(Received March 16, 1981)

Ultrasonic absorption and velocity have been measured in aqueous solution of Propyl Cellosolve (ethylene glycol monopropyl ether) in the frequency range of 7.5 to 220 MHz at 25 °C. A single relaxational process has been found and the mechanism has been attributed to the solute-solvent interaction, AB↔A+B. The rate constants obtained are $k_{12}=9.6\times10^{7}$ s^{-1} for the forward and $k_{21}=1.3\times10^{8}$ M^{-1} s^{-1} for the backward reaction. The effect of the solute on the water structure has been found to act slightly as the water structure promoter and the results have been discussed comparing with those of Butyl Cellosolve solution.

In the previous paper, we have been reporting ultrasonic properties of aqueous solutions of some alcohols.[1,2] The characteristic properties of the aqueous solutions are the observations of the Peak Sound Absorption and Peak Sound Velocity Concentrations. Depending upon the structure of the solute molecules, one or two relaxational absorptions have been found. One excess absorption which is due to the solute-solvent interaction is observed in most of the solutions of nonelectrolytes with a hydroxy group. The other excess absorption is only observed in the solutions in which the solute has a relatively large hydrophobic group, and the cause has been attributed to the perturbation of the equilibrium between the monomer and aggregate of the solute. In these respects, we have extended our dynamic studies of nonelectrolyte solutions by the ultrasonic method to ethers, one of which has been reported.[3] In this paper, we present the detail results of the ultrasonic properties in aqueous solution of Propyl Cellosolve. The result will be compared with that of Butyl Cellosolve solutions.

Experimental

Propyl Cellosolve (ethylene glycol monopropyl ether) was distilled once and the purity was more than 99.8%. Ultrasonic pulse method[4] was used to measure the absorption coefficient in the frequency range of 7.5 to 220 MHz. Sound velocity was measured at 2.5 MHz by a interferometer. A pycnometer of about 2.2 cm^3 was used to measure density of solutions. All the measurements were done at 25 °C.

Results and Discussion

The ultrasonic absorptions in aqueous solutions of Propyl Cellosolve are all characteristic of a single relaxation in the concentration range of 1.9 to 5.6 M in which the excess absorptions have been observed. The excess absorption, A, the background absorption, B, and the relaxation frequency, f_r, were determined so as to obtain the best fit of the experimental data to the single relaxational equation (Eq. 1), using a least mean square method by HITACHI Basic Master MB-6890 microcomputer.

$$\alpha/f^2 = A/[1+(f/f_r)^2] + B, \quad (1)$$

where α is the absorption coefficient. Figure 1 shows the representative absorption spectra. In Table 1, these parameters are listed as a function of the concentration along with the values of the sound velocity and the density. The sound velocity goes through a maximum at the concentration of around 2.0 M, at which the excess absorption appears and increases up to 3.0 M. Subsequently, it decreases gradually.

5.60	93.0	129	151	0.9627	1466

a) 1 M=1 mol dm^{-3}.

In order to interpret the excess absorption mechanism, we use the model which has been proposed for aqueous solutions of alcohols because the ultrasonic properties are very similar to those of alcohol solutions.[1,2] It is assumed that liquid water consists of two different states, that is, the hydrogen bonded and the nonhydrogen bonded water. Only the latter molecules may associate with the interaction with Propyl

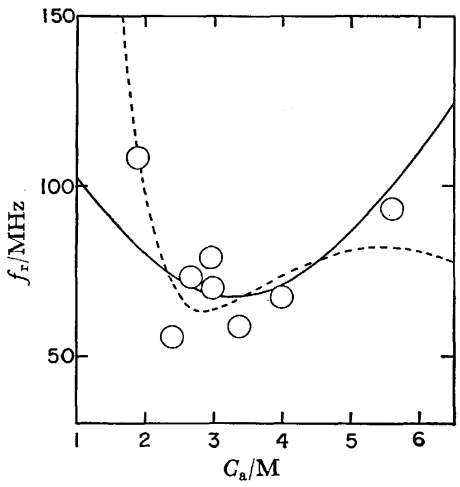

Fig. 2. Concentration dependence of the relaxation frequency for aqueous solution of Propyl Cellosolve. Solid line was calculated for the mechanism AB⟷A+B, and dashed one was for AB_2⟷A+2B mechanism.

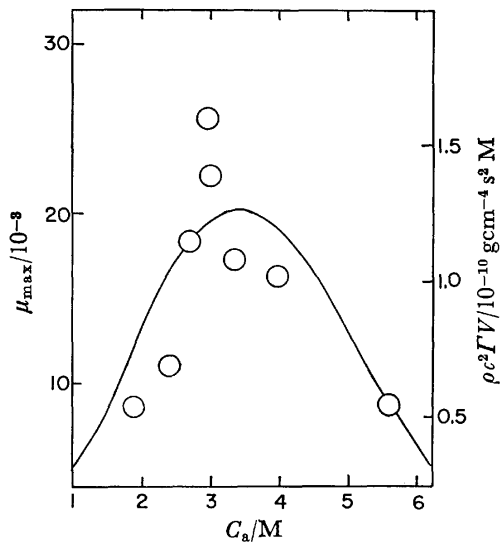

Fig. 3. The plots of μ_{max} and $\rho c^2\Gamma V$ as a function of Propyl Cellosolve concentration.

Cellosolve molecules.

$$AB_m \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} A + mB, \qquad (2)$$
$$C_1 \qquad C_2 \quad C_3$$

where A is the solute, B the monomer of liquid water, AB_m the complex and C_i the equilibrium concentration of each component. It has been shown in the previous studies[1-3] that the 1:1 complex is the most reliable. The relation between relaxation frequency and the concentration for the above reaction is given by the next equation.

$$2\pi f_r = k_{21}[(C_a-\beta C_w+K_{12})^2 + 4\beta C_w K_{12}]^{1/2}, \qquad (3)$$

where β is the mole fraction of the water monomer, C_a the analytical concentration of Propyl Cellosolve, C_w that of water and $K_{12}=k_{12}/k_{21}$. The rate constant, k_{21}, was determined so as to minimize the error defined by $r=0.675[\Sigma(p_i-\bar{k}_{21})^2/7]^{1/2}$ where $p_i=2\pi f_{ri}/[(C_{ai}-\beta C_{wi}+K_{12})^2+4\beta C_{wi}\bar{K}_{12}]^{1/2}$, and $\bar{k}_{21}$ is the most probable value of k_{21}, assuming the appropriate β value (the relation[1] between β and K_{12} is derived from the condition that the relaxation frequency goes through a minimum at 3.5 M). Figure 2 shows the plots of the experimental relaxation frequencies, f_r, and the calculated values (solid line). We have also tested the case of $m=2$, that is, the case in which two water molecules interact with a Propyl Cellosolve molecule. The relaxation frequency for this mechanism is expressed as

$$2\pi f_r = k_{21}(4C_2C_3+C_3^2) + k_{12}. \qquad (4)$$

Assuming appropriate values of β and K_{12} because no simple relation between β and K_{12} is held, contrary to that for 1:1 complex formation, each equilibrium concentration was calculated with the relations of $C_a=C_1+C_2$, $\beta C_w=2C_1+C_3$, and $K_{12}=C_2C_3^2/C_1$ and the ratio, k_{12}/k_{21} was determined from the slope and intercept of the plots of $2\pi f_r$ *vs.* $(4C_2C_3+C_3^2)$ so as to get the same value as that of assumed K_{12} and so as that the excess absorption went through a maximum.

In the range of $\beta=0.13$ to 0.17, it may be possible to obtain the parameters of β and K_{12} which seem to satisfy the above conditions. One of the results is shown in Fig. 2 by a dashed line which has been determined when $\beta=0.150$ and $K=0.715$. However, the errors of the rate constants are too large ($k_{12}=(5.7\pm1.3)\times10^7$ s^{-1} and $k_{21}=(4.2\pm10.2)\times10^7$ M^{-2} s^{-1}), and the concentration dependence of the calculated relaxation frequency exhibits a minimum and a maximum as is seen in Fig. 2. The mechanism due to the interaction between plural water molecules and one solute may not be considered as the cause of the observed excess absoprtion from the following reasons. First, even if the calculated curve for the case of $m=2$ in Fig. 2 seems to fit to the experimental relaxation frequency, reasonable rate constants were not obtained. Propyl Cellosolve may not be special or exceptional in the ultrasonic properties compared with various alcohols and ethers reported so far because the relaxation frequencies in other solute solutions only go through a minimum.[1,2,3,5] Second is the fact that the observed absorption data is fairly well expressed by a single relaxational equation, and it seems to be unplausible that many water molecules bind the solute at a fixed characteristic time.

Another parameter determined from the ultrasonic absorption measurement is the maximum excess absorption per wave length, μ_{max} which is related to the volume and enthalpy change of the reaction. It is a good approximation that μ_{max} is proportional to $\rho c^2\Gamma V$, where ρ is the density, c the sound velocity and $\Gamma=(1/C_1+1/C_2+1/C_3-1/C_T)^{-1}(1/V)$.[3] The comparison between the μ_{max} and $\rho c^2\Gamma V$ may be used to make sure if the cause of the absorption is due to the perturbation of the equilibrium expressed by Eq. 2. The solid curve in Fig. 3 represents the calculated $\rho c^2\Gamma V$ and the circles are the experimental values of the μ_{max}. These plots confirms that the excess absorption mechanism is associated with the solute-solvent interaction. In Table 2, the rate and thermodynamic constants obtained in this study are given

Table 2. Rate and thermodynamic constants determined from ultrasonic data

	k_{12} / 10^7 M^{-1} s^{-1}	k_{21} / 10^8 s^{-1}	β	Reference
Pure water			0.26	6
Propyl Cellosolve	9.6±1.3	1.3±0.2	0.10	This work
Butyl Cellosolve	4.2±0.7	1.7±0.3	0.029	3

along with those of Butyl Cellosolve[3] and pure water.[6]

The mole fraction of water monomer in the aqueous solution of Propyl Cellosolve is smaller than that in pure water, but is larger than that in Butyl Cellosolve solution. This means that Propyl Cellosolve acts as the structure promoter for liquid water. However, the effect is not so large, comparing with that of Butyl Cellosolve. This may be because of the smaller hydrophobic group of Propyl Cellosolve than that of Butyl Cellosolve. Though the excess absorption due to the aggregation reaction is observed in the Butyl Cellosolve solution, it is not found in the Propyl Cellosolve solution. Propyl Cellosolve molecule may not have enough hydrophobicity to form the aggregate in aqueous media. Aggregation by hydrogen bonding may be possible, but the rate for this process seems to be beyond our time scale.[7]

(Received December 26, 1980)

The crystal structure of diaqua(meso-tetraphenylporphinato)cobalt(III) perchlorate, $[Co^{III}(tpp)(H_2O)_2]ClO_4$, has been determined by the X-ray method. The compound crystallizes in the monoclinic space group $P2_1/c$ with four molecules in a unit cell of dimensions, $a=13.93(4)$ Å, $b=23.46(2)$ Å, $c=17.35(6)$ Å, and $\beta=129.4(2)°$. The Co(III) ion lies on the mean plane of the porphinato core, and is coordinated by the four porphinato nitrogen atoms and the two water oxygen atoms. The average Co–N distance is 1.964(4) Å, and the average Co–O(water) distance is 1.936(5) Å. The porphyrin plane is significantly ruffled and has an approximate S_4-$\bar{4}$ symmetry. The perchlorate anion is not bound directly to the cobalt(III) ion, and links the two adjacent $[Co^{III}(tpp)(H_2O)_2]^+$ cations by the hydrogen bonds with the aqua ligand oxygen atoms.

The structures of cobalt complexes with porphyrin have been of special interest because of their biological relevance to the hemoproteins[1] and vitamin B_{12} chemistry.[2] The stereochemistry of the cobalt porphinato complexes in the solid state has been reviewed by Scheidt,[1b] in which he states that the cobalt(III) derivatives are all low-spin complexes ($S=0$). Some cobalt complexes, however, have a paramagnetic nature in solution; chloro(tetraphenylporphinato)cobalt(III) complex, $[Co^{III}(tpp)Cl]$, shows a reversible paramagnetism with temperature in the inert solution,[3a] although it is the diamagnetic five coordinate complex in the solid state.[3b] Similar temperature dependence of magnetic conversion has been reported for several Co(III) complexes.[4] This paramagnetic state differs from that caused by the spin-state exchange of the metal ion as observed in the Co(II), Fe(III), or Ni(II) complexes,[5] and is considered to be arisen from the π-cation radical of the six-coordinated low-spin cobalt(III) complex, which is formed in the thermal equilibrium state.[3c].

We have, so far, studied on the structures and chemicophysical properties of several perchlorate metalloporphyrins[6] and found that diaqua(tetraphenylporphinato)cobalt(III) perchlorate, $[Co^{III}(tpp)(H_2O)_2]ClO_4$, shows the same magnetic behavior in the inert solution as observed in $[Co^{III}(tpp)Cl]$; the ^{1}H-NMR spectra of $[Co^{III}(tpp)(H_2O)_2]ClO_4$ in chloroform or benzene give the slight low-field shift and the line broadening of signals, while those spectra in the polar solvents exhibit diamagnetic properties.[6b] Thus the structure of this complex is of interest in relation to the anomalous magnetic properties. In this paper, the crystal structure of $[Co^{III}(tpp)(H_2O)_2]ClO_4$ is described, and the structural characteristics about the Co(III) ion will be discussed in comparison with those of the other metalloporphyrins.

Experimental

$[Co^{III}(tpp)(H_2O)_2]ClO_4$ was prepared by air-oxidation of $[Co^{II}(tpp)]$ in methanol containing hydroperchloric acid.[6b] Dark-violet, needle-like crystals were obtained by recrystallization using 10:1 mixture of benzene and acetone. A crystal with dimensions of 0.5 mm × 0.2 mm × 0.2 mm was used for the diffractometer experiment. Preliminary photographic examination established a monoclinic unit cell containing four chemical units of $[Co^{III}(tpp)(H_2O)_2]ClO_4 \cdot (CH_3)_2C{=}O \cdot 3/2H_2O$. The systematic absences led to the space group $P2_1/c$. The least-squares refinement of setting angles of 20 reflections, measured on a Rigaku AFC-5 diffractometer using Mo $K\alpha$ radiation ($\bar{\lambda}=0.71073$ Å), led to the cell constants: $a=13.93(4)$ Å, $b=23.46(2)$ Å, $c=17.35(6)$ Å, and $\beta=129.4(2)°$. The calculated density of 1.35 g cm^{-3} agrees with the observed density of 1.33 g cm^{-3} by the floatation method in calcium chloride solutions.

Intensity data of 6953 reflections in the range $2\theta<50°$ were collected by the use of ω-2θ scanning technique, the scanning rate being 5° in ω per minute. During the course of data collection, three reflections were monitored every 60 reflections. The intensity data were converted to the F_o data in the usual manner. Absorption correction was not applied ($\mu=5.08$ cm^{-1} for Mo $K\alpha$). The standard deviations were estimated by counting statics. A total number of 4380 independent reflections with $F_o>3\sigma(F_o)$ were retained as observed, and employed in solving and refining the structure.

The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. The locations of the crystal water and acetone molecules were determined by the difference Fourier syntheses. The hydrogen atoms were placed at the theoretically calculated positions (C–H=1.00 Å). After several cycles of refinement, the hydrogen atoms of the aqua ligand were revealed on the difference Fourier map. The further refinement was carried to convergence with the weighting scheme of $w=1/\sigma(F_o)^2$ including the hydrogen atoms in the structure factor calculation. The final R value was 0.077. Atomic scattering factors were obtained from the International Table for X-Ray Crystallography IV.[7] All computations were performed on a FACOM M-190 computer in the Data Processing Center of Kyoto University by using the program system KPAX.

Results and Discussion

The atomic parameters are listed in Table 1.[8] The structure of $[Co^{III}(tpp)(H_2O)_2]^+$ cation is shown in Fig. 1, and the crystal structure in Fig. 2. The atomic numbering scheme is given in Figs. 1 and 3.

Bond distances and bond angles are listed in Table 2. The average bond distances and bond angles for the four crystallographically nonequivalent pyrrole rings

TABLE 1. POSITIONAL AND THERMAL PARAMETERS FOR THE ATOMS OF $[Co^{III}(tpp)(H_2O)_2]ClO_4 \cdot (CH_3)_2C{=}O \cdot 3/2H_2O$

Estimated standard deviations in the least significant figure(s) are give in parentheses. B_{eq} is the equivalent isotropic temperature factor defined by Hamilton.[9]

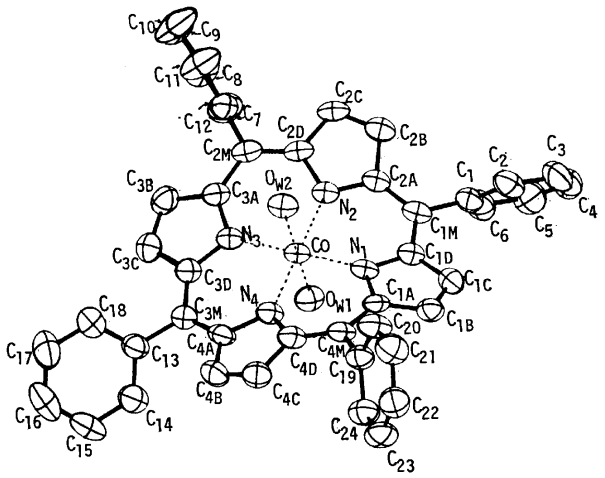

Fig. 1. Computer-drawn perspective model of $[Co^{III}(tpp)(H_2O)_2]^+$.

are given in Fig. 4. The cobalt(III) ion occupies the center of the octahedron formed by the four porphinato nitrogen atoms and the two aqua oxygen atoms, and it lies on the mean plane of the porphinato core; the displacement is 0.004 Å out of the plane defined by the four nitrogen atoms toward the O_{w2} atom and 0.006 Å out of the porphinato mean plane.

The average axial Co(III)–OH_2 bond distance of 1.936(5) Å is comparable with the sum of ionic radii of Co(III) (0.53 Å) and 0 (1.40 Å),[10] and close to the Co(III)–OCH_3 distance, 1.92 Å, observed in $[Co^{III}(OCH_3)(tpp)(py)]$.[11] The average Co–N distance of 1.964(6) Å is within the range of reported distances (1.958—1.982 Å).[1b] The Co(III)–N and Co(III)–O distance are in good agreement with those of the low-spin Co(III) ion in which d_{z^2} and $d_{x^2-y^2}$ orbitals are vacant.[1b]

Deviations of atoms from the least-squares plane of the porphinato core are given in Fig. 5. The porphinato core has a ruffled conformation with an approximate S_4-$\bar{4}$ symmetry. The four pyrrole rings are all swiveled about the metal-nitrogen bond; the dihedral angles between the pyrrole ring and the porphinato mean plane are 14, 16, 18 and 16°. Similar conformations have been observed in Ni- and Co-

TABLE 2. BOND DISTANCES AND ANGLES FOR $[Co^{III}(tpp)(H_2O)_2]ClO_4 \cdot (CH_3)_2C{=}O$
Estimated standard deviations are in parentheses.

(a) Bond distances (l/Å)

$Co-N_1$	1.959(9)	$C_{3A}-C_{3B}$	1.440(11)	$C_{3M}-C_{13}$	1.500(10)	C_3-C_4	1.370(21)

porphyrins.[12,13c] As compared with these complexes, the lengthening of the metal–N bond accompanied by increasing the C_A–N–C_A angle and decreasing the N–C_A–C_B angle seems to relieve the ruffling. The phenyl rings attached to C_M are tilted from the core plane, because of repulsions between the hydrogen atoms. The dihedral angles of each phenyl ring with the porphinato mean plane are 59, 65, 60, and 81°; their average value being 66°. As seen in Fig. 6, these angles have a linear relationship for the C_M–C_P bond distances; the C_M–C_P bond distance of 1.498(5) Å is very close to the value of 1.497(3) Å observed for the central C–C bond of planar biphenyl molecule.[14] Thus, the C_M–C_P bond has a little π-conjugation character, in spite of the steric hindrance. Although the π-conjugate system of the porphinato

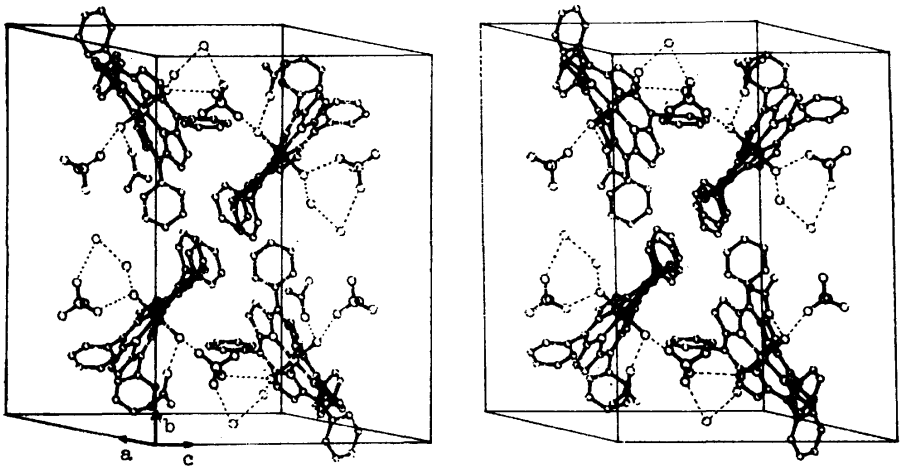

Fig. 2. Stereoscopic view of the contents in the unit cell of $[Co^{III}(tpp)(H_2O)_2]ClO_4 \cdot (CH_3)_2C{=}O \cdot 3/2H_2O$ crystal.

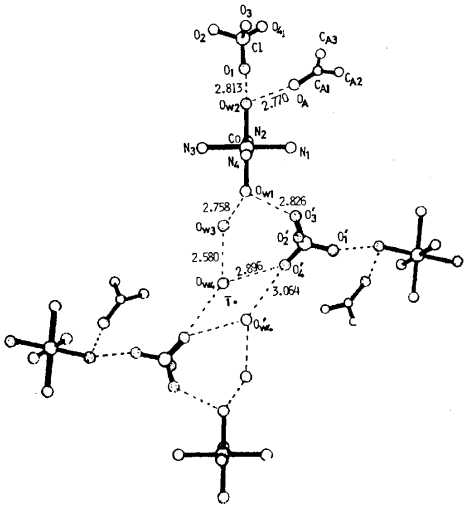

Fig. 3. Hydrogen-bonding scheme among the $[Co^{III}(tpp)(H_2O)_2]^+$ cations, the perchlorate anions, the water molecules, and the acetone molecules. The dotted lines represent hydrogen bonds. The tetraphenylporphine atoms other than the nitrogen atoms are omitted for clarity.

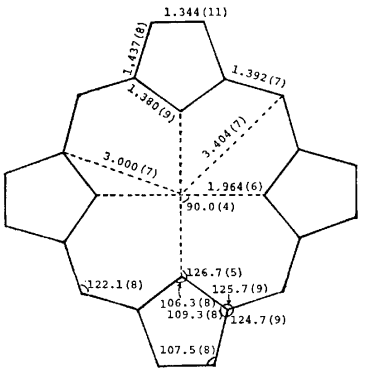

Fig. 4. Average bond distances (l/Å) and angles (ϕ/°) for the porphine skeleton of the $Co^{III}(tpp)^+$ cation (a) and for the peripheral phenyl groups (b).

core might be weakened because of its ruffled conformation, the π-conjugate system may be slightly delocalized over the phenyl rings through the C_M–C_P bond.

The crystal structure consists of the discrete $[Co^{III}(tpp)(H_2O)_2]^+$ cations, the perchlorate anions, the acetone molecules, and the water molecules other than the aqua ligands. As shown in Fig. 3, the aqua ligand O_{w1} atom forms the two hydrogen bonds with the perchlorate O_3 and water O_{w3} atoms, while the ligand O_{w2} atom forms the two hydrogen bonds with the perchlorate O_1 and acetone O_A atoms. Thus, the two $[Co^{III}(tpp)(H_2O)_2]^+$ cations are linked together by the perchlorate anion through the $O_{w1}\cdots O_3$ and $O_{w2}\cdots O_1$ hydrogen bonds. The water O_{w4} atom occupies the two positions with the half occupancy near the inversion center. This oxygen atom is hydrogen-bond to the two adjacent perchlorate anions and the water O_{w3} atom. The perchlorate O_1 atom exists near the porphinato nitrogen N_3 atom at 3.241 Å and the Co(III) atom at 4.026 Å, and it seems to have weak interactions with the central Co(III) atom because of their interorbital overlapping between the π-orbital of Co–N bond and the σ-orbital of O_1 atom. This crystal structure may, therefore, suggest that the perchlorate anion, bound directly to the Co(III) atom in the inert solvent, might be replaced by the water molecule in the crystallization process, since the water molecule acts as a little stronger ligand for the Co(III) ion than the perchlorate anion. The diamagnetic properties of $[Co^{III}(tpp)(H_2O)_2]ClO_4$ in ethanol or pyridine are considered to be caused by the strong coordination of the polar solvent molecules as the fifth and/or sixth axial ligands.

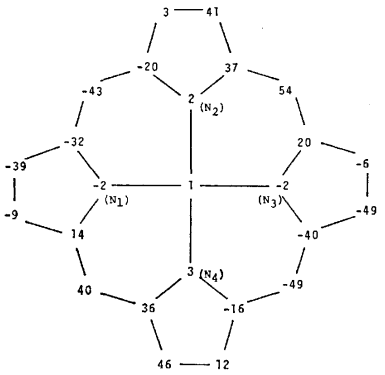

Fig. 5. Ruffling of the porphinato core. Perpendicular distances of the atoms from the porphinato mean plane are in a unit of 0.01 Å.

The authors wish to thank Professor Nobuo Morimoto and Dr. Katsutoshi Tomita, Faculty of Science in Kyoto University, for the use of the Rigaku AFC-5 diffractometer.

Microwave Spectra of *cis*- and *trans*-1-Chloro-1,2-difluoroethylene

Teruhiko OGATA

Faculty of Liberal Arts, Shizuoka University, Ohya, Shizuoka 422

(Received January 5, 1981)

The microwave spectra of the ^{35}Cl and ^{37}Cl isotope species of *cis*- and *trans*-HFC=CFCl have been studied in the 8—50 GHz region. The rotational constants and the Cl quadrupole coupling constants in MHz are obtained and listed. The quadrupole coupling constants and the structures obtained for *cis*- and *trans*-HFC=CFCl are consistent with the results of other haloethylenes.

	cis-HFC=CF^{35}Cl	*cis*-HFC=CF^{37}Cl	*trans*-HFC=CF^{35}Cl	*trans*-HFC=CF^{37}Cl
A	9 126.182(10)	9 091.714(18)	5 336.381(8)	5 232.441(10)

The microwave spectra and Cl nuclear quadrupole coupling constants have been measured for several substituted ethylenes.[1-6] Substitutional change in the quadrupole coupling constants along the carbon-chlorine bond shows that the numerical values of the coupling constant increase as the number of substituted halogen atoms increases and that fluorine has a greater effect than chlorine.

On the other hand, complete structures for several haloethylenes have been determined by microwave spectroscopy.[1,7-9] The halogen substitution effect on the structure shows that the carbon-carbon double bond and carbon-halogen bond lengths decrease as the number of substituted halogen atoms increases and that fluorine has a greater effect than chlorione.

The present work was initiated to see if the nuclear quadrupole coupling constant and the molecular structure in *cis*- and *trans*-1-chloro-1,2-difluoroethylene are consistent with previous results on haloethylenes.

Experimental

The sample of HFC=CFCl was prepared by two different methods. The first method of preparation utilized an elimination reaction of hydrogen chloride as follows:

$$HFClC\text{-}CHFCl \xrightarrow[(EtOH)]{KOH} HFC{=}CFCl + HCl.$$

Because of competing side reactions the over-all yield was low. The doublet peak of *cis*- and *trans*-HFC=CFCl and some other peaks were observed by a vapor-phase chromatograph.

The second method of preparation was by photochemical reaction of hydrogen bromide with 1,2-dichloro-1,2-difluoroethylene followed by dehalogenation of the adduct as detailed by Birchall *et al.*[10]

$$FClC{=}CFCl + HBr \xrightarrow{h\nu} HFClC\text{-}CFClBr$$

$$HFClC\text{-}CFClBr + Zn \longrightarrow HFC{=}CFCl + ZnClBr$$

The product was shown to be a *cis-trans* mixture of almost equal amount by gas chromatography (resolved easily at room temperature on a 3 m column of Silicone DC-200(20%) and steric acid(5%) on celite). The infrared spectrum was identical to that of Birchall *et al.*[10] Separation of *cis-trans* isomers has been performed by gas chromatography at about −30 °C, the former and the latter peaks on the run were identified as *trans*- and *cis*-isomer, respectively.

The microwave spectrum was investigated in the frequency region from 8 to 50 GHz by using a conventional 100 kHz Stark modulation spectrometer. All measurements were made at the temperature of Dry Ice. The frequency measurements were performed automatically under the control of a microcomputer.[11] The microwave frequency measured by a counter YHP 5340A is processed by a microcomputer YHP 9825A. When a microwave frequency coincides with the marker frequency, the computer triggers a relay actuator YHP 59306A, which actuates a marker pen on the recorder.

Results and Disscusion

Microwave Spectra. A preliminary estimate of the molecular structure for *cis*-HFC=CFCl and *trans*-HFC=CFCl indicate that the dipole moments would lie along the b axis for the *cis*-isomer and between the a and b axes for the *trans*-isomer; spectra exhibiting b-type and both a- and b-type selection rules should be observed, respectively. Nearly all of the Q- and R-branch transitions were predicted to be multiplets due to the coupling of the over-all rotation angular momentum and the nuclear spin angular momentum for both isomers in the ^{35}Cl and ^{37}Cl isotopic species. Each Q-branch transition exhibits a characteristic quartet pattern ($\Delta F = \pm 1$ transitions being weak), and the splitting between the first and second components

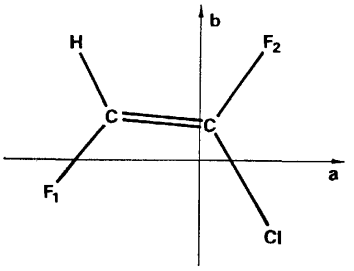

Fig. 2. Molecular structure of *trans*-HFC=CFCl.

equals that of the third and fourth components. The ratio $(\nu_C-\nu_B)/(\nu_D-\nu_A)$ (where ν_t is the frequency of the ith component of the quartet) depends only on Casimir's function. This ratio could be used to determine the J level for transitions exhibiting the characteristic Q-branch quadrupole splitting pattern.

The spectrum of *cis*-HFC=CFCl was found to be broad and moderately strong. A search was made for Q-branch transitions for the ^{35}Cl isotope in the 33—50 GHz region. Assignment was obtained by plotting $(A-C)/2$ *vs.* κ for the various Q-branch transitions. This information together with assumption of planarity, $I_c-I_a-I_b\approx 0$, give the approximate rotational constants. The measurements of R-branch transitions gave the complete assignments which were confirmed by their hyperfine structures. The final values of the rotational constants were fitted by using a least squares criterion to the rotational Hamiltonian involving a centrifugal distortion effect. In this case, when the planarity conditions are applied, only four centrifugal distortion coefficients are independent, *e.g.* τ_{aaaa}, τ_{bbbb}, τ_{aabb}, and τ_{abab}. The results are listed in Table 1. The experimental and calculated frequencies are given in Table 2. The assignment for *cis*-HFC=CF^{37}Cl was made in a manner similar to the ^{35}Cl species. The rotational constants and centrifugal distortion coefficients are listed in Table 1, and the experimental and calculated values of the transition frequency are given in Table 2.

The spectrum of *trans*-HFC=CFCl was found to be sharper and a little weaker than that of the *cis*-isomer. A search was made for Q-branch transitions for the ^{35}Cl isotope in the 8—18 GHz region and an assignment was obtained in the same way as for *cis*-HFC=CFCl. The rotational constants and centrifugal distortion coefficients are listed in Table 3, and the experimental and calculated frequencies are given in Table 4, together with the corresponding values for *trans*-HFC=CF^{37}Cl.

Nuclear Quadrupole Coupling. The Cl nuclear quadrupole interaction in 1-chloro-1,2-difluoroethylene is given by[12]

$$E_Q/h = 2\chi_{J_\tau}\cdot Y(I,J,F)/J(J+1),$$

where $Y(I,J,F)$ is Casimir's function. χ_{J_τ} is the quadrupole coupling constant (or splitting factor) for the rotational level which is given by first-order theory in terms of the diagonal elements in the χ_{J_τ} tensor in the principal inertial axis system as

$$\chi_{J_\tau} = \langle \boldsymbol{P}_a^2\rangle\chi_{aa} + \langle \boldsymbol{P}_b^2\rangle\chi_{bb} + \langle \boldsymbol{P}_c^2\rangle\chi_{cc},$$

where $\boldsymbol{P}_a^2$, $\boldsymbol{P}_b^2$, and $\boldsymbol{P}_c^2$ are the squares of the rotational angular momentum in the principal inertial-axis system. The values of $\langle \boldsymbol{P}_a^2\rangle$, $\langle \boldsymbol{P}_b^2\rangle$, and $\langle \boldsymbol{P}_c^2\rangle$ used in this work were calculated on HITAC M-200H computers at the Institute for Molecular Science and at Tokyo University.

a) Standard deviations for last figures in parentheses.
b) $\Delta=I_c-I_a-I_b$.

The χ_{aa} and χ_{bb} components of quadrupole coupling tensor were determined from the transitions with relatively large hyperfine splitting. The χ_{cc} element was then determined from the Laplace equation $\chi_{aa}+\chi_{bb}+\chi_{cc}=0$. The results are listed in Table 5. From the observed splittings and the tabulated values of the Casimir's functions, the values ν_0 for an unperturbed transitions are easily calculated and are listed in Table 2 and Table 4. Using the results in Table 5, the quadrupole splitting in all measured transitions in both *cis*- and *trans*-HFC=CFCl was computed and compared with the experimental values. These values are also listed in Tables 2 and 4.

The diagonalized χ tensors for *cis*- and *trans*-HFC=CFCl were calculated by using the molecular structures obtained later with the assumption that the z axis coincides with the C–Cl internuclear line. θ_{az}, the angle between the a and z axes, for *cis*-HFC=CF^{35}Cl is 16.03°. It is very insensitive to the structural parameters because the C–Cl bond lies almost along a-axis. The result for *cis*-HFC=CF^{35}Cl is listed in Table 5 together with that of *cis*-HFC=CF^{37}Cl. In the same way, the diagonal χ tensor for *trans*-HFC=CF^{35}Cl was calculated, with $\theta_{az}=59.29°$, and listed in Table 5 together with the corresponding values of ^{37}Cl species. The values of $\chi_{zz}=-76.46$ MHz and $\chi_{zz}=-75.57$ MHz for *cis*- and *trans*-HFC=CF^{35}Cl, respectively, are consistent with those of other haloethylenes such as, placed in order of increasing number of substituted halogen atoms, −70.16, −70.7, −77.9, −73.42, −73.7, −77.40, and −89.14(−73.7) MHz for H_2C=CHCl,[1] *cis*-HClC=CHCl,[7] H_2C=CCl_2,[7] H_2C=CFCl,[5] *cis*-HFC=CHCl,[4] F_2C=CHCl,[6] and F_2C=CFCl,[5] respectively.

Molecular Structure. In order to determine the molecular structure the bond lengths were estimated by assuming a systematic shortening caused by halogen substitution which is well established in the r_s struc-

tures of haloethylenes. The C–Cl bond lengths of 1.726, 1.717, and 1.718 Å determined for H_2C=CHCl,[1] HCl=CHCl,[7] and H_2C=CCl_2,[7] respectively, show a systematic shortening and suggest about 1.710 Å for the C–Cl bond in HFC=CFCl. Similarly, the C–F bond lenghts of 1.349, 1.335, and 1.323 Å for H_2C=CHF,[8] HFC=CHF,[9] and H_2C=CF_2,[9] respectively, suggest about 1.328 and 1.322 Å for the C–F and C–F′ bonds in HFC=CF′Cl, respectively. The C=C bond lengths of 1.332, 1.320, 1.338, 1.329, 1.324, and 1.315 Å for H_2C=CHCl,[1] HClC=CHCl,[7] H_2C=CCl_2,[7] H_2C=CHF,[8] HFC=CHF,[9] and H_2C=CF_2,[9] respectively, present a more confused situation. The C=C bond lengths in H_2C=CCl_2 and H_2C=CF_2, however, seem to have a large effect from zero point vibration because a carbon atom in either molecules lies very close to the center of mass.[7] From the rest of the molecules, the estimation of about 1.318 Å was made for the C=C bond length in HFC=CFCl.

By assuming the bond lengths estimated above, the bond angles in *cis*-HFC=CFCl were fitted so as to give the observed moments of inertia of both Cl isotopic species. The result is shown in Table 6 together with the calculated moments of inertia. The structural parameters obtained are consistent with those of other haloethylenes.

The same treatment was made for *trans*-HFC=CFCl. The θ_{az}, however, was found to be very sensitive to the structural parameters and a small deviation in θ_{az} gives an unlealistic value for the diagonal χ tensor. Therefore, three sets of structural parameters which have various θ_{az} were tentatively calculated, as shown in Table 7, by keeping the bond lengths close to the estimated values. The parameters of Set I and Set II, however, lead to $\chi_{zz}=-66.26$ MHz and $\chi_{zz}=-69.43$ MHz, respectively, and besides $\chi_{xx}<\chi_{yy}$, which does not seem possible. On the other hand, Set III gives reasonable values for the χ tensor as discussed before and is very probable for the structure of *trans*-HFC=CFCl.

I would like to thank Drs. C. Matsumura and H. Takeo of the National Chemical Laboratory for Industry for their helpful discussions and for the measurements of the microwave spectrum, and Professor E. Hirota and Dr. Y. Endo of the Institute for Molecular Science for a use of microwave spectrometer. I would also like to thank Dr. J. M. Birchall of Manchester University for providing a copy of the infrared spectrum of 1-chloro-1,2-difluoroethylene. Thanks are also due to Dr. A. P. Cox for critical reading of the manuscript and helpful suggestions.

Photoelectrochemical Studies of MoS_2 Electrode by Rotating Ring-disk Electrode Technique

Akira Fujishima,* Yoshikazu Noguchi, Kenichi Honda, and Boon H. Loo†

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 4, 1981)

Photoelectrochemical processes at both n- and p-type MoS_2 electrodes were studied by rotating ring-disk electrode technique. In comparison with other semiconductor photoelectrodes such as CdS, ZnO, and TiO_2, the competitive oxidations of various reducing agents at n-MoS_2 electrode were not clearly dependent on their redox potentials. The MoS_2 photoanode was particularly stabilized in I^- solutions, and this was attributed to the specific adsorption of I^- ions on the electrode surface. Two step waves were observed in the photocurrent-potential curves of MoS_2 photoanode in I^- solutions. The first wave was controlled by the diffusion of I^- ions from the bulk solution to the electrode surface, and the second wave at more anodic potential was dependent on the formation of the photogenerated holes.

There are about sixty kinds of transition metal dichalcogenides, and approximately 70% of them have two dimensional layer structures. This layer structure exerts great influence on the solid state properties of these dichalcogenides, in particular, the intercalation processes which have been investigated to achieve superconduction[1] and high current density batteries.[2]

Tributsch and his coworkers were the first to investigate the photoelectrochemical reactions at some layer-type semiconductor electrodes (MoS_2,[3,4] $MoSe_2$,[5,6] and WSe_2[7]). These layer type semiconductors are attractive materials for solar energy conversion because they have small bandgaps and an expected higher stability against photocorrosion, since their main photoelectrochemical reactions are based on holes from d-bands belonging to the non-bonding orbitals of the transition metals. Photoanodes using transition metal dichalcogenide semiconductor materials in photoelectrochemical cells have been reported by several groups.[3-23] Molybdenum dichalcogenide photoanodes were especially stabilized by I^-.[3-6] Electrochemical photocells based on n-WSe_2/I^- and n-$MoSe_2$/I^- systems have been reported recently to have solar conversion efficiencies of 10.2 and 9.4%, respectively.[23]

In this study we investigated in detail the photoelectrochemical processes which occurred at n-type and p-type MoS_2 electrodes by rotating ring-disk electrode (RRDE) technique, which is very useful to measure electrochemical products. Competitive reactions of I^- and other redox agents were studied to provide insights on the corrosion and stabilization processes.

Experimental

The MoS_2 single crystals (n- and p-type) used in the present study were produced naturally in Japan. The crystal was cleaved between layers and shaped into a disk of diameter 5.0 mm. Ohmic contact with a conducting wire was made by rubbing In–Ga alloy on one side of the crystal. The MoS_2 disk was then mounted on a Teflon holder using an epoxy resin with a Pt ring 7.0 mm in inner diameter and 9.0 mm in outer diameter. The MoS_2 (001) face exposed to the electrolyte was etched in 5 M HCl (1 M=1 mol dm^{-3}) for 30 s, and then rinsed with distilled water. The ring-disk electrode was set in a RRDE measurement system (Nikko Keisoku). The potentials of the disk and ring electrodes were controlled independently by means of a dual-potentiostat (Nikko Keisoku). The light source was a 250 W high pressure Hg lamp and the wavelength of illuminating light was selected with a V-Y44 (440 nm) cutoff filter (Toshiba Kasei). The rotation speed of the RRDE was set at 1000 min^{-1}. All chemicals used were of reagent grade. The experimental detail of the RRDE measurements was described elsewhere.[24]

Results and Discussion

Photoelectrochemical Reactions at an n-MoS_2 Electrode. The anodic reactions at an illuminated n-MoS_2 electrode in an inert electrolyte involved the following processes:[3]

$$MoS_2 + 8H_2O + 18h^+ \longrightarrow Mo(VI) + 2SO_4^{2-} + 16H^+, \quad (1)$$

$$MoS_2 + 4h^+ \longrightarrow Mo(IV) + 2S, \quad (2)$$

$$MoS_2 + 2H_2O + 4h^+ \longrightarrow MoS_2 + O_2 + 4H^+. \quad (3)$$

We performed quantitative analysis on all possible reaction products and found that Reaction 1 was the predominant process (Table 1), which agreed with Tributsch's results.[3] Our SEM experiments showed that elemental sulfur was present on the electrode surface in all cases. This suggests Reaction 2 always occurs to some extent in an inert electrolyte. Both Reactions 1 and 2 lead to the dissolution of the photoanode. Reaction 3 occurs in a smaller extent, however, it is the main focus of interest since water is splitted without degradation of the photoanode. Photocorrosion of MoS_2 electrode will be suppressed if Reactions 1 and 2 are suppressed.

Perhaps the photoanodic reactions at an n-MoS_2 electrode are analogous to those occuring at a pyrite (FeS_2) electrode, which has been investigated in detail by Biegler and Swift.[25] The anodic reactions at a pyrite electrode are composed of two processes which lead to formation of sulphate and elemental sulfur.

Flatband Potential of n-MoS_2 Electrode. We measured the flatband potential of n-MoS_2 electrode in 0.2 M Na_2SO_4 solution with variation in pH by impedance measurements. The flatband potential was

Table 1. Results of quantitative analysis of molybdenum ions and pH change

	Solution	Charge flowed Q	Amount of Mo[a] mg	Number of electrons or holes	pH change

found to be 0.15±0.05 V *vs.* SCE. This value agreed with those reported by others, 0.10 to 0.20 V in 1 M KCl aqueous electrolyte[6] and 0.30 V in CH_3CN.[17] Analogous to the behavior for CdS, the flatband potential of n-MoS_2 was found to be independent of the pH of the electrolyte. However, since the main photoanodic process of MoS_2 involved the reaction with water (Reaction 1 above), the onset of the photocurrent was influenced slightly by the variation of pH.

The donor concentration N_D of MoS_2 calculated by Mott-Schottky relationship was 1.3×10^{18} cm^{-3} (the dielectric constant of MoS_2: $\varepsilon=7$—8[26]). As the MoS_2 crystal used in the present study was a natural product, it might contain Si, Al, or Fe *etc.* as impurities.[27] Assuming much of the light was efficiently absorbed in the space charge region and using the relationship[28] $N_D=1.1\times10^{16}\times\Delta v\times a^2$, the voltage drop in the space charge layer Δv was 1.5 V, N_D being calculated donor density and a the absorption coefficient in the order of 10^{15} cm^{-1}.[27] This large drop in potential in the space charge region probably accounted for the slow rise in the photocurrent (see Fig. 1 curve 1).

The Behavior of n-MoS_2 Electrode in an I^--containing Electrolyte. Iodide ion effectively suppresses the anodic dissolution of n-MoS_2 and n-$MoSe_2$, and shifts the flatband potentials of the electrodes to more negative potentials.[5] Figure 1 shows the current-potential curves of MoS_2 photoanode in 0.2 M Na_2SO_4 solution containing different concentrations of I^- ions. The onset of the photocurrent was shifted to more negative potential as the I^- concentration increased. This shift in the onset of the photocurrent was due to a shift in the flatband potential. This behavior was quite similar to the two-step or three-step wave photocurrent observed at a CdS photoanode in a solution containing S^{2-}, SO_3^{2-}, or $S_2O_3^{2-}$ ions.[29,30] In our previous study of CdS–S^{2-} system,[29] we reported that the first wave was controlled by the diffusion of S^{2-} from the solution to the electrode surface and the second wave depended on the formation of the photoholes in the valence band.

We believed also the first wave (hereby referred to as region A) of the photocurrent-potential curve of n-MoS_2 in I^- solutions was due to the photo-oxidation of I^- ions, and was controlled by the diffusion of I^- ions from the solution to the electrode surface, and the second wave at more anodic potential (region B) was due to both the photo-oxidation of I^- ions and the photocorrosion of the electrode material, and would be dependent on the formation of the photogenerated holes in the valence band. To test our hypothesis, we studied the dependence of photocurrents on both the rotation speed and the illumination intensity. Figure 2 shows the photocurrent at region A was proportional to the square root of the rotation speed, this indicated that the rate-determining step was the diffusion of I^- from the solution to the electrode surface. Photocurrent at region B was found to be linearly dependent on the light intensity, irrespective of the I^- concentrations (Fig. 3(B)), this showed that the magnitude of the photocurrent at region B was determined by the amount of the photogenerated holes.

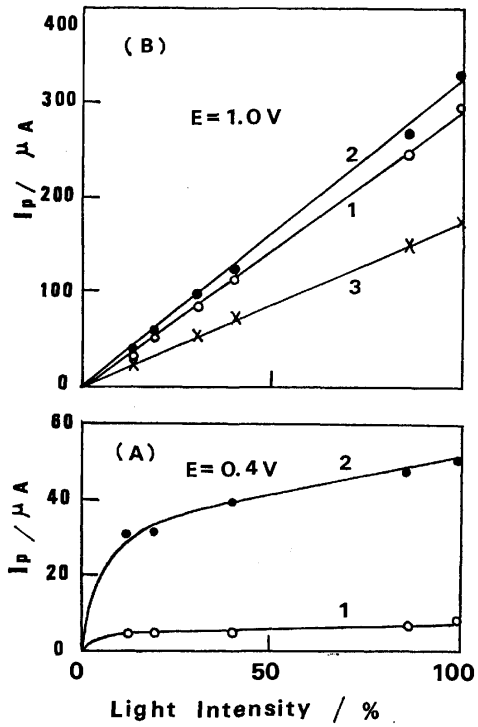

Fig. 3. Dependence of the photocurrent at n-MoS_2 electrode on the illumination intensity in 0.2 M Na_2SO_4 solutions with different concentrations of I^- ions at two different potentials. The rotation speed was 0 min^{-1}.
1: 10^{-3} M, 2: 10^{-2} M, 3: 10^{-1} M.

At region A, when I^- concentration was low ($<10^{-2}$ M) such that the duffusion process of I^- ions was important, the photocurrent was nearly independent of the light intensity (Fig. 3(A)).

Figure 4 shows the current-potential curves of Pt ring/n-MoS_2 disk RRDE. The potential of Pt ring (E_R) was held at 0 V *vs.* SCE to detect the current (I_R) due to the reduction of I_2 which was produced at the MoS_2 disk electrode. In the absence of I^-, no ring current could be observed (upper portion of Fig. 4, curve 1). This indicated that the current at the MoS_2 disk in the presence or absence of light (lower portion of Fig. 4, curve 1) was due to the dissolution of the MoS_2 electrode. Ring current was observed in the presence of I^- ions. At low E_D (<0.4 V), $-I_R/I_D$ was 0.2 which was the same as the collection efficiency of the present RRDE assembly. This meant at $E_D<0.4$ V, all of the photogenerated holes at the MoS_2 disk was totally consumed by the I^- ions, that is, the MoS_2 photoanode was 100% stabilized. At more anodic potentials, $-I_R/I_D$ was smaller than 0.2, and was significantly less than 0.2 at a lower I^- concentration. The ratio $-I_R/I_D$ describes the competitive hole capture by the I^- ions in solution (the stabilization process) and hole capture by surface atoms of the MoS_2 electrode (the corrosion process).

Figure 5 shows the ratio of the competitive hole capture by I^- ions to that by MoS_2 as a function of the I^- concentration. At $E=0.3$ V (in the region A referred to above), the ratio was 1 and was independent of the I^- concentration, since the photocurrent

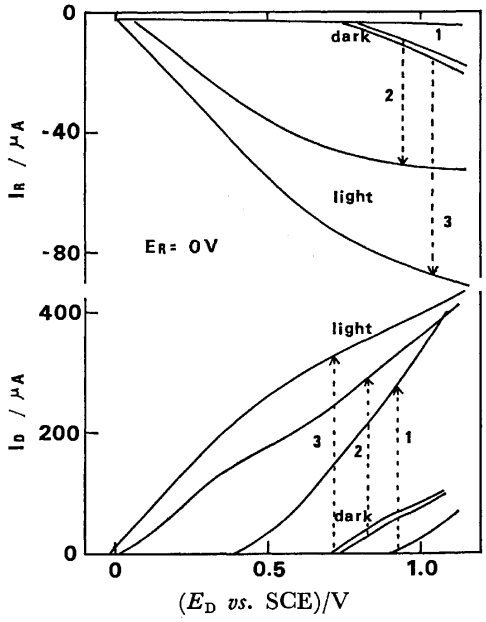

Fig. 4. I_R-E_D, I_D-E_D curves of Pt ring/n-MoS_2 disk electrode in 0.2 M Na_2SO_4 solutions with different concentrations of I^- ions. The rotation speed was 1000 min^{-1} and the scan rate was 30 s/V.
1: 0 M, 2: 2×10^{-3} M, 3: 10^{-2} M.

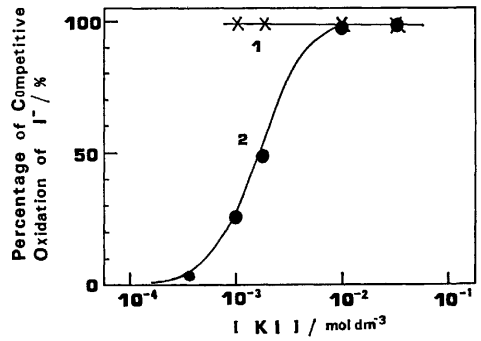

Fig. 5. Dependence of percentage of competitive reaction at n-MoS_2 electrode on concentration of I^- at two different potentials, and at constant light intensity, and rotation speed.
1: E=0.3 V, 2: 1.2 V.

was entirely due to the photo-oxidation of I^-. At more anodic potential (1.2 V), the photocurrent was due to the competitive hole capture by I^- and hole capture by MoS_2, thus the higher the I^- concentration, the larger was the ratio. Hole capture by the I^- ions was 100% when the I^- concentration was 10^{-2} M or higher.

The specific effect of I^- at the MoS_2 photoanode is similar to that of S^{2-} at the CdS photoanode.[24,32] The stabilization of the photoanode in I^- solutions may be attributed to the strong specific adsorption of I^- on the MoS_2 electrode surface, and the adsorption sites may act as surface states which participated in charge transfer.

Competitive Oxidations of Various Reducing Agents at n-MoS_2 Electrode. We reported earlier that, in the case of CdS,[24] ZnO,[31] and TiO_2,[32] the ratio of the competitive reaction increased as the redox

potential of the reducing agent became more negative. Figure 6(A) shows the ratios of the competitive reactions of various reducing agents at the n-MoS_2 electrode as a function of their redox potentials, as compared to that at the CdS electrode (Fig. 6(B)). The oxidation potentials E_D of MoS_2 and CdS were derived from the thermodynamic data. The ratios of the competitive oxidation of the various reducing agents except I^- at the n-MoS_2 electrode were very small, indicating that these reducing agents were not suitable for the stabilization of the MoS_2 photoanode. Additionally, the competitive oxidations of the reducing agents were not clearly dependent on their redox potentials.

Photoanodic Reactions at n-MoS_2 Electrode in a Non-aqueous Solvent. We also investigated the photo-

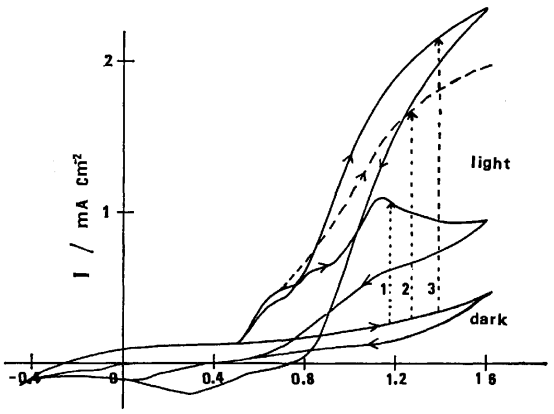

Fig. 7. *I-E* curves of n-MoS_2 in CH_3CN+0.1 M $NaClO_4$. The sweep rate was 10 s/V.
1: 1.4×10^{-3} M $I^-+1.4\times10^{-3}$ M H_2Q, no stirring,
2: 1.4×10^{-3} M $I^-+1.4\times10^{-3}$ M H_2Q, stirring, 3: 1.4×10^{-3} M I^-+10^{-2} M H_2Q, no stirring.

anodic reactions at the n-MoS_2 electrode in a non-aqueous solvent CH_3CN containing I^- and H_2Q (hydroquinine). In the presence of equal concentrations of I^- and H_2Q, some peaks could be observed (Fig. 7, curve 1), which were not seen in CH_3CN containing I^- and H_2Q individually. When excess H_2Q was added, the photocurrent increased (curve 3). These results indicated that both I^- and H_2Q contributed equally to the photoanodic reactions at MoS_2 in CH_3CN. This is in a marked contrast to the results in an aqueous electrolyte (Fig. 6(A)). Schneemeyer and Wrighton[17] also reported that Cl^- ions could be efficiently photo-oxidized at n-MoS_2 in CH_3CN.

Photoelectrochemical Reactions at p-MoS_2 Electrode. We confirmed that the cathodic reaction at the p-MoS_2 electrode was the following process,

$$2H^+ + 2e^- \longrightarrow H_2, \quad (4)$$

and the onset of the photocurrent was shifted to a more negative potential with an increase in the pH. This was because the hydrogen overvoltage was heightened, *i.e.*, $E_{onset}=-0.2$ V *vs.* SCE(in 0.5 M H_2SO_4), -0.5 V (in 0.1 M KCl), and -0.8 V (in 1 M NaOH). The onset of the photocurrent was more negative than the flatband potential. This indicates that the recombination of photogenerated electron-hole pair occurs at the small cathodic band bending.

Figure 8 shows the current-potential curves of Pt ring/p-MoS_2 disk RRDE with Fe^{3+} as the oxidizing agent. The Pt ring potential (E_R) was held at 1.0 V *vs.* SCE to detect the oxidation current (I_R) of the Fe^{2+} ions produced at the MoS_2 disk electrode. In the absence of Fe^{3+} ions, no ring current could be observed (lower portion of Fig. 8, curve 1). This indicated that the current at the MoS_2 disk in the presence or absence of light (upper portion of Fig. 8, curve 1) was due to the process (4). In the presence of the Fe^{3+} ions, the onset of the photocurrent was shifted to a more positive potential and a ring current could be observed (curves 2 and 3). Shifts in the onset of the photocurrent could also be observed with the addition of other oxidizing agents such as quinone and $Fe(CN)_6^{3-}$. This phenomenon seems to be the

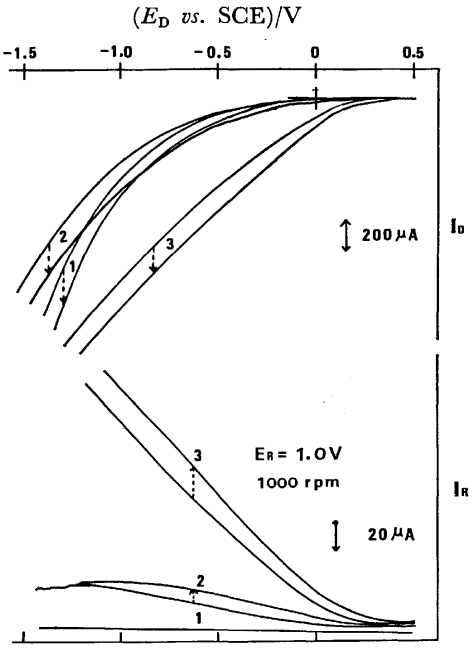

Fig. 8. I_R-E_D, I_D-E_D curves of Pt ring/p-MoS_2 disk electrode in 0.5 M H_2SO_4 solutions with different concentrations of Fe^{3+} ions. The rotation speed was 1000 min^{-1}.
1: 0 M, 2: 5×10^{-3} M, 3: 10^{-1} M.

same as in the case of n-MoS_2 electrode in I^- solutions. However, in the case of p-MoS_2, its flatband potential is not changed by the addition of oxidizing agents, for the photocurrent at the potential more positive than −0.2 V may be resulted from the process that the electron transfer from MoS_2 to Fe^{3+} is faster than the recombination of an electron-hole pair.

Figure 9 shows the ratio of the competitive electron capture by the Fe^{3+} ions to that by the H^+ ions as a function of the Fe^{3+} concentration. At E=0 V, the ratio was 1 and was independent of the Fe^{3+} concentration. This revealed that the photocurrent at 0 V was entirely due to the reduction of Fe^{3+} ions. At more cathodic potential (−0.8 V), the photocurrent was due to the competitive reduction of the Fe^{3+} ions and the hydrogen formation reaction, thus the higher the Fe^{3+} concentration, the more the hydrogen formation reaction was suppressed, and thus the larger was the ratio. Again, electron capture by the Fe^{3+} ions was 100% when the Fe^{3+} concentration was 10^{-2} or higher.

Conclusion

The MoS_2 photoanode was remarkably stabilized in I^- solutions. This effect may be attributed to the specific adsorption of I^- ions on the electrode surface, and the adsorption sites may act as surface states which participated in charge transfer. The ratios of the competitive oxidation of other reducing agents studied were very small (less than 20% hole capture), and hence they were not suitable for the stabilization of the MoS_2 photoanode. The competitive oxidations of the reducing agents were not clearly dependent on their redox potential. This was in a sharp contrast

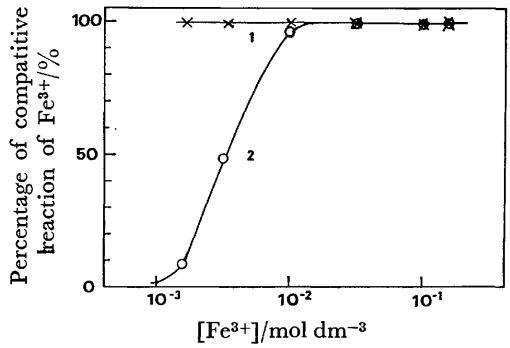

Fig. 9. Dependence of the percentage of competitive reaction of Fe^{3+} at the p-MoS_2 electrode on Fe^{3+} at two different potentials, and at constant light intensity and rotation speed.
1: E=0 V, 2: E=−0.8 V.

to that at a CdS photoanode. The cathodic reaction at the p-MoS_2 electrode was the hydrogen formation process. The onset of the photocurrent shifted in the presence of oxidizing agents. This fact may be resulted from the process that the electron transfer across the semiconductor-solution interface is faster than the recombination of an electron-hole pair.

Analysis of the Excess Gibbs Energies of Binary Mixtures Using Non-randomness Factors Determined from Excess Volume Data

Masanao KATO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received March 28, 1981)

An analytical equation for the excess Gibbs energies of mixtures was derived on the basis of the non-random two-liquid model, which was applied to the derivation of an analytical equation for excess volumes proposed by the present author. The derived equation involves new adjustable parameters of intermolecular interaction. The validity of the equation was examined for 13 binary mixtures by using the non-randomness factors determined from the excess volume data, and it was shown that the calculated excess Gibbs energies were in good agreement with the observed values. The sequence of the values of the interaction parameters seems to be reasonable.

Recently, the present author found that the excess volumes of multi-component mixtures could be analyzed by an equation containing non-randomness factors as adjustable parameters, and showed that sufficient agreements were obtained between the calculated and the observed values of the excess volumes of binary and ternary mixtures.[1,2] The non randomness factors can be considered to represent the non-ideality of the molecular rearrangement of the component molecules in the vicinity of a given molecule. On the other hand, the excess Gibbs energies of multi-component mixtures have also been analyzed by an equation containing the parameters analogous to the non-randomness factor.[3–6] These parameters have been assessed to be very useful in representing the excess Gibbs energies of mixtures and widely utilized in chemical engineering. As the parameter in the equation for excess Gibbs energy is considered to have physical meanings similar to that for the excess volume, it is expected that the non-randomness factors determined from the excess-volume data can be applied to represent the excess Gibbs energies of the mixtures.

From the considerations above, the purpose of this study is to examine the applicability of the non-randomness factors in the excess-volume equation to the representation of excess Gibbs energies. The non-randomness factors at 298.15 K were determined from the excess-volume data previously reported.[1,2] On the other hand, the data for the excess Gibbs energies at the same temperature are not utilized. As the temperature dependence of the non-randomness factors was not entirely well-defined, the excess Gibbs energies at 298.15 K were measured from the vapor pressures of the mixtures.

Experimental

All the materials were guaranteed reagents of commercial origin and were purified by the distillation of 80 theoretical plates. The middle portions were collected and provided for measurements. The observed values of density, vapor pressure, and refractive index of the purified reagents were in good agreement with the literature values.[7,8]

The vapor-pressure measurements were carried out at 298.15±0.001 K by means of an apparatus constructed at our laboratory.[9,10]

The compositions of the liquid and the vapor phases were individually determined from refractive indexes measured by means of an Abbe refractometer for the methanol+benzene, ethanol+*m*-xylene, ethanol+benzene, ethanol+cyclohexane, acetone+cyclohexane, and benzene+cyclohexane mixtures. The compositions of the 1,2-dichloroethane+benzene and 1,2-dichloroethane+cyclohexane mixtures were determined from density measurements made by means of a pycnometer, while those of ethanol+acetone mixtures were determined from their ultra-violet spectra. The accuracy was ±0.02 for the mole fractions determined from the refractive-index and density measurements, and ±0.05 for those from spectrometry.

Results and Discussion

The excess Gibbs energies, g^E/RT, were calculated from Eq. 1:

$$g^E/RT = \sum_i x_i \ln \gamma_i, \tag{1}$$

while the activity coefficient, γ_i, of the i-th component was determined from Eq. 2:

$$\ln \gamma_i = \ln \frac{py_i}{x_i p_i^*} + \frac{(B_{ii}-v_i^*)(p-p_i^*)}{RT} + \frac{(1-y_i)p\delta}{RT}, \tag{2}$$

where

$$\delta = 2B_{ij} - B_{ii} - B_{jj}. \tag{3}$$

In Eqs. 1 to 3, x_i denotes the mole fraction of the liquid phase; R, the gas constant; T, the temperature; p, the total pressure; y_i, the mole fraction of the vapor phase; p_i^*, the vapor pressure of the pure i component; B_{ii}, the virial coefficient of the i component; B_{ij}, the cross-virial coefficient between the i and j components, and v_i^*, the molar volume of the pure i component. The virial coefficients were calculated from the empirical equation reported by O'Connell and Prausnitz.[11]

The observed vapor pressures of mixtures and the excess Gibbs energies are summarized in Table 1 as a function of the liquid-phase composition. The excess Gibbs energy for each mixtures was fitted with Eq. 4 according to the ordinary method:

$$g^E/RT = x_1x_2 \sum_{r=0}^{4} A_r(x_1-x_2)^r, \tag{4}$$

where x_1 and x_2 are the mole fractions of the first and second components respectively. The values of the A_r coefficients, as determined by the least-squares procedure, are summarized in Table 2, along with the values of σ_g, the standard deviation between the experimental and calculated values of g^E/RT.

Derivation of an Equation for the Excess Gibbs Energy. An equation for the excess Gibbs energy including the non-randomness factor is derived under two restrictions. The first restriction is to use the same model of mixture as that employed in the derivation of the equation for excess volumes,[1,2] that is, the non-random two-liquid (NRTL) model.[4] The second is that the equation for the excess volume must be obtained by the differentiation of the equation for the excess Gibbs energy with respect to the pressure.

The interaction free energy of the i-th component

with the j-th component is denoted as g_{ij} (equals to g_{ji}). The local mole fraction of the j-th component in the vicinity of a given molecule of the i-th component is denoted as x_{ji}. Provided that the non-randomness factor, Λ_{ij}, is defined as a function of the local mole fractions, x_{ii} and x_{ji}, and the overall mole fractions of the mixture, x_i and x_j, as follows:

$$\frac{x_{ji}}{x_{ii}} = \Lambda_{ji}\frac{x_j}{x_i}. \tag{5}$$

We obtain the equation for the excess Gibbs energies of multi-component mixtures by means of a procedure similar to the derivation of the equation for the excess volume of multi-component mixtures:[2]

$$g^E/RT = \sum_{i=1}^{n} x_i\left[\frac{\sum_j (g_{ji}-g_{ii})x_j\Lambda_{ji}}{RT\sum_k x_k\Lambda_{ki}}\right], \tag{6}$$

$$(\Lambda_{ii}=\Lambda_{jj}=1)$$

where n denotes the number of components.

Equation 6 is in the same form as the NRTL equation well-known in chemical engineering.[4] In the NRTL equation, the non-randomness factor is defined as a function of the interaction free energy. It should be noticed that the derivation descrived above leads to the same equation. It is considered that, in the NRTL equation, the number of parameters is reduced by regarding the non-randomness factor as a function of the interaction free energy. When the Boltzmann distribution is assumed to hold in the local composition, the local mole fraction should be represented as a function of the interaction potential between molecules, as has been described by Guggenheim in his text.[12] Based on his description, the non-randomness factor is defined as follows:

$$\Lambda_{ij} = \exp\left(-\frac{w_{ij}-w_{jj}}{zRT}\right), \tag{7}$$

where w_{ij} is the interaction potential between the i and j components, and z, the coordination number of the pseudo-lattice of mixture. If both the interaction potential and the coordination number are assumed to be independent of the pressure and the temperature, the equation for the excess volume is obtained by differentiating Eq. 6 with respect to the pressure:[2]

$$v^E = \sum_{i=1}^{n} x_i\left[\frac{\sum_j (v_{ji}-v_{ii})x_j\Lambda_{ji}}{\sum_k x_k\Lambda_{ki}}\right]. \tag{8}$$

Comparison of the Calculated g^E Values with Those Observed. The values of the non-randomness factors were determined from the excess volume data,[1,2] as the values of the non-randomness factors could be obtained more accurately. The $g_{ij}-g_{jj}$ values were determined from the excess-Gibbs-energy data by an algebraic calculation of Eq. 6. The values thus obtained are listed in Table 3. The observed and the

calculated excess Gibbs energies were in good agreement, as is shown in Fig. 1.

In Fig. 2, a qualitative diagram of the interaction free-energy parameters is shown. This diagram was constructed from the values of $g_{ij}-g_{jj}$ given in Table 3. The component on the left-hand side of the diagram was established as a standard component; next, the interaction free-energy level between unlike components was calculated from the $g_{ij}-g_{jj}$ values, and finally that for the pure state of the second component was calculated from the $g_{ji}-g_{ii}$ value, where g_{ji} equals g_{ij}. In the mixtures containing ethanol, the

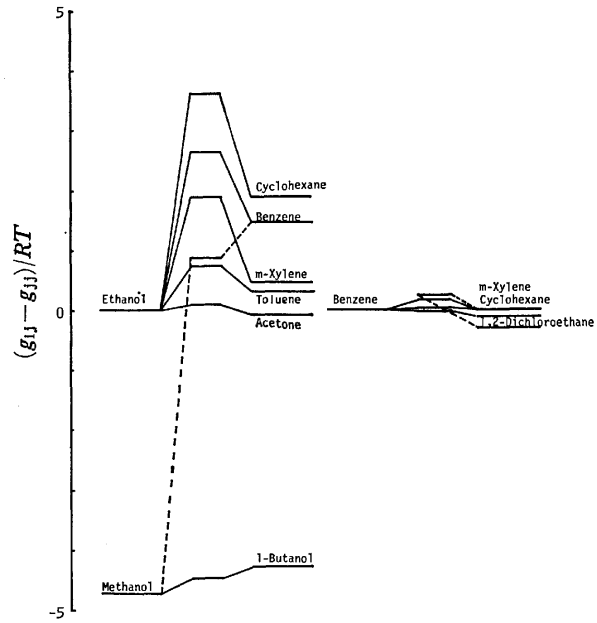

Fig. 2. The interaction free energy diagram in some binary mixtures at 298.15 K.

sequence of the interaction free-energy parameters was as follows: ethanol–acetone≈ethanol–ethanol<ethanol–toluene<ethanol–*m*-xylene<ethanol–benzene<ethanol–cyclohexane. It is likely that the hydrogen-bonding interaction or associative interaction between ethanol and acetone forms the lowest energy level among the mixtures selected. The negative values of the interaction potential parameters, $w_{ij}-w_{jj}$, of the ethanol+acetone mixture, which were calculated from the non-randomness factors by using Eq. 7, support the associative interaction. The interaction between ethanol and cyclohexane is the highest energy level, and the interaction is expected to be accompanied by the destruction of the hydrogen bond of ethanol. Ethanol is considered to interact with benzene through OH-π interaction. Toluene and *m*-xylene are expected interact slightly more strong with ethanol than benzene is, because they are slightly polar molecules (the dipole moment of toluene is 0.31 Debye, and that of *m*-xylene is 0.30 Debye, at 20 to 60 °C.[7]).

For methanol mixtures, the interaction free-energy level of methanol with benzene is much higher than that with 1-butanol. The interaction of methanol with 1-butanol is a result of the hydrogen bonding, and that with benzene is the OH-π interaction.

In the benzene+*m*-xylene, benzene+cyclohexane, 1,2-dichloroethane+benzene, and 1,2-dichloroethane+cyclohexane mixtures, the interaction free-energy parameters are relatively smaller than in ethanol mixtures. The interaction in 1,2-dichloroethane+cyclohexane is indicated by a broken line on the right-hand side in Fig. 2. Particularly, the excess Gibbs energies of the benzene+*m*-xylene and 1,2-dichloroethane+benzene mixtures are nearly zero; that is, they are almost ideal mixtures. The interaction free-energy parameters of these benzene mixtures are very small. However, the excess-volume curves of these mixtures show appreciable positive deviations from

ideal behavior. The v^E values of equimolar mixtures are 0.3 $cm^3 mol^{-1}$ for the benzene+*m*-xylene mixture and 0.2 $cm^3 mol^{-1}$ for the 1,2-dichloroethane+benzene mixture.[2] These results seem to suggest that the volumes of central molecules surrounded by different component molecules differ from those of molecules surrounded by the same component molecules, in spite of almost the same magnitude of interaction free-energy parameters between like and unlike molecular pairs.

Interaction free-energy diagrams of the non-polar or slightly polar mixtures show small free-energy gaps, as is shown in Fig. 2. When the ethanol-ethanol interaction is chosen as the standard energy level, however, a different feature appears. The interaction of ethanol molecules in pure ethanol differs remarkably from that in mixtures with non-polar or slightly polar molecules. As has been described above, the interaction of ethanol with a non-polar molecule is accompanied by a destruction of the hydrogen bonding. On the other hand, the interaction in mixtures of two non-polar substances, such as the benzene+*m*-xylene mixture, is considered not to differ essentially between pure and mixed states. It may be deduced from the above reason that the combination of the diagrams of the hydrogen bonding and the non-polar mixtures gives an inconsistent feature of interaction free energy. This fact may show the limitation of the applicability of Eq. 6.

A Reinvestigation of Small-angle Electron Scattering by CS_2 and CCl_4 Molecules†

Makoto NAGASHIMA,†† Shigehiro KONAKA, and Masao KIMURA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 30, 1981)

A small-angle electron-diffraction unit (*Jpn. J. Appl. Phys.*, **11**, 1199 (1972)) has been improved by enlarging the scattering chamber and installing a new nozzle system and a better counting unit. The intensities of 50 keV electrons scattered by CS_2 and CCl_4 molecules have been measured with a $\approx 1\%$ precision in the s-range from 1 to 11.5 $Å^{-1}$. Theoretical intensities have been calculated for the independent-atom model by taking into account the intramolecular double-scattering effect, and those intensities have been compared with the experimental intensities. The oscillatory feature appearing in the difference function, $\Delta\sigma(s)=s^4(I_{\text{expt}}-I_{\text{IAM}})$, of CCl_4 has been ascribed mainly to the deformation of the one-electron density in chlorine atoms by chemical binding.

A small-angle electron-diffraction unit equipped with a scintillation counting device was used by the present authors and their collaborators to measure the total (elastic plus inelastic) intensities of electrons scattered by gas molecules.[1–3] An observed decrease in the total scattered intensity from the theoretical value for the independent-atom model (IAM) was interpreted as the effect of chemical-bond formation. However, the qualities of the above data were limited mainly by the counting loss due to the poor resolving time of the counting system and by the uncertainties associated with the correction for the delocalization of the sample gas. The purpose of the present study is to offer refined data on the total scattered intensities for CS_2 and CCl_4 by improving these weaknesses.

Intramolecular multiple scattering is known to decrease the small-angle intensities and to produce a characteristic oscillation depending on the molecular geometry.[4–9] In the previous studies of CS_2 and CCl_4,[2] the effect of the intramolecular multiple scattering was concluded to be negligible by calculating the two-atom double-scattering cross-section for CCl_4 using the formula proposed by Bonham and Peixoto[4] and by comparing it with the single-scattering cross-section. Since then, the theory of multiple scattering has further advanced.[6,8,9] At the present stage, therefore, it seems necessary to reexamine the validity of the conclusion that multiple scattering was negligible by utilizing recent theories. In the present study, the multiple-scattering cross-sections have been calculated for CS_2 and CCl_4 and incuded in the IAM intensities, which were then used for extracting the net chemical-binding effect from the experimental data.

Improvements of the Apparatus

The main improvements are as follows: (1) the enlargement of the scattering chamber for rarefying delocalized sample gas near the scattering center, (2) the employment of a new nozzle system, and (3) the introduction of a counting system with a shorter resolving time.

Figure 1 shows a cross-sectional view of the sample chamber. The inner diameter of the chamber, 347 mm, is about five times as large as that of the old one. The two camera lengths, 1168 and 815 mm, cover a wider range of scattering angles. A cylindrical mu-metal case placed close to the inside wall of the whole chamber shields the inside from the terrestrial magnetism. The residual magnetic field inside the case is less than 10 mG.

The construction of the nozzle system is shown in Fig. 2. The nozzle is made of non-magnetic stainless steel (SUS304). The inner and outer diameters are 0.2 and 0.6 mm respectively, and the length is 10 mm. The nozzle can be shifted in a plane perpen-

† Throughout this paper 1 Å=10^{-10} m and 1 Torr≈133.322 Pa are used.

†† Present address: Japan IBM Co., Ltd., Kusatsu 525.

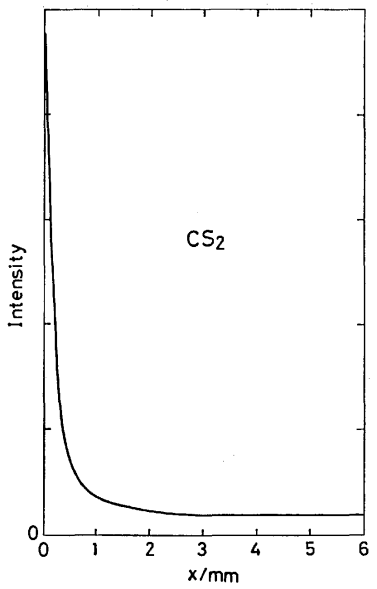

Fig. 3. Plot of the intensity of electrons scattered by carbon disulfide *versus* the nozzle position, x. The nozzle was moved along the x-direction shown in Fig. 2. The ordinate scale is arbitrary.

dicular to the incident electron beam. The interval between the nozzle tip and the incident electron beam was chosen to be about 0.5 mm. When the nozzle tip approaches the beam, the ratio of the background scattering to the main one decreases, but the reflection of scattered electrons by the nozzle increases.

Figure 3 shows the change in the intensity of electrons scattered by the sample gas when the nozzle is shifted on a horizontal plane in the direction perpendicular to the incident electron beam. Scarcely any change was found when the nozzle was placed more than 3 mm from the incident electron beam. In order to exclude a contribution corresponding to the tail of this curve, the background scattering was measured by shifting the nozzle by 5 mm and was subtracted from the scattering measured with the nozzle placed at its original position. The proportion of the background scattering to the total one varied with the molecular species as well as with the sample pressure. In the present measurement for CCl_4, the ratio was about 5% at s-values greater than 5 $Å^{-1}$, but it increased gradually with a decrease in the s-values, rising to 14—18% at $s=1$ $Å^{-1}$.

Previously, an extra nozzle for the background measurement was placed between the nozzle and the detector, about 30 cm from the nozzle and close to the wall of the diffraction chamber. With this arrangement, however, the distribution of gas injected from the extra nozzle will not reproduce successfully that of gas in the sample measurement, particularly in the neighborhood of the nozzle. In fact, systematic discrepancies of about 3% or more had previously been observed between the scattered intensities measured on both sides of the primary electron beam.[2] In the refined data, such discrepancies were reduced to about 1% or less and had no systematic feature. This refinement was achieved by enlarging the scattering chamber and by using the new nozzle system. Thus, the background correction could be made more accurately than in the previous study, and consequently, more reliable data were obtained.

The old counting system used for the detector was replaced by a new one composed of a preamplifier (ORTEC 9301), a pulse-height analyzer (9302), and a counter (770). This replacement improved the resolving time of the counting system from 3.6 μs to about 10 ns and made the statistical error in the present study one order of magnitude lower than in the previous study. After all, the limits of error for the final data could be reduced to about one-third of the estimated errors in the previous study.**

Measurement of Scattered Intensities

The ultimate vacuum pressure was about 3×10^{-6} Torr, while the pressure during the measurement on the sample gas was 1×10^{-5} Torr. By using gold foil, the product of the camera length and the electron wavelength*** and the central position of the electron beam were determined with precisions of 0.05% and 0.02 mm respectively. No change in the position or wavelength of the electron beam was detected during a continuous measurement for four hours. The beam current was about 0.05 μA, and it changed monotonously by 13% during four hours. The accelerating voltage was about 50 kV. The camera length was 815 mm, and the range of s covered by the present measurement was from 1 to 11.5 $Å^{-1}$. The room temperature was about 20 °C. Spectroscopic-grade reagents of the Merck Co., with the minimum assays of 99.9 and 99.7% for CS_2 and CCl_4 respectively, were used without further purification.

The counting rate in the present measurement was about 50 times that in the previous measurement. The counting-loss correction was made by using the following equation:

$$n = n'(1+n'\tau),$$

where n' is the apparent counting rate and τ is the resolving time.

The scannings were performed first for the sample gas. After the last data on the sample gas, $I_G^M(s_0)$, had been taken at the turning point s_0, the nozzle was shifted quickly by 5 mm to observe $I_B^M(s_0)$, and then the background measurement was performed. The scattered intensities were calculated as follows:

$$I_{\text{expt}}(s) = C\left\{\frac{I_G^D(s)}{I_G^M(s)}I_G^M(s_0) - \frac{I_B^D(s)}{I_B^M(s)}I_B^M(s_0)\right\}, \quad (1)$$

where the superscripts D and M denote the intensities measured by the detector and the monitor respectively, and where the first and second terms in the brackets are the intensities observed on the sample and the background respectively. The normalization constant, C, was determined by comparison with the theoretical intensities to be described in the next section.

** The errors listed in Table 1 of Ref. 2 were the standard errors, not the limits of error.

*** The lattice constant of 4.078 Å was used.

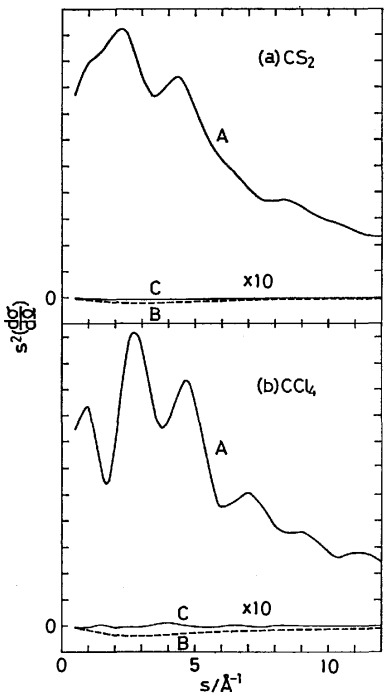

Fig. 4. Comparison of single and double scattering terms. Curves A, B, and C show $s^2\left(\frac{d\sigma}{d\Omega}\right)_{MB}$, $s^2\left(\frac{d\sigma}{d\Omega}\right)_{12}$, and $s^2\left(\frac{d\sigma}{d\Omega}\right)_{123}$, respectively. The ordinate scale is arbitrary.

Calculation of the IAM Intensities

According to the Glauber approximation,[5,6] the first-order multiple-scattering correction of the elastically scattered intensity is given by the sum of $\left(\frac{d\sigma}{d\Omega}\right)_{12}$ and $\left(\frac{d\sigma}{d\Omega}\right)_{123}$, which are two-atom and three-atom double-scattering terms respectively.

The three-atom double-scattering term was calculated by the use of the analytical expression given by Bartell.[6] It has been comfirmed by Kohl and Arvedson[8,9] that Bartell's expression reproduces very well the result of an exact numerical calculation for $s<\approx 20$ Å^{-1}. The two-atom double-scattering term was calculated according to the following formula:[10]

$$\left(\frac{d\sigma}{d\Omega}\right)_{12} = -\mathrm{Im}\sum_{i\neq j}\sum \frac{1}{ka_{ij}^2}[|f_i(s)|^2 f_j(0) + |f_j(s)|^2 f_i(0)] + \mathrm{Im}\sum_{i\neq j}\sum \frac{1}{ka_{ij}^4}[\alpha_{ij}(s) + \alpha_{ji}(s)], \quad (2)$$

where a_{ij} is the distance between i and j atoms; k, the propagation number $(2\pi/\lambda)$ of the incident electrons; $f_i(s)$, the complex scattering factor, and

$$\alpha_{ij}(s) = f_i^*(s)\left[f_j(0)\left(f_i'(s)\frac{\cos\theta}{s} + f_i''(s)\frac{\cos^2(\theta/2)}{s}\right) + 2f_i(s)\lim_{s\to 0}\frac{f_j'(s)}{2s}\right]. \quad (3)$$

The two terms in the first brackets on the right-hand side of Eq. 2 are the formulas given by Yates[5] and by Bonham and Peixoto[4] on the basis of the Glauber and second Born approximations respectively, while the terms in the second brackets are corrections derived on the basis of the second Born approximation.[10] The contribution of these correction terms to $(d\sigma/d\Omega)_{12}$ was less than 5% for CS_2 and CCl_4. The numerical values were obtained by using the scattering factors[11] based on the RHFS wave functions, the structural parameters[12,13] and the parallel and perpendicular mean amplitudes[12,14] taken from the literature. Figure 4 compares the results multiplied by s^2 with $s^2\left(\frac{d\sigma}{d\Omega}\right)_{MB}$, which is the total intensity given by the modified first Born approximation. The $\left(\frac{d\sigma}{d\Omega}\right)_{MB}$ is written as:

$$\left(\frac{d\sigma}{d\Omega}\right)_{MB} = \sum_i [|f_i(s)|^2 + (2/as^2)^2 S_i] + 2\mathrm{Re}\sum_{i<j}\sum f_i^*(s) f_j(s)\frac{\sin(sa_{ij})}{sa_{ij}}\exp\left(-\frac{1}{2}s^2 l_{ij}^2\right), \quad (4)$$

where a is the relativistic Bohr radius, and l_{ij}, the mean amplitude. The inelastic scattering factors, S_i, were taken from the literature.[11] The anharmonicity correction was omitted because it was negligible in

a) Normalized to I_{IAM} at s=9—11.5. b) The symbol ε denotes the estimated limits of error of I_{exptl}. The relative errors, ε/I_{exptl}, are shown in percentage units.

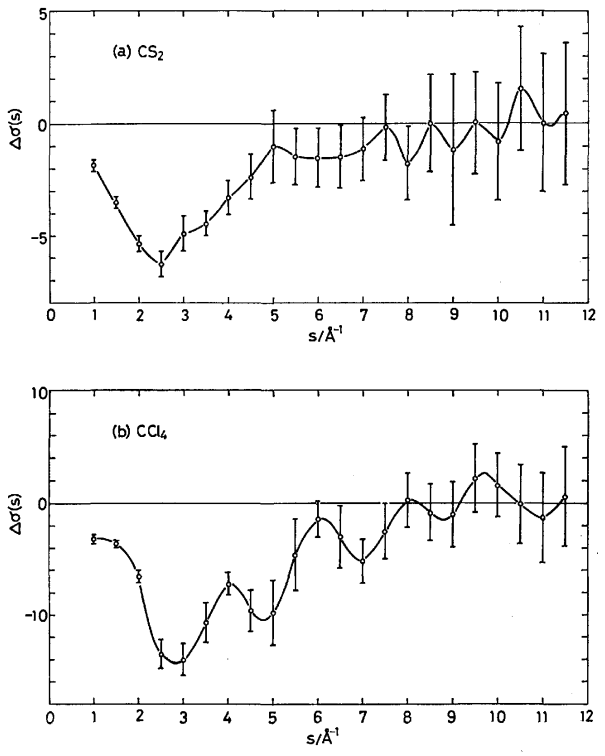

Fig. 6. Plots of $\Delta\sigma(s)$ for CS_2 (a) and CCl_4 (b). The vertical bar shows the limit of experimental error.

the s-range covered by the present work. As may be seen in Fig. 4, the double-scattering terms are insignificant for CS_2 and CCl_4, although such terms cannot be ignored for every molecule. In the present study, the I_{IAM} values defined by $(a/2)^2[(d\sigma/d\Omega)_{MB}+(d\sigma/d\Omega)_{12}+(d\sigma/d\Omega)_{123}]$ were employed; they are listed in Table 1.

Results and Discussion

The experimental intensites were normalized to I_{IAM} at s-values from 9 to 12 Å^{-1}. Four runs of measurements were performed for each sample. The experimental errors were estimated from the reproducibility of the data and the uncertainties in the s-values. Table 1 lists the experimental intensities, I_{exptl}, and the estimated limits of error. The values of s^2I_{exptl} are compared with those of s^2I_{IAM} in Fig. 5.

Figure 6 shows the $\Delta\sigma(s)$ defined by $s^4(I_{exptl}-I_{IAM})$. As in the previous work,[2] a significant oscillation is found in the $\Delta\sigma$ of CCl_4, while the oscillation in that of CS_2 is within the range of experimental error. As has been shown elsewhere,[15] the following integral relationship holds between the $\Delta\sigma$ and one-electron and two-electron deformation densities, $\Delta\rho$ and $\Delta\rho_c$.

$$\Delta j(r') = \frac{2}{\pi}\int_0^\infty ds\Delta\sigma(s)sr'\sin(sr')$$
$$= -2\sum_i(r')^2Z_i\langle\int d\Omega_{r'}\Delta\rho(\boldsymbol{r}'+\boldsymbol{r}_i)\rangle_{vlb}$$
$$+ (r')^2\langle\int d\Omega_{r'}\Delta\rho_c(\boldsymbol{r}')\rangle_{vlb}. \quad (5)$$

Here, the notations follow those given in Ref. 15. Errors in $\Delta j(r')$ were also calculated from the ex-

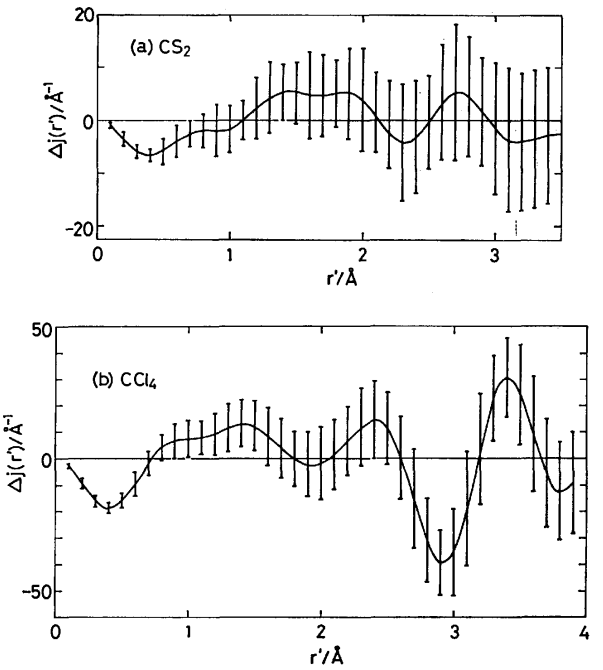

Fig. 7. Plot of $\Delta j(r')$ for CS_2 (a) and CCl_4 (b). The vertical bar corresponds to the limit of experimental error of $\Delta\sigma(s)$.

perimental errors by assuming the propagation-law of error,**** The contribution to the integral from the s-region beyond 9 $Å^{-1}$ was neglected. The results are shown in Fig. 7. The second term of Eq. 5 can be expected to be smaller than the first one.[16,17] The significant negative portion in the $\Delta j(r')$ of CS_2 at r' values of less than 1 Å corresponds to an increase in the one-electron density in the bonding region. No other conclusion can be drawn for CS_2 because of the large experimental errors. The $\Delta j(r')$ of CCl_4 has a significant valley at $\approx$2.9 Å. The position of the minimum is consistent with the Cl–Cl distance, 2.885 Å, within the range of experimental error. This valley can be ascribed to an increase in the one-electron density around chlorine atoms. This is consistent with the large electronegativity of chlorine. The other significant valley found in the small r'-region is due to an increase in the one-electron density in the C–Cl bonds. The significant positive portion at $\approx$3.4 Å can be related to the change in the distribution of the lone-pair electrons of chlorine.

In a previous paper,[2] we analysed the experimental results by the use of Tavard's energy relation. Since the relativistic atomic wave functions are used in the present study, Tavard's relation can be written as:

$$\Delta E + E_1 = E_b + E^*_{corr}, \quad (6)$$

where

$$\Delta E = \int_0^\infty \Delta\sigma(s)ds.$$

In this equation, E_b is the binding energy of the molecule, E_1 is one-half of the lowering of the potential energy of the IAM molecule from that of the separated atoms, and E^*_{corr} denotes the sum of the correlation energies for all the atoms without the contribution from the K-shell. The exclusion of the K-shell contribution is necessary because of the normalization at comparatively small s-values.[2] The contribution to the integral from the s-region beyond 9 $Å^{-1}$ was assumed to be zero. The values of $\Delta E+E_1$ are -2.0 ± 0.6 and -4.5 ± 1.4 au for CS_2 and CCl_4 respectively. These values are in good agreement with the previously reported values, -2.0 ± 0.6 and -4.1 ± 1.5 au.[2] It should be noted that the uncertainties, ε, in the present results denote the limits of error, while those quoted in the previous paper were the estimated standard errors. The present $\Delta E+E_1$ values are consistent with the calculated values of $E_b+E^*_{corr}$, -1.69 and -3.28 au for CS_2 and CCl_4 respectively.[2]

The authors wish to thank Dr. Koichi Tamagawa and Mr. Yorihiko Sasaki for their help in the calculation and Mr. Masahiko Tanisaka and his co-workers in the Workshop of the Faculty of Science for their help in the construction of the sample chamber and the nozzle system. The numerical computations were carried out on a HITAC M180 of the Hokkaido University Computing Center.

**** The program was written by Dr. Kazuyoshi Fujita, to whom the authors' thanks are due.

The Ammonolysis of Trichloroethylene to Glycine

Masami INOUE* and Saburo ENOMOTO

Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani, Toyama 930-01

(Received April 13, 1981)

Glycine was obtained by the ammonolysis of trichloroethylene with aqueous ammonia. Various alkalines, such as alkaline metal hydroxides, carbonates, and hydrogencarbonates, accelerated the reaction; the yield of glycine was 40—70% after a 4 h reaction at 180 °C. Our results on the effect of alkalines indicate that ammonolysis proceeded sequentially *via* the formation of aminoacetonitrile. A good yield of the intermediate compound, aminoacetonitrile, was obtained by heating trichloroethylene at 70 °C with anhydrous ammonia under reaction conditions.

Glycine and its derivatives are widely used in the pharmaceutical industry as materials for drugs and food additives. In the synthesis of glycine, the ammonolysis of chloroacetic acid, the Strecker reaction, and the hydrolysis of hydantoin are performed. As the Strecker reaction involves the hydrolysis of aminoacetonitrile, several method have been developed for the synthesis of aminoacetonitrile, *e.g.*, the ammonolysis of chloroacetonitrile[1] and hydroxyacetonitrile.[2] The use of cyanides as a raw material is now considered impractical by the chemical industry because it requires the laborious removal of cyanide ions from the waste solution.

We ourselves have previously reported that tetrachloroethanes and trichloroethylene, which are commercially used nonflammable solvents, readily react with aqueous ammonia to yield glycine selectively; the yield can be increased by adding various alkalines.[3] In our continuing investigations of the mechanism of ammonolysis, we obtained aminoacetonitrile, a possible intermediate compound, in a good yield with anhydrous ammonia under mild reaction conditions. We wish now to present details of the ammonolysis of trichloroethylene and the effect of alkalines.

Experimental

Ammonolysis of Trichloroethylene with Aqueous Ammonia. A mixture consisting of 20 ml of aqueous ammonia, 1 ml (11.15 mmol) of trichloroethylene, and alkaline catalysts was placed in a stainless steel autoclave (100 ml volume; SUS 32). The autoclave was then heated under a nitrogen atmosphere(30 kg/cm^2), and the mixture was stirred magnetically. After the reaction, glycine was analyzed by means of an amino-acid analyzer(KLA-5, Hitachi, Ltd.) using a Type #2661 column (10 mm i.d., ×250 mm in length).

Ammonolysis of Trichloroethylene with Anhydrous Ammonia. A test tube (30 mm i.d., ×150 mm in length) containing 1 ml of trichloroethylene and 10 ml of liquid ammonia, trapped by cooling with liquid nitrogen, was placed into the autoclave immediately after the introduction of the materials. The autoclave was then heated at 70 °C for 20 h under the conditions described above. Then, the unreacted ammonia was evaporated at room temperature, and the reaction products were diluted with distilled water. The aminoacetonitrile thus formed was analyzed using the above amino-acid analyzer and a Type #2663 column (6 mm i.d., ×70 mm in length).

14% Aq ammonia 20 ml, N_2 30 kg/cm^2, 180 °C for 2 h.

Results and Discussion

Ammonolysis of Trichloroethylene with Aqueous Ammonia. The ammonolyses of various halogenoethanes were carried out as is shown in Table 1. Tetrachloroethanes yield glycine exclusively; from 1,1,1,2- and 1,1,2,2-tetrachloroethanes, 16.3 and 21.2% glycine were yielded respectively when they were treated at 180 °C for 2 h with 14% aqueous ammonia. The ammonolysis was similar with trichloroethylene; the glycine yield was 27.4%. The dehydrochlorination of tetrachloroethane to trichloroethylene in an aqueous ammonia solution is a known process.[4] On the basis of these observations, we examined the ammonolysis of trichloroethylene to glycine under various conditions. As is shown in Fig. 1, the glycine yield increased with an increase in the ammonia concentrations; saturation was reached at 15% aqueous ammonia. The addition of Na_2CO_3 increased the yield almost two-fold, irrespective of the ammonia concentration used. Fig. 2 shows the effect of the reaction temperature on the glycine yield. In the presence of Na_2CO_3, ammonolysis took place from 80 °C; the maximum yield (*ca.* 60%) was obtained at 180 °C for 2 h. In the absence of Na_2CO_3, the yields were poor throughout the temperature range examined. The observations that apparently all trichloroethylene was consumed upon 180 °C, 2-h heating with aqueous ammonia, and that the glycine yield was remarkably increased by the addition of Na_2CO_3 to the reaction solution, suggests the formation of a precursor of glycine.

Judging from the comparison of glycine yields from chloroacetic acid, glycinamide, and aminoacetonitrile

in the presence and absence of Na_2CO_3 in 7% aqueous ammonia, aminoacetonitrile has been thought to be the most likely intermediate compound for this reaction.[3] As is shown in Table 2, the same tendency was observed in 28% aqueous ammonia. The glycine yields from glycinamide and chloroacetic acid were strikingly higher than from trichloroethylene. On the other hand, aminoacetonitrile gave a glycine yield similar to that in the ammonolysis of trichloroethylene. In fact, the initial step is a rapid intermediate formation process; about 90% of trichloroethylene was consumed in a reaction at 180 °C for 30 min in 28% aqueous ammonia. However, from trichloroethylene, we obtained glycine in a 15.0% yield, together with a small amount of aminoacetonitrile (3.7%). The other was a methanol-soluble resinous product (0.5 g) supposed to originate from aminoacetonitrile, since the same product was obtained by heating aminoacetonitrile in aqueous ammonia. The polymer was not hydrolyzed to glycine when treated with Na_2CO_3 and NaOH. On the other hand, there was no detectable formation of chloroacetic acid. Therefore, it

is considered that, in aqueous ammonia, the ammonolysis to aminoacetonitrile proceeds faster than in the second step of the hydrolysis to glycine, and that aminoacetonitrile, once formed, is then polymerized to an undesirable product. In the presence of alkalines, the hydrolysis is also accelerated. The effectiveness of alkalines may be attributable to their catalytic action on the hydrolysis of the intermediate compound, such as aminoacetonitrile. The change from aminoacetonitrile to glycine has been achieved by using $Ba(OH)_2$.[5]

The use of different types of alkalines significantly affected the glycine yield (Table 3). The effect of alkaline metal compounds on the yields was on the order of: hydrogencarbonates > carbonates > hydroxides. The most effective catalyst was $NaHCO_3$; the yield reached 71.6% at 180 °C for 4 h at a 1:88 molar ratio of trichloroethylene to ammonia. The tendencies observed in the series of alkaline catalysts could not be recognized from their activity in the hydrolysis of aminoacetonitrile, because the glycine yields obtained in the hydrolysis of aminoacetonitrile were in the reverse order: $NaOH > Na_2CO_3 > NaHCO_3$. Since the decomposition of glycine in the presence of NaOH and Na_2CO_3 is essentially negligible under our reaction conditions at 180 °C, the difference in yield may be due to other factors; possibly, a facile abstraction of halogen atoms from trichloroethylene by strong alkalines results in the formation of polymerized prod-

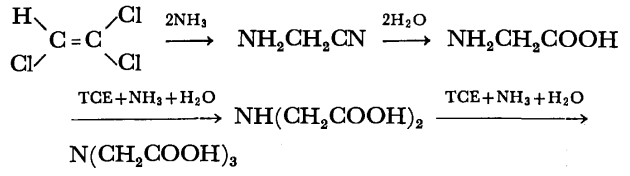
ucts.

Reaction Products and Mechanism. In the ammonolysis of trichloroethylene, glycine is the only amino-acid species detected by means of an amino-acid analyzer. However, the elementary analysis of the reaction products obtained with 7% aqueous ammonia gave a nitrogen atomic ratio lower than that of glycine. For example, trichloroethylene (11.15 mmol) was heated at 180 °C for 4 h with 7% or 28% aqueous ammonia (30 ml) in the presence of Na_2CO_3 (1.9 g). Then, unreacted ammonia was removed by evaporation, and the amino-acid species were separated from NH_4Cl by treatment with an anion-exchange-resin (IRA-400, Roam & Haas Co.), followed by a cation-exchange-resin (IR-120B): (A) with 7% aqueous ammonia, yield, 0.4 g, Found: C, 30.68; H, 6.18; N, 16.26%; Calcd for $C_2H_5NO_2$: C, 32.00; H, 6.71; N, 18.66%; and (B) with 28% aqueous ammonia, yield, 0.6 g; Found: C, 31.78; H, 6.52; N, 18.04%. These results suggest the formation of undesired amino acids, *e.g.*, *N*-substituted amino acids, in addition to glycine.

High-power liquid chromatography, using a Shodex OHpak M-614 column (6 mm i.d., ×250 mm in length; Showa Denko K.K.) and 0.002 M H_3PO_4 as the eluent, identified glycine, iminodiacetic acid, and nitrilotriacetic acid by means of their retention times (Table 4). The ratios of these by-products to glycine was higher in the case of ammonolysis using 7% rather than 28% aqueous ammonia. Therefore, the amount of undesirable side products, such as iminodiacetic and nitrilotriacetic acid, can be decreased by increasing the molar ratio of ammonia to trichloroethylene.

Based on the present findings, we suggest that the reaction path for ammonolysis is:



TCE: trichloroethylene.

On the basis of the proposed mechanism, we expected that aminoacetonitrile could be obtained by treating trichloroethylene with ammonia under mild reaction conditions. When trichloroethylene was heated in 28% aqueous ammonia at 80 °C for 24 h, almost all the trichloroethylene was recovered, while aminoacetonitrile and glycine were obtained only in 1.8% and 0.1% yields respectively. The aminoacetonitrile yield increased with increase in the ammonia concentration; in ammonia–water (7:3) media, aminoacetonitrile (30.7% yield) and a trace amount of glycine were obtained at 70 °C for 20 h. Anhydrous ammonia gave high yields (Table 5). At temperatures from 50 °C in the presence of excess ammonia (the volume of liquid ammonia was 10 times that of trichloroethylene), ammonolysis occurred, yielding aminoacetonitrile selectively. A yield of 61% was obtained at 70 °C for 30 h. At higher temperatures, the product decomposed, resulting in brown products. Due to the observed effect of alkalines in aqueous ammonia, we added NaOH of Na_2CO_3 to the system. The presence of NaOH induced the formation of a water-insoluble black polymer. The yield decreased far below that obtained in non-catalyzed reactions. On the other hand, the addition of Na_2CO_3 had little effect on the yield. Therefore, the difference in the catalytic activities of strong and weak alkalines in aqueous ammonia may be explicable in terms of instability of trichloroethylene with strong alkalines.

The authors wish to express their thanks to Dr. Shunichi Hirokami for his valuable Discussions.

Application of On-line Impedance Measurement Using Fast Fourier Transform to Electrochemical Systems

Tetsuya OSAKA* and Katsuhiko NAOI

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160

(Received April 15, 1981)

An on-line impedance measuring system based on the fast Fourier transform algorithm was constructed by application of only commercially available interfaces and the FORTRAN language available for an OKITAC System 50/10. A modification of the sampling system is effective for reducing two kinds of errors: the aliasing effect is greatly reduced because of the Nyquist frequency being doubled; the leakage effect is diminished because of the truncation interval being adjusted properly. The above modification enables us to acquire high-accuracy data with quite a small number of averagings processed during one measurement, that is, errors may greatly be reduced and the measurement time to get frequency spectra may be made extremely shorter. The modified impedance measurement using the FFT algorithm is applicable to electrochemical systems proceeding not only at a mercury electrode–solution interface but also at a solid electrode–solution interface.

Impedance (or admittance) methods, providing a powerful means for electrochemical analysis, have been made applicable to practical uses through the use of a.c. bridges and phase-sensitive devices with a support by analog cross-correlation techniques. Recently much effort has been devoted to developing automatic operation devices in order to improve accuracy and satisfy a necessity for simultaneous handling of many data points. A great deal of development has been made in impedance measurements by the introduction of the so-called Fourier and Hadamard transformation which have the multiplex advantage. Smith *et al.*[1] applied the multiplex technique using the FFT (fast Fourier transform) algorithm[2] to the electrochemical field and later Schwall *et al.*[3] extended the system so as to cover a wide frequency range from 10 Hz to 125 kHz. Multiplex techniques with construction of a pseudo-random noise spectrometer[4] using the Fourier transform algorithm and with establishment of a new digital signal processing method using the Hadamard transformation algorithm[5] have also been applied to the field of dielectric dispersion measurements. De Levie *et al.*[6] used a similar multiplex technique with sinusoidal wave collection signals in a biomembrane research and recently improved the impedance method in use in the electrochemical field by applying the digital synchronous detection using the Hadamard transformation algorithm.[7]

In this communication, we will try to take out the essential multiplex advantage by means of the modified FFT impedance measurement and to make it possible to acquire high accuracy from a short time measurement with a small number of averagings; we will also describe a simple system which can be composed only of commercially available interfaces without cumbersome hardware construction and which can be operated with the FORTRAN language available for the OKITAC System 50/10; finally, the system composed will be applied not only to mercury electrode–solution systems but also to solid electrode–solution systems.

Principle of Method

Every impedance method using various small-amplitude excitations essentially contains equivalent information as indicated in terms of mathematical transformation. The principle of this method in use in electrochemistry has been introduced.[1,8] The admittance $Y(\omega)$ of a linear or shift-invariant system is completely given by a cross-power spectrum between the excitation and response of the system as follows:

$$Y(\omega) = i(\omega)/e(\omega) = i(\omega)e^*(\omega)/e(\omega)e^*(\omega),$$

where $e(\omega)$, $e^*(\omega)$, and $i(\omega)$ are a frequency domain spectrum of the applied potential, that of its complex conjugate, and that of faradaic current, respectively. This property of $Y(\omega)$ enables us to measure all frequency components simultaneously and to reduce the Fourier transformation to a demultiplexing process. Though in principle any excitation waveforms contain the same information, cross-power spectra in practical systems have to be obtained in a finite time, which requires the most suitable excitation waveform signal to be chosen. Therefore, the present system was designated to utilize the periodic pseudo-noise, which had been studied by Smith *et al.*[1] and Husimi *et al.*[4]

Instrumentation

Hardware Arrangement. The impedance measurement scheme was implemented on an OKITAC System 50/10 minicomputer (memory cycle time 0.65 μs, 75 kB) by using a floppy-disk-oriented system equipped with DMA interface cards. The maximum sampling rate of the system is 20 μs. The schematic diagram for the system is shown in Fig. 1. Programs and data are stored on floppy disks and output data may be displayed on an interfaced oscilloscope or X-Y plotter. Low pass filters are set up for three cut-off frequencies of 2.5, 7, and 12 kHz. The frequency range is restricted mainly by both the noise-applying rate $\Delta t'(f_{max}=(2\Delta t')^{-1})$ and the potentiostat response. The low pass filters (LPF) were built up by our laboratory (40 dB Butterworth) or by Fuso-Seisakusho (80 dB Butterworth), for cutting out the aliasing effect and smoothing computer-synthesized noises. The high pass filters (HPF), which were built

TABLE 1. RELATIONSHIP OF SAMPLING RATE WITH FREQUENCY LIMITS (MAXIMUM AND MINIMUM) AND MEASUREMENT DURATION IN THE CASE OF 1024-POINT (2^{10}) PSEUDO-NOISE

	Sampling rate $\Delta t/\mu s$	Noise-applying rate $\Delta t'/\mu s$	$f_{min}=(N\Delta t')^{-1}$ Hz	$f_{max}=(2\Delta t')^{-1}$ Hz	Measurement time $f_{min}^{-1}\times 3$/ms
System 1[a)]	20	80	12.2	6250	245.8
	50	200	4.9	2500	614.4
	250	1000	1.0	500	3072.0
System 2[b)]	20	40	24.4	12500	122.9
	50	100	9.8	5000	307.2
	250	500	2.0	1000	1536.0

a) System 1 means the system consisting of simultaneous sampling process of excitation $e(t)$ and response $i(t)$ (where the excitation and response are alternatively sampled with $\Delta t/\mu s$ interval and corrected with software technique). b) System 2 means the system consisting of separate sampling process of excitation $e(t)$ and response $i(t)$ (where the excitation is stored before measuring response).

by Fuso-Seisakusho, cut out dc and frequency components lower than 1 Hz. The potentiostat with high response (home built or Fuso-Seisakusho HOPATS-3)† was used instead of a dual-potentiostat as used by Smith *et al.*[1)]

Generation of Pseudo-noise. Pseudo-noises generated by the minicomputer are subject to a synthesis as shown in Fig. 2. First, twenty frequency components are selected so as to avoid higher-harmonics (especially the second-harmonics). The phase component array is loaded with random numbers between 0 and 2π. The amplitudes of the selected frequency components are set as constant non-zero levels and those of the others as zero in order for all the frequency components to be at the same excitation energy. The "complex plane" frequency-domain array with 2048 points, which has been transformed from the "polar coordinate" frequency spectrum, is converted into the time-domain digital waveform with 1024 points by use of the inverse FFT. Real and imaginary components of the complex plane are to be set as even and odd functions, respectively, in order that time domain results may become of real function. The analog pseudo-noise thus arranged is applied ten times to the measuring cell to produce a periodic noise and steady-state response. Typical examples of frequency limits and measurement-time durations, as calculated from sampling rates, are listed in Table 1. Three kinds of sampling rates, *e.g.*, 20, 50, and 250 μs, lead to arrangement of three frequency ranges as shown in Table 1, thus allowing three frequency range measurements to provide high accuracy on wide frequency measurements. Since the measurement-time duration is equal to three times the reciprocal of f_{min} ($f_{min}=(N\Delta t')^{-1}$), the measurement time is dependent on the minimum frequency value.

Measuring System. The data acquisition and calculation processes for the transfer function are shown in Fig. 3. Two alternative sampling systems, Systems 1 and 2, are adopted. System 1, designed to perform simultaneous sampling of excitation $e(t)$ and response $i(t)$, samples both data alternately at $\Delta t/\mu s$ intervals and corrects them by the software technique based on the equation $Y(\omega)=Y'(\omega)e^{-i\omega\tau}$ (where Y, Y', and τ are the admittance of real response, that of delayed response, and the delay time Δt of sampling,

† The response rate is 2 μs under the conditions of 1:1 gain and 1 kΩ resistor.

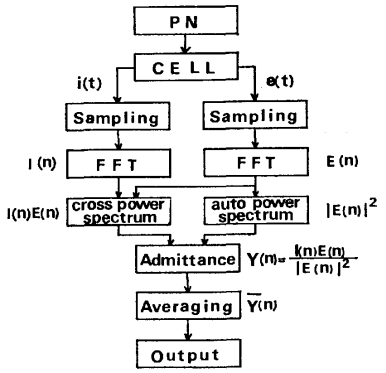

Fig. 3. Data acquisition and calculation processes for transfer function.

repectively). System 2, designed to store the excitation *e(t)* before response *i(t)* is measured, samples data of *e(t)* and *i(t)* separately. System 2 has two advantages over System 1: it can measure higher frequencies because it has its maximum frequency (f_{max}) doubled; it requires such a memory capacity as decreased to two thirds of that of System 1. We usually used System 2 because of these advantages. Data are acquired with 2048 points to be transformed into the frequency domain by means of the FFT. The transfer function of the measuring cell is calculated as admittance after the cross-power and auto-power spectra have been calculated. Final data of admittance are obtained after sampling and averaging which has been made of the last three waveform cycles of the ten-time-applied waveform signals. A remarkable feature of this sampling process is that the pseudo-noise output signal consisting of 1024 points is sampled at a doubled sampling rate (*viz.*, the noise is sampled with 2048 points). Since this sampling system causes the Nyquist frequency to be increased, errors due to the aliasing effect may be depressed (*cf.* Figs. 4 and 5). The leakage effect also may be made ineffective by adequate selection of the truncation interval which is equal to a multiple of the period. Thus, shorter-time measurement for frequency spectra may be realized by means of averaging the last three waveform signal responses.

Experimental

Polarographic measurements were performed on a Metrohm hanging mercury drop electrode (HMDE) with a surface area of 2.38×10^{-2} cm². Solutions for polarographic experiments on HMDE was purified with active charcoal after being prepared with reagent chemicals and triply-distilled water. For solid electrode–solution systems, smooth platinum (9.01×10^{-2} cm²) and gold (9.20×10^{-2} cm²) wire electrodes were used as working electrodes. To bring the solid-electrode surface into a reproducible condition, the working electrodes were cleaned with concentrated nitric acid and pretreated by allowing the electrode potentials to be scanned between the states of hydrogen and oxygen evolutions at 10 V s^{-1} for several tens of minutes. The silver–silver chloride or mercury–mercurous sulfate electrode was used as the reference electrode and the potentials were registered relative to the saturated calomel electrode (SCE). Experiments were performed in a purified nitrogen atmosphere at 25 °C.

Results and Discussion

Dummy Cell Results. Figures 4(a) and (b) show typical data on relative errors for power spectra of pseudo-noise in the case where sampling rate is equal to the noise-applying rate ($\Delta t=\Delta t'=120$ μs); Figures 4(a) and (b) correspond to before- and after-passage through the low pass filter. Since the Nyquist frequency is *ca.* 4.2 kHz for this sampling rate, the aliasing effect at the high frequency edge is clearly observed as shown in Fig. 4(a). The aliasing effect at the high frequency edge can be cut out by the low pass filter as shown in Fig. 4(b); however, relative errors of several percents are still recognized. In the case of Fig. 5 where the sampling rate is twice as high as the noise-applying rate ($\Delta t=60$ μs, $\Delta t'=120$ μs), the Nyquist frequency is made doubled to 8.3 kHz and the aliasing effect cannot be recognized even in the absence of low pass filter as seen from Fig. 5(a). The relative errors for Fig. 5(a), which are less than 0.1%, are almost equal to those obtainable after the smoothing by means of low pass filter has been applied as seen from Fig. 5(b). Therefore, the sampling system described above is obviously effective for reducing relative errors, making it feasible to reduce the apparent measurement time. A comparison with respect to transfer function between theoretical and experimental values for a typical dummy cell shown in the figure is illustrated by use of the complex impedance representation, Z_{cell}, in Fig. 6. The experimental

data for the range from 10 Hz to 2.5 kHz are in fair agreement with the theoretical values at higher frequencies than 100 Hz. The data obtained at lower than 100 Hz, especially around 50 Hz, show some deviation from the theoretical data, which results from the line frequency interference.

Electrochemical Cell Results. An electrochemical system of a cadmium-ion reduction at an HMDE-acidified $ZnSO_4$ solution interface, which is the same system as Schwall *et al.*[3a,9] studied, was examined to obtain higher rate constants. The voltammogram for cadmium-ion reduction shown in Fig. 7(a) gives the maximum value of cot Φ (shown as $(\cot\Phi)_p$) at −0.557 V (SCE). Faradaic impedance representations as Z_k, after subtraction of solution resistance and double layer capacity, and plots of $(\cot\Phi)_p$ *vs.* $\omega^{1/2}$ at −0.557 V (SCE) are shown in Figs. 7(b) and (c). The slope for $(\cot\Phi)_p$ *vs.* $\omega^{1/2}$ plots yields the standard rate constant $k_c^\circ = 4.34\times10^{-2}$ cm s^{-1}, with the aid of the transfer coefficient α=0.35 given by Schwall *et al.*[3a,9] Though the value of k_c° obtained here is as small as half the values 8.7×10^{-2} and 8.5×10^{-2} cm s^{-1} obtained by Schwall *et al.*[3a,9] with and without scanning, respectively, our value may be considered to be in a reasonable range if data of other workers[10] are referred to.

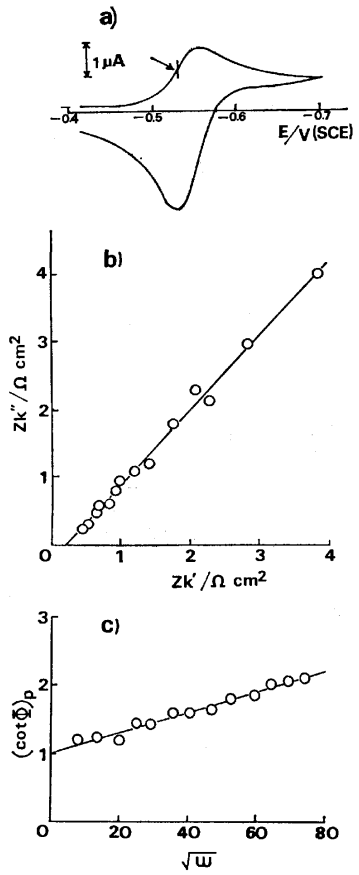

Fig. 7. Experimental results for cadmium ion reduction reaction on HMDE in 1.0 M zinc sulfate +0.18 M sulfuric acid (Cd^{2+} concentration=10^{-3} M), where M means mol dm^{-3}.
a): Single voltammogram of cadmium ion reduction, v=0.020 V s^{-1}, b): complex kinetic impedance representation of cadmium ion reduction at E=−0.557 V(SCE), c): relation between $(\cot\Phi)_p$ and $\omega^{1/2}$ of cadmium ion reduction at E=−0.557 V(SCE).

An electrochemical system of an adsorbed-hydrogen reaction at a platinum–sulfuric acid solution interface was examined as one of typical examples of solid electrode–solution systems. Figures 8(a) and (b) show typical cyclic voltammograms for reference and complex capacitance representations as $Y\omega^{-1}$ for the adsorbed-hydrogen region. The characteristic of complex capacitance representations is similar to that specified by one of the authors[11] using a phase-sensitive apparatus. The results are in accord with the equivalent circuit shown in the figure, previously proposed.[11]

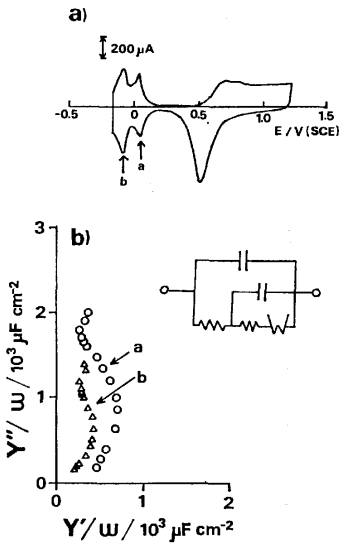

Fig. 8. Experimental results for adsorbed hydrogen reaction on platinum electrode in 0.5 M sulfuric acid.
a): Cyclic voltammogram of platinum electrode, v= 0.10 V s^{-1}, b): complex capacitance representation, $Y\omega^{-1}$, of adsorbed hydrogen reaction at 0.000 V (a) and −0.134 V(SCE) (b).

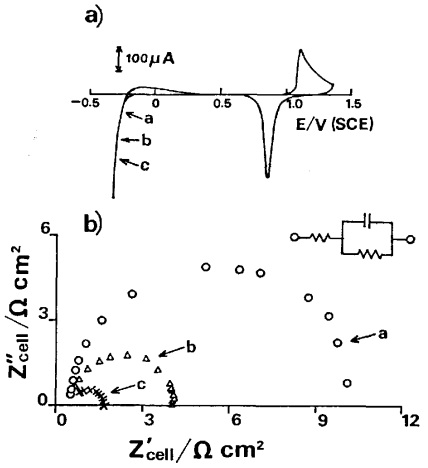

Fig. 9. Experimental results for hydrogen evolution reaction on gold electrode in 0.5 M sulfuric acid.
a): Cyclic voltammogram of gold electrode, v=0.10 V s^{-1}, b): complex impedance representation, Z_{cell}, of hydrogen evolution reaction at −0.374 V (a), −0.404 V (b), and −0.424 V(SCE) (c).

Another typical example of solid electrode-solution system, a hydrogen evolution reaction at a gold electrode–sulfuric acid solution interface, was also examined, data obtained being shown in Figs. 9(a) and (b). Figure 9(a) shows a typical cyclic voltammogram on a gold electrode and Figure 9(b) the complex cell impedance representation as Z_{cell} for the hydrogen evolution region. The characteristic of the complex cell impedance representation is of semicircle and in accord with the simple equivalent circuit shown in the figure, proposed by Masui and Ohashi.[12]

Therefore, the FFT impedance method described in the text may be concluded to be applicable to electrochemical systems proceeding not only at the mercury electrode–solution interface but also at the solid electrode–solution interface. Moreover, transient behaviors with time dependence, *e.g.*, variation in surface conditions with oxide formation, can be characterized by this method because of its short measurement time applicable.

The authors would like to thank Professor Emeritus Dr. Tadashi Yoshida, Waseda University, for his encouragement throughout this research, and Dr. Kazuhiko Nitadori, Systems Laboratory, OKI Electric Industry Company Ltd., for his valuable advice and discussion. T.O. would be greatful to Professor Dr. de Levie, Georgetown University, for calling his interest to the FFT impedance measurement. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Kinetics and Mechanism of 1,4-Cycloaddition between Tetracyanoethylene and Styrenes. III. Effects of Solvent Polarity and Temperature

Yasuhiro Uosaki, Masaru Nakahara,* and Jiro Osugi

Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received April 24, 1981)

Experimental evaluation was made of rate constants for foward and backward steps of 1,4-cycloaddition between TCNE and α-methylstyrene and of constants for their complex formations in 1,2-dichloroethane, dichloromethane, chloroform, and carbon tetrachloride at a few temperatures around 25 °C. Kirkwood's dipole model for solvation is applied to analyzing kinetic data obtained. The dipole moment of the transition state is estimated to be 8.5±0.5 Debye, which is larger than either that of the complex (assumed as 1 Debye) or that of the cycloadduct (6±1 Debye). Major cause for the high dipole moment of the transition state is breakdown of the high molecular symmetry of TCNE and minor one is a certain contribution of a zwitterionic structure. The activation entropy for the cycloreversion is negative and in the range of −21 to −48 J K^{-1} mol^{-1}, corresponding to the high polarity of the transition state.

When a strong piezochromism was discovered in dichloromethane solution of tetracyanoethylene (TCNE) and styrene half a decade ago, marked solvent and temperature effects on the rate of color change in the solution were noticed in a qualitative manner.[1] Although the phenomenon was first ascribed to formation of a zwitterion because of the large solvent effect on the reaction, later structural studies on species found led to identification of 1,4-cycloadduct.[2,3] Kinetics and mechanism of the 1,4-cycloaddition were investigated with respect to α- and para-substituent effects in Parts I and II of the present series; large substituent effects were found, suggesting a participation of a polar transition state for the 1,4-cycloaddition.[4,5] The aim of the present paper is to elucidate in a quantitative way how much polar the rate-determining state is or whether or not it is similar in polarity to a zwitterion. Applying Kirkwood's dipole model for solvation[6] to kinetic data obtained in several solvents at various temperatures, it is made clear that although the transition state is polar, it is not so much polar as a zwitterion.

Experimental

α-Methylstyrene and TCNE were purified in the same way as in a previous paper.[3] The solvents, 1,2-dichloroethane, dichloromethane, chloroform, and carbon tetrachloride, were purified by the standard method and distilled over CaH_2 before use.

Two pycnometers of the Lipkin-Davison type (about 5 cm^3) were employed for measuring densities of 1,2-dichloroethane solutions of α-methylstyrene and of TCNE. They were calibrated by using distilled water for which very accurate density data are available.[7] Temperature was controlled to ±0.01 °C at 25 °C in density measurements, while it was kept to ±0.1 °C in spectrophotometric measurements of reaction rate. Concentrations of α-methylstyrene and TCNE solutions were in the ranges of 0.1 to 0.3 and 0.04 to 0.05 mol dm^{-3}, respectively. Partial molal volumes of the donor and the acceptor varied little with concentration within experimental error. The other apparatus and procedures in the present work are the same as those in Part I of this series.[4]

Analyses in the following section require some physical properties of the solvents listed in Table 1 where α is the thermal expansivity,[8] ε the dielectric constant,[9] and q equal to $(\varepsilon-1)/(2\varepsilon+1)$.

Table 1. Properties of the used solvents at 25 °C

Solvent	α[a] / 10^{-3} K^{-1}	ε[b]	q	dq/dT[c] / 10^{-4} K^{-1}
$ClCH_2CH_2Cl$	1.17[d]	10.36	0.431	3.7

a) From Ref. 8. b) From Ref. 9. c) Estimated from the values of ε at 20 and 25 °C. d) Estimated from the densities at 25 and 30 °C.

Results and Discussion

Formation Constant of EDA Complex. α-Methylstyrene and TCNE form an EDA complex in solution. The formation constant (K_c) is defined as

$$K_c = [EDA]/([D][A]), \quad (1)$$

where EDA, D, and A denote the EDA complex, the donor, and the acceptor, respectively, and the brackets [ ] indicate the concentration of each species. The formation constant can be determined spectrophotometrically from the Scott equation under the condition of $[D]_0 \gg [A]_0$, as explained in detail elsewhere.[4] Values of K_c obtained in several solvents at various temperatures are summarized in Table 2, which includes also the wavelength (λ_{max}) of the maximum absorption for the first charge-transfer band and the molar absorption coefficient (ε_{max}) at λ_{max} utilized in the K_c determination. The higher the solvent polarity, the smaller the formation constant at any temperature. This trend is common to weak EDA complexes.[10] As a matter of fact, the complex studied here has been clarified to be weak from another criterion in a previous work.[4] Dipole moments of EDA complexes between TCNE and similar aromatic donors are reported to be approximately 1 Debye (Debye/C m$=3.33\times10^{-30}$).[11] This kind of trend for weak complexes is usually interpreted in terms of desolvation of the donor and/or acceptor during the complex formation.[10] In the present case, desolvation of TCNE seems important for the following rea-

Table 2. Formation constants of the EDA complex in several solvents at various temperatures and relevant spectroscopic and thermodynamic parameters

Solvent	λ_{max} / nm	ε_{max} / mol^{-1} dm^3 cm^{-1}	K_c/mol^{-1} dm^3 15 °C	20 °C	25 °C	30 °C	ΔH_c / kJ mol^{-1}	ΔS_c / J K^{-1} mol^{-1}
$ClCH_2CH_2Cl$	492	3330	0.092	0.088	0.084		−7.4	−45
CH_2Cl_2	495	2050	0.192	0.184	0.176		−7.2	−39
$CHCl_3$	504	1760	0.473	0.460	0.436		−6.7	−29
CCl_4	499	1510		1.49	1.39	1.31	−10.5	−32

son. Although TCNE itself has no dipole moment because of its high molecular symmetry, its CN groups have so large a bond dipole moment that they can interact strongly with polar solvent molecules. The role of higher moments like the quadrupole and octapole in TCNE is well reflected by strong dependences of its solubility[12] and heat of dissolution[13–15] on solvent polarity.

The enthalpy change (ΔH_c) and entropy change (ΔS_c) for the complex formation are obtained from the thermodynamic equations

$$\left(\frac{\partial \ln K_c}{\partial(1/T)}\right)_P = -\frac{\Delta H_c}{R} - \alpha T^2, \tag{2}$$

and

$$\Delta S_c = \frac{\Delta H_c + RT \ln K_c}{T}, \tag{3}$$

where T is the temperature, R the gas constant, and α the thermal expansivity of the solvent; values of these quantities in the temperature range studied here are given in Table 2. The negative sign of ΔH_c and ΔS_c is reasonable for the association reaction. The absolute value of ΔH_c also indicates that the complex is weak, and its decrease, though somewhat irregular, with increasing solvent polarity is compatible with the increase in solvation of TCNE mentioned above. However, the increase in magnitude of ΔS_c with increasing solvent polarity cannot be explained in terms of solvation, because the entropy loss due to the molecular association is canceled to some extent by the entropy gain due to liberation (desolvation) of polar solvent molecules on one side of the molecular plane of TCNE.

Reaction Rates and Activation Parameters. The 1,4-cycloaddition proceeds according to the scheme

$$D + A \overset{K_c}{\rightleftharpoons} \text{EDA Complex} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} P, \tag{4}$$

where k_1 and k_{-1} are the rate constants for the forward and backward cycloaddition processes, respectively, and P denotes the cycloaddition product.[5] The pseudo-first-order rate constant k_{obsd} for Reaction 4 is expressed as

$$k_{obsd} = \frac{k_1 K_c [D]_0}{1 + K_c [D]_0} + k_{-1}, \tag{5}$$

where $[D]_0$ denotes the initial concentration of the donor. The reaction is followed by observing the absorbance of the product at 325 nm,[3] and the value of k_{obsd} is determined from the Guggenheim plot. Figure 1 shows plots of k_{obsd} *vs.* $K_c[D]_0/(1+K_c[D]_0)$ in 1,2-dichloroethane at three different temperatures.

Table 3. Rate and formation constants of the 1,4-cycloaddition in several solvents at various temperatures

Solvent	Temperature/°C 15	20	25	30

a) Determined from equilibrium measurements.

Plots like these provides k_1 and k_{-1} as a slope and an intercept, respectively. Rate constants obtained in the four solvents by applying the least-squares method to plots like those in Fig. 1 are given in Table 3, together with adduct formation constants given by

$$K_1 = \frac{k_1}{k_{-1}} = \frac{[P]}{[EDA]}. \tag{6}$$

When all the steps involved in Reaction 4 are at equilibrium, we can get K_1 independently by the method described in detail elsewhere (see Eq. 11 in Ref. 4). As seen in Table 3, the kinetically and thermodynamically determined values of K_1 are in good agreement. The activation enthalpies (ΔH_1^* for k_1 and ΔH_{-1}^* for k_{-1}) and entropies (ΔS_1^* and ΔS_{-1}^*) are obtained from the Eyring equation[16]

$$R \ln \frac{hk}{k_B T} = -\frac{\Delta G^*}{T} = -\frac{\Delta H^*}{T} + \Delta S^*, \tag{7}$$

where h, k_B, and k are the Planck constant, the Boltzmann constant, and the rate constant (k_1 or k_{-1}), respectively. The activation parameters thus obtained are listed in Table 4; they will be discussed below.

TABLE 4. ACTIVATION PARAMETERS FOR THE 1,4-CYCLOADDITION IN SEVERAL SOLVENTS

Dipole Moments of the Transition State and Product. The dipole moment of the transition state can be determined by applying Kirkwood's dipole model for solvation to the kinetic data in Table 3.[6] Kirkwood's model leads to the equations

$$\Delta G_1^* = (\Delta G_1^*)_\phi - Lq\left(\frac{\mu_*^2}{r_*^3} - \frac{\mu_{EDA}^2}{r_{EDA}^3}\right), \quad (8)$$

and

$$\Delta G_{-1}^* = (\Delta G_{-1}^*)_\phi - Lq\left(\frac{\mu_*^2}{r_*^3} - \frac{\mu_P^2}{r_P^3}\right), \quad (9)$$

where

$$q = \frac{\varepsilon - 1}{2\varepsilon + 1}. \quad (10)$$

Here, ΔG_1^* and ΔG_{-1}^* are the activation free energies relating to the rate constants k_1 and k_{-1} through Eq. 7, respectively; $(\Delta G^*)_\phi$ denotes the activation free energy which is not explicitly given by Kirkwood's model (*i.e.*, a term associated with activation free energy in the hypothetical gas phase and with solvations due to van der Waals interactions, *etc.*); L is the Avogadro constant; r_*, r_{EDA}, and r_p are the radii of the transition state, the EDA complex, and the adduct, respectively (spherical symmetry is assumed here); and μ denotes the dipole moment for the species indicated.

Plots of ΔG_1^* and ΔG_{-1}^* against q in Table 1 are

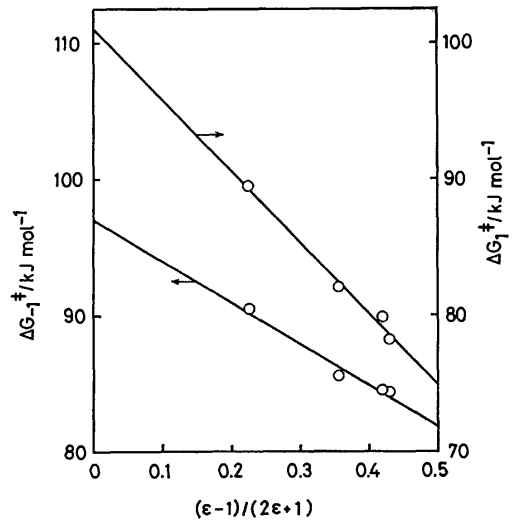

Fig. 2. Plots of ΔG_1^* and ΔG_{-1}^* *vs.* $(\varepsilon-1)/(2\varepsilon+1)$ at 25 °C.

shown in Fig. 2; they are linear as expected. If μ_{EDA} is taken to be 1 Debye and r_{EDA} and $r_* \approx r_p$ are approximated to 4.6 and 4.4 Å based on measured partial molal volumes,[17,18] respectively, the slopes in Fig. 2 corresponding to Eqs. 8 and 9 provide 8.5±0.5 and 6±1 Debye as μ_* and μ_p, respectively. Alternatively, the dipole moment of the adduct can roughly be estimated from the vector sum of dipole moments of the cyano and methyl groups; the estimated dipole moment is 7—8 Debye.[19] The fairly good agreement indicates that the present analysis is reasonable. Since the dipole moment of α-methylstyrene is 0.76 Debye,[20] we have the following polarity profile for Reaction 4:

$$\underset{0.8}{D + A} \rightleftharpoons \underset{1}{EDA\ Complex} \rightleftharpoons \underset{8.5}{TS} \rightleftharpoons \underset{6\ Debye}{P}, \quad (11)$$

where TS denotes the transition state. Although these absolute values have uncertainties as indicated above, their differences are more reliable. There is a large difference between the EDA complex and the transition state and a small difference between the adduct and the transition state. This corresponds to the fact that the forward reaction depends on solvent polarity more strongly than the backward one (see Table 3). The found polarity difference of 2.5 Debye for the backward step is very important since it suggests that a zwitterionic structure contributes to the transition state to some extent (see Fig. 1 in Ref. 5). The conclusion that the transition state is more polar than the cycloadduct, is strongly supported by the negative activation volume for the same step as determined by rapid-reaction techniques at high pressures.[21,22] A much larger dipole moment of 14 Debye is reported

for the transition state in the 1,2-cycloaddition of TCNE to *trans*-anethole where a zwitterionic intermediate is considered to exist.[23,24] Major factor for the high polarity of the transition state studied here is breakdown of the molecular symmetry of TCNE in the transition state. The symmetry breakdown is also responsible for the relatively large dipole moment for the adduct where the CN bond dipoles are not fully canceled. The large difference of 7.7 Debye between the reactants and the transition state clearly explains why the formation reaction ($k_f=K_c k_1$) has a large negative reaction constant, $\rho=-5.5\pm0.2$, for para-substituted styrenes.[5]

Effect of Solvent Polarity on Activation Entropies. To get insight into the mechanism of the cycloaddition, the cycloreversion process which is unimolecular is most important and thus, mainly the activation entropy for this process is discussed here. The negative values of $\Delta S^{\neq}_{-1}$ (-21 to -48 J mol^{-1}) correspond to the negative activation volume for the process mentioned above, and tell us that the transition state is more polar than the adduct. More negative values of $\Delta S^{\neq}_{-1}$ in the range of -40 to -100 J K^{-1} mol^{-1} have been reported for 1,2-cycloadditions in various solvents where a zwitterionic intermediate is considered to exist.[25]

By differentiating Eq. 9 with respect to temperature and neglecting temperature dependences of μ's and r's, we get the equation

$$\Delta S^{\neq}_{-1} = (\Delta S^{\neq}_{-1})_{\phi} + L\left(\frac{\mu^2_{\neq}}{r^3_{\neq}} - \frac{\mu^2_{P}}{r^3_{P}}\right)\frac{dq}{dT}. \qquad (12)$$

Inserting $\Delta S^{\neq}_{-1}$ in Table 4, dq/dT in Table 1, and the corresponding slope in Fig. 2 into Eq. 12, we obtain -20 to -40 J K^{-1} mol^{-1} as $(\Delta S^{\neq}_{-1})_{\phi}$. These negative values indicate that some solvations not explicitly represented by Kirkwood's dipole model play a role, because $(\Delta S^{\neq}_{-1})_{\phi}$ in the hypothetical gas phase is expected to be somewhat positive from the bond loosening involved in the transition state. If we plot $\Delta S^{\neq}_{-1}$ in Table 4 against dq/dT in Table 1, the slope obtained gives a larger dipole moment for the transition state. However, the differentiated form of Kirkwood's relation (Eq. 12) is no doubt less reliable than Eq. 9. Thus, the solvent effect on $\Delta S^{\neq}_{-1}$ can qualitatively be understood in terms of Kirkwood's dipole model. Influences of solvent polarity on $\Delta S^{\neq}_{1}$, $\Delta H^{\neq}_{1}$, and $\Delta H^{\neq}_{-1}$ may be explained in a similar manner.

Some other thermodynamic quantities relating to the reaction are to be mentioned in brief. The reaction enthalpy ($\Delta H_1=\Delta H^{\neq}_1-\Delta H^{\neq}_{-1}$) and entropy ($\Delta S_1=\Delta S^{\neq}_1-\Delta S^{\neq}_{-1}$) for the cycloaddition from the complex are in the ranges of -25 to -38 kJ mol^{-1} and -70 to -116 J K^{-1} mol^{-1}, respectively. Neither is unusual, telling us that the adduct is stabler and more rigid than the complex. In the literature, the activation entropy, $\Delta S^{\neq}_1=\Delta S_c+\Delta S^{\neq}_1$, from reactants is compiled for many other 1,4-cycloadditions where TCNE is involved.[26] The present values are in the range of -133 to -190 J K^{-1} mol^{-1}, comparable with those in the literature (-120 to -200 J K^{-1} mol^{-1}).

The Crystal and Molecular Structure of (Acetylacetonato)-(diacetylmethyl)(diethylamine)palladium(II)

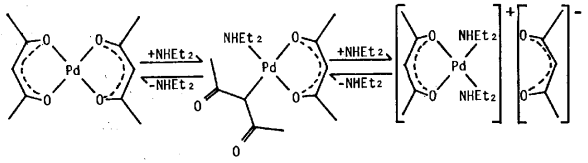
Takahiro KUROKAWA,† Kunio MIKI, Nobuo TANAKA,†† and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received April 30, 1981)

The molecular structure of $[Pd(acac)_2(NHEt_2)]$ was determined by means of X-ray diffraction. The crystal belongs to the monoclinic system: $a=14.166(1)$, $b=8.209(1)$, $c=14.764(2)$ Å, $\beta=100.75(1)°$, space group $P2_1/n$, with $Z=4$. The structure was solved by the heavy-atom method and refined anisotropically by the least-squares procedure; $R=0.067$ for 3149 non-zero reflections. The geometry around the Pd atom is square-planar: one of the two (acac) ligands coordinates to the Pd atom by O,O'-chelation, and the other, by σ-bonding of the γ-carbon atom, while the diethylamine occupies the fourth coordination site. A weak intramolecular N–H···O hydrogen bond [2.962(10) Å] is observed.

With relation to the reactions shown below,[1] the molecular structures of $[Pd(acac)_2]$[2] (**1**) and $[\{Pd(acac)(NHEt_2)_2\}^+(acac)^-]$[3] (**3**) have been determined. This paper will deal with the molecular structure of $[Pd(acac)_2(NHEt_2)]$ (**2**).



1 **2** **3**

Experimental

Yellow platelet crystals of $[Pd(acac)_2(NHEt_2)]$ were provided by Professor Seichi Okeya and Professor Shinichi Kawaguchi. A toluene–hexane mixture was used for the recrystallization. Efforts to cut out a crystal of a size suitable for an X-ray experiment was unsuccessful. A rather large crystal with dimensions of *ca.* $0.5\times0.18\times0.4$ mm was, therefore, used for the X-ray experiments, though it may limit the accuracy of the results.

Crystal Data: $C_{14}H_{25}NO_4Pd$, *F.W.* 377.8, monoclinic, $a=14.166(1)$, $b=8.209(1)$, $c=14.764(2)$ Å, $\beta=100.75(1)°$, $V=1686.7(3)$ Å^3, space group $P2_1/n$(No. 14), $D_m=1.46$(flotation), $D_c=1.488$ g cm^{-3}, $Z=4$.

The unit-cell dimensions were determined by the least-squares fit of 2θ values of 18 strong reflections measured precisely on a Rigaku automated four-circle diffractometer. The intensity data were collected using graphite-monochromatized Mo $K\alpha$ radiation on the diffractometer. The θ-2θ scan technique was applied. The scan width was $\Delta2\theta=(2.0+0.7\tan\theta)°$, and the scan rate was 4° min^{-1}. Backgrounds were measured for 7.5 s before and after the measurement of each peak. The intensity measurements were repeated up to three times for weak reflections. A total of 3694(3149 non-zero) reflections were measured up to $2\theta=54°$. Usual Lp corrections were made, but absorption corrections were ignored [μ(Mo $K\alpha$)$=10.7$ cm^{-1}].

Structure Solution and Refinement

The structure was solved by using Patterson and Fourier methods. The block-diagonal least-squares refinement (*HBLS* V)[4] with isotropic temperature factors reduced R to 0.096. The final R value was 0.066 ($R_w=0.089$) for non-zero reflections, allowing anisotropic thermal parameters for all the non-hydrogen atoms. The hydrogen atoms, except H(3) and H(6), could not be located reasonably, so they were not included in the refinement. The weighting schemes used at the final stage were $w=\{\sigma_{cs}^2(F_o)+0.0011\cdot|F_o|+0.0726|F_o|^2\}^{-1}$ for $|F_o|>0$ and $w=0$ for $|F_o|=0$, where σ_{cs} is the standard deviations obtained by the counting statistics. The final atomic positional and thermal parameters are given in Table 1.†††

The atomic scattering factors were taken from the International Tables for X-Ray Crystallography, Vol. IV.[5] The computations were done on an ACOS Series 77 NEAC System 700 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Results and Discussion

A perspective view (*ORTEP* II)[6] of the molecule is shown in Fig. 1, while the bond lengths and bond angles are given in Fig. 2. The geometry around the Pd atom is square-planar: one of the two (acac) ligands coordinates to the Pd atom by the O,O'-chelation, and the other, by σ-bonding of the γ-carbon atom, while the diethylamine occupies the fourth coordination site.

The two Pd–O lengths are unequal, Pd–O(1)= 2.008(5) and Pd–O(2)=2.061(5) Å. The *trans*-influence is observed. The former is equal to the Pd–O length *trans* to the diethylamine [2.000(3) Å],[7] and the latter, to that *trans* to the acetylacetonyl ligand [2.06(1) Å].[8]

The planarity of the acetylacetonato ligand is good (Table 2). This plane is approximately parallel to the coordination plane (Fig. 1.), the dihedral angle between these planes being 1.9(2)°. The bond lengths and bond angles in the acetylacetonato ligand in the present complex are normal, like those in $Pd(acac)_2$[2] or $[\{Pd(acac)(NHEt_2)_2\}^+(acac)^-]$.[3]

The diacetylmethyl ligand is approximately perpendicular to the coordination plane. The bond angles around the γ-carbon atom are considerably distorted. The C(7)–C(6)–C(9) angle [119.1(8)°] is larger than the tetrahedral angle, whereas the Pd–C(6)–C(7) angle [105.2(6)°] is slightly smaller. The C_β–C_γ and C_β=O bond lengths and C_β–C_γ–C_β bond angles are normal compared with the corresponding values in $[(PPh_3)Pd(acac)_2]$,[7] $[Me_3Pt(acac)(bipy)]$,[8] and $[K^+\cdot\{Pt(acac)_2Cl\}^-]$.[9] The two carbonyl groups are parallel in $[K^+\cdot\{Pt(acac)_2Cl\}^-]$ and in the present complex, whereas they are not parallel in $[(PPh_3)Pd(acac)_2]$. In the pottasium salt, the dihedral angle between the two C_α–C_β–C_γ moieties is 9.5°, while in the present complex it is 27.4(3)°. It was suggested that interactions between two carbonyl oxygen atoms and the K^+ cation in the crystalline state affect the parallel position of the two carbonyl groups and the small dihedral angle. In the present complex,

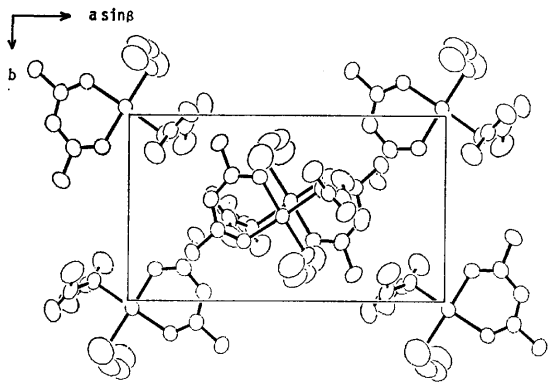

Fig. 3. Crystal structure projected along the c axis.

a weak intramolecular hydrogen bond, N–H···O(4) [2.958(10) Å], and a rather close N–H···O(3) contact [3.304(10) Å] between the two carbonyl groups and the N–H of the diethylamine ligand are observed.

The diethylamine ligand is also approximately perpendicular to the coordination plane. The two N–C bond lengths are equal [1.494(15) and 1.509(15) Å], comparable with those in $[\{Pd(acac)(NHEt_2)_2\}^+(acac)^-]$ [1.497(5) and 1.498(5) Å]. The two methyl groups are in a stable *trans* conformation.

The crystal structure projected along the c axis is shown in Fig. 3. The intermolecular atomic contacts are usual van der Waals distances, the closest being $C(10)(x,y,z)\cdots O(3)(0.5-x, -0.5+y, 0.5-z)$ [3.331(14) Å].

The authors wish to express their deep thanks to Professor Shinichi Kawaguchi, Osaka City University, and Professor Seichi Okeya, Wakayama University, for their valuable discussions and the supply of crystals.

Preparation of Surfactant-free Polystyrene Latices with High Surface Charge and Electrical Double Layer on Their Surfaces

Kunio FURUSAWA

Department of Chemistry, The University of Tsukuba, Sakura-Mura, Ibaraki 305

(Received April 27, 1981)

Polystyrene latices with a wide range of surface charges were prepared in the absolute absence of conventional emulsifiers by controlling the concentration of potassium peroxodisulfate as an initiator and allowing the polymerization to proceed at a relatively high pH to suppress the Kolthoff reaction; $KHCO_3$ or K_2HPO_4 buffer was used to keep the polymerizing system near neutral pH. Conductometric titrations with different bases (NaOH and $Ba(OH)_2$) on latices show that the Stern layer charge increases with an increase in the surface charge of latices (σ_0) and at about the same rate as σ_0 does, leading to a virtually constant diffuse layer charge.

In recent years, monodisperse polystyrene latices have been recommended as a model dispersion for studying a number of fundamental phenomena in the field of colloid science.[1] Main reasons for this recommendation are the high monodispersity of particles and the well-defined composition of surface charge.[2] In considering behaviors of polystyrene latices, it is particularly important whether they have been prepared in the presence or in the absence of emulsifier. If no emulsifiers have been used in the preparation, the surface charge is made up of chemically bound polar groups originating from the initiator used in the polymerization.[3] In the presence of emulsifier, however, besides covalently linked polar groups, adsorbed ionic groups from the emulsifier can contribute to the surface charge. According to Stone-Masui and Wattilon,[4] adsorbed emulsifiers cannot easily be eliminated from the latex surface.

In this study, efforts were first concentrated on preparing monodisperse polystyrene latices with a wide range of surface charge in the absolute absence of conventional emulsifiers and then a study was made on the structure of electrical double layers on their surfaces.

For usual surfactant-free polystyrene latices prepared with potassium peroxodisulfate as an initiator,[3] the surface charge is made up of sulfonato groups originating from the initiator. Therefore, to increase the surface charge, the number of sulfonato groups on the final particle should be made maximal.[5] This can be achieved by choosing relatively high concentrations of potassium peroxodisulfate and allowing the polymerization to proceed at neutral pH in the presence of a buffer agent; the latter condition is to suppress the Kolthoff reaction[6] leading to generation of hydroxyl radicals.

It has been established that, in the neighborhood of a charged particle, there is an ionic atmosphere which is composed of two kinds of layers with different ion distributions, the Stern layer and the Gouy diffuse layer. The present study on the structure of electrical double layers is based on analyses of titration curves of latices. Since the conductivity of a latex suspension is determined by the number and distribution of counter ions in the double layer, conductometric titration curves obtained with various bases can be expected to provide direct information on the structure of electrical double layers. Here, a lot of titrations were carried out by using NaOH and $Ba(OH)_2$ on latices with a wide range of surface charge, and the relation between the surface charge and the double layer structure was discussed on the basis of analyses of titration curves.

Experimental

Materials. The styrene monomer was purified three times by vacuum distillation and the initiator, $K_2S_2O_8$, was recrystallized from water and dried in a desiccator. All the other chemicals were of analytical grade and used without further purification. The water was doubly distilled with an all-pyrex apparatus.

Preparation of Polystyrene Latices. Surfactant-free polystyrene latices were prepared with a modification of the method described by Kotera *et al.*[3] The modification is related to how to agitate the polymerizing system and how to control the pH during the polymerization. In a glass bottle of 250 cm^3, a mixture of 20 cm^3 styrene monomer and 175 cm^3 water or solution of KCl, $KHCO_3$, and K_2HPO_4 in water was purged with argon gas at 70 °C, after which 5 cm^3 of a $K_2S_2O_8$ solution was added. Immediately the bottle had a glass stopper applied, was attached to a wheel designed to rotate at a speed of 50 min^{-1} in a water bath thermostated at 70 °C, and subjected to rotation for 24 h for polymerization. Additional data on the polymerization conditions are given in Table 1.

The average particle size of each sample was determined by measuring the diameter of particles on an electron micrograph equipped with a projection scope.

Titration Experiments. Latex samples were treated with extensively purified Dowex ion-exchange resins according to the method described by Van den Hul and Vanderhoff[7] for converting all charged groups on the latex surface into the H^+ form. After the ion-exchange process, about 40 cm^3 of the latex was titrated under an argon atmosphere with two bases, NaOH and $Ba(OH)_2$ solutions, both potentiometrically and conductometrically, in the same vessel at 25 °C. In these titrations, it was necessary to adjust the solid content at 3—4% w/w, because large experimental errors were produced at lower than 3% w/w and because titration patterns were distorted at higher than 4% w/w due to surface conductivity at the latex-solution interface, as was also found by Wright and James.[8] Potentiometric titrations were performed with a Horiba pH meter (Model F-5) equipped with a glass electrode and conductometric ones with a Philips conductivity meter PW-9501 equipped with a Philips conductivity cell (PR-9515).

Determination of Coagulation Concentrations. Coagulation concentrations, C_{cfc}, of latex samples for KCl were determined by a static method. In a glass-stoppered tube 1.0 cm^3 latex of *ca.* 0.5% w/w was mixed with one of 4.0 cm^3 KCl solutions of various concentrations and the mixture

was kept at 25 °C in a water bath. After an elapse of 20 h for equilibration the transmission coefficient of the supernatant was measured against water using an Atago spectrophotometer (440-S) at wavelength 550 nm. Transmission coefficients were plotted against the KCl concentration. Extrapolation of the linear part of the curve to the horizontal yields a KCl concentration that is taken by us as the coagulation concentration.

Results and Discussion

Preparation and Characterization of Polystyrene Latices. Some examples of results on the preparation and characterization of surfactant-free latices are shown in Table 1. Columns (5) and (6) in this table give average particle sizes determined by electron microscopy. The presence of KCl in the polymerizing system leads to larger particles; compare N-2 with K-1 or K-2. It is seen that in the absence of added electrolyte an increase in the initiator ($K_2S_2O_8$) leads to larger particles. Addition of $KHCO_3$ or K_2HPO_4, however, does not alter the radius significantly; compare N-2 with C-1 or N-3 with P-2. Size distributions are kept very narrow, with $D_w/D_n<1.01$.

The surface charge in column (7) was obtained by titration in an argon atmosphere with bases. As the example in Fig. 1 shows, both the equivalent points determined by the potentiometric and conductometric titrations are in good agreement, and the titration curves show no indication of presence of surface groups other than strong acid groups. These groups are certainly $-OSO_3^-$ groups originating from $K_2S_2O_8$.[2] Such titration curves, however, were observed only for fresh samples; for those latices left long after preparation, there were two break points on the titration curve, which suggests that surface sulfonate groups will be hydrolyzed gradually into hydroxyl or carboxyl groups during storage, with rates dependent on the conditions for storage. In each series the surface charge (σ_0) increases with increasing $K_2S_2O_8$ concentration. This tendency may be predicted from the mechanism of emulsion polymerization. Buffering the system during polymerization leads to higher values of σ_0; compare N-series with C- or P-series. As mentioned before, this is attributed to suppression of the Kolthoff reaction. The highest surface charge attained after ion exchange is 8.7 $\mu C/cm^2$. In the absence of specific adsorption it would lead to diffuse double layer potentials of 190 mV and 80 mV in 10^{-3} or 10^{-1} M† (1-1) electrolytes, respectively. However, due to specific adsorption in the Stern layer, lower values for ζ-potentials will almost certainly be found from electrokinetic study.

Double Layer Structure and Stability. The present study on the structure of electrical double layers at the polymer-solution interface is based on analysis of titration curves. The titration was carried out only for samples within a few weeks after preparation. Figure 2 shows an example of conductometric titration curves obtained by using two bases. In the case using NaOH, both the descending and ascending legs of the titration curve are linear, and the curve has

† 1 M=1 mol dm^{-3}.

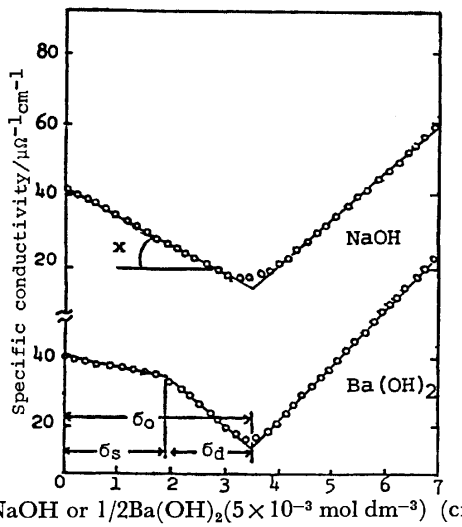

Fig. 2. Conductometric titration curves conducted using NaOH and $Ba(OH)_2$ for latex K-1.
x: Slope of the descending leg of the titration curve, σ_0: surface charge, σ_s: Stern-layer charge, σ_d: diffuse-layer charge.

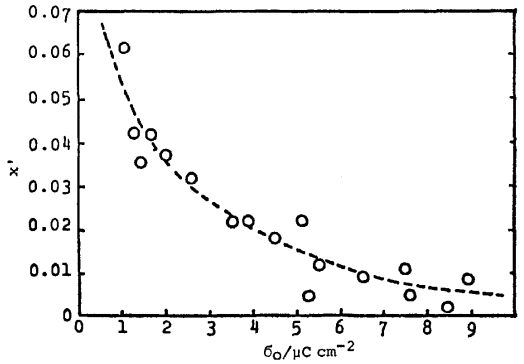

Fig. 3. Relation between the corrected slope of titration curve(x') and the surface charge(σ_0) of polystyrene latices.

a shape typical of the titration of a strong acid with a strong base. This results from equal preference of strong acid surface groups for Na^+ and H^+ ions. However, the negative slope of the descending leg is much smaller than that for a strong acid in solution; it depends on the amount of the surface charges of latex due to the limited mobility of counter ions in the double layer. Usually, the electrical conductivity of a system depends on the product of the number of mobile ions and their mobility. Therefore, the descending slope in the present system is influenced by the following three factors: (a) total surface area, (b) the amount of surface charges, and (c) the degree of binding of counter ions to the surface, which depends on the structure of the electrical double layer. If factors (a) and (b) can be controlled, the residual slope (x') gives the contribution from factor (c), which provides useful information on the structure of electrical double layer. Figure 3 shows a plot of slopes obtained by the above process against surface-charge density (σ_0) as determined from equivalent points for the same titration curves. The slope (x'), in which the dimension of x is related to the scale for

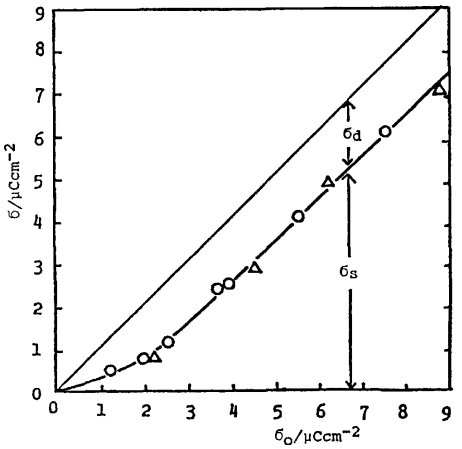

Fig. 4. Charge distribution in the Stern layer(σ_s) and the diffuse layer(σ_d) as a function of the surface charge(σ_0). △: Data reported by W. Norde.

the titration curve, decreases rapidly with an increases in σ_0, and the value for the highest surface-charge latex is about one-sixth that of the lowest one. This indicates that the higher the surface charge, the more tightly are the counter ions held on the surface.

The lower conductometric titration curve in Fig. 2 shows a result obtained using $Ba(OH)_2$, in which an inflection point is found on the descending leg. According to Van den Hul and Vanderhoff,[2] the occurrence of the inflection point is connected with fixation of counter ions in the Stern layer. Counter ions condensed closely to surface sulfonato groups are exchanged preferentially for Ba^{2+}, and then dissociated ions in the diffuse double layer are exchanged. Counter ions in the diffuse double layer contribute effectively to the conductivity through their high mobility.

Using this concept, we can determine the number of counter ions located in the Stern layer and in the diffuse layer from the position of the inflection point on the descending leg. Figure 4 shows a result derived on the basis of inflection points, which gives charge distributions in the Stern layer (σ_s) and in the diffuse double layer (σ_d) as a function of surface charge (σ_0). It is obvious that, at high σ_0 values, σ_s increases at about the same rate as σ_0, leading to a virtually constant value of σ_d.

A similar result has been reported by W. Norde[9] for polystyrene latices prepared by the same method as ours, his result being included in Fig. 4. He calculated σ_d from ζ-potentials for latices of various surface charges using the Gouy-Chapman equation. In this case, ζ-potential was derived following the method of Wiersema[10] from electrophoretic mobilities in a 0.01 M KNO_3 solution. As can be seen from Fig. 4, his data are located on the same line as ours, which suggests that the region given by the inflection point of the conductometric titration curve corresponds to the slipping plane of the electrophoresis in 0.01 M KNO_3.

According to the Derjaguin-Landau-Verway-Overbeek (DLVO) theory,[11] coagulation concentration, C_{cfc}, serves as a means for quantifying the sta-

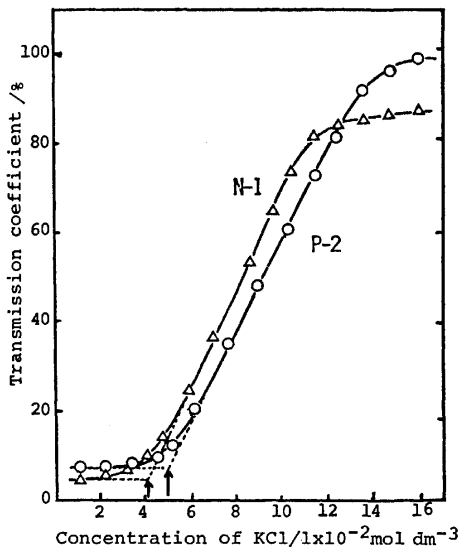

Fig. 5. Transmission coefficient *vs.* concentration of KCl plots for latex N-1(△) and latex P-2(○). The arrow indicates the derived coagulation concentration.

TABLE 2. COAGULATION CONCENTRATION OF KCl FOR THE LATICES WITH A DIFFERENT SURFACE CHARGE

Sample	Surface charge	Coagulation concn
	μC/cm²	10^{-2} M
N-1	1.1	4.02
K-1	3.2	4.35
C-2	6.9	4.71
P-2	8.7	4.97

bility of an electrostatically stabilized dispersion. Figure 5 shows an example plot of transmission coefficient *vs.* concentration of KCl. Values of C_{cfc} for latices with different surface charges are given in Table 2. It is seen that C_{cfc} increases with increasing surface charge, as expected from the DVLO theory, but C_{cfc} for the highest surface-charge latex (P-2) is not much different from C_{cfc} for the lowest-charge latex (N-1).

At any rate, it can be concluded that conductometric titration curves of polystyrene latices furnish important knowledge regarding the structure of electric double layers. From these analyses and coagulation experiments, it is realized that colloidal stability depends on the potential at the Stern layer over which the diffuse double-layer charge is distributed, because C_{cfc} is not much dependent on the surface charge of latex samples.

The author thanks Professor J. Lyklema and Dr. W. Norde, Agricultural University, Wageningen, The Netherlands, and Mr. H. Kawai, Tokyo Kyoiku University, Tokyo, Japan, for their advice and cooperation.

Further Studies of the Rate Constant for Chemical Excitation of OH in Shock Waves

Tohru KOIKE* and Kihei MORINAGA

Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239

(Received April 30, 1981)

Electronically excited $OH(^2\Sigma)$ is formed both by chemical and thermal excitations in the H_2-O_2 reaction. The $OH(^2\Sigma)$ emission in the partial equilibrium region of the reaction was measured in 1250—3450 K incident shock waves for a mixture, $H_2/O_2/Ar=2/2/96$, at starting pressures, 6—30 Torr. The correlation factor between the emission intensity and the concentration of $OH(^2\Sigma)$ was derived in the temperature region above 2800 K where the thermal excitation of $OH(^2\Sigma)$ is dominant. The factor was utilized to estimate the concentration of chemically excited $OH(^2\Sigma)$ and the rate constant of the reaction $O+H+M=OH(^2\Sigma)+M$ was determined as $10^{13.92\pm0.17}\exp[-(8.3\pm1.2)\ \mathrm{kcal}/RT)]$ ($\mathrm{cm^6\ mol^{-2}\ s^{-1}}$).

The UV emission of $OH(^2\Sigma)$, hereafter OH*, in the H_2-O_2 reaction has been studied in detail by many researchers in discharge flow systems,[1] in flames,[2] and in shock waves.[3-5] The origin of OH* in a relatively low temperature region is attributed to the chemical excitation of $O+H+M=OH^*+M$,[3,4] while, in a high temperature region, thermally excited OH* is more dominant than chemically excited.[4] The transition from chemical to thermal excitation has been observed to occur around 2300 K.[4]

The following reaction scheme represents the growth and decay of OH* in the low temperature region.[3-5]

$$O + H + M = OH^* + M \qquad (a)$$

$$OH^* + M' = OH + M' \qquad (b)$$

$$OH^* = OH + h\nu \qquad (c)$$

The reverse reaction (—b) is equivalent to the thermal excitation and it is left out in the low temperature region. The reverse reaction (—c) is self-absorption and it can be disregarded in the present experiment.[4] Since it is expected that $k_b > k_{-a}$ and $k_b[M'] > k_c$ under the present experimental conditions as discussed before,[4,5] the OH* formed is quenched mainly by reaction (b). Then, the steady state assumption for OH* leads to the following expression for OH* in the low temperature region.[4,5]

$$[OH^*]_{ch} = k_a[O][H][M]/k_b[M'] \qquad (1)$$

OH* is formed by the thermal excitation as well as by the chemical excitation as above, and the thermally excited [OH*] is expressed by the partition of OH and OH* as:

$$[OH^*]_{th} = [OH](f_{OH^*}/f_{OH})\exp(-93.4\ \mathrm{kcal}/RT), \qquad (2)$$

where the f's are partition functions of OH and OH*. The value of 93.4 kcal corresponds to the energy difference between the two states of $^2\Sigma(v=0)$ and $^2\Pi(v=0)$. Since the value of [OH] can be estimated by computer modeling with an appropriate reaction mechanism, the value of $[OH^*]_{th}$ is obtainable.

The UV emission intensity I due to the reaction (c) is related to [OH*] as:

$$I = C\,k_c[OH^*], \qquad (3)$$

where C is a correlation factor for the detecting system. In the preceding paper,[5] the dependence of $\log I$ on $10^4/T$ was analysed by computer modeling and a tentative value of k_a was reported. We mentioned in that paper that a more precise value of k_a could be obtained by absolute measurement of the emission intensity I in the low temperature region, though the method is not free from the correlation factor of a standard radiant bulb.

In the present paper, the value of $[OH^*]_{th}$ is correlated with the emission intensity I, and the constancy of $[OH^*]_{th}/I$ at high temperatures is demonstrated. The emission intensity I in the low temperature region, where the chemical excitation is predominant, is analysed to obtain more credible k_a values using the correlation factor so derived.

Experimental

The experiments were done in incident shock waves. The shock tube used in the previous work[5] was rebuilt and reinstrumented to improve the evacuation and the optics. The evacuation of the test section was less than 10^{-4} Torr (1 Torr≈133.322 Pa) before each run. A photomultiplier (Hamamatsu-TV, 7696) having S-11 response combined with a monochromator (Jarrell-Ash, JE-25, dispersion=3.3 nm/mm) was used to measure the OH* emission intensity. The wavelength of the monochromator was centered at 306.4 nm with entrance and exit slits having 1 and 2 mm width, respectively.

The gases used to prepare the test gas, $H_2/O_2/Ar=2/2/96$, were 99.99999% pure H_2, 99.999% pure O_2 and 99.999% pure Ar; all of them were from Nippon Sanso Co.

Results and Discussion

Even in the high temperature region, the oscillogram trace of the emission intensity resembles that shown in the previous paper[5] having a plateau height of I in the partial equilibrium.

The partial equilibrium $[OH^*]_{th}$ was evaluated by using a reliable partial equilibrium value of modeled [OH] and the ratio of the partition functions, f_{OH^*}/f_{OH}, in Eq. 2. The reaction mechanism adopted for the computer modeling is identical with that in the previous work.[5] The modeled [OH] along with the other species concentrations for the later discussion are shown in Fig. 1. The partition functions were evaluated using the molecular constants of OH and OH* reported.[6] If the thermal excitation is really predominant in the high temperature region, the above $[OH^*]_{th}$ divided by the emission intensity I should be constant. In Fig. 2, the values of $[OH^*]_{th}/I$ are plotted against T. Though the data are scattered,

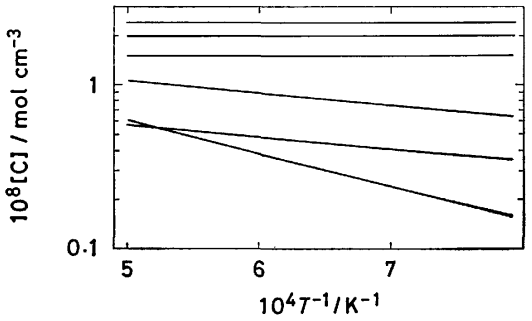

Fig. 1. Temperature variation of the modeled concentrations in the partial equilibrium (P_1=10 Torr). The species are, from top to bottom on the right hand side, H_2O, O_2, H, O, H_2, and OH.

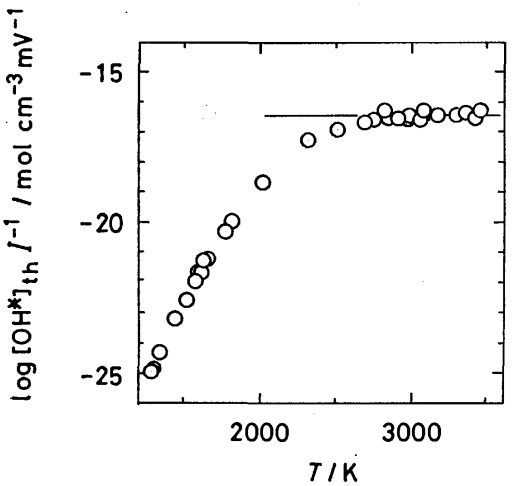

Fig. 2. Temperature variation of $[OH^*]_{th}/I$. The line shows an average value for $[OH^*]_{th}/I$ above 2800 K.

the constancy is adequate above 2800 K, and the value of $[OH^*]/I$ or C k_c in Eq. 3 was evaluated as:

$$[OH^*]/I = (3.0\pm1.0) \times 10^{-17} \text{ (mol cm}^{-3}\text{ mV}^{-1}\text{)}.$$

Because of the temperature variation of the rotational population in the $^2\Sigma(v=0)$ state, it is expected that each of the intensity maxima of six branches moves in or out of the wavelength range of 303.1—309.7 nm and, due to this effect, there might be a possibility not to hold the constancy of $[OH^*]/I$ in the temperature range. Such a temperature effect on the emission intensity could be seen by comparing following J_{max} values at different temperatures. In contrast with the vibrational and the electronic populations, the number of molecules does not simply decrease with increasing rotational quantum number. First it increases to a maximum and then decreases, and the rotational quantum number at which the number of molecules shows a maximum is given by:[6]

$$J_{max} = 0.5896 \times \sqrt{T/B} - 1/2,$$

where B=rotational constant (17.355 cm^{-1} for OH*). Since the J_{max} values increase with temperature, only the J_{max} values at the lowest and the highest ends of the temperature range need be examined. The J_{max} values evaluated are 7.0 and 7.8 at 2800 K and 3450 K, respectively. According to the spectra reported for the $^2\Sigma^+ - ^2\Pi$ transition of OH,[7] it is possible to assign each rotational transition to one of the emission lines as follows. J=7 and 8 of three branches, P_1, P_2, and Q_2 are out of the wavelength range. The J values in Q_1 branch are at the end of the wavelength range longer than 309.0 nm. As for R_1 and R_2 branches, the J values are almost at the center of the wavelength range. Thus, none of the intensity maxima of the six branches are expected to move in or out of the wavelength range in this temperature range of 2800—3450 K.

Table 1. Quenching cross section, σ, between OH* and M′ and calculated k_b value

M′	σ/Å^2	$(k_b/T^{0.5})$/cm^3 mol^{-1} s^{-1}
Ar	0.059[9]	1.5×10^{10}
H_2	6.9[9]	4.5×10^{12}
O_2	10[a]	2.6×10^{12}
H_2O	57[b]	1.7×10^{13}
H	22[9]	2.0×10^{13}
O	5[c]	1.5×10^{12}

a) H. P. Hooymayers and C. Th. Alkemade, *J. Quant. Spectrosc. Radiat. Transfer*, **7**, 495 (1967). b) M. Kaneko, Y. Mori, and I. Tanaka, *J. Chem. Phys.*, **48**, 4468 (1968). c) Assumed.

The rate constant k_c is the reciprocal of the radiative life time of OH*, which is reported to change slightly depending on the value of the rotational quantum number of the $^2\Sigma$ state.[8] In this study, such dependence of the k_c value, as well as the temperature dependence, was assumed to be negligible. Therefore, the above value of $[OH^*]/I$ could be used in the lower temperature region to obtain the chemically excited [OH*] by observing I.

Once the chemically excited [OH*] is determined, unknown parameters to evaluate the k_a value from Eq. 1 are the concentrations of H, O, M, M′, and the k_b value. The partial equilibrium concentrations of H and O are shown in Fig. 1. The third body M of the reaction (a) was assumed to be all of the species in the reaction region having the same efficiency, *i.e.*, [M]=density. The quenching partner M′ considered are shown in Table 1 along with the k_b value. The k_b values were evaluated by collision theory using the collision cross sections of M′ reported elsewhere. OH was not considered as a collision partner, since it is reported that OH has negligible quenching effect on OH*.[9]

Besides the above physical quenchings for OH*, the possibility of chemical quenchings such as $OH^*+H=H_2+O$ and $OH^*+H_2=H_2O+H$ are to be considered. The rate constant for the former reaction has been discussed in detail[9] and is elucidated to be small compared with the physical quenching of H. The rate constant for the latter reaction can be assumed to be equal to the frequency factor of the ground state reaction of $OH+H_2=H_2O+H$. If the frequency factor of 5.25×10^{13} in the H_2-O_2 reaction mechanism in Ref. 5 is adopted, the chemical quenching of OH* by H_2 is about 1/3 of the physical quench-

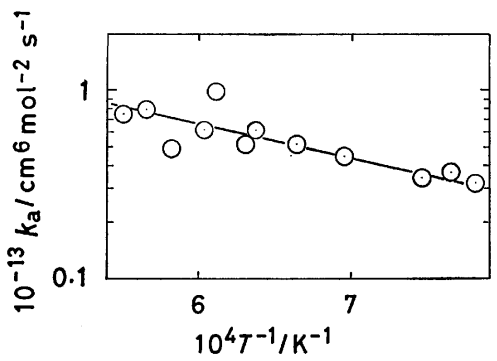

Fig. 3. Arrhenius plots for k_a.
The line shows the least squares fit for the data points.

ing by the same partner at 1500 K. Since the cross sections of the other species are larger than that of H_2, the physical quenchings are more effective than the chemical quenchings. Thus, no chemical quenchings were considered in this study.

The Arrhenius plot of k_a thus evaluated is shown in Fig. 3. The least squares fitting gave the following expression for the k_a value with one standard error.

$$k_a = 10^{13.92\pm0.17}\exp[-(8.3\pm1.2)\text{kcal}/RT)](\text{cm}^6\,\text{mol}^{-2}\,\text{s}^{-1})$$

(1 kcal=4.184 kJ)

Schiff *et al.*[1] obtained the rate constant for the chemical excitation of OH* in the course of chemiluminescence studies in a discharge flow system at pressures of 0.4—4 Torr and 300 K. They assumed the bimolecular reaction of ground state O and H to form OH* and estimated the rate constant at $(3\pm1)\times10^{-21}$ cm^3 molecule^{-1} s^{-1}. If the figure is converted to the termolecular rate constant assuming O+H+M=OH*+M, it is given as $(8.4\pm2.4)\times(10^{10}$—$10^{11})$ cm^6 mol^{-2} s^{-1}, which is 3 to 4 powers of 10 larger than our value extrapolated to 300 K. In a general discussion of Schiff's paper, Gardiner[10] remarked that the absolute intensity measurement for the chemiluminescence of OH* in the shock heated H_2-O_2 reaction done in his laboratory gave the bimolecular rate constant of 1.0×10^{-18} cm^3 molecule^{-1} s^{-1} at 1500 K. If the termolecular reaction is assumed, the figure is 3.3×10^{11} cm^6 mol^{-2} s^{-1}, which is about 10 times less than the value determined in this study. His value was derived by assuming only H_2O and O_2 to be the physical quenchers of OH*. If all of the quenchers are taken into account as was done in this study, his value should be compatible to the present value.

(Received May 2, 1981)

The interactions of tris(2,2′-bipyridine)ruthenium(II)($[Ru(bpy)_3]^{2+}$) with some polyanions have been studied by means of cation-exchange resins and the luminescence of $[Ru(bpy)_3]^{2+}$. In an aqueous solution of $[Ru(bpy)_3]^{2+}$ in the presence of sodium poly(*p*-styrenesulfonate)(PSS), the adsorbability of $[Ru(bpy)_3]^{2+}$ on the cation-exchange resins is strongly suppressed by the binding of $[Ru(bpy)_3]^{2+}$ to the polyanion. The relative luminescence intensity of $[Ru(bpy)_3]^{2+}$ in an aqueous solution is enhanced by the addition of PSS. With the addition of sodium chloride to an $[Ru(bpy)_3]^{2+}$/PSS solution, the interaction is impeded by the shielding of the electrostatic potential in the polymer domains by the counter ions. A cooperative interaction between PSS and $[Ru(bpy)_3]^{2+}$ is postulated with a view to accounting for the results. A chemical application of the interaction is demonstrated.

