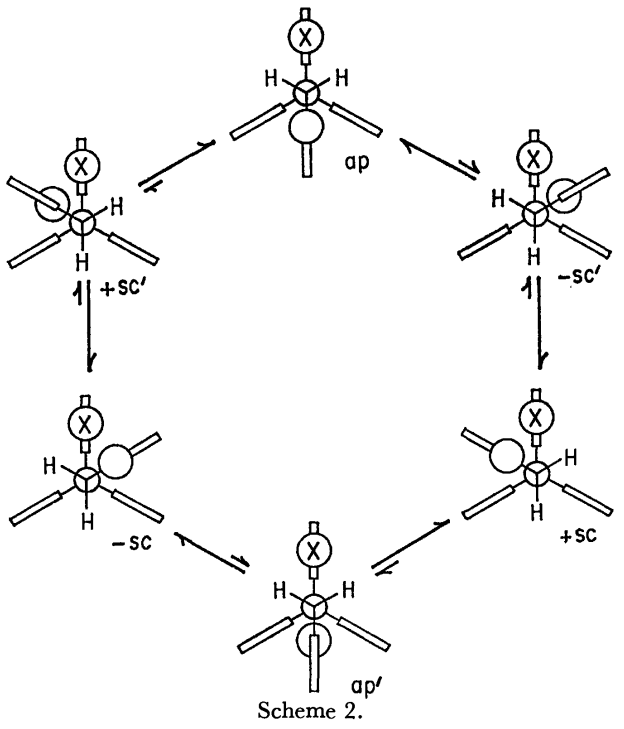
As Table 4 shows, the contrary to the above discussion is true: the $ap \rightleftharpoons \pm sc$ barrier increases with the increasing bulkiness of the *peri*-substituent. Thus the GM-IR process is not the lowest energy pathway of the $ap \rightleftharpoons \pm sc$ interconversion.

In the 2GM process, the $\pm sc \rightleftharpoons \mp sc'$ step should be rate-determining because the aryl group passes over the *peri*-substituent. The energy barrier to this process is naturally expected to increase with the bulkier *peri*-substituent, this being actually observed (Table 4). It is thus reasonable to consider that the $ap \rightleftharpoons \pm sc$ interconversion occurs by the 2GM process.

The process with two consecutive gear motion steps is concluded to be responsible not only for the $+sc \rightleftharpoons -sc$ interconversion but also for the $ap \rightleftharpoons \pm sc$ interconversion in this 9-(2-methylbenzyl)triptycene system (Scheme 2).

The energy diagram for rotation about the bridgehead-to-methylene bond can be drawn as in Fig. 1. Rotation by 720° about the bridgehead-to-methylene bond is required to complete the rotational circuit. Neither the depth of the wells corresponding to the unstable *ap'* and $\pm sc'$ rotamers is known, nor the height of the enantiomeric saddle points between the *ap* and $\pm sc'$ rotamers, which are presumably of almost the same relative height from the nearest minima as those between the *ap'* and $\pm sc$ rotamers.

Total line shape analysis of the DNMR spectra of



Scheme 2.

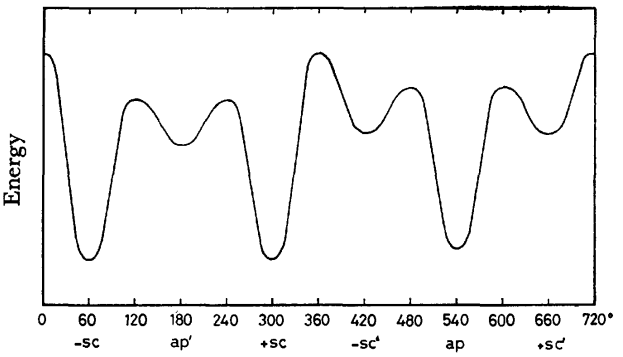


Fig. 1. Energy diagram for rotation about the bridgehead-to-methylene bond.

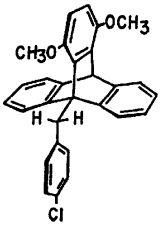
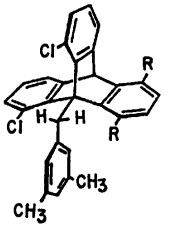
1,4-dimethoxy-9-(4-chlorobenzyl)triptycene (**18**) suggests that the $+sc \rightleftharpoons -sc$ process in which the aryl group passes over the *peri*-methoxyl group has an energy barrier *ca.* 1 kcal/mol higher than that to the $ap \rightleftharpoons \pm sc$ process in which the aryl group passes over a *peri*-hydrogen.[9a] The energy barrier difference between the $\pm sc \rightleftharpoons ap'$ and $\pm sc \rightleftharpoons \mp sc'$ steps in compound **4** is 4.8 kcal/mol from Tables 3 and 4, which is considerably larger than that of the above case. The reason for the



18



19a: R=H
19b: R=OCH_3

difference is unknown at the moment although the *o*-methyl group must affect the transition states of these two steps.

Energy barriers to the $+sc \rightleftharpoons -sc$ interconversion in compounds **19a** and **19b** were determined to be 15.7 and 22.1 kcal/mol, respectively.[2] The difference of 6.4 kcal/mol can be compared with the data for **4**. The buttressing effect of the *peri*-chloro groups in the transition state may be responsible for the larger difference for compounds **19**, if we neglect the energy difference in the ground states.

Experimental

Melting points are not corrected. ^{1}H NMR spectra at ambient temperature (*ca.* 35 °C) were recorded on either a Hitachi R-20B (60 MHz) or a Varian EM-390 (90 MHz) spectrometer with tetramethylsilane as an internal standard.

DNMR Spectra. Sample solutions were prepared by dissolving the compounds in an appropriate solvent containing 0.5% of tetramethylsilane (in case of $CDCl_3$) or hexamethyldisiloxane (in case of toluene-d_8 and chlorobenzene). The concentration was *ca.* 10% (w/v) for compounds **4**—**6** and *ca.* 6% for **7** and **8** because of the poor solubility. Variable temperature ^{1}H NMR spectra were obtained on a Hitachi R-20B spectrometer. Temperature was calibrated with ethylene glycol or methanol.[11] Rate constants at the coalescence temperatures from coalescing AB-quartet signals were calculated by[12]

$$k_c = \frac{\pi}{\sqrt{2}}\sqrt{(\Delta\delta)^2 + 6J_{AB}{}^2}.$$

Rate constants from two coalescing singlets of unequal intensity were obtained by the graphical method of Jaeschke *et al.*[10] which takes the line widths of the signals without exchange into account. Graphical method of Shanan-Atidi and Bar-Eli[13] which neglects the line widths gave similar results only when the chemical shift differences of the two singlets were sufficiently large (>20 Hz), the inconsistency between the two methods becoming large when the chemical shift differences were small.

*9-(2-Methylbenzyl)anthracene (**9a**).* To the Grignard reagent in 60 mL of diethyl ether prepared from 5.62 g (40 mmol) of 2-methylbenzyl chloride[14] was added portionwise 3.38 g (20 mmol) of anthrone powder. The mixture was stirred at room temperature for 2 h and decomposed with saturated aqueous ammonium chloride. After evaporation of the solvent, the crude 9-(2-methylbenzyl)-9,10-dihydro-9-anthrol (^{1}H NMR (CCl_4, δ): 1.40 (3H, s), 2.25 (1H, s), 2.88 (2H, s), 2.91 and 3.41 (2H, AB-q, J=19 Hz), 6.1—7.8 (12H, m) was dissolved in 50 mL of benzene and treated with 3 mL of thionyl chloride and 6 mL of pyridine at 50 °C for 1 h. The reaction mixture was cooled, washed with water and dried over sodium sulfate. The crude product was recrystallized from tetrahydrofuran–hexane to give 4.02 g (71%) of yellow granules, mp 165—167 °C. Found: C, 93.61; H, 6.22%. Calcd for $C_{22}H_{18}$: C, 93.57; H, 6.43%. ^{1}H NMR ($CDCl_3$, δ): 2.62 (3H, s), 4.81 (2H, s), 6.2—8.2 (12H, m), 8.42 (1H, s).

*1-Chloro-9-(2-methylbenzyl)anthracene (**9b**).* To the Grignard reagent in 50 mL of diethyl ether prepared from 2.11 g (15 mmol) of 2-methylbenzyl chloride[14] was added portionwise 2.29 g (10 mmol) of 1-chloroanthrone[15] and the mixture was stirred at room temperature for 2 h and decomposed with saturated aqueous ammonium chloride. Evaporation of the solvent gave 2.55 g of the crude 1-chloro-9-(2-methylbenzyl)-9,10-dihydro-9-anthrol; ^{1}H NMR ($CDCl_3$, δ): 1.47 (3H, s), 2.65 and 3.45 (2H, AB-q, J=20 Hz), 3.16 and 3.51 (2H, AB-q, J=12.6 Hz), 3.75 (1H, s), 6.17 (1H, d, J=7 Hz), 6.5—7.9 (10H, m). Treatment of the alcohol with 2 mL of thionyl chloride and 4 mL of pyridine at 50 °C for 1 h followed by column chromatography on alumina with benzene–hexane (1 : 4) as an eluent gave 1.86 g (59%) of **9b**, mp 134—135 °C (from tetrahydrofuran–hexane). Found: C, 83.62; H, 5.23; Cl, 11.15%. Calcd for $C_{22}H_{17}Cl$: C, 83.40; H, 5.41; Cl, 11.19%. ^{1}H NMR ($CDCl_3$, δ): 2.53 (3H, s), 5.13 (2H, s), 6.5—8.1 (11H, m), 8.40 (1H, s).

*1-Methoxyanthrone (**11**: $X=OCH_3$).* A mixture of 715 mg (3 mmol) of 1-methoxyanthraquinone[2] and 0.8 g of copper powder in 10 mL of concentrated sulfuric acid was stirred at 40—45 °C for 3 h, poured onto ice–water, and extracted with benzene. The benzene layer was washed with aqueous sodium hydrogencarbonate and then with water, dried over magnesium sulfate, and evaporated to give 265 mg (39%) of orange crystals upon recrystallization from dichloromethane–hexane, mp 86—88 °C. The compound was too unstable to give satisfactory elemental analysis. Spectral data were consistent with the enol form, 1-methoxy-9-anthrol; ^{1}H NMR ($CDCl_3$, δ): 3.96 (3H, s), 6.52 (1H, dd), 7.0—7.6 (4H, m), 7.76 (1H, s), 7.85 (1H, m), 8.40 (1H, m), 10.12 (1H, s). IR (Nujol): 3340 cm^{-1}, no carbonyl stretching.

*4-Methoxy-10-(2-methylbenzyl)anthrone (**14a**).* To a mixture of 1.12 g (5 mmol) of 4-methoxyanthrone (**13a**)[2] and 0.75 mL of 2-methylbenzyl chloride[14] in 40 mL of methanol under nitrogen atmosphere was added dropwise 0.4 g of potassium hydroxide in 15 mL of methanol in the course of 2 h and the mixture was stirred at room temperature for further 2h. Yellow solid formed was collected by filtration, washed with methanol and recrystallized from tetrahydrofuran–methanol to give 1.38 g (84%) of **14a**: mp 151—152 °C. Found: C, 84.26; H, 5.97%. Calcd for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%. ^{1}H NMR ($CDCl_3$, δ): 1.84 (3H, s), 2.67 (1H, *A*BX-dd, J=13.0 and 8.7 Hz), 3.25 (1H, A*B*X-dd, J=13.0 and 4.7 Hz), 3.91 (3H, s), 4.70 (1H, AB*X*-dd, J=8.7 and 4.7 Hz), 6.4—8.3 (11H, m).

*1-Methoxy-9-(2-methylbenzyl)anthracene (**9c**).* To a boiling solution of 1.68 g (5.12 mmol) of 4-methoxy-10-(2-methylbenzyl)anthrone (**14a**) in 50 mL of ethanol was added dropwise a solution of 1.5 g of sodium borohydride in 20 mL of 90% aqueous ethanol and the mixture was heated under reflux for 2 h. After evaporation of the solvent, the mixture was poured into water and extracted with chloroform. The chloroform solution was washed with water, dried over magnesium sulfate, and evaporated to give crude 4-methoxy-10-(2-methylbenzyl)-9,10-dihydro-9-anthrol (single isomer of undecided stereochemistry; ^{1}H NMR ($CDCl_3$, δ): 1.88 (3H, s), 2.18 (1H, d, J=11 Hz), 2.79 (1H, *A*BX-dd, J=12.8 and 7.5 Hz), 2.95 (1H, A*B*X-dd, J=12.8 and 5.7 Hz), 3.76 (3H, s), 4.65 (1H, AB*X*-dd, J=7.5 and 5.7 Hz), 5.19 (1H, d, J=11 Hz), 6.3—7.9 (11H, m)). The alcohol was dissolved in 50 mL of carbon tetrachloride and heated under reflux with 20 g of phosphorus pentaoxide for 1.5 h. The solid mass was filtered off and washed with carbon tetrachloride. The combined organic solution was evaporated affording 0.87 g (54%) of **9c** upon recrystallization from benzene–hexane (1 : 9): mp 145—146 °C. Found: C, 88.66; H, 6.37%. Calcd for $C_{23}H_{20}O$: C, 88.42; H, 6.45%. ^{1}H NMR ($CDCl_3$, δ): 2.57 (3H, s), 3.57 (3H, s), 5.08 (2H, s), 6.3—8.2 (11H, m), 8.33 (1H, s).

*4-Methyl-10-(2-methylbenzyl)anthrone (**14b**).* To a stirred mixture of 2.08 g (10 mmol) of 4-methylanthrone[16] and 1.4 mL of 2-methylbenzyl chloride[14] in 80 mL of methanol was added dropwise a solution of 0.6 g of potassium hydroxide in 30 mL of methanol in the course of 2 h under nitrogen atmos-

phere and the mixture was stirred at room temperature for further 2 h. After evaporation of the solvent, the residue was extracted with diethyl ether. The ether layer was washed with water, dried over sodium sulfate and evaporated to afford 1.67 g (53%) of **14b** after recrystallization from dichloromethane–hexane: mp 135—136 °C. Found: C, 88.50; H, 6.15%. Calcd for $C_{23}H_{20}O$: C, 88.42; H, 6.45%. ^1H NMR ($CDCl_3$, δ): 1.60 (3H, s), 2.52 (3H, s), 2.78 (1H, *A*BX-dd, J=13.8 and 8.1 Hz), 3.10 (1H, A*B*X-dd, J=13.8 and 5.4 Hz), 4.54 (1H, AB*X*-dd, J=8.1 and 5.4 Hz), 6.5—7.6 (9H, m), 8.0—8.3 (2H, m).

1-Methyl-9-(2-methylbenzyl)anthracene (9d). To a boiling solution of 1.26 g (4.0 mmol) of 4-methyl-10-(2-methylbenzyl)-anthrone (**14b**) in 50 mL of ethanol was added a solution of 1.3 g of sodium borohydride in 20 mL of 90% aqueous ethanol and the mixture was heated under reflux for 2 h. Evaporation of the solvent and extraction with diethyl ether gave 1.09 g (87%) of 4-methyl-10-(2-methylbenzyl)-9,10-dihydro-9-anthrol (single isomer of undecided stereochemistry); ^1H NMR ($CDCl_3$, δ): 1.74 (3H, s), 2.24 (3H, s), 2.50 (1H, d, J= 10 Hz), 2.79 (2H, d, J=6.9 Hz), 4.33 (1H, t, J=6.9 Hz), 5.27 (1H, d, J=10 Hz), 6.5—7.9 (11H, m). The alcohol in 50 mL of benzene was treated with 1 mL of thionyl chloride and 2 mL of pyridine at 70 °C for 5 h to give **9d** in 76% yield: mp 150—151 °C. Found: C, 93.19; H, 6.68%. Calcd for $C_{23}H_{20}$: C, 93.20; H, 6.80%. ^1H NMR ($CDCl_3$ δ): 2.56 (3H s), 2.75 (3H, s), 4.94 (2H, s), 6.5—7.6 (8H, m), 7.8—8.2 (3H, m), 8.48 (1H, s).

General Procedure of Benzyne Addition to Anthracenes. A solution of 2.0—3.0 mmol of an anthranilic acid in 20 mL of tetrahydrofuran was added dropwise to a boiling solution of 1.5 mmol of an anthracene and 1 mL of isopentyl nitrite in 30 mL of dichloromethane in the course of 1 h and the mixture was heated under reflux for further 1 h. After evaporation of the solvent, the residue was chromatographed through an alumina column using benzene–hexane mixture as an eluent. Recrystallization from tetrahydrofuran–ethanol gave a triptycene derivative as colorless crystals.

1-Methoxy-9-(2-methylbenzyl)triptycene (4), mp 258—259 °C, was prepared from 1-methoxy-9-(2-methylbenzyl)anthracene (**9c**) and anthranilic acid in 69% yield. Found: C, 89.77; H, 6.46%. Calcd for $C_{29}H_{24}O$: C, 89.65; H, 6.23%. ^1H NMR ($CDCl_3$, δ) showed the presence of the *ap* and $\pm sc$ rotamers in the ratio of 1 : 3.6 : 2.64 (s, *ap*/$\pm sc$), 2.94 (s, $\pm sc$), 3.83 (s, *ap*), 4.34 (br s, $\pm sc$), 4.74 (br s, *ap*), 5.40 (s, *ap*/$\pm sc$), 6.3—7.6 (m, *ap*/$\pm sc$).

1,4-Dimethyl-9-(2-methylbenzyl)triptycene (5), mp 208—209 °C, was prepared from 9-(2-methylbenzyl)anthracene (**9a**) and 3,6-dimethylanthranilic acid[17] in 76% yield. Found: C, 93.23; H, 6.79%. Calcd for $C_{30}H_{26}$: C, 93.22; H, 6.78%. ^1H NMR ($CDCl_3$, δ) showed the presence of the *ap* and $\pm sc$ rotamers in the ratio of 1 : 1: 1.97 (s, $\pm sc$), 2.44 (s), 2.54 (s), 2.61 (s), 2.64 (s), 2.78 (s, *ap*), 4.33 (br s, $\pm sc$), 4.57 (s, *ap*), 5.72 (s, *ap*/$\pm sc$), 6.3—7.6 (m, *ap*/$\pm sc$).

1-Methyl-9-(2-methylbenzyl)triptycene (6), mp 235—237 °C, was prepared from 1-methyl-9-(2-methylbenzyl)anthracene (**9d**) and anthranilic acid in 28% yield. Found: C, 93.60; H, 6.24%. Calcd for $C_{29}H_{24}$: C, 93.51; H, 6.49%. ^1H NMR ($CDCl_3$, δ) showed the presence of the *ap* and $\pm sc$ rotamers in the ratio of 1 : 1: 1.97 (s, $\pm sc$), 2.59 (s), 2.63 (s), 2.78 (s, *ap*), 4.29 (br s, $\pm sc$), 4.53 (s, *ap*), 5.33 (s, *ap*/$\pm sc$), 6.3—7.6 (m, *ap*/$\pm sc$).

1-Chloro-9-(2-methylbenzyl)triptycene (7), mp 265—266 °C, was prepared from 1-chloro-9-(2-methylbenzyl)anthracene (**9b**) and anthranilic acid in 51% yield. Found: C, 85.64; H, 5.53; Cl, 9.04%. Calcd for $C_{28}H_{21}Cl$: C, 85.59; H, 5.39; Cl, 9.02%. ^1H NMR ($CDCl_3$, δ) showed the presence of the *ap* and $\pm sc$ rotamers in the ratio of 3 : 2: 2.61 (s, $\pm sc$), 2.67 (s, *ap*), 4.46 (br s, $\pm sc$), 4.79 (s, *ap*), 5.40 (s, *ap*/$\pm sc$), 6.2—7.6 (m, *ap*/$\pm sc$).

1,2,3,4-Tetrachloro-9-(2-methylbenzyl)triptycene (8), mp 286—288 °C, was prepared from 9-(2-methylbenzyl)anthracene (**9a**) and tetrachloroanthranilic acid[18] in 22% yield. Found: C, 67.82; H, 3.96; Cl, 28.07%. Calcd for $C_{28}H_{18}Cl_4$: C, 67.77; H, 3.66; Cl, 28.57%. ^1H NMR ($CDCl_3$, δ) showed the presence of the *ap* and $\pm sc$ rotamers in the ratio of 3 : 2: 2.63 (s, $\pm sc$), 2.68 (s, *ap*), *ca.* 4.5 (br, $\pm sc$), 4.81 (s, *ap*), 6.12 (s, $\pm sc$), 6.16 (s, *ap*), 6.1—7.7 (m, *ap*/$\pm sc$).

(Received June 11, 1980)

L-Serine was transformed in 8 steps into (4*R*,5*S*)-2,2-dimethyl-4-[(*Z*)-3-pentadecenyl]-1,3-dioxan-5-amine. This chiral ε,ζ-unsaturated amine was subjected to intramolecular aminomercuration and then acid hydrolysis to give (−)-deoxoprosopinine and (−)-deoxoprosophylline.

Seven piperidine alkaloids have been isolated from *Prosopis africana* TAUB. and their structures have been determined, (+)-(2*R*,3*S*,6*R*)-prosopinine (**1**) and (±)-prosophylline (**2**) being two representatives of these Prosopis alkaloids.[3] Although some approaches to the synthesis of Prosopis alkaloids have been reported,[4] no chiral synthesis has yet been accomplished. Recently, an intramolecular aminomercuration[5] was successfully applied to the synthesis of (±)-solenopsin A and (±)-isosolenopsin A, piperidine derivatives related to fire ant venom.[6] This paper deals with a chiral and stereoselective total synthesis of (−)-deoxoprosopinine (**3**) [an enantiomer of (+)-deoxoprosopinine derived from natural **1**] and (−)-deoxoprosophylline (**4**) starting from L-serine (**5**) by a route involving the intramolecular aminomercuration of an ε,ζ-unsaturated amine (**6**).

(2*S*)-3-Acetoxy-2-phthalimidopropanal (**7**) was prepared from L-serine (**5**) *via* (2*S*)-3-acetoxy-2-phthalimidopropanoic acid (**8**) by the known procedure.[7] The carbon chain of the aldehyde (**7**) was elongated by C_{15}-unit by the Grignard reaction. A C_{15}-bromide (**9**) was prepared as follows. Hydrogenation of 3-pentadecyn-1-ol[8] in ethanol in the presence of a palladium–barium sulfate catalyst deactivated with quinoline[9] gave (*Z*)-3-pentadecen-1-ol (**10**) in a quantitative yield. The alcohol (**10**) was brominated with dibromotriphenylphosphine in dichloromethane to afford (*Z*)-3-pentadecenyl bromide (**9**) in 89% yield.

The chiral aldehyde (**7**) in a mixture of tetrahydrofuran and ether was treated with the Grignard reagent prepared from **9** at −70 °C and then at −45 °C to give a mixture of diol monoacetates (**11** and **12**), the separation of which by column and thin-layer chromatographies was unsuccessful. Acid hydrolysis of this mixture afforded, after separation by silica gel column chromatography, (2*S*,3*R*,6*Z*)-2-phthalimido-6-octadecene-1,3-diol (**13**) and (2*S*,3*S*,6*Z*)-2-phthalimido-6-octadecene-1,3-diol (**14**) in 16.5 and 2.4% yields from **8**, respectively. On treatment with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid, the diols **13** and **14** gave their acetonides **15** and **16** in 97% and 70% yields, respectively. The coupling constant between a C-4 proton and a C-5 proton was determined by ^{1}H-NMR measurements to be 10 and 5 Hz for **15** and **16**, respectively; this led to the *erythro* and *threo* configurations for **13** and **14**, respectively. The formation of **13** and **14** from **7** in a *ca.* 7 : 1 ratio showed that a stereoselective attack[7] of the Grignard reagent to the aldehyde (**7**) was effected preferentially from the less hindered side of **7** to give predominantly the desired *erythro* derivative (**11**).

Hydrazinolysis of the *N*-protective phthaloyl group of **15** gave (4*R*,5*S*)-2,2-dimethyl-4-[(*Z*)-3-pentadecenyl]-1,3-dioxan-5-amine (**6**) in a quantitative yield. The ε,ζ-unsaturated amine (**6**) was subjected to aminomercuration with mercury(II) acetate in methanol at room temperature and then demercuration with sodium borohydride to afford two piperidine acetonides, (1*R*,6*S*,8*S*)-8-dodecyl-3,3-dimethyl-2,4-dioxa-7-azabicyclo[4.4.0]decane (**17**) and its (1*R*,6*S*,8*R*)-diastereomer (**18**), in 3.3 and 76% yields, respectively; this shows that the reaction proceeded stereoselectively. The 8*S* and 8*R* stereochemistry was shown for **17** and **18** by their conversion into **3** and **4**, respectively, as described below. In the ^{1}H-NMR spectrum (270 MHz) of **17** in deuteriochloroform the proton on C-8 resonated at δ 2.99 as a broad signal with a half-band width ($W_{1/2}$) 21 Hz, while in the spectrum of **18** in deuteriobenzene the C-8 proton signal appeared at δ 2.33 as a broad signal with $W_{1/2}$=25 Hz. These $W_{1/2}$ values are in line with those ($W_{1/2}$=18 Hz[3b] and $W_{1/2}$=24 Hz[3c]) observed for the corresponding proton signals of *O*,*O*′-benzylidene

derivatives of deoxoprosopinine[3b] and deoxoprosophylline,[3c] respectively. A peak at *m/e* 170 (**19**) due to a loss of the side chain was observed as a base peak in the mass spectra of both **17** and **18**.

Finally, the acetonides **17** and **18** were hydrolyzed to afford (−)-deoxoprosopinine (**3**) and (−)-deoxoprosophylline (**4**) in 58 and 86% yields, respectively. The two synthetic piperidines **3** and **4** were found to be identical, except for optical property, with authentic (+)-deoxoprosopinine[3a,b] and (±)-deoxoprosophylline[3c] derived from natural (+)-prosopinine (**1**)[3a,b] and (±)-prosophylline (**2**),[3c] respectively. Since the absolute value of optical rotation ($[\alpha]_D$ −14.7°) of the synthetic deoxoprosopinine (**3**) is almost the same as that ($[\alpha]_D$ +12°) of deoxoprosopinine derived from natural **1**, no racemization occurred during the course of synthesis.

Thus, (−)-deoxoprosopinine (**3**) and (−)-deoxoprosophylline (**4**) were synthesized from L-serine (**5**) in overall yields of 0.12 and 4.3%, respectively. This constitutes the first example of stereoselective total synthesis of optically active Prosopis alkaloids, presenting a useful synthetic route applicable to the other piperidine alkaloids.

Experimental

Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncorrected. IR spectra were measured with a Hitachi EPI-G2, a Hitachi 260-30, or a JEOL JIR-03F (FT) spectrometer, ^{1}H-NMR spectra with a Hitachi R-20B (60 MHz), a Varian EM-390 (90 MHz), a JEOL PS-100 (100 MHz), or a Brucker WH 270 (270 MHz, FT) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, low resolution mass spectra with a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV, high resolution mass spectra and chemical ionization mass spectra (CI-MS) with a JEOL JMS-D300 mass spectrometer. Measurenents of optical rotation were carried out with JASCO DIP-SL and DIP-4 polarimeters. Vaper-phase chromatographic (VPC) analyses were performed on Shimadzu gas chromatographs GC-4A PF and GC-6A PF. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) and Alumina B-10F (Wako Pure Chemical Industries) in 0.25 mm thickness for analytical use and in 1 mm thickness for preparative use. Wakogel C-200 and Aluminiumoxid Woelm (neutral; M. Woelm, Eschwege) were used for column chromatography.

*(Z)-3-Pentadecen-1-ol (**10**).* 3-Pentadecyn-1-ol[8] (20 g) in methanol (150 ml) was hydrogenated in the presence of a 5% palladium–barium sulfate catalyst (400 mg) deactivated with quinoline[9] at room temperature for 3 h. The reaction was monitored by VPC examination. After filtration of the catalyst, the solvent was removed to give a residue, which was dissolved in hexane (200 ml). The hexane solution was washed with 1.5 M (1 M=1 mol dm^{-3}) hydrochloric acid, saturated aqueous sodium hydrogencarbonate solution, and brine, dried, and evaporated. The residue was chromatographed on a column of silica gel (150 g; elution with benzene) to give **10** (20.4 g) in a quantitative yield. (*Z*)-3-Pentadecen-1-ol (**10**): mp 12—13 °C, bp 105 °C/0.1 kPa; IR (neat) 3350, 3000, 2950, 2850, 1660, 1470, 1380, 1050, 1020, and 720 cm^{-1}; absence of absorption around 965 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.89 (3H, t, J=5 Hz, $-CH_2C\underline{H}_3$), 1.27 (18H, s, 9×CH_2), 2.00 (3H, m, $-C\underline{H}_2CH$=CH– and OH), 2.38 (2H, m, –CH=CH–$C\underline{H}_2$–CH_2OH), 3.62 (2H, t, J=6.5 Hz, $-C\underline{H}_2OH$), and 5.45 (2H, m, $-CH_2-C\underline{H}$=$C\underline{H}-CH_2$–); MS *m/e* 208 [relative intensity (%): 15; $(M-18)^+$], 186 (100), and 141 (95). Found: C, 79.32; H, 13.41%. Calcd for $C_{15}H_{30}O$: C, 79.57; H, 13.36%. On VPC examination (DEGS; 2 m; 205 °C; N_2 50 ml/min), the retention time (R_t) of **10** was found to be 8.8 min; a peak (R_t=7.2 min) due to pentadecan-1-ol was absent.

*(Z)-3-Pentadecenyl Bromide (**9**).* A solution of (*Z*)-3-pentadecen-1-ol (**10**; 14.4 g) in dichloromethane (50 ml) was added to a solution of dibromotriphenylphosphine in dichloromethane (380 ml) prepared from triphenylphosphine (52 g) and bromine (26.15 g), and the mixture was stirred at room temperature for 1.5 h. The organic solution was washed with water and brine, and concentrated to 100 ml. Hexane (700 ml) was added to this concentrated solution with vigorous stirring to produce a precipitated mass of triphenylphosphine oxide, which was separated by filtration and washed with hexane (total 200 ml). The filtrate and the washings were combined, and the solvents were removed to give a residue, which was subjected to dry column chromatography (silica gel, 150 g; elution with hexane) and then distillation under reduced pressure, giving **9** (16.3 g) in 89% yield. (*Z*)-3-Pentadecenyl bromide (**9**): a colorless oil, bp 156—156.5 °C/0.4 kPa; IR (neat) 3000, 2950, 2900, 2860, 1660, 1460, 1380, 1310, 1280, 1210, 720, 675, and 640 cm^{-1}; absence of absorption around 965 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.89 (3H, t, J=6 Hz, $-CH_2-C\underline{H}_3$), 1.27 (18H, s, 9×CH_2), 2.03 (2H, m, $-C\underline{H}_2CH$=CH–), 2.67 (2H, m, –CH=CH–$C\underline{H}_2$–CH_2Br), 3.35 (2H, t, J=6.5 Hz, $-CH_2Br$), and 5.44 (2H, m, $-CH_2-C\underline{H}$=$C\underline{H}$–CH_2–; a coupling constant between the two olefinic protons was determined to be 10.5 Hz by decoupling experiments, indicating a (*Z*)-olefin stereochemistry); MS *m/e* 290 and 288 (each 6.5; M^+), 186 (88), and 149 (100). Found: C, 62.09; H, 10.07%. Calcd for $C_{15}H_{29}Br$: C, 62.28; H, 10.10%.

When a part of **9** was left at room temperature for 6 months, **9** isomerized into (*E*)-3-pentadecenyl bromide: a colorless oil; IR (neat) 3000, 2950, 2920, 2850, 1660, 1460, 1380, 1260, 1200, 1070, 965, 800, 720, 665, and 640 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.90 (3H, t-like, $-CH_2C\underline{H}_3$), 1.27 (18H, s, 9×CH_2), 2.00 (2H, m, $-C\underline{H}_2CH$=CH–), 2.59 (2H, m, –CH=CH–$C\underline{H}_2$–CH_2Br), 3.37 (2H, t, J=7 Hz, $-CH_2Br$), and 5.44 (2H, m, $-CH_2C\underline{H}$=$C\underline{H}-CH_2$–; decoupling experiments showed a

coupling constant between the two olefinic protons to be 15 Hz, indicating an (*E*)-olefin structure).

(2S)-3-Acetoxy-2-phthalimidopropanal (7). According to the procedure described by Newman,[7] L-serine (**5**) was converted into (2*S*)-3-acetoxy-2-phthalimidopropanoic acid (**8**) in 41% yield, which was then transformed into the aldehyde (**7**) in 95% yield. Because of an unstability of the aldehyde (**7**), **7** was used immediately for the following Grignard reaction.

Grignard Reaction of (2S)-3-Acetoxy-2-phthalimidopropanal (7) with (Z)-3-Pentadecenylmagnesium Bromide. A solution of (*Z*)-3-pentadecenylmagnesium bromide (4.96 mmol) in ether (62 ml) [prepared from the bromide (**9**) and magnesium in ether by the usual procedure] was added dropwise to a solution of the aldehyde (**7**; 1.298 g; 4.97 mmol) in a mixture of tetrahydrofuran (10 ml) and ether (5 ml) with stirring under an argon atmosphere at a temperature between −72 and −70 °C. After the mixture had been stirred at this temperature for 1 h and then at −45 °C for 1 h, a saturated aqueous solution (50 ml) of ammonium chloride was added at −45 °C. The reaction mixture was treated in the usual way to give a residue (2.75 g) which was chromatographed on a column of silica gel (100 g). Elution with hexane–ethyl acetate (17 : 3) gave a mixture (760 mg; 32% yield from **7**; 30% yield from **8**) of diol monoacetate (**11** and **12**). However, separation of each of two diastereomers (**11** and **12**) by column and thin-layer chromatographies was unsuccessful. Mixture of **11** and **12**: an oil; IR (neat) 3450, 2900, 1770, 1740, 1705, 1380, 1230, 1040, 720, and 675 cm^{-1}; ^1H-NMR ($CDCl_3$) δ 0.89 (3H, t-like, $-CH_2C\underline{H}_3$), 1.24 (18H, broad s, $9\times CH_2$), 1.60 (2H, m, $-\underline{C}H(OH)-C\underline{H}_2CH_2-$), 1.95 (3H, s, CH_3CO-), 2.10 (4H, broad m, allylic H's), *ca.* 3.5 (1H, broad signal, OH), 4.15 (1H, m, HO–$C\underline{H}$–), 4.55 (3H, m, AcO–$C\underline{H}_2-\underline{C}H-N-$), 5.36 (2H, m, $-CH_2-C\underline{H}=C\underline{H}-CH_2-$), and 7.83 (4H, m, aromatic H's).

Acid Hydrolysis of the Mixture of Diol Monoacetates (11 and 12). The mixture of diol monoacetates (**11** and **12**; 838 mg) was added to a solution (20 ml) prepared from 1 M hydrochloric acid and methanol (1 : 9 v/v), and the whole mixture was refluxed for 4 h. After the solvent had been removed under reduced pressure, the mixture was extracted with ether. The ethereal solution was washed with saturated aqueous sodium hydrogencarbonate solution and brine, dried (Na_2SO_4), and evaporated to give an oil, which was chromatographed on a column of silica gel (15 g). Elution with hexane–ethyl acetate (7 : 3) gave a mixture of **13** and **14**, and then pure **13** (306 mg). This mixture was subjected to separation by TLC to afford **13** (116 mg) and **14** (59 mg; 2.6% yield from **7**; 2.4% yield from **8**). The *erythro*-diol (**13**; total 422 mg) was obtained in 17.6% yield from **7** (16.5% yield from **8**). (2*S*, 3*R*, 6*Z*)-*erythro*-2-Phthalimido-6-octadecene-1,3-diol (**13**): mp 32.5—34.5 °C [purified by molecular distillation: 110—130 °C (bath temperature)/13 Pa], $[\alpha]_D^{19}$ −15° (*c* 0.20; $CHCl_3$); IR (Nujol) 3450, 1780, and 1705 cm^{-1}; absence of absorption around 965 cm^{-1}; ^1H-NMR ($CDCl_3$) δ 0.89 (3H, t-like, $-CH_2C\underline{H}_3$), 1.26 (18H, broad s, $9\times CH_2$), 1.55 (2H, m, HO–$\underline{C}H-C\underline{H}_2CH_2-$), 2.10 (4H, broad m, allylic H's), *ca.* 3.1—3.8 (2H, broad signals, $2\times OH$), 4.17 [4H, m, HO–$C\underline{H}_2-C\underline{H}$(NPhth)–$C\underline{H}$(OH)–], 5.35 (2H, m, $-CH_2-C\underline{H}=C\underline{H}-CH_2-$), and 7.82 (4H, m, aromatic H's). Found: C, 72.74; H, 9.17; N, 3.45%. Calcd for $C_{26}H_{39}NO_4$: C, 72.69; H, 9.15; N, 3.26%. (2*S*, 3*S*, 6*Z*)-*threo*-2-Phthalimido-6-octadecene-1,3-diol (**14**): an oil [purified by molecular distillation: 110—130 °C (bath temperature)/13 Pa], $[\alpha]_D^{19}$ +5° (*c* 0.23; $CHCl_3$); IR (Nujol) 3450, 1770, and 1700 cm^{-1}; absence of absorption around 965 cm^{-1}; ^1H-NMR ($CDCl_3$) δ 0.89 (3H, t-like, $-CH_2C\underline{H}_3$), 1.27 (18H, broad s, $9\times CH_2$), 1.50 (2H, m, HO–$\underline{C}H-C\underline{H}_2-CH_2-$), 2.05 (4H, broad m, allylic H's), *ca.* 3.2—3.8 (2H, broad signals, $2\times OH$; disappeared on addition of D_2O), 4.16 (3H, m, HO–$C\underline{H}_2-\underline{C}H-\underline{N}-$ and HO–$\underline{C}H-$), 4.40 (1H, t-like, J=*ca.* 6 Hz, HO–$CH_2-\underline{C}H-N-$), 5.37 (2H, m, $-CH_2-C\underline{H}=C\underline{H}-CH_2-$), and 7.88 (4H, m, aromatic H's). Found: *m/e* 429.2883. Calcd for $C_{26}H_{39}NO_4$: M, 429.2878.

Acetalization of the erythro*-Diol (13).* The *erythro*-diol (**13**; 176 mg) was dissolved in 2,2-dimethoxypropane (10 ml) containing a trace of *p*-toluenesulfonic acid, and the solution was stirred at room temperature for 12 h. The reaction mixture was treated in the usual way to give a residue, which was purified by chromatography on a column of silica gel [3 g; elution with hexane–ethyl acetate (19 : 1)] giving an acetonide (**15**; 119 mg) in 62% yield. When the reaction was carried out for 10 d, **15** was obtained in 97% yield. (4*R*, 5*S*)-2,2-Dimethyl-4-[(*Z*)-3-pentadecenyl]-5-phthalimido-1,3-dioxane (**15**): mp 47—48 °C (crystallized from ethanol), $[\alpha]_D^{19}$ −6° (*c* 0.23, $CHCl_3$); IR (Nujol) 1780, 1720, 1705, 1110, and 1070 cm^{-1}; absence of absorption around 965 cm^{-1}; ^1H-NMR ($CDCl_3$) δ 0.88 (3H, t-like, $-CH_2C\underline{H}_3$), 1.24 (18H, broad s, $9\times CH_2$), 1.45 and 1.64 [each 3H, s, $(CH_3)_2\underline{C}-$], 1.48 (2H, m, –O–$\underline{C}H-C\underline{H}_2-CH_2-$), 2.00 (4H, broad m, allylic H's), 3.70 (1H, dd, J=10 and J=5 Hz, $C_{(6\alpha)}$–H), 4.20 (1H, td, J=10 and J=5 Hz, $C_{(5\alpha)}$–H), 4.51 (1H, t, J=10 Hz, $C_{(6\beta)}$–H), 4.65 (1H, m, $C_{(4\beta)}$–H), 5.26 (2H, m, $-CH_2-C\underline{H}=C\underline{H}-CH_2-$), and 7.80 (4H, m, aromatic H's). Found: C, 74.37; H, 9.20; N, 3.23%. Calcd for $C_{29}H_{43}NO_4$: C, 74.16; H, 9.23; N, 2.98%.

Acetalization of the threo*-Diol (14).* A soltuion of the *threo*-diol (**14**; 34 mg) in 2,2-dimethoxypropane (1 ml) containing a trace of *p*-toluenesulfonic acid was stirred at room temperature for 10 d. The reaction mixture was treated in the usual way to give a residue, which was chromatographed on a column of silica gel [elution with hexane–ethyl acetate (2 : 1)] giving the corresponding acetonide (**16**; 26.2 mg) in 70% yield, besides unchanged **14** (8.5 mg). (4*S*, 5*S*)-2,2-Dimethyl-4-[(*Z*)-3-pentadecenyl]-5-phthalimido-1,3-dioxane (**16**): mp 56—56.5 °C, $[\alpha]_D^{19}$ +2° (*c* 0.43; $CHCl_3$); IR (Nujol) 1775, 1720, 1705, 1260, 1110, and 1060 cm^{-1}; absence of absorption around 965 cm^{-1}; ^1H-NMR ($CDCl_3$) δ 0.89 (3H, t-like, $-CH_2C\underline{H}_3$), 1.26 (18H, broad s, $9\times CH_2$), 1.44 and 1.61 [each 3H, s, $(CH_3)_2\underline{C}-$], 1.46 (2H, m, –O–$\underline{C}H-C\underline{H}_2-CH_2-$), 2.05 (4H, broad m, allylic H's), 3.95 (1H, dd, J=11 and J=7 Hz, $C_{(6)}$–H), 4.15 (1H, dt, J=9 and J=5 Hz, $C_{(4\alpha)}$–H), 4.38 (1H, dd, J=11 and J=7 Hz, $C_{(6)}$–H), 4.67 (1H, td, J=7 and J=5 Hz, $C_{(5\alpha)}$–H), 5.26 (2H, m, $-CH_2-C\underline{H}=C\underline{H}-CH_2-$), and 7.81 (4H, m, aromatic H's). Found: *m/e* 469.3205. Calcd for $C_{29}H_{43}NO_4$: M, 469.3192.

Hydrazinolysis of the Acetonide (15) Derived from erythro*-Diol Phthalimide (13).* Hydrazine hydrate (100%; 40.9 mg; 0.82 mmol; *ca.* 3 equivalent moles) was added to a solution of the acetonide (**15**; 132 mg; 0.28 mmol) in ethanol (5 ml), and the mixture was refluxed under an argon atmosphere for 2.5 h. The reaction mixture was extracted with dichloromethane (total 30 ml) after addition of water (3 ml) and potassium hydroxide (*ca.* 0.2 g). The organic layer was treated in the usual way to give an *erythro*-amine (**6**; 99 mg; 0.29 mmol) in a quantitative yield. (4*R*, 5*S*)-2,2-Dimethyl-4-[(*Z*)-3-pentadecenyl]-1,3-dioxan-5-amine (**6**): an oil; IR (neat) 3350, 2930, 1660, 1460, 1380, 1270, 1200, 1160, 1070, 860, 720, and 660 cm^{-1}; absence of absorption around 965 cm^{-1}; ^1H-NMR ($CDCl_3$) δ 0.88 (3H, t-like, $-CH_2C\underline{H}_3$), 1.27

(18H, broad s, 9×CH_2), 1.38 and 1.40 [each 3H, s, $(CH_3)_2\underline{C}$–], 1.70 (2H, m, –O–$\underline{CH}$–$C\underline{H}_2$–CH_2–), 2.00 (4H, m, allylic H's), 2.60 (1H, m, $C_{(5\alpha)}$–H), *ca.* 3.0—3.9 (3H, m, $C_{(4\beta)}$–H, $C_{(6\beta)}$–H, and $C_{(6\alpha)}$–H), and 5.34 (2H, m, –CH_2–$C\underline{H}$=$C\underline{H}$–CH_2–); MS *m/e* 339 (27; M^+), 324 (81), 281 (38), 267 (40), 264 (32), 250 (34), 170 (98), 101 (100), and 100 (92); peaks at *m/e* 341 and 326 due to its dihydro derivative (**20**) were not observed (*vide infra*). Found: *m/e* 339.3134. Calcd for $C_{21}H_{41}NO_2$: M, 339.3135.

When the hydrazinolysis of **15** was carried out with 8 equivalent moles of hydrazine hydrate under reflux for 2 h, a mixture of **6** and its dihydro derivative (**20**) was obtained. Although separation of these products by means of various techniques including VPC was unsuccessful, the mass spectrum showed that the mixture consisted of **6** [*m/e* 339 (M^+) and 324 ($M-15)^+$] and **20** [*m/e* 341 (M^+) and 326 ($M-15)^+$] in a ratio of *ca.* 7 : 6. The formation of **20** could be explained by reduction of **6** with diimide, which may be produced from hydrazine by oxidation with oxygen present in the system, even when the reaction was carried out under an argon atmosphere.

Aminomercuration of the ε,ζ-Unsaturated Amine (6). A solution of mercury(II) acetate (486 mg) in methanol (20 ml) was added to a solution of the ε,ζ-unsaturated amine (**6**; 266 mg) in methanol (15 ml), the whole solution being stirred at room temperature for 2 weeks. After addition of a solution of sodium borohydride (72 mg) in 2 M aqueous sodium hydroxide solution (5 ml), the aqueous methanol solution was separated from a white precipitate of mercury by decantation. This aqueous methanol solution was evaporated under reduced pressure, and extracted with dichloromethane (total 30 ml) after addition of water (10 ml). The organic layer was washed with brine, dried ($MgSO_4$), and evaporated, giving an oil, which was chromatographed on a column of alumina (5 g). Elution with hexane–ether (6 : 1) afforded an (8*R*)-acetonide (**18**; 202 mg) in 76% yield. Successive elution with ether gave an (8*S*)-acetonide (**17**; 8.9 mg) in 3.3% yield. (1*R*, 6*S*, 8*S*)-8-Dodecyl-3,3-dimethyl-2,4-dioxa-7-azabicyclo[4.4.0]decane (**17**): an oil, $[\alpha]_D^{19}$ +2° (*c* 0.10; $CHCl_3$); IR (neat) 3300, 2920, 1460, 1380, 1270, 1200, 1160, 1095, 1060, 960, and 855 cm^{-1}; ^{1}H-NMR (270 MHz; $CDCl_3$) δ 0.89 (3H, t, *J*=7 Hz, –$CH_2C\underline{H}_3$), 1.42 and 1.51 [each 3H, s, $(CH_3)_2\underline{C}$–], 2.80 (1H, m, $C_{(6\alpha)}$–H), 2.99 (1H, broad signal, $W_{1/2}$=21 Hz, $C_{(8\beta)}$–H), 3.58 (1H, td, *J*=10 and *J*=4 Hz, $C_{(1\beta)}$–H), 3.68 (1H, dd, *J*=12.6 and *J*=10 Hz, $C_{(5)}$–H), and 3.70 (1H, dd, *J*=10 and *J*=2.5 Hz, $C_{(5)}$–H); MS *m/e* 339 (0.3; M^+), 324 (6), 264 (8), 224 (23), and 170 (100). Found: *m/e* 339.3090. Calcd for $C_{21}H_{41}NO_2$: M, 339.3135. The fragment ion peak due to **19** was observed at *m/e* 170.1200. Calcd for $C_9H_{16}NO_2$: $M-C_{12}H_{25}$, 170.1180. (1*R*, 6*S*, 8*R*)-8-Dodecyl-3,3-dimethyl-2,4-dioxa-7-azabicyclo-[4.4.0]decane (**18**): mp 45—47.5 °C (crystallized from hexane–ether), $[\alpha]_D^{23}$ +9° (*c* 0.27; $CHCl_3$); IR (Nujol) 3550, 3300, 1270, 1200, 1090, 1060, 855, and 760 cm^{-1}; ^{1}H-NMR (270 MHz; C_6D_6) δ 0.92 (3H, t, *J*=6.5 Hz, –$CH_2C\underline{H}_3$), 1.40 and 1.56 [each 3H, s, $(CH_3)_2\underline{C}$–], 2.33 (1H, broad signal, $W_{1/2}$=25 Hz, $C_{(8\alpha)}$–H); 2.56 (1H, td, *J*=10 and *J*=4.9 Hz, $C_{(6\alpha)}$–H), 3.47 (1H, ddd, *J*=10.5. *J*=10, and *J*=4 Hz, $C_{(1\beta)}$–H), 3.59 (1H, dd, *J*=10.7 and *J*=10 Hz, $C_{(5\beta)}$–H), and 3.64 (1H, dd, *J*=10.7 and *J*=4.9 Hz, $C_{(5\alpha)}$–H); MS *m/e* 339 (8; M^+), 324 (35), 224 (49), and 170 (100). Found: *m/e* 339.3114. Calcd for $C_{21}H_{41}NO_2$: M, 339.3135. The fragment ion peak due to **19** was observed at *m/e* 170.1193. Calcd for $C_9H_{16}NO_2$: $M-C_{12}H_{25}$, 170.1180.

When a mixture (*ca.* 7 : 6) of **6** and **20** (*vide supra*) was subjected to aminomercuration and then separation by column chromatography as described above, **17**, **18**, and unchanged **20** [elution with ether–methanol (9 : 1)] were obtained in 2, 41, and 46% yields, respectively. The saturated amine (**20**) was found to be identical with an authentic specimen (**20**) described below.

Preparation of the Saturated Amine (20) from its Phthalimide Derivative (21). The known (4*R*, 5*S*)-2,2-dimethyl-4-pentadecyl-5-phthalimido-1,3-dioxane[10] (**21**; *N*-phthaloyldihydrosphingosine acetonide; 25.8 mg) was added to a solution (0.4 ml) prepared from hydrazine hydrate (80%) and ethanol (1 : 7 v/v), and the mixture was refluxed under an argon atmosphere for 1.5 h. The reaction mixture was treated as described for the hydrazinolysis of **15**, giving the saturated amine (**20**; 16.8 mg) in 87% yield. (4*R*, 5*S*)-2,2-Dimethyl-4-pentadecyl-1,3-dioxan-5-amine (**20**): an oil; IR (neat) 3350, 2920, 1265, 1200, 1165, 1090, 860, and 660 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.88 (3H, t-like, –$CH_2C\underline{H}_3$), 1.27 (s, methylene protons in the side chain), 1.38 and 1.43 [each 3H, s, $(CH_3)_2\underline{C}$–], *ca.* 2.4 (1H, m, $C_{(5\alpha)}$–H), 3.44 (2H, m, $C_{(6\beta)}$–H and $C_{(4\beta)}$–H), and 3.85 (1H, dd-like, $C_{(6\alpha)}$–H); MS *m/e* 341 (7; M^+), 326 (100), and 266 (89). Found: *m/e* 341.3282. Calcd for $C_{21}H_{43}NO_2$: M, 341.3292.

Acid Hydrolysis of the (8S)-Acetonide (17). The (8*S*)-acetonide (**17**; 5.1 mg) was added to a solution (2 ml) prepared from 8 M hydrochloric acid and methanol (1 : 9 v/v), and the mixture was refluxed for 2 h. The reaction mixture was treated in the usual way to give a residue, which crystallized from acetone to afford pure **3**. The mother liquor was evaporated, giving a residue which was subjected to purification by preparative TLC to afford additional **3**. The diol (**3**; total 2.6 mg) was obtained in 58% yield. (−)-Deoxoprosopinine (**3**): mp 89.5 °C, $[\alpha]_D^{20}$ −14.7° (*c* 0.30; $CHCl_3$); MS *m/e* 299 (0.2; M^+), 268 (100), and 250 (55). Found: *m/e* 299.2780. Calcd for $C_{18}H_{37}NO_2$: M, 299.2822. The IR (FT-IR; Nujol) and the ^{1}H-NMR (270 MHz; $CDCl_3$) spectra of **3** were found to be identical with those of (+)-deoxoprosopinine[3b] [an enantiomer of **3**; mp 90.7—91 °C (lit,[3b] 85.5 °C); $[\alpha]_D^{18}$ +13° (*c* 0.31; $CHCl_3$) (lit,[3b] +12°); IR (FT-IR; Nujol) 3370, 3310, 3120, 1153, 1095, 1076, 1061, 1053, 1032, 953, and 864 cm^{-1}; ^{1}H-NMR (270 MHz; $CDCl_3$) δ 0.88 (3H, t, *J*=6 Hz, –$CH_2C\underline{H}_3$), 1.27 (24H, s, 12×CH_2), *ca.* 1.6 (2H, m, $C_{(4\alpha)}$–H and $C_{(4\beta)}$–H), 2.55 (2H, broad signal, 2×OH), 2.77 (1H, broad signal, $C_{(6\alpha)}$–H), 2.85 (1H, m, $C_{(2\beta)}$–H), 3.53 (1H, td, *J*=6.5 and *J*=4 Hz, $C_{(3\alpha)}$–H), 3.62 (1H, dd, *J*=10.6 and *J*=4.8 Hz; A part of ABX-system: HO–$C\underline{H}_2$–$\underline{C}$H–), and 3.66 (1H, dd, *J*=10.6 and *J*=8 Hz; B part of ABX-system: HO–$C\underline{H}_2$–$\underline{C}$H–)], prepared from natural (+)-prosopinine (**1**).[3b]

Acid Hydrolysis of the (8R)-Acetonide (18). The same acid hydrolysis of the (8*R*)-acetonide (**18**; 31 mg) gave a product which crystallized from acetone, affording a diol (**4**; 23.5 mg) in 86% yield. (−)-Deoxoprosophylline (**4**): mp 90.5 °C, $[\alpha]_D^{23}$ −14° (*c* 0.24; $CHCl_3$); IR (Nujol) 3400, 3200, 1260, 1120, 1100, 1070, 1060, 1020, 1000, 935, 910, 890, 865, and 830 cm^{-1}; ^{1}H-NMR (270 MHz; $CDCl_3$) δ 0.88 (3H, t, *J*=6 Hz, –$CH_2C\underline{H}_3$), 1.26 (24H, s, 12×CH_2), 1.75 and 2.05 (each 1H, m, $C_{(4\alpha)}$–H and $C_{(4\beta)}$–H), *ca.* 2.3 (2H, broad signal, 2×OH), 2.50 (1H, broad signal, $C_{(6\alpha)}$–H), 2.56 (1H, m, $C_{(2\alpha)}$–H), 3.44 (1H, td, *J*=6.5 and *J*=4 Hz, $C_{(3\beta)}$–H), 3.71 (1H, dd, *J*=10.8 and *J*=5.3 Hz; A part of ABX-system: HO–$C\underline{H}_2$–$\underline{C}$H–), and 3.83 (1H, dd, *J*=10.8 and *J*=4.6 Hz; B part of ABX-system: HO–$C\underline{H}_2$–$\underline{C}$H–); VPC: R_t=13.0 min (SP-1000; 1.5 m; 175 °C; N_2 37 ml/min), R_t=12.7 min (OV-1; 1 m; 175 °C; N_2 38 ml/min), and R_t=14.8 min (OV-17; 1.5

m; 220 °C; N_2 32 ml/min); MS *m/e* 299 (4; M^+), 250 (90), and 130 (100). Found: *m/e* 299.2800. Calcd for $C_{18}H_{37}NO_2$: M, 299.2822. The ^{1}H-NMR (270 MHz; $CDCl_3$) spectrum and retention times (under the three conditions described above) observed for **4** were found to be identical with those for (±)-deoxoprosophylline[3c] [(±)-**4**; mp 83—83.5 °C (lit,[3c] 83 °C)] derived from natural (±)-prosophylline[3c] [(±)-**2**].

The authors wish to thank Prof. Tatsuo Miyazawa, The University of Tokyo, for the measurements of ^{1}H-NMR spectra at 270 MHz, and Dr. Maki Kawai and Miss Setsuko Kagami, The University of Tokyo, for the FT-IR measurements.

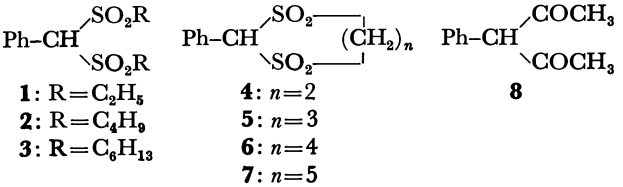
(Received June 30, 1980)

The acid dissociation constants of carbon acids activated by two sulfonyl groups were determined spectrophotometrically in aqueous solution with and without CTAB micelles. The results indicate that a cationic micelle causes larger pK_a decrease for more hydrophobic disulfones. Hydrophobic properties of cyclic and acyclic disulfones are discussed.

Cationic micelles stabilize carbanions,[1] this becoming more pronounced for more delocalized carbanions. In the H-D exchange reaction of micelle-forming sulfonium salts, micellar rate enhancement for the allyl-methylene group is much larger than that for the methyl group.[2] Similar phenomena were observed in the micellar effects on the acid dissociation constants of α-substituted *p*-nitrophenylacetonitrile,[3] the mechanism of hydrolysis of some activated carboxylic acid esters,[4] and the transition state of E2 elimination reaction of phenethyl bromide.[5] The carbanions are delocalized through conjugation with carbon-carbon or carbon-oxygen double bond. It is of interest to alter the behavior of carbanions by attaching other conjugative groups such as sulfonyl group.

We have examined the micellar effect on pK_a values of cyclic and acyclic disulfones, **1**—**3** and **4**—**7**, respectively, and also of β-diketone, **8**. The compounds were chosen because (a) their carbanions except for those of **4**, are stable, (b) the carbanions show suitable absorption for pK_a determination in UV region, and (c) possible variation of micellar effects with respect to cyclic and acyclic structures can be examined.



1: R=C_2H_5 **2**: R=C_4H_9 **3**: R=C_6H_{13} **4**: n=2 **5**: n=3 **6**: n=4 **7**: n=5 **8**

Results and Discussion

Stability of Carbanions. The carbanions of all the compounds except **4** were confirmed to be stable in alkaline solution (2 M NaOH) under a nitrogen atmosphere. While the five-membered disulfone (**4**) decomposes in an alkaline solution,[6] the spectra of sulfonyl carbanions (λ_{max} 270—286 nm) can be reproduced quantitatively by neutralization followed by addition of excess alkali. In a 0.01 M NaOH solution, **4** shows absorption at λ_{max} 253 nm (ε=6000 M^{-1} cm^{-1}), unchanged by acidification, the original spectrum of undissociated disulfone (λ_{max} 265 nm, ε=510 M^{-1} cm^{-1}) not being restored (1 M=1 mol dm^{-3}).

Determination of Acid Dissociation Constants (pK_a). Acid dissociation constants were determined spectrophotometrically by means of the following equations.[7]

$$pK_a = pH + \log \frac{OD_{S^-} - OD_{obsd}}{OD_{obsd} - OD_{SH}} \quad (1)$$

$$\varepsilon_{app} = \varepsilon_{S^-} - \frac{K_w \varepsilon_{app}}{K_a[OH^-]} \quad (2)$$

$$OD^- \quad \varepsilon_{app} = \varepsilon_{S^-} - \frac{1}{K_a}(h_- \varepsilon_{app}), \quad (3)$$

where OD_{S^-}, OD_{SH}, and OD_{obsd} denote optical densities of carbanion, undissociated disulfone and observed optical density, respectively, ε_{app} and ε_S- apparent extinction coefficient and extinction coefficient of a carbanion, respectively, and h_- denotes acidity function in concentrated NaOH solutions. Equation 1 is applicable when the carbanion is generated in buffer solutions, at a given pH and a λ_{max}. Equation 2 is applicable when the carbanion is generated in a solution of concentration below 0.1 M NaOH. It is necessary to use h_- instead of [OH^-] (Eq. 3) when the concentration of NaOH is 0.1—4 M.[8]

Optical densities at 290 nm except for **8** (310 nm) were recorded at various alkaline concentrations. The spectra of **2** and the plots of ε_{app} *vs.* $\varepsilon_{app}/[OH^-]$ are shown in Figs. 1 and 2, respectively. The K_a values were then calculated from the slopes by the least squares method.

Effect of a Cationic Micelle. The concentrations of hexadecyltrimethylammonium bromide (CTAB) were

1: ([NaOH]=0), 2: (0.005), 3: (0.01), 4: (0.025), 5: (0.05), 6: (0.1).

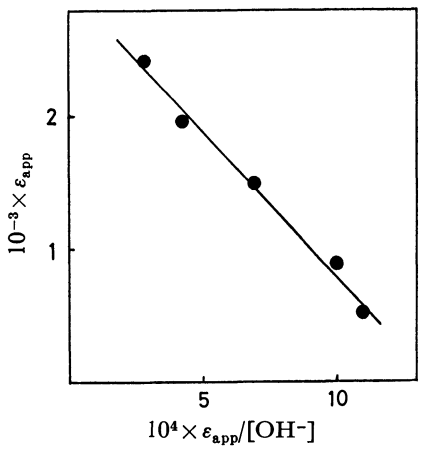

Fig. 2. Plots of ε_{app} *vs.* $\varepsilon_{app}/[OH^-]$ for **2** (see Eq. 2 and Fig. 1): $K_w/K_a=2.11\times10^{-2}$, $K_a=4.74\times10^{-13}$, $pK_a=12.33$.

TABLE 1. EFFECT OF CTAB CONCENTRATION ON pK_a

$10^3\times$[CTAB]/M	pK_a		
	1	**2**	**8**[a]
0	12.09[b]	12.33[b]	9.08
0.4	—	11.90[b]	9.08
0.6	11.86[b]	—	—
1.0	11.26[c]	10.63[d]	—
2.0	11.11[c]	10.47[d]	8.94
4.0	11.06[c]	10.41[d]	8.61
8.0	11.12[c]	10.57[d]	8.62
12.0	—	—	8.61
20.0	—	—	8.61

a) Eq. 1 used (pH 6.62—10.2, 8 or 9 points). b) Eq. 2 used (0.004—0.1 M NaOH, 6 points). c) Eq. 1 used (pH 10.00—11.92, 7 points). d) Eq. 1 used (pH 10.00—11.60, 8 points).

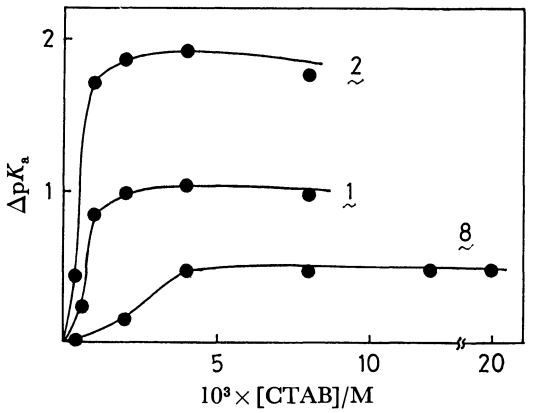

Fig. 3. Plots of ΔpK_a $[pK_a(H_2O)-pK_a(CTAB)]$ *vs.* CTAB concentration (see Table 1).

varied as usual for **1**, **2**, and **8**. The results are given in Table 1. The plots of $\Delta pK_a[pK_a(H_2O)-pK_a(CTAB)]$ against CTAB concentration gave saturation curves (Fig. 3), indicating the incorporation of substrates into the micelle. Larger ΔpK_a values were observed for more hydrophobic substrates (**2**>**1**>**8**).

The pK_a and λ_{max} of carbanions in the micellar phase and in the absence of CTAB are summarized in Table 2. The absorption spectra (λ_{max}) of the carbanions of disulfones shift to longer wave length ($\Delta\lambda$=9—12 nm) in the presence of CTAB (8×10^{-3} M), the λ_{max} of diketone (**8**) remaining unchanged irrespective of the presence of CTAB. The ΔpK_a of **8** is also small. In the case of disulfone, both equilibrium (ΔpK_a) and delocalization ($\Delta\lambda_{max}$) of carbanion are favored to a greater extent in a cationic micellar phase than in aqueous phase. In the case of diketone, the carbanion might assume the enolate form preferentially which is stablized by hydration. No change in λ_{max} and the small ΔpK_a value in **8** suggest that such hydration is little affected by incorporation into a cationic micelle.

TABLE 2. pK_a AND λ_{max} OF CARBANIONS WITH AND WITHOUT CTAB (8×10^{-3} M)

Compd	pK_a (λ_{max}/nm)		ΔpK_a	$\Delta\lambda$/nm
	CTAB=0	CTAB=8×10^{-3} M		
1	12.09[a] (274)	11.12 (284)	0.97	10
2	12.33 (274)	10.48 (286)	1.85	12

6	14.24[d] (274)	11.17[c] (283)	1.12	9
7	12.24[b] (274)	10.69[c] (284)	1.55	10
8	9.08 (305)	8.61 (305)	0.47	0

a) Reported value 12.12. b) Eq. 2 used for NaOH in the range 0.004—0.1 M. c) Eq. 1 used in the pH range 10.36—11.61. d) Eq. 3 used for NaOH in the range 0.1—2 M.

Hydrophobic Nature of Carbanion. A certain relation holds between pK_a and the hydrophobic nature of substrates. The plots of ΔpK_a against the number of methylene group of the disulfones are shown in Fig. 4. If a single least squares line is drawn for the six points, the slope gives 200 cal/mol as the standard free energy change associated with pK_a decrease per methylene group. However, if two lines are drawn separately for the acyclic and cyclic derivatives, they give 210 and 450 cal/mol, respectively. The choice of

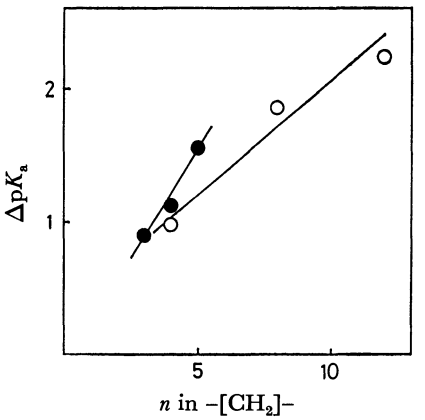

Fig. 4. Plots of ΔpK_a *vs.* methylene number of alkyl chains:
○: Acylic disulfones, ●: cyclic disulfones (see Table 2).

value is difficult due to insufficiency of data. The value of 450 cal/mol for cyclic disulfones seems to be normal as compared to the values (350—900 cal/mol) suggested for hydrophobic interactions.[9] A micellar effect associated with the change of methylene number might be larger for more rigid molecules than for flexible ones, since conformational changes such as curling up of long alkyl chain in aqueous phase are much more easy for acyclic than for cyclic compounds which reduce the free energy change (micellar effect) between aqueous and micellar phase.

The unusually high pK_a of six membered disulfone **5**, is puzzling although ΔpK_a is normal.

Experimental

Melting points are uncorrected. NMR spectra were recorded on a Varian A-60 spectrometer, the chemical shifts being given downfield from tetramethylsilane, and UV spectra on a Shimadzu UV 200 spectrophotometer. pH was measured with a Hitachi-Horiba F-7DE pH meter. Water used for pK_a measurement was purified by distillation of deionized water.

Materials. Commercial 3-phenyl-2,4-pentanedione (**8**) was used after recrystallization from benzene–hexane, mp 57—58 °C (lit,[10] 58—60 °C).

Disulfones were prepared by oxidation of the corresponding thioacetals with 30% hydrogen peroxide in acetic acid containing acetic anhydride.[11],.

1: Yield 56%, mp 133 °C (EtOH–H_2O) (lit,[11] mp 133—134 °C). NMR (DMSO-d_6): δ 1.22 (6H, t), 3.31 (4H, q), 6.56 (1H, s), 7.37—7.84 (5H, m).

2: Yield 56%, mp 90—91 °C (EtOH–H_2O) (lit,[12] mp 86 °C). Found: C, 54.36; H, 7.10; S, 19.5%. Calcd for $C_{15}H_{24}O_4S_2$: C, 54.18; H, 7.29; S, 19.28%.

3: Yield 47%. 78.5—80.5 °C (MeOH). NMR (DMSO-d_6): δ 0.84 (6H, t), 1.10—1.40 (16H, br. s), 3.25 (4H, t), 6.53 (1H, s), 7.35—7.75 (5H, m). Found: C, 59.00; H, 8.34; S 17.0%. Calcd for $C_{19}H_{32}O_4S_2$: C, 58.72; H, 8.32; S, 16.50%.

4: Yield 43%, mp 243—245 °C (benzene). NMR (DMSO-d_6): δ 4.20 (4H, s), 6.27 (1H, s), 7.50—7.70 (5H, m). Found: C, 43.90; H, 4.13; S, 26.2%. Calcd for $C_9H_{10}O_4S_2$: C, 43.88, H, 4.10; S, 26.03%.

5: Yield 49%, mp 259—262 °C (EtOH) (lit,[13] 264—265 °C). NMR (DNSO-d_6): δ 2.30—2.60 (2H, m), 3.45—3.77 (4H, m), 6.53 (1H, s), 7.45—7.75 (5H, m). Found: C, 46.13; H, 4.51; S, 24.1%. Calcd for $C_{10}H_{12}O_4S_2$: C, 46.13; H, 4.66; S, 24.63%.

6: Yield 55%, mp 249—251 °C (EtOH). NMR (DMSO-d_6): δ 2.00—2.33 (6H, m), 3.60—3.97 (4H, m), 6.63 (1H, s), 7.45—7.62 (5H, m). Found: C, 48.47; H, 5.23; S, 23.4%. Calcd for $C_{11}H_{14}O_4S_2$: C, 48.16; H, 5.14; S, 23.37%.

7: Yield 40%, mp 258—260 °C (EtOH). NMR (DMSO-d_6); δ 1.42—2.08 (6H, m), 3.14—3.62 (4H, m), 6.35 (1H, s) 7.38—7.78 (5H, m). Found: C, 49.89; H, 5.51; S, 22.3%. Calcd for $C_{12}H_{16}O_4S_2$: C, 50.00; H, 5.59; S, 22.20%.

pK_a Measurement. The pK_a values were determined by the spectrophotometric method.[7] The stock solutions (4×10^{-2} M) were prepared in EtOH for **1**, **2**, **3**, and **8**, and in CH_3CN for **4**, **5**, **6**, and **7**. Aqueous alkaline solution in a septum-rubber capped volumetric flask (5 ml) was bubbled with nitrogen for 15 min. The CTAB solution was added with a microsyringe, the solution being equilibrated at 25 °C. The substrate solution (25 μl) was added with a microsyringe, *ca.* 3 ml of the solution being put into the rubber-capped UV cell with a syringe. Optical densities at 290 nm except for **8** (310 nm) were recorded at various alkaline concentrations with a Shimadzu 200 UV instrument. Typical spectra are shown in Fig. 1. The pK_a of **3** in water (CTAB=0) could not be determined because of solubility. Thus, pK_a in H_2O was estimated from the pK_a values in 40, 60, and 80% EtOH. The pK_a values in these solvents (12.29, 12.14, and 11.81) were plotted against reciprocal of H_2O %, giving a straight line and allowing extrapolation to give $pK_a=12.37$ (Table 2).

Branched-chain Sugars. XXI. Synthesis of New Branched-chain Cyclitols Having *neo*-, *myo*-, and *chiro*-Configurations from 3-*O*-Benzyl-5,6-dideoxy-5-*C*-(1,3-dithian-2-yl)-6-nitro-D-galactofuranose and -L-altrofuranose[1]

Masaharu IWAKAWA,* Juji YOSHIMURA, and Masuo FUNABASHI†

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

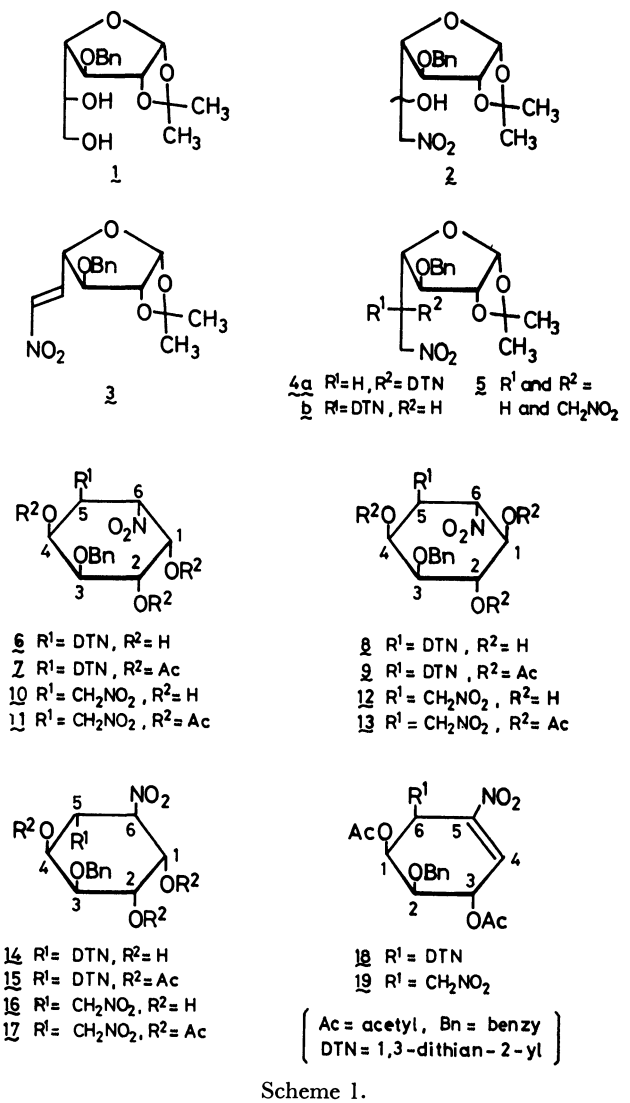
(Received July 17, 1980)

The Michael addition of 2-lithio-1,3-dithiane to 3-*O*-benzyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-β-L-*arabino*-hex-5-enofuranose afforded a 1 : 1.8 mixture of 3-*O*-benzyl-5,6-dideoxy-5-*C*-(1,3-dithian-2-yl)-1,2-*O*-isopropylidene-6-nitro-α-D-galactofuranose and -β-L-altrofuranose. Removal of the isopropylidene group and intramolecular cyclization under weakly basic conditions afforded a mixture of branched-chain cyclitols having *neo*-, *myo*-, and *chiro*-configuration. A similar cyclization of the *O*-deisopropylidenated product of 3-*O*-benzyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-5-*C*-(nitromethyl)-β-L-*arabino*-hexofuranose also afforded a mixture of cyclitols having *neo*-, *myo*-, and *chiro*-configuration. The results confirm the importance of two bulky groups such as benzyloxy at C-3 and 1,3-dithiane residue at C-5 in determining the stereodirection of cyclization.

In previous papers[2-4] it was reported that the intramolecular cyclization of 3-*O*-benzyl-5,6-dideoxy-5-*C*-(1,3-dithian-2-yl)-6-nitrohexoses gives stereoselectively a few nitro cyclitols in which bulky substituents at C-5 and C-6 exclusively occupy *trans*-orientation and the newly formed hydroxyl group substantially occupies equatorial orientation when 3-*O*-benzyl group takes an axial orientation. Thus, the corresponding D-*gluco* derivatives[2,4] gave *muco*-nitro cyclitols exclusively, and L-*ido* derivative[2] *scyllo*- and *myo*-nitroinositols in a 1 : 1 ratio. The validity of this hypothesis was confirmed by the fact that the corresponding L-*talo* derivative gave only *myo*-nitroinositol, and the D-*allo* derivative gave *epi*- and *allo*-nitroinositols in a 1 : 1 ratio.[3] We have examined our hypothesis by the intramolecular cyclization of D-*galacto*- and L-*altro*-derivatives (**4a** and **4b**).

Results and Discussion

3-*O*-Benzyl-5,6-dideoxy-5-*C*-(1,3-dithian-2-yl)-6-nitro-D-galactofuranose (**4a**) and -L-altrofuranose (**4b**) were prepared in the same manner as reported.[2-4] 3-*O*-Benzyl-1,2-*O*-isopropylidene-α-D-galactofuranose (**1**)[5] was at first oxidized with sodium periodate in aqueous methanol, and the resulting aldehyde was treated with nitromethane in methanol in the presence of sodium methoxide to give C-5 epimeric nitro alcohols (**2**)[6] in a good yield. Direct dehydration of the compound **2** with acetic anhydride–sodium acetate[7] afforded 3-*O*-benzyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-β-L-*arabino*-hex-5-enofuranose (**3**) in 95% yield. Addition of 2-lithio-1,3-dithiane to **3** in dry tetrahydrofuran at −45 to −50 °C gave a syrupy mixture of **4a** and **4b** in 50% yield after being subjected to silica gel column chromatography. The ratio of **4a** to **4b** was estimated to be 1 : 1.8 by comparison of intensities of H-1 protons. Addition of nitromethane to **3** also gave 3-*O*-benzyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-5-*C*-nitromethyl-β L-*arabino*-hexofuranose (**5**) in 65% yield.



Scheme 1.

From a theoretical point of view, D-*galacto* isomer **4a** should give branched-chain *chiro*- and/or *muco*-inositol derivatives, whereas L-*altro* isomer **4b** should give *myo*- and *neo*-inositol derivatives. However, stereo-

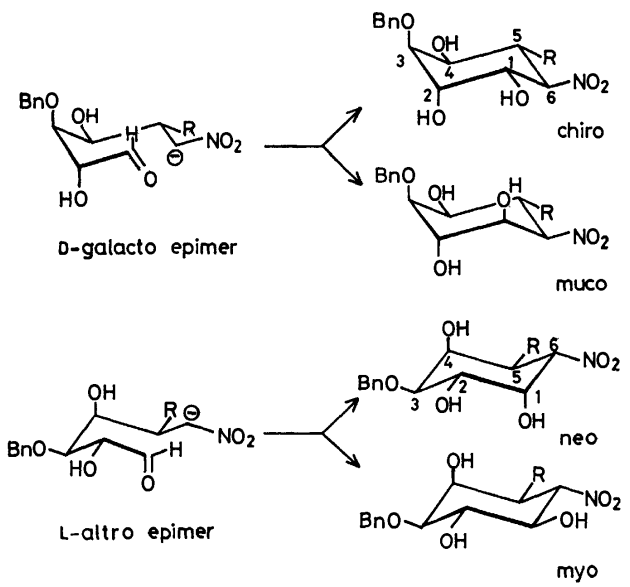

Scheme 2.

direction of the cyclization is rather limited,[2,3)] since it depends on whether or not the benzyloxy group at C-3 can occupy an axial orientation. The failure to form a *muco*-isomer would be anticipated since it would generate a 1,3-diaxial non-bonded interaction. This would destabilize the system.

Since the separation of **4a** and **4b** was unsuccessful, the mixture was refluxed in 75% acetic acid for 2 h to remove the 1,2-*O*-isopropylidene group. The free sugars obtained were treated with 2 equivalent sodium hydrogen-carbonate in aqueous methanol for 20 h to give a mixture of cyclitols, showing two main spots having R_f values of 0.43 and 0.32 on TLC (solvent C). The two components were separated by preparative TLC. From the less polar component *neo*-inositol derivative (**6**) was obtained in 27% yield as white needles. Acetylation of **6** with acetic anhydride in the presence of *p*-toluenesulfonic acid gave a crystalline triacetate (**7**) in 88% yield. Its configuration was demonstrated by NMR spectrum data (Table 1). However, recrystallization (from ethanol-hexane) or purification with preparative TLC caused a partial degradation of **7** to the corresponding nitro olefin (**18**). Such a transformation is usually observed in the cases of similar nitro cyclitols in which the nitro group and the newly formed, vicinal hydroxyl group occupy the *cis*-orientation.[2)]

A mixture of other inositol derivatives (other than *neo*-configuration) was obtained from a more polar component in 54% yield as a syrup, from which *chiro*-isomer (**14**) crystallized out as prisms in 20% yield. The structure of **14** is supported by the NMR spectrum of its triacetate (**15**). The mother liquor of **14** was evaporated and the residue was treated with acetone in the presence of anhydrous copper(II) sulfate and a few drops of concentrated sulfuric acid to remove trace of **14** from the mixture.

After separation of **14** by means of preparative TLC, compound (**8**) (*myo*-configuration) was isolated, its structure being confirmed by means of the NMR parameters of its crystalline tri-*O*-acetate (**9**).

Similar cyclization of **5** was achieved by treating **5** with 70% acetic acid and sodium hydrogencarbonate in aqueous methanol successively, three isomers of nitro cyclitols having *neo*- (**10**), *myo*- (**13**), and *chiro*- (**16**) configuration being isolated in 18, 10, and 10% yields, respectively. Each structure was confirmed by the analysis of NMR spectra of their acetates. *O*-acetyl derivatives of these nitro cyclitols were also very labile and could not be obtained in the pure state except for *myo*-isomer. In the case of *neo*-isomer **10**, its tri-*O*-acetate **11** was readily transformed into the correspond-

ing nitro olefin (**19**) during the course of recrystallization. The formation of three isomeric nitro cyclitols is of interest as compared with the results in which only two out of four possible isomers were formed in the case of 3-*O*-benzyl-5,6-dideoxy-1,2-*O*-isopropylidene-5-*C*-(nitromethyl)-6-nitro-α-D-*ribo*-hexofuranose.[3]

Such bulky groups as benzyloxy group, 1,3-dithian-2-yl group and nitromethyl group have decisive influence on the stereodirection of the intramolecular cyclization of **4** and **5** to afford branched-chain nitro cyclitols.

Experimental

Melting points were determined with a YANACO micro melting-point apparatus and are uncorrected. IR spectra were recorded on a Hitachi 260-10 spectrophotometer. Proton magnetic resonance (100 MHz) were recorded on a JNM-PS-100 spectrometer in chloroform-*d* with tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ and Hz units, respectively, and IR frequencies in cm^{-1}. Optical rotations were determined on a JASCO DIP-4 digital polarimeter or a Karl Zeiss LEP Al polarimeter. TLC and preparative TLC were performed with silica gel (E. Merck type 60) as an adsorbent in the following solvent systems (v/v): A, hexane–ethyl acetate, 3 : 1; B, 2 : 1; C, 1 : 1, D, 1 : 2. Solvents were evaporated under reduced pressure below 40 °C.

A Mixture (2) of 3-O-Benzyl-6-deoxy-1,2-O-isopropylidene-6-nitro-α-D-galactofuranose and -β-L-altrofuranose. Sodium periodate (1.90 g, 8.9 mmol) was added to an ice-cooled solution of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-galactofuranose (**1**)[5] (2.54 g, 8.2 mmol) in aqueous methanol (methanol: water=70 : 35 v/v). The reaction mixture was stirred at the same temperature for 30 min, and then at room temperature for 1.5 h. The mixture was filtered and the solid washed with methanol. The filtrate and washings were combined, concentrated to remove as much methanol as possible, and extracted several times with dichloromethane (*ca.* 150 ml). The organic layer was washed with brine, dried over anhydrous magnesium sulfate, and concentrated to afford aldehyde as a clear syrup.

To an ice-cooled solution of the aldehyde obtained above and nitromethane (35 ml) in absolute methanol (70 ml) was added 1 M sodium methoxide in methanol (8.2 ml), and the mixture was kept at room temperature for 15 h. Acetic acid (1.5 ml) was added to the light brown solution thus obtained, the solvent being removed by evaporation. The residue was partitioned between dichloromethane (100 ml) and water (50 ml), and the water layer further extracted with dichloromethane (20 ml×2). Combined dichloromethane layer was washed with brine, dried over anhydrous magnesium sulfate, and concentrated to dryness to afford an epimeric mixture of nitro aclohols as a thick syrup. One of the epimers crystallized from ethanol–hexane (1.38 g, 50%): mp 94°; $[\alpha]_D^{17.5}$ −8.7° (*c* 0.74, CH_2Cl_2). Purification of the mother liquor on a silica gel column (solvent A) afforded a mixture of epimers as a syrup (1.35 g, 37%): IR 3450 (OH), 1550, 1575 ($-NO_2$); NMR (after the addition of D_2O), 1.31, 1.51 (s, 3H each), 3.95—4.48 (m, 7H), 4.66 (d, H-2), 5.92 (d, 1H, $J_{1,2}$=4.0, H-1), 7.33 (s, 5H, Ph). Found: C, 56.59; H, 7.25; N, 4.28%. Calcd for $C_{16}H_{21}NO_7$: C, 56.63; H, 6.24; N, 4.13%.

3-O-Benzyl-5,6-dideoxy-1,2-O-isopropylidene-6-nitro-β-L-arabino-hex-5-enofuranose (3). A mixture of **2** (1.23 g, 3.63 mmol) and anhydrous sodium acetate (2.20 g) in acetic anhydride (7.1 ml) was stirred at room temperature for 48 h and poured into aqueous sodium hydrogencarbonate (50 ml). The oil precipitated was extracted with dichloromethane (50 ml×3), washed with aqueous sodium hydrogencarbonate and brine and dried with anhydrous sodium sulfate. The solvent was evaporated to afford **3** as a light yellow syrup (1.12 g, 95%), sufficiently pure for further preparation; purification on a silica gel column and/or preparative TLC was not successful: IR 1530, 1350 (C=C–NO_2).

3-O-Benzyl-5,6-dideoxy-5-C-(1,3-dithian-2-yl)-1,2-O-isopropylidene-6-nitro-β-L-altrofuranose and -α-D-galactofuranose (4). To a cooled (−45——50 °C) solution of **3** (2.22 g, 6.9 mmol) in dry tetrahydrofuran (THF, 10 ml) was added all at once a solution of 2-lithio-1,3-dithiane prepared at −45 °C from 1,3-dithiane (1.22 g, 10.2 mmol) and butyllithium (15% hexane solution, 6.2 ml, 9.68 mmol) in dry THF (14 ml). The reaction mixture was stirred at the same temperature for 45 min, then at room temperature for 30 min, and acidified with acetic acid (1 ml). The light brown solution was concentrated to a residue which was partitioned between water (50 ml) and dichloromethane (50 ml). The water layer was extracted with dichloromethane (25 ml×2). The dichloromethane layers were combined, washed with brine, dried ($MgSO_4$), and concentrated to a syrup (3.32 g); TLC (solvent A) revealed the presence of a major component having the R_f value 0.40. Isolation of the major component by means of silica gel column chromatography afforded a mixture of 5-*C*-epimers **4** as a syrup (1.51 g, 50%). In a NMR spectrum of **4** taken in benzene-d_6 in the presence of tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato)-praseodymium were observed two anomeric protons with a coupling constant of 3.75 at 5.36 and 5.48. Since *neo*-(**6**) and *myo*-nitro cyclitol (**9**) were isolated to a greater extent (the sum of 44%) than *chiro*-isomer (**14**) (20%), the peak at 5.36 was assigned to H_1 of D-*galacto*-isomer (**4a**) and the one at 5.48 to H-1 of L-*altro*-isomer (**4b**). The ratio D-*galacto*: L-*altro* was estimeted to be 1 : 1.8. Found: C, 54.70; H, 6.08; N, 2.91; S, 14.43%. Calcd for $C_{20}H_{27}NO_6S_2$: C, 54.40; H, 6.16; N, 3.17; S, 14.52%.

3-O-Benzyl-5,6-dideoxy-1,2-O-isopropylidene-6-nitro-5-C-nitromethyl-β-L-arabino-hexofuranose (5). A solution of nitro olefin **3** (642 mg, 2 mmol) in methanol (6 ml) was added to an ice-cooled solution of nitromethane (3 ml, 55 mmol) in dry methanol (15 ml) containing 1.6 ml of 1 M sodium methoxide in absolute methanol. The reaction mixture was kept at room temperature for 1 h, acidified with acetic acid (1 ml), and concentrated to dryness. The residue was partitioned between dichloromethane (70 ml) and water (20 ml). The dichloromethane layer was washed with brine, dried ($MgSO_4$), and concentrated to a syrup. TLC (solvent A) showed a presence of a major component having the R_f value 0.45. Isolation of the major component by means of preparative TLC afforded **5** as a syrup (501 mg, 66%): $[\alpha]_D^{26}$ −34.4° (*c* 0.72 chloroform); IR 1560, 1380 ($-NO_2$); NMR 1.36, 1.52 (3Hs each, C–CH_3), 3.26 (m, 1H, $J_{5,6}$=5.9, $J_{5,6'}$=4.3, H-5), 3.94 (d, 1H, $J_{3,4}$=3.8, H-3), 4.06 (dd, 1H, $J_{4,5}$=9.7, H-4), 4.4—4.8 (6H, $-CH_2NO_2\times2$, $-CH_2$–Ph), 4.68 (d, 1H, $J_{1,2}$=3.75, H-2), 5.86 (d, 1H, H-1), 7.36 (s, 5H, Ph), Found: C, 53.82; H, 5.65; N, 7.10%. Calcd for $C_{17}H_{22}N_2O_8$: C, 53.40; H, 5.80; N, 7.33%.

Hydrolysis of 4 and Intramolecular Cyclization. A solution of **4** (0.6815 g) in 75% acetic acid (35 ml) was heated to reflux for 2 h. The light brown solution was concentrated to dryness. A trace of acetic acid was codistilled with toluene. The residue was then dissolved in methanol (30 ml) and treated with sodium hydrogencarbonate (260 mg) in water (15 ml) at room temperature for 20 h. The solution was neutralized by the addition of ion exchange resin (Dowex

50 W×8, H^+ form, 4 ml). Evaporation of the solvent afforded a crude mixture of nitrocyclitols as light brown foam (567 mg, 94.2%). TLC (solvent C) indicated the presence of two components having the R_f values 0.43 and 0.32, respectively. Preparative TLC (solvent C) afforded a less polar component having the R_f value 0.43 (168.5 mg, 27%), and a more polar component having the R_f value 0.32 (334.4 mg, 54%).

1D-(1,2,6/3,4,5)-3-O-Benzyl-5-(1,3-dithian-2-yl)-6-nitro-1,2,3,4-cyclohexanetetrol (6).[8] Recrystallization of the component having the R_f value 0.43 from ethanol afforded **6** as needles: mp 166—169 °C; $[\alpha]_D^{18}$ −5.7° (*c* 2.1, methanol); IR 3420 (OH), 1545, 1370 (-NO_2). Found: C, 50.80; H, 6.10; N, 3.13%. Calcd for $C_{17}H_{23}O_6NS_2$: C, 50.86; H, 5.77; N, 3.49%.

1D-(1,2,6/3)-1,3-Di-O-acetyl-2-O-benzyl-6-(1,3-dithian-2-yl)-5-nitrocyclohex-4-ene-1,2,3-triol (18). Acetylation of **6** in acetic anhydride in the presence of catalytic amount of *p*-toluenesulfonic acid gave crude tri-*O*-acetate **7**, in 88% yield, which gradually decomposed into nitro olefin (**18**) which was isolated with preparative TLC as yellow syrup: $[\alpha]_D^{27}$ +129.7° (*c* 3.38, methanol–dichloromethane: 1 : 3 v/v); NMR 2.07, 2.10 (s, 3H each, OAC), 2.91 (m, 4H), 3.79 (m, 1H, H-6), 4.15 (dd, 1H, $J_{2,3}$=8.0, $J_{1,2}$=2.5, H-2), 4.36 (d, 1H, $J_{1',6}$=7.5, H-1'), 4.56 and 4.72 (ABq, 2H, J_{AB}=12.0, -CH_2-), 5.65 (ddd, 1H, $J_{3,6}$=1.5, $J_{3,4}$=3.5, H-3), 6.03 (t, 1H, $J_{1,6}$=2.5), 7.10 (d, 1H, H-4), 7.35 (m, 5H, Ph). Found: C, 54.56; H, 5.64; N, 2.82%. Calcd for $C_{21}H_{25}O_7NS_2$: C, 53.95; H, 5.39; N, 3.00%.

1D-(1,2,5/3,4,6)-3-O-Benzyl-5-(1,3-dithian-2-yl)-6-nitro-1,2,3,4-cyclohexanetetrol (14). The more polar component obtained above was tritulated and recrystallized from ethanol–hexane to afford **14** as prisms (20%): mp 191.5—193.5° (dec); $[\alpha]_D^{26.5}$ +5.7° (*c* 1.06, methanol); IR 3550, 3400, 3330 (OH), 1550 (-NO_2). Found: C, 50.59; H, 5.71; N, 3.31%. Calcd for $C_{17}H_{23}NO_6S_2$: C, 50.86; H, 5.77; N, 3.49%. Tri-*O*-acetate **15** was prepared by treatment **14** with acetic anhydride-*p*-toluenesulfonic acid.

1L-(1,3,4,5/2,6)-1,2,4-Tri-O-acetyl-3-O-benzyl-5-(1,3-dithian-2-yl)-6-nitro-1,2,3,4-cyclohexanetetrol (9). The mother liquor left from the isolation of **14** was concentrated to dryness and treated with acetone and anhydrous copper(II) sulfate in the presence of a catalytic amount of sulfuric acid for one week. The reaction mixture was then passed through a short column of silica gel and concentrated to dryness.

TLC of the mixture (solvent C) indicated the presence of two components, which were separated by means of preparative TLC.

The more polar component was treated with acetic anhydride in the presence of *p*-toluenesulfonic acid to afford crystalline **9** in 17% yield (from **4**): mp 215—217°; $[\alpha]_D^{18}$ +48.6° (*c* 0.5, dichloromethane); IR 1755 (-$OCCH_3$), 1560, 1370 (-NO_2). Found: C, 52.58; H, 5.72; N, 2.62%. Calcd for $C_{23}H_{29}NO_9S_2$: C, 52.36; H, 5.54; N, 2.65%.

The less polar component was treated with boiling 75% acetic acid for 2 h and acetylated with acetic anhydride-*p*-toluenesulfonic acid to give **15**.

Hydrolysis of 5 and Intramolecular Cyclization. A solution of **5** (1.15 g) in 70% acetic acid (50 ml) was heated to reflux for 2 h. The dark brown solution was concentrated to dryness and a trace of acetic acid was removed by codistillation with toluene. The residue was dissolved in methanol (50 ml) and treated with sodium hydrogencarbonate (427 mg) in water (25 ml) at room temperature for 16 h. The light brown solution was neutralized with Dowex 50 W×8 (H^+) (5 ml) and concentrated to dryness to afford a half crystalline residue (0.9825 g, 95%). TLC indicated the presence of two major components having R_f values 0.29 and 0.22 (solvent C).

1D-(1,2,6/3,4,5)-3-O-Benzyl-6-nitro-5-nitromethyl-1,2,3,4-cyclohexanetetrol (10). To the residue obtained above (983 mg) was added ethanol (*ca.* 20 ml) and the mixture was kept in a refrigerator overnight. Crystals precipitated were collected (194 mg, 18.8% from **5**) and recrystallized from ethanol to afford **10** as prisms: mp 225—228° (dec); R_f 0.29 (solvent C); $[\alpha]_D^{27.5}$ −46.1° (*c* 0.77, acetone); IR 3540, 3350, 3300 (OH), 1555, 1570, 1340, 1380 (-NO_2). Found: C, 48.89; H, 5.21; N, 8.19%. Calcd for $C_{14}H_{18}N_2O_8$: C, 49.12; H, 5.30; N, 8.18%.

1D-(1,2,6/3)-1,3-Di-O-acetyl-2-O-benzyl-5-nitro-6-nitromethylcyclohex-4-ene-1,2,3-triol (19). A solution of **10** (26.2 mg) in acetic anhydride containing a catalytic amount of *p*-toluenesulfonic acid was kept overnight at room temperature. The solution was poured into ice water, extracted with dichloromethane, washed with water, dried (Na_2SO_4), and concentrated to afford crude tri-*O*-acetate **11** (29.6 mg, 82.5%) sufficiently pure for NMR analysis. Purification of crude tri-*O*-acetate **11** was performed on preparative TLC (solvent system A). The major fraction was isolated and recrystallized from ethanol–hexane to afford cyclohexene derivative **19** as prisms (20.1 mg, 78% from **11**): mp 138—139°; $[\alpha]_D^{27}$ +57.9° (*c* 0.88, methanol: dichloromethane=5 : 1 v/v); IR 1755, 1740 (esters), 1575, 1370 (aliph-NO_2), 1535, 1340 (vinyl-NO_2); NMR 1.96, 2.10 (s, 3H each -OAc), 3.83 (dt, 1H, $J_{2,4}$=1.0, $J_{1,2}$=$J_{2,3}$=2.5, H-2), 4.34 (m, 1H, H-6), 4.46 (dd, 1H, $J_{1',1''}$=14.0, $J_{1',6}$=3.0, H-1'), 4.66 and 4.73 (ABq, 2H, J=12.5, -CH_2-), 5.22 (dd, 1H, $J_{1'',6}$=7.0, H-1''), 5.32 (dd, 1H, $J_{1,6}$=6.5, H-1), 5.62 (dd, 1H, $J_{3,6}$=1.0, $J_{3,4}$=4.0, H-3), 7.30 (dd, 1H, H-4), 7.37 (m, 5H, Ph). Found: C, 52.43; H, 4.98; N, 6.91%. Calcd for $C_{18}H_{20}N_2O_9$: C, 52.94; H, 4.94; N, 6.86%.

1L-(1,3,4,5/2,6)-1,2,4-Tri-O-acetyl-3-O-benzyl-6-nitro-5-nitromethyl-1,2,3,4-cyclohexanetetrol (13). To a suspension of an intramolecular cyclization mixture of **5** (315 mg) in dry acetone (3 ml) and 2,2-dimethoxypropane (6 ml) was added a catalytic amount *p*-toluenesulfonic acid monohydrate, and the clear solution obtained immediately was kept at room temperature overnight. The mixture was then diluted with dichloromethane (100 ml) and washed twice with aqueous sodium hydrogenecarbonate (10 ml). The water layer was extracted with dichloromethane (20 ml). Dichloromethane layers were combined, washed with brine, and dried (anhydrous sodium sulfate). Evaporation of the solvent afforded a syrupy mixture. TLC indicated the presence of two major components having R_f values 0.73 and 0.63 (solvent C).

The component having the R_f value 0.73 was isolated by preparative TLC as syrup (76.0 mg, 22%) dissolved in 80% acetic acid and heated to reflux 1.5 h. The reaction mixture was concentrated to a solid residue. The residue was acetylated with acetic anhydride (1 ml) containing a catalytic amount of *p*-toluenesulfonic acid, and the usual work-up of the acetylation mixture afforded a solid mass which recrystallized from ethanol to give **13** as prisms (44.7 mg, 10.3% from **5**): mp 141—143°; $[\alpha]_D^{30}$ +111.2° (*c* 1.0, dichloromethane); IR 1750 (ester), 1575, 1560, and 1375 (aliph-NO_2). Found: C, 51.20; H, 5.30; N, 6.14%. Calcd for $C_{20}H_{24}N_2O_{11}$: C, 51.28; H, 5.16; N, 5.98%.

1D-(1,2,5/3,4,6-)-3-O-Benzyl-6-nitro-5-nitromethyl-1,2,3,4-cyclohexanetetrol (16). The component having the R_f value 0.63 was isolated with preparative TLC as a syrup (62.4 mg, 18%), dissolved in 80% acetic acid (10 ml) and heated to reflux for 1.5 h. The reaction mixture was concentrated to a solid mass, and recrystallized from ethanol–

hexane to afford **16** as needles (38.9 mg, 10.2% from **5**): mp 187—189°; $[\alpha]_D^{27}$ −36.8° (*c* 1.0, methanol); IR 3500, 3400 (OH), 1560, 1550, 1380, 1360 (NO_2). Found: C, 49.10; H, 5.26; N, 8.17%. Calcd for $C_{14}H_{18}N_2O_8$: C, 49.12; H, 5.30; N, 8.18%.

1,2,4-Tri-*O*-acetyl derivative **7** was prepared by the treatment of **16** with acetic anhydride and *p*-toluenesulfonic acid.

Polarographic Studies on Ninhydrin in DMF and Dehydration from *gem*-Diol Structure

Mitsuaki OHMORI** and Masanosuke TAKAGI*

Laboratory of Food Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai 591
***Osaka City Institute of Public Health and Environmental Sciences, Tennoji-ku, Osaka 543*

(Received July 24, 1980)

The d.c.-polarogram of ninhydrin (I) in DMF containing 0.1 M TEAP shows three cathodic waves whose $E_{1/2}$ are −0.38, −0.65, and −1.23 V (*vs.* SCE), respectively. The first wave with a large maximum is attributed to one-electron reduction of 1,2,3-indantrione (II), the hydrated form of I, the second to one-electron reduction of I, and the third to one-electron reduction of the preceding electrochemical product from both I and II. CV Curves of I show three cathodic peaks, pc_1, pc_2, and pc_3, and two anodic peaks, pa_1, and pa_2, showing reversible character of pc_1 and pc_3 but not of pc_2. Different equilibria seem to take place between I and II in the bulk of the solution and at electrode surface. Hydration of II and dehydration of I in DMF were observed at 550 nm spectroscopically. A scheme is proposed for the electrolytic reduction of I in DMF.

The electrochemical behavior of carbonyl compounds is of interest as regards the electron transfer in biological systems. Aldehydes,[1,2] ketones,[3] α-keto acids,[4,5] di- and tricarbonyl compounds[6,7] and many other carbonyl compounds have been studied. However, ambiguities with origins mostly attributed to the hydration of carbonyl groups in aqueous systems remain and studies in nonaqueous systems are expected to clarify them.

Ninhydrin (I) is available as a stable monohydrated form of the corresponding tricarbonyl compound 1,2,3-indantrione (II). Its polarographic behavior in aqueous[8–12] and nonaqueous[13] solutions was reported. The effect of hydration and dehydration in nonaqueous solvents should be examined more in detail for the clarification of its electrochemical characteristics. We are interested in this study in relation to its partial structural similarity to dehydro-L-ascorbic acid[14,15] of biological importance.

Experimental

Chemicals. Ninhydrin (I) (analytical grade, Ishizu Pharmaceutical Co., Ltd., Osaka) was used without further purification. 1,2,3-Indantrione (II) was prepared as a purple powder by heating I under reduced pressure at 125—130 °C.[13]

Tetraethylammonium perchlorate (TEAP) (prepared for polarography, Nakarai Chemical Co., Ltd., Kyoto) was used after cautious drying under reduced pressure with appropriate heating.

Nonaqueous Solvent. *N,N*-Dimethylformamide (DMF) (analytical grade, Wako Pure Chemical Co., Ltd., Osaka) was dried as described by Mann.[16] For polarographic measurements, DMF containing 0.1 M (1 M=1 mol dm^{-3}) TEAP was deoxygenated by bubbling nitrogen gas dried with silica gel and phosphorus pentaoxide.

Apparatus. Polarographic measurements were carried out with a Yanagimoto Voltammetric Analyzer Type P-1000, characteristics of the capillary being $m=1.52$ mg/s, $t=4.00$ s^{-1} in DMF containing 0.1 M TEAP, when Hg level was 51.5 cm and −1.0 V was applied. Cyclic voltammetry was carried out with the Analyzer Type P-1000 with a function generator (NF Circuit Design Block Co., Ltd., Osaka). The working electrode was a hanging mercury electrode or a Pt electrode, a saturated calomel electrode (SCE), with a salt bridge[5] constructed of three gel layers, and an Ag/AgCl electrode being used as reference electrodes.

Results and Discussion

Polarographic Behavior of Ninhydrin (I). Polarograms of I were examined in dried and deoxygenated DMF, containing 0.1 M TEAP. A polarogram recorded immediately after direct dissolution of a necessary amount of crystalline I in the electrolyte solution (Fig. 1-a) showed an anomalous first wave with a large maximum and two other successive waves. The height of the first wave decreased with time, polarogram (a) changing into d *via* b and c. At the state of d, the first wave became stable, the shape of the wave not being anomalous. The half-wave potentials ($E_{1/2}$) of the three reduction waves were −0.38, −0.65, and −1.23V, respectively. At a very early period, the sum of the first and the second wave heights was a little higher than the height of the third wave, but decreased gradually with time and finally became equal to it. The slopes of logarithmic analysis for the three waves $dE/d \log [i_d/(i_d-i)]$ are 61, 38, and 85 mV, respectively.

When a very small amount of water (below 0.25%) was added to the electrolyte solution after recording

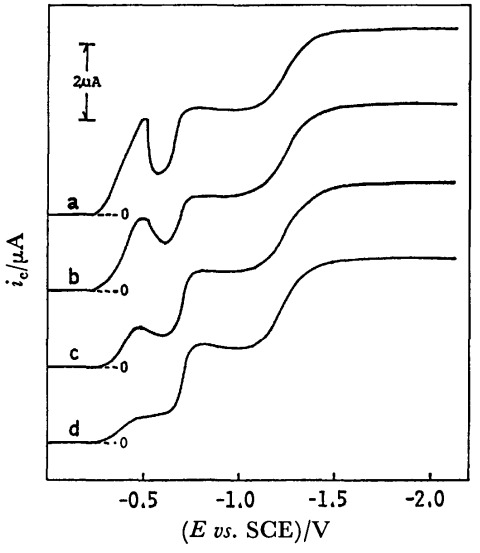

Fig. 1. Polarograms of ninhydrin.
Concn: 1×10^{-3} M, temp: 22 °C, a: Immediately after dissolving ninhydrin, b: 30 min, c: 60 min, d: 90 min.

(Fig. 1-a), a similar polarogram to d was obtained much more quickly than without addition of water.

The decrease in the first wave height seems to be related to the water content in the system. However, it is difficult to attribute the maximum observed in a to the water content. An equilibrium between the dehydrated form (II) and the hydrated form (I) in DMF should be considered, not only in the bulk of the solution but also at the electrode surface.

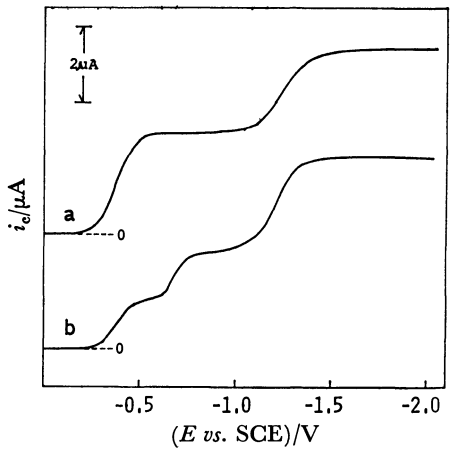

Fig. 2. Polarograms of 1,2,3-indantrione.
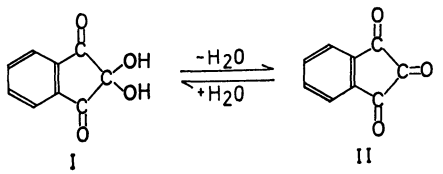
Concn: 1×10^{-3} M, temp: 19 °C, H_2O: a-0%, b-0.11%.

A polarogram of 1,2,3-indantrione (II), a dehydrated form of I, was also examined (Fig. 2-a). It showed two successive waves ($E_{1/2} = -0.38$ and -1.23 V). Kalinowski and Lasia reported that they observed two successive waves of II in absolute DMF containing 0.2 M $NaNO_3$ ($E_{1/2} = -0.39$ and -0.86 V *vs.* SCE),[13] each of which was ascribed by the authors to one-electron reduction.

When a small amount of water (0.11%) was added to the electrolyte solution after recording the polarogram (Fig. 2-a), a new wave ($E_{1/2} = -0.67$ V) appeared between the two waves at the expense of the first wave, *i.e.* in total, three waves were observed (Fig. 2-b). The first wave showed no maximum during the course of current decrease, the three waves corresponding to the three in Fig. 1-d, respectively. The newly appearing wave in Fig. 2-b may thus be attributed to I which is the hydration product of II in Eq. 1.



I II (1)

It is suggested that the first wave in Fig. 1 is attributed to II, since it has the same $E_{1/2}$ value as that of the first wave in Fig. 2. Polarogram a in Fig. 3 was observed when the necessary amount of I was added in dried DMF containing TEAP which had been exposed to atmosphere in crystalline form, the exposure time not exceeding 1 h. Polarograms b and c showed a very small but more positive wave with time (Fig. 3).

The results can be interpreted as follows. The chemically bound H_2O in I, *i.e.* in *gem*-diol structure, can be slowly removed even in an electrolyte solution dried insufficiently; equilibrium between I and II in

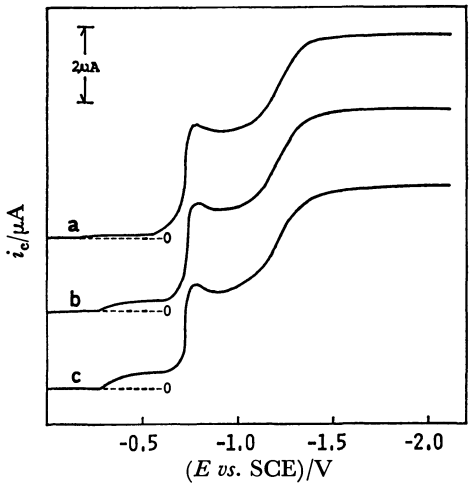


Fig. 3. Polarograms of ninhydrin taken with TEAP exposed to the atmosphere for about 1 h.
Concn: 1.1×10^{-3} M, temp: 22 °C, a: immediately after dissolving ninhydrin, b: 20 min, c: 60 min.

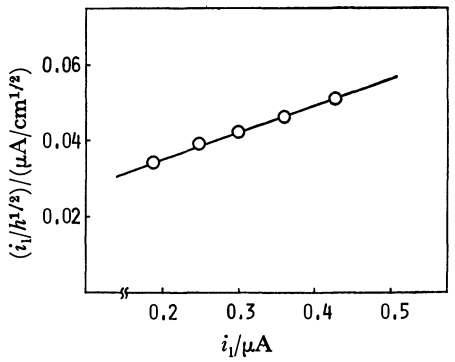

Fig. 4. Relation between i_l and $i_l/h^{1/2}$.
Concn: 1.1×10^{-3} M, h: 30—70 cm.

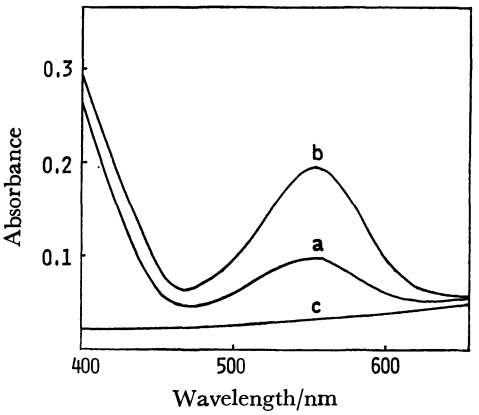

Fig. 5. Absorption spectra of ninhydrin and 1,2,3-indantrione in DMF.
a: Ninhydrin 1×10^{-2} M, b: 1,2,3-indantrione 1×10^{-2} M, c: DMF only.
Spectra were taken immediately after dissolving the specimen.

DMF can be attained with time.

However, as shown in Fig. 4, the plot of i_l of the first wave in Fig. 1-d against $i_l/h^{1/2}$ (i_l: limiting current, h: the level of the Hg reservoir) exhibited no kinetic character, suggesting a diffusion accompanied with adsorption of the electroactive chemical species for the corresponding electrode reaction.[17] It is difficult to demonstrate the direct participation of the dehydration reaction at the electrode.

On the other hand, the absorption spectra taken with I and II (Fig. 5), qualitatively supported an equilibrium between the two species in DMF. A relatively small absorption peak at 550 nm was obtained with I and a larger one with II. Prevention of the intrusion of atmospheric moisture into DMF medium was not satisfactory as compared with polarographic conditions, and the observed purple color due to the absorption at 550 nm faded with time for both I and II.

Table 1. ^{13}C-NMR chemical shifts for ninhydrin in DMF-d_7

Compound	Carbon	δ ^{13}C[ppm]
	1,3	197.6
	2	139.5
	8,9	137.7
	4,7	124.4
	5,6	88.4

(Reference: TMS)

The predominance of the hydrated form (I) in DMF was also observed by ^{13}C-NMR spectroscopy (Table 1), where no signal due to C-2 carbonyl group of II was detected, when each signal was assigned to the possible structure.

Let us discuss the first wave of reduction current with a large maximum in the polarogram (Fig. 1;. It is evidently due to the reduction of dehydrated form (II) at the electrode. If the current is due to species II in equilibrium, it would be difficult to interpret the presence of the maximum.

We might assume a different equilibrium between I and II, accompanied by adsorption at the electrode or a relatively fast dehydration from I to II, the equilibrium or rate of which may be largely dependent on the applied potential in a limited range. It is interesting to consider this characteristic phenomenon of ninhydrin in nonaqueous solution, in comparison with the observation made by Holleck and Lehman[10] that ninhydrin in aqueous buffer solutions also shows the reduction wave due to II, whose shape is very similar to the present one in DMF, though intensity and potential, *etc.* largely differ from each other.

The electrocapillary curve of the present system was also studied, an abnormal change of drop time being observed with applied potential corresponding to the maximum of curve a in Fig. 1. However, the drop time gave fairly scattered values for repeated measurements at the potential. This may suggest possible adsorption of I or II at the electrode.

Cyclic Voltammetry of Ninhydrin. Cyclic voltammetry of I was studied with use of the hanging mercury

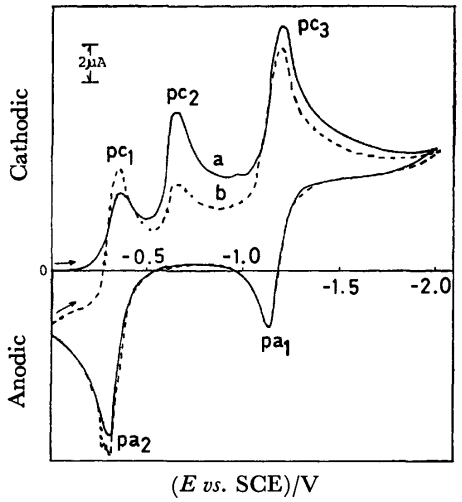

Fig. 6. Cyclic voltammograms of ninhydrin in DMF. Concn: 2.1×10^{-3} M, temp: 26 °C, sweep: 50 mV/s, electrode: HME, a: single sweep, b: multiple sweep.

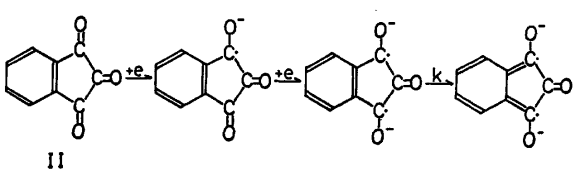
electrode (HME). The cyclic voltammogram (CV) is shown in Fig. 6, curve (a) being recorded by a single sweep and curve (b) by a multiple sweep. In both cases three cathodic peaks (pc_1, pc_2, and pc_3), corresponding to the polarographic three waves, respectively, and two anodic peaks (pa_1 and pa_2) corresponding to pc_3 and pc_1, respectively, were observed. Peak potential differences, $|E_{pc_1}-E_{pa_2}|$ and $|E_{pc_3}-E_{pa_1}|$, were found to be 60 mV for both cases, suggesting one-electron reversible redox system.[18]

In b, the peak current of pc_2 was smaller, while that of pc_1 became larger as compared with those in a. Irregularity of pa_2 in b was observed, suggesting an abrupt change in surface conditions.

A similar CV was observed with use of the Pt electrode, $|E_{pc_3}-E_{pa_1}|$ being approximately 70 mV. These cyclic voltammograms are similar to those of II observed by Kalinowski and Lasia[13] except for peak height of pc_2.

Mechanism of the Electrode Reaction. From the results of d.c.-polarography, CV and the proposed mechanism[13] of DME reaction of II, the electrode reaction mechanism of I in DMF can be discussed. Kalinowski and Lasia simplified the problem of ninhydrin (I) only in its dehydrated form (II), as proposed in Eq. 2.[13] However, the equilibrium between I and II in the bulk of the solution and also at the electrode

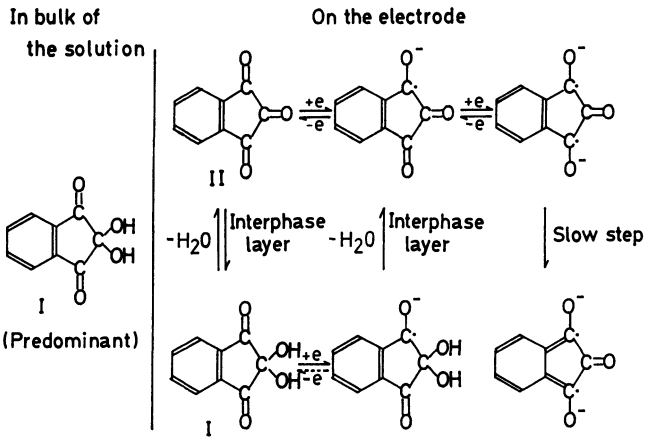


II (2)

surface should be taken into consideration. The reversibility of the electrode reaction for three steps of reduction is more clearly visualized by CV than by d.c.-polarography. The first and third waves in d.c.-polarography can be described each as reversible one-electron transfer on the basis of logarithmic analysis

and the peak potential differences $|E_{pc_1}-E_{pa_2}|$ and $|E_{pc_3}-E_{pa_1}|$. The second wave is typically irreversible, since peak pc_2 does not exhibit its corresponding anodic peak.

The following scheme is proposed for the principal process of electrolytic reduction of ninhydrin in DMF.



Scheme 1.

The hydrated form can be reduced at the electrode as the second wave, but the reduction product easily liberates H_2O and is converted into the dehydrated form identical with the direct reduction product from II. In nonaqueous solvents the dehydration is understood as an irreversible process.

Jasmonoid Synthesis from *cis*-4-Heptenoic Acid

Toshio SATO, Tatsuo KAWARA, Kazumi SAKATA, and Tamotsu FUJISAWA*

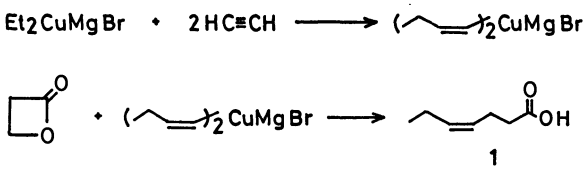
Chemistry Department of Resources, Mie University, Tsu, Mie 514

(Received August 25, 1980)

Jasmonoids with *cis*-2-pentenyl side chain such as *cis*-jasmone, methyl jasmonate, and jasmolone were easily synthesized from *cis*-4-heptenoic acid obtained by the ring opening reaction of β-propiolactone with di-*cis*-butenylcuprate.

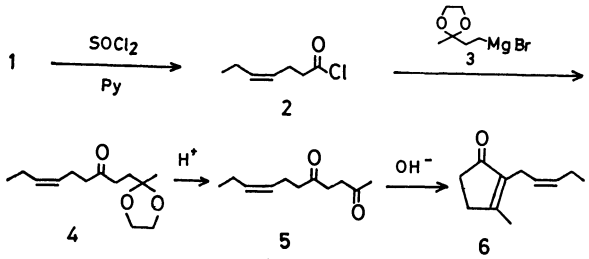
Recently there have been a large amount of researches developing synthetic routes to 2-(*cis*-2-alkenyl)-2-cyclopentenones.[1a] This has been due in large part to interest in several biologically active natural products which have this moiety as a major structural feature. In the synthesis of these compounds, stereoselective introduction of *cis*-2-alkenyl side chain has been one of the major subjects. For example, as for the synthesis of jasmonoids,[1b] the *cis*-2-pentenyl group has been formed by elaborate routes, *e.g.*, the partial hydrogenation of carbon-carbon triple bond with the Lindlar catalyst,[2,3] the Wittig reaction of a formylmethyl group with propylidenetriphenylphosphorane under salt free conditions,[4] and the reductive desulfurization of 5,6-dihydro-2*H*-thiopyran derivative.[5] Recently *cis*-4-alkenoic acids were found to be synthesized in one-pot operation from dialkylcuprates, acetylene, and β-propiolactone.[6] Among them, *cis*-4-heptenoic acid would be a useful precursor of these jasmonoids, because it has a structure corresponding to a skeleton from the side chain to the carbonyl carbon of the cyclopentenone in the jasmonoids with *cis*-2-pentenyl moiety such as *cis*-jasmone, methyl jasmonate and jasmolone. Thus, the synthetic route to the jasmonoids from *cis*-4-heptenoic acid as a key intermediate was investigated *via* well documented cyclization of 1,4-diketones.

cis-4-Heptenoic acid (**1**) was easily synthesized in a high yield by utilizing two reactions, *i.e.*, the *syn* addition of dialkylcuprates to acetylene for the formation of di-*cis*-1-alkenylcuprates[7] and the regioselective ring opening reaction of β-propiolactone with diorganocuprates.[8] Thus, acetylene was introduced at −78 °C into bromomagnesium diethylcuprate, which was prepared from copper(I) iodide and ethylmagnesium bromide in THF–Me_2S (9 : 1) at −30 °C. After the reaction mixture was allowed rapidly to warm to −30 °C and stirred for 30 min, the reaction of β-propiolactone with the cuprate was performed at −30 °C for 2 h. By quenching the reaction with 3 M (1 M=1 mol dm^{-3}) HCl solution, the desired acid **1** was isolated by distillation in a yield of 81%.



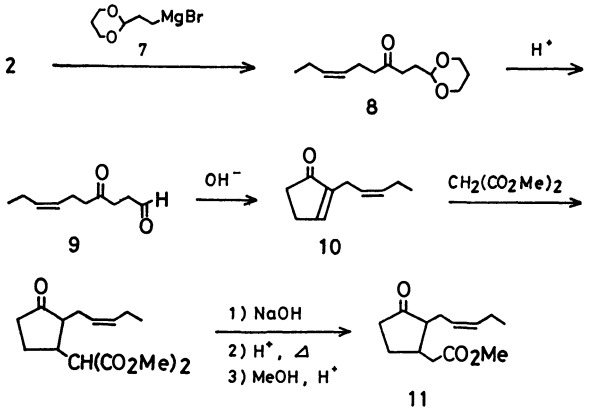
Scheme 1.

The precursor of *cis*-jasmone, *cis*-8-undecene-2,5-dione (**5**) was easily derived from *cis*-4-heptenoic acid and 3-oxo-butyl equivalent. As a latter compound, 3,3-ethylenedioxybutyl group was chosen. Treatment of **1** with thionyl chloride and pyridine in ether gave *cis*-4-heptenoyl chloride (**2**) in a yield of 74%. Condensation of **2** with the Grignard reagent **3**[9] prepared from magnesium metal and 3,3-ethylenedioxybutyl bromide, which was derived from methyl vinyl ketone, ethylene glycol, and hydrogen bromide, in THF at −78 °C and then warming to room temperature, afforded *cis*-2,2-ethylenedioxy-8-undecen-5-one (**4**) quantitatively. Deacetalization of the keto acetal **4** with dilute hydrochloric acid solution afforded the dione **5**, which was then cyclized with dilute aqueous base in the usual manner[10] to give *cis*-jasmone (**6**) in 68% yield from **3**.



Scheme 2.

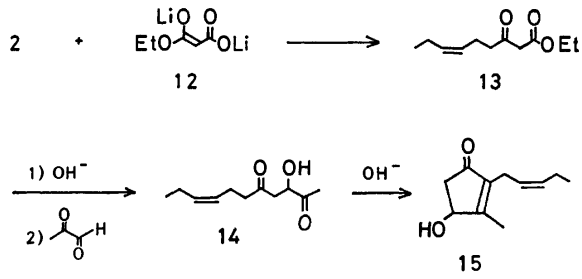
Methyl jasmonate (**11**) can also be synthesized from *cis*-4-heptenoic acid *via* 2-(*cis*-2-pentenyl)-2-cyclopentenone (**10**). In this case, 3,3-trimethylenedioxypropyl group was chosen for the stability of the Grignard reagent as functional group for the three carbon elongation. Condensation of **2** with the Grignard reagent **7**[11] of 3,3-trimethylenedioxypropyl bromide, prepared from acrylaldehyde, hydrogen bromide, and 1,3-propanediol, furnished *cis*-1,1-trimethylenedioxy-7-decen-4-one (**8**). Deacetalization of **8** with aqueous oxalic acid gave *cis*-4-oxo-7-undecenal (**9**) in 68% yield from **2**. Cyclization of aldehyde **9** with 1% sodium



Scheme 3.

hydroxide in water–dioxane (1 : 1) afforded the cyclopentenone **10** in 69% yield. According to the standard procedure[2,12] **10** was converted into methyl jasmonate (**11**), *i.e.*, the Michael addition of dimethyl malonate to **10**, followed by hydrolysis, decarboxylation, and esterification furnished **11** in a yield of 66%.

Jasmolone, an ester component of jasmoline, was also prepared from *cis*-4-heptenoic acid *via* cyclization of 1,4-diketone. The dianion **12**[13] of ethyl hydrogen malonate reacted with **2** in THF at −65 °C for 1 h to afford ethyl *cis*-3-oxo-6-nonenoate (**13**) in a yield of 76%. Then, according to the procedure by LaForge *et al.*,[14] **13** was hydrolyzed with dilute potassium hydroxide solution, followed by condensation with methylglyoxal and successive decarboxylation to give *cis*-3-hydroxy-8-undecene-2,5-dione (**14**), which was cyclized by the treatment with 2% sodium hydroxide aqueous solution to give jasmolone (**15**) in 23% yield from **13**.



Scheme 4.

As mentioned above, *cis*-4-heptenoic acid, easily prepared from β-propiolactone and di-*cis*-1-butenylcuprate, was proved to be a very useful precursor for the synthesis of the jasmonoids with *cis*-pentenyl moiety. Further, by the use of various *cis*-alkenylcuprates, the regioselective ring opening of β-propiolactone should provide a promising method for the synthesis of a wide variety of natural products possessing *cis* carbon-carbon double bond.

Experimental

The IR spectra were recorded on a Hitachi EPI-G2 spectrometer. The NMR spectra were taken with a Varian A-60 spectrometer using TMS as an internal standard. Grignard reagents and butyllithium were titrated by Eastham's method.[15] All boiling points are uncorrected.

cis-4-Heptenoic Acid (1). To a solution of copper(I) iodide (5.713 g, 30 mmol) in THF (90 ml) and dimethyl sulfide (10 ml) was added an ethereal solution of ethylmagnesium bromide (1.85 M, 32.5 ml, 60 mmol) at −30 °C. Then, acetylene (2160 ml, 90 mmol) was introduced using a gas buret through a drying tube ($CaCl_2$) into a suspension of the cuprate at −78 °C at an approximate rate of 20 ml/min. After introduction of acetylene, the temperature was allowed to warm rapidly to −30 °C and the mixture was stirred for 30 min. β-Propiolactone (1.081 g, 15 mmol) in THF (2 ml) was added dropwise and stirring was continued at −30 °C for additional 2 h. The reaction was quenched with 3 M hydrochloric acid solution (20 ml) and extracted with ether. The separated organic layer was extracted with 3 M sodium hydroxide solution. The alkaline solution was washed with ether, acidified with 6 M hydrochloric acid solution, and then extracted with ether. The ether extracts were washed with brine (10 ml) and dried over anhydrous $MgSO_4$. Distillation gave **1** (1.56 g, 81%): bp 97—99 °C/5 mmHg (lit,[16] bp 97—99 °C/4 mmHg); IR (neat) 1710 (C=O) and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.90—2.40 (6H, m), 5.10—5.60 (2H, m), and 11.90 (1H, s).

cis-4-Heptenoyl Chloride (2). A mixture of **1** (4.35 g, 34.0 mmol) and pyridine (3.06 g, 40.8 mmol) in ether (20 ml) was added to a solution of thionyl chloride (4.45 g, 37.4 mmol) in ether (50 ml) at −15 °C. The reaction mixture was stirred at room temperature for 2 h. The precipitate formed was filtered off. Distillation of the filtrate gave **2** (3.66 g, 74%): bp 63—64 °C/13 mmHg (lit,[17] bp 72—76 °C/35 mmHg); IR (neat) 1800 (C=O) and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.98 (3H, t, J=7 Hz), 1.72—2.63 (4H, m), 2.63—3.07 (2H, m), 4.83—5.61 (2H, m).

3,3-Ethylenedioxybutyl Bromide. To a solution of hydrogen bromide (12.0 g, 133 mmol) in ethylene glycol (20.0 g, 327 mmol) was added dropwise methyl vinyl ketone (7.00 g, 100 mmol) at 0 °C. The reaction mixture was stirred at room temperature for 1 h and extracted with hexane. The extracts were washed with 5% sodium hydrogencarbonate solution and dried over anhydrous $MgSO_4$. Distillation gave 3,3-ethylenedioxybutyl bromide (9.26 g, 48%): bp 88—94 °C/27 mmHg; (lit,[18] bp 58—60 °C/12 mmHg); IR (neat) 1120 (C=O) and 540 cm^{-1} (CBr); NMR (CCl_4) δ 1.31 (3H, s), 2.20 (2H, t, J=9 Hz), 3.45 (2H, t, J=9 Hz), and 3.95 (4H, s).

cis-2,2-Ethylenedioxy-8-undecen-5-one (4). To a solution of **2** (0.784 g, 5.28 mmol) in THF (5 ml) was added the Grignard reagent **3** (0.61 M, 7.87 ml, 4.80 mmol), prepared from 3,3-ethylenedioxybutyl bromide and magnesium in THF at room temperature,[9] at −78 °C. The mixture was allowed to warm to room temperature for 1.5 h. It was poured into a saturated sodium hydrogencarbonate solution (10 ml), extracted with ether, and dried over anhydrous $MgSO_4$. The crude product was purified by TLC on silica gel (R_f 0.6, benzene) to afford **4** quantitatively (1.087 g): IR (neat) 1710 (C=O), 1150, 1050 (C–O), and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.30 (3H, s), 1.66—2.67 (10H, m), 4.01 (4H, s), and 5.23—5.67 (2H, m).

cis-8-Undecene-2,5-dione (5). A solution of **4** (0.279 g, 1.23 mmol) and two drops of 3 M hydrochloric acid solution in acetone (5 ml) and water (5 ml) was refluxed for 4 h. After evaporation of the acetone, the residue was extracted with ether. The ether extracts were washed with brine and dried over anhydrous $MgSO_4$. Removal of the solvent gave **5** (0.187 g, 84%): IR (neat) 1720 (C=O), and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.97 (3H, t, J=7 Hz), 2.00—2.57 (9H, m), 2.67 (4H, s), and 5.20—5.59 (2H, m). The spectral data of **5** were in agreement with the literature.[10]

cis-Jasmone (6). According to the procedure of Büchi *et al.*,[10] a solution of the diketone **5** in 0.5 M sodium hydroxide solution and ethanol was refluxed for 6 h to give **6** (82%): IR (neat) 1720 (C=O) and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 1.00 (3H, t, J=7 Hz), 2.00—3.00 (11H, m), and 5.20—5.70 (2H, m). The spectral data of **6** were in agreement with the literature.[10]

3,3-Trimethylenedioxypropyl Bromide. To a solution of hydrogen bromide (21.6 g, 0.27 mol) in 1,3-propanediol (43.6 g, 0.57 mol) was slowly added acrylaldehyde (11.0 g, 0.18 mol, 90% purity) at room temperature. The reaction mixture was stirred at room temperature for 1 h and extracted with hexane. The extracts were washed with 5% sodium hydrogencarbonate solution and dried over anhydrous $MgSO_4$. Distillation gave 3,3-trimethylenedioxypropyl bromide (25.3 g,

† 1 mmHg=133.322 Pa.

74%): bp 89—91 °C/10 mmHg† (lit,[11] bp 67—70 °C/2.8 mmHg); NMR (CCl_4) δ 1.00—1.50 (1H, m), 1.50—2.47 (3H, m), 3.36 (2H, t, J=8 Hz), 3.75—4.25 (4H, m), and 4.57 (1H, t, J=5 Hz).

cis-*1,1-Trimethylenedioxy-7-decen-4-one (8).* To a solution of *cis*-4-heptenoyl chloride (**2**) (3.64 g, 24.8 mmol) in THF (20 ml) was added dropwise the Grignard reagent **7** (0.72 M, 31.3 ml, 22.5 mmol), prepared from 3,3-trimethylenedioxypropyl bromide and magnesium in THF,[11] at −78 °C. The mixture was allowed to warm to room temperature for 2 h and the THF was removed. The residue was extracted with ether and the organic layer was washed with water, and then dilute sodium carbonate solution, dried over anhydrous K_2CO_3. Removal of the solvent afforded **8** (5.77 g), which was used in the next reaction without purification. IR (neat) 1720 (C=O), 1150, 1050 (C–O), and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.97 (3H, t, J=7 Hz), 1.25—2.67 (13H, m), 3.32—4.25 (4H, m), 4.40 (1H, t, J=5 Hz), and 5.10—5.43 (2H, m).

cis-*4-Oxo-7-undecenal (9).* A mixture of crude **8** (2.53 g), oxalic acid (1 g), and water (20 ml) was refluxed for 3 h, during which time the product was continuously steam-distilled into a Dean Stark trap. The distillate was extracted with ether. The ether extracts were dried over anhydrous Na_2SO_4. Distillation under reduced pressure gave **9** (1.26 g, 68% from **7**): bp 104—105 °C/1.7 mmHg; IR (neat) 1725 (C=O), 1715 (CHO), and 730 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.77—2.50 (6H, m), 2.62 (4H, s), 5.20—5.63 (2H, m), and 9.60 (1H, s). The spectral data of **9** were in agreement with the literature.[12]

*2-(*cis*-2-Pentenyl)-2-cyclopentenone (10).* To a refluxing solution of water (45 ml), dioxane (45 ml) and 10% sodium hydroxide solution (10 ml) was added dropwise a dioxane solution of **9** (0.922 g, 5.49 mmol) for 1.5 h. The mixture was refluxed for 10 min. After neutralization with 1 M hydrochloric acid solution, it was extracted with chloroform. The extracts were dried over anhydrous Na_2SO_4. Distillation afforded **10** (0.565 g, 69%): bp 90 °C (bath)/0.6 mmHg (lit,[2] bp 70 °C/0.05 mmHg); IR (neat) 1700 (C=O), 1625 (CH=CH, ring), and 730 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.97 (3H, t, J=7 Hz), 1.60—3.08 (8H, m), 5.16—5.70 (2H, m), and 7.25 (1H, m). The spectral data of **10** were in agreement with the literature.[2]

Methyl Jasmonate (11). Sodium hydride (0.02 g, 0.46 mmol, 55% in mineral oil) was washed with dry hexane, and dry methanol (0.7 ml) was added. To the mixture was added dropwise dimethyl malonate (0.258 g, 1.95 mmol) and then cyclopentenone (**10**) (0.187 g, 1.25 mmol) in dry methanol (1 ml) at −5 °C for 40 min. The resulting mixture was stirred at −10—−5 °C for 3 h. After the reaction was quenched with acetic acid (2 ml), the methanol was evaporated. The residue was dissolved in ether, washed with water and dried over anhydrous Na_2SO_4. Distillation gave 3-[bis(methoxycarbonyl)methyl]-2-(*cis*-2-pentenyl) cyclopentenone (0.325 g, 92%): bp 200 °C (bath)/2 mmHg; IR (neat) 1740 ($COOCH_3$), 1700 (C=O), and 735 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.75—2.50 (10H, m), 3.47 (1H, s), 3.70 (6H, s), and 5.00—5.50 (2H, m).

To 0.269 g (1.05 mmol) of the cyclopentenone was added dropwise 10% sodium hydroxide aqueous solution (0.9 ml) for 4 h and the mixture was allowed to stand overnight. Then 3% sulfuric acid solution (0.35 ml) was added and the resulting mixture was refluxed for 5 h. The cooled reaction mixture was extracted with ether and washed with water. The ether extract were then extracted with 3 M sodium hydroxide solution. The alkaline solution was washed with ether, acidified with 6 M hydrochloric acid solution, and then extracted with ether. The extracts were dried over anhydrous Na_2SO_4 and evaporated to afford jasmonic acid (0.172 g, 78%): IR (neat) 3150 (OH), 1740 (C=O), 1750 (COOH) and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.97 (3H, t, J=7 Hz), 1.65—3.08 (12H, m), 5.15—5.67 (2H, m), and 11.0 (1H, s).

A solution of jasmonic acid (0.142 g, 0.68 mmol) in methanol (5 ml) was stirred at 40 °C for 3 h with a catalytic amount of concd H_2SO_4. The reaction mixture was cooled, and a small amount of $NaHCO_3$ and water (5 ml) was added. The mixture was extracted with ether and the extracts were dried over anhydrous Na_2SO_4. Removal of the solvent gave **11** (0.138 g, 92%): IR (neat) 1740 (C=O), 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.55—3.05 (12H, m), 3.65 (3H, s), and 4.82—5.55 (2H, m). The spectral data of **11** were identical with the literature.[2]

Ethyl cis-*3-Oxo-6-nonenoate (13).* To a solution of ethyl hydrogen malonate (0.231 g, 1.75 mmol) and 2,2′-bipyridyl (3 mg) in THF (4 ml) was added a hexane solution of butyllithium (1.52 M, 2.30 ml, 3.5 mmol) at −70 °C, during which time the temperature was raised from −70 to −5 °C.[13] To a solution of the dianion **12** was added **2** (0.147 g, 1.00 mmol) in THF (1 ml) at −65 °C. After 1 h ether (7 ml) and 1 M hydrochloric acid solution (3 ml) were added. The organic layer was washed with saturated sodium hydrogencarbonate solution and then water, and dried over anhydrous Na_2SO_4. Removal of the ether gave the crude product, which was purified by TLC on silica gel (R_f 0.5, hexane : ether=2 : 1) to give **13** (0.151 g, 76%): IR (neat) 1750 (COO), 1730 (C=O), and 730 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.20 (3H, t, J=7 Hz), 1.70—2.60 (6H, m), 3.22 (3H, s), 4.12 (2H, q, J=7 Hz), and 4.85—5.55 (2H, m).

cis-*3-Hydroxy-8-undecene-2,5-dione (14).* To **13** (0.135 g, 0.70 mmol) was added dropwise 10% potassium hydroxide solution (0.46 ml) and the mixture was allowed to stand at −3—−2 °C for 3 d. After washed with ether, the reaction mixture was acidified with 0.5 M hydrochloric acid solution to pH 3—4, extracted with ether, and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave *cis*-3-oxo-6-nonenoic acid (0.086 g, 73%): IR (KBr) 3150 (OH), 1710 (C=O), and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 1.00 (3H, t), 1.78—2.80 (6H, m), 4.80—5.50 (2H, m), and 10.88 (1H, s).

cis-3-Oxo-6-nonenoic acid (0.816 g, 1.86 mmol) in water (1 ml) was neutralized with 10% sodium hydroxide solution using phenolphthalein as an indicator at 0 °C. To the solution was added methylglyoxal (0.156 g, 2.20 mmol, 40% aqueous soln) and then 10% sodium hydroxide solution to make the mixture basic (pH 8). The resulting mixture was allowed to stand at room temperature for 2.5 d and extracted with ether. The extracts were dried over anhydrous Na_2SO_4, and evaporated. Purification by TLC on silica gel (R_f 0.4, ether : hexane=2 : 1) gave **14** (0.220 g, 60%): IR (neat) 3450 (OH), 1720 (C=O), and 720 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.80—2.90 (11H, m), 4.00—4.40 (2H, m), and 4.80—5.50 (2H, m). The spectral data of **14** were in agreement with the literature.[19]

Jasmolone (15). To **14** (0.148 g, 0.75 mmol) was added dropwise 2% potassium hydroxide solution (0.6 ml) and the mixture was allowed to stand at room temperature for overnight. The reaction mixture was extracted with ether, washed with brine, and dried over anhydrous Na_2SO_4. Purification by TLC on silica gel (R_f 0.4, ether : hexane=3 : 1, developed twice) gave **15** (0.069 g, 52%): IR (neat) 3400 (OH), 1710 (C=O), 710 cm^{-1} (*cis*-CH=CH); NMR (CCl_4) δ 0.95 (3H, t, J=7 Hz), 1.60—3.00 (9H, m), 4.10 (1H, broad), 4.45 (1H, m), and 4.80—5.50 (2H, m). The spectral

data were in agreement with the literature.[19]

The Determination of the "Flat-band" Potential of Nitrogen-stabilized n-TiO_2 Photoanode

Taketsugu HIRAI,* Isao TARI, and Tsutomu OHZUKU
Department of Synthetic Chemistry, Faculty of Engineering, Okayama University, Tsushima, Okayama 700
(Received March 28, 1980)

The differential capacitance (C) and the photocurrent onset voltage (E_p) of nitrogen-stabilized n-TiO_2 semiconductor electrodes were measured in buffered Na_3PO_4 solutions. The C^{-2} *vs.* E plots did not show the Mott-Schottky (MS) behavior. In order to explain the nonlinearity in MS plots, the distribution in donor density (N_d) at the solid side and the contribution of the electrical double layer at the solution side to the total capacitance were considered. The characterized flat-band potential (E_{fb}) and the zero-charge potential (E_{zc}) were defined from the derived equations. The roles of the defined E_{fb} and E_{zc} in the photocurrent onset voltage (E_p) were also considered, and the reason why E_p differed from E_{fb} was explained using the "Gate" model.

In semiconductor electrochemistry, the determinations of both the flat-band potential and the charge carrier density are important, for they are the basic parameters of semiconductor electrodes. These quantities can be determined by the Mott-Schottky relationship from the measurement of the differential capacitance. However, the experimental results which have been reported for single and polycrystalline semiconductor electrodes usually show some deviations from ideality.[1-6] The possible sources of such deviation from ideality have been discussed by several authors.[1,4,7-9] One of these treatments, that by De Gryse *et al.*,[7] is a quantitative one. They derived another expression by considering the effect of the Helmholtz layer at the semiconductor/electrolyte interface. However, the C^{-2} *vs.* E plots do not allow the E_{fb} values to be determined unless the Helmholtz layer capacitance is known, even when the experimental C^{-2} *vs.* E plot is a straight line.

Our differential capacitance data for nitrogen-stabilized n-TiO_2 semiconductor electrodes, to be reported here, do not show the Mott-Schottky behavior. The objective of this report is to understand the capacitance data, together with the photoelectrochemical property, and to discuss the uncertainty in the determination of the flat-band potential.

Experimental

The nitrogen-stabilized n-type semiconductor ($TiN_{0.07}O_{1.93}$) electrode, which had been proved to be highly resistive to photocorrosions, was the same as that described in a previous paper.[12]

The cell impedance between the $TiN_{0.07}O_{1.93}$ electrode and a far larger platinum electrode was measured by means of an impedance bridge, type DRZ-1 (Ando Electric Corp.), with an audio oscillator, type 4200-A (Yokogawa-Hewlett-Packard), and a tuned null detector, type 4403-A (Yokogawa-Hewlett-Packard). The absolute values of the impedance $|z|$ and the phase angle, θ, as functions of the bias voltage (*vs.* SCE) were measured at 0.3—10 kHz. The electrolytes used were 0.1 M Na_3PO_4 aqueous solutions, adjusted their pHs with a concd NaOH or H_3PO_4 solution.

The anodic photocurrent was measured in the usual manner under full illumination by a 500-W xenon arc lamp at room temperature.

Results

Differential Capacitance Measurements. Figure 1 shows the differential capacitance at 500 Hz as a function of the electrode potential for the $TiN_{0.07}O_{1.93}$ electrode in several buffered Na_3PO_4 solutions. All the C *vs.* E curves showed their peaks in the cathodic region. Although the capacitance values varied somewhat, thus showing the frequency dispersion, a similar trend was usually observed in the frequency range of 0.3—10 kHz.

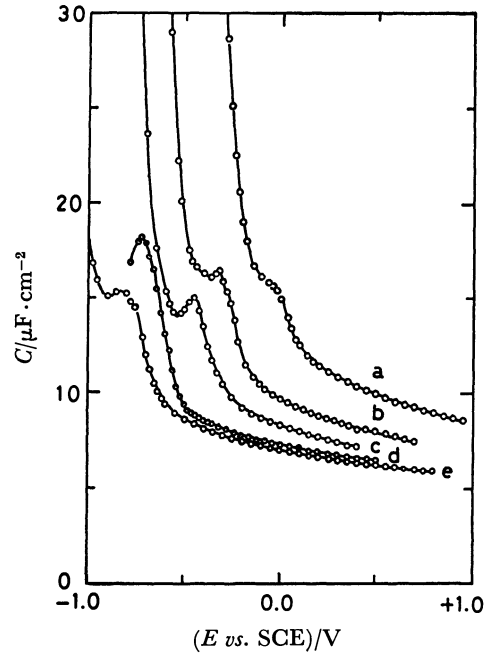

Fig. 1. C *vs.* E curves for $TiN_{0.07}O_{1.93}$ electrode in 0.1 M Na_3PO_4 solutions.
pH; (a): 1.0, (b): 5.0, (c): 7.0, (d): 10.0, (e): 12.0.

In order to determine the basic parameters for this electrode, the C^{-2} *vs.* E plots were applied. According to the Mott-Schottky relationship, the C^{-2} *vs.* E plots should give a straight line over a wide range of potentials. However, the experimental results in Fig. 2 do not show an ideal MS-behavior, so the E_{fb} and N_d values could not be determined.

Photocurrent Onset Voltage. The anodic photo-

pH; (a): 12.0, (b): 10.0, (c): 7.0, (d): 5.0, (e): 1.0.

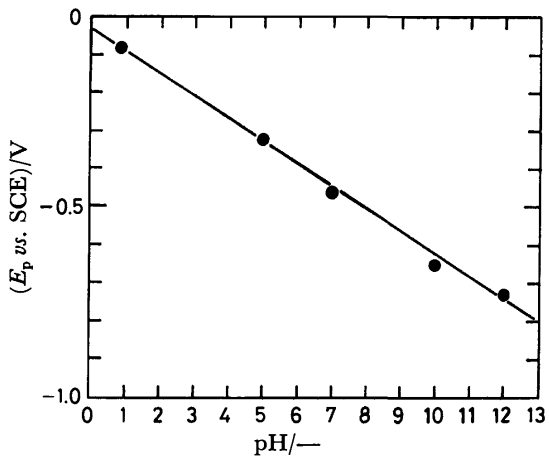

Fig. 3. The pH dependence of the anodic photocurrent onset voltage E_p.

current onset voltage (E_p) against the solution pH is plotted in Fig. 3. The anodic photocurrent onset voltage showed a linear dependence on pH, which can be represented by:

$$E_p = -0.04 - 0.06\ \text{pH}\ (vs.\ \text{SCE}).$$

Discussion

Differential Capacitance at the Semiconductor/Electrolyte Interface. In order to elucidate the nonlinearity in C^{-2} *vs.* E plots, we considered the possible sources of effects on the total capacitance. The whole differential capacity (C) across the semiconductor/electrolyte interface is represented by:

$$1/C = 1/C_{sc} + 1/C_d + 1/C_c, \quad (1)$$

where C_{sc}, C_d, and C_c indicate the capacitance of the space charge layer, the diffused double layer, and the compact double layer respectively. Some investigators omit the $1/C_d$ and/or $1/C_c$ terms in Eq. 1 when the ionic strength is fairly large. The $1/C_d+1/C_c$ term, however, cannot be omitted, especially when the potential drop across the space charge layer is nearly equal to zero, because the condition of $1/C_{sc} \gg 1/C_d + 1/C_c$ does not hold.

The C_{sc} as a function of the potential is usually represented by MS's equation. However, the practical experimental conditions seem to be far from the given conditions of MS assumptions. Among them, the assumptions concerning donor density, which is independent of the distance from the semiconductor surface and the absence of an interfacial layer, such as an insulating layer, are not fulfilled in many real cases for semiconductors exposed to an electrolyte. The semiconductor surface in contact with an electrolyte has, more or less, interfacial layers, which may be formed by a chemical reoxidation or an ion-exchange reaction, because one is a solid electric conductor, and another is a liquid ionic conductor. Therefore, the donor density at the semiconductor surface must be zero, and the distribution in the donor density is developed in the direction perpendicular to the surface. Such situations seem to be readily formed in the case of heavily doped semiconductors,[1,2] as in our case, and the ideal linearity in C^{-2} *vs.* E plots is not to be expected.

As has been stated above, we presume the distribution in donor density, N_d, to be:

$$N_d = ax, \quad (2)$$

where a is a distribution coefficient in cm^{-4} and where x is a distance in cm.

The corresponding boundary conditions are:

$$\phi = \Delta\phi_{sc} - \frac{kT}{e} \text{ at } x = 0, \quad (3)$$

$$\frac{d\phi}{dx} = 0,\ \phi = 0 \text{ at } x = d, \quad (4)$$

in which kT/e indicates the volts of the equivalent thermal energy. By solving Poisson's equation under the given boundary conditions, we obtain:

$$C_{sc}^{-2} = \left(\frac{3}{\varepsilon^2\varepsilon_0^2 ea}\right)\left(\Delta\phi_{sc} - \frac{kT}{e}\right), \quad (5)$$

where ε and ε_0 are the dielectric constants of the semiconductor and the vacuum respectively and where e is an electron charge. The $\Delta\phi_{sc}$ is related to an electrode potential by:

$$\Delta\phi_{sc} = E - E_{fb}. \quad (6)$$

E_{fb} is the flat-band potential at which the electric field is reversed in the depletion layer.

From Eq. 1, we define the capacity, C_e, as:

$$1/C_e = 1/C_d + 1/C_c. \quad (7)$$

The dependence of C_e on the potential is represented by:

$$C_e = C_0 + b(E - E_{zc})^2. \quad (8)$$

C_0 is a minimum capacity, and E_{zc} is the zero-charge potential where the charge in the diffused double layer is reduced to zero. Equation 8 is a phenomelogical equation analogous to the electrical double-layer theory for mercury electrodes.[10]

Equations 5, 7, and 8 give the whole representation

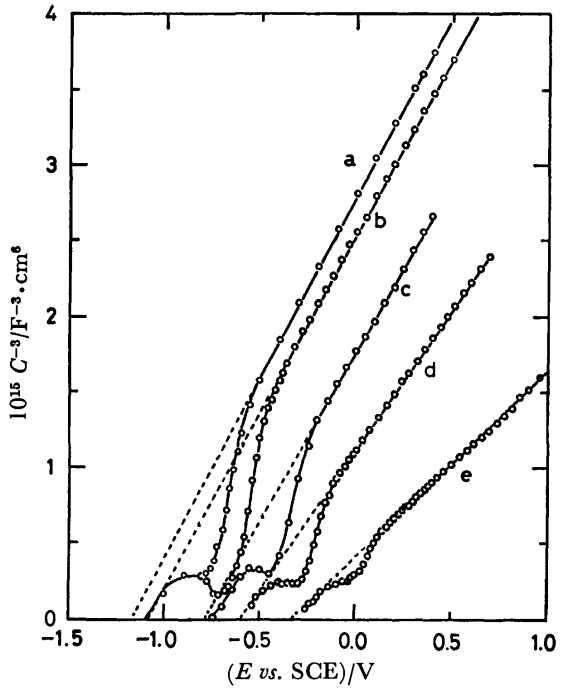

Fig. 4. C^{-3} *vs.* E plots of $TiN_{0.07}O_{1.93}$electrode in 0.1 M Na_3PO_4 buffered solutions.
pH; (a) 12.0 (b) 10.0 (c) 7.0 (d) 5.0 (e) 1.0.

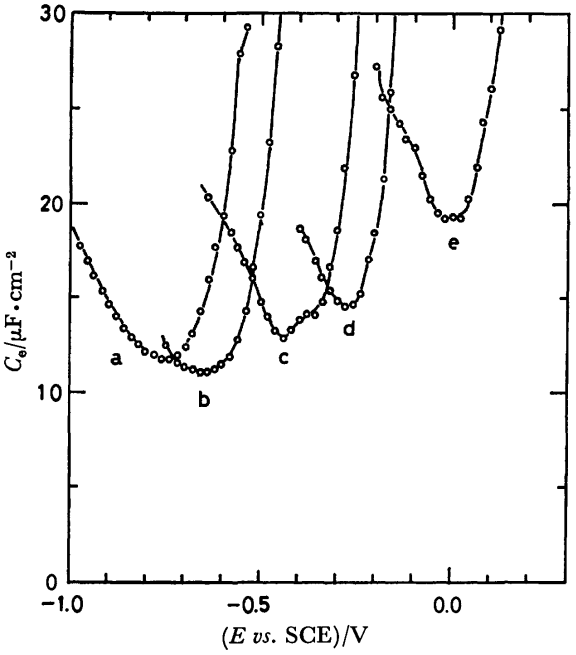

Fig. 5. C_e *vs.* E plots of $TiN_{0.07}O_{1.93}$ electrode in 0.1 M Na_3PO_4 buffered solutions.
pH; (a): 12.0, (b): 10.0, (c) 7.0, (d): 5.0, (e): 1.0.

of the differential capacity across the semiconductor/electrolyte interface as function of the electrode potential.

In order to check the validity of the above treatment, the original experimental results in Fig. 1 are replotted as Fig. 4. As predicted by Eq. 5, straight lines over adequate range of applied potentials are obtained in the C^{-3} *vs.* E plots when $C_e \gg C_{sc}$. In the region of $C_e < C_{sc}$, a distinct deviation from the straight line is observed. From Eq. 1, such a deviation can be said to be caused by the C_e component. The C_e values calculated from Eq. 1 are shown in Fig. 5. The C_e *vs.* E plots obey the parabolic relationship of Eq. 8. Consequentry, the presumptions of Eqs. 2 and 8 are valid in this case.

From the above considerations, we can determine the E_{fb}, E_{zc}, and a values in Eq. 5 as basic parameters of the semiconductor electrode in contact with an electrolyte.

Photocurrent Onset Voltage. It is said that the anodic photocurrent begins to flow at the "flat-band" potential in the case of an n-type semiconductor system.[11] This is the reason why the "flat-band" potential can be determined by measuring the E_p values, even when the capacitance measurement is not attainable. However, it is questionable whether the true E_{fb} values are thus obtained. In order to illustrate this, we compared the characterized E_{fb} and E_{zc} values with the E_p values in Table 1. E_{fb}, as defined by Eq. 5, is obtained by extrapolating to $C^{-3}=0$ in Fig. 4, while E_{zc}, as defined by Eq. 8, is obtained from the minimum of the C *vs.* E plots in Fig. 5.

Table 1. Comparison of E_{fb}, E_{zc}, and E_p values for several pH's of solutions

pH	E_{fb} *vs.* SCE / V	E_{zc} *vs.* SCE / V	E_p *vs.* SCE / V
1.0	−0.41±0.02	−0.02±0.03	−0.08±0.02
5.0	−0.57	−0.28	−0.32
7.0	−0.76	−0.44	−0.46
10.0	−1.07	−0.65	−0.65
12.0	−1.14	−0.75	−0.73

As is shown in Table 1, the E_{fb} values do not agree with the E_p values, which are usually more anodic than the E_{fb} values. However, the E_p values agree with the E_{zc} values within the limits of experimental error. This indicates that the anodic photocurrent begins to flow not at the flat-band potential, but at the zero-charge potential. In order to understand how the anodic photocurrent is allowed to pass across the semiconductor/electrolyte interface, and to find the reason why the photocurrent onset voltage differs from the flat-band potential, the following "Gate" model is proposed.

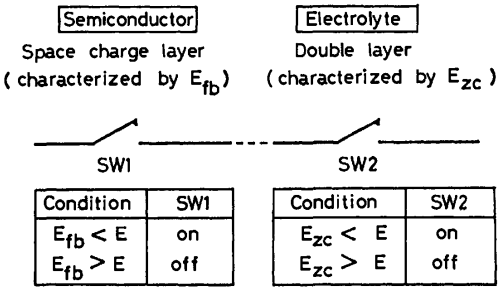

Fig. 6. "Gate" model for an explanation of the photocurrent onset voltage related to E_{fb} and E_{zc} in the case of N-type semiconductor electrode in contact with an electrolyte solution.

SW1 and SW2 in Fig. 6 behave like "Gate" because of its field effect, connected with holes and related ions for an n-type semiconductor electrode in contact with an electrolyte solution. If the condition of $E_{fb}<E_{zc}$ holds, the E_p value should be equal to the E_{zc} value. This is because the hole is permited to migrate to the semiconductor surface, *i.e.*, SW1 is closed, in the potential range of $E_{fb}<E$, but the mass transfer of the related ions is forbidden until E is more positive than E_{zc}, *i.e.*, SW2 is opened. Conversely, the E_p value should be equal to the E_{fb} value when $E_{fb}>E_{zc}$. By considering the "Gate" model, we could explain why the E_p value differed from the E_{fb} value.

We feel that all the semiconductors in contact with an electrolyte solution have the basic parameters of E_{fb} and E_{zc}. Such behavior was also observed for the reduced rutile single crystal and the CVD-TiO_2 semiconductor electrode. Recently, the existence of the surface state has been reported.[13-17] However, the argument of the surface state is not dealt with in this study. We think its capacitance probably contains the measured C_e value. From the above considerations, it can be emphasized that the determination of E_{fb} by E_p measurements has the possibility of being misleading as to the E_{fb} value.

Conclusion

We could give an explanation of the possible sources of deviation from the Mott-Schottky behavior of the nitrogen-stabilized TiO_2 semiconducting electrode, and point out some problems in the determination of the "flat-band" potential. The distribution of the donor density, N_d, in the direction perpendicular to the semiconductor surface and the contribution of the double layer to the total capacity caused the non-linearity in C^{-2} *vs.* E plots. When the distributed donor density is represented by $N_d=ax$, the C^{-3} *vs.* E plots are linear instead of the C^{-2} *vs.* E plots. The remaining capacitive component, C_e, in C^{-3} *vs.* E is proved to be an effect of the double-layer capacity by showing the C_e *vs.* E plots, which are characterized by their E_{zc} values.

In order to understand the roles of E_{fb} and E_{zc} in photoelectrochemical effect, the "Gate" model was proposed. By using the "Gate" model, which was characterized by both the E_{fb} and E_{zc} values for an n-type semiconductor electrode in contact with an electrolyte solution, we explained why the photocurrent onset, E_p, differed from E_{fb}. Moreover, a warning on the determination of the flat-band potential from the photocurrent onset voltage measurement was given.

Although the essential problems concerned with the semiconductor/electrolyte interface remain, we could partly elucidate the complicated behavior of a semiconductor electrode in contact with an electrolyte solution.

The present work was supported by a Grant-in-Aid for Energy Research No. 505035 from the Ministry of Education, Science and Culture.

Induced Circular Dichroism of β-Cyclodextrin Complexes with *o*-, *m*-, and *p*-Disubstituted Benzenes

Hiroshi SHIMIZU, Akira Kaito,† and Masahiro HATANO*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received April 23, 1980)

The induced circular dichroism (ICD) spectra of β-cyclodextrin (β-CD_x) complexes with *o*-, *m*-, and *p*-disubstituted benzenes were observed. The comparison of the observed rotational strengths with the ones calculated by using the Kirkwood-Tinoco expression is examined; the possible orientations of the guest molecules which are included in the cavity of β-CD_x are presented. These results suggest that the orientation of the guest molecule is confined about the axis of the β-CD_x torus.

The cyclodextrins (CD_x's) are α-1,4 linked oligomers of D-glucose formed during the degradation of starch by an amylase of *Bacillus macerans*, and have 6, 7, or 8 glucose residues per molecule.[1] It is known that CD_x can include aromatic compounds, alkyl halides, and gases, as guest molecules in its cavity, resulting in the formation of inclusion complexes.[2] This characteristic has led to their utilization as enzyme models.[3-6] In recent years, many extensive investigations on the suitability of modified CD_x or capped CD_x as a enzyme model have been carried out.[7-9]

The orientation of the guest molecule which is included in the cavity of CD_x plays an important role in the inclusion phenomenon. More information on the structure of the CD_x complex with mono- or di-substituted benzene will be very significant, since substituted benzenes are sometimes used as substrates of the reactions catalyzed by CD_x's.

The circular dichroism (CD) study is one of the most useful physico-chemical methods for elucidating the orientation of the guest molecule included by CD_x in solution. That is to say, the CD is expected to be induced at the absorption bands of the achiral guest molecules which are included in the cavity of the chiral CD_x host molecule, since CD_x is composed of chiral glucose units.

Harata and Uedaira[10] have recently measured the ICD spectra of β-CD_x complexes with naphthalene derivatives and determined the structure of the β-CD_x complexes on the basis of the calculation of the rotational strengths by the Kirkwood-Tinoco equation.[11] Yamaguchi *et al.* have studied the ICD spectra of β-CD_x complexes with 2-hydroxytropone[12] and azulene,[13] and have discussed the direction of the electronic transition moment of the guest molecules.

In the previous paper,[14] we have reported the ICD spectra of β-CD_x inclusion complexes with mono-substituted and para-disubstituted benzenes in aqueous solution, and have shown that these β-CD_x complexes favor the axial inclusion in which the long axis of the substituted benzenes is parallel to the axis of the β-CD_x cavity. We can estimate the orientation of the guest molecule from the comparison between the observed and calculated rotational strengths, when the direction of the electric transition dipole moment is known.

In the present article we report the ICD spectra of the β-CD_x complexes with *o*-, *m*-, and *p*-disubstituted benzenes in aqueous solution, and predict the orientation direction of the guest molecules in these inclusion complexes by the comparison between the observed rotational strengths of each ICD band and the values calculated by using the Kirkwood-Tinoco equation. In the manner of inclusion, β-CD_x complexes with *o*- and *m*-disubstituted benzenes cannot be classified into either the so-called axial or the equatorial inclusion, since the long- and/or short-axis of these molecules cannot be defined unequivocally.

Experimental

β-CD_x and homo- and hetero-disubstituted benzenes were obtained commercially. β-CD_x, *o*-nitroaniline, and *o*-, *p*-phenylenediamines were purified by the recrystallization from aqueous solutions. Pyrocatechol and hydroquinone were recrystallized from benzene. *m*-Nitroaniline, *p*-nitroaniline, resorcinol, and *m*-phenylenediamine were recrystallized from ethanol, methanol, chloroform, and ether, respectively.

An inclusion complex was prepared by mixing β-CD_x and the corresponding disubstituted benzene using the following solvents: an aqueous solution for nitroanilines, 0.1 M†† aqueous HCl for benzenediols, 1.0×10^{-3} M or 1.0×10^{-5} M aqueous KOH for phenylenediamines.

The circular dichroism and absorption spectra were measured at room temperature using a JASCO J-500 circular dichrograph with a J-DP 500 data-processor and a Hitachi EPS-3T recording spectrophotometer, respectively.

In particular, an appropriate amount of nitrogen was bubbled through each solution of the β-CD_x–phenylenediamine systems before the measurements, since phenylenediamines were easily oxidized by dissolved oxygen.

The experimental values of the dipole strengths, D, and the rotational strengths, R, of disubstituted benzenes were estimated in the same way as was used in the previous work.[14]

In the present paper, molar ellipticity was normalized by the concentration of the guest molecule.

Theoretical

The theoretical rotational strength of the transition from the ground state 0 to the excited state a in benzene derivative (i), R_{i0a}, was calculated by the following expression developed by Kirkwood and Tinoco:

$$R_{i0a} = \pi\tilde{\nu}_{a1}\mu^2_{i0a}\sum_j \frac{\tilde{\nu}^2_{bj}(\alpha_{33}-\alpha_{11})_j(GF)_{1j}}{\tilde{\nu}^2_{bj}-\tilde{\nu}^2_{a1}}, \quad (1)$$

† Present address: Research Institute for Polymers and Textiles, 1-1-4, Yatabe-Higashi, Tsukuba, Ibaraki 305.

†† 1 M=1 mol/dm³.

$$(GF)_{ij} = \frac{1}{r_{ij}^3}\left[\hat{e}_i \cdot \hat{e}_j - \frac{3(\hat{e}_i \cdot \vec{r}_{ij})(\hat{e}_j \cdot {}_i\vec{r}_j)}{r_{ij}^2}\right]\hat{e}_i \times \hat{e}_j\vec{r}_{ij}. \quad (2)$$

Here e_j is the unit vector in the direction of the symmetry axis of the bond (j) in β-CD_x; e_i is the unit vector in the direction of the electric transition dipole moment, μ_{ioa}, of the transition from the ground state 0 to the excited state a in the disubstituted benzene, and $\tilde{\nu}_{ai}$ is its wave number; α_{33} and α_{11} are bond polarizabilities at zero frequency parallel and perpendicular, respectively, to the symmetry axis of the bond in β-CD_x; $\vec{r}_{ij}$ is the vector pointing from the center of benzene derivatives to each bond in β-CD_x; and $\tilde{\nu}_{bj}$ is the averaged wave number of the electronic transitions of the bond in β-CD_x.

In this calculation, $\tilde{\nu}_{bj}$ is approximated by a wave number midway between the first absorption band in the bond of β-CD_x and its ionization potential. We

used the values of $(\alpha_{33}-\alpha_{11})$ and $\tilde{\nu}_{bj}$ for each bond as listed in our previous paper.[14]

Table 1 shows the observed and calculated wave number, $\tilde{\nu}$, and the dipole strength, D, of the electronic transitions of disubstituted benzenes, along with the assignment of each electronic transition.[15] The calculated values in this table were obtained by the Pariser-Parr-Pople (PPP) SCF-MO method. The directions of the electric transition moment in homo-disubstituted benzenes were available easily from the results of the perturbation theory formulas by Petruska.[16] The experimental values in Table 1 were used for the calculation of rotational strength except in the case of the $^1A_1\leftarrow{}^1A_1$ transition of resorcinol, the third $\pi^*\leftarrow\pi$ transition of *o*-nitroaniline, and the $^1B_2\leftarrow{}^1A_1$ and $^1A_1\leftarrow{}^1A_1$ transitions of *p*-nitroaniline.

In the present calculation, the determination of the coordinates of β-CD$_x$ was carried out in the manner used in our previous paper.[14]

Results and Discussion

Figures 1—3 show the CD (upper) and UV (lower) spectra of the β-CD$_x$ complexes with *o*-, *m*-, and *p*-disubstituted benzenes. ICD bands were observed at absorption frequencies of achiral benzene derivatives.

As shown in Fig. 1, the β-CD$_x$ complex with *o*-nitroaniline showed two positive and one negative ICD bands at 427, 286, and 222 nm, respectively. These ICD bands were assigned to the first $\pi^*\leftarrow\pi$, the second $\pi^*\leftarrow\pi$, and the fourth $\pi^*\leftarrow\pi$ transitions, respectively, on the basis of the results calculated by the PPP SCF-MO method in Table 1.

The β-CD$_x$-*m*-nitroaniline complex exhibited positive

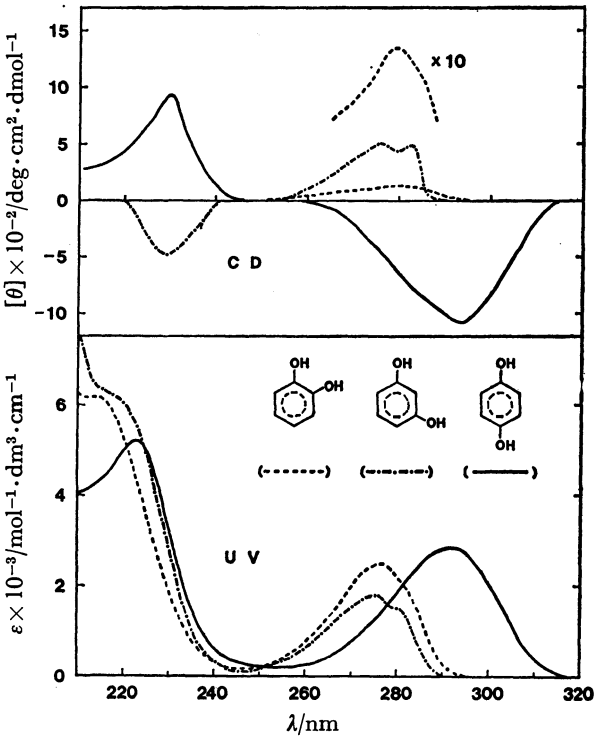

Fig. 2. CD (upper) and UV absorption (lower) spectra of the β-CD$_x$ complexes with *o*-, *m*-, and *p*-benzenediols in 0.1 M aqueous HCl at room temperature.
Broken line: β-CD$_x$ (1.17×10^{-2} M)+pyrocatechol (5.10×10^{-4} M), dotted broken line: β-CD$_x$ (1.43×10^{-2} M)+resorcinol (5.90×10^{-4} M), solid line: β-CD$_x$ (1.11×10^{-2} M)+hydroquinone (2.77×10^{-4} M).

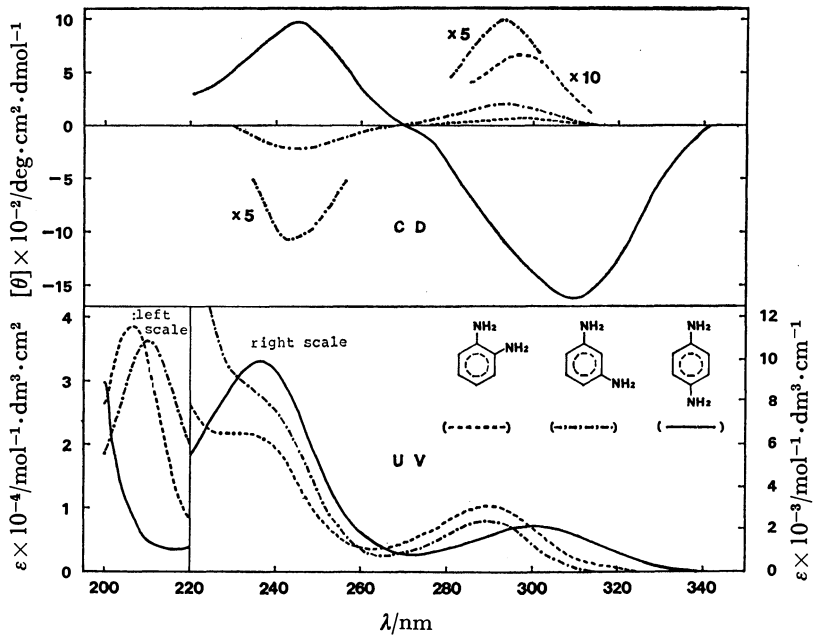

Fig. 3. CD (upper) and UV absorption (lower) spectra of the β-CD_x complexes with *o*-, *m*-, and *p*-phenylenediamines in aqueous KOH at room temperature. Broken line: β-CD_x (1.44×10^{-2} M)+*o*-phenylenediamine (1.83×10^{-4} M) (pH 7.5), dotted broken line; β-CD_x (1.43×10^{-2} M)+*m*-phenylenediamine (1.44×10^{-4} M) (pH 7.2), solid line; β-CD_x (1.45×10^{-2} M)+*p*-phenylenediamine (6.23×10^{-4} M) (pH 11.0).

ICD bands at 358, 281, and 249 nm, which are attributed to the first $\pi^*\leftarrow\pi$, the second $\pi^*\leftarrow\pi$, and the third $\pi^*\leftarrow\pi$ transitions, respectively. The lowest positive ICD band of the β-CD_x–*p*-nitroaniline complex observed at 390 nm was assigned to the $^1A_1\leftarrow{}^1A_1$ transition, and the two negative ICD bands found at 296 and 230 nm were attributed to the $^1B_2\leftarrow{}^1A_1$ transitions.

On the other hand, as seen in Fig. 2, the β-CD_x complex with pyrocatechol showed only a positive ICD band at 279 nm, originating from the $^1A_1\leftarrow{}^1A_1$ transition. But the ICD band derived from the $^1B_2\leftarrow{}^1A_1$ transition was not observed in the shorter wavelength region. The β-CD_x–resorcinol complex exhibited positive and negative ICD bands at 276 and 229 nm. These ICD bands were assigned to the $^1B_2\leftarrow{}^1A_1$ and $^1A_1\leftarrow{}^1A_1$ transitions, respectively. The β-CD_x–hydroquinone complex showed a negative ICD band attributed to the $^1B_{2u}\leftarrow{}^1A_g$ at 294 nm and exhibited a positive ICD band derived from the $^1B_{1u}\leftarrow{}^1A_g$ transition at 230 nm.

As shown in Fig. 3, each sign of the ICD spectra of the β-CD_x complexes with *o*-, *m*-, and *p*-phenylenediamines is in agreement with that of the β-CD_x complexes with *o*-, *m*-, and *p*-benzenediols (Fig. 2).

In our previous work,[14] we discussed the orientation of the guest molecule which is included in the cavity of the β-CD_x by the comparison of observed and calculated rotational strengths. One might conclude from the results of the investigation that the favorable orientation of the guest molecule about the axis of β-CD_x cavity (the Z-axis) can be estimated when the direction of the electric transition dipole moment is known. It was shown that the calculated rotational strengths were

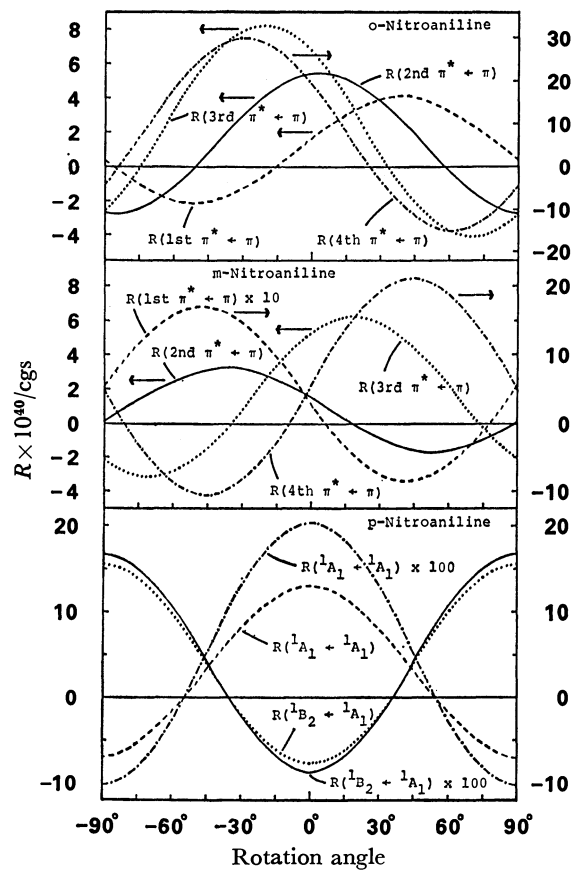

Fig. 4. The dependence of the calculated rotational strengths of the β-CD_x–nitroanilines complexes on the rotation angle in the X-Z plane.

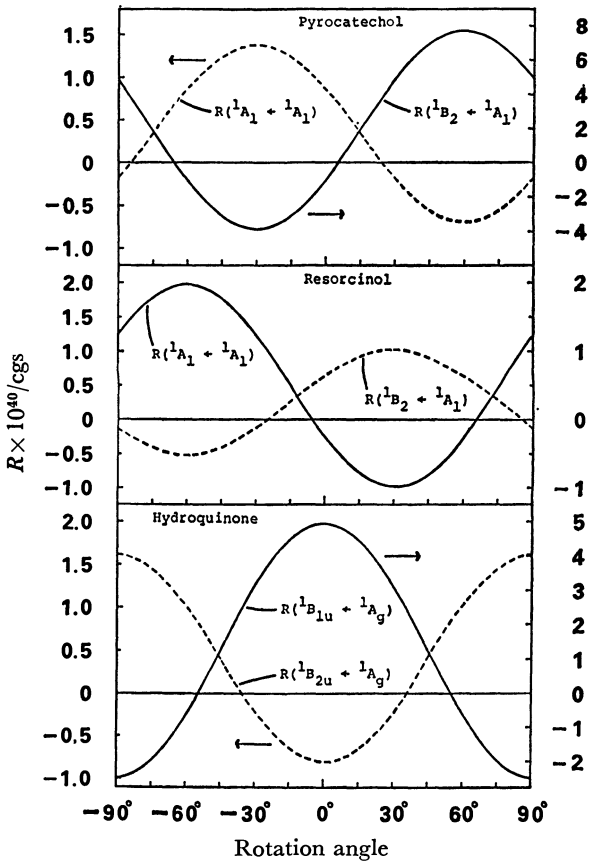

Fig. 5. The dependence of the calculated rotational strengths of β-CD$_x$–benzenediols complexes on the rotation angle in the X-Z plane.

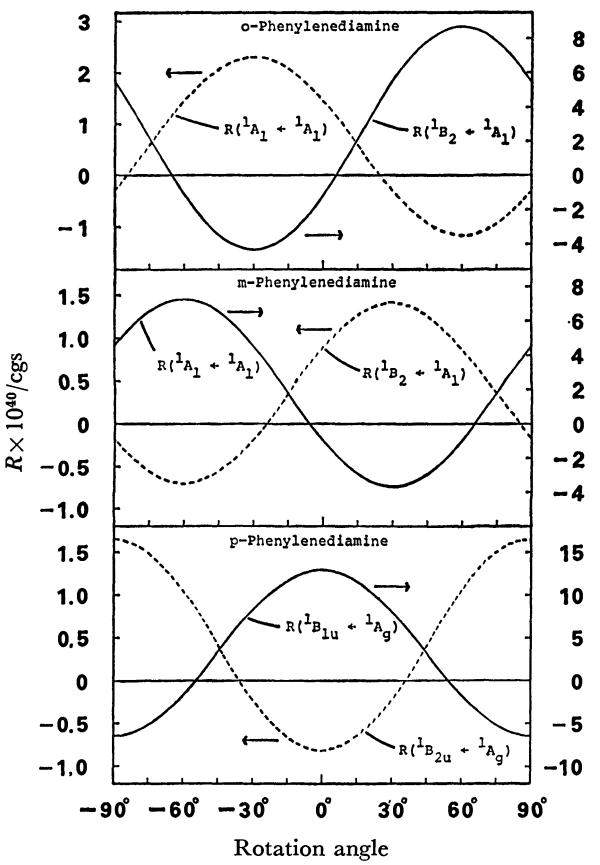

Fig. 6. The dependence of the calculated rotational strengths of β-CD$_x$–phenylenediamines complexes on the rotation angle in the X-Z plane.

very sensitive to the electric transition moment of the guest molecule and the orientation of the guest molecule in the β-CD$_x$ cavity. So, in the present work, we studied how to fit the calculated rotational strengths with the observed values obtained from ICD spectra by changing the direction of the guest molecule in the X-Z plane.

Figures 4—6 show the dependence of the calculated rotational strengths of the β-CD$_x$ complexes with disubstituted benzenes on the orientation of the guest molecule in the X-Z plane. In Fig. 4 the rotation angle on the abscissa indicates the inclined angle of the vector pointing from the center of nitroanilines to the nitro group with respect to the Z-axis (the axis of β-CD$_x$ torus). Similarly, in Figs. 5 and 6 the abscissa represents the inclined angle of the vector pointing from the center of homo-disubstituted benzenes to one of the substituents with respect to the Z-axis.

The comparison of the observed rotational strengths obtained from ICD spectra with the values calculated for the favorable orientation is listed in Table 2.

As shown at the top of Fig. 4, the calculated rotational strengths of the β-CD$_x$–*o*-nitroaniline complex in which the nitro group of *o*-nitroaniline inclines to the Z-axis by about 32° to 33° are in good agreement with the experimental values. On the other hand, in the case of *m*-nitroaniline the calculated values with an inclined angle of about −10° to −11° are compatible with the observed values. The calculated values of the β-CD$_x$–*p*-nitroaniline complex agree well with the experimental data when the nitro group of *p*-nitroaniline has an inclination with respect to the Z-axis in the range of about 0° to ±20° (bottom of Fig. 4). The experimental rotational strengths of the β-CD$_x$ complex with pyrocatechol are well reproduced by the calculation when the rotation angle is about 5° (top of Fig. 5). The calculated results of the β-CD$_x$–resorcinol complex are in accord with the observed values in the range of rotation angle from 0° to 30° (middle of Fig. 5). In this case, the orientation with roration angle 0° is equivalent to that with rotation angle 60°. The theoretical values of the β-CD$_x$–hydroquinone complex in which one of hydroxyl groups is inclined in the range of about 0° to ±20° with respect to the Z-axis are consistent with the experimental data (bottom of Fig. 5).

The same rotation angle for the β-CD$_x$ complexes with *o*-, *m*-, and *p*-phenylenediamines as that for the corresponding complexes with *o*-, *m*-, and *p*-benzenediols, respectively, gives the theoretical results in agreement with the experimental data, as demonstrated in Fig. 6 and/or in Table 2. This suggests that *o*-, *m*-, and *p*-phenylenediamines are included in the β-CD$_x$ cavity in a same way that *o*-, *m*-, and *p*-benzenediols, respectively, are included.

The results discussed above are summarized in Figs. 7 and 8. These figures illustrate the orientation directions of disubstituted benzenes included as guest molecules

c) Obtained by a curve fitting method.

in the cavity of β-CD_x. The β-CD_x cavity, in both figures, was represented schematically by a pair of rectangles with oblique lines. Each dotted line in Fig. 7 indicates the direction of the transition dipole moment obtained from the PPP SCF-MO calculation, and the numbers, 1, 2, 3, and 4 designate the first $\pi^* \leftarrow \pi$, the second $\pi^* \leftarrow \pi$, the third $\pi^* \leftarrow \pi$, and the fourth $\pi^* \leftarrow \pi$ transitions of *o*- and *m*-nitroanilines, respectively. Similarly, each dotted line in Fig. 8 indicates the directions of the electric transition moments of homo-disubstituted benzenes derived from the perturbation theory formulas by Petruska.[16] In addition, the symbols (+) and (−) give the signs of the CD spectra induced by the electronic transitions of the corresponding disubstituted benzenes.

We could make no reference to the discrimination of the top side from the bottom side of β-CD_x, because the coulombic interaction between CD_x and the guest molecule was approximated by the interaction between the distributed bond dipole of CD_x and the point dipole of the guest molecule in the present calculation.

On the other hand, it seems likely from Figs. 7 and 8 that some of the substituents of the guest molecules are linked by the hydrogen bond to the hydroxyl group of β-CD_x, or are in van der Waals contact with the interior of the β-CD_x torus. However, it appears that the conformational change in one or two of the C(5)–O(6) bonds is required for the guest-host linkage by a hydrogen bond with the primary hydroxyl group.[17]

In conclusion, the orientation of the guest molecule which is included in the β-CD_x cavity seems to be confined about the axis of the β-CD_x torus.

Mechanochemical Reactions at High Pressures. I. The Design and Construction of the Apparatus and Preliminary Experiments

Yoshiaki Ogo,* Noboru Nishiguchi,** and Yasuhiro Okuri

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received May 23, 1980)

An apparatus for investigating mechanochemical reactions at high pressures of up to 50 kbar and preliminary experiments on acrylamide are described. The essentials of the apparatus are a rotating platen inserted in a Bridgman-type opposed-anvil press. The central platen is rotated by the force of an electric motor or by manual strokes under high pressure. The pressure distribution on the anvil surface was evaluated from the changes in the electric resistances of CdSe and CdTe as calibrants. The pressure observed at the center was 4.5 times the nominal load pressure. The phase-transition pressure of naphthalene was identified as about 25 kbar from the measurement of the pressure effect on the shearing strength. The mechanochemical behavior of acrylamide was investigated at room temperature and at static pressures of up to 15 kbar. The determinations of the IR spectrum, the ESR signal, the X-ray diffraction pattern, and the molecular weight confirmed that the reaction products were amorphous polyacrylamides and that the mechanical shear stress on the conversion of acrylamide to a polymer was exceedingly effective in comparison with static pressure.

The terms "mechanochemistry" and "mechanochemical reaction" have recently been used to designate chemical behavior caused by mechanical energy. Although mechanochemistry is an ambiguous research field at present, the knowledge of mechanochemistry has been widely extended and rapidly advanced in connection with the structure, chemical properties, and reactivity of a solid, *etc.* Thus, the interest in mechanochemistry extends over a wide range of scientific and technical disciplines.

Mechanochemical reactions at high pressures are significant in two important ways.

First, we consider that a strong mechanochemical force on substances, especially on organic materials, can be easily applied at high pressures. Mechanochemical reactions are generally not so appreciable as thermochemical or photochemical reactions. Therefore, a very sensitive detector is required to follow the reaction. The application of pressures makes detection by usual instruments possible.

Second, some shear stress is unavoidable when solid materials are compressed. In other words, solid-phase reactions under high pressures are somewhat or mostly mechanochemical changes.

These experiments were initiated to study the mechanochemical reactions of organic compounds from the above two points of view by means of a self-made high-pressure apparatus which is capable of loading the mechanical force simultaneously.

This unique technique was discovered by Bridgman. However, previous investigations by using this technique have dealt almost exclusively with phase-transitions, except for the group in communist countries. Recently investigations of the organic reaction under high pressures with mechanochemical shear force have been mainly done by Russian scientists, and it seems likely that they each belong to one of two groups. The first is Enikolopyan's group in the Chemical Physics Institute of Academy Sciences USSR. The mechanochemical behavior of many organic compounds has been investigated under high pressure by his group.[1-10] The second, Gonikberg-Zhulin's group in the Zelinskii Organic Chemistry Institute of Academy Sciences USSR, was also studied the organic reactions[11-18] from the same standpoint.

Our series of studies was initiated in order to synthesize new materials by means of solid-phase organic reactions under extreme conditions and in order to investigate the mechanochemical effect, which is unavoidable in solid-phase reactions under high pressures. The present paper will describe the design and the technique of the apparatus for the mechanochemical reactions and will present some preliminary experimental results on the reaction of acrylamide.

Design and Construction of the Apparatus

Despite the great interest in high-pressure studies, very little fundamental work has been reported on the design of high-pressure units (anvils). The development of this apparatus has, therefore, been based mainly on empirical experience gained through use. In the selection of an optimum design for the apparatus, questions regarding the ratio of the diameter of the sample face to that of the body of the anvil, or of the angle of the cone, could not be answered by recourse to the results of systematic studies. It should be emphasized, however, that economical considerations are among the most important factors. The diameter of the anvil surface of 12-mm determined the minimum sample quantity (≈10-mg) required to follow the mechanochemical reaction. (A 5-mm anvil was used in a special case).

The essentials of the apparatus are a flat metal plate (central platen), inserted between Bridgman-type opposed-anvils for pressuring and shearing, and a copper jacket for controlling the temperature. Enlarged views of the anvils, central platen, and sample assemblies are shown in Fig. 1. Two powdered or crystal samples, 1, between the mating surface of three cobalt-cemented

** Present address: Daido Chemicals Co. Ltd., 28-4-4, Takeshima, Nishiyodogawa-ku, Osaka 555.

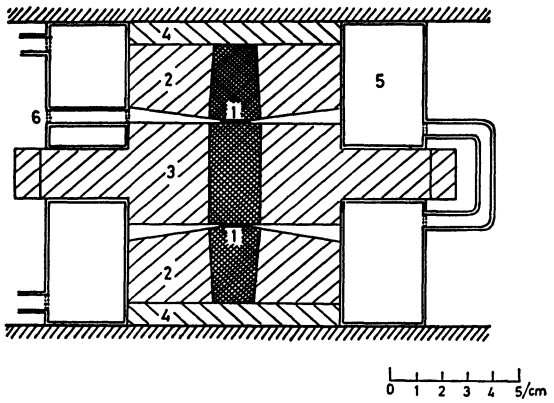

Fig. 1. Schematic diagram of anvil assembly.

tungsten carbides are compressed up to the desired pressure. The tungsten carbide conical cylinders of the opposed-anvils are 20-mm and 17-mm in diameter by 30-mm long and are supported by steel jacket shrunk around them. Both anvils, 2, are ground as truncated cones with 12-mm-diameter flats and a cone half-angle of 85°. The central platen, 3, is pinned into the hub of a 165-mm diameter spur gear. Two flat disks, 4, are attached to the top and bottom of the opposed-anvils. All the parts are surrounded by a pair of copper jackets, 5, through which thermostated water is circulated to keep the temperature constant throughout the experimental period. In order to fit a thermometer for the measurement of the temperature, a narrow hole, 6, is made in the copper jacket. A surface-type thermister thermometer is used to measure the temperature of the anvil surface near the sample region.

The load is applied to these anvils by means of a 50-t hydraulic-ram as the load unit. A pressure of up to 50 kbar (1 kbar$=10^8$ Pa) can be generated between them. During the compression, some of the sample extrudes from between the anvil faces until an equilibrium thickness is attained. Torque was applied to the gear holding the central platen by means of a mechanical drive forcing it to rotate about the common axis at various speeds with respect to the opposed-anvils. A torque can be generated by two different methods. One is the use of a continuous slow rotation in one direction of the central platen against the other by using an electric motor and various gear combinations. In our apparatus, shearing stresses are applied to the sample by rotating the central platen about its vertical axis through a maximum of 2.5° in 60 s. The other method is the use of a manual stroke. Mechanical driving is also given by the movement of the rack connected with the spur gear by means of another 10-t hydraulic-ram, serving as the shear unit instead of an electric motor. In this case, we can calculate the shear stress, τ, by the use of the following equations by assuming a constant value of shear stress across the radius, r:

$$M = \int_0^{r'} \tau r 2\pi r \cdot \mathrm{d}_r \text{ or } \tau = 3M/2\pi(r')^3 = 3PSR/2\pi(r')^3, \quad (1)$$

where M represents the torque; r', the effective radius of the anvils; P, the pressure produced in the 10-t hydraulic-ram to rotate the central platen; S, the surface area of the piston in the hydraulic-ram used as the shear unit, and R, the radius of the spur gear.

Under the conditions of our experiments, heating due to friction is negligible.

Pressure Distribution

Since the pressure at the center of the sample area in the opposed-anvil press is not equal to the applied pressure or to some predictable function of the applied pressure, it is necessary to use various internal standards (fixed points) for determining the actual pressure. We tried to measure the internal (true) pressure on the anvil surface without mechanical shear force by using acrylamide tablet as a model organic sample and cadmium selenide (CdSe) and cadmium telluride (CdTe) as the pressure-standard substances. CdSe and CdTe sharply change in their electrical resistances at 25 and 33 kbar respectively.[19]

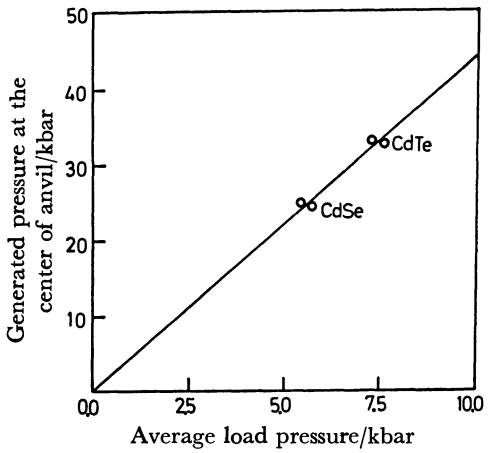

Fig. 2. Generated pressure at the center of anvil by measuring phase transitions of CdSe and CdTe.

Figure 2 shows the pressure at the center of the sample at various load pressures, which are detected by means of the changes in the electrical resistances of CdSe and CdTe. The internal pressure at the center is about 4.5 times larger than the average load pressure, and the two pressures are correlated by a single straight line through the original point. It has been concluded that the "pressure-multiplication effect" is independent of the press force in our pressure range.

Figure 3 shows the pressure distribution on the anvil surface. In this experiment, the semi-conducting materials used were placed in a certain position in the acrylamide tablet.

It can be readily shown that the press force on the anvil surface is expressed by the following formulas:

The force on the sample side, F_{ss}, is:

$$F_{ss} = \int 2\pi r \cdot P(r) \cdot \mathrm{d}r. \quad (2)$$

The force on the hydraulic-ram side, F_{rs} is:

$$F_{rs} = S_2 P_{obsd}, \quad (3)$$

where r represents the radius of the anvil surface on the sample side; $S_1(=\pi r^2)$, S_2, the surface areas of the

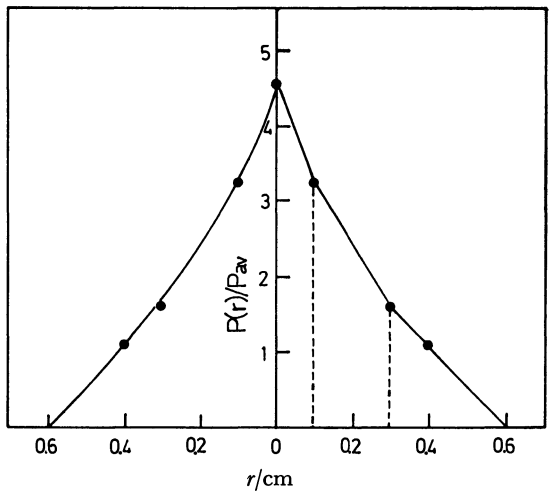

Fig. 3. Pressure distribution on anvil face.

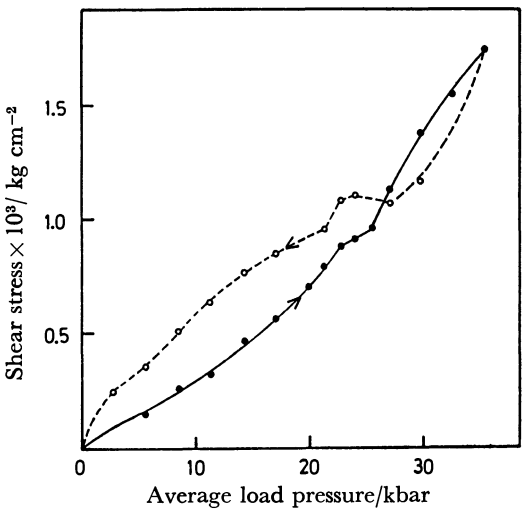

Fig. 4. Shearing curve for naphthalene by using anvil of 5 mm diameter.

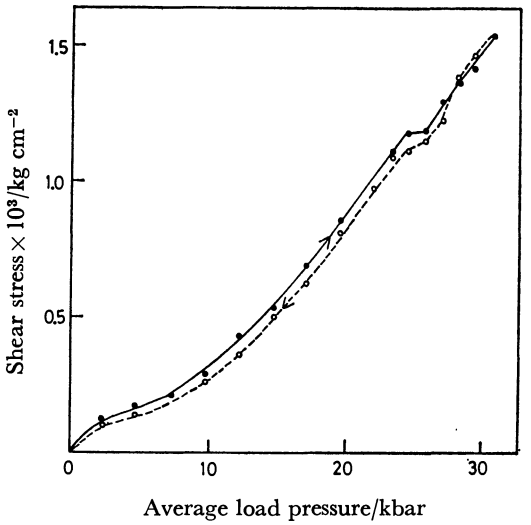

Fig. 5. Shearing curve for naphthalene by using anvil of 12 mm diameter.

anvils on the sample side and the hydraulic-ram side respectively; and P_{obsd}, the pressure as measured by means of a pressure gauge installed at the hydraulic-ram as the load unit. Moreover, one function, $P(r)$, is the pressure distribution on the anvil surface.

Theoretically

$$F_{ss} = F_{rs} = \int 2\pi r \cdot P(r) \cdot dr = S_2 P_{obsd}. \quad (4)$$

Instead of P_{obs}, the average load pressure on the anvil surface, P_{av}, as defined by Eq. 4, we obtain:

$$P_{av} = P_{obsd}(S_2/S_1) \quad (5)$$

$$\int 2\pi r \cdot P(r) \cdot dr/P_{av}S_1 = 1. \quad (6)$$

Since $S_2/S_1=62.7$ and $r=6$-mm in our apparatus, the calculation of Eq. 6 gives $1.294/1.131=1.14\fallingdotseq 1$, where it has been assumed that the pressure distribution, $P(r)$, is a linear function in the three divided regions, as is shown on the right-hand side of Eq. 3. Therefore, the value of P_{av} defined by Eq. 5 has been used as a pressure parameter in the foregoing discussion unless otherwise stated.

The distribution of pressure in the compressed material is evidently complicated when the mechanical shearing stress is loaded (that is, the central platen is rotated). At present, it is impossible to measure directly the distribution of pressure in that case. Although there is, therefore, no definite evidence, it seems reasonable to assume from the following considerations that the pressure distribution becomes uniform as a result of the plastic flow.

In general, the mechanical strengths of the organic substances are dependent on their modifications, which, of course, have different crystal structures; therefore, the curve of the shearing strength should change on passing from one modification to the other.

We have also tried to investigate the effect of the pressure on the shearing strength of naphthalene; some typical shearing curves are shown in Figs. 4 and 5. In this experiment we undertook to squeeze a purified single crystal of naphthalene in the direction of the c-axis and to rotate the central platen by 1 rad/h (1°/min) at room temperature by means of a manual stroke. The shear stress applied to the sample was calculated from Eq. 1 by assuming $r'=r$.

The curves exhibited a characteristic variation at

Table 1. Transition pressure and shear force of naphthalene

	Anvil diameter / mm	Pressure / kbar	Shear force / kg cm^{-2}

a) Transition pressure.

about 25 kbar, which corresponds to the phase-transition of naphthalene. The results of such measurements are summarized in Table 1, together with the literature values.

Under ideal conditions such a transition should be accompanied by a sharp discontinuity in the shearing force itself, but because the pressure is not perfectly uniform over the anvil surface, the transition is spread over the interval of the mean pressure. With simultaneous mechanical deformation, the pressure distribution on the anvil surface would not be so sharp as in Fig. 3. It can be seen that the mechanical shear force induces a flattening of the distribution curve and that the distribution approaches a uniform state by its plastic flow if the rotation of the central platen is appropriate. Considering that our finding agree with the literature value, regardless of the anvil size, it seems reasonable to conclude that the pressure distribution in the organic sample on the anvil surface is almost uniform when mechanical shear force is applied. Therefore, nominal load pressures, as evaluated from Eq. 5, are defined as the operative and the effective pressures.

The above discussions are based on the results for acrylamide and naphthalene. However, it is probable that many organic compounds show the same behavior.

Reaction of Acrylamide

Experimental. Acrylamides were allowed to react at a high pressure (HP) combined with simultaneous shear deformation (SSD). The apparatus described in the preceding chapter will be abbreviated below as HP+SSD. In this experiment, the reactions proceeded at the constant shearing velocity (the rotation speed of the central platen) of 2.51 rad/h (2.4°/min) at room temperature unless otherwise stated. Therefore, 1 h of reaction time corresponds to a rotation angle of the central platen of 300°.

A commercial sample of acrylamide was purified by repeated crystallizations from a benzene solution and was finally vacuum-dried at room temperature for over 24 h. The purity of this acrylamide was proved by its melting point to be 84.5—85.0 °C.

A sample tablet was obtained from the purified acrylamide powder by preforming in a N_2 stream. The preforming pressure was about 5 kbar. The sample tablet was placed into the HP+SSD apparatus, and the experiment was carried out at the desired pressure.

The ESR data were obtained by rapidly inserting the sample into the ESR cavity immediately after the HP+SSD experiment. The concentrations of free-radicals were determined by integrations of the spectra and by subsequent comparison with those of 1,3,5-triphenylverdazyl as references.

A sample sheared at a high pressure was extracted from a large amount of methanol for separating into soluble and insoluble fractions. The insoluble fraction was dried *in vacuo* at room temperature to a constant weight, and the conversion was determined. The identification of the product took place by means of measurements of the melting point, the IR spectrum, the X-ray diffraction pattern, and the intrinsic viscosity.

The molecular weight of the product (polyacrylamide, as will be described below) was determined, by means of the following relations, from the viscosity data obtained from the Ubbelohde viscometer at 25 °C:[21]

$$[\eta]_{25}^{H_2O} = 3.73 \times 10^{-4} M_v^{0.66}$$

$$[\eta]_{25}^{H_2O} = 4.65 \times 10^{-4} M_n^{0.64}.$$

Results and Discussion. Judging from the following experimental evidence, acrylamide was clearly polymerized under conditions of HP+SSD. First of all, the product did not show a definite melting point. Secondly, the IR spectra of the product were the same as those of commercial polyacrylamide, while the IR spectra of the dissolved fraction in methanol were identical with those of the acrylamide monomer. Thirdly, when the X-ray diffraction patterns of the acrylamide monomer were compared with those of the product, the product was shown to be in an amorphous state. Therefore, we concluded that the product of this reaction was amorphous polyacrylamide.

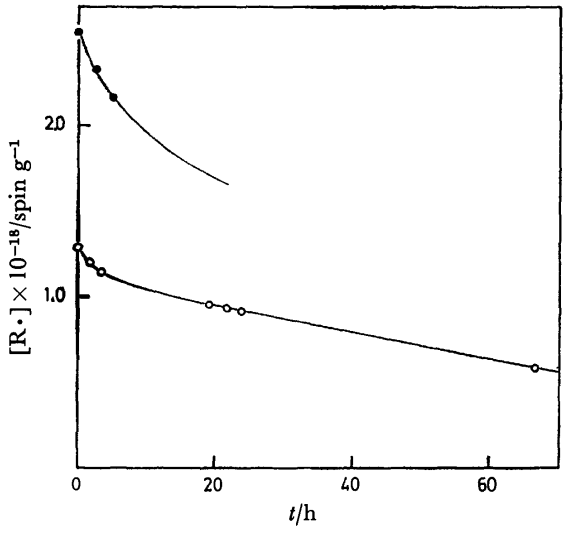

Fig. 6. Time dependence of radical concentrations at room temperature.
● 5 kbar, 4.54 rad; ○ 10 kbar, 2.27 rad.

The curve of the ESR signal yields a resolved three-peak system, about 64 G wide, with the central peak twice the height of the outer ones. No other signals could be identified under our experimental conditions. Such a signal corresponded well to that of the growing polyacrylamide radical reported by Alder and his collaborators.[22] Evidently, therefore, the reaction of acrylamide under the conditions of HP+SSD is a free-radical polymerization or depolymerization; in other words, the mechanochemical reaction of acrylamide proceeds *via* a free-radical mechanism. Figure 6 shows its time-dependence at room temperature. The resulting radicals are fairly stable for a long period. Morawetz and Fadner[23] have reported that the radical concentration obtained by γ-ray irradiation in the solid state was reduced to 67% after 60 h at 25 °C. We concluded, from our similar results shown in Fig. 6,

that the strain in the sheared sample disappears for periods up to several hours after the mechanical stress or static pressure is removed.

It is instructive to compare the experimental data with the time-dependence of the expected radical decay. If bimolecular radical termination is assumed,

$$-d[R\cdot]/dt = k_2[R\cdot]^2. \quad (7)$$

This leads to a radical decay of the form:

$$k_2t = 1/[R\cdot] - 1/[R\cdot]_0, \quad (8)$$

and if unimolecular spontaneous termination is assumed,

$$-d[R\cdot]/dt = k_1[R\cdot]. \quad (9)$$

This leads to a radical decay of the other form:

$$k_1t = \ln[R\cdot]_0/[R\cdot]. \quad (10)$$

The experimental data obtained are plotted in Figs. 7 and 8 as suggested by Eqs. 8 and 10. The initial parts of the time-dependence curves were satisfactorily expressed by Eq. 8, and the rate constants, k_2, were evaluated from the slopes of the straight line as 2.97×10^{-20} g spin^{-1} h^{-1} for the radicals generated at 10 kbar and as 1.47×10^{-20} g spin^{-1} h^{-1} for those generated at 5 kbar.

However, the hypothesis of chain termination by mutual recombination can be ruled out over the whole experimental range. Equation 10 is apparently verified in the range, as is shown in Fig. 8. Therefore, the hypothesis of a first-order termination of the chains,

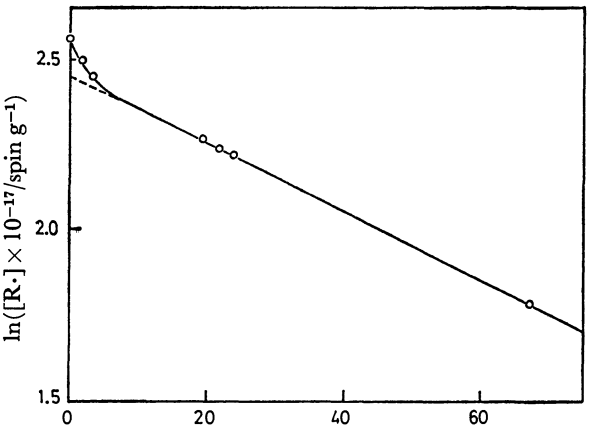

Fig. 8. Logarithm of free radical concentration as a function of time.
(Generated at 10 kbar and 2.27 rad)

deactivated by steric hindrance or by the fact that the free-radical site is "bogged down" in the mass of the polymer formed, is generally applicable.

The conversion of acrylamide to polymer was negligible without the application of mechanical shear force.

Figure 9 shows the relation between the conversion and the shearing degree at 5, 10, and 15 kbar pressures. The relation between the shearing degree and the

Table 2. Molecular weight of the product polymer and the number of polymer molecules and free radicals in a gram of the sheared sample

Pressure / kbar	Shearing / rad	Degree / °	M_v viscosity-average	M_n number-average	Polyacrylamine / molecule g^{-1}	Free radical / spin g^{-1}
5	2.27	130	175000	180000	7.62×10^{17}	2.66×10^{17}
5	4.54	260	59000	59000	7.64×10^{18}	2.56×10^{18}
5	6.81	390	61000	61000		
10	2.27	130	132000	135000	2.77×10^{18}	1.29×10^{18}
10	4.54	260	68000	68000	7.50×10^{18}	4.25×10^{18}
15	2.27	130	67000	62000		

conversion showed a *S*-type curve and was somewhat analogous to a typical solid-phase reaction. Furthermore, the shearing velocities were independent of the conversion in our experimental region.

Table 2 shows the molecular weight of polyacrylamide as obtained by HP+SSD, together with the concentrations of the polymer and of the radical in sample layer, as evaluated from the M_n and ESR data. The molecular weight of the polymer obtained by HP+SSD was considerably lower than those of the polyacrylamides obtained commercially and by radiation-induced solid-phase polymerization.[21] The order of concentration of the polymer was, however, the same as that of the radicals in the sample layer. These facts suggest that the radicals identified by ESR are almost all reacting polymer radicals, as in the preceding discussions. This table also suggests that polyacrylamide degrades at a later stage of the HP+SSD reaction, judging from the facts that the molecular weight becomes much lower with the increase in the shearing degree. It can be roughly concluded from this table that the mechanochemical degradation of polyacrylamide affects this type of reaction in the range of large shear deformations.

The authors wish to thank Dr. Akifumi Onodera of Osaka University for helpful advice on the measurement of the pressure distribution and Dr. Yozo Miura of Osaka City University for the ESR studies.

Synergistic Solvent Extraction of Alkali Metal Picrates by Crown Ethers

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received June 17, 1980)

The solvent extraction of rubidium and caesium picrates has been studied between benzene and water at 25 °C in the presence of tributyl phosphate (B), 12-crown-4 (12C4), 15-crown-5 (15C5), or both B and 15C5, and the complex-formation constants for the synergistic reactions in the benzene solution have been calculated. For both rubidium and caesium, the sequences of the complex-formation constants for these ligands are B<12C4<15C5, indicating that the complex-formation constant increases with an increase in the number of the donor oxygen atoms of the ligand. The complex-formation constant of rubidium is greater than that of caesium in every system.

For the rigid crown ethers such as 12-crown-4 (12C4), 15-crown-5 (15C5), and 18-crown-6, in a crown ether complex with a metal ion whose size is larger than the cavity size of the crown ether, the metal ion is located partly outside the plane of the crown ether ring. Thus, the exposed part of the metal ion can interact strongly with another crown ether or a neutral donor solvent in a solution; *e.g.*, benzo-15-crown-5 and dibenzo-18-crown-6 (DB18C6) form 2 : 1 complexes with rubidium and caesium ions.[1]

The solvent extraction of alkali and alkaline earth metal ions with crown ethers has been widely investigated in terms of thermodynamics[1c,2] and analytical chemistry.[3] However, few synergistic effects for alkali and alkaline earth metal ions in the crown ether-neutral donor extractant system have been reported.

In the present study, the solvent extraction of rubidium and caesium picrates has been studied between benzene and water in the presence of 12C4, 15C5, or both tributyl phosphate (B) and 15C5, and the complex-formation constants for the synergistic reactions in the benzene solution have been calculated in order to compare the synergistic effects due to the crown ethers with those due to B.

Experimental

Materials. 12C4 and analytical-grade B were obtained from Wako-Pure Chemicals, Ltd., and 15C5 from Nisso Co., Ltd. They were used without further purification. The concentrations of the alkali metal hydroxides and picric acid solutions were determined by means of acid and basic titrations respectively. Benzene (analytical-grade) was washed twice with distilled water.

Apparatus and Procedure. An aqueous phase contained the alkali metal hydroxide (4.4×10^{-3}—2.0×10^{-2} M; 1 M= 1 mol dm^{-3}) and the picric acid (2.0×10^{-3}—1.0×10^{-2} M). An organic phase contained one of the extractants (B: 9.4×10^{-2}—9.9×10^{-1} M, crown ether: 4.9×10^{-2}—7.5×10^{-1} M), or both B (6.8×10^{-2}—8.0×10^{-1} M) and the crown ether (4.8×10^{-3}—5.8×10^{-2} M). The two phases in stoppered glass tubes (30 ml) were shaken in a thermostated water bath for approx. 30 min at 25±0.2 °C and then centrifuged. The initial volume of each phase was 10 ml in all cases. A portion of the aqueous phase (8 ml) was transferred into a 10-ml beaker, and the hydrogen ion concentration was determined by a Hitachi-Horiba F-5 pH meter. The extractions were conducted at pH 8.2—11.8. The picrate in the organic phase was back-extracted into 8 ml of a 0.01 M NaOH aqueous solution, and the picrate concentration was determined at 356 nm by means of a Shimadzu UV-200 spectrophotometer ($\varepsilon=1.45\times10^4$ cm^{-1} M^{-1}).

Results

When equilibrium occurs between an aqueous solution of a univalent metal ion (M^+) and a picrate ion (A^-), and a benzene solution of B, a crown ether (L), or both B and L, the equilibrium constants may be defined by the following equations:

$$K_{ex}(MB_3A) = [MB_3A]_o[H^+]/[M^+][B]_o^3[HA]_o \quad (1)$$

$$K_{ex}(ML_2A) = [ML_2A]_o[H^+]/[M^+][L]_o^2[HA]_o \quad (2)$$

$$K_{ex}(MLBA) = [MLBA]_o[H^+]/[M^+][L]_o[B]_o[HA]_o \quad (3)$$

$$K_{D,L} = [L]_o/[L] \quad (4)$$

$$K_{ML} = [ML^+]/[M^+][L] \quad (5)$$

$$K_{ex}(HA) = [HA]_o/[H^+][A^-], \quad (6)$$

where the subscript "o" means organic and the lack of a subscript refers to the aqueous phase. The value of $K_{ex}(HA)$ was spectrophotometrically determined to be 247. For the B system the distribution ratio of the metal may be represented by

$$D = [MB_3A]_o/[M^+]. \quad (7)$$

The substitution of Eqs. 1 and 6 into Eq. 7 gives

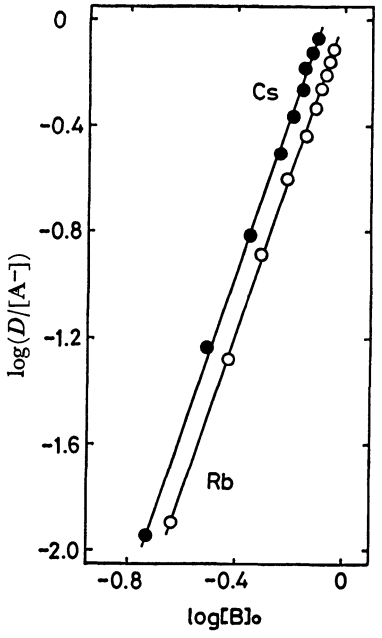

Fig. 1. Plots of $\log(D/[A^-])$ *vs.* $\log[B]_o$ for the B system.

$$D = K_{ex}(MB_3A)K_{ex}(HA)[B]_o^3[A^-]. \quad (8)$$

The log $(D/[A^-])$ *vs.* log $[B]_o$ plot in Fig. 1 shows a straight line with a slope of 3 in each case, indicating that the $K_{ex}(MB_3A)$ in the present study can be described by Eq. 1. The value of $[B]_o$ in Eq. 8 was considered to be approximately equal to that of $[B]_t$ under the present experimental conditions and that of $[A^-]$ calculated from Eq. 9:

$$[A^-] = [HA]_t - [MB_3A]_o, \quad (9)$$

where the subscript "t" denotes the total concentration.

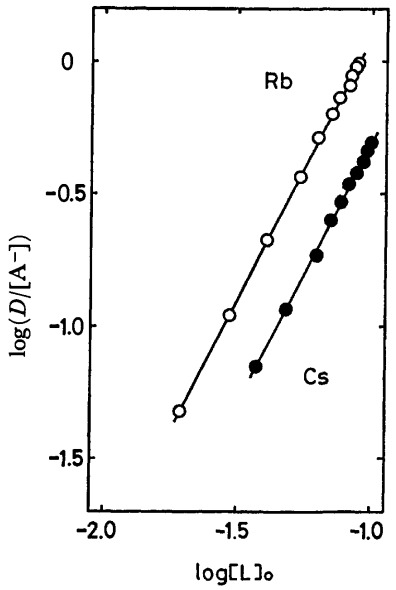

Fig. 2. Plots of $\log(D/[A^-])$ *vs.* $\log[L]_o$ for the 12C4 system.

For the 12C4 system D may be represented by

$$D = [ML_2A]_o/([M^+] + [ML^+] + [ML_2^+]). \quad (10)$$

In the case of $[M^+] \gg [ML^+] + [ML_2^+]$, Eq. 10 becomes

$$D = K_{ex}(ML_2A)K_{ex}(HA)[L]_o^2[A^-]. \quad (11)$$

The log $(D/[A^-])$ *vs.* log $[L]_o$ plot in Fig. 2 shows a linear relationship with a slope of 2 in each case, indicating that 12C4 forms a 2 : 1 complex with the monovalent metal ion. The values of $[L]_o$ and $[A^-]$ in Eq. 11 were calculated from Eqs. 12 and 13 respectively:

$$[L]_o = ([L]_t - 2[ML_2A]_o)/(1 + K_{D,L}^{-1}) \quad (12)$$

($K_{D,L} = 0.15$ for 12C4[4])

$$[A^-] = [HA]_t - [ML_2A]_o. \quad (13)$$

For the 15C5 system D may be described by Eq. 10. In the case of $[M^+] + [ML^+] \gg [ML_2^+]$, Eq. 10 becomes

$$D = K_{ex}(ML_2A)K_{ex}(HA)[L]_o^2[A^-]/(1 + K_{ML}K_{D,L}^{-1}[L]_o). \quad (14)$$

The log $\{D(1+K_{ML}K_{D,L}^{-1}[L]_o)/[A^-]\}$ *vs.* log $[L]_o$ plots of both Rb and Cs in Fig. 3 fall on the straight lines with a 2 slope. Thus, the extraction equilibrium can be represented by Eq. 2. The values of $[L]_o$ and $[A^-]$ in Eq. 14 were calculated from Eqs. 15 and 16 respectively:

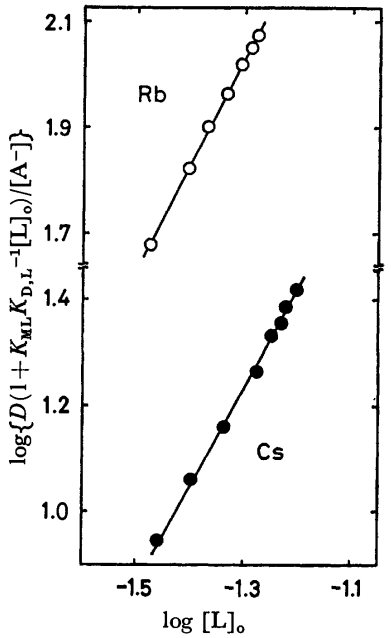

Fig. 3. Plots of $\log\{D(1+K_{ML}K_{D,L}^{-1}[L]_o)/[A^-]\}$ *vs.* $\log[L]_o$ for the 15C5 system.

$$[L]_o = ([L]_t - 2[ML_2A]_o)/(1 + K_{D,L}^{-1} + K_{ML}K_{D,L}^{-1}[M^+]), \quad (15)$$

($K_{D,L}=0.15_6$ for 15C5;[2b] $K_{ML}=4.2$ and 6.3 for Rb and Cs respectively[5])

$$[A^-] = ([HA]_t - [ML_2A]_o)/\{1 + (K_{HA} + K_{ex}(HA))[H^+]\}, \quad (16)$$

where K_{HA} is the association constant of picric acid ($K_{HA}=1.9_5$[6]).

When both 15C5 and B exist in the extraction system, D may be represented by

$$D = [MLBA]_o/([M^+]+[ML^+]). \quad (17)$$

The substitution of Eqs. 3, 4, 5, and 6 into Eq. 17 gives

$$D = K_{ex}(MLBA)K_{ex}(HA)[L]_o[B]_o[A^-]/(1 + K_{ML}K_{D,L}^{-1}[L]_o). \quad (18)$$

The log $\{D(1+K_{ML}K_{D,L}^{-1}[L]_o)/[A^-]\}$ *vs.* log $[L]_o$ and log $[B]_o$ plots are illustrated in Figs. 4 and 5 respectively.

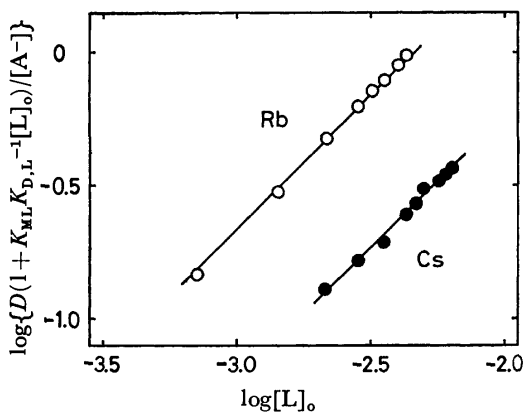

Fig. 4. Plots of $\log\{D(1+K_{ML}K_{D,L}^{-1}[L]_o)/[A^-]\}$ *vs.* $\log[L]_o$ for the 15C5–B system.

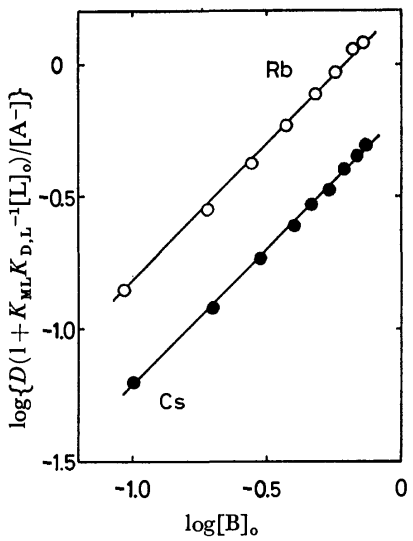

Fig. 5. Plots of $\log\{D(1+K_{ML}K_{D,L}^{-1}[L]_o)/[A^-]\}$ *vs.* $\log[B]_o$ for the 15C5–B system.

It may be noted from Figs. 4 and 5 that, in each case, the plots of both Rb and Cs have a slope of 1. Thus, the K_{ex}(MLBA) in the present study can be described by Eq. 3. The value of $[B]_o$ in Eq. 18 was considered to be nearly equal to that of $[B]_t$ under these experimental conditions, and those of $[L]_o$ and $[A^-]$ were calculated from Eqs. 19 and 20 respectively:

$$[L]_o = ([L]_t - [MLBA]_o)/(1+K_{D,L}^{-1}+K_{ML}K_{D,L}^{-1}[M^+]), \quad (19)$$

$$[A^-] = [HA]_t - [MLBA]_o. \quad (20)$$

The extraction equilibrium constants obtained from these data are summarized in Table 1, together with those from the literature.

TABLE 1. EXTRACTION EQUILIBRIUM CONSTANTS AT 25 °C

		Rb^+	Cs^+
$\log K_{ex}(MB_3A)$		−2.26	−2.14
$\log K_{ex}(MLBA)$	15C5	0.56	0.19
$\log K_{ex}(ML_2A)$	12C4	−0.29	−0.64
	15C5	2.15	1.48
	DB18C6[1c]	4.11	3.21
$\log K_{ex}(MLA)$	12C4[4]	−2.10	−2.18
	15C5[2c]	−0.25	−0.49
	DB18C6[1c]	1.36	0.68

Discussion

As can be seen from Table 1, the $\log K_{ex}(MB_3A)$ value of Rb^+, which is more strongly hydrated than Cs^+, is smaller than that of Cs^+. On the contrary, for the MLA, MLBA, and ML_2A systems, Rb^+ is more extractable than Cs^+. In the cases of 12C4 and DB18C6, the extractabilities and the difference in the extractabilities of Rb^+ and Cs^+ are enhanced in going from the MLA system to the ML_2A one, and, in the case of 15C5, those increase in the system order MLA< MLBA<ML_2A.

When MLA forms MLBA and ML_2A with B and L in the organic phase, the equilibria can be written as Eqs. 21 and 22 respectively:

$$MLA_o + B_o \rightleftarrows MLBA_o$$

$$K_{MLBA,o} = K_{ex}(MLBA)/K_{ex}(MLA) = [MLBA]_o/[MLA]_o[B]_o \quad (21)$$

$$MLA_o + L_o \rightleftarrows ML_2A_o$$

$$K_{ML_2A,o} = K_{ex}(ML_2A)/K_{ex}(MLA) = [ML_2A]_o/[MLA]_o[L]_o, \quad (22)$$

where $K_{MLBA,o}$ and $K_{ML_2A,o}$ are the formation constants for the MLBA and the ML_2A complexes in a benzene solution respectively; they are given in Table 2.

TABLE 2. COMPLEX-FORMATION CONSTANTS FOR SYNERGISTIC REACTIONS IN A BENZENE SOLUTION AT 25 °C

		Rb^+	Cs^+
$\log K_{MLBA,o}$	15C5	0.81	0.68
$\log K_{ML_2A,o}$	12C4	1.81	1.54
	15C5	2.40	1.97
	DB18C6[1c]	2.7	2.5

It has been reported that in the benzene-water system at 20±2 °C the extraction of Cs^+ is enhanced by a factor of 60 with a mixture of 2-thenoyltrifluoroacetone (HTTA) and B compared with that by HTTA alone, and that the formula for the extracted species is $Cs(TTA)B_2$;[7] in the present study, the extraction is enhanced by a factor of only 4.8 with a mixture of 15C5 and B compared with that by 15C5 alone (Table 2). The large difference in the synergistic effects of the HTTA and the 15C5 systems may chiefly depend on the fact that the HTTA complex has more B than the 15C5 complex. There were no appreciable synergistic effects for the Na^+ and the K^+–15C5–B systems. Since a cation whose size exceeds the cavity size of the crown ether cannot get into the plane of the oxygen atoms of the crown ether, for the 15C5 complex, Rb^+ (crystal ionic radius: 1.48 Å[8]) and Cs^+ (crystal ionic radius: 1.69 Å[8]) may protrude from the plane of 15C5 (cavity radius: 0.85—1.1 Å[9]) much more than Na^+ (crystal ionic radius: 0.95 Å[8]) and K^+ (crystal ionic radius: 1.33 Å[8]). Consequently, the 15C5 complexes with RbA and CsA may easily accept a B molecule, while, it may be very difficult for those with NaA and KA.

It may be noted from Table 2 that the complex-formation constant of Rb^+ is greater than that of Cs^+ in every system. For the MLBA system, this may be attributed to the higher charge density of Rb^+ compared with that of Cs^+. For the ML_2A system, this may be due to the fact that Rb^+ has higher charge density than Cs^+, and moreover that Rb^+ has a more optimum size for each of the cavities of these crown ethers (cavity radius: 12C4 (0.5—0.65 Å[9]), 18C6 (1.3—1.6 Å[9])) than Cs^+.

The sequences of the number of the donor oxygen atoms for these ligands are B<12C4<15C5<DB18C6. The small number of the donor oxygen atoms of B may be the reason why, in each case of Rb^+ and Cs^+, the complex-formation constant value of MLBA is the

smallest of all the complexes (Table 2). For the crown ethers, in each case of Rb^+ and Cs^+, the accommodation of the metal ion into the crown ether cavity and the complex-formation constant value increase in the crown ether order 12C4<15C5<DB18C6 (Table 2). These results indicate that, for the same alkali metal ion, the larger the number of the donor oxygen atoms of the crown ether and the more closely the metal ion fits into the crown ether cavity, the greater is the complex-formation constant value.

The author thanks Mr. Yasumasa Hirasawa of this laboratory for his experimental assistance.

Shock Tube Studies of the Acetylene and Ethylene Pyrolysis by UV Absorption

Tohru KOIKE* and Kihei MORINAGA

Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239

(Received July 22, 1980)

Absorption measurements at 216 and 230 nm of shock heated C_2H_2, $C_2H_2+H_2$, and C_2H_4 diluted in Ar were made over the temperature range 1800 K to 2600 K at half of atmospheric pressure. Absorptivities were evaluated for C_4H_2, which is the main product of C_2H_2 pyrolysis, as well as for C_2H_2 and C_2H_4. The relative value of C_4H_2 absorption was confirmed to decrease with the presence of H_2 in accordance with a computer modeling result using a 25-reaction mechanism. The time profile of C_4H_2 absorption could be modeled well with $k=10^{12.4}$ cm^3 mol^{-1} s^{-1} for the reaction $H_2+C_2H=C_2H_2+H$.

The pyrolysis of C_2H_2 in shock waves has been studied by many workers and has become explainable through computer modeling with a rather definite reaction mechanism.

Recently, two groups studied the C_2H_2 pyrolysis using real-time kinetic absorption spectroscopy and the laser schlieren method. Frank and Just[1] measured the [H] profile in the C_2H_2 pyrolysis by atomic resonance absorption spectroscopy (ARAS) in mixtures of C_2H_2 highly diluted in Ar to ppm order and evaluated the initiation reaction rate constant in the low pressure region. Tanzawa and Gardiner[2] did laser schlieren experiments on the C_2H_2 pyrolysis. They proposed a reaction mechanism, in which the experimental results obtained by TOF mass spectroscopy[3,4] and single pulse shock tube[5] as well as their laser schlieren results were analyzed by computer modeling studies. Their later efforts[6] led them to a final mechanism which accords with almost all of the experimental results from 625 to 3400 K.

The new mechanism of the C_2H_2 pyrolysis so derived is expected to improve the C_2H_4 pyrolysis mechanism, because C_2H_4 decomposes to C_2H_2 and H_2 by a molecular reaction very rapidly in the high temperature region.[7]

Cundall *et al.*[8] studied the C_2H_2 and C_2H_4 pyrolysis in shock waves by absorption spectroscopies with Xe-lamp and He–Ne laser. The reaction mechanism used by them was rather primitive and the values of heat of formation for C_2H and polyacetylene radicals are subject to correction,[1,2,9] though they could obtain qualitative information about soot formation.

The present paper is concerned with the C_2H_2 and C_2H_4 pyrolysis behind incident shock waves. The reaction features were examined by UV absorption at 216 and 230 nm and were interpreted more quantitatively by the computer modeling with a refined mechanism.[6]

Experimental

The shock tube used in this study has been described in detail already.[10]

The light from a D_2-lamp (Hamamatsu-TV, L544) or Xe-lamp (Ushio, UXL500D), made parallel with a quartz lens, was measured using a photomultiplier (Hamamatsu-TV, R208) with a monochrometer (Jarrell-Ash, JE25) after passing through two shock tube windows. The output from the photomultiplier was displayed on an oscilloscope (Tektronix, 7603).

The signal from piezo-gauges mounted on the shock tube every 10 cm was detected by a universal counter (Takeda-Riken, TR5002). Shock temperature was calculated from the measured shock velocity assuming full relaxation and no chemical reaction.

Gases used were 99.7% pure C_2H_2 and 99.6% pure C_2H_4 purchased from Takachiho and 99.999% pure Ar from Nippon Sanso. All gases were used without further purification. The test gas was prepared in a 20 l glass bulb manometrically and used after more than 48 h mixing time. The test gas compositions are shown in Table 1.

Table 1. Measured A and modeled $[C_4H_2]$ and $[C_6H_2]$ at 2000 K in each test gas mixture (cm and mol units)

No.	Gas composition in Ar	A	$[C_4H_2]/10^{-9}$	$[C_6H_2]/10^{-10}$
1	3.2% C_2H_2	1.11	15	11
2	2.0% C_2H_2/2.3% H_2	0.26	4.3	1.1
3	4.0% C_2H_4	0.94	10	2.0

The test section of the shock tube was evacuated to less than 10^{-4} Torr before each run. Neither emission from C_2H_2 or C_2H_4 in Ar mixtures nor absorption by Ar was observed under the present experimental conditions. (1 Torr=133.322 Pa)

Computer modeling was done using the program mentioned previously.[10] The flow model used for reflected shock waves was modified and a constant density calculation was adopted.[11] Thermochemical properties of the species which appear in the reaction mechanism were taken from the JANAF thermochemical table [12] or other available sources.[9,13,14]

Results and Discussion

A sample oscillogram of the UV absorption (216 nm, 3.2% C_2H_2 in Ar, and P_2=0.35 atm) is shown in Fig. 1. We evaluated absorptivities of C_2H_2 and C_2H_4 from the absorption at the shock front for two wavelengths, 216 and 230 nm, by using the following definition:

$$a = \ln(I_0/I)/[C]_0/d,$$

where I_0=incident light intensity, I=transmitted intensity at the shock front, $[C]_0=C_2H_2$ or C_2H_4 concentration at the shock front, and d=optical path length (7.2 cm). The obtained a values of C_2H_2 and C_2H_4 are shown in Figs. 2a and 2b.

Acetylene shows an absorption due to the electronic transition X→A in the wavelength region 210—237

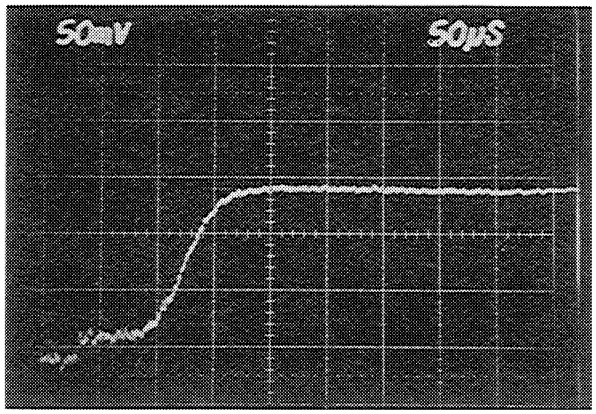

Fig. 1. A representative profile of transmitted D_2-lamp intensity for 3.2% C_2H_2 in Ar mixture, $T_2=2084$ K, and $P_2=0.35$ atm.

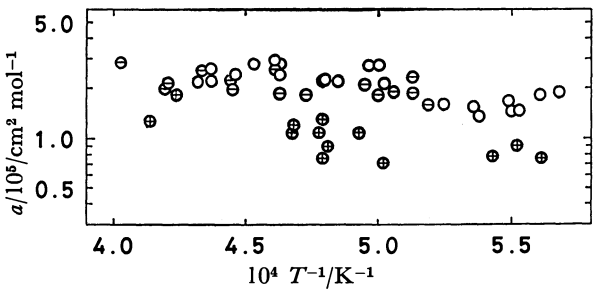

Fig. 2a. Temperature dependence of C_2H_2 absorptivity at 216 and 230 nm with D_2-lamp. The symbols are as follows.
○: for 3.2/96.8=C_2H_2/Ar at 216 nm, ⊖: for 2.0/2.2/95.8=C_2H_2/H_2/Ar at 216 nm, ⊕: for 3.2/96.8=C_2H_2/Ar at 230 nm.

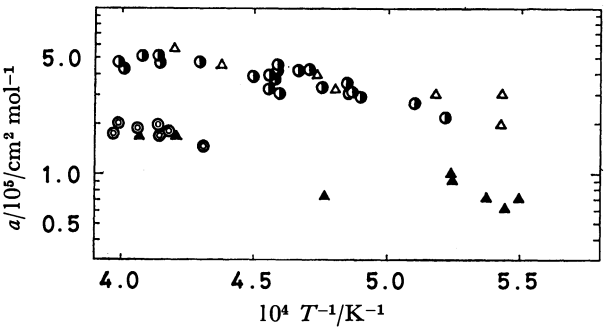

Fig. 2b. Temperature dependence of C_2H_4 absorptivity at 216 and 230 nm. The symbols are as follows.
◑: for 4.0% C_2H_4 in Ar with D_2-lamp at 216 nm, ◎: for 4.0% C_2H_4 in Ar with D_2-lamp at 230 nm, △: for 4.5% C_2H_4 in Ar with Xe-lamp at 216 nm, ▲: for 4.5% C_2H_4 in Ar with Xe-lamp at 230 nm. Data taken with Xe-lamp were corrected for higher-order wavelengths.

nm.[15] In comparison with C_2H_2, C_2H_4 has greater absorptivity in this region, though no absorption which can be attributed to an electronic transition is reported for C_2H_4.[15] Figures 2a and 2b show that the absorptivities of C_2H_2 and C_2H_4 at 216 nm are larger than those at 230 nm in the temperature range measured. This may imply that the absorption of C_2H_4 at 216 nm is attributed to an extended transition of X→A. Since the wavelength 230 nm is too far from the wavelength region of the X→A transition, the absorption at 230 nm may not be the extended transition. No clear explanations of the C_2H_4 absorption at 230 nm at these high temperatures can be given only on the basis of the present experimental results.

The a values of C_2H_2 and C_2H_4 increase slightly with increasing temperature, in contrast with the reported a values of CH_3 which have the opposite behavior.[16,17] Similar observations are reported recently for 3.39 μm He–Ne laser absorption of small hydrocarbons, *i.e.*, the infrared a values of C_2H_2 and C_2H_4 increase with increasing temperature, while those of the alkanes decrease with increasing temperature.[18,19]

The absorption measurement at 216 nm was employed to study ethane decomposition and CH_3 recombination in shock waves.[16,17] The results shown above imply that the absorption at 216 nm is not only due to CH_3 but also to C_2H_2 and C_2H_4. For alkane pyrolysis measured at high temperatures, CH_3 is usually formed at an early stage of the reaction and C_2H_2 and C_2H_4 gradually accumulate afterwards. The absorption at 216 nm at the early stage of alkane pyrolysis represents the features of CH_3 alone; the later absorption begins to show aggregate features of CH_3, C_2H_2, and C_2H_4. Our trial runs for the C_2H_6 pyrolysis measured by 230 nm absorption, on the other hand, showed neglibible absorptivity for CH_3 at the 1st stage of the pyrolysis. This result and the above may explain why we selected 216 and 230 nm absorptions to study the C_2H_2 and C_2H_4 pyrolysis. The computer program, which incorporates these absorptivities for C_2H_2 and C_2H_4 at 216 and 230 nm and the absorptivity for CH_3 at 216 nm, may solve the alkane pyrolysis measured at the two wavelengths by a procedure similar to that adopted in the C_2H_6 and C_3H_8 pyrolysis studies monitored by a 3.39 μm He–Ne laser.[14,20]

The oscillogram of Fig. 1 shows that the absorption increases almost linearly after the absorption at the shock front and finally reaches a high plateau value. The plateau absorption A was defined by $A=\ln(I_0/I_f)$, where I_f is the transmitted light intensity at the plateau and I_0 the incident light intensity. In Fig. 3, the relative A value or the value of A divided by the shock front concentration of $[C_2H_2]_0$ or $[C_2H_4]_0$ are shown *vs.* $10^4/T$.

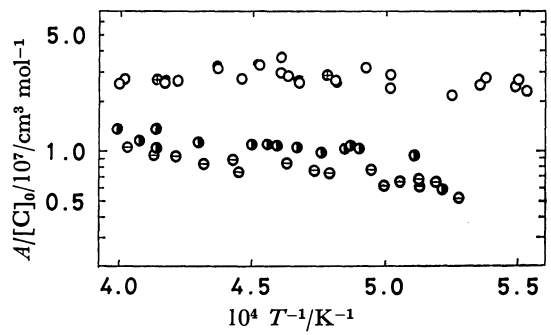

Fig. 3. Temperature dependence of relative steady absorption at 216 and 230 nm. The symbols are as in Figs. 2a and 2b.

In this case, the relative values are free from the choice between the two wavelengths, 216 and 230 nm, but the values show distinct mixture dependence, splitting into two groups as shown in Fig. 3. Searches for the chemical species which are responsible for the plateau absorption were made by the computer modeling, adopting the reaction mechanism shown in Table 2.

TABLE 2. REACTION MECHANISM AND RATE CONSTANTS $k=A\exp(-E/RT)$ (mol, cm, s, and kcal units)

Reaction	log A	E	Ref. No.
1) $C_2H_4+M=C_2H_2+H_2+M$	17.4	79.3	7
2) $C_2H_4+M=C_2H_3+H+M$	17.6	98.2	7
3) $C_2H_4+C_2H_4=C_2H_3+C_2H_5$	14.8	64.0	24
4) $C_2H_4+H=C_2H_3+H_2$	15.7	22.9	7
5) $C_2H_3+C_2H_4=C_4H_6+H$	12.0	7.3	25
6) $C_2H_3+H=C_2H_2+H_2$	13.0	0.	14
7) $C_2H_5+M=C_2H_4+H+M$	15.3	30.1	14
8) $C_2H_2+M=C_2H+H+M$	16.6	106.5	1
9) $C_2H_2+C_2H_2=C_4H_3+H$	12.3	45.0	6
10) $C_2H_3+M=C_2H_2+H+M$	14.9	31.0	25
11) $C_2H_2+C_2H_3=C_4H_4+H$	13.2	25.0	6
12) $C_4H_4+C_2H=C_4H_3+C_2H_2$	13.6	0.	6
13) $C_2H+H_2=C_2H_2+H$	12.4	0.	This work
14) $C_2H_2+C_2H=C_4H_2+H$	13.6	0.	2
15) $C_4H_3+M=C_4H_2+H+M$	16.0	60.0	2
16) $C_4H_2+M=C_4H+H+M$	17.5	80.0	2
17) $C_6H_2+M=C_6H+H+M$	16.7	80.0	2
18) $C_8H_2+M=C_8H+H+M$	16.7	80.0	2
19) $H_2+M=2H+M$	12.4	92.6	26
	$+0.5\log T$		
20) $C_4H_3+H+M=C_4H_4+M$	15.0	0.	2
21) $C_2H_2+C_4H=C_6H_2+H$	13.6	0.	2
22) $C_4H_2+C_2H=C_6H_2+H$	13.6	0.	2
23) $C_2H_2+C_6H=C_8H_2+H$	12.0	0.	2
24) $C_6H_2+C_2H=C_8H_2+H$	12.0	0.	2
25) $C_4H_2+C_4H=C_8H_2+H$	12.0	0.	2

Acetylene radical and polyacetylene radicals can not be the absorbers; if they were, they must have large, temperature-dependent absorptivities. For example, the steady concentration of C_2H at 2500 K is about 20 times larger than that at 2000 K in 3.2% C_2H_2 in Ar mixtures. This means that the absorptivity of C_2H decreases by a similar factor between the two temperatures, because the A values are almost constant over the temperature range measured. We are unaware of any species having such large, temperature-dependent absorptivity.

Table 1 shows the A values, obtained by a least squares fitting for the $A/[C]_0$ and $10^4/T$ relation shown in Fig. 3, and the steady $[C_4H_2]$ and $[C_6H_2]$, obtained by the computer modeling, at 2000 K in different three mixtures. The ratios of the A values, A_m/A_n, are not in accord with the $[C']_m/[C']_n$ values, where subscripts m and n denote the mixture number shown in Table 1 and C' is C_4H_2 or C_6H_2. Although these modeled $[C_4H_2]$ and $[C_6H_2]$ are subject to the values of heat of formation adopted, no clear-cut explanation with appropriate thermochemical data could be given.

There is an electronic transition designated as X→B over the wavelength range 200 to 265 nm for C_4H_2.[15] The reported C_4H_2 profiles in the C_2H_2 pyrolysis measured by TOF mass spectroscopy[4] are similar to the absorption profile of Fig. 1. These results strongly support the conjecture that the steady absorption is mainly due to C_4H_2. The absorptivity of C_4H_2 was evaluated as: $a(\mathrm{cm^2\ mol^{-1}})=(1.1\pm0.3)\times10^7$ at 2000 K and $(1.4\pm0.2)\times10^7$ at 2500 K.

The plateau absorption shown in Fig. 1 indicates that the overall reaction of the C_2H_2 and C_2H_4 pyrolysis reaches an equilibrium under the present experimental conditions; this was confirmed also by the computer modeling. The primary reactions of the C_2H_2 pyrolysis in these temperature ranges are:[6]

$$H + C_2H_2 = H_2 + C_2H \qquad (-13)$$

$$C_2H + C_2H_2 = C_4H_2 + H. \qquad (14)$$

Ethynyl, C_2H, and H play roles as chain carriers in the reactions. An equilibrium between these species leads to an equilibrium for $[C_4H_2]$:

$$[C_4H_2] = K_{-13}K_{14}[C_2H_2]^2/[H_2],$$

where K_{-13} and K_{14} are the equilibrium constants of the reactions, (−13) and (14). The above equation is in accordance with the result shown in Fig. 3 that the presence of H_2 inhibits the formation of C_4H_2, which is one of the precursors to soot.[8] Relative A values in the C_2H_4/Ar mixture are smaller than those in the C_2H_2/Ar mixture. This result also can be explained in the same way. Ethylene decomposes by a molecular reaction fairly rapidly in this temperature range[7] and forms C_2H_2 and H_2 in equal amounts. Therefore, in the C_2H_4/Ar mixture, C_4H_2 is produced by the pyrolysis of C_2H_2 so formed in the presence of H_2. The fact that the measured relative A values in the C_2H_4/Ar and C_2H_2/H_2/Ar mixtures are similar to each other may support the above explanation.

Figure 1 provides us with time parameters whose value can be used as a measure to estimate the overall rate of the C_2H_2 and C_2H_4 pyrolysis. In the conventional manner, the induction time can be defined as: the time between the shock arrival and the foot of the linear absorption rise. If the absorptivity of C_4H_2 is exactly known, the threshold value of $[C_4H_2]$ at the foot can be estimated and compared with the modeled $[C_4H_2]$. But there are still uncertainties in the C_4H_2 absorptivity obtained above. Instead, we defined a parameter, t_m: time between the shock arrival and the crossing point where the linear absorption rise and the steady absorption are extrapolated to each other. The parameter, t_m, so defined is independent of the C_4H_2 absorptivity. The modeled t_m was evaluated from the C_4H_2 profile. First of all, we compared the measured t_m with the modeled one using the mechanism and the rate constants in Table 2 except for the k_{13} value in the C_2H_2/Ar mixture. As for the k_{13} value, $10^{13.54}$ in Ref. 6 was used. Figure 4 shows the relation between $t_m[C_2H_2]_0$ or $t_m[C_2H_4]_0$ and $10^4/T$ for the measured and modeled results. As is shown by the broken line, the modeled t_m was found to be smaller than that measured by a similar factor over the temperature range measured. To confirm the correctness of the interpretations for the

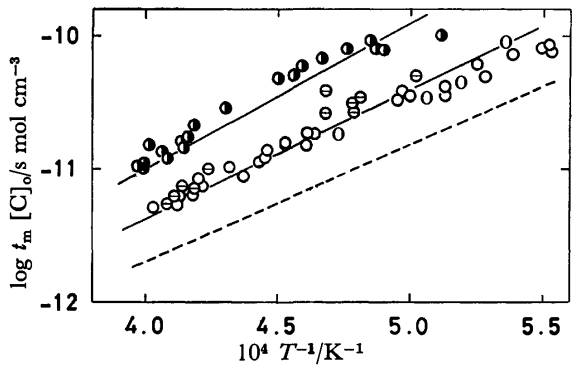

Fig. 4. $t_m[C_2H_2]_o$ or $t_m[C_2H_4]_o$ *vs.* $10^4/T$. The symbols are the same as in Figs. 2a and 2b. The solid lines show modeled value using Table 2 mechanism and rate constants. The upper one is for C_2H_4/Ar mixture and the lower one is for both of C_2H_2/Ar and C_2H_2/H_2/Ar mixtures. The broken line shows modeled value for 3.2% C_2H_2 in Ar mixture using Table 2 mechanism and rate constants except for the k_{13} value: $k_{13}=10^{13.53}$ was used.[6]

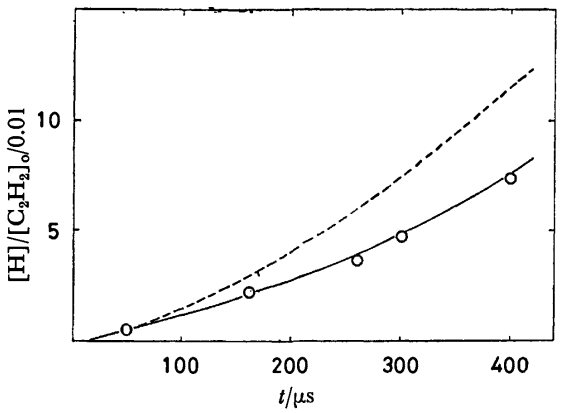

Fig. 5. Comparison measured [H] profile[1] with modeled ones. The circles are data points of measured [H] profile in reflected shock wave for 20 ppm in Ar mixture at $T_5=2450$ K and $[Ar]_5=8.2\times10^{-6}$. The solid and broken lines are modeled values as are in Fig. 4.

present experiment and modeling, another C_2H_2 pyrolysis result was adopted for the modeling.

Gas sampling problems due to boundary layer growth are present in the results obtained by the single pulse shock tube technique.[21] Since TOF mass spectroscopy may also have the same problems, we selected the results obtained by ARAS[1] for the modeling. Figure 5 shows both the measured and the modeled [H] profiles. It is clear that the modeled [H] increasing rate shown by the broken line is larger than the measured one, which is in accordance with the result obtained from Fig. 4, *i.e.*, the modeled overall reaction rate is faster than the measured one.

The first mechanism proposed by Tanzawa and Gardiner,[2] which was derived to explain the high temperature pyrolysis of C_2H_2 in shock waves, could model the results of TOF mass spectroscopy[3,4] and single pulse shock tube[5] fairly well, whereas the new mechanism in Ref. 6 gave rather poor modeling results. The new mechanism in Ref. 6 seems to have an improper

Table 3. Sensitivity spectrum with PS values[a]

Reaction	t_m[b]	$[H]_{100\,\mu s}$[c]	$[H]_{400\,\mu s}$[c]
$C_2H_2+M=C_2H+H+M$	−8/−5[d]	87/97	54/87

$C_2H+H_2=C_2H_2+H$	−29/−42	30/47	29/57
$C_2H_2+C_2H=C_4H_2+H$	−3/−18	11/3	25/15
$C_4H_2+M=C_4H+H+M$	−21/−27	—	—

a) PS=log (parameter′/parameter)/log (multiplier)×100. Details are shown in Ref. 22. b) For 3.2% C_2H_2 in Ar mixture, $P_2=0.37$ atm, and $T_2=2200$ K. c) For 50 ppm C_2H_2 in Ar mixture, $P_5=1.77$ atm, and $T_5=2420$ K. d) The first entry is obtained by multiplying each rate constant by 5; the second entry, by 0.2.

value for some rate constant. To find which reaction is responsible to the disageement shown in Figs. 4 and 5, a sensitivity calculation with PS values[22] was tried for our experiment and for the ARAS measurement.[1]

Table 3 shows the reactions having large PS values and the obtained PS values for the parameters. The reaction which has the largest PS values is different in our experiment and in the ARAS experiment. The effect of secondary reactions on the [H] profile is surpressed in the latter case, in which highly diluted test gas mixtures were used, and the measured and modeled [H] profiles reflect the initiation reaction, $C_2H_2+M=C_2H+H+M$, especially at the early stages of the reaction. The PS values of reaction 14 becomes large as the reaction proceeds, in contrast to those of the initiation reaction, while reaction 13 has an almost constant PS values. The time dependent variations of PS values imply that the chain carrier concentrations such as H and C_2H increase and the chain reactions dominate. These effects of the chain reactions on the parameters adopted are very distinct in our experiment.

Reaction 16, $C_4H_2+M=C_4H+H+M$, has the second largest PS values for t_m in our experiment. Frank and Just[1] measured the k_{16} value in the high pressure limit directly by monitoring the [H] profile produced by the C_4H_2 pyrolysis using the ARAS. Although it is possible to derive the k_{16} value suitable for the modeling of our experiment from the reported k_{16} value by making a reduced fall-off curve,[23] we left the k_{16} value used in this study at the value determined indirectly by Tanzawa and Gardiner,[2] through the computer modeling for the laser schlieren experiment because the experimental conditions selected by them are similar to the present ones except for the temperature range.

Since the C_2H_2 pyrolysis is almost equilibrated at the reaction time when the parameter t_m is measured, it is to be expected that reaction 13 has the largest PS values. So only the k_{13} value was changed so as to fit the modeled t_m to the measured over the temperature range measured. An excellent agreement between the experiment and the modeling for the [H] profiles, as well as for the t_m values, was obtained by adopting the following k_{13} value:

$$k_{13} = 10^{12.4}(\mathrm{cm^3\ mol^{-1}\ s^{-1}}).$$

This is shown in Figs. 4 and 5. In our computer

program,[10] reverse rate constant of a given elementary reaction is calculated using an equilibrium constant; an assembly of first order differential equations of both forward and reverse reactions is numerically integrated. Then, when either k_{13} or k_{-13}, where $K_{-13}=k_{-13}/k_{13}$, is incorporated into the reaction mechanism with reasonable thermochemical data, the same modeling results can be obtained. Tanzawa and Gardiner[2] proposed a non-Arrhenius temperature-dependent k_{-13} value in the first mechanism. The k_{13} value so evaluated from the k_{-13} value was found to have exactly the same value at 2200 K as the present k_{13} value. Then, it is not surprising that the k_{13} value obtained in this study is about 10 times smaller than that in Ref. 6.

We note that the modeling result of the C_2H_2 and C_2H_4 pyrolysis is affected by the ΔH°_{f0} value adopted for acetylene and polyacetylene radicals. Two recent papers about the C_2H_2 pyrolysis study[1,2] demonstrated the correctness of the new ΔH°_{f0} for C_2H.[9] As has been shown already, this new value of ΔH°_{f0} for C_2H will be a help to improve the ΔH°_{f0} values for polyacetylene radicals using the additivity rule.[27] The ΔH°_{f0} value for C_4H so derived is 180 kcal†/mol,[1] which is 26 kcal/mol larger than the old value.[13] If the old value for C_4H is adopted, unusual profiles of C_4H_2 and C_4H can be obtained, *e.g.*, steady $[C_4H]$ is larger than steady $[C_4H_2]$.

We have little to say about the C_2H_4 pyrolysis during the early reaction period on the basis of the present experimental results. The computer modeling for the C_2H_4/Ar mixture showed that almost all of C_2H_4 is pyrolyzed to C_2H_2 and H_2 already at the reaction time when the linear absorption starts.

Adsorption of D-, L-, and DL-Phenylalanines at the Mercury-Aqueous Solution Interface

Takashi KAKIUCHI and Mitsugi SENDA*

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606

(Received July 25, 1980)

The adsorption of D-, L-, and DL-phenylalanines at the mercury-aqueous sodium fluoride solution interface has been studied by measuring differential capacities, potentials of zero charge, pzc, and surface tensions at the pzc. The racemate of phenylalanine showed higher surface activity than the enantiomers. This difference has been interpreted in terms of the intermolecular interactions, orientation and re-orientation of adsorbed molecules at the interface.

In a previous paper[1] we described the adsorption properties of a series of aliphatic α-amino acids at the mercury-aqueous solution interface with reference to two factors, *i.e.*, the contribution of the zwitterion group and that of the hydrocarbon group. This paper reports adsorption behavior of D-, L-, and DL-phenylalanines at the mercury-aqueous solution interface. Our major interest in this study is to investigate a possible difference in the adsorption properties between either of the enantiomers and the racemate. Although in liquid state and in solution a racemate is usually considered to have very similar physicochemical properties to those of the pure enantiomers,[2] the difference between them may become appreciable in the processes involving interfacial phenomena, since the contribution of molecular interaction between chiral adsorbate molecules at the interface is generally much more significant owing to higher concentration and the preferential orientation of adsorbed molecules.

Inesi *et al.*[3] reported on the difference between two adsorption properties of the racemate and the enantiomer at the mercury-aqueous solution interface. They found that DL-dibenzoyltartaric acid is more surface active than the enantiomers. They interpreted this difference by the analogy of surface sate to crystal state. In this paper we describe the difference between the adsorption properties of DL-phenylalanine and D-, or L-phenylalanine at the mercury-aqueous solution interface, interpretation being given in terms of the intermolecular interaction, orientation and re-orientation of adsorbed molecules.

Experimental

The differential capacities of the interface were measured as functions of the phenylalanine concentration and electrode potential with the a.c. bridge method.[1] The bridge was adjusted to balance at the moment when a mercury drop spontaneously fell from the dropping mercury electrode. The drop time was measured as follows. The sudden unbalanced signal from the bridge due to the detachment of the drop from the capillary tip was transformed by a lock-in amplifier into an electric pulse, which was then fed to an electronic counter for pulse interval measurement. Drop times of the capillary used were between 13 and 15 s at the potential of zero charge, pzc, in 0.5 mol l^{-1} sodium fluoride. The a.c. signal superimposed to the electrode was of 1 kHz and 5 mV peak to peak.

The potentials of zero charge were determined by a streaming mercury method.[4] The surface tensions at the pzc were measured by the drop time method. Glass tubes, outer diam 4 mm and inner diam 0.1 mm, were drawn to get fine capillaries having *ca.* 0.5 mm and 0.025 mm outer and inner diameters, respectively. The capillaries were dewetted with a silicone coating reagent (Fuji Systems, Japan) and cut to expose clean orifice and give a suitable drop time. Typical characteristics of the capillaries thus prepared were $t=14$ s and $m=0.3$ mg s^{-1} when the height of mercury was 110 cm and at the pzc in 0.5 mol l^{-1} sodium fluoride. The drop times recorded 30 times for each solution were reproducible within $\pm 0.05\%$ as relative standard deviation. The drop times tended to become shorter over several sets of measurements probably due to deterioration of the capillary glass wall by chemical attack of sodium fluoride solution.[5] Thus, it was necessary to calibrate the capillary before and after each measurement. For the calibration we used 0.05 mol l^{-1} sodium sulfate for which the surface tension of mercury is 426.2 mN m^{-1} at the pzc.[6] For conversion of drop time into surface tension we used the approximate relation $\ln(\gamma/\gamma_r)=K\ln(t/t_r)$, where γ and γ_r are surface tensions for the test and a reference solutions, respectively, proposed by Verdier *et al.*[7] Parameter K is a function of the height of mercury, inner diameter of the capillary and surface tension. However, it can be taken as a constant over a fairly wide range of surface tension when the height of mercury is sufficiently large.[7] For a particular capillary of inner diameter 0.002 cm, the value of K was calculated to be 0.976 over a 390—427 mN m^{-1} range of surface tension when the height of mercury was 110 cm. The average standard deviation of the surface tensions we obtained was 0.15 mN m^{-1}.

A test solution was deaerated by bubbling nitrogen gas through the solution for 30 min before measurement and was kept under nitrogen atmosphere during the course of measurement. The electrode potentials were measured with respect to a saturated calomel electrode, SCE. All the measurements were at 25 ± 0.2 °C.

Reagent grade D-, L-, and DL-phenylalanines(Nakarai Chem. Co., Japan) were recrystallized twice from triple distilled water. Recrystallized D-, and L-phenylalanines showed 95 and 93% optical purity, respectively, in optical rotation measurements. Sodium fluoride, a standard reagent for quantitative analysis of 99.95% purity (Hashimoto Chem. Co., Japan), was used without further purification. An ultra pure grade sodium sulfate (E. Merk, Germany) was used for a standard solution in surface tension measurements.

Results

The potentials of zero charge and the surface tensions at the pzc for seventeen concentrations of L-phenylalanine (0.003—0.120 mol l^{-1}), twelve concentrations of D-phenylalanine (0.010—0.120 mol l^{-1}), and twelve

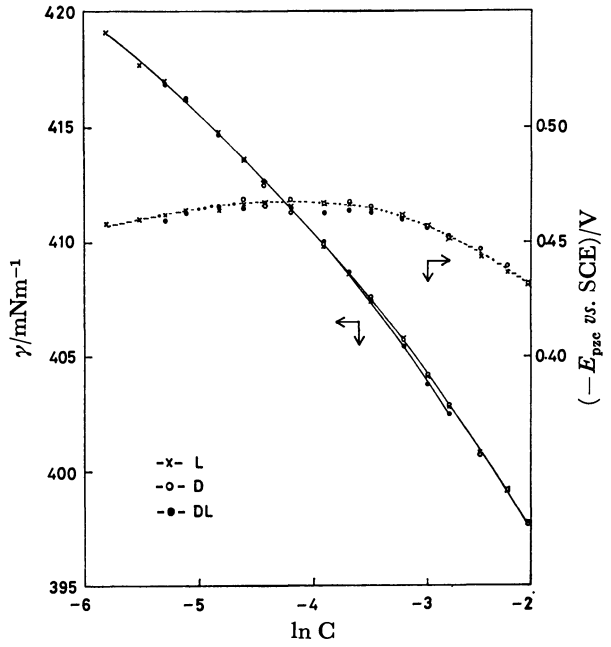

Fig. 1. Potentials of zero charge and surface tensions at the pzc for L-(×), D-(○), and DL-(●) phenylalanines as a function of the logarithm of the phenylalanine concentration in the adsorption on mercury from aqueous 0.5 mol l^{-1} sodium fluoride solutions.

concentrations of DL-phenylalanine (0.005—0.060 mol l^{-1}) in 0.500 mol l^{-1} sodium fluoride are given in Table 1. Due to the limited solubility no data were available beyond 0.06 mol l^{-1} for DL-phenylalanine. Surface tension is plotted in Fig. 1 as a function of the logarithm of phenylalanine concentration. The curves for D-, and L-phenylalanines show excellent agreement over the whole concentration range. At concentration lower than 0.030 mol l^{-1} the curve for DL-phenylalanine is indistinguishable from the curve for both enantiomers. However, with increasing concentration of phenylalanine, it starts to split away from the curve for the enantiomers and lies below them in higher concentration region. This indicates that the racemate is more surface active than the enantiomers.

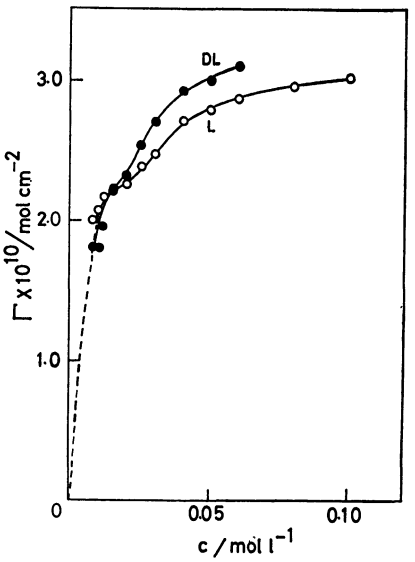

Fig. 2. Adsorption isotherms for L-(○) and DL-(●) phenylalanines at the potential of zero charge.

The surface excesses of L- and DL-phenylalanines, which may be regarded as the actual amount of adsorbed phenylalanines under the present experimental conditions,[8] are plotted in Fig. 2 as a function of the molarity of phenylalanines. As expected, the surface excesses of the racemate are greater than those of the enantiomer. Both these isomers have a kink around 0.02 mol l^{-1} which is characteristic of the change of orientation of adsorbed species at the interface.[9] We have calculated these relative surface excesses from the curves in Fig. 1 using the electrocapillary equation for ideally polarized interfaces.[10] A moving second order least square method[11] with five data points as one set was employed in the numerical differentiation of the curves. Constancy of the activity coefficients of phenylalanines was assumed over the experimental concentration range. The activity of sodium fluoride was also assumed to remain unchanged when the concentration of phenylalanine was varied, though no information is available for the present ternary system to confirm these assumptions. The possible error due to these assumptions[12] is of minor importance in our case since our primary concern here is the difference in the surface excesses between D- or L-phenylalanine and DL-phenylalanine rather than their absolute magnitude.

No significant difference was detected in the potentials of zero charge between the enantiomer and the racemate (Table 1). The potentials of zero charge are plotted against the logarithm of the phenylalanine molarity

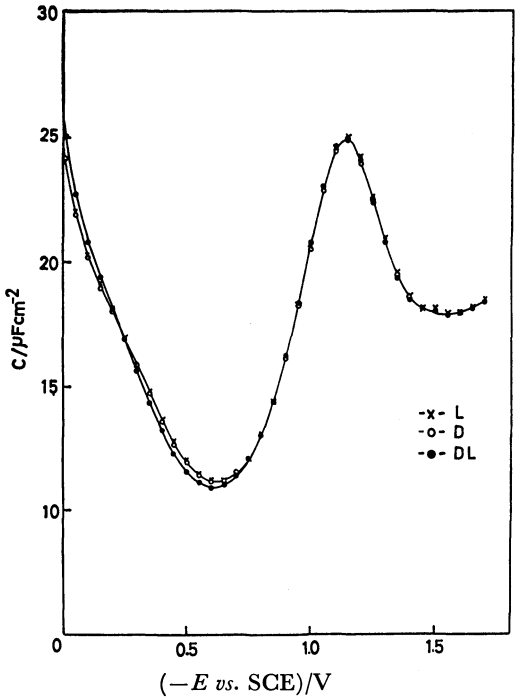

Fig. 3 Comparison of the differential capacity curves for L-(×), D-(○), and DL-(●) phenylalanines in aqueous solution of 0.5 mol l^{-1} sodium fluoride containing 0.05 mol l^{-1} phenylalanine at 25 °C.

in Fig. 1, in which the slopes of the curves change sign with increase in phenylalanine concentration. This suggests the re-orientation of adsorbed phenylalanine molecules with the increase of the surface coverage, as has often been observed in the adsorption of aromatic compounds at electrified interfaces.[13,14]

Differential capacities were measured as functions of the electrode potential and the phenylalanine concentration covering the same range as the surface tension measurements. Comparison is made of the differential capacity curves obtained for D-, L-, and DL-phenylalanines at 0.05 mol l^{-1} in Fig. 3. The curves for D- and L-phenylalanines agree with each other throughout the potential range studied. On the other hand, the curve for the racemate shows appreciable deviation from those curves and lies below them around the pzc. This also indicates the stronger adsorption of the racemate around the pzc than the enantiomers.

In order to estimate the surface excess of phenylalanines at different electrical states of the interface other than the pzc, the differential capacity curves for L- and DL-phenylalanines were twice integrated numerically with respect to the electrode potential. The potentials of zero charge and surface tensitions at the pzc (Table 1) were used as the two independent integration constants. From the electrocapillary curves thus obtained the surface excesses of phenylalanines were calculated as a function of the electrode potential at each phenylalanine concentration. The surface excess *vs.* electrode potential curves for L- and DL-phenylalanines are compared in Fig. 4 at 0.04 mol l^{-1}. The difference between the surface excesses of the racemate and the enantiomer exists not only at the pzc

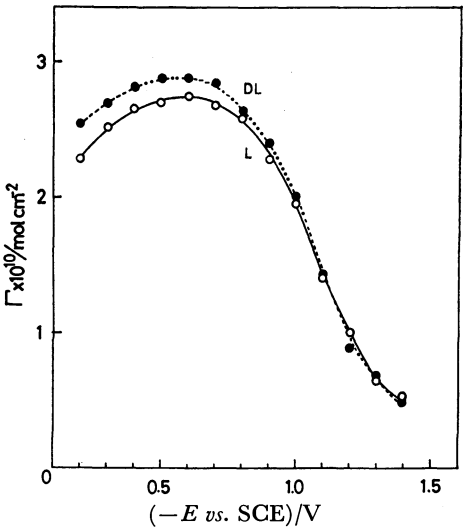

Fig. 4. Comparison of surface excesses of L-phenylalanine with those of DL-phenylalanine at 0.04 mol l^{-1} at various electrode potentials.

but throughout the positive branch, whereas it vanishes at the negative extreme of the potential.

Discussion

Figures 2 and 4 indicate that the racemate of phenylalanine has the higher surface activity than its enantiomers at the mercury-aqueous solution interface in the sense that DL-phenylalanine gives greater surface excess than L- or D-phenylalanine at a given bulk concentration and electrode potential except the cathodic extreme. In Fig. 2 the two isotherms significantly deviate from each other at increased bulk concentrations of phenylalanine, while they merge together with increasing concentration of phenylalanine giving the same limiting slope of the adsorption isotherms at infinite dilution. Similar behavior of adsorption isotherms has been reported by Inesi *et al.*[3] for the adsorption of DL- and D-(and L-)dibenzoyltartaric acids from aqueous solution onto the mercury electrode.

The difference in surface activity should be interpreted in terms of the difference between the adsorption free energy of the racemate and the enantiomers. If we choose the infinite dilution as a reference state of the chemical potentials of phenylalanines in both the adsorption phase and solution phase, the standard adsorption free energy of the racemate should be the same as that of the enantiomers. The difference in surface activity is then ascribed to the difference in the non-ideality due to the intermolecular interactions between the adsorbed phenylalanine molecules. The difference in the interaction energy in the solution phase between racemates and the corresponding enantiomers has been studied theoretically[2,15] and experimentally.[16–18] These works show that the difference in solution phase is negligible in dilute solutions as in our case. Therefore, the observed difference in the adsorbability of phenylalanines should arise from the different molecular interaction in the adsorption phase where the surface concentration of phenylalanine is much

higher than in the solution phase. For example, the surface excess of 3×10^{-10} mol cm^{-2} corresponds to the surface coverage of 0.71 if the maximum surface concentration is assumed to be 4.2×10^{-10} mol cm^{-2}, a value based on CPK model[19] of phenylalanine adsorbed with its aromatic ring plane oriented perpendicular to the mercury surface.

At the lower surface coverage and at the potential around the pzc phenylalanine probably adsorbs with its aromatic ring plane parallel to the electrode surface, as commonly observed in the adsorption of simple aromatic compounds on mercury.[13] This orientation brings the pzc to more negative potential (see Fig. 1) due to the partial charge transfer of π-electron of the aromatic ring to the electrode,[20] while the zwitterion group of phenylalanine may be oriented with its dipole axis parallel to the electrode surface. With increasing surface coverage phenylalanine molecules adsorb with their aromatic ring plane oriented perpendicular to the electrode surface, so that the closer packing of the adsorbed molecules is attained. Since the vertical orientation is unfavorable to the interaction between the π-electron and the electrode, the pzc then shifts to the positive direction[20] with increasing surface excess at the higher surface coverage (Fig. 1).

As an isotherm in which the re-orientation is taken into account, Parry and Parsons[13] and Damaskin[21] have proposed a couple of isotherms assuming that the adsorbate can take two different orientations at the interface;

$$B_1c = \frac{\theta_1}{n_1(1-\theta_1-\theta_2)^{n_1}}\exp(-2n_1a_{11}\theta_1 - 2n_1a_{12}\theta_2)$$

$$B_2c = \frac{\theta_2}{n_2(1-\theta_1-\theta_2)^{n_2}}\exp(-2n_2a_{22}\theta_2 - 2n_2a_{21}\theta_1),$$

where B_i is the adsorption coefficient, θ_i the surface coverage, n_i the ratio of the area occupied by an adsorbate molecule to that of a water molecule and a_{ij} the parameter of intermolecular interactions between adsorbed molecules; indices 1 and 2 are referred to the verical and flat orientations of adsorbed molecules. These isotherms have seven adjustable parameters apart from two maximum surface concentrations, $\Gamma_{m(1)}$ for vertically oriented species and $\Gamma_{m(2)}$ for flatly oriented one and it seems impractical in our case to determine these parameters by fitting experimental data to the theoretical isotherms. Instead, we shall show by invoking these isotherms that the basic features of the experimental adsorption isotherms can be reproduced by choosing probable values for the parameters. Because of the specific interaction between the aromatic π-electron and the mercury surface, the adsorption coefficient of the flatly oriented phenylalanine should be larger than that of the vertically oriented one.[20] We chose the values $B_1=20$ and $B_2=50$ l mol^{-1} and estimated that $n_2/n_1=1.4$ ($\Gamma_{m(1)}=4.3\times10^{-10}$ and $\Gamma_{m(2)}=3.1\times10^{-10}$ mol cm^{-2}) on the basis of the CPK model. The intermolecular interaction would be stronger for the vertical position than the flat position because of the hydrophobic interaction between the adjacent aromatic rings.[20] Hence, we assumed $a_{22}=0.2$ and calculated the isotherms with $a_{11}=1.5$, 1.3, and 1.1 for curves 1, 2, 3 in Fig. 5, in which we further assumed that $n_1=1$ and $a_{12}=a_{21}=0$. The relative surface excesses are plotted against concentration in Fig. 5, from which it is seen that the features of the isotherms are very sensitive to the choice of the interaction parameters. A comparison of Fig. 5 with the experimental isotherms in Fig. 2 suggests that the attractive interaction between the adsorbed phenylalanine molecules is larger for the racemate than for the enantiomers.

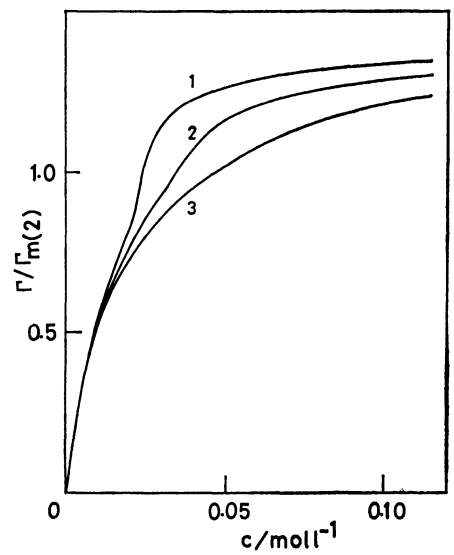

Fig. 5. Calculated curves for reduced adsorption isotherms according to equations in the text with $a_{22}=0.2$, $a_{12}=a_{21}=0$, $n_1=1.0$, $n_2=1.4$, $B_1=20$, $B_2=50$, for $a_{11}=$ 1.5 (1), 1.3 (2), and 1.1 (3).

There are two possible modes in the vertical orientation; one with the axis of the zwitterion group oriented parallel to the electrode and the other with its dipole axis oriented vertical. The former orientation mode should be predominant around the pzc, whereas the latter with the positive end of the dipole facing toward the electrode surface should prevail in the extremely negative branch. In this orientation the dipole would exert repulsive interaction between adsorbed molecules, leading to a smaller value of a_{11} parameter which would give rise to monotonic, Langmuir-type isotherms without kink (curve 3, in Fig. 5). This actually corresponds to the fact that the difference between the surface excess of DL- and D-(or L-) phenylalanines disappears in the cathodic branch away from the pzc (Fig. 4) and also the fact[22] that the adsorption isotherms for L-phenylalanine in the negative extreme have no kink and are well described by Langmuir isotherms which lack the interaction parameter.

Interaction between Aromatics and Zinc Chloride. III. The Dissociation of Triphenylmethane and 9,10-Dihydroanthracene into Ions

Mikio MORITA,* Kunio HIROSAWA, Toshio SATO, and Koji OUCHI†

Government Industrial Development Laboratory, Hokkaido, Tsukisamu-higashi, Toyohira-ku, Sapporo 061-01

†*Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received January 5. 1980)

Triphenylmethane and 9,10-dihydroanthracene were found to produce colored complexes when placed in contact with molten zinc chloride or with solid zinc chloride pulverized or supported on porous Vycor glass. The triphenylmethane complex gave the same electronic absorption spectrum as that of the triphenylmethyl cation generated by contact with silica–alumina and BF_3 on silica. The 9,10-dihydroanthracene complex exhibited the same electronic absorption band as that of the 9-anthracenium ion produced by the reaction of anthracene with concd H_2SO_4. The reaction of the triphenylmethane complex with deuterium gas provided HD gas and $(C_6H_5)_3CD$. Similarly, the 9,10-dihydroanthracene complex and deuterium gas produced HD gas and 9,10-dihydroanthracene-9-*d*. Furthermore, their colored complexes on the supported zinc chloride gave a very weak IR absorption band at about 1720 cm^{-1}, which is interpreted as corresponding to the formation of a Zn–H bond. These observations led us to conclude that triphenylmethane and 9,10-dihydroanthracene dissociate into ions upon contact with zinc chloride:

$$(C_6H_5)_3CH + n ZnCl_2 \rightleftharpoons (C_6H_5)_3C^+(ZnCl_2)_n^-H$$

As has previously been reported,[1,2] zinc chloride reacts with aromatic hydrocarbons to form (Ar^+)-$(ZnCl_2)_n^-$ electron-donor acceptor-complexes(Ar: aromatics). It has been suggested that these (Ar^+)-$(ZnCl_2)_n^-$ EDA-complexes act as reaction intermediates in the hydrogenation and hydrocracking of aromatic hydrocarbons over a zinc chloride catalyst; their conversions are correlated positively to the ionization potentials of the corresponding aromatic hydrocarbons.[3]

As a part of a systematic study to elucidate the behavior of the zinc chloride catalyst in the hydrocracking of aromatic hydrocarbons, which would be helpful for this reaction,[4,5] the mechanism of the ionization of triphenylmethane and 9,10-dihydroanthracene was investigated by measurements of the electronic and IR absorption spectra of the colored complexes formed in molten zinc chloride or on solid zinc chloride, which was powdered or supported on porous Vycor glass, by means of exchange reactions with deuterium gas and by the analyses of their reaction products.

Experimental

Materials. Triphenylmethane and 9,10-dihydroanthracene of a G. R. grade were used without further purification. Porous Vycor glass plate and powder were used as supports of the zinc chloride for measuring the IR and electronic absorption spectra. The other chemicals were the same as those mentioned in our previous work.[2]

Apparatus and Procedure. Anhydrous zinc chloride was prepared and attached onto a porous Vycor glass support as described in the previous paper.[2] Triphenylmethane or 9,10-dihydroanthracene was allowed to react with zinc chloride under various conditions, and changes in the transmittance or in the reflectance of visible light by the colored complexes were measured with a Hitachi 624 spectrophotometer equipped with an integrating sphere.

For the measurements of the IR absorption spectra, a cell device designed by Angel *et al.*[6] and Hino[7] was used. A rod of porous Vycor glass was sliced into a plate with 0.3 mm thick, and then it was cut to fit the cell windows. After zinc chloride and a plate purified by the method described previously[2] has been introduced into the cell device, the device was evacuated to below 10^{-4} Torr at about 500 °C until 10—20 wt % of the zinc chloride had evaporated onto the plate. The cell was then cooled to room temperature, and a hydrocarbon was introduced from the top of the cell under a vacuum and brought to full contact with the supported zinc chloride at the reaction temperature until colored products formed on the catalyst. The IR absorption spectra were measured with a JASCO IRA-2 spectrophotometer.

For the D_2-exchange reaction, a glass vessel 17 ml in size was used as a reactor. About 3 g of dehydrated zinc chloride or 500 mg of supported zinc chloride and about 5 mg of a reactant were charged into the vessel under a vacuum, and then deuterium gas was introduced at 600 Torr. The vessel was heated at a given temperature for a given time.

Analysis. After the measurements of the electronic absorption spectra of the colored products, water was introduced into the quartz cell and the mixture was extracted with a large amount of tetrahydrofuran and dichloromethane. The extracts were analyzed by gas chromatography. The details were described in a previous paper.[8]

The D_2-exchanged products were identified by the use of a Finnigan 3000 mass spectrometer. The formation of HD gas was confirmed by the method reported by Sato *et al.*[9]

Results and Discussion

Electronic Absorption Spectra. Triphenylmethane produced a colored complex upon contact with dehydrated solid zinc chloride, anhydrous zinc chloride supported on porous Vycor glass, and porous Vycor glass alone pretreated at 550 °C. The complex exhibited a characteristic double-peaked absorption band in the 415—450 nm region of the spectrum, as is shown in Figs. 1(a)—(d). The (a) spectrum was obtained by measuring the reflectance of the triphenylmethane

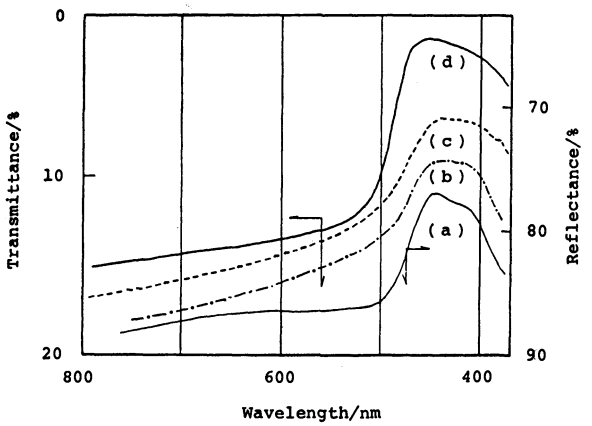

Fig. 1. Electronic spectra of triphenylmethane on zinc chloride, supported zinc chloride, and a support.
(a): On solid zinc chloride which was dehydrated by melting under a vacuum, at room temperature for 7d, (b): on powdered zinc chloride which was dehydrated at 250 °C for 3 h under a vacuum, at 220 °C for 10 min, (c): on porous Vycor glass pretreated at 550°C, at 70°C for 180 min, (d): on anhydrous zinc chloride supported on porous Vycor glass, at room temperature for 20 h.

yellow intermediate formed on the solid zinc chloride dehydrated by melting under a vacuum in a quartz cell. The spectra from (b) to (d) were measured for the transmittance of the yellow complex developed on the powdered zinc chloride, the pulverized porous Vycor glass, and the supported zinc chloride. This double-peaked absorption band disappeared when the complex was treated with water vapor.

9,10-Dihydroanthracene also gave a yellow intermediate upon contact with anhydrous zinc chloride supported on porous Vycor glass or with molten zinc chloride. It exhibited a strong absorption band at 420 nm and a weak absorption band at about 725 nm, as is shown in Fig. 2(a) and in Fig. 3(a), when reacted with supported zinc chloride at 60 °C for 10 min and with molten zinc chloride at about 300 °C for 5 min. The further reaction over supported zinc chloride at temperatures higher than 60 °C decreased the reflectance of the samples and altered the spectrum from that shown in Fig. 2(a) to that of Fig. 2(c). It is noteworthy in these spectra that the band at 420 nm was common, but the weak band at 725 nm disappeared with the progress of the reaction.

The treatment of porous Vycor glass alone, pretreated at 550 °C, with 9,10-dihydroanthracene at temperatures higher than 200 °C also gave a colored product. Its absorption spectrum is shown in Fig. 3(b).

The common band at 420 nm (Fig. 2(a) to (b) and Fig. 3(a)) disappeared when the products were decomposed with water. However, when the colored products obtained at higher temperatures, whose electronic absorption spectra are shown in Fig. 2(c) and Fig. 3(b), were decomposed with water, other, new colored products were recovered. The electronic absorption spectrum of the products in dichloromethane solution is shown in Fig. 3(c).

IR Absorption Spectra. Figures 4(a) and (b) are the IR absorption spectra of colored complexes of

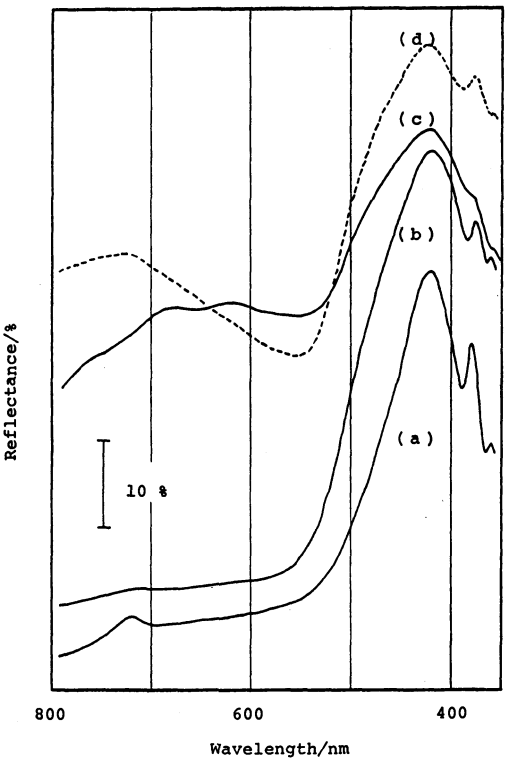

Fig. 2. Change in electronic spectra of colored products of 9,10-dihydroanthracene and anthracene on supported zinc chloride.
9,10-Dihydroanthracene; (a) at 60 °C for 10 min, (b) at 80 °C for 20 min, (c) at 100 °C for 30 min, anthracene; (d) at 60 °C for 10 min.

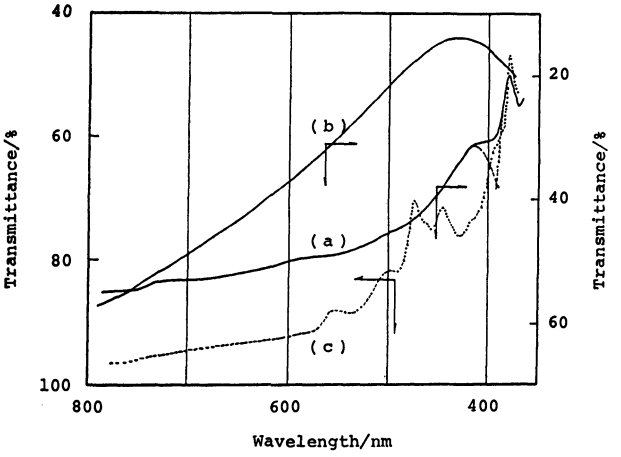

Fig. 3. Electronic spectra of 9,10-dihydroanthracene in molten zinc chloride (a) and on porous Vycor glass (b), and of polycondensed products of 9,10-dihydroanthracene formed on the supported zinc chloride and on the support (c) (in dichloromethane solution).

triphenylmethane and 9,10-dihydroanthracene absorbed on zinc chloride supported on porous Vycor glass platelets.

In these spectra, the intensity of the stretching vibration band of the aliphatic C–H relative to that of the aromatic C–H of the colored complexes seemed to be slightly smaller than that of the original molecule

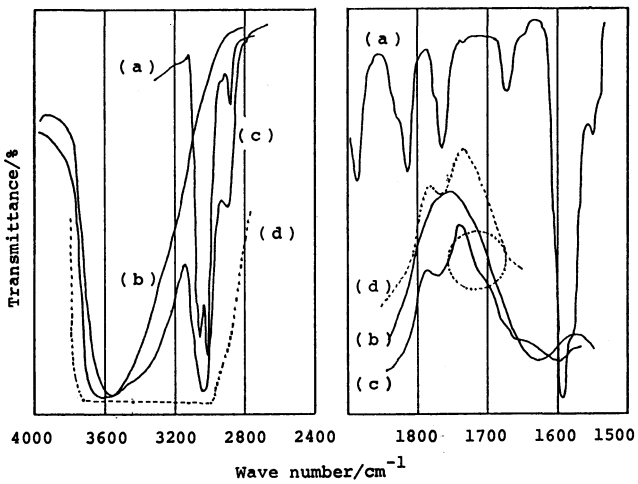

Fig. 4(a). Change in IR spectra of colored products of triphenylmethane on supported zinc chloride.
(a) Triphenylmethane on KBr, (b): zinc chloride on porous Vycor glass, (c): colored products on the catalyst after the reaction, (d) after decomposition of the colored products with water vapor.

on KBr, and the intensity of the OH groups on the silica surface increased more than that of the original. Furthermore, a very weak new absorption band appeared at about 1720 cm^{-1} for each complex. This band disappeared when the intermediates came in contact with water vapor, whereas none of the other bands, except those at 3600 cm^{-1} and 1620 cm^{-1}, changed (these two bands increased upon this water-contact).

Reaction Products. Triphenylmethane was the only identifiable product from the decomposition of its colored intermediate with water. This observation indicates that no reaction other than colored-complex formation took place on the catalyst under the present conditions.

Table 1 summarizes the analyses of the products obtained after the decomposition of 9,10-dihydroanthracene–zinc chloride colored complexes with water; these complexes had been produced by the reaction of 5 mg of the compound with 500 mg of the supported zinc chloride at various reaction temperatures for varying periods.

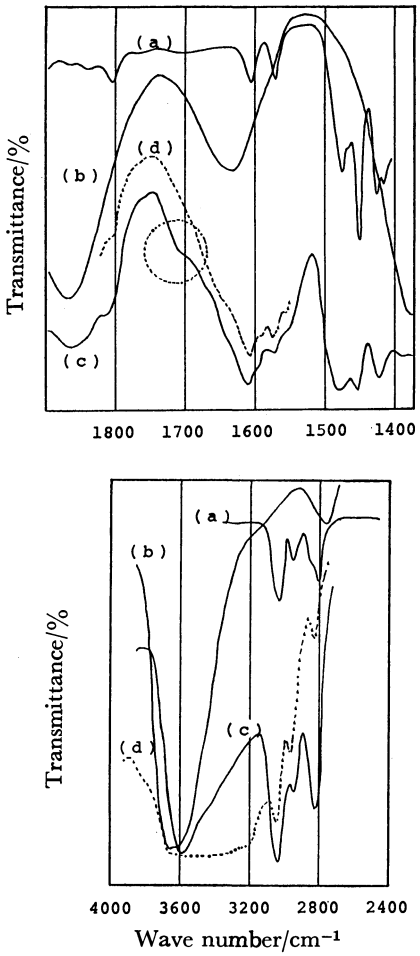

Fig. 4(b). Change in IR spectra of colored products of 9,10-dihydroanthracene on supported zinc chloride.
(a): 9,10-dihydroanthracene on KBr, (b): zinc chloride supported on porous Vycor glass, (c): colored products on the catalyst after the reaction, (d): after decomposition of the colored products with water vapor.

The electronic absorption spectra of the 9,10-dihydroanthracene-zinc chloride complexes were similar to those shown in Fig. 2(a) to (c). The products obtained below 100 °C were identified as anthracene and 1,2,3,4-tetrahydroanthracene, in nearly a 1 : 1 mol ratio. This observation indicates that the main reaction at

Table 1. Results of the decomposition of 9,10-dihydroanthracene over zinc chloride supported on porous Vycor glass

Reaction conditions: Sample/Catalyst=5mg/500 mg, Pressure 10^{-4} Torr.

Catalyst	Temp °C	Time min	9,10-Dihydroanthracene	Product distribution (wt%) 1,2,3,4-Tetrahydroanthracene +1,2,3,4-Tetrahydrophenanthrene	Anthracene
Zinc chloride on Vycor glass	150	10	39.1	34.4	26.5
	100	30	59.5	19.9	20.6
	80	90	65.9	16.2	17.9
	60	90	86.7	6.2	7.1

(Hydrogen gas and condensed compounds of 9,10-dihydroanthracene or of anthracene were confirmed as the other products at reaction temperatures higher than 100 °C. Although the analytical results fluctuate somewhat, they are enough to suggest the formation of some active species of 9,10-dihydroanthracene in the course of the reaction.)

temperatures lower than 100 °C is the disproportionation of 9,10-dihydroanthracene. When this substrate was treated at temperatures higher than 100 °C, hydrogen gas, anthracene dimers, and other polycondensed products, including anthracene and 1,2,3,4-tetrahydroanthracene (together with an unnegligible amount of 1,2,3,4-tetrahydrophenanthrene), were identified by gas and liquid chromatography, and by mass spectrometry. That is, at higher temperatures, the dehydrogenation of 9,10-dihydroanthracene and the condensation of 9,10-dihydroanthracene and anthracene occurred in addition to the disproportionation. The electronic spectrum of Fig. 3(c) can be attributed to some condensed polymers of 9,10-dihydroanthracene or anthracene.

The electronic-absorption spectrum of 9,10-dihydroanthracene in molten zinc chloride is reproduced in Fig. 3(a). This complex gave hydrogen gas and anthracene as the major products, in addition to 1,2,3,4-tetrahydroanthracene as a minor product. In this instance, the main reaction is the dehydrogenation of 9,10-dihydroanthracene.

9,10-Dihydroanthracene over porous Vycor glass alone pretreated at 550 °C was converted mainly to hydrogen gas and anthracene (Table 1). The main reaction is dehydrogenation.

D_2-exchanged Products. About 5 mg of triphenylmethane was treated with 600 Torr of deuterium gas at 280 °C for 3 h in the presence of 3 g of dehydrated zinc chloride. The products were $(C_6H_5)_3CD$ (15%) and HD. Similarly, 9,10-dihydroanthracene gave 13% of 9,10-dihydroanthracene-9-*d*, 8% of 1,2,3,4-tetrahydroanthracene (including deuterated derivatives), and 57% of anthracene (including deuterated derivatives). HD was also formed.

The treatment of 9,10-dihydroanthracene with 600 Torr of deuterium gas at 120 °C for 3 h over the supported zinc chloride also produced about 8% of 9,10-dihydroanthracene-9-*d*, 43% of 1,2,3,4-tetrahydroanthracene (including deuterated derivatives), 21% of anthracene (including deuterated derivatives), HD, and polycondensed products.

A glass wall or porous Vycor glass alone did not promote this D_2-exchange reaction under the same conditions.

Dissociation into Ions. The double-peaked absorption band at about 450 nm of a colored product from triphenylmethane is also present in the spectrum of the triphenylmethyl cation produced by the reaction of triphenylmethane with silica–alumina and BF_3 on silica.[10] We confirmed that HD and triphenylmethane-1-*d* were the products in the reaction of triphenylmethane with D_2 gas on the zinc chloride. These results lead us to the conclusion that the triphenylmethane absorbed on zinc chloride dissociates into ions as follows:

$$(C_6H_5)_3CH \rightleftarrows (C_6H_5)_3C^+ + H^-.$$

Portions of the hydride ions formed by this reaction may be supposed to be chemisorbed on the Lewis-acid centers of the zinc chloride catalyst, judging from a new, weak absorption band at 1720 cm^{-1} which is interpreted as arising from the Zn–H bond (Fig. 4(a)).[11] It was also found that the IR spectrum of triphenylmethane absorbed on zinc chloride/porous Vycor glass showed a marked absorption at about 3600 cm^{-1} of the OH groups on the silica surface; this is known to be depend on hydrogen bonding between the surface hydroxyl groups and the adsorbate,[12] but H^- ions might contribute to the formation of the OH groups on the silica surface. This should further be investigated. However, triphenylmethane on zinc chloride, even if it is not supported on porous Vycor glass, substantially dissociates into ions. Therefore, the ionization of triphenylmethane on zinc chloride can be represented as follows:

$$(C_6H_5)_3CH + n ZnCl_2 \rightleftarrows (C_6H_5)_3C^+(ZnCl_2)_n^-H.$$

9,10-Dihydroanthracene absorbs strongly at 420 nm and weakly at about 725 nm on the supported zinc chloride upon their first contact (Fig. 2(a)). Similarly, it gives the same absorption bands in molten zinc chloride (Fig. 3(a)).

Anthracene–zinc chloride complexes may be supposed to be formed, for anthracene was confirmed as an impurity of the sample and a reaction product. Therefore, the present band at 725 nm corresponds to that of the anthracene cation radical, for the anthracene–zinc chloride complexes absorb at 430 nm and at 730 nm (Fig. 2(d)), the absorption bands of which are assigned to the anthracene–zinc chloride EDA-complex and the anthracene cation radical respectively.[2] However, the band at 725 nm disappeared with increases in the contact time and the temperature, whereas the position of the band at 420 nm almost did not change. On the other hand, anthracene in concd H_2SO_4 impregnated with porous Vycor glass gave electronic absorption bands at 420 nm and at 725 nm, as is shown in Fig. 5. They are assigned to the 9-anthracenium ion and the anthracene cation radical respectively.[13,14] We may note here that the absorption band at 420 nm of the present complex is strikingly similar to that of the 9-anthracenium ion. Moreover, this band is distinctly different from the characteristic absorption band of the anthracene–zinc chloride EDA complex with regard to the strength of the absorption and the position of the peak. As has been mentioned above, it was found

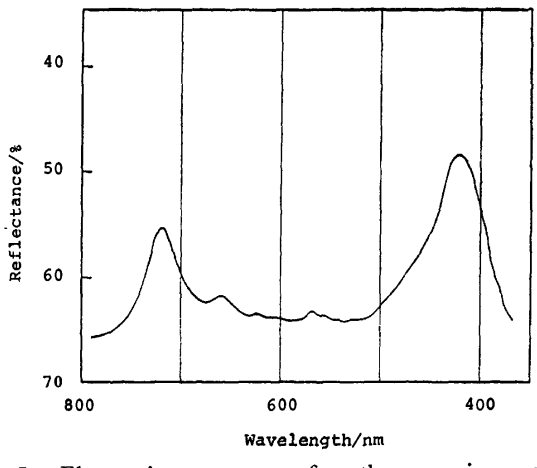

Fig. 5. Electronic spectrum of anthracene in concd H_2SO_4 impregnated with porous Vycor glass.

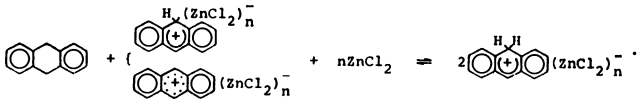
that aliphatic hydrogen of 9,10-dihydroanthracene is so mobile on zinc chloride that it can be exchanged with D_2 gas, that 9,10-dihydroanthracene decomposes into anthracene and 1,2,3,4-tetrahydroanthracene, and that zinc chloride abstracts the hydride ion from 9,10-dihydroanthracene. A colored 9,10-dihydroanthracene–zinc chloride complex formed on porous Vycor glass platelets also gave a weak absorption band at 1720 cm^{-1}. This can also be interpreted as an H^- ion from 9,10-dihydroanthracene being chemisorbed on Lewis acid centers of zinc chloride.

The results presented above lead us to the conclusion that 9,10-dihydroanthracene dissociates on zinc chloride as follows:

The disappearance of the anthracene cation radical at the early stage of the reaction can be explained if one assumes the following reaction:



The yellow complexes of triphenylmethane and 9,10-dihydroanthracene, which were formed at higher temperatures on porous Vycor glass pretreated at 550°C under a vacuum, are also supposed to be triphenylmethyl cations and 9-anthracenium ions respectively, but further investigation should be carried out before an assignment can be made certainly.

The Solubility Curves of Water in Normal Alkane Derivatives with a Polar Group

Nobuo NISHINO* and Masao NAKAMURA

Department of Chemistry, Faculty of Science, Tokai University, 1117 Kitakaname, Hiratsuka 259-12

(Received May 15, 1980)

Measurements were made of the solubility *vs.* temperature curves of water in normal alkane derivatives: alkanols, alkylamines, and alkanoic acids. The solubility of water increases monotonically with an increase in the temperature in alkanols and alkanoic acids, while it decreases in alkylamines. The solubility is so great that it often exceeds 1/2 in the mole fraction scale. Phase diagrams were constructed by combining such solubility curves with the solubility curves of these substances in water. The heat of solution at an infinite dilution *vs.* the temperature for 1-butanol in water is obtained by taking account of the activity coefficient of 1-butanol in its own phase.

When an organic substance containing a hydrophobic group, such as an alkyl group, is introduced to water, the water is considered to change in structure and to form an iceberg around the molecule, which breaks down gradually with a rise in the temperature.[1] As a result, such an aqueous solution shows various complicated phenomena.[2] The present authors have found that a minimum commonly exists on the solubility *vs.* temperature curve for normal alkane derivatives in water, such as alkanols, alkylamines, and alkanoic acids.[3] The heat of solution at an infinite dilution, which is the difference between the partial molar enthalpy of a solute at an infinite dilution and the molar enthalpy in its pure state, serves to elucidate the dissolution state of the solute molecule energetically.[4] The heat of solution at an infinite dilution should be obtained thermodynamically from the phase diagram of the solute and solvent if both phases at equilibrium are ideal. In order to construct the phase diagram for the binary system of water and an organic substance, it is necessary to know the mutual solubility *vs.* temperature curves, *i.e.*, the solubility curves, of the organic compound in water as well as of water in the organic phase. Measurements have not been made of the solubility of water in most normal alkane derivatives, whose solubility curves in water have been measured in a previous paper.[3]

Experimental

The materials used were the same as those described in a previous paper.[3] Twenty to thirty glass ampoules containing various compositions around the solubility of water at room temperature were immersed in a water thermostat. The distinction between clear and turbid ampoules was made after a time long enough for equilibrium to be established, say, *ca.* 2 h, at each temperature.

The behavior of the binary system of 1-pentanol and water is presented as an example in Fig. 1; here an open circle shows the most water-rich composition among the clear ampoules at each temperature and a solid one, the most 1-pentanol-rich among the turbid ones. The solubility curve is drawn smoothly between open and solid circles. The solubility curves for other compounds are similarly precise.

Results and Discussion

The solubility curves of water in the organic phases measured are expressed as the mole fraction of water,

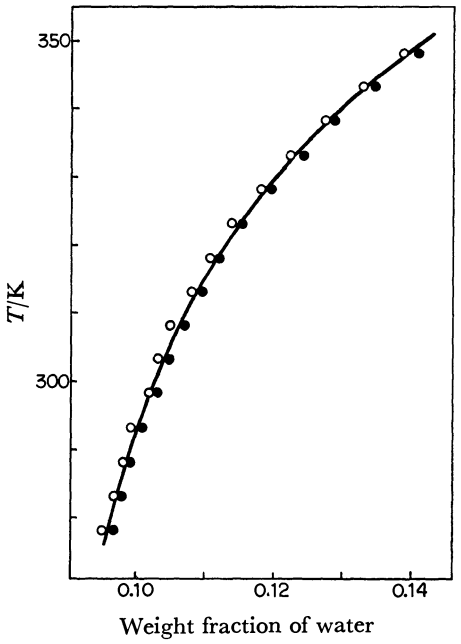

Fig. 1. Solubility behavior of water in 1-pentanol.
○: The most water-rich composition in clear ampoules,
●: the most 1-pentanol-rich composition in turbid ampoules.

x_1^{or}, *vs.* the temperature, T, in Figs. 2 and 3. The solubility of water in either hexylamine or heptylamine could not be determined below 293 or 307 K, because these mixtures were in jelly-like states at the lower temperatures. A large amount of water dissolves in each organic phase, and x_1^{or} exceeds often 1/2; this is natural, as it has been expected that the solubility of water in an organic liquid is more than that of the organic compound in water, because the molar volume of water is generally less than that of an organic liquid.[5] Particularly, hexylamine can decrease to as low as 0.10 in the mole-fraction scale in its own phase at 300 K. As expected, the greater solubility of water is seen in the compound with the smaller number of carbon atoms in a homologous series at a given temperature.

The solubility of water increases monotonically with a rise in the temperature in alkanols and alkanoic acids, while it decreases in alkylamines. The increase is steeper in alkanoic acids than in alkanols. Such behavior is significantly different from that of these substances in water.[3] When ln x_1^{or} is plotted against T^{-1}, the curve

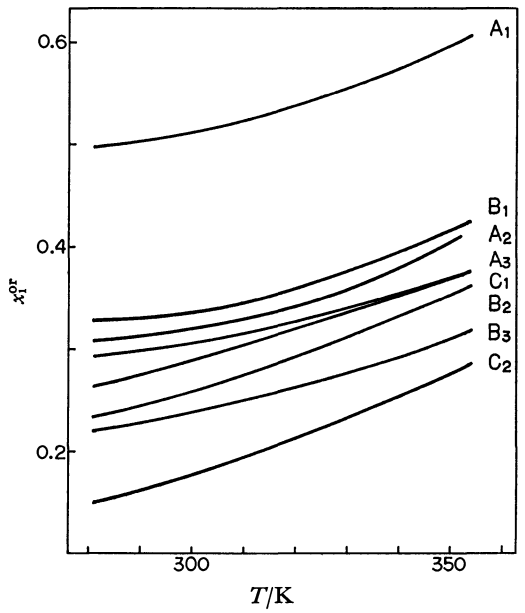

Fig. 2. Solubility curve of water in alkanols.
A_1: 1-Butanol, A_2: 1-pentanol, A_3: 1-hexanol, B_1: 2-pentanol, B_2: 2-hexanol, B_3: 2-heptanol, C_1: 3-pentanol, C_2: 3-hexanol.

does not deviate very much from a straight line for any compound. This fact reveals that the structure in an organic phase does not change with the temperature so remarkably as in an aqueous phase.

The phase diagrams of the binary systems of water and one of these substances are shown in Figs. 4, 5,

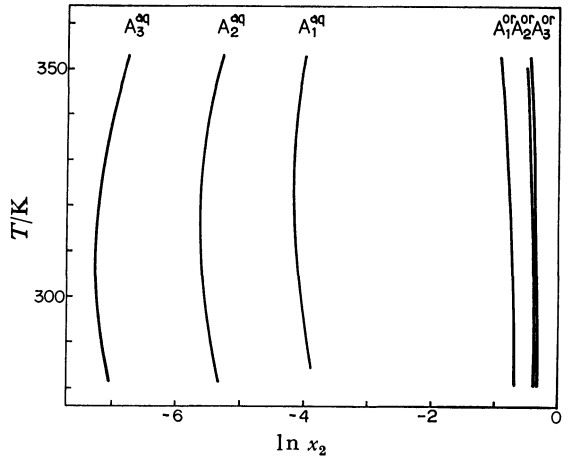

Fig. 4. Phase diagram of the binary system of water and 1-alkanol expressed as temperature *vs.* the natural logarithm of mole fraction of organic substance.
Superscripts aq and or denote aqueous and organic phases, respectively.

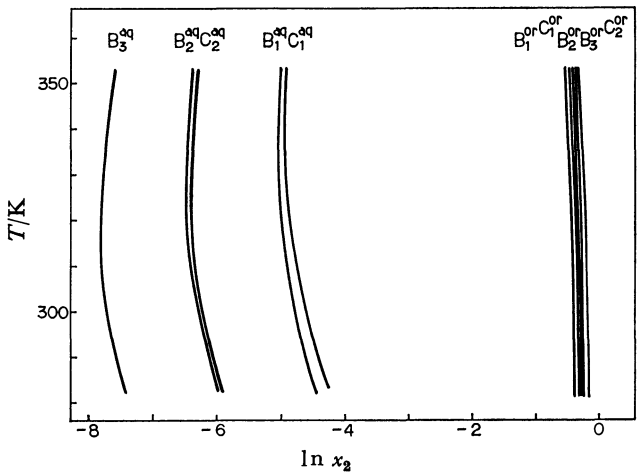

Fig. 5. Phase diagram of the binary system of water and 2- or 3-alkanol expressed as temperature *vs.* the natural logarithm of mole fraction of organic substance.

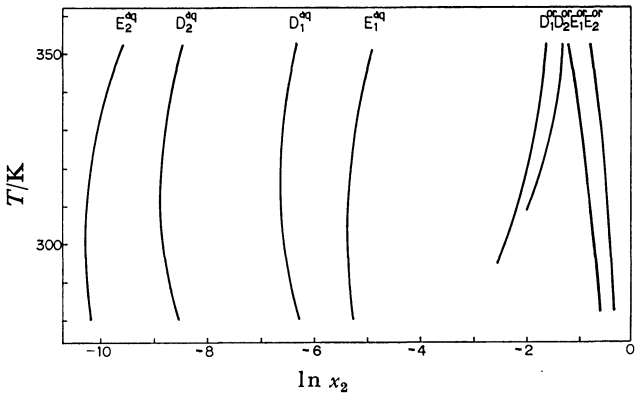

Fig. 6. Phase diagram of the binary system of water and alkylamine or alkanoic acid expressed as temperature *vs.* the natural logarithm of mole fraction of organic substance.

and 6, which were constructed by combining the solubility curves of water in Figs. 2 and 3 with the solubility curves of the substances in water reported in a previous paper.[3] The abscissa expresses the natural logarithm of the mole fraction of an organic compound. The region between two solubility curves corresponds to the turbid two-phase region; outside of this region there are clear one-phase regions.

In order to know the states of an organic substance in water, it is useful to estimate the heat of solution at an infinite dilution of the organic substance in water, $\Delta_s h_2^\ominus$.[4] If the system consists of water and an organic substance, the chemical potential of the organic substance, either in the aqueous phase, μ_2^{aq}, or in the organic one, μ_2^{or}, may be generally expressed by:[6]

$$\mu_2^{aq} = \mu_2^{\ominus aq}(T,p) + RT \ln x_2^{aq}\gamma_2^{aq}$$

and:

$$\mu_2^{or} = \mu_2^{\circ}(T,p) + RT \ln x_2^{or}\gamma_2^{or}.$$

When both phases are mutually saturated ($\mu_2^{aq}=\mu_2^{or}$), $\Delta_s h_2^\ominus$ can be expressed generally as:

$$\Delta_s h_2^\ominus = h_2^{\ominus aq} - h_2^{\circ} = \left[\frac{\partial\{\mu_2^{\ominus aq}(T,p) - \mu_2^{\circ}(T,p)\}T^{-1}}{\partial T^{-1}}\right]_p$$

$$= R\left[\frac{\partial \ln(x_2^{or}\gamma_2^{or}/x_2^{aq}\gamma_2^{aq})}{\partial T^{-1}}\right]_{p,sat.}, \quad (1)$$

where $\mu_2^{\ominus aq}(T,p)$ and $h_2^{\ominus aq}$ are the chemical potential and the partial molar enthalpy of the organic substance in the aqueous phase at an infinite dilution at a certain temperature, T, and pressure, p, where $\mu_2^{\circ}(T,p)$ and h_2° are the molar Gibbs free energy and enthalpy in its pure state, where x_2^{aq} and x_2^{or} ($=1-x_1^{or}$) are the mole fractions of the organic substance in aqueous and organic phases at mutual saturation, where γ_2^{aq} and γ_2^{or} are the activity coefficients of the substance in aqueous and organic phases, with reference to the infinite dilution and to the pure state respectively, and where R is the gas constant. When the aqueous phase is dilute enough to be an ideal solution ($\gamma_2^{aq}=1$), Eq. 1 is reduced to:

$$\Delta_s h_2^\ominus = R\left[\frac{\partial \ln(x_2^{or}\gamma_2^{or}/x_2^{aq})}{\partial T^{-1}}\right]_{p,sat.}. \quad (2)$$

When the organic phase is also ideal ($\gamma_2^{or}=1$), Eq. 2 gives:

$$\Delta_s h_2^\ominus = R\left[\frac{\partial \ln(x_2^{or}/x_2^{aq})}{\partial T^{-1}}\right]_{p,sat.}. \quad (3)$$

If, further, the amount of water in the organic phase in equilibrium with the aqueous phase is either zero or independent of the temperature, Eq. 3 is reduced to:

$$\Delta_s h_2^\ominus = -R\left[\frac{\partial \ln x_2^{aq}}{\partial T^{-1}}\right]_{p,sat.}. \quad (4)$$

Equation 4 has frequently been used to obtain the heat of solution from the solubility curve of a solid substance.[7] Such a value is almost entirely correct, because the solvent is rarely dissolved in a solid substance and $\ln x_2^{or}$ may be regarded as zero. On the other hand, $\Delta_s h_2^\ominus$ has been evaluated from the solubility curve in water for several substances which are in the liquid state under the conditions measured.[8-11] Such a solubility curve corresponds to the curve with the superscript aq on the left-hand side in Figs. 4, 5, and 6. The conditions for Eq. 4, however, would fail for most liquid organic substances, since the solubilities of water in them must exceed their solubilities in water.[5] Equation 4 cannot be used, of course, for the substances studied here, because neither $\ln x_1^{or}$ nor its derivative with respect to T is zero, as is shown by the right-hand side curves with the superscript or in Figs. 4, 5, and 6. If the mutual solubility is small and both aqueous and organic phases are ideal, $\Delta_s h_2^\ominus$ can be obtained by means of Eq. 3 from the phase diagrams shown in Figs. 4, 5, and 6. In the present cases, however, the organic phases cannot be assumed to be ideal, because the solubilities of water x_1^{or} are as high as between 0.15 and 0.90 as is shown in Figs. 2 and 3, while the aqueous phases are dilute enough to be assumed to be ideal.[3] Unfortunately, $\Delta_s h_2^\ominus$ cannot be evaluated from the phase diagram only, but it can with the use of Eq. 2. The activity coefficient, γ_2^{or}, however, is not available from the literature for most of the substances investigated in the present paper. For 1-butanol, though, the values of γ_2^{or} at 298 K have been found over a wide range of compositions.[12] If γ_2^{or} is assumed to be independent of the temperature at an equal composition,[13] $\Delta_s h_2^\ominus$ for 1-butanol can be estimated from the phase diagram in Fig. 4 by applying Eq. 2. Thus, the difference in $\Delta_s h_2^\ominus$ according to the respective assumption can be checked here for the 1-butanol–water system. The relation between the $\Delta_s h_2^\ominus$ estimated from Eq. 2 and the T for 1-butanol is shown as Curve 2 in Fig. 7. It is expected that the value for $\Delta_s h_2^\ominus$ obtained by Eq. 1 is not so very different from that on Curve 2, since the solubilities of the organic substances are small enough to be ideal. The most likely values of $\Delta_s h_2^\ominus$ shown by Curve 2 increase with an increase in the temperature. The increment of Curve 2 corresponds to the increase in the partial molar enthalpy of 1-butanol in water at an infinite dilution with the rise in the temperature, because the heat of evaporation is almost independent of the temperature.[3] The values for $\Delta_s h_2^\ominus$ which are

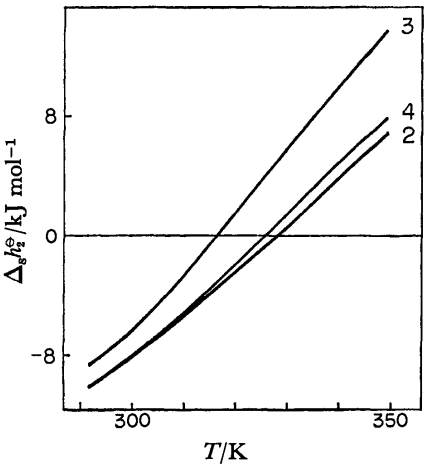

Fig. 7. Heat of solution at infinite dilution *vs.* temperature curves for 1-butanol in water estimated by three different methods.
2: Eq. 2, 3: Eq. 3, 4: Eq. 4.

obtained by the use of Eqs. 3 and 4 are also shown as Curves 3 and 4 respectively in Fig. 7 for the purposes of comparison. It is very impressive that Curve 3 is distant from Curve 2 as a result of our neglecting the deviation of γ_2^{or} from unity and that Curve 4 again approaches Curve 2 as a result of our further neglecting the solubility of water in the organic phase. This suggests that the $\Delta_s h_2^o$ value obtained by the simplest method using Eq. 4 may be close to the real value because of the compensation of the two effects of x_2^{or} and γ_2^{or}.

(Received May 19, 1980)

The absorption spectra of the transient species produced through the one-electron reduction of ferrocene and biferrocene were determined by applying a radiation-chemical method in frozen glass matrices. The spectral shapes were assigned to ferrocene- and biferrocene-anionic species on the basis of the experimental results. In the biferrocene anion, the "intervalence transfer" band was observed at about 2050 nm.

Oxidized ferrocene and biferrocene have been extensively studied by the measurement of their optical-absorption, EPR, and Mössbauer spectra, and much information about their physical and chemical properties has been accumulated.[1-8] On the contrary, nothing is known about the reduced forms of ferrocene and biferrocene, because their syntheses have not yet been completed. The failure of efforts thus far undertaken for the syntheses suggests that the reduced forms are too unstable to be isolated by the usual chemical processes. In the present work, we wish to report on the optical-absorption spectra of the transient species which are observed after a one-electron reduction of ferrocene and biferrocene by applying radiation-chemical reactions to frozen glass solution. The spectra were assigned to the ferrocene and biferrocene anions.

Experimental

All the chemicals used were of the purest grade commercially available. The biferrocene was synthesized by the ordinary method.[9] The 2-methyltetrahydrofuran (MTHF) was purified by distillation over metallic sodium. The distillate was stored in vacuo over a sodium–potassium alloy. The ferrocene was recrystallized before use.

Each ferrocene solution (15 mM) and biferrocene solution (9 mM) in MTHF was sealed in an optical cell with an optical path of 1.5 mm or in an EPR sample tube, and irradiated at 77 K with γ-rays from ^{60}Co; the total doses for the ferrocene and biferrocene MTHF-glass matrix were 215 krad and 420 krad, respectively, for H_2O.

The absorption spectra were measured on a Cary 14 RI, while the EPR measurement was carried out by using a JEOL PF 3AX at 77 K.

Radiation-chemical Method for Preparation of Ion Radicals

Although there seems to be an inveterate prejudice that says radiation-chemical processes are too complicated, it has been demonstrated that the irradiation of a frozen solution in a selected solvent with ionizing rays provides us with an excellent method for the selective preparation of solute cation or anion species.[10,11] The scheme has also been well examined as will be briefly illustrated below.

For the selective preparation of solute anion species in an alcoholic or ethereal glass solution, the processes may be described as follows:

$$e^- + S \longrightarrow S^- \quad (1)$$

$$RH^+ + RH \longrightarrow RH_2^+ + R\cdot, \quad (2)$$

where S and RH denote the solute and a solvent species; e^- and RH^+, the electrons and holes induced by ionizing radiations and S^- and RH_2^+, the solute anion species and protonated holes, respectively. The protonated holes are stable species such as hydronium ions produced in the irradiated water. The reaction of RH^+ with the surrounding solvent molecules (Reaction 2) proceeds so fast that solutes added in a small amount cannot scavenge the holes. The absorption bands of the trapped electrons, which are observed in γ-irradiated glass solutions in the absence of solutes, are replaced by the bands of solute anions when a sufficient amount of solute is added to the glass solution. No absorption band is observed for RH_2^+ and R· in the visible and near-infrared regions.

The selective production of solute cations is also proved by the use of organic halides, RX, such as Freons as solvents:

$$RX^+ + S \longrightarrow S^+ \quad (3)$$

$$e^- + RX \longrightarrow R\cdot + X^-. \quad (4)$$

In Reaction 4, RX works to prevent the solute species from forming a solute-anion species, removing electrons in the system. Those methods described above, which will hereafter be referred to as "matrix protection method," have been successfully applied to the study of radical ions of many organic compounds[10-13] and to the study of the one-electron reduction of several organometallic compounds.[14,15] We have also carefully applied this method to ferrocene and biferrocene in order to prepare their anions.

Results and Discussion

Prior to applying the method for the one-electron reduction of ferrocene and biferrocene, the absorption spectra of the cationic species produced in γ-ray irradiated frozen solutions of ferrocene and biferrocene in a freon mixture ($CFCl_3$ 1: CF_2BrCF_2Br 1) were determined. Figures 1-a and 1-b show the spectra taken after irradiating frozen freon mixture glass solutions contain-

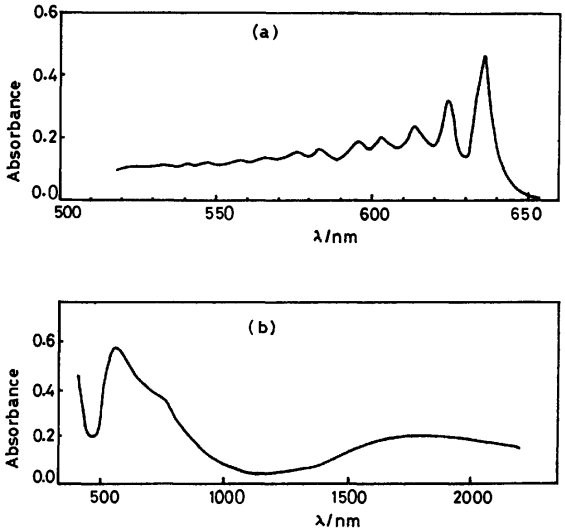

Fig. 1. Absorption spectra of ferrocenium (a) and biferrocene (b) cation obtained by a radiation-chemical method; the total dose for ferrocence (50 mM) and biferrocene (2 mM) Freon-mixture glass solution was 430 krad and 215 krad for H_2O, respectively.

ing ferrocene and biferrocene respectively. The spectral shapes agree well with those of the ferrocenium ions and biferrocene mono-cations prepared by chemical methods.[3,7,8] The dark blue precipitates obtained by warming the solutions to room temperature were determined to be cationic salts.

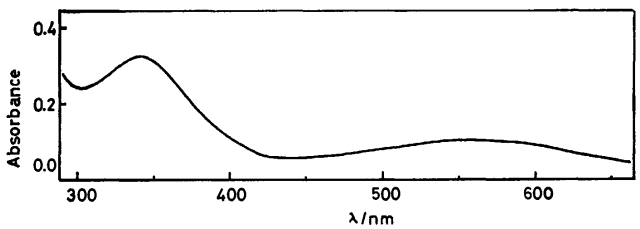

Fig. 2. Absorption spectrum of ferrocene anion taken after photobleaching of residual trapped electrons.

The spectrum taken after the photobleaching of the residual trapped electrons with a filtered light (λ>520 nm) for the γ-ray irradiated MTHF glass solution containing ferrocene is shown in Fig. 2. The two characteristic bands with peaks at 340 and 550 nm in the spectrum can not be found when the solution includes biphenyl (30 mM) as an additional solute before the irradiation, while the bands of biphenyl anions appear clearly. This suggests that the 340- and 500-nm bands are associated with a species resulting from a reaction which competes with the biphenyl-anion formation; *i.e.*, a kind of one-electron reduction process. The results also suggest that the electron affinity of ferrocene should be lower than that of biphenyl previously reported by us.[16] Another experimental result obtained in methanol glass containing ferrocene showed that trapped electrons are not scavenged by ferrocene. In the process of Reaction 1, it is obvious that solutes, S, which a lower electron affinity than the solvent cannot be reduced.

The possibility of the protonation of the anions may be excluded, because the spectrum shown in Fig. 2 is not in accordance with that of the cyclopentadiene anions observed by Shida,[17] although cyclopentadiene anions, $C_5H_6^-$, would be formed if protonation occurred. A dissociative electron attachment, like Reaction 4, was observed for solutes of certain organic halides.[10] Recent studies have revealed that cobalt(III) coordination compounds can undergo a one-electron reduction in the γ-ray irradiation of a MTHF glass solution at 77 K to form their anions, which they decompose on warming.[14,15] EPR studies of γ-ray irradiated tetraphenylporphyrinatocobalt(III) chloride in MTHF at 77 K indicate that the cobalt ions and chloride ions remain at a distance close enough to interact with each other in a transient species.[15] This suggests that MTHF glass is very effective for protecting the dissociation of any fragments at 77 K. In conclusion, therefore, the spectrum shown in Fig. 2 may be safely assigned to ferrocene anions. The disappearance of the spectra on warming the glass solution indicates that ferrocene anions are too unstable to be isolated at higher temperatures. The assignment is also verified by the resemblance of the observed spectrum of cobaltocene,[18] an isoelectronic analogue to the ferrocene anion. The band around 550 nm is attributable to the transition of an electron from a doubly occupied e_{2g} or a_{1g} orbital to the half-occupied e_{1g} orbital, by analogy to cobaltocene. EPR measurements taken for the same species with the absorption bands at 340 and 550 nm showed the g-values, g_x and g_z, to be 1.52 and 1.66 respectively. These values are close to those ($1.65<g_x<1.85$ and $g_z=1.685$) reported for cobaltocene doped in ferrocene at 4.2 K.[18]

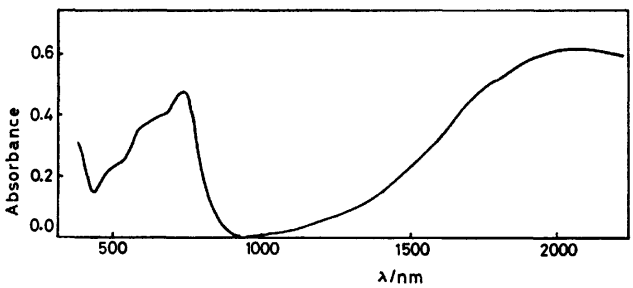

Fig. 3. Absorption spectrum of biferrocene anion taken after photobleaching of residual trapped electrons.

Figure 3 demonstrates the spectrum of a γ-ray-irradiated MTHF glass solution containing biferrocene, measured after photobleaching the residual trapped electrons with a filtered light (λ>520 nm). The spectrum consists of the visible bands (500—800 nm) and a near-infrared band with a peak at *ca.* 2050 nm. All those bands decay when the solution is warmed, and may be attributed to a single species. The spectrum can be assigned to biferrocene mono-anions, on the basis of the radiation-chemical studies described in the consideration of the ferrocene anions.

The visible bands are attributable to the ferrocene-

anion moiety in the biferrocene mono-anion because of its similarity to the 550-nm broad band in Fig. 2. (No transition occurs above 550 nm for ferrocene and biferrocene.[3,8]) The near-infrared band at 2050 nm that was not observed in the ferrocene anion is quite similar to the 1900-nm band of the biferrocene mono-cation found in Fig. 1-b, which has been known as the "intervalence transfer" band.[7,8] It seems, therefore, reasonable to ascribe the 2050-nm band to the "intervalence transfer" between $[Fc(I)Fc(II)]^- \rightarrow [Fc(II)Fc(I)]^-$, where Fc(I) and Fc(II) denote the ferrocene anion and the ferrocene moiety respectively. The near-infrared band has a shoulder at about 1700 nm, as is found in Fig. 3.

The results of the work on the ferrocene and biferrocene anions show that the reduced organometallic compounds can be prepared by applying the matrix-protection method in a MTHF glass solution. The observation of the absorption spectra on the reduced species will provide us with valuable information about the physical and chemical properties of the species too unstable to be isolated, such as the intriguing character of mixed-valence species.

The Stability of Spherical Micelles of Dodecyltrimethylammonium Chloride in Aqueous NaCl Solutions

Sumio Ozeki and Shoichi Ikeda*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 2, 1980)

Light scattering from solutions of dodecyltrimethylammonium chloride in water and 4.00 M (1 M=1 mol dm^{-3}) NaCl has been measured at 25 °C, and the critical micelle concentrations and the micellar molecular weights have been determined. The critical micelle concentration, when combined with the previous data, follows the linear Corrin-Harkins equation over the whole range of NaCl concentrations. The micellar molecular weight remains low, *i.e.*, about 20000 even in the presence of 4.00 M NaCl, and the double-logarithmic relation between the micellar molecular weight and the ionic strength is represented by a straight line over the whole range of NaCl concentrations, when plotted together with the previous data. These results indicate that only spherical micelles are formed by dodecyltrimethylammonium chloride in the presence of added NaCl. The stability of the spherical micelle is attributed to the low degree of binding of Cl^- on the cationic micelles.

In a recent work on light scattering[1] we have shown that the micelle of dodecyldimethylammonium chloride is subject to a transition of its shape from spheres to rods when the concentration of added NaCl is increased across 0.80 M (1 M=1 mol dm^{-3}) and when the surfactant concentration considerably exceeds the critical micelle concentration (c.m.c.). By measurements of the viscosity of the micellar solutions,[2] we have confirmed such a transition of micelle shape induced by the change in ionic strength.

In another work[3] we have also demonstrated that even sodium dodecyl sulfate can form rodlike micelles in concentrated NaCl solutions beyond 0.45 M. The formation of large micelles of sodium dodecyl sulfate in 0.6 M NaCl was observed by Mazer and his coworkers[4,5] and by Corti and Degiorgio,[6,7] using both quasi-elastic and elastic light scattering, although the latter workers reserved to draw a conclusion for the formation of rodlike micelles and considered other possibilities as well.

Kushner and his co-workers[8] measured both the light scattering and intrinsic viscosity of micellar solutions of dodecylammonium chloride in different concentrations of added NaCl. Their data on micellar molecular weight can be interpreted as indicating the formation of rodlike micelles in NaCl solutions more concentrated than 0.07 M.[1] The observed intrinsic viscosity of the micellar solutions also suggests the formation of rodlike micelles.[2,9]

In the previous paper[1] we have pointed out that the NaCl concentration or the ionic strength where the sphere-rod transition of an ionic micelle occurs is closely related to the preference of a surfactant molecule to a spherical micelle over a rodlike micelle. This preference is determined by the geometrical ease of packing of surfactant ions in a micelle and by the magnitude of repulsion among polar head groups on a micelle surface. From the geometry of a surfactant molecule we can see that dodecylammonium chloride is more adequately incorporated into a rodlike micelle than dodecyldimethylammonium chloride, and thus, dodecyltrimethylammonium chloride remains to form spherical micelles even in the presence of 0.5 mol kg^{-1} NaCl.[10]

In order to investigate the nature of the sphere-rod transition of ionic micelles, it is worth observing the light scattering of dodecyltrimethylammonium chloride micelles in more concentrated NaCl solutions and determining the micellar molecular weight as well as the micelle shape. This cationic surfactant has already been studied by Kushner and his co-workers[8] and by Emerson and Holtzer,[10] using the light-scattering method; they found it to associate into spherical micelles in the presence of NaCl less concentrated than 0.5 mol kg^{-1}.

Experimental

The sample of dodecyltrimethylammonium chloride was purchased from the Tokyo Kasei Kogyo Co., Inc., and was recrystallized from acetone three times. Thermal-decomposition gas chromatography was applied to this sample at the injection temperature of 300 °C and with the column temperature of 240 °C; the results showed that the sample contained 88.2% C_{12}, 9.5% C_{14}, 0.90% C_{10}, 0.86% C_{16}, and 0.55% C_8. The contaminating higher alkyl homologs would not influence the conclusion derived in this work.

NaCl was a special-grade reagent and was used after having been roasted. Water was redistilled from alkaline $KMnO_4$ in a glass still.

The light scattering and the refractive index increment were measured on Shimadzu apparatuses, PG-21 and DR-3, using the unpolarized light of 436 nm of mercury lamps. A cylindrical cell for light scattering was put in a thermostat jacket. The temperature for measurements was kept at 25±0.05 °C by circulating water of a constant temperature through the cell jackets. The procedure for the optical cleaning of the solutions and the methods of measurement and calibration were described previously.[1,3]

Measurements were carried out on solutions of dodecyltrimethylammonium chloride in water and in 4.00 M NaCl. The reduced intensity of light scattered in the 90° direction, R_{90}, was recorded, and the angular dissymmetry in the 45° direction, z_{45}, was examined. The value of dissymmetry was less than 1.02 above the c.m.c., but it was sometimes higher at lower concentrations. Data showing dissymmetries higher than 1.03 were discarded.

Results

Figure 1 shows the reduced intensity, R_{90}, of the surfactant solutions as a function of the concentration, c (g cm^{-3}). The reduced intensity increases with an

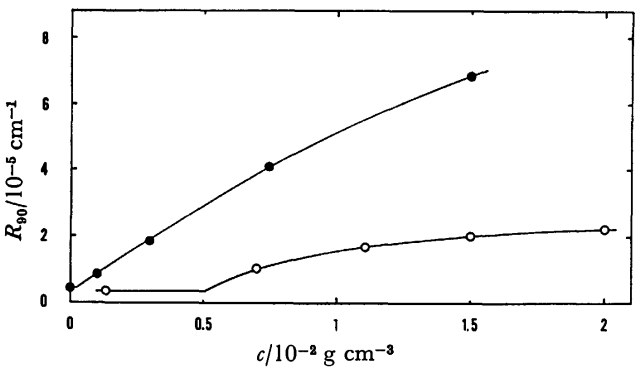

Fig. 1. Reduced intensity of scattered light plotted against surfactant concentration at 25 °C.
○: In water, ●: in 4.00 M NaCl.

Table 1. Refractive index increment and light scattering

C_s / M	$(\partial\tilde{n}/\partial c)_{C_s}$ / cm^3 g^{-1}	C_0 / 10^{-3} M	c_0 / 10^{-2} g cm^{-3}	R_{90}^0 / 10^{-6} cm^{-1}
0	0.158	19.3	0.51	3.34
4 00	0.123	0.68±0.07	0.018±0.002	4.18

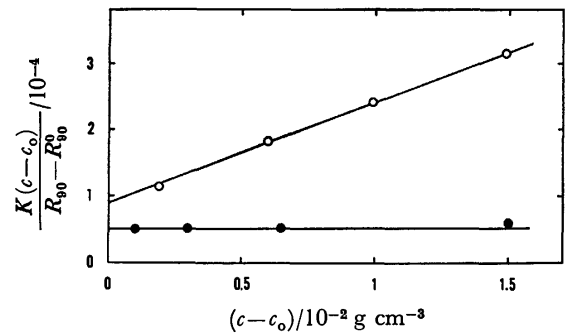

Fig. 2. The Debye plots for dodecyltrimethylammonium chloride micelles at 25 °C.
○: In water, ●: in 4.00 M NaCl.

increase in the concentration above the c.m.c. The values of c.m.c., c_0 (g cm^{-3}) or C_0 (M), and of the reduced intensity there, R_{90}^0, are given in Table 1, together with the refractive index increment, $(\partial\tilde{n}/\partial c)_{C_s}$, where C_s is the molar concentration of added NaCl.

Figure 2 shows that the Debye plots both in water and in 4.00 M NaCl are straight lines expressed by

$$\frac{K(c-c_0)}{R_{90}-R_{90}^0} = \frac{1}{M} + 2B(c-c_0), \quad (1)$$

where M is the micellar molecular weight and B is the second virial coefficient. The optical constant is

$$K = 2\pi^2\tilde{n}_0^2(\partial\tilde{n}/\partial c)^2_{C_s}/N_A\lambda^4, \quad (2)$$

where $\tilde{n}_0$ is the refractive index of the solvent; λ the wavelength of light, and N_A the Avogadro number.

Table 2. Characteristics of the spherical micelles

C_s / M	M	m'	B / 10^{-3} cm^3 g^{-1}	M_m	m	p/m
0	11 500±500	43.6	7.50	13 900	52.8	0.18
4.00	20 000±1 500	75.8	0.05	21 500	81.4	0.2

Table 2 lists the values of the micellar molecular weight, the micellar aggregation number, $m'=M/264$, and the second virial coefficient. The value of the aggregation number indicates that the micelle of dodecyltrimethylammonium chloride is spherical even in 4.00 M NaCl solutions. The positive value of the second virial coefficient also supports the formation of spherical micelles alone, because it has been previously established that rodlike micelles are formed only when the surfactant concentration exceeds the c.m.c.[1,3,6] We have also observed a negative second virial coefficient for a rodlike micelle of *N,N*-dimethyldodecylamine oxide half-neutralized by HCl in 0.2 M NaCl.[11] Debye and Anacker[12] reported positive second virial coefficients for the rodlike micelles of hexadecyltrimethylammonium bromide in 0.178 and 0.233 M KBr, but it proves that even for these solutions negative coefficients can be assigned at low micelle concentrations if lower values of c.m.c. are chosen.

To confirm the formation of spherical micelles only and the absence of rodlike micelles for dodecyltrimethylammonium chloride over the whole range of NaCl concentrations, we have performed an experiment to observe the light scattering from a solution of the cationic surfactant in saturated NaCl. To a 0.75×10^{-2} g cm^{-3} solution of the cationic in 4.00 M NaCl, solid NaCl was added in such a way as to give a 5.9 M NaCl solution if it dissolved completely. The supernatant was sufficiently clean to permit reliable light-scattering measurements and gave a value of reduced intensity slightly lower than that for the 4.00 M NaCl solution.

Discussion

The Double-logarithmic Relations of the c.m.c. and the Micellar Molecular Weight to the Ionic Strength. Figure 3 shows the Corrin-Harkins plot for dodecyltrimethylammonium chloride in the presence of NaCl. The data of previous workers[8,10] are also plotted. It is seen that the Corrin-Harkins equation

$$\log C_0 = -0.631\log(C_0+C_s) - 2.794 \quad (3)$$

proposed by Emerson and Holtzer[10] can be extended up to 4.00 M NaCl. In previous papers[1,13] we have

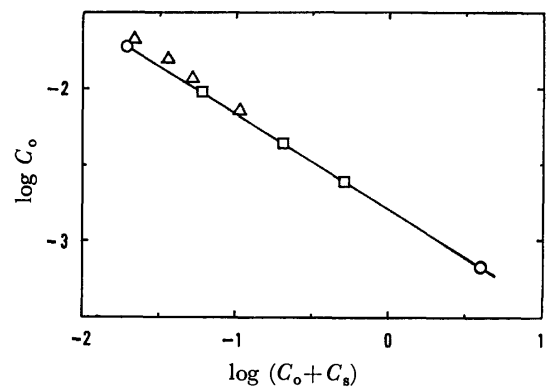

Fig. 3. The Corrin-Harkins plot for the micelles in NaCl solutions.
○: Present results, △: Kushner and his coworkers,[8]
□: Emerson and Holtzer.[10]

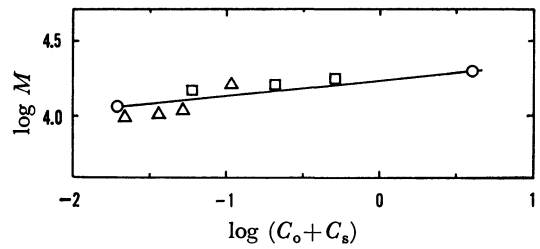

Fig. 4. The double-logarithmic relation of micellar molecular weight with ionic strength in NaCl solutions.
○: Present results, △: Kushner and his coworkers,[8]
□: Emerson and Holtzer.[10]

pointed out that the linear Corrin-Harkins relation holds only when spherical micelles are formed; now we have confirmed that proposition. For the stabilization of spherical micelles, the added salt simply serves to shield the electrostatic effect of a charged micelle.

Figure 4 shows the double-logarithmic relation of the micellar molecular weight to the ionic strength. Together with the data of other workers,[8,10] it is represented by a linear relation:

$$\log M = 0.105 \log(C_0 + C_s) + 4.26. \quad (4)$$

The low value of the coefficient of Eq. 4 is consistent with the spherical micelles.

The scatter of the points in Fig. 4 could be partly attributed to different values of the refractive index increment: *e.g.*, the value of Kushner and his coworkers[8] is 0.155 in water, but the value of Emerson and Holtzer,[10] obtained by an extrapolation, is 0.160 in water; while our value is 0.158. But the deviation seems to occur mostly in the opposite direction.

The Factors Determining the Sphere-rod Transition. In the previous paper[1] we proposed a postulate that the salt-induced transition of the micelle shape is controlled by the ratio of the size of the polar head group to the hydrocarbon part of a surfactant molecule and by the degree of counterion binding on the micelle surface. The first factor is related to the geometrical packing of surfactant molecules in a micelle. The ionic strength where the transition occurs should be higher when the head group is more bulky; this was confirmed for the head-group homologs of dodecylammonium chloride in NaCl solutions. That is, the transition occurs at 0.07 M NaCl for dodecylammonium chloride and at 0.80 M NaCl for dodecyldimethylammonium chloride. We can now add an example of dodecyltrimethylammonium chloride, for which the transition NaCl concentration is higher than the saturated NaCl concentration.

The second factor is related to the electrostatic repulsion among polar head groups. The counterion binding on the micelle surface may be examined by changing either the counterion species or the concentration of added salt. The effect of counterion species on the size of dodecyltrimethylammonium micelles in water was investigated by means of light scattering; it was found that only spherical micelles are formed, as suggested by the observed low aggregation numbers.[14-17] The effect of the concentration of added KBr or NaBr on the micelle size of dodecyltrimethylammonium bromide was also investigated by light scattering; it was demonstrated that only spherical micelles are formed in the presence of salt less than 0.5 mol kg^{-1}.[10,15,17]

Anacker and Ghose[18] measured the micellar molecular weight of dodecyltrimethylammonium bromide in 0.500 mol kg^{-1} sodium salt solutions and found that a large micelle with an aggregation number as high as 10 000 is formed in 0.500 mol kg^{-1} NaSCN. The large micelle must be rodlike, and its formation may be attributed to the reduced electrostatic repulsion among surfactant ions caused by the high degree of binding of SCN^- on the cationic. That is, only a strongly hydrophobic ion, SCN^-, can bind with the cationic micelle to an amount large enough to stabilize a rodlike micelle.

Consequently, we may conclude that the sphere-rod transition of dodecyltrimethylammonium micelles cannot be induced by the addition of NaCl, because Cl^- does not bind with the surfactant micelle sufficiently.

It is known that the Prins-Hermans-Princen-Mysels theory[19,20] can derive the apparent degree of ionization, p/m, of an ionic micelle, together with its "true" molecular weight, M_m, and its "true" aggregation number, m, based on the assumption of an ideal polyelectrolyte solution. Table 2 also includes these values of the micelles. The low degree of binding of Cl^- would be revealed in the rather large values of the apparent degree of ionization of the micelle, as given in Table 2.

If the hydrocarbon part of alkyltrimethylammonium is longer, the cationic is adapted to a rodlike micelle better than to a spherical micelle. Thus, hexadecyltrimethylammonium bromide can form the rodlike micelles in 0.178 and 0.233 M KBr,[12] while it forms spherical micelles in water and in 0.0130 M KBr.[14,15]

Small-angle X-ray scattering measurements demonstrated that the radius of gyration of an ionic micelle in water suddenly increases with an increase in the surfactant concentration beyond a certain value, and this change was attributed to the transition of the micelle shape from a sphere to a rod.[21,22] We can interpret such a transition as also being caused by the increase in ionic strength given by the surfactant itself.

In this concentration-induced transition of micelle shape, we can still see evidence for the counterion binding. Reiss-Husson and Luzzati[21] determined the surfactant concentration for the sphere-rod transition and tabulated its approximate values as 40×10^{-2} g cm^{-3} for hexadecyltrimethylammonium chloride and as 5×10^{-2} g cm^{-3} for hexadecyltrimethylammonium bromide. This difference in concentration for the transition could be considered to stand for the stronger binding of Br^- than Cl^- to the cationic micelle.

The authors are deeply indebted to Mrs. Keiko Kotani of the Aichi-ken Kogyo Shido-sho for her skilful gas-chromatographic analysis.

Structure of Mercury Layer Deposited on Platinum and Hydrogen-evolution Reaction at the Mercury-coated Platinum Electrode

Zenko YOSHIDA

Chemistry Division, Japan Atomic Energy Research Institute, Tokai, Ibaraki 319-11

(Received May 6, 1980)

The thermal evaporation of mercury is investigated in order to ascertain the structure of mercury electrodeposited on platinum. At first, Pt_2Hg is formed on platinum, and a hydrogen(H)-overpotential at the surface is identical with that at the mercury-free platinum. With the increase in the amount of mercury to more than the amount corresponding to PtHg, the H-overpotential increases. When a large amount of mercury is deposited, the layer is composed of three mercury compounds (Pt_2Hg, Pt_2Hg_2, and $PtHg_4$), metallic mercury, and adatom mercury. Even when a sufficiently large amount of mercury is deposited, *e.g.*, several thousand atomic layers, the H-overpotential is much less than that at a hanging mercury drop electrode (HMDE). From the general relationship between the hydrogen evolution at a metal electrode and the work function of the metal, the change in the H-overpotential with the increase in the amount of mercury is attributable to the work-function change.

In spite of the importance of hydrogen-evolution reaction at the surface of thin metal film deposited on a foreign metal from the viewpoints of corrosion and electrocatalytic reactions[1,2] at the surface and the utility of thin film electrodes, there have been only a few quantitative investigations of hydrogen evolution at thin metal film. Furuya *et al.* investigated hydrogen-evolution reaction at platinum[3] or palladium[4] deposited on gold and copper,[5] gold,[3] or arsenic[6] deposited on platinum. Through these studies they concluded that, when a monolayer metal was deposited, the hydrogen evolution at the surface was identical with that at the bulk metal to be deposited. On the other hand, at the surface of thin mercury film deposited on platinum[7] or silver,[8] the hydrogen evolution was far from that at pure mercury itself, even when the amount of mercury was sufficiently large. This phenomenon has been well known, because platinum- or silver-based thin mercury film electrodes (TMFE) have been widely used[7-14] as indicator electrodes in electroanalytical chemistry. Like mercury, silver on platinum[15] also behaved similarly. Many authors have empirically discussed the preparation and stability of the TMFE with regard to hydrogen evolution. Bruckenstein *et al.*[16] investigated the adsorption behavior of the hydrogen atom at less than a monolayer amount of mercury-coated platinum surface with regard to the structure of deposited mercury. In general, hydrogen-evolution reaction at a metal surface can be correlated to the work function of the electrode as well as the potential of zero charge and the strength of hydrogen adsorption.[17-22]

In this report, hydrogen-evolution reactions at the mercury layer, from less than a monolayer to several thousand atomic layers, deposited on platinum are described with regard to the structure of mercury. The structure of the deposited mercury was investigated by means of the thermal evaporation of the mercury, followed by the determination of the mercury atoms using flameless atomic absorption spectrophotometry (AAS).[23,24] Using this procedure, the quantitative determination of a trace amount of mercury as well as the characterization of the deposited mercury layer from the evaporation temperature are possible.

Experimental

The electrolysis and the determination of the mercury were carried out with the same electrolytic cell, potentiostat, and flameless AAS mercury analyzer as those reported previously.[23,24] A Hokuto Denko Co., Model HB-107A, wave-function generator was used for the linear-potential sweep.

The mercuric perchlorate solution was prepared by dissolving mercuric oxide in 2.5×10^{-1} M (1 M=1 mol dm^{-3}) perchloric acid, and the concentration of mercury (II) was determined by EDTA titration. Triple-recrystallized potassium perchlorate was used as the electrolyte, and the other chemicals used were of a reagent grade. The water used was distilled over 3% potassium permanganate in the presence of 0.1 M sulfuric acid, and then distilled twice. Argon (99.99% or more) was purified by passing it through a titanium sponge (700 °C). All the electrolytic measurements were carried out at 25±0.2 °C, and the potentials were referred to a saturated calomel electrode (SCE). The electrode surface area was 1.13 cm^2.

Pretreatment of Platinum.[25] The platinum plate (15×20×0.3t in mm) used as an electrode had a purity above 99.99%. It was electropolished anodically at 4—4.5 V *vs.* the platinum cathode for 10 s in a mixture of potassium chloride and sodium chloride (1+1) fused at 650 °C. Then it was kept in (1+1) perchloric acid for a few min and washed with water.

Deposition of Mercury. Mercury was deposited on the platinum by means of controlled-potential electrolysis at +0.55 V (underpotential region) or +0.20 V (more negative than the reversible potential for mercury (II)/(0)), unless otherwise mentioned. Electrolysis was carried out for 15 min in a deaerated electrolyte solution (1×10^{-1} M in potassium perchlorate and 1×10^{-3} M in perchloric acid) containing 10^{-6}—10^{-4} M of mercury (II).

Investigation of Hydrogen-evolution Reaction. Cylic Voltammetry: After the deposition of mercury, the solution containing mercury (II) was drained off and the cell was washed with an electrolyte solution (1×10^{-1} M potassium perchlorate and 1×10^{-3} M perchloric acid) five times. A voltammogram was run cathodically and then anodically at a rate of 2 mV s^{-1} in 10 ml of an electrolyte deaerated for 15 min by passing argon through.

Tafel Plot: The relation between the electrode potential and the current density (10^{-7}—10^{-3} A cm^{-2}) was galvanostatically investigated in 1×10^{-1} M of potassium perchlorate and 1×10^{-1} M of perchloric acid.

Thermal Evaporation. Immediately after the completion of the electrolysis, the mercury-coated platinum was washed with water and then ethanol; it was thereafter heated in a quartz tube while the temperature was raised at a rate of 20 °C min^{-1}. The evaporated mercury was introduced into the mercury analyzer by means of an argon stream (2 l min^{-1}). The absorption intensity of mercury was recorded against the temperature (*T*-Hg curve).[23]

Results

Structure of Mercury Layer Deposited on Platinum. The *T*-Hg curves of mercury (0.12—4.1 μg cm^{-2}) deposited on platinum are illustrated in Fig. 1. With the increase in the amount of mercury deposited, one to five peaks are observed. The development of each peak with the increase in the total mercury deposited is shown in Fig. 2. With a small amount of mercury (less than 0.29 μg cm^{-2}), only Peak I at 300 °C is observed (Region A in Fig. 2). After the saturation of Peak I at 0.29 μg cm^{-2}, Peak II at 160 °C and Peak III at 110 °C start to be observed (Region B). Peak II is also saturated; the saturated amount under Peak II is 0.29 μg cm^{-2}. With more mercury, Peak III develops, and Peak IV at around 20 °C and Peak V at 190 °C appear (Regions C and C'). While the ratio of the amount of mercury under Peak III to that under Peak V

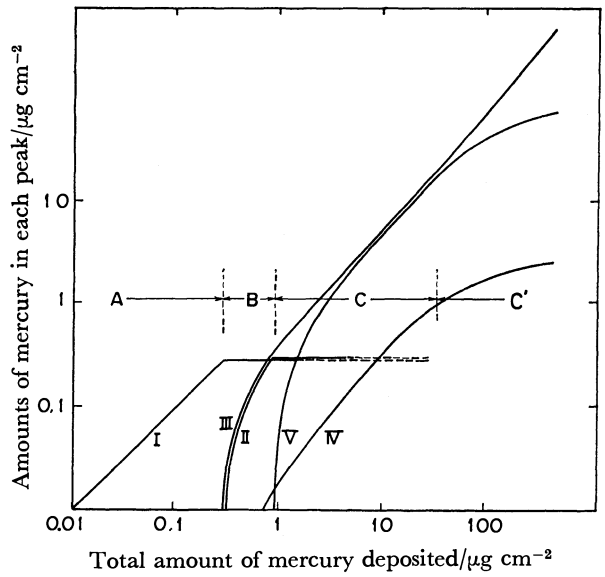

Fig. 2. Developments of various peaks in *T*-Hg curve with the increase of the amount of mercury deposited.

nearly equals unity in Region C, the ratio increases with the increase of mercury in Region C'.

The character of each peak is as follows;

Peak I. When mercury is deposited at +0.55 V (underpotential region), even in a rather concentrated mercury (II) solution (10^{-4} M), the amount of mercury under this peak, I, is also saturated at 0.29 μg cm^{-2}. Similarly to the determination of the underpotential shift, ΔU, for mercury deposition on gold,[23] the ΔU value for mercury deposition on platinum was determined to be 0.45 V from the relation between the electrode potential of controlled-potential electrolysis and the amount of mercury deposited (*E*-Hg plot). Moreover, the first wave in the *E*-Hg plot is saturated at 0.29 μg cm^{-2} of mercury, which agrees well with the saturation of Peak I in the *T*-Hg curve. In this connection, the relation between the amount of mercury deposited and the amount of hydrogen adsorbed at the platinum surface, Q_H-Hg, was investigated according to the procedure proposed by Bruckenstein *et al.*[16] The quantity of adsorbed hydrogen, Q_H, decreases linearly with the increase of mercury, and with 0.29 μg cm^{-2} of mercury Q_H comes to be zero. This indicates that the deposition of the first mercury layer proceeds *via* a site mechanism[16] showing a combination of two platinum surface atoms with one mercury atom deposited. According to the results obtained by the *E*-Hg and Q_H-Hg measurements, it is evident that Peak I in the *T*-Hg curve corresponds to the evaporation of mercury from the stable mercury layer, Pt_2Hg, which is deposited at the underpotential. Actually, the saturated value, 0.29 μg cm^{-2}, is about one-half of the amount of mercury calculated by assuming that each platinum surface atom is associated with one mercury atom and that a roughness factor of the electrode is unity.

Peak II. Because Peak II is saturated with the same amount of mercury as Peak I (0.29 μg cm^{-2}), this peak corresponds to the evaporation of one mercury

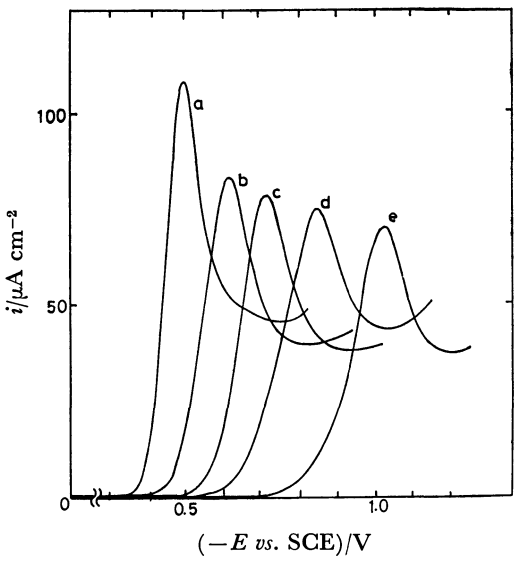

Fig. 3. Voltammograms for hydrogen evolution at platinum electrode with and without mercury.
Electrolyte: 1×10^{-1} M potassium perchlorate and 1×10^{-3} M perchloric acid. Rate of potential scanning: 2 mV s^{-1}. Amounts of mercury deposited ($\mu g\ cm^{-2}$): (a) 0—0.29, (b) 8, (c) 22, (d) 60, (e) more than 200.

atom from Pt_2Hg_2 (or 2PtHg), thus forming Pt_2Hg.

Peaks III and IV. Peaks III and IV were previously reported to be due to the evaporation of metallic mercury and adatom mercury, respectively.[23,24]

Peak V. Peak V is identical with that of the evaporation of mercury from the $PtHg_4$ alloy produced by the procedure reported by Barlow *et al.*[26] and identified by X-ray diffraction.

Hydrogen-evolution Reaction at the Mercury-coated Platinum Electrode. Voltammograms for hydrogen-evolution reaction at the platinum electrode with and without mercury are illustrated in Fig. 3. Although the reduction potential of the hydrogen ion should be determined using a constant and small current density, the hydrogen-reduction peak potential, E_p, in the voltammogram is employed for convenience for the study of the H-overpotential in the present study. The peak potential, E_p, in the second cathodic potential scan is adopted because E_p in the second scan is more negative than that in the first scan as a result of the structural change of mercury film during the first cathodic polarization.[7] E_p at the mercury-free platinum electrode is -0.50 V. The relation between E_p at the mercury-coated platinum electrode and the amount of mercury deposited is shown by Curve (a) in Fig. 4. With less than 0.29 $\mu g\ cm^{-2}$ of mercury, E_p is identical with that at platinum. With more than 0.29 $\mu g\ cm^{-2}$, E_p shifts to a negative value with the increase in the amount of mercury. With more than 200 $\mu g\ cm^{-2}$, E_p is constant at -1.05 V, E_p^1. Even when 20 mg cm^{-2} of mercury is deposited, E_p halts at E_p^1.

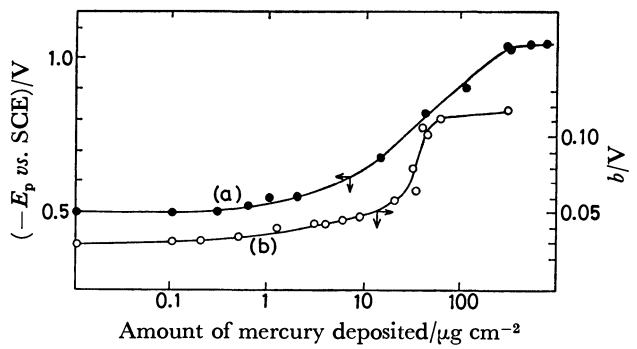

Fig. 4. Hydrogen evolution reaction at mercury-coated platinum electrode with various amount of mercury.
(a): Peak potential in cyclic voltammogram, E_p, (b): Tafel slope b.

As may be seen in Fig. 3, the slope of the voltammogram in the range of low current density decreases when an electrode with a larger amount of mercury is used. To study the polarization characteristics more quantitatively, a galvanostatical investigation of the Tafel plot was carried out. The b slope in the Tafel equation, $\eta=a+b\log i$, where a and b are constants and η is the overpotential, for a hydrogen-evolution reaction is changed with the amount of mercury deposited, as is illustrated by Curve (b) in Fig. 4. With less than 1 $\mu g\ cm^{-2}$ of mercury, b is about 0.030 V, which is identical with the value observed at mercury-free platinum. With the mercury is between 1 and 40 $\mu g\ cm^{-2}$, the slope changes from 0.030 to 0.085 V, and with more than 40 $\mu g\ cm^{-2}$ of mercury, the slope is from 0.085 to 0.120. The b slope, 0.120 V, is identical with that at a hanging mercury drop electrode (HMDE). The amount of mercury, 40 $\mu g\ cm^{-2}$, corresponds to the boundary amount of mercury between C and C′ in Fig. 2.

Stability of Mercury Layer Deposited on Platinum. The stability of the mercury layer was investigated by measuring the T-Hg and the hydrogen-evolution reaction after lefting it stand at 25 °C in a deaerated supporting electrolyte for a definite period of time. The relation between the amount of mercury and E_p, or the b value obtained at the electrode on which mercury had been deposited for 15 min in 10^{-4}—10^{-6} M mercury (II) and which was left standing for 30 min (Fig. 4), was identical with that obtained at the electrode on which mercury had been deposited for 30 s in 10^{-3}—10^{-5} M mercury (II) and which left standing for 2—5 min. Therefore, it is concluded that a standing time within 30 min exerts no significant effect on hydrogen evolution at the surface, regardless of the amount of mercury deposited. When the amount of mercury deposited was less than 10 $\mu g\ cm^{-2}$, no discrepancy was found in T-Hg and hydrogen evolution between those obtained after standing for 30 h and those obtained after only 30 min. When platinum coated with more than 10 $\mu g\ cm^{-2}$ of mercury was allowed to stand for more than 3 h, the T-Hg curve changed from that obtained after 30 min standing; *i.e.*, Peak III decreased and Peak V increased. Also, after more than 20 h's standing, T-Hg showed only Peak V. Hydrogen evolution also changed with the standing time, much as with the T-Hg curve. After 2 h's standing, E_p began to shift to a more positive value; after 3, 5, and 12 h's standings, E_p were -0.95, -0.82, and -0.65 V, respectively.

Table 1. Structure of mercury deposited on platinum and hydrogen-evolution reaction at the surface

Region	Amount of mercury deposited / $\mu g\ cm^{-2}$	Structure of mercury layer	E_p *vs.* SCE / V	b / V
A	0—0.29	Pt_2Hg	−0.50	0.030
B	0.29—1	Pt_2Hg_2+Hg	−0.50→−0.53	0.030→0.035
C	1—40	$Pt_2Hg_2+Hg+PtHg_4+Hg_{adatom}$	−0.53→−0.80	0.035→0.085
C′	More than 40	As region C but $Hg>PtHg_4$	−0.80→−1.05	0.085→0.118

With more than 20 h's standing, E_p reached −0.60 V, which was only 100 mV more negative than that at platinum.

The platinum contents in a mercury layer at various standing times were determined colorimetrically by means of a modified tin(II) chloride method[27] after dissolving the deposited mercury layer in nitric acid (60 °C) and treating it with aqua regia. The platinum content increased with the standing time; after standing for 3, 5, 12, and more than 20 h, the platinum contents were 10.5, 12.8, 16.0, and 19.2 at. %. The final platinum content, 19.2%, agrees well with the finding that Peak V in the *T*-Hg curve is $PtHg_4$.

Discussion

The structure of the mercury layer deposited on platinum and the hydrogen-evolution reaction at the surface are summarized in Table I as a function of the amount of mercury deposited. Although many platinum–mercury alloys, such as $PtHg_4$, $PtHg_2$, PtHg, Pt_2Hg, and Pt_3Hg, have been identified,[28] $PtHg_4$, PtHg, and Pt_2Hg are the main components in the mercury layer deposited on platinum. Particularly in the underpotential region, Pt_2Hg is preferentially formed (Region A in Fig. 2).

Bruckenstein *et al.*,[16] on the basis of the results of Q_H-Hg measurement, suggested the formation of Pt_2Hg in the initial step of the deposition. They deposited mercury at a more negative potential than the reversible potential for mercury (II)/(0) and reported that Q_H was not equal to be zero even when the platinum surface was covered with mercury in an amount large enough to saturate the Pt_2Hg layer. In the present study, if mercury is deposited on platinum in the underpotential region, Q_H comes to be zero at the electrode with mercury corresponding to the completion of the Pt_2Hg layer; this indicates that Pt_2Hg is preferentially formed at the underpotential. The reoxidation current peak, from which Pt_2Hg can be identified, was not observed in the anodic stripping voltammograms reported by Bruckenstein *et al.* Two evaporation peaks, Peak I and Peak II in the *T*-Hg curve in Region B, of mercury from Pt_2Hg_2 (or 2PtHg) indicates that the evaporation of one mercury atom from Pt_2Hg_2 requires less energy than that required for the evaporation of mercury from Pt_2Hg. This evaporation behavior obviously supports the preferential formation of Pt_2Hg at the initial step of the deposition. Bruckenstein *et al.* also described the development of $PtHg_4$. The anodic stripping peak of mercury from $PtHg_4$, however, was too broad to be distinguished from such other layers as Pt_2Hg. A well-defined peak, V, which corresponds to the evaporation of mercury from $PtHg_4$, is observed in the *T*-Hg curve in the present work. Although Bruckenstein *et al.* reported that $PtHg_2$ was formed on PtHg, $PtHg_2$ was not observed in the *T*-Hg curve.

The rate-determining step of the hydrogen-evolution reaction has been widely recognized[1] to be one of the following three reaction steps: (*i*) the discharge of the hydrogen ion, (*ii*) the chemical desorption of the hydrogen molecule, or (*iii*) electrochemical desorption. Because the Tafel slopes, b, for hydrogen evolution at Pt_2Hg and mercury-free platinum are 0.030 V, it is considered that the rate-determining step at their surfaces is (*ii*).[29] In the C′ region, the b value is 0.110—0.120 V, which is identical with that at the HMDE. The rate-determining step at their surfaces is (*i*),[30] which agrees with the dominant formation of metallic mercury in the C′ region, Peak III in the *T*-Hg curve. Although Peak III is observed in the *T*-Hg curves whenever more than 0.29 $\mu g\ cm^{-2}$ of mercury is deposited (Regions B, C, and C′), the electrode property of the surface is far from that of mercury in Regions B and C. In the C and C′ regions, E_p is shifted in the negative direction with the increase in mercury. The relation between E_p and the amount of mercury, given as Curve (a) in Fig. 4, can be expressed empirically by the following equation:

$$E_p = E_p^{Pt} + \alpha W(E_p^{l} - E_p^{Pt})/(1 + \alpha W), \qquad (1)$$

where E_p^{Pt} and W are E_p at mercury-free platinum and the amount of mercury in $\mu g\ cm^{-2}$, respectively. Comparing the experimental results illustrated as Curve (a) in Fig. 4 with Eq. 1, the constant, α, is determined to be 0.026.

Even at a freshly prepared electrode with a large amount of mercury, the hydrogen-evolution peak was at −1.05 V, far positive than that at the HMDE. The platinum content in the mercury layer on such an electrode was confirmed by chemical analysis to be less than 0.01 wt%. Butler *et al.*[31] discovered, by using a dropping mercury electrode, that the presence of 0.027 wt% platinum did not affect the hydrogen-evolution reaction. The present study also confirmed the absence of any effect when a hanging mercury drop containing 0—0.35 wt% platinum was used. Therefore, the lower H-overpotential at the mercury-coated

platinum with a large amount of mercury is not attributed to the trace amount of platinum dissolved in the mercury layer.

Furuya *et al.*[15] reported that the exchange-current density for hydrogen evolution at twenty atomic layers of silver deposited on platinum was far from that at pure silver metal. On the other hand, in such systems as copper on platinum,[5] gold on platinum,[3] platinum on gold,[3] and palladium on gold,[4] with the deposition of a monolayer metal, hydrogen evolution changed from that at the base metal to that at the deposited metal. Considering the hydrogen-evolution reaction at the deposited thin metal film, the combinations of deposited metal and base metal can be classified into two groups as follows: (*i*) Deposited metal forms stable intermetallic compounds with the base metal. The chemical interaction is too strong, and the property of the surface of the deposited metal is affected by an underlying layer, such as the base metal itself and/or a stable-compound layer formed. This group includes Pt/Hg and Pt/Ag, which show intermetallic compounds, PtHg, $PtHg_2$, and $PtHg_4$, and Pt_3Ag, PtAg, and $PtAg_3$, in the phase diagrams.[28] (*ii*) Deposited metal forms a solid solution with the base metal at any ratio instead of the formation of the stable intermetallic compounds. The property of the deposited metal atom is rather independent of the property of the base metal, and the electrochemical property of the deposited metal surface is hardly affected by the base metal when the base metal surface is completely covered with the deposited metal film. This group includes Pt/Cu, Pt/Au, and Pd/Au.

The remarkable standing-time effect on mercury-coated platinum is explained by the growth of stable intermetallic compounds because of the large interaction between mercury and platinum. In addition, it is also considered that the diffusion coefficient of base-metal atoms in metallic (liquid) mercury is much larger than that in other solid metals. In connection with the work function of the thin metal film surface, it has been reported that metal monolayers deposited on foreign substrates, such as alkali metals deposited on nickel or tungsten,[32-34] show the same work-function value as that of bulk alkali metal. In these systems, no intermetallic compounds have been reported, and the diffusion coefficient of nickel or tungsten in an alkali solid metal is smaller than that in liquid metal.

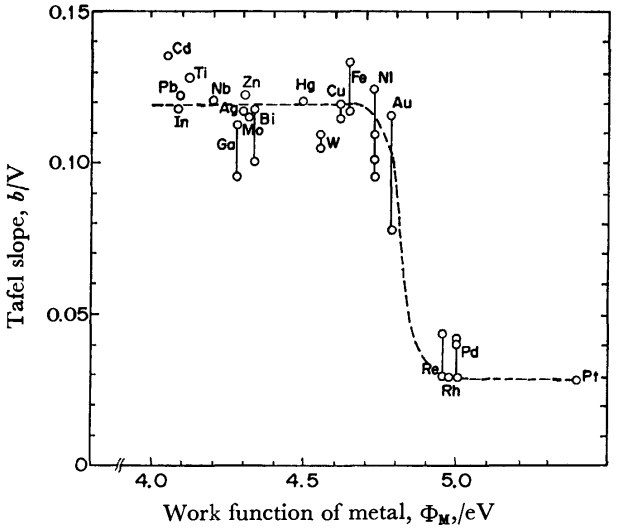

Fig. 5. Relation between Tafel slope *b* and work function of metal.
Tafel slopes *b* are cited from Ref. 35. Work function of metals are cited from Refs. 17 and 18.

Generally, hydrogen evolution at the metal surface is related to the work function of the metal.[19,20] Trasatti suggested a linear relationship between the H-overpotential at a metal surface and the work function of the metal (see Fig. 1 in Ref. 19). The relation between the Tafel slope, *b*, previously reported and the work function of the metal is shown in Fig. 5. It is evident that the *b* slopes are constant at 0.030 and 0.120 V, when the work-function values are more than 4.9 eV and less than 4.7 eV, respectively. When the work function of the metal is between 4.7 and 4.9 eV, the *b* slope shows an intermediate value of 0.030—0.120 V.

Because E_p and the *b* slope at the surface of monolayer mercury deposited on platinum is identical with those at the platinum surface, the work function of monolayer mercury film can be said to be close to that of platinum, but not to that of mercury. It is also estimated, from the difference between E_p^1 and E_p at the HMDE, that the work function at the electrode surface with a large amount of mercury deposited is still different from that of pure mercury. The experimental relation (Curve(b) in Fig. 4) shows a remarkable change in the *b* slope when 40 $\mu g\ cm^{-2}$ of mercury is deposited. Therefore, it is considered that the work function of the surface is around 4.8 eV. This is supported by the facts that the E_p values observed at gold, nickel, and copper, the work-function values of which are 4.78, 4.73, and 4.70 eV, are −0.74, −0.68, and −0.84 V, respectively, and that the E_p value at the mercury-coated platinum with 40 $\mu g\ cm^{-2}$ of mercury is −0.8 V.

Through the present study it is clear that the hydrogen-evolution reaction at the mercury-coated platinum is characterized by the structure of the mercury layer, which affects the work function of the electrode surface.

Because the platinum-based TMFE is found to be troublesome with respect to the stability, the property of thin mercury film deposited on various metals will be discussed in a subsequent paper in preparation for developing an ideal TMFE.

The author would like to thank Dr. Sorin Kihara, professor Taichiro Fujinaga and his coworkers, and Dr. Kenji Motojima for their helpful discussions and useful suggestions.

Preparation of an Ideal Thin Mercury Film Electrode and Its Electrochemical Property

Zenko Yoshida

Chemistry Division, Japan Atomic Energy Research Institute, Tokai, Ibaraki 319-11

(Received May 6, 1980)

In order to get an ideal thin mercury film electrode, the structure of mercury film electrodeposited on foreign metals was investigated with the aid of the thermal-evaporation behavior of mercury and correlated to the electrode properties of the mercury-deposited surfaces. A mercury layer deposited on gold, copper, nickel, or platinum consists of stable mercury compounds with the base metal at their interface and a uniform metallic mercury layer on them. The hydrogen(H)-overpotential at the mercury-coated surface increases with the increase in the amount of mercury deposited. Mercury on molybdenum or stainless steel forms island-like metallic mercury droplets by electrodeposition. The H-overpotential at the surface is identical with that at molybdenum or stainless steel without mercury. Mercury deposited on lead or zinc easily forms a stable amalgam with the base metal, and no metallic mercury is present. The H-overpotential at the surface is slightly less than that at a base metal without mercury. A nickel-based thin mercury film electrode is recommended for such electroanalytical uses as anodic stripping voltammetry.

Thin mercury film electrodes (TMFE) are widely used[1-6] in such electroanalytical fields as stripping analysis. Platinum and silver are usually used as base metals of such TMFE. It has been well known[1,4] that the hydrogen(H)-overpotential at the TMFE is less than that at pure mercury, even when a fairly large amount of mercury is deposited, and that the H-overpotential decreases with the standing time. These disadvantages of the TMFE restrict the electrochemical and analytical use of the TMFE. Generally, the reason for the lowering of the H-overpotential has been empirically understood[1,4] as the diffusion of base metal atoms into the mercury layer or the droplet formation of deposited mercury. However, few reports have discussed the H-overpotential at the mercury-coated electrode theoretically and systematically.

Regarding with the hydrogen-evolution reaction or other electrode properties at thin metal film electrodes, combinations of deposited metals and base metals are divided into two groups.[7] In one group, the monolayer metal deposited shows an electrode property identical with that at the pure metal to be deposited,[8-10] while in the other the electrode property at the thin metal film electrode is different from that at the pure metal, even when the amount of metal deposited is fairly large.[7,11] As a typical example of the latter, the mercury-coated platinum electrode was investigated in the preceding report.[7] The cause of the gradual change in electrode properties with the increase in the amount of mercury was explained by the development of the stable platinum-mercury intermetallic compounds, which affect the electrode property of the surface of mercury deposited. Moreover the decrease in the H-overpotential with the standing time was attributed to the formation of $PtHg_4$.

From the analytical point of view, a stable indicator electrode with a large H-overpotential is required. Mercury is indispensable because of its large H-overpotential. On the other hand, a suitable base metal for the TMFE should make the stable mercury layer both mechanically and chemically and should not lower the H-overpotential of mercury.

In the present report, the structure of the mercury layer deposited and the hydrogen-evolution reaction at the deposited mercury surface are studied employing gold, copper, nickel, molybdenum, lead, zinc, and stainless steel as base metals. On the basis of these results, a criterion for selecting the most preferable metal as the base metal of the TMFE is suggested.

Experimental

The metals used were of purities more than 99.9%. Mercury (II) and supporting electrolyte solutions were prepared using specially purified water as has been reported previously.[7] The electrolytic measurement and determination of mercury vapor by flameless atomic absorption spectrophotometry (AAS) were carried out by means of the apparatus described in the previous paper.[7] The electrolytic measurements were carried out at 25 ± 0.5 °C, and the potentials were referred to a saturated calomel electrode (SCE) unless otherwise mentioned. The surface area of the electrode was 1.13 cm^2.

Pretreatments of the Metals.[12] The gold, copper, nickel, molybdenum, lead, zinc, and stainless steel used as base metals were electropolished anodically by using a stainless steel cathode at applied potentials of 6 V in a cyanide bath,[13] at 5 V in 60% phosphoric acid in water, at 5 V in 60% sulfuric acid in water, at 5 V in 12.5% sulfuric acid in methanol, at 6 V in 60% nitric acid in methanol, at 2.5 V in 20% nitric acid in methanol, and at 8 V in 64% phosphoric acid + 15% sulfuric acid in water, respectively. Then the polished metals were washed with water.

Deposition of Mercury. Mercury was electrodeposited on metals, except on copper, by controlled-potential electrolysis for 15 min in a deaerated electrolyte solution which contained various concentrations of mercury (II), 1×10^{-1} M (1 M= 1 mol dm^{-3}) in potassium perchlorate, and 1×10^{-3} M in perchloric acid. The electrodeposition potentials of mercury on gold, nickel, molybdenum, lead, zinc, and stainless steel were at +0.20, −0.45, −0.10, −0.50, −1.30, and 0.0 V, respectively. Mercury was deposited on copper spontaneously when the copper plate was dipped in a solution containing mercury (II).

H-overpotential Measurements. The hydrogen-reduction peak potential, E_p, in a cyclic voltammogram which was obtained in 1×10^{-1} M potassium perchlorate and 1×10^{-3} M perchloric acid at a potential scanning rate of 2 mV s^{-1} was employed for convenience in studying the H-overpotential.[7] The cathodic potential scan was started at potentials about

50 mV more negative than the dissolution potential of the electrode. The galvanostatic measurements were carried out by the procedures described previously.[7]

Thermal Evaporation of Mercury (T-Hg curve). In order to ascertain the structure of the mercury layer deposited, the thermal-evaporation behavior of mercury was investigated by means of the procedure and apparatus reported previously.[7,13]

Results

Mercury-coated Gold, Copper, or Nickel. Structure of Mercury Deposited: A mercury-coated electrode was heated in an argon stream (2 l min^{-1}) at a raising rate of temperature of 20 °C min^{-1}, and the evaporated mercury was detected by means of flameless AAS (*T*-Hg curve).[13] With the increase in the amount of mercury, one to four peaks were observed.

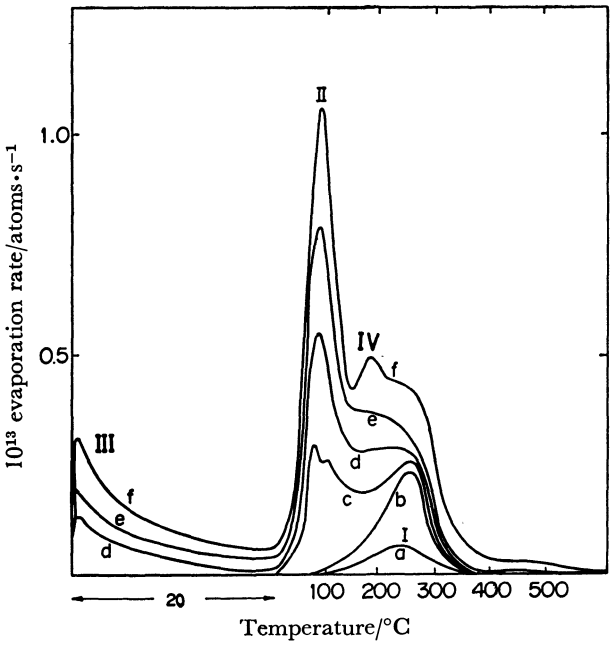

Fig. 1. *T*-Hg curves of mercury deposited on gold.
Amounts of mercury deposited (μg cm^{-2}): (a) 0.07, (b) 0.20, (c) 0.50, (d) 0.97, (e) 1.28, (f) 2.32.

The *T*-Hg curves of mercury, 0.07—2.3 μg cm^{-2}, deposited on gold are illustrated in Fig. 1. Peaks I, II, III, and IV are observed at 243, 100, 20, and 160 °C, respectively. These *T*-Hg curves are analogous to those of mercury deposited on platinum.[7] By comparing them with the results of the detailed investigations of mercury on platinum[7] or gold[13] in the previous papers, Peaks I, II, III, and IV in Fig. 1 are identified as the mercury evaporations from a stable first mercury layer, metallic mercury, adatom mercury, and alloy between gold and mercury, respectively. With a small amount of mercury (less than 0.20 μg cm^{-2}), only Peak I is observed, and this peak is saturated at 0.20 μg cm^{-2}. In the previous study,[7] the structure of the first mercury layer on platinum was confirmed to be Pt_2Hg. Assuming that each mercury atom deposited is combined with one platinum or gold atom of the electrode surface, with a roughness factor of unity, the amount of mercury which makes the complete monolayer should be about 0.5 μg cm^{-2}, because the lattice constants of platinum or gold are nearly equal to 4 Å. In view of the saturated amount of the first mercury layer on gold (0.20 μg cm^{-2}), and the generally accepted structure of stable mercury-gold intermetallic compounds,[14] the first mercury layer on gold is considered to be Au_xHg, where x is 2 or 3.

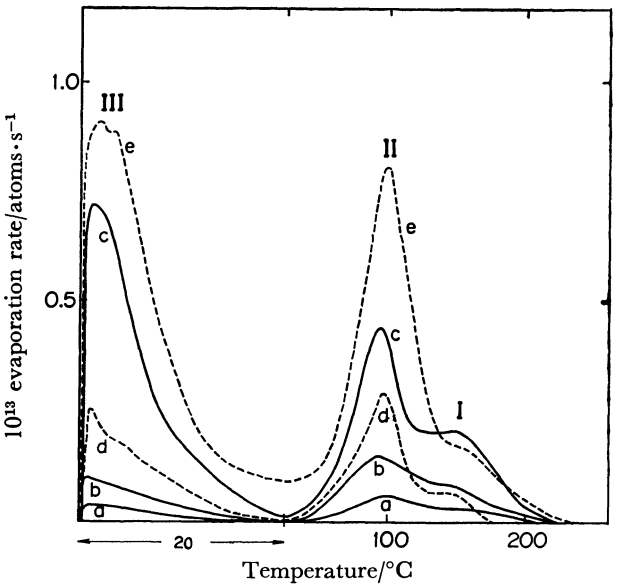

Fig. 2. *T*-Hg curves of mercury deposited on copper and nickel.
Amounts of mercury deposited (μg cm^{-2}): (a) 0.06, (b) 0.16, (c) 0.64, (d) 0.25, (e) 0.95. Based metal: (a)—(c) copper, (d), (e) nickel.

The mercury layer deposited on copper or nickel shows a different *T*-Hg behavior from those on platinum and gold, as is shown in Fig. 2. Even when less than 0.20 μg cm^{-2} of mercury is deposited, three peaks are observed in the *T*-Hg curves, *i.e.*, Peak I at about 160 °C, Peak II at 100 °C, and Peak III at about 20 °C. With the increase in mercury, these peaks develop and Peak I is not saturated. The mercury evaporates from the stable layer at a lower temperature (Peak I at 160 °C) than that of mercury on platinum or gold, indicating that the interaction between mercury and copper or nickel is less than that between mercury and platinum or gold. The idea of a small interaction is also supported by the large adatom layer on copper or nickel, shown in Fig. 2, because a large amount of the adatom layer was formed on the glassy carbon (GC) electrode,[15] which has very weak interaction with mercury. The absence of any preferential saturation of the stable mercury layer on copper or nickel can also be explained by the small interaction with mercury.

The large amount of mercury (100—250 μg cm^{-2}) deposited on gold, copper, or nickel shows the *T*-Hg curves shown in Fig. 3. The *T*-Hg curves of mercury deposited on platinum[7] or GC[15] previously investigated are also illustrated in this figure. The mercury deposited on GC is purely metallic and is unstable from the mechanical point of view, for no stable mercury layer

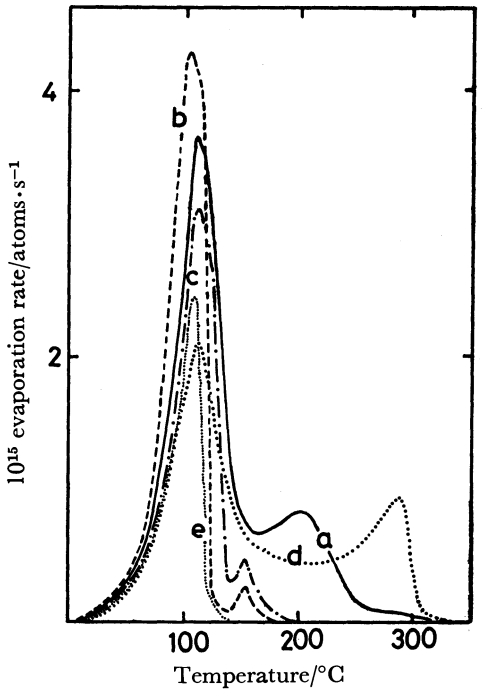

Fig. 3. *T*-Hg curves of mercury deposited on gold, copper, nickel, platinum, and glassy carbon.
Amounts of mercury deposited (μg cm^{-2}): (a) 230, (b) 172, (c) 138, (d) 190, (e) 97. Based metal: (a) gold, (b) copper, (c) nickel, (d) platinum, (e) glassy carbon.

is formed at the GC-mercury interface. The mercury layer deposited on platinum or gold consists of the stable mercury and metallic mercury layer, and the stable mercury occupies quite a large portion of the total deposited mercury, while a small amount of the stable mercury is formed in the mercury layer deposited on copper or nickel. The mercury layer on copper or nickel is mechanically stable because of the interaction between mercury and the base-metal surfaces, though the interaction is rather small.

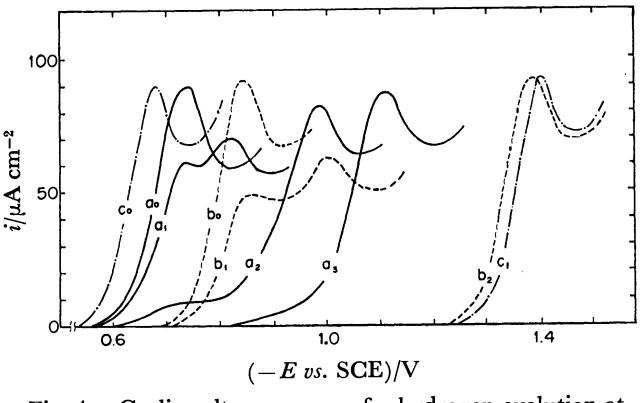

Fig. 4. Cyclic voltammograms for hydrogen evolution at gold, copper, and nickel electrodes with and without mercury.
Electrolyte: 1×10^{-1} M potassium perchlorate and 1×10^{-3} M perchloric acid. Rate of potential scanning: 2 mV s^{-1}. Based metal: (a) gold, (b) copper, (c) nickel. Amounts of mercury deposited (μg cm^{-2}): (a_0) 0, (a_1) 0.40, (a_2) 0.85, (a_3) more than 1.0, (b_0) 0, (b_1) 1.1, (b_2) more than 80, (c_0) 0, (c_1) more than 100.

Hydrogen-evolution Reaction at Mercury-coated Gold, Copper, or Nickel. The cathodic parts of cyclic voltammograms for hydrogen evolution in an electrolyte solution containing 1×10^{-1} M in potassium perchlorate and 1×10^{-3} M in perchloric acid, obtained at the gold, copper, or nickel electrode with and without mercury, are shown in Fig. 4. The cyclic voltammograms in the second potential scan are adopted in order to determine the H-overpotential at mercury-coated metals for the same reason as in the previous paper.[7] Two waves are frequently observed in voltammograms when the amount of mercury is small. The first peak corresponds to the hydrogen evolution at the base-metal surface which is not covered with mercury. The peak potential of this wave is identical with that at a base metal without mercury, and the peak current of this wave decreases with the increase in mercury. The second peak potential is employed as the H-overpotential at a mercury-coated electrode.

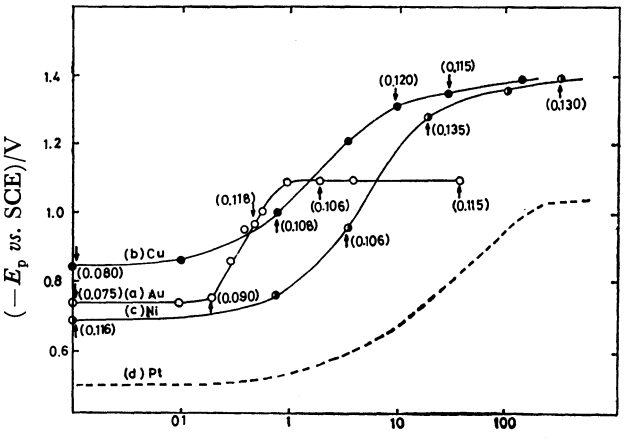

Fig. 5. Hydrogen overpotential, E_p, and Tafel slope, b, at mercury-coated gold, copper, and nickel with various amounts of mercury.
Based metal: (a) gold, (b) copper, (c) nickel, and (d) platinum (------).

The relation between the amount of mercury deposited and the second peak potential, E_p, observed is illustrated in Fig. 5. The value in parentheses indicates the Tafel slope, b[7] (in V), for the hydrogen-evolution reaction at the electrode which corresponds to the plot indicated with an arrow. When two waves are observed in a cyclic voltammogram, the Tafel slope for the second wave is employed. The dashed curve (d) shows the relation for mercury deposited on platinum, which was reported in the previous paper.[7] With the increase in the amount of mercury deposited, the b slope increases and E_p shifts to a more negative value. As has been described in the preceding section, the coverage of the surface of a gold or platinum electrode is complete with the deposition of a monolayer amount of mercury because of the large interaction between gold or platinum and mercury. E_p does not change from that at mercury-free gold or platinum when less than a monolayer amount

of mercury is deposited. With a larger amount of mercury than the monolayer, the coverage with the mercury deposited is considered not to be uniform because of the small interaction between the first mercury layer and the subsequent mercury layer to be deposited. Moreover, it is obvious from the *T*-Hg curve that compounds are formed between a base metal and mercury. On the other hand, the preferential monolayer formation is not observed when mercury is deposited on copper or nickel, because the interaction between these base metals and mercury is small. Also, the coverage of the surface increases slowly with the increase in the amount of mercury. Therefore, the gradual change in E_p with the increase in the amount of mercury, as shown in Fig. 5, is attributable both to the change in the coverage of the electrode surface and to the formation of the stable compounds.

When more than 1, 80, and 100 μg cm^{-2} of mercury are deposited on gold, copper, and nickel, the E_p values show limiting values, E_p^l, at −1.10, −1.38, and −1.40 V, respectively. These E_p^l values are more positive than that at the HMDE.

Stability of Mercury Layer Deposited on Gold, Copper, or Nickel. When the mercury (200 μg cm^{-2})-coated copper was allowed to stand at 25 °C for 70 h in a deaerated supporting-electrolyte solution, Peak II at 110 °C in the *T*-Hg curve (b) in Fig. 3 decreased to one-half of the initial peak height; instead, a peak at 164 °C and an additional peak at 175 °C develop. With the same standing time (70 h), E_p for hydrogen evolution shifted from −1.38 to −1.10 V. In view of the results of the previous study of the mercury-coated platinum,[7] the effect of the standing time on the *T*-Hg curve and H-overpotential may be attributed to the structural change in the deposited mercury layer due to the alloy formation of mercury with copper which has diffused into the mercury layer. In this connection, the peak height at 110 °C in the *T*-Hg curve for the mercury (200 μg cm^{-2})-coated platinum decreased to one-half within the standing time of only 3 h, as has been reported previously,[7] and E_p shifted from −1.05 to −0.95 V during the standing.

The mercury (200 μg cm^{-2})-coated gold and nickel are chemically stable, and no change in the *T*-Hg curve or H-overpotential is observed with a standing time of up to 70 h.

Mercury-coated Molybdenum or Stainless Steel. Only the peak at 110 °C was observed in the *T*-Hg curves for mercury (0—500 μg cm^{-2}) deposited on these metals. No peak at a higher temperature in the *T*-Hg curve was observed, even when the amount of mercury was increased up to 2—3 mg cm^{-2} and when the mercury-coated electrode was allowed to stand for 70 h. By considering the analogous *T*-Hg curve of mercury deposited on the GC electrode,[15] it is clear that the chemical interaction between mercury and molybdenum or stainless steel is negligibly small. In addition, the amount of mercury deposited on these metals decreased with the standing time.

Cyclic voltammograms at mercury (0—500 μg cm^{-2})-coated molybdenum or stainless steel were identical with those at mercury-free molybdenum or stainless steel; *i.e.*, the E_p values were −0.78 or −0.81 V, respectively.

These results indicate that mercury deposited on these metals forms an island-like deposit instead of a stable mercury layer and that the coverage of the surface of these metals by mercury is incomplete.

Mercury-coated Lead or Zinc. Mercury deposited on lead or zinc formed stable compounds with the base metal and no metallic mercury layer existed at the electrode surface, even when the amount of mercury was 1 mg cm^{-2}; this is apparent in the *T*-Hg curves in Fig. 6.

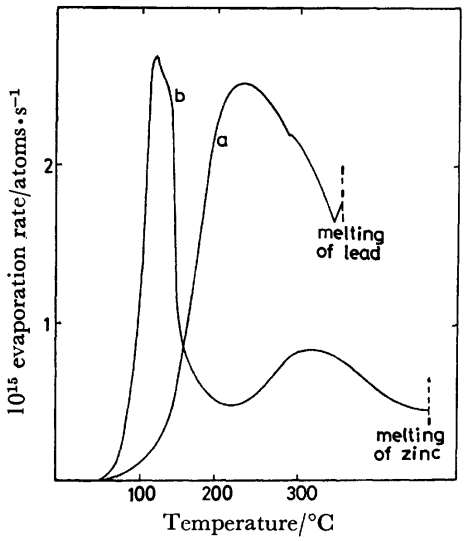

Fig. 6. *T*-Hg curves of mercury deposited on lead and zinc.
Amounts of mercury deposited: more than 1 mg cm^{-2}.
Based metal: (a) lead, (b) zinc.

The hydrogen-evolution potentials, E_p, at a large amount of mercury (about 1 mg cm^{-2})-coated lead or zinc were at −1.43 or −1.32 V, about 100 mV more positive than those at mercury-free lead (at −1.50 V) or zinc (at −1.43 V).

Discussion

Considering the structure of the mercury layer deposited on metals and the hydrogen-evolution reactions at their surfaces described in the Results, base metals can be classified into three groups.

The metals in Group I have fairly large interactions with mercury, and stable mercury layers are formed at the mercury-base metal interfaces. With more than 0.3 μg cm^{-2} of mercury, a metallic mercury surface appears. The H-overpotentials at mercury-coated surfaces increase with the increase in mercury until the limiting potentials, E_p^l, are reached.

The metals in Group II have negligibly small interactions with mercury, and the mercury deposited on these metals forms island-like metallic mercury deposits. The mercury is mechanically unstable. The H-overpotentials at the surfaces on which mercury is deposited are identical with those at mercury-free surfaces.

The metals in Group III form very stable amalgams with mercury, and metallic mercury does not coexist, even when 1 mg cm^{-2} of mercury is deposited. The H-overpotentials at their surfaces are slightly less than those at mercury-free surfaces.

Gold, copper, nickel, and platinum belong to Group I, molybdenum and stainless steel, (and GC) to Group II, and lead and zinc, to Group III.

An ideal thin mercury film electrode (TMFE) should be stable both mechanically and chemically, and it should have a large H-overpotential. In view of these requirements for the TMFE, the metals in Group I are most suitable as the base metals.

The strength of the interaction between mercury and the base metal determines the mechanical stability of mercury film; this strength is semi-quantitatively given by the peak-temperature difference between the evaporation of mercury from the stable mercury layer and the metallic mercury layer, ΔT, in the T-Hg curve. A large ΔT value certifies a stable mercury layer. On the other hand, too large ΔT value reduces the chemical stability and decreases the H-overpotential because of the structural change in the mercury layer during standing (alloy formation). For example, the H-overpotential at the mercury-coated platinum, the ΔT value of which was 190 °C, was remarkably changed with standing.[7] Among the metals studied in the present work, the best base metal for the TMFE was nickel, the ΔT value of which was about 50 °C.

Although ΔT was conventionally used to ascertain the qualitative evaporation behavior of mercury, the activation free energy of thermal evaporation, ΔG^*, was also investigated for a more quantitative treatment. The activation free energy was determined using a procedure similar to that described previously.[13] The differences between the ΔG^* value for the evaporation of the stable mercury and that for metallic mercury, $\Delta(\Delta G^*)$, here obtained were 0.98, 0.42, 0.16, and 0.16 eV for mercury deposited on platinum, gold, copper, and nickel, respectively.

The interaction between the deposited metal and the base metal has been electrochemically recognized as an underpotential[16] for the metal deposition. Kolb *et al.*[17] expressed the underpotential shift, ΔU, correlating to the work function difference between the deposited metal and the base metal, $\Delta\phi$, by using an empirical equation (1):

$$\Delta U = 0.5\,\Delta\phi/e, \tag{1}$$

where ΔU was the difference in peak potentials between the anodic oxidation of the stable layer and the bulk layer, as determined from an anodic stripping voltammogram (ASV). Employing the work function values of 5.40 and 4.50 eV for platinum and mercury reported in Ref. 19, ΔU is calculated to be 0.45 V for mercury deposition on platinum by using Eq. 1. On the other hand, if the rate-determining step in both the thermal evaporation and anodic oxidation reactions is assumed to be the same and is a breaking of the metal bond, producing an atom to be evaporated or oxidized, ΔU can be expressed by using ΔG^*, as in Eq. 2:

$$\Delta U = \Delta(\Delta G^*)/ne, \tag{2}$$

where n is the number of electrons involved in the anodic oxidation reaction. By using the experimentally obtained value as $\Delta(\Delta G^*)$, 0.98 eV for mercury on platinum, and Eq. 2, ΔU is found to be 0.49 V. The underpotential, ΔU, for mercury deposition on platinum has been reported as 0.47 V by Bruckenstein *et al.*[18] and Kolb *et al.*[17] using the ASV curve. In the previous report,[7] ΔU was determined to be 0.45 V from the relation between the electrolysis potential and the amount of mercury deposited (E-Hg plot). For mercury deposition on gold, ΔU was determined as 0.20 V using the E-Hg plot, as has been reported previously.[13] ΔU is calculated as 0.14 V using Eq. 1 or as 0.21 V using Eq. 2. Here, as a work-function value of gold, the value of 4.78 eV which was recommended by Trasatti[19] is employed, although the reported values are distributed from 4.78 to 5.32 eV.[20] The good agreement between the ΔU values calculated from both Eqs. 1 and 2 and the experimental values indicates that ΔU can be correlated to $\Delta(\Delta G^*)$ and $\Delta\phi$, and that the relation between $\Delta\phi$ and $\Delta(\Delta G^*)$ can be expressed by Eq. 3:

$$\Delta(\Delta G^*) = 0.5\,n\,\Delta\phi. \tag{3}$$

Although ΔU cannot be experimentally determined for mercury deposition on copper or nickel using the electrochemical method because of the anodic dissolution of the electrode, ΔU can be predicted from the T-Hg curve by using Eq. 2 to be 0.08 V for the mercury deposition on these metals. The ΔU values are also calculated using Eq. 1 to be 0.03—0.10 and 0.12 V by using the work-function values of copper, 4.55—4.70,[19,21] and nickel, 4.73 eV,[19] respectively.

Because interaction between deposited and base metals is a function of $\Delta\phi$, as has been mentioned above, the general criterion for selecting a suitable TMFE and other metal-film electrodes can be expressed using the work function, which is a general physicochemical parameter and which has been determined for a number of metals. For the ideal TMFE, $\Delta\phi$ should be large enough to form a stable mercury layer with respect to the mechanical stability and should be small with respect to the chemical stability and E_p^1. The reason has not yet been explained, but E_p^1 is more negative with a small value of $\Delta\phi$. $\Delta\phi$ and E_p^1 for the mercury-coated platinum, gold, copper, and nickel are 0.90, 0.28, 0.05—0.20, and 0.23 eV, and −1.05, −1.10, −1.38, and −1.40 V, respectively. By considering that the nickel-based TMFE is the best, a $\Delta\phi$ value of about 0.2 eV is considered to be most suitable for an ideal TMFE. In this connection, the cobalt-based TMFE (the work function of cobalt equals 4.7 eV,[19] $\Delta\phi$=0.2 eV) was stable and showed a large H-overpotential; *i.e.*, E_p^1 was −1.38 V at the mercury (120 μg cm^{-2})-coated cobalt electrode, and E_p^1 did not change upon standing for 70 h.

In the present work, the hydrogen-evolution reaction at the electrode surface was employed in order to investigate the electrode property because of its simplicity and reproducibility of the measurements, though other electrochemical measurements such as pzc, which may be closely correlated to the work function of the electrode surface, can be employed for this purpose.

The *T*-Hg curve is considered to be most available and the simplest for studying the structure of the deposited mercury film directly.

Application of Nickel-based TMFE

The nickel-based TMFE recommended in this work was applied to the anodicstripping voltammetric (ASV) determinations of copper(II), bismuth(III), lead(II), thallium(I), and cadmium(II) in an electrolyte which consisted of 0.5 M of ammonium acetate and 0.1 M of tartaric acid, and the results were compared with the results obtained using the platinum-based TMFE and the HMDE. The mercury layer of the TMFE was 200 μg cm^{-2} (*ca.* 0.15 μm thick). After electrolysis at −0.90 V for 2 min in a stirred solution containing 1×10^{-7} M of metal ions, the voltammogram was recorded anodically from −0.90 to 0 V at a rate of 50 mV s^{-1}.

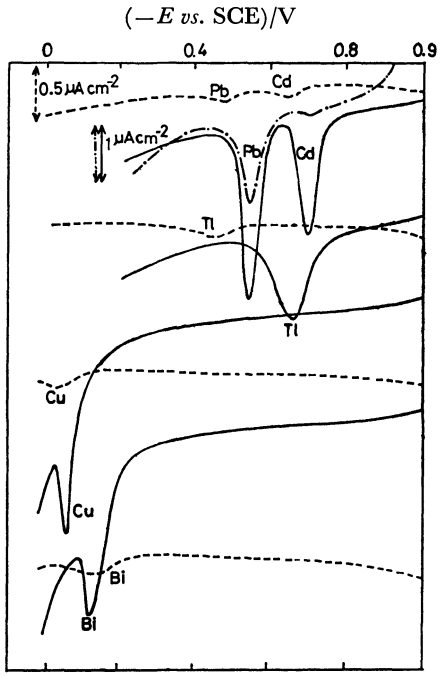

Fig. 7. ASV curves of copper (II), bismuth (III), lead (II), thallium (I), and cadmium (II) using nickel-or platinum-based TMFE and HMDE.
Electrodes; ——mercury (200 μg cm^{-2})-coated nickel, —·— mercury (200 μg cm^{-2})-coated platinum, ------ HMDE. Electrolyte solution; 0.5 M ammonium acetate and 0.1 M tartaric acid containing 1×10^{-7} M of metal ions. Pre-electrolysis; at −0.9 V for 2 min with stirring. ASV; from −0.9 to 0 V at a rate of 50 mV s^{-1}.

As is shown in Fig. 7, the ASV curves obtained by the use of the nickel-based TMFE are more quantitative than those obtained using the HMDE.

When lead and cadmium were simultaneously determined using the nickel-based TMFE, the peak heights in ASV were nearly proportional to the concentrations of the metal ions of 5×10^{-9}—2×10^{-7} M. The standard deviations for the determinations of 5×10^{-9} M of lead and cadmium obtained from five repeated runs were within 5%. The TMFE which had been left standing for 5 d after preparation gave reproducible ASV curves.

When the platinum-based TMFE was used instead of the nickel-based TMFE, the peak height in ASV for lead was proportional to the concentration of lead(II) of 2×10^{-8}—2×10^{-7} M, and 2×10^{-8} M of lead(II) was determined with a standard deviation of about 10%. No ASV peak of cadmium was obtained when the concentration was less than 1×10^{-7} M. The platinum-based TMFE was unstable and could not be used in the ASV determination of cadmium, because hydrogen evolution at the electrode started at about −0.65 V and E_p was at −0.8 V when the electrode had been left standing for 5 h after preparation.

Thus, the nickel-based TMFE is superior to the HMDE and the platinum-based TMFE which have usually been used for the determination of trace metal ions by ASV.

The author would like to thank Dr. Sorin Kihara, Professor Taichiro Fujinaga and his coworkers, and Dr. Kenji Motoiima for their helpful discussions and useful suggestions.

Metal-semiconductor Transition with Anomalous Thermal Hysteresis Observed in Hexagonal $(Ni_{1-x}Fe_x)_{1-y}S$, $(0 \leq x \leq 0.30,\ 0 \leq y \leq 0.035)$

Tsukio OHTANI,*,† Koji KOSUGE, and Sukeji KACHI

(Received July 7, 1980)

The phase relation of $(Ni_{1-x}Fe_x)_{1-y}S$ system was determined by the X-ray powder diffraction method. $Fe_{1-y}S$ can be dissolved in $Ni_{1-y}S$ in *ca.* 30 at.%. Transition temperature (T_t) was measured mainly by the DSC method. T_t increases with increase in Fe contents. T_t in the forward direction, however, shows a significant increase as high as 50 degrees, when specimens are aged at a temperature below T_t. The reverse transformation is not affected by thermal hystory at all. This is explained by the relaxation process in which the strain energy stored in the low temperature phase is relieved by aging.

NiS (NiAs structure) can be obtained by quenching from high temperature (above 600 K).[1] The first detailed investigations of NiS were performed by Sparks and Komoto[2-4] who found that NiS shows a first-order phase transition at T_t=265 K, the high temperature phase (H-phase) being a Pauli paramagnetic metal and the low temperature phase (L-phase) an antiferromagnetic semiconductor. They also found that the cell volume expands by *ca.* 2.0% through T_t with fall in temperature.[3] Trahan *et al.* performed powder X-ray diffraction measurements and found a crystal symmetry change at T_t.[5] On the other hand MacWhan *et al.* found no crystal symmetry change by X-ray study of single crystals.[6] Various electrical measurements revealed that the H-phase is a normal metal with n-type conduction and the L-phase a p-type semiconductor.[7-12] One of us (T. O.) found that the L-phase is a degenerate semiconductor in which carriers are substantially produced from Ni vacancies.[9] On the basis of magnetic measurements, the H-phase is considered to be a weakly-correlated Pauli paramagnet and the L-phase an antiferromagnet with the itinerant nature.[13,14] T_t is lowered by the deviation from stoichiometry[4] and by external pressure.[15,16] T_t is also sensitive to the impurity ions.[17-20] Thermal hysteresis at T_t was reported by many authors. The hysteresis width is several degrees.[9,21] Trahan and Goodrich, however, reported that an extremely long time is required for the equilibrium near the transition, the thermal hysteresis width being about ten degrees.[22]

There are less complete data and discussions on the origin of the transition. It was found that the enthalpy change at T_t is about 5.0 J mol^{-1} deg^{-1} for stoichiometric NiS.[21,22] Some authors assumed that the large part of entropy change at the transition is due to lattice contribution, suggesting the importance of electron-lattice interaction.[9,23] Strong electron-correlation effect would also play an important role in this transition, as in the case of some transition metal oxides such as V_2O_3 and related vanadium oxides.[24] White and Mott first discussed this transition on the basis of correlation effects.[25] So far, we have few data on NiS which suggest the effect.

The pseudo-binary NiS–FeS system was investigated by Misra and Fleet.[26] They found that the solubility of $Fe_{1-y}S$ into $Ni_{1-y}S$** increases with increasing y (metal deficiency). Continuous solid solution of this system was found to be in metal-poor region above 500 °C. T_t of NiS, Ni being substituted by Fe, has been observed.[17,19,20] We reported that T_t is raised by substitution of Fe ions (T_t increases by about 20 K for 2.0% of Fe substitution), suggesting that the increase in T_t is significantly related to the increase of cell volume.[17] Recently Coey *et al.*[23] and Barthelemy *et al.*[19] investigated the system $(Ni_{1-x}Fe_x)_{1-y}S$. The former proposed the phase diagram in the region with $x<0.10$, $y \simeq 0.04$, which is classified into three distinct regions according to their magnetic behavior. The latter observed two phases: the region with $0 \leq x \leq 0.05$ and that with $0.10 \leq x \leq 0.20$ where c-parameter is greater than that in the first region. So far, no systematic investigation on this system seems to have been performed. No detailed report has appeared on the thermal hysteresis of this transition. We have investigated $(Ni_{1-x}Fe_x)_{1-y}S$ solid solution and the effects of Fe substitution on the phase transition of NiS in the wide composition range and the anomalous thermal hysteresis of the transition.[27] In this paper, we will report the results of investigations.

Experimental

Starting samples of $Ni_{1-y}S$ and $Fe_{1-y}S$ were prepared separately from the pure elements. The method is the same as that reported.[9] $Ni_{1-y}S$ and $Fe_{1-y}S$ obtained were mixed in an appropriate ratio and heated at 1000 °C in evacuated silica tubes for a week, and then quenched into cold water after being annealed at 800 °C for 3 d. Reground samples were heated at 1000 °C and then annealed at temperatures 150—800 °C for a month. Annealed samples were quenched into cold water. Several kinds of measurements were performed for powder and ingot specimens. X-Ray powder diffraction measurements were made on annealed samples. The temperature dependence of the lattice constants was measured in the temperature range 270—360 K for $(Ni_{0.8}Fe_{0.2})_{0.965}S$. DSC measurements were carried out with a Rigaku Thermoflex DSC at 110—373 K using Al_2O_3 as a reference, measurements being made on polycrystals ground in an agate motor. Aging effects on T_t were measured by the DSC method. Electrical resistivity measurements were performed by an oridnary four

** Suffix, $1-y$, means that nonstoichiometric specimens contain only the defficient metals.

probes method on ingot samples, and aging effects on resistivity were examined at 290 K. Magnetic susceptibility was measured with a Faraday type torsion balance from liquid N_2 temperature to 373 K. Mössbauer effect measurements were carried out on $(Ni_{0.8}Fe_{0.2})_{0.985}S$ with a conventional spectrometer in a transmission setting at liquid N_2 temperature and at 373 K for samples of both immediately after quenching and after aging for 20 days.

Results

Phase Identification. Phase determination of the pseudo-binary $Ni_{1-y}S$-$Fe_{1-y}S$ system was made on the identification of X-ray powder pattern for quenched samples. Figure 1(a) shows the phase relation of $Ni_{1-y}S$-$Fe_{1-y}S$ system at 800 °C. The closed square indicates hexagonal NiAs phase and the open square two-phase region consisting of NiAs phase and cubic pentlandite phase, $(Fe,Ni)_9S_8$. Stoichiometric NiS takes only less than 30 at. % FeS into solid solution. A continuous solid solution was found to exist in the metal-poor region ($y \leq 0.035$). No extra line due to superstructure development as reported by Misra and Fleet was observed in all samples within experimental errors. At lower temperatures, the two phase region spreads out towards metal-poor compositions; for example at 150 °C the two phase region on NiS–FeS line extends from 20 to 80% of FeS concentration, while on a $Ni_{0.955}S$–$Fe_{0.955}S$ line only up to 20% of $Fe_{0.955}S$ can be dissolved into $Ni_{0.955}S$. Figure 1(b) shows the lattice spacings of the continuous solid solution of $(Ni,Fe)_{0.965}S$ at 800 °C. The a-parameter curve as a function of composition has a minimum at 50 at. % of Fe, while c-parameter changes smoothly with Fe contents.

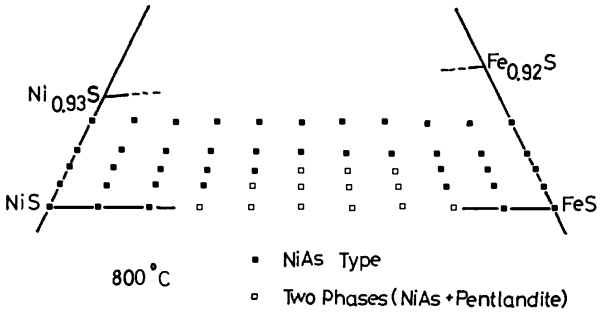

Fig. 1(a). Phase relations of pseudo-binary $Ni_{1-y}S$–$Fe_{1-y}S$ system obtained by quenching from 800 °C. The closed square indicates the hexagonal solid solution (NiAs-type), and the open square the two phase region consisting of hexagonal NiAs and cubic pentlandite phase.

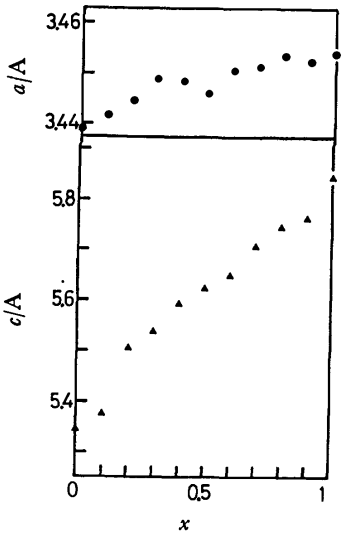

Fig. 1 (b). Lattice spacings measured at room temperature of $(Ni_{1-x}Fe_x)_{0.965}S$ quenched from 800 °C. a-axis is shown by circles and c-axis triangles. Fe contents is taken as abscissa.

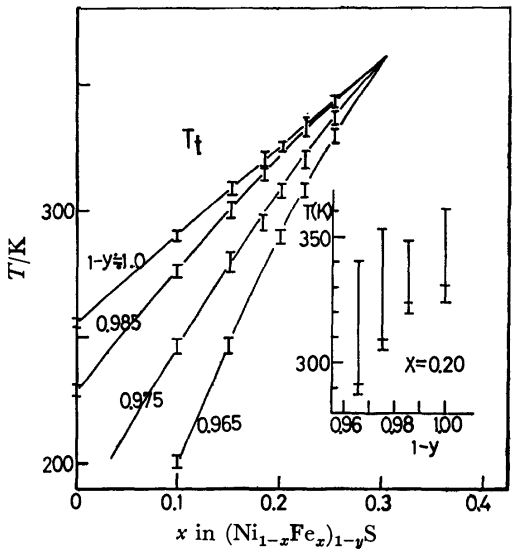

Fig. 2. Transition temperatures (T_t) of $(Ni_{1-x}Fe_x)_{1-y}S$ obtained by DSC measurements. Measurements were carried out on specimens immediately after quenching. x in $(Ni_{1-x}Fe_x)_{1-y}S$ is taken as abscissa and T_t as ordinate. The short vertical lines indicate the width of thermal hysteresis. The upper end of vertical lines corresponds to T_t in heating run, and the lower end T_t in cooling run. The inset shows the aging effects on T_t(F) (T_t in the forward direction) for $(Ni_{0.8}Fe_{0.2})_{1-y}S$. The vertical lines indicate the increase of T_t(F) for various "$1-y$" compositions. Aging temperature is 290 K. Detail is described in the text.

Phase Transition. Transition temperatures were determined mainly by the DSC method. The method of determination of T_t is shown in Fig. 3(b). T_t is very sensitive to thermal history. Results of unaged specimens are as follows. Variation of T_t with Fe contents is given in Fig. 2, where x in $(Ni_{1-x}Fe_x)_{1-y}S$ is taken as abscissa and T_t as ordinate. T_t was measured on heating-cooling cycles on specimens immediately after quenching from 800 °C. Endothermic and exothermic peaks were observed for heating and cooling, respectively. The value of T_t remained unchanged with heating-cooling rate. When "$1-y$" is fixed, T_t increases smoothly with increasing x. All curves of constant "$1-y$" seem to cross at $x=0.30$ (*ca.* 360 K). At $x=0.30$, DSC peaks are somewhat broadened after the first heating run, and for $x>0.30$, no DSC peaks could be detected in any "$1-y$" composi-

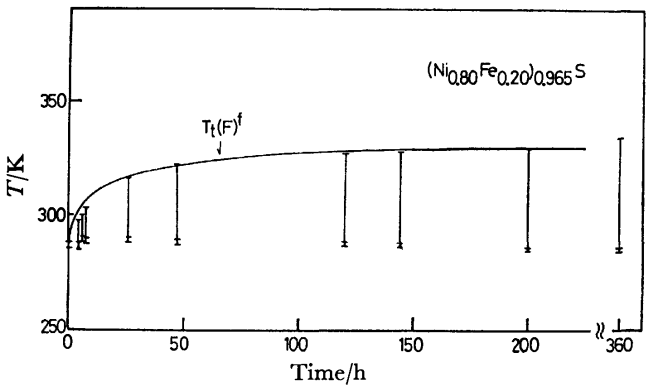

Fig. 3(a). T_t as a function of aging time for $(Ni_{0.8}Fe_{0.2})_{0.965}S$. Aging temperature is 290 K. The time elapsed from immediately after quenching is taken as abscissa. The upper end of vertical lines corresponds to T_t in the forward direction in the first heating run. Two horizontal lines in the lower end of vertical lines show the hysteresis width in the subsequent heating-cooling runs.

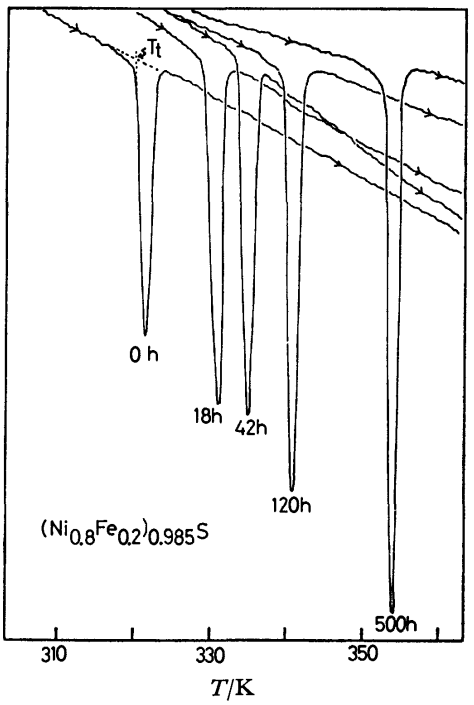

Fig. 3(b). The variation of DSC curves in the first heating runs with time elapsed for $(Ni_{0.8}Fe_{0.2})_{0.985}S$. Aging temperature is 290 K. Transition is endothermic.

tion. The short vertical lines in Fig. 2 indicate the width of thermal hysteresis observed in heating-cooling runs. The width of thermal hysteresis is within several degrees, and seems to be independent of composition. Hereafter, T_t in the heating run (forward direction) is referred to as $T_t(F)$, and T_t in the cooling run (reverse direction) $T_t(R)$.

The results on aged specimens are as follows. The forward transformation shows an anomalous thermal hysteresis in aged specimens. When samples are aged at temperatures below $T_t(R)$, $T_t(F)$ gradually increases with the lapse of time and after sufficiently long time (about 20 days), reaches the final $T_t(F)$ (the final $T_t(F)$ is referred to as $T_t(F)^f$), which is about 50 degrees higher than the initial $T_t(F)$ (the initial $T_t(F)$ is referred to as $T_t(F)^i$). T_t as a function of the time elapsed in the case of $(Ni_{0.8}Fe_{0.2})_{0.965}S$ aged at 290 K is shown in Fig. 3(a). The vertical lines show the width of increase of $T_t(F)$. Endothermic DSC peaks of $(Ni_{0.8}Fe_{0.2})_{0.985}S$ in the first heating run are shown for various aging times, the aging temperature being 290 K (Fig. 3(b)). No evidence of extra peaks can be detected throughout aging. The shape of DSC peaks is very sharp at all aging times, the height of peaks increasing with increasing $T_t(F)$. The inset in Fig. 2 illustrates the "$1-y$" dependence of the width of increase of $T_t(F)$ for $x=0.20$. The upper end of the vertical line corresponds to $T_t(F)^f$. The width of increase of $T_t(F)$ seems to decrease with increasing "$1-y$". The tendency, however, is somewhat ambiguous since the width of increase of $T_t(F)$ is sensitive to experimental conditions. x dependence of $T_t(F)$ is shown in Fig. 4 for

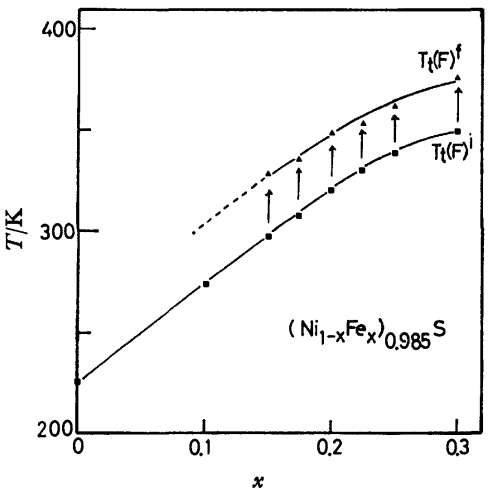

Fig. 4. x dependence of $T_t(F)$ (T_t in the forward direction) for $(Ni_{1-x}Fe_x)_{0.985}S$. Aging temperature is 290 K. Arrows show the increase of $T_t(F)$ by aging. The closed triangles show the final $T_t(F)$ ($T_t(F)^f$). The closed squares show the initial T_t (F) ($T_t(F)^i$).

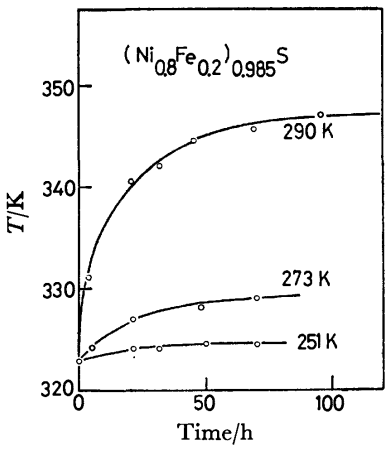

Fig. 5. Aging time dependence of transition temperatures in the first heating run of $(Ni_{0.8}Fe_{0.2})_{0.985}S$ for various aging temperatures (290, 273, and 251 K).

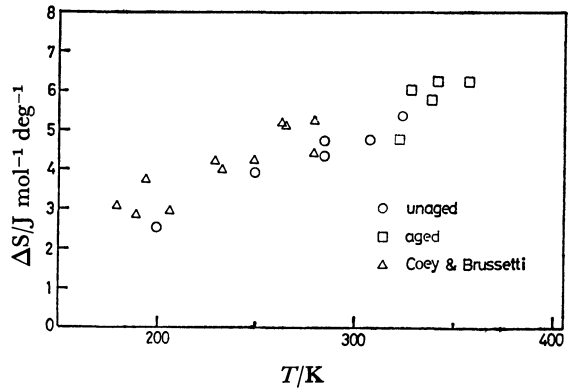

Fig. 6. Entropy change at T_t (ΔS) as a function of T_t for $(Ni_{1-x}Fe_x)_{1-y}S$ system. Open circles show ΔS for unaged specimens. Open square is ΔS for sufficiently aged specimens. Open triangles are those obtained by Coey and Brussetti.[21]

$(Ni_{1-x}Fe_x)_{0.985}S$ which was aged at 290 K. The lower curve shows the x dependence of $T_t(F)^i$ and the upper curve that of $T_t(F)^f$. The width of increase of $T_t(F)$ seems to be independent of x. In specimens of $x \leq 0.10$, the increase could not be observed since $T_t(R)$ is lower than 290 K. Figure 5 shows the variation of $T_t(F)$ with aging temperature for $(Ni_{0.8}Fe_{0.2})_{0.985}S$. Samples were aged at 290 K, 273 K (in ice water) and 251 K (in a mixture of ice, water, and NaCl). Increase in rate is more rapid at the higher aging temperatures. We tried to carry out aging at temperature immediately below $T_t(F)^f$ after aging for a sufficiently long time at 290 K. We could observe no more increase of $T_t(F)$. Increase of $T_t(F)$, however, was also observed in the case of aging at slightly higher temperatures (less than 5 degrees higher) than $T_t(F)^i$. Figure 6 shows the variation of entropy change (ΔS) at the transition with T_t. ΔS was determined from the endothermic peaks. Open circles show the entropy changes of unaged specimens, and open squares those of specimens aged for a sufficiently long time. We see that entropy change at the transition increases almost linearly with increasing T_t. We can recognize no significant difference of entropy change between unaged and aged specimens. For example, ΔS of $(Ni_{0.8}Fe_{0.2})^0{}_{.985}S$ is 4.26 and 6.01 J mol^{-1} deg^{-1} for unaged and aged speciments, respectively: both values fit the curve in Fig. 6. Our results are almost the same as those of Coey and Brussetti[21] shown by open triangles.

The increase of $T_t(F)$ was observed only in the first heating run. When aged samples are once passed through $T_t(F)$ ($>T_t(F)^i$), transition temperatures in the subsequent cooling and heating runs return to the initial $T_t(R)$ and $T_t(F)$ (Fig. 7(a)). When the samples are again aged at temperatures below $T_t(R)$, $T_t(F)$ increases asymptotically approaching $T_t(F)^f$, as in the previous aging process.

Aging effects on other physical properties were examined. X-ray powder diffraction measurements were performed on specimens aged for a sufficiently long time. No extra diffraction peak or shift of diffraction peaks was found. The temperature dependence of lattice spacings of $(Ni_{0.8}Fe_{0.2})_{0.965}S$ aged at 290 K

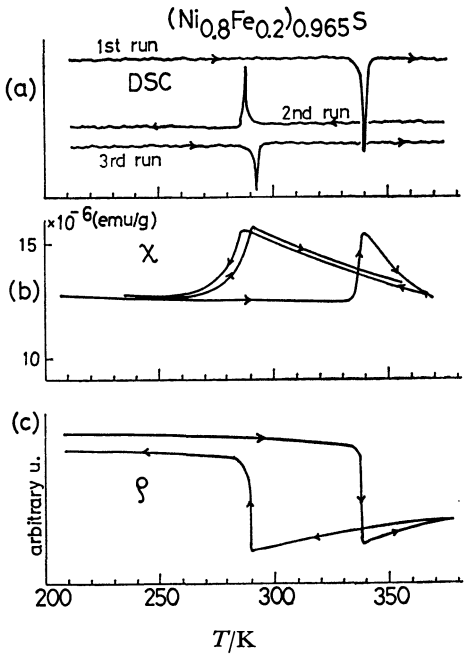

Fig. 7. Typical behaviors of the transition in the first heating run and subsequent cooling-heating runs for $(Ni_{0.8}Fe_{0.2})_{0.965}S$ aged for a long time at 290 K.
(a): DSC curves, (b): magnetic susceptibility, (c): electrical resistivity.

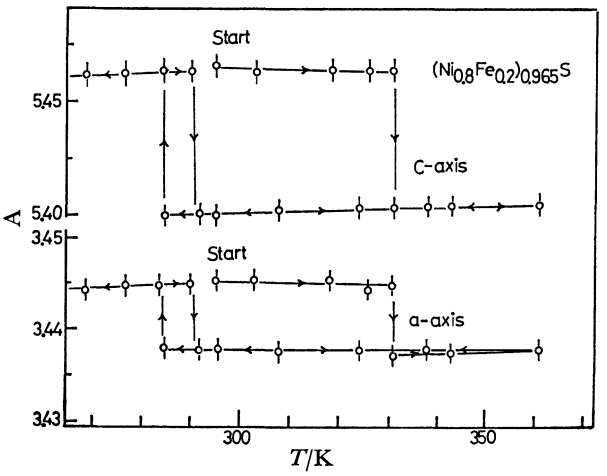

Fig. 8. Lattice spacings of $(Ni_{0.8}Fe_{0.2})_{0.965}S$ as a function of temperature. X-Ray measurements were done firstly on heating run for a sufficiently long time aged specimens, and subsequently on cooling run. Procedure of measurements is shown by arrows.

for sufficiently long time is shown in Fig. 8. The order of X-ray diffraction measurements is indicated by arrows. Both a- and c-parameters decrease slightly with temperature in the first heating run. Abrupt shrinkage was observed at $T_t(F)^f$, and abrupt expansion at $T_t(R)$ in the cooling run. In the second heating run, the transition was observed at $T_t(F)^i$. The results are in line with those of DSC measurements. Typical electrical resistivity (ρ) as a function of temperature is shown in Fig. 7(c) for $(Ni_{0.8}Fe_{0.2})_{0.965}S$ aged for a long time. In Fig. 9, the electrical resistivity (ρ)

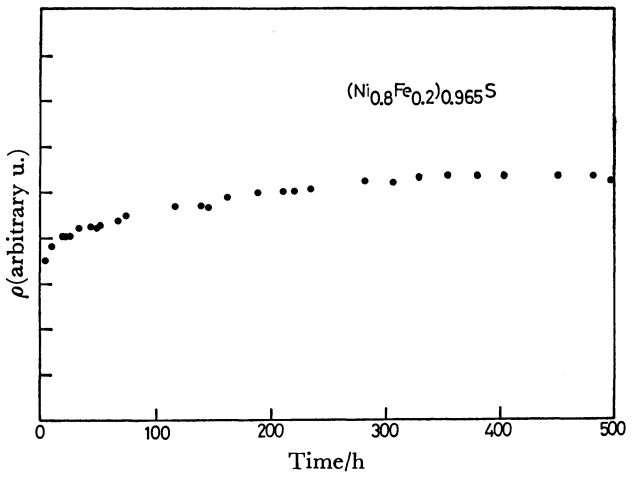

Fig. 9. Aging time dependence of electrical resistivity of $(Ni_{0.8}Fe_{0.2})_{0.965}S$. Aging temperature is 290 K.

at 290 K is plotted against the lapse of time for $(Ni_{0.8}Fe_{0.2})_{0.965}S$ which was quenched from 800 °C. Since $T_t(F)^i$ is slightly above 290 K, $T_t(F)$ increases with time elapsed. Resistivity increases with time elapsed and seems to be saturated after aging for *ca.* 400 h. Magnetic susceptibility (χ) of $(Ni_{1-x}Fe_x)_{0.085}S$ ($x \lesssim 0.30$) aged for sufficiently long time is given in Fig. 10 as a function of temperature. Heating and cooling rate is 10 °C/min. Heating and cooling cycles are shown by arrows. Typical behavior of χ is shown in Fig. 7(b) for $(Ni_{0.8}Fe_{0.2})_{0.965}S$ aged for a long time. The kinks in χ curves correspond to the transition. The difference of χ between aged and unaged samples is very small except for near transition. There is a broad maximum in χ curves in samples of $x \geq 0.250$ at about 140 K, while χ of the other samples is almost constant with temperature. The results of Mössbauer measurements are shown in Fig. 11. Measurements were carried out for both aged (for 20 d) and unaged specimens of $(Ni_{0.8}Fe_{0.2})_{0.985}S$. An absorption spectrum with quadrupole splitting was observed at 373 K

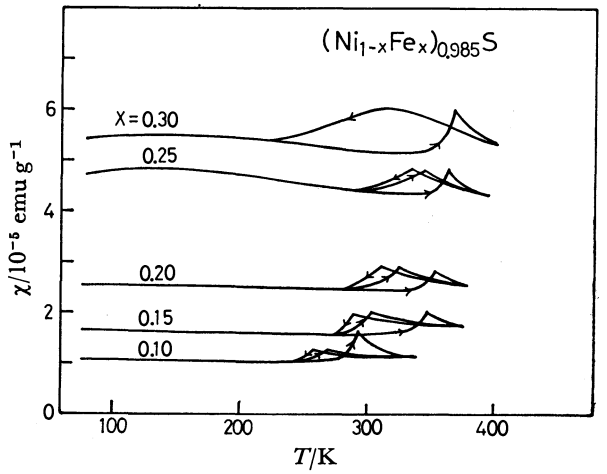

Fig. 10. Magnetic susceptibility of sufficiently long time aged $(Ni_{1-x}Fe_x)_{0.965}S$ ($x \lesssim 0.30$) as a function of temperature. Heating-cooling cycles are shown by arrows.

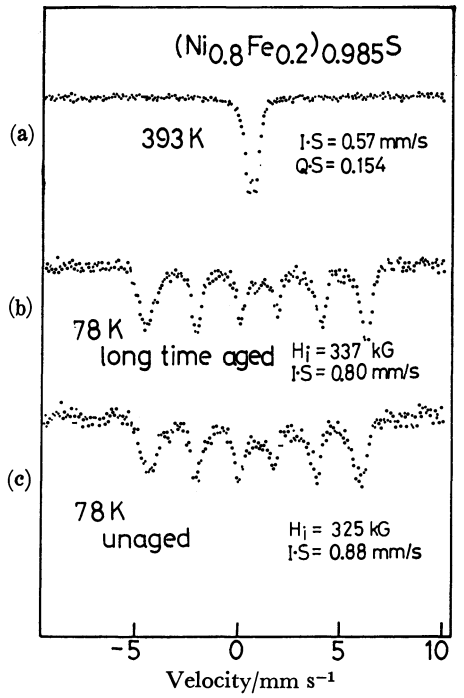

Fig. 11. Mössbauer spectra for $(Ni_{0.8}Fe_{0.2})_{0.985}S$. (a): Spectra at 393 K (above $T_t(F)^f$), (b): spectra at 78 K for a long time aged specimen, (c) spectra at 78 K for unaged specimen.

(Fig. 11(a)), the isomer shift and quadrupole splitting being 0.57 and 0.154 mm/s, respectively. Magnetic sextets were observed at 78 K. Figures 11(b) and (c) show the results obtained at 78 K for $(Ni_{0.8}Fe_{0.2})_{0.985}S$ aged for a long time and unaged, respectively. Internal magnetic field is 2.68×10^7 and 2.59×10^7 A m^{-1} for aged and unaged specimen, respectively. Isomer shift is 0.80 and 0.88 mm/s for aged and unaged specimen, respectively.

The results of anomalous thermal hysteresis are summarized as follows.

a) $T_t(F)$ increases with time, when the specimens are aged at temperature below $T_t(R)$. $T_t(F)^f$ is *ca.* 50 degrees higher than $T_t(F)^i$. $T_t(F)$ is unchanged when specimens are aged at temperatures above $T_t(F)$. $T_t(R)$ is not affected by heat treatment.

b) When aged specimens are once passed through $T_t(F)$ ($> T_t(F)^i$), $T_t(F)$ in the subsequent heating runs return to $T_t(F)^i$. When samples are again aged at temperatures below $T_t(R)$, the same aging effects are also observed.

c) Two phase mixture of the initial and the final state is not observed in the course of aging in both DSC curves and X-ray powder diffraction patterns. No new phase was observed during the course of aging.

d) Increase in the rate of $T_t(F)$ increases with rise in aging temperature.

e) The width of increase of $T_t(F)$ seems to be almost independent of x composition.

f) The nature of phase transition, *i.e.* metal-semiconductor transition accompanied by magnetic change, is essentially unchanged by aging treatment. Physical properties of both aged and unaged specimens are

compared as follows.

1) No crystallographycal difference is found in X-ray diffraction patterns.

2) Electrical resistivity of aged specimens is higher than that of unaged one.

3) Difference of magnetic susceptibility is very small.

4) Internal magnetic field of aged specimen is higher than that of aged one.

Discussion

In the course of studies on the phase transition of $(Ni_{1-x}Fe_x)_{1-y}S$ system, we found anomalous aging effects on the transition temperature. First let us consider the phase relation of this system. Misra and Fleet[26] have reported the monosulfide solid solution in the temperature range 230—600 °C. They found extra peaks such as super lines in powder patterns of all of monosulfide-bearing products. However, we found no extra peak in X-ray diffraction patterns, confirming the distinct region of solid solution of this system. Solid solution was also confirmed by DSC measurements which show smooth increase of the transition temperature with Fe contents up to 30 at. %. Barthelemy *et al.*[19] found two phases in $Ni_{1-x}Fe_xS$ with small amount of Fe at 550 °C, one with $0 \leq x \leq 0.05$, the other with $0.10 \leq x \leq 0.20$ and a mixture of two phases with $0.05 < x < 0.10$. c-parameter of the second phase is greater than that of the first one. This can be explained by our results of aging effects. T_t in the composition range of $0.05 < x < 0.10$ lies near room temperature. Thus, in the range $0 \leq x \leq 0.05$, X-ray diffraction patterns at room temperature show a pattern of the H-phase; in the range $0.10 \leq x \leq 0.20$ they show one of the L-phase which has a greater c-parameter than the H-phase. Two phase mixture in the region $0.05 < x < 0.10$ can be explained by the following results. In specimens which have T_t slightly below room temperature, T_t gradually increases with the lapse of time at room temperature. X-Ray diffraction patterns at room temperature show the two phase mixture of the H- and L-phases, both phases having the NiAs type structure while lattice spacings differ from each other. Two phase mixture has been observed for 48 h in X-ray charts; this feature is remarkable especially in (102) reflection. No lattice modification was found in the $(Ni_{1-x}Fe_x)_{1-y}S$ system.

The phase transition of this system is accompanied by the drastic changes of electrical and magnetic properties, this being metal-semiconductor transition similar to that of pure NiS. $(Ni_{1-x}Fe_x)_{1-y}S$ with Ni-rich composition has substantially the same characteristics of phase transition as that of pure NiS.

Let us consider the aging effects on the phase transition. It is important to examine whether this is characteristic of only Fe substituted $Ni_{1-y}S$. Trahan and Goodrich[22] found in their calorimetric measurements that it takes a long time for stoichiometric NiS to attain equilibrium near the transition, exhibiting a considera ble- hysteresis. T_t was observed to be 276 K in heating run, and 269 K in cooling run, while in cooling run the samples supercooled approximately by 2.5 K. All previous publications except that of Trahan and Goodrich reported that T_t of NiS lies in the neighbourhood of 265 K. The anomalous high transition temperature in heating runs of Trahan and Goodrich is presumably due to the aging effects. For the sake of confirmation we performed DSC measurements for undoped NiS. We observed the increase of T_t(F) : T_t(F) increases by about 1 degree by annealing at 250 K for 24 h, in line with the data of Fig. 5. Thus the increase of T_t(F) by aging is considered to be characteristic phenomenon in NiS as well as in $(Ni_{1-x}Fe_x)_{1-y}S$.