The luminescence behavior of $[Ru(bpy)_3]^{2+}$ and its analogous compounds has been well studied using several experimental techniques.[1–8] Meisel and Matheson[9] suggested that the luminescence from the lowest excited state of $[Ru(bpy)_3]^{2+}$, $[*Ru(bpy)_3]^{2+}$, is efficiently quenched by low concentrations of Cu^{2+} ions when poly(vinyl sulfate)(PVS) is present in the solution. The quenching reaction occurs nearly exclusively in the PVS solution. The efficient quenching results from the Cu^{2+} and $[Ru(bpy)_3]^{2+}$ residing in the potential field of the same polymer. They demonstrated a possible utilization of this system in solar-energy conversion and storage systems. The effect of PVS on the luminescence spectrum of $[Ru(bpy)_3]^{2+}$ was also studied by Meisel and Matheson.[9] However, little change in the emission spectrum from $[*Ru(bpy)_3]^{2+}$ was seen when PVS was added to an aqueous solution. This fact indicates that PVS does not affect the energy level of $[*Ru(bpy)_3]^{2+}$ in an aqueous solution.[9]

The results of the luminescence study of $[Ru(bpy)_3]^{2+}$ in an aqueous solution of sodium dodecyl sulfate[3] show that the emission maximum shifts a little to a longer wavelength in a negatively charged micellar solution, although the emission intensity is nearly the same in both micellar solution and pure water. It has been suggested that the micellar effect on the emission spectrum is caused by the hydrocarbon chains and not by the charged sulfonato groups on the surfactant molecules.[10]

The effect of hydrophobic interaction between a polyion and a metal-complex ion has been little studied. In the present study, the interaction between PSS and $[Ru(bpy)_3]^{2+}$, both of which have hydrophobic and charged moieties, has been investigated by means of ion-exchange resins and the luminescence spectrum of $[Ru(bpy)_3]^{2+}$.

Experimental

Materials. Tris(2,2′-bipyridine)ruthenium(II) chloride hexahydrate, $[Ru(bpy)_3]Cl_2 \cdot 6H_2O$,[11] and tris(1,10-phenanthroline)cobalt(III) chloride octahydrate, $[Co(phen)_3]Cl_2 \cdot 8H_2O$,[12] were prepared and purified by the methods described elsewhere. The other inorganic reagents were of a reagent-grade purity and were used without further purification. $CuSO_4 \cdot 5H_2O$ was used for the preparation of the stock solution of Cu^{2+}. Poly(*p*-styrenesulfonic acid) was prepared by the radical polymerization of *p*-styrenesulfonic acid. Freshly distilled *p*-styrenesulfonic acid was used for the polymerization. *p*-Styrenesulfonic acid was dissolved in 50 cm^3 of dimethyl sulfoxide at a total concentration of 2 mol dm^{-3}. To the solution in a 100-cm^3 flask were added a 1.0×10^{-3} mol portion of azobisisobutyronitrile; the flask was shielded after three freeze-evacuation cycles, and then the mixture was kept at 60 °C for 5 h. The resulting polymer was collected by precipitation from diethyl ether. The white powder was dissolved in aqueous dilute hydroxide and dialyzed in water for 50 h. Sodium poly(*p*-styrene sulfonate), PSS, was obtained by the evaporation of the dialyzed solution under reduced pressure. The specific-viscosity number of the PSS in 0.1 mol dm^{-3} KCl solution was 0.51 dl g^{-1} at 25 °C. Sodium poly(vinyl sulfate)-(PVS)($\overline{M}n$ 2×10^5: $\overline{M}n$ is number-average molecular weight) was prepared by the established method.[13] Poly(acrylic acid)($\overline{M}n$ 4×10^5) and poly(methacrylic acid)($\overline{M}n$ 5×10^5) were prepared by the $K_2S_2O_8$–$Na_2S_2O_3$-initiated radical polymerization of acrylic acid and methacrylic acid, respectively, in water at 30 °C. Sodium salts of poly(acrylic acid)-(PAA) and poly(methacrylic acid)(PMA) were prepared by the dialysis of the corresponding poly acid in dilute hydroxide for 50 h. The dialyzed solutions were evaporated under reduced pressure. These poly acid salts were obtained as a white powder. The concentrations of the polyions are represented by those of the monomer units.

Column-exchange Chromatography. A 2-cm^3 portion of aqueous polyelectrolyte or benzenesulfonate, BS, if necessary, sodium chloride were poured onto a water-jacketed column of cation-exchange resins (Dowex 50 W X-8, 100—200 mesh, the H form, 1 cm × 5 cm); then, an aliquot of water was passed through the column with 0.8 cm^3 min^{-1} at 25 °C. The concentrations of $[Ru(bpy)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ were determined spectrophotometrically using a Hitachi Model 320 spectrophotometer, while that of Cu^{2+} was determined by means of the atomic absorption spectra using a Hitachi Model 170-40 atomic absorption spectrometer.

Luminescence Study. Oxygen was removed from the sample solutions by bubbling a nitrogen gas which had been purified by passing it through an acidic solution of

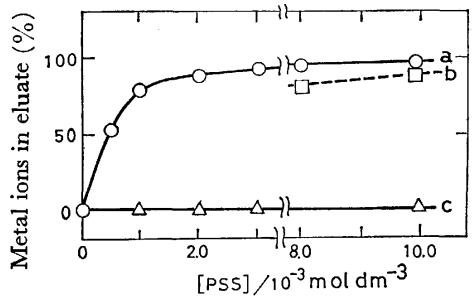

Fig. 1. Plots of the percentage of the metal ions in eluant *vs.* concentration of PSS in aqueous solution at 25 °C.
a: 1.0×10^{-4} mol dm^{-3} $[Ru(bpy)_3]^{2+}$, b: 1.0×10^{-4} mol dm^{-3} $[Co(phen)_3]^{2+}$, c: 1.0×10^{-4} mol dm^{-3} Cu^{2+}.

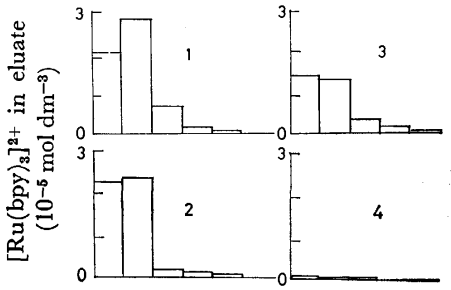

Fig. 2. Cation-exchange column chromatograms of 1.0×10^{-4} mol dm^{-3} $[Ru(bpy)_3]^{2+}$/3.0×10^{-3} mol dm^{-3} PSS/NaCl at 25 °C.
[NaCl]/mol dm^{-3}: 1; 0, 2; 1.0×10^{-4}, 3; 1.0×10^{-3}, 4; 1.0×10^{-2}.

chromium(II) sulfate for 30 min. Luminescence measurements were made in a 1 cm × 1 cm quartz cell on a Shimadzu RF-500 spectrofluorometer. The temperatures of the samples were adjusted at 25±0.1 °C by means of a thermostated cell holder. The excitation wavelength for $[Ru(bpy)_3]^{2+}$ was 455 nm. A PRA Model 3000-nanosecond fluorometer was used for the determination of the excited state lifetime of $[Ru(bpy)_3]^{2+}$.

Results and Discussion

Studies of the Effect of Polyions by Means of Ion-exchange Resins. The complex cation of $[Ru(bpy)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ and the aquacopper(II) ion, Cu^{2+}, are strongly adsorbed on the cation-exchange resins. The adsorbed $[Ru(bpy)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ ions were hardly eluted with water, dil HCl, and dil NaCl solutions. With the addition of PSS to an aqueous solution of $[Ru(bpy)_3]^{2+}$, however, some interesting effects upon the adsorbability of the metal ions were observed.

In $[Ru(bpy)_3]^{2+}$/PSS, a part or all of the $[Ru(bpy)_3]^{2+}$ passes through the column of the cation-exchange resins: the amount of the adsorbed $[Ru(bpy)_3]^{2+}$ is dependent on the PSS concentration, as is shown in Fig. 1. In the lower concentration region of PSS, the ratio of the amounts of $[Ru(bpy)_3]^{2+}$ in the eluate to the total amounts of $[Ru(bpy)_3]^{2+}$ in the initial solution increased with the increase in the PSS concentration. In the presence of a large amount of PSS (*ca.* 0.1 mol dm^{-3}) in the original solution, the $[Ru(bpy)_3]^{2+}$ ions were completely passed through the column.

In the $[Ru(bpy)_3]^{2+}$/PSS/NaCl systems, the total amount of $[Ru(bpy)_3]^{2+}$ in the eluate decreased with the increase in the NaCl concentration (Figs. 2 and 3). On the other hand, the adsorbability of $[Ru(bpy)_3]^{2+}$ on the resins was unaffected in the presence of a large amount of polyanions, such as PVS, PMA, and PAA and the monomer analogue such as benzenesulfonate.

A similar effect was observed in the $[Co(phen)_3]^{2+}$/PSS system (Fig. 1b). Unfortunately, the precipitate was formed by the addition of PSS to the $[Co(phen)_3]^{2+}$ solution when the PSS concentration was lower than about 6×10^{-3} mol dm^{-3}. The adsorbability of Cu^{2+} on the resins was, however, unaffected in the presence of PSS (Fig. 1c).

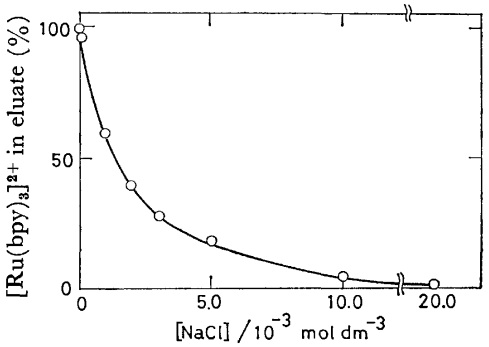

Fig. 3. Plots of the ratio of $[Ru(bpy)_3]^{2+}$ in eluate *vs.* concentration of NaCl at 25 °C.
$[Ru(bpy)_3^{2+}]=1.0\times10^{-4}$ mol dm^{-3}, $[PSS]=3.0\times10^{-3}$ mol dm^{-3}.

The decrease in the adsorbabilities of $[Ru(bpy)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ on the cation-exchange resins on the addition of PSS seems to indicate that the attractive interactions between PSS and $[Ru(bpy)_3]^{2+}$ or $[Co(phen)_3]^{2+}$ are sufficiently large to prevent the cation-exchange reaction between the hydrogen ions on the resins and the metal-complex ions in the solution. In the $[Ru(bpy)_3]^{2+}$/PSS and $[Co(phen)_3]^{2+}$/PSS systems, it is considered that the hydrophobic interaction between the complex ion and the polyanion contributes to the adsorbabilities of the metal-complex ions on the resins since few changes in the adsorbabilities of $[Ru(bpy)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ were observed in the presence of PVS, PAA, PMA, or BS. It may be concluded that a strong interaction between $[Ru(bpy)_3]^{2+}$ and PVS, PAA, PMA, or BS would not occur, since these polyelectrolytes have no hydrophobic moieties such as a phenyl ring on the polymer chains. Intimate multi-site bindings between the pendant phenyl rings, which are bound to the polymer backbone with a high density, and the metal-complex ion may be necessary for such a strong interaction, as has been seen in the cases of the $[Ru(bpy)_3]^{2+}$/PSS and $[Co(phen)_3]^{2+}$/PSS systems, since no change in the adsorbability was observed in the $[Ru(bpy)_3]^{2+}$/BS and $[Co(phen)_3]^{2+}$/BS systems.

The results seem to indicate that the $[Ru(bpy)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ ions are concentrated in the polymer domains as a result of the electrostatic attraction,

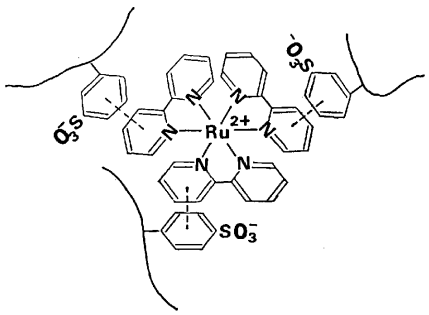

Fig. 4. Proposed structure of PSS bound $[Ru(bpy)_3]^{2+}$ by cooperative interaction.

and that, furthermore, the complex ions are bound tightly to the pendant phenyl groups of PSS by the hydrophobic interaction. The bipyridine rings of $[Ru(bpy)_3]^{2+}$ and the phenanthroline rings of $[Co(phen)_3]^{2+}$ would form intimate bindings to the pendant phenyl groups of PSS by means of hydrophobic interaction with the aid of the electrostatic force. A schematic representation of such coopertive interaction is postulated in Fig. 4. The molecular motion of the complex ions in the domains would be fairly much restricted by such interaction, and hardly none of the complex ions tightly bound to the polyanion chains should be adsorbed on the cation-exchange resins.

In the $[Ru(bpy)_3]^{2+}$/PSS/NaCl system the increase in the adsorbability of $[Ru(bpy)_3]^{2+}$ on the resins with the addition of NaCl can be explained by the fact that the $[Ru(bpy)_3]^{2+}$ ions are successively excluded from the polymer domains with increase in the concentration of the simple salt. The shielding of the potential field of the polyion domains by the counter ions reduces the electrostatic attraction for the complex ions. In the higher concentration region of NaCl, $[Ru(bpy)_3]^{2+}$ in the domains would be completely excluded from the domains. Thus, the $[Ru(bpy)_3]^{2+}$ ions are well adsorbed on the resins.

Effect of PSS on the Luminescence of $[Ru(bpy)_3]^{2+}$. The luminescence spectrum from $[*Ru(bpy)_3]^{2+}$ in an aqueous solution was greatly affected in the presence of PSS: the luminescence intensity at the luminescence maximum increased with the increase in the concentration of PSS (Figs. 5 and 6), while the absorption band in the visible region was not affected. A little change in the luminescence maximum is seen in the presence of PSS (Fig. 5): the luminescence peak of $[Ru(bpy)_3]^{2+}$ in the presence of 4.0×10^{-4} mol dm^{-3} PSS shifts to a wavelength longer by about 4 nm than that in the absence of PSS.

The variation in the relative luminescence intensity with the concentration of the polyion is given in Fig. 6. In the concentration region of PSS lower than about 2×10^{-4} mol dm^{-3}, where $[PSS]/[Ru(bpy)_3]^{2+}<10$, the relative intensity increases sharply on the addition of the polyion. However, no noticeable change in the CTTL and luminescence bands was observed in the presence of a large amount of PAA, PMA, or BS. Similar results have been reported in the luminescence study of $[Ru(bpy)_3]^{2+}$ in an aqueous PVS solution.[2] These facts seem to indicate that

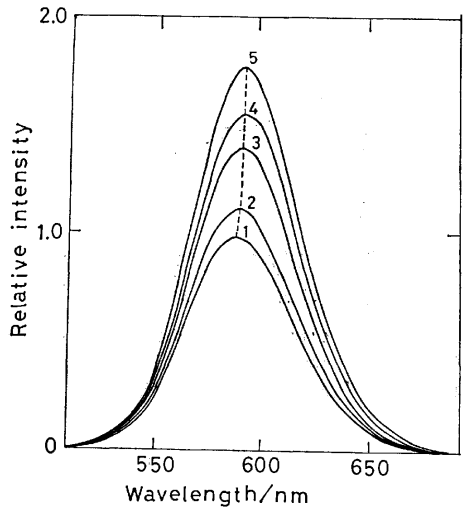

Fig. 5. Luminescence spectra of $[Ru(bpy)_3]^{2+}$ in PSS solution at 25 °C.
$[Ru(bpy)_3^{2+}]=2.0\times10^{-5}$ mol dm^{-3}, [PSS]/mol dm^{-3}: 1; 0, 2; 2.5×10^{-5}, 3; 5.0×10^{-5}, 4; 1.0×10^{-4}, 5; 4.0×10^{-4}.

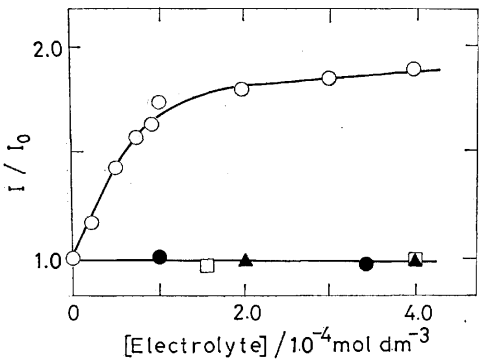

Fig. 6. Dependence of the luminescence intensity on the concentration of electrolyte at 25 °C.
$[Ru(bpy)_3^{2+}]=2.0\times10^{-5}$ mol dm^{-3}, ○: PSS, ●: BS, ▲: PAA, □: PMA.

such electrolytes as PAA, PMA, and BS do not affect the energy levels of $[Ru(bpy)_3]^{2+}$ and that no quenching or quenching reversal of the luminescence by these electrolytes occurs. These facts also suggest that the luminescence spectrum of $[Ru(bpy)_3]^{2+}$ is little affected by binding to the polyanions attributable to only the electrostatic force.

The dependence of the luminescence intensity on the concentration of urea in $[Ru(bpy)_3]^{2+}$/PSS is shown in Fig. 7. The luminescence intensity decreases with an increase in the concentration of urea. This may be due to the reduction of the hydrophobic interaction by the addition of urea. It may be concluded from the results that the enhancement of the luminescence intensity is brought about as a result of a cooperative interaction, which is also suggested by the results of the column-exchange chromatography. An intimate site binding due to the hydrophobic interaction would cause a sharp increase in the luminescence intensity upon the addition of PSS, presumably as a result of the restriction of the molecular motion of the $[Ru(bpy)_3]^{2+}$ bound to the polymer chains.

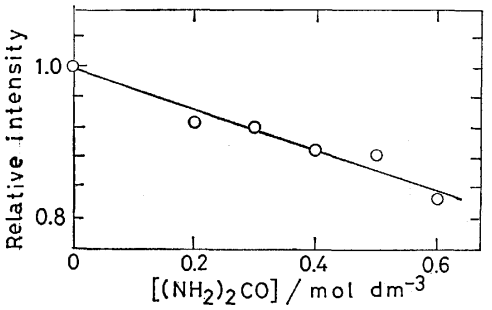

Fig. 7. Effect of urea on the luminescence intensity of $[Ru(bpy)_3]^{2+}$ in aqueous PSS solution at 25 °C. $[Ru(bpy)_3^{2+}]=2.0\times10^{-5}$ mol dm^{-3}, $[PSS]=2.0\times10^{-4}$ mol dm^{-3}.

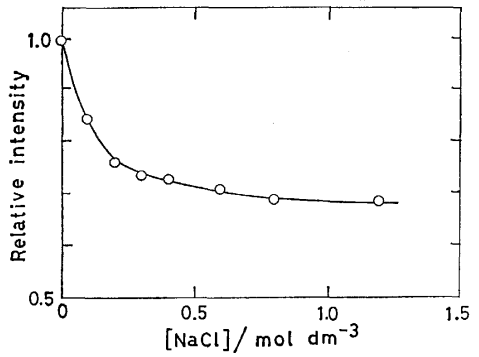

Fig. 8. Effect of sodium chloride on the luminescence intensity of $[Ru(bpy)_3]^{2+}$ in aqueous solutions at 25 °C. $[Ru(bpy)_3^{2+}]=2.0\times10^{-5}$ mol dm^{-3}, $[PSS]=2.0\times10^{-4}$ mol dm^{-3}.

Consequently, the lifetime of the lowest excited state of $[Ru(bpy)_3]^{2+}$ in the presence of 2.0×10^{-4} mol dm^{-3} PSS was longer than that in the absence of PSS: the excited-state lifetime in the presence and absence of PSS were 590±4 nsec and 450±2 nsec respectively at 28 °C.

The effect of sodium chloride on the luminescence of $[Ru(bpy)_3]^{2+}$ in an aqueous PSS solution is shown in Fig. 8. This figure shows that the luminescence intensity decreases with an increase in the salt concentration. Na^+ ions start to displace the $[Ru(bpy)_3]^{2+}$ out of the polymer domains in the higher-concentration region of sodium chloride: therefore, the luminescence intensity should be decreased with the concentration of the salt.

Application of the Cooperative Effect. In an aqueous solution of $[Ru(bpy)_3]^{2+}$ containing an excess of PSS, the $[Ru(bpy)_3]^{2+}$ ions bound to PSS should be hardly replaced by the hydrogen ions. Then, a simple application of the cooperative effect, *e.g.*, the separation of $[Ru(bpy)_3]^{2+}$ from Cu^{2+}, was tested by means of ion-exchange chromatography. To a 2-cm^3 portion of an aqueous solution containing 5.0×10^{-4} mol dm^{-3} $[Ru(bpy)_3]^{2+}$ and 5.0×10^{-4} mol dm^{-3} Cu^{2+} were added 2.0 cm^3 of 5.0×10^{-2} mol dm^{-3} PSS. The solution was poured into the column of the cation-exchange resins. Then, a 100-cm^3 portion of water was passed through the column. The Cu^{2+} ions were completely adsorbed on the resins, whereas more than 99.3% of all the $[Ru(bpy)_3]^{2+}$ ions passed through the column. The adsorbed Cu^{2+} ions could be eluted with dilute hydrochloric acid; more than 99% of the Cu^{2+} ions were recovered with 50 ml of 6 M HCl.

It is considered that the polymer domains with high local densities of negatively charged groups and the hydrophobic groups can usefully be employed as a reaction field in which the complex cations with a hydrophobic nature are concentrated and tightly bound to the polymer chains.

The authers wish to thank Dr. Akira Yamada and Dr. Masao Kaneko for their helpful discussion. The authers also indebted to Mr. Kiyomi Takato for assistance with some of the quenching studies and Mr. Yoshihiro Yamaguchi for the measurements of the lifetimes at Daini Seikosha Co.

The Crystal and Molecular Structure of Pikromycin

Akio Furusaki,* Takeshi Matsumoto, Kimio Furuhata,† and Haruo Ogura†

Department of Chemistry, Faculty of Science, Hokkaido University, Kita-ku, Sapporo 060

† *School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108*

(Received May 19, 1981)

The detailed molecular geometry of pikromycin ($C_{28}H_{47}NO_8$) has been examined by means of X-ray crystal analysis. The crystals are orthorhombic, with four molecules in a unit cell with dimensions of $a=11.295$, $b=25.734$, and $c=10.509$ Å; the space group is $P2_12_12_1$. 2259 unique intensity data were collected on a four-circle diffractometer with graphite-monochromated Cu $K\alpha$ radiation. The structure was solved by the Monte Carlo direct method, using the 30 strongest reflections as the starting set; the 215th random phase set led to the correct solution. The R value reached 0.056 by block-diagonal least-squares refinements. The conformation of the fourteen-membered macrolide ring is considerably different from that of (*p*-bromobenzoyl)pikromycin in the solid state; *e.g.*, the C=C and C=O conjugated double bonds are cisoid in pikromycin, while they are transoid in the derivative. The molecules are held together through two kinds of intermolecular hydrogen bonds, forming a three-dimensional hydrogen-bonded structure.

Pikromycin (**1a**) is an antibiotic isolated from *Streptomyces flavochromogenese*, and is active against gram-positive bacteria.[1] The structure of **1a** was determined as **1b** by chemical and spectroscopic studies,[2] and by an X-ray study of kromycin.[3] An X-ray analysis of (*p*-bromobenzoyl)pikromycin (**2**) further revealed that the conformation of the fourteen-membered macrolide ring resembles the "diamond" conformation model (diamond model D) shown in Fig. 1.[4] It was later suggested from NMR and CD experiments that the macro-ring conformation of **1a** in the solid state might differ from this conformation of **2**.[5] Therefore, in order to obtain exact and detailed information about the molecular conformation of **1a** itself, we have now undertaken an X-ray crystal analysis.

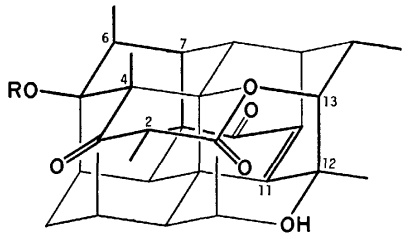

Fig. 1. Diamond model D applied to (*p*-bromobenzoyl)-pikromycin. The thick lines denote the bonds in the molecule.

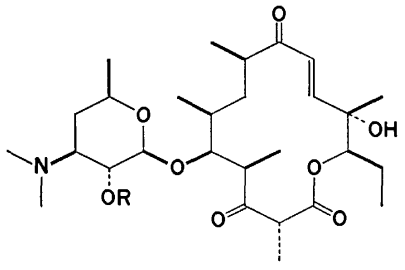

1b: R = H

2: R = p-BrC$_6$H$_4$CO

Experimental

Colorless single crystals of **1a** were grown from a methanol solution. The sample used for the X-ray measurement had dimensions of about $0.2\times0.2\times0.4$ mm^3. The crystal data are summarized in Table 1. The cell dimensions and diffraction intensities were measured on a Rigaku automatic, four-circle diffractometer with graphite-monochromated Cu $K\alpha$ radiation ($\lambda=1.5418$ Å). The θ-2θ continuous-scan technique was applied at a θ scan rate of 2° min^{-1}; the background was measured for 10 s at each end of the scan range. Three standard reflections, measured at intervals of every 50 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 125°, 2259 independent structure factors above the $\sigma(F)$ level were selected for the structure determination.

Structure Determination

Since it had already been reported that an attempt to solve the present structure with the MULTAN program[6] had been unsuccessful,[4] we tried the Monte Carlo direct method.[7] The 30 strongest reflections were chosen as the starting set. In order to extend the tentative-phase set derived from random numbers, 15 cycles of the tangent procedure were performed using 520 $|E|$ values above 1.30. As the 215th phase set showed a low R_K value of 0.297 ($R_K=\Sigma||E_o|-k|E_c||/\Sigma|E_o|$), 6 additional cycles of the tangent procedure were carried out using 617 $|E|$ values above 1.20; the R_K value thereupon dropped to 0.280. An E-map based on 586 phases revealed the locations of all the 37 non-hydrogen atoms.

The structure thus obtained was refined by the block-diagonal least-squares method with anisotropic

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the ith principal axis of the thermal ellipsoid.

temperature factors. After all the 47 hydrogen atoms had been located in a difference Fourier map, further least-squares refinements were repeated including the hydrogen atoms with isotropic temperature factors. In this refinement, the following weighting scheme was used:

$$w = 1/\{\sigma(F)^2 \exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients are constants which were determined from the $(\Delta F)^2$ values; $A=0.3052\times10^{-4}$, $B=-5.563$, $C=0.04688$, $D=-0.01148$, and $E=2.250$. The final R value was 0.056. The final atomic parameters are listed in Table 2. The tables of the anisotropic thermal parameters and hydrogen parameters, and the F_o-F_c table are kept at the Chemical Society of Japan (Document No. 8204).

The calculations were done on a HITAC M-200H computer at the Hokkaido University Computing Center, using our own programs. The atomic scattering factors were taken from the International Tables.[8)]

Results and Discussion

Molecular Structure. The molecular skeleton of **1a** obtained is illustrated in Fig. 2; it corresponds exactly to the **1b** structure. The bond distances and angles and the torsion angles are given in Tables 3 and 4 respectively.

As will be seen from Figs. 1 and 2, the macro-ring conformation of **1a** is considerably different from that of **2**; *e.g.*, very great differences of 159, 143, and 176° can be seen for the torsion angles about the C(5)–C(6), C(8)–C(9), and C(9)–C(10) bonds respectively. Of these, the difference for the last bond corresponds

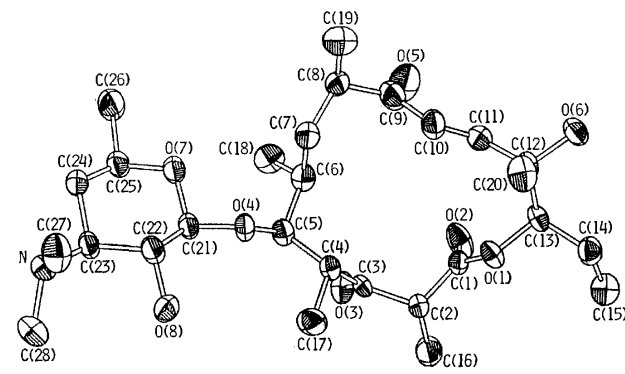

Fig. 2. A perspective view of the pikromycin molecule. Each non-hydrogen atom is represented as a thermal ellipsoid enclosing a 50% probability.

to the fact that, while the C(10)=C(11) and C(9)=O(5) conjugated double bonds are transoid for **2**, they are cisoid for **1a**. Notwithstanding the incorporation in the macrolide ring, the ester part keeps the geometry characteristic of secondary alcohol esters, *i.e.*, the synperiplanar configuration of the C(13)–O(1)–C(1)–O(2) part and the eclipsed conformation of the H–C(13)–O(1)–C(1) part.

When the macro ring is viewed along the normal of its mean plane, it looks like a somewhat-deformed right trapezoid with the four corners at the C(2), C(5), C(8), and C(12) atoms (see Fig. 2). For the cisoid configuration of the C(10)=C(11) and C(9)=O(5) bonds, the C(8)–C(9)–C(10)–C(11)–C(12) zigzag chain can form one side of such a polygon. Since the torsion angles about the C(4)–C(5), C(5)–C(6), C(7)–C(8), and C(8)–C(9) bonds do not much deviate from −60°, the C(5)–C(6)–C(7)–C(8) side makes nearly right angles with the C(2)–C(3)–C(4)–C(5) and

C(8)–C(9)–C(10)–C(11)–C(12) sides; consequently, the latter two are nearly parallel. Because of the existence of the ester group having the special geometry mentioned above, the C(12)–C(13)–O(1)–C(1)–C(2) side deviates considerably from a straight line. The reason why the present macro ring does not take a rectangular form is probably that the planar ester part would occupy exactly one corner of the rectangle as long as the C(10)=C(11) and C(9)=O(5) bonds maintain the cisoid configuration.

The C(1)=O(2), C(3)=O(3), and C(9)=O(5) carbonyl groups protrude from the mean plane of the

macro ring to the same side, while the C(20)H_3 methyl group is axially placed on the opposite side of this plane. Each of the remaining seven groups attached to the macro ring is equatorially or isoclinally oriented outside the macro ring. The pyranose ring in the D-desosamine moiety has a chair form; all the four atomic groups on this ring occupy the equatorial positions.

Crystal Structure. The molecular arrangement viewed along the c axis is shown in Fig. 3. The macro rings are nearly parallel to the (100) plane, and are arranged on the two-fold screw axis penetrating them approximately perpendicularly. The crystal contains two kinds of intermolecular hydrogen bonds, O(6)–H···N′ and O(8)–H···O(6″); the O···N and O···O distances are 2.829(4) and 2.958(4) Å respectively.** The molecules are connected by these hydrogen bonds, forming a three-dimensional hydrogen-bonded structure.

** The N′ and O(6″) positions are obtained from the N and O(6) coordinates by the symmetry operations, $(-x, -1/2+y, 3/2-z)$ and $(-1/2+x, 1/2-y, 1-z)$, respectively.

Bifunctional Oxidation of Ammonia with Metal Oxide–Pt/Al_2O_3 Mechanical Mixtures

Yukio Kosaki,* Akira Miyamoto, and Yuichi Murakami

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received May 21, 1981)

Selectivity to N_2 in the reaction of NH_3 with metal oxides has been markedly increased by the addition of Pt/Al_2O_3 to the metal oxides, whereas the activity of the metal oxides has not been changed. The metal oxides on their own have oxidized NH_3 to NO, NO_2, and N_2O as well as N_2, and furthermore, the selectivities in the reaction with metal oxides have depended markedly on the reaction temperature and inlet concentration of NH_3 in the pulse. In the oxidation of NH_3 with metal oxide–Pt/Al_2O_3 mechanical mixtures, N_2 has been selectively produced irrespective of the reaction temperature and the inlet concentration of NH_3 in the pulse. The activity of the mixtures has been shown, on the other hand, to be the same as that of the metal oxides. All of the experimental data have been explained in terms of the following scheme: In the oxidation of NH_3 with metal oxide–Pt/Al_2O_3 mixtures, NH_3 is at first oxidized by metal oxides to form NO_x(NO, NO_2, and N_2O) and N_2, then the NO_x components is transfered through the gas phase from the metal oxides to Pt particles on Al_2O_3, and finally the NO_x components react with NH_3 on Pt particles to form N_2 selectively.

Attention is focused on reactions on multi-component solid catalysts, because of their interesting catalyses which cannot be obtained for reactions on individual components. Synergistic effects appearing in their catalyses provide an important subject of investigation in heterogeneous catalytic chemistry. In other words, it is highly desirable to find new types of synergistic effects for various kinds of multi-components' catalysts and various types of reactions, and to reveal their mechanisms. Much research has been done on the synergistic effects involved in the multi-components' metal oxide catalysts, multi-components' precious metal catalysts (or alloy catalysts), and supported precious metal–metal oxide mixed catalysts. Furthermore, it has been suggested that these synergistic effects are brought about by various mechanisms including (i) the dispersion of the primary component, (ii) the control of the oxidation state or the electronic state of the primary component, (iii) the formation of a new active site by the chemical interaction of individual components, and (iv) the cooperation of different kinds of active sites by the transfer of intermediate species or reactive species from one component to another through the gas phase, surface, or bulk.[1] However, the synergistic effects appearing in the reactions on precious metal–metal oxide mixed catalysts have been not well investigated except the bifunctional catalyses involved in the reactions of hydrocarbons on Pt/Al_2O_3,[2] Pt/SiO_2–Al_2O_3,[3] and Pt–WO_3[4] catalysts, and the oxidation of H_2 with precious metal–metal oxide mixtures.[5] The precious metal–metal oxide catalysts have received increasing attention as catalysts for the automotive exhaust gas control,[6–11] selective oxidations of hydrocarbons,[12,13] and steam reforming reactions.[14,15]

In the present study, the synergistic effect in the oxidation of NH_3 with metal oxide–Pt/Al_2O_3 mixed catalysts was investigated using the pulse reaction technique. The oxidation of NH_3 was used as a test reaction for the following reasons: (i) The selective oxidation of NH_3 to N_2 is highly desirable from the environmental point of view. (ii) Since the mechanism of the oxidation of NH_3 is markedly different from that of hydrocarbons or H_2,[16] the metal oxide–Pt/Al_2O_3 is expected to show interesting synergistic effects which are significantly different from those in the oxidations of hydrocarbons or H_2. The enhanced activity of metal oxide caused by the addition of precious metal is considered to be brought about by the "hydrogen spillover" for the oxidation of H_2,[5] and by the migration of oxygen through the oxide lattice to react with hydrocarbon or hydrocarbon residues adsorbed at sites on or near precious metal additives for the oxidation of hydrocarbons.[17] Metal oxide–Pt/Al_2O_3 mixed catalysts were used for the following reasons: (i) Pt is one of the least active metals for the decomposition of NH_3. This would make it possible to propose a detailed mechanism of the synergistic effect in the oxidation of NH_3. Although a mixture of a metal oxide and a precious metal such as Ru or Rh—highly active for the decomposition of NH_3[18]—may cause an interesting synergistic effect, this system would be too complex, as a first step of investigation, to reveal a detailed mechanism of the synergistic effect. (ii) For the metal oxide–Pt/Al_2O_3 mechanical mixtures, most of the Pt particles can be considered to be separated from the metal oxides by Al_2O_3. Therefore, the migration of oxygen from the metal oxide to Pt particles on Al_2O_3 is not expected to proceed rapidly. The hydrogen spillover from Pt to the metal oxide, on the other hand, can proceed readily in the mixtures.[5] Pulse reaction technique was used for the following reasons: (i) It is considered that this technique is effective for the investigation of the behaviour of reactions on multi-components' catalysts. (ii) Since catalytic oxidations usually proceed by the redox mechanism, the stoichiometric oxidation of the reactant with the preoxidized catalyst often gives important information about their mechanisms. The stoichiometric reaction—in this study, the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixed catalysts—can be more easily investigated using the pulse reaction technique than using the flow reaction technique.

Experimental

Catalysts and Reagents. The method of preparation of metal oxides has been described previously.[16] Pt/Al_2O_3

(Pt loading of 0.5 wt%) was purchased from Nippon Engelhard. Unless otherwise specified, a metal oxide–Pt/Al_2O_3 mechanical mixture was prepared by mixing a powder of both components in an agate mortar for 20 min without water (this mixture is hereafter referred to as *Mixing* if it is necessary to discriminate it from other mixtures with different states of mixing). The weights of samples were 0.1 g for a metal oxide and 0.2 g (0.1 g of a metal oxide and 0.1 g of Pt/Al_2O_3) for a metal oxide–Pt/Al_2O_3 mixture. The weight of metal oxide (0.1 g) was common for both samples. The metal oxides and the mixtures were then pressed and granulated to be used as samples. The size of the sample granules ranged from 0.3 mm to 0.6 mm. Commercial ammonia (99.9% purity) and hydrogen (99.99% purity) were used as reactants without further purification.

Apparatus and Procedures. Experiments were conducted using a pulse apparatus. The reactant and product components were analyzed by gas chromatography with thermal conductivity detectors at room temperature. Columns used were tetraethylenepentamine on Difron for NH_3, silica gel for N_2O, and Molecular Sieve type 13X for H_2, N_2, and NO and they were connected in the intermediate cell system.[19] The confirmation of NO_2 as a product was made with the phenol disulfonic acid method. Helium or argon as carrier gas was purified with titanium metal sponge heated at 1023 K. Pulses of ammonia at various concentrations were supplied to the reactor by a 6-way valve.

Results and Discussion

Activity of Metal Oxide–Pt/Al_2O_3 Mixtures for the Oxidation of Ammonia. The Pt/Al_2O_3 catalyst was inactive for the decomposition of NH_3 under the experimental condition in the present work. On the other hand, the metal oxides have been shown to be active for the reaction with NH_3.[20] The conversion of NH_3 (X_{NH_3}) in the oxidation of NH_3 with various metal oxides is shown in Fig. 1 together with that in the reaction with the metal oxide–Pt/Al_2O_3 mixtures. It should be noted in Fig. 1 that the conversion of NH_3 in the oxidation of NH_3 with a metal oxide–Pt/Al_2O_3 mixture is almost the same as that with the metal oxide, indicating that no synergistic effect exists in the activity of the mixtures for the oxidation of NH_3.

Selectivity in the Oxidation of Ammonia with Metal Oxide–Pt/Al_2O_3 Mixtures. Oxidation of NH_3 with the metal oxides forms various products, such as N_2, N_2O, NO, and NO_2, depending on the reaction temperature and concentration of NH_3 in the pulse.[20] The selectivities to these products in the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures and the metal oxides are shown in Figs. 2 and 3. S_{NO}, S_{NO_2}, S_{N_2O}, and S_{N_2} represent the selectivities to NO, NO_2, N_2O, and N_2, respectively. Figure 2 shows the selectivities for MnO_2 and MnO_2–Pt/Al_2O_3 mixture at various temperatures. In the oxidation of NH_3 with MnO_2, N_2, N_2O, NO, and NO_2 were all produced, although the selectivities to individual products varied markedly with reaction temperature. On the other hand, in the oxidation of NH_3 with MnO_2–Pt/Al_2O_3 mixture, only N_2 was obtained as a product irrespective of the reaction temperature indicated in Fig. 2. Similarly, N_2 was selectively produced in the oxidation of NH_3 with V_2O_5–Pt/Al_2O_3 and Co_3O_4–Pt/Al_2O_3 mixtures irrespective of the reaction temperature. In the oxidation of NH_3 with V_2O_5 or Co_3O_4 alone, N_2, N_2O, and NO were produced and the selectivities to these products varied with reaction temperature. The most remarkable feature of the synergistic effect on the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures can be seen in the selectivities at various concentrations of NH_3 in the pulse. As shown in Fig. 3, in the oxidation of NH_3 with Co_3O_4 at 793 K, the conversion of NH_3 (X_{NH_3}) was 100% and all of NO, N_2O, and N_2 were formed irrespective of the inlet concentration of NH_3. Also, as the concentration of NH_3 in the pulse decreased, the selectivity

I: MnO_2, II: Pt/Al_2O_3 (upper layer)+MnO_2 (lower layer), III: MnO_2 (upper layer)+Pt/Al_2O_3 (lower layer), IV: MnO_2 (lst layer)+Pt/Al_2O_3 (2nd layer)+MnO_2 (3rd layer)+Pt/Al_2O_3 (4th layer), V: Roughly mixed sample of MnO_2 particles (0.3—0.6 mm) and Pt/Al_2O_3 particles (0.3—0.6 mm), VI: Throughly mixed sample in agate mortar.

to NO (S_{NO}) increased to 100%, whereas, the selectivities to N_2O (S_{N_2O}) and N_2 (S_{N_2}) decreased to 0%. This means that when the inlet concentration of NH_3 is low, NH_3 is oxidized almost selectively to NO by Co_3O_4. On the other hand, in the oxidation of NH_3 with Co_3O_4–Pt/Al_2O_3 mixture, the selectivity of the reaction was completely changed; N_2 was selectively formed even if the inlet concentration of NH_3 in the pulse was low. Similar phenomena were also observed for the MnO_2–Pt/Al_2O_3 and V_2O_5–Pt/Al_2O_3 mixtures. Thus, it can be said that the selectivity of the oxidation of NH_3 with the metal oxides was significantly changed by the mixing of Pt/Al_2O_3 with the metal oxides; N_2 was selectively produced irrespective of the concentration of NH_3 in pulse.

Oxidation of NH_3 by MnO_2–Pt/Al_2O_3 Mixtures under Various States of Mixing. Since, according to the previous studies,[4,21,22] the degree of mixing of a precious metal and a metal oxide can give a significant effect on the synergy between both components, it seems interesting to investigate the effect of the degree of mixing on the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures. The results for the mixtures of MnO_2 and Pt/Al_2O_3 are indicated in Fig. 4. In accordance with the data shown in Fig. 1, the conversion of NH_3 in the reactions with these mixtures was almost the same as that with MnO_2 for all kinds of mixtures. The mixing of MnO_2 and Pt/Al_2O_3 is considered to become closer as the number of state increases, *i.e.* from Mixture II to Mixture VI. As shown in Fig. 4, the selectivity of the reaction of NH_3 with the mixtures has varied significantly with the degree of mixing of both components. That is, both Mixtures V and VI have oxidized NH_3 selectively to N_2 at any of the temperatures indicated in Fig. 4. Mixture IV, which is coarser than Mixtures V and VI, also showed significant synergistic effect at 673 and 723 K. Mixtures II and III, the coarsest mixtures, exhibited little synergistic effect in the selectivity. It is worth noting in Fig. 4 that the incomplete mixing of Pt/Al_2O_3 particles (0.3—0.6 mm) with MnO_2 particles (0.3—0.6 mm), *i.e.* Mixture V (this is hereafter denoted as *Shaking*), was sufficient to oxidize NH_3 selectively to N_2, and furthermore very rough mixing, *e.g.* Mixture IV, exhibited a significant synergistic effect in the selectivity. Similar data to those shown in Fig. 4 were also obtained for V_2O_5–Pt/Al_2O_3 mixtures with various states of mixing (Table 1).

Contribution of Hydrogen Spillover or Migration of Oxygen to the Synergistic Effect. The hydrogen spillover plays an essential role in the oxidation of H_2 with the metal oxide–precious metal mixtures.[5] It is considered that the hydrogen spillover plays no role in the synergistic effect in the selectivity of the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures on the basis of the following reasons: In Table 1, the results of the oxidations of H_2 and NH_3 are shown for various samples, such as V_2O_5, Pt/Al_2O_3, V_2O_5–Pt/Al_2O_3(*Shaking*), and V_2O_5–Pt/Al_2O_3(*Mixing*).[23] X_{H_2} is the conversion of H_2 in the oxidation of H_2 with the samples, and it can be used as a measure of the extent of the hydrogen spillover. The inlet concentration of H_2 was nearly 1.5 times that of NH_3, which corresponds to the ratio of the number of hydrogen atoms in NH_3 to that in H_2. As shown in Table 1, the oxidation of H_2 takes place readily for V_2O_5–Pt/Al_2O_3(*Mixing*), whereas it hardly proceeds for

Pulse size: 18.2 cm^3.
a) Concentration of H_2 in pulse: 3.7%. b) Carrier gas (Ar) flow rate: 86 $cm^3\ min^{-1}$. c) Concentration of NH_3 in pulse: 2.65%. d) Carrier gas (He) flow rate: 86 $cm^3\ min^{-1}$.
X_{H_2} and X_{NH_3} are the conversions of H_2 and NH_3, respectively. S_{N_2}, S_{N_2O}, and S_{NO} are the selectivities to N_2, N_2O, and NO, respectively.

V_2O_5–Pt/Al_2O_3(*Shaking*). This means that the hydrogen spillover cannot take place for V_2O_5–Pt/Al_2O_3 (*Shaking*) but it can take place readily for V_2O_5–Pt/Al_2O_3(*Mixing*). If the hydrogen spillover played a significant role in the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures, the selectivity of the reaction should differ considerably between V_2O_5–Pt/Al_2O_3(*Shaking*) and V_2O_5–Pt/Al_2O_3(*Mixing*). The selectivity to N_2 for V_2O_5–Pt/Al_2O_3(*Shaking*), however, was the same as that for V_2O_5–Pt/Al_2O_3(*Mixing*) and reached 100%; neither N_2O nor NO was produced for both V_2O_5–Pt/Al_2O_3(*Shaking*) and V_2O_5–Pt/Al_2O_3 (*Mixing*), in contrast to the products' distribution for V_2O_5. Furthermore, a considerable synergistic effect was observed for the Mixture IV in Fig. 4 in the selectivity of the oxidation of NH_3, while the hydrogen spillover did not take place for the mixture.

Moreover, it has been suggested that, in the oxidation of hydrocarbons with V_2O_5–precious metal systems, the migration of oxygen through the bulk oxide takes place so as to react with hydrocarbons at or near the metal additives; thereby the reaction is much enhanced by the addition of precious metals to V_2O_5.[17] Similarly, if the migration of oxygen through the bulk oxide to Pt particles takes place easily in the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures, the reaction has to be much enhanced by the addition of Pt/Al_2O_3 to the metal oxides because of the high activity of Pt/Al_2O_3 for the oxidation of NH_3 with oxygen. The migration of oxygen from the metal oxides to Pt particles on Al_2O_3, however, hardly occurs in the metal oxide–Pt/Al_2O_3 mixtures, since most of the Pt particles are expected to be separated from the particles of the metal oxide by Al_2O_3 in the metal oxide–Pt/Al_2O_3 mixtures. This inference is in accord with the experimental data; the activity of the metal oxide–Pt/Al_2O_3 mixtures for the oxidation of NH_3 is almost the same as that of the metal oxides as shown in Fig. 1. Consequently it is noted that neither the hydrogen spillover from Pt to metal oxides nor the migration of oxygen from metal oxides to Pt plays a significant role in the oxidation of NH_3 with metal oxide–Pt/Al_2O_3 mixtures.

Recently, Il'chenko[24] reported that the addition of $Pt/BaSO_4$ to metal oxides substantially increases the activity of the metal oxides for the oxidation of NH_3, while the selectivity in the reaction slightly changes. This is in marked contrast to the present results for the metal oxide–Pt/Al_2O_3 mixtures. Since Pt particles in the metal oxide–$Pt/BaSO_4$ mixtures are considered to be in contact with the grains of the metal oxide,[24] the difference may be brought about by the migration of adsorbed ammonia activated on Pt to the metal oxides or by the migration of oxygen of the metal oxides to Pt in the oxidation of NH_3 with the metal oxide–$Pt/BaSO_4$ mixtures. According to our preliminary experiments on the oxidation of NH_3 with V_2O_5–Pt black mixtures and V_2O_5–Pt mixtures supported on Al_2O_3, in fact, the activity of the metal oxide for the oxidation of NH_3 was significantly enhanced by the presence of Pt contacting with the metal oxide. The details of the results will be reported in a subsequent paper with additional data to reveal the mechanism.

It should be noted here that such mechanisms of the synergistic effects as (i) the dispersion of the primary component, (ii) the control of the oxidation state or the electronic state of the primary component, or (ii) the formation of a new active site by the chemical interaction of individual components are not important in the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures. This is because most of the Pt particles are not in contact with the metal oxides for the mixtures and a considerable synergistic effect appears even for the reaction with the V_2O_5–Pt/Al_2O_3 (*Shaking*) and the Mixture IV shown in Fig. 4.

Mechanism of the Synergistic Effect in the Oxidation of NH_3 with Metal Oxide–Pt/Al_2O_3 Mixtures. NO has been regarded to play an important role as an intermediate in the catalytic oxidation of NH_3.[18,25,26] In the preceding work,[20] it has been found that the oxidation of NH_3 with the metal oxides proceeds by a similar scheme as follows:

$$NH_3 \xrightarrow[\text{I}]{\text{lattice oxygen}} NO \xrightarrow[\text{II}]{NH_3} N_2,\ N_2O, \qquad (1)$$

where NH_3 is first oxidized by the lattice oxygen of a metal oxide to NO (Step I), which then reacts with NH_3 (the NO–NH_3 reaction) to form N_2 and N_2O (Step II). The NO–NH_3 reaction (Step II) takes place catalytically. According to this scheme, the activity in the oxidation of NH_3 with a metal oxide is determined by Step I, whereas the selectivity is limited by the relative rate of Step II to that of Step I.

This scheme is now applied to the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures in

Table 2. Relation between NO/NH_3 ratio and the selectivities of $NO-NH_3$ reaction on Pt/Al_2O_3 catalyst at 773 K

NO/NH_3 ratio	X_{NO}/%	X_{NH_3}/%	S_{N_2}/%	S_{N_2O}/%
0.49	100	61	100	0
0.53	98	77	97	3
0.73	97	85	96	4

Catalyst weight: 0.1 g. Concentration of NO in pulse: 2.0%. Pulse size: 18.2 cm^3. Carrier gas (He) flow rate: 86 $cm^3\ min^{-1}$.
X_{NO} and X_{NH_3} are the conversions of NO and NH_3, respectively. S_{N_2} and S_{N_2O} are the selectivities to N_2 and N_2O, respectively.

order to interpret the synergistic effect involved in the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures. According to the scheme, the activity of the sample is limited by Step I. Since Pt/Al_2O_3 is not active for the decomposition of NH_3, the agreement of the conversion of NH_3 for a metal oxide–Pt/Al_2O_3 mixture with that for the metal oxide means that the activity of the metal oxide for the oxidation of NH_3 is not enhanced by its mixing with Pt/Al_2O_3. In accordance with the above-mentioned discussion either the hydrogen spillover or the migration of oxygen hardly takes place in the oxidation of NH_3 with the mixtures. The activity of the metal oxide–Pt/Al_2O_3 mixtures for the oxidation of NH_3 is therefore determined only by that of the metal oxides. On the other hand, the selectivity of the reaction is determined, according to this scheme, by the rate of the $NO-NH_3$ reaction (Step II), since the rate of Step I is not changed by the addition of Pt/Al_2O_3 to the metal oxides. The metal oxides employed in this study were all active for the $NO-NH_3$ reaction. However, the activity of the metal oxides is considered insufficient to form N_2 selectively, since considerable amounts of NO, N_2O, and NO_2 were produced in the oxidation of NH_3 with the metal oxides, especially when the inlet concentration of NH_3 was decreased as shown in Fig. 3. As it is well known, Pt/Al_2O_3 catalyst is highly active for the $NO-NH_3$ reaction,[27,28] indicating that the activity of the metal oxide–Pt/Al_2O_3 mixtures for the $NO-NH_3$ reaction is much higher than that of the metal oxides. Furthermore, as shown in Table 2, the selectivity to N_2 in the $NO-NH_3$ reaction on Pt/Al_2O_3 catalyst increased as the ratio of the concentration of NO to that of NH_3 decreased, and attained 100% when the NO/NH_3 ratio was smaller than 0.5. Thus, if it can be assumed that the NO/NH_3 ratio is small enough under the condition of the oxidation of NH_3 with metal oxide–Pt/Al_2O_3 mixtures, the high selectivity to N_2 can be explained in terms of the scheme of Reaction 1. This assumption seems to be valid, since the activity of Pt/Al_2O_3 catalyst for the $NO-NH_3$ reaction has been shown to be very high and, therefore, the concentration of NO can be considered to be kept at a low level under the reaction condition.

Since most of the Pt particles in the mixtures are separated from the metal oxides by Al_2O_3, the NO

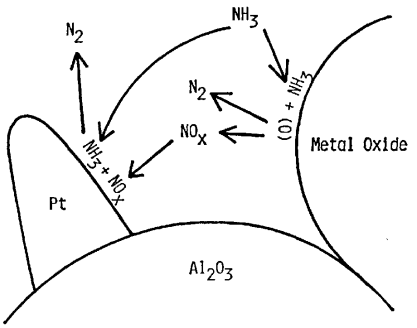

Fig. 5. Mechanism of the oxidation of NH_3 with a metal oxide–Pt/Al_2O_3 mixture.

produced by the oxidation of NH_3 should transfer from the metal oxides to Pt particles in order to react with NH_3 on Pt to form N_2 selectively. The migration of NO on the surface of Al_2O_3, however, does not seem to take place, since the migration of either oxygen or hydrogen cannot occur in the oxidations of NH_3 and H_2 with V_2O_5–Pt/Al_2O_3(*Shaking*). Consequently the migration of adsorbed NO species, which is heavier than hydrogen or oxygen, cannot be expected. Therefore, NO is considered to transfer from the metal oxides to Pt through the gas phase.

Taking into consideration that both N_2O and NO_2 can also react with NH_3 on Pt/Al_2O_3 catalyst to form N_2, the scheme shown in Fig. 5 can be proposed for the reaction of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures. That is, in the oxidation of NH_3 with the metal oxide–Pt/Al_2O_3 mixtures, NH_3 is, at first, oxidized by the metal oxides to form NO_x (NO, NO_2, and N_2O) and N_2 (Step I), then NO_x components transfer through the gas phase from the metal oxides to the Pt particles on Al_2O_3, and finally NO_x components react readily with NH_3 on Pt to form N_2 selectively (Step II). The significantly high selectivity to N_2 for the incomplete mixtures, such as Mixtures IV and V in Fig. 4 and V_2O_5–Pt/Al_2O_3(*Shaking*) in Table 1, can be understood in terms of the scheme shown in Fig. 5, since the gas-phase transfer can proceed more readily than the surface migration because of the absence of the activation energy in the transfer through the gas phase.[29] It should be emphasized that the rate of the gas-phase transfer of NO_x components is much faster than the rate of Step I. This assures the selective oxidation of NH_3 to N_2 with the metal oxide–Pt/Al_2O_3 mixtures even under conditions where the yield of NO is 100% in the oxidation of NH_3 with the metal oxides (Fig. 3).

It is interesting to investigate whether metal oxide–Pt/Al_2O_3 mixtures are also effective for the selective oxidation of NH_3 to N_2 by gaseous O_2. According to our preliminary continuous flow experiments under the dilute gas condition, the yield of NO and NO_2 in the oxidation of NH_3 with gaseous O_2 on Pt/Al_2O_3 was significantly decreased by the addition of MoO_3 or WO_3 to Pt/Al_2O_3. Details of the results and mechanisms will be reported in a subsequent paper.

As mentioned above, the synergistic effect in the oxidation of NH_3 differs considerably from that of the oxidation of hydrocarbons. The difference in the

synergistic effect may be due to the difference in the schemes of both reactions, especially in the activity of deep oxidation products. In the oxidation of NH_3, the deep oxidation products, such as NO and NO_2, are produced first and then they react with NH_3 to form the mild oxidation products, such as N_2 and N_2O, while, in the oxidation of hydrocarbons, the deep oxidation products, such as CO and CO_2, do not convert to the mild oxidation products.

Conclusion

The selective oxidation of NH_3 to N_2 with the metal oxide–Pt/Al_2O_3 mixtures has been found to involve two kinds of active sites—one is the site on the metal oxide for the oxidation of NH_3 to NO_x and N_2, and the other is the site on Pt metal for the reaction of NO_x with NH_3 to form N_2. Although these two kinds of active sites are considerably separated from each other, a rapid gas-phase transfer of the reactive intermediate (NO_x) from the metal oxide to Pt assures cooperation between both sites. In other words, this kind of synergistic effect can take place even if the different kinds of active sites are considerably separated from one another. A heterogeneous catalytic reaction usually involves two or more steps; furthermore, reactive intermediates sometimes desorb from the surface to the gas phase during the reaction. Therefore, the mechanism described in this study could be applied to various types of catalytic reactions and give important suggestion on the design of multi-component catalysts.

29) Selectivity to N_2 at 723 K in the oxidation of NH_3 with Mixture II was slightly higher than that with MnO_2 alone (Fig. 4). This may be due to the adhesion of a part of MnO_2 to the inner wall of the reactor above the Pt/Al_2O_3–MnO_2 interface of Mixture II, which causes the synergistic effect by the scheme shown in Fig. 5.

Electric Linear Dichroism Study of Sodium Poly(*p*-styrenesulfonate) and Its 9-Aminoacridinium Complex in Aqueous Solutions

Koichiro MATSUDA and Kiwamu YAMAOKA*

Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received May 25, 1981)

Electric linear dichroism (ELD) of sodium poly(*p*-styrenesulfonate) (NaPSS) and its 9-aminoacridinium (AA) complex at a mixing ratio of polymer residue-to-dye of 6.14 was studied in aqueous solutions at 20 °C. ELD signals were measured in the electric field strength range 0—*ca.* 19 kV/cm at the absorption peak wavelengths; they showed a saturating trend at extremely high fields. The average angles between the orientation axis of NaPSS and the transition moments of chromophores were estimated to be 60° at 224.5 nm and 57° at 262 nm for the side chain phenyl group and 50° at 404 nm for the bound AA by using theoretical orientation functions derived for mono- and polydisperse systems. The ELD spectra were measured at fixed field strengths; 275—215 nm for NaPSS and 440—282 nm for NaPSS–AA. The reduced dichroism of NaPSS remained nearly constant throughout the 262 nm band but steadily changed below 224 nm in the 224.5 nm band, indicating that another band exists in the far UV region. The ELD spectrum of the NaPSS–AA complex revealed that the two electronic ^1L_a and ^1L_b transition moments of the bound AA are tilted at different angles to the orientation axis of the NaPSS backbone.

The mechanism of electric field orientation of polyelectrolytes in aqueous solution is an interesting problem. Many studies on electric dipole moments of the synthetic polyelectrolytes in aqueous solutions have been carried out by the electric birefringence method.[1–11] A number of stiff or semi-flexible charged polyions are now known to be orientable by external electric fields. For example, Yamaoka and Ueda[11] recently reported reversing-pulse electric birefringence of poly(*p*-styrenesulfonate) (PSS) with various cationic counterions in aqueous solutions, attributing the orientation of PSS to the translational mobility of the counterions on the polymer surface. The electric linear dichroism (ELD) method is another powerful electrooptical technique for obtaining information on the relative disposition of the intrinsic and/or extrinsic chromophore in polyelectrolytes. However, few studies have been reported on the ELD of synthetic polyelectrolytes and their complexes with small chromophoric ligands in aqueous solutions. Soda and Yoshioka[12] investigated the ELD of Crystal Violet and Malachite Green bound to KPSS in aqueous solution, in order to clarify the metachromatic behavior of these dyes. Recently, Tricot *et al.*[13] reported the ELD of poly(*N*-alkyl-4-vinylpyridinium bromide) in aqueous solution, determining the angle between the orientation axis of the polymer backbone and the pyridinium ring.

In order to determine the conformation of polyelectrolytes and the dye complexes, the effects of the polydispersity of polymer length, the flexibility of backbone, and the transition moment direction of chromophore must be considered. In this work, the wavelength dependence of the reduced dichroism of the sodium salt of PSS (NaPSS) and its 9-aminoacridinium (AA) complex in aqueous solution was examined at 20 °C in the UV and visible absorption regions. The electric field dependence of the reduced dichroism was examined at the absorption peak wavelengths. The aims of this work are to clarify the conformations of both the phenyl ring and the bound AA relative to the molecular orientation axis of NaPSS. The limiting reduced dichroism $(\Delta A/A)_s$ was estimated by comparing the field strength dependence of reduced dichroism with theoretical orientation functions of two different types under due consideration of the polydispersity of polymer length. From this result, the angles for the transition moments of the phenyl ring and the bound AA relative to the orientation axis were obtained.

Experimental

Materials. Sodium poly(*p*-styrenesulfonate) (NaPSS) was the same sample that was used previously.[11,14,15] The original sample in the potassium salt was kindly given by Professor Koshiro Yoshioka of the University of Tokyo. The intrinsic viscosity of NaPSS in 0.1 M NaCl (1 M=1 mol dm^{-3}) was 0.9 cm^3 g^{-1}. From this value, the weight-average molecular weight (M_w) was determined to be 2.8×10^5.[16] The cationic dye, 9-aminoacridinium chloride (AA), was described in previous papers.[11,17–19]

Preparation of Sample Solutions. The freeze-dried NaPSS sample was dried under reduced pressure at 78 °C for 10 h. It was then dissolved in redistilled water. The residue concentration of NaPSS was determined by weighing the dried sample as anhydride. The concentration of AA was determined by using the molar absorption coefficient, ε, of 1.03×10^4 M^{-1} cm^{-1} at 401 nm.[18] The NaPSS–AA solution, which contained neither extra neutral salt nor buffer salt, was prepared by adding the dye solution to the NaPSS solution at a molar mixing ratio of polymer residue-to-dye (P/D) of 6.14. The final concentration of AA was 108 μM.

Absorption Measurements. The UV and visible absorption spectra were measured on a Hitachi EPS-3T spectrophotometer at 20 °C with 2 cm- and 1 cm-long quartz cells.

Measurements of Electric Linear Dichroism. The electric linear dichroism apparatus was constructed in our laboratory. Its design construction, and performance were described in detail elsewhere.[20] The measuring cell unit consists of a Kel-F "Kerr" cell and a water-jacketed cell holder. The optical path lengths of the cell were 2 cm (electrode gap 0.33 cm) and 1 cm (electrode gap 0.207 cm). An R106UH photomultiplier (Hamamatsu TV Co.) was used, and the linear response of the tube was confirmed.[20] The half-intensity band width was kept narrower than 1.5 nm through-

out. Both the parallel dichroism ($\Delta A_{//}/A$) and the perpendicular dichroism ($\Delta A_{\perp}/A$) were separately measured at 20 °C. The steady-state dichroism signal was obtained by varying both the voltage of a single square-wave pulse between 0.37 and 3.88 kV and the pulse duration between *ca.* 80 and 350 μs. External electric pulses were always applied to the NaPSS and NaPSS–AA solutions at least twice, but no degradation or irreversible change of dichroism signal was detected.

Data Analysis. The procedure for the dichroism data acquisition has been described in detail elsewhere.[20-22] The reduced dichroism ($\Delta A/A$) was calculated from $\Delta A_{//}/A$ and $\Delta A_{\perp}/A$ with the following expressions:

$$\frac{\Delta A_{//}}{A} = \frac{A_{//}^{E}-A}{A} = -\frac{1}{A}\log\left(1+\frac{\Delta I_{//}}{I_{//,0}}\right), \quad (1)$$

$$\frac{\Delta A_{\perp}}{A} = \frac{A_{\perp}^{E}-A}{A} = -\frac{1}{A}\log\left(1+\frac{\Delta I_{\perp}}{I_{\perp,0}}\right), \quad (2)$$

$$\frac{\Delta A}{A} = \frac{A_{//}^{E}-A_{\perp}^{E}}{A} = \frac{\Delta A_{//}-\Delta A_{\perp}}{A}, \quad (3)$$

where $\Delta A_{//}$ is the change in absorbances of the monochromatic light polarized parallel to the electric field direction in the presence ($A_{//}^{E}$) and the absence (A) of the externally applied pulse field, $\Delta A_{\perp}$ is the corresponding change for the perpendicularly polarized light, $\Delta I_{//}(=I_{//,E}-I_{//,0})$ is the change in transmitted intensities of light polarized parallel to the field direction in the presence ($I_{//,E}$) and the absence ($I_{//,0}$) of the pulse field, and $\Delta I_{\perp}$ is the corresponding change for the perpendicularly polarized light. If there is no electrochromism involved, the following relation should hold:[23]

$$\frac{\Delta A_{//}}{A} = -2\frac{\Delta A_{\perp}}{A} \text{ or } A = \frac{1}{3}(A_{//}^{E}+2A_{\perp}^{E}). \quad (4)$$

In this work, the validity of Eq. 4 was confirmed for NaPSS (the residue concentration of polymer, C_p=3.31 mM) below *ca.* 19 kV/cm, and both for NaPSS (C_p=0.133 mM) and for NaPSS–AA (P/D=6.14) below *ca.* 14 kV/cm.

Results

Electric Field Dependence of NaPSS and NaPSS–AA Complex. Figure 1 shows typical ELD signals of NaPSS (left) and NaPSS–AA complex (right) and applied electric pulse signals. The sign of dichroism (ΔA in Eq. 3) is negative for NaPSS in the 275—215 nm region, but it is positive for NaPSS–AA in the 440—282 nm region. Figure 2 shows the field strength dependence of the reduced dichroism ($\Delta A/A$) of NaPSS and NaPSS–AA. Values of $\Delta A/A$ were measured at the respective absorption band maxima over a wide field strength range (0—*ca.* 19 kV/cm). The similarities and differences between NaPSS at 224.5 nm (C_p=0.133 mM), NaPSS at 262 nm (C_p=3.31 mM), and NaPSS–AA at 404 nm (C_p=0.663 mM) may be summarized as follows: (1) The sign of $\Delta A/A$ is *negative* for the two NaPSS systems, but it is *positive* for NaPSS–AA system throughout the respective absorption regions, (2) the electric field dependence of $\Delta A/A$ shows a saturating trend at high fields in all cases, and (3) no electrochromic effect was observed; Eq. 4 holds for all three systems, unless the applied electric field strength is extremely large. The Kerr-law behavior was not directly observed in this work because of low signal-to-noise ratios at weak field strengths, but the Kerr law had been confirmed to hold for the same NaPSS and NaPSS–AA systems

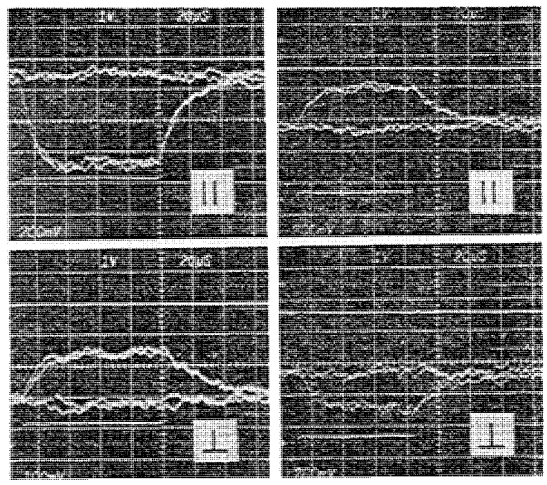

Fig. 1. Photographs of dichroism signals of NaPSS (left) and NaPSS–AA (right) and of applied pulsed electric fields at 20 °C and at 224.5 nm (left) and 404 nm (right). The parallel dichroism (//) is in the upper half and the perpendicular dichroism (⊥) is in the lower half. Electric field strengths in kV/cm are 18.8 (left) and 11.8 (right). Sweep time is 20 μs/division in all cases. Each photograph was a superposition of two displays.

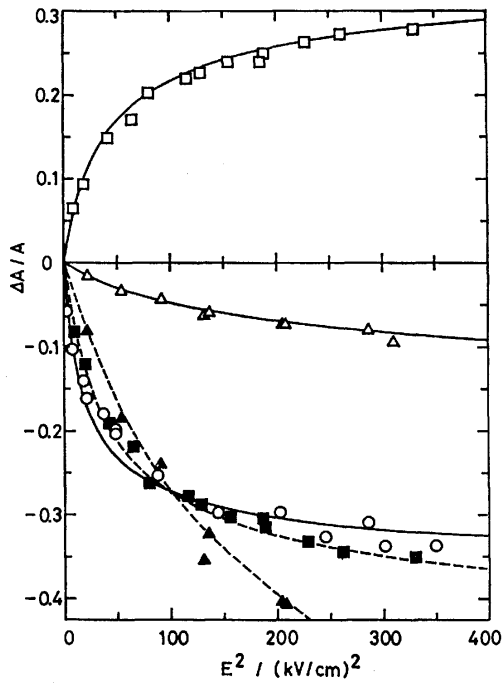

Fig. 2. Dependence of the reduced dichroism ($\Delta A/A$) of NaPSS at 224.5 nm (○) and 262 nm (△) and of NaPSS–AA at 404 nm (□) on the square of electric field strength, E^2. Open symbols were experimentally determined and solid curves were calculated by using the theoretical orientation function $\Phi(\beta,\gamma=0)$. Values of reduced dichroism of NaPSS at 262 nm were multiplied by 5.64 (--▲--▲--), and those of NaPSS–AA at 404 nm were multiplied by −1.26 (--■--■--).

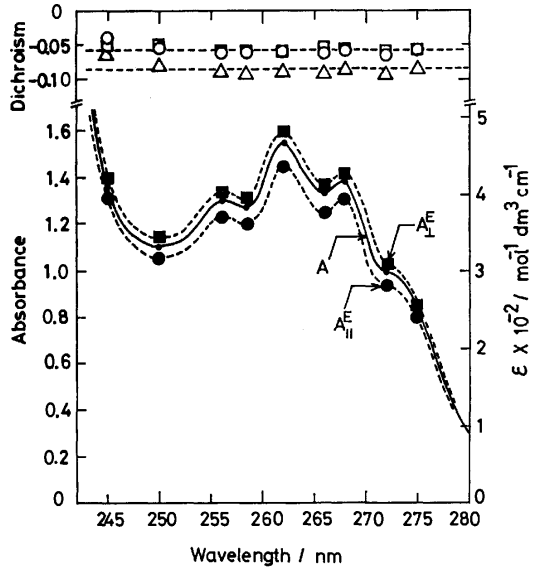

Fig. 3. Linear dichroic spectra of NaPSS in aqueous solution (C_p=3.31 mM) at 20 °C. Electric field strength=17.1 kV/cm. The lower half: Solid curve is the isotropic spectrum A in the absence of external electric field. The spectrum A_{calcd} (—•—) was calculated from the relation $A_{calcd}=(A^E_{//}+2A^E_{\perp})/3$. $A^E_{//}$ (●) and $A^E_{\perp}$(■) were calculated from Eq. 1 and Eq. 2, respectively. The upper half: The specific parallel dichroism is $\Delta A_{//}/A$ (○) and the reduced dichroism is $\Delta A/A$ (△), together with the specific perpendicular dichroism $\Delta A_{\perp}/A$ multiplied by −2 (□), in order to indicate that the relation $\Delta A_{//}/A=-2\Delta A_{\perp}/A$ holds in this case.

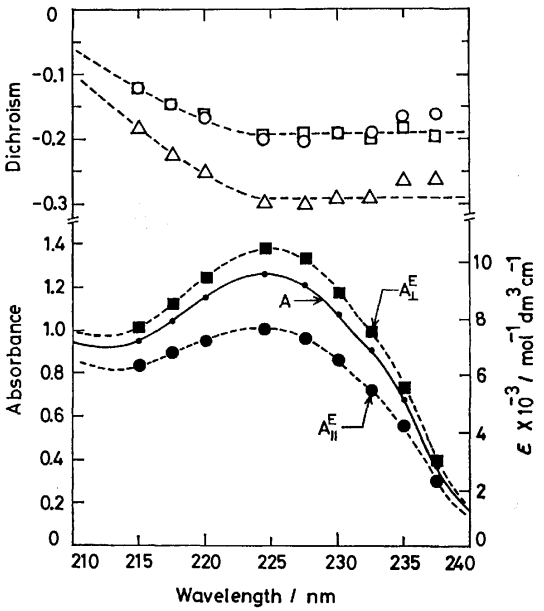

Fig. 4. Linear dichroic spectra of NaPSS in aqueous solution (C_p=0.133 mM) at 20 °C. Electric field strength=12.0 kV/cm. All notations and symbols are the same as in Fig. 3.

below *ca.* 1.2 kV/cm by an electric birefringence study.[11]

The reduced dichroism at a given electric field strength and given wavelength is the product of the orientation factor and the optical factor, which is, for example, equal to $3(3\cos^2\theta-1)/2$ for an axially symmetric molecule (*cf.* Eq. 5). If differences of the $\Delta A/A$ *vs.* E^2 curves for three systems in Fig. 2 are merely due to the optical factor, these curves should be superimposed upon one another by multiplying the observed $\Delta A/A$ by appropriate constants. In order to verify this possibility, the normalization of the three curves was attempted by multiplying the curve of NaPSS (open triangles) by 5.64 and the curve of NaPSS-AA (open squares) by −1.26 at a selected field strength (E^2=100 (kV/cm)^2). In Fig. 2, these normalized curves are represented by dashed lines with closed symbols; they do not coincide with the solid curve (open circles) of NaPSS at 224.5 nm, to which the normalization was tried. This discrepancy should be ascribed not only to the difference of the optical factor but also to the difference of the orientation factor between the above three systems. Thus, the average degree of molecular orientation by a given externally applied field differs for each, suggesting a difference in the electric moments for the three polymer systems.

Wavelength Dependence of Dichroic Spectra of NaPSS in the 275—215 nm Region. Figures 3 and 4 show absorption spectra of two NaPSS solutions in the presence ($A^E_{//}$ and $A^E_{\perp}$) and in the absence (A) of applied electric field in the lower half, and the parallel dichroism (circles), the perpendicular dichroism multiplied by −2 (squares), and the reduced dichroism (triangles) in the upper half, respectively. The isotropic spectrum of NaPSS (C_p=3.31 mM) in Fig. 3 was characterized by peaks at 268 nm (ε=418), 262 nm (468), and 256 nm (394), and by a shoulder near 272 nm (300). These values are consistent within 3.8% with those of Soda and Yoshioka,[12] but they are slightly larger than the data of Boyd.[24] The reduced dichroism is negative and constant in the 275—255 nm. Both $\Delta A_{//}/A$ and $-2\Delta A_{\perp}/A$ agree with each other within experimental uncertainty. By using values of $A^E_{//}$ and $A^E_{\perp}$, the isotropic absorbance

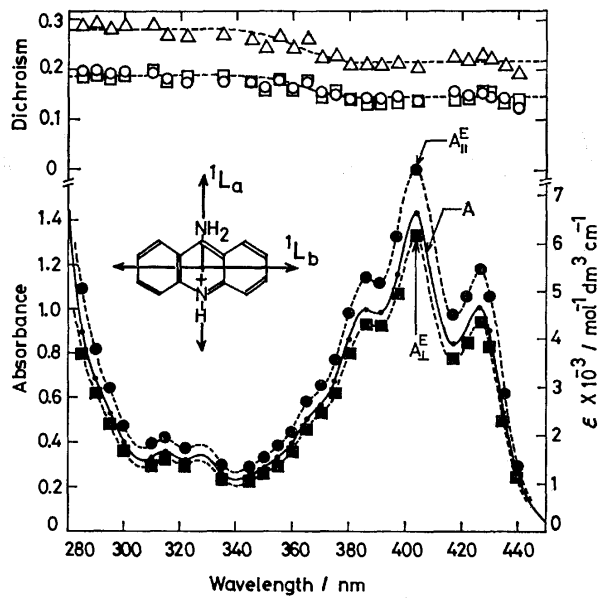

Fig. 5. Linear dichroic spectra of NaPSS–AA in aqueous solutions at a P/D value of 6.14 and at a constant field strength of 11.6 kV/cm. Symbols are all the same as in Fig. 3.

was calculated (A_{calcd}, dots) with Eq. 4. The agreement of A_{calcd} with the observed spectrum (solid curve) indicates that no detectable electrochromism is involved for the NaPSS (C_p=3.31 mM) solution.

Because of a large difference in ε between the 262 nm and 224.5 nm bands, the NaPSS solution was diluted about 25-fold (*cf.* Table 1). The isotropic spectrum of NaPSS (C_p=0.133 mM) in Fig. 4 was characterized by a peak at 224.5 nm ($\varepsilon=9.54\times10^3$) and a weak shoulder near 233 nm (6.58×10^3). The peak value was lower than Boyd's value by 10% at 224.0 nm and at 25 °C.[24] The reduced dichroism was negative throughout the 240—215 nm region. Both $\Delta A_{//}/A$ and $-2\Delta A_{\perp}/A$ agree with each other, indicating no electrochromism. The dichroic spectrum is constant only in the 240—224 nm region, increasing gradually below 224 nm, which is probably due to the influence of some higher-energy absorption bands of NaPSS in the far UV region.[25]

Wavelength Dependence of Dichroic Spectrum of NaPSS–AA Complex in the 440—280 nm Region. Figure 5 shows absorption spectra of an NaPSS–AA solution in the presence ($A^E_{//}$ and $A^E_{\perp}$) and in the absence (A) of applied electric field in the lower half, and the parallel dichroism (circles), the perpendicular dichroism multiplied by −2 (squares), and the reduced dichroism (triangles) in the upper half. The isotropic spectrum is characterized by the ^1L_a band [three peaks at 426 nm ($\varepsilon=4.68\times10^3$), 404 nm ($6.64\times10^3$), 386 nm ($4.62\times10^3$), and a weak shoulder near 370 nm (2.55×10^3)], the ^1L_b band [two weak peaks at 328 nm ($\varepsilon=1.61\times10^3$) and 315 nm ($1.63\times10^3$)], and a shoulder near 290 nm (3.16×10^3).[15] The reduced dichroism indicates that (1) its sign is always positive in the visible and near UV regions, (2) two different transitions are present (one with $\Delta A/A$ of 0.22±0.02 in the 440—370 nm region and the other with $\Delta A/A$ of 0.27±0.02 in the 335—282 nm region), (3) no electrochromism is involved, *i.e.*, $\Delta A_{//}/A=-2\Delta A_{\perp}/A$ within experimental uncertainty.

Discussion

Theoretical Orientation Functions for Monodisperse and Polydisperse Systems. The synthetic polyelectrolyte may be in a very extended form in salt-free aqueous solution at a low polymer-concentration, as a result of electrostatic repulsion between the charged side groups.[6,13] Under these conditions, the electro-optical properties of such a polyelectrolyte may be estimated, to a good approximation, with the aid of theoretical expressions for rod-like molecules (*vide post*). In order to know the highest possible reduced dichroism at infinitely high field, $(\Delta A/A)_s$, and the orientation behavior of NaPSS and NaPSS–AA complex, the field strength dependence of steady-state dichroism signals should be compared with a suitable theoretical orientation function. If the polyelectrolyte with identical chromophores in a solution can be regarded as a relatively stiff chain of axial symmetry, the reduced dichroism $\Delta A/A$ for a monodisperse system may be given as[23]

$$\frac{\Delta A}{A}=\frac{3}{2}(3\cos^2\theta-1)\Phi, \tag{5}$$

where A is the absorbance of the same solution in the absence of external electric field, $(3\cos^2\theta-1)$ is the optical term as stated before, and Φ is the orientation function.

The "classical" orientation function, $\Phi(\beta,\gamma)$, for a dipolar molecule with the permanent dipole moment (μ) and/or the polarizability anisotropy ($\Delta\alpha$) has been derived by O'Konski *et al.* (Eq. 14 of Ref. 1). The variables, β and γ, are the interaction energy terms and are given as $\beta=\mu E/kT$ and $\gamma=\Delta\alpha E^2/2kT$ (≥0), where k is the Boltzmann constant and T is the absolute temperature. In the strict sense, the O'Konski-Yoshioka-Orttung or the classical function, $\Phi(\beta,\gamma)$, was derived for the nonionic polymer in solution. Nevertheless, it has been used successfully in many cases, which include aqueous solutions of polyelectrolyte.[1,6,8,11,22] Hence, we also use $\Phi(\beta,\gamma)$ for interpreting the data of NaPSS and NaPSS–AA systems on a qualified, empirical basis. For the ionized polymer system, an orientation function, $\Phi(\kappa)$, was derived by Kikuchi and Yoshioka under consideration of ion-atmosphere polarization (Eq. 8 of Ref. 26).[26] The variable κ is given as $\kappa=ZelE/2kT$, where n is the number of condensed counterions per polyion, Z is the valence of counterion, e is the elementary charge, and l is the contour length of polyion. As Kikuchi and Yoshioka have pointed out,[6] the field strength dependence of the molecular orientation of synthetic polyelectrolyte may be related not only to the flexibility of the polyelectrolyte chain but also to the polydispersity of molecular weights. In order to explain the field strength dependence of a poly(*N*-butyl-4-vinylpridinium bromide) solution, Tricot *et al.*[8] used an orientation function with three different electric polarizabilities. Any synthetic polyelectrolyte sample

should not be the sum of a few discrete species of different molecular weights, but it should have an almost continuous molecular weight distribution. Therefore, we extend both $\Phi(\beta,\gamma)$ and $\Phi(\kappa)$ at first in such a way as to include this distribution.

Since the Schulz-Zimm function,[27,28] $f_w(M)$, has been used often for the molecular weight distribution of synthetic polymer samples, we also utilize it to describe a polydisperse NaPSS sample:

$$f_w(M) = y^{k+1}M^k e^{-yM}/\Gamma(k+1) \quad (6)$$

$$M_n = \frac{k}{y}, \quad M_w = \frac{k+1}{y}, \quad \text{and} \quad \frac{M_w}{M_n} = \frac{k+1}{k}, \quad (7)$$

where M is the molecular weight of a polymer species, M_w and M_n are the weight- and the number-average molecular weights, respectively. The conformation of polyionic NaPSS is probably in a very extended form in a dilute solution,[6,11] the molecular weight M of a particular NaPSS molecule may be equated to $m_0 l$, where l is the length of the NaPSS molecule and m_0 is the molecular weight per unit length. In this case, the ratio M_w/M_n may be equated to the ratio of weight-average length to number-average length l_w/l_n. The relation between $f_w(l)$ and $f_n(l)$, the latter of which is the distribution function for the number of molecules with the contour length l, is given as follows:

$$f_n(l) = \frac{k}{m_0 l y} f_w(l). \quad (8)$$

In the insert of Fig. 6, $f_n(l)$ is plotted against l with a value of 340 nm for l_w, which corresponds to the M_w of 2.8×10^5 daltons for NaPSS, as determined from the viscosity data, and with a value of 1.3 for l_w/l_n ($=M_w/M_n$), which was estimated for the present sample from the data of Nagasawa *et al.*[16,29] For the polydisperse system in which the limiting reduced dichroism, $3(3\cos^2\theta-1)/2$, is independent of molecular species (this is the reasonable assumption for a polymer molecule in which the number of identical chromophores is proportional to its length), Eq. 5 may be expressed in terms of the sum of the individual dichroism of the component species for which the length distribution function is defined by $f_n(l)$:

$$\frac{\Delta A}{A} = \frac{3}{2}(3\cos^2\theta-1)\int_{L_1}^{L_2} l f_n(l)\Phi dl \Big/ \int_{L_1}^{L_2} l f_n(l) dl$$
$$\equiv \frac{3}{2}(3\cos^2\theta-1)\langle\Phi\rangle_w = \left(\frac{\Delta A}{A}\right)_s \langle\Phi\rangle_w, \quad (9)$$

where $\langle\Phi\rangle_w$ is the weight-average orientation function, Φ corresponds to $\Phi(\beta,\gamma)$ or $\Phi(\kappa)$ for a monodisperse system, and $(\Delta A/A)_s$ is the limiting reduced dichroism. Both L_1 and L_2 are the lower and upper limits of l. At limiting high field strength, $\langle\Phi\rangle_w$ approaches unity; hence, $(\Delta A/A)_s = 3(3\cos^2\theta-1)/2$.

In Fig. 6(a), the field strength dependence of the weight-averaged Kikuchi-Yoshioka orientation function $\langle\Phi(\kappa)\rangle_w$ is plotted against $n\kappa_w^2/3$, where κ_w is the weight-average value equal to $Zel_wE/2kT$. The parameter n (1, 5, 10, and 50) is the number of condensed counterions on the polyion surface. Dashed curves represent $\Phi(\kappa)$ for the corresponding monodisperse system. In Fig. 6(b), the field strength dependence

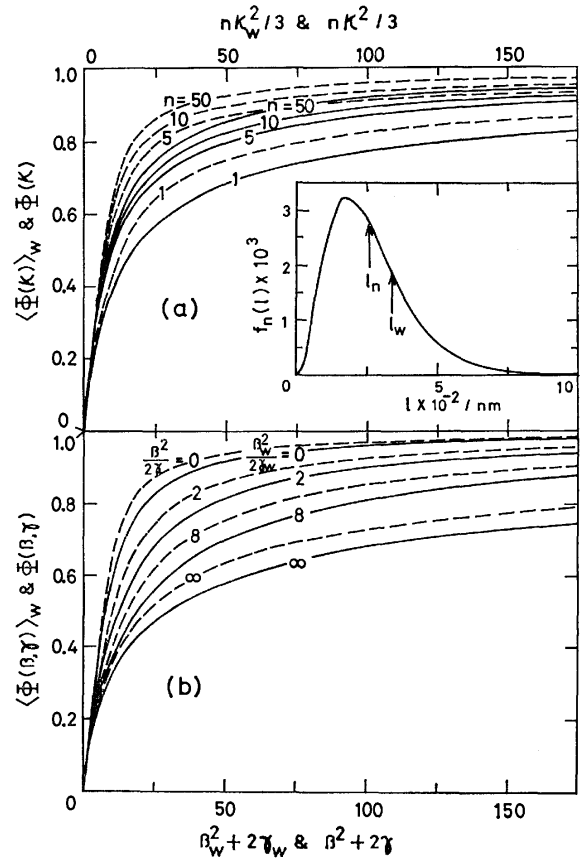

Fig. 6. The Kikuchi-Yoshioka orientation function $\Phi(\kappa)$ and the "classical" orientation function $\Phi(\beta,\gamma)$ for monodisperse and polydisperse systems. In (a), $\langle\Phi(\kappa)\rangle_w$ (——) is plotted against $n\kappa_w^2/3$ for $n=1$, 5, 10, and 50. In (b), $\langle\Phi(\beta,\gamma)\rangle_w$ (——) is plotted against $\beta_w^2+2\gamma_w$ for $\beta_w^2/2\gamma_w=0$, 2, 8, and ∞. The insert shows the Schulz-Zimm length distribution function $f_n(l)$ with the parameter l_w/l_n of 1.3, which was used for calculating both $\langle\Phi(\kappa)\rangle_w$ and $\langle\Phi(\beta,\gamma)\rangle_w$. In (a) and (b), dashed curves (----) are the respective orientation functions $\Phi(\kappa)$ and $\Phi(\beta,\gamma)$ calculated for a monodisperse system ($l_w/l_n=1.0$). The integal limits L_1 and L_2 are set at 12 and 1200 nm.

of the weight-average classical orientation function $\langle\Phi(\beta,\gamma)\rangle_w$ is plotted against $\beta_w^2+2\gamma_w$, where β_w and γ_w are values of $\mu_0 l_w E/kT$ and of $\Delta\alpha_0 l_w E^2/2kT$. Here, μ_0 and $\Delta\alpha_0$ are the permanent dipole moment and the polarizability anisotropy per unit length, respectively. Values of $\beta_w^2/2\gamma_w$ are a measure of relative contributions of those electric moments to field orientation, corresponding to the pure induced moment (0), the mixed dipole moment (2 and 8), and the permanent dipole moment (∞) orientation. Dashed curves represent $\Phi(\beta,\gamma)$ for the corresponding monodisperse system. In Fig. 6, the orientation factor (the average degree of orientation of polyions in solution) for the monodisperse system is larger than for the polydisperse system at a given field strength, except in the low field strength region.

Curve-fitting Method. Several curve fitting methods[1,6,8,22] have been used to obtain values of the intrinsic optical factor and the electric dipole moment. As shown in Fig. 7(a), the field strength dependence

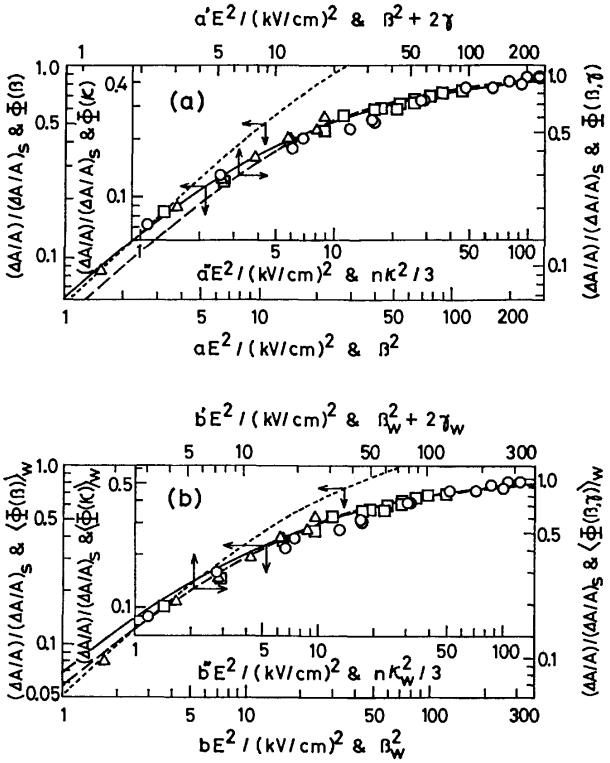

Fig. 7. Comparison of experimental values of reduced dichroism for NaPSS at 224.5 nm (○) and at 262 nm (△) and for NaPSS–AA at 404 nm (□) with theoretical orientation functions (a) for the monodisperse system and (b) for the polydisperse system. In (a), three sets of the double logarithmic plots are shown: $(\Delta A/A)/(\Delta A/A)_s$ against aE^2, $a'E^2$, $a''E^2$; $\Phi(\beta)$ against β^2 (——); $\Phi(\beta,\gamma)$ against $\beta^2+2\gamma$ (----); $\Phi(\kappa)$ against $n\kappa^2/3$ (……). The observed dichroism $\Delta A/A$ for each of NaPSS and NaPSS–AA was normalized by dividing it by the limiting value $(\Delta A/A)_s$ given in Table 2, in order to compare three sets of experimental points (○, △, and □) with a given theoretical orientation function $\Phi(\beta)$, $\Phi(\beta,\gamma)$, or $\Phi(\kappa)$ on each of three coordinates. The factors a, a', and a'' are: $a=0.806$ (○), 0.0704 (△), and 0.339 (□); $a'=0.661$ (○), 0.0577 (△), and 0.278 (□); $a''=0.140$ (□). In (b); three sets of the double logarithmic plots are shown: $(\Delta A/A)/(\Delta A/A)_s$ against bE^2, $b'E^2$, and $b''E^2$; $\langle\Phi(\beta)\rangle_w$ against β_w^2 (——); $\langle\Phi(\beta,\gamma)\rangle_w$ against $\beta_w^2+2\gamma_w$ (----); $\langle\Phi(\kappa)\rangle_w$ against $n\kappa_w^2/3$ (……). $b=0.799$ (○), 0.0610 (△), and 0.384 (□); $b'=0.769$ (○), 0.0588 (△), and 0.370 (□); $b''=0.151$ (□). Both $\Phi(\kappa)$ and $\langle\Phi(\kappa)\rangle_w$ with the n value of 1 are applicable only to the case of NaPSS–AA (□). Symblos and experimental conditions in (a) and (b) are the same as in Fig. 2.

of observed reduced dichroism of NaPSS at 224.5 and 262 nm and NaPSS–AA at 404 nm was compared with theoretical orientation functions by assuming a monodisperse system. The experimental points fit the permanent dipole moment orientation $\Phi(\beta)$ (solid curve) over a wide range of field strength. A mixed-dipole moment orientation function $\Phi(\beta,\gamma)$ with $\beta^2/2\gamma$ of 8 (dashed curve) is also plotted, but it disagrees with the experimental points except for the high field region. Although the orientation function $\Phi(\kappa)$, in which ion-atmosphere polarization is considered, seems to be the most reasonable one for the salt-free NaPSS and NaPSS–AA solutions, it fits the experimental points only in the low field strength region (dotted curve). This discrepancy may be partly due to the neglect of the effect of counterion repulsion and partly due to the polydispersity of polymer length.

In order to test the effect of polymer lengths, the field strength dependence of reduced dichroism for NaPSS and NaPSS–AA systems is compared, in Fig. 7(b), with the orientation functions which take into account the polydispersity with the length distribution function $f_n(l)$ (Fig. 6). Experimental points fit a mixed-dipole moment orientation function $\langle\Phi(\beta,\gamma)\rangle_w$ with a $\beta_w^2/2\gamma_w$ of 8 rather than the pure permanent dipole moment orientation function $\langle\Phi(\beta)\rangle_w$. On the other hand, the experimental points fit $\langle\Phi(\kappa)\rangle_w$ only in the low field strength region; $\langle\Phi(\kappa)\rangle_w$ is definitely closer to the experimental points than $\Phi(\kappa)$. At present, the best (but not necessarily unique) values of $\beta^2/2\gamma$ and $\beta_w^2/2\gamma_w$ together with those of $(\Delta A/A)_s$ were obtained by this curve fitting method and are given in Table 2. It is difficult to select either of them as the more reasonable. In order to obtain the exact value of $\beta_w^2/2\gamma_w$, the form of the length distribution function for the NaPSS sample must be known. It should be noted that the values of the limiting reduced dichroism $(\Delta A/A)_s$ are not appreciably different when they are obtained from the two best fitted orientation functions, $\Phi(\beta)$ and $\langle\Phi(\beta,\gamma)\rangle_w$. This is because both of the two functions approach unity at the limiting high field strength.

Wavelength Dependence of Reduced Dichroism of NaPSS and NaPSS–AA Complex. By comparing values of ε in Table 1 between NaPSS, sodium *p*-toluenesulfonate, and benzene,[30] the longest-wavelength band of NaPSS in the 280—245 nm region is reasonably assigned to the transition polarized in the direction bisecting the 1- and 4-carbon atoms of a phenyl plane (the $^1B_{2u}$ band), while the short-wavelength band in the 245—215 nm region is the transition polarized perpendicular to the long axis in the phenyl plane (the $^1B_{1u}$ band). The reduced dichroic spectra could not be determined at a single polymer concentration for these two bands (Figs. 3 and 4), because the $^1B_{1u}$ band absorbs light much more strongly than the $^1B_{2u}$ band. If the effect of dilution is negligibly small, the difference in $(\Delta A/A)_s$ values for these bands is interpreted as being due to the different tilt angles of the mutually perpendicular transition moments in the phenyl ring relative to the orientation axis of the NaPSS backbone. These angles are given in Table 2. The increase in $\Delta A/A$ values below 224 nm is not explained by the $^1B_{1u}$ transition moment alone, because a single transition moment should give rise to a constant reduced dichroism inside an absorption band. This result probably indicates the presence of another transition moment in the far UV region.[25]

The absorption bands of NaPSS–AA arise from the electronic transition moments of the AA molecule (^1L_a- and ^1L_b-bands), the directions of which are shown in Fig. 5.[15,31,32] They are mutually perpen-

a) The square of field strength at $\beta^2+2\gamma=10$ or $\beta_w^2+2\gamma_w=10$. b) When polydispersity is taken into account, the weight-average quantities become $\langle\mu\rangle_w$ and $\langle\Delta\alpha\rangle_w$, which are equated to $\mu_0 l_w$ and $\Delta\alpha_0 l_w$, respectively. c) 1 D=3.336×10^{-30} C m and 1 cm^3=1.113×10^{-16} F m^2.

dicular in the dye plane and are widely separated. Since the bound fraction of AA has been estimated to be more than 99% in the NaPSS–AA solution at a *P/D* of 6.14,[15] the amount of unbound AA in the present solution should be negligibly small. Therefore, the observed dichroic spectra in Fig. 5 can be considered to be the dichroic spectra of the bound AA. If the flexibility of the NaPSS chain is neglected at a low polymer concentration (C_p=0.663 mM), the average angle θ between the transition moment ^1L_a and the orientation axis of the NaPSS–AA complex is *ca.* 50°. The average angle for the ^1L_b band at 315 nm was calculated to be *ca.* 48°. Although the difference of the angles for the ^1L_a and ^1L_b bands is very small, it is definitely beyond the experimental error. The fact that the reduced dichroism of 0.22± 0.02 in the 440—370 nm region differs from that of 0.27±0.02 in the 335—282 nm region may be interpreted as follows: the angles of these transition moments of the bound AA differ from each other relative to the orientation axis of NaPSS–AA (provided that the number and the direction of the transition moments remain unaltered when the dye is bound to the NaPSS site). It should be noted that these angles are still only apparent, since more than one bound AA species may be present on the NaPSS surface.[15,18]

Apparent Dipole Moments of NaPSS and NaPSS–AA Complex. In the preceding section, the experimental points fit $\Phi(\beta,\gamma=0)$ and $\langle\Phi(\beta,\gamma)\rangle_w$ (with a $\beta_w^2/2\gamma_w$ of 8) curves better than $\Phi(\kappa)$ and $\langle\Phi(\kappa)\rangle_w$, over a wide range of field strength. On the other hand, it has been shown by reversing-pulse electric birefringence that both NaPSS and NaPSS–AA possess no appreciable intrinsic permanent dipole moment.[11] Hence, we term μ the pseudo-permanent dipole moment and retain it, until a more complete orientation function is derived for conducting polyelectrolytes. These values are given in Table 2. With an increase in concentrations of NaPSS, the pseudo-permanent dipole moment decreases in the order: NaPSS (C_p=0.133 mM) > NaPSS–AA (C_p= 0.663 mM) > NaPSS (C_p=3.31 mM). This result is qualitatively consistent with the concentration dependence of the specific Kerr constant, as observed by Kikuchi and Yoshioka for KPSS.[6] Thus, the dipole moment of NaPSS depends strongly on the concentration, indicating that, as the ionized sulfonate groups increase, the chain stiffness and, hence, the persistence length also increase.

Conclusion

The field strength dependence of reduced dichroism signals of NaPSS and NaPSS–AA in aqueous solutions can be described by the "classical" permanent dipole orientation function $\Phi(\beta)$ for the monodisperse system and also by the mixed-dipole orientation function $\langle\Phi(\beta,\gamma)\rangle_w$ for the polydisperse system. However, the seemingly more realistic orientation functions $\Phi(\kappa)$ and $\langle\Phi(\kappa)\rangle_w$, based on ion-atmosphere polarization, fit the dichroism data of NaPSS and NaPSS–AA only in the low field range. The necessity for an improved expression for the orientation function of charged, flexible polyelectrolytes is apparent. Such an orientation function must contain the effects of counterion repulsion, the flexibility, and the polydispersity of polymer chain. The reduced dichroism at limiting high field, estimated with different theoretical orientation functions, is almost identical. The wavelength dependence of reduced dichroism of NaPSS indicates that the UV band is composed not only of the $^1B_{1u}$ and $^1B_{2u}$ transitions but also of another higher-energy transition in the far UV region. The absorption spectrum of NaPSS–AA is composed of both the ^1L_a and ^1L_b in-plane transitions, whose average angles are slightly, but definitely, different from each other relative to the orientation axis of the NaPSS backbone.

Construction of an Adiabatic Calorimeter Workable under Constant High-pressure†

Masaharu OGUNI, Kazuo WATANABE,** Takasuke MATSUO, Hiroshi SUGA,* and Syûzô SEKI***

Department of Chemistry and Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 26, 1981)

An adiabatic high-pressure calorimeter was constructed. The calorimeter cell was devised for minimization of the cell mass relative to the volume of the sample chamber. The pressure in the cell was controlled by joining the cell with a transmitting tube to a stabilized high-pressure system. The adiabatic conditions were achieved by temperature control of the transmitting tube as well as of adiabatic shields inside the cryostat. Procedures for the precise pressure control and for the determination of the molar volume and heat capacity with the correction for the mass transfer of pressure-transmitting liquid in a series of measurement were discussed. The apparatus is capable of measurement under constant pressure up to 110 MPa and over the temperature range from 100 to 370 K. The results on liquid 3-methylpentane which was used as the pressure medium proved satisfactory performance of this new-type calorimeter.

Temperature and pressure are among the most fundamental parameters in specifying the thermodynamic state of substances. Various physicochemical phenomena are most profitably studied by detailed and accurate measurement of the heat capacity, volume expansivity, and compressibility as functions of both temperature and pressure. These properties under ordinary pressure have hitherto been measured with high precision and accuracy in a wide temperature range. Although volume measurements for liquids have been extended to high pressures,[1-3] few quantitative measurements of heat capacity under pressure have been reported so far. Development of such measurements is naturally expected to contribute, to a great extent, to further understanding of the behaviors of substances at ordinary pressure as well as under pressure. Among these interesting behaviors are the pressure dependences of characters of phase transitions and the details around multiple points.

The heat capacity of a condensed matter is usually measured under constant pressure because of the difficulty in keeping the volume of the specimen constant. An adiabatic calorimeter is known to give the most reliable data at the atmospheric pressure. High pressure makes it difficult to satisfy some of the conditions favorable for the adiabatic calorimetry through the requisite of placing the specimen under pressure. A fundamental problem originates from increase of the mass of the calorimeter cell. The increase of the mass of the cell necessarily results in decrease in the ratio of the sample heat capacity to the total observed heat capacity vitiating certainty of the measurement. This situation leads to two calorimetric principles applied for construction of the calorimeter, a non-adiabatic or adiabatic method, depending on the pressure range to be covered.

Non-adiabatic methods, d.c. pulse or a.c. calorimeters, are applied to the measurements in the higher pressure than about 1 GPa.[4-7] The adiabatic method, employed in the relatively low pressure range up to $\approx$1 GPa, follows the principle of the adiabatic calorimetry under the ordinary pressure. Two types of apparatuses can be devised depending upon the choice whether the pressurized specimen is isolated from the surroundings or it communicates with an external pressure reservoir. The former condition is realized in a clamp-bomb calorimeter; the high pressure is generated and clamped outside the cryostat beforehand using a screw, and then the measurement is performed with the conventional adiabatic calorimeter as is done just at ordinary pressure.[8-11] Amitin *et al.* adopted this type of apparatus for the measurements on NH_4Cl crystal.[9] The pressure applied to the sample in such a calorimeter changes with the temperature. Especially when the sample undergoes a phase transition, the change should be drastic around that temperature, resulting in quite a complicated thermodynamic path in the p-T plane followed by the specimen in a series of measurement. The latter alternative is achieved by joining the calorimeter cell to the outside pressure-control system with a pressure-transmitting tube. In such a calorimeter, transfer of a part of the pressure medium out of or into the cell is inevitable as the temperature of the cell changes. Mil'ner reported the result on NH_4Br at 35 MPa with an apparatus of this type.[12] He employed argon gas as the pressure medium, which restricted the practical pressure range to the low region in view of the danger associated.

In this paper, we report the detail of a high-pressure adiabatic calorimeter and the results on liquid 3-methylpentane obtained with it. Features of the present calorimeter are as follows; (1) it is capable of heat capacity measurement in the temperature region from 100 to 370 K and the pressure range up to 110 MPa, (2) operates under adiabatic condition, (3) operates under stabilized hydrostatic pressure, and (4) enables to measure the volume (and therefore expansivity and compressibility) simultaneously. Heat of compression can also be derived by taking an extra procedure.

Construction of Apparatus

Method of Calorimetry. Any high-pressure calorimetry is carried out at the sacrifice of some favorable conditions which are met in adiabatic calorimetry under ordinary pressure. The present calorimeter permits pressure medium to flow into or out of the cell so as to keep the pressure constant. The effect of transfer of a mass of the medium is to be corrected for later using dilatometric data. Heat capacity value obtained experimentally corresponds exactly to C_p on account of self-evident thermodynamic path in a series of measurement.

The whole apparatus consists of a calorimeter cell, a circuit for energy supply and its measurement, a temperature-measuring system, an adiabatic-control system, and a high-pressure system. Most of the parts excepting the temperature- and energy-measuring systems were installed in a room, the temperature of which was kept constant at (30.0±0.1) °C.

The calorimeter cell is equipped with a platinum resistance thermometer and a heating element. The temperature measurement of the cell was performed with a precision a.c. double bridge (AΣ*A* Inc. Model H8). The electric energy supplied to the cell was measured by using a digital voltmeter and a digital clock. An adiabatic condition of the calorimeter cell was realized by evacuating space inside the cryostat and by temperature-controlling the shields and high-pressure tube within the cryostat. The pressure in the cell was controlled by connecting the cell with the transmitting tube to the high-pressure system which consists of pressure generation, pressure transmission, pressure gauge, pressure control and dilatometry subsystems. Liquid 3-methylpentane was used as the pressure medium, because it was known to undergo neither crystallization nor glass transition down to liquid nitrogen temperature.

Calorimeter Cell. A calorimeter cell must have the strength enough to withstand the applied pressure. The requirement causes the mass of, and therefore the heat capacity of, the high-pressure cell to increase with increase of the maximum pressure to which the measurement is intended. For this reason, inaccuracy of an adiabatic calorimetry originates primarily from smallness of the heat capacity of the sample compared with that of the empty cell.

The present calorimeter cell was so designed as to maximize the volume of the sample space for the given mass of the cell material. Figure 1 shows the sectional drawing of the calorimeter cell and the annexed pressure-transmitting tube made of stainless steel. The sample vessel (D), vessel gland (M), and a packing washer (J) were made of a copper-beryllium alloy which had reasonably high thermal conductance and good mechanical properties necessary for the calorimeter cell. They were machined out from the material annealed at 315 °C for 2.5 h for the purpose of increasing the mechanical strength. A spherical shape of the vessel is one of particular devices for minimization of the mass of the empty cell and maximization of the space of the sample

chamber. A sawtooth type of screw between the vessel and the gland was devised to minimize the thickness of the cylindrical part of the gland to the limit compatible with the mechanical strength required. Sealing of the cell was based on Bridgman's principle that the pressure exerting on the indium and teflon packing is larger than the medium pressure. A pressure transmitting tube (B), whose bottom area is unsupported, was screwed into a plug (C) made of stainless steel. An annealed-copper extrusion ring (L) served to prevent the teflon and indium from flowing outside. Heater wire (H) was wound outside the sample vessel. A thin vessel cover (E), made of copper, was installed to intercept heat leak by radiation from the heater as well as to fix thermocouple (I) and a copper sheath which held the platinum thermometer. This cover was gold-plated for reduction of radiative heat leak between the cell and its surroundings. The volume of the sample chamber was 24.522 cm^3 at 19 °C and the mass of the empty cell *ca.* 550 g. The whole cell was attached to or detached from the high-pressure system through a cone connector (A).

Cryostat and Adiabatic-control System. Adiabatic control requires minimization of the heat leak between the calorimeter cell and its surroundings. The minimization was achieved by evacuation of the space inside the cryostat (10^{-4} Pa) and by temperature regulation of the shields and the pressure tube. Figure 2 is a sectional illustration of the cryostat. The shields referred to as inner (B and D) and outer (F), and block (H) were made of copper for its high thermal conductivity. The high-pressure tube and the block were soldered to each other so as to aid their thermal contact. The electrical wires were twisted pair-wise to reduce inductive interference among them. The temperature control system utilizes the temperature difference signals ΔT_1 from the chromel-constantan thermocouples to regulate the current passing through

the corresponding heater. Heat leak between the cell and the inner shield (B) and through the high-pressure tube (J_1) affected most severely the experimental results. Five pairs of thermocouple were installed between the cell and the shield. The stainless-steel pressure tube was made as slender as is compatible with the required strength, and temperature-regulated by use of PID control circuit. The bottom and the other part of the inner shield were temperature controlled separately for better temperature-homogeneity within the inner shield. The temperature of the outer shield, block, and upper pressure tube (J_2) were held at several Kelvin below that of the cell. The whole cryostat was immersed into liquid nitrogen.

High-pressure System. The high-pressure system consisted of subsystems for generation, transmission, measurement and control of the pressure, including a dilatometer in it. The whole system is schematically depicted in Fig. 3. Two liquids separated by at the dilatometer were employed as pressure media in the lines; the lines on the pressure generation side (right-hand side in the figure) of the dilatometer (L) were filled with liquid kerosene through pumping at the pressure generator (A), while the lines on the cryostat side (left-hand side) with liquid 3-methylpentane. The pressure was read from the scale of Heise gauge (G). The whole system was installed in a room controlled at (30.0±0.1) °C.

The pressure control subsystem keeps the pressure constant by cancelling pressure change which is induced by the change of the cell temperature during the heat capacity measurement. Detail of the subsystem is illustrated in Fig. 4. The pressure was controlled by adjusting the temperature of the kerosene reservoir. Change of the pressure was monitored as a change in the manganin coil resistance which constituted one arm of a Wheatstone bridge, and this electrical signal was used to regulate the current passing through the heater (B) in the reservoir. The pressure to be set up was selected by changing the variable resistance of the Wheatstone bridge. Adoption of this method enabled to control the pressure automatically within 0.1 MPa in the whole temperature range measured. The coiled manganin wire was left strain-free in a vessel (J). The resistance was measured with the method of three terminals in order to allow for the lead resistance. The whole vessel was immersed in an oil bath (C) controlled at constant temperature of (35.0±0.1) °C.

The sectional drawing of the kerosene reservoir is shown in Fig. 5. The method of unsupported area was made use of for sealing. The electrode was fixed and insulated in the same way as in the manganin gauge by using Teflon as the packing material. A high-pressure tube (P) was fixed by screwing into the plug (C) and by tightly sealing with the Araldite resin. Heater wire (D) was glued on vanes (E) with Araldite. The volume of the kerosene chamber is ≈250 cm^3 which was *ca.* 10 times larger than that of the sample chamber of the calorimeter cell. The whole vessel was installed in an air bath, the temperature of which was always kept lower by *ca.* 10 °C than that of the kerosene chamber.

Charge of liquid 3-methylpentane into the high-pressure lines was carried out by using a vacuum line as shown in Fig. 3. The liquid was first poured into the glass bulb (R) and then the bulb was connected with a joint to the vacuum line. After repeated degassing of the liquid and evacuation of the calorim-

eter cell and the dilatometer, the liquid was transferred into the high-pressure system by vacuum distillation at ≈50 °C.

Dilatometer. The present calorimeter permits the pressure medium to flow into or out of the cell for keeping the pressure constant. Calculation of the sample heat capacity from the apparent one requires the mass of the medium contained in the cell to be determined as a function of temperature. The dilatometer gives such data as well as essential information on the temperature dependence of the sample volume. A stainless-steel cylinder and Permalloy core constituted the dilatometer as shown in Fig. 6. The inner diameter of the cylinder was (2.000±0.010) cm. The core with very high magnetic susceptibility moved by pressure difference less than 0.1 MPa. The two pressure media (kerosene and 3-methylpentane) were separated by the core and an O-ring fitted up around it.

Expansion or contraction of the sample associated with the change of the temperature at the cell induced movement of the position of the core inside the cylinder. The position was detected by a combined apparatus of a cathetometer equipped with a differential transformer and a lock-in amplifier. The position of the transformer was read to 0.001 cm corresponding to 0.003 cm^3 in the error of volume measurement. The certainty was good enough for the temperature dependence of the mass of 3-methylpentane in the cell to be used in computing the heat capacity values.

Energy Supply and Temperature Measurement. Energy supply and temperature measurement were carried out by use of the apparatus already constructed.[13] A Minco thermometer of 469.740 Ω at 273.15 K was used as the temperature sensor of the calorimeter cell. The detailed procedure for determination of the temperature and the total input energy was given in the article reported before.[13]

Determination of the Volume and the Heat Capacity. Total heat capacity C consists of contributions from the pressure medium in the cell, mC_1, the empty cell, C_b, and the sample, C_s;

$$C = mC_1 + C_b + C_s. \tag{1}$$

One analyses the change of state induced by a heating experiment as follows. Let $T-\Delta T$ and $m+\Delta m$ designate the temperature and the mass of the pressure medium in the initial state, and $T+\Delta T$ and $m-\Delta m$ those in the final state. Here T and m are those in the intermediate of the initial and final states. The specific heat capacity of the medium is then approximated as C_1+at, where C_1 is the specific heat capacity at T, t the temperature difference from T, and a the differential coefficient of the heat capacity by temperature. Since the input energy causes the temperature increase of the materials constituting the calorimeter cell, the total input energy ΔH is written as follows;

$$\Delta H = 2\Delta T(C_s+C_b) + \int_{-\Delta T}^{\Delta T}\left(m-\frac{t}{\Delta T}\Delta m\right)(C_1+at)\mathrm{d}t$$
$$= 2\Delta T(C_s+C_b) + 2\Delta T m C_1 - \frac{2}{3}(\Delta T)^2 a\Delta m. \tag{2}$$

The apparent heat capacity C_e is expressed from this as follows;

$$C_e = \frac{\Delta H}{2\Delta T} = C_s + C_b + mC_1 - \frac{a\Delta T\Delta m}{3}. \tag{3}$$

The total heat capacity under constant pressure with the liquid medium of m is given by

$$C_p = C_s + C_b + mC_1, \tag{4}$$

and consequently

$$C_p = C_e + \frac{a\Delta T\Delta m}{3}. \tag{5}$$

The correction given by the second term of the right-hand side is estimated in order of magnitude in the case where the cell contains only the pressure medium 3-methylpentane. The following relations then hold for a typical measurement in which $2\Delta T \approx 2$ K and $T > 100$ K;

$$a\Delta T \lesssim 10^{-2} C_1, \tag{6}$$

$$\Delta m \lesssim 10^{-2} m, \tag{7}$$

because the volume expansivity is $\approx 10^{-3}$. It follows that the correction is smaller than $10^{-4} mC_1$ to be neglected to a good approximation in the determination of C_p. Thus the heat capacity under constant pressure is given by

$$C_p = C_e. \tag{8}$$

But the amount of the pressure-transmitting liquid,

m, at the midpoint of the initial and the final temperatures changes with temperature and pressure and is to be determined from dilatometric data.

The heat capacity of the evacuated cell $C_b(T)$ was measured and assumed to depend only on the temperature. This assumption was tested as follows. The effect of pressure on the heat capacity of the copper-beryllium alloy could be assessed from the equation

$$\left(\frac{\partial C}{\partial p}\right)_T = -T\left(\frac{\partial^2 V}{\partial T^2}\right)_p. \quad (9)$$

With the volume expansivity *vs.* temperature data around 200 K of copper similar to the copper-beryllium alloy, the estimate shows $(\partial C_b/\partial p)_T/C_b \simeq 10^{-5}$ MPa^{-1} for the cell, indicating that the influence is negligible within the error of measurement in the low pressure range ($\approx 10^2$ MPa).

The amount of pressure medium in the cell, m, naturally depends upon the volume of the cell. The volume $V_c(T, p)$ was given by

$$V_c(T,p)/\mathrm{cm}^3 = \{0.987740+3.5\times10^{-5}(T/\mathrm{K}) + 2.5\times10^{-8}(T/\mathrm{K})^2\} \times \{24.520+2.3\times10^{-4}(p/\mathrm{MPa})\}. \quad (10)$$

The volume was first calibrated, using water, to be 24.522 cm^3 at 19.0 °C and an atmospheric pressure. The temperature dependence, the former factor in Eq. 10, was determined assuming that the expansion coefficient α was given by a linear function of temperature, $\alpha=4\times10^{-5}+5\times10^{-6}\{(T/\mathrm{K})-100.0\}$, with the values 4×10^{-5} K^{-1} at 100 K and 5×10^{-5} K^{-1} at 300 K. The pressure coefficient in the latter factor, on the other hand, was estimated at 30 °C by measuring first the pressure dependence of the molar volume of 3-methylpentane, and then the pressure dependence of the volume of 3-methylpentane inside the cell.

The molar volume and the molar heat capacity of 3-methylpentane are derived from calorimetric and dilatometric data as follows. Let $\rho_0(p)$ and $m_0(p)$ be the density and mass of the liquid contained in the cell, respectively, at 30 °C (=303 K) and some constant pressure p. Decreasing the temperature of the cell from 303 K to T displaces the core in the dilatometer toward the cell by l. The mass of the pressure medium in the cell is then given by the expression

$$m(T,p) = m_0(p) + \pi r^2 l \rho_0(p), \quad (11)$$

where r is the inner radius of the dilatometer. The density is accordingly

$$\rho(T,p) = \{m_0(p)+\pi r^2 l\rho_0(p)\}/V_c(T,p). \quad (12)$$

From this, the molar volume is given by the expression

$$V_c(T,p) = M/\rho(T,p), \quad (13)$$

and the molar heat capacity

$$C_i'(T,p) = M\{Q/\Delta T - C_b(T)\}/m(T,p). \quad (14)$$

Here M represents molar mass of 3-methylpentane, and $Q/\Delta T$ the apparent experimental heat capacity at T. Volume expansivity and compressibility can be calculated through thermodynamic relations.

The similar procedure in the case where the sample replaces greater part of the medium in the cell is shown in the following. Using the same notations of $\rho_0(p)$, $m_0(p)$, $m(T,p)$, and l as described above, one obtains the same relation as Eq. (11). Therefore the molar volume of the sample is expressed by

$$V_s(T,p) = \frac{M_s}{m_s}\left[V_c(T,p) - \frac{m_0(p)+\pi r^2 l\rho_0(p)}{\rho(T,p)}\right], \quad (15)$$

where $\rho(T,p)$ is the density of pressure medium derived in Eq. 12. The molar heat capacity has the expression

$$C_s(T,p) = \frac{M_s}{m_s}\left[\frac{Q}{\Delta T} - C_b(T) - \frac{m(T,p)}{M}C_i'(T,p)\right], \quad (16)$$

where m_s is the mass of the sample and M_s its molar mass. Here $m(T,p)$ is not equal to that given by Eq. 11, but is to be derived from dilatometric data using the values of the sample density and $V_c(T,p)$ at a certain temperature and pressure.

In fact, the temperature of the tube immediately above the cell (*i.e.*, the part between a coupling and the cell) changes with the same time-dependence as that of the temperature of the cell for the adiabatic temperature control of the cell. The effect of this temperature change at the tube on the displacement of the core position should be corrected for in the processing of dilatometric data. Let $Y_0(p)$ and $Y(p)$ denote the readings of the core position at 30 °C and T, respectively. The volume inside of the tube the temperature of which changes according to the change in the temperature of the cell being taken 0.1 π cm^3, the reading after above correction, $Y_1(p)$, is derived from the equation

$$Y_1(p)/\mathrm{cm} = Y(p)/\mathrm{cm} + 0.1\left[\frac{\rho(T,p)-\rho_0(p)}{\rho_0(p)}\right]. \quad (17)$$

The amount of the pressure medium in the cell at T is therefore given by

$$n(T,p) = n_0(p) + \frac{[Y_1(p)-Y_0(p)]\pi\rho_0(p)}{M}, \quad (18)$$

assuming the amount at 30 °C is $n_0(p)$. This correction was applied to the processing of data in both the cases with and without the sample in addition to the pressure medium in the cell. In the former case, the application for the molar volume of the sample material gives,

$$V_s(T,p) = \frac{M_s}{m_s}\left\{V_c(T,p) - \frac{[n_0M+(Y_1(p)-Y_0(p)\pi\rho_0(p)]}{\rho(T,p)}\right\}. \quad (19)$$

Results on 3-Methylpentane

Experimental. All the space inside and outside of the cell was evacuated after connection of the cell into the high-pressure system. Heat capacity of the empty cell was measured under that vacuum condition in the temperature range from 80 to 370 K.

The molar volume and heat capacity of liquid 3-methylpentane were measured in the following procedure. The reagent, purchased from Nakarai Chemical Co., was first introduced into a glass bulb (R in Fig. 3) and degassed carefully. The sample was then transferred into the high-pressure system and

the cell by vacuum distillation. The core of the dilatometer was brought toward the pressure generator at the room temperature to allow for the contraction of the liquid by pressure increase and/or temperature decrease. The value of molar volume at 20 °C and an atmospheric pressure was taken from a

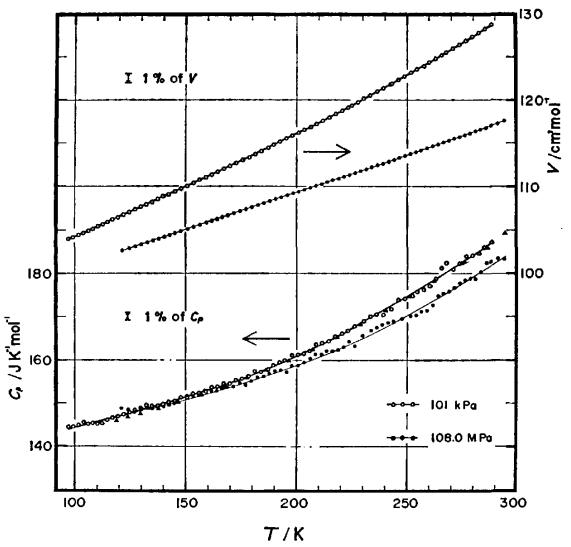

Fig. 7. Molar volume and molar heat capacity of 3-methylpentane.
○: 0.101 MPa, ●: 108.0 MPa.

reference.[14] The ratio of the molar volume at each pressure to that at 0.101 MPa was first measured at 30 °C and is collected in Table 1. The heat capacity was measured at 0.101 MPa and at 108.0 MPa in the heating direction from 100 to 300 K.

Results. The results of molar volume and heat capacity of liquid 3-methylpentane at the atmospheric pressure (0.101 MPa) and 108.0 MPa are shown in Fig. 7 and collected in Tables 2 and 3. The heat capacity at 0.101 MPa was previously measured by Finke and Messerly using a conventional adiabatic calorimeter (Δ in the figure).[16] The present value above 160 K was in good agreement with that and larger by 0.5—1 J K^{-1} mol^{-1} between 120 K and 160 K. The discrepancy in the low temperature region is approximately 0.5%. The relatively large scattering of the heat capacity data is due to the adverse situation that the sample accounted for about one tenth of the total observed heat capacity.

Comparison between the molar heat capacities at 0.101 MPa and at 108.0 MPa shows that the former values is larger by *ca.* 6 J K^{-1} mol^{-1} than the latter one around room temperature, while it is almost the same as the latter below 130 K. Self-consistency between this pressure dependence of the heat capacity and temperature dependence of the molar volume in the present experiment is checked using a thermodynamic relation (9). The second order differential coefficient of the volume with the temperature was derived from the volume data smoothed against temperature, and the average value between those at two pressures was employed in the calculation. At 280 K, the difference between the heat capacities at 0.101 MPa and at 108.0 MPa was calculated with the relation to be -7.2 J K^{-1} mol^{-1}, which should be compared with -6 J K^{-1} mol^{-1}. At 130 K, it was -1.3 J K^{-1} mol^{-1} to be compared with ≈ 0 J K^{-1} mol^{-1}. The consideration on the error included in the derivation of second-order differential coefficients of volume would make such a discrepancy as *ca.* 1 J K^{-1} mol^{-1} insignificant,

Accordingly, the results of volume and heat capacity would be concluded to be consistent each other.

These facts indicate that the present calorimeter has an excellent ability to give information of volume and heat capacity at constant pressure simultaneously in the temperature region at least from 100 to 300 K and up to 110 MPa. The imprecision and inaccuracy of heat capacity datum are estimated to be 0.5% and 1%, respectively, in comparison with the previous data which were claimed to have 0.2% inaccuracy at an atmospheric pressure.[16]

Concluding Remarks

A new type of high-pressure calorimeter was constructed in the present work which operated under constant pressure up to 110 MPa.[15] The results of heat capacities on liquid 3-methylpentane proved that this calorimeter has a satisfactory accuracy. This apparatus also enabled us to measure the temperature and pressure dependences of volume at the same time. This feature should be stressed in view of the facts that any physicochemical phenomenon could be understood through the observation of several kinds of properties.

Many kinds of interesting problems in phase transitions will be studied in relation to two thermodynamic parameters, pressure and temperature. One of the examples will be described in the subsequent paper on NH_4Br and ND_4Br crystals. Another interesting use of this calorimeter will be the application to studies on glass transition phenomena. Detailed enthalpy relaxation can be followed only under adiabatic condition and volume relaxation under constant pressure.

The work to extend the pressure range up to 250 MPa is under way.

The authors would like to express sincere thanks to the late Professor Naoto Kawai, Drs. Akifumi Onodera, and Kaichi Suito at Faculty of Engineering Science, Osaka University for their valuable suggestions in the design of the calorimeter cell and kind instruction on many high-pressure techniques.

Direct Observation of the Rate for Cis→Trans and Trans→Cis Photoisomerization of Stilbene with Picosecond Laser Photolysis

Minoru SUMITANI and Keitaro YOSHIHARA*

Institute for Molecular Science, Myodaiji, Okazaki 444

(Received June 29, 1981)

The rates for direct cis→trans and trans→cis photoisomerizations of stilbene in solution were measured with a newly developed monitor light source for picosecond laser photolysis in the UV region. The rate constant of the trans→cis isomerization is 1.2×10^{10} s^{-1} in hexane at 295 K. The fluorescence decay rate constant of the S_1 state of *trans*-stilbene has the same value. Thus, the decay of the S_1 state is the rate limiting step and the lifetime of an intermediate perpendicular state (^1p) has to be very short. The cis→trans isomerization is very fast and the half life of the excited *cis*-isomer is less than a few picosecond. These observations strongly indicate that the isomerization reaction proceeds through the potential surface of the singlet excited states.

Great attention has been paid to the mechanistic investigation of the cis-trans photoisomerization of olefinic compounds. Stilbene was chosen as one of the most prototypical molecules and studied in detail.[1] Several mechanisms have been proposed in the last decades. Earlier workers considered that the molecule in the excited state could rotate freely about the central double bond making *cis*- and *trans*-stilbenes interchangeable. Lewis *et al.*, however, pointed out that the fluorescence of *trans*-stilbene was not observed when the non-fluorescent *cis*-isomer was excited.[2] They proposed some energy dissipating levels among these excited states. Later, Förster suggested a mechanism according to which the isomerization proceeds through the lowest triplet state of each isomer.[3] This mechanism was supported by the analysis of the absorption spectrum of stilbene which seemed to indicate that the $S_1(^1B_u)$ state had a barrier high enough to make the state inaccesible for the photoisomerization.[4] However, this triplet mechanism failed to explain why azulene quenched the singlet excited state efficiently by energy transfer and reduced the efficiency of isomerization as well. Thus Saltiel proposed a singlet mechanism.[5] If stilbene is excited directly into the excited singlet state, it rotates about the central double bond to a perpendicular singlet intermediate (^1p), from which both isomers are formed.

From a theoretical point of view, Orlandi and Siebrand pointed out that the second excited singlet state $S_2(^1A_g)$ played an important role in the photoconversion of stilbene.[6] This S_2 level, which is characterized by a double electron excitation, is strongly stabilized, if the molecule rotates about the central double bond. The optical excitation to the lowest singlet state is followed by a non-adiabatic crossing to the S_2 potential surface, which has an energy minimum at the perpendicular (^1p) state, and then by a deactivation onto the ground potential surface.

Because of the inherently fast nature of the reaction, several works were made with time-resolved measurements.[7] The fluorescence lifetime and its temperature dependence,[8–12] the dynamics of the $S_n\leftarrow S_1$ absorption,[13–16] and the two-photon absorption[17,18] of stilbene were studied recently in order to investigate the photophysical and photochemical properties of its excited state. A few workers claimed to have observed a two-compornent decay of the excited singlet state by measuring either the fluorescence decay[8,9] or transient absorptions.[13,14] They ascribed these observations to the equilibration between the S_1 and ^1p states before deactivation to the ground state. On the other hand, we and others observed only a single exponential decay of the S_1 state by measuring the fluorescence decay,[10,11] and the $S_n\leftarrow S_1$ absorption.[15,16] No other transient absorption was observable except the $S_n\leftarrow S_1$ absorption of stilbene. Very recently we measured the time course of the cis→trans isomerization by the laser-induced fluorescence method with a picosecond double pulse, and pointed out that the ^1p state has a very short lifetime of less than a few picosecond.[19]

Laser-flash spectroscopy is a powerful method for studying the time course of photochemical reactions. In the picosecond range, several methods have been used for generating and detecting the monitoring light. A picosecond continuum light,[20] a flash lamp,[21,22] and a laser-induced dye emission[15] were combined with a vidicon camera, a photodiode array, or a picosecond streak camera. The picosecond continuum light has been used most widely, because it covers a rather wide spectral region and does not cause problems due to time jitter. However, it also has disadvantages, because it requires many laser shots in order to study the time profiles of transient species. Besides, it is usually difficult to generate UV light. The flash lamp technique has a large time jitter even with especially designed electric circuits. Using the laser-induced dye emission it is difficult to generate UV light. We developed a new simple method which does not require any special techniques using a jitter-free laser-induced Xe flash lamp and a streak camera. The spectrum of the monitoring light is continuous from the UV to the near IR region. By this method the time- and the wavelength-dependence of a transient can be resolved by one laser shot.

In this paper, we report the direct measurement of the reaction rates of both cis→trans and trans→cis isomerizations of stilbene with picosecond flash photolyses. We will show that the rate of trans→cis isomerization is limited by the S_1 lifetime of *trans*-stilbene and also that the rate of cis→trans isomerization is very high and the lifetime of the ^1p state is very short.

Experimental

The experimental set-up is shown in Fig. 1. The actinic light source of the photolysis system was the fourth harmonic

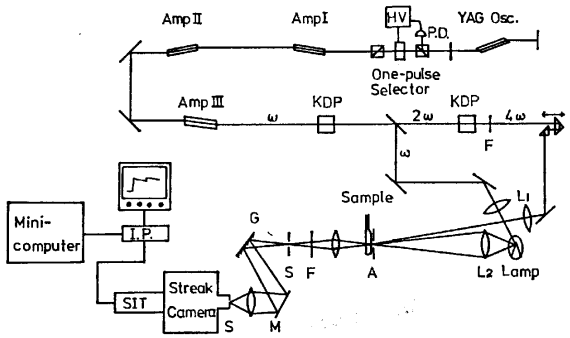

Fig. 1. Schematic diagram of apparatus employed for picosecond photolysis in the UV region.

(266 nm, ≈2 mJ) of a passively mode-locked Nd:YAG laser. A single pulse of the YAG laser was selected from the pulse train by a Pockels cell and was amplified in three stages with YAG amplifiers. The pulse width (FWHM) of the fourth harmonic was 11 ps. It was measured with a Hamamatsu streak camera/microcomputer system (C979 and C1000).

The analytic light was generated by focussing the fundamental laser beam onto the electrode of a high pressure Xe flash lamp (Xenon N722C). The break down occurred at the focal point of the laser beam at the electrode surface. An intense light emitted from this point was used as a monitoring light. No voltage was supplied on the electrodes. By this technique, the monitoring light was synchronized accurately with the actinic laser flash without any time jitter. The spectrum was similar to the Xe lamp and was continuous from the UV to the near IR region. The actinic laser and the monitoring light were focussed through an aperture onto the sample cell with lenses L_1 and L_2 (*cf.* Fig. 1), respectively. The monitoring light passed through the sample cell and a monochromator was detected by a streak camera.[23] The time delay between the start of the monitoring light and the actinic light was about 200 ps. The monochromator consisted of a Bausch & Lomb grating, G, (300 grooves/mm, 300 nm blaze wavelength), a mirror, M, and a pair of slits, S. We kept the wavelength resolution of the monochromator and the time resolution of the streak camera low in order to obtain a better signal/noise ratio. The wavelength resolution was about 10 nm at 254 nm and 313 nm. This was checked with a low pressure Hg lamp. The time resolution of this system was about 30 ps.

trans-Stilbene was purified by zone-refining and sublimation in the dark. *cis*-Stilbene was purified by means of high-speed liquid chromatography (Waters model 440). The content of *trans*-stilbene in the *cis*-isomer was less than one part in 500. The concentration of *cis*- or *trans*-stilbene was 1×10^{-4} M (1 M=1 mol dm^{-3}) in hexane.

Results

Figure 2 shows the UV absorption spectra of *cis*- and *trans*-stilbenes.[24] The molar extinction coefficients of *cis*- and *trans*-stilbenes above 240 nm are markedly different from each other except for the isosbestic point around 266 nm. By inducing the trans→cis or cis→trans isomerization the transmission of the monitoring light was, therefore, expected to change strongly by the formation of the reaction products.

Figure 3 shows the observed time-dependent transmission change after excitation of *cis*- or *trans*-stilbene

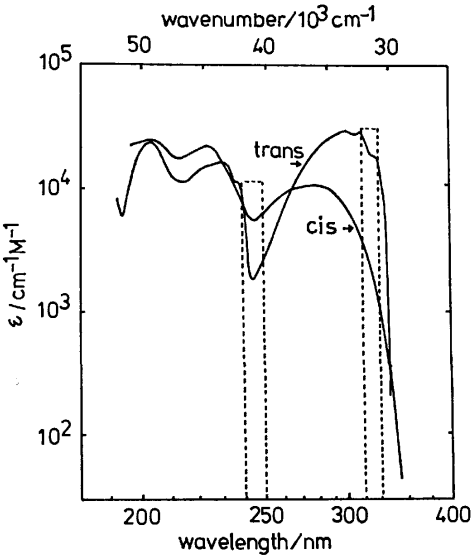

Fig. 2. UV absorption spectra of *cis*- and *trans*-stilbenes reproduced from 22. The transmission change was observed in two broken line regions.

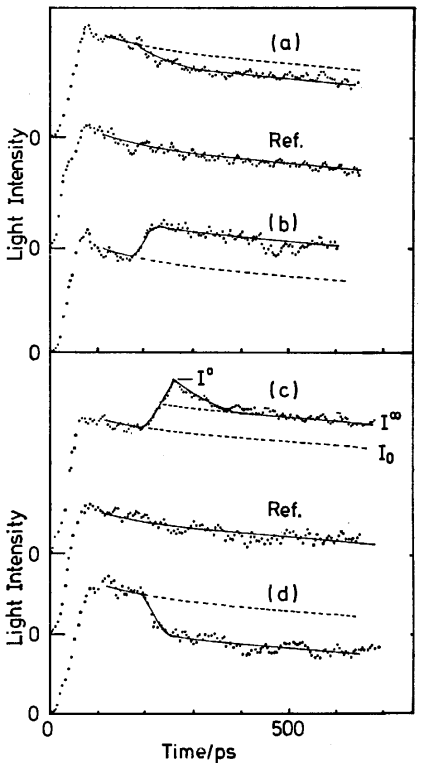

Fig. 3. Time dependent transmission change; (a) and (b) were observed at 240—250 nm upon excitation of solutions of *trans*-stilbene (a) and *cis*-stilbene (b) respectively. (c) and (d) were observed at 310—320 nm when solutions of *trans*-stilbene (c) and *cis*-stilbene (d) were excited respectively. Broken curves represent the reference light profile (ref.) at each wavelength region. The data represent the average of 5—10 shots.

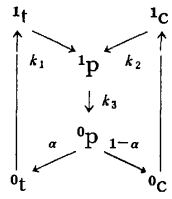
by a picosecond laser flash. At 240—250 nm the molar extinction coefficient of *cis*-stilbene is larger than that of *trans*-stilbene (Fig. 2). Therefore, the transmission will decrease if trans→cis and increase

if cis→trans isomerization occurs. Flashing a solution of *trans*-stilbene one observes a decrease in the transmission which reaches a final value after about 80 ps (Fig. 3(a)). For the cis→trans isomerization (Fig. 3(b)), the transmission increases rapidly within the resolution time of the apparatus by flashing a solution of *cis*-stilbene.

The opposite transmission changes should be observed in the 310—320 nm wavelength region, because in this case the molar extinction coefficient of *trans*-stilbene is larger than that of *cis*-stilbene (Fig. 2). Indeed, when *cis*-stilbene is excited and the cis→trans isomerization takes place, the transmission decreases (Fig. 3(d)), and it increases due to the trans→cis isomerization when *trans*-stilbene is excited (Fig. 3(c)). Since in the 310—320 nm region the molar extinction coefficient is about 10 times greater than that in the 240—250 nm region (*cf.* Fig. 2) ground state depletion becomes important and causes a more complicated time behaviour of the transmission change compared with that observed in the 240—250 nm region.

Discussion

When stilbene is excited with a 266 nm laser flash, the excited singlet state is populated, from which the isomerization takes place with a characteristic rate constant. The most probable mechanism of the cis-trans photoisomerization of stilbene is shown in Scheme 1:



Scheme 1.

where t is the trans and c the cis isomer, 1 and 0 denote the excited singlet state and the ground state, respectively, p is the perpendicular state of stilbene, and the k's are rate constants. The change of transmission with time, $\Delta(I/I_0)$, is represented as follows:

$$\Delta(I/I_0) = 10^{-(\varepsilon_s(-\Delta c)+\varepsilon_t[^0t]+\varepsilon_c[^0c])l} \quad (1)$$

$$[^0t] = \alpha k_3 \frac{k\Delta c}{k_3-k}\left(\frac{e^{-k_3t}}{k_3}-\frac{e^{-kt}}{k}\right)+\alpha\Delta c$$

$$[^0c] = (1-\alpha)k_3\frac{k\Delta c}{k_3-k}\left(\frac{e^{-k_3t}}{k_3}-\frac{e^{-kt}}{k}\right)+(1-\alpha)\Delta c$$

$$k = k_1 \text{ or } k_2$$

where ε_t and ε_c are the molar extinction coefficients of *trans*- and *cis*-stilbene, respectively, l is the optical path length, I_0 is the reference light intensity, ε_s is the extinction coefficient of the starting material (cis or trans isomer), and Δc is the concentration of the excited singlet state of stilbene at $t=0$. From both excited singlet states of *trans*- and *cis*-stilbenes an intermediate state, ^{1}p, is produced in which the two phenyl rings are perpendicular to each other. With a characteristic branching factor α the ^{1}p state decays into

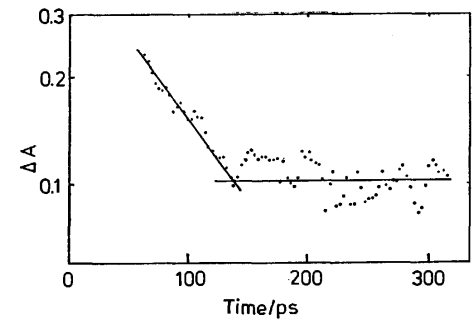


Fig. 4. Logarithmic plot of absorbance change (ΔA) taken from Fig. 3(c).

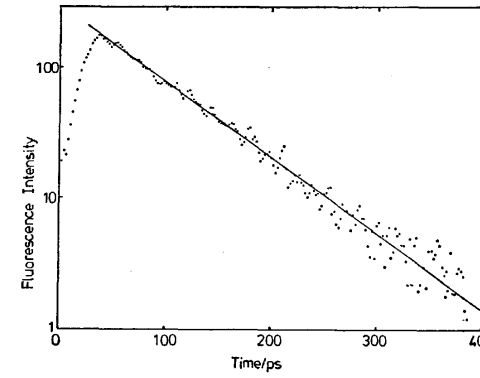

Fig. 5. Logarithmic plot of a fluorescence decay curve of *trans*-stilbene in hexane at 295 K.

^{0}t and ^{0}c. The factor α determines mainly the isomerization quantum yields ϕ_t and ϕ_c.

Trans→cis Isomerization. The lifetime of the lowest excited singlet state of *trans*-stilbene is about 75 ps, and the lifetime of the ^{1}p state is very short (less than a few picoseconds[19]), *i.e.* $k_1 \ll k_3$ and from Eq. 1, we obtain a simpler expression (2) for the absorbance change

$$\Delta A = \log(\Delta(I_0/I)) = [\varepsilon_t(-\Delta c)+\varepsilon_t\Delta c\alpha(1-e^{-k_1t}) + \varepsilon_c\Delta c(1-\alpha)(1-e^{-k_1t})]l. \quad (2)$$

In the wavelength region 240—250 nm, the molar extinction coefficient of *trans*-stilbene is smaller than that of *cis*-stilbene. Therefore, one can neglect the terms containing $\varepsilon_t\Delta cl$ and $\varepsilon_t\Delta c\alpha l$, because these are smaller than $\varepsilon_c\Delta c(1-\alpha)l$. Then we obtain Eq. 3 for the absorbance change caused by the formation of the cis isomer:

$$\Delta A = \varepsilon_c\Delta c(1-\alpha)(1-e^{-k_1t})l. \quad (3)$$

In this equation, the change of absorbance with time depends only on the rate constant k_1 of the trans→cis isomerization. In agreement with this the observed rise time was 85±10 ps (*cf.* Fig. 3(a)).

At 310—320 nm, the molar extinction coefficient of *trans*-stilbene is very large ($\approx 3\times10^4$ cm^{-1} M^{-1}) (*cf.* Fig. 2), thus the ground-state depletion contributes significantly to the observed transmission change. For this reason, the observed rise of the transmission is very fast, followed by a slower decrease to a constant value. A logarithmic plot of the latter transmission change shows that it decays exponentially with a lifetime of 85±10 ps (Fig. 4), which corresponds to

the decay of the excited singlet state of *trans*-stilbene (Fig. 5). The constant part of the depletion did not recover even 5000 ps after the laser excitation. It is due to an increase in concentration of the cis isomer which has a much smaller molar extinction coefficient than *trans*-stilbene.

The absorbance change at $t=0$ caused by the excitation of *trans*-stilbene (*cf.* Eq. 2) is given by

$$\Delta A^0 = \varepsilon_t(-\Delta c)l, \tag{4}$$

provided there is no $S_n \leftarrow S_1$ absorption in this region. After infinite time, the (permanent) decrease caused by the formation of *cis*-stilbene is

$$\Delta A^\infty = \varepsilon_t(-\Delta c\alpha)l. \tag{5}$$

In Eq. 5, we neglected the term containing $\varepsilon_c\Delta c(1-\alpha)l$, because its value is one order of magnitude smaller than the one containing $\varepsilon_t\Delta c\alpha l$ in this wavelength region. Combining Eqs. 4 and 5, we obtain Eq. 6 for the branching ratio $(1-\alpha)/\alpha$:

$$\frac{\Delta A^0-\Delta A^\infty}{\Delta A^\infty} = \frac{1-\alpha}{\alpha}. \tag{6}$$

The fluorescence process was neglected in the derivation, because of the small fluorescence quantum yield ($\phi_f=0.038$[25]). From the analysis of Fig. 4, we obtained for $\Delta A^0=0.23$ and for $\Delta A^\infty=0.10$ and the corrected branching ratio yielded $(1-\alpha)/\alpha\approx 1.3$. This ratio is also determined by a photostationary method as $(1-\alpha)/\alpha=1.4$.[1,26] These two values are in good agreement.

The fluorescence lifetime of *trans*-stilbene at room temperature was 75±5 ps in hexane as shown in Fig. 5. The observed absorbance change is caused by the isomerization of trans→cis reaction with a rise time of 85±10 ps. These observations lead us to the conclusion that the photoisomerization of *trans*-stilbene is determined by the lifetime of the excited singlet state of *trans*-stilbene. Therefore, the lifetime of the perpendicular singlet state (^{1}p), which is considered as the reaction intermediate, must be very short. The above observations are consistent with the other results in the investigations of stilbene: i) In picosecond flash experiments one observes only the $S_n \leftarrow S_1$ absorption of *cis*- or *trans*-stilbene.[15,16] ii) The fluorescence decay of *trans*-stilbene shows strictly first order kinetics between 77 K and 333 K.[10,11] In the theoretical analysis of the potential surface,[27] the perpendicular state has nearly the same energy as the S_1 state of *trans*-stilbene and the energy barrier between the excited singlet state of *trans*-stilbene and the ^{1}p state is about 14 kJ/mol. Therefore, it may be energetically possible that an equilibrium exists between these two states. However, judging from a single exponential decay of the fluorescence of *trans*-stilbene, no equilibrium between S_1 of *trans*-stilbene and the perpendicular state ^{1}p exists. This means that the lifetime of ^{1}p must be very short. iii) The fluorescence lifetime and the fluorescence quantum yield increase exactly with the same factor when the temperature is lowered from 330 K to 77 K. Moreover, in the same temperature range the trans→cis isomerization quantum yield decreases correspondingly.[10] That is to say, the isomerization is an activated process and the fluorescence lifetime becomes shorter by the increasing rate of the chemical reaction. iv) The activation energy determined from the temperature dependence of the isomerization reaction (10.5 kJ/mol[28]) is in good agreement with that calculated from the temperature dependence of the fluorescence quantum yield[4,28] and the fluorescence lifetime.[10]

Cis→trans Isomerization. The risetime of the transmission change is very fast for the cis→trans isomerization at both wavelength regions (Figs. 3(b) and (d)). The lifetime of the excited singlet state of *cis*-stilbene was observed to be 7 ps.[14] If the isomerization rate is limited by the lifetime of the excited singlet state of *cis*-stilbene, the observed risetime of the formation of *trans*-stilbene is limited by the time resolution of our flash apparatus. We already reported the rate constant of the cis→trans reaction determined by the laser-induced fluorescence method with a picosecond double pulse.[19] This isomerization rate constant was greater than 10^{11} s^{-1}. Therefore, it may be concluded that the decay of the excited singlet state of *cis*-stilbene is the rate determining step in the cis→trans isomerization reaction.

Thus the isomerization process of stilbene in solution can be described as follows: By excitation of stilbene into a higher vibrational state of the $S_1(^1B_u)$ state, the excess energy dissipated to the surrounding solvent by the vibrational relaxation. Then rotation about the central double bond with transfer to the $S_2(^1A_g)$ perpendicular state takes place. This process is the rate determining step. In the case of the trans→cis isomerization it has an activation energy of 14 kJ/mol. No energy barrier has ever been observed for the isomerization of *cis*-stilbene. The optical excitation probably leads to the maximum of the potential surface, since the ground state of *cis*-stilbene is already twisted considerably (≈40°) about the central double bond by steric hindrance.[29] After excitation a quick rotation occurs from the strongly mixed state between S_1(cis) and S_2 to the S_2(perpendicular) state across a perhaps very low energy barrier. The perpendicular state interacts strongly with the ground perpendicular $S_0(^1A_g)$ state, so that the internal conversion is very rapid. Finally the vibrational relaxation of the perpendicular $S_0(^1A_g)$ state to the cis or trans configuration takes place (α in Scheme 1).

We are indebted to Dr. K. H. Grellmann (Max-Planck-Institut für Biophysikalische Chemie and IMS) for valuable discussions.

The Extraction of Bivalent Transition Metals from Aqueous Chloride Solutions by Long-chain Alkyl Quaternary Ammonium Carboxylates

Taichi SATO* and Masahiro YAMAMOTO

Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received January 13, 1981)

The extraction of bivalent manganese, cobalt, nickel, and copper from aqueous chloride solutions by long-chain alkyl quaternary ammonium carboxylates, prepared by combination of trioctylmethylammonium chloride ($R_3R'NCl$) and carboxylic (octanoic, decanoic, and lauric) acids ($R''COOH$) in benzene, has been investigated under different conditions. The organic phases are examined by spectrophotometry and infrared spectral measurement. The mechanism of the extraction is discussed on the basis of the results obtained. The extraction efficiency follows the order $Cu > Co \simeq Ni > Mn$, and the extraction process is expressed as $M^{2+}(aq) + 2Cl^-(aq) + 3R_3R'NR''COO(org) \rightleftarrows (R_3R'N)[M(R''COO)_3](org) + 2R_3R'NCl(org)$, in which M=Mn, Co, Ni, and Cu. The extracted species of bivalent manganese, cobalt, nickel, and copper exist as the complex $(R_3R'N)[M(R''COO)_3]$ in an octahedral arrangement.

The extraction of metals from acid solutions by high molecular weight amines has been reported by a number of investigators, but there are few observations on the extraction of metals from aqueous solution in the vicinity of neutral range. Although carboxylic acids are a possible group of reagents to extract the metals in the vicinity of neutral range,[1] their extraction efficiencies depend remarkably on the pH of the aqueous phase. Accordingly the mixed ionic solvent system consisting of long-chain alkyl quaternary ammonium carboxylates is considered of effective for such extraction. This system has been mainly applied to the extraction of magnesium,[2-4] but observations on the extraction of other metals are limited. We have been studying the extraction systems with long-chain alkyl quaternary ammonium compounds,[5] and the present study extends the work to the extraction of bivalent manganese, cobalt, nickel, and copper from aqueous chloride solutions by alkyl quaternary ammonium carboxylates.

Experimental

Reagent. The alkyl quaternary ammonium carboxylates were prepared by mixing calculated amounts (equal volumes of solutions in 0.5 mol dm^{-3} each) of trioctylmethylammonium chloride (General Mills, $R_3R'NCl$, Aliquat-336) and carboxylic acids (octanoic, decanoic, and lauric acids represented as $C_nH_{2n+1}COOH$ with $n=7$, 9, and 11, respectively or $R''COOH$), and treated with an excess amount of sodium hydroxide, and then washed thoroughly with distilled water to remove sodium and chloride ions. The resulting materials ($R_3R'NR''COO \cdot 5H_2O$) which exhibit the properties illustrated in Table 1 are diluted with benzene. The aqueous solution of nickel (II) chloride was prepared by dissolving nickel chloride hydrate ($NiCl_2 \cdot 6H_2O$) in water and its pH value was adjusted by adding perchloric acid. The aqueous solutions of other bivalent metals were similarly prepared by dissolving their salts ($MnCl_2 \cdot 4H_2O$, $CoCl_2 \cdot 6H_2O$, $CuCl_2 \cdot 2H_2O$) in water. The used reagents were of analytical grade.

Extraction and Analytical Procedures. The procedure for obtaining distribution coefficient (the ratio of the equilibrium concentration of metal in the organic phase to that in the aqueous phase), E_a^0, was described previously:[6] equal volumes (15 cm^{-3}) of the organic and aqueous phases were shaken for 10 min, and then the metal in the organic phase was stripped with 1 mol dm^{-3} hydrochloric acid. All experiments were carried out at 20 °C except the examination on temperature-dependence of distribution coefficient. The concentration of nickel was determined by edta titration using Cu–PAN (1-(2-pyridylazo)-2-naphthol) as an indicator.[7] Following indicators were used for the determination of other metals by edta titration: BT (Eriochrome Black T) for manganese;[8] XO (Xylenol Orange) for cobalt;[9] PAN for copper.[10] The concentration of chloride in the organic phase was determined by Volhard's method, and the water content of the organic phase by Karl-Fischer titration. The complexes freed from benzene were prepared by drying the metal saturated organic phase *in vacuo* at 50 °C.

Spectrophotometry and Infrared Spectral Measurement. The absorption spectra were obtained on a Shimadzu Model QV-50 spectrophotometer, using matched 1.00 cm fused silica cells, and the infrared spectra on a JASCO Model IRA-1 grating infrared spectrophotometer for measurement at 4000—650 cm^{-1}, and Model IR-F for measurement at 700—200 cm^{-1}, using a capillary film between thallium halide or polyethylene plates.

Results and Discussion

Extraction Isotherm. When nickel(II) is extracted with trioctylmethylammonium laurate from aqueous nickel chloride solution of 1 g dm^{-3} at varying pH values, the distribution coefficient steeply rises with increasing pH in the range of pH 2—3, and then becomes almost constant at $pH > \approx 3$, as shown in Fig. 1. The lowering in the distribution coefficient at low pH arises from the decrease of the available extractant, caused by the extraction of acid from aqueous solution. This interpretation is supported by the fact that hydrochloric acid is extracted by quaternary compound according to the reaction:

$$H^+(a) + Cl^-(a) + R_3R'NR''COO(o) \rightleftharpoons R_3R'NCl(o) + R''COOH(o), \quad (1)$$

in which (a) and (o) mean aqueous and organic phases, respectively. In order to elucidate further the reaction between a benzene solution of quaternary compound and aqueous hydrochloric acid solution, the variation of $[Cl]_{org}$ with $[HCl]_{initial\ aq}$ was examined by the extraction of aqueous solutions containing hydrochloric acid in the absence of nickel chloride with 0.2 mol dm^{-3} quaternary ammonium laurate. The chloride concentration in the organic phase revealed a constant

Table 1. Properties of trioctylmethylammonium carboxylate

Property		Trioctylmethylammonium carboxylate			Aliquat-336
		Octanoate	Decanoate	Laurate	
Molecular weight[a]		607	660	679	442
Appearance at room temperature		Viscous liquid	Viscous liquid	Viscous liquid	Viscous liquid

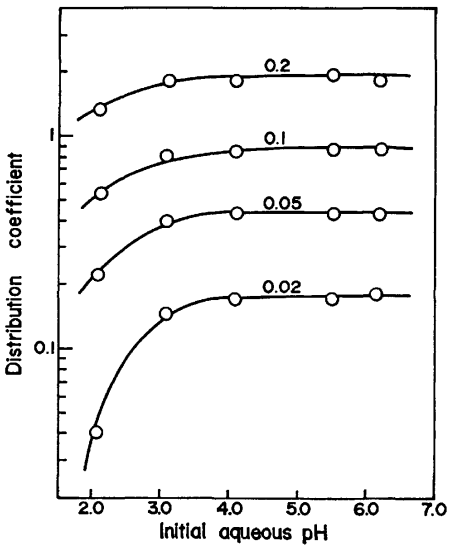

Fig. 1. Extraction of nickel chloride from aqueous solutions containing perchloric acid by trioctylmethylammonium laurate in benzene (numbers on curves are quaternary compound concentrations, mol dm^{-3}).

value of 0.02 mol dm^{-3} at the aqueous hydrochloric acid concentration above 0.02 mol dm^{-3} (Fig. 2). Additionally, the infrared spectra of the organic phase showed the formation of carboxylate supporting the reaction in Eq. 1. In addition, as the similar results are obtained in the extraction of perchloric acid with the quaternary compound, the reaction analogous to Eq. 1 holds in the extraction of perchloric acid, as well. Accordingly the quaternary compound is favorably utilized to extract metals from nearly neutral aqueous solutions at pH 5—8, since its compound is easily decomposed by acid.

In the extraction of aqueous solution containing nickel chloride at a constant pH of 5.5 with 0.01 mol dm^{-3} quaternary compound, the molar ratios of $[R_3R'NR''COO]_{org}$ and $[Cl]_{org}$ to $[Ni]_{org}$ plotted as a function of $[Ni]_{initial\ aq}$ approach the limiting values of 3 and 2, respectively, indicating the composition of the organic phase in the molar ratio of

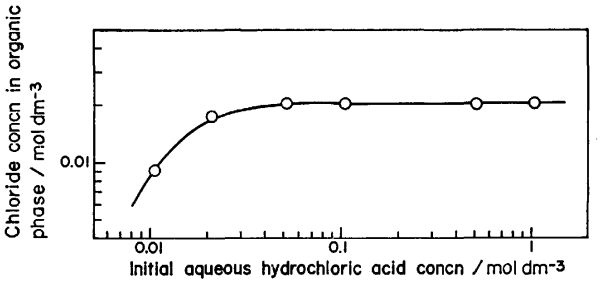

Fig. 2. Variation of the chloride concentration in the organic phase with initial aqueous hydrochloric acid concentration for the extraction of hydrochloric acid by 0.02 mol dm^{-3} trioctylmethylammonium laurate in benzene.

nickel/chlorine/quaternary compound=1:2:3. However, when the initial aqueous nickel concentration increases above 10 g dm^{-3}, the latter molar ratio becomes over 2, because the hydrochloric acid arising from the hydrolysis of nickel chloride in the aqueous phase is extracted into the organic solution. This stoichiometry corresponds to the result obtained by the continuous variation method. In the extraction at a constant $[Cl]_{aq}$ of 0.1 mol dm^{-3}, the variation of $[Ni]_{org}$ as a function of the molar fraction of $[Ni]_{initial\ aq}/([Ni]_{initial\ aq}+[R_3R'NR''COO]_{org})$ at a fixed concentration of 0.1 mol dm^{-3} gives a maximum at the molar ratio of $[Ni]_{initial\ aq}$ to $[R_3R'NR''COO]_{org}$ of 1:3. Accordingly the extraction of nickel chloride from aqueous solutions by trioctylmethylammonium compound is expressed by the equilibrium equation:

$$Ni^{2+}(a) + 2Cl^-(a) + 3R_3R'NR''COO(o) \rightleftharpoons (R_3R'N)[Ni(R''COO)_3](o) + 2R_3R'NCl(o). \quad (2)$$

This is also supported by the dependence of distribution coefficient on the concentrations of extractant and aqueous chloride. Equation 2 leads to the relationship:

$$K = [(R_3R'N)[Ni(R''COO)_3]]_{org}[R_3R'NCl]^2_{org}/[Ni^{2+}]_{aq}[Cl^-]^2_{aq}[R_3R'NR''COO]^3_{org}, \quad (3)$$

in which K is the equilibrium constant. If we assume that $E^0_d=[Ni]_{org}/[Ni]_{aq}$, $[Cl^-]_{aq}=2[Ni]_{aq}$, and $[R_3R'NCl]_{org}=2[Ni]_{org}$, the following relation is derived:

$$K = E_a^0[R_3R'NCl]_{org}^3/[Cl^-]_{aq}^2[R_3R'NR''COO]_{org}^3 \quad (4)$$

$$= E_a^{0\,3}/[R_3R'NR''COO]_{org}^3. \quad (5)$$

Thus Eqs. 4 and 5 should be satisfied by

$$\log\{E_a^0[R_3R'NCl]_{org}^3/[R_3R'NR''COO]_{org}^3\} = \log K + 2\log[Cl^-]_{aq} \quad (6)$$

and

$$\log E_a^0 = (1/3)\log K + \log[R_3R'NR''COO]_{org}. \quad (7)$$

In the extraction of nickel chloride from aqueous solutions containing perchloric acid, the log-log plots of E_a^0 *vs.* the free quaternary compound concentration, $[R_3R'NR''COO]_{org}$, give straight lines with the slopes of 1.0 and 1.1 for the initial aqueous acidities of 0 and 0.01 mol dm^{-3}, respectively, suggesting a first-power dependence of the distribution coefficient on the solvent concentration. For the extraction of nickel chloride from aqueous solutions containing lithium chloride, the distribution coefficient rises with increasing the initial aqueous lithium chloride concentration (Table 2). However, when the extraction of aqueous lithium chloride solutions in the absence of nickel chloride is examined as in the case of acid extraction (Fig. 2), the increase of $[Cl]_{org}$ is slight with increasing the aqueous lithium chloride concentration (Table 2). Therefore, in the extraction of nickel chloride from aqueous solutions containing lithium chloride, the increase of the distribution coefficient with the initial aqueous lithium chloride concentration is attributed to the salting-out effect of lithium chloride. In this extraction, the log-log plots of $E_a^0[R_3R'NCl]^2_{org}/[R_3R'NR''COO]^3_{org}$ *vs.* $[Cl^-]_{aq}$ suggest a second-power dependence of the distribution coefficient on the aqueous chloride concentration.

The result for the extraction of bivalent manganese, cobalt, and copper from aqueous solutions containing their chlorides at 1 g dm^{-3} with trioctylmethylammonium laurate in the absence of perchloric acid are shown in Table 3, compared with that for nickel (II). Although the extraction efficiency is in the order Cu>Co≃Ni>Mn, the log-log plots of E_a^0 *vs.* $[R_3R'NR''COO]_{org}$ for bivalent manganese, cobalt, and copper give straight lines with the slope of approximately unity, suggesting that their equilibria are indicated by the expression similar to Eq. 2 in the extraction of nickel(II). These facts are also supported by the variation in the stoichiometric composition of their organic phases as a function of the initial aqueous metal concentrations, and, in addition, by the continuous variation method for the metal concentrations in their organic phases. Hence it is presumed that the extraction of bivalent transition metals from aqueous chloride solutions by quaternary compound proceeds in the following expression:

$$M^{2+}(a) + 2Cl^-(a) + 3R_3R'NR''COO(o) \rightleftharpoons (R_3R'N)[M(R''COO)_3](o) + 2R_3R'NCl(o), \quad (8)$$

where M=Mn, Co, Ni, and Cu.

Temperature Effect. The extraction of aqueous solution (pH 5.5) containing nickel chloride at 1 g dm^{-3} with 0.02 mol dm^{-3} trioctylmethylammonium laurate at the temperature 10—50 °C gives the result that the distribution coefficient is little influenced by varying the temperature. When the similar experiments were carried out for the extraction of bivalent manganese, cobalt, and copper, the effect of temperature on the distribution coefficients was small (Fig. 3). From the thermodynamic values (the change in free energy, enthalpy, and entropy) for Eq. 8 estimated together with the equilibrium constants at 20 °C (Table 4), the order Cu>Co≃Ni>Mn corresponds to the increase in the free energy change and/or the decrease in the equilibrium constant, although the individual change in enthalpy or entropy does not indicate a reciprocal relation with the extraction efficiency. The equilibrium constants calculated by Eq. 7 agree with those indicated in Table 4. Especially the order of the extraction efficiency depends presumably on the variation in the equilibrium constants with different metal ions.

Infrared and Absorption Spectra. The infrared

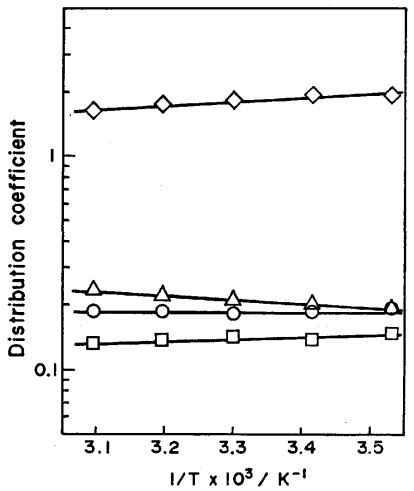

Fig. 3. Temperature-dependence of distribution coefficient for the extraction of bivalent transition metals from aqueous solutions containing their chlorides at 1 g dm^{-3} by 0.02 mol dm^{-3} trioctylmethylammonium laurate in benzene (□, △, ○, and ◇ represent the extractions of manganese, cobalt, nickel, and copper, respectively).

spectra of the organic extracts from the extraction of aqueous nickel chloride solutions at trioctylmethylammonium laurate were compared with that of the quaternary ammonium compound. The frequencies and possible band assignments are given in Table 5. In the infrared spectrum of carboxylic acid, the C–O stretching bands appear at 1710 and 1400—1200 cm^{-1}.[11] However, the quaternary compound shows the similar bands at 1560 and 1380 cm^{-1}, indicating that the extractant exists in the organic phase as a carboxylate,[12] $R_3R'NR''COO \cdot 5H_2O$. As for the infrared spectra of the organic nickel(II) extracts, the C–O stretching modes appear at the same frequencies as those of the quaternary compound. However, the relative intensity relation between the absorption band at 1465 cm^{-1} (the CH_3 degenerate bending and CH_2 scissoring) and the band at 1380 cm^{-1} (the C–O stretching vibration superposed on the CH_3 symmetrical bending absorption) becomes converse in comparison with that for the quaternary compound, in which the former band is slightly stronger than the latter one. For the nickel(II) complex, the latter band is more intense than the former one because the carboxylate group is coordinated to nickel ion as a bidentate ligand.[12,13] At higher loading, the C–O stretching bands appear at 1720, 1425, and 1180 cm^{-1}; this is ascribed to the presence of carboxylic acid formed by the combination of a part of extractant with the hydrochloric acid which results from the hydrolysis of nickel chloride in the aqueous phase at high concentrations. Further, the absorption due to the Ni–Cl vibration is not observed in far-infrared region, indicating that the chloride ion in the organic phase is not coordinated to nickel ion. Similar infrared results are also observed for the extraction of aqueous solutions containing chlorides of manganese, cobalt, and copper (Table 5).

In addition, the absorption spectra of the organic solutions from the extraction of manganese, cobalt, nickel, and copper chlorides with the quaternary compound are illustrated in Fig. 4. The spectrum of the organic nickel(II) species reveals the characteristic feature of a six-coordinated complex ion,[14] showing absorption bands at 25000, 14700, 13300, and 8300 cm^{-1} which are ascribed to three spin-allowed transitions from the ground state $^3A_{2g}(F)$ to the states

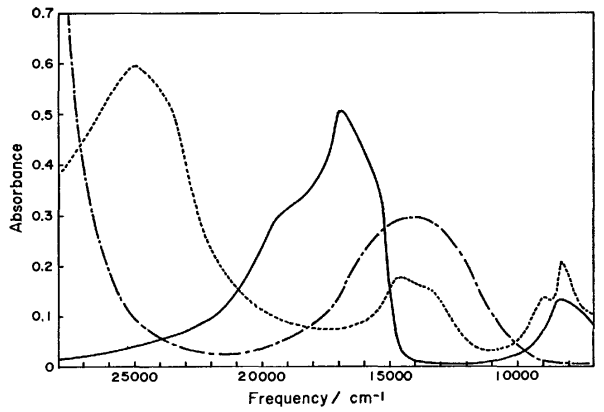

Fig. 4. Absorption spectra of the organic solutions from the extraction of aqueous solution containing chlorides of cobalt, nickel and copper at 100, 100, and 20 g dm^{-3}, respectively, with 0.05 mol dm^{-3} trioctylmethylammonium laurate in benzene (continuous, broken and chain lines represent the organic solutions of cobalt, nickel, and copper, respectively).

$^3T_{1g}(P)$, $^3T_{1g}(F)$, and $^3T_{2g}(F)$, respectively. The ligand field parameters for the complex $(R_3R'N)[Ni(R''COO)_3]$ are calculated by using the matrix elements determined by Tanabe and Sugano:[15] $B=950\ cm^{-1}$ and $10\,D_q=8550\ cm^{-1}$. The difference between the calculated value of $10\,D_q$ and the observed one (8300 cm^{-1}) may be attributed to the assignment of the absorption at 8300 cm^{-1} to the transition to $^3T_{2g}(F)$, although two absorptions appear at 8200 and 8300 cm^{-1}. This is because the state $^2T_{2g}(F)$ should be split into two states ^3E and $^3A_1$, if the symmetry of the complex is lowered from O_h to D_3.[16] Further the factor β is estimated to be 0.88, implying relative low covalent bond character in the nickel(II) complex. The spectrum of the organic cobalt(II) species exhibits the typical absorption of a six-coordinated complex at 19230, 16950, and 8260 cm^{-1}, transitions from $^4T_{1g}(F)$ to $^4T_{1g}(P)$, $^4A_{2g}(F)$, and $^3T_{2g}(F)$, respectively. Accordingly the calculated value of 10 D_q (9500 cm^{-1}) in the cobalt(II) complex is close to the value of $10\,D_q$ (9300 cm^{-1}) in the aqua ion $[Co(H_2O)_6]^{2+}$.[14] For the organic extract of copper(II) complex, the value of $10\,D_q=13990\ cm^{-1}$ resembles that in the hexaaquacopper(II) species. In contrast, the organic manganese(II) extract reveals a strong charge-transfer absorption at 34000—20000 cm^{-1}, covering the weak absorption due to the spin-forbidden transitions.

Therefore, the extracted species of bivalent manganese, cobalt, nickel, and copper exist as the octahedral complex $(R_3R'N)[M(R''COO)_3]$.

Effect of Carboxylic Acid. In the extraction of solution (at pH 5.5) containing nickel chloride at 1 g dm^{-3} by quaternary ammonium compounds with octanoic, decanoic, and lauric acids, the plots of the distribution coefficient *vs.* the free quaternary compound concentration gave a straight line with the slope of nearly unity for respective carboxylates (Fig. 5). From this the effect of the different kinds of carboxylic acid on the extraction efficiency is not remarkable, although their efficiencies increase in the

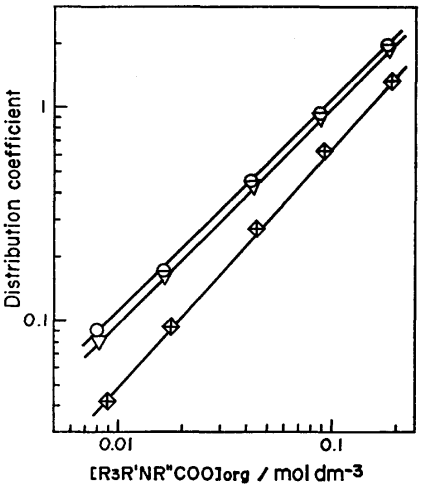

Fig. 5. Log-log plots of distribution coefficient *vs.* free alkylammonium carboxylate concentration for the extraction of aqueous solution containing nickel chloride by quaternary compounds (⊕, ▽, and ○ represent quaternary compounds with octanoic, decanoic, and lauric acids).

order of octanoic, decanoic, and lauric acids. Thus the extraction mechanism of nickel by quaternary compounds is supposed to be almost the same for each carboxylate (Eq. 2). Similar results are obtained for the extraction of bivalent manganese, cobalt, and copper by quaternary compound, as well.

Recovery of Heavy Metals with Calcium Silicon Alloy. II. Recovery of Copper(II) Ions

Shuzo TOKUNAGA

National Chemical Laboratory for Industry, Yatabe, Ibaraki 305

(Received January 20, 1981)

In the 20.0-matom dm^{-3} Cu(II) solution of an initial pH of 4.0, more than 99% of it was removed by addition of calcium silicon alloy in *ca.* 5 min, and the pH decreased to below 2. The X-ray diffraction pattern of the solid reaction product indicated that the Cu(II) removal took place through reduction to metallic Cu. In the 1.0-matom dm^{-3} Cu(II) solution, the pH increased from 4.0 to above 9.0 in 30 min, which consequently maintained high removal for a long time. In the constant pH runs, relation of the equivalents of Ca and Si dissolved against that of Cu(II) ions removed showed that not only the Ca moiety but also the Si moiety participated in the reduction of Cu(II) ions. It is desirable to control pH value at 3.0 or higher, or to separate the solid phase from the liquid phase in the first 30—60 min in order to avoid excess dissolution of calcium silicon alloy and to attain high Cu(II) removal. Copper(I) oxide was formed in a solution of pH above *ca.* 5, which was in contact with the air. In a HNO_3 solution, the removal decreased considerably. Sodium nitrate also caused strong interference with the removal which can be prevented by acidifying the solution with HCl to pH *ca.* 1. When Hg(II) or Cr(VI) ions are present, the Cu(II) removal tends to decrease depending on the amount of calcium silicon alloy added.

In the previous study,[1] calcium silicon alloy proved to be effective for reducing metal ions such as Cd(II), Sn(II), Pb(II), Cu(II), Ag(I), and Hg(II) ions to the elemental state. Fe(III) and Cr(VI) ions were reduced to Fe(II) and Cr(III), respectively. The solubility of calcium silicon alloy is insignificant at pH 3—8, making its use as a reductant possible in aqueous solutions without causing excess dissolution. The reduction of Hg(II) ions with the alloy was studied in detail previously.[2] The purpose of the present paper is to study in detail the recovery of copper(II) ions with calcium silicon alloy and to find the optimum conditions for recovering them in metallic powder which is more advantageous for further utilization than copper(I) compounds.

Experimental

Materials. The same calcium silicon alloy as used previously[1] was used. All other chemicals were of reagent grade. As Cu(II) solution copper(II) chloride was used.

Analysis. Analyses of Cu, Cd, Pb, Fe, Hg, Cr, Ca, and Si were made as reported previously.[1]

X-Ray Powder Diffraction. The X-ray powder diffraction pattern of a solid product was obtained with a Model 2025 Diffractometer (Rigaku Corporation) with Ni-filtered Cu $K\alpha$ radiation. Quantitative determination of copper(I) oxide was carried out by preparing a calibration curve with standard mixtures of copper(I) oxide and copper metal powder, and with the diffraction peaks at 2.47 and 2.08 Å, respectively.

Recovery of Copper(II) Ions without pH Control. A 2.0 dm^3 of 20.0- or 1.0-matom dm^{-3} Cu(II) solution was prepared in a beaker and the pH was adjusted to 4.0 with HCl. The beaker was placed in a 20 °C thermostat, and its opening was covered with a film of polyethylene which had a short rift for addition of calcium silicon alloy and for sampling. Six grams of calcium silicon alloy was added, and the solution was stirred continuously with a magnetic stirrer. Then an aliquot was taken at intervals and filtered through a membrane filter (Millipore, WH) as quickly as possible. Analysis was made on the filtrate for Cu, Ca, and Si, and the pH was determined. Selected samples of the solid product obtained from the 20.0-matom dm^{-3} Cu(II) run were washed with a small amount of water and dried in a vacuum drying oven at *ca.* 60 °C for 2 d, and then analyzed by the X-ray powder diffraction method.

Recovery of Copper (II) Ions at Constant pH. To a 2.0 dm^3 of 30.0-, 20.0-, 10.0-, 5.0-, or 1.0-matom dm^{-3} Cu(II) solution was added 6.0 g of calcium silicon alloy. The pH was maintained constant at 4.0 by automatically adding either NaOH or HCl solution with a Model HSM-10A pH Stat (Toa Electronics Ltd.). Furthermore the pH of a 1.0-matom dm^{-3} Cu(II) solution was controlled at 6.0, 4.0, 3.0, or 2.0 with HCl. The same procedure was followed as above.

Air Oxidation of Metallic Copper. A 20.0-matom dm^{-3} Cu(II) solution of an initial pH of 4.0 was treated in the same way as above without covering the opening of the beaker with a polyethylene film.

Interferences on the Reduction of Copper(II) Ions. Interference from Acids. A 100 cm^3 of 1.0-matom dm^{-3} Cu(II) solution was prepared in a 100-cm^3 Erlenmeyer flask whose acidity was adjusted with HCl, HNO_3, H_2SO_4, or $HClO_4$ to pH *ca.* 3, *ca.* 1, and 1.0 mol dm^{-3} acid. To the solution was added 0.3 g of calcium silicon alloy and the opening of the flask was sealed with "Parafilm." The solution was stirred with a magnetic stirrer in a 20 °C thermostat, and filtered through a membrane filter 30 min after the addition of calcium silicon alloy. Determination was made for Cu, Ca, Si, and pH on the filtrate.

Interference from Sodium Salts. A 100 cm^3 of 1.0-matom dm^{-3} Cu(II) solution was prepared in a 100-cm^3 flask which contained NaCl, $NaNO_3$, Na_2SO_4, or $NaClO_4$ in the concentration of 0.1, 1.0, 10.0, or 100.0 mmol dm^{-3}. The pH was adjusted to *ca.* 3 with HCl. Then the sample solution was treated in the same way as above.

Interference from Metal Ions. A 100 cm^3 of 1.0-matom dm^{-3} Cu(II) solution was prepared, which contained $CdCl_2$, $PbCl_2$, $FeCl_3$, $HgCl_2$, or K_2CrO_4 in the concentration of 0.1, 1.0, 5.0, or 20.0 mmol dm^{-3}. The pH was adjusted to *ca.* 3 with HCl. As the reference, a 100 cm^3 of metal mixture solution was prepared containing 1.0 mmol dm^{-3} of $CuCl_2$ and each 1.0, 5.0, or 10.0 mmol dm^{-3} of $CdCl_2$, $PbCl_2$, $FeCl_3$, and $HgCl_2$. The sample solution was treated in the same way as above.

Results and Discussion

Recovery of Copper(II) Ions without pH Control.

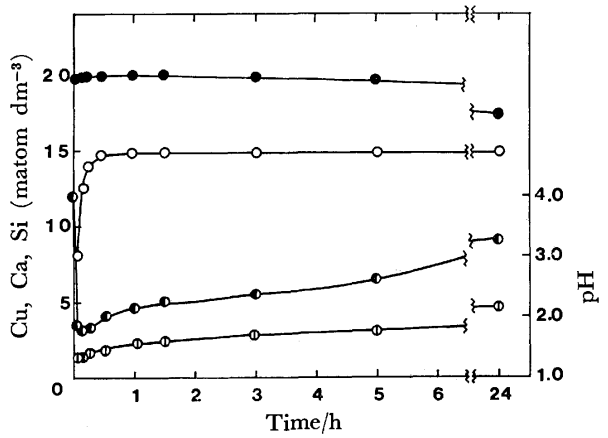

Fig. 1. Recovery of Cu(II) ions at an initial pH of 4.0. 20.0-matom dm^{-3} Cu(II) solution.

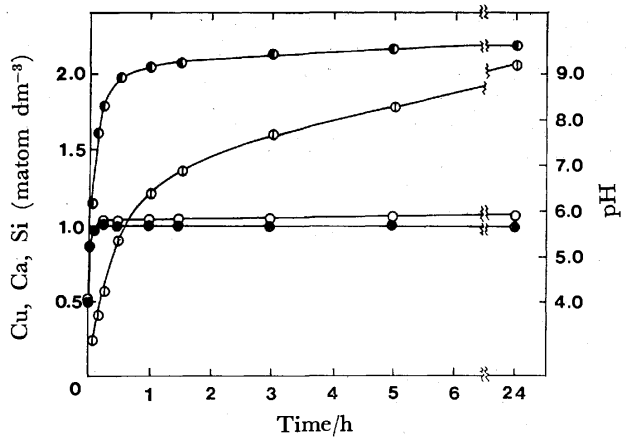

Fig. 2. Recovery of Cu(II) ions at an initial pH of 4.0. 1.0-matom dm^{-3} Cu(II) solution.
●: Cu(II) removed, matom dm^{-3}, ○: Ca dissolved, matom dm^{-3}, ⊕: Si dissolved, matom dm^{-3}, ◐: pH.

The efficiency of calcium silicon alloy for recovering Cu(II) ions was studied by determining removal rates of Cu(II) ions, dissolution rates of the Ca and Si moieties from the alloy, and the variation of pH, and by using the X-ray diffraction patterns of the obtained solid product. The pH of the Cu(II) solutions was initially adjusted to 4.0. The results are given in Figs. 1 and 2.

In the 20.0-matom dm^{-3} Cu(II) solution, the removal rate of Cu(II) ions was so great at the initial stage of the reaction that more than 99% removal was attained in *ca.* 5 min, the remaining Cu(II) concentration being lower than *ca.* 0.03 matom dm^{-3}. With the Cu(II) removal, the pH decreased remarkably from 4.0 to below 2.0, and then increased slowly. Such a great decrease in pH was observed for solutions of more concentrated than *ca.* 5-matom dm^{-3} Cu(II). The X-ray diffraction analysis showed that all of the solid products recovered on the membrane filter contained only metallic Cu as the copper component, indicating that Cu(II) ions were removed through reduction to metallic Cu. The dissolution of Ca and Si increased in accordance with the Cu(II) removal at the initial stage of the reaction, and thereafter the former reaction terminated in *ca.* 30 min, whereas the latter reaction continued to increase slowly with time. Although excess calcium silicon alloy was present in the solution, the Cu(II) concentration in the solution began to increase after *ca.* 3 h, indicating dissolution of deposited Cu again into solution. In this case, the amount of Ca dissolved was *ca.* 15 matom dm^{-3}, amounting to *ca.* 64% of the Ca moiety initially present. The Ca dissolution seems to take place from the surface of the alloy, the Ca moiety remaining just inside the alloy particles, and it was made inactive by being surrounded by silicates and the Si moiety. The reduction of Cu(II) ions by the Si moiety seems to be slower than the dissolution of metallic Cu.

In the 1.0-matom dm^{-3} Cu(II) solution (Fig. 2), the removal rate of Cu(II) ions was also great at the initial stage of the reaction, and the Cu(II) concentration was held below 0.001 matom dm^{-3}. The removal rate in percentage was slightly smaller than that for the 20.0-matom dm^{-3} Cu(II) solution. In contrast to the 20.0-matom dm^{-3} run, the pH increased considerably to above 9.0 in 30 min, which acted to depress dissolution of deposited metallic Cu, and consequently high Cu(II) removal was maintained for as long as 24 h. The amount of Ca dissolved increased with that of Cu(II) removed, their equivalents showing a good agreement. The increase in pH seems to depress excess Ca dissolution. On the other hand, the Si dissolution increased linearly independent of the Cu(II) removal, exceeding the dissolved Ca moles after *ca.* 40 min. It can be concluded that Cu(II) ions are removed by being reduced to the metal mainly with the Ca moiety.

Recovery of Copper(II) Ions at a Constant pH. The pH of the sample solution tends to vary considerably during the reaction, decreasing for Cu(II) concentrations higher than *ca.* 5 matom dm^{-3}, and increasing for lower Cu(II) concentrations. Similar experiments were carried out keeping the pH constant in order to study the reaction in detail without the effects of the pH variation.

Effects of initial Cu(II) concentrations on the reaction were studied with 30.0-, 20.0-, 10.0-, 5.0-, and 1.0-matom dm^{-3} Cu(II) solutions of pH 4.0, where the dissolution of the alloy is insignificant in a metal-free solution(blank).[1] Since the pH decreased at the initial stage of the reaction (*ca.* 5 min) for Cu(II) concentrations higher than 5 matom dm^{-3}, 1—4 mol dm^{-3} NaOH solution was added to control the pH. The results are given in Table 1 (Runs 1 to 5). In all the runs more than 99% removal was attained in as soon as 15 min, showing a very high removal efficiency. The removal rate (%) in the first 5 min was greater for higher initial Cu(II) concentrations. All the X-ray diffraction patterns of the solid products obtained from the 30.0—5.0-matom dm^{-3} runs showed that only metallic Cu was contained as the copper component. Thus, it can be concluded that the Cu(II) removal takes place through reduction to metallic Cu. Though the solid products obtained from the 1.0-matom dm^{-3} Cu(II) run failed to give X-ray diffraction pattern of copper compounds due to their

low contents, metallic Cu seems to be present in them.

The dissolution of Ca and Si took place in accordance with the Cu(II) removal. In the 30.0- and 20.0-matom dm^{-3} solutions, the amount of Ca dissolved reached a plateau several min after the Cu(II) removal had completed, where greater part (*ca.* 50—60%) of the Ca moiety initially contained in the alloy dissolved. The Si dissolution amounted to, at most, less than 5% of the initial Si moiety, increasing linearly even after the completion of Cu(II) removal. For the stoichiometrical discussion, the equivalents of Ca and Si dissolved and their sum are plotted against that of Cu(II) ions removed (Fig. 3), where the values at 5 min after the alloy addition are used, since the Ca and Si dissolutions tend to increase even after the completion of Cu(II) removal. The Ca dissolution showed a relation not linear to the Cu(II) removal, but it is undoubtful that the Ca moiety mainly acted to reduce Cu(II) ions. The Si dissolution showed a direct proportionality to the Cu(II) removal, indicating that not only the Ca moiety but also the Si moiety participated in the reduction, but the extent of its participation was much smaller than that of the former. The ratios of the sum of the equivalents of Ca and Si dissolved to that of Cu(II) ions removed were close to unity at 1.0 and 5.0 matom dm^{-3}, well accounting for the Cu(II) removal. At higher Cu(II) concentrations, however, the ratios became smaller, the reason of which is not clear yet.

Then, the effects of pH on the reaction were studied with 1.0-matom dm^{-3} Cu(II) solutions whose pH was controlled at 6.0, 4.0, 3.0, and 2.0 (Table 1, Runs 5 to 8). The removal rate of Cu(II) ions at the initial stage of the reaction was appreciably greater at lower pH, showing that an acid condition favors the reduction of Cu(II) ions. But the dissolution of deposited metallic Cu became more significant in stronger acid solutions, the Cu(II) removal decreasing down to almost zero after 3 h at pH 2.0. Furthermore the

dissolution of Ca and Si was much greater in such a strong acid condition. In the pH 6.0—3.0 runs, the equivalents of Ca dissolution at the initial stage well accounted for that of Cu(II) removal, increasing linearly with time after the completion of Cu(II) removal. It is, therefore, desirable to control pH value at 3.0 or higher, or to separate the solid phase from the solution in the first 30—60 min in order to avoid excess dissolution of the alloy and to establish complete Cu(II) removal.

Air Oxidation of Metallic Copper. When a solid product containing metallic Cu had been dried, copper was stable to the air for a long time, but when a wet product was placed in the air, formation of copper(I) oxide was recognized by its X-ray diffraction pattern, its intensity becoming significant with time. This indicates that metallic Cu is subject to air oxidation under a wet condition. When the product had been dried under reduced pressure as quickly as possible, the oxidation did not take place. Thus the air oxidation can be avoided in this way. Then the conditions were examined to cause the air oxidation of metallic Cu by making a similar experiment in the air, *i.e.* without a polyethylene film in the opening of a beaker. The result is shown in Fig. 4, and compared with that of the above-mentioned run with the solution isolated from the air (Fig. 1). The Ca dissolution showed a similar tendency with that of the above run. On the other hand, the Si dissolution was slightly greater. More than 99% Cu(II) removal was maintained for *ca.* 3 h. Thereafter the Cu(II) concentration in the solution began to increase with an increase in pH. At that time the solid product contained only metallic Cu as the copper component, indicating the reaction $Cu+1/2\ O_2+H_2O=Cu^{2+}+2\ OH^-$. After *ca.* 9 h the pH rose above *ca.* 5, and the increase in the Cu(II) concentration ceased. Then formation of copper(I) oxide was recognized in the solid product, and its content increased with time, indicating progress of its air oxidation. After 24 h metallic Cu in the solid phase changed entirely into copper(I) oxide. In another run in the air at pH 4.0, no appreciable amount of copper(I) oxide was found, and high Cu(II) removal was held for a long time. Therefore, it is found that deposited metallic Cu is stable for *ca.* 3 h in the air, and that its air oxidation is made insignificant by separating the solid product from the solution in a short time even if the reaction is carried out in the air. Thus the air oxidation yields Cu(II) ions when the pH is below *ca.* 5, decreasing the Cu(II) removal, and yields copper(I) oxide at pH higher than 5.

Interferences on the Reduction of Copper(II) Ions. For the actual calcium silicon alloy process, effects of commonly used acids and salts on the reduction of Cu(II) ions were studied, and those of metal ions as well, which are reduced to the lower oxidation state with the alloy. The results obtained in 30 min after addition of the alloy were discussed, when the removal was complete and the dissolution of deposited

a) A mixture of $CdCl_2$, $PbCl_2$, $FeCl_3$, and $HgCl_2$ solutions was added to a 1.0-matom dm^{-3} Cu(II) solution so that each metal concentration was kept at 1.0, 5.0, or 10.0 matom dm^{-3}. b) Cd 60.0%, Pb 97.5%, Fe 0.8%, and Hg 99.9%. c) Cd 1.1%, Pb 64.3%, Fe 1.4%, and Hg 99.3%. d) Cd 0.3%, Pb 16.2%, Fe 0.6%, and Hg 98.4%.

metallic Cu was insignificant. Since the pH tends to increase during the reaction in the 1.0-matom dm^{-3} solution and hydrolysis of Cu(II) ions occurs from pH *ca.* 5.5, the initial pH was adjusted to 3 excluding the runs for examining acid effects. The sample solutions whose final pH exceeded 6 were acidified to pH *ca.* 3 with HCl and the pH was maintained for a minute before filtration and copper determination. The results are given in Tables 2, 3, and 4.

Of the acids examined here, HNO_3 strongly decreased Cu(II) removal even in small amount. This remarkable interference seems to be related to very low solubility of calcium silicon alloy in HNO_3 solution, possibly due to passivation by a film of silica formed on the solid surface. In the recovery of Hg(II) ions this effect was not so strong,[2] and the reduction rate of Hg(II) ions is greater than that of the film formation. In the HCl, H_2SO_4, and $HClO_4$ solutions, satisfactorily high Cu(II) removal was attained regardless of the acid concentration, because the amount of the alloy added was much greater, in equivalent, than that of Cu(II) ions present in solution. In solutions of high Cu(II) concentrations, the removal percentage will decrease with increasing acid concentration because of significant Ca dissolution. In comparison with the HCl solution, Ca dissolution was smaller in the H_2SO_4 or $HClO_4$ solution, and thus the alloy can be used more effectively for the recovery of Cu(II) ions.

Sodium salts of the conjugate bases of the above-mentioned acids were added to 1.0-matom dm^{-3} Cu(II) solutions with varying their concentration from 0.1 to 100 times the Cu(II) concentration. Effects of sodium salts can be considered to be as of the conjugate base ions. Similarly to the above runs in HNO_3, the interference from nitrate ions was significant, becoming appreciable from *ca.* 1 mmol dm^{-3}. Consequently the dissolution of Ca and Si decreased with increasing the salt concentration. When the pH of the 10.0-mmol dm^{-3} $NaNO_3$ solution decreased to 1.0 with HCl, the interference from nitrate ions can be prevented and high Cu(II) removal was attained. The Cu(II) removal, however, did not increase appreciably in the 100.0-mmol dm^{-3} $NaNO_3$ solution even when the pH decreased. The interference from sulfate ions became appreciable from 10.0 mmol dm^{-3}, and also can be prevented by decreasing pH to 1.0. NaCl and $NaClO_4$ did not decrease the Cu(II) removal at any concentration, but the dissolution of Ca and Si increased at high salt concentrations accompanying with an increase in pH.

Effects of metal ions on the reduction of Cu(II) ions are related to their reducibility, and the relative amount of the alloy added to that of the metal ions to be reduced. Since Cd(II) ions are least reducible with the alloy, it gave no appreciable effect on the Cu(II) removal, and thus the Cd(II) removal was low. Pb(II) ions, with lower standard electrode potential than Cu(II) ions, did not affect the Cu(II) removal either, and it was removed with high percentages. High Cu(II) removal was attained in the Fe(III) ion solutions. As shown previously,[1] Fe(III) ions are reduced to Fe(II) ions with the alloy, and the Fe(III) removal seems to be due to hydrolysis. Cu(II) removal decreased with increasing Hg(II) concentration, and Hg(II) ions, one of the most reducible ions, were removed with higher percentages than Cu(II) ions. Dichromate ions, having the highest standard electrode potential among the metal ions examined here, strongly suppressed the Cu(II) removal, whereas the dichromate removal was not so high, since they are efficiently reduced only in strong acid solutions and removed as Cr_2O_3(hydrated) and $CaCrO_4$.[1] Finally mixtures of Cd(II), Pb(II), Fe(III), and Hg(II) ions with various concentrations were added to a 1.0-matom dm^{-3} Cu(II) solution. In the 1.0-matom dm^{-3} metal solution, the highest removal was attained for each metal except for Fe(III). In the 5.0- and 10.0- matom dm^{-3} metal solutions, removal of the respective metal ions was in the order of increasing standard electrode potential. Thus when the concentration of a metal ion to be reduced increases in comparison to that of added calcium silicon alloy, its removal is strongly dependent on its standard electrode potentials, *i.e.* its reducibility.

(Received January 31, 1981)

The valence state analysis to determine selenide in mixtures of selenide, elemental selenium, selenite, and selenate compounds was devised by the selective volatilization of selenium as its hydride. As the optimum conditions of the reaction, 6 M (this unit is defined to 1 M=1 mol dm^{-3} as below.) hydrochloric acid solution was dropped into the mixture and the hydrogen selenide gas generated was absorbed in a solution of sodium hydroxide and hydrogen peroxide. The optimal reaction temperature was found to be 170 °C for 40 min using nitrogen as the carrier gas. Utilizing this method, the fluctuation of the oxidation state of selenium was observed during the storage of zinc selenide samples.

The oxidation state of selenium in the lithosphere, hydrosphere, and atmosphere, selenium is mainly classified into the following species; sexivalent, quadrivalent, elemental, minus bivalent, and organically complexed species such as selenate, selenite or selenium dioxide, red amorphous or gray metallic selenium,[1] selenide, and selenomethyonine,[2] respectively.

Although numerous methods for the total analysis of selenium in rock, soil, and sediment samples have been devised. The analysis of the oxidation state of selenium in powdered solid samples has rarely been reported. A method to separate the high valent species of selenium (sexivalent and quadrivalent) from the low valent species (elemental and minus bivalent) in sediment samples was deviced by Terada *et al.*[3] Utilizing a chemical leaching method,[4] the high and low valent species of selenium in marine core sediments with its core depth were analysed by Tamari.[5]

In this work, the reaction conditions in order to determine selenium after separating selenide constituents as the gas of hydrogen selenide from the powdered samples containing elemental selenium, selenite, and selenate were investigated in detail. This study establishes the optimum conditions for the generation of the hydride and its subsequent trapping in absorbents.

Experimental

Reagents and Apparatus. Standard samples of selenide were prepared as follows. Selenide standard was prepared by mixing 0.02 g of zinc selenide powder with 1 g of silica powder in an agate mill for 10 min, and the mixture homogenized by quartering four times.[6] After this preparation, total selenium content of the selenide standard was determined to be 10.04±0.95 μg/mg.[7] Approximately 10 mg of this standard was used for experiments.

Silica powder was used to dilute the selenide standard. Fine quarts powder to pass through the sieve of 100 mesh size was taken in a beaker, and boiled with the solution of 6 M hydrochloric acid. The powder was filtered with a membrane filter (pore size: 3 μ) and rinsed with water, then dried at 110 °C.

The apparatus designed for the generation of hydrogen selenide and the collection of its hydride, is shown in Fig. 1. As can be seen in this figure, a funnel and two traps were connected to a reactor.

All chemicals used were analytical reagent grade; the other reagents and apparatus have been reported by Tamari *et al.*[8]

Recommended Procedure. About 10 mg of a sample was placed in the reactor (see Fig. 1), and 20 cm^3 of 6 M hydrochloric acid solution were added to the funnel. The mixed solution of 2.5 cm^3 of 0.1 M sodium hydroxide and 7.5 cm^3 of 30% hydrogen peroxide were placed in the trap vessels. The reactor connected to the funnel and the traps was set in the hole of an aluminium-block adjusted to 170 °C with a hot-plate. The hydrochloric acid solution was dropped into the reactor using a carrier gas of nitrogen. The hydrogen selenide generated was carried with the gas into the absorbent solution. This reaction was subjected to heating for 40 min at 170 °C. After the reaction, the reactor and the traps were disconnected, and each of the traps to which 1 cm^3 of 30% hydrogen peroxide was added was heated on a hot-plate for a few minutes in order to oxidize the selenide. Then, 1 cm^3 of concd nitric acid was added to each vessel from its tube, and the solution was boiled for a few minutes to oxidize to selenate. After cooling, the solution in each trap was placed in a 100 cm^3 or 250 cm^3 measuring flask, and diluted to the mark with water. The solution in the reactor was filtered with a membrane filter (pore size: 3 μ) and the filtrate was diluted with water to 100 cm^3 or 250 cm^3. To the aliquots of the solution, 0.5 cm^3 of 70% perchloric acid solution was added and evaporated until the perchloric acid vapor appeared. Selenium in the sample solution was completely reduced to selenite by boiling for 3 min after the addition of 2 cm^3 of 6 M hydrochloric acid solution. The selenite solution prepared was determined by fluorometry with 2,3-diaminonaphthalene.[8]

		Reactor	Trap (A)	Trap (B)
43—49	73.3	16	84	0
99—103	70.6	27	72	1
170	43.5	7	91	2

Results and Discussion

All experiments were carried out in order to consider the optimum conditions of the reactions based on the generation of hydrogen selenide and its absorption into solutions.

Effect of Carrier Gas. Using air as a carrier gas instead of nitrogen, a considerable amount of selenium remained in the reactor, and red condensates were observed on the wall of the tube between the reactor and the trap (A). The condensate could be red amorphous selenium generated by oxidation of the hydride to elemental selenium. Accordingly the use of nitrogen gas was recommended as the carrier.

Effect of the Concentration of Hydrochloric Acid. Solutions of 2, 6, 9, and 12 M hydrochloric acid were examined. Each 20 cm^3 of the solution was added to the reactor from the funnel under the conditions of the reaction at 170 °C for 40 min and the addition of the solution mixed 19 cm^3 of 0.1 M sodium hydroxide with 1 cm^3 of 30% hydrogen peroxide to each trap. As shown in Table 1, no selenium was found in the trap (B), and the best concentration of the acid solution was considered to be 6 M hydrochloric acid from the results of the data of the recovery of hydrogen selenide in the trap (A).

Effect of Reaction Temperature. The reaction temperature for the generation of hydrogen selenide was examined under the conditions of addition of 6 M hydrochloric acid solution and the same reaction system as described above. Table 2 gives the results of the examination. Since the highest percentage of selenium was found in the trap (A) when the temperature attained 170 °C, this temperature was applied to the experiments below.

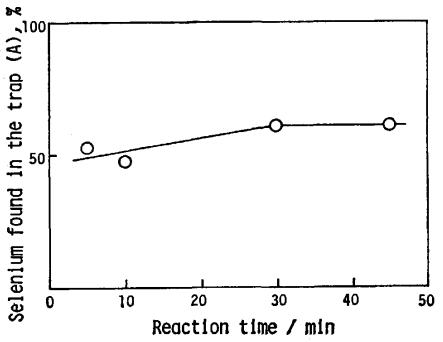

Fig. 2. Effect of reaction time on the generation of hydrogen selenide.

In the case of selenide samples containing selenite and selenate, selenate was reduced to selenite by boiling with the solution of 6 M hydrochloric acid, and the subsequent selenite may be volatilized as selenium tetrachloride above *ca.* 200 °C.[1] In this work therefore it is important to keep the reaction temperature at 170 °C to avoid the volatilization of selenium.

Effect of the Chemical Composition of the Absorbent. Sodium hydroxide solution is generally considered to be an effective absorbent for trapping of hydrogen selenide as well as hydrogen sulfide. However hydrogen selenide can be changed to a more stable chemical form as a red colored precipitate by oxidizing the hydride to avoid the revolatilization of the hydride in the trap. Hence the solutions of hydrogen peroxide and nitric acid were tested for efficiency as oxidant and absorbant of the hydride.

In the chemical system of sodium hydroxide solution containing hydrogen peroxide, the recovery percentage of selenium in the traps was fairly good, whereas in the system of nitric acid solution containing hydrogen peroxide it was relatively low because of the revolatilization of hydrogen selenide due to the acid solution. Futhermore in the latter system, selenium was absorbed into the solution in both the trap (A) and the trap (B). Therefore the fomer system was used for the experiment of hydrogen selenide as an absorbent. Table 3 lists the results of the chem-

Table 3. Effect of the chemical composition of absorbent

Chemical composion of absorbent		Found selenium (μg)	Ratio of selenium/%		
0.1 M NaOH (cm^3)	30% H_2O_2 (cm^3)		Reactor	Trap (A)	Trap (B)
19	1	91.2	1	99	0
15	5	87.2	12	88	0
10	10	108	8	92	0
5	15	107	3	97	0
0	20	87.3	7	93	0

Table 4. Recovery of hydrogen selenide in the recommended procedure

Taken (mg)	Added (μg)		
11.4	114	90.3	79.2
10.0	100	76.7	76.7
10.9	109	99.4	91.2
12.0	120	104	86.7
10.4	104	81.2	78.1
			Average±standard deviation 82.4±6.3
Elemental selenium added (μg) 1000		0	100
Selenium(IV) added (μg) 100		3	97

ical composition of the absorbent in the system for trapping the hydride. As can be seen in Table 3, no selenium was found in the trap (B) in each absorbent solution, and the solution obtained by mixing 19 cm^3 of 0.1 M sodium hydroxide with 1 cm^3 of 30% hydrogen peroxide was selected as the best absorbent. This was based not only on the results representing the highest value in the trap (A) but also consideration of the post-preparation for the fluorometric determination of selenium with 2,3-diaminonaphthalene.[8]

Effect of Reaction Time. The effect of the reaction time on the generation of hydrogen selenide was investigated under the optimum conditions described above. As is shown in Fig. 2, the constant percentage of selenium in the trap (A) was obtained by reacting for more than 30 min. Hence the reaction for 40 min was undertaken for all the experiments.

Recovery of Hydrogen Selenide in the Recommended Procedure. In the optimum conditions of the reaction for the generation of hydrogen selenide and its trapping in the absorbent, *i.e.*, in the recommended procedure, the experiments for the recovery of selenium were carried out. It can be seen from Table 4 that the selenium recovered was 82.4±6.3%. From the consideration of the homogeneity of selenium in the selenide standard, 10.01±0.95 μg/mg, it was indicated that the coefficient variation of the former value, 7.9%, was included in the latter case, 9.5%. This method was applied to the samples involving the other oxidation state of selenium; 100 μg of selenite and 1 mg of elemental selenium were used for the experiment. As is seen from the results, neither selenite nor elemental selenium was volatilized, and little selenium was found in the trap (A).

Since the proposed method is useful for the determination of selenide, the method will be applied to the samples of the selenium compounds as the valence state analysis of selenide. The authors will report later on the application of this method to the samples.

Kinetics of Thermal Pyridine Dissociation of Ni(*N*-arylsalicylideneaminato)$_2$-(pyridine)$_2$ in Solid Phase

Kikuo MIYOKAWA,* Hidenori HIRASHIMA, and Isao MASUDA

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814-01

(Received February 16, 1981)

The kinetics of the thermal pyridine dissociation reactions of Ni[*N*-(R-C_6H_4)salam]$_2$py$_2$, where R=H(**1**), *p*-F(**2**), *p*-CH_3O(**3**), *p*-CH_3(**4**), *p*-Cl(**5**), and *p*-Br(**6**), in solid phase, were analyzed by the isothermal weight-loss measurements. On pyrolysis, these pyridine adducts with an octahedral coordination geometry of Ni(II) liberated pyridine to leave products with the formula Ni[*N*-(R-C_6H_4)salam]$_2$. The product obtained from **2** was the diamagnetic monomer, those from **4**—**6** were paramagnetic polymers with μ_{eff}=(3.11—3.30) μ_B, and that from **3** was paramagnetic with an intermediary moment of μ_{eff}=1.45 μ_B. Reaction mechanisms were different depending on the nature of R: **2** followed the contracting disk equation with E =163 kJ/mol; **3**—**6** followed the contracting disk equation in the initial period of the reaction (the E_a values were 97 for **3**, 134 for **4**, 173 for **5**, and 172 kJ/mol for **6**) and then all except **3** followed Jandar's equation, in the subsequent period. These E_a values were considered to reflect the bond stability between the central Ni(II) ion and the axial pyridine ligands; these values increased with an increase in the electron-withdrawing property of R. The pyridine dissociation reaction may give rise to the complexes of the monomeric square-planar or to those of the associated, polymeric octahedral structure. Which result occurs does not depend only on the tendency of the central Ni(II) ion to accept, at the apical positions, the coordinate bond from the adjacent molecules.

Extensive investigations on bis(*N*-substituted salicylideneaminato)nickel(II) complexes have revealed that, in non-donor solvents, these complexes exist as a mixture of square-planar, tetrahedral, dimeric square-bipyramidal, and polymeric octahedral species.[1] The di- or polymeric species is thought to arise from the association of the planar species through the coordination bonding of the phenolato oxygen atoms in the complex molecule with the central Ni(II) ion of the adjacent molecules at the apical positions.[2] Thus, the association seems to be related to the Lewis base accepting ability of the central Ni(II) ion. However, the diversity of the solute species makes it difficult to evaluate the Lewis acidity of Ni(II) ions in these complexes, in solution.[3]

In order to estimate the Lewis acidity of the Ni(II) ion, the series of the complexes bis[*N*-(*p*-substituted aryl)salicylideneaminato]bis(pyridine)Ni(II), abbreviated as Ni[*N*-(R-C_6H_4)salam]$_2$py$_2$, have been subjected to a kinetic study of the thermal pyridine liberation reaction in solid phase.

Experimental

Materials. The parent complexes Ni[*N*-(R-C_6H_4)-salam]$_2$ were prepared by the published procedure.[4,5] Their bis(pyridine) adducts were isolated as previously described.[6] The adducts were identified by the nickel and pyridine analyses.

Measurements. TG and DSC curves were recorded on a Rigaku Denki Thermal Analyzer Model 8002 and isothermal weight-loss curves on a Sinku Riko micro-DTA apparatus Model TGD-3000-RH. These measurements were carried out under a constant flow of nitrogen, 100 ml/min. No influence from the variation of the nitrogen flow rate (in the range from 50 to 150 ml/min) was observed. Other physicochemical data were obtained as previously reported.[6]

Results and Discussion

The effective magnetic moments of the bis(pyridine) adducts and the products obtained after the adducts were heated up to 200 °C to eliminate pyridine, are compared with those of the parent Ni[*N*-(R-C_6H_4)-salam]$_2$ complexes in Table 1. The reflectance spectral data are also shown in Table 1. Parent complex **2**, as well as **1**, is diamagnetic, corresponding to the singlet state of Ni(II), and the spectrum exhibits an absorption maximum at 16.1×10^3 cm^{-1}; this is ascribed to the square-planar crystal field band, $^1A_{1g}\rightarrow{}^1A_{2g}$ transition of Ni(II).[7] On the other hand, the new parent complexes **3** and **6** are paramagnetic and these paramagnetisms correspond to the triplet state of Ni(II). Moreover, their spectra comprise two peaks with the maxima around 10.0 and 16.5×10^3

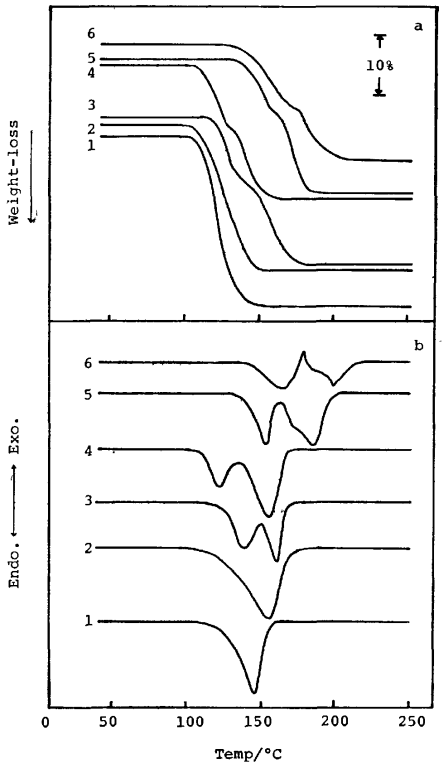

Fig. 1. TG(a) and DSC(b) curves of pyridine adducts; heating rate 10 °C/min. The numbers correspond to those given in Table 1.

Table 1. Magnetic, electronic spectral, and thermal data on the parent complexes Ni[*N*-(R-C_6H_4)salam]$_2$ and their bis(pyridine) adducts Ni[*N*-(R-C_6H_4)salam]$_2$py$_2$

cm^{-1}; these are respectively ascribed to the $^3A_{2g} \rightarrow {}^3T_{2g}$ and the $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ transitions of Ni(II) in the octahedral crystal field.[7] The magnetic and the spectral characteristics indicate the coordination structure of the parent complexes to be square planar for **1** and **2** and octahedral for **3**—**6**.

In Fig. 1, the TG and DSC curves of the pyridine adducts are reproduced. The TG curves show that all the adducts investigated lose 2 mol of pyridine per mole of the adduct in the range (100—200) °C. Adduct **2**, like **1**,[6] shows one endothermic DSC peak and a weight-loss of 2 mol pyridine per mole of the adduct on one stage in the TG curve. But adducts **3**—**6** show two endothermic DSC peaks and, in the corresponding TG curves, they show the loss of 2 mol pyridine per mole of the adduct through two stages. Up to the break point temperature in the TG curve, the weight-loss amounts to *ca.* 40—60% of the total pyridine loss. This fact implies that in the cases of adducts **3**—**6** pyridine is liberated in two steps and hence that the formation of mono(pyridine) adduct may be expected. However, pyrolysis of these adducts at 120 °C, apparently lower than their first DSC peak temperatures, only resulted in leaving a product with the formula Ni[*N*-(R-C_6H_4)salam]$_2$. Dakternieks *et al.* have reported that the mono(pyridine) adducts of Ni(*N*-*n*-Bu-salam)$_2$ and Ni(*N*-*n*-Bu-5-Cl-salam)$_2$ are formed along with their bis(pyridine) adducts in the toluene solution containing pyridine, though the TG curves of these bis(pyridine) adducts show a smooth continuous weight-loss, indicating no evidence for the formation of a five-coordinated intermediate.[3]

As seen in Table 1, the products obtained by eliminating pyridine show either dia- or paramagnetism, in accord with the respective parent complexes, excluding product **3** which shows an intermediary magnetic moment. Product **3** is thought to be composed of both paramagnetic and diamagnetic species. It is noticed that for the diamagnetic monomeric product **1**[6] and **2**, their X-ray powder diffraction patterns were coincident with those of the respective parent complexes, while for the paramagnetic polymeric products **4**—**6**, the X-ray patterns did not agree with those of the respective parent complexes. Clark and

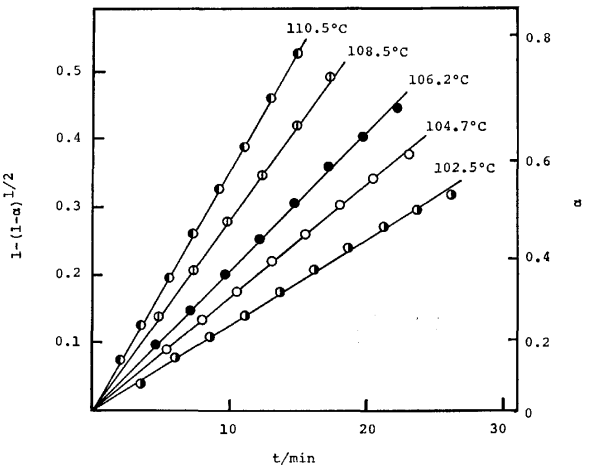

Fig. 2. Contracting disk rate plots for the pyridine liberation reaction of Ni[*N*-(*p*-F-C_6H_4)salam]$_2$py$_2$ (**2**).

O'Brien noted that for polymeric Ni(*N*-CH_3-5-Cl-salam)$_2$ the X-ray pattern of the sample obtained from the solution is not completely identical to that obtained by heating the monomeric modification in solid phase.[8]

The pyridine liberation process of adduct **1** has already been reported to follow the first order equation (Eq. 1) through α=0—0.70[6]

$$-\ln(1-\alpha) = kt, \quad (1)$$

where α, k, and t are the molar fraction of the adduct which liberated pyridine, the rate constant, and the reaction time, respectively. Adduct **2** differs from **1**; its pyridine liberation process is found to fit the contracting disk equation (Eq. 2) through α=0—0.65, as shown in Fig. 2:

$$1-(1-\alpha)^{1/2} = kt. \quad (2)$$

This fact may be interpreted by assuming that the reaction rate is determined by the reaction occurring at the phase boundary.[9]

The pyridine liberation process for adducts **3**—**6** were somewhat complicated in comparison with those for the above two cases. As is exemplified in Fig. 3 with the rate plots for **4**, the reaction mechanism appears to be altered with the progression of the pyridine dissociation reaction. The rate plots indicate

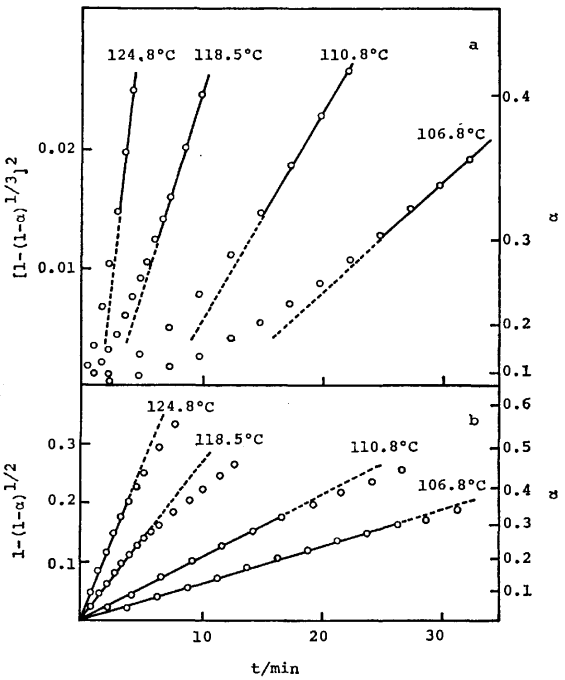

Fig. 3. Jandar's rate plots(a) and contracting disk rate plots(b) for pyridine liberation reaction of Ni[*N*-(*p*-CH_3-C_6H_4)salam]$_2$py$_2$ (**4**).

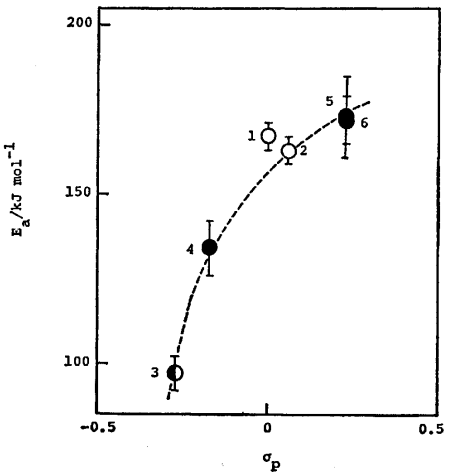

Fig. 4. Plots of activation energy, E_a *vs.* Hammett's σ_p value.
The numbers correspond to those in Tables 1 and 2. ○: Monomeric product, ●: polymeric product, ◐: (monomeric+polymeric) product.

that, in the initial period during α=0—0.35, the reaction progresses according to the contracting disk equation, as was observed for adduct **2**; however, in the subsequent period of α=0.35—0.75, it follows Jandar's equation (Eq. 3):[10]

$$[1-(1-\alpha)^{1/3}]^2 = kt. \quad (3)$$

Thus, these two processes of pyridine liberation would cause the apparent doubling observed in the TG and DSC curves of adducts **3**—**6**, as described above. The fact that the reaction follows Jandar's equation could be interpreted as meaning that the reaction is strongly influenced by the diffusion process of the liberated pyridine. For adducts **4**—**6**, which form the octahedral polymeric products upon pyrolysis, we think that as the pyridine dissociation proceeds, it becomes difficult for the free pyridine molecule to diffuse through the close product layer consisting of the polymeric species. An attempt to describe the isotherms for adduct **3** in the above subsequent period was unsuccessful.

The kinetic data are summarized in Table 2. With respect to the reactions described by Eq. 2, the values of the activation energy, E_a, are plotted against Hammett's substitution constant σ_p of R[11] in Fig. 4; the plots indicate that the E_a value increases with an increase in the electron-withdrawing property of R. As to the reaction described by Eq. 1, the E_a value does not deviate from this relation. No relation like the above was found for the reactions following Eq. 3. The electron-withdrawal through R is expected to stabilize the bonding of Ni(II) toward the axial pyridine ligands, as it may increase the Lewis acidity of the Ni(II) ion. Hence, the E_a values for the reactions following Eqs. 1 and 2 are considered to reflect mostly the bond stability between Ni(II) ion and the axial pyridine. From the solution equilibrium data on the pyridine adduct formation of Cu(*N*-R-salam)$_2$, which includes the Schiff bases with substituted aryl groups, Ewert *et al.*[12] have concluded that the electron-withdrawal by the substituent R on

the aryl ring is transmitted *via* N atom, thus decreasing the electron-density on Cu(II) ion.

Furthermore, Fig. 4 indicates that whether pyridine dissociation reaction gives rise to a square-planar monomer or to an associated octahedral polymer is not determined only by the E_a values; that is, the association of monomeric square-planar Ni(II) complexes forming the octahedral polymeric complexes is not affected solely by the Lewis acidity of the central Ni(II) ion. Though the basicity of the phenolato O atom should be taken into account in a discussion of the present association, the results of Ewert *et al.*[12] suggest that the substitution on aryl ring will exert its electronic effect on Ni(II) ion predominatly *via* N atom. Another factor would be a steric effect caused by substitution. Tsuchiya *et al.* have reported that "deaquation" of [Ni(diamine)$(H_2O)_2$]X_2 (diamine=*N*,*N*′-diethyl-, *N*,*N*′-dimethyl-, and *N*,*N*-diethylethylenediamine; X=anion) gives either octahedral [Ni(diamine)$_2X_2$] or square-planar [Ni(diamine)$_2$]X_2 depending on the steric effects arising from the *N*-substituents.[13] As far as the present complexes are concerned, the rather more bulky R seems to favor the associated form.

Preparation and Characterization of Dichlorobis(*N*-alkylsalicylideneaminato)manganese(IV) Complexes

Takayuki MATSUSHITA,* Yoshihisa HIRATA, and Toshiyuki SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received February 23, 1981)

The chlorobis(*N*-alkylsalicylideneaminato)manganese(III) complexes, $Mn^{III}(N\text{-Rsai})_2Cl$, react with hydrogen chloride to give the corresponding dichloromanganese(IV) complexes, $Mn^{IV}(N\text{-Rsai})_2Cl_2$, as deep green crystals; R can be *n*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, *n*-C_6H_{13}, *c*-C_6H_{11}, *n*-C_8H_{17}, *n*-$C_{12}H_{25}$, *n*-$C_{18}H_{37}$, $CH_2C_6H_5$, or $CH_2CH_2C_6H_5$. These complexes were characterized by the magnetic susceptibilities, electronic spectra, infrared spectra, and cyclic voltammograms. The complexes (R=*n*-$C_{12}H_{25}$ and *n*-$C_{18}H_{37}$) are found to be stable toward water in the solid state. A *trans*, six-coordinate configuration is proposed for these Mn(IV) complexes on the basis of the infrared spectra.

Manganese-(III) and -(IV) complexes are of interest in connection with the biological redox systems involving manganese ions, such as the oxygen evolution process of photosystem II in green plants and the disproportionation of superoxide ion, O_2^-, by the manganese-containing superoxide dismutases.[1] In these systems the involvement of various oxidation states: Mn(II), Mn(III), and/or Mn(IV) have been proposed.[2–5] However, very few Mn(IV) complexes have been isolated and characterized so far, because Mn(IV) ion is very unstable toward water.[6,7] We have previously reported on the dichloromanganese-(IV) complexes with the Schiff bases derived from substituted salicylaldehydes with diamines or butylamine.[7] These Mn(IV) complexes are unstable toward moisture even in the solid state and decompose to the reduced manganese complexes. This may be caused because the coordinated chlorine atoms are displaced by water molecules. Thus we have aimed to obtain Mn(IV) complexes which are stable toward water.

In this paper we describe the preparation and characterization of a series of dichloromanganese(IV) complexes with the bidentate Schiff bases derived from salicylaldehyde and primary monoamines (Fig. 1). The reactivity of the Mn(IV) complexes toward water decreased as the chain length of the alkyl groups increased.

Fig. 1. Manganese(IV) Schiff base complexes, $Mn(N\text{-Rsai})_2Cl_2$.

Experimental

Preparation of Mn(III) Complexes, Mn(N-Rsai)$_2$Cl. All the Mn(III) Schiff base complexes were obtained by a modification of the method described previously.[7]

Chlorobis(N-hexylsalicylideneaminato)manganese(III), Mn(N-Hxsai)$_2$Cl. The tetrahydrofuran (THF) solution (50 cm^3) containing salicylaldehyde (2.44 g) and hexylamine (2.02 g) was refluxed for 1 h. The solvent was evaporated under reduced pressure. The resulting yellow oily residue was dissolved in a mixture of dichloromethane (30 cm^3) and methanol (30 cm^3). Manganese(III) acetate dihydrate (2.68 g) and lithium chloride (0.63 g) were added to the solution. The mixture was refluxed for 1 h. The solvent was evaporated under reduced pressure to yield olive-green solids. They were collected on a glass filter, washed with 2-propanol and ether, and then dried *in vacuo*. They were recrystallized from dichloromethane. The yield was 3.2 g.

The other Mn(III) complexes were prepared in a similar manner. These complexes are soluble in dichloromethane, acetone, and acetonitrile. The analytical data are given in Table 1, together with the magnetic moments determined at room temperature.

Preparation of Mn(IV) Complexes. Dichlorobis(N-hexylsalicylideneaminato)manganese(IV), Mn(N-Hxsai)$_2$Cl$_2$. To a mixed solution of dichloromethane (20 cm^3) and 2-propanol (50 cm^3) containing $Mn^{III}(N\text{-Hxsai})_2Cl$ (1.0 g), a 2-propanol solution of HCl (1.5 molar folds over the complex) was added drop by drop with stirring at room temperature. The solution changed from greenish-brown to deep green with precipitation of deep green crystals. The mixture was cooled to 0 °C and allowed to stand for 3 h. The crystals precipitated were collected on a glass filter, washed with 2-propanol and ether, and then dried *in vacuo*. The yield was *ca.* 0.4 g. Further purification was not carried out.

The other Mn(IV) complexes (Fig. 1) were obtained in a similar manner. The analytical data are given in Table 2, together with the magnetic moments determined at room temperature. All the complexes are soluble in dichloromethane and the solutions show no noticeable change for an hour if kept isolated from contact with moisture. The complexes with R=Pr, Bu, *i*-Bu, Hx, *c*-Hx, Oct, Dod, Bz, and PE are soluble in acetone and acetonitrile; the complex with R=Octd is slightly soluble in the above solvents. All the complexes are soluble in coordinating solvents such as dimethyl sulfoxide and pyridine, but the solutions change rapidly from deep green to yellow-brown. The complexes with R=Dod and Octd have been found to be unreactive toward water in the solid state.

Reagents. All reagents were of reagent grade. Solvents were purified by refluxing over sodium (ether), calcium oxide (2-propanol), and calcium chloride (dichloromethane, acetone), and then distilled. Acetonitrile was distilled twice

from diphosphorus pentaoxide before use.

Measurements. The UV and VIS absorption spectra were obtained from a Hitachi 340 recording spectrophotometer. The IR spectra were recorded on a Hitachi EPI-215 and a Hitachi EPI-L grating spectrophotometer for the 4000 to 650 cm^{-1} and the 700 to 250 cm^{-1} regions, respectively. The magnetic susceptibilities were measured by the Gouy method at room temperature. The cyclic voltammograms were made with a Yanagimoto P-8 polarograph connected with a Yanagimoto P8-PT potentiostat. A platinum wire and a platinum spiral were used as a working and an auxiliary electrode, respectively. An aqueous saturated calomel electrode was used as a reference electrode; this was inserted in an aqueous solution of 1 M (1 M= 1 mol dm^{-3}) KCl, which was connected with an agar salt bridge to a solution under investigation *via* an acetonitrile solution containing 0.1 M electrolyte. Tetrabutylammonium perchlorate was used as a supporting electrolyte.

Results and Discussion

The analytical data for the Mn(III) and Mn(IV) complexes are in agreement with the empirical formulas of MnL_2Cl and MnL_2Cl_2, respectively; here L denotes monoanion of *N*-alkylsalicylideneamines (Tables 1 and 2).

In general, most of the Mn(IV) compounds are not stable and are thus readily hydrolysed and reduced. The dichloromanganese(IV) complexes such as Mn^{IV}(salen)Cl_2 obtained previously are unstable in a moist air even in the solid state, where salen denotes dianion of *N*,*N*′-disalicylideneethylenediamine. Therefore many difficulties arose in the syntheses of these complexes. In this study we prepared a series of dichloromanganese(IV) Schiff base complexes (Fig. 1) in order to obtain water-resistant Mn(IV) complexes. This idea is based on the hope that the long chain alkyl groups such as *n*-$C_{12}H_{25}$ and *n*-$C_{18}H_{37}$ may protect against the attack of water molecules on the central manganese atom of the complex. Figure 2 shows the absorption spectral changes on the addition of water to an acetone solution of Mn(*N*-*c*-Hxsai)$_2$Cl$_2$. The intensity of the characteristic absorption band at 600 nm for the Mn(IV) complex decreased with time. The final absorption spectrum is almost the same as that of Mn^{III}(*N*-*c*-Hxsai)$_2$Cl in a mixture of acetone and water, indicating that water resulted in the reduction of the Mn(IV) complex. Figure 3 shows the time courses of the absorbances in the characteristic absorption bands for the complexes: Mn(*N*-Prsai)$_2$Cl$_2$, Mn(*N*-*c*-Hxsai)$_2$Cl$_2$, Mn(*N*-Octsai)$_2$Cl$_2$, and Mn(*N*-Dodsai)$_2$Cl$_2$, when water was added to these acetone solutions. It is apparent that their reactivity with water depends on the alkyl groups and decreases in the order of R= Dod<Oct<Pr<*c*-Hx. The most rapid change in absorbance observed for Mn(*N*-*c*-Hxsai)$_2$Cl$_2$ may be

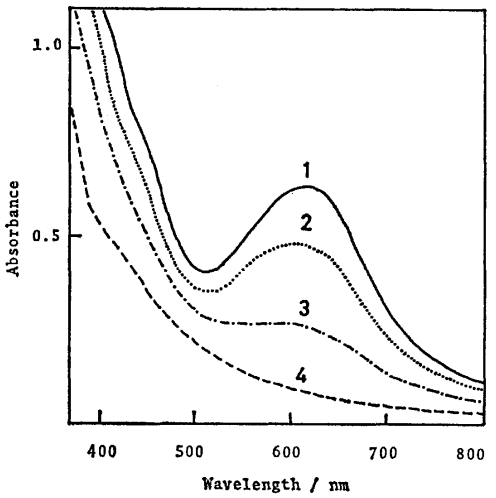

Fig. 2. Spectral changes on the addition of water (0.05 cm³) to an acetone solution of 1.6×10^{-4} M $Mn^{IV}(N\text{-}c\text{-Hxsai})_2Cl_2$ (5 cm³).

caused by the instability of the complex due to steric hindrance of the cyclohexyl group. In the case of $Mn(N\text{-Octdsai})_2Cl_2$, such spectral changes could not be measured owing to its solubility restriction in acetone. However, this complex may be more water-resistant than the others investigated here, because that it showed no significant change on washing with water.

Magnetic Properties. The magnetic moments of the Mn(III) complexes fall within the range of 4.85 to 5.03 BM, with the exception of $Mn(N\text{-Bzsai})_2Cl$ (Table 1). This indicates that these complexes may have a d^4 high-spin electron configuration. The low value (4.26 BM) observed for the above complex may be caused by magnetic exchange interactions due to the formation of a binuclear complex in the solid state like Fe(salen)Cl.[8] Further investigation on the complex was not made in this work. On the other hand, the magnetic moments of the Mn(IV) complexes fall within the range of 3.84 to 4.08 BM; such moments are consistent with the spin-only value expected for a complex with a d^3 high-spin electron configuration.

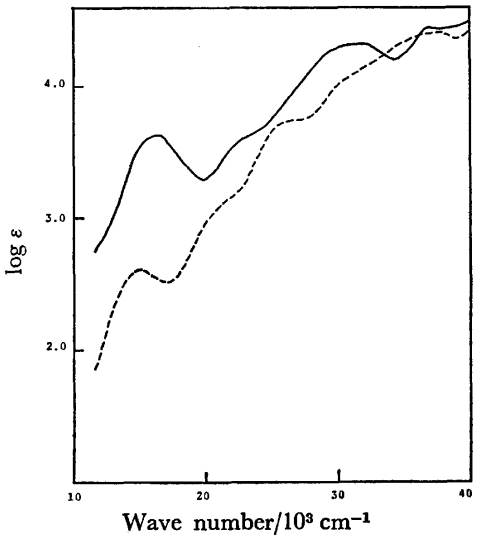

Fig. 4. Electronic spectra in dichloromethane.
——: $Mn^{IV}(N\text{-Octsai})_2Cl_2$, ----: $Mn^{III}(N\text{-Octsai})_2Cl$.

Electionic Spectra. Figure 4 shows the electronic spectra of the complexes $Mn^{III}(N\text{-Octsai})_2Cl$ and $Mn^{IV}(N\text{-Octsai})_2Cl_2$ in dichloromethane. In the Mn(III) complex, three absorption bands were observed in the visible region: at 15200, 21300 sh, and 26300 cm^{-1}. On the other hand, the electronic spectrum of the Mn(IV) complex shows an intense absorption band at 16000 cm^{-1} ($\log\varepsilon=3.62$). The frequencies of the absorption maxima for the Mn(III) and Mn(IV) complexes are summarized in Table 3. It is apparent from the Table that the alkyl groups of the Schiff base ligands have little effect on the frequencies for either Mn(III) or Mn(IV) complexes. These results suggest that the Mn(III) and Mn(IV) complex pairs may have similar configurations.

Recently, Boucher *et al.* have reported the absorption spectra of Mn^{III}(X-salen)Cl[9] and Mn^{III}(acacen)Cl[10] in noncoordinating solvents; here X-salen and acacen denote dianions of *N,N'*-di(substituted salicylidene)ethylenediamine and *N,N'*-bis(2-acetyl-1-methylethylidene)ethylenediamine, respectively. The X-ray structural analysis of the latter complex has revealed that its coordination polyhedron approximates an idealized C_{4v} symmetry.[10] They have assigned the three absorption bands observed for Mn(acacen)Cl in chloroform as follows; the band at 16400 cm^{-1} ($\log\varepsilon=2.31$) to $d_{xy}\rightarrow d_{x^2-y^2}$, the band at 22400 cm^{-1} (3.23) to $d_{xy}\rightarrow\pi^*$ (azomethine) involving $d_{yz},d_{zx}\rightarrow d_{x^2-y^2}$ as a lower energy shoulder, and the band at 26200 cm^{-1} (3.81) to $d_{yz},d_{xz}\rightarrow\pi^*$ (azomethine). The absorption spectra of the present Mn(III) complexes are similar to that of the above complex, suggesting that these Mn(III) complexes may have a five-coordinate structure ($\approx C_{4v}$) in dichloromethane. Therefore, the absorption bands near 15200 cm^{-1} can be safely assigned to the ligand field transition due to $d_{xy}\rightarrow d_{x^2-y^2}$.

PE	15.1	(2.60)	21.3 sh	26.3 (3.75)	305	16.1	(3.53)	22.4 sh	31.4 (4.26)	347

a) Measured in dichloromethane.

Previously we have observed intense absorption bands around 16000 cm^{-1} (log $\varepsilon \approx 3.5$) for the complexes Mn^{IV}(X-salen)Cl_2 and $Mn^{IV}(N\text{-Bu-X-sai})_2Cl_2$ and have assigned them to the charge transfer transition due to Cl to Mn on the basis of the intensity. Thus the intense absorption bands near 16000 cm^{-1} observed for the present Mn(IV) complexes can be assigned to the same transition. The ligand field transitions which are expected for a complex with a d^3 high-spin configuration may be obscured by the intense charge transfer band. Therefore, the absorption bands near 23600 cm^{-1} cannot be easily assigned.

Infrared Spectra. The IR spectra of the Mn(IV) complexes are almost the same as those of the corresponding Mn(III) complexes in the 4000 to 500 cm^{-1} region, indicating that the Schiff base ligands coordinate with manganese ions by the same fashion in both complexes. However, in the 500 to 250 cm^{-1} region, the IR spectra of the Mn(III) and Mn(IV) complexes differ markedly, especially in the region sensitive to the ν(Mn–Cl). The absorption bands observed at 310 cm^{-1} for $Mn(N\text{-Prsai})_2Cl$[11], at 290 cm^{-1} for Mn(acac)Cl,[12] and at 279 cm^{-1} for Mn(acacen)Cl[10] have been assigned to the ν(Mn–Cl); here acac denotes the monoanion of acetylacetone. In the present Mn(III) complexes, strong bands were observed around 310 cm^{-1}; these may be assigned to the ν(Mn–Cl). The band positions are listed in Table 3. On the other hand, the IR spectra of the Mn(IV) complexes showed strong bands around 350 cm^{-1}. The absorption band observed at 358 cm^{-1} for $K_2Mn^{IV}Cl_6$ has been assigned to the ν(Mn–Cl).[13] It is expected that the band due to the ν(Mn–Cl) may be shifted to higher frequencies on going from Mn(III) to Mn(IV), since the Mn(III) complexes have a five-coordinate structure, while the Mn(IV) complexes have a six-coordinate structure. The absorption bands observed around 350 cm^{-1} for the Mn(IV) complexes are assigned to the ν(Mn–Cl). The band positions are listed in Table 3. In the previous paper we have pointed out that the dichloromanganese(IV) complexes with the bidentate Schiff base ligands may have a *cis*- or *trans*-octahedral configuration; with the com-

a) Measured in acetonitrile containing 0.1 M Bu_4NClO_4 at 25 °C. b) Half-peak potentials for the corresponding manganese(III) complexes. c) Measured in acetonitrile–dichloromethane (2/1 volume ratio).

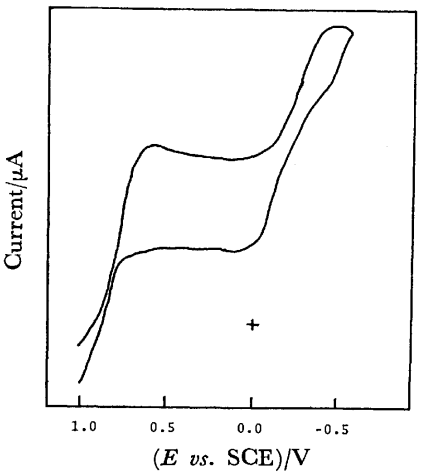

Fig. 5. Current-potential curve of $Mn^{IV}(N\text{-}i\text{-Busai})_2Cl_2$ measured in acetonitrile at 25 °C. Scan rate was 0.06 V s^{-1}.

plexes in which two chlorine atoms coordinate with manganese ion in a *cis*-form two absorption bands due to the ν(Mn–Cl) would be observed, while there is only one band in a *trans*-form. In the present Mn(IV) complexes, one strong band assignable to the ν(Mn–Cl) was observed, suggesting that two chlorine atoms may coordinate with manganese ion in a *trans*-form.

The coordination features of the bidentate Schiff base ligands cannot be determined from the available data. However, the structures of the Ni(II) complexes with the *N*-alkylsalicylideneamines have been investigated extensively and explained as follows. The complexes with *n*-alkyl groups have a *trans*-planar configuration. If the alkyl chain is branched at the β-carbon, as in the Ni(*N*-*i*-Busai)$_2$, the steric situation is very similar to the *n*-alkyl case and no tetrahedral form is observed.[14] In the present work, attempts to isolate Mn^{IV}(*N*-Rsai)$_2Cl_2$ (R=*i*-C_3H_7 and *s*-C_4H_9) were unsuccessful, perhaps because of the instability due to the steric hindrance of these groups. These results suggest that the present Mn(IV) complexes are in a *trans*, six-coordinate configuration, as shown in Fig. 1, but the Schiff base ligands may deviate from planarity to varying degrees.

Electrochemical Properties. The current-potential curve of the complex Mn^{IV}(*N*-*i*-Busai)$_2Cl_2$, is shown in Fig. 5. Two-step cathodic waves with a similar wave height were observed at the half-peak potentials of +0.81 and −0.18 V(*vs.* SCE); these can be assigned to the reductions of Mn(IV) to Mn(III) and Mn(III) to Mn(II), respectively. The reduction potentials for the Mn(IV) complexes are given in Table 4, together with those for the Mn(III) complexes. The potentials for both reductions are not much affected by the alkyl groups of the Schiff base ligands. These results are consistent with the spectroscopic data.

The Preparation of Ti_5S_8

Masanobu SAEKI* and Mitsuko ONODA

National Institute for Research in Inorganic Materials, 1-1, Namiki, Sakura-mura, Niihari-gun, Ibaraki 305

(Received April 15, 1981)

Ti_5S_8 (12R type), which had never been prepared in a pure state, was obtained as a single phase by the chemical-transport method. The conditions for the preparation were determined experimentally. The existence range of the phase was examined for composition and temperature.

Several phases have been reported in the TiS–TiS_2 composition range, namely, TiS (2H), Ti_8S_9 (9R), Ti_4S_5 (10H), Ti_3S_4 (21R), Ti_2S_3 (4H), Ti_5S_8 (12R), and TiS_2 (2H). (The designations in parenthesis indicate the structures in the Ramsdell notation.) Of these, the TiS phase is of the NiAs-type, while TiS_2 is of the CdI_2-type, structure. Both have a hexagonal close packed of sulfur. However, the intermediate phases have complex structures involving both the hexagonal and cubic packing of sulfur and varying stacking sequences, with a specific titanium-to-sulfur ratio. Titanium atoms are situated in the octahedral holes of the sulfur packing.

In spite of many reports on titanium sulfide, its phase diagram has not yet been established because of the variation in experimental data reported by many investigators, as has been pointed out by Jeannin[1] or Kjekshus and Pearson.[2] Furthermore, Tronc and Huber[3] reported that, at the composition of $Ti_{1.18}S_2$, there are many structures with different periods in the c-direction, *e.g.*, polytypism. These observations have indeed indicated that the titanium–sulfur system is complicated.

The existence of Ti_5S_8 has been reported by Jeannin,[4] Flink *et al.*,[5] and Tronc and Huber,[3] although it was not prepared by any of them as a single phase. They obtained it as a mixture with other structures, like Ti_2S_3 (4H type). We ourselves were not able to prepare Ti_5S_8 from the respective elements sealed in an evacuated silica tube. However, Ti_5S_8 was obtained as a single phase by the chemical-transport method when iodine was used as the transport agent. The aim of this paper is to describe the experimental conditions needed to obtain Ti_5S_8 as a single phase.

The preparation conditions of Ti_5S_8 will first be described, and then procedure for the identification of the obtained Ti_5S_8. Finally, the range of composition and temperature of Ti_5S_8 will be shown.

Results

Preparation Conditions. The preparation of Ti_5S_8 was performed according to the following procedure. The titanium sulfide (1.5 g), the composition and structure of which will be described later, and the iodine (0.15 g) were sealed in an evacuated silica tube 150 mm in length and 12 mm inner diameter. The tube was held in a horizontal resistance furnace, where the high-temperature end was set at 600 °C and the low-temperature end at 500 °C. The titanium sulfide was transported from the low- to the high-temperature side. The transported titanium sulfide was then deposited as plate-shaped, grey-black crystals.

To prepare Ti_5S_8 in a pure form by chemical transport, several important factors had to be ascertained: (1) the preparation temperature of the starting material, (2) the composition of the starting material, (3) the transport temperature, and (4) the iodine concentration. The specimen obtained by chemical transport was influenced by the following factors.

The Effect of the Preparation Temperature of the Starting Material. The synthesis of the titanium sulfide used as the starting material was carried out according to the following procedure. Titanium metal powder (purity, 99.0%) and sulfur (purity, 99.9999%) were mixed together in a calculated ratio; the mixture was then allowed to react for a few days at 350 °C, after which the temperature was raised to 500—900 °C. With respect to the composition in the range from $Ti_{1.38}S_2$ to $Ti_{1.16}S_2$, at 500 °C the structure of the specimen was of the 2H type; at 600—700 °C, a disordered stacking of the sulfur layers was detected, and above 800 °C the 4H type was the result. The 2H type specimen prepared at 500 °C might have been heterogeneous because of the incomplete reaction.

By using the 2H type as the starting material, the transport was found to take place, but when the starting materials prepared at a temperatures above 600 °C were used, transport did not occur. The reason for this was not clear. However, it can be seen from Table 1 that whether or not the transport take place is dependent on the crystal structure of the starting material.

The Effect of the Composition of the Starting Material. How the transport was influenced by the composition of the starting material was then examined. The curve in Fig. 1 shows the transport rate *versus* the composition of the starting material. As can be seen

Table 1. Relation of the preparation temperature of the starting material and average transport rate

Iodine concentration: 5.96 mg cm^{-3}, transport time: 144 h, composition of the starting material: $Ti_{1.21}S_2$, temperature: 500 °C (low-temperature end)→600 °C (high-temperature end).

Temp/°C	Structure	Transport rate/mg h^{-1}
500	TiS_2(2H) type	0.8
600	Random	Negligibly small
700	Random	Negligibly small
800	Ti_2S_3(4H) type	0
900	Ti_2S_3(4H) type	0

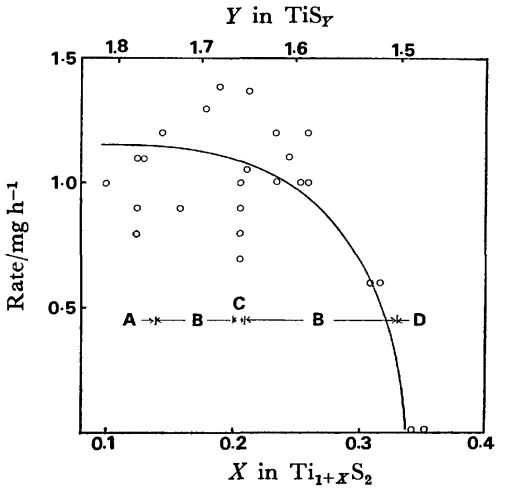

Fig. 1. Average transport rate versus composition of the starting material. (Iodine concentration: 5.96 mg cm^{-3}, transport time: 144 h, temperature: 500 °C(low temperature side)→600 °C(high temperature side)).
A: Phase with disordered stacking of sulfur layers, B: mixed phase of Ti_2S_3 and Ti_5S_8, C: single phase of Ti_5S_8, D: no transport took place.

TABLE 2. RELATION OF THE TRANSPORT TEMPERATURE AND TRANSPORTED CRYSTALS

Iodine concentration: 5.96 mg cm^{-3}, transport time: 144 h, composition of the starting material: $Ti_{1.21}S_2$.

Temp/°C	Transported crystal
400→500	—
500→600	Ti_5S_8
600→700	$Ti_5S_8+Ti_2S_3$
700→800	$Ti_5S_8+Ti_2S_3$

from this figure, the titanium sulfide was not transported by using a starting material whose composition was poorer in sulfur than $Ti_{1.33}S_2$. The transported crystals were composed of a mixed phase consisting of Ti_2S_3 and Ti_5S_8 when $Ti_{1.33}S_2$–$Ti_{1.22}S_2$ was used as the starting material. A single phase of Ti_5S_8 resulted when $Ti_{1.21}S_2$ was used. A mixed phase of Ti_2S_3 and Ti_5S_8 resulted when $Ti_{1.19}S_2$–$Ti_{1.14}S_2$ was used and a phase with disordered stacking of sulfur layers when a specimen richer in sulfur than $Ti_{1.13}S_2$ was used.

Therefore, Ti_5S_8 in a pure form was obtained by using a starting material whose composition was $Ti_{1.21}S_2$. The sulfur content of the transported crystals was always found to be smaller than that of the starting materials.

The Effect of the Transported Temperature. The transport was carried out at various temperatures in order to determine the most suitable temperature conditions. As can be seen in Table 2, Ti_5S_8 was obtained in a pure form only at the temperature of 500 °C (low temperature side)→600 °C (high temperature side). At any temperature above this, the transported crystals were found to be two phases consisting of Ti_5S_8 and Ti_2S_3. From the observation of the electron diffractometry, it was found that the needle-shaped crystal was Ti_2S_3, and the plate-shaped one, Ti_5S_8.

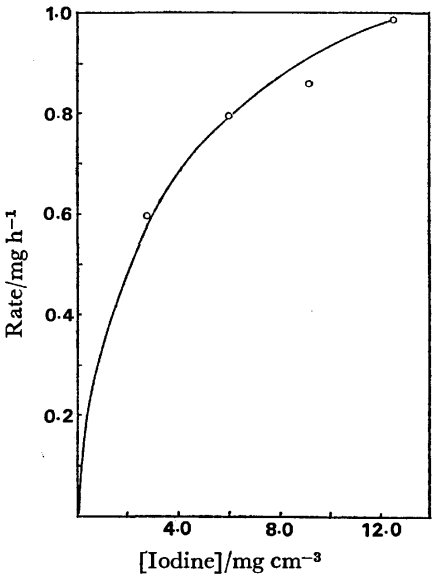

Fig. 2. Average transport rate versus iodine concentration. (Transport time: 144 h, composition of the starting material: $Ti_{1.21}S_2$, temperature: 500 °C (low temperature side)→600 °C (high temperature side)).

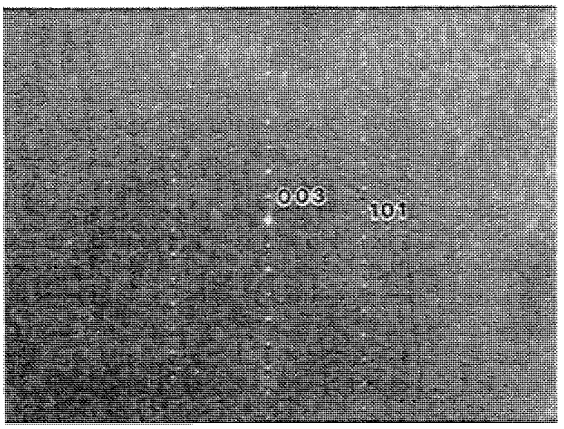

Fig. 3. Electron diffraction photograph of Ti_5S_8 obtained by the chemical transport method.

On the contrary, the transport was found no longer to take place at temperature below 500 °C (low temperature end)—600 °C (high temperature end).

The Effect of the Iodine Concentration. In order to determine the most suitable conditions, the transport was carried out at various iodine concentrations. The results are shown in Fig. 2, where the transport rate increases with the increase in the iodine concentration. Crystals with stacking faults were produced at concentrations of more than 12 mg cm^{-3}.

Identification by Means of Electron and X-Ray Diffractometry. Figure 3 shows an electron diffraction pattern taken from a crystal fragment obtained by grinding a transported crystal. The incident beam was directed parallel with the [010] direction. The distance of the repeating unit along the c-axis in the hexagonal setting was found to be 34 Å, containing 12 layers. The systematic absence, $-h+k+l=3n$, in-

* Indicates the indices affected by the preferred orientation.

dicates the rhombohedral symmetry of the structure. Therefore, the structure of this crystal may be referred to as a 12R type using Ramsdell notation, this is consistent with the structure of Ti_5S_8 as described by Flink *et al.*,[5] and Tronc and Huber.[3]

The powder X-ray diffraction pattern of the Ti_5S_8 sample (composition, $Ti_{1.31}S_2$) obtained by crushing the transported crystals was taken by the counter-diffractometer technique using Ni-filtered Cu $K\alpha$ radiation. The pattern was indexed on the basis of the hexagonal cell (a=3.431 and c=34.25 Å), where the systematic absence, $-h+k+l\neq 3n$, is consistent with the case of the electron diffraction. Powder X-ray diffraction intensities were calculated for the structure model by Tronc *et al.*[6] for the composition of $Ti_{1.31}S_2$ (Ti_5S_8 phase) with an overall temperature factor of B=1.0. The intensities, calculated and observed, are listed in Table 3. These do not agree with each other for the 00*l* and 110 peaks because of the preferred orientation in the sample. The reliability factor R, defined by $R=\Sigma|I_{obsd}-I_{calcd}|/\Sigma|I_{obsd}|$, was 0.39; this was excessive. However, the R-value estimated by eliminating the 00*l* and 110 peaks, which were affected by the preferred orientation, was 0.14. Therefore, this specimen was identified as Ti_5S_8 (12R type), as has previously been reported by Tronc *et al.*[6]

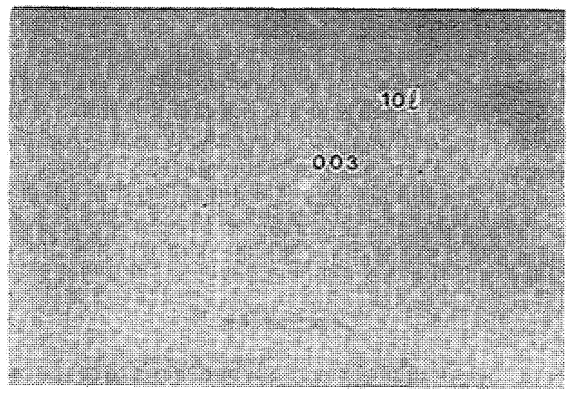

Fig. 4. Electron diffraction photograph of the specimen annealed at 1200 °C.

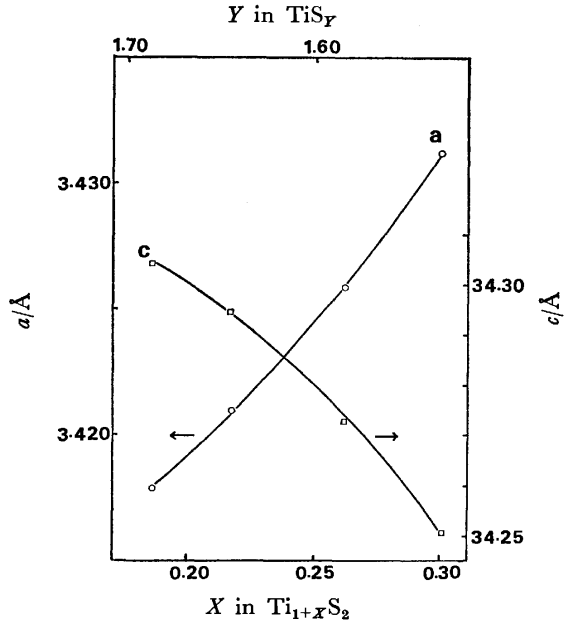

Fig. 5. Relation of the lattice constants and composition.

The information obtained from X-ray and electron diffractometry showed that the specimen prepared by the method described above was indeed a pure single phase and did not contain any other phases, like Ti_2S_3 (4H type) or TiS_2 (2H type).

Range of the Temperature and Composition in Which Ti_5S_8 Can Exist. The range of temperature and composition in which Ti_5S_8 can exist was also examined. At first, Ti_5S_8 (composition $Ti_{1.23}S_2$) was kept in evacuated tubes at 800, 900, 1000, 1100, and 1200 °C for 3 d. Disorder in sulfur stacking at 1100 °C and 1200 °C was found, although no change was detected in the specimens annealed below 1000 °C. Figure 4 is an electron-diffraction photograph of the specimen annealed at 1200 °C. In this figure, the diffusion for $h-k=3n\pm1$ shows disorder caused by sulfur stacking.[7] At 1100 °C, Ti_5S_8 began to change to another structure, but the rate of the transformation was so slow that a stable structure could not be ascertained at this temperature.

The composition range where the Ti_5S_8 phase could exist was examined through the sulfurization or desulufurization in the atmosphere of the H_2–H_2S mixture at 900 °C. After being quenched from 900 °C to room temperature, the specimens were examined by means of X-ray diffractometry. The lattice constants are shown in Fig. 5. From this experiment, it was found that Ti_5S_8 can exist in compositions from at least $Ti_{1.31}S_2$ to $Ti_{1.16}S_2$ at 900 °C.

Conclusion

From the results presented above, it can be concluded that: (1) Ti_5S_8 in a pure form can be prepared by the chemical transport method under the following conditions: transport agent; iodine (6—9 mg cm^{-3}), starting material; titanium sulfide (composition $Ti_{1.21}S_2$) prepared at 500 °C, transport temperature; 500 °C (low temperature end)→600 °C (high temperature end), and (2) Ti_5S_8 can exist over a large composition range at 900 °C.

The authors wish to thank Professor Mitsuoki Nakahira of the Okayama College of Science and Dr. Isao Kawada of our Institute for their helpful discussions.

Gas-chromatographic Measurements of Dinitrogen Oxide in Air

Hisafumi Muramatsu, Michio Hirota,* and Yukio Makino
Meteorological Research Institute, 1-1 Nagamine, Yatabe-machi, Tsukuba-gun, Ibaraki 305
(Received April 17, 1981)

To obtain an average tropospheric mixing ratio of dinitrogen oxide over Japan, 90 air samples were collected by aircraft at altitudes up to 7 km from Autumn, 1978, to Spring, 1979, and were analysed by the GC-ECD method. The mean volume-mixing ratio of N_2O was 0.31_0 ppm, and the standard deviation was 0.01_4 ppm. These results show that the tropospheric N_2O is well mixed and that its mixing ratio is higher than 0.30 ppm.

The natural dinitrogen oxide is produced by the nitrification of the ammonium ion as well as the denitrification of nitrates through microbiological activity in soil and water.[1-6]

Though some sinks of N_2O have been proposed,[6-8] the atmospheric N_2O is rather unreactive in the troposphere and is transferred to nitrogen monoxide mainly by Reaction (1) in the stratosphere:[9]

$$\begin{aligned} N_2O + O(^1D) &\longrightarrow N_2 + O_2 \\ &\longrightarrow 2NO. \end{aligned} \quad (1)$$

The NO is strongly related to the stratospheric ozone (O_3) by Reaction (2); *i.e.*, an increase in NO leads to a depletion of the stratospheric O_3:[10-13]

$$\begin{aligned} NO + O_3 &\longrightarrow NO_2 + O_2 \\ NO_2 + O &\longrightarrow NO + O_2 \\ \text{net}\quad O_3 + O &\longrightarrow 2O_2. \end{aligned} \quad (2)$$

To know the behavior of the N_2O in the atmosphere, from the ground surface[8,14-26] through the troposphere[14,17,20,26-32] to the stratosphere,[14,17,27,30-37] and also in the sea and over the sea surface[17,29,38-43] is important in understanding the global nitrogen cycle[1,2,44] and the stratospheric O_3 chemistry.[10-13]

In a previous study,[45] several measurements of the atmospheric N_2O were performed at the Meteorological Research Institute, Koenji, Tokyo, by the gas chromatographic (GC) method, using a thermal conductivity detector (TCD); the error of the measurement was estimated to be about ±7%. It has been shown, however, that an electron-capture detector (ECD) has an increased sensitivity for N_2O at elevated temperatures[46] and needs an air sample of only a few millilitres, while the N_2O must be preconcentrated from about 30 l of air when a TCD is used.[14,15,19,38,39,47]

To obtain an average tropospheric mixing ratio of N_2O over Japan, air samples obtained by aircraft from Autumn, 1978, to Spring, 1979, have been analysed by the GC-ECD method.

Experimental

Sampling of Air. Three aircraft, an Aerocommander 685, a Piper Seneca, and a Cessna 404, were used for the air sampling. On the aircraft, the air was sampled through a silicone rubber tube or a *tylon* tube (1 m×8 mm i.d.) in stainless steel cylinders (Whitey, 0.3, 0.5, and 1.0 l) by means of two air pumps connected in series up to the pressure of 3.5—4.0 kg/cm². Before use, the cylinders were evacuated by means of an oil rotary pump and heated to 200 °C for several hours. DK shut-off valves (Whitey) were used for these cylinders. The N_2O concentration was constant for more than 40 d (<±2.0%) in the cylinder.

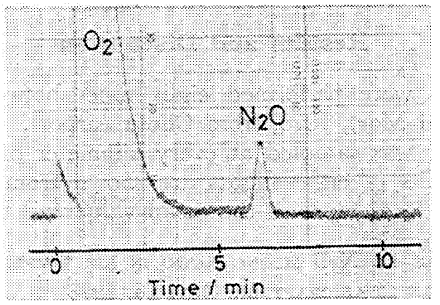

Fig. 1. The typical chromatogram of N_2O. Standing current: 2.0 nA, pulse frequency: 2.5 kHz, detector temperature: 300 °C, sample air: 2 ml. N_2O was 0.34 ppm.

Gas-chromatographic Analysis. GC measurements were performed using a Shimadzu Gas Chromatograph GC-6AM equipped with an ECD (10 mci ^{63}Ni, 300 °C). Nitrogen gas (99.9995%) passed through the tube filled with molecular sieve 5A (1/16 in. pellets) was used as the carrier gas at a flow rate of 40 ml/min. The sample air was transferred to a 2-ml gas sampler (Shimadzu, MGS-4) and then introduced into a glass column (3 m×3 mm i.d.) filled with 30—60 mesh molecular sieve 5A.† The peak of N_2O appeared 5 min after that of oxygen gas at the column temperature of 245 °C.

The reference gas of 1 ppm N_2O was prepared by diluting 15 μl of pure N_2O (>98%, Showa Denko) in 15 l of air, which was measured by means of a gas meter and passed through a tube (30 cm×3 cm i.d.) containing silica gel and three U-shaped tubes (8 mm i.d.) containing drierite, ascarite, and molecular sieve 5A (1/16 in. pellets, 0 °C) respectively. A 15 μl portion of N_2O was measured by means of a gas-tight syringe (SGE, 100A-RN-GSG). The molecular sieve tube was heated to 350 °C for 3 h before use. The air purified by this method was also used as a zero gas. The error in repeated measurements of single reference gas was less than ±0.9%. The concentrations of five reference gases made in 20-l *tedlar* bags over a period of a week were in good agreement with each other; *i.e.*, the standard deviation was 1.7%.

A typical chromatogram of N_2O is shown in Fig. 1. The peak heights of N_2O were proportional to the quantities of N_2O from 0.39 ng to 3.9 ng, which corresponded to 0.1 ppm and 1 ppm of N_2O in 2 ml of air respectively. The error in repeated peak-height measurements for 0.3 ppm of N_2O was about ±2%. The total error in the measurements of N_2O was estimated as about ±4%.

† Porapak Q and QS and Porasil B and C were also suitable for the analysis of N_2O.[29]

In the present study, measurements were performed as follows; the reference gas was first measured, and then the sample air was measured two times, and finally the reference gas was measured again. The volume-mixing ratio of N_2O in the sample air was calculated from the ratio of the two mean values of the sample air and the reference gas. The average difference between two measurements of 90 air samples was ±2%. The detection limit in this method was about 0.01 ppm of N_2O in 2 ml of air.

The temperature of the ECD was controlled in a range of ±2 °C. No effect of this temperature variation could be detected on the chromatogram.

Results and Discussion

Flights were performed eight times between Oct., 1978, and Mar., 1979, from Chofu Airport. In many cases, air was sampled at every kilometer of altitude. The results of eight flights are shown from Table 1 to Table 8, along with the mean value and the stand-

TABLE 1. N_2O MIXING RATIO IN AIR SAMPLED BY AIRCRAFT ON OCT. 26, 1978

ard deviation (SD) for each flight. The air samples taken on Dec. 7 and Dec. 12, 1978, and Jan. 19, Feb. 2, Feb. 9, and Mar. 27, 1979, were each measured for single reference gas respectively. The mean values of each altitude are shown in Fig. 2, along with the SDs(——). The number of samples at each altitude is also shown in Fig. 2. The value at 1.5 km was that of a constant-level flight on Dec. 7, 1978. The values at 2.5 km and 0.75 km were also those of constant-level flights on Feb. 9, 1979.

The mean value of the total of 90 samples was 0.31_0 ppm, and the SD was 0.01_4 ppm (4.4%). The mean value of 48 samples, for which the difference between two measurements was less than ±2%, was 0.31_2 ppm, and the SD was 0.01_3 ppm (4.2%). These results show that the tropospheric N_2O is well mixed from the ground surface to the altitude of 7 km, and that its mixing ratio is higher than 0.30 ppm.[1,17,21,26,32] The latter has also been shown in the measurements of the surface air in Japan,[23,25] though the results in Refs. 19 and 24 were very low (0.25 ppm).†† The mixing ratio of N_2O in the air over the sea surface is rather low (<0.29 ppm)[38,39,41-43] except for the values of the Caribbean Sea[40] and the NE Pacific Ocean.[17] This has been considered due to systematic errors among the analytical procedures.[42]

In a previous study, the mixing ratios of N_2O in the air over the ground surface were very scattered from 0.25 ppm to 0.45 ppm.[45] This wide distribution, which was also observed by Katou *et al.*,[19] has not

been observed in the measurements made by the GC-ECD method. The same results have been observed in the measurements made by a GC-MS method.[24] Values such as 0.45 ppm are too high to be explained by the effect of the exhaust gas of automobiles.[25] The error in the direct preconcentration of N_2O from the outdoor air must have been much larger than the estimated one (±3%).

The SD of the sample measurements was nearly equal to the error in the measuring technique. This would imply that the tropospheric mixing ratio of N_2O is more uniform than the results of the present study indicate and that the tropospheric lifetime of N_2O is quite long.[26]

Before the ECD was equipped with, from 20 l to 30 l of air was sampled in *tedlar* or *aflon* bags. The N_2O in the sample air in these bags was preconcentrated on molecular sieve 5A (−72 °C) and then analysed by the same GC-TCD method as was adopted in the previous study.[45] The concentration of N_2O in these bags was constant for at least a week.††† The results of 8 air samples, which are shown in Table 9, were considered to be in agreement with the results obtained by the GC-ECD method.

We would like to thank Dr. Masao Misaki, Mr. Yoshio Toyama, Mr. Izuo Kanazawa, and Mrs. Miwako Ikegami for their collaboration in the air sampling by aircraft.

Partition Coefficients of Chlorobenzenes in Heptane-Water and Heptane-Acetonitrile Systems

Nobuo SUZUKI,* Toshinobu YOSHIDA, and Hitoshi WATARAI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received May 6, 1981)

Partition coefficients (K_D) of benzene and 11 chloro derivatives of benzene were determined at 25 °C in two liquid-liquid partition systems: heptane/water and heptane/acetonitrile. Increase of K_D with increase of the numbers of Cl atoms in the solute is discussed in terms of surface and cohesive energies. The small difference in K_D of the isomers whose Cl atom numbers are 2, 3, or 4 was correlated with a difference in the dipole moment of the solute.

The liquid-liquid partition coefficient is utilized in measuring various solution properties: for example, transfer activity coefficient of non-electrolyte,[1] solvent effect on catalytic reaction,[2] capacity ratio in liquid chromatography,[3] and toxicity of drugs.[4] Accumulation of precise partition coefficient data is important for practical uses as well for an elucidation of the factors which influence their values. Hansch *et al.* investigated the regularity in the partition coefficients of various organic compounds. They proposed a substitution constant, π, for a variety of groups, by analogy to the Hammet σ constant.[4] Additivity of corresponding values for the components makes it possible to predict the partition coefficient of a certain compound. The additive-constitutive property is useful for practical purposes, but gives only a little insight into the nature of the solute-solute interaction.

Recently, we reported the importance of cavity formation in the partition of non-electrolytes.[5-7] In the present study, the partition equilibrium of a series of chlorobenzenes between heptane and water or acetonitrile was investigated. Chlorobenzenes are considered to be representative compounds of chlorinated organic compounds. The behavior of these compounds in the environment has recently become important. Acetonitrile was chosen to examine a difference from water in solvent effect. The partition coeffcients will be discussed in connection with the cavity formation energy in the partition systems.

Experimental

Chemicals. Monochlorobenzene (Wako G.R.) and o-dichlorobenzene (Tokyo Kasei G.R.) were washed with dilute alkaline solution, dried, and fractionally distilled under ambient pressure. *m*-Dichlorobenzene and 1,2,4-trichlorobenzene (Tokyo Kasei G.R.) were washed with dilute alkaline solution, dried, and distilled under reduced pressure. *p*-Dichlorobenzene, 1,2,3-trichlorobenzene, 1,3,5-trichlorobenzene, tetrachlorobenzene, pentachlorobenzene and hexachlorobenzene, which were all purchased from Tokyo Kasei, were purified by vacuum sublimation. Purity of the reagents was checked by GLC or mp measurement. Benzene was of spectral grade (Dotite) and used without further purification. Heptane (Kanto G.R.) was stirred with 30% fumic sulfuric acid over-night, washed with water and dilute sodium hydroxide solution, dried with sodium hydroxide and fractionally distilled. Acetonitrile (Wako G.R.) was dried with molecular sieves 3A and calcium hydride, distilled on phosphorus pentaoxide, and then redistilled on calcium hydride. Purity of the organic solvent was checked by UV spectra. Redistilled water was used throughout the experiment.

Partition Measurement. Heptane–Water System: Heptane solution of chlorobenzene of known concentration was agitated with water for 15 min by a mechanical shaker in a thermostated room at 25±1 °C. After centrifugation at 3000 rpm, an aliquot of aqueous phase was pipetted out for analysis. For benzene, monochlorobenzene, and dichlorobenzene systems, this aqueous phase was used for direct photometric determination. For trichlorobenzene and tetrachlorobenzene with quite high partition coefficients, the equilibrated aqueous phase was removed and agitated with a small volume of fresh heptane in order to re-extract and concentrate the solute dissolved in the aqueous phase. The second heptane phase was used for the photometric determination. Photometric measurement was made at 254 nm for benzene and at 220 nm for the others. The recovery in the re-extraction process was satisfactorily quantitative. The partition coefficient was calculated from this equation:

$$K_D = \frac{C_{o,init}V_o - C_aV_a}{C_aV_o}, \quad (1)$$

where $C_{o,init}$ is an initial concentration in heptane, C_a an observed concentration in aqueous phase, and V_a and V_o are volumes of aqueous and organic phases. The ratio of V_a/V_o is 1 or 10, corresponding to the magnitude of the partition coefficient. The partition coefficients of pentachlorobenzene and hexachlorobenzene were measured by means of GLC equipped with a electron capture detector.[8] The partition coefficient for every system showed no dependency on initial concentration of the solutes in the range of 0.05—0.2 mol dm^{-3}.

Heptane–Acetonitrile System: A 5-cm^3 portion of 0.003 mol dm^{-3} chlorobenzene in heptane was agitated with 5 cm^3 of acetonitrile under the same experimental conditions as used in the heptane/water system. Absorbance of the heptane phase was measured at the absorption maximum wavelength for each substance (250—300 nm). The partition coefficient was calculated by this equation:

$$K_D = \frac{A_o}{A_{o,init} - A_o}, \quad (2)$$

where $A_{o,init}$ and A_o are the absorbances of heptane solutions before and after equilibration, respectively. The acetonitrile and heptane used for partition experiments were saturated with each other prior to use. Spectrophotometry was carried out by Hitachi 356 and JASCO UVIDEC-2 spectrophotometers.

Results

In Table 1, the observed partition coefficients for the two partition systems are listed, along with the

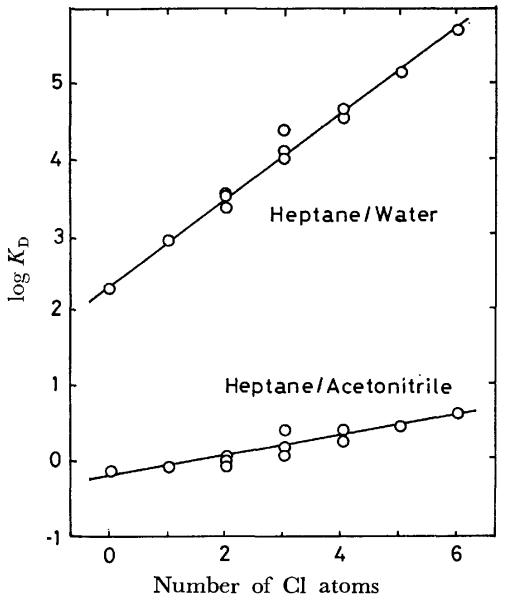

Fig. 1. Correlation between the partition coefficient and the number of chlorine atoms.

spectral data used for photometric determination. It is clearly observed that the K_D values for the heptane/water system are much larger than those for the acetonitrile system and that the values of both systems increase with an increase of number of Cl atoms in chlorobenzene. Figure 1 shows a linear relationship between log K_D and the number of Cl atoms, n. For the two partition systems, these experimental equations were obtained:

$$\left.\begin{aligned} \log K_D &= 0.566n + 2.37 \quad \text{for Heptane–}H_2O \\ \log K_D &= 0.132n - 0.203 \quad \text{for Heptane–Acetonitrile} \end{aligned}\right\}. \quad (3)$$

Increase of Cl atoms will cause an increase in molar volume and in molar surface area, as well as in the cohesive energy density of the compound. Hence, the influences of the molar surface area and the solubility parameter, defined as (cohesive energy density)$^{1/2}$, of chlorobenzene on the partition coefficient should be discussed.

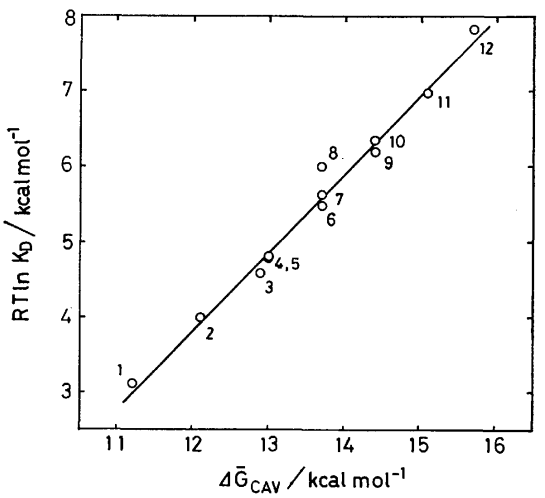

Fig. 2. Correlation between the partition coefficient and the cavity formation energy in heptane–water system. Numbers in this figure correspond to those in Table 1.

Discussion

Contribution of Surface Work. Chemical potential of solute in dilute solution is considered to be governed by two kinds of solute-solvent interaction energies, *i.e.*, a formation energy of cavity to acommodate the solute molecule and an interaction energy between the solute introduced into the cavity and the solvent molecule surrounding the solute molecule. Then, the free energy governing the partition equilibrium is represented by

$$RT \ln K_D = \Delta\bar{G}_{cav} + \Delta\bar{G}_{int}, \quad (4)$$

where $\Delta\bar{G}_{cav}$ and $\Delta\bar{G}_{int}$ correspond to free energy contributions from cavity formation and interaction accompanying the transfer of solute from organic phase into aqueous phase.

The cavity formation energy can be estimated from the molecular surface area of solute and the surface tension of bulk solvent. Sinanoglu has reported the next equation for the calculation of cavity formation energy:[9]

$$\bar{G}_{cav} = \kappa^e(\phi) 9.76\, V^{2/3}\gamma\left\{1-(1-\eta)\left(\frac{\partial \ln\gamma}{\partial \ln T}\right)+\frac{2}{3}\alpha T\right\}, \quad (5)$$

$$\eta = \frac{\kappa^s(\phi)}{\kappa^e(\phi)} = \frac{1+\phi^{2/3}(\kappa^s-1)}{1+\phi^{2/3}(\kappa^e-1)},$$

where V is molar volume of solute (cm^3 mol^{-1}), γ surface tension of solvent, α thermal expansion coefficient of solvent, ϕ molar volume ratio of solvent to solute, and κ^s and κ^e are microscopic cavity factors for surface energy and surface entropy.[10] According to Eq. 5, the cavity energy difference, $\Delta\bar{G}_{cav}$, was calculated for heptane–water system using κ^s=0.542 and 1.235, and κ^e=0.687 and 1.277 for heptane and water, respectively.[10] A correlation between RT ln K_D and $\Delta\bar{G}_{cav}$ is shown in Fig. 2. For the heptane–

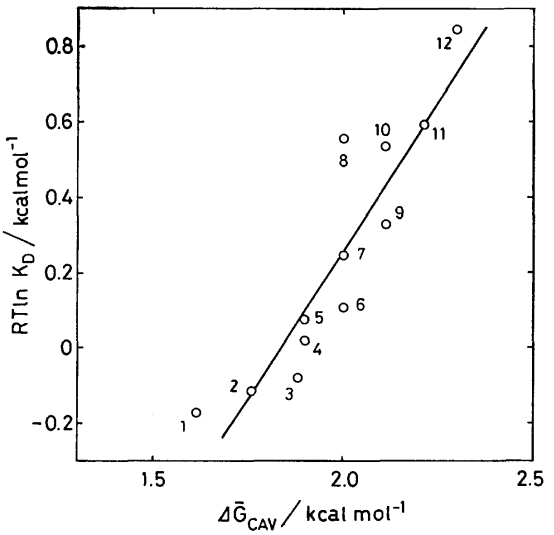

Fig. 3. Correlation between the partition coefficient and the cavity formation energy in heptane–acetonitrile system.
Numbers in this figure correspond to those in Table 1.

acetonitrile system, $\Delta\bar{G}_{cav}$ was calculated using approximated value of $\kappa^e=\kappa^s=1.0$ for acetonitrile.[9] A correlation with $RT\ln K_D$ is shown in Fig. 3. The linear relations appearing in Figs. 2 and 3 strongly suggest that the order of magnitude of the partition coefficient is governed by the cavity formation energy.

Contribution of Cohesive Work. The contributions of molar volume and of cohesive energy density of solute to the partition coefficient are accounted for by solubility parameter theory.[11] The next equation has been proposed for the partition coefficient by Suzuki *et al.*:[12]

$$\log K_D = \frac{V}{2.303RT}(\delta_a+\delta_o'-2\delta)(\delta_a-\delta_o), \quad (6)$$

$$\delta_o' = \delta_o + \frac{RT(V_o^{-1}-V_a^{-1})}{(\delta_a-\delta_o)},$$

where molar volume, V, V_o, and V_a, and solubility parameters δ, δ_o, and δ_a refer to those of solute, organic phase, and aqueous phase, respectively. This relation was successfully applied to the partition of several metal chelate compounds.[13]

Equation 6 was applied to the results of the heptane–water system. The molar volumes of chlorobenzenes were taken from the literature or estimated from the linear relationship between the molar volume and number of Cl atoms. The solubility parameters for chloro derivatives of benzene, except chlorobenzene and *o*-dichlorobenzene, were estimated from the additivity rule of group contributions in solubility parameter proposed by Renick and Lin.[14] The solubility parameter of water calculated from thermodynamic properties is 23.4 $cal^{1/2}\,cm^{-3/2}$ (conversion factor: 1 $cal^{1/2}\,cm^{-3/2}=2.0455\,J^{1/2}\,cm^{-3/2}$), but for practical use 17.15 $cal^{1/2}\,cm^{-3/2}$ is recommended by Suzuki *et al.* from their extensive study on solvent extraction of β-diketones and its metal chelates.[15] The $\log K_D$ value for chlorobenzene calculated using 17.15 $cal^{1/2}\,cm^{-3/2}$, however, decreases with increase of Cl atoms and disagrees with the observed value, *e.g.*, the calculated $\log K_D$'s are 2.50 for benzene and −0.29 for hexachlorobenzene. The same treatment, estimation of K_D according to Eq. 6, was applied to the heptane–acetonitrile system. In this system, the mutual solubility of two solvents cannot be neglected, hence the small changes in solubility parameter and molar volume of two solvent phases were corrected for by employing the solubility data reported previously.[2] The calculated results in heptane–acetonitrile did not show good agreement with the observed one, *e.g.*, the calculated $\log K_D$'s are −0.28 for benzene and −2.26 for hexachlorobenzene. When δ_a was treated as an adjustable parameter, the value of δ_a calculated introducing the observed $\log K_D$ into Eq. 6 varied from 17.4 for the benzene system to 20.9 for the hexachlorobenzene system. The value is related δ and V by the next equation:

$$\delta_a = 1.70\delta + 1.77 = 1.03V + 6.42. \quad (7)$$

The calculated values seem to be reasonable so long as the calculated δ_a value is between $\delta_v=6.4$ $cal^{1/2}\,cm^{-3/2}$ and $(\delta_v^2+\delta_r^2)^{1/2}=23.4$ $cal^{1/2}\,cm^{-3/2}$. Here δ_v and δ_r refer to the solubility parameters defined as (internal pressure)$^{1/2}$ and {(cohesive energy density) − (internal pressure)}$^{1/2}$. These reflect the physical interaction (repulsion, dispersion, and weak dipole-dipole interaction) and chemical interaction (hydrogen bonding), respectively.[16] However, in the heptane–acetonitrile system, the solubility parameters of acetonitrile calculated from the observed partition coefficient (12.4 $cal^{1/2}\,cm^{-3/2}$ for benzene system and 16.2 $cal^{1/2}\,cm^{-3/2}$ for hexachlorobenzene system) are larger than the solubility parameter calculated from the heat of vaporization (11.9 $cal^{1/2}\,cm^{-3/2}$). This suggests that the uncertainty of the solubility parameter of polar phase is not the only source of the discrepancy between the calculated and the observed partition coefficients. As another important source, the deviation from the simple geometric mean assumption should be examined. The deviation is taken into account by introducing a coefficient, l_{12}, into the activity equation derived from the regular solution theory:[11]

$$RT\ln a_2 = RT\left[\ln\phi_2+\ln\phi_1\left(1-\frac{V_2}{V_1}\right)\right] + V_2\phi_1^2[(\delta_1-\delta_2)^2+2l_{12}\delta_1\delta_2], \quad (8)$$

where a is activity, ϕ volume fraction, and subscript 1 and 2 refer to solvent and solute, respectively. Using the above expression, the partition coefficient Eq. 6 can be revised as:

$$\log K_D = \frac{V}{2.303RT}(\delta_a+\delta_o'-2q\delta)(\delta_a-\delta_o), \quad (9)$$

$$q = 1 - \frac{l_a\delta_a-l_o\delta_o}{\delta_a-\delta_o}.$$

Here q is equal to one if the strict geometric mean relation of $l_a=l_o=1$ or the apparent relation of $l_a\delta_a=l_o\delta_o$ holds, and otherwise q is different from one. The values of q are calculated using the observed $\log K_D$ and the available parameters for heptane–water and heptane–acetonitrile systems. The results

Table 2. Physical properties and parameters of the chlorobenzenes

No.	Solute	Chlorine number	Molar volume[a]	Dipole moment[c]	Solubility parameter	q value[e]	
						Hep/H_2O[f]	Hep/AN

5	*p*-Dichlorobenzene	2	115	0	9.8	0.92	0.88
6	1,2,3-Trichlorobenzene	3	125	2.33	10.3	0.87	0.83
7	1,2,4-Trichlorobenzene	3	125	1.26	10.3	0.86	0.81
8	1,3,5-Trichlorobenzene	3	125[b]	0.28	10.3	0.85	0.78
9	1,2,3,4-Tetrachlorobenzene	4	136[b]	1.92	10.5	0.84	0.79
10	1,2,4,5-Tetrachlorobenzene	4	136[b]	0.73	10.5	0.84	0.77
11	Pentachlorobenzene	5	146[b]	0.88	10.9	0.80	0.74
12	Hexachlorobenzene	6	156[b]	0.21	11.2	0.77	0.71

a) $cm^3\ mol^{-1}$. b) Estimated value from the relationship between molar volume and chlorine number. c) Debye. d) Calculated from the heat of vaporization. e) See Eq. 9 in the text. f) $\delta_a = 17.15\ cal^{1/2}\ cm^{-3/2}$ was used in the calculation. (Conversion factor: $1\ cal^{1/2}\ cm^{-3/2} = 2.0455\ J^{1/2}\ cm^{-3/2}$).

are listed in Table 2. The values of q are 2—30% smaller than 1.0, a result which is easily expected in simple geometric mean assumption as in Eq. 6, and decrease with increases of number of Cl atoms of solutes. This also suggests that the deviation becomes larger for larger molecule. An evaluation of l_a and l_o is difficult at the present stage, but it is probable that l_o is negative for a system composed of a large-sized solute and small-sized solvent.[11]

Equation 9 can be rearranged:

$$\log K_D = \frac{V}{2.303RT}(\delta_a^2 - \delta_o^2) + RT\left(\frac{1}{V_o} - \frac{1}{V_a}\right) - \frac{2\delta Vq}{2.303RT}(\delta_a - \delta_o). \quad (10)$$

Comparing Eq. 10 with Eq. 4, the first and the second terms in Eq. 10 are considered to refer to cavity energy and interaction energy respectively in the framework of the regular solution theory. The cavity, in this case, corresponds to the solute taking $\delta=0$ and V. Since the second term is laways negative because $\delta_a > \delta_o'$ the increase of $\log K_D$ with increase of V, observed in this study, confirmes a predominance of the cavity energy contribution.

Comparison among the Partition Coefficient of Isomers. As the partition coefficients of isomers (Cl=2,3, and 4) are compared, a slight difference among them is observed. A principal difference in physical properties of these solutes will be the difference in dipole moment, which is listed in Table 2 for each chlorobenzene.

Beveridge *et al.* derived the next equation for an electrostatic interaction energy:[17]

$$\bar{G}_{es} = -14.39\frac{\mu^2}{a^3}D\left(1+\frac{D}{3}\right) \quad (\text{kcal mol}^{-1}) \quad (11)$$

$$D = \frac{3(\varepsilon-1)}{2\varepsilon+2},$$

where ε is the dielectric constant of the solvent, μ (Debye) the dipole moment of the solute, and a(Å) the radius of solute cavity. The difference in the electrostatic interaction energy between solute–heptane and solute–water or solute–acetonitrile was calculated and compared with the partition coefficient of the solute. Figure 4 shows the correlation of the differences in $\log K_D$ between isomeric compounds of $\mu=0$ and $\mu\neq0$ with the calculated electrostatic energy difference. It is concluded from Fig. 4 that $\log K_D$ for the chlorobenzene of large dipole moment is smaller than that for a smaller dipole moment solute.

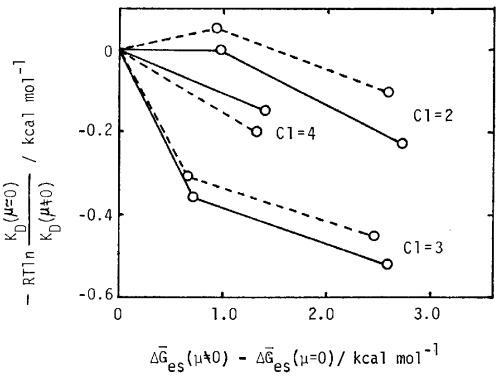

Fig. 4. Correlation between the difference in partition free energy of the isomers and the difference in electrostatic interaction energy, where $\Delta\bar{G}_{es} = \bar{G}_{es,dod} - \bar{G}_{es,polar}$.
——: Heptane–H_2O, – – –: Heptane–AN.

As a conclusion, we suggest that the partition coefficients of chlorobenzene is governed primarily by cavity formation and the difference of partition coefficient in isomers can be understood by taking into account the electrostatic interaction. More extensive study of the partition coefficient of halobenzenes is in progress, including an application of the Scaled Particle theory.[8]

Structure and Properties of Diaquabis(ethylthioacetato)copper(II), $[Cu(C_4H_7SO_2)_2(H_2O)_2]$

Takashi Ogawa, Mamoru Shimoi, and Akira Ouchi*

Department of Chemistry, College of General Education, The University of Tokyo, Komaba 3-8-1, Meguro-ku, Tokyo 153

(Received May 7, 1981)

The crystal and molecular structure of the title complex has been determined by the X-ray diffraction method. The crystal was triclinic, space group $P\bar{1}$, $a=7.554(1)$, $b=9.001(1)$, $c=5.345(1)$ Å, $\alpha=104.83(1)$, $\beta=99.20(1)$, $\gamma=71.02(1)°$, $Z=1$, $D_x=1.684(1)$, $D_m=1.69(1)$ Mg m^{-3}, μ(Mo $K\alpha$)=2.03 mm^{-1}, and the final R value was 0.030 for 1818 reflections. The molecular arrangement has a center of symmetry and has a slightly distorted octahedral configuration around the central copper(II) atom; each ethylthioacetato ligand forms a chelate ring by coordinating through a sulfur atom and a carboxyl oxygen atom, and two water molecules are also coordinated to the central metal. The solid complex is deep green, different from the diaquabis(alkylthioacetato)copper(II) complexes of the higher alkyl groups (number of C≥3), and it is likely due to the CT band caused by the strong copper–sulfur bond in the complex.

The coordination compounds of copper(II) with sulfur containing ligands are now studied very actively in relation to the model compounds of copper proteins. The (alkylthio)acetic acids** are coordinated to the central metal atom through a sulfide sulfur atom, however, their sulfur-metal bonding is not always stable. The authors have already reported the syntheses and properties[1–5] as well as the structures[6–8] of some metal alkylthioacetates. In the case of copper (II) complexes, the formation of the strong metal-sulfur bond is expected to be due to the relatively soft character of the copper(II) atom, and also to the observed relatively high stabilities of the complexes. Moreover, they are divided into three groups according to their colors; pale blue ones (the majority of them), deep green ones (the methylthio- and ethylthioacetates), and the violet isomer of the isopropylthioacetate. The complexes of each color seems to possess characteristic structures, and we had already begun to clarify their structure by the X-ray technique, and by spectroscopic methods. The structure of the violet isomer was already elucidated.[7] This paper presents the structure of a deep green complex. Although the X-ray diffraction technique was not yet applied to the pale blue complexes, due to the difficulty in obtaining the appropriate crystals, the comparison of the visible, infrared, and electron paramagnetic resonance spectroscopic data of these alkylthioacetate complexes, suggested some relations between their structures and their spectral properties.

Experimental

Synthesis of Diaquabis(ethylthioacetato)copper(II); $[Cu(C_2H_5SCH_2CO_2)_2(H_2O)_2]$. The ligand was obtained by the condensation reaction between ethyl iodide and mercaptoacetic acid in alkaline aqueous medium as shown by Larsson.[9] The copper(II) complex was obtained by reaction between the freshly obtained copper(II) hydroxide and the free acid ligand. The pure crystals were obtained when the concentrated aqueous solution of the complex was kept overnight at ambient temperature. Analyses of the complex: Found: Cu, 18.66; C, 28.66; H, 5.41%. Calcd for $CuC_8H_{18}S_2O_6$: Cu, 18.80; C, 28.44; H, 5.37%.

X-Ray Measurement. The crystals obtained were deep-green in color, and were stable in air. The crystal used for the X-ray diffraction study was reshaped into a sphere ($\phi=0.4$ mm). The crystallographic data are as follows: $CuC_8H_{18}S_2O_6$, F.W.=337.89, triclinic, space group $P\bar{1}$, $a=7.554(1)$, $b=9.001(1)$, $c=5.345(1)$ Å, $\alpha=104.83(1)$, $\beta=99.20(1)$, $\gamma=71.02(1)°$, $Z=1$, $D_x=1.684(1)$, $D_m=1.69(1)$ Mg m^{-3}, μ(Mo $K\alpha$)=2.03 mm^{-1}. The reflections within the range of $2\theta<60°$ were collected on a Philips 1100 automated four-circle diffractometer, using Mo $K\alpha$ radiation (0.7107 Å), applying the (ω-2θ) scan technique. The 1818 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction.

All the calculations were carried out on a HITAC M-200H computer at the Computer Center of The University of Tokyo using the local version of UNICS program.[10] The atomic scattering factors were taken from the tables.[11]

Structure Determination. The structure was solved by the heavy-atom method. The position of the copper atom was fixed at the origin. The position of the sulfur atom was deduced from a three dimensional Patterson map, and the other non-hydrogen atoms were successively located by Fourier syntheses; their positions and their parameters were refined by a repeated block-diagonal least squares method. Then the positions of all hydrogen atoms were obtained from a difference Fourier synthesis, and were also refined. In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value was 0.030.[12]

Other Measurements. The infrared spectra of the samples were obtained by means of a JASCO infrared spectrophotometer type 403G, using Nujol and hexachloro-1,3-butadiene mulls.

The visible absorption spectra of the samples were obtained on a Hitachi 124 spectrophotometer, and the reflectance spectra on the same instrument with the appropriate attachment, using magnesium oxide as the reference substance.

The electron paramagnetic resonance spectra of the solid sample were measured on a JEOL PE3X electron paramagnetic resonance spectrometer, at room temperature, using 2,2-diphenyl-1-picrylhydrazyl (DPPH) as the standard for the determination of the g-values.

** For the simplicity, hereafter, the parentheses in the name of this type of compounds are neglected.

Results and Discussion

The final atomic parameters are listed in Table 1,[13] the interatomic distances and the bond angles in Table 2. A perspective drawing of the complex

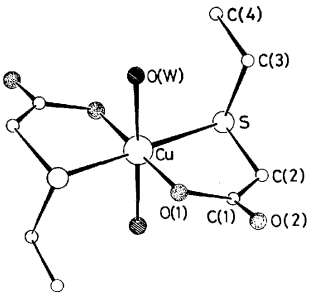

Fig. 1. A perspective drawing of the title compound with the numbering scheme of atoms.

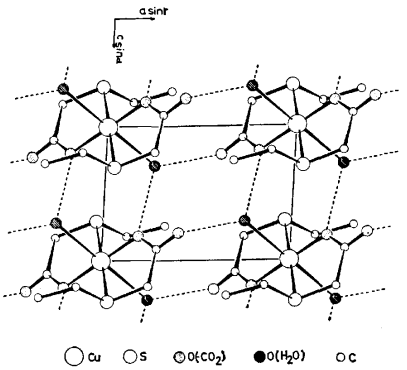

Fig. 2. Crystal packing diagram projected along b.

and the numbering scheme of atoms are shown in Fig. 1, and a projection of the structure along b in Fig. 2. The crystal consists of discrete molecules of $[Cu(C_2H_5SCH_2CO_2)_2(H_2O)_2]$ except for weak hydrogen bondings. The molecule has a center of symmetry, occupied by a copper atom. As shown in Fig. 1, and in Table 2, the central metal in this complex is in a deformed octahedral environment, elongated to both of the oxygen atoms of the coordinated waters. The ethylthioacetato ligand forms a five-membered chelate ring, being coordinated through a sulfur atom and a carboxyl oxygen atom. As shown in the previous paper,[2] the value of the magnetic moment of this complex shows no interaction between copper atoms.

The Cu–S distance is 2.381(1) Å, which is a little longer than that in the violet isomer of bis(isopropylthioacetato)copper(II) dihydrate,[7] but shorter than that of the diaquabis(methylthioacetato)cobalt(II) (2.531(1) Å).[8] The structures of some copper(II) complexes of the aliphatic ligands containing sulfide sulfur, where the sulfur atom is coordinated with the central metal, were already clarified by X-ray method.[14–22] The observed Cu–S distances for them are about 2.3—2.4 Å, and the Cu–S distance of this complex seems to be a normal one; not weak, nor very strong.

The Cu–O(1) (where O(1) is the carboxyl oxygen) is 1.916(2) Å. On the other hand, the Cu–O(W) (where O(W) is the coordinated water oxygen) is 2.457(1) Å, which is much longer than the former one. Therefore, the octahedron around the copper (II) atom was elongated to the direction of this O(W)–Cu–O(W′) axis. As the C(1)–O(1), 1.289(2) Å, is

1 G=1×10^{-4} T.

longer than C(1)–O(2), 1.227(2) Å, the carboxyl group of the ligand seems to be the covalently bonded in the chelate.

The coordinated water molecule forms hydrogen bonds both with the O(1) atom of a complex adjacent in c-axis direction, and with the O(2) atom of the adjacent complex in a-axis direction.

Some infrared spectral data for the copper(II) ethylthioacetate together with some related complexes, are shown in Table 3.

The ν(O–H) band of methylthio- and ethylthioacetates appears at about 3300—3450 cm^{-1}, while the corresponding band of the hydrated copper(II) propylthio-, and butylthioacetates appears in the lower wave number region. (Although it is not shown in the table, the higher homolog of the alkylthioacetates also have the lower wave number ν(O–H) band.) The band of the violet isomer of the isopropylthioacetate appears in the intermediate region of them. Therefore, the grouping of the complexes in color, deep-green, pale-blue, and violet, corresponds with the grouping by the wave numbers of the ν(O–H) band. The lower wave number of the band was observed also in the spectra of diaquabis(methylthioacetato)cobalt(II), where the Co–O(W) (where O(W) is the oxygen atom of the coordinated water), is 2.066 (3) Å, and it is much shorter than that of Cu–O(W) in the present complex, even considering the difference of the radii of cobalt(II) and copper(II). On the other hand, there is no clear relation between the colors and the wave numbers of the ν_{as}(COO) and ν_s(COO) bands.

The reflectance spectra of the three types of complexes, ethylthio-, propylthio-, and isopropylthioacetates of copper(II) are shown in Fig. 3. As is shown in the figure, the pale blue complex, the propylthioacetate, has a d-d band at about 718 nm. On the other hand, the isopropylthioacetate (violet isomer), as well as the present ethylthioacetate show a broad band at 500—700 nm. Although the exact analysis of the absorption pattern has not yet been carried out, at least, it is likely that a band stronger than the common d-d one overlaps the latter one in these

two cases. The ovelapping band seems to have the maximum in the 500—600 nm region, which is shorter than that of the pure d-d band. Probably this band is due to a $p\pi$-$p\pi$ back donation from copper to sulfur, as the Cu–S bands of these complexes are short enough. On the other hand, this kind of charge transfer band does not exist in the spectra of the pale blue complexes, and therefore, their Cu–S bonds are expected to be longer than the deeper colored ones.

The electron paramagnetic resonance spectra of the complexes in the powdered solid state at room temperature are shown in Fig. 4, together with their integral curves. From these results, it can be seen that diaquabis(ethylthioacetato)copper(II) as well as diaquabis(propylthioacetato)copper(II) has three different axes like copper(II) chloride dihydrate.[23] Although the features of their spectral patterns are different from each other, their integral curves resemble each other. Therefore, the difference is likely to be a quantitative one concerning their g-values, only. On the other hand, bis(isopropylthioacetato)copper(II) dihydrate has only two kinds of axes, $g_{//}$ and $g_{\perp}$, like copper(II) sulfate pentahydrate,[23] and the structure is expected to be different from the other copper(II) alkylthioacetates. Therefore, the pale-blue copper(II) alkylthioacetates are expected to have a coordination structure similar to that of the green ones.

The authors wish to thank Professor Yoichi Iitaka of the Faculty of Pharmaceutical Sciences, The University of Tokyo, for the measurement of the intensities. The measurements of electron paramagnetic resonance spectra by Professor Ryo Hirasawa of our College are gratefully acknowledged. We are also deeply obliged to Professor Kunio Nakano, Faculty of Science, Rikkyo University, concerning the integration of the EPR spectral curves and the analysis of the data.

The Reduction of Cobalt(III) Complexes by Ascorbic Acid. II.[1] The Kinetics and Mechanisms of the Reactions of Diaqua and Aquahydroxo Macrocyclic N_4 Complexes

Keiichi Tsukahara,* Tatsuo Izumitani, and Yasuo Yamamoto
Department of Chemistry, Faculty of Science, Shimane University, Nishikawatsu-cho, Matsue 690
(Received June 3, 1981)

The kinetics of the reductions of several macrocyclic N_4 cobalt(III) complexes by L-ascorbic acid (H_2A) have been studied at 25.0 °C, at an ionic strength of 0.10 mol dm^{-3} ($LiClO_4$), and over the pH range from 1.64 to 3.47. The second-order rate constants in dm^3 mol^{-1} s^{-1} are 3.4 ± 0.6 (Me_6[14]4,11-dieneN$_4$),† $(4.2\pm0.2)\times10$ (Me_4[14]tetraeneN$_4$), and $(4.2\pm0.1)\times10$ (*ms*-Me_6[14]aneN$_4$) for the reactions of $[Co(N_4)(H_2O)_2]^{3+}$ with HA^- ions and $(1.1\pm0.1)\times10^2$ (Me_6[14]4,11-dieneN$_4$), $(1.3\pm0.1)\times10^3$ (Me_4[14]tetraeneN$_4$), $(5.5\pm0.1)\times10$ (*ms*-Me_6[14]aneN$_4$), and $(2.9\pm0.6)\times10$ ([14]aneN$_4$) for the reactions of $[Co(OH)(N_4)(H_2O)]^{2+}$ with HA^- ions. The mechanisms of these reactions are discussed, and it is concluded that the lack of saturation of macrocyclic ligands facilitates the electron-transfer reaction between cobalt(III) and ascorbic acid.

L-Ascorbic acid plays a significant role in biological redox systems.[2] Kinetic studies of the ascorbate reductions of metal complexes may be useful in understanding the role of ascorbic acid.

The reactions of metal complexes with ascorbic acid, as with the other organic reducing agents, are classified into three categories:[3] (i) outer-sphere electron transfer, (ii) inner-sphere electron transfer, which occurs subsequent to the substitution of a ligand for ascorbate, and (iii) a bridging mechanism in which ascorbate is bound at a ligand of the complex prior to electron transfer.

In a previous paper we reported the outer-sphere electron-transfer reactions of cobalt(III) complexes ligating 1,10-phenanthroline or 2,2′-bipyridine with ascorbic acid.[1] Cobalt(III) tetraazamacrocyclic and porphyrin complexes have a soft character, and it is expected that ascorbic acid, which is a π donor, interacts with these complexes; consequently, Mechanism (ii) or Mechanism (iii) may be possible. In this paper we will report on the ascorbate reductions of diaqua and aquahydroxo cobalt(III) complexes containing tetraazamacrocycles, Me_4[14]tetraeneN$_4$, Me_6-[14]4,11-dieneN$_4$, *ms*-Me_6[14]aneN$_4$, and [14]aneN$_4$ (Fig. 1), whose cobalt(II) complexes are low-spin species in an aqueous solution.

Experimental

Reagents. The complexes, $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2](ClO_4)_3$,[4] $[Co(Me_4[14]tetraeneN_4)(H_2O)_2](ClO_4)_3\cdot2.5H_2O$,[5] $[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2](ClO_4)_3$,[4,6] and $[Co([14]aneN_4)(H_2O)_2](ClO_4)_3$,[7] were prepared as reported in the literature. All the complexes are *trans* isomers. The L-ascorbic acid and sodium L-ascorbate were supplied by Wako Pure Chemical Industries. The $LiClO_4\cdot3H_2O$ was obtained according to the procedure reported previously.[8] All the solutions used for the measurements were prepared using water obtained by the distillation of alkaline permanganate solutions. A solution of ascorbic acid was freshly prepared under a nitrogen atmosphere which had been scrubbed twice with alkaline potassium pyrogallate.

Kinetic Measurements. All the measurements were made under a nitrogen atmosphere. The reaction was initiated by injecting a solution of ascorbic acid into a solution containing the required amounts of a complex and lithium perchlorate. The change in the absorbance with the time was followed with a Hitachi 200-20 spectrophotometer. The wavelengths used for the measurements were 320 nm ($[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$), 340 nm ($[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$), 500 nm ($[Co([14]aneN_4)(H_2O)_2]^{3+}$), and 540 nm ($[Co(Me_4[14]tetraeneN_4)(H_2O)_2]^{3+}$). In order to ensure a pseudo-first order condition, ascorbic acid was used in at least a twentyfold excess over the cobalt(III) complexes. In an aqueous solution of $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$ ions[9] or $[Co(Me_4[14]tetraeneN_4)(H_2O)_2]^{3+}$ ions, a dimerization was gradually observed. In order to minimize this dimerization, the concentrations of the complexes were restricted below 4×10^{-4} mol dm^{-3} and the solution was used within 20 min after preparation.

The temperature was controlled at 25.0 ± 0.1 °C, and the ionic strength (I) was adjusted to 0.10 mol dm^{-3} with lithium perchlorate. The pH of the solution was adjusted with sodium ascorbate or perchloric acid and was measured on a Hitachi-Horiba F-7 pH meter with a 3.33 mol dm^{-3} NaCl solution as a junction. The hydrogen-ion concentrations were computed from the pH, using a value of 0.83 for the activity coefficient of H^+.[10]

† Abbreviations: Me_6[14]4,11-dieneN$_4$ = 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene, Me_4-[14]tetraeneN$_4$ = 2,3,9,10-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,3,8,10-tetraene, *ms*-Me_6[14]aneN$_4$ = *meso*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane, [14]aneN$_4$ = 1,4,8,11-tetraazacyclotetradecane.

Stoichiometric Determinations. The stoichiometry of the reaction of $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$ with ascorbic acid was determined spectrophotometrically. The reaction was initiated by mixing solutions of the complex and of ascorbic acid under a nitrogen atmosphere ($[Co(III)]_0 = 1.20\times10^{-2}$ mol dm^{-3} and $[H_2A]_0 = (0.136\text{–}1.32)\times10^{-2}$ mol dm^{-3}). Then the reaction was monitored with a Shimadzu UV 140-02 spectrophotometer until no spectral changes were observed. After the hydrogen-ion concentrations of the solutions had been adjusted to 0.10 mol dm^{-3} with perchloric acid under a nitrogen atmosphere, the absorbance at 445 nm (absorption maximum of Co(II) complex) was recorded.

Acid-dissociation Constants. The acid-dissociation constants of the diaqua ligands of $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$ were determined by pH titrations with a standard sodium hydroxide solution at 25 °C and $I=0.1$ mol dm^{-3} ($LiClO_4$) under a nitrogen atmosphere. The pK values thus obtained were 3.93 ± 0.02 and 8.6 ± 0.1, compared with the literature values of 4.02 ± 0.01 and 8.2 ± 0.1 at 25 °C and $I=1.0$ mol dm^{-3} ($NaClO_4$).[11] The acid-dissociation constants of the diaqua ligands of the other complexes and of ascorbic acid were used of the literature values for the analysis of the rate constants without any correction of the ionic strength: the pK values at 25 °C are 3.5 ± 0.1 and 6.5 ± 0.1 ($I=0.50$ mol dm^{-3}) for $[Co(Me_4[14]tetraeneN_4)(H_2O)_2]^{3+}$,[12] 2.7 ± 0.05 and 6.4 ± 0.05 ($I=1.0$ mol dm^{-3}) for $[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$,[11] 2.9 ± 0.1 and 7.2 ± 0.1 ($I=0.50$ mol dm^{-3}) for $[Co([14]aneN_4)(H_2O)_2]^{3+}$,[13] and 4.04 and 11.3 ($I=0.10$ mol dm^{-3}) for H_2A.[14]

Results

The Reactions of $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$, $[Co(Me_4[14]tetraeneN_4)(H_2O)_2]^{3+}$, and $[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$ with Ascorbic Acid. Spectrophotometric titrations confirm to the following stoichiometry for the reaction of $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$ with ascorbic acid ($[Co(III)]/[H_2A]=1.96\pm0.04$):

$$2Co(III) + H_2A = 2Co(II) + \text{dehydroascorbic acid}. \quad (1)$$

The spectral changes observed during the reaction of $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$ with ascorbic acid gave three isosbestic points over the range from 370 to 650 nm (Fig. 2). The spectrum at infinity corresponds to that of $[Co^{II}(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{2+}$.[15] In the reactions of $[Co(Me_4[14]tetraeneN_4)(H_2O)_2]^{3+}$ and $[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$, the spectra at infinity also agree with those of the corresponding cobalt(II) complexes.[15,16]

The kinetics of the title reactions were studied in various concentrations of ascorbic acid ($(0.380\text{–}2.10)\times10^{-2}$ mol dm^{-3}), cobalt(III) ($(1.42\text{–}3.41)\times10^{-4}$ mol dm^{-3}), and hydrogen ions (4.08×10^{-4}–1.19×10^{-2} mol dm^{-3}). The plots of $-\ln(A_t - A_\infty)$ *vs.* time were linear for at least 90% completion (A_t and A_∞ represent the absorbance at time t and infinity respectively). The observed first-order rate constants (k_{obsd}) obtained from the slope of this straight line were also linearly dependent on the initial concentrations of ascorbic acid (Fig. 3). Thus, the rate law was described as follows:

$$-\frac{1}{2}d[Co(III)]/dt = k[Co(III)][H_2A]_0. \quad (2)$$

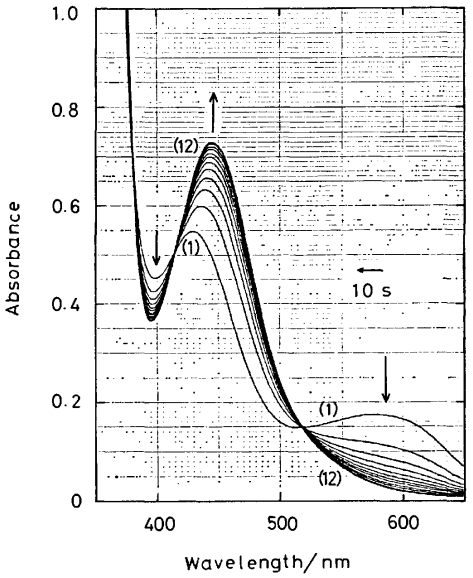

Fig. 2. Spectral changes during the reaction of $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$ with ascorbic acid at $[H_2A]_0=1.00\times10^{-1}$ mol dm^{-3}, $[Co(III)]_0=8.40\times10^{-3}$ mol dm^{-3}, pH=2.60, 25.0 °C, and $I=0.50$ mol dm^{-3}: (1) 15 s; (2) 3 min; (3) 5 min 40 s; (4) 8 min 20 s; (5) 11 min 10 s; (6) 14 min; (7) 17 min; (8) 20 min; (9) 25 min; (10) 30 min; (11) 40 min; (12) 50 min after the reaction. The times given are for the start of scan at 650 nm.

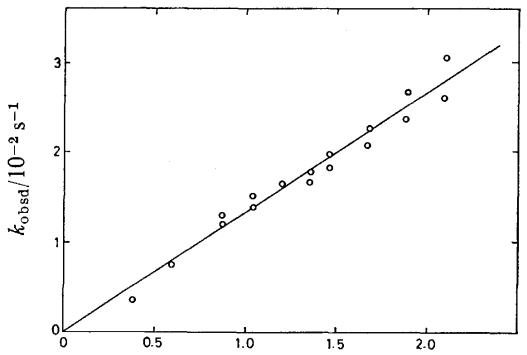

Fig. 3. Plots of k_{obsd} *vs.* $[H_2A]_0$ for the $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$–ascorbic acid system at $[Co(III)]_0=2.34\times10^{-4}$ mol dm^{-3}, pH=3.12, 25.0 °C, and $I=0.10$ mol dm^{-3} ($LiClO_4$).

The second-order rate constants obtained from $k_{obsd}/[H_2A]_0$ increased with a decrease in the acidity (Fig. 4). The dependence of k on the hydrogen-ion concentrations may be explained by Scheme 1, considering that cobalt(III) complexes are not reduced by H_2A species.[1] The above mechanism leads to Eq. 3 for the second-order rate constant:

$$k = \{k_1K_{a1} + (k_0K_{a1}K_{a2} + k_1^{OH}K_1K_{a1})[H^+]^{-1} + k_0^{OH}K_1K_{a1}K_{a2} + k_1^{(OH)_2}K_1K_2K_{a1})[H^+]^{-2} + k_0^{(OH)_2}K_1K_2K_{a1}K_{a2}[H^+]^{-3}\}/\alpha(H)\beta(H)[H^+], \quad (3)$$

where the symbols are abbreviated as in Scheme 1 and where $\alpha(H)=1+K_{a1}[H^+]^{-1}+K_{a1}K_{a2}[H^+]^{-2}$ and $\beta(H)=1+K_1[H^+]^{-1}+K_1K_2[H^+]^{-2}$. The plots of the values of $k\alpha(H)\beta(H)[H^+]$ *vs.* $[H^+]^{-1}$ gave a straight

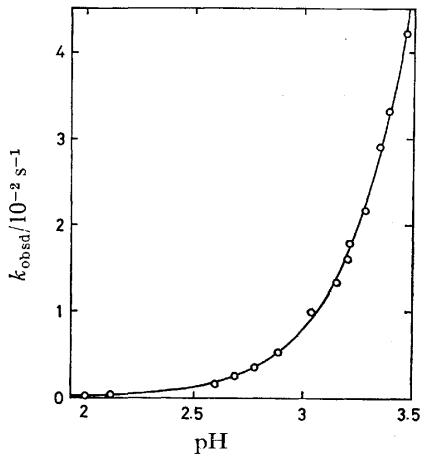

Fig. 4. Plots of k_{obsd} *vs.* pH for the $[Co(Me_6[14]4,11\text{-dieneN}_4)(H_2O)_2]^{3+}$–ascorbic acid system at $[H_2A]_0 = 1.00\times10^{-2}$ mol dm^{-3}, $[Co(III)]_0 = (2.30—3.41)\times10^{-4}$ mol dm^{-3}, 25.0 °C, and $I=0.10$ mol dm^{-3} ($LiClO_4$).

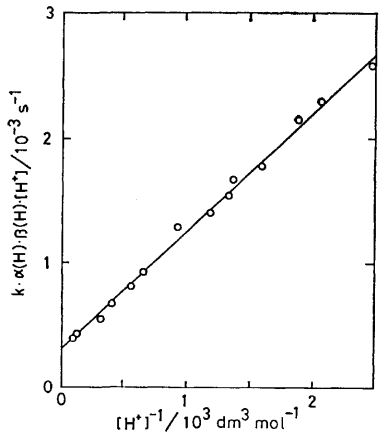

Fig. 5. Plots of $k\alpha(H)\beta(H)[H^+]$ *vs.* $[H^+]^{-1}$ for the $[Co(Me_6[14]4,11\text{-dieneN}_4)(H_2O)_2]^{3+}$–ascorbic acid system.

line (Fig. 5), showing that the k_0^{OH}, $k_1^{(OH)_2}$, and $k_0^{(OH)_2}$ paths do not contribute under the present experimental conditions. The values of k_1K_{a1} and of $(k_0K_{a1}K_{a2}+k_1^{OH}K_1K_{a1})$ are obtained from the intercept and the slope of this straight line respectively. In order to be comparable to the k_1^{OH} term, k_0 must exceed 10^{10} dm^3 mol^{-1} s^{-1}, which is in excess of the highest previously reported second-order rate constants. Therefore, the k_0 term does not contribute to the

present reaction ($k_0K_{a1}K_{a2} \ll k_1^{OH}K_1K_{a1}$). The second-order rate constants, k_1 and k_1^{OH}, were obtained by the use of the values of K_1, K_{a1}, and K_{a2}. The same analysis was also employed for the $Me_4[14]tetraeneN_4$ and the $ms\text{-}Me_6[14]aneN_4$ systems (Fig. 6). The values of k_1 and k_1^{OH} are listed in Table 1.

The Reactions of $[Co([14]aneN_4)(H_2O)_2]^{3+}$ with Ascorbic Acid. Figure 7 shows an example of the change in the absorbance at 500 nm against the time and of the consecutive reaction treatment for the evaluation of the pseudo-first-order rate constants, k_1^{obsd} and k_2^{obsd}, for the first and second stages of the title reaction.[17] The absorption spectra at infinity in the second stage at pH>3 show those of the $[Co^{II}([14]aneN_4)(H_2O)_2]^{2+}$ ion, but not at pH<2. The situation for the biphasic kinetics under the pseudo-first-order conditions can be represented by the following sequence:

$$A \xrightarrow{k_1^{obsd}} B \xrightarrow{k_2^{obsd}} C. \quad (4)$$

Equation 5 describes the change in the absorbance with the time, where ε_A, ε_B, and ε_C are the molar ab-

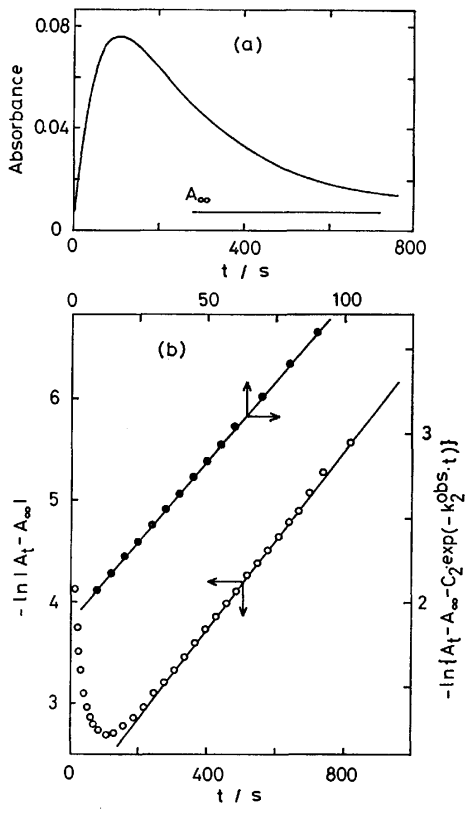

Fig. 7. Reaction of $[Co([14]aneN_4)(H_2O)_2]^{3+}$ with ascorbic acid at $[H_2A]_0=1.04\times10^{-2}$ mol dm^{-3}, $[Co(III)]_0=1.70\times10^{-4}$ mol dm^{-3}, pH=3.14, 25.0 °C, and $I=0.10$ mol dm^{-3} ($LiClO_4$) followed at 500 nm: (a) absorbance-time profile; (b) resolution of the kinetic data into its two component exponentials.

sorption coefficients of the species and where $[A]_0$ is the initial concentration of A:

$$A_t - A_\infty = C_1 \exp(-k_1^{obsd}t) + C_2 \exp(-k_2^{obsd}t), \quad (5)$$

$$C_1 = \frac{[A]_0\{k_1^{obsd}(\varepsilon_A-\varepsilon_B)-k_2^{obsd}(\varepsilon_A-\varepsilon_C)\}}{k_1^{obsd}-k_2^{obsd}}, \quad (6)$$

$$C_2 = \frac{[A]_0 k_1^{obsd}(\varepsilon_B-\varepsilon_C)}{k_1^{obsd}-k_2^{obsd}}. \quad (7)$$

The second-stage rate constant, k_2^{obsd}, is given by the slope of the linear portion observed by means of a plot of $-\ln(A_t-A_\infty)$ *vs.* t:

$$-\ln(A_t-A_\infty) = k_2^{obsd}t - \ln C_2. \quad (8)$$

A plot of the left-hand side of Eq. 9 against the time gives the first-stage rate constant, k_1^{obsd}, as a slope:

$$-\ln\{A_t-A_\infty-C_2\exp(-k_2^{obsd}t)\} = k_1^{obsd}t - \ln C_1. \quad (9)$$

The values of k_1^{obsd} and k_2^{obsd} at various concentrations of ascorbic acid and hydrogen ions are listed in Table 2. It is found that $k_1^{obsd}=a[H_2A]_0$ and that $k_2^{obsd}=b+c[H_2A]_0$, where the constants a, b, and c depend on the hydrogen-ion concentrations.

The reaction products were examined by the use of an SP-Sephadex C-25 column (Na^+ form). The reaction was initiated by mixing solutions of $[Co([14]aneN_4)(H_2O)_2]^{3+}$ ($(1.0-2.0)\times10^{-2}$ mol dm^{-3}) and of H_2A (1.0×10^{-2} mol dm^{-3}) at pH 4 and 25.0 °C under a nitrogen gas, an argon gas, or air. The reaction was monitored with a Hitachi 200-20 spectrophotometer. The first increase in absorption was observed over the range from 400 to 700 nm in each case ($\lambda_{max}\approx440$ nm and $\lambda_{sh}\approx550$ nm); thereafter, the absorbance decreased. After the first-stage reaction had been completed, the solution was poured into a Sephadex column and three species were separated with a 0.1 mol dm^{-3} $NaClO_4$ solution–violet, violet, and brown from the bottom to the top of the column. The first violet band turned green when treated with a 0.2 mol dm^{-3} $HClO_4$ solution, and the green species may have a 2+ charge (λ_{max} 620±5 nm, λ_{max} 525±5 nm, and λ_{sh} 420 nm). It has not yet been identified. The second violet band also turned green when treated with a 0.2 mol dm^{-3} $HClO_4$ solution; the green species was identified as $[Co([14]aneN_4)(H_2O)_2]^{3+}$. The last brown species have a 4+ charge and changed to $[Co([14]aneN_4)(H_2O)_2]^{3+}$ when treated with a 0.4 mol dm^{-3} $HClO_4$ solution. The brown species was identified as $[\{(H_2O)Co([14]aneN_4)\}_2O_2]^{4+}$.[18] A $[Co^{II}([14]aneN_4)(H_2O)_2]^{2+}$ ion is very sensitive to a trace of oxygen;[18-20] therefore, it is concluded that the biphasic behavior in the present system is ascribable to a trace of oxygen in a nitrogen or an argon gas. Accordingly, the present reaction is considered to be represented as follows:

$$[Co([14]aneN_4)(H_2O)_2]^{3+} \text{ or } [Co(OH)([14]aneN_4)(H_2O)]^{2+} + HA^- \longrightarrow [Co([14]aneN_4)(H_2O)_2]^{2+} + HA\cdot \quad (10)$$

$$2[Co([14]aneN_4)(H_2O)_2]^{2+} + O_2 \longrightarrow [\{(H_2O)Co([14]aneN_4)\}_2O_2]^{4+} \quad (11)$$

($k=4\times10^9$ dm^6 mol^{-2} s^{-1} at 25 °C[20])

$$[\{(H_2O)Co([14]aneN_4)\}_2O_2]^{4+} + HA^- \xrightarrow{\text{reduction}} \quad (12a)$$

$$[\{(H_2O)Co([14]aneN_4)\}_2O_2]^{4+} + H^+ \xrightarrow{\text{decomposition}} \quad (12b)$$

The first-stage reaction (Eq. 10) was only analyzed in detail on the basis of Scheme 1. The plot of $k\alpha(H)\beta(H)[H^+]$ *vs.* $[H^+]^{-1}$ ($k=k_1^{obsd}/[H_2A]_0$) gave a straight line, with an intercept of nearly zero (Fig.

Table 2. Observed rate constants of the first and the second stages for the $[Co([14]aneN_4)(H_2O)_2]^{3+}$-ascorbic acid system at 25.0 °C and $I=0.10$ mol dm^{-3} ($LiClO_4$)

8). The second-order rate constant, k_1^{OH}, is obtained from the slope of this straight line.

Discussion

The rate constants of the reactions of $[Co(N_4)(H_2O)_2]^{3+}$ and $[Co(OH)(N_4)(H_2O)]^{2+}$ with HA^- ions are summarized in Table 3, along with the data for the other reducing agents.

The Reactions of the $[Co(N_4)(H_2O)_2]^{3+}$ *Ions.* The trend in the relative rates of the reactions is Me_4-tetraeneN$_4$ ≃ *ms*-Me_6[14]aneN$_4$ > Me_6[14]4,11-dieneN$_4$ ≫ [14]aneN$_4$, similar to that for a $[Ru(NH_3)_6]^{2+}$ or $[V(H_2O)_6]^{2+}$ reduction, which proceeds by means of an outer-sphere mechanism.[5,9] As the water-exchange reactions of the $[Co(N_4)(H_2O)_2]^{3+}$ species may be very slow,[21] the water molecules of the $[Co(N_4)(H_2O)_2]^{3+}$ ions may not be replaced by the HA^- ions prior to electron transfer. Therefore, the reactions of the diaqua complexes are considered to proceed by an outer-sphere electron-transfer mechanism.

The rate constants of the reactions of $[Co(N_4)(H_2O)_2]^{3+}$ with HA^- are calculated on the basis of the Marcus cross relationships[22] in the way reported previously:[1]

$$\Delta G^*_{12} = \lambda(1+\Delta G^{\circ\prime}_{12}/\lambda)^2/4, \quad (13)$$

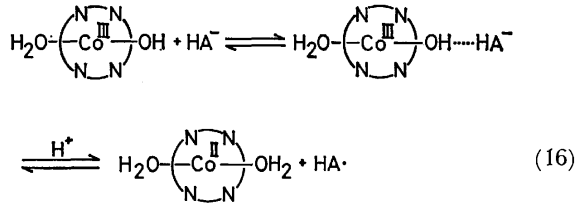
$$k_{12} = Z\exp(-\Delta G^*_{12}/RT), \quad (14)$$

$$\lambda = 2(\Delta G^*_{11}+\Delta G^*_{22}), \quad (15)$$

where Z is the collision frequency in solution (10^{11} dm³ mol^{-1} s^{-1}), where ΔG^*_{11} and ΔG^*_{22} refer to the self-exchange reactions of the reagents, and where $\Delta G^{\circ\prime}_{12}$ is the free-energy change in the reactions. The calculated rate constants are listed in Table 4. All the observed rate constants exceed the calculated ones by a factor of 10—10^2. This may be ascribable, at least in part, to the work terms neglected or to the small effect of the bond-length changes from Co^{III}–OH_2 to Co^{II}–OH_2.[25] The latter is considered to be a significant factor in the self-exchange reaction of the cobalt(III)/(II) couple.[25]

The Reactions of the $[Co(OH)(N_4)(H_2O)]^{2+}$ *Ions.*

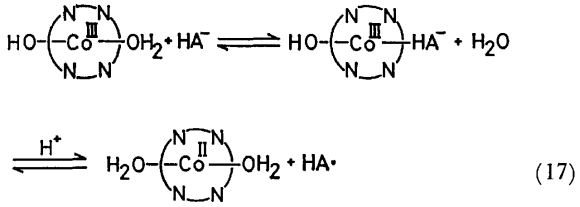
The rate constants of these reactions tend to decrease in the following order: $Me_4[14]tetraeneN_4$ > $Me_6[14]4,11\text{-}dieneN_4$ > *ms*-$Me_6[14]aneN_4$ > $[14]aneN_4$; the ratios of k_1^{OH}/k_1 are 31 for $Me_4[14]tetraeneN_4$, 32 for $Me_6[14]4,11\text{-}dieneN_4$, 1.3 for *ms*-$Me_6[14]aneN_4$, and $\gg 29$ for $[14]aneN_4$. These results are in contrast to those of typical outer-sphere electron-transfer reactions; for example, $k_1 > k_1^{OH}$ for a cobalt(III) porphyrin–dithionite system.[26] It is suggested that the reactions of $[Co(OH)(N_4)(H_2O)]^{2+}$ with HA^- proceed *via* an OH-bridged mechanism:



(16)

The trend in the relative rate of this reaction corresponds to the extent of the lack of saturation of the macrocyclic ligands. As the polarizability of the central cobalt(III) ion is expected to be enhanced with an increase in the extent of electronic delocalization between the cobalt(III) ion and the macrocyclic ligand, an electron of ascorbic acid, which is a π-donor, may be more easily transferred to the cobalt (III) moiety, which has an unsaturated ligand. The small difference in reactivity between $Me_6[14]4,11\text{-}dieneN_4$ and *ms*-$Me_6[14]aneN_4$ is probably due to the steric hindrance of methyl groups.

These reactivities can also be explained by an alternative pathway which is a substitution-limited inner-sphere mechanism:



(17)

It is expected that the OH^- ligand accelerates the dissociation of the water molecule in the trans position; in fact, the dissociation of the water molecule of $[Co(OH)([14]aneN_4)(H_2O)]^{2+}$ is not slow ($k_d = (1.4\pm0.3)\times10^{-2}\ s^{-1}$ at 25 °C and I=0.1 mol dm^{-3} [21]). Studies of the kinetics of the water displacement of these macrocyclic complexes are in progress in order to establish the mechanism of the reactions of $[Co(OH)(N_4)(H_2O)]^{2+}$ with ascorbic acid.

(Received June 8, 1981)

The title paramagnetic complexes, $[Co(5\text{-}NOsal)(NH_3)_4]X_2 \cdot nH_2O$ (X_2=Cl(NO_3), $Cl_2 \cdot HCl$, and Cl_2), all brown in color, have been isolated and characterized by analytical, spectroscopic, and magnetic methods. The effective magnetic moments of the complexes are 1.6—1.8 BM, and the absorption spectra have two peaks, at 387 and 518 nm. In the XPS of the complex, the cobalt 2p peaks have satellites, and the peak of the nitrogen 1s could be deconvoluted to that of NH_3 nitrogen at 400.2 eV and to that of NO nitrogen at 402.2 eV. This binding energy of the NO nitrogen of the complex is different from that (405.6 eV) of the NO_2 nitrogen of the green Paramagnetic tetraammine(5-nitrosalicylato)cobalt(III) complexes, $[Co(5\text{-}NO_2sal)(NH_3)_4]X_2$, and establishes the difference between these two series of complexes.

In previous papers, we reported several green paramagnetic amine(5-nitrosalicylato)cobalt(III) complexes,[2-7] $[Co(5\text{-}NO_2sal)L]^{2+}$ (L: $(NH_3)_4$, $(en)_2$, $(bpy)_2$, trien), which are prepared from 60% nitric acid and the corresponding diamagnetic amine(salicylato)cobalt(III) complexes, $[Co(sal)L]Cl \cdot nH_2O$.[8,9] Gillard *et al.*[10,11] claimed, however, that the green compounds prepared in this way contain the 5-nitrososalicylato ligand rather than the 5-nitrosalicylato ligand, and the problem has so far remained unsolved. We have, though, recently been able to exclude this latter possibility by isolating a true tetraammine-(5-nitrososalicylato)cobalt(III) complexes as $[Co(5\text{-}NOsal)(NH_3)_4]X_2$, which is brown, paramagnetic, and is clearly distinguished from the green paramagnetic tetraammine(5-nitrosalicylato)cobalt(III) complexes, $[Co(5\text{-}NO_2sal)(NH_3)_4]X_2$, especially by the N ls peaks in the X-ray photoelectron spectra.

Results and Discussion

By the digestion of ammoniacal cobalt(III) chloride with 5-nitrososalicylic acid and the subsequent treatment of the precipitated substance with 60% nitric acid, brown complexes with the constitution $[Co(5\text{-}NOsal)(NH_3)_4]X_2 \cdot nH_2O$ (**1**) (X_2=Cl·(NO_3)·$2H_2O$ (**1a**), $Cl_2 \cdot H_2O \cdot HCl$ (**1b**), and $Cl_2 \cdot H_2O$ (**1c**); *cf.* Experimental sections) were obtained. They are soluble in water, nitric acid, and hydrochloric acid, but are insoluble in most organic solvents. The magnetic susceptibility obeyed the Curie-Weiss law, with effective magnetic moments of 1.6—1.8 BM, suggesting the presence of one unpaired electron.

The formula conforms to the quadrivalence of cobalt, while the rocking frequency of ligand ammonia was observed at around 830 cm^{-1} in the IR spectrum, which is within the range of those of Co(III) ammine complexes.[12,14] This, like the behavior to be described below, is similar to that of the green paramagnetic tetraammine(5-nitrosalicylato)cobalt(III) complex,[5] $[Co(5\text{-}NO_2sal)(NH_3)_4]X_2$ (**2**), reported previously. Thus, in both complexes, only the proton signals of the ammine ligands appeared in the ^1H NMR spectra in 65% DNO_3, and no proton signals of the substituted salicylato ligand were observable. The ^{13}C NMR spectrum did not show the expected signals because of paramagnetism. Also, the cobalt 2p peaks of XPS of **1** have satellites and have a somewhat greater FWHM (2.6 eV for Co $2p_{3/2}$ at 220 K), as is shown in Fig. 1, and some carbon atoms (estimated to be 17.8% of the total carbon in **1** and 22.2% thereof in **2**)[7] have a higher ls binding energy (289 eV, sh), as is shown in Fig. 2. This behavior[7] suggests that, in **1** also, the unpaired electron spends its time partly on the cobalt atom and partly on the ring of the substituted salicylato ligand.

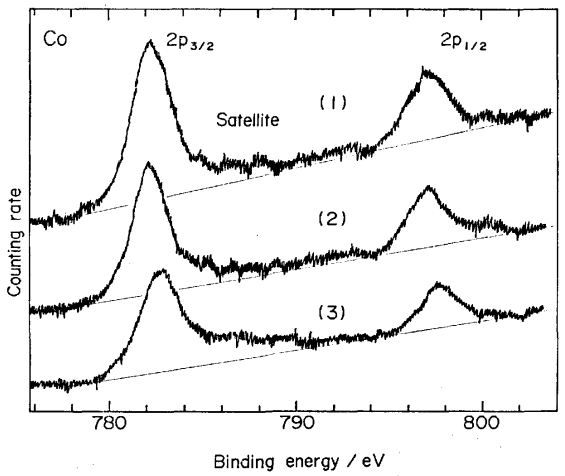

Fig. 1. The XPS in the Co_{2p} region at 220 K of **1b**, **2**, and **3** complexes.
(1): $[Co(5\text{-}NOsal)(NH_3)_4]Cl_2 \cdot H_2O \cdot HCl$, (2): $[Co(5\text{-}NO_2sal)(NH_3)_4]Cl(NO_3) \cdot 3H_2O$, (3): $[Co(5\text{-}NOsal)(NH_3)_4]Cl$.

A clear distinction between **1** and **2** was found in the XPS N ls spectra (Fig. 3): in the former, the N ls peak could be deconvoluted to that of NH_3 at 399.5 and 400.2 eV and an NO N ls peak at 402.0 eV, whereas in the latter, deconvolution gave an NH_3 N ls peak at 400.2 eV and an NO_2 N ls peak at 405.6 eV. In the ^1H NMR spectra, the proton signals of the coor-

dinated ammine ligands of **1** split into three with the intensity ratio of 1:2:1, while those of **2**[5] split into two with the intensity ratio of 2:2. The chemical shift (δNH_3 at 2.7 ppm) of ammine protons in a position trans[5] to the carboxyl oxygen of the 5-nitrososalicylato ligand in **1** was at a higher field than that (3.76 ppm) of **2**. Another point of difference was found in the visible and UV absorption spectra reflecting their color differences.[2]

Paramagnetic tetraammine(5-nitrososalicylato)cobalt(III) complexes of another type, $[Co(5\text{-}NOsal)(NH_3)_4]Cl$ (**3**), has been isolated from the reaction mixture as a much less soluble minor component (*cf.* Experimental section). The formula shows that this compound has an oxidation state less by unity than that of the **1** complexes; it was at first thought to be a simple Co(III) complex. However, the measurement of the magnetic susceptibility of the complex in a solid state from 77.4 K—r.t. gave an effective magnetic moment of 2.84 BM, suggesting the presence of two unpaired electrons, and the cobalt 2p peaks of the XPS have strong satellites, as is shown in Fig. 1. Thus, the compound can be regarded as a sort of biradical complex, two electrons being accomodated in a molecular orbital formed from the ligand orbital and the Co-e_g orbital. The ^1H NMR spectrum of **3** in 11 mol dm^{-3} D_2SO_4 at room temperature showed two singlets of ammine ligands and a multiplet of the 5-nitrososalicylato ligand in the integral ratio of 6:6:3, as is shown in Table 1. The appearance of the latter seems to suggest the absence of any appreciable spin density on the 5-nitrososalicylato ligand in solution, making a marked contrast to the behavior of **1** and **2**. An ESR study which is now going on is expected to give further information as to the electronic state of the complex.

The data of various physicochemical measurements of **1**—**3** are collected in Table 1.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 apparatus (JEOL) for ^{13}C NMR and with an R-40 apparatus (Hitachi) for ^1H NMR. The IR spectra were recorded on potassium bromide disks with an IR-27G apparatus (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The magnetic susceptibilities were measured by the Faraday's method using a magnetic balance (Shimadzu) from liq. N_2 to r.t. The XPS were obtained by irradiating the compounds with Mg $K\alpha$ X-rays (120 W) in a vacuum at a pressure of less than 3×10^{-7} Pa and at around 220 K.[7] The instrument used was a VG ESCA 3 electron spectrometer.

Preparation of 5-Nitrososalicyclic Acid. 5-Nitrososalicyclic acid of a green color was prepared by Gulinov's method.[15] The absorption spectrum of 5-nitrososalicylic acid in methanol has three peaks, at 268, 348, and 710 nm. The ^1H NMR spectrum of 5-nitrososalicylic acid in methanol-d_4 is different from that of 5-nitrosalicylic acid, as is shown in Table 1.

*Preparation of Complex. Tetraammine(5-nitrososalicylato)cobalt(III) Chloride Nitrate Dihydrate (**1a**).* A 28% ammonia solution (9.6 cm^3) was added to an aqueous solution (12.0 cm^3) of $CoCl_2 \cdot 6H_2O$ (5.71 g, 24.00 mmol). After the mixture has been stirred at room temperature, about 6.4 cm^3 of a 20% hydrogen peroxide solution was slowly added to the solution. 5-Nitrososalicylic acid (4 g, 24.00 mmol) was then added to the solution at 50 °C, and the mixture was concentrated at 60 °C. The precipitate (**A**) thus obtained was filtered off, washed with water, and dried. Yield: 6.88 g. Four cubic centimeters of 60% nitric acid were added to 2 g of **A**. Heat was evolved. The cooled

solution was filtered with a glass filter (G 4), and the filtrate was added to ethanol. The brown substance thus separated out was filtered with a glass filter (G 3), washed with ethanol, and dried in a vacuum desiccator. This complex is slightly unstable in nitric acid. Yield: 1.1 g. Found: C, 19.95; H, 4.73; Cl, 8.37%. Calcd for $CoC_7H_{19}N_6O_9Cl$ (MW 425.65) C, 19.75; H, 4.50; Cl, 8.33%. Dec≈172 °C.

*Tetraammine(5-nitrososalicylato)cobalt(III) Dichloride Hydrate Hydrogen Chloride (**1b**).* Two milliliters of 36% hydrochloric acid were added to 1 g (2.35 mmol) of the above complex (**1a**), the brown solution was filtered with a glass filter (G 4), and the filtrate was added to ethanol. The brown complex thus precipitated was filtered with a glass filter (G 3), washed with ethanol, and dried in a silica gel desiccator. Yield: 0.65 g. (66.2%) Found: C, 19.86; H, 4.55; Cl, 24.23%. Calcd for $CoC_7H_{18}N_5O_5Cl_3$ (MW 417.54) C, 20.13; H, 4.35; Cl, 25.47%. Dec≈182 °C.

*Tetraammine(5-nitrososalicylato)cobalt(III) Dichloride Hydrate (**1c**).* This complex was formed when Complex **1b** was dried in a vaccum desiccator over potassium hydroxide. Found: C, 22.49; H, 4.34; Cl, 19.78%. Calcd for $CoC_7H_{17}N_5O_5Cl_2$ (MW 381.08) C, 22.06; H, 4.50; Cl, 18.61%. Dec. ≈180 °C.

*Tetraammine(5-nitrososalicylato)cobalt(III) Monochloride (**3**).* Five and two-tenths grams of A were extracted with 100 cm^3 of water at 50 °C. The brown extract was concentrated in a rotary evaporator at 45 °C. The solution was cooled, and the **3** complex thus precipitated was filtered and dried. It was then recrystallized from water. Yield: 0.10 g. Found: C, 25.70; H, 4.58; Cl, 12.50%. Calcd for $CoC_7H_{15}N_5O_4Cl$ (MW 327.61) C, 25.66; H, 4.62; Cl, 10.82%. Dec 160—163 °C.

Cobalt(III) Complexes with Tripodlike Quadridentate Ligands. II.[1] Preparations, Absorption Spectra and Circular Dichroism of (Amino carboxylato or 1,2-diamine)[*N*,*N*-bis(2-aminoethyl)-glycinato]cobalt(III) Complexes

Keiji Akamatsu,* Takashi Komorita, and Yoichi Shimura

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 13, 1981)

Four glycinato, six L-alaninato, and three (*R*)-propylenediamine cobalt(III) complexes of a tripodlike quadridentate ligand, *N*,*N*-bis(2-aminoethyl)glycinate have been prepared. The geometrical configurations are assigned on the basis of their absorption and circular dichroism spectra, ^{1}H-NMR spectra, the elution behavior in ion-exchanger column chromatography, and the optical resolution of chiral isomers. The absolute configurations of the chiral complexes are tentatively assigned and the characteristics of the tripodlike ligand are discussed.

A tripodlike quadridentate ligand *i*-dtma[2] can take two different configurations in six-coordinate metal complexes (Fig. 1). The left configuration with a plane of symmetry and the right one without it are called *s*-type (symmetrical) and *u*-type (unsymmetrical), respectively. An *s*-type configuration is achiral, while a *u*-type chiral. A complex with a tripodlike ligand of *s*-type configuration can also become chiral when unsymmetrical (such as *meso*-2,4-pentanediamine or *meso*-2,3-butanediamine) or asymmetric (such as L-alaninate or (*R*)-propylenediamine) bidentate ligands occupy the remaining two coordination sites. Only *s*-type configuration is possible for some typical tripodlike ligands, ata^{3-} and tren. It was pointed out in the previous paper[1] concerning the ata and tren cobalt(III) complexes with chiral bidentate (L-amino carboxylate or 1,2-diamine) that the CD spectra in the first and second d-d absorption band region for these complexes were considerably different in pattern and/or intensity from those for the corresponding bis- or tris(bidentate) or tetrakis(unidentate) complexes with the same L-amino carboxylate or 1,2-diamine. The differences were attributed to a new source of optical activity, which was called the "quasi-enantiomeric" effect, because this mainly determined the CD patterns in the first and second d-d band region: the CD patterns in the region are helpful in determining the coordination modes of the residual bidentate ligands, especially, those of L-amino carboxylates.

A further problem arises on the complexes of *u*-type structure which are chiral regardless of the residual ligands. Absolute configurations of cobalt(III) complexes with multidentate ligands have generally been correlated with that of a simple tris(bidentate) complex, for example, $[Co(en)_3]^{3+}$, by use of the ring-pairing-method.[3] Meanwhile, the method cannot be applied to *u*-type isomers of the complexes with tripodlike ligands such as aeida and *i*-dtma, because these isomers lack the ring-pairing chirality. Furthermore, the available data are too limited to derive any empirical rule, though Koine *et al.* have reported some L- or D-alada[4] and *β*-alada[5] complexes with amino carboxylate.

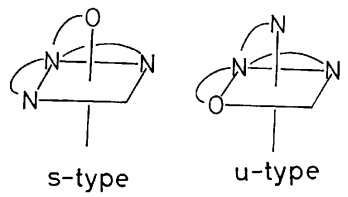

Fig. 1. Two different coordination modes of *i*-dtma ligand.

In the present paper the isomers of *i*-dtma cobalt(III) complexes with amino carboxylate or 1,2-diamine are reported.

Experimental

Preparations. *(1)* *[Co(gly)(i-dtma)]*$^+$: Two grams of *fac(N)*-[CoCl(*i*-dtma)(H_2O)]Cl·H_2O[6] was dissolved in 10 cm^3 of water, and to this violet solution was added a solution of glycine (1 g) neutralized with an equimolar amount of NaOH. The mixture was mechanically stirred at 70 °C for 2 h. The resulting red solution was poured onto a cation-exchanger column (SP-Sephadex C-25, Na^+ form) and the adsorbed complex was eluted with a 0.2 M NaCl aqueous solution (1 M=1 mol dm^{-3}). Two bands appeared; a red-orange and a purple one in this order. The second band contained mainly $[Co(i\text{-dtma})(H_2O)_2]^{2+}$. To the first eluate which had been evaporated to a small volume below 40 °C on a rotary evaporator was added a small amount of methanol to precipitate NaCl, which was filtered off with suction, as much sodium chloride as possible was removed by repetition of the procedure.

The resulting red-orange solution was then loaded on a strongly acidic cation exchanger column (Dowex 50w-x8, 2.6×40 cm, 200—400 mesh, Na^+ form) and eluted with a NaH_2PO_4–Na_2HPO_4 buffer of pH 6.8 ($NaH_2PO_4\cdot 2H_2O$, 25 g and $Na_2HPO_4\cdot 12H_2O$, 14 g per 1 dm^3 of solution). The adsorbed band had split into four well-resolved bands, which were eluted out in the following order; yellow-orange, orange, purple, and red-orange one. These are called G-1, G-2, G-3, and G-4, respectively. Each of the four fractions was treated with 44 g of $CaCl_2\cdot 2H_2O$ and 14 g of NaOH for every 1 dm^3 of eluate to convert the phosphate salts into the corresponding chloride salts. After removal of $Ca_3(PO_4)_2$ by filtration, the filtrate was evaporated to a small volume and to this was added methanol to precipitate NaCl, which was then filtered off. The procedure was repeated to remove as much sodium chloride as possible. Sodium perchlorate was added to the concentrated solution almost free from NaCl and the solution was kept standing in a refrigerator. After a few days, deposited crystals were collected with suction and recrystallized from warm water,

washed with methanol and ether and dried in air. Found for G-1: C, 23.17; H, 4.85; N, 13.64%. Calcd for [Co(gly)(*i*-dtma)]$ClO_4 \cdot H_2O$: C, 23.39; H, 4.92; N, 13.65%. Found for G-2: C, 24.24; H, 4.65; N, 14.18%. Calcd for [Co(gly)(*i*-dtma)]ClO_4: C, 24.47; H, 4.63; N, 14.27%. Found for G-3: C, 24.36; H, 4.61; N, 14.29%. Calcd for [Co(gly)(*i*-dtma)]ClO_4: C, 24.47; H, 4.63; N, 14.27%. Found for G-4: C, 24.33; H, 4.72; N, 14.20%. Calcd for [Co(gly)(*i*-dtma)]ClO_4: C, 24.47; H, 4.62; N, 14.27%.

(2) Optical Resolution of G-2: The orange isomer (G-2) of [Co(gly)(*i*-dtma)]ClO_4 (0.72 g; 1.8×10^{-3} mol) was dissolved in 10 cm^3 of warm water and converted into the chloride with a Dowex anion-exchanger column (1-x8, 100—200 mesh, Cl^- form). To the eluate was added $(+)_{589}$-Na[$Co(NO_2)_3$(edma)](vide post) (0.31 g; 0.91×10^{-3} mol) with stirring at 40 °C, and the mixture was kept standing overnight in a refrigerator. The pale orange powder deposited was filtered and washed with a small amount of water. The less-soluble diastereomer was recrystallized from warm water, washed with water, and then with methanol and ether and dried in air. Found: C, 22.56; H, 4.78; N, 19.82%. Calcd for [Co(gly)(*i*-dtma)][$Co(NO_2)_3$(edma)]·$1.5H_2O$: C, 22.72; H, 4.78; N, 19.88%.

A solution of the diastereomer in warm water was poured onto a Sephadex column (C-25, Na^+ form) and after being washed with water the adsorbed band was eluted with an aqueous $NaClO_4$ solution. The eluate was evaporated almost to dryness and a small amount of methanol was added to the residue. The $(-)_{589}$-perchlorate salt deposited was recrystallized from water. Found: C, 24.27; H, 4.60; N, 13.99%. Calcd for $(-)_{589}$-[Co(gly)(*i*-dtma)]ClO_4: C, 24.47; H. 4.63; N, 14.27%. $[M]_{589} = -520°$.

(3) [Co(L-ala)(i-dtma)]$^+$: A solution containing the desired products was prepared by the same method as that for the glycinato analogs using L-alanine instead of glycine. The red-orange solution (free from bivalent complex cations) was loaded on a Dowex cation-exchanger column (50w-x8, 200—400 mesh, Na^+ form). When eluted with the NaH_2PO_4–Na_2HPO_4 buffer described in (1), the adsorbed band separated into six, which are named A-1, A-2-a, A-2-b, A-3-a, A-3-b, and A-4 in the elution order. The eluted phosphate salts were converted into the corresponding chloride in the following way: each of the six fractions was diluted with triple volumes of water and then passed through a Dowex cation-exchanger column (50w-x8, 200—400 mesh, Na^+ form). The band on the column was washed with water and eluted with an aqueous NaCl solution. After removal of NaCl by the method previously mentioned, the desired complexes were obtained as perchlorate salts by adding $NaClO_4$ to the concentrated solution and recrystallized from warm water. The crystallization of A-3-a was not carried out because of the low yield and the high solubility in water of the isomer. Found for A-1: C, 26.05; H, 5.13; N, 13.76%. Calcd for [Co(L-ala)(*i*-dtma)]ClO_4·$0.5H_2O$: C, 26,00; H, 5.10; N, 13.48%. Found for A-2-a: C. 26.78; H, 5.04; N, 13.94%. Calcd for [Co(L-ala)(*i*-dtma)]ClO_4: C, 26.58; H, 4.93; N, 13.78%. Found for A-2-b: C, 26.82; H, 5.00; N, 13.95%. Calcd for [Co(L-ala)(*i*-dtma)]ClO_4: C, 26.58; H, 4.93; N, 13.78%. Found for A-3-b: C, 25.03; H, 5.33; N, 12.95%. Calcd for [Co(L-ala)(*i*-dtma)]ClO_4·$1.5H_2O$: C, 24.92; H, 5.36; N, 12.92%. Found for A-4: C, 26.05; H, 5.18; N, 13.30%. Calcd for [Co(L-ala)(*i*-dtma)]ClO_4·$0.5H_2O$: C, 26.00; H, 5.10; N, 13.48%.

(4) [Co(i-dtma)((R)-pn)]$^{2+}$: One gram of *fac(N)*-[CoCl(*i*-dtma)(H_2O)]Cl·H_2O[6] was suspended in 60 cm^3 of DMF (*N,N*-dimethylformamide). (*R*)-Propylenediamine (0.5 g) was added dropwise to this blue suspension with stirring and the mechanical stirring was continued for 2 h at 60 °C in a water bath. The orange powder formed was filtered, washed with methanol and ether and air-dried. A solution of this powder in 15 cm^3 of water was poured onto a cation-exchanger column (SP-Sephadex C-25, 2.6 cm × 50 cm, Na^+ form). When the adsorbed band was eluted with a NaH_2PO_4–Na_2HPO_4 buffer solution ($NaH_2PO_4 \cdot 2H_2O$, 12.5 g and $Na_2HPO_4 \cdot 12H_2O$, 7 g per 1 dm^3 of solution), it split into two orange bands. These are called P-1 and P-2 in the elution order, respectively. Each fraction was diluted with the same volume of water, passed through a Sephadex column (SP-Sephadex C-25) and then the column was washed with water to remove phosphate salts. The P-2 band concentrated on the column was eluted with an aqueous $NaClO_4$ solution. The eluate was evaporated almost to dryness below 40 °C on a rotary evaporator and to this residue was added ethanol to precipitate the perchlorate salt of P-2, which was filtered off, washed with methanol and dried in air. Found for P-2; C, 21.48; H, 5.04; N, 13.94%. Calcd for [Co(*i*-dtma)((*R*)-pn)]$(ClO_4)_2 \cdot 0.5H_2O \cdot 0.53NaClO_4$: C, 21.52; H, 5.03; N, 13.95%.

Although P-1 did not split completely, both ends of the band revealed nearly enantiomeric CD spectra. Two isomers, P-1-a and -b, were separated from the P-1 band by means of fractional crystallizations; the P-1 band was treated in the same way as that for P-2, described above, using NaCl instead of $NaClO_4$ as the eluting agent. The eluate was evaporated amost to dryness and to the residue was added methanol to remove NaCl. The deposited P-1-a including NaCl was filtered and recrystallized from warm water. The filtrate containing P-1-b was then evaporated to dryness and from the residue P-1-b was extracted into methanol. The chloride salt of P-1-a was converted into the chloride perchlorate by adding $NaClO_4$ to the solution and that of P-1-b into the perchlorate by use of a column chromatographic method similar to that in (2). Found for P-1-a: C, 24.97; H, 5.62; N, 16.40%. Calcd for [Co(*i*-dtma)((*R*)-pn)]Cl(ClO_4): C, 25.24; H, 5.66; N, 16.36%. Found for P-1-b: C, 21.88; H, 4.98; N, 14.04%. Calcd for [Co(*i*-dtma)((*R*)-pn)]$(ClO_4)_2 \cdot 0.25H_2O$: C, 21.76; H, 4.98; N, 14.10%.

(5) [Co(i-dtma)(en)]$^{2+}$: This complex was prepared with a method similar to that for the corresponding (*R*)-pn complex. Two isomers (E-1 and E-2 in the elution order) were isolated as perchlorates. Found for E-1: C, 20.05; H, 4.60; N, 14.91%. Calcd for [Co(*i*-dtma)(en)]$(ClO_4)_2$: C, 20.09; H, 4.65; N, 14.65%. Found for E-2: C, 19.82; H, 4.73; N, 14.45%. Calcd for [Co(*i*-dtma)(en)]$(ClO_4)_2 \cdot 0.5H_2O$: C, 19.72; H, 4.77; N, 14.38%.

(6) Optical Resolution of E-1: An aqueous solution of E-1, [Co(*i*-dtma)(en)]$(ClO_4)_2$ (1.3 g; 2.7×10^{-3} mol) was passed through an anion-exchanger column (Dowex 1-x8, 50—100 mesh, Cl^- form). To the eluate concentrated to 20 cm^3 on a rotary evaporator was added silver antimony tartrate (2.1 g; 2.8×10^{-3} mol) with stirring at 60 °C. After 10 min the precipitated silver chloride was filtered off and the filtrate was cooled in an ice bath with scratching the beaker to induce crystallization. The orange crystals deposited were collected by filtration, recrystallized from warm water, washed with a small amount of water, with methanol and ether and dried in air. Found: C, 22.62; H, 3.59; N, 8.29%. Calcd for [Co(*i*-dtma)(en)][Sb_2(tart)$_2$]·$2H_2O$: C, 22.58; H, 3.56; N, 8.23%.

The less-soluble diastereomer was converted into $(-)_{589}$-perchlorate salt by use of the same method as that in (2). Found: C, 20.22; H, 4.63; N, 14.73%. Calcd for $(-)_{589}$-

$[Co(i\text{-dtma})(en)](ClO_4)_2$: C, 20.09; H, 4.65; N, 14.65%. $[M]_{589}=-850°$.

(7) Preparation and Optical Resolution of $[Co(NO_2)_3(edma)]^-$: The racemate, $Na[Co(NO_2)_3(edma)]\cdot 3H_2O$, was isolated in the course of the preparation for $Na[Co(NO_2)_2(aeida)]\cdot 2H_2O$[7] by a usual column chromatographic method. Found: C, 12.34; H, 3.79; N, 18.01%. Calcd for $Na[Co(NO_2)_3(edma)]\cdot 3H_2O$: C, 12.28; H, 3.87; N, 17.91%.

The optical resolution was carried out as follows: one and four tenths gram of $Na[Co(NO_2)_3(edma)]\cdot 3H_2O$ (3.6×10^{-3} mol) was dissolved in 50 cm^3 of water at 50 °C, and to this solution was added $(-)_{589}$-$[Co(ox)(en)_2]Cl\cdot H_2O$ (0.6 g; 2.3×10^{-3} mol). Mechanical stirring was continued for 10 min after orange crystals began to deposite. While the reaction mixture was still warm, crystals of the diastereomer were collected on a glass filter, recrystallized from warm water, washed with a small amount of water and then with methanol and ether and dried in air. Found: C, 19.59; H, 4.74; N, 20.50%. Calcd for $[Co(NO_2)_3(edma)][Co(ox)(en)]\cdot 2H_2O$: C, 19.45; H, 4.74; N, 20.42%.

The less-soluble diastereomer was converted into the $(+)_{589}$-sodium salt by passing through a cation-exchanger column (Na^+ form) and evaporating the eluate on a rotary evaporator. Found: C, 14.39; H, 2.89; N, 20.58%. Calcd for $(+)_{589}$-$Na[Co(NO_2)_3(edma)]$: C, 14.25; H, 2.70; N, 20.78%. $[M]_{589}=+475°$.

Measurements. The visible and ultraviolet absorption spectra were measured with a Shimadzu UV-200 spectrophotometer in aqueous solutions. The CD spectra were recorded on a JASCO MOE-1 spectropolarimeter and the ^{1}H-NMR spectra were obtained in deuterium oxide (D_2O) on a Varian XL-100-15 spectrometer using DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as an internal standard.

Results and Discussion

Four isomers are possible for a [Co(am)(*i*-dtma)]-type complex (Fig. 2). As both ends are indistinguishable in free ethylenediamine, only two isomers, *s*-α (or *s*-β) and *u*-α (or *u*-β), are possible for the complex containing en instead of gly$^-$. The upper two (*s*-type) have a plane of symmetry in the absence of a substituent group on the chelate ring, while the lower two (*u*-type) have none of the plane of symmetry even for the glycinato and ethylenediamine complexes and are optically resolvable. Accordingly, the en complex has one achiral isomer and a pair of enantiomers, the glycinato complex two achiral ones and two pairs of enantiomers, and the L-alaninato and (*R*)-pn complexes six chiral ones.