The phenomenon can be regarded as thermal hysteresis, a common feature of the first order transition. In the reversible transformation of the first order, the hysteresis width is closely related to the volume change at the transition, ΔV.[28,29] For example, for the transition of NH_4Cl ($P_{m3m} \rightarrow F_{m3m}$) the width of hysteresis is 35 K, and $\Delta V + 7.14$ cm^3/mol; for CsCl ($P_{m3m} \rightarrow F_{m3m}$) hysteresis width is 33 K, $\Delta V + 10.28$ cm^3/mol. In the case of $(Ni_{1-x}Fe_x)_{1-y}S$, the reversible thermal hysteresis is observed in unaged specimens, where the hysteresis width is several degrees. This seems to be reasonable since ΔV is relatively small, *ca.* -0.3 cm^3/mol. The increase of T_t(F) by aging, as high as 50 degrees, seems to be enormously large.

Gradual increase of T_t(F) with aging indicates that the initial unaged state is in thermally non-equilibrium, passing gradually into equilibrium. This has been reported, *e.g.* anatase-rutile or brookite-rutile in TiO_2[30] or hexagonal-tetragonal transformation in GeO_2.[31] The transformation is a function of time and temperature. In the transient state from metastable to stable one, two phases usually coexist. Transformation kinetics has been investigated by using the Avrami equation. The present case differs a great deal from above cases. DSC measurements show continuous shift of T_t(F), but X-ray diffraction measurements show no two phase mixture. Thus, the present case can not

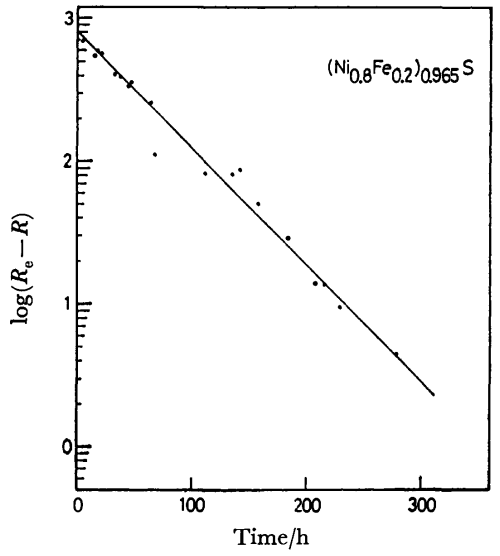

Fig. 12. The logarithm of $(R_e - R)$ as a function of elapsed time. $(R_e - R)$ is the difference between the resistivity at $t = \infty$ and time t.

be interpreted in a similar manner to the above substance.

As shown in Fig. 9, the electrical resistivity (ρ) increases very gradually with elapsed time if samples are aged at 290 K (below T_t(R)). After a sufficiently long time, ρ attained the value of thermal equilibrium state, R_e. In Fig. 12, the logarithm of the difference between the resistivity at time $t=\infty$ and time t, (R_e-R) is plotted against t (data are the same as in Fig. 9). For an exponential change the graph should be a straight line, and this is the case. Thus, it is presumed that the time dependence of ρ has the form

$$R_e - R = Ae^{-t/\tau},$$

where A is a constant and τ the relaxation time. From the slope, we estimated τ to be 118 h. A similar treatment was performed by Trahan and Goodrich,[22] who measured the electrical resistivity near the transition temperature of stoichiometric NiS, and estimated τ to be 48 h. They did not, however, specify the aging temperature. From analogy with the present case, we suppose their measurements were taken at temperature below T_t(R). Thus, we can conclude that the aging effect is the relaxation process from thermally non-equilibrium state to equilibrium one.

Generally, phase transition is described in terms of nucleation and growth. At the start of transition, the nuclei of a new phase are first formed in the parent phase, followed by development of the new phase. If specific volumes differ from each other, the product phase in the parent phase produces strain. If the parent phase is not sufficiently soft, the elastic strain energy might be stored in the crystal. The interfacial energy formed between the product and the parent phase should also be considered. Ubbelohde[32] suggested that extra terms for the strain energy and the interfacial energy should be added to the usual independent variables that determine the free-energy; the strain energy is a main factor controlling thermal hysteresis.

We should consider the following characteristics of the transition. The transition is accompanied by drastic volume expansion with fall in temperature (about 2.0%). The material becomes brittle below T_t; *i.e.* specimens cracked through transition with lowering temperature. The mechanism of phase transition differs for the case of the forward and reverse directions. In the forward direction (a), the relatively soft phase grows in the brittle phase associated with volume contraction, while in the reverse direction (b) a brittle phase grows in soft matrix associated with volume expansion. In (a) the product phase is strained under tension, and in (b) it is strained under compression. The large difference in the sensitivity of the transition temperature between (a) and (b) may be due to such different transition mechanism. Since the L-phase is brittle, it has a larger contribution to the strain energy than the H-phase. Thus, (a) would be more sensitive to the thermal treatments than (b).

Considering the L-phase which is in a state immediately after reverse transition (non-equilibrium state), excess energy such as strain energy would be expected to be stored in the crystal. Such a state would

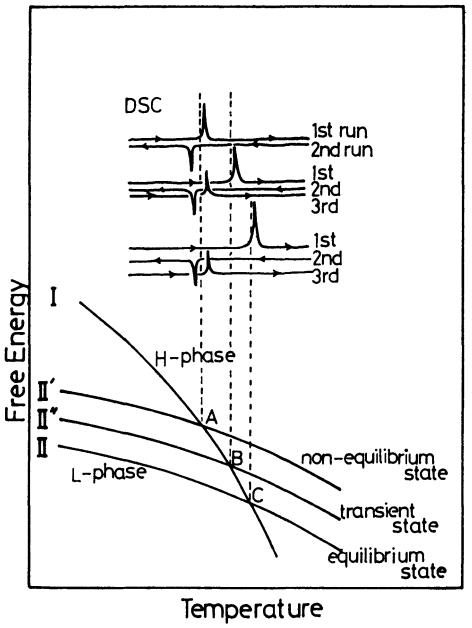

Fig. 13. Tentative Gibbs free-energy diagram for $(Ni_{1-x}Fe_x)_{1-y}S$ system. Curve I, II, II′, and II″ are Gibbs free-energy curves of the H-phase, equilibrium state of L-phase, non-equilbrium state of L-phase and the transient state from non-equilibrium to equilibrium state of L-phase, respectively. Free-energy curve of nonequilibrium state is in a higher energy state than the equilibrium state due to the stored strain energy in the L-phase. Curve I is assumed to be invariant to thermal treatments. The upper side of the figure indicates DSC curves corresponding to each state.

be in a higher energy state than the equilibrium state stabilized by aging for long time below T_t(R). Thus, free energy-temperature curve for the non-equilibrium state is expected to lie slightly above that of the equilibrium one. Such a relation is schematically illustrated in Fig. 13, where curves I, II, II′, and II″ are Gibbs free-energy curves, corresponding to the H-phase, the equilibrium state of L-phase, the nonequilibrium state of L-phase and the transient state from non-equilibrium to equilibrium state of L-phase, respectively. Curve I is assumed to be independent of thermal history of the specimens. Curve II′, II″, and II intersect with curve I at points A, B, and C, respectively. DSC curves are shown for each state. Relaxation phenomenon would be considered to be the process where the stored strain energy is relieved by aging, corresponding to the lowering in free energy curve from II′ to II, accompanied by the increase of transition temperature.

The relaxation phenomenon would be also considered as an order-disorder process, where non-equilibrium disordered state is transformed to the equilibrium ordered state with aging. The disordered state would be expected to have higher energy than the ordered one. In Fig. 13, the disordered state corresponds to curve II′, and the ordered state curve II. The order-disorder transition is considered to occur at the same temperature as T_t(F). If this is not the case, aging effect should be observed also in the H-phase. This mechanism,

however, does not seem to be applicable to the present case. If the ordering is due to metal vacancies, superlines due to ordering should be observed in X-ray charts. This could not be confirmed. If the ordering process occurred between Ni and Fe atoms, no aging effects should be observed in pure NiS. According to Trahan and Goodrich,[22] and our present measurements, aging effects were observed also in NiS. The difference of entropy change at T_t between aged and unaged state could not be detected by DSC measurements.

So far, aging effects similar to the present case have been observed in a few materials. Murray and Allison[33] observed the aging effects in ZrO_2, where the tetragonal to monoclinic phase transition (reverse transition) is slightly affected by heat treatments; *i.e.* the transition temperature of the reverse direction is drastically raised by either heating-cooling cycles through the transition or aging at tetragonal phase (above the transition temperature). They interpreted this phenomenon as the ordering process in the tetragonal phase. On the other hand, Maiti *et al.*[34] attributed this to the superplastic nature of the tetragonal phase. Another example was reported by Murakami *et al.*,[35] who found a very similar phenomenon to the present case in Au-Cu-Zn alloys. Martensite reverse transition temperature of $Au_{26}Cu_{30}Zn_{44}$ alloy increases by about 20 K, when it is aged at 290 K (below the transition temperature). They assumed that the aging effect is due to the stabilization and pinning of the martensite plate boundaries, which give rise to an increase in the driving force for the transition.

In conclusion, we have observed a new type of thermal hysteresis in $(Ni_{1-x}Fe_x)_{1-y}S$ system. It is considered to be a relaxation process where the strain energy stored in the L-phase is relieved by aging.

The author wish to express their sincere thanks to Prof. T. Takada and Dr. T. Shinjo for enabling them to carry out the Mössbauer measurements.

(Received February 18, 1980)

The stereoselective deacylation of H–$(CH_2)_{\overline{n-1}}$CONHCH(R)CO_2–$C_6H_4NO_2$-*p* (R = CH_3, $CH(CH_3)_2$, $CH_2CH(CH_3)_2$, and $C_6H_5CH_2$; *n*=2—16) with *N*-acyl-L-histidine (acyl=octanoyl, dodecanoyl, and hexadecanoyl) and cationic surfactants ($C_mH_{2m+1}\overset{+}{N}(CH_3)_2R$ X; (R,X,m)=(CH_3,Br,16), (C_2H_5,Br,16), ($C_6H_5CH_2$,Cl,16), and ($\overset{*}{C}H(CH_3)C_6H_5$,Br, 14—18) was examined with particular reference to the structural effects of surfactants, nucleophiles, and substrates on both the deacylation rates and the stereoselectivity. The cationic surfactant, R-(+)-$C_{16}H_{33}\overset{+}{N}(CH_3)_2\overset{*}{C}H(CH_3)C_6H_5$ Br, which possesses the hydrophobic and chiral groups near the polar head, formed the stereoselectively most effective comicelles with *N*-dodecanoyl-L-histidine. The order of stereoselectivity observed in the deacylation of the amino acid esters including the identical acyl chain length (n), phenylalanine>leucine>alanine~valine, suggested steric effects of the substituent bound to the asymmetric carbon atom of the substrate on the stereoselectivity. The highest stereoselectivity (enantiomer rate ratio=4.4 at 25 °C under pH 7.61) was observed in the deacylation of the *N*-decanoylphenylalanine *p*-nitrophenyl ester, involving an appropriately long acyl chain.

The stereoselective micelle-catalyzed deacylation of amino acid esters has recently received considerable attention in the field of enzyme model reactions, and the deacylation of *N*-protected amino acid esters including *N*-CH_3CO, *N*-CH_3OCO, or *N*-$C_6H_5CH_2OCO$ by the amino acid-functionalized surfactants[1-5] or by the mixed micelles of *N*-acyl-L(or D)-histidine (acyl=CH_3CO, C_6H_5CO, $C_7H_{15}CO$, $C_{11}H_{23}CO$, or $C_{17}H_{35}CO$) and hexadecyltrimethylammonium bromide(CTAB)[6-8] has hitherto been documented at enantiomer rate ratios below or around 3.0. However, the stereoselective catalysis of mixed micelles composed of structurally different nucleophiles and surfactants in the deacylation of amino acid esters including long *N*-acyl chains has not yet been investigated systematically. Therefore, we have examined the stereoselective deacylation of amino acid esters possessing a series of *N*-acyl chain lengths by chiral micelles of *N*-acyl-L-histidine and various cationic surfactants at 25 °C (pH 7.61).

In this paper, we wish to report the structural effects of surfactants, nucleophiles, and substrates on the deacylation rate and stereoselectivity when the following compounds were used:

Substrate

H–$(CH_2)_{\overline{n-1}}$CONHCHCO$_2$C$_6$H$_4$NO$_2$-*p*
(R on the CH)

Phe–S_n (R=$CH_2C_6H_5$; *n*=2,6,10,12,14, and 16)
Ala–S_n (R=CH_3; *n*=10)
Val–S_n (R=$CH(CH_3)_2$; *n*=10)
Leu–S_n (R=$CH_2CH(CH_3)_2$; *n*=10)

Nucleophile

RCONH$\overset{*}{C}$H(CO$_2$H)CH$_2$–(imidazole)

OctHis (R=C_7H_{15})
LauHis (R=$C_{11}H_{23}$)
PalHis (R=$C_{15}H_{31}$)

Surfactant

$C_mH_{2m+1}\overset{+}{N}(CH_3)_2R$ X

CTAB (R=CH_3; X=Br; *m*=16)
CEAB (R=C_2H_5; X=Br; *m*=16)
CBzAC (R=$CH_2C_6H_5$; X=Cl; *m*=16)
R-(+)-SUR$_{14}$ (R = $C_6H_5\overset{*}{C}H(CH_3)$; X = Br; *m* = 14)
R-(+)-SUR$_{16}$ (R = $C_6H_5\overset{*}{C}H(CH_3)$; X = Br; *m* = 16)
R-(+)-SUR$_{18}$ (R = $C_6H_5\overset{*}{C}H(CH_3)$; X = Br; *m* = 18)

Experimental

N-Acylphenylalanine p-Nitrophenyl Esters (Phe-S_n). Phe–S_n (*n*=2—16) esters were prepared from *N*-benzyloxycarbonyl-D(or L)-phenylalanine by the esterification of the CO_2H group, the hydrobromination of the NH_2 group, and then the acylation of the NH_2HBr group in a way similar to the previous method.[9] Satisfactory results of elemental analyses were obtained for Phe–S_n (*n*=2—16). L-Phe–S_2: mp 137.5—138 °C (lit,[9] mp 140.0—140.5 °C). $[\alpha]_D^{25}$ −17.57° (*c* 2, $CHCl_3$) (lit,[9] $[\alpha]_D^{20}$ −18.6° (*c* 2, $CHCl_3$)). Found: C, 61.96; H, 5.00; N, 8.66%. Calcd for $C_{17}H_{16}N_2O_5$: C, 62.19; H, 4.91; N, 8.53%. D-Phe–S_2: mp 133.5—134.0 °C (lit,[9] 135—137 °C). $[\alpha]_D^{25}$ +18.15° (*c* 2, $CHCl_3$) (lit,[9] $[\alpha]_D^{20}$ +17.4° (*c* 2, $CHCl_3$)). Found: C, 62.06; H, 4.84; N, 8.66%. Calcd for $C_{17}H_{16}N_2O_5$: C, 62.19; H, 4.91; N, 8.53%. L-Phe–S_6: mp 113.7—114.5 °C. $[\alpha]_D^{25}$ −14.71° (*c* 2, $CHCl_3$). Found: C, 65.98; H, 6.28: N, 7.35%. N-Acyl-L-histidine (OctHis, LauHis, and PalHis). These nucleophiles were prepared by the reaction of L-histidine and the corresponding acid chlorides.[10] Satisfactory results of elemental analyses were also obtained for these compounds. OctHis: mp 179—181 °C. Found: C, 52.97; H, 7.36; N, 13.29%. Calcd for $C_{14}H_{23}N_3O_3 \cdot HCl$: C, 52.90; H, 7.61; N, 13.22%. LauHis: mp 161—162 °C (lit,[11] 160—161 °C). Found: C, 64.03; H, 9.27; N, 12.11%. Calcd for $C_{18}H_{31}N_3O_3$: C, 64.06; H, 9.27; N, 12.45%. PalHis: mp 153—155 °C. Found: C, 67.13; H, 10.18; N, 10.37%. Calcd for $C_{22}H_{39}N_3O_3$: C, 67.14; H, 9.99; N, 10.68%.

Surfactants (CTAB, CEAB, CBzAC, R-(+)-SUR$_m$ (m=14, 16, and 18)). Commercially available CTAB, CEAB, and CBzAC were used after recrystallization with absolute ethanol and diethyl ether. The chiral surfactants were prepared by the reaction of R-(+)-*N,N,α*-trimethylbenzylamine and the corresponding alkyl bromide in accordance with the previous method.[12] R-(+)-SUR_{14}: mp 109.0—110.0 °C. Found: C, 68.02; H, 10.55; N, 3.30%. Calcd for $C_{24}H_{44}NBr$: C, 67.57; H, 10.42; N, 3.28%. R-(+)-SUR_{16}: mp 110.5—112.5 °C (lit,[12] 111.5—113.0 °C). $[\alpha]_D^{18}$ +20.44° (*c* 4, CH_3OH) (lit,[12] $[\alpha]_D^{21}$ +19.82° (*c* 45, CH_3OH)). Found: C, 67.38; H, 10.87; N, 2.98%. Calcd for $C_{26}H_{48}NBr$: C, 68.70; H, 10.64; N, 3.22%. R-(+)-SUR_{18}; mp 112.0°—113.5 °C. Found: C, 68.76; H, 10.99; N, 2.84%. Calcd for $C_{28}H_{52}NBr$: C, 69.67; H, 10.88; N, 2.90%.

Deacylation. The stereoselective micelle-promoted deacylation of L or D-substrates (5×10^{-5} mol dm^{-3}) with and without the nucleophile (9×10^{-5} mol dm^{-3}) in the presence of the cationic surfactant ($(4.5—55)\times10^{-4}$ mol dm^{-3}) was carried out at 25 °C (pH 7.61) in a Tris buffer (0.083 mol dm^{-3}) containing KCl (0.083 mol dm^{-3}) in 10% (v/v) CH_3CN–H_2O. The above concentrations of the surfactants were higher than their critical micelle concentrations (CMC); for example, the CMC values of CTAB, CBzAC, and R-(+)-SUR_{16} are 1×10^{-3},[13] 2.7×10^{-4},[12] and 2.08×10^{-4} mol dm^{-3} [12] respectively. The deacylation rate was followed by the spectrophotometric determination of *p*-nitrophenolate (400 nm). In the present experiments, the substrate deacylation by the nucleophile was not performed in the absence of the cationic surfactant because the precipitation of the substrates during the reaction was observed in the absence of the surfactant under the present conditions.

Determination of Rate Constants. The rate constants for the present reaction with and without the nucleophile (k_ψ and $k_{surfact}$ respectively) were obtained from good pseudo-first-order deacylation rates, while the apparent catalytic rate constant (k_{cat}) was evaluated in the usual way ($k_{cat}=(k_\psi - k_{surfact})/[\text{nucleophile}]$).

Results and Discussion

Structural Effects of Surfactants and Nucleophiles. The structural effects of the polar head groups of the cationic surfactants (CTAB, CEAB, CBzAC, and R-(+)-SUR_{16}) involving the same alkyl chain length on both the deacylation rate and the stereoselectivity were first examined in the deacylation of Phe-S_n (n= 2, 10, and 16) with LauHis; the results of a series of experiments are shown in Table 1. In the deacylation

Table 1. Structural effects of surfactants on deacylation rate and stereoselectivity[a]

Surfactant	Phe-S_n	k_{cat}/mol^{-1} dm^3 s^{-1}		k_{cat}^L/k_{cat}^D
		L	D	
CTAB	n=2	57	35	1.6

	=16	362	114	3.2

a) Tris buffer (0.083 mol dm^{-3}) containing KCl (0.083 mol dm^{-3}) at 25 °C, pH 7.61, in 10% (v/v) CH_3CN–H_2O; [LauHis]$=9\times10^{-5}$ mol dm^{-3}, [Phe-S_n]$=5\times10^{-5}$ mol dm^{-3}, and [Surfactant]$=2.5\times10^{-3}$ mol dm^{-3}.

of the short-chain substrate (Phe-S_2), neither the deacylation rate nor the stereoselectivity (defined by k_{cat}^L/k_{cat}^D) was affected remarkably by the surfactant structure. The increase in the acyl chain length of Phe-S_n from n=2 to n=10, however, increased both the rate and the selectivity in all the cases by intensifying the stereoselective micellar catalysis through the substrate incorporation by the comicelles of LauHis and the surfactant. The rate increase was about 4—5 fold for the L-enantiomer, while it was about 2—3 fold for the D-enantiomer. Therefore, the nucleophilic attack of the imidazolyl group of LauHis on the susceptible carbonyl group of the substrate incorporated into the comicelles occurred more favorably in the L-Phe-S_{10}

a) The reaction conditions are the same as in Table 1 except for the surfactant concentration. Substrate=Phe-S_{10}.

deacylation than in the D-Phe-S_{10} deacylation. In this respect, the comicelles of LauHis and R-(+)-SUR_{16} resulted in the highest deacylation rate of L-Phe-S_{10} (and a slightly lower rate of D-Phe-S_{10}) as compared with the other comicellar systems. Since the stereoselective efficiency of R-(+)-SUR_{16} *per se* was negligibly small ($k^L_{surfact}/k^D_{surfact}$=1.00—1.08), the hydrophobic and chiral α-methylbenzyl group at the polar head of R-(+)-SUR_{16} might facilitate the interaction of LauHis with L-Phe-S_{10}. In the deacylation of Phe-S_{16}, the structural effects of CTAB and CEAB on the deacylation rate and the stereoselectivity were appreciably different from those of CBzAC and R-(+)-SUR_{16}; that is, CTAB and CEAB decreased both the rate and the stereoselectivity of Phe-S_{16} remarkably as compared with those of Phe-S_{10}, while CBzAC and R-(+)-SUR_{16} did not reduce the rate of L-Phe-S_{16}, but increased the rate of D-Phe-S_{16} considerably. The rates of L and D-Phe-S_{16} in the LauHis+CBzAC (or R-(+)-SUR_{16}) system were about 6—7 fold and about 3.5—5 fold with respect to those in the LauHis+CTAB (and +CEAB) systems respectively. Therefore, the hydrophobicity of the benzyl (or α-methylbenzyl) group of CBzAC (or R-(+)-SUR_{16}) contributes to the rate enhancement of the long-chain substrates (Phe-S_{10} and Phe-S_{16}). It is noteworthy, with respect to the stereoselectivity, that the enantiomer-rate ratio of 4.4 for Phe-S_{10} (or that of 3.2 for Phe-S_{16}) in the case of the LauHis+R-(+)-SUR_{16} system is 1.5 times as high as the rate ratio of 2.9 for Phe-S_{10} (or that of 2.1 for Phe-S_{16}) in the case of the LauHis+CBzAC system. This might be due not to the hydrophobicity difference in the polar-head groups of the surfactants, but to the chirality of the hydrophobic α-methylbenzyl group of R-(+)-SUR_{16}. It is deduced, therefore, that the comicelles consisting of chiral nucleophiles and chiral surfactants tend to enhance the stereoselectivity of the long-chain substrates, especially such substrates as Phe-S_{10} which possess an appropriately long acyl chain.

The concentration effects of surfactants on the stereoselective comicellar catalysis were, then, examined in the deacylation of Phe-S_{10} with LauHis and R-(+)-SUR_m (m=14, 16, and 18); the experimental results are shown in Table 2. In all the comicellar systems of LauHis+R-(+)-SUR_m (m=14—18), the increase in the surfactant concentration in the range of 4.5×10^{-4}—5.5×10^{-3} mol dm^{-3} with respect to 9×10^{-5} mol dm^{-3} of LauHis decreased the deacylation rate of Phe-S_{10} monotonously. The stereoselectivity in the deacylation of Phe-S_{10} (5×10^{-5} mol dm^{-3}) with LauHis (9×10^{-5} mol dm^{-3}) and R-(+)-SUR_m (m=14—18) was also affected by the surfactant concentration; the highest enantiomer-rate ratios (k^L_{cat}/k^D_{cat}=3.6, 4.4, and 3.2) were obtained under the conditions of [R-(+)-SUR_{14}]=4.5×10^{-3} mol dm^{-3}, [R-(+)-SUR_{16}]=2.5×10^{-3} mol dm^{-3}, and [R-(+)-SUR_{18}]=1.8×10^{-3} mol dm^{-3}

Table 3. Structural effects of nucleophiles on deacylation rate and stereoselectivity[a)]

System	Phe-S_2			Phe-S_{10}			Phe-S_{16}

PalHis+R-(+)-SUR_{18}	111	60	1.9	636	174	3.7	483	181	2.7

a) Tris buffer (0.083 mol dm^{-3}) containing KCl (0.083 mol dm^{-3}) at 25 °C, pH 7.61, in 10% (v/v) CH_3CN–H_2O; [OctHis]=[LauHis]=[PalHis]=9×10^{-5} mol dm^{-3}, [Substrate]=5×10^{-5} mol dm^{-3}, [R-(+)-SUR_{14}]=4.5×10^{-3} mol dm^{-3}, [R-(+)-SUR_{16}]=2.5×10^{-3} mol dm^{-3}, and [R-(+)-SUR_{18}]=1.8×10^{-3} mol dm^{-3}.

respectively. Therefore, the stereoselective efficiency of the comicelles of the Phe-S_{10} deacylation followed the order of LauHis+R-(+)-SUR_{16}>LauHis+R-(+)-SUR_{14}>LauHis+R-(+)-SUR_{18}. This fact might imply that the hydrophobic chain length of the nucleophile requires an appropriately long (not too short and not too long) hydrophobic chain length of the surfactant for the formation of stereoselectively effective comicelles. The effects of the hydrophobic chain length of the surfactant on the stereoselective comicellar catalysis were also recognized in the deacylation of Phe-S_n (n=2, 10, and 16) with PalHis and R-(+)-SUR_m (m=14, 16, and 18) (see Table 3); the comicellar system of PalHis+R-(+)-SUR_{16} was rather more efficient for the stereoselective deacylation of the long-chain substrate (Phe-S_{10}) than that of PalHis+R-(+)-SUR_m (m=14 and 18).

The experimental results shown in Table 3 also indicate the effects of the hydrophobic chain length of nucleophiles on the stereoselective comicellar catalysis. In the deacylation of Phe-S_n (n=2, 10, and 16) with the nucleophile (OctHis, LauHis, or PalHis) and R-(+)-SUR_{16}, the lengthening of the alkyl chain of the nucleophile increased the deacylation rate of Phe-S_n (n=2—16) monotonously, and the enantiomer-rate ratios in the deacylation of the identical substrate followed the order of LauHis+R-(+)-SUR_{16}>PalHis+R-(+)-SUR_{16}≫OctHis+R-(+)-SUR_{16}. At any rate, among the present comicellar systems, the LauHis+R-(+)-SUR_{16} system was found to contain the most efficient comicelles for the stereoselective deacylation of Phe-S_n (n=2—16). Therefore, stereoselectively efficient comicellar systems do not require too long hydrophobic chains for the nucleophile or the surfactant. Table 3 also indicates that the comicelles of LauHis+R-(+)-SUR_m (m=16 and 18) or PalHis+R-(+)-SUR_m (m=14,16, and 18) resulted in a high stereoselectivity (k^L_{cat}/k^D_{cat}=3.2—4.4) in the deacylation of Phe-S_{10} rather than in the deacylation of Phe-S_{16} or Phe-S_2.

Structural Effects of Substrates. Although the effects of the *N*-acyl chain length of the amino acid esters on the stereoselectivity have already been briefly discussed, a more detailed explanation of the structural effects of the substrates will be developed in this section. With regard to the dependence of the rates and stereoselectivity on the *N*-acyl chain length of a substrate in the deacylation of Phe-S_n (n=2—16) by the LauHis+R-(+)-SUR_{16} system (Fig. 1), the rate increases upon a change in the chain length (n) from n=2 to n=6 were 2.7 and 2.3 fold for the L and D-enantiomer respectively, while the stereoselectivity enhancement was very slight. However, the rate increase upon a change in the chain length from n=2 to n=10—16 was remarkable for the L-enantiomer (4.2—4.4 fold), but slight for the D-enantiomer (1.8—2.4 fold). Therefore, the stereoselectivity enhancement became larger with the increase in the chain length from n=6 to n=10—16, and the highest stereoselectivity was found in the Phe-S_{10} deacylation; that is, Phe-S_{10} incorporated into the comicelles (LauHis+R-(+)-SUR_{16}) might be exposed to the asymmetric environment of the comicelles more directly than with the other Phe-S_n substrates.

Table 4. Structural effects of substrates on deacylation rate and stereoselectivity[a)]

Substrate	k_{cat}/mol^{-1} dm^3 s^{-1}		k^L_{cat}/k^D_{cat}
	L	D	
Ala-S_{10}	89	73	1.1
Val-S_{10}	19	16	1.2
Leu-S_{10}	221	70	3.2
Phe-S_{10}	380	86	4.4

a) The deacylation reactions were carried out by the use of the comicelles of LauHis and R-(+)-SUR_{16} under the same conditions as are shown in Table 1.

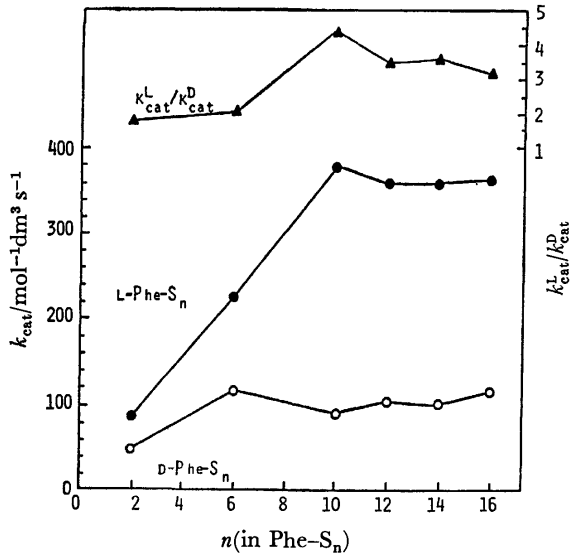

Fig. 1. Dependence of deacylation rate and stereoselectivity on the acyl chain length of Phe-S_n (The deacylation was carried out with LauHis and R-(+)-SUR_{16} under the same conditions as shown in Table 1).

The structural effects of amino-acid esters on the stereoselectivity were also observed in the deacylation of Ala-S_{10}, Val-S_{10}, Leu-S_{10}, and Phe-S_{10} by the comicelles of LauHis+R-(+)-SUR_{16} (Table 4). The deacylation rates followed the order of L-Phe-S_{10}>L-Leu-S_{10}≫L-Ala-S_{10}≫L-Val-S_{10} for the L-enantiomers or of D-Phe-S_{10}>D-Leu-S_{10}~D-Ala-S_{10}≫D-Val-S_{10} for the D-enantiomers. The very low rates of L- and D-Val-S_{10} might be due to the steric hindrance of the isopropyl group, which is adjacent to the susceptible carbonyl group in the substrate, toward the nucleophilic attack of LauHis. In this regard, the very low rate of the *N*-benzyloxycarbonylvaline *p*-nitrophenyl ester was observed in the deacylation of *N*-(benzyloxycarbonyl)-amino acid esters by the L (or D)-LauHis+CTAB system.[8)] Such a steric hindrance might be reduced in the other substrates, $RCH_2CH(NHCO(CH_2)_8CH_3)$-$CO_2C_6H_4NO_2$-*p* (R=H, $(CH_3)_2CH$, and C_6H_5); the deacylation rate increases with the increase in the bulkiness (and/or hydrophobicity) of the R group in the substrate. Table 4 also indicates that the order of the stereoselectivity. Phe-S_{10}>Leu-S_{10}>Val-S_{10}~

Ala–S_{10}, is parallel with the bulkiness (and/or hydrophobicity) of the substituent in the ester. Presumably, the bulkiness (and/or hydrophobicity) of the substrate plays an important role in the increase in the energy difference between the interaction of L-S_{10}–LauHis and D-S_{10}–LauHis in the transition state of the present deacylation.

Synthesis of (+)-Hinokiol, (+)-Hinokione, (+)-Salviol, and (+)-2-Oxoferruginol

Takashi MATSUMOTO,* Shuji USUI, Hiroyuki KAWASHIMA, and Masanori MITSUKI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received August 11, 1980)

Reduction of abieta-5,8,11,13-tetraen-3-one with lithium aluminium hydride afforded the corresponding alcohol, which was submitted to catalytic hydrogenation to yield abieta-8,11,13-trien-3β-ol (**7**) together with its 5βH-isomer. Acetylation of **7**, followed by the Friedel-Crafts acylation, afforded 3β-acetoxy-12-acetylabieta-8,11,13-triene. This compound was converted into 3β,12-diacetoxyabieta-8,11,13-triene (**11**) by the Baeyer-Villiger oxidation. Treatment of **11** with lithium aluminium hydride yielded hinokiol, which was oxidized to hinokione. Subsequently, hinokiol was methylated and the resulting 12-methyl ether was dehydrated to afford 12-methoxyabieta-2,8,11,13-tetraene. The tetraene was then submitted to hydroboration-oxidation to give 12-methoxyabieta-8,11,13-trien-2α-ol (**15**) which, on demethylation with ethanethiol and anhydrous aluminium chloride, afforded salviol. Oxidation of **15** with pyridinium chlorochromate, followed by demethylation, gave 2-oxoferruginol.

Hinokiol (**1**) and hinokione (**2**) have been isolated from the heartwood of *Chamaecyparis obtusa*, Sieb. et. Zucc.,[1] *Cupressus torulosa* Don,[2] and *Tetraclinis articulata* (Vahl) Masters,[3] and from the leaf of *Torreya nucifera* Sieb. et. Zucc.[4] The similar diterpenes, salviol (**3**) and 2-oxoferruginol (**4**), have also been isolated from the roots of *Salvia miltiorrhiza* Bunge[5] and from the bark of *Podocarpus ferrugineus* D. Don,[6] respectively. All these natural diterpenes possess the oxygen functions in both the rings A and C of the abietane skeleton. As a part of our synthetic studies on the naturally-occurring terpenes, we have attempted the syntheses of these tricyclic diterpenes. This paper will describe the syntheses of (+)-hinokiol (**1**), (+)-hinokione (**2**),[7] (+)-salviol (**3**), and (+)-2-oxoferruginol (**4**), starting from the optically active abieta-5,8,11,13-tetraen-3-one (**5**) which was prepared from (+)-dehydroabietic acid by the known procedure.[8]

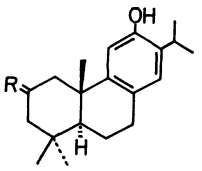
2 R=O



3 R=α-OH, β-H
4 R=O

Reduction of **5** with lithium aluminium hydride in ether afforded abieta-5,8,11,13-tetraen-3β-ol (**6**). The β-configuration of the hydroxyl group at the C-3 position was supported by its NMR spectrum, which showed a triplet at δ 2.80 ppm with a half-height width of 16 Hz, suggesting the presence of an axial α hydrogen. Catalytic hydrogenation of **6** in methanol over Pd–C, followed by chromatographic purification, gave abieta-8,11,13-trien-3β-ol (**7**) as a major product and its 5βH-isomer (**8**) as a minor one. The NMR spectrum of **7** showed signals at δ 0.89 and 1.06 ppm due to the *gem*-dimethyl groups at the C-4 position, while that of **8** showed the corresponding signals at δ 0.39 and 0.99 ppm. The *cis*-configuration of the A/B ring junction in **8** was supported by the appearance of the signal due to one of the *gem*-dimethyl groups in very high field (δ 0.39 ppm),[9] owing to the shielding effect of the C ring The *trans*-isomer (**7**) was acetylated with acetic anhydride in pyridine to give 3β-acetoxyabieta-8,11,13-triene (**9**). The Friedel-Crafts acylation of **9** with acetyl chloride in dichloromethane in the presence of anhydrous aluminium chloride afforded 3β-acetoxy-12-acetylabieta-8,11,13-triene (**10**), whose IR spectrum showed carbonyl bands at 1725 and 1675 cm^{-1}. The NMR spectrum of **10** showed two singlets at δ 6.98 and 7.32 ppm due to the two aromatic protons. These spectral data of **10** supported the presence of an acetyl group at the C-12 position. The Baeyer-Villiger oxidation of **10** with *m*-chloroperbenzoic acid in dichloromethane afforded 3β,12-diacetoxyabieta-8,11,13-triene (hinokiol diacetate) (**11**).[1,4] Treatment of **11** with lithium aluminium hydride in ether yielded abieta-8,11,13-triene-3β,12-diol (hinokiol) (**1**)[1-4] which, on methylation with methyl iodide and anhydrous potassium carbonate in refluxing ethyl methyl ketone, afforded 12-methoxyabieta-8,11,13-trien-3β-ol (hinokiol 12-methyl ether) (**12**).[1] The synthetic **1** was then oxidized with Jones reagent to give 12-hydroxyabieta-8,11,13-trien-3-one (hinokione) (**2**).[1-3]

Our next effort was directed toward the syntheses of salviol (**3**) and 2-oxoferruginol (**4**). The methyl ether (**12**) was dehydrated with phosphoryl chloride in refluxing pyridine to yield 12-methoxyabieta-2,8,11,-13-tetraene (**13**). Hydroboration of **13**, followed by oxidation with alkaline hydrogen peroxide, afforded a mixture of alcohols. This was separated by column chromatography on silica gel to give 12-methoxyabieta-8,11,13-trien-3α-ol (**14**), **12**, and 12-methoxyabieta-8,11,13-trien-2α-ol (**15**). Oxidation of **14** with pyridinium chlorochromate[10] in dichloromethane afforded 12-methoxyabieta-8,11,13-trien-3-one(hinokione methyl ether) (**16**).[1,11] The alcohol (**14**) was also converted into **13** by dehydration with phosphoryl chloride in refluxing pyridine. The stereochemistry of the hydroxyl group at the C-2 position in **15** was assigned to be α-configuration by its NMR spectrum, which showed a signal due to the C-2 proton at δ 4.08 ppm with a half-height width of 22 Hz, suggesting the presence of an axial β hydrogen. Demethylation of **15** with anhydrous aluminium chloride and ethanethiol[12] in dichloro-

methane afforded abieta-8,11,13-triene-2α,12-diol (salviol) (**3**).[5] Subsequently, the alcohol (**15**) was oxidized with pyridinium chlorochromate in dichloromethane to give 12-methoxyabieta-8,11,13-trien-2-one (**17**) which, on demethylation with boron tribromide in dichloromethane, afforded 12-hydroxyabieta-8,11,13-trien-2-one (2-oxoferruginol) (**4**).[6]

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, t: triplet, m: multiplet. Column chromatography was performed using Merck silica gel (0.063 mm).

Abieta-5,8,11,13-tetraen-3-one (5). According to the known procedure,[8] (+)-dehydroabietic acid was converted into **5**, $[\alpha]_D$ +32.9°, IR: 1705 cm^{-1}, NMR: 1.17, 1.23, and 1.32 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}-CH_3), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.37 (2H, d, J=4 Hz, $=CH-C\underline{H}_2-$), 5.90 (1H, t, J=4 Hz, C_6-H). Found: C, 84.76; H, 9.38%. Calcd for $C_{20}H_{26}O$: C, 85.05; H, 9.28%.

Abieta-5,8,11,13-tetraen-3β-ol (6). A mixture of **5** (1.159 g) and lithium aluminium hydride (156 mg) in dry ether (25 ml) was stirred at room temperature for 90 min. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was purified by column chromatography on silica gel (30 g), using ether–benzene (2 : 98) as the eluent, to give **6** (1.107 g: 94.8%), $[\alpha]_D$ −69.7°; IR: 3615, 3450 cm^{-1}; NMR: 1.15, 1.20, and 1.27 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}-CH_3), 1.21 (6H, d, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 2.80 (1H, t, J=7 Hz, $W_{1/2}$= 16 Hz, C_3-H), 3.31 (2H, bd, J=4 Hz, $=CH-C\underline{H}_2-$), 5.95 (1H, t, J=4 Hz, C_6-H). Found: C, 84.36; H, 10.04%. Calcd for $C_{20}H_{28}O$: C, 84.45; H, 9.92%.

Catalytic Hydrogenation of 6. A mixture of **6** (1.007 g) and 5% Pd-C (500 mg) in methanol (15 ml) was subjected to catalytic hydrogenation at room temperature for *ca.* 20 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (60 g), using ether-benzene (0.5 : 99.5) as the eluent, to give 5βH-abieta-8,11,13-trien-3β-ol (**8**) (104 mg: 10.3%), $[\alpha]_D$ +22.4°; IR: 3628, 3463 cm^{-1}; NMR: 0.39, 0.99, and 1.18 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}-CH_3), 1.22 (6H, d, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.87 (1H, s, -OH), 3.25 (1H, m, $W_{1/2}$=7 Hz, C_3-H). Found: C, 83.76; H, 10.73%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

Further elution with ether-benzene (5 : 95) afforded abieta-8,11,13-trien-3β-ol (**7**) (683 mg: 67.3%), which was recrystallized from hexane; mp 136.5—138 °C; $[\alpha]_D$ +50.4°; IR: 3617, 3453 cm^{-1}; NMR ($CDCl_3$): 0.89, 1.06, and 1.18 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}-CH_3), 1.22 (6H, d, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.68 (1H, s, -OH), 3.30 (1H, m, $W_{1/2}$=17 Hz, C_3-H). Found: C, 84.03; H, 10.75%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

3β-Acetoxyabieta-8,11,13-triene (9). A solution of **7** (679 mg) and acetic anhydride (2.5 ml) in pyridine (7.0 ml) was heated at 74—77 °C for 1.5 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (30 g), using hexane–benzene (35 : 65) as the eluent, to give **9** (750 mg: 96.3%), which was recrystallized from hexane; mp 112—114 °C; $[\alpha]_D$ +58.9°; IR: 1720 cm^{-1}; NMR: 0.94 (6H, s, $-\dot{C}(CH_3)_2$), 1.19 (3H, s, C_{10}-CH_3), 1.20 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.00 (3H, s, $-OCOCH_3$), 4.5 (1H, m, C_3-H), 6.79 (bs), 6.87 (bd, J=8 Hz), and 7.07 (bd, J=8 Hz) (each 1H, aromatic protons). Found: C, 80.71; H, 9.99%. Calcd for $C_{22}H_{32}O_2$: C,80.44; H, 9.83%.

3β-Acetoxy-12-acetylabieta-8,11,13-triene (10). Anhydrous aluminium chloride (850 mg) was added at 0—5 °C to a stirred solution of **9** (696 mg) and acetyl chloride (500 mg) in dichloromethane (10 ml). The mixture was stirred at this temperature for 30 min and then at room temperature for 24 h, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried extract was evaporated *in vacuo* to give a crude product, which was purified by column chromatography on silica gel (15 g), using ether–benzene (1 : 99) as the eluent, to afford **10** (748 mg: 95.3%). This was recrystallized from a mixture of acetone and hexane; mp 163.5—165.5 °C; $[\alpha]_D$ +62.6°; IR: 1725, 1675 cm^{-1}; NMR: 0.95 (6H, s, $-\dot{C}(C\underline{H}_3)_2$), 1.16 and 1.20 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.21 (3H, s, C_{10}-CH_3), 2.00 (3H, s, $-OCOCH_3$), 2.46 (3H, s, $-COCH_3$), 3.46 (1H, m, $-C\underline{H}(CH_3)_2$), 4.45 (1H, m, C_3-H), 6.98 (1H, s, C_{14}-H), 7.32 (1H, s, C_{11}-H). Found: C, 77.85; H, 9.48%. Calcd for $C_{24}H_{34}O_3$: C, 77.80; H, 9.25%.

3β,12-Diacetoxyabieta-8,11,13-triene (Hinokiol Diacetate) (11). A mixture of **10** (739 mg), *m*-chloroperbenzoic acid (85%: 610 mg), and *p*-toluenesulfonic acid (40 mg) in 1,2-dichloroethane (10 ml) was refluxed for 3.5 h. The mixture was then cooled, diluted with ether, and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and water. The dried ether solution was evaporated *in vacuo* and the residue was purified by column chromatography on silica gel (25 g), using ether–benzene (1 : 99) as the eluent, to give **11** (647 mg: 83.9%), which was recrystallized from ethanol; mp 145—146 °C; $[\alpha]_D$ +69.8° (EtOH) (lit,[1] mp 143 °C, $[\alpha]_D$ +70.39° (EtOH)); IR: 1750, 1725 cm^{-1}; NMR: 0.94 (6H, s, $-\dot{C}(CH_3)_2$), 1.16 (6H, d, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.22 (3H, s, $C_{10}-CH_3$), 2.00 (3H, s, $C_3-OCOCH_3$), 2.22 (3H, s, $C_{12}-OCOCH_3$), 4.48 (1H, m, C_3–H), 6.76 and 6.89 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 74.27; H, 8.92%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

Further elution gave the recovered **10** (58 mg: 7.9%).

Abieta-8,11,13-triene-3β,12-diol (Hinokiol) (1). A mixture of **11** (575 mg) and lithium aluminium hydride (140 mg) in dry ether (10 ml) was stirred at 0—5 °C for 45 min and then at room temperature for 30 min. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was purified by column chromatography on silica gel (30 g), using acetone–benzene (3 : 7) as the eluent, to give hinokiol (**1**) (401 mg: 89.1%), which was recrystallized from ethanol; mp 240—242 °C; $[\alpha]_D$ +66.2° (EtOH) (lit, mp 240—242 °C,[3] $[\alpha]_D$ +67.3° (EtOH)[4]); IR (KBr): 3540, 3280 cm^{-1}; NMR (pyridine-d_5): 1.09, 1.23, and 1.25 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.39 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 7.15 and 7.18 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.19; H, 10.11%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%. The identity of the synthetic **1** with natural hinokiol provided by Professor T. Hirose was confirmed by mixed melting point determination and by IR spectral comparison.

12-Hydroxyabieta-8,11,13-trien-3-one (Hinokione) (2). A solution of **1** (69 mg) in acetone (6.0 ml) was oxidized with Jones reagent (1 M†: 0.2 ml) at 5 °C for 3 min. The mixture was diluted with ether, washed with water, and dried over sodium sulfate. The ether solution was evaporated and the residue was purified by column chromatography on silica gel (10 g), using ether–benzene (3 : 97) as the eluent, to give **2** (49.2 mg: 71.8%), which was recrystallized from a mixture of ether and hexane; mp 192—193 °C; $[\alpha]_D$ +115.6° (EtOH) (lit,[3] mp 191—192 °C, $[\alpha]_D$ +111.9° (EtOH)); IR: 3605, 3380, 1696 cm^{-1}; NMR ($CDCl_3$): 1.14, 1.18, and 1.30 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 6.66 and 6.89 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.71; H, 9.53%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

12-Methoxyabieta-8,11,13-trien-3β-ol (12). A mixture of **1** (99 mg), methyl iodide (0.5 ml), anhydrous potassium carbonate (1.0 g), and ethyl methyl ketone (5.0 ml) was stirred and refluxed for 8 h. The mixture was cooled, diluted with ether, and water was added. The organic layer was separated, washed first with aqueous sodium thiosulfate and then with water, and then dried over sodium sulfate. After the solvent had been evaporated *in vacuo*, the residue was purified by column chromatography on silica gel (10 g), using ether–benzene (1 : 99) as the eluent, to give **12** (75.8 mg: 72.8%), which was recrystallized from hexane; mp 105.5—107.5 °C (softened at *ca.* 94 °C); $[\alpha]_D$ +61.0° (EtOH) (lit,[1] mp 95—96 °C, $[\alpha]_D$ +59.46° (EtOH)); IR: 3625, 3455 cm^{-1}; NMR: 0.86, 1.04, and 1.19 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.61 (1H, s, –OH), 3.75 (3H, s, $-OCH_3$), 6.58 and 6.72 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.46; H, 10.35%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

12-Methoxyabieta-2,8,11,13-tetraene (13). a): A mixture of **12** (938 mg), phosphoryl chloride (1.4 ml), and pyridine (10 ml) was refluxed for 1 h, cooled, and then poured into ice-dilute hydrochloric acid. The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (40 g), using hexane–benzene (7 : 3) as the eluent, to give **13** as an oil (764 mg: 86.3%); $[\alpha]_D$ +163°; IR: 1655 cm^{-1}; NMR: 0.98, 1.03, and 1.23 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.21 (1H, m, $-C\underline{H}(CH_3)_2$), 3.75 (3H, s, $-OCH_3$), 5.49 (2H, s, C_2–H and C_3–H), 6.58 and 6.71 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 84.49; H, 10.32%. Calcd for $C_{21}H_{30}O$: C, 84.51; H, 10.13%.

b): A mixture of 12-methoxyabieta-8,11,13-trien-3α-ol (**14**) (56.4 mg), phosphoryl chloride (0.09 ml), and pyridine (2.0 ml) was refluxed for 1 h. After the work-up described in *a*), the crude product was chromatographed on silica gel (5 g) to give the tetraene derivative (46.2 mg: 86.9%), whose IR and NMR spectra were identical with those of **13**.

Hydroboration-oxidation of 13. Boron trifluoride etherate (1.16 ml) was added dropwise at 0—5 °C to a stirred mixture of **13** (759 mg) and sodium borohydride (260 mg) in dry tetrahydrofuran (12 ml) in a stream of nitrogen. After the mixture had been stirred at this temperature for 2 h, there was added successively aqueous tetrahydrofuran (50%: 1.0 ml), aqueous sodium hydroxide (12%: 3.0 ml), and hydrogen peroxide (30%: 3.0 ml) at −5—0 °C. The mixture was stirred at −5—0 °C for 30 min and then at room temperature for 1 h, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (70 g), using ether–benzene (2 : 98) as the eluent, to give 12-methoxyabieta-8,11,13-trien-3α-ol (**14**) (305 mg: 37.9%), which was recrystallized from hexane; mp 114—114.5 °C; $[\alpha]_D$ +49.1° (EtOH) (lit,[1] mp 117—118 °C, $[\alpha]_D$ +45.25° (EtOH)); IR: 3630, 3455 cm^{-1}; NMR: 0.90, 0.96, and 1.16 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.72 (1H, s, –OH), 3.20 (1H, m, $-C\underline{H}(CH_3)_2$), 3.36 (1H, m, $W_{1/2}$=7 Hz, C_3–H), 3.75 (3H, s, $-OCH_3$), 6.59 and 6.71 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.70; H, 10.48%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

Further elution gave **12** (102 mg: 12.7%). Elution with ether–benzene (5 : 95) gave 12-methoxyabieta-8,11,13-trien-2α-ol (**15**) (141 mg: 17%), which was recrystallized from hexane; mp 130—131.5 °C; $[\alpha]_D$ +64.3°; IR 3611, 3430 cm^{-1}; NMR ($CDCl_3$): 0.98, 1.01, and 1.24 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.19 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.25 (1H, m, $-C\underline{H}(CH_3)_2$), 3.80 (3H, s, $-OCH_3$), 4.08 (1H, m, $W_{1/2}$= 22 Hz, C_2–H), 6.76 and 6.88 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.99; H, 10.40%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

12-Methoxyabieta-8,11,13-trien-3-one (16). Pyridinium chlorochromate (220 mg) was added at 0—5 °C to a stirred solution of **14** (193 mg) in dichloromethane (4.5 ml). The mixture was stirred at room temperature for an additional 1.5 h and then diluted with ether. After the addition of

† 1M = 1 mol dm^{-3}.

water, the mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (10 g), using ether–benzene (1 : 99) as the eluent, to give **16** (132 mg: 68.4%), which was recrystallized from ethanol; mp 123.5—124.5 °C; $[\alpha]_D$ +132° (EtOH) (lit,[1] mp 126 °C, $[\alpha]_D$ +122.2° (EtOH)); IR: 1700 cm^{-1}; NMR: 1.10 (6H, s, $-\dot{C}(CH_3)_2$), 1.16 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (3H, s, $C_{10}-CH_3$), 3.20 (1H, m, $-C\underline{H}-(CH_3)_2$), 3.77 (3H, s, $-OCH_3$), 6.58 and 6.75 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 80.03; H, 9.86%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

Abieta-8,11,13-triene-2α,12-diol (Salviol) (3). A mixture of **15** (51.5 mg), ethanethiol (0.5 ml), anhydrous aluminium chloride (150 mg), and dichloromethane (1.5 ml) was stirred at room temperature for 1 h, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (5 g), using ether–benzene (4 : 6) as the eluent, to give salviol (**3**) (47.3 mg: 96.1%), which was recrystallized from benzene; mp 106—107 °C (softened at *ca.* 103 °C); $[\alpha]_D$ +55.7° (EtOH) (lit,[5] mp 108 °C); IR (KBr): 3395 cm^{-1}; NMR ($CDCl_3$, 90 MHz): 0.96, 1.00, and 1.23 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.23 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$). 3.15 (1H, m, $-C\underline{H}(CH_3)_2$) 4.09 (1H, m, $W_{1/2}$=22 Hz, C_2–H), 6.06 (1H, s, $=\dot{C}-OH$), 6.68 and 6.83 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.15; H, 10.13%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%. The IR and NMR spectra of the synthetic **3** were identical with those of natural salviol provided by Professor H. Kakisawa.

12-Methoxyabieta-8,11,13-trien-2-one (17). Pyridinium chlorochromate (148 mg) was added at 0—5 °C to a stirred solution of **15** (140 mg) in dichloromethane (2.5 ml) and the mixture was stirred at room temperature for 1.5 h. After the work-up described for the preparation of **16**, the crude product was purified by column chromatography on silica gel (10 g), using ether–benzene (3 : 97) as the eluent, to give **17** (109 mg: 78.1%). This was recrystallized from ethanol; mp 152.5—153.5 °C; $[\alpha]_D$ +48.6°; IR: 1703 cm^{-1}; NMR: 0.98, 1.13, and 1.21 (each 3H and s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.20 (1H, m, $-C\underline{H}-(CH_3)_2$), 3.77 (3H, s, $-OCH_3$), 6.51 and 6.76 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.93; H, 9.83%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

12-Hydroxyabieta-8,11,13-trien-2-one (2-Oxoferruginol) (4). A mixture of **17** (76.9 mg) and boron tribromide (0.07 ml) in dichloromethane (1.5 ml) was stirred at 0—5 °C for 30 min. The reaction mixture was poured into ice–water and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (7 g) using chloroform as the eluent, to give 2-oxoferruginol (**4**) (61.8 mg: 84.1%), which was recrystallized from methanol; mp 237—239 °C; $[\alpha]_D$ +48.3° (MeOH) (lit,[6] mp 232—234 °C, $[\alpha]_D$ +50° (MeOH)); IR (KBr): 3450, 1706 cm^{-1}; NMR ($CDCl_3$, 90 MHz): 0.99, 1.15, and 1.21 (each 3H and s, $-\dot{C}-(CH_3)_2$ and $C_{10}-CH_3$), 1.23 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.14 (1H, m, $-C\underline{H}(CH_3)_2$), 5.48 (1H, s, –OH), 6.55 and 6.85 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 80.08; H, 9.56%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

The authors are grateful to Arakawa Chemical Co. Ltd. for a generous gift of rosin. Thanks are also due to Professor H. Kakisawa, Tsukuba University, and to Professor T. Hirose, Science University of Tokyo, for kindly supplying the spectral data and natural hinokiol.

Studies on the Uptake of Some Complex Cations of Copper by Molecular Sieves 4A and 5A

S. S. Thantry, K. Veeramoni Iyer, and P. S. Ramanathan*

Analytical Chemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay-400 085, India

(Received September 22, 1979)

Studies on the uptake of Cu^{2+} and a few of its complex cations (*i.e.*, $[Cu(NH_3)_4]^{2+}$, $[Cu(en)]^{2+}$, $[Cu(en)_2]^{2+}$, $[Cu(pn)]^{2+}$, $[Cu(pn)_2]^{2+}$, and $[Cu(tea)]^{2+}$, where en, pn, and tea represent ethylenediamine, propylenediamine, and triethanolamine respectively) by molecular sieves 4A and 5A were undertaken using batch equilibration procedure. $[Cu(pn)]^{2+}$, $[Cu(en)_2]^{2+}$, $[Cu(pn)_2]^{2+}$, and $[Cu(tea)]^{2+}$ showed very little affinity for the zeolite phases, while the uptake of Cu^{2+} and $[Cu(en)]^{2+}$ was comparatively higher. $[Cu(NH_3)_4]^{2+}$ occupied a position in between these two sets. During the equilibration of $[Cu(en)]^{2+}$ and $[Cu(pn)]^{2+}$ some side reactions could be observed leading to the conclusion that the 1:1 complex species underwent disproportionation, generating Cu^{2+} and an equivalent amount of $[Cu(en)_2]^{2+}$ or $[Cu(pn)_2]^{2+}$. These conclusions drawn from the batch equilibration studies were confirmed by appropriate column experiments.

Ion exchange studies using zeolite exchangers of various types have been reviewed from time to time by different workers.[1-9] Scores of publications have appeared in the literature dealing with the studies on the uptake of simple cations by molecular sieves 4A(MS4). Similar studies on molecular sieves 5A-(MS5) are comparatively fewer in number. Recently Schoonheydt and coworkers[10] prepared complexes of ammonia and ethylenediamine with Cu^{2+} on zeolite A and conducted EPR and reflectance spectral studies of the various complexes. The existing literature does not appear to contain any other information on the uptake of complex cations by MS4 and MS5. It was, therefore, decided to undertake a systematic study of the uptake of a few complex cations** of Cu^{2+} (*i.e.*, $[Cu(NH_3)_4]^{2+}$, $[Cu(en)]^{2+}$, $[Cu(pn)]^{2+}$, $[Cu(en)_2]^{2+}$, $[Cu(tea)]^{2+}$, and $[Cu(pn)_2]^{2+}$) by MS4 and MS5. Studies were also carried out with Cu^{2+} for comparison.

Experimental

Chemical analyses of Anasorb MS4 and MS5 samples (40—60 mesh, supplied by Analabs Inc., U.S.A.) were carried out, following procedures given in standard books. Loading studies were carried out by the batch equilibration procedure. All reagents/chemicals used were of Analytical reagent or C.P. grade.

For studying the uptake as a function of time, 20 ml of solutions of Cu^{2+} (0.1 M), $[Cu(en)]^{2+}$ (0.05 M), $[Cu(en)_2]^{2+}$ (0.1 M), $[Cu(pn)]^{2+}$ (0.01 M), $[Cu(pn)_2]^{2+}$ (0.05 M), $[Cu(tea)]^{2+}$ (0.1 M), and $[Cu(NH_3)_4]^{2+}$ (0.1 M) were equilibrated with 0.5 g of the sieve at 30 °C for the prescribed period. The ligand to metal ratio maintained in the last 6 cases were 1, 2, 1, 2, 6, and 60 respectively. The pH values of the solutions of the first six cations used for equilibration were 2.0, 5.0, 7.0, 5.5, 7.0, and 8.0 in that order.

The quantitative and exclusive formation of the complex cation of interest, under the conditions specified above, was confirmed by comparing the spectra of their solutions with those reported in the literature.

To arrive at the 'K' values (mmol of M^{n+} per g of the sieve/mmol of M^{n+} per ml of the solution, at any contact time 't'), the concentrations of the cation of interest in the original solution and in the external solution left out after equilibration were estimated spectrophotometrically. Cu^{2+} was estimated after converting it to $[Cu(NH_3)_4]^{2+}$ by adding aqueous ammonia in excess (6 M) and measuring the absorbance(E) at 600 nm(λ_{max}). In the case of the other complex cationic species (*i.e.*, $[Cu(en)]^{2+}$, $[Cu(pn)]^{2+}$ *etc.*) the 'E' values were measured at the corresponding λ_{max} (after appropriate dilution to bring the concentration within the range of the corresponding calibration graph). The concentrations were then computed. In a few cases the amount of Na^+(or Ca^{2+}) displaced from the molecular sieve was also estimated to understand the extent of uptake by ion exchange. These estimations were carried out after removing the copper from the solutions by electrolysis in the Fischer Electroanalyser.

Equilibration studies were also carried out to understand the influence of concentration on the uptake. In these cases, solutions containing different concentrations of the cation of interest were equilibrated for 24 h. The 'K' values were then calculated as described in the earlier paragraph.

Results and Discussion

Chemical Analysis of the MS4 and MS5 Specimens. The number of AlO_2, Na, and H_2O species per unit cell of the MS4(computed from the results of chemical analysis, on the assumption that the SiO_2 content corresponds exactly to 12 SiO_2 groups) worked out to 11.60, 11.00, and 20.80 respectively. The corresponding figures for MS5 were 12.82, 1.66, and 21.52. In this case, the number for Ca was 4.34.

The results of chemical analysis speak against the possible presence of occluded $NaAlO_2$ in the MS4. The Na, H_2O, and AlO_2 figures are all smaller than those expected from the generally accepted unit cell formula ($Na_{12}(AlO_2)_{12}(SiO_2)_{12}\cdot 27H_2O$). In the MS5 specimen, there is (i) a marginal decrease in the number of Ca atoms and (ii) a significant decrease and increase in the Na and AlO_2 contents respectively(in comparison to the unit cell formula of MS4 in which 75% Na^+ has been replaced by Ca^{2+}). The results provide a measure of free Al_2O_3 and SiO_2 in the zeolite samples.

Equilibration Studies. The pH of the equilibrated Cu^{2+} solution increased from 2.0 to around 4.0 during equilibration.*** The uptake of Cu^{2+} was so slow

** In the subsequent sections, the symbols 'en', 'pn', and 'tea' will be used to represent ethylenediamine, propylenediamine, and triethanolamine respectively.

*** In this case, an undesirable but unavoidable side-effect of the comparatively higher acidity maintained (to keep the Cu^{2+} in solution) is the structural breakdown of a small fraction of the zeolite matrix.

that final equilibrium was attained only after about 48 h. The 'K' values observed in the case of MS4 and MS5, after this time interval, were 42 and 27 respectively(when the initial concentration of Cu^{2+} solution employed was 0.1 M).

Analysis of Na^+ released during equilibration revealed that the uptake of Cu^{2+} by MS4 was predominantly by ion exchange. In the case of MS5, however, the Ca^{2+} released was only around 30% of the amount equivalent to the total Cu^{2+} taken up.

When 20 ml of water at pH 2.0 were equilibrated with 0.5 g of the sieves, the Na^+ and Ca^{2+} released were found to be 4 mg and 0.8 mg respectively in the two cases.

Spectral studies of Cu^{2+}-aqueous ammonia mixtures revealed that the formation of $[Cu(NH_3)_4]^{2+}$ was complete only when $C_{NH_3}/C_{Cu} \geq 40$(when C_{Cu}=0.1 M). 'K' values for this cation were lower ($\approx$5 for a solution of concentration of 0.1 M) than those found for Cu^{2+}. Only marginal increases in 'K' were observed beyond 2 h. The much faster kinetics suggest that the uptake is probably restricted to the external surfaces which are in direct contact with the solution.

Increase in the concentration of aqueous ammonia (to 60 and 80 times the concentration of Cu^{2+}) produced only a marginal change in the uptake of $[Cu(NH_3)_4]^{2+}$ species. The uptake of NH_4^+ by ion exchange was then investigated in each case by equilibrating aqueous ammonia solution of the same concentration, but in the absence of Cu^{2+}. While 8 M aqueous ammonia released about 15 mg of Na^+ from MS4, the release of Ca^{2+} from MS5 was insignificant($\approx$0.2%).

The 'K' values found for $[Cu(en)_2]^{2+}$, $[Cu(pn)_2]^{2+}$, and $[Cu(tea)]^{2+}$ were extremely small($\approx$1). The uptake was also very quick, suggesting thereby, that the process involved was probably pure physical adsorption. It appears that the sizes of these ions are unfavourable for entry into the pores of the zeolites. On this basis it can be qualitatively concluded that the size of each of these three complex cations (in the hydrated form) may be greater than 5Å, the pore dimension of MS5.

The pH of $[Cu(en)]^{2+}$ solution used for equilibration was adjusted to 5.0 as the complex forms quantitatively when the reactants are mixed in stoichiometric amounts at this acidity. The pH of the external solution rose to around 6.0 after equilibration. In this case the exchange was slow(as in the case of Cu^{2+}). 0.01 M solution, when equilibrated with MS4 for 24 h became practically colourless, indicating a nearly quantitative uptake in this concentration range. The uptake was, however, not quantitative when more concentrated solutions($\approx$0.02 M and above) were employed for equilibration. Moreover, the post-equilibration spectra of these concentrated solutions were not superimposable on that of the 1:1 complex. The λ_{max} shifted from 650 nm(expected for the 1:1 complex) to a lower value. The extent of shift depended on the time of equilibration as well as the concentration of the solution used. Some typical spectra are shown in Fig. 1. The results obtained with MS5 were of the same nature except for the fact that the uptake was not quantitative at low concentrations(*i.e.*, $\approx$0.01 M). Some typical spectra obtained in the case of MS5 are shown in Fig. 2.

A careful scrutiny of the spectra of the external solutions indicated the possibility of the presence of varying amounts of the higher complex(1:2, with λ_{max} at 550 nm) in them. As both 1:1 and 1:2 complexes are known to be very stable under the experimental conditions employed, and Cu^{2+} cannot remain in/solution in the weakly acidic conditions

maintained, the possibility of the presence of free Cu^{2+} in the external solutions was ruled out. Taking the external solutions (equilibrated for 24 h) as mixtures of 1:1 and 1:2 complexes, the individual concentrations(C_1 and C_2)/of the two complexes were calculated by solving simultaneous equations. The results obtained are given in Table 1.

The above-mentioned observations may be interpreted as shown below: It appears that the MS4 phase induces the dissociation of $[Cu(en)]^{2+}$ and takes up the Cu^{2+} generated *in situ*(along with $[Cu(en)]^{2+}$, for which also MS4, shows comparable affinity). The 'en' generated by the above process combines with $[Cu(en)]^{2+}$ present in the external solution, giving rise to an equivalent amount of $[Cu(en)_2]^{2+}$. When dilute solutions($\approx$0.01 M) are employed, the uptake of all the three cationic species occurs practically quantitatively, making the external solution practically colourless. However, with increase in concentration of the external solution, a comparatively larger concentration of the 1:2 complex is formed. As it is a strong complex and it has very little affinity for the zeolite phase, the post-equilibration solution phase gradually becomes a mixture of $[Cu(en)]^{2+}$ and $[Cu(en)_2]^{2+}$. The side equilibria represented by Eqs. 1—3 summarise the above-mentioned points.

$$[Cu(en)]^{2+} \rightleftharpoons Cu^{2+} + en \quad (1)$$

$$Cu^{2+} + 2NaZ \rightleftharpoons CuZ_2 + 2Na^+ \quad (2)$$

$$[Cu(en)]^{2+} + en \longrightarrow [Cu(en)_2]^{2+} \quad (3)$$

In Eq. 2, Z stands for the zeolite anion.

In the case of MS5, the results(Table 1) were qualitatively of the same type(*i.e.*, as described above in the case of MS4). The notable differences were: (i) The uptake was not quantitative in low concentrations. (ii) The quantity of $[Cu(en)]^{2+}$ taken up was smaller and the uptake of Cu^{2+} was greater than those found in the case of MS4. (iii) The total uptake (as Cu^{2+} and $[Cu(en)]^{2+}$) was, however, much lower. Equation 2 takes the following form in this case, while (1) and (3) continue to remain applicable.

$$0.5Cu^{2+} + Ca_{0.5}Z \rightleftharpoons Cu_{0.5}Z + 0.5Ca^{2+} \quad (4)$$

In this context it is worth mentioning that a significant part(>60%) of Cu^{2+} and $[Cu(en)]^{2+}$ going to the MS5 phase is by physical adsorption. Irrespective of whether the uptake is by ion exchange or by physical adsorption, the arguments presented earlier concerning the apparent disproportionation of $[Cu(en)]^{2+}$ (giving Cu^{2+} and an equivalent amount of $[Cu(en)_2]^{2+}$) will hold good.

To understand the nature of the results obtained in a column experiment, a MS4 column(5 g packed in a column of i.d. 1.2 cm) was fed with 100 ml of $[Cu(en)]^{2+}$ solution of concentration 0.05 M(pH= 5.0). The flow rate was 0.5 ml per min. The effluent solution was colourless. When 50 ml of 0.05 M $[Cu(en)]^{2+}$ solution were passed through a column containing 2 g of MS4, the effluent contained about 5% of the total copper as the 1:2 complex, while the effluent was colourless when 25 ml of 0.01 M solution were passed through the same column. All these observations point out that the disproportionation reaction does take place in the column experiment as well. When dilute solutions are employed, copper is not found in the effluent as $[Cu(en)]^{2+}$, as well as the small amount of Cu^{2+} and $[Cu(en)_2]^{2+}$, formed by the disproportionation reaction, are all retained by the column. On increasing the concentration, a small amount of the 1:2 complex leaks out as its affinity for the adsorbent is low.

In the case of MS5, the effluent contained around 50% of the copper as a mixture of 1:1 and 1:2 complexes(in approximately equal concentrations) when 20 ml of 0.05 M $[Cu(en)]^{2+}$ solution at pH 5.0 were passed through a column containing 2 g of the sieve. The higher extent of disproportionation and the comparatively lower affinities for the cations seem

B. MS5				
5	5.0	0.4	2.3	4.6
6	10.0	1.3	4.3	8.6
7	15.0	2.8	6.0	12.0
8	20.0	6.5	6.7	13.4

a) N.D. means not detectable. The calculations reveal that 0.022, 0.017, 0.014, and 0.016 millimoles of Cu-pn complex species go to the MS4 phase in the four cases respectively. The uptake is negligible in the case of MS5.

to be responsible for this situation.

In view of the above-mentioned side reactions, 'K' values, as defined earlier, cannot be given for $[Cu(en)]^{2+}$ uptake by MS4 and MS5. One can, however, arrive at 'K_{av}' and 'K^*' values, defined as shown below:

$$K_{av}=\frac{\text{mmol of } Cu^{2+} \text{ in all forms per g of sieve}}{\text{mmol of } Cu^{2+} \text{ in all forms per ml of the solution}}$$

$$K^*=\frac{\text{mmol of } [Cu(en)]^{2+} \text{ per g of sieve}}{\text{mmol of } [Cu(en)]^{2+} \text{ per ml of the solution}}.$$

These values are tabulated in Table 3.

From the earlier sections it becomes obvious that Cu^{2+} and $[Cu(en)]^{2+}$ exhibit good affinity for the zeolite phase. Uptake of these preferred cationic species, with the consequential breakdown of the less favoured $[Cu(en)_2]^{2+}$, is not observed because of the very high stability of the 1:2 complex.

In this context it is worth pointing out that Schoonheydt *et al.*[10] recently reported the preparation of the following complexes (by gas phase adsorption) on the A type zeolite surface:

(i) $[Cu(NH_3)_4]^{2+}$ and a small amount of tetrahedrally coordinated Cu^{2+} ions by adsorption of NH_3 on a dehydrated CuA zeolite,

(ii) $[Cu(en)]^{2+}$ by the adsorption of 'en' on a dehydrated CuA zeolite and

(iii) $[Cu(en)_2]^{2+}$ and $[Cu(en)_3]^{2+}$ by adsorption of 'en' on CuA in the presence of water.

They also found that $[Cu(en)]^{2+}$ could be loaded on NaA by ion exchange from aqueous solution, but the bis-complex could not be loaded in this way. The impossibility of loading the bis-complex has been attributed by them to the fact that its dimensions (0.47×0.77 nm) exceed the free diameter of the 8-membered windows ($\approx$0.44 nm). Another factor was the instability of the bis-complex in the supercage of zeolite A. They found that the bis-complex could be synthesised *in situ* by equilibrating either the Cu^{2+} or the mono-complex loaded zeolite with excess of 'en'. They also observed the uptake of both Cu^{2+} and $[Cu(en)]^{2+}$ by the zeolite when the solution of the latter was equilibrated with NaA at pH 6. The above-mentioned conclusions were drawn by them from EPR and reflectance spectral studies of the various complex loaded zeolites. Our findings reported in the earlier paragraphs have been obtained by the spectrophotometric investigations of the solutions prior to and after equilibration with the zeolite. They are thus complementary to those reported by Schoonheydt *et al.*[10]

Results of equilibration studies using $[Cu(pn)]^{2+}$ were somewhat similar to those described in the case of $[Cu(en)]^{2+}$. In this case also computations were made to arrive at the distribution of the different cationic species between the aqueous and zeolite phases. The results are tabulated in Table 2. As discussed in the case of $[Cu(en)]^{2+}$ the affinity of Cu^{2+} for the zeolite phase stimulates the dissociation of $[Cu(pn)]^{2+}$ also. Essentially, the zeolite phase gets loaded with Cu^{2+}, leaving behind a mixture of $[Cu(pn)]^{2+}$ and $[Cu(pn)_2]^{2+}$ (formed by the combination of $[Cu(pn)]^{2+}$ and free 'pn' released during the migration of Cu^{2+} to the zeolite phase) in the external solution. In other words, the side equilibria of the type represented by Eqs. 1—4 apply for the case of $[Cu(pn)]^{2+}$ as well. The low uptake of $[Cu(pn)]^{2+}$ compared to $[Cu(en)]^{2+}$ is to be attributed to the larger size of the former (>0.5 nm). Moreover, even this small uptake may be due to physical adsorption.

The conclusions concerning the disproportionation reaction were confirmed further by carrying out column experiments. The spectrum of the effluent was that of the 1:2 complex. The copper content was found to be slightly less than 50% of that present in the initial solution. These results indicate that the disproportionation reaction is practically complete in this case (*i.e.*, 1 mol of the 1:1 complex gives 0.5 mol

TABLE 3. VARIATION OF 'K', 'K_{av}', AND K^* AS A FUNCTION OF CONCENTRATION

A=1.0 for Cu^{2+}; 10.0 for all other cations. a) The values are very high (as the solution left out after equilibration was practically colourless and did not show any measurable E value at 550 and 650 nm). I and II are data for MS4 and MS5 respectively.

of Cu^{2+} and 0.5 mol of the 1:2 complex). As a small amount of the 1:2 complex is retained on the sieves, besides Cu^{2+}, the concentration of copper in the effluent turns out to be slightly less than 50% of the total amount taken.

Because of the above-mentioned disproportionation reactions, 'K' values for $[Cu(pn)]^{2+}$ also cannot be calculated. In view of the low uptake of $[Cu(pn)]^{2+}$ by the sieves, K^* values were not computed. The 'K_{av}' values were, therefore, the only set computed in this case. These are included in Table 3. These 'K_{av}' values can be considered as an indirect measure of the influence of 'pn' on the uptake of Cu^{2+}.

Interestingly enough, 20 ml of a solution of 'pn' (0.22 M), when equilibrated for 3 h with 0.5 g of 75% Cu^{2+} substituted MS4, eluted about two thirds of Cu^{2+} as $[Cu(pn)_2]^{2+}$. The MS4 phase ceased to have the green colour characteristic of Cu^{2+} form, but attained the blue colour characteristic of $[Cu(pn)]^{2+}$. From this experiment it was qualitatively concluded that 'pn', taken up by the MS4 phase, complexed Cu_2^+ present there (to give 1:1 complex *in situ*), even though $[Cu(pn)]^{2+}$ itself was not taken up (inside the pores) by MS4 because of its larger size.

It would be quite fruitful to refer here once again to the earlier work of Schoonheydt *et al.*[10] According to them $[Cu(en)_2]^{2+}$ is unstable in the supercage of zeolite A. The bis-complex can be synthesized in aqueous suspensions by first exchanging Cu^{2+} or the monocomplex and then adding large excess of 'en' to the suspensions (pH≥11). The instability of the bis-complex was further substantiated by the observation of Schoonheydt and others that Cu^{2+} moved out of the zeolite phase into the 'en' solution upon standing overnight.

From considerations of electroneutrality, reactions of the type discussed above (in which about two-thirds of Cu^{2+} is eluted out by the amine) cannot be classified as regular ion exchange processes. As the loss of Cu^{2+} from the solid phase occurs without the uptake of an equivalent amount of another cation, a change in the nature of the solid phase becomes an inevitable consequence. It would then be logical to conclude that structural alterations may have to occur to satisfy electroneutrality conditions in the solid phase left out after equilibration.

Table 3 includes the following parameters obtained as a function of concentration: (i) 'K' values of Cu^{2+} and $[Cu(NH_3)_4]^{2+}$, (ii) 'K_{av}' values of $[Cu(en)]^{2+}$ and $[Cu(pn)]^{2+}$ and (iii) K^* values of $[Cu(en)]^{2+}$. The data for the other cations are not being included as they are too small to deserve any consideration.

A scrutiny of the data included in Table 3 reveals that the 'K', K^*, and 'K_{av}' values decrease with increase in concentration of the cation equilibrated. This is to be attributed to the fact that the uptake tends to reach a saturation value with increase in concentration of the equilibrated solution.

From a comparison of the data given in Table 3 one can understand the relative affinities of the different cationic species for the two sieves. The 'K', K^*, or 'K_{av}' (as the case may be) for the same ion on MS4 and MS5 reveal that the uptake on the latter sieve is considerably less in the case of all the cations included in the Table. One possible reason for this may be the fact that the Ca^{2+} ions preferentially occupy a more stable site in the A type zeolites. (The difficulty encountered in displacing the Ca^{2+} is further illustrated by equilibration experiments with water at pH 2.0 and 8 M aqueous ammonia discussed earlier). In addition to this, the influence of cation valency on the ion exchange process cannot be ignored. The cation to be displaced in the case of MS5 has the same charge (+2) as the displacing (simple or complex) one, while the displacement of a univalent ion (Na^+) by bivalent ones is involved in the case of MS4. Though the larger pore dimension of MS5 is a favourable factor for migration of ions into the zeolite phase, the occupation of preferential sites by Ca^{2+} and its higher charge turn out to be unfavourable factors (from the point of view of ion exchange).

As already stated, dilute solutions of $[Cu(en)]^{2+}$ give colourless effluents when passed through a MS4

column. Solutions of $[Cu(pn)]^{2+}$, however, give around 50% of the total copper in the effluent (as the 1:2 complex). These differences can be fruitfully used to estimate (with some limitations) the amounts of 'en' and 'pn' in their mixture. In principle, this type of estimation can be extended further to cover mixtures of 'en' and other higher homologues of 'pn' as well. Experimental data substantiating this expectation have been obtained by the authors.

The authors are grateful to Dr. M. Sankar Das, Head, Analytical Chemistry Division and Dr. Ch. Venkateswarlu for their constructive suggestions.

Exchange Kinetics of Rubidium and Caesium Ions on Pyridinium Tungstoarsenate Exchanger

Ajay K. Jain,* Raj P. Singh, and Sushma Agrawal
Chemistry Department, University of Roorkee, Roorkee-247672, India
(Received February 12, 1980)

The Kinetics of exchange of Rb^+ and Cs^+ has been investigated on pyridinium tungstoarsenate ion exchanger using limited bath technique. The exchange rate was studied as a function of concentration, temperature and particle size of exchanger to determine the slowest step. It was found that Rb^+ exchange is particle diffusion controlled whereas Cs^+ exchange shows dual behaviour at low concentration level. However, at higher concentrations, particle diffusion controls Cs^+ exchange but the rate is concentration dependent. This anomalous behaviour has been explained by assuming that Cs^+ exchange approaches closely to a chemical reaction. Thermodynamic parameters of exchange such as effective diffusion coefficient (D), activation energy (E_a) and entropy of activation (ΔS^*) were calculated. The D and E_a values were found in the same order as that of ionic size, ΔS^* value being positive for Cs^+ exchange and negative for Rb^+ exchange. A negative ΔS^* value is usual but a positive value for Cs^+ exchange might be due to dehydration of the cation while passing through the channels of the exchanger. This explanation is in line with that of interaction energy for the exchange of Cs^+ on pyridinium tungstoarsenate.

The study of the kinetics of ion exchange process is important since it provides information on the mechanism of the rate controlling process, reactions accompanying the ion exchange, as well as internal physical structure of the exchanger and the extent of hydration of exchanging ion.

Systematic kinetic studies on ion exchangers were started by Nachod and Wood,[1,2] the earliest theory being developed by Boyd *et al.*[3] The kinetics of cation exchange in organic resins[4-6] and synthetic zeolites[7-9] has been studied in length. However, little information is available on other inorganic ion exchangers. Of synthetic inorganic ion exchangers, kinetic studies on hydrated oxides of thorium,[10] titanium[11] and zirconium,[12] zirconium phosphate,[13] hydrated alumina,[14] tantalum arsenate[15] and zirconium antimonate[16] have been reported.

Heteropolyacid salts form well defined crystalline inorganic ion exchangers.[17] They show high affinity for Tl^+, Cs^+, and Rb^+ and are used for ^{137}Cs separation in nuclear waste. However, no kinetic studies, necessary for ion exchange mechanism, seem to have been carried out on these exchangers.

Malik and coworkers[18] reported on the ion exchange properties of pyridinium tungstoarsenate, a new heteropolyacid salt, showing its selectivity for Rb^+ and Cs^+ amongst alkali metal ions. In order to explain their results they assumed the dehydration of Cs^+ during the course of exchange. In the present communication, we report on the kinetic studies of exchange of Rb^+ and Cs^+ on pyridinium tungstoarsenate (PWA). Effective diffusion coefficient, activation energy, and entropy of activation have been calculated, the results confirming the assumption that Cs^+ becomes dehydrated before undergoing exchange.

Experimental

Reagents and Materials. All the reagents used were of AR grade. The exchanger, pyridinium tungstoarsenate ($(C_5H_5NH)_3W_{12}AsO_{40}$) was prepared by the method reported.[18]

Apparatus. A unicam SP 500 spectrophotometer was used for the estimation of pyridine. A Leitz Wetzler microscope, Germany, model 12.5 X was used for the determination of the particle size of exchanger.

Kinetic Measurements. Limited bath technique[19] was used to study the exchange rate. PWA was ground and sieved to the desired mesh size (−50 to +100, −100 to +200). Solutions of Rb^+ and Cs^+ were thermostated at the required temperature in stoppered pyrex boiling tubes containing pyridinium nitrate and nitric acid,[18] the total volume in each tube being made 10 cm^3. The final concentrations of pyridinium nitrate and nitric acid were 0.001 mol dm^{-3} and 0.01 mol dm^{-3}, respectively, while that of the cation were varied from 0.05—0.2 mol dm^{-3} (for Rb^+) and 0.05—0.3 mol dm^{-3} (for Cs^+).

A weighed amount (0.1 g) of the exchanger of desired mesh size was added to these tubes which were thoroughly shaken, mechanically. After appropriate intervals of time the contents of the tubes were filtered with Whatman No. 1 filter paper, the extent of exchange being measured by determining pyridinium cations released spectrophotometrically at 256 nm. The exchange between Rb^+/Cs^+ and pyridinium cation is stoichiometric.[18] Experiments were conducted at 300.5, 305.5, 310.5, 315.5, and 320.5±0.1 K.

Particle Size. The average particle radius of each sieved fraction was determined by measuring the diameter of about 100 beads on a micrometer microscope. Measurements were carried out on dry particles as well as on particles which had been immersed for 24 hours in an appropriate electrolyte solution (concentration 0.1 mol dm^{-3}). There was no significant difference between the size of dry and immersed particles.

Results and Discussion

According to the theory developed by Boyd *et al.*,[3] the following equation holds in particle diffusion controlled exchange:

$$F = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{\exp(-n^2Bt)}{n^2},$$

where F is the extent of exchange at time t, $B=\pi^2D/r^2$, r is the average radius of the exchanger particle and D the effective diffusion coefficient. Thus the rate of particle diffusion controlled exchange should be dependent on r but independent of the concentration of exchanging ion; a plot of Bt *vs.* t (Reichenberg's test[20]) should be a straight line passing through origin.

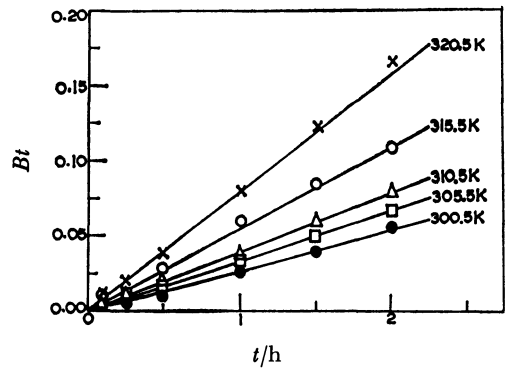

Fig. 1. Plots of *Bt vs. t* for Rb^+ exchange at different temperatures (r=0.0160 cm, concentration=0.1 mol dm^{-3}).

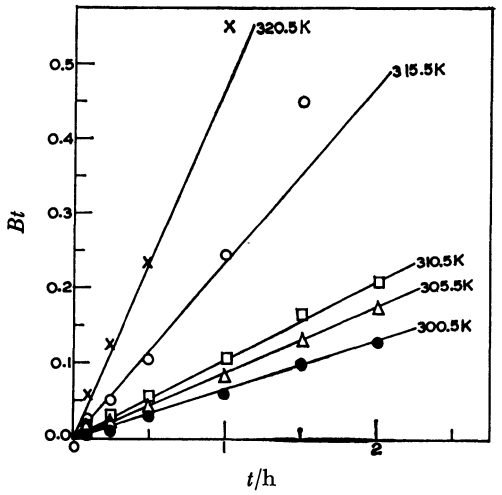

Fig. 2. Plots of *Bt vs. t* for Cs^+ exchange at different temperatures (r=0.0160 cm, concentration=0.1 mol dm^{-3}).

The kinetics of exchange of Rb^+ and Cs^+ on PWA was studied in the light of these considerations.

Figures 1 and 2 show the plots, *Bt vs. t*, for the exchange of Rb^+ and Cs^+ at different temperatures. These plots are linear, passing through origin, showing that the exchange is particle diffusion controlled. The plots of $-\log(1-F)$ *vs. t* (Mc Kay plots[21]) are nonlinear, supporting the above result. The effect of particle size of the exchanger shows that in both cases rate increases with decrease in particle radius. The rate of exchange of Rb^+ was found to be independent of concentration (Fig. 3), but not for Cs^+ exchange. Figure 4 shows *Bt vs. t* plots for Cs^+ exchange at four different concentrations. At concentration 0.05 mol dm^{-3}, the nonlinear behavior and fast uptake of Cs^+ shows that film diffusion also contributes to exchange.[3,22] At concentrations 0.1, 0.2, and 0.3 mol dm^{-3}, though the plots are linear (for 0.2 and 0.3 mol dm^{-3}, only initially) the rate is concentration dependent. Such an anomalous behavior was also reported.[23-25] Helfferich[26] showed theoretically that particle diffusion controlled exchange accompanied by ionic reactions (association, neutralization or complex formation) would exhibit such a behavior.

In the present case, it seems that the Cs^+ is dehydrated[18] during the course of exchange, getting chemically associated to tungstoarsenate ion. The resulting compound forms a shell around the exchanger particle which prevents further entry of Cs^+ into the core. This would eliminate Donnan exclusion of the co-ions. If a sufficient number of counter ions pass through the shell, they should carry with them co-ions so as not to disturb electroneutrality.[26] The invasion of counter and co-ions should be concentration dependent. This may also be the reason why the *Bt vs. t* plots (Fig. 4) are a bit nonlinear towards the end. The assumption of Cs^+ becoming dehydrated while exchanging with pyridinium cation is further supported by the entropy data.

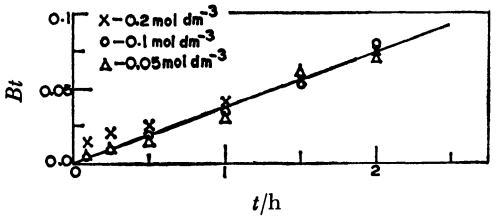

Fig. 3. Plots of *Bt vs. t* for Rb^+ exchange at different concentrations (r=0.0160 cm, T=310.5 K).

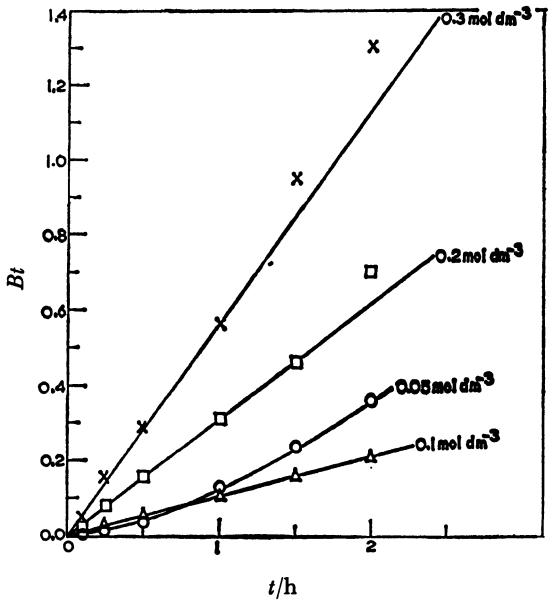

Fig. 4. Plots of *Bt vs. t* for Cs^+ exchange at different concentrations (r=0.0160 cm, T=310.5 K).

The exchange data at different temperatures (Figs. 1 and 2) have been used to calculate the values of effective diffusion coefficient (D), activation energy (E_a) and entropy of activation (ΔS^*). The D values computed from the B values are given in Table 1. They are in the order $Cs^+ > Rb^+$, in line with the order reported for alkali metal ions exchange on other exchangers.[12,27] The values are much lower than those reported on organic resins.[27,28] Nancollas and Paterson[10] inferred that crystallinity of the exchanger affects the D values such that more crystalline the exchanger, the lower the values. For PWA, a crystalline heteropolyacid salt, the D values of Rb^+ and Cs^+ exchange on it are very low.

Table 1. B values and effective diffusion coefficient D as a function of temperature (average particle radius of the exchanger = 0.0160 cm, concentration of Rb^+ and Cs^+ = 0.1 mol dm^{-3})

S. No.	Temp/K	Rb^+-exchange		Cs^+-exchange	
		B/s^{-1}	$D/m^2\ s^{-1}$	B/s^{-1}	$D/m^2\ s^{-1}$
1	300.5	0.75×10^{-5}	1.95×10^{-14}	1.81×10^{-5}	4.68×10^{-14}
2	305·5	0.97×10^{-5}	2.52×10^{-14}	2.64×10^{-5}	6.85×10^{-14}
3	310.5	1.11×10^{-5}	2.88×10^{-14}	2.92×10^{-5}	1.07×10^{-13}
4	315.5	1.53×10^{-5}	3.96×10^{-14}	6.67×10^{-5}	1.73×10^{-13}
5	320.5	2.22×10^{-5}	5.76×10^{-14}	13.19×10^{-5}	3.42×10^{-13}

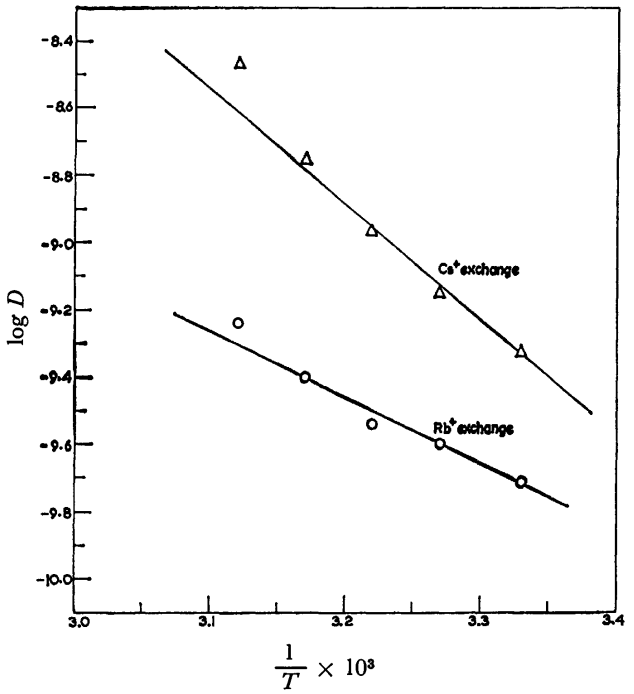

Fig. 5. Plots of $\log D$ *vs.* $1/T$.

The linearity of $\log D$ *vs.* $1/T$ plots (Fig. 5) indicates the validity of the Arrhenius equation

$$D = D_0 \exp(-E_a/RT),$$

which is used to calculate E_a values. The activation energy of a cation diffusion process reflects the ease with which cations can pass through exchanger particles. Freeman and Stamirs[29] observed an increase in E_a with increase in ion size of the alkaline earth metal ions. The increase is explained in terms of an increase in the strength of bonding to two crystallographically separated sites for the large, more polarizable cations. Similar findings were also observed for monovalent cations on analcite[30] and for alkaline earth metal ions on tantalum arsenate.[15] Our results (Table 2) which show that E_a for Cs^+ exchange is higher as compared to that of Rb^+ are in agreement with the increasing ion size.[15,29,30] In the present case the E_a values are higher as compared to the values 20—40 kJ mol^{-1} obtained for the exchange of hydrogen by monovalent ions on strong cation exchangers.[4,5] This may be due to low swelling of the exchanger. Similar findings were obtained by Heitner-Wirguin and Markovits.[19]

Table 2. D_0 values and thermodynamic parameters for Rb^+/Py^+ and Cs^+/Py^+ exchange on PWA exchanger

S. No.	System	$D_0/m^2\ s^{-1}$	E_a/kJ mol^{-1}	ΔS^*/J $mol^{-1}\ K^{-1}$
1	Rb^+/py^+	3.1×10^{-8}	35.7	−40.2
2	Cs^+/Py^+	3.4×10^{-2}	68.4	+75.7

Py^+ = pyridinium ion

The Arrhenius equation was also used to calculate D_0 which in turn is used to obtain ΔS^* by means of the following equation proposed by Barrer *et al.*[31]

$$D_0 = 2.72\, d^2k\, T/h \exp(\Delta S^*/R)$$

where k is Boltzmann constant, h Planck constant, d the distance between adjacent exchanging sites in the exchanger, and T is 273 K. For the calculation of ΔS^*, the value of d has usually been assumed to be equal to 5×10^{-8} cm.[15,16,32] We have also used the same value for ΔS^* calculation (Table 2). The entropy change normally depends on the extent of hydration of the exchangeable and exchanging ions along with any change in water structure around ions that may occur when they pass through the channels of exchanger particles. In general, negative values of ΔS^* have been reported.[15,16,29] ΔS^* for Rb^+ exchange in our case is negative whereas a positive value is obtained for Cs^+ exchange.

The positive value for Cs^+ exchange is unusual but not exceptional, being accounted for on the basis of disordering of water structure[32] around exchanging cations or their dehydration[33] during exchange. In our case, it appears that hydrated Cs^+ cation becomes dehydrated before exchanging with pyridinium ions of the exchanger. The explanation is in line with the one given by Malik, Srivastava and Satish[18] to explain higher interaction energy value for Cs^+ exchange on PWA which we utilized to explain the dependence of Cs^+ exchange rate on concentration.

Two of the authors (RPS and SA) are grateful for financial assistance from the Council from Scientific and Industrial Research (New Delhi).

Photopolymerization of Methyl Methacrylate Using *N,N*-Dimethylformamide–Sulfur Dioxide Complex as the Photoinitiator

Premamoy Ghosh,* Samir Biswas, and Subhankar Jana

Plastics and Rubber Technology Division, Department of Applied Chemistry, Calcutta University, 92, A. P. C. Road, Calcutta-700 009, India

(Received August 8, 1980)

Photopolymerization of MMA in visible light was studied at 40 °C using DMF–SO_2 complex as the photoinitiator. Initiator exponent was found to be 0.41 and monomer exponent varied between 1.12 to 1.50 depending on the nature of the solvent. Analysis of data revealed that the photopolymerization was induced by a free radical mechanism. Nonideality of the kinetics was explained on the basis of (a) monomer-dependent chain initiation and (b) initiator-dependent chain termination *via* degradative initiator transfer.

In recent years the role of SO_2 in catalytic concentrations in vinyl polymerization has been studied in detail. It is now well established that SO_2 can act both as an initiator and as a comonomer in vinyl polymerization.[1] SO_2, being a good acceptor, also forms charge transfer complexes with many donor compounds. SO_2 complexes of pyridine and quinoline are reported[2-4] to effectively induce polymerization of methyl methacrylate (MMA). In the polymerization of MMA initiated by pyridine–SO_2 complex, it was found that the presence of such additives as *N,N*-dimethylformamide (DMF) greatly accelerated the rate of polymerization[5] probably through participation of DMF in the initiation step. This idea led us to the preparation of the C.T. complex of SO_2 with DMF with the objective of examining its suitability as an independent initiator of vinyl polymerization using MMA as the monomer. Related results and the kinetics of polymerization under photoactivation are reported in the present paper.

Experimental

Materials. Methyl methacrylate (MMA) monomer was purified by usual procedures.[6] *N,N*-Dimethylformamide (DMF) obtained from E. Merck and stored over KOH pellets, was purified by distillation. All solvents used were of reagent grade and were distilled once before use in polymerization reaction.

Preparation of N,N-*dimethylformamide-sulfur dioxide Complex.* DMF (5 ml) was taken in a test tube which was then cooled to about −5 °C in crushed ice/salt mixture. Pruified sulfur dioxide gas was bubbled through the cold DMF. SO_2 gas generated by heating fresh copper turnings with reagent grade concentrated sulfuric acid was passed through a scrubber of concentrated sulfuric acid before its final passage in DMF. Bubbling was stopped when the liquid appeared supersaturated with SO_2. Excess SO_2 was allowed to bubble out at room temperature, occasionally aided by slow stirring with a glass rod. The theoretical SO_2-content of 1:1 DMF–SO_2 complex is 46.7%. Analysis by iodimetry showed that the SO_2 content of the prepared complex was 46.92%.

UV absorption spectra of dilute solutions of SO_2 (0.002 mol l^{-1}) and of DMF–SO_2 complex (0.002 mol l^{-1}) in CCl_4 are given in Fig. 1, A, curves 1 and 4 respectively. λ_{max} for each spectrum is 290 nm. DMF itself has no absorption in the wavelength range studied. For a fixed SO_2-content (0.002 mol l^{-1}) in CCl_4, the absorbance at λ_{max} increased progressively with increasing proportion of DMF till the latter was used in equimolar proportion (0.002 mol l^{-1}), Fig. 1, A, and with further increase in DMF content, no further change in the absorbance of the mixture was visible.

The absorbance values at λ_{max} (290 nm) for solutions of SO_2 and of DMF–SO_2 complex in CCl_4 at several concentrations were measured and the data were plotted as in Fig. 1, B. In each case the plot, passing through the origin, is linear, DMF–SO_2 plot giving a higher slope than the SO_2 plot. The overall absorbance at λ_{max} (290 nm) for each of the various mixtures of DMF and SO_2, Fig. 1, A, is equal to the summation of the absorbance corresponding to the calculated amount of 1:1 DMF–SO_2 complex formed *in situ* in the system and that of SO_2 present in excess of DMF.

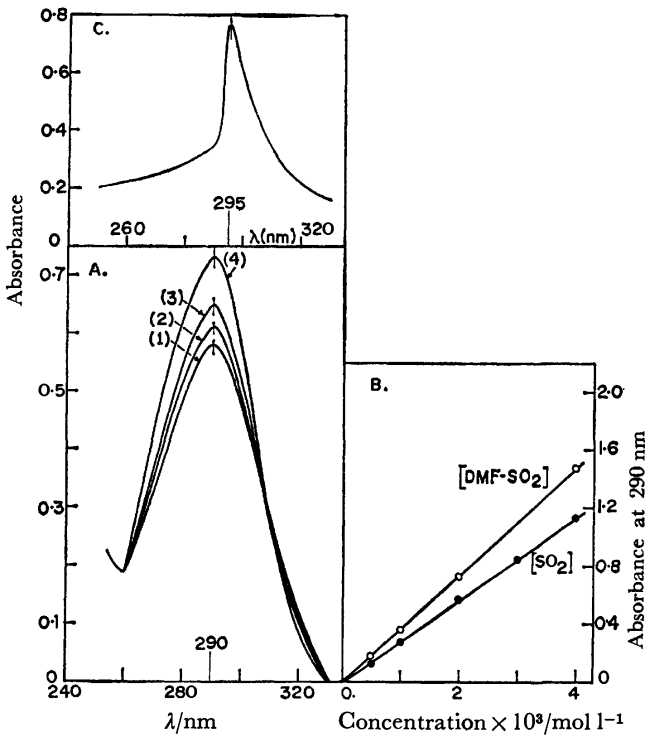

Fig. 1. A) UV absorption spectra of SO_2, (DMF–SO_2), complex and different mixtures of SO_2 and DMF in CCl_4 solution using CCl_4 in the reference cell in each case:
1) SO_2=0.002 mol l^{-1}; 2) SO_2=0.002 mol l^{-1} and DMF=0.0005 mol l^{-1}; 3) SO_2=0.002 mol l^{-1} and DMF=0.001 mol l^{-1}; 4) SO_2=0.002 mol l^{-1} and DMF=0.002 mol l^{-1}, 0.003 mol l^{-1}, 0.005 mol l^{-1}; and DMF–SO_2 complex=0.002 mol l^{-1}.
B) Plot of absorbance at 290 nm *vs.* concentration for SO_2 and DMF–SO_2 complex, each in CCl_4 solution (CCl_4 in the reference cell).
C) UV absorption spectra of DMF–SO_2 complex, 0.002 mol l^{-1}, in MMA (MMA in the reference cell).

Table 1. Photopolymerization of MMA at 40 °C using DMF-SO_2 complex as the photoinitiator

$[DMF\text{-}SO_2]\times10^4$ / mol l^{-1}	$R_p\times10^5$ / mol l^{-1} s^{-1}	$R_p/[M]^2\times10^7$ / l mol^{-1}	$[\eta]$ / dl g^{-1}	$1/\bar{P}_n\times10^4$	Initiator exponent	$(k_p^2/k_t)\times10^2$ / l mol^{-1} s^{-1}
2.051	5.400	6.379	2.900	1.120		
2.56	6.010	7.097	2.690	1.230		
4.85	7.515	8.875	2.300	1.460		
5.82	8.350	9.861	2.22	1.590	0.41	1.42
7.25	8.810	10.400	2.125	1.680		
9.70	9.6025	11.340	1.880	1.980		
12.16	10.850	12.810	1.500	2.66		
20.00	9.6129	—	—	—		

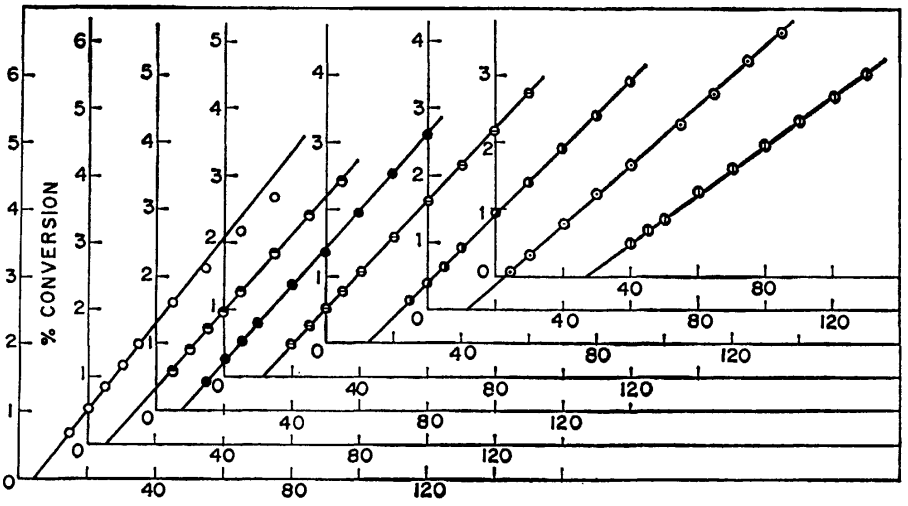

Fig. 2. Photopolymerization of MMA using DMF-SO_2 complex as initiator at 40 °C, for each curve $[DMF\text{-}SO_2]$ in mol l^{-1} is,
◓: 20.00×10^{-4} mol l^{-1} $[DMF\text{-}SO_2]$, ◑: 5.82×10^{-4} mol l^{-1} $[DMF\text{-}SO_2]$,
○: 12.16×10^{-4} mol l^{-1} $[DMF\text{-}SO_2]$, ⊙: 4.85×10^{-4} mol l^{-1} $[DMF\text{-}SO_2]$,
●: 9.70×10^{-4} mol l^{-1} $[DMF\text{-}SO_2]$, ⓘ: 2.56×10^{-4} mol l^{-1} $[EMF\text{-}SO_2]$,
⊖: 7.25×10^{-4} mol l^{-1} $[DMF\text{-}SO_2]$.

Excess DMF wherever present has little influence on the overall absorbance. It is, thus, clearly indicated that complexation between DMF and SO_2 takes place almost instantaneously and that the complex is of the 1:1 kind.

When taken in MMA solution, the peak absorption of DMF-SO_2 complex shifts slightly to higher wave length (λ_{max}=295 nm, MMA in reference cell), Fig. 1, C, indicating further complexation of DMF-SO_2 complex with MMA.

Polymerization. The polymerization of MMA in bulk or in solution was studied dilatometrically in visible light at 40±0.05 °C using DMF-SO_2 complex initiator following usual procedures.[7-9] Polymers formed at low conversions (<10%) in the dilatometers were removed and isolated by precipitation with petroleum ether and drying at 50 °C under vacuum.

Intrinsic Viscosity. Intrinsic viscosity, $[\eta]$ in dl/g of polymers taken in benzene solution were obtained from measurements of solution viscosity at 30±0.05 °C using a Ubbelohde viscometer. Molecular weights ($\bar{M}_n$) of poly(methyl methacrylate) (PMMA) were calculated from the viscosity data using the following equation:[10]

$$[\eta] = 8.69\times10^{-5}\,\bar{M}_n^{0.76}. \quad (1)$$

Results and Discussion

In presence of DMF-SO_2 complex, no polymerization of MMA was observed within 2 h at 40 °C in the dark. Polymerization was, however, readily induced in presence of light after inhibition periods (IP) of the order of 5—30 min, lower $[DMF\text{-}SO_2]$ giving higher IP in general. IP is considered to arise due to adventitious impurities (such as, last traces of oxygen) in the polymerization system.

Initiator Exponent. Data on bulk photopolymerization of MMA at 40 °C using different $[DMF\text{-}SO_2]$ (0.000256—0.002 mol l^{-1}) are presented in Table 1. Rates of polymerization, R_p, were calculated from the initial linear zones of % conversion *vs.* time plots, Fig. 2. Initiator exponent determined from the slope of the plot of log R_p *vs.* log $[DMF\text{-}SO_2]$, is 0.41, Fig. 3. Photopolymerization in open dilatometers (in contact with air) produced slightly enhanced inhibition but in presence of dissolved hydroquinone (0.001 mol l^{-1}) there was much pronounced inhibition of polymerization. The polymers gave positive response to

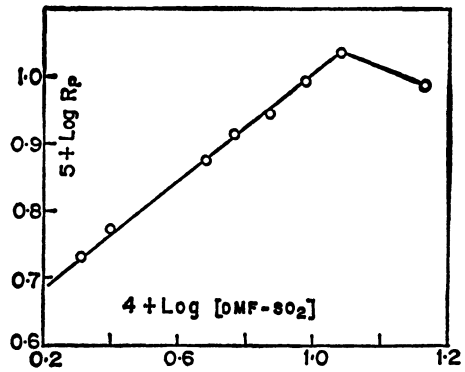

Fig. 3. Photopolymerization of MMA (bulk) using DMF-SO_2 complex as initiator at 40 °C.

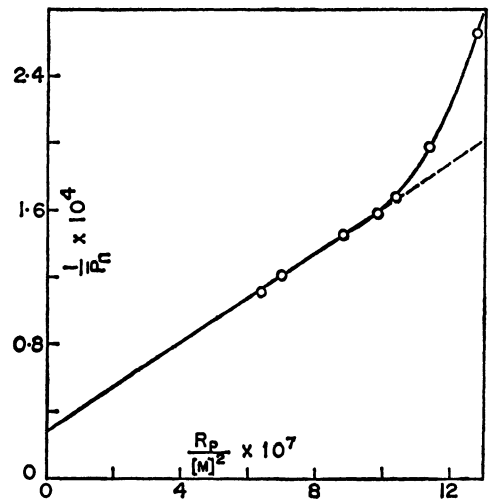

Fig. 4. Photopolymerization of MMA (bulk) using DMF-SO_2 complex as initiator.

dye partition test[11] for (anionic) sulfoxy end groups.

k_p^2/k_t Value. The kinetic parameter k_p^2/k_t at 40 °C was evaluated from the slope of the plot of $1/\overline{P}_n$ *vs.* $R_p/[M]^2$, Fig. 4 (Table 1), in accordance with the Mayo equation:

$$1/\overline{P}_n = 1.85\frac{k_t}{k_p^2} \cdot \frac{R_p}{[M]^2} + \Sigma\frac{R_{tr}}{R_p}, \quad (2)$$

where the last term in the right hand side was included to account for chain transfer effects, assuming this would not affect the slope of the plot over low range of initiator concentration. The apparent k_p^2/k_t value, calculated from the slope of the initial linear zone of the plot, is 1.42×10^{-2} l mol^{-1}; it was assumed in the calculation that any perturbation of the termination process from the usual bimolecular mechanism (85% disproportionation, 15% combination)[10,12] will not measurably affect the initial slope of the plot in Fig. 4.

Monomer Exponent. With a fixed [DMF-SO_2], (0.000205 mol l^{-1}), photopolymerization of MMA was further studied in presence of different concentrations of several solvents such as benzene, toluene, DMF, carbon tetrachloride, pyridine, and tetrahydrofuran (THF). Monomer exponents calculated from the slope

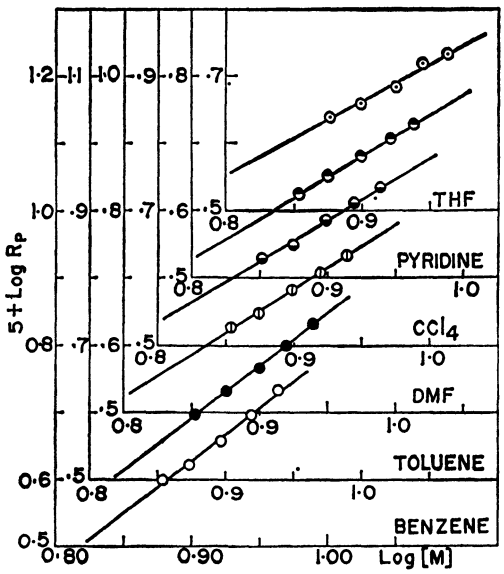

Fig. 5. Photopolymerization of MMA (solution) using DMF-SO_2 complex as initiator.
[DMF-SO_2] = 2.05×10^{-4} mol l^{-1} (fixed); data given for each curve are, solvent and slope (monomer exponent).
○: Benzene, 1.50, ●: toluene, 1.50, ⊙: THF, 1.12, ◒: CCl_4, 1.20, ◓: pyridine, 1.20, ⓓ: DMF, 1.30.

of the respective plots of log R_p *vs.* log [M], Fig. 5, range between 1.12—1.50, depending on the nature of the solvent used.

Mechanism. Kinetic data, the inhibitory effect of hydroquinone and the results of end group analysis indicate a radical mechanism. The radical generation process may be considered to follow an initial complexation reaction between monomer and initiator molecules:

$$\text{DMF-SO}_2 + \text{M} \overset{K}{\rightleftharpoons} \underset{\text{Initiating Complex (I)}}{\text{DMF-SO}_2\cdots\text{M}} \quad (3)$$

$$\text{I} \xrightarrow{h\nu} \text{Pair of radicals (R}\cdot\text{)}. \quad (4)$$

Initial concentration of the initiating complex (I) is then equal to K[DMF-SO_2][M], where K is the equilibrium constant of the initiator monomer complexation reaction envisaged.

Initiator Transfer. Equation 2 may be used in the following form to determine the initiator transfer parameter (C_IK), where C_I is the initiator transfer constant, in the photopolymerization of MMA in bulk:

$$\frac{1}{\overline{P}_n} - 1.85\frac{k_t}{k_p^2} \cdot \frac{R_p}{[M]^2} = C_M + C_IK\,[\text{DMF-SO}_2]. \quad (5)$$

Here, [DMF-SO_2] is the initial concentration of *N,N*-dimethylformamide-sulfur dioxide complex and C_M is the monomer transfer constant. A plot of left hand side of Eq. 5 *vs.* [DMF-SO_2] is given in Fig. 6, and initial slope of the plot, giving the value of C_IK, is 8×10^{-3} l mol^{-1}. A deviation from linearity of this plot, prominent at high [DMF-SO_2], indicates that the transfer process apparently of the normal kind at low [DMF-SO_2], becomes largely degradative in

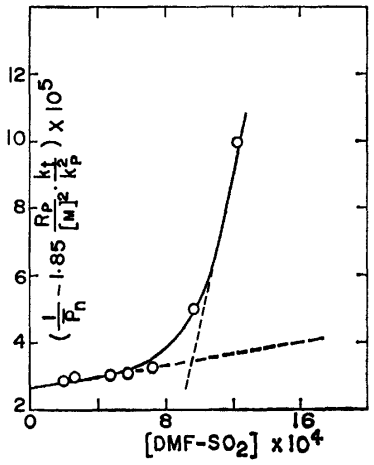

Fig. 6. Photopolymerization of MMA using DMF-SO_2 complex as initiator.

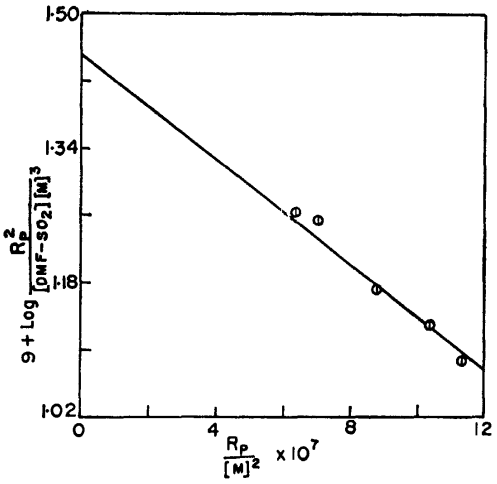

Fig. 7. Photopolymerization of MMA using DMF-SO_2 complex as initiator. Analysis of primary radical termination effect.

nature at high [DMF-SO_2].

Termination. The observed initiator exponent of 0.41 indicates that some initiator dependent termination process is significant along with the usual bimolecular termination.

The initiator dependent termination process may be of two different kinds:

1) Primary radical termination

$$M^{\cdot} + R^{\cdot} \xrightarrow{k_{prt}} \text{Polymer product}$$

and

2) Termination *via* degradative initiator transfer, which may be considered to proceed by two distinctive mechanisms:

a) With reinitiation effect, such as:

$$M^{\cdot} + I \xrightarrow{k_{trI}} \text{Polymer product} + I^{\cdot} \quad \text{(Initiator transfer)}$$

$$I^{\cdot} + M^{\cdot} \xrightarrow{k_{rtI}} \text{Polymer product} \quad \text{(Chain termination)}$$

$$I^{\cdot} + M \xrightarrow{k_{1I}} M^{\cdot} \quad \text{(reinitiation)}$$

or,

b) With little reinitiation effect, such as:

$$M^{\cdot} + I \xrightarrow{k_t'} \text{Polymer product (Chain termination giving non radical or inactive radical by product).}$$

1) *Analysis of Primary Radical Termination Effect.*

The equation of Deb and Meyerhoff[13] which would assume the following form for present polymerization, may be used to evaluate primary radical termination effect (in absence of degradative initiator transfer process)

$$\log \frac{R_p^2}{[\text{DMF-SO}_2][M]^3} = \log \frac{Kfk_dk_p^2}{k_t} - 0.8686 \cdot \frac{k_{prt}}{k_1k_p} \cdot \frac{R_p}{[M]^2}. \quad (6)$$

Negative slope for the plot of left hand side of Eq. 6 *vs.* $R_p/[M]^2$, Fig. 7, indicating measurable primary radical termination effect, was obtained for photopolymerization of MMA in bulk at 40 °C. The value of k_{prt}/k_1k_p calculated from the slope of this plot is 3.135×10^5 mol s l^{-1}.

2) *Analysis of Degradative Chain (Initiator) Transfer Effect.* *a) Degradative Initiator Transfer with reinitiation Effect*: An equation derived by Deb[14] to analyse degradative chain (initiator) transfer with reinitiation effect was simplified by Ghosh *et al.*[15] to the following form:

$$\ln \frac{R_p^2}{[I][M]^2} = \ln \frac{fk_dk_p^2}{k_t} - \frac{k_p^2}{k_t} \cdot \frac{k_{rtI}}{k_{1I}k_p} \cdot C_I \cdot \frac{[I]}{[M]}.$$

In the present case $[I]=K$ [DMF-SO_2][M] and hence we have

$$\log \frac{R_p^2}{[\text{DMF-SO}_2][M]^3} = \log Kfk_d\frac{k_p^2}{k_t} - 0.434\frac{k_p^2}{k_t} \cdot \frac{k_{rtI}}{k_{1I}k_p} \cdot C_IK[\text{DMF-SO}_2]. \quad (7)$$

Here, C_I is the initiator transfer constant. A plot of left hand side of Eq. 7 *vs.* [DMF-SO_2], is shown in Fig. 8. The plot gives a straight line with a negative slope, thereby clearly indicating the existence of degradative initiator transfer process. The value of $k_{rtI}/(k_{1I}k_p)$ obtained from the slope of the plot is 5.486×10^6 mol s l^{-1}.

b) Degradative Initiator Transfer with Little Reinitiation Effect: This aspect may be analysed according to the following approach:

Under steady state condition, we have

$$\frac{R_I}{R_p} = \frac{R_t}{R_p} = \frac{2k_t[M^{\cdot}]^2 + k_t'[I][M]}{R_p} = \frac{2k_t[M^{\cdot}]^2 + k_t'K[\text{DMF-SO}_2][M][M^{\cdot}]}{R_p}$$

or,

$$R_I = \frac{2k_t}{k_p^2} \cdot \frac{R_p^2}{[M]^2} + \frac{k_t'K}{k_p} \cdot R_p[\text{DMF-SO}_2] = 2\phi\varepsilon I_0K[\text{DMF-SO}_2][M]$$

or,

$$2\frac{k_t}{k_p^2} \cdot \frac{R_p^2}{[M]^3[\text{DMF-SO}_2]} = 2\phi\varepsilon I_0K - \frac{k_t'K}{k_p} \cdot \frac{R_p}{[M]}. \quad (8)$$

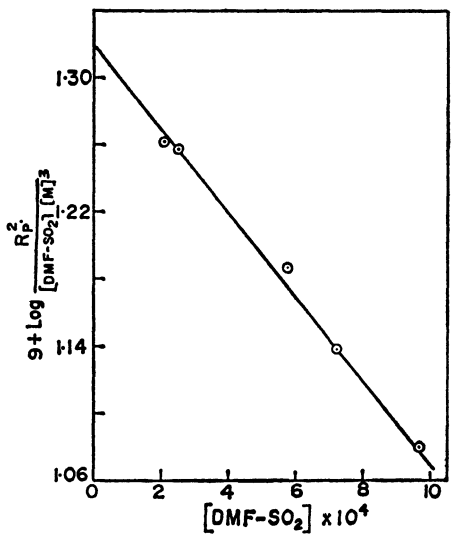

Fig. 8. Photopolymerization of MMA using DMF-SO_2 as initiator. Analysis of degradative initiator transfer (with reinitiation effect).

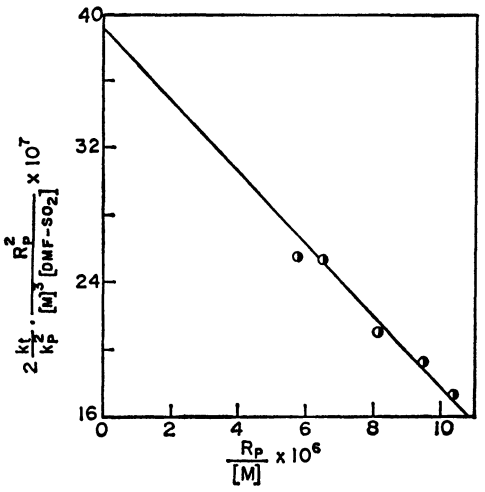

Fig. 9. Photopolymerization of MMA using DMF-SO_2 complex as initiator. Analysis of degradative initiator transfer (no reinitiation effect).

The left hand side of Eq. 8 is plotted *vs.* $R_p/[M]$, Fig. 9. The plot gives a straight line with a negative slope indicating that degradative initiator transfer with no reinitiation effect is significant. The value of $k_t'K/k_p$ obtained from the slope of the plot is 0.23 l mol^{-1}.

It is interesting to note that this value is reasonably close to the value of the final slope of the plot in Fig. 6, corresponding to high [DMF-SO_2], indicating degradative nature of the initiator transfer process at high initiator concentration. Thus, the degradative effect is detectable from analysis of both $\bar{P}_n$ and R_p data and from each analysis degradative effects of comparable order are more or less indicated, particularly for high [DMF-SO_2]. The value of Kfk_d, equivalent to $K\phi\varepsilon I_0$ for photopolymerization (where ϕ is the quantum yield for chain initiation, ε is the molar absorptivity for the active radiation and I_0 is the incident light intensity) obtained from the three plots, Figs. 7—9, are in reasonably close agreement, the mean value being 1.80×10^{-6} l mol^{-1} s^{-1}.

Although, primary radical termination may be considered as a possible cause for non-ideality, consideration of dependence of R_p on [M] predicts it to be of much less consequence. If the present photopolymerization followed the normal kinetics (bimolecular termination) one would expect a value of 1.5 for monomer exponent on the basis of initiation mechanism envisaged; for significant primary radical termination, the expected monomer exponent would be >1.5, the limiting value being 2.0 and for some kind of significant degradative initiator transfer, the expected value of monomer exponent would be <1.5, the limiting value being 1.0. With observed monomer exponent in the range of 1.12—1.50 the non-ideality in the present polymerization appears to be largely due to degradative initiator transfer effect.

Thanks are due to the Council of Scientific and Industrial Research and University Grants Commission, India for supporting this research through Fellowship Grants to S. J. and S. B. respectively.

Liquid-Liquid Extraction and Separation of Lanthanum (III)

A. D. Langade and V. M. Shinde*

Analytical Laboratory, Department of Chemistry, Shivaji University, Kolhapur 416 004, India

(Received May 19, 1980)

Separation of lanthanum(III) from iron(III), molybdenum(VI), vanadium(V), chromium(VI), titanium (IV), bismuth(III), zirconium(IV), scandium(III), uranium(VI), and beryllium is achieved by solvent extraction with mesityl oxide from sodium salicylate solution (0.1 M adjusted to pH 7). Lanthanum from the organic phase is stripped with water and determined photometrically as its arsenazo complex at 570 nm. The extracted species is trisolvated *i.e.* $La(HOC_6H_4COO)_3 \cdot 3MeO$. The results of separation are reported.

Mesityl oxide has been used in this laboratory for the solvent extraction of uranium from salicylate media.[1] In this communication we propose a simple and rapid method for the selective extraction of lanthanum from 0.1 M sodium salicylate solution (adjusted to pH 7) into mesityl oxide. The lanthanum (III) from the organic phase is stripped with water and determined photometrically with arsenazo[2] at 570 nm. The method affords separation of lanthanum from iron (III), molybdenum(VI), vanadium(V), chromium(VI), titanium(IV), bismuth(III), zirconium (IV), scandium(III), uranium(VI), and beryllium.

Extraction of lanthanum with various chelating agents have been reviewed by Stary in his monograph.[3] The extraction of lanthanum from nitric acid, perchloric acid or thiocyanate media with oxygen containing solvents, organophosphorus acids, esters and oxides have been earlier reported.[4-17] Extraction with high molecular weight amines and carboxylic acids have also been reported,[18-20] but systematic separation studies of lanthanum is lacking. This communication describes a simple and rapid method for the solvent extraction of lanthanum(III) from sodium salicylate solution (pH 7) using mesityl oxide as an extractant. The method permits selective separation of lanthanum from metal ions such as iron, molybdenum, vanadium, chromium, titanium, zirconium, bismuth, scandium, uranium, and beryllium.

Experimental

Apparatus and Reagents. Absorbances were measured with a Zeiss Spectrophotometer (Jena) employing 1 cm quartz cells and pH values were measured with Philips pH meter (Precision type).

The stock solution of lanthanum was prepared by dissolving 0.587 g of lanthanum(III) oxide (BDH, England) in 4 ml of concentrated hydrochloric acid and diluting to 100 ml with distilled water. The solution was standardized by known method[21] and further diluted as required for working solutions.

Mesityl oxide, bp 125—128 °C (BDH) was used after double distillation.

Arsenazo I, 0.05% aqueous solution was used.

All other chemicals used in this work were of guaranteed grade.

General Extraction Procedure. Take an aliquot solution containing 40 μg of lanthanum, add sodium salicylate (0.4 g) to give the final concentration of 0.1 M in a total volume of 25 ml. Adjust the pH of the solution to 7 by diluted NaOH/HCl solutions and transfer into a 100 ml separatory funnel. Equilibrate the mixture for 30 s with 10 ml of neat mesityl oxide. Allow the layers to settle and strip lanthanum from organic phase with two 10 ml portions of water (containing a few drops of HCl to avoid emulsion) and determine it photometrically with arsenazo I at 570 nm.

Results and Discussion

Effect of pH, Salicylate Concentration and Mesityl Oxide Concentration. The extraction of lanthanum was studied at various pH. The extraction commences at pH 3, becomes quantitative at pH 7 and then decreases (Fig. 1). The pH was adjusted with diluted NaOH/HCl solutions. The optimum pH for quantitative extraction of lanthanum is 7. The concentration of mesityl oxide was varied from 35 to 100% with benzene as diluent and the sodium salicylate concentration was varied from 0.01 to 0.1 M. The results show that lanthanum extracts quantitatively from 0.1 M sodium salicylate solution with neat mesityl oxide. The percentage extraction of the metal ions was computed by stripping the metal ion from the organic phase and subsequent photometric determination with arsenazo I. The distribution ratio was calculated by using relationship.

$$\%E = \frac{100D}{D(V_w/V_o)}$$

where V_w and V_o are the volumes of aqueous and organic phase respectively. A log-log plot of distribution ratio *vs.* mesityl oxide concentration at fixed

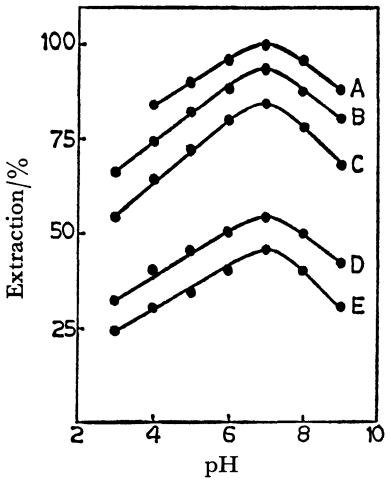

Fig. 1. Extraction behaviour of lanthanum-salicylate into mesityl oxide as function of pH and sodium salicylate concentration.
A=0.1 M; B=0.075 M; C=0.05 M; D=0.025 M; E=0.01 M sodium salicylate.

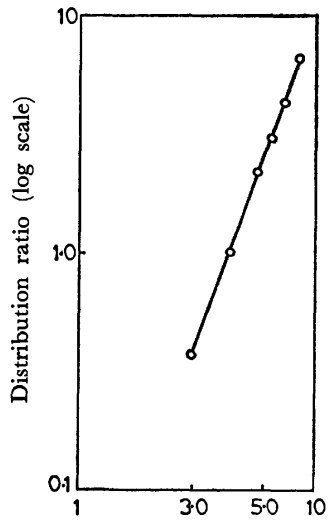

Fig. 2. Distribution ratio of lanthanum as a function of mesityl oxide concentration at 0.05 M sodium salicylate concentration and pH 7.

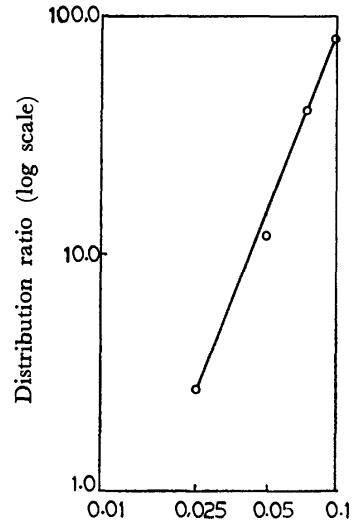

Fig. 3. Distribution ratio of lanthanum as a function of sodium salicylate concentration at pH 6.5

pH (7.0) and salicylate concentration (0.05 M) gave a slope of 2.7 (Fig. 2) indicating the presence of three solvent molecules in the extracted species. Similarly the log-log plot (Fig. 3) of distribution ratio *vs.* salicylate concentration at fixed pH (6.5) and mesityl oxide concentration gave a slope of 2.6 indicating a molar ratio of 1:3 for the reaction of lanthanum and salicylate ion. The extraction equilibria for lanthanum (III) extraction (from salicylate media) into mesityl oxide could be written as:

$$La^{3+} + 3(HOC_6H_4COO)^- \rightleftharpoons La(HOC_6H_4COO)_3 \quad (1)$$

$$La(HOC_6H_4COO)_3 \cdot 3\,H_2O + 3\,MeO \rightleftharpoons La(HOC_6H_4COO)_3 \cdot 3\,MeO + 3\,H_2O. \quad (2)$$

MeO stands for mesityl oxide.

The extractable species is thus trisolvated.

Distribution of Salicylic Acid and Sodium Salicylate.

Table 1. Distribution ratio of salicylic acid (A) and sodium salicylate (B) between mesityl oxide and aqueous solution

$\mu = 0.1$ M sodium perchlorate

	pH[a]	D_{Sal} (Exptl)	$D_{Sal}\left(1+\frac{K_1}{[H^+]}\right)$	D_{Sal} (Calcd)
(A)	4.5	2.86	115.7	2.03
	5.5	2.33	177.4	0.30
	6.5	2.16	768.1	0.13
(B)	5	0.31	129.5	0.72
	6	0.19	311.4	0.17
	7	0.11	2122.0	0.12

a) Before extraction.

The distribution of salicylic acid and sodium salicylate between mesityl oxide and aqueous solution of different pH values (adjusted with diluted perchloric acid and sodium hydroxide solution) at constant ionic strength (0.1 M sodium perchlorate) was studied by equilibrating known concentration of salicylic acid or sodium salicylate for more than 16 hours at room temperature. The volume of aqueous phase and organic phase was kept equal (10 ml). After equilibration the layers were allowed to settle and separate and concentration of unextracted salicylic acid or salicylate ions in the aqueous phase is determined colorimetrically. The experimental distribution ratio and the calculated one are obtained by equations given by Irwing and Sinha[22] and reported in Table 1. Both salicylic acid and sodium salicylate show extraction into mesityl oxide but the probability of dimerization of salicylic acid in mesityl oxide which is a ketone is negligible.

The period of equilibration was varied and for quantitative extraction of lanthanum, single extraction for 30 s with neat mesityl oxide is adequate. Prolonged shaking has no adverse effect on the extraction.

An interference study showed that for the extraction of 40 μg of lanthanum by the recommended procedure, 2500 μg each of Ag, Ca, Ba, Zn, Hg, Ni, Bi, As(III), Au(III), Ti(IV), Zr(IV), Ga(III), Mo(VI), tartrate, ascorbate, nitrate, thiocyanate, sulfate, thiourea, phosphate and carbonate do not interfere. Similarly no interference is observed for 2000 μg each of Co, Mn, Fe(III); 1000 μg each of Pd, Cd, Pb, V(V), Cr(VI), fluoride; 500 μg each of Sn(II), Al, Rh, Ru, W(VI), and 100 μg of Cr(III). However, cerium (III and IV) and Nd(III) interfere severely.

Separation of Lanthanum(III) from Iron(III), Molybdenum(VI), Vanadium(V), Chromium(VI), Titanium(IV), and Beryllium. Ions such as iron, molybdenum, vanadium(V), chromium(VI), beryllium, and titanium(IV) do not extract into mesityl oxide. Hence their separation (from binary mixtures) is achieved by extraction of lanthanum by the recommended procedure. Lanthanum from the organic phase is stripped and determined as described above and the added ions, are estimated in the aqueous phase by standard procedure. The recovery of lanthanum and added

Note: (1) Lanthanum is estimated photometrically with arsenazo I. (2) Aqueous solution containing titanium, scandium, or beryllium is evaporated to dryness, treated with HNO_3 and $HClO_4$ to decompose salicylate and residue is dissolved in water and then used for titanium or scandium or beryllium estimation.

ions is >99.0%. The results of the analysis of synthetic mixtures are reported in Table 2.

Separation of Lanthanum from Zirconium(IV) and Bismuth(III) Both zirconium and bismuth show co-extraction with lanthanum, but do not back extract with water. Separation of lanthanum from binary mixture is achieved by first stripping lanthanum with water and subsequent scrubbing of zirconium with two 10 ml portions of 1 M HCl solution and bismuth with two 10 ml portions of 1 M NaOH solution. The results of the separation are reported in Table 2.

Separation of Lanthanum(III) from Scandium(III) and Uranium(VI). Lanthanum (from 0.1 M sodium salicylate solution adjusted to pH 7) also extracts into 4-methyl-2-pentanol but scandium and uranium do not. This facilitates separation of lanthanum from scandium and uranium. Binary mixture containing lanthanum–scandium or lanthanum–uranium in 0.1 M sodium salicylate solution adjusted to pH 7, is extracted for 30 sec with 10 ml of undiluted 4-methyl-2-pentanol. Lanthanum transfers into organic phase keeping scandium and uranium in the aqueous phase. Lanthanum is stripped with two 10 ml portions of water containing few drops of HCl and then determined as described above. Scandium and uranium in the aqueous extract are estimated by known methods. Separation results are reported in Table 2.

The reproducibility of results was satisfactory and results were found to be accurate within ±0.5% with the standard deviation of ±0.8%. The total operation requires only 15 min. The wide applicability of the method is shown by the satisfactory analysis of a variety of samples.

Thanks are due to Council of Scientific and Industrial Research, New Delhi, for awarding fellowship to one of us (ADL) and University grants commission, New Delhi for financing the project.

Reaction between Azibenzil and Diarylmethanimine

Kailash Nath MEHROTRA* and Girija PRASAD
Department of Chemistry, Banaras Hindu University, Varanasi-221005, India
(Received March 24, 1980)

The thermal reaction of azibenzil with diarylmethanimine (**1**) leads to *N*-(diarylmethylene)diphenylacetamide (**2**) which from methanol or ethanol yields *N*-(α-alkoxydiarylmethyl)diphenylacetamide (**4**). The reduction of **2** with sodium borohydride gives *N*-(diarylmethyl)diphenylacetamide. The photochemical reaction of azibenzil and **1** results in the formation of cyano ethers besides the amido ethers **4**. A mechanism of formation of products is discussed.

Azibenzil (2-diazo-1,2-diphenylethanone) has been known to form 1,3-oxathiole[1] in the reaction with thiobenzophenone and oxazoles[2] with benzonitrile. It has been observed that ketocarbenes undergo cycloaddition with olefins leading to cyclopropanes.[3] The benzoylphenylcarbene, formed from the thermal or photochemical decomposition of azibenzil, may add on carbon-nitrogen double bond of diarylmethanimine (**1**) giving rise to substituted aziridines. The interest in the attempted synthesis of aziridines[4] prompted us to carry out the above reaction. We now report the formation of *N*-(diarylmethylene)diphenylacetamide (**2**) on treatment of a benzene solution of 2-diazo-1,2-diphenylethanone with diarylmethanimine (**1**) at refluxing temperature. The products **2** lead to amido ethers (**4**) with alcohols. On irradiation of the reaction mixture with UV light, cyano ethers (**5**) are obtained besides the amido ethers (**4**).

Results and Discussion

The product mixture, obtained by refluxing 2-diazo-1,2-diphenylethanone and diphenylmethanimine (**1a**, Ar=Ar′=C_6H_5) in benzene, was crystallized from 2-propanol; it gave *N*-(diphenylmethylene)diphenylacetamide (**2a**, 90%). The structure was assigned on the basis of analytical and spectral data (Table 1). The product **2a** resulting from an intermediate **A** presumably can be formed as an adduct of diphenylketene, generated from the decomposition of 2-diazo-1,2-diphenylethanone,[5] and diphenylmethanimine (**1a**) (Scheme 1). A similar zwitterionic intermediate has been proposed[6] in the formation of 2-azetidinones from the reaction of *N*-benzylideneaniline with diphenylketene. The migration of hydrogen appears to be more feasible than the cyclization of the intermediate **A** to the β-lactam **B** due to steric factors (presence of four bulky aryl groups on the terminal carbon atoms in **A**). The reaction of **2a** with sodium borohydride in 2-propanol at room temperature yields the reduction product **3a** (Table 1).

The crystallization of the above reaction products obtained from 2-diazo-1,2-diphenylethanone and **1a** from methanol afforded *N*-(α-methoxydiphenylmethyl)-diphenylacetamide (**4a**). Crystallization of **2a** from

methanol also gave **4a**. The structure assignment of product **4a** has been made on the basis of analytical and spectral data (Table 2). On treatment with 0.1 mol dm^{-3} HCl the amido ethers (**4**) gave diphenylacetamide, mp 166—167 °C and the IR spectrum shows bands at 3400 (ν_{NH_2}) and 1660 cm^{-1} ($\nu_{C=O}$). The amido ether **4a** on heating at 225 °C for 15 min gave **2a** presumably with the loss of alcohol. The formation of products can be explained as shown in Scheme 1.

Similar treatment of imines **1b—c** gave the *N*-acylimines **2b—c** and amido ethers **4b—d**. The reduction of **2b—c** in 2-propanol gave **3b—c**. These products (**2a—c** and **4a—d**) were also obtained in the reaction of diphenylketene with diarylmethanimines (**1a—c**).

Irradiation of a solution of 2-diazo-1,2-diphenylethanone and diphenylmethanimine (**1a**) in dry benzene with UV light gave α-(diphenylmethoxy)diphenylacetonitrile (**5a**) and amido ether (**4a**). The cyano ether (**5a**)

did not lead to amido ether (**4a**) on treatment with methanol. The probable reaction sequence is shown in Scheme 2.

The loss of nitrogen from 2-diazo-1,2-diphenylethanone would lead to ketocarbene, which would condense with diphenylmethanimine (**1a**) *in situ* to form 1,3-oxazole in an analogous manner as observed in the case of the reaction of 2-diazo-1,2-diphenylethanone and thiobenzophenone.[1] The oxazole may further rearrange to cyano ether (**5a**) (Scheme 2) as observed in the ring opening of 2-thiazolines.[7]

Similar irradiation of imines **1b—c** gave cyano ethers (**5b—c**) besides amido ethers (**4b—d**). The amido ethers (**4b—d**) are presumably formed from diphenylketene and **1** through zwitterionic intermediate **A** as shown in Scheme 1.

Experimental

Melting points have been determined in capillaries on Büchi apparatus and are uncorrected. The NMR spectra were recorded with a Varian A-60 D spectrometer, with tetramethylsilane as an internal standard. The IR spectra were measured on a Perkin-Elmer 720 spectrophotometer and the UV spectra on a Beckman DB-G spectrophotometer.

Preparation of N-*(Diarylmethylene) diphenylacetamide (2) and Amido Ethers (4). General Procedure From 2-Diazo-1,2-diphenylethanone*: A solution containing 3.0 g (13.5 mmol) of 2-diazo-1,2-diphenylethanone[8] (freshly prepared by the oxidation of benzil monohydrazone with yellow mercury(II) oxide) and diarylmethanimine (**1**)[9] (14.0 mmol) in 60 ml of dry benzene was heated under reflux for 6 h and kept overnight at room temperature. The solvent was removed under reduced pressure and the residue on recrystallization from 2-propanol afforded *N*-(diarylmethylene)diphenylacetamide (**2**). The analytical and spectral data are shown in Table 1.

Crystallization of the products from methanol or ethanol yielded the amido ethers (**4**). The analytical and spectral data are given in Table 2.

From Diphenylketene: A solution containing 1.94 g (10 mmol) of diphenylketene[10] in 5 ml of dry benzene and 10 mmol of diarylmethanimine (**1**) in 5 ml of dry benzene were mixed at room temperature. The vessel became hot at once and the contents were kept overnight at room temperature. Crystallization of the reaction mixture from alcohol afforded the same amido ethers (**4a—d**) as obtained from 2-diazo-1,2-diphenylethanone.

Preparation of Cyano Ethers 5. General Procedure: A solution containing 4.9 g (22.0 mmol) of 2-diazo-1,2-diphenylethanone and 24.0 mmol of diarylmethanimine (**1**) in 330 ml of dry benzene was irradiated by UV light from a 200 W Hanovia mercury arc lamp under a continuous slow stream of nitrogen for 6 h and kept overnight at room temperature. The solvent was removed under reduced pressure and the residual material was fractionally crystallized from benzene–methanol mixture to afford the cyano ethers (**5**, 34—38%) (Table 3) and amido ethers (**4**, 45—50%) (Table 2).

Conversion of 4a to 2a: 1.0 g of the amido ether (**4a**) was allowed to melt at 225 °C in an oil bath and was kept for 15 min at 225 °C. The flask was cooled and the residual material was recrystallized from 2-propanol to give 0.9 g (90%) of **2a**. Similarly **4b** and **4c** were converted to **2b** and **2c**, respectively.

Reduction of 2a to 3a: To a solution of 1.0 g of **2a** in 20 ml of 2-propanol was added 30 mg of sodium borohydride and was allowed to stand at room temperature (40 °C) for 30 min. The solvent was evaporated and the residual matter recrystallized from ethanol to give 0.87 g (87%) of **3a**. Similar reduction of **2b** and **2c** gave **3b** and **3c**, respectively (Table 1).

Chemistry at Hydrocarbon-Water Phase Boundaries. Biphase Hydrolysis of Organic Halides[1]

Noritaka OHTANI,[2] Jacques J. BESSE, and Steven L. REGEN*

Contribution from the Department of Chemistry, Marquette University, Milwaukee, Wisconsin 53233, U.S.A.

(Received August 7, 1980)

The kinetics of the biphase hydrolysis of 1-bromoadamantane and 1-phenylethyl chloride in toluene–water and decane–water systems have been investigated. Evidence has been obtained for the first examples of rate-limiting S_N1 reactions occurring at a hydrocarbon–water phase boundary, based on (1) the influence of temperature, mild stirring, interfacial area, reaction volume, and pH on the observed first-order rate constants, (2) comparison of absolute rates and activation energies with analogous homogeneous hydrolysis reactions, (3) the temperature dependence of the initial rate of diffusion of tritiated 1-methoxyadamantane from toluene into water, and (4) the initial rate of diffusion of ^3H_2O into toluene.

Hydrocarbon–water interfaces are found in many important bioorganic and synthetic organic systems.[3-6] Despite this fact, their precise structure and overall chemical significance have not been well characterized.[7-9] Several years ago, Menger reported a detailed study of the biphase hydrolysis of *p*-nitrophenyl laurate catalyzed by imidazole in a heptane–water system.[3-10] Compelling evidence was presented which supported an interfacial reaction. Based on a very low apparent activation energy, it was also concluded that mass transport of the reactants to the interface makes a significant contribution to the observed kinetics. Remarkably few studies have since appeared which consider organic reactions at liquid–liquid interfaces.[11,12]

In the present paper we report the results of a kinetic study of the biphase hydrolysis of 1-bromoadamantane and 1-phenylethyl chloride carried out in toluene–water and decane–water systems.[13] Our data provide strong evidence for what we believe are the first examples of rate-limiting S_N1 reactions at a hydrocarbon–water liquid–liquid phase boundary. As such, they represent the simplest interfacial organic reactions investigated to date.

Results

Kinetics of the Hydrolysis. Biphase hydrolysis of 1-bromoadamantane and 1-phenylethyl chloride were carried out using culture tubes as reaction vessels. Rates were monitored by following the disappearance of the organic halide from the organic phase. For 1-bromoadamantane, hydrolysis rates were identical to those determined by following the appearance of 1-hydroxyadamantane in the organic phase (material balance was >95%). Partitioning of 1-phenylethyl alcohol into water was too high to permit the simultaneous analysis of reactant and product. In all cases, clean first-order kinetics was maintained over at least three half-lives. A typical first-order plot is shown in Fig. 1.

Table 1 shows the influence of mild stirring on observed first-order rate constants, k_{obsd}. For both organic halides, stirred reactions were similar in rate to unstirred processes. 1-Phenylethyl chloride hydrolized more than one order of magnitude faster than 1-bromoadamantane, and was carried out under mild stirring conditions in all subsequent experiments.

In order to evaluate the dependence of k_{obsd} on the hydrocarbon–water interfacial area, S, as well as the volumes of the aqueous (V_{aq}) and organic (V_{org}) phases used, biphase hydrolyses were carried out in culture tubes of varying dimensions. Results for 1-phenylethyl chloride, reported in Table 2, show that a normalized rate constant, k_0 (where $k_0=k_{obsd}\ V_{org}/S$), is constant over a wide range of experimental

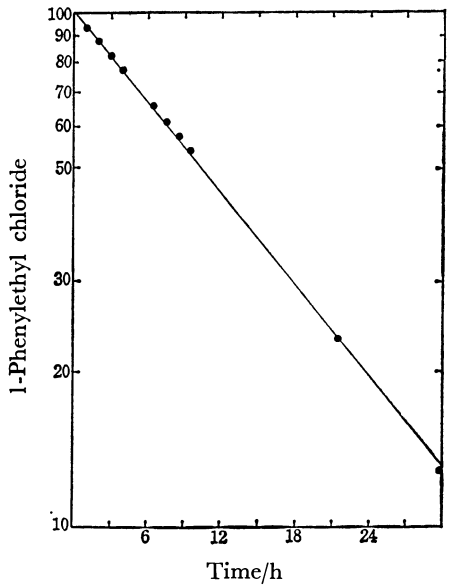

Fig. 1. Plot of percent of 1-phenylethyl chloride in the organic phase as a function of time for reaction of 4 ml of 0.01 M 1-phenylethyl chloride in toluene with 10 ml of 0.1 M aqueous sodium hydroxide at 90 °C, carried out as a mildly stirred process ($S\approx4.16$ cm^2).

TABLE 1. EFFECT OF STIRRING ON K_{obsd}[a]

Organic halides	Stirring speed / rpm	Interfacial area / cm^2	$10^5\,k_{obsd}$ / s^{-1}
1-Phenylethyl chloride	0	4.16	1.50
	70	≈4.16	1.90
1-Bromoadamantane	0	4.16	0.10
	70	≈4.16	0.16

a) Reaction of 4.0 ml of 0.01 M organic halide in toluene with 10 ml of 0.1 M aqueous sodium hydroxide in a 50 ml culture tube at 90 °C.

conditions and is independent of the volume of the aqueous phase.[14] Exactly analogous results have been obtained for 1-bromoadamantane.[13]

Data presented in Table 3 show the influence of temperature, hydroxide ion concentration, added sodium bromide and the nature of the hydrocarbon solvent on the biphase hydrolysis of 1-bromoadamantane. The apparent activation energy E_a for toluene–water and decane–water systems was 23.1 and 19.2 kcal mol^{-1} respectively. These values lie in the range found for comparable homogeneous hydrolysis (Table 4).[15] Values of k_0 at 100 °C using pure water, 0.1 M NaOH, or 1.0 M NaBr as the aqueous phase were very similar. When decane was used as the organic solvent in place of toluene, higher rates were observed. Similar results have been obtained for 1-phenylethyl chloride (Tables 4 and 5).

Diffusion of ^3H_2O into Toluene. The initial rate of diffusion of tritiated water from 0.1 M aqueous sodium hydroxide into dry toluene was measured at 70 °C and found to be 1.3×10^{-6} M s^{-1}; V_{org} and S used in this experiment were 4 ml and 1.26 cm^2, respectively.

Table 2. Influence of V_{org}, V_{aq}, and S on k_0 for 1-phenylethyl chloride[a]

V_{org} / cm^3	V_{aq} / cm^3	S / cm^2	$10^3 k_0$ / min^{-1} cm
1	2	1.26	1.1
2	5	2.83	1.2
4[b]	10	4.16	1.1
10	40	9.08	1.2

a) Reaction of 0.05 M 1-phenylethyl chloride in toluene with 0.1 M aqueous sodium hydroxide at 90°C, using mild stirring; $k_0=k_{obsd}V_{org}/S$. b) Organic halide concentration used was 0.01 M.

Discussion

Two fundamental questions which are central to this investigation are (1) what is the rate-controlling process and (2) where does reaction occur. In principle the rate-limiting step could be (a) diffusion of the organic halide through the bulk organic phase or through the aqueous–organic phase boundary, (b) diffusion of water into the bulk organic phase, (c) chemical reaction, or (d) a combination of (a)—(c). Based on the hydrolysis data, several lines of evidence point to chemical reaction as being the rate-determining step. First, the apparent activation energy observed for both organic halides is high and is similar to that measured for comparable homogeneous reactions. These values contrast sharply with activation energies found for diffusion in most liquids (3—5 kcal mol^{-1}).[16] Furthermore, the rate of diffusion of tritiated 1-methoxyadamantane from toluene into 0.1 M aqueous sodium hydroxide has previously been shown to be only slightly sensitive to temperature ($E_a\leq3.5$ kcal mol^{-1}).[13] This shows that the diffusional resistance for organic substrates, similar to those investigated in the present work, through the interface is low, as expected. Second, mild stirring has a relatively small effect on the biphase hydrolysis rates. This result further argues against diffusion as being an important contributor to the observed kinetics. Third, if water transport were rate limiting, the observed hydrolyses should obey zero order kinetics; also the rate for both organic halides would be equal to the diffusion rate of water into toluene. Experimentally, however, clean first-order kinetics are followed and the initial diffusion rate of water into toluene (70 °C) and the initial reaction velocity for 1-phenylethyl chloride (70 °C) and 1-bromoadamantane

Table 3. Biphase hydrolysis of 1-bromoadamantane

Organic solvent	Aqueous solution	V_{org} / cm^3	V_{aq} / cm^3	S / cm^2	Temp / °C	$10^7 k_0$[b] / s^{-1} cm	E_a / kcal mol^{-1}

Decane	0.1 M NaOH	70	6.83	13.33
		80	12.78	
		90	19.94	

a) Reaction of 1.0 ml of 0.01 M 1-phenylethyl chloride with 10 ml of 0.1 M aqueous sodium hydroxide using mild stirring ($S \approx 4.16$ cm^2).

(75 °C) are 1.3×10^{-6}, 1.6×10^{-7}, and 6.9×10^{-9} M s^{-1}, respectively ($S=4.16$ cm^2; $V_{org}=1$ ml; [organic halide]=0.01 M). Taken together, these data provide very strong evidence that diffusion plays a minor role in the apparent kinetics and that chemical reaction dominates.

For a rate-limiting chemical reaction, the constancy of k_0 over a wide range of V_{org}, V_{aq}, and S can be rationalized only in terms of an interfacial process. If reaction were occurring in the bulk water phase, the rate should increase with increasing V_{aq}, due to an increase in the molar amount of water soluble organic halide. Experimentally, the observed rate was independent of V_{aq}. That reaction is not occurring in the bulk organic phase is further demonstrated by a comparison of observed first-order rate constants for hydrolysis in toluene–water (two phase) *vs.* dioxane–water (one phase) systems. At 100 °C, k_{obsd} found for reaction of 1 ml of 0.01 M 1-bromoadamantane with 2 ml of 0.1 M aqueous sodium hydroxide ($S=1.26$ cm^2) was 2.87×10^{-6} s^{-1}. In contrast, k_{obsd} for the hydrolysis of 2.0 ml of 0.01 M 1-bromoadamantane in homogeneous 92% (v/v) dioxane–water was 1.28×10^{-6} s^{-1}. Similarly, at 90 °C, k_{obsd} for the biphase hydrolysis of 1.0 ml of 0.01 M 1-phenylethyl chloride with 10 ml of 0.1 M aqueous sodium hydroxide ($S=4.16$ cm^2) was 6.26×10^{-5} s^{-1}. The k_{obsd} for homogeneous hydrolysis of 4 ml of 0.01 M 1-phenylethyl chloride in 90% (v/v) dioxane–water was 1.54×10^{-5} s^{-1}. Thus, the observed first-order rate constants for homogeneous reactions which contained substantial amounts of water were *lower* than those found for comparable biphase reactions. Finally, the higher biphase hydrolysis rates observed with decane–water *vs.* toluene–water, while difficult to rationalize in terms of chemical reaction occurring in the organic phase (water is more soluble in toluene than in decane), is easily accounted for as an interfacial process; *i.e.*, partitioning of the relatively polar organic halide into the phase boundary should be greater when a less polar solvent (decane) is used.

The results presented in this paper provide strong evidence that chemistry at hydrocarbon–water phase boundaries can play an important role in liquid–liquid biphase ractions.[3,11,12] Further studies aimed at establishing the generality and chemical significance of interfacial organic chemistry are in progress.

Experimental

General Methods. 1-Bromo- and 1-hydroxyadamantane (Aldrich Chem. Co.) were purified by sublimation at 90 °C (1 mm), and 120 °C (1 mm) respectively. 1-Phenylethyl chloride was prepared from 1-phenylethyl alcohol using established procedures. Toluene and decane (Aldrich Chem. Co., spectrophotometric grade) were used as obtained. Deionized water was purified by distillation from $KMnO_4/Ba(OH)_2$. The temperature of the oil bath used for the kinetic experiments was controlled (±0.5 °C) with the aid of a "Therm-O-Watch" electronic controller Model L6-1000 (I^2R Co., Cheltenhan, Pa), attached to a thermometer. All kinetic experiments were conducted in culture tubes equipped with a Teflon-lined screw cap. Reaction mixtures were analyzed by GLC on a Hewlett-Packard Model 5830A flame ionization instrument (2 ft.×0.125 in UCW-982 on Chromosorb W column). Culture tubes (interfacial area) used were the following: Corning No. 9826, 13×100 mm (1.26 cm^2); Corning No. 9825, 20×125 mm (2.83 cm^2); Corning No. 9825, 25×150 mm (4.16 cm^2); Kimax No. 45066, 38×200 mm (9.08 cm^2). Radioactivity was measured using a Packard Tri-Carb Model 3330 scintillation spectrometer.

Kinetic Methods. All biphase hydrolysis reactions were studied between 70 and 120 °C. In a typical experiment, 1 ml of a solution of 1-phenylethyl chloride (0.01 M) in toluene containing a known quantity of undecane (internal standard) and 10 ml of (0.1 M) sodium hydroxide were introduced *via* pipet into a 50-ml culture tube (Corning No. 9826, 25×150 mm) containing a Teflon-coated magnetic stirring bar (1/2×5/16 in octagonal bar with pivot ring).

The tube was sealed with a Teflon-lined screw cap and was placed in an oil bath maintained at the desired temperature. The reaction was followed by withdrawing 1-μl samples of the organic phase at different times (no less than 30 min intervals) and monitoring the disappearance of the reactant by GLC. For sampling, the tube was removed from the oil bath, quickly cooled to nearly room temperature, opened, resealed, and returned to the bath (the overall process took less than 1 min). In all cases, clean first-order kinetics was observed over at least 3 half-lives. First-order rate constants were calculated with a least-squares program. The reproducibility of the observed rate constants was good (±10%). For biphase hydrolysis of 1-bromoadamantane, reactions were conducted in 8-ml culture tubes as unstirred processes using procedures previously described.[13] Apparent activation energies were derived from Arrhenius plots made by plotting k_0 as a function of $1/T$.

Diffusion of ^3H_2O into Toluene. An 8-ml culture tube was charged with 4.0 ml of dry toluene (distilled from sodium benzophenone ketyl) and sealed with a Teflon-lined screw cap. The tube was placed in an oil bath maintained at 70 °C. After thermal equilibration (15 min), 0.5 ml of 0.1 M NaOH in ^3H_2O (preequilibrated at 70 °C) was injected into the bottom of the toluene phase. The appearance of tritium in the organic layer was then monitored as a function of time by withdrawing 10 μl aliquots. The aliquots were blended with 2 ml of a scintillation liquid (dioxane solution of Omnifluor (New England Nuclear)) and the concentration of ^3H_2O in toluene computed using a standard curve.

The Crystal Structure of Bis(acetylacetonato)platinum(II) Benzene Solvate

Mitsunori KATOH, Kunio MIKI, Yasushi KAI, Nobuo TANAKA, and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 7, 1980)

Synopsis. The crystal structure of bis(acetylacetonato)platinum(II) benzene solvate has been determined by means of X-ray diffraction. The geometry around the platinum atom is square-planar. Acetylacetonato ligands are bonded to the Pt atom by the *O,O'*-chelation, the Pt–O bond lengths being 2.008 (15) and 1.979 (14) Å.

The transition metal complexes containing acetylacetonato (abbreviated as acac hereafter) ligands have been widely studied, and some of their structures have been reported hitherto. In the case of group VIII transition metal complexes, especially the nickel group transition metal complexes, molecular structures of $[Ni(acac)_2]$,[1,2] $[Ni(acac)_2]_3$,[3] and $[Pd(acac)_2]$[4,5] have been determined by means of diffraction methods. This paper will deal with the crystal structure analysis of bis(acetylacetonato)platinum(II) benzene solvate.

The yellow, prismatic crystals were obtained by recrystallization from a benzene solution. A well-shaped crystal with approximate dimensions of $0.40\times0.43\times0.25$ mm was sealed in a glass capillary tube with a small amount of benzene in order to prevent its decomposition.

Crystal Data. $C_{10}H_{14}O_4Pt\cdot C_6H_6$, F.W.=471.4, $F(000)=452$, monoclinic, space group $P2_1/c$, $a=7.165(2)$, $b=12.836(2)$, $c=9.240(1)$ Å, $\beta=92.17(2)°$, $V=849.1(2)$ Å^3, $D_m=1.84$ g cm^{-3} (by flotation in $ZnBr_2$ aqueous solution), $D_c=1.85$ g cm^{-3} for $Z=2$, μ(Mo $K\alpha$)=87.0 cm^{-1}.

Intensity data were collected on a Rigaku automated four-circle diffractometer with graphite monochromatized Mo $K\alpha$ radiation employing the θ-2θ scan technique. The scan rate was 4° min^{-1}. A total of 1959 reflections were obtained, of which 1460 reflections were $F_o>3\sigma(F_o)$. Lorentz and polarization corrections were made, but no absorption nor extinction correction was applied, which might limit the accuracy of the present structure determination.

TABLE 1. ATOMIC COORDINATES

Atom	x	y	z

† Complete F_o-F_c data and Tables of anisotropic thermal parameters are kept at the Chemical Society of Japan, Document No. 8113.

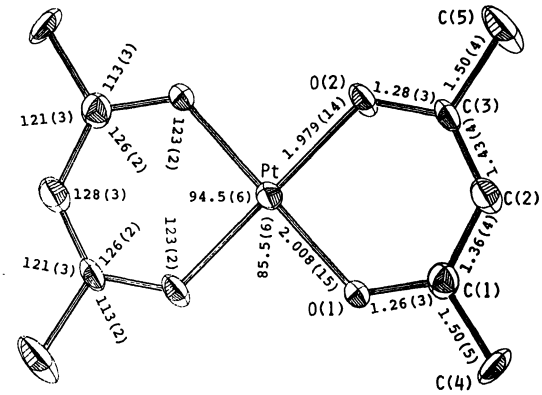

Fig. 1. An *ORTEP* drawing[9] of a $[Pt(acac)_2]$ molecule together with the atomic numbering system and selected bond lengths (l/Å) and angles (φ/°). The thermal ellipsoids correspond to 20% probability level.

The structure was solved by the heavy atom method, and refined anisotropically by the block-diagonal least-squares procedure using *HBLS*-V program.[6] The weighting scheme of Hughes,[7] $w=(50.0/|F_o|)^{-2}$ for $|F_o|>50.0$ and $w=1$ for $|F_o|\leq50.0$, was employed. Atomic scattering factors used were taken from International Tables for X-Ray Crystallography.[8] The final R value is 0.086 for 1460 reflections.† Atomic coordinates are listed in Table 1.

Figure 1 represents an *ORTEP* drawing[9] of the $[Pt(acac)_2]$ molecule together with the atomic numbering system and selected bond lengths and bond angles.

Similar to $[Pd(acac)_2]$,[4,5] the $[Pt(acac)_2]$ molecule is centrosymmetric. The Pt atom is located on a crystallographic center of symmetry, and surrounded by four oxygen atoms of acac ligands. The geometry around the Pt atom is square-planar. Two Pt–O bond lengths are 2.008(15) and 1.979(14) Å, which are approximately

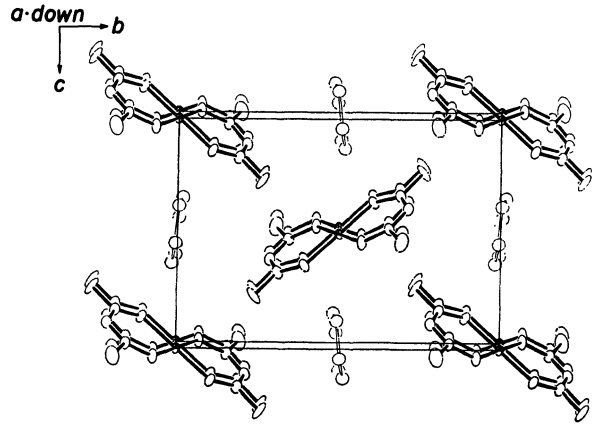

Fig. 2. Crystal structure(*ORTEP*[9]) projected along the c axis. Atoms in $[Pt(acac)_2]$ complex are drawn as thermal ellipsoids with 20% probability ,while those in benzene molecule as spheres with $B=5.0$ Å^2.

equal to the sum of the single bond radius of O atom (0.74 Å)[10] and the covalent bond radius of Pt(1.295 Å).[11]

The acac ligand is planar, the maximum atomic deviation from the least-squares plane being 0.02 Å. The dihedral angle between the acac plane and the plane defined by the Pt, O(1), and O(2) atom is 176.9°. Bond lengths and bond angles in the acac ligand are nearly equal to the values found for $[Pd(acac)_2]$.[5]

Very recently, Onuma *et al.* reported the crystal structure analysis of the triclinic crystal of $[Pt(acac)_2]$ which contains no crystalline benzene molecule.[12] The molecular structure of $[Pt(acac)_2]$ in the present crystal is essentially identical with that obtained by Onuma *et al.*

Figure 2 shows an *ORTEP* drawing[9] of the crystal structure. The $[Pt(acac)_2]$ molecules are piled up to form columns along the a axis. The crystalline benzene molecules lie, approximately parallel to the ac plane, in channels formed by piles of $[Pt(acac)_2]$ molecules and are linked loosely with adjacent $[Pt(acac)_2]$ and benzene molecules, which may explain the instability of the crystal.

All computations were carried out on an ACOS 700 computer at Crystallographic Research Center, Institute for Protein Research, Osaka University.

The authors wish to express their thanks to Professor Seichi Okeya, Wakayama University for crystals.

X-Ray Photoelectron Spectra of Adsorbed Methyl Acetoacetate and Coordinated Tartaric Acid, Aspartic Acid and Alanine on the Nickel Surface

Yasunobu INOUE,* Kiyomi OKABE, and Iwao YASUMORI
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received June 18, 1980)

Synopsis. The adsorption of methyl acetoacetate and the coordination of tartaric acid, aspartic acid, and alanine on the nickel surface were studied by means of X-ray photoelectron spectroscopy. The adsorbed methyl acetoacetate was partly in the enol-form, and the amino acids were coordinated with the surface through COO^- and NH_2 groups in a manner similar to the corresponding nickel chelate complexes, whereas the interaction of OH groups of tartaric acid with the surface was rather weak.

In the study of asymmetric hydrogenation catalyzed by metals modified with optically active molecules, it is of particular importance to ascertain not only the surface conditions of metals, but also the adsorbed states of the modifiers and reacting molecules. Few attempts have so far been made to analyze the surfaces from a physicochemical point of view. By using X-ray photoelectron spectroscopy (XPS), we previously studied nickel metals coordinated with tartaric acid and characterized the surface states of nickel responsible for the enantioface-differentiating hydrogenation.[1] In this work, we extended the XPS study to reveal the structures of the tartaric acid, aspartic acid, and alanine modifiers adsorbed on the Ni surface and to investigate the effect upon their stability of heat treatments in a hydrogen atmosphere. The adsorbed state of the reactant, methyl acetoacetate, was also studied.

Experimental

The X-ray photoelectron spectra were recorded at room temperature on a Hewlett-Packard 5950A ESCA spectrometer using monochromatized Al *Kα* exciting radiation. The nickel powder catalyst was prepared by decomposing nickel formate of an extra pure grade *in vacuo* and by then reducing with H_2 at 573 K. The modifications of the catalysts with (2*R*,3*R*)-tartaric acid, (*S*)-aspartic acid or (*S*)-alanine were performed in a manner analogous to those used in the previous studies.[1,2] The unmodified Ni catalyst used as a reference was also prepared similarly except for the absence of these optically-active modifiers. The catalysts were subjected to the *in situ* treatment in the preparation chamber of the spectrometer. The C 1s peak due to contaminant carbons, 285.0 eV, was taken as standard. For the experiments on the adsorption of methyl acetoacetate, a nickel foil of a 99.99% purity, obtained from the Material Research Co., was employed after being cleaned by an argon-ion bombardment following oxidation-reduction treatments.

Results and Discussion

Figure 1(a) compares the C 1s photoelectron spectrum of tartaric acid adsorbed on Ni with the spectra of nickel tartrate, sodium tartrate, and tartaric acid. Two peaks with almost the same intensity appeared apart from Peak I due to contaminant carbons; Peak II at

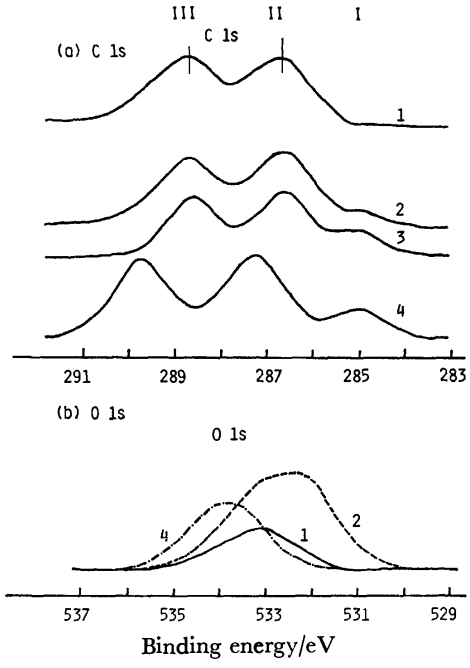

Fig. 1. X-Ray photoelectron spectra in the C 1s (a) and O 1s (b) regions.
1: Difference spectrum between unmodified nickel and tartaric acid-modified nickel (pH=5), 2: nickel tartrate, 3: sodium tartrate, 4: tartaric acid.

286.8 eV is assigned to the carbon atom combining with a hydroxyl group, whereas Peak III, 288.8 eV, is assigned to the carbon atom in the carboxyl group. These binding energy values were closer to those from nickel tartrate (286.7 and 288.7 eV) and sodium tartrate (286.6 and 288.6 eV) than to those for tartaric acid (287.3 and 289.7 eV). Figure 1(b) shows the O 1s spectra. The peak of the adsorbed tartaric acid appeared at the higher binding-energy side of a broad peak of nickel tartrate and was lower by 0.6 eV than that of tartaric acid. The broad O 1s peak of nickel tartrate is due to the characteristic structure of the complex; oxygen atoms in the carboxyl and hydroxyl groups undergo strong interactions with central nickel ions.[3] The close similarity on the C 1s level, while there is a difference in the O 1s level between the complex and the adsorbate, suggests that the adsorbed tartaric acid is linked to a surface Ni atom through a carboxyl group by dissociating hydrogen atoms, whereas the hydroxyl groups have little interaction with the surface atoms. Such a description of the adsorbed structure agreed substantially with the model proposed previously.[1]

The doublet peaks in the C 1s region, due to the adsorbed tartaric acid, remained almost unchanged with heat treatments in a H_2-atmosphere up to 353 K,

indicating that the adsorbed modifier retains its original structure. By a treatment at 383 K, the peak intensity was considerably attenuated but the doublet structure still existed. Further heating at 603 K changed the doublets to a single peak appearing at 284.4 eV, indicating that the adsorbed tartaric acid underwent decomposition to produce a carbonaceous deposit by this treatment, corresponding to a complete loss of the enantioselective capacity of this surface. The O 1s and Ni $2p_{3/2}$ spectra showed that the modification of Ni catalysts in air, as an ordinary procedure, gave rise to the oxygen peaks associated with NiO and Ni_2O_3 oxides, but the subsequent H_2-treatment at 353 K resulted in an almost complete removal of both oxides. The corresponding oxygen species with binding energies of 529.3 and 531.5 eV were reproduced by exposing to a O_2-atmosphere at room temperature and were then again reacted off with H_2 at 353 K. Such high reactivity suggests that the catalyst surfaces, even though they were modified in air, were readily changed to be oxide-free under the conditions of hydrogenation at 323—373 K.

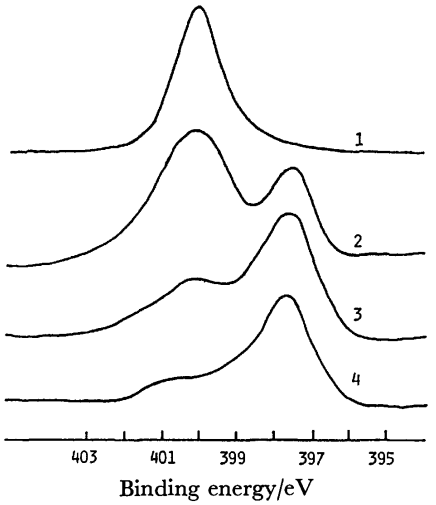

Fig. 2. Nitrogen 1s photoelectron spectra of adsorbed amino acids.
1: Aspartic acid, evacuated at room temperature, 2: aspartic acid, exposed to 6 Torr of H_2 at 363 K, 3: alanine, exposed to 10 Torr of H_2 at 373 K, 4: aspartic acid, exposed to 6 Torr of H_2 at 553 K.

Figure 2 shows the N 1s spectra of the adsorbed amino-acids. A single peak appeared at 400.1 eV by the coordination of aspartic acid; the binding-energy value was lower by 0.8 eV than that of aspartic acid (which is in the form of a zwitter ion, NH_3^+ and COO^-) and was close to that of the nickel ammine complex, *e.g.*, 400.0 eV for N atom in $[Ni(NH_3)_6]Cl_2$. The C 1s peak in the carboxyl group, 288.7 eV, was virtually identical with Peak III for the adsorbed tartaric acid. A similar correspondence was observed between the adsorbed alanine and the nickel–alanine complex. These spectral coincidences confirm a model[4] in which the amino acid is linked to a surface Ni atom through both amino and carboxyl groups. The heat treatment at 373 K gave rise to an additional N 1s peak at 397.5 eV (Spectra 2 and 3). Since such a low binding energy is characteristic of a nitride-like species,[5] it is evident that a part of the adsorbed amino acids was decomposed to produce nitrogen atoms.

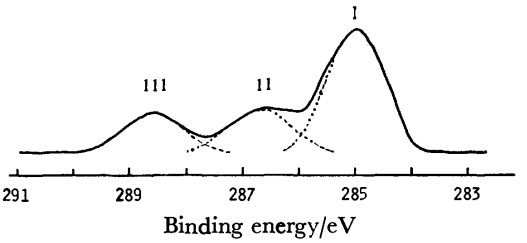

Fig. 3. Carbon 1s photoelectron spectrum of methyl acetoacetate adsorbed at room temperature on nickel surface.

As is shown in Fig. 3, the adsorption of methyl acetoacetate on a clean Ni surface provided three peaks in the C 1s region; they appeared at 285.0 (Peak I), 286.6 (Peak II) and 288.6 (Peak III) with an intensity ratio of 2.7 : 1 : 1. Peak III can apparently be assigned to C atoms in the carbonyl groups, whereas Peak I is associated with C atoms of hydrocarbons. Peak II is due to the carbon atom in the methoxy group, and its binding energy is close to that of a carbon atom combining with a hydroxyl group.[6] The appreciably higher intensity of Peak I, relative to the other two peaks, is partly due to contaminant carbons accumulated during prolonged evacuation following the adsorption. As for Peaks II and III, the original keto-form of methyl acetoacetate should provide the intensity ratio of 1 : 2, and it is to be noted that the observed equal intensity is derived on the basis of the assumption that about a half of the adsorbed species is in the enol-form. This finding is in line with the conclusion obtained from the tracer and IR spectroscopic studies.[1]

Characterization of Intramolecular Charge-transfer Transitions. 1-Aryl-1,2,2-tricyanoethylenes and 7-Aryl-7,8,8-tricyanoquinodimethanes

Jun-ichi AIHARA,* Kotaro ARAYA, and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 8, 1980)

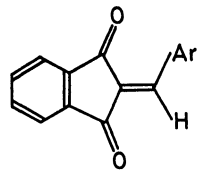
Synopsis. For the title compounds, the energy of the first electronic transition is linearly related to the vertical ionization potential of the aromatic nucleus (*e.g.*, benzene in the case of 1-phenyl-1,2,2-tricyanoethylene). This relationship gives a definite experimental support to the charge-transfer character of the electronic transitions concerned.

An intramolecular charge-transfer (CT) compound is an organic compound in which an electron-attracting group is attached to an electron-donor molecule, forming a single conjugated system as one whole.[1] In previous papers,[2-5] we have identified various types of compounds as such species by analyzing electronic spectra of the solutions and the condensed phases carefully. We found that, for a series of 2-(arylmethylene)-1,3-indandiones (A), the first intramclecular CT transition energy, $h\nu_{ICT}$, can be expressed in the form:[4]

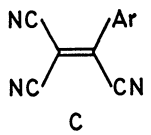
$$h\nu_{ICT} = aI_p - b, \quad (1)$$

where a and b are constants which are substantially characteristic of the acceptor part (*i.e.*, 2-methylene-1,3-indandione), and where I_p is the vertical ionization potential of the donor part (*e.g.*, anthracene in the case of 2-(9-anthrylmethylene)-1,3-indandione). The same relationship was found to hold for the first absorption bands of 1-aryl-2,2-dicyanoethylenes (B).[5]

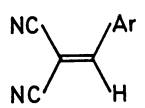
In this connection, we can fully anticipate the existence of such a linear relationship for the first absorption bands of 1-aryl-1,2,2-tricyanoethylenes (C) and for those of 7-aryl-7,8,8-tricyanoquinodimethanes (D) alike, because both tricyanoethylene and 7,8,8-tricyanoquinodimethane are supposedly good electron acceptors. If so, it would constitute the most conclusive evidence for a CT character of the electronic transitions concerned.[6]



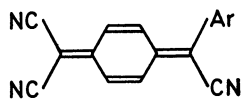
A



C



B



D

In order to see this, the spectroscopic data available on 1-aryl-1,2,2-tricyanoethylenes were first collected in Table 1.[7-13] The first absorption maxima of the seven 1-aryl-1,2,2-tricyanoethylenes in chloroform were then found to correlate well with the ionization potentials of the donor parts. As has been anticipated, a linear relationship between the two quantities was deduced thereform with a correlation coefficient of 0.989. By the least-squares analysis, we obtain

$$(h\nu_{ICT}/\text{eV}) = 0.614\,(I_p/\text{eV}) - 2.14. \quad (2)$$

It is now quite natural to attribute the first absorption band of every compound in Table 1 to the intramolecular CT transition from the highest occupied molecular orbital (HOMO), localized largely in the aryl group, to the lowest unoccupied molecular orbital (LUMO), localized largely in the tricyanoethylene part.

Next, Bespalov *et al.* prepared many 7-aryl-7,8,8-tricyanoquinodimethanes, and measured their electronic absorption spectra in acetonitrile.[14] They suggested that the first electronic transition might be of the CT type. This is exactly true from the present viewpoint. By the least-squares analysis, we again see with certainty the existence of a linear relationship between the first absorption maxima of these compounds[15] and the best vertical ionization potentials of the donor parts, namely,

$$(h\nu_{ICT}/\text{eV}) = 0.619\,(I_p/\text{eV}) - 2.78. \quad (3)$$

The correlation coefficient is 0.969. We can, hence, attribute the first absorption band of every such compound to the intramolecular CT transition from the HOMO, localized largely in the aryl group, to the LUMO, localized largely in the tricyanoquinodimethane part.

TABLE 1. INTRAMOLECULAR CT ABSORPTION BANDS OF 1-ARYL-1,2,2-TRICYANOETHYLENES (C) IN CHLOROFORM

Ar	$h\nu_{ICT}$ / 10^3 cm^{-1}	ε[a] / mol^{-1} dm^3 cm^{-1}	I_p/eV
Phenyl	29.15[b]	16600[b]	9.24[f]
2-Furyl	26.11[b]	25200[b]	8.89[g]

Here, it is noteworthy that, as in the case of 2-(arylmethylene)-1,3-indandiones[4] and 1-aryl-2,2-dicyanoethylenes,[5] the a value is relatively small for both 1-aryl-1,2,2-tricyanoethylenes and 7-aryl-7,8,8-tricyanoquinodimethanes. Considering that the a value for binary CT complexes usually lies in the 0.82—0.97 range,[16] the a=0.614 value for 1-aryl-1,2,2-tricyano-

Table 2. The relationship $h\nu_{ICT}=aI_p-b$ for intramolecular CT transitions

B[b]	Chloroform	0.675	2.23
C[c]	Chloroform	0.614	2.14
D[c]	Acetonitrile	0.619	2.78

a) Ref. 4. b) Ref. 5. c) Present work.

ethylenes and the $a=0.619$ value for 7-aryl-7,8,8-tricyanoquinodimethanes are obviously small. The a values determined for the four types of intramolecular CT bands are summarized in Table 2. It has now been established that the a value is close to 0.6 in the case of typical intramolecular CT bands measured in solution. According to Flurry's molecular orbital description of CT transitions,[17] the $a\approx0.6$ value indicates that about 1.6 of the two frontier electrons, on the average, reside in the donor ring in the ground state. Therefore, all these intramolecular CT compounds can assuredly be regarded as undissociable CT complexes.

On the other hand, the b value reflects the acceptor electron affinity and some other effects including structural factors, so it is quite difficult to analyze the b value in detail. However, the smallest b value for 2-(arylmethylene)-1,3-indandiones may be an indication of the smallest electron affinity of the common acceptor part (*i.e.*, 2-methylene-1,3-indandione).

In 1953, the study of intramolecular CT spectra was initiated with monosubstituted benzenes, such as aniline and benzaldehyde.[1] We have now a number of colorful intramolecular CT compounds, which are quite similar in many respects to binary CT complexes.[4] Most of them indeed show CT absorption bands isolated in the visible region. These compounds can, hence, be viewed as model compounds of binary CT complexes, each with a fairly fixed molecular geometry. As suggested in previous papers,[4,5] they will be of great help in obtaining insight into various electronic processes related to the CT transition in binary CT complexes.

One of us (J.A.) is grateful to the Ministry of Education, Science and Culture, Japan, for a Scientific Research Grant-in-Aid (No. 164116).

Effect of Halogen Substituents of Anion Radicals on the Electronic States of Crystalline Anion Radical Salts; K^+ *p*-Chloranil$^{\cdot-}$, K^+ 2,5-Dibromo-3,6-dichloro-*p*-benzoquinone$^{\cdot-}$, and K^+ *p*-Bromanil$^{\cdot-}$

Yôichi IIDA

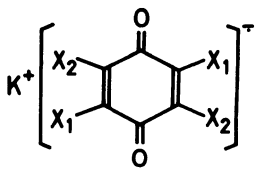
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 23, 1980)

Synopsis. The intermolecular interactions in crystalline anion radical salts of K^+ *p*-Chloranil$^{\cdot-}$, K^+ 2,5-Dibromo-3,6-dichloro-*p*-benzoquinone$^{\cdot-}$, and K^+ *p*-Bromanil$^{\cdot-}$ were examined in terms of one-dimensional half-occupied Hubbard model. Effect of substituents of the anion radicals on the crystal electronic states was discussed with the parameter values estimated by the Hubbard model.

Many papers have been written on the prominent magnetic, electrical and optical properties of a number of crystalline ion radical salts.[1-4] In such ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated stacking into one-dimensional columns so as to make a large overlap between their half-occupied molecular orbitals. In this case, since any individual radical molecule interacts through charge transfer most strongly with two adjacent radicals, the electronic and magnetic properties of the solid salt differ distinctly from those of the ion radical monomer.[1] In a previous paper,[3] we examined crystalline anion radical salts derived from halogen-substituted *p*-benzoquinones, and explained their optical and magnetic properties by applying half-occupied Hubbard model to the segregated stacks of those *p*-benzoquinone anion radicals. In the present paper, we take K^+ *p*-Chloranil$^{\cdot-}$, K^+ 2,5-Dibromo-3,6-dichloro-*p*-benzoquinone$^{\cdot-}$, and K^+ *p*-Bromanil$^{\cdot-}$, and compare the magnitudes of the Hubard-model parameters together with the ground-state stabilization energies of those anion radical salts.[5] Since the counter K^+ cation is common, we shall discuss the effect of halogen substituents of the anion radicals on the electronic states of those anion radical salts.

First, we consider the electronic state of solid K^+ *p*-Chloranil$^{\cdot-}$ salt. At room temperature, although there are several polymorphs, in the structure of the orthorhombic α-form, the *p*-chloranil anion radicals are stacked in themselves with equal intervals, forming non-alternant one-dimensional columns parallel to the c-axis, the interplanar spacing being 3.47 Å.[6] The K^+ ion lies at a center of a rectangle formed by four oxygen atoms of the *p*-chloranil anion radicals related by the c translation. In order to understand the optical and magnetic properties of this salt, we applied non-alternant one-dimensional half-occupied Hubbard model to the segregated stack of the *p*-chloranil anion radicals.[3] This model is a simplification of the real crystal and is described by two parameters, I and T.[7] Here, T is the transfer matrix element of an unpaired electron which describes hopping between adjacent molecular sites, while I is the Coulomb repulsion between two electrons with up and down spins on the same site. Then, T favors electron delocalization through band formation, whereas I favors localization due to electron-electron repulsions. On the basis of this model, we can well understand the reasons why the intermolecular charge-transfer absorption appears in the solid-state spectrum of K^+ *p*-Chloranil$^{\cdot-}$ at 11800 cm^{-1} and why the antiferromagnetic spin exchange interaction, $J=113$ cm^{-1}, acts between adjacent *p*-chloranil anion radicals.[2-4] The values of $I=11800$ cm^{-1} and $T=-820$ cm^{-1} explain well those observed optical and magnetic data of K^+ *p*-Chloranil$^{\cdot-}$. Once the I and T values are obtained experimentally, it is easy to determine the magnitude of ground-state energy stabilization, E, due to charge-transfer interaction between ion radicals in non-alternant one-dimensional system of the ion radicals. In previous papers,[4] we obtained in a limit of $I/|T|=\infty$ the expression of $E=-(4NT^2/I)$ ln 2, where N is the number of ion radicals. In the case of the one-dimensional system of *p*-chloranil anion radicals, where $I=11800$ cm^{-1} and $T=-820$ cm^{-1}, the magnitude of $I/|T|=14.39\cdots$ is found to be much larger than unity. Therefore, the condition of $I/|T|=\infty$ is approximately fulfilled in our case, and the value of E is estimated to be -1.87 kJ mol^{-1}.



(a); $X_1 = X_2 = Cl$
(b); $X_1 = X_2 = Br$
(c); $X_1 = Br$, $X_2 = Cl$

Fig. 1. Halogen-substituted *p*-benzoquinone anion radical salts with potassium cation; (a) *p*-chloranil anion radical salt, (b) *p*-bromanil anion radical salt, and (c) 2,5-dibromo-3,6-dichloro-*p*-benzoquinone (*p*-QBr_2Cl_2) anion radical salt.

In a similar way, the electronic state of solid K^+ *p*-Bromanil$^{\cdot-}$ salt was analyzed in terms of a segregated stack of *p*-bromanil anion radicals. The non-alternant one-dimensional half-occupied Hubbard model was then applied to this segregated stack, and the values of $I=10900$ cm^{-1} and $T=-730$ cm^{-1} were obtained.[3] Since the magnitude of $I/|T|=14.93\cdots$ is also much larger than unity, the ground-state stabilization energy, E, in the one-dimensional system of *p*-bromanil anion radicals is calculated, in a way similar to the case of *p*-chloranil anion radicals, to be -1.61 kJ mol^{-1}.

As for the electronic state of solid K^+ *p*-$QBr_2Cl_2^{\cdot-}$ salt,

two models were previously proposed to explain its optical and magnetic properties; one is a dimer model of p-QBr_2Cl_2 anion radicals and the other, non-alternant one-dimensional model of p-QBr_2Cl_2 anion radicals.[3] However, because of the reason given in Ref. 8, the latter model is more probable in K^+ p-$QBr_2Cl_2^{\cdot}$ than the former model, and our approach of non-alternant one-dimensional half-occupied Hubbard model is still applicable to that system. The values of $I=11500$ cm^{-1} and $T=-750$ cm^{-1} were thus estimated for the one-dimensional system of p-QBr_2Cl_2 anion radicals. When we note that $I/|T|=15.33\cdots$ is also much greater than unity, the ground-state stabilization energy, E, of this system is calculated to be -1.61 kJ mol^{-1} by using the estimated I and T values.

In the following, we compare the magnitudes of the parameters in the Hubbard model, that is, on-site Coulomb repulsion (I), transfer matrix element (T) and ground-state stabilization energy (E) estimated for K^+ p-Chloranil$^{\cdot}$, K^+ p-$QBr_2Cl_2^{\cdot}$, and K^+ p-Bromanil$^{\cdot}$ salts. Since the counter K^+ cation is common to these salts, and since all the anion radicals are closely related chloro- and bromo-substituted p-benzoquinone anion radicals, the difference in the values of those physical parameters should come from the difference in the substituents of the anion radicals. As for the on-site Coulomb repulsion, I, the order of its magnitude is found to be 11800 cm^{-1} (p-Chloranil$^{\cdot}$)$>$11500 cm^{-1} (p-$QBr_2Cl_2^{\cdot}$)$>$10900 cm^{-1} (p-Bromanil$^{\cdot}$). The magnitude of Coulomb repulsion between two electrons with up and down spins on the same site will be decreased if the molecular size of ion radical is extended and if polarizable substituents are introduced into ion radical. In this respect, we can understand the successive decrease of on-site Coulomb repulsion in going from p-chloranil anion radical to p-QBr_2Cl_2 and p-bromanil anion radicals, because the replacement of chloro-substituents of the anion radical by bromo-substituents leads to the expansion of the size of the molecule and also to the introduction of more polarizable substituents into the anion radical.

The transfer matrix element, T, between adjacent anion radical molecules is closely related to the overlap integral between the half-occupied molecular orbitals of the anion radicals. The absolute values of $|T|$ are found to range as 820 cm^{-1} (p-Chloranil$^{\cdot}$)$>$750 cm^{-1} (p-$QBr_2Cl_2^{\cdot}$)$>$730 cm^{-1} (p-Bromanil$^{\cdot}$). This result is also reasonable, because the replacement of the chloro-substituents in the anion radical by the bulky bromo-substituents increases the intermolecular spacing between adjacent anion radicals, and thus, decreases definitely the overlap between their half-occupied molecular orbitals.

As for the ground-state stabilization energy due to charge-transfer interaction between anion radicals, E, the absolute value of 1.87 kJ mol^{-1} of p-chloranil anion radical salt is greatest. The value of 1.61 kJ mol^{-1} of p-QBr_2Cl_2 anion radical salt coincides with that of 1.61 kJ mol^{-1} of p-bromanil anion radical salt, and these two values are smaller than the 1.87 kJ mol^{-1} value of p-chloranil anion radical salt. As has been mentioned, the ground-state stabilization energy, E, is given by $-(4NT^2/I)\ln 2$, and both I and $|T|$ values decrease progressively in going from p-chloranil anion radical salt to p-QBr_2Cl_2 and p-bromanil anion radical salts. However, the value of T^2/I is found to be greatest in p-chloranil anion radical salt. For p-QBr_2Cl_2 and p-bromanil anion radical salts, although both I and $|T|$ values of the former salt are larger than those of the latter salt, the quantities of T^2/I are of the same magnitudes.

7) J. Hubbard, *Proc. R. Soc. London, Ser. A*, **276**, 238 (1963); **281**, 401 (1964).

8) According to Ref. 3, if dimer Hubbard model is applied to p-QBr_2Cl_2 anion radicals in solid K^+ p-$QBr_2Cl_2^{\cdot}$ salt, the values of I and T have been reported to be 11300 cm^{-1} and -710 cm^{-1}, respectively. Then, the ground-state stabilization energy due to charge-transfer interaction between p-QBr_2Cl_2 anion radicals in a dimer is given by $I/2-\sqrt{(I/2)^2+(2T)^2}=-153$ cm^{-1} per dimer or -0.92 kJ mol^{-1}. On the other hand, if non-alternant one-dimensional model is applied to the anion radicals, the ground-state stabilization energy is estimated to be -1.61 kJ mol^{-1} (see text). Unfortunately, at the present time, no data on the crystal Madelung energy, which is a major source of cohesive energy, are available for K^+ p-$QBr_2Cl_2^{\cdot}$ salt. However, if the Madelung energy of the crystal lattice of the dimer model is almost the same as that of the one-dimensional model, the ground-state stabilization energy due to the charge-transfer interaction becomes important for the cohesive energy. In this respect, the ground state of the non-alternant one-dimensional model seems to be more stable in K^+ p-$QBr_2Cl_2^{\cdot}$ salt than that of the dimer model.

Equilibria of Aluminium(III) Complexes with 3,3′-Bis[*N*,*N*′-bis-(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein

Sadaaki MURAKAMI* and Takashi YOSHINO

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received February 23, 1980)

Synopsis. A potentiometric and spectrophotometric study of aluminium(III) complexes with 3,3′-bis[*N*,*N*′-bis-(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein has been performed. Evidence was found for the formations of 1 : 1 and 2 : 1 (metal : ligand) complexes and it was assumed that protonated and hydroxo complexes are formed in addition to the simple complexes. The formation constants for these complexes were determined and suggestions are made concerning the probable structures of the complexes.

Xylenol Orange (abbreviated as XO or H_6xo) has been widely used as an indicator in chelatometric and spectrophotometric determinations of numerous metal ions.[1,2] These are also many findings concerning the solution chemistry of its metal complexes. However, most of these reports have treated bivalent metal ions,[3-6] but not trivalent ones. In a previous work,[7] the Fe(III) complexes of XO were investigated and it was found that hydroxo complexes are formed in neutral and alkaline media. With regard to Al(III), Otomo[8] pointed out that its complex formation equilibria are complicated, when he studied the spectrophotometric determination of aluminium with XO. The complexes for the Al(III) system are expected to be similar to those found in the Fe(III). This paper reports the results of a potentiometric and spectrophotometric study on the Al(III) complexes with XO.

Experimental

XO was synthesized and purified as described in reference 9. The other reagents and procedures were the same as described previously.[10,11] All the measurements were performed at 25±0.1 °C; the ionic strength of the solutions was maintained at 0.1 with sodium perchlorate.

The formation constants of the complexes were calculated in the manner described previously.[10,11] The acid formation constants of XO used in the calculations were those determined previously[9] (log k_i: 12.23, 10.56, 6.74, 2.85, 2.32, and 1.5 for $i=1$ to 6, respectively).

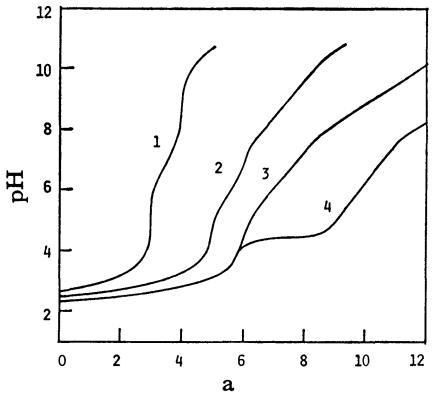

Fig. 1. Potentimetric titration curves of Al(III) and XO solutions. a=number of moles of base added per mole of XO.
1-XO, 2, 3 and 4-1/1, 2/1 and 3/1 solutions, respectively. [XO]=about 1×10^{-3} mol/1, and [Al(III)] is varied.

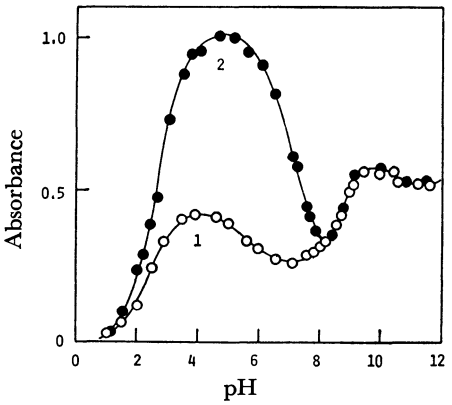

Fig. 2. Variations in the absorbances of Al(III) and XO solutions at a given wavelength as a function of pH. 1-1/1 and 2-2/1 solutions, respectively. Wavelength: 1-554 and 2-555 nm.

Results

Potentiometric titrations of XO solutions containing 1 : 1, 2 : 1, and 3 : 1 molar ratios of Al(III) to XO were performed (the molar ratios of Al(III) to XO, hereinafter, are referred to as "1/1", "2/1", and "3/1"). The results are shown in Fig. 1. The visible absorption spectra of the 1/1 and 2/1 solutions at various pH

$Al^{3+}+Hxo^{5-} \rightleftharpoons {}^*AlHxo^{2-}$	16.3	554	3.67
$2Al^{3+}+xo^{6-} \rightleftharpoons {}^*Al_2xo$	27.0	555	8.29
$H^+ + {}^*Al(OH)Hxo^{3-} \rightleftharpoons AlHxo^{2-}+H_2O$	5.8 5.6[a]	502	3.51
$2H^+ + {}^*[Al(OH)]_2xo^{2-} \rightleftharpoons Al_2xo+2H_2O$	13.4 13.1[a]	510	3.45

*The complexes corresponding to the λ_{max} and ε values. a) Determined spectrophotometrically (the others potentiometrically).

values (pH 1—13) were measured between 350 and 700 nm. Figure 2 shows the variations in the absorbances at a given wavelength as a function of pH. The formation constant, absorptivity, and wavelength of each complex species are listed in Table 1.

Discussion

Complex Formation Equilibria. Both 1/1 and 2/1 titration curves have two inflections: at $a=5$ and 6, and at $a=6$ and 8, respectively. The 3/1 titration curve is quite the same as the 2/1 curve up to $a=6$, but beyond this a value up to 9 there is another buffer region in which aluminium(III) hydroxide was precipitated. The extent of this buffer region over three units of a indicates that there exists one mole of free Al(III) ion per mole of XO, and that not more than two Al(III) ions can combine with one XO molecule.[11] One proton in a XO molecule remains undissociated at $a=5$ for the 1/1 solution, and all available protons dissociate at $a=6$ for the 2/1 solution, indicating the formations of the complexes, $AlHxo^{2-}$ and Al_2xo, at the respective a values. The extent of the buffer region from $a=6$ to 8 for the 2/1 solution is just double that from $a=5$ to 6 for the 1/1 solution. These facts suggest that each Al(III) ion in the 1 : 1 and 2 : 1 complexes is hydrolyzed to liberate one proton from a water molecule in its inner coordination sphere.[12] Thus, the hydroxo complexes, $Al(OH)Hxo^{3-}$ and $[Al(OH)]_2xo^{2-}$, are assumed to be formed as found in the Fe(III) and XO system.[7]

Both 1/1 and 2/1 titration curves show a long buffer region beyond $a=6$ and $a=8$, respectively. The change in the absorbance is observed in Fig. 2 between pH 7 and 10 for the 1/1 solution and between pH 8 and 10 for the 2/1 solution. With increase in pH from 7 and from 8, each spectrum shifted to longer wavelengths (502 to 578 nm for the 1/1 solution and 510 to 578 nm for the 2/1 solution). Both 1/1 and 2/1 spectra above pH 10 were exactly the same as those of the free XO solutions. These facts suggest that the complexes, $Al(OH)Hxo^{3-}$ and $[Al(OH)]_2xo^{2-}$, are further hydrolyzed to dissociate into $Al(OH)_4^-$ and XO in such alkaline media. In acidic media, the 1/1 and 2/1 titration curves have a long buffer region. The change in the absorbance is observed in Fig. 2 from pH 4 down to 1 for the 1/1 solution and from pH 5 to 1 for the 2/1 solution. With decrease in pH from 4 and from 5, the 1/1 and 2/1 spectrum bands at 554 and at 555 nm respectively disappeared and a new band appeared at 435 nm for both 1/1 and 2/1 solutions. Both 1/1 and 2/1 spectra around pH 1 were just the same as those of the free XO solutions. These facts suggest that the complexes, $AlHxo^{2-}$ and Al_2xo, dissociate into Al(III) aquo ion and XO in such acidic media.

Summarizing the foregoing discussion, the equilibria of complex formations for the Al(III) and XO system are as indicated in the following scheme.

The 1/1 solution:

$$\underset{}{\overset{pH<1}{Al^{3+} + H_6xo}} \rightleftharpoons \underset{}{\overset{pH\ 4}{AlHxo^{2-}}} \rightleftharpoons \underset{}{\overset{pH\ 7}{Al(OH)Hxo^{3-}}} \rightleftharpoons \underset{}{\overset{pH>10}{Al(OH)_4^- + H_2xo^{2-}}}.$$

The 2/1 solution:

$$\underset{}{\overset{pH<1}{2Al^{3+} + H_6xo}} \rightleftharpoons \underset{}{\overset{pH\ 5}{Al_2xo}} \rightleftharpoons \underset{}{\overset{pH\ 8}{[Al(OH)]_2xo^{2-}}} \rightleftharpoons \underset{}{\overset{pH>10}{2Al(OH)_4^- + H_2xo^{4-}}},$$

where each pH value indicates that the corresponding species is predominant in the solution around this pH value.

Complex Structures. The XO molecule has two chelating groups on each side of its large sulfonphthalein nucleus; each chelating group reacts with metal ion independently of each other.[2] Thus, the proton of the 1 : 1 complexes, $AlHxo^{2-}$ and $Al(OH)Hxo^{3-}$, may be the one which attaches to the amino nitrogen of another bis(carboxymethyl)aminomethyl group which is not coordinating to an Al(III) ion, because the amino nitrogen may dissociate the proton in more alkaline media.[9]

With regard to the 1 : 1 hydroxo complex, $Al(OH)Hxo^{3-}$, there is some possibility of a dimerized structure with hydroxo bridges, $[Hxo\cdot Al\langle^{OH}_{OH}\rangle Al\cdot Hxo]^{6-}$, as discussed for $Al(OH)sxo^{2-}$[12] and $Fe(OH)Hxo^{3-}$.[7] A polynuclear complex[13,14] is possible for the 2 : 1 hydroxo complex, $[Al(OH)]_2xo^{2-}$, as a result of hydrolysis of two Al(III) ions attached to either side of the sulfonphthalein nucleus, $[_{HO}\rangle Al\cdot XO\cdot Al\langle^{OH}\ ]_n^{2n-}$ ($n\geqslant 2$), as discussed for $[Fe(OH)]_2xo^{2-}$.[7] However, a complete discussion of the structures for these hydroxo complexes must await further investigation.

Synthesis and Activity of Antitumor Agents, Methyl [*N'*-(2-Chloroethyl)-*N'*-nitrosoureido]deoxygentiobiosides

Yoshimasa FUKUDA and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received January 24, 1980)

Synopsis. Chlorozotocin[1-4] and GANU[5-7] are nitrosoureido derivatives of D-glucose, exhibiting remarkable antitumor activities against leukemia L1210 in mice. We wish to report a synthesis of the derivatives of gentiobioside.

Tritylation of methyl 2-(benzyloxycarbonylamino)-2-deoxy-α-D-glucopyranoside,[8] followed by acetylation, afforded methyl 3,4-di-*O*-acetyl-2-(benzyloxycarbonylamino)-2-deoxy-6-*O*-trityl-α-D-glucopyranoside. Detritylation of the compound gave methyl 3,4-di-*O*-acetyl-2-(benzyloxycarbonylamino)-2-deoxy-α-D-glucopyranoside. Condensation of the compound with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide[9] yielded methyl hexa-*O*-acetyl-2-(benzyloxycarbonylamino)-2-deoxy-α-gentiobioside, which was further converted into methyl 2-(benzyloxycarbonylamino)-2-deoxy-α-gentiobioside (**1**). Catalytic hydrogenolysis of **1**, followed by addition with 2-chloroethyl isocyanate, gave the 2-[*N'*-(2-chloroethyl)ureido] compound (**2**). Nitrosation of **2** with N_2O_3 gave the *N'*-nitroso compound (**3**).

Starting from methyl hexa-*O*-acetyl-2'-(benzyloxycarbonylamino)-2'-deoxy-α-gentiobioside (**4**), methyl 2'-[*N'*-(2-chloroethyl)-*N'*-nitrosoureido]-2'-deoxy-α-gentiobioside (**7**) was obtained by analogous reactions. The position of the nitroso group was demonstrated by ammonia-induced degradation[10] of **3** and **7**.

4	28.9	0/5	61.1	0/5

a) Male BDF_1 hybrid mice were inoculated intraperitoneally with 10^6 cells of lymphoid leukemia L1210. Intraperitoneal injection of a compound was begun 24 h after the inoculation and performed once a day for 3 d. b) Percentage increase in life span of treated animals compared with control tumor bearers [100(T/C-1)].

Compounds **3** and **7** were subjected to determination of antitumor activity against leukemia L1210 in mice by the established protocol[11] (Table 1). Both compounds are highly active, **7** seeming to be more effective than **3**.

Experimental

Methyl 3,4-Di-O-acetyl-2-(benzyloxycarbonylamino)-2-deoxy-6-O-trityl-α-D-glucopyranoside. Trityl chloride (20.0 g) was added to a stirred solution of methyl 2-(benzyloxycarbonylamino)-2-deoxy-α-D-glucopyranoside[8] (10.0 g) in pyridine (120 ml), acetic anhydride (50 ml) being added after 24 h. After 16 h, the mixture was poured into ice cold water. The product precipitated was collected and recrystallized from ethanol, giving 8.7 g (44%) of the product, mp 90—91 °C, $[\alpha]_D^{20}$ +85° (*c* 1.2, chloroform).

Found: C, 69.67; H, 6.18; N, 2.30%. Calcd for $C_{38}H_{39}NO_9$: C, 69.82; H, 6.01; N, 2.14%.

Methyl 3,4-Di-O-acetyl-2-(benzyloxycarbonylamino)-2-deoxy-α-D-glucopyranoside. Acetic acid (0.3 ml) containing HBr was added under ice cooling with agitation to a solution of the trityl derivative (1.0 g) in glacial acetic acid (4 ml). After 1 min, the mixture was quenched in ice cold water and extracted with $CHCl_3$. The organic layer was washed with $NaHCO_3$ solution and water, and concentrated. Recrystallization of the residue from ether–petroleum ether gave 294 mg (37%) of the product, mp 112—113 °C, $[\alpha]_D^{20}$ +110° (*c* 0.8, chloroform). ^1H NMR (60 MHz, $CDCl_3$): δ 1.88 (s, 3, OAc), 2.03 (s, 3, OAc), 3.37 (s, 3, OCH_3), 4.76 (d, 1, J=4 Hz, H-1).

Found: C, 55.59; H, 6.14; N, 3.62%. Calcd for $C_{19}H_{25}NO_9$; C, 55.47; H, 6.13; N, 3.41%.

Methyl 2-(Benzyloxycarbonylamino)-2-deoxy-α-gentiobioside (1). A solution of the 3,4-di-*O*-acetyl derivative (995 mg) and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide[9] (2.0 g) in benzene (40 ml) was heated under reflux in the presence of $Hg(CN)_2$ (1.6 g) and Drierite (2.0 g) for 20 h. The mixture was diluted with $CHCl_3$ (60 ml) and filtered. The filtrate was washed with brine and water, and concentrated. The residue was purified on a silica gel column using 2 : 5 (v/v) acetone–benzene. Fractions (R_f 0.56 on TLC) were concentrated. The residue was deacetylated in methanolic ammonia and recrystallized from methanol to give 303 mg (42%) of **1**, mp 235—236 °C, $[\alpha]_D^{20}$ +50.9° (*c* 1.0, water).

Found: C, 51.78; H, 6.41; N, 2.75%. Calcd for $C_{21}H_{31}NO_{12}$: C, 51.53; H, 6.38; N, 2.86%.

Methyl 2-[N'-(2-Chloroethyl)ureido]-2-deoxy-α-gentiobioside (2). Compound **1** (850 mg) was hydrogenated in methanol (25 ml) with Pd black under H_2 (2.7 kg/cm²) for 2.5 h. The product was treated with 2-chloroethyl isocyanate (0.2 ml) in methanol (15 ml) overnight and the mixture was concetnrated. The residue was triturated in ethanol-ethyl acetate to give 620 mg (72%) of **2**, mp 151—152 °C (dec), $[\alpha]_D^{20}$ +54.2° (*c* 1.0, water).

Found: C, 41.74; H, 6.21; N, 5.88; Cl, 7.49%. Calcd for

$C_{16}H_{29}N_2ClO_{11}$: C, 41.70; H, 6.34; N, 6.08; Cl, 7.69%.

Methyl 2-[N'-(2-Chloroethyl)-N'-nitrosoureid]-2-deoxy-α-gentiobioside (3). N_2O_3 was bubbled into a suspension of **2** (200 mg) in acetone (5 ml) at 0 °C for 3 min. The solution was concentrated and the residue was washed with hexane-diisopropyl ether to give 153 mg (73%) of **3**, mp 67—68 °C (dec), $[\alpha]_D^{22}$ +39.4° (*c* 1.0, water).

Found: C, 39.21; H, 5.99; N, 8.58; Cl, 7.24%. Calcd for $C_{16}H_{28}N_3ClO_{12}$: C, 38.97; H, 5.77; N, 8.92; Cl, 6.92%.

Degradation of **3** in methanolic ammonia gave methyl 2-deoxy-2-ureido-α-gentiobioside, which was identified by TLC and by comparison of its IR spectrum [(KBr) 1650, 1610, 1565 cm^{-1}] with that of an authentic sample prepared by a definite route.

Methyl 2,3,3',4,4',6'-Hexa-O-acetyl-2'-(benzyloxycarbonylamino)-2'-deoxy-α-gentiobioside (4). A mixture of methyl 2,3,4-tri-*O*-acetyl-α-D-glucopyranoside[12] (1.7 g) and 3,4,6-tri-*O*-acetyl-2-(benzyloxycarbonylamino)-2-deoxy-α-D-glucopyranosyl bromide[13] (2.9 g) in benzene (35 ml) was heated under reflux for 2 h in the presence of $Hg(CN)_2$ (2.7 g) and Drierite (3.5 g). The mixture was diluted with $CHCl_3$ and filtered. The filtrate was washed with brine and water, and concentrated. Recrystallization of the residue from ethanol gave 943 mg (26%) of **4**, mp 162—163 °C, $[\alpha]_D^{25}$ +68.7° (*c* 1.0, chloroform).

Found: C, 53.29; H, 5.96; N, 1.99%. Calcd for $C_{33}H_{43}NO_{18}$: C, 53.43; H, 5.84; N, 1.89%.

Methyl 2'-(Benzyloxycarbonylamino)-2'-deoxy-α-gentiobioside (5) A solution of **4** (195 mg) in methanolic ammonia was settled overnight and concentrated. Recrystallization of the residue from methanol afforded 91 mg (72%) of **5**, mp 212—214 °C, $[\alpha]_D^{20}$ +37.6° (*c* 1.0, water)

Found: C, 51.32; H, 6.30; N, 2.83%. Calcd for $C_{21}H_{31}NO_{12}$: C, 51.53; H, 6.38; N, 2.86%.

Methyl 2'-[N'-(2-Chloroethyl)ureido]-2'-deoxy-α-gentiobioside (6). Compound **5** (393 mg) was hydrogenated in a similar way to that described above, and the product was treated with 2-chloroethyl isocyanate to give 172 mg (47%) of **6**, mp 189—190 °C (dec), $[\alpha]_D^{20}$ +29.9° (*c* 0.6, water).

Found: C, 41.74; H, 6.21; N, 5.88, Cl, 7.49%. Calcd for $C_{16}H_{29}N_2ClO_{11}$: C, 41.70; H, 6.34; N, 6.08; Cl, 7.69%.

Methyl 2'-[N'-(2-Chloroethyl)-N'-nitrosoureido]-2'-deoxy-α-gentiobioside (7). Compound **6** (200 mg) was nitrosated in a similar way to that described above to give 198 mg (97%) of **7**, mp 116 °C (dec), $[\alpha]_D^{20}$ +27.1° (*c* 1.0, water).

Found: C, 39.53; H, 5.99; N, 8.24; Cl, 7.28%. Calcd for $C_{16}H_{28}N_3ClO_{12}$: C, 39.21; H, 5.76; N, 8.58; Cl, 7.24%.

Degradation of **7** in methanolic ammonia gave the 2'-ureido derivative as described above.

Enolate Anions. IV. The ^{13}C NMR Spectra of Sodium Enolates of Ethyl Phenylacetates in DMSO[1)]

Syun-ichi KIYOOKA* and Kojiro SUZUKI

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

(Received April 7, 1980)

Synopsis. The ^{13}C NMR spectra of the sodium enolates of ethyl (*p*-substituted phenyl)acetates are presented. The polar interactions between the substituents and the anionic moiety in the sodium enolates are estimated by means of their ^{13}C chemical shifts.

In previous papers,[1)] the ^{13}C NMR data of sodium enolate from diethyl malonates were reported and the substituent effects on the structures of the enolate anions from ethyl phenylacetates and diethyl malonates in DMSO were investigated by means of their UV-visible, IR, and ^1H NMR spectra. The ^1H chemical shifts of the residual methine protons of the sodium enolates from ethyl phenylacetates were correlated to the σ^- constant as well as the carbonyl-stretching vibrations of the enolates. The substituent effects seem mainly to depend on the variation in the electron density of the delocalized-anion moiety. The studies of the IR and ^1H NMR spectra of sodium enolates prepared from ethyl phenylacetates found the existence of extremely different ρ values for meta-line and para-line against σ and σ^-, and suggested two different modes of explanation of the substituent-transmission mechanism. Many workers have reported on the correlations between the ^{13}C substituent chemical shifts (^{13}C SCS) and the relative electron densities on the carbon atoms of interest.[2)]

Table 1 shows the ^{13}C chemical shifts of the parent ester (A) and their sodium enolates (B) and the chemical-shift differences ($\Delta\delta$), which are given by $\delta_A-\delta_B$. These ^{13}C chemical shifts were assigned according to the additivity rule.[3)] In the case of the NO derivative, all benzene-ring ^{13}C signals of the enolate were distinguished because of the fixation of the partial double bond between the benzene ring and the enolate-anion moiety on the NMR time scale, as supported by ^1H NMR.[1b)] The nonequivalence of the two signals of C-m and C-m′ in the enolates with the CN and MeCO substituents is also supported by such a partial double-bond character.

The $\Delta\delta$ values at C-α and C-p were observed as downfield shifts, while those at C-γ and C-ipso were observed as upfield shifts, despite the kinds of substituents. The $\Delta\delta$ values at C-m and C-o are very small. The signs of the $\Delta\delta$ values at C-β are plus (downfield shifts) with electron-releasing substituents and minus (upfield shifts) with electron-attracting substituents. An analogous trend has also been found in

a) A; Ethyl phenylacetates. B; Enolate anions. C; $\Delta\delta=\delta_A-\delta_B$. A plus sign denotes a downfield shift.
b) These chemical shifts could not be assigned to any carbons in the benzene ring.

the $\Delta\delta$ values of the residual methine protons.[1b] The $\Delta\delta$ values at C-γ and C-δ are affected by the negative moiety of the enolate anions in the same pattern as those of the malonate system.[1a]

In the case of benzyl methyl ketone, the $\Delta\delta$ value at benzyl carbon has been reported to be +42.5 ppm (a downfield shift), and the chemical-shift difference of the sodium enolate from the enol acetate, to be −23.2 ppm (an upfield shift).[4] By anion formation, the hybridization of the benzyl carbon changes from sp^3 to sp^2, accompanied by a large downfield shift of the ^{13}C chemical shift; *e.g.*, ethylene carbon resonates at a point downfield by more 117 ppm than that of ethane carbon; simultaneously, the increase in the pi-electron density on the carbon atom is forced to shift the chemical shift upfield.[5] These two opposing effects seem to cancel each other out and to give an apparent $\Delta\delta$ value to such an anionic carbon. The $\Delta\delta$ value at C-α of ethyl phenylacetate was +5.6 ppm. This small value appears to be attributable to the above-mentioned cancelling. Consequently, the small downfield shift at C-α seems to be associated with the increase in the electron density on the carbon rather than with the decrease based on sp^2 hybridization. The sign of the $\Delta\delta$ value at C-β in ethyl phenylacetate shows a downfield shift, while those at C-p and C-ipso show downfield and upfield shifts respectively. The $\Delta\delta$ values indicate the existence of pi-interaction between the benzene ring and the anion moiety (C=C=O$^-$), even in a nonsubstituted case.[6]

Several studies of ^{13}C SCS have been reported.[7] The purpose of this ^{13}C SCS study is to clarify the direction of the ^{13}C SCS on the carbons in the enolates against σ^- and σ. Such an anion system attached directly to a benzene ring is very rare in ^{13}C SCS studies.[8]

In Fig. 1, the ^{13}C chemical shifts at C-α, C-β, C-p, and C-ipso of sodium enolates are plotted against σ^-; those at the other carbons are scarcely affected at all by any substituents. The effect by the electron-attracting groups is quite different from that by the electron-releasing groups, as has been suggested by other physical data.[1] The electron-releasing groups act much like an H substituent, without any strong interaction between the substituents and the anion moiety, while the electron-attracting groups conjugate strongly with the anionic moiety through the benzene ring.