Amino Carboxylato Complexes with i-*dtma*: Several attempts were made under different conditions to prepare the glycinato and L-alaninato complexes; temperature and time in the substitution reaction were varied and activated charcoal was added or not. As for the reaction temperature and time, the condition described in the experimental section is suitable to prepare all the four and six isomers for the glycinato and L-alaninato complexes, respectively. Though, in the presence of activated charcoal, the complete substitution took place at low temperature in short time and none of the bivalent complex cation $[Co(i\text{-dtma})(H_2O)_2]^{2+}$ was detected, only two isomers (G-1 and G-2) of the four for the glycinato and only three (A-1, A-2-a, and-b)

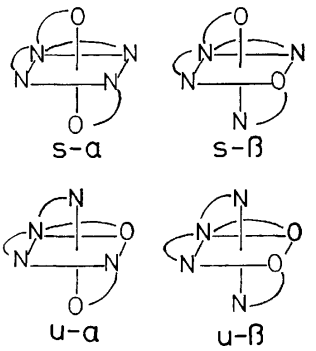

Fig. 2. Four geometrical isomers of [Co(am)(*i*-dtma)]-type complex (am=amino carboxylate).

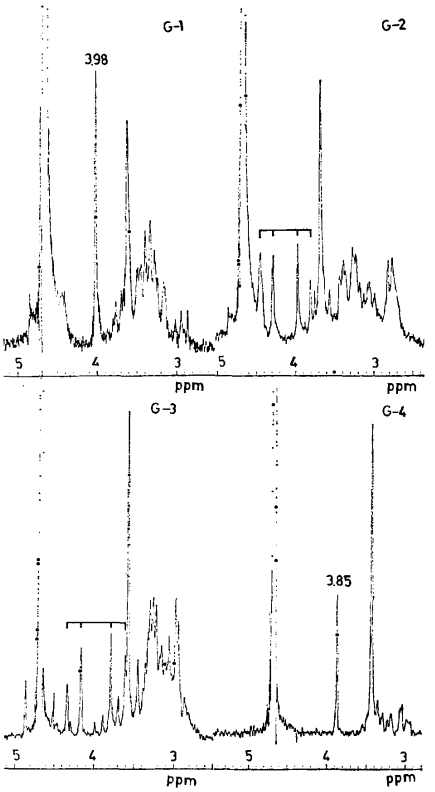

Fig. 3. ^{1}H-NMR spectra of isomers of [Co(gly)(*i*-dtma)]$^+$.

of the six for the L-alaninato complex were formed.

All isomers of the glycinato and L-alaninato complexes were ultimately isolated as crystals except for one isomer of the L-alaninato complex, A-3-a. Isomers, G-1, G-2, G-3, and G-4 were found from their absorption spectra to correspond to A-1, A-2, A-3, and A-4, respectively. A-2 and A-3 were separated into the respective pairs of the diastereomers on an ion-exchanger column. These facts indicate that G-1, G-4, A-1, and A-4 have either structure *s*-α or *s*-β and G-2, G-3, A-2, and A-3 either *u*-α or *u*-β. The two isomers, *s*-α and *s*-β are also distinguishable from *u*-α and *u*-β by means of ^{1}H-NMR spectra.

Figures 3 and 4 show the ^{1}H-NMR spectra of the gly and the en isomers. The isomers, G-1, G-4, and E-2, show a singlet due to the methylene protons of the acetate group in *i*-dtma (3.98 ppm for G-1; 3.85

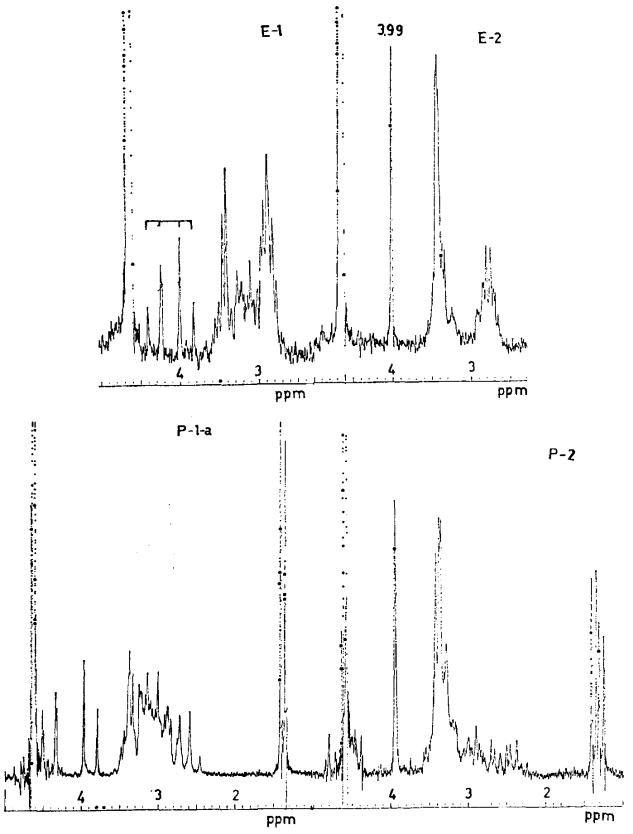

Fig. 4. ^{1}H-NMR spectra of isomers of [Co(en)(*i*-dtma)]$^{2+}$ and [Co((*R*)-pn)(*i*-dtma)]$^{2+}$.

ppm for G-4; and 3.99 ppm for E-2), while the other isomers and AB quartet due to the relevant protons with the coupling constants of 17—19 Hz (4.45, 4.28, 3.97, and 3.79 ppm for G-2; 4.31, 4.13, 3.76, and 3.57 ppm for G-3; and 4.40, 4.22, 3.99, and 3.82 ppm for E-1). The gly complex has another acetate group, not the constituent of *i*-dtma but that of glycine. The methylene protons should also show a singlet for G-1 and G-4 and an AB quartet for G-2 and G-3, and can be assigned to the signals at 3.4—3.6 ppm, though it is difficult to distinguish them from the signals of the ethylene protons of *i*-dtma.

With regard to the complexes of CoN_4O_2 chromophore, the splitting of the first spin-allowed d-d absorption band is larger for a *trans*(*O*) isomer than for a *cis*(*O*). G-1 and A-1 which show the splitting (Figs. 5 and 6) are assigned to (structure) *s*-α, and therefore, G-4 and A-4 to *s*-β. It is difficult to distinguish G-2 and A-2 from G-3 and A-3 by means of their absorption and ^{1}H-NMR spectra. G-2 and G-3 have only one kind of chirality, which is due to chiral arrangement of the tripodlike *i*-dtma ligand. On the other hand, A-2 and A-3 have two kinds of chiralities, one being the same as in G-2 and G-3 and the other a vicinal chirality of the L-alaninate ligand. In the previous paper of this series,[1] it has been shown that the vicinal chirality is such [Co(am)(tripod)]-type complexes consists of two factors, one being asymmetric carbon of the am$^-$ ligand, the other quasi-enantiomeric chirality due to the geometrical configurations. The observed CD pattern is mainly

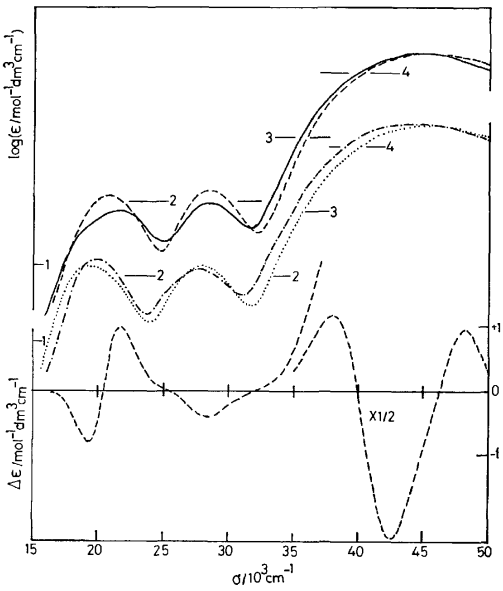

Fig. 5. Absorption and CD curves of four isomers of [Co(gly)(*i*-dtma)]$^+$: G-1 (——), G-2 (----), G-3 (·····), and G-4 (—·—).

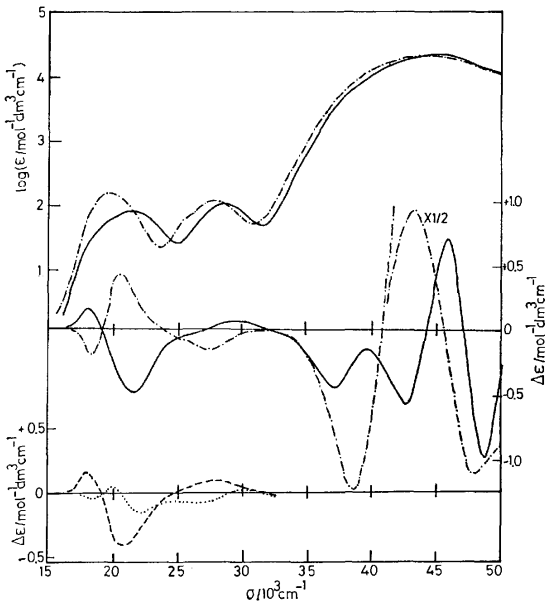

Fig. 6. Absorption and CD curves of A-1 (——) and A-4 (—·—) isomers of [Co(L-ala)(*i*-dtma)]$^+$. Calculated CD curves for asymmetric carbon (·····) and quasi-enantiomeric (----) effects are also shown.

determined by the quasi-enantiomeric effect. The CD contribution of the quasi-enantiomeric effect of [Co(L-ala)(tripod)]-type complexes in the first d-d transition band region is (+) and (—) from the longer wavelength for *s*-α isomers, and (—) and (+) for *s*-β ones, the pattern being almost unaffected by the geometry of chromophores. On the assumption that contributions from the chiral arrangement of *i*-dtma and from the vicinal effect are additive, calculated vicinal CD curves of 1/2{CD[A-2-a]+CD[A-2-b]} and 1/2{CD[A-3-a]+CD[A-3-b]} are shown together with the original CD of the isomers in Figs. 7 and 8. The calculated vicinal curves show the patterns (+) and (—)

a) The $\Delta\varepsilon$ values were determined on assumption that the absorption spectrum of A-3-a is identical with that of A-3-b.

gave a mixture of the four isomers, whose formation ratios decreased in the following order; *u*-α, *u*-β, *s*-α, and *s*-β. Activated charcoal caused the formation of only *s*-α and *u*-α isomers, for which the nitrogen donor atom of the amino carboxylate is located at the trans position of the tertiary amine of *i*-dtma, with a preponderant yield of *u*-α.

The absorption spectra of the amino carboxylato complexes studied in the present work are rather distinct from those of usual tris-bidentate complexes with the same CoN_4O_2 chromophore. The color of G-1, *trans*(*O*), is yellow-orange, while that of *trans*(*O*)-[Co(gly)$_2$(en)]$^+$ is red. This can be explained by the fact that the intensity ratio of the split components of the first d-d absorption band is reversed between the two complexes: $18.5\times10^3\,cm^{-1}$ (sh, log ε=1.5) and 21.5 (1.85) for G-1 and 18.9 (1.94) and 22 (sh, 1.6) for *trans*(*O*)-[Co(gly)$_2$(en)]$^+$ [8]. As for the other three *cis*(*O*) isomers, the absorption maxima due to d-d transitions are generally at lower energies than those of C_1- and C_2-*cis*(*O*)-[Co(gly)$_2$(en)]$^+$ with the order of increasing energies; G-3 (*u*-β), G-4 (*s*-β), and G-2 (*u*-α) (Fig. 5). G-4 and A-4 show a trend of splitting in the second d-d transition band region (see also Table 1).

A-1 and A-4 are mutually quasi-enantiomeric isomers[1] and the CD spectra are approximately enantiomeric in the d-d transition band region but similar in the charge-transfer transition region (Fig. 6 and Table 2). On the basis of the same assumption as for the ata and tren complexes that the "quasi-enantiomeric" contribution, CD[*trans*]=−CD[*cis*], and the "asymmetric carbon" contribution, CD[S], are additive, the individual CD curves calculated from the observed CD curves of A-1 and A-4 are shown in Fig. 6. The CD[*trans*](=1/2{CD[A-1]−CD[A-4]}) curve showed a pattern similar to those of the corresponding ata and tren complexes:[1] two (+ and −) components in the first and one (+) component in the second d-d transition band region, respectively, while the pattern of CD[S] contribution for the *i*-dtma complex, 1/2{CD[A-1]+CD[A-4]} also resembled that of the vicinal CD for *trans*(*O*)-[Co(L-ala)$_2$-(en)]$^+$ [8] in the first d-d transition band region.

Isomers A-2-a and -b as well as A-3-a and -b are a pair of the diastereomers, which reveal approximately enantiomeric CD spectra over the whole range of wave numbers (Figs. 7 and 8). These CD curves consist of two contributions from the vicinal effect of the L-alaninate ligand and from the chiral arrange-

ment of *i*-dtma ligand. The contributions were separated into two, those of the chiral arrangement of the *i*-dtma; 1/2{CD[A-2-b]−CD[A-2-a]} for A-2 and 1/2{CD[A-3-a]−CD[A-3-b]} for A-3 and those of the vicinal; 1/2{CD[A-2-b]+CD[A-2-a]} for A-2 and 1/2-{CD[a-3-a]+CD[A-3-b]} for A-3, respectively, which are also shown in Figs. 7 and 8. The patterns of the former contributions are similar to that of $(+)_{589}$-(G-2)-[Co(gly)(*i*-dtma)]$^+$ which shows three (−, + and −) components in the d-d transition band region. Those of the latter contributions in the d-d transition band region are approximately enantiomeric, which means that A-2 and A-3 have the quasi-enantiomeric configurations in regard to the L-alaninate ligand. Both contributions of A-2 in the d-d transition band region are twice larger than those of A-3. For both A-2 and A-3 the CD contributions of chiral arrangement of *i*-dtma are larger than those of the vicinal; that is, the patterns of the observed CD for these *u*-type complexes are mainly determined by the chiral arrangement of the *i*-dtma ligand.

1,2-Diamine Complex with i-*dtma*: On preparing the 1,2-diamine complexes, the substitution reaction in an aqueous solution on a steam bath with activated charcoal[6] yielded a brown product (probably, organic compound) and a tris-bidentate complex besides the desired complex. However, none of the brown product and a rather small amount of the tris-diamine complex were formed when DMF was used as solvent. The main product was isomer E-1 or P-1, irrespective of the solvent, DMF or water.

Both the possible two isomers (E-1 and -2) were isolated for the en complex and the chiral isomer (E-1) was optically resolved. Six chiral isomers, four of which are two pairs of diastereomers, are possible for the (*R*)-pn complex but only three (P-1-a and -b and P-2) were isolated. It is found from their absorption spectra that P-1 and P-2 are analogous to E-1 and E-2, respectively. On the basis of the ^{1}H-NMR spectra (Fig. 4) E-1 is assigned to *u*-type, and E-2 to *s*-type. The optical resolution of E-1 confirms this assignment. The ^{1}H-NMR spectrum of P-2 (*s*-type) shows two doublets (1.40 and 1.34; 1.30 and 1.24 ppm) due to the methyl protons of the (*R*)-pn, while that of P-1-a one methyl doublet (1.38 and 1.32 ppm) and an AB quartet (4.53, 4.34, 3.97, and 3.79 ppm) due to the acetate methylene protons of *i*-dtma (Fig. 4). It is concluded from these results that P-2 is a mixture of the two *s*-type isomers, *s*-α and *s*-β, and that P-1-a comprises only one isomer of structure *u*-α or *u*-β.

The (*i*-dtma)(1,2-diamine) complexes have a CoN_5O chromophore. Figures 9, 10, and 11 show the electronic absorption and CD spectra of the en and (*R*)-pn complexes. The isomers of *u*-type, E-1 and P-1, have the absorption maxima at the energies slightly higher than *s*-type, E-2 and P-2 (Table 1). This suggests that the *i*-dtma ligand has different average ligand-field strengths in the different configurations; the strength of the *i*-dtma coordinating to the central metal facially with the three nitrogen atoms of *u*-type is smaller than that of the same ligand with *meridional*-(*N*)-coordination of *s*-type. The same argument seems

to hold for the other complexes, [Co(*i*-dtma)(A-A)] (A-A=CO_3^{2-} [9], ox^{2-}, and $acac^-$[6]). For the *i*-dtma complexes, the molar extinction coefficients of the *u*-type *fac*(*N*) isomers are generally larger than those of the *s*-type *mer*(*N*) isomers.

[Co(NO$_2$)$_3$(edma)]$^-$: Two geometrical isomers, *mer*-*(NO$_2$)* and *fac(NO$_2$)*, are possible for the edma complex. Though both isomers should be optically resolvable, the sources of their optical activities may be quite different from each other; for *mer*(*NO$_2$*) isomer the contribution from the asymmetric nitrogen atom in edma, while for *fac*(*NO$_2$*) isomer two contributions from the asymmetric nitrogen and from the chiral arrangement of the edma ligand. It has been known that the active *mer*-$[Co(dien)_2]^{3+}$ (dien=diethylenetriamine) completely racemizes within 5 min in an aqueous solution at pH 10, though it is stable in an acidic solution at 20 °C.[10] Figure 12 shows the absorption and CD spectra of $(+)_{589}$-$[Co(NO_2)_3$-(edma)]$^-$. The fact that the CD spectrum was little affected in a LiOH solution (pH 10) at room temperature for 12 h indicates that the obtained isomer is *fac(NO$_2$)*.

Absolute Configurations: The ring-pairing method cannot be applied to the absolute configurations of the *u*-type complexes. The absolute configurations for the isomers are tentatively predicted as follows. Isomers, A-2-a and A-3-b, should have the same absolute configurations as $(-)_{589}$-(G-2)-[Co(gly)(*i*-dtma)]$^+$ (Fig. 7) in regard to *i*-dtma. The isomers of the L-alaninato complex were separated on an ion-exchanger column by eluting with a NaH_2PO_4–Na_2HPO_4 buffer. Figure 13 shows four absolute configurations of the diastereomers, where **N** signifies an amino group which can associate with phosphate species. The upper two isomers have three **N**'s in facial arrangement while the lower two have three **N**'s in meridional arrangement. The facial arrangement of the three amino group is preferable to the meridional arrangement for the association.[11] The formation of such an ion pair will decrease the average positive charge on the cationic

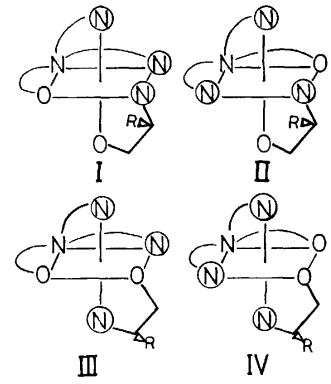

Fig. 13. Absolute configurations of four diastereomers of [Co(L-ala)(*i*-dtma)]$^+$ with u-type structure, where R=CH_3.

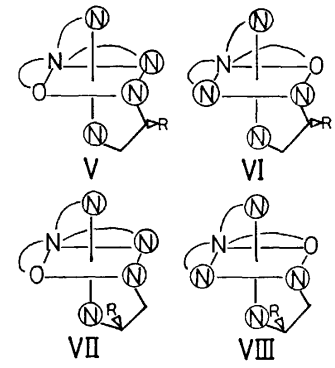

Fig. 14. Absolute configurations of four diastereomers of [Co(*i*-dtma)((*R*)-pn)]$^{2+}$ with *u*-type structure, where R=CH_3.

species and facilitate the elution of the complex. Hence it is predicted that *fac*(**N**) isomers, (I and II), should be eluted faster than *mer*(**N**), (III and IV). The *fac*(**N**) and the *mer*(**N**) isomers correspond to the structure *u*-*α* and *u*-*β*, respectively. In *fac*(**N**) isomers, isomer I should be eluted faster than II, because the methyl substituent of II will make the ion pair less stable than that of I. As for *mer*(**N**) isomers which may form an ion pair with phosphate anions not so firmly as the *fac*(**N**) isomers, the phosphate will yet prefer isomer IV to III, the former having a methyl substituent directed far from the plane of three **N**'s. Thus, the A-2-a, -b, A-3-a, and -b isomers are assigned to I, II, IV, and III, respectively, and the absolute configuration of $(-)_{589}$-[Co-(gly)(*i*-dtma)]$^+$ (G-2) to I.

From the CD spectra the P-1-b should have the same absolute configuration of *i*-dtma as that of $(-)_{589}$-[Co(*i*-dtma)(en)]$^{2+}$ (Fig. 9) and also those of A-2-a, A-3-b, and $(-)_{589}$-(G-2)-[Co(gly)(*i*-dtma)]$^+$ (Figs. 4, 6, and 7), because the CD contribution from the *u*-type configurational effect of *i*-dtma is expected to be larger than that from the so-called "vicinal" effect of (*R*)-pn and to show the same pattern as that of L-alaninato complex in the first and second d-d transition band region. Thus the absolute configurations of P-1-a and -b may be assigned to (VI or VII) and (V or VIII), respectively.

(Received June 15, 1981)

A series of the complexes, $[Co(CN)_{4-2n}(acac)_n(P)_2]^{(n-1)+}$ (acac=acetylacetonate ion, P=$P(CH_3)_x(C_6H_5)_{3-x}$) and several related complexes were prepared. For $[Co(acac)_2(P)_2]^+$, the $P(CH_3)_3$ and $P(CH_3)(C_6H_5)_2$ complexes afford only the *cis* and the *trans* isomers, respectively, while the $P(CH_3)_2(C_6H_5)$ complex forms both *cis* and *trans* isomers. No $P(C_6H_5)_3$ ligand gave the bis(acac)-type complex. The *trans* isomers show a strong absorption band in the region of the first absorption band, which is assumed to involve charge transfer transitions between the cobalt(III) ion and a phosphine, while the *cis* isomers give usual absorption spectra, exhibiting the first d-d absorption band of medium intensity. The methyl and phenyl groups on a phosphorus atom in both *cis* and *trans* isomers show triplet signals in the ^1H and ^{13}C NMR spectra due to virtual coupling. A *trans*(P,P) configuration was assigned to all the complexes of $[Co(CN)_2(acac)(P)_2]$ on the basis of the NMR and electronic spectra. For $[Co(CN)_4(P)_2]^-$, a *trans* configuration was assigned from the electronic spectra.

Little work has been reported for cobalt(III) complexes containing unidentate phosphines,[1] except for those of organo cobalt(III)- and bis(dimethylglyoximato)cobalt(III)-type, the latter type of which has been studied extensively as a model compound of Vitamin B_{12}.[2,3] In previous papers,[4,5] one of the present authors (M.S.) prepared several cobalt(III) complexes containing triphenylphosphine. Very recently we succeeded in isolating a pair of geometrical isomers of the bis(acetylacetonato)bis(dimethylphenylphosphine)cobalt(III) complex, and clarified some chemical and spectroscopic properties.[6] The difference in electronic spectra between the isomers was quite remarkable. In this paper, we extended the study to complexes of the type, $[Co(CN)_{4-2n}(acac)_n(P)_2]^{n-1}$ (acac=acetylacetonate ion, n=0,1,2) containing a series of phosphines, $P(CH_3)_x(C_6H_5)_{3-x}$ (x=0,1,2,3). Cyanide and acetylacetonate ions appear to afford fairly stable cobalt(III) complexes with unidentate phosphine ligands. Chemical properties such as stability and geometrical isomerism of those complexes would depend on the kinds of not only phosphine ligands, but also other ligands coexisting in a complex.

Experimental

The phosphine ligands were prepared according to the methods reported,[7] and handled under nitrogen atmosphere until they formed cobalt(III) complexes. Solvents were dried in the usual way and degassed in a stream of nitrogen. Absorption, and ^1H and ^{13}C NMR spectra were recorded on a Hitachi 323 spectrophotometer, and JEOL JNM-PMX 60 and JNM-FX 100 spectrometers, respectively.

trans-$[Co(acac)_2(PMePh_2)_2]PF_6$ *and* trans-$[Co(acac)_2(H_2O)(PMePh_2)]PF_6$. Methyldiphenylphosphine ($PMePh_2$) (0.9 g, 4.5 mmol) was added to a mixture of $[Co(acac)_3]$ (0.7 g, 2 mmol) and a small amount of active charcoal in ethanol (60 cm^3). The mixture was stirred at 25 °C for a day, and filtered. The dark red brown filtrate was diluted to 4 dm^3 with a mixture of water and ethanol (2:1). The solution was poured onto a small column of SP-Sephadex C-25 (ϕ2 cm×3 cm) in the Na^+ form. After the column had been thoroughly washed with a mixture of water and ethanol (2:1), the product adsorbed was eluted with a 0.05 mol/dm^3 NaCl solution in a mixture of water and ethanol (2:1). The eluate gave a red brown precipitate on addition of $NaPF_6$. The precipitate was filtered and dissolved in a small amount of CH_2Cl_2. The solution was mixed with ethanol and stored in a refrigerator to give red brown crystals of *trans*-$[Co(acac)_2(PMePh_2)_2]PF_6$. Yield: 35%. The corresponding *cis* complex was not yielded.

A methanol solution (*ca.* 30 cm^3) of *trans*-$[Co(acac)_2(PMePh_2)_2]PF_6$ (*ca.* 50 mg) was allowed to stand for a while at room temperature, and then chromatographed by use of a column of Sephadex LH-20 (ϕ2.7 cm×50 cm). By elution with methanol, the band was separated into two, the first blue-green and the second red brown (the starting complex) bands. The effluent of the first band was concentrated to a small volume under reduced pressure. The concentrate was mixed with a small amount of water and allowed to stand at room temperature to yield blue-green crystals of *trans*-$[Co(acac)_2(H_2O)(PMePh_2)]PF_6$.

cis- *and* trans-$[Co(acac)_2(PMe_2Ph)_2]PF_6$, *and* trans-$[Co(acac)_2(H_2O)(PMe_2Ph)]PF_6$. These complexes were prepared by modifiing the method reported previously.[6] A mixture of $[Co(acac)_3]$ (0.7 g, 2 mmol), PMe_2Ph (0.55 g, 4 mmol), and a small amount of active charcoal in ethanol (60 cm^3) was stirred at room temperature for 2 h, and filtered. The red brown filtrate was diluted with water to 3 dm^3. The solution was poured onto a small column (ϕ 2.7 cm×3 cm) of SP-Sephadex C-25, and then the column was washed with water. The Sephadex adsorbed the product was charged on the top of an SP-Sephadex C-25 column (ϕ 2.7 cm×50 cm). By elution with an aqueous 0.02 mol/dm^3 NaCl solution, the column showed two bands. The fraction of the first blue-violet band was concentrated to a small volume under reduced pressure. The concentrate gave a blue-violet precipitate on addition of $NaPF_6$. The precipitate was dissolved in a mixture of methanol and water (5:1). The solution was allowed to stand at room temperature to give blue-violet crystals of *trans*-$[Co(acac)_2(H_2O)(PMe_2Ph)PF_6$. Yield: *ca.* 15%. The effluent of the second red brown band gave red brown crystals of *cis*-$[Co(acac)_2(PMe_2Ph)_2]PF_6$ by the same method as the above. Yield: *ca.* 50%.

The *trans*-$[Co(acac)_2(PMe_2Ph)_2]PF_6$ complex was obtained by adding a slight excess of PMe_2Ph to an ethanol solu-

tion of *trans*-$[Co(acac)_2(H_2O)(PMe_2Ph)]PF_6$, red orange crystals being deposited in *ca.* 15 min. Yield: 80%.

cis-$[Co(acac)_2(PMe_3)_2]PF_6$. Red crystals of this complex were obtained by a method similar to that for the PMe_2Ph complex, using PMe_3 instead of PMe_2Ph. Yield: 50%. The formation of the corresponding *trans* isomer and the aqua complex was not observed in column chromatography.

$[Co(acac)_2(Ph_2PCH_2CH_2PPh_2)]PF_6$. This complex was prepared by the method reported previously.[8]

$[Co(acac)_2(Me_2PCH_2CH_2PMe_2)]PF_6$. A methanol solution (100 cm^3) containing $[Co(acac)_3]$ (0.25 g, 0.7 mmol) and 1,2-bis(dimethylphosphino)ethane (0.1 g, 0.7 mmol) was stirred at room temperature for 20 h. A mixture of diethyl ether and water (400 cm^3, 1:3) was added to the resulting orange solution in order to extract the unreacted free diphosphine into the diethyl ether. The diethyl ether layer was separated off, and the aqueous solution was diluted ten times with water. The solution was chromatographed by a method similar to that for the PMe_2Ph complex. The first orange eluate was evaporated to dryness under reduced pressure, and the residue was extracted with chloroform. The extract was evaporated to dryness, and the residue was again dissolved in water. Red crystals of the complex were obtained on addition of $NaPF_6$. Yield: *ca.* 20%.

trans(P,P)-$[Co(CN)_2(acac)(PPh_3)_2]$. This complex was prepared by the method reported previously.[4]

trans(P,P)-$[Co(CN)_2(acac)(PMePh_2)_2]$. A mixture of $K[Co(CN)_2(acac)_2]$[9] (0.7 g, 2 mmol) and $PMePh_2$ (0.8 g, 4 mmol) in ethanol (60 cm^3) was stirred at 30 °C for 6 h. The resulting orange yellow solution was concentrated under reduced pressure to *ca.* 15 cm^3. An orange precipitate of the crude complex was obtained on standing, which was filtered. The filtrate was chromatographed by use of an alumina column (ϕ 4 cm × 50 cm) and a mixture of hexane and ethanol (1:10). The orange yellow eluate was concentrated to a small volume. The concentrate was rechromatographed by use of a Sephadex LH-20 column (ϕ 3 cm × 60 cm) and a mixture of hexane and ethanol (5:1). Another crop of the complex was obtained by evaporating the eluate to dryness under reduced pressure. The combined first and second crops were recrystallized from a mixture of dichloromethane and ethanol (4:1). Yield: *ca.* 55%.

trans(P,P)-$[Co(CN)_2(acac)(PMe_2Ph)_2]$. This complex was prepared by a method similar to that for the $PMePh_2$ complex, using PMe_2Ph instead of $PMePh_2$. The eluate which was obtained by rechromatography with a Sephadex LH-20 column was concentrated to a small volume under reduced pressure. The concentrate was mixed with a small amount of water and allowed to stand, yielding orange yellow crystals of the complex. Yield: *ca.* 25%.

trans(P,P)-$[Co(CN)_2(acac)(PMe_3)_2]$ *and* cis-$[Co(CN)(acac)_2(PMe_3)]$. A mixture of $K[Co(CN)_2(acac)_2]$ (0.7 g, 2 mmol) and PMe_3 (0.2 g, 2.6 mmol) in methanol (100 cm^3) was stirred for 20 h at room temperature. The resulting orange solution was chromatographed by using an alumina column (ϕ2 cm × 30 cm) and methanol. The eluate was concentrated to a small volume under reduced pressure. The concentrate was rechromatographed by use of a Sephadex LH-20 column (ϕ2 cm × 50 cm) and a mixture of hexane and ethanol (10:1). Each eluate of the first red and the second orange bands was evaporated to dryness, and the residue was dissolved in a small amount of chloroform. The chloroform solutions obtained from the first and the second eluates gave crystals of red *cis*-$[Co(CN)(acac)_2(PMe_3)]$ and orange *trans*(P,P)-$[Co(CN)_2(acac)(PMe_3)_2]$, respectively, on addition of hexane. Yield: *ca.* 7% for each complex.

cis-$[Co(CN)_2(acac)(Ph_2PCH_2CH_2PPh_2)]$. A mixture of $K[Co(CN)_2(acac)_2]$ (0.2 g, 0.6 mmol) and $Ph_2PCH_2CH_2PPh_2$ (0.25 g, 0.6 mmol) in methanol (100 cm^3) was stirred at 55 °C for 4 h. The resulting orange solution was evaporated to dryness, and the residue was extracted with hot benzene. The extract afforded orange crystals of the complex on standing at room temperature. Yield: 50%.

trans(P,P)-$K[Co(CN)_4(PPh_3)_2]$. The previous method[5] was modified. A mixture of PPh_3 (5.2 g, 20 mmol) and $K_3[Co(CN)_5I]$[10] (4.3 g, 10 mmol) in glacial acetic acid (70 cm^3) was stirred at 75 °C for 6 h, and filtered. The yellow filtrate was mixed with water (500 cm^3) and stored in a refrigerator to yield a yellow precipitate. It was filtered, washed with benzene in order to remove free PPh_3, and then dissolved in a mixture of dichloromethane and methanol (1:1). The solution was chromatographed by use of a Sephadex LH-20 column (ϕ1.5 cm × 30 cm) and a mixture of dichloromethane and methanol (1:1). The first main yellow eluate was concentrated to a small volume under reduced pressure. The concentrate was mixed with a small amount of water and stored in a refrigerator to yield orange crystals of the complex. Yield: 15%.

trans(P,P)-$Na[Co(CN)_4(PMePh_2)_2]$. The method of Maki and Ohshima[11] for the PPh_3 complex was modified. A suspension of $Na_5[Co(SO_3)_2(CN)_4]3H_2O$[12] (1.2 g, 3.5 mmol) and $PMePh_2$ (1.1 g, 5.5 mmol) in glacial acetic acid (40 cm^3) was stirred at 75 °C for 7 h. The resulting orange yellow solution was evaporated to dryness under reduced pressure. The residue was extracted with methanol, and the extract was evaporated to dryness. The residue was again extracted with methanol. The extract was concentrated to *ca.* 20 cm^3 under reduced pressure to yield a yellow precipitate. It was filtered and dissolved in methanol. The methanol solution was chromatographed by use of a Sephadex LH-20 column (ϕ1.5 cm × 30 cm) and methanol. The first main yellow eluate was concentrated to a small volume. The concentrate was mixed with a small amount of water and stored in a refrigerator to give orange crystals of the complex. Yield: 10%. The complex can also be prepared from $K_3[Co(CN)_5I]$ and $PMePh_2$ by a method similar to that for the PPh_3 complex.

trans(P,P)-$K[Co(CN)_4(PMe_2Ph)_2]$. A mixture of PMe_2Ph (2.2 g, 16 mmol) and $K_3[Co(CN)_5I]$ (3.4 g, 8 mmol) in a mixture (60 cm^3) of dioxane and water (5:2) was stirred at 50 °C for 4 h, and filtered. The filtrate was evaporated to dryness under reduced pressure. The residue was extracted with a mixture of methanol and dichloromethane (3:1). The extract was chromatographed by use of a Sephadex LH-20 column (ϕ 1.5 cm × 30 cm) and a mixture of methanol and dichloromethane (3:1). The first main yellow eluate was concentrated to a small volume. The concentrate was mixed with a small amount of ethanol and stored in a refrigerator to yield yellow crystals of the complex. Yield: 10%.

$K[Co(CN)_4(Ph_2PCH_2CH_2PPh_2)]$. A mixture of $K_3[Co(CN)_5I]$ (4.3 g, 10 mmol) and $Ph_2PCH_2CH_2PPh_2$ (4.0 g, 10 mmol) in a mixture (100 cm^3) of dioxane and water (7:3) was stirred at 75 °C for 7 h, and filtered. The filtrate was evaporated to dryness under reduced pressure, and the residue was extracted with methanol. The extract was evaporated to dryness, and the residue was again extracted with methanol. The extract was chromatographed by use of a Sephadex LH-20 column (ϕ 1.5 cm × 30 cm) and methanol. The second main yellow eluate was concentrated to a small volume under reduced pressure. The concentrate was mixed with a small amount of ethanol and stored

by a reaction of $[Co(acac)_3]$ with PMe_2Ph in ethanol in the presence of active charcoal. The geometrical configurations of these complexes can be easily assigned on the basis of the ^1H and ^{13}C NMR spectra (Tables 2 and 3). The bis(PMe_2Ph) complexes isolated as hexafluorophosphate are insoluble in water, but soluble in common organic solvents such as ethanol or dichloromethane. The *cis* isomer is quite stable in such solvents. The corresponding *trans* isomer is stable in dichloromethane, but hydrolyzes in ethanol (not anhydrous) to afford *trans*-$[Co(acac)_2(H_2O)(PMe_2Ph)]^+$ which is stable to further hydrolysis. The hydrolysis is depressed in the presence of excess PMe_2Ph Thus the *trans* bis(PMe_2Ph) isomer in hydrous ethanol gives the following equilibrium:

$$trans\text{-}[Co(acac)_2(PMe_2Ph)_2]^+ + H_2O \rightleftharpoons trans\text{-}[Co(acac)_2(H_2O)(PMe_2Ph)]^+ + PMe_2Ph$$

The *trans* bis(PMe_2Ph) isomer in ethanol slowly isomerizes to the *cis* isomer on addition of active charcoal, attaining an equilibrium between the two isomers. In fact the *cis* isomer also isomerizes to the *trans* isomer under the same conditions, the *cis* isomer being predominant at equilibrium at room temperature as indicated by the preparative experiment.

The $PMePh_2$ and PMe_3 ligands used in this study give only *trans*-$[Co(acac)_2(PMePh_2)_2]^+$ and *cis*-$[Co(acac)_2(PMe_3)_2]^+$, respectively under similar experimental conditions to that for the PMe_2Ph complex. The *trans*-$[Co(acac)_2(H_2O)(PMePh_2)]^+$ complex was derived from the *trans* bisphosphine complex by hydrolysis. These experimental results including those of the PMe_2Ph complex suggest that the $[Co(acac)_2(P)_2]^+$-type complex is stabilized in the *cis* isomer, unless there is steric hindrance between two phosphine ligands in the *cis* positions. The preponderance of *cis* coordination of phosphine ligands will be brought about by the strong *trans* effect of a phosphine ligand.[13] The $PMePh_2$ ligand might be too bulky to occupy *cis* positions in the bis(acac)cobalt(III) complex. No PPh_3 reacted with $[Co(acac)_3]$ in ethanol in the presence of active charcoal. On raising the reaction temperature reduction of Co(III) took place.

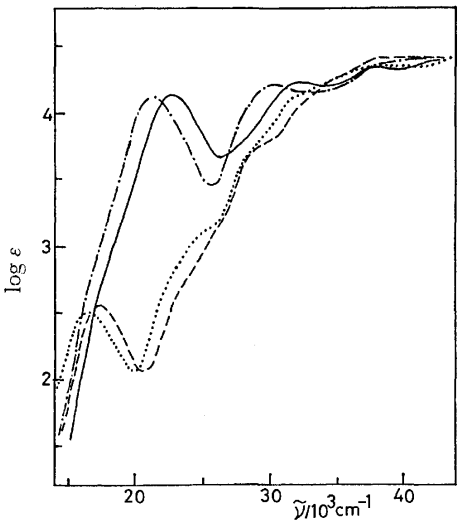

Fig. 1. Absorption spectra of *trans*-$[Co(acac)_2(PMe_2Ph)_2]^+$ (——), *trans*-$[Co(acac)_2(PMePh_2)_2]^+$ (—·—), *trans*-$[Co(acac)_2(H_2O)(PMe_2Ph)]^+$ (----), and *trans*-$[Co(acac)_2(H_2O)(PMePh_2)]^+$ (·····).

The absorption spectra of *trans*-$[Co(acac)_2(P)_2]^+$ and *trans*-$[Co(acac)_2(H_2O)(P)]^+$ ($P=PMePh_2$, PMe_2Ph) are compared in Fig. 1. The spectra of the *trans* bisphosphine complexes differ markedky from those of the aqua complexes; the formers show a very strong band around 22000 cm^{-1}. The *cis*-$[Co(acac)_2(P)_2]^+$ ($P=PMe_2Ph$, PMe_3) complexes exhibit no such strong bands in this region (Fig. 2). The strong bands of the *trans* bisphosphine complexes can be assigned to a charge transfer transition between the Co(III)–phosphine because of the strong intensity. The bands have a shoulder in the low energy side, which can be assigned to a part of the first d-d band. The aqua complexes show clearly the first d-d band, and the spectra resemble that of *trans*-$[Co(acac)_2(NH_3)_2]^+$ which gives the first d-d band at 18500 cm^{-1} (log $\varepsilon=1.89$).[14] The *cis*-$[Co(acac)_2(P)_2]^+$ ($P=PMe_2Ph$, PMe_3) complexes give a band at *ca.* 18500 cm^{-1} and a shoulder at *ca.* 22000 cm^{-1}. They can be assigned to two split components of the first d-d band. The Me_2-

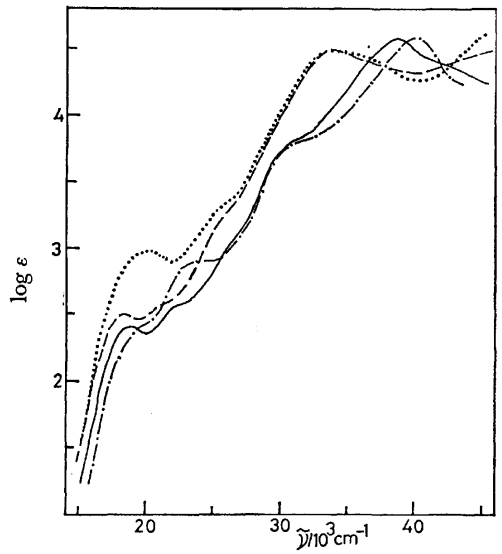

Fig. 2. Absorption spectra of *cis*-$[Co(acac)_2(PMe_3)_2]^+$ (——), *cis*-$[Co(acac)_2(PMe_2Ph)_2]^+$ (----), $[Co(acac)_2(Me_2PCH_2CH_2PMe_2)]^+$ (—·—), and $[Co(acac)_2(Ph_2PCH_2CH_2PPh_2)]^+$ (·····).

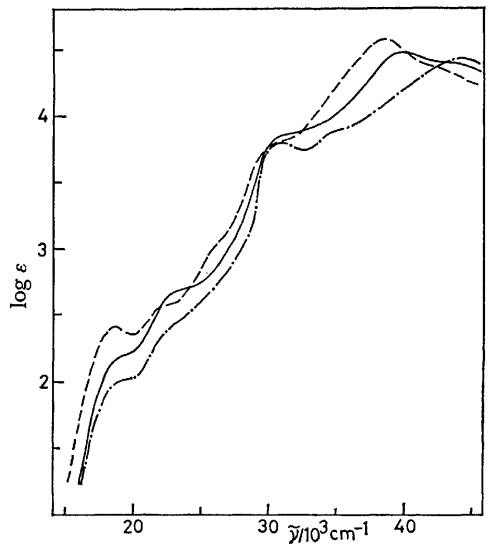

Fig. 3. Absorption spectra of *cis*-$[Co(acac)_2(PMe_3)_2]^+$ (----), *cis*-$[Co(CN)(acac)_2(PMe_3)]$ (——), and *cis*-$[Co(CN)_2(acac)_2]^-$ (—·—).

$PCH_2CH_2PMe_2$ complex also shows two components of the first d-d band, although the spectral pattern is somewhat different from that of the above bisphosphine complexes. The $Ph_2PCH_2CH_2PPh_2$ complex gives a broad, fairly strong single d-d band at 20200 cm^{-1}, but the band splits into two components (19400 and 20600 cm^{-1}) at 173 K.[8] A similar splitting spectral pattern in the first d-d band region has been observed for *cis*-$[Co(CN)_2(acac)_2]^-$[4] (Fig. 3) and *cis*-$[Co(CN)_2(C_2O_4)_2]^{3-}$.[15] In the ultraviolet region, all the complexes show complicated spectra due to absorptions arising from intramolecular transitions of the ligands and charge transfer transitions between the cobalt(III) ion and the ligands. In the complexes of each type including other cyano complexes studied here, both d-d and charge transfer bands are shifted remarkably depending on the kind of phosphine ligands. The shift occurs to the high energy side in the following order of ligands; $PPh_3 < PMePh_2 < PMe_2Ph \approx Ph_2PCH_2CH_2PPh_2 < PMe_3 < Me_2PCH_2CH_2PMe_2$. This order agrees with the decreasing order of the cone angles (θ(degree), steric effect) of phosphines given by Tolman;[16] $PPh_3(145) > PMePh_2(136) > Ph_2PCH_2CH_2PPh_2(125) \geq PMe_2Ph(122) > PMe_3(118) > Me_2PCH_2CH_2PMe_2(107)$. It also agrees with the decreasing order of the substituent additivity values ($\Sigma\chi_i$ (cm^{-1}), electronic effect) given by the same author;[16] $PPh_3(12.9) > PMePh_2(11.2) > PMe_2Ph(9.5) > PMe_3(7.8)$.

Figure 3 shows the absorption spectra of *cis*-$[Co(CN)_n(acac)_2(PMe_3)_{2-n}]^{(n-1)+}$ (n=0,1,2). By replacing the PMe_3 ligand by a cyanide ion, the first absorption band remains almost unshifted, but decreases the intensity. The band or shoulder around 30000 cm^{-1} can be assigned to a transition between the Co(III)–acac. The bands at 38800 cm^{-1} and 39900 cm^{-1} of the bisphosphine and the monocyano complexes, respectively, can be assigned to a transition between the Co(III)–PMe_3.

The ^1H NMR spectral data for the methyl and methine parts of the complexes are summarized in Table 2. Except for the *cis*-$[Co(acac)_2(PMe_2Ph)_2]^+$ complex, the methine protons of acac of the bis(acac) complexes with the phosphine ligand having a phenyl group resonate at a remarkably high field (4.47—4.94 ppm) as compared with those of the complexes with the trialkylphosphine ligand (5.42—5.50 ppm). A phenyl ring of the phosphine ligand in the former complexes comes over an acetylacetonate ring so that the methine proton should be shielded by the phenyl ring to cause the high field shift.[8] The methine proton of *cis*-$[Co(acac)_2(PMe_2Ph)_2]^+$ shows no such high field shift. The two PMe_2Ph ligands in this complex would be prohibited to rotate freely around the Co–P bond, and the conformation with the two phenyl rings stacking each other seems to be stable from studies with molecular models. When the complex has such a conformation, the methyl group(s) of the phosphine is placed over the acetylacetonate ring, and the resonance value of the methine proton would be similar to that in the PMe_3 complex. The P–CH_3 groups in $[Co(acac)_2(P)_2]^+$ (P=PMe_2Ph, $PMePh_2$) give triplet signals due to so-called virtual coupling, although those of the trialkylphosphine complexes become multiplets. The *cis* PMe_2Ph complex exhibits two kinds of the P–CH_3 signals, indicating the *cis*, chiral structure. The carbons of the methyl and phenyl groups on phosphorus except for the *p*-carbon also show triplet signals in the ^{13}C NMR spectra of both *cis* and *trans* bisphosphine complexes (Table 3). The spectral assignment was made according to the reference.[8] Thus there exists virtual coupling in both *cis* and *trans* bisphosphine complexes. In planar complexes, such virtual coupling is, in general, observed for only a *trans* isomer.[17] For some octahedral complexes of the *cis* type, however, the coupling has been reported to be remarkable.[18] Virtual coupling as a diagnosis for the *trans* arrangement of two phosphorus donor atoms seems to be limited to only planar complexes.

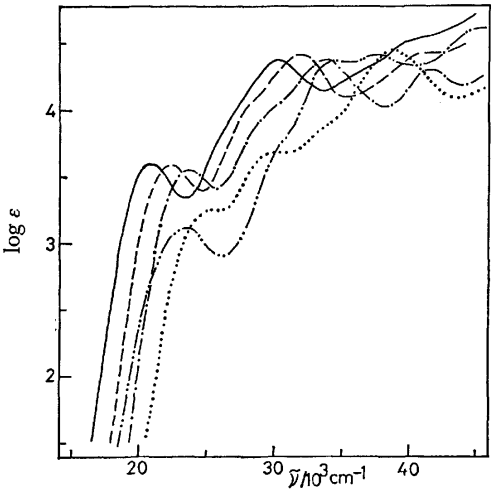

Fig. 4. Absorption spectra of *trans*(P,P)-[Co(CN)$_2$(acac)(PPh$_3$)$_2$] (——), *trans*(P,P)-[Co(CN)$_2$(acac)(PMePh$_2$)$_2$] (----), *trans*(P,P)-[Co(CN)$_2$(acac)(PMe$_2$Ph)$_2$] (—·—), *trans*(P,P)-[Co(CN)$_2$(acac)(PMe$_3$)$_2$] (·····), and *cis*-[Co(CN)$_2$(acac)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)] (—··—).

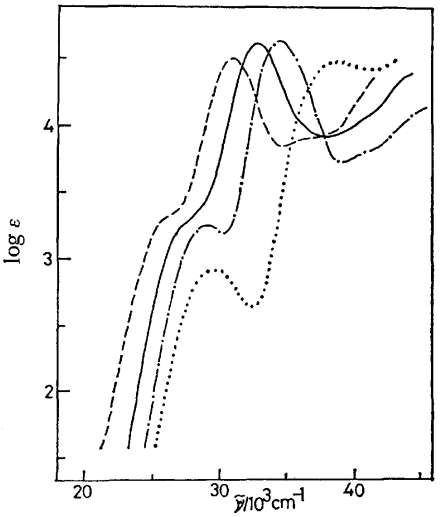

Fig. 5. Absorption spectra of *trans*-[Co(CN)$_4$(PPh$_3$)$_2$]$^-$ (----), *trans*-[Co(CN)$_4$(PMePh$_2$)$_2$]$^-$ (——), *trans*-[Co(CN)$_4$(PMe$_2$Ph)$_2$]$^-$ (—·—), and [Co(CN)$_4$(Ph$_2$PCH$_2$CH$_2$PPh$_2$)]$^-$ (·····).

The [Co(CN)$_2$(acac)(P)$_2$] Complexes. The [Co(CN)$_2$(acac)(P)$_2$]-type complex has three possible geometrical isomers, *trans*(P,P), *trans*(C,C), and *trans*(P,C) isomers. In this study, the reactions between *cis*-[Co(CN)$_2$(acac)$_2$]$^-$ and P(CH$_3$)$_n$(C$_6$H$_5$)$_{3-n}$ (n=0,1,2, or 3) afforded only one isomer for each phosphine ligand. All the complexes isolated can be assigned to either a *trans*(P,P) or a *trans*(C,C) configuration from the ^{1}H and ^{13}C NMR spectra (Tables 2 and 3). In addition the remarkable high field shift of the methine proton signals of acac in the complexes containing a phenylphosphine derivative as compared with that of the PMe$_3$ complex strongly suggests that the complexes have one or two phosphine ligands at the coordination sites perpendicular to the acetylacetonate ring. Thus the bisphosphine complexes except for the PMe$_3$ complex can be assigned to the *trans*(P,P) isomers. This assignment is supported by absorption spectra of those complexes. The complexes show the strong first d-d band as compared with that of the corresponding Ph$_2$PCH$_2$CH$_2$PPh$_2$ complex which is easily assigned to the *cis* isomer by appearance of two kinds of the methyl signals of acac in the ^{1}H NMR spectrum (Fig. 4). The bisphosphine complexes of a *cis*(P,P) type would show the first d-d band weaker than that of the Ph$_2$PCH$_2$CH$_2$PPh$_2$ complex by analogy with spectra of the [Co(acac)$_2$(P)$_2$]$^+$-type complexes as stated previously. The PMe$_3$ complex shows the weaker first d-d band than those of the other three bisphosphine complexes, but it is still stronger than that of the Ph$_2$PCH$_2$CH$_2$PPh$_2$ complex, suggesting the *trans*(P,P) isomer.

The preference of the *trans*(P,P) configuration in the [Co(CN)$_2$(acac)(P)$_2$]-type complex would result from the stronger *trans* effect of a cyanide ion than that of a phosphine. In general, ligands which exhibit a strong *trans* effect tend to avoid the *trans* positions to each other.[13] Hence the *trans*(C,C) and *trans*(P,C) configurations will be less favorable than the *trans*(P,P) configuration. Further, the bulkiness of phosphine ligands would still facilitate the *trans*(P,P) configuration.

The [Co(CN)$_4$(P)$_2$]$^-$ Complexes. There are two possible geometrical isomers, *cis* and *trans*, for the [Co(CN)$_4$(P)$_2$]-type complex. In this study, only one isomer was obtained for each of the bisphosphine complexes of this type. For the structural assignment of the bisphosphine complexes, no NMR spectra give useful information. However, the complexes show absorption spectra similar to one another, indicating the same geometrical configuration, although the spectra shift remarkably depending on the kind of the phosphine ligands (Fig. 5). In addition, the complexes exhibit a strong band or shoulder in the first d-d band region, the intensities of which are much stronger than that of the corresponding band of [Co(CN)$_4$(Ph$_2$PCH$_2$CH$_2$PPh$_2$)]$^-$. Thus the bisphosphine complexes can be assigned to the *trans*(P,P) configuration on the same consideration as that described for the other phosphine complexes. The reason for the preference of the *trans*(P,P) configuration in the [Co(CN)$_4$(P)$_2$]$^-$-type complex is not clear. When the strength of the *trans* effect of cyanide and phosphine ligands is taken into account, the *cis*(P,P) configuration would be more favorable than the *trans*-(P,P) one as stated previously. There might be a factor that stabilizes the planar-type coordination of four cyanide ligands in the complexes concerned.

This work was partly supported by the Kurata Research Grant of the Kurata Foundation. The authors wish to thank Dr. T. Ito of Institute for Molecular Science for obtaining ^{13}C NMR spectra.

The Solvent Extration of Amino Acids with Crown Ether[1)]

Hideyuki Noguchi,* Hiroyoshi Nakamura, Masatoshi Nagamatsu, and Masaki Yoshio

Faculty of Science and Engineering, Saga University, Saga 840

(Received July 3, 1981)

Protonated amino acids were extracted with crown ether and Metanil Yellow anion into 1,2-dichloroethane. The overall extraction constants (K_{ex}) for the 1:1:1 complex, AHLIn, of 18-crown-6 (L) with protonated amino acid (AH^+), and the Metanil Yellow anion (In^-) between 1,2-dichloroethane and water have been determined at 25.0 °C. The values of the extraction constants (log K_{ex}) were found to be 5.2, 6.2, 6.4, 6.3, 5.5, 6.2, and 5.5 for L-α-alanine, L-valine, L-leucine, L-phenylalanine, β-alanine, L-lysine, and aspartic acid respectively at 25.0 °C. The dependence of the varieties of crown ether on the extractability of L-leucine has been investigated. The highest extractability was obtained when water-soluble crown ether was used.

The solvent extraction of cationic metal ions with crown ether (L) has been widely carried out,[2)] the results indicate the dependence of the extractability on the cavity size of crown ether. Very few studies of the solvent extraction of organic species with crown ether have, however, been done. This work has been carried out in order to study the extraction of some organic species, amino acids, with crown ether. It is well known that the ammonium ion and protonated amine make a relatively stable complex with crown ether. A small difference in stability constant between primary and secondary amine complexes with crown ether has been observed.[3)] The present authors have previously indicated that the selectivity of crown ether for various type of amines can be improved by using the solvent-extraction method.[4)] Most amino acids include the $-NH_2$ group, its protonated form being able to complex with crown ether.

Therefore, the solvent extraction of amino acids (A) with crown ether as Metanil Yellow salt (AH^+LIn^-) has been attempted in this work. Metanil Yellow (In^-) was selected as the counter anion because of its larger dissociation constant and because it has its absorption in the visible region for spectrophotometric analysis.

Experimental

Reagents. 18-Crown-6 was synthesized by Gokel's method[5)] and recrystallized twice from acetonitrile. The acetonitrile was removed under a high vacuum (0.5 mmHg†) over a 5-h period. Crown ether shows no significant hydroxyl or cyano vibration in the 3500 and 2000 cm^{-1} infrared region. "Dibenzo-18-crown-6" was synthesized by the method of Pedersen[6)] and recrystallized from benzene. The polyether thus obtained showed a melting point and an infrared spectrum identical with those of an authentic sample. "Dicyclohexyl-18-crown-6" and the other crown ethers were obtained from the Nisso Co. and were used without further purification. The 1,2-dichloroethane and other reagents were of an analytical or special grade, and were used without purification.

Extraction Procedures. A typical extraction procedure was as follows: 25 ml of an aqueous solution containing 4×10^{-4} M (1 M=1 mol/dm^3) L-leucine and 6×10^{-5}—2.4×10^{-4} M Metanil Yellow was shaken with 10 ml of 1,2-dichloroethane containing 2×10^{-3}—1.6×10^{-2} M crown ether when 18-crown-6 was used. After equilibrium had been reached, the absorbance in the organic phase was measured at 404 nm with a Hitachi 124 spectrophotometer in a 10 mm cell.

HIn, HLIn, and AHLIn contribute to the absorbance in the organic phase at 404 nm. HIn, however, did not show the absorbance in the pH range from 2 to 4. Therefore, the absorbance of AHLIn can be corrected by the blank test, which is related to that of HLIn. The constant pH value of 2.8±0.1 was selected in order to produce a precipitate at the phase boundary in the pH range lower than 2.

† 1 mmHg≈133.322 Pa.

Results and Discussion

When a protonated amino acid (AH^+) forms a complex with a crown ether, the complex can be extracted as an ion-pair with a large anion (In^-); the distribution ratio of amino acid, D, in the pH range 2—4 can be written as:

$$D = \frac{[AHLIn]_{org}}{[A]+[AH^+]}. \quad (1)$$

Here, K_{ex} is the overall extraction constant for the complex:

$$K_{ex} = \frac{[AHLIn]_{org}}{[AH^+][L]_{org}[In^-]}. \quad (2)$$

Combining these two equations gives the following equation:

$$D = K_{ex}[L]_{org}[In^-]\left(1+\frac{K}{[H^+]}\right)^{-1}, \quad (3)$$

where K is the dissociation constant of protonated amino acid.

Under the condition of a constant pH, the distribution ratio as a function of the concentration of the crown ether in the organic phase at 25.0 °C showed a straight line with a slope of 1, while that as a function of the Metanil Yellow also showed a straight line with a slope of 1, as is shown in Figs. 1 and 2. These results show that the 1,2-dichloroethane extracts is a 1:1:1 complex composed of crown ether, amino acid, and Metanil Yellow. From Figs. 1 and 2, the values of log K_{ex} are found to be 5.2, 6.2, 6.4, 6.3, 5.5, 6.2, and 5.5 for L-α-alanine, L-valine, L-leucine, L-phenylalanine, β-alanine, L-lysine, and L-aspartic acid respectively at 25.0 °C. As was seen in the previous paper,[4)] the value of K_{ex} depends greatly on the number of hydrogen atoms available for hydrogen bonding with crown ether. In this case, the difference in K_{ex} is very small, because all of the amino acids investigated have the same number

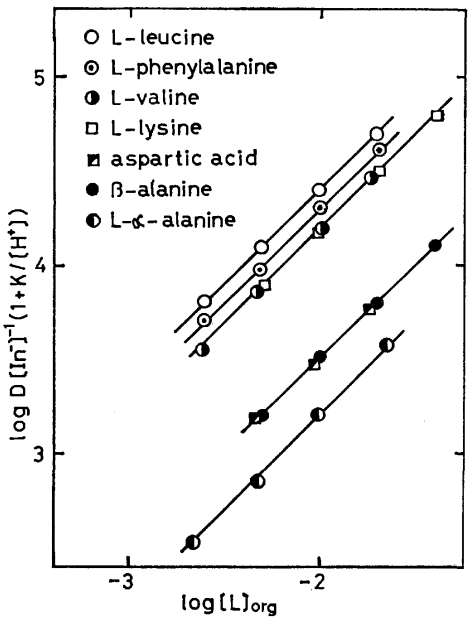

Fig. 1. Plots of $\log D\,[In^-]^{-1}\,(1+K/[H^+])$ *vs.* $\log [L]_{org}$ for amino acids at 25.0 °C.

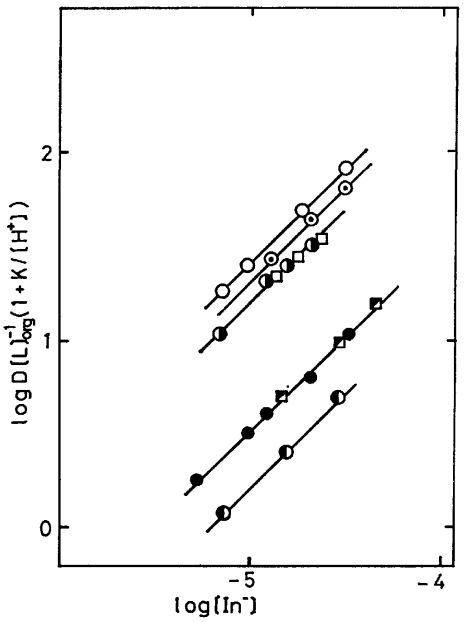

Fig. 2. Plots of $\log D\,[L]_{org}^{-1}\,(1+K/[H^+])$ *vs.* $\log [In^-]$ for amino acids at 25.0 °C.

of hydrogen atoms, $-NH_3^+$. The small difference in K_{ex} may be due to the effect of the size of the amino acids, which was also shown in the previous paper.[4]

The dependence of the varieties of crown ether on the extractability of amino acid, L-leucine, was also investigated. The extractability of L-leucine decreased in the following order: 18-crown-6>"dicyclohexyl-18-crown-6">"dibenzo-18-crown-6".

18-Crown-6, which is very soluble in water, gives rise to the most enhanced extractability, indicating that extractability is increased with an increase in the solubility of crown ether in water when the ring size of crown ether is the same.

Table 1. Extraction constants and related values of L-leucine at 25 °C

	$\log K_{ex}$	$K_{d,L}$	K_{dAHLIn}/K_{AHLIn}[a]
18-Crown-6	6.4	1.1	2.8×10^6
"Dicyclohexyl-18-crown-6"	6.1	760	9.6×10^8
"Dibenzo-18-crown-6"	4.5	3200	1.0×10^8

a) Values calculated from K_{ex} and $K_{d,L}$ using Eq. 4.

The overall extraction constant could be written as follows:

$$K_{ex} = \frac{K_{d,AHLIn}K_{AHLIn}}{K_{d,L}}, \quad (4)$$

where $K_{d,L}=[L]_{org}/[L]$, $K_{d,AHL\,In}=[AHL\,In]_{org}/[AHL\text{-}In]$, and $K_{AHL\,In}=[AHLIn]/[AH^+][L][In^-]$. The overall extraction constants (25.0 °C) obtained are shown in Table 1.

Table 1 also shows the values of $K_{d,L}$ and $K_{d,AHL\,In}$ $K_{AHL\,In}$, which were calculated from the values of K_{ex} and $K_{d,L}$.

Equation 4 shows that the trend for K_{ex} reflects $K_{AHL\,In}$ and the distribution coefficients of the AHLIn and L species. It is well known that the hydrophobic species are extracted more easily than the hydrophilic species. The values of $K_{d,AHL\,In}$ $K_{AHL\,In}$ increase with an increase in the hydrophobic nature of crown ether, which may reflect the extractability of the compound, AHLIn. However, the effect of $K_{d,L}$ on the extractability is much greater than that of the last term in Table 1.

The extraction of L-leucine with crown ether having a bigger pore size than 18-crown-6 was also investigated. The same trend of extractability was obtained: "dicyclohexyl-24-crown-8">"dibenzo-24-crown-8". The extractability of L-leucine with the 18-membered crown ethers is much greater than with the 24-membered.

Thus, the distribution coefficient of the crown ether, $K_{d,L}$ in Eq. 4 is the most important factor in determining the magnitude of K_{ex} for amino acid. Thus, a soluble crown ether in water, such as 18-crown-6, may be considered a promising reagent for the separation and extraction of amino acids.

Attractive Interactions between Carbonyls and Groups Bearing Lone-pair Electrons in Triptycene Systems[1]

Michinori Ōki,* Giichi Izumi, Gaku Yamamoto, and Nobuo Nakamura

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

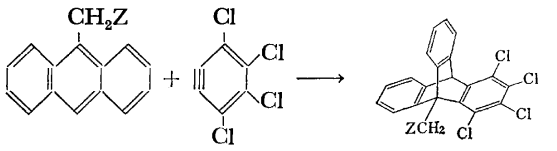
(Received February 2, 1981)

Compounds which carry a methoxyl or a chloro group in 1-position and a substituted carbonylmethyl group in 9-position of the triptycene system have been prepared to examine populations of rotamers by ^{1}H NMR spectra. The methoxy compounds favored the $\pm sc$ conformations, whereas the *ap* conformations were relatively favored in the chloro compounds. The results indicate that there are attractive interactions between the carbonyls and a methoxyl or a chloro group and are discussed from the electron-accepting ability of the carbonyl group and the electron-donating ability of the methoxyl and the chloro groups. An aldehyde group was apparently less able to interact with electron-donors than a ketone. This apparent anomaly was discussed from the intramolecular dipolar interactions.

Some five years ago, we encountered an unusual phenomenon that in a triptycene system a charge-transfer type interaction can occur between a phenyl and a dimethoxybenzo group, of which the former is acting as an electron-acceptor.[2] It is not unusual to observe that a benzene derivative carrying strongly electronegative group(s) does act as an electron-acceptor; usually, benzene and its alkyl derivatives are considered to be an electron-donor. This unusual phenomenon may be considered to appear in the situation that two substituents located in the 1 and 9 positions of the triptycene skeleton are so close to each other that a weak, otherwise not-detectable interaction is made observable. This consideration aroused our interest in extending our work to find potential, weak interactions which are theoretically feasible but have not yet been observed experimentally.

Carbonyl groups are known to possess low-lying π^* orbitals[3] which should facilitate interactions with easily ionizable electrons. Indeed, nitrogen-carbonyl interactions in medium-sized rings are well-documented.[4] Bürgi *et al.*[5] performed X-ray crystallographic studies of such compounds and suggested a pyramidal, rather than planar, configuration for the carbonyl group. Oxygen-carbonyl interactions, though much weaker, are also known.[6] Although our system will not permit us to adopt a variety of electron donating groups because of difficulties in syntheses, yet it allows us at least to vary peri-substituents to some extent. This method of approach will enable us to explore possibilities of interactions involving less electron-donating systems, especially when a strongly electron-accepting group such as the carbonyl group is present in the bridgehead position. In addition, a variety of carbonyl moieties may be introduced into the bridgehead position. This introduction will afford information about the electron-accepting ability of various carbonyl derivatives and is intriguing in that the information made available so far is confined to ketones niteracting with nitrogen or oxygen atoms. Thus, we planned to introduce formyl, acetyl, methoxycarbonyl, and cyano groups as carbonyl modifications into the bridgehead position and methoxyl and chloro groups into the *peri*-position.

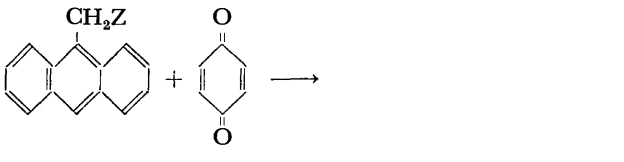
Syntheses of the compounds examined were carried out in essentially four ways. When appropriate 9-(substituted methyl)anthracenes were available, they were treated with tetrachlorobenzyne (Eq. 1).



(1)

1 Z=COOCH$_3$
2 Z=CN

In the syntheses of 1,4-dimethoxytriptycene derivatives, the anthracenes were treated with *p*-benzoquinone to afford Diels-Alder adducts (**3**) which were enolized by a base and were methylated with dimethyl sulfate (Eq. 2).

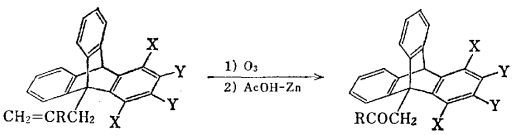


(2)

3

4 Z=C(CH$_3$)=CH$_2$
5 Z=CN
6 Z=COOCH$_3$
7 Z=C≡CCH$_3$

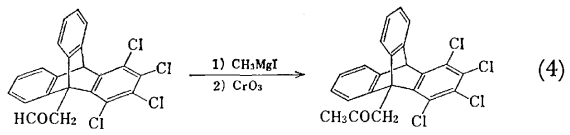
Some of the carbonyl derivatives were prepared by ozonolysis of the corresponding olefins (Eq. 3).



(3)

8 X=OCH$_3$, Y=R=H
9 X=OCH$_3$, Y=H, R=CH$_3$
10 X=Y=Cl, R=H
12 X=CH$_3$, Y=R=H
13 X=Y=H, R=CH$_3$

9-(Acetylmethyl)-1,2,3,4-tetrachlorotriptycene (**11**) was prepared from the corresponding aldehyde (**10**) by a Grignard reaction followed by oxidation (Eq. 4). The similar treatment of the methoxy derivative has failed to give the expected ketone because of cyclization.[7]



(4)

10 **11**

Detection of *ap* and ±*sc* isomers owes to the fact that, if the internal rotation about the C_9–C_{subst} bond is frozen on the NMR time scale, the methylene protons in the bridgehead give an AB quartet signal for the ±*sc* and a singlet for the *ap* in its proton NMR spectrum. The triptycene derivatives usually showed a broad signal due to the methylene protons in the 9-position at room temperature and the signal split into a set of AB quartet and a singlet in typical cases at low temperatures.

Experimental

9-(Formylmethyl)-1,4-dimethoxytriptycene (8). To a solution of 1.6 g of 9-allyl-1,4-dimethoxytriptycene[7] in 80 mL of dichloromethane was introduced ozone at −78 °C until the solution changed to faint blue. The solvent was removed below 30 °C and the residue was heated with 1.5 g of zinc dust, 30 mL of acetic acid, and 5 mL of water for 1 h. The acetic acid was removed and the residue was extracted with dichloromethane. Recrystallization of the product from benzene–hexane afforded the desired compound as crystals, mp 252—253 °C, in 91% yield. Found: C, 81.02; H, 5.57%. Calcd for $C_{24}H_{20}O_3$: C, 80.88; H, 5.65%. ^{1}H NMR ($CDCl_3$, δ): 3.63 (3H, s), 3.81 (3H, s), 3.60—4.60 (2H, br. m), 5.96 (1H, s), 6.54 (2H, s), 6.90—7.60 (8H, m), 9.96 (1H, t, J=1.8 Hz).

9-(Formylmethyl)-1,2,3,4-tetrachlorotriptycene (10), mp 223—224 °C, was similarly prepared from 9-allyl-1,2,3,4-tetrachlorotriptycene[8] in 92% yield. Found: C, 60.71; H, 2.69; Cl, 32.10%. Calcd for $C_{22}H_{12}OCl_4$: C, 60.89; H, 2.79; Cl, 32.66%. ^{1}H NMR ($CDCl_3$, δ): 3.50—5.00 (2H, br. m), 6.11 (1H, s), 6.90—7.80 (8H, m), 9.40—10.5 (1H, br. m).

9-(Formylmethyl)-1,4-dimethyltriptycene (12), mp 227—228.5 °C, was similarly prepared by ozonation of 9-allyl-1,4-dimethyltriptycene.[8] Found: C, 88.99; H, 5.96%. Calcd for $C_{24}H_{20}O$: C, 88.86; H, 6.21%. ^{1}H NMR ($CDCl_3$, δ): 2.46 (6H, s), 4.14 (2H, d, J=2 Hz), 5.69 (1H, s), 6.58 (1H, d, J=8 Hz), 6.62 (1H, J=8 Hz), 6.80—7.50 (8H, m), 9.92 (1H, t, J=2 Hz).

1,4-Dimethoxy-9-(2-methyl-2-propenyl)triptycene (4). A mixture of 2 g (82 mmol) of magnesium, 2 mL of 2-methyl-2-propenyl chloride, 5 mL of tetrahydrofuran, and a small amount of iodine was allowed to react. After the initial reaction subsided, 50 mL of tetrahydrofuran was added. To the mixture, 10 mL of 2-methyl-2-propenyl chloride in 50 mL of tetrahydrofuran was added in 3 h at room temperature. Anthrone (5 g or 26 mmol) was added to the mixture in small portions and the mixture was sitrred for 1 h. The mixture was treated with water and then with concentrated hydrochloric acid. The mixture formed two layers. The tetrahydrofuran layer was separated, dried over calcium chloride, and concentrated. The product was chromatographed on silica gel, hexane being used as an eluent. 9-(2-Methyl-2-propenyl)anthracene was obtained in 75% yield. ^{1}H NMR ($CDCl_3$, δ): 1.94 (3H, s), 4.26 (3H, apparent s), 4.78 (1H, br. s), 7.30—8.25 (8H, m), 8.35 (1H, s).

The anthracene (1.5 g) and 0.8 g of *p*-benzoquinone in 20 mL of toluene were heated under reflux under a nitrogen atmosphere for 3 h and allowed to stand for 24 h. A Diels-Alder adduct which crystallized out from the mixture was collected and dissolved in 50 mL of dioxane. The solution was treated with 0.5 g of sodium hydroxide in 10 mL of water and dimethyl sulfate was added until an intense color faded. The process was repeated a few times until the coloration could not be observed on addition of alkaline solutions. The mixture was poured into water and the resulted solid was collected. It was recrystallized from benzene–hexane, mp 199.5—200.5 °C. The yield was 81%. Found: C, 84.84; H, 6.40%. Calcd for $C_{26}H_{24}O_2$: C, 84.75; H, 6.56%. ^{1}H NMR ($CDCl_3$, δ): 2.10 (3H, s), 3.62 (3H, s), 3.78 (3H, s), *ca.* 3.75 (2H), 4.21 (1H, br. s), 4.90 (1H, br. s), 5.89 (1H, s), 6.48 (2H, s), 6.80—7.50 (8H, m).

9-(Acetylmethyl)-1,4-dimethoxytriptycene (9). A solution of 1,4-dimethoxy-9-(2-methyl-2-propenyl)triptycene in dichloromethane was ozonized as above and the resulted ozonide was decomposed in the presence of zinc dust to give the product, mp 289.0—289.8 °C, in 73% yield. Found: C, 81.21; H, 5.87%. Calcd for $C_{25}H_{22}O_3$: C, 81.06; H, 5.98%. ^{1}H NMR ($CDCl_3$, δ): 2.47 (3H, s), 3.80 (3H, s), 3.60—4.70 (2H, br. m), 5.90 (1H, s), 6.51 (2H, s), 6.80—7.30 (8H, m). At −30 °C, the broad signal at *ca.* δ 4 became a distinct quartet, δ's being 4.60 and 3.81 and J being 17 Hz.

9-(Acetylmethyl)triptycene (13), mp 217—218 °C, was similarly prepared from 9-(2-methyl-2-propenyl)triptycene by ozonation. Found: C, 89.06; H, 5.97%. Calcd for $C_{23}H_{18}O$: C, 89.00; H, 5.85%. ^{1}H NMR ($CDCl_3$, δ): 2.55 (3H, s), 4.09 (2H, s) 5.49 (1H, s), 6.80—7.50 (12H, m).

9-(Cyanomethyl)-1,4-dimethoxytriptycene (5), mp 273—274 °C, was prepared as above: 9-(cyanomethyl)anthracene[9] and *p*-benzo quinone were allowed to react and the product was methylated. The yield was 78%. Found: C, 81.54; H, 5.28; N, 4.26%. Calcd for $C_{24}H_{19}NO_2$: C, 81.57; H, 5.42; N, 3.96%. ^{1}H NMR ($CDCl_3$, δ): 3.80 (6H, s), 4.18 (2H, br. s), 5.92 (1H, s), 6.58 (2H, s), 6.90—7.70 (8H, m).

9-(Methoxycarbonylmethyl)-1,4-dimethoxytriptycene (6). 9-(Methoxycarbonylmethyl)anthracene was prepared from the corresponding carboxylic acid[10] by the usual esterification. An adduct between 9-(methoxycarbonylmethyl)anthracene and *p*-benzoquinone was prepared as above and converted to the triptycene derivative, mp 223.8—224.8 °C. The yield was 85%. Found: C, 77.98; H, 5.72%. Calcd for $C_{25}H_{22}O_4$: C, 77.70; H, 5.74%. ^{1}H NMR ($CDCl_3$, δ): 3.62 (3H, s), 3.78 (3H, s), 3.80 (3H, s), 3.40—4.40 (2H, br. m), 6.53 (2H, s), 6.80—7.60 (8H, m).

9-(2-Butynyl)-1,4-dimethoxytriptycene (7). To a solution of 2.8 g (32 mmol) of 1-chloro-2-butyne and 5.6 g (29 mmol) of anthrone in 150 mL of ethanol, was added a solution of 1.7 g (30 mmol) of potassium hydroxide in 30 mL of methanol in 3 h under a nitrogen atmosphere. The mixture was stirred for an additional hour after the addition. The solvent was evaporated and the residue was taken up in dichloromethane. The solution was washed with water and evaporated. The residue was taken up in 100 mL of methanol and to the solution was added 0.7 g of sodium borohydride in 30 mL of methanol. The solvent was evaporated and the residue was shaken with dichloro-

methane and dilute hydrochloric acid. The organic layer was evaporated and the residue was chromatographed on a silica-gel column. The crude anthracene derivative thus obtained was treated with *p*-benzoquinone and then converted to the triptycene derivative. The desired compound was obtained by recrystallization from benzene–hexane in 42% yield based on 1-chloro-2-butyne. Mp 253.0—253.3 °C. Found: C, 85.14; H, 5.89%. Calcd for $C_{26}H_{22}O_2$: C, 85.22, H, 6.05%. ^{1}H NMR ($CDCl_3$, δ): 1.73 (3H, t, J=2.5 Hz), 3.69 (3H, s), 3.75 (3H, s), 4.13 (2H, br. q, J=2.5 Hz), 5.89 (1H, s), 6.80—8.00 (8H, m).

9-(Acetylmethyl)-1,2,3,4-tetrachlorotriptycene (11). To a Grignard solution prepared by adding methyl iodide in ether until 0.5 g (21 mmol) of magnesium disappaered, was added 0.9 g (21 mmol) of 9-(formylmethyl)-1,2,3,4-tetrachlorotriptycene in 20 mL of dichloromethane in 20 min. After further 10 min, the mixture was decomposed with dilute hydrochloric acid. The organic layer gave 93% 9-(2-hydroxypropyl)-1,2,3,4-tetrachlorotriptycene, mp 232—234 °C. High resolution MS (observed M^+): 447.9933, 449.9917, 451.9940, and 453.9963. $C_{23}H_{16}OCl_4$ requires 447.9956, 449.9927, 451.9897, and 453.9868. The relative intensities of the peaks agreed well with those calculated from the natural abundance of ^{35}Cl and ^{37}Cl. ^{1}H NMR ($CDCl_3$, δ): 1.69 (1H, br. s), 1.77 (3H, d, J=6.51 Hz), 3.81 (2H, m), 4.31 (1H, m), 6.03 (1H, s), 7.00—7.76 (7H, m), 8.49 (1H, m).

The hydroxylic compound (0.5 g) in 30 mL of acetone–dichloromethane (2:1) was oxidized at 0 °C by mixing with 0.42 g of chromium(VI) oxide, 0.2 mL of sulfuric acid, and 0.2 mL of water for 2 h. The solvent was evaporated and the mixture was extracted with dichloromethane. The organic layer was washed with water and evaporated. The residue was recrystallized from tetrahydrofuran–hexane to afford a pure sample, mp 276—277 °C, in 95% yield. Found: C, 61.82; H, 2.94; Cl, 31.51%. Calcd for $C_{23}H_{14}OCl_4$: C, 61.64; H, 3.15; Cl, 31.64%. ^{1}H NMR ($CDCl_3$, δ): 2.56 (3H, s), 3.40—5.10 (2H, br. q), 6.01 (1H, s), 6.80—7.70 (8H, m).

9-(Methoxycarbonylmethyl)-1,2,3,4-tetrachlorotriptycene (1). To a boiling solution of 0.73 g of 9-(methoxycarbonylmethyl)-anthracene and 0.8 mL of isopentyl nitrite in 10 mL of dichlomethane, was added a solution of 0.85 g of tetrachloroanthranilic acid[11] in 5 mL of acetone in 1.5 h. The mixture was heated for further 1 h and filtered while hot to remove an acridone derivative. The solvent was evaporated and the residue was chromatographed to give a mixture of a 1,4-adduct and the desired 9,10-adduct. Since the solubility of the desired product in carbon tetrachloride was very low, the solvent could be used for separation. Recrystallization from tetrahydrofuran–hexane gave a pure sample, mp 247.3—248.0 °C, in 8% yield. Found: C, 59.25; H, 2.95%. Calcd for $C_{23}H_{14}O_2Cl_4$: C, 59.52; H, 3.04%. ^{1}H NMR ($CDCl_3$, δ): 3.81 (3H, s), 3.5—5.2 (2H, br. m), 6.05 (1H, s), 7.00—7.80 (8H, m).

9-(Cyanomethyl)-1,2,3,4-tetrachlorotriptycene (2), mp >300 °C, was prepared similarly from 9-(cyanomethyl)anthracene and tetrachlorobenzyne. Found: C, 61.58; H, 2.39; N, 3.51; Cl, 32.56%. Calcd for $C_{22}H_{11}NCl_4$: C, 61.29; H, 2.57; N, 3.25; Cl, 32.89%. ^{1}H NMR ($CDCl_3$, δ): 4.48 (2H, br. s), 6.09 (1H, s), 7.00—7.80 (8H, s).

9-(2-Hydroxypropyl)-1,4-dimethoxytriptycene. 9-(Formylmethyl)-1,4-dimethoxytriptycene was treated with a Grignard solution prepared from magnesium and methyl iodide in ether. The reaction gave 9-(2-hydroxypropyl)-1,4-dimethoxytriptycene, mp 224—225 °C. Found: C, 80.69; H, 6.31%. Calcd for $C_{25}H_{24}O_3$: C, 80.62; H, 6.49%. ^{1}H NMR ($CDCl_3$, δ): 1.50 (3H, d, J=7 Hz), 2.55 (1H, m), 3.45 (2H, d, J=7 Hz), 3.70 (3H, s), 3.77 (3H, s), 4.65 (1H, m), 5.89 (1H, s), 6.90—8.15 (8H, m).

Table 1. $\pm sc/ap$ ratios of 1,4-dimethoxytriptycene derivatives

Compound	9-Substituent	$\pm sc/ap$	Observed temp/°C
9	CH_2COCH_3	≥10	−30
6	CH_2COOCH_3	≥10	−30
8	CH_2CHO	≥10	−45
5	CH_2CN	1.5	−50
7	$CH_2C{\equiv}CCH_3$	0.1	−60

Table 2. $\pm sc/ap$ ratios of 1,2,3,4-tetrachlorotriptycene derivatives

Compound	9-Substituent	$\pm sc/ap$	Observed temp/°C
11	CH_2COCH_3	≥10	−20
1	CH_2COOCH_3	6	−40
10	CH_2CHO	1.1	−20
2	CH_2CN	0	−40

Spectral Measurements and Population Determinations. ^{1}H NMR spectra were obtained on a Hitachi R 20B spectrometer, operating at 60 MHz and equipped with a temperature variation accessory, and ^{13}C NMR spectra on a JEOL FX-60 spectrometer operating at 15 MHz. Low temperatures were calibrated by the chemical shift difference of methanol protons. Infrared spectra were obtained on a JASCO DS-402G spectrometer with a CaF_2 cell of 0.05 mm thickness. All the spectra were obtained as solution in chloroform or chloroform-*d* unless otherwise stated. Populations of rotamers were obtained by integration of the methylene signals (an AB quartet and a singlet) in the ^{1}H NMR spectra. Where proton signals, other than those of the 9-CH_2, which are split for the respective rotamers at low temperatures are available, those were used to obtain the population ratios, because they give usually clearer results. Examples are formyl protons of **8** and **10**, and dimethoxybenzo protons of **5**.

X-Ray Crystallography. Crystals of 9-(formylmethyl)-1,4-dimethyltriptycene (**12**) suitable for the X-ray diffraction study were grown from hexane–benzene. A crystal of 0.4 mm × 0.4 mm × 0.2 mm size was mounted on a Rigaku Automatic Structure Analysis System RASA-II and data were obtained with graphite-monochromated Cu $K\alpha$ radiation. A total of 3576 independent reflections were observed up to 135° in 2θ, and 2575 of the total was judged effective ($F \geq 2\sigma$). The crystal was orthorhombic with space group *Pbca*, having the following crystal data: a=15.374(4), b=9.801(2), c=23.112(3), Z=8, D_x=1.24 g cm^{-3}. The structure was solved by the direct method with the use of the MULTAN program. The final R factor was 7.0% including hydrogens.

Results and Discussion

Population ratios obtained by integrating ^{1}H NMR signals due to the $\pm sc$ and the ap forms are listed in Tables 1 and 2.

The data in Table 1 suggest that, if an electron-accepting group is an aldehyde, a ketone, or an ester and an electron-donor is a methoxyl group, the ap

form is not detectable. Since the steric effect is expected to disfavor the $\pm sc$ form, as discussed later, the results indicate that there exists a strong attractive interaction between those carbonyl groups and a methoxyl group in proximity.

In contrast, if the electron-accepting group is a nitrile, the population ratio $\pm sc/ap$ is greatly decreased. Since the $\pm sc/ap$ ratio is 2.0 from the statistical stand point, the value of 1.5 may be argued that there is no attractive interaction between a cyano and a methoxyl group. It is especially so, if one takes into account a fact that 9-ethyl-1,4-dimethoxytriptycene, in which no attractive interaction is apparent, is reported to give $\pm sc/ap$ ratio of 0.7.[12] In order to diagnose the presence or absence of the attractive interactions in the nitrile (**2**), we have used a model compound. Since the carbon atom in the cyano group is triply bonded to a nitrogen, an acetylenic bond may be used as a model for the cyano group: an acetylene group is sterically of a similar size with a cyano group but the electron-accepting ability is far less than the cyano. As is seen in Table 1, the $\pm sc/ap$ ratio of 9-(2-butynyl)-1,4-dimethoxytriptycene (**7**) is only 0.1. Thus we conclude that there is an attractive interaction, although weak, between a cyano and a methoxyl group in this system. Since the steric effect disfavors the $\pm sc$ form, the observed value becomes less than the statistical, reflecting the weakness of the interaction.

As to a model for other compounds, an allyl group may be used as a model for a formylmethyl group: the steric sizes of these two groups are similar as far as we discuss the steric interactions between those and the methoxyl group in 1 position, because the main effect is given by CH= groups in both cases, and the electronic interaction should be minimal between the methoxyl group and the vinyl group. The population ratio $\pm sc/ap$ of 9-allyl-1,4-dimethoxytriptycene was 0.7 to indicate that the interaction between the formyl and the methoxyl group in compound **8** is fairly strong.

The data in Table 2 are indicative of several interesting points. The most apparent phenomenon is that the $\pm sc/ap$ ratios are greatly diminished relative to the methoxy derivatives, although the existence of an attractive interaction is certain. ^{13}C NMR data obtained with $CDCl_3$ solutions were in accord with the indication by the ^1H NMR spectra (chemical shifts given from TMS): **1** showed a broad singlet for the methylene carbon at 34 ppm and two singlets at 170.6 and 171.7 ppm for the carbonyl carbon at −50 °C, whereas **10** gave two singlets both for methylene (41.0 and 42.4 ppm) and for carbonyl (200.7 and 202.4 ppm) carbons. Being a weak electron-acceptor, the cyano group of **2** does not make it possible to show a sign of existence of the $\pm sc$ isomer. A similar phenomenon was found in more congested systems.[13] The results are in conformity with the expectation from the ionization potentials of 1,4-dimethoxybenzene[14] and 1,2,3,4-tetrachlorobenzene,[15] the former being lower than the latter.

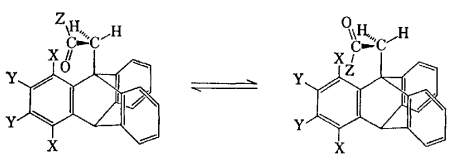
Since we are looking at the population ratios as the results of combination of electronic, steric and other effects, we may not forget the steric effect. The chloro group is known to be a little larger than the methoxyl group, if the steric effect is given by the oxygen atom only in the latter. Therefore, the steric effect of the chloro group disfavors the $\pm sc$ form as well, relative to the methoxyl group. The critical case is the formyl compound (**10**), since its population ratio is lower than the statistical value: there remains a problem whether we should conclude that the attractive interaction is apparent in this compound. We used 9-(formylmethyl)-1,4-dimethyltriptycene (**12**) as a model compound which has a substituent of a similar size in the peri-position, yet the electronic effect between the formyl and the substituent in the peri-position is negligible: a methyl group is known to be a little larger than a chloro group but the difference is not large. The results show that **12** exists as the *ap* form exclusively. From these, we conclude that there is an attractive interaction between the chloro and the formyl group in this system.

Table 3. Carbonyl stretching absorptions

Compound	*peri*-Substituent	Bridgehead Substituent	$\nu_{C=O}/cm^{-1}$
10	Cl	CH_2CHO	1725
1	Cl	CH_2COOCH_3	1731, 1754
11	Cl	CH_2COCH_3	1741
8	OCH_3	CH_2CHO	1720
6	OCH_3	CH_2COOCH_3	1722, 1751
9	OCH_3	CH_2COCH_3	1742
13	H	CH_2COCH_3	1732

The third and the most striking feature of the data in Table 2 is the fact that the apparent strength of the interaction between the formyl and the chloro groups is weaker than those involving a methoxycarbonyl or an acetyl group. This is rather astonishing since, in ordinary organic reactions, aldehydes are more reactive and are consequently considered to be more electrophilic than ketones and esters. There must be reasons causing this anomalous phenomenon.

When the molecules like the aldehydes (**8**, **10**, and **12**), the ketones (**9** and **11**), and the esters (**1** and **6**) are considered, the stereoisomerism about the C_{CO}–C_α bond is possible in addition to that about the C_9–C_{subst} bond. The possible conformations of the carbonyl moiety are depicted in the following scheme, the $\pm sc$ conformations being taken as examples. Indeed, the rotational isomerism of the esters of a similar system has been found by ^1H NMR and IR spectra.[16] In order to obtain information about the conformation of the carbonyl moieties, the infrared spectra were examined. The results are shown in Table 3.



O-inside *O*-outside

A peculiarity is immediately singled out from the

a) The form of the anisotropic temperature factor is: $T=\exp(-B_{11}h^2-B_{22}k^2-B_{33}l^2-2B_{12}hk-2B_{13}hl-2B_{23}kl)$.

data in Table 3. Whereas the esters show two absorptions, other carbonyls give only one absorption. Although it is clear that there are two conformations, *O*-inside and *O*-outside, for the esters from the analogy of the similar system,[16] it is not apparent that other carbonyls exist in a single conformation. Especially because there is only one band in spite of the fact that at least there are two conformations concerning the rotation about the C_9–C_{subst} bond, there is a possibility that the infrared spectra cannot distinguish the rotamers which are actually present. The infrared spectra do suggest, however, that the data in Table 3 are anomalous in that the aldehydes show absorptions due to the C=O stretching at lower frequencies than those of ketones. This is the opposite of normal trends[17] and the anomaly is caused because the ketones absorb at abnormally high frequencies.

There may be various reasons for raising frequencies of C=O stretching vibrations. The most commonly encountered reason is the syn-parallel arrangement of two strong dipoles. For example, 2-halocyclohexanone is known to show C=O stretching absorptions at higher frequencies when the halogen is equatorial.[18] This kind of effect is considered to be stronger if the conformation is $\pm sc$ than the case of ap conformation in the systems examined here because the distance between the two parallel dipoles, C–Cl and C=O, is smaller in the former. Thus if the diople interaction is the cause for the IR results, the ketones should take *O*-inside conformations and the aldehydes *O*-outside conformations. Another possible cause is the steric effect. 2,6-Di-*t*-butylphenols are known to show abnormally high frequencies for the O–H stretching vibration[19] and the shift to the high frequency is attributed to the steric effect of the *t*-butyl groups. Schleyer *et al.* used this interpretation for the assignment of the two O–H stretching absorptions of cyclohexanol derivatives.[20] Birdcage compounds are known to show ν_{C-H} absorptions at abnormally high frequencies[21] and bicyclo[3.3.1]nonane systems show high C–H stretching absorptions as well.[22] If it is the *O*-inside conformation, the carbonyl stretching vibration will absorb at higher frequencies, as judged from the analogous phenomena presented above. Then the ketones take *O*-inside conformations and the aldehyde *O*-outside conformations, if the steric effect is the cause.

These discussions lead to a prediction that, if we can see the real conformation of these compounds and if the carbonyl absorptions correspond to one conformation, we can see the real reason for the phenomenon. Consideration of the steric effect gives, although not definite, a clue for judging the probability of the two possible causes. The reason for the existence of the two conformers, *O*-inside and *O*-outside, of the esters in the literature[16] is the similar bulkinesses of a methoxyl and an oxo group of the ester moiety. If the bulkiness of one side of a plane is much different from the other side, a conformation, in which the bulkier side is outside of the triptycene skeleton, is favored to a great extent relative to another which

has the bulkier group inside.[23] Since the sizes of a hydrogen and an oxo group in a formyl group are different to a large extent, the formyl group in compounds **8**, **10**, and **12** will take an *O*-outside conformation. Similar consideration suggests that the acetyl group in compounds **9**, **11**, and **13** will take *O*-inside conformations. Thus the steric effect hypothesis is more likely than the dipole interaction hypothesis.

If the charge-transfer type interaction is responsible to the observed population ratios, the interacting carbonyl groups are expected to have elongated C=O bond, thus shifting the carbonyl stretching frequencies to the low side. The fact that the C=O stretching absorption of compound **8** is at a little lower frequency than that of compound **10** may be taken as an indication of this effect, but we failed to obseve any bifurcation of absorptions in the ordinary measurements. The tetrachloroaldehyde (**10**) was shown to exist as a mixture of almost 1:1 *ap* and ±*sc* conformations. Therefore this compound was considered to have the highest possibility of showing two bands in the $\nu_{C=O}$ region. A detailed study of this compound did show two absorptions at 1725 and 1720 cm^{-1}, the latter being a shoulder. This fact suggests that the carbonyls in these compounds absorb at similar frequencies if their types, aldehydes or ketones, are given, irrespective to the presence or absence of the interaction. Alternatively, the interaction is not so strong as to cause a large shift in C=O stretching vibrations in these compounds.

The final and strongest support to the conformation of the ketones and the aldehydes can be obtained by X-ray crystallography. Accordingly X-ray-diffraction study was carried out on crystals of 9-(acetylmethyl)-1,2,3,4-tetrachlorotriptycene (**11**)[24] and 9-(formylmethyl)-1,4-dimethyltriptycene (**12**). The details of

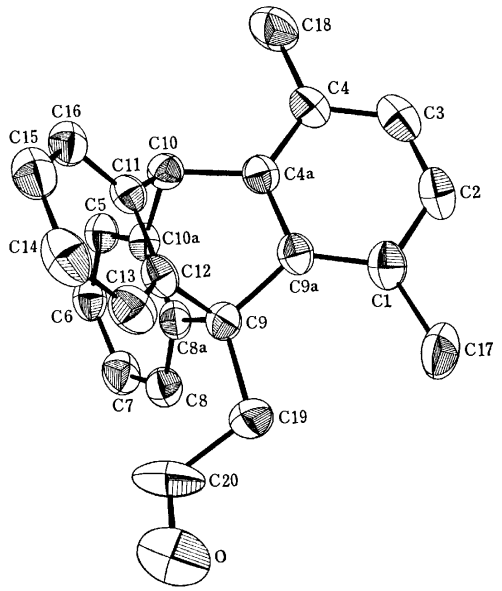

Fig. 1. An ORTEP diagram of 1,4-dimethyl-9-(formylmethyl)triptycene.

the results of the former will be described elsewhere but it is clear that the acetyl group takes an *O*-inside conformation both in $\pm sc$ and *ap* forms of **11**. The results of the X-ray structural determination of compound **12** are shown in Tables 4 and 5 and in Fig. 1, where carbon atoms are numbered, as shown in the figure for the convenience of discussion.

The feature of the structure of **12** is that the formyl group takes the *O*-outside conformation among others which follow. The steric strain caused by the substituents in 1- and 9- positions is released by deformation of the molecule throughout, as was the case of 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene.[25] Although $\angle$C(4a)–C(4)–C(18) is widened from the normal value due to the steric effect of C(10), the angle is smaller than $\angle$C(9a)–C(1)–C(17). The 9-substituent is tilted against C(17) as well to relieve the steric strain. Consequently, $\angle$C(19)–C(9)–C(9a) is considerably widened. It is interesting to note also that the trigonal pyramid, of which apex is C(9) and base atoms are C(9a), C(8a), and C(12), has a smaller apex angle than that composed of an apex of C(10) and a base of C(4a), C(10a), and C(11). This may be attributed to the steric effect caused by the two substituents. The steric strain is also eased by widening angles, which are made by the bonds connecting C(9) (and C(10) to a lesser extent) and aromatic rings, and the aromatic C–C's which are outside of the triptycene skeleton. Finally the lengths of the bonds connecting C(9) with aromatic carbons are definitely longer than those connecting C(10) with aromatic carbons, although the degree of elongation is much less than those in 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene. The dihedral angles made by benzene rings are as follows: $\phi(C_{8a}$–C_9–$C_{12})=121.0°$, $\phi(C_{9a}$–C_9–$C_{12})=119.4°$, $\phi(C_{8a}$–C_9–$C_{9a})=119.5°$. The hydrogen of the aldehyde group, being small, does not seem to affect the dihedral angle, in contrast to the case of 9-(acetylmethyl)-1,2,3,4-tetrachlorotriptycene.[24] Although we do neither have any piece of evidence that the structure in the solid state is retained in solutions, nor that the structure is common in all compounds of the same type, we may conclude, from pieces of evidence given by various sources discussed above, that the aldehydes take *O*-outside conformations and the ketones *O*-inside conformations.

After establishing the conformations of the aldehydes and the ketones, we may now discuss the cause for the unexpected stability of the $\pm sc$ conformation of ketone **11**. In the ketone, if the acetyl group takes the *O*-inside conformation, we realize that the bond dipoles of the C=O and the C–Cl in the *peri*-position are anti-parallel in the $\pm sc$ conformation. In contrast, the bond dipoles of the C=O in the aldehyde (**10**) and the C–Cl in the *peri*-position are syn-parallel. These arrangements of the dipoles will make the $\pm sc$ conformation of **10** less stable in nonpolar solvents and that of **11** favorable in the same solvents: the relative arrangements of the bond dipoles are the same in *ap* conformations as well, but the long distance will diminish the interaction probably due to the solvent intervention. Although the charge-transfer itself is of polar nature, this polar effect is very small on the populations, probably because of the weakness of the interaction. In conclusion, the apparently unusual phenomenon that the acetyl group stabilizes $\pm sc$ conformations more than the formyl group is mainly caused by the dipolar interaction within the molecules. The methoxycarbonyl compound (**1**) may be in the same category with ketone **11** because it can take the *O*-inside conformation.

Further support for the above discussion should be obtained by examining the population ratios in solvents of different polarity. Thus population ratios of compounds **5** and **10** were examined in mixed solvents. The examination of the populations of the ketones and others was abandoned because the populations were lop-sided. The results are shown in Table 6.

It may be difficult to compare the polarities of rotamers of compound **5** but we can assume that the group dipoles of the cyano and the methoxyl in the *ap* conformation is close to syn-parallel, because the methoxyl group is within the plane of the benzo-bridge and the methyl of the methoxyl group will be away from the bridgehead substituent: this conformation of the methoxyl group is probable if one considers the steric effect. Thus the *ap* form will be more polar than the $\pm sc$ form. The population ratios in solvents of different polarity agree with these considerations. The behaviors of the chloro-aldehyde (**10**) are in accord with expectation as well. Being more polar than the *ap* form, the $\pm sc$ conformation is favored in the more polar solvents.

Finally we wished to obtain thermodynamic parameters of the compounds examined. Unfortunately, however, it was not possible for many compounds to do so because of the lop-sided population of one isomer. The only compound we could examine its populations at various temperatures was 9-(formylmethyl)-1,2,3,4-tetrachlorotriptycene (**10**). The $\pm sc/ap$ ratios of this compound were 1.1 at 0, -20, and -50 °C: the populations were temperature independent. The

Table 6. $\pm sc/ap$ ratios of triptycenes in various solvents

Compound	Substituents 9-	Substituents *peri*-	$\pm sc/ap$	Temperature °C	Solvent (vol/vol)

			1.7	−25	$CDCl_3$-CD_3CN (7 : 10)
5	CH_2CN	OCH_3	1.5	−50	$CDCl_3$
			1.3	−45	$CDCl_3$-$(CD_3)_2CO$ (5 : 6)
			1.2	−45	$CDCl_3$-CD_3CN (5 : 7)

ΔH and ΔS were obtained as 0.0 kcal/mol (1 kcal= 4.18 J) and +1.0 e.u.

In conclusion we wish to point out that, for the first time, we have demonstrated that attractive interactions can be detected experimentally between carbonyl moieties, like cyano, formyl, and methoxycarbonyl, and a chloro or a methoxyl group. It is especially noteworthy because the presence of the interaction between ketones and oxygen was questionable by means[26,27] other than X-ray crystallography.[6,28] This finding is possible because two groups in *peri*- and bridgehead positions are well within the sum of van der Waals radii.[25] Therefore this triptycene system is considered very good in revealing an interaction experimentally which is not otherwise possible to do so because of its weakness. We wish to search other weak interactions with the use of this system in the future. Nitrogen carbonyl interactions were studied by X-ray crystallography and treated as an incipient transition state for the addition of a nucleophile to a ketone.[29] This work extends the possibility of studying the transition state of other systems. This aspect of the present work may have further extension.

We wish to thank Mr. Toshihiko Hori of Rigaku Denki Co., who performed the X-ray crystallography. We also wish to express our thanks to the Ministry of Education, Science and Culture for a Grant-in-Aid for Scientific Research from which a part of the cost was defrayed.

(Received March 2, 1981)

The Friedel-Crafts alkylation of benzene with (+)-2-methyloxetane in the presence of Lewis acids ($AlCl_3$, $SnCl_4$, and $TiCl_4$) gave 3-phenyl-1-butanol with 20—60% inversion of configuration at the reaction center and a mixture of 4-chloro-2-butanol and 3-chloro-1-butanol in optically active form as the by-products. These by-products were formed by the attack of the chlorine atom in Lewis acid. The stereochemical course of the reaction to 3-chloro-1-butanol varied with the kind of catalyst, *i.e.*, inversion with $AlCl_3$ or $TiCl_4$ and retention with $SnCl_4$. The addition of nitromethane to the reaction system promoted the retentive ring-opening to 3-chloro-1-butanol.

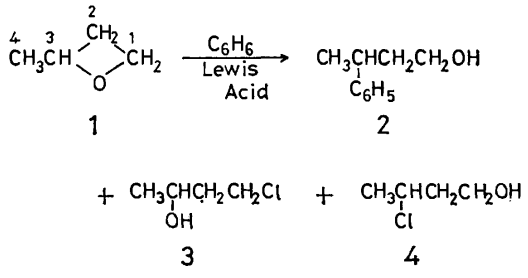
Although the entire field of Friedel-Crafts chemistry has been reviewed in great detail,[1] the stereochemical view has been limited because of the long-standing acceptance of the free carbonium ion mechanism in the aromatic alkylation.[2] Some examples of Friedel-Crafts reactions with extensive stereochemical integrity have appeared during this decade. Brauman and his co-workers reported that the alkylation of benzene with (+)-γ-valerolactone[3] or (+)-2-methyltetrahydrofuran[4] proceeded with some inversion (47 or 35%) of configuration, and concluded that the stereospecificity was due to the cyclic nature of the alkylating reagent or the enforced proximity of ion-pairs produced from the ring opening. Previous studies in our laboratory demonstrated that optically active oxiranes reacted with benzene in the presence of Lewis acid to give the corresponding 2-phenyl-1-propanols with complete inversion of configuration.[5]

The difference in the degree of stereospecificity between the above reactions with five- and with three-membered ether prompted us to study the stereochemistry of the similar alkylation with oxetane. There have been few reports on the reaction of oxetane in the presence of Lewis acid,[6] but no stereochemical information is obtained even in the ring-opening of oxetane.

This paper describes the alkylation of benzene with (+)-2-methyloxetane in the presence of Lewis acid and the stereochemistry of the ring-opening reaction.

Results and Discussion

Treatment of (+)-2-methyloxetane (**1**) with Lewis acid in benzene below 0 °C gave 3-phenyl-1-butanol (**2**) as the alkylated product, and a mixture of 4-chloro-2-butanol (**3**) and 3-chloro-1-butanol (**4**). No 4-phenyl-2-butanol was obtained under these conditions. The structures of **2**, **3**, and **4** were identified by IR and NMR spectroscopy, and by comparison of the retention time of gas chromatography (GLC) with those of authentic samples. The yield and isomer distribution were determined by GLC analysis. The results under various conditions are summarized in Tables 1 and 2.



(+)-2-Methyloxetane (**1**) has S configuration, since it was prepared from (*S*)-(+)-ethyl-3-hydroxybutanoate by a series of chemical interconversions not affecting bonds to the asymmetric center, as mentioned in the experimental section. The absolute configurations of (−)-**2**, (+)-**3**, and (+)-**4** have been established to be R,[7] S,[8] and S,[9] respectively. Accordingly, it is apparent that the alkylation of benzene with (+)-**1** to (−)-**2** and the ring-opening reaction of the oxetane (formation of **4**) by aluminium chloride proceeded with inversion of configuration at the reaction center. Aluminium chloride at first coordinates with the oxygen atom of oxetane, which would result in appreciable polarization of the C_3–O bond, and then benzene attacks the C_3 atom from the back-side of the C_3–O bond.

In the case of $AlCl_3$ catalyst, as shown in Table 1, the alkylation exhibited less stereospecificity than that using propylene oxide[5a] or γ-valerolactone.[3] The optical yield of **2** increased slightly with decreasing reaction temperature. The following interpretations can be given for the less stereospecificity in the formation of **2** from **1**: first, the racemization *via* a carbonium ion intermediate and, secondly, the apparent racemization owing to the competitions between two reactions (path a and b in Scheme 1) which result in the alkylated products having the opposite configuration. Accordingly, the two-step reaction mechanism *via* (*R*)-**4** becomes significant along with the direct substitution. In fact, (*S*)-**4** reacted with benzene in the presence of $AlCl_3$ to give (*R*)-**2** with 46% inversion of configuration.[10]

When $SnCl_4$ or $TiCl_4$ was used as a catalyst, the alkylation of benzene exhibited a moderate stereospecificity with 62 and 55% optical yield, respectively. This seems to mean that the racemization mechanism through carbonium ion was depressed because of the weaker catalytic ability of $SnCl_4$ compared with that

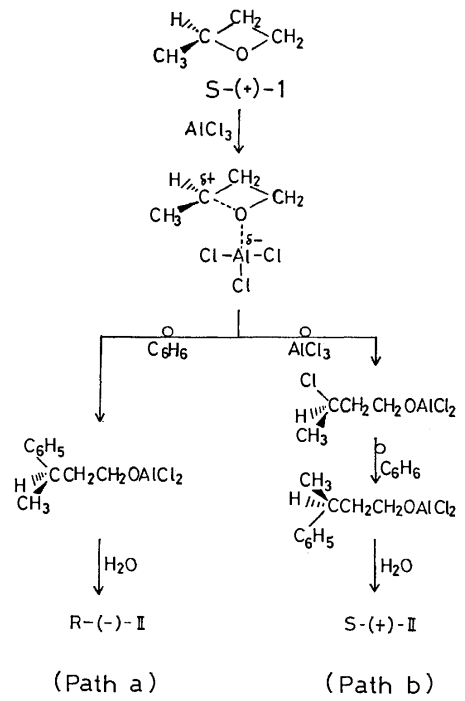

Scheme 1.

of $AlCl_3$. Furthermore, benzene did not react with 3-chloro-1-butanol in the presence of $SnCl_4$ or $TiCl_4$, so that path b in Scheme 1 should be excluded. In order to examine the possibility of racemization of the product during the reaction, (+)-**2** was treated with these Lewis acids in benzene under the same conditions as those of the alkylation. The specific rotation of this compound remained almost unchanged before and after the treatment (Table 3). Thus, it turns out that the optical yield in the presence of $SnCl_4$ or $TiCl_4$ shows a net stereospecificity in this alkylation (Table 1).

Chlorobutanol isomers (**3** and **4**), which were by-products, were separated by preparative GLC and their specific rotations were determined. As shown in Table 2, the ring-opening reaction toward **4** involves two opposite stereochemical courses: inversion with $AlCl_3$ or $TiCl_4$ and retention with $SnCl_4$. It is interesting that the formation of **4** took place with complete inversion in the presence of $AlCl_3$, despite the less stereospecificity in the alkylation (runs 1—4 in Table 1). On the other hand, the retentive ring-opening in the presence of $SnCl_4$ was observed. This retentive result was not observed in the reaction with three-membered ring oxiranes.[5] This result could be

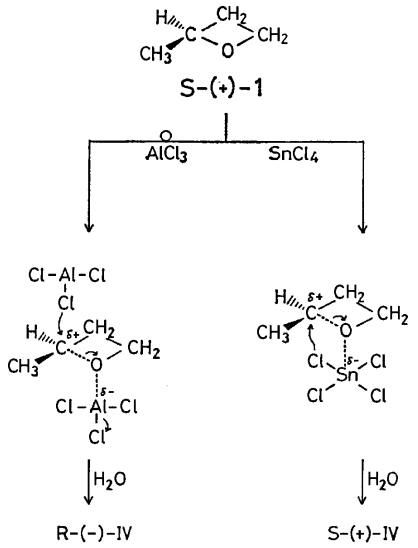

Scheme 2.

explained by considering that the conformation of the transition state fits a steric requirement which gives rise to the internal attack of the chlorine atom on the secondary carbon (Scheme 2). The configuration of 4-chloro-2-butanol (**3**) was completely retained. This shows that the successive racemization of the starting oxetane did not occur in all reactions. Further, the ring-opening of (+)-**1** with $SnCl_4$ yielded regioselectively **4** with C_3–O bond cleavage (runs 6 and 7 in Table 2).

In connection with the reaction under Friedel-Crafts condition, we examined the ring-opening reaction of (+)-**1** with aqueous hydrogen chloride or Lewis acids in CS_2 solvent. The results are presented in Table 4. The direction of ring-opening with Lewis acid differed from that with aqueous hydrogen chloride. This result is similar to that of the ring-opening reaction of propylene oxide with acids.[5a] Under Lewis acid catalyst both the C_1 and the C_3 atom adjacent to oxygen atom of **1** would develop a cationic nature to a certain extent by coordination of the Lewis acid, but especially the C_3 atom would be further stabilized because of an electron-releasing effect or a hyperconjugation of a methyl group.[11] Thus, it seems that the nucleophilic attack of the chlorine atom should take place at the C_3 atom preferentially.

Finally, some interesting results were obtained when nitromethane was added in a reaction system. $AlCl_3$–CH_3NO_2 catalyst had no influence on the stereochemistry of alkylated product, but promoted the retentive reaction of **1** to **4**, as in the case of $SnCl_4$ catalyst. The high regioselective ring-opening with C_3–O bond cleavage was observed. Similar results have been observed in the reaction of oxiranes, in which $AlCl_3$–CH_3NO_2 1:1 addition compound[12] in solution was concluded to be important for the retentive reaction and the direction of ring-opening.[13] This consideration may explain the result in the case of oxetane.

Experimental

The optical rotations were measured on a JASCO DIP-SL polarimeter with use of a 0.1 dm tube. The IR and ^{1}H-NMR spectra were recorded on a JASCO DS-301 spectrometer and a JEOL PS-100 spectrometer, respectively. Chemical shifts are given in ppm downfield from internal TMS. GLC analyses were carried out on a 2 m column of 10% Carbowax 20 M on Diasolid L with a Shimadzu GC-3A instrument.

Benzene was washed with concentrated sulfuric acid and distilled after drying on sodium ribbon. Carbon disulfide and nitromethane were dried over phosphorus pentachloride and distilled prior to use. Commercial grade aluminium chloride was purified by sublimation under a nitrogen gas stream. Commercial grade tin(IV) chloride and titanium (IV) chloride were used without further purification.

Substrate. (+)-2-Methyloxetane (1): Ethyl acetoacetate was reduced microbiologically by the reductase of baking yeast to (+)-ethyl-3-hydroxybutanoate,[14] bp 78—81 °C/17 mmHg,† $[\alpha]_D$ +36.5° (*c* 5.5, $CHCl_3$) [Lit,[14] $[\alpha]_D$ +38.5° (*c* 1.0, $CHCl_3$)], yield 73%. The hydroxybutanoate was heated under reflux with lithium aluminium hydride in THF for 30 hours and converted to (+)-1,3-butanediol, bp 108 °C/17 mmHg, $[\alpha]_D$ +32.3° (*c* 5.0, EtOH) [Lit,[15] $[\alpha]_D$ −29.6° (*c* 10, EtOH)], yield 89%. The treatment of (+)-1,3-butanediol and acetyl chloride gave a mixture of 1-chloro-3-acetoxybutane and 3-chloro-1-acetoxybutane.[16] This mixture was converted to (+)-**1** with concentrated alkali solution according to the procedure of Searles,[17] bp 60 °C, $[\alpha]_D$ +33.5° (*c* 5.0, $CHCl_3$) (Lit,[18] $[\alpha]_D$ +20.2°], yield 25%. (+)-**1** obtained in this manner seems optically pure. NMR (CCl_4, 10%): δ 1.33 (d, J=6.4Hz, 3H, $-CH_3$), 1.91—2.83 (m, 2H, $-CH_2-$), 4.19—4.63 (m, 2H, $-CH_2O-$), and 4.66—5.03 ppm (sex, J=7.2 Hz, 1H, $-CH=$).

Reaction of (+)-2-Methyloxetane (1) with Benzene in the Presence of Lewis Acid. The following example shows a typical experimental procedure. To a stirred mixture of dry benzene (18 ml) containing tin(IV) chloride (4.3 g, 16.6 mmol) and carbon disulfide (7 ml), cooled in an ice bath, a mixture of (+)-**1** (1.0 g, 13.9 mmol), benzene (2 ml), and carbon disulfide (1 ml) was added at a rate sufficient to maintain the reaction temperature. After an additional 4.0 h at 0 °C, the reaction was quenched with cooled 5% hydrochloric acid (40 ml). The organic layer was neutralized with 5% sodium hydrogencarbonate and then dried over anhydrous sodium sulfate. The yield of alkylated product was determined by GLC. After the removal of solvent, the residue was fractionated *in vacuo* to give chlorobutanol isomers (bp 70 °C/17 mmHg) and 3-phenyl-1-butanol (**2**) (bp 125 °C/17 mmHg). The water layer was extracted five times with 20 ml portions of ether. The combined organic layers were washed with water and dried over anhydrous sodium sulfate. After the removal of solvent, the residue was distilled *in vacuo* to give chlorobutanols (**3** and **4**), bp 70 °C/17 mmHg. The isomers could be separated by preparative GLC. The results are summarized in Tables 1 and 2.

Ring-opening Reaction of (+)-2-Methyloxetane (1) with Lewis Acid or Hydrochloric Acid. To a cooled and stirred mixture of carbon disulfide (12 ml) and Lewis acid or concentrated hydrochloric acid (16.6 mmol) was added a solution of (+)-**1** (1.0 g, 13.9 mmol) in carbon disulfide (2 ml) at 0 °C. The reaction mixture was worked up as mentioned above. The results are summarized in Table 4.

† 1 mmHg≈133.322 Pa.

(Received March 16, 1981)

The thermal oligomerization of 3-methyl-3-buten-2-one oxime leads to crystalline nitrone derivatives, 8-hydroxy-1,4,5,7-tetramethyl-6,8-diazabicyclo[3.2.1]oct-6-ene 6-oxide. Its crystal structure has been determined by X-ray diffraction. The space group is $P2_1/n$ with $a=9.459(3)$, $b=10.335(3)$, $c=11.352(4)$ Å, $\beta=105.50(2)°$, and $Z=4$.

α,β-Unsaturated aldehyde and ketone oximes which have a vinylic double bond conjugated with a C=N double bond are heated to give oligomers. For example, heating of acrylaldehyde oxime leads to an amorphous oligomer with a molecular weight of *ca.* 2000.[1] Methacrylaldehyde oxime is easily converted into the crystalline trimer, 2,4,7-trimethylperhydroisoxazolo[2,3-*a*]pyridine-2,7-dicarbaldehyde dioxime, on heating at 80 °C, but no dimer can be isolated.[2] In the course of the study of the polymerization of 3-methyl-3-buten-2-one oxime (MIKOM), it was found that MIKOM gives preferentially the cyclic dimer, 8-hydroxy-1,4,5,7-tetramethyl-6,8-diazabicyclo[3.2.1]-oct-6-ene 6-oxide (**1**). The most plausible reaction mechanism has been reported in the preceding paper;[3] *i.e.*, the Diels-Alder reaction must occur first, followed by the Michael addition. Since colorless needle-like crystals of **1** were obtained, the three-dimensional structure of this cyclic dimer was determined by X-ray analysis.

Experimental

Materials and Oligomerization. 3-Methyl-3-buten-2-one was prepared according to the procedure of White,[4] and then treated with aqueous hydroxylamine hydrochloride to give MIKOM in a 40% yield. Oligomerization of MIKOM was carried out at 80 °C for 375 h in an ampoule. The colorless solution gradually turns yellow with time. After unreacted MIKOM had been removed by distillation under reduced pressure, the residue was treated with a large amount of ether to precipitate the dimer. Yield 12%, IR (KBr): 3150 (OH), 1601 (C=N). Found: C, 60.85; H, 9.33; N, 14.42%. Calcd for $C_{10}H_{18}N_2O_2$: C, 60.58; H, 9.15; N, 14.12%. Recrystallization of the dimer from methanol solution gave colorless needle-like crystals. Mp, 147 °C.

Mass and NMR Measurements. The mass spectra were measured on a Shimadzu LKB-9000 mass spectrometer, equipped with a gaschromatographic inlet system. The ionizing potential was 70 eV, and the ionizing current was 60 μA. The ^{13}C-NMR spectra were obtained with a Hitachi R-42 FT apparatus (22.6 MHz), using DMSO-d_6 as the solvent and the internal standard.

X-Ray Measurements. A crystal of 0.2 mm × 0.2 mm × 0.3 mm in dimensions was used for data collection on a Syntex R-3 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The accurate unit-cell dimensions were determined by least-squares calculation. The crystal data are summarized in Table 1.

Table 1. Crystal data

$C_{10}H_{18}N_2O_2$,	M.W. = 198.27
Space group	$P2_1/n$
a/Å 9.459(3)	U/Å^3 1069(1)
b/Å 10.335(3)	$Z=4$
c/Å 11.352(4)	D_x/g cm^{-3} 1.23
β/° 105.50(2)	μ(Mo $K\alpha$)/cm^{-1} 0.9

All reflections within the range of $3° \leqq 2\theta \leqq 60°$ were collected by the use of the ω scan mode at a scan speed varying with intensities.[5] The intensities of three reference reflections were measured periodically; they showed no significant fluctuation during the course of data collection. A total of 3563 independent reflections were collected, among which 1586 reflections with $I \geqq 1.96\sigma(I)$ were used for structure refinement. The intensities were corrected for Lorentz and polarization effects, but not for absorption.

Structure Determination and Refinement. The structure was solved by the direct method and the atomic parameters were refined by the block-diagonal least-squares method. The final R-value for 710 reflections of $F_o \geqq 5$ was 0.083. In the least-squares procedure, the function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where $w=1$ for 710 reflections of $F_o \geqq 5$ and $w=0$ for the others. The computer programs used were MULTAN program[6] modified for the Syntex R-3 diffractometer. All the calculations were carried out on a NOVA computer connected to the diffractometer. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[7] The final atomic parameters are given in Table 2. The $F_o - F_c$ table and anisotropic temperature factor table are kept as Document No. 8202 at the Chemical Society of Japan.

Results and Discussion

The bond distances and bond angles are listed in Tables 3 and 4, respectively. The N(6)–C(7)–C(12) and C(7)–N(6)–O(14) angles agree fairly well with those expected from the sp^2 hybrid orbital. Considerable deviations of the N(6)–C(7)–C(1) and C(7)–N(6)–C(5) angles from the theoretical values for the sp^2 orbital may be ascribed to the highly-strained ring system. Figure 1 shows the perspective drawing of the molecule and the numbering scheme. It is a bicyclic compound having three rings; the seven-

using Newman's projection formula.

Figure 3 shows the crystal structure viewed along the b-axis. Only oxygen atoms take part in the hydrogen bond; O(13) forms a intermolecular hydrogen bond with O(14), the O(13)···O(14) distance being 2.659(5) Å.

Figure 4 shows the mass spectrum of **1**, which is

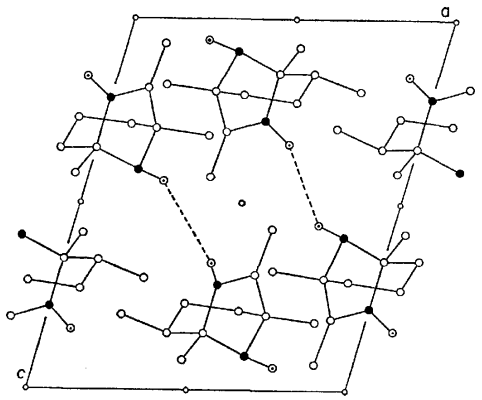

Fig. 3. The projection of the crystal structure along the b-axis.
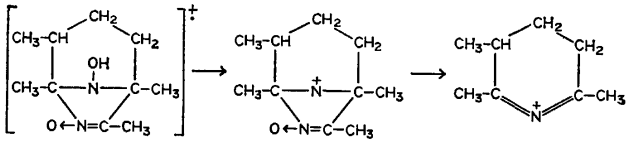
○: Carbon, ●: nitrogen, ⊙: oxygen.

characterized by the appearance of peaks *m/e* 198 (M^+), 181, and 124, and can be satisfactorily explained on the basis of the following fragmentation pattern.[5]



As can be expected from the structure, ^{13}C-NMR spectrum of **1**, shown in Fig. 5, shows four quartet (δ=9.24, 14.06, 16.02, and 18.94), two triplet (δ=27.73 and 32.70), one doublet (δ=36.51), and three singlet peaks (δ=71.88, 98.97, and 142.88). The quartet, triplet, and doublet peaks correspond to the methyl, methylene, and methyne carbons, respectively, and it can be presumed that the singlet peaks at 71.88, 98.97, and 142.88 ppm are assigned to the tertiary carbons linked by N–C<, $\overset{N}{N}$>C<, and $\overset{\ominus}{O}\!>\!\overset{\oplus}{N}$=C< bonds, respectively.

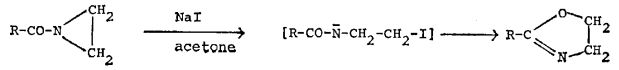
Studies on 2-Aziridinecarboxylic Acid. V.[1] Formation of Dehydroamino Acid Containing Peptides *via* the Isomerization by NaI of 2-Aziridinecarboxylic Acid Containing Peptides

Kenji Okawa,* Kiichiro Nakajima, Takumi Tanaka, and Masahiro Neya
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received March 25, 1981)

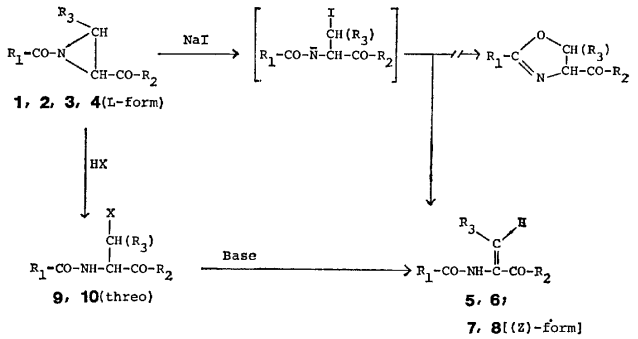
The 2-aziridinecarboxylic acid residue in peptides was isomerized with NaI in an acetone solution into the corresponding dehydroalanine or dehydro-2-aminobutyric acid derivatives, but not into the corresponding 2-oxazoline derivatives.

The isomerization of 1-acyl-2-aziridines into 2-aryl- or 2-alkyl-2-oxazolines by various nucleophiles has been investigated, and its mechanisms(Scheme 1) has been



Scheme 1.

proposed.[2] The isomerization of the 2-aziridinecarboxylic acid(Azyline, Azy) residue in peptides was investigated next. Two types of Azy-peptides, *e.g.* 1-acyl-2-aziridinecarboxylic acid(**1**, **2**) and 1-acyl-3-methyl-2-aziridinecarboxylic acid peptides(**3**, **4**), were synthesized according to the procedure described in the previous paper,[3] as is summarized in Table 1.



Scheme 2.

The treatment of 1-acyl-2-aziridinecarboxylic acid(**1**, **2**) and the 1-acyl-3-methyl-2-aziridinecarboxylic acid (**3**, **4**) derivatives with NaI in an acetone solution afforded dehydroalanine(⊿Ala) (**5**, **6**) peptides and dehydro-2-aminobutyric acid(⊿Aba) (**7**, **8**) peptides in high yields without any concomitant formation of 2-oxazoline derivatives, as is shown in Scheme 2, the results are summarized in Table 2. The dehydroamino acid function of these products was readily characterized by the presence of vinyl protons in the NMR spectra, as is summarized in Table 3.

In the next approach, we tried to clarify the reaction mechanism of the isomerization of Azy residues and the structure of dehydro-2-aminobutyric acid derivatives. The treatment of 1-acyl-3-methyl-2-aziridinecarboxylic acid(**4**) and 1-acyl-2-aziridinecarboxylic acid peptide(**3**) with hydrogen halide readily afforded L-*threo*-2-amino-3-halogenobutyric acid(**9**, **10**) and β-halogenoalanine derivative(**11**) respectively. These derivatives can be considered as the corresponding intermediates in the isomerization reaction of Azy residues with NaI. The subsequent treatment of these derivatives(**9**, **10**) with a tertiary amine as a base gave the corresponding dehydroamino acid peptide(**8**), which were identical with the products obtained by the isomerization of the Azy peptides with NaI in an acetone solution. The results of the dehydrogen halide reaction are also summarized in Table 2.

Based on the above data, the mechanism of the isomerization of the Azy residue upon NaI treatment was thought to be the *trans*-E_2-elimination of a 2-amino-3-iodobutyric acid intermediate, followed by the direct elimination of an α-hydrogen atom. The NMR data of the dehydro-2-aminobutyric acid derivatives indicated that both the isomerization of Azy and the dehydrogen halide reaction of L-*threo*-2-amino-3-halogenobutyric acid [Thr(Cl) or Thr(I)] derivatives occurred *via* the stereospecific *trans*-E_2-elimination reaction. Thus, only dehydro-2-aminobutyric acid derivatives of the (*Z*)-geometory were prepared.

Experimental

Uncorrected melting points are reported. The homogeneity of the products was checked by thin-layer chromatography on silica-gel plates. The optical rotations were determined at the D line on a Perkin-Elmer 141 polarimeter. The NMR spectra were obtained with a Hitachi R-20B High-resolution NMR Spectrometer, the chemical shifts being obtained using TMS as the internal reference.

All the Azy peptides used in this study were synthesized by the method described in the literature;[3] their properties and yields are summarized in Table 1.

Z-Gly-ΔAla-Gly-OBzl(5). Via *the Isomerization of Azy*: A solution of Z-Gly-L-Azy-Gly-OBzl(**1**) (200 mg, 0.47 mmol) and NaI (282 mg, 1.88 mmol) in acetone (5 ml) was refluxed for 2 h. After the solvent has been removed *in vacuo*, the residue was extracted with ethyl acetate. The ethyl acetate solution was washed with water, dried over Na_2SO_4, and then concentrated *in vacuo*. The residue was crystallized from hexane; 154 mg (78.2%); mp 134—135 °C. NMR(DMSO-d_6) δ: 5.55 (1H m, $=CH_2$), 6.20 (1H m, $=CH_2$), 9.08 (1H bs, -NH-C=). Found: C, 61.53; H, 5.50; N, 10.04%. Calcd for $C_{22}H_{23}O_6N_3 \cdot 1/2H_2O$: C, 60.82; H, 5.57; N, 9.63%.

Z-L-Ala-ΔAla-Gly-OBzl(6). Via *the Isomerization of Azy*: A solution of Z-L-Ala-L-Azy-Gly-OBzl(**2**) (200 mg, 0.46 mmol) and NaI (273 mg, 1.82 mmol) in acetone (5 ml) was refluxed for 7 h. Then the reaction mixture was worked-up as has been described above. The product was crystallized from ethyl acetate–hexane; 142 mg (71.2%); mp 128—131 °C, $[\alpha]_D^{25}$ −8.8 (*c* 1.0, DMF). NMR (DMSO-d_6) δ: 5.49 (1H m, $=CH_2$), 6.38 (1H d, J=2.0 Hz, $=CH_2$), 8.50

Table 1. Properties and yields of Azy peptides

Azy peptide	Yield/%[a]	Mp/°C	$[\alpha]_D^{23}$
Z-Gly-L-Azy-Gly-OBzl (**1**)	92.3	118—119	−52.5 (*c* 1.0, MeOH)
Z-L-Ala-L-Azy-Gly-OBzl (**2**)	83.0	128—128.5	−71.2 (*c* 1.0, $CHCl_3$)
Z-Gly-3-MeAzy-Gly-OBzl (**3**)	89.0	123.5—124.5	−58.2 (*c* 1.0, AcOEt)

a) ⊿Ala: Dehydroalanine. b) ⊿Aba: (*Z*)-dehydro-2-aminobutyric acid.

(1H bs, -NH-CH=). Found: C, 62.76; H, 5.82; N, 9.70%. Calcd for $C_{23}H_{25}O_6N_3$: C, 62.86; H, 5.73; N, 9.56%.

Z-Gly-(Z)-ΔAba-Gly-OBzl (7). Via *the Isomerization of Azy*: A solution of Z-Gly-3-MeAzy-Gly-OBzl (**3**) (150 mg, 0.34 mmol) and NaI (205 mg, 1.36 mmol) in acetone (5 ml) was refluxed for 5 h. Then the reaction mixture was worked up as has been described above. The product was crystallized from ethyl acetate–hexane; 117 mg (78%); mp 102—104 °C. NMR (DMSO-d_6) δ: 1.61 (3H d, J= 7.0 Hz, =$CHCH_3$), 6.42 (1H q, J=7.0 Hz, =CH-), 9.01 (1H bs, -NH-C=). Found: C, 61.94; H, 6.04; N, 9.73%. Calcd for $C_{23}H_{25}O_6N_3 \cdot 1/2H_2O$: C, 61.60; H, 5.84; N, 9.37%.

Z-L-Ala-(Z)-ΔAba-Gly-OBzl (8). Via *the Isomerization of Azy*: A solution of Z-L-Ala-3-MeAzy-Gly-OBzl (**4**) (150 mg, 0.33 mmol) and NaI (200 mg, 1.32 mmol) in acetone (5 ml) was refluxed for 2 h. Then the reaction mixture was worked up as has been described above. The product was crystallized from ethyl acetate–hexane; 139.6 mg (92.4%); mp 141—143 °C, $[\alpha]_D^{23}$ −8.7 (*c* 1.0, DMF). NMR (DMSO-d_6) δ: 1.60 (3H d, J=7.0 Hz, =$CHCH_3$), 6.44 (1H q, J=7.0 Hz, =CH-), 9.08 (1H bs, -NH-C=). Found: C, 63.25; H, 5.93; N, 9.01%. Calcd for $C_{24}H_{27}O_6N_3$: C, 63.56; H, 6.00; N, 9.27%.

Via *the β-Elimination of β-Halogeno Derivative*: *i*) A solution of Z-L-Ala-L-Thr(Cl)-Gly-OBzl (**9**) (150 mg, 0.3 mmol) and 1,4-diazabicyclo[2.2.2]octane (Dabco, 67 mg, 0.6 mmol) in ethyl acetate was stirred overnight at room temperature, and then water was added to the reaction mixture. The ethyl acetate solution was dried over Na_2SO_4 and concentrated *in vacuo*. The residue was crystallized from ethyl acetate–ether–hexane; 136 mg (100%); mp 139—141 °C, $[\alpha]_D^{25}$ −9.0 (*c* 1.1, DMF).

ii) A solution of Z-L-Ala-L-Thr(I)-Gly-OBzl (**10**) (174 mg, 0.3 mmol) and Dabco (67 mg, 0.6 mmol) in ethyl acetate (10 ml) was stirred for 20 min at room temperature. The product was obtained as has been described above; 125 mg (91.9%); mp 141—142 °C, $[\alpha]_D^{25}$ −8.0 (*c* 1.0, DMF). The NMR data of these products were identical to those of the product (**8**) obtained *via* the isomerization of Azy.

Z-L-Ala-L-Thr(Cl)-Gly-OBzl (9): To a solution of Z-L-Ala-3-MeAzy-Gly-OBzl (**4**) (454 mg, 1 mmol) in acetone (10 ml) was added 1 M hydrochloric acid† (1 ml, 1 mmol) at 0 °C. After the reaction mixture had then been allowed to stand at 0 °C for 2 h, the precipitated crystals were filtered off, washed with water, and recrystallized from $CHCl_3$–ether; 478 mg (97.6%); mp 138—141 °C, $[\alpha]_D^{24}$ −1.8 (*c* 1.1, DMF). Found: C, 56.90; H, 5.51; N, 7.90; Cl, 6.70%. Calcd for $C_{24}H_{30}O_7N_3Cl$: C, 56.75; H, 5.95; N, 8.27; Cl, 6.98%.

Z-L-Ala-L-Thr(I)-Gly-OBzl (10): To a solution of Z-L-Ala-3-MeAzy-Gly-OBzl (**4**) (454 mg, 1 mmol) in acetone (10 ml) was added 1 M hydriodic acid (1 ml, 1 mmol) at 0 °C. After the reaction mixture had been allowed to stand at 0 °C for 30 min, water was added; then the precipitated crystals were filtered off, washed with water, and recrystallized from $CHCl_3$–ether; 567 mg (97.5%); mp 136—138 °C, $[\alpha]_D^{24}$ −10.4 (*c* 1.0, DMF). Found: C, 48.39; H, 4.83; N, 6.97; I, 20.86%. Calcd for $C_{24}H_{30}O_7N_3I$: C, 48.09; H, 5.04; N, 7.01; I, 21.17%.

Z-Gly-L-Ser(Cl)-Gly-OBzl (11): To a solution of Z-

† 1 M=1 mol dm^{-3}.

Gly–L-Azy–Gly–OBzl (**1**) (425 mg, 1 mmol) in acetone (10 ml) was added 1 M hydrochloric acid (1 ml, 1 mmol) at 0 °C. After the reaction mixture had been allowed to stand at 0 °C for 1 h, water was added; then the precipitated crystals were filtered off, washed with water, and recrystallized from $CHCl_3$–ether–hexane; 522 mg (100%); mp 143—145 °C, $[\alpha]_D^{24}$ −9.0 (*c* 1.0, DMF). (Received April 8, 1981)

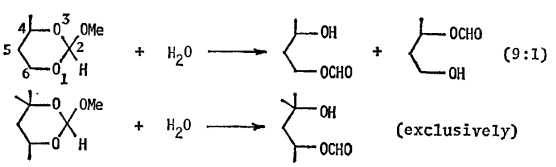
Regio- and stereochemical studies of the solvolyses of various kinds of 2,4-pentanediol derivatives, including 2-acetoxy-4-tosylates, cyclic orthoformates and orthoacetates, have been done and the previously proposed mechanism has been partially revised. The reactions of the proposed intermediate acetoxonium ions with carbanions and with a hydride ion have also been studied.

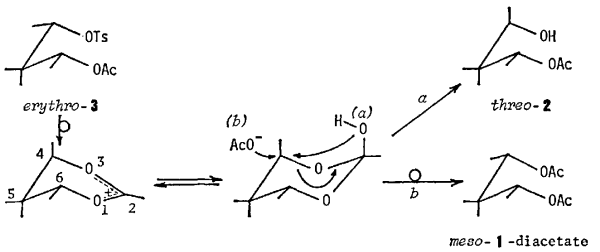
In a previous paper,[1] some of us reported that the hydrolyses of *threo*- and *erythro*-3-acetoxy-1-methylbutyl chlorides or tosylates proceeded with inversion of configuration, while the acetolyses of the same substrates proceeded with retention of configuration; we proposed a mechanism involving a formation of a cyclic acetoxonium ion (1,3-dioxan-2-ylium ion). Further studies with the related substrates, however, have shown that a part of the proposed mechanism should be modified. This paper describes these additional results, together with the chemical behavior of the above acetoxonium ion towards several kinds of carbanions and a hydride ion.

Hydrolyses of *erythro*- and *threo*-3-acetoxy-1,2,2-trimethylbutyl tosylates (*erythro*- and *threo*-**3**) proceeded with almost complete inversion of configuration. Refluxing of *erythro*-**3** (0.45 M, 1 M=1 mol dm^{-3}) solution in ethanol–water (98:2) containing potassium acetate (0.45 M) gave a product consisting of *threo*-4-acetoxy-3,3-dimethyl-2-pentanol (*threo*-**2**, 98%), its *erythro* isomer (*erythro*-**2**, trace), and *meso*-3,3-dimethyl-2,4-pentanediol diacetate (**1**-diacetate, 2%). Under the same conditions, *threo*-**3** gave a product consisting of *erythro*-**2** (90%), *threo*-**2** (trace), and *dl*-**1**-diacetate (10%).

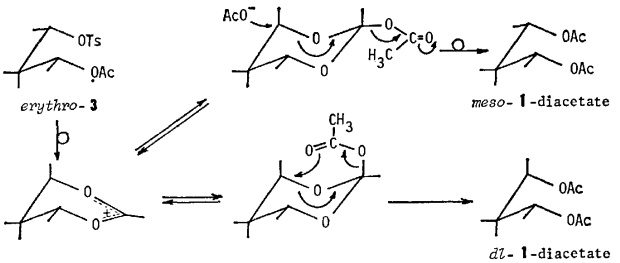
Acetolyses of **3** proceeded with retention of configuration, although the specificities were lower than those in the hydrolyses. *erythro*-**3** gave *meso*- and *dl*-**1**-diacetates in a ratio of 75:25, while *threo*-**3** gave a mixture of *meso*- and *dl*-**1**-diacetates and unidentified products in a ratio of 35:50:15.

These stereochemical results are qualitatively the same as the previous results with unsubstituted 2,4-pentanediol derivatives, supporting the mechanism proposed previously. However, the results of the hydrolyses of the cyclic orthoformates of 1,3-butanediol and 2-methyl-2,4-pentanediol, which should proceed through the same intermediates as those of **3**, have shown that the substitution with hydroxyl groups occurred at the more substituted carbons and that the proposed mechanism should thus be partially modified.





Scheme 1. Mechanism of hydrolysis of *erythro*-**3**.



Scheme 2. Mechanism of acetolysis of *erythro*-**3**.

The previous mechanism assumed the heterolytic bond breaking of C^2–C^3 in the cyclic intermediate in Scheme 1. Instead, the bond breaking of C^4–O^3 or C^6–O^1 is more plausible, since the methyl substitution at C^4 or C^6 will make the latter type of breaking easier. Although the final decision requires a tracer experiment with isotopic oxygen, the revised mechanism can explain the results obtained so far.

As was proposed previously, the stereochemistry of the hydrolysis and acetolysis are determined by the relative rates of S_Ni and S_N2 reactions in the cyclic intermediate.

In the case of hydrolysis (Scheme 1), a cyclic intermediate with an axial hydroxyl group at C^2 can be formed preferentially because the antiparallel attack of a nucleophile to the dioxocarbonium ion will be preferred,[2] and the axial hydroxy compound thus formed is also more stable than the equatorial isomer because of the anomeric effect of hydroxyl oxygen.[3] This intermediate leads to the formation of the inversion product. In the case of acetolysis (Scheme 2), the steric hindrance of acetoxyl group against the anomeric effect prevents the formation of the intermediate with the axial acetoxyl group at C^2 and results in the formation of the one with the equatorial acetoxyl group. In the latter type of intermediate, the bond reconstruction by S_Ni path does not proceed.

As a result, the S_N2 attack of acetate ion becomes predominant and results in the formation of the retention product through double inversion.

The lower specificity observed in the acetolysis of the present substrate **3** than in the previous case without two methyl groups at C^3 can be explained by the slower S_N2 attack of acetate ion due to the steric hindrance.

The nature of the by-products appears to support the mechanism also. The minor products in the hydrolysis of **3** included the diacetate with retention of configuration, showing that the S_N2 attacks of acetate ion are operative also in this case, although the extent was small. Why the acetolysis of *threo*-**3** gave a considerable amount of unidentified products, while *erythro*-**3** gave no such products, is discussed later.

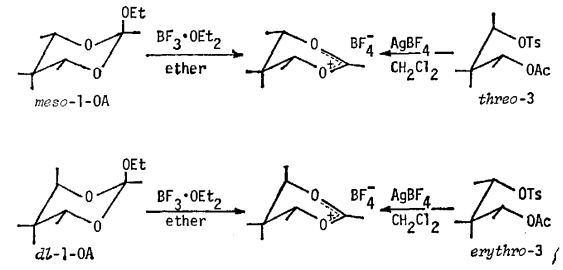
The solvolysis of cyclic orthoacetate (**1**-OA), which is expected to proceed through the formation of the same intermediate, should give the same results as those of **3**. This presumption was confirmed by the following experiments. Reaction of *meso*-**1**-OA with 80% aqueous ethanol gave *erythro*-**2**, while *dl*-**1**-OA gave *threo*-**2**. The yields were almost quantitative and no other products could be detected. Reaction of *dl*-**1**-OA with acetic acid gave a mixture of *meso*-**1** diacetate (75%) and *dl*-**1** diacetate (25%), while *meso*-**1**-OA gave a mixture of *meso*-**1** diacetate (35%), *dl*-**1** diacetate (50%) and unidentified products (15%).

The above-mentioned considerations have been extended to the case of 1,1-bis(1-hydroxyethyl)cyclopropane which is formally formed by combining the two methyl carbons attached to C^3 of **1** to form a cyclopropane ring. Hydrolyses of the orthoacetates of *meso*- and *dl*-isomers gave the *erythro*- and *threo*-diol monoacetates with excellent yields, respectively, showing that the reactions proceeded with retention of configuration as in the case of **3**, and that the solvolyses do not involve the formation of cyclopropylcarbinyl type cation, since no rearrangement products could be detected.

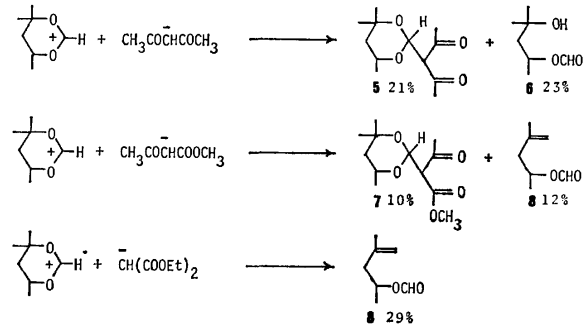
For reference, several kinds of cyclic orthoformates and orthoacetates of 1,3-diols and their acetoxonium ion salts were prepared; these are listed in Table 1. The preparation of the acetoxonium salt from 1,3-propanediol was unsuccessful. The salts were very sensitive to atmospheric moisture. The crystalline salt from *meso*-**1** was much more unstable than that from *dl*-**1** and decomposed, giving colored materials, within several hours after isolation. This instability of the former may be the reason why the acetolyses of *meso*-**1**-OA and *threo*-**3** gave considerable amounts of unidentified products in contrast with the clean-cut results of the other isomers.

The following results show clearly that the solvolyses of **3** and cyclic **1**-OA proceed through the same intermediate. Addition of $BF_3 \cdot OEt_2$ to an ether solution of **1**-OA formed a crystalline salt of the acetoxonium ion. The same salt was obtained by the addition of $AgBF_4$ to a dichloromethane solution of **3** (see Scheme 3).[4] The identity was confirmed by NMR spectra.

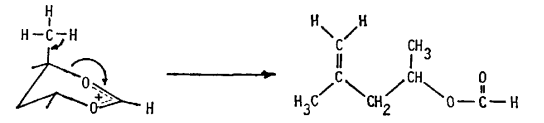
Acetoxonium ion is a stable carbonium ion. No trial of trapping this carbonium ion with an anionic



Scheme 3. Preparation of acetoxonium ion from cyclic orthoester and acetoxytosylate.



Scheme 4. Reactions of acetoxonium ions with carbanions.



Scheme 5.

species of carbanion or with a hydride ion has been reported. Using the crystalline salt obtained above, these reactions have been examined.

For experimental convenience, the salts obtained from the orthoformate (**4**-OF) and the orthoacetate (**4**-OA) of 2-methyl-2,4-pentanediol were used as the substrate. The experimental difficulty was the purification of the acetoxonium salts. The removal of the excess $BF_3 \cdot OEt_2$, which was added to precipitate the salts from ether solutions of **4**-OA and **4**-OF, was essential to obtain the products, since BF_3 reacted with the active methylene compounds to form inactive addition products. Repeated washing with ether was required. To avoid the effects of atmospheric moisture, the weights of the starting salts before washing were used as the bases of the yield calculations; therefore, the yields are only qualitative. The results are shown in Scheme 4.

The reaction of the salt from **4**-OF with sodium salt of 2,4-pentanedione in refluxing ether for 4—5 h gave a condensation product, 2-(1-acetyl-2-oxopropyl)-4,4,6-trimethyl-1,3-dioxane (**5**), and the hydrolysis product of the acetoxonium salt, 3-hydroxy-1,3-dimethylbutyl formate (**6**). By the reaction with sodium salt of methyl acetoacetate, the expected product of 2-(1-methoxycarbonyl-2-oxopropyl)-4,4,6-trimethyl-1,3-dioxane (**7**) was obtained, together with 1,3-dimethyl-3-butenyl formate (**8**). The reaction with sodium salt of diethyl malonate gave only **8** but no condensation product.

	**10**-OA	$C_{11}H_{20}O_3$ *cis*, bp 90 °C/13 mmHg *trans*, bp 95—97 °C/13 mmHg	C, 65.97; H, 10.07	C, 65.83; H, 10.09 C, 66.19; H, 9.93

These results show that the condensation and the deprotonation proceeded in parallel and that the preferences depend on the reagents. The deprotonation could proceed as depicted in Scheme 5. This was consistent with the fact that the less bulky carbanions gave the condensation products and deprotonation was preferred in the case of more bulky carbanions.

The salt from **4**-OA was also treated with the carbanion, but no condensation nor deprotonation could be observed even after prolonged reaction times. The reason why the reactions did not proceed is still unclear.[5]

A trapping of the carbonium ion with hydride ion was examined by a reaction of 6-methyl-5,7-dioxaspiro-[2.5]octan-6-ylium salt with sodium borohydride. The reaction in DMF gave the same acetal (**9**-OA) as that prepared by the acetallisation of the corresponding diol (**9**).

Experimental

The IR spectra were recorded on a Hitachi EPI-G2 apparatus. The NMR spectra were taken on a Varian HR-220 apparatus at 220 MHz in $CDCl_3$ unless otherwise noted, with TMS as an internal standard.

Materials. 1,3-Propanediol, 1,3-butanediol, and 2-methyl-2,4-pentanediol were commercially available and distilled before use. Preparations of the diols containing cyclopropane rings were reported previously.[1,6]

*Preparations of Stereoisomers of **1**, **2**, and **3**.* By a reaction of 2,4-pentanedione (261 g) with methyl iodide (452 g) in acetone (600 ml) containing potassium carbonate (356 g) under reflux for 6.5 h and the usual work-up, 3-methyl-2,4-pentanedione, bp 65.0—65.5 °C/20 mmHg,† was obtained in a yield of 83%. The product (223 g) was again methylated by refluxing with methyl iodide (331 g) in acetone (600 ml) containing potassium carbonate (300 g) for 30 h. After the usual work-up, 3,3-dimethyl-2,4-pentanedione, bp 58.0—58.5 °C/12 mmHg, was obtained in a yield of 82%.

† 1 mmHg ≈ 133.322 Pa.

Into this dione (99 g) solution in ethanol (150 g), sodium borohydride (47 g) solution in water (150 g) containing sodium hydroxide (0.8 g) was added slowly under cooling in an ice-bath. After standing overnight, the solution was neutralized with hydrochloric acid. After removal of inorganic crystals, the diol layer was separated from the water layer. The latter was extracted with chloroform, and the chloroform solution was combined with the diol layer. After adding glycerol (100 ml), the solution was distilled to give 3,3-dimethyl-2,4-pentanediol (80 g). As in the case of 2,4-pentanediol,[1] the reaction of the diol with thionyl chloride gave cyclic sulfite. Distillation gave the *cis*-form, bp 63—64 °C/4.5 mmHg, and the *trans*-form, bp 78—78.5 °C/4.5 mmHg, but the complete separation was difficult even with a high reflux ratio. In contrast, a recrystallization worked well, since the *cis*-isomer was solid, while the *trans*-form was liquid. Recrystallization from petroleum ether at −18 °C gave pure *cis*-isomer, mp 32—32.5 °C. Alkaline hydrolyses of the *cis*- and *trans*-isomers with 20% aqueous sodium hydroxide gave *meso*-**1** (bp 118 °C/16 mmHg; NMR δ= 0.70 (s, 3H), 0.87 (s, 3H), 1.14 (d, 6H, J=6.8), and 3.78 (q, 2H)) and *dl*-**1** (bp 115 °C/16 mmHg; NMR δ=0.87 (s, 6H), 1.16 (d, 6H), and 3.79 (2H)).

The structures of the diols were confirmed by NMR analyses of the corresponding cyclic acetals of benzaldehyde, which were prepared as in the reported case of 2,4-pentanediol.[1] Acetal of *meso*-**1**: bp 122—123 °C/8 mmHg; NMR δ=0.78 (s, 3H), 1.00 (s, 3H), 1.20 (d, 6H), 3.67 (q, 2H) and 5.52 (s, 1H). Found: C, 76.04; H, 9.01%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%. Acetal of *dl*-**1**: NMR δ=0.75 (s, 3H), 1.14 (d, 3H), 1.24 (s, 3H), 1.41 (d, 3H), 3.81 (q, 1H), 5.85 (s, 1H) and 5.90 (q, 1H). Found: C, 76.26; H, 9.36%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

According to the method reported previously,[1,6] the diols were converted to the cyclic orthoacetates (see Tables 1 and 2). *meso*-**1**-OA (8.8 g) was stirred into a water (5 g)–ethanol (20 g) mixture at room temperature for 1 h. After removal of ethanol, the reaction mixture was extracted with ether, washed with saturated aqueous sodium chloride solution, dried over sodium sulfate, and then distilled to give *erythro*-**2** (6.7 g), bp 79—80 °C/4.5 mmHg. GLC analy-

sis showed that the purity was more than 99%. NMR δ=0.81 (s, 3H), 0.92 (s, 3H), 1.12 (d, 3H), 1.16 (d, 3H), 2.02 (s, 3H), 3.68 (q, 1H), 4.93 (q, 1H); IR $\nu_{C=O}$ 1740, 1720 (sh); ν_{C-O} 1270, 1255 cm^{-1}. Found: C, 62.10; H, 10.56%. Calcd for $C_9H_{18}O_3$: C, 62.04; H, 10.41%. Similarly, *dl*-**1**-OA gave *threo*-**2** in a yield of 90%, bp 84.0—84.5 °C/5.6 mmHg; NMR δ=0.81 (s, 3H), 0.85 (s, 3H), 1.10 (d, 3H), 1.18 (d, 3H), 2.05 (s, 3H), 3.56 (q, 1H), 5.00 (q, 1H); IR $\nu_{C=O}$ 1725, 1710; ν_{C-O} 1265, 1250 cm^{-1}. Found: C, 62.08; H, 10.57%. Calcd for $C_9H_{18}O_3$: C, 62.04; H, 10.41%.

Into an anhydrous pyridine (25 ml) solution of *erythro*-**2** (6 g), *p*-toluenesulfonyl chloride (6.84 g) was added. After the mixture was kept in a refrigerator for 3 d, crystalline pyridine hydrochloride was filtered off. The filtrate was treated with ice–water and then the pH of the solution was adjusted to 5 by addition of cold hydrochloric acid. The solution was extracted with ether. After drying over K_2CO_3–Na_2SO_4, the ether was removed. To the residue, petroleum ether (70 ml) was added. After filtration, the filtrate was kept in a refrigerator to give crystals (9.4 g). After recrystallization from petroleum ether, pure *erythro*-**3** was obtained, mp 72.0—72.5 °C; NMR δ=0.83 (s, 3H), 0.88 (s, 3H), 1.09 (d, 3H), 1.23 (d, 3H), 2.04 (s, 3H), 2.45 (s, 3H), 4.62 (q, 1H), 4.80 (q, 1H), 7.36 (d, 2H), 7.81 (d, 2H). Found: C, 58.66; H, 7.65; S, 9.92%. Calcd for $C_{16}H_{24}O_5S$: C, 58.51; H, 7.37; S, 9.76%. *threo*-**3** was prepared by the same procedure, mp 59.5—60.0 °C; NMR δ= 0.82 (s, 3H), 0.87 (s, 3H), 1.14 (d, 3H), 1.26 (d, 3H), 2.04 (s, 3H), 2.43 (s, 3H), 4.77 (q, 1H), 4.79 (q, 1H), 7.31 (d, 2H), 7.78 (d, 2H). Found: C, 58.39; H, 7.15; S, 9.72%. Calcd for $C_{16}H_{24}O_5S$: C, 58.51; H, 7.37; S, 9.76%.

Solvolyses of **3**. The reaction procedure was analogous to that previously reported.[1] The product ratios were determined by GLC (EGSS-X 1 m column) using 1-methylnaphthalene as an internal standard.

Hydrolyses of Orthoformates of 1,3-Butanediol and 2-Methyl-2,4-pentanediol. The primary hydrolysis products of these substrates are hydroxy formates which are readily hydrolyzed further to glycols. In order to determine the primary products, the following procedure was used. Orthoformate of 2-methyl-2,4-pentanediol (24 g) was stirred into a mixture of carbon tetrachloride (100 ml) and water (20 ml) at room temperature for 4 h. The carbon tetrachloride layer was distilled after evaporation of the solvent to give 3-hydroxy-1,3-dimethylbutyl formate in a yield of 50%, bp 88.5—91.5 °C/10 mmHg; NMR δ=1.23 (s, 3H), 1.79 (m, 2H), 2.23 (s, 1H), 5.20 (m, 1H), and 8.0 (s, 1H). Found: C, 58.01; H, 9.63%. Calcd for $C_7H_{14}O_3$: C, 57.51; H, 9.65%. The rather low yield was due to the hydrolysis to the diol. The hydrolysis of orthoformate of 1,3-butanediol did not proceed at room temperature and required refluxing for 1 h. The product was obtained from the water layer by distillation, bp 99.5—101 °C/18 mmHg. This was a mixture of 3-hydroxybutyl formate and 3-hydroxy-1-methylpropyl formate in a ratio of 9:1. The ratio was determined by NMR. NMR of the former: δ=1.20 (d, 3H), 1.70 (m, 2H), 2.46 (s, 1H), 3.50—4.43 (m, 2H), and 8.0 (s, 1H). NMR of the latter: δ=1.30 (d, 3H), 1.70 (m, 2H), 2.46 (s, 1H), 3.50—4.43 (m, 2H), 5.20 (1H), and 8.0 (s, 1H).

Authentic Samples of meso- *and* dl-*1 Diacetates.* According to the conventional method, the diacetates were prepared by the reactions of the diols with acetyl chloride (6 mole equivalent) in pyridine. *meso*-**1**-diacetate, bp 114.0—114.5 °C/18.5 mmHg; NMR δ=0.89 (s, 3H), 0.94 (s, 3H), 1.15 (d, 6H), 2.08 (s, 3H), and 4.95 (q, 2H); IR $\nu_{C=O}$ 1735, 1730; ν_{C-O} 1260, 1235 cm^{-1}. Found: C, 61.14; H, 9.30%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32%. *dl*-**1**-diacetate, bp 106—107 °C/15.5 mmHg; NMR δ=0.91 (s, 6H), 1.16 (d, 6H), 2.03 (s, 6H), and 4.91 (q, 2H). Found: C, 60.93; H, 9.36%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32%.

Preparation of Acetoxonium Salts. The following example shows the typical experimental procedure. Into a *meso*-**1**-OA (1.1 g) solution in dry ether (5 ml), $BF_3 \cdot OEt_2$ (1.2 g) was added slowly. After allowing the mixture to stand for 24 h at room temperature, crystals of the salt had been formed. The crystals were separated by filtration using a sintered glass filter, dissolved in dry nitrobenzene and subjected to NMR measurement. The crystals were very sensitive to atmospheric moisture and not stable enough to allow us to perform elemental analyses and IR measurements.

Reactions of Acetoxonium Ion with Carbanions. To a solution of 4-OF (16 g) in dry ether (100 ml) was added $BF_3 \cdot OEt_2$ (21 g). The resulting crystals were ground in ether and washed three times with dry ether. The crystals and sodium acetylacetonate (12 g) were added to ether (200 ml) and refluxed for 4 h. After filtering the inorganic crystals formed, the reaction mixture was distilled to give 3-hydroxy-1,3-dimethylbutyl formate, bp 79.5—80 °C/13 mmHg, 3.4 g; and **5**, bp 126—133 °C/13 mmHg, 4.7 g; NMR δ=0.89 (d, 3H), 0.93 (s, 3H), 0.98 (m, 2H), 1.03 (s, 3H), 1.78 (s, 6H), 3.07 (d, 1H), 3.04 (t, 1H), and 4.21 (d, 1H); IR $\nu_{C=O}$ 1725, 1710 cm^{-1}. Found: C, 62.87; H, 8.52%. Calcd for $C_{12}H_{20}O_4$: C, 63.16; H, 8.77%.

Similarly, the reaction with the sodium salt of methyl acetoacetate gave **8**, bp 64—65 °C/60 mmHg; NMR δ= 1.30 (d, 3H), 1.91 (s, 3H), 2.25 (s, 3H), 2.32 (q, 1H), 5.11 (d, 2H), 5.45 (s, 1H); and **7**, bp 92—93 °C/2 mmHg; NMR δ=0.92—1.08 (11H), 1.35 (s, 3H), 2.00 (s, 3H), 3.30 (m, 1H), 3.06 (m, 1H), 4.41 (s, 1H). Found: C, 59.74; H, 8.34%. Calcd for $C_{12}H_{20}O_5$: C, 59.02; H, 8.25%.

5) In the case of the acetoxonium ion from **4**-OA, the referee, to whom the authors' thanks are due, suggested that the deprotonation might occur at the 2-methyl group giving 2-methylene-4,4,6-trimethyl-1,3-dioxane, which would decompose in the subsequent reaction. This sequence of reaction looked like a plausible one, but none of the products expected from these reactions could be detected by GLC analysis of the reaction mixture.

(Received April 11, 1981)

Pyrolyses of a series of selenides and diselenides were studied. Selenides and diselenides bound with an active methylene group like benzyl gave a variety of substituted bibenzyls and related ethane derivatives in high yields. Other diselenides were easily caused to cleave to give various aromatic and aliphatic olefins in good yields together with elemental selenium. Lepidopterene, [2.2]paracyclophane, and benzocyclobutene were prepared by thermal cleavage of their corresponding phenylselenomethyl-substituted compounds as an application of the pyrolysis concerned.

Formation of carbon-carbon bond by sulfur extrusion is of importance as a synthetic method. For example, pyrolysis of cyclic sulfones made a significant contribution to the remarkable development of cyclophane chemistry.[1] In contrast, little attention has been paid to selenium extrusion of organoselenium compounds, partly because high oxidation states of selenium are usually unstable. Recently Chu and Lewicki[2] reported that bis(diphenylmethyl) diselenide thermally decomposed with loss of elemental selenium to give 1,1,2,2-tetraphenylethane. Couture *et al.*[3] studied pyrolysis of bis(9-anthrylmethyl) selenide and diselenide to 1,2-di(9-anthryl)ethane. We found that on gas-phase pyrolysis, dibenzyl selenide **1** gave bibenzyl in a high yield, in contrast to no reaction occurring with dibenzyl sulfide.[4] Several pieces of information on such labile C–Se bonds stimulated us to initiate an extensive study on thermal behaviors of various organoselenium compounds. Here we report on thermal decomposition of mono- and diselenides **2**—**13** and some applications to synthesis of related compounds.[5]

Results and Discussion

Selenides **2**—**13** were prepared by the conventional methods described in the experimental part. Selenium extrusion on them was carried out by the flash vacuum pyrolysis which had successfully been used for dibenzyl selenide **1**.[4] The reaction of **1** is capable of proceeding above 400 °C with the optimal yield at 600 °C under 20 mmHg (1 mmHg≈133.322 Pa). The best results obtained in the present study with almost the same conditions are summarized in Table 1. As seen from this table, pyrolysis products are significantly dependent on characters of selenium bonds, which are classified into four groups as follows:

1. Selenides **4**, **7**, and **9** were recovered because they possess no readily cleavable bonds. In spite of being highly susceptible to homolysis to phenylseleno radical, diphenyl diselenide **2** was exceptionally unreactive. Probably the fragment radical favors recombination to the original molecule over fragmentation.
2. Selenides **1** and **5**, both having labile bilateral bonds of selenium, readily underwent selenium extrusion to form C–C bonds.
3. Pyrolysis of benzyl phenyl selenide **3** gave a mixture of bibenzyl and diphenyl diselenide **2** in high yields. These two products were formed apparently by individual dimerizations of benzyl and phenylseleno radicals which had been generated by homolytic cleavage of the benzyl-Se bond of **3**.

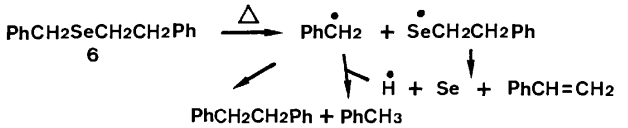
a) Ref. 19.

Allyl phenyl selenide **11**, phenylselenoacetonitrile **12**, and phenylselenoacetone **13** underwent analogous cleavages to give biallyl, succinonitrile, and 2,5-hexanedione, respectively, together with diphenyl diselenide.

4. Diphenethyl diselenide **8** was caused to cleave to yield styrene and elemental selenium but no 1,4-diphenylbutane, as expected on the simple selenium extrusion sequence. Dihexyl diselenide **10** showed a similar behavior in yielding 1-hexene with a minute amount of dodecane. Pyrolyses of dioctyl diselenide **14** and dioctyl disulfide **15** were examined for comparison of reactivities between both the organochalcogen compounds. 1-Octene was obtained in a high yield (93%) from **14**, while in a low yield (18%) from **15**.

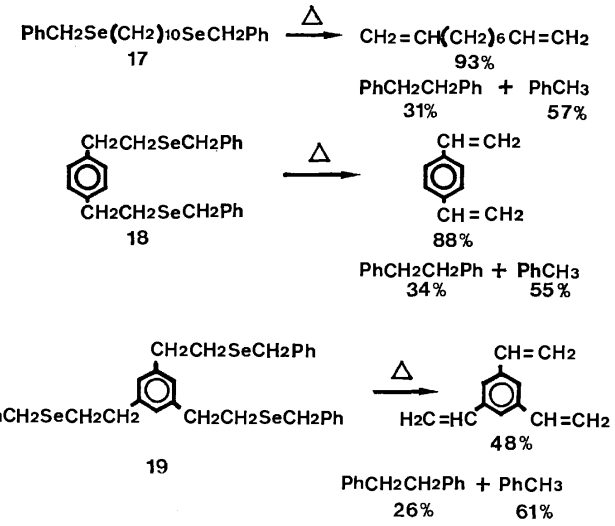
$$\underset{\mathbf{14}}{C_8H_{17}SeSeC_8H_{17}} \xrightarrow{\Delta} \underset{93\%}{C_6H_{13}CH{=}CH_2} \xleftarrow{\Delta} \underset{18\%}{\underset{\mathbf{15}}{C_8H_{17}SSC_8H_{17}}}$$

Benzyl phenethyl selenide **6** is particularly interesting, for it can combine with functional groups of types 3 and 4 specified above. In fact, it gave four products, bibenzyl, styrene, toluene, and elemental selenium, in a high total yield. As seen from the scheme, the formation of a considerable amount of toluene indicates that part of benzyl radicals are possibly quenched by H· radicals derived from phenethylseleno radicals.

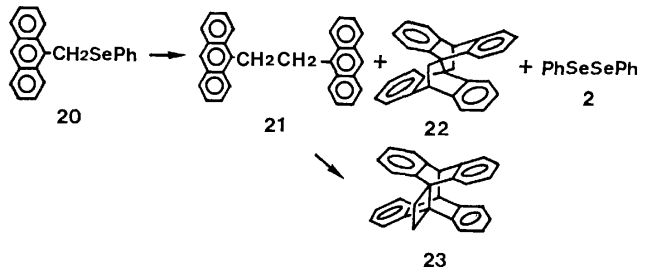


In the case of sulfur derivatives, on the other hand, benzyl phenethyl sulfide failed to undergo any pyrolytic reactions, while its sulfone **16** decomposed to give a mixture of bibenzyl, styrene, and 1,3-diphenylpropane. The pyrolysis of **6** and **16** indicates that the pyrolytic mechanism of selenide is somewhat different from that of sulfone. Analogous pyrolytic reactions were observed with polyfunctional compounds **17**, **18**, and **19** which yield polyolefins.

$$\underset{\mathbf{16}}{PhCH_2SO_2CH_2CH_2Ph} \xrightarrow{\Delta} \underset{56\%}{PhCH_2CH_2Ph} + \underset{34\%}{PhCH{=}CH_2} + \underset{28\%}{PhCH_2CH_2CH_2Ph} + SO_2$$



Of many synthetic methods for bibenzyls the most convenient ones utilize the Grignard reaction and the Wurtz reaction on benzyl halides. However, some functional groups have a reactivity so variable with reaction conditions as to make it difficult to synthesize their related bibenzyls by these methods. Extrusion reactions of dibenzyl sulfone,[6] dibenzyl oxalate,[7] and dibenzyl selenide[4] have been useful for preparation of some bibenzyls. Benzyl phenyl selenide **3** also can be utilized as a starting material for synthesis of bibenzyls. Thus, pyrolyses of derivatives of **3**, which are readily prepared by treatment of the corresponding benzyl halides with benzeneselenolate (Table 2), gave various bibenzyls and 1,2-diarylethanes in high yields (Table 3). It is noticeable that diphenyl diselenide **2** concomitantly formed in such reactions is reusable to generate benzeneselenolate. Accordingly, the present method surpasses the extrusion methods with regard to yield and wide applicability, as described below. Vapor pressures of sulfones, oxalates, and selenides with bifunctional polar groups are very low and hence they are often subject to undesirable decomposition before being vaporized for extrusion. For example, 4,4′-dimethoxybibenzyl could be obtained by the present method, but not by pyrolysis of its corresponding dibenzyl oxalate.[7]



A flash vacuum pyrolysis of 9-anthrylmethyl phenyl selenide **20** gave 1,2-di(9-anthryl)ethane **21** as expected (see Table 4). On the other hand, a thermal reaction of **20** in solid state or in toluene solution at 150—170 °C provided in a high yield a unique structure compound, lepidopterene **22** which had previously been synthesized by reaction of 9-(chloromethyl)-anthracene with methylmagnesium iodide[8] or photolysis of 9-anthrylmethyl sulfide or selenide.[3] The yields of **22** by the present method are much higher than those by the previous methods. Photolysis of **20** also led to **22** as well as a photodimer biplanene **23**. In every case, diphenyl diselenide **2** was a concomitant product with almost a quantitative yield.

The ring contraction accompanying the extrusion of sulfur dioxide from cyclic sulfones is very suitable for synthesis of cyclic hydrocarbons. For example, a heating of cyclic disulfone **24** gave [2.2]paracyclophane **25** in 15—18% yield.[9] In contrast, no synthesis of cyclophanes by organoselenium has yet been known, because no cyclic selenides have so far been made available.[10] One may expect that heating of 1,4-bis(phenylselenomethyl)benzene **27** would generate, with elimination of diphenyl diselenide **2**, biradical **28** which, in equilibrium with quinodimethane **29**, is dimerized to form [2.2]paracyclophane **25**.[11] In fact, acyclic diselenide **27** was readily prepared in 85% yield from 1,4-bis(chloromethyl)benzene **26** and gave [2.2]paracyclophane **25** (23% yield) and diphenyl di-

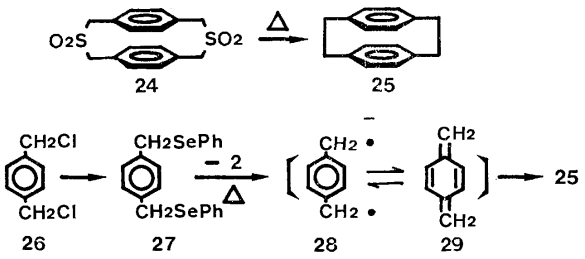
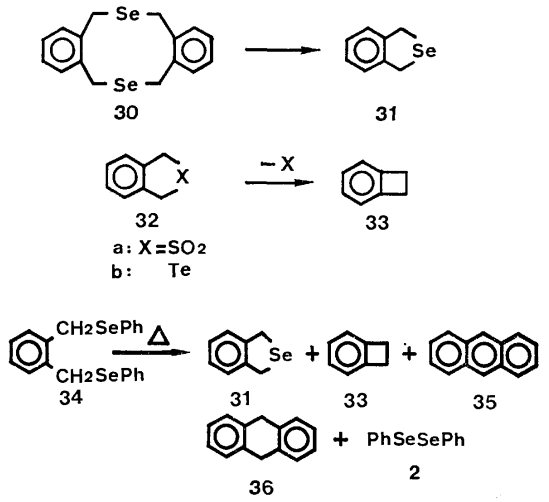
600 °C, 20 mmHg	47	38	7	0	16	8

selenide **2** (69%) on pyrolysis at 650 °C under 7 mmHg.



In connection with the formation of bibenzyl from dibenzyl selenide, it is expected that pyrolysis of 2,11-diselena[3.3]orthocyclophane **30** would give 1,2:5,6-dibenzo-1,5-cyclooctadiene. However, **30** gave 1,3-dihydro-2-benzoselenophene **31**[14] in 92% yield instead of 1,2:5,6-dibenzo-1,5-cyclooctadiene. Selenophene **31** is thermally stable in contrast to the fact that similarly constructed compounds **32a**[12] and **32b**[13] can easily afford 1,2-dihydrobenzocyclobutene **33** on pyrolysis. On the other hand, **33** was obtained by pyrolysis of 1,2-bis(phenylselenomethyl)benzene **34**. As shown in Table 5, the reaction conditions available are critical and the products are dependent on the vacuum pressure of the pyrolytic system. The best yield (40%) of **33** was attained under 8 mmHg. Under higher vacuum (3 mmHg), most of **34** was recovered and under lower vacuum (20 mmHg) other products, 1,3-dihydro-2-benzoselenophene **31**, anthracene **35**, and 9,10-dihydroanthracene **36**, were favored. In the present stage, the formation mechanism for **35** and **36** is equivocal.



In conclusion, pyrolyses of organoseleniums are capable of providing a new method for the preparation of olefins, bibenzyls, and related compounds.

Experimental

Melting points were not corrected. All the solvents were of reagent grade. NMR spectra were recorded on a JEOL FX-100 (100 MHz) spectrometer using deuterochloroform as the solvent and tetramethylsilane as the internal standard. MS spectra were recorded on a Hitachi RMU-7 spectrometer (70 eV) using the direct injection technique. MS spectra of organoseleniums are characteristic of isotope patterns with respect to selenium atoms and description of molecular ion peaks is based on ^{80}Se only. IR spectra were recorded on a Hitachi EPI-G2 spectrometer for neat or nujol mull.

*General Synthetic Method of Selenides **3**, **4**, **6**, **7**, **9**, **11**, **12**, **13**, **20**, and Bis- and Tris-selenides **17**, **18**, **19**, **27**, and **34**.* Alkyl phenyl selenides **3**, **4**, **11**, **12**, **13**, **20**, **27**, and **34** were prepared by treatment of their corresponding alkyl halides with sodium benzeneselenolate which had been generated by reduction of diphenyl diselenide **2**[15] or phenyl selenocyanate[16] with sodium borohydride. The substitutional derivatives of **3** shown in Table 2 were prepared in the same way. The other selenides were similarly prepared by using phenethyl selenocyanate[17] for **6** and **7**, hexyl selenocyanate[18] for **9**, and benzyl selenocyanate[4] for **17**, **18**, and **19** as precursors for the above selenolates.

The general procedure will be illustrated below by using the synthesis of benzyl phenyl selenide **3** as an example. Sodium borohydride (0.32 g, 8.4 mmol) was carefully added with ice-cooling to a solution of phenyl selenocyanate (1.5 g, 8.2 mmol) in ethanol (50 ml), with nitrogen being bubbled through the solution. After the solution was allowed to stand at room temperature, a solution of benzyl chloride (1.1 g, 8.6 mmol) in ethanol (20 ml) was added dropwise over a period of 30 min. The mixture was refluxed for 5 h and cooled to room temperature. Water (100 ml) and benzene (200 ml) were successively added. The organic layer was separated, washed with saturated aq sodium chloride solution, and dried over anhyd magnesium sulfate. After evaporation, the residue was chromatographed on silica gel (Wako gel C-200) with hexane and a recrystallization of the first eluate from benzene–hexane gave colorless plates of **3** in 92% yield: mp 33.5—34 °C (lit,[19] 34—35 °C); NMR δ=4.08 (s, CH_2), 7.19 (bs, ArH), and 7.23—7.41 (m, SePhH); MS, *m/e*, 248 (M^+).

4: yield 95%; colorless oil; NMR δ=3.02, 3.12 (A_2B_2m, CH_2), and 7.02—7.47 (m, ArH); MS, *m/e*, 262 (M^+). Found: C, 64.23; H, 5.47%. Calcd for $C_{14}H_{14}Se$: C, 64.36; H, 5.36%.

6: yield 95%; colorless oil; NMR δ=2.70, 2.81 (A_2B_2m, CH_2CH_2), 3.72 (s, CH_2), and 7.21 (m, ArH); MS, *m/e*, 276 (M^+). Found: C, 65.21; H, 5.89%. Calcd for $C_{15}H_{16}Se$: C, 65.46; H, 5.82%.

7: yield 83%; pale yellow oil; NMR δ=2.81, 2.91 (A_2B_2m, CH_2), and 7.20 (m, ArH); MS, *m/e*, 290 (M^+). Found: C, 66.28; H, 6.28%. Calcd for $C_{16}H_{18}Se$: C, 66.44; H, 6.23%.

9: yield 88%; pale yellow oil; NMR δ=0.89 (t, CH_3), 1.32—1.66 (m, CH_2), and 2.55 (t, $SeCH_2$); MS, *m/e*, 250 (M^+). Found: C, 57.68; H, 10.64%. Calcd for $C_{12}H_{26}Se$: C, 57.83; H, 10.44%.

11:[20] yield 93%; pale yellow oil; NMR δ=3.50 (d, CH_2), 4.87, 5.02, 5.88 (ABXm, $CH{=}CH_2$), and 7.23—7.49 (m, ArH); MS, *m/e*, 198 (M^+); IR 1630 cm^{-1} ($\nu_{C=C}$).

12: yield 94%; colorless oil; NMR δ=3.34 (s, CH_2) and

7.34—7.65 (m, ArH); MS, *m/e*, 197 (M^+); IR 2250 cm^{-1} ($\nu_{C\equiv N}$). Found: C, 48.79; H, 3.62; N, 7.30%. Calcd for C_8H_7NSe: C, 48.98; H, 3.57; N, 7.14%.

13: yield 94%; pale yellow oil; NMR δ=2.25 (s, CH_3), 3.57 (s, CH_2), and 7.27—7.51 (m, ArH); MS ,*m/e*, 214 (M^+); IR 1715 cm^{-1} ($\nu_{C=O}$). Found: C, 50.58; H, 4.90%. Calcd for $C_9H_{10}OSe$: C, 50.70; H, 4.69%.

17: yield 89%; colorless oil; NMR δ=1.24, 1.56 (m, CH_2), 2.49 (t, $SeCH_2$), 3.76 (s, $PhCH_2$), and 7.26 (m, ArH); MS, *m/e*, 482 (M^+). Found: C, 59.73; H, 7.11%. Calcd for $C_{24}H_{34}Se_2$: C, 60.00; H, 7.08%.

18: yield 87%; colorless oil; NMR δ=2.73, 2.80 (A_2B_2m, CH_2CH_2), 3.74 (s, CH_2Se), 7.04 (s, ArH), and 7.25 (m, ArH); MS, *m/e*, 474 (M^+). Found: C, 60.95; H, 5.57%. Calcd for $C_{24}H_{26}Se_2$: C, 61.02; H, 5.51%.

19: yield 78%; colorless oil; NMR δ=2.72, 2.82 (A_2B_2m, CH_2CH_2), 3.75 (s, CH_2Se), 6.75 (s, ArH), and 7.26 (m, ArH); MS, *m/e*, 672 (M^+). Found: C, 58.94; H, 5.33%. Calcd for $C_{33}H_{36}Se_3$: C, 59.19; H, 5.38%.

20: yield 94%; pale yellow prisms from hexane–benzene; mp 124.5—126.0 °C; NMR δ=5.15 (s, CH_2), 7.25, 7.46 (m, PhH), 7.94, 8.22 (m, AnthH), and 8.37 (s, AnthH); MS, *m/e*, 348 (M^+). Found: C, 72.75; H, 4.58%. Calcd for $C_{21}H_{16}Se$: C, 72.62; H, 4.61%.

27: yield 85%; colorless plates from hexane–benzene; mp 137—138 °C; NMR δ=4.06 (s, CH_2), 7.06 (s, ArH), and 7.25—7.42 (m, PhH); MS, *m/e*, 418 (M^+). Found: C, 57.53; H, 4.34%. Calcd for $C_{20}H_{18}Se_2$: C, 57.69; H, 4.33%.

34: yield 87%; colorless plates from hexane–benzene; mp 30.5—31.5 °C; NMR δ=4.18 (s, CH_2), 7.05 (s, ArH), and 7.23—7.43 (m, PhH); MS, *m/e*, 418 (M^+). Found: C, 57.96; H, 4.44%. Calcd for $C_{20}H_{18}Se_2$: C, 57.69; H, 4.33%.

*General Synthetic Method of Diselenides **5**, **8**, **10**, and **14**.* Diselenides **5**, **8**, **10**, and **14** were prepared by alkaline hydrolysis of benzyl selenocyanate,[4] phenethyl selenocyanate,[17] hexyl selenocyanate,[18] and octyl selenocyanate,[21] respectively. The general procedure will be illustrated below by using the synthesis of dibenzyl diselenide **5** as an example.

A solution of benzyl selenocyanate (3.88 g, 19.8 mmol) in methanol (30 ml) was added dropwise to methanol (30 ml) containing potassium hydroxide (0.6 g, 23.2 mmol) at room temperature. After stirring for 3 h, water (100 ml) and benzene (200 ml) were added. The organic layer was separated, washed with saturated aq sodium chloride solution, and dried over anhyd magnesium sulfate. After evaporation, the residue was chromatographed on silica gel (Wako gel C-200) with hexane and a recrystallization of the first eluate gave **5** in 95% yield: pale yellow needles from hexane–benzene; mp 91—92 °C (lit,[22] 92—93 °C); NMR δ=3.84 (s, CH_2) and 7.25 (bs, ArH); MS, *m/e*, 342 (M^+). Found: C, 49.64; H, 4.22%. Calcd for $C_{14}H_{14}Se_2$: C, 49.41; H, 4.11%.

8: yield 98%; colorless oil; NMR δ=3.03, 3.11 (A_2B_2m, CH_2), and 7.22 (m, ArH); MS, *m/e*, 370 (M^+). Found: C, 52.42; H, 5.12%. Calcd for $C_{16}H_{18}Se_2$: C, 52.17; H, 4.89%.

10: yield 96%; pale yellow oil; NMR δ=0.89 (t, CH_3), 1.34—1.73 (m, CH_2), and 2.29 (t, CH_2Se); MS, *m/e*, 330 (M^+). Found: C, 43.76; H, 7.97%. Calcd for $C_{12}H_{26}Se_2$: C, 43.90; H, 7.93%.

14: yield 97%; colorless oil; NMR δ=0.88 (t, CH_3), 1.30—1.76 (m, CH_2), and 2.91 (t, CH_2Se); MS, *m/e*, 386 (M^+). Found: C, 50.00; H, 9.07%. Calcd for $C_{16}H_{34}Se_2$: C, 50.00; H, 8.85%.

Dioctyl disulfide **15** was prepared according to the procedure of Yiannios and Karabinos.[23] Benzyl phenethyl sulfide and sulfone **16** were prepared according to the procedure of Böhme *et al.*[24]

*2,11-Diselena[3.3]orthocyclophane **30** and 1,3-Dihydro-2-benzoselenophene **31**.* A solution of 1,2-bis(bromomethyl)benzene (2.3 g, 8.0 mmol) in benzene (30 ml) and a solution of sodium selenide (1.12 g, 8.9 mmol) in 60% ethanol (100 ml) were added simultaneously and dropwise to a stirred ethanol (150 ml) at room temperature under a nitrogen atmosphere. The addition took 1.5 h. After an additional stirring for 2 h, benzene (300 ml) was added and the mixture was washed with saturated aq NaCl solution and dried over anhyd $MgSO_4$. After evaporation of the solvent, the residue was triturated with 1:1 benzene–hexane and the insoluble solid was recrystallized from dichloromethane–benzene to give colorless needles of **30** in 25% yield: mp 201—202 °C; NMR δ=3.66 (s, CH_2), 7.21, and 7.29 (A_2B_2m, ArH); MS, *m/e*, 368 (M^+). Found: C, 52.74; H, 4.37%. Calcd for $C_{16}H_{16}Se_2$: C, 52.46; H, 4.37%.

The benzene–hexane solution was chromatographed on silica gel (Wako gel C-100) with hexane to give a minute amount of **31** from the first eluate: mp 31—33 °C. The spectral data of this specimen were identical with those of product **31** obtained by pyrolysis of **30**. **31**: NMR δ=4.30 (s, CH_2), 7.14, and 7.20 (A_2B_2m, ArH); MS, *m/e*, 184 (M^+); mol wt 191 (vapor pressure osmometry, CH_2Cl_2). Found: C, 52.60; H, 4.29%. Calcd for C_8H_8Se: C, 52.46; H, 4.37%.

General Method for Flash Vacuum Pyrolysis. A Pyrex tube closed at one end, 40 cm long and 1 cm in diameter, was used for pyrolysis. The sample (50—300 mg) of organoselenium was placed at the closed end of the tube. The other open end was connected to a vacuum system and cooled with Dry Ice or liq. nitrogen. The middle part was enclosed within an electric furnace (25 cm long) preheated at 600 °C. After heating for *ca.* 2 min, the sample part was slidden into the furnace. Pyrolysis immediately occurred and the pyrolysates condensed at the cool part. The organic products were extracted with dichloromethane and isolated by preparative gel-permeation liquid chromatography (Nihon Bunseki Kogyo LC-08) with chloroform as eluent. All of them were identified by comparison of their melting points and spectral data with those of authentic samples or reported data.[25]

*Pyrolysis of 9-Anthrylmethyl Phenyl Selenide **20**.* *a) In Solid State*: Selenide **20** (20 mg) was heated in an oil bath at 150 °C for 5 min. A gel-permeation liquid chromatography of the pyrolysates gave 1,2-di(9-anthryl)ethane **21** (1.3 mg, 14%), lepidopterene **22** (7.8 mg, 82%), and diphenyl diselenide **2** (9.2 mg, 96%), successively.

21: pale yellow plates from toluene; mp 318.5—320.5 °C (lit,[8] 320 °C); NMR δ=4.07 (s, CH_2), 7.53, 8.03, and 8.39 (m, ArH); MS, *m/e*, 382 (M^+).

22: colorless columns from toluene; mp 298—299 °C (lit,[8] 298 °C); NMR δ=2.89 (d, J=3 Hz, CH_2), 4.63 (t, J=3 Hz, CH), 6.76, 6.81, 6.98, and 7.30 (m, ArH).

b) In Solution: Selenide **20** (20 mg) was placed in an NMR tube and dissolved in 0.7 ml of toluene-d_8. The tube was degassed by the freeze-pump-thaw method and sealed. The reaction at 170 °C was followed by NMR measurement. After *ca.* 12 h, the signals of **20** completely disappeared. A gel-permeation liquid chromatography of the products gave **21** (2.2 mg, 24%), **22** (6.5 mg, 68%), and **2** (95%).

*Photolysis of 9-Anthrylmethyl Phenyl Selenide **20**.* Selenide **20** (20 mg) was dissolved in benzene (20 ml) and irradiated with a high pressure mercury lamp in a nitrogen atmosphere. After evaporation, a gel-permeation liquid chro-

matography of the residue gave **22** (6.4 mg, 66%), biplanene **23** (2.3 mg, 25%), and **2** (9.1 mg, 95%).

23: colorless columns from benzene–toluene; mp 329 °C dec (lit,[8] 320 °C); NMR δ=3.01 (s, CH_2), 4.5 (s, CH), and 6.82—7.13 (m, ArH); MS, *m/e*, 382 (M^+).

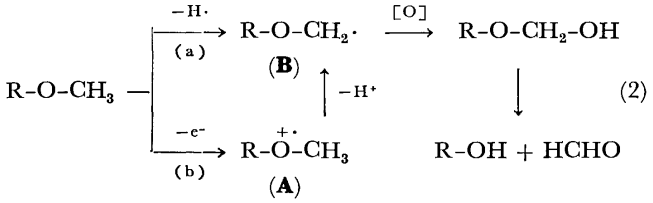
(Received April 13, 1981)

Oxygenations of thioanisole derivatives have been shown to be promoted with phenobarbital induced rabbit liver microsomes. In order to understand the mechanistic details of the oxygenations, a kinetic study on the *S*-oxygenation promoted by a reconstituted system with purified cytochrome P-450 has been carried out. Log-(V_{max}) were correlated with the one electron oxidation potentials of the sulfides (E_p). The oxygenation is considered to proceed *via* one electron transfer from the sulfides to the iron-bound "oxenoid" intermediate of the enzyme. A similar *O*-demethylation of anisoles has been investigated. In the oxidative *O*-demethylation of *p*-methoxy-d_3-anisole with rabbit liver microsomes, an intramolecular kinetic isotope effect of 3.4 was observed. Meanwhile, a large isotope effect of 5.1 was observed in the competitive *O*-demethylation of *p*-dimethoxybenzene and *p*-di(methoxy-d_3)benzene. In order to clarify the oxidation pathway of *O*-demethylation with the enzymatic system of cytochrome P-450, the rates of the *O*-demethylation of *p*-substituted anisoles have been measured. Unlike the enzymatic oxygenation of sulfides, there was no correlation between the rates of *O*-demethylation reaction and one electron oxidation potentials of anisoles. These observations suggest that the *O*-demethylation of anisoles proceeds *via* the initial hydrogen abstraction with the iron-bound "oxenoid" intermediate of the cytochrome P-450.

Oxidative *O*-demethylation of methyl ethers catalyzed by the hepatic microsomal cytochrome P-450 system, requiring NADPH and O_2, is one of typical oxidation reactions by mono-oxygenases,[1,2] and numerous substrates have been considered to be demethylated *via* forming the corresponding hemiacetal intermediates (Eq. 1).[3] This reaction involves the

$$\text{R-O-CH}_3 \xrightarrow{\text{enzyme}} [\text{R-O-CH}_2\text{-OH}] \xrightarrow{\text{non-enzyme}} \text{R-OH} + \text{HCHO} \quad (1)$$

initial removal of α-hydrogen and subsequent recombination of the resulting intermediate ((B) in Eq. 2) with the iron-bound "oxenoid" intermediate ($(FeOH)^{III}$) before collapsing to afford the hemiacetal intermediate. Since all the subsequent steps which involve highly reactive intermediates after the initial hydrogen removal would be quite fast, the initial hydrogen removal is presumed to be the rate-determining step of the overall reaction of demethylation. However, the removal of α-hydrogen could proceed *via* a different mechanistic route, as shown below.



(2)

If the direct hydrogen-removal (a) is the actual path, one would find a relatively large kinetic isotope effect of α-hydrogen, whereas a small secondary kinetic isotope effect, k_H/k_D, would be observed when the proton removal takes place after the rate-determining electron transfer to form the cation radical (**A**). Thus, the kinetic isotope effect was studied to diagnose the mechanistic pathway of enzymatic demethylations and oxygenations.

In the *O*-demethylation of *o*-nitroanisole,[4] *p*-methoxy-acetanilide,[5] and *p*-dimethoxybenzene[5] and their methyl-d_3 derivatives, mediated by rat liver microsomes, the kinetic isotope effects, *i.e.* k_H/k_D of *ca.* 2 have been observed, whereas in the mono-*O*-demethylation of *p*-methoxy-d_3-anisole a large primary isotope effect ($k_H/k_D=10$)[5] was observed by the intramolecularly competitive reaction. In the *O*-dealkylation o propyl *p*-nitrophenyl ether, however, a rather small kinetic isotope effect ($k_H/k_D=1.1$) was observed during the metabolism with the rat and guinea pig hepatic enzyme systems.[6]

Recently, Hamilton and others postulated an iron-bound "oxenoid" intermediate as the active component species of mono-oxygenases.[7–13] This iron-bound "oxenoid" intermediate has been postulated to be analogous to the Compound I of peroxidase[10,13] and this postulate has been supported by extensive investigation with a few enzyme-model systems.[14,15] In other enzymatic oxidations of hydrocarbons, several *in vitro* measurements of the primary isotope effect give rather low values, such as $k_H/k_D \approx 2.0$.[16–20] In these experiments, kinetic isotope effects, k_H/k_D, were obtained by comparison of the reactivities of the deuterated and the undeuterated substrates, in separate kinetic runs. However, the enzymatic oxidation reaction consists of several succesive steps and hence the measured isotope effects are the summation of some steps of the overall enzymatic oxidation reaction. In order to avoid the complication of the kinetic treatment due to the different pre-oxygenation processes such as an electron transfer reduction of the cytochrome P-450-substrate complex and to estimate the real kinetic isotope effect of the enzymatic hydroxylation of hydrocarbons, it is desirable to measure the kinetic isotope effect of an intramolecularly competitive reaction.

Both Hjelmeland *et al.*[21] and Groves *et al.*[22] ob-

tained large values of $k_H/k_D \doteqdot 11$ for intramolecular isotope effects, using compounds which have both deuterated and undeuterated methylene groups in one molecule in the oxygenation of benzylic carbon and aliphatic carbon. These results suggest that the rate-determining step of the oxygenation is the hydrogen abstraction from hydrocarbons with the iron-bound "oxenoid" intermediate.[22]

Recently we have reported a few typical examples of enzymatic oxygenation of divalent sulfur compounds to the corresponding monoxides by both liver microsomes and its purified cytochrome P-450 system[23,24] and postulated that the oxygenation of sulfides by cytochrome P-450 involves the formation of sulfenium radical as a key intermediate.[25] Since the iron-bound "oxenoid" intermediate is considered to be a higher valent iron-oxo species and hence it would be highly electron deficient, the *S*-oxygenation of sulfur compounds would be initiated by an electron transfer from a divalent sulfide to the iron-bound "oxenoid" intermediate.[26] Meanwhile, we have also shown in the oxygenation of sulfides with a Fenton system[27] that *S*-oxygenation reaction involves generation of a cation radical of the sulfide. These observations on the oxygenation of sulfides suggest that even in the *O*-demethylation of anisole derivatives, the two mechanistic pathways shown in Eq. 2 are conceivable; i) the path (a), direct hydrogen abstraction and subsequent hydroxylation of methyl group (mechanism a), ii) the path (b), one electron transfer process prior to hydroxylation similar to the concurrent *S*-oxygenation and *S*-dealkylation.[25]

This paper gives kinetic evidence to support the one electron transfer mechanism for the *S*-oxygenation of *p*-substituted thioanisoles and to rule out the one electron transfer mechanism for the *O*-demethylation of *p*-substituted anisoles.

Results

Kinetic Experiment on The S-*Oxygenation of* p-*Substituted Thioanisole Derivatives.* When a 40—600 μM of methanolic solution of thioanisole (**1c**) was aerobically incubated in the reconstituted system, containing both purified cytochrome P-450 and NADPH-cytochrome P-450 reductase, oxidation of NADPH was observed. The addition of thioanisole (**1c**) induced a sudden increase of the rate of the NADPH consumption. Similar results were obtained in the oxidation of all the other sulfides (**1a**—**e**). Since a small amount of NADPH consumption was found to be devoured by the substrates even with a complete reconstituted system minus cytochrome P-450, the rates of the oxygenation were calculated by subtracting the rates of these undesired side reactions from the overall rates of NADPH consumption.

The V_{max} and K_m parameters of the oxygenation of sulfides by the reconstituted cytochrome P-450 system calculated from the Lineweaver-Burk plots are listed in Table 1, which also lists the effects of *p*-substituents in the oxygenation of thioanisole derivatives. Except *p*-chlorothioanisole (**1d**), the rate of oxygenation of the sulfide was found to decrease by the electron-withdrawing substituent while V_{max} value of the oxygenation increased by the electron-donating substituent.

Table 1. Kinetics of oxidation of NADPH in the reconstituted system with purified cytochrome P-450

Substrate	K_m (μM)	V_{max}[a] (μM/min)	V_{max}[a] (nmol/min/nmol P-450)	Binding type

a) Oxidation potentials were measured in 0.1 M of n-Bu_4NClO_4/CH_3CN.

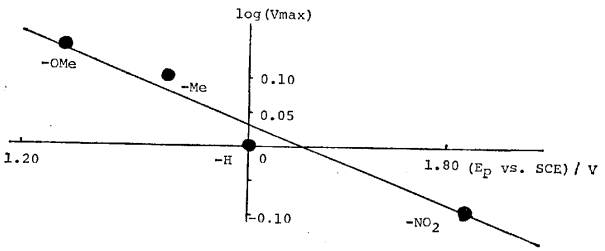

Fig. 1. Relationship between log (V_{max}) and E_p of *p*-substituted phenyl methyl sulfides.

In order to examine the possible relationship between the V_{max}'s of the oxygenation and one electron oxidation potentials of sulfides (**1a**—**e**), the cyclic voltammograms of the sulfides were obtained in acetonitrile (Table 2).

The V_{max} values in Table 1 were found to be correlated better with Hammett σ^+-values rather than σ-values ($\rho^+ = -0.16$), and the one electron oxidation potentials of the sulfides (except **1d**) are also correlated linearly with log(V_{max})'s of the enzymatic oxygenation of the sulfides (Figs. 1 and 2). E_p's (one electron oxidation potential) of the sulfides are con-

Microsomal oxidation of sulfides and ethers were carried out for 20 min. a) $100 \times K_m$ (see Table 1) of sulfides were incubated in the oxidation. b) 250 μmol of ethers were incubated (see Experimental). c) In the oxidation of sulfides the corresponding sulfoxides were analyzed by GLC, and in the case of ethers yields of formaldehyde were determined by using Nash reagent.

sidered to correspond to the first oxidation peak potentials instead of $E_{1/2}$, due to the irreversible nature of the cyclic voltammograms.[28]

Incidentally, all the sulfides were found to be typical compounds of type I[29] having a maximum at 385—390 nm and a minimum at about 420 nm from the substrate-induced difference spectrum.

A methanolic solution of thioanisole (**1c**, 260 μmol, $100 \times K_m$) was added into a phosphate buffer (0.2 M, pH 7.4) containing both NADPH generating system and rabbit liver microsomes (see Experimental) and the incubation was carried out at 37 °C for 20 min with stirring. The oxygenation was stopped by adding 20 ml of acetone and 5 ml of trichloroacetic acid (0.5 M)† into the solution. After centrifugation of the reaction mixture, the supernatant solution was extracted with chloroform and the chloroform solution was dried over anhydrous magnesium sulfate. The product analysis was performed by GLC, and the sulfoxide (**2c**) was obtained as the sole product in

† 1 M=1 mol dm^{-3}.

the microsomal oxygenation. Similar results were obtained with all the sulfides used (**1a—e**) (Table 3).

Kinetic Experiment on The O-Demethylation of p-*Substituted Anisole Derivatives.* Rates of the *O*-demethylation of *p*-substituted anisoles (**3a—e**) were measured according to the method described in the *S*-oxygenation. The K_m and V_{max} values of oxygenation of anisole derivatives (**3a—e**) in Table 1 show clearly that all the substrates have similar V_{max}'s values. Unlike the *S*-oxygenation or *S*-dealkylation, $\log(V_{max})$'s of enzymatic oxidations of the ethers cannot be correlated with either Hammett σ-values, σ^+-values or with one electron oxidation potentials (Fig. 3).

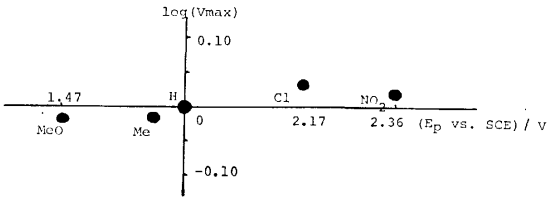

Fig. 3. Relationship between $\log(V_{max})$ and oxidation potential of *p*-substituted anisols.

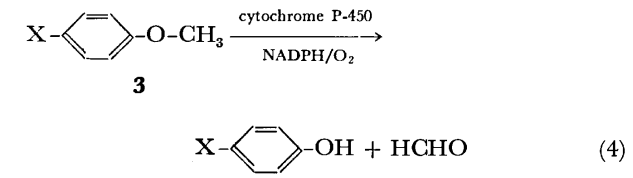
On the other hand, one electron oxidation potentials of ethers (**3a—e**) in acetonitrile were correlated linearly with Hammett σ^+-values (Table 2 and Fig. 2).

The oxygenation of ethers (**3a—e**) by the reconstituted system of purified cytochrome P-450 gave *p*-substituted phenols (**4a—e**) and formadehyde. Oxygenation of anisole derivatives (**3a—e**) by the micro-



3

X: a, MeO b, Me c, H d, Cl e, NO_2

somal system were also performed similarly. After aerobical incubation, microsomal protein was removed from the mixture and formaldehyde formed was assayed using the Nash reagent,[30] and the extract was acidified with 2 M HCl and extracted with chloroform to obtain the other products such as phenols. The residure was analyzed by GLC and TLC. Only *p*-substituted phenols were obtained as the sole oxygenation product. In Table 3, the amounts of formaldehyde generated in the enzymatic reactions are listed.

O-Demethylation of p-*Substituted Anisoles and Its Methyl-d_3 Analogues.* When *p*-substituted anisole (**3**, 250 μmol) was aerobically incubated with the microsomes for 20 min, *O*-demethylation takes place as described in Table 3. Similarly, its methyl-d_3 analogue (**3**-d_3) was also oxygenated by the microsomes to give for-

Table 4. Intermolecular isotope effect by deuterium substitution on the metabolism of anisole by rabbit liver microsomes

Substrate		HCHO (μmol)	k_H/k_D[a]
Cl-C$_6$H$_4$-O-CH$_3$	**3d**	21.3	
Cl-C$_6$H$_4$-O-CD$_3$	**3d**-d_3	19.5	1.1
CH$_3$O-C$_6$H$_4$-OCH$_3$	**3a**	34.0	
CH$_3$O-C$_6$H$_4$-OCD$_3$	**3a**-d_3	32.1	1.1
CD$_3$O-C$_6$H$_4$-OCD$_3$	**3a**-d_6	15.9	2.1

a) $k_H/k_D = [HCHO]_H/[HCHO]_D$.

maldehyde and *p*-substituted phenol (**4**). (Table 4) This kinetic isotope effect, between deuterated and undeuterated anisoles, was 1.1 by the comparison of the amounts of formaldehyde. In the oxygenation of *p*-di(methoxy-d_3)benzene (**3a**-d_6), the kinetic isotope effect of 2.1 was observed.

When a solution of *p*-methoxy-d_3-anisole (**3a**-d_3) was incubated with the microsomes for three different periods (20, 60, and 90 min), the ^{1}H-FT-NMR spectrum of the mixture of **4a** and **4a**-d_3 was measured at 20—40 pulses. Since the chemical shifts of aromatic ring protons of **4a** and **4a**-d_3 appear at 6.78 ppm (δ-value, 4H,s) while that of methoxyl protons of **4a** is found at 3.76 ppm (3H, s) in $CDCl_3$, the ratio of the two products **4a** and **4a**-d_3 at three periods is given by Eq. 5.

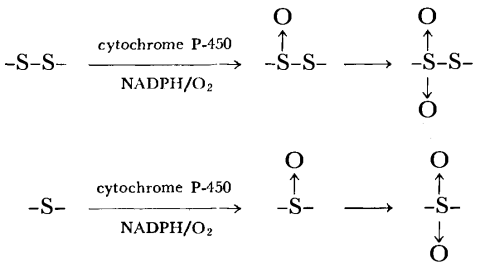
$$[\mathbf{4a}]/[\mathbf{4a}\text{-}d_3] = \frac{[\text{methoxyl proton}]/3}{[(\text{aromatic ring proton}) - 4/3(\text{methoxyl proton})]/4} \quad (5)$$

From the intensities of the two singlet peaks of ethers, the ratios (*e.g.* **4a**:**4a**-d_3=23:77) were obtained (Table 5). From the ratio between **4a** and **4a**-d_3, the genuine kinetic isotope effect (k_H/k_D=3.4) for the *O*-demethylation was estimated.

A mixture of *p*-dimethoxybenzene (**3a**) and *p*-di(methoxy-d_3)benzene (**3a**-d_6) (1:1) was incubated with the microsomes for 20 min. In the intermolecularly competitive reaction, a kinetic isotope effect of 5.1 was obtained from ^{1}H-FT-NMR. (Table 6).

Discussion

We have recently reported a few examples of the enzymatic oxygenation of divalent sulfur compounds to the corresponding monooxides by both rabbit liver microsomes and a reconstituted system with the purified cytochrome P-450.[23,24] We have also shown



(6)

that sulfides are good substrates for the oxygenation with cytochrome P-450 enzyme and are readily oxidized to the corresponding sulfoxides and even further to sulfones,[25] or undergo *S*-dealkylation, indicating clearly that there are two reaction pathways in the enzymatic oxygenation of sulfides;[26] one is the *S*-dealkylation of sulfides to give thiols (or further oxidized disulfides) and aldehydes while the other is the ordinary *S*-oxygenation, as illustrated in Eq. 7. These two types of reactions appear to take place simultaneously while the acidity of α-hydrogen of alkyl

sulfides and the stability of α-sulfenyl radicals seem to play important roles in determining the mode of the enzymatic oxygenation of sulfides, similar to the

$$R\text{-}S\text{-}CH_2R' \xrightarrow[NADPH/O_2]{\text{cytchrome P-450}} \begin{cases} \rightarrow R\text{-}\overset{\overset{O}{\uparrow}}{S}\text{-}CH_2R' \quad (S\text{-oxygenation}) \\ \rightarrow 1/2\ R\text{-}S\text{-}S\text{-}R + OHCR' \quad (S\text{-dealkylation}) \end{cases} \tag{7}$$

R=aryl, R′=alkyl.

N-oxygenation and *N*-dealkylation of tertiary amines with enzymatic and biomimetic model systems.[31,32] In the reaction of alkyl sulfides with hydroxyl radical generated by the Fenton's reagent,[27] a similar mode of oxidation reaction was observed. The initial step of this reaction is known to be the generation of sulfenium radical intermediate[33] (Eq. 8). Thus the similar mode of reaction and of products distribution suggests strongly that the enzymatic oxygenation of sulfide with cytochrome P-450 involves the formation of the cation radical intermediate.[25]

In order to confirm that the enzymatic oxygenation also proceeds through one electron transfer process, a kinetic study on the *S*-oxygenation promoted by the reconstituted system with purified cytochrome P-450 was performed by following the disappearence of the UV absorption of NADPH, since we had already shown that the rates of oxidation of NADPH in the

$$R\text{-}S\text{-}CH_2R' + \cdot OH \rightarrow \underset{\text{sulfenium radical}}{[R\text{-}\overset{+\cdot}{S}\text{-}CH_2R']} \begin{cases} \xrightarrow{\cdot OH} R\text{-}\overset{\overset{O}{\uparrow}}{S}\text{-}CH_2R' \\ \xrightarrow{-H^+} R\text{-}S\text{-}\dot{C}HR' \end{cases} \tag{8}$$

$$\xrightarrow{\cdot OH} R\text{-}S\text{-}\underset{|}{\overset{OH}{C}}HR' \longrightarrow R\text{-}SH\ (+OHCR')$$

$$\longrightarrow 1/2\ R\text{-}S\text{-}S\text{-}R$$

R=aryl, R′=Ph, CN, COPh *etc.*

reconstituted system with cytochrome P-450 are proportional to that of the generation of the sulfoxide.[23] Fine correlations between $\log(V_{max})$'s of the oxygenation of sulfides (**1a**—**e**) except (**1d**)[34] and both one electron oxidation potentials and Hammett σ^+-values are illustrated in Table 1 and Fig. 1. While the rates of the oxidation of these sulfides with hydrogen peroxide are correlated nicely with Hammett σ-values ($\rho=-1.17$),[35] V_{max}'s in Table 1 are correlated better with σ^+-values than σ-values ($\rho^+=-0.16$). These data cannot be explained on the basis of the simple nucleophilic attack of divalent sulfur atom of the sulfide on the electrophilic center of the iron-bound "oxenoid" intermediate, unlike the oxidation of sulfides with hydrogen peroxide. The good correlation between one electron oxidation potentials and the oxygenation rates of sulfides mediated by cytochrome P-450 system suggests clearly that the *S*-oxygenation is initiated by one electron transfer from the divalent sulfide to the iron-bound "oxenoid" intermediate of cytochrome P-450, as shown below.

$$Ar\text{-}S\text{-}CH_3 \xrightarrow{\text{cytochrome P-450 } (FeO)^{3+}} Ar\text{-}\overset{+\cdot}{S}\text{-}CH_3 + (FeO)^{2+}$$

$$\longrightarrow Ar\text{-}\overset{\overset{O}{\uparrow}}{S}\text{-}CH_3 + \text{cyt. P-450 } Fe^{3+} \tag{9}$$

The relatively small substituent effect on the V_{max} can be rationalized in term of the extremely facile nature of the one electron transfer process because of the highly electron-demanding character of the iron-bound "oxenoid" intermediate.[36]

In the enzymatic oxidative *N*-demethylation of tertiary amines, similar cation radical intermediates have been considered to be involved and the oxidation of aminopyrine by horseradish peroxidase has also been suggested to involve the cation radical intermediate on the basis of the ESR spectroscopic studies.[37] Our kinetic data on the *S*-oxygenation are in keeping with the mechanism of the *N*-demethylation promoted by horseradish peroxidase in the generation of cation radical intermediate of the substrate.

Lewis and Ho carried out photochemical oxidation of *N*-methyl-*N*-methyl-d_3-*t*-butylamine and estimated the kinetic isotope effect (k_H/k_D) of 2.2 on the basis of the amount of CD_2O and CH_2O formed in the reaction.[38] The isotope effect, 2.2 they found in the photochemical oxidation of the tertiary amine, is believed to result from the deprotonation process going from the aminium radical to the α-amino alkyl radical. Meanwhile, in the enzymatic oxidation of tertiary amines (*N*-demethylation), kinetic isotope effects of similar magnitude, *i.e.*, 1.6—2.0 were observed by Miwa *et al.*[39] The isotope effects of a similar size in both chemical and enzymatic oxidations of tertiary amines suggest that one electron transfer process described above is also taking place in the enzymatic system. The enzymatic *N*-demethylation promoted by the rat liver microsomal cytochrome P-450 also involves the similar formation of an aminium radical intermediate prior to give an α-amino alkyl radical, which reacts subsequently with iron-bound "oxenoid" intermediate, eventually affording the *N*-monodemethylated amine and formaldehyde.

Alkyl ethers, such as anisole derivatives having a nucleophilic hetero atom, also have an isoelectronic structure of alkyl sulfides and tertiary amines. However, since the ether-oxygen is highly electronegative, one-electron transfer from the ether oxygen cannot be so facile unlike tertiary amines or sulfides. Therefore a process involving direct α-hydrogen abstraction and subsequent hydroxylation as shown in Eq. 2 (a) is more conceivable.

$$R\text{-}\ddot{S}\text{-}R', \qquad R\text{-}\overset{R''}{\underset{|}{N}}\text{-}R', \qquad R\text{-}\ddot{O}\text{-}R'$$

In order to clarify the oxidation pathway of *O*-demethylation with the enzymatic system of cytochrome P-450, a kinetic study of the *O*-demethylation of *p*-substituted anisoles (**3a**—**e**) was performed.

Unlike the enzymatic oxygenation of sulfides, there

was no correlation between the rates of oxidation of NADPH and one electron oxidation potentials of anisoles. The effect of *p*-substituent in anisoles (**3**) on one electron oxidation potential is higher than that of thioanisoles (**1**); namely, the difference between the oxidation potentials of *p*-nitroanisole (**3e**) and *p*-methoxyanisole (**3a**) is 0.89 (V *vs.* SCE) while it is 0.59 (V *vs.* SCE) between those of thioanisole derivatives (**1a**) and (**1e**) (Table 2 and Fig. 2).

These results strongly suggest that the cation radical mechanism in Eq. 2 (b) is not acceptable.

In the electrochemical oxidation of several benzyl ethers, carried out by Mayeda *et al*,[40] however, they postulated a mechanistic pathway containing a cation radical intermediate (Eq. 10).

$$\mathrm{R\text{-}\ddot{O}\text{-}CH_2Ph} \xrightarrow{-e^-} \mathrm{R\text{-}\overset{+\cdot}{O}\text{-}CH_2Ph} \xrightarrow[ii)\ -e^-]{i)\ -H^+} \mathrm{R\text{-}\ddot{O}\text{-}\overset{+}{C}HPh} \xrightarrow{H_2O} \mathrm{R\text{-}O\text{-}\underset{OH}{\underset{|}{C}}HPh} \longrightarrow \mathrm{R\text{-}OH + OHCPh} \quad (10)$$

Recently, the mechanism of the anodic cleavage of benzyl ethers was examined by Boyd *et al.*[41] using benzyl benzyl-α,α-d_2 ether. When it was oxidized by electrochemically, an intramolecular primary kinetic isotope effect of 1.9 was observed. This kinetic isotope effect was interpreted to be due to the deprotonation process *via* the cation radical intermediate of the ether (Eq. 10).

In the enzymatic oxygenation of several substrates leading to the hydroxylation and/or *O*-demethylation, small kinetic isotope effects were observed.[4,16-20] For example, in the *O*-demethylation of *p*-chloroanisoles (**3d**, **3d**-d_3) the value of 1.1 for k_H/k_D was obtained (Table 4). Generally the observed intermolecular isotope effect was small.

If one electron transfer from the oxygen atom of an ether to the iron-bound "oxenoid" intermediate of cytochrome P-450 takes place at the rate-determining step, the kinetic isotope effect would be around unity, when a mixture of *p*-dimethoxybenzene (**3a**) and *p*-di(methoxy-d_3)benzene (**3a**-d_6) is aerobically incubated with a microsomal cytochrome P-450 system, since ethers **3a** and **3a**-d_6 would have roughly the same one electron oxidation potential. The subsequent deprotonation from the cation radical of ether (Eq. 2 (b)) would be fast and irreversible. Meanwhile a kinetic isotope effect of ≈ 2 is expected to be obtained in the internal competitive enzymatic oxygenation of *p*-methoxy-d_3-anisole (**3a**-d_3) as in the electrochemical oxidation of benzyl benzyl-α,α-d_2 ether.[41]

However, a large isotope effect of 5.1 was observed in the competitive *O*-demethylations of *p*-dimethoxybenzene (**3a**) and *p*-di(methoxy-d_3)benzene (**3a**-d_6), and the kinetic isotope effect of 3.4 was observed in the oxidative *O*-demethylation of *p*-methoxy-d_3-anisole (**3a**-d_3) with rabbit liver microsomes (Tables 5 and 6). Recently, even a large kinetic isotope effect of 10 was reported in the oxidative *O*-demethylation of ether (**3a**-d_3) with the rat liver microsomes by Foster *et al.*[5]

All these large values of isotope effects and the kinetic result found on the enzymatic *O*-demethylation of anisoles support the hydroxylation to involve initial α-hydrogen abstraction and subsequent hydroxylation as illustrated in Eq. 2 (a), although we cannot rule out completely an alternative mechanism involving a direct insertion of active oxygen (oxene) into methoxy C–H bond.[42]

Experimental

Reagents. The following compounds were obtained from the commercial sources as indicated below; NADPH, $NADP^+$, D-glucose 6-phosphate (G6P), and D-glucose 6-phosphate dehydrogenase (G6P-DH), Oriental Yeast. *p*-Substituted thiophenols, methyl iodide, dimethyl disulfide, and triethylbenzylammonium chloride, Wako Chemicals. *p*-Substituted phenols and *p*-substituted anisoles, Tokyo Chemicals Co. Ltd. Methyl-d_3 iodide (min. 99.5%), Merck.

Organic Synthesis. *p*-Methyl- and *p*-chlorothioanisole (**1b**, **1d**) were obtained by treating *p*-methyl- and *p*-chlorothiophenol with methyl iodide in the presence of sodium hydroxide in good yield,[43,44] and isolated upon SiO_2-column chromatography (Merck Kieselgel 60, benzene as an eluent). *p*-Methoxythioanisole (**1a**) was prepared by the reaction of anisole and *S*-methyl methanethiosulfinate as described in a recent work by Oae *et al.*[45] *p*-Nitrothioanisole (**1e**) was synthesized by treatment of *p*-nitroaniline and dimethyl disulfide with *t*-butyl thionitrate.[46] Both **1a** and **1e** were purified through SiO_2-column chromatography. ^1H NMR (δ-values in $CDCl_3$, ppm); *p*-$MeOC_6H_4$–SMe,[45] 2.4 (3H, s), 3.75 (3H, s), 6.86 (2H, d J=9.0), 7.29 (2H, d J=9.0). *p*-MeC_6H_4–SMe,[47] 2.28 (3H, s), 2.41 (3H, s), 7.12 (4H, brs). *p*-ClC_6H_4–SMe,[48] 2.41 (3H, s), 7.03 (2H, d J=8.7), 7.12 (2H, d J=8.7). *p*-$NO_2C_6H_4$–SMe,[46] 2.55 (3H, s), 7.25 (2H, d J=9.4), 8.15 (2H, d J=9.4).

All the sulfoxides (**2**) used as authentic samples were synthesized by oxidation of the corresponding sulfides (**1**) with hydrogen peroxide[49] (in acetic acid) or *m*-chloroperbenzoic acid[50] (in dichloromethane), and were isolated through Al_2O_3-column chromatography (Wako, Alumina activated 200 mesh, AcOEt:$CHCl_3$=4:1 as eluent). ^1H NMR (δ-values in $CDCl_3$); *p*-$MeOC_6H_4$–$\underset{\downarrow}{\underset{O}{S}}$Me,[51] 2.70 (3H, s), 3.85 (3H, s), 7.01 (2H, d J=9.0), 7.60 (2H, d J=9.0). *p*-MeC_6H_4–$\underset{\downarrow}{\underset{O}{S}}$Me,[51] 2.4 (3H, s), 7.27 (2H, d J=8.6), 7.54 (2H, d J=8.6). C_6H_5–$\underset{\downarrow}{\underset{O}{S}}$Me,[52] 2.64 (3H, s), 7.4—7.6 (5H, m). *p*-ClC_6H_4–$\underset{\downarrow}{\underset{O}{S}}$Me,[53] 2.64 (3H, s), 7.39 (2H, d J=8.9), 7.44 (2H, d J=8.9). *p*-$NO_2C_6H_4$–$\underset{\downarrow}{\underset{O}{S}}$Me,[54] 2.8 (3H, s), 7.84 (2H, d J=9.0), 8.40 (2H, d J=9.0).

All the deuterated anisoles (**3a**-d_3, **3a**-d_6, and **3d**-d_3) were prepared by the reaction of the corresponding phenols (**4**) with methyl-d_3 iodide (min. 99.5%) and sodium hydroxide using a phase transfer catalyst (triethylbenzylammonium chloride) described by McKillop.[55] ^1H NMR (δ-values in $CDCl_3$) and *m/e*; *p*-$CD_3OC_6H_4OCH_3$,[5] 3.80 (3H, s), 6.80 (4H, s). *m/e*, 141 (M^+, 100%), 138 (0%). *p*-$CD_3OC_6H_4$-OCD_3,[5] 6.80 (4H, s). *m/e*, 144 (M^+, 100%), 141, 138 (0%). *p*-$CD_3OC_6H_4Cl$, 6.76 (2H, d J=9.0), 7.18 (2H, d J=9.0). *m/e*, 147 (M^+, ^{37}Cl 35%), 145 (M^+, ^{35}Cl 100%), 144, 142 (0%).

All the substrates were distilled or recrystallized prior to use. ^{1}H NMR spectra described above were recorded on a Perkin Elmer Hitachi R-20 (60 MHz) and mass spectra were recorded on a Hitachi RMU-6MG Mass Spectrometer.

Preparation of Microsomes, Purified Cytochrome P-450 and NADPH-Cytochrome P-450 Reductase. The liver microsomes (cytochrome p-450, 2.45 nmol/mg protein) were obtained from male rabbits (2—3 kg) pretreated with sodium phenobarbital (50 mg/kg of body weight, each day for 5 d) according to the procedure reported earlier,[23] while the purified cytochrome P-450 was obtained by the method of Imai and Sato.[56] NADPH-cytochrome P-450 reductase was purified by the method of Iyanagi *et al.*[57]

Enzyme Assay. The standard reaction mixture for assaying the *S*-oxygenation and the *O*-demethylation activities were made to contain 76—250 μmol of the substrates, the hepatic microsomes (130 mg protein), the NADPH generating system [30 μmol of $NADP^+$, 300 μmol of G6P (2 Na salt) and 36 units of G6P-DH], and phosphate buffer (pH 7.4, 0.2 M) in a final volume of 20 ml. The reaction mixture without G6P-DH was incubated for 5 min at 36 °C with stirring to dissolve the substrates, prior to the addition of G6P-DH into the mixture. After incubating the reaction mixture for 20 min at 36 °C under air, the reaction was stopped by adding 10 ml of acetone and 0.5 M of trichloroacetic acid (to pH 3) (or 5 ml of 15% zinc sulfate and 5 ml of saturated barium hydroxide) into the mixture which was cooled for 10 min at 0 °C to precipitate the protein. After centrifugation (3000 min^{-1}) of the mixture for 15 min, the supernatant was separated, neutralized by addition of aqueous KOH solution, and then was extracted 4 times with chloroform. The chloroform layer was dried over anhydrous magnesium sulfate and concentrated under reduced pressure. The residue was diluted to 1 ml with acetone and analyzed by gas chromatography (GLC: Hitachi 163 Gas Chromatography, 1 m glass column, 10% SE-30) and thin layer chromatography (TLC: Merck, Kieselgel 60-GF_{254}, and Aluminiumoxid GF-254, 60/E). The oxidation products were isolated by preparative TLC (chloroform was used as an eluent), and identified by comparison with authentic samples. Formaldehyde was measured by the Nash reagent.[30]

Kinetic Conditions of Oxidation of Both Sulfides and Ethers with Reconstituted System Containing Purified Cytochrome P-450. The reconstituted system (1.1 nmol of cytochrome P-*450* and 1.7 nmol of NADPH-cytochrome P-450 reductase) was allowed to stand at room temperature for 10 min in UV micro-cell, and then was diluted by 0.1 M phosphate buffer (pH 7.7) containing 100 nmol of NADPH and 6.6×10^{-3}% of detergent (Emalgen 913; KAO-ATLAS Chemicals) to 1 ml. After measuring the natural consumption of NADPH by following the absorbance at 340 nm due to NADPH, a methanolic solution of the substrate (2—30 μl, 20 mM) was added into the UV micro-cell and the mixture was aerobically incubated to initiate the reaction. The rate of oxygenation of the sulfide or ether was monitored at several time intervals by following the consumption of NADPH.

Measurement of the Difference Spectra Caused by Addition of Substrates to the Purified Cytochrome P-450. Cytochrome P-450 (1.1—10 μM in 0.2 M of phosphate buffer containing 20% glycerol) was placed into a 10 mm cuvette for spectrometric recording. The substrate was dissolved in methanol (0.5—30 μl), into which was added the sample solution. The same amount of methanol was placed in the reference cuvette for spectroscopic comparison.

Analytic Procedure. The amount of protein in the microsomes was determined by Lowry's method,[58] using bovin serum albumin. The concentration of cytochrome P-450 was determined by comparison with the carbon monoxide-difference spectrum of the dithionite-treated liver microsomes. The absorbance between 450 and 490 nm ($\Delta A_{450-490}$) was used for calculation of cytochrome P-450 content (ε, 91 $mM^{-1}\,cm^{-1}$).[59,60] The concentration of the purified cytochrome P-450 was determined by measuring the absorption of the oxidized form ($\Delta A_{418-500}$), which has a molar extinction coefficient of 107 $mM^{-1}\,cm^{-1}$.[56] (UV: JASCO UVIDEC-1 and Hitachi Model 200-20 Spectrophotometer).

The ratio of *p*-methoxyphenol (**4a**) to *p*-methoxy-d_3-phenol (**4a**-d_3) was calculated from the intensities of methoxyl and aromatic ring protons which were recorded on ^{1}H-FT-NMR spectroscopy. (JEOL FX-100). ^{1}H NMR (δ-values in $CDCl_3$); *p*-$CH_3OC_6H_4OH$, 3.76 (3H, s), 6.78 (4H, s). *p*-$CD_3OC_6H_4OH$, 6.78 (4H, s).

Measurement of Cyclic Voltammograms. Cyclic voltammograms of substrates were obtained in 0.1 M *n*-Bu_4NClO_4/CH_3CN. (scan rate; 300, 150, and 50 mV/s) (HOKUTO DENKO Ltd., POTENTIOSTAT/GALVANOSTAT HA-301)

Reduction by a Model of NAD(P)H. 36. First and Direct Evidence for the Multi-step Mechanism

Shinro YASUI, Kaoru NAKAMURA, Atsuyoshi OHNO,* and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

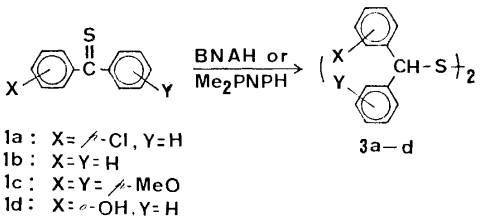
(Received April 16, 1981)

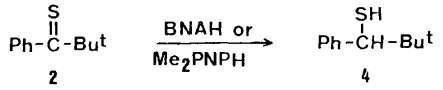
Reductions of thiobenzophenone derivatives with a model compound of NAD(P)H, 1-benzyl-1,4-dihydronicotinamide (BNAH) or *N*-(α-methylbenzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2PNPH), in a solvent containing an *O*-deuterated alcohol afforded products partially deuterated at their methine positions. The deuterium content depends both on the character of substituents in the substrate and on the polarity of solvent. In contrast, no incorporation of deuterium into the product was observed in the reduction of thiopivalophenone with BNAH or Me_2PNPH under the same conditions. These results can be accounted for in terms of an electron transfer followed by a proton transfer from the model to substrate. This is the first and direct evidence for the ion radical-pair intermediacy for reductions by model compounds of NAD(P)H.

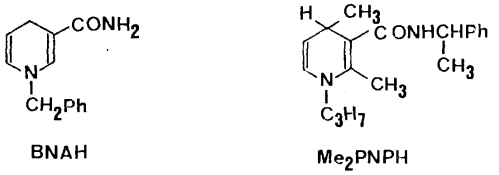
Although many investigators have studied the mechanism of reductions with model compounds of NAD(P)H, several points are still ambiguous. Of these, the mechanism of transfer of a "net hydride" from a model compound to substrate has frequently been subjected to discussion. In 1957, Abeles *et al.*[1] examined reductions of thiobenzophenone derivatives with 1-benzyl-1,4-dihydronicotinamide (BNAH) and concluded that a hydride would transfer directly from a model to substrate. On the other hand, a multi-step mechanism including at least one intermediate was proposed by Steffens and Chipman[2] in order to explain a discrepancy between kinetic isotope effect and isotopic ratio in products found in a reduction of α,α,α-trifluoroacetophenone with 1-substituted 1,4-dihydronicotinamide-4-*d*. They suggested that the intermediate in this reaction would be a non-covalent charge-transfer complex generated through an electron transfer from the dihydropyridine derivative to the substrate. Thereafter, such discrepancies have been reported for reductions of substituted α,α,α-trifluoroacetophenones,[3] 1,10-phenanthroline-2-carbaldehyde,[4] *N*-methylacridinium ion,[5,6] and 2-acylisoquinolines.[7] We detected radical species on ESR spectra for reductions of benzil[8] and thiobenzophenone[9] with BNAH. These facts strongly support existence of an ion radical-pair intermediate in reduction with model compounds of NAD(P)H.

The spectroscopic detection of an ion radical, however, cannot necessarily be an unambiguous proof for its intermediacy. One can argue that at least part of hydrogen atoms incorporated in products should come from solvents or some sources other than NAD(P)H-models, if an ion radical-pair is an intermediate in the reduction. The fact that no such observations have yet been reported may be taken to be an indication that the spectroscopically detected ion radicals might be abortive species. On the other hand, one can also propose that hydrogen transfer between reactive ion radicals might take place so fast within a cage of solvent that no incorporation of hydrogen might be brought about from the solvent into product. The latter argument necessarily predicts that out-of-cage reactions may be detected chemically when one employs such substrates as are capable of affording relatively unreactive ion radical-pairs as intermediates. Thus, we tried for such reduction systems and found that a hydrogen atom from solvent is incorporated into products in some reductions of certain thiocarbonyl compounds.

In this paper we report that reductions of *p*-chlorothiobenzophenone (**1a**), thiobenzophenone (**1b**), *p,p'*-dimethoxythiobenzophenone (**1c**), or *o*-hydroxythiobenzophenone (**1d**) with BNAH or N-(α-methylbenzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2PNPH) afford products whose methine protons partially originate from the solvent and that the hydrogen atom at the 4-position of the model compound transfers directly to thiopivalophenone (**2**). Contrary to the conclusion by Abeles *et al.*,[1] this result clearly indicates an existence of intermediate in the reductions.







Results

One of substrates **1** was allowed to react with BNAH in a DMSO–methanol mixture at room temperature in the dark under a nitrogen atmosphere. For each run, after usual work-up, the product was isolated and assigned by NMR and mass spectrometries to the corresponding dibenzhydryl disulfide derivatives (**3**). No other products except the pyridinium salt were detected on TLC, indicating quantitative forma-

Table 1. Reaction with BNAH[a]

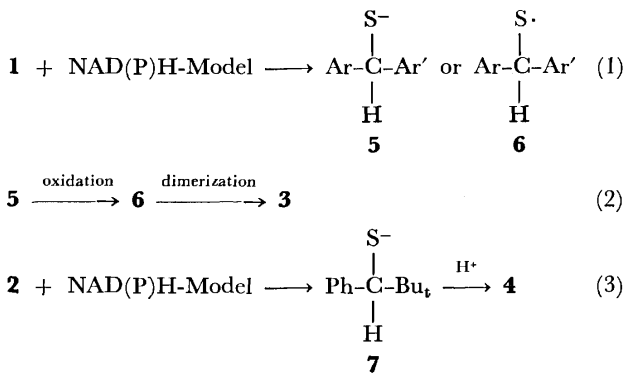
tion of **3**. In contrast, reaction of **2** with BNAH or Me_2PNPH afforded 1-phenyl-2,2-dimethyl-1-propanethiol (**4**) quantitatively.

When the reduction was carried out in a DMSO–methanol-d_4 mixture, the isolated product contained a deuterium atom in its methine position except in the case with **1d**. It is apparent that this deuterium atom originates from the solvent. Analyses by NMR and mass spectrometries gave deuterium contents 84%, 35±3%, and 15%, for **3a**, **3b**, and **3c**, respectively. Solvent effect also was examined by carrying out the reduction in several solvent systems containing methanol-d_4 or other deuterated compounds. Reductions of **1d** in DMSO–methanol-d_4 or ethanol-*O*-*d* and of **2** in DMSO–methanol-d_4 gave no deuterated products. On the other hand, reductions of these substrates with BNAH-4,4-d_2 afforded products having wholly deuterated methine groups. Results obtained are summarized in Table 1 together with those for reductions under other conditions.

A more dramatic hydrogen-incorporation from solvent into product was seen in reductions with Me_2PNPH in DMSO–methanol-d_4 or DMSO–ethanol-*O*-*d*. Even **1d** afforded a considerably deuterated product. Results obtained are listed in Table 2.

Discussion

In the reaction course leading to product **3** it is sure that **1** will be reduced by the model compound in the first stage (Eq. 1) to afford, as the primary reduction product, a thiolate anion (**5**) or thiyl radical (**6**), which will then dimerize to yield **3** during work-up or *in situ* (Eq. 2).[1,9] On the other hand, **2** is known to be reduced with the model compound to a thiolate anion (**7**),[11] which is protonated upon the



sulfur atom during work-up (Eq. 3). Here, we should recall the fact that the hydrogen on the methine position of **3** does not exchange with any hydrogens from solvents even under basic conditions.[12] Moreover, the dimerization of **5** or **6** to **3** is not likely to be accompanied by hydrogen exchange. Therefore, there is no doubt that in any cases the incorporation of hydrogen from solvent into product does occur during the first reduction step, Eq. 1, which implies involvement of at least one intermediate in this reduction step.

That the hydrogen picked up from the solvent has entered the product as a proton is obvious from the fact that no deuterium is incorporated into the product in the reduction in DMSO–acetonitrile-d_3, whereas deuterium is incorporated into the product when the reduction is carried out in ethanol-*O*-*d*. Thus, the intermediate which undergoes the out-of-cage reaction should be anionic in character. The anionic character of the intermediate is further confirmed by the following evidence. Table 1 indicates that the deuterium incorporation becomes deeper as the substituent on substrate becomes more electron-withdrawing and the solvent becomes more polar. The reduction with Me_2PNPH, as listed in Table 2, results in a deeper deuterium incorporation than that with BNAH. Me_2PNPH has two methyl groups on its dihydropyridine ring and a methylbenzyl moiety on its carbamoyl group, so that the electron-releasing power of Me_2PNPH is stronger than that of BNAH.[13] On the other hand, the presence of the 4-methyl group and less abundant reacting hydrogens makes Me_2PNPH less reactive toward proton releasing than BNAH. Consequently, the intermediate in the reduction with Me_2PNPH has more chance to escape from the solvent cage than the one in the reduction with BNAH; note that even **3d** contains deuterium from the solvent in a considerable amount.

The above discussion has revealed that the intermediate should be an anion radical, in agreement with previous evidence from kinetic,[3,11,14,15] ESR,[8,9,16] and several other studies.[5,17–19]

An anomaly with reaction of **1d** has been recognized[1] that the reduction of **1d** with BNAH takes place faster than expected from the simple electronic substituent effect. This phenomenon was interpreted in terms of general acid catalysis by *o*-hydroxyl proton on the basis of the "hydride transfer" mechanism. However, with the idea of "multi-step" mechanism,

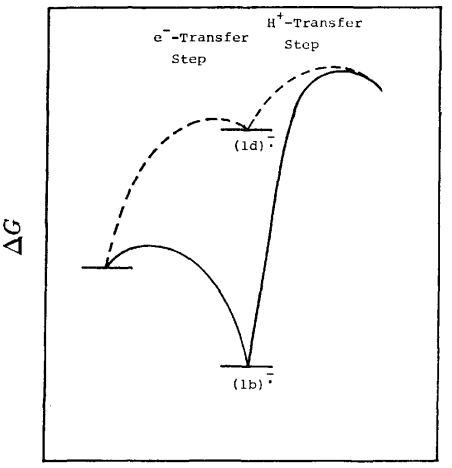


Fig. 1. Schematic illustration of energy diagrams for the reduction of thiobenzophenone (——) and *o*-hydroxythiobenzophenone (----).

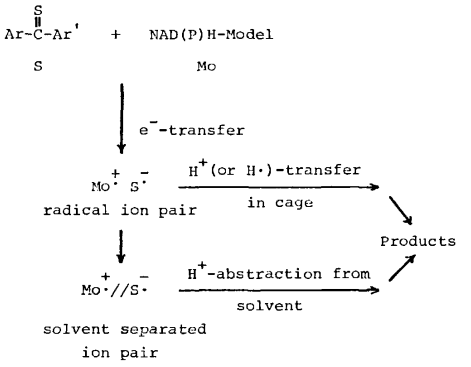

Scheme 1.

this phenomenon may be accounted for in terms of the stability of the intermediate anion radical. Reduction of **1b** and some other substrates is retarded by the presence of bivalent metal ion.[11,19] The retardation is due to an extraordinary stability of the cation-radical intermediate; a stable cation radical necessarily requires high transition energy for proton-accepting reaction.[3,6,19] In **1d**, the hydroxyl proton chelates on the thiocarbonyl sulfur by hydrogen bonding, which can be recognized by its abnormal low-field shift of proton (δ=12.7 in $CDCl_3$) in NMR spectrum and by its low-frequency shifts of ν_{OH} (3430 cm^{-1}) and $\nu_{C=S}$ (1228 cm^{-1})(in 2.5% CCl_4) in IR spectrum. Thus, the thiocarbonyl group in **1d** is different in character from the one in **1b**. The electron-accepting power of the former thiocarbonyl group is, therefore, weaker than that of the latter, and the initial electron-transfer process requires more energy for **1d** than for **1b**. In other words, the energy barrier for the proton-transfer process is less for **1d** than for **1b**, resulting in more opportunity for **1d** than for **1b** to undergo the in-cage reaction. Figure 1 visualizes energy diagrams for the reduction schematically. As mentioned above, Me_2PNPH is more electron-releasing but less proton-releasing than BNAH. Therefore, the energy diagram for the reduction with Me_2PNPH may be represented by a full line (**1b**-like relationship)

in Fig. 1. Since anion radical from **2** is the least stable of all, it has no chance to escape from the solvent cage to pick up a proton from the solvent even in the reduction with Me_2PNPH.

In conclusion, the reduction of a substrate by models of NAD(P)H proceeds *via* an intermediate of ion radical-pair. The anion radical can pick up a proton from the solvent when it has life-time long enough to escape from the solvent cage as shown in Scheme 1. Thus, "direct transfer of a hydrogen from a model to a substrate" is valid only for those substrates which will afford unstable anion radicals.

In enzymic reactions, a substrate is kept in a pocket of enzyme, and it has no chance to escape from the pocket into the bulk of solvent. It should also be kept in mind that all substrates susceptible to reduction by NAD(P)H-dependent dehydrogenases are such as afford unstable intermediates. Therefore, it is reasonable that "direct transfer of a hydrogen" is observed in all enzymic reactions.

Experimental

Materials. *p*-Chlorothiobenzophenone (**1a**), thiobenzophenone (**1b**), *p,p'*-dimethoxythiobenzophenone (**1c**), and *o*-hydroxythiobenzophenone (**1d**) were prepared from their corresponding ketones according to literature procedures,[1] and were purified by column chromatography using Florisil and carbon tetrachloride eluent (for **1a** and **1d**) or with recrystallization from ethanol (for **1b** and **1c**). Preparations of 1-benzyl-1,4-dihydronicotinamide (BNAH),[20] BNAH-4,4-d_2,[11,21] *N*-(α-methylbenzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2PNPH),[22] and thiopivalophenone (**2**)[23,24] were described previously. Spectral data of each material were satisfactory. The deuterium content of BNAH-4,4-d_2 was 99.0±1.0%. Each non-deuterated solvent was distilled and dried according to the usual method before use. Deuterated solvents were commercially available (Commissariat a l'Energie Atomique).

Product Analysis. In a vessel equipped with a Silicone-rubber stopper, a mixture of **1** or **2** and a model compound in an appropriate solvent was stirred under a nitrogen atmosphere in the dark. When the reaction was complete (on TLC), water was added to the mixture and the product was extracted three times with dichloromethane. The organic layer was washed twice with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. The resulting residue was purified by HPLC using silica gel and benzene eluent (for **1a** and **1d**), with recrystallization from ethanol (for **1b** and **1c**), or by column chromatography using silica gel and hexane eluent (for **2**). Identification of isolated product was based on NMR (JASCO JNM-FX 100 FT NMR Spectrometer), MS (Hewlett-Packard 18947A GC/MS), and IR (Hitachi EPI-S-2 Spectrometer) spectra. Deuterium contents for products from reactions in deuterated solvent were estimated through comparison with those of authentic samples obtained from corresponding reactions in non-deuterated solvent.

Studies on Heteropentalenes. IV.[1] Heteroannelations to Pyrrolo-[2,1-*b*]benzothiazole and Pyrrolo[2,1-*b*]thiazoles

Noritaka ABE,* Tarozaemon NISHIWAKI, Toshimasa OMORI, and Emiko HARADA

Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753

(Received May 6, 1981)

2,3-Dibenzoylpyrrolo[2,1-*b*]benzothiazole (**2**) and 6,7-dibenzoylpyrrolo[2,1-*b*]thiazoles (**5a—b**) have been synthesized by utilizing the cycloaddition reactions of imidazo[2,1-*b*]benzothiazole and imidazo[2,1-*b*]thiazoles, respectively, with dibenzoylacetylene followed by the elimination of a nitrile from each of the cycloadducts. Heteroannelations to **2** and **5** have been achieved by their reactions with hydrazine, aminoacetonitrile, ethyl glycinate, and phosphorus pentasulfide. The annelations by the second and third reagents proceed fairly regioselectively. Facile dimerizations of thieno[3′,4′:3,4]pyrrolo[2,1-*b*]benzothiazole and thieno[3′,4′:3,4]-pyrrolo[2,1-*b*]thiazoles to be produced by the reactions with the last reagent are also described.

We have recently disclosed that the cycloadditions of imidazo[2,1-*b*]benzothiazole (**1a**) and imidazo[2,1-*b*]thiazoles (**4a—c**), respectively, with dimethyl acetylenedicarboxylate (DMAD),[2] but not with methyl propiolate,[1] are accompanied by the elimination of a nitrile from the adduct to form pyrrolo[2,1-*b*]benzothiazole and pyrrolo[2,1-*b*]thiazole ring systems. It is now reported that the reactions of dibenzoylacetylene (DBA) with the above heteropentalenes are similar to those of DMAD and that the products thereof, like other 1,2-dibenzoly-substituted aromatics,[3–7] readily undergo heteroannelations.

2,3-Dibenzoylpyrrolo[2,1-*b*]benzothiazole (**2**) and 6,7-dibenzoylpyrrolo[2,1-b]thiazoles (**5a—b**) were obtained in moderate to good yields from the reactions of **1a—b** and **4a—c**, respectively, with DBA in xylene. Their structures were proved by elemental analyses, and ^{1}H NMR and IR spectral data, the latter of which, in common with the spectra of diaryl ketones, possessed a ν(C=O) band at 1630—1650 cm^{-1}. Reactions of **2** and **5a**, respectively, with hydrazine gave 1,4-diphenylpyridazino[4′,5′:3,4]pyrrolo[2,1-*b*]benzothiazole (**3**) and 3-methyl-6,9-diphenylthiazolo[3′,2′:1,2]pyrrolo[3,4-*d*]pyridine (**6**) in exellent yields.

6

When **2** was heated under reflux with cyanomethylammonium hydrogensulfate in 1-butanol, a fluorescent yellow 5:1 mixture of **7a** and **8a** was obtained in almost quantitative yield, among which **7a** could be isolated by careful fractional crystallizations; separation of the products from the above mixture by means of chromatography was not successful and resulted in gradual discoloration on contact with silica gel or alumina. The structure of **7a** was assigned as 1,4-diphenylpyrido[3′,4′:3,4]pyrrolo[2,1-*b*]benzothiazole-3-carbonitrile on the basis of elemental analyses and spectral data. Whilst the ^{1}H NMR spectrum of **7a** displays a 1H singlet at δ 7.93 assignable to a H-5 proton, the spectrum of the above mixture has an additional singlet at δ 8.30 which we assign to an H-5 proton of **8a**. The H-5 proton of **7a** appears at higher field than that of **8a**; shielding by 4-Ph of **7a** will most probably result from the steric repulsion with the 3-CN group.

Likewise, **2** yielded **7b** upon reaction with ethyl glycinate hydrochloride, whose ^{1}H NMR spectrum exhibited an ester methyl singlet at δ 0.97, its higher field shift compared to that of common ethyl esters being also attributed to the shielding effect of the 4-Ph. The material before recrystallizations had a broad range of mp (140—152 °C), and its ^{1}H NMR spectral peaks were not satisfactorily integrated. Although there was only a singlet around δ 8.0, we tentatively conclude from the foregoing observations that **8b** may have been formed in addition to **7b** in the reaction.

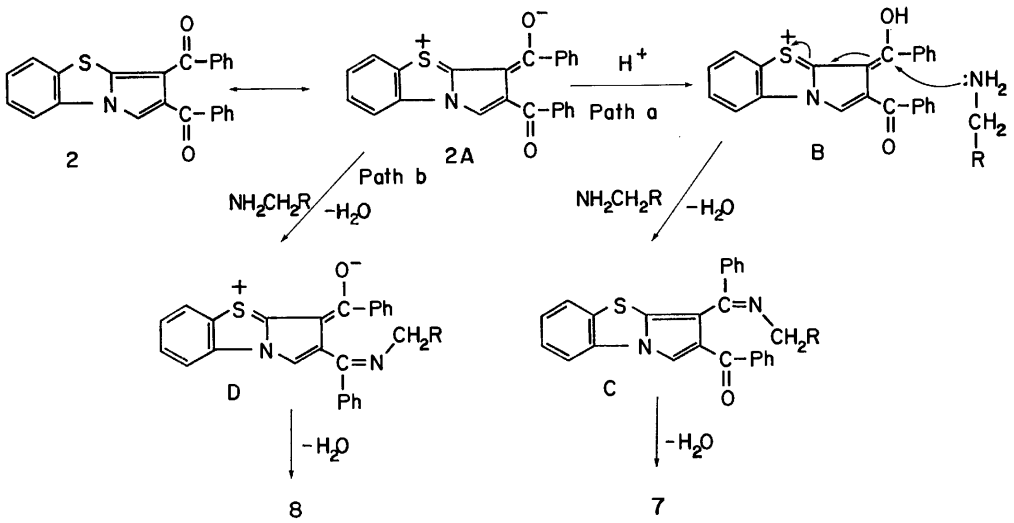
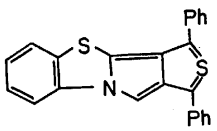


Scheme 1.

The reaction of **5a** with cyanomethylammonium hydrogensulfate gave a 6:1 mixture of 3-methyl-6,9-diphenylthiazolo[3′,2′:1,2]pyrrolo[3,4-*c*]pyridine-7-carbonitrile (**9a**) and its isomer (**10a**), as evidenced by the presence of two singlets at δ 7.93 and 8.47 in the ^{1}H NMR spectrum of the product before recrystallizations. However, the H-9 proton of each of **10b—d** was not discerned probably due to the overlap with aromatic protons in each of the ^{1}H NMR spectra of the products derived from **5b** and aminoacetonitrile or from **5a—b** and ethyl glycinate.

It may be concluded that heterocyclizations of **2** or **5** are fairly regioselective. Plausible mechanisms leading to **7** or **9** are shown in Scheme 1. Preferential attack of a proton on the carbonyl group at C-3 takes place by virtue of conjugation involving the sulfur 3d orbital (**2A**) to give an intermediate **B**, which undergoes a nucleophilic attack by an amine to form a Schiff base **C** followed by loss of water to produce **7** (Path a). Alternatively, if the amine directly attacks the carbonyl group at C-2 of **2A**, dehydration of a Schiff base **D** thereby produced would lead to **8** (Path b). Under the acidic conditions, the Path a is obviously favored and, in fact, when the reaction was effected in the presence of a base (NaOEt or DBU), an inseparable mixture of products was obtained.

Annelation of thiophene ring to **2** was achieved by its reaction in short period with phosphorus pentasulfide in pyridine followed by the rapid quenching of the reaction mixture with water. 1,3-Diphenylthieno[3′,4′:3,4]pyrrolo[2,1-*b*]benzothiazole (**11**) thus



11

prepared, though not analyzed because of its hygroscopic property, showed an M^+ ion at *m/e* 381 (rel intensity 63%, base peak *m/e* 175) and M^{2+} ion at *m/e* 190.5 (6%), and had a λ_{max} absorption at 620 nm (log ε 2.11). IR and ^{1}H NMR spectra of **11** are also in keeping with the structure proposed.[8] The compound **11**, when heated in acetone or xylene, readily changed to a dimer **12**,[8,9] which is independently obtained from the reaction of **2** with phosphorus pentasulfide in boiling xylene. It has an M^+ ion at *m/e* 762 in its mass spectrum and displays a 2H singlet at δ 5.78 and a multiplet at δ 7.25—8.25 corresponding to 28 aromatic protons in its ^{1}H NMR spectrum. The reactions of **5a** and **5b**, respectively, with phosphorus pentasulfide in pyridine produced dimers alone, whose ^{1}H NMR spectra were very simple in keeping with their symmetrical structures.

Experimental

Melting points were uncorrected. IR spectra were recorded for Nujol mulls and ^{1}H NMR spectra with either of a Hitachi R-24B spectrometer at 60 MHz or a JEOL FX-100 spectrometer at 100 MHz (Me_4Si as internal standard). Mass spectra were determined with a Hitachi M-80 instrument by means of electron impact or field desorption ionization methods. Chromatography was performed on Kieselgel 60. Yields are based on consumed starting materials. Imidazo[2,1-*b*]benzothiazole (**1a**) and imidazo[2,1-*b*]thiazoles (**4a—c**) were prepared as described in the previous paper[2] and imidazo[2,1-*b*]benzothiazole (**1b**) was prepared according to the literature.[10]

*Reactions of **1a—b** and **4a—c** with DBA. General Procedure*: A mixture of **1** or **4** (0.005 mol) and DBA (0.015 mol) in xylene (30 ml) was heated under reflux for 5—24 h and then evaporated to dryness under reduced pressure. The residue was chromatographed with benzene. Thus, **1a** and **1b** gave **2** (47 and 81% yield respectively), **4a** and **4b** gave **5a** (47 and 52% yield, respectively), and **4c** gave **5b** (90% yield), respectively.

2: Colorless prisms (from EtOH), mp 209—210 °C, λ_{max} (EtOH) 250 nm (log ε 4.49), 285^{sh} (4.21), 335 (4.06). IR 1640 and 1630 cm^{-1} (C=O). ^{1}H NMR ($CDCl_3$) δ= 7.1—8.0 (14H, m, phenyl and H-5,6,7,8), 7.95 (1H, s, H-1). Found: C, 75.34; H, 3.98; N, 3.82; S, 8.58%. 5a: Colorless prisms (from EtOH), mp 137—138 °C,

λ_{max} ($CHCl_3$) 254 nm (log ε 4.49), 344 (4.08). IR 1650 and 1640 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=2.74 (3H, d, J=1 Hz, Me), 6.62 (1H, q, J=1 Hz, H-2), 7.0—7.7 (10H, m, phenyl), 7.47 (1H, s, H-5). Found: C, 73.27; H, 4.25; N, 4.20; S, 9.21%. Calcd for $C_{21}H_{15}NO_2S$: C, 73.02; H, 4.38; N, 4.06; S, 9.28%.

5b: Colorless needles (from EtOH), mp 157—158 °C, λ_{max} (EtOH) 252^{sh} nm (log ε 4.42), 262 (4.42), 335 (4.11). IR 1710 and 1640 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ= 1.45 (3H, t, J=7 Hz, Me), 2.85 (3H, s, Me), 4.45 (2H, q, J=7 Hz, CH_2), 7.1—7.75 (10H, m, phenyl), 7.60 (1H, s, H-5). Found: C, 68.94; H, 4.56; N, 3.36; S, 7.83%. Calcd for $C_{24}H_{19}NO_4S$: C, 69.05; H, 4.59; N, 3.36; S, 7.68%.

Reaction of ***2*** *with Hydrazine Hydrate.* A mixture of **2** (0.20 g) and 100% hydrazine hydrate (10 ml) in EtOH (30 ml) was heated under reflux for 2 h and then diluted with water to precipitate pyridazine **3** (0.189 g, 96% yield).

3: Yellow needles (from aq EtOH), mp 252—253 °C, λ_{max} ($CHCl_3$) 272 nm (log ε 4.62), 403 (3.87). IR 700 cm^{-1} (phenyl). ^1H NMR (DMSO-d_6) δ=7.4—8.2 (12H, m, phenyl and H-7,8), 8.4—8.6 (2H, m, H-6,9), 8.97 (1H, s, H-11). Found: C, 76.56; H, 3.79; N, 11.07; S, 8.63%. Calcd for $C_{24}H_{15}N_3S$: C, 76.37; H, 4.01; N, 11.13; S, 8.49%.

Reaction of ***5a*** *with Hydrazine Hydrate.* **6a** was prepared in 91% yield by the reaction of **5a** (0.20 g) and 100% hydrazine hydrate (10 ml) in EtOH (10 ml) as described for **2**.

6a: Yellow needles (from aq EtOH), mp 220—222 °C, λ_{max} ($CHCl_3$) 272 nm (log ε 4.53), 400 (3.92). IR 700 cm^{-1} (phenyl). ^1H NMR (DMSO-d_6) δ=2.62 (3H, d, J= 0.5 Hz, Me), 7.38 (1H, q, J=0.5 Hz, H-2), 7.4—7.7 (6H, m, phenyl), 7.8—8.25 (4H, m, phenyl) 8.25 (1H, s, H-5). Found: C, 73.73; H, 4.35; N, 12.31; S, 9.36%. Calcd for $C_{21}H_{15}N_3S$: C, 73.87; H, 4.43; N, 12.31; S, 9.39%.

Reactions of ***2*** *and* ***5*** *with Cyanomethylammonium Hydrogensulfate.* A mixture of **2** (0.20 g) and cyanomethylammonium hydrogensulfate (0.807 g) in 1-butanol (10 ml) was heated under reflux for 6 h and poured into water. The mixture was extracted with $CHCl_3$, washed with dil HCl followed by water, and dried (Na_2SO_4). The extracts were evaporated to dryness and the residue was triturated with ligroine to give a mixture (0.205 g, 97% yield) of **7a** and **8a**, from which **7a** (0.120 g, 57% yield) was obtained by careful fractional crystallizations from EtOH.

7a: Yellow needles (from EtOH), mp 180 °C (dec), λ_{max} ($CHCl_3$) 275 nm (log ε 4.46), 326 (4.08), 420 (3.59), 430^{sh} (3.54). IR 2200 cm^{-1} (CN). ^1H NMR ($CDCl_3$) δ= 7.2—8.1 (14H, m, phenyl and H-7,8,9,10), 7.93 (1H, s, H-5). Found: C, 77.83; H, 3.98; N, 10.17; S, 7.75%. Calcd for $C_{26}H_{15}N_3S$: C, 77.78; H, 3.77; N, 10.47; S, 7.99%.

Similarly, **5a** gave a mixture (97% yield) of **9a** and **10a** and **5b** a mixture (84% yield) of **9b** and **10b**. **9a** and **9b**, respectively, were isolated by recrystallizations of the mixture from EtOH.

9a: Yellow needles, mp 242—243 °C, λ_{max} ($CHCl_3$) 285 nm (log ε 4.45), 324 (3.81), 416 (3.86), 430^{sh} (3.80). IR 2200 cm^{-1} (CN). ^1H NMR (DMSO-d_6) δ=2.59 (3H, d, J=1 Hz, Me), 7.45 (1H, q, J=1 Hz, H-2), 7.6—8.1 (10H, m, phenyl), 7.93 (1H, s, H-5). Found: C, 75.69; H, 4.07; N, 11.35; S, 8.86%. Calcd for $C_{23}H_{15}N_3S$: C, 75.59; H, 4.14; N, 11.50; S, 8.77%.

9b: Yellow needles, mp 250—253 °C, λ_{max} ($CHCl_3$), 268^{sh} nm (log ε 4.52), 288 (4.57), 325^{sh} (3.99), 420^{sh} (3.68), 439 (3.78), 461 (3.66). IR 2200 (CN) and 1710 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=1.39 (3H, t, J=7 Hz, Me), 2.88 (3H, s, Me), 4.38 (2H, q, J=7 Hz, CH_2), 7.4—7.8 (11H, m, phenyl and H-5), 7.85—8.0 (2H, m, phenyl). Found: C, 71.29; H, 4.66; N, 9.63; S, 7.54%. Calcd for $C_{26}H_{19}N_3O_2S$: C, 71.38; H, 4.38; N, 9.60; S, 7.33%.

Reactions of ***2*** *and* ***5*** *with Ethyl Glycinate Hydrochloride.* A mixture of **2** (0.20 g) and ethyl glycinate hydrochloride (0.731 g) in 1-butanol (10 ml) was heated under reflux for 24 h and then poured into water. The organic matter was extracted with ether, and washed with dil HCl followed by water. The dried (Na_2SO_4) extracts were evaporated to dryness. Trituration of the residue with ligroine afforded a mixture (0.220 g, 94% yield) of **7b** and **8b**, from which **7b** (0.138 g, 59% yield) was obtained by careful fractional crystallizations from ligroine.

7b: Yellow needles (from ligroine), mp 149—150 °C, λ_{max} ($CHCl_3$) 280 nm (log ε 4.59), 320^{sh} (4.11), 415 (3.82), 428^{sh} (3.78). IR 1720 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=0.98 (3H, t, J=7 Hz, Me), 4.14 (2H, q, J=7 Hz, CH_2), 7.1—7.7 (12H, m, phenyl and H-7,8,9,10), 7.50 (1H, s, H-5), 7.8—8.05 (2H, m, phenyl). Found: C, 71.81; H, 4.55; N, 5.59; S, 6.92%; M^+, m/e 448. Calcd for $C_{28}H_{20}N_2O_2S \cdot H_2O$: C, 72.08; H, 4.75; N, 6.00; S, 6.89%. M, 448.

Similarly, **5a** gave a mixture (96% yield) of **9c** and **10c** and **5b** a mixture (76% yield) of **9d** and **10d**, respectively. **9c** and **9d**, respectively, were isolated by recrystallizations of the mixture from ligroine.

9c: Yellow needles (from ligroine), mp 145—148 °C (dec), λ_{max} ($CHCl_3$) 260 nm (log ε 4.33), 315^{sh} (3.88), 410 (3.25). IR 1720 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=0.97 (3H, t, J=7 Hz, Me), 2.17 (3H, bs, Me), 4.07 (2H, q, J= 7 Hz, CH_2), 6.83 (1H, bs, H-2), 7.1—7.6 (8H, m, phenyl), 7.37 (1H, s, H-5), 7.8—8.05 (2H, m, phenyl). Found: C, 69.52; H, 5.13; N, 6.59; S, 7.09%; M^+, m/e 412. Calcd for $C_{25}H_{20}N_2O_2S \cdot H_2O$: C, 69.68; H, 5.15; N, 6.50; S, 7.45%; M, 412.

9d: Yellow needles (from ligroine), mp 92—93 °C, λ_{max} ($CHCl_3$) 265 nm (log ε 4.39), 283^{sh} (4.37), 330^{sh} (3.98), 425^{sh} (3.38), 441 (3.41), 463 (3.31). IR 1720 and 1710 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=0.97 (3H, t, J=7 Hz, Me), 1.27 (3H, t, J=7 Hz, Me), 2.57 (3H, s, Me), 4.10 (2H, q, J=7 Hz, CH_2), 4.27 (2H, q, J=7 Hz, CH_2), 7.1—7.8 (11H, m, phenyl and H-5). Found: C, 66.89; H, 5.14; N, 5.61; S, 6.25%; M^+, m/e 484. Calcd for $C_{28}H_{24}N_2O_4S \cdot H_2O$: C, 66.92; H, 5.21; N, 5.57; S, 6.38%. M, 484.

Reaction of ***2*** *with Phosphorus Pentasulfide. (a)*: A mixture of **2** (0.40 g) and phosphorus pentasulfide (1.17 g) in pyridine (5 ml) was heated under reflux for 10 min under nitrogen and then poured into ice–water (200 ml) containing acetic acid (5 ml) to give green precipitates. They were collected by filtration and recrystallized for several times from pyridine–petroleum ether to give **11** (0.075 g, 19% yield).

11: Hygroscopic green amorphous crystals, mp 120—122 °C (dec), λ_{max} (pyridine) 415^{sh} nm (log ε 2.40), 620 (2.11). IR 760 and 690 cm^{-1} (phenyl). ^1H NMR (pyridine-d_5) δ=7.0—8.2 (15H, m). M^+, m/e 381. Calcd for $C_{24}H_{15}NS_2$: M, 381.

(b): A mixture of **2** (0.10 g) and phosphorus pentasulfide (0.058 g) in xylene (30 ml) was heated under reflux for 50 min under nitrogen and then evaporated to dryness under reduced pressure. The residue was chromatographed with benzene–$CHCl_3$ to give **12** (0.051 g, 51% yield).

12: Yellow needles (from EtOH–$CHCl_3$), mp 182—183 °C, λ_{max} ($CHCl_3$) 287 nm (log ε 4.49). IR 775, 760, and 690 cm^{-1} (phenyl). ^1H NMR (CF_3CO_2D) δ=5.78 (2H, s), 7.25—8.25 (28H, m). Found: C, 75.30; H, 3.81; N, 3.73; S, 17.02%; M^+, m/e 762. Calcd for $C_{48}H_{30}N_2S_4$: C, 75.56; H, 3.96; H, 3.67; S, 16.81%; M, 762.

Dimerization of ***11***. A mixture of **11** (0.40 g) in xylene

(or acetone, 50 ml) was heated under reflux for 1 h under nitrogen and then evaporated to dryness under reduced pressure. The residue was chromatographed with benzene–$CHCl_3$ to give **12** (0.348 g, 87% yield).

*Reaction of **5a** with Phosphorus Pentasulfide.* A mixture of **5a** (0.40 g) and phosphorus pentasulfide (1.288 g) in pyridine (5 ml) was heated under reflux for 10 min under nitrogen and then poured into ice–water. Precipitates were collected by filtration, further heated in xylene under reflux for 1 h, and collected by filtration. Recrystallization from MeOH–$CHCl_3$ gave dimer **13a** (0.230 g, 57.5% yield).

13a: Yellow needles, mp 158—159.5 °C, λ_{max} ($CHCl_3$) 302 nm ($\log \varepsilon$ 4.41), IR 755 and 680 cm^{-1} (phenyl). ^1H NMR (CF_3CO_2D) δ=2.72 (6H, s), 5.57 (2H, s), 7.2—7.8 (22H, m). Found: C, 73.35; H, 4.62; N, 4.01; S, 18.21%; M^+, *m/e* 690. Calcd for $C_{42}H_{30}N_2S_4$: C, 73.43; H, 4.40; N, 4.09; S, 18.09%; M, 690.

*Reaction of **5b** with Phosphorus Pentasulfide.* A mixture of **5b** (0.40 g) and phosphorus pentasulfide (0.319 g) in pyridine (5 ml) was heated under reflux for 1 h under nitrogen and then poured into ice–water (200 ml) containing acetic acid 5 ml). Precipitates were collected by filtration, dried, and chromatographed with benzene–$CHCl_3$ to give dimer **13b** (0.262 g, 66% yield).

13b: Colorless micro needles (from benzene–$CHCl_3$), mp 256—257 °C, λ_{max} ($CHCl_3$) 285 nm ($\log \varepsilon$ 4.40). IR 1715 (C=O) and 770 and 700 cm^{-1} (phenyl). ^1H NMR δ=1.53 (6H, t, J=7 Hz), 2.68 (6H, s), 4.61 (4H, q, J=7 Hz), 6.37 (2H, s), 7.15—7.55 (20H, m). Found: C, 69.04; H, 4.41; N, 3.33; S, 15.20%; M^+, *m/e* 834. Calcd for $C_{48}H_{38}N_2O_4S_4$: C, 69.03; H, 4.59; N, 3.36; S, 15.20%; M, 834.

We thank Dr. Masafumi Yasunami, Tohoku University, for NMR spectral determinations.

Phosphinyl- and Phosphinothioylamino Acids and Peptides. VI. The Protection of the Hydroxyl Function in the Tyrosine Side-chain by the Dimethylphosphinothioyl Group

Masaaki UEKI* and Toshiyuki INAZU

Department of Applied Chemistry, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 12, 1981)

The use of the dimethylphosphinothioyl(Mpt) group for the protection of the hydroxyl function in the tyrosine side-chain was studied. *N,O*-Bis(Mpt)tyrosine was obtained directly by a Schotten-Baumann-type reaction of Mpt–Cl with tyrosine. The *O*-Mpt group was stable under acidic conditions, and it could be removed easily by alkaline hydrolysis or ester-exchange reaction. The usefulness of this new protecting group for the peptide synthesis was shown in the solid-phase synthesis of [D-Ala^2, L-Leu^5]-enkephalin(H–L-Tyr–D-Ala–Gly–L-Phe–L-Leu–OH) and its *N*-allyl derivative.

In the previous papers from our laboratory it was reported that a series of phosphinothioyl groups, such as diphenylphosphinothioyl(Ppt) and dimethylphosphinothioyl(Mpt), was useful as acid-labile amino-protecting groups for amino acids.[1–5] In accordance with the well-known acid lability of the phosphorus-nitrogen bond, these protecting groups could be removed by such mild HCl reagents as 0.2 M(1 M= 1 mol dm^{-3}) HCl in dichloromethane containing 0.2 M of triphenylphosphine(TPP). Since phosphinothioyl chlorides produced by cleavage do not react with the aromatic rings of tryptophan and tyrosine, the phosphinothioylamino acids have been successfully utilized for the synthesis of tryptophan homooligomers[6] and enkephalins.[7] When these groups are introduced into such other functional groups as hydroxyl and mercapto groups, they can be expected to become alkali-labile protecting groups according to the nature of the P–O and P–S bonds. As the first example of this line of investigation, the protection of the hydroxyl function in the tyrosine side-chain was attempted.

Tyrosine is a key amino acid in many biologically active peptides, such as enkephalin,[8,9] angiotensin II,[10] and gastrin.[11] A strategy which uses no side-chain protecting group for the tyrosine OH function has been recommended for the synthesis of a luteinizing hormone-releasing hormone,[12] and our previous syntheses of [L-Leu^5]-enkephalin and its analog were performed according to this strategy. However, the OH function of tyrosine should be protected for the synthesis of larger peptides. Benzyl ether-type protecting groups have been widely used, although the undesirable rearrangement to 3-benzyltyrosine during deprotection by acid[13] is one of the most hazardous side-reactions in peptide synthesis. In this report we would like to propose a new type of protecting group which would enable the direct alkylation of tyrosyl peptides.

Results and Discussion

A reaction of dimethylphosphinothioyl chloride (Mpt–Cl) with ethyl L-tyrosinate(H–L-Tyr–OEt) in the presence of triethylamine (TEA) gave a mixture of *N*-mono- and *N,O*-bis(Mpt)-L-tyrosine ethyl esters (**1** and **2**), which could then be separated by silica-gel column chromatography. When **2** was treated for 3 h with 0.2 M HCl in dichloromethane containing 0.1 M of TPP at room temperature, the *N*-Mpt group was removed selectively to give ethyl *O*-Mpt-L-tyrosinate hydrochloride(**3**) quantitatively. On the other hand, when the mixture of **1** and **2** was hydrolyzed by 1 M aqueous sodium hydroxide solution, *N*-Mpt-L-tyrosine was obtained in a 65% yield.[5] These results clearly show that the *O*-Mpt group was, unlike the acid-labile *N*-Mpt group, stable under acidic conditions and removable under basic conditions.

$$\text{H-L-Tyr-OEt} \xrightarrow[\text{CHCl}_3]{\text{2Mpt-Cl+2TEA}} \underset{(\mathbf{1})}{\text{Mpt-L-Tyr(Mpt)-OEt}} + \underset{(\mathbf{2})}{\text{Mpt-L-Tyr(Mpt)-OEt}}$$

$$\mathbf{2} \xrightarrow{\text{HCl}} \underset{(\mathbf{3})}{\text{HCl·H-L-Tyr(Mpt)-OEt}}$$

In order to determine the utility of the *O*-Mpt derivative of tyrosine, the alkali-lability of the *O*-Mpt group was examined more precisely by means of the pH-controlled alkaline hydrolysis of **2**. At pH 10.3, the cleavage of the *O*-Mpt group was still slow, and 90% of the **2** was recovered after a reaction period of 8 h at room temperature. This result was utilized for the preparation of *N,O*-bis(Mpt)tyrosine(**4**), a key derivative for the synthesis of tyrosine peptides, as will be described below.

With an increase in the pH value, the hydrolysis rate of the *O*-Mpt group became much faster. In these experiments, the reaction products were analyzed by means of high-performance liquid chromatography (HPLC); the results are shown in Fig. 1. At pH 11.9, the *O*-Mpt was removed rapidly, while the carboxylate ester bond was almost unaffected.

$$\mathbf{2} \xrightarrow[\text{rapid}]{\text{OH}^-} \text{Mpt-L-Tyr-OEt} \xrightarrow[\text{slow}]{\text{OH}^-} \text{Mpt-L-Tyr-O}^- \quad (\text{pH } 11.9)$$

Then, various kinds of basic reagents were examined in order to determine the most proper conditions for the removal of the *O*-Mpt group. The results are summarized in Table 1. It should be noted that the reagents with nucleophilic oxygen were clearly

Table 1. Time required for the removal of the *N*-Mpt or *O*-Mpt group from **2**

Reagent[a]	Time[b]	
	N-Mpt of **2**[c]	*O*-Mpt of **2**[c]
0.2 M HCl/0.2 M TPP/CH_2Cl_2	15 min	Stable for 24 h
1 M HCl/CH_3CO_2H	15 min	Stable for 24 h
HBr/CH_3CO_2H	5 min	Stable for 24 h
CF_3CO_2H	60 min	Stable for 24 h
1 M NaOH:CH_3OH(1:1)	Stable for 24 h	5 min
Tesser's base[14]	Stable for 24 h[d]	5 min[d]
1 M TEA/CH_3OH(RT)	Stable for 48 h	Incomplete for 48 h (66%)[e]
1 M TEA/CH_3OH(reflux)	Stable for 12 h	12 h
1 M TEA/C_2H_5OH(RT)	Stable for 48 h	Incomplete for 48 h (7%)[e]
1 M TEA/C_2H_5OH(reflux)	Stable for 12 h	Incomplete for 12 h (13%)[e]
20% NH_2NH_2/CH_3OH[f]	Stable for 48 h	24 h

a) The reagents were used in 4 cm^3 portions. b) Detected by TLC. c) The **2** was used in 0.2 mmol portions. d) The **2** was used in a 0.1 mmol portion. e) Isolated yield. f) The reagent was used in a 2 cm^3 portion.

preferrable to those with nucleophilic nitrogen.

In order to confirm the usefulness of the *O*-Mpt group for the synthesis of tyrosine-containing peptides, the solid-phase syntheses of [D-Ala^2, L-Leu^5]-enkephalin(**5**) and its *N*-allyl derivative were attempted. The synthetic scheme is outlined in Fig. 2.

The procedures of solid-phase synthesis were the same as those previously described.[5] All the amino acids were incorporated as Mpt derivatives except for glycine, which was coupled as its diethylphosphinothioyl (Ept) derivative. *N,O*-Bis(Mpt)-L-tyrosine(**4**) was obtained directly from tyrosine by a Schotten-Baumann-type reaction. When tyrosine was allowed to react with 3 equiv. of Mpt–Cl with special care to keep the pH of the reaction mixture in the range between 9.0 and 10.0, **4** was obtained in a 51% yield

$$\text{H-L-Tyr-O}^- \xrightarrow[\text{pH 9.0—10.0}]{\text{3Mpt-Cl + OH}^-} \xrightarrow{\text{H}^+} \text{Mpt-L-Tyr-OH} \quad (4)$$

(51% as DCHA salt)

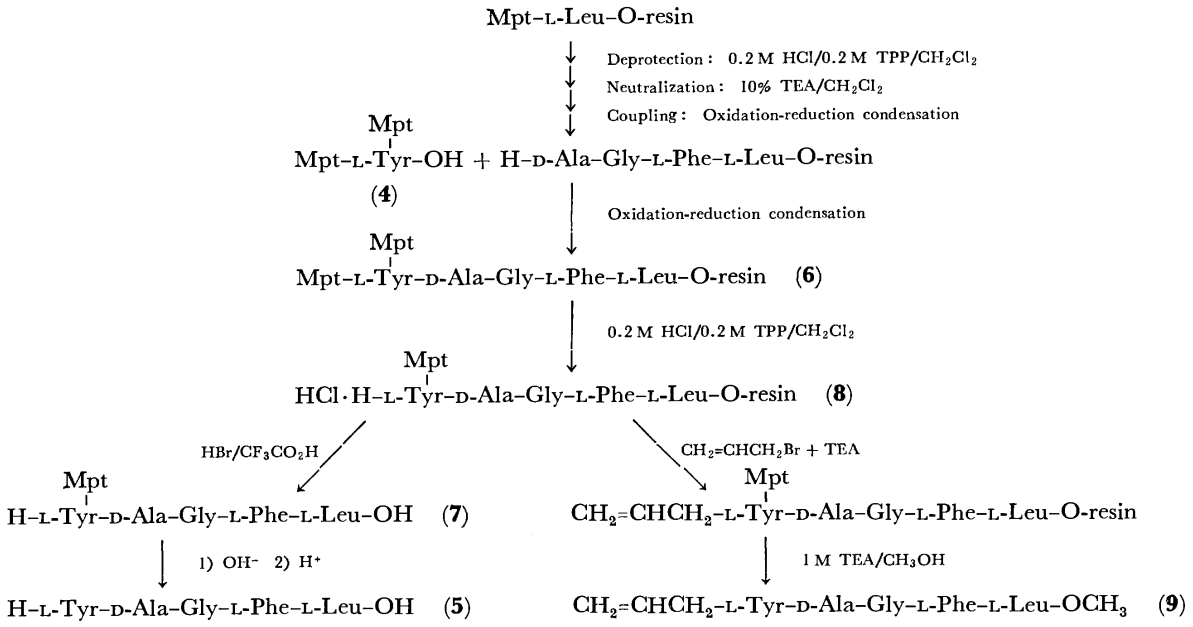

Fig. 2. Synthetic scheme for [D-Ala^2, L-Leu^5]-enkephalin and its *N*-allyl derivative.

as its dicyclohexylamine(DCHA) salt. All the couplings were mediated with the oxidation-reduction condensation method,[15] using tris(*p*-methoxyphenyl)-phosphine and 2,2'-dithiodipyridine. After the coupling of **4**, the *N*-Mpt group of *N*,*O*-bis(Mpt)pentapeptide resin(**6**) was selectively removed by the use of 0.2 M HCl solution in dichloromethane containing 0.2 M of TPP. Then, *O*-Mpt-[D-Ala^2, L-Leu^5]-enkephalin(**7**) was cleaved from the resin support by the use of HBr in trifluoroacetic acid. Pure **7** was obtained in a 53% yield as colorless crystals by purifying it by means of preparative thin-layer chromatography and successive gel chromatography on Sephadex LH-20. The removal of the *O*-Mpt group was performed by treating it with 1 M aqueous sodium hydroxide solution(1.1 equiv.) in methanol at room temperature overnight. Purification in a manner similar to that in **7** gave pure **5** in a 94% yield. Both **5** and **7** were homogeneous on thin-layer chromatography, and **7** gave satisfactory amino-acid ratios.

The biological activity of the **5** synthesized was measured by Professor Tetsuo Oka of Tokai University and found to be identical with that of an authentic sample by Mouse vas Deference assay and Guinea Pig Ileum assay.

For *N*-allylation, **8** was neutralized and further treated with 50 equiv. of allyl bromide in chloroform in the presence of TEA at room temperature for 12 h and then washed. The same treatments were repeated twice more. After thorough washing, the crude *N*-allylpentapeptide methyl ester(**9**) was cleaved from the resin support by transesterification with 1 M TEA in methanol, accompanied by the simultaneous removal of the *O*-Mpt group. After usual purification, pure **9** was obtained in a 38% yield, calculated from Mpt-L-Leu-resin. The structure of **9** was ascertained by NMR, MS, and amino-acid analysis. The acid hydrolyzate of **9** gave appropriate amino-acid ratios except for *N*-allyltyrosine, the amount of which could not be determined because of its low color value.[16]

N-Allyl-[L-Leu^5]-enkephalin is an interesting derivative of enkephalin because it shows partial agonistic and antagonistic activities,[17] but the synthesis of selectively alkylated tyrosyl peptides was not easy. This new method will be a useful route for these compounds. The syntheses of various kinds of alkylated derivatives of enkephalins are now in progress. The biological activity of these compounds will be reported by Professor Oka elsewhere.

Experimental

Thin-layer chromatography (TLC) was performed on silica-gel plates (Merck $60F_{254}$) in the following solvent systems: diethyl ether (R_f^1), chloroform–methanol–acetic acid (95:5:3, R_f^2), 1-butanol–acetic acid–water (4:1:1, R_f^3), chloroform–methanol–aqueous ammonia (60:30:5, R_f^4) and chloroform–methanol (9:1, R_f^5). The products were detected on TLC plates using ultraviolet light, iodine vapor, ninhydrin, and the Pauly reagent.

N,O-Bis(dimethylphosphinothioyl)-L-tyrosine Ethyl Ester (2) and N-Dimethylphosphinothioyl-L-tyrosine Ethyl Ester (1) (Mpt-L-Tyr(Mpt)-OEt and Mpt-L-Tyr-OEt). A solution of Mpt–Cl (25.71 g, 0.2 mol) in 50 cm^3 of chloroform was added to a suspension of H-L-Tyr-OEt·HCl (24.57 g, 0.1 mol) in 150 cm^3 of chloroform and 42 cm^3 (0.3 mol) of TEA at 0 °C. After having been stirred overnight at room temperature, the solution was evaporated *in vacuo*. The residue was dissolved in ethyl acetate. The solution was washed successively with water, an ice-cold 5% citric acid solution, water, a 5% sodium hydrogencarbonate solution, water, and a saturated sodium chloride solution, dried over anhydrous sodium sulfate, and evaporated. The oily residue was dissolved in dichloromethane and placed in a silica-gel column (3 cm × 50 cm). Elution with 600 cm^3 of dichloromethane gave **2** as colorless crystals; 26.11 g (66%). Mp 79—82 °C; $[\alpha]_D^{25}$ −12.5° (*c* 1, ethanol); R_f^1 0.37, R_f^2 0.69. Found: C, 45.43; H, 6.41; N, 3.69; P, 16.06%. Calcd for $C_{15}H_{25}NO_3P_2S_2$: C, 45.79; H, 6.40; N, 3.56; P, 15.75%. Further elution with the same solvent (about 3 dm^3) gave **1** as colorless crystals; 2.82 g (9%). Mp 68—69 °C; $[\alpha]_D^{25}$ −15.0° (*c* 1, ethanol); R_f^1 0.55, R_f^2 0.48. Found: C, 51.76; H, 6.77; N, 4.47; P, 10.32%. Calcd for $C_{13}H_{20}NO_3PS$: C, 51.81; H, 6.69; N, 4.65; P, 10.28%.

O-Dimethylphosphinothioyl-L-tyrosine Ethyl Ester Hydrochloride (H-L-Tyr(Mpt)-OEt·HCl) (3). Compound **2** (0.74 g, 2 mmol) was treated with 0.2 M HCl in dichloromethane containing 0.1 M of TPP. After having been kept standing at room temperature overnight, the solution was evaporated. The residue was distributed between water and diethyl ether, and the organic layer was extracted with 1 M hydrochloric acid several times. The combined aqueous layer and extracts were evaporated and dried over sodium hydroxide pellets *in vacuo*. The solid residue was washed with diethyl ether to give the product, 0.68 g (100%), which was then recrystallized from ethanol–diethyl ether to give pure **3** as colorless crystals; 0.56 g (83%). Mp 154—156.5 °C; $[\alpha]_D^{25}$ −15.0° (*c* 1, ethanol); R_f^2 0.17, R_f^3 0.62. Found: C, 45.40; H, 6.37; N, 4.25; P, 8.51%. Calcd for $C_{13}H_{21}NO_3PSCl\cdot 1/2H_2O$: C, 45.02; H, 6.68; N, 4.04; P, 8.93%.

N,O-Bis(dimethylphosphinothioyl)-L-tyrosine Dicyclohexylamine Salt (Mpt-L-Tyr(Mpt)-OH·DCHA) (4). L-Tyr (5.44 g, 30 mmol) was dissolved in 1 M sodium hydroxide solution (60 cm^3), and then Mpt–Cl (11.56 g, 90 mmol) in diethyl ether (30 cm^3) was added, drop by drop, at 0 °C. While the mixture was being stirred vigorously, 1 M sodium hydroxide solution was added carefully at a rate chosen so as to maintain the pH of the solution between 9.0 and 10.0 until no drop in the pH was observed. Then the solution was extracted twice with ethyl acetate. The aqueous layer was acidified with solid citric acid to pH 3—4 at 0 °C and was then extracted with ethyl acetate several times. The organic layer was washed with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The oily residue was dissolved in 40 cm^3 of ethyl acetate and treated with DCHA (6 cm^3, 30 mmol). DCHA salt was collected by filtration, washed with ethyl acetate and diethyl ether, and dried. Recrystallization from ethanol gave **4** as colorless crystals; 8.32 g (51%). Mp 169—170 °C; $[\alpha]_D^{25}$ −15.0° (*c* 1, ethanol); R_f^2 0.44, R_f^3 0.81. Found: C, 55.09; H, 8.00; N, 4.66%. Calcd for $C_{25}H_{44}N_2O_3P_2S_2$: C, 54.92; H, 8.11; N, 5.11%.

Solid-phase Synthesis of H-L-Tyr(Mpt)-D-Ala-Gly-L-Phe-L-Leu-OH (7). Mpt-L-Leu-resin was prepared from chloromethyl resin by the method of Gisin,[18] and the amount of esterified Leu was obtained as 0.33 mmol/g by means of amino-acid analysis. Mpt-L-Leu-resin (1 g) was placed in a reaction vessel of a Beckman Model 990 peptide synthesizer, after which synthesis was carried out according to the previously reported schedule,[5] using **4** at the final acylating step. After the final deprotection of the *N*-ter-

minal Mpt group, the *O*-Mpt-pentapeptide resin (**8**) was washed thoroughly with dichloromethane, ethanol, and diethyl ether, and dried *in vacuo*. The *O*-Mpt-pentapeptide was removed from the resin by anhydrous hydrogen bromide in trifluoroacetic acid (TFA) in the presence of 50 equiv. of anisole. The filtrate and TFA washings were combined and evaporated *in vacuo*. The residue was dried over sodium hydroxide pellets *in vacuo* and triturated with diethyl ether to yield the white solid. This crude peptide was then submitted to preparative silica-gel thin-layer chromatography using the chloroform–methanol–acetic acid (85:25:20) solvent system. The desired band (R_f=0.7—0.8) was eluted with methanol and evaporated *in vacuo*. The residue was again dissolved in a small volume of methanol and placed in a Sephadex LH-20 column (2×100 cm) monitored by means of UV absorbancy at 260 nm. The methanol eluate (flow rate 0.8 cm³/min) was collected as fractions of 4 cm³ each. The fractions (Nos. 34—43) containing a single component were collected and evaporated *in vacuo* to give **7** as colorless crystals; 0.116 g (53%). Mp 159—163 °C (dec); $[\alpha]_D^{25}$ −10° (*c* 1, methanol); R_f[3] 0.68, R_f[4] 0.66. Found: C, 55.15; H, 6.77; N, 10.24%. Calcd for $C_{31}H_{44}N_5O_7PS\cdot CH_3OH$: C, 55.40; H, 6.97; N, 10.09%. Amino-acid ratios in hydrolyzate obtained by the use of 6 M HCl at 110 °C for 24 h: $Tyr_{0.70}$, $Ala_{0.99}$, $Gly_{1.02}$, $Phe_{0.99}$, $Leu_{1.00}$. The low value for Tyr is attributable to the difficulty of the acid hydrolysis of *O*-Mpt–Tyr.

[D-*Ala*², L-*Leu*⁵]-*enkephalin* (***5***). Compound **7** (0.020 g, 0.03 mmol) was dissolved in 1 cm³ of methanol. To this solution, 0.1 cm³ of a 1 M aqueous sodium hydroxide solution was added at 0 °C. After having been stirred overnight, the solution was neutralized and evaporated *in vacuo*. The residue was placed in a Sephadex LH-20 column (2× 100 cm), and the desired fractions were collected to yield **5** as colorless crystals (0.0179 g, 94%). Mp 182—184 °C (lit,[5] 182—184 °C); $[\alpha]_D^{25}$ −20° (*c* 0.1, methanol) (lit,[5] −25.0° (*c* 0.1, methanol)); R_f[4] 0.50 (lit,[5] 0.49). Amino-acid ratios in hydrolyzate obtained by the use of 6 M HCl at 110 °C for 24 h: $Tyr_{0.97}$, $Ala_{1.02}$, $Gly_{0.99}$, $Phe_{0.99}$, $Leu_{1.02}$.

N-*Allyl*-[D-*Ala*², L-*Leu*⁵]-*enkephalin Methyl Ester* (***9***). Compound **8** synthesized from Mpt-L-Leu-resin (0.5 g, Leu content: 0.30 mmol/g) as has been described above, was used. After neutralization, the resin was treated by the following steps: (1) washing three times with chloroform, (2) allylation with 50 equiv. of allyl bromide and TEA in chloroform for 12 h, (3) washing three times with chloroform, (4) repetition of step (2) and (3) twice more, (5) washing two times with *N*,*N*-dimethylformamide, (6) washing two times with ethanol, followed by drying *in vacuo* over phosphorus pentaoxide. For the removal from resin, the peptide resin was refluxed in methanol containing 1 M of TEA for 12 h and then filtered. The same procedure was repeated, after which all the filtrates and methanol washings were collected and evaporated. The residue was distributed between water and ethyl acetate, and the organic layer was extracted with 1 M hydrochloric acid three times. The aqueous layer was neutralized with solid sodium hydrogencarbonate at 0 °C and then extracted with ethyl acetate three times. The collected extracts were washed with water and dried over anhydrous sodium sulfate. The solution was evaporated *in vacuo*, and the residue was purified by means of preparative thin-layer chromatography using the chloroform–methanol (95:5) solvent system. The desired band (R_f=0.2—0.3) was eluted with methanol and evaporated *in vacuo*. The residue was dissolved in methanol again, placed in a Sephadex LH-20 column (2×100 cm), and eluted with methanol (flow rate 0.75 cm³/min). The desired fractions (Nos. 37—42; 4.5 cm³/fraction) were collected to yield **9** as colorless crystals (0.0723 g, 38% from Mpt-L-Leu-resin): Mp 155—156 °C; NMR (CD_3OD) δ=0.97 (6H, d), 1.27 (3H, d), 3.70 (3H, s), 4.97—5.77 (3H, m), 6.73, 7.04 (4H, m), and 7.28 (5H, s); MS (70 eV), *m/e* (relative intensity), 623 (M^+, 2), 515 (22), 176 (100), 120 (65), 107 (19), 91 (13), and 77 (5). R_f[3] 0.75, R_f[5] 0.52. Amino-acid ratios in hydrolyzate obtained by the use of 12 M HCl–propionic acid at 130 °C for 2 h: $Ala_{0.94}$, $Gly_{1.05}$, $Phe_{0.97}$, $Leu_{1.04}$. *N*-Allyl-Tyr was detected, but not measured because of its low color value.

The authors wish to thank Professor Tetsuo Oka (Tokai University) for the bilogical-activity measurement.

Synthesis of *dl*-3-Hydroxycuparene by a Claisen Rearrangement of Allyl Aryl Ether

Yoshinobu INOUYE,* Satoru INOMATA, Yasumasa ISHIHARA, and Hiroshi KAKISAWA
Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received May 14, 1981)

The Claisen rearrangement of 1-methyl-2-[(3-methylphenoxy)methyl]cyclopentene in *N,N*-dimethylformamide gave 5-methyl-2-(1-methyl-2-methylenecyclopentyl)phenol(**5**) *via* its trimethylsilyl ether. The methylation of **5**, followed by a Simmons-Smith reaction and by the catalytic hydrogenolysis, afforded 3-hydroxycuparene.

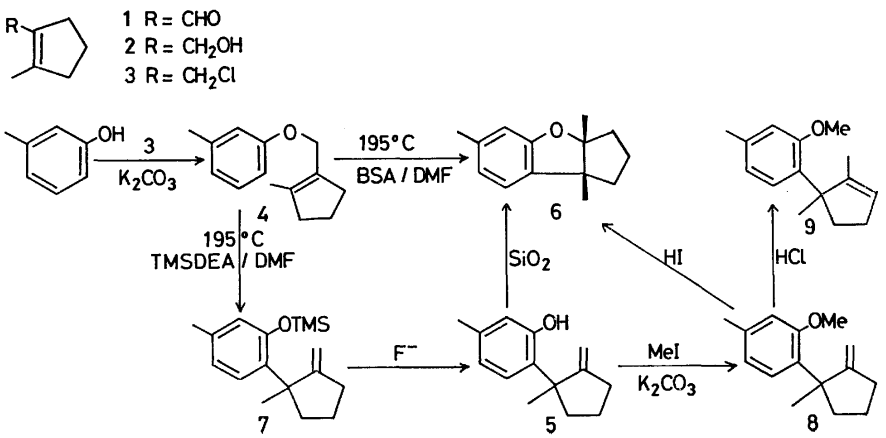
Claisen rearrangement[1] is one of the most attractive synthetic methods in natural-product chemistry because a new C–C bond can be created at the relatively hindered site of a molecule, where such intermolecular reactions as alkylation or acylation are frequently unsuccessful because of their steric demands. Several successes have been reported.[2] Most of them, however, have utilized the thermal reorganization of allyl vinyl ethers to γ,δ-unsaturated aldehydes or their variants.

We wish to report here the synthesis of hydroxycuparene *via* *o*-*t*-alkylphenol **5**, which is itself obtained by means of the Claisen rearrangement[3] of allyl aryl ether **4**.[4] This hydroxycuparene is expected to be a valuable intermediate for the synthesis of various cuparene derivatives found in the organisms.

6-Oxoheptanal, prepared from 1-methylcyclohexene, was cyclized with piperidinium acetate[5] to give 2-methyl-1-cyclopentenecarbaldehyde (**1**), which was then reduced with sodium borohydride to the corresponding alcohol **2**. The conversion of **2** into chloride **3** was problematic, however, because **3** was very unstable and, when isolated, immediately changed into unidentifiable green materials. Moreover, **3** was volatile, and an extraction procedure was undesirable. On this account, the alcohol **2** was treated with hexachloroacetone–triphenylphosphine,[6] after which the chloride **3** was isolated by flash distillation from the reaction mixture into a cooled (−70 °C) receiver containing small pieces of galvinoxyl. The immediate treatment of **3** with *m*-cresol in the presence of potassium carbonate gave 1-methyl-2-[(3-methylphenoxy)-methyl]cyclopentene (**4**), though the yield was low (18%). The structure of **4** was confirmed by the presence of an aromatic methyl at 2.37 ppm and an olefinic methyl at 1.82 ppm, together with the –O–CH_2–C= group at 4.49 ppm in the NMR spectrum of **4**.

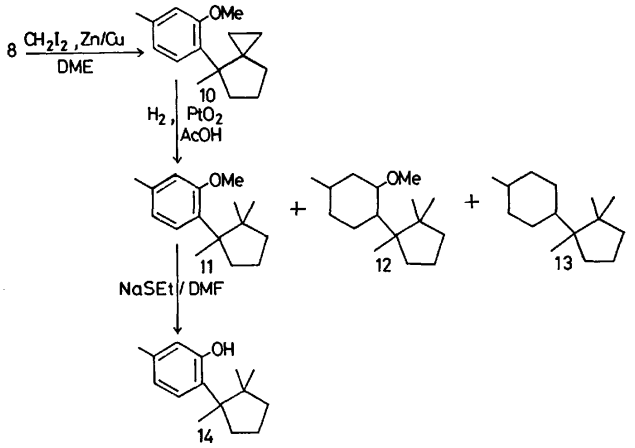
The Claisen rearrangement of simple allyl aryl ethers has been extensively investigated by Schmid *et al.*;[7] they showed that *N,N*-dimethylformamide (DMF) was the most effective solvent in giving an ortho-rearranged phenol.

When **4** was heated in DMF at 195 °C, the rearrangement occurred slowly in the anticipated direction to afford 5-methyl-2-(1-methyl-2-methylenecyclopentyl)phenol (**5**); however, a prolonged heating caused the gradual isomerization of **5** into the cyclic ether **6**. Thus, **5** could not be isolated in a pure form. The trapping of the initially rearranged phenol **5** as a trimethylsilyl derivative was successively performed when the reaction was carried out in the presence of *N*-trimethylsilyldiethylamine (TMSDEA). The GC analysis of the crude products showed the absence of any material other than **7**. On the other hand, *N,O*-bis(trimethylsilyl)acetamide (BSA) was undesirable because the decomposition of BSA at a high temperature accelerated the isomerization of **5** into **6** (see Experimental). The pure **5** was obtained in a 71% yield from **4** by the treatment of **7** with benzyltrimethylammonium fluoride[8] and by subsequent chromatography on neutral alumina. The structures of **5** and **6** were confirmed by their spectroscopic properties. Besides three aromatic protons which are located in a 2,5-dialkylphenol, two methyl groups at 1.38 and 2.18 ppm, and one exocyclic methylene group at 4.82 and 4.98 ppm as broad singlets are recognized in the NMR spectrum of **5**. On the other hand, in **6** three methyl groups appear, at 1.25, 1.30, and 2.20 ppm, while the signals due to the exocyclic methylene protons in **5** vanish completely. The chemical



shifts of 1.25 and 1.30 ppm of the two methyl groups on the ring juncture show the *cis*-relationship of these groups in comparison with those of aplysin (1.25 and 1.30 ppm).[9]

As **5** was sensitive toward acid, the phenolic hydroxyl group was protected by methylation. Attempted hydrohalogenations of the exocyclic methylene group in **8** were unsucessful; the treatment of **8** with potassium iodide/85% phosphoric acid[10] or hydrogen iodide/carbon tetrachloride gave **6** exclusively, while the action of hydrogen chloride/ether on **8** converted it into the endocyclic olefin **9**.



The Simmons-Smith reaction of **8** in the presence of 1,2-dimethoxyethane (DME) afforded the cyclopropane derivative **10**, which was then subjected to a careful catalytic hydrogenolysis (PtO_2 in acetic acid, 1.5 atom, 15 min) to give 3-hyrdoxycuparene methyl ether **11** in a crystalline form, together with a small amount of the octahydro compound **12** and the deoxy compound **13**.

The ether **11** was treated with sodium ethanethiolate in DMF to give oily *dl*-3-hydroxycuparene (**14**); the chemical shifts of four methyl signals (0.71, 1.13, 1.35, and 2.19 ppm) and the signal pattern of an aromatic region [6.29(br.s), 6.49(br.d, J=8 Hz), and 7.01 (d, J=8 Hz)] in the NMR spectrum of **14** are quite different from those reported for isomeric 2-hydroxycuparene.[11]

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi 215 grating spectrophotometer. The NMR spectra were measured with Hitachi H-60 and JEOL MH-100 spectrophotometers, using TMS as the internal standard. The mass spectra were obtained with a Hitachi RMU-6MG mass analyzer. The gas chromatograms were taken on a Shimadzu 3B-F analyzer, using a glass column (3 mϕ × 1.7 m, 5% OV-1). The flash chromatographies were performed using Wakogel C-300 as the adsorbent.

6-Oxoheptanal. 1-Methylcyclohexene (29.5 g) was dissolved in 1400 ml of water–dioxane (2:5) in a 3-liter three-necked flask equipped with a mechanical stirrer and a nitrogen-inlet tube. $NaIO_4$ (177 g) was added, and the mixture was cooled to 0 °C. After the system had been flushed with nitrogen, a solution of 1 g of OsO_4 in 100 ml of water was added; the whole was then allowed to warm to room temperature. After 15 hours' stirring under nitrogen, white precipitates were removed by filtration, and the filtrate was extracted with ether. The subsequent removal of the solvent gave an oil, which was then purified by distillation to afford 17.8 g (43%) of 6-oxoheptanal as a slight yellow oil; bp 57—58 °C/0.7 mmHg (1 mmHg ≈ 133.322 Pa) (Lit,[12]: bp 91—96 °C/4 mmHg): δ ($CDCl_3$): 1.46—1.76 (m, 4H), 2.14 (s, 3H), 2.22—2.68 (m, 4H), and 9.76 (t, 1H, J=1.5 Hz).

(2-Methyl-1-cyclopentenyl)methanol (2). 6-Oxoheptanal (8.49 g) was dissolved in 350 ml of dry benzene in a 1-liter three-necked flask equipped with a mechanical stirrer and a condenser. Traces of hydroquinone and a solution of dry piperidine (2.5 ml)–acetic acid (1.5 ml) in dry benzene (20 ml) were added, after which the mixture was stirred under nitrogen for 9 h at 60 °C. Water (300 ml) was then added, and the products were taken up in ether. The organic layer was washed with water and brine, and dried over Na_2SO_4. The subsequent evaporation of the solvent gave 6.89 g of crude 2-methyl-1-cyclopentenecarbaldehyde (**1**); ν ($CHCl_3$): 1660 cm^{-1}; δ ($CDCl_3$): 1.64—2.00 (m, 2H), 2.08 (s, 3H), 2.36—2.68 (m, 4H), and 9.84 (s, 1H).

The crude aldehyde **1** (6.89 g) was dissolved in 200 ml of methanol. After cooling to 0 °C, 4.13-g portions of $NaBH_4$ were gradually added; stirring was then continued for 80 min at 0 °C. Water was added, and the products were extracted with ether. The organic layer was washed with water and brine. After concentrating *in vacuo*, the oil which remained was purified by distillation to afford 3.77 g (51%) of **2** as a colorless oil; bp 42—43 °C/10 mmHg; ν ($CHCl_3$): 3600, 3400br, and 990 cm^{-1}; δ ($CDCl_3$): 1.70 (s, 3H), 1.75—2.10 (m, 2H), 2.10—2.68 (m, 4H), 2.88 (br.s, 1H), and 4.15 (br.s, 2H).

Elementray analysis was performed on its *p*-nitrobenzoate derivative; mp 71—72 °C; ν (KBr): 1720 and 1520 cm^{-1}. Found: C, 64.39; H, 5.81; N, 5.46%. Calcd for $C_{14}H_{15}NO_5$: C, 64.35; H, 5.78; N, 5.36%.

1-Methyl-2-[(3-methylphenoxy)methyl]cyclopentene (4). The alcohol **2** (736 mg) was mixed with 5 ml of hexachloroacetone[6] in a three-necked flask equipped with a thermomether and a distillor connected to a trap cooled with a Dry Ice–acetone bath. Traces of galvinoxyl were then added to the flask and the trap. Triphenylphosphine (5.2 g) was stirred in small portions into the mixture, during which the temperature of the content was controlled below 10 °C. The mixture was then allowed to warm to room temperature, and stirring was continued for a further 4 h. Crude 1-chloromethyl-2-methylcyclopentene (**3**) was flashly distilled (room temperature/0.2—0.3 mmHg) into the trap; *m/e* of **3**: 132 (11%, M^++2), 130 (33%, M^+), and 95 (100%, M^+−Cl). The chloride **3** was quite unstable and changed into a green material in the absence of galvinoxyl. Thus, the crude **3** was used immediately in the subsequent reaction.

A mixture of 0.75 ml of *m*-cresol and 1.05 g of K_2CO_3 in 5 ml of dry acetone was placed in a flask under nitrogen. A solution of **3** in 2 ml of acetone was then added into the above flask. The whole was then stirred at room temperature for 48 h. The reaction mixture was poured into water, and the products were taken up in ether. The organic layer was washed with 1 M (1 M = 1 mol dm^{-3}) NaOH and water, and dried over Na_2SO_4. After concentrating *in vacuo*, the residual oil was chromatographed on alumina (15 g) with hexane to give crude **4** (348 mg). A pure sample was obtained by repeated flash chromatographies (3 times, 1.0 ϕ, hexane) to give 239 mg (18%) of **4**; Kugelrohr dist: bath temp 80—83 °C/0.3 mmHg; ν (CCl_4): 1590, 1580,

1480, 1250br, and 1150 cm^{-1}; δ (CCl_4): 1.82 (br. s, 3H), 2.37 (s, 3H), 4.49 (s, 2H), and 6.5—7.3 (m, 4H). Found: C, 82.89; H, 9.04%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.96%.

Claisen Rearrangement[7] *of* **4**. *A)*: A mixture of 68 mg of **4**, 0.01 ml of BSA, and 0.25 ml of dry DMF was sealed in a test tube under argon. The tube was heated for 19 h at 195 °C. The whole was then poured into water, and the products were extracted with ether. The organic layer was washed with water and brine, dried, and concentrated *in vacuo* to give crude **6** (51 mg), which was subsequently purified by chromatography on silica gel with hexane–ethyl acetate (1:1) to give pure **6**; Kugelrohr dist: bath temp 50—65 °C/0.3 mmHg; ν ($CHCl_3$): 1640, 1615, 1590, 1490, 1110, and 945 cm^{-1}; δ ($CDCl_3$, 100 MHz): 1.25 (s, 3H), 1.30 (s, 3H), 2.20 (s, 3H), 6.24 (br.s, 1H), 6.57 (br.d, 1H, J=7 Hz), and 6.63 (d, 1H, J=7 Hz); *m/e*: 202 (67%, M^+) and 187 (100%). Found: C, 83.01; H, 9.09%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.96%.

B): A mixture of 225 mg of **4**, 0.5 ml of freshly distilled TMSDEA, and 4 ml of dry DMF was placed in a sealed tube under argon. The tube was heated for 30 h at 195 °C. The reaction mixture was then worked up as in A) to give crude **7**; *m/e*: 274 (M^+) and 259 (base). The GC analysis (140 °C) showed **7** was a single product. Crude **7** was treated with benzyltrimethylammonium fluoride[5] (20 mg) in 5 ml of THF for 4 h, and the products subsequently obtained by evaporating the solvent were chromatographed on neutral alumina (activity grade III, 10 g) with hexane to give **5** (159 mg, 71%). Some (20 mg) of the **4** was recovered from the earlier fractions.

An analytical sample of **5** was obtained by Kugelrohr dist: bath temp 67—70 °C/0.05 mmHg; ν (CCl_4): 3480, 1620, 1240, 1160, and 895 cm^{-1}; δ (CCl_4, 100 MHz): 1.38 (s, 3H), 2.18 (s, 3H), 4.82 (br.s, 1H), 4.98 (br.s, 1H), 5.32 (br.s, 1H), 6.42 (br.s, 1H), 6.49 (br.d, 1H, J=8 Hz), and 6.98 (d, 1H, J=8 Hz). Found: C, 83.00; H, 8.99%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.96%.

*1-(2-Methoxy-4-methylphenyl)-1-methyl-2-methylenecyclopentane (**8**).* To a stirred mixture of 159 mg of **5** and 2 ml of methyl iodide in 5 ml of acetone, 1 g of K_2CO_3 was added, after which the whole was stirred at room temperature for 43 h. The solids were removed by filtration, and the filtrate was evaporated to give an oil, which was chromatographed on silica gel (5 g). From the hexane eluates, 141 mg (83%) of methyl ether **8** was obtained. Kugelrohr distillation gave a pure sample; bath temp 70—75 °C/0.05 mmHg; ν (CCl_4): 1645, 1600, 1250, 1170, 895, and 880 cm^{-1}; δ (CCl_4, 100 MHz): 1.38 (s, 3H), 2.22 (s, 3H), 3.66 (s, 3H), 4.54 (br.s, 1H), 4.82 (br.s, 1H), 6.46 (br.s, 1H), 6.46 (br. d, 1H, J=8 Hz), and 7.00 (d, 1H, J=8 Hz). Found: C, 83.29; H, 9.32%. Calcd for $C_{15}H_{20}O$: C, 83.28; H, 9.31%.

Attempted Hydrohalogenation of **8**. *With KI–85% H_3PO_4*:[10] A mixture of 15 mg of **8**, 35 mg of KI, and 0.5 ml of 85% H_3PO_4 was heated at 80 °C for 3 h. The products were taken up in ether to give **6**.

With HI–CCl_4. Through a cooled (0 °C) solution of 12 mg of **8** in 1.5 ml of CCl_4 there was passed a dry HI gas, prepared from I_2 and tetralin, for 2 h. The product was found to be **6**.

With HCl–Ether. A dry HCl gas was passed through a solution of 11 mg of **8** in 2 ml of anhydrous ether at 0 °C, and then the mixture was allowed to warm to room temperature. A work-up as usual gave 8.5 mg (77%) of **9** by chromatography on silica gel (hexane). Kugelrohr dist: bath temp 40—50 °C/0.03 mmHg; ν (CCl_4): 1605, 1250, 1185, 1165, 1060, and 1035 cm^{-1}; δ (CCl_4, 100 MHz): 1.37 (s, 3H), 1.51 (br.s, 3H), 2.24 (s, 3H), 3.68 (s, 3H), 5.28 (m, 1H), 6.44 (br.d, 1H, J=8 Hz), 6.46 (br.s, 1H), and 6.75 (d, 1H, J=8 Hz). Found: C, 83.09; H, 9.34%. Calcd for $C_{15}H_{20}O$: C, 83.28; H, 9.31%.

*4-(2-Methoxy-4-methylphenyl)-4-methylspiro[2.4]heptane (**10**).* To a suspension of 280 mg (4.3 mmol) of a freshly prepared Zn–Cu couple in 5 ml of dry ether, 0.35 ml (4.3 mmol) of diiodomethane was added, after which the mixture was irradiated with IR lamp for 2 min. The whole was stirred at 40 °C for 1.5 h, after which 0.45 ml (4.3 mmol) of DME was added. A solution of 95 mg (0.43 mmol) of **8** in 3 ml of ether was then added, and the mixture was stirred at that temperature for 48 h. After the removal of the precipitates, the filtrate was washed with water and brine, dried, and evaporated to give an oil. The oil was subjected to flash chromatography with hexane to afford **10** (44 mg, 44%).

Kugelrohr dist: bath temp 75—80 °C/0.04 mmHg; ν (CCl_4): 3075, 1610, 1250, and 1170 cm^{-1}; δ (CCl_4, 100 MHz): 0.0—0.8 (m, 4H), 1.09 (s, 3H), 1.2—2.0 (m, 5H), 2.23 (s, 3H), 2.4—2.7 (m, 1H), 3.71 (s, 3H), 6.46 (br.s, 1H), 6.47 (br.d, 1H, J=8 Hz), and 7.13 (d, 1H, J=8 Hz); *m/e*: 230 (35%, M^+), 215 (64%), and 202 (100%). Found: C, 83.38; H, 9.46%. Calcd for $C_{16}H_{22}O$: C, 83.43; H, 9.63%.

*1-(2-Methoxy-4-methylphenyl)-1,2,2-trimethylcyclopentane (**11**).* A solution of 54 mg of **10** in 10 ml of acetic acid was shaken with 50 mg of PtO_2 under a hydrogen atmosphere (1.5 atm) for 15 min. The catalysts were then removed by filtration, and the filtrate was evaporated to give an oil (49 mg; GC showed the presence of four compounds, **10**:**11**:**12**:**13**=1.5:7.0:2.5:1.0). Repeated flash chromatographies with hexane separated the components:

11: mp 44—45 °C (from pentane, −78 °C); ν (CCl_4): 1615, 1255, 1060, and 1040 cm^{-1}; δ (CCl_4, 100 MHz): 0.64 (s, 3H), 1.10 (s, 3H), 1.29 (s, 3H), 2.24 (s, 3H), 3.71 (s, 3H), 6.45 (br.s, 1H), 6.48 (br.d, 1H, J=9 Hz), and 6.96 (d, 1H, J=9 Hz); *m/e*: 232 (67%, M^+), 217 (22%), 175 (41%), 162 (63%), and 149 (100%). Found: C, 82.97; H, 10.54%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%.

12: Kugelrohr dist: bath temp 50—60 °C/0.5 mmHg; ν (CCl_4): 1120 and 1095 cm^{-1}; δ (CCl_4, 100 MHz): 0.87 (s, 3H), 0.93 (s, 3H), 0.97 (s, 3H), 1.08 (br.d, 3H, J=7 Hz), and 3.18 (s, 3H); *m/e*: 238 (7%, M^+), 206 (53%,) 149 (78%), and 82 (100%). Found: C, 81.15; H, 12.63%. Calcd for $C_{16}H_{30}O$: C, 80.60; H, 12.68%.

13: oil; ν (CCl_4): 1460br and 1375 cm^{-1}; *m/e*: 208 (20%, M^+) and 124 (100%).

*5-Methyl-2-(1,2,2-trimethylcyclopentyl)phenol (**14**,3-hydroxycuparene).* A solution of 11 mg of the ether **11** in 0.5 ml of DMF in the presence of 25 equivalents of NaSEt was heated at 160 °C for 3 h. The mixture was then poured into dil hydrochloric acid, and the products were extracted with ether. The ether was dried over Na_2SO_4 and evaporated to give an oil. The oil was purified by flash chromatography with hexane to give phenol **14** (8 mg, 70%). Kugelrohr dist: bath temp 85—90 °C/0.04 mmHg; ν (CCl_4): 3630sh, 3600, 1620, 1290, and 1140 cm^{-1}; δ (CCl_4, 100 MHz): 0.71 (s, 3H), 1.13 (s, 3H), 1.35 (s, 3H), 2.19 (s, 3H), 4.42 (s, 1H), 6.29 (br.s, 1H), 6.49 (br.d, 1H, J=8 Hz), and 7.01 (d, 1H, J=8 Hz); *m/e*: 218 (50%, M^+), 203 (10%), 161 (30%), 148 (100%), and 135 (56%). Found: C, 82.34; H, 10.25%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.15%.

Cobalt(II)-substituted Horseshoe Crab Hemocyanins

Shinnichiro Suzuki,* Jun Kino, and Akitsugu Nakahara
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received May 27, 1981)

The horseshoe crab Co(II) hemocyanins were prepared by dialyses of *Tachypleus tridentatus*, *Tachypleus gigas*, *Limulus polyphemus*, and *Carcinoscorpius rotundicauda* apohemocyanins against Tris–HCl buffer (pH 8.0) containing Co(II) ion. The amounts of Co(II) introduced into apohemocyanins reached almost 100% of the total sites for copper ion in native hemocyanins. However, all the four Co(II) hemocyanins did not take up oxygen molecule at all. The extremely similar spectral data for the four species revealed that there is no essential difference in the structure of the respective active sites. Both the two Co(II) ions at an active site are in the high spin state and in an distorted tetrahedral geometry, having no such ligating groups as cysteinyl or methionyl sulfur, but at least three nitrogenous ligands, probably histidine imidazoles. On the basis of these data, the environment of active site in native horseshoe crab hemocyanin is discussed.

Hemocyanins(Hc) are known as respiratory proteins for arthropods and molluscs, binding one oxygen molecule per two adjacent copper atoms that constitute an active site unit.[1–4] The deoxy forms containing Cu(I) are colorless and diamagnetic. The deep blue color of the oxy form stems from the absorption band at 570—580 nm, of which the extinction coefficient (ε_{Cu}) was estimated to be *ca.* 500 M^{-1} cm^{-1}.† Resonance Raman studies of oxyhemocyanins established that the O–O stretching band for bound dioxygen is observed at 744—749 cm^{-1}, which is characteristic of peroxide, implying complete transfer of two electrons from each Cu(I) to O_2 on binding of an oxygen molecule (Cu(II) O_2^{2-} Cu(II)).[5,6] The oxyHc is not detectably paramagnetic, indicating that the copper(II) ions are arranged as an antiferromagnetically coupled pair.[7,8] A broad resonance Raman band was recently observed at 1075 cm^{-1}, which is plausibly assigned to the singlet→triplet transition of coupled Cu(II) ions.[9]

Various approaches have hitherto been carried out by many investigators to shed light on the structure and properties of the active site of hemocyanins. Mason and his coworkers prepared methemocyanin by treating *C. magister* hemocyanin with H_2O_2,[10] and reported that the resulting products of H_2O_2-oxidation consist of 80—95% of diamagnetic species, small amount of ESR-detectable Cu(II) and some unreacted native hemocyanin. The active site of the diamagnetic species was assumed to contain spin coupled binuclear Cu(II) cluster which is interpreted in terms of a relaxation of superexchange through one or more bridging ligands such as tyrosine, histidine, serine, or cysteine.

Recently a model for the oxygen binding site of hemocyanin was proposed, based on extended X-ray absorption fine structure studies.[11] The coordination number of copper was proposed as five for oxyHc (three imidazoles, O_2, and the putative extra bridging ligand) and three for deoxyHc (three imidazoles, presumably in a trigonal-like arrangement). This suggests that two ligand groups are detached from each copper upon deoxygenation. The Cu–Cu distance was estimated to be 0.37 nm for oxyHc and 0.34 nm for deoxyHc.

Solomon *et al.* prepared a series of active site derivatives of mollusc and arthropod hemocynains, namely half-apo, met-apo, half-met, ESR-detectable met, ESR-silent met forms.[12] Based on their spectroscopic data, they described that the binuclear copper site in oxyHc contains an endogenous ligand bridge together with the exogenous μ-peroxide bridge between the equatorial planes of two tetragonal coppers. They also pointed out that the active sites in both phyla are quite similar, although the active site of arthropod is distorted from that of mollusc as is indicated by their CD-spectral differences.

We recently prepared a cobalt(II)-substituted Hc in order to disclose the environment of the active site of squid Hc.[13] Substitution of Co(II) ion for a native metal ion in metalloproteins has been an effective approach to the understanding of the structure of metal-site because of intensive and distinct visible absorption and magnetic circular dichroism (MCD) spectra given by Co(II) ion,[14] as clearly demonstrated through the studies of carbonic anhydrase, carboxypeptidase A, thermolysin, plastocyanin *etc.* The amount of Co(II) introduced into *S. lessoniana* apoHc reached 47% of the total sites for Cu in native form, being estimated as nearly complete formation of the half-apoCo(II) hemocyanin. The visible absorption and MCD spectra indicated that the Co(II) is in the tetrahedral geometry (high-spin state), and some histidine imidazoles are coordinated around Co(II). The binding of the imidazole ligands was also considered from the superhyperfine structure in the ESR spectrum of the purple hemocyanin formed on addition of ethylene glycol to oxyhemocyanin.[15–17]

This paper describes the preparation and the spectroscopic studies of Co(II)-substituted hemocyanins of all the four horseshoe crabs found in the world.

Experimental

Materials. Hemocyanins of the horseshoe crabs, *Tachypleus tridentatus*, *Tachypleus gigas*, *Limulus polyphemus*, and *Carcinoscorpius rotundicauda* were supplied by Professor K. Sekiguchi of the University of Tsukuba. These were purified from the respective hemolymphs according to the method of Omura *et al.*[18] The dark blue pellets of pure hemocyanins were dissolved in 50 mM Tris–HCl buffer (pH 8.0)†† and

† In this paper 1 M=1 mol dm^{-3}.

†† Tris: tris(hydroxymethyl)aminomethane.

Tabke 1. Electronic and CD absorption spectra of oxyhemocyanins

Hemocyanins	UV and VIS[a] λ_{max}/nm (ε_{Cu})	CD[a] λ_{max}/nm ($\Delta\varepsilon_{Cu}$)
T. tridentatus	340 (9320), 577 (514)	341 (−11.5), 495 (+0.752), 610 (+0.813)
T. gigas	340 (10300), 578 (500)	341 (−13.3), 495 (+0.886), 610 (+0.960)
C. rotundicauda	340 (11000), 577 (550)	341 (−14), 495 (+0.95), 610 (+1.0)
L. polyphemus	340 (10600), 578 (557)	341 (−14.0), 495 (+0.941), 610 (+1.05)

a) 50 mM Tris-HCl buffer (pH 8.0).

kept in a refrigerator at 4 °C except when the spectra were recorded. The purity of hemocyanin was checked by the ratio of the absorption coefficient at 280 nm to that at 340 nm. The ratios of the four horseshoe crab hemocyanins were in the range of 4.1—4.3.

Preparation of Co(II)-substituted Hemocyanin. First, apoHc was prepared by dialysis of oxyHc against pH 8.0 Tris-HCl buffer (50 mM) which contained 10 mM KCN at 4 °C for 3 d. The copper ion was completely removed from the active site of protein. The Co(II)-Hc was prepared by dialysis of the apoHc against the Tris-HCl buffer which contained about 1 mM $CoCl_2$ at 4 °C for 2 d under nitrogen. When a denatured protein was deposited by Co(II) ion, the dialysis bag was washed against Co(II)-free buffer to remove excess Co(II) ion bound to the protein until the turbid protein became transparent. After treating the apoHc with Co(II) ion, the Co(II)-Hc was dialyzed against Tris-HCl buffer of 2 l. Further the excess of Co(II) ion contained in the resulting crude sample was removed by treating with Chelex 100 resin (50% by volume, pre-equilibrated with the Tris-HCl buffer). The concentration of Co(II) in the final product was determined to be 85—100% of the total sites for Cu in native Hc by employing the method of standard addition, using an atomic absorption spectrophotometer (Nippon Jarrell-Ash AA-1 spectrometer).

In order to examine whether or not the Co(II) exists at the active site of Hc, reconstitution of holoHc was carried out by treating the Co(II)-Hc with $[Cu(CH_3CN)_4]ClO_4$ according to the method of Konings *et al.*[19] The introduction of Cu ion into Co(II)-Hc was observed to be inhibited by the substituted Co(II) ion. The recovery of oxyHc from Co(II)-Hc was thus limited to only 20% of that from apoHc. The extent of recovery of oxyHc was evaluated on the basis of CD intensity at 440 nm where oxyHc exhibited a maximum intensity, while Co(II)-Hc gave actually no CD absorption.

Instruments. The absorption, CD, and ESR spectra were recorded with a Hitachi 323 spectrophotometer, a JASCO J-500C circular dichroism spectrometer, and a JEOL JES-FE1X ESR spectrometer, respectively. The MCD spectra were recorded at 11500 G††† with a JASCO J-500C spectrometer equipped with an electromagnet. The measurements of spectra were carried out at 15—20 °C except for the ESR spectra which were recorded at 77 K.

Results and Discussion

Four Horseshoe Crab Oxyhemocyanins, and Effects of Addition of Ethylene Glycol to Them. The electronic absorption and CD spectra of oxyHc (*T. tridentatus*) are represented in Fig. 1. Other than the characteristic protein band at near 280 nm, two bands were

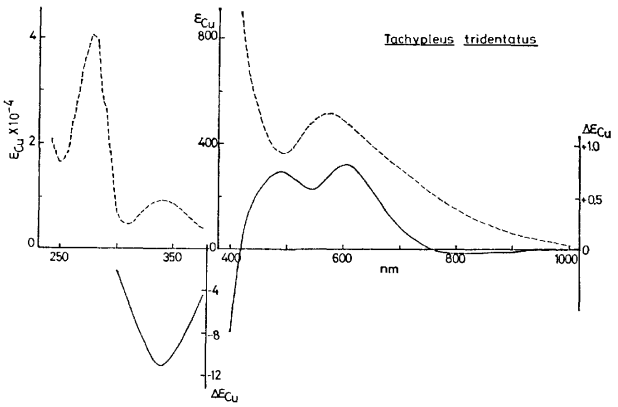

Fig. 1. Electronic absorption spectra (----) and CD spectra (——) of *T. tridentatus* oxyhemocyanin. Conditions: hemocyanin, 0.59 mM; 50 mM Tris-HCl buffer (pH 8.0). ε_{Cu}(M^{-1} cm^{-1}) and $\Delta\varepsilon_{Cu}$(M^{-1} cm^{-1}) are expressed per mol of Cu.

recorded in the near ultraviolet (340 nm), and visible (near 580 nm) regions. These two bands were absent in deoxy- and apo-Hc's. The electronic absorption band at 340 nm has been interpreted as arising from peroxide to copper charge transfer. However, the absorption band at 580 nm, which is responsible for the blue color is still controversial as to whether it should be assigned as peroxide to copper charge transfer[5,12] or as d-d transitions based on Cu(II).[20]

T. tridentatus Hc exhibited three CD bands in the visible region, namely two positive bands at 495 and 610 nm as observed in other arthropod oxyHc,[21] and a weak negative band at around 800 nm. On the other hand, molluscan oxyhemocyanins such as squid (*S. lessoniana*) oxyHc have three CD bands in the visible region; a positive band at 450 nm, a negative band at 570 nm and a positive band at around 710 nm.[21] Oxyhemocyanins of both the phyla display an intensive negative CD band at around 340 nm. The spectral data for the four horseshoe crab oxyhemocyanins bear a strong resemblance to each other as listed in Table 1. From these data it may be considered that the ligating groups and the coordination geometries around the Cu(II) ions are actually the same for the four hemocyanins.

It has been known that oxyhemocyanins exhibit no ESR signal on account of the spin-coupling of the two Cu(II) ions at the active site. However, addition of ethylene glycol (83 v/v% of the total volume) to the buffer solutions of the oxy forms produces a state containing ESR-detectable metHc. The X-band

††† 1 G=1×10^{-4} T.

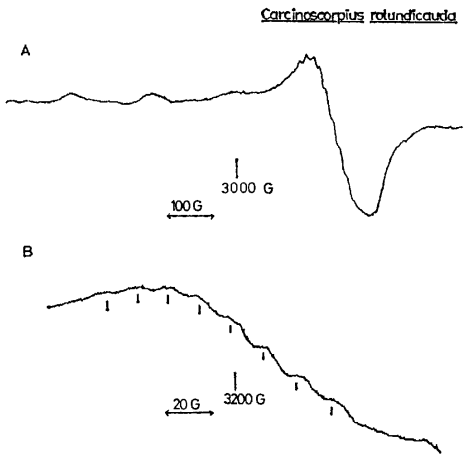

Fig. 2. (A) ESR spectrum of *C. rotundicauda* oxyhemocyanin treated with ethylene glycol (83 v/v%). $g_{//}$ 2.27, $A_{//}$ 178 G, $g_{\perp}$ 2.05. (B) Nitrogen nuclear superhyperfine structure of spectrum (A). Condition: hemocyanin, 0.25 mM.

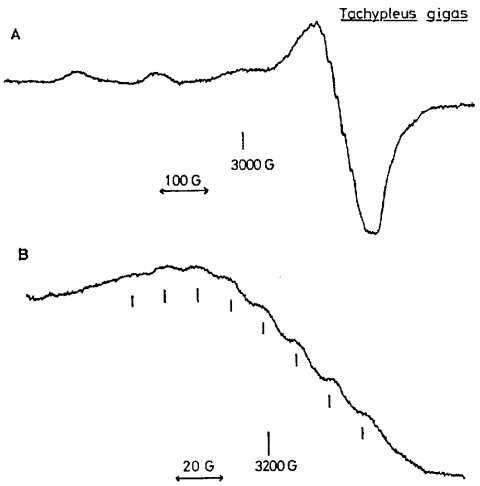

Fig. 3. (A) ESR spectrum of *T. gigas* oxyhemocyanin treated with ethylene glycol (83 v/v%). $g_{//}$ 2.27, $A_{//}$ 176 G, $g_{\perp}$ 2.05. (B) Nitrogen nuclear superhyperfine structure of spectrum (A). Condition: hemocyanin, 0.54 mM.

ESR spectra of *C. rotundicauda* and *T. gigas* are illustrated in Figs. 2 and 3, respectively. The periods between the preparations of the samples and the measurements of ESR spectra were 40 h at 4 °C. The amounts of ESR-active copper in the two samples were estimated to be *ca.* 20% of the total copper in the respective native Hc. The spectrum in Fig. 2A exhibited a signal at $g_{//}$=2.27 with spacings ($A_{//}$) between successive peaks of 178 G. The ESR parameters ($g_{//}$=2.27, $A_{//}$=176 G, $g_{\perp}$=2.05) of the spectrum in Fig. 3A are quite similar to those of *C. rotundicauda*. These values indicate that the Cu(II) ion has a tetragonal geometry. The patterns of the ESR spectra also suggested that there is no magnetic dipole-dipole interaction between the two coppers at the active sites. In other words, the ESR-active copper was supposed to be in a monomeric Cu(II) complex. The spin Hamiltonian parameters of these horseshoe crab hemocyanins were similar to those of

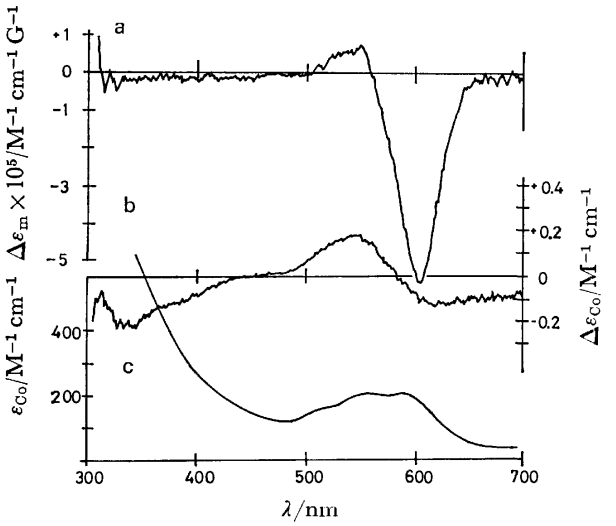

Fig. 4. MCD (a), CD (b), and electronic absorption (c) spectra of *T. gigas* Co(II) hemocyanin. Conditions: hemocyanin, 0.37 mM; 50 mM Tris–HCl buffer (pH 8.0). ε_{Co}, $\Delta\varepsilon_{Co}$, and $\Delta\varepsilon_m$ are expressed per mol of Co(II).

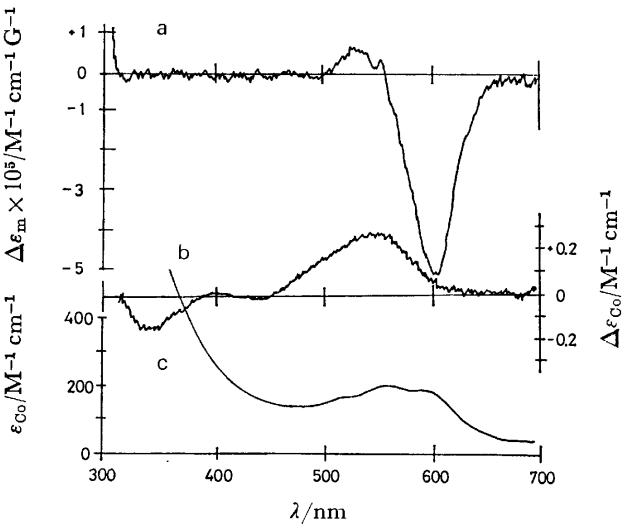

Fig. 5. MCD (a), CD (b), and electronic absorption (c) spectra of *L. polyphemus* Co(II) hemocyanin. Conditions: hemocyanin, 0.34 mM; 50 mM Tris–HCl buffer (pH 8.0).

the squid Hc treated with ethylene glycol (80 v/v%), where the values of $g_{//}$, $g_{\perp}$, and $A_{//}$ were 2.261, 2.059, and 173.8 G, respectively.[16] Further it is noteworthy that at least eight superhyperfine lines due to nitrogens with spacing (A_N) of about 14 G were observed in the region of $g_{\perp}$ (Figs. 2B and 3B), suggesting that at least three nitrogenous ligands are coordinated around Cu(II). The same kind of ESR signals and the superhyperfine structure were also observed for the other two hemocyanins (*T. tridentatus* and *L. polyphemus*) upon addition of ethylene glycol.

Preparation and Spectral Properties of Co(II)-substituted Horseshoe Crab Hemocyanins. We have already succeeded in preparing Co(II) substituted squid hemocyanin.[13] By employing the same procedure, Co(II) hemocyanins of the four horseshoe crabs were prepared. All the Co(II) hemocyanins were pink-violet.

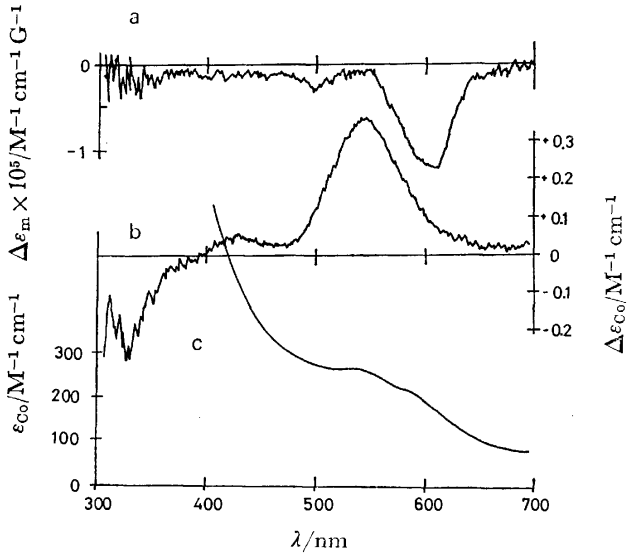

Fig. 6. MCD (a), CD (b), and electronic absorption (c) spectra of aged *T. gigas* Co(II) hemocyanin. Conditions: hemocyanin, 0.55 mM, 50 mM Tris–HCl buffer (pH 8.0). The period between the preparation and the measurement was 20 d at 4 °C.

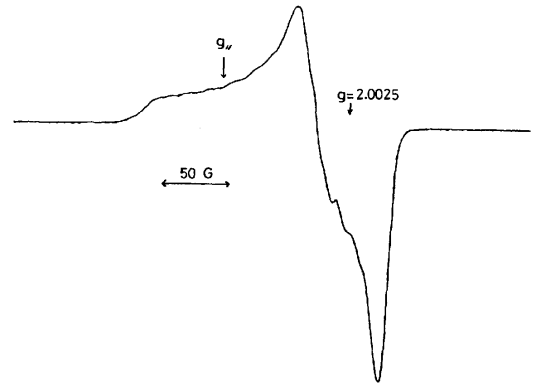

Fig. 7. ESR spectrum of mixture of *T. gigas* Co(II) hemocyanin and cyanide. Conditions: hemocyanin (Co(II), 5.5 mM) plus cyanide(22 mM); 50 mM Tris–HCl buffer (pH 8.0); 77 K.

The absorption, CD, and MCD spectra of *T. gigas* and *L. polyphemus* Co(II) hemocyanins measured at room temperature are represented in Figs. 4 and 5, which display that all the spectra of the two species are remarkably similar to each other. The appearance of CD band at 500—600 nm is indicative of the binding of Co(II) ion with the protein. The absorption and MCD bands of the Co(II)-chromophore at 500—650 nm are attributed to the d-d transition ($^4A_2(F) \rightarrow {}^4T_1(P)$) arising from a tetrahedral Co(II) in the high spin state. In general, Co(II) complexes with tetrahedral geometry are known to show a negative MCD band at a longer wavelength region and one or two weaker positive bands at a shorter wavelength region.[14] The patterns of MCD spectra in Figs. 4 and 5 further reveal that there is no MCD band arising from S→Co(II) charge transfer transition[22-24] in the range of 300—400 nm, suggesting that there is no thiol-coordination of cysteinyl residue around Co(II).[14,25] Cysteinyl sulfur (also probably methionyl sulfur) might not be a ligating atom around the two copper ions in native horseshoe crab hemocyanins. The negative CD band at around 350 nm is not assigned to charge transfer transition of the Co(II)-chromophore because of the absence of MCD band in the range of 300—400 nm. It is suggested at present that the negative CD band might be attributed to the protein structure and/or the amino acid residues (*e.g.* disulfide group) in the protein.

The active sites of the four horseshoe crab hemocyanins were almost completely filled with Co(II) ion, being contrasted to the case of the squid hemocyanin, from which the half-filled Co(II)–Hc was obtained, as already communicated.[13] However, the horseshoe crab Co(II) hemocyanins did not take up oxygen molecule either. With storage at 4 °C for several weeks pink-violet Co(II) hemocyanins turned light brown. This may be due to a kind of aging of hemocyanins, and is visuallized through absorption, CD, and MCD spectra of *T. gigas* Co(II)–Hc as illustrated in Figs. 4 and 6. Comparative inspection of these Figures apparently indicates that the intensity of the ultraviolet absorption band increased significantly and patterns of CD and MCD spectra changed considerably with aging of Co(II)–Hc. The change in 500—600 nm MCD band suggests that the distorted tetrahedral geometry of Co(II) center is converted into another geometry, probably to a five- or six-coordinate structure. It was also confirmed that the oxidation state of Co ion in Co(II)–Hc does not change with aging of the sample. This was proved through an ESR study of aged Co(II)–Hc (*vide infra*).

At liquid nitrogen temperature (77 K) we could not observe the ESR peak for the high spin Co(II) center in the hemocyanin because of the extremely broadening and low amplitude of signal. Addition of one-equivalent cyanide to Co(II) ion gave no ESR-signal either. However, the ESR signal was observed at $g=2$, upon addition of above 2-equivalent cyanide, as shown in Fig. 7 (*T. gigas* Co(II) hemocyanin). The signal did not increase any more with further addition of cyanide, whereas the signal ultimately disappeared by allowing the sample to stand for a day at 4 °C. The ESR signal having the spin Hamiltonian parameters of $g_{//}=2.06$, $A_{//}^{Co}=16$ G, and $A_{\perp}=11$ G,[26] is suggestive of the formation of 1:1 O_2:low spin Co(II) complex with CN^- donor groups and probably endogenous ligands. The characteristic feature of ESR spectrum ($g_{//}>g_{\perp}\simeq 2.00$) closely resembles those of various monomeric Co(II)–dioxygen complexes in literatures.[27-31] The result of evaluation according to the method of Hoffman *et al.* indicated that above 90% of unpaired spin density resides on the dioxygen moiety and below 10% resides on Co(II) ion.[27] The aged *T. gigas* Co(II)–Hc also quantitatively afforded the 1:1 dioxygen adduct with the addition of above 2-equivalent cyanide. This finding implies that no oxidation of the cobalt ion (from Co(II) to Co(III)) took place in the course of the aging.

Metal Binding Site of Hemocyanin. The ESR spectra of oxyhemocyanins treated with ethylene glycol are considered from g and A values to be characteristic

of many square-planar or tetragonally-distorted octahedral Cu(II) complexes with small ligands (Figs. 2 and 3). The copper nuclear hyperfine splitting constants, $A_{//}$, were 176—178 G. These values are more compatible with those observed for Type II copper proteins (150 to 190 G[32,33]) than those for Type I copper proteins (30 to 100 G[32]). The spin Hamiltonian parameters of these denatured hemocyanins are remarkably similar to that of $[Cu(imidazole)_4]^{2+}$ complex ($g_{//}=2.26$, $A_{//}=179$ G, $g_{\perp}=2.05$ at pH 8). The superhyperfine structures on the $g_{\perp}$ region are probably attributable imidazole nitrogens of histidine residues judging from the spacing of about 14 G. The seven or nine superhyperfine lines are theoretically an indicative of coordination of three or four equivalent nitrogens around Cu(II), respectively. In Figs. 2B and 3B, eight nitrogen superhyperfine lines are observed. Thus the present findings do not permit us to conclude which of $(N)_3$- or $(N)_4$-coordination is valid. However, on the basis of these superhyperfine structures, we can actually understand that copper ions at the active site in all horseshoe crab hemocyanins are surrounded by at least three nitrogens, probably histidine imidazoles.

Contrary to the case of squid Co(II)–Hc,[13] the amount of Co(II) introduced into horseshoe crab apohemocyanins essentially reached 100% of the total sites for copper. In the light of the absorption and MCD spectra illustrated in Figs. 4 and 5, coordination geometries around the two Co(II) ions at the active site were proved to be tetrahedral and almost equal to each other. Horseshoe crab Co(II) hemocyanins did not take up molecular oxygen either, although they have two adjacent Co(II) ions contrary to the case of squid Hc. This may be understood by taking into account the structural restriction of the Co(II)-binding site that favors the tetrahedral but not the octahedral geometry which enables binding of dioxygen as exhibited by many Co(II)–dioxygen complexes of low molecular weights.[29,34] The previous experimental results of squid Co(II)–Hc revealed that at least one of the two adjacent copper sites in deoxyhemocyanin provides copper with a tetrahedral-like environment, where some histidine–imidazoles are arranged as ligating groups. In the case of horseshoe crab hemocyanins, the environment of the two adjacent metal sites in deoxy form is considered to be a little more seriously distorted from tetrahedral geometry than that of the active site of squid deoxyhemocyanin, as displayed by the broad splitting of the spin allowed transition ($^4A_2(F)\rightarrow{}^4T_1(P)$) band. The amino acid residues around the metal sites in deoxy-form might be at least three histidyl imidazoles in the light of the ESR measurements of oxyhemocyanins treated with ethylene glycol. Furthermore the fourth coordination site of tetrahedral Co(II) might be occupied by a water molecule.

Recently Spiro *et al.* described a trigonal-like geometry of Cu(I) center bound by three imidazoles in deoxyhemocyanin.[9] Their conclusion does not necessarily contradict our present data, since the Cu(I) sites in deoxy form are supposed to undergo a geometrical rearrangement from a trigonal-like coordination geometry into a tetrahedral-like geometry upon substitution of Co(II) for Cu(I). Thus the active site of native oxyhemocyanin is considered as constituted from a pair of five-coordinate Cu(II) ions (distorted trigonal bipyramidal or square pyramidal geometries) which are bridged by the bound O_2^{2-} and by a putative extra bridging ligand. Although the existence of a bridging protein ligand such as tyrosine phenol was proposed by many investigators,[9,20,35] based on ESR-silent character of metHc, there has been no direct evidence for the presence of phenolate residue.[36] From the spectral investigations (MCD) of the Co(II)–substituted hemocyanins, possibility of presence of tyrosine bridge still remains unknown.

We should like to thank Prof. Koichi Sekiguchi and Dr. Hiroaki Sugita of the University of Tsukuba for providing the horseshoe crab hemocyanins and for their helpful discussions, and Prof. Seizo Misumi of Kyushu Sangyo University for measurements of CD and MCD spectra and for valuable discussion. The kindly suggestions by Dr. Wasuke Mori of this College of General Education are also acknowledged. This work was supported by a Grant-in-Aid for special Project Research No. 56109009 from the Ministry of Education, Science and Culture of Japan.

A New Type of P-C and C-C Bond Cleavage Reactions in α-Trimethylsilyloxy-β-oxo Phosphonates and α-Ethoxy-β-oxo Phosphonates. The Synthesis of Unsymmetrical α-Hydroxy Ketones Utilizing 1:1 Carbonyl Adducts of Diethyl Trimethylsilyl Phosphite with Benzaldehyde

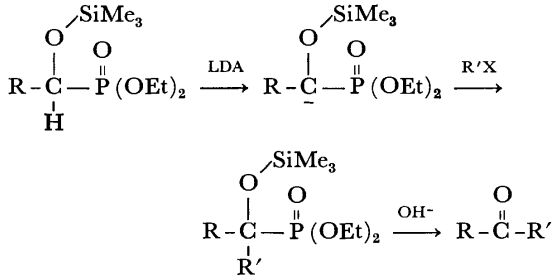
Mitsuo SEKINE, Masashi NAKAJIMA, and Tsujiaki HATA*

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received April 10, 1981)

α-Lithiated diethyl α-(trimethylsilyloxy)benzylphosphonate underwent facile acylation with various acylating agents to afford the corresponding α-acylated products in good yields. On treatment of the α-acylated products with 1 M† NaOH–EtOH (1:1, v/v) the P–C bond was cleaved with elimination of diethyl phosphate to give α-hydroxy ketones predominantly. On the other hand, when diethyl α-acyl-α-ethoxybenzylphosphonates were treated under the same conditions, they were rather stable and recovered. However, the prolonged alkaline treatment or the use of 4 M NaOH–EtOH (1:1, v/v) resulted in the C–C bond cleavage giving carboxylic acids and diethyl α-ethoxybenzylphosphonate in quantitative yields, respectively. The mechanisms of the above two reactions were proposed and discussed in connection with the Perkow reaction and related reactions.

Our recent studies on the unsymmetrical ketone synthesis,[2,3] using 1:1 carbonyl adducts of diethyl trimethylsilyl phosphite with aldehydes, have shown that α-alkylated α-trimethylsilyloxy phosphonates were converted by one-step treatment with dilute sodium hydroxide solution to carbonyl compounds with elimination of diethyl phosphonate ion. The simultaneous



removal of the trimethylsilyl group and the tervalent phosphoryl group was considered to be the result of the neighboring participation of α-phosphoryl group where hydroxide ion attacked the phosphoryl center followed by intramolecular migration of the trimethylsilyl group from the α-oxygen to the phosphoryl oxygen so that trimethylsilanol could be eliminated.[2] Thus, it is now recognized that α-lithiated 1-(trimethylsilyloxy)alkylphosphonates can serve as a new type of acyl anion equivalents.

In this paper, we wish to report acylation of diethyl α-(trimethylsilyloxy)benzylphosphonate (**1**), conversion of the acylated products to α-hydroxy ketones, and also a novel type of C–C bond cleavage reactions in connection with the α-hydroxy ketone formation. A preliminary report of this work has already appeared.[5]

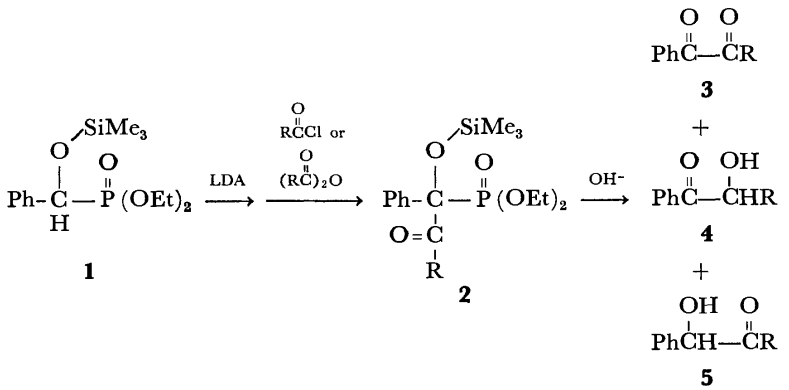
Results and Discussion

In order to obtain α-diketones from α-acylated α-(trimethylsilyloxy)benzylphosphonates in a manner similar to that described in the synthesis of unsymmetrical ketones,[2,3] we examined the acylation of **1** and the alkaline treatment of the acylated products (**2**) which would be expected to give α-diketones. Acylation of lithiated **1** with various acylating agents is summarized



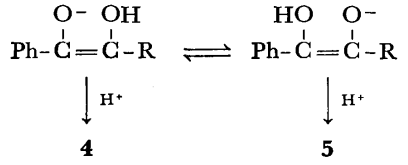
† 1 M=1 mol dm^{-3}.

Table 2. Alkaline treatment of acylated products **2**

Phosphonate	Time/min	Products	
		Yield of **3**/%	Yields of **4** and **5**/%[a]
2a	5	8	77 (**4a**)
2b	5	10	72 (**4b**)
2c	30	4	88 (**5c**)
2d	5	0	66 (**4d**:**5d**=1:2.8)
2e	10	0	83 (**4e**:**5e**=1:1.3)
2f	10	0	66 (**4f**:**5f**=1:2)

a) The ratio of **4** and **5** was determined by NMR spectra.

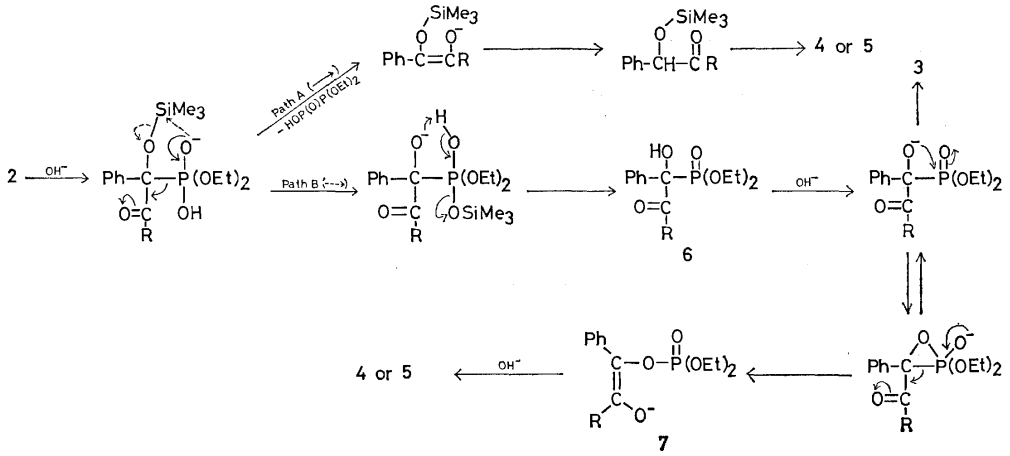
in Table 1. As in the case of the α-alkylation of lithiated **1**,[2,3] the acylation was also satisfactory. In the α-acylation of **1** with aliphatic acylating agents, acid anhydrides were found to be superior to acyl chlorides. The acylated products **2** were treated with 1 M NaOH–EtOH (1:1, v/v) under the same conditions as in the case of the unsymmetrical ketone synthesis. However, the alkaline treatment of **2a** resulted in the formation of benzil in only 8% yield. The main product in this reaction was found to be benzoin (**4a**) which was isolated in 77% yield. Similar results were obtained in the case of **2b** and **2c**. Especially, in the case of **2d**—**f**, α-hydroxy ketones were exclusively obtained. As shown in Table 1, the formation of **4** and/or **5** depends on the substituent of R. Under the alkaline conditions where α-hydroxy ketones were obtained, initially formed α-hydroxy ketones might be in equilibrium between the following two possible enediol enolates. In the case of **2b**, the equilibrium



lies so far to the left because *p*-chlorophenyl group, an electron-withdrawing group, stabilizes the anion of the left compound through the double bond so that **4b** was exclusively obtained. Contrary to this result, the alkaline treatment of **2c** gave **5c** owing to the resonance effect of *p*-methoxyphenyl group as the electron-donating group.

If R is alkyl groups as in the case of the alkaline treatment of **2d**—**f**, the equilibrium lies to the right. Consequently, **5** was obtained predominantly over **4**. The ratio of **5**/**4** decreased in the order of methyl, isopropyl, butyl. This order, however, was reverse to that expected from the electronic effect of the alkyl substituents. Although the reason is not clear, in these cases probably the steric effects in the the protonation of the endiol enolates might be more important factor than the electronic environment.

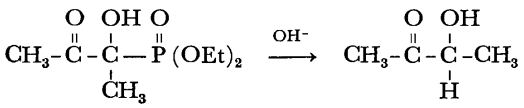
There might be two possible mechanisms for the predominant formation of α-hydroxy ketones. One of them is the mechanism involving an initial attack of hydroxide ion on the phosphorus followed by P–C bond cleavage with concomitant formation of enolate ion (see Path A in Scheme 1).[6] The other mechanism is as follows: The trimethylsilyl group was first eliminated according to a mechanism similar to that described in the case of the alkaline treatment of α-alkylated 1-(trimethylsilyloxy)alkylphosphonates[2,3] and the resulting α-hydroxy β-oxo phosphonate (**6**) is deprotonated followed by phosphoryl migration from carbon to oxygen and the subsequent hydrolysis of the resulting enediol phosphate (**7**) (see Path B in Scheme 1). The latter is closely related to the mechanisms of the Perkow reaction[7] and the Kukhtin-Ramirez oxyphosphorane formation[8] which are thought to proceed *via* an initial attack of the phosphorus on the carbonyl carbon followed by phosphoryl rearrangement.[9,10] In the present α-hydroxy ketone formation, the latter mechanism (Path B) was indirectly supported by the following experiment: Treatment of **2a** with a catalytic amount of *p*-toluenesulfonic acid in methanol–water (1:1, v/v) under reflux for 2 h gave diethyl α-benzoyl-α-hydroxybenzylphosphonate (**6**) in 66% yield. On treatment of **6** with 1 M NaOH–EtOH under the same conditions as with the alkaline treatment of **2a**, **3a**, and **4a** were obtained in 67 and 11% yields, respectively. The ratio of **3a** to **4a** was quite similar to that obtained from **2a**.



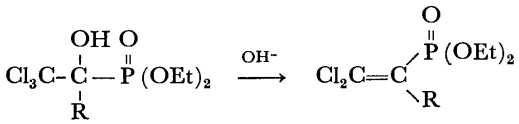
Scheme 1.

$$\mathbf{2a} \xrightarrow{H^+} \mathbf{6} \xrightarrow{OH^-} \mathbf{3a} + \mathbf{4a}$$

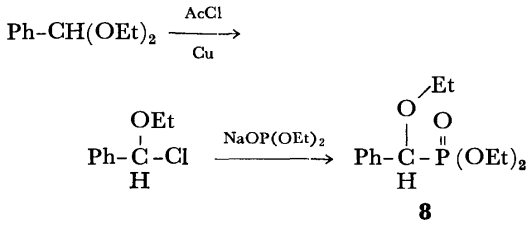
In connection with the mechanism *via* Path B, Kukhtin[11] reported a similar type of phosphoryl rearrangement in the alkaline treatment of the 1:1 carbonyl adduct of diethyl phosphonate with biacetyl.



Moreover, α-hydroxy-β,β,β-trichloro phosphonates were known to undergo phosphoryl rearrangement on treatment with alkali leading to the corresponding enol phosphates.[12]



In order to ascertain the mechanism *via* Path B, we prepared α-alkoxybenzylphosphonate (**8**) substituted with an ethoxy group in place of the trimethylsilyloxy group according to the following equation.

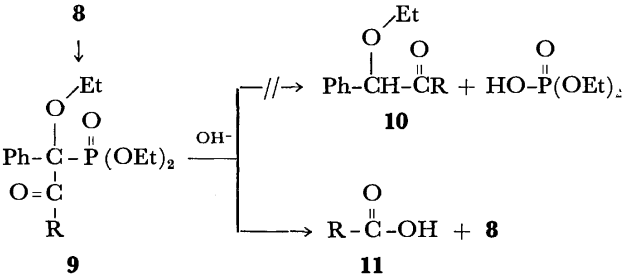


The acylation of **8** with acyl chlorides or acid anhydrides was essentially almost the same as that of **1**. The results are summarized in Table 3.

We considered that, if the α-hydroxy ketone formation from **2** was attributed to Path A, the alkaline treatment of the acylated products (**9**) would give α-ethoxy ketones (**10**). On the other hand, if Path B was the real process, **9** would be recovered unchanged since the ethyl group could not be migrated to the phosphoryl oxygen under these conditions owing to the stable Et–O bond. Therefore, we examined the hydrolysis of **9a** under the same alkaline conditions as described in the alkaline treatment of **2a**. When **9a** was treated with 1 M NaOH–EtOH (1:1, v/v) for 5 min, no reaction took place and 96% of **9a** was recovered. Similar results were obtained also in the case of **9b**—**d**. These results are summarized in Table 4. From these results, we concluded that **4** or **5** was formed *via* Path B.

Table 3. Acylation of diethyl α-ethoxybenzylphosphonates (**8**)

Acylating agent	Acylated product R		Yield of **9** %
$C_6H_5C(O)Cl$	**9a**	C_6H_5	81
$4\text{-}ClC_6H_4C(O)Cl$	**9b**	$4\text{-}ClC_6H_4$	63
$4\text{-}MeOC_6H_4C(O)Cl$	**9c**	$4\text{-}MeOC_6H_4$	81
$CH_3C(O)Cl$	**9d**	CH_3	61



C–C Bond Cleavage of **9**. In connection with the above alkaline treatment of **9**, we found a new type of C–C bond cleavage reactions. When the alkaline treatment of **9a** was prolonged or more concentrated sodium hydroxide solution was employed, some reaction occurred. However, the reaction observed was not P–C bond but C–C bond cleavage reaction. When **9a** was treated with 1 M NaOH–EtOH (1:1, v/v) for 5 h, benzoic acid and **8** were obtained in quantitative yields, respectively. The above C–C bond cleavage reaction is regarded as a

Table 4. Alkaline treatment of acylated products **9**

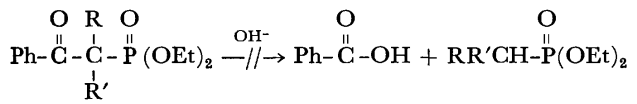
a) The ratio of NaOH and EtOH was 1:1 (v/v) and the reaction was carried out at room temperature. b) No efforts to isolate acetic acid were made.

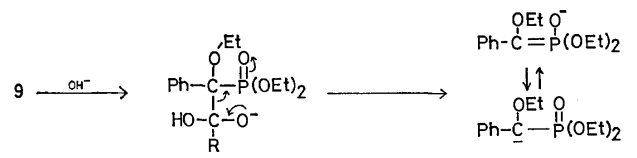
similar type of "acid degradation" to that in acetoacetate synthesis.[13] The conditions and results of the alkaline treatment of **9a—d** are summarized in Table 4. Table 4 implies that the reaction rate of the C–C bond cleavage is increased by an electron-withdrawing group substituted at the *p*-position of the benzoyl group and retarded by an electron-donating group. Although a numerous examples have appeared of C–C bond cleavage reactions in acetoacetate synthesis, the present type of fragmentation has not been reported in the chemistry of β-oxo phosphonates to our knowledge. This is substantially because alkoxycarbonyl groups in acetoacetates can stabilize α-carbanions more effectively than dialkoxyphosphoryl groups so that the C–C bond cleavage of acetoacetate derivatives takes place easily.

In order to study the effect of α-substituents of phosphonates in the C–C bond cleavage reaction, the following three compounds were treated with alkali: As a consequence, α-unsubstituted benzoylmethylphosphonate (**12**), α-monoalkylated and dialkylated benzoylmethylphosphonates (**13**) and (**14**) were found to



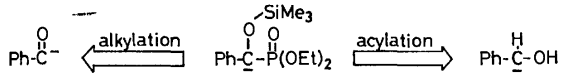
12: R=R′=H
13: R=H, R′=CH_3
14: R=R′=CH_3

be quite stable under the alkaline conditions where the fission of the C–C bond of **9** took place. The facile cleavage of the C–C bond of **9** might be due to both ethoxy and phenyl substituents which could stabilize the α-carbanion (**15**) of **8** and hence assist the fission of the C–C linkage at the stage of the transition state.