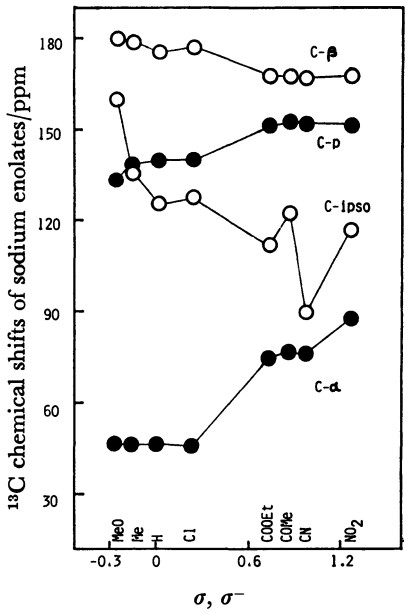

Fig. 1. Plots of the ^{13}C chemical shifts at C-α, C-β, C-p, and C-ipso of the sodium enolates derived from ethyl phenylacetates in DMSO-d_6 against σ^- and σ constants.

In the case of the electron-attracting groups, large downfield shifts were observed at C-α: the electron densities on the carbons decrease, while large upfield shifts were observed at C-ipso that is, the electron densities on the carbons increase. The ^{13}C SCS at C-ipso show a little irregularity which is directly affected by the inductive effect of the attached substituents. Small downfield shifts at C-p by electron-attracting groups are observed. At the β-carbonyl carbon atoms, the electron-attracting groups in the enolate cause small, but definite, upfield shifts. The above explanations for the ^{13}C SCS must be verified using the perturbation molecular-orbital theory.

Experimental

The proton-decoupled ^{13}C FT NMR spectra were measured at 25.15 MHz on a JEOL MH-100/PFT-100 spectrometer (pulse width, 31 μs; spectral width, 6250 Hz; data points, 4096; aquisition time, 327.8 ms). The spectra were observed on 0.5 M solutions in DMSO-d_6 in 5-mm tubes at 35—45 °C. The chemical shifts were obtained using the signal of DMSO in a 99% d-enriched solvent as the internal standard (δ 40.5 ppm), and were then converted to the TMS scale.

The sodium enolates of ethyl (p-substituted phenyl)acetates were prepared in a manner similar to that described in a previous report.[1b]

Oxidation of Steroidal π-Allyl Palladium Chloride Complexes Using Chromium(VI) Oxide in *N,N*-Dimethylformamide†

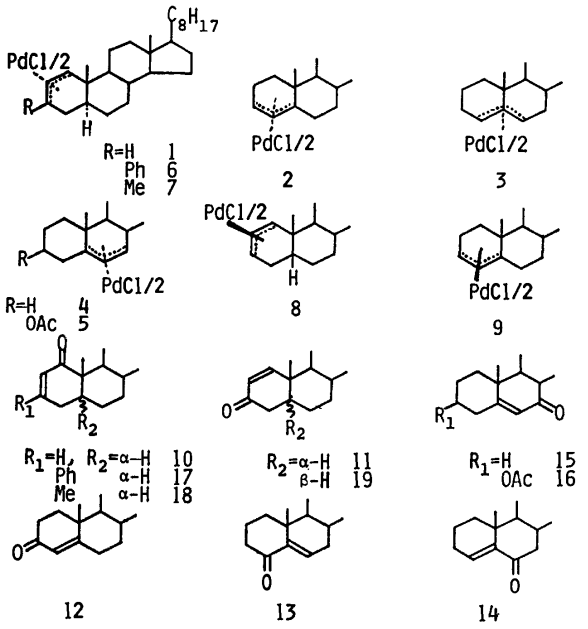
J. Yasuo SATOH and C. Akira HORIUCHI*

Department of Chemistry, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received June 7, 1980)

Synopsis. The oxidation of steroidal π-allyl palladium chloride complexes with the mild oxidizing agent composed of chromium(VI) oxide in *N,N*-dimethylformamide containing ether to dissolve the complex and a trace of sulfuric acid, afforded efficiently the corresponding α,β-unsaturated ketones.

It has been reported[1] that the oxidation of π-allyl palladium complexes in the presence of palladium(II) chloride and sodium acetate in aqueous acetic acid gave unsaturated aldehyde or ketone. However, the more heavily substituted π-allyl complexes such as the π-allyl complex of 3-methyl-2-pentene did not react with palladium(II) chloride. The oxidation of π-allyl complexes of the chain compounds[1] and complexes of 1-*p*-menthene[2] with, respectively, sodium dichromate containing sulfuric acid in ether and manganese dioxide containing sulfuric acid in 25% aqueous acetic acid has also been investigated. However, the yields of the α,β-unsaturated ketones were quite low. We have previously reported[3] that the reaction of the cholestene derivatives with palladium(II) chloride in the presence of potassium acetate in acetic acid afforded the corresponding steroidal palladium complexes. Hence, we attempted the oxidation of steroidal π-allyl complexes according to the procedures described by R. Hüttel and H. Christ,[1] G. A. Gray *et al.*,[2] and Jones reagent;[4] but we found that they gave the corresponding α,β-unsaturated ketone and considerable quantities of by-products, namely, carboxylic acids. In the present paper, we would like to report that the oxidation of the steroidal complexes with the mild oxidizing agent[5] composed of chromium(VI) oxide in *N,N*-dimethylformamide containing ether to dissolve the complex and a trace of sulfuric acid, gave the corresponding α,β-unsaturated ketones.



Results and Discussion

The oxidation of the steroidal π-allyl palladium complexes with chromium(VI) oxide in *N,N*-dimethylformamide and ether, containing a trace of sulfuric acid yielded in all cases the α,β-unsaturated ketones. These ketones were isolated by preparative TLC on silica gel, and identified by comparison with the IR and UV spectral data, and with the melting points of authentic samples. The reaction of di-μ-chloro-bis-[(1-3η-alkyl-5α-cholesten-2α-yl)palladium(II)] (**6**, **7**) gave the 3-alkyl-α,β-unsaturated ketone (**17**, **18**), which showed IR absorptions at 1660 and 1615 cm^{-1} (for R=phenyl); 1673 and 1644 cm^{-1} (for R=methyl). This α,β-unsaturated ketone was determined to be 3-alkyl-5α-cholest-2-en-1-one by means of its NMR spectrum, which showed a singlet at δ 6.10 ppm (CCl_4) (for R=phenyl) and at δ 5.63 ppm ($CDCl_3$) (for R=methyl) due to the olefinic proton.

The results of the oxidation of the steroidal π-allyl complexes are given in Table 1. On the basis of these results, it can be concluded that the mild oxidizing agent

† A preliminary report of this work was presented at the 38th National Meeting of the Chemical Society of Japan, Yokohama, April 1978.

used in this work is efficient in comparison to the various methods reported in the literature for the oxidation of the steroidal π-allyl complexes. In the case of the α-1-3η-type complex of 5α-cholestene, an oxo group was introduced in the direction of the C_1 and C_3 positions. In the case of the β-1-3η-type complex of 5β-cholestene, the oxidation occurred in the direction of the less hindered C_3 position rather than in the direction of the C_1 position, and formed Δ^1- and Δ^4-3-oxo derivative. In the reaction of the α-1-3η-type complex with a functional group at the C_3 position, the product was Δ^2-1-oxo derivative, and the oxidation occurred more slowly than in the case of a complex possessing no functional group. The α- and β-3-5η-type complex yielded cholest-4-en-3-one, and the α-5-7η-type complex gave the Δ^5-7-oxo derivative, quantitatively.

Experimental

All the melting points are uncorrected. The IR, UV, and NMR spectra were measured using a Hitachi model 215 grating infrared spectrometer, a Hitachi recording spectrophotometer model 323, and a nuclear magnetic resonance spectrometer, Hitachi-Perkin Elmer R-20A, in carbon tetrachloride and in deuteriochloroform with TMS as the internal standard.

General Procedure. A mixture of steroidal π-allyl palladium complex (6.0×10^{-1} mmol), chromium(VI) oxide (3.96 mmol), and *N*,*N*-dimethylformamide–ether (1 : 1) (50 ml) containing a trace of sulfuric acid was stirred at 25 °C for 5—20 h. After the usual work-up, the resultant oil was purified by preparative TLC coated with silica gel (2 mm thick) (E. Merck). Elution with benzene–ether (10 : 1) gave the α,β-unsaturated ketone from ethanol.

Materials. The steroidal π-allyl palladium complexes were synthesized by the methods described in the previous paper.[3]

The authors are indebted to Mr. Takayuki Sugiyama for his collaboration in the experimental work. This research was supported in part by a Matsunaga Research Grant from the Matsunaga Science Foundation.

The Selective Preparation of *N*-Acylindigo

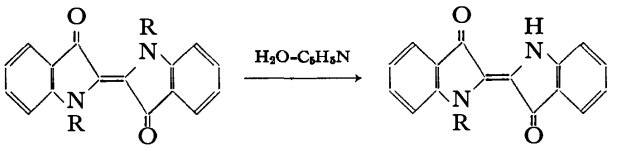
Yoshimori OMOTE,* Kiyoko FUJIKI,† Hiroshi AWANO, Ikuo KUBOTA, Takehiko NISHIO, and Hiromu AOYAMA

Department of Chemistry, The University of Tsukuba, Sakuramura, Niihari, Ibaraki 305
†*Department of Agricultural Chemistry, Faculty of Agriculture, Meiji University, Ikuta, Tama-ku, Kawasaki 214*

(Received July 5, 1980)

Synopsis. The hitherto unknown *N*-acylindigo has been selectively prepared by heating the corresponding known *N,N'*-diacylindigo in aqueous pyridine. The data of *N*-acetyl, *N*-benzoyl, *N*-(*p*-toluoyl), *N*-(*p*-chlorobenzoyl), *N*-(*p*-nitrobenzoyl), and *N*-(3,5-dinitrobenzoyl)indigo are summarized.

Indigo is a *trans* compound; it is stable and cannot be converted to the *cis*-isomer, not even by irradiation, while *N,N'*-diacetyl[1] and *N,N'*-dimethyl[2] derivatives have been known to show phototropic behavior. Recently we reported the *cis*-to-*trans* isomerization of *N,N'*-diacylindigo (**1**).[3] Therefore, it is of interest to see if *N*-acylindigo (**2**) can isomerize photochemically just like *N,N'*-diacylindigo.



1 R **2**

a: CH_3CO, **b**: C_6H_5CO, **c**: *p*-$CH_3C_6H_4CO$, **d**: *p*-ClC_6H_4CO, **e**: *p*-$NO_2C_6H_4CO$, **f**: 3,5-$(NO_2)_2C_6H_3CO$.

To our surprise, we cannot find any *N*-acylindigo in the literature, although several *N,N'*-diacylindigo have been known. In order to obtain *N*-acylindigo, we attempted to modify the partial acylation of indigo as well as the partial hydrolysis of *N,N'*-diacylindigo, and finally found a facile method of selectively preparing **2** from **1**.

The first trial at the acylation of indigo was as follows. Indigo and an equivalent amount of acetyl chloride were heated in acetic anhydride under reflux. The conditions were similar to those in the preparation of *N,N'*-diacetylindigo (**1a**)[4] except that excess molar acetyl chloride was used in the latter method. The products were found to be indigo and **1a**. The partial hydrolysis of **1a** was then examined. When **1a** was partially hydrolyzed by potassium hydroxide, the products were found to be indigo and **1a**. In neither case could we obtain an economical amount of **1a**. In the next trial, indigo was treated with sodium hydride in hexamethylphosphoric triamide, and then an excess amount of acetyl chloride was added. The product was a mixture of **2a** and **1a**; however, it seemed difficult to regulate the reaction, in which the formation of **2a** was predominant.

Finally, the partial hydrolysis of **1a** which had been heated in aqueous pyridine was found to be successful in giving **2a**. The reaction products were analyzed at time intervals by liquid chromatography and by means of the visible-absorption spectrum. The suitable conditions for the formation of **2a** were established to be as will be shown in the Experimental section.

TABLE 1. PROPERTIES OF N-ACYLINDIGO (**2**)

R	Mp °C	$\nu_{C=O}$ cm^{-1}	ν_{N-H} cm^{-1}	$\lambda^{C_6H_6}_{max}$ nm	ε
CH_3CO	185—186	1700 1650	3320	568	12000
C_6H_5CO	268	1690 1655	3300	575	14000
p-$CH_3C_6H_4CO$	276—277	1690 1645	3310	575	15000
p-ClC_6H_4CO	290—291	1690 1660	3310	574	13000
p-$NO_2C_6H_4CO$	> 290	1700 1650	3320	574	12000
3,5-$(NO_2)_2$-C_6H_3CO	> 290	1690 1655	3350	572	9000

The infrared and visible spectra of *N*-acylindigo are summarized in Table 1. The data support the structure of monoacylindigo. Furthermore, the preliminary experiment shows that these examples of *N*-acylindigo do not show any phototropic behavior.

Experimental

N-Acetylindigo (2a). *a)*: Sodium hydride (227 mg) was washed with petroleum ether and dispersed in HMPA (15 ml); indigo (500 mg) was then added, and the solution was stirred for 4 h at 0 °C under an argon atmosphere. Then acetyl chloride (725 mg) was added, and the solution was stirred for 15 h. The products were extracted with dichloromethane, dried over anhydrous magnesium sulfate, and chromatographed over silica gel with chloroform–acetone (60 : 1) to give reddish-purple needles (89 mg). Mp 185—186 °C. Found: C, 71.41; H, 4.04; N, 8.91%. Calcd for $C_{18}H_{12}N_2O_3$: C, 71.04; H, 3.97; N, 9.20%.

b): A solution of **1a** (20 mg) in a pyridine–water mixture (80 : 20 v/v, 100 ml) was heated at 88 °C for 120 min. After the pyridine had been removed under reduced pressure, the product was recrystallized from ethyl acetate–hexane. The yield was 37%. Mp 185—186 °C (dec).

N-Benzoylindigo (2b). A solution of **1b** (273 mg) in a pyridine–water mixture (60 : 40 v/v, 100 ml) was heated at 88 °C for 80 min. After the pyridine had been evaporated the product was precipitated and recrystallized from chloroform–hexane and then acetone–hexane to give purple needles. Mp 268 °C (dec). 85%. Found: C, 75.35; H, 3.77; N, 7.48%. Calcd for $C_{23}H_{14}N_2O_3$: C, 75.40; H, 3.85; N, 7.64%.

N-(p-Toluoyl)indigo (2c). *N,N'*-Bis(*p*-toluoyl)indigo (4.0 mg) (**1c**) was dissolved in aqueous pyridine (50 : 50 v/v, 10 ml), and the solution was heated at 70 °C for 4 h. After having been treated with 6 M hydrochloric acid, the reaction mixture was extracted with chloroform, washed with water, and dried over magnesium sulfate. The product was purified by silica gel chromatography using ethyl acetate–benzene. The residue was recrystallized from acetone–hexane, as purple needles. Found: C, 75.42; H, 4.06; N, 7.15%. Calcd for

$C_{24}H_{16}N_2O_3$: C, 75.77; H, 4.23; N, 7.36%.

N-(p-*Chlorobenzoyl)indigo (**2d**)*. Fine purple needles. Found: C, 68.78; H, 3.20; N, 6.83%. Calcd for $C_{23}H_{13}N_2O_3Cl$: C, 68.92; H, 3.26; N, 6.98%.

N-*(p-Nitrobenzoyl)indigo (**2e**)*. Fine purple needles. Found: C, 66.94; H, 3.10; N, 9.86%. Calcd for $C_{23}H_{13}N_3O_5$: C, 67.15; H, 3.18; N, 10.21%.

N-*(3,5-Dinitrobenzoyl)indigo (**2f**)*. A solution of **1f** (377 mg) in a pyridine–water mixture (90 : 10 v/v, 100 ml) was heated at 60 °C for 80 min. After the pyridine had been evaporated under reduced pressure, the residue was added to boiling water. The precipitates were collected, dried, and recrystallized from ethyl acetate–hexane and then benzene, as purple plates. Found: C, 60.01; H, 2.68; N, 11.96%. Calcd for $C_{23}H_{12}N_4O_7$: C, 60.53; H, 2.65; N, 12.27%.

Reaction of Allyl Diphenyl Phosphates with Soft Bases

Shuki ARAKI, Kazuhiro MINAMI, and Yasuo BUTSUGAN*

Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received July 21, 1980)

Synopsis. The title phosphates were found to react with a variety of soft bases to give nucleophilic substitution products in high yields. The reaction proceeded regiospecifically under mild reaction conditions with preservation of the double bond geometry.

It was first reported in 1958 that soft nucleophiles attack the alkyl group of trialkyl phosphates while hard bases attack the hard phosphorus atom.[1] However, the reaction of allylic phosphates with various nucleophiles has received relatively little attention. In 1968, Miller and Wood synthesized a series of allyl diphenyl phosphates (**1**) and examined their reactions with phenols[2] and β-diketones[3] as a model for the biosynthesis of phenolic isoprenoids. Kitagawa *et al.* reported the regio- and stereospecific substitution of allylic phosphates using organoaluminum reagents.[4] In the present paper, we describe the reaction of **1** with a variety of soft nucleophiles which involves the regio- and stereospecific substitutions of the diphenoxyphosphinyloxy group leading to good yields of allylic products (**2**).

The reactions were carried out as follows. The phosphates **1** were stirred with a slight excess (1.0—1.5 eq) of nucleophiles in *N,N*-dimethylformamide at room temperature for 3 h. The reaction mixtures were poured into water, and the products were extracted with ether or collected by filtration. Analytically pure materials were obtained after distillation, column chromatography on silica gel, or recrystallization. Products were identified by their analytical and spectral properties and, in the case of known materials, by comparison of these physical constants with those of the reported ones.[5] Treatment of **1** with soft bases such as iodide, cyanide, benzenethiolate and sulfide anions resulted in smooth displacement of the diphenoxyphosphinyloxy group to yield the corresponding allylated products in high yields. The results are given in Table 1. The phosphates **1B** and **1C** reacted with thiourea to give *S*-geranyl- and *S*-nerylisothiuronium salts (**2f** and **2j**), respectively, as colorless crystals. The reaction of **1B** with sodium thiocyanate gave an equilibrium mixture (**2g**) of linalyl isothiocyanate and geranyl thiocyanate. The ratio (81/19) estimated by ^{1}H-NMR analysis (in CCl_4 at 31.5 °C) is in good agreement with the reported one[6] (80.56/19.44, in CCl_4 at 36 °C). The reaction of **1** with carbanionic reagents such as Grignard reagents and organolithium reagents is of special interest in view of a carbon-carbon bond formation.[7] In fact, it has been demonstrated that the treatment of allyl diphenyl phosphates **1** with aryl Grignard reagents gives allylbenzenes in high yields.[8] In contrast, we have found that excess (5 eq) phenyllithium, a carbanion harder than aryl Grignard reagents, attacked the phosphorus atom of **1B** to produce triphenylphosphine oxide (80% yield) together with geraniol (92%) and phenol (86%). The reaction of **1B** with sodium ethoxide, a representative of hard bases, in ethanol at room temperature gave a complex product mixture.

It has been shown that the reaction of **1** with soft

Table 1. Reaction of allyl diphenyl phosphates (**1A**—**1C**) with soft nucleophiles

a) Counter cation: Na^+. b) Allyl: Geranyl: Neryl:  Linalyl: 
bases proceeds with complete preservation of the double bond geometry as evidenced by the fact that geranyl diphenyl phosphate **1B** gave geranyl derivatives (**2c**—**2f**) and the corresponding *cis*-isomer **1C** yielded neryl ones (**2h**—**2j**). All the reactions (except entry g) are regiospecific, exclusively leading to the α-substituted products. No evidence for the allylic rearrangement (γ-substitution) was detected.

Experimental

Melting points are uncorrected. The elemental analyses were performed at the Elemental Analysis Center of Kyoto University. IR spectra were measured with a JASCO IRA-1 spectrometer. ^{1}H- and ^{13}C-NMR were obtained on a Hitachi R-24A spectrometer and a JEOL JNM-FX100 spectrometer, respectively, in deuteriochloroform using tetramethylsilane as an internal standard. Phosphates **1A**—**1C** were prepared according to the method of Miller and Wood.[2] The following preparation of **2f** is representative of the reactions between **1** and soft nucleophiles.

Reaction of Geranyl Diphenyl Phosphate (1B) with Thiourea. A mixture of **1B** (386 mg, 1 mmol) and thiourea (76 mg, 1 mmol) in 2 ml of *N,N*-dimethylformamide was stirred at room temperature for 3 h. The reaction mixture was poured into water and the resulting white precipitate was collected by filtration, and washed with water. The crude product was recrystallized from ethanol to afford colorless needles of *S*-geranylisothiuronium diphenyl phosphate (**2f**) (253 mg, 56% yield), mp 134.5—135.5 °C. IR (KBr): 3280, 3068, 1676, 1500, 1240, 1218, 1094, and 922 cm^{-1}. ^{1}H-NMR: δ 9.81 (2H, br, NH), 8.03 (2H, br, NH), 7.04 (10H, m, Ph), 4.90 (2H, m, olefin), 3.37 (2H, d, J=7 Hz, SCH_2), 1.91 (4H, m, CH_2), 1.61, 1.52, 1.46 (each 3H, s, CH_3). ^{13}C-NMR: 171.7 ($SC^+(NH_2)_2$), 153.3 (P–O–C), 144.9 (=C–), 132.7 (=C–), 129.9 (=CH–), 124.2 (=CH–), 121.1 (=CH–), 120.9 (=CH–), 115.5 (=CH–), 40.1 (CH_2), 30.1 (CH_2), 26.9 (CH_2), 26.4 (CH_3), 18.4 (CH_3), 17.0 (CH_3). Found: C, 59.75; H, 6.87%. Calcd for $C_{23}H_{31}N_2O_4PS$: C, 59.73; H, 6.76%.

In a similar way, *S*-nerylisothiuronium diphenyl phosphate (**2j**) was obtained in 63% yield, mp 128.5—130.0 °C. IR (KBr): 3250, 3000, 1678, 1500, 1240, 1218, 1096, and 926 cm^{-1}. ^{1}H-NMR: δ 9.90 (2H, br, NH), 8.00 (2H, br, NH), 7.10 (10H, m, Ph), 4.96 (2H, m, olefin), 3.42 (2H, d, J=7 Hz, SCH_2), 1.92 (4H, m, CH_2), 1.62 (6H, m, CH_3), 1.50 (3H, s, CH_3). ^{13}C-NMR: 171.4 ($SC^+(NH_2)_2$), 153.3 (P–O–C), 144.5 (=C–), 132.8 (=C–), 129.8 (=CH–), 124.1 (=CH–), 121.0 (=CH–), 120.8 (=CH–), 116.5 (=CH–), 32.5 (CH_2), 29.8 (CH_2), 27.0 (CH_2), 26.3 (CH_3), 24.0 (CH_3), 18.3 (CH_3). Found: C, 59.21; H, 6.72%. Calcd for $C_{23}H_{31}N_2O_4PS$: C, 59.73; H, 6.76%.

We wish to thank the Instrument Center, the Institute for Molecular Science, for assistance in obtaining the ^{13}C-NMR spectra.

Polymer-bound "Dimethylaminopyridine" as a Catalyst for Facile Ester Synthesis

Seiji SHINKAI,* Hifumi TSUJI, Yōichiro HARA, and Osamu MANABE
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received July 21, 1980)

Synopsis. Polystyrene beads which covalently link a dimethylaminopyridine unit act as a catalyst for ester synthesis by the DCC method. The polystyrene beads are reusable and the synthetic method is very simplified.

The dicyclohexylcarbodiimide (DCC) method has been widely adopted for the synthesis of some sugar and amino acid derivatives. Recently, it was communicated that the method is applicable to the esterification of carboxylic acids in the presence of catalytic amounts of 4-dimethylaminopyridine (DMAP).[1,2] Klotz *et al.*[3] reported that the catalytic activity is due to both the increased electron-donating ability of the ring nitrogen and the augmented stability of the *N*-acylpyridinium species. Although this is an excellent, mild one-pot esterification method, there are two defects: (i) in the conventional DCC method in the amide synthesis the product is directly recovered by filtration owing to the precipitating nature of *N,N'*-dicyclohexylurea, whereas in the presence of DMAP one has to isolate the product ester from DMAP, and (ii) DMAP is relatively expensive. It occurred to us that two defects would be improved by immobilizing the DMAP unit in polymer beads. Here, we wish to report the method of the immobilization and the catalytic activity of the immobilized DMAP unit.

p-Chlormethylated polystyrene (**1**) (4% crosslinked, 4.0 mequiv Cl/g) was kindly supplied from Mitsubishi Kasei Co. Ltd. The polystyrene beads were treated according to the following reaction sequence. **1**→**2** : **1** was swelled in *N,N*-dimethylformamide and dry methylamine gas was introduced into the solution. The reaction was continued for 12 h at 60—70 °C. **2**→**3** : **2** was swelled in an ampule containing water and ethanol (3 : 1 in vol), and 4-chloropyridine and triethylamine (excess) were added. After sealing the ampule, the reaction mixture was heated at 150 °C for 4 d. **3**→**4** : **3** in dichloromethane was treated with acetic anhydride (excess). The reaction was continued for 3 h at room temperature. All the reactions were performed under efficient stirring. We also prepared the catalytic beads which have a spacer between the polymer surface and the DMAP unit. **5** was prepared according to the method of Molinari *et al.*[4] The reaction methods from **5** to **8** were similar to those from **1** to **4**. The DMAP contents determined by acid-base titration were: 1.6 mequiv DMAP/g for **4** and 0.60 mequiv DMAP/g for **8**.

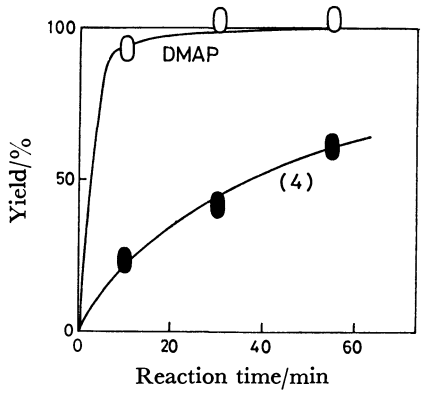

Fig. 1. Yield of methyl benzoate *vs.* reaction time. The yield was determined by GLC method (interanal standard, anisole). 20 °C, 10 ml of dichloromethane, 10 mmol of benzoic acid, 100 mmol of methanol, 12 mol of DCC, and 1.0 mmol of DMAP or DMAP unit in **4**.

Figure 1 shows the plots of the yield of methyl benzoate *versus* reaction time. The reaction conditions are recorded in the caption for Fig. 1. The homogeneous reaction catalyzed by DMAP was completed within 10 min, and the conversion was almost quantitative.[5] On the other hand, the reaction catalyzed by **4** was relatively slow, the half-life being about 30 min. After one day, the precipitate (*N,N'*-dicyclohexylurea) and **4** were removed by filtration and the filtrate was analyzed by GLC. The dichloromethane solution contained only methyl benzoate and methanol, so that the concentration *in vacuo* readily gave "pure" methyl benzoate. The yield of methyl benzoate was 65%, but unreacted benzoic acid was not detected in the filtrate. The loss may be caused by the adsorption to the polystyrene

Table 1. Yield of esters[a)]

Catalyst	Acid	Alcohol	Yield (%) after 1 h	3 h	1 d
DMAP	$C_6H_5CO_2H$	MeOH	100[d)]		
4	$C_6H_5CO_2H$	MeOH	61	59	65
4 reused	$C_6H_5CO_2H$	MeOH		65	
4[b)]	$C_6H_5CO_2H$	MeOH		51[e)]	
8	$C_6H_5CO_2H$	MeOH		41	53
4	$C_6H_5CO_2H$	*t*-BuOH		0	0
4	$CH_2(CO_2H)_2$	MeOH		84	98
4	$CH_5CH=CHCO_2H$	MeOH		61	
4[c)]	CH_3CO_2H	$C_6H_5CH_2OH$		40	47

a) The reaction solution (10 ml of dichloromethane) contains 1.0 mmol of catalyst, 10 mmol of acid, 100 mmol of alcohol, and 12 mmol of DCC. The yields were calculated on the basis of acid. b) 20 mmol of DCC were added. c) The reaction solution (10 ml of dichloromethane) contains 1.0 mmol of catalyst, 20 mmol of acetic acid, 10 mmol of benzyl alcohol, and 20 mmol of DCC. The yield was calculated on the basis of benzyl alcohol. d) 30 min. e) 4 h.

beads. The same reaction was carried out with **8**, but the yield was not improved significantly (yield 53%). After washing the recovered **4** by hot *N*,*N*-dimethylformamide, it was reused for the synthesis of methyl benzoate. The yield after 3 h was 53%. The result indicates that **4** is reusable without losing the catalytic activity.

The yields of other esters are summarized in Table 1. As mentioned above, starting carboxylic acids were not found in the filtrate. Table 1 shows that the yields in the present two phase system are somewhat lower than those in the homogeneous system.[2)] In particular, the yield of *t*-butyl benzoate was extremely low. Also in the homogeneous system catalyzed by DMAP,[2)] the low yield (40%) resulted for this ester due to the steric hindrance. The steric term may be further amplified in the solid catalyst system. On the contrary, dimethyl malonate was produced quantitatively. We cannot explain readily the difference in the yield between methyl benzoate and dimethyl malonate. One possible explanation is that benzoic acid which is more apolar than malonic acid is adsorbed to the resin surface in a non-productive manner in preference to malonic acid.

In conclusion, the catalytic activity of the DMAP unit bound to polystyrene beads is somewhat lower than that of DMAP in the homogeneous system. However, there are two merits in the immobilized DMAP catalysis: (i) the product esters are directly recovered by filtration, and (ii) the catalytic resin is reusable by simply washing with *N*,*N*-dimethylformamide.

The Copyrolysis of 1,2,3-Trichloropropane and Methanol on Activated Alumina

Kiyonori SHINODA* and Kensei YASUDA
Toyama Technical College, Hongo, Toyama 930-11
(Received July 21, 1980)

Synopsis. The copyrolysis of 1,2,3-trichloropropane and methanol gave 1,2-dichloro-3-methoxypropane as well as dichloropropenes and their derivatives. The formation of 1,2-dichloro-3-methoxypropane is also described.

Significant amounts of methoxy compounds are obtained by the copyrolyses of such allylic compounds as 3,4-dichloro-1-butene and 1,4-dichloro-2-butenes with methanol on activated alumina.[1,2] Allylic halides have been reported to undergo bimolecular nucleophilic replacement reactions in solutions.[3-5] On the other hand, the reaction of 1,2,3-trichloropropane (TCP) with methanolic sodium hydroxide affords only 2,3-dichloropropene (2,3-DCP), and scarcely no formation of 1,2-dichloro-3-methoxypropane (DCM) is observed.[6] The formation of DCM, which is formed by substituting a methoxyl group for a α-chlorine of TCP, characterizes the copyrolysis of TCP and methanol on activated almina. It is a great difference in comparison with the previous works that TCP is substituted by a methoxyl group at the α-position. The copyrolysis of TCP and methanol on activated alumina was carried out under various conditions in order to understand the formation of DCM.

Results and Discussion

Time Factor(W/F). The time factor was varied by adjusting the feed rate of TCP (F : g-mol/h), the weight of catalyst (W : g) being kept at 20 g. The TCP was mixed with methanol at the mole ratio of 1.00 : 12.7. The product distributions in the copyrolysis with various time factors at 250 °C are shown in Table 1. 2,3-Dichloropropene and 1,3-dichloropropene are abbreviated as 2,3-DCP and 1,3-DCP respectively. As the time factor increased, the conversion of TCP and the formation of such methoxy compounds as DCM were conclusively increased.

Mole Ratio(MeOH/TCP). A 20 g portion of the catalyst was placed in the middle of the reactor, the reaction temperature being kept at 300 °C. Mixtures of TCP and methanol were prepared at various mole ratios, while the time factor was kept constant at 416.3 (g of catalyst/g-mol of TCP/h). Figure 1 shows the effect of the mole ratio on the product composition.

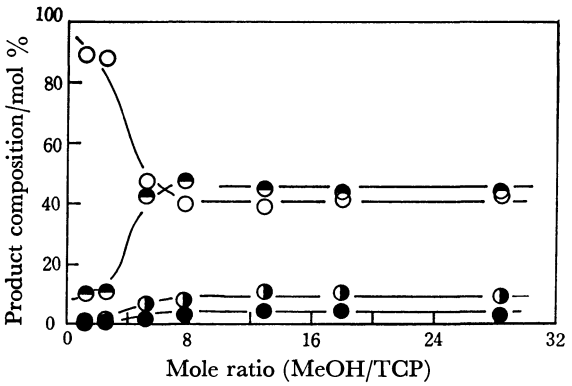

Fig. 1. The effect of the mole ratio on the product composition.
Reaction temperature: 300 °C, W/F=416.3 (g·h/g-mol). ○: TCP, ◓: $CH_2=CClCH_2Cl+CH_2=CCl-CH_2OMe$, ◑: $CHCl=CHCH_2Cl+CHCl=CHCH_2-OMe$, ●: DCM.

With a mole ratio of more than 7.0, the conversion of TCP remained constant, regardless of the mole ratio.

Reaction Temperature. TCP was mixed with methanol at the mole ratio of 1.0 : 12.7. The mixture was fed in over 20 g of activated alumina at a constant temperature with various feed rates. As the reaction temperature increased, the conversion of TCP increased. The effect of the reaction temperature on the conversion of TCP into DCM is shown in Fig. 2. Because of the decomposition of DCM on the alumina surface at higher temperatures, the yield of DCM showed a maximum value at 270 °C. DCM might catalytically dehydrochlorinate to the chloro(methoxy)propenes.

The methoxide anion generated on the basic sites of alumina[7] might play an important role, much as in the copyrolyses of allylic chlorides and chloroethanes with methanol.[1,2,8] However, it has been suggested that a β-chlorine of TCP was abstracted on the acidic sites of alumina, while a carbonium ion was formed and converted into 1,3-DCP (E1). E2 and S_N2 reactions were predominant in the copyrolysis of TCP and methanol on activated alumina, as is shown in Fig. 1. 2,3-DCP and 1,3-DCP were substituted for a chlorine in the allyl position with methanol to form chloro-

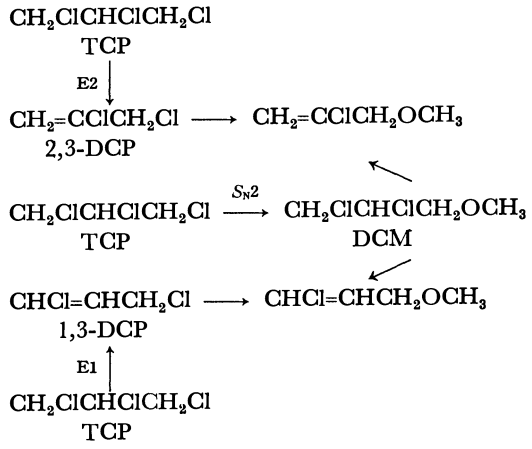
(methoxy)propenes, according to the reaction mechanisms described in a previous paper.[2]

Therefore, the reaction scheme can be given by the following equations:



Experimental

Catalyst. The activated alumina (KHO-24) was obtained from the Sumitomo Chemical Co.; the particle diameter was in the range of 2—4 mm.

Reagents. The methanol was purchased from the Nakarai Chemicals as guaranteed-reagent-grade. TCP of a guaranteed-reagent-grade was obtained from the Tokyo Kasei Co. 2,3-DCP, *cis*- and *trans*-1,3-DCP were purchased from the Tokyo Kasei Co. as extra-pure-grade. These reagents were used without further purification.

Equipment and Procedure. The experiments were conducted a continuous-flow type reactor, the details of which were reported in a previous paper.[8]

Analytical Methods. The IR, NMR, and mass spectra were recorded on a Hitachi 125 spectrophotometer, a JMN-MH 100 spectrometer using TMS as the internal standard, and a Hitachi RMU-6MG spectrometer respectively. Gas-chromatographic analyses were performed on a Shimadzu GC-5A apparatus using a 2 m×3 mm column with 10% PEG 6000 operating at 100 °C with a helium flow.

Syntheses of Authentic Samples. *DCM*: Allyl methyl ether, generated by the action of allyl chloride with sodium hydroxide in methanol, was chlorinated in carbon tetrachloride. The DCM thus obtained was distilled at atmospheric pressure; bp 169.5 °C.

Chloro(methoxy)propenes: Chloro(methoxy)propenes were prepared from 2,3-DCP and 1,3-DCP by modifying the method of Henne and Haeckl.[6]

Identification of Products. The crude solution obtained by the copyrolysis was poured into water. The organic layer was taken up and washed with water, dried ($CaCl_2$), and distilled. Each component of the products was separated by means of VPC. The identification was carried out by a comparison of their IR, NMR, and MS spectra with those of authentic samples. The spectroscopic data are as follows:

2-Chloro-3-methoxypropene. IR (cm^{-1}): 720 (C-Cl), 900 (C=C(H)H), 1110 (C-O-C), 2830 (-OMe), 2940 ($-CH_2-$), NMR (CCl_4) δ (ppm): 3.17 (3H, s) [$-OCH_3$], 3.75 (2H, s, t) [$-CH_2OMe$], 5.09 (H, s, m)[H(Cl)C=C], 5.17 (H, s. m) [H(C=C)CH_2OMe], MS (*m/e*) (%): P+2=108 (2.5), P+1= 107 (5.0), P=106 (6.0), P−1=105 (5.4), 71 (100), 45 (81), 41 (100).

Synopsis. The reduction of various 2-benzylidene-3(2*H*)-benzofuranones with lithium aluminium hydride–aluminium chloride in ether gave the corresponding 2-benzylbenzofurans in moderate yields. The reduction of 6-methoxy-2-(4-methoxybenzoyl)benzofuran also yielded 6-methoxy-2-(4-methoxybenzyl)benzofuran.

Although the syntheses of 2-benzylidene-3(2*H*)-benzofuranones (**1**) (aurones) were investigated in detail,[1] the synthesis of 2-benzylbenzofurans (**2**) which have the same carbon skeleton has not been reported. Our interest in the preparation of new C_6–C_3–C_6 type compounds[2,3] led us to examine the reduction of **1** with lithium aluminium hydride–aluminium chloride. It has often been observed that the reduction of α,β-unsaturated carbonyl compounds with lithium aluminium hydride–aluminium chloride proceeds with a double bond migration.[4-10] Therefore, it could be expected that the reduction of **1** with these reagents gives stable 2-benzylbenzofuran (**2**) rather than 2-benzylidene-2,3-dihydrobenzofuran (**3**) (Fig. 1).

2-Benzylidene-3(2*H*)-benzofuranones (**1a—h**) were prepared from 2′-hydroxychalcones by the procedures reported by Donnelly *et al.*[11] and by one of the authors.[12] When 6-methoxy-2-(4-methoxybenzylidene)-3(2*H*)-benzofuranone (**1d**) was treated with lithium aluminium hydride in ether, followed by the addition of aluminium chloride, a single product was obtained. Its NMR showed the presence of two methoxyl groups [δ=3.72 (3H, s) and δ=3.75 (3H, s)], a methylene group [δ=3.93 (2H, s)], a vinylic proton [δ=6.11 (1H, broad s)], and aromatic protons [δ=6.5—6.9 (4H, m) and δ=6.95—7.3 (3H, m)]. The IR spectrum showed absorptions at 1625, 1615, and 1590 cm^{-1}. The reduction of 6-methoxy-2-(4-methoxybenzoyl)benzofuran[13] (**4**) with lithium aluminium hydride–aluminium chloride yielded identical **2d**. These results indicate that the product is not 6-methoxy-2-(4-methoxybenzylidene)-2,3-dihydrobenzofuran (**3**, R=OCH_3), but 6-methoxy-2-(4-methoxybenzyl)benzofuran (**2d**). The oxidation of **2d** with manganese(IV) oxide gave **4**.

Seven other 2-benzylidene-3(2*H*)-benzofuranones (**1a—c** and **1e—h**) were also subjected to the reduction, which gave the corresponding 2-benzylbenzofurans (**2a—c** and **2e—h**) in moderate yields. The results are shown in Table 1. The reduction of **1b** with lithium aluminium hydride without the addition of aluminium chloride gave an intractable mixture of products. This may be due to the instability of the allylic alcohol formed by the reduction of **1b**. In the reduction of **1a**, 3-(2-hydroxyphenyl)-1-phenyl-1-propene (**5**) was obtained together with 2-benzylbenzofuran (**2a**), which was the major product. There were a number of minor products which could not be purified.

Thus it can be concluded that the reduction of 2-benzylidene-3(2*H*)-benzofuranones (**1**) with lithium aluminium hydride–aluminium chloride can be used for a preparation of 2-benzylbenzofuran derivatives (**2**).

Fig. 1.

Experimental

All the ^1H NMR spectra were recorded for the carbon tetrachloride solution with a Hitachi-Perkin-Elmer R-24 spectrometer, with tetramethylsilane as the internal standard. The IR spectra were taken for the chloroform solution on a JASCO grating spectrometer, while the UV spectra were recorded for the methanol solution, unless otherwise stated, with a Hitachi EPS-3T spectrophotometer. The high-resolution mass spectra were recorded on JMS-OlSG-2 instrument with direct inlet at 75 eV. The melting points were determined with a Yanagimoto micro-melting point apparatus and were not corrected.

2-Benzylidene-3(2H)-benzofuranones (***1a—h***). **1a—e** and **1g** were prepared by the procedure described by Donnelly *et al.*,[11] and **1f** and **1h** were obtained by the oxidation[12] of the

corresponding 2'-hydroxychalcones with manganese(III) acetate.

*Reduction of 2-Benzylidene-3(2H)-benzofuranones (**1a**—**h**) with Lithium Aluminium Hydride–Aluminium Chloride.* The general procedure for the reduction of **1** was as follows. To a stirred solution of lithium aluminium hydride (2 mmol) in anhydrous ether (30 ml), a 2-benzylidene-3(2*H*)-benzofuranone (**1**) (1 mmol) was added and the reaction mixture was stirred at room temperature for the time shown in Table 1. Then aluminium chloride (2 mmol) was added and the mixture was again stirred for the time shown in Table 1. The reaction mixture was passed through a silica gel column, eluting with ether, and the ether was evaporated. The crude product was chromatographed on TLC and crystalline products were recrystallized from ethanol. In the case of **1a**, the reaction mixture was treated with 1 M sulfuric acid (30 ml) and extracted with ether. The ethereal solution was washed with a saturated sodium chloride solution and then evaporated. The resulting liquid was chromatographed on TLC with benzene as the developing solvent.

*2-Benzylbenzofuran (**2a**)*: Colorless liquid (lit,[16] bp_{15} 180—185 °C); IR 1600 and 1618 cm^{-1}; UV λ_{max} (ε) 251 (17000), 280 (4770), and 287 nm (4690); NMR δ=3.97 (2H, s, $-CH_2-$), 6.17 (1H, s, =CH–), and 6.9—7.5 (9H, m, aromatic).

*3-(2-Hydroxyphenyl)-1-phenyl-1-propene (**5**)*: Colorless liquid (lit,[4] mp 67—68 °C); IR 975, 3340, and 3600 cm^{-1}; UV (EtOH)[4] λ_{max} (ε) 254 (18100), 277_{sh} (6260), 284_{sh} (4950), 293_{sh} (2180), and 304 nm (1240); NMR δ=3.58 (2H, m, $-CH_2-$), 5.0 (1H, broad s, OH), 6.32 (2H, m, –CH=CH–), and 6.5—7.4 (9H, m, aromatic). When the methylene group at δ=3.58 was irradiated, the vinyl protons became singlet.

*2-(4-Methoxybenzyl)benzofuran (**2b**)*: MP 60—62 °C; IR 1590 and 1615 cm^{-1}; UV λ_{max} (ε) 253 (17000), 280 (6310), and 287 nm (6170); NMR δ=3.73 (3H, s, OCH_3), 4.00 (2H, s, $-CH_2-$), 6.28 (1H, broad s, =CH–), 6.6—7.4 (8H, m, aromatic) (Found: C, 80.78; H, 5.61%. Calcd for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%).

*2-Benzyl-6-methoxybenzofuran (**2c**)*: Colorless liquid; IR 1580 and 1625 cm^{-1}; UV λ_{max} (ε) 252 (17000) and 292 nm (6780); NMR δ=3.69 (3H, s, OCH_3), 3.97 (2H, s, $-CH_2-$), 6.11 (1H, broad s, =CH–), 6.5—6.85 (2H, m, $H_{(5)}$ and $H_{(7)}$), 7.11 (1H, d, J=8.5 Hz, $H_{(4)}$), and 7.13 (5H, s, Ph); MS *m/e* 238.0989 (100%, M^+) (Calcd for $C_{16}H_{14}O_2$, MW 238.0994), 223 (49%, M^+-15), and 161 (26%, $C_{10}H_9O_2$).

*6-Methoxy-2-(4-methoxybenzyl)benzofuran (**2d**)*: Mp 90—91 °C; UV λ_{max} (ε) 255 (18600) and 291 nm (8320) (Found: C, 76.44; H, 5.81%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%).

*2-(2,4-Dimethoxybenzyl)benzofuran (**2e**)*: Colorless liquid; IR 1585 and 1610 cm^{-1}; UV λ_{max} (ε) 251 (16200), 280 (7550), and 287 nm (7650); NMR δ=3.62 (3H, s, OCH_3), 3.64 (3H, s, OCH_3), 3.90 (2H, s, $-CH_2-$), 6.10 (1H, broad s, =CH–), 6.0—6.4 (2H, m, aromatic), and 6.9—7.4 (5H, m, aromatic); MS *m/e* 268.1144 (100%, M^+) (Calcd for $C_{17}H_{16}O_3$, MW 268.1099) 253 (78%, M^+-15), 237 (62%, M^+-31), and 131 (90%, C_9H_7O).

*2-(2,4-Dimethoxybenzyl)-6-methxybenzofuran (**2f**)*: Colorless liquid; IR 1585 and 1615 cm^{-1}; UV λ_{max} (ε) 253 (19400) and 289 nm (8780); NMR δ=3.69 (3H, s, OCH_3), 3.71 (3H, s, OCH_3), 3.72 (3H, s, OCH_3), 3.90 (2H, s, $-CH_2-$), 6.03 (1H, broad s, =CH–), 6.2—7.3 (6H, m, aromatic); MS *m/e* 298.1161 (43.8%, M^+) (Calcd for $C_{18}H_{18}O_4$, MW 298.1205), 283 (16%, M^+-15), 267 (14%, M^+-31), and 161 (13%, $C_{10}H_9O_2$).

*2-(3,4-Dimethoxybenzyl)-6-methoxybenzofuran (**2g**)*: Mp 63—64 °C; IR 1595 and 1625 cm^{-1}; UV λ_{max} (ε) 253 (20000) and 290 nm (10100); NMR δ=3.68 (9H, s, $3\times OCH_3$), 3.87 (2H, s, $-CH_2-$), 6.09 (1H, broad, s, =CH–), 6.55—7.3 (6H, m, aromatic) (Found: C, 72.41; H, 6.22%. Calcd for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%).

*6-Methoxy-2-(2,3,4-trimethoxybenzyl)benzofuran (**2h**)*: Colorless liquid; IR 1580, 1590, and 1620 cm^{-1}; UV λ_{max} (ε) 253 (17300) and 292 nm (6900); NMR δ=3.71 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.78 (6H, s, $2\times OCH_3$), 3.93 (2H, s, $-CH_2-$), 6.11 (1H, broad s, =CH–), 6.45 (1H, d, J=9.0 Hz, $H_{(5')}$), 6.5—6.9 (3H, m, $H_{(5)}$, $H_{(6')}$, and $H_{(7)}$), and 7.19 (1H, m, $H_{(4)}$); MS *m/e* 328.1316 (100%, M^+) (Calcd for $C_{19}H_{20}O_5$, MW 328.1311), 313 (55%, M^+-15), 297 (25%, M^+-31), and 161 (49%, $C_{10}H_9O_2$).

*Reduction of 6-Methoxy-2-(4-methoxybenzoyl)benzofuran (**4**).* To a stirred solution of lithium aluminium hydride (43.4 mg) in anhydrous ether (20 ml), **4** (140.8 mg) was added at room temperature and the reaction mixture was stirred for 50 min. Aluminium chloride (141.7 mg) was added and the reaction mixture was further stirred for 96 min. After working-up in a manner similar to the above experiments, **2d**, mp 90—91 °C (111 mg, 83%), was obtained.

*Oxidation of 6-Methoxy-2-(4-methoxybenzyl)benzofuran (**2d**).* A mixture of **2d** (134 mg), freshly prepared manganese(IV) oxide (1 g), and anhydrous ether (30 ml) was heated under reflux for 8 h. After manganese (IV) oxide was removed by filtration, the ether was distilled off and the resulting solid was recrystallized from ethanol to give **4** (93.4 mg, 66%), mp 149 °C (lit,[13] mp 149 °C).

The authors wish to thank Professor Hitoshi Takeshita and Assistant Professor Akira Mori of Research Institute of Industrial Science, Kyushu University, for their kind arrangements for the mass spectra measurements.

Palladium Catalyzed Cyanocarbonylation of Organic Iodides

Masato TANAKA

National Chemical Laboratory for Industry, Yatabe, Tsukuba, Ibaraki 305

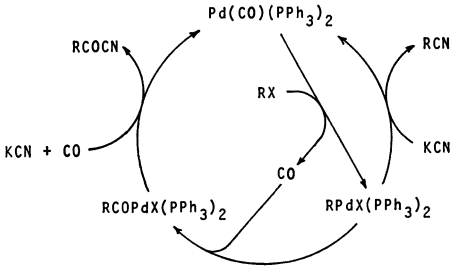
(Received August 14, 1980)

Synopsis. Palladium complex catalyzed carbonylation of aromatic and heteroaromatic iodides in the presence of potassium cyanide gave aroyl cyanides in fair to excellent yields, offering the first example of cyanocarbonylation.

Palladium complex catalyzed carbonylation of organic halides has been successfully performed, but limited to synthesis of carboxylic acids and their derivatives such as esters, aldehydes, and amides.[1] We have recently found that ketones are formed in excellent yield when the reaction was run with organotin compounds.[2] In the catalytic cycle of this reaction, an electrophilic attack of an acyl-palladium intermediate on an organotin compound is postulated. As a continuation of halide carbonylation with carbon nucleophiles, we tried the reaction with potassium cyanide. This paper describes the results of this entirely new carbonylation, namely, cyanocarbonylation of halides.

$$R\text{-}X + CO + KCN \longrightarrow R\text{-}CO\text{-}CN + KX$$

The cyanocarbonylation was effected using a palladium complex, $C_6H_5PdI[P(C_6H_5)_3]_2$, as a catalyst precursor. This complex is believed to be an intermediate in other carbonylation reactions of organic halides by palladium complex catalysts.[3] Aromatic and heteroaromatic iodides were smoothly carbonylated in the presence of potassium cyanide to give aroyl cyanide in fair to excellent yields. Nitriles were generally formed as by-products, but the amount was negligible except the iodothiophene reaction. The catalysis of this reaction was quite sensitive to the ratio of potassium cyanide to the palladium complex. At a much higher ratio than that specified in Table 1 for each halide, the reaction did not work well. This may be connected with poisoning effect of cyanide ion[4] which makes the palladium catalyst inactive. The extent of poisoning seemed to be very dependent on the structure of halides. Thus, the yield of aroyl or acyl cyanide from ethyl *p*-iodobenzoate, *p*-dibromobenzene, *p*-bromoacetophenone, *β*-bromostyrene, and benzyl chloride was some 10% at best or even below under the analogous reaction conditions. This may be because of diminishing catalytic activity due to poisoning which eventually led to the cease of catalysis.[5] Hopefully, the poisoning problem will be solved by a slow addition of potassium cyanide to the reaction system as Cassar and co-workers did for nickel-catalyzed cyanation of aromatic halides.[6]



Scheme 1.

The cyanocarbonylation can be accounted for by the mechanism outlined in scheme 1.[3] Oxidative addition of an iodide to the palladium(0) complex affords an aryl-palladium intermediate which is then transformed into an aroyl-palladium species through CO insertion. Electrophilic attack of potassium cyanide on the aroyl moiety of the latter species would give aroyl cyanide, regenerating the palladium(0) species. Another possibility would be displacement of iodide from the aroyl-palladium-iodide complex by cyanide. The aroyl-palladium-cyanide complex thus formed would undergo reductive elimination to give aroyl cyanide and the palladium(0) catalyst.

In summary, a novel aroyl cyanide synthesis occurs by carbonylation of aryl iodides with potassium cyanide. This paper offers another useful variation of halide carbonylation.

Experimental

Melting points were determined using a Yanagimoto hot-stage apparatus and are uncorrected. PMR and IR spectra were recorded on a Hitachi R-40 and JASCO A-302 spectrometers, respectively. Tetrahydrofuran was dried and purified by the standard techniques. Iodophenylbis(triphenylphosphine)palladium[8] and 2-iodothiophene[9] were prepared by the published methods. Other halides were purchased and purified before use.

Carbonylation of Iodobenzene. General Procedures: A 27 ml stainless steel autoclave was charged with iodophenylbis(triphenylphosphine)palladium (20.9 mg, 2.5×10^{-2} mmol),

Table 1. Cyanocarbonylation of organic halides[a]

RX / mmol	KCN / mmol	Amount of solvent/ml	P_{CO} / atm	Time / h	RCOCN[b] (%)	RCN[b] (%)
C_6H_5I (7.5)	3.75	1.5	20	20	91 (83)	1.4

a) 100 °C, $PhPdI(PPh_3)_2=2.5\times10^{-2}$ mmol, tetrahydrofuran solvent. b) Estimated by GLC analysis using internal standard. Yields for isolated samples are shown in parentheses. c) 2-Thienyl iodide.

dry potassium cyanide powder (245 mg, 3.75 mmol), iodobenzene (0.84 ml, 7.5 mmol), and 1.5 ml of tetrahydrofuran. Carbon monoxide was introduced at 20 atm. The mixture was stirred at 100 °C overnight, diluted with ether, and was filtered. The solvent was evaporated. The residue was subjected to chromatography through a short silica gel column, iodobenzene being first eluted by hexane followed by benzoyl cyanide eluted by benzene, 410 mg, 83.2%. A short-path distillation gave an analytical sample, mp 33.0—34.0 °C. PMR ($CDCl_3$) δ 7.45—8.30 (aromatic). IR (melt) 2220 (ν_{CN}) and 1677 cm^{-1} (ν_{CO}). Found: C, 73.24; H, 3.91%. Calcd for C_8H_5NO: C, 73.27; H, 3.91%.

Melting points, spectral, and analytical data for other aroyl cyanides were as follows.

p-*Methoxybenzoyl Cyanide*: Mp 58.1—59.0 °C. PMR ($CDCl_3$) δ 3.99 (3H, s, CH_3), 7.10 (2H, d, J=9 Hz, meta protons), and 8.16 (2H, d, ortho protons). IR (nujol) 2220 (ν_{CN}) and 1675 cm^{-1} (ν_{CO}). Found: C, 67.06; H, 4.37%. Calcd for $C_9H_7NO_2$: C, 67.08; H, 4.38%.

p-*Methylbenzoyl Cyanide*: Mp 49.5—50.0 °C. PMR ($CDCl_3$) δ 2.53 (3H, s, CH_3), 7.45 (2H, d, J=8 Hz, meta protons), and 8.11 (2H, d, ortho protons). IR (melt) 2225 (ν_{CN}) and 1670 cm^{-1} (ν_{CO}). Found: C, 74.31; H, 4.84%. Calcd for C_9H_7NO: C, 74.47; H, 4.86%.

2-Thenoyl Cyanide: Mp 53.1—54.6 °C. PMR ($CDCl_3$) δ 7.25—7.43 (1H, m, 4-position) and 7.93—8.22 (2H, m, 3- and 5-positions). IR (melt) 2220 (ν_{CN}) and 1648 cm^{-1} (ν_{CO}). Found: C, 52.55; H, 2.31%. Calcd for C_6H_3NOS: C, 52.54; H, 2.20%.

The author is grateful to Dr. Ikuei Ogata for a fruitful discussion.

(Received May 30, 1980)

Synopsis. Two separate equations, one cubic in K and the other quadratic in ε, have been developed for calculating K and ε of molecular complexes independently of each other. The equations on testing with various spectrophotometric data yielded values of K and ε which agree with those obtained by others using well known procedures.

After the important observation of Benesi and Hildebrand[1] and subsequently the interpretation of the phenomenon by Mulliken,[2] several equations[1,3-6] have been derived and tested for the evaluation of equilibrium constants of molecular complexes. The applicability of these equations are, for some obvious reasons,[7] specific. The reported values of K and ε while showing fair constancy among the values obtained by different investigators for strong complexes deviate widely for weak complexes. Various explanations have been suggested[8-19] to account for the observed discrepancies. However, Person[8] has mentioned about some criteria for the reliable determination of equilibrium constant in the case of weak molecular complexes. But this requires a previous knowledge of an approximate value of the equilibrium constant and, due to solubility restriction of the components, it is difficult to fulfil the criteria in all cases. Briegleb[20] and Person[8] indicated that one difficulty in obtaining reliable values of K and ε for weak molecular complexes may be due to the difficulty in the independent determination of K and ε using spectral method, although it is easy to determine the product $K\varepsilon$.

In the present communication we have developed single parameter equations for independent evaluation of K and ε from spectral data, and these equations have been tested for different systems, including strong and weak CT complexes, using the experimental data of various workers from literature.

Principle and Derivation of the Equations

Equation for K Independent of ε. Considering the following equilibrium

$$A + D \rightleftharpoons AD \qquad (1)$$

the equilibrium concentration, C_c, in terms of the equilibrium constant K, is given by

$$C_c = \frac{1+K(C_A^0+C_D^0)-[\{K(C_D^0-C_A^0)\}^2+2K(C_A^0+C_D^0)+1]^{1/2}}{2K} \qquad (2)$$

where C_A^0 and C_D^0 denote the initial concentrations of the acceptor and donor respectively. Substituting $C_c=d/\varepsilon l$ in Eq. 2, we obtain

$$d = \frac{1+Kx-(yK^2+2xK+1)^{1/2}}{2K}\varepsilon l \qquad (3)$$

where $d=d_{obsd}-d_A^0-d_D^0$, $\varepsilon=\varepsilon_C-\varepsilon_A-\varepsilon_D$, l is the optical path length, d's are the optical densities and ε's the molar absorptivities and $x=C_A^0+C_D^0$ and $y=(C_D^0-C_A^0)^2$.

Now, the ratio of the optical densities of the ith and jth solution

$$\frac{d_i}{d_j} = \frac{1+x_iK-(y_iK^2+2x_iK+1)^{1/2}}{1+x_jK-(y_jK^2+2x_jK+1)^{1/2}} \qquad (4)$$

which on rearrangement gives

$$z+(d_ix_j-d_jx_i)K = d_i(y_jK^2+2x_jK+1)^{1/2} - d_j(y_iK^2+2x_iK+1)^{1/2} \qquad (5)$$

where $z=d_i-d_j$. Equation 5, on squaring and rearrangement, yields

$$pK^2+qK+r = r\{(y_jK^2+2x_jK+1)(y_iK^2+2x_iK+1)\}^{1/2} \qquad (6)$$

where

$$p = (d_ix_j-d_jx_i)^2 - d_i^2y_j - d_j^2x_i$$
$$q = 2\{(d_ix_j-d_jx_i)Z - d_i^2x_j - d_j^2x_i\}$$

and

$$r = -2d_id_j = z^2 - d_i^2 - d_j^2.$$

Equation 6 on squaring, rearranging and using the following substitutions

$$a = p^2 - r^2y_iy_j,\ b=2(pq-r^2x_iy_j-r^2y_ix_j),$$
$$g = q^2 + 2pr - r^2y_i - r^2y_j - 4r^2x_ix_j,$$

and $h = 2(qr-r^2x_i-r^2x_j)$,

yields

$$aK^4 + bK^3 + gK^2 + hK = 0$$

or,

$$aK^3 + bK^2 + gK + h = 0 \qquad (7)$$

Since $K \neq 0$

This cubic equation in K is independent of ε. Equation 7 has been solved numerically by a general method of root determination for real polynomials. The Burroughs system program Library subroutine RLPOLY has been employed for this part, which uses a three-stage variable-shift iteration method developed by Jenkins and Traub.[21] Equation 7 is more general than that developed and used by Nagakura[7] in connection with his studies on amine–iodine systems.

Equation for ε Independent of K. Considering a pair, ith and jth of solutions, we get from the equation

$$K/C_c = \frac{1}{(C_A^0-C_C)(C_D^0-C_c)}$$

an equation

$$\frac{d_j}{d_i} = \frac{S_j\varepsilon^2l^2+d_j^2-d_jx_j\varepsilon l}{S_i\varepsilon^2l^2+d_i^2-d_ix_i\varepsilon l} \qquad (8)$$

where $S=C_A^0C_D^0$. Equation 8, after suitable rearrangement and substitution yields

$$m\varepsilon^2l^2 - n\varepsilon l + f = 0 \qquad (9)$$

† An abstract of this work was presented at the 14th European Congress on Molecular Spectroscopy held in Frankfurt in September (3—7), 1979.

*** Present address: Eye Research Institute of Retina Foundation, 20 Staniford St., Boston, MA 02114, U.S.A.

where

$m = d_jS_i - d_iS_j$, $n = d_id_j(x_i - x_j)$, and $f = d_id_j(d_i - d_j)$.

Equation 9 is quadratic in εl and yields

$$\varepsilon = [n \pm (n^2 - 4mf)^{1/2}]/2\,ml \qquad (10)$$

which is independent of K. Only one value of ε is accepted, neglecting the physically inadmissible one.

Results and Discussion

Equations 7 and 10 have been solved by Burroughs 6700 systems using our program for calculating the values of K and ε, independent of one another, of a large number of wide variety of molecular complexes, using the experimental data of different investigators from existing literature. These include the data on strong and weak complexes, wavelength dependence of K and ε and also the effects of solvents. Some representative results are shown in Table 1. The noted differences in many cases may be due to the different approach of the two types of methods. While our procedure evaluates K and ε independent of each other, the reported ones require the separation of K and ε, through the intercept and slope of linear plots, from the product $K\varepsilon$ occurring in the derived equations.

The accuracy of the proposed method like any pairwise evaluation procedure depends on the precision of the experimental data. With precise data our equations yield values of K and ε whose standard deviations lie within 1 to 12%.

Sincere thanks are due to Prof. S. K. Siddhanta, Head of the Department of Chemistry, Burdwan University for constant encouragement received during progress of the work.

Mass Spectral Dehydration and Decarboxylation in Cyclic α-Hydroxy Acids, Alcohols, and Carboxylic Acids

Khalid H. Akkari, Michael S. Matta, and Timothy B. Patrick*
Department of Chemistry, Southern Illinois University, Edwardsville, Illinois 62026, U.S.A.
(Received June 30, 1980)

Synopsis. The relative ease of mass spectral decarboxylation is greater than the ease of mass spectral dehydration as determined from a comparison of the alcohols **1a—4a** with acids **1b—4b**. However, the relative ease is reversed in α-hydroxy acids **2c—4c**; and dehydration predominates over decarboxylation.

The dehydration of alcohols and the decarboxylation of acids are both well known mass spectrometric processes.[1] Alcohol dehydration in the mass spectrometer usually occurs by a 1,4 or 1,3 elimination pathway as opposed to the 1,2 elimination found in solution chemistry. Mass spectrometric decarboxylation of aliphatic acids often occurs by simple α-fragmentation similar to reactions observed in solution. α-Hydroxy acids, although little studied, prefer a fragmentation pathway that favors decarboxylation over dehydration.[2]

A problem of considerable importance is the analysis of hydroxy and carboxy metabolites occurring in natural processes.[3,4] In connection with this problem we have conducted a study designed to determine the preferred mass spectrometric fragmentation pathway, decarboxylation or dehydration, in a series of acyclic and cyclic alcohols, acids, and α-hydroxy acids. The substances studied, shown below, also permit an evaluation of ring size effects on the fragmentation process.

Results and Discussion

The results are summarized in Tables 1 and 2. Dehydration in alcohols **1a—4a** occurs with less facility than does decarboxylation in acids **1b—4b**. Only 2-hydroxytetralin (**3a**) can dehydrate by a favorable 1,3 elimination pathway whereas a 1,2 elimination is required in **1a** and **2a**. Decarboxylation appears as a very favorable process in the cyclic acids

	R_1	R_2

Fig. 1.

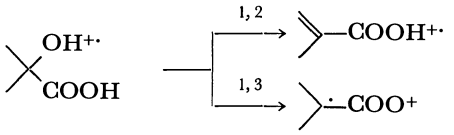
Table 1. Relative ion intensities for the loss of H_2O and COOH in **1a—4c**[a]

Compd	$[M-H_2O]^{+\cdot}$ [b]	$[M-CO_2H]^+$	Base peak[c]
1a	0	—	$[T]^+$
2a	23	—	$[CH_3T]^+$
3a	100	—	$[M-H_2O]^{+\cdot}$
4a	4	—	$[T]^+$
1b	—	67	$[M]^{+\cdot}$
2b	—	100	$[M-COOH]^+$
3b	—	100	$[M-COOH]^+$
4b	—	18	$[T]^+$
2c	68	26	$[M-CO_2H, H_2O]^+$
3c	46	26	$[M-CO_2H, H_2O]^+$
4c	11	0	$[T]^+$

a) Intensities are related to the base peak (100%) in each spectrum. b) $[T]^+$ means tropylium ion. c) M means molecular ion.

1b, **2b**, and **3b**, and is responsible for formation of the base peak in **2b** and **3b**. Decarboxylation can occur by either a thermal reaction or α-fission process. The high abundance of the M—COOH peak is moderately independent of ring size. Both acyclic analogies **4a** and **4b** prefer fragmentation to form the tropylium ion, but the trend of decarboxylation favored over dehydration is still evident in these compounds.

Interestingly fragmentation of α-hydroxy acids **2c—4c** shows that dehydration is preferred over decarboxylation in contrast to the monosubstituted analogues previously discussed. This phenomenon can be explained by using either a 1,2 thermal elimination process which produces a conjugated acid or a 1,3 elimination which produces a saturated carboxy cation radical as shown below.[5]



The base peak in the cyclic hydroxy acids **2c** and **3c** arises through loss of both COOH and H_2O. The acyclic hydroxy acid shows preference for α-fission to form the tropylium ion, similar to the acyclic compounds **4a** and **4b**.

In conclusion, decarboxylation is preferred over dehydration in the monosubstituted compounds, but the trend reverses in α-hydroxy acids with dehydration preferred over decarboxylation. Furthermore, dehydration and decarboxylation occur in the hydroxy acids, perhaps synergystically, to produce the base peak.

TABLE 2. MASS SPECTRA (80 eV) OF COMPOUNDS **1a—4c**[a]

1a	120 (62, $[M]^{+\cdot}$), 119 (88, $[M-H]^{+}$), 106 (4, $[M-CH_2]^{+\cdot}$), 91 (100, [tropylium]$^{+}$), 77 (4, $[M-C_2H_3O]^{+}$), 65 (25), 51 (8), 39 (16).
2a	134 (35, $[M^{+\cdot}]$), 116 (23, $[M-H_2O]^{+\cdot}$), 117 (28, $[M-H_3O]^{+}$), 105 (100, [CH_3−tropylium]$^{+}$), 91 (28, [tropylium]$^{+}$), 79 (39), 77 (40), 65 (19), 63 (25), 51 (40).

3b	176 (1, $[M]^{+\cdot}$), 159 (30, $[M-OH]^{+}$), 148 (18, $[M-CO]^{+\cdot}$), 131 (100, $[M-CO_2H]^{+}$), 104 (10, $[M-CH_2{=}CHCOOH]^{+\cdot}$), 91 (25, [tropylium]$^{+}$), 77 (8).
4b	150 (56, $[M]^{+\cdot}$), 132 (15, $[M-H_2O]^{+\cdot}$), 106 (11, $[M-CO_2]^{+\cdot}$), 105 (18, $[M-COOH]^{+}$), 91 (100, [tropylium]$^{+}$), 77 (15), 65 (10), 51 (14).
2c	178 (7, $[M]^{+\cdot}$), 160 (68, $[M-H_2O]^{+\cdot}$), 134 (22, $[M-CO_2]^{+\cdot}$), 135 (26, $[M-CO_2H]^{+}$), 116 (98, $[M-CO_2, H_2O]^{+\cdot}$), 115 (100, $[M-CO_2H, H_2O]^{+}$), 105 (58, $[M-HOCCO_2]^{+}$), 104 (60, $[M-HOCCOOH]^{+\cdot}$), 91 (13, [tropylium]$^{+}$), 77 (50), 65 (30).
3c	192 (3, $[M]^{+\cdot}$), 174 (46, $[M-H_2O]^{+\cdot}$), 148 (12, $[M-CO_2]^{+\cdot}$), 147 (26, $[M-CO_2H]^{+}$), 129 (100, $[M-H_2O, CO_2H]^{+\cdot}$), 105 (10, $[M-HOCCO_2]^{+}$), 104 (54, $[M-HOCCO_2H]^{+\cdot}$), 77 (12).
4c	166 (12, $[M]^{+\cdot}$), 148 (11, $[M-H_2O]^{+\cdot}$), 91 (100, [tropylium]$^{+}$), 77 (12), 65 (19), 51 (11).

a) *m/e* (relative abundance [probable genesis]). The genesis is based on standard mass spectrometric fragmentations.

Experimental

The compounds used in this study have been previously described.[6,7] Mass spectra were recorded on a low-resolution Varian MAT-111 magnetic sector instrument at 80 eV. All samples were introduced into the ionization chamber by the use of a direct probe at ambient temperature. The mass spectra are reported in Table 2.

This research was supported by the African-American Institute, through the Republic of Sierra Leone, in the form of a fellowship to K.H.A., and by the National Institutes of Health Grant GM 18652 (M.S.M).

The Concentration Dependence of the Apparent Molal Adiabatic Compressibility of Electrolytes in Water

Masao SAKURAI,* Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 8, 1980)

The apparent molal adiabatic compressibilities of NaCl, KCl, NaBr, and KBr in water have been measured in the concentration range from 0.01 to 1 mol kg^{-1} at 5, 25, and 45 °C. The results have been fitted to a Redlich-type equation: $\phi_{Ks}=\phi_{Ks}^{\circ}+S_{Ks}c^{1/2}+B_{Ks}c$. The limiting slope, S_{Ks}, was found experimentally as 5.6×10^{-4} at an ordinary temperature. Convenient equations for the conversion of adiabatic to isothermal compressibilities have been derived; the limiting slope for isothermal compressibility, S_{KT}, should be larger than S_{Ks} at all the temperatures studied. The value of S_{Ks} determined experimentally has been compared with that predicted from the S_{KT} values calculated by Mathieson and Conway, by Millero, and by Bradley and Pitzer.

In earlier papers,[1] we have shown that the effects of polar groups on the hydrophobic hydration play an important role in the volumetric behavior of aqueous organic electrolyte solutions. Compressibility study is of great use in obtaining further information concerning the structural effects. For dilute nonelectrolyte solutions, the limiting partial molal adiabatic compressibility, $\bar{K}_s^{\circ}(=\phi_{Ks}^{\circ})$, can readily be determined from a linear plot of the apparent molal adiabatic compressibility, ϕ_{Ks}, against the molal concentration;[2] on the contrary, the reliable estimation of $\bar{K}_s^{\circ}$ of electrolytes may be difficult for reasons to be described below.

In dilute solutions, the apparent molal quantities of electrolytes are usually fitted to a Redlich-type equation in terms of molarity, c:

$$\phi_X = \phi_X^{\circ} + S_X c^{1/2} + B_X c, \quad (1)$$

where ϕ_X° is the limiting apparent (partial) molal quantity, S_X is the theoretical slope given by the limiting Debye-Hückel law, and B_X is a deviation constant. The values of ϕ_X° and B_X can be determined from a linear plot of $(\phi_X-S_Xc^{1/2})$ against c. For the apparent molal adiabatic compressibility, unfortunately such a linear plot cannot be obtained because the limiting slope, S_{Ks}, has not yet been calculated. Mathieson and Conway[3] measured the ϕ_{Ks} values of various electrolytes in a very low concentration range and represented its concentration dependence by this simple limiting-law equation:

$$\phi_{Ks} = \phi_{Ks}^{\circ} + S_{Ks}m^{1/2}. \quad (2)$$

This extrapolation procedure, however, may be disadvantageous, since Eq. 2 holds only in highly dilute solutions (where the $B_{Ks}c$ term in Eq. 1 should be negligible) and the error in ϕ_{Ks} is progressively increased with a decrease in the concentration.

In our opinion, a more reliable evaluation of ϕ_{Ks}° would be based on Eq. 1; therefore, it is necessary to estimate the limiting slope, S_{Ks}. In a preliminary study,[4] we derived a simple relation for the conversion of the limiting slope for isothermal compressibility, S_{KT}, to S_{Ks} and showed that S_{KT} is larger by about 10% than S_{Ks} at 25 °C. In the present paper, we wish to report on our measurements of the adiabatic compressibility of NaCl, KCl, NaBr, and KBr solutions at 5, 25, and 45 °C and compare the experimental with the theoretical S_{Ks} values in order to obtain a reasonable value of the limiting slope.

Experimental

All the salts used were of a "Merck Ultra Pure" grade and were dried at 50 °C *in vacuo*. All the solutions were prepared in molalities with doubly distilled water.

The ultrasonic velocities, v cm s^{-1}, in solutions were measured at 5, 25, and 45 °C using a "sing-around" velocimeter which is capable of a precision of 1 cm s^{-1}. The details of the apparatus and procedure have been reported elsewhere.[2] The densities, d g ml^{-1}, of the solutions were determined at 5 and 45 °C with a float densimeter described previously.[5,6]

The adiabatic compressibility, β_s bar^{-1}, and the apparent molal adiabatic compressibility, ϕ_{Ks} ml mol^{-1} bar^{-1}, are given by:

$$\beta_s = 10^6/v^2d, \quad (3)$$

$$\phi_{Ks} = 10^3(\beta_s-\beta_{s0})/c + \beta_{s0}\phi_V, \quad (4)$$

where ϕ_V ml mol^{-1} is the apparent molal volume related to the solution density and the solute molecular weight, M_2, by

$$\phi_V = 10^3(d_0-d)/d_0c + M_2/d_0. \quad (5)$$

Here, the subscript zero refers to pure water. The density and sound-velocity data for water were taken from Kell[7] and from Del Grosso and Mader[8] respectively.

Results and Discussion

The sound velocities in aqueous NaCl, KCl, NaBr, and KBr solutions were measured relative to pure water at 5, 25, and 45 °C from 0.01 to 1 mol kg^{-1}. The results are given in Table 1,[9] along with the calculated ϕ_{Ks} values.

In dilute solutions, the concentration dependence of ϕ_V is represented by the Redlich-type equation 1:[10]

$$\phi_V = \phi_V^{\circ} + S_V c^{1/2} + B_V c. \quad (6)$$

The values of ϕ_V° and B_V obtained at 5 and 45 °C are summarized in Table 2, along with the values derived by Desnoyers *et al.*[11] at 25 °C. The ϕ_V° values obtained here were in good agreement with the literature values, and the accuracy of the data was confirmed by the additivity principle.[10] The additivity was within ±0.05 ml mol^{-1} units. On the other hand, the agreement between the B_V values obtained here and the literature values was less satisfactory, especially at 45 °C.

TABLE 2. LIMITING APPARENT MOLAL VOLUMES AND DEVIATION CONSTANTS OF ALKALI HALIDES IN WATER AT 5, 25, AND 45 °C

	ϕ_V°/ml mol^{-1}			B_V/l ml mol^{-2}

a) Ref. 11.

Error in ϕ_{Ks}. The accuracy of ϕ_{Ks} depends on the precision of the determination of the density, the sound velocity, and the concentration. In this study, the apparent molal volume, and hence the density, of each solution used for the sound-velocity measurement were evaluated from Eqs. 5 and 6, where a succesive approximation method was applied to the conversion of the molality to molarity. In view of the accuracies of the ϕ_V° and B_V data mentioned above, it seems that the uncertainty in d or ϕ_V may be small, but it *increases* as the concentration is *increased.*

Now, neglecting the density errors and differentiating Eqs. 3 and 4, the uncertainty in ϕ_{Ks} caused by uncertainties in the sound velocity and concentration, δv and δc, is given by:

$$\delta\phi_{Ks} = \frac{2\times10^3\beta_s}{c}\left(\frac{\delta v}{v}\right) + \frac{10^3(\beta_{s0}-\beta_s)}{c}\left(\frac{\delta c}{c}\right). \quad (7)$$

The absolute error in determining the sound velocity is $\delta v = \pm 1$ cm s^{-1}; hence, the relative error is $(\delta v/v) = \pm 6.6\times10^{-6}$. The uncertainty due to the sound-velocity error rapidly decreases with an increase in the concentration, whereas the uncertainty due to the concentration error is approximately constant. The scatter of ϕ_{Ks} values at higher concentrations observed in Fig. 1 is, therefore, mainly due to the concentration error. We estimated the uncertainty in the concentration determination to be within 0.1%, *i.e.*, $(\delta c/c) = 10^{-3}$. Thus, the total error in ϕ_{Ks} is:

$$\delta\phi_{Ks} = \frac{1}{c}\{1.33\times10^{-2}\beta_s + (\beta_{s0}-\beta_s)\}. \quad (8)$$

Experimental Estimation of S_{Ks}. A typical example of the plot of ϕ_{Ks} against $c^{1/2}$ is shown in Fig. 1, from which it is apparent that the simple limiting-law equation 2 does not hold in the concentration range studied. Alternatively, our ϕ_{Ks} data should be represented by Eq. 1. Thus,

$$\phi_{Ks} = \phi_{Ks}^\circ + S_{Ks}c^{1/2} + B_{Ks}c. \quad (9)$$

Taking into account the large error in ϕ_{Ks} at lower concentrations, the estimation of three parameters was based on the relationship between β_s and c instead of on the ϕ_{Ks} *vs.* $c^{1/2}$ plot. The combination of Eqs. 4, 6, and 9 leads to an expression with this form:

$$10^3(\beta_s-\beta_{s0}) = (\phi_{Ks}^\circ - \beta_{s0}\phi_V^\circ)c + (S_{Ks}-\beta_{s0}S_V)c^{3/2} + (B_{Ks}-\beta_{s0}B_V)c^2. \quad (10)$$

The parameters, ϕ_{Ks}°, S_{Ks}, and B_{Ks}, were calculated by the least-squares method and are given in Table 3. Since S_{Ks} corresponds to the limiting Debye-Hückel slope for adiabatic compressibility, it depends only on the temperature and solvent properties for electrolytes of a fixed valency. As is shown in Table 3, however, we could not obtain a constant S_{Ks} value for four alkali halides; furthermore, we found no simple relationship between S_{Ks} and the temperature. These empirical S_{Ks} values for various salts and temperatures ranged between 4.2×10^{-4} and 6.7×10^{-4}, with the mean value being $(5.6\pm0.7)\times10^{-4}$ ml mol$^{-3/2}$ l$^{1/2}$ bar^{-1}. This mean value is in fair agreement with that

a) The values in parentheses are those calculated by using Eq. 10 over the entire concentration range.

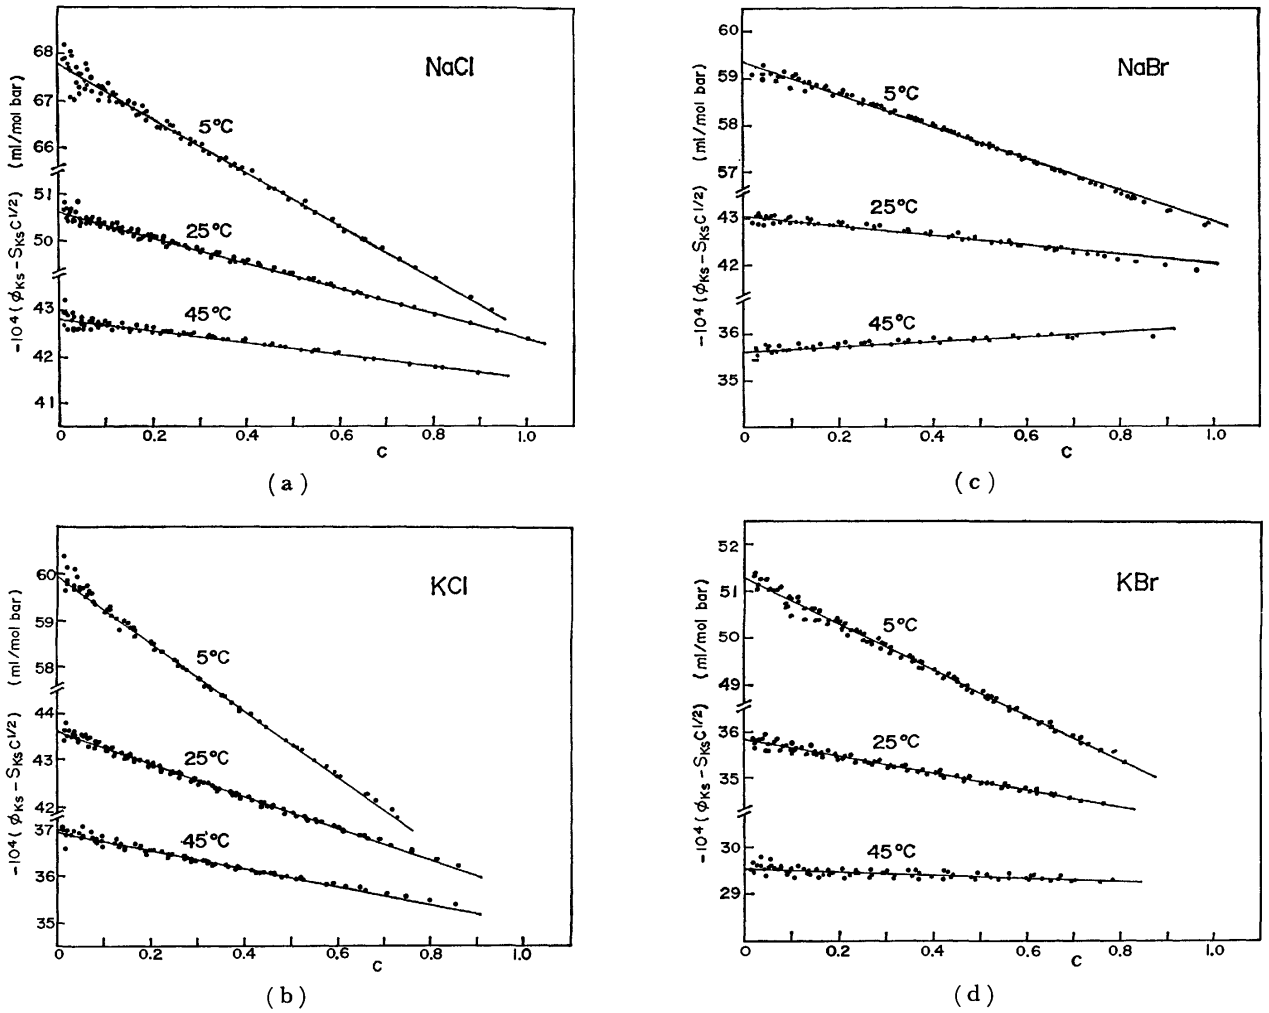

Fig. 2. $\phi_{Ks}-S_{Ks}c^{1/2}$ as a function of c for NaCl, KCl, NaBr, and KBr in water at 5, 25, and 45 °C, where S_{Ks} was taken as 5.6×10^{-4} ml mol$^{-3/2}$ l$^{1/2}$ bar^{-1}.

estimated by Mathieson and Conway[3] using Eq. 2 at very low concentrations for most 1:1 electrolytes at 25 °C.

Gucker and his co-workers[12] studied the concentration dependence of ϕ_{Ks} for some alkali halides at 25 °C. They also calculated the empirical S_{Ks} value by using Eq. 10; their mean S_{Ks} value is $(10.5\pm1.6)\times10^{-4}$, which is considerably higher than that estimated in this study. This disagreement seems to be ascribable to the fact that their work was performed at higher concentrations (up to 2—6 mol kg^{-1}) than those used here. Millero and his coworkers[13] have recently reported on their sound-velocity measurements of 28 electrolyte solutions at 25 °C and fitted the ϕ_{Ks} data to Eq. 9. The S_{Ks} values thus determined ranged between 1.74×10^{-4} and 7.79×10^{-4}. They have regarded S_{Ks} as an adjustable parameter for the purpose of the estimation of the ϕ°_{Ks} values. However, we believe that the S_{Ks} should be the limiting slope, which is independent of the electrolyte species except for the valency.

Figure 2 shows the plot of $(\phi_{Ks}-S_{Ks}c^{1/2})$ *vs.* c, where S_{Ks} was taken as 5.6×10^{-4}, irrespective of the temperature. As may be anticipated from Table 3, good linearities were obtained over the concentration range studied, except for KCl and NaBr solutions at higher concentrations. The values of ϕ°_{Ks} and B_{Ks}, estimated graphically from Fig. 2, are given in Table 4. The ϕ°_{Ks} values at 25 °C agree very well with those obtained from Eq. 2 by Mathieson and Conway.[3] This means that the absolute values of B_{Ks} are small for alkali halides at 25 °C (see Table 4) and that the

accuracy of their ϕ_{Ks} determination is very excellent in spite of the measurements having been done at very low concentrations. The self-consistency of our data can be confirmed by the additivity principle; the differences in ϕ°_{Ks} between chlorides and bromides, or between sodium and potassium salts, show that the ϕ°_{Ks} values are additive to a precision of 0.2 ml mol^{-1} bar^{-1} at all the temperatures studied.

It is evident from Fig. 1 and Table 4 that the deviation constant, B_{Ks}, is increased with a decrease in the temperature and varies with the electrolytes. Particularly large deviations are anticipated for organic salts or polyvalent electrolytes considering that the ϕ_v data show large deviations from the limiting law for these salts.[10] These facts suggest that the extrapolation procedure based on Eq. 2 is, even in a very low concentration range, not convincingly applicable to solutions of any electolyte or at any temperature. Furthermore, as has been described in the previous section, the error in the measurement of ϕ_{Ks} becomes significantly larger as the concentration is decreased. Therefore, despite the limitations in the experimental determination of S_{Ks}, the linear extrapolation method based on Eq. 9, as shown in Fig. 2, appears to be more reliable than that based on Eq. 2 for the evaluation of ϕ°_{Ks}. Based on our linear extrapolation method, we recalculated the ϕ°_{Ks} values of several 1:1 electrolytes from the sound velocity and density data recently reported by Millero and his co-workers.[13] The results are summarized in Table 5, which gives the differences in the ϕ°_{Ks} of the cations (K^+–Na^+) and anions (Br^-–Cl^-). Compared with the results of Millero and his co-workers,[13] given in parentheses, the recalculated ϕ°_{Ks} values agree more closely with our results and the results reported by Mathieson and Conway.[3] Furthermore, it may be pointed out that the accuracy of the recalculated values was checked from the additivity of the ϕ°_{Ks}, except in the case of fluorides: $\phi^\circ_{Ks}(K^+)-\phi^\circ_{Ks}(Na^+)=(7.2\pm0.1)\times10^{-4}$ and $\phi^\circ_{Ks}(Br^-)-\phi^\circ_{Ks}(Cl^-)=(7.7\pm0.1)\times10^{-4}$. These results are in fair agreement with our results (Table 4).

Relation between S_{Ks} and S_{KT}. The difference between ϕ_{Ks} and the apparent molal isothermal compressibility, ϕ_{KT}, is also given by Eq. 1 as a function of the concentration. Thus,

$$\phi_{KT}-\phi_{Ks}=(\phi^\circ_{KT}-\phi^\circ_{Ks})+(S_{KT}-S_{Ks})c^{1/2}+(B_{KT}-B_{Ks})c. \quad (11)$$

The difference, $\phi_{KT}-\phi_{Ks}$, is related to the volume, the expansivity, and the heat capacity by:

$$\phi_{KT}-\phi_{Ks}=10^3(\delta-\delta_0)/c+\delta_0\phi_V, \quad (12)$$

$$\delta=\beta_T-\beta_s=\alpha^2T/10\sigma, \quad (13)$$

where α is the thermal expansivity and σ is the volumetric specific heat.[14] Here, α and σ can be converted to the apparent molal expansibility, ϕ_E, and heat capacity, ϕ_C, using these relations:

$$\phi_E=10^3(\alpha-\alpha_0)/c+\alpha_0\phi_V, \quad (14)$$

$$\phi_C=10^3(\sigma-\sigma_0)/c+\sigma_0\phi_V. \quad (15)$$

The combination of these equations with Eqs. 12 and 13 leads to:

$$\phi_{KT}-\phi_{Ks}=\frac{10^3\delta_0\sigma_0\{10^{-3}(\phi_E-\alpha_0\phi_V)c+\alpha_0\}^2}{\alpha_0^2c\{10^{-3}(\phi_C-\sigma_0\phi_V)c+\sigma_0\}}+\delta_0\left(\phi_V-\frac{10^3}{c}\right). \quad (16)$$

Since, as in the case of ϕ_V, the concentration dependence of ϕ_E or ϕ_C is also given by Eq. 1, Eq. 16 can be expressed in terms of ϕ°_X, S_X, and B_X (X=V, E, and C). Now, expanding this equation with respect to $c^{1/2}$, and neglecting the terms higher than $c^{3/2}$, we may rewrite it in the same form as in Eq. 11. Thus, we obtain the following simple relations:[4]

$$\phi^\circ_{KT}-\phi^\circ_{Ks}=\delta_0(2\phi^\circ_E/\alpha_0-\phi^\circ_C/\sigma_0), \quad (17)$$

$$S_{KT}-S_{Ks}=\delta_0(2S_E/\alpha_0-S_C/\sigma_0), \quad (18)$$

$$B_{KT}-B_{Ks}=\delta_0\{2B_E/\alpha_0-B_C/\sigma_0+10^{-3}(\phi^\circ_E/\alpha_0-\phi^\circ_C/\sigma_0)^2\}. \quad (19)$$

Equation 17 is the same as that derived by Desnoyers and Philip.[15] We note that, for the conversion of ϕ_{Ks} to ϕ_{KT}, Harned and Owen[14] have derived alternative formulas, which can be reduced to much simpler expressions, 17 and 18.

Since the expansivity[7] and heat capactity[16] of pure water are known, and since the limiting slopes, S_E,[17] S_C,[18] and S_{KT},[3,19,20] have been calculated, we can estimate the value of S_{Ks} from Eq. 18. The results at 5, 25, and 45 °C are given in Table 6. Unfortunately, the S_{KT} values reported in the references are inconsistent with one another; nevertheless, the calculated S_{Ks} (even S_{KT}) values are, in any event, smaller than the experimental S_{Ks} value obtained in the previous section. Mathieson and Conway[3] have stated that S_{Ks} appears experimentally to be about twice the isothermal S_{KT} value at 25 °C. The difference ($S_{KT}-S_{Ks}$) in Table 6, however, clearly shows

a) Units: S_E, ml mol$^{-3/2}$ l$^{1/2}$ deg^{-1}; S_C, J mol$^{-3/2}$ l$^{1/2}$ deg^{-1}; S_{KT} and S_{Ks}, ml mol$^{-3/2}$ l$^{1/2}$ bar^{-1}; α_0, deg^{-1}; σ_0, J deg^{-1} cm^{-3}; δ_0, bar^{-1}. b) Ref. 17; c) Ref. 18; d) Ref. 7; e) Ref. 16; f) Ref. 3; g) Ref. 19; h) Ref. 20.

that the isothermal S_{KT} value should be *larger* than the adiabatic S_{Ks} value at all the temperatures studied. It seems to us that the S_{KT} values in Table 6 are too small; this may originate from difficulties in the estimation of the second derivatives of the dielectric constant and the density of water with respect to the pressure *at one atmosphere* used for the calculation of S_{KT}. It appears that a reliable S_{KT} or S_{Ks} value cannot yet be definitely determined theoretically, although S_{KT} values over a wide range of temperatures and pressures have very recently been tabulated by Bradley and Pitzer.[20] Attempts to linearize the plot of $\phi_{Ks}-S_{Ks}c^{1/2}$ against c by using $S_{Ks}=2.65\times10^{-4}$ at 25 °C were unsuccessful, even in a very low concentration range.

In conclusion, it seems to us at present that the concentration dependence of ϕ_{Ks} of the 1:1 electrolytes in dilute aqueous solutions is reasonably represented by Eq. 9, with $S_{Ks}=5.6\times10^{-4}$ ml mol$^{-3/2}$ l$^{1/2}$ bar^{-1} at an ordinary temperature, although there still remains some uncertainty as to the absolute accuracy of the S_{Ks} value.

The authors would like to thank Dr. Hatsuho Uedaira and Mr. Toshio Nakajima for their helpful discussions. The financial support of this work by a Grant-in-Aid for Scientific Research No. 174134 from the Ministry of Education, Science and Culture is gratefully acknowledged.

A Solid-state Electrochemical Study on the Phenothiazine–Iodine and Related Complexes

Toshiyuki MATSUMOTO and Yoshio MATSUNAGA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 30, 1980)

The electromotive force (emf) of a solid-state galvanic cell, Ag|AgI|PT–I_n, where PT–I_n is the phenothiazine–iodine complex, was examined as functions of the composition, n, and also of the temperature. Below n=2.5, a value of 616 mV was obtained at 25 °C. The emf increases stepwise to 620 mV at n=2.5 in conformity with the formation of a complex cation radical pentaiodide, as established by our earlier work. A continuous increase up to 649 mV was found before n=3, indicating the appearance of a nonstoichiometric phase covering the range from n=2.8 to 3. The upper limit of the existence region exactly corresponds with the minimum in the resistivity-composition isotherm. Similar studies with benzo[*a*]- and benzo[*c*]phenothiazines revealed the formation of three or four distinct nonstoichiometric complexes in each system. The Gibbs energy, enthalpy, and entropy of cell reactions and complex formation reactions are presented. The stability of the iodine complexes was found in the following order: benzo[*a*]phenothiazine>benzo[*c*]phenothiazine>phenothiazine.

The phenothiazine–iodine complex (PT–I_n) has been known as a semiconducting material with a relatively low electrical resistivity.[1] The vibrational spectrum of the complex at n=3, where the minimum resistivity is obtainable, has been shown to be distinctly different from that of the parent organic compound but nearly identical with that of the cation radical bromide prepared by the method of Kehrmann and Diserens.[2] Our subsequent studies have distinguished two vibrational patterns for the bromide samples,[3] and established the existence of both the simple and complex bromides.[4] The spectrum of the iodine complex is in accordance with that of the complex bromide where the two thiazine molecules share a unit positive charge and are equivalent in the time scale of infrared spectroscopy. This conclusion is in conflict with the fact that six atoms of iodine per $(phenothiazine)_2^+$ ion do not fit to the composition of any polyiodide. We have also examined the electrical properties as a function of the composition.[5] Such a study has showed that the resistivity-composition isotherm measured with polycrystalline compactions consists of three portions of smooth curves. A sharp edge is located at n= 2.5, the value at room temperature being about 800 Ω cm. At the same composition, a decrease in the activation energy for semiconduction by a factor of a half and a change in the sign of the Seebeck coefficient from negative to positive have been noted. These results clearly indicate the formation of a complex cation radical salt, $(phenothiazine)_2^+I_5^-$, and resolve, at least in part, the above-mentioned conflict. By further addition of iodine, the resistivity reaches a minimum of about 20 Ω cm at n=3 and then increases rapidly. The drastic decrease between n=2.5 and 3 was attributed to the charge carriers generated by the incorporation of extra iodine into the complex cation radical pentaiodide. However, the exact form of the incorporated iodine remains to be clarified.

Undoubtedly the careful examination of the electrical properties as functions of the composition could have served as a powerful tool available for elucidating the constitution of semiconducting phenothiazine–iodine complex. Nevertheless, we are not certain that the observed edge is indicative of the formation of a stoichiometric complex or of the ideal composition of a nonstoichiometric one. As to the resistivity minimum, it may represent the composition of a stoichiometric complex or the limit of the deviation from n=2.5 or some other stoichiometry. Moreover, the formation of other complexes which do not show significant anomalies in the isotherm cannot be ruled out. Consequently, it seemed desirable to examine the other physical quantity which depends on the composition quite differently from the electronic properties studied before. Of particular interest for this purpose are experiments on solid-state galvanic cells, as two-phase mixtures should be identified by constant electromotive force (emf), a stoichiometric complex by a discontinuous increase and a nonstoichiometric single-phase region by a continuous increase in emf with n.

Gutmann *et al.* were the first to explore solid-state galvanic cells using the electronically-conducting iodine complexes as cathodes.[6] The development of similar cells consisting of AgI-based solid electrolyte and the perylene–iodine complex has been described by Louzos *et al.*[7] Furthermore, Pampallona *et al.* have shown that iodine electrodes based on phenothiazine and its *N*-methyl derivative offer excellent prospects as practical cathodes.[8] Aside from such applied research results, attempts to determine the thermodynamic formation values for some solid iodine complexes have been made by measuring the emf of solid-state cells by Aronson *et al.* and also by McKechnie *et al.*[9,10] The complexes studied by the latter group include the phenothiazine–iodine (n=3).

Experimental

Materials. The phenothiazine was commercially obtained and purified by recrystallization and then by sublimation in a vacuum. The benzo[*a*]- and benzo[*c*]phenothiazines were prepared by the reaction of sulfur on *N*-phenyl-1- and -2-naphthylamines respectively, using a small amount of iodine as the catalyst.[11] The former thiazine was purified by recrystallization from ligroine, mp 135—136 °C. The melting point of the latter after recrystallization was found to be 177 °C, in agreement with the value reported by Knoevenagel, 176 °C;[11] however, this value was raised to 185 °C by sublimation in a vacuum. The complexes were obtained by careful grinding of the weighed

thiazine and iodine in an agate mortar in the presence of a small amount of benzene. The samples thus prepared were heated to 80 °C in a short time to complete the reaction and also to remove all traces of the solvent. The iodine contents were determined by microanalysis.

Measurements. The galvanic cell, Ag|AgI|thiazine-iodine complex (T-I_n), was assembled in the following way. A cylindrical block of Teflon with a 1-cm-diameter hole was placed on a piece of platinum plate fixed on a brass block. Silver powder and then silver iodide powder were pressed inside the Teflon cylinder. An 8-mm-diameter compaction of the iodine complex was made and was placed on the flat surface of the silver iodide. The upper surface of the compaction accommodated in the Teflon cylinder was covered with another piece of platinum plate fixed on a 1-cm-diameter brass rod with a rim, which was fitted into the hole of the second cylindrical block of Teflon. The cell placed between the two platinum electrodes was tightened employing three pairs of bolts and nuts applied to the brass block and the second block of Teflon, so that the iodine complex compaction made good contact with the silver iodide layer. Platinum leads provided electrical contact to the electrodes. The whole assembly, with a diameter of 3 cm and a height of less than 4 cm, was placed in a glass tube and dipped into an oil-bath. The temperature was regulated between room temperature and 80 °C with an accuracy better than ±0.25 °C. The emf was measured by means of a high-impedance ($\approx 10^{10}\,\Omega$) universal digital meter, Yokogawa 2502. For the readings of emf, the cell was kept at each temperature for about one hour. The measurements were made only while the temperature was increased and were repeated until steady, reproducible emf data could be attained. The emf was a linear function of the temperature in most of the examined temperature range. When the emf near room temperature deviated from the expected linear relationship, the value at 25 °C was estimated by the extrapolation of the high-temperature data.

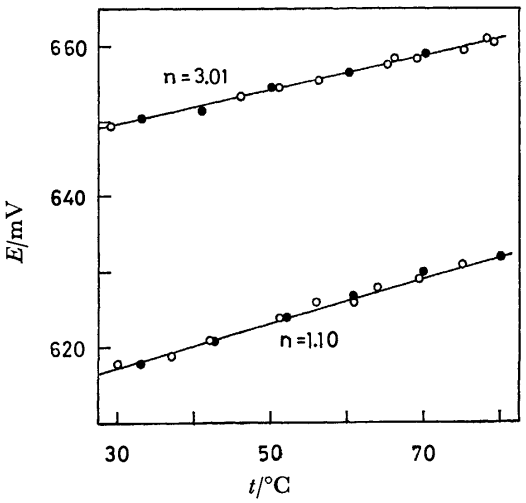

Fig. 1. Electromotive force of the solid-state cells, Ag|AgI|phenothiazine-iodine (PT-I_n).

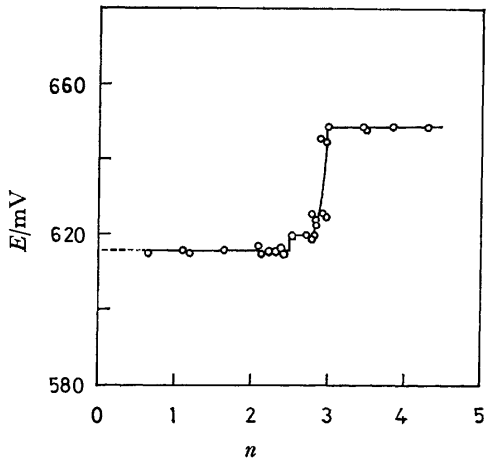

Fig. 2. Electromotive force of the solid-state cell, Ag|AgI|phenothiazine-iodine (PT-I_n) *versus* n at 25 °C.

Results and Discussion

Phenothiazine–Iodine. The emf increases linearly by raising the temperature. For example, the data at $n=1.10$ and 3.01 are presented in Fig. 1. The open and shaded circles indicate the values measured by different runs on the same cell. They are expressed by $E/\mathrm{mV}=616+0.300(t-25)$, and by $E/\mathrm{mV}=649+0.230(t-25)$ respectively.

The compositional variation of the emf at 25 °C is shown in Fig. 2. Below $n=2.5$, the cell maintains an emf of 616 mV. Attempts to obtain steady, reproducible emf with the complexes below $n=0.5$ were unsuccessful, probably because of the high electrical resistivity of the complex.[5] As the vibrational spectrum of a sample at $n=0.65$ clearly shows the coexistence of free phenothiazine, the samples below $n=2.5$ may be mixtures of the parent organic compound and its iodine complex ($n=2.5$). In our previous work, we tried to prepare "monoiodide" by the reaction of hydroiodic acid with an equimolar mixture of phenothiazine and its *S*-oxide and obtained a product which is approximately expressed by PT-$I_{1.35}$.[5] It now seems probable that the "monoiodide" does not exist in this system.

The emf increases stepwise at $n=2.5$, indicating that the complex is stoichiometric. This composition corresponds exactly to the edge appearing in the resistivity-composition isotherm. The two solid phases are involved in the composition range from $n=2.5$ to 2.8. Then, a continuous increase observed between $n=2.8$ and 3.0 implies that the complex is homogeneous over this range. In other words, a nonstoichiometric complex is formed. Although the lower limit of the region of existence was not detected by the resistivity-composition isotherm, the upper limit is in accordance with the composition of a deep minimum. Pampallona *et al.* have reported an emf of 630 mV for the cell Ag, $RbAg_4I_5$|$RbAg_4I_5$|PT-I_3,[8] and also McKechnie *et al.* have obtained 646 mV with the cell, Ag|AgI|PT-I_3.[10] These values are lower than ours at $n=3$; however, small deviations of n from 3 may easily give rise the observed differences. Both the reported values fit into the emf range of the nonstoichiometric complex.

A plateau indicative of a two-phase region appears above $n=3$, giving an emf of 649 mV. As this value is markedly lower than 688.3 mV reported by McKechnie *et al.* for the cell reaction, $\mathrm{Ag(s)}+1/2\mathrm{I_2(s)}\rightarrow \mathrm{AgI(s)}$, another complex with $n>4.3$ must exist in

the present system. We noted before that the vibrational spectrum of phenothiazine mixed with a large amount of iodine is different from that of the complex at $n=3$, but essentially identical with that of the simple cation radical bromide;[5] therefore, the expected complex may be some kind of simple polyiodide. No attempt was made to determine its composition by the present technique, because of the high vapor pressure of iodine and also of the high electrical resistivity.

Since only silver ions migrate in AgI, the emf values observed in the two-phase regions below $n=2.5$ and between $n=2.5$ and 2.8 are determined by the following virtual cell reactions:

$$Ag + 1/2.5\ PT\text{-}I_{2.5} \longrightarrow AgI + 1/2.5\ PT$$

and

$$Ag + 1/0.3\ PT\text{-}I_{2.8} \longrightarrow AgI + 1/0.3\ PT\text{-}I_{2.5}.$$

If the Gibbs energies are calculated in terms of the reactions,

$$2.5\ Ag + PT\text{-}I_{2.5} \longrightarrow 2.5\ AgI + PT \quad (1)$$

and

$$0.3\ Ag + PT\text{-}I_{2.8} \longrightarrow 0.3\ AgI + PT\text{-}I_{2.5}, \quad (2)$$

they are -148.5 and -17.9 kJ mol^{-1} (of the complex). These values represent the area under the emf composition curve between the upper and lower limits of n defined in each cell reaction.[12] Consequently, the Gibbs energy for the cell reaction to which the nonstoichiometric complexes with $n=2.8$ and 3 par-

$$0.2\ Ag + PT\text{-}I_3 \longrightarrow 0.2\ AgI + PT\text{-}I_{2.8} \quad (3)$$

ticipate, may be estimated by a graphic method to be -12.3 kJ mol^{-1} (of the complex). Combining with $\Delta G_f^\circ(AgI) = -66.4$ kJ mol^{-1},[10] the Gibbs energies in terms of the complex formation reactions,

$$PT + 2.5/2\ I_2 \longrightarrow PT\text{-}I_{2.5},$$

$$PT + 2.8/2\ I_2 \longrightarrow PT\text{-}I_{2.8},$$

and

$$PT + 3/2\ I_2 \longrightarrow PT\text{-}I_3$$

are determined to be -17.5, -19.5, and -20.5 kJ mol^{-1} respectively. McKechnie *et al.* have assumed that the reaction occurring in their cell is

$$Ag + 1/3\ PT\text{-}I_3 \longrightarrow AgI + 1/3\ PT,$$

and computed the ΔG value of -62.3 kJ mol^{-1} (of Ag). As the assumed reaction is not correct, their Gibbs energy of the complex formation, -12.3 kJ mol^{-1} (of the complex), is appreciable smaller than ours.

The slope of the emf *versus* the temperature graph shows considerable scatter and differs up to 15% from the mean value; this is shown in Fig. 3. The entropy changes for the cell reactions (1), (2), and (3) are estimated to be 73.5 ± 1.3, 8.8 ± 0.2, and 4.4 ± 0.1 J K^{-1} mol^{-1}. The application of Gibbs-Helmholtz equation yields enthalpies of -126.6 ± 0.4, -15.3 ± 0.04, and -11.0 ± 0.03 kJ mol^{-1} for these cell reactions. With the aid of $\Delta S_f^\circ(AgI) = 13.4\pm0.1$ J K^{-1} mol^{-1},[10] the entropy changes in terms of the complex formation reactions can be computed to be -40.0 ± 1.5, -44.8 ± 1.7, and -46.5 ± 1.8 J K^{-1} mol^{-1}, and

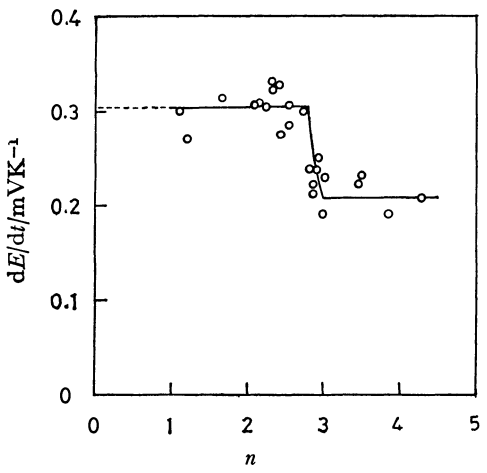

Fig. 3. Temperature coefficient of electromotive force of the solid-state cell, Ag|AgI|phenothiazine-iodine ($PT\text{-}I_n$) versus n.

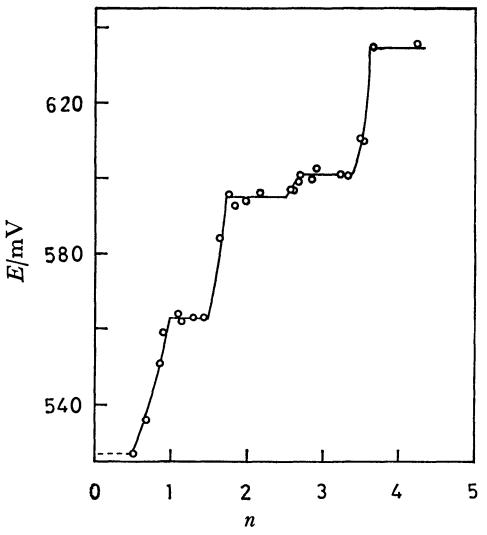

Fig. 4. Electromotive force of the solid-state cell, Ag|AgI|benzo[*a*]phenothiazine-iodine ($B[a]PT\text{-}I_n$) *versus* n at 25 °C.

with $\Delta H_f^\circ(AgI) = -62.4$ kJ mol^{-1}, the enthalpy changes are found to be -29.4 ± 0.5, -32.8 ± 0.5, and -34.3 ± 0.5 kJ mol^{-1}. It must be added that the temperature coefficient of the emf at and above $n=3$ is twice as large as that reported by McKechnie *et al.*, 0.114 mV K^{-1}, for unknown reasons. Since their coefficient is less than that for the cell reaction, Ag(s)+1/2 I_2(s)→AgI(s), the entropy change for the complex formation reported by them is positive and the magnitude is smaller by a factor of one-tenth.

Benzo[a]*phenothiazine–Iodine.* The results presented in Fig. 4 clearly indicate the formation of four distinct complexes, $B[a]PT\text{-}I_n$, in the examined composition range. The interesting feature of this system is the nonstoichiometry in all the phases. The first phase appears at and below $n=1$, the second, between $n=1.5$ and 1.7, the third, between $n=2.5$ and 2.7, and the fourth, between $n=3.4$ and 3.6. The two-phase region appearing between $n=1$ and 1.5 exhibits an emf of 563 mV; the region between

a) One-phase region.

n=1.7 and 2.5, 595 mV; the region between n=2.7 and 3.4, 601 mV; and the region above n=3.6, 635 mV. Earlier, one of the present authors attempted the preparation of "monoiodide" and succeeded in isolating a product whose composition almost agrees with the ideal one.[13] Now it is certain that the monoiodide is formed in this system at the higher extreme of the existence region of a nonstoichiometric complex. On the other hand, the existence of the complex with n=3 studied earlier is not supported by the present work.[14] The resistivity-composition isotherm exhibits a sharp maximum at n=2.5 and broad minima which may be located anywhere near n=2 and 3. The composition at the resistivity maximum is the lower extreme of the third phase, possibly representing the ideal composition. The resistivity minimum located below n=2.5 is now identified as the upper limit of the existence region of the second phase (n=1.7) and that located above n=2.5 must be the lower limit of the existence region of the fourth phase (n=3.4). The complex at the former minimum may be regarded as (B[*a*]PT)$_2$$^+$$I_3^-$ containing an excess of iodine, and the complex at the latter as (B[*a*]PT)$_2$$^+$$I_7^-$ containing an excess of the thiazine.

The Gibbs energies are to be determined for the following eight cell reactions:

$$0.5\,Ag + B[a]PT\text{-}I_{0.5} \longrightarrow 0.5\,AgI + B[a]PT \quad (4)$$

$$0.5\,Ag + B[a]PT\text{-}I \longrightarrow 0.5\,AgI + B[a]PT\text{-}I_{0.5} \quad (5)$$

$$0.5\,Ag + B[a]PT\text{-}I_{1.5} \longrightarrow 0.5\,AgI + B[a]PT\text{-}I \quad (6)$$

$$0.2\,Ag + B[a]PT\text{-}I_{1.7} \longrightarrow 0.2\,AgI + B[a]PT\text{-}I_{1.5} \quad (7)$$

$$0.8\,Ag + B[a]PT\text{-}I_{2.5} \longrightarrow 0.8\,AgI + B[a]PT\text{-}I_{1.7} \quad (8)$$

$$0.2\,Ag + B[a]PT\text{-}I_{2.7} \longrightarrow 0.2\,AgI + B[a]PT\text{-}I_{2.5} \quad (9)$$

$$0.7\,Ag + B[a]PT\text{-}I_{3.4} \longrightarrow 0.7\,AgI + B[a]PT\text{-}I_{2.7} \quad (10)$$

$$0.2\,Ag + B[a]PT\text{-}I_{3.6} \longrightarrow 0.2\,AgI + B[a]PT\text{-}I_{3.4}. \quad (11)$$

We failed to obtain steady reproducible emf values for the cell reaction (4). As none of the known existence regions of the nonstoichiometric complexes is wider than 0.5 in the present system, we tentatively assumed the appearance of a two-phase region below n=0.5 where one of the phases is the parent organic compound. The computed Gibbs energies are summarized in Table 1. The Gibbs energy of complex formation and the value per iodine atom are given in Table 2. The latter value becomes less negative as more iodine is combined with benzo[*a*]phenothiazine. It must be emphasized that the benzo[*a*]phenothiazine complexes are far more stable than the phenothiazine complexes are. For example, the Gibbs energy divided by the number of iodine atoms at n=2.5 is −12.0 kJ mol^{-1} for the former complex, while the corresponding value is −7.0 kJ mol^{-1} for the latter.

As there are so many phases in this system, our data are insufficient to assign a temperature coefficient to each one. The coefficient decreases from about 0.8 mV K^{-1} at n=0.5 to 0.3 mV K^{-1} at n=1, and then maintains roughly the latter value (0.32±0.02 mV K^{-1}) up to n=2.5. Between n=2.7 and 3.4, the cells show a steady value of 0.234±0.005 mV K^{-1}. Because of the lack of data for the cell reaction (4) and also the inaccurate data for the other reactions, the probable errors of ΔH and ΔS values of the complex formation reactions are, much larger than those for the phenothiazine–iodine complexes (see Table 2).

Benzo[c]*phenothiazine–Iodine.* The emf *versus* the composition graph indicates the formation of three nonstoichiometric complexes, B[*c*]PT-I_n, in the studied range (see Fig. 5). The first complex covers the range from n=0.5 to 1, the second, n=2.3 to 2.5, and the third, n=3.0 to 3.5. The emf is 614 mV in the two-phase region between n=1 and 2.3, 616 mV be-

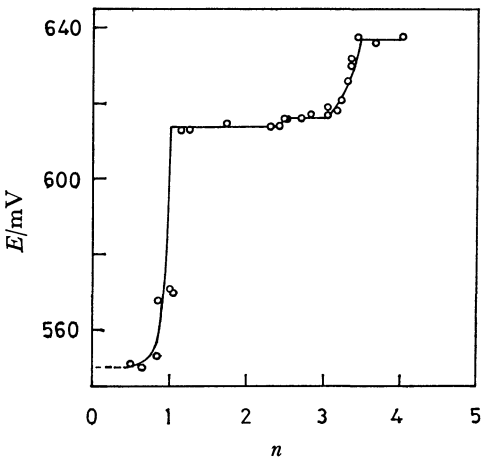

Fig. 5. Electromotive force of the solid-state cell, Ag|AgI|benzo[*c*]phenothiazine-iodine (B[*c*]PT-I_n) *versus* n at 25 °C.

tween n=2.5 and 3.0, and 637 mV above n=3. The "monoiodide" isolated in our previous work does exist in this system at the upper limit of a single phase region. Furthermore, the existence of the complex with n=3 is also firmly established by the emf data. The resistivity-composition isotherm shows an edge at n=2.5 and a broad minimum around n=2. The emf data strongly suggest that the minimum is located at n=2.3. The complex at this composition is the lower limit of a nonstoichiometric complex, the ideal composition of which is $(B[c]PT)_2{}^+I_5{}^-$.

The following six cell reactions are conceivable:

$$0.5\,Ag + B[c]PT\text{-}I_{0.5} \longrightarrow 0.5\,AgI + B[c]PT \quad (12)$$

$$0.5\,Ag + B[c]PT\text{-}I \longrightarrow 0.5\,AgI + B[c]PT\text{-}I_{0.5} \quad (13)$$

$$1.3\,Ag + B[c]PT\text{-}I_{2.3} \longrightarrow 1.3\,AgI + B[c]PT\text{-}I \quad (14)$$

$$0.2\,Ag + B[c]PT\text{-}I_{2.5} \longrightarrow 0.2\,AgI + B[c]PT\text{-}I_{2.3} \quad (15)$$

$$0.5\,Ag + B[c]PT\text{-}I_3 \longrightarrow 0.5\,AgI + B[c]PT\text{-}I_{2.5} \quad (16)$$

$$0.5\,Ag + B[c]PT\text{-}I_{3.5} \longrightarrow 0.5\,AgI + B[c]PT\text{-}I_3. \quad (17)$$

In this system too, we assumed that the samples with $n<0.5$ contain the free parent organic compound. The Gibbs energies computed for the cell reactions and the complex formation reactions are presented in Tables 1 and 2 respectively. The stabilities of these complexes are intermediate between those of the respective benzo[*a*]phenothiazine and phenothiazine complexes, the Gibbs energy divided by the number of iodine atoms at n=2.5 being −9.4 kJ mol^{-1}.

The temperature coefficients of the emf for Eqs. 12—16 are not distinguishable from each other; therefore, the average value of 0.22±0.01 mV K^{-1} was employed in the whole composition range below n=3. Above this limit, the coefficient decreases by a factor of a half by n=3.5. It must be noted that the ΔS values of the complex formation reactions for these three thiazines are so different that the value at n=2.5 in the benzo[*c*]phenothiazine complex is about a half of that in the phenothiazine complex, which in turn is about a half of that in the benzo[*a*]phenothiazine complex. As mentioned above, the ΔG values of the complex formation reactions for benzo[*c*]phenothiazine are considerably larger than those for phenothiazine; nevertheless, the ΔH values for these two thiazines are almost identical. In conclusion, the solid-state electrochemical study on these thiazine–iodine complexes has been able to determine clearly a number of phases which are often nonstoichiometric. We believe that the present technique deserves more attention in the investigation of electronically-conducting iodine complexes.

This work was partly supported by two Grants-in-Aid for Scientific Research Nos. 234028 and 434023 from the Ministry of Education, Science and Culture.

(Received May 30, 1980)

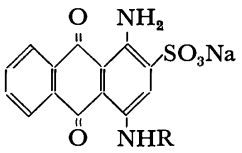
The mean activity coefficients of sodium salts of 1-amino-4-alkylaminoanthraquinone-2-sulfonic acid (alk= Me(MAS), Et, *n*-Pr, or *n*-Bu (*n*-BAS)) in aqueous solutions ranging in concentration from 10^{-3} to 10^{-2} mol kg^{-1} have been determined by means of isopiestic measurements at 50 and 60 °C respectively. It has been found that the mean activity coefficients of these dyes are much smaller than unity, the coefficients of MAS being the largest, and those of *n*-BAS, the smallest. The coefficients have been found to decrease with an increase in the dye concentration. An examination of the results obtained by Milicéivic treatment suggests that the MAS exists as dimer or trimers, and the other dyes, as tetramers, at 60 °C.

In a previous paper,[1] we have reported on the mean activity coefficients of such azo-acid dyes as Methyl Orange and its homologs in aqueous solutions, and on the effects of the hydrophobic groups on the activity coefficients. The derivatives of sodium salts of 1-aminoanthraquinone-2-sulfonic acid also belong to the acid dye class. The behavior of aminoanthraquinone acid dyes in aqueous solutions is known to be different from that of azo-acid dyes; *e.g.*, the aqueous solutions of sodium salts of 1-amino-4-alkylaminoanthraquinone-2-sulfonic acid (alk=Me, Et, *n*-Pr, or *n*-Bu) have been found to have their critical concentration for dimer formation at from 1 to 4×10^{-3} mol kg^{-1}, and the critical concentrations have been found to decrease with an increase in the alkyl groups in the dye molecules.[2] The mean activities of these dyes are supposed to be influenced strongly by dimerization; however, there have been few reports on the mean activities of sodium salts of 1-amino-4-alkylaminoanthraquinone-2-sulfonic acid. Therefore, it would seem valuable to examine the mean activities of these dyes.

In this paper, the mean activity coefficients of sodium salts of 1-amino-4-alkylaminoanthraquinone-2-sulfonic acid (alk=Me, Et, *n*-Pr, or *n*-Bu) in aqueous solutions will be determined by means of isopiestic measurements, and the results will be examined by means of a Milicéivic treatment in order to obtain information on the association of these dyes.

Experimental

Materials. The sodium salts of 1-amino-4-alkylaminoanthraquinone-2-sulfonic acid (AAS) used in this experiment were as follows;



R: CH_3 (MAS)
R: C_2H_5 (EAS)
R: n-C_3H_7 (*n*-PAS)
R: n-C_4H_9 (*n*-BAS)

These dyes were prepared as follows. 1-Amino-4-bromoanthraquinone-2-sulfonic acid (50 g) was refluxed with the corresponding alkylamine (10 g) for 8 h in the presence of copper(II) sulfate and sodium carbonate. The product was isolated by column chromatography on activated alumina, and then purified by recrystallization from ethanol.

Vapor-pressure Osmotic Measurements. The vapor-pressure osmotic measurements were carried out by the procedures described in the previous paper[1] at 50 and 60 °C. The measured resistance difference, ΔR, is dependent upon the osmotic concentration of the dye solution according to Eq. 1:[3]

$$\Delta R\,k = -\ln(p/p_0) = \nu\phi m_2/m_1, \quad (1)$$

where k is the constant[4] dependent on the temperature of the solution and the instrumental characteristics; p and p_0 are the partial pressures of the solvent over the solution and over the solvent; ν is the number of the particles into which the dye dissociates; ϕ is the osmotic coefficients, and m_2 and m_1 are the solute and solvent molalities respectively.

The evaluation of the mean activity coefficients ($\gamma_\pm$) of the dye from the ϕ values can be made by means of Eq. 2:

$$\ln\gamma_\pm = (\phi-1) + \int_0^m (\phi-1)d\ln m_2. \quad (2)$$

The integration can be carried out graphically from the plot of $(1-\phi)\,m_2^{-1}$ *vs.* m_2.

Results and Discussion

Measured Resistance Differences. The measured resistance differences, ΔR, of MAS, EAS, *n*-PAS, and *n*-BAS solutions at 50 and 60 °C are plotted against m_2 in Figs. 1 and 2 respectively. From Figs. 1 and 2, it may be seen that the plots of urea solutions are almost linear, while the plots of the dye solutions display slight downward curvatures. It is noteworthy that the ΔR values of MAS solutions are the largest, while those of *n*-BAS are the smallest. All of the ΔR values of the dye solutions are smaller than twice the ΔR values of urea solutions.

Osmotic Coefficients. The osmotic coefficients, ϕ, of MAS, EAS, *n*-PAS, and *n*-BAS solutions ragning in concentration from 10^{-3} to 10^{-2} mol kg^{-1} were obtained from ΔR values in Figs. 1 and 2 by means of Eq. 1; they are given in Table 1. The ϕ values of all four kinds of dyes may be seen to be much smaller than unity. The ϕ values of the MAS solutions are the largest, while those of the *n*-BAS solutions are the smallest. In Fig. 3, the ϕ values of the MAS and *n*-BAS solutions at 50 °C are plotted against m_2. Since the ϕ values of these dye solutions were found to decrease monotonically with an increase in m_2, no evidence for the presence of Iyer's critical concentrations of the dimerization of these dyes was found. The ϕ values given in Table 1 strongly suggest that the aqueous solutions of the AAS deviate from the ideal.

Determinations of Mean Activity Coefficients. The determinations of the mean activity coeeficients, $\gamma_{\pm}$, was done as follows. The $(1-\phi)m_2^{-1}$ value at 50 °C was plotted against m_2, as shown in Fig. 4. After the plots had been extrapolated to zero concentration, the area under the curve was measured and the $\gamma_{\pm}$ values were calculated according to Eq. 2. The $\gamma_{\pm}$ values of MAS, EAS, *n*-PAS, and *n*-BAS at 50 and 60 °C are shown in Table 2. In Table 2 it can be seen that the $\gamma_{\pm}$ values are much smaller than unity and that they decrease with an increase in the chain length of the alkyl groups in the dye molecules.

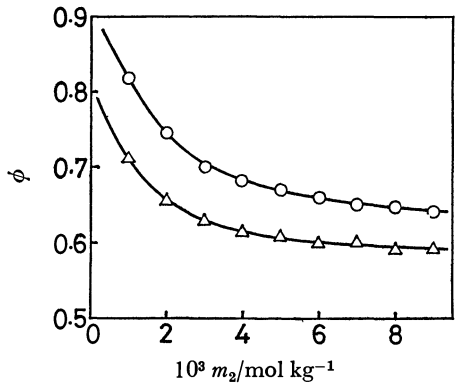

Fig. 3. Osmotic coefficients of solutions of MAS and *n*-BAS at 50 °C.
○: MAS, △: *n*-BAS.

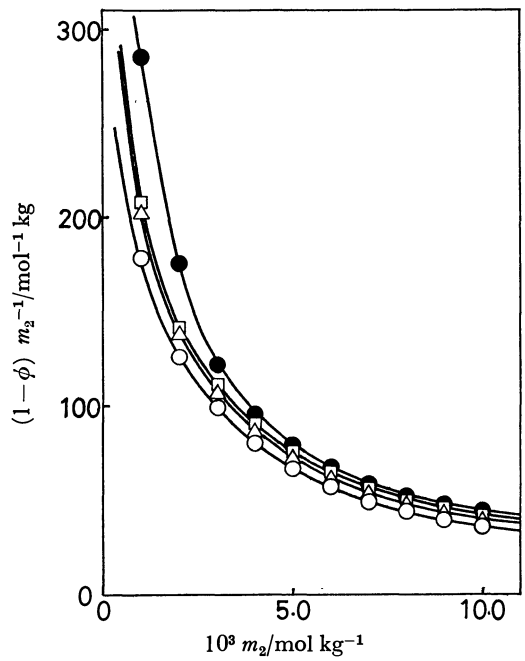

Fig. 4. Plots of $(1-\phi)\ m_2^{-1}$ against m_2.
○: MAS, △: EAS, □: *n*-PAS, ●: *n*-BAS.

Generally, the $\gamma_{\pm}$ values of the AAS dyes seem to be less than those of Methyl Orange and its homologs reported in the previous paper.[1] These $\gamma_{\pm}$ values

strongly suggest that the $\gamma_\pm$ values of the AAS dyes are also dependent on the hydrophobic parts of the dye molecules; *i.e.*, the differences in the $\gamma_\pm$ values among these dyes are due to the association of the dye anions.

Examination of Results Obtained by Milicéivic Treatment. Since these dyes are known to dissociate completely, and since the ionic strengths of these solutions are small, the Debye-Hückel limiting law can also hold.

The relation between the mean activity, $a_\pm$, and the mean association number of the dye anions, n, was given by Milicéivic as:[5]

$$\log a_\pm = \log m_2 - \frac{1}{n+1}\log n - A\,n\,m_2\sqrt{\frac{1+n}{2}}, \qquad (3)$$

where A is the constant and where the numerical values at 50 and 60 °C are 0.5320 and 0.5425 respectively.

The mean activities of MAS, EAS, *n*-PAS, and *n*-BAS at 50 and 60 °C are plotted against $\log m_2$ in Figs. 5 and 6 respectively. The solid lines in Figs. 5 and 6 are Milicéivic lines drawn according to Eq. 3.

In Fig. 5 the plots of MAS, EAS, and *n*-PAS are seen to be close to the trimer (n=3) and tetramer (n=4) curves. The plots of *n*-BAS are close to the pentamer (n=5) curves. The results suggest that MAS, EAS, *n*-PAS dye anions are present as trimers or tetramers, and n-BAS dye anions, as tetramers, on the average usually, at 50 °C. From Fig. 6, MAS dye anions are seen to exist as dimers or trimers, and EAS, *n*-PAS, and *n*-BAS, as tetramers, at 60 °C. These results also suggest that there is no evidence for the presence of Iyer's critical concentration of the dimerization of these dyes. The quantities of the dye association become larger with an increase in the number of alkyl groups in the dye molecules.

(Received July 9, 1980)

The molecular structure of grayanotoxin XVIII $C_{20}H_{28}O_4$, has been determined by means of X-ray crystal analysis. The crystals are monoclinic, with two molecules in a unit cell with dimensions of $a=9.592$, $b=11.414$, $c=8.180$ Å, and $\beta=93.21°$; the space group is $P2_1$. 1484 unique intensity data were collected on a four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The structure was solved by the Monte Carlo direct method, using the 20 strongest reflections as the starting set; the 25th random-phase set led to the correct solution. The R value reached 4.6% by block-diagonal least-squares refinements. The structure thus obtained corresponds to 3-dehydrograyanotoxin VII. The C-ring takes a boat conformation. The force-field calculations suggest that this energy loss is probably compensated for by the stabilization of the B-ring conformation. The crystal consists of hydrogen-bonded molecular layers parallel to the (100) plane.

A number of grayanane diterpenoids have been isolated from *Leucothoe grayana Max.*, *Pieris japonica* D. Don, *Rhododendron japonicum* Suringer, *etc.*, and their structures have been extensively investigated.[1-4] In this paper, we wish to report on the X-ray structure determination and molecular geometry of grayanotoxin (hereafter G) XVIII, a new constituent from *Leucothoe grayana Max.*

Experimental

Isolation of G XVIII. Grayathol A[5] was crystallized and removed from a diethyl ether solution of the unknown-compound-containing fraction (81 mg)[6] obtained from the crude extract of *Leucothoe grayana Max.* The chromatography of the filtrate on silica gel (1 g) afforded G XVIII (15 mg) in a 4×10^{-7}% yield from dried leaves; mp 204—210 °C (recrystallized from methanol), $[\alpha]_D$ −102° (c 1, MeOH); IR (Nujiol) 3400, 1725, 1655, 1628 cm^{-1}; ^{1}H-NMR (C_5D_5N) 1.35, 1.58 (each 3H, s), 1.70 (3H, d, $J=2$ Hz), 3.37 (1H, q, $J_{AX+BX}=6+10$ Hz), 4.70 (1H, s), 5.04, 5.11 (each 1H, s), 5.25 (1H, bs); MS m/e 332 (M^+). Found: C, 72.58; H, 8.98%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49%. The PMR spectrum was recorded on a Hitachi R-20B spectrometer by the use of TMS as the internal reference. The chemical shifts are given on the δ scale (s=singlet, d=doublet, q=quartet, bs=broad singlet). The IR spectrum was obtained on a JASCO Model IR-S spectrophotometer.

X-Ray Measurement. A colorless single crystal with dimensions of about $0.4\times0.5\times0.6$ mm^3 was used. The crystal data are summarized in Table 1. The cell dimensions and reflection intensities were measured on a Rigaku four-circle diffractometer using Ni-filtered Cu $K\alpha$ radiation (40 kV, 60 mA, $\lambda=1.5418$ Å). The θ-2θ continuous-scan technique was applied at a θ scan rate of 8° min^{-1}; the background was measured for 5 s at each end of the scan range. Three standard reflections, measured at intervals of every 60 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 125°, 1484 unique structure-factor magnitudes above the $\sigma(F)$ level were selected for the structure determination.

Table 1. The crystal data

	$b=11.414(1)$ Å
	$c=8.180(1)$ Å
	$\beta=93.21(1)°$
V	894.2 Å^3
Z	2
D_x	1.235 g cm^{-3}
μ(Cu $K\alpha$)	6.43 cm^{-1}

Structure Determination

The structure was solved by the Monte Carlo direct method.[7] The 20 strongest reflections were chosen as the starting set. Tentative phase values for the starting reflections were derived from successively-generated random numbers. In order to extend this tentative phase set, 10 cycles of the tangent procedure were performed using 300 $|E|$ values above 1.30. Since the 25th phase set showed a low R_K value of 26.6% ($R_K=\Sigma||E_o|-k|E_c||/\Sigma|E_o|$), 6 additional cycles of the tangent procedure were carried out using 386 $|E|$ values above 1.20; the R_K value thereupon dropped to 22.2%. An E-map calculated with 375 phases clearly revealed the locations of all the 24 non-hydrogen atoms.

The structure thus obtained was refined by the block-diagonal-matrix least-squares method, first with isotropic and then with anisotropic temperature factors. After all the 28 hydrogen atoms had been located in a difference Fourier map, further least-squares refinement was repeated including these hydrogen atoms with isotropic temperature factors. For this refinement, the following weighting scheme was used:

$$W = 1/\{\sigma(F)^2 \exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients are constants which were determined from the $(\Delta F)^2$ values. The final value of $R=\Sigma|$

Table 2. The final atomic parameters and estimated standard deviations

The coordinates of the non-hydrogen and hydrogen atoms are multiplied by 10^4 and 10^3 respectively.

a) The hydrogen atoms are denoted by the number of the carbon atom to which they are attached, suffixed by a, b, or c where necessary.

$|F_o|-k|F_c||/\Sigma|F_o|$ was 4.6%. The atomic parameters are listed in Table 2. The tables of the anisotropic thermal parameters and of the observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8102).

The calculations were performed on an ACOS 700 computer at the Institute for Protein Research, Osaka University, and on a FACOM 230-75 computer at the Hokkaido University Computing Center. The atomic scattering factors were taken from the International Tables.[8]

Results and Discussion

Molecular Structure. The molecular structure of G XVIII is illustrated in Fig. 1, where each atom is represented as a thermal ellipsoid enclosing a 50% probability. As can be seen in Fig. 1, the molecular framework obtained corresponds to **1**. The bond distances and angles are listed in Table 3; all these

Table 3. The bond distances (l/Å) and angles (ϕ/°), with their standard deviations
The standard deviations given in parentheses refer to the last decimal position.

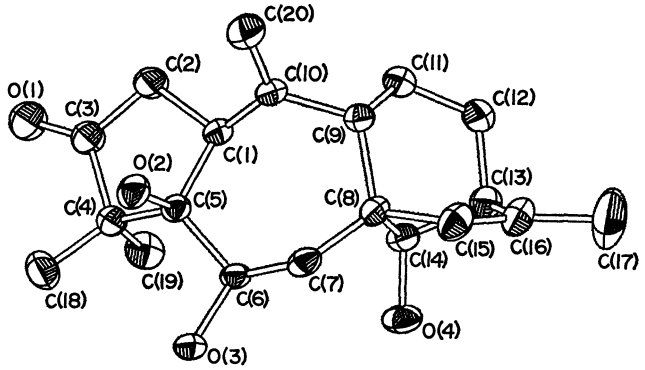

Fig. 1. A perspective view of the G XVIII molecule.

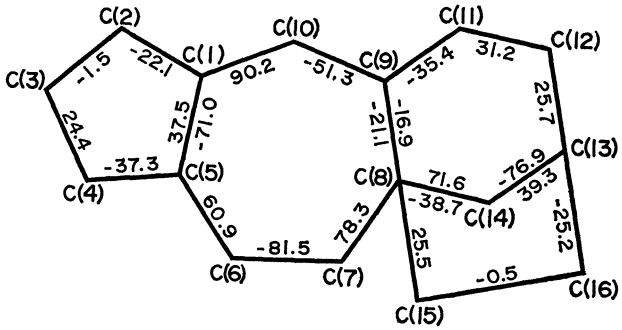

Fig. 2. The torsion angles (ϕ/°) of the A-, B-, C-, and D-rings. Only the torsion angles relevant to atoms which form the same ring are given in the ring.

values are normal. The torsion angles for the tetracyclic system are given in Fig. 2.

The five-membered A-ring takes an envelope form different from those of the A-rings in G II (**2**)[9] and G XVI (**3**):[10] In the former an approximate mirror plane runs through the C(5) atom, while in the latter two it goes through the C(4) atom. The conformation of the latter type is probably unfavorable to the present A-ring, because it makes the O(1) carbonyl oxygen atom almost eclipse the C(18)H_3 methyl group around the C(3)–C(4) bond.

The C(5)–C(4)–C(18) and C(5)–C(4)–C(19) bond angles, 116.1 and 112.2°, are somewhat larger than the C(3)–C(4)–C(18) and C(3)–C(4)–C(19) angles, 111.4 and 106.5°, respectively. This distortion of the C(4)–C(18) and C(4)–C(19) bonds may be caused by the steric repulsions between the C(18)H_3 and O(2)H groups and between the C(19)H_3 and C(6)H groups; C(18)···O(2), 2.780(4) Å; C(19)···C(6), 3.016(5) Å. As is found also in **2** and **3**, these steric repulsions further result in a small lengthening of the C(4)–C(5) bond.

The conformation adopted by the seven-membered B-ring is intermediate between the chair form with the mirror plane through the C(5) atom and the twist-chair form with the two-fold rotation axis through the C(9) atom. In this conformation, the severe 3a-3'a or 2a-3'a repulsion characteristic of the chair and twist-chair cycloheptane rings[11] is much relieved, since the exocyclic methylene group, C(20)H_2, occupies exactly the 3a or 2a position. This suggests that the present B-ring conformation may contain less strain than the twist-chair form in **2** and the twist-chair and chair forms** in **3**. This tentative conclusion is supported by a comparison of the values of

**The G XVI hemihydrate crystal contains two conformers with regard to the B-ring conformation: (a) the twist-chair form and (b) the chair form.

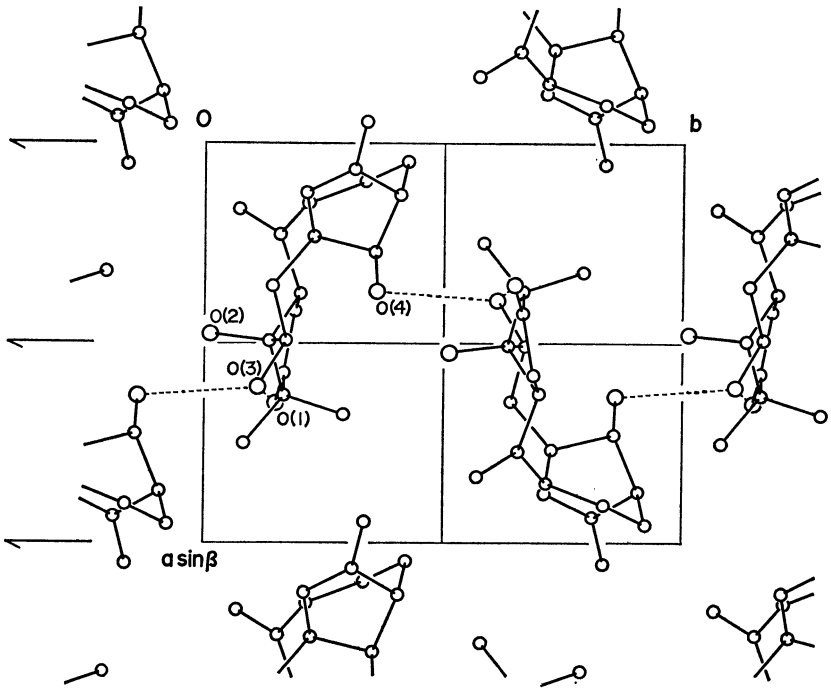

Fig. 3. The crystal structure viewed along the c axis.

$EB=(\theta_i-\theta^0_i)^2$, where the θ_i's ($i=1, 2, \cdots, 7$) are the observed bond angles in the B-ring and where the θ^0_i's are 109.5 and 116.6° for the sp^3 and sp^2 bond angles respectively. The calculated values of *EB* are as follows: G II, 438; G XVI (a), 345; G XVI (b), 288; G XVIII, 166 (°)[2].

The possibility exists that the O(2)H hydroxyl group may form an intramolecular hydrogen bond of the O–H···π type:[12] O(2)···C(10), 2.895(4) Å; H(O2)···C(10), 2.59(5) Å; H(O2)···C(20), 2.78(4) Å. This weak interaction may also contribute to the stability of the present B-ring conformation.

It should be noted that the six-membered C-ring adopts the unstable boat conformation, while it takes the chair conformation in both **2** and **3**. In order to clarify the cause of this boat conformation, we performed force-field calculations for **4**—**7**, using the MMI program.[13] The calculated heats of formation are as follows: **4**, −28.8; **5**, −22.4; **6**, −4.7; **7**, −0.1 kcal/mol. These results show that the transformation of the C(15)–C(16) single bond into the double bond reduces the chair-boat enthalpy difference of the C-ring from 6.4 to 4.6 kcal/mol. Therefore, if one assumes that the present B-ring conformation is more stable than those in **2** and **3** by more than 4.6 kcal/mol and by less than 6.4 kcal/mol, the conformational behavior of the C-ring can be easily understood.

Crystal Structure. The crystal structure viewed along the c axis is shown in Fig. 3. There are two kinds of intermolecular hydrogen bonds, O(3)–H···O(1′) and O(4)–H···O(3″); their O···O distances are 2.937(3) and 2.854(4) Å respectively. Through these hydrogen bonds, the molecules form a molecular layer parallel to the (100) plane. These molecular layers are further held together mainly by the van der Waals interactions.

We wish to thank Dr. Eiji Ōsawa of Hokkaido University for allowing the free use of the MMI program. We are also grateful to Dr. Hiroshi Yoshioka of Kwansei Gakuin University for his valuable discussion of hydrogen bonds.

Electrode Kinetics of Eu(III) Ion in the Presence of 1,4-Benzenedimethanol

Osamu IKEDA,* Katsuhiko TSUURA, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 23, 1980)

In order to know the role of aromatic ring on the electrode kinetics, d. c. polarogram of Eu(III) ion was measured in the presence of 1,4-benzenedimethanol (1,4-BDM). The effect of the adsorption has been discussed by correlating the kinetic data to the adsorption behaviors of 1,4-BDM estimated from the electrocapillary curves. At the standard potential of Eu(III)/Eu(II) (−0.600 V *vs.* SCE), 1.4-BDM on the electrode changed its orientation from horizontal to vertical with an increase in the coverage. Both orientations showed an inhibition effect for the electroreduction of Eu(III) ion. When the coverage due to the horizontal orientation is less than 0.8, the inhibition was interpreted by an additional energy to deform the surface layer. On the other hand, the inhibition at full coverage due to both the horizontal and the vertical orientations was interpreted by the tunneling probability through the adsorbed layer differed in the thickness.

Electroinactive organic compounds adsorbed on the electrode influence the reduction rate of metal cations. It has been proposed that various factors influence the reduction rate, for example blocking effect,[1-6] interaction between the activated complex and the adsorbed ions or molecules,[7] additional energy to bring the discharging ion to the pre-electrode state,[8] electrostatic potential[9] and dipole,[10] and so on. The above factors have been reviewed by Lipkowski and Galus,[11] and Damaskin and Afanas'ev.[12]

Organic compounds adsorbed on the electrode usually inhibit the reduction rate of metal cations. However, Loshkarev *et al.*[13] observed that 1-naphthol inhibited the reduction rate of Bi(III) when its aromatic ring was vertical to the electrode surface, but it did not prevent the electron transfer to the discharging ion when the ring was horizontal. They explained these results on the basis of the idea proposed by Dyatkina and Damaskin[14] that aromatic compounds, adsorbed horizontally on the electrode, extend the metal surface toward the solution. Dutkiewicz and Paucz[15] have also discussed the electrode reaction of Cd(II) ion in the presence of benzenesulfonate ion on the same explanation as Loshkarev *et al.*[13] However, such an effect of aromatic compounds is observed only for the electroreduction of deposition type such as Bi(III)/Bi(0) and Cd(II)/Cd(0). It is of interest to study their effect on the electroreduction of simple charge transfer type, namely Eu(III)/Eu(II).

In this study, 1,4-benzenedimethanol (1,4-BDM) was chosen as the aromatic compound, because it has a good solubility in water and it is a neutral compound which does not form a complex with Eu(III) ion. The initial study was the adsorption behaviors of 1,4-BDM at the mercury/water interface, and then the effect of the adsorption on the electrode kinetics of Eu(III)/Eu(II).

Experimental

All chemicals were analytical grade materials. 1,4-Benzenedimethanol (1,4-BDM) was recrystallized twice from distilled water. Aqueous 1 M $NaClO_4$† prepared from triply distilled water was used as the supporting electrolyte, and was treated with purified active charcoal before use. Mercury was purified by treatment with dilute nitric acid, then distilled triply in a vacuum. Nitrogen gas, after passing through a purification line, was used for deaeration.

Adsorption behaviors of 1,4-BDM were estimated from the analysis of the electrocapillary curves, which were measured with the maximum bubble pressure method.[16,17] Twelve different concentrations of 1,4-BDM solutions were prepared to cover between 0.2 mA and 15 mA. The interfacial tension was measured at 50 mV intervals, except for positive and negative extremes where 25 mV intervals were chosen. The error of the measurement was ±0.1 mN m^{-1} near the electrocapillary maximum, and ±0.3 mN m^{-1} at positive and negative extremes. Most of the parameters essential to adsorption were derived by analyzing the electrocapillary curves with a computer programme. At the analysis, no corrections were taken into consideration for the medium effect on the activity coefficient of the supporting electrolyte,[18,19] and the activity coefficient of the adsorbate.[20]

Differential capacity was measured with a cell and a bridge similar to those described by Hills and Payne.[21] The measurement was carried out at a frequency of 850 Hz with an amplitude of 5 mV, and at 7.0 s after the birth of a mercury drop whose total life was about 12 s in 1.0 M $NaClO_4$.

The capillaries used in the above two measurements were siliconed on the internal wall by passing a vapor of dimethyldichlorosilane for several seconds.

Polarographic measurement, in which an instantaneous current at the end of the drop life was recorded, were carried out with a three-electrode system consisting of a Yanagimoto Voltammetric Analyzer (Model P-1000). The drop time was adjusted to 3.5 s, and the flow rate of mercury was determined by weighing mercury recovered during a given time, and it was 1.781 mg s^{-1} at a mercury height of 60 cm. The concentration of Eu(III) ion was 0.98 mM. Currents were corrected for the residual current which was measured independently. The true standard rate constant was obtained following the method due to Asada *et al.*[22] The apparent heat of activation of the electrode reaction at the standard potential was determined from the dependence of the apparent standard rate constant on temperature.

All the measurements except for the apparent heat of activation were carried out in a water bath thermostated at 25±0.1 °C, and potentials were measured against a saturated calomel electrode (SCE).

Results and Discussion

Electrocapillary and Differential Capacity-potential Curves.

† 1 M = 1 mol dm^{-3}.

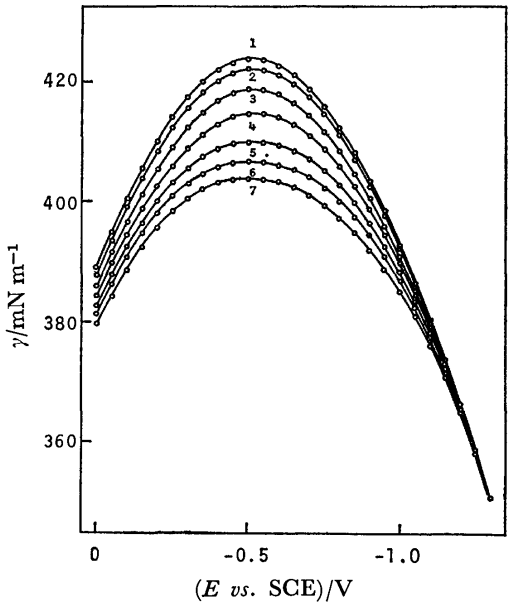

Fig. 1. Electrocapillary curves for aqueous 1.0 M $NaClO_4$ solutions containing 1,4-benzenedimethanol in various concentrations at 25 °C.
The concentrations (mM): (1) 0 (base solution, 1.0 M $NaClO_4$), (2) 0.5, (3) 2.0, (4) 4.0, (5) 7.0, (6) 10.0, and (7) 15.0.

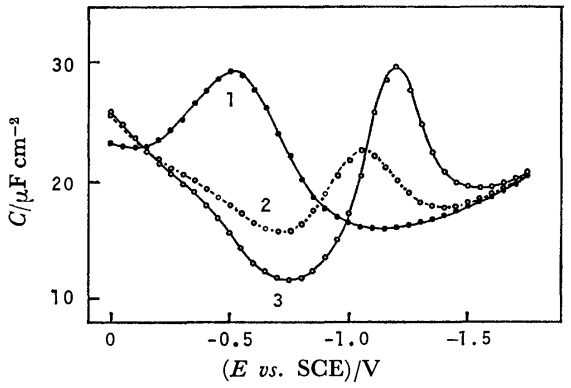

Fig. 2. Typical differential capacity-potential curves of the mercury electrode in aqueous 1.0 M $NaClO_4$ solutions with and without 1,4-benzenedimethanol at 25 °C.
The concentrations of 1,4-benzenedimethanol (mM): 0 (base solution, 1.0 M $NaClO_4$), (2) 3.0, and (3) 15.0.

Figure 1 shows the electrocapillary curves obtained for the 1.0 M $NaClO_4$ containing 1,4-BDM in various concentrations. The drop in the interfacial tension, γ, due to an increase in the concentration is most remarkable at -0.5 V, which approximately corresponds to the electrocapillary maximum, E_{ecm}. This suggests that 1,4-BDM adsorbed on the electrode does not take an orientation with a large dipole moment in the direction normal to the electrode surface.

Figure 2 shows the typical differential capacity-potential curves obtained for the 1.0 M $NaClO_4$ containing 1,4-BDM. The adsorption-desorption peak at more positive potentials was not observed clearly, in contrast to that at more negative potential. This indicates that π-electrons in 1,4-BDM interact with the positive charge on the electrode, as have been

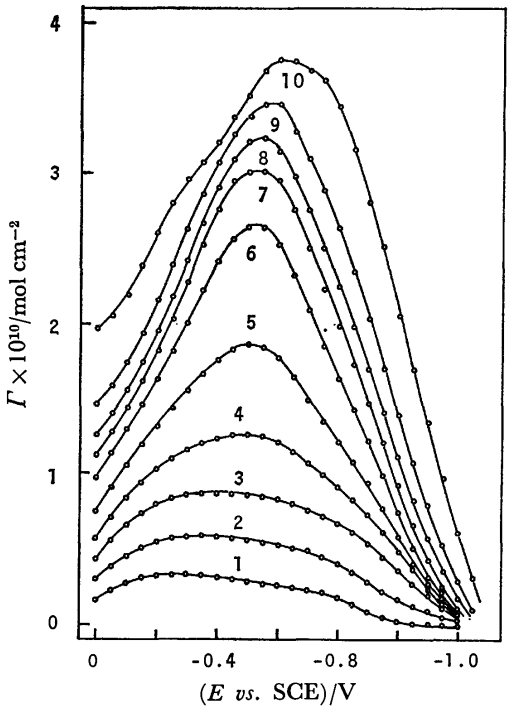

Fig. 3. Surface excess of 1,4-benzenedimethanol as a function of potential.
The concentrations of 1,4-benzenedimethanol (mM): (1) 0.2, (2) 0.5, (3) 1.0, (4) 1.4, (5) 2.0, (6) 3.0, (7) 4.0, (8) 5.0, (9) 7.0, and (10) 15.0.

accounted for in organic compounds with π-electrons.[23–25]

The curve for the base 1.0 M $NaClO_4$ showed a large peak due to specific adsorption of perchlorate anion.[26] However, the peak was diminished with an increase in the concentration of 1,4-BDM, and completely disappeared at more concentrated solutions than 1.0 mM. It was thought that the specific adsorption of perchlorate anion becomes unimportant at higher concentrations of 1,4-BDM.

Adsorption Behaviors. Surface excess, Γ, of 1,4-BDM was obtained using Eq. 1,

$$(\partial\gamma/\partial \ln C_{org})_{E,P,T} = -RT\Gamma, \quad (1)$$

where C_{org} is the concentration of 1,4-BDM, and the others have usual meaning. The surface excess at various concentrations is shown in Fig. 3 as a function of potential. Figure 4 shows a relation between the

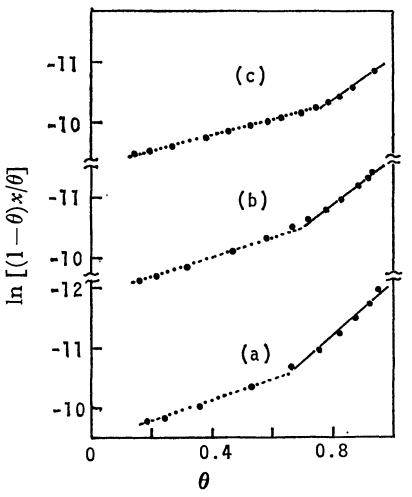

Fig. 5. Test of the Frumkin isotherm at different potentials. Potential and Γ_s used for the estimation of coverage: (a) −0.5 V and 3.5×10^{-10} mol cm^{-2}, (b) −0.6 V and 3.9×10^{-10} mol cm^{-2}, and (c) −0.7 V and 4.0×10^{-10} mol cm^{-2}.

potential and the surface excess at saturation, Γ_s, which are obtained by extrapolating the plots of $1/\Gamma$ *vs.* $1/C_{org}$ at a given potential to $1/C_{org}=0$. The value of Γ_s obtained in this way reflects the orientation at higher surface excess from the nature of the plots. Two limiting values of Γ_s were observed depending on the potential. One was 3.0×10^{-10} mol cm^{-2} and the other was 4.0×10^{-10} mol cm^{-2}. Since the center of the change in Γ_s was −0.5 V which nearly corresponded to E_{ecm}, this change was thought to result from an interaction between π-electrons in the adsorbed 1,4-BDM molecules and the surface charge on the electrode. Then, it was considered that the lower value of Γ_s corresponds to a horizontal orientation and the higher one to a vertical orientation with a smaller projected area.

As the adsorption behavior of 1,4-BDM was expected to be complicated, it was somewhat closely examined by fitting to a Frumkin isotherm with two parameters, Γ_s and the interaction parameter. Equation 2 shows the Frumkin isotherm,

$$\beta x = \theta/(1-\theta)\exp(-2a\theta), \quad (2)$$

where β is the adsorption coefficient being a function of the standard free energy of adsorption, x and θ are the molar fraction and the coverage defined as Γ/Γ_s, respectively, and $2a$ is the interaction parameter whose positive (negative) value means that an attractive (repulsive) force acts among adsorbed molecules. The Frumkin isotherm plot at various potentials is shown in Fig. 5. The value of θ necessary for this plot was evaluated using the value of Γ_s corresponding to each potential in Fig. 4. In this treatment, it is assumed that the orientation of 1,4-BDM around E_{ecm} is intermediate between the horizontal and the vertical orientation, regardless of coverage. However, a linear relation over the whole coverage, which was actually observed for −0.2 and −0.9 V far from E_{ecm}, was not obtained for the potentials around E_{ecm}. A change in the orientation owing to coverage seems to be the cause, because the plots

Table 1. Interaction parameter at various potentials

(Potential *vs.* SCE)/V	−0.4	−0.5	−0.6	−0.7	−0.8
$2a$	1.5	1.9	2.0	1.5	1.0

in Fig. 5 change the slope at higher coverage. It has already been described that aromatic compounds have a tendency to change the orientation with the surface charge on the electrode, namely a horizontal orientation at positive charge owing to attractive interaction with π-electrons and a vertical orientation at negative charge owing to repulsive interaction with π-electrons. Except for this electrostatic effect, at potentials around E_{ecm} where the surface charge density is low, the hydrophobic interaction between the adsorbate and the electrode with a structured water, and the need for an increased packing seem to control the orientation. From this point of view, 1,4-BDM around E_{ecm} was considered to take a horizontal orientation with higher hydrophobicity at lower surface excess and a vertical one with a smaller projected area at higher surface excess. Then, the Frumkin isotherm in Fig. 5 was replotted using $\Gamma_s=3.0\times10^{-10}$ mol cm^{-2} for $\theta\leq0.7$. In this case, the plot showed an inflection at $\theta\simeq0.8$—0.9. The values of $2a$ obtained from the above treatment are summarized in Table 1. They were positive, and it was found that the attractive interaction acts among the adsorbed 1,4-BDM molecules in the horizontal orientation. It was also observed that the interaction parameter changes with potential. Although the cause is not clear, a change in the configuration of the hydroxyl groups due to the electric field seems to be a cause.

There remains a problem how to interpret the intermediate values of Γ_s around E_{ecm}. It can be interpreted in connection with the consideration of the orientation state of 1,4-BDM at higher surface excess. Thus, 1,4-BDM begins to take the vertical orientation, as the coverage evaluated with respect to the horizontal orientation exceeds 0.8—0.9. Then, the electrode surface is thought to be completely covered with 1,4-BDM molecules which consist of the two orientations. The fraction of the vertical orientation in the mixed two orientations increases with an increase in the surface excess, but the maximum fraction which is associated with the value of Γ_s changes with the potential or the surface charge on the electrode. Above consideration seems to be more natural than that of the intermediate orientation corresponding to each Γ_s, and was actually verified in the following discussion with respect to adsorption effect of 1,4-BDM on the electrode kinetics of Eu(III).

Orientation Model. Figure 6 shows the variation of E_{ecm} with the surface excess. E_{ecm} showed a slight cathodic shift with an increase in the surface excess, but at higher surface excess it showed a slight anodic shift oppsitely. This result was thought to be another proof for the change in the orientation due to coverage. When 1,4-BDM is adsorbed without net dipole moment, one can expect a positive shift of E_{ecm} by 30 mV[27] or 70 mV,[28] which has been

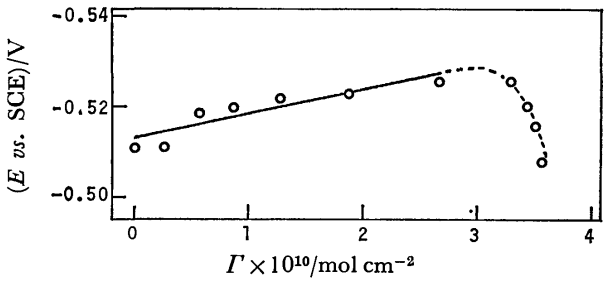

Fig. 6. Variation of the electrocapillary maximum, E_{ecm}, due to adsorption of 1,4-benzenedimethanol.

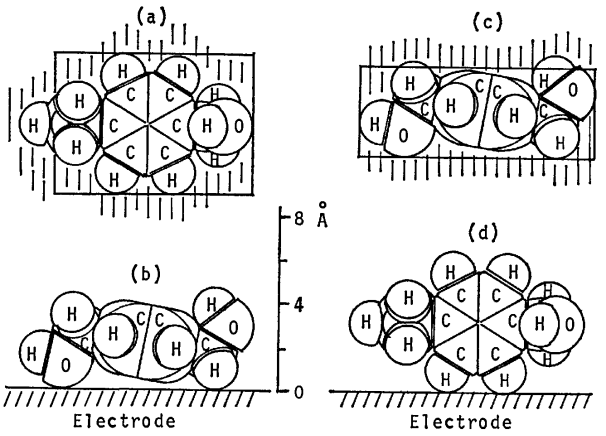

Fig. 7. Scale drawings of a 1,4-benzenedimethanol molecule adsorbed on the electrode through the horizontal orientation (a) and (b), and the vertical orientation (c) and (d). (a) and (c) show the top view, and (b) and (d) the side view. At the determination of the molecular configuration, the CPK precision molecular model was used.

estimated for the potential drop due to water dipoles at E_{ecm}. Therefore, the result in Fig. 6 can be interpreted as follows: the horizontal orientation at lower surface excess has a small dipole moment and at the interface the negative end of the dipole directs to the electrode, but the normal component of this dipole becomes unimportant with the change in the orientation from horizontal to vertical.

On the basis of the above consideration and the two different values of Γ_s, such orientation models as shown in Fig. 7 were considered for the horizontal and the vertical orientations at the potentials around E_{ecm}. The area of the rectangles enclosing the molecule in Figs. 7-a and 7-c are 55.3 Å^2 or 3.0×10^{-10} mol cm^{-2} and 41.5 Å^2 or 4.0×10^{-10} mol cm^{-2}, respectively. Moreover, the height of the molecule estimated from Figs. 7-b and 7-d were about 4.2 Å and 6.3 Å, respectively. When these molecules form a monolayer on the electrode, the difference in the thickness of the layer can be expected to be about 2.1 Å.

Kinetic Data for the Reduction of Eu(III) in the Presence of 1,4-BDM. In order to know the effect of π-electrons in 1,4-BDM on the reduction rate of Eu(III) ion, d.c. polarogram was measured with the aqueous 1.0 M $NaClO_4$ solution containing 0.98 mM Eu(III) ion and 1,4-BDM in various concentrations. Figure 8 shows the polarograms. It is obvious that

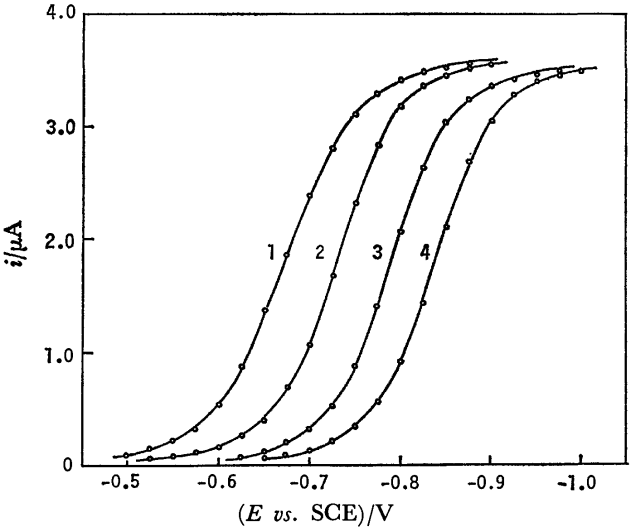

Fig. 8. D.c. polarograms of 0.98 mM Eu(III) ion in aqueous 1.0 M $NaClO_4$ solutions containing 1,4-benzenedimethanol at 25 °C.
The concentrations of 1,4-benzenedimethanol (mM): (1) 0 (base solution, 1.0 M $NaClO_4$), (2) 1.0, (3) 4.0, and (4) 15.0.

the presence of 1,4-BDM in the solution inhibits the reduction of Eu(III) ion.

The true standard rate constant was determined from the analysis of the *i-E* curve at the foot of the wave ($i\leq0.05\ i_d$). Equation 3 represents the current for the reduction of Eu(III) to Eu(II),

$$i_\theta = FAk_s^\theta C^\circ_{Eu(III)}\exp\{(\alpha-z)F\phi_2/RT\}\exp(-\alpha F\eta/RT), \quad (3)$$

where A is the electrode area, $C^\circ_{Eu(III)}$ is the bulk concentration of Eu(III) ion, α is the true transfer coefficient, z is the ionic valence of Eu(III) ion, ϕ_2 is the inner potential at the outer Helmholtz plane which was determined using the Gouy-Chapman theory,[29] η is the overpotential, k_s^θ is the true standard rate constant, and the others have usual meaning. As a first approximation, Eu(III) ion was assumed to take an electron at the outer Helmholtz plane with its hydration shell.[30] Various kinetic data are summarized in Table 2 with the adsorption data of 1,4-BDM at the standard potential of Eu(III)/Eu(II) (−0.600 V *vs.* SCE[31]). For lower surface excess, the coverage θ was evaluated as Γ/Γ_s, where $\Gamma_s=3.0\times10^{-10}$ mol cm^{-2}. However, for surface excess higher than 3.0×10^{-10} mol cm^{-2}, the fraction of the vertical orientation in the mixture which consists of the vertical and the horizontal orientations, θ_V was estimated on the basis of the previous consideration of the full coverage. The diffusion constant of Eu(III), D, was constant throughout the solutions in an experimental error. On the other hand, the apparent heat of activation at the standard potential, ΔH_s^*, was increased with an increase in the coverage, but it came to constant near and at full coverage.

Inhibition Effect at Intermediate Coverage. The rate constant in the presence of organic adsorbates is generally a function of coverage, and it has been expressed in theoretical equations by considering various factors.

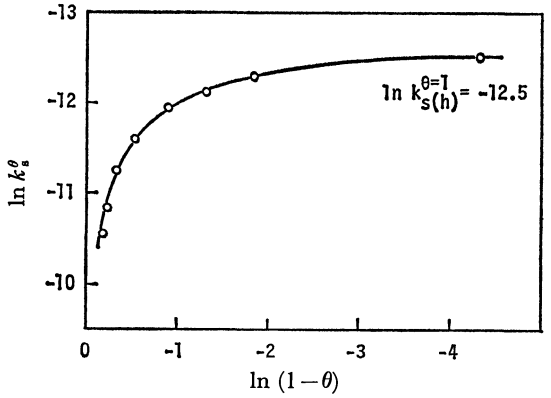

Fig. 9. Plot of $\ln k_s^\theta$ against $\ln(1-\theta)$.

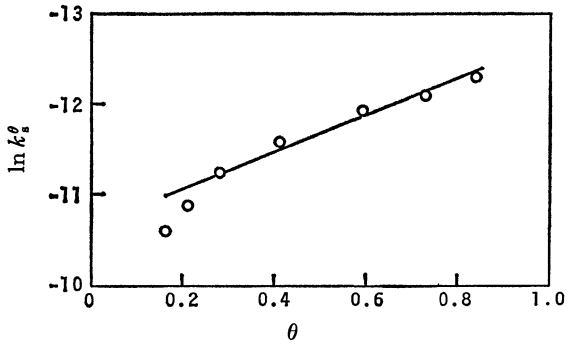

Fig. 10. Plot of $\ln k_s^\theta$ against θ.

The most simple form is the following equation,[1-3]

$$k_s^\theta = k_s^{\theta=0}(1-\theta) + k_s^{\theta=1}, \quad (4)$$

where $k_s^{\theta=0}$ and $k_s^{\theta=1}$ are the standard rate constants at zero and full coverage, respectively. Equation 4 is the sole equation that predicts a linear relation between k_s^θ and θ. When $k_s^{\theta=0} \gg k_s^{\theta=1}$, it changes to Eq. 5,

$$k_s^\theta = k_s^{\theta=0}(1-\theta), \quad (5)$$

which describes a simple blocking effect. However, Lipkowski and Galus[32] have recently pointed out that the interpretation of Eq. 5 is different depending on the thermodynamics of the interface.

Figure 9 shows the plot of $\ln k_s^\theta$ against $\ln(1-\theta)$. In contrast to the prediction of Eq. 5, this plot showed a curvature. Further the plot based on Eq. 4 also showed a curvature, thus it was concluded that the electroreduction of Eu(III) ion in the presence of 1,4-BDM could not be described by Eqs. 4 and 5.

Afanas'ev and Ternovskoi[8] have presented the next equation which is one of the equations predicting a non-linear relation between k_s^θ and θ,

$$k_s^\theta = k_s^{\theta=0}\exp(-2ar\theta), \quad (6)$$

where $2a$ is the interaction parameter of the Frumkin isotherm for adsorbate in the absence of discharging ion, r is a coefficient taking into consideration the decrease in the attractive interaction between the adsorbed molecules when the discharging ion is transferred into the adsorbed layer. This equation is based on the consideration that the concentration of the discharging ion in the surface layer is determined by the additional energy ($2ar\theta RT$) required to transfer the discharging ions from the bulk of the solution into the structured surface layer consisting of water and the adsorbed molecules.

Figure 10 shows the plot based on Eq. 6 in the region of $\theta \leq 0.8$. A linear relation was observed in the region of $0.2 \leq \theta \leq 0.8$. The deviation of the plot from the linear relation in $\theta < 0.2$ seems to result from a specific adsorption of perchlorate anion which acts as an accelerator. The slope was 2.0 and it agreed well with the value of $2ar$ at $r=1$, 2.0 which was estimated from the fit to the Frumkin isotherm.

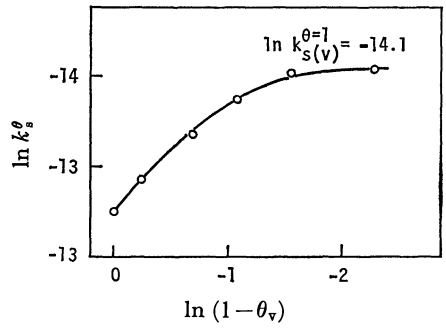

Fig. 11. Plot of $\ln k_s^\theta$ against $\ln(1-\theta_v)$.

It was pointed out in Ref. 8 that Eq. 6 is set up when the transfer of the discharging ion into the surface layer is reversible, while the electrode reaction rate is limited by the electron transfer step. Such a surface layer also does not influence the diffusion limiting current.[32] The constancy of D in Table 2 satisfies the requirement. Further, the increase in ΔH_s^* due to adsorption of 1,4-BDM is thought to support the above inhibition effect, although the change is somewhat larger than that expected from the additional energy.

Inhibition Effect at Full Coverage. Figure 11 shows the plot of $\ln k_s^\theta$ against $\ln(1-\theta_v)$. The standard rate constant was diminished with an increase in θ_v, and showed a limiting value of -14.1. A similar limiting value of -12.5 has also been observed in Fig. 9. Taking into consideration the adsorption behavior of 1,4-BDM, the former can be assigned to the rate constant relating to the vertical orientation $\ln k_{s(v)}^{\theta=1}$, indeed the vertical orientation at this time is not so perfect as in $E \leq -0.7$ V, and the latter to that relating to the horizontal one $\ln k_{s(h)}^{\theta=1}$. The difference between above two values was 1.6, and the inhibition effect due to the vertical orientation was larger than that due to the horizontal one.

It is also considerable for this result that the deformation of the structured surface layer is a factor for the inhibition of the electroreduction of Eu(III) ion at full coverage.

However, the process that Eu(III) ion penetrates into the adsorbed monolayer by surmounting only the deformation energy seems to be improbable at full coverage, because the penetration at full coverage needs another additional energy due to the displacement of 1,4-BDM adsorbed on the electrode, which is larger than the deformation energy and nearly the same as the adsorption energy, about 23 kJ mol^{-1}. As can be seen from Table 2, the values of ΔH_s^* near and at full coverage were approximately constant, regardless of the structure of the adsorbed monolayer. This result can not be explained by the penetration process based on the deformation or the displacement. As the another factor for the inhibition effect at full coverage, the electron tunneling process through the adsorbed monolayer was considered. This process explains the constancy of ΔH_s^*. Thus, the reactant which accepts an electron at the tunneling transition is not Eu(III) ion at the ground state, but the ion at the activated state. Eu(III) ion is thought to be

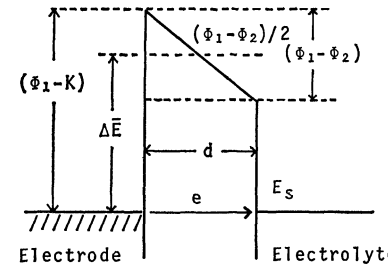

Fig. 12. Idealized rectangular barrier model for the electron tunneling from the mercury electrode to Eu(III) ion through the adsorbed 1,4-benzenedimethanol monolayer. Here, Φ_1 and Φ_2 are the electronic energy of the electrode and the electrolyte, respectively, K and $\Delta\bar{E}$ are the electron affinity of the monolayer and the mean height of the barrier, respectively, E_s is the standard potential of Eu(III)/Eu(II) in the absolute potential scale, and d is the thickness of the monolayer.

activated through the thermal and the electrostatic interactions of the ion with the sorrounding water molecules, the so-called solvent rearrangement,[33] and the energy necessary for such an activation can be expected to be independent of the surface layer structure, if a specific interaction between the reactant and the adsorbed molecules is not present.

Furthermore, appearance of the limiting value of $\ln k_s^\theta$ as shown in Fig. 9 has been attributed to a possibility of the electron tunneling through the adsorbed organic layer.[34] Therefore, such a possibility was examined using the theory of elastic tunneling. Application of such a tunneling theory to the electrode kinetics has been carried out by Gurney[35] and Gerisher,[36] and has been verified by the experiment at the oxide covered electrodes.[37-40] The electron tunneling through organic monolayer between metals has also been verified with respect to various fatty acid salts.[41,42]

If the current at the electroreduction of Eu(III) ion is governed by the electron tunneling through the adsorbed organic monolayer, it is represented by Eq. 7,

$$i_{\theta=1} = e_0 \int_{-\infty}^{+\infty} \upsilon(E) N_b(E) D_{ox}(E) dE, \quad (7)$$

where e_0 is the charge of an electron, $N_b(E)$ and $D_{ox}(E)$ are the density of occupied electron states in the electrode and that of unoccupied states in the electrolyte, respectively, and $\upsilon(E)$ is the electronic frequency factor involving the tunneling probability. This tunneling probability is a function of the thickness of the adsorbed layer, d, and the mean height of the potential barrier, $\Delta\bar{E}$. On the basis of the idealized rectangular barrier model shown in Fig. 12, $\upsilon(E)$ is represented by the following equation,

$$\upsilon(E) \propto \exp\{-(4\pi d/h)\sqrt{2m_e\Delta\bar{E}}\}, \quad (8)$$

where h and m_e are Planck's constant and the mass of an electron, respectively. The frequency factor can be assumed to be independent of the energy, E. Further, assuming that $\Delta\bar{E}$ does not change with the

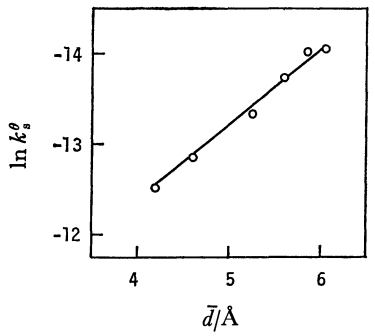

Fig. 13. Plot of $\ln k_s^\theta$ against $\bar{d}$.

orientation of 1,4-BDM, one obtains the next relation for the ratio of the true standard rate constant at full coverage with the horizontal and the vertical orientations,

$$\ln\{k_{s(v)}^{\theta=1}/k_{s(h)}^{\theta=1}\} = -(4\pi\Delta d/h)\sqrt{2m_e\Delta\bar{E}}, \quad (9)$$

where Δd is the difference in the thickness of the adsorbed organic layer. The possibility of the electron tunneling process can be proved by using Eq. 9.

In general, $\Delta\bar{E}=(\Phi_1+\Phi_2)/2-K$, where Φ_1 and Φ_2 are the electronic energy of the mercury used as the electrode and of the electrolyte, respectively, and K is the electron affinity of the adsorbed organic monolayer. One can use the work function of mercury and the standard potential of Eu(III)/Eu(II) in the absolute potential scale as Φ_1 and Φ_2, respectively. One obtains 4.5 eV[43] for Φ_1, and 4.1 eV for Φ_2 using the value of 4.43 V[44] as the absolute potential of the standard hydrogen electrode. Further, K is defined as (I_p-E_g), where I_p and E_g are the ionization potential and the band gap of the adsorbed 1,4-BDM monolayer, respectively. These values must be actually for the monolayer, but those for the molecule were used. The value of E_g was evaluated from the ultraviolet spectrum measured in the 1.0 M $NaClO_4$ solution dissolved 1,4-BDM, and it was 5.69 eV for $\lambda_{max}=218$ nm. Since the value of I_p was not found in the literature, instead, that of benzenemethanol 9.14 eV[45] was used.

Finally, one obtains 1.7 Å for Δd by introducing $\ln\{k_{s(v)}^{\theta=1}/k_{s(h)}^{\theta=1}\}=-1.6$ and the others into Eq. 9. Taking into consideration the imperfection of the adsorbed monolayer and rough approximations used, this calculated value of 1.7 Å seems to agree well with 1.9 Å, which was estimated by applying the arithmetic mean to Γ_s of 3.9×10^{-10} mol cm^{-2} at -0.600 V on the basis of the consideration of the mixed orientation and the orientation model in Fig. 7.

Figure 13 shows the plot of $\ln k_s^\theta$ against the arithmetic mean thickness of the adsorbed layer saturated with the two orientations, $\bar{d}$. A linear relation observed in this Figure is considered to support the previous consideration of the full coverage at higher surface excess, and also the electron tunneling process through the adsorbed organic monolayer.

Concluding Remarks. In the results and the discussions so far mentioned, it was clarified that the horizontal orientation of the benzene ring inhibited the electroreduction rate of Eu(III) ion, which is known as the reaction of simple charge transfer type. This result was distinct from that obtained by Loshkarev *et al.*[13] with respect to the reaction of deposition type. In considering that Eu(III) ion takes an electron with its hydration shell, the reduction intermediates of Bi(III) and Cd(II), which seem to be partially dehydrated, may have such an interaction with π-electrons that does not lead to the inhibition of charge transfer rate. However, the idea[14] that aromatic compounds adsorbed horizontally extend the electrode surface toward the solution side through the aromatic rings was not applicable to the system in this study.

On Behaviors of a New Chemical Reaction Model Showing Hard Oscillations

Kazutoshi IWAMOTO and Manabu SENŌ*

Institute of Industrial Science, The University of Tokyo, 7-22, Roppongi, Minato-ku, Tokyo 106

(Received August 1, 1980)

The behavior of a new chemical reaction model was studied and the existence of hard oscillations was confirmed. This chemical reaction model is useful because it is easy to apply to investigations of the behavior of a chemically oscillating system surrounded by membranes or in a well-stirred continuous flow reactor. The latter was discussed relating to the chaotic oscillations due to the Belousov-Zhabotinskii reaction in a well-stirred continuous flow reactor reported by Schmitz *et al.*

Until now many papers about behaviors of chemical systems far from equilibrium states have been presented.[1-20] A system far from an equilibrium state occasionally shows a characteristic phenomenon like chemical oscillations.[1-6] The representative exemplified phenomenon is observed on the Belousov-Zhabotinskii reaction.[1] This chemical system has been investigated by many investigators and especially Noyes *et al.* of Oregon University studied in detail[11] and proposed a well-known chemical reaction model called "Oregonator."[4] The fundamental theory of nonequilibrium thermodynamics has been developed mainly by Prigogine and his school.[2] According to them, the steady state of the system far from an equilibrium state is not always stable and transits to formation of a new type of structures when the system changes beyond a critical point of instability. These structures, which are occasionally heterogeneous and oscillatory states, are called the dissipative structures. It is quite remarkable that some of the most spectacular aspect of biological activities, such as control of cellular division, cellular differentiation and morphogenesis, can be modeled in terms of dissipative structures.[2,12]

We have studied a model chemical system having multiple steady states in order to investigate the chemically oscillatory phenomena,[13] and these studies were applied to the problem of absolutely asymmetric synthesis.[14] In this paper, a new chemical reaction model, which is derived from our model of chemical oscillations,[13] is proposed and studied in detail. This chemical system shows stable oscillations around a stable steady state and pulse generations around the sustained oscillatory state with a small amplitude.

The present chemical reaction model can be applied to investigate the behavior of a chemical oscillatory system which is enclosed by a membrane or in a well-stirred continuous flow reactor. It seems that the application to the latter system is useful for interpreting the chaotic oscillations of the Belousov-Zhabotinskii reaction in a well-stirred continuous flow reactor observed by Schmitz *et al.*[15]

Behaviors of Chemical Reaction Model

Chemical Reaction Model. We consider the following reaction system;

$$P \xrightarrow{k_1} E, \tag{R-1}$$

$$E + X \xrightarrow{k_2} X + R, \tag{R-2}$$

$$A + 2X + E \underset{k_4}{\overset{k_3}{\rightleftharpoons}} 3X + E, \tag{R-3}$$

$$B + X \underset{k_6}{\overset{k_5}{\rightleftharpoons}} C, \tag{R-4}$$

$$E \xrightarrow{k_7} S, \tag{R-5}$$

$$X \xrightarrow{k_8} T. \tag{R-6}$$

These reaction steps proceed homogeneously at constant temperature and pressure. The concentrations of P, A, B, and C are kept constant by means of an external control in order to sustain the system far from equilibrium. E and X are the reaction intermediates and the rates of changes in the concentrations of E and X are expressed respectively by

$$\frac{dE}{dt} = k_1P - k_2EX - k_7E, \tag{1}$$

$$\frac{dX}{dt} = k_3AEX^2 - k_4EX^3 - k_5BX + k_6C - k_8X. \tag{2}$$

In order to study the behavior of this chemical system at the steady state, the conditions $dE/dt=0$ and $dX/dt=0$ are applied to Eqs. 1 and 2 to obtain

$$k_1P - k_2EX - k_7E = 0, \tag{3}$$

$$k_3AEX^2 - k_4EX^3 - k_5BX + k_6C - k_8X = 0. \tag{4}$$

We put $k_7=k_8=\alpha$ hereafter for simplicity. The steady state values of X and E were obtained by solving these equations and plotted in Fig. 1 as a function of α for various values of P. The solid and dotted portions indicate stable and unstable steady states, respectively. Parameter values used are as follows;

$A=1.332$, $B=5.02$, $C=5.35$, $k_1=0.1$, $k_2=0.476$,

$k_3=100.0$, $k_4=48.64$, $k_5=10.0$, $k_6=1.0$,

$P=1.50$(a), 2.0(b), 2.5(c), 2.9(d), and 3.2(e).

These parameter values were also used for study of a chemical oscillation model in the preceding paper.[13] In the case (e), the steady state is stable in a range of adequately small α values and changes into unstable when α increases beyond a critical point near $\alpha=0.014$ and again returns stable in a range beyond a critical point near $\alpha=0.224$; that is, it is expected that a sustained oscillatory state is realized in the dotted line region. To confirm this expectation, Eqs. 1 and 2 were solved for $P=3.2$ by the Runge-Kutta method with a digital computer. Three of calculated results are shown in Fig. 2. In the case (a), the amplitude of oscillations is small, but in the cases (b) and (c), the amplitudes are equally large. In Fig.

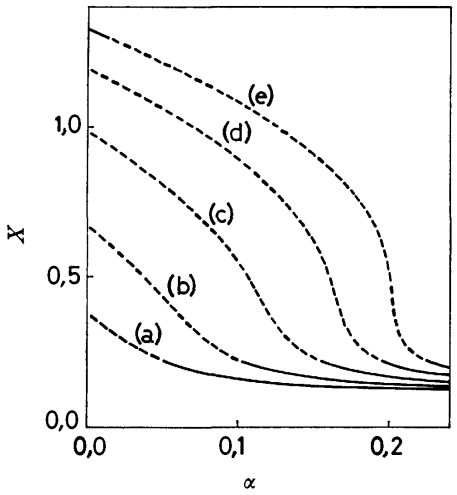

Fig. 1. Plots of steady state concentration of X obtained from Eqs. 3 and 4 against α. Solid lines represent stable steady states and dotted lines represent unstable ones. Parameter values used are; $A=1.332$, $B=5.02$, $C=5.35$, $k_1=0.1$, $k_2=0.476$, $k_3=100.0$, $k_4=48.64$, $k_5=10.0$, $k_6=1.0$, (a) $P=1.50$, (b) $P=2.0$, (c) $P=2.5$, (d) $P=2.9$, and (e) $P=3.2$.

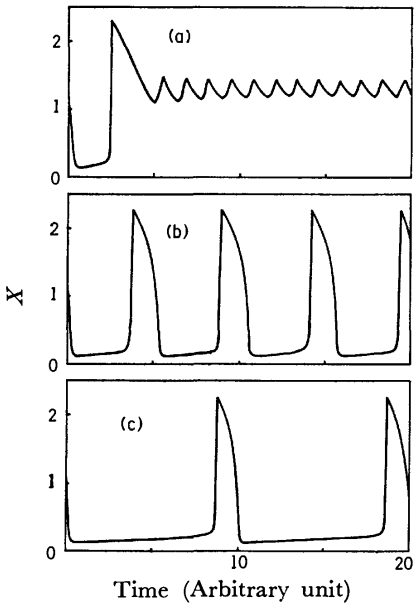

Fig. 2. Results of numerical solution of Eqs. 1 and 2 for $P=3.2$, (a) $\alpha=0.015$, (b) $\alpha=0.14$, and (c) $\alpha=0.222$. Other paremeter values used are the same with those of Fig. 1. The steady states are unstable for these parameter values and oscillations occur.

3, the amplitude of oscillation is plotted against α. The upper and lower thin dotted lines show the width of oscillations. The thick solid and dotted line indicates stable and unstable steady state, respectively. The amplitude of oscillation decreases drastically at the critical point of $\alpha=0.2238$, and this suggests coexistence of stable oscillatory and stable non-oscillatory states, where the oscillatory states are not self-induced but are initiated by a finite perturbation at the stable non-oscillatory states. This phenomenon is called hard oscillations.[16] Actually, it was confirmed from cal-

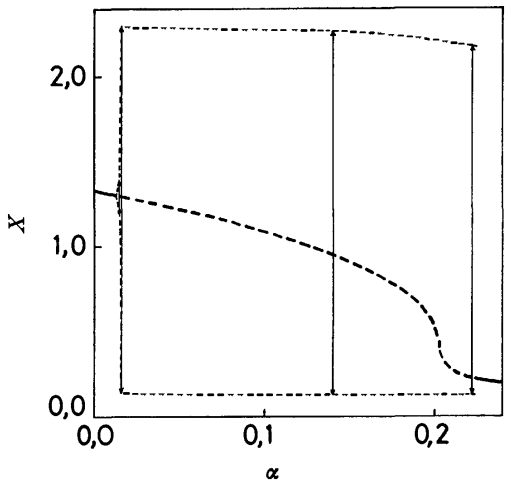

Fig. 3. Plot of amplitude of oscillations against α value determined from Eqs. 1 and 2. All the parameter values are the same with those of Fig. 1. Two types of transition points are shown. At the transition point near $\alpha=0.014$, the amplitude increases continuously with an increasing value of α, while a hard oscillation occurs at the transition point near about $\alpha=0.2238$. See Fig. 5.

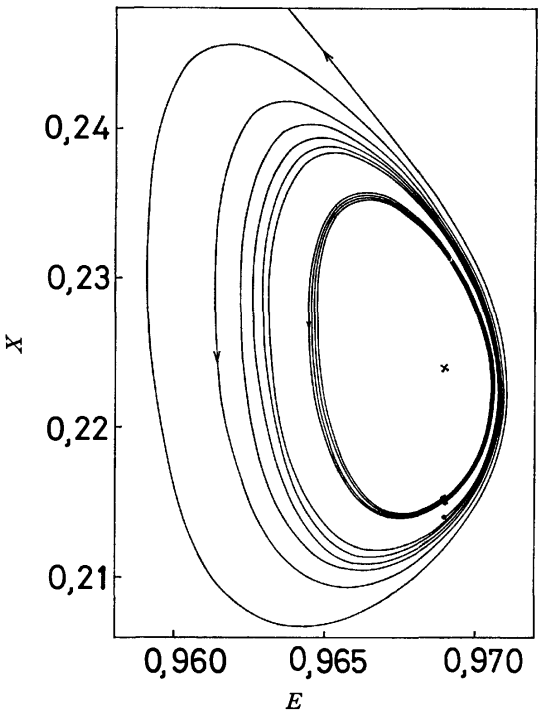

Fig. 4. Behaviors of the chemical system around the stable steady state. × indicates the stable steady state. When a calculation is started from the initial state of $X=0.215$ and $E=0.969$, the chemical system falls into the stable steady state and it is started from the initial state of $X=0.214$ and $E=0.969$, the system falls into the stable oscillatory state. $\alpha=0.2237$. × ($X=0.224$, $E=0.9689$).

culations of Eqs. 1 and 2 at $\alpha=0.2237$ that a sustained oscillatory state encloses a stable steady state. The enlarged picture of a region around the stable steady state is shown in Fig. 4. When a calculation is started

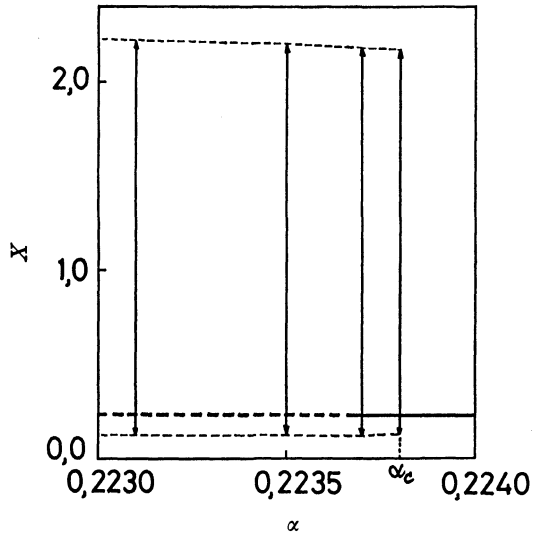

Fig. 5. Amplitude behavior of oscillations at the transition point. $\alpha_c=0.2238$.

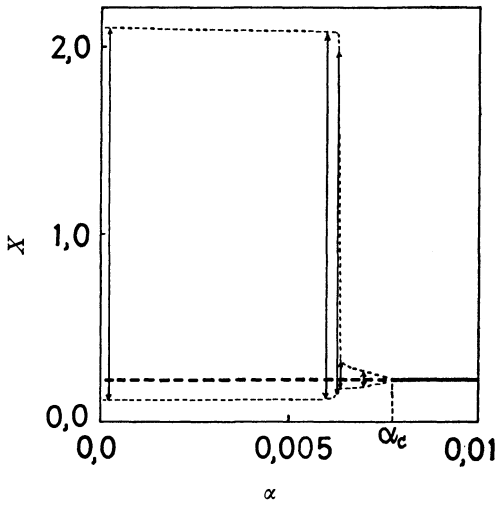

Fig. 6. Amplitude behavior of oscillations near $\alpha=0.0077$ for $k_1=0.5$, $k_2=2.38$, and $P=1.05$. Other parameter values are the same with those of Fig. 1. $\alpha_c=0.0077$.

from the initial state of $X=0.215$ and $E=0.969$, the chemical system falls into the stable steady state and when it is started from the initial state of $X=0.214$ and $E=0.969$, the system falls into the stable oscillatory state. In this case, both the oscillatory and non-oscillatory states coexist, and the transition from (or to) sustained oscillatory state to (or from) non-oscillatory state has a threshold.[16]

The diagram relating the amplitude of hard oscillations to α is depicted in Fig. 5. Hysteresis behavior would be observed for the transition between the sustained oscillatory state and the stable steady state. When α decreases from 0.224 to lower values, the steady non-oscillatory state would result until α becomes to 0.22366; at this point the transition from the non-oscillatory to the oscillatory states would occur. When α is lower than 0.22366, only the oscillatory state appears. Reversely, the oscillations would persist until α increases beyond 0.2238. This situation

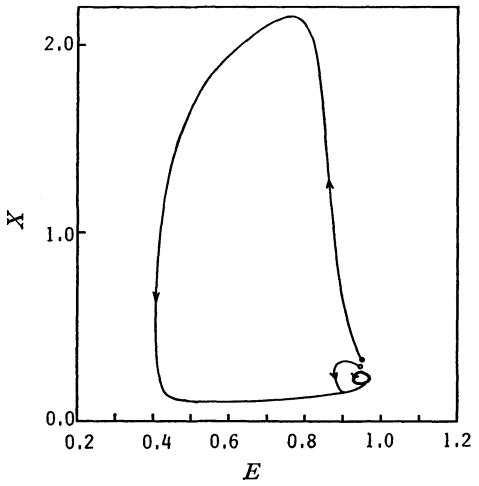

Fig. 7. Behaviors of the chemical system starting from two different initial states. When it starts from ($X=0.33$, $E=0.95$), the chemical system goes on a long excursion before falling into the stable oscillatory state displayed with a thick closed line. While, when it start from ($X=0.30$, $E=0.95$), it falls into the stable oscillatory state accompanying damped oscillations. $\alpha=0.0072$.

results in a hysteresis phenomenon.

Excitation Around a Sustained Oscillatory State. The solution of Eqs. 1 and 2 are shown in Fig. 6 for $k_1=0.5$, $k_2=2.38$, and $P=1.05$. The amplitude of oscillation changes drastically at about $\alpha=0.0064$, and the amplitude decreases gradually with increasing α and eventually disappears when the stability of steady state becomes stable. When $\alpha=0.0072$, this chemical system has an oscillatory state with a small amplitude. This oscillatory state is shown with a closed cycle drawn by thick line in Fig. 7. The chemical system falls into this stable oscillatory state from any initial states, although the routes to the oscillatory state depend greatly on the initial states. When it starts from the state ($X=0.33$, $E=0.95$), the chemical system goes on a long excursion before falling into the sustained oscillatory state, and when it starts from the state ($X=0.30$, $E=0.95$), it falls into the stable oscillatory state accompanying a damped oscillatory behavior. Only pulse generation is observed when the system is brought by a certain distance from the oscillatory state. This system shows therefore the phenomenon of pulse generation with a threshold.[5,13,17,18]

Application to a Membrane-chemical System

Now let us consider a membrane-chemical system which consists of the chemically oscillatory model (R-1)—(R-4) surrounded by a membrane. This model was used in our preceding paper[13] to investigate the chemically oscillatory behaviors. In this system, the concentrations of A, B, C, and P inside the membrane are kept constant by means of an external control, and the concentrations of E and X outside the membrane are maintained to be zero. All of the chemical species are homogeneously distributed inside the mem-

brane. Then, the rates of permeation of E and X through the membrane are expressed as;

$$J_E = h_E E, \tag{5}$$

$$J_X = h_X X, \tag{6}$$

where h_E and h_X are the permeation coefficients of E and X, respectively. Then, the rate equations of E and X inside the membrane are written as;

$$\frac{dE}{dt} = k_1 P - k_2 EX - h_E ES/V, \tag{7}$$

$$\frac{dX}{dt} = k_3 AEX^2 - k_4 EX^3 - k_5 BX + k_6 C - h_X XS/V, \tag{8}$$

where S and V are the surface area and the volume of the reaction region surrounded by the membrane, respectively. If we put $h_E S/V = h_X S/V = \alpha$, Eqs. 7 and 8 become the same type equations with Eqs. 1 and 2, respectively. Therefore, we can discuss the behaviors of the chemical system surrounded by a membrane with the completely same method described in the preceding section.

Every living system is constructed of cells and every cell is surrounded by a lipid bilayer membrane which transports substances necessary for living process, and, therefore, it is important to explain behaviors of the chemically oscillatory system surrounded by membrane.[3,6,10]

Behaviors of the Chemically Oscillatory Model in a Well-stirred Continuous Flow Reactor

In this section, let us study behaviors of the chemically oscillatory model (R-1)—(R-4) in a well-stirred continuous flow reactor. Schmitz *et al.* studied the behaviors of the Belousov-Zhabotinskii reaction in a well-stirred continuous flow reactor and observed chaotic oscillations in a certain region of flow rate.[15] They explained this behavior based on the idea of Rösseler;[19] that is, a phase point moves on a folded surface with an unstable steady state in a phase space of three variables, and hysteresis transition across a fold generates chaotic behaviors.

Noyes *et al.*[20] reported that chaotic oscillations of the Oregonator can be explained by some modifications of their chemical model. They used a model containing seven intermediates and analyzed the stability of steady states by introducing a new variable P, which represents the concentration of the intermediate HOBr. There exists a certain value of P where the stability of steady state reverses, and the linkage of P with other chemical species results in random oscillations of large and small amplitudes under suitable conditions.

The present investigation shows that the chaotic behaviors can be explained without any modification of the reaction steps of the original model and, therefore, the chaotic oscillations of the Oregonator observed by Schmitz *et al.*[15] can be also explained by the present method, which is quite different from the method by Noyes *et al.*[20]

Now let us consider a well-stirred continuous flow reactor, in which a series of reactions (R-1)—(R-4) is taking place with a constant feed of a fresh raw solution and a continuous removal of a reacted solution. The feed solution is composed of chemical species A, B, C, and P and the reacted solution is composed of A, B, C, E, P, R, and X. The total flow rate of the solution into the reactor is J and the volume of the flow reactor is V. We put J/V as β for abbreviation.

The material balance of these chemical species in the reactor is expressed as

$$\frac{dP}{dt} = \beta(P_0 - P) - k_1' P, \tag{9}$$

$$\frac{dA}{dt} = \beta(A_0 - A) - k_3' AEX^2 + k_4' EX^3, \tag{10}$$

$$\frac{dB}{dt} = \beta(B_0 - B) - k_5' BX + k_6' C, \tag{11}$$

$$\frac{dC}{dt} = \beta(C_0 - C) + k_5' BX - k_6' C, \tag{12}$$

$$\frac{dE}{dt} = k_1' P - k_2' EX - \beta E, \tag{13}$$

$$\frac{dX}{dt} = k_3' AEX^2 - k_4' EX^3 - k_5' BX + k_6' C - \beta X. \tag{14}$$

Here A_0, B_0, C_0, and P_0 are concentrations in the feed solution and A, B, C, and P are uniform concentrations in the reactor. The terms including β represent flow terms.

Equation 9 is solved to give the solution

$$P = \frac{\beta P_0}{\beta + k_1'} + \left(P' - \frac{\beta P_0}{\beta + k_1'}\right) e^{-(\beta + k_1')t}, \tag{15}$$

where P' is an initial value of P. When t is adequately large, P becomes to $\beta P_0/(\beta + k_1')$, independently of P' value. Here we adopt the following values; $k_1' = 0.5 \times 10^{-5}$, $k_2' = 2.38$, $k_3' = 1.0 \times 10^{-3}$, $k_4' = 48.64$, $k_5' = 1.0 \times 10^{-4}$, and $k_6' = 1.0 \times 10^{-5}$. Then, P is nearly equal to P_0 when β is sufficiently larger than k_1'. The values of A, B, and C are similarly discussed and it was shown that their final concentrations are nearly equal to A_0, B_0, and C_0, respectively.[21] When we put $P_0 = 1.05 \times 10^5$, $A_0 = 1.332 \times 10^5$, $B_0 = 5.02 \times 10^5$, and $C_0 = 5.35 \times 10^5$, the values of $k_1' P_0$, $k_3' A_0$, $k_5' B_0$, and $k_6' C_0$ are equal to those of $k_1 P$, $k_3 A$, $k_5 B$, and $k_6 C$, which were used in the preceding sections. Then, we can discuss the behaviors of the chemical system (R-1)—(R-4) in a well-stirred continuous flow reactor by the aid of the results shown in Figs. 6 and 7, where α is exactly equivalent to β. In this situation there is an abrupt change in amplitude at about $\beta = 0.0064$ and a small deviation causes pulse generation around the sustained oscillatory state, as shown already. Therefore, small random deviations of flow rate cause randomly large or small amplitude oscillations. Moreover, any actual system is under influences of fluctuation. Then, we have to use the rate equations including fluctuation terms in order to investigate the behaviors of the chemical system at a critical point.[13]

$$\frac{dE}{dt} = k_1' P_0 - k_2' EX - [\beta + \beta' F(t)]E + \gamma G(t), \tag{16}$$

$$\frac{dX}{dt} = k_3'A_0EX^2 - k_4'EX^3 - k_5'B_0X + k_6'C_0 - [\beta+\beta'F(t)]X + \delta H(t), \quad (17)$$

where $F(t)$, $G(t)$, and $H(t)$ are the fluctuation terms of Gaussian type.[13] The average values $\langle F(t)\rangle$, $\langle G(t)\rangle$, and $\langle H(t)\rangle$ are zero and the standard deviations are set to be 0.1. The coefficients β', γ, and δ represent the strengths of fluctuations, and $\beta'F(t)$ corresponds to the fluctuation of flow rate and $\gamma G(t)$ and $\delta H(t)$ correspond to the concentration fluctuations of E and X, respectively. Figure 8 illustrates behaviors of the chemical reaction model in a well-stirred continuous flow reactor for various values of β. At lower values of flow rate J, only large amplitude oscillations appear and in some range of flow rate, shown by (c) and (d), both large and small amplitude oscillations appear randomly. When the flow rate increases much more, only small amplitude oscillations occur and fade out, as shown by the cases of (e) and (f). These results agree essentially well with that of Schmitz *et al.*[15]

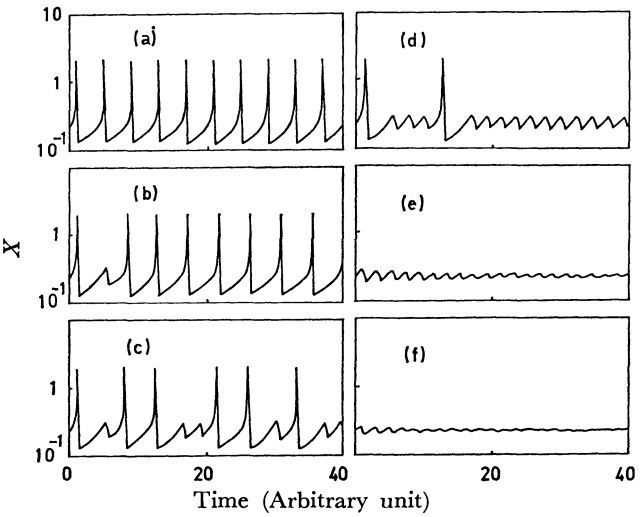

Fig. 8. Oscillatory behaviors under influences of fluctuations. $\beta=J/V$. $\beta'=0.001$, $\gamma=0.001$, $\delta=0.001$, (a) $\beta=0.001$, (b) $\beta=0.006$, (c) $\beta=0.0065$, (d) $\beta=0.007$, (e) $\beta=0.008$, and (f) $\beta=0.01$. $A_0=1.332\times10^5$, $B_0=5.02\times10^5$, $C_0=5.35\times10^5$, $P_0=1.05\times10^5$, $k_1'=0.5\times10^{-5}$, $k_2'=2.38$, $k_3'=1.0\times10^{-3}$, $k_4'=48.64$, $k_5'=1.0\times10^{-4}$, and $k_6'=1.0\times10^{-5}$.

A Study of the Calcium Oxide–Water Vapor System by Means of the Transpiration Method

Kazutoshi MATSUMOTO* and Toshiyuki SATA
Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received August 7, 1980)

The system of calcium oxide and water vapor was studied using the transpiration method. Under the conditions of a temperature range from 1678 to 2016 K and P_{H_2O} values from 1.2×10^{-2} to 4.7×10^{-1} atm, the predominant reaction in this system was found to be $CaO(s)+H_2O(g)=Ca(OH)_2(g)$. The standard Gibbs free energy of the reaction is given by this equation: $\Delta G_r^\circ=(61300\pm820)-(12.8\pm0.48)T$ (cal/mol) in the present temperature range. From the thermochemical cycle, the dissociation energy, $D_0^\circ(Ca\text{-}(OH)_2)$, was estimated to be 206.4 kcal/mol.

The volatility of alkaline-earth oxides is greatly increased by the presence of water vapor as a result of the formation of volatile hydroxide vapors by the following reactions:

$$MO(s) + H_2O(g) = M(OH)_2(g), \quad (1)$$

and:

$$MO(s) + \frac{1}{2}H_2O(g) = MOH(g) + \frac{1}{4}O_2, \quad (2)$$

where M is a Group IIa element. This has been shown to be true for BeO,[1-3] MgO,[4,5] and BaO.[6,7]

Although calcium oxide is one of the most important components in the ceramic industry, no systematic investigation of its vaporization behavior under various atmospheres had been made. Only a few investgators[8-11] have measured the dissociation energy, D_0°, for the $Ca(OH)_2(g)=Ca(g)+2OH(g)$ reaction using flamespectral measurements.

In the present study, the reaction of water vapor with solid calcium oxide was investigated by means of the transpiration method as part of a series of studies[5,7] of the effects of water vapor upon the vaporization of alkaline earth oxides. The vapor pressures of the gaseous $Ca(OH)_2$ formed according to Reaction 1 and the related thermodynamic properties were evaluated.

Experimental

Transpiration Apparatus. Figure 1 shows a schematic drawing of the reaction zone in the apparatus used in this study. The sample was placed in a reaction chamber, N (12 mm i.d.×30 mm long), made of Pt/20% Rh alloy. The reaction chamber had a capillary, L (1 mm i.d.×10 mm long), to prevent the vapor species formed in the chamber from back-diffusing and had a bottom with holes below which a Pt/Rh 20—40 themocouple, calibrated at the melting points of Pd and Pt (IPTS-68) and placed in a protective alumina tube was located.

The vaporized species were collected in a condenser, J, made of Pt/20% Rh alloy (3.4 mm i.d.×300 mm long). The capillary, L, had a thorium oxide sleeve, M, in order to minimize the leakage of vapor species through the space between the condenser and the capillary and to prevent sticking with the condenser at high temperatures. The temperature of the reaction chamber was raised by the use of 6 rods of a $LaCrO_3$ heater up to 2016 K and then regulated with ±3 °C.

A wet gas mixture, O_2–H_2O–Ar, was obtained by bubbling a dry O_2–Ar gas in water controlled about 10 degrees higher than desired temperature; it was then passed through a scerwed glass coil around which precisely thermostatted water was passed continuously to condense the oversaturated water vapor in the wet gas. This method has already been described in a preceding paper.[5] The partial pressure of the water vapor was determined from the weight increase in the P_2O_5 powder placed in a stream of the wet gas. The vapor pressure thus determined agreed with the saturated water vapor pressure at the temperature of the coil within ±2%. The water vapor pressure in the range from 1.2×10^{-2} to 4.7×10^{-1} atm was used in the experiments.

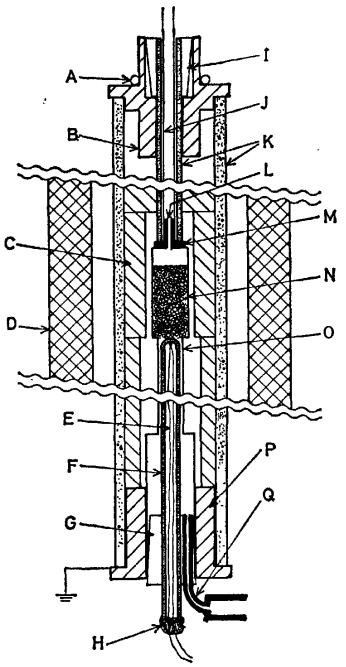

Fig. 1. Cross section of reaction zone in transpiration apparatus. A: cooling water, B: brass, C: alumina insulator, D: $LaCrO_3$ heater, E: Pt/Rh 20—40 thermocouple, F: alumina protective tube, G: Viton stopper, H: silicone seal, I: silicone stopper, J: condenser(Pt/20%Rh), K: alumina tube, L: capillary, M: thoria sleeve, N: reaction chamber and charge, O: reaction tube (Pt/20%Rh), P: brass, and Q: stainless steel.

Sample. Powder of CaO from $CaCO_3$ with a 99.9% purity (supplied by Merck), fired at 1200 °C, was pressed and sintered at 2400 °C by means of H_2/O_2 flames and then crushed to particles of 15—30 mesh. The particles of CaO were used to fill about 80% of the reaction chamber, and

Table 1. Impurity content of CaO used in this experiment

Element	Content ppm	Element	Content ppm
Na	9	V	<1
Mg	116	Cr	144
Al	25	Fe	11
Si	38	Mn	<1
P	<1	Co	<1
S	23	Cu	1
K	5	Zn	2
Ti	<1		

These values were measured by means of a spark-source mass spectrograph.

a rid with the capillary was welded.

The impurities in the CaO specimens were analyzed by means of spark-ion-source mass spectrometry; the results are given in Table 1.

Procedure. The wet carrier gas, with a constant partial pressure of water vapor, was allowed to flow in a pipe leading the reaction tube. The pipe was heated to about 100 °C by means of a ribbon heater around it in order to keep the water vapor from condensing. The water vapor reacted with CaO in the reaction chamber at a constant temperature to form Ca-bearing hydroxide vapors. The carrier gas was saturated with vapors formed at an appropriate flow rate, and the vapors were transported into the condenser. The condenser was washed with a hot nitric-acid solution, and calcium in the solution was analyzed quantitatively using an atomic-absorption spectrophotometer.

The partial pressure of the volatile calcium hydroxide has been calculated from the amount of collected calcium. Assuming that each molecule of the volatile species contains one atom of calcium, and that the vapor is approximated to an ideal gas, the partial pressure at equilibrium is given by:

$$p(\mathrm{Ca(OH)_{2x}}) = n_v P/(n_c + n_v), \quad (3)$$

where n_c is the number of moles for the carrier gas; n_v, that for the sample vapor, and P, the total pressure, assumed here to be 1 atm.

Results and Discussion

Effect of Flow Rate on Vapor Pressure. Figure 2 shows the apparent vapor pressure of the assumed molecule, $Ca(OH)_{2x}$, as a function of the flow rate at 1926 K and $p(H_2O)$ of 1.52×10^{-1} atm. A "plateau region" is seen in the range from 1.0 to 2.0 cm^3/s. The decrease in the vapor pressure at the flow rate< 1.0 cm^3/s is thought to be due to vapor escaping from the space between the condenser and the capillary.

The "plateau region" for other temperatures and $p(H_2O)$ were obtained in a similar flow-rate region.

The output gas from the condenser was passed into a nitric solution, and the solution was subjected to the atomic-absorption analysis. Since no calcium was detected in the solution, the amount of Ca uncondensed in the condenser was considered negligible under the present experimental conditions.

Water-vapor Dependence. In addition to Eqs. 1 and 2, the following reactions must be considered

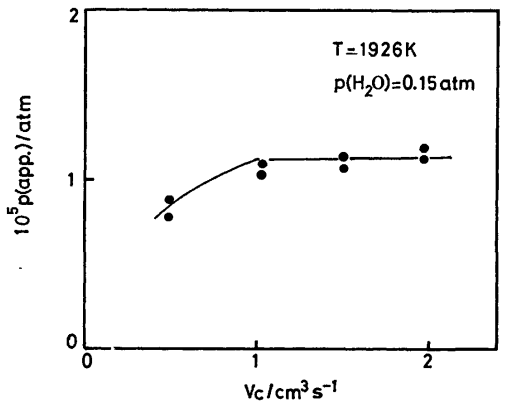

Fig. 2. Apparent vapor pressure, p(app.), *vs.* flow rate of carrier gas at $T=1926$ K and $p(H_2O)=0.15$ atm.

under these conditions:

$$\mathrm{CaO(s) = Ca(g) + \frac{1}{2}O_2}, \quad (4)$$

$$\mathrm{CaO(s) = CaO(g)}. \quad (5)$$

Using the JANAF data,[12,14,15] the partial pressures of Ca(g) and CaO(g) at $p(O_2)$ of 0.5 atm are 2.8×10^{-16} and 4.8×10^{-14} atm at 1600 K, and 4.1×10^{-11} and 9.2×10^{-10} atm at 2000 K, respectively. On the other hand, the apparent vapor pressure is 1.1×10^{-5} atm at 1926 K, judging from Fig. 2. Hence, no correction was made for Reactions 4 and 5.

A logarithmic plot of the equilibrium pressure of the volatile complex as a function of the partial pressure of water at a constant temperature and partial pressure of oxygen will indicate whether Reaction 1 or 2 occures.

Combining Reaction 1 with 2 yields the following equation for the CaO–H_2O–O_2 system:

$$\mathrm{CaO(s) + xH_2O(g) = Ca(OH)_{2x}(g) + \frac{1-x}{2}O_2}. \quad (6)$$

The equilibrium constant, k_p for the above reaction is written as:

$$k_p = \frac{p(\mathrm{Ca(OH)_{2x}})\,p(\mathrm{O_2})^{(1-x)/2}}{a(\mathrm{CaO})\,p(\mathrm{H_2O})^x}. \quad (7)$$

Assuming $a(CaO)=1$, and taking the logarithms of both sides, we obtain:

$$\log p(\mathrm{Ca(OH)_{2x}}) = x\log p(\mathrm{H_2O}) - \frac{(1-x)}{2}\log p(\mathrm{O_2}) + \log k_p. \quad (8)$$

The value of x in Eq. 8 can be determined to ascertain the contribution of Reaction 1 or 2.

A series of measurements were made at 1678 to 2016 K and $p(O_2)=0.5$ atm with a varied water vapor pressure at atmospheric pressure; the results are shown in Fig. 3. The values of x were obtained from the slopes of a log $p(Ca(OH)_{2x})$ versus log $p(H_2O)$ plot. The average value of x was 1.04 ± 0.04, which was very close to unity. Considering the experimental errors, the value of x has been determined as unity. Therefore, the predominant reaction of water vapor with calcium oxide under these experimental conditions is:

$$\mathrm{CaO(s) + H_2O(g) = Ca(OH)_2(g)}. \quad (9)$$

——: This work, ----: JANAF data.

The high partial pressure of oxygen in the carrier gas would suppress the formation of gaseous CaOH and lead to a value of x close to unity.

Vapor Pressure of $Ca(OH)_2(g)$ and Related Thermodynamic Values. The vapor pressures of gaseous $Ca(OH)_2$ and the equilibrium constant, k_p, have been calculated from the amount of calcium collected; the results are given in Table 2 and illustrated graphically in Fig. 4. The values of k_p for Reaction 9, obtained from the JANAF data[12–15] are also shown in Fig. 4. The results of this work differ from those of the JANAF data by 20%.

The solid line in Fig. 4, obtained from a least-square treatment for the data of 47 points, corresponds to the expression:

$$\log k_p = (2.80\pm0.10) - (13400\pm180)/T\ (1678-2016\ K). \quad (10)$$

Hence, the standard Gibbs energy for Reaction 9 is given by:

$$\Delta G^\circ_r = (61300\pm820) - (12.8\pm0.48)T. \quad (11)$$

This gives:

$$\Delta H^\circ_r(1850\ K) = 61.3\pm0.8\ kcal/mol, \quad (12)$$

and:

$$\Delta S^\circ_r(1850\ K) = 12.8\pm0.5\ cal/mol\ K, \quad (13)$$

Using the changes of heat capacity, ΔC_p, for Reaction 9 obtained from the JANAF data, Eqs. 12 and 13 lead to:

$$\Delta H^\circ_r(298\ K) = 62.6\pm0.8\ kcal/mol, \quad (14)$$

and:

$$\Delta S^\circ_r(298\ K) = 13.9\pm0.5\ cal/mol\ K. \quad (15)$$

This entropy change at 298 K coincides with the value, 14.0±2.0 cal/mol K, obtained from the JANAF data.

From the free-energy functions, *fef*, of CaO(s),[14] $H_2O(g)$,[12] and $Ca(OH)_2(g)$[15] and the following rela-

tionship:

$$\Delta H_r^\circ(298\,\mathrm{K}) = -RT\ln k_p - T\Delta fef, \quad (16)$$

the ΔH_r° (298 K) was calculated for each k_p; the results are given in the last column of Table 2. The average value of the ΔH_r° (298 K) values obtained by a third-law treatment, 62.8±0.4 kcal/mol, agrees well with the second-law treated value (Eq. 14); this indicates the high reliability of this work.

Using the JANAF data, the ΔH_r° (298 K) obtained by the 3rd-law treatment leads to:

$$\Delta H_r^\circ(0\,\mathrm{K}) = 63.1\pm0.4\ \mathrm{kcal/mol}. \quad (17)$$

Dissociation Energy of $Ca(OH)_2(g)$. The dissociation energy of $Ca(OH)_2(g)$ into 2OH(g) and Ca(g), $D_0^\circ(Ca\text{–}(OH)_2)$, has been estimated using the following thermochemical cycle:

$$\begin{array}{ccc} Ca(OH)_2(g) & \xrightarrow{D^\circ} & Ca(g) + 2OH(g) \\ \uparrow \Delta H_r^\circ & & \uparrow \Delta H_s^\circ \quad \uparrow \Delta H_f^\circ \\ CaO(s) + H_2O(g) & \xleftarrow{\Delta H_r^\circ} & Ca(s) + \frac{1}{2}O_2 + H_2O(g) \end{array} \quad (18)$$

whereby:

$$D_0^\circ(Ca\text{–}(OH)_2) = -\Delta H_{r,0}^\circ(Ca(OH)_2) - \Delta H_{f,0}^\circ(CaO) + \Delta H_{s,0}^\circ(Ca) + 2\Delta H_{f,0}^\circ(OH), \quad (19)$$

where $\Delta H_{r,0}^\circ(Ca(OH)_2)$ represents the heat of reaction for Reaction 9; $\Delta H_{f,0}^\circ(CaO)$, the heat of formation for CaO(s); $\Delta H_{s,0}^\circ(Ca)$, the heat of sublimation for Ca(s), and $\Delta H_{f,0}^\circ(OH)$, the heat of formation for OH(g) from $H_2O(g)$ and O_2. The values required were 63.12±0.4 (Eq. 17), −150.99±0.21,[14] 42.74±0.3,[12] and 37.90±0.04[12] kcal/mol at 0 K, respectively. The substitution of these values into Eq. 19 gives the value of $D_0^\circ(Ca\text{–}(OH)_2)$. This result is shown in Table 3, along with the literature values.[8–11]

This value is in very good agreement with the JANAF table's recommended value (No. 1 in Table 3). From the D_0° thus obtained, we calculated $\Delta H_{f,0}^\circ(Ca(OH)_2, g) = -145.0\pm1.0$ kcal/mol.

(Received August 30, 1980)

The reaction of metastable Ar atoms with propylene was studied in a discharge flow system. The major product is ethylene, although ethane, propane and butadiene are also identified as minor products. Within a limited range of propylene concentration the yield of ethylene is proportional to the concentration of propylene. Competitive quenching methods using mixtures of propylene and N_2O or CO_2 provided a rate constant of $(8.4\pm 0.3)\times 10^{-10}$ cm^3 molecule^{-1} s^{-1} for the reaction of metastable Ar atom with propylene to yield ethylene. The assumption of a radical mechanism for the main reaction is consistent with the results of competitive quenching, radical scavenger and spin trapping experiments. Measurements of ion current in the reaction mixtures allow an estimation that ionic species contribute less than 2% to the reaction path leading to the formation of ethylene. The metastable Ar atom reaction was also compared to the direct and mercury-sensitized photolysis of propylene.

Reactions of metastable rare gas atoms have been studied by many workers interested in both the physical and chemical aspects of the reaction.[1-5] Various types of ionizations (Penning, associative and dissociative) and the chemiluminescence of atoms and molecules on collision with metastable rare gas atoms have been studied.[6-8] Quenching rate constants of the metastables by various atoms and molecules also have been determined in discharge flow systems or pulsed radiolysis systems. However, in contrast to the many studies on mercury-sensitized photolysis of inorganic and organic compounds, studies on the reaction mechanism of excited rare gas atoms by product analysis are quite few in number apart from several papers on the rare gas sensitized photolysis of simple alkanes.[9,10] In the rare gas sensitized photolysis, the wavelength for the exciting light is in the far ultraviolet region, and it is usually difficult to differentiate the direct photolysis and the sensitized photolysis, unless the reactant is transparent or has only a weak absorption at the wavelength corresponding to the atomic resonance line of the rare gas atom.

The comparison between direct photolysis, rare gas sensitized photolysis and the metastable rare gas atom reaction would be interesting in order to help to elucidate the reaction modes of molecules electronically excited to high energy states near or above their ionization levels. Here we will report on the reaction of metastable Ar atoms with propylene. Electron impact methods including discharge and radiolysis are required for the generation of metastable rare gas atoms. The discharge flow method may be preferable to the radiolysis method for the product analysis, since the metastable atom source can be separated from the reaction region, and the metastables can be brought together with the reactant downstream from the source of the metastable atom. One difficulty in working with flow methods, in particular if the reactants are volatile compounds, is how to achieve quantitative recovery of the volatile products in the flow system. We succeeded in carrying out the quantitative determination of the product yield by working at a conveniently selected flow rate.

Experimental

Apparatus and Procedures. A schematic diagram of the apparatus is shown in Fig. 1. Metastable Ar atoms are produced by cold discharge in a hollow cathode. A mixture of $Ar(^3P_2)$ and $Ar(^3P_0)$ is produced by the discharge, but their differentiation is not possible in the system, and hereafter we will describe the mixture as Ar*. In order to avoid exposing the reactant to UV light from discharge source, the discharge tube is equipped with a rightangle bend and a light trap between the reaction zone and the discharge region. The flow rate is monitored by a rotar meter (Ueshima Brooks tube). Since the rotar meter was calibrated with Ar at 1 atm of pressure, the flow rate at reduced pressure was determined by measuring the decrease in the amount of Ar in a container, keeping the flow conditions same as in the actual discharge experiment. Discharge current was kept at 10—11 mA. Reactant propylene and quenching materials (N_2O, CO_2, and NO) were introduced through a sintered glass disk into the Ar flow. The reaction part of the tube is 20 mm in diameter and 300 mm in length. Pressure in the tube was measured by an oil manometer. Two pairs of electrodes (P_1 and P_2) are furnished in the reaction tube upstream and downstream from the reactant mixing position.

Condensable amounts of product and propylene were collected in a helical trap, D, cooled by liquid nitrogen. Quantitative recovery of products of high vapor pressure in the flow system was carefully checked by measuring the

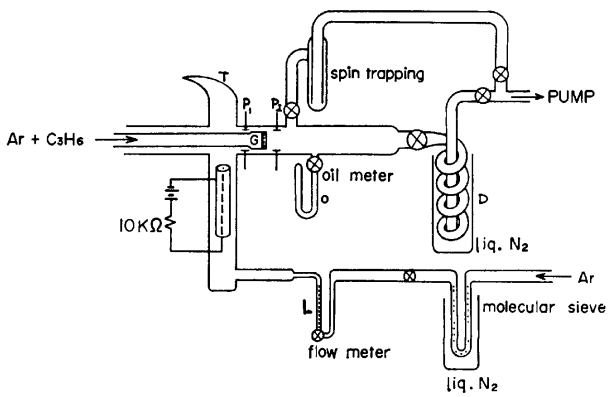

Fig. 1. The schematic diagram of the apparatus.

amounts of ethylene, ethane and propane contained in the original propylene at three different flow rates from 4.5 to 20.8 μmol s^{-1} of Ar. The quantitative recovery of the impurity hydrocarbons was achieved when the flow rate of Ar was 4.5 μmol s^{-1} (0.2 Torr (1 Torr≈133.3 Pa) and 1.3 m s^{-1} linear flow velocity). With larger flow rates, the recovery of the impurity hydrocarbons was not sufficient. We could not determine the recovery efficiency for the propylene reactant because of its large amount, but we may assume that it is nearly quantitative, considering its low vapor pressure compared with those of ethylene and ethane. All experimental runs described hereafter were carried out with a flow rate of 4.5 μmol s^{-1} at 0.2 Torr.

Product identification and yield determination were performed by GC with a TCD and a FID in train with He carrier. For ethylene, ethane and propane analysis, an activated alumina TR column of 3.75 m was used. The retention times of these compounds at 90 °C are 3 min 30 s for ethane, 6 min 50 s for ethylene, 9 min for propane and 20 min 42 s for propylene. A 3 m long activated charcoal column was used for the analysis of acetylene, propyne, and allene. The retention times for authentic compounds at 190 °C are 3 min 30 s for acetylene, 19 min 20 s for allene, 19 min 40 s for propyne and 27 min 50 s for propylene.

Before each reaction run, the system was cleaned by passing Ar for 30 to 60 min with discharge. Several minutes after the propylene was introduced, the helical trap D was cooled with liquid nitrogen. We assumed that the starting time of the reaction corresponds to the time when the trap was first cooled. The run time for each reaction was usually 10 min. No appreciable change in flow rate was noticed when the trap was cooled with liquid nitrogen. The collected condensates were transferred to a gas sampler and analyzed by GC.

The formation of Ar* in the system was confirmed by observing the well known emission of N_2 ($C^3\Pi_u \rightarrow B^3\Pi_g$) at 337 nm, introducing N_2 into the Ar flow. Since the linear flow velocity was small (1.3 m s^{-1}), the intensity of the emission was very weak, and a photon counting technique was necessary to take the spectrum. A determination of the Ar* concentration was not attempted. When a mixture of N_2 and propylene was introduced into the Ar flow, the emission disappeared.

Materials. Ar was obtained from a cylinder with a stated purity of 99.999% and was used after passage through a molecular sieve column cooled with liquid nitrogen. Propylene, N_2O, CO_2, and NO were obtained from Takachiho Co. The propylene contained 2.1×10^{-3}% ethane, 2.2×10^{-3}% propane, and 2.3×10^{-4}% ethylene, but these amounts were much smaller than those produced by the reaction, so the propylene was used without further purification. For the competitive experiments with propylene and other quenchers, mixtures of propylene and N_2O or CO_2 of three different concentration ratios were prepared, and their exact concentration ratios were determined by GC.

Results and Discussion

Product Identification, and the Relationship between Product Yields and Propylene Concentration. The major product was ethylene, with ethane and propane as minor products. Although usually H_2 and CH_4 were not collected in the present sampling method using a liquid nitrogen trap, occasionally some amount of CH_4 was detected. Butadiene was identified by a MS analysis of the products, but a quantitative determination of its amount was not attempted. Acetylene, propyne, and allene were carefully searched for, but not found in the product. Figure 2 shows the relationship between the yields of ethylene, ethane and propane and the propylene concentration. The concentration of the products is defined as the final concentration at the end of the reaction path, and it is calculated from the yield of the product per unit time and the linear flow velocity (1.3 m s^{-1}). It is the yield of the product integrated over a given residence time (0.3 s) in the flow system (see Eqs. 12 and 13). Over a limited range the yield of ethylene is proportional to the concentration of propylene; however, the yield decreases at higher concentrations of propylene. The yields of ethane and propane also appear to increase with an increase of propylene concentration, but their proportionalities are not conclusive due to their low yields. The plot of ethylene yield *vs.* propylene concentration appears not to pass through origin, but we consider this to be due to the experimental error. Although we could not determine the initial concentration of Ar*, the yield of ethylene, *ca.* 3×10^{10} molecule cm^{-3}, may indicate a lower limit for the Ar* con-

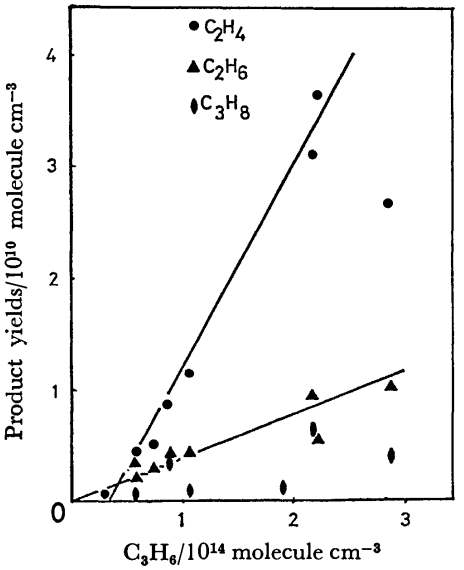

Fig. 2. Product yields *vs.* propylene concentration.

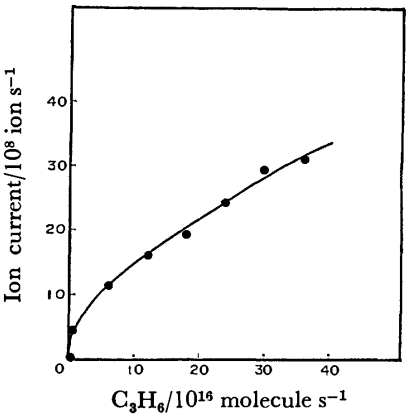

Fig. 3. Dependence of ion current on propylene concentration.

TABLE 1. RATIO OF ION YIELD TO ETHYLENE YIELD

Flow rate of propylene molecule s^{-1}	Ion yield per unit time ion s^{-1}	Ethylene yield per unit time molecule s^{-1}	Ratio of ion yield to ethylene yield
1.2×10^{17}	1.6×10^{11}	8.5×10^{12}	1.9×10^{-2}
2.5×10^{17}	2.5×10^{11}	1.3×10^{13}	1.9×10^{-2}

centration, if we assume one atom of Ar* produces one molecule of ethylene.

Ion Current Measurement. Ion current was measured at electrodes P_1 and P_2. Ion current upstream from the reactant inlet position is less than 1.0×10^{-11} A (6×10^7 ion s^{-1}), indicating that the participation of charged particles (possibly Ar^+) as reactants is negligible compared with Ar* ($\approx3\times10^{10}$ atom s^{-1}). In Fig. 3 the relationship between ion current at P_2 and propylene concentration is shown. The ion current increases with increasing propylene concentration, but not exactly linear. Since the measured ion current corresponds approximately to the amount of ions produced in the volume defined by the two electrodes P_2, we would need parallel electrodes 300 mm long in order to know the total ion yield in the flow system. Here we calculated an upper limit of the yield in the total volume of the reaction region by multiplying the measured ion current a factor of 100 (the ratio of the total volume of the reaction region to the volume defined by the two electrodes). Table 1 gives the ion yield (calculated upper limit), ethylene yield under the same conditions, and ratio of ion yield to ethylene yield. From these results we may conclude that the formation of ionic species is less than 2% of the ethylene yield.

In the present experimental setup the identification of ionic products was not possible, but we may assume that the measured ions are propylene parent ions or associated ions[11] (possibly $Ar(C_3H_6)^+$) and not fragment ions. Since the ionization potential of propylene is 9.73 eV, and the energy of Ar* is 11.5 eV for $Ar(^3P_2)$ and 11.7 eV for $Ar(^3P_0)$, the formation of propylene parent ion is possible. However, the formation of fragment ions is less likely, since the appearance potentials for allyl and vinyl ions from propylene are 12.1 eV and 13.8 eV respectively.[12]

The competitive quenching method for determining the rate constant for the Ar+propylene reaction.* If we assume ethylene is formed through the propylene quenching of Ar*, the following two processes compete when a mixture of propylene and another quencher is mixed with Ar*:

$$Ar^* + C_3H_6 \xrightarrow{k_1} Ar + C_3H_6^* \longrightarrow \text{ethylene and other product(s)}, \quad (1)$$

$$Ar^* + Q\,(\text{another quencher}) \xrightarrow{k_q} Ar + Q^*(\text{or product(s) from } Q^*). \quad (2)$$

According to the conventional treatment of competitive reactions, we may obtain the following equation:

$$[C_2H_4]_0/[C_2H_4]_q = 1 + (k_q[Q]/k_1[C_3H_6]), \quad (3)$$

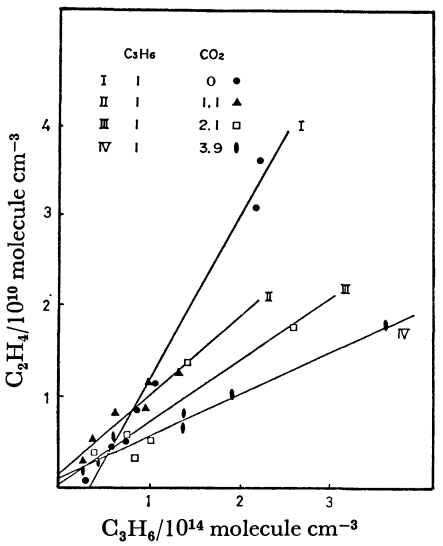

Fig. 4. Ethylene yields *vs.* propylene concentration in the absence and in the presence of CO_2.

where $[C_2H_4]_0$ and $[C_2H_4]_q$ are the yields of ethylene in the absence and in the presence of another quencher Q but with the same concentration of propylene. In the present flow system we need a more detailed consideration to derive Eq. 3 which is different from the case of batch photolysis. This will be given later. If Eq. 3 holds, we may expect that a plot of ($[C_2H_4]_0/[C_2H_4]_q$) *vs.* concentration ratio of Q to propylene should give an intercept of unity and a slope of k_q/k_1.

This seems to be the case for this system as is shown in Fig. 4, which presents ethylene yield as a function of propylene to CO_2 ratio for three different concentration ratios. It is seen that the slope decreases with an increase in the $[CO_2]/[C_3H_6]$ ratio, indicating the decrease of ethylene yield with increase of CO_2 concentration. In order to see if Eq. 3 holds or not, we plot the value of $[C_2H_4]_0/[C_2H_4]_q$ against $[CO_2]/[C_3H_6]$ and $[N_2O]/[C_3H_6]$ at a normalized propylene concentration as Fig. 5 shows. The intercepts of the plots for CO_2 and N_2O are both 1.1 ± 0.1, and the slope is 0.67 ± 0.04 for CO_2 and 0.51 ± 0.03 for N_2O. Combining these values with the quenching rate constants determined by Setser et al.[12] for $Ar(^3P_2)$ (5.3×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for k_{CO_2} and 4.4×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for k_{N_2O}) we obtain $(7.9\pm0.5)\times10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} from the CO_2 experiment and $(8.6\pm0.5)\times10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} from the N_2O experiment for the value of k_1. We consider these two values of k_1 determined from two different series of experiments to be identical within the range of experimental error. Unfortunately the rate constant for propylene quenching of Ar* as determined by

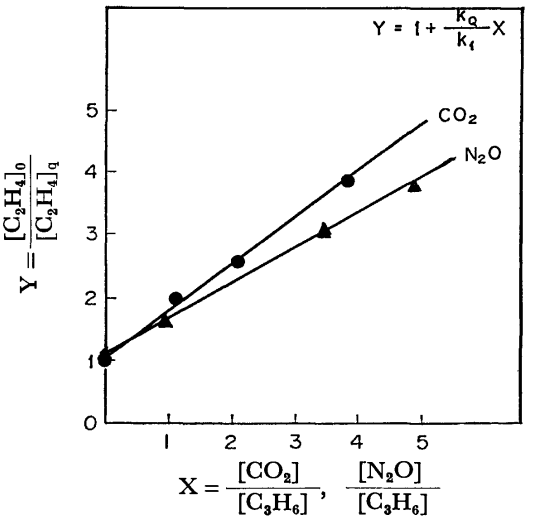

Fig. 5. Plots of $[C_2H_4]_0/[C_2H_4]_Q$ *vs.* $[CO_2]/[C_3H_6]$ and $[N_2O]/[C_3H_6]$

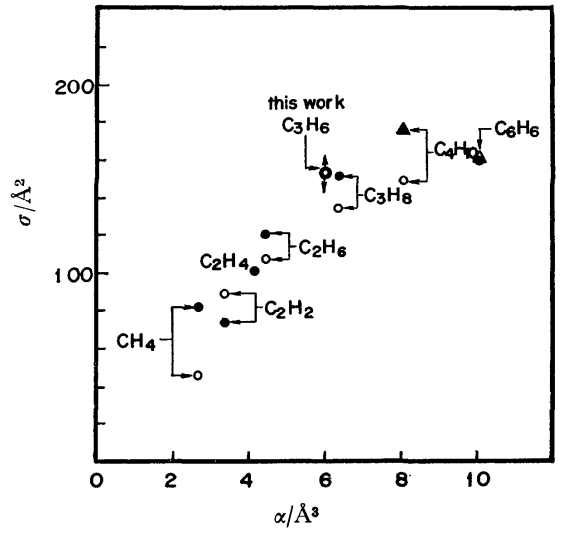

Fig. 6. Ar* quenching cross section by propylene and its polarizability in Bourène's plot.

the atomic absorption method has not been reported yet, and we cannot compare our value with what may be called a physical quenching rate constant or the total quenching rate constant including all quenching processes of Ar*.

Several authors have claimed a good correlation between the quenching cross sections of Ar* and several physical parameters such as polarizability,[13] van der Waals dispersion parameter,[14] and molecular diameter.[15] We would not judge which parameter is the best, but we tentatively plot our value for propylene against polarizability according to Bourène and Le Calvé in Fig. 6. It is seen that our value fits Bourène's plot.

When we used a mixture of propylene and NO for the reaction with Ar*, we observed a more remarkable decrease of ethylene yield than would be expected from a simple competing quenching of Ar* by NO which has an observed quenching rate constant for $Ar(^3P_2)$ of 2.2×10^{-10} cm^3 molecule^{-1} s^{-1}.[12] This

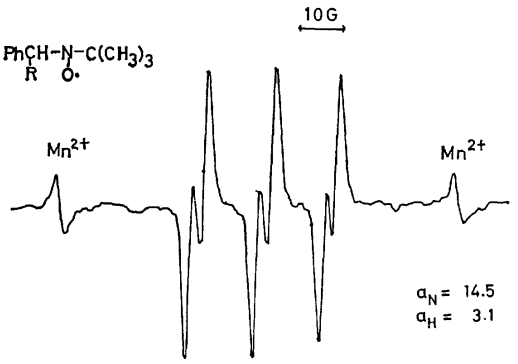

Fig. 7. ESR spectrum of a spin adduct of BPN produced in the reaction of Ar* with propylene.

decrease may be ascribed to NO scavenging of the intermediate vinyl radical.

Spin Trapping Experiment. Presuming that the reaction proceeds through a radical mechanism, we applied spin trapping technique to the present system to identify the intermediate radical(s), (vinyl, methyl, allyl radicals, and H atom might be considered possible). *N-t*-Butyl-α-phenylnitrone (*N*-benzylidene-*t*-butylamine *N*-oxide, BPN),[16] 2-methyl-2-nitrosopropane and nitrosobenzene were tested as spin trapping materials. BPN was used by sprinkling powder BPN over glass fibers and placing it in a straight trap instead of the helical trap D. After passing the reaction mixture for several hours with discharge under reaction conditions similar to those in the usual experiment, the powder was dissolved in cyclohexane. The ESR spectrum of the deaerated cyclohexane solution (JRS-PF-3X ESR spectrometer) is shown in Fig. 7. The coupling constants of the spin adduct are 14.5 G (1 G= 10^{-4} T) for a_N and 3.1 G for a_H. On comparing the spin coupling constants with the reported values of several spin adducts,[17] this spectrum is interpreted as that of an alkyl radical. Since the coupling constant of the BPN spin adducts is not very sensitive to the structure of the alkyl radical, we are not able to identify its structure uniquely, but methyl radical adduct may be the most probable.

We could not find any evidence of a vinyl radical adduct in the spectrum. Although the values of the spin coupling constants of vinyl radical adduct have not been reported in the literature, we would expect the value of a_H for vinyl radical adduct to be much smaller than those of an alkyl radical, considering that the a_H value of phenyl radical adduct is 2.08—2.14 G. It is, however, to be noted that the absence of ESR signals from a vinyl radical adduct in the spectrum does not necessarily mean that vinyl radical is not formed as a reaction intermediate, since the lifetime of some spin adducts is too short to be detected. Generally spin adducts of 2-methyl-2-nitrosopropane and nitrosobenzene show ESR spectra more sensitive to the radical structure. Although we obtained spin adduct ESR spectra with 2-methyl-2-nitrosopropane as the spin trap, we could not obtain an ESR spectrum of the adduct, when nitrosobenzene was used as the spin trap. The 2-methyl-2-nitrosopropane was too volatile to use as a powder, so the

Ar and propylene mixture was bubbled through a dibutyl phthalate solution of the trapping compound. Although the spin adduct spectrum could be observed, the adduct concentration was so low, and we could determine only a_N (14.5 G) but not a_H.

Reaction Mechanism and Rate Equations. The experimental results may be summarized as follows:
(1) Ethylene is the major product, with ethane, propane and butadiene identified as minor products. Hydrogen and methane may be products also, but they could not be confirmed due to sampling difficulties. Acetylene, propyne, and allene were not found in the product.
(2) Within a limited range of propylene concentration, the ethylene yield is proportional to the concentration of propylene.
(3) The remarkable decrease of ethylene yield from a mixture of propylene and NO suggests that ethylene is formed through a radical mechanism.
(4) The spin trapping experiments indicate the formation of an alkyl radical as an intermediate.
(5) The competitive quenching experiments with CO_2 and N_2O show that ethylene formation is directly related to the quenching of Ar* by propylene, and allow the determination of a reasonable rate constant for the propylene quenching of Ar*.
(6) The yield of ionic species as primary product is estimated to be less than 2% of the ethylene yield.

In consideration of these results, the following reaction mechanism is proposed:

$$Ar^* \longrightarrow Ar \text{ (including quenching by wall collision, two and three body collisions with Ar)} \quad (4)$$

$$Ar^* + C_3H_6 \xrightarrow{k_1} Ar + C_3H_6^* \quad (1)$$

$$Ar^* + Q \xrightarrow{k_q} Ar + Q^* \text{ (or products from Q*)} \quad (2)$$

$$C_3H_6^* \xrightarrow{k_5} C_2H_3 \text{ (vinyl radical)} + CH_3 \quad (5)$$

$$C_3H_6^* + C_3H_6 \xrightarrow{k_6} 2C_3H_6 \quad (6)$$

$$C_2H_3 + C_3H_6 \xrightarrow{k_7} C_2H_4 + C_3H_5 \text{ (allyl radical)} \quad (7)$$

$$2C_2H_3 \xrightarrow{k_8} C_4H_6 \text{ (butadiene)} \quad (8)$$

$$2C_2H_3 \xrightarrow{k_9} C_2H_4 + C_2H_2. \quad (9)$$

In order to assess accurately the contribution of these elementary processes, we would need a more complete product analysis and determination of intermediate radical. Here, however, we concentrate our concern on the mechanism of ethylene formation. We consider Reaction 1, 2, and 7 as essentially important in the ethylene formation, but we will briefly discuss the contribution of Reactions 6 and 9. Deactivation of Ar* by wall collision, two and three body quenching with Ar have been studied and discussed by several workers. Wall collision is in the diffusion regime, and the values for two body and three body quenching rate constants are not consistent but depending on the authors. Here in order to estimate the magnitude of these quenching processes under the present conditions, we calculated the sum of the rates of these three terms at 0.2 Torr of Ar (expressed as K),

$$K = (D/\Lambda^2 P) + k'[Ar] + k''[Ar]^2 = 1.5\times10^3\ s^{-1}, \quad (10)$$

where D is the diffusion rate of Ar at 1 Torr of Ar (54 Torr cm^2 s^{-1}), P is the pressure of Ar in Torr, Λ is the characteristic diffusion length given as $1/\Lambda^2=(\pi/l)^2+(2.4/R)^2$ (l: length of the reaction tube, R: radius of the reaction tube, both in mm).[18] For the values of k' and k'', we used the large ones from the reported values, that is, 6×10^{-15} cm^3 molecule^{-1} s^{-1} for k'[19] and 8.6×10^{-31} cm^6 molecule^{-2} s^{-1} for k''.[20] The concentration of Ar* decreases exponentially with travel time or travel length along the reaction tube:

$$[Ar^*] = [Ar^*]_0\exp(-(K+k_1[C_3H_6]+k_q[Q])t), \quad (11)$$

where $[Ar^*]_0$ is the concentration of [Ar*] at $t=0$.

Ionization processes of propylene and molecular formation of ethylene from propylene are disregarded. The reaction of propylene with Ar excimer is also neglected considering the excimer concentration is supposed to be much smaller than the Ar* concentration. Although the electronic state of the C_3H_6* formed through excitation transfer is not known, it may be a superexcited state locating above the first ionization level of propylene. The excited propylene may decompose either through a direct process or through a vibrationally excited ground state. Since the concentration of propylene is low, the rate of the deactivation process 6 may be slower than Reaction 5 and can be neglected. The disproportionation Reaction 9 is also neglected in consideration of the small magnitude of k_9 (5×10^{-12} cm^3 molecule^{-1} s^{-1}) at room temperature.[21] Our experimental finding that acetylene is not found as a product is consistent with this assumption.

According to the proposed reaction mechanism the derivation of the rate equations for C_3H_6*, C_2H_3, and C_2H_4 are straight-forward, assuming the local steady states for the concentrations of the intermediates. In order to solve the rate equations, the additional approximation of discarding the term $k_8[C_2H_3]^2$ is also introduced for mathematical convenience. Although k_8 must be larger than k_9, we believe that neglecting this term does not lead to any serious change in the present analysis of the kinetics.

In the flow system we need an expression for the integrated yield of ethylene as a function of residence time ($\tau=l/v$) which can be expressed as follows:

$$[C_2H_4]_q = \int_0^\tau k_7[C_2H_3][C_3H_6]dt$$

$$= \frac{k_1[Ar^*]_0[C_3H_6]}{(k_1[C_3H_6]+k_q[Q]+K)}(1-\exp(-k_7[C_3H_6]\tau)). \quad (12)$$

When we take a value of τ as 0.3 s, $[C_3H_6]$ as 10^{14} molecule cm^{-3}, and 10^{-14} cm^3 molecule^{-1} s^{-1} for the tentative value of k_7, the following approximation is possible:

$$[C_2H_4]_q \fallingdotseq \frac{k_1[Ar^*]_0[C_3H_6]}{(k_1[C_3H_6]+k_q[Q]+K)}k_7[C_3H_6]\tau. \quad (13)$$

This is consistent with our finding that the ethylene yield is nearly proportional to the propylene concentration in a limited low concentration range.

Bearing in mind that $K(\approx10^3\ s^{-1})$ is much smaller

TABLE 2. PRODUCT DISTRIBUTION IN THE REACTION OF Ar* WITH PROPYLENE, THE DIRECT PHOTOLYSIS, AND THE MERCURY-SENSITIZED PHOTOLYSIS OF PROPYLENE

Products	Present work	Direct photolysis			Hg-sensitized photolysis
	$Ar(^3P_2)$ + $Ar(^3P_0)$ (11.5 eV) (11.7 eV)	123.6 nm[a] (10.0 eV)	147.0 nm[b] (8.4 eV)	184.9 nm[c] (6.7 eV)	$Hg(^3P_1)$[d] (4.9 eV)

than $k_1[C_3H_6]+k_q[Q]$, when we take the ratio $[C_2H_4]_0/[C_2H_4]_q$ for a given propylene concentration, we obtain Eq. 3 as presented before.

Finally we have to admit that the proposed reaction mechanism does not cover all the reaction products. Ethane may be formed through the recombination of two methyl radicals, but the mechanism for propane formation is not certain. In the proposed mechanism the formation of allyl radical is assumed to take place by the abstraction of H atom from propylene, but we do not know the final destiny of the allyl radical. Further, we discarded the addition reaction of vinyl radical to propylene, although usually radical addition is faster than abstraction. In order to elucidate answers to these still unresolved problems we will need a more thorough product analysis in the future.

Reaction of Ar with Propylene in Comparison with the Direct and Mercury-sensitized Photolysis.* The comparison between the reaction of Ar* with propylene and the direct photolysis[22-25] and mercury-sensitized photolysis[26-28] would be interesting in order to see how the exciting energy and the exciting mode affect the reaction behavior of the excited molecule. In order to compare the reactions in detail we would need to know the electronic state of the excited molecule and the quantum yields of the primary processes or branching ratios. Our experimental results for the product analysis itself is incomplete, and most works on the far ultraviolet photolysis of propylene lack any estimation of the quantum yields of the primary processes. Furthermore, the results reported by the authors in two laboratories are not completely consistent. Bearing these points in mind, we give in Table 2 the relative yields of the final products normalizing the yields to ethylene yield, and discuss the reaction characteristics qualitatively. In the mercury-sensitized photolysis the yield of allene is distinct. Allene is probably formed through H atom abstraction by a $Hg(^3P_0)$ atom. The photolysis of propylene with 184.9 nm radiation was reported by Arai *et al.*[24] Acetylene, propane, allene, propyne and various C_4- and C_5- hydrocarbons are identified in addition to ethylene. Borrel *et al.*[25] also investigated the same photolysis. Their results are not completely consistent with the previous results, and they estimated the quantum yields of the primary processes as follows:

$$C_3H_6^* + h\nu \longrightarrow CH_2{=}CHCH_2 + H \qquad \phi = 0.41$$
$$\longrightarrow C_2H_3 + CH_3 \qquad \phi = 0.36.$$

They found that the quantum yields of the products decrease with the addition of an inert gases and ascribed this pressure effect to the participation of a Rydberg state as well as the valence bond excited state.

Becker *et al.*[22] studied the photolysis of propylene with 147.0 nm and 123.6 nm radiations and determined the relative yields of the products. Tsuikow-Roux[23] reinvestigated the photolysis at 147.0 nm and compared his results with the previous ones. In all these photolysis the formation of acetylene is confirmed, and with 147.0 and 123.6 nm radiations its yields exceed those of ethylene. Some portions of acetylene may be formed through a disproportionation reaction between two vinyl radicals. However, in order to explain acetylene yields that are twice or three times larger than ethylene yield in the direct photolysis at 147.0 and 123.6 nm, we must call for the direct formation of acetylene from excited propylene or of the decomposition of vibrationally excited ethylene as is assumed in the various reaction systems.[29] In view of the high excitation energy available in Ar*, it is rather unexpected that acetylene is not found in the products of Ar* reaction.

As a whole, the complete reaction system of Ar* with propylene appears to be simpler than that in the direct photolysis in spite of the comparable amounts of energy. One possible explanation for this simple reaction features may be due to the flow technique used in these experiments and the suppression of successive radical reactions by the rapid cooling of the reactant mixture to liquid nitrogen temperature. However, we would like to suggest that in the energy transfer reaction between metastable atoms and acceptor molecules only electron in the outer valence orbital may be subject to excitation,[30] while in the direct photolysis electrons both in outer and inner shells may be excited resulting in more violent or complicated

reaction pathways even if the amounts of the excitation energies are comparable. However, at present this suggestion remains speculative one and requires theoretical and experimental evidence.

The authors would like to express sincere thanks to Prof. Soji Tsuchiya and Dr. Seiichiro Koda of The University of Tokyo for their valuable discussions, and to Dr. Shiegeo Tsujimura for his kindness to give facilities for one of the authors (A.S.) to carry out a part of this study at Japan Atomic Energy Research Institute. The authors are also indebted to Prof. Yasuo Itoh and Prof. Rei Hirasawa of The University of Tokyo in the measurement and interpretation of the spin trapping ESR spectra, and to Prof. R. A. Loeliger of International Christian University for careful reading and revision of the manuscript.

Photodissociation Reaction from Higher Excited Triplet States of [2.2]Paracyclophane

Shun-ichi Ishikawa, Junko Nakamura,† and Saburo Nagakura*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

† *The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received September 3, 1980)

The mechanism of photodissociation of [2.2]paracyclophane in glassy solvent at 77 K was studied. It is concluded that the dissociation of the CH_2–CH_2 bridge occurs from higher triplet states (T_n) *via* the lowest triplet state as an intermediate. The efficiency of the reaction depends on the characters of T_n states; high from the locally excited state, and low from the charge-transfer state.

The electronic structure of [2.2]paracyclophane (PC) has been studied both experimentally and theoretically.[1] The most predominant character of the molecule is the transannular interaction. In PC, there exist two different kinds of excited states, the locally excited (LE) state within the constituent moieties, the benzene rings of PC, and the charge-transfer (CT) state. The LE and CT bands were observed in the $S_n \leftarrow S_0$ and $T_n \leftarrow T_1$ absorption spectra.[1] When PC is excited to different kinds of electronic states, photoreactions characteristic of respective states are expected to occur.

Helgeson and Cram studied photochemistry of PC in the alcoholic solution at room temperature.[2] From the analysis of photoproducts at various exciting wavelengths, they proposed an interpretation that the excitation to different singlet electronic states of PC produces different reaction intermediates.[2] In a previous paper,[3] we found that photodissociation occurred on the CH_2–CH_2 bridge of PC in glassy solvents at 77 K, and that a species with two benzyl radicals linked together ($H_2\dot{C}$–  –CH_2–CH_2–  –$\dot{C}H_2$) was produced. The reaction rate was found to be proportional to the square of the exciting light intensity.

In this paper, the relation between the reactivity and the nature of excited states of PC was investigated.

Experimental

PC and the solvents, 2-methylpentane (2-MP) and 2-methyltetrahydrofuran (MTHF), were purified by the same methods as described previously.[3] The samples with the concentration of 10^{-3} mol dm^{-3} in each solvent were degassed by freeze-pump-thaw cycles.

For photolysis of PC, the following exciting sources were used; a 1 kW super high-pressure mercury lamp (Pyrex and $NiSO_4$ solution filters for 313 nm light, and Toshiba UV-D33 S and UV 35 filters for 365 nm), a 500 W super high-pressure mercury lamp with a Jarrell-Ash 1/4 m monochromator, and a nitrogen laser (Molectron UV 24) pumped dye laser (DL 14). Dyes used are 2-(4-biphenylyl)-5-phenyl-1,3,4-oxadiazole (365—380 nm), 4,4‴-bis(2-butyloctyloxy)-*p*-quarterphenyl (380—395 nm), 2-(4-biphenylyl)-6-phenylbenzoxazole (395—405 nm), 4,4′-diphenylstilbene (405—415 nm), 1,4-bis(2-methylstyryl)benzene (415—425 nm), coumarin 120 (425—445 nm), and 7-diethylamino-4-methylcoumarin (445—450 nm). The intensity of the dye laser was monitored by the use of a power meter (Laser Precision RKP 312).

The optical alignment used for pursuing radical production from PC is of the parallel beam type[1b] (Fig. 1). An

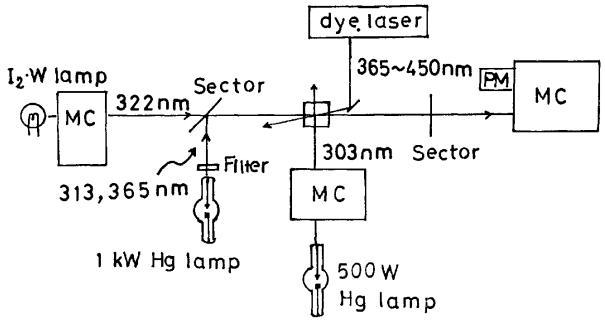

Fig. 1. Optical alignment used for the measurement of the reaction rate of PC.

exciting light (1 kW mercury lamp or dye laser) and a monitoring light were set to pass the same part of a sample. The wavelength of the monitoring light is 322 nm which corresponds to the absorption peak of the radical produced from PC.[3]

Results and Discussion

In the present study, experiments were made by using two different exciting light beams; a weak monochromatic light beam at 303 nm from a 500 W mercury lamp (first beam) and a strong light beam at 365 nm from a 1 kW mercury lamp (second beam). The second beam alone caused no reaction because PC has no absorption at 365 nm. With the use of the first beam only, the reaction occurs very slowly. With the simultaneous use of both beams, the reaction proceeds faster by an order of magnitude than with the use of the first beam alone. The reaction product is known to be $H_2\dot{C}$–  –CH_2–CH_2–  –$\dot{C}H_2$.[3] Since the produced radical is stable at 77 K, the relative reaction rate, R, can be defined by the absorbance change, ΔA, at an appropriate wavelength. Actually we measured ΔA at 322 nm corresponding to one of the peak wavelengths of the product. The reaction rate is proportional to the intensity of the second beam. This experimental result confirms that the reaction proceeds through an intermediate state.

In rigid media at 77 K, the most appropriate state for this intermediate is the lowest triplet state, T_1, which has a sufficiently long lifetime (a few seconds).

This is supported by the facts that the reaction occurs by the irradiations of the first and second beams with intervals of several seconds as well as by their

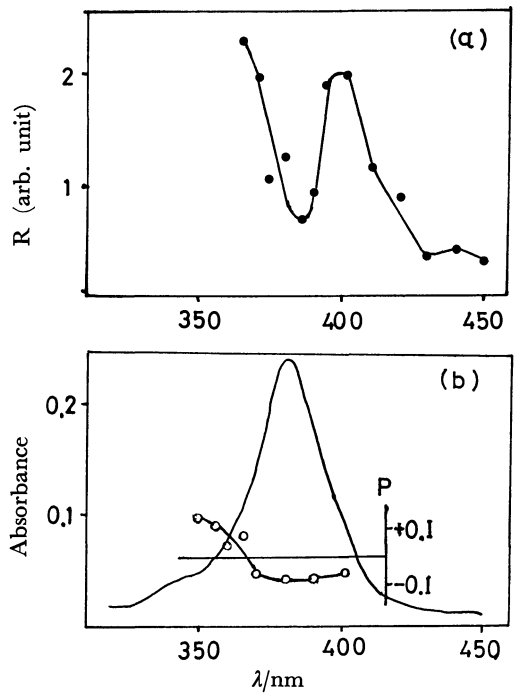

Fig. 2. (a) Dependence of reaction rate, R (ΔA (322 nm) s^{-1}), upon the wavelength of second exciting light. (b) $T_n \leftarrow T_1$ absorption spectrum of PC along with its polarization, P.

simultaneous irradiations and also that the reaction does not occur at room temperature at which the lifetime of T_1 is very short. From this veiw, the higher triplet states which are populated by $T_n \leftarrow T_1$ absorption are considered to be the reactive state of PC.

Several reactions show the biphotonic nature in the rigid media at low temperature; photoionization,[4] decomposition of solvent sensitized by solute,[4b] photoisomerization,[5] β-bond fission of substituted aromatics[6] and hydrogen abstraction from solvent.[7] The intermediate states of these reactions were found to be T_1.

In the next experiment, a weak 313 nm light (first beam) by which the reaction occurs to a negligibly small extent and a dye laser (second beam) were used for excitation. The dye laser beam is suitable for the present experiment since it is highly monochromatic (line-width is less than 0.01 nm) and the intensity per unit wavelength is high. Figure 2(a) shows the relative reaction rate (normalized to the second beam intensity) with 365—450 nm light as the second beam. The $T_n \leftarrow T_1$ absorption spectrum of PC and its polarization are also shown in Fig. 2(b).

In the present case where the first beam is weak, the concentration of the molecules populated in the T_1 state is small. Under these conditions, the reaction rate, R, is proportional to the second beam intensity, $I(\lambda)$, the molar extinction coefficient of $T_n \leftarrow T_1$ absorption, $\varepsilon(\lambda)$, and the reaction efficiency of the T_n state, $\phi_n(\lambda)$. Here λ is the wavelength of the second beam.

$$R \propto I(\lambda)\varepsilon(\lambda)\phi_n(\lambda).^{8)}$$

A plot of R *versus* λ in Fig. 2(a) shows the λ dependence of $\varepsilon(\lambda)\phi_n(\lambda)$, since the R values are normalized to the second beam intensity. We can see from this figure that the rate of radical production around 380 nm which corresponds to the maximum of the $T_n \leftarrow T_1$ absorption is smaller compared with the rate at the shorter and longer wavelengths. This means that ϕ is much smaller for the upper triplet state of the 380 nm band than for the neighboring triplet states.

The $T_n \leftarrow T_1$ absorption spectrum of PC was analyzed previously.[1b] According to the analysis, the upper state of the 380 nm band is the CT state and the LE states exist at the higher and lower energy sides. Therefore, it is reasonable to consider that the radical production occurs effectively from the LE state but ineffectively from the CT state. This indicates that the photoreactivity is sensitive to the electronic structure of the excited state from which the reaction occurs.

Pressure-induced Phase Transition and Compressive Behavior of Substituted Adamantanes

Kimihiko HARA,* Yoshikazu KATOU, and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

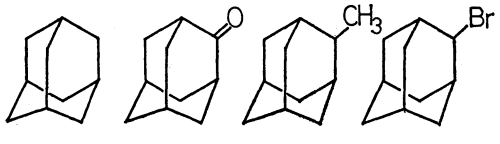
(Received September 11, 1980)

The compressive behavior of adamantane and its secondary monosubstituted derivatives; adamantanone, 2-methyladamantane, and 2-bromoadamantane was measured at various temperatures in a piston-cylinder apparatus. A first-order solid-solid phase transition was found under pressure in each system. The transition pressures, the equilibrium pressures, the volume changes, and the entropy changes for the transition were determined. The compression data for the low pressure phases were fitted to an equation of the form $-\Delta V/V_0=a_0+a_1P+a_2P^2$. The effects of substituent groups on the entropy changes of the transitions of these molecular crystals were discussed.

The first-order phase transitions undergone by crystals containing globular (or cage-like) molecules that form plastic crystals have been studied from various viewpoints. Adamantane is one of the few compounds whose phase transition is fully characterized at atmospheric pressure. This compound is known to undergo a phase transition under pressure from a disordered face-centered cubic (fcc) structure to an ordered body centered tetragonal structure,[1] which is the same as the temperature-induced transition at 208.62 K.[2,3] The transition pressure was determined as 4.8 kbar at 20 °C by X-ray measurement. The volume change for the transition ΔV is reported to be -1.8 cm^3 mol^{-1} at 4.1 kbar and 20 °C by Pistorius and Resing[4] and $-\Delta V/V_0$ is 1.4% at 4.1 kbar and 25 °C by Breitling, Jones, and Boyd.[5] For adamantanone and 2-methyladamantane, as reported in our previous papers,[6-8] the analogous phase transitions from fcc to tetragonal structure were found at high pressures. For 2-bromoadamantane the high pressure phase was not determined, although the atmospheric phase was fcc.

Such a simple crystal structure in the low pressure phase is not only due to the high symmetrical globular, cage-like molecular structure, but also due to the disordered phase, where the molecules are able to rotate rather freely[9] or to assume different and hence random orientation on the lattice sites. By the application of pressure the transition from the disordered phase to the ordered phase is expected.

We report here the pressure-induced phase transitions of adamantane, or tricyclo[3.3.1.1^{3,7}]decane (**1**) and its secondary monosubstituted derivatives, *i.e.* adamantanone (**2**), 2-methyladamantane (**3**), and 2-bromoadamantane (**4**).



1 **2** **3** **4**

Precise measurements were made of the pressures of the transitions and the volume changes of the transitions at various temperatures. The entropy changes were calculated. Such thermodynamic data characterize phase transitions and are particularly useful in interpreting solid-solid transformations in which order-disorder effects are predominant.

Experimental

Materials. Guaranteed-grade adamantane (**1**) (Nakarai Chem. Co.) was repeatedly recrystallized from light petroleum and dried *in vacuo*. Adamantanone (**2**) (Aldrich Chem. Co.) and 2-bromoadamantane (**4**) (Aldrich Chem. Co.) were recrystallized from ethanol. 2-Methyladamantane (**3**) was prepared from adamantanone by published procedures[10] and purified by recrystallization from ethanol. No impurity was detectable in gas-chromatographic analysis of the purified samples.

Measurements. The phase transitions and compression data were obtained in a piston-cylinder device, using a tungsten carbide piston and a 12 mm i.d., 50 mm o.d. cylinder of hardened maraging steel supported by Ni–Cr–Mo steel. The pressure was generated by a 60 t hydraulic press. Extrusion was prevented by the gasket rings which are made from hardened maraging steel. The oil pressure in the press was measured to about 0.1 bar by a 250 bar Heise bourdon gauge. A thin coat of Moly-Kote which was lubricated on the piston and inside of the cylinder as friction reducer has little effect on the transition pressures. The same sample length with a mass of about 1.54 g was used throughout. The transition pressure was affected by the sample length within *ca.* 9% for (**2**).

Each sample was precompressed to the maximum pressure before each run. The displacement of piston was measured by a dial micrometer accurate to $\pm$0.001 mm. It should

be mentioned that the correction was made for the compression of piston as a function of pressure. The effective area was taken as that of cylinder. The effect of elastic distortion of the cylinder on the volume is less than 0.7% at 10 kbar. The internal pressure was calibrated with I-II and II-III transitions of NH_4F, which is shown in Fig. 1. The transition pressures at 25 °C are 3.605 kbar and 11.531 kbar,† respectively.[11] The friction of this apparatus was symmetrical between compression and decompression cycles.

The sample temperature could be maintained to within better than ±0.1 °C by circulating the water of constant temperature into the outer jacket of the cylinder. The temperature was measured with a calibrated chromel-alumel thermocouple inserted in the cylinder.

Results

Every compound exhibits a discontinuous volume change at high pressure below 20 kbar, which indicates a first-order phase transition. The relative volume change $-\Delta V/V_0$ against pressure are shown in Fig. 2 (a), (b), (c), and (d) for (**1**), (**2**), (**3**), and (**4**), respectively. They are the results after correcting the friction of apparatus. The curves represent the best fit passing through the experimental points. The inflection point was used to characterize the transition pressure P_t, and the equilibrium pressure P for transition was taken as the average between the transition pressures for the compression and decompression cycles. The volume change at the transition ΔV_t was obtained by extrapolating the compression curve to the inflection pressure and measuring the difference of displacement. The volume change for the transition ΔV was determined as the average

a) DSC data at atmospheric pressure.

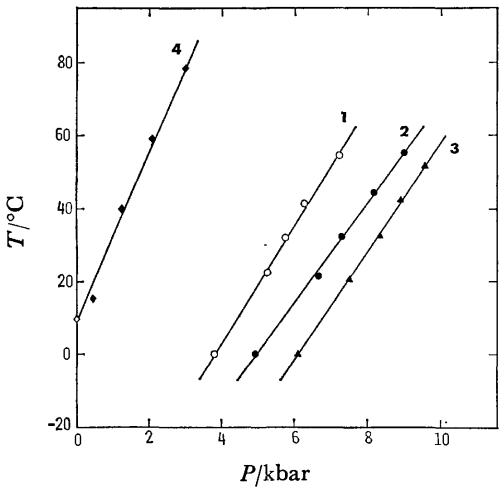

Fig. 3. Phase diagrams of **1**, **2**, **3**, and **4**.

between the volume changes at the transition pressure in compression cycle P_t and that in decompression cycle P_t', *i.e.* $1/2(\Delta V_t+\Delta V_t')$, which is shown in Fig. 2 (b). The volume changes of the transition were determined to an accuracy of 0.2 cm³ mol⁻¹. The transition pressures, the equilibrium pressures, and the volume changes for the transitions at various temperatures are summarized in Table 1. The transition pressure for (**1**), which has been determined previously from X-ray measurements as 4.8 kbar at 20 °C,[1] is in reasonable agreement with the present equilibrium pressure of 5.1 kbar at 20 °C. But the values of the transition pressure and the volume change reported by Pistorius *et al.*[4] and by Breitling *et al.*[5] are a little lower than those of the present work. Hysteresis, the reproducible difference in the transition pressure between compression and decompression cycles, ΔP is quite large for (**2**), as compared with other compounds. Its temperature dependence was not beyond the experimental errors.

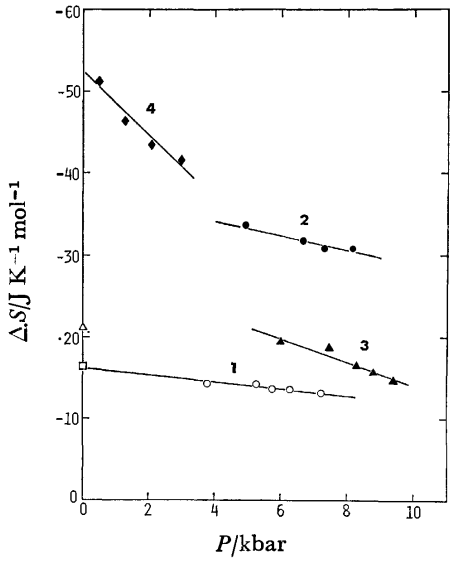

Fig. 4. Entropies of transitions against pressure.

The obtained phase diagrams are shown in Fig. 3. The slopes (dP/dT) of the equilibrium lines were obtained by means of least square fit. They were used in conjunction with ΔV to determine the entropies and enthalpies of transitions by the Clausius-Clapeyron equation.

The transition temperature of 14.0 °C for (**4**) at atmospheric pressure was determined by the differential scanning calorimetry (dsc).

The entropy changes ΔS and enthalpy changes ΔH of the transitions are listed in Table 1. The values of ΔS are plotted against the pressure in Fig. 4. The value of ΔS for (**1**) obtained from the dsc at atmospheric pressure by Chang *et al.* (16.2 J K⁻¹ mol⁻¹)[12] is just on the extrapolated line of the present data. As for (**3**) the value from the dsc by Clark *et al.*[13] is smaller than the extrapolated value.

Discussion

It is interesting to note that by the application of pressure all of the secondary monosubstituted adamantanes examined here, which have disordered fcc structure at atmospheric pressure, undergo the phase transitions to ordered body centered tetragonal structure. The structural results were reported previously.[7,8] We found that (**4**) underwent the corresponding phase transition at atmospheric pressure and that the phase diagram could be determined to atmospheric pressure. Presumably, for both (**2**) and (**3**) the temperature-induced transition with the same structural change will appear at low temperature on the extrapolated line of the phase diagram just in the similar way as (**4**).

Figure 4 indicates that ΔS increases with pressure, *i.e.*

$$\frac{\partial \Delta S}{\partial P} = \frac{\partial S(\mathrm{h})}{\partial P} - \frac{\partial S(\mathrm{l})}{\partial P} > 0,$$

where $S(\mathrm{h})$ and $S(\mathrm{l})$ refer to the entropy of high pressure phase and that of low pressure phase, respectively. This means a normal phenomenon that the pressure dependence of entropy is higher in the low pressure phase than in the high pressure phase, since $(\partial S/\partial P)<0$ for the most substances. On the other hand, we can see in Table 1 that the temperature dependence of ΔH, which indicates ΔC_p, is too small to find a comprehensive trend.

Compressibility and Crystal Density of Low Pressure Phase. The compression data of the low pressure phases at around 20 °C shown in Fig. 2 were fitted to the following equation by using the method of least squares.

$$\mathbf{1}: \quad -\frac{\Delta V}{V_0} = 1.94\times10^{-3} + 2.26\times10^{-5}P - 1.22\times10^{-9}P^2,$$

$$\mathbf{2}: \quad -\frac{\Delta V}{V_0} = 5.80\times10^{-3} + 1.93\times10^{-5}P - 0.83\times10^{-9}P^2,$$

$$\mathbf{3}: \quad -\frac{\Delta V}{V_0} = 1.85\times10^{-3} + 2.80\times10^{-5}P - 1.51\times10^{-9}P^2,$$

where V_0 is the volume of the crystal under atmospheric pressure and the unit of P is bar. For (**4**) the transition pressure was too low to get the reliable compression data of low pressure phase. The initial compressibility β_0, which is given by

$$\beta_0 = -\frac{1}{V_0}\left(\frac{\mathrm{d}V}{\mathrm{d}P}\right)_{P=0},$$

and the crystal density that was obtained from the measurement of the sample size are listed in Table 2. The size of the unit cell and the crystal desity calculated from X-ray data are also included in Table 2. The agreement between both data of the crystal density is satisfactory. We can find a correlation that the higher compressibility corresponds to the structure with the larger unit cell parameter, or the loose structure. This correlation may confirm an evidence that in molecular crystals hydrostatic compression causes the contraction of intermolecular free volume in the crystal especially in an early stage of compression and that the contraction of molecules themselves (or electron clouds) is negligible in the first approximation.

Table 2. Initial compressibility and crystal density

Compound	Initial compressibility β_0 / 10^{-6} bar^{-1}	Crystal density ρ / g cm^{-3}

3	28.0	1.03	0.99
4	—	1.43	1.40

a) Determined in the present work. b) Calculated from the X-ray data.

Entropy of Transition. Much information has been obtained about the disordered phases of molecular crystals from the entropies of transition.[14] There has been an attempt to interpret the entropy of transition of caged hydrocarbon crystals in terms of the Guthrie-McCullough method[15] which is treated for simple tetrahedral molecules and is based on sets of equivalent, distinguishable molecular orientations obtained by combining the symmetry elements of the crystal lattice with the symmetry elements of the molecule. In this method the orientational disorder is assumed to account for the entropy of transition entirely, all other effect being negligible. This treatment, however, includes some oversimplifications and is invariance with various experimental results except for some typical examples. Clark *et al.*,[13,16] on the other hand, proposed that the lattice slackening and other effects contribute a significant proportion of the entropy of transition and separated this contribution as excess entropy $\Delta S_{\mathrm{excess}}$ from the orientational entropy.

$$\Delta S = R \ln (N_{\mathrm{I}}/N_{\mathrm{II}}) + \Delta S_{\mathrm{excess}},$$

where N_{I} is the number of molecular orientational states statistically occupied in the low pressure disordered phase, N_{II} is the corresponding number in the high pressure ordered phase which is usually unity, and R is the gas constant.

Adamantane is a simple polycyclic saturated hydrocarbon with carbon atoms arranged in a cage-like skelton and has tetrahedral symmetry. Its orientational entropy change based on the Guthrie-McCullough method is $R \ln 2 = 5.8\ \mathrm{J\ K^{-1}\ mol^{-1}}$, since two distinguishable orientations are allowed in the disordered phase. By comparing with the observed entropy of transition (14.1 J K^{-1} mol^{-1} at 22.4 °C), 8.3 J K^{-1} mol^{-1} is the excess entropy of transition.

By the analogous application of this method, the orientational entropy change of adamantanone should be $R \ln 12 = 20.7\ \mathrm{J\ K^{-1}\ mol^{-1}}$, since there are six orientations in each one of adamantane. Thus, the excess entropy of 11 J K^{-1} mol^{-1} is obtained by comparing with the observed entropy of transition (31.7 J K^{-1} mol^{-1} at 21.5 °C). This is in accord with the result of Clark *et al.*[16] that the excess entropy is 10—

15 J K^{-1} mol^{-1}. Namely, the most part of the difference between the transition entropies of adamantane and adamantanone is originated from the difference in the orientational entropy change.

In the case of (**3**) and (**4**), on the other hand, there are two further distinguishable orientations in each one of (**2**), so that the orientational entropy change should be R ln 24=26.4 J K^{-1} mol^{-1}. If we compare the orientational entropy of (**4**) with the observed entropy of transition (51.3 J K^{-1} mol^{-1} at 20.0 °C), the excess entropy becomes 25 J K^{-1} mol^{-1}. This value is beyond the range proposed by Clark *et al.*, although the larger value is expected for the compounds having the larger substituents. By the application of the semiempirical equation of Clark *et al.*, since the temperature range for the orientational disordered phase, $T_m - T = 129$ °C is obtained at atmospheric pressure, we get a little lower excess entropy of 16.6 J K^{-1} mol^{-1}. As for (**3**), the value of the observed entropy is much lower than that would be expected. This abnormality may come from the fact that has been pointed out by Clark et al. Thus, the obtained order of ΔS_{excess} is (**4**)<(**1**)<(**2**)<(**3**).

The values of ΔS_{excess} can be explained if we take the effects of intermolecular ordering and intermolecular forces into account. The value of ΔS_{excess} of (**2**) is greater than that of (**1**), although they have almost the same molecular size, and hence must have similar intermolecular ordering. The same is the case for the larger value in (**4**), as compared with (**3**). Thus, we can propose that the dipolar interactions in the ordered crystal are considerably more favorable than those in the disordered phase, increasing ΔS_{excess}. The intermolecular ordering effect is another striking effect that must be considered. Large substituent groups loosen the ordered crystal lattice. This would be the reason why the values of ΔS_{excess} of (**1**) and (**3**) are smaller than (**2**) and (**4**), respectively. We can say conclusively that the molecules with the more sphericity and the higher dipole moment can give more stable ordered crystal.

We wish to thank Dr. Yoshihiro Taniguchi of Ritsumeikan University for measuring dsc of (**4**) and Mr. Fujitsugu Amita of this university for his technical assistance.

Influence of Chemisorption of 2-Propanethiol on the Electrical Properties of Silver Oxide Compaction

Naoto YAMAMOTO,* Shoichiro TONOMURA, Tsugufumi MATSUOKA, Takashi AMAMIYA, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received September 18, 1980)

The work function of silver oxide (Ag_2O) decreased by as much as 0.8 eV on exposure to 2-propanethiol [$(CH_3)_2CHSH$]. The change in work function was irreversible at room temperature, and proportional to the amount of thiol in case where the partial pressure is low, but reversible at 200 °C. The conductivity of the Ag_2O disk showed no substantial change by exposure to thiol. From the infrared absorption spectral studies, it was found that the thiol reacted with the silver oxide forming a $(CH_3)_2CH$–S–Ag group on the surface. The relationship between the work function and the chemical processes occurirng at the solid surface is discussed.

Recently, the employment of semiconductors for specific detection of gases taking advantage of the change in electric conductivity has been attempted by many authors.[1–5] Concerning the mechanism in such systems, it is essentially important to clarify how the electrical properties of the semiconductors are correlated with chemical processes occurring at the solid-gas interface. From this point of view, we have studied the influence of gases on the surface potentials and other electrical properties of metals and metal-semiconductor assemblies.[6] The surface potentials have also been studied for electrodes chemically modified with antibodies or enzymes. The change in electrode potentials by specific reactions between biological substances at the electrode-solution interface[7,8] has been found to be capable of serving as a sensitive device for analysis of these substances.

In this work, the effect of thiol gas on the electrical properties of silver oxide in the form of compaction (compressed powder) or thin film has been investigated. It has been found that the conductivity is insensitive, but the surface potential is very sensitive to the gas. The results are discussed in relation with informations obtained on the chemical processes on the solid surface from infrared absorption measurements.

Experimental

Materials. Copper plate, 99.9% pure, 1 mm thick, was used as the reference electrode, or the substrate for evaporated metal films. The purities of Ag, Fe, Ni, Pd, and Al used were higher than 99.9%. 2-Propanethiol gas used was evolved from the liquid 98% pure 2-propanethiol, obtained from Tokyo Kasei Kogyo Co. The silver oxide powder 99.9% pure, having the grain size of about 0.5 μm, was obtained from Kishida Chemical Co.

Procedure. The contact potential of the silver oxide samples against copper was measured by use of a vibrating capacitor method.[9] The experimental setup is schematically shown in Fig. 1. The metal to be studied, Ag, Fe, Ni, Pd, or Al, was evaporated on a Cu plate at 2×10^{-5} Torr (1 Torr=133.322 Pa). Silver oxide powder, 1.0 g in weight, was compressed at 150 kg/cm² into a disk form and the disk was attached onto a Cu plate with silver paste.

The reference electrode, a semicircular Cu plate 15 mm in radius, was rotated with a speed of 30 Hz by use of a synchronous motor. The space between both electrodes was adjusted with a micrometer to *ca.* 0.2 mm. The ac current arising from the capacity change between the electrodes was measured by use of a Teledyne Philbrick 1702 parametric amplifier and an NF LI-573 lock-in-amplifier. The contact potential between these electrodes was determined by employing the null current method with the aid of a potentiometer. The electrodes were kept in a box, 7 l in capacity. For electric conductivity measurements, gold was vacuum-evaporated onto the silver oxide disk as shown in Fig. 2.

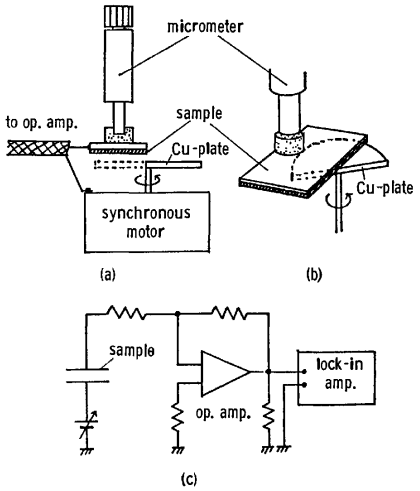

Fig. 1. Schematic representation of the experimental setup for contact potential measurements: (a) a front view and (b) a bird's-eye view. (c) The electric circuit.

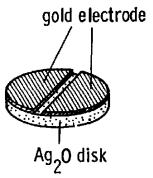

Fig. 2. The Ag_2O disk used for measuring its electric conductivity.

Infrared spectra were measured by use of a JEOL JIR 10 Fourier transform infrared spectrometer. Silver film to be measured was prepared by vacuum-deposition onto a NaCl disk, the transmittance of the film being 40% at 600 nm.

Results and Discussion

Surface Potential of Ag_2O. The average contact potential difference between an Ag_2O disk and a

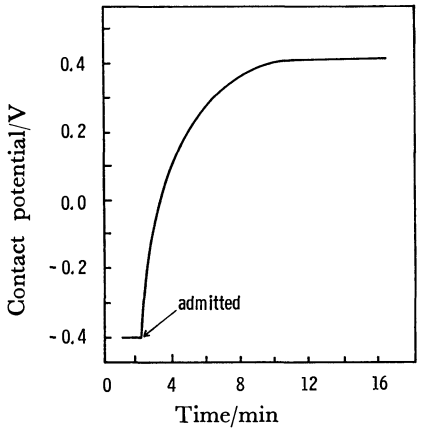

Fig. 3. The response in the contact potential of the Ag_2O disk to 2-propanethiol at room temperature.

copper reference electrode was found to be −0.40 V, when measured in air, indicating that the work function of Ag_2O is 0.40 eV larger than that of the copper electrode. The copper electrode is presumably covered with a thin copper oxide film in air and the absolute value of its work function cannot be determined directly by the capacitor method.

Figure 3 shows the change in the contact potential caused by admission of 5.0×10^{17} molecules of 2-propanethiol, into the box. The potential increased from −0.40 V to +0.40 V and became constant after about 10 min. No change in potential was observed by dissipating the gas into open air. When a disk previously exposed to thiol was heated at 200 °C in air, the potential decreased and returned to the value of unexposed Ag_2O, −0.40 V. These changes in potential are obviously due to chemisorption of the thiol on the Ag_2O surface.

It was confirmed from the following experiment that the work function of the copper reference did not change by the introduction of 2-propanethiol: First, the thiol gas was introduced into the box. The contact potential of the Ag_2O disk against the copper electrode changed as shown above. After that, the gas was removed from the box and only the Ag_2O disk was replaced by a new Ag_2O disk. The contact potential between the new disk and the copper electrode exposed to the gas showed the same value as that obtained between fresh Ag_2O and Cu electrodes in air. On replacement of the disk by a new copper plate, the contact potential was almost zero between the new and the gas exposed copper electrode. These experimental results indicate that the change in surface potential of Cu plate by exposure to thiol is negligible.

The induced potential is plotted against the amount of 2-propanethiol admitted into the box (Fig. 4). In the low partial pressure region, it is proportional to the amount of thiol introduced, but gradually saturated at higher pressure region.

The work function, ϕ, of Ag_2O, corresponding to the energy required to transfer an electron from its Fermi level to vacuum, is determined from our experiment in air as 5.6 eV, taking the work function of copper to be 5.2 eV that was obtained in the presence of oxygen.[10,11] Before chemisorption, the po-

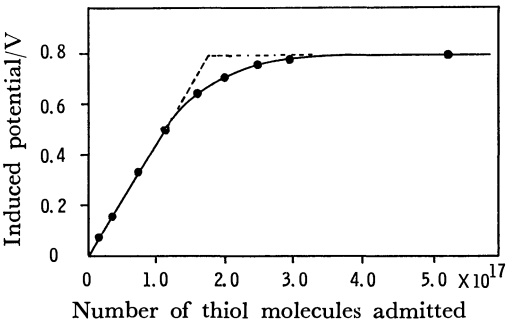

Fig. 4. The induced change of potential of the Ag_2O disk against the amount of 2-propanethiol introduced.

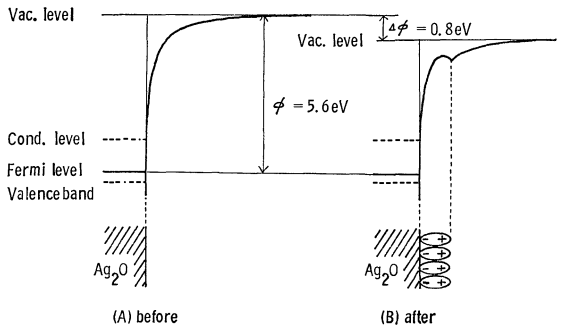

Fig. 5. Schematic energy diagrams of the Ag_2O disk near the surface before and after the introduction of 2-propanethiol gas.

tential for an electron near the disk surface may be described as shown in Fig. 5(A)[12] by taking account of the image force. The chemisorbed thiol will form an electric dipole on the Ag_2O surface (Fig. 5(B)). The potential can, then, be expressed by the superposition of the image force and electric double layer potentials as illustrated, lowering the vacuum level outside the Ag_2O surface by $\Delta\phi=0.8$ eV at its maximum.

The electrical behavior of a silver film against the gas introduction was almost similar to that of Ag_2O disk. The contact potential difference of the evaporated silver film was −0.25 eV against a copper reference electrode in air. The magnitude of surface potential change was 0.45 eV by admission of 5.0×10^{17} molecules of 2-propanethiol. The surface of the Ag film is presumably covered with a thin film of the oxide in air, and therefore the chemisorption mechanism on the film is essentially the same as on the Ag_2O disk.

As described earlier the changes in surface potential resulting from the reaction of 2-propanethiol can be explained by taking account of the induced dipole moment, $\Delta\mu$, by the chemisorption. The electrical potential, $\Delta\phi$, owing to the double layer formation is expressed by the following equation.

$$\Delta\phi = -\Delta\mu\cdot N/\varepsilon_0 \qquad (1)$$

Where N is surface density of the chemisorbed thiol and ε_0 is permittivity of vacuum. An 2-propanethiol molecule has a cross section of about 26 Å^2. Then, taking $\Delta\phi=0.8$ V, the highest value obtained, and $N=3.7\times10^{18}$ m^{-2}, calculated from the closest array

a) Taken from Ref. 14.

of thiol molecular layer on the surface, $\Delta\mu$ is calculated to be 0.57 D, which seems to be a reasonable value in view of the dipole moment of 2-propanethiol molecule, 1.64 D, in liquid state.[13)]

Crystalline Ag_2O has a body centered cubic structure, where four silver atoms exist in a unit cell and its lattice constant is 4.72 Å. If the unit cells are assumed to align regularly at the surface, the cross-sectional area of 2-propanethiol is comparable to that of a unit cell of Ag_2O, so that approximately one of the four silver atoms in the cell can react with the thiol.

As up to *ca.* 4.0×10^{17} molecules of 2-propanethiol is capable of changing the disk surface potential, the actual area of the disk surface is estimated to be 0.1 m^2 under the assumption of monomolecular chemisorption. The radius of the grain of Ag_2O powder is *ca.* 0.25 μm, so that the total surface area of the powder of 1 g is calculated to be *ca.* 1.7 m^2 before making the disk. Such a decrease in the surface area seems reasonable as a result of compression in the process of disk formation.

The Pd electrode shows very high response to hydrogen gas as described in a previous paper.[6)] The Ag_2O electrode was, however, insensitive to hydrogen or carbon monoxide, but showed a small response to water and carbon dioxide. The electrode of Ni or Al had no response to the thiol up to the concentration of 2.5 ppm. The potential of the electrode of Fe changed by 23 mV with 0.3 ppm thiol.

Electrical Resistance of Ag_2O. The electrical resistance of an Ag_2O disk in a 1.0 mm gap between gold electrodes (Fig. 2) was *ca.* 6.5 MΩ in air at room temperature. No change in electrical resistance was observed as 1.0×10^{18} molecules of 2-propanethiol was introduced into the box. This fact indicates that the conductivity is mostly through the bulk of Ag_2O disk, and is not affected by the chemical processes occurring at the solid surface.

Infrared Spectra of 2-Propanethiol Adsorbed on Ag and Ag_2O. Infrared absorption spectrum was measured for the thiol adsorbed on an Ag_2O disk, 0.1 mm thick, and the band positions observed are shown in column 1 of Table 1. The IR spectrum measured for thiol adsorbed on a silver film evaporated on a sodium chloride disk (Fig. 6) gives more clear bands than on the Ag_2O disk. The spectrum was taken from fifty sweeps of transmittance measurements at room temperature. The negative absorption at around 2349 cm^{-1} is due to carbon dioxide present in air. Even after allowing to stand for 8 d in contact with air, the film showed almost the same spectrum as that in Fig. 6. The absorption peak positions are also listed in column 2 of Table 1. These assignments given in the last column in Table 1 were based on the spectral data obtained for gaseous 2-propanethiol by Smith and Devlin.[14)]

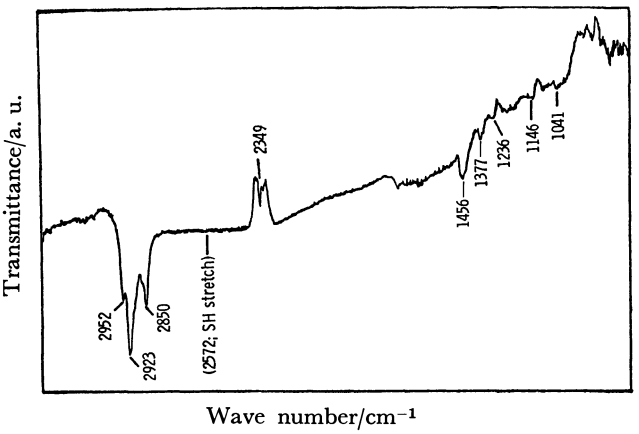

Fig. 6. Infrared absorption spectrum of Ag film exposed to the thiol gas.

The adsorbed thiol on the silver film shows several bands ascribable to CH_3 symmetric and unsymmetric stretchings at 2850 and 2952 cm^{-1}, CH wagging at 1236 cm^{-1} and CH stretching at 2923 cm^{-1}, but does not show any absorption at 2572 cm^{-1} where gaseous 2-propanethiol shows a band assigned to the S–H stretching. It was also confirmed that the infrared spectrum of silver 2-propanethiolate powders synthesized by the reaction of 2-propanethiol and $AgNO_3$ in solution is essentially the same as that shown in Fig. 6 (column 3 of Table 1). These results indicate

that most of the chemisorbed molecules are dissociatively adsorbed as follows,

$$RSH \longrightarrow RS\cdots\overset{|}{\underset{|}{Ag}} + (H).$$

It can thus be concluded that the potentiometric response of the silver oxide disk arises predominantly from the surface potential change due to the chemisorption, and that the electric property of bulk is little affected by the change of the surface structure.

Vanadium(V) can be quantitatively extracted from an aqueous solution into carbon tetrachloride as the ion-association system formed between its Pyrocatechol Violet complex anion and tridodecylethylammonium salt. The optimum pH range for the extraction is around 5. The ternary complex has an absorption maximum at 570 nm in the organic layer. The distribution ratio and the molar absorptivity are 1.78×10^2 and 4.0×10^4 l mol^{-1} cm^{-1} respectively. Omitting the other adducts which may be combined with vanadium, the composition of the ternary complex is estimated to be $V(PV)_2(R_3R'N)_2$. The extraction constant is given by log K_{ex}= 12.58. The interference of foreign ions is discussed, too.

The extraction of the ionic associates formed between metal-complex anions with bulky organic cations offers bright prospects of the separation of many metals, because the extraction of the ionic associates usually proceeds rapidly and the miscellaneous metal-complex anions are widely extracted under various conditions. Vanadium can be extracted with 8-hydroxy-5-quinolinesulfonic acid–zephiramine,[1] tiron–diphenylguanidine,[2] *o*-mercaptobenzoic acid–pyridine,[3] Bromopyrogallol red–diphenylguanidine,[4] 3-methylcatechol–dodecyltrimethylammonium,[5] 4-(2-thiazolylazo)resorcinol–trioctylamine,[6] 4-(2-pyridylazo)resorcinol(PAR)–nitron,[7] ascorbic acid–methyltrioctylammonium,[8] thiocyanate–pyridine,[9] ferron–tribenzylamine,[10] Pyrocatechol Violet(PV)–1,10-phenanthroline,[11] PV–diphenylguanidine,[12] pyrocatechol–aniline,[13] thiocyanate-diantipyrylmethane,[14] thiocyanate–N^2-hydroxy-N',N'-diarylbenzamidines,[15] and PAR–zephiramine[16] systems. In the process of investigating the extraction of the metal–PV complex anions with tridodecylethylammonium bromide (TDEABr), we ourselves previously reported on the extraction systems for copper,[17] tin,[18] aluminium,[19] zirconium,[20] niobium,[21] and iron.[22] The vanadium(V)–PV complex also can be extracted with TDEABr in carbon tetrachloride around pH 5. In this paper, the extraction equilibrium and the fundamental conditions will be discussed for extracting the vanadium(V)–PV complex with TDEABr.

Experimental

Reagent. A 2.5×10^{-3} mol/l vanadium(V) solution was prepared by dissolving a definite amount of ammonium vanadate(V) in a 0.25 mol/l surfuric acid solution. The solution was then diluted as required. A 5×10^{-4} mol/l PV solution was prepared by dissolving the Dotite PV in de-ionized water without further purification. TDEABr was prepared by the method described in a previous work.[22] A 5×10^{-3} mol/l TDEABr solution was prepared by dissolving TDEABr in purified carbon tetrachloride. A 2 mol/l sodium acetate solution was used as the buffer solution. All the other chemicals used were of a guaranteed reagent quality.

Apparatus. A Hitachi 101 spectrophotometer, a Hitachi 200-20 UV-VIS recording spectrophotometer, and a Hitachi Horiba F-7 pH meter were employed.

Standard Procedure. Up to 5 μg of vanadium(V), a definite amount of 1 mol/l sulfuric acid, and 3 ml of a 5×10^{-4} mol/l PV solution were mixed in a 100-ml polypropylene beaker. The pH of the solution was adjusted to 5 by the addition of 2 ml of a 2 mol/l sodium acetate solution, and then the solution was diluted to 20 ml with de-ionized water. The solution was transferred into a 35-ml test tube, and 5 ml of 5×10^{-3} mol/l TDEABr in carbon tetrachloride was added. The extraction was carried out for 5 min by turning the test tube upside down twice every 5 s. After the phase separation, the organic layer was taken out and centrifuged for 2 min at 3000 rpm. The extract was then transferred into an absorption cell, and the absorbance at 570 nm was measured against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. Figure 1 shows the absorption spectra of the ternary complex extracted into carbon tetrachloride, of the vanadium(V)–PV complex anion in an aqueous solution, and also of the respective blank solutions. As is evident from Fig. 1, the ternary complex and the vanadium(V)–PV complex anion have their absorption maxima at 570

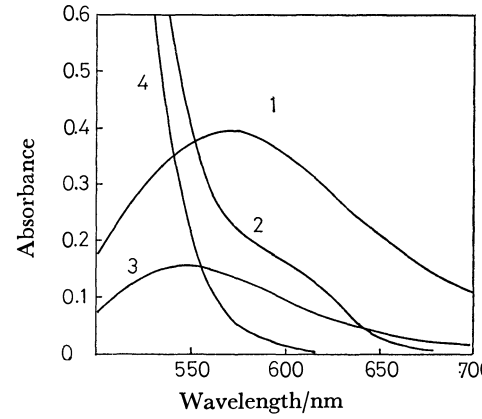

Fig. 1. Absorption spectra of the V–PV–TDEA in carbon tetrachloride and the V–PV complexes in aqueous solution.
pH=5.0, $[TDEABr]_o=5\times10^{-3}$ mol/l, $V_{aq}=20$ ml, $V_o=5$ ml.
1: V–PV–TDEA in carbon tetrachloride $[V]=2.5\times10^{-6}$ mol/l, 2: V–PV in aq soln $[V]=1\times10^{-5}$ mol/l, 3: PV–TDEA in carbon tetrachloride $[PV]=7.5\times10^{-5}$ mol/l, 4: PV in aq soln $[PV]=3\times10^{-4}$ mol/l.

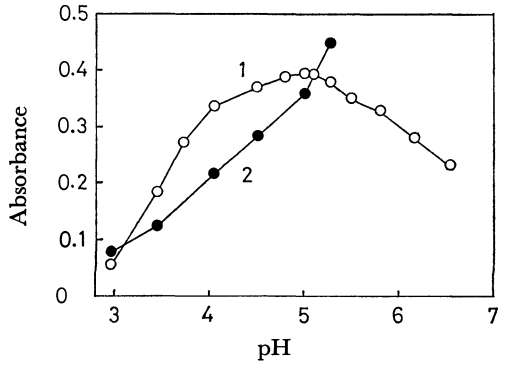

Fig. 2. Effect of pH on the extraction of the V–PV–TDEA complex.
$[V]=2.5\times10^{-6}$ mol/l, $[PV]=7.5\times10^{-5}$ mol/l, $[TDEABr]_o=5\times10^{-3}$ mol/l, 570 nm.
1: V–PV–TDEA, 2: PV–TDEA.

nm and 550 nm respectively. As compared with the corresponding absorption maximum of the complex anion, that of the ternary complex is shifted toward wavelengths longer by 20 nm. The increase in the absorbance at the absorption maximum in the case of the ternary complex over the absorbance of the binary complex is considerable. PV itself is readily extracted from an aqueous solution by TDEABr in carbon tetrachloride.

Effect of pH. Figure 2 shows that the extraction of the ternary complex starts about pH 3, reaches a maximum around pH 5, and thereafter decreases gradually. The extract is stable for at least 30 min.

Organic Solvents. Of the solvents examined, carbon tetrachloride, butyl acetate, chloroform, and benzene are suitable for the quantitative extraction of the ternary complex. The absorbance of the extract is maximal when the carbon tetrachloride is used.

Effect of the Reagent Concentration. The variation in the absorbance was investigated as a function of the PV concentration in an aqueous solution and as a function of the TDEABr concentration in carbon tetrachloride for extracting the ternary complex. The optimum concentration range or PV is from 6×10^{-5} mol/l to 1.25×10^{-4} mol/l. Besides, the concentration range of TDEABr for the quantitative extraction is from 4×10^{-4} mol/l to 5×10^{-3} mol/l.

Extractability and Molar Absorptivity. An aqueous solution of 20 ml containing 6.37 μg of vanadium(V) and 3 ml of 5×10^{-4} mol/l PV was shaken with 5 ml of 5×10^{-3} mol/l TDEABr in carbon tetrachloride under optimum conditions. Extraction was repeated for the remaining aqueous phase after the separation of the extract. The extractability of vanadium(V) was calculated from the absorbances of the extracts. It was found that 97.8% of the vanadium(V) was extracted by one extraction. The distribution ratio and the molar absorptivity were 1.78×10^2 and 4.0×10^4 l mol^{-1} cm^{-1} respectively. A calibration curve for the determination of vanadium(V) was made under optimum conditions. A good linear relationship is obtained over the concentration range from 0.25 μg to 5 μg of vanadium(V) per 5 ml of carbon tetrachloride. The coefficient of variation of ten measurements was 3.9%.

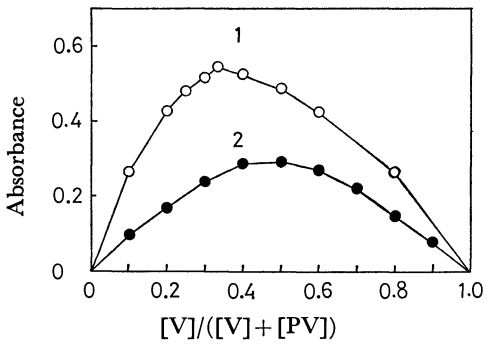

Fig. 3. Continuous variation method applied to the V–PV–TDEA and the V–PV complexes (V:PV).
1: V–PV–TDEA; $[V]+[PV]=1\times10^{-4}$ mol/l, $[TDEABr]_o=5\times10^{-3}$ mol/l pH=5.0, 570 nm. 2: V–PV; $[V]+[PV]=1\times10^{-4}$ mol/l, pH=5.0, 550 nm.

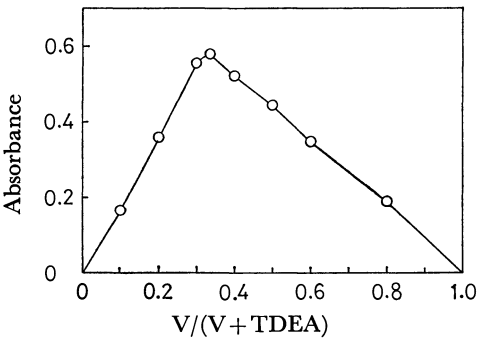

Fig. 4. Continuous variation method applied to the V–PV–TDEA complex (V:TDEA).
$V\text{–}PV+TDEA=1.5\times10^{-6}$ mol, pH=5.0, 570 nm.

The Composition of the Ternary Complex. The estimate of the composition of the complexes was attempted by means of the continious-variation method. Figure 3 shows that the mole ratios of vanadium(V): PV in the ternary complex and in the vanadium(V)–PV complex anion were found to be 1:2 and 1:1 respectivery. Figure 4 shows the mole ratio of vanadium(V): TDEA to be 1:2. Thus, the composition of the ternary complex is estimated to be $V(PV)_2(R_3R'N)_2$.

Extraction Constant. When the ionic associate of the vanadium(V)–PV complex anion with the TDEA cation is extracted in the organic layer, the extraction equilibrium may be expressed by the following equation:

$$V(PV)_2^{2-} + 2R_3R'N^+ = V(PV)_2(R_3R'N)_{2(o)}, \quad (1)$$

where we omit the other adducts which may be combined with vanadium. The extraction constant, K_{ex}, is given by:

$$K_{ex} = \frac{[V(PV)_2(R_3R'N)_2]_o}{[V(PV)_2^{2-}][R_3R'N^+]^2}, \quad (2)$$

where the subscript o denotes the organic layer. An attempted direct determination of each concentration of the components in Eq. 1 was unsuccessful, for the pure ternary complex can not be prepared easily. The equilibrium in Eq. 1 can be represented by the following two steps:

$$V(PV)_2^{2-} + 2R_3R'N\cdot NS_{(o)} = V(PV)_2(R_3R'N)_{2(o)} + 2NS^- \quad (3)$$

$$K = \frac{[V(PV)_2(R_3R'N)_2]_o[NS^-]^2}{[V(PV)_2^{2-}][R_3R'N\cdot NS]_o^2}, \quad (4)$$

where NS denotes 2-naphthalenesulfonic acid.

$$NS^- + R_3R'N^+ = R_3R'N\cdot NS_{(o)} \quad (5)$$

$$K'_{ex} = \frac{[R_3R'N\cdot NS]_o}{[NS^-][R_3R'N^+]}, \quad (6)$$

Thus, K_{ex} is given by

$$K_{ex} = K \times (K'_{ex})^2. \quad (7)$$

The concentration of the $V(PV)_2(R_3R'N)_{2(o)}$ species in Eq. 3 was determined spectrophotometrically as a function of $[NS^-]$, and the value of K was calculated from Eq. 4. The extraction constant, K'_{ex}, of $R_3R'N\cdot NS$ in Eq. 6 was also determined from the extraction equilibrium between $R_3R'N\cdot NS$ in CCl_4 and the PV anion. Table 1 shows the value of log K_{ex} as calculated from Eq. 7. It is given by log $K_{ex}=12.58$.

Effect of Foreign Ions. The effect of foreign ions on the determination of 2.55 μg vanadium(V) was examined under optimum conditions. Cadmium, cobalt, chromium, lanthanum, lead, magnesium, manganese, mercury, nickel, and zinc do not interfere when present separately 0.1-mg amounts, but aluminium, beryllium, bismuth, iron, molybdenum, tin, thorium, uranium, and tungsten interfere seriously. Of the anions tested, 10 mg of iodide, thiocyanate, and perchlorate interfere seriously, giving a negative error. Chelating agents such as EDTA and citrate also interfere. Table 2 shows the main interfering ions.

Table 1. Equilibrium extraction data for $V(PV)_2^{2-}$ with $R_3R'N^+$ in carbon tetrachloride at 25 °C ($I=0.005$ in NaOAc and Na_2SO_4 solutions) pH=5.0 in an acetate buffer solution (2×10^{-3} mol/l), $[V]=2.5\times10^{-6}$ mol/l, $[PV]=7.5\times10^{-5}$ mol/l, $[TDEABr]_o=5\times10^{-3}$ mol/l, $V_{aq}=20$ ml, $V_o=5$ ml

10^3 $[NS^-]$/mol l^{-1}	log K_{ex}
0.5	12.54
1.0	12.56
1.5	12.62
2.0	12.58
2.5	12.59
	log $K_{ex}=12.58$

All the concentrations in Table 1 show the initial concentrations.

Table 2. Effects of diverse ions on the determination of vanadium(V)

Negative Ions Formed by Vacuum Spark Discharge. II.[1] Relative Sensitivity Coefficients for Negative Ions of the Elements Contained in Compressed Aluminium Powder Electrodes for Spark Source Mass Spectroscopy

Hiroshi KISHI*

Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received May 13, 1980)

The relative sensitivity coefficients for negative ions of 15 elements contained in compressed aluminium powder electrodes were measured by spark source mass spectroscopy. The relative sensitivity coefficients for the halogens and group VIB elements were found to be the largest, the difference of relative sensitivity coefficients between the elements being larger than in the case of positive ion relative sensitivity coefficients. The logarithm of the relative sensitivity coefficients of negative ions are linearly correlated to the electron affinities of the elements.

A study on negative ion spark source mass spectroscopy has been carried out with a Mattauch-Herzog type double focusing mass spectrograph. The formation of atomic negative ions of 48 elements was reported.[1] Formation of negative ions with a spark discharge type ion source is more difficult than that of positive ions. No negative ion formation took place in rare gas elements, alkaline earth elements, Zn, Cd, Hg, Mn, Re, and rare earth elements. On the other hand, negative ion formation is easy for halogen elements and the group VIB elements. Qualitative investigation was made on the relation between the formation of atomic negative ions by spark discharge and the polarity of the electron affinities of the elements.[1] In the present study, the relative intensities of the negative ions formed by the spark discharge ion source were measured and the results compared with the reported electron affinities of the elements.

The relative sensitivity coefficients of positive ions in spark source mass spectroscopy reported by various authors[2-5] are correlated to the square root of the ionization potentials of the elements and to the heats of sublimation and dissociation energies of the compounds contained in the electrodes. Various empirical formulas[6,7] have been applied to the chemical analysis of solids.[8-10] However, except for the work of Schuy *et al.*,[11] Hintenberger *et al.*,[12] Kishi *et al.*,[13] and Kodera *et al.*,[14] few mass spectroscopic studies have been made on negative ions formed by a spark discharge ion source. The relative sensitivity coefficients of negative ions seem to have hardly been examined at all. This might be due to the difficult formation of negative ions by spark discharge as compared with positive ions.[15]

The results of this study can be applied to the chemical analysis of solids. The relative sensitivity coefficients for negative ions are necessary for applying spark source nagative ion mass spectroscopy to chemical analysis. The present study deals with the relative sensitivity coefficients of negative ions formed by the spark discharge of the elements contained in compressed aluminium powder electrodes, the results being correlated to the electron affinities of the elements.

* Present address: Oyama Technical College, Nakakuki, Oyama, Tochigi 323.

Experimental

Apparatus. A Mattauch-Herzog type double focusing mass spectrograph equipped with an r. f. spark discharge ion source was used. Details of the instrument were reported.[16-18] Operational conditions: spark voltage 20 kV; pulse width, 200 μs; repetition rate 100 s^{-1}; ion accelerating potential, 15 kV for both positive and negative ions.

Materials. Powdered samples containing an equal weight (1.28% for each element) of 49 common elements (SPEX MIX 1000; SPEX MIX INDUSTRIES INC.), and powdered samples containing 10 noble metal elements (SPEX MIX 1041) were used. Various metal alloy samples were also used (Table 6). Compounds and gravity factors for SPEX MIX 1000 are given in Table 1. SPEX MIX 1041 contains 9.32% Au, Ga, Hf, In, Ir, Pd, Pt, Re, Rh, and Ru by weight, some of them being solutions and the others salts or powdered metals. The powdered samples were ground down to 325 mesh with a ball-mill for a few hours. In order to compress them, the samples were mixed thoroughly with pure aluminium powder in 1:1 ratio by weight (Mitsuwa-Kagaku Co. Ltd., purity 99.999%; impurities Cu, As, B (each 1 ppm), Mg, Si (each 0.5 ppm)). In negative ion spark source mass spectra, background peaks of hydrocarbon ions are usually very intense. Thus graphite powder is not suitable as compressing material, since C_n^-, C_nH^-, and $C_nH_2^-$ ion peaks are very intense in the spark discharge of a graphite electrode, the peaks interfering with the mass spectral peaks of the sample elements. The powders were compressed[19] into pellets, 12 mm × 3 mm × 1 mm with an 8 t/cm^2 press. Aluminium powder only was also compressed in order to measure background peak spectra.

Procedure for Calculating RSC. Positive ion mass spectra and negative ion mass spectra were both recorded on an Ilford Q2, 30 × 150 mm^2 photographic plate. Characteristic curves of the emulsions were constructed from positive ion spectra using the isotope peaks of Pt^+ and Zn^+ ions from the spectra obtained by the spark discharges of different exposure times. In a characteristic curve, the abscissa represents the logarithm of (monitor ion current) × (isotopic abundance ratio), and the ordinate the values $D=\log(I_0/I)$ or $\Delta=\log((I_0-I)/I)$. In order to estimate weak line intensity, Δ(Seidel function[20]) in which the curve is linear in the region of low ion intensity, was used. A characteristic curve obtained by means of positive ion mass spectra was used to calculate negative ion peak intensity. It was assumed that the response of the photographic emulsion is the same for positive and negative ions.

Table 1. Compounds and gravity factors for SPEX MIX 1000

Magnesium	MgO	1.66			

In order to compare the results with those reported and to confirm the method, the relative sensitivity coefficients of positive ions were first measured and then those of negative ions. The procedure for calculation is essentially the same for positive and negative ion mass spectra. In the latter, however, the background hydrocarbon peaks are very intense and seem to originate from the diffusion pump oil. For the purpose of reducing the background peak intensity, the cryopumping system[21] was considered, but the discharge between the cryopumping plate (earth potential) and the ion accelerating plate (−15 kV from earth) prevented this attempt. It was thus necessary to make background subtraction in the spectra. In the negative ion spark spectra, the mass spectral peaks were broadened by discharge between the accelerating electrode and the earth (defining) electrode. Line width correction was also necessary.

The procedure for calculating the relative sensitivity coefficients is as follows. (1) The relative ion intensities of the isotope peaks are obtained from the characteristic curve, and correction for isotopic abundance ratio is made. (2) The data are further corrected for peak width at half maximum, and the emulsion sensitivity is corrected by means of the $(m)^{-1/2}$ law.[22] (3) Background subtraction is made. For the positive ion mass spectra, multicharged peak intensity is subtracted by estimation from the non-integral isotopic ion intensities. Background peak intensities, *e.g.*, hydrocarbon ions and Al_n^+ ions, are subtracted from the Al/Al blank spark spectra by means of the monitor ion current.

In the negative ion mass spectra, no multicharged negative ion peaks were detected,[1] but background hydrocarbon peaks were very intense. Because of the electron current, the monitor ion current was unreliable and could not be used to estimate the background ion peak intensity. In the negative ion spectra, the m/z 34 peak was not a sample ion peak but a background ion peak. The background peak intensities of the mass spectra of the Al/Al spark spectra were normalized (m/z 34 peak intensity = 1), and subtracted from those of the sample/sample spark spectra, in which peak intensities were also normalized (m/z 34 peak intensity = 1). When the background peak intensity exceeded 50% of the sample peak intensity, no peak intensity was estimated. In A/B spark spectra, A and B indicate the substances in the vacuum spark discharge electrodes.

Results and Discussion

Positive Ion Relative Sensitivity Coefficients. The relative sensitivity coefficients of positive ions for 49 common elements are given in Table 2, and those of 10 noble metal elements in Table 3.

The relative sensitivity values are larger than those reported,[6] except for those for the elements Fe, Co, Si, V, and Cu. The difference between the two values for alkali metal elements is very large. For the halogen elements, the relative sensitivity values are larger than the reported values, the discrepancy between the two values being larger than that for the other elements. The alkali metal elements and halogen elements are present as carbonate and ammonium salt, respectively, and are probably more easily volatilized than other compounds in the spark discharge. The discrepancy in the relative sensitivity coefficients can thus be explained by the assumption that the spark discharge condition in this experiment is more discriminative for volatilization of the compounds contained in the spark electrodes. Aluminium

a) Mean of each run. b) Standard deviation of each value.

powder was used as compressing material, and the spark voltage was 20 kV; Konishi used graphite, the spark voltage being 40 kV.[6]

The standard deviation σ is large for the elements Ba, Ta, and Cl, but less than 40% for the other elements (Table 2). This value is usually given[23] on spark source mass spectroscopy.

Indium and Ga have the largest relative sensitivity values, and Ru and Ir the smallest values (Table 3). The standard deviation of each relative sensitivity value is less than 30%. This might be due to the fact that the relative sensitivity values do not differ a great deal between these elements as in the case of 49 common elements (SPEX MIX 1000). Nearly the same parts and the linear portion of the emulsion characteristic curve could be used for estimating the peak intensity.

Both SPEX MIX 1000 and SPEX MIX 1041 contain Ga. The relative sensitivity values of the noble metal elements can be normalized to Fe=1 by multiplying all values by 2.47. These relative sensitivity values of 54 elements are plotted against the $(\text{I.P.})^2$ in Fig. 1. We see that the relative sensitivity coefficients are inversely correlated with the $(\text{I.P.})^2$, by a gradient of *ca.* -1.0. The result is in line with other results reported.[6,7] Na, Te, Zn, and the halogen elements deviate upward, and the transition metal elements and the noble metal elements deviate downward from the straight line. This might be due to the fact that the heats of evaporation of the transition metal elements are large as compared with those of the other typical elements.[6]

Negative Ion Relative Sensitivity Coefficients. The relative sensitivity coefficient values for negative ions were obtained for 15 of the 49 common elements, and for 8 of the 10 noble metal elements. No relative sensitivity coefficients were obtained for the other elements, since no negative ion peaks for these elements were detected or the peak intensities were too low to estimate the relative sensitivity coefficients. The results are given in Table 4 for the 15 common elements, and in Table 5 for the 8 noble metal elements, with the published values of electron affinities.[24-34] N and σ indicate run number and standard deviation as in Tables 2 and 3.

In Table 4, a large standard deviation is observed

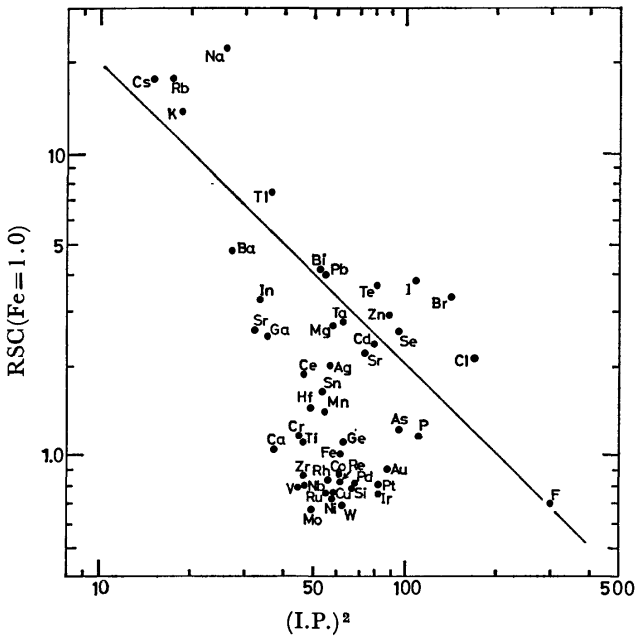

Fig. 1. Relation between the relative sensitivity coefficients for positive ions *versus* $(I.P.)^2$.

for the elements of low relative sensitivity coefficient values except Cu and Na. For the elements of high relative sensitivity coefficient values, such as Cl, I, and Br, the standard deviation is small. There are two possible reasons: (1) In the calculation of the relative sensitivity coefficients of negative ions, a background subtraction procedure is involved, the background peak intensity becoming relatively larger for a negative ion peak of weak intensity than for one of strong intensity. (2) The absolute values of the relative sensitivity coefficients for negative ions are diverse covering the range $1—10^{-3}$. It is necessary to use the non-linear portion of the emulsion characteristic curve for estimating the peak intensity.

On the other hand, for the noble metal elements (Table 5), the standard deviation for each relative sensitivity coefficient value is smaller than 20%. This might be due to the fact that the relative sensitivity coefficient values for the negative ions of these elements do not diverge so widely as in the common elements. The values cover the range only $1—10^{-1}$. Thus the linear portion of the emulsion characteristic curve can be used for estimating the peak intensity. Of noble metal elements, no Hf^- and Re^- ions were detected. Au^- and Pt^- were the most intense, and Ir^- and In^- were the least intense.

It is desirable to estimate the relative sensitivity coefficients of negative ions with use of samples which contain elements with near values of the relative sensitivity coefficients. Various metal alloy samples were also examined (Table 6). In these samples, the concentration of each element was not certain. The positive ion intensity ratio of the elements was measured first, the ratio being considered to be the concentration ratio of the elements in samples. The negative ion intensity ratio was then estimated, and the ratio was divided by the positive ion intensity ratio. This quotient was considered to be the relative sensitivity coefficient for the negative ions of these elements. The results are given with the published values of the electron affinity of the elements (Table 6). The run number is 1 for all the elements, no standard deviation being given.

From the results of the experiment with the Pt–Au–Ag–Pd–Cu–Zn alloy we see that the relative sensitivity coefficients of the elements Pt and Au are 1:0.4 (0.3:1 in the results from SPEX MIX 1041). The discrepancy might be due to the difference in the state of the compounds contained in samples. For the other elements, the values of the relative sensitivity coefficients are in the same order between the two samples, though the absolute values hardly change. For example, Ni^-:Cu^- is 1:1.3 for Ni–Cu alloy, and 1:1.2 for the SPEX MIX 1000. Ni^-:Cr^- is 1:0.20 for the Ni–Cr alloy, and 1:0.26 for the SPEX MIX

Table 6. Relative sensitivity coefficients for negative ions of the elements contained in various metal alloys

Element	Positive ion intensity ratio	Negative ion intensity ratio	RSC	E.A./eV
(1) Nichrom-1				
Fe	1.0	1.0	1.0	0.58
Ni	1.13	10.1	9.7	1.28
(2) Nichrom-2

Au	1.00	0.41	0.4	2.128
Ag	54.4	2.5	0.050	1.303
Pd	34.0	1.3	0.040	1.03
Cu	25.8	2.3	0.10	1.226
Zn	4.4	—	—	−0.67

1000. Pt^-: Rh^- is 1:0.24 for the Pt–Rh alloy, and 1:0.48 for the SPEX MIX 1041.

We see that the relative sensitivity coefficient values for the elements of large electron affinity values are large, and small for the elements of small electron affinity values (Tables 4, 5, and 6). The logarithm of the relative sensitivity coefficients of negative ions versus the published values of the electron affinities of the elements are plotted. The results are given for the samples of SPEX MIX 1000 and SPEX MIX 1041, respectively (Figs. 2 and 3). The logarithms of the relative sensitivity coefficients has a rough linear correlation to the electron affinities of the elements. Se and Te deviate upward from the linear line, but the reported values of the electron affinities of Se and Te diverge from 2.2 eV[23] to 3.7 eV,[35] and from 2.1 eV[36,37] to 3.6 eV,[35] respectively (Fig. 2). Correlation seems to exist between the logarithm of the relative sensitivity coefficient and the electron affinity of the element. Ga having low melting point shows upward deviation.

The author would like to express his hearty thanks to Dr. K. Kodera and Dr. T. Makita, Kyoto University, for their encouragement and helpful suggestions throughout this work, and to Dr. F. Konishi, the Central Research Laboratory of Matsushita Electric Co. Ltd., for his technical help in preparing the compressed aluminium powder electrodes.

A part of this study was reported at the International Conference on Mass Spectroscopy held in Kyoto.[38,39]

An X-Ray Photoelectron Spectroscopic Study of Several Hydroxy Azo Metal Complexes

Tooru YOSHIDA

Osaka Prefectural Industrial Research Institute, 2-1-53, Enokojima, Nishi-ku, Osaka 550

(Received June 3, 1980)

The X-ray photoelectron spectra of the copper(II) and nickel(II) complexes of five *o*-hydroxy azo compounds were measured. The N(1s) electron spectra of the complexes of 1-phenylazo- and 1-(1-naphthylazo)-2-naphthols showed the presence of only one kind of nitrogen atom, suggesting an equalization in the electron densities on the two nitrogen atoms of an azo group. Such equalization was observed also in the complexes of 1-(8-quinolylazo)-2-naphthol. The N(1s) spectra of the complexes of 1-(2-pyridylazo)- and 1-(2-thiazolylazo)-2-naphthols, on the other hand, showed the presence of three kinds of nitrogen atoms, suggesting the non-equalization of the two nitrogen atoms of an azo group. These results were explained mainly on the basis of the mode of ligand coordination and the resonance structure of the sodium salt of the ligand. Furthermore, the relation between the structures of the complexes and the O(1s) chemical shifts was discussed.

o-Hydroxy azo dyes are very important in analytical chemistry, particularly in the spectrophotomeric and titrimetric determination of metal ions.[1] Furthermore, it is interesting to know whether the azo group is coordinated to the metal ion as a whole or through one of the component nitrogen atoms, since the N=N system is isoelectronic with the CH=CH group, which is capable of coordinating through the π-systems to transition metals, as in Zeise's salt.[2] Therefore, there have been several studies of the structures of their metal complexes by means of some physicochemical techniques.[3] It has been found by X-ray structural analysis that, in the complexes of *o*-hydroxy azo compounds with transition metal ions, one of the component nitrogen atoms of an azo group is coordinated to a metal ion.[3c-3g]

X-Ray photoelectron spectroscopy (XPS), which is sensitive to the charge distribution,[4] is suitable for the examination of the mode of ligand coordination in coordination compounds. The examination is based primarily upon the concept that the coordination of a ligand to a metal ion causes a decrease in the electron density on the coordination atom, giving rise to an increase in the core-electron binding energy of the atom. The XPS study of several hydroxy azo compounds has been reported.[5] The purpose of the present study is to examine the chemical structures of the copper(II) and nickel(II) complexes of several *o*-hydroxy azo compounds by means of XPS.

Experimental

The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. Al $K\alpha$ (1486.6 eV) X-ray radiation was used as the excitation source. The samples were ground to a powder and dusted onto double-backed adhesive tape. The measurements were conducted at room temperature under a vacuum of about 10^{-7} Torr. The binding energy of the C(1 s) electron peak was used as the energy standard throughout the present work; it has been taken to be 285.0 eV. The reproducibilities of the values thus obtained were within ± 0.1 eV. No appreciable X-ray damage was observed throughout the experiments. All the compounds used and their binding energies measured are given in Table 1. 1-Phenylazo-, 1-(1-naphthylazo)-, 1-(2-pyridylazo)-, 1-(2-thiazolylazo)-, and 1-(8-quinolylazo)-2-naphthols (abbreviated as L_AH, L_BH, L_CH, L_DH, and L_EH respectively) were used as ligands. 1,1′-Azonaphthalene (abbreviated as L) was used as the reference compound. 1-(2-Thiazolylazo)-2-naphthol was obtained commercially and was used after recrystallization from an ethanol-water mixture. The sodium salt of 1-(2-pyridylazo)-2-naphthol (abbreviated as L_CNa) was obtained by treating the naphthol with NaOH in a mixture of ethanol and water. This salt was fairly stable compared with the sodium salt of 1-phenylazo-2-naphthol (abbreviated as L_ANa), which was subject to hydrolysis by water.[5] Attempts to prepare the sodium salts of L_BH and L_EH were unsuccessful. The other free azo compounds in Table 1 were obtained in the way indicated in the literature.[5] All the complexes were prepared based upon the literature.[3a] However, in the preparation of the complexes in a 1:1 ratio of an azo ligand to a metal ion, the chlorides were used instead of the acetates as metal salts. Furthermore, in the preparation of the complexes of L_BH and L_EH, an *N,N*-dimethylformamide–ethanol mixture was used as the solvent because of the insuffcient solubility of L_BH and L_EH in ethanol only. When we attempted to prepare $Ni(L_C)Cl$ and $Ni(L_D)Cl$, these complexes were not obtained at all, but $Ni(L_C)_2$ and $Ni(L_D)_2$ were obtained. All the compounds used were dried in an air oven at 95 °C and were checked by elemental analysis.

Results

The N(1s) electron spectra of L_AH, L_CH, and their sodium salts are shown in Figs. 1 and 2. Eb in the figures indicates the binding energy. The peaks indicated by the broken lines in the spectra, as well as those in the other N(1s) spectra, were obtained by graphical resolution on the basis of the symmetrical peak with almost the same full-width at half-maximum height (FWHM) as that (1.6 eV) of L containing one type of nitrogen atom. The spectrum of L_AH as well as that of L_BH showed a single peak with an FWHM value of about 1.6 eV, while the spectrum of L_ANa showed two comparable peaks. The spectrum of L_CH as well as those of L_DH and L_EH showed two peaks with an intensity ratio of approximately 2:1, while the one of L_CNa showed peaks with a ratio of 1:2.

The N(1s) spectra of $Cu(L_A)_2$, $Cu(L_C)_2$, and $Cu(L_E)_2$ are shown in Fig. 3. The spectrum of $Cu(L_A)_2$, like those of $Ni(L_A)_2$, $Cu(L_B)_2$, and $Ni(L_B)_2$, was almost the same as that of L_AH in shape. The spectrum of $Cu(L_C)_2$, like those of $Ni(L_C)_2$, $Cu(L_D)_2$, $Ni(L_D)_2$, $Cu(L_C)Cl$, and $Cu(L_D)Cl$, showed a broad

Table 1. Measured binding energies

Compound[a]	Binding energy/eV

a) L, L_AH, L_BH, L_CH, L_DH, and L_EH indicate 1, 1'-azonaphthalene, 1-phenylazo-, 1-(1-naphthylazo)-, 1-(2-pyridylazo)-, 1-(2-thiazolylazo)-, and 1-(8-quinolylazo)-2-naphthols respectively. L_ANa and L_CNa indicate the sodium salts of L_AH and L_CH.

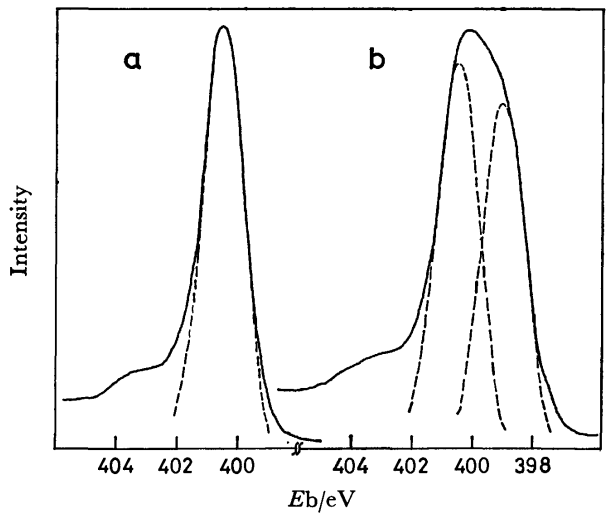

Fig. 1. N(1s) electron spectra of a: L_AH and b: L_ANa.

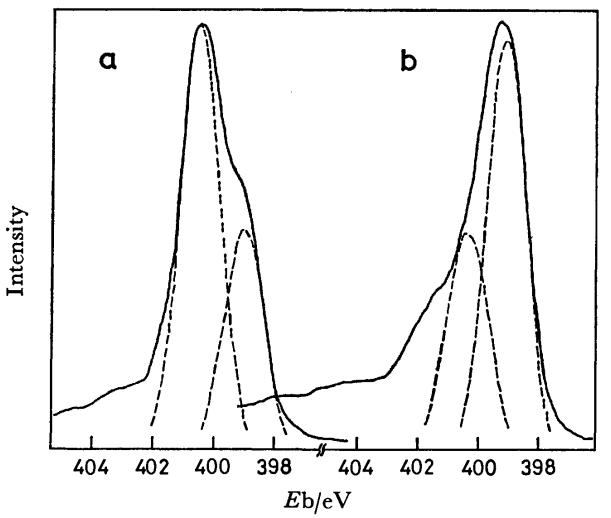

Fig. 2. N(1s) electron spectra of a: L_CH and b: L_CNa.

peak with an FWHM value of about 2.4 eV comprising three peaks with similar intensities. The spectrum of $Cu(L_E)_2$, like those of $Ni(L_E)_2$, $Cu(L_E)Cl$, and $Ni(L_E)Cl$, showed two peaks with an intensity ratio of approximately 2:1.

Satellite signals on the higher-energy side of the primary peak, as are seen in Figs. 1—3, were observed in the N(1s) spectra of all the compounds in Table 1.

The O(1s) spectra of L_AH and $Cu(L_A)_2$ are shown in Fig. 4. The spectrum of L_AH as well as those of L_BH, L_CH, L_DH, and L_EH showed two peaks with comparable intensities, while the spectrum of $Cu(L_A)_2$ as well as those of the other complexes showed one primary peak.

Discussion

All the N(1s) spectra of five free ligands indicated that the electron densities on the two nitrogen atoms of an azo group are almost the same. Here, the peak with the lower binding energy in Fig. 2a was easily

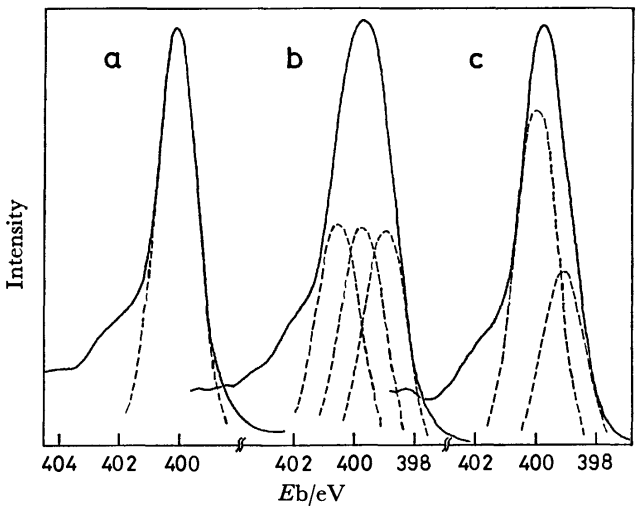

Fig. 3. N(1s) electron spectra of a: $Cu(L_A)_2$, b: $Cu(L_C)_2$, and c: $Cu(L_E)_2$.

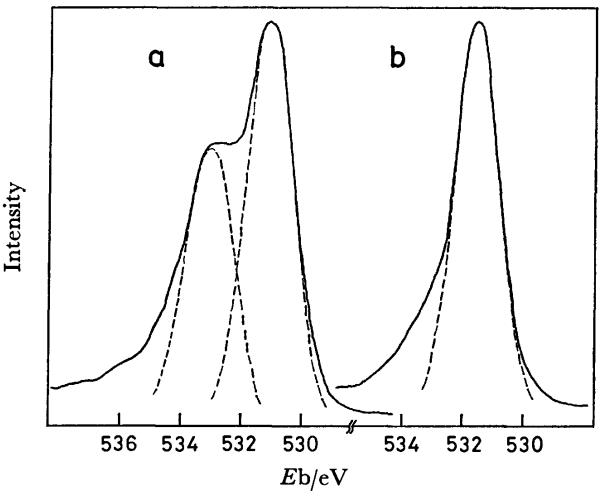

Fig. 4. O(1s) electron spectra of a: L_AH and b: $Cu(L_A)_2$.

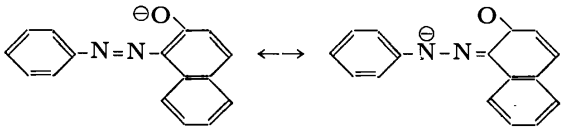
assigned to the nitrogen atom of a hetero ring by comparing with Fig. 1a.

The presence of two kinds of peaks in Fig. 1b was due to the following resonance structures:[5]



This resonance suggests that the electron density on the nitrogen atom of an azo group farthest from a naphthalene ring is higher than that on the other nitrogen. Therefore, the peak with the lower binding energy in Fig. 1b can be assigned to the former nitrogen atom, and the other peak to the latter nitrogen.

The peak with the higher energy in Fig. 2b may be assigned to the nitrogen atom of an azo group nearest to a naphthalene ring, and the lower-energy peak, to the other nitrogen of the azo group in addition to the nitrogen of a pyridine ring, by considering the resonance structure of L_CNa to be similar to that of L_ANa. Such resonance structures as those in L_ANa may be expected also in the sodium salts of the other *o*-hydroxy azo compounds in this study.

The spectra of the complexes may be explained in the following way, based upon the structure of the sodium salt estimated above.

In the complexes of L_AH, the hydroxyl group and the nitrogen atom of an azo group farthest from a naphthalene ring are involved in chelate formation.[3c,3d] Therefore, such complex formation may be considered to act to equalize the electron densities on the two nitrogen atoms of an azo group due to the electron transfer from a coordinating atom to a metal ion.

The N(1s) binding energies of an azo group (400.1—400.2 eV) of the complexes of L_AH were slightly lower than the value (400.5 eV) of the nitrogen atom nearest to a naphthalene ring in L_ANa, which does not participate in bond formation. This may be due to the delocalization of π-electrons in the chelate ring suggested by the IR study of the metal complexes of 2-hydroxyazobenzene.[3a] Such delocalization may be supported also by the results of X-ray structural analysis that the N–N distances in $Cu(L_A)_2$ and $Ni(L_A)_2$ are 1.32 Å[3c] and 1.28 Å,[3d] while that of azobenzene is 1.23—1.24 Å.[6] That is, the distances for the complexes are slightly longer than that for azobenzene.

The mode of ligand coordination in the complexes of L_BH is considered to be almost the same as that in the complexes of L_AH, because the N(1s) spectra of the former complexes are very close to those of the latter.

In the complexes of L_CH and L_DH, each of the ligands acts as a terdentate ligand, the hydroxyl group, the nitrogen atom of an azo group nearest to a naphthalene ring, and the heterocyclic nitrogen atom, to give two five-membered chelate rings.[3e–3g] The nitrogen atom farthest from a naphthalene ring, which is expected to be rich in electron density, cannot be coordinated to a metal atom because of steric hindrance. This suggests that the electron densities on the two nitrogen atoms of an azo group cannot become equal on complex formation, unlike in the case of the complexes of L_AH and L_BH.

Therefore, it seems reasonable to assign the three peaks in the N(1s) spectra of the complexes of L_CH and L_DH to the nitrogen atom of an azo group nearest to a naphthalene ring, the nitrogen of a hetero ring, and the remaining nitrogen of the azo group, successively from the higher-energy side.

The N(1s) chemical shifts (0.6—0.8 eV) of the nitrogen atom of a hetero ring of the complexes of L_CH and L_DH, *i.e.* the difference between the N(1s) binding energies of the complex and the free ligand, were comparable with those (0.5—0.9 eV) of the copper and nickel complexes of 8-quinolinol and 2-pyridinecarboxylic acid.[7] This may support the above assignment of the three peaks in the N(1s) spectra. The N(1s) chemical shifts (<0.3 eV) of the nitrogen atom of an azo group which participates in bond formation were smaller than those of the nitrogen of a hetero ring. This seems to be associated with the coordination ability of the donor atoms.

In the complexes of L_EH, it is not known which

nitrogen atom of an azo group is coordinated to a metal ion because of the absence of the data of the X-ray structural analysis. In this study, it may be easily expected from the following facts that the nitrogen atom farthest from a naphthalene ring participates in the bond formation, as in the complexes of L_AH and L_BH.

The spectra of the complexes of L_EH showed the presence of two kinds of nitrogen atoms in the proportion of 2:1, unlike the spectra of the complexes of L_CH and L_DH, which show three kinds of peaks. Furthermore, the binding energy (400.0—400.2 eV) of the peak with the larger intensity was very close to those (400.1—400.2 eV) of the nitrogen atoms of an azo group of the complexes of L_AH and L_BH. Therefore, it seems reasonable to assign the peak with the larger intensity to the two nitrogen atoms of an azo group, and the other peak, to that of a quinoline ring. Here, the equalization in the electron densities on the two nitrogen atoms of an azo group can be explained much as in the case of the complexes of L_AH and L_BH.

The N(1s) chemical shifts (0.2—0.5 eV) of a hetero ring in the complexes of L_EH were slightly smaller than those in the complexes of L_CH and L_DH. This may be due to the difference of the mode of the coordination of an azo group in the two groups of complexes.

In hydroxy azo compounds, two kinds of oxygen atoms, keto and enol forms, usually coexist as a result of tautomerism. The peak with the higher binding energy in the O(1s) spectra of L_AH, L_BH, L_CH, L_DH, and L_EH corresponds to the protonated oxygen atom, and the other to the deprotonated oxygen.[5]

The O(1s) binding energies of $Cu(L_A)_2$, $Ni(L_A)_2$, $Cu(L_B)_2$, $Ni(L_B)_2$, $Cu(L_C)Cl$, $Cu(L_D)Cl$, $Cu(L_E)Cl$, and $Ni(L_E)Cl$, all of which are four coordinate species, were 0.3—0.9 eV higher than those of the deprotonated oxygen atom of the corresponding free ligands, while in the other complexes, which are all six-coordinate species, there were no appreciable chemical shifts of the O(1s) binding energies. Such a result suggests that the interaction between the metal and the oxygen atoms in the complexes of the former group is stronger than that of the latter group. This is consistent with the fact that the nickel–oxygen distance (1.85 Å)[3d] in $Ni(L_A)_2$, one of the complexes of the former group, is slightly shorter than that (1.98 Å)[3f] in $Ni(L_D)_2$, one of the complexes of the latter.

The differences of the metal($2p_{3/2}$) binding energies of the complexes were small throughout the present experiment; the values for all the copper complexes were 934.2—934.7 eV, and those for all the nickel complexes were 855.2—855.7 eV. Therefore, no notable information concerning the structures of the complexes could be obtained from the metal binding energies.

In the complexes of L_DH, the thiazole sulfer atom was not considered to participate in the chelate-ring formation, because there was no appreciable chemical shift in the S($2p_{3/2}$) binding energy. This agrees with the results of X-ray analysis.[3f,3g]

The satellites at $\approx$4 eV on the higher-binding energy side of the primary peak in the N(1s) spectra in this study may be partly assigned to the shake-up satellite, which is mainly due to the co-excitations of valence electrons, n-π^*, π-π^*, on the ejection of the inner electrons, on the basis of the following facts. These satellites are observed in the spectra of both free ligands and their metal complexes. Such satellites have previously been observed in the N(1s) spectra only of compounds containing the unsaturated bonds with a hetero-atom.[8] Furthermore, the electron spectra of the aromatic azo compounds generally show the absorption bands due to n-π^*, π-π^* transitions in a region of about $(17—40)\times10^3$ cm^{-1}, which approximately corresponds to 2—5 eV.[1a,9]

The author wishes to thank Drs. Kiyoshi Yamasaki and Shigemasa Sawada for their helpful discussions and suggestions during this work, Dr. Masakazu Miyagi for his help in performing this experiment, and Mr. Taichiro Hirohara for the elemental analysis.

Nuclear Magnetic Resonance and Circular Dichroism Spectra of 2-(Aminomethyl)cyclohexylamine Platinum(II) Complexes

Koji Okamoto,* Masahide Noji, and Yoshinori Kidani

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received June 30, 1980)

Six-membered platinum(II) complexes of 2-(aminomethyl)cyclohexylamine (=amcha), whose four isomers are (1*R*,2*R*)-, (1*S*,2*S*)-, (1*R*,2*S*)-, and (1*S*,2*R*)-amcha, were synthesized. The conformations of [Pt(en)(1*S*,2*R*-amcha)]Cl_2, [Pt(NH_3)$_2$(1*S*,2*R*-amcha)]Cl_2, [Pt(en)(1*R*,2*R*-amcha)]Cl_2, and [Pt(NH_3)$_2$(1*R*,2*R*-amcha)]Cl_2 were determined by ^{1}H-NMR, ^{13}C-NMR, and CD spectra. It is proposed that [Pt(en)(1*S*,2*R*-amcha)]Cl_2 and [Pt(NH_3)$_2$(1*S*,2*R*-amcha)]Cl_2 take a fixed chair form with a dihedral angle (Pt–N–C(1)–C(6)) of 180°, while [Pt(en)(1*R*,2*R*-amcha)]Cl_2 and [Pt(NH_3)$_2$(1*R*,2*R*-amcha)]Cl_2 are interconverting between two chair forms.

2-(Aminomethyl)cyclohexylamine (=amcha) has four isomers, which are represented as 1*R*,2*S* (*trans-l*), 1*S*,2*R* (*trans-d*), 1*R*,2*R* (*cis-l*) and 1*S*,2*S* (*cis-d*) isomers (Fig. 1). Various platinum(II) complexes containing these amcha isomers were synthesized and their antitumor activities were tested against leukemia P388.[1] Some differences were found among their activities. Therefore, it would be meaningful to study the conformations of six-membered platinum(II) complexes of amcha isomers.

In general, a six-membered chelate ring is more flexible than a five-membered one and the possible conformations of the former are chair, skew, or boat forms. The chair conformation has been considered to be the most stable form, and ^{1}H-NMR and ^{13}C-NMR spectral data supporting this view have been reported by Hall[2] and Yano *et al.*[3] But few CD spectral studies of platinum(II) complexes containing optically active diamine forming six-membered chelate have been done. In order to determine the conformations of amcha we prepared the following types of complexes for the first time: [Pt(en)(amcha)]Cl_2 and [Pt(NH_3)$_2$(amcha)]Cl_2 (amcha=(1*S*,2*R*)- and (1*R*, 2*R*)-2-(aminomethyl)cyclohexylamine). In the present paper, we will discuss the conformations of these platinum(II) complexes from NMR and CD spectral data.

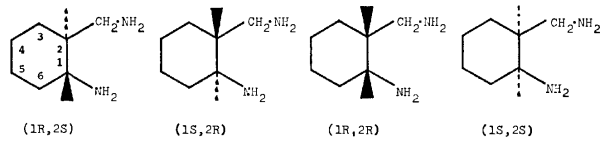

Fig. 1. Absolute configurations of 2-(aminomethyl)-cyclohexylamine.

Experimental

Ligands. *1) Synthesis of* cis- *and* trans-*2-(Aminomethyl)-cyclohexylamine*: They were prepared from the corresponding *cis-* and *trans-*1,2-cyclohexanedicarboxylic acid according to the method reported by Armarego *et al.*[4]

2) Resolution of trans-*2-(Aminomethyl)cyclohexylamine*: A hot filtered solution of (2*R*,3*R*)-di-*O*-benzoyltartaric acid monohydrate (46.7 g) in ethanol (307 cm^3) was added to a solution of freshly distilled *trans-dl*-amcha (15.9 g) in water (307 cm^3). After the solution was kept standing overnight at 0 °C, fibrous crystals and a few plate crystals were deposited. When the solution was kept standing for several hours at room temperature, only the plate crystals were dissolved again. The fibrous crystals were collected by filtration and were recrystallized from an aqueous ethanol (1:1 V/V) solution, giving 6.9 g of (1*R*,2*S*)-amcha (2*R*,3*R*)-di-*O*-benzoyltartrate with $[\alpha]_D=-106°$ (1% H_2O:EtOH= 1:1 V/V). Found: C, 59.50; H, 6.30; N, 5.55%. Calcd for $C_{25}H_{30}N_2O_8\cdot H_2O$: C, 59.50; H, 6.41; N, 5.55%.

The filtrate of (1*R*,2*S*)-amcha (2*R*,3*R*)-di-*O*-benzoyltartrate was evaporated to dryness and the residue was recrystallized from an aqueous ethanol (1:1 V/V) solution. The plate crystals of (1*S*,2*R*)-amcha (2*R*,3*R*)-di-*O*-benzoyltartrate obtained showed $[\alpha]_D=-75°$ (1% H_2O: EtOH=1:1 V/V).

The free amine from the (2*R*,3*R*)-di-*O*-benzoyltartrate was regenerated by the method of Bosnich.[5] The free (1*R*,2*S*)-amcha (1.5 g) and (1*S*,2*R*)-amcha (2.5 g) gave specific rotations of $[\alpha]_D=-39°$ and +40° (1% EtOH), respectively.

3) Resolution of cis-*2-(Aminomethyl)cyclohexylamine*: A hot solution of (2*R*,3*R*)-di-*O*-benzoyltartaric acid monohydrate (44 g) in ethanol (395 cm^3) was added to a solution of freshly distilled *cis-dl*-amcha (15 g) in water (80 cm^3). When the resultant solution was kept standing overnight at 0 °C, prism crystals were deposited. They were collected by filtration, washed with ethanol, and dried in air, yielding 26 g of (1*R*, 2*R*)-amcha (2*R*,3*R*)-di-*O*-benzoyltartrate with a specific rotation of $[\alpha]_D=-87°$ (1% H_2O: EtOH=1:1 V/V). According to the method of Bosnich,[5] 3.6 g of free (1*R*,2*R*)-amcha were obtained with a specific rotation of $[\alpha]_D=-15°$ (1% EtOH).

The filtrate was allowed to stand overnight at 0 °C to precipitate fibrous crystals. Alkalization and extraction[5] with ether gave 0.2 g of free (1*S*,2*S*)-amcha with a specific rotation of $[\alpha]_D=+14°$ (1% EtOH).

Among the four resolved optical isomers, (1*S*,2*R*)- and (1*R*,2*R*)-amcha were used as the ligands in this work because of their better specific rotations.

Preparation of 2-(Aminomethyl)cyclohexylamine Platinum(II) Complexes. [Pt(en)(1*S*,2*R*-amcha)]Cl_2, [Pt(NH_3)$_2$(1*S*,2*R*-amcha)]Cl_2, [Pt(en)(1*R*,2*R*-amcha)]Cl_2, and [Pt(NH_3)$_2$(1*R*, 2*R*-amcha)]Cl_2 were synthesized according to the method reported by Appleton and Hall,[6] and their analytical data are tabulated in Table 1.

Measurements. ^{1}H-NMR spectra were recorded at 100 MHz (JEOL JNM-MH-100). DSS was used as an internal reference.

FT ^{13}C-NMR spectra were obtained at 25 MHz with broad-band proton decoupling on a JEOL JNM-FX-100 spectrometer employing the solvent deuterium signal as an internal lock. A total of 1000—21200 FID's (8192 points) was averaged to provide the desired signal to noise ratio in the 2.5-kHz frequency spectra. Pulse angles of 45° were employed with no pulse delay. The ambient temperature was room temperature. TMS sealed in a capillary was used as an external reference. All NMR spectra were measured in D_2O solutions.

Table 1. Analytical data of the amcha Pt(II) complexes

Complexes	C%		H%		N%	
	Found	Calcd	Found	Calcd	Found	Calcd
$[Pt(en)(1S,2R\text{-amcha})]Cl_2$	23.71	23.79	5.18	5.33	12.61	12.33
$[Pt(NH_3)_2(1S,2R\text{-amcha})]Cl_2 \cdot 1/2H_2O$	19.21	19.22	5.07	5.31	12.06	12.81
$[Pt(en)(1R,2R\text{-amcha})]Cl_2$	23.55	23.79	5.32	5.33	12.49	12.33
$[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2 \cdot 3/2H_2O$	18.70	18.46	5.27	5.55	11.65	12.31

Absorption spectra were obtained in H_2O with a Shimadzu UV 200 Recording Spectrometer.

CD spectra were measured in H_2O with a JASCO J-40 Spectropolarimeter. All measurements were performed at room temperature.

Results and Discussion

^{1}H-NHR Spectra. As shown in Fig. 2, two multiplet peaks around 1.20 and 1.78 ppm can be assigned to the axial and equatorial methylene protons in the cyclohexane ring of (1*S*,2*R*)-amcha. From the integrated intensities, a peak of the methine proton (>CH–C) in the cyclohexane ring seems to be overlapping with these equatorial methylene protons. Two multiplet peaks around 2.48 and 2.88 ppm are attributable to the resonance of aminomethyl protons ($-CH_2-N$) and the methine proton (>CH–N). For (1*S*,2*R*)-amcha, two chair forms with diequatorial or diaxial orientation of amino and aminomethyl groups can be expected. But the behavior of the methylene protons in the cyclohexane ring indicates a fixed chair form with preferential diequatorial orientation.

The multiplet peak around 1.50 ppm (Fig. 2(b)) can be assigned to eight methylene protons and a methine proton (>CH–C) in the cyclohexane ring of (1*R*,2*R*)-amcha. Two multiplet peaks around 2.56 and 3.08 ppm can be assigned to aminomethyl protons ($-CH_2-N$) and a methine proton (>CH–N) by the integrated intensities. For (1*R*,2*R*)-amcha, two chair forms with axial and equatorial orientations of the amino and aminomethyl groups are possible, but the multiplet peak of the methylene protons in the cyclohexane ring indicates an averaging of axial and equatorial protons by rapid interconversion between two chair forms on the NMR time scale.

Figure 3 shows ^{1}H-NMR spectra of $[Pt(en)(amcha)]Cl_2$ and $[Pt(NH_3)_2(amcha)]Cl_2$ (amcha=(1*S*,2*R*)- and (1*R*,2*R*)-amcha) in D_2O. In the spectrum of $[Pt(en)(1S,2R\text{-amcha})]Cl_2$, multiplets due to axial and equatorial methylene protons in the cyclohexane ring were observed at 1.26 and 1.70 ppm, respectively. This behavior of the methylene protons suggests that the cyclohexane ring takes a fixed chair form preferentially. In the spectrum of $[Pt(en)(1R,2R\text{-amcha})]Cl_2$, a multiplet due to methylene protons in the cyclohexane ring was observed at 1.30 ppm, suggesting the averaging of axial and equatorial protons by rapid interconversion between two chair forms. ^{1}H-NMR spectra of $[Pt(NH_3)_2(1S,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$ are almost similar to those of $[Pt(en)(1S,2R\text{-amcha})]Cl_2$ and $[Pt(en)(1R,2R\text{-amcha})]Cl_2$, respectively, except for peaks of ethylenediamine.

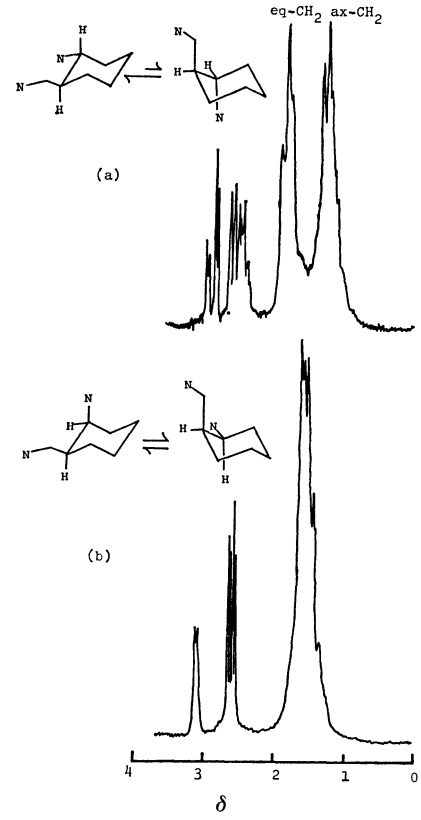

Fig. 2. ^{1}H-NMR spectra of (a) (1*S*,2*R*)-amcha and (b) (1*R*,2*R*)-amcha.

Recent studies[2,7] suggest that the dihedral angle dependence of the vicinal coupling constant $^3J_{Pt-H}$ in Pt–N–C–H fragments would parallel the Karplus equation for the $^3J_{H-H}$ in H–C–C–H fragments. The $^3J_{Pt-H}$ value has offered very important information for determining the conformation of 1,2-diamine and 1,3-diamine platinum(II) complexes. $[Pt(en)(1S,2R\text{-amcha})]Cl_2$ and $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ gave a single sharp peak, together with satellite peaks due to the coupling with ^{195}Pt (I=1/2, 34% abundance) at 2.73 ppm. The single sharp peak and the satellite peaks are overlapping with the aminomethyl protons ($-CH_2-N$) and the methine proton (>CH–N), but by comparing $[Pt(en)(1S,2R\text{-amcha})]Cl_2$ and $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ with $[Pt(NH_3)_2(1S,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$, the single sharp peak can be assigned to methylene protons of ethylenediamine. The observed $^3J_{Pt-H}$ values of $[Pt(en)(1S,2R\text{-amcha})]Cl_2$ and $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ were 41.0 Hz. This $^3J_{Pt-H}$ value is in good harmony with $^3J_{Pt-H}$ values previously reported for $[Pt(en)_2]Cl_2$ (41.0 Hz) and

Table 2. ^{13}C-NMR chemical shifts[a] and coupling constants[b]

Complexes	C(1)	C(2)	C(3)	C(4)	C(5)	C(6)	N-CH_2
[Pt(en)(1*S*,2*R*-amcha)]Cl_2	57.75	41.40	29.73	25.02	24.24	33.53	48.97
	(23.8)	(17.7)				(43.3)	(28.7)
[Pt(NH_3)$_2$(1*S*,2*R*-amcha)Cl_2	57.94	41.44	29.92	25.17	24.41	33.65	49.22
	(22.6)	(18.9)				(43.9)	(26.9)
[Pt(en)(1*R*,2*R*-amcha)]Cl_2	53.53	37.13	27.51	22.88	21.03	28.75	44.03
	(26.3)	(21.4)				(20.2)	(28.1)
[Pt(NH_3)$_2$(1*R*,2*R*-amcha)]Cl_2	53.63	37.23	27.48	22.90	21.37	28.97	44.42

a) ^{13}C shifts in ppm from external TMS. b) The values in parentheses are the coupling constants (^{195}Pt–^{13}C).

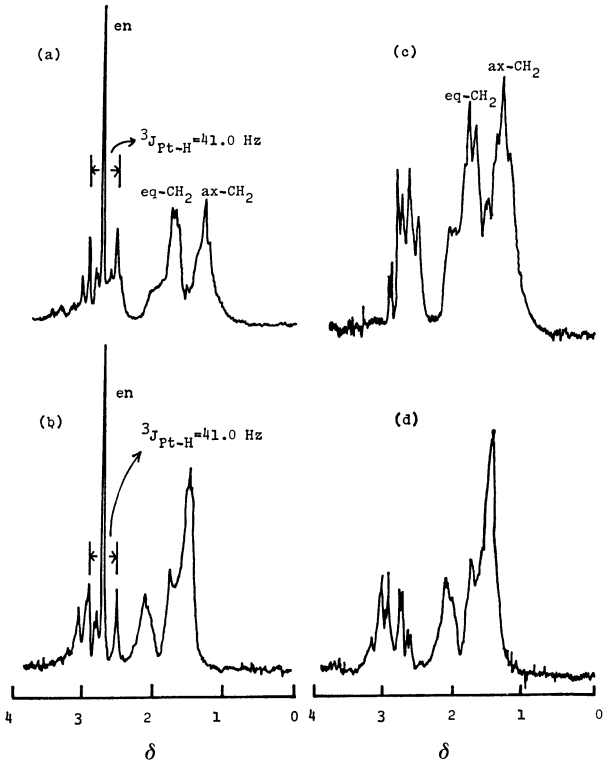

Fig. 3. ^{1}H-NMR spectra of (a) [Pt(en)(1*S*,2*R*-amcha)]-Cl_2, (b) [Pt(en)(1*R*,2*R*-amcha)]Cl_2, (c) [Pt(NH_3)$_2$-(1*S*,2*R*-amcha)]Cl_2, and (d) [Pt(NH_3)$_2$(1*R*,2*R*-amcha)]Cl_2.

[Pt(en)(NH_3)$_2$]Cl_2 (41.5 Hz),[2] indicating that the chelate ring of ethylenediamine shows a rapid conformational interconversion.

Unfortunately, other satellite peaks could not be assigned, and information on six-membered chelate ring could not be obtained from the $^3J_{Pt-H}$ value.

^{13}C-NMR Spectra. Figure 4 shows ^{13}C-NMR spectra of [Pt(en)(1*S*,2*R*-amcha)]Cl_2 and [Pt(en)(1*R*,2*R*-amcha)]Cl_2 in D_2O. In both complexes, assignments of C(1), C(2), C(6), aminomethyl carbons, and methylene carbons of ethylenediamine were facilitated on the basis of the spectrum with off-resonance proton decoupling. Three peaks on the upfield side are attributable to the resonance of C(3), C(4), and C(5) carbons, but assignments of these three peaks may be difficult because of complicated steric factors.

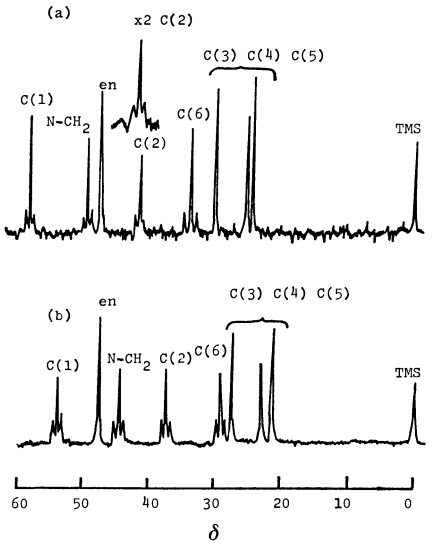

Fig. 4. ^{13}C-NMR spectra of (a) [Pt(en)(1*S*,2*R*-amcha)]-Cl_2 and (b) [Pt(en)(1*R*,2*R*-amcha)]Cl_2.

Table 2 shows chemical shifts and coupling constants (^{195}Pt–^{13}C) of these platinum(II) complexes. By comparing the coupling constants of these complexes, a significant difference in $^3J_{Pt-C(6)}$ values was detected. [Pt(en)(1*S*,2*R*-amcha)]Cl_2 and [Pt(NH_3)$_2$(1*S*,2*R*-amcha)]Cl_2 gave 43.3 and 43.9 Hz, respectively, while [Pt(en)(1*R*,2*R*-amcha)]Cl_2 and [Pt(NH_3)$_2$(1*R*,2*R*-amcha)]Cl_2 gave 20.2 and 22.0 Hz. Recently, Bagger[8] and Erickson *et al.*[9] have demonstrated that in five-membered platinum(II) complexes the coupling constant $^3J_{Pt-N-C-C}$ shows a Karplus-type angle dependence on the dihedral angle between the planes Pt–N–C and N–C–C. It turns out that the significant difference in $^3J_{Pt-C}$ found would be explained if the relationship $^3J_{Pt-N-C-C}=a\cos^2\phi$ is also valid in six-membered platinum(II) complexes, ϕ being the dihedral angle between the planes Pt–N–C and N–C–C, and a being a constant. The molecular models suggest that [Pt(en)(1*S*,2*R*-amcha)]Cl_2 and [Pt(NH_3)$_2$ (1*S*,2*R*-amcha)]Cl_2 may take either a chair form or a δ-skew form. Whichever form these platinum(II) complexes take, the dihedral angle of Pt–N–C(1)–C(6) is about 180° (Fig. 5). The $^3J_{Pt-C(6)}$ values for [Pt(en)(1*S*,2*R*-amcha)]Cl_2 and [Pt(NH_3)$_2$(1*S*,2*R*-amcha)]Cl_2 were 43.3 and 43.9 Hz, respectively. A

similar value has been reported for (*R,S*)-1,3-diphenyl-1,3-propanediamine platinum(II) complexes in which both phenyl groups are equatorial.[10] The *a* values in the equation $^3J_{Pt-N-C-C}=a\cos^2\phi$ seem to be 43—44 Hz. $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$ may take two chair forms or a λ-skew form, but may not take a δ-skew form because of the steric hindrance. As shown in Fig. 5, an angle of 180° may be expected for one chair form or the λ-skew form and about 60° for the other chair form. The ^{1}H-NMR data show that the cyclohexane ring of (1*R*,2*R*)-amcha platinum(II) complexes is interconverting between two chair forms, and hence that the chelate ring will interconvert. When two chair forms interconvert with each other rapidly on a NMR time scale, the averaged coupling constant due to a rapid ring interconversion would be $^3J_{Pt-C(6)}=1/2$ $(a\cos^2180°+a\cos^260°)$ $(a=43—44$ Hz), that is $^3J_{Pt-C(6)}=$ 27.0—27.5 Hz. If the population of a λ-skew intermediate which appears in interconverting between two chair forms cannot be neglected, the $^3J_{Pt-C(6)}$ value is expected to be larger than 27.0—27.5 Hz. According to the conformational analysis of the planar $ML_2(tn)$ type complex (L=a monodentate ligand, tn=1,3-propanediamine), the interconversion occurred *via* a skew intermediate,[3,11] but the population of the intermediate conformer was small at room temperature.[3,11] Experimental values of $^3J_{Pt-C(6)}$ for $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$ were 20.2 and 22.0 Hz, respectively. Thus the λ-skew may be neglected because the experimental values are smaller than the values calculated from the 1:1 abundance ratio of the two chair forms. Assuming the equatorial and axial C–C(6) chair form exactly take the angles of 180° and 60°, respectively, the population of the former conformer may be smaller than the latter.

Absorption and CD Spectra. In aqueous solution, $[Pt(en)(1S,2R\text{-amcha})]Cl_2$ exhibited five absorption bands in the ultraviolet region, as shown in Fig. 6. The band at 37000 cm^{-1}, on the basis of D_{4h} symmetry, can be assigned to $^1A_{1g}$-^3E_g (band II), and those at 41700 (shoulder), 44400, and 47000 cm^{-1} to $^1A_{1g}$-$^1A_{2g}$ (band III), $^1A_{1g}$-^1E_g (band IV), and charge transfer transitions, respectively. The shoulder at 31300 cm^{-1} may be assigned to the $^1A_{1g}$-$^3A_{2g}$ (band I) transition.[12] Similarly, $[Pt(NH_3)_2(1S,2R\text{-amcha})]Cl_2$ exhibited four bands. The band at 35700 cm^{-1} can be assigned to band II and the bands at 41700 (shoulder), 44400, and 48100 cm^{-1} to band III, band IV, and charge transfer transitions, respectively. As shown in Fig. 7, $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$ exhibited four absorption bands. The bands at 35700, 41700 (shoulder), 44400, and 48100 cm^{-1} may be assigned to band II, band III, band IV, and charge transfer transitions, respectively.[12]

Figure 6 also shows the CD spectra of $[Pt(en)(1S,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1S,2R\text{-amcha})]Cl_2$ in water. $[Pt(en)(1S,2R\text{-amcha})]Cl_2$ exhibited three CD bands at 32700, 37000, and 42600 cm^{-1} with signs of positive, negative, and positive, respectively. These CD bands correspond to bands I, II ,and III in the absorption spectrum. $[Pt(NH_3)_2(1S,2R\text{-amcha})]Cl_2$ exhibited two CD bands, corresponding to bands II

and III in the absorption spectrum. Although the peak of band IV in both complexes could not be detected in the CD spectra, its sign can be estimated to be negative, as shown in Fig. 6. The CD spectral data of the platinum(II) complexes are presented in Table 3. The absolute CD strength ($=|\Delta\varepsilon|$) of [Pt(en)(1*S*,2*R*-amcha)]Cl_2 and [$Pt(NH_3)_2$(1*S*,2*R*-amcha)]Cl_2 is lower than that of the five-membered platinum(II) complexes containing (*R*)-1,2-propanediamine and (*R*,*R*)-1,2-cyclohexanediamine.[12] The optical activity due to the chelate ring of amcha may be expected to arise from (i) the conformational effect of the chelate ring and (ii) the vicinal effect of the asymmetric carbon. However, only the vicinal effect of the asymmetric carbon seems to contribute to the $|\Delta\varepsilon|$ values of [Pt(en)(1*S*,2*R*-amcha)]Cl_2 and [$Pt(NH_3)_2$(1*S*,2*R*-amcha)]Cl_2. Namely, the observed low $|\Delta\varepsilon|$ values of these complexes can be explained by considering as preferential the chair form which does not make any conformational contribution to the CD spectra. The chair and the λ-skew form could not be distinguished by ^{13}C-NMR analyses, but the CD spectral data indicate a fixed chair form with a dihedral angle of 180° (Fig. 8). As shown in Fig. 7, the CD spectra of [Pt(en)(1*R*,2*R*-amcha)]Cl_2 and

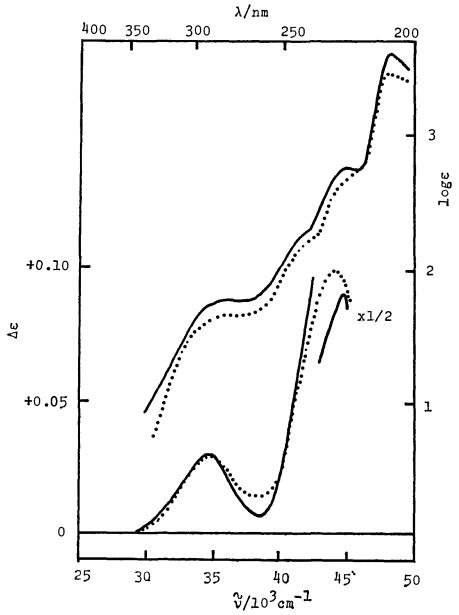

Fig. 7. Absorption and CD spectra of ——: [Pt(en)(1*R*,2*R*-amcha)]Cl_2 and ·····: [$Pt(NH_3)_2$(1*R*,2*R*-amcha)]Cl_2.

Table 3. Absorption and CD spectral data

Complexes	Absorption $\tilde{\nu}/10^3$ cm^{-1} (log ε)	CD $\tilde{\nu}/10^3$ cm^{-1} ($\Delta\varepsilon$)
[Pt(en)(1*S*,2*R*-amcha)]Cl_2	31.3(1.15)	32.7(+0.019)
	37.0(1.82)	37.0(−0.036)
	41.7 sh	42.6(+0.160)
	44.4(2.78)	
	47.0(3.23)	
[$Pt(NH_3)_2$(1*S*,2*R*-amcha)]Cl_2	35.7(1.75)	35.7(−0.061)
	41.7 sh	41.7(+0.099)
	44.4(2.74)	
	48.1(3.57)

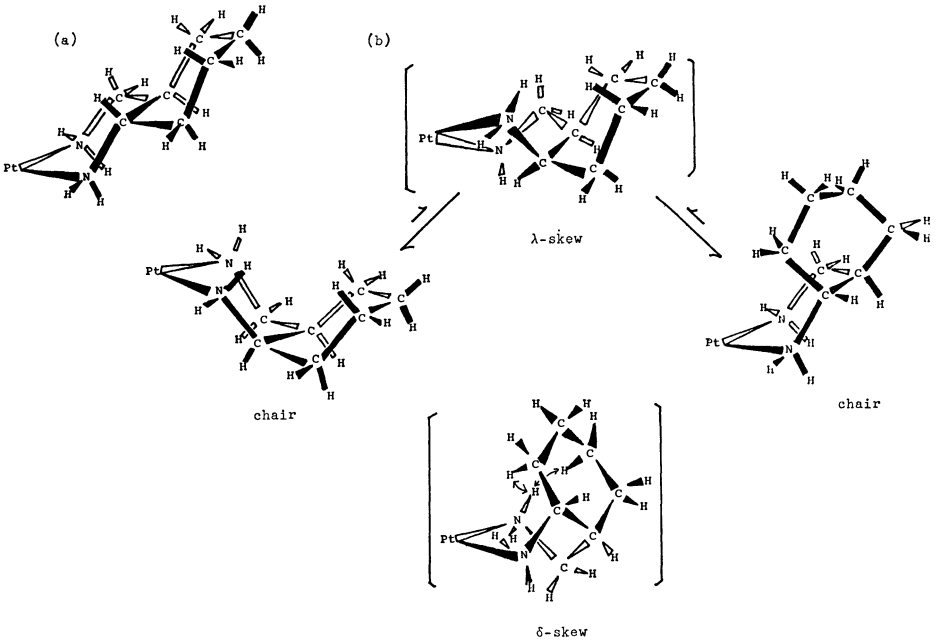

Fig. 8. Proposed conformations of (a) [PtX(1*S*,2*R*-amcha)]Cl_2 and (b) [PtX(1*R*,2*R*-amcha)]Cl_2 (X=en, $(NH_3)_2$).

$[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$ showed positive bands at 34500 and *ca.* 44000 cm^{-1}, corresponding to bands II and IV in their absorption spectra. As shown in Table 3, the $|\Delta\varepsilon|$ values of $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$ indicate that these complexes take a chair form, which has no conformational effect. Although two chair forms may be interconverting with each other *via* a λ-skew intermediate, the population of the λ-skew form can be neglected, according to the ^{13}C-NMR and CD spectral data. It is concluded that $[Pt(en)(1R,2R\text{-amcha})]Cl_2$ and $[Pt(NH_3)_2(1R,2R\text{-amcha})]Cl_2$ are apparently interconverting between two chair forms (Fig. 8).

The authors are sincerely grateful to Dr. John C. Bailar, Jr., University of Illiois, for his helpful advice and suggestions in reviewing this paper. This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan.

A Kinetic Study of the Base Hydrolysis of (2-Aminoethanol)bis-(ethylenediamine)halogenocobalt(III) Complexes

Kazuko Ogino* and Hitoshi Seki**

College of Medical Sciences, Tohoku University, Seiryo-machi, Sendai 980

(Received July 1, 1980)

The base hydrolysis of *cis*-$[CoX(etaH)(en)_2]^{2+}$(X=Cl or Br, etaH=2-aminoethanol, en=ethylenediamine) has been studied. The hydrolysis results in the formation of $[Co(eta)(en)_2]^{2+}$ (≈35%) and $[Co(OH)(etaH)(en)_2]^{2+}$ (≈65%) at I=1.0 (KNO_3), 25 °C, the product ratio being independent of the pH. The base hydrolysis has also been studied in the presence of sodium azide.

The base hydrolysis of *cis*-$[CoX(etaH)(en)_2]^{2+}$ has been studied by several workers. Chan and Leh,[1] Hay and Cropp[2] and Udovenko *et al.*[3] reported that the hydrolysis product of the chloro complex was the hydroxo complex $[Co(OH)(etaH)(en)_2]^{2+}$ in which the etaH is unidentate. On the other hand, the synthesis of $[Co(etaH)(en)_2]^{3+}$ complexes containing the chelated etaH *via* the base hydrolysis of *cis*-$[CoBr(etaH)(en)_2]^{2+}$ was reported by Buckingham *et al.*[4] Similarly, several complexes of the $[Co(amOH)(diamine)_2]^{3+}$ type (amOH=2-amino-1-alkanol) were synthesized through the base hydrolysis of $[CoX(amOH)(diamine)_2]^{2+}$.[5,6] The present investigation has been undertaken in order to clarify the products of the hydrolysis of *cis*-$[CoX(etaH)(en)_2]^{2+}$ and to elucidate the mechanism of the reaction.

Experimental

Materials. The *cis*-$[CoX(amine)(en)_2]X_2$(amine=$C_2H_5NH_2$ or etaH) and $[Co(etaH)(en)_2]Br_3$ were prepared according to the literature method.[4,7] All the other reagents were of a reagent grade.

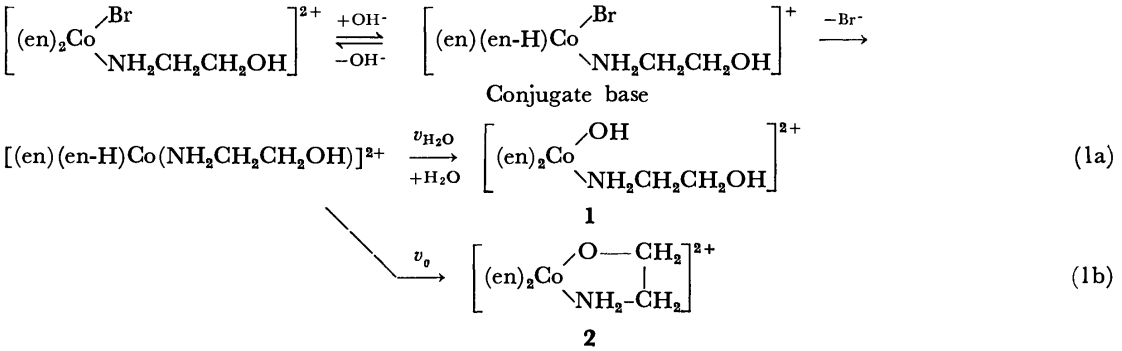
Kinetic Measurements. The base hydrolysis of *cis*-$[CoX(amine)(en)_2]^{2+}$ was followed by the pH stat method using a Metrohm Combi 6-1 titrator under a nitrogen atmosphere at 25 °C and I=1.0 (KNO_3). Product analyses were performed pH-metrically. The titrant was 0.05 M NaOH (1 M=1 mol dm^{-3}).

Results and Discussion

Equivalent amounts of the base are consumed during the course of base hydrolyses of $[CoX(amine)(en)_2]^{2+}$.[8] The rate of hydrolysis was measured by the pH stat method at pH 9—10. The data fit the rate law of $k_{obsd}=k[OH^-]$, the values of k being 51 and 31 M^{-1} s^{-1} for *cis*-$[CoBr(etaH)(en)_2]^{2+}$ and *cis*-$[CoBr(C_2H_5NH_2)(en)_2]^{2+}$ respectively at I=1.0(KNO_3) and 25 °C. The values for the former is somewhat smaller than that at I=0.1 reported by Buckingham *et al.*[4]

After the base hydrolyses had been completed, the solutions were acidified with appropriate amounts of 0.1 M HCl and were then titrated with 0.05 M NaOH. The titration curve remained unchanged after the solution had been left standing at pH 10 at 25 °C for 1 h. The base hydrolysis of *cis*-$[CoBr(C_2H_5NH_2)(en)_2]^{2+}$ resulted in the formation of a product with a pK_a value of 6.25 at I=1.0(KNO_3) and 25 °C; this indicates that the product should be $[Co(H_2O)(C_2H_5NH_2)(en)_2]^{3+}$. The titration curve of the hydrolysis products of *cis*-$[CoBr(etaH)(en)_2]^{2+}$ shows two inflection points, as is shown in Fig. 1, indicating that two species, **1** and **2**, are produced during the base hydrolysis of $[CoBr(etaH)(en)_2]^{2+}$. The abundance ratio and pK_a values of these two species were determined by analyzing the titration curves in the manner described in the Appendix. The results are given in Table 1. Species **1** with a pK_a value of 6.2, is considered to be $[Co(H_2O)(etaH)(en)_2]^{3+}$ by a comparison of the pK_a value with those of several cobalt(III) complexes with a coordinated water.[9] Species **2** with a pK_a value of 4.0, is considered to be $[Co(etaH)(en)_2]^{3+}$, because the titration of the solution of $[Co(etaH)(en)_2]Br_3$ showed its pK_a to be 4.0 at I=1.0, 25 °C. These values are somewhat larger than those at lower ionic strengths reported in previous papers.[4,5]

The conjugate-base mechanism has been established for the base hydrolyses of cobalt(III) aniono amine complexes. According to the S_N1 CB mechanism, the base hydrolysis of $[CoX(etaH)(en)_2]^{2+}$ can be expressed by the following scheme.



** Present address: Osaka Research Laboratory, Rasa Industries, Ltd., 9-134, 1-Chome, Takami, Konohana-ku, Osaka 554.

Table 1. Products of the base hydrolysis of *cis*-$[CoX(etaH)(en)_2]^{2+}$ as determined by the analysis of the titration curves. $I=1.0(KNO_3)$, 25 °C

X	pH[a]	Complex-hydrolyzed / mmol[b]	Species **1** / mmol[c]	pK_1	[1] / [Complex-hydrolyzed]
Br	9.3	0.0229	0.0142	6.22	0.62
Br[d]	10.0	0.0304	0.0190	6.16	0.63
Br	10.6	0.0241	0.0151	6.27	0.62
Cl	10.0	0.0354	0.0232	6.22	0.65

a) The pH at which base hydrolysis was performed. b) The volume of the solution was 4 cm³. c) The deviation is ±0.005 mmol. d) In this run, the amount of Species **2** formed and the pK_2 were obtained as 0.0109 mmol and 3.98 respectively.

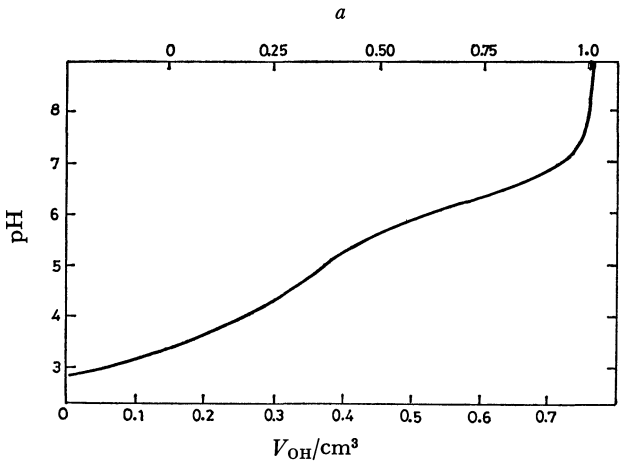


Fig. 1. Titration curve of products formed by the base hydrolysis of 0.0304 mmol *cis*-$[CoBr(etaH)(en)_2]Br_2$ at pH 10.0, followed by the addition of 0.038 mmol of HCl. $I=1.0$ (KNO_3), 25 °C. The abscissa V_{OH} is the volume of 0.05 M NaOH added during the titration and a is the ratio: [Moles of NaOH consumed for the dissociation of the complex]/[Moles of total complex].

The results in Table 1 show that the product ratio [Species **1**]/[Total amount of complex-hydrolyzed] is independent of the pH within the limit of experimental error. This means that both v_{H_2O} and v_0 are independent of the pH. Table 1 shows also that Species **2**, which contains an amino alcohol chelate ring, is the minor product of the base hydrolysis. The reaction paths by which Species **1** is converted into Species **2** will be described elsewhere.

Buckingham *et al.*[10-12] disclosed that the base hydrolyses of complexes of the *cis*-$[CoBr(\widehat{NO})(en)_2]^{m+}$ type ($\widehat{NO}$=$NH_2CH_2COO^-$, $NH_2CH_2COOC_3H_7$, $NH_2CH_2CONH_2$, *etc.*; the underlining denotes the coordinating atom) result in the formation of two types of products, $[Co(OH)(\widehat{NO})(en)_2]^{m+}$ and $[Co(\widehat{NO})(en)_2]^{m+}$. The relative amounts of these two products were also reported; the formation ratio of the chelated species is 35—45% for various $\widehat{NO}$ ligands.[10-12] The similarity of the product ratios, including ours given in Table 1, indicates that the lifetime of the five-coordinate intermediate is not long enough to be able to distinguish various entering moieties, $-CH_2COO^-$, $-CONH_2$, $-CH_2OH$, *etc.*, with differing nucleophilicities.

The product ratio study was also performed in the presence of sodium azide. In this case, the procedure described in the Appendix could not be used because of the interference due to the HN_3–N_3^- equilibrium ($pK_a \approx 4.7$). In the presence of azide, the base hydrolysis is assumed to proceed by Path 1c in addition to Paths 1a and 1b, by analogy with the base hydrolyses of various pentaaminehalogenocobalt(III) complexes.[12-15]

$$[(en)(en\text{-}H)Co(NH_2CH_2CH_2OH)]^{2+} \xrightarrow[+N_3^-,\ +H^+]{v_{N_3^-}} \left[(en)_2Co\begin{matrix}N_3\\ NH_2CH_2CH_2OH\end{matrix}\right]^{2+} \quad (1c)$$

3

The formation of the azido complex was confirmed spectrophotometrically by the appearence of an intense absorption at 516 nm. Since the azido complex is formed from the bromo complex without consuming the base, the amount of base consumed during the base hydrolysis should correspond to the amount of Species **1** and **2** formed:[8]

$$\alpha \equiv \frac{\text{Moles of base consumed}}{\text{Moles of complex hydrolyzed}} = \frac{[1]+[2]}{[1]+[2]+[3]}. \quad (2)$$

According to the S_N1 CB mechanism, the product ratio should be related to the relative magnitudes of the rates of Paths 1a—1c:

$$\alpha = \frac{v_0+v_{H_2O}}{v_0+v_{H_2O}+v_{N_3^-}}. \quad (3)$$

Equation 3 can be transformed to:

$$\frac{1-\alpha}{\alpha} = \frac{v_{N_3^-}}{v_0+v_{H_2O}}. \quad (4)$$

The plots of the left-hand side of Eq. 4 against the azide concentration are given in Fig. 2 for $[CoBr(etaH)(en)_2]^{2+}$ and $[CoBr(NH_2C_2H_5)(en)_2]^{2+}$. They are almost straight lines, implying that $v_{N_3^-}$ is proportional to $[N_3^-]$ within the limits of experimental error. Such first-order dependence of product ratios has been reported and discussed for the base hydrolyses of several anionopentaaminecobalt(III) complexes.[13,14] At the same azide concentration (1 M), the ratio of the amount of the azido complex in the products is 10% for $[CoBr(NH_3)_5]^{2+}$,[13,14] 20% for $[CoBr(NH_2CH_2COO)(en)_2]^+$,[12] 24% for $[CoBr(NH_3)(en)_2]^{2+}$,[13] 30% for $[CoBr(etaH)(en)_2]^{2+}$, and 40% for $[CoBr(NH_2C_2H_5)$-

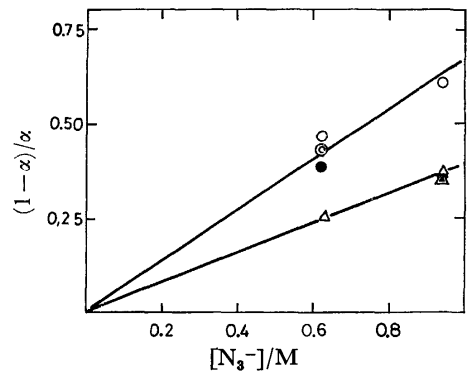

Fig. 2. The dependence of the product ratio of base hydrolysis on azide concentration, I=1.0 (KNO_3), 25 °C.
$[CoBr(NH_2C_2H_5)(en)_2]^{2+}$: pH 9.0 (○), pH 9.3 (◎), pH 9.6 (●) $[CoBr(etaH)(en)_2]^{2+}$: pH 9.3 (△), pH 9.6 (▲), pH 10.6 (◬).

$(en)_2]^{2+}$. The rather large variation in these competition ratios is in contrast with the similarity of the $[Co(\widehat{NO})(en)_2]$/[Total amount of complex hydrolyzed] ratio. It may at least partly be attributed to the ion-pair effect between the cobalt(III) complex and azide ions; the $[CoBr(NH_2CH_2COO)(en)_2]^+$ ions show a smaller value than the $NH_2C_2H_5$ or the etaH complex with a +2 charge. The importance of the ion-pair effect in the product ratio has been pointed out by Buckingham *et al.*[12,16] The smaller value for the etaH complex than that for the $NH_2C_2H_5$ complex may be partly due to the presence of Path 1b in the hydrolysis of the former.

Appendix

The titration curves of mixtures of $[Co(H_2O)(etaH)(en)_2]^{3+}$ (abbreviated as AH) and $[Co(etaH)(en)_2]^{3+}$ (BH) are analyzed in the following manner in order to determine the ratio of the amounts of these species as well as their pK_a values. The abbreviations given by Eqs. 5—8 are used:

$$[A]_T = [AH] + [A^-] = [AH](1+K_1/[H^+]), \quad (5)$$

$$[B]_T = [BH] + [B^-] = [BH](1+K_2/[H^+]), \quad (6)$$

where K_1 and K_2 are the acid-dissociation constants of AH and BH respectively;

$$[Co]_T = [A]_T + [B]_T, \quad (7)$$

$$[Cl^-] = (\text{Moles of HCl added after base hydrolysis})/V, \quad (8)^{8)}$$

where V is the volume of the solution under titration. When the balance of the positive and negative charges is taken into account, the following equation is obtained:

$$[AH] + [BH] + [H^+] = [Cl^-] - \frac{N_{OH}V_{OH}}{V}, \quad (9)$$

where N_{OH} is the concentration of sodium hydroxide used for the titration and V_{OH} is the volume of the hydroxide solution added during the titration. The substitution of Eqs. 5—8 into Eq. 9 gives:

$$\frac{[B]_T(K_2-K_1)}{[H^+]+K_2} = [H^+] + [Co]_T - [Cl^-] + \frac{N_{OH}V_{OH}}{V} - \frac{K_1}{[H^+]}\left([Cl^-] - \frac{N_{OH}V_{OH}}{V} - [H^+]\right), \quad (10)$$

$$\frac{[A]_T(K_2-K_1)}{[H^+]+K_1} = [Cl^-] - [H^+] - [Co]_T - \frac{N_{OH}V_{OH}}{V} + \frac{K_2}{[H^+]}\left([Cl^-] - \frac{N_{OH}V_{OH}}{V} - [H^+]\right). \quad (11)$$

When $K_2 \gg K_1$ and $[H^+] \ll K_2$, Eq. 11 can be simplified as:

$$\left([Cl^-] - \frac{N_{OH}V_{OH}}{V}\right)^{-1} = \left(1+\frac{K_1}{[H^+]}\right)\frac{1}{[A]_T}. \quad (12)$$

Plotting the left-hand side of Eq. 12 against $[H^+]^{-1}$, one should obtain a straight line; from its slope and intercept, the values of K_1 and $[A]_T$ can be calculated. The $[B]_T$ value can be obtained by the use of Eq. 7 if $[A]_T$ is known.

The right-hand side of Eq. 10 can be calculated provided the K_1 value is known. The condition $K_2 \gg K_1$ being assumed, the following equation is obtained:

$$(\text{The right-hand side of Eq. 10})^{-1} = \left(1+\frac{[H^+]}{K_2}\right)\frac{1}{[B]_T}. \quad (13)$$

The plot of the left-hand side of Eq. 13 against $[H^+]$ gives a straight line; from its slope and intercept, the values of K_2 and $[B]_T$ can be calculated.

We wish to acknowledge a Grant-in-Aid for Scientific Research No. 25419 from the Ministry of Education, Science and Culture.

8) Strictly speaking, the amount of base required is in a slight excess (≈0.001 mmol) over the amount of complex hydrolyzed. The excess base is required to bring the pH of the solution to the pH at which the base hydrolysis is performed. This amount was evaluated by titrating the solution containing an appropriate amount of KNO_3 (and/or NaN_3), but no complex. The amount of base in Eq. 2 and those of hydrochloric acid in Eq. 8 and Fig. 1 are the values corrected for the excess base.

The Polarized Spectra and Thermal Diffusivity of Brown Tourmaline as Studied by Photoacoustic Spectroscopy

Yoshinori SUGITANI* and Masahisa FUJINAMI
Institute of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received August 21, 1980)

The strong pleochroic band of brown tourmaline at around 24000 cm^{-1} in the E⊥c photoacoustic spectra was assigned to d-d($^6A_1 \rightarrow {}^4A_1$, ^4E) transition of Fe and to charge transfer of Ti, that in the E//c spectra being entirely assigned to charge transfer of Ti. The analysis of the photoacoustic signal intensity *vs.* chopping frequency gave the thermal diffusivity constant of tourmaline as $\alpha = 0.15$ cm^2/s.

Tourmaline is a complex solid-solution mineral represented by $Na(Mg,Fe)_3Al_6(BO_3)_3(Si_6O_{18})(OH)_4$.[1,2] The color is usually black but varies a great deal with composition, being brown, blue, green, colorless (iron-free varieties) and pink (lithium-bearing varieties). Some varieties with intermediate coloration of brown or bluish green show strong pleochroism. The origin of the colors and the pleochroism of silicate minerals including tourmaline have been extensively studied mainly by means of polarized absorption spectra. Many of the bands or peaks observed are explained in terms of the d-d transitions and/or charge transfer electron hopping within transition metal ions contained.[3] However, the strong pleochroic band of brown tourmaline observed around 22000—24000 cm^{-1}, has not yet been clarified. Two contradicting explanations have been given,[4,5] ascribing the band to (a) the d-d transition of Fe and (b) the electron hopping (charge transfer) of $Ti^{3+} \rightarrow Ti^{4+}$ type.

Polarized photoacoustic spectra of a brown tourmaline we observed in both the in-phase and out-of-phase modes will help clarify the nature of the relaxed thermal energy and make assignment of the band. The dependence of the photoacoustic intensity on the chopping frequency of the irradiating light gives information on the thermal diffusivity of the sample.

Experimental

Sample. A single crystal of brown tourmaline was used (locality unknown). ICP analysis gave the metal contents of Mg: 0.64 wt%, Ti: 0.32%, Mn: 0.28%, Fe: 5.74%, and Li: 0.54%, showing that the sample has the intermediate composition of typical endmembers of dravite $NaMg_3Al_6B_3Si_6O_{27}(OH,F)_4$, schorl $Na(Fe,Mn)_3Al_6B_3Si_6O_{27}(OH,F)_4$, and elbaite $Na(Li,Al)_3Al_6B_3Si_6O_{27}(OH,F)_4$.[1]

The structure of dravite has been determined by Donnay and Buerger.[6] Each magnesium ion is surrounded by four oxygen and two OH ions forming a fairly regular octahedron. Three of these octahedra are combined in an arrangement similar to the "trigonal brucite units", where each octahedron shares two of its octahedral edges with its neighbors in the 001 plane. Aluminium ion is centered in distorted (O,OH) octahedra. Each shares two of its edges with another two Al-octahedra diagonally above and below the 001 plane, resulting in spiral chains of Al-octahedra parallel to the c-axis. The ratios $Fe^{2+}:Fe^{3+}$ and $Ti^{3+}:Ti^{4+}$ are not known. However, small amounts of Fe^{3+} and Ti^{4+} are considered to occupy the Al sites.

Apparatus. The apparatus for measuring photoacoustic spectra consists of a 300 W xenon lamp, mechanical light chopper, spectrometer (25 cm, CT-25N, JASCO), photoacoustic cell with a microphone, lock-in amplifier (NF Circuit Design Block, LI-574) and a recorder. The block diagram and a brief account of the setup was reported.[7,8] In order to normalize the power spectrum of the xenon lamp, a part of the incident light was reflected by a mirror and led to another photoacoustic cell with a carbon black reference, the output of which was also lock-in amplified and compared with the signal from the main cell at the dividing unit (Rika-Denki, XB-20).

For the measurement of polarized spectra, the spectra of the tourmaline and the carbon black sample were recorded in separate runs, the comparison (division) of the results being manually conducted. This is because the intensity of the exciting light gets down to 1/4—1/5 of that just before the polarizer, resulting in an unstable work of the dividing unit. Separate measurement is also appropriate for avoiding the polarizing characteristics of the reflecting mirror.

Results and Discussion

Figure 1 shows the photoacoustic spectra of the tourmaline crystal for the case of E⊥c, *i.e.*, when the electric vector is vibrating in the plane perpendicular to the c-axis, and for the case of E//c. The solid lines indicate the in-phase spectra and the dashed lines the out-of-phase spectra which show the 90° phase-delayed signal (slow heat) with respect to the in-phase signal. The in-phase spectral patterns are very similar to those of the optical absorption spectra

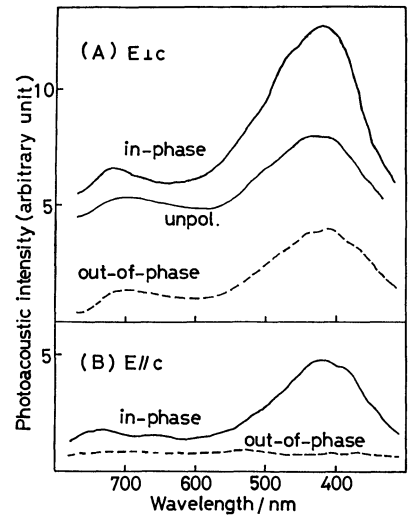

Fig. 1. In-phase and out-of-phase photoacoustic spectra of brown tourmaline at 80 Hz for polarized irradiation of E⊥c (A), and E//c (B). Unpolarized spectrum is also shown in (A).

of a Brazilian dravite[4] or a Gouverneur dravite,[5] suggesting that the origin of the color and the strong pleochroism is attributed to a similar mechanism in these tourmalines. The pleochroism is considered to arise from the band at 24000 cm^{-1}, which is larger in the E⊥c spectrum than in the E//c spectrum. The 14500 cm^{-1} band has little influence on the color of the crystal, since the spectrum is strongly dominated by the pleochroic band at 24000 cm^{-1}.

Wilkins *et al.*[4] assigned the 24000 cm^{-1} band to the d-d transition of Fe^{3+} ($^6A_1 \rightarrow {}^4A_1$, ^4E) which might be present in the aluminium position of dravite from Brazil containing 1.38% total Fe. On the other hand, Manning[5] assigned the band to the charge transfer of titanium ions located at Mg and Al site in a dravite sample containing Ti 1.15% and Fe 1.01% (the ratio Ti^{3+}:Ti^{4+} not known). According to his discussion lobes of t_{2g} orbitals of a cation located in the trigonal units are directed towards neighboring cations in the same trigonal units and in the spiral chains, making t_{2g}-t_{2g} orbital overlap in the 001 plane. Thus the charge transfer is most likely to occur in the trigonal cation plane, as represented by the E⊥c spectra. A small fraction of the Ti^{3+} is located in the spiral chains which run parallel to the c-axis. Metal-metal orbital overlap also takes place. The transition t_{2g}-e_g would have appreciable intensity in E//c spectra.

The key to the assignment of the 24000 cm^{-1} band should be found in the out-of-phase spectra, where an appreciable band intensity is observed in the E⊥c spectra and none in the E//c spectra. This shows that the band at 24000 cm^{-1} in the in-phase E⊥c spectra consists of thermally delayed signal (slow heat) with a certain contribution from fast heat component, while that in the in-phase E//c spectra entirely consists of the fast heat component. Assuming that the transition occurs only between the two energy levels concerned, a rough estimation of the characteristic lifetime of the slow heat is made by means of the relation

$$\tan\theta = 2\pi\nu\tau,$$

where θ is the phase delay angle and ν the chopping frequency. With the data of ν=80 Hz and θ=10.0°, lifetime τ is obtained as slow as $3\text{—}4\times10^{-4}$ s. This suggests that the transition responsible for the slow heat is due to the forbidden d-d type transition. The fast heat should be attributed to the allowed charge transfer type transition and order of magnitude greater than the d-d transition. Consequently the 24000 cm^{-1} band in the in-phase E⊥c spectra should be assigned to the d-d ($^6A_1$—$^4A_1$, ^4E) transition of Fe^{3+} as proposed by Wilkins *et al.*, as well as to the charge transfer of $Ti^{3+}\rightarrow Ti^{4+}$ as proposed by Manning. The band in the in-phase E//c spectra should be assigned entirely to the charge transfer of Ti located in the spiral chains of Al-centered octahedra as explained by Manning. Although the ratio of the contributions from the d-d transition of Fe and the charge transfer of Ti is not known in the in-phase E⊥c spectra, the latter contribution should not be completely neglected, since the tourmaline sample contains 0.32% Ti which exceeds the detectable amount for the charge transfer band as in the in-phase E//c spectra.

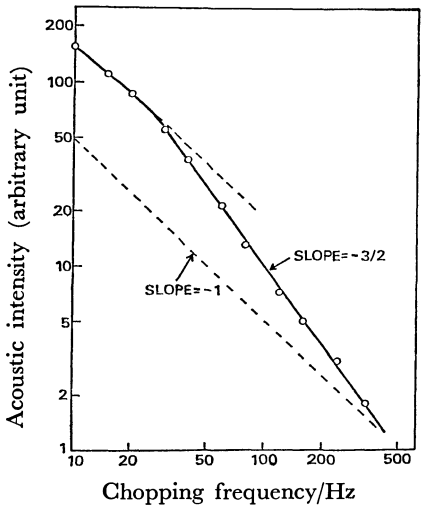

Fig. 2. A log-log plot of the photoacoustic intensity *versus* chopping frequency for brown tourmaline at 588 nm.

Thermal Diffusivity of Tourmaline. By photoacoustic study we can measure the thermal diffusivity of materials, since the intensity of photoacoustic signal depends on the thermal characteristics of the specimen as well as on the extent of the optical absorption. Adams and Kirkbright[9] estimated the thermal diffusivity of macromolecular film by measurement of phase delay as a function of the chopping frequency. An alternative way of measuring the thermal diffusivity of materials is presented here by way of the analysis of the photoacoustic signal intensity as a function of the chopping frequency.

Rosencwaig and Gersho[10] solved a heat flow equation for the treatment of the photoacoustic effect, and showed six cases depending on the relative magnitude of the optical absorption length μ_β and the thermal diffusion length μ_s with respect to the thickness l of the material. The μ_β is defined as an inverse of the optical absorption coefficient β, μ_s being defined by $\mu_s=\sqrt{2\alpha/\omega}$, where α is thermal diffusivity of the material. The photoacoustic signal would show ω^{-1} dependence for the case $\mu_s>l$ corresponding to the cases 1a and 1b, and $\omega^{-3/2}$ dependence for the case $\mu_s<l$ corresponding to the case 1c.[10,11]

The experiment on the tourmaline sample with thickness of l=0.044 cm belongs to the $\mu_\beta>l$ case (case 1), since the μ_β value is obtained as 0.08 cm at the wavelength 588 nm.

Figure 2 shows the plots of the photoacoustic intensity of the toumaline sample as a function of the chopping frequency. With the increase of ω it moves at around $\omega/2\pi$=25 Hz from a region where the dependence is primarily ω^{-1} to another region where it is $\omega^{-3/2}$. The moving point corresponds to the state of $\mu_s=l$, giving the thermal diffusivity α as

$$\mu_s = l = 0.044 = \sqrt{\frac{\alpha}{\pi\times25}}$$

$$\alpha \approx 0.15\ \mathrm{cm^2\ s^{-1}}.$$

A similar procedure was applied to a synthetic ruby sample with l=0.025 cm, giving the value of α=0.12 cm^2 s^{-1}, very close to that of tourmaline.

The authors wish to express their thanks to Prof. Kozo Nagashima, The University of Tsukuba, for his valuable advice. The work was partially supported by a Grant-in-Aid for Scientific Research No. 484032 from the Ministry of Education, Science and Culture.

(Received October 6, 1980)

Bis(acetylacetonato)cobalt(III) complexes containing a variety of 2-aminoalkylphosphines, $NH_2CH_2CH_2P(C_6H_5)_2$, $(CH_3)_2NCH_2CH_2P(C_6H_5)_2$, (*S*)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$, *rac*-$NH_2CH_2CH_2P(CH_3)(C_6H_5)$, (*R*)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$, and $NH_2CH_2CH_2P(CH_3)_2$, and a diphosphine, $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$ were prepared and resolved (or separated) into optical isomers by SP-Sephadex column chromatography. Absorption, circular dichroism, and ^1H and ^{13}C NMR spectra of the new complexes were measured and the results compared with those of the related complexes. Positions of the 2-aminoalkylphosphine and the related ligands in the spectrochemical series were as follows; $CN^- > NH_2CH_2CH_2P(CH_3)_2 > (C_6H_5)_2PCH_2CH_2P(C_6H_5)_2 > NH_2CH_2CH_2P(CH_3)(C_6H_5) \geqq NH_2CH_2CH_2P(C_4H_9)(C_6H_5) > NH_2CH(CH_3)CH_2P(C_6H_5)_2 \geqq NH_2CH_2CH_2P(C_6H_5)_2 \geqq NH_2CH_2CH_2NH_2 > (CH_3)_2NCH_2CH_2P(C_6H_5)_2$. For the ^{13}C NMR spectra, all the signals including those due to two diastereotopic phenyl groups on a phosphorus atom were assigned, and the chemical shifts and the coupling constants were determined. The methyl and carbonyl carbons which are *trans* to a phosphorus atom give a doublet signal due to four-bond (^4J(C,P)=6—7 Hz) and three-bond (^3J(C,P)=2—3 Hz) couplings, respectively, through a cobalt(III) ion.

A 2-aminoalkylphosphine can act as a bidentate ligand with phosphorus and nitrogen donor atoms, forming a five-membered chelate ring. Issleib and his coworkers prepared 2-aminoethyldiphenylphosphine[1] and its derivatives including those with a chiral phosphorus atom.[2] However, little metal complexes with such ligands have been prepared[3] and no cobalt(III) complex seems to be reported. A cobalt(III) ion which belongs to a hard acid would prefer a hard base such as a nitrogen or oxygen donor atom rather than a phosphorus donor atom which belongs to a soft base,[4] and a few cobalt(III)–phosphine complexes have been known.[5] Since 2-aminoalkylphosphines have an amino group which can strongly coordinate to a cobalt(III) ion, they might form stable chelate complexes facilitating the bond-formation between cobalt(III) and phosphorus. In this paper, we have prepared bis(acetylacetonato)cobalt(III) complexes of various 2-aminoalkylphosphines, resolved or separated them into optically active forms, and characterized the complexes by absorption, circular dichroism (CD), and ^1H and ^{13}C NMR spectroscopy. The results would be useful for studying detailed stereochemistry of other chiral metal phosphine complexes which recently attract much attention as complex catalysts in asymmetric hydrogenation of some organic compounds.[6]

Experimental

Free aminophosphines were handled under nitrogen atmosphere until they formed air-stable cobalt(III) complexes. Solvents were dried in the usual way and degassed by distillation in a stream of pure nitrogen. Absorption, CD, and ^1H and ^{13}C NMR spectra were recorded on a Hitachi 323 spectrophotometer, a JASCO J-40 spectropolarimeter, and JEOL JNM-PMX 60 and JNM-FX 100 spectrometers, respectively. Low-temperature absorption and CD measurements were made using a Union Giken SM 404 spectrophotometer and a JASCO J-40 spectropolarimeter, respectively, equipped with a Oxford Cryostat CF 204 and a DTC-2-CLOl controller.

Preparation of Aminophosphines. 2-Aminoethyldiphenylphosphine: The method of Issleib and Haferburg[1] was modified. Small pieces of lithium metal (1.7 g, 240 mmol) were added to a refluxing tetrahydrofuran (THF) solution (300 cm^3) of triphenylphosphine (32.5 g, 120 mmol). The mixture was refluxed for 6 h with stirring to give a deep red solution. *t*-Butyl chloride (11.5 g, 114 mmol) was added dropwise to the solution with stirring under cooling in an ice–salt bath. After 1 h, aziridine (7.0 g, 160 mmol) was added dropwise to the solution at 60 °C, which was then refluxed for 8 h and filtered. To the filtrate was added water (5 cm^3) dropwise and then anhydrous magnesium sulfate (*ca.* 10 g) to remove excess water. The mixture was stirred for 5 h and permitted to stand for a while. The desicant was filtered and the residue was washed with diethyl ether. The filtrate and washings were combined and the solvents were evaporated under reduced pressure. The residue was distilled to give viscous liquid at *ca.* 150 °C and *ca.* 60 Pa. Yield: 6.5 g (60%).

(S)-2-Aminopropyldiphenylphosphine: Hydrogen chloride gas was bubbled into a chloroform solution (50 cm^3) of (*S*)-2-amino-1-propanol[7] (5 g, 65 mmol), yielding a red oily product. $SOCl_2$ (7 cm^3, 100 mmol) was added to the solution dropwise with stirring. The resulting solution was gradually warmed, refluxed for 4 h, and allowed to stand overnight at room temperature. Needle crystals of (*S*)-1-chloro-2-aminopropane hydrochloride (3.3 g) thus formed were filtered. They were then added to sodium diphenylphosphide which was prepared from 1.8 g of sodium metal and 5.6 g of chlorodiphenylphosphine in liquid ammonia (70 cm^3). The solution was stirred for 3 h and mixed with THF (100 cm^3). Liquid ammonia was evaporated at room temperature, and the solution was filtered. The filtrate was concentrated under reduced pressure and an oily product remained was distilled to give colorless liquid at *ca.* 130 °C and *ca.* 10 Pa. Yield: 1.5 g.

2-Aminoethylmethylphenylphosphine: This was prepared from lithium methylphenylphosphide[8] and aziridine by a method similar to that for 2-aminoethyldiphenylphosphine. The

optical resolution was unsuccessful with $(+)_{589}$-di-μ-chloro-bis[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2*C*,*N*]dipalladium(II).[9] Yield: 25%.

Other 2-aminoalkylphosphines: (*R*)-2-Aminoethylbutylphenylphosphine,[10] 2-(dimethylamino)ethyldiphenylphosphine,[11] and 2-aminoethyldimethylphosphine[12] were prepared according to the methods reported.

Preparation of $[Co(acac)_2(L)]^+$ *Complexes. L=achiral phosphines*; $NH_2CH_2CH_2P(C_6H_5)_2$, $(CH_3)_2NCH_2CH_2P(C_6H_5)_2$, *and* $NH_2CH_2CH_2P(CH_3)_2$: A methanol solution containing $[Co(acac)_3]$ and an achiral phosphine (1:1) was stirred with active charcoal overnight at room temperature. The resulting dark red solution was filtered, adjusted the pH to *ca.* 7 with hydrochloric acid, and diluted ten times with water. This was passed through a column ($\phi 3\times 120$ cm) of an SP-Sephadex C-25 ion exchanger. The product adsorbed was eluted with a 0.02 mol/dm^3 aqueous solution of Na_2SO_4. A main red violet eluate was saturated with NaCl and the complex was extracted with chloroform except for the case of 2-aminoethyldimethylphosphine complex. The chloroform was removed under reduced pressure and the residue was dissolved in water. The complex was precipitated by the addition of excess $NaPF_6$. The 2-aminoethyldimethylphosphine complex was isolated as tetraphenylborate by the addition of $NaB(C_6H_5)_4$ to the main red violet eluate which had been concentrated under reduced pressure. The tetraphenylborate was converted to bromide with a Dowex 1×8 ion exchanger in methanol.

L=chiral phosphines; (S)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$, *rac*-$NH_2CH_2CH_2P(CH_3)(C_6H_5)$, *and* (R)-$NH_2CH_2CH_2P(C_4H_9)$-$(C_6H_5)$: The complexes were prepared by a method similar to that for 1). By elution with a 0.02 mol/dm^3 aqueous sodium $(+)_{589}$-tartratoantimonate(III) solution, two red violet bands, F-I and F-II were obtained, F-I being eluted faster than F-II. From the eluates, a pair of diastereomers, $\Lambda(S)$ (F-I) and $\Delta(S)$ (F-II) for the optically active aminophosphines,[13] and $\Delta(R)$-$\Lambda(S)$ (F-I) and $\Lambda(S)$-$\Delta(R)$ (F-II) for the racemic aminophosphine, were isolated as hexafluorophosphate or tetraphenylborate by a method similar to that described for 1) (Table 1). Δ and Λ represent the absolute configuration of a cobalt(III) ion, and *R* and *S* that of a phosphorus and carbon atom.

Bis(acetylacetonato)[1,2-bis(diphenylphosphino)ethane]cobalt(III) hexafluorophosphate: This was prepared from $[Co(acac)_3]$ and 1,2-bis(diphenylphosphino)ethane (Strem. Chem. Inc.) by a method similar to that for the aminophosphine complexes.

Optical Resolution: Resolutions of the $NH_2CH_2CH_2P$-$(C_6H_5)_2$ and $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$ complexes were attempted by SP-Sephadex column chromatography using a 0.02 mol/dm^3 aqueous sodium $(+)_{589}$-tartratoantimonate(III) solution as an eluent. However, the bands of enantiomers were separated incompletely, so that the chromatography was repeated until no further increase in $\Delta\varepsilon/\varepsilon$ values for the first and the last fractions was observed. From the eluates, the optical isomers were isolated by a method similar to that for the racemates. Resolutions of the methylphenyl- and dimethyl-phosphine complexes were poor in similar SP-Sephadex column chromatography.

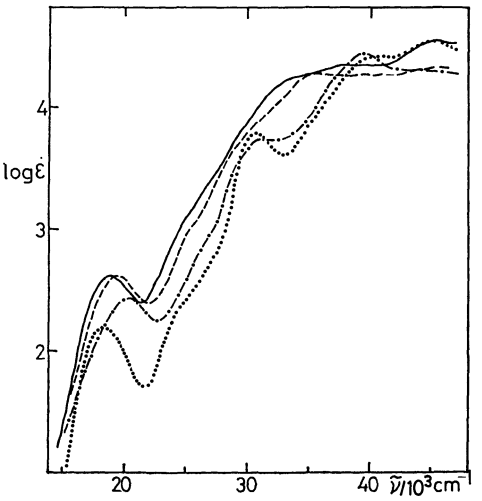

Fig. 1. Absorption spectra of complexes, **1**(———), **4c**(------), **6**(—·—·—·—), and $[Co(acac)_2(en)]ClO_4$ (·····) in ethanol.

Analytical data of the new complexes are given in Table 1.

Results and Discussion

Absorption Spectra. Reports have been given on the spectrochemical series of various unidentate[14,15] and bidentate[16] phosphine ligands, although there are some discordances among the reports. The bis(acetylacetonato)aminophosphine–cobalt(III) complexes prepared in this study show the first absorption bands around 20000 cm^{-1} with fairly strong intensity. Figure 1 shows absorption spectra of the NH_2CH_2-$CH_2P(CH_3)_n(C_6H_5)_{2-n}$ (n=0,1,2) complexes along

a) **8**: $[Co(acac)_2(NH_2CH_2CH_2NH_2)]ClO_4$, R. D. Archer and B. P. Cotsoradis, *Inorg. Chem.*, **4**, 1584 (1965). b) **9**: $K[Co(CN)_2(acac)_2]$.[18]

with that of the corresponding ethylenediamine complex for comparison. Spectral data of all the aminophosphine and the related complexes are summarized in Table 2. When a phenyl group on a phosphorus atom is replaced by a methyl group, the absorption peaks shift to higher energy. The spectrochemical series of the ligands is determined as $CN^- > NH_2CH_2CH_2P(CH_3)_2 > (C_6H_5)_2PCH_2CH_2P(C_6H_5)_2 > NH_2CH_2CH_2P(CH_3)(C_6H_5) \geqq NH_2CH_2CH_2P(C_4H_9)(C_6H_5) > NH_2CH(CH_3)CH_2P(C_6H_5)_2 \geqq NH_2CH_2CH_2P(C_6H_5)_2 \geqq NH_2CH_2CH_2NH_2 > (CH_3)_2NCH_2CH_2P(C_6H_5)_2$, and that of the donor groups as $CN^- > -P(CH_3)_2 > -P(CH_3)(C_6H_5) \geqq -P(C_4H_9)(C_6H_5) > -P(C_6H_5)_2 \geqq -NH_2 > -N(CH_3)_2$. Since a phosphorus donor group occupies a fairly higher position than an acetylacetonate ion in the spectrochemical series, it is expected that the first absorption band of a bis(acetylacetonato)phosphine–cobalt(III) complex splits into two components[17] as observed for analogous complexes, *cis*-$[Co(CN)_2(acac)_2]^-$ (19000 and *ca.* 23300 cm^{-1})[18] and *cis*-$[Co(CN)_2(C_2O_4)_2]^{3-}$ (18000 and 23400 cm^{-1}).[19] The 1,2-bis(diphenylphosphino)ethane complex (**7**) gives only a single broad band at 20160 cm^{-1} at 304 K. However, the band clearly exhibits two components at *ca.* 19400 and 20600 cm^{-1} at 173 K (Fig. 2). The 2-aminoethyldiphenylphosphine complex (**1**) shows no indication of such a splitting even at 173 K.

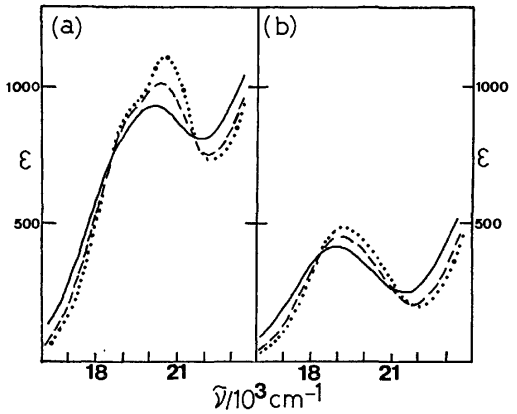

Fig. 2. Absorption spectra of complexes, **7**(a) and **1**(b) at 304 K (———), 223 K(------), and 173 K (·····) in ethanol.

The intensities of the first absorption bands increase with an increase in the number of phenyl groups on a phosphorus atom. Two diastereomers **4a** and **4b** show fairly different intensities from each other (ε(**4b**)/ε(**4a**)=1.7). However, the average intensity (2.51) of these isomers is nearly the same as that (2.55) of the diphenylphosphine (**1**) and the dimethylphosphine (**6**) complexes. The difference in intensity between diastereomers **4a** and **4b** might be related with the relative location of a phenyl group to an acetylacetonate ring, since the intensities of **4a** and **4b** are similar to those of the dimethylphosphine (**6**) and the diphenylphosphine (**1**) complexes, respectively. Complexes **4a** and **6**, and **4b** and **1** have a methyl and a phenyl group, respectively, over one acetylacetonate ring (*vide post*, Fig. 7). A similar difference in intensity is seen between diastereomers of the butylphenylphosphine complex, **5a** and **5b**.

The second absorption bands of the present complexes are hidden by intense absorptions due to charge transfer transitions between the ligands and the cobalt(III) ion or internal transitions of the ligands. The absorptions around 30500 and 33000 cm^{-1} could be assigned to those due to the acetylacetonate and phenylphosphine moieties, respectively.

Circular Dichroism Spectra. Absorption and CD spectra of complexes **1**, **7**, and $[Co(acac)_2(NH_2CH_2CH_2NH_2)]^+$ (**8**) are shown in Fig. 3, and the spectral data in Table 2 with those of the related complexes. In the region of the first absorption band, the CD intensities increase remarkably with an increase in absorption intensity. The phosphine complexes **1** and **7** show three CD bands with minus, plus, and minus signs from the low energy side, while the ethylenediamine complex (**8**) two negative CD bands. However, the CD spectrum of complex **8** shows remarkable temperature dependence in the region of the first absorption band and exhibits three

CD bands at 168 K (Fig. 4), the spectral pattern being very similar to those of complexes **1** and **7**. The phosphine complexes also show temperature dependence in the CD, but the spectral patterns remain unchanged (Fig. 4). The enantiomer of the ethylenediamine complex with the negative main CD band has been assigned to Λ configuration.[20] Thus both phosphine complexes in Fig. 3 can be assigned to the same Λ configuration. These enantiomers are those moving more slowly on columns of SP-Sephadex (Experimental).

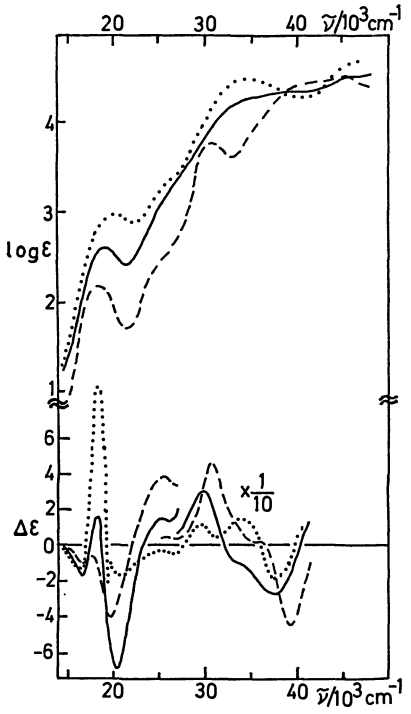

Fig. 3. Absorption and CD spectra of complexes, **1** (———), **7**(·····), and Λ-$[Co(acac)_2(en)]^+$ [20] (------) in ethanol.

A pair of diastereomers, $\Lambda(S)$ and $\Lambda(S)$ of the (S)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$ complex show CD spectra nearly enantiomeric to each other as observed for the corresponding diastereomers of the (S)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ complex[21] (Fig. 5). The results indicate that the vicinal effects of the chiral ligands to CD are small compared with the configurational effect in these complexes. The vicinal and configurational effect curves were calculated in the usual way[21] (Fig. 6). The configurational effect CD curves of the (S)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$ and (S)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ complexes are nearly the same as the CD spectrum of the $NH_2CH_2CH_2P(C_6H_5)_2$ complex, although the curve of the (S)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ complex in the ultraviolet region deviates a little from the other curves probably because of the substituent variation on the donating phosphorus atom. Thus the additivity rule[22] for the configurational and vicinal effects can be applied to the CD spectra of cobalt(III) phosphine complexes. The vicinal effect CD curve of the (S)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$ chelate ligand should be caused by the chiral conformation and the chiral carbon atom. In general, the effect of a chiral conformation is much stronger than that of a non-ligating chiral atom,[23] and the effect of a δ-gauche chelate ring gives negative CD in the region of the first absorption band.[24] The vicinal effect CD curve of the (S)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$ ligand shows a negative main CD band in this region, indicating the δ-gauche conformation. When the ligand is in the δ-gauche form, the methyl group is disposed equatorially. The vicinal effect CD curve of the (S)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ ligand shows two CD bands with different signs in the region of the first absorption band, the higher energy negative band being stronger than the lower energy positive one (Fig. 6). The chelate conformation of this ligand might not be fixed in a particular chirality, δ or λ,

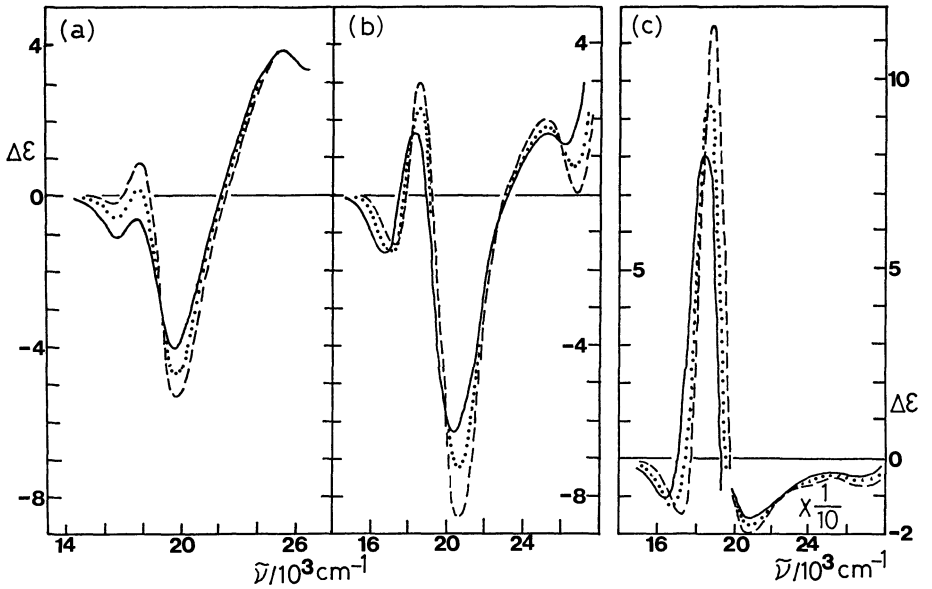

Fig. 4. CD spectra of complexes, Λ-$[Co(acac)_2(en)]ClO_4$(a), **1**(b), and **7**(c) at 298 K(———), 223 K(·····), and 168 K(------) in ethanol.

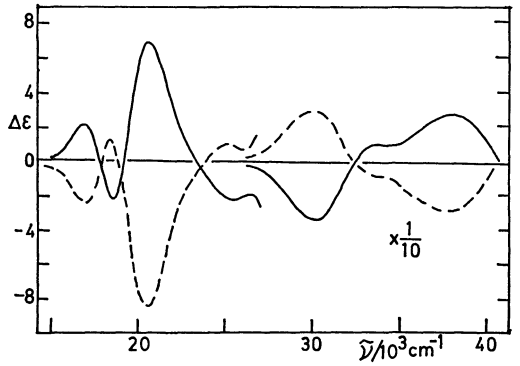

Fig. 5. CD spectra of complexes, **3a**(———) and **3b** (------) in ethanol.

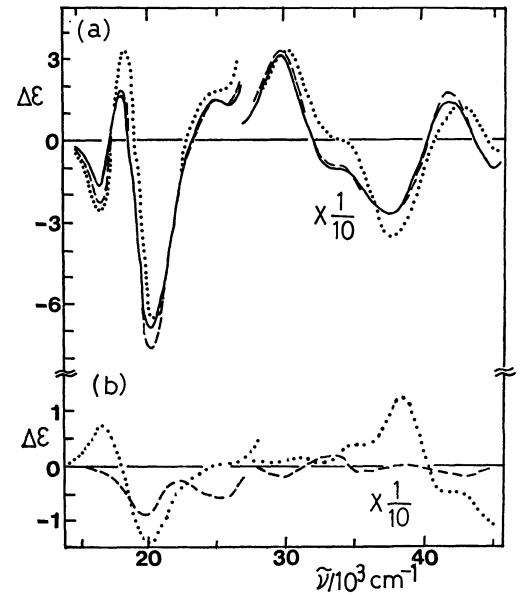

Fig. 6. (a) Calculated configurational CD curves of bis(acetylacetonato)cobalt(III) complexes of (*S*)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$ (--------) and (*R*)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ (·····) and the CD spectrum of Δ-$[Co(acac)_2\{NH_2CH_2CH_2P(C_6H_5)_2\}]^+$ (———). (b) Calculated vicinal CD curves of bis(acetylacetonato)cobalt(III) complexes of (*S*)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$ (--------) and (*R*)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ (·····).

since X-ray analysis on *trans*-$[CoCl_2\{(S)\text{-}NH_2CH_2CH_2P(C_4H_9)(C_6H_5)\}_2]ClO_4$ reveals that one chelate ring forms a δ-gauche conformation and the other λ-gauche one.[25] Hence, the vicinal effect of the (*S*)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ ligand should arise primarily from the chiral phosphorus atom. The vicinal effect of such a chiral phosphorus donor atom seems to be as strong as that of a chiral nitrogen donor atom.[26] The relation between the CD sign and the absolute configuration remains unknown.

^1H NMR Spectra. ^1H NMR spectral data of the acetylacetonate group and the methyl group of phosphines in the aminophosphine and the related complexes are given in Table 3. The methine and methyl groups of acetylacetonate ligands give two or one, and four or two peaks, respectively, depending on the symmetry of the complexes. The methine signals

a) The tetraphenylborate was converted to bromide by an ion exchanger. b) All signals are a triplet, the values being $|J_{AX}+J_{Bx}|$ of an ABX pattern (X=^{13}C). c) I, II, and III; see Table 4.

isomer is disposed far from two acetylacetonate rings to give their methine signals at similar frequencies in the low field region (Fig. 7). A pair of diastereomers, (**4a**, F-I) and (**4b**, F-II) of the $NH_2CH_2CH_2P(CH_3)(C_6H_5)$ complex give very similar spectra to those of complexes **5a** and **5b**, respectively, and can be assigned to the $\Lambda(S)$-$\Lambda(R)$ and $\Lambda(S)$-$\Lambda(R)$ racemic pairs, respectively. From the strength of such well separated methine signals, the formation ratio of F-II/F-I for the (*S*)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ complex was determined to be *ca.* 2.7. The same shielding effect of a phenyl group to methine protons of the acetylacetonate ligands is observed for all the other phenylphosphine complexes. The diphosphine complex **7** gives a sharp singlet in the high field region by this effect. No assignment for the methyl group was made because of complexity.

^{13}C NMR Spectra. ^{13}C NMR spectral data of the phosphine complexes and the free ligands measured in this study were summarized in Tables 4, 5, and 6. The assignments were made on the basis of the chemical shifts, the magnitudes of coupling constants, the intensities, and the off-resonance spectra. A representative spectrum (complex **4c**) is shown in Fig. 8.

Spectral Assignments for Diastereotopic Phenyl Carbons: The diphenylphosphine complexes, **1**, **2**, and **7** give complicated spectra in the phenyl region (Fig. 9), since the two phenyl groups in each complex are diastereotopic to each other. Such complicated spectra were successfully assigned by comparing with spec-

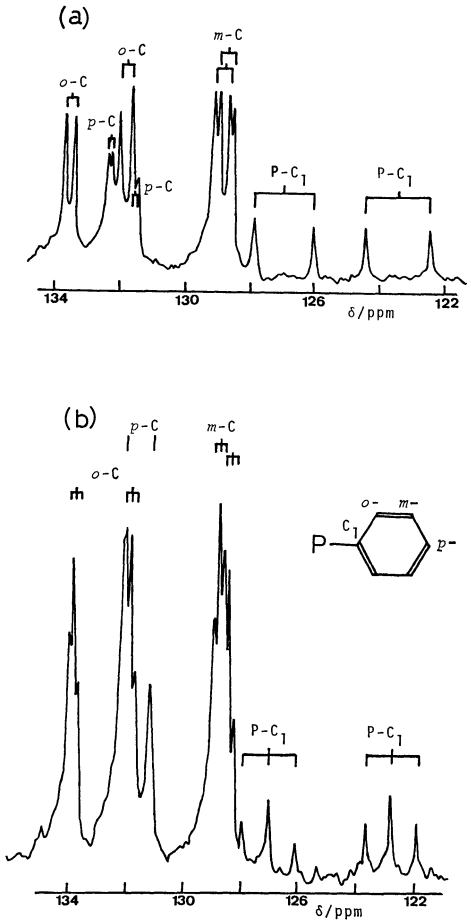

Fig. 9. ^{13}C NMR spectra of complexes, **1**(a) and **7**(b) in the phenyl region.

tra of the methylphenylphosphine complexes, **4a** and **4c**. These complexes are a pair of diastereomers formed with the ligand having a single phenyl group and thereby give a simple spectrum in the phenyl region (Fig. 10). The spectrum of **4c** isomer in Fig. 10 consists of four kinds of doublets. The carbon bonded to the phosphorus atom ($P-C_1$) and the *p*-carbon were assigned on the bases of the off-resonance and the intensities. The *o*- and *m*-carbons can be assigned from their chemical shifts. It is known that the chemical shift of *m*-carbon of a monosubstituted benzene remains almost unchanged from that of benzene, 128.7 ppm.[27] Thus the doublet at 129.2 ppm is assigned to the *m*-carbon and the remaining doublet at 131.2 ppm to the *o*-carbon. Table 5 gives the coupling constants, ^{n}J(C,P) observed from the spectra.

The spectrum in the phenyl region of another isomer, **4a** was similarly assigned, although the doublet of the *p*-carbon is overlapped by one of the doublet signals of the *o*-carbon. With the aid of the chemical shifts and the coupling constants for these isomers, the complicated phenyl signals of the diphenylphosphine complexes, **1**, **2**, and **7** were assigned (Fig. 9 and Tables 4 and 5).

Carbon-Phosphorus Couplings through a Cobalt(III) Ion: Four methyl and four carbonyl carbons of two acetylacetonate ligands in the aminophosphine complexes exhibit fairly different chemical shifts in the region of each kind of carbons (Fig. 11 and Table 6). Furthermore, each one of the methyl and carbonyl carbons

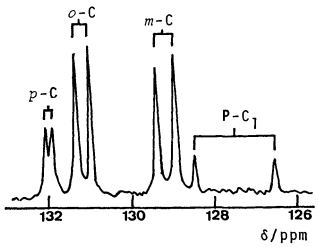

Fig. 10. The ^{13}C NMR spectrum of complex **4c** in the phenyl region.

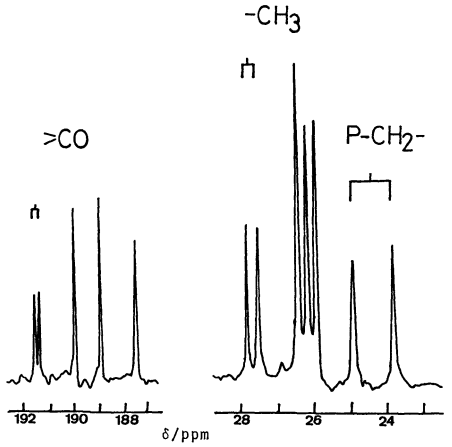

Fig. 11. ^{13}C NMR spectra of complex **2** in the methyl and carbonyl regions.

gives a doublet due to coupling with a phosphorus atom *trans* to the carbon, ^4J(C,P) and ^3J(C,P), respectively. Both doublet are observed at the lowest field among each kind of carbons and the values of ^4J(C,P) for the methyl and ^3J(C,P) for the carbonyl carbons are 6—7 and 2—4 Hz, respectively. Such long-range couplings through a cobalt(III) ion would be useful for assigning structures of cobalt(III)–phosphine complexes. No coupling between carbon and phosphorus in the *cis* positions is observed.

Spectral Parameters in Free and Complexed Aminoalkylphosphines: Spectral data of the free and complexed aminoalkylphosphines are given in Tables 4 and 5. The effects of coordination of the ligands on spectral parameters are summarized as follows.

1) Carbons bonded to a phosphorus atom shift to an upfield upon coordination, and the coupling constants, ^1J(C,P) become much larger.

2) Methylene carbons bonded to a nitrogen atom shift slightly to a downfield upon coordination, and no coupling with a phosphorus atom is observed.

3) Chemical shifts of P–C_1 and *o*-carbon atoms depend largely on the kind of compounds, but those of *m*- and *p*-carbon atoms do not. Such trends are similar to those for monosubstituted benzenes.

These features will provide useful information not only for assigning ^{13}C NMR spectra of cobalt(III) phosphine complexes, but also for elucidating bonding properties between a phosphorus atom and a cobalt(III) ion.

(Received April 17, 1980)

The stability of calcium silicon in aqueous solutions was studied by determining dissolution rates of Ca and Si at a constant pH. Calcium silicon was found to be fairly stable in solutions of pH 3.0—8.0, at most less than 2.8%of Ca and 0.5% of Si being dissolved after 24 h. In a strong acid solution of pH 2.5 or less the dissolution rates of Ca and Si considerably increased. Ca dissolution reached a plateau and the whole amount of Ca did not dissolve even in a 3.0-mol dm^{-3} HCl solution, while Si dissolution continued to increase. Calcium silicon apparently reduces metal ions to the elemental state for metal ions having higher standard electrode potentials than Cd(II) ions except Ni(II) and Co(II) ions. For Ag(I) ions, nitrate ions interfere with the reduction, but chloride ions favor it. Reduction of Cr(VI) and Fe(III) ions terminated at the stage of Cr(III) and Fe(II). Pb-(II), Cu(II), and Hg(II) ions were reduced to the metals, the acidity of the solution and the metal ion concentration not affecting the reduction. Calcium silicon is effective also for low-solubility compounds of these elements in suspension.

The amount of heavy metals discharged into water has increased with development of industrial activities, causing serious environmental pollution. On the other hand the heavy metals are valuable resources and it is important to develop techniques for their recovery. The method utilizing reducing agents is effective for recovering metals. Base metals such as iron, aluminum, or zinc in the form of powder or scrap have been used for recovering metals of higher standard electrode potentials, such as Cu and Hg.[1-5] However, such processes are generally low in efficiency, requiring time and post-treatment of the reductant brought into solution.