15

Conclusion. It is noted that the α-carbanion of diethyl α-(trimethylsilyloxy)benzylphosphonate can serve as the benzyl anion equivalent when it was allowed to react with acylating agents followed by the successive alkaline treatment. The α-hydroxy ketone synthesis has proved to involve a phosphoryl rearrangement where the phosphoryl group was eliminated as diethyl phosphate. This is in contrast to the unsymmetrical ketone synthesis from the same carbanion where the phosphoryl group was removed as diethyl phosphonate.



In summary, the compounds having both benzoyl and diethoxyphosphoryl groups on a quarternary carbon undergo C–C bond cleavage reactions with alkali, while the P–C bond cleavage occurs especially when a hydroxyl group is substituted on the quarternary carbon. The ease of the former cleavage reaction depended on the substituents on the quarternary carbon.

Experimental

Melting points and boiling points were uncorrected. IR spectra were recorded on a Hitachi 124 spectrophotometer. ^1H NMR spectra were recorded on a Hitachi R-24B spectrometer. Tetrahydrofuran (THF) was purified by distillation from NaOH pellets followed by redistillation from sodium ribbon and used finally after distillation from benzophenone ketyl. All lithiation and acylation reactions were carried out under argon atmosphere. Lithium diisopropylamide (LDA) was prepared by treatment of diisopropylamine with one equivalent of butyllithium (1.8 M solution in hexane) in THF at −78 °C for 30 min under argon atmosphere.

*General Procedure for Acylation of Lithiated Diethyl α-Trimethylsilyloxybenzylphosphonate (**1**).* To a cooled solution (−78 °C) of LDA (3.3 mmol) in THF (10 ml) was added dropwise diethyl α-trimethylsilyloxybenzylphosphonate (**1**) (928 mg, 3.0 mmol). The mixture was stirred for 0.5 h and then an appropriate acylating agent (3.3 mmol) was added at −78 °C. After being stirred for 0.5 h, the resulting mixture was warmed to room temperature and poured into a mixture of 1 M NH_4Cl (20 ml) and CH_2Cl_2 (20 ml) with vigorous stirring. The organic layer and further extracts with CH_2Cl_2 (3×20 ml) were combined, dried over Na_2SO_4, and evaporated *in vacuo*. The residual oil was chromatographed on silica gel with hexane–ether to afford the corresponding **2**.

*Diethyl α-Trimethylsilyloxy-α-benzoylbenzylphosphonate (**2a**).* The structure of this compound was confirmed by direct comparison with an authentic sample prepared previously.[14]

*Diethyl α-Trimethylsilyloxy-α-(4-chlorobenzoyl)benzylphosphonate (**2b**).* Mp 49—52 °C; NMR (CCl_4) δ 0.12(9H, s, Me_3Si), 1.20(3H, t, $J_{H-H}=J_{H-P}=7$ Hz, one of CH_3C–O), 1.24(3H, t, $J_{H-H}=J_{H-P}=7$ Hz, one of CH_3C–O), 3.76—4.42(4H, m, CH_2O), 7.15(2H, d, $J_{H-H}=8.5$ Hz, ArH), 7.25(3H, m, ArH), 7.52(2H, m, ArH), 7.72(2H, d, $J_{H-H}=8.5$ Hz, ArH).

Found: C, 55.68; H, 6.12%. Calcd for $C_{21}H_{28}O_5ClPSi$: C, 55.44; H, 6.20%.

*Diethyl α-Trimethylsilyloxy-α-(4-methoxybenzoyl)benzylphosphonate (**2c**).* Mp 92—98 °C; IR(NaCl) 968, 1027, 1055, 1146, 1192, 1255 (νP=O), 1320, 1516, 1579, 1604, 1672 (C=O), 2800, 2900, and 3065 cm^{-1}; NMR(CCl_4) δ 0.14(9H, s, Me_3Si), 1.19(3H, t, $J_{H-H}=J_{H-P}=7$ Hz, one of CH_3C–O), 1.23(3H, t, $J_{H-H}=J_{H-P}=7$ Hz, one of CH_3C–O), 3.68(3H, s, CH_3O), 4.02(4H, m, CH_2O), 6.67(2H, d, $J_{H-H}=10$ Hz, ArH), 7.25(3H, m, ArH), 7.58(2H, m, ArH), 7.78(2H, d, $J_{H-H}=10$ Hz, ArH).

Found: C, 59.09; H, 6.85%. Calcd for $C_{22}H_{31}O_6PSi$: C, 58.65; H, 6.94%.

*Diethyl α-Trimethylsilyloxy-α-acetylbenzylphosphonate (**2d**).* Oily substance: NMR(CCl_4) δ 0.20(9H, s, Me_3Si), 1.16 (3H, t, $J_{H-H}=J_{H-P}=7$ Hz, one of CH_3C–O), 1.25(3H, t, $J_{H-H}=J_{H-P}=7$ Hz, one of CH_3C–O), 2.22(3H, s, $CH_3C(O)$), 3.73—4.32(4H, m, CH_2O), 7.30(3H, m, ArH), 7.65(2H, m, ArH).

Found: C, 53.65; H, 7.81%. Calcd for $C_{16}H_{27}O_5PSi$: C, 53.61; H, 7.59%.

*Diethyl 1-Trimethylsilyloxy-3-methyl-2-oxo-1-phenylbutylphosphonate (**2e**).* Oily substance: NMR(CCl_4) δ 0.20(9H, s, Me_3Si), 0.70(3H, d, $J_{H-H}=7$ Hz, one of $(CH_3)_2C$), 0.99 (3H, d, $J_{H-H}=7$ Hz, one of $(CH_3)_2C$), 1.16(3H, t, $J_{H-H}=$

7 Hz, one of CH_3C–O), 1.28(3H, t, J_{H-H}=7 Hz, one of CH_3C–O), 3.42(1H, m, CH), 3.70—4.33(4H, m, CH_2O), 7.25(3H, m, ArH), 7.70(2H, m, ArH).

Found: C, 55.96; H, 8.21%. Calcd for $C_{18}H_{31}O_5PSi$: C, 55.94; 8.09%.

*Diethyl 1-Trimethylsilyloxy-2-oxo-1-phenylpentylphosphonate (**2f**).* Oily substance: NMR(CCl_4) δ 0.20(9H, s, Me_3Si), 0.80(3H, t, J_{H-H}=7 Hz, CH_3C), 1.14(3H, t, J_{H-H}=7 Hz, one of CH_3C–O), 1.24(3H, J_{H-H}=7 Hz, one of CH_3C–O), 1.50(2H, m, $CH_2CC(O)$), 2.57(2H, m, $CH_2C(O)$), 3.70—4.30(4H, m, CH_2O), 7.25(3H, m, ArH), 7.61(2H, m, ArH).

Found: C, 55.45; H, 7.92%. Calcd for $C_{18}H_{31}O_5PSi$: C, 55.94; H, 8.09%.

*Conversion of Acylated Compounds (**2**) into Acyloins (**4** and **5**) under Alkaline Conditions.* An appropriate acylated compound **2** was dissolved in ethanol (20 ml) at room temperature. To the solution was added 1 M sodium hydroxide (20 ml). The resulting solution was stirred at room temperature until **2** had disappeared and then poured into a mixture of 1 M NH_4Cl (20 ml) and CH_2Cl_2 (20 ml) with stirring. The organic layer was collected, combined with further extracts with CH_2Cl_2 (3×20 ml), dried over Na_2SO_4, and evaporated to dryness. The residual oil was chromatographed on silica gel with hexane–ether to afford the corresponding **4** and **5** as listed Table 2.

*Diethyl α-Benzoyl-α-hydroxybenzylphosphonate (**6**).* To a solution of **2a** (1.846 g, 4.39 mmol) in methanol–water (1:1, v/v, 30 ml) was added a catalytic amount of *p*-toluenesulfonic acid monohydrate (50 mg). The solution was refluxed for 2 h and diluted with water (30 ml) after cooling. The aqueous solution was extracted with CH_2Cl_2 (4×30 ml) and the organic layers were combined, dried over Na_2SO_4, and evaporated *in vacuo* to dryness. The residue was chromatographed on silica gel with hexane–ether to afford **6** (1.014 g, 66%): Mp 76—78 °C; NMR($CDCl_3$) δ 1.15(3H, t, J_{H-H}=J_{H-P}=7 Hz, one of CH_3C–O), 1.27(3H, t, J_{H-H}=J_{H-P}=7 Hz, one of CH_3C–O), 3.67—4.40(6H, m, CH_2O and CH_2Cl), 3.85(1H, s, OH), 7.27(3H, m, ArH), 7.48 (2H, m, ArH).

Found: C, 61.17; H, 6.29%. Calcd for $C_{18}H_{21}O_5P\cdot 1/4H_2O$: C, 61.27; H, 6.14%.

*Diethyl α-Ethoxybenzylphosphonate (**8**).*[15] Diethyl phosphonate (7.95 g, 57.6 mmol) was added dropwise to sodium (1.50 g, 65.2 mmol) in dry ether (25 ml) at 10 °C. After evolution of hydrogen gas ceased, the mixture was refluxed for an additional 5 h and cooled in an ice bath to 0 °C. To the cooled solution was added dropwise α-chlorobenzyl ethyl ether (10.2 g, 59.8 mmol) and the mixture was stirred at room temperature for 1 h. The resulting solution was poured into a mixture of 1 M NH_4Cl (30 ml) and CH_2Cl_2 (30 ml). The organic phase was collected and the aqueous layer was further extracted with CH_2Cl_2 (3×30 ml). The extracts were combined, dried over Na_2SO_4, evaporated *in vacuo*, and chromatographed on silica gel with hexane–ether to afford **8** (10.7 g, 68%): Bp 121—136 °C/0.49—0.53 mmHg; IR(NaCl) 960, 1023, 1050, 1094, 1160, 1254 (νP=O), 1388, 1450, 1490, 2900, and 2960 cm^{-1}; NMR (CCl_4) δ 1.14(3H, t, J_{H-H}=J_{H-P}=7 Hz, one of CH_3C–O), 3.46(2H, q, J_{H-H}=7 Hz, CH_2O–C), 3.67—4.21(4H, m, CH_2O–P), 4.45(1H, d, J_{H-P}=15.5 Hz, CH), 7.27(5H, m, ArH).

Found: C, 57.16; H, 7.99%. Calcd for $C_{13}H_{21}O_4P$: C, 57.35; H, 7.7%.

*General Procedure for Acylation of Diethyl α-Ethoxybenzylphosphonate (**8**).* To a cooled (−78 °C) solution of LDA (8.8 mmol) in dry THF (20 ml) was added **8** (2.18 g, 8 mmol). After stirring at −78 °C for 0.5 h, an appropriate acyl chloride (9.6 mmol) was added dropwise to the mixture. The usual work-up described in the case of acylation of **1** afforded the corresponding **9**.

*Diethyl α-Ethoxy-α-benzoylbenzylphosphonate (**9a**).* Oily substance: IR(NaCl) 965, 1045, 1100, 1162, 1182, 1240 (νP=O), 1260, 1392, 1448, 1485, 1597, 1680, 2915, 2970, and 3020 cm^{-1}; NMR(CCl_4) δ 1.07(3H, t, J_{H-H}=7 Hz, CH_3C–O–C), 1.22(3H, t, J_{H-H}=J_{H-P}=7 Hz, one of CH_3C–O), 1.26(3H, t, J_{H-H}=J_{H-P}=7 Hz, one of CH_3C–O), 3.05—3.65(1H, m, one of CH_2–O–C), 3.72—4.45(5H, m, one of CH_2–O–C and CH_2O–P), 7.25(5H, m, ArH), 7.25(3H, m, ArH), 7.67—7.90(2H, m, ArH).

Found: C, 63.48; H, 6.83%. Calcd for $C_{20}H_{24}O_5ClP$: C, 63.82; H, 6.70%.

*Diethyl α-Ethoxy-α-(4-chlorobenzoyl)benzylphosphonate (**9b**).* Oily substance: NMR(CCl_4) δ 0.98—1.40(9H, m, CH_3), 3.06—4.58(6H, m, CH_2), 7.05—7.60(5H, m, ArH), 7.18 (2H, d, J_{H-H}=9 Hz, ArH), 7.75(2H, d, J_{H-H}=9 Hz, ArH).

Found: C, 58.36; H, 6.17; Cl, 9.06%. Calcd for $C_{20}H_{24}O_5ClP$: C, 58.47; H, 5.89; Cl, 8.63%.

*Diethyl α-Ethoxy-α-(4-methoxybenzoyl)benzylphosphonate (**9c**).* Oily substance: NMR(CCl_4) δ 0.99—1.04(9H, m, CH_3), 3.10—4.48(6H, m, CH_2), 3.75(3H, s, CH_3O), 6.65(2H, d, J_{H-H}=9 Hz, ArH), 7.00—7.57(5H, m, ArH), 7.87(2H, d, J_{H-H}=9 Hz, ArH).

Found: C, 61.88; H, 6.73%. Calcd for $C_{21}H_{27}O_6P$: C, 62.06; H, 6.70%.

*Diethyl α-Ethoxy-α-acetylbenzylphosphonate (**9d**).* Oily substance: NMR(CCl_4) δ 1.07—1.63(9H, m, CH_3), 2.01 (3H, s, $CH_3C(O)$), 3.23—4.30(6H, m, CH_2), 7.03—7.60 (5H, m, ArH).

Found: C, 57.12; H, 7.32%. Calcd for $C_{15}H_{23}O_5P$: C, 57.32; H, 7.37%.

*Reaction of Diethyl α-Ethoxy-α-acylbenzylphosphonate (**9**) with Alkali.* An appropriate diethyl 1-ethoxy-2-oxobenzylphosphonate (**9**) (2 mmol) was dissolved in ethanol (20 ml) and 20 ml of 1 M NaOH was added at once with stirring. The reaction conditions are summarized in Table 4. After the reaction was complete, the mixture was poured into a mixture of 1 M NH_4Cl (30 ml) and CH_2Cl_2 (30 ml) put in a separatory funnel. The organic phase was collected and the aqueous layer was extracted with CH_2Cl_2 (2×30 ml). The extracts were combined, dried over Na_2SO_4, evaporated *in vacuo*, and chromatographed on silica gel with hexane–ether to afford **8** and/or the starting material **9**. The aqueous layer was acidified to pH 1.0 by concd HCl and then extracted with CH_2Cl_2 (3×20 ml). The extracts were combined and dried over Na_2SO_4. Removal of the solvent gave a carboxylic acid. The structures of the products were confirmed by comparison with authentic samples.

*Preparation of Diethyl 1-Benzoylethylphosphonate (**13**) and Diethyl 1-Benzoyl-1-methylethylphosphonate (**14**).* To a suspension of sodium hydride (50%, 144 mg, 3 mmol) in dry THF (6 ml) was added diethyl benzoylmethylphosphonate (587 mg, 2.3 mmol) at room temperature. After stirring for 18 h, the resulting homogeneous solution was treated with 1 M NH_4Cl (20 ml) and extracted with CH_2Cl_2 (3×20 ml). The extracts were combined, dried over Na_2SO_4, evaporated, and chromatographed on silica gel with benzene–ethyl acetate to afford **13**[16] (260 mg, 42%) and **14** (228 mg, 35%): NMR($CDCl_3$) δ 1.29(6H, t, J_{H-H}=7 Hz, CH_3C–O), 1.68(6H, d, J_{H-P}=17 Hz, CH_3C–P), 4.08(2H, t, J_{H-H}=J_{H-P}=7 Hz, one of CH_2O), 4.19(2H, t, J_{H-H}=J_{H-P}=7

† 1 mmHg≈133.322Pa.

Hz, one of CH_2O), 7.42(3H, m, ArH), 7.97(2H, m, ArH).

Found: C, 59.08; H, 7.43%. Calcd for $C_{14}H_{21}O_4P$: C, 59.15; H, 7.45%.

Stability of ***12***, ***13***, *and* ***14*** *under Alkaline Conditions.* Compound **12**, **13**, or **14** (0.5 mmol) was dissolved in ethanol (5 ml) and 5 ml of 1 M NaOH was added. TLC after 1 h showed that these compounds were stable under these conditions and remained as single spots.

Silyl Phosphites. XVIII. Versatile Utility of α-(Trimethylsilyloxy)-alkylphosphonates as Key Intermediates for Transformation of Aldehydes into Several Carbonyl Derivatives[1)]

Mitsuo SEKINE, Masashi NAKAJIMA, Akiko KUME, Akio HASHIZUME, and Tsujiaki HATA*

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received May 28, 1981)

Carbonyl addition compounds of diethyl trimethylsilyl phosphite (DTMSP) with aldehydes were converted, by treatment with lithium diisopropylamide (LDA) followed by the successive alkylation and alkaline hydrolysis, to carbonyl derivatives involving aldehydes, unsymmetrical ketones, β,γ-unsaturated ketones, and carboxylic acids. β-Substituted carboxylic esters and γ-substituted lactones were prepared by use of the carbonyl addition compounds of DTMSP with α,β-unsaturated aldehydes.

Since Corey and Seebach[2)] introduced acyl anion equivalents by use of 1,3-dithianes in 1965, a number of reagents belonging to this category have appeared in the literature and have proved to be useful key intermediates in modern organic synthesis. A few years ago, Seebach advocated the concept of "Umpolung."[3k)] These studies in this field have recently been reviewed.[3)]

In this paper, we wish to report versatile utility of the carbonyl addition products of DTMSP with aldehydes in detail.[4)]

In connection with our study, several related reactions have recently been reported.[5)]

Results and Discussion

It is well known that the carbon-phosphorus bond of dialkyl α-hydroxy phosphonates is readily cleaved under alkaline conditions to give carbonyl compounds and dialkyl phosphonates.[6)] This reaction pattern

$$R^1R^2\overset{OH}{\overset{|}{C}}\text{-P(O)(OR}^3)_2 \xrightarrow{OH^-} R^1\text{-}\overset{O}{\overset{\|}{C}}\text{-}R^2 + \text{H-P(O)(OR}^3)_2$$

led us to study alkylation of the carbonyl addition compounds obtained by the reaction of silyl phosphites with aldehydes, since the formation of unsymmetrical ketones were expected on treatment of the α-alkylated products with acid followed by alkali.

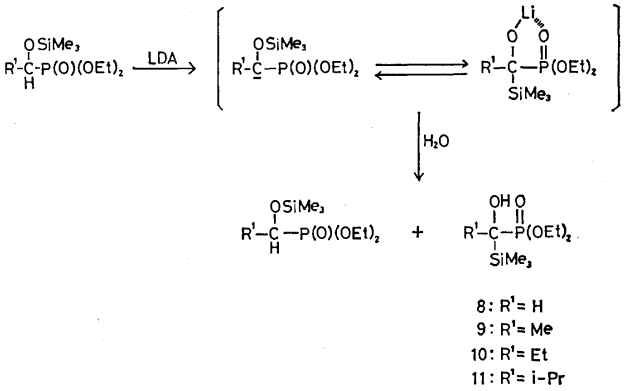
$$R^1\text{-}\overset{OSiMe_3}{\overset{|}{C}}\text{H—P(O)(OR}^3)_2 \xrightarrow{R^2X}$$

1—7

$$R^1\text{-}\overset{OSiMe_3}{\overset{|}{C}}(R^2)\text{—P(O)(OR}^3)_2 \xrightarrow{H^+} \xrightarrow{OH^-} R^1\text{-}\overset{O}{\overset{\|}{C}}\text{-}R^2$$

1: R^1=Ph **5**: R^1=*i*-Pr
2: R^1=H **6**: R^1=*n*-C_7H_{15}
3: R^1=Me **7**: R^1=$PhCH_2$
4: R^1=Et

It was found that metalation of diethyl α-(trimethylsilyloxy)benzylphosphonate (**1**) with LDA in THF proceeded quite easily to afford relatively stable α-carbanion species which reacted with alkyl halides to give the alkylated products (**18—30**) in good yields. However, in the case of addition compounds (**2—4**) of DTMSP with aliphatic aldehydes, the lithiation of **2—4** caused the Wittig rearrangement[7)] (or the anti-Brook rearrangement[8)]) of trimethylsilyl group.



Scheme 1.

The product distributions of **2—4**/**8—10** after quenching with 1 M† NH_4Cl at −78 °C or at room temperature are summarized in Table 1. Table 1 implies that the equilibrium between the carbanion and the oxido ion is affected by both the alkyl substituent and the temperature. The ratio of the carbanion to the oxido ion grows up with a rise in temperature and also with an increase in the bulkiness of the α-substituent. The equilibrium between **4** and **10** in 1,2-dimethoxyethane (DME) is in favor of **10** as compared with THF (see Table 1). The above-mentioned facile Wittig rearrangement of the trimethylsilyl group can be explained as follows; the *O*-lithio derivatives (oxido ion) can be stabilized by an intramolecular chelation with the neighboring group of $P(O)(OEt)_2$. The Wittig rearrangement of this type has been known little.[9)] Only one example has been reported by West where benzyl trimethylsilyl ether underwent the Wittig rearrangement under special conditions using an excess amount of strong lithiating agents such as *t*-butyllithium.[9a)]

Hünig[10a—e)] reported that synthesis of aromatic ketones utilizing the addition compounds of aldehydes with trimethylsilyl cyanide. In connection with the Wittig rearrangement of α-trimethylsilyloxy phosphonates mentioned above, alkylation of 2-(trimethylsilyloxy)propionitrile (**12**) was conducted. However, all attempts to obtain the alkylated products (**13**) were unsuccessful. It is likely that the lithiated intermediate decomposes *via* the Wittig rearrangement to an acylsilane and cyanide ion which in turn react

† 1 M = 1 mol dm^{-3}.

to give a complex mixture. In this respect, the utility of α-trimethylsilyloxy phosphonates should be emphasized since α-oxido phosphonates do not decompose owing to the stable chelation as shown in Scheme 1 and exist in equilibrium with the reactive carbanion species so that the alkylation proceeds under certain conditions. In this sense, it is interesting that Stork[11] and other groups[12—14] reported the usefulness of anions of protected cyanohydrins as acyl carbanion equivalents which were also stabilized through intramolecular chelations.

In order to avoid the Wittig rearrangement of α-trimethylsilyloxy phosphonates, we attempted the preparation of diphenyl α-trimethylsilyloxy phosphonates (**14**) substituted by an electron-withdrawing group such as $P(O)(OPh)_2$ group in place of diethoxyphosphinyl group. However, diphenyl trimethylsilyl phosphite (**15**) could not be prepared as a pure material. We failed also to prepare the corresponding carbonyl addition compound (**14**) by the *in situ* reaction of diphenyl phosphonate with propionaldehyde in the presence of sodium followed by trimethylsilylation. On the other hand, trimethylsilyl diphenylphosphinite (**16**) could be prepared according to the reported procedure.[15] The phosphinite (**16**) underwent facile addition reaction with propionaldehyde to afford the corresponding adduct (**17**). However, this adduct was

found to be rather unstable compared with **4**. During the isolation of **17** by means of silica gel column chromatography, its decomposition to α-hydroxypropylphosphinite was observed to a considerable extent. Moreover, the lithiation of **17** led to a complex mixture.

From the above results, we finally chose the diethyl esters **1**—**7** as the precursors of acyl anion equivalents for transformation of aldehydes to ketones. The alkylation of **1** was satisfactory and a variety of alkyl halides could be employed. Since Table 1 suggested that at higher temperatures the equilibrium between the α-carbanion and the α-oxido ion was in favor of the former, the alkylation of **2**—**6** was carried out by

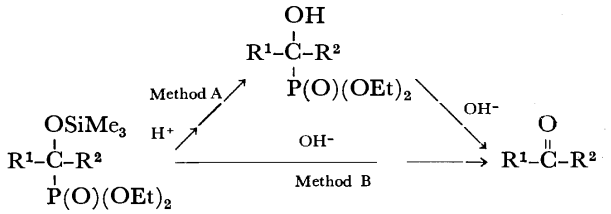
raising the temperature from −78 °C to room temperature. Consequently, the alkylated products **3**, **4**, and **31**—**40** were obtained in good yields. When the alkylation was performed at −78 °C, the alkylated product was not obtained and the Wittig rearrangement product was recovered. In the case of the alkylation of **7** having a relatively acidic β-proton, (*E*)-1-alkenylphosphonates were obtained as the main products (**41**—**43**). These conditions and results are summarized in Table 3. The conversion of the α-alkylated products into carbonyl compounds is illustrated in the following scheme. Acid treatment of



the alkylated products gave quantitatively α-hydroxy phosphonates, which in turn were treated with dilute sodium hydroxide solution to give the carbonyl compounds. The alkylated α-silyloxy phosphonates were converted also directly to ketones by the alkaline treatment as reported in a previous communication.[4a] These results are summarized in Table 5. In the case of the preparation of β,γ-unsaturated ketones, Method A was found to be essential. When Method B was employed, considerable amounts of isomers of α,β-unsaturated ketones were formed. However, the conversion of **31** into aldehyde under the conditions of Method A or Method B led to the aldol condensation product as the main product. It is generally recognized that adducts of aldehydes with nucleophiles, such as alcohols, sodium sulfite, and hydrogen cyanide, are more stable than those of ketones under neutral or alkaline conditions.[16] The aldol condensation product seems to be formed predominantly owing to the relatively slow cleavage of P–C bond in the α-hydroxy phosphonates initially formed by alkali. In fact, when **31** was treated with 0.5 M NaOH–EtOH (1:1, v/v)

TABLE 5. CONVERSION OF THE α-ALKYLATED α-TRIMETHYLSILYLOXY PHOSPHONATES TO CARBONYL COMPOUNDS

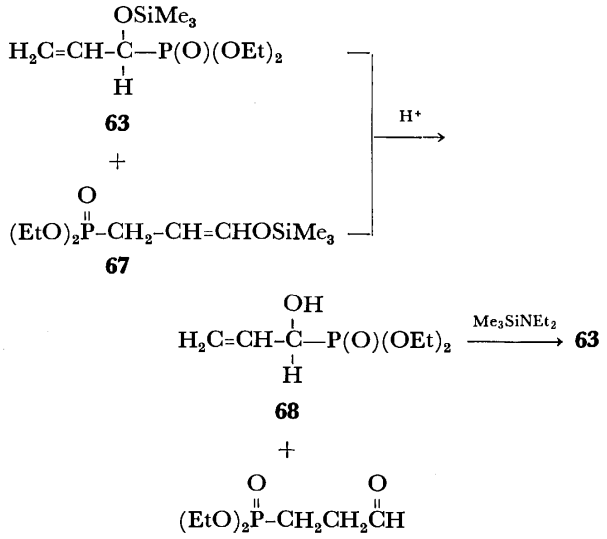
a) See Experimental.

and the reaction was quenched quickly after 1 min, diethyl 1-hydroxy-3-phenylpropylphosphonate (**60**) was isolated in quantitative yield. When **60** was further treated with the same alkali, the aldol condensation product was obtained as the main product. Therefore, our efforts were focussed on the P–C bond cleavage of **31** under milder conditions where the aldol condensation could be avoided. Thus, various conditions were tested in order to obtain aldehydes selectively. Finally, it was found that 3-phenylpropionaldehyde (**61**) could be obtained from **60** in 71% yield by employing the conditions of dilute sodium hydrogencarbonate in aqueous methanol under reflux for 2 h. In a similar manner, octanal (**62**) was obtained in 80% yield from **5**.

Synthesis of β-Alkylated Esters and Lactones. In order to extend the utility of 1:1 carbonyl adducts of DTMSP, we examined alkylation of 1,2-addition products obtained from DTMSP and α,β-unsaturated aldehydes.

The reaction of DTMSP with α,β-unsaturated aldehydes provided predominantly 1,2-carbonyl addition compounds (**64**—**66**).[4a] In the case of acrylaldehyde, 1,4-addition product (**67**), however, was formed along with the 1,2-carbonyl adduct (**63**). These products could not be separated by distillation or column chromatography. In order to separate **63** from the mixture, it was first treated with acid for removal of the trimethylsilyl group and the resulting α-hydroxy phosphonate (**68**) was obtained by column chromatography. This material was further trimethylsilylated by treatment with *N,N*-diethyltrimethylsilylamine to afford **63**.



It was found that the alkylation of these 1,2-addition products occurred at the γ-position to give (*E*)-1-(trimethylsilyloxy)-1-alkenylphosphonates (**69**), while deuteration of the lithio derivatives gave α-deuterated 1-trimethylsilyloxy phosphonates exclusively. These results are of interest since Hünig[10e] reported that the 1,2-adducts of trimethylsilyl cyanide with unsaturated aldehydes were transformed to α-alkylated products exclusively on treatment with LDA followed by alkyl halides. Stork[11] also described that a similar alkylation of protected cyanohydrins of α,β-unsaturated aldehydes resulted in the exclusive for-

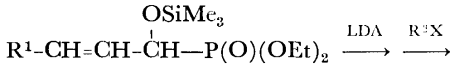
a) In this case, $CDCl_3$ was used as the solvent.

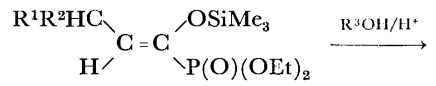
mation of α-alkylated products. Our results are in contrast to their two reports. The results of the highly regioselective γ-alkylation in the present reaction might be due to steric hindrance of the neighboring phosphoryl group. The (*E*)-1-(trimethylsilyloxy)-1-alkenylphosphonate **69** were sensitive toward moisture during work-up and tend to decompose gradually into acylphosphonates (**70**). Acylphosphonates are known to be labile toward moisture and decompose into carboxylic acids and dialkyl phosphonates.[17] It has been reported that reactions of acylphosphonates with nucleophiles such as alcohols,[18] amines,[18c,19] and carbanions[20] gave acylated products. Because of the instability of the alkylated products, the reaction mixture was further treated with alcohols in the presence of *p*-toluenesulfonic acid, whereupon the alkylated products were successfully converted *via* acylphosphonates to β-alkyl-substituted esters (**71**—**84**). These results

were summarized in Table 6.

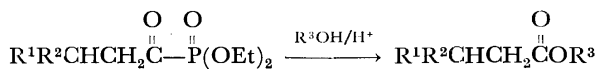


63—66

63: $R^1=H$ **65**: $R^1=n$-Pr
64: $R^1=Me$ **66**: $R^1=Ph$

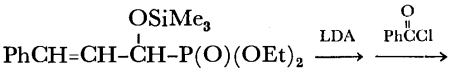


69a: $R^1=Ph$, $R^2=Me$
69b: $R^1=Ph$, $R^2=CH_2Ph$
69c: $R^1=n$-Pr, $R^2=CH_2Ph$

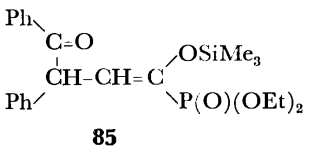


70 **71—84**

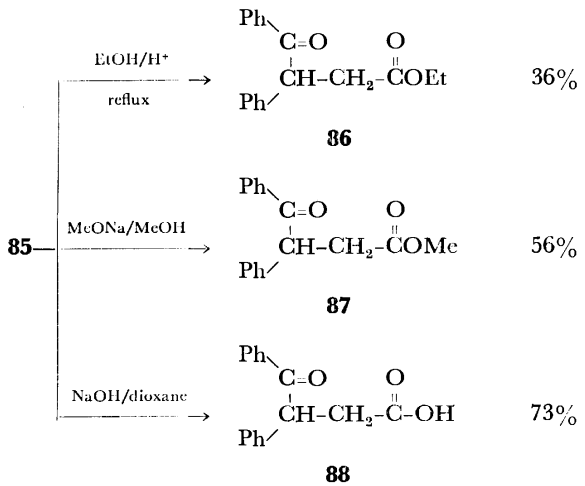
In a similar manner, benzoylation of the lithio derivative of **66** followed by treatment with alcohols under alkaline or acidic conditions or with aqueous sodium hydroxide solution gave the products depicted in the following scheme.



66

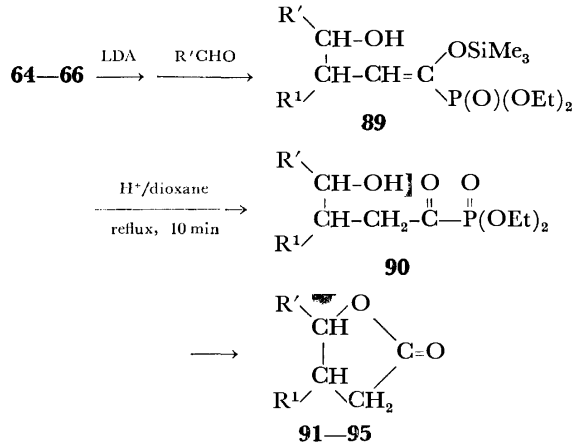


85



86 **87** **88**

Next, we examined the lactonization in term of intramolecular acylation utilizing the promising feature of acylphosphonate intermediates as acylating species. By treatment of the lithiated derivatives of **64—66** with aldehydes, 4-hydroxy-1-trimethylsilyloxy-1-alkenylphosphonates (**89**) could be expected to be formed. These phosphonates were also expected to be converted by acid treatment into 4-hydroxy-1-oxoalkylphosphonates (**90**), which would be cyclized under such acidic conditions to give lactones. Thus, several lactones (**91—95**) were obtained by one-pot reaction in good yields. These results are summarized in Table 8. Evans has recently reported a similar type of lactonization utilizing 1:1 carbonyl addition products of triethylsilyl *N,N,N′,N′*-tetramethylphosphorodiamidite with α,β-unsaturated aldehydes in which tetrabutylammonium fluoride was used for the removal of the trimethylsilyl group and for the cyclization.[21]



89 **90** **91—95**

In conclusion, it is noted that 1:1 carbonyl adducts of aldehydes with DTMSP could be used widely as the precursors of acyl anion equivalents and homoenolates.

Experimental

NMR spectra were measured at 60 MHz on a Hitachi R 24-B spectrometer. IR spectra were recorded on a Hitachi Model EPI-G3 spectrophotometer.

Materials. Tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) were distilled over potassium hydroxide after reflux for 6 h, redistilled over sodium wire after reflux for 6 h, and finally purified by distillation from benzophenone ketyl. Alkyl halides, acyl halides, carbonyl compounds, and other reagents were purified by distillation or recrystallization before use. Diethyl trimethylsilyl phosphite (DTMSP) was prepared according to the method previously reported.[1] Butyllithium (2—3 M) in hexane, kindly gifted from Sankyo Kasei Co., was used after titration.

All lithiation, alkylation, and acylation reactions were carried out under argon atmosphere.

Diethyl α-(Trimethylsilyloxy)benzylphosphonate (1).
Method A: To a solution of DTMSP (6.18 g, 29.4 mmol) in dry benzene (5 ml) was added dropwise benzaldehyde (3.21 g, 30.2 mmol) with continuous stirring. The mixture was stirred at room temperature for 6 h. After removal of the benzene *in vacuo*, distillation gave **1** (8.49 g, 91%): Bp 118—123 °C/0.08 mmHg† (lit,[22] 124—125 °C/1.0—1.5 mmHg); NMR($CDCl_3$) δ 0.25(9H, s, Me_3Si), 1.37(6H, t, $J=7$ Hz, CH_3), 4.18(4H, m, CH_2), 5.15(1H, d, $J=14$ Hz, CHP), 7.50(5H, m, ArH). Found: C, 53.38; H, 8.07%. Calcd for $C_{14}H_{25}O_4PSi$: C, 53.14; H, 7.96%.

Method B: Diethyl phosphonate (6.61 g, 47.9 mmol) was added dropwise to sodium (1.18 g, 51.3 mmol) in dry ether (50 ml). Exothermic reaction took place with evolution of hydrogen gas and a white precipitate was formed gradually. After 3 h benzaldehyde (4.82 g, 45.4 mmol) was added. The precipitate was dissolved at once and the solution turned bright brown. Then, chlorotrimethylsilane (5.11 g, 47.0 mmol) was added, and a precipitate appeared. After removal of the ether, distillation without separation of the precipitate gave **1** (9.64 g, 67%).

Diethyl Trimethylsilyloxymethylphosphonate (2). Diethyl

† 1 mmHg≈133.322 Pa.

Table 8. Preparation of lactones (**91**—**95**) from **64**—**66**

Adduct	Aldehyde or ketone[a)]	Time/min	Product	Compd No.	Yield/% (*trans*/*cis*)[b)]
64	PhCHO	40		**91**	51 (75/25)
65	PhCHO	60		**92**	54 (75/25)
66	PhCHO	40		**93**	78 (85/15) (59%, TBAF)
66	*i*-C_3H_7CHO	40		**94**	80 (60/40)
66		40		**95**	33

a) In these reactions 1.2 equiv. of aldehyde or ketone was employed. b) The ratio of *trans*/*cis* was calculated on the base of the NMR spectra of **91**—**94** (see Table 9).

Table 9. ^1H NMR data of lactones (**91**—**95**)

Compound	^1H NMR($CDCl_3$) δ
91	0.60(3H, d, J=7 Hz, *trans* CH_3), 1.03(3H, m *cis* CH_3), 1.90—2.97(3H, m, CH_2 and CHC-O), 4.80(1H, d, J=8 Hz, *cis* CH-O), 5.46(1H, d, *trans* CH-O), 7.20(5H, m, Ph)
92	1.43—0.53(7H, m, $CH_3(CH_2)_2$), 2.50(3H, m, CH_2 and CH-O), 4.93(d, J=7 Hz, *cis* CH-O), 5.53 (1H, d, J=7 Hz, *trans* CH-O), 7.23(5H, m, Ph).
93	2.90(2H, m, CH_2), 3.50(1H, m, CHC-O), 5.35(1H, d, J=8 Hz, *trans* CH-O), 5.73(1H, d, J= 7 Hz, *cis* CH-O), 7.17(10H, s, Ph)
94	0.93(6H, m, CH_3), 1.87(1H, m, $CH(CH_2)_2$), 2.70(2H, d, J=7 Hz, *cis* CH_2), 2.85(2H, d, J=7 Hz, *trans* CH_2), 3.43(1H, m, CHC-O), 4.27(1H, d, J=7 Hz, *trans* CH-O), 4.37(1H, d, J=7 Hz, *cis* CH-O), 7.27(5H, s, Ph)
95	0.50—2.33(10H, m, $(CH_2)_5$), 2.89(2H, m, $CH_2C(O)$), 3.43(1H, m, CH), 7.13(5H, s, Ph)

phosphonate (6.02 g, 43.6 mmol) was added to sodium (1.2 g, 52.2 mmol) in dry ether (20 ml). After stirring for 2 h, paraformaldehyde (1.50 g, 50.0 mmol) in dry ether (10 ml) was added. A white precipitate appeared at once but it was dissolved on addition of chlorotrimethylsilane (5.85 g, 53.8 mmol). The mixture was stirred at room temperature for 6 h. After removal of the solvent distillation gave **2** (7.20 g, 69%): Bp 72—75 °C/0.6 mmHg (lit,[23] 113 °C/9 mmHg); NMR ($CDCl_3$) δ 0.13(9H, s, Me_3Si), 1.30(6H, t, J=7 Hz, CH_3), 3.75(2H, d, J=9 Hz, CH_2P), 3.80—4.32(4H, m, CH_2O). Found: C, 40.04; H, 8.66%. Calcd for $C_8H_{21}O_4PSi$: C, 39.98; H, 8.81%.

*Diethyl 1-(Trimethylsilyloxy)ethylphosphonate (**3**).* To a solution of DTMSP (11.0 g, 52.3 mmol) in dry benzene (20 ml) was introduced acetaldehyde (90 mmol) which was generated from paraaldehyde by heating with a catalytic amount of *p*-toluenesulfonic acid (TsOH). After standing for 4 h, the solvent was removed *in vacuo* and distillation afforded **3** (11.7 g, 88%): Bp 62—63 °C/0.4 mmHg (lit,[22] 82 °C/1 mmHg); NMR(CCl_4) δ 0.15(9H, s, Me_3Si), 1.29 (6H, t, J=7 Hz, CH_3C-O), 1.33(3H, dd, J=7 Hz, J=16.5 Hz, CH_3CP), 3.78—4.22(5H, m, CH_2O and CHP).

*Diethyl 1-(Trimethylsilyloxy)propylphosphonate (**4**).* To a solution of DTMSP (5.66 g, 26.9 mmol) in dry benzene (10 ml) was added dropwise propionaldehyde (1.74 g, 30.0 mmol) at room temperature. After being stirred for 6 h, the solution was concentrated *in vacuo* and the residual oil was distilled to give **4** (5.30 g, 72%): Bp 80—82 °C/1 mmHg; IR(NaCl) 968, 1030, 1060, 1117, 1170, 1230, 1255 (νP=O), 1394, 1448, 1460, 2970 cm^{-1}; NMR(CCl_4) δ 0.15 (9H, s, Me_3Si), 0.99 (3H, t, J=7 Hz, CH_3CC), 1.34(6H, t, J=7 Hz, CH_3C-O), 1.10—1.85(2H, m, CCH_2C), 3.51—3.80(1H, m, CHP), 3.80—4.35(4H, m, CH_2O). Found: C, 44.44; H, 9.81%. Calcd for $C_{10}H_{25}O_4PSi$: C, 44.76; H, 9.39%.

*Diethyl 1-Trimethylsilyloxy-2-methylpropylphosphonate (**5**).* To a solution of DTMSP (7.58 g, 36.0 mmol) in dry benzene (15 ml) was added isobutyraldehyde (2.80 g, 38.8 mmol) dropwise at room temperature. The mixture was stirred for 6 h. The usual work-up as described before gave **5** (8.65 g, 83%): Bp 69—72 °C/0.35 mmHg; NMR(CCl_4) δ 0.14 (9H, s, Me_3Si), 0.97(6H, d, J=7.3 Hz, $(CH_3)_2C$), 1.31

(6H, t, J=7 Hz, CH_3C–O), 1.62—2.40(1H, m, CHCP), 3.59(1H, dd, J=7.5 Hz, J=4.5 Hz, CHP), 3.78—4.31(4H, m, CH_2O). Found: C, 46.75; H, 9.64%. Calcd for $C_{11}H_{27}O_4PSi$: C, 46.78; H, 9.64%.

*Diethyl 1-(Trimethylsilyloxy)octylphosphonate (**6**).* To a solution of DTMSP (18.3 g, 87.1 mmol) in dry benzene (10 ml) was added dropwise octanal (9.67 g, 75.4 mmol) at room temperature. After stirring for 3 h, the solvent was removed and distillation of the residual oil gave **6** (23.1 g, 91%): Bp 104—105 °C/0.04 mmHg: NMR(CCl_4) δ 0.15 (9H, s, Me_3Si), 0.92(3H, t, J=4.5 Hz, terminal CH_3), 1.32(6H, t, J=7 Hz, CH_3C–O), 1.31(12H, m, $(CH_2)_6$), 3.73(1H, m, CHP), 3.75—4.35(4H, m, CH_2O). Found: C, 52.85; H, 10.55%. Calcd for $C_{15}H_{35}O_4PSi$: C, 53.22; H, 10.42%.

*General Procedure for the Synthesis of Diethyl 1-Hydroxy-1-(trimethylsilyl)alkylphosphonates (**8—10**). The Wittig Rearrangement of Diethyl 1-(Trimethylsilyloxy)alkylphosphonates (**2—4**).* To a cold solution (−78 °C) of diisopropylamine (0.5 ml, 3.58 mmol) in dry THF (10 ml) or DME (10 ml) was added butyllithium (3.58 mmol) in hexane. After 0.5 h, an appropriate 1-trimethylsilyloxyphosphonate (**2—5**) was added. The mixture was stirred at −78 °C for the time given in Table 1, and then or after warming to room temperature the resulting solution was poured into a vigorously stirred mixture of 1 M NH_4Cl (20 ml) and CH_2Cl_2 (20 ml). The CH_2Cl_2 layer was collected and the aqueous layer was further extracted with CH_2Cl_2 (3×10 ml). The organic extracts were combined, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was chromatographed on silica gel (hexane–ether) to give a 1-hydroxy-1-(trimethylsilyl)alkylphosphonate (**8**, **9**, or **10**) and the starting phosphonate. The physical properties of the new compounds **8—10** are listed in Table 2.

*Trimethylsilyl Diphenylphosphinite (**16**).*[15] A mixture of diphenylphosphine oxide (10.5 g, 52 mmol) and *N*,*N*-diethyltrimethylsilylamine (9.08 g, 62.5 mmol) was stirred at room temperature for 4 h under slightly reduced pressure. Distillation gave **16** (12.8 g, 89%): Bp 110 °C/0.8 mmHg. This compound was identified with an authentic sample reported by Issleib by comparison with its physical data.[15]

*[1-(Trimethylsilyloxy)propyl]diphenylphosphine Oxide (**17**).* To a solution of propionaldehyde (1.17 g, 20.2 mmol) in dry benzene (10 ml) was added **16** (5.41 g, 19.7 mmol). The exothermic reaction took place. After the mixture was stirred at room temperature for 3 h, the solvent was removed *in vacuo*. The residue was chromatographed on silica gel (hexane–ether) to give **17** (2.5 g, 38%) as a crude material and (1-hydroxypropyl)diphenylphosphine oxide (1.98 g, 39%). While the former was too sensitive toward moisture to be purified, the latter was well characterized by its NMR spectrum and elemental analysis: NMR($CDCl_3$) δ 0.99(3H, t, J=7 Hz, CH_3), 1.65(2H, m, CH_2), 4.21(1H, m, CHP), 5.14(1H, s, OH), 7.32(6H, s, ArH), 7.70(4H, m, ArH). Found: C, 68.90; H, 6.80%. Calcd for $C_{15}H_{17}O_2P$: C, 69.22; H, 6.59%.

*General Procedure for Alkylation of α-Lithiated 1-(Trimethylsilyloxy)alkylphosphonates (**1—7**).* To a cooled solution (−78 °C) of diisopropylamine in dry THF was added an equimolar amount of butyllithium in hexane. After 0.5 h an appropriate phosphonate was added. The lithiation time was listed in Table 3. Then an alkyl halide or a disulfide was added to the mixture. The reaction time was also shown in Table 3. The mixture was poured into a vigorously stirred mixture of 1 M NH_4Cl and CH_2Cl_2. The organic layer was collected and the aqueous layer was further extracted with CH_2Cl_2 three times. The organic extracts were combined, dried over Na_2SO_4, evaporated *in vacuo* to dryness, and chromatographed on silica gel (hexane–ether) to give an α-alkylated phosphonate as listed in Table 3. The amounts of the reagents used are listed in Table 3. All new compounds were characterized by their NMR spectra and elemental analyses. The previously known compounds were identified by comparison with their NMR spectra. These data are listed in Table 4.

General Procedure for Transformation of 1-(Trimethylsilyloxy)-alkylphosphonates into Carbonyl Compounds. Method A: An appropriate alkylated phosphonate (2 mmol) was dissolved in a mixture of methanol (10 ml) and water (1 ml) and then a catalytic amount (30 mg) of *p*-toluenesulfonic acid was added. The mixture was refluxed for the time given in Table 5. The mixture was first treated with a mixture of CH_2Cl_2 (25 ml) and water (25 ml). The organic layer was collected and the aqueous layer was further extracted with CH_2Cl_2 (3×10 ml). The organic extracts were combined, dried over Na_2SO_4, and evaporated *in vacuo* to afford a crude 1-hydroxyalkylphosphonate derivative. It was further treated with a mixture of EtOH (30 ml) and 1 M NaOH (30 ml). After the time given in Table 5, the mixture was extracted with CH_2Cl_2 (3×10 ml). The extracts were combined, dried over Na_2SO_4, evaporated *in uacuo*, and chromatographed on silica gel to give a pure carbonyl compound.

In the following cases, special conditions were employed: 1) Diethyl 1-trimethylsilyloxy-1-phenylbutylphosphonate (**20**) was treated with 2 M HCl (2.5 ml) in MeOH instead of TsOH and the reaction was carried out at room temperature. 2) Allyl phenyl ketone was obtained by treatment of the detrimethylsilylated intermediate with a large excess amount of Na_2CO_3 (1 g) in a mixture of CH_2Cl_2 (20 ml) and EtOH (10 ml) at room temperature for 3 d or by treatment with a catalytic amount of tetrabutylammonium hydroxide for 1 min in a heterogeneous mixture of ether (20 ml) and 1 M NaOH (20 ml). According to the former treatment allyl phenyl ketone was obtained in 36% yield along with (*E*)-1-phenyl-2-buten-1-one (10%) and the latter gave the ketone in 36% yield.

Diethyl 1-Hydroxy-1-phenyl-3-butenylphosphonate(Purified Intermediate). Mp 71—73 °C; NMR($CDCl_3$) δ 1.15 and 1.19 (3H and 3H, t and t, J=7 Hz, CH_3C–O), 2.96(2H, dd, J=J=7 Hz, $C{=}CCH_2$), 3.63—4.30(4H, m, CH_2O), 4.53 (1H, s, OH), 4.80—5.17(2H, m, $CH_2{=}C$), 5.26—5.90(1H, m, $C{=}CH$), 7.13(3H, m, ArH), 7.45(2H, m, ArH). Found: C, 59.34; H, 7.33%. Calcd for $C_{14}H_{21}O_4P$: C, 59.15; H, 7.45%.

Method B: To a solution of an alkylated phosphonate (2—3 mmol) in ethanol (30 ml) was added 1 M NaOH (30 ml). The solution was stirred for the period as shown in Table 5. The mixture was poured into a mixture of CH_2Cl_2 (20 ml) and 1 M NH_4Cl (20 ml). The organic layer was collected, and the aqueous layer was further extracted with CH_2Cl_2 (3×50 ml). The CH_2Cl_2 extracts were combined, dried over Na_2SO_4, concentrated, and chromatographed on silica gel (hexane–ether) to give a carbonyl compound.

*Diethyl 1-Trimethylsilyloxy-2-propenylphosphonate (**63**).* To a solution of acrylaldehyde(1.17 g, 20.8 mmol) in dry benzene (5 ml) was added DTMSP (4.46 g, 21.2 mmol) with stirring on an ice bath. After stirring at room temperature for 6 h the solvent was removed, and distillation gave a mixture (4.90 g, Bp 105 °C/1.25 mmHg) of **63** and **67**. The mixture (32 g) was treated with $TsOH{\cdot}H_2O$ (1 g) in MeOH (500 ml) and H_2O (20 ml) under reflux for 3 h. After extraction with CH_2Cl_2 (4×100 ml) and drying

over Na_2SO_4, and removal of the solvent, the residue was chromatographed on silica gel (hexane–ether) to give a detrimethylsilylated phosphonate of **63** (14.3 g, 38%). The α-hydroxy phosphonate (14 g) was further treated with *N,N*-diethyltrimethylsilylamine (16.5 ml) at 50 °C under slightly reduced pressure for 3 h. Then, the mixture was evaporated *in vacuo* and chromatographed on silica gel (hexane–ether) to give **63**: NMR(CCl_4) δ 0.15(9H, s, Me_3Si), 1.29(6H, t, J=7 Hz, CH_3C–O), 4.05(4H, m, CH_2O), 4.33(1H, m, CHP), 4.98—5.50(2H, m, CH_2=C), 5.69—6.27(1H, m, C=CH). This product was used further for alkylation without purification.

*Diethyl 1-Trimethylsilyloxy-2-butenylphosphonate (**64**).* To a solution of *trans*-2-butenal (1.54 g, 21.9 mmol) in dry benzene (5 ml) was added DTMSP (4.71 g, 22.4 mmol). The reaction mixture was stirred at room temperature for 6 h. After removal of the benzene *in vacuo*, distillation gave **64** (4.45 g, 72%): Bp 110—113 °C/1.8 mmHg; NMR($CDCl_3$) δ 0.15(9H, s, Me_3Si), 1.30(6H, t, J=7 Hz, CH_3C–O), 1.57—1.81(3H, m, CH_3C=C), 3.80—4.53(5H, m, CH_2–O and CHP), 5.62(2H, m, CH=CH). Found: C, 46.87; H, 9.49%. Calcd for $C_{11}H_{25}O_4PSi$: C, 47.12; H, 8.99%.

*Diethyl 1-Trimethylsilyloxy-2-hexenylphosphonate (**65**).* To a solution of *trans*-hexenal (9.95 g, 101 mmol) in dry benzene (10 ml) was added DTMSP (19.52 g, 92.8 mmol) with stirring on an ice bath. Then the mixture was stirred at room temperature for 8 h. After removal of the solvent *in vacuo*, distillation gave **65** (21.6 g, 73%): Bp 90—100 °C/0.15—0.20 mmHg; NMR(CCl_4) δ 0.20(9H, s, Me_3Si), 0.95(3H, t, terminal CH_3), 1.33(6H, t, J=7 Hz, O–C–CH_3), 1.40(2H, m, CH_2CC=C), 1.80—2.30(2H, b, CH_2C=C), 3.80—4.33(4H, m, CH_2–O), 4.25—4.50(1H, m, CHP), 5.50—5.77(2H, m, CH=CH). Found: C, 50.48; H, 9.95%. Calcd for $C_{13}H_{29}O_4PSi$: C, 50.63; H, 9.48%.

*Diethyl 1-Trimethylsilyloxy-3-phenyl-2-propenylphosphonate (**66**).* To a solution of cinnamaldehyde (3.82 g, 28.9 mmol) in dry benzene (5 ml) was added dropwise DTMSP (6.27 g, 29.8 mmol) with stirring at room temperature. The mixture was further stirred at room temperature for 6 h. After removal of the solvent, distillation of the residual oil gave **66** (6.94 g, 70%): Bp 134—137 °C/0.10 mmHg; NMR(CCl_4) δ 0.19(9H, s, Me_3Si), 1.29(6H, t, J=7 Hz, CH_3C–O), 3.78—4.33(4H, m, CH_2O), 4.50(1H, dd, J=16, J=5.5 Hz, CHP), 5.97—6.80(2H, m, CH=CH), 7.23(5H, m, Ph). Found: C, 55.97; H, 8.18%. Calcd for $C_{16}H_{27}O_4PSi$: C, 56.12; H, 7.95%.

*Lithiation and Deuteration of **63**.* To a cooled (−78 °C) solution of LDA(3.58 mmol) in dry THF (10 ml) was added 805 mg (3.02 mmol) of **66**, whereupon the solution turned orange yellow. After 0.5 h, CD_3OD (0.2 ml) was added and the solution was treated with 1 M ammonium chloride (20 ml). The mixture was extracted with CH_2Cl_2 (4× 20 ml). The organic extracts were combined, concentrated to dryness, and chromatographed on silica gel (hexane–ether) to give deuterated diethyl 1-hydroxy-2-propenylphosphonate (169 mg, 29%) and deuterated **63** (68 mg, 8%).

*Lithiation and Deuteration of **64**.* Deuterated diethyl 1-hydroxy-2-butenylphosphonate (557 mg, 78%) and deuterated **64** (110 mg, 12%) were obtained from **64** (952 mg, 3.40 mmol), LDA (3.58 mmol) in dry THF (10 ml), and CH_3OD (0.5 ml).

*Lithiation and Deuteration of **65**.* The deuterated **65** (587 mg, 84%) was similarly obtained from **65** (905 mg, 2.94 mmol), LDA (3.58 mmol) in dry THF (10 ml), and CH_3OD (0.5 ml).

*Lithiation and Deuteration of **66**.* Deuterated 1-hydroxy-3-phenyl-2-propenylphosphonate (169 mg, 29%) and deuterated **66** (68 mg, 8%) were similarly obtained from **66** (970 mg, 2.83 mmol), LDA (3.19 mmol) in dry THF (10 ml), and CD_3OD (0.2 ml).

*Preparation of **85**.* To a solution of 4 mmol of LDA in THF (15 ml) at −78°C was added **66** (1.23 g, 3.6 mmol) and the solution was stirred for 30 min. Benzoyl chloride (607 mg, 4.32 mmol) was added and the mixture was warmed gradually to room temperature. After being stirred at room temperature for 30 min, the solution was poured into a stirred heterogeneous mixture of 1 M NH_4Cl (10 ml) and CH_2Cl_2 (10 ml). The CH_2Cl_2 layer was collected and the aqueous solution was further extracted with CH_2Cl_2 (3× 10 ml). The organic extracts were combined, dried over Na_2SO_4, and evaporated to give the crude **85**, which was used without purification for further transformations into **86—88**.

*Esterification of **85**. Under Acidic Conditions*: The crude **85** was dissolved in dry ethanol (20 ml) and TsOH·H_2O (5 mg) was added. After being refluxed for 2 h, the mixture was poured into a stirred mixture of 1 M NaOH (20 ml) and CH_2Cl_2 (20 ml). The organic layer was collected, combined with further CH_2Cl_2 extracts (3×10 ml), dried over Na_2SO_4, evaporated, and chromatographed on silica gel (hexane–ether) to give **86** (362 mg, 36%): NMR($CDCl_3$) δ 7.90 and 7.17(10H, m, ArH), 5.07(1H, dd, J=9 Hz, J=6 Hz, CHPh), 4.00(2H, m, CH_2O), 3.36(1H, dd, J=16 Hz, J=9 Hz, $CH^aC(=O)O$), 2.63(1H, dd, J=16 Hz, J=6 Hz, $CH^bC(=O)O$), 1.10(3H, t, CH_3).

Under Alkaline Conditions. The crude **85** was prepared from **66** (1.86 g, 5.38 mmol) and was treated with sodium methoxide prepared from sodium (143 mg, 6.2 mmol) in dry methanol (20 ml). The solution turned reddish brown. After being stirred for 30 min, the mixture was poured into a mixture of 1 M NH_4Cl (20 ml) and CH_2Cl_2 (20 ml). The usual work-up gave **87** (813 mg, 56%).

*Synthesis of **88**.* The crude **85** was prepared from **66** (1.48 g, 4.32 mmol), dissolved in dioxane (30 ml), treated with 1 M NaOH (30 ml). After being stirred for 15 min, the solution was treated with a mixture of 1 M NH_4Cl (20 ml) and CH_2Cl_2 (20 ml). Dilute hydrochloric acid was added until the aqueous layer had been acidified to pH 1. The aqueous layer was extracted with CH_2Cl_2 (4× 20 ml). The usual work-up gave **88** (802 mg, 73%). The products **86—88** were identified with the authentic samples by comparison with their spectral data.

General Procedure for the Synthesis of Lactones. To a THF solution of 3.3 mmol of LDA at −78 °C was added 3 mmol of an appropriate phosphonate (**64—66**). The mixture was stirred at −78 °C for the time given in Table 8 and warmed gradually to room temperature. The mixture was poured into a stirred mixture of 1 M NH_4Cl (20 ml) and CH_2Cl_2 (20 ml). The CH_2Cl_2 layer was collected and the aqueous layer was extracted with CH_2Cl_2 (3×20 ml). The combined CH_2Cl_2 extracts were dried over Na_2SO_4, evaporated, and dissolved in dioxane (10 ml). To the solution was added 571 mg (3 mmol) of TsOH·H_2O, and the mixture was refluxed in the presence of molecular sieves 3A for 10 min. After cooling to room temperature, the solution was diluted with water (20 ml) and extracted with CH_2Cl_2 (3×20 ml). The combined extracts were dried over Na_2SO_4, evaporated, and chromatographed on silica gel (hexane–ether) to give a lactone given in Table 8. All of the products were identified by comparison with their spectral data with authentic samples previously reported.[21,24–26]

*Diethyl 1-Trimethylsilyloxy-3-phenyl-1-butenylphosphonate (**69a**).* To a cooled (−78 °C) solution of LDA (3.31 mmol) in dry THF (10 ml) was added **66** (1048 mg, 3.06 mmol),

the solution turned bright brown. After 0.5 h methyl iodide (515 mg, 3.63 mmol) was added. The solution turned yellow. Then the mixture was gradually warmed to room temperature. After 3 h, the solution was quenched with 1 M NH_4Cl, extracted with CH_2Cl_2 (3×25 ml) and dried over Na_2SO_4. After removal of the solvent, chromatography on silica gel afforded **69a** (473 mg, 43%) as a crude material: NMR(CCl_4) δ 0.18(9H, s, Me_3Si), 1.25 and 1.28(3H and 3H, t and t, J=7 Hz, CH_3C–O), 2.35—3.33(1H, m, CH), 3.98 (4H, m, CH_2O), 5.92(1H, dd, J=J=10 Hz, CH=C–P), 7.13(5H, s, Ph).

*Diethyl 1-Trimethylsilyloxy-3,4-diphenyl-1-butenylphosphonate (**69b**).* To a cooled (−78 °C) mixture of **66** (1594 mg, 4.66 mmol) and LDA (5.45 mmol) in dry THF (10 ml) was added benzyl bromide (984 mg, 5.75 mmol). After stirring at −78 °C for 0.5 h, the usual work-up gave **69b** (1305 mg, 69%) as a crude material: NMR(CCl_4) δ 0.07 (9H, s, Me_3Si), 1.19(6H, t, J=7 Hz, CH_3C–O), 2.90(1H, d, J=8.1 Hz, one of CH_2Ph), 2.91(1H, d, J=6.6 Hz, one of CH_2Ph), 2.40—3.20(1H, m, CH), 5.97(1H, dd, J=J= 10 Hz, CH=C), 7.00(5H, s, Ph), 7.07(5H, s, Ph).

*Diethyl 1-Trimethylsilyloxy-3-benzyl-1-hexenylphosphonate (**69c**).* To a cooled (−78 °C) solution of **65** (1051 mg, 3.29 mmol) and LDA (3.58 mmol) in 10 ml of dry THF was added benzyl bromide (0.420 ml, 3.54 mmol). After stirring at −78 °C for 0.5 h, the usual work-up gave **69c** (755 mg, 58%) as a crude material: IR(NaCl): 1045, 1260(P=O), 1370, 1394, 1606, 1635, 1696, 1728, 2920, 2955, 3015 cm^{-1}; NMR(CCl_4) δ 0.13 (9H, s, Me_3Si), 0.90(3H, t, J=6 Hz, CH_3CC), 1.30(10H, m, CH_2CH_2 and CH_3C–O), 2.75(3H, m, $PhCH_2$ and CH), 3.98(4H, m, CH_2O), 5.50(1H, dd, J=J=9.5 Hz, CH=C), 7.15(5H, s, Ph).

General Procedure for the Synthesis of β-Substituted Carboxylates. To a cooled solution of diisopropylamine (1.12±0.09 equiv.) in dry THF was added an equimolar amount of butyllithium in hexane. After 0.5 h an appropriate phosphonate (3.0 mmol) was added. After stirring at −78 °C for 0.5 h, alkyl halide (1.12±0.09 equiv.) was added. The reaction time and the temperature were given in Table 6. The mixture was poured into a mixture of CH_2Cl_2 (20 ml) and 1 M NH_4Cl (20 ml) with vigorous stirring. The CH_2Cl_2 layer was collected and the aqueous layer was further extracted with CH_2Cl_2 (3×20 ml). The organic extracts were combined, dried over Na_2SO_4, and concentrated *in vacuo*. The residual oil was dissolved into ethanol (30 ml) without further purification and a catalytic amount of TsOH was added. The reaction time and the temperature were given in Table 6. The resulted solution was diluted with water and extracted with CH_2Cl_2 (3×20 ml). The combined organic layers were dried over Na_2SO_4, concentrated to dryness, and chromatographed on silica gel (hexane–ether) gave a β-substituted carboxylate. The data of the NMR spectra and elemental analyses for all new compounds are summarized in Table 7. The previously known products are characterized by their NMR spectra.

Protection of Phosphonate Function by Means of Ethoxycarbonyl Group. A New Method for Generation of Reactive Silyl Phosphite Intermediates

Mitsuo SEKINE, Hiroyuki MORI, and Tsujiaki HATA*

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

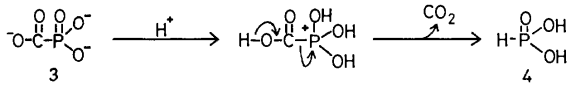
(Received June 12, 1981)

Nucleoside ethoxycarbonylphosphonates were prepared by condensation of appropriately protected nucleosides with ethoxycarbonylphosphonic acid. They were easily converted by treatment with 1 M NaOH followed by trimethylsilylation to highly reactive bis(trimethylsilyl) nucleoside phosphite intermediates which were allowed *in situ* to react with water, diphenyl disulfide, 2,2′-dipyridyl disulfide, and aldehydes to afford the corresponding nucleoside phosphonates, nucleoside *S*-phenyl phosphorothioates, nucleoside phosphates, and nucleoside α-hydroxy phosphonates in good yields, respectively. The nucleoside phosphonates were further converted to nucleosides under mild acidic conditions. Thus, the ethoxycarbonyl group proved to serve as a versatile protecting group for not only H–P(O) but also HO–P(O) and hydroxyl groups of sugars.

Nucleoside phosphonates (**1**) have been shown as versatile synthetic intermediates in nucleotide chemistry. For example, **1** could be converted to highly reactive "nucleoside bis(trimethylsilyl) phosphites (**2**)" having tervalent form by simple trimethylsilylation. Fixation of phosphonates in the tervalent form has proved to be quite useful for the synthesis of various phosphate and phosphonate derivatives.[2-11] The trimethylsilyl group of the silylated products was readily removed by addition of water or alcohols. The above feature enhances the synthetic value of **2**. Thus, the preparation of **1** as the starting materials for the synthesis of **2** has become of more importance in nucleotide chemistry. However, the preparative method of **1**, *i.e.*, the introduction of a hydroxyphosphinyl group [H(HO)P(O)–] into nucleoside hydroxyl groups has been extremely limited,[12-17] because **1** is unstable under weakly acidic conditions (for example, 80% acetic acid[12]) though it is quite stable under alkaline conditions. The H–P(O) group of **1** is also sensitive to oxidizing agents,[12,17,18] halogenating agents,[19-23] and condensing agents.[24]

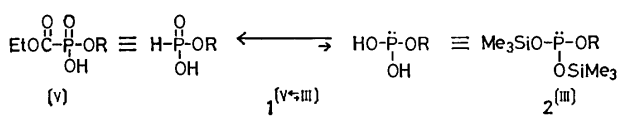
In order to overcome the problems owing to the instability of the hydroxyphosphinyl group, an appropriate masking group is required. We feel that, in this case, the protection of the H–P(O) function should be designed not in reactive phosphite form but in nonreactive phosphonate form.

Warren[25] described an interesting study on decarboxylation of carboxyphosphonic acid (**3**) to give phosphonic acid (**4**) under relatively drastic condi-



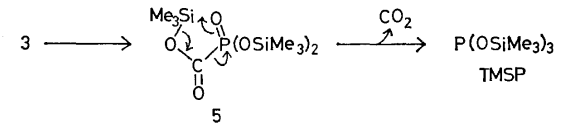
3 **4**

tions using strong acids. This fact suggests that the H–P(O) group of **1** can be protected by alkoxycarbonyl groups such as ethoxycarbonyl group. Therefore, our attention has been paid to the P–C bond cleavage of **3** with elimination of carbon dioxide under milder conditions than those reported by Warren.



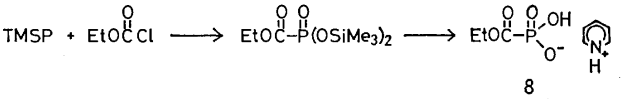
(V) **1** (V+III) **2** (III)

Consequently, we found a unique method for the decarboxylation of **3** *via* trimethylsilylation. When the pyridinium salt of **3** was treated with trimethylsilyl chloride and triethylamine (3.3 equiv. each) in tetrahydrofuran at room temperature for 30 min and then water was added, phosphonic acid was isolated as barium salt in 96% yield. When the reaction mixture was distilled without addition of water, tris(trimethylsilyl) phosphite (TMSP) was obtained in 81% yield. The mechanism of formation of TMSP might involve intramolecular rearrangement of one trimethylsilyl group *via* a five-membered ring transition state from a fully trimethylsilylated intermediate (**5**). Furthermore, the formation of TMSP was supported by the fact that treatment of the reaction mixture with diphenyl disulfide and benzaldehyde gave *S*-phenyl phosphorothioate (**6**) and α-hydroxybenzylphosphonic acid (**7**)



5

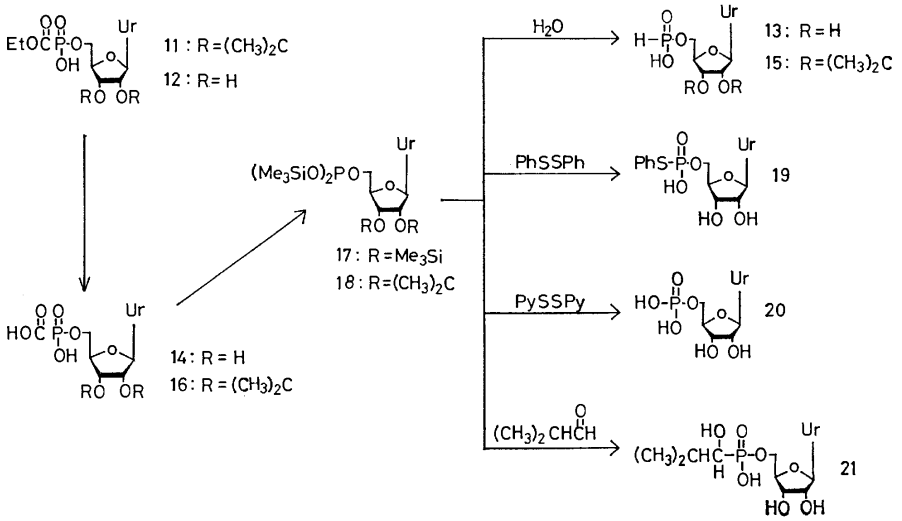
in 95 and 35% (quant. on TLC) yields, respectively. These results led us to study the protection of the H–P(O) group of **1** with ethoxycarbonyl group. Pyridinium ethoxycarbonylphosphonate (**8**) was prepared starting from TMSP and ethyl chloroformate according to the following equation. When com-



8

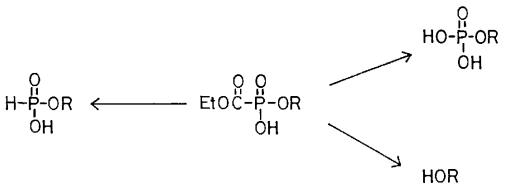
pound **8** was condensed with 2′,3′-*O*-isopropylideneuridine (**10**) in the presence of 1-(*p*-toluenesulfonyl)-1*H*-1,2,4-triazole[26] at r.t. overnight, 2′,3′-*O*-isopropylideneuridine 5′-(ethoxycarbonyl)phosphonate (**11**) was obtained in 84% yield by paper chromatography. It was found that the ethoxycarbonyl group of **11** was quite stable under acidic conditions required for removal of the isopropylidene group. Accordingly, treatment of **11** with 60% formic acid at r.t. for 2 h gave **12** in 93% yield. The ethoxycarbonyl group was found to be stable toward agents such as iodine, *N*-bromosuccimide,[27] and 2,4,6-triisopropylbenzenesulfonyl chloride.[24,28]

Compound **12** was treated with 1 M NaOH at r.t. for 5 min followed by neutralization with DIAION



SK 1B (pyridinium form). After the mixture was evaporated to dryness, the residual syrup was successively treated with *N,O*-bis(trimethylsilyl)acetamide (BSA) in pyridine at r.t. for 3 h. By treatment of the mixture with water, uridine 5′-phosphonate (**13**) was obtained in 92% yield. In this reaction, the first intermediate **14** was clearly detected as a single spot on TLC and electrophoresis. The intermediate **14** was characterized by its NMR spectrum. However, attempts to purify **14** by chromatographical methods were unsuccessful because **14** decomposed to **13** and uridine during the chromatography. In a similar manner, **11** was converted to 2′,3′-*O*-isopropylidene 5′-phosphonate (**15**) in 86% yield *via* intermediate **16**. It should be emphasized that the "*in situ*" treatment of **14** with BSA gave rapid and simultaneous generation of a silyl phosphite intermediate (**17**). The presence of **17** was confirmed by the subsequent reaction with diphenyl disulfide, which gave *S*-phenyl uridine 5′-phosphorothioate (**19**)[2] in 94% yield. Furthermore, the use of 2,2′-dipyridyl disulfide[3] in place of diphenyl disulfide gave uridine 5′-phosphate (**20**) in 95% yield. In addition, a new type of nucleotide derivative, uridine 5′-(1-hydroxy-2-methylpropyl)phosphonate (**21**), could be obtained in 84% yield through the reaction of the intermediate **19** with isobutyraldehyde at r.t. for 3 h. Moreover, it was found that the phosphonate group was removed from **13** by treatment with 80% acetic acid at 100 °C for 2 h[12] to give uridine in 90% yield.

Conclusion. In contrast with the fixation of **1** in the tervalent form **2** by the silylation described previously,[2] nucleoside ethoxycarbonylphosphonates can serve as the synthetic equivalents of **1** fixed perfectly in the phosphonate form **3**. It is significant that H–P(O) group can be fixed rigidly in the phosphonate form by the introduction of the (ethoxycarbonyl)hydroxyphosphinyl group. No study has appeared on protection of the H–P(O) group. From this point of view, the present work is the first example in phosphorus chemistry. It is also noteworthy that nucleoside derivatives having the (ethoxycarbonyl)hydroxyphosphinyl group can be converted under the varied conditions to nucleoside bis(trimethylsilyl) phosphites, nucleoside phosphonates, nucleoside phosphates, and nucleosides. From the different point of view, it can be said that the ethoxycarbonyl or (ethoxycarbonyl)hydroxyphosphinyl group can serve as a versatile protecting group for H–P(O), HO–P(O), or HO–R.



Experimental

Melting points and boiling points are uncorrected. ^{1}H NMR spectra were recorded at 60 MHz on a Hitachi R 24-B spectrometer using DSS and benzene (δ 7.24) as internal standards in D_2O and $CDCl_3$, respectively. IR spectra were measured on a Hitachi Model EPI-G3 spectrometer. ^{31}P NMR spectra were obtained on a JEOL PS-100 FT spectrometer at 40.50 MHz using 85% H_3PO_4 as an external standard. UV spectra were recorded with a Hitachi 124 spectrophotometer.

Paper chromatography was performed by descending technique with Toyo Roshi No. 51 and Whatman 3 MM papers. The solvent systems used were Solvent I: ethanol–1 M ammonium acetate (pH 7.5) (7:3, v/v); Solvent II: 1-butanol–water (84:16, v/v); Solvent III: 2-propanol–concentrated aqueous ammonia–water (6:1:3, v/v/v). Solvent IV: 2-propanol–concentrated aqueous ammonia–water (7:1:2, v/v/v). Paper electrophoresis was carried out by using Buffer I (0.05 M phosphate, pH 8.0) at 1200 V for 1.5 h. The Rm values relative to **13** were described. Estimation of the yields of products was carried out spectrophotometrically by using the ε value (10.1×10^3) of uridine at pH 7.0 after elution of the spots from paper chromatograms.

Phosphorus-containing spots were detected on TLC or paper by spraying Hanes-Isherwood reagent[29] followed by irradiation of UV.

Pyridine was distilled over *p*-toluenesulfonyl chloride and stored over calcium hydride. Tetrahydrofuran (THF) was distilled over $LiAlH_4$ and stored over sodium wire. Trimethylsilyl chloride was purchased from Nihon Silicon

Shokai Ltd. and distilled over calcium hydride before use. *N,O*-Bis(trimethylsilyl)acetamide (BSA) was purchased from Tokyo Kasai Ltd. and distilled before use.

Preparation of Tris(trimethylsilyl) Phosphite. An aqueous solution (100 ml) of trisodium carboxyphosphonate (2.83 g, 9.43 mmol) was passed through a column of DIAION SK 1B (pyridinium salt) (3×20 cm). The column was washed with 500 ml of pyridine–water (1:4, v/v). The eluents were combined, evaporated *in vacuo*, coevaporated with dry pyridine several times, and dissolved in dry THF (30 ml). Triethylamine (4.4 ml, 31.1 mmol) and trimethylsilyl chloride (3.9 ml, 31.1 mmol) were added and the mixture was vigorously stirred at room temperature. After 2 h, dry ether (15 ml) was added. The resulting precipitate was removed by filtration and washed with dry ether (10 ml). The filtrate and washings were combined, evaporated *in vacuo*, and the residue was distilled to give TMSP (2.27 g, 81%): Bp 76—77 °C/10 mmHg (lit,[30] 90—92/20 mmHg); ^{31}P NMR ($CDCl_3$) −113.2 ppm.

The same experiment was performed until washing with dry ether had been done. The residual liquid was treated with methanol (50 ml) and the solution was evaporated to dryness. The residue was dissolved in water (50 ml) and 9.5 ml of 1 M barium acetate aqueous solution was added. To the resulting solution was added with stirring ethanol (250 ml). The resulting precipitate was collected by filtration, washed with ethanol (50 ml) and ether (30 ml) and dried *in vacuo* over P_4O_{10} at 100 °C to give barium phosphonate **5** (1.98 g, 96%). This product was identified with the authentic sample by its IR spectra and paper chromatography (Solvent II).

*S-Phenyl Phosphorothioate (**6**).*[2] Trisodium carboxyphosphonate (90 mg, 0.3 mmol) was converted to the pyridinium salt as described in the above experiment. The salt was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in dry THF (5 ml). Diphenyl disulfide (71.9 mg, 0.33 mmol) was added and the mixture was treated with trimethylsilyl chloride (0.23 ml, 2 mmol) and triethylamine (0.25 ml, 2 mmol) at room temperature for 1 h. The reaction mixture was diluted with pyridine by using a measuring flask to 10.0 ml. A one-tenth of the solution was chromatographed on Whatman 3 MM paper (Solvent III) to give **6** (95%): R_f 0.42; $UV_{max}^{pH\ 7.0}$ 248 nm (ε=6560), $UV_{min}^{pH\ 7.0}$ 235 nm.

*α-Hydroxybenzylphosphonic Acid (**7**).* Trisodium carboxyphosphonate (900 mg, 3 mmol) was converted to the pyridinium salt as described before. The salt was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in dry THF (3 ml). To the solution was added successively benzaldehyde (318 mg, 3 mmol), triethylamine (2.52 ml, 18 mmol), and trimethylsilyl chloride (2.27 ml, 18 mmol). After the mixture was stirred at room temperature for 1 h, a white precipitate of triethylamine hydrochloride was removed by filtration. Ethanol (10 ml) was added to the filtrate. The resulting solution was concentrated to a small volume and hexane (100 ml) was added to the concentrated solution. A precipitate was collected by filtration, washed with hexane (20 ml), and dried over P_4O_{10} *in vacuo* to afford **7** (197 mg, 38%): Mp 171—174 °C (lit,[9] 179—180 °C). Found: C, 44.65; H, 4.84%. Calcd for $C_7H_9O_4P$: C, 44.69; H, 4.83%.

*2′,3′-O-Isopropylideneuridine 5′-(Ethoxycarbonyl)phosphonate (**11**).* An aqueous solution (100 ml) of anilinium ethoxycarbonylphosphonate[11] (296.6 mg, 1.2 mmol) was passed through a column (1×5 cm) of DIAION SK 1B (pyridinium salt). The column was washed with pyridine–water (1:5, v/v, 200 ml). The combined eluents were concentrated to a small volume and diluted with pyridine by using a measuring flask to 20 ml. From the measuring flask, 6.67 ml (0.75 mmol) of the standard solution was taken and 2′,3′-*O*-isopropylideneuridine (142 mg, 0.5 mmol) was added. The mixture was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in dry pyridine (2.5 ml). 1-(*p*-Toluenesulfonyl)-1*H*-1,2,4-triazole (227 mg, 1 mmol) was added. After being stirred at room temperature for 16 h, the mixture was quenched by addition of water and chromatographed on Whatman 3 MM papers (Solvent I). A band of R_f 0.90 was cut and eluted with water (1 l). The eluent was concentrated and applied to Whatman 3 MM papers. Rechromatography was performed by using Solvent II. A band of R_f 0.37 was cut and eluted with water (500 ml) to give the ammonium salt of **11** (4240 OD, 84%): R_m 0.92 (Buffer I); $UV_{max}^{pH\ 7.0}$ 262 nm, $UV_{min}^{pH\ 7.0}$ 232 nm; NMR (D_2O) δ 1.10 (t, 3H, J=7 Hz, CH_2CH_3), 1.18 (s, 3H, CH_3), 1.43 (s, 3H, CH_3), 3.53 (m, 2H, 5′-H), 4.04 (t, 2H, J=7 Hz, CH_2–CH_3), 4.47 (m, 1H, 4′-H), 4.85 (m, 2H, 2′- and 3′-H), 5.66 (d, 1H, J=8.2 Hz, 6-H), 5.72 (s, 1H, 1′-H), 7.61 (d, 1H, J=8.2 Hz, 5-H).

*Uridine 5′-(Ethoxycarbonyl)phosphonate (**12**).* The ammonium salt of **11** (0.062 mmol) was dissolved in 60% formic acid (30 ml). The solution was kept at room temperature for 2 h. The solvent was removed *in vacuo* and the residue was chromatographed on Whatman 3 MM paper (Solvent II). A band of R_f 0.11 was cut and eluted with water (200 ml) and water–ethanol (3:1, v/v, 300 ml) to give the ammonium salt of **12** (576 OD, 93%): $UV_{max}^{pH\ 7.0}$ 262 nm, $UV_{min}^{pH\ 7.0}$ 230 nm; NMR (D_2O) δ 1.11 (t, 3H, J_{H-H}=7 Hz, CH_3), 3.90—4.38 (m, 5H, 2′, 3′, 4′, 5′-H), 5.72 (d, 1H, J_{H-H}=8.2 Hz, 6-H), 5.80 (s, 1H, 1′-H), 7.70 (d, 1H, J=8.2 Hz, 5-H).

*Alkaline Hydrolysis of **12**.* The ammonium salt of **12** (0.05 mmol) was treated with 1 M NaOH (0.8 ml) at room temperature. After being kept for 5 min, the solution was neutralized with DIAION SK 1B (NH_4^+ form). The resin was filtered and washed with water (20 ml). The filtrate and washings were combined and evaporated *in vacuo* to give the diammonium salt of **14**. Its analyses using paper electrophoresis and TLC showed a homogeneous spot: R_f 0.12 (Solvent I), 0.01 (Solvent II); R_m 1.40 (Buffer I); NMR (D_2O) δ 3.85—4.32 (m, 5H, 2′,3′,4′-H and 5′-H), 5.74 (d, 1H, J_{H-H}=8.2 Hz, 6-H), 5.78 (d, 1H, J_{H-H}=3.8 Hz, 1′-H), 7.84 (d, 1H, J_{H-H}=8.2 Hz, 5-H).

*Uridine 5′-Phosphonate (**13**).* The diammonium salt of **14** (0.01 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in dry pyridine (0.5 ml). BSA (0.2 ml) was added and the mixture was stirred at room temperature for 30 min. Water (0.5 ml) was added and the resulting solution was kept for 1 h. The solution was applied to Whatman 3 MM papers. Chromatography using Solvent IV was performed. A band of R_f 0.36 was cut and eluted with water (200 ml) to give the ammonium salt of **13** (93 OD, 92%): This product was identified with the authentic sample by comparison with its R_f and R_m values and UV spectrum.

*S-Phenyl Uridine 5′-Phosphorothioate (**19**).* The diammonium salt of **14** (0.01 mmol) was rendered anhydrous as described in the above experiment. The dried material was mixed with diphenyl disulfide (2.6 mg, 0.012 mmol) and dissolved in dry pyridine (0.5 ml). BSA (0.2 ml) was added and the solution was kept at room temperature for 30 min. Water (0.5 ml) was added and the mixture was kept at room temperature for 1 h. Paper chromatography on Whatman 3 MM papers using Solvent IV gave a band of **19** (R_f 0.52, 100 OD, 94%): R_m (Buffer I); $UV_{max}^{pH\ 7.0}$ 244,

260 nm, $UV_{min}^{pH\ 7.0}$ 231, 251 nm. This compound was identified with the authentic sample obtained by the reaction of **15** with diphenyl disulfide in the presence of triethylamine and trimethylsilyl chloride in pyridine followed by treatment with 80% acetic acid.

*Uridine 5'-Phosphate (**20**).* The above mentioned reaction was done by using 2,2'-dipyridyl disulfide (2.7 mg, 0.012 mmol) in place of diphenyl disulfide. The usual work-up gave **20** (96 OD, 95%): R_f 0.10 (Solvent IV). $UV_{max}^{pH\ 7.0}$ 261 nm, $UV_{min}^{pH\ 7.0}$ 230 nm. The compound was identified with the authentic sample.

*Uridine 5'-(1-Hydroxy-2-methylpropyl)phosphonate (**21**).* The ammonium salt of **12** (0.038 mmol) was converted to **14** according to the method described before. Compound **14** was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in dry THF (1 ml). BSA (0.114 ml) was added and the mixture was kept at room temperature for 20 min. Then, isobutyraldehyde (0.066 ml) was added and the mixture was stirred for 3 h. The solution was applied to Whatman 3 MM papers and chromatographed using Solvent IV. A band of R_f 0.39 was cut and eluted with water (100 ml) to give the ammonium salt of **21** (323 OD, 84%): $UV_{max}^{pH\ 7.0}$ 262 nm, $UV_{min}^{pH\ 7.0}$ 231 nm; NMR (D_2O) δ 0.84 (d, 6H, J_{H-H}=6.4 Hz, $(CH_3)_2C$), 1.88 (m, 1H, CHCP), 3.42 (dd, 1H, J_{H-H}=5.4 Hz, J_{P-H}=8.9 Hz, CHP), 3.73—4.29 (m, 6H, 2',3',4'-H and 5'-H), 5.72 (d, 1H, J_{H-H}=8.4 Hz, 6-H), 5.76 (s, 1H, 1'-H), 7.80 (d, 1H, J_{H-H}=8.4 Hz, 5-H).

*2',3'-O-Isopropylideneuridine 5'-Phosphonate (**15**).* The ammonium salt of **11** (0.1 mmol) was dissolved in 1 M NaOH (1 ml). After being kept at room temperature for 5 min, the solution was neutralized with DIAION SK 1B (pyridinium salt). The resin was washed with water (20 ml). The eluent was concentrated and diluted with pyridine–H_2O (2:1, v/v) to 10 ml. The analysis by paper electrophoresis and TLC showed that **16** [R_m 1.44 (Buffer I); R_f 0.36 (Solvent I)] was obtained. The solution was evaporated and rendered anhydrous by repeated coevaporation with dry pyridine. The residue was dissolved in dry THF (1 ml) and triethylamine (0.084 ml, 0.6 mmol) and trimethylsilyl chloride (0.076 ml, 0.6 mmol) were added. After being kept at room temperature for 5 min, the solution was analyzed by paper electrophoresis, which showed that **15** [R_f 0.76 (Solvent III): R_m 0.95 (Buffer I); $UV_{max}^{pH\ 7.0}$ 262 nm, $UV_{min}^{pH\ 7.0}$ 231 nm] was obtained in 86% yield.

*Removal of Phosphonate Group from **13**.* Compound **13** (0.05 mmol) was dissolved in 80% acetic acid (100 ml). The solution was heated at 100 °C for 2 h and then cooled to room temperature. After the solvent was removed *in vacuo*, the residue was chromatographed on Whatman 3 MM paper (Solvent IV) to give a band of R_f 0.75 which was eluted with water and identified with the authentic sample of uridine. The yield was spectrophotometrically estimated to be 90%.

Synthesis and Reactions of *o*-Naphthothioquinone Methides

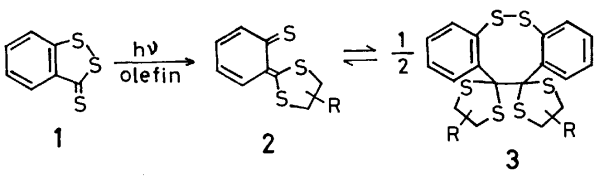
Renji Okazaki,* Kazuhiko Sunagawa, Mitsuharu Kotera,
Kyung-Tae Kang, and Naoki Inamoto

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 5, 1981)

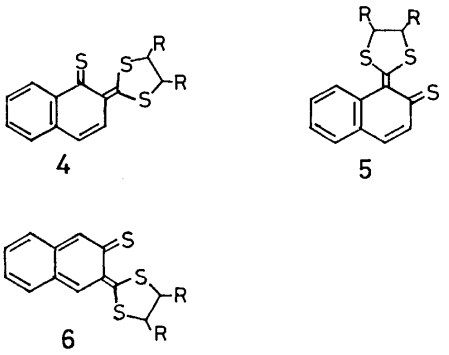
Photochemical reactions of naphtho[1,2-*c*][1,2]dithiole-3-thione (**7**), naphtho[2,1-*c*][1,2]dithiole-1-thione (**10**), and naphtho[2,3-*c*][1,2]dithiole-3-thione (**16**) with cyclohexene and 2,3-dimethyl-2-butene afford the corresponding naphthothioquinone methides. The thioquinone methide from **7** exists only as a monomeric form and is the first isolable *o*-thioquinone methide, while that from **16** exists as a dimer of [4+4] type in the solid state although the chemical behavior suggests the presence of a monomeric form in solution to a very minor extent. In the case of the thioquinone methide from **10**, there exists an equilibrium between a monomer and a dimer of [4+2] type. Some cycloadditions of these thioquinone methides are also described.

In a previous report,[1] we described the photochemical formation of *o*-benzothioquinone methides (**2**) from benzo-1,2-dithiole-3-thione (**1**) and olefins and their some reactions. The deep blue thioquinone methide **2** is equilibrated with colorless dimer **3**, thus representing a unique thermochromic system.



The pure monomeric *o*-thioquinone methide **2**, however, could not be obtained although its existence in solution was established by spectroscopic data and chemical reactions.

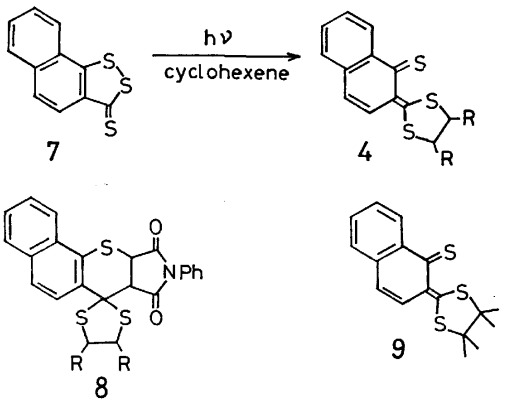
The study described in this paper was initiated in the hope that (i) three isomers (*i.e.* **4**, **5**, and **6**), are possible for the naphtho analog of **2** and comparison of them would shed light on the detailed properties of the *o*-thioquinone methide, (ii) **4** and **5** are reasonably expected to be more stable than **2** and hence they might be isolated as monomer.[2]



Results and Discussion

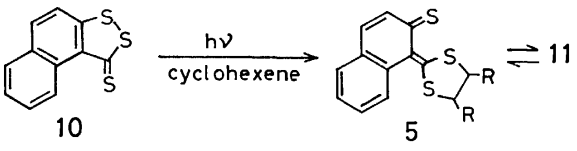
Photoreaction of Naphtho[1,2-c][1,2]dithiole-3-thione (7) with Cyclohexene. Irradiation of **7** in the presence of cyclohexene afforded thioquinone methide **4** (RR= $(CH_2)_4$ hereafter in this paper unless otherwise noted) as deep purple cyrstals in a quantitative yield. The monomeric nature of **4** was established by molecular weight determination (Found 319; Calcd 316.5) and by electronic spectrum (λ_{max} 323 (ε 24300), 353 (10800), 392 (sh, 2540), and 540 nm (11800)), which showed no concentration dependence. This is the first example of isolation of stable *o*-thioquinone methide. Reaction of **4** with *N*-phenylmaleimide gave 1:1-adduct **8** in 83% yield.

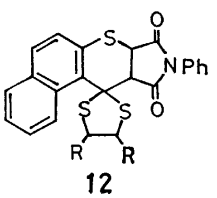
Photoreaction of **7** with 2,3-dimethyl-2-butene also



gave deep violet thioquinone methide **9** in a quantitative yield. Here also, there was no evidence which indicated the presence of a dimeric form; the NMR spectrum showed only two resonances due to the methyl group with the intensity ratio of 1:1.[3]

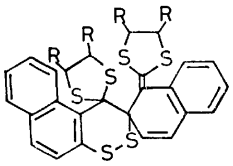
Photoreaction of Naphtho[2,1-c][1,2]dithiole-1-thione (10) with Cyclohexene. Irradiation of **10** with cyclohexene led to a deep red solution, the thin layer chromatography (TLC) of which showed the presence of a single product together with a small amount of the starting **10**. The addition of *N*-phenylmaleimide to the reaction mixture affords 1:1-adduct **12** (54%), the structure of the red compound thus being established as **5**. Purification of the reaction mixture by



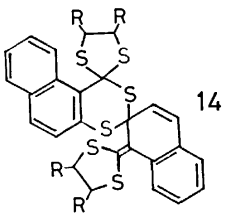


dry column chromatography (DCC) to remove **10**, however, resulted in the formation of a yellow crystalline compound **11** besides the red compound **5** (total yield 95%).

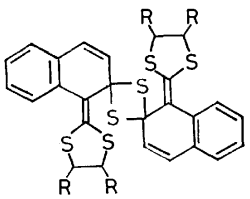
A sample rich in the yellow compound **11** could also be obtained by heating the solution of the red compound **5** at about 60 °C and subsequent cooling. Therefore, attempts to obtain pure **5** by TLC or recrystallization always formed the yellow compound, thus precluding us to get a completely pure specimen of **5**. However, almost pure **5** was obtained by TLC purification and a strong absorption at longer wavelength (496 nm (ε *ca.* 5000)) in the electronic spectrum is consistent with the monomeric structure. The yellow compound **11** free from **5** was obtained by purification with TLC, and was identified as a dimer of **5** on the basis of molecular weight determination (Found 666; Calcd 633) and its reversion to **5** by heating. When the benzene solution of **11** and *N*-phenylmaleimide was heated at about 60 °C, **12** was formed in 64% yield. The structure of the dimer **11** was established as [4+2] adduct **13** or **14** in the following way. The visible absorption at 450 nm (ε 9540) eliminates the possibility of [4+4] dimer, [2+2] dimer other than **15**, and [4+2] dimer other than **13** and **14**, since the [4+4] dimer has only naphthalene chromophore and the dimers of the latter two types have a conjugated thione system which would show an n-π^* absorption around 570 nm.[4] The NMR spectrum with intensity ratio of the aromatic to the olefinic protons of 10:2 rules out the structure **15**. Although we can not determine which of **13** or **14** is correct, the head-to-head structure in **3** suggests that the [4+2] dimer probably has the disulfide structure **13**.



13



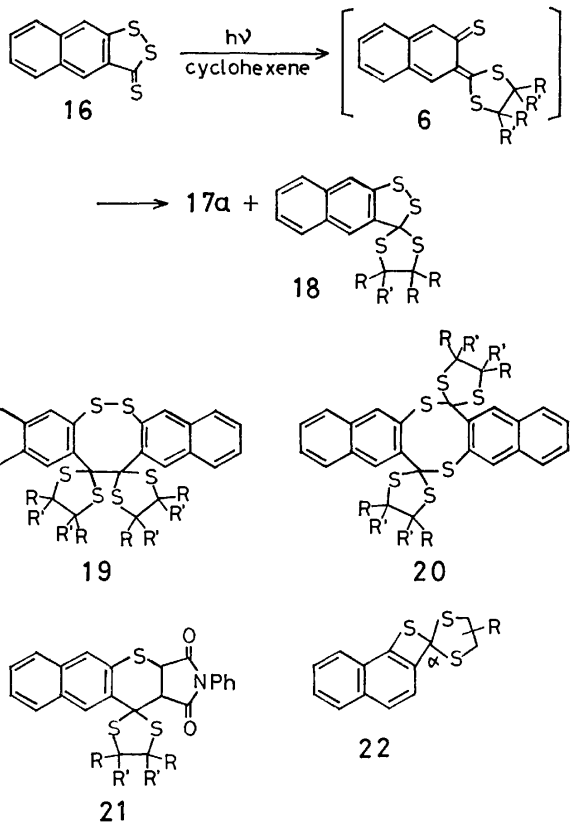
14



15

*Photoreaction of Naphtho[2,3-c][1,2]dithiole-3-thione (**16**) with Cyclohexene.* Irradiation of **16** in the presence of cyclohexene afforded **17a** (61%) and **18** (RR=$(CH_2)_4$, R′=H) (3.8%) as white and yellow crystals, respectively.

The compound **17a** was found to be [4+4] dimer of naphthothioquinone methide **6a** (RR=$(CH_2)_4$, R′=H), on the basis of molecular weight determination (Found 629; Calcd 632) and the spectral and analytical data. The UV (λ_{max} 243 (sh, ε 18300), 339 (2340), and 374 nm (sh, 488)) and NMR spectra indicated only the presence of naphthalene and cyclohexane rings, thus [4+4] adducts **19a** (RR=$(CH_2)_4$, R′=H) and **20a** (RR=$(CH_2)_4$, R′=H) remaining as possible structures for the photoproduct **17a** to the exclusion of [4+2] and [2+2] adducts.



Desulfurization with Raney nickel resulted in the formation of 1,2-di(2-naphthyl)ethane (4.6%) along with 2-methylnaphthalene (29.8%), suggesting that the dimer is of head-to-head type **19** as in the case of the benzo counterpart.[1] The dimer **17a** reacts with *N*-phenylmaleimide in benzene at room temperature for a month or at 80 °C for 1 h to afford white crystals **21** which is derived from the monomer **6a**.

This fact shows that **19a** is dissociated to the monomer **6a** in solution to a very minor extent in spite of the absence of any color due to the monomer **6a** even upon heating at 80 °C.

In order to observe the monomeric naphthothioquinone methide,[5] a similar photoreaction of **16** with 2,3-dimethyl-2-butene in dichloromethane was carried out at −78 °C, but the color due to monomer **6b** (R=R′=CH_3) was not observed, suggesting that *o*-thioquinone methide of this type is too unstable to be observed even at such a low temperature. This photoreaction in benzene at about 0 °C afforded a dimer **19b** (R=R′=CH_3) in 81%.

Since irradiation of **19a** afforded **18** (75%), the formation of **18** in the photoreaction of **16** with cyclohexene described above is due to a secondary photodecomposition of **19a**. The compound **18** reacted with triphenylphosphine to give **19a** and triphenylphosphine sulfide, indicating that such a 1,2-dithiole as **18** is a good precursor of the *o*-thioquinone methide,

which has been demonstrated in our recent report.[6]

Comparison of the Stability of the Three Isomeric Naphthothioquinone methides **4**, **5**, *and* **6**. The above results indicate that the stability of monomeric naphthothioquinone methides **4**, **5**, and **6** is in the order of **4**>**5**>**6**. The instability of **6** compared with **4** and **5** is reasonable in view of the loss of aromaticity in the former structure.[7] The lower stability of **5** than **4** is probably attributed to the steric interaction of the dithiolane ring with the peri hydrogen; dimerization would reduce such an interaction to some extent. The difference in structure of the dimer between benzo **2** and naphtho system **5** (*i.e.* [4+4] *vs.* [4+2]) may also be due to strong steric interaction between the dithiolane ring and the aromatic ring in [4+4] adduct of the latter. The isolation of **4** and **5** suggests that an isomeric naphthothiete structure like **22** is rendered less stable than the corresponding *o*-thioquinone methide structure by the presence of two sulfur atoms on the α carbon. Some benzothietes have recently been reported to be stable isolable compounds.[8]

Experimental

All the melting points were not corrected. NMR spectra were recorded with a Hitachi R-20B or R-24 spectrometer using tetramethylsilane as an internal standard. Electronic spectra were recorded on a Hitachi EPS-3 spectrophotometer. IR spectra were taken with a Hitachi EPI-G2 spectrometer. Mass spectra were measured with a Hitachi RMU-6L spectrometer (beam energy 70 eV). High pressure liquid chromatography was done with a Hitachi 634 liquid chromatograph (column: Hitachi 3010). Molecular weight were measured with a Hitachi 117 Molecular Weight Apparatus (vapor pressure osmometry in benzene at 40 °C). All the photoreactions were carried out using Pyrex-filtered light (100 W medium pressure mercury lamp) while nitrogen was being bubbled through the reaction solution during the reaction. Thin layer (TLC), preparative layer (PLC), and dry column chromatography (DCC) were performed with silica gel.

*Photoreaction of Naphtho[1,2-c][1,2]dithiole-3-thione (***7***) with Cyclohexene.* The dithiolethione **7**[9] (534 mg, 2.3 mmol) and cyclohexene (7 cm³) were dissolved in 70 cm³ of benzene and the solution was irradiated for 90 min. The evaporation of the solvent gave the thioquinone methide **4** (713.6 mg, *ca.* 100%): mp 153.8—155.3 °C (from ethanol); NMR ($CDCl_3$): δ=1.1—2.3 (8H, m), 3.7—4.2 (2H, m), 7.05 (1H, B part of AB quartet, J=10 Hz), 7.42—7.53 (4H in total, m), 7.68 (1H, A part of AB quartet, J=10 Hz), and 8.8—9.0 (1H, m); UV (CH_2Cl_2): 323 (ε 24300), 353 (10800), 392 (sh, 2540), and 540 nm (11800); molecular weight, Found: 319; Calcd for $C_{17}H_{16}S_3$: 316. Found: C, 64.21; H, 4.97; S, 29.92%. Calcd for $C_{17}H_{16}S_3$: C, 64.51; H, 5.10; S, 30.39%.

Reaction of **4** *with* N-*Phenylmaleimide.* The thioquinone methide **4** (55 mg, 0.17 mmol) and *N*-phenylmaleimide (36 mg, 0.24 mmol) were dissolved in 16 cm³ of benzene and the solution was allowed to stand for 1 d at room temperature. The evaporation of the solvent and PLC (CH_2Cl_2) of the residue gave **8** (71.1 mg, 83%): mp 235.0—237.0 °C (dec) (from ethanol); NMR ($CDCl_3$): δ=1.1—2.2 (8H, m), 3.6—4.0 (2H, m), 4.53 (2H, s), 6.7—8.0 (9H, m), and 8.2—8.6 (2H, m); IR (KBr): 1710 cm^{-1} (C=O); MS: *m/e* (rel intensity) 489 (M^+, 14) and 234 (100). Found: C, 66.29; H, 4.76; N, 2.98; S, 19.39%. Calcd for $C_{27}H_{23}NO_2S_3$: C, 66.23; H, 4.74; N, 2.86; S, 19.64%.

*Photoreaction of Naphtho[2,1-c][1,2]dithiole-1-thione (***10***) with Cyclohexene.* The dithiolethione **10**[9] (350 mg, 1.5 mmol) and cyclohexene (7 cm³) were dissolved in 70 cm³ of benzene and the solution was irradiated for 45 min. After the irradiation, the color of the solution turned deep red. The TLC of the reaction mixture showed a single product, **5**. The solution was evaporated and DCC (CCl_4) of the residue gave a mixture of **5** and **11** (450.5 mg, 95%), as indicated by TLC.

Pure **11** free from **5** was obtained by TLC (CH_2Cl_2) and subsequent recrystallization from ethanol and dichloromethane at −78 °C, and **5** which contained a small amount of **11** was obtained by TLC (CH_2Cl_2): **5**; NMR ($CDCl_3$): δ=1.0—2.5 (8H, m), 3.2—4.2 (2H, m), 7.3—8.2 (5H, m), and 8.3—8.6 (1H, m); UV (CH_2Cl_2): 235 (ε 23900), 263 (17800), 295 (12100), 327 (7160), 392 (sh, 3170), 412 (4440), and 496 nm (4630); **11**; mp 119.0—121.0 °C (from CH_2Cl_2 and ethanol); NMR ($CDCl_3$): δ=1.0—2.5 (16H, m), 3.5—4.2 (4H, m), 6.82 (1H, B part of AB quartet, J=9 Hz), 7.2—8.1 (11H in total, m), and 7.55 (1H, A part of AB quartet, J=9 Hz); UV (CH_2Cl_2): 263 (ε 19400), 354 (sh, 4650), and 450 nm (9540); molecular weight, Found: 666; Calcd: 632. Found: C, 63.91; H, 5.15; S, 30.28%. Calcd for $C_{34}H_{32}S_6$: C, 64.51; H, 5.10; S. 30.39%.

Reaction of **5** *and* **11** *with* N-*Phenylmaleimide.* The thioquinone methide **5** (26.6 mg, 0.08 mmol) and *N*-phenylmaleimide (19.5 mg, 0.11 mmol) were dissolved in 20 cm³ of benzene and the solution was kept at 63 °C for 8.5 h under nitrogen atmosphere. The solvent was evaporated and the residue was subjected to PLC (benzene) to give **12** (22.1 mg, 54%). A benzene solution of **11** (91.5 mg, 0.14 mmol) and *N*-phenylmaleimide (63.9 mg, 0.37 mmol) was kept at 63 °C under nitrogen atmosphere for 8.5 h. The solvent was evaporated and the residue was subjected to PLC (benzene) to give **12** (90.5 mg, 64%): mp 238.0—239.5 °C (dec) (from ethanol); NMR ($CDCl_3$): δ=1.0—2.5 (8H, m), 3.8—4.2 (2H, m), 4.62 (AB q, 2H, J=9 Hz), and 6.8—8.0 (11H, m); IR (KBr): 1720 cm^{-1} (C=O). Found: C, 65.87; H, 4.69; N, 3.08%. Calcd for $C_{27}H_{23}NO_2S_3$: C, 66.23; H, 4.74; N, 2.86%.

*Photoreaction of Naphtho[2,3-c][1,2]dithiole-3-thione (***16***) with Cyclohexene.* The dithiolethione **16**[10] (1.02 g, 4.4 mmol) and 14 cm³ of cyclohexene were dissolved in 200 cm³ of benzene and the solution was irradiated for 100 min. The solution was concentrated to afford white crystals of **19a** (531 mg), which contained one molecule of benzene as solvent of crystallization. The filtrate was subjected to DCC (CH_2Cl_2–CCl_4 1:9) to give **18** (27.9 mg, 3.8%) and **19a** (463 mg), which contained one molecule of CCl_4 as solvent of crystallization. The total yield of **19a** was 994 mg (61%). It was recrystallized from CH_2Cl_2 and the crystals contained one molecule of CH_2Cl_2 as solvent of crystallization: **19a**; mp 200.0—201.0 °C (dec) (from CH_2Cl_2); NMR (in C_6D_6 at 80 °C): δ=1.65 (16H, s), 4.47 (4H, s), 6.7—7.4 (8H, m), 8.15 (1H, bs), 8.26 (1H, bs), 8.38 (1H, bs), and 8.47 (1H, bs); (in CS_2 at 50 °C): δ=1.3—2.3 (16H, m), 3.0—4.5 (4H, m), 7.0—7.7 (8H, m), 7.7—7.9 (2H, m), 7.98 (1H, bs), and 8.07 (1H, bs): UV (CH_2Cl_2): 243 (sh, ε 18300), 339 (2340), and 374 nm (sh, 488); molecular weight, Found: 629; Calcd: 632. Found: C, 58.74; H, 4.99; S, 26.92; Cl, 10.08%. Calcd for $C_{35}H_{34}S_6Cl_2$: C, 58.55; H, 4.77; S, 26.80; Cl, 9.88%. **18**; mp 139—145 °C (from ethanol); NMR ($CDCl_3$): δ=1.2—2.5 (8H, m); 3.8—4.3 (2H, m), 7.2—8.0 (4H, m), 7.70 (1H, s), and 7.99 (1H, s); UV (CH_2Cl_2): 258 (ε 22000), 285 (sh, 13000),

and 342 nm (2750); molecular weight, Found: 355; Calcd: 348; MS: *m/e* (rel intensity) 348 (M^+, 36) and 266 (100). Found: C, 58.58; H, 4.63; S, 36.79%. Calcd for $C_{17}H_{16}S_4$: C, 58.37; H, 4.48; S, 36.63%.

*Photoreaction of **16** with 2,3-Dimethyl-2-butene.* The dithiolethione **16** (1 g, 4.3 mmol) and 5 cm^3 of 2,3-dimethyl-2-butene were dissolved in 80 cm^3 of benzene and the solution was irradiated for 20 min. The solvent was removed and DCC (CCl_4–CH_2Cl_2 5:1) of the residue gave yellow crystals **19b**. The product contained one molecule of CCl_4 as solvent of crystallization. The yield was 1.52 g (81%). The pure product free from CCl_4 was obtained by recrystallization from CS_2 and ethanol: **19b**; mp 172.0—173.5 °C (dec) (from CS_2 and ethanol); NMR ($CDCl_3$): δ=1.22 (6H, bs), 1.35 (6H, bs), 1.66 (6H, bs), 1.78 (6H, bs), 7.1—7.7 (8H, m), 7.87 (2H, s), and 8.28 (2H, s). Found: C, 63.75; H, 5.61; S, 30.28%. Calcd for $C_{34}H_{36}S_6$: C, 64.10; H, 5.70; S. 30.20%.

*Reaction of **19a** with N-Phenylmaleimide.* The dimer **19a** (22.4 mg, 0.06 mmol) and *N*-phenylmaleimide (12.5 mg, 0.07 mmol) were dissolved in 16 cm^3 of benzene and the solution was allowed to stand for 17 d at room temperature. After removal of the solvent, PLC (hexane–ether 1:1) of the residue gave **21** (33 mg, 94%). *N*-Phenylmaleimide (44.4 mg, 0.26 mmol) and **19a** (33 mg, 0.09 mmol) were dissolved in 20 cm^3 of benzene and the solution was refluxed for 1 h. The solvent was evaporated and the residue was recrystallized from benzene to give white crystals **21** (42.2 mg, 83%): mp 258.0—259.5 °C (dec) (from CH_2Cl_2); NMR ($CDCl_3$): δ=1.0—2.3 (8H, m), 3.5—4.4 (2H, m), 4.70 (2H, s), 6.7—7.0 (3H, m), 7.0—8.2 (7H, m), 8.70 (1H, s); NMR (DMSO-d_6): δ=1.2—2.1 (8H, m), 3.8—4.3 (2H, m), 4.70 (2H, s), 6.5—6.9 (3H, m), 7.2—8.1 (7H, m), and 8.68 (1H, s); IR (KBr): 1716 cm^{-1} (C=O); MS: *m/e* (rel intensity) 489 (M^+, 6) and 234 (100). Found: C, 66.30; H, 4.68; N, 2.93%. Calcd for $C_{27}H_{23}NO_2S_3$: C, 66.23; H, 4.74; N, 2.86%.

*Desulfurization of **19a** by Raney Nickel.* Under nitrogen atmosphere at 30 °C, **19a** (206 mg, 0.29 mmol) was added to Raney Ni (W-4), prepared from 20 g of Raney Ni alloy, in 100 cm^3 of benzene and the mixture was kept stirring for 45 min. After **19a** was consumed, the mixture was refluxed for 30 min. Raney Ni was removed by filtration and 1,2-di(2-naphthyl)ethane and 2-methylnaphthalene were analyzed for the filtrate with high pressure liquid chromatography by comparison with authentic samples (solvent: NH_3–MeOH 1:10 for 1,2-di(2-naphthyl)ethane; NH_3–MeOH 1:19 for 2-methylnaphthalene). The yields of 1,2-di(2-naphthyl)ethane and 2-methylnaphthalene were 4.6 and 29.8%, respectively. 1,2-Di(2-naphthyl)ethane was prepared by bromination (*N*-bromosuccinimide) of 2-methylnaphthalene followed by coupling with magnesium; mp 194—194.3 °C ($CHCl_3$).

*Photolysis of **19a**.* A benzene solution (50 cm^3) of **19a** (50 mg, 0.14 mmol) was irradiated for 100 min. The solvent was evaporated and the residue was subjected to PLC (benzene) to give **18** (17.8 mg, 75%). The spectral data of **18** were in agreement with those obtained in the photoreaction of **16** with cyclohexene.

*Desulfurization of **18** with Triphenylphosphine.* Triphenylphosphine (116 mg, 0.44 mmol) and **18** (128 mg, 0.37 mmol) were dissolved in 30 cm^3 of benzene and the solution was allowed to stand for 1 d at room temperature. The solvent was removed and PLC (benzene–hexane 1:1) of the residue gave **19a** and triphenylphosphine sulfide quantitatively.

*Photoreaction of **16** with Olefins at −78 °C.* The dithiolethione **16** (29 mg, 0.12 mmol) and 0.5 cm^3 of cyclohexene were dissolved in 5 cm^3 of dichloromethane and the solution was irradiated at −78 °C for 90 min, but the color derived from **6** was not observed. Dichloromethane solution (5 cm^3) of **16** (5 mg, 0.02 mmol) and 2,3-dimethyl-2-butene (0.5 cm^3) was irradiated for 30 min under the same conditions. However, the color of **6** was not observed.

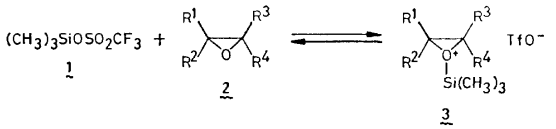
Ring Opening of Oxiranes by Trimethylsilyl Trifluoromethanesulfonate†

Sizuaki MURATA, Masaaki SUZUKI, and Ryoji NOYORI*
Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 29, 1981)

Trimethylsilyl trifluoromethanesulfonate promotes ring opening reactions of oxirane derivatives. The reaction course is highly affected by the structures and substitution pattern of the substrates. Tetra-, tri-, and 2,2-disubstituted oxiranes and simple cycloalkene oxides are converted to the corresponding allylic alcohol trimethylsilyl ethers. The overall transformation is interpreted in terms of trans addition of the silyl trifluoromethanesulfonate to the oxirane ring followed by base-promoted anti elimination of a trifluoromethanesulfonic acid element. 2,3-Dialkyl- or monoalkyloxiranes isomerize to the corresponding ketones and aldehydes, respectively. (*Z*)-Cyclooctene oxide undergoes the transannular reaction to give *endo-cis*-2-trimethylsiloxybicyclo[3.3.0]octane. The reaction of 6-methyl-5-hepten-2-one oxide produces 2,2,6-trimethyl-3-trimethylsiloxy-3,4-dihydro-2*H*-pyran. 1,2-Methyl migration takes place in the reaction of (*E*)-3α-*t*-butyldimethylsiloxy-5α-pregnene 17α,20-oxide to afford 3α-*t*-butyldimethylsiloxy-17β-methyl-17α-[1-(trimethylsiloxy)ethyl]-18-nor-5α-androst-13(14)-ene. α-Pinene oxide gives *trans*-carveol trimethylsilyl ether.

Trimethylsilyl trifluoromethanesulfonate (triflate) (**1**)[1,2] is known as a powerful reagent for the silylation of various active hydrogen compounds such as alcohols, carbonyl compounds, imines, nitriles, *etc.*[3] The efficiency is based on the strong tendency of the trimethylsilyl moiety to coordinate to hetero atoms, particularly an oxygen atom, in the organic substrates. We have been intrigued by the reaction with oxiranes which possess a basic oxygen atom.[4] The strained oxonium salts of type **3**, formed from **1** and oxiranes (**2**), are anticipated to undergo a variety of unique transformations depending on the structures of the substrates and reaction conditions. This paper describes the silyl triflate promoted reactions of a series of oxirane substrates.



Results and Discussion

Conversion of Oxiranes to Allyl Trimethylsilyl Ethers.[5] Certain classes of oxiranes (**4**) were converted smoothly to the allyl trimethylsilyl ethers of type **5** by the treatment with **1** and a nitrogen base in aromatic hydrocarbon media. The trimethylsilyl group of **5** was easily removed by exposure to dilute hydrochloric acid or potassium fluoride in methanol to give the allylic alcohol **6**. Simple cycloalkene oxides were con-

verted to the allyl silyl ethers by exposure to a 1:1 mixture of **1** and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in benzene at ambient temperature (method A). Tetra-, tri-, and 2,2-dialkylated oxiranes are even more reactive and the ring opening reaction has been usually accomplished by the treatment with an equimolar mixture of **1** and 2,6-lutidine in toluene at temperatures as low as −78 °C and then with 1.2—1.3 equiv of DBU at room temperature (method B). Some examples are given in Table 1.

Although ketonic and ester substrates are susceptible to the silylation with **1** in the presence of a nitrogen base,[3] the oxirane ring is much more reactive under these reaction conditions and is cleaved in an ordinary manner, leaving these functions intact. The chemoselective transformations of the bifunctional substrates **17** and **19** illustrate this feature (entries 8 and 9). Oxiranes containing a hydroxyl function were converted to the bis(trimethylsilyl) ethers by using 2 equiv of **1** (entries 10—12).

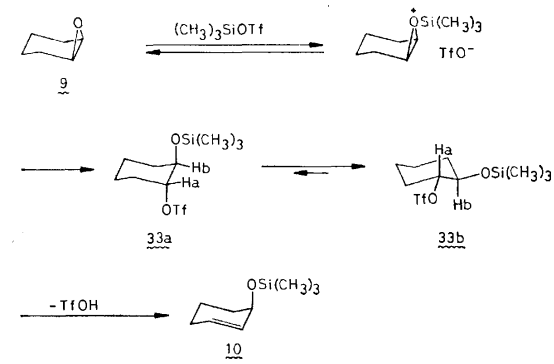
The overall transformation, **4**→**5**, is accomplished *via* trans addition of **1** to the oxirane ring[6] followed by anti elimination of a TfOH element away from the trimethylsiloxy group. Under the present reaction conditions, trimethylsilylammonium triflates of type **31** or **32** may serve as active species.[7] Triflate,

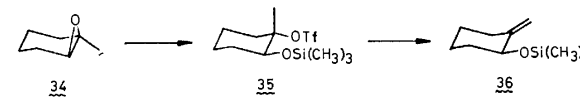
though is a feeble nucleophile, displaces the oxirane ring activated through coordination of a trimethylsilyl group, giving the addition product. When an unsymmetrically alkylated oxirane is used, the triflate displacement takes place preferentially at the more substituted carbon atom. This regioselection is readily understood by considering the electronic properties of the silylated oxirane structure; the alkyl substitution decreases the relative magnitude of electron density at the carbon attached to it and increases the LUMO coefficient of the same carbon, resulting in enhancement of the electrophilic reactivity.[6]

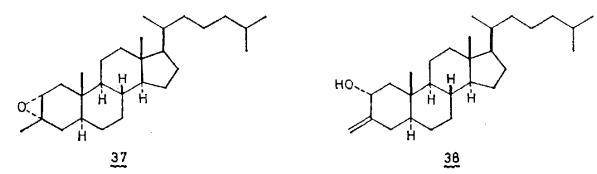
When cyclohexene oxide (**9**) was treated with **1** equiv of **1** and triethylamine in hexane at room temperature, a single, labile product **33** was produced. The ^{1}H NMR spectrum exhibited Ha and Hb signals at δ 4.46 (ddd) and 3.57 (ddd) with the vicinal coupling constant of 10 Hz, substantiating the trans stereochemistry. Treatment of **33** with DBU led to the olefinic compound **10**. The production of the allyl silyl ether **10** (not an enol silyl ether) is a consequence

† Dedicated to Professor Hitosi Nozaki on the occasion of his 60th birthday.

of anti elimination of TfOH; the two conformers, **33a** and **33b**, are possible for **33**, but only the less stable conformer **33a** can undergo the E2 elimination reaction.[8] It is worth noting that such controlling factors display a unique selectivity in the reaction of certain cyclic trisubstituted oxirane derivatives. For instance, the reaction of 1-methylcyclohexene oxide (**34**) with **1** produces the initial adduct **35**. Since the TfO group locates in an equatorial position in the stable conformer, the base-promoted anti elimination of TfOH occurs selectively in such a way to produce **36** which possesses an exocyclic methylene group.[8e,f] In a like manner, the reaction of the steroidal substrate **37** with **1** and 2,6-di-*t*-butylpyridine afforded after desilylation the alcoholic product **38** exclusively.







When a monocyclic oxirane is subjected to the displacement by **1**, a conformationally flexible adduct of type **39a**⇄**39b**⇄**39c** is formed. The E2 elimination reaction occurs from the most stable conformer **39a** in which the dipole repulsion is minimized, resulting in the regioselective formation of the allyl silyl ether. The stereoselective production of *E* dienes from geraniol or nerol 2,3-oxide (**23** and **25**, respectively) is interpreted in terms of the preference of the conformer **40a** over **40b**[8a-d] (entries 11 and 12).

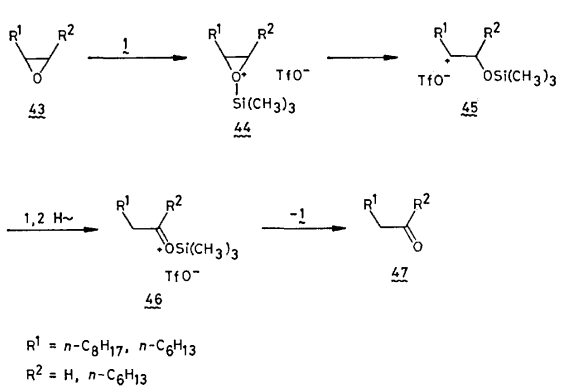
a) Isolated yield. b) Determined by GLPC analysis. c) Based on consumed starting material. d) The reaction was carried out in toluene by using 2,6-di-*t*-butylpyridine as base. e) Isolated yield of desilylated product. f) The reaction was carried at 80 °C. g) A mixture of isomeric enol silyl ethers was obtained in 65% yield.

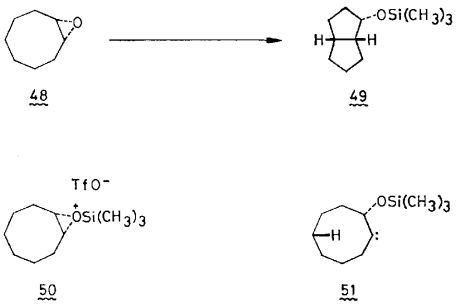
The oxirane to allylic alcohol conversion is an important operation from the synthetic point of view, and a number of effective reagents have been devised for this purpose. Oxiranes derived from five- to seven-membered cyclic olefins can be converted to the corresponding allylic alcohols by strongly basic lithium amide reagents in refluxing solvents.[9] The recently developed dialkylaluminum amides[10] and a dialkylboron triflate[11] are applicable to the reaction of *trans*-2,3-dialkylated or further alkylated oxiranes. These reagents are not utilized for the isomerization of the *cis*-2,3-dialkylated oxiranes, however. A mild, two-step procedure by the use of an organoselenium compound was also elaborated; reaction of oxiranes with sodium benzeneselenolate followed by oxidative deselenation of the addition products gives rise to the allylic alcohols.[12] Here when an unsymmetrically substituted oxirane is used, the ring opening occurs preferentially at the less substituted carbon atom, and the sense of the regioselection is opposite that observed in this work. The present procedure based on the use of the organosilicon compound **1** requires very mild reaction conditions and displays unique stereo-, regio-, and chemoselectivity. As such this method, complementary to the existing recipes, provides a useful tool in organic synthesis. It should be added that silyl iodides[13] and silyl selenides in the presence of a Lewis acid[14] behave in a similar manner in the reaction with oxiranes.

Isomerization of Oxiranes to Carbonyl Compounds. Unlike cycloalkene oxides, simple 2,3-dialkylated and monoalkylated oxiranes were inert to the standard reaction conditions. When these substrates with **1** added amines were subjected to the more forcing conditions, there were obtained the corresponding carbonyl compounds as exclusive or major products. For instance, reaction of 1-decene oxide with **1** and 2,6-lutidine in benzene at 80 °C led to decanal in 89% yield. Likewise, (*Z*)-7-tetradecene oxide was converted to 7-tetradecanone quantitatively. The reaction of the *E* isomer gave some allylic alcohol derivatives. Thus, reaction of (*E*)-7-tetradecene oxide (**41**) with **1** and 2,6-lutidine in benzene at 80 °C followed by treatment with DBU at room temperature afforded (*E*)-8-trimethylsiloxy-6-tetradecene (**42**) (17% yield) in addition to isomeric enol silyl ethers of 7-tetradecanone (65% combined yield) (Table 1, entry 15).[15] The isomerization to carbonyl compounds would proceed *via* carbocation intermediates. The oxonium species



44, generated from a di- or monosubstituted oxirane **43**, is not reactive enough to suffer nucleophilic displacement by triflate anion.[5] When **44** is heated, however, it undergoes unimolecular C–O bond rupture to produce the unstable carbocation **45**,[16] which readily isomerizes to the stable carboxonium intermediate **46** *via* 1,2-hydride transfer. Subsequent desilylation gives rise to the carbonyl product **47**.

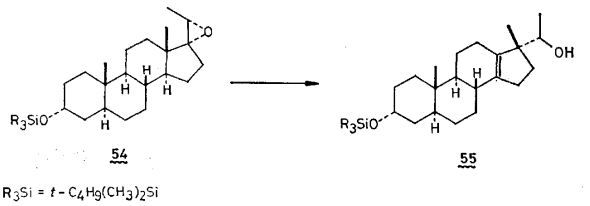
Reaction of Cyclooctene Oxide (48). In the presence of 2,6-lutidine the title reaction proceeded cleanly at room temperature to give the bicyclic compound **49** in quantitative yield. Although the mechanism has not yet been clarified, the carbene species **51** formed by base-aided α-elimination of the trimethylsilylated oxirane **50** seems to be an attractive candidate for the intermediate.[17] The lithium amide-generated carbene is known to undergo the same type of transannular reaction.[18] When reaction of **48** and **1** was conducted in the absence of any added amines, cyclooctanone was formed (87% yield), probably *via* a carbocation mechanism.



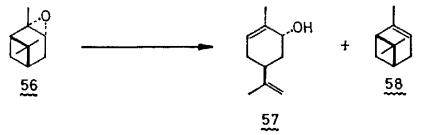
Neighboring Group Participation in the Oxirane Ring Opening. When oxirane substrates contain some nucleophilic atom or bond at a spatially suitable position, the ring opening is facilitated by electron release from such moiety.[19]

The keto oxirane **52** upon sequential treatments by a mixture of **1** and 2,6-lutidine and then by DBU underwent clean cyclization *via* carbonyl group participation to give the dihydropyran derivative **53** in 80% yield.

The carbon-carbon σ bond participation is exemplified by the reaction of the steroidal 17α,20-oxide **54** which affords after removal of the trimethylsilyl group the product **55** in 86% yield. Here the triflate attack on the silylated oxirane species is prevented by screening effect of the adjacent methyl group and, instead, this angular methyl undergoes 1,2-migration to form the rearranged product.[20]

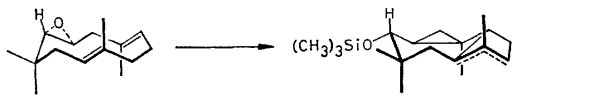


When α-pinene oxide (**55**) was exposed to a mixture of **1** and 2,6-lutidine and then DBU, there was obtained after desilylation *trans*-carveol (**57**) in 72% yield.[21] In addition, α-pinene (**58**), a deoxygenation product, was formed in 6% yield.



56 57 58

The recently discovered conformationally selective transannular cyclization of humulene 9,10-oxide (**59**) to the tricyclic compounds **60** and **61**[22,23] is an example of the C=C bond participation in the silyl triflate promoted ring cleavage.



59 60 and 61 (two isomers)

Deoxygenation of Oxiranes. With certain oxirane substrates, the deoxygenation becomes a significant pathway. For example, squalene 2,3-oxide (**62**) was converted to squalene (**63**) in 70% yield by the treatment with **1** and 2,6-lutidine at −78 °C. The mechanism is unclear.[24]

62 63

Experimental

*General.*** Melting points and boiling points were uncorrected. IR spectra were recorded on a JASCO IR A-1 spectrometer in a noted phase. ^{1}H NMR spectra were determined on a Varian NV-21 or HA-100 spectrometer. Chemical shifts are reported as δ values in parts per million relative to tetramethylsilane=0. Splitting patterns are indicated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet, and br means a broad signal. Mass spectra were determined on a JEOL D-100 spectrometer, operating with an ionization energy of 75 eV. Elemental analyses were performed at Department of Applied Chemistry, Nagoya University. All reactions using trimethylsilyl triflate (**1**) were carried out in a dried vessel under argon atmosphere. Unless otherwise stated, the organic extracts were dried by passing through a short column of anhydrous K_2CO_3. For concentration of solutions, unless otherwise stated, a vacuum (50—100 mmHg) rotary evaporator was used. Bulb-to-bulb short-path distillation was performed by using a Büchi Kugelrohrofen. The cited temperatures for these distillations refer to the maximum temperature attained by the oven during the distillation and are thus not true boiling points.

Chromatography. Silica gel 60 F_{254} precoated plates (E. Merck) at 0.25 mm thickness were used for both analytical and preparative TLC. Analytical plates were visualized by spraying with a solution of 2% $Ce(SO_4)_2$ in 5% H_2SO_4 or 2% *p*-anisaldehyde in 5% ethanolic H_2SO_4 followed by heating on a hot plate, or exposure to I_2 vapor. Column chromatography was conducted by using 70—230 mesh silica gel 60 available from E. Merck. In certain cases silica gel was used after ammonia treatment; silica gel was mixed with about 30% parts of 10% ammonia solution and then heated at 130 °C for 2 h. GLPC analyses were performed on a Hitachi 063 or 163 instrument, using nitrogen or helium as the carrier gas (9.807×10^4 Pa), respectively. A Varian 1700 instrument was used for preparative GLPC, using helium as the carrier gas (1.961×10^5 Pa).

Solvents and Materials. Trimethylsilyl triflate (**1**), prepared from chlorotrimethylsilane and trifluoromethanesulfonic acid,[2c] was distilled twice with *ca.* 1 vol% of triethylamine to remove all protic substances. Commercial oxiranes, **9**, **29**, and **48**, obtained from Tokyo Kasei Kogyo, Wako Junyaku, and Aldrich Chemical Co, respectively, were used without further purification. Oxiranes, **7**, **11**, **19**, **21**, **31**, **36**, **52**, **56**, 1-decene oxide, and (*Z*)- or (*E*)-7-tetradecene oxide were prepared from commercial alkenes by oxidation with 25% acetone solution of peracetic acid or 85% *m*-chloroperbenzoic acid in dichloromethane at 0 °C. The purities (>99%) of these oxiranes were confirmed by the ^{1}H NMR, GLPC, and TLC analises. Other oxiranes, **13**, **23**, **25**, **27**, **39**, **54**, and **62**, were prepared according to the procedures in the literatures.[10c, 25-29] DBU, 2,6-lutidine, and 2,6-di-*t*-butylpyridine were dried by distillation from CaH_2 before use. Benzene, toluene, and hexane were distilled from Na. Dichloromethane was distilled from P_2O_5. Other commercially supplied materials and solvents were used as received.

*Preparation of 4,8-Dimethyl-7-nonen-2-one Oxide (**17**).* To a 1.1 mol dm^{-3} ethereal solution of methylmagnesium bromide (70 ml, 0.077 mol) was added citronellal (10.0 g, 0.065 mol) dissolved in dry ether (50 ml) drop by drop over a period of 30 min at 0 °C. The mixture was stirred at 22 °C for 1 h and at reflux temperature for 3 h. The mixture was cooled to 0 °C and to this was added 1 mol dm^{-3} HCl (100 ml) slowly. The organic layer was separated and the aqueous layer was extracted with ether (50 ml × 2). The combined organic layers were dried over anhydrous $MgSO_4$ and concentrated. The residue was dissolved in acetone (300 ml) and to this was added a 3 M CrO_3 solution in 50% H_2SO_4 (150 ml) drop by drop at 0 °C. The mixture was poured into ice water (800 g) and extracted with ether (100 ml × 2) and benzene (100 ml × 3). The combined extracts were washed with saturated KNO_3, dried over anhydrous $MgSO_4$, and concentrated. Distillation (76—82 °C/3 mmHg) gave 4,8-dimethyl-7-nonen-2-one (7.68 g, 70%) as a colorless oil.

To a mixture of 4,8-dimethyl-7-nonen-2-one (3.00 g, 0.018 mol) thus obtained and anhydrous Na_2CO_3 (3.0 g) in dichloromethane (80 ml) was added in a dropwise manner a 2 mol dm^{-3} acetone solution of peracetic acid (11 ml, 0.022 mol) at 0 °C. After stirring at 0 °C for 4 h, the mixture was poured into water (300 ml). The organic layer was separated and the aqueous layer was extracted with dichloromethane (30 ml × 3). The combined organic layers were washed with saturated $NaHCO_3$ and twice with saturated Na_2SO_3, dried, and concentrated. Distillation (80—86 °C/1 mmHg) afforded pure **17** (2.81 g, 85%) as a colorless oil: IR (neat) 1716 cm^{-1} (C=O); NMR (CCl_4) 0.90 (3H, d, J=6.5 Hz, CH_3), 1.20 (3H, s, CH_3), 1.24 (3H, s, CH_3), 1.65—1.25 (5H, m, methylene and methine), 2.04 (3H, s, CH_3C=O), 2.27 (2H, triplet-like, J=7 Hz, CH_2C=O), and 2.51 (1H, t, J=5.2 Hz, CHO). Found:

** 1 mmHg≈133.3 Pa; 1 ml=0.001 dm^3.

C, 71.5; H, 10.7%. Calcd for $C_{11}H_{20}O_2$: C, 71.7; H, 10.9%.

*Reaction of Cyclopentene Oxide (**7**) with **1**.* To a solution of **1** (1.01 g, 4.56 mmol) in benzene (12 ml) was added a mixture of **7** (0.348 g, 4.13 mmol) and DBU (0.8 ml) in benzene (5 ml) drop by drop over a period of 5 min at 32 °C. The mixture was stirred for 19 h and then poured into 0.1 mol dm^{-3} HCl. The mixture was extracted with pentane (20 ml×3). The extracts were dried, concentrated at 200 mmHg, and chromatographed on a column of NH_3-treated silica gel, eluting with a 1:1 mixture of benzene and hexane, to afford pure **8** (0.236 g, 33%) as a colorless oil. GLPC analysis of the extracts on a column of 5% FFAP on Chromosorb W AW (3 mm×2 m) at 60 °C indicated the yield of **8** (t_R=2.3 min) to be 59%: IR (neat) 1251 cm^{-1}; NMR ($CDCl_3$) 0.14 (9H, s, CH_3Si), 2.5—1.4 (4H, m, two methylenes), 4.88 (1H, m, CHO), 5.71 (1H, br d, J=5.7 Hz, CH=), and 5.98 (1H, br d, J=5.7 Hz, CH=).

*Reaction of Cyclohexene Oxide (**9**) with **1**.* A mixture of **1** (2.26 g, 10.2 mmol), **9** (1.06 g, 10.7 mmol), and DBU (2 ml) in benzene (25 ml) was stirred at 22 °C for 20 h. The mixture was poured onto a column of NH_3-treated silica gel (15 g) and eluted by a 2:1 mixture of hexane and ether (300 ml). The eluate was cocentrated at 200 mmHg and distilled. Redistillation of the fraction boiling at 50—60 °C/50 mmHg gave pure **10** (1.51 g, 87%) as a colorless oil; IR (neat) 1250 cm^{-1}; NMR ($CDCl_3$) 0.13 (9H, s, CH_3Si), 2.1—1.2 (6H, m, methylene), 4.19 (1H, m, CHO), and 5.67 (2H, m, CH=).

*Reaction of Cyclohexene Oxide (**9**) with **1** in the Absence of DBU.* A mixture of **1** (0.225 g, 1.15 mmol), triethylamine (0.16 ml), and **9** (0.110 g, 1.12 mmol) in hexane (5 ml) was stirred at 21 °C for 10 h and then the solvent was removed at 1 mmHg. The adduct **35** (0.339 g) was obtained as a pale brown oil: NMR (CCl_4) 0.14 (9H, s, CH_3Si), 2.4—1.2 (8H, m, methylene), 3.57 (1H, ddd, J=10.0, 7.8, and 4.2 Hz, CHOSi), and 4.47 (1H, ddd, J=10.0, 7.8, and 4.0 Hz, CHOTf).

*Treatment of **35** with DBU.* The adduct **35** (0.339 g, 1.13 mmol) was mixed with DBU (0.3 ml) in benzene (5 ml) and the mixture was stirred at 21 °C for 18 h. This was then poured into water and extracted with hexane (5 ml×3). The extracts were dried and concentrated. Column chromatography on NH_3-treated silica gel, eluting with a 1:1 mixture of benzene and hexane, gave pure **10** (0.133 g, 71%).

*Reaction of Cycloheptene Oxide (**11**) with **1**.* A mixture of **1** (1.14 g, 5.01 mmol), **11** (0.506 g, 4.51 mmol), and DBU (1 ml) in benzene (15 ml) was stirred at 22 °C for 14 h. This was then poured into water and extracted with pentane (5 ml×3). The extracts were dried, concentrated, and chromatographed on a column of silica gel, eluting with a 1:1 mixture of benzene and hexane, to give **11** (0.298 g, 59%) and pure **12** (0.317 g, 40%, 100% based on consumed **11**): IR (neat) 1251 cm^{-1}; NMR ($CDCl_3$) 0.12 (9H, s, CH_3Si), 2.2—1.2 (8H, m, four methylenes), 4.38 (1H, m, CHO), and 5.68 (2H, m, CH=).

*Reaction of (E)-Cyclododecene Oxide (**13**) with **1**.* A mixture of **1** (0.502 g, 2.26 mmol), **13** (0.392 g, 2.15 mmol), and DBU (0.4 ml) in benzene (11 ml) was stirred at 27 °C for 40 h, and then to this was added a mixture of hexane (10 ml) and 0.1 mol dm^{-3} HCl (3 ml). The organic layer was separated and the aqueous layer was extracted with pentane (5 ml×6). The combined organic layers were washed with 0.1 mol dm^{-3} HCl and 5% $NaHCO_3$, dried, and concentrated. Column chromatography on silica gel, eluting with a 1:1 mixture of benzene and hexane, gave pure **14** (0.208 g, 38%): IR (neat) 1249 cm^{-1}; NMR (CCl_4) 0.12 (9H, s, CH_3Si), 2.5—1.2 (18H, m, nine methylenes), 3.94 (1H, br, CHO), and 5.28 (2H, m, CH=).

*Reaction of 2,3-Dimethyl-2-butene Oxide (**15**) with **1**.* To a solution of **1** (0.195 g, 0.88 mmol) and 2,6-lutidine (0.10 ml) in toluene (4 ml) was added **15** (0.105 g, 1.10 mmol) dissolved in toluene (1 ml) at −78 °C drop by drop over a period of 5 min. The mixture was stirred at −78 °C for 4 h, and then to this was added DBU (0.15 ml). After stirring at 15 °C for 5 h, a solution of 1-trimethylsiloxycyclohexene (0.158 g, 0.93 mmol) in hexane (2 ml) was added as the internal standard. The mixture was washed with 0.1 mol dm^{-3} HCl and dried. The GLPC analysis on a column of 3% Silicone OV-1 on Chromosorb W AW (3 mm×2 m) at 90 °C indicated the yield of **16** (t_R=4.6 min) to be 87%. Pure **16** was isolated by preparative GLPC, by using a column of 10% Silicone OV-1 on Chromosorb W AW (7 mm×3 m) at 110 °C: IR (neat) 1248 cm^{-1}; NMR (CCl_4) 0.08 (9H, s, CH_3Si), 1.33 (6H, s, CH_3), 1.76 (3H, br s, CH_3C=), 4.68 (1H, m, CH_2=), and 4.87 (1H, m, CH_2C=).

*Reaction of 4,8-Dimethyl-7-nonen-2-one Oxide (**17**) with **1**.* A mixture of **1** (0.545 g, 2.45 mmol), 2.6-lutidine (0.28 ml), and **17** (0.516 g, 2.45 mmol) in toluene (7 ml) was stirred at −78 °C for 4 h, and to this was added DBU (0.35 ml). The mixture was stirred at 20 °C for 30 min and poured into a mixture of hexane (30 ml) and water (10 ml). The mixture was extracted with hexane (5 ml×3). The extracts were washed with 0.1 mol dm^{-3} HCl and 5% $NaHCO_3$, dried, and concentrated. Column chromatography on silica gel, eluting with benzene, gave pure **18** (0.437 g, 69%) as a colorless oil: IR (neat) 1718 (C=O) and 1249 cm^{-1}; NMR (CCl_4) 0.02 (9H, s, CH_3Si), 0.86 (3H, d, J=6.1 Hz, CH_3), 1.62 (3H, br s, CH_3C=), 2.0—1.0 (5H, m, two methylenes and methine), 2.03 (3H, s, CH_3C=O), 2.18 (1H, d, J=6.5 Hz, CH_2C=O), 2.26 (1H, d, J=6.5 Hz, CH_2C=O), 3.91 (1H, t, J=6.0 Hz, CHO), 4.68 (1H, m, CH_2=), and 4.78 (1H, m, CH_2=); Ms *m/e* (rel intensity) 256 (15), 143 (100), and 73 (44). Found: C, 65.8; H, 10.8%. Calcd for $C_{14}H_{28}O_2Si$: C, 65.6; H, 11.0%.

*Reaction of Methyl Citronellate Oxide (**19**) with **1**.* A mixture of **1** (0.346 g, 1.55 mmol), 2,6-lutidine (0.18 ml), and **19** (0.306 g, 1.53 mmol) in toluene (6 ml) was stirred at −78 °C for 4 h. Then to this was added DBU (0.15 ml) at −78 °C. The mixture was stirred at 15 °C for 2 h and diluted by hexane (30 ml). The mixture was washed with 0.1 mol dm^{-3} HCl and saturated $NaHCO_3$, dried, and concentrated. Column chromatography on silica gel, eluting with a 20:1 mixture of benzene and ethyl acetate, gave pure **20** (0.330 g, 79%) as a colorless oil: IR (neat) 1742 (C=O) and 1250 cm^{-1}; NMR (CCl_4) 0.02 (9H, s, CH_3Si), 0.90 (3H, d, J=6.2 Hz, CH_3), 1.64 (3H, br s, CH_3C=), 2.3—1.0 (7H, m, three methylenes and methine), 3.61 (3H, s, CH_3O), 3.92 (1H, t, J=6.0 Hz, CHO), 4.76 (1H, m, CH_2=), and 4.81 (1H, m, CH_2=); Ms *m/e* (rel intensity) 272 (8), 257 (7), 143 (100), 73 (59), and 59 (21). Found: C, 61.7; H, 10.4%. Calcd for $C_{14}H_{28}O_3Si$: C, 61.8; H, 10.3%.

*Reaction of Citronellol Oxide (**21**) with **1**.* To a solution of **1** (0.429 g, 1.93 mmol) and 2,6-lutidine (0.22 ml) in toluene (5 ml) was added in a dropwise manner **21** (0.170 g, 0.99 mmol) dissolved in toluene (3 ml) at −78 °C. The mixture was stirred at −78 °C for 5 h and then to this was added DBU (0.3 ml). The mixture was stirred at 28 °C for 4 h, poured into 0.1 mol dm^{-3} HCl, and extracted with hexane (8 ml×4). The combined extracts were dried and

concentrated. Bulb-to-bulb distillation (120 °C/1 mmHg) gave pure **22** (0.217 g, 71%) as a colorless oil: IR (neat) 1248 cm^{-1}; NMR ($CDCl_3$) 0.10 (18H, s, CH_3Si), 0.83 (3H, d, J=6.2 Hz, CH_3), 1.7—1.0 (7H, m, three methylenes and methine), 1.70 (3H, br s, CH_3C=), 3.62 (2H, t, J=6.5 Hz, CH_2O), 4.20 (1H, t, J=6.5 Hz, CHO), 4.80 (1H, m, CH_2=), and 4.87 (1H, m, CH_2=).

*Reaction of Geraniol 2,3-Oxide (**23**) with **1**.* To a solution of **1** (0.264 g, 1.19 mmol) and 2,6-lutidine (0.14 ml) in toluene (3 ml) was added **23** (0.109 g, 0.64 mmol) dissolved in toluene (2 ml) in a dropwise manner over a period of 5 min at −78 °C. After stirring at −78 °C for 4 h, DBU (0.2 ml) was added. The mixture was stirred at 30 °C for 54 h, poured into 0.1 mol dm^{-3} HCl, and extracted with hexane (5 ml×3). The combined extracts were dried, concentrated, and chromatographed on a column of NH_3-treated silica gel, eluting with a 1:1 mixture of benzene and hexane, to give bis(trimethylsilyl) ether of (*E*)-3,7-dimethyl-3,6-octadiene-1,2-diol[10] (**24**) (0.124 g, 66%) as a colorless oil: IR (neat) 1250 cm^{-1}; NMR ($CDCl_3$) 0.09 (18H, s, CH_3Si), 1.58 (3H, s, CH_3C=), 1.72 (3H, s, CH_3C=), 2.71 (2H, t, J=7.0 Hz, =CCH_2C=), 3.48 (2H, d, J=6.3 Hz, CH_2O), 4.04 (1H, t, J=6.2 Hz, CHO), 5.11 (1H, br t, CH=), and 5.38 (1H, t, J=7.0 Hz, CH=).

*Reaction of Nerol 2,3-Oxide (**25**) with **1**.* To a mixture of **1** (0.330 g, 1.48 mmol) and 2,6-lutidine (0.17 ml) in toluene (4 ml) was added a solution of **25** (0.132 g, 0.78 mmol) in toluene (2 ml) drop by drop over a period of 10 min at −78 °C. After stirring at −78 °C for 3 h, DBU (0.25 ml) was added and the mixture was stirred at 32 °C for an additional 14 h. The reaction was quenched by pouring into 0.1 mol dm^{-3} HCl. The mixture was extracted with hexane (5 ml×3). The extracts were dried and concentrated. Column chromatography on NH_3-treated silica gel, eluting with a 1:2 mixture of benzene and hexane, afforded a 4:1 mixture of **24** and bis(trimethylsilyl) ether of 7-methyl-3-methylene-6-octene-1,2-diol[10d] (**26**) (totally 0.188 g, 81%) as a colorless oil: IR (neat) 1252 cm^{-1}; NMR (CCl_4) 0.07 and 0.09 (totally 18H, two singlets, CH_3Si), 1.55 and 1.72 (totally 8.4H, two broad singlets, CH_3C= of **24** and **26**), 2.04 (0.4H, m, CH_2C= of **26**), 2.72 (1.6H, t, J=7.0 Hz, =CCH_2C= of **24**), 3.45 (2H, m, CH_2O of **24** and **26**), 4.06 (1H, m, CHO of **24** and **26**), 4.83 (0.2H, m, CH_2= of **26**), 5.3—5.0 (1.2H, m, CH_2= of **26** and CH= of **24**), and 5.41 (0.8H, t, J=6.3 Hz, CH= of **24**).

*Reaction of Methylenecyclohexane Oxide (**27**) with **1**.* To a stirred solution of **1** (0.987 g, 4.40 mmol) and 2,6-lutidine (0.52 ml) in toluene (7 ml) was added in a dropwise manner **27** (0.490 g, 4.37 mmol) dissolved in toluene (3 ml) over a period of 5 min at −78 °C. The mixture was stirred at −78 °C for 3 h and to this was added DBU (0.52 ml). The mixture was stirred at 32 °C for 14 h, then poured into 0.1 mol dm^{-3} HCl, and extracted with hexane (5 ml×3). The combined extracts were dried and concentrated. Bulb-to-bulb distillation (150 °C/40 mmHg) gave pure **28** (0.581 g, 72%) as a colorless oil: IR (neat) 1250 cm^{-1}; NMR (CCl_4) 0.11 (9H, s, CH_3Si), 1.60 (4H, m, two methylenes), 1.98 (4H, m, CH_2C=), 3.96 (2H, s, CH_2O), and 5.62 (1H, br, CH=).

*Reaction of 2-Methylpropene Oxide (**29**) with **1**.* To a solution of **1** (0.473 g, 2.13 mmol) in toluene (7 ml) was added 2,6-lutidine (0.25 ml) at 13 °C. The mixture was cooled in a Dry Ice–acetone bath (−78 °C), and to this was added a solution of **29** (0.164 g, 2.27 mmol) in toluene (1 ml). After the mixture was stirred at −78 °C for 10 h, DBU (0.33 ml) was added. Then the cooling bath was removed and the mixture was stirred at 13 °C for 0.5 h. To this was added 1-trimethylsiloxycyclopentene (0.229 g, 1.47 mmol) as the internal standard and poured into water. The mixture was extracted with pentane (10 ml). The GLPC analysis on a column of 5% Apiezone-L on Neopak 1 A (3 mm×2 m) at 70 °C indicated the yield of **30** (t_R= 5.6 min) to be 62%. The product identification was made by coinjection with authentic sample prepared from 2-methyl-2-propen-1-ol and chlorotrimethylsilane.

*Reaction of 1-Methylcyclohexene Oxide (**34**) with **1**.* To a mixture of **1** (0.705 g, 3.17 mmol) and 2,6-lutidine (0.37 ml) in toluene (5 ml) was added **34** (0.368 g, 3.28 mmol) dissolved in toluene (2 ml) drop by drop over a period of 10 min at −78 °C. The mixture was stirred at −78 °C for an additional 2 h, and then to this was added DBU (0.55 ml). The mixture was stirred at 24 °C for 3 h, poured into 0.1 mol dm^{-3} HCl, and extracted with hexane (5 ml× 4). The extracts were washed with water, dried, concentrated, and chromatographed on a column of silica gel, eluting with a 2:3 mixture of benzene and hexane, to afford pure **36** (0.459 g, 80%) as a colorless oil: IR (neat) 1252 cm^{-1}; NMR ($CDCl_3$) 0.11 (9H, s, CH_3Si), 2.6—1.1 (8H, m, four methylenes), 4.04 (1H, m, CHO), 4.69 (1H, m, CH_2=), and 4.86 (1H, m, CH_2=).

*Reaction of 3β-Methyl-5α-cholest-2-ene 2α,3α-Oxide (**37**) with **1**.* A 0.2 M toluene solution of **1** (0.5 ml, 0.1 mmol) was cooled to −78 °C and to this was added 2,6-di-*t*-butylpyridine (0.03 ml) followed by the addition of **37** (0.020 g, 0.05 mmol) dissolved in toluene (1.5 ml). The mixture was stirred at −78 °C for 10 h and quenched by adding methanol (1 ml) and 3 drops of concd HCl. The mixture was stirred at 17 °C for 2 h, poured into water, and extracted with petroleum ether (5 ml×3). The extracts were dried and concentrated. Preparative TLC on a silica gel plate, developing with a 7:1 mixture of petroleum ether and ethyl acetate, gave pure **37** (0.008 g) and pure **38** (0.012 g, 58%, 95% based on consumed **37**) as colorless crystals: mp 112—114 °C (lit,[30] mp 113—114 °C); IR (KBr) 3640—3250 cm^{-1} (OH); NMR (CCl_4) 2.2—0.6 (45H, m, methyl, methylene, and methine), 4.13 (1H, m, CHO), 4.65 (1H, m, CH_2=), and 4.80 (1H, m, CH_2=).

*Reaction of 1-Decene Oxide with **1**.* A mixture of **1** (0.260 g, 1.17 mmol), 2,6-lutidine (0.1 ml), and 1-decene oxide (0.167 g, 1.07 mmol) in benzene (4 ml) was heated at 80 °C for 10 h. After cooling to 18 °C, the mixture was poured into water and extracted with hexane (5 ml×3). The extracts were washed with saturated $NaHCO_3$, dried, and concentrated. Bulb-to-bulb distillation (120 °C/100 mmHg) gave pure decanal (0.148 g, 89%) as a colorless oil. The identification was made by GLPC analysis on a column of 5% DEGS on Neopak 1A (3 mm×2 m) at 110 °C (t_R=6.4 min).

*Reaction of (Z)-7-Tetradecene Oxide with **1**.* A mixture of **1** (0.542 g, 2.44 mmol), 2.6-lutidine (0.19 ml), and (*Z*)-7-tetradecene oxide (0.536 g, 2.53 mmol) in benzene (5 ml) was heated at 80 °C for 10 h. After cooling to 15 °C, the mixture was poured into water and extracted with hexane (5 ml×3). The extracts were washed with saturated $NaHCO_3$, dried, and concentrated. Bulb-to-bulb distillation (100 °C/1 mmHg) gave 7-tetradecanone (0.511 g, 100%) as a colorless oil. The identification was made by GLPC analysis on a column of 5% DEGS on Nepopak 1A (3 mm× 2 m) at 150 °C (t_R=5.1 min).

*Reaction of (E)-7-Tetradecene Oxide (**41**) with **1**.* A mixture of **1** (0.270 g, 1.20 mmol), 2,6-lutidine (0.14 ml), and **41** (0.260 g, 1.22 mmol) in benzene (5 ml) was heated at 80 °C for 8 h in a sealed tube. After cooling to 13 °C, to this was added DBU (0.19 ml). The mixture was stirred

at 13 °C for 2 h and then poured into 0.1 mol dm^{-3} HCl. The mixture was extracted with hexane (10 ml×3), and the extracts were dried and concentrated. Bulb-to-bulb distillation (125 °C/0.5 mmHg) gave a mixture (0.305 g, 89%) of **42** and four isomers of 7-tetradecanone enol silyl ethers as a colorless oil: IR (neat) 1675 (C=C) and 1251 cm^{-1}; NMR (CCl_4) 0.04 (2H, s, CH_3Si), 0.14 (7H, s, CH_3Si), 0.88 (6H, br t, CH_3), 1.28 (16H, br s, eight methylenes), 1.94 (3H, br, CH_2C=), 2.26 (1H, t, CH_2C=), 3.98 (0.2H, m, CHO of **42**), 4.35 (0.2H, t, J=7.4 Hz, CH= of enol silyl ethers trans to OSi),[31] 4.47 (0.6H, t, J=7.0 Hz, CH= of enol silyl ethers cis to OSi),[31] 5.27 (0.2H, m, CH= of **42**), and 5.51 (0.2H, dd, J=14.8 and 6.3 Hz, =CCHO of **42**).

Reaction of Cyclooctene Oxide (48) with 1. To a solution of **1** (0.344 g, 1.55 mmol) and 2,6-lutidine (0.18 ml) in toluene (3 ml) was added **48** (0.205 g, 1.63 mmol) dissolved in toluene (2 ml) drop by drop over a period of 5 min at −50 °C. After 3-h reaction at −50 °C, the mixture was warmed to 26 °C and stood for 40 h. The mixture was poured into water and extracted with hexane (5 ml×4). The combined extracts were dried and concentrated. The crude products consisted of the silyl ether **49** and the desilylated alcohol. This was dissolved in 5% methanolic HCl (10 ml), stirred at 26 °C for 1 h, and concentrated. Bulb-to-bulb distillation (125 °C/20 Torr) gave pure *endo-cis*-bicyclo[3.3.0]octan-2-ol[9r] (0.203 g, 100%): IR (neat) 3650—3300 cm^{-1} (OH); NMR (CCl_4) 1.9—1.2 (10H, m, five methylenes), 2.40 (2H, m, bridgehead CH), 3.2—2.7 (1H, br, OH, exchangeable with D_2O), and 4.11 (1H, m, CHO).

Reaction of Cyclooctene Oxide (48) with 1. Formation of Cyclooctanone: A mixture of **1** (0.919 g, 4.14 mmol) and **48** (0.464 g, 3.68 mmol) in toluene (5 ml) was stirred at 0 °C for 2 h. The mixture was poured into saturated $NaHCO_3$ and extracted with hexane (7 ml×3). The combined extracts were dried and concentrated. Bulb-to-bulb distillation (120 °C/40 mmHg) gave cyclooctanone (0.403 g, 87%) as colorless crystals: mp 39—41 °C.

Reaction of 6-Methyl-5-hepten-2-one Oxide (52) with 1. To a solution of **1** (0.408 g, 1.83 mmol) and 2,6-lutidine (0.22 ml) in toluene (4 ml) was added **52** (0.242 g, 1.83 mmol) dissolved in toluene (2 ml) at −78 °C. After stirring at −78 °C for 3 h, to this was added DBU (0.28 ml), and stirring was continued at 15 °C for 1 h. The mixture was quenched by pouring into water and extracted with hexane (5 ml×3). The extracts were dried, concentrated, and chromatographed on a column of NH_3-treated silica gel, eluting with a 10:1 mixture of pentane and ether, gave pure **53** (0.314 g, 80%) as a colorless oil: IR (neat) 1684 (C=C) and 1245 cm^{-1}; NMR (CCl_4) 0.06 (9H, s, CH_3Si), 1.06 (3H, s, CH_3), 1.19 (3H, s, CH_3), 1.63 (3H, br s, CH_3C=), 1.96 (2H, m, CH_2), 4.53 (1H, dd, J=8.6 and 6.0 Hz, CHO), and 5.22 (1H, t, J=3.6 Hz, CH=). Found: C, 61.6; H, 10.4. Calcd for $C_{11}H_{22}O_2Si$: C, 61.6; H, 10.4.

Reaction of (E)-3α-t-Butyldimethylsiloxy-5α-pregnene Oxide (54) with 1. A mixture of **1** (0.075 g, 0.34 mmol), 2,6-lutidine (0.04 ml), and **54** (0.104 g, 0.24 mmol) in toluene (4 ml) was stirred at −78 °C for 4 h and then at 15 °C for 10 h. The mixture was poured into 0.1 mol dm^{-3} HCl and extracted with hexane (5 ml×3). The combined extracts were washed with saturated $NaHCO_3$, dried, and concentrated. Column chromatography on silica gel, eluting with a 10:1 mixture of benzene and ethyl acetate, gave pure **55** (0.090 g, 86%) as colorless crystals: mp 118—120 °C; IR (CCl_4) 3635 (OH) and 1253 cm^{-1}; NMR (CCl_4) 0.04 (6H, s, CH_3Si), 0.76 (3H, s, CH_3), 0.94 (9H, s, $(CH_3)_3CSi$), 1.04 (3H, s, CH_3), 2.2—1.0 (24H, m, methyl, methylene, and methine), 3.60 (1H, q, J=6.5 Hz, CHO), and 4.01 (1H, m, CHO); Ms *m/e* (rel intensity) 432 (4), 414 (7), 387 (72), 255 (25), and 75 (100). Found: C, 75.1; H, 10.9%. Calcd for $C_{27}H_{48}O_2Si$: C, 74.9; H, 11.2%.

Reaction of α-Pinene Oxide (56) with 1. To a mixture of **1** (0.483 g, 2.17 mmol) and 2,6-lutidine (0.25 ml) in toluene (5 ml) was added a solution of **56** (0.332 g, 2.18 mmol) in toluene (2 ml) at −50 °C. The mixture was stirred at −50 °C for 1 h and then to this was added DBU (0.4 ml) at −50 °C. The mixture was stirred at 26 °C for 10 h, quenched by pouring into 0.1 mol dm^{-3} HCl, and extracted with hexane (7 ml×4). The combined extracts were dried, concentrated, and chromatographed on a silica gel column, eluting with a 5:1 mixture of benzene and ethyl acetate. Careful concentration of the eluates gave α-pinene (**58**) (0.023 g, 6%) and pure **57** (0.240 g, 72%) as a colorless oil. **57**: IR (neat) 3660—3300 (OH) and 1643 cm^{-1} (C=C); NMR (CCl_4) 2.7—1.1 (6H, m, CH_2, CH, and OH, 1H was D_2O exchangeable), 1.73 (6H, br s, CH_3C=), 3.98 (1H, br, CHO), 4.62 (2H, br s, CH_2=), and 5.44 (1H, m, CH=).

Reaction of Squalene Oxide (62) with 1. A mixture of **1** (0.392 g, 1.76 mmol) 2,6-lutidine (0.15 ml), and **62** (0.512 g, 1.20 mmol) in toluene (7 ml) was stirred at −78 °C for 12 h, then poured into 0.1 mol dm^{-3} HCl, and extracted with hexane (10 ml×3). The combined extracts were dried, concentrated, and chromatographed on a silica gel column, eluting with benzene, to give pure squalene (**63**) (0.348 g, 70%) as a colorless oil.

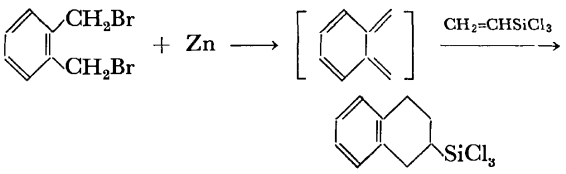
(Received August 5, 1981)

Described herein are several representative examples of cleavage reactions of otherwise hardly accessible organopentafluorosilicates which are obtainable *via* the Diels-Alder reaction, ene reaction, and the Friedel-Crafts reaction of vinyl-, ethynyl-, or allyl-trichlorosilanes. The Diels-Alder reaction between vinyltrichlorosilane and *o*-xylylene generated *in situ* by debromination of α,α′-dibromo-*o*-xylene afforded (1,2,3,4-tetrahydro-2-naphthyl)-trichlorosilane which was converted to the corresponding silicate. The silicate reacted with NBS and MCPBA to give the respective bromide and alcohol. The Diels-Alder reaction between ethynyltrichlorosilane and methyl coumalate gave a mixture of meta and para isomers of methyl (trichlorosilyl)benzoate in the ratio of 55/45, the silicate of which reacted with NBS to give two positional isomers of methyl bromobenzoate. The electronic effect of the methoxycarbonyl group on the Si–C bond cleavage was small. The silicate derived from 4-octenyltrichlorosilane which was obtained by the ene reaction between vinyltrichlorosilane and 1-hexene afforded, upon treatment with NBS, 4-octenyl bromide in the ratio of E/Z=83/17. The sterically crowded neophylsilicate obtainable *via* the Friedel-Crafts reaction of 2-methyl-1-propenyltrichlorosilane with benzene underwent the cleavage reaction with NBS in methanol. Neophyl bromide was formed with $CuBr_2$ in a low yield, no product being formed arising from rearrangement of the neophyl radical.

The Diels-Alder reaction,[2] ene reaction,[3] and the Friedel-Crafts reaction[4] of the compounds containing silyl groups provide the useful methods for preparation of organosilanes. Since the trichlorosilyl group has strong electron-withdrawing ability, vinyltrichlorosilane and ethynyltrichlorosilane are efficient dienophiles and enophiles which readily react with various dienes and olefins to give the corresponding adducts containing the trichlorosilyl group.[2a-d] The Friedel-Crafts reaction of allylic trichlorosilanes with aromatic compounds has been known to give rise to the introduction of the aromatic ring onto the carbon β to the silicon atom. Such organotrichlorosilanes that are usually difficult to prepare by hydrosilylation of olefins or acetylenes are expected to be useful precursors of organopentafluorosilicates. Thus we have developed a new methodology involving the synthesis of organosilicates *via* the Diels-Alder reaction, ene reaction, and the Friedel-Crafts reaction followed by their characteristic reactions with electrophiles. One of the unique applications of such methodology has already been demonstrated in the previous paper,[5] where the Diels-Alder reaction between vinyltrichlorosilane and cyclopentadiene followed by hydrogenation and silicate formation gave 2-norbornylpentafluorosilicate which reacted with NBS or Br_2 to afford 2-norbornyl bromide. This paper describes several new aspects on the reactivity of organopentafluorosilicates which are otherwise hardly accessible.

Results and Discussion

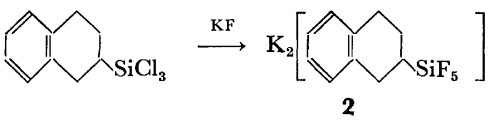
Preparation and Reaction of 1,2,3,4-(Tetrahydro-2-naphthyl)pentafluorosilicates. Since *o*-xylylene (5,6-dimethylene-1,3-cyclohexadiene) is known to be a highly reactive diene which readily reacts with various dienophiles to give the 1,2,3,4-tetrahydronaphthalene derivatives,[6] we examined the Diels-Alder reaction between vinyltrichlorosilane and *o*-xylylene generated *in situ* by debromination of α,α′-dibromo-*o*-xylene. A solution of α,α′-dibromo-*o*-xylene in acetonitrile was slowly added to a mixture of zinc powder and vinyltrichlorosilane in acetonitrile at 50 °C. After work-up (1,2,3,4-tetrahydro-2-naphthyl)trichlorosilane (**1**), the Diels-Alder adduct, was isolated by distillation in 55% yield.



1

Acetonitrile was the most suitable among the solvents examined. The reaction in DMF, which had usually been used for debromination of α,α′-dibromo-*o*-xylene, THF, or ethyl acetate did not give the Diels-Alder adduct at all, but gave a mixture of unidentified products. Without solvent α,α′-dibromo-*o*-xylene was recovered unchanged. The reaction was also examined at three different temperatures (20 °C, 50 °C, and acetonitrile reflux), and the reaction at 50 °C gave the most satisfactory result.

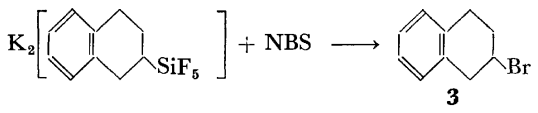
(1,2,3,4-Tetrahydro-2-naphthyl)trichlorosilane could be readily converted into the corresponding silicate **2** in 97% yield on treatment with KF in ethanol. Treatment of the adduct with aqueous KF resulted in lower yield.



2

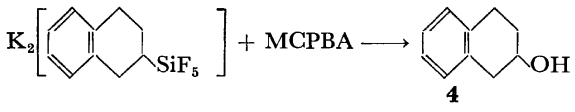
The silicate **2** thus obtained was found to react with NBS in dioxane to give the corresponding bromide **3** in 52% yield. The product was contaminated with a small amount of naphthalene which was considered to be formed by bromination of the benzylic

carbon of the initial product followed by the dehydrobromination. The formation of naphthalene, however, could not be retarded even in the presence of a radical inhibitor such as 2,4,6-tri-*t*-butylphenol.



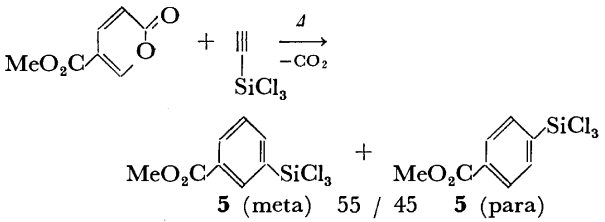
3

Silicate **2** also reacted exothermically with MCPBA[7] in DMF to give 1,2,3,4-tetrahydro-2-naphthol **4** in 65% yield. The result shows that vinyltrichlorosilane provides a vinyl alcohol equivalent in the Diels-Alder reaction. 1,2,3,4-Tetrahydro-2-naphthol is known to be an effective insect repellent with the requisite properties of low irritancy and low toxicity, and several procedures for its preparation have been reported involving hydrogenation of 2-naphthol.[8] The present procedure provides a new alternative route to this highly valuable insect repellent.



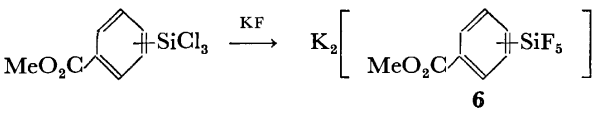
4

Preparation and Reaction of (Methoxycarbonylphenyl)pentafluorosilicate. The Diels-Alder reaction between methyl coumalate and ethynyltrichlorosilane[2c] followed by spontaneous decarboxylation afforded methyl (trichlorosilyl)benzoate **5** in 90% yield. GLC analysis of the methylated (MeMgBr in ether) product showed that both meta and para isomers were formed in the ratio of 55/45, showing a poor regioselectivity.



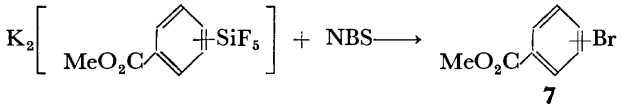
5 (meta) 55 / 45 **5** (para)

The mixture of meta- and para-trichlorosilyl derivatives was converted into the corresponding silicate **6** by treatment with KF in water in the usual manner (54% yield).



6

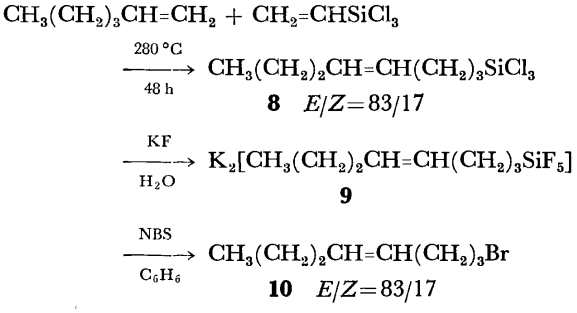
The silicate thus obtained was allowed to react with one equiv of NBS in methanol to give a mixture of meta and para isomers of methyl bromobenzoate **7** in the ratio of 58/42 (54% yield). The use of a half equiv of NBS did not change the product ratio significantly, implying that both the meta- and para-silicate have similar reactivities toward NBS.



7

It should be mentioned here that the unusually low ionization potentials assignable to the π- and Si–C σ-bonding electrons, suggested by the MO calculation,[5] may screen the rather small substituent effects and level up the reactivities of the meta and para isomers.

Preparation and Reaction of 4-Octenylpentafluorosilicate. 4-Octenylpentafluorosilicate was prepared *via* the ene reaction between vinyltrichlorosilane and 1-hexene.[3] Heating a mixture of vinyltrichlorosilane and 1-hexene at 280 °C for 48 h gave 4-octenyltrichlorosilane (**8**) in 52% yield. The adduct, a mixture of the *E* and *Z* isomers (*E*/*Z*=83/17), was converted into the silicate on treatment with aqueous KF in the usual manner. 4-Octenylpentafluorosilicate (**9**) thus obtained was relatively unstable and decomposed after standing at room temperature for 1 month. IR analysis of the decomposed matters showed characteristic bands of the hexafluorosilicate. The 4-octenylsilicate reacted with NBS exothermically to give a mixture of (*E*)- and (*Z*)-4-octenyl bromide (**10**) in 36% yield in the ratio of *E*/*Z*=83/17.

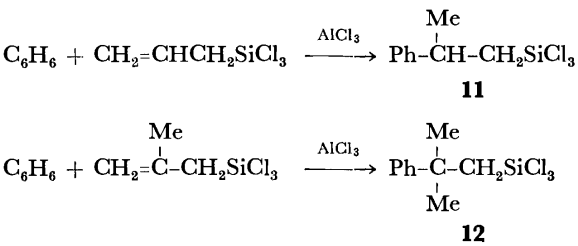


8 *E*/*Z*=83/17

9

10 *E*/*Z*=83/17

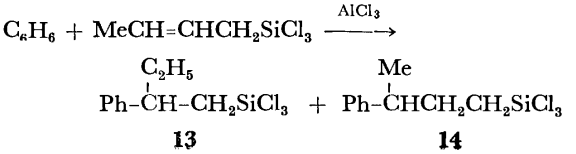
Reactions of Organopentafluorosilicates Synthesized via *the Friedel-Crafts Reaction of Allylic Trichlorosilanes.* In this study, we carried out the Friedel-Crafts reaction of allyl-, 2-methylpropenyl-, and crotyl-trichlorosilane. Of particular interest is that the method provides the most convenient route to otherwise hardly accessible (2-methyl-2-phenylpropyl)trichlorosilane (**12**) (hereafter abbreviated to neophyltrichlorosilane).



11

12

We have found that crotyltrichlorosilane gave a mixture of two positional isomers, (2- and 3-phenylbutyl)trichlorosilane, **13** and **14**. The initial product **13** isomerized thermally to the 3-phenyl isomer **14** in the presence of aluminum chloride, eventually the equilibrium mixture, **13**/**14**=9/91, being formed. Only **14** was isolated in a pure state by fractional distillation. The results show that the Cl_3Si– group, unlike the Me_3Si– group,[9] exhibits no stabilizing effect on the β-carbocation, and the γ-secondary carbocation is thermally more stable.



13 **14**

Table 1. Reactions of phenyl-substituted silicates with NBS or $CuBr_2$

Silicate	Reagent	Conditions	Product	Yield/%[a]
$K_2[Ph\text{-}CH(Me)CH_2SiF_5]$	NBS	Et_2O, r.t., 4 h	$Ph\text{-}CH(Me)CH_2Br$	84
		MeOH, r.t., 2 h		48
	$CuBr_2$	Et_2O, r.t., 6 h		53
$K_2[Ph\text{-}CH(Me)(CH_2)_2SiF_5]$	NBS	MeOH, r.t., 5 h	$Ph\text{-}CH(Me)(CH_2)_2Br$	71
	$CuBr_2$	Et_2O, r.t., 6 h		55
$K_2[Ph\text{-}C(Me)_2\text{-}CH_2SiF_5]$	NBS	Et_2O, r.t., 4 h	$Ph\text{-}C(Me)_2\text{-}CH_2Br$	trace[b]
		MeOH, r.t., 5 h		53
		MeOH, r.t., 20 h		62
	$CuBr_2$	Et_2O, reflux, 4 h		16[c]

a) Determined by GLC. b) $PhCMe_2CH_2SiF_3$ was formed in 76% yield. c) $PhCMe_2CH_2SiF_3$ was formed in 71% yield.

The silicates, even the sterically crowded neophyl derivative **17**, could be readily prepared in the usual manner (KF in water).

$K_2[Ph\text{-}CH(Me)(CH_2)_nSiF_5]$ $n=1$; **15** $n=2$; **16**

$K_2[Ph\text{-}C(Me)_2\text{-}CH_2SiF_5]$ **17**

The transformation of these silicates to the corresponding bromides has been examined with NBS or $CuBr_2$.[10] The results are summarized in Table 1. The reactivity of these silicates may reflect primarily the steric effect on the cleavage reactions. These three silicates were converted to the bromides in satisfactory yields. It seems interesting to note that the most crowded neophylsilicate **17** was cleaved in MeOH, but in ether dissociation of the silicate to the corresponding trifluorosilane occurred exclusively. With $CuBr_2$ silicates **15** and **16** gave the corresponding bromides in fair yields, while silicate **17** took the dissociation process predominantly, together with the formation of neophyl bromide in a low yield. As reported previously,[10] the CuX_2-cleavage of alkylsilicates may proceed through an alkyl radical intermediate, but the neophylsilicate gave no rearranged product, showing that the halogen-transfer proceeds much faster than the neophyl radical rearrangement, the rate of which has been estimated to be 10^5 s^{-1} at 100 °C.[11] This observation is consistent with the previous result on the 5-hexenylsilicate which gave no cyclization product upon treatment with $CuBr_2$; the rate of the cyclization of 5-hexenyl radical being reported to be 10^5 s^{-1} at 25 °C.[12]

$K_2[Ph\text{-}CH(Me)(CH_2)_nSiF_5]$ (**15** or **16**) + MCPBA $\xrightarrow[\text{r.t., 2h}]{\text{DMF}}$ $Ph\text{-}CH(Me)(CH_2)_n\text{-}OH$ $n=1$, 83% $n=2$, 92%

17 + MCPBA $\xrightarrow[\text{r.t., 8 h}]{\text{DMF}}$ $Ph\text{-}C(Me)_2\text{-}CH_2OH$ trace

The MCPBA-cleavage reaction was also examined. Silicates **15** and **16** reacted smoothly with MCPBA to give the corresponding alcohols in high yields. In contrast, neophylsilicate **17** was reluctant to react under the similar conditions, indicative of the importance of the steric effect also in the MCPBA cleavage.