McKaveney *et al.*[6] proposed an alloy process in which silicon alloys including Ca, Al, Ba, Fe, or Mg are used as reductants to remove heavy metals from waste water and brine solution in the pH range of 2—12. Both batch and continuous flow operations can be applied, As, Cd, Cu, Cr, Fe, Hg, Pb, and Zn being removed successfully. By using Ca or Mg silicon alloy, no post-treatment of the exchanged metal ions is necessary. Case[7] studied the silicon alloy process using magnesium ferrosilicon and calcium silicon granules. Both alloys afforded a high rate removal of Cu(II), Zn(II), Cr(III), and Cr(VI) ions, but a difference in percentage removal and pH variation was observed among the methods of contact between the alloy and metal-bearing solution (magnetic stirring, tumbling and continuous flow methods were examined). Calcium silicon was found to be very effective for removing Hg(II) ions, which were removed as insoluble Hg(I) compound and Hg(0); as much as *ca.* 40 matom (*ca.* 8 g) of Hg(II) ions were removed per unit mass of calcium silicon.[8]

Calcium silicon has long been used in the steel manufacturing industry as a deoxidizing agent, and was rarely used in water until the time McKaveney *et al.* carried out their study. In this report discussions are given on the behavior of calcium silicon in aqueous solutions and its use for the recovery of various metal ions.

Experimental

Calcium Silicon. Calcium silicon (Shin-Etsu Chemical Industry Co., Ltd.) was pulverized with a crusher. Particulates passed through a 200-mesh sieve (0.074 mm) were used. The composition was 31.3% Ca, 60.4% Si, and 0.40% C.

Reagents. Chlorides were used for the runs of Mn(II), Zn(II), Cr(III), Cd(II), Co(II), Ni(II), Sn(II), Pb(II), Cu(II), Fe(III), and Hg(II) ions. $FeSO_4$, K_2CrO_4, and $AgNO_3$ were used. All of these were of reagent grade and used by dissolving in distilled water.

Analysis. Concentration of metals in solution was determined with a Model 503 Atomic Absorption Spectrophotometer (The Perkin-Elmer Corporation). Mn, Zn, Fe, Cr, Cd, Ni, Sn, Pb, and Cu were determined by flame atomic absorption spectrophotometry, and Ca, Co, and Ag by flame emission spectrophotometry. Hg was determined by flameless atomic absorption spectrophotometry with a MV-253 Mercury Vapor Meter (Beckman-Toshiba, Ltd.). Cr(VI) and Fe(II) were determined by colorimetry[9] with diphenylcalbazide and 1,10-phenanthroline, respectively. Silicate was determined by the Molybdenum Blue method.[10] Solid products were analyzed for chemical species by means of X-ray diffraction with a Model 2100 Diffractometer (Rigaku Corporation) with Ni-filtered Cu $K\alpha$ radiation.

Stability of Calcium Silicon in Aqueous Solutions. Three grams of calcium silicon was added to 2.0 dm^3 of aqueous solution, which was placed in a 25 °C thermostat and agitated with a magnetic stirrer. The pH of the solution was maintained constant in the course of the run by using a Model HSM-10A pH Stat (Toa Electronics Ltd.) with 0.1-mol dm^{-3} HCl for a run of pH 8.0, 0.25-mol dm^{-3} HCl for runs of pH 6.0, 4.0, and 3.0, and with 1.0-mol dm^{-3} HCl for runs of pH 2.5 and 2.0. Calcium silicon was added to a 1.0-mol dm^{-3} HCl solution, the acidity not being controlled. At intervals an aliquot was taken and filtered through a glass fiber filter paper (Whatman GF/A), analysis being made on the filtrate for Ca and Si.

Recovering Metals with Calcium Silicon. In a 100-cm^3 glass-stoppered Erlenmeyer flask, 100 cm^3 of *ca.* 18- or 0.2-matom dm^{-3} metal ion solution was prepared, the acidity being adjusted to pH 1∼4, 0.1 mol dm^{-3}, and 1.0 mol dm^{-3} with HCl. With addition of 0.3 g of calcium silicon, the solution was shaken intermittently at room temperature. After 24 h it was filtered through a glass fiber filter paper, and the filtrate was analyzed for the metal, Ca, and Si. The residue was dried at *ca.* 60 °C under reduced pressure and its X-ray diffraction pattern was obtained.

Results and Discussion

Stability of Calcium Silicon in Aqueous Solutions. In reducing metal ions in an aqueous solution with a reductant, its stability in water is an important factor especially in acid solutions, since too strong a reductant decomposes water, evolving hydrogen gases in solutions of high acidity. Calcium silicon is composed of elemental calcium and silicon, both strong reducing agents; the former reacts with water violently while the latter is stable in water due to the irreversibility of the oxidation-reduction reaction and to passivation by a film of silica in acid solution.[11] The reactivity of elemental calcium and silicon with water has been studied but not that of calcium silicon.

When calcium silicon is added to water, the pH tends to increase with dissolution of Ca moiety ($Ca+2H_2O=Ca(OH)_2+H_2$), the dissolution rate decreasing when the solution turns alkaline. In order to find the relation between pH and the stability of calcium silicon, the dissolution rates of Ca and Si were determined in solutions of constant pH maintained with a pH stat. The concentrations of dissolved Ca and Si were found to be lower than their respective solubilities, and thus they exist in the soluble form. The results are given in Figs. 1 and 2. The amounts of Ca and Si dissolved in solution are given in terms of percentage to the respective initial amounts contained in the calcium silicon added.

The dissolution of Ca was very small at pH 3.0 or higher; only 1.2, 1.8, 1.9, and 2.8% of Ca dissolved after 24 h at pH 8.0, 6.0, 4.0, and 3.0, respectively. When pH was not maintained constant, the dissolution decreased to less than 1% in a solution of an initial pH of 3.9 (final pH 9.1). At pH below 2.5 the dissolution became significant but did not increase continuously with lapse of time, plateaus being observed according to the acidity. At pH 2.5 and 2.0, a steady state was reached after *ca.* 8 and 3 h with dissolution of 21.4 and 62.8% of Ca, respectively. In the 1.0-mol dm^{-3} HCl solution, the plateau was reached within 5 min with dissolution of 74.3% of Ca. In the 2.0- and 3.0-mol dm^{-3} HCl solutions, 83.7 and 84.1% of Ca dissolved, respectively. The Ca moiety would not entirely dissolve even in a strong acid solution, possibly due to the formation of silica film on the surface of calcium silicon which prevents the dissolution.

Percentages of dissolved Si were fairly low in comparison to those of Ca. The stability of calcium silicon in an aqueous solution is mainly affected by that of Ca moiety. Dissolution of Si was insignificant at pH 3.0 or higher, less than 0.5% of Si being dissolved. This was also the case even in the alkaline solution of pH 8.0. In strong acid solutions of pH 2.5 or less, the dissolution of Si as well as of Ca increased significantly, spontaneously combustible silicon hydride, SiH_4, being produced in a 1.0-mol dm^{-3} HCl solution at the first stage of the reaction. On the other hand, elemental silicon dissolves in a hot alkaline solution but not in an acid solution.[11] Significant increase in Ca dissolution in a solution of low pH might promote Si dissolution, *i.e.*, degradation of alloy particulates

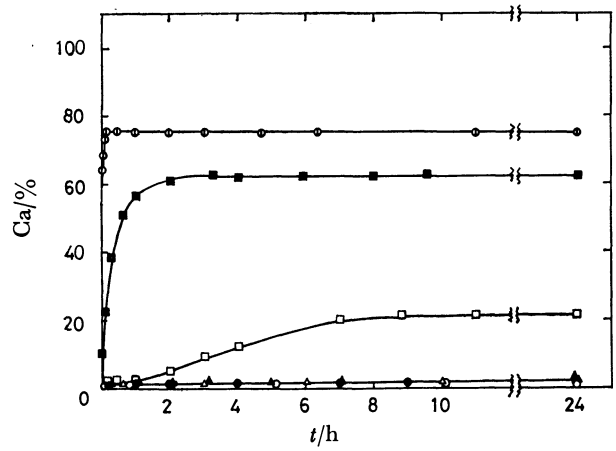

Fig. 1. Dissolution rates of calcium at various acidities. Acidity; ○: pH 8.0, ●: pH 6.0, △: pH 4.0, ▲: pH 3.0, □: pH 2.5, ■: pH 2.0, ⓘ: 1.0 mol dm^{-3} HCl.

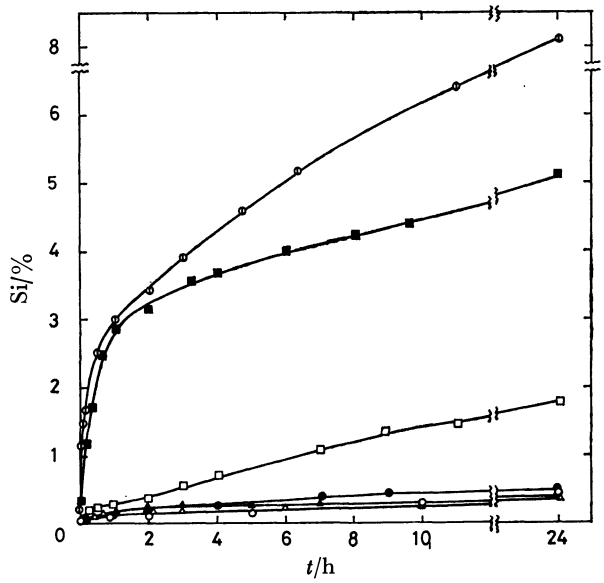

Fig. 2. Dissolution rates of silicon at various acidites. Acidity; ○: pH 8.0, ●: pH 6.0, △: pH 4.0, ▲: pH 3.0, □: pH 2.5, ■: pH 2.0, ⓘ: 1.0 mol dm^{-3} HCl.

caused by dissolution of Ca moiety may favor Si dissolution. Since the amount of Si dissolved is much lower than the solubility of silicate, the dissolution of Si increases continuously without reaching a plateau.

The explosive reactivity of elemental Ca with water is thus reduced considerably by making an alloy containing silicon. The Si moiety is very stable against water. Calcium silicon is sufficiently stable as a solid reducing agent in aqueous solutions of pH higher than 3.0.

Recovering Metals with Calcium Silicon. The reduction-oxidation reaction of a metal in an aqueous solution can be discussed in terms of the standard electrode potential. For practical use in acid solutions, the standard electrode potential of a reductant should be higher than *ca.* −0.7 V to avoid decomposition of water, and somewhat lower than that of a metal

Table 1. Recovery of metal ions with calcium silicon

a) Standard electrode potential for an electrode reaction $M^{z+}+ze=M$ (unless otherwise noted); the value being quoted from "Kagaku Binran Kiso-hen II," Maruzen, Tokyo (1977), pp. 1203—1206. b) Adjusted with HCl, and the values are in mol dm^{-3} unless ohterwise noted. c) For the reaction $Cr^{3+}+e=Cr^{2+}$. d) For the reaction $Fe^{3+}+e=Fe^{2+}$. e) For the reaction $2Hg^{2+}+2e=Hg_2^{2+}$. f) For the reaction $Hg_2^{2+}+2e=2Hg$.

to be reduced for accomplishing the reduction-oxidation reaction. Since the standard electrode potential of calcium silicon is unknown, we estimated its strength as a reductant by reactions with various metal ions whose potentials are known. We employed finer particulates of calcium silicon and higher concentrations of metal ions than those used in the previous studies in order to analyze the solid products by means of X-ray diffraction. Since metal-ion reducing reactions proceed efficiently in acid solutions, reactions were carried out in solutions of various acidities in order to suppress hydrolysis of metal ions and examine the effects of acidity.

The results of metal ion recovery are given in Table 1. When occurrence of hydrolysis of metal ions was expected from the final pH, an aliquot of the sample solution was filtered after being maintained at near the initial pH for 5 min to dissolve the hydroxide. The metal ion removal thus attained is indicated in parentheses. Discussions are given on 0.2-matom dm^{-3} solutions of metal ions which proved to be reduced by calcium silicon.

Practically no reducing effects were observed for Mn(II), Zn(II), and Fe(II) ions which show very low standard electrode potentials. In the study of McKaveney *et al.*,[6] more than 99% removal was attained for Zn(II) ions in the column contact operation by using a parent solution of 0.15 Zn matom dm^{-3} and pH 5.6. More than 98% removal was attained at final pH of 9.95—7.95 in the batch operations by using a parent solution of 0.66 Zn matom dm^{-3} and pH 2.05.[7] At final pH of 5.05, the extent of removal significantly decreased down to 9%. Thus, it can be concluded that Zn(II) ions do not undergo reduction with calcium silicon but are removed only by hydrolysis which becomes significant from above pH *ca.* 6.5. The dissolution of Ca was much lower for Fe(II) ions than that for other cases, which seems to be due to presence of sulfate ions.

For Cr(III) ions, 20% removal was achieved in the run of initial pH of 2.9. The amounts of Ca and Si dissolved were much higher than those obtained in the above-mentioned metal-free solution of nearly the same pH (*ca.* 0.3 and 0.1 matom dm^{-3} for Ca and Si, respectively). This indicates the reduction of Cr(III) ions, the reaction $Cr^{3+}+e=Cr^{2+}$ being most likely to occur according to its standard electrode potential. However, no Cr(II) was detected since it is extremely unstable in aqueous solution and readily oxidized to Cr(III). Formation of Cr(0) is very unlikely to occur, since the standard electrode potentials for the reactions $Cr^{3+}+3e=Cr$ and $Cr^{2+}+2e=Cr$ are -0.774 and -0.913 V,[12] respectively. Although no pattern of chromium compounds was obtained by means of X-ray diffraction, the chromium removed was entirely recovered from the solid phase as Cr(III) ions by alkali digestion of the product. The removal of Cr(III) ions seems to be due to the formation of chromium(III) hydroxide.

For Cd(II) ions, removal higher than for the above-mentioned metal ions was achieved in the 18.0-matom dm^{-3}, 0.1-mol dm^{-3} HCl solution, formation of Cd(0) being recognized by X-ray diffraction of the solid product obtained. The removal deteriorated in the solutions of both lower and higher acidities as well as of lower cadmium concentration. Optimum conditions of acidity and cadmium concentration should be established in order to attain high efficiency of the reduction.

Although Co and Ni show higher standard electrode potentials than Cd does, the ions were not removed in acid solution. The cause of the ineffectiveness of calcium silicon on these ions is unknown. Thus, the reduction of metal ions with calcium silicon can not always be interpreted only in terms of standard electrode potential.

The high removal of Sn(II) ions in the 0.1-mol dm^{-3} HCl solution and the presence of Sn(0) confirmed by means of X-ray diffraction indicate that Sn(II) ions were removed by reduction to the metal.

For 18.0 Pb matom dm^{-3} solution, removal was attained regardless of the acidity and formation of Pb(0) was recognized in every case. In the run of initial pH of 3.5, removal of Pb(II) ions would not decrease significantly even by adjusting the final pH. This indicates that the removal of Pb(II) ions is due to the reduction of the ions to the metal. In the run of 0.2 matom dm^{-3}, initial pH of 3.5, the increase in pH interfered with the reduction of Pb(II) ions. The 40% removal for the run of 0.2 matom dm^{-3}, 0.1 mol dm^{-3} HCl, shows that the reduction of Pb(II) ions would not proceed so efficiently at such low concentration.

Considerably high removal was attained for Cu(II) ions in every solution irrespective of the acidity and Cu(II) concentration, indicating that Cu(II) ions can be reduced efficiently. The solid product was found to consist of Cu(0) and a trace amount of Cu_2O. The reaction was complete in 30 min after addition of calcium silicon.

Removal of Fe(III) ions was very low. However, the colorimetric determination of Fe(II) ions in the solution showed that Fe(III) ions are almost entirely reduced to Fe(II) ions. Reduction to Fe(0) is unlikely to occur according to the standard electrode potential.

Since no effect was observed with $AgNO_3$ solutions whose acidity was adjusted with HNO_3, the effect of calcium silicon on Ag(I) ions was examined with a suspension of AgCl precipitate prepared by addition of HCl to a $AgNO_3$ solution followed by addition of calcium silicon after 10 min. Thus the solid phase might contain AgCl precipitate, and the removal values given in Table 1 do not necessarily indicate that the removal was due to reduction of Ag(I) ions. Determination of Ag and AgCl in the solid product was made by means of X-ray diffraction. The areas of the diffraction peaks corresponding to d=2.359 and 2.774 Å for Ag and AgCl, respectively, were obtained by the integral mode, and their ratio was compared with a calibration curve similarly prepared by using mixtures of standard Ag and AgCl of various compositions. The silver compositions of the solid products were *ca.* 100, 100, and 43% for the runs at initial pH 3.9, 0.1-mol dm^{-3}, and 1.0-mol dm^{-3} HCl, respectively. The low Ag content for the 1.0-mol dm^{-3} HCl run can be attributed to flocculation of AgCl

precipitate which interfered with the contact with calcium silicon. Chloride ions favored the reduction of Ag(I) ions while nitrate ions disturbed it. When calcium silicon was added 1 h after the formation of AgCl, the silver compositions of the solid phase were *ca.* 100 and 55% Ag for the runs at initial pH 3.3 and 0.1 mol dm^{-3}, respectively, a trace amount of Ag being contained in the solid phase of the 1.0-mol dm^{-3} run. Aging of AgCl precipitate adversely affected the reduction reaction.

Reduction of Hg(II) ions proceeded efficiently in all solutions, the recovered solid products consisting of Hg(0) and Hg_2Cl_2.[8]

For Cr(VI) ions, 50% removal was attained in the 18.0-matom dm^{-3}, 0.1-mol dm^{-3} HCl solution. Of the chromium ions remaining in the solution, Cr(III) ions accounted for 72.5% and Cr(VI) ions the remainder, indicating that the reduciton of Cr(VI) to Cr(III) occurred. According to Pourbaix,[12] both Cr(VI) and Cr(III) ions would not hydrolyze at the pH we employed. We carried out analysis of the solid phase obtained in order to find the cause for the removal of Cr(VI) ions. The solid product dried at 60 °C under reduced pressure was poorly soluble in HCl solution and completely soluble in NaOH solution, which showed a chromium composition of 89.7% Cr(III) and the remainder Cr(VI). Cr(VI) ions were reduced to Cr(III) ions which partly remained in the solution and partly precipitated into the solid phase. The solid product was further analyzed by X-ray diffraction to identify the chromium compounds. Although the product dried at 60 °C gave no evidence for the existence of any chromium compound on its X-ray diffraction pattern, the one heated at *ca.* 700 °C for 6 h gave patterns corresponding to chromium(III) oxide, Cr_2O_3 (ASTM File No. 6-0504), and calcium chromate, $CaCrO_4$ (ASTM File No. 8-458). We might attribute the formation of Cr_2O_3 and $CaCrO_4$ to the dehydration of their hydrous forms which were amorphous to X-rays but determined by the alkali digestion. Therefore, the reduction reaction $Cr_2O_7^{2-} + 8H^+ + 6e = Cr_2O_3(\text{hydrated}) + 4H_2O(\varepsilon^\circ = 1.242 - 0.0788pH$[12]) is most likely to occur, supporting the increase in pH from *ca.* 1 to 2.7. The reduction of Cr(VI) ions did not proceed efficiently at both higher and lower acidities than pH *ca.* 1, where bulk of the Cr(VI) ions remained not reduced to Cr(III). No reduction of Cr(VI) ions took place in dilute solutions.

Since calcium silicon exhibited reducing action on the suspension of AgCl precipitate, we examined the effectiveness on low-solubility compounds of Cd(II), Ag(I), Cu(I), Cu(II), Hg(II), and Pb(II). The effectiveness was judged on the X-ray diffraction pattern of the solid product obtained. Great reducing effect was observed on Cu_2Cl_2, in which formation of Cu(0) and a trace amount of Cu_2O was recognized. Partial reducing effect was observed on Ag_2O, Ag_2SO_4, $Cu(OH)_2$, CuS, PbO, HgO, and $HgSO_4$, in which metallic species were recognized as well as the starting material. It seems that the reduction of these low-solubility compounds is due to that of the metal ions dissolving in trace amount into the metal, which consequently causes dissociation of the molecular species.

Appreciable reducing effect to the metal is recognized on metal ions that show standard electrode potentials equal to or higher than that of Cd, except Ni(II) and Co(II) ions. The reduction reaction of Cr(VI) and Fe(III) ions terminates at the stage of formation of Cr(III) and Fe(II) ions, neither Cr(0) nor Fe(0) being produced. Dissolution of calcium silicon in aqueous solution increases pH, favoring the removal of metal ions through hydrolysis. The acidity of a solution would not affect the reducing effect for Pb(II), Cu(II), and Hg(II) ions that show high standard electrode potentials. Calcium silicon is effective also for low-solubility compounds of these metals.

The Mechanism of the Hydrolysis of Polyphosphates. V.[1] The Effect of Cations on the Hydrolysis of Pyro- and Triphosphates

Makoto WATANABE,* Makoto MATSUURA, and Tamotsu YAMADA
Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai, Aichi 487

(Received May 15, 1980)

The effect of cations on the rate of hydrolysis of pyro- and triphosphates was studied by adding metal chloride to aqueous solutions of the phosphates. The concentrations of the phosphates and metal chlorides were 0.025 and 0.1 mol dm^{-3} respectively. Alkali metal, alkaline earth metal, aluminium, and some transition-metal (Mn(II), Co(II), Ni(II), Cu(II), and Zn(II)) cations retarded the hydrolysis of the phosphates in acidic media. The following sequence of efficiency resulted:

trivalent > bivalent > univalent.

The efficiency of elements within one group of the periodic table decreased from top to bottom. On the other hand, in alkaline solutions, alkali metal cations accelerated the hydrolysis of the phosphates and the catalytic effectiveness decreased with an increase in the ionic radius.

Though many papers have been reported about the hydrolysis of polyphosphates, there have been few studies concerning the effect of cations except for hydrogen and oxonium ions. Many workers have discussed the rate order, the pH dependence, and the reaction process of the hydrolysis of polyphosphates, but no explanation of the reaction mechanism from the point of view of the interaction between a water molecule and a phosphate ion has ever been made. One of the present authors (M. W.) discussed the reaction mechanism of the hydrolysis of polyphosphates from this point of view by using aqueous organic solvents; he pointed out that the rate of the hydrolysis of chain and small-ring phosphates is seriously affected by the nucleophilicity of water molecules and that the hydrolysis is of an S_N2 type.[1-4] Thilo and Wieker reported the catalytic efficiencies of cations on the hydrolysis of high polyphosphates at pH 8 and obtained the following sequence of efficiency:

$Al^{3+} > Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+} > H^+ > Li^+ > Na^+ > K^+$.[5-7]

In this paper, the effects of alkali metal, alkaline earth metal, aluminium, and some transition metal cations of the hydrolysis of pyro- and triphosphates will be discussed.

Experimental

Materials and Procedure. The materials used other than triphosphate were of a commercial grade. The sodium triphosphate was made by the method described in Ref. 8. The concentration of sodium pyro- or triphosphate was controlled to be 0.025 mol dm^{-3} because that concentration was suitable for analysis. Metal chloride was added to the phosphate solution to make it 0.1 mol dm^{-3}. The metal chlorides used were LiCl, NaCl, KCl, $MgCl_2$, $CaCl_2$, $AlCl_3$, $MnCl_2$, $CoCl_2$, $NiCl_2$, $CuCl_2$, and $ZnCl_2$. The pH of the solution was controlled with hydrochloric acid and/or aqueous tetramethylammonium hydroxide, with the aid of a Hitachi-Horiba pH meter, F-7, at a given reaction temperature. The separation and determination of the phosphate species in the sample solution were carried out by the method described in our previous paper.[2] The phosphates in the solution containing aluminium ions were not separated well by one-dimensional paper chromatography, so only the measurement of the hydrolysis of pyrophosphate to orthophosphate was done by means of the molybdenum-blue method. When any precipitate was formed during the experiment, no further treatment was made. Pyro- and triphosphate solutions free from sodium ions were prepared by passing the phosphate solutions mentioned above through cation-exchange resin in the H^+ form. The same treatment as in the case of sodium pyro- and triphosphate solutions was done for the phosphate solutions thus prepared in order to test the effect of coexisting sodium ions; the effect of alkali metal cations on the rate of the hydrolysis of triphosphate in basic media was also studied by using the triphosphate solution, but the effect of cations on the hydrolysis of pyrophosphate could not be studied because the rate of the hydrolysis of pyrophosphate was too slow to measure in basic media.

Results and Discussion

The Effect of Cations. The rate of the hydrolysis of pyro- and triphosphates obeyed first-order kinetics with respect to the concentration of the respective phosphates under all the conditions studied. As Tables 1 and 2 show, in every reaction system the rate of the hydrolysis of either phosphate decreased with an increase in the pH value of the solutions. These results agree well with those of previous studies.[1,2,9] The hydrolysis of pyro- and triphosphates was retarded by the addition of the alkali metal ions in the pH ranges smaller than 7.0 and by the addition of other metal ions in the pH ranges smaller than 3.0. The rate of the hydrolysis of pyrophosphate in the system containing aluminium ions, measured at pH 0.9, was smaller than those of other systems measured at pH 1.0. As has been mentioned above, the hydrolysis of pyrophosphate is an acid-catalyzed reaction. Therefore, the retardation efficiency of aluminium ions is the largest among the cations tested here. According to the results, the following order of the retardation efficiency of metal ions on the rate of hydrolysis of short-chain polyphosphates resulted at pH 1.0:

$$\underbrace{Mg^{2+} > Ca^{2+}}_{\text{typical element}}$$

$$\underbrace{Al^{3+} > Mn^{2+} > Cu^{2+} > Zn^{2+} > Co^{2+} > Ni^{2+} > Li^+ > Na^+ > K^+}_{\text{transition element}}.$$

(trivalent) (bivalent) (univalent)

Similar retardation effects were observed for alkali metal, alkaline earth metal, manganese(II), cobalt(II), and nickel(II) ions at pH 2.0 or at higher pH regions than that. However, the order of efficiency of man-

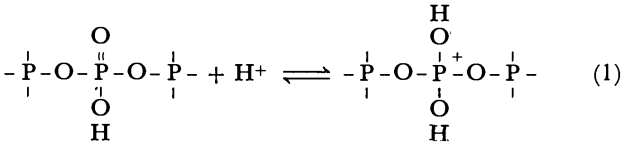
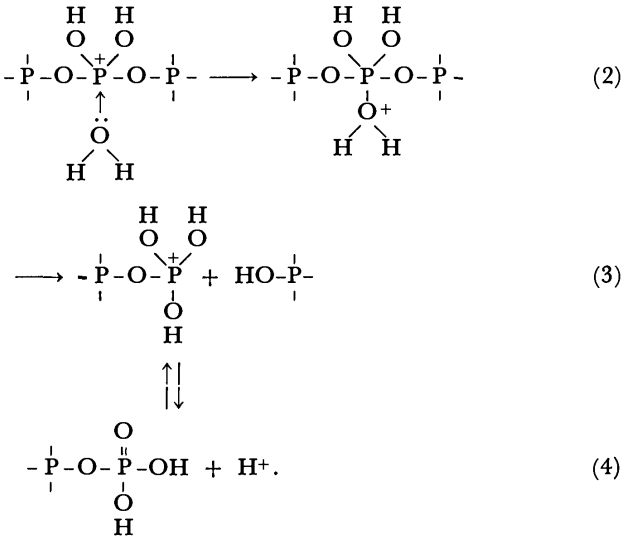
ganese(II) ions for the hydrolysis of triphosphate at pH 2.0 is not the same as that at pH 1.0. As is also shown in Tables 1 and 2, the rate of the hydrolysis of pyro- and triphosphates is larger than that of the respective sodium phosphates, and a similar retardation effect of lithium ions is observed in the pH regions smaller than 7.0. On the other hand, the rate of the hydrolysis of triphosphate was remarkably accelerated by the addition of alkali metal ions at pH 10.0 and 11.5. The order of the acceleration efficiency of alkali metal ions is as follows:

$$Li^+ > Na^+ > K^+.$$

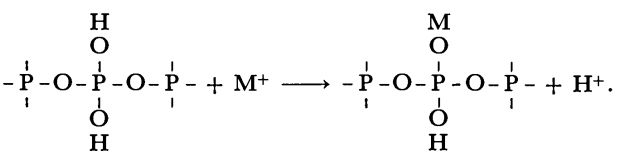
Reaction Mechanism. The activation parameters for the hydrolysis of pyro- and triphosphates were calculated by means of the Arrhenius plot; they are listed in Tables 3 and 4 respectively. In any reaction system, the activation energy and the frequency factor increase with an increase in the pH value. This indicates that the catalytic action of H^+ affects exclusively the energy term of the hydrolysis of short-chain polyphosphates. In our previous papers,[2,4] we proposed the following hydrolysis mechanism for pyro- and triphosphates and concluded that Reaction (2) is the rate-determining step:



(1)



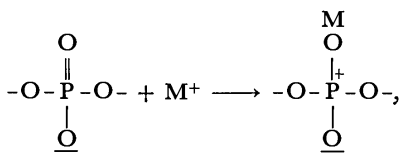
The present kinetic measurements have shown that the retardation efficiency within one group of the periodic table decreases from top to bottom, that is, with an increase in the ionic radius, and increases with an increase in the charge of the cation. Since the reaction rate is retarded and the activation energy increases upon the addition of a metal cation in any reaction system, it could be considered that the elementary reactions (1) and (2) are affected by metal ions. Therefore, the retardation of the degradation reaction by metal ions in acidic solutions may be explained by the exchange of protons by the catalytically less effective metal ions. The ion-exchange efficiency of a cation increases with an increase in the charge. This fact well explains the order of the retardation efficiency of metal cations for the hydrolysis of pyro- and triphosphates. In one group of the periodic system, the ion-exchange efficiency of a cation decreases with a decrease in the ionic radius because of strong hydration. This tendency does not agree with the results obtained in this work. However, Strauss and Ross indicated that the binding constant of alkali metal and alkaline earth metal cations with phosphate ions decreases in the order of an increase in the ionic radius of the cations.[10] This result well explains the order of the retardation efficiency of alkali metal and alkaline earth metal cations obtained here. Accordingly, the retardation of the degradation may be caused by the following exchange reaction:



In the case of transition metal-ions, the order of ionic radius is as follows:

$$Mn^{2+} > Zn^{2+} > Co^{2+} > Ni^{2+},$$

and the order of the retardation efficiency at pH 1.0 is the same as that of the ionic radius. Therefore, the binding force of these transition metal ions with the phosphate ions may increase with an increase in the ionic radius in strongly acidic media. The catalytic effect of alkali metal ions for the degradation of triphosphate ions in alkaline solutions may be explained by the formation of the complex as follows:



because the phosphate ion on the right-hand side is considered to be more susceptible to the nucleophilic attack of a water molecule than that on the left-hand side.

Kinetics of the Catalytic Decomposition of Hydrogen Iodide in the Magnesium-Iodine Thermochemical Cycle

Yoshinao Oosawa,* Toshiya Kumagai, Susumu Mizuta, Wakichi Kondo, Yoshio Takemori, and Kinjiro Fujii

National Chemical Laboratory for Industry, Higashi, Yatabe-cho, Tsukuba-gun, Ibaraki 305

(Received July 11, 1980)

The decomposition of hydrogen iodide serves as the hydrogen-evolution step in several thermochemical water-splitting cycles, including the Magnesium–Iodine cycle. A kinetic analysis of the catalytic decomposition of hydrogen iodide has been carried out by the use of a flow method at 500—700 K. The platinum-supported active carbon catalyst (1 wt%) and the active carbon catalyst which have been found effective in the research reported previously, are used as the catalysts. The contact time-conversion relationships for both the catalysts are simulated successfully on the basis of an assumed reaction scheme. The influence of water vapor on the rate and the equilibrium of the decomposition of hydrogen iodide is negligibly small. The inhibition effect of iodine on the rate of the decomposition of hydrogen iodide over the platinum-supported active carbon catalyst is remarkable below 550 K.

The decomposition of hydrogen iodide serves as the hydrogen-evolution step in several thermochemical water-splitting cycles,[1–4] including the Magnesium–Iodine cycle[5] previously proposed by the present authors. It is favorable for the reaction to be carried out around or below 700 K from the standpoint of the construction of the present cycle. However, since the rate of the reaction in the form of a homogeneous gas-phase reaction is low in the temperature range below 700 K, the present authors attempted to carry out the reaction catalytically.

In the first step of the study of the catalytic decomposition of hydrogen iodide, a screening test of various catalysts prepared by an impregnation method from the compounds of all the members of the first transition-metal series, from the compounds of the members of the platinum-group metals, and so on, and from various catalyst supports were carried out. In the research, a platinum-supported active carbon catalyst (abbreviated as the Pt/C catalyst) and an active carbon catalyst were found to reveal favorable catalytic activities.[6]

For the second step of the research, a kinetic analysis of the reaction, a quantitative investigation of the influence of iodine and water vapor that may coexist with the hydrogen iodide to be decomposed on the rate and the equilibrium of the reaction, and a life test of the catalysts were necessary.

There have been very few reports on the kinetic studies of the decomposition of hydrogen iodide. Hinshelwood and Burk,[7] however, reported that the reaction over platinum wire under the conditions of a continuous removal of the iodine formed proceeded according to the following rate equation:

$$-\frac{dP_{HI}}{dt} = k,$$

where P_{HI} is the partial pressure of hydrogen iodide and where k is the rate constant. Iida[8] reported recently that the reaction over platinum supported on Teflon under the conditions of a continous removal of the iodine formed proceeded according to the following rate equation:

$$-\frac{dP_{HI}}{dt} = \frac{P_{HI}}{14.76P_{H_2} + 7.49P_{HI} + 208},$$

where P_{HI} is the partial pressure of hydrogen iodide, and so on. In both the researches, the reaction systems were simplified by the continuous removal of the iodine formed. The results of both the researches gave only insufficient information, however, on the unresolved questions related to thermochemical water splitting.

Therefore, the present authors have investigated the influence of the contact time and the partial pressure of hydrogen iodide, iodine, and water vapor on the reaction rate over the Pt/C catalyst and the active carbon catalyst, and analyzed the results on the basis of an assumed reaction scheme. They have also examined the lifetime of both the catalysts and the water-gas reaction of the carbon used as a catalyst or a support. On the basis of the results, it was confirmed that both the catalysts can be used for the decomposition of hydrogen iodide in the presence of water vapor at 550—700 K.

Experimental

The Pt/C catalyst (1.05 wt%) was prepared from the active carbon (Shirasagi-C granular, Takeda) and $H_2PtCl_6 \cdot 6H_2O$ by an impregnation-calcination method (Ar stream, 1000 K, 6 h), and was ground to a diameter of less than 0.30 mm (0.30—0.15 mm, 47 wt%; 0.15—0.03 mm, 42 wt% <0.03 mm, 11 wt%) before use. The active carbon catalyst was prepared by a calcination-grinding treatment of the active carbon similar to that used for the Pt/C catalyst. The experiments were carried out by the use of a tubular reactor with the aid of argon carrier gas. The apparatus was similar to that depicted in the preceding paper.[6] Hydrogen iodide was fed in the form of hydriodic acid (7.5 mol l^{-1}, Wako, Sp. Gr.) to obtain reaction conditions similar to those in the decomposition of hydrogen iodide included in the present thermochemical cycle, in which a certain amount of water vapor might coexist with hydrogen iodide. The reactant and the carrier gas were fed in at the following rates: HIaq, 32.3 ml/h; Ar, 9.0 l/h (P_{HI}=0.125 atm, P_{H_2O}=0.682, P_{Ar}= 0.193), unless otherwise stated. In all cases, the reactions were carried out under a total pressure equal to 1 atm. The contact time was varied by varying the catalyst amount at a fixed feed rate of the reactants and the carrier gas. The catalyst amount of 1.71 g (for both the Pt/C catalyst and the active carbon catalyst) corresponded to the contact time of 2.86×10^{-1} s (S.V.=1.26×10^4 h^{-1}). All the exhaust components except for hydrogen and argon were condensed out in the scrubber. The hydrogen concentration of the

exhaust gas was determined by the use of gas chromatography (YANACO, G180) with a molecular sieve 13 X column, while the flow rate of the exhaust gas (H_2+Ar) was measured with a soap-film flowmeter. The conversions of hydrogen iodide at each temperature were monitored by measuring the hydrogen concentration of the exhaust gas for about 1 h. After the concentration had become constant, the conversions were determined in each run in the directions of both the decreasing and increasing temperatures by taking the flow rate of the exhaust gas into account. The steady state of the reaction was confirmed by the close agreement of both conversions at each temperature. As the conversion in the blank experimentation was low (5.3×10^{-5} (600 K), 4.5×10^{-4} (650 K), 1.6×10^{-3} (700 K), it was clear that both the thermal decomposition in the gas phase and the catalytic decomposition on the surface of the glass wall of apparatus were negligible. The relative error in the conversion measurement was, in general, less than 4%.

Results and Discussion

Water-gas Reaction and Life Test. Active carbon is consumed through the reaction with water vapor, yielding hydrogen and carbon monoxide at high temperatures.

$$C + H_2O \longrightarrow H_2 + CO;\ \text{water-gas reaction}$$

It was assumed that the life of both catalysts for the decomposition of hydrogen iodide in the presence of water vapor was mainly dependent on the rate of the water-gas reaction. The rate of the hydrogen evolution through the reaction of both the catalysts with water vapor was measured. The results are presented in Table 1. The rate over the Pt/C catalyst was higher than that over the active carbon catalyst over the whole range of temperatures studied. It would be desirable to use the former catalyst below 700 K or the latter below 800 K to avoid a catalyst loss through the water-gas reaction. The conversion of hydrogen iodide over the Pt/C catalyst (0.171 g, 650 K) or the active carbon catalyst (0.570 g, 700 K) was confirmed to remain almost unchanged after 100 h of operation under the following feed rates: HIaq, 36.2 ml/h; Ar, 4.5 l/h.

Effect of Mass Transfer on the Reaction Rate.[9-11] When 0.171 g of the Pt/C catalyst was used, the ratio of the length of the catalyst layer to the average diameter of the catalyst particle was about 15. As it is accepted that the back-mixing effect is negligible when the ratio is about 20 or more, the back-mixing effect was almost negligible in the present experiment.

Both the feed rate and the catalyst amount were varied at a fixed contact time (2.86×10^{-2} s) over the Pt/C catalyst that shows a higher catalytic activity of the two kinds of catalysts: HIaq 32.3 ml/h, Ar 9.0 l/h, Pt/C 0.171 g and HIaq 21.5 ml/h, Ar 6.0 l/h, Pt/C 0.114 g. As the conversions were almost the same for each feed rate at 500—700 K, the external film diffusion did not seem to influence the reaction rate in this range of feed rates.

Table 1. Hydrogen evolution rate through water-gas reaction

T/K	Pt/C ml(STP)/h	Active carbon ml(STP)/h
500	0	0
600	0.2	0
700	2.2	0.1
800	9.5	0.4

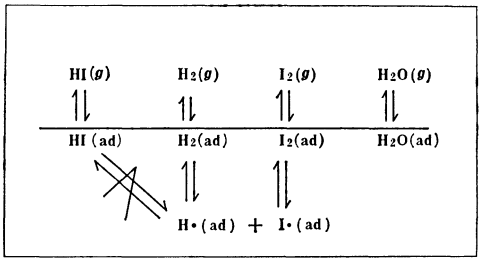

Fig. 1. Assumed reaction scheme for the catalytic decomposition of hydrogen iodide over the Pt/C catalyst or the active carbon catalyst in the presence of water vapor.

The conversion by the use of the Pt/C catalyst with a particle diameter of less than 0.15 mm differed little from that over the Pt/C catalyst with a diameter of less than 0.30 mm at a contact time of 1.43×10^{-2} s at 500—700 K. Therefore, the effect of internal diffusion in the micro pore of the catalyst on the reaction rate was considered to be insignificant.

Reaction Scheme. As the basis of the kinetic analysis of the catalytic decomposition of hydrogen iodide over the Pt/C catalyst or the active carbon catalyst, an appropriate reaction scheme was assumed. In the preceding paragraph, the effect of mass transfer on the reaction rate was shown to be negligibly small under the present experimental conditions. Therefore, the present authors assumed, on the basis of the results obtained by Hinshelwood and Burk[7] and Iida[8] that: (i) the reaction proceeds according to the reaction scheme depicted in Fig. 1 and (ii) the reaction kinetics can be analyzed according to a Langmuir-Hinshelwood type of mechanism.

Under the above assumption, the rate equation of the decomposition of hydrogen iodide, V_f, is written as follows, where k_f is the rate constant of the first-order surface reaction and θ_{HI} is the surface coverage by hydrogen iodide:

$$V_f = -\frac{dP_{HI}}{dt} = k_f\theta_{HI}. \quad (1)$$

θ_{HI} is written as follows, where K_{HI} is the adsorption coefficient of hydrogen iodide, p_{HI} is the partial pressure of hydrogen iodide, K_H is the adsorption coefficient of dissociated hydrogen, and so on:

$$\theta_{HI} = \frac{K_{HI}P_{HI}}{1+K_{HI}P_{HI}+K_{H_2}P_{H_2}+\sqrt{K_HP_{H_2}}+K_{I_2}P_{I_2}+\sqrt{K_IP_{I_2}}+K_{H_2O}P_{H_2O}}. \quad (2)$$

As has been mentioned above, Iida found that the rate equation of the catalytic decomposition of hydrogen iodide over the Pt/Teflon was expressed as follows under his experimental conditions:

$$-\frac{dP_{HI}}{dt} = \frac{P_{HI}}{14.76P_{H_2}+7.49P_{HI}+208}. \quad (3)$$

In Eq. 3, no term corresponding to the dissociated chemical species is included. Therefore, the present authors eliminate $\sqrt{K_H P_{H_2}}$ and $\sqrt{K_H P_{I_2}}$ from Eq. 2 as negligible and thus obtain the following equation:

$$\theta_{HI} = \frac{K_{HI}P_{HI}}{1+K_{HI}P_{HI}+K_{H_2}P_{H_2}+K_{I_2}P_{I_2}+K_{H_2O}P_{H_2O}}. \quad (4)$$

P_{HI}, P_{H_2}, and P_{I_2} are expressed as follows under the conditions that no condensed phase is present, where P is the initial partial pressure of hydrogen iodide and where x is the conversion of hydrogen iodide:

$$\left.\begin{aligned} P_{HI} &= P(1-x) \\ P_{H_2} &= Px/2 \\ P_{I_2} &= Px/2 \end{aligned}\right\}. \quad (5)$$

Substituting Eq. 5 in Eq. 4, Eq. 6 is obtained:

$$\theta_{HI} = \frac{PK_{HI}(1-x)}{1+K_{H_2O}P_{H_2O}+K_{HI}P+(K_{H_2}/2+K_{I_2}/2-K_{HI})Px}. \quad (6)$$

With Eq. 1 and Eq. 5, Eq. 7 is obtained:

$$-\frac{dP_{HI}}{dt} = -\frac{d(P(1-x))}{dt} = \frac{Pdx}{dt} = k_f\theta_{HI}. \quad (7)$$

Substituting Eq. 6 in Eq. 7, the following equation is given:

$$\frac{Pdx}{dt} = \frac{k_fPK_{HI}(1-x)}{1+K_{H_2O}P_{H_2O}+K_{HI}P+(K_{H_2}/2+K_{I_2}/2-K_{HI})Px} = \frac{\dfrac{k_fPK_{HI}(1-x)}{1+K_{H_2O}P_{H_2O}+K_{HI}P}}{1+\dfrac{(K_{H_2}/2+K_{I_2}/2-K_{HI})Px}{1+K_{H_2O}P_{H_2O}+K_{HI}P}}. \quad (8)$$

Consequently, the rate equation for the catalytic decomposition of hydrogen iodide is expressed by Eq. 9:

$$\frac{dx}{dt} = \frac{k(1-x)}{1+ax}, \quad (9)$$

where:

$$a = \frac{(K_{H_2}/2+K_{I_2}/2-K_{HI})P}{1+K_{H_2O}P_{H_2O}+K_{HI}P} \quad (10)$$

$$k = \frac{k_fK_{HI}}{1+K_{H_2O}P_{H_2O}+K_{HI}P}. \quad (11)$$

As the reaction rate of the formation of hydrogen iodide from hydrogen and iodine, V_b is proportional to the product of the surface coverage by the dissociated hydrogen and that by the dissociated iodine, according to the reaction scheme assumed in Fig. 1, V_b is expressed as follows, where k_b is the rate constant of the formation of hydrogen iodide:

$$V_b = \frac{dP_{HI}}{dt} = k_b\theta_H\theta_I. \quad (12)$$

θ_H and θ_I are expressed as follows by a treatment similar to that for Eq. 4;

$$\theta_H = \frac{\sqrt{K_HP_{H_2}}}{1+K_{HI}P_{HI}+K_{H_2}P_{H_2}+K_{I_2}P_{I_2}+K_{H_2O}P_{H_2O}} \quad (13)$$

$$\theta_I = \frac{\sqrt{K_IP_{I_2}}}{1+K_{HI}P_{HI}+K_{H_2}P_{H_2}+K_{I_2}P_{I_2}+K_{H_2O}P_{H_2O}}. \quad (14)$$

Equation 15 is obtained by substituting Eqs. 5, 13, and 14 into Eq. 12:

$$-\frac{Pdx}{dt} = \frac{k_bPx\sqrt{K_HK_I}}{2(1+K_{H_2O}P_{H_2O}+K_{HI}P)^2\left(1+\dfrac{(1+K_{H_2}/2+K_{I_2}/2-K_{HI})Px}{1+K_{H_2O}P_{H_2O}+K_{HI}P}\right)^2}. \quad (15)$$

Equations 15 is transformed to give Eqs. 16 and 17:

$$-\frac{dx}{dt} = \frac{k'x}{(1+ax)^2}, \quad (16)$$

where:

$$k' = \frac{k_b\sqrt{K_HK_I}}{2(1+K_{H_2O}P_{H_2O}+K_{HI}P)^2} \quad (17)$$

and where P is the initial partial pressure of hydrogen iodide.

Consequently, combining Eq. 9 with Eq. 16 gives the rate equation of the catalytic decomposition of hydrogen iodide, including the backward reaction:

$$\frac{dx}{dt} = \frac{k(1-x)}{1+ax} - \frac{k'x}{(1+ax)^2}. \quad (18)$$

Integrating Eq. 18 under the initial conditions (when t equals zero, x equals zero) and the equilibrium conditions (when x equals x_e, the equilibrium conversions of hydrogen iodide, dx/dt equals zero) yields the following expression:

$$-kt = ax + \frac{(ax_e^2+2x_e-1)}{x_e}\ln\left(\frac{x_e-x}{x_e}\right) + \frac{(x_e-1)^2}{x_e(ax_e^2+1)}\ln\frac{(x_e-x)}{x_e(ax_ex-1)}, \quad (19)$$

where k and a are expressed as in Eqs. 10 and 11 respectively.

Thus, the contact time-conversion relationship of the catalytic decomposition of hydrogen iodide is expressed by the Rate Equation 19, which has two constants independent of the contact time: k, mainly concerned with the reaction rate, and a, mainly concerned with the adsorption.

Contact Time-Conversion Relationship. The experimental results obtained over the Pt/C catalyst and the active cabon catalyst are depicted as the points in Figs. 2 and 3. The error in the measurement of the conversion of hydrogen iodide caused by the water-gas reaction, significant only in the case of the Pt/C catalyst at 700 K, was corrected by assuming that the rate of hydrogen evolution by the water-gas reaction was proportional to both the feed rate of water vapor and the amount of the catalyst. The results were simulated on the basis of Eq. 19. By considering the form of the equation, the simulation of the experimental results was performed by first determining the value of a which gave the least coefficient of variation of k, $(((k_i-\bar{k})^2/n)^{1/2}/\bar{k})$, then, the value of k as the average of k corresponding to the respective data in each run by employing the value of the a. The values

Table 2. Values of k, a, and x_e(equilibrium conversion) for Eq. 20

T/K	Pt/C		Active carbon		x_e
	k/s	a	k/s	a	
500	4.45×10^{-1}	3.75×10	1.78×10^{-1}	1.92×10^{2}	0.151
550	1.47	1.47×10	7.46×10^{-1}	9.66×10	0.166
600	3.64	2.76	1.06	2.21×10	0.182
650	8.47[a]	1.20[a]	1.44	2.90	0.195
700	1.71×10[a]	5.10×10^{-1} [a]	2.25	5.74×10^{-1}	0.210

a) As the number of the effective data for the calculation is small, both k and a are obtained by extrapolation assuming the linearity of the $\ln k$ *vs.* $1/T$ plot and the $\ln a$ *vs.* $1/T$ plot, respectively.

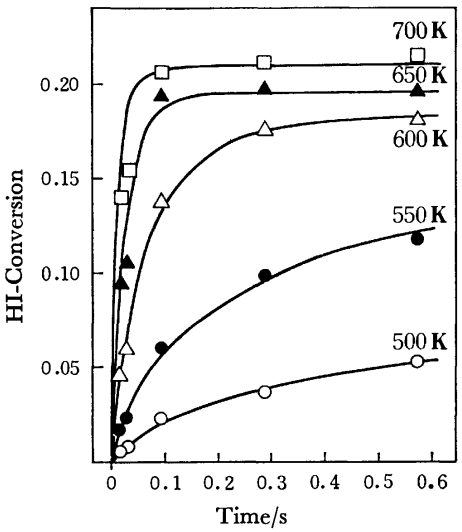

Fig. 2. Contact time-conversion relationship of hydrogen iodide over the Pt/C catalyst.

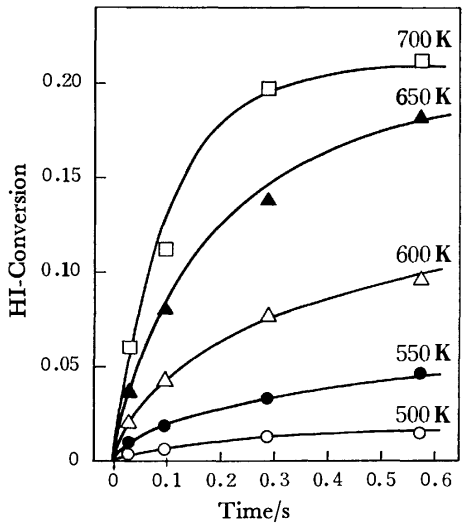

Fig. 3. Contact time-conversion relationship of hydrogen iodide over the active carbon catalyst.

of k and a are presented in Table 2. The continuous curves in Figs. 2 and 3 are obtained by employing Eq. 19 along with the k and a in Table 2. Because the equilibrium conversions of hydrogen iodide at temperatures of 600 K, 650 K, or 700 K in the presence of water vapor differed little from the values calculated by employing the free-energy changes cited from the JANAF Thermochemical Tables,[12] as will be explained in the section on the "Influence of the Partial Pressure of Water Vapor," the authors adopted the latter for x_e at each temperature from 500 K to 700 K for simulation by the use of Eq. 19. The continuous curves in Figs. 2 and 3 simulate the experimental data fairly well, supporting the conclusion that the assumed reaction scheme is comparatively appropriate.

Influence of the Partial Pressure of Hydrogen Iodide. For the rate equation at the initial stage, Eq. 20 is obtained by substituting zero for x in Eq. 8:

$$v = \frac{P\mathrm{d}x}{\mathrm{d}t} = \frac{k_f K_{HI} P}{1+K_{H_2O}P_{H_2O}+K_{HI}P}. \quad (20)$$

Equation 20 is transformed to Eq. 21:

$$\frac{v}{P} = \frac{\mathrm{d}x}{\mathrm{d}t} = \frac{k_f K_{HI}}{1+K_{H_2O}P_{H_2O}+K_{HI}P}. \quad (21)$$

It is reasonable to regard the data at 500 K, 550 K, and 600 K at a contact time of 1.43×10^{-2} s in Fig. 2 as those for the initial stage of the reaction. The conversion obtained when P, P_{H_2O}, and P_{Ar} were equal to 0.0761 atm, 0.415 atm, and 0.509 atm respectively at a contact time of 1.43×10^{-2} s were 0.00521 (500 K), 0.0159 (550 K), and 0.0444 (600 K). These values differ little from those shown in Fig. 2, for which the following partial pressures were used: P (0.125 atm), P_{H_2O} (0.682 atm), and P_{Ar} (0.193 atm). From these results, it is concluded that both $K_{H_2O}P_{H_2O}$ and $K_{HI}P$ are negligibly small compared to 1 in this range of their partial pressure by considering the form of Eq. 21, as $k_f K_{HI}$ remains constant.

Influence of the Partial Pressure of Water Vapor. The polarity of hydrogen iodide is strong. However, the polarities of hydrogen and iodine, the decomposition products of hydrogen iodide are weak. Therefore, there is the possibility that only hydrogen iodide is stabilyzed by the interaction with water vapor and that the conversion of hydrogen iodide decreases in the presence of water. The influence of the coexistence of water vapor on the equilibrium conversion of hydrogen iodide is small, as is shown by a comparison of the experimental conversions corresponding to that at the long contact time at 600—700 K in Fig. 2 with the calculated equilibrium conversions presented in Table 2.

When water vapor is added to the vapor of hydriodic acid, the rate equation at the initial stage is expressed as follows, on the basis of Eq. 20, where P_{H_2O} is the partial pressure of the water vapor including the added

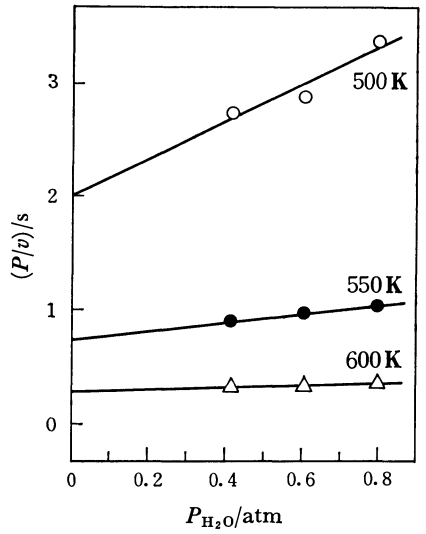

Fig. 4. Effect of water vapor addition on the initial rate of the decomposition of hydrogen iodide over the Pt/C catalyst (0.086 g): $P=0.0761$ atm, $P_{H_2O}=0.415$, 0.605, and 0.795 atm, P_{Ar}=balance.

water vapor:

$$v=\frac{P\mathrm{d}x}{\mathrm{d}t}=\frac{k_fK_{HI}P}{1+K_{H_2O}P_{H_2O}+K_{HI}P}. \quad (22)$$

The transformation of Eq. 22 yields Eq. 23:

$$\frac{P}{v}=\frac{1}{\frac{\mathrm{d}x}{\mathrm{d}t}}=\frac{1+K_{HI}P}{k_fK_{HI}}+\frac{K_{H_2O}P_{H_2O}}{k_fK_{HI}}. \quad (23)$$

It is shown in Eq. 23 that the plot of $1/(\mathrm{d}x/\mathrm{d}t)$ against the partial pressure of water vapor gives a straight line and that the intercept of the extrapolated line at the partial pressure zero is the reciprocal of $(\mathrm{d}x/\mathrm{d}t)$ in the absence of water vapor. The experimental results are depicted in Fig. 4. If the extrapolation of the straight line is significant even in the range where the partial pressure of water vapor is small or near zero, it can be said that the reaction rate of the decomposition of hydrogen iodide in the presence of water vapor does not differ so much from that in its absence.

Influence of the Partial Pressure of Iodine. Figure 5 shows the calculated values of the equilibrium conversion of hydrogen iodide in the presence of iodine in the gas phase added in advance of the decomposition. Calculation was carried out according to the following equation, where K is the equilibrium constant for the decomposition of hydrogen iodide, m is the ratio of the pressure of iodine added in advance of the decomposition to that of hydrogen iodide, and x is the conversion of hydrogen iodide:

$$K=\frac{\sqrt{x(x+2m)}}{2(1-x)}.$$

It can be seen from Fig. 5 that the coexistence of iodine in the gas phase lowers the equilibrium conversion of hydrogen iodide remarkably.

When iodine is added to hydriodic acid, the rate equation at the initial stage of the reaction is expressed as follows on the basis of Eq. 20, where $P^\circ_{I_2}$ is the

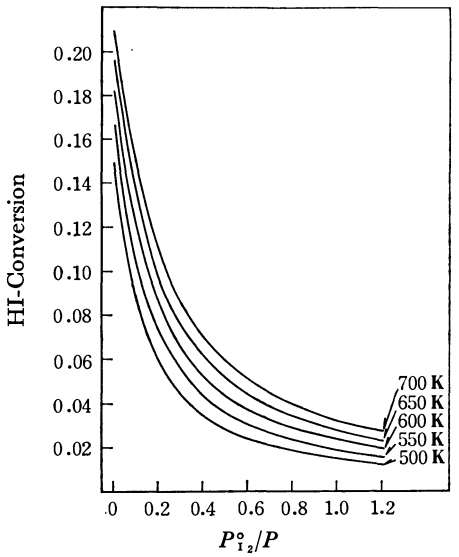

Fig. 5. Dependence of the equilibrium conversion of hydrogen iodide on the ratio of the pressure of iodine present in advance of the reaction ($P^\circ_{I_2}$) to the initial pressure of hydrogen iodide (P).

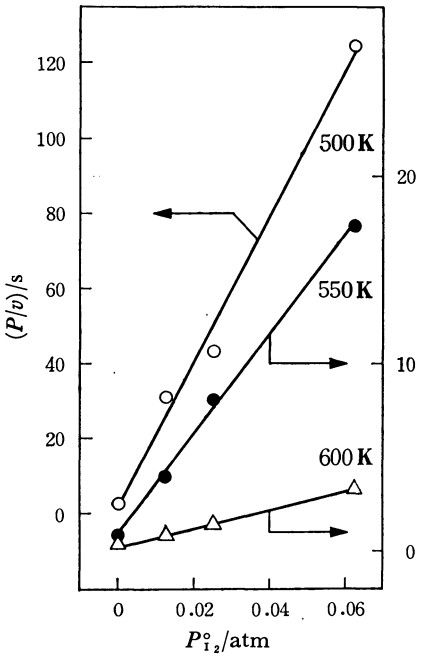

Fig. 6. Effect of iodine addition on the initial rate of the decomposition of hydrogen iodide over the Pt/C catalyst (0.086 g): $P=0.125$ atm, $P_{H_2O}=0.682$ atm, $P^\circ_{I_2}=0$, 0.0125, 0.0250, and 0.0625 atm, P_{Ar}=balance.

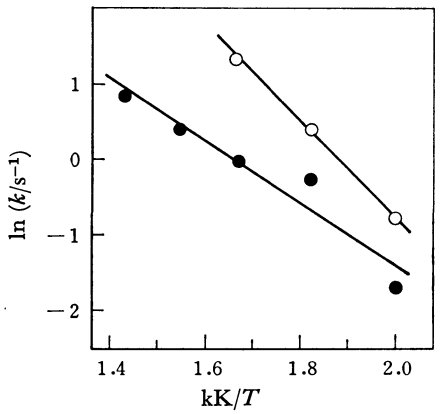
partial pressure of the added iodine:

$$v=\frac{P\mathrm{d}x}{\mathrm{d}t}=\frac{k_fK_{HI}P}{1+K_{H_2O}P_{H_2O}+K_{HI}P+K_{I_2}P^\circ_{I_2}}. \quad (25)$$

The transformation of Eq. 25 yields Eq. 26:

$$\frac{P}{v}=\frac{\mathrm{d}t}{\mathrm{d}x}=\frac{1+K_{H_2O}P_{H_2O}+K_{HI}P}{k_fK_{HI}}+\frac{K_{I_2}P^\circ_{I_2}}{k_fK_{HI}}. \quad (26)$$

Therefore, the plot of $1/(\mathrm{d}x/\mathrm{d}t)$ against the partial pressure of iodine gives a straight line, and the intercept at the zero pressure, the reciprocal of $(\mathrm{d}x/\mathrm{d}t)$ in the absence of iodine. The experimental results



Fif. 7. Arrhenius plots for the decomposition of hydrogen iodide over the Pt/C catalyst and active carbon catalyst.
○: Pt/C catalyst, ●: active carbon catalyst.

are shown in Fig. 6. It is notable that the reaction rate at the initial stage decreased remarkably with the addition of iodine in the low-temperature range. For example, the reaction rate at the initial stage in the presence of 0.0625 atm ($P_{HI}/P^{\circ}_{I_2}=2$) of iodine was about a fiftieth of that in the absence of iodine at 500 K.

Activation Energy and Heat of Adsorption. As has been described above, k and a are expressed as follows:

$$k = \frac{k_f K_{HI}}{1+K_{H_2O}P_{H_2O}+K_{HI}P} \tag{10}$$

$$a = \frac{(K_{H_2}/2+K_{I_2}/2-K_{HI})P}{1+K_{H_2O}P_{H_2O}+K_{HI}P}. \tag{11}$$

As has been mentioned above, $K_{H_2O}P_{H_2O}$ and $K_{HI}P$ are negligible compared to 1 under the present experimental conditions. Therefore, Eqs. 10 and 11 are transformed to give the following equations:

$$k \approx k_f K_{HI} \tag{27}$$

$$a \approx (k_{H_2}/2+K_{I_2}/2-K_{HI})P. \tag{28}$$

Equation 27 shows that k is nearly equal to the apparent rate constant of the decomposition reaction of hydrogen iodide on the catalyst surface. Figure 7 shows the plot of ln k *vs.* $1/T$; the straight line in the figure was obtained by the treatment of least-squares fitting. From Fig. 7, the apparent activation energy of the decomposition of hydrogen iodide was given as 12.7 kcal/mol over the Pt/C catalyst and as 8.21 kcal/mol over the active carbon catalyst. The value obtained over the Pt/C catalyst is near to that obtained over the Pt wire by Hinshelwood and Burk[7] (14 kcal/mol).

K_{H_2}, K_{I_2}, and K_{HI} in Eq. 28 are expressed as follows by the use of the heats of adsorption of the corresponding chemical species:

$$K_{H_2} = \exp(-\Delta G^{\circ}_{H_2}/RT) = \exp(\Delta S^{\circ}_{H_2}/R)\cdot\exp(-\Delta H^{\circ}_{H_2}/RT)$$
$$= c_1\cdot\exp(q(H_2)/RT)$$
$$K_{I_2} = c_2\cdot\exp(q(I_2)/RT)$$
$$K_{HI} = c_3\cdot\exp(q(HI)/RT), \tag{29}$$

where $\Delta G^{\circ}_{H_2}$, $\Delta S^{\circ}_{H_2}$, $\Delta H^{\circ}_{H_2}$, and $q(H_2)$ are the standard Gibbs free energy change, the standard entropy change, the standard enthalpy change of adsorption of hydrogen, and the heat of adsorption of hydrogen, respectively. The other symbols are defined as above. By substituting Eq. 29 in Eq. 28, Eq. 30 is obtained:

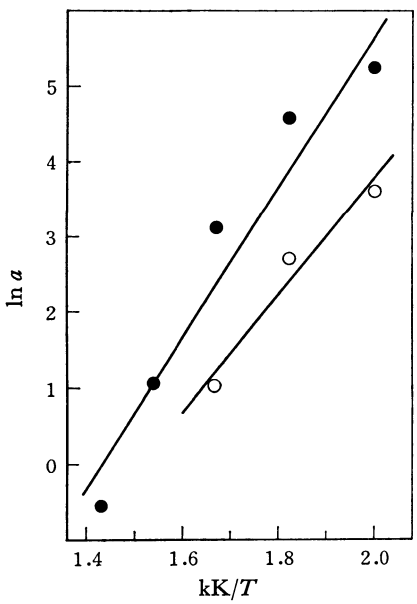


Fig. 8. Relations between the reciprocal of T and ln a.
○: Pt/C catalyst, ●: active carbon catalyst.

$$a = (c_1\cdot\exp(q(H_2)/RT)/2 + c_2\cdot\exp(q(I_2)/RT)/2$$
$$- c_3\cdot\exp(q(HI)/RT))P. \tag{30}$$

The values of $q(H_2)$ and $q(HI)$ on the active carbon have been reported in the literature: $q(H_2)$ is 2.5 kcal/mol[13] and $q(HI)$ is 21—23[14] kcal/mol. As is shown in Table 2, the values of a on the active carbon are positive, and when ln a is plotted against $1/T$ on a straight line by the least-squares fitting, the slope of the line is positive and big as is shown in Fig. 8. Therefore, none of the terms except for $c_2\cdot\exp(q(I_2)/RT)/2$ are considered to be dominant in Eq. 30. On the basis of this discussion, the following equation is obtained:

$$\ln a \approx q(I_2)/RT + \ln(c_2\cdot P/2). \tag{31}$$

Equation 31 means that, when ln a is plotted against $1/T$ on a straight line, the slope of the line gives $q(I_2)/R$. The value of $q(I_2)$ on the active carbon has not yet been reported. However, it may be estimated as follows:

$$q(I_2) = 2q(C_2H_5I) - q(n\text{-}C_4H_{10}),$$

where $q(C_2H_5I)$ and $q(n\text{-}C_4H_{10})$ are the heat of adsorption of ethyl iodide and butane on an active carbon, as reported in Ref. 13. The value of $q(I_2)$, 16.4 kcal/mol, is obtained by the use of the values of $q(C_2H_5I)$, 14.0 kcal/mol, and $q(n\text{-}C_4H_{10})$, 11.6 kcal/mol. The estimated value of $q(I_2)$ on the active carbon is comparable to that obtained from the slope of the ln a *vs.* $1/T$ plot of the active carbon catalyst (20.7 kcal/mol). This fact also supports the validity of the kinetic analysis employed in the present research.

The results obtained in the present research may be summarized as follows: 1) The contact time-

conversion relationship of the catalytic decomposition of hydrogen iodide over the Pt/C catalyst and the active carbon catalyst was simulated successfully by the use of a rate equation derived from an assumed reaction scheme. 2) The influence of water vapor on the rate and equilibrium of the decomposition of hydrogen iodide was small. 3) The Pt/C catalyst and the active carbon catalyst were consumed through the water-gas reaction in the high-temperature range (above 700 K for the former catalyst and above 800 K for the latter). 4) The presence of iodine in the gas phase in advance of the decomposition of hydrogen iodide lowers its equilibrium conversion remarkably, as judged on the basis of a thermodynamic calculation. 5) The inhibition effect of iodine on the rate of the catalytic decomposition of hydrogen iodide over the Pt/C catalyst was remarkable below 550 K.

On the basis of these results, the present authors have concluded that the Pt/C catalyst and the active carbon catalyst should be used in the temperature range of 550—700 K, where the water-gas reaction is almost negligible and where the inhibition effect of iodine is small. For the catalytic decomposition of hydrogen iodide in the lower temperature range, the development of a catalyst which suffers little inhibition effect from iodine is required, or the decomposition should be carried out in combination with a separation method that can continuously remove the iodine formed in the gas phase, even in the presence of water.

The authors wish to thank Drs. Naoyuki Todo, Kenzo Fukuda, and Etsuo Akiba for their valuable discussions. We also would like to thank Mr. Eiji Miyazawa for his cooperation in the experiment and Mr. Atsushi Kinase for his cooperation in several calculations.

Ion-exchange studies of crystalline zirconium titanium phosphate with variable zirconium-to-titanium mole ratios have been extended to sodium-ion exchange on the exchangers with Zr-to-Ti mole ratios of 0.37 and 0.61, and to lithium and potassium ion exchange on the exchanger with a Zr-to-Ti mole ratio close to unity. In the sodium-ion exchange, a mono-sodium phase formed up to about a half of the exchange; then a disodium phase with a different amount of water of crystallization formed. In the lithium-ion exchange, the reaction proceeded with the formation of fully exchanged phases whose water content varied depending upon the environment in which the exchanger was placed during or after the reaction. The exchange amount of potassium ions was much less than that of sodium or lithium ions, and the ion exchange proceeded in parallel with an extensive hydrolysis of the exchanger. The half-exchanged phase could not be confirmed in this case. For the three alkali metal ions studied, the selectivity series was found as a function of loading, *i.e.*, within the range of the load from 0 to 1.3 meq/g, the selectivity is in the order of $Na^+>K^+>Li^+$, between 1.3 and 4.5 meq/g, it is $Na^+>Li^+>K^+$, and above 4.5 meq/g loading, it turns out to be $Li^+>Na^+>K^+$.

The sodium-ion-exchange behavior on crystalline zirconium titanium phosphate (ZTP) with three different Zr-to-Ti mole ratios has been reported in some detail, and it was revealed[1] that, in the titanium-rich exchanger, a disodium phase was formed without the formation of the intermediate monosodium phase, as was the case in H^+–Li^+ or H^+–Na^+ exchange on α-titanium phosphate(α-TP). The investigation has now been extended to sodium-ion exchange on ZTP with some other Zr/Ti mole ratios, and further to lithium and potassium-ion exchange on ZTP with the Zr/Ti mole ratio close to unity. A comparison of the exchange behavior of these alkali metal ions with each other is of interest from the viewpoint of ion selectivity as well as the ion-sieve effect.

Experimental

ZTP Exchangers. The ZTP exchangers used in this experiment were prepared as has been described earlier[1] with the refluxing time of 200 h. The Zr/Ti mole ratio in the starting solutions was varied between the sodium-ion experiment and the lithium- and potassium-ion experiment.

Analysis of the Exchangers. The sum of Zr and Ti was determined gravimetrically by means of precipitation with cupferron.[1] In a separate experiment, the exchanger (300 mg) was dissolved in hot concd H_2SO_4 (40 cm^3). After cooling, 10% H_2O_2 (10 cm^3) was added to the solution. The mixture was heated, and the resulting clear solution was diluted to 150 cm^3. Then the solution was transferred into a reduction vessel containing a liquid zinc amalgam, carbon dioxide gas was introduced to repalce the air, and the vessel was shaken vigorously for 10 min under slight warming. Titanium(IV) was thus quantitatively reduced to a trivalnet state. Then the aqueous phase was titrated with a standard $NH_4Fe(SO_4)_2$ solution in the presence of a saturated KSCN solution (10 cm^3), the Zr-to-Ti mole ratio being calculated from the results.[2]

Ion Exchange. The experiment was conducted by means of the batch method in the way described previosuly. Mixed solutions of MCl (0.1 mol dm^{-3}) and MOH (0.1 mol dm^{-3}), where M is Li, Na, or K, were prepared in variable mixing ratios. The sodium experiment was carried out at 25 °C, whereas the lithium and potassium experiments were made at 25, 45, and 60 °C. After equilibration with the exchanger in interest, the solution was centrifuged, and then the pH of the supernatant liquid was measured. Analyses for Na, Li, and K was performed by flame photometry with a Hitachi atomic absorption/flame spectrophotometer, while P was analyzed colorimetrically by the phosphomolybdic acid method. X-Ray powder diffractometry was made on exchangers obtained at various stages of ion exchange by using a Rigaku Geigerflex X-ray diffractometer.

Results and Discussion

Synthesized Exchangers. Three kinds of ZTP exchangers have been prepared, as is shown in Table 1. ZTP(Zr/Ti=0.37) and ZTP(0.61) were used for the Na^+-ion exchange, and ZTP(1.02), for the Li^+- and K^+-ion exchange.

The interlayer distance (d_{002}), as estimated from the X-ray powder patterns, was approximately 7.6 Å in all three cases. As has been reported,[1] the exchangers are considered as solid solutions of zirconium and titanium phosphate and as isomorphous with α-zirconium phosphate(α-ZP) and α-TP.

Sodium-ion Exchange. Figure 1 illustrates the pH-titration curves for Na^+-ion exchange and the corresponding phosphate-release curves. The titration

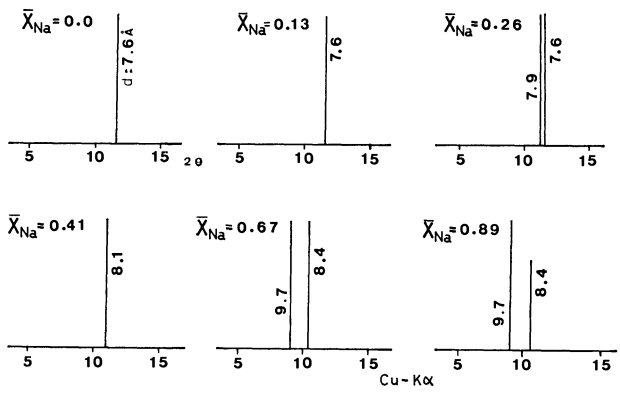

Fig. 3. The lowest angle regions of the X-ray powder diffraction patterns of ZTP(0.61) at several stages of exchange.

curve for ZTP(0.37) has a small point of inflection at approximately 2.3 meq Na^+/g ZTP. The curve for ZTP(0.61) also has an inflection at approximately 2.4 meq Na^+/g ZTP. The titration curve for Na^+-ion exchange on α-TP given by Takaguchi[3] is included in the figure, where an inflection exists at approximately 2 meq Na^+/g TP. The titration curve for Na^+-ion exchange on α-TP is similar to those given by previous investigations, but the existence of any inflection was not very clear[4,5] previously, except for the recent study by Clearfield and Frianeza.[6] The shift of the inflection toward a lower sodium loading with a decrease in the Zr content has been observed in the experiment[1] for ZTP(3.25) [3.5 meq/g], ZTP (0.93) [3 meq/g], and ZTP(0.25) [2.2 meq/g]. The data given in the present study again confirms the trend.

The X-ray powder patterns for ZTP(0.37) and ZTP (0.61) at several stages of exchange were measured; their lowest angle regions are shown in Figs. 2 and 3. The reflection peak at the lowest angle corresponds to the interlayer distance (d_{002}). The ionic fraction of sodium in the exchanger phase is denoted by $\bar{X}_{Na}$. As is shown in Fig. 2, in ZTP(0.37), the intensity of the peak at 7.6 Å representing the unexchanged phase decreased with an increase in sodium loading, and a peak appeared at 8.2 Å. This peak seems to correspond to the monohydrate of monosodium salt (d= 7.9 Å), with some excess of water obtained in the dehydration process of pentahydrate (d=11.9 Å). Beyond a 50% exchange, the unexchanged phase was no longer present and the peaks at 8.4 and 9.7 Å arose. These peaks indicate disodium phases with different amounts of water of crystallization.[1] These patterns suggest that ZTP(0.37) still behaves toward the Na^+ ion like α-ZP in that the monosodium phase exists as an intermediate.

In ZTP(0.61), the interlayer distance remained almost constant until $\bar{X}_{Na}$=0.26, where the peak at 7.9 Å appeared at the expense of the peak at 7.6 Å (Fig. 3). Thus, it shows the formation of the solid solution of ZTP with the Na^+ ion up to about 25% exchange. At $\bar{X}_{Na}$=0.41, the 7.6 Å peak disappeared, leaving only the peak at 8.1 Å. The d-values for the monosodium form seem to vary between 7.9 and 8.2 Å depending upon the drying condition of the samples used for X-ray examination. If the sample was dried in a silica-gel desiccator, d-values of around 7.9 Å were obtained, whereas the samples only air-dried gave somewhat higher values.

In conclusion, for the Na^+-ion exchange process, the monosodium phase is present in ZTP(0.37) and ZTP(0.61), as was the case for α-ZP, ZTP(3.25), and ZTP(0.93).

Lithium-ion Exchange. The ion-exchange experiment was conducted by using ZTP(1.02), its formula being $Zr_{0.505}Ti_{0.495}(HPO_4)_2 \cdot H_2O$. The pH-titration curves and the phosphate-release curves measured at 25, 45, and 60 °C are given in Fig. 4. At any temperature examined, the titration curve reached a plateau at a pH close to about 5 soon after the exchange started. In the case of the experiment at 25 °C, the plateau continued until the exchange proceeded up to 80% of the theoretical exchange capacity. Thereafter, the curve steeply rose to the pH of 7.5 and recorded the maximum exchange of 88.5%. At a higher pH value, the exchange amount of the Na^+ ion decreased as a result of the hydrolysis of the exchanger. The absence of any pH jump at a half-exchange reminds one of the lithium-ion exchange on α-TP.[7] As the temperature rose, the hydrolytic decomposition of the exchanger proceeded further, resulting in a decrease in the maximum exchange

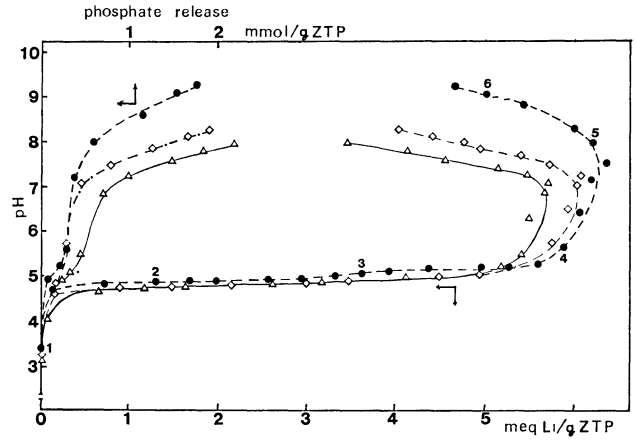

Fig. 4. The pH-titration curves for lithium ion exchange and the phosphate release curves.
—●—: 25 °C, —·◇·—: 45 °C, —△—: 60 °C.
The exchanger is ZTP(1.02) in all the cases.

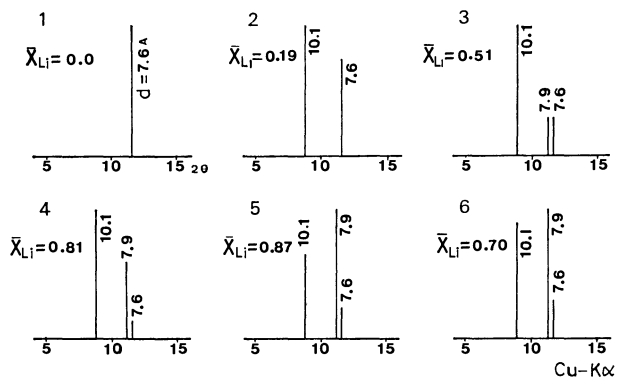

Fig. 5. The lowest angle regions of the X-ray powder diffraction patterns of ZTP(1.02) at several stages of lithium exchange at 25 °C. The numbers 1 to 6 indicate the extent of reaction shown in the titration curve in Fig. 4. $\bar{X}_{Li}$ denotes the ionic fraction of lithium ion in the exchanger.

amount of the Li^+ ion, which was 84% at 45 °C and 79% at 60 °C compared to the theoretical value. As far as the ion-exchange behavior is concerned, however, the temperature dependence is very little, as is clearly observed in the fact that there is almost the same pH value in the plateau region. In other words, the exchange equilibrium is attained within 4 d even at 25 °C, but hydrolysis tends to proceed even further if the exchanger is in contact with alkaline solutions for a longer period.

The lowest-angle regions of the X-ray powder patterns of the exchanger at several stages of Li^+-ion exchange are reproduced in Fig. 5. Numbers 1 to 6 indicate the extent of exchange shown in the titration curve (Fig. 4). Unlike the Na^+-ion exchange on ZTP (0.61), a hardly no formation of the solid solution was observed in the present case; that is, as soon as the exchange started, the reflection peak at 10.1 Å appeared, followed by the peak at 7.9 Å. These two peaks retained considerable intensities up to the maximum exchange, namely, to the end of the reaction. At the same time, the peak at 7.6 Å representing the unexchanged phase also survived with much smaller intensity. It is considered that the increasing steric hindrance occurred as the hydrated Li^+ ions replaced protons, and that this resulted in incomplete substitution. The peaks at 10.1 and 7.9 Å correspond to the tetra- and mono-hydrate of dilithium salt, (Zr, Ti)$(LiPO_4)_2 \cdot 4H_2O$ and (Zr, Ti)$(LiPO_4)_2 \cdot H_2O$, as assumed from the lithium-exchanged phases formed in α-ZP.[8] In fact, if the exchanged solid was heated at 100 °C for 30 min, the peak at 10.1 Å completely disappeared and the peak at 7.9 Å remained.

From the shape of the titration curves and the X-ray evidence, it may be concluded that, in the Li^+-ion exchange on ZTP(1.02), the reaction proceeds with the formation of fully exchanged phases whose water content varies depending upon the environment during or after the exchange process.

It is interesting to compare the Li^+-ion exchange behavior on ZTP with that on α-ZP and α-TP. In α-ZP, two exchangeable protons are said to have differing acidities, and a half-exchanged phase is often observed for the reaction with many counter ions. This exchanger also allows variations in the water content at various stages of ion exchange, and it leads to a change in the interlayer spacing. In α-TP, on the other hand, the formation of a half-exchanged phase is difficult to confirm.† Especially for the Li^+-ion exchange, the water content is rather unchanged throughout the reaction and the interlayer spacing is also kept constant. The case of ZTP(1.02) is just intermediate inbetween α-ZP and α-TP. It resembles α-TP in that a monolithium phase is absent, but it resembles α-ZP in that the water content varies during exchange, resulting in a change in the interlayer distance. However, taking the exchange behavior of Na^+ ion into consideration, the existence or absence of a half-exchanged form is not always simply related to the difference in the acidity of the two exchangeable protons of ZTP. To elucidate the mechanism of the direct formation of the fully exchanged phase, further investigation, including that of the diffusion kinetics of cations in the exchanger solid, are needed.

Potassium-ion Exchange. The same exchanger as used for the Li^+-ion exchange, ZTP(1.02), was utilized. The potassium-uptake curves and the phosphate-release curves obtained at 25, 45, and 60 °C are shown in Fig. 6. It is clear that potassium uptake on ZTP(1.02) is not so easy compared to the sodium and lithium uptake. Thus, up to pH 7 about 2 meq K^+ ions per g of exchanger were taken up. This value falls to between the corresponding potassium uptakes on α-TP and α-ZP, about 1 meq/g[3] and 3 meq/g[9] respectively. These values are much less than the exchange amount of alkali metal ions with smaller ionic radii for this pH. The equilibrium pH reached a plateau at about 7.1, where the K^+-ion exchange proceeded in parallel with the hydrolysis of the exchanger. No step-by-step exchange such as has been observed in the K^+-ion exchange on α-ZP[9] was found in the case of ZTP(1.02).

† Clearfield and Frianeza reported the formation of two sodium-ion-exchanged phases.[6]

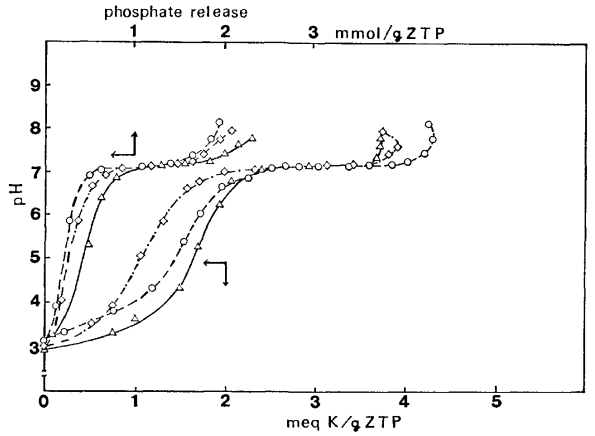

Fig. 6. The pH-titration curves for potassium ion exchange and the phosphate release curves.
—○—: 25 °C, —·◇·—: 45 °C, —△—: 60 °C.
The exchanger is ZTP(1.02) in all the cases.

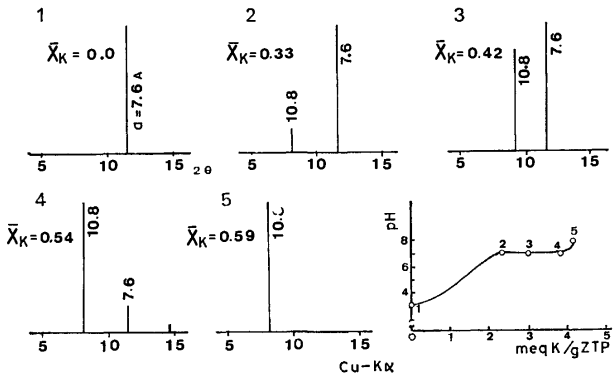

Fig. 7. The lowest angle regions of the X-ray powder diffraction patterns of ZTP(1.02) at several stages of potassium exchange at 25 °C. The numbers 1 to 5 indicate the extent of reaction shown in the titration curve given at the bottom right. $\bar{X}_K$ denotes the ionic fraction of potassium ion in the exchanger.

The maximum exchange was about 60% of the theoretical capacity at 25 °C and even less at higher temperatures. The phosphate release in alkaline solutions was much more extensive in the K^+ uptake than in the Li^+ and Na^+ ion exchange, reflecting the large ionic radius of the K^+ ion, which encounters cavity openings of comparable size.

In Fig. 7, the lowest angle region of the X-ray powder diffractograms of various exchanged solids for the 25 °C experiment are given schematically. Up to an exchange of about 33%, where the equilibrium pH is still below 7, no new solid phase can be observed, indicating the formation of a solid solution; *i.e.*, the K^+ ions are incorporated with ZTP without changing its structure. Above this point, the reflection corresponding to d_{002}=10.8 Å appeared, while the peak at 7.6 Å diminished. It should be noted that the exchanger decomposes to such an extent that, at $\bar{X}_K$= 0.59, no reflection from the unexchanged phase was observed any longer. The X-ray powder patterns obtained in the 45 and 60 °C experiments were similar to those described above, except that the degree of crystallinity became poorer in the exchange at a higher pH.

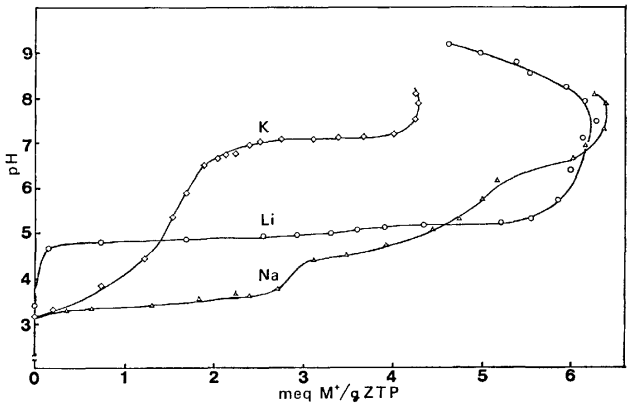

Fig. 8. The alkali metal ion uptake curves at 25 °C. For sodium ion uptake, ZTP(0.93) exchanger was used. For other two ions, ZTP(1.02) was employed.

In the K^+-ion exchange on α-ZP, monopotassium salt, $Zr(KPO_4)(HPO_4)\cdot H_2O$, with an interlayer distance of 7.95 Å, and dipotassium salt, $Zr(KPO_4)_2\cdot 3H_2O$, with an interlayer distance of 10.8 Å, were produced during the exchange process.[9] In the present study, the new solid phase confirmed has the interlayer distance of 10.8 Å, which most probably corresponds to a trihydrate of dipotassium salt, $(Zr, Ti)(KPO_4)_2\cdot 3H_2O$. This means that the half-exchanged phase could not be confirmed in this case either.

Ion-selectivity Series. Comparison is now possible between the ion-exchange behavior of three alkali metal ions on this particular inorganic exchanger. Titration curves measured under quite similar conditions are reproduced in Fig. 8. The selectivity series depends on the load of exchanger. Thus, within the range of loads from 0 to 1.3 meq/g, the selectivity is in the order: $Na^+>K^+>Li^+$, while between 1.3 and 4.5 meq/g, it is $Na^+>Li^+>K^+$. Above 4.5 meq/g loading, it turns out to be $Li^+>Na^+>K^+$, and practically no potassium ions are taken up at all.

It is noticeable that the lithium-ion selectivity increases relative to other ions as the load of the exchanger increases. However, this is a result of the rather constant equilibrium pH for lithium exchange compared to the case of sodium or potassium. In lithium exchange, essentially a single exchanged crystal form seems to exist. Thus, the tetrahydrate of dilithium salt is the most probable form on the exchange site. On the other hand, in the case of sodium exchange, the shape of the titration curve seems to be related to two exchanged forms, mono- and disodium salts. Further, in potassium exchange, the initial formation of a solid solution, followed by the formation of a potassium salt phase, may be responsible for the unique shape of its titration curve.

Phase Relations in the System PbO–$PbSiO_3$

Kazushi HIROTA* and Yasutoshi T. HASEGAWA

National Institute for Research in Inorganic Materials, Namiki, Sakura-mura, Niihari-gun, Ibaraki 305

(Received July 24, 1980)

Phase relations in the system PbO–$PbSiO_3$ were determined at temperatures above 650 °C. Two new lead silicate phases, Pb_5SiO_7 and $Pb_{11}Si_3O_{17}$ were found to be stable. The former melts incongruently at 733±1 °C to solid PbO plus liquid, and decomposes below 702±1 °C. The latter melts congruently at 728±1 °C. The compound Pb_4SiO_6, which has been accepted as stable, could not be confirmed.

Considerable work has been done by various investigators[1-11] on the system PbO–SiO_2. These workers agree about the temperature region of liquidus and solidus lines of the PbO–SiO_2 system, and the phase diagram given by Geller *et al.*[6] has long been accepted as definitive by many investigators.[7-11] Beyond this, however, there is little agreement. Compounds with the PbO:SiO_2 molar ratios of 4:1, 3:1, 2:1, 3:2, 1:1, 5:8, and 1:2 have been reported. Billhardt,[7] Ott and McLaren,[8] and Smart and Glasser[9] have studied subsolidus reactions and compound formation in this system, with the result that there are 3 quite different sets of conclusions regarding the identity, polymorphism, and thermodynamic stability of the lead silicates.

In the present study, we re-examined the phase equilibrium relations of the system PbO–$PbSiO_3$ in the region above 650 °C, of which the phase diagram has been given by Geller *et al.*[6] Two new lead silicate phases, 5:1 and 11:3, were found to be stable.

Experimental

The reaction products quenched in the equilibration runs were examined by X-ray diffraction of powdered specimens, by electron probe microanalysis, and by microscopy. The approach to equilibrium was studied as a function of run durations. Starting from a mixture of PbO and SiO_2, a complex mixture of more than three phases was obtained when the run duration was too short to attain an equilibrium state. A quenched specimen was judged to be at equilibrium when two phases or a single phase only was found. The starting mixtures were enclosed by welding them in platinum capsules 6 mm in diameter and 35 mm long. Otherwise, sublimation of components during the run durations was not negligible.

A fine powder of SiO_2 used as the starting material was prepared from a commercial $SiCl_4$ (Shin-Etsu Chemical Co. Ltd.) prepared for semiconductor use. The $SiCl_4$ was added to water in a platinum dish. The product was dried on a sand bath. Then the product silica was crushed into a powder and heated at 1300 °C to eliminate the volatile impurities. The PbO used as starting material was prepared from a commercial basic lead carbonate (Nakarai Chemicals, Ltd., CP grade). About 10 ppm of Al and Ni were detected in the PbO by means of spectroscopic analysis. Further details of the experimental procedures are the same as those given in our previous report on the PbO–$PbGeO_3$ system.[12]

Results

Observed equilibrium phase relations are summarized in Fig. 1. In the PbO–$PbSiO_3$ system, three intermediate compounds, Pb_5SiO_7, $Pb_{11}Si_3O_{17}$, and Pb_2SiO_4, appear above 650 °C. The last one, Pb_2SiO_4 has been already reported by Krakau *et al.*,[5] but the former two phases have not yet been reported.

In the present investigation, electron probe microanalysis was used successfully for identification of phases in quenched samples. Results of analysis for equilibration runs are shown in Table 1. Each starting mixture was sealed by welding it inside a plutinum

a) Computational method was taken from Bence and Albee.[13] Under experimental conditions of 20 kV accelerating potential and 40° take-off angle, the correction factors α were: $\alpha^{Pb}_{SiO_2}=1.60$ and $\alpha^{Si}_{PbO}=1.04$.

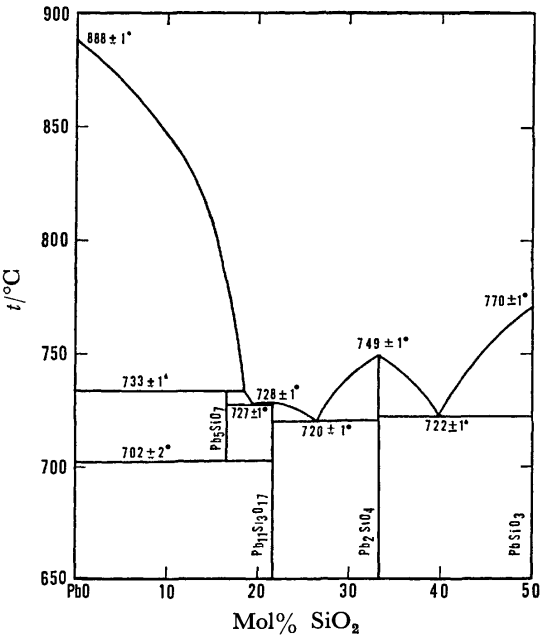

Fig. 1. Phase relations in the system PbO-$PbSiO_3$.

capsule. This was kept at 718 °C for 820 h and then quenched to room temperature. Only two phases were found in each capsule. Crystals in the quenched samples thus obtained were several tens of microns or more in size, and were large enough to allow the analysis. The standard deviation σ for SiO_2 concentration in the $Pb_{11}Si_3O_{17}$ phase was determined to be 0.08 wt% SiO_2; this was sufficient to determine the chemical composition of this phase.

Pb_5SiO_7. The Pb_5SiO_7 phase was determined to be stable only between 733±1 °C and 702±2 °C. By spontaneous crystallization of a melt of composition $5PbO \cdot SiO_2$, brown plates of Pb_5SiO_7, together with PbO and fine crystals of $Pb_{11}Si_3O_{17}$, were obtained. Well developed crystals of Pb_5SiO_7 were obtained by keeping a mixture of PbO and $Pb_{11}Si_3O_{17}$ for a week at 725 °C. The Pb_5SiO_7 decomposes slowly into PbO and $Pb_{11}Si_3O_{17}$ at temperatures below 702 °C. Runs of several weeks duration were necessary to attain an equilibrium state.

$Pb_{11}Si_3O_{17}$. The phase $Pb_{11}Si_3O_{17}$ melts congruently at 728±1 °C. The composition of this phase was determined, at the first stage of investigation, by means of electron probe microanalysis. The results of this analysis were scattered in a range from 78.4_3 to 78.9_6 mol% PbO. The average value was 78.6_5 mol% PbO. The atomic ratio Pb/Si=11/3 (78.57 mol% PbO) is the simplest integral ratio for these analytical results. To confirm this conclusion, a mixture of the composition $11PbO \cdot 3SiO_3$ was enclosed in a platinum capsule by welding. Keeping the mixture at a temperature only slightly lower than that required for melting, and grinding repeatedly, it was possible to prepare a microscopically single-phase product of $Pb_{11}Si_3O_{17}$. A rapid and reversible structural inversion at 145±5 °C was detected by X-ray powder diffraction measurement of this phase.

Discussion

In the early investigations,[1-5] the workers agree on the existence of the compounds Pb_2SiO_4 and $PbSiO_3$. The phase "Pb_4SiO_6" has been reported by Geller *et al.*[6] In their investigations, they came to the conclusion that "Pb_4SiO_6" has three crystal modifications: alpha form stable above 720 °C and melting incongruently at 725 °C to PbO and liquid, beta form stable between 720° and about 140 °C, and gamma form stable below 140 °C. The phase "Pb_4SiO_6" has been accepted by Billhaldt,[7] by Ott and McLaren[8] and by Smart and Glasser,[9] who studied subsolidus phase equilibria in the system PbO–SiO_2. In their investigations, a single phase "Pb_4SiO_6" was obtained both when the constituent oxides were sintered and when the glass was devitrified. X-Ray powder data for the alpha form and the gamma form were given by McMurdie and Bunting,[10] by Billhardt,[7] and by Argyle and Hummel.[11] Their data coincide with each other satisfactorily within their experimental errors.

But, as regards the alpha-beta inversion of "Pb_4SiO_6," some ambiguities have been pointed out. Geller *et al.*[6] reported that the results of heating curves obtained by a DTA method, as well as of the quenching tests, were not entirely satisfactory as regards the establishment of the alpha-beta inversion, but these results were believed to indicate that the tetralead silicate, on heating, undergoes an inversion at 720±2 °C. Billhaldt[7] has reported that the questions whether the chemical formula given for the phase α-Pb_4SiO_6 is the right one and wherther the composition of this phase is Pb_3SiO_5 could not be solved. He also reported that a crystallized single phase sample is necessary to determine the chemical composition of this phase.

The synthesis of "α-Pb_4SiO_6" was readily repeated by Smart and Glasser.[9] But they reported that the available data are insufficient to prove that the composition ratio of this phase is 4:1. Irrespective of the bulk composition of the mixture or the time and temperature used in the experiment, a single-phase product was never obtained in either isothermal or dynamic runs. They also reported that the α-phase was sometimes obtained free of other crystalline phases, but these preparations always contained glass, and, more often, the α-phase occurred with β-Pb_4SiO_6, PbO, or both. They added that the narrow range of temperatures essential to formation of this phase makes more detailed investigation difficult.

It is possible to suspect that the "α-Pb_4SiO_6" is the Pb_5SiO_7 obtained in the present investigation. Certainly, X-ray powder data for this phase given by McMurdie and Bunting,[10] and Billhaldt[7] coincide with that for the Pb_5SiO_7 phase found in the present investigation. Practically all reflections in their X-ray powder data of "α-Pb_4SiO_6" are found also in that of Pb_5SiO_7 phase; these are shown in Table 2.

Similarly, the phases "β-Pb_4SiO_6" and "γ-Pb_4SiO_6" correspond with the compound $Pb_{11}Si_3O_{17}$ in the present investigation. X-Ray powder data for "γ-

Pb_4SiO_6" given by McMurdie and Bunting,[10] and X-ray powder data for "T-Pb_4SiO_6" given by Billhaldt[7] coincide with that of $Pb_{11}Si_3O_{17}$ at room temperature in the present investigation. The difference in composition between "Pb_4SiO_6" and $Pb_{11}Si_3O_{17}$ is only 0.534 wt% SiO_2. The experimental techniques used in the previous investigations may not have been sufficient to distinguish such a small difference in chemical compositions.

The authers are greately indebted to Professor Takashi Katsura of Tokyo Institute of Technology for his encouragement and helpful discussions.

Effect of the Buffering Capacity of a Supporting Solution on Paper Electrophoretic Migrations of Adenine, Adenosine, and Adenosine Nucleotides

Yoshinori KITAOKA

Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04

(Received September 1, 1980)

Paper electrophoretic migrations of adenine, adenosine, and adenosine nucleotides as a function of pH-values of various supporting solutions have been studied. The buffering capacity of the supporting solution played an important role in the migration and is discussed along with the electroosmosis. The R_f-values of adenines in the supporting solutions are also presented.

In the previous paper,[1] we reported the electrophoretic behavior of adenine, adenosine, and adenosine nucleotides as a function of the pH and of the concentration of inorganic acids. In the case of a supporting solution of lower buffering capacity, the deprotonation of protonated adenine or the dissociation of the secondary hydrogen of the phosphate moiety in the nucleotides did not take place at the pH-value expected from other chemical analyses. In order to elucidate the cause of this behavior, we carried out more paper electrophoresis in supporting solutions having different buffering capacities in a range of pH=2—13. Electroosmotic flows and the R_f-values of samples in solutions to be used for the electrophoresis are also shown.

Experimental

Materials. Adenine and adenosine were purchased from Wako (Osaka, Japan), and the sodium salts of the nucleotides from Sigma (St. Louis, Mo., U.S.A). Guaranteed grades of chemicals were used for preparation of supporting solutions without further purification.

Paper Electrophoresis. The procedures and apparatus[1] used were similar to those described previoulsy. Supporting solutions (ionic strength $\mu=0.1$) of NaOH in various concentrations were prepared by diluting 0.1 M NaOH solution with 0.1 M NaCl solution (1 M=1 mol dm^{-3}). The supporting solution of pH=13 was a 0.1 M NaOH solution containing no NaCl. Sørensen's buffer solutions[2] were prepared in the following way. A 0.1 M sodium citrate solution was prepared by dissolving 21 g (0.1 M) of $C_6H_8O_7\cdot H_2O$ and 8.0 g (0.2 M) of NaOH in one liter of distilled water. The citrate solution was mixed with 0.1 N HCl or 0.1 N NaOH solution to obtain citrate buffer solutions of different pH values. Glycine buffer solutions were prepared by mixing 0.1 M glycine +0.1 M NaCl solution with 0.1 M NaOH, and phosphate buffers by mixing 0.2 M Na_2HPO_4 and 0.2 M NaH_2PO_4. The buffering capacity (β) of the supporting solution was calculated by this equation:[3]

$$\beta = 2.303\{[C]\cdot[H^+]\cdot K_a/([H^+]+K_a)^2+[H^+]+10^{-14}/[H^+]\},$$

where C is the concentration of the solute, K_a the dissociation constant of the solute, and $[H^+]$ the concentration of hydrogen ions. The calculated buffering capacities of the solutions are listed in Table 1.

Adenosine and adenosine nucleotides were dissolved in distilled water and adenine was dissolved in 0.1 M sodium acetate. A 5 μl volume of sample solution (5×10^{-2} M) was spotted at the center of a filter paper (Toyo Roshi No. 51A, 1×40 cm) wetted with a supporting solution. The filter paper was dipped in hexane in the migration chamber and a voltage gradient (1000 V/30 cm) was applied it for 30 min at *ca.* 20 °C. Adenines after migration on the filter paper were detected using the absorption band at 253 nm.

Table 1. Buffering capacities(β) of supporting solutions

Component	pH	β
HCl+0.1 M NaCl	2.0	2.3×10^{-2}
	3.0	2.3×10^{-3}
	4.0	2.3×10^{-4}
	5.0	2.3×10^{-5}
	6.0	2.5×10^{-6}
0.1 M NaCl	7.0	4.6×10^{-7}
NaOH+0.1 M NaCl	8.0	2.5×10^{-6}
	9.0	2.3×10^{-5}
	10.0	2.3×10^{-4}
	11.0	2.3×10^{-3}
	12.0	2.3×10^{-2}
	13.0	2.3×10^{-1}
Citric acid buffer	2.0	3.3×10^{-2}
	3.0	2.5×10^{-2}
	4.0	2.2×10^{-2}
	5.0	5.6×10^{-2}
	6.0	3.0×10^{-2}
	6.7	2.6×10^{-2}
Phosphoric acid buffer	7.0	2.8×10^{-2}
	8.0	6.6×10^{-3}
Glycine+NaOH buffer	8.9	2.5×10^{-2}
	10.1	2.9×10^{-2}
	11.0	7.8×10^{-3}
	12.0	2.4×10^{-2}
	12.9	1.8×10^{-1}

The electroosmotic flows were estimated from the movement of glucose (5×10^{-2} M), which migrated along with the sample solution. The results are shown in Fig. 1. The different migrations of glucose among spotting positions are due to a capillary action, which is towards the center of a filter paper and almost disappears in 1 h.[4] The contribution of the capillary action to the movement of glucose is minimum at the center and usually zero within experimental errors. That is why the samples are spotted at the center of a filter paper. Since electroosmotic flows[5] should vary with the charge and porosity of filter paper, different batches of the same type of filter paper may give different results. The different electroosmotic flow for Toyo Roshi No. 51A filter papers were within 0.5 cm at 1000 V per 30 cm at 20 °C for 30 min. Glucose on a filter paper was detected by spraying *o*-aminophenol solution.[6]

Paper Chromatography. No ideal method to evaluate the adsorption effects of migrants on a filter paper has been proposed.[7] The measurement of R_f-value may be one convenient method, since it is useful for the estimation of

the interaction between a filter paper and the migrants in a given solvent. Samples were developed in solvents used for the paper electrophoresis for 3.5—4 h at 15 °C

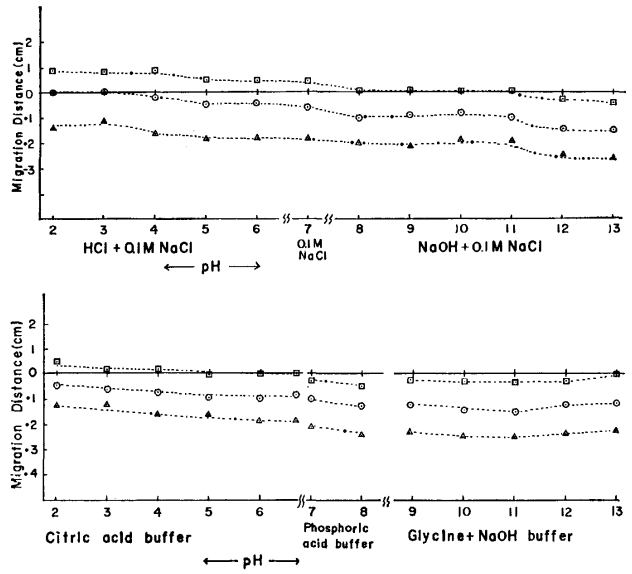

Fig. 1. The movement of glucose.
Conditions: voltage gradient, 1000 V per 30 cm; migration time, 30 min; migration temperature, *ca.* 20 °C; supporting solutions are referred to Experimental. Spotting positions: ⊡, 5 cm to the cathodic side from the center of the filter paper; ⊙, the center; ▲, 5 cm to the anodic side from the center. Positive movement is towards the anode, negative movement towards the cathode.

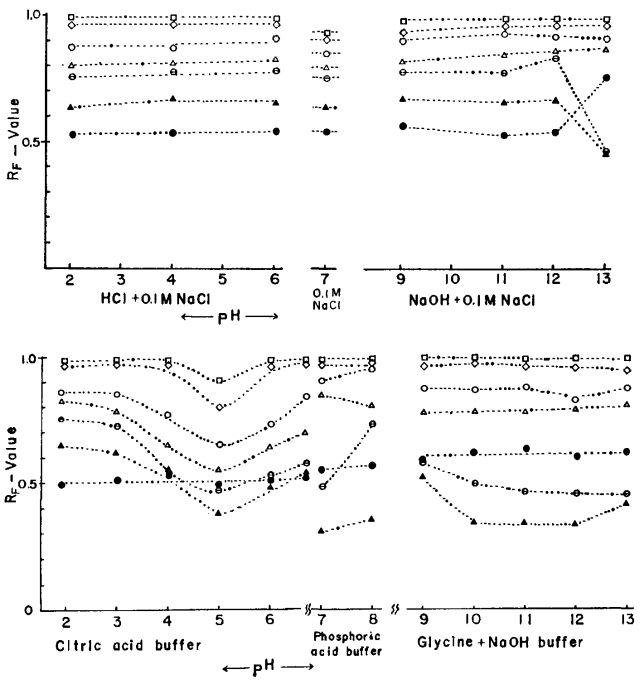

Fig. 2. R_f-values of paper chromatography in various solvents.
Conditions: developing time, 3.5—4.0 h; temperature, *ca.* 15 °C; ascending method. Developing solvents are referred to Experimental. ○: AMP, △: c-AMP, ◇: ADP, □: ATP, ▲: adenine, ⊖: adenosine, ●: picric acid.

on Toyo Roshi No. 51A (2×40 cm) filter paper by an ascending method. The results are shown in Fig. 2. Adenosine nucleotides showed larger R_f-values than adenosine and adenine; ATP moved nearly the same distances in all solvents as the solvent moved. The lower R_f-values of adenine and adenosine in phosphoric acid and glycine buffers suggest the presence of specific weak interactions in these solutions. The R_f-values of picric acid were almost constant in all solvents (R_f=0.5—0.6). The R_f-values decreased in the order: ATP>ADP>AMP>c-AMP>adenosine>adenine.

Results and Discussion

Under ideal conditions, the relationship between the electrophoretic migration distance and the pH value of the supporting solution could be expressed by a sigmoid curve having an inflection point at the pH value equal to pK_a of the migrant.[8] The pK_a-values of the adenine, adenosine, and adenosine nucleotides which are studied in this experiment are shown in Table 2.[9] The values are determined by the

Table 2. pK_a-Values
The ionic strength in each instance was 0.1 at 25 °C.

Compound	pK_a (base)	pK_a (secondary phosphate)	pK_a (>N_9H)
Adenine	4.2	—	9.7
Adenosine	3.6	—	—
5′-AMP	3.8	6.2	—
5′-ADP	3.9	6.4	—
5′-ATP	4.1	6.5	—

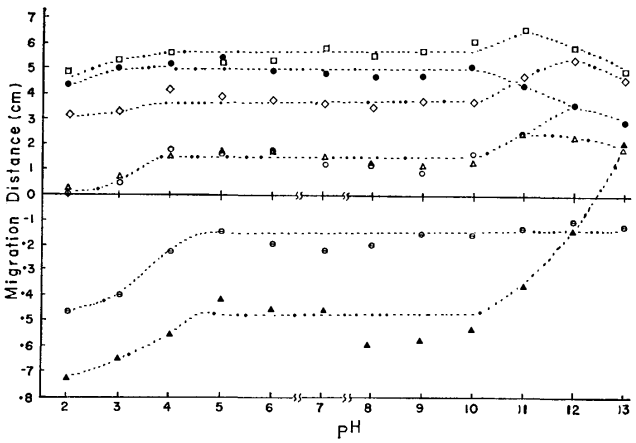

Fig. 3. Migration distances of adenine, adenosine and adenosine nucleotides in supporting solutions of low buffering capacity. Conditions: voltage gradient, 1000 V per 30 cm; migration time, 30 min, migration temperature, *ca.* 20 °C. Supporting solution, HCl+0.1 M NaCl (pH=2—6); 0.1 M NaCl (pH=7.0); NaOH+0.1 M NaCl (pH=8—13). Positive movement is towards the anode, negative movement towards the cathode. Symbols as in Fig. 2. Buffering capacity of each solution is referred to Table 1.

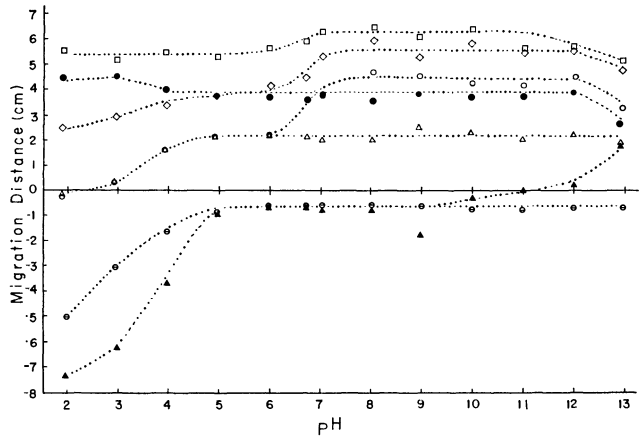

Fig. 4. Migration distances of adenine, adenosine, and adenosine nucleotides in supporting solutions of high buffering capacity. Electrophoresis conditions and symbols as in Fig. 3. Supporting solutions, citric acid buffer (pH=1.9—6.7); phosphoric acid buffer (pH=7—8); glycine+NaOH buffer (pH=8.9—12.9). Buffering capacity is referred to Table 1.

usual chemical methods, such as pH titration and spectrophotometry, rather than by electrophoresis.

The dependence of the observed migration distances of adenine, adenosine and adenosine nucleotides on the pH values of the supporting solutions are shown in Fig. 3. The migration distances in acidic region (HCl) in the previous experiment[1] and those in basic regions(NaOH) in this experiment are plotted against the pH values of the supporting solutions. Both adenine and adenosine moved to the cathode and showed an inflection point near pH=4. For pH values higher than pH=5, considerable migration was observed, showing that the deprotonation of protonated adenine or adenosine is incomplete. In the range of pH=11—13, the rapid decrease in the negative movement (the movement towards the cathode) of adenine and the increase in the positive movement with increasing pH values seem to be due to a dissociation of the imino hydrogen atom ($>N_9H$) of the purine ring, resulting in anions of adenine. Although the primary-hydrogen dissociation in the phosphate moiety of nucleotides took place near pH=1.0, AMP and c-AMP (adenosine cyclic 3′,5′-monophosphate) almost did not move in the range of pH=2—3 because adenine moiety of the nucleotide was protonated. ADP and ATP, which have two and three dissociable primary-hydrogen atoms respectively, moved to the anode. The migration distances of AMP, c-AMP, ADP and ATP increased in the range of pH=3—4. The nucleotides showed almost constant migration distances in the range of pH=5—10 and no inflection point near pH=7.

The graphs in Fig. 4 show the results obtained in the usual supporting solutions of rather high buffering capacity over a range of pH=2—13. Citric acid has three dissociable hydrogen atoms (pK_a=3.1, 4.8, and 6.4 at 25 °C[10]) and is a good supporting solution, having high buffering capacity, in the range of pH=2—7. Adenine and adenosine showed an inflection point near pH=3.5. The small negative migrations of adenine and adenosine (*ca.* −0.6 cm) at more than pH=5 are due to an electroosmotic flow (see Experimental). The electrophoretic behavior of adenine and adenosine in the strong basic region are similar to those in Fig. 3. The migration curves of the nucleotides in Fig. 4 show two inflection points, around pH=4 and 7.

Comparing the graphs in Fig. 3 with those in Fig. 4, we will find the differences of electrophoretic behavior to be larger in the range of pH=5—10. Assuming that an electroosmotic flow would coincide with the movement of glucose, we tried to correct the observed migrations for the flow. Although we subtracted the migration distance of glucose from that of a sample in a given solution (in the case of anions, we added the migration distances of glucose to that of a sample), graphs in Fig. 3 did not agree with those in Fig. 4, because the differences of the electroosmotic flow among graphs in Fig. 1 are within 0.5 cm. The considerable migrations of adenine and adenosine in Fig. 3 are unreasonable because the protonated adenine or adenosine should dissociate a proton in basic region and result in a neutral molecule, and because the contribution of the electroosmotic flow to the migration was within 1.0 cm, as seen in Fig. 1. The most probable explanation for the discrepancy between Figs. 3 and 4 would be made on the basis of the buffering capacity of the supporting solution. When the buffering capacity of a supporting solution is not large enough to neutralize the acid groups present as contaminants in a filter paper(probably -COOH), the pH value of the solution in the filter paper during electrophoresis will be shifted to be more acidic than the pH value initially prepared. The considerable negative migration distances of adenine and adenosine in pH=5—10 in Fig. 3, and the absence of dissociation of the secondary-hydrogen atom of the phosphate moiety (no inflection point of the curve near pH=7) are considered to reflect the effects of acid groups of the filter paper. The strength of the effect depends on the physicochemical nature of the filter paper as a supporting material. In the migration of a strong acid or base in a paper electrophoresis, we may not need to take so much a care about the buffering capacity. However, in the migration of a weak acid or base, its dissociation is often not observed at the expected pH value in a supporting solution of lower buffering capacity, as seen in Fig. 3; it is therefore necessary to consider the buffering capacity of the supporting solution. Further, to get good reproducibility and to lessen the chemical effects of the supporting material, a supporting solution of high buffering capacity is desirable. In our experimental conditions, a buffering capacity of more than β=0.023 is desirable to keep the pH value of the supporting solution constant during migration. These results remind us that the buffering capacity of the supporting solution should be paid attention to in paper electrophoresis in addition to its pH value.

The Crystal and Molecular Structure of [*trans*-1,2-Bis(diphenylphosphinamino)cyclohexane](1,5-cyclooctadiene)rhodium(I) Perchlorate Dichloromethane Solvate

Ken-ichi ONUMA* and Asao NAKAMURA

Central Research Laboratories, Ajinomoto Co., Inc. 1-1, Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received March 28, 1980)

The molecular structure of the title compound has been determined from three-dimensional X-ray diffraction data. The crystal belongs to the triclinic system: $P\bar{1}$, $a=11.488(2)$, $b=18.163(2)$, $c=10.998(2)$Å, $\alpha=101.70(2)$, $\beta=118.29(1)$, $\gamma=85.32(3)°$, $Z=2$. The structure has been refined by block-diagonal least-squares techniques using 3749 non-zero reflections to the final R value of 0.067. The rhodium atom is coordinated in a slightly distorted square-planar geometry by the bisphosphine and the diene ligand, with average Rh–P and Rh–C distances of 2.301(2) and 2.26(1)Å, respectively. The seven-membered chelate ring takes a distorted boat conformation, and the two phenyl groups of diphenylphosphine are arranged in a face-edge manner and those of the other diphenylphosphine are in a helical arrangement like a propeller, viewed from cyclooctadiene.

The stereoselectivity in the asymmetric hydrogenation of α-acylaminocinnamic acid by the rhodium complex with (1*R*,2*R*)-1,2-bis(diphenylphosphinamino)-cyclohexane has been reported to be inverted by *N*-methylation of the ligand.[1] We have been interested in such a chiral inversion of the stereoselectivity. In order to elucidate the stereochemistry of those complexes, the crystal structure of the title compound has been determined.

Experimental and Structure Determination

Preliminary Weissenberg photographs showed that crystals of [(1*S*,2*S*)-1,2-bis(diphenylphosphinamino)cyclohexane](1,5-cyclooctadiene)rhodium(I) perchlorate were unsuitable for X-ray analysis. Therefore, we determined the crystal structure of the racemic complex of [*trans*-1,2-bis(diphenylphosphinamino)cyclohexane](1,5-cyclooctadiene)rhodium(I) perchlorate.

Crystal and Intensity Data. Wine-red rhombohedral crystals were obtained from dichloromethane solution. Preliminary Weissenberg photographs suggested that the crystals were triclinic, and the space group was confirmed to be $P\bar{1}$ by the following structure analysis. The crystal chosen for data collection had approximate dimensions of $0.1\times0.3\times0.3$ mm. Accurate unit-cell parameters were obtained by least-squares refinement of 18 high angle reflections. The crystal data are summarized in Table 1. Intensity data were collected on a Phillips PW-1100 computer-controlled diffractometer using a θ-2θ scan technique with monochromated Cu $K\alpha$ radiation in the range of $2\theta\leqq100°$. A total of 3749 non-zero independent reflections was collected at room temperature. Standard reflections monitored during the course of data collection showed that no significant decomposition and no mispositioning had occurred. No absorption correction was applied.

Structure Solution and Refinement. The positional parameters of the Rh atom were determined from a three-dimensional Patterson synthesis. All the non-hydrogen atoms were found from subsequent Fourier and difference electron density maps. The electron densities of all the oxygen atoms were broad, and particularly the O(1) atom showed only a half of the densities of the other oxygen atoms. The positional and thermal parameters were refined by block-diagonal least-squares techniques; seven cycles for isotropic and four cycles for anisotropic parameters of non-hydrogen atoms. Three types of weight factors were assigned, depending on the value of F_o: $w=0.5$ ($F_o\leqq5.0$), $w=1$ ($5.0<F_o\leqq20.0$), $w=20.0/F_o$ ($20.0<F_o$). The electron density map at this stage showed that the perchlorate anion was disordered, so that another oxygen atom O(1)′ occupied the opposite position across the Cl atom from O(1). The perchlorate anion was further refined by assuming a half occupancy for O(1) and O(1)′ atoms. The final R value was 0.067 for non-zero reflections. The positional and thermal parameters are given in Tables 2 and 3,[2] respectively. The observed and calculated structure factors are listed in Table 4.[2] Atomic scattering factors of the rhodium cation and the other neutral atoms were taken from International Tables for X-Ray Crystallography.[3]

Results and Discussion

A perspective view of the molecule is given in Fig. 1, together with the numbering system of the atoms. A stereographic drawing of the molecule is shown in Fig. 2. A stereographic drawing of the packing of the molecules in a unit cell is shown in Fig. 3, excluding the O(1)′ atom.

Bond distances and bond angles are listed in Table 5. The bond distances show that C(51)–C(58) and C(54)–C(55) are the double bonds in cyclooctadiene. The rhodium atom is coordinated in a slightly distorted square-planar geometry to the bisphosphine and the two double bonds in the diene ligand. The dihedral angle between the plane defined by P(1)–Rh–P(2) and the plane containing Rh and mid-points of the two double bonds is 20.0°. Bond distances of Rh–P(1) and Rh–P(2) are 2.286(2) and 2.315(2)

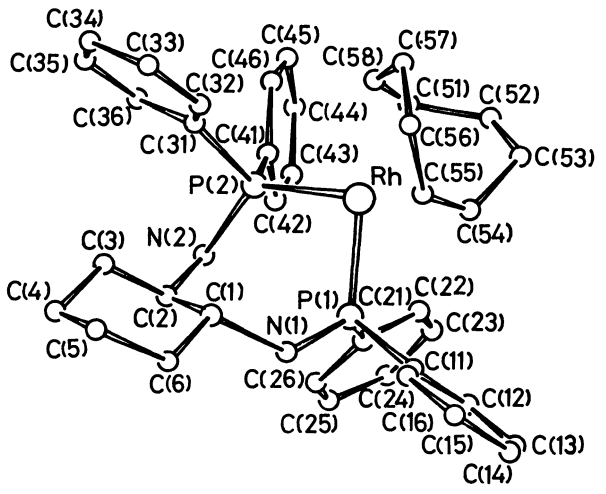

Fig. 1. Perspective view of the molecule with the numbering system of atoms.

Å, respectively, and the bond angle of P(1)–Rh–P(2) is 89.91(8)°.

A seven-membered chelate ring can take three types of conformations, boat, chair, and twist-chair forms, in which four atoms lie on a plane.[4] In the present complex, the seven-membered chelate ring consists of Rh, P(1), P(2), N(1), N(2), C(1), and C(2) atoms, and its conformation is a boat form, in which the nitrogen atom N(2) lies nearly on the plane of P(1)–Rh–P(2); the deviation of the N(2) atom from the plane is 0.21 Å. This conformation is, however, a little distorted and has no mirror symmetry, because the bond distance of N(2)–P(2) is not equal to that of Rh–P(1).

The chair conformation of seven-membered chelate ring has been observed in several complexes: *e.g.* in (1,5-cyclooctadiene)[(2*S*,4*S*)-*N*-pivaloyl-4-diphenylphosphino-2-(diphenylphosphinomethyl)pyrrolidine]-rhodium(I),[5] (1,5-cyclooctadiene)[(2*S*,4*S*)-4-diphenylphosphino-2-(diphenylphosphinomethyl)pyrrolidine]-rhodium(I),[6] chloro(1,5-cyclooctadiene)[(+)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane]iridium(I),[7] and dichloro[(−)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane]nickel(II).[8] Thus the boat conformation of the present complex seems to be unusual. The intramolecular distance of Rh–C(1) is found to be 3.71(1) Å. Although the distance is not so short to make a bond,[9] it might be close enough to have some interaction.[10] The coordinates of the hydrogen atom bonded to C(1) are estimated to be (−0.1967, 0.2774, 0.3062) by assuming that the C(1) is sp^3 and that the C–H distance is 1.08 Å. A projection of this hydrogen atom on the P(1)–Rh–P(2) plane is shown in Fig. 4. As seen in this figure, the hydrogen projects toward the rhodium atom. The Rh–H distance thus calculated is 3.13 Å. Therefore, the boat conformation may be caused by the intramolecular interaction between rhodium and hydrogen.

The configuration of a product in the asymmetric

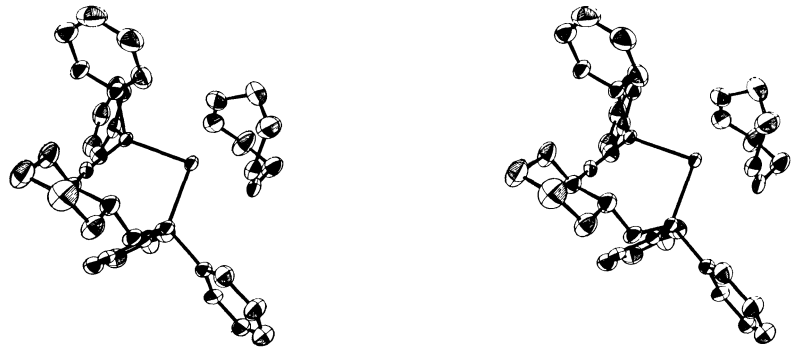

Fig. 2. Stereographic drawing of the molecule. Non-hydrogen atoms are represented by thermal ellipsoids of 50% probability.

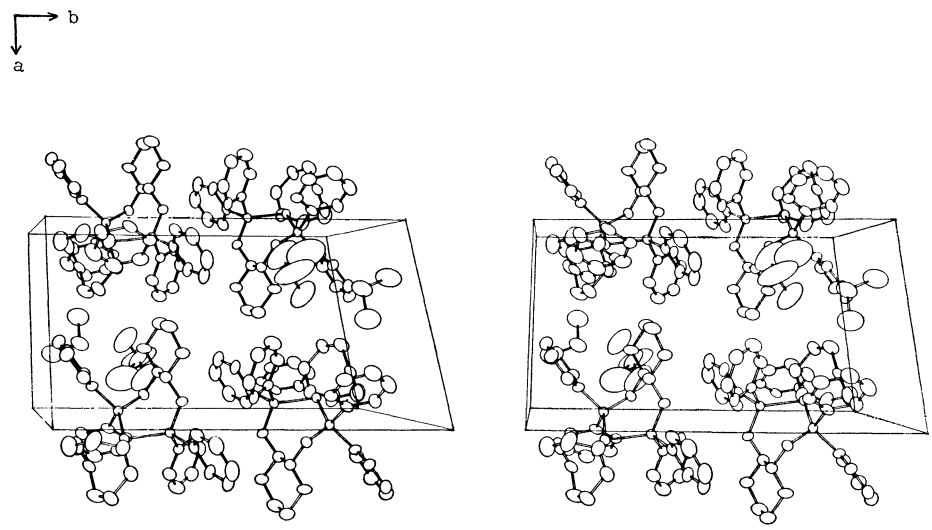

Fig. 3. Stereographic drawing of the packing of the molecules along the c axis.

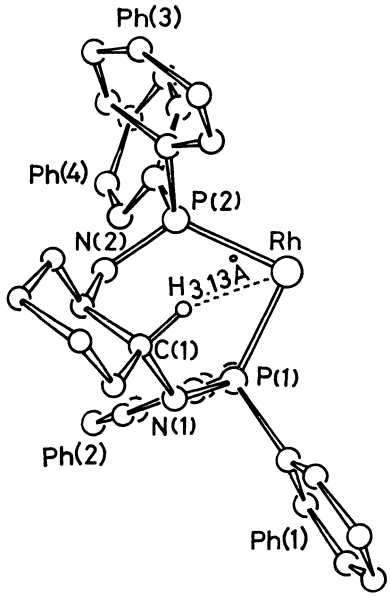

Fig. 4. Projection of the selected atoms on the P(1)–Rh–P(2) plane. Ph(1) is composed of C(11)–C(16), Ph(2) is composed of C(21)–C(26), Ph(3) is composed of C(31)–C(36), and Ph(4) is composed of C(41)–C(46).

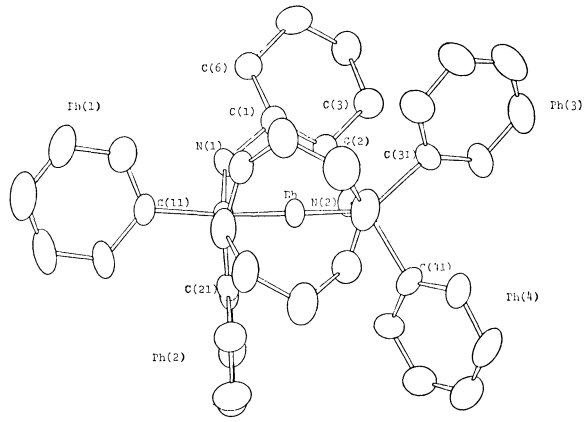

Fig. 5. The arrangement of the four phenyl groups.

hydrogenation may be derived from a chiral arrangement of the four phenyl groups which differentiate an enantiomeric face of a substrate. The arrangement of the phenyl groups, looked at from the side of cyclooctadiene, is shown in Fig. 5. As can be seen there, Ph(1) and Ph(2) are arrayed in a face-edge manner and, Ph(3) and Ph(4) are twisted like a propeller. Ph(2) and Ph(4) stretch out below the coordination lane so that there is a vacancy between Ph(1) and

Ph(3). If this structure is maintained in solution, the substrate may approach from the space between Ph(1) and Ph(3).

The positions of hydrogen atoms on N(1) and N(2) are estimated by assuming that the nitrogen atoms are sp^3 and that the N–H distance is 1.03 Å. The coordinates for N(1) are (H-1: −0.1073, 0.3964, 0.3021) or (H-2: −0.0814, 0.4209, 0.4684), and those for N(2) are (H-3: −0.0334, 0.3364, 0.6349) or (H-4: −0.1331, 0.2849, 0.6585). The shortest distances between each of the hydrogen atoms and their adjacent atoms are 2.4 Å for H-1···C(6), H-1···C(11), and H-1···C(16); 2.5 Å for H-2···C(2) and H-2···C(26); 2.4 Å for H-3···C(26); 2.5 Å for H-4···C(3). These distances are almost the same. Therefore, the hydrogen atoms on the nitrogens may actually occupy either of the two positions.

To examine the *N*-methylation effect, a hypothetical structure was given for the *N,N'*-dimethyl derivative on the basis of the present structure, and by assuming the N–C distance to be 1.45 Å. The coordinates of the methyl carbon on N(1) are (CH_3-1: −0.1154, 0.4045, 0.2658) or (CH_3-2: −0.0789, 0.4391, 0.5000), and those on N(2) are (CH_3-3: −0.0041, 0.3535, 0.6544) or (CH_3-4: −0.1446, 0.2810, 0.6877). The shortest distances between the methyl carbons and their adjacent atoms are 2.2 Å for CH_3-1···C(16); 2.3 Å for CH_3-2···C(26); 2.0 Å for CH_3-3···C(26); 2.7 Å for CH_3-4···C(3) and CH_3-4···C(41). Considering that the sum of the van der Waals radii of the methyl group and the carbon atom is 3.7 Å, there are no sufficient space for the methyl groups in the present structure. The complex with the *N,N'*-dimethylated ligand, therefore, seems to take another conformation.

Nonbenzenoid Aromatic Compounds Containing an *anti*-Aromatic Four-membered Ring. Synthesis and Some Properties of 7-Hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (Benzo[3,4]cyclobuta[1,2-*e*]tropolone)

Masaru Sato, Seiji Ebine,* Kazumi Nishijima, and Josuke Tsunetsugu

(Received May 6, 1980)

Biphenylene-2,3-quinone reacts with diazomethane in the presence of boron trifluoride etherate to give 7-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**5**) and its boron difluoride chelate. The latter is convertible quantitatively into the former. Compound **5** has a reduced troponoid character due to fusion of the benzocyclobutadiene ring. Tautomerism of the tropolone ring in **5** seems to be imposed exclusively to one of the tautomers. Protonation of **5** gives a tropylium ion whose positive charge is partially localized. Bromination, nitration, and azo-coupling of **5** give only 7-substituted products. The reaction of **5** with maleic anhydride gives the Diels-Alder adduct in good yield.

Much information has been obtained on the fused polycyclic aromatic compounds containing both $4n\pi$- and $(4n+2)\pi$-electron ring systems. Of these compounds, tropone and tropolone analogs of biphenylene are of particular interest, since their tropone and tropolone nuclei would have relatively small resonance energy because of perturbation caused by the fused anti-aromatic four-membered ring. The chloro derivative of 6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**1a**) was found to have more bond-alternated tropone nucleus.[1,2] The parent compound (**1b**) further confirmed the above indication.[3] The formation of 7*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-7-one (**2**) was also confirmed by trapping it as the adduct with cyclopentadiene.[7] 5*H*-Cyclobutacyclohepten-5-one (**3**), a lower homolog of **1**, was isolated as the $Fe(CO)_3$ complex.[5]

The first tropolone analog (**4**) of biphenylene was prepared by the ring-enlargement of 1,2-dimethoxybiphenylene with dichlorocarbene, and the tautomerism of **4**, unlike that of monocyclic tropolones,[6] was found to be extremely inclined to one tautomer. We report the synthesis and some reactions of the parent 7-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**5**).[7]

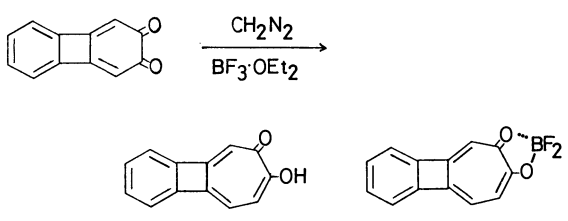
(4)

A convenient route to tropolone derivatives is the ring-enlargement of quinone with diazomethane.[8] Biphenylene-2,3-quinone was treated with diazomethane in the presence of boron trifluoride etherate to give the desired tropolone **5** in 45% yield and its boron difluoride chelate (**6**) in 26% yield. A catalytic amount of boron trifluoride is indispensable for the formation of **5** and **6**. Their spectral data agree with the assigned structure. In the mass spectrum, **5** has the ion peaks at *m/e* 196 (M^+ 100%), 168 (M^+—CO, 62%), and 139 (M^+—CO—CHO, 45%), and **6** at *m/e* 244 (M^+, 100%) and 216 (M^+—CO, 51%). The IR spectrum of **5** showed a strong absorption at 1570 cm^{-1} characteristic of tropolones and **6** a broad absorption at 1200—1000 cm^{-1} characteristic of chelate compounds. The ^{1}H-NMR spectrum of **5** ($CDCl_3$, 100 MHz) showed two doublets (J=9.0 Hz) at δ 6.32 (H-9) and 6.64 (H-8), a singlet at δ 6.70 (H-6), a multiplet at δ 7.11 (benzenoid), and a broad singlet at 8.27 (OH). The ^{1}H-NMR spectrum of **6** (DMSO-d_6, 100 MHz) showed a multiplet at δ 7.06 (H-9 and benzenoid), a doublet (J=9.1 Hz) at δ 7.34 (H-8), and a singlet at δ 7.54 (H-5). The chelate **6** was hydrolyzed in acidic aqueous ethanol to **5** quantitatively, which returned to **6** quantitatively on treatment with boron trifluoride etherate.



(5) (6)

The tropolone **5** showed some chemical features characteristic of monocyclic tropolones:[9] it gave red coloration in the chloroform layer with aqueous iron(III) chloride, reacted with aqueous sodium carbonate forming a red precipitate of the sodium salt, but not with aqueous sodium hydrogencarbonate, and dissolved in concentrated sulfuric acid or trifluoroacetic acid forming a red solution of the corresponding proto-

a) Ref. 11.

nated species (*vide infra*). In contrast to 6-hydroxy-5*H*-benzocyclohepten-5-one (3,4-benzotropolone) (**9**), it gave the methyl ether (**7**) in 59% yield on treatment with ethereal diazomethane for 9 d, no alternate methyl ether of (**5'**) being detected. The structure of **7** was assigned by the following ^{1}H-NMR spectrum: δ 3.78 (s, 3H, methoxyl protons), 6.11 (d, 1H, J=9.1 Hz, H-8), 6.58 (s, 1H, H-5), and 7.13 (m, 4H, aromatic protons). The results suggest that the troponoid character of **5** decreases with fusion of the benzocyclobutadiene ring but the extent of the decrease seems to be smaller than that of tropolone character caused by fusion of benzene in 3,4-benzotropolone (**9**), since **9** gives no methyl ether on treatment with diazomethane.[10]

The potentially expectable tautomerism **5**⇄**5'**, unlike that of monocyclic tropolones, seems to be imposed to one tautomer **5**. The shape of the electronic spectrum of **5** is closely similar to those of the methyl ether **7** and 7-chloro-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**8**),[2] except for the bathochromic shift in the long-wavelength region. This indicates that these compounds have a similar conjugate system. The ^{1}H-NMR spectral coupling constants of the vicinal protons intervening a single bond in the seven-membered ring in **5** and the related compounds are summarized in Table 1. The coupling constant J_{vic}=9.0 Hz of the seven-membered ring in **5** is the same as J_{vic}=9.1 Hz in **7**, and is smaller than the corresponding $J_{vic}(J_{7,8})$=9.8 Hz in 3,4-benzotropolone **9** and J_{vic}= 10.1 Hz in tropolone methyl ether, where the latter two compounds have a nearly planar structure but no tautomerism.[11] Moreover, the difference in the vicinal coupling constant (ΔJ_{vic}=0.1 Hz) between benzocyclobutatropolone **5** and its methyl ether is smaller than not only that (ΔJ_{vic}=0.8 Hz) between monocyclic tropolone and its methyl ether, but also that (ΔJ_{vic}=0.5 Hz) between 3,4-benzotropolone **9** and its methyl ether. This suggests that the seven-membered ring in **5** has larger bond alternation and deviation from planarity than tropolone and benzotropolone. The fact that only one methyl ether **7** was obtained on methylation of **5** might support the exclusive inclination to the one tautomer **5** in the tautomerism **5**⇄**5'**. The ^{13}C-NMR spectrum of **5** has thirteen signals containing only one carbon resonance at 182.3 ppm. The lack of the tautomerism in **5** would be due to the fusion of the benzocyclobutadiene ring. However, it is questionable whether the effect is caused only by the anti-aromaticity of the benzocyclobutadiene ring, since a similar tautomerism con-

Table 2. Difference in ^{1}H-NMR spectral chemical shifts and coupling constants of the ring protons between the neutral and protonated species of troponoids

Compound	$\Delta\delta$				$\Delta J_{8,9}$/Hz

8	0.44	0.56	0.43	0.08	0.6

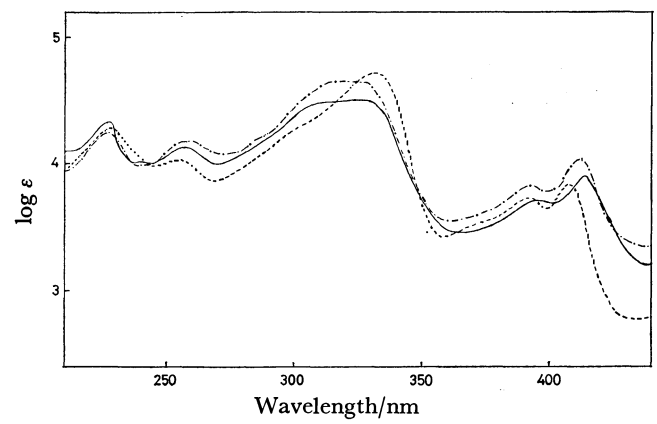

Fig. 1. The electronic spectra of 7-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**5**) (——), its derivatives (**7**) (—·—·), and (**8**) (——) in concd sulfuric acid.

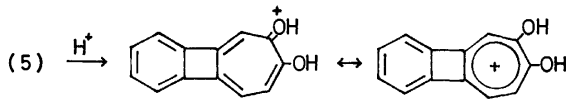
siderably inclined to one tautomer was also observed in 1,2-dihydrocyclobuta[*e*]tropolone.[12]

The protonation of monocyclic tropolones affords the corresponding dihydroxytropylium ion, in which the positive charge is delocalized in all the ring carbon atoms. The electronic spectrum of the protonated 7-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one **5** is shown in Fig. 1, along with the spectra of the protonated 7-chloro- (**8**) and 7-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**7**). The shape of their spectra is similar. The λ_{max} peaks of these cations are nearly in line with those of benzo[3,4]cyclobuta[1,2]tropylium ion having a partially localized positive charge.[13] The ^{1}H-NMR spectrum of **5** in trifluoroacetic acid showed two doublets (J=9.6 Hz) at δ 6.82 (H_9) and δ 7.44 (H_8) and a multiplet at δ 7.1—7.2 (H_5 and benzenoid). Protonation of **5** resulted in a significant low-field shift ($\Delta\delta_8$=0.80 and $\Delta\delta_9$=0.50 ppm) of the seven-membered ring protons, while the benzenoid protons remained naerly unchanged (Table 2). The low-field shifts ($\Delta\delta_8$ and $\Delta\delta_9$) of the seven-membered ring protons of the protonated **5** is nearly similar to those ($\Delta\delta_8$ and $\Delta\delta_9$) of the protonated **8**, but much smaller than the corresponding shifts ($\Delta\delta_9$=1.12 and $\Delta\delta_8$=0.96 ppm) of the protonated 7*H*-benzocyclohepten-7-one (4,5-benzotropolone). The large low-field shift in **7** seems to be due to protonation on the methoxyl group, because the signal of the methoxyl group shifted to low field by 0.39 ppm on protonation. The difference ($\Delta J_{8,9}$) in the coupling constants between **5** and protonated **5** is similar

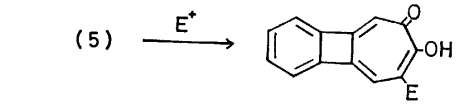
to the corresponding values ($\Delta J_{8,9}$) of other 6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one derivatives **7** and **8** (Table 2). The spectral data indicate that the positive charge in the protonated 6*H*-benzocyclobutacyclohepten-6-one system is insufficiently delocalized in the seven-membered ring and considerably localized on the carbonyl oxygen, that is, the protonated **5** is derived more from the canonical form **A** than **B**.



(A) (B)

On protonation of **5**, the low-field shift of the benzenoid protons is very small, suggesting no perpheral 12π-conjugation. This is in contrast to the fact that, on protonation of 4,5-benzotropolone, the positive charge delocalized to the benzene ring completing the 10π-electron conjugation, as indicated by the large low-field shift (*ca.* 0.5 ppm). The insufficient positive charge delocalization and the absence of the peripheral conjugation of the protonated **5** might be caused by the requirement that the central four-membered ring of **5** does not take *anti*-aromatic cyclobutadiene structure, while the strained 1,2-dihydrocyclobuta[*e*]tropolone, like monocyclic tropolones, showed a positive charge delocalization on protonation.[12]

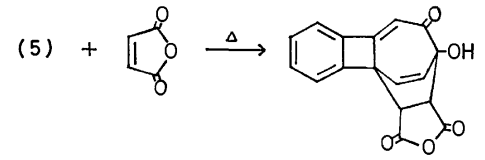
One of the characteristics of tropolonoid compounds is that they react with various electrophilic reagents to afford the substitution products. The tropolone **5** underwent the following electrophilic substitutions, reacting with bromine to give 8-bromo-7-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**10**) in 47% yield. Similarly, **5** underwent nitration and azo-coupling reactions to give 8-nitro (**11**) and 8-tolylazo derivatives (**12**), in 30 and 89% yields, respectively.



(10) E=Br
(11) E=NO_2
(12) E=$N_2C_6H_4CH_3$-p

The results indicate that **5** has a character similar to that of monocyclic tropolones. Its extremely inclined tautomerism is suggested also by the fact that **5** undergoes electrophilic substitution only at the 8-position excluding 5-position. This is in line with the behavior of 6-hydroxy-7*H*-benzocyclohepten-7-one (4,5-benzotropolone) which has no tautomerism and is attacked by electrophiles only at the 5-position.[13,14] However, the chemical behavior of **5** differs somewhat from that of 6-hydroxy-5*H*-benzocyclohepten-5-one **9** which is attacked by electrophiles at 7-position as well as 9-position,[10,15,16] undergoing also ring contraction.[17]

Tropolone **5** reacted with maleic anhydride to give 1:1 Diels-Alder adduct (**13**) in a good yield. The structure of **13** was assigned mainly by its ^{1}H-NMR spectrum: two aliphatic doublets (δ 3.61 and 3.85, J=9.0 Hz), two olefinic doublets (δ 6.22 and 6.62, J=9.0 Hz) and an olefinic singlet (δ 6.16). The Diels-Alder adduct (**13**) was obtained by refluxing both



(13)

in xylene and in benzene, no isomerization of the adduct being observed.[18] Monocyclic tropolones undergo no Diels-Alder reaction in refluxing benzene[19] but they do in refluxing xylene with maleic anhydride.[20] Thus, **5** seems to have considerable bond localization, becoming susceptive of the cyclo-addition owing to the fusion of benzocyclobutadiene. Tropolone **5** and its methyl ether were subjected to Diels-Alder reaction with 1,3-diphenylisobenzofuran and condensation with guanidine, respectively, no definite product being obtained.

Experimental

Reaction of Biphenylene-2,3-quinone with Diazomethane in the Presence of Boron Trifluoride. Boron trifluoride etherate (0.9 ml of 47% solution, 3 mmol) was added to a solution of biphenylene-2,3-quinone (455 mg, 2.5 mmol) in dichloromethane (20 ml) on an ice-water bath under an atmosphere of nitrogen. A yellow precipitate appeared. After 10 min, to the mixture was added a solution of diazomethane in ether (45 ml) prepared from *N*-nitroso-*N*-methylurea (2.06 g, 20 mmol) and alkali. The mixture turned to a red-violet solution. After being stirred for 30 min, the solution was poured into water. The mixture was extracted with dichloromethane. The extract was washed with water and dried over anhydrous sodium sulfate. After evaporation, the residue was chromatographed on silica gel to give the following products in turn. Boron difluoride chelate (**6**) of 7-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (156 mg, 25.6%), red-violet needles (from acetonitrile), mp 237.2—237.9 °C. Found: C, 63.75; H, 2.76%. Calcd for $C_{13}H_7O_2BF_2$: C, 63.99, H, 2.89%. IR(KBr): 1524, 1409, 1310, 1150—1040, 849, and 748 cm^{-1}. NMR (DMSO-d_6, 100 MHz): δ 7.34 (d, 1H, J=9.1 Hz, H_8), 7.45 (s, 1H, H_5), 7.06—7.27 (m, 5H, aromatic and H_9). MS(75 eV): *m/e* 244 (M^+, 100%) and 216 (M^+-CO, 51%). UV (CH_3CN): 231 (log ε 4.33), 262 (4.32), 308 (4.74), 393 (3.85), and 416 nm (4.00). 7-Hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**5**), 219 mg (44.7%), yellow needles (from ethanol), mp 166—167 °C. Found: C, 79.53; H, 4.22%. Calcd for $C_{13}H_8O_2$: C, 79.58; H, 4.11%. IR (KBr): 3250, 1580, 1450, 1430, 1241, 1206, 903, 757, and 680 cm^{-1}. NMR($CDCl_3$, 100 MHz): δ 6.32 (d, J=9.0 Hz, H_9), 6.64 (d, 1H, J=9.0 Hz, H_8), 6.70 (s, 1H, H_5), 7.11 (m, 4H, aromatic), and 8.27 (s, 1H, OH). NMR (CF_3COOH): δ 6.82 (d, 1H, J=9.5 Hz), 6.82—7.19 (m, 5H), and 7.44 (d, 1H, J=9.5 Hz). ^{13}C-NMR($CDCl_3$): 113.7, 117.9, 118.4, 119.0, 120.7, 130.0, 132.4, 146.6, 147.1, 149.9, 157.3, 160.8, and 182.3 ppm. MS (75 eV): *m/e* 196 (M^+, 100%), 168 (M^+-CO, 28%), and 139 ($M^+-CO-CHO$, 45%). UV(EtOH): 228 (log ε 4.09), 249 (4.13), 290 (4.52), 372 (3.77), 390 (3.83), and 422 nm (3.71). UV(H_2SO_4): 227 (log ε 4.34), 257 (4.14), 308sh (4.48), 325 (4.51), 394 (3.70), and 413.5 nm (3.90). At last, the

unreacted starting material (7 mg, 1.5% recovery) was eluted out.

Hydrolysis of the Chelate **6**. A mixture of the chelate **6** (50 mg, 0.21 mmol), hydrochloric acid (2 mol dm^{-3}, 3 ml), water (1 ml) and acetone (15 ml) was refluxed for 2 h. The mixture was poured into water. The aqueous mixture was extracted with dichloromethane. The extract was washed with water and dried over anhydrous sodium sulfate. After evaporation, the residue was sublimed under reduced pressure (≈125 °C/2 mmHg). Tropolone **5** (38 mg, 92%) was obtained.

Reaction of Tropolone **5** *with Boron Trifluoride Etherate.* Boron trifluoride etherate (47% solution, 0.03 ml, 0.1 mmol) was added to a mixture of tropolone **5** (20 mg, 0.1 mmol) in anhydrous ether (10 ml). The mixture was stirred for 1 h and the solvent evaporated. The residue was chromatographed on silica gel with elution of dichloromethane. Chelate **6** (24 mg, 96%) was obtained.

Tropolone Methyl Ether **7**. Tropolone **5** (49 mg, 0.25 mmol) was dissolved in a solution of diazomethane, prepared from *N*-nitroso-*N*-methylurea (0.93 g, 0.9 mmol) and alkali, in ether (20 ml). The solution was kept in refrigerator for 9 d. After evaporation, the residue was chromatographed on silica gel with elution of dichloromethane. Tropolone methyl ether **7** (yellow needles, mp 191—193 °C) (30 mg, 59%) was obtained, the starting material (17 mg, 35%) being recovered. Found: C, 80.16; H, 5.05%. Calcd for $C_{14}H_{10}O_2$: C, 79.98; H, 4.79%. IR(KBr): 1608, 1541, 1330, 1234, 1078, 1010, 842, and 764 cm^{-1}. NMR($CDCl_3$): δ 3.79 (s, 3H, methyl), 6.13 (d, 1H, J=9.4 Hz, H_9), 6.31 (d, 1H, J=9.4 Hz, H_8), 6.60 (s, 1H, H_5), and 7.13 (m, 4H, aromatic). NMR(CF_3COOH): δ 4.18 (s, 3H, methyl), 7.03 (d, 1H, J=10.0 Hz, H_9), 7.18 (s, 1H, H_5), 7.48 (d, 1H, J=10.0 Hz, H_8), and 7.23 (s, 4H, aromatic). UV (EtOH): 227 (log ε 4.12), 244 (4.15), 288 (4.63), 320 (3.79), 361 (3.98), and 376 nm (3.95). UV(H_2SO_4): 227 (log ε 4.25), 258 (4.18), 315 (4.65), 328 (4.64), 393 (3.82), and 412 nm (4.03).

8-Bromo-7-hydroxy-6H-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**10**). To a solution of **5** (0.1 g, 0.5 mmol) in acetic acid (5 ml) was added a solution of bromine (90 mg, 0.56 mmol) in acetic acid (1 ml) over a period of 5 min. After being stirred for 30 min, the solvent was evaporated under reduced pressure. The residue was dissolved in dichloromethane. The solution was washed with water and dried over anhydrous sodium sulfate. After evaporation, the crystalline residue was recrystallized from ethanol to give the title compound (67 mg, 47%) as yellow-orange needles, mp 166—168 °C. Found: C, 57.23; H, 2.37%. Calcd for $C_{13}H_7O_2Br$: C, 56.76; H, 2.56%. IR(KBr): 3300, 1580, 1340, and 1230 cm^{-1}. NMR($CDCl_3$): δ 6.61 (s, 1H, H_9), 6.70 (s, 1H, H_5), 7.13 (m, 4H, aromatic), and 8.88 (broad s, 1H, OH). UV(EtOH): 234 (log ε 4.13), 291 (4.54), 370 sh, 388 (3.75), and 425 sh nm.

8-Nitro-7-hydroxy-6H-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**11**). To a solution of **5** (0.1 g, 0.5 mmol) in acetic acid (5 ml) was added a solution of concentrated nitric acid (60—62%, 64 mg, 6 mmol) in acetic acid (0.1 ml) at 0 °C over a period of 5 min. After being stirred for 30 min, the solution was diluted with water (40 ml). The resulting yellow crystals were collected by filtration and washed with water. After drying, the crystals were recrystallized from ethanol to give pure title compound **11** (36 mg, 29%), yellow-orange needles, mp 174—175 °C. Found: C, 64.38; H, 2.72; N, 5.48%. Calcd for $C_{13}H_7O_4N$: C, 64.73; H, 2.92; N, 5.81%. IR(KBr): 3200, 1600, 1580, 1530, 1320, and 1220 cm^{-1}. NMR($CDCl_3$): δ 6.55 (s, 1H, H_9), 6.76 (s, 1H, H_5), and 7.27 (m, 4H, aromatic). UV (EtOH): 233 (log ε 4.28), 254 (4.25), 305 (4.49), 382 (4.12), and 537 nm (3.63).

8-Tolylazo-7-hydroxy-6H-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**12**). To a solution of **5** (0.1 g, 5 mmol) and sodium acetate (3 g) in water (4 ml) and acetic acid (24 ml) was added a solution of the diazonium salt, prepared from *p*-toluidine (70 mg, 0.56 mmol), hydrochloric acid (2 mol dm^{-3}, 0.5 ml) and sodium nitrite (43 mg, 0.62 mmol), at 0—2 °C over a period of 15 min. After being stirred for 20 min, the solution was kept in a refrigerator overnight. The solvent was then evaporated. The dark violet residue was diluted with water. The aqueous solution was controlled at pH 3 and the resulting crystals (0.142 g, 88%) were collected by filtration. Recrystallization from acetonitrile gave the pure title compound **12** as blue-violet needles (mp 213—214 °C). Found: C, 76.37; H, 4.39; N, 8.89%. Calcd for $C_{20}H_{14}O_2N_2$: C, 76.42; H, 4.49; N, 8.91%. IR (KBr): 3300, 1630, 1480, and 1300 cm^{-1}. NMR($CDCl_3$): δ 2.38 (s, 3H, CH_3), 6.53 (s, 1H, H_9), 6.70 (s, 1H, H_5), and 7.30 (m, 8H, aromatic). UV(EtOH): 252 (log ε 4.55), 340 (4.67), and 564 nm (4.32).

Diels-Alder Reaction of **5**. A solution of **5** (0.1 g, 0.5 mmol) and maleic anhydride (0.15 g, 1.5 mmol) in anhydrous xylene (2.5 ml) was refluxed for 5.5 h. The solvent was evaporated. The resulting pale yellow residue was recrystallized from benzene–dichloromethane to give the adduct **13** (0.103 g, 68.8%) as colorless prisms (mp 194—196 °C). Found: C, 69.50; H, 3.41%. Calcd for $C_{17}H_{10}O_5$: C, 69.39; H, 3.43%. IR(KBr): 1855, 1760, and 1650 cm^{-1}. NMR ($CDCl_3$): δ 3.61 (d, 1H, J=9.0 Hz, methine), 3.85 (d, 1H, J=9.0 Hz, methine), 5.2 (broad s, 1H, OH), 6.16 (s, 1H, H_5), 6.22 (d, 1H, J=9.0 Hz, H_8), 6.62 (d, 1H, J=9.0 Hz, H_9), and 7.3—7.9 (m, 4H, aromatic). UV(EtOH): 223 sh, 287 (log ε 4.21), and 310 nm (4.15).

The authors wish to thank Dr. K. Takahashi and Prof. K. Takase, Tohoku University, for measurement of 100 MHz ^{1}H-NMR and ^{13}C-NMR spectra.

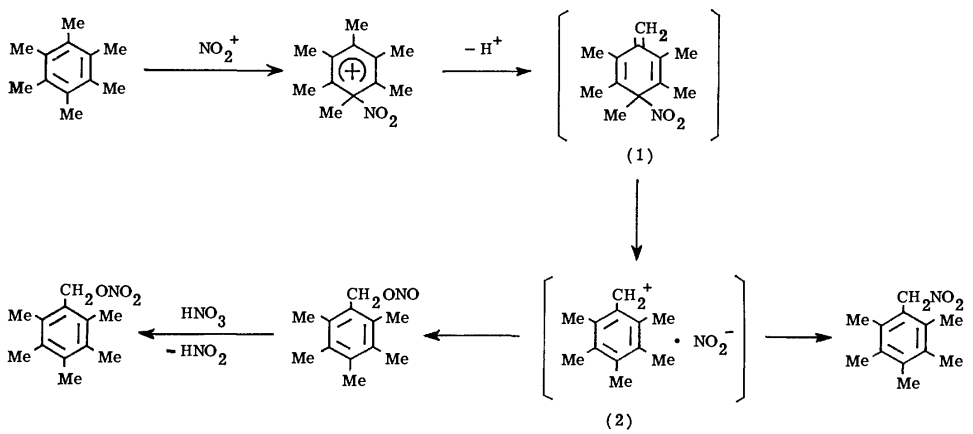
(Received June 7, 1980)

The reaction of 2,5-dimethylthiophene with copper(II) nitrate in acetic anhydride gave 3-nitro-2,5-dimethylthiophene and 2,5-dimethyl-3-(5-methyl-2-thenyl)thiophene as major isolable products. The treatment of 3,4-dibromo-2,5-dimethylthiophene with nitric acid ($d=1.5$) in dichloromethane in the presence of a catalytic amount of sulfuric acid afforded 3,4-dibromo-5-methyl-2-(nitrooxymethyl)thiophene, which, on thin-layer chromatography over silica gel using hexane as the eluant, underwent a partial novel coupling reaction through the loss of one methylene carbon atom, thus giving 3,3′,4,4′-tetrabromo-5,5′-dimethyldi-2-thienylmethane along with the expected 3,4-dibromo-2-hydroxymethyl-5-methylthiophene and bis(3,4-dibromo-5-methyl-2-thenyl) ether.

When treated with nitric acid in dichloromethane at a low temperature, polymethylbenzenes and their derivatives often undergo the nitrooxylation of the alkyl group to give benzyl nitrates.[2] Under similar conditions, polymethylnaphthalenes and polymethylanthracenes yield naphthylnitromethanes and anthrylnitromethanes respectively.[3] For these side-chain reactions of arenes, we have previously proposed an ionic S_Ni' mechanism involving a methylenecyclohexadiene intermediate (**1**); the heterolytic fission of the C–N bond in **1** to form a benzyl cation/nitrite anion pair (**2**) and the subsequent recombination of these ions at the benzylic carbon atom, either *via* a C–N bond or *via* a C–O bond, the ratio of the C–N/C–O bond formation being mainly determined by the electronic requirements of the *exo*-cyclic sp^2 carbon atom (Scheme 1).[3,4] Thus, the marked change in the modes of reaction toward nitrating agents observed on going from the benzenes to naphthalenes and anthracenes has been related to the change in the development of the carbonium ion character on the methylene carbon atom of the intermediate ion pair, **2**. In order to test the validity of our proposal further, we have now investigated the effect of the fused benzene ring on the side-chain reactions of heteroaromatic systems.

There has, to our knowledge, been only one report in the literature pertaining to the side-chain nitration of heteroaromatics; Bordwell and Cutshall treated 2,3-dimethylbenzo[*b*]thiophene (**3**) with nitric acid in acetic anhydride and obtained 3-methyl-2-(nitromethyl)-benzo[*b*]thiophene (**4**) and 3-methylbenzo[*b*]thiophene-2-carboaldehyde (**6**) (Scheme 2). The carbonyl compound presumably arose from the initially formed nitrate (**5**). Preferential substitution occurred at an alkyl group attached to the heterocycle.[5] If the S_Ni' mechanism shown in Scheme 1 works in that case, we may reasonably expect that the removal of a fused benzene ring from the benzo[*b*]thiophene system would lead to a change in the mode of the side-chain reaction of the thiophene nucleus from nitration to nitrooxylation. Thus, we have prepared several polymethylthiophenes and their derivatives and treated them with nitrating agents under a variety of conditions.

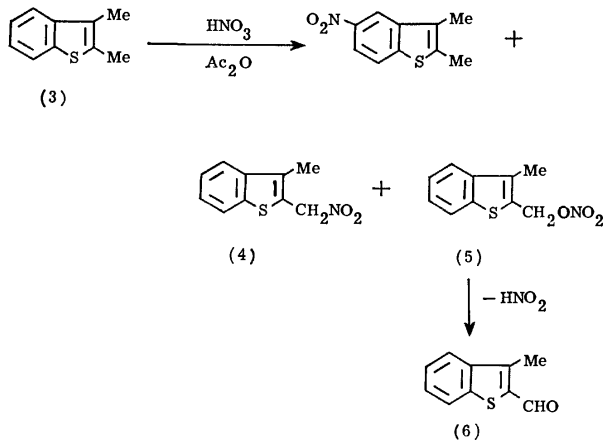
Trimethylthiophenes and tetramethylthiophene were extremely reactive toward a nitrating agent and failed to give any isolable products. A significant part of the substrate suffered the destruction of the thiophene nucleus. Even with such a mild nitrating agent as copper(II) nitrate in acetic anhydride, these reactive thiophenes were converted into a complicated mixture of products which were difficult to separate. We therefore turned our interest to the nitration of 2,5-dimethylthiophene (**7**) and its dibromo derivative (**8**).



Scheme 1.

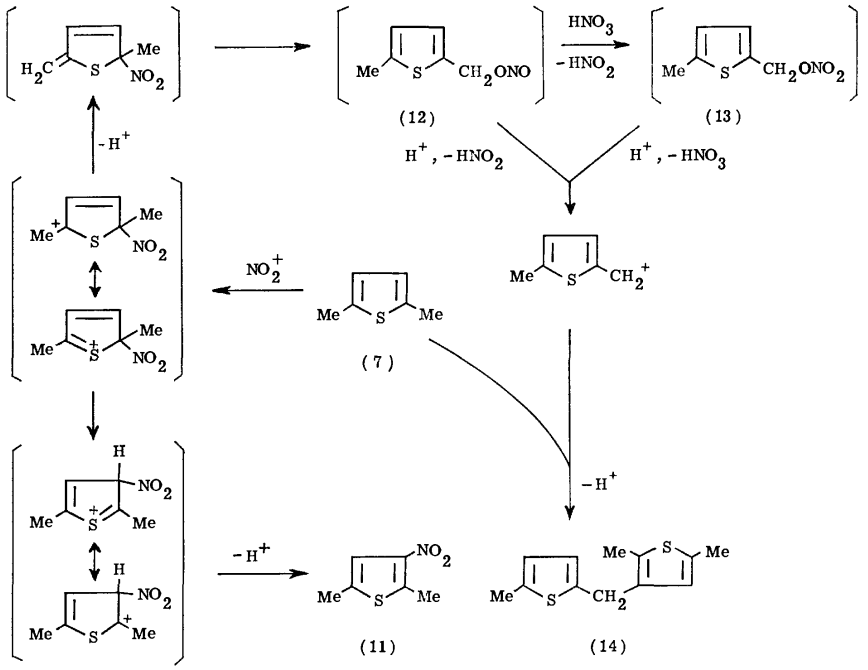
The reaction of **7** with copper(II) nitrate proceeded smoothly in acetic anhydride at a low temperature; the two major products thus obtained were identified as 3-nitro-2,5-dimethylthiophene (**11**) and 2,5-dimethyl-3-(5-methyl-2-thenyl)thiophene (**14**) respectively on the basis of IR, ^{1}H NMR and mass spectroscopy as well as elemental analysis. Although the crude product mixture was shown by its IR and NMR spectra to contain small amounts of a nitrate supposed to be **13**, it could not be isolated as such. However, the significant formation of dithienylmethane, **14**, strongly suggests the initial formation of a nitrite, **12**, or a nitrate, **13**, and the subsequent acid-catalyzed condensation of these with **7** to yield **14** (Scheme 3).

In order to avoid complications arising from a further reaction of the reactive nitrate, **13**, we then filled the unoccupied positions in **7** with bromine atoms and treated the dibromo derivative, **8**, thus obtained with nitric acid. Compound **8** was quite slow to react with nitric acid alone in dichloromethane at a low temperature. However, in the presence of a catalytic amount of sulfuric acid, it underwent a facile side-chain substitution to afford a pasty substance, from which 3,4-dibromo-5-methyl-2-(nitrooxymethyl)-thiophene (**15**) was isolated as a major product. Thus, the removal of a benzene ring from the benzo[*b*]-thiophene system led to a change in the mode of the side-chain reaction of the thiophene nucleus from nitration to nitrooxylation. This remarkable effect of the fused benzene ring parallels that observed in the reactions of benzenes and higher polybenzenoid hydrocarbons and may be taken to indicate that the side-chain reaction of the thiophenes also proceeds through a heterolytic mechanism similar to that depicted in Scheme 1.

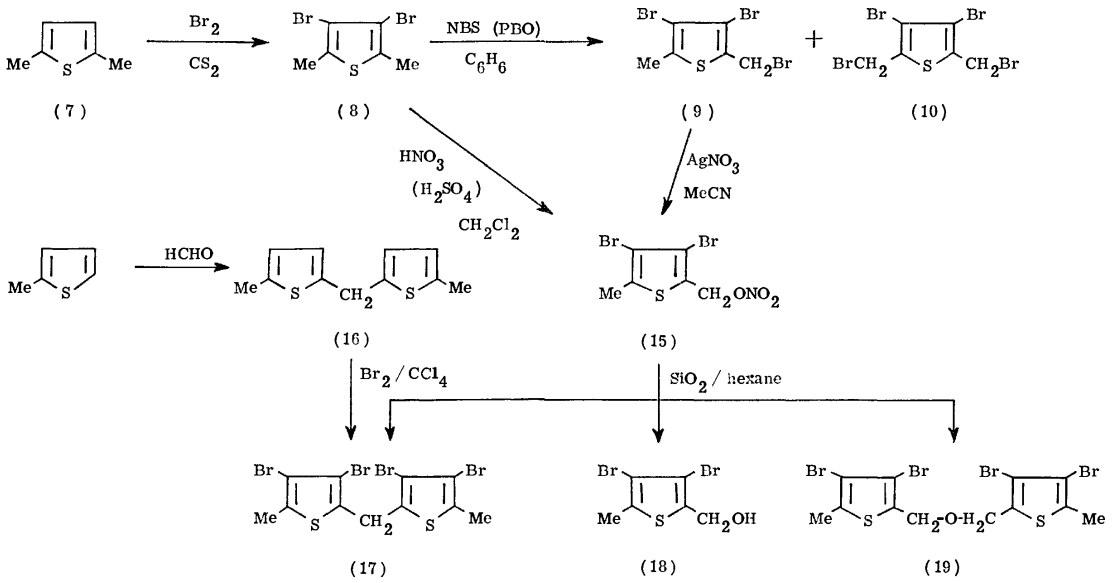


Scheme 2.

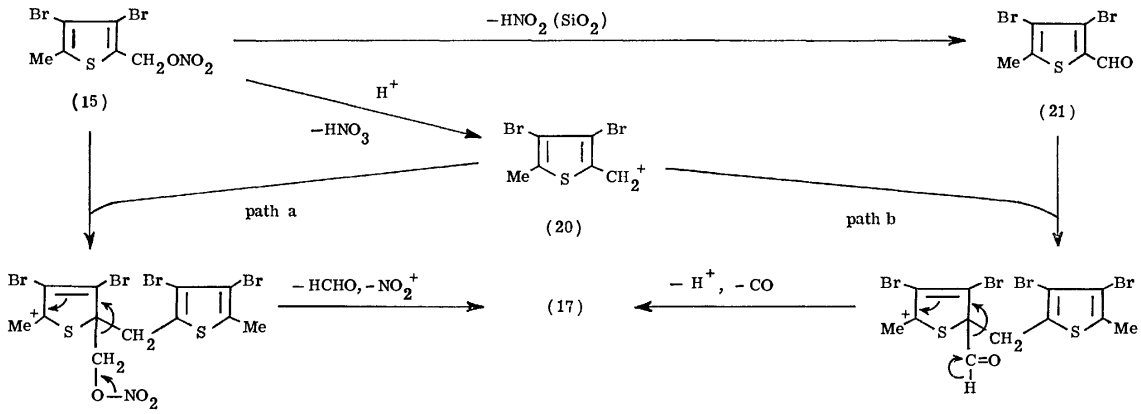
When an attempt was made to purify crude **15** by thin-layer chromatography over silica gel (Merck Kieselguhr 60 GF_{254}), using hexane as the eluant, we obtained a small amount of a crystalline compound, **17** (mp 149—150 °C), in addition to the expected 3,4-dibromo-2-hydroxymethyl-5-methylthiophene (**18**) and bis(3,4-dibromo-5-methyl-2-thenyl) ether (**19**) (Scheme 4). The elemental analysis and molecular weight of **17** were consistent with a formula of $C_{11}H_8Br_4S_2$. Its infrared spectrum ($CDCl_3$) showed prominent bands at ν_{max} 1540, 1420, 1300, 1120, and 835 cm^{-1}, and its ^{1}H NMR spectrum ($CDCl_3$) contained peaks at δ 2.40 and 4.22 ppm, with a relative intensity ratio of 3:1. Its mass spectrum exhibited peaks at *m/e* 524 (M^+), 445 (M^+—Br), 364 (M^+—2 Br), and 269 ($M^+-C_5H_3Br_2S$). These data are consistent with the structure of 3,3′,4,4′-tetrabromo-5,5′-dimethyldi-2-thienylmethane (**17**). This structural assignment was confirmed by an unequivocal synthesis of an authentic sample of **17**; 2-methylthiophene was condensed with formaldehyde in the presence of an acid catalyst to give 5,5′-dimethyldi-2-thienylmethane (**16**), which was



Scheme 3.



Scheme 4.



Scheme 5.

then brominated in the dark to give **17** (mp 150—151 °C), identical in all respects with a sample obtained from **15**. That compound **17** had been formed during chromatography over silica gel was confirmed by an experiment in which **15** and silica gel were stirred together in hexane overnight at room temperature to yield an appreciable amount of **17**, along with other products. The previous literature contains no references to the formation of diarylmethanes during the chromatography of arylalkyl nitrates. The unexpected formation of **17** from **15** lacks a convincing explanation at present; so, too, does the fate of the missing carbon atom. However, we suggest two possible reaction pathways, as outlined in Scheme 5. According to this scheme, nitrate **15** undergoes the acid-induced C–O bond cleavage on the silica gel surface to form a carbonium-ion intermediate, **20**, which may subsequently replace the nitrooxymethyl group in **15** (Path a) or expel the formyl group from aldehyde **21** (Path b). Activated primary nitrates are known to undergo acid-catalyzed decomposition to give aldehydes.[6]

It is interesting to compare this coupling reaction with that reported by King and Brown, where diethyl 4,4′-dimethyl-5,5′-methylenedi-2-pyrrolecarboxylate is obtained in the nitration of ethyl 4,5-dimethyl-2-pyrrolecarboxylate.[7] Although they suggested the implication of a nitromethyl function in the unexpected pyrromethane formation, the present result seems to favor the role of a nitrooxymethyl function. The scope and possible utility of this novel coupling reaction is currently being investigated.

Experimental

The melting points were determined on a hot-stage apparatus and are uncorrected. The infrared spectra were run as Nujol mulls on a Hitachi 215 spectrophotometer. The ^{1}H NMR spectra were determined in deuteriochloroform on a Varian T-60 spectrometer, using TMS as the internal standard, unless otherwise stated. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with an ionizing current of 70 eV, and bromine-containing peaks have been reported for ^{79}Br. Thin-layer chromatographic separations were carried out on Merck Kieselguhr 60 GF_{254} plates. 2,5-Dimethylthiophene (**7**) was prepared from 2,4-pentanedione as has previously been reported.[8] 2,3,5-

Trimethylthiophene and tetramethylthiophene were obtained by treating an appropriate polymethylthiophene with *N*-methylformanilide and phosphoryl chloride and by then reducing the resulting aldehyde by the Wolff-Kishner method.[9,10]

3,4-Dibromo-2-(bromomethyl)-5-methylthiophene (9). A solution of 3,4-dibromo-2,5-dimethylthiophene (**8**; mp 45—46 °C; 0.9 g; 3.3 mmol) and benzoyl peroxide (BPO; 10 mg; 0.04 mmol) in dry benzene (5 ml) was brought to reflux; a mixture of *N*-bromosuccinimide (0.6 g; 3.4 mmol) and BPO (10 mg; 0.04 mmol) was then added, portion by portion over a period of 10 min. The mixture was kept under reflux for another 10 min and then allowed to cool. A white precipitate was removed by filtration, and the filtrate evaporated under reduced pressure. The solid residue (1.20 g) crystallized out from hexane in two different forms, which were separated by hand-picking.

Large cubes were recrystallized from hexane and identified as **9**. Mp 68—69 °C. Yield, 0.54 g (46%). ^{1}H NMR (CCl_4): δ 2.40 (s, 3H) and 4.60 ppm (s, 2H); IR ν_{max} 1425, 1300, 1205, 1190, 1160, 1100, and 900 cm^{-1}. Found: C, 20.79; H, 1.46%. Calcd for $C_6H_5Br_3S$: C, 20.65; H, 1.44%.

Needles were recrystallized from hexane and identified as *3,4-dibromo-2,5-bis(bromomethyl)thiophene (10).* Mp 117—118 °C. Yield, 0.20 g (14%). ^{1}H NMR (CCl_4): δ 4.61 ppm (s, 4H); IR ν_{max} 1420, 1305, 1220, 1200, 1115, and 905 cm^{-1}. Found: C, 17.11; H, 0.97%. Calcd for $C_6H_4Br_4S$: C, 16.84; H, 0.94%.

3,4-Dibromo-5-methyl-2-(nitrooxymethyl)thiophene (15). Silver nitrate (0.09 g; 0.53 mmol) was added to a solution of **9** (0.175 g; 0.50 mmol) in acetonitrile (5 ml), after which the mixture was stirred at room temperature for 1 h. The silver bromide was removed by filtration, and the filtrate was evaporated to give a solid residue, which was subsequently recrystallized from pentane; white needles; mp 50—51 °C. Yield, 0.09 g (54%). ^{1}H NMR (CCl_4): δ 2.47 (s, 3H) and 5.53 ppm (s, 2H); IR: ν_{max} 1620, 1295, 950, and 880 cm^{-1}. Found: C, 22.06; H, 1.57%; N, 3.97%. Calcd for $C_6H_5NO_2Br_2S$: C, 21.77; H, 1.52; N, 4.23%.

5,5'-Dimethyldi-2-thienylmethane (16). A mixture of 2-methylthiophene (3.63 g; 37 mmol), zinc chloride (3.40 g; 25 mmol), and concentrated hydrochloric acid (2.55 ml; 43 mmol) was stirred at −7—0 °C, after which an aqueous solution of formaldehyde (2.35 g; 29 mmol) was added, drop by drop, over a period of 1.5 h. After the addition was complete, stirring was continued for 1 h, and then the mixture was diluted with water. A white precipitate was collected by filtration, the aqueous phase was extracted with ether, and the solvent was evaporated. The solid products were combined and recrystallized from methanol to give **16** as white needles (0.956 g; 25%); mp 32—34 °C. ^{1}H NMR: δ 2.42 (s, 6H), 4.10 (s, 2H), and 6.53 ppm (s, 4H). Found: C, 63.29; H, 5.86%. Calcd for $C_{11}H_{12}S_2$: C, 63.41; H, 5.81%.

3,3',4,4'-Tetrabromo-5,5'-dimethyldi-2-thienylmethane (17). Into a solution of the above dithienylmethane, **16** (0.1 g; 48 mmol), in carbon disulfide (5 ml) cooled to −10 °C, bromine (0.308 g; 198 mmol) in the same solvent (5 ml) was stirred, drop by drop, over a period of 4 h. The mixture was kept for 5 h at this temperature and then worked up as usual, giving a crude bromo derivative (0.22 g). This was chromatographed on a thick-layer silica gel plate, using hexane as the eluant, to afford **17** as fine needles (0.089 g; 35%); mp 148—149 °C. ^{1}H NMR: δ 2.43 (s, 6H) and 4.23 ppm (s, 2H); IR: ν_{max} 1290 and 940 cm^{-1}.

Reaction of 2,5-Dimethylthiophene with Copper(II) Nitrate in Acetic Anhydride. To a solution of copper(II) nitrate trihydrate (1.2 g; 5 mmol) in acetic anhydride (15 ml), cooled to −10—−15 °C, **7** (1.1 g; 9.8 mmol) in the same solvent (15 ml) was added, drop by drop, over a period of 30 min; the mixture was then stirred at this temperature for an additional 30 min. A change in color from blue to deep green was observed. Water (20 ml) and then ether (20 ml) were added, and the acetic anhydride was allowed to hydrolyze at room temperature. The organic phase was separated, and the aqueous phase was extracted with hexane. The combined organic solutions were washed with water until neutral, and then evaporated. An oily residue (0.937 g) was chromatographed over silica gel, using hexane as the eluant, to give *2,5-dimethyl-3-(5-methyl-2-thenyl)thiophene* (**14**; 0.253 g; 23%) and *3-nitro-2,5-dimethylthiophene* (**11**; 0.263 g; 17%) as major products.

11: yellow needles; mp 29—30 °C; ^{1}H NMR (CCl_4): δ 2.42 (s, 3H), 2.70 (s, 3H), and 7.12 ppm (s, H); IR (neat): ν_{max} 1530, 1485, 1360, 1315, 1260, 1195, 790, and 750 cm^{-1}. MS: *m/e* 157 (M^+), 140, 127, 112, 110, 85, 72, 67, and 59. Found: C, 46.06; H, 4.76; N, 9.16%. Calcd for $C_6H_7O_2NS$: C, 45.85; H, 4.49; N, 8.91%.

14: liquid; ^{1}H NMR (CCl_4): δ 2.28 (s, 3H), 2.33 (s, 3H), 2.38 (s, 3H), 3.77 (s, 2H), 6.30 (s, H), 6.33 (s, H), and 6.38 ppm (s, H); IR (neat): ν_{max} 1035, 1145, and 1215 cm^{-1}; MS: *m/e* 222 (M^+), 207, 124, and 111. Found: C, 64.52; H, 6.55%. Calcd for $C_{12}H_{14}S_2$: C, 64.81; H, 6.35%.

Reaction of 3,4-Dibromo-2,5-dimethylthiophene with Nitric Acid. To a stirred solution of **8** (1.0 g; 3.7 mmol) in dichloromethane (20 ml), nitric acid (1.17 g; d=1.5) in the same solvent (10 ml) was added, drop by drop. The reaction mixture gradually changed from pale violet to red purple. Then a drop of concentrated sulfuric acid was added, and the mixture was heated gently for 1 h. During this period, nitrogen dioxide was slowly evolved. The reaction mixture was then diluted with water, and the organic phase was separated, washed thoroughly with water, and evaporated *in vacuo* to give an oily residue (1.15 g), which solidified to a crystalline mass on standing in a refrigerator. This solid product was extracted with pentane to give **15** as white crystals; mp 47—48 °C. Yield, 0.614 g (50%). Mixed melting point determination with an authentic sample showed no depression (47—49 °C).

When the crude nitrate was subjected to thin-layer chromatography over silica gel, using hexane as an eluant, **17** was obtained along with **18** and **19**. Product **17** was recrystallized from hexane to give fine needles (0.020 g; 4.2%) (mp 150—151 °C), identical in all respects with an authentic sample prepared by the other route.

Found: C, 25.26; H, 1.54%. Calcd for $C_{11}H_8Br_4S_2$: C, 25.04; H, 1.66%.

Coupling of 3,4-Dibromo-5-methyl-2-(nitrooxymethyl)thiophene in the Presence of Silica Gel. Silica gel (1 g) was added to a solution of **15** (70 mg) in hexane (6 ml), after which the mixture was stirred overnight at room temperature. The supernatant liquid was then decanted and evaporated to give a solid residue (53 mg), which was chromatographed on a thin-layer silica gel plate, using hexane as the eluant. From the main band, **17** (7.6 mg; 14%) was obtained and identified by means of its melting point and spectral characteristics.

We are grateful to the Ministry of Education and the Saneyoshi Scientific Foundation for financial support of this work.

(Received June 10, 1980)

The reaction of dialkyl acetals derived from α,β-unsaturated aldehydes with Grignard reagents using $TiCl_4$ in THF afforded the cross coupling products, allyl ethers, in high yields. The $TiCl_4$-promoted reaction of alkyl 2,4-dichlorophenyl acetals, synthesized from 3,4-dihydro-2*H*-pyran or ethyl vinyl ether and 2,4-dichlorophenol, with Grignard reagents in THF at low temperature afforded the corresponding unsymmetrical ethers in high yields. When alkyl 2,4-dichlorophenyl acetals, synthesized from aromatic aldehyde or vinyl ethers and 2,4-dichlorophenol, were treated with Grignard reagents in benzene or toluene at room temperature in the absence of $TiCl_4$, the cross coupling reaction took place and the corresponding ethers were isolated in good yields.

We briefly reported in two previous papers[1-2] that the reaction of dialkyl acetals derived from α,β-unsaturated aldehydes with Grignard reagents using $TiCl_4$ and the reaction of alkyl 2,4-dichlorophenyl acetals, synthesized from 3,4-dihydro-2*H*-pyran or vinyl ether and 2,4-dichlorophenol, with Grignard reagents in benzene or toluene afforded the corresponding allyl ethers and ethers. In this report, the reactions are explained in detail and additional results are presented.

In general, acetals, the most commonly encountered protective group for aldehydes and ketones, are stable to most alkaline reagents and known to be inert toward various nucleophiles such as Grignard reagents and organolithium compounds except for cyclic acetals, steroidal cyclic acetals and cyclic acetals of halogenated saturated ketone.[3-7] No similar reactions have hitherto been know for dialkyl and mixed acetals derived from various aldehydes and ketones.

We have studied various synthetic reactions using $TiCl_4$ and have reported in the previous paper[8] that the reduction of dialkyl acetals derived from aromatic aldehydes and ketones with $TiCl_4$–$LiAlH_4$ in THF or diethyl ether at room temperature afforded the coupling products, pinacol ethers or olefins, in high yields. We also reported that various olefins were prepared in good yields by the treatment of allyl methyl ethers with $TiCl_4$–$LiAlH_4$ in THF or diethyl ether.[9]

In the present work, the reaction of various acetals with Grignard reagents in the presence and absence of $TiCl_4$ was tried; it was found that the various ethers were given in good yields. The $TiCl_4$-promoted reaction of dimethyl acetals derived from α,β-unsaturated aldehydes with Grignard reagents was examined in THF at −78 °C. For example, 1.5 molar amount of phenethylmagnesium bromide (**2**) was added to a mixture of an equimolar amount of cinnamaldehyde dimethyl acetal (**1**) and $TiCl_4$ in THF at −78 °C under argon atmosphere. After stirring at −78 °C for 6 h, the mixture was quenched with aqueous potassium carbonate. Purification by column chromatography (silica gel) gave 3-methoxy-1,5-diphenyl-1-pentene (**3**) in 81% yield.

$$\underset{\mathbf{1}}{C_6H_5CH{=}CH\text{-}CH(OCH_3)(OCH_3)} + \underset{\mathbf{2}}{C_6H_5CH_2CH_2MgBr}$$

$$\xrightarrow[-78\,^\circ C]{TiCl_4} \xrightarrow{H_2O} C_6H_5CH{=}CHCH(OCH_3)CH_2CH_2C_6H_5$$

6 h

3 81%

In a similar manner, the reactions of various acetals derived from α,β-unsaturated aldehydes in the presence of $TiCl_4$ were tried in THF at −78 °C, and the corresponding allyl ethers were obtained in high yields, as shown in the following equation:

$$\underset{\mathbf{1}}{C_6H_5CH{=}CHCH(OCH_3)(OCH_3)} + \underset{\mathbf{4}}{CH_3CH_2MgBr}$$

$$\xrightarrow{TiCl_4} \xrightarrow{H_2O} \underset{\mathbf{5}}{C_6H_5CH{=}CHCH(OCH_3)CH_2CH_3} \quad 83\% \qquad (1)$$

$$\underset{\mathbf{1}}{C_6H_5CH{=}CHCH(OCH_3)(OCH_3)} + \underset{\mathbf{6}}{CH_2{=}CHCH_2MgBr}$$

$$\xrightarrow{TiCl_4} \xrightarrow{H_2O} \underset{\mathbf{7}}{C_6H_5CH{=}CHCH(OCH_3)CH_2CH{=}CH_2} \quad 71\% \qquad (2)$$

$$\underset{\mathbf{8}}{CH_3CH{=}CHCH(OCH_3)(OCH_3)} + \underset{\mathbf{2}}{C_6H_5CH_2CH_2MgBr}$$

$$\xrightarrow{TiCl_4} \xrightarrow{H_2O} \underset{\mathbf{9}}{CH_3CH{=}CHCH(OCH_3)CH_2CH_2C_6H_5} \quad 79\% \qquad (3)$$

$$\underset{\mathbf{10}}{CH_2{=}CHCH(OCH_2CH_3)(OCH_2CH_3)} + \underset{\mathbf{2}}{C_6H_5CH_2CH_2MgBr}$$

$$\xrightarrow{TiCl_4} \xrightarrow{H_2O} \underset{\mathbf{11}}{CH_2{=}CHCH(OCH_2CH_3)CH_2CH_2C_6H_5} \quad 70\% \qquad (4)$$

It was found that γ-arylation took place to afford vinyl ethers when phenylmagnesium bromide (**12**) was employed in the above reactions. For example, 1-methoxy-3-phenyl-1-butene (**13**) was obtained in 42% yield by the reaction of crotonaldehyde dimethyl acetal (**8**) and phenylmagnesium bromide (**12**) in the presence

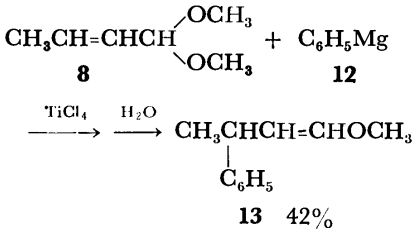
a) Isolated by silica gel chromatography. b) Isolated by distillation. c) The unsymmetrical ether was obtained in 82% yield when the reaction was carried out in toluene. d) The composition of the product as determined by GLPC analysis, comparing with the authentic sample, was 32% *cis* and 68% *trans* isomer. e) The composition of the product was 19% *cis* and 81% *trans* isomer.

of $TiCl_4$, and 1-methoxy-1-phenyl-2-butene could not be detected.

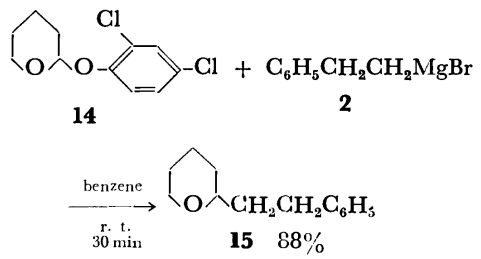


8 **12** **13** 42%

Contrary to such results, dialkyl acetals derived from aromatic and aliphatic aldehydes, such as benzaldehyde dimethyl acetal and β-phenylpropionaldehyde dimethyl acetal, were not alkylated by the coupled use of $TiCl_4$ and Grignard reagents, considerable amounts of the starting materials were recovered. But it was established that the $TiCl_4$-promoted reaction of some mixed acetals, alkyl aryl acetals synthesized from 3,4-dihydro-2*H*-pyran or ethyl vinyl ether, and phenol with Grignard reagents gave various unsymmetrical ethers by the replacing the aryloxyl group with an alkyl group (Table 1).

As shown in Table 1, when various mixed acetals synthesized from 3,4-dihydro-2*H*-pyran and phenol were treated with Grignard reagent in the presence of $TiCl_4$ in THF at −78 °C, it was found that the reaction of 2-(2,4-dichlorophenoxy)tetrahydropyran with Grignard reagent afforded the cross coupling product in higher yield than that obtained for mixed acetals. The generality of $TiCl_4$-promoted reaction was examined by the use of various alkyl 2,4-dichlorophenyl acetals, and in all cases the corresponding ethers were obtained in good yields (see Table 1).

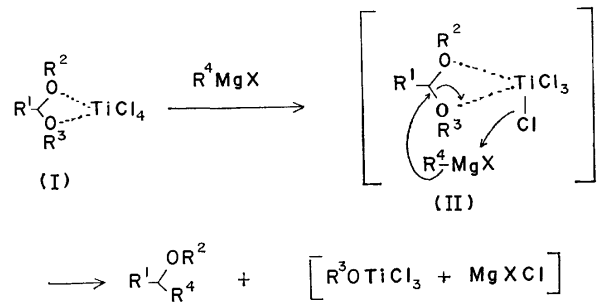
Further, the reaction of 2-(2,4-dichlorophenoxy)-tetrahydropyran with a Grignard reagent such as phenethylmagnesium bromide in the absence of $TiCl_4$ took place in benzene or toluene at room temperature and the corresponding unsymmetrical ether was isolated in 88% yield. Even when the same reaction



14 **2** **15** 88%

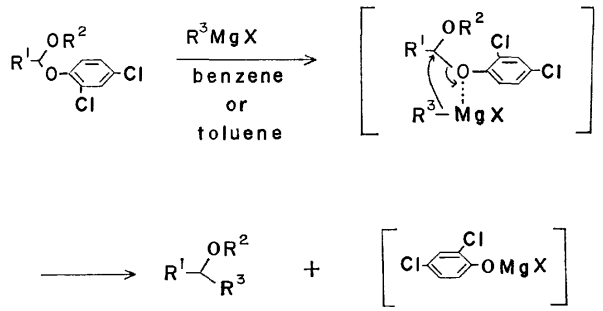
was carried out in tetrahydrofuran under refluxing, the yield of the unsymmetrical ether was below 60%. In a similar manner, various unsymmetrical ethers were obtained in good yields, as shown in Table 2.

The mechanism of the $TiCl_4$-promoted reaction of α,β-unsaturated acetals and alkyl aryl acetals with Grignard reagents may be explained as follows; the acetal forms a coordinated compound (I) with $TiCl_4$, which subsequently reacts smoothly with the Grignard reagent, probably through a six-membered cyclic intermediate (II), to afford the corresponding ethers, as sketched below:



(I) (II)

The 2,4-dichlorophenoxyl group of alkyl 2,4-dichlorophenyl acetals can leave easily; thus the mechanism of the reaction of alkyl 2,4-dichlorophenyl acetals with Grignar dreagents in bezene or toluene may be a magnesium-promoted replacement reaction of 2,4-dichlorophenoxyl group with alkyl group, as shown below.



In conclusion, it has been shown that the reaction of dialkyl acetals derived from α,β-unsaturated aldehydes and mixed acetals synthesized from 3,4-dihydro-2*H*-pyran or ethyl vinyl ether and phenols with Grignard reagents, using $TiCl_4$ in THF at low temperature, afforded the cross-couling products, various ethers, in high yields. Further, when the mixed acetals synthesized from aromatic aldehydes or vinyl ethers and 2,4-dichlorophenol were treated with Grignard reagents in an aromatic hydrocarbon such as benzene or toluene at room temperature, various ethers are obtained in good yields.

Experimental

Spectra. The proton NMR spectra were recorded using a Hitachi R-24 spectrometer and a Varian EM 360 spectrometer. Chemical shifts are reported on δ scale relative to tetramethylsilane as an internal standard. Infrared spectra were taken using a Hitachi 215 grating infrared spectrophotometer. Products were identified by NMR and IR spectra and elemental analyses.

Material. Commercially available $TiCl_4$ was distilled under argon atmosphere before use. All solvents used here were distilled according to the usual methods and were stored over sodium metal as a drying agent. Various α,β-unsaturated acetals were readily prepared from α,β-unsaturated aldehyde and orthoformic esters in alcoholic solution in the presence of a catalyst such as anhydrous hydrogen chloride. Alkyl 2,4-dichlorophenyl acetals were easily prepared by the addition of 2,4-dichlorophenol to vinyl ether derivatives and by the replacement reaction of sodium 2,4-dichlorophenoxide to α-methoxybenzyl chloride.[10]

Descriptions in this experimental section are typical examples; other products are shown in the table.

Reaction of Cinnamaldehyde Dimethyl Acetal (1) with Phenethyl-

magnesium Bromide (2) in the Presence of $TiCl_4$. To a mixture of cinnamaldehyde dimethyl acetal (0.89 g, 5 mmol) and $TiCl_4$ (0.95 g, 5 mmol) in 20 ml of dry THF was added a THF solution of 7.5 mmol of phenethylmagnesium bromide, prepared from phenethyl bromide (1.29 g, 7.5 mmol) and magnesium metal (0.19 g, 7.5 mmol), at −78 °C under an argon atmosphere. The reaction mixture was stirred for 6 h at −78 °C. The reaction was quenched by the addition of 20 ml of 10% aqueous potassium carbonate. The white precipitate which appeared was filtered off. The filtrate was extracted with diethyl ether. The ether extract was washed with saturated sodium chloride solution and dried over sodium sulfate. After removal of the solvent under reduced pressure, 3-methoxy-1,5-diphenyl-1-pentene (**3**) was isolated by column chromatography (silica gel), using benzene–dichloromethane (1:2) as an eluent, in 81% (1.02 g) yield.

Reaction of Crotonaldehyde Dimethyl Acetal (8) with Phenylmagnesium Bromide (12) in the presence of $TiCl_4$. To a mixture of crotonaldehyde dimethyl acetal (0.58 g, 5 mmol) and $TiCl_4$ (0.95 g, 5 mmol) in 20 ml of dry THF was added a THF solution of 7.5 mmol of phenylmagnesium bromide at −78 °C under an argon atmosphere. The reaction mixture was stirred for 6 h at −78 °C. The reaction mixture was worked up as mentioned in the previous case. After removal of the solvent and purification by column chromatography (silica gel), 1-methoxy-3-phenyl-1-butene (**13**) was isolated in 42% (0.34 g) yield.

Reaction of 2-(2,4-Dichlorophenoxy)tetrahydropyran (14) with Phenethylmagnesium Bromide (2). To a benzene solution[11] (4 ml) of phenethylmagnesium bromide (4 mmol) was added a benzene solution (2 ml) of 2-(2,4-dichlorophenoxy)tetrahydropyran (0.50 g, 2 mmol) under an argon atmosphere at room temperature. The reaction mixture was stirred for 30 min. After quenching with water, the product was extracted with ether. The ether extract was washed with 10% aqueous sodium hydroxide and dried over sodium sulfate. After removal of the solvent under reduced pressure, 2-phenethyltetrahydropyran (**15**) was isolated by column chromatography (silica gel) using hexane–dichlorometane (1:1) as an eluent in 88% (0.35 g) yield. The NMR and IR spectra of the product (**15**) are shown in Table 3.

Reaction of α-Methoxy-α-(2,4-dichlorophenoxy)toluene (31) with Phenethylmagnesium Bromide (2). To a benzene solution (5 ml) of phenethylmagnesium bromide (10 mmol) was added a benzene solution (5 ml) of α-methoxy-α-(2,4-dichlorophenoxy)toluene (1.42 g, 5 mmol) under an argon atmosphere at room temperature. The reaction mixture was stirred for 30 min and then worked up as mentioned in the previous case. After removal of the solvent, purification by column chromatography (silica gel) using hexane-dichloromethane (1:1) gave 1.06 g (94%) of 1,3-diphenyl-1-methoxypropane (**32**).

Transformation of Dihydrostreptomycin into 3″-Deoxydihydrostreptomycin

Takayuki Usui, Tsutomu Tsuchiya,* Hamao Umezawa, and Sumio Umezawa
Institute of Bioorganic Chemistry, 1614, Ida, Nakahara-ku, Kawasaki 211

(Received June 20, 1980)

3″-Deoxydihydrostreptomycin active against resistant bacteria was prepared from dihydrostreptomycin (DHSM). The key intermediate in this synthesis is a protected derivative of DHSM in which all hydroxyl groups except the 3″-hydroxyl group are protected, namely, 2″-*N*-(benzyloxycarbonyl)-2,5,6-tris(*O*-tetrahydropyran-2-yl)-3′,3$_a$′:4″,6″-bis(*O*-*p*-methylbenzylidene)-1,3-di-N^G-tosyldihydrostreptomycin. 3″-Deoxygenation was successfully performed by 3″-*O*-imidazolylthiocarbonylation followed by treatment with tributylstannane. The $\Delta[M]_{TACu}$ value of the synthetic 3″-deoxydihydrostreptomycin supports the structure.

3″-Deoxydihydrostreptomycin (3″-DDHSM) (**14**) prepared by a total synthesis[1] exhibits remarkable activity against resistant as well as sensitive bacteria except *Pseudomonas aeruginosa*. The present paper describes another synthesis of the 3″-DDHSM by regiospecific deoxygenation of dihydrostreptomycin (DHSM).

Results and Discussion

The 2″-methylamino group of DHSM was protected by the phenoxycarbonyl group in order to obtain a 2″,3″-cyclic carbamate in a later step, since the phenoxycarbonyl derivative gives a better yield of the cyclic carbamate (**3**) than benzyloxycarbonyl derivative.[2] The *N*-phenoxycarbonyl DHSM (**1**) was isolated as its *p*-toluenesulfonic acid salt. The *p*-toluenesulfonic acid salts of **1** and other guanidino derivatives (**2**—**4**) showed much higher solubility in usual organic solvents than the corresponding hydrochlorides, acetates or carbonates.

Selective acetalation of **1** with *p*-tolualdehyde dimethyl acetal was achieved by a controlled procedure to give 3′,3$_a$′:4″,6″-bis(*O*-*p*-methylbenzylidene) derivative (**2**) in high yield. The purity of the *p*-methylbenzylidene derivatives (**2**—**10**) was easily estimated by the signals of the *p*-methylbenzylidene methyls in their NMR spectra.

The positions of the two cyclic acetals in **2** were presumed from the fact that the 3′,3$_a$′-positions of the dihydrostreptose portion of DHSM were acetalated in preference to the 4″,6″-positions[3] which are generally acetalated more readily than *trans*-diequatorial 5,6-positions. Attempts were also made to prepare 1-*N*, 2-*O*-(or 2-*O*, 3-*N*)-(*p*-methylbenzylidene)-5,6:3′,3$_a$′:4″,6″-tris(*O*-*p*-methylbenzylidene) derivative,[4] in which only the 3″-hydroxyl group is not protected. However, the compound could not be separated from another product suggested to be 5,6:3′,3$_a$′:4″,6″-tris(*O*-*p*-methylbenzylidene) derivative judging from its R_f value on TLC and NMR spectrum.

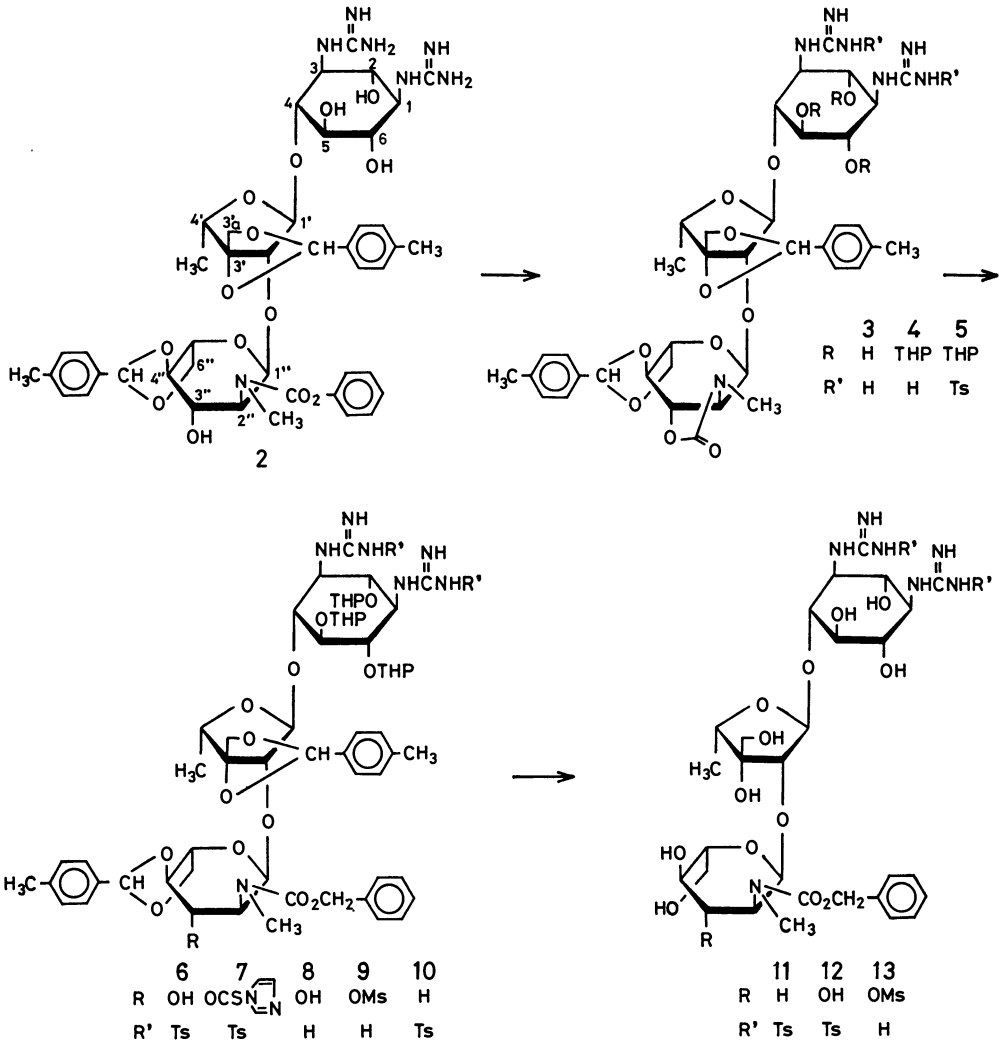
Treatment of the bis(*O*-*p*-methylbenzylidene) derivative (**2**) with potassium *t*-butoxide in *N*,*N*-dimethylformamide gave the cyclic carbamate (**3**). This reagent was found to give better yield than sodium hydride usually used.[2] In the NMR spectra of **2** and **3**, each peak attributable to 5′-methyl, 2″-*N*-methyl and one of the methyl groups of the *p*-methylbenzylidene groups appeared as two peaks in the ratio of approximately 6:4, indicating the mixtures of two diastereomers originating from the new-born chirality at the methine carbon of the 3′,3$_a$′-*O*-(*p*-methylbenzylidene) portion.

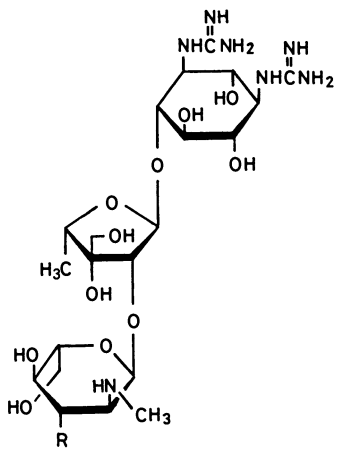
Tetrahydropyranyl protection of **3** by the conventional procedure gave a mixture of pertetrahydropyranyl derivatives. The mixture was negative for diacetyl-coloration test for guanidine and found to have more than five tetrahydropyranyl groups (mainly seven, judging from the NMR spectrum), indicating that the tetrahydropyranyl groups are introduced into the guanidine nitrogens as well as the hydroxyl groups. However, treatment of the mixture with ethanolic ammonia gave tris(tetrahydropyranyl) derivative (**4**) which was diacetyl-positive. This shows that the tetrahydropyranyl groups intoduced into guanidine are unusually sensitive to base.

Benzyloxycarbonylation of the guanidino groups of **4** was unsuccessful, yielding no definite product. However, tosylation was successful to give the di-N^G-tosyl derivative (**5**) in pure state and good yield. Use of excess sodium hydride and tosyl chloride resulted in ditosylation at each guanidino group, the yield of the tetra-N^G-tosyl derivative[5] being 50% at most. From a comparison of the IR spectra of **1**—**4** with those of **5**—**7**, we could determine the absorption peaks assignable to the *N*-tosylguanidine of DHSM derivatives to be 1540 and 1260 cm^{-1}.

In the derivative (**5**), the cyclic carbamate group is the only function sensitive to alkaline treatment. Cleavage of the cyclic carbamate (**5**) by alkaline hydrolysis followed by 2″-*N*-benzyloxycarbonylation gave the desired product (**6**) having a free function only at C-3″. The structure of **6** was confirmed by absence of the absorption peak at 1770 cm^{-1} (cyclic carbamate).[6]

Since deoxygenation at C-3″ of **6** through S_N2 process was presumed to be difficult[7] on account of the 1,3-diaxial interaction between the axial substituent at C-1″ and the approaching nucleophile at C-3″, several radical-type deoxygenation reactions were attempted. Among the preliminary experiments tested, 3″-*O*-dimethylsulfamoylation[7] followed by treatment of the product with sodium in liquid ammonia, and another method reported by Barton and McCombie[8] involving thiocarbonylation followed by reduction with tributylstannane gave 3″-DDHSM (**14**). The latter was found to be superior to the former in the ease of purification and yield. Treatment of **6** with 1,1′-thiocarbonyldiimidazole in boiling 1,2-dichloroethane gave the 3″-*O*-imidazolylthiocarbonyl derivative (**7**) in good yield. This procedure was found to be superior to other methods of thiocarbonylation without use of sodium





hydride.[8] Most of the other methods require sodium hydride which causes thiocarbonylation at the guanidino groups as well as at the 3″-hydroxyl.

Treatment of **7** with tributylstannane in boiling toluene gave a mixture of 3″-deoxy (**10**) and 3″-hydroxy (**6**) derivatives in a ≈5:1 ratio which was determined by the yield ratio of deprotected products, 3″-DDHSM (**14**) and DHSM. Since isomers **10** and **6** have the same mobility in column chromatography, they could not be separated. Treatment of a mixture of **10** and **6** with aqueous acetic acid to remove the acid-labile protecting groups gave a mixture of 2″-*N*-(benzyloxycarbonyl)-3″-deoxy-di-N^G-tosyl-DHSM (**11**), its 3″-hydroxy derivative (**12**) and a slight amount of 1,3-di-*N*-tosylstreptidine, which were separated by column chromatography. Formation of the last product showed that the glycoside linkage between streptidine and dihydrostreptose is notably unstable to acid.

Finally, **11** was treated with sodium in liquid ammonia to give 3″-DDHSM (**14**), the absence of the 3″-hydroxyl group being shown by its NMR spectrum. The 3″-deoxy structure was confirmed by its small value (−50°) of $\Delta[M]_{TACu}$; DHSM has a large value +1020.[9] The 3″-DDHSM (**14**) showed antibacterial activity against resistant bacteria producing 3″-adenylyltransferase and 3″-phosphotransferase, the antibacterial spectrum being the same as that of 3″-DDHSM prepared by a total synthesis.[1]

It may be worthwhile to describe another attempted route from **4** involving intermediates having unprotected guanidino groups. The cyclic carbamate (**4**) was treated with benzyl alcohol in the presence of sodium hydride to give 2″-*N*-benzyloxycarbonyl-3″-hydroxy derivative (**8**) which was mesylated to give

9. Removal of the *p*-methylbenzylidene and tetrahydropyranyl groups from **9** gave the 3″-*O*-mesyl derivative (**13**) having free guanidino groups, the yield not being high. The absence of the mesyl group on the guanidine portion of **13** was shown by the result of the acidic hydrolysis (2 M HCl in 80% methanol 55 °C, 2 h) of **13**; streptidine was produced quantitatively, indicating that the mesyl group was introduced to C-3″. However, when the 3″-hydroxy compound (**8**) was treated with dimethylsulfamoyl chloride in the presence of sodium hydride by the procedure as described above[7] or with 1,1′-thiocarbonyldiimidazole[8,10] in boiling tetrahydrofuran, no definite product was obtained.

Experimental

^{1}H-NMR spectra were recorded at 90 MHz with a Varian EM-390 spectrometer except for **14**, the spectra of which being recorded at 100 MHz with a Varian XL-100A Spectrometer. Thin-layer chromatography (TLC) was performed on Kieselgel H (Type 60) using a sulfuric acid spray for detection. Silica gel (Kieselgel 60, 230—400 mesh, E Merck Darmstadt, W. Germany) was used for separation of products by column chromatography.

2″-N-(Phenoxycarbonyl)dihydrostreptomycin (1). Anhydrous sodium carbonate (225 mg) and phenyl chloroformate (0.26 ml) were added to an ice-cold solution of DHSM trihydrochloride hydrate (990 mg) in aqueous acetone (2:1, 30 ml), and the mixture was vigorously stirred for 5 min. Ether (20 ml) was added and, after stirring, the aqueous solution was separated and washed with ether twice more. The aqueous solution was neutralized (pH 7) with hydrochloric acid and concentrated to 1 ml. Addition of ethanol (10 ml) gave a precipitate, which was removed by filtration. Concentration of the organic solution gave a solid (Solid A, 1.18 g). The solid, after being well dried, was dissolved in dry DMF (10 ml), filtered, and the solution was concentrated to give a solid. An aqueous ethanol (1:1) solution of the solid was passed through a Dowex 1×2 column (TsO$^-$ form, 200 ml, 200—400 mesh, pretreated with aqueous ethanol (1:1)) with the same solvent mixture. Concentration of the diacetyl-positive fractions gave a solid[11] of bis(*p*-toluenesulfonate) of **1**, 1.31 g (88%), $[\alpha]_D^{25}$ −48° (*c* 1, methanol); IR(KBr): 1670 cm^{-1}.

^{1}H-NMR (D_2O at 25 °C): δ 1.22 (3H d, J=6.5 Hz, CCH_3), 2.37 (6H s, CH_3 of TsOH), 3.10 and 3.21 (each ≈1.5 H s, NCH_3); at 80 °C: δ 1.32 (3H d), 2.47 (6H s), 3.25 (3H s, NCH_3).

Found: C, 47.36; H, 5.98; N, 8.64; S, 6.47%. Calcd for $C_{28}H_{45}N_7O_{14}\cdot 2C_7H_8O_3S\cdot H_2O$: C, 47.32; H, 5.96; N, 9.20; S, 6.01%.

2″-N-(Phenoxycarbonyl)-3′,3′$_a$:4″,6″-bis(O-p-methylbenzylidene)dihydrostreptomycin (2). Anhydrous *p*-toluenesulfonic acid (95 mg) and *p*-tolualdehyde dimethyl acetal (1.85 ml, ≈10 mol eq for **1**) were added to a solution of well dried crude **1** (Solid A, 874 mg) in dry DMF (9 ml, dried over molecular sieves 4A), and the solution was kept at room temperature for 1 h. On TLC with benzene–pyridine–ethanol–water–acetic acid (6:3:3:1:0.5) the solution showed a strong spot at R_f 0.47 with a slight spot at R_f 0.2 (mono(*p*-methylbenzylidene) products) (*cf* **1**, R_f 0.1). Triethylamine (0.08 ml) was added and the solution was concentrated *in vacuo* to give a syrup. The chloroform solution of the syrup was washed with saturated aqueous sodium hydrogencarbonate (10 ml) and saturated aqueous sodium chloride and dried over sodium sulfate. Concentration gave a residue, which was dissolved in acetone (10 ml). After filtration, the acetone solution was treated with ether and the precipitate was thoroughly washed with ether. The solid (980 mg) was passed through a Dowex 1×2 column (TsO$^-$ form, 50 ml) with aqueous ethanol (1:3) as a developer. The fractions containing **2** were collected and concentrated to give a solid, which was extracted with chloroform (*cf.* hydrochloride of **2** did not dissolve in chloroform). The chloroform solution was washed with water which dissolved the mono(*p*-methylbenzylidene) products. After being dried over sodium sulfate, the chloroform solution was concentrated to give a solid. The solid, after being dried well *in vacuo*, was suspended in hot water (0.5 ml) and stirred vigorously. After cooling, the suspension was filtered and the solid was again treated similarly and dried to give **2** as the bis(*p*-toluenesulfonate). Slight occlusion of chloroform was removed by this procedure. Yield, 980 mg (75%, based on DHSM·3HCl·H_2O), $[\alpha]_D^{25}$ −52° (*c* 1, chloroform); IR(KBr): 1670 cm^{-1}.

^{1}H-NMR (CD_3OD): δ 1.28 and 1.40 (≈6:4 in strength, 3H in total, each d, J=6.5 Hz, CCH_3), 2.24 and 2.31 (each s, 4:6 in strength, 3H in total, *p-methyl*benzylidene), 2.39 (9H s, CH_3 of Ts and *p-methyl*benzylidene). The peak of NCH_3 could not be discerned by overlapping with other signals.

Found: C, 54.85; H, 6.22; N, 7.76; S, 5.15%. Calcd for $C_{44}H_{57}N_7O_{14}\cdot 2C_7H_8O_3S\cdot H_2O$: C, 54.84; H, 5.95; N, 7.72; S, 5.05%.

In pyridine-d_5–D_2O (5:1 at 70 °C): δ 1.43 and 1.54 (≈6:4 in strength, CCH_3); 2.20 (≈7.2H s, CH_3 of Ts and a part of *p-methyl*benzylidene), 2.32 (≈4.8H s, *p-methyl*benzylidene); 3.43 and 3.58 (each s, in the ratio of 4:6, 3H in total, NCH_3).

An aqueous ethanol (1:3) solution of the above toluenesulfonic acid salt of **2** (190 mg) was passed through a Dowex 1×2 column (Cl$^-$ form, 5 ml) with the same aqueous ethanol to give dihydrochloride of **2**, 143 mg (96%), R_f 0.37 on TLC with benzene–ethanol–pyridine–water–acetic acid 6:3:3:1:0.5 (*cf.* bis(*p*-toluenesulfonate) of **2**: 0.47) $[\alpha]_D^{25}$ −55° (*c* 1, methanol).

^{1}H-NMR (pyridine-d_5–D_2O 5:1 at 70 °C): δ 1.41 and 1.50 (≈6:4, CCH_3); 2.18 (≈1.2H s) and 2.28 (≈4.8H s) (*p-methyl*benzylidene); 3.43 and 3.60 (each s, 4:6 in strength, 3H in total, NCH_3).

Found: C, 52.43; H, 5.96; N, 9.33 Cl, 7.77%. Calcd for $C_{44}H_{57}N_7O_{14}\cdot 2HCl\cdot H_2O$: C, 52.90; H, 6.15; N, 9.82; Cl, 7.10%.

2″-N:3″-O-Carbonyl-3′,3′$_a$:4″,6″-bis(O-p-methylbenzylidene)-dihydrostreptomycin (3). Fresh potassium *t*-butoxide (110 mg, ≈3.3 mol eq for **2**) was added under nitrogen atmosphere to an ice-cold solution of bis(*p*-toluenesulfonate) of **2**, (380 mg) in dry DMF (3.8 ml), and the solution was kept in the cold for 20 min. *p*-Toluenesulfonic acid monohydrate (190 mg) in ethanol (1 ml) was added and the solution was concentrated *in vacuo*. The chloroform (20 ml) solution of the residue was washed successively with saturated aqueous sodium hydrogencarbonate, water, 40% aqueous sodium *p*-toluenesulfonate and water, dried over sodium sulfate and concentrated. Ether was added to the chloroform (3 ml) solution of the residue, and the resulting precipitate was washed thoroughly with ether to give a solid of bis(*p*-toluenesulfonate), which was further washed with water thoroughly as described for **2** and dried. Yield, 311 mg (88%), $[\alpha]_D^{25}$ −63° (*c* 1, chloroform); IR(KBr): 1770 (cyclic carbamate), 1680 cm^{-1}.

^{1}H-NMR (pyridine-d_5–D_2O 5:1 at 70 °C): δ 1.3—1.6 (two kinds of d, 3H in total, J=6.5 Hz, CCH_3); 2.22 (6H

s, CH_3 of Ts), 2.27 and 2.30 (6H in total, *p-methyl*benzylidene); 2.78 and 3.11 (each s, 4:6 in strength, 3H in total, NCH_3).

Found: C, 52.83; H, 5.88; N, 8.02; S, 5.34%. Calcd for $C_{38}H_{51}N_7O_{13}\cdot 2C_7H_8O_3S\cdot H_2O$: C, 53.10; H, 5.91; N, 8.34; S, 5.45%.

Dihydrochloride of **3** was prepared by passing the aqueous methanol (1:9) solution of bis(*p*-toluenesulfonate) (181 mg) of **3** with a column of Dowex 1×2 (Cl^- form, 5 ml, 200—400 mesh). Yield, 136 mg (97%).

^{1}H-NMR (pyridine-d_5–D_2O 5:1): δ 1.47 (3H, CCH_3); 2.28 and 2.30 (6H, each s, *p-methyl*benzylidene); 2.90 and 3.20 (each s, 4:6 in strength, 3H in total, NCH_3).

Found: C, 50.41; S, 5.96; N, 10.58; Cl, 7.95%. Calcd for $C_{38}H_{51}N_7O_{13}\cdot 2HCl\cdot H_2O$: C, 50.44; H, 6.13; N, 10.84; Cl, 7.84%.

*2″-N:3″-O-Carbonyl-2,5,6-tris(*O*-tetrahydropyran-2-yl)-3′,3′ₐ:4″,6″-bis(*O*-p-methylbenzylidene)dihydrostreptomycin (**4**).* Fuse-dried anhydrons *p*-toluenesulfonic acid (12 mg) and freshly distilled 3,4-dihydro-2*H*-pyrane (0.8 ml) were added to a solution of bis(*p*-toluenesulfonate) of **3** (235 mg, dried at 60° *in vacuo*) in 1,2-dichloroethane (4 ml, after distillation the solvent was dried over molecular sieves 4A activated at 350 °C under a stream of nitrogen). The solution was kept at room temperature for 10 min. Triethylamine (0.02 ml) was added and the solution was poured into saturated aqueous sodium hydrogencarbonate (3 ml) with vigorous stirring. The lower layer separated was washed with 40% aqueous sodium *p*-toluenesulfonate and water, dried over sodium sulfate and concentrated. The syrup was triturated with cyclohexane to give a solid, which was thoroughly washed with cyclohexane. On TLC with chloroform–methanol–pyridine (5:1:0.2), the solid showed one spot (R_f 0.68) which was negative for diacetyl-coloration. The solid was dissolved in 1.5 M ethanolic ammonia (8 ml), heated at 70 °C for 1.5 h and concentrated. On TLC with the same solvent mixture as described above, the residue showed a diacetyl-positive spot at R_f 0.27. The chloroform solution of the residue was washed with 40% aqueous sodium *p*-toluenesulfonate, water, dried over sodium sulfate and concentrated. The residue was successively treated with chloroform, ether and water as described for **3** to give a solid of bis(*p*-toluenesulfonate), 240 mg (84%), $[\alpha]_D^{25}$ −42° (*c* 1, chloroform); IR(KBr): 1770, 1670 cm^{-1}.

^{1}H-NMR (CD_3OD): δ 1.1—2.0 (21H, CCH_3 and H-3,4,5 of THP).

Found: C, 56.38; H, 6.38; N, 6.88; S, 4.29%. Calcd for $C_{53}H_{75}N_7O_{16}\cdot 2C_7H_8O_3S\cdot H_2O$: C, 56.33; H, 6.56; N, 6.86; S, 4.49%.

*2″-N:3″-O-Carbonyl-2,5,6-tris(*O*-tetrahydropyran-2-yl)-3′,3′ₐ:4″,6″-bis(*O*-p-methylbenzylidene)-1,3-di-*N*^{G}-tosyldihydrostreptomycin (**5**).* Dry toluene (1 ml) was added to a solution of bis(*p*-toluenesulfonate) (144 mg) of **4** in dry DMF (4.5 ml), and the mixture was concentrated *in vacuo* to a volume of ≈4 ml. After ice-cooling, 50% oily sodium hydride (net 12 mg) was added and the mixture was stirred under an atmosphere of nitrogen for 1 h in the cold. *p*-Toluenesulfonyl chloride (42 mg) was added, stirring being continued for 1 h. The mixture was poured into phosphate buffer (pH 7, 10 ml) and the whole mixture was extracted with chloroform. The organic solution was washed with saturated aqueous sodium hydrogencarbonate and water, dried over sodium sulfate and concentrated to give a solid. The solid was chromatographed on silica gel with chloroform–ethanol–pyridine (15:1:0.3). The fractions containing **5** were concentrated to give a solid, which was thoroughly washed with water to give diacetyl-negative product, 99 mg (71%), $[\alpha]_D^{25}$ −46° (*c* 0.5, chloroform); IR(KBr) (the figures in parenthesis are for **4**): 1770(1770), (1670), 1620(1630), 1540(1440), 1380(1380), 1260, (1180), 1130(1120), 1070 (1070), 1030(1030), 810(810) cm^{-1}.

Found: C, 57.50; H, 6.39; N, 6.88; S, 4.49%. Calcd for $C_{67}H_{87}N_7O_{20}S_2\cdot H_2O$: C, 57.78; H, 6.44; N, 7.04; S, 4.60%.

*2″-N-(Benzyloxycarbonyl)-2,5,6-tris(*O*-tetrahydropyran-2-yl)-3′,3′ₐ:4″,6″-bis(*O*-p-methylbenzylidene)-1,3-di-*N*^{G}-tosyldihydrostreptomycin (**6**).* A solution of **5** (278 mg) in a mixture of dioxane (18 ml) and 0.2 M aqueous sodium hydroxide (10 ml) was heated at 80 °C for 5 h. After being cooled to room temperature, benzyloxycarbonyl chloride (0.17 ml) was added and the mixture was stirred vigorously for 5 min. After 1 M aqueous ammonium hydroxide (2 ml) had been added (to decompose the reagent chloride) with subsequent stirring for 3 h, the mixture was concentrated and the residue was extracted with chloroform. The chloroform-soluble portion was chromatographed on silica gel (8.5 g) at first with chloroform–pyridine (50:1, 40 ml), then with chloroform–ethanol–pyridine (15:1:0.3) to give a solid, which was thoroughly washed with water and dried, 270 mg(90 %), $[\alpha]_D^{25}$ −50° (*c* 1, chloroform); IR(KBr): 1690, 1625, 1540, 1440, 1380, 1270, 1130, 1075, 1020, 810 cm^{-1}.

Found: C, 59.25; H, 6.47; N, 6.29; S, 4.12%. Calcd for $C_{74}H_{95}N_7O_{21}S_2\cdot H_2O$: C, 59.22; H, 6.51; N, 6.53; S, 4.27%.

*2″-N-(Benzyloxycarbonyl)-3″-O-(imidazolylthiocarbonyl)-2,5,6-tris(*O*-tetrahydropyran-2-yl)-3′,3′ₐ:4″,6″-bis(*O*-p-methylbenzylidene)-1,3-di-*N*^{G}-tosyldihydrostreptomycin (**7**).* To a solution of **6** (300 mg) in 1,2-dichloroethane (10 ml) were added 1,1′-thiocarbonyldiimidazole (270 mg) and imidazole (30 mg) and the solution was gently refluxed for 6 h under nitrogen atmosphere. Concentration by addition of dioxane gave a residue, which was suspended in water, agitated for 3 h (yellow color disappeared), and then filtered. The solid collected was dried and chromatographed on silica gel (6 g) with chloroform–ethanol–pyridine (15:1:0.3) to give a solid, which was dissolved in benzene. The solution was washed with water, dried over sodium sulfate, and after concentration to a small volume, cyclohexane was added to cause precipitation, 273 mg (86%), $[\alpha]_D^{25}$ −43° (*c* 1, chloroform); on TLC with chloroform–ethanol (15:1) it gave the same R_f value (0.5) with that of **6**; IR(KBr): 1700, 1625, 1540, 1440, 1390, 1320, 1280, 1225, 1130, 1080, 1030, 990, 810 cm^{-1}.

^{1}H-NMR (acetone-d_6–D_2O 8:1): δ 8.4—8.5 (1H, H-2 of imidazolyl group).

Found: C, 58.53; H, 6.06; N, 7.74; S, 5.80%. Calcd for $C_{78}H_{97}N_9O_{21}S_3$: C, 58.81; H, 6.14; N, 7.91; S, 6.04%.

*2″-N-(Benzyloxycarbonyl)-2,5,6-tris(*O*-tetrahydropyran-2-yl)-3′,3′ₐ:4″,6″-bis(*O*-p-methylbenzylidene)dihydrostreptomycin (**8**).* Benzyl alcohol (0.1 ml) and 50% oily sodium hydride (net 55 mg) were added to a solution of bis(*p*-toluenesulfonate) (285 mg) of **4** in dry dioxane (3 ml), and the mixture was stirred under nitrogen atmosphere at room temperature for 30 min. The solution was poured into cold water (4 ml) containing *p*-toluenesulfonic acid monohydrate (450 mg) and the mixture was extracted with chloroform. The chloroform solution was washed with aqueous 40% sodium *p*-toluenesulfonate solution (5 ml) and then with water, dried over sodium sulfate and concentrated. The residue was chromatographed on a silica gel (6 g) column firstly with chloroform (15 ml) and then with chloroform–ethanol (3:1). The diacetyl-positive fractions were concentrated and the chloroform solution of the residue was washed with aqueous 40% sodium *p*-toluenesulfonate, then with water, dried over sodium sulfate and concentrated. Addition of cyclohexane

to the concentrate gave a solid, which was thoroughly washed with water and dried well to give bis(*p*-toluenesulfonate) of **8**, 251 mg (82%), $[\alpha]_D^{25}$ −31° (*c* 1, chloroform).

Found: C, 57.84; H, 6.51; N, 6.19; S, 3.91%. Calcd for $C_{60}H_{83}N_7O_{17}\cdot 2C_7H_8O_3S\cdot H_2O$: C, 57.83; H, 6.62; N, 6.38; S, 4.17%.

*2″-N-(Benzyloxycarbonyl)-3″-O-mesyldihydrostreptomycin (**13**).* Methanesulfonyl chloride (0.072 ml, 8 mol equiv for **8**) was added to an ice-cold solution of bis(*p*-toluenesulfonate) (180 mg) of **8** in dry pyridine (1.8 ml), and the solution was kept at the temperature for 1 h, and then at room temperature for 1 h. After addition of water (0.03 ml) followed by standing for 1 h at room temperature, the solution was concentrated. Addition of water to the concentrate gave a thick syrup which was collected by centrifugation. Chloroform solution of the syrup was washed successively with water, saturated aqueous sodium hydrogencarbonate, 10% aqueous potassium hydrogensulfate, water, 40% aqueous sodium *p*-toluenesulfonate and water, centrifuged to remove accompanying water, and concentrated to give bis(*p*-toluenesulfonate) of 3″-*O*-mesylate (**9**), 197 mg. The solid (195 mg) was dissolved in 90% aqueous acetic acid (6 ml) heated at 55 °C for 3 h and the solution was concentrated with occasional addition of toluene to give a syrup. Addition of ether gave a crude solid of **13**, 135 mg, which showed, on TLC (benzene–pyridine–ethanol–water–acetic acid 6:3:3:1:0.5), spots at 0.4, 0.37, 0.18 (slight), 0.1 and 0.05 (very slight, 2″-*N*-(benzyloxycarbonyl)dihydrostreptomycin[3]). Since the appearance of multiple spots on TLC was suspected to be caused by the formation of salts of **13** with anions (possibly by *p*-toluenesulfonate and acetate anions), the crude **13** was transformed into acetic acid salt. The crude solid (134 mg) was passed through a column of Dowex 1×2 (AcO^- form, 4 ml, 200—400 mesh) with aqueous methanol (3:1). Concentration of the eluate gave a solid (104 mg) which on being subjected to TLC, showed spots at R_f 0.22 (slight), 0.18(minor), 0.1(major) and 0.05(very slight), the spots at R_f 0.4 and 0.37 (possibly caused by the *p*-toluenesulfonic acid salts) disappearing. The solid (103 mg) was then chromatographed (6 g silica gel) with chloroform–methanol–pyridine–25% aqueous acetic acid (6:3:4:1) and the fractions (38—53 ml) containing the major component (R_f 0.1) were collected and concentrated. The resulting residue was thoroughly washed with ether to give a solid, 48 mg, which was chromatographically pure and contained no *p*-toluenesulfonic acid as proved by the NMR spectrum. The solid (47 mg) was passed through a column of Dowex 1×2 (Cl^- form, 9 ml) with water. Concentration of the eluate (4—5.5 ml) gave the solid of dihydrochloride of **13**, 39 mg (38% based on **8**), $[\alpha]_D^{25}$ −69° (*c* 0.6, water). The solid showed the same R_f value (0.1) with that of acetic acid salt described above.

^{1}H-NMR (D_2O): δ 1.24 (3H d, *J*=6.5 Hz, CCH_3) [2″-*N*-(benzyloxycarbonyl)dihydrostreptomycin dihydrochloride (D_2O): 1.22], 3.10 (3H s, NCH_3) [3.06], 3.20 (3H s, SO_2CH_3), 5.38 (1H d, *J*=3 Hz, H-1″) [5.26]; on heating to 60 °C, all the above peaks of **13** became sharpened.

Found: C, 40.73; H, 5.91; N, 10.81%. Calcd for $C_{30}H_{49}N_7O_{16}S\cdot 2HCl\cdot H_2O$: C, 40.63; H, 6.02; N, 11.06%.

*2″-N-(Benzyloxycarbonyl)-3″-deoxy-1,3-di-N^G-tosyldihydrostreptomycin (**11**).* Tributylstannane (0.4 ml) was added to a solution of **7** (280 mg) in dry toluene (7 ml), and the solution was gently refluxed under nitrogen atmosphere for 2 h. Concentration gave a syrup which was thoroughly washed with cyclohexane. The resulting solid was dissolved in benzene, washed with water, dried over sodium sulfate and concentrated to give a solid, which gave, on TLC with chloroform–ethanol (15:1), the same R_f value (=0.5) as that of **6** or **7**. In the NMR spectrum no peak near δ 8.4—8.5 (see the description of **7**) was observed. The solid was chromatographed on silica gel (5.5 g) first with chloroform–pyridine (50:1, 20 ml) (to remove an impurity) and then with chloroform–ethanol–pyridine (15:1:0.3) to give crude **10**, 210 mg.

A solution of the crude **10** (180 mg) in aqueous acetic acid (1:9, 18 ml) was heated at 55 °C for 4 h, and then concentrated with addition of toluene to give a residue. The residue, on TLC with chloroform–methanol (3:1), gave spots at R_f 0.54(minor), 0.46(slight), 0.34(major, **11**), 0.16 (minor **12**) and 0.11 (minor, 1,3-di-*N*-tosylstreptidine). The mixture was chromatographed on silica gel (15 g) with chloroform–methanol (3:1) to give **11**, **12**, and 1,3-di-*N*-tosylstreptidine in amounts of 65, 13, and 10 mg, respectively. Ether was added to **11** dissolved in methanol to cause precipitation, 62 mg (40% based on **7**), $[\alpha]_D^{25}$ −35° (*c* 0.6, methanol); IR(KBr): 1680, 1625, 1580, 1540, 1440, 1400, 1260, 1130, 1075, 1030, 1010, 830, 810 cm^{-1}.

^{1}H-NMR (CD_3OD at 50 °C): δ 1.23 (3H d, *J*=6.5 Hz, CCH_3), 2.40 (6H s, CH_3 of Ts), 3.01 (3H s, NCH_3), 4.90 (1H d, *J*=3.5 Hz, H-1″), 5.17 (2H s, CO_2CH_2Ph), 5.23 (1H d, *J*=2 Hz, H-1′).

Found: C, 50.43; H, 5.88; N, 9.22; S, 6.31%. Calcd for $C_{43}H_{59}N_7O_{17}S_2\cdot H_2O$: C, 50.23; H, 5.98; N, 9.53; S, 6.24%.

*3″-Deoxydihydrostreptomycin (**14**).* A solution of **11** (28 mg) in methanol was passed through a column (0.5 ml) of Sephadex LH-20 with the aid of methanol and the eluate was concentrated to give a solid, which was thoroughly dried *in vacuo* at 50 °C. Ammonia (≈1.5 ml as the liquid) was introduced to a solution of the solid in THF (0.5 ml, freshly distilled over LAH) cooled at −50 °C, sodium metal (≈30 mg) being added to the solution. The resulting deep-blue solution was kept at the same temperature for 1 h. Methanol was added until the color disappeared and the solution was gradually warmed with gradual decrease in pressure. The methanol solution of the residue was filtered and the filtrate was concentrated. The strongly alkaline aqueous solution of the resulting syrup was charged on a column of Amberlite CG50 (NH_4^+ form 2.5 ml) and the column was washed with water (25 ml). The column was then washed with 0.5% aqueous ammonium carbonate until the eluate gave no flame reaction for sodium. The eluting solution was then replaced by 6% aqueous ammonium carbonate, when a diacetyl-positive product was eluted. The eluate was concentrated *in vacuo* with addition of water and dried to give a constant weight (≈11 mg). An aqueous solution of the solid almost free from ammonium carbonate was passed through a Dowex 1×2 column (OH^- form, 1 ml) with water, and the strongly alkaline, diacetyl-positive fractions were concentrated, after bubbling carbon dioxide for a while, to give a solid, 10 mg (53%), $[\alpha]_D^{25}$ −67° (*c* 1, water) (lit,[1] −85° as carbonate); $\Delta[M]_{TACu}$ −50° (*cf.* DHSM +970°, lit,[9] +1020°).

^{1}H-NMR (20% ND_3 in D_2O): δ 1.20 (3H d, *J*=6.5 Hz, CCH_3), 1.55 (1H q, *J* ≈12 Hz, H_{ax}-3″), 2.15 (1H double t, *J* ≈4.5, ≈4.5, 12 Hz, H_{eq}-3″), 2.31 (3H s, NCH_3), 2.71 (1H incomplete double t, *J* ≈4, ≈4, 12 Hz, H-2″), 5.05 (1H d, *J*=3.5 Hz, H-1″), 5.31 (1H d, *J*=1.5 Hz, H-1′).

Irradiation of H-1″ caused the signals of H-2″ to become double doublets (*J* ≈4.5 and 12 Hz). Irradiation of H_{ax}-3″ caused the signals of H-2″ and H_{eq}-3″ to become a narrow triplet, respectively.

Found: C, 40.15; H, 6.66; N, 13.87%. Calcd for $C_{21}H_{41}N_7O_{11}\cdot 2H_2CO_3$: C, 39.94; H, 6.56; N, 14.17%.

The Oligomerization and Co-oligomerization of Active Methylene Compounds and Isocyanides Catalyzed by Octaisocyanidedicobalt[1)]

Yasuhiro YAMAMOTO* and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received June 30, 1980)

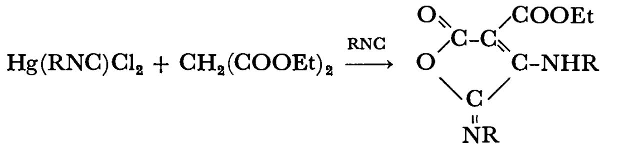
The reactions of RNC with $CH_2R^1R^2$ (R=2,6-$Me_2C_6H_3$; R^1, R^2=COOMe, COOEt, CN) in the presence of $Co_2(RNC)_8$ or $Co_2(CO)_8$ gave cyclic compounds in a 4:1 molar ratio. $Co_2(RNC)_8$ also catalyzed $CH_2(CN)_2$ to give a pyridine derivative.

Octacarbonyldicobalt has been widely used as a precursor of the catalyst of the hydroformylation of olefins and the carbonylation of various unsaturated organic compounds.[2)] Recently we have reported the synthesis and characterization of $Co_2(RNC)_8$, by analogy with $Co_2(CO)_8$.[3)] From the versatile reactivities of $Co_2(CO)_8$, one can expect catalytic actions similar to those of the corresponding isocyanide complexes. In fact, we established the hydrogenation of acetylene and the co-oligomerization of acetylene or azobenzene with isocyanide, catalyzed by $Co_2(RNC)_8$.[4,5)]

The compounds with an active methylene group, such as the malonic ester, malononitrile, and the cyanoacetic ester, have become keystones for syntheses of a heterocyclic system.[6)] Saegusa *et al.* reported that the reactions of *t*-butyl isocyanide with active methylene compounds gave three substituted olefins in the presence of Cu_2O (Eq. 1).[7)]

$$CH_2XY + t\text{-BuNC} \longrightarrow XYC{=}CHNHBu\text{-}t \quad (1)$$

Sawai and Takizawa have described producing a 2:1 cyclic adduct consisting of RNC and CH_2XY by the reactions of isocyanide–mercury(II) chloride complex with active methylene compounds in the presence of Et_3N (Eq. 2).[8)]



(2)

We wish here to report on cyclo-cooligomerization reactions between CH_2XY and RNC and on the oligomerization of an active methylene compound in the presence of a catalytic amount of $Co_2(RNC)_8$.

Results and Discussion

A mixture of $CH_2(COOMe)_2$, 2,6-$Me_2C_6H_3NC$, and $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$ was heated in toluene at 120—125 °C.[9)] The subsequent chromatography of the mixture on alumina gave two compounds: a reddish brown compound **1a**, formulated as $(C_9H_9N)_4(C_4H_4O_3)$ from the mass spectrum, M^+ 624 (624.75), and brown crystals, **2**, with the empirical formula of $(C_6H_6N)_6$. Compound **2** was identical with the compound obtained from the oligomerization of 2,6-xylyl isocyanide with $HgCl_2$ by Sawai and Takizawa.[10)] The infrared spectrum of **1a** showed an absorption at 3403 cm^{-1} due to a NH group, two bands at 1712 and 1688 cm^{-1} due to the carbonyl groups, and two broad bands at 1616 and 1593 cm^{-1} due to the C=N groups. The ^1H NMR spectrum showed four singlets, at δ 1.90, 2.03, 2.19, and 2.39, due to the *o*-methyl groups, a singlet at δ 3.21 due to a methoxycarbonyl group, and a broad signal at δ 4.91 due to a NH group. These spectral characteristics suggest a cyclic imino derivative. The other derivatives **1b** and **1c** were also prepared from the reaction of $CH_2(COOEt)_2$ with 2,6-xylyl isocyanide, or from that of $CH_2(COOMe)_2$ with *o*-tolyl isocyanide in the presence of $Co_2(CO)_8$, respectively. However, a similar reaction with *t*-butyl isocyanide led to the recovery of the starting material without undergoing a cyclic cooligomerization.

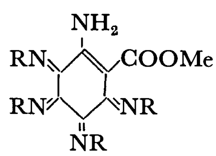
a R=2,6-$Me_2C_6H_3$, R′=Me
b R=2,6-$Me_2C_6H_3$, R′=Et
c R=4-MeC_6H_4 R′=Me

When malononitrile was treated with 2,6-xylyl isocyanide at 120—125 °C in the presence of $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$ or $Co_2(CO)_8$, two compounds, **3** and **4**, were isolated as brown and pale yellow crystals respectively. Compound **3** was formulated as a 1:4 adduct of malononitrile and 2,6-xylyl isocyanide. The infrared spectrum showed the presence of the C≡N, C=N, and NH groups. The ^1H NMR spectrum showed four bands, at δ 1.90, 2.01, 2.23, and 2.44, due to the ortho-methyl groups and a broad singlet at δ 4.67 due to the NH group. Compound **4** was a trimer of malononitrile and was identified as 4-cyanomethyl-2,6-diamino-3,5-dicyanopyridine by a comparison of its infrared and UV spectra with those of an authentic sample.[6)] When the reactions were carried out in the absence of isocyanide, a trimerization of malononitrile occurred to give **4**. The results are listed in Table 1. The reaction of 2,6-xylyl isocyanide with methyl cyanoacetate in the presence of $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$ gave a yellow compound consisting with the formula of $(C_9H_9N)_4(NCCH_2COOCH_3)$, **5**. The infrared spec-



5

R=2,6-$Me_2C_6H_3$

trum showed the presence of the NH and methoxy-

TABLE 1. TRIMERIZATION OF MALONONITRILE

Catalyst[a)]	Temp/°C	Time/h	Yield/%
$Co_2(2,6\text{-}Me_2C_6H_3NC)_8$	r.t.	15	0
$Co_2(2,6\text{-}Me_2C_6H_3NC)_8$	80	2	51
$Co_2(t\text{-}BuNC)_5Co(CO)_4$[b)]	80	2	56
$Co_2(2,6\text{-}Me_2C_6H_3NC)_8$	120	1	65

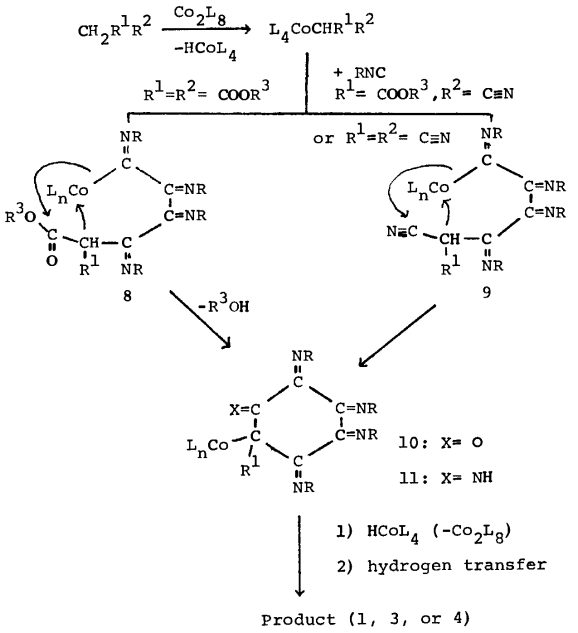
(3)

The initial step of the co-oligomerization is probably the formation of $HCo(RNC)_4$ and $R^1R^2HCCo(RNC)_4$ by a cleavage of the metal-metal bond, followed by a successive insertion of isocyanide molecules into a carbon-metal bond. The step-by-step insertion of isocyanide has been explored in various alkyl metal complexes.[11)] The intermediates, **10** and **11**, are generated by a nucleophilic attack of a tertiary carbon on the cobalt atom, accompanied by ring closure through an elimination of ROH or a transfer of hydrogen onto the cyano group. The resulting tetraimino cyclic intermediates are reduced with the $HCo(RNC)_4$ formed in the initial step. Thus, the reactions are achieved by a transfer of hydrogen to an imino nitrogen. The $Co_2(RNC)_8$ reformed in these reactions again undergoes a cleavage of a metal-metal bond, and the catalytic cycle is complete. Pyridine derivatives are probably formed by a transformation similar to that of the base-promoted reaction of active methylene compounds.[6)]

Experimental

The reactions were carried out under an atmosphere of nitrogen. The melting points are uncorrected. The IR spectra were recorded with a Shimadzu IR-27G spectrometer. The NMR spectra were measured with a JEOL C-60HL



Scheme 1. Possible path for the formation of tetraiminocyclic compounds.

apparatus. The mass spectra were measured on a JEOL Type JPS-1S mass spectrometer with a directinlet system. The isocyanides were prepared according to the literature.[12)] The $Co_2(CO)_8$[13)] and $Co_2(RNC)_8$[3)] were prepared by procedures described in the ilterature.

Reactions of Isocyanides with Active Methylene Compounds. Some representative examples will be described below.

Reaction of 2,6-Xylyl Isocyanide with Dimethyl Malonate. A mixture of 2,6-$Me_2C_6H_3NC$ (0.21 g, 1.6 mmol), $CH_2(COOMe)_2$ (1.3 g, 10 mmol), and $Co_2(2,6\text{-}Me_2C_6H_3NC)_8$ (0.16 g, 0.10 mmol) in toluene (10 ml) was heated at 120—125 °C for 4 h. The solvent was then removed *in vacuo*, and the residue was chromatographed on alumina. Compounds **1a** (0.12 g, 48%) and **2** (0.07 g, 7%) were isolated by using benzene or benzene–CH_2Cl_2 (10:1) respectively as the eluents. **1a** (mp 244—246 °C). Found: C, 76.35; H, 6.43; N, 8.95%. Calcd for $C_{40}H_{40}N_4O_3$: C, 76.89; H, 6.45; N, 8.87%. By using an analogous procedure except for the use of $Co_2(CO)_8$ instead of $Co_2(RNC)_8$, the following compounds were prepared.

1b (51%, mp 247—248 °C). NMR ($CDCl_3$): δ 1.20 (t, 3.5 Hz, Me), 1.87, 2.02, 2.19, 2.38 (s, *o*-Me), 3.71 (q, 3.5 Hz, CH_2), 4.89 (b, NH), and 6.5—7.3 (c, aromatic protons). IR (KBr): 3398 (NH), 1713, 1689, 1676, 1615, and 1591 (C=O and C=N) cm^{-1}. Mass: 638 (668.78). Found: C, 77.04; H, 6.63; N, 8.77%. Calcd for $C_{41}H_{42}N_4O_3$: C, 77.09; H, 6.63; N, 8.77%. **1c** (43%, mp 186—188 °C). IR (KBr): 3498 (NH), 1740, 1693, 1625, and 1598 (C=O and C=N) cm^{-1}. Mass: 568 (568.65). Found: C, 76.32; H, 5.76; N, 9.98%. Calcd for $C_{36}H_{32}N_4O_3$: C, 76.03; H, 5.67; N, 9.85%.

Reaction of 2,6-Xylyl Isocyanide with Malononitrile. A mixture of $Co_2(CO)_8$ (0.035 g, 0.1 mmol) and 2,6-xylyl isocyanide (0.21 g, 1.6 mmol) was stirred in toluene (10 ml) at reflux. After 0.5 h, $CH_2(CN)_2$ (0.7 g, 10.6 mmol) was added to the solution. After the reaction was over (2 h), the resulting solids, **4** (0.03 g, 13%), identified as 4-cyanomethyl-2,6-diamino-3,5-dicyanopyridine, were removed by filtration. The orange-brown solution was chromatographed on alumina, CH_2Cl_2 being used as the eluent. The subsequent removal of the solvent and crystallization

of the residue from benzene–hexane gave **3** (0.1 g, (42%), mp 265 °C) as brown crystals. NMR ($CDCl_3$): δ 1.90, 2.01, 2.23, 2.44 (s, *o*-CH_3), 4.67 (b, NH_2), and 6.5—7.4 (c, aromatic protons). IR (KBr): 3310 (NH), 2195 (C≡N), 1625, 1610, and 1590 (C=N) cm^{-1}. Mass: 590 (590.78). Found: C, 79.27; H, 6.46; N, 14.43%. Calcd for $C_{39}H_{38}N_6$: C, 79.26; H, 6.48; N, 14.23%.

5 (45%, mp 203—204 °C) was obtained from 2,6-Me_2-C_6H_3NC (0.22 g), methyl cyanoacetate (0.5 g), and $Co_2(CO)_8$ (0.04 g). IR (KBr): 3350 (NH), 1755, 1740, 1623, and 1595 (C=O and C=N) cm^{-1}. Mass: 623 (623.77). Found: C, 76.80; H, 6.65; N, 11.09%. Calcd for $C_{40}H_{41}N_5O_2$: C, 77.02; H, 6.46;, N, 10.95%.

Oligomerization of Methyl Cyanoacetate. A mixture of $CH_2(CH)$ (COOMe) (0.5 g, 5.0 mmol) and Co_2[2,6-$Me_2C_6H_3NC]_8$ (0.2 g, 0.17 mmol) in toluene was stirred in toluene (10 ml) at reflux for 2 h. The solvent and the unreacted ester were then removed *in vacuo*. The residue was chromatographed on alumina, CH_2Cl_2–benzene and CH_2Cl_2 being used as the eluents. The dimer, **6** (0.03 g, 12%), from the first band was isolated. The product, **7**, from the second band was a trimer (0.01 g, (6%), mp 114—119 °C). IR (KBr): 3510, 3430 (NH), 1735, 1683, 1632, 1586, and 1538 (C=O and C=N) cm^{-1}. Mass: 297 (297.26). UV (CH_3OH): λ_{max} 244 (ε 8400), 260 (ε 7300), and 324 (ε 2800). Found: C, 48.15; H, 5.03; N, 13.78%. Calcd for $C_{12}H_{15}N_3O_6$: C, 48.48; H, 5.09; N, 14.14%.

The Addition of (Thioacyloxy)silanes to Carbonyl Compounds

Toyokazu Horii,* Shunichi Kawamura, Takeshige Nakabayashi, and Yasuo Abe
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593
(Received July 7, 1980)

The reactions of (thioacyloxy)silane (*O*-trimethylsilyl thioacetate and thiobenzoate) with some aldehydes (propionaldehyde, butylaldehyde, and benzaldehyde) gave *S*-(1-substituted alkyl) thioacetates (*S*-[1-(trimethylsilyloxy)propyl, and -butyl] thioacetates, and *S*-[α-(trimethylsilyloxy)benzyl] thioacetate), and the three corresponding thiobenzoates respectively. The reactions were catalyzed by 1,8-diazabicyclo[5.4.0]undec-7-ene(DBU), and also by its salt with thiobenzoic acid.

Trimethylsilylated thiols were recently disclosed to undergo a carbonyl-insertion reaction at their Si–S bonds under mild conditions and to be useful as protecting reagents of the carbonyl group.[1] Although the products formed by the trimethylsilylation of thio-

$$RCHO + R'S\text{-}Si(CH_3)_3 \longrightarrow RCH\begin{matrix}\diagup OSi(CH_3)_3\\ \diagdown SR'\end{matrix}$$

carboxylic acids have been reported to be (thioacyloxy)-silanes[2,3] with a Si–O bond, there have been only a few reports[2,4] concerning the reactions of these compounds. It is interesting to examine whether or

$$RCSH + (CH_3)_3SiX \xrightarrow[-XH]{} RCOSi(CH_3)_3$$
$$\quad\ \ \|\qquad\qquad\qquad\quad\ \ \|$$
$$\quad\ \ O\qquad\qquad\qquad\quad\ \ S$$

not carbonyl insertion at the Si–O bond of the (thioacyloxy)silane occurs.

In this paper, we wish to describe the reaction of (thioacyloxy)silanes(**1** and **2**) with aldehydes(**3a**—**c**), and the isolations, identification, and physical properties of the resulting adducts (**4a**—**c** and **5a**—**c**).

Results and Discussion

Thiocarboxylic acids are known[5] to react with aldehydes to produce the corresponding adducts, which are so stable as to be isolated even at room temperature. On the other hand, thioacetic acid–ketone adducts have been reported[6] to be present only at low temperatures, while over *ca.* −60 °C they are in fast equilibrium with the reactants:

$$RCHO + CH_3COSH \longrightarrow RCH\text{-}S\text{-}CCH_3$$
$$\qquad\qquad\qquad\qquad\quad\ \ |\quad\ \ \|$$
$$\qquad\qquad\qquad\qquad\quad OH\quad O$$

$$\text{Ketone} + CH_3COSH \xrightarrow{\text{at r.t.}} \text{No reaction.}$$

Trimethylsilylated compounds of these adducts are expected to be produced by the reaction of (thioacyloxy)silanes with carbonyl compounds.

Our preliminary studies indicated that (thioacyloxy)-silanes (**1** and **2**) react slowly at room temperature with several aldehydes to afford the corresponding

$$R\text{-}\underset{\|}{C}\text{-}OSi(CH_3)_3 + R'CHO \longrightarrow R\text{-}\underset{\|}{C}\text{-}S\text{-}\underset{|}{C}HR'$$
$$\quad\ \ S\qquad\qquad\qquad\qquad\quad\ \ O\quad\ OSi(CH_3)_3$$

1: R=CH_3 **3a—c** **4a—c**: R=CH_3
2: R=C_6H_5 **5a—c**: R=C_6H_5
a: R′=CH_3CH_2
b: R′=$CH_3CH_2CH_2$
c: R′=C_6H_5

adducts. In order to search for more appropriate conditions, *O*-trimethylsilyl thioacetate(**1**) and benzaldehyde(**3c**) were chosen as representative substances and were allowed to react in an NMR tube under several conditions; the progress was observed by monitoring the decrease in the ^1H NMR trimethylsilyl signal of the starting material(**1**) and the increase in that of the product(**4c**). The heating of equimolar amounts of **1** and **3c** at 115 °C for 6.5 h in an NMR tube resulted in the formation of the adduct(**4c**) (see Table 1). However, the reaction in the presence of a small amount (0.03 equiv) of DBU was completed within 15 min at room temperature. Also, by the addition of triethylamine, the reaction was accelarated to afford the adduct in an 82% yield after 4 h. These results show that catalytic amounts of the amines accelerate the present reaction.

Thus, a series of thiocarboxylates(**4a**—**c** and **5a**—**c**) were synthesized by the addition of a small amount (*ca.* 0.03 equiv) of DBU to an equimolar mixture of **1** or **2** and **3** at room temperature without a solvent. The yields and the properties of the products are

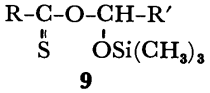
a) The values are isolated yields based on the aldehydes (**3a—c**) used.

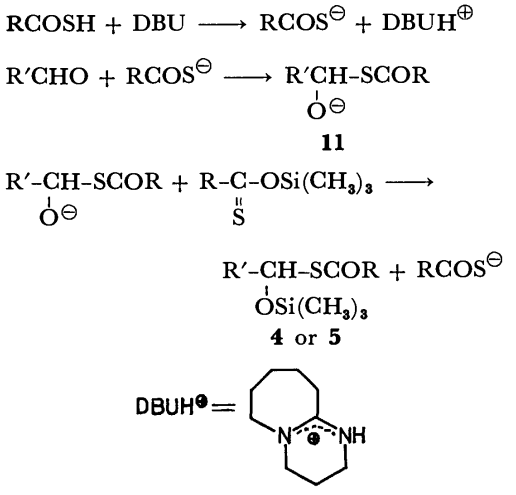
summarized in Table 2.

The IR spectra of the products (**4a—c** and **5a—c**) showed strong absorption bands in the region of 1655—1690 cm^{-1} which were considered to be a characteristic of the carbonyl stretching mode. The results indicate that these products were not the thiocarboxylic *O*-ester (**9**), but the *S*-esters (**4** and **5**).



9

The present reaction was found to be catalyzed also by the salt (**10**). For example, the reaction of **2** with **3b** in chloroform-*d*, which did not proceed at room temperature even after 20 h in the absence of the catalyst, was completed within 1 h by the addition of traces of **10** prepared separately (see Table 1). Consequently, in the acceleration by DBU, the first step seems to involve the formation of the salt of DBU with thiocarboxylic acid, which may be present in traces as a hydrolysis-product of (thioacyloxy)-silane (**1** or **2**). As is shown in Scheme 1, the possible reaction mechanism of the catalytic behavior of DBU or the salt (**10**) involves the carbonyl addition of $RCOS^-$, affording the resulting **11** in equilibrium concentrations; **11** is converted to the adduct (**4** or **5**) by the subsequent bimolecular silicon transfer. Similar schemes have been presented by Evans *et al.*[1] concerning the anion-catalyzed addition reactions of a variety of silicon derivatives to aldehydes and ketones, in which cases the catalysts were the potassium cyanide–crown ether complex, tetrabutylammonium cyanide, and tetrabutylammonium fluoride.



Scheme 1.

The additions of **1** or **2** to ketones, *i.e.*, acetophenone, acetone, or cyclohexanone, did not occur at high temperatures (70—115 °C) nor in the presence of a catalytic amount of DBU. However, in the presence of an equimolar amount of DBU, acetophenone reacted with **1** in benzene at room temperature to produce the corresponding *O*-silylated enolate in a 38% yield:

$$C_6H_5\overset{\overset{O}{\|}}{C}CH_3 + CH_3\overset{\overset{S}{\|}}{C}OSi(CH_3)_3 + DBU \longrightarrow C_6H_5\overset{\overset{OSi(CH_3)_3}{|}}{C}=CH_2 + DBUH^{\oplus}\ {}^{\ominus}S\overset{\overset{O}{\|}}{C}CH_3.$$

The lack of any production of the adducts of ketones seems to reflect the character of the adducts of thiocarboxylic acids to ketones.

Experimental

The NMR spectra were taken on a JEOL MH-100 spectrometer, using carbon tetrachloride as the solvent and tetramethylsilane as the internal standard, unless otherwise stated. The abbreviations in the NMR spectra are as follows: s, singlet; d, doublet; qd, quartet of doublets; m, multiplet. The infrared spectra were recorded on a JASCO IR-S or JASCO 701G spectrometer. The mass spectra were measured on a Shimadzu-LKB 9000 spectrometer. Alumina (M. Woelm, activity I) was used for the column chromatography.

Materials. The *O*-trimethylsilyl thioacetate (**1**) and thiobenzoate (**2**) were prepared by the method in the literature.[2] The DBU and aldehydes (**3a—c**) were commercially available, and the latter were used after distillation.

*General Procedure for the Preparations of **4a—c** and **5a—c**.* To a stirred mixture of 4.2 mmol of (thioacyloxy)silane (**1** or **2**) and 4 mmol of aldehyde (**3a—c**) we added one drop (0.1—0.15 mmol) of DBU. After about 15 min at room temperature, the mixture was dissolved in hexane and filtered through a short alumina column to remove any minor impurities. The subsequent removal of the solvent under a vacuum gave a colorless liquid, which was found to be pure **4a—c** or **5a—c** by NMR analyses. The samples obtained by molecular distillation were subjected to elemental analyses and spectral measurements (see Table 2).

*Preparation of DBU·PhCOSH Salt (**10**).* DBU (3.0 g, 20 mmol) was added dropwise to stirred solution of thiobenzoic acid (2.76 g, 20 mmol) in ether at room temperature. Stirring was then continued for an additional 1 h. The precipitate was collected by filtration and recrystallized from chloroform-ether to give the title compound (4.5 g) in a 75.5% yield; mp 116.5—117.5 °C; MS *m/e* 152 (DBU^+). 137 ($PhCOS^+$). Found: C, 66.26; H, 7.77; N, 9.55; S, 10.98%. Calcd for $C_{16}H_{22}N_2OS$: C, 66.17; H, 7.64; N, 9.65; S, 11.04%.

Mechanism of the Reaction of Nitriles with Alkaline Hydrogen Peroxide. Reactivity of Peroxycarboximidic Acid and Application to Superoxide Ion Reaction[1]

Yasuhiko SAWAKI and Yoshiro OGATA*

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 14, 1980)

Formation of peroxycarboximidic acid (**1**) is not rate-determining in the reaction of nitrile with alkaline hydrogen peroxide to form amide and oxygen; the yield of amide based on H_2O_2 varies from 20 to 60%. When dimethyl sulfoxide (DMSO), a reactive substrate, is added, the rate is independent of [DMSO] and governed in turn by a rate-determining addition of HOO^- to nitrile. This reaction gives a reliable α-value of k_{HOO^-}/k_{HO^-}, which is 10000 for benzonitrile. A facile conversion of nitrile to amide may be achieved by the reaction in the presence of DMSO, unaccompanied by side reactions such as the epoxyamide formation from α,β-unsaturated nitrile. Kinetics and product analysis suggest that a predominant reaction is not a non-radical oxidation of H_2O_2 with **1** but a radical decomposition of H_2O_2 which is induced by the homolysis of anion of **1** (**1A**). No singlet oxygen could be trapped chemically. The reaction of superoxide ion, $O_2^{\cdot-}$, with acetonitrile is shown to be analogous to that of HOO^-; the decomposition of $O_2^{\cdot-}$ is fast in the presence of MeCN and DMSO in benzene, affording acetamide and dimethyl sulfone.

The reaction of nitrile with alkaline hydrogen peroxide is well documented[2,3] and the intermediate peroxycarboximidic acid (**1**) has been utilized as a convenient epoxidizing agent.[4,5] Because the reaction can be run under weakly basic conditions, the oxidant is useful for the epoxidation of olefins leading to acid-sensitive epoxides[4] or olefinic ketones susceptible to the Baeyer-Villiger reaction,[6] and also applicable to imines.[7] The reactivity of **1** is interesting in connection with these oxidations and with chemiluminescence from nitriles.[8,9]

$$RC{\equiv}N + H_2O_2 \xrightarrow{\text{base}} \underset{\displaystyle OOH}{\overset{\displaystyle |}{RC{=}NH}} \qquad (1)$$

1

The reaction has also been studied kinetically in relation to an α-effect of HOO^- nucleophile,[2,10,11] where a rate-determining step was assumed to be the addition of HOO^- to nitrile. By contrast, our previous study on the epoxidation of olefins with a mixture of nitrile and alkaline H_2O_2 showed that the epoxidation with **1** is rate-determining.[3] Here, we wish to report our mechanistic study on the formation and reaction of **1**, revealing that the formation of **1** becomes rate-determining in the presence of DMSO and that the oxidation of H_2O_2 with **1** is not important, no singlet oxygen being generated. The reaction of superoxide ion, $O_2^{\cdot-}$, with nitrile is also shown to be analogous to the case of HOO^-.

Results and Discussion

Stoichiometry. The stoichiometry for the reaction of nitrile with alkaline hydrogen peroxide was sometimes written as[2]

$$RCN + 2\,H_2O_2 \xrightarrow{HO^-} RCONH_2 + O_2 + H_2O. \qquad (2)$$

Table 1. Rates and product from the reaction of nitriles and alkaline hydrogen peroxide[a]

RCN	Solvent % MeOH	Base	% HOO^- [b]	Additive[c]	Rate/$M^{-1}\,s^{-1}$ [d]		Yield/%[e]

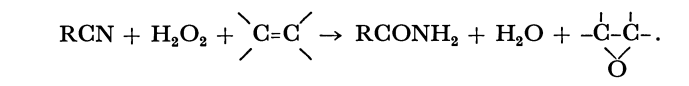
a) Reaction with 0.1 M RCN and 0.017 M H_2O_2 at 25 °C. b) % Dissociation of H_2O_2 into HOO^- as determined by UV absorbance at 280 nm (±3%). c) 0.1 M of DMSO. d) The rates were determined by iodometric titration of the remaining H_2O_2. The k_{HOO^-} value was calculated according to Eq. 5; the values in parentheses are shown to exemplify no constancy of the k_{HOO^-} value in the absence of DMSO. e) Yields were determinined by GLC and based on H_2O_2 consumed. f) When 0.04 M cumene was added, 3—6% of 2-phenyl-2-propanol was obtained. g) Oxygen was evolved in 60% yield. h) The k_{obsd} value was practically same (*i.e.*, 1.46 and 1.55) with 0.05 and 0.5 M DMSO. i) Benzaldehyde (1%) and benzyl alcohol (8%) were also detected by GLC.

However, the reaction is not so simple; the yields of amides based on H_2O_2 consumed vary in the range of 20—60% depending on the conditions and substrates (Table 1). A lower yield of amide was obtained at higher pH, perhaps suggesting a radical decomposition of H_2O_2 as discussed later.

On the other hand, the reaction in the presence of olefins was shown to have a simple stoichiometry affording a nearly quantitative yield of amide and epoxide by an ionic mechanism:[3]



(3)

The same is true for the oxidation of dimethyl sulfoxide (DMSO) to sulfone in phosphate buffer, which shows the stoichiometry of reactant, RCN:H_2O_2:substrate= 1:1:1. The yields of amide and sulfone decrease at high alkanity, again suggesting an intervention of a radical decomposition of H_2O_2. The oxidation of sulfoxide to sulfone with alkaline H_2O_2 alone is ineffective in these protic solvents as reported previously.[12]

Kinetics. The reaction of nitrile with alkaline hydrogen peroxide has mostly been explained by a rate-determining addition of HOO^- to nitrile, the intermediary perimidic acid (**1**) being a potent oxidant capable of oxidizing H_2O_2 itself rapidly.[2,10,11] This explanation, however, contrasts with our previous observation[3] that the epoxidation of olefins with nitrile and alkaline H_2O_2 obeyed third-order kinetics:

$$v = k_4[\mathrm{RCN}][\mathrm{H_2O}][\mathrm{C{=}C}]. \quad (4)$$

Here, k_4 value was practically independent of $[HO^-]$ or $[HOO^-]$ at pH 10—12 in 75% MeOH; moreover, the consumption of H_2O_2 in the absence of olefin was very small (*i.e.*, mostly<2%). These results suggest that the rate-determining step is not the formation of **1** but the epoxidation with it.

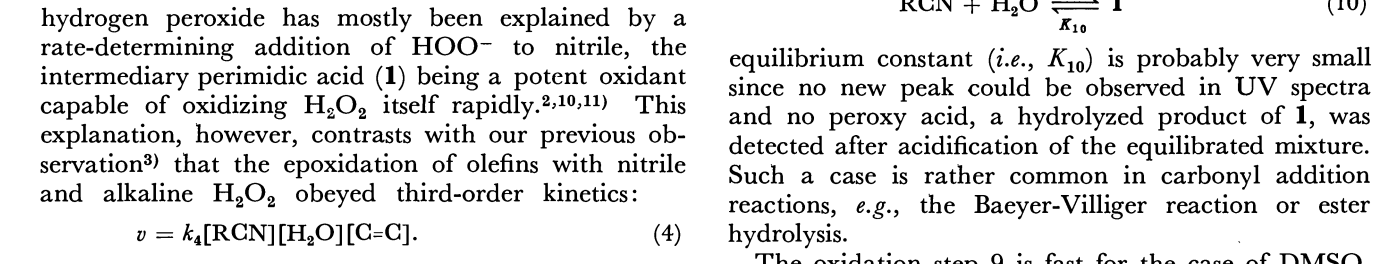
To clarify this discrepancy, we reinvestigated the reaction of nitrile with alkaline H_2O_2 kinetically by following H_2O_2 iodometrically. As shown in Table 1, the reaction of nitrile with H_2O_2 changes with the kind and concentration of base; the resulting k_{HOO^-} value, calculated according to a rate equation 5, is far from constant.

$$v = k_{\mathrm{obsd}}[\mathrm{RCN}][\mathrm{H_2O_2}] = k_{\mathrm{HOO^-}}[\mathrm{RCN}][\mathrm{HOO^-}] \quad (5)$$

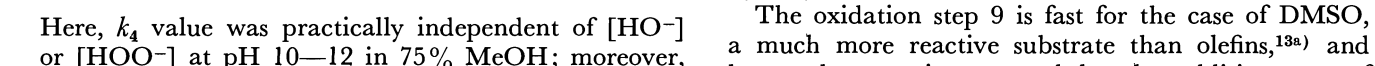
No constancy of k_{HOO^-} value indicates that the addition of HOO^- to nitrile is not rate-limiting in the reaction of nitrile and alkaline H_2O_2 alone.

When DMSO is added to the reaction mixture, the reaction is significantly accelerated under weakly alkaline conditions, the maximum being over one hundred times. In contrast to the case of olefin epoxidation (Eq. 4), the oxidation of DMSO to sulfone is independent of substrate concentration (see footnote h in Table 1) but dependent on $[HO^-]$ or $[HOO^-]$. Similar results were obtained for the case of acetonitrile, the $10^3 k_{\mathrm{obsd}}$ value being constant at $1.21 \pm 0.07\ M^{-1}\ s^{-1}$ with varying concentration of DMSO from 0.05 to 0.7 M MeCN in 75% MeOH containing 5 mM Na_3PO_4. The constancy of the k_{HOO^-} value in the presence of DMSO (Table 1) seems to be adequate in view of the accuracy in estimating $[HOO^-]$. Thus, the rate expression in the presence of DMSO is Eq. 5 where no term of [DMSO] is involved.

All of the above results may be well understood by the following scheme.



Here, k_7 equals k_{HOO^-} in Eq. 5. For olefin epoxidation, step 9 is rate-determining and preequilibrium reactions 6—8 are attained; the three equilibria could be simply written as Eq. 10, leading to the observed rate equation (Eq. 4) independent of pH. The magnitude of the



equilibrium constant (*i.e.*, K_{10}) is probably very small since no new peak could be observed in UV spectra and no peroxy acid, a hydrolyzed product of **1**, was detected after acidification of the equilibrated mixture. Such a case is rather common in carbonyl addition reactions, *e.g.*, the Baeyer-Villiger reaction or ester hydrolysis.

The oxidation step 9 is fast for the case of DMSO, a much more reactive substrate than olefins,[13a] and hence the rate is governed by the addition step of HOO^- to C≡N (step 7), thus being independent of [DMSO] as is observed. The apparent large solvent effect in k_{obsd} is due to the change in $[HOO^-]$ owing to the change in K_6 value. The constancy in k_{HOO^-} values was observed only for the DMSO oxidation, indicating the rate-determining addition of HOO^- to C≡N.

As for the reaction of nitrile with H_2O_2 alone, previous kinetics[2,10] were carried out at pH<10 and explained by assuming a rate-limiting addition of HOO^- to C≡N. This assumption is not substantiated by the fact that the k_{HOO^-} values are not constant and the reaction in the presence of olefin or sulfoxide is much faster under these weakly alkaline conditions. Thus, the preequilibrium 10 must be attained in the absence of added substrate. Then there might be a case where the oxidation of H_2O_2 with **1** occurs and determine the overall rate, requiring a rate expression: $v=k[\mathrm{RCN}][\mathrm{H_2O_2}]^2$ which was obtained by substituting $[H_2O_2]$ for [C=C] in Eq. 4. However, this case is not probable in view of the fact that the observed order in $[H_2O_2]$ is not second-order.[2,3,10] We ascertained this again; for example, the reaction of 0.05 M benzonitrile with 0.01 and 0.03 M H_2O_2 afforded $10^5 k_{\mathrm{obsd}}$ value of 0.36 and 0.34 $M^{-1}\ s^{-1}$, respectively, in the presence of 5 mM Na_2HPO_4 in 50% MeOH (1 M=1 mol dm^{-3}).

At high alkanity, *e.g.*, 0.1 M NaOH, the consump-

tion of H_2O_2 becomes independent of the presence of DMSO and the yields of amide and/or sulfone are low (*i.e.*, 20—30% based on H_2O_2 consumed). Moreover, the effect of EDTA is rather small at these higher alkaline concentrations. These facts suggest a radical decomposition of H_2O_2 induced by the homolysis of peroxyimidate ion **1A**.[13b]

$$\underset{\underset{\text{OOH}}{|}}{\text{RC=N}} \longrightarrow \text{R-C}\overset{\text{N}}{\underset{\text{O}}{\vdots}} + \text{HO}\cdot \qquad (11)$$

1A

$$\text{R'O}\cdot + \text{H}_2\text{O}_2 \longrightarrow \text{R'OH} + \text{HOO}\cdot \text{ (or } \text{H}^+ + \text{O}_2^{-}\text{)} \qquad (12a)$$

$$\text{HOO}\cdot + \text{O}_2^{-} \longrightarrow \text{HOO}^- + \text{O}_2 \qquad (12b)$$

$$\text{R'O}\cdot + \text{O}_2^{-} \longrightarrow \text{R'O}^- + \text{O}_2 \qquad (12c)$$

Here, R'O· is **2** or HO·. It is well known that the base-catalyzed decomposition of hydrogen peroxide is complex and sensitive to contaminating metal ions.[14a] Although many steps are involved in the radical decomposition of H_2O_2,[14b-d] a major step to produce oxygen is probably the reaction 12b or 12c; the pK_a value of HOO· being 4.85 in water.[14e]

Four lines of evidence were obtained for the intervention of radical decomposition of H_2O_2. First, the yield of amide or sulfone was sometimes as low as 20—30% on the basis of H_2O_2 consumed. Second, 2-phenyl-2-propanol (3—6%) was obtained when cumene was added (footnote f in Table 1), suggesting an initiation of radical autoxidation of added cumene. Third, the oxidation of 1,2-dimethylcyclohexene yielded, in addition to epoxide, products from its autoxidation as discussed later (Table 4). The fourth line of evidence for the homolysis of **1A** is the formation of benzyl alcohol and benzaldehyde from benzyl cyanide (footnote i in Table 1) (Eq. 13).

$$\text{PhCH}_2\text{CN} \xrightarrow{\text{HOO}^-} \underset{\underset{\text{OOH}}{|}}{\text{PhCH}_2\text{C=N}^-} \xrightarrow{-\text{HO}\cdot} \underset{\underset{\text{O}\cdot}{|}}{\text{PhCH}_2\text{C=N}^-}$$

3

$$\xrightarrow{-\text{OCN}^-} \text{PhCH}_2\cdot \xrightarrow{\text{O}_2} \longrightarrow \text{PhCH}_2\text{OH} + \text{PhCHO} \qquad (13)$$

Facile β-scission of benzyl radical is known.[15] Formation of benzaldehyde might be explained by a scheme *via* α-hydroperoxy nitrile;[9] but the base-catalyzed autoxidation of benzyl cyanide does not occur appreciably under these conditions. Thus, the evidence for the radical decomposition of H_2O_2 induced by the homolysis of **1A** seems to be convincing. A similar homolysis such as Eq. 11 was proposed in the reaction of nitriles with alkaline *t*-butyl hydroperoxide.[16]

On the basis of ^{18}O-tracer study yielding 81% of unscrambled oxygen, the reaction of **1** with HOO^- was proposed as a predominant pathway.[10a]

$$\text{RCN} + \text{HOO}^- \longrightarrow \mathbf{1} \xrightarrow{+\text{HOO}^-} \underset{\underset{\text{OOH}}{|}}{\overset{\overset{\text{NH}^-}{|}}{\text{R-C-OOH}}}$$

$$\longrightarrow \text{RCONH}_2 + \text{O}_2 + \text{HO}^- \qquad (14)$$

But this pathway can not be predominant since our kinetic data show that the formation of **1** is not rate-determining and, moreover, the overall rate is not governed by the reaction of **1** with HOO^- as discussed above. One possible route to the observed unscrambled oxygen, which was conducted at pH 10 in water, is a homolytic one such as Eqs. 12a—c. This seems to be not unreasonable in view of the fact that the reported k_{HOO^-} value of *ca.* 2×10^{-2} M^{-1} s^{-1} (for *p*-cyanobenzoate in water)[10a] is much higher than the present value of 3×10^{-4} M^{-1} s^{-1} in phosphate buffer (entry 1 in Table 1). The large value of the former seems to reflect an intervention of radical decomposition of H_2O_2 to yield oxygen. Since the base-catalyzed decomposition of H_2O_2 is complex[14] and peroxyl radicals yield scrambled oxygen,[17] it is not easy to clarify or explain the ^{18}O-tracer study (*i.e.*, 81% unscrambled and hence 19% scrambled).

α-Effect. The rate of addition of HOO^- to nitrile could be determined in the presence of DMSO (Table 2). The k_{HOO^-} value changes with nitriles, ranging from 10^{-3} to 3. Aliphatic nitriles are about ten times less reactive than aromatic ones. The substituent effect on benzonitrile affords a ρ-value of 1.54 (σ, r=0.991), suggesting a nucleophilic attack of HOO^- on C≡N.

Much attention has been concentrated on the origin of α-effect.[11] Although several explanations have been noted,[18] it seems to be that there is no single factor govering the α-effect. A typical example of α-effect is the addition of HOO^- to C≡N. The original value (k_{HOO^-}/k_{HO^-}) of 2×10^4 to 7×10^4 for benzonitriles[2] was often cited, but later it was corrected to be 900—1200.[10] As discussed above, a rate-determining step under these conditions is not the attack of HOO^- to C≡N but the decomposition of **1**. The obscurity may be overcome by the addition of DMSO; the results listed in Table 3 show that the α-effect is certainly large, the value of k_{HOO^-}/k_{HO^-} being in the range of 3×10^3 to 10^4.

Reactivity of Peroxyimidic Acid. Peroxyimidic acid (**1**) is a convenient epoxidizing agent.[4-6,19] The electrophilic character of **1** was shown for substituted styrenes ($\rho=-0.48$),[3] although the substituent effect was somewhat smaller compared to the epoxidation with peroxy acid ($\rho=-1.30$).[20] The epoxidation of aliphatic olefins with **1** was also shown to be less selective and possesses a greater steric demand than the case of RCO_3H.[21] Stereochemistry is retained in the present epoxidation as is the case with RCO_3H; that is, GLC analysis demonstrates that *trans*- and *cis*-β-methylstyrenes give the corresponding *trans*- and *cis*-epoxides, respectively, in the reaction with MeCN, H_2O_2, and Na_3PO_4 in 75% MeOH.

Intramolecular epoxidation was shown to occur effectively for α,β-unsaturated nitriles.[22] However, this epoxy amide formation is not so facile; for example, cinnamonitrile gave the amide: epoxy amide ratio of 90:10 (see Table 2). Similarly, a relatively low yield of epoxy amide was also obtained (*i.e.*, **5**:**6**=4:1) from β,γ-unsaturated nitrile (**4**) (Eq. 15).

The addition of DMSO to the system dramatically accelerated the conversion of nitriles to amides un-

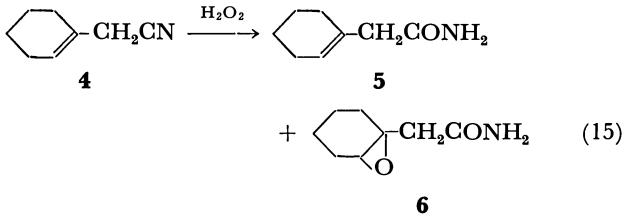
a) Reaction with 0.1 M RCN, 0.015 M H_2O_2, 0.05 M DMSO, and 0.01 M Na_3PO_4 at 25 °C. See footnotes in Table 1. The value in parentheses is from the reaction without DMSO. b) % Yields isolated, if not noted otherwise, from the reaction with 10 mmol RCN, 15 mmol H_2O_2, 12 mmol DMSO, and 0.2 mmol NaOH in 25 ml of 80% MeOH at 50 °C for 1 h. See experimental section. c) Ph=C_6H_4. d) Not determined. e) Reaction with 0.011 M RCN and H_2O_2. f) % Yield determined by NMR. g) NMR yield is 95%.

Table 3. α-Effect on the addition of nitriles a)

Nitrile	Nucleophile	Solvent	k/M^{-1} s^{-1}	k_{HOO^-}/k_{HO^-}
PhCN	HOO^-	25% Dioxane	2.02×10^{-1}	1.02×10^4
	HO^-	25% Dioxane	1.97×10^{-5}	
MeCN	HOO^-	25% Dioxane	2.53×10^{-2}	4.0×10^3
	HO^-	25% Dioxane	0.63×10^{-5}	
MeCN	HOO^-	Water	1.40×10^{-2}	3.0×10^3
	HO^-	Water	0.47×10^{-5}	

a) Reaction at 25 °C with hydrogen peroxide: 0.1 M RCN, 0.02 M H_2O_2, 0.1 M DMSO, and 0.1 M Na_2CO_3; the k_{HOO^-} values were calculated accoding to Eq. 5 (20.1% dissociation of H_2O_2 into HOO^- by UV). The alkaline hydrolysis: 0.1—0.4 M NaOH, 1—2.5 M MeCN or 0.1 M PhCN.



(15)

contaminated with epoxy amide (Table 2). The accelerating effect was large especially for the case of hindered nitriles such as *o*-tolunitrile or cinnamonitrile (*i.e.*, *ca.* thousand-fold increase in rate). The reaction at 50 °C for 1 h gave a high yield of pure amide even with 1 mmol scale, which may be useful as a convenient identification of nitriles. In any case, it is

Table 4. Oxidation of 1,2-dimethylcyclohexene (**7**) with nitrile and alkaline hydrogen peroxide

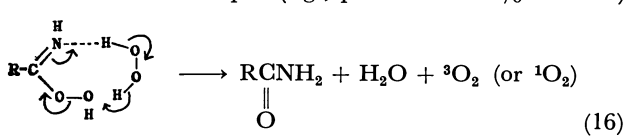
a) Reaction time of 30—60 min at room temperature if not noted otherwise. Reaction with 0.1 M olefin and, for the nitrile-H_2O_2 reaction, 0.2 M each of PhCN and H_2O_2. b) Product distribution (%) determined by GLC after the reduction with $NaBH_4$. c) Reaction time 4 h. d) In the presence of 1 mM EDTA. e) Reaction time 24 h.

apparent that the intramolecular epoxidation in the peroxyimidic acid intermediate is not so fast and the acid may be completely reduced by DMSO affording pure olefinic amide.

On the basis of approximate stoichiometry of RCN: H_2O_2=1:2, peroxyimidic acid **1** was noted as a potent oxidant capable of oxidizing H_2O_2 to O_2.[2] In analogy to the oxidation with RCO_3H,[8,23] hydrogen peroxide may be oxidized by **1** to oxygen (Eq. 16). However, the kinetics at lower pH (*e.g.*, pH<12 in 75% MeOH)



(16)

Table 5. Reaction of superoxide ion in benzene[a)]

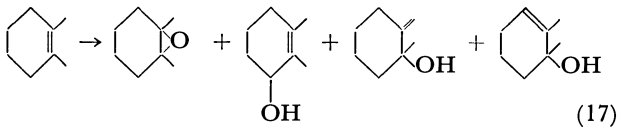
KO_2-**7**	<10	—	—	Yes[h)]

a) Reaction with 0.5 mmol KO_2 (suspension) and 0.1 mmol 18-crown-6 in benzene (4 ml) at 25 °C for 2 h. Acetonitrile was added in a large excess as a co-solvent, *i.e.*, 25 vol% in benzene. DMSO was 0.3 M and olefins were of 0.1 M concentration. b) Approximate value of decomposed KO_2 by titration. c) Yields were determined by GLC and based on the charged KO_2. d) Water (0.25 mmol) was added. e) α-Methylstyrene. f) Epoxide or acetophenone was not detected. g) Yields of **8**, **9**, **10**, and **11** were 1.4, 0.3, 0.3, and 2.4%, respectively. h) Yields of **8**, **9**, **10**, and **11** were 0.7, 0.1, 0.2, and 1.0%, respectively.

is not in accordance with this scheme; if the reaction 16 were operative as a major rate-determining pathway, the overall rate should be second-order in $[H_2O_2]$ and the yield of amide based on H_2O_2 should not exceed 50% (in the absence of DMSO or olefin), both of which were not the case. At high alkalinity, **1** should shift to **1A**[13b)] which easily decomposes homolytically inducing radical decomposition of H_2O_2. This leads to the lower yield of amide or sulfone as is observed. Thus, it may be concluded that the oxidation of H_2O_2 by **1** or **1A** like Eq. 16 is not operating as a predominant reaction.

In order to examine a possible formation of singlet oxygen even as a minor reaction, 1,2-dimethylcyclohexene (**7**), a useful $^1O_2$ trapper,[24a)] was oxidized with nitrile and alkaline H_2O_2. The results in Table



(17)

7 **8** **9** **10** **11**

4 shows that the product distributions are different from singlet oxygen reaction, but are similar to that of the radical autoxidation. A relatively high yield of epoxide was obtained by the radical autoxidation of **7** as observed for other tetrasubstituted aliphatic olefins.[25)] The oxidation of α,β,β-trimethylstyrene, which is also a $^1O_2$ trapper[24a)] but resistant to radical autoxidation at 60 °C, gave a high yield of epoxide (95% yield) together with minor products, where allyl alcohols produced by the $^1O_2$ reaction could not be detected by GLC (*i.e.*, within 1%, if any). Thus, singlet oxygen is not formed in the RCN–H_2O_2 reaction. This results are in contrast to the reported efficient formation of $^1O_2$ from H_2O_2 and cyanates ROCN under anhydrous neutral conditions.[24b)]

Finally, a comment should be added on the reported chemiluminescence from nitriles and H_2O_2.[8a)] Contrary to the report that the luminescence is visible, blue or red, we could not see or detect it as described below. We tested acetonitrile, isobutyronitrile, benzonitrile, benzyl cyanide, and acrylonitrile under the conditions of 0.01—0.1 M each of nitrile, H_2O_2, and KOH in MeOH or EtOH. The addition of dibromo- or diphenylanthracene was of no effect. Our results show that the quantum yield of the reported luminescence is much less than 10^{-9}, if any. To our knowledge, the reported chemiluminescence might be *via* α-hydroperoxy nitrile formed by the base-catalyzed autoxidation of nitriles.[9)] The reported luminescence

$$RCH_2CN \xrightarrow{base/O_2} \underset{\underset{OOH}{|}}{RCHC{\equiv}N} \longrightarrow \underset{\underset{O-O}{|\ \ |}}{RCH\text{-}C{=}NH} \longrightarrow \text{Luminescence} \qquad (18)$$

intensity of $CH_2{=}CHCN > PhCH_2CN \gg PhCN$ may be understood on the basis of Eq. 18, where an α-proton is necessary for the base-catalyzed autoxidation. Although the authors[8a)] suggested singlet oxygen formation by reaction 16, this is not in accordance with the fact that singlet oxygen could not be trapped chemically.

Reaction of Superoxide Ion with Nitrile. Much interest has been concentrated on the reactivity of superoxide ion.[26)] Acetonitrile is sometimes used as an aprotic solvent,[27)] but it is noted that the reactivity of $O_2^{\cdot-}$ in MeCN is different from that in other solvents,[16b,28)] typically the lifetime of $O_2^{\cdot-}$ is ten times shorter in the nitrile.[28a)]

As shown in Table 5, superoxide ion $O_2^{\cdot-}$ reacts with acetonitrile just as hydroperoxide ion HOO^- does. All the experiments were carried out in the presence of 18-crown-6 in benzene to dissolve some fraction of KO_2. Suspended potassium superoxide was stable in benzene but decomposed in acetonitrile–benzene. Interestingly, considerable yields of acetamide were obtained by the reaction of KO_2–MeCN–DMSO. Since it is known that sulfoxides are oxidized to sulfones by alkyl hydroperoxide ion in aprotic solvents,[29)] the sulfone might be produced by the reaction of HOO^- produced by the disproportionation of $O_2^{\cdot-}$. However, the yield of sulfone was much lower when water was added as a proton source to produce

HOO^-. These facts suggest the following scheme.

$$RC{\equiv}N + O_2^{\cdot-} \longrightarrow \underset{\underset{OO\cdot}{|}}{RC{=}N^-} \xrightarrow{O_2^{\cdot-}} \underset{\underset{OO^-}{|}}{RC{=}N^-}$$

12 **13**

$$\xrightarrow{Me_2SO} RCONH_2 + Me_2SO_2 \qquad (19)$$

The reduction of radical **12** with $O_2^{\cdot-}$ to form **13** and O_2 is similar to a known process.[26c,30] Since α-methylstyrene was not epoxidized by KO_2–MeCN (Table 5), the intermediary oxidant for the sulfoxide is probably **13** as a nucleophilic oxidant. It is known that sulfoxides are efficiently oxidized by nucleophilic oxidants.[12,29] In the absence of DMSO, **13** decomposes homolytically just as the case of RCN–HOO^- reaction at high alkalinity (*cf.* Eq. 11). The product distribution from **7** seems to be in this line, suggesting a radical autoxidation (Table 5). Thus, it may be concluded that the chemistry is essentially same for the reaction of nitrile with $O_2^{\cdot-}$ or with HOO^-.

Experimental

Melting points were measured by a Yanagimoto micro melting point apparatus and are corrected. ^1H NMR spectra were recorded with a Hitachi R-24B spectrometer. GLC analyses were performed with a Yanagimoto G180 gas chromatograph using two different columns: PEG 20 M, 10% on Chromosorb W; Silicone OV-17, 5% on Shimalite W. Chemiluminescence was monitored by a Hitachi MPF-2A fluorescence spectrophotometer.

Materials. Methanol and water were purified by redistillations. Substituted benzonitriles were described in our previous paper.[3] *trans*-Cinnamonitrile,[31] bp 124—125 °C/8 Torr (lit,[32] bp 137 °C/16 Torr), and 1-cyclohexenylacetonitrile (**4**),[33] bp 105—107 °C/21 Torr (lit,[33] 110—112 °C/25 Torr), were obtained by the literature method. 2-Methyl-3-phenyl-2-butene, bp 91—92 °C/25 Torr (lit,[34] 191—192 °C), was prepared by dehydration[35] of 2-methyl-3-phenyl-2-butanol in 40% yield. 1,2-Dimethylcyclohexene (**7**) was obtained by dehydration of 1,2-dimethylcyclohexanol (50% sulfuric acid, 100 °C, 1 h) and fractionated three times with a 30 cm Vigreux column, bp 135—136 °C (lit,[36] bp 136.2 °C). Purification *via* dibromide formation[37] was unsatisfactory. 18-Crown-6 was synthesized from triethylene glycol[38] and KO_2 from xanthone-catalyzed autoxidation of potassium in THF.[39]

Rates and Products Determination. Rates were followed iodometrically and a typical procedure was noted in the previous paper.[3] The decomposition of alkaline H_2O_2 alone was negligibly small. The reaction of nitrile with alkaline H_2O_2 was not affected by the addition of 10^{-4} M EDTA, which indicates that there was no contamination by metallic ions.

The hydrolysis rate of benzonitrile was determined by following the decrease of the nitrile by GLC analysis. The reaction of acetonitrile was followed by titrating the produced acetic acid after flashing out ammonia by passing N_2 gas for 5 min. The results are shown in Table 3.

Products were determined by GLC and/or NMR, directly or after extraction with CH_2Cl_2, in comparison to an authentic sample. Authentic samples of epoxides or epoxy amide were obtained by RCO_3H or alkaline H_2O_2 oxidation.

Facile Conversion of Nitriles to Amides. *o*-Tolunitrile (1.17 g, 10 mmol) and DMSO (0.85 ml, 12 mmol) were dissolved in MeOH (20 ml), followed by addition of 11% H_2O_2 (4.85 ml, 15 mmol) and 0.2 M NaOH (1 ml, 0.2 mmol). The reaction mixture was stirred at 50 °C for 1 h, and about half of the solvent MeOH was distilled off (*ca.* 15 min). Standing at room temperature (*ca.* 30 min) afforded pure crystals of *o*-toluamide in 83% yield, mp 142—142.5 °C (lit,[40] 141—141.5 °C).

According to this convenient procedure (total working time; 2 h) the following amides were isolated in pure form (see Table 2 for the yields): *p*-toluamide, mp 161—162 °C; phenylacetamide, mp 159—160.5 °C; benzamide, mp 129—130 °C; cyclohexenylacetamide, mp 153—154 °C; *trans*-cinnamamide, mp 148.5—149.5 °C; diphenylacetamide, mp 172—174 °C. The latter two amides were isolated without evaporation of methanol. An alternative procedure for the isolation is the addition of water (20 ml), which gave a slightly lower yield of amide. The reaction in the absence of DMSO was very slow and incomplete.

Oxidation of 1,2-Dimethylcyclohexene (7). The reaction was started by adding 1 M NaOH (0.1 ml) to the mixture of 1 mmol each of **7**, benzonitrile, and H_2O_2 in 90% MeOH (5 ml). After 1 or 19 h, 0.1 g of $NaBH_4$ was added and analyzed by GLC.

For comparison, azobisisobutyronitrile (AIBN)-initiated autoxidation of the olefin was performed under O_2 in MeCN at 60 °C for 4 h; the reaction mixture was reduced by $NaBH_4$ and MeOH, and analyzed by GLC. The results are shown in Table 4.

Reaction of KO_2 with Acetonitrile. In a dry 20 ml flask were placed benzene (2 ml), MeCN (1 ml), 0.1 M 18-crown-6 (1 ml), and DMSO (0.085 ml). The reaction was started by addition of powdered KO_2 (0.5 mmol) and stirred for 2 h at 25 °C. Products were analyzed by GLC (PEG 20 M) directly or after the reduction with $NaBH_4$ and MeOH. The remaining KO_2 was determined iodometrically after pouring the reaction mixture into AcOH–MeOH–H_2O (1:1:2). Since oxygen was evolved in each run, the recovered KO_2 is mostly unchanged. The results are listed in Table 5.

We are grateful to Professor Isao Kamiya and Dr. Keizo Aoki for their aid in the measurement of chemiluminescence.

Cyclic Carbene–Palladium(II) Complexes Derived from the Reactions of Isocyanide–Palladium(II) Complexes with Nitrilimines and Nitrilylides

Yoshio FUCHITA,* Kazuhisa HIDAKA, Shigeki MORINAGA, and Katsuma HIRAKI*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852

(Received July 16, 1980)

cis-[$PdCl_2(PPh_2R^1)(CN-C_6H_4-CH_3-p)$] ($R^1$=Ph or Et) reacts with nitrilimines or nitrilylides, derived from the reactions of either *N*-phenylarenecarbohydrazonoyl chlorides or *N*-(*p*-nitrobenzyl)arenecarboximidoyl chlorides with triethylamine, to afford novel cyclic carbene–palladium(II) complexes, *viz.* 1,2,4-triazol-5(4*H*)-ylidene- or 2-imidazolin-5-ylidenepalladium(II) ones, respectively. Halogen exchange reactions of the carbene complexes with lithium bromide or sodium iodide give the corresponding dibromo- or diiodocarbene complexes, respectively. *trans*-[$PdI_2(PPh_2-C_6H_4-CH_3-p)(CN-C_6H_4-NO_2-p)$] also reacts with the nitrilimine or the nitrilylide to produce cyclic carbene–palladium(II) complexes. All the complexes prepared in this study are characterized by elemental analysis, IR and ^{1}H-NMR.

It has been reported that coordinated isocyanide molecules undergo nucleophilic attack by alcohols and amines to yield alkoxyamino- and diamino-carbene complexes, respectively.[1-3] Recently, these carbene complexes have received considerable interest due to their important role in the catalytic formations of formimidates,[4] formamidines,[4] and heterocyclic compounds.[5] It is well known in organic chemistry that 1,3-dipolar compounds such as nitrilimines, nitrilylides, and azides react with dipolarophiles to produce various heterocycles.[6] However, hardly any work has been reported concerning the reactions between metal complexes and the 1,3-dipolar compounds except for diazo compounds.[7-9] It has been reported that tetrakis(*t*-butyl isocyanide)nickel(0) reacts with dicyanodiazomethane to afford bis(*t*-butyl isocyanide)(*N*-*t*-butyldicyanoketenimine)nickel(0),[8] and that (*t*-butyl isocyanide)nickel(0) and -palladium(0) complexes react with diazofluorene to give *N*,*N*′-coordinate complexes.[9]

It is interesting to investigate the reactions of the 1,3-dipolar compounds with isocyanide ligands coordinated to transition metals, as an extension of the 1,3-dipolar cycloaddition reaction. It has been reported from our laboratory that both the nitrilimines[10] and the nitrilylides[11] react with *cis*-dichloro(tertiary phosphine)(*p*-tolyl isocyanide)palladium(II) complexes to afford novel cyclic carbene–palladium(II) complexes. This paper deals both with the details of the reactions mentioned above and with the reactions of the nitrilimine and the nitrilylide with a palladium(II) complex containing *p*-nitrophenyl isocyanide, which increases the electrophilicity of the carbon atom linked to palladium.

Experimental

General. All the experiments were carried out in an atmosphere of dry nitrogen. IR and ^{1}H-NMR spectra, conductivities and melting points were measured according to the previous paper.[12] *N*-Phenylbenzohydrazonoyl chloride **1**,[13] *N*-(*p*-nitrobenzyl)benzimidoyl chloride **2**,[14] diphenyl-*p*-tolylphosphine,[15] and *p*-nitrophenyl isocyanide[16] were prepared according to the published methods. *N*-Phenyl-*p*-toluohydrazonoyl chloride **3** and *N*-(*p*-nitrobenzyl)-*p*-toluimidoyl chloride **4** were synthesized in the analogous way to **1** and **2**, starting from the reactions of *p*-toluoyl chloride with phenylhydrazine and *p*-nitrobenzylamine, respectively.

cis-Dichloro(triphenylphosphine)(*p*-tolyl isocyanide)palladium(II) **5**[3] and new complexes, *cis*-dichloro(ethyldiphenylphosphine)(*p*-tolyl isocyanide)palladium(II) **6**[3] and di-μ-iodo-diiodobis(diphenyl-*p*-tolylphosphine)dipalladium(II)[17] were synthesized according to the reported procedure with slight modification.

Preparation of trans-*Diiodo(diphenyl*-p-*tolylphosphine)(*p-*nitrophenyl Isocyanide)palladium(II)* **7**. *p*-Nitrophenyl isocyanide (0.78 mmol) was added to di-μ-iodo-diiodobis(diphenyl-*p*-tolylphosphine)dipalladium(II) (0.39 mmol) in dichloromethane (20 ml) and the mixture was stirred for 20 h at room temperature. After the reaction mixture had been evaporated to dryness, the residue was recrystallized twice from dichloromethane and diethyl ether to give reddish orange crystals **7**.

Yields and some properties of the new compounds, **3**, **4**, **6**, and **7** are summarized in Table 1.

Reactions of **5** *or* **6** *with* **1** *or* **3**. A benzene solution (10 ml) of triethylamine (6.5 mmol) was added to a benzene suspension (10 ml) containing **5** (0.67 mmol) and **1** (0.81 mmol). After stirring for 24 h at room temperature, the reaction mixture was filtered and the filter cake was washed with water. Recrystallization from dichloromethane and pentane gave white crystals **8a**. Yield 23%, mp 293—295 °C(dec). Complex **8b** or **8d** was also prepared in this manner from the reactions between **5** and **3**, or **6** and **3**, respectively. **8b**; yield 28%, mp 295 °C(dec): **8d**; yield 25%, mp 273 °C(dec).

Halogen-exchange Reactions of **8a** *and* **8b** *with Lithium Bromide or Sodium Iodide.* A methanol suspension containing **8a**(or **8b**) and five equivalents of lithium bromide was heated under reflux for 8 h. The resulting white solid was separated and washed with methanol to yield **9a**(or **9b**). **9a**; yield 65%, mp>300 °C: **9b**; yield 60%, mp>300 °C. The reaction between **8a** and sodium iodide was carried out in acetone in the same way as described above, and **10a** was produced: yield 70%, mp 275—280 °C(dec).

Reaction of **5** *with* **4**. To a benzene suspension (10 ml) containing **5** (1.14 mmol) and **4** (1.42 mmol) was added triethylamine (14.2 mmol) in 5 ml of benzene, and the reaction mixture was stirred for 4 d at ambient temperature. Addition of diethyl ether and pentane yielded an orange-yellow powder, which was washed with water and purified by passing through a silica gel column (200 mesh, 12ϕ×150 mm). The eluent was initially benzene/hexane (1/1) and finally acetone. Yellow eluate thus obtained was evaporated to dryness, and the residue was recrystallized from dichloromethane and diethyl ether to produce **11b**: yield 33%, mp 203—204 °C(dec).

Reactions of **6** *with* **2** *or* **4**. This reaction was carried out in the same way as described for **11b** except for omitting the chromatography technique, and **11c** or **11d** was obtained

Table 1. Yields and properties of the new compounds

from the reactions between **6** and **2**, or **6** and **4**, respectively. **11c**; yield 35%, mp 187—189 °C(dec): **11d**; yield 33%, mp 189—191 °C(dec).

*Halogen-exchange Reactions of **11c** and **11d** with Lithium Bromide.* These reactions were carried out in acetone in the analogous way as described for **9a**, and yellow crystals, **12c** and **12d** were produced. **12c**; yield 43%, mp 185—190 °C(dec): **12d**; yield 45%, mp 195—198 °C(dec).

*Reaction of **7** with **3** or **4**.* Triethylamine (5.38 mmol) in 10 ml of benzene was added to a benzene solution (10 ml) of **7** (0.45 mmol) and **3**(or **4**) (0.54 mmol), and the reaction mixture was stirred for 3 d at room temperature. After the solvent had been removed under a reduced pressure, the residue was washed with water and recrystallized twice from benzene and hexane to give yellow brown powders **13**(or **14**). **13**; yield 13%, mp 270—275 °C (dec): **14**; yield 7%, mp 208—218 °C(dec).

Results and Discussion

The 1,3-dipolar compounds, *N*-phenylarylnitrilimines and nitrilylides can be generated under an inert atmosphere by the reactions of triethylamine with the corresponding *N*-phenylarenecarbohydrazonoyl chlorides (Eq. 1) and *N*-(*p*-nitrobenzyl)arenecarboximidoyl chlorides (Eq. 2), respectively.[6]

Reactions of (*p*-tolyl isocyanide)palladium(II) complexes (**5** and **6**) with the nitrilimines and the nitrilylides in benzene at room temperature gave the white complexes **8a—d**[18] and the yellow complexes **11b—d**,[18] respectively (Scheme 1). These complexes are very stable in both air and water, and remain unchanged after more than a half year under an inert atmosphere. Elemental analysis, ^{1}H-NMR and IR spectra together with some properties of the new complexes prepared in this work are summarized in Tables 2 and 3.

The IR spectra of **8a—d** lacked the ν(C≡N) frequency observed in the starting complexes (**5**, 2200 cm^{-1}; **6**, 2190 cm^{-1} in KBr disk), and a new band appeared at 1610 cm^{-1}. This band was assigned to a ν(C=N) frequency of the 1,2,4-triazol-5(4*H*)-ylidene group, which was formed by the cycloaddition reaction of the coordinated isocyanide with nitrilimines. The presence of two ν(Pd–Cl) frequencies in **8a—d** (Table 3) is consistent with the *cis* isomer, indicating that during the addition reaction the initial configuration is retained.

As for the ^{1}H-NMR spectrum of **8d** in CD_2Cl_2, the methyl proton resonance of the phosphine moiety appeared at δ 1.01 as a double triplet due to coupling with the ^{31}P nucleus ($^3J_{PH}$=21.3 Hz, $^3J_{HH}$=8.2 Hz). On the other hand, methylene proton signal of the phosphine ligand could not be distiguished clearly owing to overlapping with the two methyl resonances at δ 2.40 and 2.56, which were derived from the isocyanide group and the nitrilimine. A lower field doublet at δ 8.88 (2H, $^3J_{HH}$=*ca.* 8 Hz) was ascribed to the *o*-protons of the *p*-tolyl group derived from the isocyanide. Possible explanations for such a low field shift can be given by an electron transfer from the *p*-tolyl group to the electron-deficient carbene carbon and/or by a close interaction of the *p*-tolyl group with the central palladium metal. Similar signals were also observed in other triazolinylidene complexes **8a** and **8b** at δ 8.60 and 8.58 ($^3J_{HH}$=*ca.* 8 Hz), respectively. As for the ^{13}C-NMR spectrum of **8b**, the carbene signal of the 1,2,4-triazol-5(4*H*)-ylidene moiety was so weak and unresolved that it could not be detected clearly.

Metathetical reactions of **8a** and **8b** with lithium bromide or sodium iodide were performed in refluxing methanol or acetone to produce corresponding dibromo derivatives **9a**, **9b**, or diiodo one **10a**. In contrast to

a) Values in KBr disk. b) Molar conductivity in 10^{-3} mol dm^{-3} solution at 25 °C. c) In acetone. d) In dichloromethane. $\Lambda_M = 91.3\ \Omega^{-1}\ cm^2\ mol^{-1}$ in 0.24×10^{-3} mol dm^{-3} methanol solution.

the moderate solubility of **8a—d** in dichloromethane, these dibromo or diiodo complexes have very low solubility in this solvent, and so ^{1}H-NMR spectra could not be obtained.

On the basis of these results and the elemental analyses, **8a—d**, **9a—b**, and **10a** are assigned to new cyclic carbene–palladium(II) complexes, which are formed by the 1,3-dipolar cycloaddition reactions of nitrilimines onto the C≡N triple bond of the coordinated isocyanide ligand.

Complexes **11b—d** were also ascribed to novel cyclic carbene–palladium(II) complexes containing a 2-imidazolin-5-ylidene group, which was formed by the reaction of nitrilylides with the ligating isocyanide in the analogous way as described for **8a—d** (Scheme 1). In the IR spectra of **11b—d**, both the ν(C=N) band at 1590 cm^{-1}, associated with the 2-imidazolin-5-ylidene group, and the $\nu(NO_2)$ band of the nitrilylide moiety were observed (Table 3). The far-IR spectra of **11b—d** showed only one broad band due to ν(Pd–Cl) frequency ranging from 261 to 272 cm^{-1}, in contrast to two bands in **8a—d**. It is known that ν(Pd–Cl) frequencies in *trans*-$[PdCl_2L_2]$ fall in the range of 357—5 cm^{-1} [19] and is almost insensitive of the ligand L. This suggests that **11b—d** have a *cis* configuration rather than a *trans* one, and broadening of the band probably comes from the partial overlapping of two bands.

As for the ^{1}H-NMR spectra of **11c** and **11d**, the ethyl resonances of the phosphine moiety were observed at rather low field in comparison with those of **8d**. This suggests that a relatively stronger electron transfer from the phosphine ligand to the carbene moiety is present in **11b—d**, Complex **11b**, whic has a weaker σ-donor ability ligand, triphenylphosphine, instead of ethyldiphenylphosphine, always contains some amounts of triethylamine, unless a column chromatography purification is performed. This triethylamine probably interacts with the electron-deficient carbene carbon and forms a weak ylidic bond. This fact also supports the deshielded ethyl resonance of the phosphine ligand. The methine proton resonance of the 2-imidazolin-5-ylidene moiety could not be distinguished because of its overlapping with phenyl signals.

Molar conductivity of **11b—d** (Table 3) exhibited rather high values in acetone and methanol attributable to the dissociation equilibria as shown in Eq. 3. However, **11c** behaved as a nonelectrolyte in dichloromethane showing a very low molar conductivity value. These facts indicate that the solvent which has coordinating ability, displaces the chloro ligand linked to palladium to afford ionic species.

$$[PdCl_2(\text{Phosphine})(\text{Carbene})] + \text{Solv.} \rightleftharpoons [PdCl(\text{Phosphine})(\text{Carbene})(\text{Solv})]^+ + Cl^- \quad (3)$$

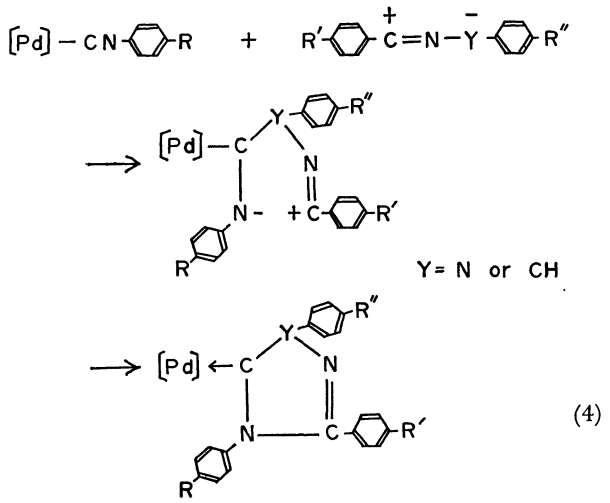
Complexes **11c** and **11d** reacted with lithium bromide in the analogous way as described for **9** to afford dibromo derivatives **12c** and **12d**, respectively. In the ^{1}H-NMR spectra of these two complexes, the splitting of the ethyl signals was not observed clearly owing to their fairly low solubility in CD_2Cl_2 or $CDCl_3$. It is not obvious whether *trans-cis* isomerization took place during the metathetical reaction or not.

A new (*p*-nitrophenyl isocyanide)palladium(II) complex **7** was synthesized from the reaction of di-μ-iododiiodobis(diphenyl-*p*-tolylphosphine)dipalladium(II) with *p*-nitrophenyl isocyanide in dichloromethane at room temperature, and reacted with the nitrilimine or the nitrilylide to produce **13** or **14**, respectively, similar to the cases of **5** and **6**. Complexes **13** and **14** contain one molecule of benzene as a solvent of crystallization (δ 7.38 in their ^{1}H-NMR).

The IR spectra of these two complexes lacked the C≡N stretching frequency at 2180 cm^{-1}, which was observed in the original complex **7**. The $\nu(NO_2)$ bands were also observed at 1490, 1320 (for **13**), and 1510, 1240 cm^{-1} (for **14**), but ν(C=N) bands were obscured owing to overlapping with the absorptions of benzene at 1590 cm^{-1}. The ^{1}H-NMR spectrum of **13** showed only one broad methyl resonance, which possibly arises from an accidental coincidence of the two methyl resonances in both the nitrilimine and the phosphine moieties. On the other hand, **14** showed two methyl resonances derived from the nitrilylide

and the phosphine ligand, but the assignment of these resonances could not be performed.

A stepwise mechanism was proposed for the reactions of ligating isocyanides with the 1,3-dipolar compounds resulting in the formation of cyclic carbene–palladium(II) complexes, analogous to the mechanism for nucleophilic attack of amine on the ligating isocyanide.[2] It may involve a nucleophilic attack of the anion of the 1,3-dipolar compound upon the isocyanide carbon to result in the formation of an amide anion. Subsequently, the ring closure took place between the amide anion and a carbonium ion of the 1,3-dipolar compound to yield the cyclic carbene complex (Eq. 4).



(4)

Another 1,3-dipolar compound, *p*-tolyl azide, reacted with **7** in refluxing benzene, but gave no isolable product. In the case of the reaction with **5**, only the starting materials were recovered.

We wish to express our gratitude to Professor Keinosuke Hamada and Mr. Hirofumi Morishita of Nagasaki University for far-IR measurements, and also to Mrs. Hisako Mazume and Miss Yumi Kojima of Nagasaki University for their technical assistance.

Silylation of Relatively Acidic Compounds with Alkyl Trimethylsilylacetates[1)]

Eiichi NAKAMURA, Koichi HASHIMOTO, and Isao KUWAJIMA*

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Recieved July 26, 1980)

Silylation of ketones, alcohols, alkanethiols, phenols, and carboxylic acids with alkyl trimethylsilylacetates has been described from synthetic and mechanistic points of view.

In a previous paper we described the reaction of silylated esters with carbonyl compounds.[2,3)] In the presence of tetrabutylammonium fluoride, rather surprisingly, silyl esters underwent desilylation to effect the transfer of the silyl group onto ketones (R-H)[4)] as in Eq. 1. Subsequent studies have shown this

$$RH + Me_3SiCH_2COOR' \xrightarrow{F^-} RSiMe_3 + CH_3COOR' \quad (1)$$

silyl transfer reaction even more versatile; a wide variety of relatively acidic compounds[5)] could also be silylated by this new reaction. The purpose of this paper is to describe the scope of the reaction from synthetic and mechanistic points of view.

The use of trialkylsilyl groups, especially trimethylsilyl group, for protection or activation of some functional groups has become one of the standard tools in organic chemistry,[6)] and a number of silylation methods (replacement of acidic protons with silyl groups) have been reported.[7)] Nonetheless, the number of the basic principles has been rather small. A large body of reactions are based on the equilibrium between a substrate and a silylating reagent with a weak Si–X bond, *e.g.* silylamine or silylamide, as shown in Eq. 2.

$$RH + MeSiX \rightleftharpoons RSiMe_3 + HX \quad (2)$$

Though this methology allows the use of mild conditions, thermodynamic factors control the selectivities of the reaction.[8)] Further the silylation reactions usually result in the production of nonvolatile by-products such as tertiary amine hydrochloride, amide, *etc.*

Quenching preformed anions with a trialkylchlorosilane constitutes another important methodology, and has a distinctive advantage in enolate chemistry;[9)] this usually allows us to trap the kinetically preffered isomer of enolate anions as its stable silyl derivatives. Rather strong reaction conditions and somewhat laborious procedures, however, generally render this method to be the second choice. As described below, the reaction of an alkyl trimethylsilylacetate, with its characteristic mechanistic pathway and applicability, has proved to provide another useful methodology for silylation of various acidic compounds.

Results and Discussion

The silylation reaction was performed in a very simple manner. Treatment of a mixture of a substrate and ethyl trimethylsilylacetate (ETSA; slight excess) with 2—5 mol% tetrabutylammonium fluoride trihydrate (TBAF) either in a dry aprotic solvent such as tetrahydrofuran (THF) or without a solvent produced the silylated product and ethyl acetate in high yields. Commercially available TBAF was the catalyst of choice because of the ease of handling and the high solubility in organic solvents. Though ETSA was used generally, the methyl ester or its higher homologues could also serve the purpose nicely. The reaction proceeded at room temperature and the product was isolated either after aqueous workup or direct distillation of the reaction mixture. The silylating ability of ETSA–TBAF system is quite high. The reaction with sterically hindered tertiary alcohols and thiols[10)] proceeded exothermically at room temperature. Even such a less acidic substrate as phenylacetylene was silylated in high yield, whereas triphenylmethane remained unchanged after prolonged reaction period. Table 1 shows the examples.

TABLE 1. SILYLATION OF RELATIVELY ACIDIC COMPOUNDS

Compound	% yield	Compound	% yield

			83[a)]

a) Bis-silylated product.

Interestingly, simple aliphatic ketones were silylated faster than more acidic compounds like phenols. This aroused our interests to examine the reaction in some detail. Thus, brief studies about the reaction rate with representative substrates were carried out. An equimolar mixture of methyl trimethylsilylacetate (MTSA) and the substrate was treated at 35 °C with a catalytic amount (1.5—3 mol%) of TBAF in an NMR sample tube, and the reaction was monitored mainly by observing the change of the relative intensities of the trimethylsilyl groups; the trimethylsilyl group of MTSA appeared consistently at a slightly higher field than that of the product. Measurements were done for 1-hexanethiol, phenylmethanethiol, *p*-cresol, propionic acid, and benzenethiol, and the results are shown in Fig. 1, where the product yields are plotted against the reaction time. Under these conditions aliphatic ketones and primary alcohols were silylated instantaneously, while triphenylmethane and benzenethiol were not silylated even after 10 d. While 100% conversion of MTSA was observed in

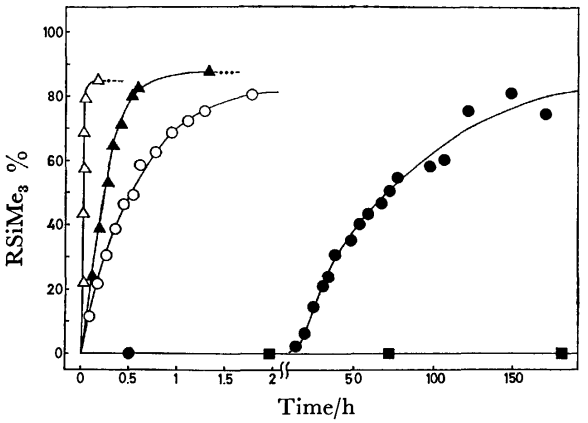

Fig. 1. Silylation of various substrates at 35 °C. △: 1-Hexanethiol (1.9 mol% TBAF), ▲: phenylmethanethiol (2.2), ○: *p*-cresol (2.6), ●: propionic acid (2.3), ■: benzenethiol (1.5).

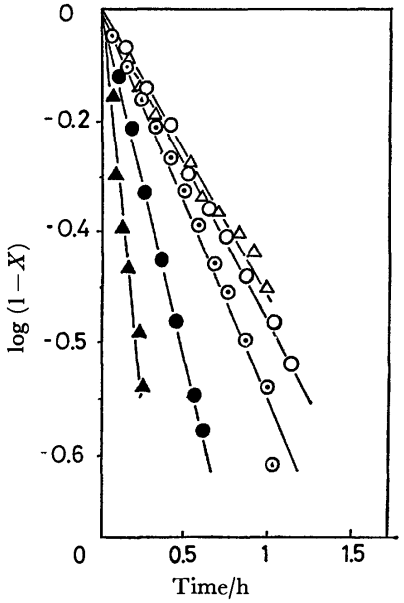

Fig. 2. Silylation of phenylmethanethiol at 35 °C. X=% yield/100, ○: 1.4 mol% TBAF, ⊙: 1.6 mol% TBAF, ●: 2.2 mol% TBAF, ▲: 3 mol% KCN-18-crown-6, △: 2.4 mol% KOMe-18-crown-6.

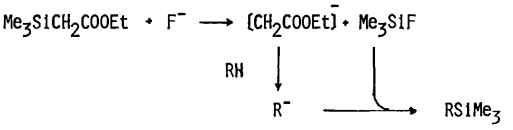
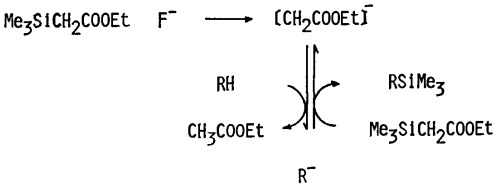
all runs in Fig. 1 except the case of benzenethiol, 10—15% of the substrate remained unchanged. The content of water in the system, *e.g.* in the catalyst, seems to account for the imcomplete conversion of the substrate. In fact, the substrate underwent 100% conversion when 20—30% excess MTSA was used.

Some efforts to rationalize the reaction rate revealed that the reactions fall into two types. The reaction of cresol followed a first order rate expression, whereas those of thiols and propionic acid (after an induction period) followed second order ones. However, this point was not pursued further because of the experimental difficulties due to the highly sensitive nature of the reaction.[11] Though a specific role of fluoride anion was previously suggested for the present silylation reaction (Scheme 1), the present studies implied another mechanism, namely, an autocatalytic



Scheme 1.



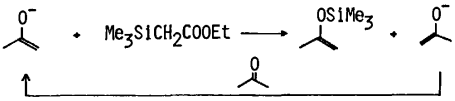
Scheme 2.

one (Scheme 2).

That fluoride is not the only effective catalyst (unlike other similar reactions[3]) was one of those implications. Treatment of a mixture of ETSA and acetophenone with a catalytic amount of KCN/18-crown-6, $KOCH_3$/18-crown-6, or Triton B effected smooth conversion of the ketone into the corresponding enol silyl ether at 0 °C. Silylation of 1-hexanethiol could also be done with those catalysts. The equal efficacy of these catalysts was further proved, in a somewhat quantitative manner, by NMR experiments in which an equimolar mixture of MTSA and phenylmethanethiol was treated with the catalysts (KCN/crown ether, $KOCH_3$/crown ether, or Triton B) as described above (Fig. 2).

In addition to this semiquantitative evidence, a qualitative but direct evidence of the autocatalytic pathway (Scheme 2) was also obtained. Thus, when a mixture of acetophenone and ETSA was treated with 10 mol% of preformed potassium enolate of this ketone solvated by 18-crown-6, quantitative silylation of the ketone occurred within 1 min at 0 °C. Similarly, 10 mol% of potassium 1-hexanethiolate and 18-crown-6 initiated the smooth reaction of 1-hexanethiol with ETSA.

In contrast to the catalytic ability of a potassium enolate/crown ether in the silylation of a ketone, this anion itself could not be silylated by MTSA or ETSA in a stoichiometric reaction. Treatment of the potassium enolate of acetophenone with one equivalent of perhydrodibenzo-18-crown-6 followed by ETSA did not yield any detectable amount of the enol silyl ether, and gave back the starting ketone in high yield. These results fit well with the proposed mechanism, since Eq. 3 involved in the overall reaction pathway does not favor the formation of the enol silyl ether unless the ester enolate on the right side is irreversibly protonated by the neutral ketone to regenerate the ketone enolate.



(3)

The reaction mechanism and the rate profiles described above suggest a certain perspective over the synthetic utility of ETSA as a silylating reagent. One apparent factor that limits the application is the acidity

Table 2. Silylation with ETSA-TBAF[a]

Substrate g (mmol)		ETSA g (mmol)	TBAF mg	Reaction period, h	Yield g (%)	Bp °C/mmHg[b]
3-Phenyl-1-propanol	1.36(10.0)	1.92(12.0)	50	2	1.91(92)	87/4[c]
2,4-Dimethyl-3-phenyl-3-pentanol	1.94(10.2)	1.93(12.1)	63	2.5	2.44(92)	110/7
p-Cresol	1.08(10.0)	1.61(11.0)[d]	83[e]	7	1.49(83)	77/12[f]
1-Hexanethiol	1.77(15.0)	2.40(15.0)	74	5	2.60(91)	62/5[g]
Phenylmethanethiol	3.16(25.5)	4.74(28.0)	228	22	4.42(88)	130/32[h]
2-Mercaptoethanol	0.78(10.0)	3.36(21.0)	87	3	1.85(83)[i]	51/4

a) Reactions were performed by a procedure similar to Method A. b) 1 mmHg = 133.322 Pa. c) *Cf.* Ref. 18. d) MTSA was used in place of ETSA. e) BTAF was used in place of TBAF. f) *Cf.* Ref. 19. g) *Cf.* Refs. 16 and 20. h) *Cf.* Ref. 21. i) The product was obtained as a bis-silylated form.

of the substrate relative to that of the alkyl acetate. This, however, does not appear significant for relatively acidic substrates reported here. Among these substrates, on the other hand, the nucleophilicity (toward silicon atom) of the conjugate base of the substrate (R^- in Scheme 1) appears to be important. Prominent decrease of the reaction rate on passing from alcohol to phenol and to acid, or from 1-hexanethiol, phenylmethanethiol, and finally to benzenethiol[12] is in accord with the decrease of the reactivity of their conjugate base. Striking difference of the rate between phenol and benzenethiol is in keeping with the known difference of the affinities of oxygen and sulfur toward silicon.

Thermodynamically controlled silylation reactions are performed under very mild conditions using silylating reagents such as silylamide,[7] whereas kinetically controlled ones have usually been conducted by using strongly basic reagents such as LDA or NaH. In the present reaction, being catalytic with the reactive species, the bulk of the reaction medium remains almost neutral, while the deprotonation takes place in an irreversible manner.

Finally, we draw attention to the absence of any nonvolatile side-products in this reaction, which may allow the use of the unpurified silylation product for further elaboration. Therefore, the present reaction will prove to be complementary to the various existing methodologies of the silylation reactions.

Experimental

All reactions were performed under either argon or nitrogen with magnetic stirring. Tetrahydrofuran (THF) was purified shortly before use by distillation over sodium-benzophenone. TBAF (Fluka AG) was used after overnight evacuation (0.5 mmHg,[13] room temperature) and kept under an inert atmosphere. BTAF was prepared from Triton B methanolic solution (Tokyo Kasei Co.) by the reported method.[3a] Alkyl trimethylsilylacetates were prepared as reported.[14] NMR spectra were taken on a Varian T-60 spectrometer, and chemical shifts are recorded in parts per million downfield from internal tetramethylsilane. IR spectra were taken on a Hitachi EPI G-3 or 260-10 spectrometer, and mass spectra on a Hitachi RMU-7M at 70 eV ionizing irradiation. Gas liquid chromatography (GLC) was performed on a Hitachi 163 instrument equipped with a 0.25 mm × 20 m glass capillary tube coated with OV-101. All boiling points are uncorrected.

Silylation of 2-Methyl-2-propanethiol (Method A). To a stirred mixture of 2-methyl-2-propanethiol (1.58 g, 17.6 mmol) and TBAF (992 mg, 0.35 mmol) at room temperature was added ETSA (2.96 g, 18.5 mmol) over a period of 2 min. The reaction was slightly exothermic. After stirring for 2 h, the orange colored reaction mixture was transferred to a distillation apparatus with exclusion of moisture, and distilled under a reduced pressure to give 2.33 g (82%) of (*t*-butylthio)trimethylsilane[15,16] as a colorless oil. Bp 92 °C/88 mmHg[13]; IR(neat): 1364, 1250, 1157, 842, and 754 cm^{-1}; NMR(neat): δ 0.30 (s, 9H) and 1.43 (s, 9H); MS: *m/e* (%) 162 (M^+, 15), 147 (5), 107 (33), 91 (85), 75 (8), 73 (61), 57 (100).

Silylation of l-Menthol (Method B). The reaction was carried out as described above by using *l*-menthol (4.43 g, 28.4 mmol) in 15 ml of THF, TBAF (72 mg, 0.3 mmol), and ETSA (4.77 g, 29.8 mmol). After the reaction was over, the reaction mixture was diluted with 100 ml of hexane, and poured into water. The organic layer was separated and washed once with aq NaCl. Drying over anhydrous $MgSO_4$ and concentration followed by distillation afforded *l*-menthyl trimethylsilyl ether (5.85 g, 92%), which was identical with the authentic sample by NMR and GLC. Bp 135 °C/68 mmHg;[13,17] MS: *m/e* (%) 228 (M^+, 3), 213 (8), 171 (5), 157 (5), 143 (100), 138 (14), 123 (6), 95 (11), 81 (20), 75 (57), 73 (40).

Trimethyl(phenylethynyl)silane. Phenylacetylene (100 mg, 1.0 mmol) and ETSA (192 mg, 1.2 mmol) were added to TBAF (13 mg, 0.05 mmol) in 2 ml of THF. After 26 h, the reaction mixture was diluted with hexane, filtered, and concentrated. Purification of the crude product on preparative TLC gave 151 mg (88%) of the title compound which was identical with the authentic sample by NMR, IR, and GLC.

3-Phenyl-1-(trimethylsiloxy)propane. The product obtained by the present method was identical with the authentic sample[18] by NMR and GLC. MS: *m/e* (%) 208 (M^+, 10), 193 (23), 175 (11), 165 (12), 147 (14), 135 (14), 118 (100), 107 (14), 91 (38), 89 (40), 75 (30), 73 (38).

2,4-Dimethyl-3-phenyl-3-(trimethylsiloxy)pentane. IR (neat): 850, 758, and 705 cm^{-1}; NMR(CCl_4): δ 0.28 (s, 9H), 0.75 (d, J=7 Hz, 3H), 0.80 (d, J=7 Hz, 3H), 1.9—2.7 (m, 2H), 7.17 (s, 5H); MS: *m/e* (%) 249 ($M^+ - 15$, 5), 221 (100), 131 (12), 75 (26), 73 (96).

1-Methyl-4-(trimethylsiloxy)benzene. The product obtained by the present method was identical with the authentic sample[19] by NMR and IR analyses.

(Hexylthio)trimethylsilane.[16,20] IR(neat): 1463, 1253, 1183, 1057, 845, 758 cm^{-1}; NMR(neat): δ 0.25 (s, 9H), 0.7—1.8 (m, 11H), 2.1—2.7 (m, 2H); MS: *m/e* 190 (M^+), 175, 91, 73; Exact mass: 190.1188. Calcd for $C_9H_{22}SSi$: 190.1212.

(Benzylthio)trimethylsilane.[21] Mass spectrum was identical with the reported one.[21] IR(neat): 1250, 840, 755, 700 cm^{-1}; NMR(neat): δ 0.17 (s, 9H), 3.54 (s, 2H), 6.95—7.45 (m, 5H); Exact mass: 196.0731. Calcd for $C_{10}H_{16}SSi$: 196.0742.

[2-(Trimethylsiloxy)ethylthio]trimethylsilane. IR(neat): 1253, 1090, 840 cm^{-1}; NMR(neat): δ 0.07 (s, 9H), 0.26 (s, 9H), 2.48 (t, J=7 Hz, 2H), 3.55 (t, J=7 Hz, 2H); MS: *m/e* (%) 222 (M^+, 1), 207 (19), 149 (100), 119 (35), 103 (31), 75 (40), 73 (47).

Trimethylsilyl Propionate. To a clear solution of BTAF (335 mg, 1.4 mmol) in propionic acid (1.48 g, 20 mmol) was added ETSA (3.84 g, 24 mmol), and the resulting mixture was kept at room temperature for 10 d while crystalline material separated. NMR and IR analyses of the crude reaction mixture indicated nearly complete conversion of the reactants (especially no hydroxylic absorption on IR spectrum). Distillation of the reaction mixture gave 3.08 g of forerun as a 1:1 mixture of ethyl acetate and the title compound, and 1.37 g of the title ester as a fraction boiling at 105—115 °C (lit,[22] bp 122 °C). NMR and GLC analyses of the main fraction indicated the presence of ethyl acetate (11%) and hexamethyldisiloxane (5%) as impurities. The NMR spectrum was identical with the authentic sample except for the impurities, and coinjection on GLC also supported the assignment. Typical retention times of GLC (90 °C) were 3.0, 3.4, and 5.5 min for ethyl acetate, hexamethyldisiloxane, and the title ester, respectively.

Measurement of the Reaction Rates. To preweighed TBAF in an NMR tube under argon kept at −78 °C was added an equimolar mixture of MTSA and the substrate. The tube was sealed and brought to 35 °C and inserted to NMR probe (35 °C). The progress of the reaction was monitored mainly by observing trimethylsilyl groups.

Silylation of Acetophenone in the Presence of Various Catalysts. *a) KCN/18-crown-6 Catalysis*: To a mixture of the title ketone (120 mg, 1.0 mmol) and KCN/perhydrodibenzo-18-crown-6[23] (22 mg, 0.05 mmol) in 2 ml of THF under nitrogen was added ETSA (177 mg, 1.1 mmol) at 0 °C. TLC of the reaction mixture after 10 min showed virtually 100% conversion of the ketone to the corresponding silyl ether. Workup according to Method B gave the crude enol silyl ether (200 mg, 100%) whose NMR spectrum was identical with the authentic one.

b) $KOCH_3$/18-crown-6 Catalysis: The same procedure as described in a) except for the catalyst ($KOCH_3$/perhydrodibenzo-18-crown-6, 22 mg) gave the expected silyl ether in 98% yield (NMR).

c) Triton B Catalysis: To a mixture of acetophenone (2.40 g, 20 mmol) and ETSA (3.84 g, 24 mmol) under nitrogen was added 2 drops of Triton B (40% in methanol) at room temperature. Exothermic reaction occurred, and TLC after 30 min showed complete conversion of the ketone to the enol silyl ether. The crude reaction mixture obtained according to Method B consisted of the enol silyl ether (99%) and the starting ketone (1%).

d) Enolate Catalysis: To a suspension of oil-free KH (1 mmol) and perhydrodibenzo-18-crown-6 (372 mg, 1.0 mmol) in 10 ml of THF was added acetophenone (128 mg, 1.0 mmol) at 20 °C.[24] A Mixture of acetophenone (1.20 g, 10 mmol) and ETSA (1.60 g, 10 mmol) in 2 ml of THF was added to the enolate solution at 0 °C. TLC after 1 min indicated high yield formation of the silyl ether. Workup by Method B gave a mixture of the enol silyl ether (8.1 mmol) and the starting ketone (1.5 mmol) as judged by NMR analysis using 1,1,2,2-tetrachloroethane as an internal standard.

Autocatalytic Silylation of 1-Hexanethiol. 1-Hexanethiol (118 mg, 1.0 mmol) was added to a mixture of oil-free KH (1 mmol) and perhydrodibenzo-18-crown-6 (372 mg, 1.0 mmol) in 8 ml of THF. To the resulting white solution was added a mixture of 1-hexanethiol (1.18 g, 10 mmol) and ETSA (1.60 g, 10 mmol) at −3 °C, and the mixture was stirred for 1 h at 0 °C. NMR of the reaction mixture indicated the formation of the expected silyl sulfide. Workup of the reaction mixture by Method A gave the silyl sulfide in 68% yield (1.30 g) on distillation.

Formation and Molecular Dynamics of Cycloamylose Inclusion Complexes with Phenylalanine

Yoshio INOUE* and Yoshiaki MIYATA

Department of Polymer Chemistry, Tokyo Institute of Technology, O-okayama 2-12-1, Meguro-ku, Tokyo 152

(Received August 4, 1980)

The molecular dynamics of the inclusion complexes of cycloamyloses with phenylalanine in aqueous solution at different pD have been studied by means of carbon-13 NMR spectroscopy. As host cycloamyloses we have chosen cyclohexaamylose, cycloheptaamylose, and cyclooctaamylose. The influences of the cavity size of cycloamyloses and of medium pD values on the molecular dynamics of inclusion complexes were studied by using the $NT_1\eta$ values, where T_1 is the carbon-13 spin-lattice relaxation time, N is the number of directly bonded proton to a given carbon, and η is the viscosity of solution. Upon complexation, the $NT_1\eta$ values of phenyl carbons of guest phenylalanine show larger decreases than those of other carbons, indicating that the guest forms the inclusion complexes with the host by the insertion of its phenyl ring into the host cavity even in the case of cyclooctaamylose. It was found that the strength of the dynamic coupling between host and guest depends on the cavity size and pD values of medium. The strongest coupling was observed for the cycloheptaamylose–phenylalanine system at pD 11.3, where the phenyl ring is deeply and tightly included into the cavity. The inclusion of phenyl ring is shallow and loose in the case of cyclohexaamylose and deep and loose in the case of cyclooctaamylose.

The cycloamyloses, well known as cyclodextrins, are a series of cyclic oligosaccharides containing six and more α-1,4-linked D-glucopyranose units. Cycloamylose has the shape of a hollow truncated cone with primary and secondary hydroxyl groups crowning opposite ends of its torus. The CH groups of carbon 3 and 5 of each glucose unit compose the inside of the hollow torus. Thus the inside and the outside of the cycloamylose cavity should be relatively hydrophobic and hydrophilic, respectively. One of the most interesting properties of cycloamyloses are their ability to make a inclusion complex with a variety of guest molecules in their hydrophobic cavity in solution as well as in the solid state, and in some cases they catalyze the reaction of the guest molecule.[1] Because of this property, the cycloamyloses are attractive for many investigators as enzyme recognition and active site models. In particular, cycloamyloses are adequate models for hydrolytic enzyme such as esterase and protease in which the hydroxyl group of a catalytic serine residue attacks the acyl group of a bound substrate.[1,2] It is well known that a typical serine protease chymotrypsin selectively cleaves peptide bonds on the carboxyl side of residues with aromatic side chains and of bulky hydrophobic residues. In these enzymatic reaction, aromatic and bulky nonpolar side chains of substrates are considered to be fitted neatly into a nonpolar pocket on chymotrypsin chain.

It is of great interest to investigate the molecular dynamics of inclusion complexes between cycloamylose and aromatic amino acids as models for enzyme-substrate specific binding. Determination of the geometry of the cycloamylose–substrate complexes as well as the tightness of complexation is essential for a right understanding of the mechanism of enzymatic catalysis of the cycloamylose.

Because of the symmetry of the cycloamyloses and the simplicities of amino acid structures, their carbon-13 nuclear magnetic resonance (^{13}C-NMR) spectra are very simple to analyze. The measurements of carbon-13 spin-lattice relaxation times (T_1) are particularly useful for the investigation of molecular dynamics of cycloamylose inclusion complexes in detail. In a preceding paper,[3] the molecular motions of both host and guest molecules in the inclusion complexes of cyclohexaamylose (α-cyclodextrin, α-CD) with L-phenylalanine (Phe), L-tyrosine, L-tryptophan, glycyl-L-phenylalanine, and L-phenylalanyl-L-lysine in acidic solution have been studied by means of carbon-13 spin-lattice relaxation. It was confirmed there that the complexation of the guest amino acids with the host α-CD are induced by an insertion of aromatic side chain into a cavity of α-CD. The overall correlation times of the substrates are about one third to one seventh shorter than those of the host molecule. It suggests the binding force between the host and the guest is relatively weak and the aromatic ring is shallowly trapped into the cavity. The shallowness of the insertion is also suggested by building a space-filling model in which the diameter of α-CD's cavity is too small for a deep insertion of phenyl ring. Thus the shape matching between the host cavity and the substrate is one of the important factors determining the strong dynamic coupling between host and substrate.

In this paper, we will study the influences of cavity size of the cycloamylose and of pH value of medium on the molecular dynamics of cycloamylose inclusion complexes with L-phenylalanine. As host cycloamyloses we will choose cyclohexaamylose (α-CD), cycloheptaamylose (β-CD), and cyclooctaamylose (γ-CD). Their internal diameters are *ca.* 4.5, 7.0, and 8.5×10^{-10} m, respectively.[1] Molecular model suggests that β-CD makes the most stable and the dynamically strongest inclusion complex with the guest phenylalanine among these cycloamyloses because of its best fitting geometry. The diameter of phenyl ring including the van der Waals radii of proton is about 6.8×10^{-10} m. The cavity sizes of α- and γ-CD may be slightly smaller and larger, respectively, for the fitted complexation with the guest phenylalanine. Since the cycloamylose has the ionizable secondary hydroxyl groups (pK= 12.1[4,5]) on the entrance region for the guest insertion, it is interesting to study the pH dependence of the molecular dynamics of the inclusion complexes between the cycloamyloses and the substrates with ionic

groups such as amino acids. In this paper, carbon-13 spin-lattice relaxation times will be measured in acidic (pD=2), phosphate buffer (pD=11), and highly alkaline (1 mol dm^{-3} NaOD) solutions.

Experimental

Materials. Cyclohexa-, cyclohepta-, and cycloocta-amyloses, D-glucose, and L-phenylalanine were purchased from Nakarai Chemicals, Ltd., Kyoto. The values of specific rotation $[\alpha]_D^{25}$ of α-, β-, and γ-CD's were +149.9, +161.9, and +177.2, respectively, which agreed well with previously reported values (*i.e.*, +150.5±0.5, +162.5±0.5, and +177.4±0.5).[1,6] D_2O (isotopic purity 99.7 atom%), 38% DCl solution in D_2O, 40% NaOD solution in D_2O, and 85% D_3PO_4 solution in D_2O were purchased from Merck Sharp and Dohme Canada Ltd..

Methods. ^{13}C-NMR spectra were measured on a JEOL JNM PS-100 spectrometer (25 MHz) equipped with a PFT-100 Fourier transform system and proton noise decoupler. Data were accumulated in a JEOL JEC-6 computer and JEOL CM-219 IC core memory (8 K) using 4000 Hz sweep widths in 4096 points. ^{13}C spin-lattice relaxation times (^{13}C-T_1) were measured by the inversion-recovery method using a 180°-t-90° pulse sequence, where t is time in seconds between the 180° and 90° pulses. The 90° pulse recycle times were chosen to be at least five times longer than the longest ^{13}C-T_1 to be measured. The estimated error in T_1 was less than ±10%. Unless otherwise specified, the molar concentrations of cycloamyloses were 1.2 times larger than those of phenylalanine to measure the relaxation times of phenylalanine and *vice versa* to measure the relaxation times of cycloamyloses.

The buffer solutions were made up with 85% D_3PO_4, 40% NaOD, and solute phenylalanine in D_2O and the final pD value was 11.3±0.1 and the ionic strength was about 0.5. The acidic solutions were prepared with 38% DCl in D_2O and they were adjusted to be pD 2.0. The 1 mol dm^{-3} NaOD solutions were prepared with 40% NaOD. The pH values were read on a pH-meter Toko Model TP-101 with a micro combination electrode CE103, which enabled the measurement of pH value of solution contained in a NMR sample tube. The pD value was obtained by adding 0.4 to the pH-meter reading for the correction of isotope effect.[7]

The macroscopic viscosities of the solutions used in the ^{13}C relaxation experiments were measured using a Cannon-Finske viscometer. The values of viscosity η were calculated from the formula $\eta=B t\rho$, where B is the calibration constant for viscometer, t is the efflux time between the two predetermined marks, and ρ is the density of the solution. The constant B was determined by using extremely pure water and the η value of water reported in literature.[8]

Ultraviolet absorption (UV) spectra were measured on a Beckman-25 spectrometer.

The temperature was kept at 34±1 °C for all experiments.

Results

Carbon-13 Chemical Shifts. All peaks appeared in the ^{13}C-NMR spectra of both cycloamyloses and phenylalanine have been assigned previously.[3] Among three cycloamyloses, any conspicuous differences in spectral pattern were not observed. As found previously, the spectra of each cycloamylose–phenylalanine system consists of only one set of peaks, indicating that only one type of complexation occurs and/or the chemical exchange of Eq. 1 is rapid process compared with the ^{13}C-NMR time scale,

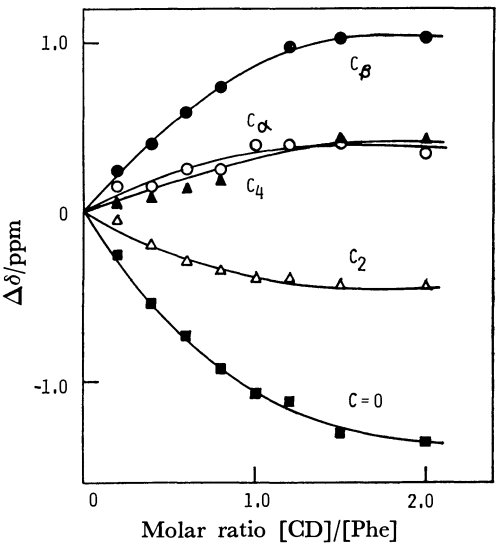

Fig. 1. ^{13}C chemical shifts displacements $\Delta\delta$ of phenylalanine carbons upon addition of β-CD in 1 mol dm^{-3} NaOD solutions as a function of molar ratio [β-CD]/[Phe].

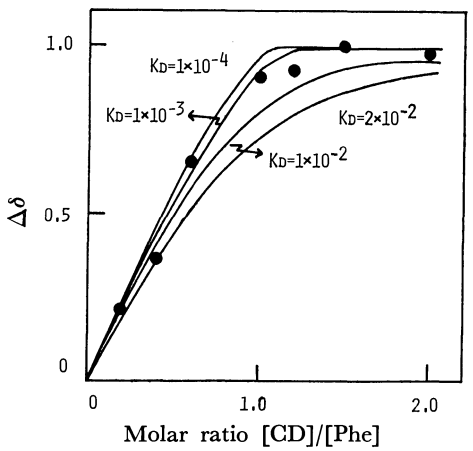

Fig. 2. Theoretically calculated binding curves for a simple CD+Phe⇄[CD,Phe] equilibrium with different dissociation constants K_d. Observed ^{13}C chemical shifts displacements shown in Fig. 1 are normalized and plotted (●).

$$CD + S \rightleftharpoons [CD, S], \quad (1)$$

where CD, S, and [CD, S] are host cycloamylose, guest (substrate) phenylalanine, and cycloamylose–phenylalanine complex, respectively.

Complexation induced small ^{13}C chemical shifts of cycloamyloses and phenylalanine because ^{13}C-NMR is not so much sensitive to perturbation through space as ^{1}H-NMR. By an addition of β-CD in alkaline solution, the resonances of phenylalanine showed exceptionally large shifts, although it is not easy to interpret the magnitudes and the directions of the shifts. Figure 1 shows the chemical shift displacements of phenylalanine carbons upon addition of β-CD in 1 mol dm^{-3} NaOD solutions. No substantial changes in

chemical shifts occur above molar ratio R=[CD]/[Phe] larger than unity, indicating a formation of a 1:1 complex. From this figure, it is possible to determine the value of dissociation constant K_d (reciprocal of the association constant K_a) for cycloamylose–phenylalanine complex by assuming the 1:1 complexation and by using a modified Hildebrand-Benesi equations.[9,10]

Figure 2 shows theoretically calculated binding curves for a simple CD+S⇄[CD,S] equilibrium with different dissociation constants. They realized by the plot of normalized ^{13}C chemical shift changes $\Delta\delta$ against molar ratios [CD]/[Phe]. In Fig. 2 the experimental $\Delta\delta$ corresponding to cycloheptaamylose–phenylalanine system in 1 mol dm^{-3} NaOD solutions were also included. The dissociation constant K_d for this system was estimated to be approximately 10^{-3} M ($K_a=10^3$ M^{-1}:1 M=1 mol dm^{-3}), which was comparable with K_d values of about 3×10^{-3} M for phenylalanine–cyclohexaamylose[3] and –cyclooctaamylose complexes in acidic solutions at pD 2 measured using UV spectral changes.[3,11]

Carbon-13 Spin-Lattice Relaxation Times. In Table 1 are given the values of ^{13}C spin-lattice relaxation times measured for free cycloamyloses, free phenylalanine, and cycloamylose–phenylalanine complexes.

In the limit of rapid exchange process of Eq. 1, one measures an average relaxation rate $(1/T_1)$[12]

$$1/T_1 = P_f\frac{1}{T_{1f}} + P_c\frac{1}{T_{1c}}, \qquad (2)$$

where T_{1f} and T_{1c} are intramolecular spin-lattice

relaxation times for a ^{13}C spin at the free and complexed states, and P_f and P_c ($P_f+P_c=1$) are the probabilities that cycloamyloses or the substrates are found in the free and complexed states, respectively. For the reaction (1), the values P_c and P_f can be determined from the association constant.[3] For example, if K_a is 2×10^2 M^{-1} and molar ratio [CD]/[S] is 1.2, the substrate of about 99% exists in the complexed state. In our experimental condition, the values of K_a were larger than 10^2 M^{-1} and the molar concentrations of the cycloamyloses were 1.2 times larger than those of phenylalanine to measure the relaxation times of phenylalanine and *vice versa* to measure the relaxation times of cycloamyloses. Thus we can conclude that the T_1 values observed in the cycloamylose–phenylalanine mixtures are exclusively those of the complexed states. From the T_1 values in Table 1 we shall analyze the molecular motions and discuss the dynamical properties of cycloamylose–phenylalanine complexes.

The Models of Molecular Motion to Describe the Observed T_1 Values. For rapidly rotating molecules with medium size, the ^{13}C relaxation mechanism of the protonated carbon nucleus seems to be governed by ^{13}C-^1H dipole-dipole interaction.[12] In this case, ^{13}C-T_1 for the isotropically reorienting molecule is given by

$$1/NT_1 = \hbar^2\gamma_C^2\gamma_H^2 r_{CH}^{-6}\tau_{eff}, \quad (3)$$

where τ_{eff} is the effective correlation time for overall molecular reorientation, r_{CH} is the carbon-hydrogen bond length, γ_H and γ_C are the gyromagnetic ratios of ^1H and ^{13}C nuclei, and N is the number of directly bonded proton.

According to the Brownian diffusion model,[13] τ_{eff} can be related to the isotropic rotational diffusion constant D by the manner of

$$\tau_{eff} = 1/6D = \frac{8\pi\eta f_r r_o^3}{6kT} = \frac{V_m\eta f_r}{kT}, \quad (4)$$

where k is Boltzmann's constant, T is the absolute temperature, η is the viscosity of the solution in poise (1P=0.1 Pas), r_o is the radius of spherical solute molecule, V_m is the molecular volume $V_m=4/3\pi r_o^3$, and f_r is a microviscosity factor.

For anisotropic molecular motion two or more correlation times must be introduced to interpret the observed T_1 value and τ_{eff} represents a weight average of various correlation times. In general, lengthy procedure is required to construct a model of anisotropic molecular motion. In the case of a rigid ellipsoidal molecule, molecular motions are characterized by two rotational diffusion constants,[13,14] *i.e.*, the diffusion constant for rotation about the symmetry axis, D_a, and that for rotation about any axis perpendicular to the symmetry axis, D_b. For a rigid ellipsoidal molecule in which the C–H internuclear vector makes an angle θ with the symmetry axis, τ_{eff} is defined as a function of angle θ, viscosity η, diffusion constants D_a and D_b, and the lengths of the ellipse semiaxes.[14]

For the group undergoing an additional internal motion as well as isotropic overall molecular reorientation such as phenyl group of phenylalanine,[3] the NT_1 value of a protonated carbon with N directly bonded hydrogens is given by[12,15]

$$\frac{1}{NT_1} = \frac{\hbar^2\gamma_C^2\gamma_H^2}{r_{CH}^6}\tau_{eff}\left[A+B\frac{6\tau_G}{6\tau_G+\tau_{eff}}+C\frac{3\tau_G}{3\tau_G+2\tau_{eff}}\right], \quad (5)$$

where τ_G is the correlation time for internal motion and $A=1/4\ (3\cos^2\theta-1)^2$, $B=3\sin^2\theta\cos^2\theta$, $C=3/4\sin^4\theta$, and θ is the angle between the C–H vector and the axis of internal rotation.

From these discussions, it is clear that the NT_1 value depends on the viscosity of solution, molecular shape and size of rotor, and that the greater the NT_1 value, the more mobile is the ^{13}C moiety and the additional internal rotation faster than the overall one makes the NT_1 value lengthen.

Here we examine the viscosity dependences of ^{13}C-T_1 values. According to model predictions, $NT_1\eta$ values for a specified ^{13}C nuclei must be constant. As seen from Table 2, the expected constancy of $NT_1\eta$ values were certainly observed for phenylalanine in 1 M NaOD aqueous solutions, where the solution viscosities were controlled by adding various amounts of D-glucose. Thus the macroscopic viscosities (macroviscosities[16]) of these solutions, in which there are no specific interaction among solute phenylalanine,

a) Here, T_1 is the spin-lattice relaxation time, N is the number of protons attached to the carbon, and η is the solution viscosity. The $NT_1\eta$ values correspond to the underlined species. The corresponding NT_1 values are given in Table 1. See the footnotes of Table 1, also. b) The mean values of $T_1\eta$ for C_{1-5}.

glucose, and solvent water, could be related to the observed T_1 behavior. We have shown in the previous paper[3] that the isotropic diffusion model expressed by Eqs. 3 and 4 was applicable to analyses of the overall molecular reorientation of both free α-CD and aromatic amino acids in acidic aqueous solutions.

In this paper we shall adopt the value of $NT_1\eta$ to investigate the complexation effect on the molecular motions. The $NT_1\eta$ values were tabulated in Table 3 with the viscosities. As shown in Table 1, for cycloamyloses in the free and the complexed states, the T_1 values for the pyranose ring carbons C_{1-5} are equal within experimental error in each system, indicating the absence of specific fast internal motion. Thus the mean value $\langle NT_1\eta\rangle_{1-5}$ could be used to discuss the overall motion of cycloamyloses. It is noticeable that α-, β-, and γ-CD in the free states have nearly the same $\langle NT_1\eta\rangle_{1-5}$ values. These results contradict to the model prediction of Eqs. 3 and 4, which stand for the inverse dependence of ^{13}C-T_1 value on molecular volume V_m. The lack of inverse correlation between ^{13}C-T_1 and V_m have been found for several molecules with higher molecular weight in which the various local motions such as segmental motions (localized motion along a backbone of a chain molecule) play a predominant role in ^{13}C relaxation.[17,18] The $\langle NT_1\eta\rangle_{1-5}$ values of cycloamyloses may be looked upon as standing for the measures of segmental motions.

In the case of phenylalanine, the axis of rotation of the phenyl ring about C_β–C_γ bond is identical with the C_ζ–H bond. Therefore, the rotation about C_β–C_γ bond cannot affect the T_1 values of C_ζ, since $\theta=0°$ and Eq. 5 is reduced to Eq. 3. Thus we can estimate the contribution of phenyl ring rotation to the T_1 values of ring carbons by comparing the T_1 values of $C_{\delta,\varepsilon}$ and C_ζ.[19,20] The $NT_1\eta$ values show the existence of rapid internal rotation of the primary alcohol group of cycloamyloses and the phenyl group of phenylalanine even in the complexed states. The $NT_1\eta$ values of free phenylalanine are not constant but increase greatly with pD values of solutions. According to model prediction, these pD dependences reflect the changes in apparent molecular volume of phenylalanine probably due to the pD depending changes in solvation states of charged groups. If the dynamic coupling between solute and solvent is strong, it is necessary to increase to molecular volume of the solute with that of strongly bound solvent molecules in order for it to fit the theoretical prediction.

We will discuss the complexation effect on the molecular motion of phenylalanine at different pD by comparing $NT_1\eta$ ratios between free and complexed states at same pD.

Discussion

Effect of Complexation on the Molecular Motion of Cycloamyloses and Phenylalanine. As can be seen in Table 3, all the $NT_1\eta$ values for phenylalanine greatly decrease by complexation with cycloamyloses, while those for cycloamyloses decrease slightly or remain unchanged. The reductions of the $NT_1\eta$ values are explainable with a term of the increase in apparent molecular volume by complexation as expected from Eqs. 3 and 4. Since the molecular volumes of cycloamyloses are six to nine times larger than that of phenylalanine, the change in molecular dimension induced by complexation is relatively small for cycloamyloses and relatively large for phenylalanine, namely the reductions in $NT_1\eta$ values of the former are smaller than the latter.

For the substrate phenylalanine, the greater the dynamic coupling with the host cycloamyloses, the greater is the increase in apparent molecular volume of phenylalanine. Thus the degree of $NT_1\eta$ reduction may be used as the measure of the strength of dynamic coupling of phenylalanine with cycloamyloses. In Table 4, it is shown the ratios of $NT_1\eta$ values of the complexed to the free states of phenylalanine. It is noticeable that the $NT_1\eta$ values of phenyl carbons show larger changes by complexation than those of other carbons indicating the larger slowing down of the internal rotation of the phenyl ring than that of the overall reorientation. These results are clearly showing the formation of the inclusion complexes of the guest phenylalanine with the host cycloamyloses by an insertion of the phenyl ring into the cavity of cycloamylose even in the case of γ-CD. The results that the NT_1 values of C_δ and C_ε in phenyl ring agree well with each other and they are always larger than those of C_ζ indicate that cycloamyloses favor the axial inclusion in which the internal rotation axis C_γ–C_ζ of the phenyl ring is parrallel to the axis of the cycloamylose cavity.

TABLE 4. VALUES OF $NT_1\eta$[a] RATIOS OF THE COMPLEXED STATES TO FREE STATES OF PHENYLALANINE

a) Here, T_1 is the spin-lattice relaxation time, N is the number of protons attached to the carbon, and η is the solution viscosity. The corresponding $NT_1\eta$ values are given in Table 3. See the footnotes of Table 1, also. b) The mean values of $NT_1\eta$ for C_δ and C_ε were used.

Effects of Cavity Size of Cycloamyloses and Medium pD on Complexation. As can be seen in Table 4, the phenyl $NT_1\eta$ values of phenylalanine suffer the largest reduction by complexation with β-CD. In these systems, the C_α- and C_β-$T_1\eta$ values also suffer the largest reductions. On the other hand, the phenyl $NT_1\eta$ values show the comparable reductions by complexation with α-CD and with γ-CD. These findings are observed in spite of the medium pD values, and can be explained with a term of the cavity size effect on complexation. According to the space-filling models, β-CD has the best fitting cavity size for the complete and tight inclusion of phenyl ring. The molecular model also suggests that the complete inclusion of the phenyl ring of phenylalanine into the α-CD cavity is sterically unfavorable and the extent of inclusion is shallow. On the contrary, γ-CD has enough cavity size for deep and loose inclusion of phenyl ring. As the results, the substrate phenylalanine is more strongly fixed in β-CD cavity and rather loosely in α- and γ-CD cavities. The shallow and deep inclusions of the phenyl ring into the cavities of α-CD and γ-CD, respectively, are also suggested by the reductions of $NT_1\eta$ values of C_β (Table 4), *i.e.*, those in [γ-CD, Phe] systems are larger than those in [α-CD, Phe] systems. The deep insertion of the phenyl ring obstructs a rotational motion of C_β around the C_α–C_β and C_β–C_γ bonds due to an increase in steric hindrance.

Several mechanisms have been proposed for the formation of cycloamylose inclusion complexes,[21-24] but the forces leading the complexation are still unclear and a matter of speculation.[1,23] Among the proposed mechanisms, hydrophobic interaction seems to be the most probable as the driving force for cycloamylose–phenylalanine complexation investigated here. In this case, the presence of additional interactions will be alter the strength of dynamic coupling between cycloamylose and phenylalanine. The pD dependences of $NT_1\eta$ values of phenylalanine must be analysed by taking into account of at least three additional factors, *i.e.*, hydrogen bonding, electrostatic interactions between host cycloamylose and guest phenylalanine, and solvation of charged groups.[25]

Since the complexation geometry which disturbs a solvation of the protonated amino group (pK 1.8) or the carboxylate anion (pK 9.24) of phenylalanine is energetically unpreferable, the inclusions of these groups into the cavity of cycloamylose are excluded. It is noticeable that the $NT_1\eta$ values of phenylalanine show the largest complexation-induced reductions at pD 11.3. Especially the reductions of C_α-$NT_1\eta$ values in three phenylalanine–cycloamylose systems at pD 11.3 are pronounced as compared with those at other pD values. These results suggest the existence of the hydrogen bond between the peripheral secondary hydroxyl groups and the amino and carboxyl (carboxylate) groups of phenylalanine. The reduction of C_α motion of phenylalanine may be due to the anchoring effect of the hydrogen bond at the chain end.[25,26]

In 1 mol dm^{-3} NaOD solutions, secondary hydroxyl groups of cycloamyloses (pK 12.0) are dissociated and

they interact repulsively with carboxylate anion of phenylalanine. These interactions reduce the strength of complexation and are explaining the reason why the reductions of $NT_1\eta$ values in 1 mol dm^{-3} NaOD solution are smaller than those in buffer solution. It is not clear at present that the $NT_1\eta$ values of phenylalanine show the smallest reductions at pD 2. More informations, especially about the solvation states, are required for the definitive explanation.

Conclusion

The cycloamylose inclusion complexes with phenylalanine show some characteristics like general peculiarities of enzyme–substrate complex. The host cycloamyloses have the hydrophobic cavity leading to specific binding of guest. The hydrophobic interaction seems to be the most probable as the driving force for the complexation of cycloamylose with phenylalanine. For these systems, the shape matching between the host cavity and the guest inserting group is one of the factors determining the strong coupling between them. It was found that the strength of the dynamic coupling depends on the cavity size of cycloamylose and pD value of solution. The strongest coupling was observed for the β-CD–phenylalanine system in phosphate buffer solution at pD 11.3, where the phenyl ring of guest is deeply and tightly included into the cavity. The inclusion of phenyl ring into the cavity is shallow and loose in the case of α-CD and is deep and loose in the case of γ-CD. The dynamic coupling is strengthened by the hydrogen bonding between the secondary hydroxyl groups of cycloamylose and the amino and carboxyl groups of phenylalanine, and is weakened by the repulsive interaction between alkoxyl anion of cycloamylose and carboxylate anion of phenylalanine. It is noteworthy that, even in the tightly coupled [β-CD, Phe] system in phosphate buffer, the $NT_1\eta$ values of phenylalanine are about four times larger than the $<NT_1\eta>_{1-5}$ values of cycloamylose and phenyl ring rotate rapidly in the cavity. Thus the dynamic coupling of phenylalanine and cycloamylose is weak and they have extensive independency of molecular motions. The characterizations of cycloamylose complexation by molecular dynamics as well as thermodynamics should offer useful informations for an application of cycloamyloses in various fields.

Finally we should refer to the validity of assignment η appeared in Eq. 4 to the solution macroviscosity. It is known that in some cases the macroviscosities of solutions are not related to the observed ^{13}C-T_1 behavior.[16] For these cases the microviscosities as defined by the various local molecular motions and local molecular interactions should be used as the values of viscosity η. Thus the alternative explanations are possible for the causes of the changes in $NT_1\eta$ values of phenylalanine carbons induced by complexation; in the first one the macroviscosity is used as the η value and the changes in $NT_1\eta$ values are attributed to those in apparent molecular volume; in another the molecular volume is looked upon as constant and the changes are attributed to those in microviscosities. In this paper we discussed the changes in $NT_1\eta$ values based on the first one, because we have no mean to measure the microviscosity. Since the NT_1 values of phenylalanine in the free states at constant pD value were inversely proportional to the macroviscosity as expected from the diffusion model, we can safely discuss the complexation effects on the molecular motions based on the first explanation.

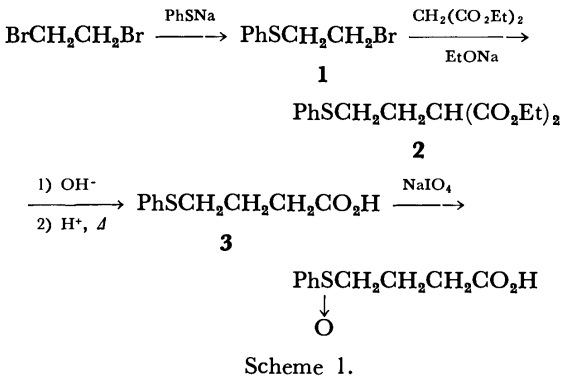
(Received August 6, 1980)

The Pummerer rearrangement reaction of 2- or 3-substituted 4-(phenylsulfinyl)butyric acids in the presence of an excess amount of acetic anhydride and a catalytic amount of *p*-toluenesulfonic acid in refluxing toluene for 1 h afforded 2- or 3-substituted 4-phenylthio-4-butanolide (**17a—f**). Thermolysis in pyridine of 4-phenylsulfinyl 4-butanolides, which were prepared by oxidation of **17a—f**, afforded 2- or 3-substituted 2- or 3-buten-4-olides.

The Pummerer rearrangement reaction is an important reaction in the sulfoxide chemistry because of its wide applicability to the synthesis of many types of organic compounds. However, only few instances have been reported of applications of this rearrangement to a cyclization reaction. Numata and Oae reported that *o*-carboxyphenyl alkyl sulfoxide was cyclized easily by the pummerer reaction to give 3,1-benzoxathiin-4-one.[1] In our earlier studies, we showed that 2- or 3-phenylthio-4-butanolide derivatives could be used for the synthesis of 3- or 2-substituted 2-buten-4-olides.[2,3] In this paper, we wish to report a new synthetic route to 2- or 3-substituted 4-phenylthio-4-butanolides (**17a—f**) from 2- or 3-substituted 4-(phenylsulfinyl)butyric acids (**9a—f**); this route involves the Pummerer rearrangement in the cyclization step. We also investigated the dehydrosulfenylation reaction of **17a—f** to form 2- or 3-buten-4-olides.

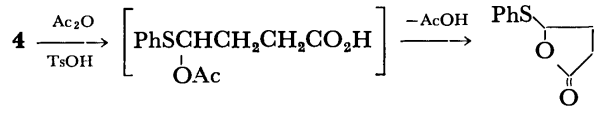
Results and Discussion

Synthesis of 4-(Phenylsulfinyl)butyric Acid (4) and Cyclization Reaction of 4 to Form 4-Phenylthio-4-butanolide (6). Preparation of 4-(phenylsulfinyl)butyric acid was carried out by the usual oxidation of 4-(phenylthio)-butyric acid, which had been synthesized by the method of Lamdan and Albarracin[4] (see Scheme 1).



Scheme 1.

It was found that when **4** was allowed to react with acetic anhydride in the presence of *p*-toluenesulfonic acid in refluxing toluene for 1 h, 4-phenylthio-4-butanolide (**6**) was obtained in 75% yield. This reaction involves an intramolecular ester exchange reaction of intermediate (**5**) which was formed by the Pummerer rearrangement of **4**.



5 **6**

When the reaction was carried out in the absence of *p*-toluenesulfonic acid, starting material **4** was recovered completely. The investigation of other acid catalysts, such as phosphoric acid and chloroacetic acid, did not give good results. In this reaction, benzene and xylene were also examined as solvents, but **6** was obtained only in lower yields (see Table 1).

Preparation of 2- or 3-Substituted 4-Phenylthio-4-butanolides. The reaction sequence for the preparation of 2- or 3-substituted 4-phenylthio-4-butanolides (**17a—f**) is shown in Scheme 2.

The alkylation of **2** by alkyl halides such as methyl iodide, butyl bromide or allyl bromide were carried out in the usual way to give diethyl 2-alkyl-2-(2-phenylthioethyl)malonates (**7a—c, 7g**) in 66—89% yields (see Table 2). However, for the synthesis of **7a—c** and **7g**, when the reaction of alkyl halide with diethyl malonate was carried out as the first step and the resulting alkylated diethyl malonate was allowed to react with **1**, the yields of **7a—c** and **7g** became very low because of the formation of phenyl vinyl sulfide.

TABLE 1. THE CYCLIZATION REACTION OF **4** TO FORM **6**

Entry	Catalyst	Reaction conditions Solvent	Reflux time	Yield/%
1	—	Benzene	10 h	—
2	TsOH	Benzene	3 h	56
3	$ClCH_2CO_2H$	Benzene	14 h	10
4	H_3PO_4	Benzene	6 h	15
5	TsOH	Toluene	1 h	75
6	TsOH	Xylene	0.5 h	50
7	TsOH	$CHCl_3$	2 h	40
8	TsOH	THF	3 h	20

Further steps to form 2-substituted 4-(phenylsulfinyl)butyric acids (**9a**—**c**) were conducted as in the preparation of **4**. Yields and spectral data of **8a**—**c** are summarized in Table 3. **9a**—**c** could be used for the next cyclization step without further purification. In the case of the hydrolysis and decrboxylation of **7g**, it was found that the resulting carboxylic acid derivative was converted spontaneously to 4-methyl-2-(2-phenylthioethyl)-4-butanolide (**16**) in 55% yield by the intramolecular addition of a carboxyl group to the double bond.

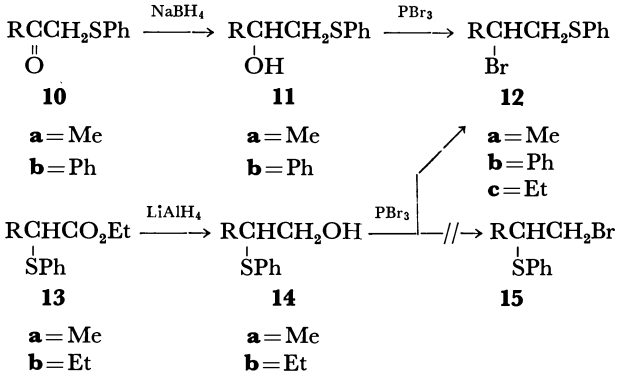
16

For the preparation of 3- or 4-substituted 4-(phenylsulfinyl)butyric acid, bromides **12** and **15** were required, and α-phenylthio ketones and α-phenylthio esters were employed as the starting materials. Reduction of α-(phenylthio)acetone (**10a**) or α-(phenylthio)-acetophenone (**10b**) with sodium borohydride in methanol at 0 °C gave the corresponding alcohols (**11a**, **b**) in high yields. These alcohols were allowed to react with phosphorus tribromide in refluxing carbon tetrachloride to give 2-bromopropyl phenyl sulfide (**12a**) and 2-bromo-2-phenylethyl phenyl sulfide (**12b**).



In a similar way, α-phenylthio esters such as ethyl 2-(phenylthio)propionate (**13a**) or ethyl 2-(phenylthio)butyrate (**13b**) were reduced with lithium aluminium hydride in THF at 0 °C to form corresponding alcohols (**14a**, **b**) in good yields. However, bromination of **14a** and **14b** by phosphorus tribromide gave the unexpected result of yielding **12a** and **12c** because of migration of the phenylthio group. Formation of **8d**—**f** to **9d**—**f** as performed in the usual way, as mentioned above.

The yield and spectral data of **7a**—**g** and **8a**—**f** are summarized in Table 2 and Table 3 respectively.

The reaction of **9a**—**f** thus obtained with acetic anhydride in the presence of *p*-toluenesulfonic acid in refluxing toluene for 1 h resulted in the formation of 4-phenylthio-4-butanolide derivatives (**17a**—**f**) in 27—73% yields. These results are summarized in Table 4.

*Elimination of Phenylthio Group from **17a**—**f** to Buten-4-olides.* It is well known that 2-phenylsulfinyl or 2-alkylsulfinyl-4-butanolide derivatives were converted smoothly to 2-buten-4-olides by thermal decomposition.[6-8] Further, in our previous paper, we described how 3-phenylsulfinyl-4-butanolides were also decom-

posed to 2-buten-4-olides by refluxing THF in the presence of triethylamine.

Oxidation of **17a—f** with *m*-chloroperbenzoic acid (MCPBA) in dichloromethane at 0 °C gave 4-phenylsulfinyl-4-butanolide derivatives (**18a—f**). When the elimination reaction of **18a—f** carried out in refluxing pyridine for 3 h, the double bond of some products isomerized to 2-position from 3-position of buten-4-olide.[9] In the cases of **18d** and **18f**, the double bond

20e	1740	48

remained at 3-position; the other cases, however, gave only products in which the double bond was isomerized to 2-position.

The structures of these compounds were determined by IR and NMR spectra. In particular, the IR spectrum of **20a—c** and **20e** showed the carbonyl absorption at 1750 cm^{-1} and **19d** and **19f** showed the carbonyl absorption at 1800 cm^{-1}.

Experimental

Preparation of 4-Phenylthio-4-butanolide (6). A mixture of 4-(phenylsulfinyl)butyric acid (**4**, 0.69 g, 3 mmol), 1.53 g (15 mmol) of acetic anhydride, and a catalytic amount of

p-toluenesulfonic acid in 20 ml of toluene was heated under reflux for 1 h. The solvent and excess acetic anhydride were removed under reduced pressure. The residue was chromatographed on silica gel using benzene, and gave 0.44 g (75%) of **6**. IR (NaCl): 1780 cm^{-1} (C=O). NMR ($CDCl_3$) δ=1.88—2.52 (4H, m), 5.44 (1H, t), 6.75—7.22 (5H, m). MS: *m/e* 194 (M^+). Found: C, 61.73; H, 5.21%. Cacld for $C_{10}H_{10}O_2S$: C, 61.85; H, 5.19%.

Preparation of Diethyl 2-Methyl-2-(2-phenylthioethyl)malonate (7a). To a solution of sodium ethoxide, prepared from sodium (0.42 g, 18 mmol) and 25 ml of ethanol, was added a solution of **2** (4.50 g, 18 mmol) in ethanol (5 ml). The mixture was refluxed for 15 min. After the reaction mixture was cooled to room temperature, methyl iodide (2.59 g, 18 mmol) was added into the reaction mixture, which was then refluxed for 4 h. The resulted precipitate was filtered and the solvent was evaporated under reduced pressure. 10% Hydrochloric acid (20 ml) was added into the residue and the mixture was extracted with ether and dried. After removal of the solvent, the residue was chromatographed on silica gel using benzene to give **7a** (3.81 g, 81%). Spectral data are summarized in Table 2.

In a similar manner, **7b**, **c**, **d** were prepared from **2** with butyl bromide, benzyl bromide, or allyl bromide. These results are also summarized in Table 2.

Preparation of 1-Phenylthio-2-propanol (11a) and 1-Phenyl-2-(phenylthio)ethanol (11b). Sodium borohydride (1.96 g, 52 mmol) was added slowly to a 50 ml methanol solution of α-(phenylthio)acetophenone (6.64 g, 40 mmol) at 0 °C. The reaction mixture was stirred for 3 h at 0 °C and then quenched with 10 ml of acetic acid. After removal of the solvent, 50 ml of water was added to the mixture and the mixture was extracted with ether and dried. Removal of ether and distillation of residual oil under reduced pressure gave **11a** (5.29 g, 79%). Bp 115 °C/9 mmHg.

In a similar manner, **11b** was obtained in quantitative yield. In this case, product **11b** was isolated by column chromatography on silica gel by using benzene.

Bromination of 11a, b. A carbon tetrachloride (10 ml) solution of **11a** (10.00 g, 60 mmol) was added dropwise to phosphorus tribromide (16.13 g, 60 mmol) in 50 ml of carbon tetrachloride by refluxing gently. The reaction mixture was poured into ice-cold water, extracted with carbon tetrachloride, and dried. Removal of the solvent and distillation under reduced pressure gave 2-bromo-1-(phenylthio)-propane (**12a**) in 80% yield. Bp 115—122 °C/10 mmHg.

In the case of **11b**, the bromination reaction was conducted in a similar manner bromide **12b** was used for the next reaction without further purification because it was hydrolized easily to **11b**.

Preparation of Diethyl (1-Substituted 2-Phenylthioethyl)malonate (7d—f). To an abs ethanol solution of sodium salt of diethyl malonate, which was prepared from diethyl malonate (2.98 g, 19 mmol) and sodium (0.43 g, 19 mmol) in 50 ml of abs ethanol, was added a ethanol solution of bromide **12a** (3.58 g, 15 mmol). The reaction mixture was refluxed for 4 h. After removal of the resulting sodium bromide by filtration, the filtrate was evaporated under reduced pressure. 10% Hydrochloric acid (20 ml) was added to this residue. The mixture was extracted with ether and dried. After removal of the solvent, the excess amount of diethyl malonate was distilled away under reduced pressure. The residue was chromatographed on silica gel by using benzene–petroleum ether (1:1) and gave **7d** (2.95 g, 61%).

In a similar manner, **7e** and **7f** were obtained. The yields and spectral data are summarized in Table 2.

Preparation of 2- or 3-Substituted 4-(Phenylthio)butyric Acid (8a—f). A solution of **7a** (8.97 g, 29 mmol) and 50 ml of 20% sodium hydroxide in 50 ml of ethanol was refluxed for 6 h. After removal of ethanol, 80 ml 10% hydrochloric acid was added to this residue. The mixture was extracted with ether and then the etheral layer was evaporated under reduced pressure. To this residue was added 50 ml of 3 mol dm^{-3}-sulfuric acid. The reaction mixture was heated under reflux for 10 h and then cooled to room temperature. The reaction mixture was extracted with ether and dried. After removal of the solvent, the residue was chromatographed on silica gel using benzene–ether (10:1) to give 2-methyl-4-(phenylthio)butyric acid (**8a**, 3.03 g, 50%).

In a similar manner, **8b**—**f** were also obtained the yields and spectral data of **8a**—**d** are given in Table 3.

Elemental analyses of **8a**—**f** are as follows:

2-Methyl-4-(phenylthio)butyric Acid (8a). Found: C, 62.75; H, 7.09%. Calcd for $C_{11}H_{14}O_2S$: C, 62.84; H, 6.71%.

2-Butyl-4-(phenylthio)butyric Acid (8b). Found: C, 66.44; H, 7.94%. Calcd for $C_{14}H_{20}O_2S$: C, 66.64; H, 7.79%.

2-Benzyl-4-(phenylthio)butyric Acid (8c). Found: C, 66.49; H, 6.28%. Calcd for $C_{17}H_{18}O_2S$: C, 66.65; H, 5.82%.

3-Methyl-4-(phenylthio)butyric Acid (8d). Found: C, 61.26; H, 6.44%. Calcd for $C_{11}H_{14}O_2S$: C, 61.21; H, 6.19%.

3-Phenyl-4-(phenylthio)butyric Acid (8e). Found: C, 69.77; H, 5.61%. Calcd for $C_{16}H_{16}O_2S$: C, 69.75; H, 5.46%.

3-Ethyl-4-(phenylthio)butyric Acid (8f). Found: C, 63.83; H, 7.10%. Calcd for $C_{12}H_{16}O_2S$: C, 64.25; H, 7.19%.

Oxidation of 8a—f. To a solution of sodium metaperiodate (4.00 g, 19 mmol) in water (50 ml) was added a 50 ml of ethanol solution of **8a** (3.03 g, 14 mmol) with stirring at 0 °C. The reaction mixture was stirred for 12 h at 0 °C and was then filtered. The precipitate of sodium iodate was washed with chloroform. The filtrate was extracted with chloroform and dried. After removal of the solvent, the residue was chromatographed on silica gel using benzene–ether (1:1) to give (3.10 g, 99%) of **9a**.

Preparation of 2- or 3-Substituted 4-Phenylthio-4-butanolide (17a—f). The Pummerer reaction of **9a**—**f** was conducted as in the preparation of **6**. These results are summarized in Table 4. Elemental analyses of **17a**—**f** are as follows;

2-Methyl-4-phenylthio-4-butanolide (17a). Found: C, 63.20; H, 5.67%. Calcd for $C_{11}H_{12}O_2S$: C, 63.45; H, 5.81%.

2-Butyl-4-phenylthio-4-butanolide (17b). Found: C, 67.47; H, 7.12%. Calcd for $C_{14}H_{18}O_2S$: C, 67.16; H, 7.25%.

2-Benzyl-4-phenylthio-4-butanolide (17c). Found: C, 71.65%; H, 5.47%. Calcd for $C_{17}H_{16}O_2S$: C, 71.82; H, 5.64%.

3-Methyl-4-phenylthio-4-butanolide (17d). Found: C, 63.51; H, 5.16%. Calcd for $C_{11}H_{12}O_2S$: C, 63.43; H, 5.81%.

3-Phenyl-4-phenylthio-4-butanolide (17e). Found: C, 70.56; H, 4.95%. Calcd for $C_{16}H_{14}O_2S$: C, 71.08; H, 5.22%.

3-Ethyl-4-phenylthio-4-butanolide (17f). Found: C, 64.98; H, 6.57%. Calcd for $C_{12}H_{14}O_2S$: C, 64.83; H, 6.35%.

General Procedure for Oxidation of 17a—f. To a solution of 4-phenylthio-4-butanolide derivative in dichloromethane (15 ml, for 1 g of the lactone) was added 1.2 equiv of *m*-chloroperbenzoic acid at 0 °C. The reaction mixture was stirred for 1 h at 0 °C, washed with 10% aqueous sodium

hydrogencarbonate, and dried. Evaporation of the solvent under reduced pressure gave 4-phenylsulfinyl-4-butanolide derivative (**18a—f**). **18a—f** were used for subsequent thermolysis without further purification.

*General Procedure for Thermolysis of **18a—f**.* A solution of 4-(phenylsulfinyl)lactone derivative in pyridine (20 ml for 1 g of the lactone) was refluxed for 3 h. After removal of pyridine under reduced pressure, the residue was chromatographed on silica gel by using benzene–ether (3:1) as an eluent to give 2- or 3-buten-4-olide. Yields are given in Table 5.

Halogenation with *N*-Halo-2-oxazolidinones. The Chain-carrying *N*-Centered Radicals

Toshihiko Migita,* Mitsumasa Nakayama, Toshiro Watanuki, Mikio Suzuki, and Masanori Kosugi

Department of Applied Chemistry, Faculty of Technology, Gunma University, 1-5-1, Tenjin-cho, Kiryu, Gunma 376

(Received August 12, 1980)

Selectivities in halogenation of 2,3-dimethylbutane, 1-chlorobutane and substituted toluenes with *N*-chloro- or *N*-bromo derivatives of 4,4-dimethyl-2-oxazolidinone (NXDMO), 2-oxazolidinone (NXO), and succinimide (NXS) were examined. In the presence of olefin, halogenation of the substituted butane by these *N*-halo reagents were found to proceed involving hydrogen abstraction by the *N*-centered radicals, since chlorination by the *N*-chloro reagents and bromination by the corresponding *N*-bromo reagents showed the same selectivities. The relative reactivity of a *t*-C–H bond compared with a *prim*-C–H bond RS_p^t markedly depends on the structure of the *N*-radical, being 200, 70, and 11 at 80 °C toward the radicals derived from NXDMO, NXO, and NXS, respectively. Reaction constant ρ of hydrogen abstraction from the toluenes by the *N*-radical from NXDMO was −1.0 at 130 °C.

There has been considerable controversy about the mechanism of halogenations by *N*-halo reagents. At first, for bromination by *N*-bromosuccinimide (NBS), Bloomfield proposed the radical chain mechanism involving the nitrogen centered imidyl radical.[1] In 1953 Goldfinger explained chlorination by *N*-chlorosuccinimide (NCS) by the mechanism in which actual halogenating agent is halogen molecule produced by the reaction of NCS with hydrogen chloride.[2]

Many subsequent studies showed that selectivities or isotope effects in halogenations by various *N*-halo compounds are almost the same as those in photohalogenations by elemental halogens, supporting that the Goldfinger mechanism, if not exclusively, is operative at least as the main path.[3–8]

Bloomfield mechanism

$$\rangle N\cdot + RH \longrightarrow \rangle N\text{-}H + R\cdot$$

$$R\cdot + \rangle N\text{-}X \longrightarrow R\text{-}X + \rangle N\cdot$$

Goldfinger mechanism

$$X\cdot + RH \longrightarrow R\cdot + HX$$

$$R\cdot + X_2 \longrightarrow R\text{-}X + X\cdot$$

$$HX + \rangle N\text{-}X \longrightarrow X_2 + \rangle N\text{-}H$$

Consequently hydrogen abstraction by *N*-radicals has received only a little attention,[9] except intramolecular abstraction and its application to synthetic chemistry.[10] Recently, however, it has been reported that in some cases selectivities in halogenations by *N*-halo compounds differ from those by elemental halogens. The cases are classified as follows: i) NBS bromination of substrates which are relatively unreactive toward bromine atom:[11] ii) using a good solvent for NBS, for example, CH_2Cl_2;[12] iii) presence of olefin or base which can trap halogen or hydrogen halide.[12,13]

These findings may suggest that under these conditions the Bloomfield mechanism plays an important role in the halogenation by *N*-halo compounds. However, discrepancy in selectivity in halogenation between by halogen and by *N*-halo compound is not necessarily an unequivocal evidence for the contribution of the nitrogen centered radical. Mosher and Estes, for example, demonstrated that selectivity of chlorination by *N*-chlorophthalimide depended on the reaction conditions, and explained the feature in terms of the Goldfinger mechanism complicated by the reversible hydrogen abstraction.[14]

$$X\cdot + RH \rightleftharpoons H\text{-}X + R\cdot$$

If the *N*-radicals are the true chain carrier, selectivity of chlorination by the *N*-chloro reagent should be the same to that of bromination by the corresponding *N*-bromo reagent. From the view of this criteria, in this work, selectivities in halogenations by several *N*-halo reagents were examined, aiming to elucidate the chemical nature of the *N*-radicals.

Besides NBS and NCS, we chose 3-halo-4,4-dimethyl-2-oxazolidinone(NXDMO) and 3-halo-2-oxazolidinone(NXO) as the reagents, since these two *N*-halides have been found to have "lower positive halogens," and to react with hydrogen halides, giving halogens, much slower relative to *N*-halosuccinimides,[15] and consequently are expected to have natures less favorable to take place the Goldfinger processes.

Results and Discussion

Selectivities in halogenations of 2,3-dimethylbutane, 1-chlorobutane, and substituted toluenes by the *N*-halo reagents were determined by intra- and intermolecular competition methods.

2,3-Dimethylbutane. Halogenations initiated by benzoyl peroxide (BPO) were conducted at 80 °C by using 0.2 equivalent amounts of the *N*-halo regents to avoid dichlorination. In order to eliminate the occurence of the Goldfinger processes, the reaction was carried out in a good solvent for the *N*-halo reagents, CH_2Cl_2,[12] and in the presence of 3,3-dimethyl-1-butene as a halogen scavenger or γ-collidine as a hydrogen halide acceptor.[12,13]

Change in isomer distribution of monohalogenated products was examined as a function of the initial

Table 1. BPO-initiated halogenation of 2,3-dimethylbutane by the *N*-halo reagents (80 °C)

a) 2,3-Dimethylbutane 1.25 mmol, halogenating agent 0.25 mmol, BPO 0.01 mmol, additive 0.25 mmol, solvent: CH_2Cl_2 5 cm^3 80 °C 15 h. b) Determined by VPC, based on the reagent used. c) Only trace amounts were detected. d) Not determined.

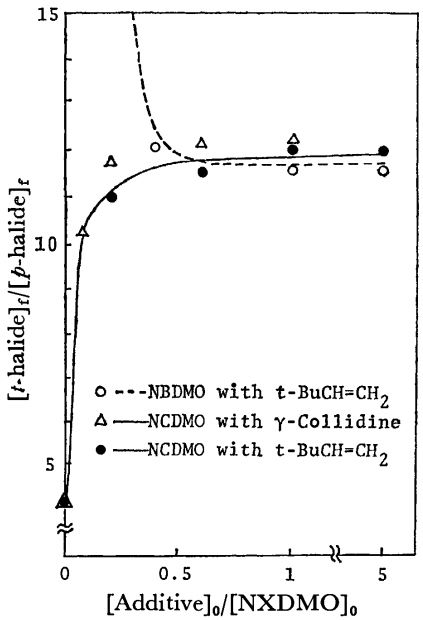

Fig. 1. Dependence of relative yield of tertiary halide to primary halide on relative concentration of additives.

concentration of the olefinic or basic additive. Typical tendencies observed in halogenation with NXDMO are shown in Fig. 1. In the absence of the additives NBDMO halogenated the tertiary C–H of the substrate almost exclusively, while chlorination by NCDMO gave the primary and the tertiary chloride in a ratio of 4:1.

A small amount of the additives brought about marked effects on the distribution of the product, and in the presence of their equimolar amount to the reagents, bromination by NBDMO and chlorination by NCDMO showed the almost same selectivity.

Table 2. Selectivity factor RS^t_p in halogenation of 2,3-dimethylbutane

Reagent	No additive	RS^t_p(80 °C) *t*-BuCH=CH_2 added	γ-Collodine added
NCDMO	25.8±3.6	70.5±1.1	70.8±3.0
NBDMO	—[a]	65.2±4.7	—[b]
NCO	91.6	175±15	—[b]
NBO	—[a]	206±7	—[b]
NCS	7.6±0.1	11.3±0.9	12.8±2.7
NBS	—[a]	10.7	—[b]

a) *prim*-C–H bonds are almost inactive. b) The reaction mixtures are too complex to be analyzed.

This shows, under these conditions both halogenations proceed almost exclusively through the Bloomfield mechanism, involving the common *N*-centered radical as a hydrogen abstracting species.

Table 1 shows the yields of the products of halogenation of 2,3-dimethylbutane by various halogenating agents in the absence and the presence of an equimolar amount of the olefin or the base. Apparently, the presence of the additives reduced the total yield of the halogenated products, and also lowered the relative amount of the halogenated products to the amides (or imide) produced. These facts indicate that the *N*-halo reagents can be consumed also by some side reactions, perhaps, with the additives. Particularly, the presence of γ-collidine gave the complicated mixture containing several unidentified by-products.

Neverthless, in all cases, relative yields of the tertiary to the primary halides fairly coincide with each other between bromination by the *N*-bromo reagent and chlorination by the corresponding *N*-chloro reagent. From the relative yield of the halides obtained in at least three runs for each reaction, selectivity factor between *t*- and *pirm*-C–H bonds, that is the reactivity

of a *t*-C–H bond relative to a *prim*-C–H bond in the substrate, RS^t_p was calculated to be as shown in Table 2.

In the absence of the additives, bromination hardly occurs on a *t*-C–H. The tendency is essentially the same to that in bromination by bromine.[16] Therefore, bromination by *N*-bromo amides or imide seems to mainly proceed through the Goldfinger mechanism. Selectivities of chlorination depend on the nature of *N*-chloro reagents and are different from that of chlorination by chlorine (RS^t_p=3—4).[17] Thus, chlorinations by *N*-chloro reagents may proceed through both of the Bloomfield and the Goldfinger mechanism.

In the presence of the olefin, halogenation proceed through the Bloomfield mechanism almost exclusively, since the selectivity depends on the structure of the amide or imide groups but not on the nature of halogen.

1-Chlorobutane. Based on the information obtained in the study of halogenation of 2,3-dimethylbutane described above, 1-chlorobutane was halogenated by the *N*-halo reagents in the presence of 3,3-dimethyl-1-butene. From the isomer distribution of the halogenated products, relative reactivity of a C–H bond at each position was estimated. In Table 3 the reactivity values refered to those of a C–H bond at 3-position were listed as well as the results of photochlorination[18] and bromination.[19]

TABLE 3. RELATIVE REACTIVITIES OF C–H BONDS OF 1-CHLOROBUTANE TOWARD HALOGENATIONS[a),b)]

Cl_2[c)]	0.09	0.40	1.00	0.19
Br_2(60 °C)[c)]	0.45	0.48	1.00	—

a) 1-Chlorobutane: 1.25 mmol. *N*-halogeno reagent: 0.25 mmol. 3,3-dimethyl-1-butene: 0.25 mmol. BPO: 0.01 mmol. solvent: CH_2Cl_2 5 cm³, 80 °C 15 h. b) Reactivity of a C–H bond at 3-position was taken as unity. c) Calculated from the results in the references.[18,19]

Relative reactivities of C–H bonds toward a *N*-chloro reagent are in tolerable agreement with those toward the corresponding *N*-bromo reagent, except abnormally high reactivity at 1-position toward NBDMO, the reason for which is not clear. It can be seen that the selectivities of these halogenation are quite different from these of photohalogenation, suggesting that hydrogen abstracting species are the *N*-centered radicals.

Selectivity in Hydrogen Abstraction by the N-*Radicals.* Recognizing that halogenations of aliphatic compounds by *N*-halo amide or imide proceed by the Bloomfield mechanism, the selectivities in the halogenation would reveal the relative rates of hydrogen abstraction by the *N*-centered radicals.

From the results of intramolecular competitive reactions of 2,3-dimethylbutane and 1-chlorobutane, relative reactivities of *prim*-, *s*-, and *t*-C–H bonds toward the *N*-centered radicals were found to be as shown in Table 4. Since polar effects of a chlorine substituent in 1-chlorobutane are only slightly operative on 3- and 4-positions,[20] relative reactivities of C–H bonds between these two positions may be used approximately for the selectivity factor between ordinary *s*- and *prim*-C–H bonds. For comparison, selectivity factors in hydrogen abstraction by other radicals are also shown in Table 4.

The *N*-centered radicals are found to be much less selective than bromine atom,[16] but more selective than chlorine atom,[17] *t*-butoxyl[21] and phenyl radicals.[22] The trend is understandable on the basis of the available values of dissociation energies of the bonds forming through hydrogen abstraction: H–Br

87, average N–H 93.4, *t*-BuOH 102, Ph–H 104, H–Cl 103 kcal mol^{-1}.[23] Comparing with the radicals derived from NXO and NXDMO, succinimidyl radical is less selective. This is perhaps due to that difference in effective electronegativity of the nitrogen atom affects on the bond energy of the forming N–H bond.

The radical derived from NXDMO appears less selective than that from NXO, especially in discrimination between *prim*- and *t*-C–H. This apparent less selectivity can be explained in terms of steric effects. Two methyl groups neighboring the radical center will sterically interfer the attack of the radical center on the more crowded position. As a result, reactivities of a C–H bond at more hindered positions, *e.g.* *t*-C–H, may be apparently lessered. More pronounced similar steric effects have been demonstrated in the selectivities of *N*-methyl- and *N*-*t*-butylacetamidyl radicals.[13] And these acyclic amidyl radicals seem less selective than the cyclic *N*-radicals studied in this work. These can be also considered to be the results of similar steric effects. In the acyclic systems blocking effects of the groups bonded to the nitrogen atom will be much larger. Consequently abstractions by the acyclic radicals are less selective, and more sensitive to steric hindrance by the groups in substrates, than those by the cyclic radicals.

Table 5. Halogenation of toluene by NXDMO

	DTBP	130	22	70

Substituted Toluenes. In order to obtain preliminary information about polar selectivities of hydrogen abstraction by the *N*-radicals, substituted toluenes were intended to be halogenated competitively by the *N*-halo reagents in the presence of 3,3-dimethyl-1-butene.

Bromination of toluene by NBDMO was initiated by either BPO or AIBN, and the reaction (at 80 °C) gave benzyl bromide in a reasonable yield. However, chlorination by NCDMO was quite sluggish under these conditions and afforded benzyl chloride in a quite poor yield. Perhaps, this is due to dif-

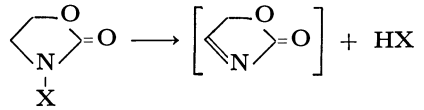
ficulty in chlorine abstraction from the N–Cl bond by the relatively stable benzyl radical. However, when the reaction was carried out at 130 °C using di-*t*-butyl peroxide (DTBP) as a radical generator, toluene was smoothly halogenated by either NCDMO or NBDMO, giving benzyl halides in good yields, as shown in Table 5. Even under these conditions NCS could not chlorinate toluene in an appreciable yield. On the basis of the observations, competitive experiments were conducted with NXDMO and NXO at 130 °C in CH_2Cl_2 solvent using DTBP as an initiator, and relative reactivities of substituted toluenes were compared between bromination and chlorination.

Table 6 shows the results obtained about halogenation by NXDMO. Relative reactivity of each substituted toluene was obtained with satisfactory reproducibility, and the values obtained for chlorination and bromination were coincide with each other. This obviously supports that the reagent attacking benzylic hydrogen in both reactions is the common *N*-radical, and the radical has fairly electron seeking nature ($\rho=-1.0$).

Competitive experiments with NXO gave, however, poorer reproducible results, as shown in Table 7. Although there can be seen the tendencies that the presence of the olefin makes the chlorination with NCO more selective and the bromination with NBO less selective, no numerical coincidence in relative reactivity was obtained between chlorination and bromination. This may arise probably from that both of the Bloomfield and the Goldfinger processes proceed concurrently even in the presence of the olefin. Contrasting with 3-halo-4,4-dimethyl-2-oxazolidinone, 3-halo-2-oxazolidinone, bearing α-hydrogens, is though to take place dehydrohalogenation at higher temperature.[10] Hydrogen halide thus formed will ac-



celarate the Goldfinger process through the reaction with NXO producing halogen molecule. Under the drastic conditions used in this study, therefore, halogen will form too rapidly to be entirely scavenged by the olefin added. Increasing the amount of the olefin might suppress the Goldfinger process. Under these circumstances, however, yield of the benzyl halides became too low for reliable competitive study.

Table 8 shows the results of bromination with NBS in the absence and the presence of the olefin. The reaction constant obtained in the absence of the olefin are derived to be *ca.* −1.8 ($r=0.95$), being somewhat larger negative compared with the values reported so far ($\rho=-1.46$,[4] $\rho^+=-1.38$[6] at 80 °C in CCl_4). This is perhaps due to that a more polar solvent, CH_2Cl_2 was used in this work. The presence of the olefin makes the reaction slightly more electron seeking ($\rho=-1.9$, $r=0.97$). We feel, this reveals the polar selectivity of hydrogen abstraction by the succinimidyl radical, although comparison with chlorination by NCS could not be accomplished owing to the difficulty described above.

Experimental

Materials. NCO and NCDMO were prepared by the modified known method.[24] The precipitated NCO was filtered, dried under reduced pressure, and crystallized from dichloromethane-petroleum ether. Yield 50%, mp 62.5—63.5 °C. The sample in a vacuum sealed tube wrapped with aluminum foil was reserved in a refrigerator. NCDMO was recrystallized from benzene–petroleum ether. Yield, 70%, mp 69—70 °C. NBDMO was prepared by the known method[15] and recrystallized from dichloromethane–petroleum ether. Yield 76%, mp 118—119 °C. NBO was prepared by bromination of 2-oxazolidinone (7 g) with *t*-butyl hypobromite[25] in dichloromethane. The crystal was filtered and recrystallized from dichloromethane–petroleum ether. The sample was reserved in a evacuated tube wrapped with aluminum foil. Yield 50%, mp 115—120 °C (partially decomposed).[15] NCS were prepared by the usual method.[26] NBS was commercially available and purified by recrystallizing from water. All substrates were purified by distilling the commercial materials.

Halogenation of 2,3-Dimethylbutane and 1-Chlorobutane. A solution of an *N*-halo reagent (0.25 mmol), 2,3-dimethylbutane (1.25 mmol), BPO (0.01 mmol), and γ-collidine or 3,3-dimethyl-1-butene (0.25 mmol) in dichloromethane (5 cm^{-3}) was taken in a reaction tube and degassed by successive freezing-thawing processes. The tube was sealed under vacuum, and immersed in a thermostat at 80 °C for 15 h. The products were collected by GLPC, identified spectroscopically and determined by GLPC. All products were well known in the literature.[3-8] The results were summarized in Tables 1—3.

Competitive Hologenation of Substituted Toluenes. In a

5 cm^{-3} graduated flask, an *N*-halo reagent (0.2—0.5 mmol), DTBP (0.2 mmol), 3,3-dimethyl-1-butene (0—0.5 mmol) and precisely weighed toluene (*ca.* 5 mmol) and a substituted toluene were taken, and the mixture was diluted with dichloromethane to 5 cm^{-3}. Then the solution was devided to 3—4 fractions. Each fraction was degassed in a tube, which then was evacuated and sealed. The tube was immersed in a thermostat at 130 °C at 15 h. Molar ratio of halogenated products was determined by GLPC using calibration curves. From the molar ratios of initial concentration of toluenes and final concentration of benzylic halides, relative reactivity of the substituted toluene was calculated. The results were tabulated in Tables 6—8. In the reaction with NXO, the fractions from the same solution did not necessarily give the results in reasonable agreement with each other.

Carbon-13 NMR Study on the Cyclodextrin Inclusion Complexes in Solution

Makoto KOMIYAMA* and Hidefumi HIRAI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 19, 1980)

A correlation between the penetration depth of the carbon atoms of 4-nitrophenolate, benzoic acid, 4-nitrophenol and 2,6-dimethyl-4-nitrophenolate in the cavity of α-cyclodextrin and the changes of their ^{13}C-chemical shifts has been investigated. By use of this relationship and the observed changes of the ^{13}C-chemical shifts of 3-nitrophenol on the complex formation with α-cyclodextrin, the time-averaged conformation of the α-cyclodextrin-3-nitrophenol complex is determined.

The attention to the catalyses by cyclodextrins, cyclic oligosaccharides composed of 6—8 glucose units, has been increasing. This mainly comes from the inclusion complex formation of cyclodextrins with the substrates prior to the catalytic function in the similar way as enzymatic reactions, resulting in specificities.[1]

Although almost all of the reactions catalyzed by cyclodextrins are carried out in aqueous solutions, little is known on the positions of the substrates in the cavities of cyclodextrins. The information on the structures of inclusion complexes is quite important, since the characteristics of the cyclodextrin-catalyzed reactions are mainly due to the formation of the complexes.

In the previous paper,[2] the time-averaged conformations of the complexes of α-cyclodextrin with 4-nitrophenol and benzoic acid as well as their anions were determined by fitting the changes of the ^{1}H-chemical shifts of α-cyclodextrin to the calculated values of the anisotropic shielding effects of the aromatic rings of the guest compounds.

This paper describes the extension of the previous study to the ^{13}C-NMR spectroscopy. The relationship between the positions of the carbon atoms of the guest compounds in the cavity of α-cyclodextrin and the changes of the ^{13}C-chemical shifts of these atoms is shown for the complex of α-cyclodextrin with 4-nitrophenolate, benzoic acid, 4-nitrophenol, and 2,6-dimethyl-4-nitrophenolate. Furthermore, the conformation of the complex of α-cyclodextrin with 3-nitrophenol is determined by use of this relationship.

Experimental

Materials. The guest compounds and α-cyclodextrin were purified by recrystallization. Deuterium oxide (the minimum purity 99.75%) from Merck Co. was used as the solvent for the ^{13}C- and ^{1}H-NMR measurements.

Spectrometry. ^{13}C-NMR spectra were taken at ambient temperature (about 25 °C) on a JEOL PFT-100 spectrometer operating at 25.03 MHz, connected with JEOL EC-100 computer. The ^{13}C-chemical shifts were determined with the accuracy of ±0.01 ppm by use of sodium formate as the internal standard. The assignments of the signals were made according to the literatures for 4-nitrophenolate,[3] benzoic acid[4] and 4-nitrophenol,[3] and by using the additivity rule[5] for 2,6-dimethyl-4-nitrophenol and 3-nitrophenol. The changes of the ^{13}C-chemical shifts of the guest compounds (Δ_c's) on the complex formation with α-cyclodextrin were determined with the accuracy of ±0.05 ppm by plotting the observed changes of the ^{13}C-chemical shifts *vs.* the concentration of α-cyclodextrin.

^{1}H-NMR spectra were measured at 60 °C by use of JEOL PS-100 spectrometer. Assignments of the signals of α-cyclodextrin followed the literature.[6]

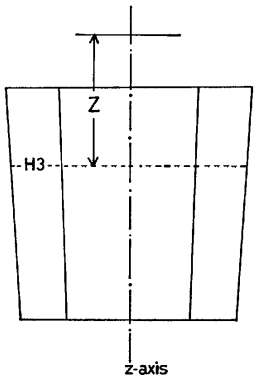

Fig. 1. Schematic drawing showing the definition of *Z*. ---H3--- shows the plane comprised of the six H-3 atoms of α-cyclodextrin.

Determination of the Time-averaged Position of the Guest Compound by ^{1}H-NMR Spectroscopy. The time-averaged position of the guest compound in the cavity of α-cyclodextrin was determined by the following method, the detailed description of which was made in the previous paper;[2]

1) The change of the ^{1}H-chemical shifts of the H-3 and H-5 atoms of α-cyclodextrin due to the complex formation with the guest compound were experimentally determined.

2) The magnitudes of the anisotropic shielding effects of the aromatic ring of the guest compound on the H-3 and H-5 atoms were calculated by using the table of Johnson and Bovey.[7]

3) The optimal position of the guest compound was determined by shifting the aromatic ring along the longitudinal axis (z-axis) of the cavity of α-cyclodextrin. In the optimal position, the calculated values of the shielding effects of the guest compound on the both H-3 and H-5 atoms show the maximal agreements with the corresponding observed values.

and

4) The optimal position was taken as the time-averaged position of the aromatic ring of the guest compound.

The position of the center of the aromatic ring and the carbon atoms of the guest compounds were expressed in terms of the heights (*Z*, in Å) from the plane comprised of the six H-3 atoms of α-cyclodextrin as shown in Fig. 1.

Results

Time-averaged Positions of the Guest Compounds in the Cavity Determined by the ^{1}H-NMR Spectroscopy. Table 1 shows the heights of the centers of the aromatic rings (*Z*-values) of 4-nitrophenolate, benzoic acid, 4-nitrophenol and 2,6-dimethyl-4-nitrophenolate, determined by the ^{1}H-NMR spectroscopy as described

Table 1. Penetration depth (the Z value) for the center of the aromatic ring of the guest compound and the observed and calculated changes of the ^{1}H-chemical shifts of the H-3 and H-5 atoms of α-cyclodextrin

Guest compound	Z of the center of the aromatic ring/Å[a]	^{1}H-Chemical shift change/ppm[b]			
		H-3		H-5	
		Obsd	Calcd	Obsd	Calcd
4-Nitrophenolate[c]	−1.1	+0.20	+0.21	−0.05	−0.08
Benzoic Acid[c]	−0.1	+0.41	+0.40	−0.08	−0.09
4-Nitrophenol[c]	−0.7	+0.25	+0.26	−0.04	−0.08
2,6-Dimethyl-4-nitrophenolate	−1.4	+0.15	+0.15	−0.06	−0.08

a) The negative sign refers to the shallower penetration with respect to the plane composed of the six H-3 atoms of α-cyclodextrin. b) The positive sign shows the increase in the shielding. c) From Ref. 2.

Table 2. Values of Δ_c and Z for the complex formation of α-cyclodextrin with various guest compounds

Guest compound	Carbon atom[a]	Δ_c/ppm[b]	Z/Å[c]
4-Nitrophenol	C-1	+0.25	−1.8
	C-2	−1.05	−0.4
Benzoic acid	C-3	−1.61	+0.6
	C-4	+0.14	−0.8
	C-5	−0.28	−1.5
4-Nitrophenol	C-6	−0.27	−1.3
	C-7	−1.26	0.0
2,6-Dimethyl-4-nitrophenolate	C-8	+0.59	−2.1
	C-9	+0.10	−0.8

a) The numbering system is shown in the legend for Fig. 2. b) The positive sign refers to the increase in the shilding. c) The negative sign shows the shallower penetration with respect to the plane comprised of the six H-3 atoms.

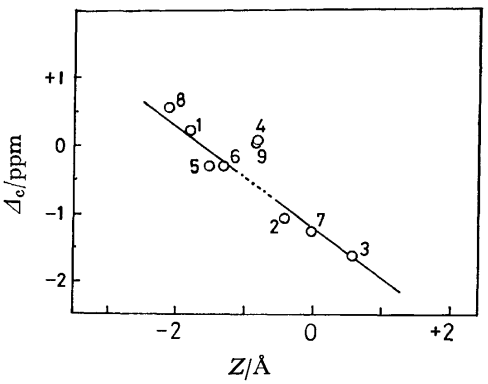

Fig. 2. Plot of the changes of the ^{13}C-chemical shifts (Δ_c in ppm) of the guest compounds on the inclusion complex formation with α-cyclodextrin *vs.* the penetration depth (Z in Å).
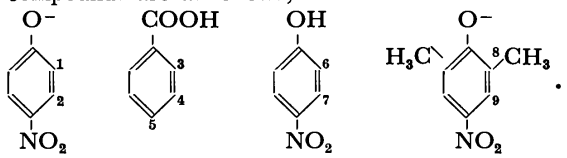
The positive sign in Δ_c shows the increase in the shielding, and the positive sign in Z shows the deeper penetration with respect to the plane (Z=0) comprised of the six H-3 atoms of α-cyclodextrin; the numbering system of the carbon atoms of the guest compounds are as follows;



in the Experimental Section. The agreements between the observed values of the changes of the ^{1}H-chemical shifts and the calculated ones are fair for both the H-3 and H-5 atoms.

The conformations of the inclusion complexes can be definitely determined from the Z-values of the centers of the aromatic rings listed in Table 1, since the directions of the penetrations of the guest compounds were known.[8,9] 4-Nitrophenolate, 4-nitrophenol and 2,6-dimethyl-4-nitrophenolate form the complexes with α-cyclodextrin in which the nitro groups are located inside the cavity with the hydroxyl group and phenoxide oxygen atoms protruding from the secondary hydroxyl side of the cavity.[8] In the α-cyclodextrin–benzoic acid complex, the carboxyl group penetrates as a head from the secondary hydroxyl side.[9] Thus, the Z-values for all of the carbon atoms of the guest compounds were determined as shown in Table 2.

Relationship between the Penetration Depth and the Change of the ^{13}C-Chemical Shift. Table 2 lists the changes of the ^{13}C-chemical shifts (Δ_c) as well as the Z-values for the complex formations of α-cyclodextrin with 4-nitrophenolate, benzoic acid, 4-nitrophenol, and 2,6-dimethyl-4-nitrophenolate.

A fair correlation between Δ and Z are found as shown in Fig. 2. The seven points except for those of the C-4 and C-9 atoms showed linearity. As the carbon atom was included more deeply in the cavity, its chemical shift moved from the values in the absence of α-cyclodextrin towards the lower magnetic field to a greater extent. The C-4 and C-9 atoms, both of which have the Z-values of around −0.8 A, showed almost the identical Δ_c values (+0.1 ppm), although the corresponding points considerably deviated from the linear straight line for the other seven points.

The most important conclusion from Fig. 2 is that Δ_c is virtually governed only by the penetration depth in the cavity. The positions of the carbon atoms with respect to the substituents in the guest compounds are less important. Thus, the relationship in Fig. 2 is applicable to other guest compounds, especially to the substituted benzenes.

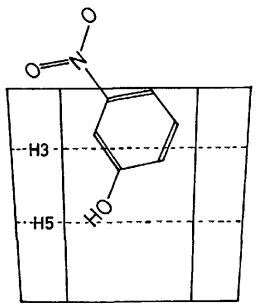


Fig. 3. The time-averaged conformation of the α-cyclodextrin-3-nitrophenol complex.
---H3--- and ---H5--- show the planes comprised of the six corresponding atoms of α-cyclodextrin.

Application of the Relationship between Δ_c and Z to the Complex Formation of α-Cyclodextrin with 3-Nitrophenol. The time-averaged position of 3-nitrophenol in the cavity of α-cyclodextrin can be estimated as shown in Fig. 3. Here, the Z-values of the carbon atoms of 3-nitrophenol are determined by use of the observed Δ_c's and the relationship in Fig. 2. The Δ_c's for the C-10, C-11, and C-13 atoms are evaluated from the straight line, and that for the C-12 atom, which is located at $Z=-0.9$ A, is taken as the average of the values for the C-4 and C-9 atoms. The agreements between the observed values of Δ_c and the calculated values are fair as shown in Table 3.

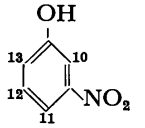
Supports for the conformation in Fig. 3 and thus the method for the determination were provided by the ^{1}H-NMR spectroscopy. The magnitudes of the anisotropic shielding effects of the aromatic ring of 3-nitrophenol on the H-3 and H-5 atoms, respectively, of α-cyclodextrin can be calculated to be +0.30 and −0.05 ppm. These values were determined by averaging the magnitudes of the shielding effects of the aromatic ring on the six H-3 or H-5 atoms, each of which are estimated by using the table of Johnson and Bovey.[7] These values are in fair agreements with the observed values (+0.29 and −0.05 ppm, respectively).

Penetration of the hydroxyl group of 3-nitrophenol in the cavity rather than the nitro group was further confirmed by the absorption spectroscopy. Table 4 shows the dissociation constant (K_d) of the inclusion complexes of α-cyclodextrin with 3-nitrophenol, 2-methyl-3-nitrophenol, and 4-methyl-3-nitrophenol, determined at 25 °C in 0.1 mol dm^{-3} HCl by using the change of the absorbance at 340 nm. The methyl substitution in the ortho position of the hydroxyl group prevents the complex formation with α-cyclodextrin, although the methyl substitution in the para-position of the hydroxyl group enhances it. These results are consistent with the conformation shown in Fig. 3, since the steric hindrance around the hydroxyl group shows larger effect on the complex formation than the steric hindrance around the nitro group does.

Table 3. Vales of Δ_c and Z for the α-cyclodextrin-3-nitrophenol complex

Carbon atom[a]	Z/Å[b]	Δ_c/ppm[c]	
		Obsd	Calcd
10	−0.4	−0.78	−0.92
11	−1.9	−0.13	+0.16
12	−0.9	0.00	+0.12
13	+0.4	−1.45	−1.48

a) The numbering system is as follows:



b) The negative sign shows the shallower penetration with respect to the plane composed of the six H-3 atoms. c) The positive sign shows the increase in the shielding.

Table 4. The equilibrium constant (K_d) of the dissociation of the inclusion complex of α-cyclodextrin[a]

Guest compound	K_d/10^{-2} mol dm^{-3}
3-Nitrophenol	1.7
2-Methyl-3-nitrophenol	2.2
4-Methyl-3-nitrophenol	0.065

a) At 25°C in 0.1 mol dm^{-3} HCl.

Discussion

It has been shown that the ^{13}C-NMR spectroscopy as well as the ^{1}H-NMR spectroscopy[2] can be applicable to the determination of the time-averaged positions of the guest compounds in the cavity. An advantage of the ^{13}C-NMR spectroscopy over the ^{1}H-NMR spectroscopy is that it can provide the direct informations on the positions of all the carbon atoms of the guest compounds and thus on the directions of the penetrations of the guest compounds in the cavity. However, only the position of the aromatic ring of the guest compound in the cavity can be determined by use of the ^{1}H-NMR spectroscopy. The positions of the carbon atoms of the guest compounds can be estimated by ^{1}H-NMR spectroscopy only when the directions of the penetrations are determined by other methods. In the complex formations of 4-nitrophenolate and 4-nitrophenol, for example, the absorption spectroscopy showed the penetration of the nitro group as a head, since the steric hindrance due to the methyl substitution(s) around the nitro group exhibited much larger suppression of the complex formations than the steric hindrance around the hydroxyl group or phenoxide ion does.

The deviations for the C-4 and the C-9 atoms from the straight line in Fig. 2 are associated with the secondary hydroxyl groups of α-cyclodextrin which are located around $Z=-1.0$ A. Apolar property near the hydroxyl groups is smaller than estimated from the Z-value.

The penetration of the hydroxyl group in the cavity in the α-cyclodextrin–3-nitrophenol complex is attributable to the attraction of the dipole of the nitro group of 3-nitrophenol mainly by the negative charge at

the O-2 oxygen atom of α-cyclodextrin. The O-2 oxygen atoms are located near the nitro group, since the corresponding secondary hydroxyl groups orient inside the cavity. In the α-cyclodextrin–4-nitrophenol complex, however, the interaction between the nitro group and the negative charge is less important because of the larger distance between them, resulting in the penetration of the more apolar nitro group in the cavity.

The conformation of the α-cyclodextrin–3-nitrophenol complex in solution in Fig. 3 is consistent with that in the crystal[10] where the benzene ring is located near the secondary hydroxyl side of the cavity. The complex in the crystal, however, has the nitro group inside the cavity, whereas that in solution has the hydroxyl group inside the cavity. This discrepancy is probably associated with the process of the crystallization.

Small discrepancies between the observed and calculated values of Δ_c's for the C-10 and C-11 atoms (Table 3) are due to the minor contribution of the inclusion complex where the nitro group penetrates the cavity as a head, in addition to the major contribution of the inclusion complex where the hydroxyl group penetrates the cavity as a head (Fig. 3).

Conclusion

1) A correlation between the penetration depth of the carbon atoms of the aromatic guest compounds and the changes of the ^{13}C-chemical shifts was found.
2) The time-averaged conformation of the α-cyclodextrin–3-nitrophenol complex in solution was determined by use of the relationship.

Acylchlorination and Related Reactions of Fluoroethenes Using $AlCl_3$ and $FeCl_3$

Nobuo Ishikawa,* Hiroshi Iwakiri, Kazuya Edamura, and Satoshi Kubota
Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received September 4, 1980)

Acylchlorination of mono-, 1,1-di-, and trifluoroethenes with carboxylic acid chlorides using $AlCl_3$ and $FeCl_3$ as a Lewis acid was investigated. In $AlCl_3$-catalyzed reactions, fluorine-chlorine exchange reaction always occurred in part, while in $FeCl_3$-catalyzed reactions Claisen-type condensation giving β-diketones was observed. Preparations of 2-chloro-2-fluoroethyl, 2-chloro-2,2-difluoroethyl, and 2-chloro-1,2,2-trifluoroethyl ketones are given.

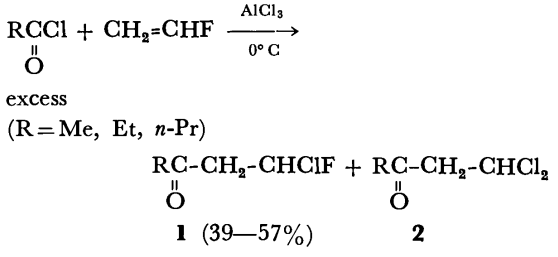
Although the reactivity of fluoroethenes towards electrophiles is lowered by the presence of negative fluorine atoms, several examples of the electrophilic addition across the double bond of mono-, di-, and trifluoroethenes appeared in the literature.[1)]

As to the Friedel-Crafts acylhalogenations of the fluoroethenes, the additions of acyl chlorides or acetyl fluoride to 1,1-difluoroethene and trifluoroethene catalyzed by $AlCl_3$[2)] and SbF_5[3)] were reported by Soviet workers.

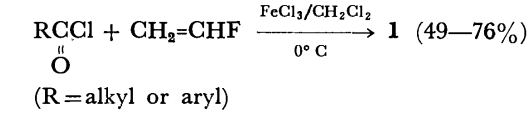
In this paper we wish to report on the reactions of various carboxylic acid chlorides with mono-, di-, and trifluoroethenes using $AlCl_3$ and $FeCl_3$ as a Lewis acid, and on the preparations of chlorofluoroethyl ketones and β-diketones, which are expected as useful intermediates for synthesis of fluorine containing organic compounds.

Results and Discussion

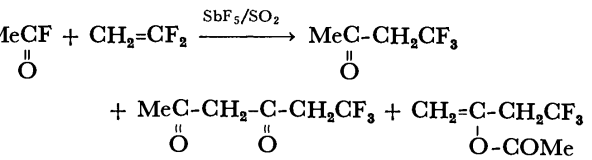
Acylchlorination of Fluoroethene. Among fluoroethenes, monofluoroethene is expected to be the most susceptible to the attack of electrophiles, however, only a few electrophilic reactions of fluoroethene, *e.g.* additions of fluorosulfuric acid[4)] and arenesulfenyl chlorides,[5)] are known. No reports on the acylchlorination of fluoroethene have appeared in literatures so far. We found that fluoroethene was readily acylchlorinated by various carboxylic acid chlorides in the presence of $AlCl_3$ or $FeCl_3$ even under mild conditions. For example, when fluoroethene gas was allowed to be absorbed in a mixture of excess acyl chlorides and $AlCl_3$ (4:1 mole ratio) at 0 °C, 2-chloro-2-fluoroethyl ketones (**1**) were obtained. However, 2,2-dichloroethyl ketones (**2**), formed by a halogen exchange reaction, were always found as a side product in the reaction mixture. Expecting to avoid this dichloroethyl ketone formation, dichloromethane was used as a solvent and equimolar amounts of acyl chloride and fluoroethene were made to react under the same conditions. The formation of **2**, however, could not be controlled by this method, and from benzoyl chloride, in particular, 2,2-dichloroethyl phenyl ketone (**3**) was formed in a yield of 43%. The fluorine-to-chlorine exchange reaction by $AlCl_3$ forming dichloroethyl ketones in these reactions was confirmed experimentally. For example, when a mixture of equimolar amounts of 2-chloro-2-fluoroethyl propyl ketone **1** (R=*n*-Pr) and $AlCl_3$ in dichloromethane was stirred at 0 °C for 40 min, **1** and **2** were found in a ratio 68:32, based on the ^1H NMR signal intensities, in the resulting mixture.



Then we carried out the acylchlorination of fluoroethene, using $FeCl_3$ instead of $AlCl_3$ in the above procedure, because $FeCl_3$ is known to be a milder Lewis acid than $AlCl_3$.[6,7)] By this method, the expected 2-chloro-2-fluoroethyl ketones were obtained exclusively in good yields (Table 1). Even aroyl chlorides afforded corresponding ketones in fairy good yields (≈50%). These 2-chloro-2-fluoroethyl ketones were readily dehydrochlorinated by heat or by a base, giving unstable vinyl ketones.



Acylchlorination of 1,1-Difluoroethene. More than twenty years ago Knunyants and his co-workers reported the addition of acetyl, propionyl, and butyryl chlorides to 1,1-difluoroethene using $AlCl_3$ in trichloromethane at low temperature (−10—−5 °C), affording 2-chloro-2,2-difluoroethyl ketones in rather low yields (33—48%).[2)] More recently, Belen'kii and German reported the reaction between acetyl fluoride and 1,1-difluoroethene in sulfur dioxide using SbF_5 as a Lewis acid, obtaining a normal adduct together with condensation products, a β-diketone and an ester.[3)]



By tracing the procedure reported by Knunyants *et al.*, 2,2,2-trichloroethyl ketones (**5**) were formed as well as 2-chloro-2,2-difluoroethyl ketones (**4**) according

Avoiding the halogen exchange between **4** and **5** with $AlCl_3$, we examined $FeCl_3$ instead of $AlCl_3$ in these cases again. Thus 1,1-difluoroethene was allowed to be absorbed into a mixture of acyl chlorides and $FeCl_3$ in dichloromethane at 0 °C. By this method, chlorodifluoroethyl ketones were obtained in 50% yield, and no formation of trichloroethyl ketone was observed in the reaction mixture (Table 2).

However, other unidentified by-products were always included in the main product and these contaminants were assumed to be further acylated condensation products such as β-diketone (**6**) or enol ester (**7**) as Belen'kii *et al.* observed in their reaction. The formation of these kind of condensation products is reasonable as $FeCl_3$ is known to accelerate Claisen-type condensation under acidic conditions.[8] Actually, when butyryl chloride was made to react with 2-chloro-2,2-difluoroethyl methyl ketone using $FeCl_3$, β-diketone was obtained though in a low yield.

a) Method (A): $RCOCl+C_2HF_3$ ($FeCl_3$), Method (B): $RCOCl+MeCOCHFCClF_2$ ($FeCl_3$).

Since, 1,1-difluoroethene is less reactive to electrophiles than fluoroethene, the acylchlorination must be sluggish, and it is natural that other side reactions likely occur. Further, aroyl chlorides, which are weaker electrophiles than aliphatic carboxylic acid chlorides, gave no reaction products either by $AlCl_3$ or by $FeCl_3$.

Reaction of Trifluoroethene with Acyl Chlorides. As trifluoroethene is even less susceptible to the Friedel-Crafts acylchlorination than mono- and difluoroethenes, it does not react with acyl chlorides under atmospheric pressure. Knunyants *et al.* made trifluoroethene react with an excess amount of acetyl chloride in a sealed vessel and obtained 2-chloro-1,2,2-trifluoroethyl methyl ketone in 34% yield.[2] Belen'kii also reported that the reaction between acetyl fluoride and trifluoroethene with SbF_5 in SO_2 resulted in the formation of the adduct and its further acylated products.

Various carboxylic acid chlorides were tried to use for the reaction with trifluoroethene using $AlCl_3$ in dichloromethane in a sealed vessel. By making them react at room temperature for a prolonged time, 2-chloro-1,2,2-trifluoroethyl ketones (**8**) were obtained in rather good yields (Table 3).

$$RC(=O)Cl + CHF=CF_2 \xrightarrow[\text{r.t., 20—48 h}]{AlCl_3/CH_2Cl_2} RC(=O)-CHF-CF_2Cl$$

(R=Me, *n*-Pr, *n*-C_5H_{11}, *n*-C_9H_{19}) **8** (70—82%)

However, a small amount of 1,1,1,2-tetrachloroethane was always formed as a side-product, which was assumed to have been formed by chlorination of trifluoroethene with $AlCl_3$ followed by hydrochlorination with HCl. This was confirmed experimentally by allowing trifluoroethene and $AlCl_3$ to react in the presence of a trace of water. Substantial amount of tetrachloroethane was obtained by this reaction.

$$CHF=CF_2 + AlCl_3 \longrightarrow [CHCl=CCl_2] \xrightarrow{HCl} CH_2ClCCl_3$$

As a matter of interest, when $FeCl_3$ was used instead of $AlCl_3$, β-diketones (**9**) were obtained as a main product and only a small or trace amount of acylchlorinated product was formed (Table 4-Method A).

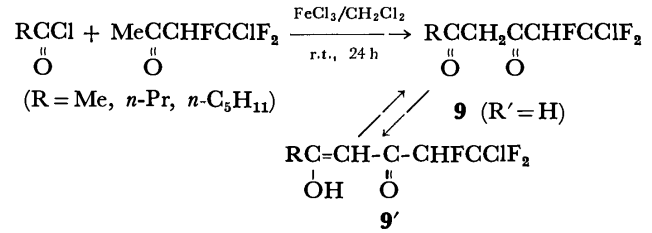
$$RC(=O)Cl + CHF=CF_2 \xrightarrow{FeCl_3/CH_2Cl_2} [\mathbf{8}] \xrightarrow[FeCl_3]{RCOCl} RC(=O)-CH(R')-C(=O)-CHF-CF_2Cl$$

(R=R′CH_2) **9**

This also means that $FeCl_3$ worked as an effective catalyst for the Claisen-type condensation.

In order to prepare the β-diketones carrying an active CH_2 group, chlorotrifluoroethyl methyl ketone **8**, obtained by the $AlCl_3$ catalyzed reaction, was allowed to react with an acyl chloride using $FeCl_3$. Diketones **9** (R=Me, *n*-Pr, *n*-C_5H_{11}; R′=H) were obtained in considerable yields by this method (Table

4-Method B), and they existed in an enol form (**9'**) based on the ^1H NMR.



Consequently, it was concluded that trifluoroethene was acylchlorinated by using $AlCl_3$ under more vigorous conditions than the cases of mono- and difluoroethenes, and that when $FeCl_3$ was used, the formation of β-diketone occurred dominantly, presumably because the Claisen-type further acylation proceeded faster than the preceding acylchlorination.

Experimental

2-Chloro-2-fluoroethyl Methyl Ketone **1** *(R=Me). (A)*: Into a solution of $AlCl_3$ (13.3 g, 0.1 mol) in acetyl chloride (31.4 g, 0.4 mol), fluoroethene gas was introduced through the bottom of the vessel. The temperature was kept below 0 °C and the introduction was continued until no more absorption was observed (≈40 min). The reaction mixture was then poured into a mixture of ice (50 g) and concd hydrochloric acid (10 ml) and a separated oily material was extracted with diethyl ether. The extract was washed with aqueous solution of $NaHCO_3$ to remove a free carboxylic acid, then with water, and dried over $MgSO_4$. After evaporating the solvent, the residue was subjected to distillation under reduced pressure, giving **1** (R=Me) (5.0 g), bp 38—39 °C/9 mmHg**, in a yield of 39% based on the used $AlCl_3$.

(B): Into a suspension of $FeCl_3$ (19.4 g, 0.12 mol) in dichloromethane (100 ml), acetyl chloride (7.85 g, 0.10 mol) was added dropwise with cooling in an ice-bath. Then fluoroethene gas was introduced to the solution keeping the temperature below 0 °C until no more gas was absorbed (3 h). The reaction mixture was treated similarly as mentioned in (A) and distillation gave **1** (R=Me) (8.70 g) in 70% yield.

The other carboxylic acid chlorides were allowed to react with fluoroethene in similar procedures (Table 1). When the aroyl chlorides were used, the products came out as a solid after removal of the solvent, which were purified by recrystallization from cyclohexane. All of the 2-chloro-2-fluoroethyl ketones were readily dehydrochlorinated by distillation at high temperature. Therefore it was necessary to distill them at lower than 60 °C under reduced pressure. They gradually decomposed even kept in a refrigerator.

2,2-Dichloroethyl Phenyl Ketone (3). Into a mixture of benzoyl chloride (14.1 g, 0.10 mol), $AlCl_3$ (13.3 g, 0.10 mol) and dichloromethane (38 ml), fluoroethene gas was absorbed, and the reaction mixture was worked up as usual. After evaporation of the solvent, the residue was recrystallized from hexane, giving **3** (7.44 g, 43%), mp 58—59 °C; NMR (CCl_4): δ 3.82 (2H), 6.27 (H), 7.30—8.00 (5H); $\nu_{C=O}$; 1670 cm^{-1}. Found: C, 53.82; H, 3.95%. Calcd for $C_9H_{18}Cl_2O$: C, 53.23; H, 3.97%.

2-Chloro-2,2-difluoroethyl Methyl Ketone (4) (R=Me). (A): The reactions between acetyl chloride and 1,1-difluoroethene in chloroform were carried out after the Knunyants procedure. Somewhat higher yield was obtained (Table 2).

(B): 1,1-Difluoroethene was absorbed into a mixture of acetyl chloride, $FeCl_3$, and dichloromethane at 0 °C. The procedure was similar to that of fluoroethene mentioned above, though the reaction was sluggish and it took ≈5 h. The product, even after distillation, was contaminated with unidentified impurities and the purity of **4** was ≈90% from the signal intensities of ^1H NMR.

2-Chloro-1,2,2-trifluoroethyl Methyl Ketone (8) (R=Me). A mixture of $AlCl_3$ (16.0 g, 0.12 mol), acetyl chloride (7.85 g, 0.10 mol), and dichloromethane (100 ml) was placed in a pressure vessel, and was cooled in a Dry Ice–acetone bath. Liquefied trifluoroethene (9.0 g, 0.11 mol) was introduced into the vessel and the mixture was stirred at room temperature for 48 h and was poured onto a mixture of ice (100 g) and concd hydrochloric acid (10 ml). An oily layer was separated, washed with an aqueous solution of $NaHCO_3$, and dried over $MgSO_4$. After evaporating the solvent, distillation of the residue gave **8** (R=Me) (11.3 g), bp 98—100 °C (lit,[2] bp 99—100 °C), in 70% yield.

The reactions of trifluoroethene with other carboxylic acid chlorides using $AlCl_3$ were carried out in a similar manner. When benzoyl chloride was used, the product was separated by column chromatography on silica gel (solvent : hexane).

6-Chloro-5,6,6-trifluoro-2,4-hexanedione (9) (R=Me; R'=H). (A): Into a mixture of $FeCl_3$ (32.4 g, 0.2 mol), acetyl chloride (15.7 g, 0.2 mol), and dichloromethane (100 ml) was introduced liquefied trifluoroethene (8.2 g, 0.1 mol) as described above. The mixture was allowed to react for 20 h at room temperature and the reaction mixture was worked up as usual. β-Diketone **9** (R=Me; R'=H) (8.1 g), bp 70—74 °C/23 mmHg, was obtained in 40% yield.

(B): Into a suspension of $FeCl_3$ (1.95 g, 12 mmol) in dichloromethane (10 ml), a mixture of acetyl chloride (0.40 g, 5 mmol) and 2-chloro-1,2,2-trifluoroethyl methyl ketone (0.80 g, 5 mmol) was dropped and the mixture was stirred for 24 h at room temperature under atmospheric pressure. The reaction mixture was worked up giving a β-diketone **9** (R=Me; R'=H) (0.70 g) in 70% yield.

**1 mmHg≈133.3 Pa.

The σ-Bonded Palladium(II) Complex of [π-(Dimethylaminomethyl)-cyclopentadienyl]tetraphenylcyclobutadienecobalt(I)

Taeko Izumi, Mitsugi Maemura, Kazuyoshi Endoh, Tadashi Oikawa, Satoshi Zakozi, and Akira Kasahara*

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received September 8, 1980)

[π-(Dimethylaminomethyl)cyclopentadienyl]tetraphenylcyclobutadienecobalt(I) reacts with lithium tetrachloropalladate(II) in the presence of sodium acetate to give an ortho-palladated binuclear complex. The σ-bonded structure of the complex was confirmed by studies of the IR and ^{1}H-NMR spectra and of the reactions with triphenylphosphine, thallium(I) acetylacetonate, and lithium aluminum deuteride. The reactions of the σ-bonded complex with carbon monoxide and olefins have been examined.

Following the first observation by Cope and Siekman[1] that azobenzene reacts with palladium(II) chloride to give an intramolecular ortho-palladation product with a carbon-to-metal σ-bond, considerable interest developed in this area and numerous ortho-metalated complexes have been prepared.[2] In connection with the ortho-metalation, Alper[3] reported the first example of the intramolecular ortho-palladation of a metallocene by the reaction of thiopivaloylferrocene with sodium tetrachloropalladate(II); subsequently the intramolecular ortho-palladations of (dimethylaminomethyl)ferrocene,[4] acetylferrocene *N,N*-dimethylhydrazone,[5] 2-pyridylferrocene,[6] and (dimethylaminomethyl)ruthenocene[7] were also reported. In this report, we wish to report on the intramolecular ortho-palladation of [π-(dimethylaminomethyl)cyclopentadienyl]tetraphenylcyclobutadienecobalt(I) (**1**) and the reaction of the metalation product (**2**) with carbon monoxide and olefins.