Experimental

General. Infrared spectra were recorded on a Hitachi EPI-G3 grating infrared spectrometer. ^1H NMR spectra were determined with a JEOL JNM-MH-100 (100 MHz) spectrometer in carbon tetrachloride. Chemical shifts (δ) are recorded in ppm downfield from Me_4Si. Mass spectra were measured on a JEOL JMS-D300 mass spectrometer connected with a JEOL LGC-20K gas chromatograph, equipped with a 1 m glass column packed with OV-17 (1%) on Chromosorb B, and a JMA-2000 data processing system. Ionization voltage was 24 eV for all compounds. GLC analyses and preparative purification were performed on a Shimadzu GC-4B gas chromatograph, equipped with a 3 m column packed with 30% Silicone DC550 on Chromosorb B or Celite 545. GC peak integrals were recorded using a Shimadzu Chromatopac C-E1B integrator.

Materials. Vinyltrichlorosilane provided by Shin-etsu Chemical Co., Ltd. was purified by distillation. Ethynyltrichlorosilane[2c] allyl-, 2-methylpropenyl- and 2-butenyltrichlorosilanes[13] and methyl coumalate[14] were prepared according to the reported method. All solvents were dried in the usual manner and distilled before use. Other chemicals were used as obtained commercially.

1,2,3,4-Tetrahydro-2-naphthyltrichlorosilane (1). Vinyltrichlorosilane (161.5 g; 1.00 mol), zinc powder (90% purity, 21.8 g; 0.30 mol) and dry acetonitrile (100 ml) were placed in a three-necked flask equipped with a reflux condenser, a mechanical stirrer, and a dropping funnel. α,α'-Dibromo-*o*-xylene (26.4 g; 0.10 mol) in acetonitrile (260 ml) was added dropwise at 50 °C with stirring over a period of 19 h. After the addition was completed the reaction mixture was stirred further at 50 °C for 4 h. The solvent and excess vinyltrichlorosilane were evaporated. Pentane was added to the residue and the insoluble matters were removed by filtration. The solvent was evaporated and the residue was distilled under reduced pressure (118—127 °C/5 mmHg) to

give 20.07 g of the crude product, which was purified by fractional distillation to give 14.31 g (54% yield) of pure **1**: bp 122—127 °C/5 mmHg; mp 23.5—25.0 °C; ^{1}H NMR 1.55—1.9 (m, 2H), 2.05—2.35 (m, 1H), 2.7—3.05 (m, 4H), 7.00 (br s, 4H); MS *m/e* (%) 268 (M^++4, 4), 266 (M^++2, 14), 264 (M^+, 14), 131 (M^+-SiCl_3, 100); Found: Cl, 40.48%. Calcd for $C_{10}H_{11}Cl_3Si$: Cl, 40.04%.

1,2,3,4-Tetrahydro-2-naphthylpentafluorosilicate (2). 1,2,3,4-Tetrahydro-2-naphthyltrichlorosilane (6.94 g; 26.1 mmol) was added dropwise to a mixture of KF (37.92 g; 653 mmol) and ethanol (76 ml) at 0 °C. After the addition the mixture was stirred at room temperature overnight. The mixture was poured into 150 ml of cold water in order to dissolve an excess of KF and the resulting KCl. White powder was separated by filtration, and washed with water, ethanol, and ether. Drying under vacuum gave 8.41 g (97% yield) of potassium 1,2,3,4-tetrahydro-2-naphthylpentafluorosilicate: IR (KBr) 3060(w), 3010(w), 2900 (m), 2830(m), 1445(m), 1255(m), 1050(m), 769(s), 738(s), 650(vs), 523(s) cm^{-1}. The product was not analytically pure, but used in the subsequent reaction without further purification.

2-Bromo-1,2,3,4-tetrahydronaphthalene (3). A mixture of 1,2,3,4-tetrahydronaphthylpentafluorosilicate (997 mg; 3.0 mmol), 2,4,6-tri-*t*-butylphenol (8.6 mg), NBS (587 mg; 3.3 mmol), and dry dioxane (10 ml) was stirred at 50 °C for 16 h. Pentane was added and insoluble matters were removed by filtration. After evaporation of the solvent the residue was dissolved in pentane. The solution was washed with water and dried over Na_2SO_4. After evaporation of the solvent bulb-to-bulb distillation (200 °C/3 mmHg) of the residue gave 326 mg (52% yield) of 2-bromo-1,2,3,4-tetrahydronaphthalene which was contaminated with *ca.* 10% of naphthalene: IR (liquid film) 3070, 3020, 2945, 1580, 1495, 1450, 745 cm^{-1}; ^{1}H NMR 1.95—2.5 (m, 2H), 2.6—3.05 (m, 2H), 3.05—3.5 (m, 2H), 4.2—4.55 (m, 1H), 6.8—7.2 (m, 4H); MS *m/e* (%) 212 (M^++2, 27), 210 (M^+, 32), 131 (M^+-Br, 100); High MS 210.0055 (Calcd for $C_{10}H_{11}{}^{79}Br$, 210.0041), 212.0029 (Calcd for $C_{10}H_{11}{}^{81}Br$, 212.0021).

1,2,3,4-Tetrahydro-2-naphthol (4). A mixture of (1,2,3,4-tetrahydro-2-naphthyl)pentafluorosilicate (1.662 g; 5.0 mmol), *m*-chloroperbenzoic acid (90% pure, 1.150 g; 6.0 mmol as active oxygen), dry DMF (10 ml) was stirred at 50 °C for 14 h. Ether was added and the mixture was washed with water and aq $NaHCO_3$, and dried over Na_2SO_4. After evaporation of the solvent bulb-to-bulb distillation (150 °C/3 mmHg) of the residue gave 482 mg (65% yield) of 1,2,3,4-tetrahydro-2-naphthol: An analytical sample was purified by preparative GLC. n_D^{20} 1.5607 (lit,[8] n_D^{25} 1.5630); IR (liquid film) 3700—3100 (br. OH), 3060, 3020, 2920, 1580, 1490, 1450, 1040, 740 cm^{-1}; ^{1}H NMR 1.5—2.1 (m, 2H), 1.98 (br s, 1H), 2.5—3.15 (m, 4H), 3.85—4.15 (m, 1H), 6.92 (br s, 4H); MS *m/e* (%) 148 (M^+, 13), 130 (M^+-H_2O, 100).

Methyl (Trichlorosilyl)benzoate (5). A mixture of methyl coumalate (3.10 g; 20.1 mmol), ethynyltrichlorosilane (5.85 g; 37 mmol), and hydroquinone (50 mg) was heated at 175±5 °C (bath temperature) until the methyl coumalate was completely consumed (*ca.* 50 h). The extent of the reaction could be monitored by GLC analysis or ^{1}H NMR. After the reaction was completed the mixture was distilled under reduced pressure to give 4.9 g (90% yield) of methyl (trichlorosilyl)benzoate: bp 154—155 °C/21 mmHg; Found: Cl, 39.04%. Calcd for $C_8H_7Cl_3O_2Si$: Cl, 39.46%.

The product appeared as a single peak on GLC (Silicone DC550 or SE 30), but ^{1}H NMR showed that the product consisted of meta and para isomers. Since the ratio could not be determined by the ^{1}H NMR spectrum, an aliquot (293 mg, 1.08 mmol) of the product was methylated (MeMgBr in ether, 15 mmol, reflux, 2 h). Usual work-up and distillation gave a distillate (151 mg) boiling over the range of 190—220 °C/15 mmHg (bath temperature). GLC analysis of the distillate showed the formation of two major products (A and B) in the ratio of 55:45, together with two minor ones. Products were isolated by preparative GLC (Silicone DC550, 200 °C). Product A, having the shorter retention time, was characterized as 2-(3-trimethylsilylphenyl)-2-propanol: mp 70.5—71.0 °C (lit,[15] 62—63 °C); IR (KBr) 755, 710 cm^{-1} (1,3-disubstituted benzene); ^{1}H NMR 0.27 (s, 9H), 1.52 (s, 6H), 2.13 (br s, 1H), 7.1—7.6 (m, 4H). The other major product B was identified as the para isomer, 2-(4-trimethylsilylphenyl)-2-propanol: a liquid contaminated with some decomposition products (lit,[15] mp 52—52.5 °C); IR (liquid film) 820 cm^{-1} (1,4-disubstituted benzene); ^{1}H NMR 0.25 (s, 9H), 1.15 (s, 6H), 7.37 (s, 4H). The two minor products were collected as a mixture and characterized as the dehydrated olefinic compounds of the above two products: ^{1}H NMR 0.25 and 0.27 (total 9H), 2.15 (br s, 3H), 5.0—5.1 (m, 1H), 5.25—5.35 (m, 1H), 7.25—7.55 (m, 4H). High MS *m/e* 190.1184 (Calcd for $C_{12}H_{18}Si$, 190.1179).

(Methoxycarbonylphenyl)pentafluorosilicate (6). Methyl trichlorosilylbenzoate (2.52 g; 9.35 mmol) was added dropwise to a solution of KF (13.6 g; 234 mmol) in water (20 ml) at 0 °C with vigorous stirring. After stirring at room temperature for 5 h the mixture was filtered, washed with water, ethanol, and ether, and then dried *in vacuo*. The silicate weighed 1.76 g (54% yield): IR (KBr) 3020(w), 2970(w), 1730(s), 1710(s), 1600(w), 1440(m), 1300(s), 1265 (m), 1195(w), 1167(w), 1130(m), 1095(m), 1020(w), 847(w), 747(m), 720(w), 675(vs), 660(sh), 580(w), 557(w), 492(w), 470(w), 455(w) cm^{-1}; Found: C, 28.26; H, 2.33; F, 27.81%. Calcd for $C_8H_7F_5K_2O_2Si$: C, 28.56; H, 2.10; F, 28.24%.

Methyl Bromobenzoate (7). Reaction of $K_2[MeO_2CC_6H_4SiF_5]$ with NBS. A mixture of the silicate **6** (172 mg; 0.51 mmol), NBS (93 mg; 0.52 mmol), and methanol (5.0 ml) was stirred at room temperature for 24 h. After usual work-up GLC analysis showed a single peak, the retention time of which was the same as that of authentic methyl 4-bromobenzoate. GLC yield was 54%. The product was isolated by column chromatography on silica gel (hexane/benzene 1/1). ^{1}H NMR showed that the product was a mixture of meta and para isomers of methyl bromobenzoate: ^{1}H NMR 3.86 and 3.87 (total 3H), 7.25 (t, J=8 Hz), 7.35—7.67 (m), 7.78—7.97 (m), 8.05—8.15 (m), (total 4H). High MS *m/e* 213.9640 (calcd for $C_8H_7O_2{}^{79}Br$, 213.9630), 215.9599 (Calcd for $C_8H_7O_2{}^{81}Br$, 215.9609). The very close two signals due to the methyl protons were separated by the addition of Eu(fod)$_3$, fod=1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato. For example, a solution of the sample (0.0338 M) containing Eu(fod)$_3$ (0.0169 M) in CCl_4 exhibited two methyl signals at δ 5.15 for the para isomer and at 4.85 for the meta isomer. In this way, the meta/para ratio of the product was determined to be 58/42.

The silicate (328 mg; 0.975 mmol) was allowed to react with a half equiv of NBS (90 mg; 0.506 mmol) in methanol (5.0 ml) at room temperature for 5 h. The insoluble precipitate was filtered and washed with ether. The organic layer and the washings were combined and analyzed by GLC which indicated that the bromide was formed in 40% yield. The ^{1}H NMR spectrum of the isolated product showed that the meta/para ratio was 57—60/43—40. The filter cake was further treated with NBS (100 mg) in methanol (5.0 ml) as above to give the bromide in 14% yield, the

meta/para ratio being 50/50.

4-Octenyltrichlorosilane (8).[3] A mixture of 1-hexene (10.10 g; 120 mmol) and vinyltrichlorosilane (10.0 g; 62 mmol) was heated in a sealed tube at 280 °C for 48 h. After the reaction, distillation of the reaction mixture gave 7.85 g (52% yield) of 4-octenyltrichlorosilane: bp 63—64 °C/7 mmHg; ^{1}H NMR 0.94 (t, J=6 Hz, 3H), 1.1—1.85 (m, 6H), 1.85—2.3 (m, 4H), 5.0—5.6 (m, 2H). GLC analysis of the product showed two peaks in a ratio of 17/83, probably due to the *Z* and *E* isomers.

4-Octenylpentafluorosilicate (9). To a solution of KF (32.0 g; 550 mmol) in deionized water (48 ml) was added dropwise 4-octenyltrichlorosilane (5.40 g; 22.0 mmol) at 0 °C. After the addition the mixture was stirred overnight at room temperature. White powder thus obtained was separated by filtration, and washed with water, ethanol, and ether. After drying under vacuum 4.64 g (68% yield) of 4-octenylpentafluorosilicate was obtained: IR (KBr) 2950 (m), 2900(m), 1460(w), 1375(w), 970(w), 745(s), 640(vs), 540(m), 445(m) cm^{-1}; Found: C, 28.02; H, 4.50; F, 28.23%. Calcd for $C_8H_{16}F_5K_2Si$: C, 30.75; H, 4.84; F, 30.40%.

1-Bromo-4-octene (10). 4-Octenylpentafluorosilicate (937 mg; 3.0 mmol) was allowed to react with NBS (587 mg; 3.3 mmol) in dry benzene (5.0 ml) at room temperature for 3 h. GLC analysis of the reaction mixture showed that two products were formed in a ratio of 17/83. The GCMS spectra of them showed the same parent peaks (*m/e*= 192 and 190), indicating that they were isomers of bromooctene. The major product was isolated by preparative GLC: n_D^{20} 1.4687; IR (liquid film) 970 cm^{-1} (*trans*-CH=CH–); ^{1}H NMR 0.90 (t, J=6 Hz, 3H), 1.15—1.6 (m, 2H), 1.7—2.35 (m, 6H), 3.36 (t, J=6 Hz, 2H), 5.1—5.6 (m, 2H). Irradiation at the methylene protons adjacent to the double bond gave AB quartet (J=16 Hz): MS *m/e* (%) 192 (M^++2, 18), 190 (M^+, 19), 150 (22), 148 (24), 111 (M^+−Br, 8), 69 (100); High MS *m/e* 190.0381 (calcd for $C_8H_{15}{}^{79}Br$, 190.0353), 192.0350 (calcd for $C_8H_{15}{}^{81}Br$, 192.0333). On the basis of these spectral data the major product was identified as (*E*)-1-bromo-4-octene. The minor product could not be isolated; it was probably the (*Z*)-1-bromo-4-octene.

Friedel-Crafts Reaction between Allylic Trichlorosilanes and Benzene. A typical procedure is given for the reaction of 2-methylpropenyltrichlorosilane. To a mixture of 27 g (0.142 mol) of 2-methylpropenyltrichlorosilane and benzene (118 g; 1.5 mol) was added 3.3 g (25 mmol) of freshly sublimed aluminum chloride at 0 °C with stirring. After stirring at 0 °C for 15 min the mixture was stirred at room temperature. A slightly exothermic reaction occurred and was completed in about 3 h. Dried sodium chloride (11.5 g) was added and the mixture was stirred at room temperature for 0.5 h and then under refluxing for another 0.5 h. The resulting black mixture was filtered quickly under suction through a filter aid (Hyfrosuper cell). The filtrate was distilled, after evaporation of benzene, to give (2-methyl-2-phenylpropyl)trichlorosilane (neophyltrichlorosilane) (**12**) as a colorless liquid boiling at mainly 99—100 °C/7 mmHg in 72% yield (29.1 g); ^{1}H NMR 1.57 (s, 6H), 2.00 (s, 2H), 7.15—7.45 (m, 5H). (Found: Cl, 39.37%).

(2-Phenylpropyl)trichlorosilane (**11**) was prepared in a similar manner: bp 98—106 °C/3 mmHg; ^{1}H NMR 1.40 (d, J=7 Hz, 3H), 1.70—1.85 (m, 2H), 3.17 (sextet, J=7 Hz, 1H), 7.0—7.3 (m, 5H). (Found: Cl, 41.54%).

Friedel-Crafts Reaction of Crotyltrichlorosilane with Benzene. To a mixture of crotyltrichlorosilane (28.4 g; 0.15 mol) and dry benzene (133 ml; 1.5 mol) was added aluminum chloride (2.2 g). An exothermic reaction started and benzene began to reflux. The reaction was controlled by intermittent cooling with a water bath. After the exothermic reaction ceased, the mixture was heated to reflux for 1 h. Sodium chloride-treatment, filtration, and distillation gave 34.9 g (87% yield) of a colorless liquid boiling over the range of 99—102 °C/4 mmHg. The fraction consisted of two isomers. Fractional distillation through a column packed with glass helices gave 11.8 g (29% yield) of (3-phenylbutyl)trichlorosilane (**14**) as the major product: bp 98—102 °C/2 mmHg; ^{1}H NMR 1.05—1.45 (m) and 1.30 (d, J=7 Hz) (total 5H), 1.7—2.0 (m, 2H), 2.70 (sextet, J=7 Hz, 1H), 7.0—7.4 (m, 5H). (Found: Cl, 39.84%). The minor product could not be isolated pure but characterized by ^{1}H NMR to be (2-phenylbutyl)trichlorosilane (**13**): ^{1}H NMR 0.78 (t, J=7 Hz, 3H), *ca.* 1.6—2.0 (m, 4H), *ca.* 2.6—3.0 (m, 1H), *ca.* 7.0—7.45 (m, 5H).

The isomer distribution was dependent upon the reaction conditions. The reaction was followed by GLC which showed the following ratios of **13**/**14**: 63/37 (0 °C, 10 min), 54/46 (0 °C, 20 min), 56/44 (0 °C, 1 h), 38/62 (r.t., 24 h), 13/87 (reflux, 1 h), 9/91 (reflux, 2 h).

Preparation of Silicates. Preparation of silicates was performed in a similar manner to that described in the previous paper[5] ($RSiCl_3$/KF=1/25, in water, 0 °C—r.t., overnight). Yield, infrared absorption bands, and analytical data are given below.

K_2[PhCHMeCH$_2$SiF$_5$] (15): 54%; IR (KBr) 3020(w), 2950(w), 2875(m), 2810(w), 1602(w), 1520(w), 1490(m), 1450(m), 1360(w), 1277(w), 1255(w), 1225(w), 1192(w), 1100(w), 1072(w), 910(w), 768(s), 740(s), 702(s), 640(br, vs), 540(m), 500(m), 482(m), 450(m) cm^{-1}; Found: C, 32.10; H, 3.40%. Calcd for $C_9H_{11}F_5K_2Si$: C, 33.73; H, 3.46%.

K_2[PhCHMeCH$_2$CH$_2$SiF$_5$] (16): 78%; IR (KBr) 3025(w), 2950(sh), 2900(s), 2840(w), 1603(w), 1520(br, w), 1492(m), 1450(m), 1370(w), 1258(w), 1215(w), 1180(w), 1150(w), 1075(w), 1032(w), 900(br, w), 785(w), 750(s), 725(s), 700(s), 645(br, vs), 550(w), 518(m), 490(w), 450(m) cm^{-1}; Found: C, 34.82; H, 3.88; F, 29.60%. Calcd for $C_{10}H_{13}F_5K_2Si$: C, 35.91; H, 3.92; F, 28.40%.

K_2[PhCMe$_2$CH$_2$SiF$_5$] (17): 63%; IR (KBr) 3050(w), 3010(w), 2970(m), 2950(m), 2925(m), 2900(m), 2875(m), 1600(w), 1580(w), 1520(br, m), 1495(m), 1440(w), 1370 (m), 1352(m), 1263(m), 1200(w), 1190(w), 1100(br, w), 1075(w), 1032(w), 860(w), 790(m), 770(m), 735(s), 717(s), 702(s), 655(vs), 630(vs), 550(m), 505(m), 445(m) cm^{-1}; Found: C, 35.19; H, 3.91; F, 27.30%. Calcd for $C_{10}H_{13}F_5K_2Si$: C, 35.91; H, 3.92; F, 28.40%.

Cleavage Reactions with NBS and $CuBr_2$. The cleavage reactions of **15**—**17** were carried out in a similar manner to that described above and previously. The reaction conditions are listed in Table 1. Products were characterized as follows.

PhCHMeCH$_2$Br: n_D^{20} 1.5488; ^{1}H NMR; 1.41 (d, J=7 Hz, 3H), 3.10 (sextet, J=7 Hz, 1H), 3.3—3.62 (m, 2H), 7.1—7.45 (m, 5H); MS *m/e* (%) 200 (M^++2, 6), 198 (M^+, 6), 105 (100), 91 (11); High MS *m/e* 198.0041 (calcd for $C_9H_{11}{}^{79}Br$; 198.0043), 200.0027 (calcd for $C_9H_{11}{}^{81}Br$; 200.0025). *PhCHMeCH$_2$CH$_2$Br*: ^{1}H NMR 1.30 (d, J=7 Hz, 3H), 2.10 (q, J=7 Hz, 2H), 2.85—3.45 (m, 3H), 7.05—7.35 (m, 5H); MS *m/e* (%) 214 (M^++2, 4), 212 (M^+, 4), 105 (100); High MS *m/e* 212.0190 (calcd for $C_{10}H_{13}{}^{79}Br$; 212.0199), 214.0202 (calcd for $C_{10}H_{13}{}^{81}Br$; 214.0182).

PhCMe$_2$CH$_2$Br: n_D^{20} 1.5458; ^{1}H NMR 1.45 (s, 6H), 3.50 (s, 2H), 7.1—7.45 (m, 5H); High MS *m/e* 212.0153 (calcd for $C_{10}H_{13}{}^{79}Br$; 212.0199), 214.0200 (calcd for $C_{10}H_{13}{}^{81}Br$; 214.0182).

The MCPBA Cleavage of 15—17. These cleavage

reactions were also performed in the same manner as described above and previously. $PhCHMeCH_2OH$ was identified by IR spectrum (*cf.* The Aldrich Library of IR Spectra, 616A) and ^1H NMR: 1.23 (d, $J=7$ Hz, 3H), 2.70—3.0 (m, 1H), 2.92 (s, 1H), 3.52 (d, $J=7$ Hz, 2H), 7.0—7.3 (m, 5H). $PhCHMeCH_2CH_2OH$: n_D^{20} 1.5185; IR (neat) 3325, 1045, 760, 700 cm^{-1}; ^1H NMR 0.90 (br s, 1H), 1.26 (d, $J=7$ Hz, 3H), 1.77 (q, $J=7$ Hz, 2H), 2.87 (sextet, $J=7$ Hz, 1H), 3.45 (dt, $J=7$ Hz and 3 Hz, 2H), 7.05—7.25 (m, 5H). (Found: C, 80.00; H, 9.67%).

We thank the Ministry of Education for the Grant-in-Aid for Scientific Research (No. 303523) and Shinetsu Chemical Co., Ltd. for support of this work.

Configuration of Alanine Part in Natural Octopine[1)]

Kazuo Goto, Michinori Waki, Nobuo Mitsuyasu,† Yasuo Kitajima, and Nobuo Izumiya*

Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received February 12, 1981)

Octopine has a structure of N^2-(1-carboxyethyl)arginine or N-(1-carboxy-4-guanidinobutyl)alanine. Configuration of the arginine part in natural octopine is determined as (*S*), whereas that of the alanine part has been assumed as (*R*). The configuration of the alanine part was concluded to be (*R*) by the present synthesis of (+)-octopine, which was identical with the natural one, by a sequence of reactions starting from (*R*)-alanine and (*R*)-2-bromo-5-acetamidopentanoic acid. The reaction of (*R*)-alanine and (*R*)-2-bromo-5-acetamidopentanoic acid in alkaline conditions gave N^2-((*R*)-1-carboxyethyl)-N^5-acetyl-(*S*)-ornithine which was converted to N^2-((*R*)-1-carboxyethyl)-(*S*)-ornithine ((*R*),(*S*)-octopinic acid) by hydrolysis with hydrochloric acid. (*R*),(*S*)-Octopinic acid gave (+)-octopine ((*R*),(*S*)-octopine) by guanidination. The reaction of (*S*)-alanine and (*R*)-2-bromo-5-acetamidopentanoic acid led to give (*S*),(*S*)-octopinic acid and subsequently (+)-isooctopine ((*S*),(*S*)-octopine).

Octopine is an unusual amino acid first isolated from octopus muscle in 1927[2)] and from crown-gall tissue.[3)] A number of imino acids structurally related to octopine have recently been found in crown-gall tumors of plants, and the use of these imino acids as markers of a possible transfer of gene from the tumor-inducing bacterium into host plant cells has sparked further interest in these compounds.[4)]

The chemical structure of octopine was established as N^2-(1-carboxyethyl)arginine or N-(1-carboxy-4-guanidinobutyl)alanine.[5,6)] The configuration of the arginine (Arg) part in natural octopine has been determined to be (*S*) by either enzymic method or synthetic approach as follows. Akasi demonstrated that natural octopine is susceptible to arginase which decomposes (*S*)-arginine, but not (*R*)-arginine.[7)] Akasi also prepared identical compound with natural octopine from (*S*)-arginine and (*S*)-2-bromopropionic acid; in this reaction the configuration of the (*S*)-Arg part is retained.[5)]

However, no definite conclusion in respect to the configuration of the alanine (Ala) part has been reached. (*R*)-Configuration of the Ala part in natural octopine has been assumed by two groups. Izumiya *et al.* assumed the (*R*)-configuration by data of optical rotatory dispersions of natural octopine and its diastereomer.[8)] They also assumed the (*R*)-configuration by occurrence of Walden inversion of (*S*)-2-bromopropionic acid from kinetic data on the reaction of (*S*)-arginine and (*S*)-2-bromopropionic acid in alkaline conditions.[8)] Biellmann *et al.* demonstrated the (*R*)-configuration by an elegant method; they prepared octopine mixture from (*R*)-alanine and 2-oxo-5-guanidinopentanoic acid by reduction with cyanoborohydride, and observed the presence of natural octopine in the octopine mixture by enzymic method.[9)] They, however, failed to separate the octopine diastereomers mentioned above, despite that they could isolate crystalline (+)-octopine corresponding to the natural one and its diastereomer in good yields after reduction of (*S*)-arginine and 2-oxopropionic acid by cyanoborohydride.[9)] Previously, Izumiya *et al.* observed a similar result that hydrogenation of a mixture of (*S*)-arginine and 2-oxopropionic acid in the presence of palladium black produced octopine, but hydrogenation of a mixture of (*R*)-alanine and 2-oxo-5-guanidinopentanoic acid did not.[8)]

This paper presents a definite conclusion for (*R*)-configuration of the Ala part by the synthesis of (+)-octopine corresponding to natural octopine starting from (*R*)-alanine and (*R*)-2-bromo-5-acetamidopentanoic acid.

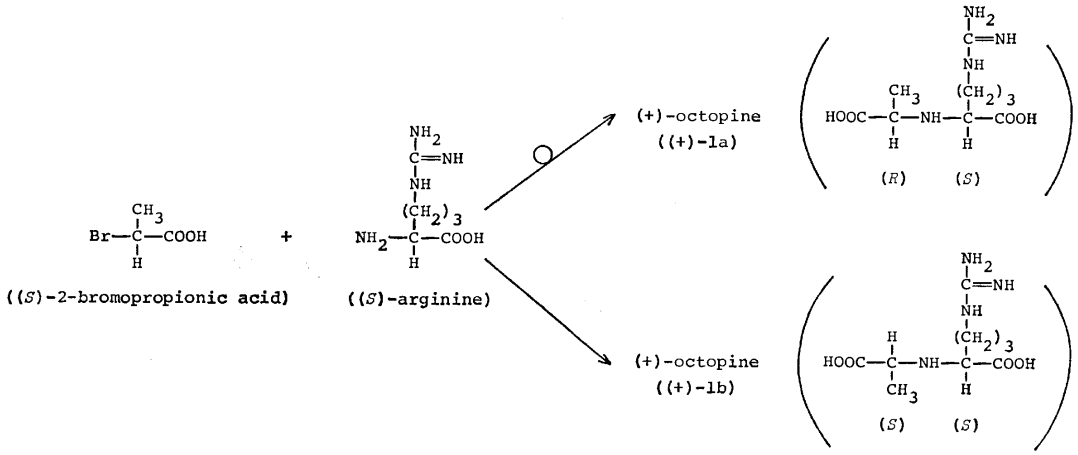
Results and Discussion

Approach in Determination of Configuration of Ala Part in Natural Octopine. Two groups reported that the reaction of (*S*)-arginine and (*S*)-2-bromopropionic acid produces (+)-octopine which is confirmed to be identical with natural octopine.[5,8)] Since the configuration at an asymmetric carbon of the Arg part is in full retention, the configuration of Ala part of natural octopine should be either (*R*) or (*S*) as shown in Scheme 1. Supposed natural octopine containing (*R*)-alanine residue is designated as (+)-**1a**, and the one containing (*S*)-alanine residue as (+)-**1b**. We designed to synthesize an octopine starting from (*R*)-alanine and (*R*)-2-bromo-5-acetamidopentanoic acid ((*R*)-2-Br-5-Acpa) as shown in Scheme 2. We postulated that the configuration of the Ala part in natural octopine should be (*R*) if we would obtain (+)-octopine ((+)-**1a**) which is identical with natural one, whereas the configuration should be (*S*) if we obtain (−)-octopine ((−)-**1b**) which is an antipode of supposed natural octopine ((+)-**1b**).

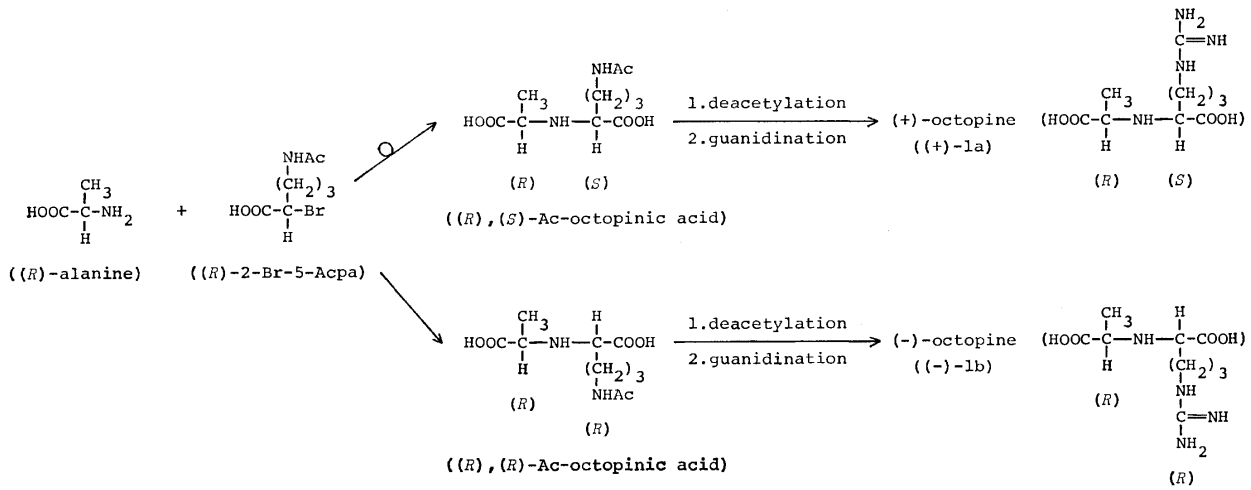
Conclusion for Configuration of Ala Part in Natural Octopine. We could isolate (+)-octopine ((+)-**1a**) after a sequence of the reactions shown in Scheme 2, therefore we conclude that the configuration of the Ala part in natural octopine is (*R*). Then, we propose new nomenclature for four isomers of octopine as given in Table 1. It is also concluded that the asymmetric carbon with (*R*)-configuration in (*R*)-2-Br-5-Acpa is converted to (*S*) by Walden inversion during the formation of (*R*),(*S*)-Ac-octopinic acid.

Reaction of (R)-Alanine and (R)-2-Br-5-Acpa. The route to synthesize (*R*),(*S*)-octopine is shown in Fig. 1. Izumiya *et al.* reported that (+)-octopine and (+)-isooctopine were obtained in good yields

† Present address: Laboratory of Chemistry, College of General Education, Saga University, Saga 840.



Scheme 1. Formation of (+)-octopine ((+)-**1a** or (+)-**1b**) from (*S*)-arginine and its supposed configuration.



Scheme 2. Supposed formation of (+)-octopine ((+)-**1a**) or (−)-octopine ((−)-**1b**) from (*R*)-alanine.

Table 1. Configurations of isomers of octopine

Nomenclature		Configuration of		Source	$[\alpha]_D(H_2O)$
By Akasi[a] and Izumiya *et al.*[b]	By present authors	Ala part	Arg part		°
(+)-Octopine	(*R*),(*S*)-Octopine	(*R*)	(*S*)	Natural or Synthetic	+20.8

(*ca.* 50%) from (*S*)-arginine, (*RS*)-2-bromopropionic acid, and $Ba(OH)_2$ in 1:2:2 molar ratio at 37 °C for 2 d.[8] However, the reaction of (*R*)-alanine, (*R*)-2-Br-5-Acpa, and $Ba(OH)_2$ under the same conditions gave the desired N^2-((*R*)-1-carboxyethyl)-N^5-acetyl-(*S*)-ornithine ((*R*),(*S*)-Ac-octopinic acid) in only trace amount. We assume that poor yield compared with the reaction of arginine and 2-bromopropionic acid is due to the presence of a bulky 3-acetamidopropyl group in 2-Br-5-Acpa and/or absence of basic guanidino group in alanine moiety. Then, we had to search for the conditions to give Ac-octopinic acid in fairly good yield.

In order to estimate a yield of Ac-octopinic acid and a possible occurrence of epimerization in N^5-acetylornithine part, we tried to separate (*R*),(*S*)- and (*S*),(*S*)-forms of N^2-(1-carboxyethyl)ornithine (octopinic acid) by an amino acid analyzer,[11] and found the conditions (see Experimental) to achieve the separation as shown in Fig. 2. A mixture of (*R*)-alanine, (*R*)-2-Br-5-Acpa, and $Ba(OH)_2$ was incubated for certain intervals, and a part of the mixture was refluxed with 2 M HCl, and the yield and the degree of epimerization of (*R*),(*S*)-octopinic acid in the acid hy-

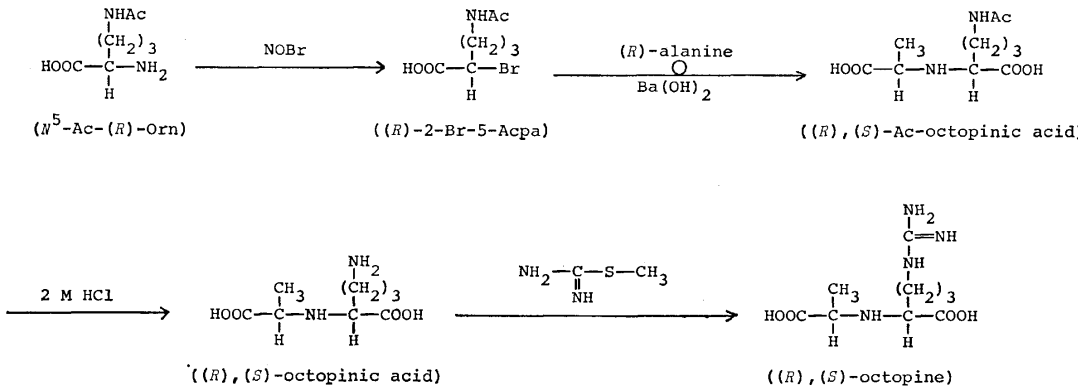

Fig. 1. Synthetic route for (*R*),(*S*)-octopine from (*R*)-alanine and (*R*)-2-Br-5-Acpa.

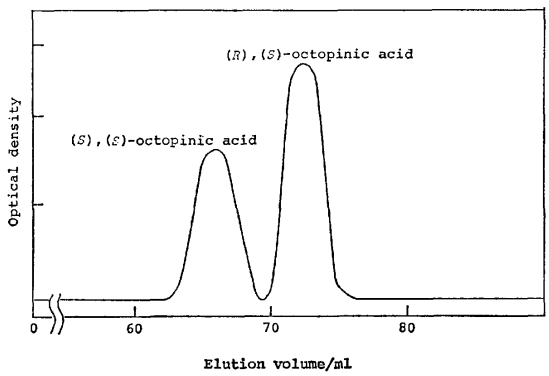

Fig. 2. Chromatogram of isomers of octopinic acid by an amino acid analyzer.

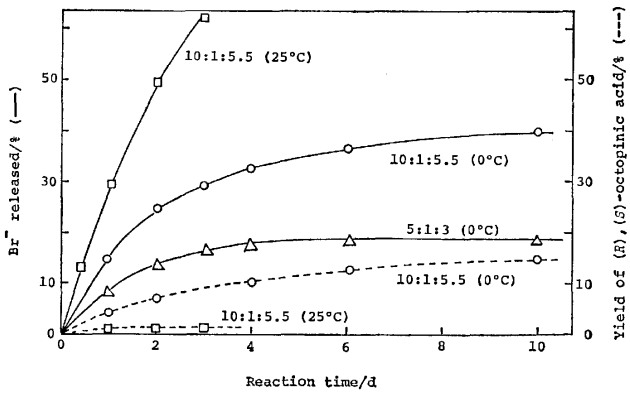

Fig. 3. Liberation of Br^- and formation of (*R*),(*S*)-Ac-octopinic acid during the reaction of (*R*)-alanine and (*R*)-2-Br-5-Acpa. Ratio of *e.g.* 10:1:5.5 means that of (*R*)-Ala:(*R*)-2-Br-5-Acpa:$Ba(OH)_2$ in molar term.

drolysate were determined by an amino acid analyzer using (*R*),(*S*)- and (*S*),(*S*)(instead of (*R*),(*R*))-forms of octopinic acid as reference substances under the conditions described above. At the same time, Br^- released during the reaction was analyzed by the Volhard titration method.

In Fig. 3, time-courses of Br^- release and (*R*),(*S*)-octopinic acid formation are given. The increase of the reaction temperature to 25 °C or 37 °C resulted in rapid liberation of Br^-, but the formation of Ac-octopinic acid was very poor. Molar ratios of the

Table 2. Effect of ratio of reactants on formation of acetyl octopinic acid[a)]

(*R*)-Alanine	(*R*)-2-Br-5-Acpa	$Ba(OH)_2$	
1	2	2	1
2	1	1.5	5
5	1	3	12
10	1	5.5	15

a) The reaction was carried out at 0 °C for 10 d. b) Yields are calculated from (*R*)-2-Br-5-Acpa and estimated from (*R*),(*S*)-octopinic acid derived from (*R*),(*S*)-Ac-octopinic acid by an amino acid analyzer.

reactants gave also some influences on a yield; some of the results of the experiments are summarized in Table 2. We observed that the formation of Ac-octopinic acid was favored when the ratios of (*R*)-alanine to (*R*)-2-Br-5-Acpa were increased. Based on the above results, the favorable conditions to yield Ac-octopinic acid were settled as follows: a mixture of (*R*)-alanine, (*R*)-2-Br-5-Acpa, and $Ba(OH)_2$ in molar ratio of 10:1:5.5 is allowed to react at 0 °C for 10 d. It was observed, however, that the occurrence of possible (*R*),(*R*)-Ac-octopinic acid was 5—6% of the desired (*R*),(*S*)-isomer. We assume that the reasons of epimerization will be that (*R*)-2-Br-5-Acpa contains already some (*S*)-form and/or racemization at N^5-acetyl-(*R*)-ornithine part occurs during the reaction. Nevertheless, an undesirable (*R*),(*R*)-isomer in a small amount could be removed by recrystallization as mentioned latter.

Syntheses of (R),(S)- *and* (S),(S)-*Forms of Ac-octopinic Acid, Octopinic Acid, and Octopine.* Employing the favorable conditions mentioned above, recrystallized (*R*),(*S*)-Ac-octopinic acid was obtained from (*R*)-alanine and (*R*)-2-Br-5-Acpa in a yield of 16%. This compound still contained 3% of its possible isomer, (*R*),(*R*)-Ac-octopinic acid. However, (*R*),(*S*)-octopinic acid, obtained from the (*R*),(*S*)-Ac-octopinic acid by hydrolysis and recrystallized from water–ethanol, was free from (*R*),(*R*)-octopinic acid; the (*R*),(*R*)-isomer might be removed during the recrystallization. Alternatively, octopinic acid was also obtained from (+)-octopine ("natural octopine"), derived from (*S*)-

arginine and (*S*)-2-bromopropionic acid, with the treatment of $Ba(OH)_2$ at 80 °C. The octopinic acid obtained above showed the same properties as those of the (*R*),(*S*)-octopinic acid derived from the (*R*),(*S*)-Ac-octopinic acid (*e.g.*, melting point, R_f values on paper, and specific rotations). Finally, crystalline (*R*),(*S*)-octopine was prepared from (*R*),(*S*)-octopinic acid, derived from (*R*),(*S*)-Ac-octopinic acid, and *S*-methylisothiourea in a yield of 61%. Identity between this (*R*),(*S*)-octopine and (+)-octopine ("natural octopine") was established by comparison of chromatographies on paper and silica gel-thin layer, and specific rotations. In the same manner, (*S*),(*S*)-Ac-octopinic acid was synthesized from (*S*)-alanine and (*R*)-2-Br-5-Acpa. Subsequently, (*S*),(*S*)-forms of octopinic acid and octopine were prepared by the same procedure as for the (*R*),(*S*)-forms. Their physical properties were different from those of the corresponding octopinic acid and octopine derived from (+)-octopine ("natural octopine") or (+)-octopine itself.

Experimental

All the melting points are uncorrected. Paper chromatography was carried out on Toyo Roshi No. 52 paper with the solvent system: R_f, *n*-BuOH–AcOH–pyridine–H_2O (15:3:10:12, v/v). TLC was carried out on silica gel G (Merck) with the same solvent system as described above: R_f (TLC). Material possessing an amino group was detected by spraying with 0.2% ninhydrin solution in acetone, followed by heating at 100 °C. Material having a guanidino group was detected by spraying with an alkaline pentacyanonitrosylferrate(III)–hexacyanoferrate(III) reagent.[12] Material having blocked amino group was detected by spraying with 10% H_2SO_4, followed by heating on a hot plate. Optical rotations were measured on a Yanagimoto polarimeter OR-20. Amino acid analyses were performed with a Hitachi amino acid analyzer KLA-3B.

N^5-Acetyl-(R)-ornithine (N^5-Ac-(R)-Orn). This was prepared from (*R*)-ornithine monohydrochloride (16.9 g, 100 mmol) in the same manner as the preparation of *N^5*-Ac-(*S*)-Orn,[13] and was recrystallized from water–EtOH; yield, 15.9 g (91%); mp 233—234 °C (dec); $[\alpha]_D^{20}$ −24.6° (*c* 1, 5 M HCl); R_f 0.29. Reported value for *N^5*-Ac-(*S*)-Orn; $[\alpha]_D^{25}$ +24.0° (*c* 1, 5 M HCl).[13]

(R)-2-Bromo-5-acetamidopentanoic Acid ((R)-2-Br-5-Acpa). This was prepared from *N^5*-Ac-(*R*)-Orn (8.71 g, 50 mmol), KBr (20.9 g, 175 mmol) and sodium nitrite (5.58 g, 80 mmol) in 1.25 M H_2SO_4 (105 ml) according to the procedure of Izumiya[14]; yield of an oil, 6.43 g (54%); R_f (TLC) 0.70.

Chromatography of (R),(S)- or (S),(S)-Form of Octopinic Acid with Amino Acid Analyzer. Certain amount (5 μmol) of either (*R*),(*S*)- or (*S*),(*S*)-form of octopinic acid was dissolved in 0.2 M citrate buffer of pH 2.2, and an aliquot (0.5 μmol) of the solution was subjected to the analyzer. The following conditions were sufficient to permit the separation of two isomers; column with spherical resin, 0.9 cm × 50 cm; buffer, the standard citrate at pH 3.25; flow rate, 60 ml/h; jacket temperature, 55 °C. A chromatogram with a mixture of both isomers is shown in Fig. 2. The ratio of color intensities in the chromatogram of equimolar amount of (*R*),(*S*)-form and (*S*),(*S*)-form of octopinic acid was found to be 140:100.

Reaction of (R)- or (S)-Alanine and (R)-2-Br-5-Acpa. Determination of Bromide Ion: (*R*)- or (*S*)-Alanine, (*R*)-2-Br-5-Acpa and $Ba(OH)_2 \cdot 8H_2O$ in each specified amount were dissolved in water (20 ml). An aliquot (1 ml) of the solution was withdrawn for certain intervals, and was subjected to the Volhard titration. An amount of Br^- released was determined, the result being shown in Fig. 3.

Determination of (R),(S)- or (S),(S)-Form of Ac-octopinic Acid: An aliquot (1 ml) of the reaction mixture described above for certain intervals was put on a column (1.1 cm × 6 cm) of Dowex 50X8 (H^+ form), and the column was washed with water and eluted with 2 M NH_3 aq. The eluate was evaporated, and the residue was dissolved in 2 M HCl. After being refluxed for 2 h, the solution was evaporated, and the residue was dissolved in 0.2 M citrate buffer (pH 2.2). An aliquot was subjected to an amino acid analyzer as described previously. Yield of (*R*),(*S*)- or (*S*),(*S*)-form of Ac-octopinic acid was calculated from a peak of corresponding octopinic acid. Elution volume of unchanged alanine on the analyzer was 98 ml, and the ratio of color intensities in the chromatogram of equimolar amount of (*R*),(*S*)-octopinic acid and alanine was found to be 85:100.

(R),(S)-Ac-octopinic Acid. A solution of (*R*)-alanine (4.45 g, 50 mmol), (*R*)-2-Br-5-Acpa (1.19 g, 5 mmol), and $Ba(OH)_2 \cdot 8H_2O$ (8.68 g, 27.5 mmol) in water (50 ml) was stirred at 0 °C. After being stirred for 10 d at 0 °C, the solution was applied to a column (2.8 cm × 26 cm) of Dowex 50X8 (H^+ form), which was washed with water and eluted with 2 M NH_3 aq (300 ml). The eluate was evaporated and the residual solid was dissolved in a small amount of 0.1 M AcOH. The solution was put on a column (1.1 cm × 50 cm) of Amberlite IR-45 pre-equilibrated with 0.1 M AcOH. Elution was performed with 300 ml of 0.1 M AcOH and then 2 M AcOH (each fraction, 25-ml), fractions being monitored by TLC; the fractions 2—6 contained (*R*)-alanine. The fractions 17—21 were evaporated, and recrystallized from water–EtOH–acetone; yield, 197 mg (16% based on (*R*)-2-Br-5-Acpa); R_f (TLC) 0.36. This compound contained small amount (*ca.* 3%) of possible (*R*),(*R*)-Ac-octopinic acid, which was determined by an amino acid analyzer on an acid hydrolysate of a part of the product (197 mg).

Found: C, 46.85; H, 7.41; N, 10.46%. Calcd for $C_{10}H_{18}O_5N_2 \cdot 2/3H_2O$: C, 46.51; H, 7.55; N, 10.85%.

(S),(S)-Ac-octopinic Acid. This was prepared from (*S*)-alanine (4.45 g, 50 mmol) and (*R*)-2-Br-5-Acpa (1.19 g, 5 mmol) as described above; yield, 172 mg (14%); R_f (TLC) 0.36. This compound contained small amount (*ca.* 4%) of possible (*S*),(*R*)-Ac-octopinic acid.

Found: C, 47.92; H, 7.31; N, 11.19%. Calcd for $C_{10}H_{18}O_5N_2 \cdot 1/4H_2O$: C, 47.90; H, 7.44; N, 11.17%.

(R),(S)-Octopinic Acid. From (R),(S)-Ac-octopinic Acid: A solution of (*R*),(*S*)-Ac-octopinic acid (123 mg, 0.5 mmol) in 2 M HCl was refluxed for 2 h and evaporated. The residue dissolved in a small amount of water was put on a column (1.1 cm × 6 cm) of Dowex 50X8 (H^+ form), and the column was washed with water and eluted with 2 M NH_3 aq. The eluate was evaporated and recrystallized from water–EtOH; yield, 76 mg (74%); mp 275—277 °C (dec); $[\alpha]_D^{20}$ +19.2° (*c* 0.5, H_2O); R_f 0.11. This compound was pure (*R*),(*S*)-octopinic acid showing no contamination of possible (*R*),(*R*)-isomer.

Found: C, 45.90; H, 7.84; N, 13.23%. Calcd for $C_8H_{16}O_4N_2 \cdot 1/4H_2O$: C, 46.04; H, 7.97; N, 13.42%.

From (+)-Octopine: (+)-Octopine (246 mg, 1 mmol)[8] derived from (*S*)-arginine and (*S*)-2-bromopropionic acid was dissolved in saturated aqueous $Ba(OH)_2$ solution (100 ml) at 0 °C, and the solution was left to stand at 75—80 °C for 6 h. After removal of Ba^{++} by H_2SO_4, the filtrate was treated with a column of Dowex 50X8 as described above.

The eluate with 2 M NH_3 aq was evaporated and the residue dissolved in 0.1 M pyridine–formate buffer (pH 3.1) was put on a column (1.1 cm×40 cm) of Dowex 50X8 pre-equilibrated with the same buffer. Elution was performed with the same buffer (each fraction, 10-ml), and the fractions 10—15 were evaporated to afford crude (*R*),(*S*)-octopinic acid which contained *ca.* 1.5% possible (*R*),(*R*) (or (*S*),(*S*))-octopinic acid. Crude product was recrystallized from water–EtOH to give pure (*R*),(*S*)-octopinic acid; yield, 80 mg (39%); mp 276—278 °C (dec); $[\alpha]_D^{20}$ +19.1° (*c* 0.5, H_2O); R_f 0.11. Reported values[15] for octopinic acid derived from natural octopine: mp 270—271 °C; $[\alpha]_D^{20}$ +18.48° (*c* 0.5, H_2O).

(S),(S)-Octopinic Acid. This was prepared from (*S*),(*S*)-Ac-octopinic acid (123 mg, 0.5 mmol) as described for the preparation of (*R*),(*S*)-octopinic acid from (*R*),(*S*)-Ac-octopinic acid; yield, 73 mg (72%); mp 237 °C (dec); $[\alpha]_D^{20}$ +24.6° (*c* 0.5, H_2O); R_f 0.11.

Found: C, 45.80; H, 7.89; N, 13.28%. Calcd for $C_8H_{16}O_4N_2 \cdot 1/3H_2O$: C, 45.71; H, 7.99; N, 13.33%.

(R),(S)-Octopine. A solution of (*R*),(*S*)-octopinic acid (41 mg, 0.2 mmol), derived from (*R*),(*S*)-Ac-octopinic acid, and *S*-methylisothiourea sulfate (56 mg, 0.4 mmol) in 0.1 M NaOH (4 ml) was kept at 35 °C for 6 d, and the solution was put on a column (1.1 cm×6 cm) of Dowex 50X8 (H^+ form). The column was washed with water and eluted with 2 M NH_3 aq. The eluate was concentrated and applied to a column (1.4 cm×3 cm) of Dowex 1X2 (OH^- form), and the column was washed with water and eluted with 1 M AcOH. The eluate was evaporated, and the residue dissolved in 0.1 M pyridine–formate buffer (pH 3.1) was put on a column (0.9 cm×33 cm) of Dowex 50X8 (pyridinium form). The column was washed with the same buffer (75 ml), and eluted with 1 M pyridine. The eluate containing octopine was evaporated and recrystallized from water–EtOH–acetone; yield, 30 mg (61%); mp 280—283 °C (dec); $[\alpha]_D^{20}$ +20.8° (*c* 1, H_2O); R_f 0.15.

Found: C, 43.78; H, 7.32; N, 22.83%. Calcd for $C_9H_{18}O_4N_4$: C, 43.89; H, 7.37; N, 22.75%. Reported values[15] for natural octopine: mp 281—282 °C; $[\alpha]_D^{17}$ +20.94° (*c* 2.6, H_2O). Reported values[8] for (+)-octopine prepared from (*S*)-arginine and (*S*)-2-bromopropionic acid; mp 283—284 °C; $[\alpha]_D^{24}$ +20.8° (*c* 2, H_2O).

Identity of (*R*),(*S*)-octopine obtained from (*R*)-alanine and (*R*)-2-bromo-5-acetamidopentanoic acid, and (+)-octopine[8] prepared from (*S*)-arginine and (*S*)-2-bromopropionic acid was ascertained by co-chromatographies on paper and silica gel-thin layer with several solvent systems in addition to the same specific rotations described above.

(S),(S)-Octopine. (*S*),(*S*)-Octopinic acid (41 mg, 0.2 mmol) was treated with *S*-methylisothiourea sulfate followed by work-up as described above. The crude product was recrystallized from water–EtOH–acetone; yield 32 mg (65%); mp 263—264° (dec); $[\alpha]_D^{20}$ +26.7° (*c* 1, H_2O); R_f 0.15.

Found: C, 43.67; H, 7.48; N, 22.65%. Calcd for $C_9H_{18}O_4N_4$: C, 43.89; H, 7.37; N, 22.75%. Reported values[8] for (+)-isooctopine prepared from (*S*)-arginine and (*R*)-2-bromopropionic acid; mp 264—265 °C; $[\alpha]_D^{24}$ +26.8° (*c* 2, H_2O).

We thank Dr. N. Nishino in this laboratory for his discussion.

A Theoretical Study of the Resonance Raman Scattering from a Molecular System. Effects of Vibronic and Nonadiabatic Couplings

Katsumi Seo, Hirohiko Kono,† and Yuichi Fujimura*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received March 30, 1981)

A theory of the resonance Raman scattering (RRS) from a molecular system in which the vibronic levels of the resonance state are perturbed by both the Herzberg-Teller vibronic and the nonadiabatic coupling is developed. By using the time-independent Green-function formalism, an expression for the RRS is derived in the three-electronic-state model. The RRS cross-sections obtained are classified into four types: the pure RRS cross-section, independent of the coupling mode: the vibronically induced one, the nonadiabatically induced one, and the interference term. Assuming that the molecular system consists of a totally symmetric mode characterized by a displaced harmonic oscillator, with a nontotally symmetric mode as the inducing mode, analytical expressions for the relevant RRS cross-sections of the n_s-th order vibrational transition for the totally symmetric mode are derived. Model calculations of the cross-sections indicate that, for an increasing potential displacement parameter, Δ, between the coupled states, the nonadiabatic correction to the higher-order vibrational transitions, as well as the zero-order vibrational transition, makes a significant contribution.

The mechanisms of the resonance Raman scattering (RRS) from molecules have been investigated by many authors.[1–12] It is experimentally and theoretically recognized that the intensity of the RRS is enhanced as a result of the Herzberg-Teller vibronic coupling in the resonant state and/or the nonadiabatic coupling between the resonant and other electronically excited states.[13–27] Considering a simple model for the RRS by using a nontotally symmetric vibrational mode, Mortensen[3] has shown that the excitation energy profile of the RRS derived within the conventional linear Herzberg-Teller vibronic coupling approximation consists of two identical maxima corresponding to a resonance with 0-0 and 0-1 bands, neglecting the incident-photon-frequency dependence. Zgierski[4] has investigated the effect of nonadiabatic coupling to explain the asymmetry of the 0-0 and 0-1 bands. Hassing and Mortensen[18] have claimed that the asymmetry may be explained by taking into account the interference from a displaced totally symmetric mode in the RRS of the nontotally symmetric mode. By using the third-order perturbation theory, Johnson, Nafie, and Peticolas[7] have calculated the excitation energy profile of the zero-order vibrational transition for a displaced totally symmetric mode, and have concluded that the importance of the nonadiabatic correction is minimal relative to the adiabatic contribution unless the vibronic energy level of the upper state is within a few vibrational quanta of the resonant state.

The main purpose of this paper is to develop a theory of the RRS from a molecular system in which the vibronic levels of the resonant state are perturbed by both the Herzberg-Teller vibronic and the nonadiabatic coupling, and to clarify the role of the couplings on the excitation profiles of the RRS using the adiabatic basis set. Our theory is applicable to a molecular system with any potential energy surface displacements, and includes the results obtained by Zgierski[4] and by Johnson *et al.*[7] as special cases. Their theoretical treatments are restricted to a molecular system with small potential energy surface displacements between the resonant and the ground or upper electronic states. A preliminary study of the effect of the nonadiabatic coupling on the RRS was reported in a previous paper.[28]

In theory section, on the basis of the time-independent Green-function formalism, an expression for the RRS cross-section in the weak radiation field is derived using the three-electronic-state model. The RRS cross-sections are classified in terms of its mechanisms: the pure RRS, which is irrelevant to the inducing mode; the vibronically induced RRS; the nonadiabatically induced RRS, and the RRS originating from their interference, which are further divided into three groups. The most important terms of the interference are those between the components of the RRS within the same resonant state. The interference term between the vibronically induced and nonadiabatically induced RRS contributes to the asymmetry of the vibrational transitions of the excitation profile. In displaced harmonic oscillator model section, assuming that the molecular system consists of a totally symmetric mode characterized by a displaced harmonic oscillator, with a nontotally symmetric mode as the inducing mode, analytical expressions for the relevant RRS cross-sections of the n_s-th order vibrational transition for the totally symmetric mode are derived. The RRS cross-section thus obtained is explicitly expressed as a function of two displacement parameters between the equilibrium points in the relevant state. In the final section, model calculations of the excitation-energy profiles of the RRS cross-section of the n_s-th order vibrational transitions are performed in order to compare the effects of the couplings. It is shown that, for increasing the displacement, Δ, between the two coupled states, the nonadiabatic correction to the higher-order vibrational transitions as well as the zero-order vibrational transition makes a significant contribution.

Theory

Time-independent Green-function Formalism of the RRS Cross-sections in the Three-electronic-state Model. In

† Present address: Department of Chemistry, Arizona State University, Tempe, Arizona, U.S.A.

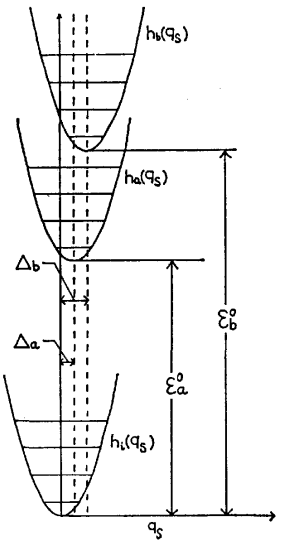

Fig. 1. Displaced harmonic potential model for three electronic state system. $h_i(q_s)$ represents the molecular Hamiltonian of a totally symmetric mode q_s in the ground state, and $h_a(q_s)$ and $h_b(q_s)$ those in the two electronic states a and b, respectively. Δ and ε^0 represent the dimensionless displacement between the equilibrium points, and the energy gap between the bottoms in the ground and relevant excited states, respectively.

a previous paper,[11] the time-independent Green-function formalism was applied to the derivation of the RRS cross-sections in the two-electronic-state model. In this section, in order to take systematically into account the effects of the vibronic and nonadiabatic couplings, we consider a typical model consisting of three electronic states. The total system of the molecular states and radiation field is assumed to be composed of an initial state, $|I\rangle = |\varepsilon_i; \{n_i\hbar\omega_i\}|$; two intermediate states, $|A\rangle = |\{\varepsilon_a\}; \{n_a\hbar\omega_a\}\rangle$ and $|B\rangle = |\{\varepsilon_b\}; \{n_b\hbar\omega_b\}\rangle$, and a final state, $|F\rangle = |\{\varepsilon_f\}; \{n_f\hbar\omega_f\}\rangle$, where ε_i denotes the lowest state in the molecular-ground state; $\{\varepsilon_a\}$ the manifold in the a-th electronically excited state, and $n\hbar\omega$, the photon energy. The energy diagram of the molecular system is shown in Fig. 1.

The time evolution of the initial state, $|I\rangle$, is expressed by:

$$|\Psi_I(t)\rangle = \exp[-i\hat{H}t/\hbar]|I\rangle \tag{1}$$

where the total Hamiltonian, $\hat{H}$, is given by:

$$\hat{H} = \hat{H}_0 + \hat{V}. \tag{2}$$

Here,

$$\hat{H}_0 = \hat{H}_m^0 + \hat{H}_r^0 \tag{2a}$$

and

$$\hat{V} = \hat{V}_{nd} + \hat{V}_{mr}, \tag{2b}$$

where $\hat{H}_m^0$ and $\hat{H}_r^0$ are the molecular Hamiltonian in the Born-Oppenheimer basis set, and the Hamiltonian for the free electromagnetic field, respectively, while $\hat{V}_{nd}$ and $\hat{V}_{mr}$ denote the nuclear kinetic energy, $\hat{T}_N$, and the molecule-radiation interaction respectively.

The transition amplitude, U_{FI}, from the initial state, I, to the final state, F, is expressed in terms of the transformation of the time-independent Green function as:

$$U_{FI}(t) = \langle F|\Psi_I(t)\rangle = \frac{1}{2\pi i}\int \exp(-iEt/\hbar)G_{FI}dE, \tag{3}$$

where G_{FI} is the matrix element of the Green-function. Equations for the relevant matrix elements of the Green-function in the present model are written as:

$$G_{FI} = \sum_A G_{FF}^0 V_{FA} G_{AI} + \sum_B G_{FF}^0 V_{FB} G_{BI}, \tag{4a}$$

$$G_{AI} = G_{AA}^0 V_{AI} G_{II} + \sum_F G_{AA}^0 V_{AF} G_{FI} + \sum_B G_{AA}^0 V_{AB} G_{BI}, \tag{4b}$$

$$G_{BI} = G_{BB}^0 V_{BI} G_{II} + \sum_F G_{BB}^0 V_{BF} G_{FI} + \sum_A G_{BB}^0 V_{BA} G_{AI}, \tag{4c}$$

and:

$$G_{II} = G_{II}^0 + \sum_A G_{II}^0 V_{IA} G_{AI} + \sum_B G_{II}^0 V_{IB} G_{BI}, \tag{4d}$$

where G^0 represents the zero-order Green-function,[11] the summations in Eqs. 4 are carried out over both the molecular vibronic states and the radiation-field variables. By substituting Eqs. 4a and 4d into Eqs. 4b and 4c, we obtain:

$$(E-E_A^0-\Lambda_{AA})G_{AI} = V_{AI}G_{II}^0 + \sum_{A'\neq A}\Lambda_{AA'}G_{A'I} + \sum_B (V_{AB}+\Lambda_{AB})G_{BI}, \tag{5a}$$

and:

$$(E-E_B^0-\Lambda_{BB})G_{BI} = V_{BI}G_{II}^0 + \sum_{B'\neq B}\Lambda_{BB'}G_{B'I} + \sum_A (V_{BA}+\Lambda_{BA})G_{AI}. \tag{5b}$$

Here, $\Lambda_{AA'}$ and Λ_{AB} represent the diagonal and off-diagonal self-energy terms respectively.[11]

In order to solve the coupled equations 5a and 5b, we substitute G_{BI}, neglecting the term involving $G_{B'I}$ in Eq. 5b, into 5a:

$$(E-E_A^0-\tilde{\Lambda}_{AA})G_{AI} = \tilde{V}_{AI}G_{II}^0 + \sum_{A'\neq A}\tilde{\Lambda}_{AA'}G_{A'I}, \tag{6}$$

where:

$$\tilde{\Lambda}_{AA'} = \Lambda_{AA'} + \sum_B (V_{AB}+\Lambda_{AB})(E-E_B^0-\Lambda_{BB})^{-1}\times(V_{BA'}+\Lambda_{BA'}), \tag{7}$$

and:

$$\tilde{V}_{AI} = V_{AI} + \sum_B (V_{AB}+\Lambda_{AB})(E-E_B^0-\Lambda_{BB})^{-1}V_{BI}. \tag{8}$$

Equation 6 can be solved by using the iterative method described in Ref. 11. By using the similar procedure described above, the decoupled equation for G_{BI} is obtained.

Substituting the decoupled equations for G_{AI} and G_{BI} into Eq. 4a, the matrix element of the Green function G_{FI} is expressed as:

$$G_{FI} = \sum_A G_{FF}^0 V_{FA}(E-E_A^0-\tilde{\Lambda}_{AA})^{-1}\tilde{V}_{AI}G_{II}^0 + \sum_B G_{FF}^0 V_{FB}(E-E_B^0-\tilde{\Lambda}_{BB})^{-1}\tilde{V}_{BI}G_{II}^0, \tag{9}$$

where the effect of the off-diagonal terms involving $\tilde{\Lambda}_{AA'}$ and $\tilde{\Lambda}_{BB'}$ were neglected. The energy-dependent

self-energy part is, at the zero-order approximation, expressed as:

$$\tilde{\Delta}_{AA} = \Delta_{AA}(E_A^0) = D_A - \frac{i\Gamma_A}{2}, \tag{10a}$$

and, in the first-order approximation, as:

$$\tilde{\Delta}_{AA} = \tilde{\Delta}_{AA}(E_A^0) = \tilde{D}_A - \frac{i\tilde{\Gamma}_A}{2}, \tag{10b}$$

where:

$$\tilde{D}_A = D_A + \sum_B \frac{(E_A^0 - E_B^0 - D_B)|V_{BA}|^2}{(E_A^0 - E_B^0 - D_B)^2 + (\Gamma_B/2)^2}, \tag{11}$$

and:

$$\tilde{\Gamma}_A = \Gamma_A + \sum_B \frac{\Gamma_B|V_{AB}|^2}{(E_A^0 - E_B^0 - D_B)^2 + (\Gamma_B/2)^2}. \tag{12}$$

Here, the level shift, D_A, and the decay width, Γ_A, of the A intermediate state are given in Ref. 11. In a case of weak nonadiabatic coupling, Eq. 10a can be used.

Neglecting the terms involving Δ_{AB} in $\tilde{V}_{AI}$ and Δ_{BA} in $\tilde{V}_{BI}$ of Eq. 9 because these terms give rise to the higher-order photon processes, and substituting Eq. 9 into Eq. 3, the transition amplitude U_{FI}, is expressed as:

$$\begin{aligned}
U_{FI}(t) = \sum_A \Bigg(& \frac{V_{FA}V_{AI}\exp(-iE_I^0t/\hbar)}{E_I^0 - E_A + i\tilde{\Gamma}_A/2} \frac{\{1-\exp[-i(E_F^0-E_I^0)t/\hbar]\}}{E_I^0 - E_F^0} \\
& + \frac{V_{FA}V_{AI}\exp[-i(E_A - i\tilde{\Gamma}_A/2)t/\hbar]}{(E_A - E_F^0 - i\tilde{\Gamma}_A/2)(E_A - E_I^0 - i\tilde{\Gamma}_A/2)} - \frac{V_{FA}V_{AI}\exp(-iE_F^0t/\hbar)}{(E_I^0 - E_A + i\tilde{\Gamma}_A/2)(E_F^0 - E_A + i\tilde{\Gamma}_A/2)} \Bigg) + \sum_B (A \to B) \\
& + \sum_A \sum_B \Bigg(\frac{V_{FB}V_{BA}V_{AI}\exp(-iE_I^0t/\hbar)}{(E_I^0 - E_A + i\tilde{\Gamma}_A/2)(E_I^0 - E_B + i\tilde{\Gamma}_B/2)} \frac{\{1-\exp[-i(E_F^0-E_I^0)t/\hbar]\}}{E_I^0 - E_F^0} \\
& + \frac{V_{FB}V_{BA}V_{AI}\exp[-i(E_B - i\tilde{\Gamma}_B/2)t/\hbar]}{(E_B - E_A - i\tilde{\Gamma}_B/2 + i\tilde{\Gamma}_A/2)(E_B - E_I^0 - i\tilde{\Gamma}_B/2)(E_B - E_F^0 - i\tilde{\Gamma}_B/2)} \\
& + \frac{V_{FB}V_{BA}V_{AI}\exp[-i(E_A - i\tilde{\Gamma}_A/2)t/\hbar]}{(E_A - E_B - i\tilde{\Gamma}_A/2 + i\tilde{\Gamma}_B/2)(E_A - E_I^0 - i\tilde{\Gamma}_A/2)(E_A - E_F^0 - i\tilde{\Gamma}_A/2)} \\
& - \frac{V_{FB}V_{BA}V_{AI}\exp(-iE_F^0t/\hbar)}{(E_I^0 - E_A + i\tilde{\Gamma}_A/2)(E_I^0 - E_B + i\tilde{\Gamma}_B/2)(E_F^0 - E_B + i\tilde{\Gamma}_B/2)} \\
& - \frac{V_{FB}V_{BA}V_{AI}\exp(-iE_F^0t/\hbar)}{(E_I^0 - E_A + i\tilde{\Gamma}_A/2)(E_F^0 - E_A + i\tilde{\Gamma}_A/2)(E_F^0 - E_B + i\tilde{\Gamma}_B/2)} \Bigg) + \sum_A \sum_B (A \rightleftarrows B),
\end{aligned} \tag{13}$$

where $E_A = E_A^0 + D_A$ and $E_B = E_B^0 + D_B$. When we use the on-the-energy-shell approximation ($E_I^0 \to E_F^0$) and the limit, $t \to \infty$, it seems that the following terms make the dominant contribution to the scattering cross-section:

$$\begin{aligned}
U_{FI}(t) = \Bigg[& \sum_A \frac{V_{FA}V_{AI}\exp(-E_I^0t/\hbar)}{E_I^0 - E_A + i\tilde{\Gamma}_A/2} + \sum_B (A \to B) \\
& + \sum_A \sum_B \frac{V_{FB}V_{BA}V_{AI}\exp(-iE_I^0t/\hbar)}{(E_I^0 - E_A + i\tilde{\Gamma}_A/2)(E_I^0 - E_B + i\tilde{\Gamma}_B/2)} \\
& + \sum_A \sum_B (A \rightleftarrows B) \Bigg] \frac{1-\exp[-i(E_F^0 - E_I^0)t/\hbar]}{E_I^0 - E_F^0}.
\end{aligned} \tag{14}$$

By using the dipole and rotating wave approximations, and after integrating over the radiation-field variables, the differential cross-section for the Raman scattering is given by:

$$\begin{aligned}
\frac{d\sigma(\omega_1)}{d\Omega} = & \frac{\omega_1(n_2+1)}{2^4\pi^2\varepsilon_0^2c^4} \sum_f \int_0^\infty d\omega_2 \omega_2^3 \\
& \times \Bigg| \sum_c \frac{\langle f|e_2\cdot\mu|c\rangle\langle c|e_1\cdot\mu|i\rangle}{\varepsilon_1 + \hbar\omega_1 - \varepsilon_c + i\tilde{\Gamma}_c/2} \\
& + \sum_{\substack{c,d \\ (c\neq d)}} \frac{\langle f|\hat{e}_2\cdot\mu|d\rangle\langle d|\hat{T}_N|c\rangle\langle c|\hat{e}_1\cdot\mu|i\rangle}{(\varepsilon_1 + \hbar\omega_1 - \varepsilon_c + i\tilde{\Gamma}_c/2)(\varepsilon_1 + \hbar\omega_1 - \varepsilon_d + i\tilde{\Gamma}_d/2)} \\
& + (\text{non-resonant terms}) \Bigg|^2 \delta\left(\frac{\varepsilon_1 - \varepsilon_f + \hbar\omega_1 - \hbar\omega_2}{\hbar}\right),
\end{aligned} \tag{15}$$

where $\hbar\omega_1$ and $\hbar\omega_2$ denote the excitation and emission energies of the photon respectively, and where the summations, c and d, are taken over the vibronic states of two electronic states, a and b. Compared with the expression for the differential cross-section derived in the one-intermediate electronic state,[11] it should be noted that, in the two-intermediate-state model, the term originating from the nonadiabatic interaction appears in Eq. 15.

Mechanisms of the RRS from Randomly Oriented Molecules. We note that the complex tensor, t, for the RRS cross-section is written as the sum of symmetric and antisymmetric tensors, $\{t\} = \{S\} + \{A\}$, where $S_{12} = 1/2(t_{12} + t_{21})$ and $A_{12} = 1/2(t_{12} - t_{21})$. Here, the suffixes 1 and 2 specify the molecular fixed Cartesian coordinates, x, y, and z. We assume that the molecules are randomly oriented. If the incident radiation is linearly polarized, and if the polarization lies on the XY plane, the RRS cross-section, $d\sigma(\omega_1)/d\Omega$, along the Z axis is given by:[29]

$$\frac{d\sigma(\omega_1)}{d\Omega} = \frac{1}{15}\left\{7\frac{d\sigma_S(\omega_1)}{d\Omega} + 5\frac{d\sigma_A(\omega_1)}{d\Omega}\right\}, \tag{16}$$

where $d\sigma_S(\omega_1)/d\Omega$ and $d\sigma_A(\omega_1)/d\Omega$ represent the symmetric and antisymmetric parts of the cross-section and are given by:

$$\frac{d\sigma_I(\omega_1)}{d\Omega} = \frac{\omega_1(n_2+1)}{2^6\pi^2\varepsilon_0^2c^4} \sum_f \int_0^\infty d\omega_2 \omega_2^3$$

$$\left|\sum_c\left(\frac{\langle f|\mu_2|c\rangle\langle c|\mu_1|i\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2}\pm\frac{\langle f|\mu_1|c\rangle\langle c|\mu_2|i\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2}\right)\right.$$
$$+\sum_{\substack{c,d\\(c\neq d)}}\left(\frac{\langle f|\mu_2|d\rangle\langle d|\hat{T}_N|d\rangle\langle d|\mu_1|i\rangle}{(\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2)(\varepsilon_1+\hbar\omega_1-\varepsilon_d+i\tilde{\Gamma}_d/2)}\right.$$
$$\left.\left.\pm\frac{\langle f|\mu_1|d\rangle\langle d|\hat{T}_N|c\rangle\langle c|\mu_2|i\rangle}{(\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2)(\varepsilon_1+\hbar\omega_1-\varepsilon_d+i\tilde{\Gamma}_d/2)}\right)\right|^2$$
$$\times\delta\left(\frac{\varepsilon_1-\varepsilon_f+\hbar\omega_1-\hbar\omega_2}{\hbar}\right), \tag{17}$$

where the + and − signs correspond to the symmetric (I=S) and antisymmetric (I=A) cross-sections respectively. In the above expression, the non-resonant terms were disregarded.

To classify the RRS into the pure RRS irrelevant to the couplings, vibronically induced, and nonadiabatically induced types, we expand the matrix element of the transition dipole and the nonadiabatic coupling matrix element as:

$$\langle f|\mu_2|a\rangle=\langle\chi_f|M_{fa}(2)|\chi_a\rangle$$
$$+\langle\chi_f|(M_{fb}(2)V_{ba}-V_{fb}M_{ba}(2))q|\chi_a\rangle+\cdots, \tag{18}$$

and:

$$\langle a|\hat{T}_N|b\rangle=\left\langle\chi_a\left|\left(\Phi_a\left|-\frac{\hbar\omega}{2}\frac{\partial^2}{\partial q^2}\right|\Phi_b\right)\right|\chi_b\right\rangle$$
$$\simeq-\hbar\omega\left\langle\chi_a\left|V_{ab}\frac{\partial}{\partial q}\right|\chi_b\right\rangle, \tag{19}$$

respectively, where $M_{fa}(2)=\langle\Phi_f|\mu_2|\Phi_a\rangle_{q=q_0}$ and where $V_{ba}=\left[\frac{\langle\Phi_b|\partial V/\partial q|\Phi_a\rangle}{\varepsilon_a-\varepsilon_b}\right]_{q=q_0}$. Here, Φ, χ, and V denote the BO electronic wave function, the nuclear wave function, and the electrostatic interaction between electron and nucleus respectively. The above matrix elements are evaluated at the equilibrium nuclear configuration (q_0) in the ground state. Restricting ourselves to the first-order variation of the nuclear coordinate, q, and disregarding the vibronic coupling between the ground (final or initial) and intermediate states because of $|\varepsilon_a(q_0)-\varepsilon_b(q_0)|<|\varepsilon_b(q_0)-\varepsilon_f(q_0)|$, the symmetric and antisymmetric cross-section of the spontaneous RRS can be written as:

$$\frac{d\sigma_I(\omega_1)}{d\Omega}=\frac{\omega_1}{2^6\pi^2\varepsilon_0^2c^4}\sum_f\int_0^\infty d\omega_2\omega_2^3\delta\left(\frac{\varepsilon_1-\varepsilon_f+\hbar\omega_1-\hbar\omega_2}{\hbar}\right)$$
$$\left|\sum_c\left(\frac{\langle\chi_f|M_{fc}(2)|\chi_c\rangle\langle\chi_c|M_{c1}(1)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2}\pm\frac{\langle\chi_f|M_{fc}(1)|\chi_c\rangle\langle\chi_c|M_{c1}(2)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2}\right)\right.$$
$$+\sum_c^{(elec)}\sum_{\substack{d\\(c\neq d)}}\left[\left\{-\frac{\langle\chi_f|M_{fc}(2)|\chi_c\rangle\langle\chi_c|V_{cd}M_{d1}(1)q|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2}+\frac{\langle\chi_f|M_{fd}(2)V_{dc}q|\chi_c\rangle\langle\chi_c|M_{c1}(1)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2}\right\}\right.$$
$$\left.\pm\left\{-\frac{\langle\chi_f|M_{fc}(1)|\chi_c\rangle\langle\chi_c|V_{cd}M_{d1}(2)q|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_d/2}+\frac{\langle\chi_f|M_{fd}(1)V_{dc}q|\chi_c\rangle\langle\chi_c|M_{c1}(2)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2}\right\}\right]$$
$$-\sum_c\sum_{\substack{d\\(c\neq d)}}\left\{\hbar\omega\frac{\langle\chi_f|M_{fd}(2)|\chi_d\rangle\langle\chi_d|V_{dc}\partial/\partial q|\chi_c\rangle\langle\chi_c|M_{c1}(1)|\chi_1\rangle}{(\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2)(\varepsilon_1+\hbar\omega_1-\varepsilon_d+i\tilde{\Gamma}_d/2)}\right.$$
$$\left.\left.\pm\hbar\omega\frac{\langle\chi_f|M_{fd}(1)|\chi_d\rangle\langle\chi_d|V_{dc}\partial/\partial q|\chi_c\rangle\langle\chi_c|M_{c1}(2)|\chi_1\rangle}{(\varepsilon_1+\hbar\omega_1-\varepsilon_c+i\tilde{\Gamma}_c/2)(\varepsilon_1+\hbar\omega_1-\varepsilon_d+i\tilde{\Gamma}_d/2)}\right\}\right|^2, \tag{20}$$

where $\sum_d^{(elec)}$ means the summation over the electronic states, a and b. Here, the first and second terms independent of q and $\partial/\partial q$ express the pure RRS; the terms involving q the vibronically induced RRS, and the terms involving $\partial/\partial q$, the nonadiabatically induced RRS.

In this paper, since we are interested in the RRS originating from the couplings between a and b electronic states, we will consider the special case in which the irreducible representations of the point group of the electronic states, Φ_a and Φ_b, at the equilibrium configuration in the ground state are different from each other: $M_{fa}(2)=0$ and $M_{b1}(1)=0$, which also means that $M_{1a}(2)=0$ and $M_{fb}(1)=0$, while the inducing mode, q, belongs to a nontotally symmetric mode. In this case, the pure RRS terms vanish and Eq. 20 is reduced to:

$$\frac{d\sigma_I(\omega_1)}{d\Omega}=\frac{\omega_1}{2^6\pi^2\varepsilon_0^2c^4}\sum_f\int_0^\infty d\omega_2\omega_2^3\delta\left(\frac{\varepsilon_1-\varepsilon_f+\hbar\omega_1-\hbar\omega_2}{\hbar}\right)$$
$$\left|\sum_a^{(vibro)}\frac{\langle\chi_f|M_{fb}(2)V_{ba}q|\chi_a\rangle\langle\chi_a|M_{a1}(1)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_a+i\tilde{\Gamma}_a/2}-\sum_b^{(vibro)}\frac{\langle\chi_f|M_{fb}(2)|\chi_b\rangle\langle\chi_b|V_{ba}qM_{a1}(1)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_b+i\tilde{\Gamma}_b/2}\right.$$
$$\pm\sum_b^{(vibro)}\frac{\langle\chi_f|M_{fa}(1)V_{ab}q|\chi_b\rangle\langle\chi_b|M_{b1}(2)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_b+i\tilde{\Gamma}_b/2}\mp\sum_a^{(vibro)}\frac{\langle\chi_f|M_{fa}(1)|\chi_a\rangle\langle\chi_a|V_{ab}qM_{b1}(2)|\chi_1\rangle}{\varepsilon_1+\hbar\omega_1-\varepsilon_a+i\tilde{\Gamma}_a/2}$$
$$-\sum_{\substack{a,b\\(a\neq b)}}^{(vibro)}\hbar\omega\left\{\frac{\langle\chi_f|M_{fb}(2)|\chi_b\rangle\langle\chi_b|V_{ba}\partial/\partial q|\chi_a\rangle\langle\chi_a|M_{a1}(1)|\chi_1\rangle}{(\varepsilon_1+\hbar\omega_1-\varepsilon_a+i\tilde{\Gamma}_a/2)(\varepsilon_1+\hbar\omega_1-\varepsilon_b+i\tilde{\Gamma}_b/2)}\right.$$
$$\left.\left.\pm\frac{\langle\chi_f|M_{fa}(1)|\chi_a\rangle\langle\chi_a|V_{ab}\partial/\partial q|\chi_b\rangle\langle\chi_b|M_{b1}(2)|\chi_1\rangle}{(\varepsilon_1+\hbar\omega_1-\varepsilon_a+i\tilde{\Gamma}_a/2)(\varepsilon_1+\hbar\omega_1-\varepsilon_b+i\tilde{\Gamma}_b/2)}\right\}\right|^2. \tag{21}$$

Utilizing the Fourier transformations, and carrying out the summations over the vibronic states in Eq. 21 by using the closure property of the states,[11] we obtain:

$$\frac{d\sigma_I(\omega_1)}{d\Omega} = \frac{d\sigma_I^{VI}(\omega_1)}{d\Omega} + \frac{d\sigma_I^{NA}(\omega_1)}{d\Omega} + \frac{d\sigma_I^{INT(VI)}(\omega_1)}{d\Omega} + \frac{d\sigma_I^{INT(NA)}(\omega_1)}{d\Omega} + \frac{d\sigma_I^{INT(VI-NA)}(\omega_1)}{d\Omega}, \quad (22)$$

where $d\sigma_I^{VI}(\omega_1)/d\Omega$ and $d\sigma_I^{NA}(\omega_1)/d\Omega$ represent the vibronically induced and nonadiabatically induced RRS cross-sections respectively; $d\sigma_I^{INT(VI)}(\omega_1)/d\Omega$ and $d\sigma_I^{INT(NA)}(\omega_1)/d\Omega$, the interference term between the vibronically induced RRS and that between the nonadiatically induced RRS respectively, and $d\sigma_I^{INT(VI-NA)}(\omega_1)/d\Omega$, the interference term between the vibronically induced and the nonadiabatically induced RRS. It should be noted that the signs specifying the symmetric and antisymmetric cross-sections are involved in the interference terms.

The vibronically induced and nonadiabatically induced cross sections are expressed as:

$$\frac{d\sigma_I^{VI}(\omega_1)}{d\Omega} = \frac{\omega_1}{2^7\pi^3\varepsilon_0^2c^4\hbar^2}|M_{gb}(2)V_{ba}M_{ag}(1)|^2 \sum_{ca,b}\int_0^\infty d\omega_2\omega_2^3\int_0^\infty d\tau'\int_0^\infty d\tau\int_{-\infty}^\infty dt \exp[-i(t-\tau+\tau')\omega_1+it\omega_2] \times\{\langle\chi_1|\exp[(i\hat{H}_c^0-\tilde{\Gamma}_c/2)\tau'/\hbar]q_n\exp(i\hat{H}_I^0t/\hbar)q_n \exp[-(i\hat{H}_c^0+\tilde{\Gamma}_c/2)\tau/\hbar]\exp[-i\hat{H}_I^0(t-\tau+\tau')/\hbar]|\chi_I\rangle + \langle\chi_I|q_n\exp[(i\hat{H}_c^0-\tilde{\Gamma}_c/2)\tau'/\hbar] \exp(i\hat{H}_I^0t/\hbar)\exp[-(i\hat{H}_c^0+\tilde{\Gamma}_c/2)\tau/\hbar]q_n \exp[-i\hat{H}_I^0(t-\tau+\tau')/\hbar]|\chi_I\rangle\}, \quad (23)$$

and:

$$\frac{d\sigma_I^{NA}(\omega_1)}{d\Omega} = \frac{\omega_1\omega_n^2}{2^7\pi^3\varepsilon_0^2c^4\hbar^2}|M_{gb}(2)V_{ba}M_{ag}(1)|^2 \sum_{\substack{c\\(c\neq d)}}\sum_d\int_0^\infty d\omega_2\omega_2^3\int_0^\infty d\tau'\int_0^\infty d\xi'\int_0^\infty d\tau\int_0^\infty d\xi\int_{-\infty}^\infty dt \exp[-i(t-\tau-\xi+\tau'+\xi')\omega_1+it\omega_2] \times\langle\chi_I|\exp[(-i\hat{H}_c^0-\tilde{\Gamma}_c/2)\tau'/\hbar](\partial/\partial q_n)^\dagger \exp[(i\hat{H}_d^0-\tilde{\Gamma}_d/2)\xi'/\hbar]\exp(i\hat{H}_I^0t/\hbar) \exp[-(i\hat{H}_d^0+\tilde{\Gamma}_d/2)\xi/\hbar]\partial/\partial q_n\exp[-(i\hat{H}_c^0+\tilde{\Gamma}_c/2)\tau/\hbar] \exp[-i\hat{H}_I^0(t-\tau-\xi+\tau'+\xi')/\hbar]\chi_I\rangle, \quad (24)$$

respectively, where n denotes a nontotally symmetric mode and $\hat{H}^0$, the relevant vibronic Hamiltonian, while the vibronic-level dependence of the decay width, $\tilde{\Gamma}$, is disregarded. Because Eqs. 23 and 24 are expressed in terms of the vibronic Hamiltonians and are independent of the summation over the intermediate vibronic levels, these equations are suitable for the investigation of the coupling effects of the RRS from a molecular system consisting of any potential energy surfaces. They can thus be used as a basis for studying the frequency change[30] and anharmonic effects of the RRS. The expressions for the interference RRS cross-sections are given in Appendix A.

Displaced Harmonic Oscillator Model

In this section, we are concerned with the derivation of analytical expressions for the vibronically induced RRS, the nonadiabatically induced RRS, and their interference RRS in the displaced harmonic oscillator model. The molecular Hamiltonians of the ground and two excited states, a and b consist of a totally symmetric mode (q_s) with a nontotally symmetric mode (q_n) as the inducing mode. These potential surfaces are assumed to be harmonic and to be displaced for the totally symmetric mode. The frequency change in the vibrationsl modes were disregarded. In terms of the Boson annihilation and creation operators, $\hat{b}$ and $\hat{b}^\dagger$, which satisfy $[\hat{b}, \hat{b}^\dagger]=1$, these Hamiltonians are expressed as:

$$\hat{H}_I^0 = \hat{h}_I(q_s) + \hat{h}_I(q_n), \quad (25a)$$

$$\hat{h}_I(q_s) = \frac{\hbar\omega_s}{2}(p_s^2+q_s^2) = \hbar\omega_s\left(\hat{b}_s^\dagger\hat{b}_s+\frac{1}{2}\right), \quad (25b)$$

$$\hat{h}_I(q_n) = \frac{\hbar\omega_n}{2}(p_n^2+q_n^2) = \hbar\omega_n\left(\hat{b}_n^\dagger\hat{b}_n+\frac{1}{2}\right), \quad (25c)$$

$$\hat{H}_a^0 = \hat{h}_I(q_s-\Delta_a) + \hat{h}_I(q_n) + \varepsilon_a^0 = \hbar\omega_s\left(\hat{b}_s^\dagger\hat{b}_s+\frac{1}{2}\right) - \frac{\hbar\omega_s\Delta_a}{\sqrt{2}}(\hat{b}_s+\hat{b}_s^\dagger) + \frac{\hbar\omega_s\Delta_a^2}{2} + \hbar\omega_n\left(\hat{b}_n^\dagger\hat{b}_n+\frac{1}{2}\right)+\varepsilon_a^0, \quad (25d)$$

and

$$\hat{H}_b^0 = \hat{h}_I(q_s-\Delta_b) + \hat{h}_I(q_n) + \varepsilon_b^0, \quad (25e)$$

where we have taken into account the potential displacement between the potential energy surfaces of the two intermediate excited states; Δ_a and Δ_b represent the dimensionless displacements between the equilibrium points in the ground and excited states, a and b respectively, and ε^0, the electronic energy gap between the bottoms in the ground and excited states.

Nonadiabatically Induced RRS. The nonadiabatically induced RRS cross-section, $d\sigma_I^{NA}(\omega_1)/d\Omega$, Eq. 24 is written as:

$$\frac{d\sigma_I^{NA}(\omega_1)}{d\Omega} = \omega_n^2k(\omega_1)\sum_{\substack{c\\(c\neq d)}}\sum_d\int_0^\infty d\omega_2\omega_2^3 \int_0^\infty d\tau'\int_0^\infty d\xi'\int_0^\infty d\tau\int_0^\infty d\xi\int_{-\infty}^\infty dt \exp\left[-i(t-\tau-\xi+\tau'+\xi')\omega_1+it\omega_2-\frac{\tilde{\Gamma}_c}{2\hbar}(\tau+\tau') -\frac{\tilde{\Gamma}_d}{2\hbar}(\xi+\xi')+\frac{i\varepsilon_c^0}{\hbar}(\tau'-\tau)+\frac{i\varepsilon_d^0}{\hbar}(\xi'-\xi)\right] f_n(\tau',\xi',\tau,\xi,t)g_s(\tau',\xi',\tau,\xi,t), \quad (26)$$

where $k(\omega_1)=\frac{\omega_1}{2^7\pi^3\varepsilon_0^2c^4\hbar^2}|M_{gb}(2)V_{ba}M_{ag}(1)|^2$,

$$f_n(\tau',\xi',\tau,\xi,t) = \left\langle 0_n\middle|\exp\left[\frac{i\hat{h}_I(q_n)\tau'}{\hbar}\right]\left(\frac{\partial}{\partial q_n}\right)^\dagger\right.$$

$$\exp\left[\frac{i\hat{h}_l(q_n)\xi'}{\hbar}\right]\exp\left[\frac{i\hat{h}_l(q_n)t}{\hbar}\right]$$
$$\exp\left[-\frac{i\hat{h}_l(q_n)\xi}{\hbar}\right]\frac{\partial}{\partial q_n}\exp\left[-\frac{i\hat{h}_l(q_n)\tau}{\hbar}\right]$$
$$\exp\left[-\frac{i\hat{h}_l(q_n)(t-\tau-\xi+\tau'+\xi')}{\hbar}\right]\Big|0_n\Big\rangle, \quad (27a)$$

and

$$g_s(\tau',\xi',\tau,\xi,t)=\Big\langle 0_s\Big|\exp\left[\frac{i\hat{h}_l(q_s-\Delta_c)\tau'}{\hbar}\right]$$
$$\exp\left[\frac{i\hat{h}_l(q_s-\Delta_d)\xi'}{\hbar}\right]\exp\left[\frac{i\hat{h}_l(q_s)t}{\hbar}\right]$$
$$\exp\left[-\frac{i\hat{h}_l(q_s-\Delta_d)\xi'}{\hbar}\right]\exp\left[-\frac{i\hat{h}_l(q_s-\Delta_c)\tau}{\hbar}\right]$$
$$\exp\left[-\frac{i\hat{h}_l(q_s)}{\hbar}(t-\tau-\xi+\tau'+\xi')\right]\Big|0_s\Big\rangle. \quad (27)$$

By using the Feynman-disentangle and Boson-operator techniques, the generating functions for the nontotally symmetric and totally symmetric modes, $f_n(\tau',\xi',\tau,\xi,t)$ and $g_s(\tau',\xi',\tau,\xi,t)$, can be evaluated as:

$$f_n(\tau',\xi',\tau,\xi,t)=\frac{1}{2}\exp\left[i\omega_n(\xi'-\xi+t)\right], \quad (28)$$

and:

$$g_s(\tau',\xi',\tau,\xi,t)=\exp\left[\frac{\Delta_c^2}{2}\{\exp(i\omega_s\tau')-1\}\right.$$
$$+\frac{\Delta_c^2}{2}\{\exp(-i\omega_s\tau)-1\}+\frac{\Delta_d^2}{2}\{\exp(i\omega_s\xi')-1\}$$
$$\left.+\frac{\Delta_d^2}{2}\{\exp(-i\omega_s\xi)-1\}\right]\exp\left[\lambda_c^*(\tau')\lambda_c^*(\xi')\right.$$
$$+\lambda_c(\tau)\lambda_c(\xi)+\exp(i\omega_s t)\{\lambda_c^*(\tau')\exp(i\omega_s\xi')+\lambda_d^*(\xi')\}$$
$$\left.\{\lambda_c(\tau)\exp(-i\omega_s\xi)+\lambda_d(\xi)\}\right], \quad (28)$$

where

$$\lambda_c(\tau)=\frac{\Delta_c}{\sqrt{2}}\{1-\exp(-i\omega_s\tau)\}. \quad (29)$$

The $\frac{\partial}{\partial q_n}=\frac{1}{2}(\hat{b}_n-\hat{b}_n^\dagger)$ relation was used. A derivation of Eq. 28 is given in detail in Appendix B. Expanding the last term in Eq. 28, the generating function for the totally symmetric mode, $g_s(\tau',\xi',\tau,\xi,t)$, is written as:

$$g_s(\tau',\xi',\tau,\xi,t)=\sum_{n_s=0}^{\infty}\frac{1}{n_s!}\{\lambda_c^*(\tau')\exp(i\omega_s\xi')+\lambda_d^*(\xi')\}^{n_s}$$
$$\{\lambda_c(\tau)\exp(-i\omega_s\xi)+\lambda_d(\xi)\}^{n_s}\exp\left[\frac{\Delta_c^2}{2}\{\exp(i\omega_s\tau')-1\}\right.$$
$$+\frac{\Delta_c^2}{2}\{\exp(-i\omega_s\tau)-1\}+\frac{\Delta_d^2}{2}\{\exp(-i\omega_s\xi)-1\}$$
$$\left.+\lambda_c^*(\tau')\lambda_d^*(\xi')+\lambda_c(\tau)\lambda_d(\xi)+in_s\omega_s t\right]. \quad (30)$$

By substituting Eqs. 28 and 30 into Eq. 26 and by integrating over t, we obtain:

$$\frac{d\sigma_I^{NA}(\omega_1)}{d\Omega}=k(\omega_1)\sum_c\sum_{d\,(c\neq d)}\sum_{n_s=0}^{\infty}\frac{\pi\omega_n^2}{n_s!}\int_0^\infty d\omega_2\omega_2^3$$
$$\left|\int_0^\infty d\tau\int_0^\infty d\xi\{\lambda_c(\tau)\exp(-i\omega_s\xi)+\lambda_c(\xi)\}^{n_s}\right.$$
$$\exp\left[i\tau\left(\omega_1-\frac{\varepsilon_c^0}{\hbar}+\frac{i\tilde{\Gamma}_c}{2\hbar}\right)+\frac{\Delta_c^2}{2}\{\exp(-i\omega_s\tau)-1\}\right.$$
$$+i\xi\left(\omega_1-\frac{\varepsilon_d^0}{\hbar}-\omega_n+\frac{i\tilde{\Gamma}_d}{2\hbar}\right)+\frac{\Delta_d^2}{2}\{\exp(-i\omega_s\xi)-1\}$$
$$\left.\left.+\lambda_c(\tau)\lambda_d(\xi)\right]\right|^2\delta(\omega_1-\omega_2-\omega_n-n_s\omega_s). \quad (31)$$

Integrating over ω_2, using the binomial and Taylor expansions, and finally integrating over τ and ξ, we obtain an analytical expression for the nonadiabatically induced RRS cross-section as:

$$\frac{d\sigma_I^{NA}(\omega_1)}{d\Omega}=\pi\omega_m^2k(\omega_1)\sum_c\sum_{d\,(c\neq d)}\sum_{n_s=0}^{\infty}\frac{(\omega_1-\omega_n-n_s\omega_s)^3}{n_s!}$$
$$\left|\sum_{l=0}^{n_s}\binom{n_s}{l}\left(\frac{\Delta_c}{\sqrt{2}}\right)\left(\frac{\Delta_d}{\sqrt{2}}\right)^{n_s-l}\sum_{m=0}^{\infty}\frac{1}{m!}\left(\frac{\Delta_c\Delta_d}{2}\right)^m\right.$$
$$\sum_{p=0}^{l}\binom{l}{p}(-1)^p\sum_{r=0}^{m}\binom{m}{r}(-1)^r$$
$$\sum_{t=0}^{\infty}\frac{S_{10,ct}}{\omega_1-\varepsilon_c^0/\hbar-(p+r+t)\omega_s+i\tilde{\Gamma}_c/(2\hbar)}$$
$$\sum_{q=0}^{n_s-l}\binom{n_s-l}{q}(-1)^q\sum_{s=0}^{m}\binom{m}{s}(-1)^s$$
$$\left.\sum_{u=0}^{\infty}\frac{S_{10,du}}{\omega_1-\varepsilon_d^0/\hbar-\omega_n-(l+q+s+u)\omega_s+i\tilde{\Gamma}_d/2\hbar}\right|^2, \quad (32)$$

where $S_{10,ct}$ is the optical Franck-Condon factor between the lowest level in the ground state and the t-th vibrational level in the excited state c; it is given by $S_{10,ct}=\left(\frac{\Delta_c^2}{2}\right)^t e^{-\frac{\Delta_c^2}{2}}/t!$. Eq. 32 is the desired analytical expression for the RRS cross-section originating from the nonadiabatic coupling between the two excited states a and b; it consists of the n_s-th order vibrational transition for a totally symmetric mode. In Ref. 28, the results have been given without a detailed derivation.

Vibronically Induced RRS. An analytical expression for the RRS cross-section originating from the vibronic coupling has been derived in Ref. 26.

Interference Terms. In Theory section, the interference RRS cross-sections have been classified into three groups. Because the significant terms are those between the components of the RRS within the same resonant state, and because the interference between the components of the resonant and other excited states can be safely disregarded, the expressions for the RRS cross-section due to the interference are written as:

a): Interference between the components of the vibronically induced RRS:

$$\frac{d\sigma_I^{INT(VI)}(w_1)}{d\Omega}\simeq\pm2\pi k(\omega_1)$$
$$\sum_c\sum_{n_s=0}^{\infty}\frac{(\omega_1-\omega_n-n_s\omega_s)^3}{n_s!}(\Delta_c^2/2)^{n_s}$$
$$\mathrm{Re}\left\{\sum_{j=0}^{n_s}\sum_{j'=0}^{n_s}\binom{n_s}{j}\binom{n_s}{j'}(-1)^{j+j'}\right.$$

$$\sum_{k=0}^{\infty}\sum_{k'=0}^{\infty}\frac{S_{\mathrm{I0,ck}}}{\omega_1-\varepsilon_c^0/\hbar-(j+k)\omega_s-\mathrm{i}\tilde{\Gamma}_c/2\hbar}\frac{S_{\mathrm{I0,ck'}}}{\omega_1-\varepsilon_c^0/\hbar-\omega_n-(j'+k')\omega_s+\mathrm{i}\tilde{\Gamma}_c/2\hbar}\Bigg\}, \quad (33)$$

and:

b): Interference between the components of the vibronically and the nonadiabatically induced RRS:

$$\frac{\mathrm{d}\sigma_I^{\mathrm{INT(VI-NA)}}(\omega_1)}{\mathrm{d}\Omega}=2\pi\omega_n k(\omega_1)\sum_{\substack{c\\(c\neq d)}}\sum_{d}\sum_{n_s=0}^{\infty}\frac{(\omega_1-\omega_n-n_s\omega_s)^3}{n_s!}\left(\frac{\Delta_c}{\sqrt{2}}\right)^{n_s}\mathrm{Re}\Bigg\{\sum_{j=0}^{n_s}\binom{n_s}{j}(-1)^j\sum_{k=0}^{\infty}\frac{S_{\mathrm{I0,ck}}}{\omega_1-\varepsilon_c^0/\hbar-(j+k)\omega_s-\mathrm{i}\tilde{\Gamma}_c/2\hbar}\sum_{l=0}^{n_s}\binom{n_s}{l}\left(\frac{\Delta_c}{\sqrt{2}}\right)\left(\frac{\Delta_d}{\sqrt{2}}\right)^{n_s-l}\sum_{m=0}^{\infty}\frac{1}{m!}\left(\frac{\Delta_c\Delta_d}{2}\right)^m\sum_{p=0}^{l}\binom{l}{p}(-1)^p\sum_{r=0}^{m}\binom{m}{r}(-1)^r\sum_{t=0}^{\infty}\frac{S_{\mathrm{I0,ct}}}{\omega_1-\varepsilon_c^0/\hbar-(p+r+t)\omega_s+\mathrm{i}\tilde{\Gamma}_c/2\hbar}\sum_{q=0}^{n_s-l}\binom{n_s-l}{q}(-1)^q\sum_{s=0}^{m}\binom{m}{s}(-1)^s\sum_{u=0}^{\infty}\frac{S_{\mathrm{I0,du}}}{\omega_1-\varepsilon_d^0/\hbar-\omega_n-(l+q+s+u)\omega_s+\mathrm{i}\tilde{\Gamma}_d/2\hbar}-\sum_{j=0}^{n_s}\binom{n_s}{j}(-1)^j\sum_{k=0}^{\infty}\frac{S_{\mathrm{I0,ck}}}{\omega_1-\varepsilon_c^0/\hbar-\omega_n-(j+k)\omega_s-\mathrm{i}\tilde{\Gamma}_c/2\hbar}\sum_{l=0}^{ns}\binom{n_s}{l}\left(\frac{\Delta_d}{\sqrt{2}}\right)\left(\frac{\Delta_c}{\sqrt{2}}\right)^{n_s-l}\sum_{m=0}^{\infty}\frac{1}{m!}\left(\frac{\Delta_c\Delta_d}{2}\right)^m\sum_{q=0}^{n_s-l}\binom{n_s-l}{q}(-1)^q\sum_{s=0}^{m}\binom{m}{s}(-1)^s\sum_{u=0}^{\infty}\frac{S_{\mathrm{I0,cu}}}{\omega_1-\varepsilon_c^0/\hbar-\omega_n-(l+q+s+u)\omega_s+\mathrm{i}\tilde{\Gamma}_c/2\hbar}\sum_{p=0}^{l}\binom{l}{p}(-1)^p\sum_{r=0}^{m}\binom{m}{r}(-1)^r\sum_{t=0}^{\infty}\frac{S_{\mathrm{I0,dt}}}{\omega_1-\varepsilon_d^0/\hbar-(p+r+t)\omega_s+\mathrm{i}\tilde{\Gamma}_d/2\hbar}\Bigg\}. \quad (34)$$

Discussion

In Theory Section, using the Born-Oppenheimer basis set, the RRS cross-section has been formulated. It is shown that the cross-section can be classified into four terms. In this paper, one is called pure RRS, while the others are the vibronically induced and the nonadiabatically induced RRS, and their interferences. The pure RRS, independent of the inducing mode, corresponds to Albrecht's A term,[31] and the vibronically induced RRS, to the B term. The RRS cross-section corresponding to the C term was disregarded because this term makes a negligibly small contribution to the Raman scattering in the resonance region.

In Fig. 2, the excitation profiles of the RRS within the weak coupling limits are analyzed. The spectra on the low- and high-frequency sides reflect the RRS

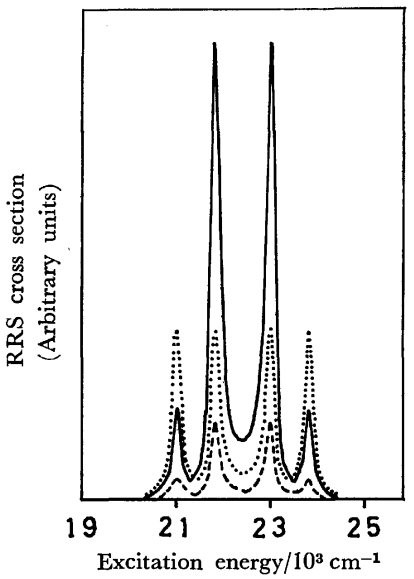

Fig. 2. Excitation profiles of the RRS in the case of $\Delta_a=0$ and $\Delta_b=0$. The dotted, broken, and solid lines represent the excitation profile of the vibronically induced RRS, that of the nonadiabatically induced RRS, and that of the RRS with both the vibronic and nonadiabatic couplings including the interference terms, respectively. The molecular parameters used are $\varepsilon_0^a=21000\ \mathrm{cm^{-1}}$, $\varepsilon_0^b=23000\ \mathrm{cm^{-1}}$, $\omega_n=800\ \mathrm{cm^{-1}}$, and $\tilde{\Gamma}_a=\tilde{\Gamma}_b=200\ \mathrm{cm^{-1}}$. The profiles were plotted neglecting the constants involving the transition moments.

from the *a* and *b* electronic states respectively, and they have a mirror symmetry with respect to the plane intersecting the center because the same potential energy surfaces and the same decay widths in the two excited states are assumed. The molecular parameters used are $\varepsilon_a^0=21000\ \mathrm{cm^{-1}}$, $\varepsilon_b^0=23000\ \mathrm{cm^{-1}}$, $\omega_n=800\ \mathrm{cm^{-1}}$, $\tilde{\Gamma}_a=\tilde{\Gamma}_b=200\ \mathrm{cm^{-1}}$, and $\Delta_a=\Delta_b=0$. The dotted, broken, and solid lines represent the excitation profile of the vibronically induced RRS, that of the nonadiabatically induced RRS, and that of the RRS with both the vibronic and nonadiabatic couplings, including the interference terms respectively.

For the vibronically induced RRS, two bands, 0-0 and 0-1, sometimes called Mortensen's doublet, appear on the low- and high-frequency sides of the excitation profile. It is recognized that the RRS from the molecular system with small potential displacements is expressed by the succession of absorption from the ground to the resonance state and emission from the resonance state to the ground state.[11] For the 0-0 and 0-1 bands, the inducing mode operates in the course of the emission and absorption processes respectively. It can easily be seen that the intensities of the two bands are equal, for they have the same energy-denominator dependence of the polarizability.

As a result of the nonadiabatic coupling between the resonant and other excited states, two bands, 0-0 and 0-1, appear in the excitation profile as well. The band intensity of the nonadiabatically induced RRS is inversely proportional to the square of the

energy difference between the relevant states; from Eq. 32, the intensities of the 0-0 and 0-1 bands in the case of the resonance with the lower excited state, a denoted by $I_{0\text{-}0}^{\mathrm{NA(a)}}$ and $I_{0\text{-}1}^{\mathrm{NA(a)}}$, are given by:

$$I_{0\text{-}0}^{\mathrm{NA(a)}} \propto \left| \frac{\tilde{\Gamma}_a}{2}(\varepsilon_a^0 - \varepsilon_b^0 - \hbar\omega_n + i\tilde{\Gamma}_b/2) \right|^{-2}, \tag{35a}$$

and:

$$I_{0\text{-}1}^{\mathrm{NA(a)}} \propto \left| \frac{\tilde{\Gamma}_a}{2}(\varepsilon_a^0 - \varepsilon_b^0 + \hbar\omega_n + i\tilde{\Gamma}_b/2) \right|^{-2}, \tag{35b}$$

respectively, from which we obtain the relation:

$$I_{0\text{-}0}^{\mathrm{NA(a)}} < I_{0\text{-}1}^{\mathrm{NA(a)}}. \tag{36}$$

Similarly, for the case of the resonance with the upper state b, we obtain:

$$I_{0\text{-}0}^{\mathrm{NA(b)}} \propto \left| \frac{\tilde{\Gamma}_b}{2}(\varepsilon_b^0 - \varepsilon_a^0 - \hbar\omega_n + i\tilde{\Gamma}_a/2) \right|^{-2}, \tag{37a}$$

$$I_{0\text{-}1}^{\mathrm{NA(b)}} \propto \left| \frac{\Gamma_b}{2}(\varepsilon_b^0 - \varepsilon_a^0 + \hbar\omega_n + i\tilde{\Gamma}_a/2) \right|^{-2}, \tag{37b}$$

and then:

$$I_{0\text{-}0}^{\mathrm{NA(b)}} > I_{0\text{-}1}^{\mathrm{NA(b)}}$$

As is shown in Fig. 2, the asymmetry of the 0-0 and 0-1 bands originates from the interference between the vibronically induced RRS and nonadiabatically induced one. The main contribution of the interference comes from Eq. 34. In the cases of the small displacement, Eq. 34 can be expressed as:

$$\frac{d\sigma_I^{\mathrm{INT(VI-NA)}}(\omega_1)}{d\Omega} \simeq 2\pi\omega_n(\omega_1-\omega_n)^3 \sum_c \sum_{d\,(c\neq d)} \left\{ \frac{\omega_1 - \varepsilon_d^0/\hbar - \omega_n}{[(\omega_1-\varepsilon_c^0/\hbar)^2+(\tilde{\Gamma}_c/2\hbar)^2][(\omega_1-\varepsilon_d^0/\hbar-\omega_n)^2+(\tilde{\Gamma}_d/2\hbar)^2]} - \frac{\omega_1-\varepsilon_d^0/\hbar}{[(\omega_1-\varepsilon_c^0/\hbar)^2+(\tilde{\Gamma}_c/2\hbar)^2][(\omega_1-\varepsilon_d^0/\hbar)^2+(\tilde{\Gamma}_d/2\hbar)^2]} \right\}. \tag{38}$$

This expression indicates that, for the resonance with the lower excited state, a, the interference term between the vibronically induced RRS and the nonadiabatically induced one decreases the 0-0 band intensity and increases the 0-1 band intensity. On the other hand, for the resonance with the higher excited state, b, this term interferes, constructively near the 0-0 band and destructively near the 0-1 band. Eq. 33, representing the interference between the vibronically induced RRS, does not contribute to the asymmetry of the excitation profile, but makes an important contribution to the depolarization ratio.[26]

Let us now focus our attention on the effects of the RRS on the molecular parameters. In the displaced harmonic oscillator model, analytical expressions for the n_s-th order vibrational transitions of the RRS cross-sections have been derived; these cross-sections are expressed in terms of the molecular parameters, such as the dimensionless potential displacements, the molecular vibrational frequencies, the decay widths, and the electronic energy gaps. Using the analytical expressions, we have performed model calculations of the excitation profiles of the n_s-th order vibrational transitions.

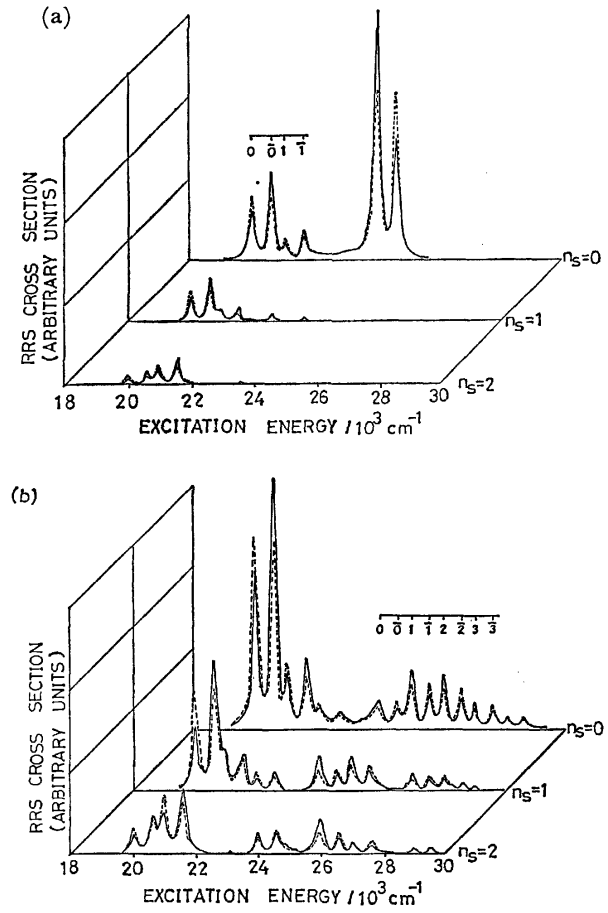

Fig. 3. The dimensionless displacements Δ_a and Δ_b dependence of the excitation profiles of the n_s-th order vibrational transition. The progressions of the totally symmetric vibration built upon one quantum of the coupling mode are monitored. The following parameters are used: $\varepsilon_a^0=20000\ \mathrm{cm^{-1}}$; $\varepsilon_b^0=24000\ \mathrm{cm^{-1}}$; $\omega_n=600\ \mathrm{cm^{-1}}$ and $\omega_s=1000\ \mathrm{cm^{-1}}$; $\tilde{\Gamma}_a=\tilde{\Gamma}_b=200\ \mathrm{cm^{-1}}$; $\Delta_b=0.1$, and 1.0 in Figs. 3a and 3b, respectively, and $\Delta_a=1.0$. The ordinate is shown without $k(\omega_1)$. The broken line represents the excitation profile without the nonadiabatic coupling, and the solid line the whole excitation profile with both the nonadiabatic and vibronic couplings including the interference terms. The band peaks which appear in the zero order vibrational transition ($n_s=0$) of the excited state, a in Fig. 3a and those of the excited state, b in Fig. 3b are indicated by the vibrational quantum number of the displaced oscillator excited in the resonant states. The band peaks with the wavy line above the number represent the one quantum excitation of the inducing mode in addition to the excitation of the displaced oscillator.

It should be noted that the expressions derived in this paper are applicable to the RRS of the molecular system with any displacement. In Figs. 3, the effects of the dimensionless displacements, Δ_a and Δ_b, are shown. The excitation profiles of the first order, $n_s=1$ and the second order, $n_s=2$, vibrational transitions, in addition to the zero-order transition, are plotted. The progressions of the totally symmetric vibrational mode built upon one quantum of the inducing mode were monitored. The broken line represents the

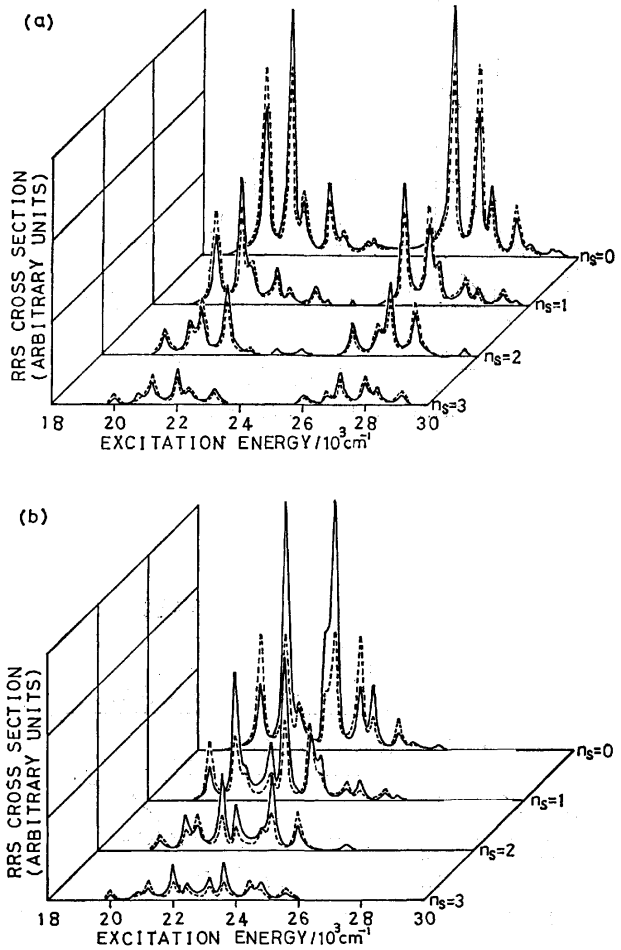

Fig. 4. The electronic gap dependence of the excitation profiles of the n_s-th order vibrational transition. The following molecular parameters are used: $\omega_n = 800\ \mathrm{cm^{-1}}$ and $\omega_s = 1200\ \mathrm{cm^{-1}}$; $\Delta_a = \Delta_b = 1.0$; $\varepsilon_b^0 = 26000\ \mathrm{cm^{-1}}$, and $22400\ \mathrm{cm^{-1}}$ in Figs. 4a and 4b, respectively. The others are the same as those in Fig. 3.

excitation profile without the nonadiabatic coupling, and the solid line, that with both the nonadiabatic and vibronic couplings. The displacements used are $\Delta_a = 1.0$, and $\Delta_b = 0.1$ and 2.0 in Figs. 3a and 3b respectively. The other parameters are $\varepsilon_a^0 = 20000\ \mathrm{cm^{-1}}$, $\varepsilon_b^0 = 24000\ \mathrm{cm^{-1}}$, $\omega_n = 600\ \mathrm{cm^{-1}}$, $\omega_s = 1000\ \mathrm{cm^{-1}}$, and $\tilde{\Gamma}_a = \tilde{\Gamma}_b = 200\ \mathrm{cm^{-1}}$. In Figs. 3a and 3b, the band peaks which appear in the zero-order vibrational transitions of the excited states, *a* and *b*, are indicated by the vibrational quantum number of the respective displaced oscillator excited in the resonant states. The band peaks with the wavy line above the number represent the one-quantum excitation of the inducing mode in addition to the excitation of the displaced oscillator. It can be seen that, as the displacements increase, the first- and second-order vibrational transitions, as well as the zero-order transition, appear in the excitation profiles. The nonadiabatic coupling makes significant contributions not only to the latter transition, but also to the former transitions.

In Figs. 4, the electronic-energy-gap dependence of the RRS is shown as a function of the incident photon frequency, ω_1. The progressions for the totally symmetric vibration of $\omega_s = 1200\ \mathrm{cm^{-1}}$, built upon one quantum of the inducing mode of $\omega_n = 800\ \mathrm{cm^{-1}}$, are monitored. In these figures, $\Delta_a = \Delta_b = 1.0$ was assumed. The electronic-energy-gaps, ε_b^0 are taken to be $26000\ \mathrm{cm^{-1}}$ and $22400\ \mathrm{cm^{-1}}$ in Figs. 4a, and 4b respectively. The others are the same as those in Figs. 3. The Figures 4 indicate that the nonadiabatic coupling plays an important role, as the two excited states exist close to each other. The nonadiabatic coupling effect on the higher-order vibrational transitions is qualitively similar that on the zero-order transition.

In the model calculations shown in Figs. 3 and 4, the effects of the potential displacements and those of the electronic-energy gap between two excited states are examined, the other parameters being fixed. In order to apply the theoretical results developed in this paper to analyzing the observed excitation profiles of the RRS, such molecular parameters as the decay widths, $\tilde{\Gamma}_a$ and $\tilde{\Gamma}_b$, should be properly chosen.[32]

In summary, in this paper, we have developed a theory of the RRS from two electronically excited states coupled by a nontotally symmetric mode. The vibronic and nonadiabatic coupling effects on the RRS cross-sections have been examined. The RRS cross-sections have been classified into four groups according to the mechanisms: one is the RRS independent of the inducing mode, while the others are the vibronically induced and the nonadiabatically induced RRS, and their interference terms. Assuming a model system with two vibrational modes, the inducing mode, and a totally symmetric mode characterized by a displaced harmonic oscillator, analytical expressions for the RRS cross-sections have been derived. The expressions consisting of the n_s-th order vibrational transition of the totally symmetric mode are explicitly formulated as a function of the two displacement parameters between the equilibrium points in the ground state and in the two excited states, and are applicable to the system with any potential displacement.

We are grateful to Professor Takeshi Nakajima for his stimulating discussions and for his encouragement during the course of this work. One of us (Y. F.) wishes also to thank Professor Sheng. H. Lin for his gracious hospitality.

Appendix A: Expressions for the Interference RRS Cross-sections

The interference term between the vibronically induced RRS is given by:

$$\frac{d\sigma_I^{INT(VI)}(\omega_1)}{d\Omega} = k(\omega_1)\int_0^\infty d\omega_2\omega_2^3\int_0^\infty d\tau'\int_0^\infty d\tau\int_0^\infty dt$$
$$\exp[-i(t-\tau+\tau')\omega_1+it\omega_2]$$
$$\{\sum_c[\pm\langle\chi_1|\alpha_c^*(\tau')q_n\beta_1(t)\alpha_c(\tau)q_n\beta_1(t-\tau+\tau')|\chi_1\rangle$$
$$\pm\langle\chi_1|q_n\alpha_c^*(\tau')\beta_1^*(t)q_n\alpha_d(\tau)\beta_1(t-\tau+\tau')|\chi_1\rangle$$
$$+\sum_{\substack{c\\(c\neq d)}}\sum_d[\mp\langle\chi_1|\alpha_c^*(\tau')q_n\beta_1^*(t)q_n\alpha_d(\tau)\beta_1(t-\tau+\tau')|\chi_1\rangle$$
$$-\langle\chi_1|\alpha_c^*(\tau')q_n\beta_1^*(t)\alpha_d(\tau)q_n\beta_1(t-\tau+\tau')|\chi_1\rangle$$
$$-\langle\chi_1|q_n\alpha_d^*(\tau')\beta_1^*(t)q_n\alpha_1(\tau)\beta_1(t-\tau+\tau')|\chi_1\rangle$$
$$\mp\langle\chi_1|q_n\alpha_c^*(\tau')\beta_1^*(t)\alpha_d(\tau)q_n\beta_1(t-\tau+\tau')|\chi_1\rangle]\}, \quad (A.1)$$

where

$$k(\omega_1) = \omega_1|M_{gb}(2)V_{ba}M_{ag}(1)|^2/(2^7\pi^3\varepsilon_0^2c^4\hbar^2),$$
$$\alpha_c(\tau) = \exp[-(i\hat{H}_c^0-\tilde{\Gamma}_c/2)\tau/\hbar],$$

and

$$\beta_1(t) = \exp[-i\hat{H}_1^0t/\hbar].$$

The interference term between the nonadiabatically induced RRS is given by:

$$\frac{d\sigma_I^{INT(NA)}(\omega_1)}{d\Omega} = \mp\omega_n^2k(\omega_1)\sum_{\substack{c\\(c\neq d)}}\sum_d$$
$$\int_0^\infty d\omega_2\omega_2^3\int_0^\infty d\tau'\int_0^\infty d\xi'\int_0^\infty d\tau\int_0^\infty d\xi\int_{-\infty}^\infty dt$$
$$\exp[-i(t-\tau-\xi+\tau'+\xi')\omega_1+it\omega_2]$$
$$\langle\chi_1|\alpha_c^*(\tau')(\partial/\partial q_n)^\dagger\alpha_c^*(\xi')\beta_1^*(t)\alpha_c(\tau)$$
$$(\partial/\partial q_n)\alpha_d(\xi)\beta_1(t-\tau-\xi+\tau'+\xi')|\chi_1\rangle. \quad (A.2)$$

The interference term between the vibronically induced and the nonadiabatically induced RRS is given by:

$$\frac{d\sigma_I^{INT(VI-NA)}(\omega_1)}{d\Omega} = \omega_nk(\omega_1)\sum_{\substack{c\\(c\neq d)}}\sum_d$$
$$\int_0^\infty d\omega_2\omega_2^3\int_0^\infty d\tau'\int_0^\infty d\tau\int_0^\infty d\xi\int_{-\infty}^\infty dt$$
$$\{\exp[-i(t-\tau-\xi+\tau')\omega_1+it\omega_2]$$
$$[\langle\chi_1|\alpha_c^*(\tau')q_n\beta_1(t)\alpha_d(\xi)(i\partial/\partial q_n)\alpha_c(\tau)$$
$$\beta_1(t-\tau-\xi+\tau')|\chi_1\rangle$$
$$\mp\langle\chi_1|\alpha_c^*(\tau')q_n\beta_1^*(t)\alpha_c(\tau)(i\partial/\partial q_n)\alpha_d(\xi)\beta_i(t-\tau-\xi+\tau')$$
$$|\chi_1\rangle\pm\langle\chi_1|q_n\alpha_c^*(\tau')\beta_1^*(t)\alpha_d(\xi)(i\partial/\partial q_n)\alpha_c(\tau)$$
$$\beta_1(t-\tau-\xi+\tau')|\chi_1\rangle-\langle\chi_1|q_n\alpha_c^*(\tau')\beta_1^*(t)\alpha_c(\tau)(i\partial/\partial q_n)$$
$$\alpha_d(\xi)\beta_1(t-\tau-\xi+\tau')|\chi_1\rangle]+$$
$$\exp[-i(t-\tau+\tau'+\xi)\omega_1+it\omega_2][\langle\chi_1|\alpha_c^*(\tau')(i\partial/\partial q_n)^\dagger$$
$$\alpha_d^*(\xi')\beta_1^*(t)q_n\alpha_c(\tau)\beta_1(t-\tau+\tau'+\xi)|\chi_1\rangle$$
$$\mp\langle\chi_1|\alpha_d^*(\xi)(i\partial/\partial q_n)^\dagger\alpha_c^*(\tau')\beta_1^*(t)q_n\alpha_c(\tau)\beta_1(t-\tau+\tau'+\xi)$$
$$|\chi_1\rangle\pm\langle\chi_1|\alpha_c^*(\tau')(i\partial/\partial q_n)^\dagger\alpha_d^*(\xi)\beta_1^*(t)\alpha_c(\tau)q_n\beta_1$$
$$(t-\tau+\tau'+\xi)|\chi_1\rangle-\langle\chi_1|\alpha_d^*(\xi)(i\partial/\partial q_n)^\dagger$$
$$\alpha_c^*(\tau')\beta_1^*(t)\alpha_c(\tau)q_n\beta_1(t-\tau+\tau'+\xi)|\chi_1\rangle]\}. \quad (A.3)$$

Appendix B: Derivation of Eq. 28

In this appendix, we will present a brief derivation of Eq. 28 by utilizing the Boson operator algebra. By using this relation:[11]

$$\exp\left[\frac{i\hat{h}_1(q_s-\Delta_c)\tau'}{\hbar}\right] = \exp\left[\frac{\Delta_c^2}{2}\{\exp(i\omega_s\tau')-1\}\right]$$
$$\exp\left(\frac{i\hat{h}_1\tau'}{\hbar}\right)\exp[-\lambda_c(\tau')\hat{b}_s^\dagger]\exp[\lambda_c^*(\tau')\hat{b}_s], \quad (B.1)$$

where $\lambda_c(\tau')=\frac{\Delta_c}{\sqrt{2}}[1-\exp(-i\omega_s\tau')]$, Eq. 27 is expressed as:

$$g_s(\tau',\xi',\tau,\xi,t) = \exp\left[\frac{\Delta_c^2}{2}\{\exp(i\omega_s\tau')-1\}\right.$$
$$+\frac{\Delta_c^2}{2}\{\exp(-i\omega_s\tau)-1\}+\frac{\Delta_d^2}{2}\{\exp(i\omega_s\xi')-1\}$$
$$\left.+\frac{\Delta_d^2}{2}\{\exp(-i\omega_s\xi)-1\}\right]\langle 0_s|\exp_*(i\omega_s\tau\hat{b}_s^\dagger\hat{b}_s)$$

$$\exp[-\lambda_c(\tau')\hat{b}_s^\dagger]\exp[\lambda_c^*(\tau')\hat{b}_s]\exp[i\omega_s\xi\hat{b}_s^\dagger\hat{b}_s]$$
$$\exp[-\lambda_d(\xi')\hat{b}_s^\dagger]\exp[\lambda_d^*(\xi')\hat{b}_s]\exp[i\omega_s t\hat{b}_s^\dagger\hat{b}_s]$$
$$\exp[\lambda_d(\xi)\hat{b}_s^\dagger]\exp[-\lambda_d^*(\xi)\hat{b}_s]\exp[-i\omega_s\xi\hat{b}_s^\dagger\hat{b}_s]$$
$$\exp[\lambda_c(\tau)\hat{b}_s^\dagger]\exp[-\lambda_c^*(\tau)\hat{b}_s]\exp[-i\omega_s\tau\hat{b}_s^\dagger\hat{b}_s]$$
$$\exp[-i\omega_s(t-\tau-\xi+\tau'+\xi')\hat{b}_s^\dagger\hat{b}_s]|0\rangle. \qquad (B.2)$$

By using the Boson operator algebra,[11] Eq. (B.2) is expressed as:

$$g_s(\tau',\xi',\tau,\xi,t) = \exp\left[\frac{\Delta_c^2}{2}\{\exp(i\omega_s\lambda')-1\}\right.$$
$$+\frac{\Delta_c^2}{2}\{\exp(-i\omega_s\tau)-1\}+\frac{\Delta_d^2}{2}\{\exp(i\omega_s\xi')-1\}$$
$$+\frac{\Delta_d^2}{2}\{\exp(-i\omega_s\xi)-1\}+\lambda_c^*(\tau')\lambda_d^*(\xi')$$
$$+\lambda_c(\tau)\lambda_d(\xi)+\lambda_d^*(\xi')\lambda_d(\xi)\exp(i\omega_s t)$$
$$+\lambda_c(\tau)\lambda_d^*(\xi')\exp(-i\omega_s\xi+i\omega_s t)$$
$$+\lambda_c^*(\tau')\lambda_d(\xi)\exp(i\omega_s\xi+i\omega_s t)$$
$$\left.+\lambda_c^*(\tau')\lambda_c(\tau)\exp(i\omega_s\xi'-i\omega_s\xi+i\omega_s t)\right]. \qquad (B.3)$$

This expression is equivalent to Eq. 28.

A Displaced Harmonic Oscillator Model for the Time-resolved Emission Spectra

Yuichi FUJIMURA,* Kenji SATO,† and Takeshi NAKAJIMA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received March 30, 1981)

In a displaced harmonic oscillator model for an energy-accepting mode, analytical expressions for the time-resolved emission intensity distribution are derived for both the allowed and vibronically induced electronic transitions. In the case of the vibronically induced transition, the inducing mode as well as the accepting mode is assumed to undergo a collisional vibrational relaxation. A linear vibrational quantum-number-dependence of the electronic and collisional vibrational relaxation constants is assumed. Model calculations of the time-resolved emission-intensity distribution for a molecular system are performed using the expressions derived. The calculated time-resolved emission spectra of benzene in the vapor phase after an excitation to a single vibronic level semi-quantitatively account for the experimental results.

It is well known that time-resolved spectroscopy plays an important role in elucidating the dynamics as well as the static behavior of vibronically excited molecules. The time-resolved emission spectra have been reported by several authors. Hochstrasser and Wessel[1] have observed the time-resolved fluorescence of anthracene in mixed crystals of low temperatures. Werkhoven *et al.*[2] have investigated the vibrational redistribution effects by analyzing the time-resolved emission spectrum of the isolated pyrene molecule. Swords and Phillips[3] have observed the nano-second time-resolved emission of benzene in order to study the collisional processes.

The purpose of this paper is to develop a theory for the time-resolved emission of a molecular system. The time-resolved emission intensity distribution is expressed as the emission intensity weighted by the time-dependent population of the single vibronic level in the excited state. In other words, the observed intensity distribution is governed by both the Franck-Condon factor and the kinetics of the excited state. The time-dependence of the population is determined by solving the kinetic equation in the excited state in which the vibronic level undergoes the electronic relaxation, the collisional vibrational relaxation, and/or the vibrational redistribution among the vibrational modes.

A similar time-dependent theory has been proposed for analyzing the time-resolved absorption spectra of electronically excited molecules.[4-6] Fleming *et al.*[7] have developed a theory for the time-resolved emission spectra of molecules in which the single vibronic emission-intensity distribution of the δ-function form is adopted. A master-equation approach to the time-dependent luminescence during the vibrational relaxation has been used by Seshadri and Kenkre.[8]

In Theory section, analytical expressions for the time-resolved emission-intensity distribution are given for both the allowed and vibronically induced electronic transitions in the displaced harmonic oscillator model for an accepting mode. Both Lorentzian and Gaussian single vibronic level intensity distributions are assumed. It is assumed that the electronic and vibrational relaxation constants are linear functions of the vibrational quantum number. This assumption is valid for a molecular system with low excited vibronic levels. In the case of the vibronically induced transition, the inducing mode as well as the accepting mode is assumed to undergo a collisional deactivation. In discussion, model calculations of the time-resolved emission intensity distribution are performed. A non-exponential fluorescence decay can be predicted if the rate of vibrational relaxation is fast compared with those of the radiation and electronic relaxations. For the vibronically induced transition, a fast fluorescence decay can be expected upon the excitation to the vibronic level of the inducing mode.

Theory

We will consider an electronic transition, $a \leftarrow b$, of a molecular system. The time-resolved emission-intensity distribution, $P_{ab}(\nu, t)$, as a function of the optical frequency, ν, and time, t, is given by:[7]

$$P_{ab}(\nu, t) = \sum_{\{v\}} \sum_{\{v'\}} I_{a\{v\},b\{v'\}}(\nu) \chi_{b\{v'\}}(t), \quad (1)$$

where $I_{a\{v\},v\{b'\}}(\nu)$ represents the intensity of the emission from a single vibronic level of the b electronic state, $b\{v'\}$, to that of the ground state $a\{v\}$, and $\chi_{b\{v'\}}(t) = \prod_j \chi_{bv'_j}(t)$, the population of the molecule in the single vibronic level, $b\{v'\}$, at time t.

The $\chi_{bv'}(t)$ population, depends on the dynamical behavior in the electronic state, such as the electronic and/or vibrational relaxations. χ satisfies the following equation for the molecular system undergoing the electronic and vibrational relaxations after the optical transition:

$$\frac{d\chi_{bv'}(t)}{dt} = C_{bv'}(t) - K_{bv',bv'}\chi_{bv'}(t) - \sum_{v''} R_{bv'bv''}\chi_{bv''}(t), \quad (2)$$

where K is a diagonal matrix element involving the radiative and nonradiative decay constants; R represents the vibrational relaxation matrix in the electronic state b, and $C_{bv}(t)$ is a function related to the optical excitation. Equation 2 can be solved by using i) the diagonalization method of the matrix[9] or ii) the generating-function method.[10] In this paper, we use the generating-function method. Assuming, for the rates of vibrational and nonradiative relaxations, linear dependences on the vibrational quantum num-

† Present address: The Institute for Molecular Science, Okazaki, Aichi 444.

bers of the vibronic levels, *i.e.* $k_v^{c\prime}=v'k^c$ and $k_v^{n\prime}=k+v'k^n$ respectively, with the effect of the radiative decay being included as the k parameter, the solution of Eq. 2 is given by:[4,5]

$$\chi_{bv'}(t)=\frac{v_0'!}{v'!(v_0'-v')!}\left\{\frac{k^c}{k^c+k^n}[1-\exp\{-(k^c+k^n)t\}]\right\}^{v_0'-v'}\exp[-kt-v'(k^c+k^n)t], \tag{3}$$

where an optical exitation to a single vibronic level, bv_0', at $t=0$ has been assumed.

Two types of emission, dipole-allowed transitions and vibronically induced transitions, are taken into account of in this paper.

Dipole-allowed Transition. In the case of the Lorentzian single-vibronic-level-intensity distribution, the intensity from the vibronic level, bv', to av is given by:

$$I_{av,bv'}(\nu)=\frac{4\pi\nu^3}{3\hbar c^3}|M_{ab}^0|^2|\langle\theta_{av}|\theta_{bv'}\rangle|^2\frac{\Gamma_{av,bv'}}{(\omega_{bv',av}-\nu)^2+\Gamma_{av,bv'}^2}, \tag{4}$$

where M_{ab}^0, θ, $\Gamma_{ab,bv'}$, and $\omega_{bv',av}$ represent the electronic transition moment evaluated at the equilibrium nuclear configuration in the initial electronic state, the nuclear wave function, the damping constant, and the energy gap between two single-vibronic levels, bv' and av, respectively. Using the transformation:

$$\frac{a}{x^2+a^2}=\frac{1}{2}\int_{-\infty}^{\infty}d\tau\exp[-i\chi\tau-a|\tau|], \tag{5}$$

and summing over the vibronic level, v, in the electronic state, a, Eq. 4 can be expressed as:

$$\begin{aligned}I_{a,bv'}(\nu)&=\sum_v I_{av,bv'}(\nu)\\&=\frac{2\pi\nu^3}{3\hbar c^3}|M_{ab}^0|^2\int_{-\infty}^{\infty}d\tau\exp[i\nu\tau-\Gamma_{ab}|\tau|]\\&\quad\langle\theta_{bv'}|\exp[-i\hat{H}_b\tau/\hbar]\exp[i\hat{H}_a\tau/\hbar]|\theta_{bv'}\rangle,\end{aligned} \tag{6}$$

where $\hat{H}_a$ and $\hat{H}_b$ represent the nuclear Hamiltonian in the electronic states, a and b, respectively; the vibronic-level dependence of the damping constant is neglected *i.e.*, $\Gamma_{ab}\simeq\Gamma_{av,bv'}$.

In the displaced-harmonic-oscillator model (the other modes are assumed to be common in the electronic states a and b),

$$\hat{H}_b=\frac{\hbar\omega}{2}\{p^2+(q-\Delta)^2\}+\omega_{ba}, \tag{7a}$$

and

$$\hat{H}_a=\frac{\hbar\omega}{2}(p^2+q^2), \tag{7b}$$

where ω and Δ are the frequency and the displacement of the vibrational mode respectively, with ω_{ba} the electronic energy difference between two states, b and a. Equation 6 can be expressed as:

$$\begin{aligned}I_{a,bv'}(\nu)&=\frac{2\pi\nu^3}{3\hbar c^3}|M_{ab}^0|^2\exp\left(-\frac{\Delta^2}{2}\right)\int_{-\infty}^{\infty}d\tau\\&\quad\exp\left[i\tau(\nu-\omega_{ba})-\Gamma_{ab}|\tau|+\frac{\Delta^2}{2}e^{i\omega\tau}\right]\\&\quad\sum_{n=0}^{v'}\frac{v'!(\Delta^2/2)^n}{(v'-n)!(n!)^2}(\cos\omega\tau-1)^n.\end{aligned} \tag{8}$$

Substituting Eqs. 3 and 8 into Eq. 1, and summing over v', the time-resolved emission intensity for the allowed transition can be expressed as:

$$\begin{aligned}P_{ab}(\nu,t)&=\frac{4\pi\nu^3}{3\hbar c^3}|M_{ab}^0|^2\exp\left(-\frac{\Delta^2}{2}\right)\exp(-kt)\\&\quad\sum_{l=0}^{\infty}\sum_{n=0}^{v_0'}\sum_{r=0}^{2n}\frac{v_0'!(2n)!\left(\frac{\Delta^2}{2}\right)^{l+n}}{l!(n!)^2(v_0'-n)!(2n-r)!r!}\\&\quad\exp[-n(k^c+k^n)t]\left\{\frac{k^c}{k^c+k^n}+\frac{k^n}{k^c+k^n}\right.\\&\quad\left.\exp[-(k^c+k^n)t]\right\}^{v_0'-n}\frac{\Gamma_{ab}}{\{\nu-\omega_{ba}+\omega(l+n-r)\}^2+\Gamma_{ab}^2}.\end{aligned} \tag{9}$$

By assuming the homogeneous broadening, the Lorentzian band shape has so far been used. In the case of an inhomogeneous broadening, the band shape is usually expressed by a Gaussian form. After the Fourier transformation, the band-shape function, $A(x)$, is given by:

$$A(x)=\frac{1}{2\sqrt{\pi a}}\int_{-\infty}^{\infty}\exp\left[-i\chi\tau-\frac{\tau^2}{4a}\right]d\tau, \tag{10}$$

where $a=\ln 2/\tilde{\Gamma}^2$, in which $\tilde{\Gamma}$ is the half width at the half-maximum. In this case, the time-resolved emission-intensity distribution can be formulated by using a method similar to that described above. The result is written as:

$$\begin{aligned}P_{ab}(\nu,t)&=\frac{4\pi\nu^3}{3\hbar c^3}|M_{ab}^0|^2\exp\left(-\frac{\Delta^2}{2}\right)\exp(-kt)\\&\quad\sum_{l=0}^{\infty}\sum_{n=0}^{v_0'}\sum_{r=0}^{2n}\frac{v_0'!(2n)!\left(\frac{\Delta^2}{2}\right)^{l+n}}{l!(n!)^2(v_0'-n)!(2n-r)!r!}\exp[-n(k^c+k^n)t]\\&\quad\left\{\frac{k^c}{k^c+k^n}+\frac{k^n}{k^c+k^n}\exp[-(k^c+k^n)t]\right\}^{v_0'-n}\\&\quad\exp[-a\{\nu-\omega_{ba}+\omega(l+n-r)\}^2].\end{aligned} \tag{11}$$

Vibronically Induced Transition. The emission intensity from the single vibronic level, $bv_d'v_i'$, to av_dv_i is given by:

$$\begin{aligned}I_{bv_d'v_i',av_dv_i}(\nu)&=\frac{4\pi\nu^3}{3\hbar c^3}\left(\frac{\partial M_{ab}}{\partial q_i}\right)_{q_i=0}|\langle\theta_{av_i}|q_i|\theta_{bv_i'}\rangle|^2\\&\quad|\langle\theta_{av_d}|\theta_{bv_d'}\rangle|^2\frac{\Gamma_{ab}}{(\omega_{bv_d'v_i',av_dv_i}-\nu)^2+\Gamma_{av}^2},\end{aligned} \tag{12}$$

where i and d specify the inducing and accepting modes respectively; the Lorentzian band shape has been assumed. In Eq. 12, one inducing mode and one accepting mode were assumed (*i.e.*, the other modes are disregarded), and the v_i-dependence of the damping constant was neglected.

We will consider a model system in which the accepting and inducing modes consist of a displaced harmonic oscillator and a harmonic oscillator with no frequency change and no displacement respectively. After summing over the vibronic levels, v_i and v_d, Eq. 12 can be expressed as:

$$\begin{aligned}I_{a,bv_d'v_i'}(\nu)&=C(\nu)\exp\left(-\frac{\Delta^2}{2}\right)\int_{-\infty}^{\infty}d\tau\\&\quad\exp\left[-i(\nu-\omega_{ba})\tau-\Gamma_{ab}|\tau|+\frac{\Delta^2}{2}\exp(i\omega\tau)\right]\end{aligned}$$

$$\{(1+v_i')\exp(-i\omega_i\tau)+v_i'\exp(i\omega_i\tau)\}$$
$$\sum_{n=0}^{v_d'}\frac{v_d'!\Delta^{2n}}{(v_d'-n)!(n!)^2}(\cos\omega\tau-1)^n, \quad (13)$$

where ω_i represents the frequency of the inducing mode; the constant, $C(v)$, is given by:

$$C(v)=v^3\left(\frac{\partial M_{ab}}{\partial q_i}\right)_{q_i=0}\Big/3\hbar c^3\beta_i \text{ in which } \beta_i=(\omega_i/\hbar)^{1/2}.$$

The time-resolved emission intensity in a case in which the molecular system is excited to a singlet vibronic level $bv_{d0}'v_{i0}'$ at $t=0$ can be expressed as:

$$P_{ab}(v,t)=C(v)\exp\left(-\frac{\Delta^2}{2}\right)\exp(-kt)$$
$$\sum_{l=0}^{\infty}\sum_{n_d=0}^{v_{d0}'}\sum_{n_i=0}^{v_{i0}'}\sum_{r=0}^{n_d2}\frac{v_{i0}'}{n_i!(v_{i0}'-n_i)!}$$
$$\left[\frac{k_i^c}{k_i^c+k_i^n}\{1-\exp[-(k_i^c+k_i^n)t]\}\right]^{v_{i0}'-n_i}$$
$$\exp[-n_i(k_i^c+k_i^n)t-n_d(k^n+k^c)t]$$
$$\frac{(-1)^r v_{i0}'!(2n_d)!\left(\frac{\Delta^2}{2}\right)^{l+n_i}}{l!(n_d!)^2(v_{d0}'-n_i)!(2n_d-r)!r!}$$
$$\left\{\frac{k^c}{k^c+k^n}+\frac{k^n}{k^c+k^n}\exp[-(k^c+k^n)t]\right\}^{v_{d0}'-n_d}$$
$$\left[(n_i+1)\frac{\Gamma_{ab}}{\{v-\omega_{ba}+\omega(l+n_d-r)+\omega_i\}^2+\Gamma_{ab}^2}\right.$$
$$\left.+n_i\frac{\Gamma_{ab}}{\{v-\omega_{ba}+\omega(l+n_d-r)-\omega_i\}^2+\Gamma_{ab}^2}\right], \quad (14)$$

where a linear dependence of the relaxation constants on the vibrational quantum number of the inducing mode as well as the accepting mode has been assumed; $k_{v_i'}^c=v_i'k_i^c$, $k_{v_i'}^n=k_i^0+v_i'k_i^n$; and $k\equiv k+k_i^0$. The time-resolved emission-intensity distribution in which the vibronic band shape is expressed by the Gaussian form can easily be derived.

Model Calculations and Discussion

Figures 1 and 2 show the time-dependence of the emission spectra calculated by using Eq. 9 in the case of $v=\omega_{ba}$. The ordinate expresses the emission intensity relative to that at $t=0$. The excitation to the first vibronic level, $v_0'=1$, from the lowest level in the ground state is assumed. Figures 1 and 2 correspond to the slow and fast vibrational-relaxation cases respectively. The parameters used for Figs. 1 and 2 are $k=10^8\ s^{-1}$, $k^c=2\times10^7\ s^{-1}$. $k^n=4\times10^7\ s^{-1}$, and $\Delta=0.14$, and $k=2\times10^7\ s^{-1}$, $k^c=10^8\ s^{-1}$, $k^n=4\times10^7\ s^{-1}$, and $\Delta=0.14$, respectively. In Fig. 1, a single exponential decay is shown, while in Fig. 2, a nonexponential time-dependence is seen. The appearance of the nonexponential decay can be qualitatively explained by examining Eq. 9. For simplicity, we consider the weak coupling limit to be where $\Delta\to0$. Then, in the case of v near ω_{ba}, Eq. 9 for $v_0'=1$ can be expressed as:

$$P(v,t)\propto\left\{\frac{k^c}{k^c+k^n}\exp(-kt)+\frac{k^n}{k^c+k^n}\exp[-(k+k^n+k^c)t]\right\}\frac{\Gamma}{(v-\omega_{ba})^2+\Gamma^2}. \quad (15)$$

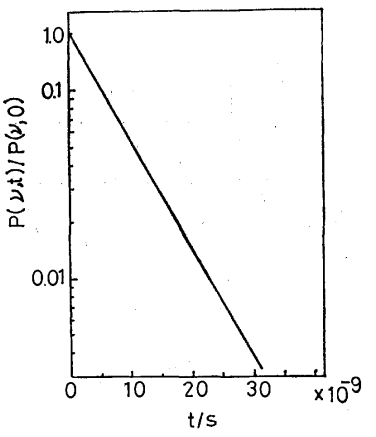

Fig. 1. Time-dependence of the emission intensity in the case of the slow collisional vibrational relaxation. The intensity relative to that at $t=0$ is plotted by using Eq. 9 for $v=\omega_{ba}$. The excitation to the first vibronic level $v_0'=1$ from the lowest level in the ground state is assumed. The parameters used are $k=10^8\ s^{-1}$, $k^c=2\times10^7\ s^{-1}$, $k^n=4\times10^7\ s^{-1}$, and $\Delta=0.14$.

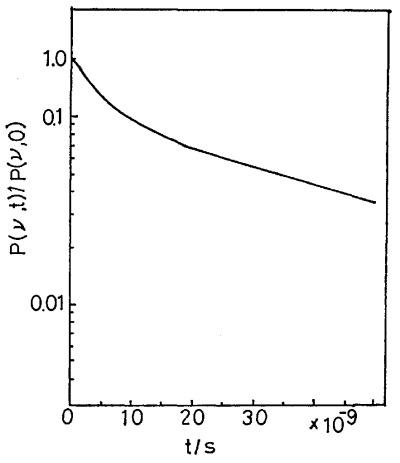

Fig. 2. Time-dependence of the emission intensity in the case of the fast collisional vibrational relaxation. The excitation and emission monitoring conditions are the same in Fig. 1. The parameters used are $k=2\times10^7\ s^{-1}$ and $k^c=10^8\ s^{-1}$, and the other parameters are the same in Fig. 1. When $k<k^c$ and $k^n\approx k^c$, the bi-exponential decay of fluorescence may be observed as shown in this figure.

Equation 15 indicates that, when $k\gg k^c+k^n$ (or $k^c\gtrless k^n$), $P(v,t)$ obeys a single exponential decay, while when $k\ll k^c+k^n$ and $k^n\approx k^c$, a bi-exponential fluorescence decay can be expected.

Figures 3 and 4 show model calculations of the time-resolved emission-intensity distribution as a function of the frequency for a model system corresponding to a vibronically induced optical transition such as $^1A_{1g}\leftarrow{}^1B_{2u}$ of benzene. The emission intensity distribution relative to its maximum value, $\tilde{P}(\omega_0,t)$, is plotted by using Eq. 14. In Figs. 3 and 4, the intensity distribution is plotted in the case of the excitation to a vibronic level with $v_{d0}'=1$ and $v_{i0}'=0$, and with $v_{d0}'=v_{i0}'=1$, respectively. The parameters used are $\omega=993\ cm^{-1}$, $k^n=3.67\times10^6\ s^{-1}$, and $\Delta=$

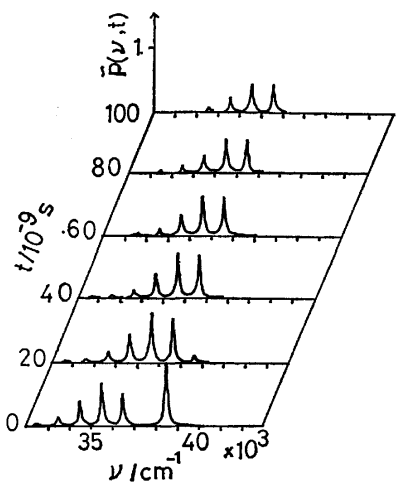

Fig. 3. Calculated time-resolved emission intensity distribution for a model system corresponding to a vibronically induced optical transition. The emission intensity distribution relative to its maximum value, $\tilde{P}(\nu,t)=P(\nu,t)/P(\nu,t)_{max}$ is plotted by using Eq. 12. The excitation to the vibronic level $v'_{a0}=1$ and $v'_{i0}=0$ is assumed. The parameters used are $\omega_{ab}=38090$ cm^{-1}, $\omega=993$ cm^{-1}, $\omega_i=522$ cm^{-1}, $\Delta=1.43$, $k^n=3.67\times10^6$ s^{-1}, $k_i^n=1.35\times10^6$ s^{-1}, $k=7.8\times10^6$ s^{-1}, and $\Gamma_{ab}=75$ cm^{-1}.

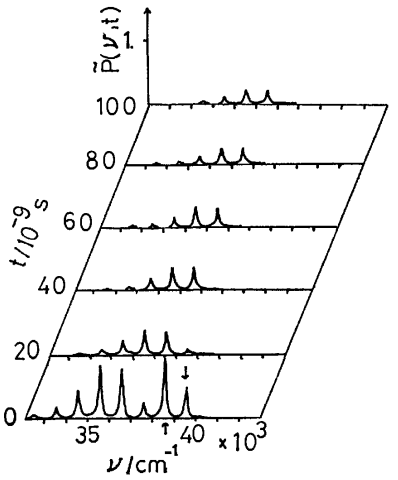

Fig. 4. Calculated time-resolved emission intensity distribution. The excitation to the vibronic level with $v'_{a0}=1$ and $v'_{i0}=1$ is assumed. The parameters used are the same in Fig. 3. The downward and upward arrows indicate the origins of the progressions, $6_0^1 1_n^1$ and $6_2^1 1_n^1$, respectively.

1.43[11] for the accepting mode (ν_1); $\omega_i=522$ cm^{-1} [12] and $k_i^n=1.35\times10^6$ s^{-1} for the inducing mode (ν_6), and $k=7.8\times10^6$ s^{-1},[13] $\omega_{ab}=38090$ cm^{-1}, and $\Gamma_{ab}=75$ cm^{-1}. These parameters are taken from the calculated and experimental data for the $^1A_{1g}\leftarrow{}^1B_{2u}$ transition of benzene. The collisional vibrational-relaxation constants, which depend on pressure, are assumed to be $k^c=0.1\times10^9$ s^{-1} and $k_i^c=0.2\times10^9$ s^{-1}. In Fig. 3, the diffuse spectrum as a function of the emission frequency at $t=0$ is shown, and we can see no band peak corresponding to the $1\leftarrow1$ vibronic transition for the accepting mode near 37600 cm^{-1}. This can be explained by the vanishingly small Franck-Condon

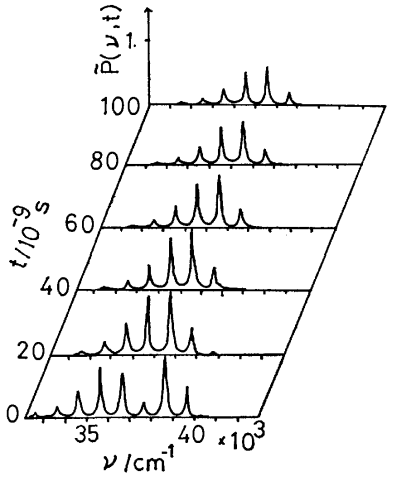

Fig. 5. Calculated time-resolved emission intensity distribution in the case of no collisional vibrational and electronic relaxations relevant to the inducing mode. The excitation to the vibronic level with $v'_{a0}=1$ and $v'_{i0}=1$ is assumed. The parameters used are the same in Fig. 3 except for $k_i^c=k_i^n=0$.

overlap for $\Delta^2/2\simeq1$. It is shown that the intensity decay in Fig. 4 is faster than that in Fig. 3. This is qualitatively due to the fact that, in the case of the one-vibrational quantum excitation of the inducing mode, not only are there two emission-decay paths, but also there are a collisional vibrational relaxation and a nonradiative decay path involving the inducing mode compared with the case of the zero-quantum excitation.

It is shown in Fig. 4 that the emission spectrum at $t=0$ consists of two progressions, $6_0^1 1_n^1$ and $6_2^1 1_n^1$, where n=0, 1,$\cdots$(their origins are indicated by downward and upward arrows respectively), while after time enough to reach the steady state, the emission-intensity distribution consists of one progression, $6_1^0 1_n^0$. These spectral features have been observed by Blondeau and Stockburger[15] and by Swords and Phillips.[3] Blondeau and Stockburger have also studied the resonance flourescence spectra of benzene in the vapor phase, and have compared them with the fluorescence spectra from a Boltzmann distributed vibrational levels in the first excited state; the resonance fluorescence from the $6^1 1^1$ level consists of two progressions, $6_0^1 1_n^1$ and $6_2^1 1_n^1$; the main progression in the equilibrated fluorescence by the 253.7 nm excitation is $6_1^0 1_n^1$. The time-resolved fluorescence spectra of benzene in the gas phase have been reported by Swords and Phillips.[3] In the time-resolved fluorescence spectra observed at $t=70$ ns after the excitation at 257.25 nm in which two major transitions, $6_1^0 1_0^1 16_0^2$ and $6_0^1 16_1^3$, are involved, the bands related to the inducing mode decrease, while those belonging to the $6_1^0 1_n^0$ progression increase, in intensity compared with those observed at $t=20$ ns.

In Fig. 5, the relative emission-intensity distribution in the case of no collisional vibrational and electronic relaxations related to the inducing mode, $k_i^c=k_i^n=0$, is shown. The emission-intensity distribution is plotted by using Eq. 14. The other parameters used are the same as in Fig. 4. We can see that the vi-

bronic-intensity distribution in Fig. 5 after a long time is different from that in Fig. 4. In Fig. 5, the band peak at about 38600 cm^{-1}, which corresponds to the 0←1 transition for the inducing mode, still remains because of the absence of any relaxation for the mode.

Finally, we should mention the value of the damping constant. The damping constant is expressed by a sum of two terms: $\Gamma_{ab}=1/2(\Gamma_{aa}+\Gamma_{bb})+\Gamma^{(d)}_{ab,at}$,[16] where Γ_{aa} and Γ_{bb} are the population-decay constants of the a and b states respectively, and where $\Gamma^{(d)}_{ab,ab}$ denotes the pure dephasing constant originating from elastic interaction processes between molecules and heat bath. A value of Γ_{ab} close to that observed in nanosecond time-resolved emission spectroscopy[3] has been used in this paper. In other words, the value does not always represent the real damping constant, for there are no corrections for the optical detection or for the inhomogeneous broadening.

Effect of 1,4-Dioxane on the Structure of Aqueous *t*-Butyl Alcohol. Sound Velocity Studies

Neriyanuri MANOHARA MURTHY and Saraswatula Venkata SUBRAHMANYAM*

Department of Physics, SVU Autonomous Post-Graduate Center, Anantapur 515003, India

(Received December 19, 1980)

The structure of aqueous *t*-butyl alcohol in the water rich region is known to be more structured than pure water. 1,4-dioxane is known to be a weakly hydrophobic solute. The effect of 1,4-dioxane on the structure of aqueous *t*-butyl alcohol has been studied by fixing the temperature of sound velocity maximum in the ternary solution from the experimentally determined ultrasonic velocity data at different temperatures. The structural contribution to the shift in the temperature of sound velocity maximum of the aqueous *t*-butyl alcohol solution due to the addition of 1,4-dioxane, $[\Delta T_{str.}]_{exptl}$, has been found to be positive having the nature of variation similar to that of the effect of 1,4-dioxane on pure water, when the concentration (X_s) of *t*-butyl alcohol is 0.0075. But, for aqueous *t*-butyl alcohol solutions having $X_s=0.0025$ and $X_s=0.0046$, $[\Delta T_{str.}]_{exptl}$, has been found to be negative reaching maximum values around $X_2=0.0045$ and there after decreasing with a tendency to become positive at higher concentrations of 1,4-dioxane. These results have been explained in the light of structure breaking and formation of dioxane complexes in the ternary solutions.

The hydrophobic nature of *t*-butyl alcohol has been established beyond doubt[1–16] whereas controversial views exist on the structural propensity of 1,4-dioxane.[17–27] Our earlier studies on the effect of *t*-butyl alcohol[28,29] and 1,4-dioxane[30] on the temperature of sound velocity maximum (TVM) and adiabatic compressibility minimum (TACM) indicated both the solutes to enhance the ordered structure of water when present in small amounts. In our earlier work,[31] we have carried out the TVM studies on ternary systems namely water+glycerol+1-butanol and water+pyridine+1-butanol and found to be useful in delineating the temperature dependence of structural propensity of 1-butanol. In continuation of TVM studies in probing the structure of ternary systems, we have taken up the studies on the effect of 1,4-dioxane on the temperature of sound velocity maximum of aqueous mixtures of *t*-butyl alcohol of different concentrations and the results are reported in this paper. Our interest in these studies is to see how a structure promoter (1,4-dioxane) influences the aqueous binary solution structure containing a structure promoter (*t*-butyl alcohol).

Experimental

Triple distilled degassed water was used to prepare stock solutions of aqueous *t*-butyl alcohol. This stock solution was used to prepare ternary solution of 1,4-dioxane of desired concentration. The concentration of 1,4-dioxane in the ternary solution was calculated by considering aqueous binary stock solution as a cosolvent of effective molecular weight M_{12} given by $X_wM_w+X_sM_s$ where M_w,M_s and X_w,X_s represent the molecular weights and mole fractions respectively of water and *t*-butyl alcohol. AR grade *t*-butyl alcohol and 1,4-dioxane were used after necessary purification following the procedure given by Weissberger.[32] Ultrasonic velocity in the solutions was determined using a single crystal variable path interferometer working at 3 MHz with an accuracy of ±0.003%, the details of which were discussed elsewhere.[28]

Results

Diffraction corrected ultrasonic velocity as a function of temperature at different concentrations of 1,4-dioxane in aqueous *t*-butyl alcohol ($M_{12}=18.1556$, $X_s=0.0025$; $M_{12}=18.2735$, $X=0.0046$, and $M_{12}=18.4884$, $X_s=0.0075$) are presented graphically in Figs. 1—3.

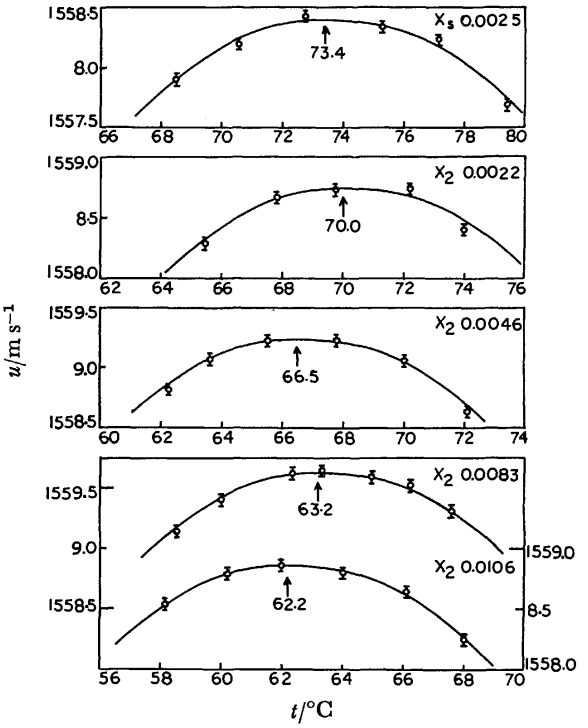

Fig. 1. Ultrasonic velocity *versus* temperature in aqueous solutions of *t*-butyl alcohol ($X_s=0.0025$) at different mole fractions of 1,4-dioxane.

The TVM in the ternary solution was fixed using the template of the velocity-temperature curve for pure water with an accuracy of ±0.2 °C as described earlier.[31]

Discussion

The shift in the temperature of sound velocity maximum of aqueous *t*-butyl alcohol due to the addition of 1,4-dioxane may be given by

$$\Delta T = (T_{\text{exptl}})_{\text{ternary soln}} - (T_{\text{exptl}})_{\text{binary soln}} \quad (1)$$

ΔT arises due to two effects namely dilution effect and structural effect which may be separated by considering the expressions representing the temperature dependence of velocity in aqueous *t*-butyl alcohol and 1,4-dioxane. The structural contribution to the shift in the temperature of sound velocity maximum in the ternary solution can be calculated using the following expressions that may be obtained on the same lines as that for pure water.[29]

$$[\Delta T_{\text{str.}}]_{\text{exptl}} = T_{\text{exptl}} - T_{\text{id.}} \quad (2)$$

where

$$T_{\text{id.}} = T_{\text{binary soln}} - \left(\frac{\phi_2}{\phi_{12}}\right)^2\left(\frac{W_{12}}{W_2}\right)\frac{2\beta}{\alpha}\left(\frac{u_{12}}{u_2}\right)^3. \quad (3)$$

In the above expression ϕ_{12}, ϕ_2 and W_{12}, W_2 represent the volume fractions and weight fractions of aqueous *t*-butyl alcohol and 1,4-dioxane respectively in the terary solution. α represents the temperature coefficient of sound velocity in 1,4-dioxane and u_{12} and u_2 the velocities in the aqueous *t*-butyl alcohol and 1,4-dioxane respectively. For 1,4-dioxane u_2 is given by

$$u_2 = u_2^0 - \alpha t, \quad (4)$$

where u_2^0 and α are 1452.42 ms^{-1} and 4.33 ms^{-1} $°C^{-1}$ respectively and t represents the temperature in °C. u_{12} may be written as

$$u_{12} = u_{12}^0 - \beta(T-t)^2. \quad (5)$$

The values of u_{12}, β, and T for aqueous *t*-butyl alcohol for different X_s are given in Table 1.

In all cases $T_{\text{id.}}$ was calculated using the method of successive approximations. Table 2 gives the values of T_{exptl}, $T_{\text{id.}}$, and $[\Delta T_{\text{str.}}]_{\text{exptl}}$ at different concentrations of 1,4-dioxane. The variation of $[\Delta T_{\text{str.}}]_{\text{exptl}}$ *versus* mole fraction X_2 of 1,4-dioxane in different aqueous *t*-butyl alcohol solutions are shown graphically in Fig. 4 along with the $[\Delta T_{\text{str.}}]_{\text{exptl}}$ *versus* X_2 of

1,4-dioxane in pure water taken from literature.[30] From the figure it is clear that the structural contribution to the shift in TVM of aqueous *t*-butyl alcohol is negative for the binary mixtures in which X_s= 0.0025 and 0.0046 reaching maximum values around $X_2 \simeq 0.0045$ and thereafter decreases with a tendency to become positive at higher concentrations of 1,4-dioxane. But, when the mole fraction of *t*-butyl alcohol in the aqueous *t*-butyl alcohol is 0.0075,

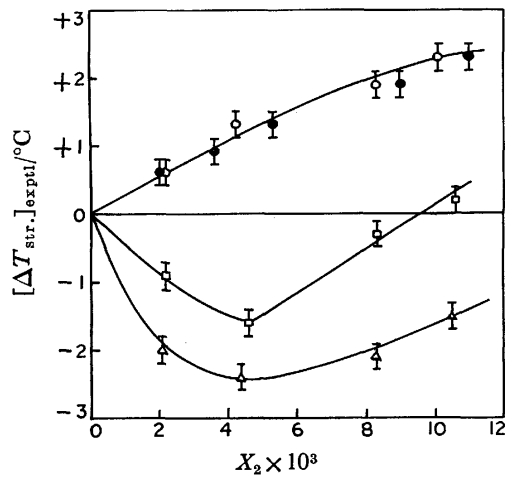

Fig. 4. $\Delta T_{str.\ exptl}$ *versus* mole fraction X_2 of 1,4-dioxane in different solvents.

: Aqueous *t*-butyl alcohol X_s=0.0025, TVM 73.6 °C, : Aqueous *t*-butyl alcohol X_s=0.0046, TVM 73.0 °C, : Aqueous *t*-butyl alcohol X_s=0.0075, TVM 66.1 °C, : Pure water, TVM 74 °C.

$[\Delta T_{str.}]_{exptl}$ is positive increasing with increase in the concentration of 1,4-dioxane and is quite similar to the structural contribution to the shift in TVM of water, not only with respect to sign but even with respect to the magnitude of the structural shift. These results indicate that the structural propensity of 1,4-dioxane remains the same whether the solvent is pure water or aqueous *t*-butyl alcohol in which X_s=0.0075. But, the negative values of the structural shifts when X_s=0.0025 or 0.0046 point out the existence of a complex behavior. It is worthwhile to note here that the structural contribution to the shift in TVM of pure water due to the addition of *t*-butyl alcohol[29] reaches maximum around $X_s \simeq 0.0046$. Beyond this the structural shift decreases with increasing concentration of *t*-butyl alcohol. Hence it may be concluded that when $X_s \simeq 0.0046$ the rate of collapse of the hydrogen bonded clusters due to the addition of 1,4-dioxane may be more than the rate at which water molecules become organized into clusters around 1,4-dioxane molecules leading to the negative values of the structural shifts. But as the concentration of 1,4-dioxane increases, the rate of cluster formation around 1,4-dioxane molecules due to the hydrophobic nature of its methylene groups overtakes the rate of disintegration of the hydrogen bonded clusters. This situation is reflected in the tendency of $[\Delta T_{str.}]_{exptl}$ to become positive as the concentration of 1,4-dioxane increases. When X_s=0.0075, the time average of the structure of aqueous *t*-butyl alcohol resembles that of pure water and free water molecules try to form clusters around 1,4-dioxane and positive structural shifts may be thought of as due to the ordering of water structure owing to the formation of hydrates of dioxane as reported in literature.[18,19,33]

X_D: Mole fraction of 1,4-dioxane when aqueous *t*-butyl alcohol is treated as cosolvent of effective molecular weight $M_{B,W}$. X_B: Mole fraction of *t*-butyl alcohol when aqueous 1,4-dioxane is treated as cosolvent of effective molecular weight $M_{D,W}$.

The structural shifts have been evaluated based on the assumption that aqueous *t*-butyl alcohol as seen by 1,4-dioxane is aqueous implying that the cosolvent (aqueous *t*-butyl alcohol) solute (1,4-dioxane) interactions are similar to that of pure solvent (water) and solute. This is true only if the interactions between 1,4-dioxane and *t*-butyl alcohol are negligible when compared with the interaction of 1,4-dioxane with aqueous nature of the solution structure. Even though the parabolic nature of velocity *versus* temperature profile of ternary solutions, as is evident from Figs. 1—3, support the validity of the above contention; we have calculated the shift in TVM of water due to the addition of the two organic solutes (independently) namely 1,4-dioxane and *t*-butyl alcohol to water, ΔT_{calcd}, and a comparison is made with the observed shift, ΔT_{obsd}, (74 °C-T_{exptl} in the ternary solution) to see whether the shift ΔT is additive with respect to them. Our earlier data[30,31] on TVM of aqueous 1,4-dioxane and *t*-butyl alcohol are taken for the evaluation of the shifts corresponding to the concentrations of these solutes in the ternary systems. The shift in TVM of water corresponding to the concentrations of the present study are obtained by least square fitting of the data.[30,31] As per the data presented in Table 3, the agreement between the calculated and observed shifts is quite good in the case of ternary system for which X_s=0.0075. But when X_s=0.0025 or 0.0046 the observed shifts and calculated shifts differ significantly. This disparity may be attributed to the hindrance caused by *t*-butyl alcohol molecules in the formation of hydrates of dioxane or to some enhancement in the structural propensity of both *t*-butyl alcohol and 1,4-dioxane due to the presence of each over the other in destabilizing the three dimensional structure of water. The agreement between the observed and calculated shifts when X_s= 0.0075 clearly indicates that the structure of aqueous *t*-butyl alcohol as seen by 1,4-dioxane is the same as that of pure water. In other words the structural propensity of 1,4-dioxane is unaffected by the presence of *t*-butyl alcohol when its mole fraction is 0.0075. This behavior may be due to the fact that for aqueous *t*-butyl alcohol in which X_s=0.0075, further addition of *t*-butyl alcohol or 1,4-dioxane destabilize the hydrogen bonded clusters and the monomers so formed take part readily in the formation of hydrates of dioxane leading to a positive sign for the structural shifts.

Electroreduction of 4-(2-Thienyl)quinazoline in Acetonitrile

T. Priyamvada Devi, Chatty Kalidas, and
Chitoor Sivaramakrishnan Venkatachalam*
Department of Chemistry, Indian Institute of Technology, Madras-600 036, India
(Received February 6, 1981)

The electroreduction of 4-(2-thienyl)quinazoline (4-TQ) in acetonitrile solutions gave a single two-electron well-defined polarographic wave. The well-defined wave was found to be diffusion-controlled and irreversible on the basis of the usual criteria. Based on the controlled-potential electrolysis and cyclic voltammetric experiments, a disproportionation reaction mechanism is suggested for 4-TQ reduction in acetonitrile.

4-(2-Thienyl)quinazoline (4-TQ) possesses some biologically-active properties. It is found to be an analgesic, antiinflammatory, and antipyretic.[1,2] During our detailed electrochemical investigations on the reduction of this compound in amphiprotic[3] (methanol–water mixtures) and dipolar aprotic (*N*,*N*-dimethylformamide)[4,5] media, very interesting results have been obtained. In continuation of this work, we present here the results obtained on the electrochemical behaviour of 4-TQ in acetonitrile.

Experimental

4-(2-Thienyl)quinazoline was prepared according to the literature procedure and its purity tested by mp (65 °C), TLC, IR, and mass spectrometry.[6,7] AR(BDH) tetrabutylammonium iodide (TBAI) was used as supporting electrolyte without further purification. Acetonitrile (S. Merck) was dried by keeping it over heated anhydrous sodium sulfate for a day with intermittent shaking and the clear supernatant liquid was then distilled using all glass assembly in the presence of silver nitrate.[8] The middle fraction boiling at 82 °C was collected and stored in glass vessel painted black.[9] The purified sample had a water content of 0.04% (Karl Fischer titration). The measured specific conductance of the purified acetonitrile sample ($6.0\times10^{-8}\,\Omega^{-1}$ at 25 °C) was found to be in agreement with the reported value.[10] In the present investigation, the purification method outlined above was found to be satisfactory as shown by the absence of polarographic reduction waves in the region of potentials studied. However, in certain cases where the supporting electrolyte polarograms showed appreciable residual currents, a pre-electrolysis[11] of the distilled sample was necessary and it was carried out at a potential which is slightly positive to the decomposition potential of the supporting electrolyte.

The polarographic measurements using a three electrode system were similar to those described previously.[3] The dropping mercury electrode (d.m.e.) used in acetonitrile solution containing 0.1 M TBAI (1 M=1 mol dm^{-3}) supporting electrolyte at 55 cm height of the mercury column (height uncorrected for back pressure) had the following capillary characteristics under open circuit conditions: 'm'= 0.6885 mg s^{-1}; 't'=7.1 s. The details of the cyclic voltammetric (CVM) experiments for 4-TQ reduction using hanging mercury drop electrode (HMDE) and the analysis of cyclic voltammograms for obtaining the kinetic parameters of the electrode process have been described previously.[4] All the measurements were carried out at 25 °C.

Results and Discussion

The d.c. and a.c. polarograms of 4-TQ (1.0×10^{-3} M) obtained in acetonitrile solution containing 0.1 M TBAI supporting electrolyte are shown in Fig. 1 and the corresponding polarographic data are presented in Table 1. It is seen from Fig. 1 that 4-TQ gives a single well-defined d.c. wave and the a.c. polarogram shows a single peak corresponding to the d.c. step. The well-defined wave was found to be diffusion-controlled as indicated by the linearity in the plots passing through the origin of (i) limiting currents *versus* concentration of 4-TQ and (ii) limiting

currents *versus* square root of the height of the mercury column. A slope of 0.50 in the (log i_l—log h) linear plot further confirmed the diffusion-controlled nature of the wave in acetonitrile solutions. The larger values of ($E_{3/4}$—$E_{1/4}$) and the slopes of the logarithmic plots[—E *vs.* log (i_d—i)/i] for different concentrations of 4-TQ indicate irreversible nature of the wave (Table 1). This is further supported by the dependence of half-wave potential on the concentration of 4-TQ. The product of the average corrected diffusion current constant (I_d) and square root of the viscosity of acetonitrile ('η'=0.350 cP), $I_d\eta^{1/2}$ for 4-TQ reduction was calculated to be 4.17. This value is in good agreement with 4.20 reported by Wasa and Elving[12] for a two-electron reduction in acetonitrile.

The total number of electrons (n_{app}) involved in 4-TQ reduction in acetonitrile at the limiting region of the polarographic wave (—1.300 V *vs.* silver wire electrode) was calculated from microscale controlled-potential electrolysis (CPE) experiments[3] and found to be 1.97, 2.03, and 2.00 (accuracy ±0.04), respectively, for three separate experiments. Macroscale CPE experiments were not carried out due to volatility of acetonitrile.