Results and Discussion

In the presence of sodium acetate trihydrate, the reaction of **1** with mole equivalents of lithium tetra-

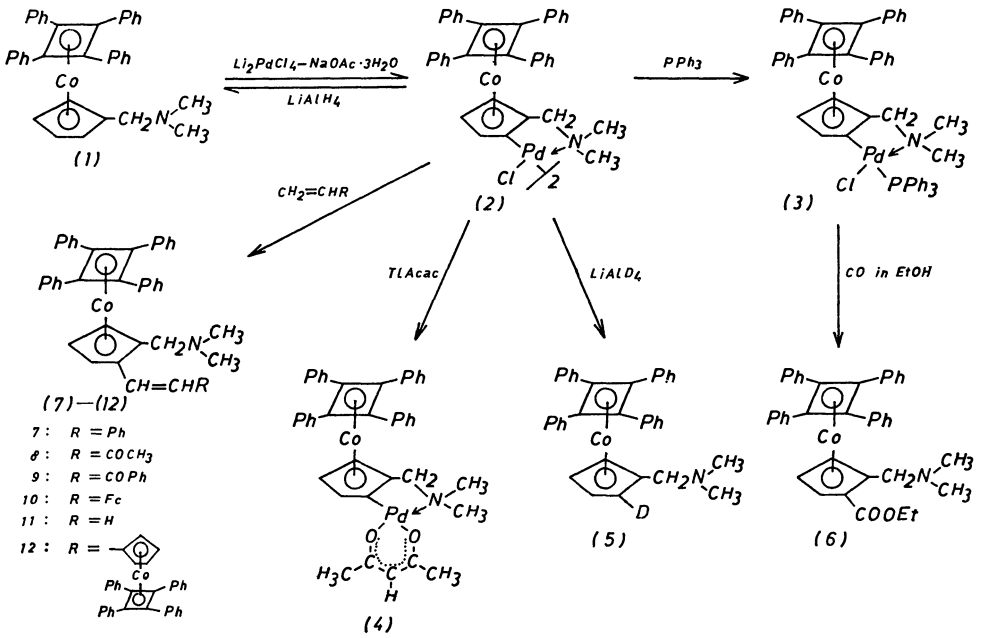

Fig. 1.

chloropalladate(II) gave di-μ-chloro-bis{[π-1-(dimethylaminomethyl)cyclopentadienyl-2*C*,*N*]tetraphenylcyclobutadienecobalt(I)}dipalladium(II) (**2**) in 96% yield. The complex **2** was shown to be an intramolecularly ortho-palladated complex on the bases of its reactions and of the microanalytical and spectroscopic results. Measurement of the molecular weight using a vapor pressure osmometer was not conducted because of the low solubility of **2** in all common solvents. However, the binuclearly σ-bonded structure of the complex **2** was supported by the bridged splitting reaction with triphenylphosphine and thallium(I) acetylacetonate to give readily soluble monomeric triphenylphosphine derivative **3** and a monomeric acetylacetonate derivative **4**, respectively. Moreover, the far-infrared spectrum of **2** showed a bridged Pd–Cl streching absorption at about 303, 275, and 255 cm^{-1}. The low solubility of **2** in all common solvents precluded any NMR studies at room temperature. However, the ^{1}H-NMR spectra of derivative **3** and **4** clearly demonstrated that Pd–C σ-bonds and Pd–nitrogen coordination bonds existed in these complexes (Table 1). *N*-Methyl and *N*-methylene protons of **1** appear as singlets, whereas in **3** and **4** the *N*-methyl protons appear as two singlets and the *N*-methylene protons as two doublets. The non-equivalence of the *N*-methyl and *N*-methylene protons in **3** and **4** can be explained in terms of a cyclic system in which the nitrogen is coordinated to the palladium and a palladium–carbon σ-bond is involved.[8] Furthermore, to ascertain the formation of the σ-bond between palladium and the cyclopentadienyl ring in **2**, **3**, and **4**, the compound **2** was reduced with lithium aluminum deuteride to give [π-1-(dimethylaminomethyl)cyclopentadienyl-2-*d*]tetraphenylcyclobutadienecobalt(I) (**5**). On the other hand, the lithium aluminum hydride reduction of **2** gave **1**, whose mass spectrum was identical with that of an authentic sample. The IR spectrum of the compounds prepared in this study is recorded in Table 2. In ferrocene derivatives, generally, 1,2-disubstituted derivatives exhibited one peak, while the 1,3-isomers showed two peaks in the region near 900 cm^{-1}; this was the characteristic absorption band of the C–H out-of-plane bending mode on the ferrocene ring.[9] The infrared frequencies of the C–H bending modes of ruthenocene derivatives are also similar to those ferrocene.[7,10] Compounds **2**, **3**, and **4** and another derivatives from **2** all exhibited a single peak in the 900 cm^{-1} region. Taking these results into account, it has been confirmed that **2**, **3**, and **4** are 1,2-disubstituted cyclopentadienyl derivatives.

The reactions of ortho-palladation products from α-aryl-nitrogen derivatives with numerous reagents have been reported.[2] The carbonylation of ortho-palladation products of azobenzene, Schiff bases, and *N*,*N*-dialkylbenzylamines usually gives a variety of heterocyclic compounds.[11,12] The derivative **3** in ethanol was readily carbonylated at 100 °C to produce an uncyclic ester [π-1-(dimethylaminomethyl)-2-ethoxycarbonylcyclopentadienyl]tetraphenylcyclobutadienecobalt(I) (**6**) in 42% yield. On the other hand, in the presence of triethylamine, the complex **2** reacted with simple olefins, such as styrene, methyl vinyl ketone, phenyl vinyl ketone, and vinylferrocene, in toluene at 100 °C, leading to the formation of [π-1-(dimethylaminomethyl)-2-alkenylcyclopentadienyl]-tetraphenylcyclobutadienecobalt(I) (**7**—**10**) in moderate yields. Moreover, the reaction of the complex **2** with ethylene led to the formation of vinyl derivative (**11**) and disubstituted ethylene derivative (**12**) in 78 and 1.5% yield, respectively. The IR and ^{1}H-NMR spectra of compounds **5**—**12** were all consistent with the proposed structures. The compounds **5**—**12** also exhibited a single peak absorption in the 900 cm^{-1} region characteristic of homoannularly 1,2-disubstituted metallocene derivatives.

Table 3. Properties and analysis of [π-1-(dimethylamenomethyl)cyclopentadienyl]-tetraphenylcyclobutadienecobalt(I) derivatives

Compound	
6	pale yellow crystals, mp 112—113 °C. Found: C, 76.71; H, 5.84; N, 2.13%. MS: *m/e* 609 (M^+). Calcd for $C_{39}H_{36}CoNO_2$: C, 76.83; H, 5.95; N, 2.29%; mol wt, 609.
7	pale yellow crystals, mp 86—88 °C. Found: C, 82.48; H, 5.86; N, 2.05%. MS: *m/e* 639 (M^+). Calcd for $C_{44}H_{38}CoN$: C, 82.61; H, 6.01; N, 2.18%; mol wt, 639.
8	pale yellow crystals, mp 109—111 °C. Found: C, 79.23; H, 5.88; N, 2.25%. MS: *m/e* 605 (M^+). Calcd for $C_{40}H_{36}CoNO$: C, 79.32; H, 5.99; N, 2.31%; mol wt, 605.
9	pale yellow crystales, mp 157—159 °C. Found: C, 80.61; H, 5.59; N, 1.88%. MS: *m/e* 667 (M^+). Calcd for $C_{45}H_{38}CoNO$: C, 80.79; H, 5.73; N, 2.09%; mol wt, 667.
10	reddish yellow crystals, mp 79—81 °C. Found: C, 76.87; H, 5.71; N, 1.73%. MS: *m/e* 747 (M^+). Calcd for $C_{48}H_{42}CoFeN$: C, 77.08; H, 5.67; N, 1.87%; mol wt, 747.
11	pale yellow crystals, mp 124—125 °C. Found: C, 80.90; H, 5.95; N, 2.33%. MS: *m/e* 563 (M^+). Calcd for $C_{38}H_{34}CoN$: C, 80.97; H, 6.07; N, 2.48%; mol wt, 536.
12	yellow crystals, mp 244—246 °C. Found: C, 80.77; H, 5.72; N, 2.45%; mol wt 1094 (in $CHCl_3$). Calcd for $C_{74}H_{64}Co_2N_2$: C, 80.86; H, 5.86; H, 2.54%; mol wt, 1099.

Experimental

Materials. All the melting points are uncorrected. [π-(Dimethylaminomethyl)cyclopentadienyl]tetraphenylcyclobutadienecobalt(I) (**1**) was prepared according to the method described by Rausch and Genetti.[13] Phenyl vinyl ketone[14] and vinylferrocene[15] were synthesized according to known procedures. The other olefins were obtained from commercial sources.

Measurements. The ^{1}H-NMR spectra were determined in $CDCl_3$ with a Hitachi R-22 spectrometer (90 MHz), using TMS as the internal standard (δ, ppm). The IR spectra were measured (4000—650 cm^{-1}) and Nujol mulls mounted on thin polythene windows (700—200 cm^{-1}) with Hitachi 215 and EPI-L spectrometers. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer, using a direct insertion probe at an ionization energy of 70 eV. The molecular weight was determined in $CHCl_3$ with a Hitachi 115 vapor pressure osmometer.

*Di-μ-chloro-bis{[π-1-(dimethylaminomethyl)cyclopentadienyl-2C,N]tetraphenylcyclobutadienecobalt(I)}dipalladium(II) (**2**).* A mixture of lithium tetrachloropalladate(II) (2.62 g, 10 mmol) and sodium acetate trihydrate (1.36 g, 10 mmol) in methanol (50 ml) was stirred for 30 min at room temperature. To the reaction mixture, a solution of **1** (5.37 g, 10 mmol) in methanol (100 ml) was added, and the mixture was stirred for 36 h at room temperature. The yellow precipitate which formed was filtered and washed successively with several portions of methanol and then ether. The solid (6.5 g, 96% yield) was insoluble in all common solvents; mp 208—210 °C (dec). Found: C, 60.68; H, 4.67; N, 2.02%. Calcd for $C_{64}H_{62}Cl_2Co_2N_2Pd_2$: C, 60.96; H, 4.95; N, 2.22%.

*Chloro(triphenylphosphine{[π-1-(dimethylaminomethyl)cyclopentadienyl-2C,N]tetraphenylcyclobutadienecobalt(I)}palladium(II) (**3**).* A mixture of the complex (5.0 g, 3.7 mmol) and triphenylphosphine (1.94 g, 7.4 mmol) in benzene (50 ml) was stirred for 12 h at room temperature. After removal of the solvent *in vacuo*, the column chromatography of the residue on silica gel ($CHCl_3$) gave triphenylphosphine derivative (**3**) (6.9 g, 99% yield); mp 235—237 °C (dec). Found: C, 67.33; H, 5.31; N, 1.71%; mol wt 884 (in $CHCl_3$). Calcd for $C_{50}H_{46}ClCoNPPd$: C, 67.27; H, 5.19; N, 1.55%; mol wt 892.

*Acetylacetonato{[π-1-(dimethylaminomethyl)cyclopentadienyl-2C,N]tetraphenylcyclobutadienecobalt(I)}palladium(II) (**4**).* A suspension of the complex **2** (0.80 g, 0.6 mmol) and thal-

lium(I) acetylacetonate (0.33 g, 1.2 mmol) in benzene (20 ml) was stirred for 24 h at room temperature. The filtrate was evaporated *in vacuo*, and the residue was purified by column chromatography on silica gel ($CHCl_3$) and gave the acetylacetonate derivative (**4**) (0.7 g, 80% yield); mp 219—221 °C (dec). Found: C, 64.15; H, 5.62; N, 2.17%; mol wt 686 (in $CHCl_3$). Calcd for $C_{37}H_{38}CoNO_2Pd$: C, 64.03; H, 5.51; N, 2.01%; mol wt 694.

Reduction of Complex 2 with Lithium Aluminum Hydride. Lithium aluminum hydride (0.08 g, 2 mmol) in dry ether (50 ml) was slowly added to a solution of the complex **2** (2.52 g, 2 mmol) in dry THF (50 ml). The resulting black mixture was stirred at 50 °C for 8 h; then water (20 ml) was added with cooling. The ether layer was washed with water and dried over anhydrous $MgSO_4$. After the removal of the solvent, **1** was obtained as yellowish needles from benzene–cyclohexane; mp 189—190 °C (lit,[13] mp 189—190 °C). The ^{1}H-NMR, IR, and mass spectra of **1** were consistent with those of an authentic sample.

Reduction of Complex 2 with Lithium Aluminum Deuteride. The reduction of the complex **2** (1.0 g) with lithium aluminum deuteride (0.035 g) was conducted under the same conditions as in the preceeding experiment. After recrystallization from benzene–cyclohexane, the product (mp 189—191 °C) was identified as [π-1-(dimethylaminomethyl)cyclopentadienyl-2-*d*]tetraphenylcyclobutadienecobalt(I) (**5**) on the basis of the following evidence; ^{1}H-NMR ($CDCl_3$): δ 2.23 (s, 6H, $-N(C\underline{H}_3)_2$), 2.71 (s, 2H, $-C\underline{H}_2-$), 4.63 (s, 3H, Cp–H), 7.10—7.65 ppm (m, 20H, Ar–H). MS: *m/e* 538 (M^+). Found: C, 80.16; H, 6.01; N, 2.45%. Calcd for $C_{36}H_{31}CoDN$: C, 80.27; H, 6.19; N, 2.60%; mol wt, 538.

Carbonylation of Complex 3 in Ethanol. In an autoclave, a suspension of the complex **3** (2.0 g, 2.1 mmol) in ethanol (80 ml) was stirred for 24 h at 100 °C under carbon monoxide pressure of 50 atm. The reaction mixture was filtered to remove precipitated palladium, and the filtrate was evaporated *in vacuo*. The residue was dissolved in $CHCl_3$ and column chromatographed on silica gel to afford [π-1-(dimethylaminomethyl)-2-ethoxycarbonylcyclopentadienyl]-tetraphenylcyclobutadienecobalt(I) (**6**): mp 112—113 °C, (0.41 g, 42% yield). The structure of **6** has been confirmed by elemental analysis and ^{1}H-NMR, IR, and mass spectra (Tables 1, 2, and 3).

General Procedure for the Reaction of Complex 2 with Olefins. In a closed vessel, a mixture of the complex **2** (1.26 g, 1 mmol), 3 mmol of olefin (styrene, methyl vinyl ketone, phenyl vinyl ketone, and vinylferrocene) and triethylamine (0.20 g, 2 mmol) in toluene (50 ml) was stirred for 8 h at 80 °C under a nitrogen atmosphere. The reaction mixture was cooled and filtered to remove precipitated palladium, and the filtrate was evaporated *in vacuo*. The residue was dissolved in $CHCl_3$ which had been washed with brine, and dried over anhydrous $MgSO_4$. After removal of the solvent, purification of the crude product by column chromatography (silica gel–$CHCl_3$) gave [π-1-(dimethylaminomethyl)-2-styryl-cyclopentadienyl]tetraphenylcyclobutadienecobalt(I) (**7**), [π-1-(dimethylaminomethyl)-2-(2-acetylvinyl)cyclopentadienyl]-tetraphenylcyclobutadienecobalt(I) (**8**), [π-1-(dimethylaminomethyl)-2-(2-benzoylvinyl)cyclopentadienyl]tetraphenylcyclobutadienecobalt(I) (**9**), and [π-1-(dimethylaminomethyl)-2-(2-ferrocenylvinyl)cyclopentadienyl]tetraphenylcyclobutadienecobalt(I) (**10**) in 30, 45, 57, and 40% yields, respectively.

In the case of the reaction with ethylene, a suspension of the complex **2** (2.52 g, 2 mmol) in triethylamine (30 ml) was stirred for 20 h at 100 °C under ethylene pressure of 50 atm in an autoclave. The crude products were purified by column chromatography on silica gel. First elution with $CHCl_3$ and recrystallization from benzene–cyclohexane afforded pale yellow crystals (78% yield), which were identified to [π-1-(dimethylaminomethyl)-2-vinylcyclopentadienyl]tetraphenylcyclobutadienecobalt(I) (**11**). Further elution with $CHCl_3$ and recrystallization from benzene–cyclohexane afforded yellow crystals, which were identified as μ-{bis[π-2-(dimethylaminomethyl)cyclopentadienyl]ethylene}-bis[tetraphenylcyclobutadienecobalt(I)] (**12**) (1.5% yield). The structure of the compounds (**7**—**12**) has been confirmed by elemental analysis and the ^{1}H-NMR, IR, and mass spectra (Tables 1, 2, and 3).

"Naked" Hydrogencarbonate Ion as a Bifunctional Catalyst toward Amide Substrates.[1] Nucleophilic Ion Pairs. 9

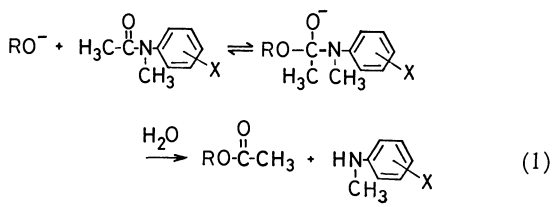
Seiji SHINKAI,** Naotoshi NAKASHIMA, and Toyoki KUNITAKE*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Naka-ku, Fukuoka 812

(Received September 16, 1980)

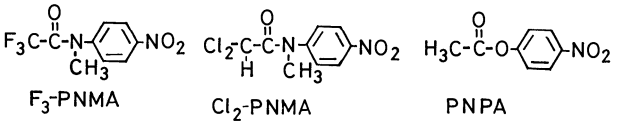
The cleavage of amide substrates(*p*-nitro-*N*-methyltrifluoroacetanilide and *p*-nitro-*N*-methyldichloroacetanilide) with anionic nucleophiles was studied at 30 °C in aprotic (acetonitrile and *N*,*N*-dimethylformamide) and protic(ethanol) media. Hydrogencarbonate ion acted as catalyst much more efficiently in the aprotic solvents (about 10^3 fold) than expected from its aqueous pK_a, but in ethanol, its reactivity was close to those of simple nucleophiles (*p*-cyanophenolate anion and *N*-hydroxysuccinimide anion) that possess analogous pK_a values in water. The reaction rate in the aprotic solvents was sensitive to small amounts of water. The kinetic isotope effect showed that proton transfer was involved (at least partially) in the rate-determining step. Thus, hydrogencarbonate ion behaves in aprotic media as a nucleophilic-general acid catalyst for the amide cleavage. The biochemical implication with regard to the action of biotin was discussed.

The catalytic hydrolysis of amide substrates has been of special concern as model systems of hydrolytic enzymes. Amide groups are generally very stable toward nucleophiles, so that investigation has been limited to the alkaline hydrolysis of amide substrates containing strongly electron-attracting groups.[2-5] In the previous publications of this series, we reported that the cleavage of amide linkages which was virtually impossible in aqueous systems did take place in very dry aprotic solvents with tetraalkylammonium hydroxamate ion pairs.[6,7] The rate augmentation observed reached 10^8—10^9 fold in comparison with that in the aqueous system. We proposed, on the basis of several pieces of evidence, that the amide cleavage is achieved due to (i) enhanced nucleophilicity of the hydroxamate anion(or probably oxide anions in general: RO^-) which is desolvated in aprotic solvents[8,9] and (ii) efficient proton transfer from poorly solvated water molecules to the tetrahedral intermediate.[6,7] Particularly, the second factor is characteristic of the amide cleavage, since it requires proton sources to avoid the formation of energetically-unfavorable amine anions.[10] Obviously, these are opposing factors: that is, factor (i) arises from enhanced basicity(nucleophilicity) of oxide anions and factor (ii) is related to the enhanced reactivity of water molecules as proton source. Thus, the combination of these two factors in a single reaction medium is not easy.



(1)

However, a tautomer which combines within a molecule structural characteristics of acid(s) (proton source) and base(s) (oxide anions) may serve as an efficient catalyst for the amide cleavage. Tautomeric catalysts have been extensively employed as bifunctional catalysts in mutarotation and acyl transfer reactions.[11] However, they cannot be applied directly to the amide cleavage, because their nucleophilic reactivities are not sufficiently large. Therefore, we adopted potassium hydrogencarbonate ($HCO_3^-K^+$) as a bifunctional catalyst which has an oxide anion group (pK_a=6.37 in H_2O)[12] as well as a dissociable OH group. As monofunctional nucleophiles, potassium *p*-cyanophenolate(*p*-$CNC_6H_4O^-K^+$: pK_a=7.95 in H_2O)[12] and potassium salt of *N*-hydroxysuccinimide(SIO$^-$K$^+$: pK_a=6.0 in H_2O)[13] were employed. These salts were solubilized in desired solvents with 10 times excess perhydrodibenzo-18-crown-6. Substrates employed are recorded below with their abbreviations.



F_3-PNMA Cl_2-PNMA PNPA

Experimental

Materials. Equimolar amounts of *p*-cyanophenol and potassium hydroxide were mixed in methanol and the solvent was evaporated. The residue was recrystallized from acetonitrile and methanol to give monohydrate of potassium *p*-cyanophenolate. The potassium salt of *N*-hydroxysuccinimide was prepared in the same way. *p*-Nitro-*N*-methyltrifluoroacetanilide (F_3-PNMA) was prepared by Dr. T. Sakamoto in these laboratories from *p*-nitro-*N*-methylaniline and trifluoroacetic anhydride, mp 129—131 °C (lit,[14] 126.5—131 °C). *p*-Nitro-*N*-methyldichloroacetanilide (Cl_2-PNMA) was obtained from dichloroacetyl chloride and *p*-nitro-*N*-methylaniline in the presence of triethylamine in benzene. Recrystallization from benzene–hexane gave slightly yellow powders; mp 131—133 °C, Found: C, 41.38; H, 3.10; N, 10.59%. Calcd for $C_9H_8N_2O_3Cl_2$: C, 41.05; H, 3.07; N, 10.65%. The purification of solvents was described previously.[7]

Kinetics. The potassium salts were dissolved in desired solvents with 10 times excess perhydrodibenzo-18-crown-6 by sonication (1.5 h). All kinetic measurements were carried out at 30±0.1 °C in modified Thunberg cuvettes. The details of the procedure have been described elsewhere.[8,9] The progress of the reaction was monitored spectrophotometrically by following the increase in the absorption of *p*-nitro-*N*-methylaniline or that of *p*-nitrophenolate: 401 nm for PNPA and 390 nm for F_3-PNMA and Cl_2-PNMA. Since excess nucleophiles were present in all the cases, pseudo

** Present address: Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852.

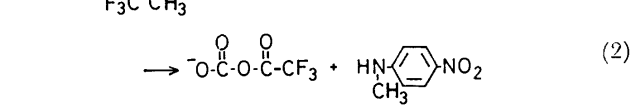
first-order behavior was observed. The water content of the reaction medium was evaluated immediately after the reaction, using a coulometric Karl-Fisher apparatus (Hiranuma Aquacounter AQ-1). The water concentration listed is the average of two to three determinations (relative error, less than 10%).

Product Analysis. A mixture of potassium hydrogencarbonate (3.9×10^{-3} M) (1 M=1 mol dm^{-3}), perhydrodibenzo-18-crown-6 (3.9×10^{-2} M), F_3-PNMA (7.0×10^{-3} M), and aniline (1.0×10^{-2} M) in acetonitrile was refluxed for 3 h, and evaporated to dryness *in vacuo*. The residue taken in methanol was subjected to high-speed liquid chromatography (Hitachi type 635 instrument; solvent, methanol; column, Hitachi gel 3010; wavelength, 254 nm). The following peaks appeared in this order and were identified by comparison with authentic samples: trifluoroacetanilide, aniline, substrate, and *p*-nitro-*N*-methylaniline. The peak height of trifluoroacetanilide was almost the same as that of aniline.

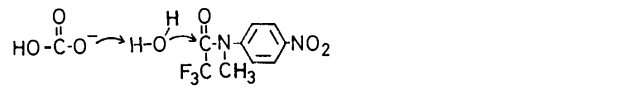
On the other hand, trifluoroacetanilide was not detected in the reaction of aniline and trifluoroacetic acid (7.0×10^{-3} M) under the comparable reaction conditions. Salt formation occurred immediately after mixing as confirmed by UV spectroscopy.

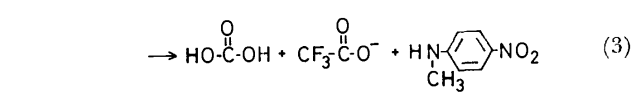
Results

Nucleophilic vs. *General Base Attack of Hydrogencarbonate.* In order to assess whether HCO_3^- acts as a nucleophile or as a general base, the semi-quantitative product analysis was performed with a high-speed liquid chromatograph.



(2)





(3)

If HCO_3^- acts as a general base, it directly produces trifluoroacetate and *p*-nitro-*N*-methylaniline (Eq. 2). On the other hand, the nucleophilic reaction would give a mixed acid anhydride, $^-OCOOCOCF_3$ (Eq. 3), which then, decomposes rapidly to trifluoroacetate and hydrogencarbonate. The intermediacy of the mixed anhydride was confirmed by the aniline trap-

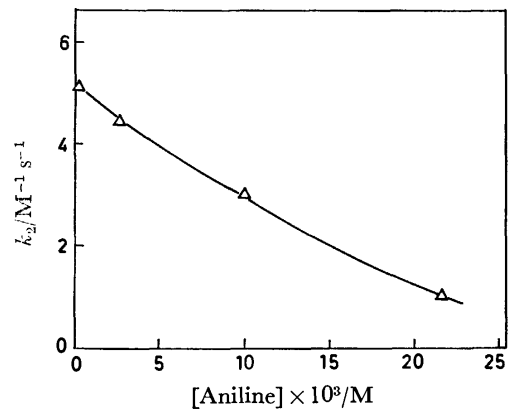

Fig. 1. Second-order rate constants for the reaction of HCO_3^- and F_3-PNMA in acetonitrile ([H_2O]=4±1 mM), plotted as a function of added aniline. [HCO_3^-]=1.28×10^{-3} M, [F_3-PNMA]=4.87×10^{-5} M.

ping experiment (Eq. 4) described in Experimental. It was confirmed in separate experiments that the trapping product, trifluoroacetanilide, was not formed directly by the reaction of aniline with F_3-PNMA substrate or with trifluoroacetic acid. The possibility that trifluoroacetanilide is formed *via* a mechanism related to the general base mechanism of Eq. 3 (Eq. 5) may be denied by the following argument. Provided that Eq. 5 is the predominant path, added aniline should accelerate the reaction. In Fig. 1, the second-order rate constant(k_2) for the reaction of HCO_3^- and F_3-PNMA is plotted as a function of added aniline. Since aniline retards the reaction, Eq. 5 is not likely to occur.

The presence of trifluoroacetanilide in the product of the aniline experiment, together with the rate-retarding effect of aniline, clearly indicates that the amide cleavage proceeds *via* direct attack of hydrogencarbonate ion on the amide substrate.

Absorption Spectra of Nucleophilic Anions. Prior to the kinetic examination, the relative absorbance of nucleophilic anions was measured as a function of water concentration in order to obtain reliable information on prototropic equilibria. *p*-Cyanophenol (*p*-CNC_6H_4OH) in very dry acetonitrile ([H_2O]=11.7 mM) possesses the absorption maximum at 243 nm with ε=18400, and the spectrum was not affected by added perhydrodibenzo-18-crown-6 (10 times excess). On the other hand, the absorption maximum of *p*-$CNC_6H_4O^-K^+$ solubilized in acetonitrile with 10 times excess of perhydrodibenzo-18-crown-6 appeared at 294 nm (ε=19800), which can be clearly differentiated from that of *p*-CNC_6H_4OH. The absorbance decreased only slightly with increasing water concentrations, the relative absorbance at [H_2O]=999 mM being 86% of the original value in very dry acetonitrile. At this water concentration a weak shoulder was observed at 243 nm which is ascribable to the absorption of *p*-CNC_6H_4OH. The relative amount of the neutral species calculated with ε=18400 was 12%, which is in good accord with the decrease of *p*-$CNC_6H_4O^-K^+$ ($\approx$14%) within the experimental error. Therefore, the increase in the water concentration causes a small shift in the prototropic equilib-

Table 1. Second-order rate constants for the cleavage of amide and ester substrates[a)]

Solvent[b)]	Nucleophile	$k_2/M^{-1}\,s^{-1}$		
		F_3-PNMA	Cl_2-PNMA	PNPA
DMF	HCO_3^-	59	3.7	19
DMF	p-$CNC_6H_4O^-$	1.3	0.51	26
DMF	SI-O^- [d)]	1.6	—	*ca.* 10^3
Acetonitrile	HCO_3^-	0.37—3.9[c)]	0.048—0.15[c)]	46
Acetonitrile	p-$CNC_6H_4O^-$	0.035	0.0033	22
Acetonitrile	SI-O^- [d)]	0.0030—0.032[c)]	—	400
Ethanol	HCO_3^-	1.5	0.16	0.38
Ethanol	p-$CNC_6H_4O^-$	1.1	0.085	0.32

a) [nucleophile] = (0.4—20) × 10^{-4} M, [substrate] = (5—20) × 10^{-5} M, [perhydrodibenzo-18-crown-6] = 10 × [nucleophile salt]. b) [H_2O]: 6.2—9.2 mM in DMF, 4.9—7.0 mM in acetonitrile, 100±15 mM in ethanol. c) The probable range of k_2 estimated from the non-linear plots. d) Potassium salt of *N*-hydroxysuccinimide.

rium between p-$CNC_6H_4O^-K^+$ and p-CNC_6H_4OH.

The absorption spectra of SI-O^-K^+ were somewhat more complicated. SI-O^-K^+ solubilized in very dry acetonitrile ([H_2O] = 14.1 mM) with 10 times perhydrodibenzo-18-crown-6 gave rise to two absorption maxima at 278 nm (ε 2320) and 294 nm (ε=2360). The absorption peak at 278 nm gradually increased upon addition of water and the peak at 294 nm disappeared almost completely at [H_2O] > 200 mM. However, the increase in the absorption of *N*-hydroxysuccinimide (ε=*ca.* 7000 at 210 nm (shoulder)) was not detected. This means that the spectral change cannot be ascribed to the prototropic equilibrium. Conceivably, added water may affect the nature of the ion pair which is reflected in the absorption spectrum.

Unfortunately, HCO_3^- ion does not have an absorption maximum in the UV region suitable to study the prototropic equilibrium. We thus measured the IR spectrum of $HCO_3^-K^+$ solubilized in acetonitrile with 10 times perhydrodibenzo-18-crown-6. The $\nu_{C=O}$ absorption band of the carboxylate group appeared at 1632 cm^{-1} which is comparable to that of solid $KHCO_3$ (KBr disc, $\nu_{C=O}$ 1628 cm^{-1}). The absorption peak hardly changed even in acetonitrile containing 1000 mM of water.

It is assumed from the above experimental data that the shift of prototropic equilibria due to small quantities of added water is not extensive, as compared with dramatic rate retardations observed (see below). Although a clear, quantitative analysis of prototropy was possible only in the p-CNC_6H_4OH system, the similarity in the aqueous pK_a values[12,13)] suggests that the prototropic equilibria for SI-O^- and HCO_3^- would not differ greatly from that for p-$CNC_6H_4O^-$.

Estimation of Rate Constants. In the presence of excess nucleophile, the formation of p-nitro-*N*-methylaniline from the amide substrates gave good first-order plots for up to 70% reaction, so that the reactions are first-order in substrates. The pseudo first-order rate constants(k_{obsd}) thus determined were plotted against the concentration of nucleophile. As shown in Fig. 2, plots of k_{obsd} *vs.* [nucleophile(hydrogencarbonate)] were not always linear. The second-order rate constants(k_2) were calculated as k_{obsd}/[nucleophile]

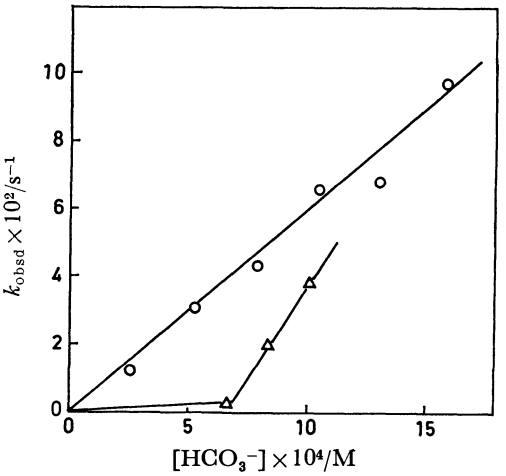

Fig. 2. Pseudo-first-order rate constants for the reaction of HCO_3^- and F_3-PNMA in DMF(○) and acetonitrile(△) plotted as a function of [HCO_3^-]. [F_3-PNMA] = 8.80 × 10^{-5} M. Water concentrations are recorded in Table 1.

and listed in Table 1. In the case of the non-linear plots, the probable range of k_2 is given.

In accordance to close pK_a values in aqueous solution, the second-order rate constants for the reaction of PNPA with HCO_3^- and p-$CNC_6H_4O^-$ are not much different in three solvents employed (two times difference at the largest). The much higher reactivity of SI-O^- toward PNPA may be attributed to the so-called α-effect. It is known that the nucleophilic attack is wholly rate-determining in water for phenyl esters with good leaving groups such as p-nitrophenolate.[10)] Whether or not this holds true in aprotic solvents is not clear at the moment. However, the relative reactivity of the nucleophiles used shows approximately parallel tendencies between the aqueous and aprotic media (Table 1).

Interestingly, HCO_3^- acted as the most efficient catalyst toward amide substrates: for example, the reaction of HCO_3^- and F_3-PNMA in DMF was faster by factors of 37—45 than the corresponding reactions with p-$CNC_6H_4O^-$ and SI-O^-. On the other hand, the rate difference between HCO_3^- and p-$CNC_6H_4O^-$ was very small in ethanol (protic solvent).

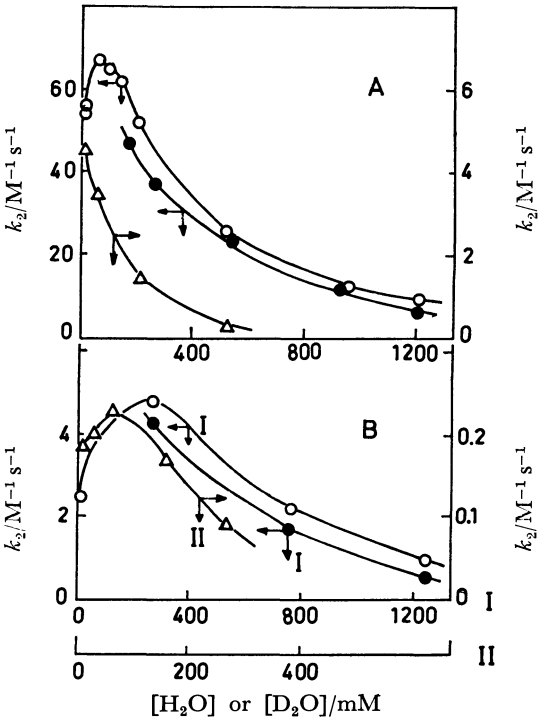

Fig. 3. Second-order rate constants for F_3-PNMA cleavage plotted as a function of [H_2O] or [D_2O]. (A) HCO_3^-+F_3-PNMA: ○; H_2O in DMF, ●; D_2O in DMF, △; H_2O in acetonitrile. (B) *p*-$CNC_6H_4O^-$+F_3-PNMA: symbols used stand for the same as above.

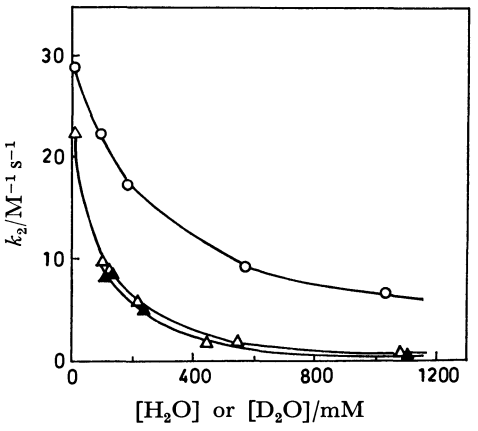

Fig. 4. Second-order rate constants for PNPA cleavage plotted as a function of [H_2O] or [D_2O]. ○: H_2O for *p*-$CNC_6H_4O^-$+PNPA in DMF, △: H_2O for HCO_3^-+PNPA in acetonitrile, ▲: D_2O for HCO_3^-+PNPA in acetonitrile.

Influence of Small Amounts of Water on Reaction Rates. The experiments described above were performed at almost constant water concentrations, which are recorded in the caption for Figures or in the footnote for Tables. Followingly, we determined the second-order rate constant as a function of water concentration in the respective reaction media. The results are illustrated in Figs. 3 and 4. It is clear that the rates are sensitive to small amounts of water. The rate constants are almost meaningless without accurate

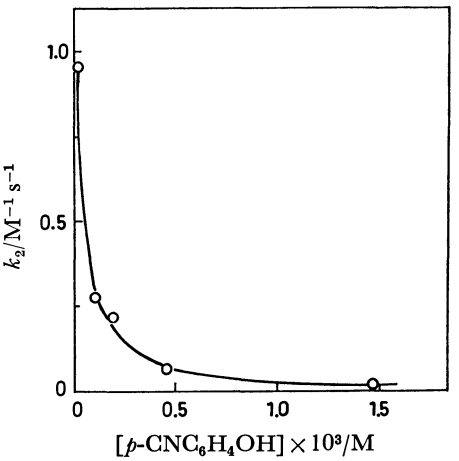

Fig. 5. Second-order rate constants for the reaction of *p*-$CNC_6H_4O^-$ and F_3-PNPA in DMF ([H_2O]= 4±2 mM) plotted as a function of added *p*-CNC_6H_4-OH. [*p*-$CNC_6H_4O^-$]=1.61×10^{-3} M, [F_3-PNMA]= 2.51×10^{-5} M.

indication of the water concentration. In some of the amide cleavage(HCO_3^-+F_3-PNMA in DMF, *p*-$CNC_6H_4O^-$+F_3-PNMA in DMF, and *p*-$CNC_6H_4O^-$+ F_3-PNMA in acetonitrile), rate maxima were observed at about 100—300 mM H_2O. On the other hand, F_3-PNMA cleavage by HCO_3^- in acetonitrile (Fig. 3A) and the nucleophilic reaction of HCO_3^- and *p*-$CNC_6H_4O^-$ toward PNPA (Fig. 4) did not provide such rate maxima. Thus, the phenomenon seems to be confined to the amide cleavage, but is not limited to the catalysis by HCO_3^-.

Water may suppress the reaction by neutralizing *p*-$CNC_6H_4O^-$ ion or by reducing reactivity of *p*-$CNC_6H_4O^-$ due to solvation.[7-9] If added water produces *p*-CNC_6H_4OH which then act as general acid in the amide cleavage, a rate maximum could arise from the cooperative action of *p*-$CNC_6H_4O^-$ and *p*-CNC_6H_4OH.

Figure 5 shows the second-order rate constant at the constant water concentration plotted against the concentration of added *p*-CNC_6H_4OH. The reaction rate diminished with increasing *p*-CNC_6H_4OH concentration, contrary to the expectation. *p*-CNC_6H_4OH quenches the reactivity of *p*-$CNC_6H_4O^-$ probably due to the hydrogen-bonded solvation, instead of assisting the reaction as general acid. Therefore, it appears that only the intramolecular proton in the tetrahedral intermediate of HCO_3^- and amide substrates is capable of acting as effective proton source (see Eqs. 7 and 8).

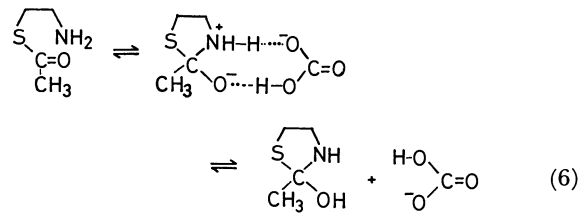
Kinetic Isotope Effects. If the rate-determining step involves proton transfer to the tetrahedral intermediate, the reaction will be retarded by replacing H_2O with D_2O. Figures 3 and 4 indicate that at the same water concentration the rate constants in the D_2O-containing medium are smaller than those in the H_2O-containing medium: $k_{2,H_2O}/k_{2,D_2O}=1.3\pm0.2$ for HCO_3^-+F_3-PNMA, 1.2±0.1 for *p*-$CNC_6H_4O^-$+ F_3-PNMA, and 1.10±0.06 for HCO_3^-+PNPA. Since the acyl transfer reaction with PNPA is considered not to be general acid catalyzed,[10] the isotope effect

of 1.1 may be associated with the simple nucleophilic step. The $k_{2,H_2O}/k_{2,D_2O}$ value for the F_3-PNMA is somewhat greater than this, and suggests the involvement of general acid catalysis.

The kinetic isotope effect was also assessed for the reaction in ethanol-*d*. The rate constants were relatively insensitive to the water concentration (or D_2O concentration in ethanol-*d*). Though the relative error of 10—20% must be assumed, the magnitude of $k_{2,EtOH}/k_{2,EtOD}$ for HCO_3^-+F_3-PNMA and HCO_3^-+Cl_2-PNMA (2.2 and 1.6, respectively) is greater than that for PNPA (1.1—1.5).

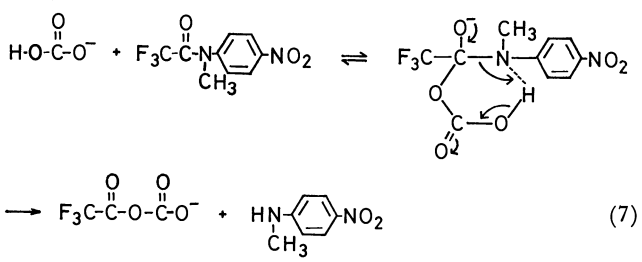
Discussion

Polyvalent inorganic salts have been considered to act as bifunctional catalyst, since they can accept and release proton simultaneously.[11] Cunningham and Schmir[15] and Barnett and Jencks[16] reported that intramolecular aminolysis is accelerated by hydrogencarbonate ion. The kinetic examination established that HCO_3^- partitions the zwitterionic tetrahedral intermediate in favor of the products. For example, the rate constant for hydrogencarbonate-catalyzed intramolecular aminolysis of *S*-(2-aminoethyl)thioacetate exhibits positive deviation of two orders of magnitude.[16] Thus, it is concluded that HCO_3^- interacts with the tetrahedral intermediate in a cyclic manner to accelerate its decomposition (Eq. 6).



(6)

A similar acceleration of the breakdown of the tetrahedral intermediate by HCO_3^- was reported for the alkaline hydrolysis of trifluoroacetanilide,[4] but not for that of *p*-nitrotrifluoroacetanilide.[5] However, HCO_3^- by itself cannot cleave the amide substrate in an aqueous system. Since the nucleophilicity of anions is drastically enhanced in aprotic solvents,[7,17] HCO_3^- in aprotic solvents can act as a bifunctional catalyst toward amide substrates. The product analysis strongly indicates that HCO_3^- in acetonitrile directly attacks the amide group of F_3-PNMA. The rate data suggest that the OH group of HCO_3^- acts as general acid during the breakdown of the tetrahedral intermediate. The most reasonable reaction scheme would be the following.



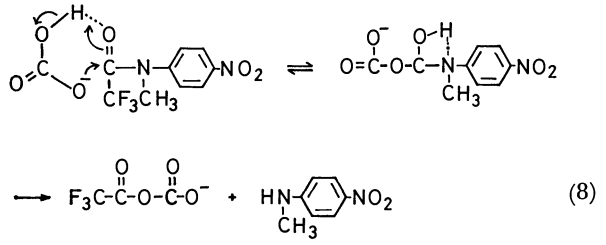
(7)

Table 2. Relative reaction rates and efficiency parameters for amide cleavage[a]

Solvent		F_3-PNMA	Cl_2-PNMA	PNPA
DMF	$k_{rel,CNC_6H_4O^-}$	45	7.3	0.73
	$k_{rel,SI-O^-}$	37	—	0.019
	$r_{CNC_6H_4O^-}$	62	10	1.0
	r_{SI-O^-}	*ca.* 1900	—	1.0
Acetonitrile	$k_{rel,CNC_6H_4O^-}$	11—110	15—45	2.1
	$k_{rel,SI-O^-}$	120	—	0.12
	$r_{CNC_6H_4O^-}$	5.2—52	7.1—21	1.0
	$r_{rel,SI-O^-}$	*ca.* 1000	—	1.0
Ethanol	$k_{rel,CNC_6H_4O^-}$	1.4	1.9	1.2
	$r_{CNC_6H_4O^-}$	1.2	1.6	1.0

a) $k_{rel}=k_2$ for HCO_3^-/k_2, $r=k_{rel}$ for amide/k_{rel} for PNPA. For detail see text (Eqs. 9, 10, and 11).

However, the bifunctional attack of hydrogencarbonate ion followed by efficient proton transfer (Eq. 8), if it occur, would not be differentiated kinetically.



(8)

In Table 2, we summarize relative reaction rates (k_{rel}) and efficiency parameters (r) for the amide cleavage. The r value given by Eq. 11 stands for a measure

$$k_{rel,CNC_6H_4O^-} = \frac{k_2 \text{ for } HCO_3^-}{k_2 \text{ for } p\text{-}CNC_6H_4O^-} \quad (9)$$

$$k_{rel,SI-O^-} = \frac{k_2 \text{ for } HCO_3^-}{k_2 \text{ for SI-O}^-} \quad (10)$$

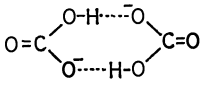
$$r = \frac{k_{rel} \text{ for a substrate}}{k_{rel} \text{ for PNPA}} \quad (11)$$

of relative efficiency of HCO_3^- catalysis for amide cleavage *versus* PNPA cleavage. The r value for PNPA is, of course, equal to unity. The data of Table 2 substantiates that (i) r-values in DMF and acetonitrile are always much greater than unity and r_{SI-O^-} amounts to 10^3; in contrast, (ii) r-values in ethanol are almost equal to unity. Therefore, in the present system, the general acid catalysis by the hydroxyl group of HCO^-_3 is effective only in aprotic solvents. Proton transfer from hydrogencarbonate hydroxyl group may not be particularly favorable in ethanol due to its hydrogen bonding with the solvent and/or due to proton transfer from solvent ethanol. In addition, SI–O$^-$ (highly nucleophilic toward PNPA) is not effective in the amide cleavage, which again points to the importance of proton transfer.

As shown in Figs. 4 and 5, the isotope effect for the amide cleavage is greater than that for PNPA cleavage. The corresponding data in organic media are scarce. Breslow and McClure[18] gave k_{H_2O}/k_{D_2O}= 1.47—2.27 for the general-acid catalyzed cleavage of maleamic acid in acetonitrile containing 1 M H_2O. Schowen *et al.*[19] also reported that, in the basic meth-

anolysis of amide substrates, $k_{2,EtOH}/k_{2,EtOD}$ approaches 2.0 when proton transfer becomes involved in the rate-limiting step. The isotope effects observed in the present study for the amide cleavage are: $k_{2,H_2O}/k_{2,D_2O}$ =1.3 (for F_3-PNMA) and $k_{2,EtOH}/k_{2,EtOD}$=1.6—2.2. These data are comparable to those observed for other general acid catalyses, and proton transfer is supposedly involved (at least partially) in the rate-limiting step in the present case.

The dependence of rate constants on the nucleophile and water concentrations is complicated. Among conceivable factors, (1) added water lowers the nucleophilicity of HCO_3^- and p-$CNC_6H_4O^-$ [5,6,8] and (2) added water changes the aggregation structure of the nucleophilic ion pairs, tightness of ion pairs, *etc.* The rate maximum observed is not amenable to simple interpretation. The non-linear dependence on nucleophile concentrations may reflect a similar phenomenon. In particular, HCO_3^- ion pairs may exhibit a strong association tendency in aprotic solvents as shown below.



(12)

Finally, we would like to point out the analogy of the hydrogencarbonate catalysis with the action of biotin. Mg-ATP and HCO_3^- are believed to form mixed acid anhydride, which (in a stepwise manner or in a concerted manner) reacts with enzyme-bound biotin.[20] The present study would suggest that the efficiency of HCO_3^- as acyl-group (or probably phosphate-group) acceptor can be enhanced in the aprotic environment. We could prepare mixed acid anhydride from HCO_3^- and F_3-PNMA, but trifluoroacetyl group, not hydrogencarbonate, was transfered to aniline.

In conclusion, the present study substantiates that HCO_3^- in aprotic media acts as a proper nucleophilic-general acid catalyst in the cleavage of amide substrates.

The Photo-Beckmann Rearrangement of Steroidal β,γ-Unsaturated Ketone Oximes[1)]

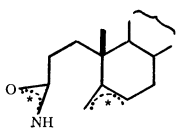
Hiroshi SUGINOME,*,** Norio MAEDA, Yuko TAKAHASHI, and Nobuyoshi MIYATA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 8, 1979)

The photoreaction of 4,4-dimethylcholest-5-en-3-one oxime, a β,γ-unsaturated ketone oxime, has given two lactams, 4a,4a-dimethyl-3-aza-*A*-homocholest-5-en-4-one and 4a,4a-dimethyl-4-aza-*A*-homocholest-5-en-3-one resulting from photo-Beckmann rearrangement. 4,4,6-Trimethylcholest-5-en-3-one oxime behaved analogously on photolysis, yielding two lactams but accompanied by 4,6-dimethyl-4-methylene-3,4-secocholest-5-ene-3-nitrile as a minor product. In contrast, major products in the ordinary Beckmann rearrangement are nitriles resulting from the second order Beckmann rearrangement.

Our previous studies on the photo-Beckmann rearrangement of several steroidal ketone oximes established that the chirality of the migrating group center is retained in the product lactams, indicating that the lactams are formed *via* a concerted reorganization of the intermediate oxaziridines and that the migrating group center does not become separated from the migration terminus in the course of the photo-rearrangement.[2-4)] This conclusion was further supported by our recent study on the photoreaction of a β,γ-cyclopropyl ketone oxime.[5)] We have found, however, that there are some exceptional cases[6)] in which ionic or radical species resulting from a cleavage of a bond α to their hydroxyimino group should be considered to be involved as intermediate species in the photochemical lactam formation from oximes. Moreover, the possibility of lactam formation occurring *via* coupling of radical pairs or biradical species has been suggested for photochemical lactam formation from some fused bicyclic oxaziridines.[7)]

In connection with these paths of the photochemical lactam formation, it is worth studying whether cyclic β,γ-unsaturated ketone oximes give lactams or nitriles and other products which originate from the radical pair or biradical species on photolysis. This group of oximes is considered to be particularly susceptible to the fission into biradical or ionic species by virtue of generation of stabilized allyl radicals or ions (*e.g.*, A).



(A) * radical or ion

In this paper, the results on the photoreactions of two steroidal β,γ-unsaturated ketone oximes are described.

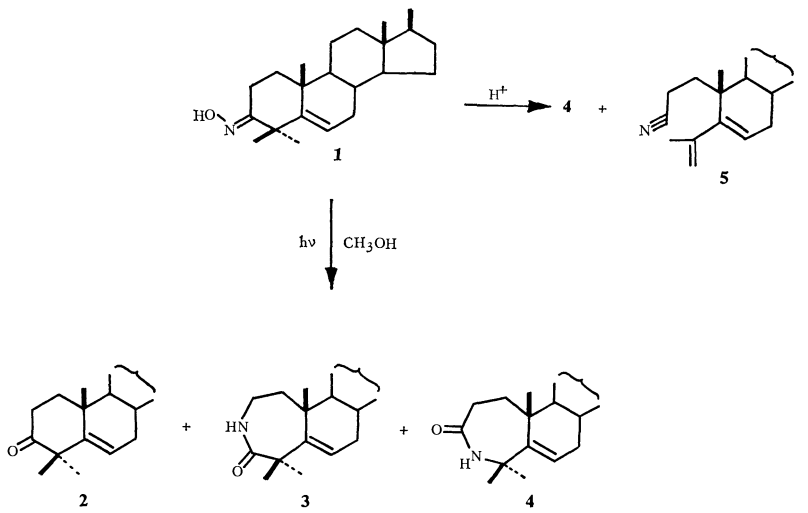
Results and Discussion

4,4-Dimethylcholest-5-en-3-one oxime (**1**) and 4,4,6-trimethylcholest-5-en-3-one oxime (**12**), prepared from the parent ketones (**2** and **11**)[8,9)] by the standard method, were chosen as steroidal β,γ-unsaturated ketone oximes. 4,4,6-Trimethylcholest-5-en-3-one (**11**)[9)] was prepared from 5,6α-epoxy-5α-cholestan-3β-ol (**6**) *via* 4 steps (Scheme 4).[10-12)] In the course of these preparations, it was found that the reaction of epoxide (**6**) with methylmagnesium iodide to yield 6β-methyl-5α-cholestane-3β,5α-diol (**7**)[12)] is accompanied by at least 6% yield of 3β-hydroxy-5α-cholestan-6-one (**8**)[12,13)] resulting from a hydride shift followed by isomerization.

^{1}H NMR spectroscopy proved that the conformation of the ring A of oximes **1** and **12** is a *quasi* boat, as in the corresponding ketones,[14)] and that the geometries of their hydroxyimino groups are *syn* with respect to their $C_{(2)}$–$C_{(3)}$ bond. Thus, the chemical shifts of the 19-H of the oximes **1** and **12** deviated considerably from those predicted by the additivity rule, indicating that their ring A is in a non-chair conformation; signals due to the 19-H of the oximes **1** and **12** were found at τ 9.14 and 9.19, whereas chemical shifts of their 19-H predicated by the additivity rule of deshielding effects[15)] are about τ 8.79 based on the chemical shift (τ 9.10) of the 19-H of (*E*)- and (*Z*)-5α-cholestan-3-one oximes,[16)] the ring A of which is in a chair conformation. Inspections of the Dreiding model indicated that when their ring A takes a *quasi* boat conformation, their hydroxyimino groups are almost eclipsed by their 2β-H. Thus, when the hydroxyl group is *syn* with respect to the $C_{(2)}$–$C_{(3)}$ bond, their 2β-H is deshielded.[2)] The ^{1}H NMR spectrum of oximes **1** and **12** showed one-proton multiplets at τ 6.78—7.26 and at τ 6.79—7.19. These signals are assigned to their 2β-protons in the *quasi* boat conformations.[17)] There were other one-proton double doublet centered at τ 7.59 (J=7.5 and 19.2 Hz) and at τ 7.68 (J=7.5 and 18.6 Hz) in the spectra of the oximes **1** and **12**. These signals are assigned to their 2α-proton on the basis of their chemical shifts and coupling constants.

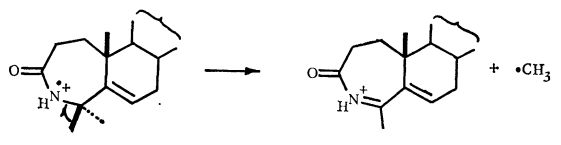
A preliminary experiment showed that irradiation of oxime **1** in methanol until all the oxime was photolyzed would cause the secondary decompositions of appreciable amounts of product lactams. Therefore, irradiation was discontinued after three hours when TLC indicated that still about a half of the starting oxime remained unchanged. At this point, besides the starting oxime, spots due to the parent ketone (**2**) and two products were detected. Column chromatography afforded the parent ketone **2** (11%), the starting oxime **1** (53%), and two new products, **3** (10%) and **4** (9%) successively. The structures of

** Present address: Organic Chemistry Laboratory, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060.



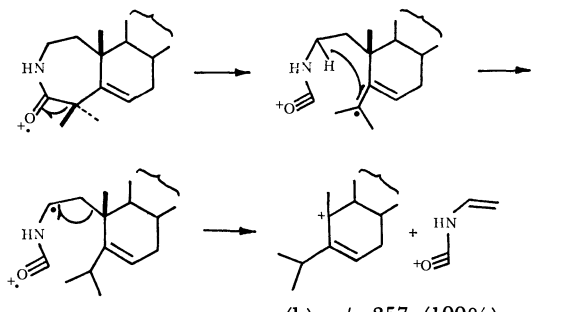
Scheme 1.

3 and **4** were determined to be 4a,4a-dimethyl-3-aza-*A*-homocholest-5-en-4-one (**3**) and 4a,4a-dimethyl-4-aza-*A*-homocholest-5-en-3-one (**4**) by their NMR, IR, and MS spectra (Scheme 1). The mass spectrum[18] of lactam **4** showed a weak molecular ion peak at *m/e* 427; the M^+-CH_3 fragment peak was the base peak assignable to an immonium species (a) in Scheme 2. In contrast, the mass spectrum of lactam **3** showed a distinct molecular ion peak at *m/e* 427 and the base peak at *m/e* 357. The intensity of the M^+-CH_3 peak (*m/e* 412) was only 13.5%, confirming the assigned structure. Scheme 3 shows the structure and a plausible genesis of this ion (b).



(a) *m/e* 402 (100%)

Scheme 2.

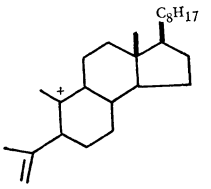


(b) *m/e* 357 (100%)

Scheme 3.

The ordinary Beckmann rearrangement of the oxime **1** with thionyl chloride afforded a product, which was shown to be a seconitrile (**5**) resulting from the second order Beckmann rearrangement by the MS, IR, and NMR (Table 1) spectra, and only a trace amount of the lactam **4** (Scheme 1). The mass spectrum of seconitrile **5** showed the molecular ion at *m/e* 409 as the base peak and only three distinct peaks at *m/e* 394 (M^+-CH_3), *m/e* 355, and *m/e* 296 ($M^+-C_{(17)}$ substituent) beyond *m/e* 200. The species *m/e* 355 is assignable to a species (c).

Photoreaction of the oxime **12** in methanol was performed under conditions similar to those used for the photoreaction of the oxime **1**. Three-hour irradiation gave an isomeric oxime (**13**) (10%), the starting oxime **12** (41%), 4,6-dimethyl-4-methylene-3,4-seco-



(c) *m/e* 355

cholest-5-ene 3-nitrile (**14**) (3%), 4a,4a,6-trimethyl-3-aza-*A*-homocholest-5-en-4-one (**15**) (16%), and 4a,4a,6-trimethyl-4-aza-*A*-homocholest-5-en-3-one (**16**) (11%) (Scheme 4). Structures of these products were confirmed by spectral analysis. The isomeric oxime showed M^+ of *m/e* 441 and M^+-CH_3 peak as the base peak in the MS spectrum. The nitrile **14** was obtained only as a mixture with 3-aza lactam **15**; the yield was estimated by NMR spectroscopy. The $C_{(2)}$ methylene protons in the ^1H NMR spectrum of 3-aza lactam (**15**) appeared as two broad signals centered at τ 6.48 and 7.05. After D_2O exchange of the NH proton, the signal at τ 6.48 changed to a broad triplet and the signal at τ 7.05 to a broad doublet. Irradiation at τ 8.41 changed the broad triplet to a sharper triplet with J=13.5 Hz and the broad doublet to a double doublet (J=13.5 and 4.5 Hz). The splittings and the results of the decoupling experiments exclude a *quasi* chair conformation and are consistent with a *quasi* boat conformation of the ring A, in which the C_6–CH_3 bond nearly bisects the angle between gem dimethyl at $C_{(4a)}$; the dihedral angles between the 1β- and 2β-protons, the 1β- and 2α-protons, the 1α- and 2β-protons, and the 1α- and 2α-protons are around 40°, 160°, 80°, and 40°, respectively. Assuming this conformation and that the signal at τ 8.41 arises

Table 1. NMR parameters (100 MHz) for 5α-cholestane derivatives, 4,4-dimethylcholest-5-en-3-one 4,4,6-trimethylcholest-5-en-3-one, their oximes, and the reaction products in $CDCl_3$ solution [chemical shifts (τ) and splittings (Hz; in parenthesis)]

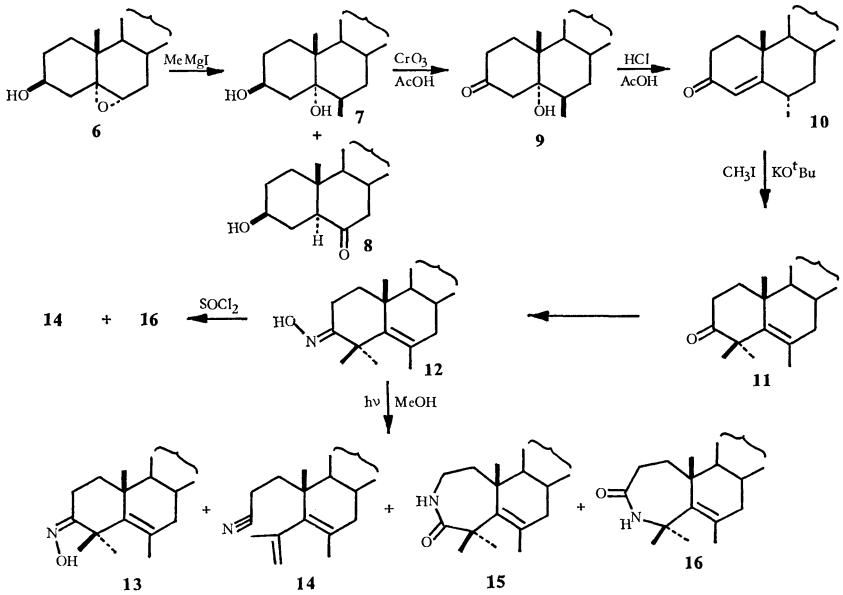
a) Unassignable.



Scheme 4.

from the 1α-proton, the signals at τ 6.48 and 7.05 can be assigned to the 2α- and 2β-protons with $J_{2\alpha,2\beta}$ = 13.5 Hz, $J_{1\beta,2\alpha}$ = 13.5 Hz, and $J_{1\beta,2\beta}$ = 4.5 Hz respectively. Such assignments fit in with the coupling constants required by the above dihedral angles. Two 1,3-diaxial interactions of methyl groups are involved in the chair conformation of the 3-aza lactam. This interaction prohibits the lactam from taking the chair conformation. Fragmentations in the mass spectra of the nitrile **14** and the lactams **15** and **16** were entirely analogous to those of the nitrile **5** and the lactams **3** and **4**, respectively. Thus, the MS spectra of the lactams **15** and **16** showed their base peaks at *m/e* 371 and at *m/e* 426, corresponding to the species (b) and (a).

The ordinary Beckmann rearrangement of the oxime **12** was also studied. The treatment of oxime **1** with thionyl chloride gave two products, nitrile **14** and 4-aza lactam **15**, in 46 and 44% yields.

The present experiments confirmed that cyclic β,γ-unsaturated ketone oximes undergo photo-Beckmann rearrangements to lactams in yields comparable to those in the case of cyclic saturated ketone oximes.[2] Such results reinforce our previous conclusion[2,3] that the lactam formation resulting from the photo-rearrangement of cyclic saturated ketone oximes does not involve coupling of biradical or ions since, if a radical pair or ion pair were involved in the present photoreaction, these species would lead immediately to seconitriles; also, lactam formation by recombination of the cleaved species in the present case is very unlikely. Since there is a difference in the major products between acid-catalyzed reactions and photoreactions, the present photoreaction is of value for synthesis of unsaturated lactams (*e.g.*, **3** and **15**) which are not readily accessible by the ground state reactions.

Experimental

For instruments used and general procedures see Ref. 2. IR spectra were determined for Nujol mull with a JASCO IRA-1 spectrophotometer. The MS were recorded with a Hitachi JMS-D 300 spectrometer (direct inlet system, ion source temperature, *ca.* 180 °C, ionizing voltage, 70 eV) in the Faculty of Pharmaceutical Sciences or the Faculty of Agriculture. Only the Fragment peaks of the relative intensities over 20% for the lactams **3** and **4** and those over 30% for the seconitrile **5** are described.

Preparation of 4,4-Dimethylcholest-5-en-3-one Oxime (1). To a solution of 4,4-dimethylcholest-5-en-3-one (**2**) (800 mg) in methanol (200 ml) was added a solution of hydroxylamine hydrochloride (1 g) and sodium acetate trihydrate (1 g) in water (4 ml). The solution was stirred at 40 °C for 1.5 h and a further amount of methanol (100 ml) was added to the solution. The solution was refluxed for 2.5 h. The solvent was partly removed and the solution was extracted with diethyl ether. The diethyl ether solution was worked up in the usual way and evaporated. The residue was recrystallized from diethyl ether–methanol to afford the oxime **1** (726 mg), mp 223—226 °C. (Found: C, 81.26; H, 11.48; N, 3.14. Calcd for $C_{29}H_{49}NO$: C, 81.44; H, 11.55; N, 3.28%); IR 3304 (OH), 949 and 929 cm^{-1}; for NMR see Table 1; UV_{max} (MeOH) 207 nm (ε 5100).

The Photo-Beckmann Rearrangement of 4,4-Dimethylcholest-5-en-3-one Oxime (1). The oxime **1** (79 mg) in methanol (special grade, Wako) (230 ml) was irradiated with a Rayonet RPR-208 preparative photochemical reactor under an atmosphere of nitrogen for 3 h. TLC indicated four spots, due to the parent ketone **2**, the unchanged oxime **1**, and two lactams, in the order of their mobility. Three further photoreactions (80, 81, and 66 mg) were carried out under the same procedure. Products from the four photolyses were combined and subjected to column chromatography (Wako gel C-200, 10 g). Elution with a 3:1 mixture of benzene and hexane gave the parent ketone (32 mg). Further elutions with a 19:1 mixture of benzene and hexane and with pure benzene gave oxime **1** (162 mg). Successive elutions with a 4:1 mixture of benzene and ethyl acetate gave 3-aza lactam **3** (30 mg) which was recrystallized from methanol. Mp 175—177 °C. (Found: C, 81.30; H, 11.32; N, 3.10%. Calcd for $C_{29}H_{49}NO$: C, 81.44; H, 11.55; N, 3.28%); $[\alpha]_D^{18}$ −4.2° (*c* 0.5 $CHCl_3$); IR 1657 (lactam carbonyl), 3062 and 3198 cm^{-1} (NH); for NMR see Table 1;

MS *m/e* (rel intensity) 429 (M^+, 1.9), 427 (30.8), 358 (29.5), 357 (100), and 42 (24.2). Continued elutions with the same solvent mixture gave 4-aza lactam **4** (29 mg), which was recrystallized from methanol. Mp 198.5—201.0 °C. (Found: C, 80.86; H, 11.69; N, 3.21%. Calcd for $C_{29}H_{49}NO$: C, 81.44; H, 11.55; N, 3.28%); $[\alpha]_D^{20}$ −11.3° (*c* 1.0 $CHCl_3$); IR 1656 and 1611 (lactam carbonyl) 3062 and 3198 cm^{-1} (NH); for NMR see Table 1; MS *m/e* (rel intensity) 42 (M^+ 0.4), 427 (3.7), 413 (31.5), 412 (100), and 58 (26.6).

The Beckmann Rearrangement of 4,4-Dimethylcholest-5-en-3-one Oxime (1). To a solution of the oxime **1** (200 mg) in dioxan (10 ml) was added some freshly purified thionyl chloride (0.1 ml) at room temperature. The solution was stirred for 20 min at room temperature and poured into water. The mixture was neutralized with sodium hydrogencarbonate. The aqueous solution was extracted with diethyl ether. The diethyl ether solution was worked up as usual. TLC showed that the product (184 mg) (R_f= 0.8) is nearly a single compound, with only traces of minor products (R_f=0.1 and 0). The residue was subjected to preparative TLC with benzene. The more mobile major product (162 mg) was recrystallized from methanol to afford the nitrile (**8**), mp 43.5—45.0 °C, (54 mg). (Found: C, 84.68; H, 11.39; N, 3.41. Calcd for $C_{29}H_{47}N$: C, 85.02; H, 11.56; N, 3.42%); IR 2243 (C≡N), 1610 and 906 cm^{-1}; for NMR see Table 1; MS *m/e* (rel intensity) 409 (100, M^+), 394 (28.7), 296 (33.6), 147 (30.9), 145 (52.3), 121 (31.1), 107 (32.6), 105 (40.2), 95 (46.9), 93 (34.0), 81 (47.1), 69 (41.4), 57 (53.6), 55 (66.2), 43 (70.4), and 41 (55.3). The less mobile fraction (10 mg) was an unidentified gum. The least mobile fraction (R_f=0) (19 mg) was recrystallized from methanol to afford 4-aza lactam **4**, identical with the specimen obtained by the photo-Beckmann rearrangement.

Reaction of 5,6α-Epoxy-5α-cholestan-3β-ol (6) with Methylmagnesium Iodide.[11,12] A solution of epoxide **6** (18.8 g) in dry benzene (300 ml) was added to a solution of methylmagnesium iodide prepared with magnesium (4.6 g) and methyl iodide (30 ml) in dry diethyl ether (50 ml) and dry benzene (100 ml). The solution was refluxed for 5 h. After cooling, aqueous solution of ammonium chloride (300 ml) was added and the solution was extracted with diethyl ether (200 ml). After the usual work-up, the product was recrystallized from diethyl ether–ethanol to give 6β-methyl-5α-cholestane-3β,5α-diol **7** (3.3 g). The residue from the filtrate was subjected to column chromatography. (alumina, 660 g). Elutions with a 1:1 mixture of hexane and benzene and then benzene gave a fraction (2.78 g) which was recrystallized from methanol to give 3β-hydroxy-5α-cholestan-6-one (**8**) (1.12 g, 6%) mp 148—150 °C (lit,[11] 145—146 °C). The acetate, mp 129—131.5 °C (methanol) (lit,[12] 128—129 °C), was obtained in usual way. Continued elutions with benzene gave a second fraction which was recrystallized from dichloromethane–ethanol to give an additional 3β,5α-diol **7** (5.59 g), 182—183 °C (lit,[11] 182—183 °C). The total yield of the diol was 47%.

Preparation of 6α-Methylcholest-4-en-3-one (10).[9] Diol **7** (13 g) in acetic acid (240 ml) was oxidized with chromium trioxide.[10] The crude 5α-hydroxy-6β-methylcholestan-3-one (**9**) obtained was dissolved in acetic acid (100 ml). To this solution was added concd hydrochloric acid (10 mg). The solution was stirred for 13 h and was extracted with diethyl ether. The usual work-up afforded a residue which was subjected to column chromatography (Wako C-200, 400 g). Successive elutions with 1:3, 1:5, and 1:10 mixtures of hexane and benzene, benzene only, and a 1:10 mixture of benzene and diethyl ether gave a fraction which was once recrystallized from methanol to yield ketone **10**, mp 126—127 °C (lit,[9] 127—128.5 °C). For NMR spectrum see Table 1.

Preparation of 4,4,6-Trimethylcholest-5-en-3-one (11). The ketone **10** (360 mg) in dry *t*-butyl alcohol (6 ml) was added to potassium (110 mg) in the same solvent (100 ml) under a nitrogen atmosphere. Methyl iodide (0.33 ml) was added and the mixture was heated under reflux for 75 min. After the addition of methyl iodide (0.1 ml) the solution was heated under reflux for an additional 25 min. The solution was extracted with dichloromethane and the organic layer was worked up in the usual manner. The product was subjected to preparative TLC with benzene to yield ketone **11** (189 mg). Recrystallization from methanol gave the pure material, mp 134—136 °C. (Found: C, 84.39; H, 11.84%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%); $[\alpha]_D^{21}$ = −7.8° (*c* 1.1 $CHCl_3$); IR 1609 (carbonyl), and 1026 cm^{-1}.

Preparation of 4,4,6-Trimethylcholest-5-en-3-one Oxime (12). The ketone **11** (770 mg), hydroxylamine hydrochloride (2.5 g), and sodium acetate trihydrate (2.5 g) in a mixture of ethanol (300 ml) and water (15 ml) were refluxed for 2 d. After the addition of a further amount of hydroxylamine hydrochloride (1 g) in water (3 ml), the solution was refluxed for another 3 d. A part of the solvent was evaporated under a reduced pressure and the solution was extracted with diethyl ether. The ethereal solution was worked up in the usual way and the product was subjected to column chromatography (silica gel Wako C-200, 27 g). Elutions with a 1:3 mixture of hexane and benzene gave the starting material (384 mg after recrystallization from methanol) and continued elutions gave the oxime **12**. The oxime was recrystallized from aq methanol to yield crystals (339 mg, 43%), mp 179.0—180.5 °C. (Found: C, 81.17; H, 11.89; N, 3.33%. Calcd for $C_{30}H_{51}NO$: C, 81.57; H, 11.64; N, 3.17%); $[\alpha]_D^{21}$ −3.2 (*c* 1.0 $CHCl_3$); IR 3311 (OH), 949, 918, and 720 cm^{-1}; MS *m/e* (rel intensity), 441 (M^+, 32.9), 426 (M^+-CH_3, 82.7), 425 (M^+-O, 29.8), 424 (M^+-OH, 100), 369 (25.0), 95 (32.8), 57 (26.7), 55 (29.6), and 43 (33.3). For the NMR see Table 1. UV_{max}(MeOH) 208 nm (ε 7600).

The Photo-Beckmann Rearrangement of 4,4,6-Trimethylcholest-5-en-3-one Oxime (12). Oxime **12** (80 mg) in methanol (special grade, Wako) (230 ml) was irradiated with a preparative photochemical reactor under an atmosphere of nitrogen for 4 h. TLC indicated five spots due to an isomeric oxime (**13**), a recovered oxime **12**, nitrile **14**, and two lactams **15** and **16**, in the order of their mobility. The photoreaction was repeated three times under the same conditions as the first one (80, 81, and 81 mg) and the products were combined and subjected to column chromatography. Elutions with a 3:1 mixture of benzene and hexane gave four fractions: A (32 mg), B (146 mg), C (61 mg), and D (35 mg). Fraction A was isomeric oxime **13** and was recrystallized from methanol. Mp 145—148 °C. IR, 3450 cm^{-1} (OH); MS *m/e* (rel intensity) 441 (M^+, 14.0), 426 (M^+-CH_3, 100), 424 (M^+-OH), 411 (51.4), 410 (51.0), 369 (77.2), 327 (26.9), 95 (83.7), 57 (74.2), 55 (79.2), and 43 (96.5). For NMR spectra see Table 1. Fraction B was recovered oxime **12**. Fraction C was a mixture of seco-nitrile **14** and 3-aza lactam **15**, based on its NMR analysis. Its recrystallization from methanol gave pure 3-aza lactam **15** (42 mg), mp 197—199 °C. (Found: M^+, *m/e* 441.3969). Calcd for $C_{30}H_{51}NO$: M^+ 441.3969; $[\alpha]_D^{21}$ −33.6 (*c* 0.25 $CHCl_3$); IR 3250 (NH), 1677 and 1742 (lactam carbonyl), and 720 cm^{-1}; MS *m/e* (rel intensity) 441 (M^+, 0.4), 426 (M^+-CH_3, 2.1), 398 (1.0), 372 (20.0), and 371 (100); for NMR see Table 1.

The residue (19 mg) from the filtrate in the above re-

crystallization was a 1:1 mixture of nitrile **14** and 3-aza lactam **15**, as estimated by the relative intensities of the signals due to their 10β-methyl in the NMR spectrum. Fraction D was 4-aza lactam **16**, which was recrystallized from methanol. Mp 178—180 °C. (Found: C, 81.33; H, 11.72; N, 3.14%. Calcd for $C_{30}H_{51}NO$: C, 81.57; H, 11.64; N, 3.17%); $[\alpha]_D^{22}$ −31.7 (*c* 1.0 $CHCl_3$); IR 3240 (NH), 1685 (lactam carbonyl), and 774 cm^{-1}; MS *m/e* (rel intensity) 441 (M^+, 3.4), 426 (M^+-CH_3, 100), and 58 (55.0); for the NMR see Table 1.

The Beckmann Rearrangement of 4,4,6-Trimethylcholest-5-en-3-one Oxime. To oxime **12** (74 mg) in dry dioxane (3 ml) and dry diethyl ether (0.1 ml) was added thionyl chloride (0.5 ml) at 0 °C. The solution was stirred for 30 min at 10 °C. The solution was extracted with diethyl ether and the organic layer was washed with 5% sodium hydrogencarbonate and water successively and dried. The product was subjected to preparative TLC with benzene to give three major fractions: A (34 mg), B (10 mg), and C (33 mg), in the order of their mobility. Fraction A was an oil and was identified as seconitrile **14**. (Found: N, 3.34%. Calcd for $C_{30}H_{49}N$: N, 3.31%); MS *m/e* (rel intensity), 423 (M^+, 26.7), 408 (M^+-CH_3, 20.2), 369 ($M^+-C_{(10)}$ side chain, 100), 265 (9.8), and 57 (54.9); for NMR see Table 1. Fraction C was 4-aza lactam **16**, which was recrystallized from methanol to afford a pure specimen (18 mg). It was identical with **16** obtained by the photoreaction.

We thank Mrs. T. Okayama and Miss H. Maki for ^1H NMR measurements and spin decoupling experiments.

17) The conclusions on the conformations of the ring A and the geometries of hydroxyimino groups of oximes **1** and **12** are further supported by a study of the ^1H NMR spectrum of 17β-acetoxy-4,4-dimethyl-19-norandrost-5-en-3-one oxime prepared by A. Osada in this laboratory. The ring A of this oxime should be in a *quasi* chair conformation since no 1,3-diaxial interaction of methyl groups is involved in the molecule. In fact, its NMR spectrum showed a one-proton double doublet at τ 6.74 with $J=13.5$ and 4.5 Hz. The chemical shift and the coupling constants are in agreement with those of the 2α-proton deshielded by the adjacent hydroxyimino group in the ring A in a *quasi* chair conformation.

Catalytic hydrogenation of (22*S*,25*S*)-*N*-acetyl-3β,23β-dihydroxyveratra-5,13(17)-dien-11-one 3-acetate over rhodium-platinum catalyst in acetic acid gave (22*S*,25*S*)-N-acetyl-3β,23β-dihydroxyveratranin-11-one 3-acetate (**2**) in *ca* 70% yield, together with two minor products. Irradiation of **2** in benzene containing mercury(II) oxide and iodine gave 20-formyl-3β-hydroxy-12α,17β-ethyletiojervan-11-one 3-acetate (**5**) in 43% yield, accompanied by the 17-epimer of (22*S*,23*R*,25*S*)-N-acetyl-3β-hydroxy-5α-jervanin-11-one 3-acetate (4%). Aldehyde **5** was transformed into 3β-hydroxy-12α,17β-ethyletiojervane-11,20-dione 3-acetate (**15**) (79% yield) by photo- or copper-catalysed oxygenation of the corresponding enamine. Reduction of **15** with sodium borohydride gave 3β,20β-dihydroxy-12α,17β-ethyletiojervan-11-one 3-acetate (**17**) as a major product (69%), together with the 20-epimer. The hypoiodite reaction of **17** gave 18,20β-epoxy-3β-hydroxy-17β-ethyl-12α-etiojervan-11-one 3-acetate (**19**) in 92% yield. Hydrolysis of **19** resulted in the isomerization of the C/D ring junction to give 18,20β-epoxy-3β-hydroxy-17β-ethyletiojervan-11-one (**20**), the first 18-functional C/D *trans* *D*-homo-*C*-norsteroid ever prepared. Wolff-Kishner reduction of **20** gave the corresponding 11-deoxo compound; its acetylation followed by oxidation yielded 18,20β-epoxy-3β-hydroxy-17β-ethyletiojervan-18-one 3-acetate. The 11-oxo function of **19** can be reduced quite easily with lithium aluminum hydride to give the corresponding 11β-ol.

Despite the extensive studies on the synthesis of 18-functional steroids, little has been done on the synthesis of 18-functional *D*-homo-*C*-norsteroids which may be useful for the synthesis of biologically active compounds. In the previous paper,[1] we reported the transformation of jervine into 18-functional C/D *cis* fused *D*-homo-*C*-norsteroids.

In this paper, the transformation of jervine into an 18-functional C/D *trans* fused *D*-homo-*C*-norsteroid, (20*R*)-18,20β-epoxy-3β-hydroxy-17β-ethyletiojervan-18-one 3-acetate,[3] *via* a C/D *cis* fused 11-oxo-*D*-homo-*C*-norsteroid, is reported. The method involved a series of photoinduced reactions reported in the previous paper.[1]

Results

Catalytic hydrogenation of (22*S*,25*S*)-*N*-acetyl-3β,23β-dihydroxyveratra-5,13(17)-dien-11-one 3-acetate (**1**), derived from jervine *via* two steps,[4] over rhodium-platinum catalyst in acetic acid[1,5] gave a mixture of products from which a perhydro derivative, (22*S*,25*S*)-*N*-acetyl-3β,23β-dihydroxyveratranin-11-one 3-acetate (**2**), was obtained by a single recrystallization in 62% yield (Scheme 1). Hydrogenation of the mixture recovered from the reaction gave a further amount (10%) of perhydro derivative **2**. The structure of **2** was confirmed by the IR, NMR, and mass spectra. The NMR spectrum (Table 1) showed the absence of an olefinic proton and showed three doublets arising from three secondary methyl groups (the 18-H, 21-H, and 26-H). The assigned stereochemistry at C-5, C-13, and C-17 centers is based on a *cis* addition analogous to the closely related substrate.[1,4] TLC of the crude product in this catalytic hydrogenation indicated the presence of two minor products **3** and **4**, which are more mobile than the perhydro derivative **2**. The structure of crystalline product **3**, mp 218.5—219.5 °C, was ascertained to be (22*S*,25*S*)-*N*-acetyl-23β-hydroxyveratr-13(17)-en-11-one by the mass, IR, and NMR spectra. Its mass spectrum showed a M^+ peak at *m/e* 455 and a fragment ion of low abundance at *m/e* 299 due to a species resulting from the removal of the heterocyclic ring from the molecular ion. Its IR spectrum showed bands due to the 23β-hydroxyl, 11-oxo- and *N*-acetyl groups. The NMR spectrum showed no 3β-acetoxyl

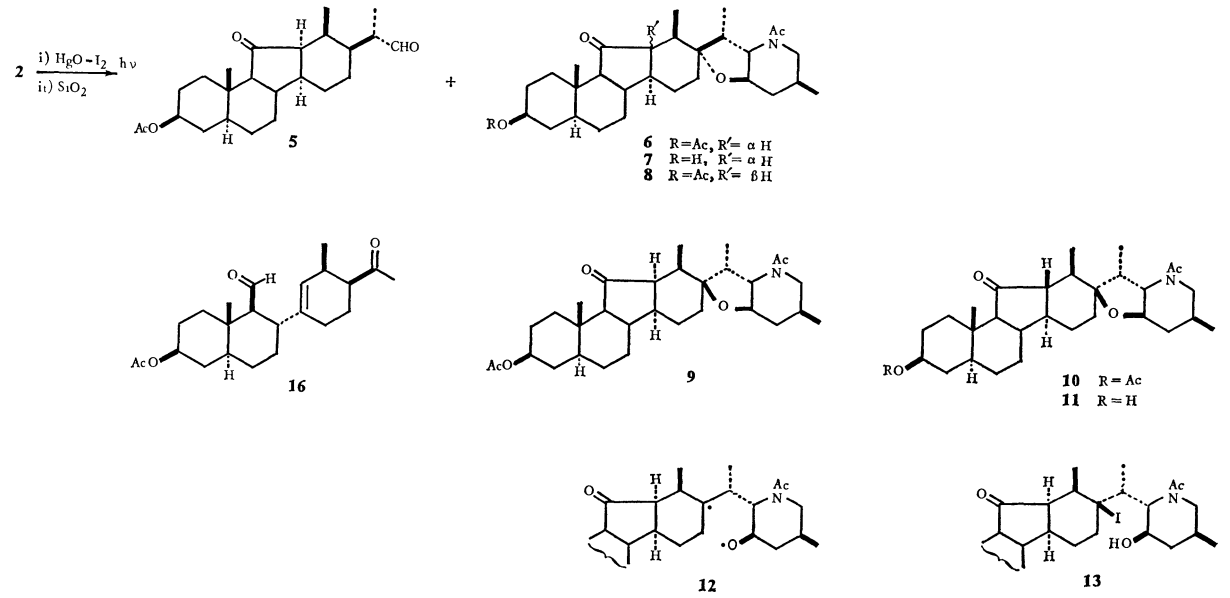
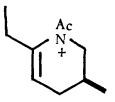


Scheme 2.

group and the presence of a 3H singlet at τ 8.14 due to the 18-H.

The structure of the amorphous product **4** was shown to be (22*S*,25*S*)-*N*-acetyl-3β,23β-dihydroxyveratr-13(17)-en-11-one 3-acetate by spectrometry. The mass spectrum showed a M^+ peak of *m/e* 513. The IR spectrum showed bands due to the 23β-hydroxyl, 11-oxo-, *N*-acetyl, and 3β-acetoxyl groups. The NMR spectrum showed a three-proton singlet at τ 8.14 due to the 13-methyl group and the absence of olefinic protons, proving the product to be the 5,6-dihydro derivative of the starting diene.

The transformation of the perhydro derivative **2** into a 12α-etiojervane **15** was accomplished by the series of photoinduced reactions described in the previous paper.[1,6] (Schemes 2 and 3) Irradiation of **2** in benzene containing three equivalents each of mercury(II) oxide and iodine with a 100-W high pressure mercury arc gave the expected crystalline aldehyde, 20-formyl-3β-hydroxy-12α,17β-ethyletiojervan-11-one 3-acetate (**5**), mp 144—146 °C, in 43% yield after column chromatography with silicic acid and recrystallization. The various spectra were in agreement with the structure assigned. The TLC of the crude photolysate showed the formation of a very minor product **6**, which was more mobile than aldehyde **2**. It was isolated by column chromatography in 4% yield and had mp 219—220 °C. Its mass spectrum (M^+ 513) and the elemental analysis were in agreement with the molecular formula $C_{31}H_{47}O_5N$, indicating it to be a product from an intramolecular hydrogen abstraction by a 23β-oxyl radical arising from the 23β-ol **2**. Hydrogens available for the intramolecular abstraction by the oxyl radical would be the 16α-H, the 17-H, and the 21-H and the abstraction reactions involving these hydrogens should take place *via* six or seven-membered cyclic transition state.[7] The ^{1}H NMR spectrum of **6** showed three three-proton doublets assigned to the 18-H, 21-H, and 26-H, excluding any structure arising from the abstraction of the 21-H. The ^{13}C NMR spectrum of **6**, aided with off-resonance spectrum, showed a signal at δ 86.64 ppm ascribed to a quarternary carbon carrying an oxygen.[8] This result proved that the 23β-oxyl radical abstracted the 17α-H, resulting in a N-acetyltetrahydrojervine O-acetate, the signal at 86.64 ppm thus arises from the C-17. A tetrahydro derivative of jervine, (22*S*, 23*R*, 25*S*)-*N*-acetyl-3β-hydroxy-5α-jervanin-11-one acetate, (**9**) and its 12β-isomer (**10**) (the C-17 signal at δ 86.52 ppm) have already been prepared by catalytic hydrogenation of jervine in acetic acid followed by acetylation.[9,10] The direct comparison showed that **6** is not identical with *N*-acetyltetrahydrojervine **9**.[9] Therefore, the structure of **6** should be the 17-epimer of (22*S*,23*R*,25*S*)-*N*-acetyl-3β-hydroxy-5α-jervanin-11-one 3-acetate. The mass spectra of **6** and **10** showed their base peaks at *m/e* 167 could be assigned to a fragment of structure (A)[11]



(A)

in accordance with the assigned structure. Hydrolysis of **6** with aqueous methanolic potassium hydroxide under reflux gave the corresponding 3β-ol (**7**). The C/D ring junction of **7** was proved to be *cis*, since **7** reverted back to **6** on acetylation. It is noteworthy that, while treatment of (22*S*,23*R*,25*S*)-*N*-acetyl-3β-hydroxy-5α-jervanin-11-one 3-acetate (**9**) with base readily causes an epimerization at the C-12 and gives the 12β-epimer (**11**), no isomerization of the C-12 hydrogen takes place in the basic hydrolysis of **6**. Inspection of Dreiding models of **6** and its 12β-epimer **8** showed that the most stable conformation of the ring D of **6** would be a *quasi* chair conformation with the 13-axial substituent, but that of the 12β-epimer **8** would be a *quasi* chair conformation with the 13-equatorial substituent. It also showed that the 13β-

methyl and the 20α-methyl of **8** are nearly in a 1,3-diaxial relationship and therefore the 12β-epimer **8** (C/D *trans* isomer) appears to be less stable than the 12α-epimer **6**, in which the C(13)–C(18) and C(20)–C(21) bonds are in nearly orthogonal positions. On the other hand, there are no non-bonded interactions between the 13β-methyl and the 20α-methyl of **9** and its 12β-epimer **10**. Thus, the situation differs sharply from that of the pair of 17-epimers **6** and **8**.

The jervanine **6** may be formed *via* an intramolecular radical combination of a biradical intermediate **12**. In this step, the attack of the 23β-oxyl radical to the C-17 radical center from the β-face should be hindered by the presence of the 13β-methyl group and therefore the observed product **6** will result. The formation of **6** through an iodohydrin intermediate (**13**) is unlikely, since the combination of an iodine atom with the C-17 radical from the β-face would be severely hindered by the 13β-methyl group.

The aldehyde **5** was transformed into a crystalline enamine **14** with morpholine and *p*-toluenesulfonic acid in toluene under reflux in an almost quantitative yield. The enamine **14** was then subjected to a copper-catalysed oxygenation[12] or an oxidative cleavage with

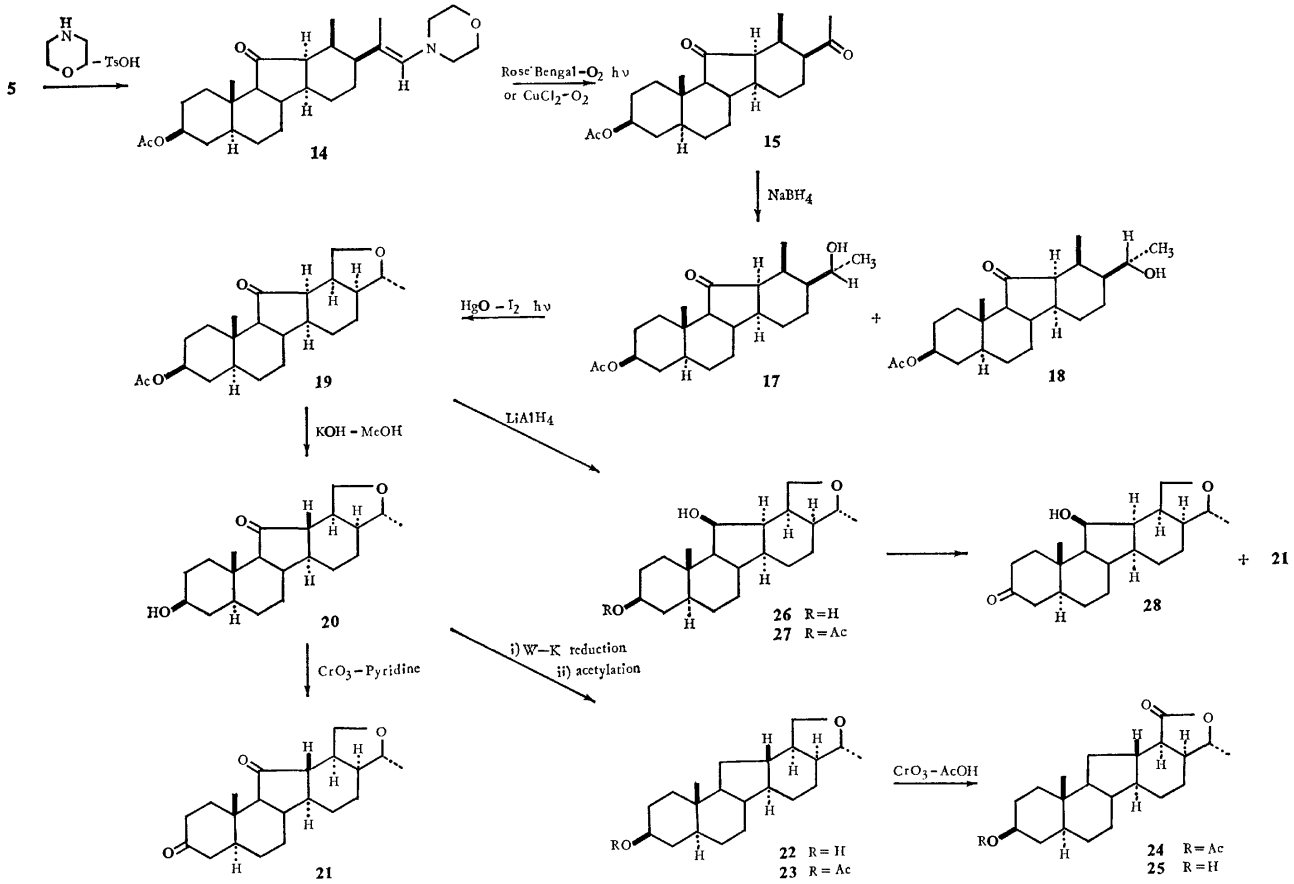
after irradiation at τ 8.71. e) (9.8) after irradiation at τ 8.65.

dye-sensitized singlet oxygen[13] (Scheme 3).

In the copper-catalyzed oxygenation, oxygen was bubbled through a chloroform solution of the enamine **14** containing copper(I) chloride for 24 h under cooling. The expected product, 3β-hydroxy-12α,17β-ethyletiojervane-11,20-dione 3-acetate (**15**), mp 134—135 °C, was obtained in 91% yield after recrystallization from diethyl ether.

In the dye-sensitized oxidative cleavage, the enamine **14** in dry benzene containing Rose Bengal was irradiated with a 90-W high pressure mercury arc under an atmosphere of oxygen for 48 h. Column chromatography of the product gave dione **15**, which is identical with the dione obtained by the copper-catalyzed oxygenation, in 79% yield. Although this photochemical procedure was successful in most of the experiments with 90-W Hg arc, the irradiation was found in some experiments to lead to the exclusive formation of an aldehyde **16** resulting from α-fission of an excited 11-oxo group; in these experiments a lamp of a wattage slightly above 100-W was used. The structure of the aldehyde **16** was confirmed to be 3β-hydroxy-11,12-seco-17β-ethyletiojervane-11,20-dione 3-acetate by spectrometry. The high



Scheme 3.

resolution mass spectrum of **16** indicated that it had the molecular formula $C_{23}H_{34}O_4$. The IR spectrum of **16** showed three bands arising from the acetoxyl, the formyl, and the acetyl groups. The NMR spectrum showed two one-proton doublets at τ 0.55 (J= 5.4 Hz) and at τ 4.52 (J=3.0 Hz) assignable to the C-11 hydrogen and the olefinic C-12 hydrogen, and other signals consistent with the assigned structure. The use of the high pressure Hg arc lamps of wattage as intense as 100 watts for the oxygenation seems to be just on a critical line for the cleavage and may be inappropriate, even though the excited 11-oxo group is being quenched by oxygen during oxygenation, which is a faster process than the α-fission.

The 20-oxo group of the 11,20-dione **15** was selectively reduced with sodium borohydride in ethanol containing ethyl acetate to give a mixture of 3β,20β-dihydroxy-17β-ethyletiojervan-11-one 3-acetate (**17**) and its 20α-epimer (**18**). Recrystallization and preparative TLC of the mixture gave 20β-ol **17**, mp 169—171 °C, and 20α-ol **18**, mp 175—176 °C, in 69 and 11% yields respectively. It was not possible to deduce the configurations at the C-20 centers of these compounds by NMR spectroscopy, since the differences in the splitting and the chemical shifts of their 20-H signals and the differences in the chemical shifts of their 18-H were too small to distinguish the configurations of their C-20 centers. However, consideration of the steric course of the reduction with complex metal hydrides, in a manner analogous to the case of the reduction of the 11-deoxo analogue[5] of dione **15**, allowed us to assign a 20β-configuration for the major product and a 20α- for the minor one. These assignments were further supported by an analysis of the NMR spectrum of 18,20β-epoxy-3β-hydroxy-17β-ethyletiojervan-11-one 3-acetate (**19**) obtained by the hypoiodite reaction of the alcohol **17** (*vide infra*). Interestingly, the 11-oxo group of **15** exerts an influence on the steric course of the reduction, as shown by the formation of an appreciable amount of 20α-isomer **18** from **15** and the exclusive formation of 20β-isomer from a 11-deoxo analogue of **15**.[5]

The 20β-ol **17** in benzene containing mercury(II) oxide and iodine was then irradiated for 2.5 h under an argon atmosphere.[1,7b] Column chromatography of the product gave **19** in 81% yield together with the recovered material (7%). Various spectra of the product was in agreement with (20*R*)-18,20β-epoxy-3β-hydroxy-17β-ethyl-12α-etiojervan-11-one 3-acetate (**19**). Thus, high resolution mass spectrometry confirmed the molecular formula $C_{23}H_{34}O_4$. IR spectrum showed the absence of any hydroxyl group and the presence of a superimposed band at 1732 cm^{-1} arising from the 3β-acetoxyl and the 11-oxo groups. The very intense molecular ion peak (67.8%) in the mass spectrum of **19** contrasts to that of the 11-deoxo analogue,[5] in which the intensity of the molecular ion is only 2% and M^+-CH_3 ion peak is intense. The NMR spectrum showed a three-proton doublet at τ 8.82 with J=6.3 Hz assigned to the 21-H. It also

showed a one-proton double quartet at τ 6.32. Irradiation at τ 8.82 caused a collapse of the double quartet at τ 6.32 to a doublet with J=4.2 Hz. On this basis, the signal at τ 6.32 is asigned to the 20-H. The NMR spectrum showed another double doublet at τ 6.84 with J=10.5 Hz and 7.5 Hz and a triplet at τ 6.12 with J=7.5 Hz; these are assigned to the 18β-H and the 18α-H respectively. Model inspection indicates that the dihedral angles between the 18α-H and the 13α-H, and the 18β-H and the 13α-H in a twisted boat conformation of the ring D are about 20° and 140° respectively, in accord with the observed magnitudes of the couplings. The relevant coupling constants are $J_{18\alpha,18\beta}$=7.5 Hz, $J_{18\beta,13\alpha}$=7.5 Hz, and $J_{18\beta,13\alpha}$=10.5 Hz. The Dreiding molecular model also shows that the dihedral angle between the 17α-H and the 20β-H is about 120° in the above conformation. The observed coupling constant 4.2 Hz allows us to assign the configuration of the methyl group at the C-20 to be α. Therefore, **17** should be the 20β-ol.

Hydrolysis of **19** with methanolic potassium hydroxide gave a crystalline alcohol **20**, mp 229—229.5 °C, the first 18-functional C/D *trans* *D*-homo-*C*-norsteroid ever prepared. The epimerization of the C-12 center of **19** was proved by the ^{1}H NMR spectrum of **20**. The ^{1}H NMR spectra of **20** and 3-oxo compound **21** showed an appreciable change of the splitting of the signals arising from their 18-methylene protons, in comparison with the correponding ones of C/D *cis* compound **19**. The spectrum of **20** showed a broad doublet at τ 5.64 with J=8.6 Hz and a double doublet at τ 6.17 with J=8.6 Hz and 4.9 Hz. The inspection of the model of C/D *trans* ketone **20** having the ring D in a *quasi* chair conformation indicated that the dihedral angle between the 18β-H and the 13α-H is about 90° and that between the 18α-H and the 13α-H is about 30°. On the other hand, the two corresponding dihedral angles in the model of C/D *trans* ketone having the ring D in a boat conformation were about 130° and 30°. The observed coupling constants are thus in agreement with the predicted ones for the hydroxy ketone having the ring D in a chair; the doublet at τ 5.64 and the double doublet at τ 6.17 are ascribed to the 18β-H and the 18α-H. A signal due to the 20β-H was superimposed on the signal arising from the 18α-H; the superimposed signal shape changed when a three-proton doublet at τ 8.82 (the 21-H) was irradiated. The isomerization of the C/D junction of **19** in the hydrolysis was finally confirmed by a comparison of its 11-deoxo compound (**23**) with (20*R*)-18,20β-epoxy-17β-ethyl-12α-etiojervan-3β-ol 3-acetate[1,5] previously prepared. This showed that the two compounds are not identical (*vide infra*).[1,5]

The ketone **20** was then oxidized to 18,20-epoxy-17β-ethyletiojervane-3,11-dione (**21**) with chromium trioxide-pyridine. Oxidation of **21** with chromium trioxide-acetic acid failed to give the lactone. It is almost certain that the 11-oxo group hinders the oxidation of the 18-methylene to a 18-oxo group, since the 18-methylene group of the corresponding 11-deoxo compound (**23**) can readily be oxidized to 18-oxo group (*vide infra*).

The 11-oxo group of **20** was removed by a modified procedure[14] of the Wolff-Kishner reduction. The reduction by this procedure gave 11-deoxo alcohol (**22**), mp 171—174 °C, as a single product. It gave an O-acetyl derivative (**23**), which was proved to be not identical with 18,20β-epoxy-17β-ethyl-12α-etiojervan-3β-ol 3-acetate reported previously.[1,5] The NMR spectra of **22** and **23** showed that the splittings of the signals arising from their 18-methylene protons were similar to those of their 11-oxo analogue **20**, with the exception that the doublet arising from the 18β-H shifted significantly to a higher field (Δ 0.74 ppm for **22**). Oxidation of **23** with chromium trioxide in acetic acid gave an amorphous γ-lactone (**24**) in 39% yield. The IR spectrum showed two bands due to an acetoxyl and a γ-lactone groups. Its NMR spectrum exhibited a double quartet at τ 5.65 due to the 20β-H and a doublet at τ 8.71 due to the 21-H. Irradiation at τ 8.71 caused a collapse of the former to a doublet with J=9.3 Hz. The mass spectrum showed only a weak molecular ion peak at *m/e* 374 (0.3%), a base peak at *m/e* 314, and a prominent peak at *m/e* 299 (35.7%). The last two fragments are attributable to $M^+-CH_3CO_2H$ and $M^+-CH_3CO_2H-CH_3$.

Hydrolysis of the lactone **24** in a mixture of chloroform and methanol with dilute hydrochloric acid at room temperature gave the corresponding 3β-ol **25**, mp 202—205 °C.

The aforementioned experiments indicated that the cyclic ether **19** with the C/D *cis* junction is a less stable isomer and readily isomerizes with a base to the more stable cyclic ether **20** with C/D *trans* junction. Attempts have been made to modify the 11-oxo function of **19** without affecting the stereochemistry of the C/D *cis* ring junction. Reduction of the 11-oxo function of **19** with lithium aluminum hydride for 1.5 h at room temperature gave 3β,11β-diol (**26**), mp 211—214 °C, as a single product. This remarkably facile reduction of the 11-oxo group is surprising. The conformation of the molecule **19** should be one in which the degree of steric hindrance around the 11-oxo group for the attack of hydride ion is appreciably reduced. The *cis* stereochemistry of the C,D-ring junction was supported by NMR spectroscopy. The NMR spectrum showed a one-proton triplet at τ 5.68 (J=6.0 Hz) assigned to the 11α-H, a two-proton singlet ($W_{1/2}$= 5 Hz) at τ 6.07 assigned to the 18-methylene protons, and a one-proton double quartet centered at τ 6.12 with J=2.3 and 6.0 Hz ascribed to the 20β-H. Apart from these signals it showed a one proton multiplet centered at τ 7.49 and a three-proton doublet at τ 8.85 (J=6.0 Hz) ascribed to the 17α-H and the 21-H. These assignments were supported by the following spin decoupling studies. Irradiation at τ 8.85 resulted in a collapse of the double quartet at τ 6.12 into a doublet with J=2.3 Hz. Irradiation at τ 7.49 decoupled the double quartet at τ 6.12 into a quartet with J=6.0 Hz. Finally, irradiation at τ 6.12 resulted in collapses of the doublet at τ 8.85 to a singlet and of the multiplet at τ 7.49 into a diffused triplet. On the basis of these results, the relevant coupling constants are $J_{21\text{-H},\,20\beta\text{-H}}$=6.0 Hz, $J_{20\beta\text{-H},\,17\alpha\text{-H}}$=2.3

Hz, $J_{18\alpha\text{-H},\,18\beta\text{-H}} \simeq J_{18\alpha\text{-H},\,13\alpha\text{-H}} \simeq J_{18\beta\text{-H},\,13\alpha\text{-H}} < 5$ Hz. The unusually small gem-coupling of the 18-methylene protons should be noted.

Acetylation of **26** by the standard procedure gave a 3-acetate **27**. To transform 3β-hydroxyl group into a 3-oxo group, diol **26** was subjected to the Oppenauer oxidation. However only a low yield of 3-oxo compound **28** was obtained, together with 3,11-dione **21**. An analysis of the signals arising from the 18-methylene protons and the 20β-proton of **28** is given in the Table.

Experimental

For instruments used and general procedures see Ref. 1. Low resolution mass spectra of compounds **2,4—7, 14, 15, 17, 18, 20—26**, and all the high resolution mass spectra were recorded at the Faculty of Agriculture of this University with a Hitachi JMS-D 300 spectrometer. Low resolution mass spectra of compounds **3, 18**, and **28** were recorded at the Faculty of Pharmaceutical Sciences with a Hitachi RMU-6E spectrometer.

Catalytic Hydrogenation of (22S, 25S)-N-Acetyl-3β,23β-dihydroxyveratr-5,13(17)-dien-11-one 3-Acetate (1). (*a*): Rhodium–platinum catalyst (38.65 g) in glacial acetic acid (350 ml) was shaken under an atmosphere of hydrogen for *ca.* 11.5 h. To this solution was added the diene **1** (25.0 g) dissolved in glacial acetic acid (250 ml). The resulting solution was shaken under an atmosphere of hydrogen for 43.5 h and then a further amount of freshly prepared catalyst (4 g) in glacial acetic acid (150 ml) was added. The solution was again shaken under an atmosphere of hydrogen for 18.5 h. During this period, 3.25 l of hydrogen were absorbed. After the removal of the catalyst and the solvent, water (300 ml) was added to the residue and the solution was neutralized with aq 10% sodium carbonate solution. The solution was then extracted with chloroform (500 ml × 3). The chloroform solution was washed with water and dried. After the usual work-up, the residue was recrystallized from acetone–diethyl ether to yield perhydro derivative **2**, mp 204—206 °C. (15.60 g) in colorless crystals in two crops. (Found: C, 72.24; H, 9.75; N, 2.67%. Calcd for $C_{31}H_{49}NO_5$: C, 72.19; H, 9.58; N, 2.72%); $[\alpha]_D^{25}$ −1.5° (*c* 1.5, $CHCl_3$); IR, 3319 (OH), 1734 and 1722 (5-membered ring ketone and OAc), 1606 (NAc), 1236 and 1015 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*), 515 (M^+, 0.4), 500 ($M^+ - CH_3$, 0.3) 472 (0.3), 198 (0.3), 185 (0.7), 156 ( , 100), and 114 ( , 17.3); for NMR see Table 1.

Examination of the residue (9.4 g) from the filtrate by TLC indicated that it was a mixture of the starting material, which was the major component, and two other minor products. This residue in glacial acetic acid (200 ml) was again hydrogenated in the presence of rhodium–platinum catalyst (14.4 g). About 0.74 l of hydrogen were absorbed during 50 h. The product was recrystallized from diethyl ether to yield perhydro derivative **2** (0.794 g). The residue from the filtrate was subjected to column chromatography (Mallinckrodt silicic acid, 100 mesh, 100 g). Elutions with hexane, benzene, and a 1:1 mixture of chloroform and benzene gave a mixture (6.85 g). An analysis of a part of the mixture by preparative TLC (a 5:3 mixture of diethyl ether–chloroform as the solvent) indicated that it contained 1.01 g of perhydro derivative **2**. Further elutions with diethyl ether gave a fraction which gave the perhydro derivative **2** (0.505 g) after recrystallization from diethyl ether. The total yield of perhydro derivative **2** was thus 71.6%. Isolations of the minor products **3** and **4** are described in the following procedure (b).

(*b*): Rhodium–platinum catalyst (2.0 g) in glacial acetic acid (30 ml) was shaken under an atmosphere of hydrogen for 4 h. During this period, 578 ml of hydrogen were absorbed. To this solution was added diene **1** (2 g) in glacial acetic acid (30 ml) and the solution was shaken under an atmosphere of hydrogen for 46 h, 180 ml of hydrogen being absorbed. After removal of the catalyst and the solvent, the product was dissolved in chloroform and the solution was washed with water, then dried over anhydrous sodium sulfate. The residue (2.472 g) showed four spots on TLC (a 5:3 mixture of diethyl ether–chloroform). A part of the product (750 mg) was subjected to preparative TLC with a 5:3 mixture of diethyl ether and chloroform to give four fractions: A (69 mg), B (337 mg), C (62 mg), and D (388 mg) in the order of decreasing mobility. Fraction A was recrystallized from acetone–diethyl ether to yield product **3**, mp 218.5—219.5 °C (15 mg). (Found: C, 76.54; H, 9.94; N, 3.14%. Calcd for $C_{29}H_{45}O_3N$: C, 76.44; H, 9.95; N, 3.07%); IR 3314 (OH), 1725 (5-membered ring ketone), 1608 (NAc), 1254, and 1017 cm^{-1}; MS (80 eV), *m/e* (*rel intensity*), 455 (M^+, 0.3), 299 (1), 298 (0.9), 156 (100), 114 (45), 55 (9), and 43 (9); for NMR see Table 1.

Fraction B was identified as an olefin **4** but could not be induced to crystallize. (Found: *m/e* 513.3453. $C_{31}H_{47}NO_5$ requires M^+ 513.3453); $[\alpha]_D$ +1.64° (*c*, $CHCl_3$); IR, 3320 (OH), 1727 (OAc and 5-membered ring ketone), 1604 (NAc), 1240, and 1028 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*), 513 (M^+, 0.2), 357 ($M^+ - C - 20$ substituent, 0.5), 156 (100), and 114 (20.6); for NMR see Table 1.

Fraction C was a mixture; fraction D was recrystallized from acetone–diethyl ether to yield perhydro derivative **2**, (238 mg).

The Removal of Heterocyclic Moiety of (22S,25S)-N-Acetyl-3β,23β-dihydroxyveratranin-11-one 3-Acetate **2** by *Irradiation in the Presence of Mercury(II) Oxide and Iodine.* The perhydro compound **2** (13.5 g) in dry benzene (700 ml) in the presence of mercury(II) oxide (27.0 g) and iodine (33.8 g) was irradiated with a 100-W high pressure mercury arc while being stirred. After a period of 24 h, more iodine (3 g) and mercury(II) oxide (3 g) were added and the irradiation was continued for another 24 h. Precipitates were removed by filtration and washed with hot benzene. The solution and the washing were combined, washed with saturated aq sodium hydrogensulfite solution (300 ml) and water (500 ml × 2), and dried over anhydrous sodium sulfate. Removal of the solvent at below 40 °C gave a brown residue. TLC indicated that this was largely aldehyde **5**, together with a small amount of a less mobile compound **6**. The residue was subjected to column chromatography with Mallincrodt silicic acid (35 g). Elutions with a 1:1 mixture of benzene and hexane and then benzene only gave three fractions. The first fraction gave crystalline aldehyde **5**. Recrystallization from diethyl ether gave pure aldehyde **5** (4.0 g), mp 144—146 °C (Found: *m/e* 388.2608. Calcd for $C_{24}H_{36}O_4$: M^+ 388.2613); $[\alpha]_D^{25}$ −3.3° (*c* 0.4, $CHCl_3$); IR, 1731, (broad, CHO, OAc and 5-membered ring ketone), 1234, and 1020 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 388 (M^+, 34.1), 360 ($M^+ - CO$, 52.7), 345 (9.3), 330 ($M^+ - C -$ 17 substituent-H, 17.7), 328 ($M^+ - CH_3CO_2H$, 39.5), 300 ($M^+ - CO - CH_3CO_2H$, 77.4), 147 (89.0), 123 (70.3), 95 (73.2), 93 (87.8), 81 (75.8), 67 (61.8), 55 (70.4), and 43 (100); for NMR see Table 1.

The second fraction gave an amorphous mixture (800 mg), which was subjected to preparative TLC with a 20:1 mixture of chloroform and diethyl ether to give aldehyde **5** (300 mg) and a new compound **6** (479 mg). The aldehyde **5** was recrystallized from diethyl ether to give a pure specimen (259 mg). The new compound **6** was recrystallized from diethyl ether to give a pure specimen, mp 221—222 °C. (Found: C, 72.25; H, 9.18; N, 2.58%. Calcd for $C_{31}H_{47}NO_5$; C, 72.48; H, 9.22; N, 2.73%); $[\alpha]_D^{25}$ −2.7 (*c* 1.1, $CHCl_3$); IR, 1733 (OAc and 5-membered ring ketone) and 1671 cm^{-1} (NAc); MS, (70 eV) *m/e* (*rel intensity*), 513 (M^+, 11.9), 277 (5.2), 222 (20.3), 211 (31.5), 167 (100), 156 (24.5), 114 (9.8), and 43 (17.3); for NMR see Table 1.

Hydrolysis of Compound ***6***. Product **6** in methanol (5 ml) containing potassium hydroxide (250 mg) was heated under reflux and an atmosphere of nitrogen for 40 min. After the removal of methanol, water (20 ml) and 2 mol dm^{-3} hydrochloric acid (5 ml) were added to the residue. The solution was extracted with chloroform. The organic layer was worked up as usual. The amorphous residue (41 mg) was recrystallized from acetone–diethyl ether to give 3β-ol **7**, mp 242—244°. (Found: *m/e* 471.3334. Calcd for $C_{29}H_{45}NO_4$: M^+ 471.3346); MS ,(70 eV) *m/e* (*rel. intensity*), 471 (M^+, 19.7), 222 (18.5), 211 (31.2), 167 (100), and 156 (19.1).

Preparation of Enamine ***14*** *from 20-Formyl-3β-hydroxy-12α-17β-ethyletiojervan-11-one 3-Acetate.* Aldehyde **5** (4 g), morpholine (10 ml), and p-toluenesulfonic acid (200 mg) in dry toluene (150 ml) were heated under reflux in a flask fitted with a Dean Stark trap for 5.5 h. After the removal of the solvent, an oily residue was extracted with chloroform (200 ml×2). The solution was washed with an aq 5% sodium carbonate solution (100 ml) and water (100 ml×2) and dried over anhydrous sodium sulfate. Removal of the solvent left crystals of enamine **14** (4.45 g), mp 106—108 °C. This enamine **14** was used immediately for the next step without further purification. (Found: *m/e* 457.3203. Calcd for $C_{28}H_{43}NO_4$: M^+ 457.3192); $[\alpha]_D^{25}$ −4.4 (*c* 1.1, $CHCl_3$); IR, 1732 (OAc and 5-membered ring ketone), 1260, 1123, 1031, 874, and 735 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 457 (M^+, 72.0), 388 (11.2), 360 (18.9), 328 (18.5), 300 (31.3), 166 (100), 147 (38.9), 123 (34.3), 100 (43.9), 95 (44.3), 93 (42.8), 81 (39.4), 67 (31.2), 55 (36.6), and 43 (70.0); for NMR see Table 1.

*Preparation of 3β-Hydroxy-12α,17β-ethyletiojervane-11,20-dione 3-Acetate (****15****) from Enamine* ***14***. (*a*): Enamine **14** (500 mg) and copper(I) chloride (300 mg) in chloroform (100 ml) were cooled with ice–water and oxygen was bubbled through the solution for 9.5 h. After about 3 h, precipitates appeared in the yellow-green solution. At this point 10 ml of chloroform were added and the solution was allowed to stand under an atmosphere of oxygen for an additional 14.5 h. The precipitates were removed by filtration and washed with chloroform (100 ml). The filtrate and the washings were combined and worked up in the usual way. The crystalline residue was recrystallized from diethyl ether to yield dione **15** (343 mg), mp 134—135 °C. (Found: C, 73.99: H, 9.42%. Calcd for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15%); $[\alpha]_D^{25}$ −1.4 (*c* 1.0, $CHCl_3$); IR, 1732 (OAc and 5-membered ring ketone), 1704 (Ac), 1242, 1024, 992, and 896 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 374 (M^+, 77.7), 359 (M^+-CH_3, 4.8), 314 ($M^+-CH_3CO_2H$, 19.5), 299 ($M^+-CH_3CO_2H-CH_3$, 25.2), 219 (9.8), 205 (10.3), 147 (18.3), 107 (14.7), 105 (16.6), 95 (57.3), 93 (20.3), 91 (15.8), 81 (15.5), 79 (16.4), 67 (17.7), 55 (17.4), and 43 (100); for NMR see Table 1.

(*b*): Enamine **14** (4.276 g) and Rose Bengal (100 mg) in dry benzene (600 ml) were irradiated with a 90-W high pressure mercury arc under an atmosphere of oxygen for 48 h. Oxygen was occasionally bubbled into the stirred solution. The solution was washed with water (300 ml×3) and dried over anhydrous sodium sulfate. After removal of the solvent, the crystalline residue (4.744 g), which was almost a single product, was subjected to column chromatography (Mallincrodt SiO_2, 7 g) to remove some polar substances. Elutions with benzene containing an increasing amount of chloroform gave dione **15**. It was recrystallized from diethyl ether to give 2.79 g in two crops.

(*c*): Enamine **14** (8.95 g) and Rose Bengal (250 mg) in dry benzene (1.3 l) were irradiated with a 103-W high pressure mercury arc for 48 h while oxygen was bubbled through slowly. After work-up as in procedure (b), the product (6.35 g) was subjected to column chromatography (Mallincrodt SiO_2, 15 g). Elutions with benzene gave a fraction which was recrystallized from diethyl ether–hexane to yield aldehyde (**16**) (3.4 g). The residue from the filtrate was subjected to preparative TLC with 50:1 chloroform–diethyl ether to yield a further amount of aldehyde (16) (0.31 g), mp 132—134 °C. (Found: *m/e* 374.2447. Calcd for $C_{23}H_{34}O_4$. M^+ 374.2455). IR, 1738 (OAc), 1726 (CHO), 1717 ($COCH_3$), and 1248 cm^{-1}. MS, *m/e* (*rel intensity*), 374 (M^+, 3.2), 346 (3.0), 286 (2.8), 271 (3.6), 253 (3.8), 107 (22.0), 105 (14.5), 95 (14.9), 93 (16.3), and 43 (100).

Reduction of Dione **15** *with Sodium Borohydride.* Dione **15** (600 mg) in absolute ethanol (60 ml) containing sodium borohydride (260 mg) and ethyl acetate (2 ml) was stirred for 2.5 h at room temperature. The reaction mixture was worked up as usual to give a residue (713 mg). Examination of the product by TLC with a 1:20 mixture of diethyl ether–chloroform showed it to be a mixture of a major product (R_f 4.4) and a minor product (R_f 5.5). Recrystallization from diethyl ether gave 3β,20β-dihydroxy-12α,17β-ethyletiojervan-11-one 3-acetate **17**, mp 169—171 °C, (349 mg). (Found: C, 73.22; H, 9.59%. Calcd for $C_{23}H_{36}O_4$. C, 73.36; H, 9.64%); $[\alpha]_D^{25}$ −0.62 (*c* 1.7, $CHCl_3$); IR, 3544 (OH), 1724 (OAc and 5-membered ring ketone), 1235, 1121, 1031, and 899 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*), 376 (M^+, 2.4), 358 (M^+-H_2O), 332 (45), 272 (100), 235 (27.4), 218 (31.8), 147 (43.9), 123 (32.4), 107 (36.1), 105 (32.6), 95 (92.2), 93 (58.5), 91 (31.9), 81 (41.6), 79 (36.2), 67 (40.6), 55 (38.4), and 43 (73.9); for NMR see Table 1.

Removal of the solvent from the filtrate gave a mixture of 20α- and 20β-ols (283 mg). The mixture was subjected to preparative TLC with a 1:20 mixture of diethyl ether–chloroform to give two fractions. The less mobile fraction (124 mg) was 20β-ol; this was recrystallized from diethyl ether to give pure 20β-ol **13** (64 mg). The more mobile fraction (68 mg) was recrystallized from diethyl ether to give 20α-ol **18**, mp 175—176 °C. (Found: C, 73.13; H, 9.54%. Calcd for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64%); $[\alpha]_D^{25}$ −1.1 (*c* 1.2, $CHCl_3$); IR 3564 (OH), 1726 (OAc and 5-membered ring ketone), 1232, 1106, 1019, and 895 cm^{-1}; MS, (80 eV) *m/e* (*rel intensity*) 376 (M^+, 4), 358 (M^+-H_2O, 8), 332 (29), 272 (78), 218 (57), 177 (30), 147 (54), 123 (43), 107 (47), 105 (37), 95 (100), 93 (59), 91 (46), 81 (55), 79 (47), 67 (66), 55 (60), and 43 (95); for NMR see Table 1.

The Hypoiodite Reaction of 3β,20β-Dihydroxy-12α,17β-ethyletiojervan-11-one 3-Acetate ***17***. Alcohol **17** (267 mg) in dry benzene (40 ml) containing mercury(II) oxide (550 mg) and iodine (850 mg) was irradiated with a 100-W high pressure mercury arc through a Pyrex filter under an argon atmosphere. The solution was stirred during irradiation. The irradiation was discontinued after 2.5 h when the starting material disappeared as shown by TLC. The precipitates

were removed by filtration and washed with hot benzene (100 ml×2). The filtrate and the washings were combined and washed with 10% sodium hydrogen sulfite solution (30 ml) and then with water and dried over anhydrous sodium sulfate. Evaporation of the solvent left a residue (308 mg) which was subjected to column chromatography (Mallincrodt silicic acid, 2.6 g). Elution with a 1:1 mixture of hexane and benzene gave a fraction (10 mg); further elution with benzene, a 2:1 mixture of benzene and chloroform, and a 1:1 mixture of benzene and chloroform gave acetate **19** (216 mg). (Found: *m/e* 374.2438. Calcd for $C_{23}H_{34}O_4$: M$^+$ 374.2455); IR ($CHCl_3$) 1732 (OAc and 5-membered ring ketone), 1240, 1028, and 758 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 374 (M$^+$, 67.8), 359 (M$^+-CH_3$, 3.6), 314 (M$^+-CH_3CO_2H$, 9.9), 299 (M$^+-CH_3CO_2H-CH_3$, 12.9), 235 (7.7), 147 (26.7), 105 (25.1), 95 (35.0), 93 (30.7), 91 (29.0), 79 (33.3), 67 (25.1), 55 (19.7), and 43 (100).

The final fraction (19 mg) eluted with a 1:1 mixture of chloroform and diethyl ether was the starting material. Acetate **19** was subjected to hydrolysis without further purification.

*Hydrolysis of Acetate **19**.* Acetate **19** (560 mg) in methanol containing potassium hydroxide (2.5 g), water (0.5 ml), and chloroform (8 ml) was stirred for 2.5 h at room temperature and then warmed for another 0.5 h (bath temp 40 °C). The solvent was removed by a rotary evaporator and the residue in added water (30 ml) was neutralized with 2 mol dm^{-3} hydrochloric acid (*ca.* 50 ml) and extracted with chloroform (100 ml×3). The chloroform solution was washed with water and dried over anhydrous sodium sulfate. The residue (532 mg) was recrystallized from diethyl ether to yield 3β-hydroxy-12β-ketone **20**. Preparative TLC of the residue from the filtrate with a 1:1 mixture of diethyl ether and benzene gave a further amount of ketone **20** (27 mg), mp 229—229.5 °C. (Found: *m/e* 332.2352. Calcd for $C_{21}H_{32}O_3$. M$^+$ 332.2351); $[\alpha]_D^{25}-4$ (*c* 1.4, $CHCl_3$); IR 3410 (OH), 1724 (5-membered ring ketone), 1080, and 1041 cm^{-1}; MS, (70 eV), *m/e* (*rel intensity*) 332 (M$^+$, 100), 317 (M$^+-CH_3$, 6.2), 302 (M$^+-2CH_3$, 26.1), 147 (17.9), 110 (17.7), 109 (13.3), 107 (16.9), 105 (24.0), 97 (28.6), 96 (30.9), 93 (30.3), 91 (30.3), 79 (49.2), 67 (24.9), 55 (25.1), 43 (16.7), and 41 (25.0).

Oxidation of 3β-Hydroxy-12β-ketone with Chromium Trioxide–Pyridine. The 3β-ol **20** (150 mg) and chromium trioxide (150 mg) in pyridine (3 ml) were stirred for 3.5 h at room temperature. To this solution was added more (100 mg) of chromium trioxide in pyridine (1 ml) and the solution was stirred for another 1.5 h. After an excess of chromium trioxide was decomposed by adding saturated sodium hydrogensulfite solution (20 ml), the solution was extracted with chloroform (30 ml×3). The chloroform solution was worked up as usual. A product was recrystallized from acetone to yield 3,11-dione **21**, mp 127—129 °C. (Found: *m/e* 330.2193. Calcd for $C_{21}H_{30}O_3$. M$^+$ 330.2193); IR, 1706 (6-membered ring ketone), 1728 (5-membered ring, ketone), 1258, 1129, 1084, and 861 cm^{-1}; MS, (70 eV), *m/e* (*rel intensity*), 330 (M$^+$, 100), 315 (M$^+-CH_3$, 9.8), 300 (M$^+-2CH_3$, 37.5), 286 (11.5), 245 (24.2), 191 (18.5), 121 (17.4), 97 (38.3), 96 (42.0), 93 (31.0), 91 (22.5), 81 (21.0), 79 (44.6), 67(20.1), 55 (25.7), 43 (20.9), and 41 (22.9).

*Wolff-Kishner Reduction of Ketone **20**.* Ketone **20** (102 mg), hydrazine hydrate (1 ml), and hydrazine hydrochloride (280 mg) in triethylene glycol (7.2 ml) were heated at 130 °C for 4 h under an atmosphere of nitrogen. To this solution was added potassium hydroxide pellets (370 mg) and the solution was distilled until the temperature rose to 210 °C. The solution was heated at that temperature for another 2.5 h (bath temp 223 °C). After cooling, the solution was poured into a water–ice mixture. Crude 11-deoxo compound **22**, (78 mg), mp 158—165 °C, was collected by filtration. The specimen for analysis, mp 171—174 °C, was obtained by recrystallization from acetone–diethyl ether. (Found: C, 78.71; H, 10.72%. Calcd for $C_{21}H_{34}O_2$. C, 79.19; H, 10.76%); IR, 3400 (OH), 1084, and 1049 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 318 (M$^+$, 45.6), 303 (M$^+-CH_3$, 47.6), 300 (M$^+-H_2O$, 11.8), 285 (32.7), 274 (11.2), 259 (71.1), 241 (43.7), 149 (72.6), 148 (100), 147 (37.6), 107 (76.1), 105 (48.9), 95 (44.1), 93 (81.1), 91 (77.0), 81 (70.0), 79 (80.6), 67 (71.6), 55 (66.8), 43 (39.4), and 41 (62.1), for NMR see Table 1.

The 3-acetate **23**, mp 135—137 °C, was prepared in a usual manner. (Found: C, 76.68; H, 10.10%. Calcd for $C_{26}H_{36}O_3$: C, 76.62; H, 10.07%. (Found: *m/e* 360.2654. Calcd for $C_{26}H_{36}O_3$. M$^+$, 360.2664); IR, ($CHCl_3$) 1732 (OAc), 1243, 1087, 1031, and 762 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 360 (M$^+$, 10.5), 345 (19.2), 300 (100), 285 (45.1), 256 (23.9), 255 (23.3), 241 (80.8), 149 (39.0), 148 (53.0), 147 (33.0), 107 (47.0), 105 (33.9), 93 (51.5), 91 (40.6), 81 (40.9), 79 (43.8), 67 (36.7), 55 (32.9), and 43 (93.0).

*Preparation of the γ-Lactone **24** from Acetate **23** with Chromium Trioxide–Acetic Acid.* To a solution of acetate **23** (74 mg) in glacial acetic acid (8.5 ml), under reflux, was added chromium trioxide (234 mg) dissolved in glacial acetic acid (4.5 ml) and water (0.5 ml). The solution was heated under reflux for 2.5 h. After removal of the solvent at below 70 °C, the residue was extracted with chloroform (50 ml×3). The chloroform solution was worked up as usual to yield amorphous γ-lactone **24** (30 mg). All attempts to induce the lactone to become crystals were unsuccessful. (Found: *m/e* 314.2248. Calcd for $C_{21}H_{30}O_2$ (M$^+-CH_3CO_2H$ 314.2245). IR, 1729 (OAc), 1765 (γ-lactone), 1258, and 1023 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 374 (M$^+$, 0.3), 314 (100), and 299 (35.7); for NMR see Table 1.

*Hydrolysis of the γ-Lactone **24** with Hydrochloric Acid.* The γ-lactone **24** (40 mg) in methanol (8.1 ml) and chloroform (0.9 ml) containing 12 mol dm^{-3} hydrochloric acid (0.9 ml) was stirred for 17 h at room temperature. The solution was neutralized with aq 5% sodium carbonate solution and the solvent was partly removed by a rotary evaporator. The crystals of the 3β-hydroxy γ-lactone **25** were collected by filtration and recrystallized from methanol–water to yield **25**, mp 202—205 °C. (Found: *m/e* 332.2340. Calcd for $C_{21}H_{32}O_3$: M$^+$ 332.2350); IR 3400 (OH) and 1765 cm^{-1} (γ-lactone); MS, *m/e* (70 eV) (*rel intensity*) 332 (M$^+$, 27.4), 314 (M$^+-H_2O$, 95.8), 299 (22.2), 285 (10.2), 260 (45.1), 259 (30.2), 258 (100), 149 (12.8), 147 (25.5), 108 (14.3), 93 (23.7), 91 (24.6), 79 (24.3), 55 (22.1), and 41 (14.3).

*Reduction of Ketone **19** with Lithium Aluminum Hydride.* To 12α-ketone **19** (522 mg) in dry THF (30 ml) cooled by ice–water was added slowly lithium aluminum hydride (400 mg). The solution was stirred for 1.5 h at room temperature and an excess of lithium aluminum hydride was decomposed by addition of small amounts of ethyl acetate and methanol. To this solution were added water (50 ml) and chloroform (100 ml) and the two-layered solution was stirred for 30 min. The solution was filtered and the aqueous filtrate was extracted with chloroform (50 ml×20). The chloroform solution was worked up in the usual manner. The product was recrystallized from diethyl ether to yield **26** (241 mg), mp 211—214 °C. A residue (185 mg) from the filtrate was subjected to preparative TLC with a 1:1 mixture of chloroform–diethyl ether to yield a further amount of diol **26** (26 mg). (Found: M$^+$ *m/e* 334.2505. Calcd for

$C_{21}H_{34}O_3$: M^+ 334.2506); $[\alpha]_D^{25}$ −3.0 (*c* 0.75, $CHCl_3$); IR, 3428 (OH), 1040, and 851 cm^{-1}; MS, (70 eV) *m/e* (*rel intensity*) 334 (M^+, 6.6), 316 (M^+-H_2O, 100), 301 ($M^+-H_2O-CH_3$, 47.3), 298 (M^+-2H_2O, 10.6), 290 (41.0), 283 (34.6), 147 (66.6), 133 (33.0), 121 (37.6), 119 (37.1), 109 (36.7), 107 (76.8), 105 (66.6), 97 (37.4), 96 (41.1), 95 (77.2), 93 (94.0), 91 (78.1), 81 (75.1), 79 (95.3), 67 (80.7), 55 (80.8), 43 (71.3), and 41 (70.7).

The diol **26** (13 mg) and acetic anhydride (5 mg) in pyridine (0.5 ml) were stirred for 20 h at room temperature. At the time intervals of 1.5 h and 5 h, a more acetic anhydride (0.05 ml) was added. Work-up of the reaction mixture in the usual manner gave a product (13 mg), which was recrystallized from methanol to yield **27**, mp 170—171 °C. (Found: *m/e* 376.2612. Calcd for $C_{23}H_{36}O_4$: M^+ 376.2612), IR, 3490 (OH), 1734 (OAc), and 1242 cm^{-1}; MS *m/e* (*rel intensity*) 376 (M^+, 2.6), 358 (M^+-H_2O, 69.4), 343 (15.8), 316 ($M^+-CH_3CO_2H$, 18.6), 298 ($M^+-CH_3CO_2H-H_2O$, 35.2), 283 (39.9), 147 (43.8), 107 (60.9), 105 (40.0), 95 (55.8), 93 (69.2), 91 (43.9), 81 (55.9), 79 (61.8), 67 (42.5), 55 (38.1), and 43 (100%).

Oppenauer Oxidation of Alcohol ***26***. Alcohol **26** (288 mg) and aluminum isopropoxide (120 mg) in toluene (25 ml) and dry cyclohexanone (2.3 ml) were heated for 1 h under reflux (bath temp 120 °C). More aluminum isopropoxide (140 mg) was added to the solution. The mixture was heated under reflux for another 1 h and then subjected to a steam distillation to give 150 ml of a distillate. To the solution there were added chloroform (50 ml) and water; then the solution was stirred for 1 h. The aqueous layer was again extracted with chloroform. The combined chloroform solution was worked up as usual. The residue (260 mg) was recrystallized from acetone to yield ketone **28** (69 mg), mp 151—152 °C. The filtrate was evaporated and the residue (143 mg) was subjected to column chromatography (Mallincrodt silicic acid, 2.0 g). Elution with a mixture of a 2:1 benzene and hexane gave fraction (120 mg), which was recrystallized from acetone to yield more **28** (16 mg). The residue from the filtrate was subjected to preparative TLC with a 10:1 mixture of chloroform and diethyl ether to yield two fractions. The more mobile fraction gave dione **21** and the less mobile fraction (45 mg) was recrystallized to yield ketone **28** (35 mg), (Found: C, 75.81; H, 97.0%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%), $[\alpha]_D^{25}$ −2.0 (*c* 0.5, $CHCl_3$); IR ($CHCl_3$) 3416 (OH), and 1707 cm^{-1} (carbonyl); MS, (80 eV) *m/e* (*rel intensity*) 332 (M^+, 15), 314 (M^+-H_2O, 70), 299 (32), 288 (48), 95 (82), 93 (78), 91 (65), 79 (85), 67 (70), 55 (95), 43 (100), and 41 (78); for NMR see Table 1.

The authors thank Mrs. Tomoko Okayama in this laboratory for the measurements of the NMR spectra and the spin-decoupling experiments and Miss Yuko Chiba in the Faculty of Agriculture for the measurements of the mass spectra. The authors also wishes to thank Mr. Maki Kuramoto for his help in preparing some starting materials.

Kinetic Studies of the Interaction of Bromphenol Blue with Bovine Serum Albumin by Pressure-jump Method

Kiyofumi MURAKAMI, Takayuki SANO, and Tatsuya YASUNAGA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received August 5, 1980)

The interaction of Bromphenol Blue (BPB) with bovine serum albumin (BSA) was studied statically, by spectrophotometry, and kinetically, by the pressure-jump method. The absorbance changes of BPB were monitored at 20 °C, pH 7.00 in 0.2 M† phosphate buffer. The static measurements showed that there were two binding classes. The number of binding sites and the binding constants for each class are $n_1=1$, $K_1=1.4\times10^7$ M^{-1} and $n_2=3$, $K_2=9.5\times10^4$ M^{-1}. Kinetically, the binding of BPB to the primary binding site of BSA proceeds *via* at least 4 steps. Two models are offered for the possible binding mechanism. In these models, a fast, probably diffusion controlled, second order step is followed by three first order steps. A correlation between the number of binding steps and the magnitude of the binding constant is discussed. The positive activation entropies associated with the backward reactions of the second and third steps show that these reactions proceed through disordered activation states. From the comparison of the present results to those for other ligands, it was found that the ligand is intimately involved in which activated configuration is adopted.

Albumin reversibly binds many kinds of small molecules such as fatty acids, bilirubin, amino acids, drugs and hormones, and plays important roles as carrier and buffer for these molecules. The binding of albumin with small molecules, therefore, is one important factor which determines the distribution, metabolism and excretion of small molecules in the body. It has been extensively studied by static methods.

On the other hand, until the past few years, the kinetics of the interactions of albumin with small molecules had not been extensively studied since the investigation of Froese *et al.*,[1] probably because the binding of small molecules with albumin was thought to be too fast to be a rate-limiting process in physiological phenomena.[2,3] However, recently, many kinetic studies have been performed in the attempt to elucidate the detailed binding mechanism of physiologically important substances such as bilirubin[4-8] and fatty acid.[9]

The interactions of organic dyes with albumin have often been studied as the model systems of protein-small molecule interaction. Besides the role of a model system, the binding of Bromphenol Blue with albumin has physiologically and clinically important applications such as the quantitative analyses of proteins[10] and the determination of the concentration of available bilirubin binding sites in serum[11,12] using the spectrum shift of Bromphenol Blue on binding to albumin. The investigation of the detailed binding mechanism may offer a better basis for such procedures.

In the present study, the binding mechanism of Bromphenol Blue to bovine serum albumin was investigated through both static and kinetic experiments. The kinetic study was concerned with binding to the highest affinity site, which is the most important site for physiological effects.

Experimental

Materials. Bovine serum albumin fraction V(BSA) was obtained from Armour Laboratories and was used without further purifications. The dimer content was about 5%, as determined by gel chromatography with Sephadex G-150. The fatty acid content was determined to be 0.33 mole per mole of protein by the method of Dole.[13] The BSA solutions were prepared by weight, assuming a molecular weight of 69000. Bromphenol Blue (BPB) was of special reagent grade from Wako Pure Chemical Industries, Ltd. and recrystallized from a mixture of acetone and acetic acid. All other chemicals used were reagent grade and used without further purification. All the sample solutions were prepared in 0.2 M phosphate buffer of pH 7.00.

Apparatus. The absorption spectra were measured with a Union Giken SM401 Spectrophotometer. The kinetic measurements were performed with an optical detection pressure-jump apparatus constructed in our laboratory. The pressure of the sample solution was suddenly decreased from 150 atm to 1 atm by rupture of brass film within a time of 100 μs. The light source used was a halogen lamp (250 W) and the path length of the cell was 10 mm. The details of the pressure-jump apparatus can be found elsewhere.[14] All measurements were performed at 20±0.2 °C with the exception of the experiments on the temperature dependence of the relaxation times.

Results

Spectrophotometric Studies. The absorption spectra of the BSA–BPB complex under the various polymer-to-dye ratios (P/D) are shown in Fig. 1. The peak of the spectrum of the free dye around 590 nm decreases with increasing P/D, and that of the complex at 610 nm increases. The increase of the absorbance in the whole range of wavelength with the change of P/D from 4 to 20 shows that the contribution of the absorbance of the protein can not be ignored. The binding parameters were determined from the absorbance change at 590 nm by applying the correction for the contribution of the protein. The extinction coefficients of the free and bound dyes were determined to be $\varepsilon_f=7.9\times10^4$ M^{-1} cm^{-1} and $\varepsilon_b=4.5\times10^4$ M^{-1} cm^{-1} respectively. The latter value was determined from the absorbance at the higher limit of P/D. The concentration of the free dye C and the average number of bound dye molecules per molecule of BSA $\bar{\nu}$ were determined from the equations:

† In this paper 1 M = 1 mol dm^{-3}.

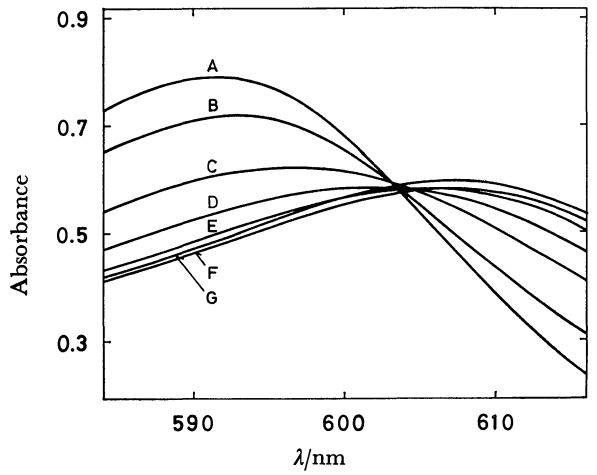

Fig. 1. P/D dependence of absorption spectra of BPB–BSA complex at 20 °C, pH 7.00 and $C_0=1\times10^{-5}$ M. A: Dye only, B: P/D=0.1, C: P/D=0.3, D: P/D=0.5, E: P/D=1, F: P/D=4, G: P/D=20.

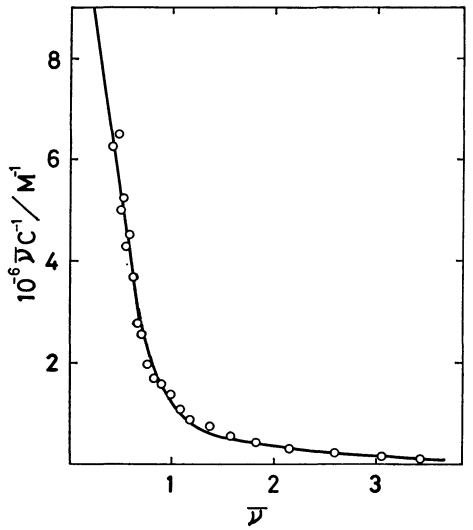

Fig. 2. Scatchard plot of the binding of BPB to BSA.

$$C=\frac{\varepsilon_{app}-\varepsilon_b}{\varepsilon_f-\varepsilon_b}C_0, \quad (1)$$

$$\bar{\nu}=\frac{C_0-C}{P_0}, \quad (2)$$

with

$$\varepsilon_{app}=\frac{A}{C_0 l},$$

where C_0 and P_0 are the total concentrations of the dye and the polymer, respectively, A is the absorbance at 590 nm, and l is the path length of the cell. The Scatchard plot[15] for the present system is shown in Fig. 2. The analysis of this plot yields the following binding parameters:

$$n_1=0.8, \qquad K_1=1.4\times10^7\ M^{-1},$$

$$n_2=3.4, \qquad K_2=9.5\times10^4\ M^{-1},$$

where n_1 and n_2 are the number, of binding sites for the primary and secondary binding sites, respectively. The solid line in Fig. 2 represents the theoretical curve calculated using these values. Good agreement can be seen between the observed and calculated curves. For the calculation of equilibrium concentrations, we used $n_1=1$, $n_2=3$, since these are the closest integers to 0.8 and 3.4.

In the present study, the number of binding sites and the equilibrium constants were determined using the absorbance at the wavelength 590 nm with the same extinction coefficient for all kinds of complexes. At this wavelength, the absorbance decreases to the saturation value with increasing concentration of BSA, and reaches saturation at P/D$\simeq$5. On the other hand, at the wavelength 610 nm, where the absorbance increases with the concentration of BSA, a gradual increase of the absorbance was observed above P/D$\simeq$5. This effect is probably due to dimer formation, which makes the environment around BPB more hydrophobic. This can also be presumed from the fact that the effect becomes more pronounced in more concentrated solutions.

The binding isotherm of BPB with BSA has also been investigated by other researchers. Bjerrum[16] has obtained $n_1=3$, $K_1=5\times10^5\ M^{-1}$, and $n_2=4$, $K_2=2.5\times10^4\ M^{-1}$ at 4.5 °C, pH 7.00 in 0.1 M phosphate buffer by the gel chromatography method. His studies were confined to values of $\bar{\nu}$ above 1; the primary binding sites in his study may thus correspond to the secondary binding sites in the present study. Peeters *et al.*[7] have reported $n_1=1$, $K_1=7.8\times10^5\ M^{-1}$, $n_2=3$, $K_2=7.6\times10^3\ M^{-1}$, $n_3=12$, $K_3=3.1\times10^2\ M^{-1}$ with the defatted BSA at 25 °C, pH 6.62 in 0.1 M phosphate buffer using the microcalorimetry method. The number of binding sites for both of the stronger two binding classes agrees with those of the present study, but the binding constants are about one order of magnitude smaller. The differences in the binding constants may be due to differences in the fatty acid content[7] and/or pH.[18]

Kinetic Studies. Four separate relaxation processes could be observed. The relaxation amplitudes were very small, and 4 to 20 repetitions were averaged to measure the relaxation times. Typical relaxation curves observed at 540 nm are shown in Fig. 3. These relaxations were observed from 400 nm to 560 nm. The relaxation time of the fastest process, which appears as the sudden decrease at $t=0$ in Fig. 3(a), was shorter than the time constant of the apparatus and could not be measured even at a temperature of 5 °C. To obtain the relaxation time of the fastest process, temperature-jump measurements with a temperature increase of about 2 degrees were tried for the same samples, but no relaxation was observed. The static absorption spectra were also insensitive to temperature. All relaxations were observed at 610 nm with opposite direction to and same relaxation times as those observed in the shorter wavelength region. In addition to these four relaxation processes, a relaxational phenomenon with a longer time constant, around 1 min, was observed. This phenomenon has a very small relaxation amplitude, and could be seen only for relatively concentrated samples. Therefore, this phenomenon was not discussed in the present study. These four relaxation processes were numbered 1, 2, 3, 4 in order of the relaxation times,

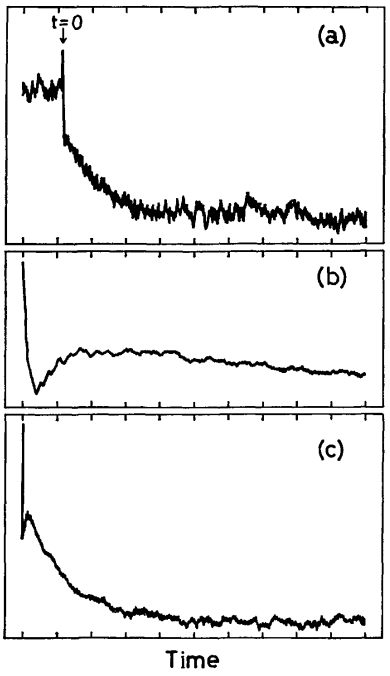

Fig. 3. Typical relaxation spectra of the BPB-BSA system at 20 °C, pH 7.00, λ=540 nm, $C_0=1\times10^{-5}$ M, and $P_0=2\times10^{-5}$ M.
(a) 2ms/div., (b) 40ms/div., (c) 400ms/div.

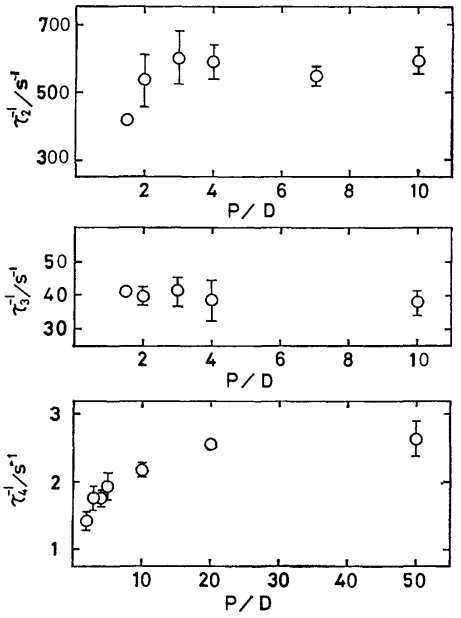

Fig. 4. P/D dependences of the reciprocal relaxation times for slower three processes.

from fast to slow.

Interpretation of the Kinetic Data. The P/D dependences of the relaxation times of the slower three processes, 2, 3, 4 in the region of P/D>1, where the binding of the dye to the highest affinity site of protein occurs, are shown in Fig. 4. All these processes show saturation behavior with P/D. This fact shows that these processes are essentially first order processes. Considering the existences of the very fast process and the three first order processes, the following six models, which are the simplest available under the assumption that the extinction coefficients of the complexes are equal, were examined.

First, the series model which is represented by Eq. 3 was examined.

Model 1

$$\mathrm{D} + \mathrm{P} \underset{k_{-1}}{\overset{K_1'}{\underset{k_1}{\rightleftarrows}}} \mathrm{C}_1 \underset{k_{-2}}{\overset{K_2'}{\underset{k_2}{\rightleftarrows}}} \mathrm{C}_2 \underset{k_{-3}}{\overset{K_3'}{\underset{k_3}{\rightleftarrows}}} \mathrm{C}_3 \underset{k_{-4}}{\overset{K_4'}{\underset{k_4}{\rightleftarrows}}} \mathrm{C}_4, \qquad (3)$$

very fast fast slow very slow

where D, P, and C_i denote free dye, free polymer and complexes of the dye and the polymer, respectively, K_i' is the equilibrium constant, and k_i and k_{-i} are the forward and backward rate constants, respectively. The relaxation times and the overall equilibrium constant for this model are expressed by

$$\tau_1^{-1} = k_1(C+P) + k_{-1} \qquad (4)$$

$$\tau_2^{-1} = k_2\frac{K_1'(C+P)}{1+K_1'(C+P)} + k_{-2} \qquad (5)$$

$$\tau_3^{-1} = k_3\frac{K_1'K_2'(C+P)}{1+K_1'(1+K_2')(C+P)} + k_{-3} \qquad (6)$$

$$\tau_4^{-1} = k_4\frac{K_1'K_2'K_3'(C+P)}{1+K_1'\{1+K_2'(1+K_3')\}(C+P)} + k_{-4} \qquad (7)$$

$$K_\Sigma = K_1'\{1+K_2'(1+K_3'(1+K_4'))\}. \qquad (8)$$

The relaxation time τ_1 of the fast bimolecular step could not be obtained in the present experiment, so that it is difficult to determine all the constants of each reaction step from the fast to slow step successively. Moreover, the experimental errors of the relaxation times are relatively large. Thus, the validity of the reaction mechanism was examined from the standpoint of determining whether proper constants satisfying the concentration dependences of the relaxation times could be chosen. First, from the data of τ_2 and τ_4, the allowable ranges of the combinations of the parameters were estimated as follows:

k_2K_1'	1×10^7—2.6×10^8 M^{-1} s^{-1}
K_1'	3.3×10^4—4.4×10^5 M^{-1}
k_{-2}	0—400 s^{-1}
$k_4K_1'K_2'K_3'$	3.1×10^4—2×10^5 M^{-1} s^{-1}
$K_1'\{1+K_2'(1+K_3')\}$	1.9×10^4—1×10^5 M^{-1}
k_{-4}	0—1.4 s^{-1}.

Next, we get $3.3\times10^4\ M^{-1}\leqslant K_1'\leqslant7\times10^4\ M^{-1}$ from the condition $K_3'\geqslant0$. Using $5\times10^4\ M^{-1}$ as the value of K_1' from the reduced range, the range of K_2' was estimated to be $0.5\leqslant K_2'\leqslant1$. In this range, the value of K_2' which satisfies the concentration dependence of τ_2 is 0.5 (k_2=200 s^{-1}, k_{-2}=400 s^{-1}). From the τ_3 data, we get $K_3'\leqslant0.05$($k_3\leqslant2$ s^{-1}, k_{-3}=40 s^{-1}) using the above values for K_1' and K_2'. Furthermore, we get $K_4'\geqslant1.1\times10^4$ ($k_4\geqslant160$ s^{-1}, 2.3×10^{-3} $s^{-1}\leqslant k_{-4}\leqslant1.5\times10^{-2}$ s^{-1}) using the overall equilibrium constant $K_\Sigma=1.4\times10^7\ M^{-1}$ which was determined as the equilibrium constant for the primary binding site by the spectrophotometric measurements. The results are summarized in Table 1. The comparison of the plots of the reciprocal relaxation times *versus* $K_1'(C+P)$/

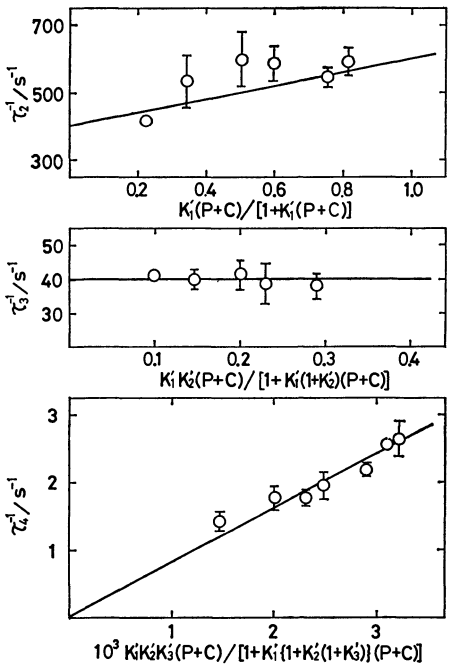

Fig. 5. Plots of the reciprocal relaxation times with Model 1.

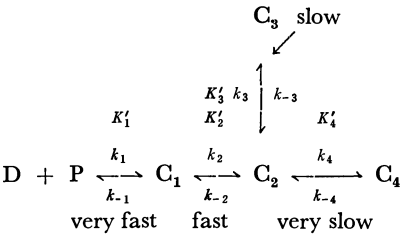
$\{1+K_1'(C+P)\}$ for τ_2, $K_1'K_2'(C+P)/\{1+K_1'(1+K_2')(C+P)\}$ for τ_3, and $K_1'K_2'K_3'(C+P)/[1+K_1'\{1+K_2'(1+K_3')\}(C+P)]$ for τ_4 between observed and calculated relaxation times are shown in Fig. 5, in which the solid lines were calculated using the following values: $K_1'=5\times10^4\ M^{-1}$, $K_2'=0.5$ ($k_2=200\ s^{-1}$, $k_{-2}=400\ s^{-1}$), $K_3'=0.01$ ($k_3=0.4\ s^{-1}$, $k_{-3}=40\ s^{-1}$) and $K_4'=5.6\times10^4$ ($k_4=800\ s^{-1}$, $k_{-4}=1.5\times10^{-2}\ s^{-1}$). As can be seen, the theoretical and experimental plots agree relatively well. Therefore, Model 1 seems to be possible as the reaction mechanism of the present system.

Next, the branch model was examined.

Model 2



(9)

The relaxation times and the overall equilibrium constant for this model become

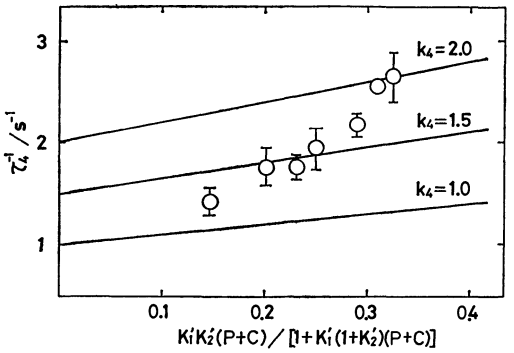


Fig. 6. Plot of τ_4^{-1} with Model 2.

$$\tau_1^{-1} = k_1(C+P) + k_{-1} \tag{10}$$

$$\tau_2^{-1} = k_2\frac{K_1'(C+P)}{1+K_1'(C+P)} + k_{-2} \tag{11}$$

$$\tau_3^{-1} = k_3\frac{K_1'K_2'(C+P)}{1+K_1'(1+K_2')(C+P)} + k_{-3} \tag{12}$$

$$\tau_4^{-1} = k_4\left\{\frac{K_1'K_2'(C+P)}{1+K_1'(1+K_2')(C+P)}+\frac{1}{1+K_3'}\right\} + k_{-4} \tag{13}$$

$$K_\Sigma = K_1'\{1+K_2'(1+K_3'+K_4')\}. \tag{14}$$

The parameters of the Model 2 were determined as follows from an analysis similar to that used in the case of Model 1.

K_1' $5\times10^4\ M^{-1}$

K_2' 0.5 ($k_2=200\ s^{-1}$, $k_{-2}=400\ s^{-1}$)

K_3' $\leqslant 0.05$ ($k_3\leqslant 2\ s^{-1}$, $k_{-3}=40\ s^{-1}$)

K_4' 560 ($1.2\ s^{-1}\leqslant k_4\leqslant 8\ s^{-1}$, $1.8\times10^{-3}\ s^{-1}\leqslant k_{-4}\leqslant 1.4\times10^{-2}\ s^{-1}$).

The expressions of the relaxation times of the faster three processes are the same as those of Model 1, so that the same results were obtained for these processes. Since the allowable values of K_3' and k_{-4} do not contribute to the value of τ_4^{-1}, the comparison of the plot of τ_4^{-1} against $K_1'K_2'(C+P)/\{1+K_1'(1+K_2')(C+P)\}$ between observed and calculated relaxation times for some allowable values of k_4 was made as shown in Fig. 6. Model 2 does not explain the concentration dependence of τ_4, so it may be excluded from possible mechanisms of the present system.

In the same way, the following models were also examined.

Model 3

$$\begin{array}{ccccccc} & & & & C_2 & & \\ & & & & \uparrow\downarrow \text{fast} & & \\ D + P & \longleftrightarrow & C_1 & \longleftrightarrow & C_3 & \longleftrightarrow & C_4 \\ & \text{very fast} & & \text{slow} & & \text{very slow} & \end{array}$$

Model 4

$$\begin{array}{ccccccc} & & & & C_3 & & \\ & & & & \uparrow\downarrow \text{slow} & & \\ D + P & \longleftrightarrow & C_1 & \longleftrightarrow & C_2 & \longleftrightarrow & C_4 \\ & \text{very fast} & & \text{fast} & & \text{very slow} & \end{array}$$

Model 5

$$\begin{array}{ccccccc} & & & & C_4 & & \\ & & & & \uparrow\downarrow \text{very slow} & & \\ D + P & \longleftrightarrow & C_1 & \longleftrightarrow & C_2 & \longleftrightarrow & C_3 \\ & \text{very fast} & & \text{fast} & & \text{slow} & \end{array}$$

Model 6

$$\begin{array}{ccccc} & & C_3 & & \\ & & \uparrow\downarrow \text{slow} & & \\ D + P & \longleftrightarrow & C_1 & \longleftrightarrow & C_2 \\ & \text{very fast} & \uparrow\downarrow & \text{fast} & \\ & & C_4 \text{ very slow} & & \end{array}$$

The concentration dependences of the relaxation times of the second and the third processes can be explained by all of those models, as in the cases of Model 1 and Model 2. Thus, the validity of these models was checked by calculating the concentration dependency of τ_4. The results are shown in Fig. 7 to 10 for the models from 3 to 6, respectively. In these models, only Model 5 can explain the concentration dependence of τ_4. The values of the parameters which were determined with Model 5 are summarized in Table 1, omitting the values for the faster three steps which are same as those of Model 1. From the above analyses, both Model 1 and Model 5 are left as the possible mechanisms from the point of view of the concentration dependences of the relaxation times.

The activation parameters were determined from the temperature dependences of the relaxation times. From the results of the analysis of the reaction mechanism, it was found that the relaxation times whose temperature dependences can be attributed to particular rate constants are τ_2 and τ_3, and the corresponding rate constants are k_{-2} and k_{-3}, respectively. The Eyring plots of those rate constants are shown in Fig. 11. From the slope and the intercept, the activation enthalpy ΔH_{-2}^{*} and the entropy ΔS_{-2}^{*} of the backward reaction of the second step were determined to be 19 kcal/mol and 17 cal/mol K, respectively, and those of third step ΔH_{-3}^{*} and ΔS_{-3}^{*} were determined to be 36 kcal/mol and 71 cal/mol K, respectively. The results are listed in Table 1.

Although the first second order process was too rapid for the values of the rate constants to be determined, the values of 4×10^{8} M^{-1} s^{-1} and 8×10^{3} s^{-1} were evaluated as the lower limit values of the forward and backward rate constants respectively. This calculation used the equilibrium constant $K_1'=5\times10^{4}$ M^{-1}

Discussion

The kinetic behaviour of the interaction of BPB with albumin is of interest in terms of competition binding with bilirubin. It was found from the present study that the binding of BPB to the primary binding site of BSA consists of many first order steps following a fast second order step. The multiplicity of the binding steps has also been observed in the case of the binding of bilirubin with albumin.[4,6] Reed *et al.*[19] have shown through peptic hydrolysis that bilirubin and Bromcresol Green bind to the same position on the BSA molecule, p-14 (residues 186—306). Bromphenol Blue and Phenol Red, which are sulfonphtalein dyes, have structures similar to that of Bromcresol Green, so that these dyes can be thought to bind to the same position. However, multiple binding steps for Phenol Red were not observed,[20] in contrast with the results of bilirubin and BPB. On the other hand, it can be seen from the comparison of the binding constants to the highest affinity site of albumin in Table 2 that the binding constants of bilirubin and BPB are about two or three orders of magnitude larger than that of Phenol Red. These facts seems to indicate the existence of a strong correlation between the multiplicity of the binding processes and the magnitude of the binding constant: that is, ligands having higher affinity bind in more steps than ligands having lower affinity. This can be interpreted as follows. The ligand molecule which has a large binding constant can migrate deeply into the hydrophobic crevice of the albumin molecule. For such a molecule, there must exist many barriers to be overcome during the migration. The existence of those barriers, which correspond to activated states, may yield multiple relaxations. This migration process seem to be driven by entropy rather than enthalpy, considering the insensitivity of the present system to temperature.

Although the reaction mechanism of the binding of BPB to BSA could not be uniquely determined from only the concentration dependences of the relaxation times, the series model (Model 1) seems to be more likely from the viewpoint of the stepwise migration of BPB into the deep site of the hydrophobic crevice of BSA molecule. The magnitude of the rate constant of the first association process was found to be larger than 4×10^{8} M^{-1} s^{-1} from the present analysis. This value suggests that the first association process is the diffusion controlled process. The rate constant of the dissociation process has also a relatively large value. Therefore, the first process can be thought of as the association-dissociation reaction of BPB at the cation rich hairpin turn located on the end of loop 2A[26] of the albumin molecule, which is governed by electrostatic forces. Moreover, the large value of K_1' suggests that there still exist complex formation processes in the longer time region. This can also be understood from the existence of the slow fifth process which was not analyzed in the present study.

From the analysis of the temperature dependences of the relaxation times, it was found that the activation entropies of the backward process in the second and third steps take positive values. This fact shows that those processes occur through the disordered activated states. On the other hand, Scheider[9] has reported for the association-dissociation reaction between oleate and human serum albumin that the first order process which follows the assumed fast second order process occurs with a negative activation entropy, that is, through the ordered activated state. He has pointed out two possibilities for the role of the ligand in the activated configuration. One possibility is that the ligand plays no role in activation *i.e.*, the protein can take the activated configuration on a purely probabilistic basis without any ligand help. The other is that the ligand is closely involved in the activation process *i.e.*, the ligand's movement on the exterior surface brings it to the mouth of the hydrophobic

crevice, facilitating the formation of the activated configuration. Considering both results, it can be seen that the different ligand species yield different activated configurations, and we may consider that the ligand is closely involved in the activation process. If the present argument is correct, the difference in albumin between the two studies may not be the decisive factor to explain the characteristically different results.

In the present analysis, it was assumed that the extinction coefficients of BPB in all the complexes have the same value. This assumption should be regarded as a first approximation. Strictly speaking, each extinction coefficient probably has a different value. To take account of this difference in the consideration of the reaction mechanism, ε_i, ΔV_i, K'_i, which are, respectively, the extinction coefficient of the ith complex, the volume change and the equilibrium constant of the ith process, must be determined by simulation using the data of the concentration dependence of the relaxation amplitudes along with the relaxation times. However, the relaxation amplitudes of the present system are too small for us to get data of enough accuracy to perform the above mentioned simulation.

Reexamination of the Molecular Size Dependence of Diffusivities of Hydrocarbons in Natural Rubber†

Mitsuyasu KAWAKAMI, Hideaki IWANAGA, and Shuichi KAGAWA*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received May 24, 1980)

Diffusion coefficients at zero concentration, D_0, for hydrocarbon vapors in natural rubber have been determined, and their dependence on the size and shape (or length) of the penetrants has been reexamined. For normal hydrocarbons, D_0 decreased gradually with increasing the number of carbon atoms up to 5 and then leveled off. For branched hydrocarbons, such as iso- and neo-paraffins, D_0 was considerably lower than that for the corresponding normal ones. The dependence of D_0 on the size and shape of penetrants could be explained by assuming that the principal resistance to diffusion is defined by the cross-sectional area at the most bulky portion of the major axis and also that an additional resistance due to the molecular length contributes for relatively lower hydrocarbons. The latter resistance was practically negligible for hydrocarbons with more than 4 carbon atoms in the major chain. The effective cross-sectional dimension could be estimated successfully in terms of the group dimension of Pauling.

Extensive studies of gas or vapor diffusion in polymers have been made for elucidating the mechanisms of diffusion and the microstructure of polymers. The free volume theory seems to succeed in interpreting diffusion phenomena in polymer substances (see, for example, Refs. 1—3). However, estimation of the critical size of a hole required for diffusion to take place has not been achieved.

Natural rubber is one of the materials studied from the earliest period because of its high permeability. For common gases, the general dependence of diffusion properties in natural rubber on the size of diffusant molecule seems to be fairly well established and predictable. For organic vapors, on the other hand, the phenomena are more complicated. The diffusion coefficient varies, in general, with the concentration of the vapor in the rubber. Therefore, the diffusion coefficient at zero concentration, D_0, has often been employed to estimate the diffusivity; it is found to be a function not only of the size but also of the shape of a given penetrant molecule.

According to information published earlier (see, for example, Refs. 4 and 5), the characteristic behavior of D_0 for hydrocarbons in rubber can be summarized as follows. (1) D_0 for normal hydrocarbons decreases with an increase in the number of carbon atoms up to 4 and then levels off, (2) D_0 for branched hydrocarbons such as iso- or neo-paraffins are remarkably lower than the values for the corresponding normal ones.

The effect of length or branching of a penetrant molecule on diffusivity has been studied, but few attempts have been made to explain all these effects together. It is the purpose of this work to reexamine the dependence of D_0 for hydrocarbons in rubber on the size and shape of penetrants, and to discuss how a penetrant molecule moves through rubber.

Experimental

The average permeability coefficient, $\bar{P}$ was determined by means of a conventional permeation apparatus.[6] That is, the pressure increase at the low pressure compartment due to vapor transport through a rubber film was measured as a function of time with a Pirani gauge which was calibrated previously through a McLeod gauge.[7] $\bar{P}$ was calculated, then, from the steady state permeation rate, $\Delta p/\Delta t$, using the expression

$$\bar{P} = \frac{273.2}{76T}\frac{V_c}{p_h}\frac{l}{A}\frac{\Delta p}{\Delta t}, \quad (1)$$

where V_c and T are the volume and temperature, respectively, of the measuring chamber, p_h is the applied pressure of the penetrant, and A and l are the effective area and the thickness of the membrane. The change of l due to swelling was not taken into account in the calculation of $\bar{P}$ from Eq. 1. However, the resulting effect on the diffusion coefficient will be compensated for when the average diffusion coefficient is extrapolated to zero concentration.

The solubility coefficient, S, is defined as

$$S = \frac{c}{p}, \quad (2)$$

where c is the equilibrium concentration of a penetrant in the film and p is the partial pressure at sorption equilibrium. When Henry's law is obeyed, S is a constant. Sorption isotherms were measured by a volumetric method. The apparatus used in this experiment was essentially the same as that of Aitken and Barrer.[8]

The average diffusion coefficient, $\bar{D}$, was calculated from $\bar{P}$ and the solubility coefficient, S_h at the high pressure side of the membrane using the relation

$$\bar{D} = \frac{\bar{P}}{S_h}, \quad (3)$$

where the sorption equilibrium is assumed to be established at the both surfaces of the film. A series of $\bar{D}$ was measured as a function of $c_h(=p_hS_h)$, and the diffusion coefficient at zero concentration, D_0, was obtained by extrapolating $\bar{D}$ to $c_h=0$.

The rubber film was prepared by casting a benzene solution of smoked sheet on a glass plate. This was first air dried, followed by vacuum drying at room temperature for at least 2 days. The average thickness of a film used in the measurements was determined from the density and the weight per unit area of the film. Six kinds of lower hydrocarbons of 99.0% minimum purities (Seitetsu Kagaku Co.) and four kinds of liquid ones of commercial reagent grade (Tokyo Kasei Kogyo Co.) were employed. They

† A preliminary report of this work was presented at the 40th National Meeting of the Chemical Society of Japan, Fukuoka, October 1979.

were subjected to repeated freeze-thaw cycles to remove dissolved gases before being introduced into the apparatus.

Results and Discussion

For lighter hydrocarbons such as methane, ethane, and propane, P did not show any pressure dependence in the applied pressure range (up to about 50 kPa for lighter hydrocarbons) and Henry's law was obeyed. In this case, the diffusion coefficient, D, is essentially independent of c and may be also determined directly from the time lag observed in the permeation measurement. Actually, the values of D obtained by the time lag method and those from Eq. 3 were in excellent agreement.

For heavier hydrocarbons, on the other hand, the concentration dependence of solubility coefficients was observed. Thus, Henry's law was no longer obeyed. In the range of measurements (the range was limited by the vapor pressure at room temperature for liquid hydrocarbons), the sorption isotherms could be well represented by the equation

$$S = S_0 \exp(\alpha c), \tag{4}$$

where S_0 is the solubility coefficient at zero concentration and α is a constant. Equation 4 can be derived from a simplified form of the Flory-Huggins equation

$$\ln a = \ln v + (1-v) + \chi(1-v)^2, \tag{5}$$

where a and v are the activity and the volume fraction of the penetrant, and χ is the interaction parameter. That is, assuming $a=p/p_0$ (where p_0 is the vapor pressure of the penetrant at the measuring temperature), making the substitutions and neglecting higher terms, we obtain the expression

$$S = S_0 \exp[2(1+\chi)c]. \tag{6}$$

Therefore, it is clear that the parameter α in Eq. 4 is approximately equal to $2(1+\chi)$.[9-12] The solubility coefficient, S_h required to calculate $\overline{D}$ from Eq. 3 was estimated from Eq. 4.

Average permeabilities, and therefore, average diffusion coefficients varied with the applied pressure for C_4 and higher hydrocarbons. The concentration dependence of $\overline{D}$ could be expressed fairly well by the equation

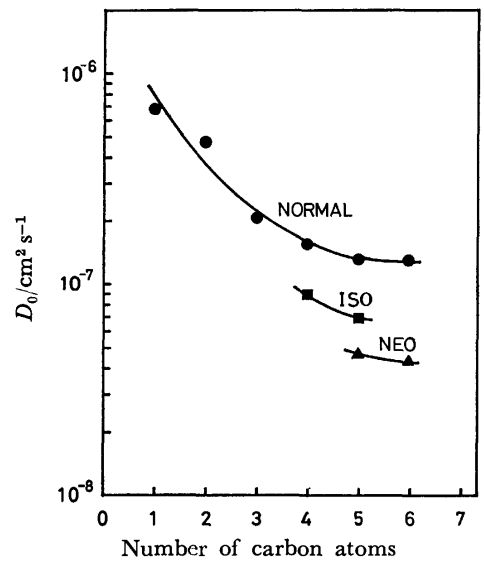

Fig. 1. Dependence of D_0 for hydrocarbons in natural rubber at 298 K on the number of carbon atoms.

$$\overline{D} = D_0 \exp(\beta c_h), \tag{7}$$

where β is a constant (see, for example, Refs. 9—12). Then, D_0 was determined readily by extrapolation of the ln $\overline{D}$ *vs.* c_h plot. The results are shown in Table 1. The vslues of D_0 for methane and propane are in fair agreement with those obtained by Michaels and Bixler.[13]

The values of S_0 satisfy the relation between S_0 and the boiling or critical temperature which has been reported earlier.[14] The parameter α can be taken as being roughly constant for the seven hydrocarbons examined. This means that the Flory-Huggins interaction parameters are also the same for the systems of these hydrocarbons and natural rubber. According to the free volume theory,[1-3] the concentration dependence parameter of D is a function of the critical size of the hole required for diffusion to take place. In the present work, however, the parameter β only represents the extent of the concentration dependence of $\overline{D}$ and has a complicated meaning. Moreover, these values can not be compared as such, be-

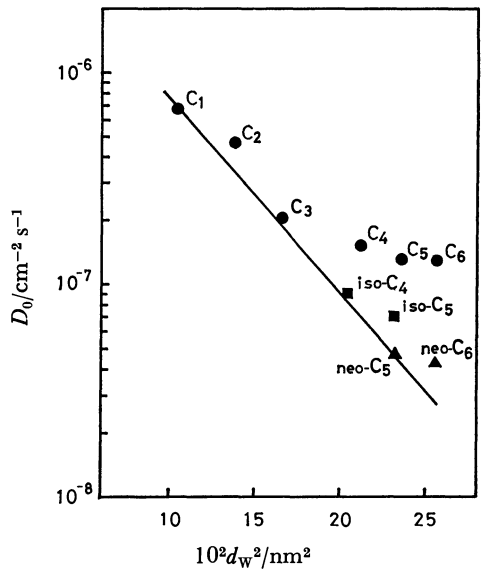

Fig. 2. Correlation of D_0 with d_W^2. Symbols refer to hydrocarbons given in Table 1.

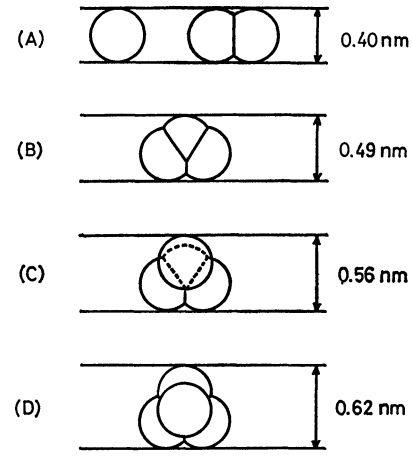

Fig. 3. Schematic drawing of the effective cross-sectional dimension, d_P. (A) Methane and Ethane, (B) Normal hydrocarbons above Propane, (C) Branched hydrocarbons with a single methyl group, (D) Branched hydrocarbons with two methyl groups on the same carbon atom.

cause the concentration ranges measured are appreciably different. The dependence of D_0 on the size of a penetrant molecule will now be discussed.

In Fig. 1, D_0 values are plotted against the number of carbon atoms. Obviously, D_0 for normal paraffins decreases with the chain length from C_1 to C_5, to reach a constant value at C_5 and higher homologues. Note also that the branching of a penetrant molecule increases somewhat its effective dimension and hence yields a lower value of D_0.

For diffusion in polymers it is generally accepted that the hole formation in a given polymer-diffusant system as a result of thermal fluctuations of the diffusant molecule and/or the polymeric jumping unit is responsible for the diffusivity. According to Fujita's free volume theory,[2,5] the diffusivity is proportional to the probability of finding a hole exceeding a critical volume, and can be described as

$$D = A_d \exp\left(-\frac{B_d}{f}\right), \tag{8}$$

where B_d is a parameter corresponding to the minimum hole required for diffusion, f is the average fractional free volume of the system, and A_d is a proportionality factor which is considered to be dependent primarily on the size and shape of the diffusant molecule. Some attempts have been made to correlate the diffusivities with the size and shape of diffusant vapors.

As one idea, the "diffusive cross-section" difined as the ratio of the molar volume $\bar{V}$ and the maximum molecular length $\bar{L}$ of the penetrant has been proposed for the diffusivities of organic vapors (see, for example, Refs. 15—17). This parameter, however, could not be applied to the present systems, as shown in Fig. 1. The value of D_0 decreases with the number of carbon atoms from C_3 to C_6 normal hydrocarbons, while that of $\bar{V}/\bar{L}$ is almost constant for them. This measure tends to overestimate the effective size, especially for lighter hydrocarbons.

In Fig. 2, D_0 is plotted against the square of the van der Waals diameter, d_W^2, instead of the number of carbon atoms. This dimension can be considered to represent the size of molecule regarded as spheres. In the figure, the points of methane (C_1) and neopentane (neo-C_5), whose the shapes are practically spherical, are connected by a solid line for convenience. It can be noted that all the points for other non-spherical hydrocarbons studied here are above this line. This means these hydrocarbons have more preferable shape for diffusion than a spherical molecule. The effective size of such penetrants, therefore, must be smaller than d_W^2.

As previously described, D_0 for normal paraffins decreases gradually with an increase in the number of carbon atoms and finally levels off for homologues higher than C_4. This implies a mode of diffusion in which the diffusant molecule moves through rubber with its major axis aligned with the diffusion direction. Under such circumstances the resistance to diffusion may be a function of the cross-sectional area normal to the main axis and the length of a given penetrant. When the cross-sectional dimension is not uniform along the axis, that at the most bulky part must become the predominant factor. Thus, for estimating such a dimension, an alternative measure, d_P, was proposed. Speculations on these dimensions in terms of the group dimension of Pauling[18] are illustrated in Fig. 3, where the diameters of methylene and methyne group have been both assumed to be 0.4 nm, which is the methyl group diameter.

The relationship between D_0 and d_P^2 is shown in Fig. 4, in which a line joining the points of C_1 and neo-C_5 is also drawn for convenience. This line can be considered to reflect the effective size of the spherical penetrant. For isomeric butanes and pentanes in cross-linked natural rubber, Aitken and Barrer[8] have demonstrated that D_0 decreased linearly with the size expressed as the product of the minimum dimension, l_1 and the next smallest dimension, l_2 of the molecule. Such a dimension $l_1 l_2$ may be a useful measure of

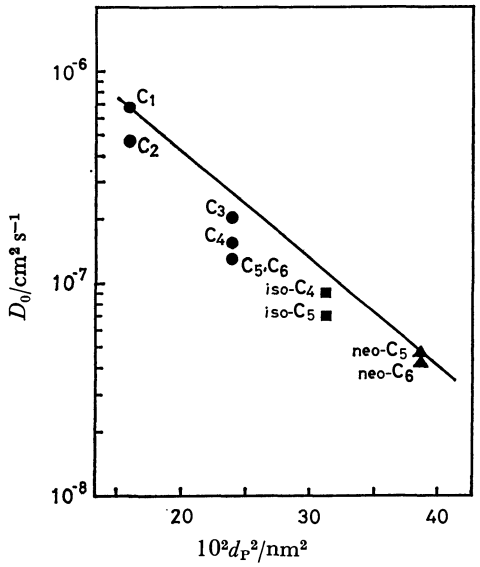

Fig. 4. Correlation of D_0 with d_P^2. Symbols refer to hydrocarbons given in Table 1.

the cross-section when the diffusant is not spherical. They have suggested that the maximum dimension has little significance, but did not explain further. We have also confirmed that a reasonably linear relationship holds between D_0 and $l_1 l_2$ for isomeric butanes, pentanes, and hexanes. The data for C_1 and C_2, however, deviated considerably from the rectilinear relationship. In addition, the appreciable difference between D_0 for C_1 and C_2 implies that the maximum length of the molecule has some significance. In Fig. 4, the distance along the ordinate between a certain point and the line may suggest the effect of the molecular length. It is inferred that the extent of this effect is more significant at the first increase in the number of carbon atoms in major axis, and then gradually diminishes with a subsequent increase in length. Thus, Fig. 4 is a convenient illustration for understanding the effects of both the size and shape (or length) of hydrocarbon penetrants on their diffusivities.

From above discussion, we obtain the following conclusions. A hydrocarbon molecule moves through rubber matrix with its major axis aligned in the diffusion direction. The largest resistance to diffusion is thus determined by the cross-sectional area at the most bulky part of the axis. An additional effect is caused by the length of major chain, but this effect practically diminishes for more than 4 carbon atoms. The effective cross-sectional area at the most bulky part can be estimated successfully using the group dimension concepts of Pauling.

The Electronic Absorption and Emission Spectra of Biphenylene-2,3-dione in Solutions

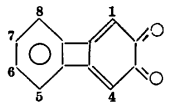
Akira KUBOYAMA

National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305

(Received June 12, 1980)

The electronic absorption and MCD spectra and phosphorescence spectra at 77 K, in solutions, have been studied by the use of P-P-P-method calculations. The longest-wavelength S–S $\pi\pi^*$ band, near 370 nm, is proved to consist of two $\pi\pi^*$ bands, the $^1A_1$ and $^1B_2$ bands. The $n\pi^*$ absorption, and phosphorescence bands in various kinds of solutions are compared in many respects with those of the *o*-quinones previously studied.

Previously, we have theoretically and experimentally studied the electronic absorption spectra of the *o*-quinones, *o*-benzoquinone,[1-3] and 1,2-naphthoquinone,[1,4,5] and the electronic absorption and emission spectra of the *o*-quinones, acenaphthenequinone,[4,6,7] and 9,10-phenanthrenequinone,[1,4,6,8,9] in solutions. Heretofore, however, the $n\pi^*$ absorption spectra of *o*-benzoquinones have not been studied in detail because of their instability. The emission spectra of *o*-benzoquinones and 1,2-naphthoquinones have never been reported, either, as far as we know. Biphenylene-2,3-dione[11,12] (BPD), which may be classified as a *o*-benzoquinone, is stable and is unique for its containing a fused four-membered ring. As for BPD, only the positions and intensities of its $\pi\pi^*$ absorption maxima in a solution have been reported. Therefore, we have studied the $\pi\pi^*$ and $n\pi^*$ absorption and emission spectra of BPD in solutions.



BPD

Experimental

Measurements. The absorption spectra in solutions were measured in the same manner as in previous works.[3-5,8] The magnetic circular dichroism (MCD) spectra in solutions were obtained by means of a J-20C recording spectropolarimeter of the Japan Spectroscopic Co., with a magnetic field of 0.93 T. The magnetic field was measured by means of a gauss meter. The phosphorescence spectra in solutions at 77 K were measured in the same manner as in previous works.[6,7,9] The dichroism of the phosphorescence spectrum in the 1-chlorobutane solution was measured by the photoselection method.[6,13]

Materials. BPD prepared by Sato *et al.*[12] was used (mp 213.5—214.5 °C).[14] Commercially available cyclohexane, methylcyclohexane, carbon disulfide, toluene, dioxane, methanol, 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) of a spectro-grade, and 1-chlorobutane of Tokyo Kasei's Special Use grade were used without further purification. Commercially available chloroform of a special grade was washed five times with water, dried with calcium chloride, and distilled.

Results. The absorption, MCD, and phosphorescence spectra obtained are shown in Figs. 1—4. The wavelengths and molar absorption coefficients of the absorption maxima, and the oscillator strengths of the absorption bands are shown in Table 1. The band names in Table 1 will be presented later. The MCD spectra in the toluene and cyclohexane solutions were similar to that in the 1-chlorobutane solution in Fig. 3. The MCD spectra were obtained with a relatively high noise-level because a low magnetic field was used. However, their accuracy is thought to be

not so low as to affect the discussion in this work. The wavelengths of the phosphorescence maxima were 575, 579, and 584 nm for the 1-chlorobutane, dioxane, and toluene solutions respectively. As for the dichroism of the phosphorescence-excitation spectrum, the qualitative results to be presented later were obtained. The lifetimes of the phosphorescence bands have not yet been accurately obtained with the phosphoroscope, partly because these phos-

phorescence bands are weak and partly because their lifetimes are short. They were estimated to be around 0.3 ms on the basis of the observed relationships between the phosphorescence intensities and the rotational speeds of the phosphoroscope.

Calculations

Method. The electronic integral values for BPD in the P-P-P method[15] were the same as those previously used for other quinones,[3,5,8] except for those of the core-resonance integrals. Since BPD containes a fused four-membered ring, the core-resonance integrals between non-adjacent atoms were also included. The core-resonance integral (β_{ij}) between the i-th and j-th atoms was obtained according to the following formula;

$$\beta_{ij} = -31.35 \exp(-1.86 R_{ij}) \text{ (eV)},$$

except for those of the carbonyl bonds, which were taken as −2.5 eV, as in the previous works.[3,4,8] R_{ij} (Å) denotes the bond distance between the two atoms. This formula gives values close to those previously used for *o*- and *p*-benzoquinones and 9,10-anthraquinone,[3] −2.0, −2.5, and −2.3 eV for the conventional single and double bands and the benzene bonds respectively. The changes in the excitation energy of the lowest $\pi\pi^*$ states of BPD with the alkyl-group substitutions were also calculated in the same manner as in the previous works.[3,5,8] In the calculations, the thirty lowest singly excited configurations were included. The dimensions of BPD shown in Fig. 5, where the molecular structure of BPD is planar and has the C_{2v} symmetry,[16] were assumed considering the previously reported dimensions of *o*-benzoquinone[17] and biphenylene.[18]

Results. The calculated results for the lower singlet excited states are shown in Table 2. The molecular plane and symmetry axis of BPD are regarded as the yz-plane and the z-axis respectively. In this table, the first column denotes an order based on the magnitudes of the calculated excitation energies. Y and Z in the second column denote the directions of the elctronic-transition moments from the ground state. The assignment in the last column will be discussed later.

Table 2. The calculated results

No.	Symmetry	$\frac{E}{\text{eV}}$	f	Band
1	$^1B_2(Y)$	3.68	0.137	a_1
2	$^1A_1(Z)$	3.75	0.102	a_2
3	$^1B_2$	4.44	0.094	
4	$^1A_1$	4.51	0.003	
5	$^1A_1$	4.71	1.895	b
6	$^1B_2$	4.98	0.002	
7	$^1B_2$	5.37	0.206	c

Discussion

In Figs. 1 and 2, an $n\pi^*$ band is observed near 500 nm and four $\pi\pi^*$ bands appear to be near 370, 260, 240, and 210 nm, the 260 nm band being the strongest. These four $\pi\pi^*$ bands are denoted as the a-, b-, c-, and d-bands respectively. The largest red-shift of the a- and b-bands, and the large intensification of the a-band in the HFP solution in comparison with the cases of other solutions, are noticeable. Those facts may be attributed to the strong hydrogen-bond formation between BPD and HFP.[5,8] The fact that the intensity near 300 nm of the $\pi\pi^*$ absorption spectrum in the toluene solution is stronger than those in other solutions shows that, in this wavelength region, there is an intermolecular charge-transfer band between toluene and BPD. The emission bands in Fig. 4 may be assigned to the $n\pi^*$ phosphorescence band in view of their positions relative to those of the $n\pi^*$ absorption bands in Fig. 2 and their short lifetimes. Previously, similar $n\pi^*$ phosphorescence bands have been observed for 9,10-phenanthrenequinone[9] and acenaphthenequinone,[7] as will be discussed later. Therefore, the lowest triplet state of BPD may be the $n\pi^*$ state, as in the case of the other *o*-quinones.[6,7,9]

The MCD spectrum in Fig. 3, clearly shows that the a-band consists of two $\pi\pi^*$ bands, where the MCD signs of the longer and shorter wavelength bands are minus and plus respectively.[19,20] The observed dichroism of the phosphorescence-excitation spectrum is consistent with this fact and shows that the above-mentioned shorter wavelength band has its absorption maximum, which may be its 0-0 band, near the second peak of the a-band. These two $\pi\pi^*$ bands are denoted as the a_1- and a_2-bands for the longer and shorter wavelength bands respectively. Furthermore, the dichroism of the phosphorescence-excitation spectrum shows that the direction of the polarization of the a_1- and c-bands and that of the a_2- and b-bands are the same as, and different from, that of the phosphorescence band respectively.

The assignments of the a_1-, a_2-, b-, and c-bands are shown in the last column in Table 2. As may be seen from the comparison between the observed

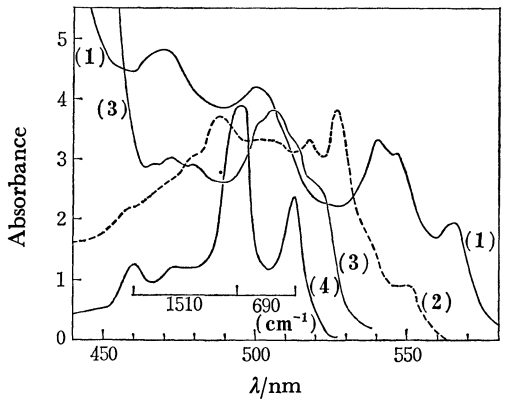

Fig. 6. nπ* Absorption bands of *o*-quinones in heptane solutions.
(1) 1,2-naphthoquinone, (2) biphenylene-2,3-dione, (3) 9,10-phenanthrenequinone, (4) acenaphthenequinone.

(a) Acenaphthenequinone, (b) 9,10-Phenanthrenequinone, (3) Biphenylene-2,3-dione.
(1) Dioxane, (2) 1-chlorobutane, (3) toluene, (4) heptane.

and calculated results, these assignments seems reasonable. Therefore, the a_1- and c-bands and the phosphorescence band may be said to be polarized along the short axis (Y-axis) of BPD, and the a_2- and b-bands to be polarized along the long axis (Z-axis). The assignment of the d-band is ambiguous. The calculated results show that the excited state of the a_1-band is of the local excitation type in the benzoquinone group and is similar to that of the longest-wavelength ππ* ($^1B_2$) band (near 370 nm) of *o*-benzoquinone.[3] However, the intensity of the a_1-band is far larger than that of the corresponding band of *o*-benzoquinone.[1,10] As for the changes in the calculated excitation energy of the lowest ππ* states (the Nos. 1 and 2 states) of BPD with the symmetrical two-alkyl-group substitutions, a relatively large energy decrease in the No. 1 state of 1,4-dialkyl-BPD was found.

Since it is generally accepted, on the basis of the observed photoelectron spectra, that the energy difference between the n_+ and n_- orbitals[21] of α-dicarbonyls is *ca.* 2 eV,[22,23] where the n_+ orbital energy is higher, the nπ* bands of BPD in Fig. 2 may contain only the $\pi^* \leftarrow n_+$ transition band,[24] as in the case of the α-diketones.[23,25] The nπ* absorption bands of the *o*-quinones in saturated hydrocarbon solutions are situated in the following order from the longer wavelength side, as may be seen from a comparison of Figs. 2 and 6:

o-Benzoquinone > 1,2-Naphthoquinone > BPD
> 9,10-Phenanthrenequinone > Acenaphthenequinone.

The nπ* band of *o*-benzoquinone[1,10] is situated at far longer wavelengths than those of the other *o*-quinones.[4] This order is just the reverse of that in the numbers of carbon atoms in the π-electronic systems of these *o*-quinones, except for the case of acenaphthenequinone. A similar phenomenon is observed in the *p*-quinones[4,26] (*p*-benzoquinone, 1,4-naphthoquinone, and 9,10-anthraquinone).

As for the nπ* bands of BPD in Fig. 2, it is noticeable that its blue-shift in the dioxane solution, in comparison with the case of the saturated hydrocarbon solutions, is smaller than those in other *o*-quinones,[4] acenaphthenequinone, 9,10-phenanthrenequinone, and 1,2-naphthoquinone, which are remarkably large, and that its intensity remarkably increases with the hydrogen-bond formation between BPD and the protic solvents, as may be seen from a comparison between the cases of toluene and the protic solvents, chloroform, and methanol. The former point corresponds to a fact about the phosphorescence bands which will be presented later. This point may show that the charge-transfer interaction between dioxane and BPD is weaker than those between dioxane and other quinones. The calculated π-electronic structures of these *o*-quinones give no information about this difference between BPD and other *o*-quinones. As for the latter point, nothing similar is observed in acenaphthenequinone,[4] but in the thiocarbonyl nπ* band of styrene trithiocarbonate[27,28] there is a similarity. This intensity enhancement may be due to the symmetry degradation of the n_+ orbital of BPD and the increased mixing of the nπ* and its neighbouring ππ* states, accompanied by the decreased energy gap between them, resulting from the hydrogen-bond formation. Acenaphthenequinone's failure to show anything similar may be an interesting problem to be solved in future.

In the nπ* band in the methylcyclohexane solution, the energy difference between the longest-wavelength shoulder near 550 nm and the sharp peak at 527 nm is *ca.* 790 cm^{-1}, while the one between the two main peaks at 527 and 488 nm is *ca.* 1520 cm^{-1}, as is shown in Fig. 2. A similar vibrational structure is also observed in the case of acenaphthenequinone, though the intensity distributions are different, as may be seen in Fig. 6. The structures of 790 cm^{-1} and 1520 cm^{-1} may be assigned to the ring-breathing[29] and C–O stretching vibrations respectively.

In the nπ* phosphorescence bands in Fig. 4, only the 0-0 band appears clearly; this pattern is similar to those in 9,10-phenanthrenequinone[9] and acenaphthenequinone.[7] No phosphorescence band can be observed in saturated hydrocarbon solutions. The estimated lifetimes (*ca.* 0.3 ms) are far shorter than those in the above two *o*-quinones, which are around 10 ms.[6,7,9] A similar difference is observed between *p*-benzoquinone (*ca.* 0.08 ms)[30,31] and 9,10-anthraqui-

none (*ca.* 3 ms).[6,32] The phosphorescence band in the dioxane solution is situated between those in the 1-chlorobutane and toluene solutions, while in the above two *o*-quinones[7,9] it is at far shorter wavelengths than the others, as may be seen in Fig. 7. This fact is consistent with the before-mentioned fact about the $n\pi^*$ absorption band of BPD in the dioxane solution.

The author wishes to express his thanks to Profs. Seiji Ebine and Josuke Tsunetsugu of the Faculty of Science of Saitama University for their kindness in furnishing him with biphenylene-2,3-dione.

The Reaction of Magnesium Hydroxide with Soluble Silica under Hydrothermal Conditions below the Critical Temperature

Haruto MURAISHI

Department of Chemistry, Fukuoka University of Education, Munakata-cho, Fukuoka 811-41

(Received July 14, 1980)

$Mg(OH)_2$ powder packed into a basket was placed apart from solid SiO_2 in an autoclave so that the SiO_2 might react with the solid $Mg(OH)_2$ in the state of soluble silica. At given temperatures of 250—360 °C, the $Mg(OH)_2$ changed into talc($Mg_3Si_4O_{10}(OH)_2$) through serpentine($Mg_3Si_2O_5(OH)_4$): the reaction was a first-order consecutive-irreversible reaction which can be represented as:

$$Mg(OH)_2 \xrightarrow{+SiO_2} Mg_3Si_2O_5(OH)_4 \xrightarrow{+SiO_2} Mg_3Si_4O_{10}(OH)_2.$$

The reaction rate of serpentine into talc as a single reaction was also first-order. The formation of serpentine was much faster than that of talc. The reaction rate depended on the silica concentration in the hydrothermal solution rather than on the reaction temperature. In the course of the reaction, the crystallite size of the $Mg(OH)_2$ and the serpentine was hardly changed. In addition, the crystallite size of $Mg(OH)_2$ did not affect that of the resulting serpentine. From these results, the rate-limiting step is presumed to be the formation of the crystal nuclei of the serpentine or talc.

The mechanism of the synthetic reaction of silicates under hydrothermal conditions is of interest, but it has not been investigated except for the syntheses of zeolite below 100 °C.[1-5] The purpose of this study is to gain some insight into the mechanism of silicate formation under high temperatures and high pressures. From this point of view, the rate of the formation of serpentine and talc from $Mg(OH)_2$ powder and soluble silica has been investigated at the vapor pressures of hydrothermal solutions.

In the previous investigations[6-9] of the synthetic reaction of the MgO–SiO_2–H_2O system, mixtures of solid MgO (or $Mg(OH)_2$) and solid SiO_2 were used as the starting materials. In this study, in order to observe more simply the reaction process, solid $Mg(OH)_2$ is placed apart from solid SiO_2 in an autoclave so that the SiO_2 may react with the solid $Mg(OH)_2$ surely in the state of soluble silica.

Experimental

The apparatus used for separating the two starting materials from each other is shown in Fig. 1. The silica gel or α-quartz powder used as the silica source was placed at the bottom of a modified Morey-type autoclave with a capacity of 30 ml, while the $Mg(OH)_2$ powder, packed naturally into a basket which was mounted on a holder, was placed above the silica source: distilled water was then introduced into the autoclave to fill it by 60%. The reaction was carried out in the temperature range of 250—360 °C at an autogeneous pressure of the autoclave. The heating rate up to a fixed temperature was 75 °C/h. After a definite time of heating, the autoclave was quenched rapidly with water. The reaction products were taken out of the basket and dried at 110 °C for 12 h. The products were identified by the use of the X-ray diffractometer and DTA. Their quantities could be determined with the gravimetric technique (TG), as will be shown in the following section. The solution was filtered off, and the soluble silica and magnesium ion in the solution were determined by means of the silico molybdate method[10] and EDTA titrimetry[11] respectively. The crystallite size of the reactant and products was measured by the X-ray diffraction method.[12] These methods have also been described fully in previous papers.[13,14]

Results

Effects of Amount of Silica and $Mg(OH)_2$ on the Reaction Rate. Approximately 0.2 g of $Mg(OH)_2$, packed into a basket, was allowed to react with various amounts of 0.5—6.0 g of the silica source at 330 °C for 3 h. After each run, the conversion fraction was determined from the amount of remaining $Mg(OH)_2$. The results are shown as a function of the amount of silica in Fig. 2(a). It was found that, when 1 g or more of silica was used, the conversion fraction was independent of the amount of silica: it was 0.4 for silica gel and 0.2 for α-quartz under these conditions. The silica concentration in the solution during the reaction was about 1200 ppm for silica gel and 400 ppm for α-quartz: these values are approximately equal to their equilibrium solubilities at that temperature.[15,16] The distinction between the conversion fractions for silica gel and α-quartz can be explained in terms of the difference between their solubilities.

On the other hand, various amounts of $Mg(OH)_2$ (0.05—0.60 g) were allowed to react with a fixed amount of 2.0 g of silica at 360 °C for 6 h. The results were shown in Fig. 2(b). The conversion fraction diminished with an increase in the amount of $Mg(OH)_2$. In addition, it was found, from the deter-

Silica gel (○) and α-quartz powder (●) were used as silica source. (a) is for a fixed amount of $Mg(OH)_2$ (0.2 g) and treatment at 330 °C for 3 h, and (b) for a fixed amount of SiO_2 (2.0 g) and treatment at 360 °C for 6 h.

mination of silica concentration in the solution during the reaction, that the silica concentration decreased with an increase in the amount of $Mg(OH)_2$. The decrease in the silica concentration is explicable as a result of the faster rate of taking out of silica by $Mg(OH)_2$ than the rate of dissolution of silica. The relation between the silica concentration and the conversion was examined in detail. In the case of an amount of $Mg(OH)_2$ of 0.2 g or less, the solution was saturated with silica during the reaction (about 1400 ppm for silica gel and 500 ppm for α-quartz). The conversion fraction, however, was decreased with the amount of $Mg(OH)_2$. The drop in the conversion may be due to the fact that soluble silica penetrates slowly into the interior of the pack of $Mg(OH)_2$ powder. When the amount of $Mg(OH)_2$ was 0.05 g or below, the reaction went to completion too rapidly for us to measure the reaction rate. Therefore, 0.2 g of $Mg(OH)_2$ and 2.0 g of silica were employed as the standard amounts of reactants in order to keep the silica concentration constant throughout the reaction and in order to allow the reaction to proceed steadily and at a moderate speed.

Reaction Products. Under these experimental conditions, serpentine($Mg_3Si_2O_5(OH)_4$) and talc ($Mg_3Si_4O_{10}(OH)_2$) were identified as the products.

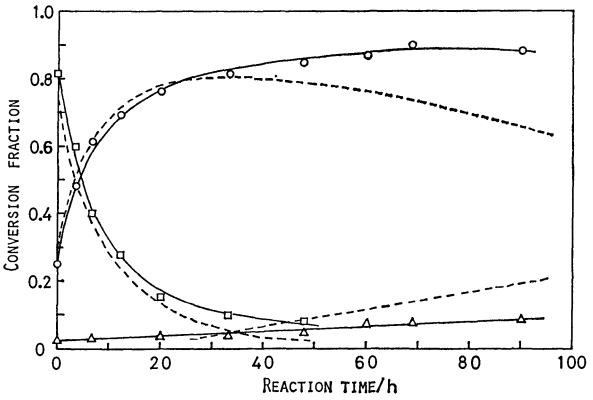

Fig. 4. Effect of temperature on the reaction rate. Reaction temperature: ----, 250 °C;[a] ——, 360 °C. Silica gel and α-quartz powder were used as silica source at 250 and 360 °C, respectively, and the silica concentration in the solution was 900 and 500 ppm. Symbols are the same as in Fig. 3.
a) This curve has been already shown in Fig. 3.

The results were compatible with the phase boundary in the phase diagram of the MgO–SiO_2–H_2O system presented by Bowen and Tuttle.[17] These silicates possess a layer structure and essential water analogues with $Mg(OH)_2$. It was found, from the TG and DTA curves of $Mg(OH)_2$ and synthesized serpentine and talc, that the essential water was quantitatively dehydrated and that the dehydration temperatures were 400, 640, and 860 °C respectively. These silicates, therefore, could be determined gravimetrically from mixtures of reactant and products.

Effect of the Temperature and Silica Concentration on the Reaction Rate. Figure 3 shows the conversion curves plotted against the time for the formation of serpentine and talc at the temperatures of 250 and 360 °C. When the autoclave reached a prescribed temperature (0 h of the reaction time), the reaction had proceeded considerably. Although the real initial stage could not be observed, it was found that both conversion curves obtained for serpentine reach a maximum in a certain time, and that for talc increases monotonously with the time throughout the reaction. Therefore, the reaction can be written as:

$$Mg(OH)_2 \xrightarrow{+SiO_2} \text{serpentine} \xrightarrow{+SiO_2} \text{talc}.$$

This is a typical consecutive two-stage reaction.

The two conversion curves at 250 and 360 °C shown in Fig. 3 are those obtained at different concentrations of silica as well as at different temperatures, since the equilibrium solubility of silica gel is dependent on the temperature (*e.g.*, the silica concentrations at 250 and 360 °C were about 900 and 1400 ppm respectively). As long as silica gel is used as the silica source, it is difficult to control the experimental conditions so as to keep the same silica concentration at the different reaction temperatures. Therefore, α-quartz powder, which has a different solubility[15] from silica gel, was also used as a silica source. The effect of the reaction temperature on the reaction rate was measured semiquantitatively under the conditions of a somewhat similar silica concentration but at dif-

ferent temperatures. The results are shown in Fig. 4. There was no difference in the mode of the two conversion curves in the initial stage of the reaction, but in the later stage the position of the maximum of the curve for serpentine was shifted to the right in the case of lower silica concentrations, while the slope of the curve for talc became more gentle. In other words, the rate of the reaction of serpentine into talc may be more affected by the silica concentration than by the reaction temperature.

Effect of Diffusion of Soluble Silica. Since the two starting materials were separated from each other in the autoclave, and since $Mg(OH)_2$ powder was packed into the basket, there may be a concentration gradient of soluble silica in the solution and in the pack of $Mg(OH)_2$ powder. Therefore, two processes of the diffusion of soluble silica may be considered; one is the diffusion through the solution (intrasolution diffusion), and the other is the diffusion across the interstice constructed by $Mg(OH)_2$ particles (interstice diffusion). In order to study the effect of the former,

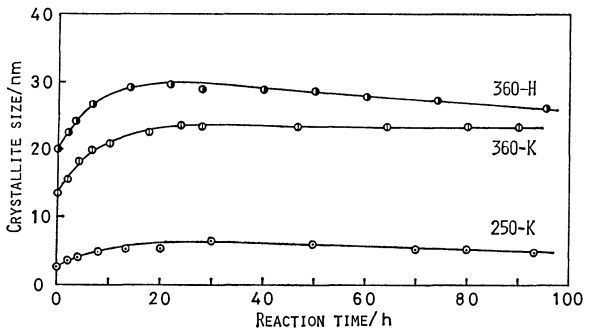

Fig. 7. Effect of reaction temperature and crystallite size of starting $Mg(OH)_2$ on the crystallinity of product (serpentine).
Silica source: silica gel.

Symbol	Reaction temperature	Crystallite size of starting $Mg(OH)_2$	Shorthand
⊙:	250 °C	16.4 nm	250-K
◫:	360 °C	16.4 nm	360-K
◑:	360 °C	58.0 nm	360-H

the distance between the silica on the bottom of the autoclave and the $Mg(OH)_2$ powder in the container was allowed to vary. The variation in the distance between them did not enable us to distinguish the conversion. In order to study the effect of the latter, a large amount of $Mg(OH)_2$ powder was used. The pack of $Mg(OH)_2$ powder was, after the reaction, divided into several parts beginning with the outside, and the conversion fraction of each part was measured. Consequently, the conversion fraction decreased with an increase in the distance from the outside, and thus the reaction rate was found to be influenced by the interstice diffusion. Some typical conversion curves obtained for the outside and inner parts of the pack are shown in Fig. 5.

Effect of Particle Size of $Mg(OH)_2$ on the Reaction Rate. Two kinds of $Mg(OH)_2$ with different particle sizes were used as reactants. These $Mg(OH)_2$ powders were about 35 and 18 m^2/g in surface area, while the crystallite sizes were about 16 and 58 nm respectively. The distinction of the reaction rate due to different particle size is shown in Fig. 6. The reaction rate for larger particles was slower, but the conversion curves obtained for them differed in form from those for small particles. The alteration in the form of the conversion curves suggests that a part of the reaction process varied in the case of larger particles, as will be described in the following section.

Effect of the Crystallite Size of $Mg(OH)_2$ and the Reaction Temperature on the Crystallinity of Serpentine. It has been reported that the crystallite size of the starting material influences the crystallinity of products in some solid reactions—for example, the hydration of MgO,[18] the oxidation of Fe_3O_4 into γ-Fe_2O_3[19] and the reaction of $MgO+Al_2O_3 \rightarrow MgO \cdot Al_2O_3$.[20] Similar behavior can also be expected for the serpentinization of $Mg(OH)_2$, since serpentine has a layer structure consisting of linked SiO_2 tetrahedra and Mg–O(OH) octahedra sheets,[21] like the structure of $Mg(OH)_2$. In order to examine this tendency, two kinds of $Mg(OH)_2$ with different crystallite sizes were allowed

Table 1. Effect of the crystallite size of $Mg(OH)_2$ on the crystallinity of products (serpentine)
Reaction temperature: 360 °C
Silica source: α-quartz blocks

2	28.0	28.7
3	29.8	30.5
4	31.9	31.3

a) The crystallite sizes of $Mg(OH)_2$-K and $Mg(OH)_2$-H are, respectively, 16.4 and 58.0 nm.

to react at 360 °C. The serpentine produced from large crystals (360-H) was slightly larger than that produced from small crystals (360-K), as is shown in Fig. 7. The distinction of the crystallinity may also have been caused by the variation in the reaction rate due to the different crystallite size. In order to minimize this effect, α-quartz blocks were used as the silica source because their slow dissolution rate may limit the rate of reaction. The results showed that the crystallite size of the resulting serpentine was not affected by that of $Mg(OH)_2$, as is shown in Table 1.

On the other hand, the reaction temperature apparently had an effect on the crystallinity of the products, as may be seen from the curves of 250-K and 360-K in Fig. 7. The crystallite size was about 5 nm at 250 °C and 23 nm at 360 °C for 30 h.

Discussion

As has been described above, the reaction of $Mg(OH)_2$ with soluble silica proceeds consequently in two stages as follows:

$$Mg(OH)_2 \xrightarrow{\text{(Reaction 1)}} \text{serpentine} \xrightarrow{\text{(Reaction 2)}} \text{talc}.$$

It is assumed that Reactions 1 and 2 proceed *via* a similar reaction process. The process may consist of the following steps:[22]

(1) Dissolution of silica.
(2) Diffusion of soluble silica in solution.
(3) Diffusion of soluble silica along interstices constructed by $Mg(OH)_2$ (or serpentine) particles.
(4) Adsorption of soluble silica on the $Mg(OH)_2$ (or serpentine) surface.
(5) Formation of crystal nuclei for serpentine (or talc).
(6) Crystal growth.

An excess of the silica source was used in this experiment, and the solution was kept saturated with silica throughout the reaction. As has been described above, under these conditions Steps (1) and (2) are not rate-limiting. Furthermore, Step (4), that is, surface reaction, proceeds much faster than the other steps, as has been reported in a previous paper.[14] Accordingly, Steps (3), (5), or (6) may be considered to be the rate-limiting steps.

The conversion curves obtained were analyzed on the basis of the kinetics in order to clarify the reaction mechanism. The full reaction scheme is represented as follows:

$$\begin{array}{lccccc} & Mg(OH)_2 & \xrightarrow[+SiO_2]{k_1} & Mg_3Si_2O_5(OH)_4 & \xrightarrow[+SiO_2]{k_2} & Mg_3Si_4O_{10}(OH)_2 \\ t=0 & [A]_0 & & 0 & & 0 \\ t=t & [A] & & [B] & & [C] \end{array} \quad (1)$$

where k_1 and k_2 are the rate constants, $[A]_0$ is the amount of $Mg(OH)_2$ at $t=0$, and [A], [B], and [C] are, respectively, the amounts of $Mg(OH)_2$, serpentine, and talc at $t=t$. Since the silica concentration is almost constant throughout the reaction, as has been described above, the silica concentration is not contained in the rate equation, but is one of the constant factors that are contained in the rate-constant term. The reaction rate also depends on the surface area of $Mg(OH)_2$ powder. However, the surface area is constant in the same sample.

If the reaction is a first-order reaction, the rate equation is expressed as follows:[23]

$$\frac{d[A]}{dt} = -k_1[A], \quad (2)$$

$$\frac{d[B]}{dt} = k_1[A] - k_2[B], \quad (3)$$

$$\frac{d[C]}{dt} = k_2[B]. \quad (4)$$

The above three simultaneous differential equations are solved as follows:

$$[A] = [A]_0 e^{-k_1 t}, \quad (5)$$

$$[B] = [B]_0 e^{-k_2 t} + \frac{k_1[A]_0}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t}), \quad (6)$$

$$[C] = [C]_0 + [A]_0(1 - e^{-k_1 t}) + [B]_0\left(1 - e^{-k_2 t} - \frac{[A]_0/[B]_0}{1 - k_2/k_1}\right)(e^{-k_2 t} - e^{-k_1 t}), \quad (7)$$

where $[A]+[B]+[C]=1$ and the initial concentrations are $[A]_0=1$ and $[B]_0=[C]_0=0$. These equations can be simplified by writing $k=k_2/k_1$ and $\tau=k_1 t$:

$$[A] = e^{-\tau}, \quad (8)$$

$$[B] = (e^{-\tau} - e^{-k\tau})/(k-1), \quad (9)$$

$$[C] = \{k(1-e^{-\tau}) - (1-e^{-k\tau})\}/(k-1). \quad (10)$$

The values of [A], [B], and [C] are equal to the conversion fractions. They can be represented as a function of τ by changing the value of k in Eqs. 8, 9, and 10. When an appropriate k value was given, the conversion curves determined from Eqs. 8, 9, and 10 agreed with those obtained from this measurement. Some typical model curves determined to correspond to the experimental curves are shown in Fig. 8. Table 2 shows the experimental conditions under which these experimental conversion curves were obtained and also the k values selected to determine these model curves. From the k values, the conversion into serpentine was proved to be much faster than that into talc. Moreover, the dependence of the k values on the

silica concentration showed that the k values become greater with an increase in the silica concentration. In other words, an increase in the silica concentration accelerates the formation of talc rather than that of serpentine.

When a larger quantity of $Mg(OH)_2$ was packed in the sample container, the rate of the reaction was slowed down toward the center of the pack of $Mg(OH)_2$ powder. Regardless of whether a part or the whole of the sample is involved, these rate equation could be applied only if the k value was varied. The reaction proceeded in a first-order manner at any part of the pack of $Mg(OH)_2$ powder, although there was a concentration gradient attributable to the interstice diffusion. This may be explained as follows. The term referring to the interstice diffusion rate as well as that of the silica concentration is contained in the rate constant k.

In order to measure the reaction rate of serpentine into talc as a single reaction, a synthesized serpentine was used as the starting material. The results are shown in Fig. 9. It was confirmed from the decrease in the amount of serpentine that the reaction of serpentine into talc is also first-order.

These results suggest that diffusion is not a rate-limiting step under the present experimental conditions, since diffusion is not represented by a first-order rate equation.[23] Therefore, Step (5), the formation of crystal nuclei, which is considered to be independent of the diffusion,[22] seems to be the rate-limiting step.

The change in the crystallite size of $Mg(OH)_2$ and serpentine with the reaction time was followed by the use of an X-ray diffractometer in order to obtain some further information about the reaction mechanism. The results for serpentine can be seen in Fig. 8. The amount of $Mg(OH)_2$ was reduced to one-half of its initial value after 1—5 h, while its crystallite size was hardly changed at all. Thus, in the $Mg(OH)_2$——→serpentine——→talc reaction, the crystallite of the reactions did not decrease despite the decrease in their amount as the reaction proceeded. In the course of the reaction, the reactants may be either completely transformed into products (serpentine or talc) or may still be kept in the initial state. This result suggests that the crystal growth, Step (6), will finish immediately following the formation of the nucleus, Step (5). Thus, this evidence supports the idea that the formation of nuclei is the rate-limiting step. This conception is reasonable, however, only in the case of $Mg(OH)_2$ powder with a small particle size, since the use of larger particles gives rise to an apparent deviation from the typical model curve described above. The reaction mechanism for large particles may be more complex than that for small par-

ticles.

It has been reported that solid-phase reactions, such as the crystallization of zeolite[1] and the dehydration of $Mg(OH)_2$[24] and kaolinite ($Al_2Si_2O_5(OH)_4$),[25,26] are first-order. In these reactions, the mechanism is thought to involve a rate-limiting heterogeneous nucleation. For the dehydration of larger particles of kaolinite,[27,28] however, the rate-limiting step is taken as the diffusion process and the reaction is not a first-order. These reports seem to support our proposal.

The author would like to express his hearty thanks to Professor Shigeto Kitahara for his valuable guidance and for his critical reading of this manuscript.

Electrochemical Oxidation and Reduction of Flavin Mononucleotide Adsorbed on a Mercury Electrode Surface

Tadaaki KAKUTANI,* Kenji KANO, Shinji ANDO, and Mitsugi SENDA
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Kyoto 606
(Received Augast 4, 1980)

The electrochemical redox reaction of flavin mononucleotide (FMN) adsorbed on a hanging mercury drop electrode was studied in a pH 6.9 phosphate buffer and a pH 4.9 acetate buffer by means of cyclic d.c. and phasese lective a.c. voltammetry. Both the oxidized and reduced forms of FMN are strongly adsorbed on the electrode surface, and a stable adsorption layer of FMN($(FMN)_{ad}$) is formed. The cyclic d.c. and a.c. voltammetric behavior of $(FMN)_{ad}$ is explained by equations for a two-step one-electron surface redox reaction. The formal standard redox potentials, semiquinone formation constants, and charge transfer-rate constants of the surface redox reaction of FMN at the mercury electrode were determined.

Recently an increasing number of papers have appeared regarding redox-modified electrodes, which are prepared by attaching redox species, by chemical binding or irreversible adsorption, to the surface of an electrode material (for reviews, see Refs. 1 and 2). Electrocatalysis and electroanalysis have been in particular considered as possible applications of these electrodes. In such applications, data are essential on the kinetics of the surface redox reaction, *i.e.*, the electrode processes exhibited by redox species confined to the electrode surface. In previous papers, we have presented theories of a.c. polarography and voltammetry for simple one-step[3] and two-step surface redox reactions.[4] The theories have also been applied to the electrode processes of ferredoxins irreversibly adsorbed on the mercury electrode surface.[5,6]

The electrochemical behavior of flavin mononucleotide(FMN) has been studied by many authors (for review, see Ref. 7). Senda *et al.*[8] have shown by a.c. polarography that both the oxidized and reduced forms of FMN are adsorbed on the mercury electrode surface; this was confirmed by Takemori[9] and by Hartley and Wilson.[10] However, these authors did not consider the surface redox reaction of FMN, which will be discussed below. In this work, the electrochemical redox reaction of FMN adsorbed on the surface of the hanging mercury drop electrode (HMDE) has been studied in terms of the surface redox reaction, using cyclic d.c. and a.c. voltammetric techniques. We have also determined the kinetic and thermodynamic parameters of the surface redox reaction of FMN. The results and discussion are presented here.

Experimental

Chemicals. Flavin mononucleotide(FMN), a reagent-grade chemical purchased from Nakarai Chemicals Co., was used without further purification. The supporting electrolyte salt and buffers were commercially available reagent-grade materials, used as received. Triply distilled water was used to prepare the electrolysis solution.

Electrochemical Measurements. Cyclic d.c. voltammograms were obtained with a potentiostat, Yanaco Model PE-21-TB2S, equipped with a function generator, YHP 3310B or Nikko Keisoku Model NFG-3. The a.c. voltammetric measurements were performed with a lock-in amplifier, NF LI-574, equipped with the above potentiostat system. A lock-in amplifier, NF LI-572B, was used as an a.c. signal generator. This instrumental system allows the simultaneous measurement of the real (in-phase) and imaginary(out-of-phase) components of the a.c. voltammetric current, which are recorded against the d.c. sweep voltage applied to a hanging mercury drop electrode (HMDE).