Cyclic voltammograms of 4-TQ obtained at different sweep rates in acetonitrile solutions in the presence of 0.1 M TBAI supporting electrolyte are shown in Fig. 2. The CVM data are presented in Table 2. The cyclic voltammograms show two cathodic peaks in the forward scan and one anodic peak during the reverse scan. The first cathodic peak potential corresponds to the d.c. polarographic step and the anodic peak corresponds to the first cathodic peak. At lower sweep rates (less than 0.05 V s^{-1}, for example, at 0.008 V s^{-1}), the second cathodic and the first anodic peaks are absent and these peaks once again appear with increase in sweep rate (Fig. 2). Although a single well-defined two-electron wave is obtained in acetonitrile a *small* EPR signal observed[13] when 4-TQ in acetonitrile solution was electrolysed at the limiting region of the wave (—1.300 V *vs.* silver wire electrode) indicates single electron addition in the first step. The neutral radical of 4-TQ formed during the reduction undergoes a *fast* disproportionation (secondary) reaction[4] and the average disproportionation rate constant (k_d) in acetonitrile solution was calculated to be (2.14±0.38)×10^{-2} M^{-1} s^{-1} (Table 3). The presence of a fast second-order reaction following the first charge-transfer step is expected

to cause a shift in $E_{1/2}$ to positive values with increase in concentration of 4-TQ[14] (Table 1). A comparison of disproportionation rate constants in DMF[4] and acetonitrile solutions shows that in acetonitrile, the disproportionation reaction is about forty times faster than in DMF solutions. The observation of a single two-electron wave obtained under polarographic conditions is thus clear on the basis of a fast disproportionation reaction[15] in acetonitrile.

Mechanism for 4-TQ Reduction (CEC-type) in Acetonitrile. Based on the polarographic and CPE experiments, the following mechanism is suggested for 4-TQ reduction in acetonitrile solution:

$$\text{4-TQ} + H^+ \rightleftharpoons [\text{4-TQH}]^+ \text{ (fast)},$$

$$[\text{4-TQH}]^+ + e \rightleftharpoons [\text{4-TQH}]^\cdot \text{ (first electron-transfer)},$$

$$2[\text{4-TQH}]^\cdot \longrightarrow \text{4-TQH}_2 + \text{4-TQ} \text{ ("fast" homogeneous disproportionation)}.$$

However, it may be pointed out that 4-TQ obtained in the fast homogeneous disproportionation step may undergo again single-electron reduction to give the final dihydro-4-TQ product *via* the free radical formation step. It is quite likely that the formation of the dihydro-4-TQ from 4-TQ radical also takes place through the uptake of a proton and an electron. The pre-protonation of 4-TQ in the suggested mechanism (prior to electron-transfer step) is brought out by the trace amount of water (proton donor) present in acetonitrile[16] and this has been further evidenced by the correlation of EPR results with theoretical Hückel molecular orbital (HMO) calculations.[5] It is also known that acetonitrile solvent itself could donate protons[17] according to the equilibrium, $H_3C-C\equiv N \rightleftharpoons H_2C^{(-)}-C\equiv N+H^{(+)}$, since the conjugate base of acetonitrile is a resonance stabilised species. Mann also refers to the abstraction of protons from tetraalkylammonium ions.[16]

It may be mentioned here that the mechanism suggested for 4-TQ reduction in acetonitrile solutions is similar that encountered in DMF solutions.[4]

Kinetics and Mechanism of the Oxidation of (Substituted Phenylthio)acetic Acids by Chloramine T

Chockalingam SRINIVASAN* and Kasi PITCHUMANI
School of Chemistry, Madurai Kamaraj University, Madurai 625 021, India
(Received February 20, 1981)

The kinetics of oxidation of (phenylthio)acetic acid and several (para-substituted phenylthio)acetic acids by chloramine T has been studied in alkaline medium (pH 10.06). A first-order dependence in chloramine T and (phenylthio)acetic acid and a near inverse first-order dependence in hydroxide ion has been observed. The oxidation rate considerably decreases with increase of pH. The reaction exhibits positive salt effect and added *p*-toluenesulfonamide increases the rate. The oxidation process has been shown to proceed *via* two paths, the major path involving *N*-chloro-*p*-toluenesulfonamide as the main oxidizing species and the other involving hypochlorite ion. Studies with (para-substituted phenylthio)acetic acids show an excellent correlation of the rate constants with σ constants. The reaction exhibits a reaction constant ρ of -2.46 at 308 K ($r=0.998$, $s=0.05$, confidence limit on $\rho \pm 0.15$). The activation parameters and isokinetic temperature have been determined.

Chloramine T (CAT) is a strong oxidant in both acidic and alkaline media. Its redox potential varies with the pH of the medium (E_{red} 1.138 V at pH 0.65 and 0.5 V at pH 12).[1] The reactions of several organic compounds[2] with CAT have been reviewed. A wide range of alkyl and aryl sulfides[2,3] yield the corresponding sulfimides and sulfoxides with CAT. Vasudeva Murthy and co-workers[4] have reported the oxidation of some acyclic sulfur compounds and also some phosphorus-sulfur compounds. However, the detailed kinetics of the reaction of several dialkyl, alkyl aryl, and diaryl sulfides with CAT (Mann-Pope reaction) were investigated in buffered water–ethanol solution by Kucsman and co-workers[5,6] and a mechanism has been proposed on the basis of kinetic measurements and product analysis. Oxidation of (phenylthio)acetic acid by sodium salt of *N*-chlorobenzenesulfonamide[7] yields (phenylsulfinyl)acetic acid. However, an abnormal reaction was encountered[8] when CAT reacted with sodium salt of (phenylthio)acetic acid, affording not the sulfimide, but the *N*-(*p*-tolylsulfonyl)benzenesulfimidic *p*-tolylsulfonylamide (**1**).

$$C_6H_5SCH_2COO^- \xrightarrow{CAT} C_6H_5-\underset{\underset{NTs}{\|}}{S}-NHTs$$

1

During the course of our detailed studies on the kinetics of oxidation of organic sulfur compounds by several oxidants, we have recently reported the kinetics of the reaction of (substituted phenylthio)acetic acids with peroxodisulfate.[9] In this paper we report the results of the kinetic investigations of the oxidation of (substituted phenylthio)acetic acids by CAT in alkaline medium.

Experimental

Materials. Chloramine T from May & Baker which was pure as found by iodometric method, was used as such and its aqueous solution was stored in black coated vessels to prevent its photochemical deterioration. (Substituted phenylthio)acetic acids were prepared by standard procedures.[9] All other reagents were of AnalaR grade. Equimolar amounts of (phenylthio)acetic acids and potassium hydroxide were dissolved and used in kinetic runs. Sodium hydrogencarbonate–sodium carbonate buffer was used to maintain the pH. Measurements of the pH were carried out using a digital pH meter (pH 5651, Electronic corporation of India Limited).

Kinetics. Kinetic studies were carried out in sodium hydrogencarbonate–sodium carbonate aqueous buffer (pH 10.06 unless mentioned otherwise) under pseudo first-order conditions with the substrate and oxidant concentrations in the ratio of 10:1. The reaction was followed by estimating the unconsumed CAT iodometrically.[10] Aliquots (5 ml) of the reaction mixture were quickly transferred at regular intervals of time to iodine flasks containing five ml of 2 M (1 M=1 mol dm^{-3}) hydrochloric acid and 10 ml of 10% aqueous solution of potassium iodide. Unconsumed CAT liberated an equivalent amount of iodine and the latter was estimated by standard sodium thiosulfate solution using starch as indicator.

Reactions were generally followed to 70—80% completion; reproducible results giving good first-order plots ($r>0.995$) were obtained for reactions run in duplicate. The kinetic constants, k_ψ, were calculated by the method of least squares using a Micro 2200 computer (Hindustan Computers Limited). The precision of k values is given in terms of 95% confidence limit calculated with 'student t'. From the k_ψ values, the second-order rate constants were obtained ($k=k_\psi/$[substrate]).

Stoichiometry. The reaction stoichiometry was found to be 1:1 by allowing an excess of CAT to react with (phenylthio)acetic acid overnight and estimating the unreacted CAT.

Product Analysis. The product of the reaction was found to be (phenylsulfinyl)acetic acid. A thin layer chromatography (silica gel) analysis of the reaction mixture developed in a solvent system of butanol–water–acetic acid (4:5:1—upper layer) gave two spots corresponding to (phenylthio)acetic acid (R_f 0.84) and (phenylsulfinyl)acetic acid (R_f 0.45) respectively. IR spectrum of the product separated from the reaction mixture shows an intense absorption band at 1050 cm^{-1} characteristic of SO stretching in (phenylsulfinyl)acetic acid and the IR spectrum is superimposable with that of an authentic sample of (phenylsulfinyl)acetic acid. The overall reaction in the oxidation is given by Eq. 2.

$$C_6H_5SCH_2COO^- + TsNCl^- + H_2O \longrightarrow C_6H_5SOCH_2COO^- + TsNH_2 + Cl^- \quad (2)$$

In an earlier work,[8] the product of the reaction between sodium salt of (phenylthio)acetic acid and CAT was found to be **1**. The authors obtained **1** (yield<10%) when a large excess of CAT was employed and also by heating the

mixture on a steam bath for 30 min. In our kinetic conditions, the substrate was taken in large excess and hence the (phenylsulfinyl)acetic acid formed did not undergo further reaction. It may be noted here that the oxidation of (phenylthio)acetic acid by sodium salt of *N*-chlorobenzenesulfonamide[7] yields the corresponding sulfoxide.

Results and Discussion

Kinetic data were obtained for all the (phenylthio)-acetic acids investigated, but as the results are similar, only those of (phenylthio)acetic acid (PTAA) are presented in detail.

The reaction exhibits a clean first-order kinetics with respect to CAT as evidenced by good first-order linear plots for the disappearance of CAT. The order with respect to PTAA is also one as demonstrated by the constant numerical values of k in Table 1 and also by the good linear plot of log k_ϕ *versus* log[PTAA] with a slope of 0.98±0.05 (r=0.999, s=0.01). Further a plot of k_ϕ *versus* [PTAA] gave a good straight line passing through the origin indicating the absence of any substrate independent path and the second-order nature of the reaction.

There is a slight increase in rate with an increase in [CAT]. Since a positive salt effect has been observed in the oxidation, the increase in rate with [CAT] has been accounted for by the reaction between the (phenylthio)acetate and hypochlorite ions. (*cf.* mechanism).

Dependence of pH. The oxidation is highly susceptible to changes in pH of the medium (Table 2). An increase in pH considerably retarded the rate. A plot of log k against pH gave a straight line (slope= −0.93±0.09, r=0.999, s=0.04) indicating a near inverse first-order dependence on hydroxide ion concentration.

Table 1. Dependence of rate on initial concentration of reactants[a]

10^3[CAT] / mol dm^{-3}	10^2[PTAA] / mol dm^{-3}	$10^5 k_\phi$[b] / s^{-1}	$10^3 k$[b] / dm^3 mol^{-1} s^{-1}

a) In aqueous buffer, at 308 K and pH=10.06. b) The error quoted in k is the 95% confidence limit of the 'student t'.

Effect of Salt Concentration. The rate constant for the oxidation of PTAA by CAT at different concentrations of sodium perchlorate and potassium chloride have been determined (Table 3). Though there is a positive salt effect, the presence of chloride ion has no specific effect on the rate of oxidation.

Effect of p-*Toluenesulfonamide.* Addition of *p*-toluenesulfonamide causes a slight increase in the rate of oxidation (Table 4).

Activation Parameters. The rate constants were determined at three temperatures for the oxidation of PTAA by CAT and the data fit the Arrhenius and Eyring equations. The activation parameters are given in Table 5 along with those for (substituted phenylthio)acetic acids. The reaction is characterized by a low enthalpy of activation and an appreciable negative entropy of activation implying that the activated complex should have an exacting specificity of orientation. Ruff and Kucsman[5] report than the enthalpy and entropy of activations are 41.0 kJ mol^{-1} and −79.1 J K^{-1} mol^{-1} for the reaction of TsNHCl (active species of CAT) with methyl phenyl sulfide.

Mechanism and Rate Law. An aqueous solution of CAT undergoes hydrolysis giving a variety of products, the relative amounts of which depend on the pH of the solution. Thus the oxidizing species

$$TsNNaCl + H_2O \rightleftharpoons TsNHCl + NaOH \quad (3)$$

$$TsNHCl + NaOH \rightleftharpoons TsNH_2 + Na^+ + ClO^- \quad (4)$$

$$2TsNHCl \rightleftharpoons TsNCl_2 + TsNH_2 \quad (5)$$

$$TsNCl_2 + NaOH \rightleftharpoons TsNHCl + Na^+ + ClO^- \quad (6)$$

of CAT are dichloramine T ($TsNCl_2$), *N*-chloro-*p*-toluenesulfonamide (TsNHCl), hypochlorite ion (ClO^-) and CAT itself. One of the above will be the main oxidizing species and their reactivities[5] should follow the order $TsNCl_2 > TsNHCl > ClO^- > CAT$.

In an alkaline medium dichloramine T does not exist (Eq. 6, the equilibrium will be more towards TsNHCl). Higuchi and Hussain[11] have already concluded that only in the pH range 6.35—6.85 the formation of dichloramine T is significant. Further, a second-order dependence of rate on CAT is predicted if dichloramine T is assumed to be the active species. The observed first-order dependence on CAT in the oxidation of PTAA clearly points out that dichloramine T is not the active oxidizing species. Since an increase in hydroxide ion concentration (or pH) decreases the rate of oxidation (Table 2 and Eq. 4), it has to be concluded that TsNHCl is the main oxidizing species of CAT in the oxidation of PTAA. This conclusion gains further support from the observation that addition of *p*-toluenesulfonamide increases the rate (Table 5). Addition of $TsNH_2$ shifts the equilibrium (4) towards the left which results in the increased formation of TsNHCl and hence

Table 2. Dependence of the reaction rate on pH[a]

pH	8.980	9.570	10.06	10.48	10.75
$10^3 k$ / dm^3 mol^{-1} s^{-1}	174±2.5	45.4±1.5	16.6±0.37	7.73±0.07	3.59±0.07

a) In aqueous buffer, at 308 K, [CAT]=0.001 M and [PTAA]=0.01 M.

the enhanced rate becomes understandable.

On the basis of the experimental data discussed earlier, the following mechanism has been suggested:

$$TsNNaCl + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} TsNHCl + NaOH, \quad (3)$$

$$TsNHCl + C_6H_5SCH_2COO^- \xrightarrow[\text{slow}]{k_2}$$

$$\left[TsNH^- \overset{+}{S}\overset{C_6H_5}{\underset{CH_2COO^-}{Cl}} \right], \quad (7)$$

2

$$\mathbf{2} \xrightarrow{\text{fast}} TsNH^- + \overset{+}{S}\overset{C_6H_5}{\underset{CH_2COO^-}{Cl}} \xrightarrow[\text{fast}]{H_2O}$$

$$C_6H_5SOCH_2COO^- + TsNH_2 + HCl. \quad (8)$$

Application of steady state treatment for TsNHCl with a reasonable approximation that $k_{-1}[NaOH] \gg k_2[C_6H_5SCH_2COO^-]$ yields the rate law as

$$\frac{-d[CAT]}{dt} = \frac{k_1k_2[CAT][C_6H_5SCH_2COO^-]}{k_{-1}[NaOH]} = \frac{k'[CAT][C_6H_5SCH_2COO^-]}{[NaOH]}, \quad (9)$$

where $k' = k_1 k_2/k_{-1}$. At constant[NaOH] or pH,

$$\frac{-d[CAT]}{dt} = k''[CAT][C_6H_5SCH_2COO^-]. \quad (10)$$

Thus the proposed mechanism involves the intermediate **2** formed by the reaction between (phenylthio)acetate ion and TsNHCl and the subsequent disintegration of **2** in a fast step to give the products.

The kinetic studies discussed above clearly demonstrate that under our experimental conditions, TsNHCl is the main oxidizing species of CAT. However, the following observations are not accounted for by the above mechanism: i) a small positive salt effect implying a small fraction of the reaction between ions of the same charge and ii) deviation of order in hydroxide ion concentration from −1. Hence it is proposed that a small fraction of the overall reaction proceeds *via* the formation of ClO^- (Eqs. 11 and 12). It is worth mentioning here that though the reaction is carried out under alkaline conditions, the generation of ClO^- is only small since i) ClO^- is generated from TsNHCl which is very reactive and ii) the relative order of reactivity is found[5] to be $TsNCl_2 > TsNHCl > ClO^- > TsNCl^-$.

$$C_6H_5SCH_2COO^- + ClO^- \xrightarrow[\text{slow}]{k_2'} C_6H_5SOCH_2COO^- + Cl^-, \quad (11)$$

$$C_6H_5SCH_2COO^- + ClO^- + H_2O \xrightarrow[\text{slow}]{k_2'} C_6H_5SOCH_2COO^- + HCl + OH^-, \quad (12)$$

Table 3. Effect of salt concentration on the reaotion rate[a]

Salt concentration / mol dm^{-3}	$10^3 k$ / dm^3 mol^{-1} s^{-1}

a) In aqueous buffer, at [CAT]=0.001 M, [substrate]=0.01 M, and pH=10.06. b) The precision of ΔH^* and ΔS^* values were calculated using the method of Petersen *et al.*[15]

leading to the rate law

$$\frac{-\mathrm{d[CAT]}}{\mathrm{d}t} = k'''[\mathrm{CAT}][\mathrm{C_6H_5SCH_2COO^-}]. \quad (13)$$

Rate law (9) predicts an inverse first-order dependence in [NaOH] and rate law (13) suggests a zero-order dependence in [NaOH]. The net outcome of these two satisfactorily accounts for the fractional inverse order in [NaOH].

Substituent Effects. Since an analysis of the substituent effects can give more informations about the nature of the transition state and thereby the mechanism, kinetic studies were carried out with a number of (para-substituted phenylthio)acetic acids at three temperatures. The second-order rate constants and the activation parameters are presented in Table 5. The rate constants fit the simple Hammett equation at all the three temperatures. The reaction constant, ρ, at 308 K is -2.46 ($r=0.998$, $s=0.05$, confidence limit on $\rho \pm 0.15$). The marked negative value of ρ shows that electron-donating groups cause a considerable increase in the reactivity of $XC_6H_5SCH_2COO^-$ with CAT. This is consistent with a significant positive polarity of the sulfur atom in the transition state. It may be mentioned here that Ruff and Kucsman[5] observed a value of -4.25 as the reaction constant for the reaction of $XC_6H_5SCH_3$ with TsNHCl wherein a chlorosulfonium ion intermediate has been postulated and Miotti, Modena, and Sedea[12] have reported a ρ value of -3.2 for the oxidation of $XC_6H_5SCH_3$ with bromine proceeding *via* a bromosulfonium ion intermediate. Hence the large negative value obtained with (phenylthio)acetic acids justifies the assumption of the intermediate **2**. It is interesting to note here that, in contrast with the excellent correlation with σ in the reaction of (phenylthio)acetic acids with CAT, in the reactions of (phenylthio)acetic acids with peroxodisulfate[9] and peroxodiphosphate[13] (acetic acid medium) better correlations are observed only when σ^+ values are employed. This may be due to the fact that in CAT oxidations, (phenylthio)acetic acids are present as their anions in which the resonance interaction of the substituents with the reaction site would be small.

Thus the results of the oxidation of (phenylthio)-acetic acid by CAT may be interpreted as a two process reaction, the predominating path involving *N*-chloro-*p*-toluenesulfonamide as the oxidizing species and a small path involving hypochlorite ion as the oxidizing species.

From Table 5, it becomes evident that these oxidation reaction is of isoentropic type. Thus changes in rate are caused chiefly by changes in ΔH^* when ΔS^* is substantially constant. Many reaction series that follow the Hammett $\rho\sigma$ relationship falls within this category. However, the isokinetic temperature is found to be -116 K for the reaction series by the method of Exner.[14]

We thank Prof. N. Arumugam for helpful discussion, Prof. N. R. Subbaratnam for his interest in this work and CSIR, New Delhi for the award of a Senior fellowship to one of us (K.P.).

Conductometric Study of Ion-Ion and Ion-Solvent Interactions. III.† Conductances of Silver Acetate in Acetonitrile–Water Mixtures at 25 °C

U. G. Krishnam Raju, Bangalore Sethuram, and T. Navaneeth Rao*
Department of Chemistry, Osmania University, Hyderabad-500 007, India
(Received March 7, 1981)

Conductances of the solutions of silver acetate in 10 to 90% (w/w) acetonitrile–water mixtures were measured at 25 °C. The molar conductances at infinite dilution and association constants were calculated, using the Fuoss-Hsia equation with Fernandez-Prini coefficients. There was no association in 10 and 20% acetonitrile. The log K_A *vs.* $1/D$ plot was a straight line with negative intercept in accordance with the modified Denison-Ramsey theory of ion-pair formation. Walden products were also calculated. From these results it was concluded that silver ions are preferentially solvated by acetonitrile whereas acetate ion is hydrated in acetonitrile–water mixtures.

Existing literature indicates that in aqueous solutions of alkali metal halides ion-association increases from lithium to caesium whereas in solutions of their acetates, hydroxides and fluorides a reverse trend is observed *i.e.*, ion-association increases from caesium to lithium.[1] Eventhough ion-pair formation in solutions of alkali metal halides and halides of small metal ions have been extensively investigated[2] both in aqueous and aquo-organic solvents, such studies on acetates[3] of small metal ions are sporadic. The extended Fuoss-Hsia equation[4] with Fernandez-Prini coefficients,[5] which is based on the hard spheres model can be used for the analysis of the conductance data. A number of papers have been published by Lee and Wheaton[6] and Fuoss[7] proposing different models for ion-pair formation and new conductance equations. Beronius[8] comments that these equations based on solvent separated as well as contact ion-pairs are not exceptions to the Fuoss-Hsia conductance equation as they yield identical association constants when the values are above 15. Therefore in the present investigation, the electrical conductances of silver acetate in 10, 20, 40, 60, 80, and 90% (w/w) acetonitrile–water mixtures at 25 °C were measured and analysed using the Fuoss-Hsia equation[4] with Fernandez-Prini coefficients[5] with a view to calculate the association constants. The applicability of various theories of ion-pair formation such as those of Bjerrum,[9] Fuoss,[10] Denison-Ramsey (DR),[11] and Ebeling-Kraeft-Yokoyama-Yamatera(EKYY)[12,13] has also been discussed. The Walden products were calculated and the possible ion-solvent interactions were also discussed.

Experimental

Silver acetate (Fluka:Purum) was used after repeated recrystallisations from ethanol and drying. Acetonitrile (BDH) was purified as described by Vogel[14] and had a specific conductance of less than 1.0×10^{-7} S cm^{-1}. Water with a specific conductance less than 5.0×10^{-7} S cm^{-1} was used. Due correction was made for the solvent contribution to the conductance values of all the salt solutions. All the solutions were prepared freshly just before use and protected from light by covering the reaction vessel with a thick dark cloth. The experimental arrangement was the same as reported earlier.[15] The overall accuracy of the measured molar conductances was better than ±0.05%.

† Part II: *Rev. Roum. Chim.* (Communicated).

Results and Discussion

The molar conductances of the solutions of silver acetate in 10, 20, 40, 60, 80, and 90% (w/w) acetonitrile–water mixtures at 25 °C are given in Table 1. The dielectric constants and viscosities of the solvent mixtures were taken from literature.[16]

The conductance data was analysed using the Fuoss-Hsia equation[4] with Fernandez-Prini coefficients[5]

$$\Lambda = \Lambda_0 - s(\propto c)^{1/2} + E \propto c \ln(\propto c) + J_1 \propto c - J_2(\propto c)^{3/2} - K_A \Lambda y_\pm^2 \propto c, \quad (1)$$

where the various symbols have their usual significance. The activity coefficients ($y_\pm$) were calculated by the equation

$$-\log y_\pm = A(\propto c)^{1/2}/\{1+Ba(\propto c)^{1/2}\}. \quad (2)$$

Equation 1 was solved as originally described by Justice.[17] This procedure envisages the replacement of the distance of closest approach of ions (a) by the Bjerrum critical distance (q) term. The standard deviation (σ) values were calculated from the relation

$$\sigma = \{\Sigma(\Lambda_{exp}-\Lambda_{cal})^2/(N-3)\}^{1/2}. \quad (3)$$

All these calculations were carried out on a TDC-12 computer and the results are given in Table 2.

The functional dependence of log K_A *vs.* $1/D$ was used to test the applicability of various theories of ion-pair formation. Figure 1 shows that the association constants of silver acetate in water is very high and far off from the values in the other solvent mixtures. It is observed that there is no association in 10 and 20% acetonitrile–water mixtures. Strechlow and Koepp[18] have shown that silver ions are preferentially solvated by acetonitrile molecules than water. The solubility of silver acetate is more in acetonitrile–water mixtures than in pure solvents. Further the solubility is least in pure acetonitrile. This could be due to the non-solvation of acetate ion in acetonitrile. When small amounts of acetonitrile were added to aqueous solutions of silver acetate, Ag^+ ion gets heavily solvated by acetonitrile and prevents the acetate ions from reaching the Ag^+ ions so that no association could be found in 10 and 20% acetonitrile–water

mixtures. At higher percentages of acetonitrile, the decrease in the dielectric constant dominates the solvation and hence association is observed from 40% acetonitrile onwards. Leaving the K_A value for water the rest of the values at 40, 60, 80, and 90% acetonitrile exhibit a good linear trend, (drawn as a chained line in Fig. 1) with a correlation coefficient of 0.999. The linearity of the plot suggests the applicability of either DR theory or Fuoss theory excluding Bjerrum and EKYY theories from consideration. From the slope and intercept values of the log K_A *vs.* $1/D$ plot, the relative merits of the DR and Fuoss theories can be elucidated. Both DR and Fuoss theories predict the same slope *i.e.*, $|Z_+Z_-|e^2/(2.303\,akT)=96.23$ whereas the experimentally obtained line is having a slope of 109.33 and intercept −1.1472. But DR theory predicts zero intercept and Fuoss theory predicts log $(4\pi Na^3/3000)$ as intercept. Equating the experimental slope of 109.33 to $|Z_+Z_-|e^2/(2.303\,akT)$ the average ion-size parameter (a) for silver acetate in these solvents was obtained as 2.23 Å. However, when experimentally obtained intercept was equated to $3\log a+\log(4\pi N/3000)$, the '$a$' value calculated form there had a value 3.05 Å. Thus Fuoss theory predicts contradictory and different 'a' values of 2.23 Å and 3.05 Å from the slope and intercept values respectively of the same plot for the same ion-pair studied. On the other hand the finite value of the intercept could be accommodated by the modified DR expression

$$K_A = K_A^\circ \exp(|Z_+Z_-|e^2/aDkT). \quad (4)$$

Table 2. Association parameters for silver acetate obtained using Fuoss-Hsia equation in acetonitrile-water mixtures for $a=q$ at 25 °C

a) Ref. 20.

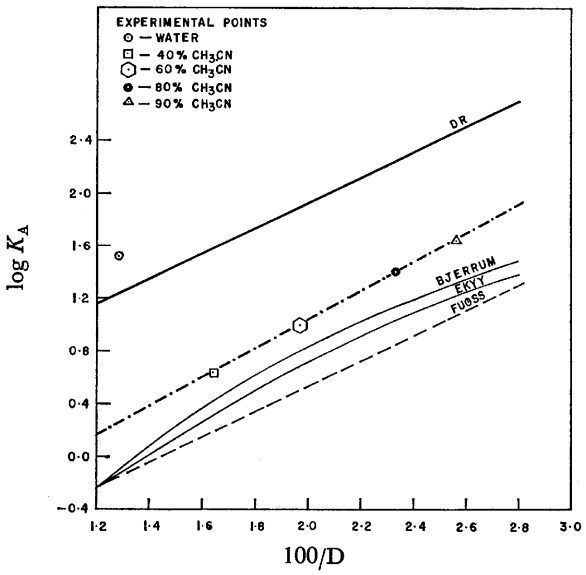

Fig. 1.

The experimental results could be fitted into this expression as

$$\log K_A = -1.1472 + 109.33/D, \quad (5)$$

$$\text{or } K_A = 0.0713 \exp(251.7/D), \quad (6)$$

and $a = 2.23$ Å.

This is slightly less (≈12%) than the crystallographic value of 2.53 Å (The ionic radius of Ag^+ is 1.26 Å and the effective radius of CH_3COO^- is 1.27 Å). Similar results are reported in the literature.[19] Bodenseh and Ramsey[19] reported that the 'a' value for tetrapropylammonium bromide obtained from the slope of the straight line of the plot of log K_A *vs.* $1/D$ was approximately 17% less than the corresponding minimum distance in the crystals. These deviations may be due to the fact that each ion in an isolated ion-pair whether in solution or in the vapour state is bound or coordinated with only one ion of opposite charge whereas in the crystalline state it will be coordinated with more than one oppositely charged ions. This explanation conforms to the fact that the smaller the number of nearest neighbours of oppositely charged associated ions in the crystal, the smaller will be the minimum distance between the oppositely charged ions in the salt. Figure 1 also shows the theoretical log K_A *vs.* $1/D$ plots corresponding to Bjerrum, Fuoss, DR, and EKYY theories using a=2.53 Å.

The ion-size parameter (a) values required by different theories to predict the experimental K_A values are compared with the 'a' values calculated from crystallographic data *i.e.*, 2.53 Å. In the solvent mixtures containing acetonitrile it is evident that the Bjerrum, EKYY, and Fuoss theories predict very low values of 'a' in the range of 1.45 to 1.88 Å which are unreasonable. The DR theory predicts meaningful 'a' values of 3.79 to 6.25 Å. In water[20] the DR theory predicts 2.04 Å which is much better than the values predicted by other theories *i.e.*, 0.61 to 0.67 Å. Getting higher 'a' values than the crystallographic value can be explained by considering the solvent separated ion-pairs.

The main effect of ion-association on ion-pair formation is either to decrease K_A due to increase in contact distance for the formation of 'solvent separated ion-pairs' (SSIP) or to increase K_A due to the formation of the additional associated species such as 'contact ion-pairs' (CIP). Earlier work[21] shows that silver acetate exists mostly as CIP in water. Whereas in acetonitrile–water mixtures the preferential solvation of Ag^+ ions by acetonitrile and CH_3COO^- ions by water suggests the formation of SSIP. The crystallographic radius of AgOAc is 2.53 Å. For this 'a' value the expected association constants are 37.64, 77.59, 174.7, and 287.7 $dm^3\,mol^{-1}$ for 40, 60, 80, and 90% (w/w) acetonitrile–water mixtures respectively. But the corresponding experimental values are 4.343, 10.17, 25.43, and 43.76 $dm^3\,mol^{-1}$. These low values of experimental association constants compared to the theoretical values indicate that there might be a large contribution of weakly bound solvent separated ion-pairs. Therefore, SSIP and CIP may be in equilibrium as shown below.

$$M^+S + S'A^- \rightleftharpoons M^+SS'A^- \text{ or } M^+SA^-S' \text{ or } SM^+S'A^-$$

$$\Downarrow\Uparrow$$

$$SM^+M^-S' \text{ or } [M^+A^-]S[M^+A^-]S'$$

By assuming perfect 'Stick' of the solvent at the surface of the ion, Walden[22] modified the Stokes law and obtained the relation

$$\lambda_0^{\pm}\eta = 0.820|Z_{\pm}|1/r_s^{\pm}, \quad (7)$$

$$\text{or } \Lambda_0\eta = 0.820(|Z_+|1/r_s^+ + |Z_-|1/r_s^-),$$

$$= \text{constant}, \quad (8)$$

where $\lambda_0^{\pm}$ is the limiting ionic conductances of hydrodynamic entity of radius $r_s^{\pm}$ and charge $Z_{\pm}$ in a medium of viscosity η. The Walden product $\Lambda_0\eta$ is expected to be constant for a given electrolyte in a series of solvents/solvent mixtures in which ion-solvent interactions are uniform. It is evident from the Walden products calculated (Table 3) that $\Lambda_0\eta$ decreases with increasing percentage of acetonitrile in acetonitrile–water mixtures indicating that the total solvation increases with increasing percentage of acetonitrile.

Table 3. Walden products and Stokes law radii for silver acetate at 25 °C

Solvent	$\Lambda_0\eta$	λ_0^+	λ_0^-	r_s^+/Å	r_s^-/Å
Water	0.9114	61.92	40.41	1.49	2.27
40% AN	0.6771	45.64	34.11	2.12	2.83
60% AN	0.6040	56.83	34.41	2.18	3.60
80% AN	0.5266	70.90	42.84	2.50	4.13
90% AN	0.3877	78.52	21.66	2.70	9.78

Interesting results could be obtained by splitting the salt conductance (Λ_0) into its ionic conductances. The limiting single ion conductances of Ag^+ ion were taken from the plot of $\lambda_0^+\eta$ *vs.* mole fraction of acetonitrile. By subtracting this from Λ_0 value, the limiting ionic conductance of acetate ion were obtained. The hydrodynamic radii of the Ag^+ and acetate ions were calculated by substituting these λ_0^+ and λ_0^- in Eq. 7 and the values thus obtained are presented in Table 3. The r_s^+ values for Ag^+ increase from 2.12 Å in 40% acetonitrile to 2.70 Å in 90% acetonitrile whereas it is only 1.49 Å in water which clearly indicates that in the acetonitrile–water mixtures Ag^+ is preferentially solvated by acetonitrile. The r_s^- values for acetate ion go on increasing from 2.27 to 9.78 Å. These odd values for acetate ion could be attributed to the unsymmetrical shape and distribution of the charge between the two oxygen atoms of the carboxylate group. This could also be the reason for the departure from the Stoke's law in the polarizable solvent. From these results one can conclude that Stoke's law may be applicable to the simple ions like Ag^+ and not to the ions in which charge is distributed.

One of the authors (UGKR) is thankful to CSIR-(New Delhi) for the award of a postdoctoral fellowship.

Studies on the Interaction between Mercury(II) Chloride and Copper(I) Halides in Solid State

Mirza Aijaz Beg* and Afaq Ahmad

Department of Chemistry, Aligarh Muslim University, Aligarh-202001, India

(Received April 5, 1981)

Kinetics and mechanism of $HgCl_2$–CuI and $HgCl_2$–CuBr reactions were studied in solid state. It has been demonstrated that $HgCl_2$ reaches CuI by surface migration and the reaction proceeds through counter diffusion of Cu^+ and Hg^{2+}. Both the reactions follow the parabolic rate law and the activation energies are 77.11 ± 3.84 and 51.08 ± 1.29 kJ/mol. While the former is a complex multi-stage reaction, the latter is a simple exchange process.

Like Ag_2HgI_4, Cu_2HgI_4 is also known to be formed from the reaction of CuI and HgI_2 in solid state[1] but neither the kinetics and mechanisms of this reaction nor the interaction of CuI with other mercury(II) halides seem to be reported. In an attempt to obtain some new solid state materials and mixed halide complexes like $AgHgClI_2$ and $AgHgCl_2I$ formed in solid state[2], we studied the reaction of $HgCl_2$ with CuI and CuBr in solid state. Though the expected mixed halides could not be detected, the information obtained on the mechanistic aspect is worth reporting. The reaction of $HgCl_2$ with CuI is multi-step, and different molar ratios of reactants give rise to different products, HgI_2 being formed as an intermediate in all cases. Contrary to the above, $HgCl_2$–CuBr reaction is a simple exchange process. Formation of several solid solutions among the reactants and products were also noted.

Experimental

Materials. $HgCl_2$ (BDH, AR Grade) was used without further purification. Copper(I) iodide and copper(I) bromide, being photosenstive, were prepared afresh for each set of experiments following the methods of Berthemot,[3] Guichard[4] and Lean and Whatmough.[5] X-Ray patterns of the products showed them to be single phase γ-CuI[6] and γ-CuBr.[7]

Cu_2HgI_4 was prepared as reported elsewhere.[8] Its X-ray pattern showed it to be single phase β-Cu_2HgI_4.[9]

Rate Measurements. The kinetics of the reactions were studied by placing mercury(II) chloride over copper(I) halides (each above 300 mesh size) in a vertically held glass tube described elsewhere[10,11] (The readability of the microscope was 0.001 cm and the average deviation of the measured values was ±0.00043 cm). Each experiment was performed in triplicate and the average of the three respective values was taken as the thickness of the product.

X-Ray Studies. Different molar mixtures of the reactants (above 300 mesh size) were mixed thoroughly in an agate mortar. One part of each mixture was heated in an air thermostat at 120 ± 0.05 °C, while the other was kept at 25 °C. Each set of mixtures was analysed, after about 60 h by Norelco Geiger Counter Diffractometer using Cu $K\alpha$ radiations with a Ni-Filter, applying 32 kV at 12 mA. The compounds present were identified by calculating the d values and comparing them with the standard values of the expected compounds.

Thermal Studies. Weighed amounts of $HgCl_2$ and CuI in molar ratios 1:4, 1:3, 1:2, and 1:1 were mixed in a Dewar flask, and the rise in temperature was noted against time. Similarly, thermal studies were carried out with different molar mixtures of $HgCl_2$ and CuBr. Same proportions of $HgCl_2$ and CuX (X is Br^- or I^-) as weighed for thermal studies were weighed separately, mixed thoroughly and pressed into tablets. Conductance of each tablet was measured by current ratio I–C bridge, applying 0.2 V and frequency 5×10^3 Hz.

Table 1. Dependence of parabolic rate constant on temperature for CuI–$HgCl_2$ reaction

Temperature °C	K/cm h^{-1}
80	4.01×10^{-9}
95	11.11×10^{-9}
110	23.33×10^{-9}
115	43.25×10^{-9}
121	80.00×10^{-9}

Table 2. Dependence of parabolic rate constant on temperature for CuBr–$HgCl_2$ reaction

Temperature °C	K/cm h^{-1}
75	0.4×10^{-7}
85	0.72×10^{-7}
96	1.11×10^{-7}
101	1.50×10^{-7}
107	1.75×10^{-7}

Results and Discussion

It is clear from Tables 3 and 4 that $HgCl_2$ reacts differently with CuBr and CuI.

CuI–$HgCl_2$ Reaction. CuI reacts with $HgCl_2$ in 4:1 molar ratio, giving Cu_2HgI_4 and CuCl.

$$4CuI + HgCl_2 \longrightarrow 2CuCl + Cu_2HgI_4 \quad (1)$$

Thermal (Fig. 1) as well as conductance (Fig. 2) measurements carried out at 25 °C provided no evidence for any sub-step in this reaction. However, the presence of HgI_2 (Table 3) in addtion to CuCl and Cu_2HgI_4 in the mixture kept at 25 °C, is indicative of the fact that HgI_2 is first formed:

$$2CuI + HgCl_2 \longrightarrow 2CuCl + HgI_2, \quad (1a)$$

which subsequently disappears giving Cu_2HgI_4 through (1b)

$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4. \quad (1b)$$

Table 3. X-Ray diffraction analyses of CuI-$HgCl_2$ reaction mixtures

Molar ratio CuI : $HgCl_2$	Compounds identified in mixtures: Kept at 25 °C	Compounds identified in mixtures: Heated at 120 °C and then cooled to 25 °C
4 : 1	CuCl, Cu_2HgI_4, and HgI_2	CuCl and Cu_2HgI_4
3 : 1	CuCl, Cu_2HgI_4, and HgI_2	CuCl, Cu_2HgI_4, and HgI_2
2 : 1	CuCl, Cu_2HgI_4, and HgI_2	CuCl and HgI
1 : 1	CuCl, Cu_2HgI_4, HgI_2, and $HgCl_2$	CuCl, HgI_2, and $HgCl_2$
1 : 2	CuCl, HgI_2, and $HgCl_2$	CuCl, HgI_2, and $HgCl_2$

Table 4. X-Ray diffraction analyses of CuBr-$HgCl_2$ reaction mixtures

Molar ratio CuBr : $HgCl_2$	Compounds identified in mixtures: Kept at 25°C	Compounds identified in mixtures: Heated at 120 °C and then cooled to 25 °C
4 : 1	CuBr, CuCl, and $HgBr_2$	CuBr, CuCl, and $HgBr_2$
3 : 1	CuBr, CuCl, and $HgBr_2$	CuBr, CuCl, and $HgBr_2$
2 : 1	$HgBr_2$ and CuCl	CuCl and $HgBr_2$
1 : 1	CuCl, $HgCl_2$, CuBr, $HgBr_2$, and $HgCl_2$	CuCl and HgClBr
1 : 2	CuCl, HgClBr, $HgBr_2$, and $HgCl_2$	CuCl, HgClBr, and $HgCl_2$

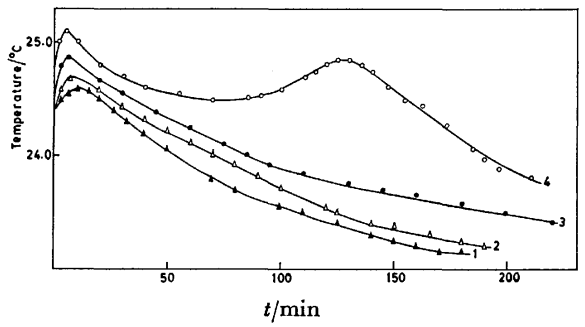

Fig. 1. Temperature rise as a function of time for CuI and $HgCl_2$ reaction.
Molar ratios (1) 4:1, (2) 3:1, (3) 2:1, (4) 1:1.

As reaction (1b) is extremely fast, disappearance of HgI_2 through (1c) looks improbable:

$$HgCl_2 + HgI_2 \longrightarrow 2HgClI. \quad (1c)$$

However, at higher temperature, reaction (1c) is known to occur appreciably, but on cooling the product HgClI decomposes immediately into its components.[12]

An equimolar mixture of HgI_2 and $HgCl_2$ kept at 25 °C did not show any evidence for the formation of HgClI even after about 6 d. Hence, the possibility that HgI_2 is consumed by $HgCl_2$ through step (1c) is completely ruled out. The overall reaction in 4:1 molar mixture of CuI and $HgCl_2$ will therefore, be as follows:

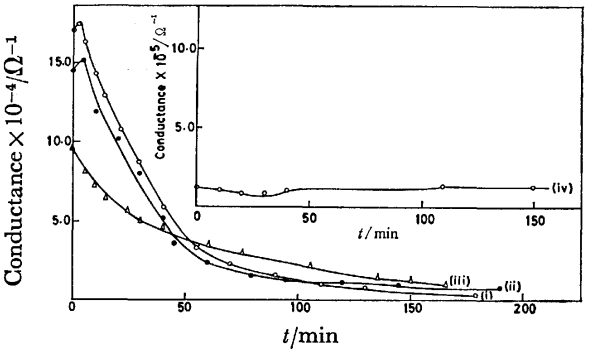

Fig. 2. Change in conductance as function of time for CuI and $HgCl_2$ reaction.
Molar ratios (i) 4:1, (ii) 3:1, (iii) 2:1, (iv) 1:1.

$$2CuI + HgCl_2 \longrightarrow 2CuCl + HgI_2 \quad \text{(Slow)}$$
$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4 \quad \text{(Fast)}$$
$$4CuI + HgCl_2 \longrightarrow Cu_2HgI_4 + 2CuCl$$

The results of thermal (Fig. 1) and conductance (Fig. 2) measurements made with 3:1 molar mixture are similar to those obtained with 4:1 molar mixture. The presence of HgI_2 in 3:1 molar mixture even at higher temperature confirms the above view point and it is detected here in the end products because CuI in these mixture is not sufficient to convert whole of HgI_2 into Cu_2HgI_4. Hence, the overall reaction in 3:1 molar mixture is as follows:

$$4CuI + 2HgCl_2 \longrightarrow 2HgI_2 + 4CuCl \quad (2a)$$
$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4 \quad (2b)$$
$$6CuI + 2HgCl_2 \longrightarrow Cu_2HgI_4 + HgI_2 + 4CuCl$$

The X-ray analysis of the products of 2:1 molar mixture of CuI and $HgCl_2$ heated at 120 °C and cooled to 25 °C indicated the presence of only CuCl and HgI_2.

$$2CuI + HgCl_2 \longrightarrow 2CuCl + HgI_2 \quad (3)$$

The thermal (Fig. 1) curve for 2:1 molar mixture of CuI and $HgCl_2$ has only one inflection. It thus appears that this is a simple exchange reaction. The X-ray analysis of this mixture kept at 25 °C did show the presence of Cu_2HgI_4 but the one that was heated to 120 °C and then cooled to 25 °C did not indicate the presence of Cu_2HgI_4. It is presumed that Cu_2HgI_4 is consumed at higher temperature by the excess $HgCl_2$ present in this mixture:

$$Cu_2HgI_4 + HgCl_2 \longrightarrow 2HgI_2 + 2CuCl. \quad (3a)$$

This was confirmed by heating an equimolarmixture of Cu_2HgI_4 and $HgCl_2$ at 120 °C. The X-ray analysis showed only the presence of HgI_2 and CuCl. Hence, the overall reaction sequence for 2:1 molar ratio at high temperatures is as follows:

$$2CuI + HgCl_2 \longrightarrow HgI_2 + 2CuCl \quad (3a)$$
$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4 \quad (3b)$$
$$Cu_2HgI_4 + HgCl_2 \longrightarrow 2HgI_2 + 2CuCl \quad (3c)$$
$$4CuI + 2HgCl_2 \longrightarrow 2HgI_2 + 4CuCl$$

Product analysis of 1:1 molar mixture of CuI and $HgCl_2$ heated to 120 °C (Table 3) indicated that CuCl and HgI_2 are the final products. The presence

of Cu_2HgI_4 in addition to CuCl, HgI_2, and $HgCl_2$, in the 1:1 mixture kept at room temperature (25 °C) indicated that the reaction is multi-step. Thermal (Fig. 1) and conductance (Fig. 2) measurements at room temperature did show two maxima in the curves.

The first inflection in the curve may be due to the formation of HgI_2 and its subsequent elimination by excess of CuI giving Cu_2HgI_4, both the steps being fast.

$$2CuI + HgCl_2 \longrightarrow 2CuCl + HgI_2 \quad (4a)$$

$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4 \quad (4b)$$

The second inflection in the curve may be due to the fact that presence of $HgCl_2$ pushes the reaction (3c) to an appreciable extent. This reaction, however, does not occur to an appreciable extent in 2:1 and other molar mixtures at the room temperature, hence the second inflection does not show up. This viewpoint is confirmed by the fact that Cu_2HgI_4 is completely consumed and is not detected even at room temperature in 1:2 mixture (Table 3).

1:1 Molar mixture of CuI and $HgCl_2$, kept at 120 °C, turns yellow after some time which on cooling to room temperature changes into red. HgClI is light yellow and stable at high temperature, and decomposes into HgI_2 and $HgCl_2$ when brought to room temperature.[12]

$$HgI_2 + HgCl_2 \xrightarrow{120°C} 2HgClI \xrightarrow{\text{cooled}} HgI_2 + HgCl_2 \quad (4d)$$

Hence, the overall reaction sequence in 1:1 molar mixture will be as follows:

$$2CuI + HgCl_2 \longrightarrow HgI_2 + 2CuCl \quad (4a)$$

$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4 \quad (4b)$$

$$Cu_2HgI_4 + HgCl_2 \longrightarrow 2CuCl + 2HgI_2 \quad (3c)$$

$$2HgCl_2 + 2HgI_2 \longrightarrow 4HgClI \quad (4d)$$

$$4CuI + 4HgCl_2 \longrightarrow 2HgI_2 + 2HgCl_2 + 4CuCl \quad (4d')$$

The X-ray analysis of 1:2 molar mixtures of CuI and $HgCl_2$ (Table 3) showed the presence of CuCl, HgI_2, and $HgCl_2$. By all account, the reaction sequence occurring in this mixture is the same as that in 1:1 molar mixture.

CuBr–$HgCl_2$ Reaction. CuBr reacts with $HgCl_2$ in 2:1 molar ratio giving CuCl and $HgBr_2$ (Table 4).

$$2CuBr + HgCl_2 \longrightarrow 2CuCl + HgBe_2 \quad (5)$$

Product analysis (Table 4) suggests that the reaction sequence in 4:1 and 3:1 molar mixtures is the same as in 2:1 molar mixture. CuBr in excess over 2:1 stoichiometry is left as such. Thermal (Fig. 3) and conductance (Fig. 4) measurements also support this view.

The products obtained in 1:1 molar mixture heated at 120 °C are CuCl and HgClBr (Table 4). In addition to these, the room temperature mixture shows $HgCl_2$ and $HgBr_2$.

The occurrence of second inflection in thermal (Fig. 3) as well as in conductance (Fig. 4) curves clearly shows that this is a two step reaction. The first step in this case as well, may be the formation of $HgBr_2$ through the simple exchange reaction (5). The second inflection refers to the consecutive reaction of $HgBr_2$ with the remaining amount of $HgCl_2$

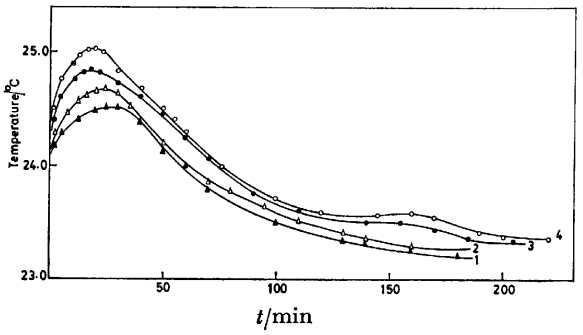

Fig. 3. Temperature rise as a function of time for CuBr–$HgCl_2$ reaction.
Molar ratios (1) 4:1, (2) 3:1, (3) 2:1, (4) 1:1.

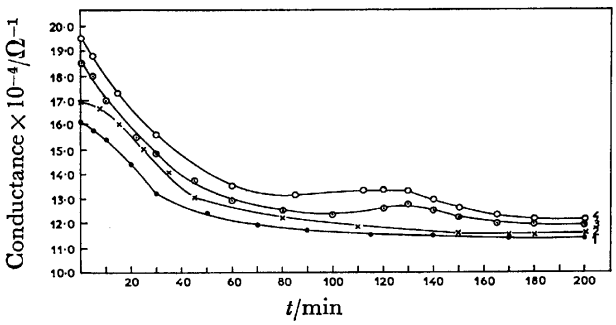

Fig. 4. Change in conductance as function of time for CuBr and $HgCl_2$ reaction. Molar ratios (1) 4:1, (2) 3:1, (3) 2:1, (4) 1:1.

in the reaction mixture giving HgClBr[12] through the much slower step:

$$HgCl_2 + HgBr_2 \longrightarrow 2HgClBr. \quad (6)$$

In case of 1:2 molar mixture, still larger proportion of $HgCl_2$ pushes reaction (6) to a still greater extent, making the second inflection slightly more pronounced. Hence, the complete reaction may be written as follows:

$$2CuBr + HgCl_2 \longrightarrow 2CuCl + HgBr_2$$

$$HgBr_2 + HgCl_2 \longrightarrow 2HgClBr$$

$$2CuBr + 2HgCl_2 \longrightarrow 2CuCl + 2HgClBr$$

Formation of HgClBr in earlier cases did not occur probably due to lesser proportion of $HgCl_2$ in the mixture.

Mechanism of Lateral Diffusion: In the kinetic experiment of the CuI–$HgCl_2$ system, soonafter the placement of $HgCl_2$ over CuI in the reaction tube, a dark brown layer appeared at the interface, which increased on CuI side with time, separating later into white and brown layers. On cooling to room temperature, the dark brown layer changed to scarlet red (Cu_2HgI_4 is dark brown above 70 °C and scarlet red below this temperature.[13] The analyses of the white and scarlet product layer at room temperature revealed them to be CuCl and β-Cu_2HgI_4. In the CuBr–$HgCl_2$ system also, the layer appearing at the interface increased on CuBr side and later separated into white and very light yellowish layers. They were analysed for CuCl and HgClBr.

The growth rate of the thickness of the product

layer in either case when reactants were in contact, follow the parabolic rate equation, $X^2=Kt$. The parabolic rate constant, K, in each case follows Arrehenius equation (Tables 1 and 2). The activation energies for the two reactions are respectively 77.11 ± 3.84 and 51.08 ± 1.29 kJ/mol.

The formation of the product on copper(I) halide side in another lateral diffusion experiment, where the reactants were placed with an air gap in between and the high vapour density of $HgCl_2$ suggest the possibility of vapour phase reaction. However, in a set of lateral diffusion experiments, the rate of product growth was found to decrease with increase in the length of the air gap. This fact and also the magnitude of activation energy[14] show that these reactions proceed through surface migration. The reaction continues *via* counter diffusion of Cu^+ and Hg^{2+} through the product layers.

Product analyses by X-ray diffraction, indicated the formation of solid solutions between CuI–CuCl, CuCl–Cu_2HgI_4, and CuBr–CuCl.

We are thankful to Dr. B. Rama Rao, Regional Research Laboratory, Hyderabad for the help in X-ray measurements and to Council of Scientific & Industrial Research, New Delhi for supporting this project.

The Separation of Cobalt(II), Copper(II), Zinc(II), Lead(II), and Cadmium(II) as Their 3-Methyl-1-phenyl-4-thiobenzoyl-5-pyrazolone (SBMPP) Chelates by Thin-layer Chromatography on Silica Gel

V. S. Chouhan and G. N. Rao*

Chemistry Department, Indian Institute of Technology, New Delhi 110016, India

(Received September 16, 1980)

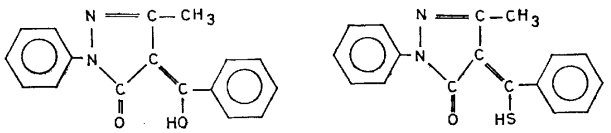
Thin-layer chromatographic separation technique has been employed for the separation of Co(II), Ni(II), Cu(II), Zn(II), Pb(II), and Cd(II) as their 3-methyl-1-phenyl-4-thiobenzoyl-5-pyrazolone (SBMPP) chelates. Metal chelates are intensely coloured and so no additional reagent was needed for the development of spots. Silica gel G was used as an adsorbent in the form of thin layer coating (0.25 mm) on glass plates (5 cm×20 cm). The R_f values of SBMPP and metal–SBMPP chelates have been determined by the ascending method with pure solvents and various binary solvent mixtures on thin layer of silica gel. In benzene the order of R_f values is Cd(II)<Pb(II)<Zn(II)<Co(II)<SBMPP<Ni(II)=Cu(II). By employing solvents like dichloromethane, benzene, and toluene, mutual separation of metal complexes was achieved successfully. The mixed solvents are more useful for the mutual separation of chelates than the pure solvents.

Thin-layer chromatography has been employed to separate metal ions using some chelating ligands.[1] In our laboratory extensive work has been conducted on the analytical applications of acylpyrazolones[2–6] in solvent extraction, spectrophotometric estimations and gravimetric determinations. Recently the authors have reported the solvent extraction of cobalt(II), zinc(II), and europium(III) with a new chelating ligand 3-methyl-1-phenyl-4-thiobenzoyl-5-pyrazolone (SBMPP),[5,7] Preliminary results on the utility of SBMPP[8] have been also published. It has been found that 4-benzoyl-3-methyl-1-phenyl-5-pyrazolone (BMPP) is comparable to thenoyl trifluoroacetone (TTA) in the solvent extraction of metals.[9] It is reasonable to expect SBMPP to be comparable to (thiothenoyl) trifluoroacetone (STTA) as analytical reagent since these are thioderivatives of BMPP and TTA respectively. In this paper the results of our original studies on thin-layer chromatographic separation of metals as their SBMPP chelates on silica gel are reported. Honjo and Kiba[10] have earlier described the separation of transition metals as their STTA chelates by thin-layer chromatography on silica gel.

Experimental

Apparatus and Reagents. Glass chromatographic plates (5 cm×20 cm), chromatographic chamber and universal applicator (Toshniwal) were used. Sample solutions were prepared by dissolving the metal chelates in acetone. Silica gel G (BDH), incorporating 13% calcium sulphate as binder was used as adsorbent for the thin-layer chromatography.

Developing Solvents. Analar reagent grade of methanol, ethanol, 2-propanol, 1-butanol, diethyl ether, dichloromethane, chloroform, carbon tetrachloride, benzene, toluene, cyclohexane, and hexane were used. They were purified by standard methods, if necessary. It has been found that SBMPP forms stable and extractable chelates with a specific color with many metal ions.[8] Spectrophotometric methods for the estimation of cobalt(II) and nickel(II) with SBMPP have been developed.[5] Solid complexes of cobalt(II), nickel(II), copper(II), zinc(II), lead(II), and cadmium(II) with SBMPP were prepared by dissolving their respective acetates in aqueous media followed by adding requisite amounts of ethanolic solution of SBMPP. The complexes were filtered, purified by recrystallization from suitable solvents and analysed. The ligand SBMPP was prepared by passing hydrogen sulphide gas and hydrogen chloride gas through a solution of BMPP in absolute ethanol, maintaining the temperature at 0 °C. This method is similar to the one employed by Honjo and Kiba[11] for the preparation of (thiothenoyl) trifluoroacetone. Structural formulas of SBMPP and BMPP are shown in Fig. 1. Cryoscopic determination of molecular weight in benzene gave a value of 296±4 (calculated molecular weight of SBMPP is 294). Analytical data and some important characteristics like λ_{max} and ε_{max} of the ligand SBMPP and complexes of SBMPP with metals are given in Table 1.



BMPP SBMPP

Fig. 1. Structural formulas of SBMPP and BMPP.

Procedure. Chromatographic plates were prepared by applying 0.25 mm thick coating of silica gel slurry with the help of universal applicator. Coated plates of the silica gel were dried for 20—30 min at 25±2 °C and then they were activated in an oven for two hours at 110 °C. The plates were stored over calcium chloride in a desiccator. With the help of a capillary tube a 5-μl portion of sample solution is spotted on the thin layer at definite intervals within about 2 cm from one end of the plate. One millimolar solutions of the metal chelates in acetone were used to prepare the sample. The spots were then air dried at room temperature (25±2 °C). The plate was placed in a chromatographic chamber containing an organic solvent or solvent mixture (20 ml), so that the plate dips into the solvent upto 1 cm below the sample spot. The solvent migrates upwards through the thin layer separating the sample into spots by ascending development. When the solvent proceeded to ≈10 cm from the sample spot the development was stopped and the plate was taken out of the chromatographic chamber. It was then exposed to air. Since the metal chelates showed characteristic colours (colours are mentioned in Table 1) no spraying with additional developing reagent was needed.

The resulting chromatogram is generally characterized

a) Spots disappear during development. Average deviation of R_f values = 0.02.

by R_f values which are calculated from the following equation.

$$R_f = \frac{\text{Distance (cm) travelled by the substance}}{\text{Distance travelled by the solvent}}$$

Results and Discussion

The R_f value measures the velocity of movement of the spot relative to that of the solvent front. Moreover the R_f value is a measure of the interaction among solute, solvent and adsorbent and is reproducible and characteristic for each solute in a given solvent–adsorbent system under specified conditions.

Some typical results of the development of SBMPP and its metal STTA chelates with individual pure solvents on a silica gel employing the ascending method are summarised in Table 2. Metal chelates can be divided into three groups on the basis of their chromatographic behaviour. (1) Chelates which do not migrate from the sample spot (with carbon tetrachloride, cyclohexane and hexane) (2) Chelates which can be developed to moderate distances over a comparatively wide range (with toluene, benzene and dichloromethane) (3) Chelates which move upto solvent front (methanol, ethanol, chloroform, diethyl ether, and 2-propanol). The average deviation of R_f values was 0.02. The R_f values of SBMPP chelates in benzene increased in the order of Cd(II)<Pb(II)<Zn(II)<Co(III)<SBMPP<Ni(II), Cu(II). By employing solvents like dichloromethane, benzene and toluene, separation of metal complexes was obtained successfully. Representative chromatograms of SBMPP and its metal chelates in benzene and dichloromethane are shown in Fig. 2. Results indicate that the distance of the development on the chromatographic plate depends on the polarity of the solvent. Honjo and Kiba[10] reported that R_f values of STTA chelates generally increased in the order of: Cd(II)<Zn(II)<Pb(II), STTA<Hg(II)<Co(II), (III)<Cu(II)<Ni(II).

It was considered interesting to study the effect of binary mixtures of solvents in the thin layer chromatography of SBMPP and its metal chelates and some representative results are listed in Table 3. The average deviation of the R_f values is 0.02. It is seen that the mixed solvents could separate the SBMPP chelates of metals more successfully than the pure

Average deviation of R_f values=0.02.

solvents. Some typical results are shown in Fig. 3. Among these binary solvent mixtures the pairs of benzene–carbon tetrachloride, toluene–chloroform, and chloroform–carbon tetrachloride were suitable for the separation of metal chelates. The R_f values of SBMPP chelates in benzene–carbon tetrachloride increased in the order Cd(II)<Co(III)<SBMPP<Pb(II)<Zn(II)<Cu(II)<Ni(II).

The effectiveness of binary solvent mixtures in the separation of SBMPP chelates is probably due to some demixing of mixed solvents leading to some changes in the solvent ratio. Since the adsorbability of each solvent on the silica gel is different, this may lead to better separation of the developed spots. According to Honjo and Kiba[10] binary mixtures of solvents show a similar beneficial effect in the thin layer chromatographic separation of STTA chelates of metals on silica gel.

The sequence of R_f values obtained with the SBMPP chelates differs from the acetylacetonate series,[12,13] the dithiazonate series[14,15] or the diethyldithiocarbamate.[16,17] Chelates of SBMPP are similar to those of STTA and do not form hydrates like acetylacetonate chelates of metals. Further nickel chelate of SBMPP is red and diamagnetic while that of BMPP is green dihydrate which is paramagnetic.[4,5] Cobalt(II) forms stable paramagnetic chelate with BMPP which is a dihydrate while it forms diamagnetic chelate containing three moles of ligand with SBMPP in which cobalt is present in the oxidation state three.[4] Though there are some differences, the behaviour of SBMPP chelates is closer to that of STTA chelates than others such as dithiazonates and acetylacetonates.

In conclusion it can be stated that thin layer chromatographic separation technique is useful for the separation of transition metal ions as their SBMPP chelates using certain solvents and mixtures of solvents.

^{14}N Nuclear Quadrupole Relaxation in *N*-Methylpiperidine

Hisao NEGITA,* Tsuneo KUBO, and Michio MAEKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received March 23, 1981)

Synopsis. Two crystal modifications of *N*-methylpiperidine were found by means of the nuclear quadrupole resonance (NQR) of Nitrogen-14. From the temperature dependence of the ^{14}N spin-lattice relaxation times (T_1), it is deduced that the α-form has a lower activation energy for the reorientation of the methyl group than the β-form.

The ^{14}N nuclear quadrupole resonance (NQR) spectrum of *N*-methylpiperidine was first reported by Colligiani *et al.*[1] In the present research we have attempted to obtain further information on the dynamical properties of this compound from the ^{14}N nuclear quadrupole relaxation. The spin-lattice relaxation time (T_1) was measured by the pulse method, and the molecular motions in this compound will be discussed.

Experimental

^{14}N NQR measurements were carried out using a pulse spectrometer described previously.[2] The resonance lines were observed by means of the spin-echo signals, using a 90°—180° pulse sequence series. The spin-lattice relaxation time (T_1) was determined by the repeating-90°—180°-pulse method.[3] The pulse width of a 90° pulse was about 50 μs. The spin-echo signal was averaged by means of a Nicolet Instrument Model 527 signal averager. The temperature was controlled by the method of Abe.[4] The temperature was stabilized within ±0.1 K. The frequency was measured by means of a frequency counter, TR-5104, from the Takeda Riken Co.

N-Methylpiperidine of an extra-pure reagent grade was purchased from the Wako Pure Chemical Ind. Co. and was purified by distillation. About 20 g of the reagent was used for the measurement.

Results and Discussion

In the case of the nitrogen-14 resonance, a pair of NQR absorption lines, ν_- and ν_+, are observed, and the frequencies are expressed as follows:

$$\nu_\pm = \frac{|e^2Qq|}{4h}(3\pm\eta), \qquad (1)$$

where $|e^2Qq/h|$ and η are the quadrupole coupling constant and the asymmetry parameter respectively. Table 1 shows the results at the temperature of liquid nitrogen. The α-form, the ^{14}N NQR spectrum of which was observed by Colligiani *et al.*,[1] is obtained by cooling the compound to the temperature of liquid nitrogen. This form is transformed to the β-form at about 157 K by rapid warming, but remains the same upon slow warming and melts at about 163 K. The data for the α-form were checked again and are listed for comparison.

TABLE 1. ^{14}N NQR PARAMETERS IN α- AND β-FORMS OF *N*-METHYLPIPERIDINE

	ν_-/MHz	ν_+/MHz	$(\|e^2Qq/h\|)$MHz	η/%
α-Form	3.6898	3.7803	4.9801	3.63
β-Form	3.7674	3.8262	5.0624	2.32

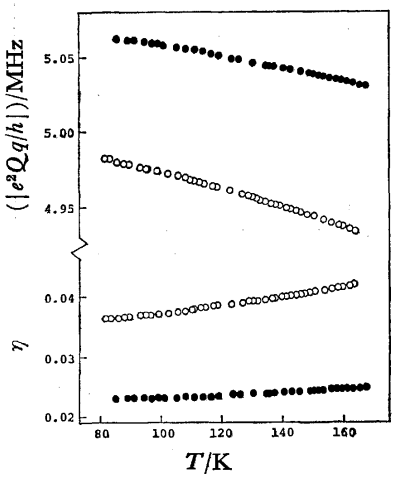

Fig. 1. The temperature dependence of the quadrupole coupling constant and asymmetry parameter in the α-form (○) and β-form (●) of *N*-methylpiperidine.

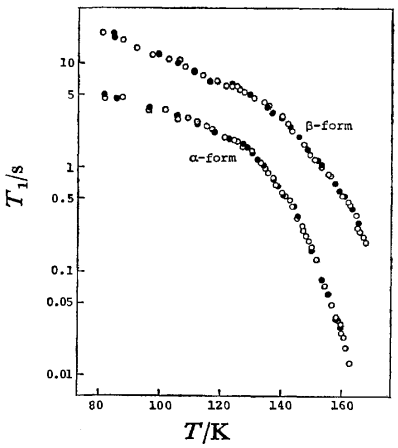

Fig. 2. The temperature dependence of the spin-lattice relaxation times in *N*-methylpiperidine. ●: ν_- line; ○: ν_+ line.

The temperature dependences of the quadrupole coupling constant and the asymmetry parameter in *N*-methylpiperidine in the temperature range from the temperature of liquid nitrogen to the melting point are shown in Fig. 1. The temperature coefficient of the quadrupole coupling constant in the α-form (denoted by the open circle) is slightly smaller than that in the β-form (denoted by the filled circle). This may indicate that the packing of the molecules in the β-form is closer than that in the α-form.

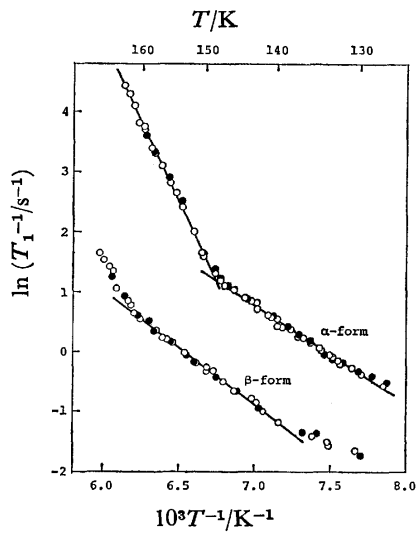

Fig. 3. $\ln(1/T_1)$ *vs.* $10^3/T$ in *N*-methylpiperidine. ●: ν_- line; ○: ν_+ line.

The temperature dependences of the spin-lattice relaxation times (T_1) for the ν_- and ν_+ lines in the α-form and β-form of *N*-methylpiperidine are shown in Fig. 2. In each form, the T_1's for both ν_- and ν_+ lines are coincident within the limits of experimental error. This suggests that the molecular motions equally contribute to T_1 for both resonance lines.

In the case of the α-form, up to 115 K the spin-lattice relaxation time decreases monotonously as the temperature rises. In this region, T_1 is determined by the torsional lattice vibration and is dominated by two indirect phonon processes, so that $1/T_1 \propto T^2$. In the temperature range from about 130 K to the melting point, T_1 drops exponentially as the temperature rises. This process can be attributed to the reorientation of the methyl group around the N–C bond. In this case, the relaxation formula is expressed as follows:

$$1/T_1 = C\tau/(1+\omega^2\tau^2), \tag{2}$$

and:

$$\tau = \tau_0 \exp(E_a/RT), \tag{3}$$

where C is a constant which describes the strength of the interaction; ω is the resonance angular frequency; τ is the correlation time of the motion, which changes according to the Arrhenius relation (Eq. 3); τ_0 is the inverse frequency factor, and E_a is the activation energy of the motion. In the low-temperature region of the T_1 minimum, where $\omega\tau \gg 1$, the following equation is obtained:

$$\ln(1/T_1) = -E_a/RT + f(\omega), \tag{4}$$

where $f(\omega)$ is a function of ω, the temperature dependence of which is negligible. In Fig. 3, the $\ln(1/T_1)$ value is plotted as a function of $1/T$. A break point is found near 150 K; T_1 values below 150 K are dominated by different molecular motions. That is, the dominant relaxation mechanism below 150 K is considered to be caused by the reorientation of the methyl group around the N–C bond, whereas that above 150 K is brought about by the reorientation of the molecule. In fitting Eq. 4 to the experimental T_1 values, the activation energies for these motions are determined to be 12.6 kJ/mol for the former motion and 51.2 kJ/mol for the latter.

The ^{14}N spin-lattice relaxation times (T_1) in *N,N'*-dimethylpiperazine were measured in the temperature range from 77 K to the melting point by Tzalmona and Kaplan.[5] T_1 drops exponentially above 200 K. It is considered that this is caused by the switching between the two chair configurations. The activation energy for this motion is calculated to be 56.5 kJ/mol. Therefore, we consider that the molecular motion with the barrier of 51.2 kJ/mol in *N*-methylpiperidine is the switching motion between the two chair configurations.

In the case of the β-form, below 130 K the spin-lattice relaxation time is determined by the torsional lattice vibration. On the other hand, in the temperature range from 140 K to the melting point (about 168 K), T_1 drops rapidly as a function of the temperature. This may be caused by the reorientation of the methyl group. In Fig. 3, the $\ln(1/T_1)$ value is plotted as a function of $1/T$. In fitting Eq. 4 to the experimental T_1 values, the activation energy for this motion is evaluated to be 15.8 kJ/mol. This value is larger than that in the α-form. This indicates that the methyl group in the β-form is slightly more suppressed than is the α-form. That is, the packing of the molecules in the α-form is less compact than that in the β-form. This is parallel to the finding of the temperature dependence of the quadrupole coupling constant.

(Received March 30, 1981)

Synopsis. The crystal structure of $(H_3O)_2[(Mo_6Cl_8)Cl_6]\cdot 6H_2O$ was determined by the X-ray method and its near-infrared absorption spectra were measured. These results can be interpreted by a view that the molybdenum nuclei of this complex are regarded as a small metallic particle.

The energy levels of conduction electrons in metal are generally regarded as continuous. However, in small metallic particles, the intervals of the energy levels are no longer small in comparison with other energies such as the thermal energy, kT and the electronic Zeeman energy, μH. It has been theoretically predicted[1] that anomalies occur in the macroscopic properties of small metallic particles, such as the electron heat capacity and the spin paramagnetic susceptibility, due to the restriction of the excitations of conduction electrons.

Some experiments have been recently performed[2] in order to detect these kinds of anomalies. The samples used in these experiments were small metallic particles prepared by the gas evaporation method and other techniques, the average diameters of which were 40—200 Å. With regard to such samples, size and shape of each particle were inhomogeneous, and only the average properties of all particles were measurable. Then the authors paied their attention to a polynuclear complex $(H_3O)_2[(Mo_6Cl_8)Cl_6]\cdot 6H_2O$ as the sample of this kind. They thought that the molybdenum nuclei of this complex could be regarded as a small metallic particle homogeneous in both size and shape, and some anomalies as small metallic particles would be detectable. In the present paper, the X-ray structure analysis and the near-infrared absorption spectra measurement for $(H_3O)_2[(Mo_6Cl_8)Cl_6]\cdot 6H_2O$ crystal are reported.

Experimental and Structure Determination

The sample was prepared by the method of Sheldon modified by Jolly.[3] Single crystals were obtained from the 6 mol dm^{-3} HCl solution by evaporating the solvent slowly. For the X-ray experiment a single crystal enclosed in a glass capillary with its mother liquor was used to prevent its efflorescence. Intensity data were collected on the Weissenberg camera with Ni-filtered Cu $K\alpha$ radiation. Crystal data are: Monoclinic, $a=17.27(11)$, $b=9.17(6)$, $c=18.55(12)$ Å, $\beta=98.0(7)°$, $Z=4$, and space group C2/c. The structure factors for 865 independent reflections were obtained. The structure was solved by the heavy atom method, refined by the full-matrix least-squares method, and the final R factor was 0.117. The positions of H atoms could not be determined. The near-infrared absorption spectra were measured on a Varian Cary 17-I spectrophotometer at 77 K and room temperature. In the measurement a quartz Dewer vessel was used. The measured data were corrected for the blank data measured in the absence of the sample.

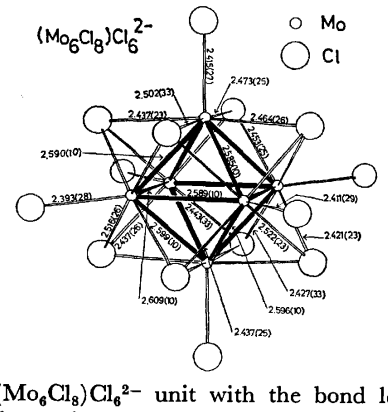

Fig. 2. $(Mo_6Cl_8)Cl_6^{2-}$ unit with the bond lengths(Å). There is an inversion center at the center of this unit. The estimated standard deviations are in parentheses.

Results and Discussion

The atomic parameters are deposited as Document No. 8212 at the Office of the Editor of the Bulletin of the Chemical Society of Japan, and Fig. 1 shows the crystal structure viewed along the b axis. The structure consists of the discrete units of $(Mo_6Cl_8)Cl_6^{2-}$ (shown in Fig. 2). In this unit, six Mo atoms form an approximate regular octahedron, and their configuration is very similar to that in bulk Mo metal, *i.e.*, b.c.c.structure. However, the distance between the neighboring Mo atoms (2.59 Å on the average) is shorter than in bulk Mo metal (2.72 Å), in other words, the Mo atoms are packed closer so that the overlap of the Mo atomic orbitals is large in this unit.

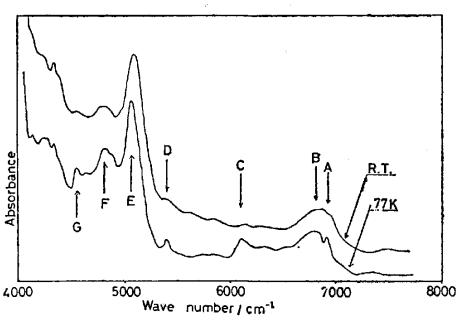

Fig. 3. The near-infrared absorption spectra of $(H_3O)_2[(Mo_6Cl_8)Cl_6]\cdot 6H_2O$ crystal at 77 K and room temperature.

Also eight Cl atoms form an approximate cube outside the Mo octahedron. The distance between Mo atoms and these 8 Cl atoms (2.46 Å on the average) agrees with the sum of the ion radii of sexivalent Mo^{6+} (0.62 Å) and Cl^- (1.81 Å), in contrast with that the Mo atoms are formally divalent in this material. Hence, the valence electrons of Mo atoms may be delocalized. These facts suggest that the feature of metallic bonding is still present even in such a small quasi-metallic system. In addition, these units are apart from one another in the crystal. It is quite possible to regard the crystalline state of this material as an aggregation of small metallic particles which are homogeneous in both size and shape.

Then the authors tried to estimate the order of the energy level interval of conduction electrons at the Fermi energy(δ), by regarding the 24 d-electrons of Mo atoms as conduction electrons and by applying the free electron model to this system. The formula $\delta=2\varepsilon_F/3N$ (ε_F: Fermi energy, N: number of electrons), which is applicable to a cube of bulk metal, was used in this estimation. The obtained order of energy level interval (about 1.0×10^{-19} $J=5.0\times10^3$ cm^{-1}) corresponded to the photon energy of the near-infrared region. Figure 3 shows the near-infrared absorption spectra measured for this crystal. The seven peaks observed are divided into two groups on the basis of their behaviors against temperature, *i.e.*, the A, C, D, F, and G peaks become broader at room temperature, while the B and E peaks do not show such temperature dependence. The latter peaks were ascertained to be attributable to the vibrational overtones of the water of crystallization. On the other hand, it is not adequate to attribute the former peaks to the molecular or lattice vibration of $(Mo_6Cl_8)Cl_6^{2-}$ unit, considering the heavy masses of the atoms which constitute this unit. In fact, the absorptions which arise from such vibrations were found in the far-infrared region.[4] Therefore, the peaks, except for B and E, should be related to various electronic transitions, where electronic levels split by low symmetry of the crystal may be involved. Also their peak positions fall satisfactorily within the range estimated above, though it remains a question that the valence electrons of molybdenum atoms in this case are assumed as free electrons. Then it is concluded that these absorption peaks may be attributed to the electronic transitions between the energy levels of conduction electrons which manifest the smallness of the system. From the standpoint of small metallic particles, the observation of such transitions is one of the evidences of energy quantization with respect to conduction electrons.

The basic concept of the authors is to regard the nuclei in a polynuclear complex as a small metallic particle. However, since the nuclei of single complex ion in the present material consist of only six molybdenum atoms, the energy level intervals of electrons are too large and the electronic states may not be well described by the Bloch functions. It is highly desired for the study of small metallic particles to synthesize complex ions which involve more metal atoms.

The authors wish to thank Dr. Hanako Kobayashi and Prof. Tsuyoshi Murao of Kyoto University for their continuous encouragement, and Prof. Tadamasa Shida of Kyoto University for his kind offer of the spectrophotometer.

Nuclear Quadrupole Resonance of Chlorine-35 in Molybdenum(V) and Rhenium(III) Chlorides. Evidence for the Crystal Modifications of $MoCl_5$

Yoshio KUME*,† and Daiyu NAKAMURA

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 13, 1981)

Synopsis. The ^{35}Cl NQR frequencies were determined for molybdenum(V) and rhenium(III) chlorides at various temperatures. Two crystal modifications, showing two and three ^{35}Cl NQR frequencies, were found for the former compound. The three resonance frequencies observed for the latter compound are attributable to three chemically different chlorine atoms in the crystal.

Molybdenum(V) and rhenium(III) chlorides are known to form crystals in which polymeric units, Mo_2Cl_{10} and Re_3Cl_9, respectively, are discernible.[1,2] It is interesting to examine the temperature dependence of ^{35}Cl NQR frequencies for both compounds, because there exist both terminal and bridging chlorine atoms, which usually yield temperature dependences considerably different from each other.

Experimental

Molybdenum(V) chloride $MoCl_5$ was procured from commercial sources and was purified by means of a sublimation method similar to that described in the literature.[3] Commercial $MoCl_5$ was placed in the end of a Pyrex bulb train, and the sublimation system including the train was evacuated. When the bulb containing crude $MoCl_5$ was heated to about 130 °C, dark purple crystals were deposited in the next-neighboring bulb. The temperature of this bulb was maintained at a lower temperature than about 40 °C. After the sublimation process had finished, the bulb was sealed off at each side, with great care being taken not to heat the deposited crystals. The sample thus prepared is called $MoCl_5$ (I). When the bulb containing $MoCl_5$ (I) was heated very rapidly by a flame to the melting point of $MoCl_5$, the deposited crystals were melted without breaking the Pyrex bulb. The melted $MoCl_5$ was cooled very slowly, and black crystals with a bluish gloss were obtained. The sample obtained after melting is called $MoCl_5$ (II). Since the X-ray analysis of $MoCl_5$ was carried out with the sample prepared by melting,[1] $MoCl_5$ (II) is considered to have a dimeric structure. Commercial rhenium(III) chloride $ReCl_3$ was purified by use of a similar sublimation method. The chloride was sublimed at a temperature of about 450 °C under reduced pressure.

Chlorine NQR was observed by means of a modified Dean-type spectrometer in a frequency-modulation mode.[4]

Results and Discussion

Table 1 shows the NQR frequencies of ^{35}Cl in $MoCl_5$ and $ReCl_3$ at room, Dry Ice, and liquid-nitrogen temperatures.

The sample $MoCl_5$ (I) yielded four rather closely separated resonance frequencies at various temperatures observed. The second-highest frequency line was broad and weak, whereas other lines were moderately strong and had a relatively narrow line-width. The relative intensity of the second-highest line to that of other lines varied depending on the samples, which were different from each other in the deposit temperature in the sublimation purification process. The sample deposited at a lower temperature gave a weaker second-highest line. Furthermore, the resonance frequencies of the second-highest line determined at various temperatures agree with those reported by Brown and Kent[5] for Mo_2Cl_{10}. The sample $MoCl_5$ (II), prepared by melting, showed two widely separated broad resonance lines at liquid N_2 temperature, the higher-frequency line of which yielded a resonance frequency identical with that of the second-highest line of $MoCl_5$ (I). The lower-frequency line of the doublet, which escaped detection in the study of Brown and Kent,[5] was weaker. With increasing the tem-

† Present address: Faculty of General Education, Azabu University, Fuchinobe 1-17-71, Sagamihara, Kanagawa 229.

perature from liquid N_2 temperature, this line showed a positive temperature coefficient, as shown in Fig. 1; it gradually became weaker until it faded out at about −50 °C. These experimental facts indicate that molybdenum(V) chloride directly crystallized by sublimation gives three ^{35}Cl NQR frequencies at various temperatures, whereas the compound once melted yields two widely separated lines. Accordingly, it is concluded that there exist two crystalline modifications in molybdenum(V) chloride: one, the crystal directly deposited from its vapor, has at least three nonequivalent chlorine atoms in the crystal, while the other is the crystal once melted and contains at least two chemically different chlorine atoms.

Three widely separated ^{35}Cl NQR frequencies were observed for rhenium(III) chloride at various temperatures studied. This indicates that there exist three chemically nonequivalent chlorine atoms in the crystal. According to the X-ray crystal analysis by Cotton and Mague,[2] crystallographically equivalent trimer units, Re_3Cl_9, exist in the crystal. In a trimer unit, there are three chemically nonequivalent chlorine atoms: terminal chlorine, **a**, asymmetric bridging chlorine, **b**, and symmetric bridging chlorine, **c**. Consequently, the present NQR results agree well with those of the X-ray analysis.

The highest-frequency line of the triplet is greatly separated from the remaining two lines. By referring to the NQR results of dimeric IIIB metal halides,[6,7] this line can be assigned to the terminal chlorine, **a**, and the lower-frequency lines, to the bridging chlorine atoms, **b** and **c**. Since the asymmetric bridging chlorine **b** forms a weak bridge bond with rhenium in the neighboring trimer, the chlorine atom may have a character of terminal chlorine to some extent. Accordingly, the middle-frequency and the lowest-frequency lines can be assigned to the bridging chlorine atoms, **b** and **c**, respectively.

The temperature coefficients, $|d\nu/dT|$, of the middle-frequency and lowest-frequency lines were very small (0.09 and 0.15 kHz K^{-1}, respectively, in the temperature range of −196—27 °C). Since bridging chlorine is usually bound more tightly than terminal chlorine, the thermally excited vibrational amplitude of the former chlorine atom is smaller than that of the latter. According to the simple Bayer-Kushida theory,[8,9] the coefficient, $|d\nu/dT|$, is proportional to the vibrational amplitude. This fact supports the above assignments of the observed resonance frequencies.

Further Comments on the Line-broadening of the Chlorine 35 NMR Spectra and the Local Structure around a Chloride Ion in Aqueous Solutions of Non-electrolytes

(Received May 15, 1981)

Synopsis. The remarkable line-broadenings of the ^{35}Cl NMR spectra observed for the KCl in aqueous solutions of non-electrolytes were explained well by considering the formation of water-cages which surround the non-electrolytes. This result, in turn, suggests that the line-width measurement is a useful method for determining local structures formed in solutions.

In the previous report on the ^{35}Cl NMR spectra,[1] we have reported the remarkable line-broadening observed for the KCl in the aqueous acetone system. This result seemed important because the line-broadening cannot be observed in an aqueous solution of KCl in which a so-called "contact-ion pair" is not formed. Stimulated by this line-broadening observation, we have now extended our study of line-widths to aqueous solutions of non-electrolytes in order to establish the origin of the line-broadening.

Let us first add a supplemental finding on the aqueous solution of dimethyl sulfoxide (DMSO hereafter). The ^{35}Cl line-width in of KCl in the H_2O–DMSO system was observed for various solvent components. In this mixed solution, KCl dissociates completely or does not exist in the form of a contact-ion pair. The results and the related physical quantities are summarized in Table 1. The observed concentration-dependence of the line-width is illustrated in Fig. 1. It can be seen from the figure that the line-width is as narrow as about 5—10 Hz both in pure water and in pure DMSO, while it becomes broader in a mixed solvent. For example, the viscosity-corrected line-width[2] in a 0.5 mole fraction of an aqueous DMSO solution is almost twenty times as broad as those observed in pure solvents. A chloride ion is known to be symmetrically solvated by water molecules in an aqueous solution. As DMSO is also known to solvate a chloride ion as strongly as water does, it is natural to consider that DMSO molecules can also exist as the nearest neighbours of a chloride ion. Therefore, the water molecules which solvate a chloride ion in the aqueous solution of KCl are replaced by DMSO molecules, one by one, by adding DMSO to the aqueous solution of KCl. That is to say, the field gradient at a chloride ion increases with the increase in the DMSO concentration, this results in the line-broadening due to the increase in the DMSO concentration. In the high-concentration range of DMSO, on the other hand, a chloride ion comes to be surrounded mostly by DMSO molecules, which again increases the symmetry around the chloride ion. Therefore, the line-width will again become narrower at a very high concentration of DMSO.

Let us now turn back to the aqueous acetone solution. We wanted to know why we observed line-broadening upon adding acetone to an aqueous solution of KCl.[1] As salts like KCl and NaCl are not dissolved in pure acetone, the line-broadening cannot be ascribed to the direct interaction between acetone and a chloride ion. It has been established in our previous works[3] that, in an aqueous acetone solution, water molecules form a cage-structure by surrounding

Table 1. Chemical shifts, δ, line-width, $\Delta\nu$, and viscosity-corrected line-width, $\Delta\nu^\circ$, of ^{35}Cl NMR in the DMSO–H_2O solvent system at 62 °C

Concentration x_{DMSO}	Chemical shift[a] δ/ppm	Line-width $\Delta\nu$/Hz	Viscosity[b] η/cP	Viscosity corrected line-width $\Delta\nu^\circ$/Hz

0.902	256	41	1.25	33
1.000	265	4.8	1.35	3.6

a) The exact Larmor frequency was divided by the ^{35}Cl resonance frequency (7.794 MHz) and expressed in ppm. Chemical shifts relative to aqueous potassium chloride can be obtained by subtracting 200 ppm from each value. b) 1 cP = 10^{-3} Pa s.

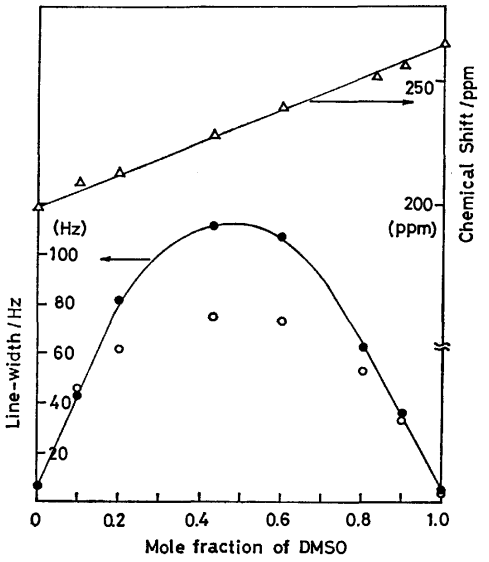

Fig. 1. Line-width and chemical shift of the ^{35}Cl NMR as a function of solvent component in DMSO–H_2O system.
△: Chemical shift, ●: observed line-width, ○: viscosity corrected line-width.

an acetone molecule. On the base of this idea, we can reasonably explain the observed line-broadening. In an aqueous acetone solution, chloride ions can exist in two ways. Some chloride ions can exist as isotropically solvated ions which can be responsible for narrower line-widths. Some other chloride ions, on the other hand, can take part in the formation of the cage which is formed by water molecules in the aqueous acetone solution. In the latter case, the local symmetry around a chloride ion is not spherical, which results in the appearance of a large field gradient at the chloride ion. Therefore, the line-width arising from this chloride ion is much broader than that of the isotropically solvated ion.

Next, let us consider the line-broadening observed in the ^{35}Cl NMR spectra of tetraethylammonium chloride (Et_4NCl hereafter) in a water solution. It has been shown in our previous report[1] that the concentration dependence of the line-width can be explained well by considering the equilibrium between two chemical species, namely, a free ion (the line-width of which is 11.6 ± 0.3 Hz) and a contact-ion pair (the line-width of which is 546 ± 194 Hz). Now we can give a more accurate image of the species referred to as a "contact-ion pair". As the outer part of an Et_4N^+ ion is composed of methyl groups which have a strong hydrophobic character, water-cage can be formed around the Et_4N^+ ion.[3] A chloride ion can exist in this solution either by dissolving in bulk water or by taking part in the formation of the cage-structure in place of a water molecule. The line-width corresponding to the former case is very narrow, because the local symmetry around the chloride ion is spherical. As the local symmetry is lowered by the asymmetric hydration in the latter case the line-width corresponding to this case can be very greatly broadended because of the large field gradient produced by the surrounding water dipoles.[4] Thus, we can conclude that the "contact-ion pair" which has been described in our previous report corresponds to the chemical species whose structure is composed of an Et_4N^+ ion surrounded by a water-cage and a chloride ion which takes part in the formation of the cage. Such a caging-in effect of fluoride ions has been ascertained by the X-ray diffraction study of the solid clathrate hydrate of tetraisopentylammonium fluoride.[5] It is of interest to add that the ^{35}Cl NMR lines corresponding to these two species are observed to be averaged single Lorentzians. This result suggests that the exchange rate between the free and in-cage species is faster than the NMR-time scale ($\approx10^{-7}$ s) and that the lifetime of the in-cage chloride ion is longer than the rotational correlation time of the chloride ion ($\approx10^{-11}$ s).[6] Incidentally, this type of line-broadening has not been observed for these aqueous solutions of KCl, NaCl, and NH_4Cl, simply because these cations cannot form water-cages in aqueous solutions. Thus, the apparent complexities observed for the concentration dependences of the line-widths can be understood by considering the local symmetry of the hydrations around chloride ions. This, in turn, suggests that the line-width measurement of the ^{35}Cl NMR spectra is a powerful and straightforward method for demonstrating cage-structure formations in aqueous solutions.

The authors wish to express their thanks to Mr. Yukihiro Yokoyama for his help in the ^{35}Cl NMR spectral measurements.

2) A viscosity-corrected line-width, $\Delta\nu^\circ$, is defined as follows using the measured line-width, $\Delta\nu$, and the viscosity, η:

$$\Delta\nu^\circ = \Delta\nu/(\eta/\eta_0),$$

where η_0 is a unit of viscosity. The validity of using a viscosity-corrected line-width for the discussion of line-broadening was confirmed as follows. The line-width of NaCl was measured in aqueous polyethylene glycol (av. MW 200, 4000, 20000). The line-width was found to be proportional to the mobility of the chloride ion as determined by conductivity measurements (R. Tamamushi, private communication) and also proportional to the viscosity of the solution, as long as the Walden product of the solution is less than 2.

Thermal Stability Enhancement of Liquid-crystal Phase by Charge-transfer Interaction in Binary Mixtures. Application of Solid-solution Model

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

Synopsis. Phase transition in liquid crystal of binary mixture consisting of electron donor and acceptor was examined by using modified solid-solution model. The charge-transfer interaction between donor and acceptor is essential for parallel molecular arrangement in liquid crystal, resulting in thermal stability enhancement of mesophase in binary mixture.

Much attention has been paid to a great number of liquid crystals, which show intermediate state between crystalline solid and isotropic liquid.[1] Intermolecular attractions appear to be essential for producing the parallel molecular arrangement characteristic of such a state. Binary systems have been often used to achieve extended liquid crystalline temperature ranges.[2,3] Usually, the mesophase→isotropic liquid transition temperature of binary mixture varies linearly with composition. However, large deviations from such a linearity are observable, if molecular complex formation takes place between the components of the binary system. Complex formation due to electron donor-acceptor (charge-transfer) interaction may be effective for parallel molecular arrangement in liquid crystals. Park *et al.* examined nematic phase→isotropic liquid transition temperature (T_{NI}) in the binary system of *N*-(*p*-methoxybenzylidene)-*p*-*n*-butylaniline (MBBA) and 4-cyano-4′-pentylbiphenyl (CPB) and in several closely related binary mixtures, because there was a possibility of a weak charge-transfer interaction between a donor of MBBA and an acceptor of CPB.[2] As is shown in (a) of Fig. 1, the experimental relation of T_{NI} to composition of MBBA–CPB mixtures exhibits a broad curve whose maximum is located near 1:1 mole ratio, and T_{NI} of mixture is higher than the straight line joining T_{NI} of the two components ((c) of Fig. 1). In the present paper, using modified solid-solution model, we shall show that the attractive forces between donor and acceptor due to charge-transfer interaction is essential for such a thermal stability enhancement of liquid-crystal phase.

In the following, we discuss nematic phase induced by charge-transfer interaction in binary mixtures composed of rod-like donors and acceptors. Let us denote mole fractions of donors and acceptors as x_D and x_A, ($x_D+x_A=1$), respectively. The nematic→isotropic transition temperatures of pure donor and acceptor components are indicated by T_D and T_A, respectively. In general, nematic phase has a high degree of long range orientational order of the molecules, but no long range translational order. The molecules are spontaneously oriented with their long axes approximately parallel. In the present paper, we only consider how Gibbs free energy of nematic phase is influenced by the manner of mixing of donors and acceptors. For this purpose, we examine a three-dimensional lattice where molecules are oriented with their long axes parallel. It is assumed that such

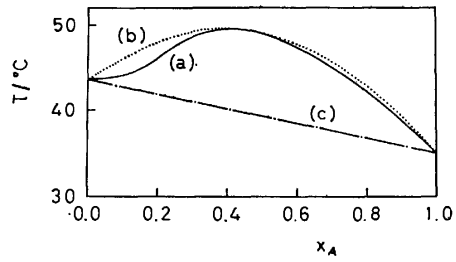

Fig. 1. Phase transition temperature of binary system of *N*-(*p*-methoxybenzylidene)-*p*-*n*-butylaniline (MBBA) and 4-cyano-4′-pentylbiphenyl (CPB). (a) indicates the experimental relation of nematic→isotropic transition temperature (T_{NI}) to mole fraction of CPB (x_A), as given by Ref. 2; (b), the theoretical relation of order→disorder transition temperature (T_c) to x_A; (c), the straight line joining T_{NI} of the two components. See text.

a lattice can be subdivided into two sublattices D and A, and that one site of D or A sublattice is surrounded by z equivalent nearest neighbor sites of A or D sublattice, respectively. Then, if the charge-transfer interaction between donor and acceptor is essential for parallel molecular arrangement to induce nematic phase, the nematic→isotropic phase transition should correspond to order→disorder phase transition for mixing of donors and acceptors. In other words, if the order of molecular arrangement of donors and acceptors remains, the system is supposed to be in nematic phase, while if the order is lost, it goes to isotropic liquid.

In order to show this situation more clearly, we take an approach of solid-solution model. Let us denote the numbers of sites of D and A sublattices as $N/2$ and $N/2$, respectively. The total number of donor and acceptor molecules in binary mixture is N, so that each site of D and A sublattices is occupied by either donor or acceptor. It is assumed that charge-transfer interaction acts in (1:1) manner between nearest neighbor donor and acceptor. In the system of pure donors ($x_D=1.00$), all the sites of D and A sublattices are occupied by donors at temperature T_D, while in the system of pure acceptors ($x_A=1.00$), by acceptors at temperature T_A. For binary mixtures, let us denote the numbers of donors and acceptors in D sublattice as $[^d_D]$ and $[^a_D]$, respectively, while the numbers of donors and acceptors in A sublattice as $[^d_A]$ and $[^a_A]$, respectively. We introduce order parameter X, ($0\leq X\leq 1$), in such a way that, if $0\leq x_D\leq 1/2$, $[^d_D]=(1/2)N\ x_D(1+X)$, $[^a_D]=(1/2)N\ (x_A-x_DX)$, $[^d_A]=(1/2)N\ x_D(1-X)$ and $[^a_A]=(1/2)N\ (x_A+x_DX)$. In other words, if $X=1$, all donors occupy sites of D sublattice, while if $X=0$, donors and acceptors occupy sites of D and A sublattices randomly. Similar expressions can be obtained in the case of $0\leq x_A\leq 1/2$. The state of $X=0$ is called disordered phase with

respect to mixing of donors and acceptors, while $X=1$, ordered phase. For order parameter X, the entropy for mixing donors and acceptors in binary mixture with composition (x_D, x_A) is then calculated as

$$S = k \ln \frac{\frac{N}{2}!}{[\frac{d}{D}]![\frac{a}{D}]!} \frac{\frac{N}{2}!}{[\frac{d}{A}]![\frac{a}{A}]!}$$
$$= -\frac{N}{2}k\{x_D(1+X)\ln x_D(1+X) + (x_A-x_DX)\ln(x_A-x_DX) + x_D(1-X)\ln x_D(1-X) + (x_A+x_DX)\ln(x_A+x_DX)\}. \quad (1)$$

Next, we examine the energy of our binary system in terms of order parameter X. We take only into consideration the intermolecular interaction energies between nearest neighbor molecules. The terms v_{DD}, v_{AA} and v_{DA} indicate the energies between a pair of donor-donor, acceptor-acceptor and donor-acceptor molecules in nearest neighbor sites, respectively. Note that v_{DD} and v_{AA} are weak stabilization energies due to van der Waals forces, while v_{DA} corresponds to stabilization energy due to charge-transfer interaction which is much stronger than v_{DD} and v_{AA}. Then, $v=(1/2)(v_{DD}+v_{AA})-v_{DA}\geq 0$. In terms of v, the energy, E, of binary mixture is given by

$$E = \frac{z}{2}N\{v_{DD}x_D^2 + 2v_{DA}x_Dx_A + v_{AA}x_A^2\} - zNx_D^2vX^2. \quad (2)$$

For binary mixture, because of strongly attractive charge-transfer interaction, the order parameter at temperature $x_DT_D+x_AT_A$ is assumed to be $X=1$. If there is no volume change, Gibbs free energy of the system is given by

$$G_o = E_o - (x_DT_D+x_AT_A)S_o, \quad (3)$$

where $E_o=zNv_{DA}x_D+(z/2)Nv_{AA}(x_A^2-x_D^2)$ and $S_o=-(Nk/2)\{2x_D\ln 2x_D+(x_A-x_D)\ln(x_A-x_D)\}$. At temperatures above $x_DT_D+x_AT_A$, we are only concerned with how Gibbs free energy is changed by the manner of mixing of donors and acceptors. For this purpose, we consider G_o at temperature $x_DT_D+x_AT_A$ as a standard. When temperature is elevated from $x_DT_D+x_AT_A$, the order parameter decreases from $X=1$, and at certain temperature $T>x_DT_D+x_AT_A$, the energy and the entropy of our system change from E_o and S_o to E and S with order parameter $1>X\geq 0$, as are given by Eqs. 2 and 1, respectively. As long as we consider the effect of mixing upon free energy change, we can only discuss the difference of Gibbs free energy, ΔG, with respect to G_o, so that we obtain, at $T\geq x_DT_D+x_AT_A$,

$$\Delta G = E - E_o - (T-x_DT_D-x_AT_A)\cdot(S-S_o). \quad (4)$$

Eq. 4 means that, if temperature increases further, the order parameter decreases progressively, and at critical temperature T_c, the system undergoes a phase transition from ordered state with $X\neq 0$ to disordered state with $X=0$. In order to examine this condition, we consider $(\partial\Delta G/\partial X)=0$. The equation to determine X is given by

$$\frac{zx_Dv}{k(T-x_DT_D-x_AT_A)}X = \frac{1}{4}\ln\left(\frac{1+X}{1-X}\cdot\frac{x_A+x_DX}{x_A-x_DX}\right). \quad (5)$$

After some manipulation of Eq. 5, the transition temperature is found to be $T_c=x_DT_D+x_AT_A+4x_Dx_AT_c^\circ$, where $T_c^\circ=zv/2k$. The magnitude of the thermal stability enhancement of ordered phase, $4x_Dx_AT_c^\circ$, above temperature $x_DT_D+x_AT_A$ is closely related to that of $v=(1/2)(v_{DD}+v_{AA})-v_{DA}\geq 0$. If $v=0$, then $T_c^\circ=0$, $T_c=x_DT_D+x_AT_A$ and we obtain no thermal stability enhancement of ordered state. However, if greater energy stabilization of v_{DA} occurs with parallel molecular arrangement of donors and acceptors, both v and T_c° increase appreciably and the stability enhancement of ordered state occurs accordingly.

Let us examine how the order→disorder phase transition for mixing of donors and acceptors corresponds to the nematic→isotropic phase transition of MBBA–CPB mixtures reported by Park *et al.*[2] If we take $T_D=43.5$ °C, $T_A=35.0$ °C, and $T_c^\circ=9.6$ °C, the order→disorder transition temperature $T_c=x_DT_D+x_AT_A+4x_Dx_AT_c^\circ$ *versus* composition is given by curve (b) of Fig. 1. This is compared with curve (a) of the experimental relation of T_{NI} to composition. In the composition range $0.4\leq x_A\leq 1.0$, both curves are found to agree quite well. The maximum temperature of T_c occurs at $x_A=0.39$, while that of T_{NI}, at $x_A=0.40$, so that the agreement of both values is very good. In the range $0.0\leq x_A\leq 0.4$, T_c is found to be somewhat higher than T_{NI}. This discrepancy implies that, in the range $0.0\leq x_A\leq 0.4$, some specific intermolecular interaction may take place in MBBA and CPB, so that our solid-solution model is not enough to describe that situation exactly. Except for this little discrepancy, the relation of T_c to composition appears to agree well with that of T_{NI} to composition. Therefore, the order→disorder transition for mixing of donors and acceptors corresponds well to the nematic→isotropic phase transition in MBBA–CPB mixtures. This means that the charge-transfer interaction between donor of MBBA and acceptor of CPB is essential for parallel molecular arrangement to induce nematic phase above temperature $x_DT_D+x_AT_A$. From the value of $T_c^\circ=9.6$ °C together with $T_c^\circ=zv/2k$, the magnitude of zv in the nematic phase of MBBA–CPB mixture is estimated to be 0.16 kJ mol^{-1}.

Finally, we have to say a few words about our solid-solution model. As was mentioned, nematic phase has a high degree of long range orientational order of the molecules but no long range translational order, whereas in solid-solution model, we consider a three-dimensional lattice where not only orientational order but also translational order are assumed. In the present paper, however, we have only discussed how Gibbs free energy of binary mixture is changed by the manner of mixing of donors and acceptors. As long as the problem is limited to such a difference in the degree of mixing, the solid-solution model is still applicable to liquid crystals where long range translational order no longer exists.

The Electron-donor Property of Zirconia

Kunio Esumi* and Kenjiro Meguro

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 22, 1981)

Synopsis. The electron-donor property of zirconia was investigated by means of the adsorption of TCNQ. The TCNQ anion radicals were formed as a result of electron transfer to adsorbed TCNQ from the zirconia surface. The radical concentration decreased with an increase in the calcining temperatures, reached a minimum value at 700 °C, and then increased. This behavior can be explained by a change in the electron-donor site number and the strength of the electron-donor site.

The adsorption of electron acceptors on metal oxides has been investigated, in order to characterize the electron-donor properties of the metal-oxide surfaces. Flockhart *et al.*[1] attempted the adsorption of tetracyanoethylene (TCNE) for the estimation of the electron-donor properties of the alumina surface. In this respect, they associated the electron-donor sites with the unsolvated hydroxide ions and the defect centers involving oxide ions. Meguro and Esumi,[2] carrying out a study of the adsorption of electron acceptors with electron affinities ranging from 1.26 to 2.84 eV on the surface of alumina, have shown that the limit of electron transfer from the alumina surface to the electron acceptors ranged between 1.77 and 1.26 eV in the affinity of the electron acceptor. Thus, the utility of electron-acceptor adsorption for the study of the electron-donor properties of metal oxides has been established.

Zirconia is an important promoter of various dispersed catalysts. To characterize zirconia catalysts, it is necessary to study the surface properties of zirconia. Already, works involving the adsorption of gases, the heat of immersion, and infrared spectroscopy for zirconia have been reported.[3–5] The present study will discuss the electron-donor property of zirconia when 7,7,8,8-tetracyanoquinodimethan (TCNQ) adsorption is used.

Zirconia was prepared by the hydrolysis of zirconium tetrachloride, which had been dissolved in distilled water. The solution was neutralized by ammonium hydroxide, and the precipitate thus formed was washed with distilled water until free from chloride ions. The precipitate was dried for 48 h at 120 °C. The final products were then obtained by calcination in air for 2 h at temperatures between 300 and 1000 °C in an electric furnace, followed by cooling *in vacuo*. The pertinent properties of these samples are given in Table 1.

The TCNQ was supplied by Dainippon Ink Chemical Ltd., and was recrystallized from an acetonitrile solution. The acetonitrile used was of a reagent grade. The apparatus and procedure used in this study have been described elsewhere.[2]

The adsorption isotherms of TCNQ at 25 °C from a solution in acetonitrile on the surface of zirconia calcined between 300 and 1000 °C are shown in Fig. 1. All of the isotherms are convex to the concentration axes, and all follow the Langmuir plots. The half-value of the limiting amount of TCNQ adsorbed on the zirconia surfaces, as estimated from the Langmuir plots, is given in the first column of Table 2. As shown in Table 2, it can be seen that the amount of TCNQ adsorbed on the ziconia surfaces increases with an increase in the calcining temperature, reaches a maximum value at 500 °C, and then decreases.

Table 1. Pertinent properties of zirconia

Sample	Calcining temp/°C	Phase[a]	Surface area[b] m^2/g^{-1}
A	300	A[c]+T(tr)	276.9
B	500	M+T(tr)	88.1
C	700	M	60.1
D	900	M	42.8
E	1000	M	34.5

a) From X-ray analysis. b) From the nitrogen adsorption at 77 K after outgassing at 100 °C. c) A=amorphous, T=tetragonal, M=monoclinic, (tr)=trace.

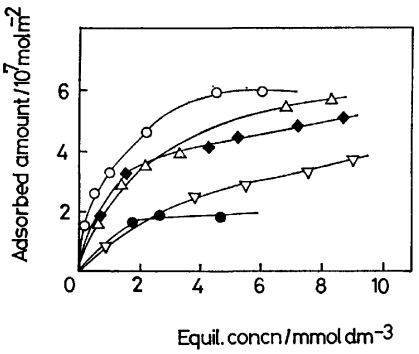

Fig. 1. Adsorption isotherm of TCNQ on zirconia (at 25 °C). Calcination temperature; ○: 300 °C, △: 500 °C, ◆: 700 °C, ▽: 900 °C, ●: 1000 °C.

When TCNQ was adsorbed from a solution in acetonitrile on the surfaces of zirconia, the zirconia surfaces developed a remarkable coloration. The color was violet in all of the samples. It has previously been reported[2,6,7] that the adsorption of electron acceptors onto metal oxides produces a surface coloration. The samples colored by the TCNQ adsorption gave unresolved ESR spectra with a *g*-value of 2.003. These spectra can be attributed to the hindered freedom of the adsorbed species, which obscures the hyperfine structure of the spectra. The spectra have been identified as being those of TCNQ anion radicals.[2]

The above results support the idea that the TCNQ anion radicals are formed as a result of electron transfer from the zirconia surfaces to the TCNQ adsorbed.

The TCNQ-radical concentration formed on the surface of zirconia is plotted against the equilibrium

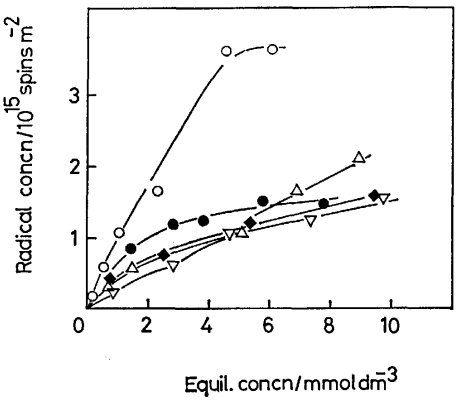

Fig. 2. Radical concentration on zirconia *vs.* equilibrium concentration of TCNQ (at 25 °C). Calcination temperature; ○: 300 °C, △: 500 °C, ◆: 700 °C, ▽: 900 °C, ●: 1000 °C.

concentration of TCNQ at 25 °C in Fig. 2. Many of the isotherms were of a Langmuir type. Therefore, to compare the TCNQ-radical concentration on the surface of zirconia as a function of the calcination temperature, the TCNQ-radical concentration corresponding to the half-value of the limiting amount of TCNQ adsorbed is employed, it is given in the second column of Table 2. It is found that the TCNQ radical concentration decreases with an increase in the calcining temperatures, reaches a minimum value at 700 °C, and then increases.

The nature of the electron-donor sites responsible for the electron-transfer process is not well understood. However, it has been proposed[5,6] that the electron-donor sites of metal oxides, such as alumina and titania, are associated with surface hydroxide ions at lower calcining temperatures and with surface oxide ions at higher temperatures. In the case of zirconia, it is also expected that the electron-donor sites are correlated with the two different sites described above. Indeed, it has been observed by infrared spectroscopy[7] that the surface of zirconia contains hydroxide ions.

The change in the TCNQ radical concentration as a function of the calcination temperatures might be interpreted as follows. At the calcining temperature of 300 °C, the electron-donor sites are surface hydroxide ions. The decrease in the TCNQ radical concentration between 300 and 700 °C corresponds to a reduction in the number of hydroxide ions on the surface. Above 900 °C, surface oxide ions play an important role as electron-donor sites.

Table 2. Data of TCNQ adsorption on zirconia

Sample	Adsorbed amount	Radical concn	Radical concn adsorbed amount
	10^{-7} mol m^{-2}	10^{4} spins m^{-2}	10^{21} spins mol^{-1}
A	3.4	10.0	3.2
B	3.6	6.8	1.9
C	2.9	5.3	1.8
D	2.5	8.5	3.4
E	1.1	6.4	5.8

The ratio of the transformation from the TCNQ adsorbed into the TCNQ radical on the surface of zirconia is important to an understanding of the strength of the electron-donor sites. That is, the larger the ratio, the stronger the electron-donor sites. This ratio can be estimated by dividing the TCNQ radical concentration by the corresponding half-value of the limiting amount of TCNQ. The values are given in the third column of Table 2. This ratio decreases with an increase in the calcining temperatures, reaches a minimum value at 700 °C, and then increases. This result suggests that, in the electron-transfer process, the surface oxide ions are much stronger electron-donor sites than the surface hydroxide ions.

Substituent Effect on a Photo-Smiles Rearrangement by Laser Photolysis

Kenji YOKOYAMA, Junko NAKAMURA, Kiyoshi MUTAI,† and Saburo NAGAKURA*

The Institute of Physical and Chemical Research, Wako, Saitama 351

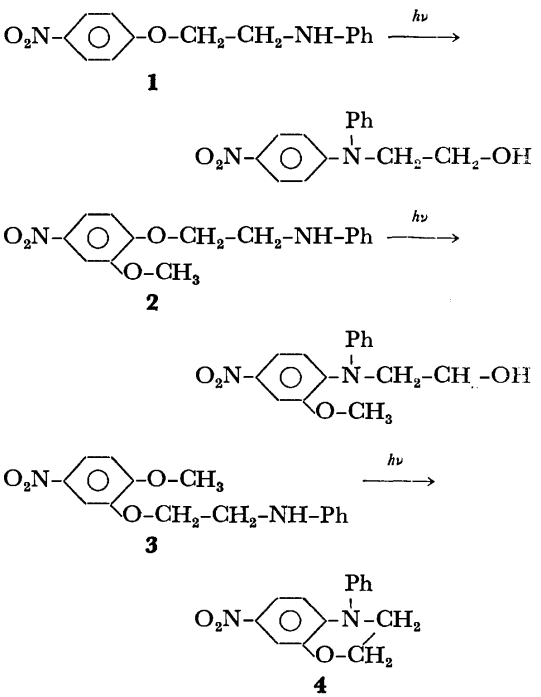
† *Department of Chemistry, College of General Education, The University of Tokyo, Meguro-ku, Tokyo 153*

(Received July 4, 1981)

Synopsis. The photo-Smiles rearrangement was studied for two homologues of *N*-[2-(4-nitrophenoxy)ethyl]-aniline by laser photolysis, an importance being attached to the effect of the alkoxyl substituent on the reactive position. The nitro group enhances the substitution at the para position, but the alkoxyl group does not play a significant role in the photosubstitution of the molecules.

The photo-Smiles reaction of *N*-[2-(4-nitrophenoxy)-ethyl]aniline (**1**) is a typical example of intramolecular nucleophilic photosubstitution.[1] In the previous study,[1] the authors demonstrated by the aid of laser photolysis that this reaction proceeds *via* an intramolecular ion radical pair and the Meisenheimer-type complex. This means that the substitution takes place through interaction between the ground state cation and anion radicals in pair. From this point of view, it is reasonable that the photosubstitution reaction is para directing with regard to the NO_2 group as is usual for the thermal nucleophilic substitution. This is also supported by the theoretical consideration that in the nitrobenzene anion radical the free valency is larger at the para position than at the other positions, that is, the NO_2 group activates the para position.[2]

Mutai *et al.*[3] studied the photo-Smiles reaction of *N*-[2-(2-methoxy-4-nitrophenoxy)ethyl]aniline (**2**) and *N*-[2-(2-methoxy-5-nitrophenoxy)ethyl]aniline (**3**) in polar solvents by analyzing their final products and reported that the substitution takes place at the para position with regard to the NO_2 group.



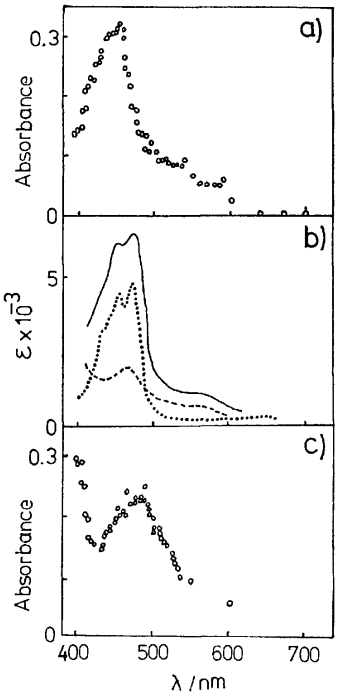


Fig. 1. a) Absorption spectrum of **a** 10 ns after the excitation. b) Broken line: absorption spectrum of the DMNB anion radical. Dotted line: absorption spectrum of the NMA cation radical. Solid line: the 1:1 superposition of the spectra of the DMNB anion and NMA cation radicals. c) $T_n \leftarrow T_1$ absorption spectrum of DMNB in the acetonitrile solution (present study).

These results indicate that NO_2 group plays a significant role in the photo-Smiles reactions. Therefore, in the present study, we have carried out the laser photolysis experiment of **2** and **3** together with **1** in acetonitrile to confirm the effect of NO_2 and CH_3O group upon the photosubstitution by elucidating their reaction mechanism directly.

1, **2**, and **3** were prepared as mentioned previously and purified by chromatography.[3] 1,2-Dimethoxy-4-nitrobenzene (DMNB) (Aldrich Chemical Co.) was purified by a sublimation and repeating recrystallizations. Acetonitrile (Wako, spectroscopic grade) was used as solvent without further purifications. Sample solutions for transient absorption measurements were degassed by repeating freeze-and-thaw cycles. The transient absorption was measured with the same apparatus as mentioned previously.[1,4]

Results and Discussion

The transient absorption of **2** was measured in the acetonitrile solution containing triethylamine (0.1 mol dm^{-3}) by the excitation with an N_2 laser at 337 nm.

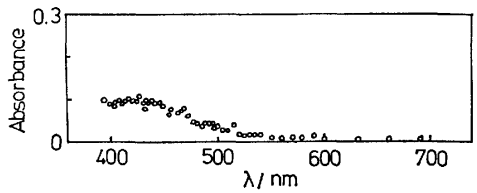

Fig. 2. Absorption spectrum of **b** 3 μs after the excitation.

It consists of two components, the faster one, **a**, and the slower one, **b**, their decay time constants being 35 ns and more than 200 μs, respectively. Figure 1a) shows the spectrum of **a**. Component **a** cannot be observed in nonpolar solvents like benzene and cyclohexane. Furthermore, the spectrum of **a** is different from $T_n \leftarrow T_1$ absorption spectrum of DMNB which is measured in the present study (see Fig. 1c)) and also from that of aniline and *N*,*N*-dimethylaniline.[5] In Fig. 1b) is shown a 1:1 superoposition of the spectrum of the DMNB anion radical[6] and that of the *N*-methylaniline (NMA) cation radical.[7] The superposition is very similar to the spectrum in Fig. 1a). Thus, **a** is assigned to an intramolecular ion radical pair, and the photosubstitution of **2** proceeds *via* the ion pair as that of **1** does.[1]

The other component, **b**, whose spectrum is shown in Fig. 2, is assigned to the relating Meisenheimer-type complex. The spectrum of **b** is not remarkably different from that of the relating complex of 1.[1] This implies that the conjugation of the CH_3O group with the residual system is not so significant for the complex. Polliff and Saunder showed that the spectra of 1,1-dimethoxy-2,6-dinitrocyclohexadienide and 1,1,4-trimethoxy-2,6-dinitrocyclohexadienide, are very similar to each other.[8]

These results mean that the photosubstitution reactions of **1** and **2** are very similar in their mechanism to each other. Particularly, the fact that the substitution takes place for **2** at the para position with regard to the NO_2 group shows that in the DMNB anion radical the NO_2 group activates the para position, but the CH_3O group does not play a significant role in activation of the benzene ring.

The acetonitrile solution of **3** shows the transient absorption with two components by the excitation with an N_2 laser. Both components of **3**, however, are different from those of **2**. The fast component of **3** rises up very fast and decays with the time constant of 1.0 μs, which is much larger than that of **2**, 35 ns. The slow component of **3** rises up with the time constant of 20 μs and does not decay within the time domain of the monitor light pulse (200 μs). Both components of **3** are not quenched by the addition of O_2 gas.

Figure 3a) and 3b) show the spectrum of the fast and slow components of **3**, respectively. The latter

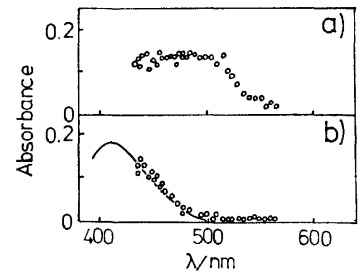

Fig. 3. Transient absorption spectrum of **3**.
a): Absorption spectrum of the fast component 10 ns after the excitation. b): Absorption spectrum of the slow component 45 μs after the excitation. Solid line; absorption spectrum of the final product, **4**.

may be assigned to that of the final product, **4**, because both spectra are very similar to each other, as shown in Fig. 3b). The assignment of the fast component is not clear so far. The built up time constant of the slow one is twenty times larger than the decay time constant of the fast one. Consequently, the fast component is not a direct precursor of the slow component. These results suggest that the reaction mechanism of **3** is different from those of **1** and **2**, that is, the para directing character with regard to the NO_2 group in **3** should not be due to the same origin as in **1** and **2**.

The present study indicates that the orientation rule should be discussed taking not only the final products but also the respective reaction mechanisms into account. Furthermore, it is shown that in **1** and **2** the para directing character is due to the activation by the NO_2 group but not the CH_3O group. The reaction mechanism of **3** should be studied further.

The Crystal Structure of *p*-Iodobenzoic Acid Investigated by X-Ray Powder Diffraction

Yoshito TAKAKI,* Arifumi KURISU, and Kazuaki NAKATA
Department of Physics, Osaka Kyoiku University, Tennoji-ku, Osaka 543
(Received July 10, 1981)

Synopsis. The crystal of the title compound is monoclinic with space group $P2_1/a$, $a=30.36(3)$, $b=6.04(1)$, $c=4.16(1)$ Å, $\beta=97.4(1)°$ and $Z=4$. The crystal structure was solved from X-ray powder diffractometer data by the packing analysis based on an ellipsoid-model and by the pattern-fitting structure refinement. The final R (profile) value was 0.168. This structure is isostructural with that of *p*-bromobenzoic acid.

In order to obtain single crystals of *p*-iodobenzoic acid suitable for X-ray intensity data collection, many attempts were made but they were all unsuccessful. Then the crystal structure was solved from X-ray powder diffractometer data using the method of pattern-fitting refinement with structural constraints.[1)]

Experimental

Crystals grown from an aqueous solution occur as very thin lamellas with the well-developed (100) plane. The intensity measurements were made on an X-ray powder diffractometer (Rigaku-Denki, Ru-200PL) with Cu $K\alpha$ radiation monochromatized by a curved graphite monochromator. A scan was made from 11 to 44° in 2θ with scanning speed of 0.25 °/min; in this angular range there are 82 contributing reflections. The background-corrected intensities were measured on the chart in steps of 0.05° (in 2θ) over the above angular range. The intensity measurements of the profile with 2θ greater than 44° were not made because a large number of diffraction peaks overlap each other considerably.

Crystal data of this compound have been reported by Toussaint.[2)] They are: monoclinic with cell dimensions, $a=30.46$, $b=6.05$, $c=4.16$ Å, $\beta=97°19'$, space group $P2_1/a$ and $Z=4$. The cell dimensions were refined by using diffraction data from a powder sample mixed with the silicon powder as internal standard. They are $a=30.36(3)$, $b=6.04(1)$, $c=4.16(1)$ Å and $\beta=97.4(1)°$.

Structure Determination

Trial structures were obtained by the packing analysis based on an ellipsoid-model[3)] which was obtained on the assumption that two planar molecules with conventional bond lengths and angles form a centrosymmetric dimer and the three orthogonal molecular axes coincide with the principal axes of the ellipsoid. The dimensions of the ellipsoid, 10.6, 3.0, and 1.8 Å, were obtained from a consideration of van der Waals radii of the atoms. The center of the ellipsoid was placed on the center of symmetry and its orientation was described by the use of Eulerian angles ϕ, θ, and ψ, where ϕ and θ are the ordinary polar-coordinate angles of the major axis L of the ellipsoid referred to the axes a and b* and ψ is the angle measuring the rotation about the axis L.

By the above method five sets of ellipsoid-packing each having quite different packing mode were obtained. After transforming the coordinates of atoms in a molecule referred to the principal axes of the ellipsoid to those referred to the crystal axes, we calculated powder intensity profiles by using the expression given below. In the structure-factor calculation, an overall temperature factor, $B=3.0$ Å^2, was used and the contribution from the H atoms was neglected. A structure having an intensity profile strikingly similar to the observed one was chosen as the starting structure for refinement; the Eulerian angles were $\phi=165$, $\theta=55$, and $\psi=150°$. The R value defined by

$$R = \sum_i |y_i(\text{obsd}) - y_i(\text{calcd})| / \sum_i y_i(\text{obsd})$$

was 0.26, where y_i is an intensity at a given point $2\theta_i$ in a profile and is expressed in the form

$$y_i = \sum_k \left[\frac{2}{3} I_k \Omega(2\theta_i, 2\theta_{k1}) + \frac{1}{3} I_k \Omega(2\theta_i, 2\theta_{k2}) \right].$$

Here summation is taken over all possible contributing reflections at $2\theta=2\theta_i$; I_k is the calculated intensity of reflection k for Cu $K\alpha$; $\Omega(2\theta_i, 2\theta_{k1})$ and $\Omega(2\theta_i, 2\theta_{k2})$ are the line shape functions for Cu $K\alpha_1$ and Cu $K\alpha_2$ respectively and are represented by Cauchy functions with full width (in 2θ) at half height of a peak, H_k, given by

$$H_k = v \tan\theta_k + w,$$

where v and w are parameters.

The pattern-fitting refinement was made by visual comparison of observed and calculated intensity profiles. The parameters varied in the refinement were: three Eulerian angles, one C–I bond distance, one temperature factor for the I atom and two for the peak shape. Note that the refinements of positional and thermal parameters for the atoms except the I atom were not made since their contributions to the structure factors can be considered to be very small as compared with that of the I atom. The final values of the parameters are: Eulerian angles, $\phi=166$, $\theta=56$, and $\psi=150°$, C–I=2.03 Å (initial value, 2.15 Å), $B=3.0$ Å^2 and peak shape parameters, $v=0.24$ and $w=0.13$. The final R value is 0.168 for

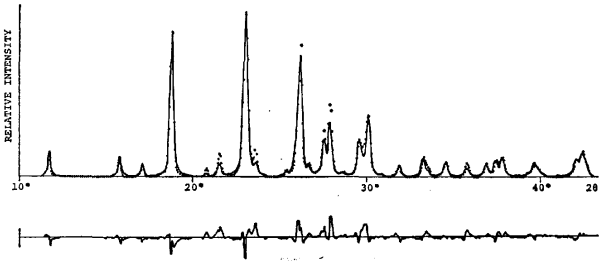

Fig. 1. Observed (dots) and calculated (full line) intensity profiles for *p*-iodobenzoic acid. The lower trace is the difference between observed and calculated profiles.

The bond lengths are C-C(benzene ring) = 1.39 Å, C_1-C_7 = 1.49 Å, C-O = 1.20 Å, C-I = 2.03 Å, and OH···O = 2.65 Å.

631 intensities from 11.5 to 43° in 2θ.

Figure 1 shows observed and calculated intensity profiles together with the differences between them. The final coordinates of non-hydrogen atoms are listed in Table 1. The structure viewed along the c axis is shown in Fig. 2. This structure is isostructural with that of *p*-bromobenzoic acid.[4]

In conclusion we may say that the use of structural constraints in the powder-pattern-fitting refinement[1,5] is certainly very useful, especially when only low-angle intensity data with highly overlapped peaks are available. Further, in such a case, it would be very important to find a starting structure very close to the final one for obtaining a stable refinement.

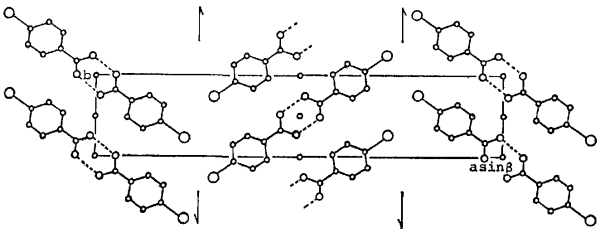

Fig. 2. The crystal structure viewed along the c axis.

The authors thank Mr. M. Setoguchi of Goverment Industrial Research Institute, Osaka, for use of the X-ray powder diffractometer. They also thank Prof. K. Sakurai for his continued interest and Mr. Y. Kubota and Mr. M. Satoh for assistance with the computing.

Zero-field Splitting Tensor and Orientation of the Phosphorescent-state Benzo[*h*]quinoline in Biphenyl Host

Hiroshi Sekiya and Yasuhiko Gondo*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 24, 1981)

Synopsis. ESR absorption has been observed in a single-crystal solid solution of benzo[*h*]quinoline in biphenyl under UV irradiation at 120 K. The triplet-state zero-field splitting tensor and the guest orientation are reported, in comparison with the previous results on benzo[*f*]-quinoline.

In order to investigate the nature of the triplet-state wave function, it is important to determine the zero-field splitting (ZFS) principal axes, not to speak of the principal values. However, the number of compounds for which the ZFS principal axes were determined are limited.[1] The main object of this work is to determine the ZFS principal axes in the phosphorescent state of benzo[*h*]quinoline (BHQ), to be compared with those of benzo[*f*]quinoline (BFQ) reported previously.[1]

Experimental

BHQ (Nakarai GR) was treated with sulfuric acid and sodium hydroxide,[2] and then zone-refined extensively. Single-crystal samples were grown from the melts.[1]

The ESR measurements were performed as described previously,[1] except for the use of a microwave frequency of 9.15 GHz instead of 9.25 GHz. The sample crystals were cooled at 120±10 K by a flow of cold nitrogen gas, and irradiated with a 250-W high-pressure mercury lamp. Quartz wedges were used in order to rotate the static external magnetic field in the particular magnetic planes associated with one type of BHQ molecule in the crystal. We have also studied the phosphorescence spectra and decays of BHQ in biphenyl at 77 and 4.2 K, and identified the phosphorescent state, as described previously.[1]

Results and Discussion

General Remarks. Figure 1 shows the molecular axes adopted, designation of the ZFS principal axes, x, y, z, and the in-plane rotation of the ZFS tensor, θ. For the sake of convenience, the two sites in a unit cell of the biphenyl crystal are designated as sites A and B, respectively, the quartz wedges being assumed to fit site A. The main features of the biphenyl crystal have been summarized previously,[1] and there are two magnetically inequivalent orientations of the BHQ molecule at each site. Since the procedures in this work resemble the previous for BFQ,[1] the presentation will duly be brief.

ESR Spectra in the yz Plane and Tilt of the Guest Plane. Figure 2 shows the resonance fields obtained by rotating the static external magnetic field $\boldsymbol{H}$ nearly in the yz plane with the wedge of an inclination of 17.8° which gave a maximum resonance field; four wedges of inclination in the range 13.8°—19.0° were actually used, while the biphenyl crystal structure specifies the inclination of 17.7° for $\boldsymbol{H}$ to be in the M'N' plane.

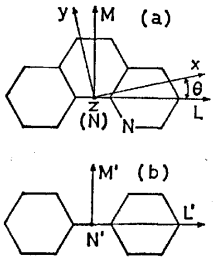

Fig. 1. Axis systems for (a) benzo[*h*]quinoline and (b) biphenyl. ZFS principal axes are denoted by x, y, and z.

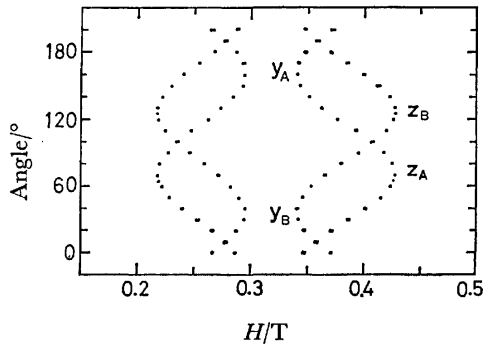

Fig. 2. Magnitude of $\boldsymbol{H}$ for resonance *vs.* rotation of $\boldsymbol{H}$ in a plane close to the yz plane.

The two patterns correspond to sites A and B, and are identical to each other except for the phase. The largest separations correspond to the z axes, while the smallest to the y axes. With very poor resolutions, eight lines could be recognized for some orientations of $\boldsymbol{H}$ between the y and z axes. This indicates the small value of θ to be discussed later on, and that the molecular planes of the two inequivalent guests at each site are parallel to each other within experimental errors. Thus, the angle of 55.0° between the fine-structure z axes may represent the dihedral angle between the planes of the A- and B-site BHQ molecules, in contrast with the corresponding angle of 69.3° for the A- and B-site biphenyl molecules.[3] The difference of 14.3° in the two angles amounts to a decrease of 7° in the tilt of the guest plane relative to the host, in coincidence with the case of BFQ in biphenyl,[1] and in a slight deviation from the tilt of 5°—6° found for phenanthrene in biphenyl.[4,5] The nitrogen-atom location essentially does not affect the tilt of the guest plane.

ESR Spectra in the xy Plane. Five wedges were used in order to rotate $\boldsymbol{H}$ in the xy plane, *i.e.*, LM plane, their dihedral angles ranging from 101.0° to 105.9°. Taking account of the yz-plane measurements, the b axis of the crystal was set at 62° on the wedge

Table 1. Observed zero-field splitting parameters[a)]

surface as detailed previously.[1)] The wedge of a dihedral angle of 103.3° gave a maximum resonance field. The y-axis resonance-field separations are the same as those in the yz-plane measurements. In addition, the L axes of sites A and B are practically parallel to each other, since the four lines draw closer together and coalesce into one as $\boldsymbol{H}$ moves to the x axes, as it is the case for BFQ.[1)]

*ZFS Tensor, **g**-Tensor, and Hyperfine Structure.* The ZFS parameters were determined with the procedure of Hutchison and Mangum,[6)] the principal axes of the $\boldsymbol{g}$-tensor being assumed to coincide with those of the ZFS tensor. The parameters fitting the spin-Hamiltonian are given in Table 1. The D value is somewhat smaller in biphenyl than in ethanol glass,[7)] while the E value is essentially indifferent to the solvents, as it is the case for BFQ.[1,7)] The resemblance of the D and E values of BHQ to those of BFQ[1)] and phenanthrene[4)] confirms the $\pi\pi^*$ nature of the phosphorescent state in BHQ.

The two pairs of curves in the xy-plane measurements correspond to the two magnetically inequivalent orientations at site A, as exemplified in Fig. 6 of Ref. 1. From the phase difference of 1° between the two curves, we obtain a θ value of ±0.5°, in good agreement with a theoretical value of +0.2°,[8)] and in contrast with the larger value of ±4° for BFQ,[1)] as shown in Table 1.

Although the hyperfine structures could be observed for $\boldsymbol{H}$ nearly on the three ZFS principal axes, they actually are complicated owing to the low molecular symmetry and to overlapping of the signals due to the different sites. Accordingly, the hyperfine coupling constants could not be determined, as it was the case for BFQ.[1)]

The present work was partially supported by the Ito Science Foundation and by the Grants-in-Aid for Scientific Research Nos. 334026 and 347014 from the Ministry of Education, Science and Culture.

Kinetics of Gas Phase Addition Reactions of Trichlorosilyl Radicals. IV.[1] Relative Rates of Additions to 1-Alkenes

Takaaki DOHMARU* and Yoshio NAGATA

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

(Received August 5, 1981)

Synopsis. Trichlorosilyl radical additions to a mixture of ethene, propene, 1-butene, and 1-pentene and to a mixture of propene and 2-methylpropene have been investigated. The rate of adduct formation from each olefin was obtained relative to that from propene between 403 K and 548 K. These relative rates are in good agreement with those calculated from the rate parameters obtained previously in this laboratory.

Kinetic data relating to elementary reactions of silyl radicals are quite important since reliable thermochemical or kinetic informations are now still very scarce.

Previously,[2] we obtained Arrhenius parameters for forward and reverse steps of $\cdot SiCl_3$ additions to 1-alkenes between 405 K and 524 K by a competitive method in which an addition to acetone was employed as a reference reaction. To check the reliability of these results and to obtain precise relative rates of additions to 1-alkenes, we conduct a series of experiments in which mixtures of 1-alkenes are subjected to reactions with $\cdot SiCl_3$ radicals.

Experimental

The materials were prepared, purified and checked in the way described previously.[2] Sample preparations and photolyses were performed on a conventional greaseless and mercury-free vacuum line. The full light from a 50 W medium pressure mercury arc was used. Given amounts of $HSiCl_3$ and a mixture of olefins were admitted into a quartz reaction vessel of 139 cm^3 which was heated in an electrical oven controlled to better than ± 1 K. Probably very weak photoabsorption by olefins in the ultraviolet region initiates the reactions, since $HSiCl_3$ was found almost transparent in this region. After photolyzed, the reaction mixture was allowed to diffuse to a gas sampling loop which was directly attached to a gas chromatograph with a Gow-Mac gas density detector. All the analyses were made on a 2 m column of 30% SE 30 on Chromosorb W mixed with 30% Silicone DC QF-1 on Chromosorb W (1:1 by weight). Reactant conversions were kept smaller than 5%.

Results and Discussion

Equimolar mixtures of ethene, propene, 1-butene and 1-pentene (0.267×10^{-6} mol cm^{-3} each) were photolyzed in the presence of $HSiCl_3$ (5.34×10^{-6} mol cm^{-3}). Products were $C_2H_5SiCl_3$, n-$C_3H_7SiCl_3$, n-$C_4H_9SiCl_3$, and n-$C_5H_{11}SiCl_3$; additions occur exclusively at their terminal carbons. Since it was difficult to separate i-$C_4H_9SiCl_3$ completely from n-$C_4H_9SiCl_3$ in gas chromatographic analyses, 2-methylpropene was subjected to another photolysis in which propene and 2-methylpropene (0.134×10^{-6} mol cm^{-3} each) were photolyzed with $HSiCl_3$ (5.34×10^{-6} mol cm^{-3}). In both series of photolyses, the amounts of the products were measured at various temperatures between 403 K and 548 K. The results are summarized in Table 1.

Table 1. Relative rates of additions of $HSiCl_3$ to 1-alkenes

T/K	C_2H_4	C_3H_6	Δ^1-C_4H_8	Δ^1-C_5H_{10}	i-C_4H_8
403	0.27	1	1.1	1.0	4.1
428	0.32	1	1.1	1.2	4.1
452	0.34	1	1.1	1.1	3.0
477	0.39	1	1.2	1.0	2.0
501	0.52	1	1.1	0.9	1.3
525	0.85	1	1.1	1.0	1.0
548	1.1	1	1.2	1.0	0.8

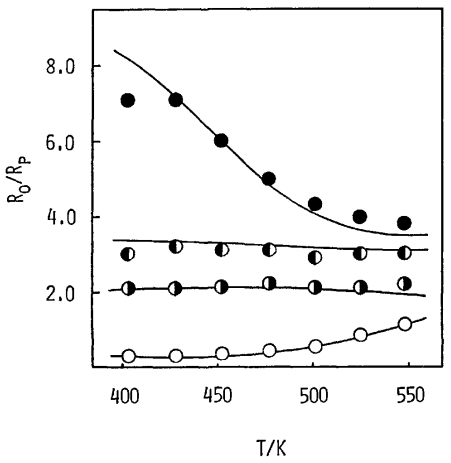

Fig. 1. Observed and calculated relative rates of addition between 403 K and 548 K.
○: C_2H_4, ◑: Δ^1-C_4H_8 (shifted by +1), ◐: Δ^1-C_5H_{10} (shifted by +2), ●: i-C_4H_8 (shifted by +3)
The solid curves represent the calculated values.

Features characteristic of the number of the alkyl substituents around the double bond are clear in Table 1. Monosubstituted ethenes (C_3H_6, Δ^1-C_4H_8, and Δ^1-C_5H_{10}) are very similar in reactivity with each other throughout the temperature range. Ethene has a small rate at low temperature but gets to the same rate as that of propene at 548 K. 2-Methylpropene behaves in a quite opposite way to ethene. It is quite interesting to note that each relative rate attains almost the same value at about 530 K.

The photolytic addition of $HSiCl_3$ to olefin is known to proceed by the following radical chain reactions.[3]

$$\cdot R + HSiCl_3 \longrightarrow RH + \cdot SiCl_3 \quad (1)$$

$$\cdot SiCl_3 + CR_1R_2{=}CH_2 \rightleftharpoons \cdot CR_1R_2CH_2SiCl_3 \quad (2, -2)$$

$$\cdot CR_1R_2CH_2SiCl_3 + HSiCl_3 \longrightarrow HCR_1R_2CH_2SiCl_3 + \cdot SiCl_3 \quad (3)$$

$\cdot R$ in Reaction 1 represents any radicals formed as a result of photoabsorption by some olefins.

The rate of the formation of the respective adduct, R_o, is derived as in Eq. 4 applying the steady state treatment of the above scheme; the conditions of long reaction chains and low conversion of reactants are satisfied in the present runs.[2]

$$R_o = \frac{k_2[\text{Olefin}][\cdot SiCl_3]}{1+(k_{-2}/k_3)[HSiCl_3]^{-1}}. \quad (4)$$

We have already obtained rate constant ratios k_2/k_5 and k_{-2}/k_3 for 1-alkenes where k_5 denotes the rate constant of the $\cdot SiCl_3$ addition to acetone.[2] Accordingly, the relative rates of adduct formations among olefins can be calculated from Eq. 4. The rates of adduct formation from the respective olefin, R_o, relative to that from propene, R_p, are compared with the calculated values at various temperatures in Fig. 1. The experimental rate ratios are in good agreement with the calculated values; the present study lends support to the rate parameters obtained previously.[2]

Preparation of Alkylnickel(II)-Phosphine Complexes by Reactions of $Ni(acac)_2$ with Alkylaluminums in the Presence of Tertiary Phosphine

Takakazu YAMAMOTO,* Masakatsu TAKAMATSU, and Akio YAMAMOTO
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta, Midori-ku, Yokohama 227

(Received May 6, 1981)

Synopsis. Four new alkylnickel(II)-phosphine complexes, $NiR_2(PR'_3)_2$ ($R=CH_3$, C_2H_5; PR'_3=triethylphosphine (PEt_3), tributylphosphine (PBu_3), 1,2-bis(diphenylphosphino)ethane(dpe)) and $Ni(CH_3)(acac)(PEtPh_2)$ ($PEtPh_2$=ethyldiphenylphosphine), have been prepared by reactions of $Ni(acac)_2$ with $AlR_2(OC_2H_5)$ in the presence of phosphine ligands.

Alkylnickel complexes are regarded as intermediates in important catalytic reactions such as isomerization and oligomerization of olefins and dienes.[1] Although several groups have been engaged in research on the preparation and chemical properties of alkylnickel complexes,[1a,2] the number of well-characterized alkylnickel complexes is still not large. We now report preparation of four new alkylnickel(II) complexes by reactions of $Ni(acac)_2$ (acac=2,4-pentanedionato) with alkylaluminums in the presence of tertiary phosphines (L).

Results and Discussion

Reactions of $Ni(acac)_2$ with $AlR_2(OEt)$ below −30 °C in the presence of phosphine ligands give NiR_2L_2, NiR(acac)L, zero-valent nickel complexes, or Ni–Al binary complexes depending on the alkylaluminum and phosphine ligand employed,

$$Ni(acac)_2 + AlR_2(OEt) + L \xrightarrow[Et_2O]{-30\,^\circ C \text{ or below}} NiR_2L_2,\ NiR(acac)L,\ NiL_4,\ \text{Ni–Al complex} \quad (1)$$

R	L	Product
Me	PEt_3	$NiMe_2(PEt_3)_2$ **1**

Me=CH_3, Et=C_2H_5, Bu=*n*-C_4H_9, Ph=C_6H_5, acac=2,4-pentanedionato, dpe=1,2-bis(diphenylphosphino)-ethane

Among the complexes listed above, the dimethylnickel complex, **4**,[2g] and zero-valent nickel complexes, **7**[3] and **9**,[4] have been prepared by other researchers through different pathways. The comparison of the products obtained using the phosphine ligands listed above reveals that subtle differences in electronic and steric effects of the phosphine ligands exerts a pronounced influence on the course of alkylation reaction. Properties of the complexes are described below.

NiR_2L_2: Dialkylnickel(II) complexes **1**, **3**, and **5** have relatively low thermal stabilities, the thermal decomposition proceeding gradually even at room temperature in a solid, with evolution of CH_4 and C_2H_6 from the dimethyl complexes and C_2H_6 and C_2H_4 from **5**. The absence of butane in the thermolysis product of **5** contrasts with the results of thermolysis of $NiEt_2$(2,2′-bipyridine), which liberates mainly butane during the thermolysis.[2a,2c] The low thermal stabilities of the dialkyl complexes not only require the researchers to carry out the preparation and work-up below −30 °C, but also prevent characterization of the complexes by microanalysis. Thus characterization of NiR_2L_2 was performed mainly on the basis of macroanalysis of Ni, the amount of RH released on acidolysis with H_2SO_4, and spectroscopy (IR and NMR). As for **3**, we characterized it by the amount of RH released on the acidolysis and by ^1H NMR spectroscopy, due to its high instabilities. As for **1** and **5**, their chemical reactivities with active hydrogen compounds[5] and CO[6] support the proposed structures. All the dialkyl complexes are free of aluminum, as proved by qualitative analyses.

Table 1 summarizes spectroscopic data of the new complexes prepared by Reaction 1. IR spectra show signals due to R and L ligands. In the ^1H NMR spectrum, the dimethyl complexes **1** and **3** give rise to the Ni–CH_3 signal at higher magnetic field than TMS; similar results were reported for dimethylnickel complexes.[2] The triplet pattern ($J(^1H–^{31}P)=8$ Hz) of the Ni–CH_3 signal of **1** at −70 °C reveals that **1** has a *trans* configuration. The $^1H–^{31}P$ spin-spin coupling, however, is not observable at −60 °C or above, presumably due to rapid exchange between PEt_3 in **1** and free PEt_3 partly liberated from **1**. The Ni–CH_2– signal of **5** is located at higher magnetic field than the Ni–CH_2–CH_3 signal, as is found for $NiEt_2$(2,2′-bipyridine).[2b]

$NiMe(acac)(PEtPh_2)$ **6**: Complex **6** has higher thermal stabilities than the dialkylnickel complexes. The IR spectrum of **6** shows ν(C=O) bands at 1590 and 1520 cm^{-1} characteristic of a bidentate acac ligand. ^1H-NMR spectrum shows two singlets for the two CH_3 groups of the acac ligand, indicating **6** has a

Table 1. IR and NMR data of new alkylnickel(II) complexes

square planar structure like that known for NiEt(acac)(PPh_3)[7] and NiR(acac)(PCy_3).[8]

Binary Complexes Containing Nickel and Aluminium Components: The Ni(acac)$_2$/$AlEt_2$(OEt)/PEt_3 and Ni(acac)$_2$/$AlMe_2$(OEt)/P(OEt)$_3$ systems afford yellow crystalline complexes. The complexes contain both nickel and aluminum. Electric conductivities of solutions of the complexes reveal that they have ionic structures. Their IR spectra show characteristic bands of aluminate anion at *ca.* 650 cm^{-1}. ^{1}H NMR spectra show signals not only due to R groups and L ligands but also one due to Al-OC$\underline{H}_2$CH$_3$ group at about 3.7 ppm. These results suggest that the complexes have ionic structures like [CoR_2(2,2′-bipyridine)$_2$]$^+$-[AlR_4]$^-$, which were isolated from Co(acac)$_3$/AlR_3/2,2′-bipyridine systems.[9] The ^{1}H NMR spectrum of **8** is consistent with the structure: [NiMe(P(OEt)$_3$)$_3$]$^+$-[$AlMe_3$OEt]$^-$.

Experimental

General. Manipulation of complexes, analysis, and measurement of IR and NMR spectra were carried out as reported.[2a-2c,5-7]

Preparation of Complexes. *NiR_2L_2*: $AlMe_2$(OEt) (13 cm^3, 100 mmol) was added to a mixture of Ni(acac)$_2$ (6.0 g, 23 mmol) and PEt_3 (8.0 cm^3, 54 mmol) in Et_2O (60 cm^3) at −60 °C. Stirring the mixture at −30 °C for 10 h gave a brown homogeneous solution, which was condensed to *ca.* 20 cm^3. Cooling the solution to −78 °C gave brown needles (6.1 g, 84%). The brown needles were separated by filtration, washed repeatedly with Et_2O at −78 °C, and recrystallized from Et_2O to obtain 4.4 g (60%) of **1**. Mp 35 °C (dec). Found: Ni, 18.0%. Calcd for $NiMe_2(PEt_3)_2$: Ni, 18.1%. CH_4/**1** (acidolysis with H_2SO_4)=1.8.

Complex **3** was obtained analogously from a mixture of Ni(acac)$_2$ (5.0 g, 19 mmol), PBu_3 (9.3 cm^3, 37 mmol), and $AlMe_2$(OEt) (11 cm^3, 88 mmol); the reaction time was 5 h and the temperature was −40 °C; yield=14%. Mp 0 °C (dec): CH_4/**3** (acidolysis)=2.0.

$AlEt_2$(OEt) (24 cm^3, 150 mmol) was added to a mixture of Ni(acac)$_2$ (6.5 g, 25 mmol) and dpe (10 g, 25 mmol) in 100 cm^3 of Et_2O at −50 °C. Stirring the mixture for 10 h at −20 °C gave a yellowish orange precipitate, which was separated by filtration, washed repeatedly with Et_2O, and dried in a vacuum to obtain **5** (yield=12%). Mp 50 °C (dec). Found: Ni, 10.3%. Calcd for $NiEt_2$(dpe)-(Et_2O)$_{0.5}$: Ni, 10.6%. C_2H_6/**5** (acidolysis)=2.0.

Complex **4** was prepared analogously and characterized by comparing its NMR data with those reported in the literature.

NiMe(acac)(PEtPh$_2$) **6**: $AlMe_2$(OEt) (14 cm^3, 110 mmol) was added to a mixture of Ni(acac)$_2$ (7.3 g, 28 mmol) and $PEtPh_2$ (14 cm^3, 57 mmol) in Et_2O (60 cm^3) at −70 °C. Stirring the mixture at −40——25 °C for 10 h gave a brown solution and a yellow precipitate. After condensing the solution to *ca.* 20 cm^3, the yellow precipitate was separated by filtration, washed with Et_2O, and dried in vacuum to yield 3.5 g (35%) of **6**. Mp 80 °C (dec). Found: C, 62.1; H, 6.5; Ni, 15.2%. Calcd for NiMe(acac)($PEtPh_2$): C, 62.3; H, 7.0; Ni, 15.1%. CH_4/**6** (acidolysis)=1.0.

Ni–Al Complexes: $AlMe_2$(OEt) (5.0 cm^3, 44 mmol) was added to a mixture of Ni(acac)$_2$ (2.6 g, 10 mmol) and P(OEt)$_3$ (3.4 cm^3, 20 mmol) in Et_2O (45 cm^3) at −50 °C. Stirring the mixture at −10 °C for 10 h gave a brown hoogeneous solution, which was condensed to *ca.* 30 cm^3. Coolming the solution to −78 °C gave transparent brown prisms. After washing with a mixture of Et_2O and hexane, the complex was recrystallized from Et_2O to yield 2.0 g of **8**. ^{1}H NMR (acetone-d_6, −60 °C): δ=−0.98 (9H, s, Al-C$\underline{H}_3$), −0.90 (3H, s, Ni-CH_3), 1.18 (3H, Al-$OCH_2C\underline{H}_3$), 1.30 (27H, t, 7 Hz, P-$OCH_2C\underline{H}_3$), 3.70 (2H, q, 7 Hz, Al-O$C\underline{H}_2CH_3$), 4.20 (18H, q, 7Hz, P-O$C\underline{H}_2CH_3$). Equivalent conductivity: 35% of the equivalent conductivity of KI in acetone at −72 °C. Complex **2** was prepared analogously.

Ni(0)-Complexes: Complexes **7** and **9** were prepared under similar conditions to those adopted to prepare **1**—**6** and **8**. They were characterized by elemental analysis.

A Voltammetric Study of the Reduction of Ruthenium(II) Complexes with Mixed Ligands

Junya WATANABE, Tetsuo SAJI,* and Shigeru AOYAGUI

Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received May 25, 1981)

Synopsis. Each cyclic voltammogram for the reduction of $[Ru(bpm)_3]^{2+}$ (bpm=2,2′-bipyrimidine) and $[Ru(bpm)L_2]^{2+}$ (L=2,2′-bipyridine and dimethyl derivatives) exhibits three reversible one-electron steps. The relation between the half-wave potentials of the complexes and those of ligands suggests that the lowest redox orbital of $[Ru(bpm)L_2]^{2+}$ should be localized on a single bpm molecule.

We have previously reported cyclic voltammograms for the reduction of complexes of the $[M(II)L_3]$ and $[M(II)L_2]$ forms with Fe and Ru as M and 2,2-bipyridine (bpy) and some other polypyridines as L.[1–4] The tris(or bis) complexes had one or two sets of three (or two) nearly neighbouring reduction steps. They were all reversible one-electron steps whose half-wave potentials ($E^{red}_{1/2,C}$) were related to the reversible half-wave potentials for the first reduction steps of the ligands ($E^{red}_{1/2,L}$) by the following equation:[1]

$$E^{red}_{1/2,C} = E^{red}_{1/2,L} + \text{const.} \quad (1)$$

This finding led us to the conclusion that the excess electrons over d^6 should be added to the ligand π^*-orbitals or, strictly speaking, that the redox orbitals should be molecular orbitals to which ligand π^*-orbitals make a predominant contribution. The characteristic patterns of the cyclic voltammograms suggested, furthermore, that the redox orbitals of the tris(or bis) complexes are probably three(or two)-fold degenerate. Molecular orbital calculations of the energies of the redox orbitals led to the same conclusion.[5] The present work is an extension of these works; it deals with mixed-ligand complexes.

The $[Fe(bpm)_3(PF_6)_2]$[6] (bpm=2,2′-bipyrimidine), $[Ru(bpm)_3(PF_6)_2]$[7,8] and $[Ru(bpm)(bpy)_2(PF_6)_2]$[7,9] complexes were prepared by the literature methods, while $[Ru(bpm)L_2(PF_6)_2]$ (L=4,4′-dimethyl-2,2′-bipyridine (4-dmbpy) and 5,5′-dimethyl-2,2′-bipyridine (5-dmbpy) were prepared by a method similar to that was used for $[Ru(bpm)(bpy)_2(PF_6)_2]$. The $[Ru(4\text{-dmbpy})_3(ClO_4)_2]$ and $[Ru(5\text{-dmbpy})_3(ClO_4)_2]$ complexes were described previously.[1] Cyclic voltammograms for the reduction of these complexes were obtained on a platinum working electrode with an acetonitrile base solution containing 0.1 M (1 M= 1 mol dm^{-3}) tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) at room temperature, unless otherwise noted. A $Ag/AgNO_3$(sat.) electrode was used as the reference electrode. The rate of potential sweep was 0.1 V s^{-1}.

The cyclic voltammogram of $[Ru(bpm)_3]^{2+}$ was similar to that of $[Ru(bpy)_3]^{2+}$ in exhibiting three nearly neighbouring steps. They were all reversible one-electron steps, judging from the well-defined anodic current peaks and from the separation between the cathodic peak potential and the anodic one (ΔE_p).

Table 1. Reversible half-wave potentials for the reduction of iron(II) and ruthenium(II) complexes in acetonitrile containing 0.1 Bu_4NPF_6 at room temperature

Complex	$[-E^{red}_{1/2,C}$ *vs.* $(Ag/AgNO_3)]$/V (ΔE_p/mV)		
	1st	2nd	3rd
$[Fe(bpm)_3]^{2+}$	1.41 (45) [a]	1.57 (48) [a]	1.75 (50) [a]
$[Ru(bpm)_3]^{2+}$	1.40 (60)	1.55 (60)	1.75 (63)
$[Ru(bpy)_3]^{2+}$	1.81 (60)	2.01 (65)	2.25 (60)
$[Ru(4\text{-dmbpy})_3]^{2+}$	1.94 (60)	2.13 (65)	2.37 (64)
$[Ru(5\text{-dmbpy})_3]^{2+}$	1.98 (62)	2.19 (62)	2.44 (65)
$[Ru(bpm)(bpy)_2]^{2+}$	1.51 (61)	1.95 (65)	2.14 (70)
$[Ru(bpm)(4\text{-dmbpy})_2]^{2+}$	1.52 (60)	2.05 (65)	2.26 (68)
$[Ru(bpm)(5\text{-dmbpy})_2]^{2+}$	1.53 (60)	2.12 (65)	2.36 (65)

a) At −40 °C, the $E^{red}_{1/2,C}$ values are almost unaffected by the temperature.

The ratios of the anodic to the cathodic peak currents could not be determined, however, because of the proximity of the reduction steps. A similar pattern of voltammogram was obtained for $[Fe(bpm)_3]^{2+}$ at −40 °C, but at room temperature no reversible steps were observed besides the one for the liberated ligand molecules. The cyclic voltammograms for $[Ru(bpm)(bpy)_2]^{2+}$ and methyl derivatives were quite similar. They had one remote and two nearly neighbouring reversible one-electron steps. The reversible half-wave potentials and the peak separations thus obtained are listed in Table 1. The $E^{red}_{1/2,L}$ values for the first reduction steps of bpm, bpy, 4-dmbpy, and 5-dmbpy were, respectively, −2.33, −2.71, −2.77, and −2.82 V *vs.* $Ag/AgNO_3$(sat.).

The $E^{red}_{1/2,C}$ values for the (a) first, (b) second, and (c) third reduction steps of the unmixed-ligand complexes, $[Ru(bpm)_3]^{2+}$, $[Ru(bpy)_3]^{2+}$, $[Ru(4\text{-dmbpy})_3]^{2+}$, and $[Ru(5\text{-dmbpy})_3]^{2+}$, are plotted in Fig. 1 against the $E^{red}_{1/2,L}$ values. The experimental points for each step obey Eq. 1 approximately. Consequently, we may conclude that the redox orbitals of $[Ru(bpm)_3]^{2+}$ are also three-fold degenerate ligand π^*-orbitals.

Figure 2 shows similar plots for the mixed-ligand complexes, $[Ru(bpm)(bpy)_2]^{2+}$, $[Ru(bpm)(4\text{-dmbpy})_2]^{2+}$, and $[Ru(bpm)(5\text{-dmbpy})_2]^{2+}$. A striking feature is that the $E^{red}_{1/2,C}$ values for the first steps are almost independent of the ligands. All the experimental points for the second and the third steps lie on straight lines. Their slopes are inconsistent with Eq. 1, but this is not surprising because only two of the three ligands are changed in this case.

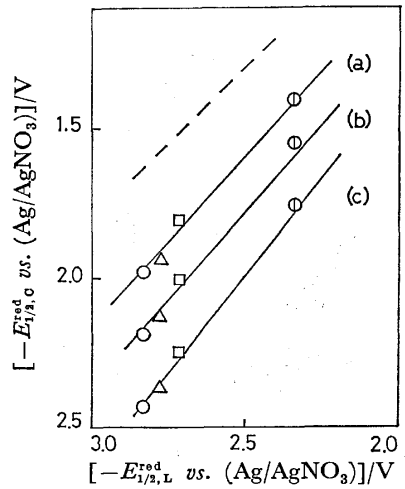

Fig. 1. Plots of $E^{1/2,c}_{red}$ for (a) $[RuL_3]^{2+}$, (b) $[RuL_3]^{+}$, and (c) $[RuL_3]$ *vs.* $E^{red}_{1/2,L}$ for L. L=(①) bpm, (□) bpy, (△) 4-dmbpy and (○) 5-dmbpy. The broken line shows the slope given by Eq. 1.

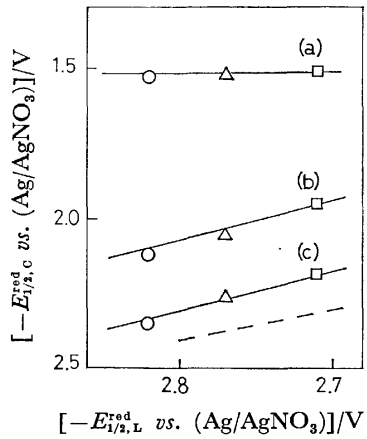

Fig. 2. Plots of $E^{1/2,c}_{red}$ for (a) $[Ru(bpm)L_2]^{2+}$, (b) $[Ru(bpm)L_2]^{+}$, and (c) $[Ru(bpm)L_2]$ *vs.* $E^{red}_{1/2,L}$ for L. L=(□) bpy, (△) 4-dmbpy and (○) 5-dmbpy. The broken line shows the slope given by Eq. 1.

The feature of Fig. 2 can be explained as follows. When we construct the MO of a $[Ru(bpm)L_2]^{2+}$ complex by the configuration interaction of the d_π atomic orbitals of the central metal and the LUMO's (lowest unoccupied molecular orbitals) of bpm and two L's, the metal orbitals are not taken into consideration.[5] Since the LUMO of bpm is lower than the LUMO's of L's by about 0.4 to 0.5 eV, it does not mix with the latter, which form two-fold degenerate orbitals. In $[Ru(bpm)_3]^{2+}$, three LUMO's of bpm can mix with each other and form three-fold degenerate orbitals, which are probably lower than the unmixed bpm orbital. This orbital order is consistent with the experimental finding that $[Ru(bpm)_3]^{2+}$ is reducible at a more positive potential than $[Ru(bpm)L_2]^{2+}$ (Table 1). When three electrons are added to $[Ru(bpm)L_2]^{2+}$, they may occupy these redox orbitals with parallel spins, because the energy of repulsion between a pair of electrons on the same MO may be much greater than the promotion energy between the lowest and the second lowest orbitals. Since the lowest orbital of $[Ru(bpm)L_2]^{2+}$ should be insensible to the small perturbation of methyl substitution applied to bpy, the $E^{red}_{1/2,c}$ values for the first steps should be invariable among the three $[Ru(bpm)L_2]^{2+}$ complexes.

In conclusion, the LUMO of $[Ru(bpm)L_2]^{2+}$ is actually localized on a single ligand bpm and is not delocalized over three ligand molecules. On the basis of the emission spectra of the mixed-ligand complexes of Rh(III) with bpy and 1,10-phenanthroline, Halper and DeArmond[10] have concluded that π^*-orbitals are localized on each ligand molecule, even when the $E^{red}_{1/2,L}$ values are almost identical. If their conclusion is right, though we are not in a position to comment on it now, it should be quite natural to get our present result.

We wish to thank Dr. Eiichi Ichikawa for his guidance in the synthesis of 2,2′-bipyrimidine.

Pyrolytic Sulfurization Gas Chromatography. X. The Reduction of the Analysis Time by Means of High-frequency Heating

Tadashi Hara* and Fujio Okui

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku Kyoto 602

(Received May 27, 1981)

Synopsis. With the objective of reducing the analysis time in the previous PSGC method, a high-frequency induction furnace was used instead of an electric furnace. By using the present furnace, the time necessary for the pyrolytic sulfurization was reduced from 40 min to 1 min with satisfactory results.

By using pyrolytic sulfurization gas chromatography (PSGC), which was originated by the present authors, the atomic ratio between C, H, O, and N in a usual organic compound,[1] a metal organic chelate compound,[2] a polymer,[3] and an organic halogen compound[4] has been successfully and simultaneously determined. Moreover, the atomic ratio between C, H, O, N, Cl, Br, and I in an organic halogen compound has been successfully determined[5] using only one sample by a combination of gas chromatography and ion chromatography. Since the analysis by the PSGC was, however, batch-by-batch and time-consuming, a high-frequency induction furnace instead of the electric furnace used in the previous work[1-7] has been employed in order to reduce the reaction time of the pyrolytic sulfurization. The new furnace designed by the present authors consists of a work coil and an ampule holder in which an outer quartz tube is packed with granulated tungsten. By the use of the present furnace, the reaction temperature between a sample and S in a quartz ampule can be raised from the 950 °C in the previous work[1] to about 1500 °C; also, the reaction time is reduced from 40 min to 1 min. Various organic compounds were analyzed under experimental conditions similar to those used in the previous PSGC method.

Experimental

Apparatus. To subject an organic compound to the pyrolytic sulfurization, a high-frequency induction furnace (type: HFT-10S, frequency: 13.5 MHz, maximum power: 1 KW) was introduced instead of the electric furnace used in the previous work.[1] The furnace consists of a work coil and an ampule holder in which an outer quartz tube is packed with *ca.* 10 g of granulated tungsten as the heating medium. The furnace is shown in detail in Fig. 1.

Reagents. The granulated tungsten used as the heating medium was commercially available (purity: 99.9%; particle size; 10—20 mesh). The organic compounds used as standard samples were of a reagent grade for elemental analysis except for cyanoguanidine, which was of a reagent grade for a melting-point standard.

Procedure. The ampule containing a sample and S was prepared in a manner similar to that used in the previous work,[1] except that the ampule was shortened from 5 cm to 3 cm because of the furnace conditions, and placed in the ampule holder in the furnace. After replacing the contents of the furnace with helium, the ampule was treated for 1 min by high-frequency heating and then left standing for 3 min in the furnace. The ampule thus obtained was inserted into a gas sampler, and the reaction products in the ampule were analyzed by means of gas chromatography under the same conditions as in the previous work.[6]

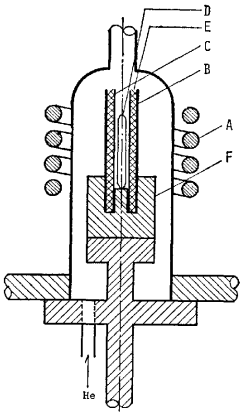

Fig. 1. High-frequency induction furnace.
A: Work coil, B: outer quartz tube (10.5 i.d., 12.5 o.d., 50 mm long), C: inner quartz tube (5.5 i.d., 6.5 o.d., 50 mm long), D: ampule containing a sample and S, E: granulated tungsten (10—20 mesh), F: ceramic support.

The atomic ratio between C, H, O, and N was calculated by the use of correction factors[6] which had been obtained from the analytical results of cyanoguanidine and sucrose by the above-mentioned procedure.

Results and Discussion

High-frequency Heating. Several kinds of granulated metals were examined as heating medium in high-frequency heating, and tungsten was found to be best. Since tungsten was easily oxidized to the oxide under the experimental conditions in the air, it was used in an atmosphere of helium, the tungsten being usable repeatedly. By using 10 g of granulated tungsten as the heating medium, an ampule containing a sample and S could be heated at about 1500 °C in a moment.

Reaction Time. The time necessary for the reaction between a sample and S in an ampule was investigated for 8-quinolinol as a standard sample; the relationship between the reaction time and the amounts of gases evolved from 1 mg of a sample is shown in Fig. 2. As can be seen from Fig. 2, the reaction between the sample and S in an ampule was completed within 40 s. The reaction products also indicated the same composition as in the previous PSGC method. In the present study, therefore, an ampule containing a sample and S was heated for 1 min by means of a high-frequency induction furnace.

Table 1. Analytical results of various organic compounds

Sample	C (wt%)			H (wt%)			O (wt%)			N (wt%)		
	Theor.	Found	Error	Theor.	Found	Error	Theor.	Found	Error	Theor.	Found	Error
8-Quinolinol	74.47	74.18	−0.29	4.86	4.93	+0.07	11.02	10.99	−0.03	9.65	9.90	+0.25
Cholesterol	83.87	84.23	+0.36	11.99	11.98	−0.01	4.14	3.79	−0.35			
Thiourea[a)]	27.26	27.08	−0.18	9.15	9.11	−0.04				63.59	63.81	+0.22
2,2-Bis(ethyl-sulfonyl)propane[a)]	51.21	51.30	+0.09	9.82	10.06	+0.24	38.97	38.64	−0.33			
Naphthalene	93.71	93.56	−0.15	6.29	6.44	+0.15						
Anthraquinone	80.76	80.53	−0.23	3.87	4.05	+0.18	15.37	15.42	+0.05			
Tris(2,4-pentane-dionato)iron(III)	60.59	60.72	+0.13	7.12	7.19	+0.07	32.29	32.09	−0.20			
Bis(2,4-pentane-dionato)-magnesium(II)	51.27	51.32	+0.05	7.75	7.77	+0.02	40.98	40.91	−0.07			

a) The sulfur atom was neglected in considering the composition of a sample, since it could not be determined.

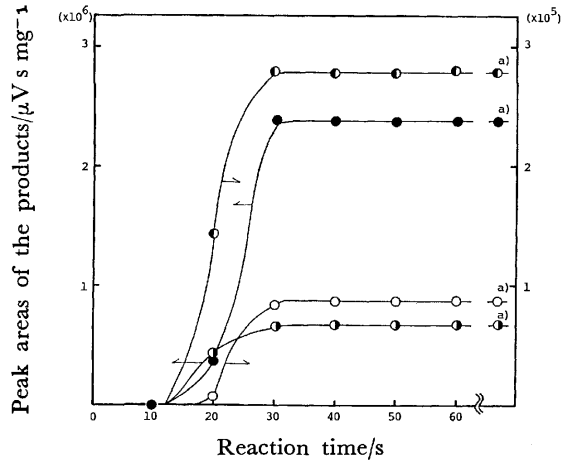

Fig. 2. Relationship between the reaction time and the amount of the reaction product.
○: N_2, ◑: H_2S, ◐: COS, ●: CS_2. a): By the previous PSGC method.

Standing Time after the Reaction. The effect on the result of the standing time of an ampule after high-frequency heating was investigated for 8-quinolinol as a standard sample. A standing time of less than 20 min had no effect on the analytical results of organic compounds analyzed by the present procedure. Therefore, the reaction products in an ampule were analyzed after leaving the ampule standing for 3 min in the furnace.

Analytical Results of Various Organic Compounds. Various organic compounds and metal organic chelate compounds were analyzed by the present procedure; the results are shown in Table 1. As can be seen from Table 1, both the precision and the accuracy were similar to those in the previous PSGC method.

From the results obtained by the present study, it can be concluded that the introduction of a high-frequency induction furnace reduces not only the reaction time between a sample and S in an ampule, but also the overall time necessary for an analysis. This will be very valuable for the further improvement of the PSGC method.

Dysprosium and Holmium Complexes of *N*-(2-Pyridyl)salicylideneamine

Megh SINGH* and K. Singh GHARIA

Department of Chemistry, University of Jodhpur, Jodhpur-342001, India

(Received January 23, 1981)

Synopsis. Dysprosium and holmium isopropoxides react with monofunctional bidentate Schiff base, *N*-(2-pyridyl)salicylideneamine, in 1:1, 1:2, and 1:3 molar ratios in benzene to yield complexes of the types $Ln(OPr^i)_2(sap)$, $Ln(OPr^i)(sap)_2$, and $Ln(sap)_3$ (where Ln=Dy or Ho and sap^- is the anion of the Schiff base sapH). Probable structures for these complexes are proposed on the basis of molecular weight and IR spectroscopic data. Reports on metal complexes derived from Schiff bases have aroused considerable interest in the field of coordination chemistry, and have been extensively studied.[1-4] A literature survey reveals that no work has been done on Dy(III) and Ho(III) complexes of heterocyclic Schiff base, *N*-(2-pyridyl)salicylideneamine. However, complexes of this Schiff base with d-transition elements[5,6] have been reported. The present paper deals with the synthesis of Dy(III) and Ho(III) complexes of *N*-(2-pyridyl)salicylideneamine and their characterization by infrared spectra.

Experimental

Dy(III) and Ho(III) isopropoxides were prepared from the respective trichlorides by sodium alkoxide method.[7] The Schiff base was prepared by usual method.[6] The reactions of Dy(III) and Ho(III) isopropoxides with the Schiff base in different molar ratios (1:1, 1:2, and 1:3) were carried out in refluxing benzene and the 2-propanol liberated in these reactions was collected azeotropically and estimated by oxidation method.[8] For brevity the reactions and their analyses have been summarized in Table 1. The lanthanoid content was determined by ignition to sesquioxide. Nitrogen was estimated by the Kjeldahl method. Molecular weights were determined in refluxing benzene by Cottrell's method.[9] IR spectra were recorded in the 4000—200 cm^{-1} range on a Perkin-Elmer 621 instrument using KBr pellets and as mulls in Nujol.

Results and Discussion

The reactions of Dy(III) and Ho(III) isopropoxides with the Schiff base in 1:1, 1:2, and 1:3 molar ratios in anhydrous benzene liberated one, two and three moles of 2-propanol respectively and resulted in the formation of the corresponding mono-, bis-, and tris-Schiff base derivatives of Dy and Ho.

Diisopropoxy-mono(Schiff base) derivatives are orange-red solids, soluble in benzene and they decompose at temperature ≈150 °C whereas monoisopropoxy-bis(Schiff base) derivatives are benzene insoluble orange coloured solids. Tris(Schiff base) derivatives are isolated as dark yellow powders, insoluble in benzene but fairly soluble in *N*,*N*-dimethylformamide.

The molecular weights of diisopropoxy-mono(Schiff base) derivatives of Dy(III) and Ho(III) in boiling benzene indicate them to be essentially trimeric involving the most probable structure of the type (I).

The products $Ln(OPr^i)(sap)_2$ were found to be insoluble in benzene. The insolubility of these derivatives in common organic solvents prevented determination of molecular weights which could have otherwise useful information about their structures. On serric grounds it can be said that this Schiff base cannot form monomeric structures. With the help of previous work on similar type of derivatives,[10-12] we suggest that these complexes may be present in dimeric form (II) where two metal octahedra are bridged through isopropoxide oxygen bridges. The probability of other structures having lanthanoid atom with more than six coordination number, however, cannot be ruled out since lanthanoids have tendency to show coordination number more than six.[13]

The tris(Schiff base) derivatives of Dy(III) and Ho(III) are also insoluble in benzene and common organic solvents. The insolubility in common noncoordinating solvents and high melting or decomposition temperature (≈260 °C) indicate their associated or polymeric nature. A polymeric structure has also

Ln = Dy or Ho ($\overset{O}{N}$ = anion of Schiff base SAPH.

been suggested for tris(salicylideneamino)triethylenetetramine complexes of lanthanoids on the basis of their practically insoluble nature in any available solvents.[14]

The IR spectrum of ligand exhibited a broad band around 2990—2800 cm^{-1} due to O–H stretching vibration, shifted to lower frequency as a result of intramolecular hydrogen bonding OH···N. The disappearance of this band (ν O–H) in the complexes suggests the participation of OH group of Schiff base in bound formation.

A strong band is observed at 1610 cm^{-1} in the free ligand. This is a characteristic absorption band of the azomethine (>C=N–) group. This band (ν C=N) in the spectra of all the complexes appears at almost the same position and remain unaffected on complexation. Since these bands are associated with –C=N– stretching frequencies, this is consistent with observation of Sarma and Bailar[15] that indicate coordination through the nitrogen atom of azomethine group. However, some workers have reported a shift of ν C=N frequency either to higher[16] or to lower[17] wave number on complexation.

The phenolic C–O stretching vibration in free ligand is observed at 1280 cm^{-1}. This band in complexes is slightly shifted to higher frequency ($\approx$1295 cm^{-1}) indicating the bonding of the ligand to the metal atom through phenolic oxygen. The higher ν C–O in complexes may be ascribed to delocalization of electron density from the oxygen atom to the metal resulting in greater ionic character of the C–O bond and a consequent increase in the C–O vibration frequency. A similar observation was observed by Kovacic for Cu(II) complexes of salicylidene–anilines.[18]

The mono and diisopropoxy derivatives of Schiff base show characteristic frequencies of isopropyl group at $\approx$1385, 1160, 1150, and 1000 cm^{-1}.[19] The medium strong band at $\approx$1385 and 1000 cm^{-1} may be assigned to the *gem*-dimethyl structure and bridged C–O stretching vibrations respectively. The value of C–O stretching vibration in mono- and diisopropoxy derivatives of Dy(III) and Ho(III) *ca.* $\approx$1000 cm^{-1} agrees with C–O vibration of bridging alkoxy group.[20]

The coordination of pyridine molecule to metal is known to cause an upward shift of the four principal bands of pyridine between 1600 and 1430 cm^{-1}, which corresponds to ν C=C and ν C=N vibrations.[21] In our case no appreciable shift was observed in these bands. This suggests that pyridine nitrogen is not involved in coordination.

The medium and weak bands between 700—200 cm^{-1} are observed in these complexes. These bands are assigned to ν M–O and ν M–N vibrations. No significant differences among the IR spectra were observed for the mono-, bis-, and tris-Schiff base complexes in this region. The bands at $\approx$660, 535, 505, and 460 cm^{-1} are due to metal-oxygen vibrations[22] whereas the bands observed in the region 400—200 cm^{-1} are assigned to metal-nitrogen vibrations.[23]

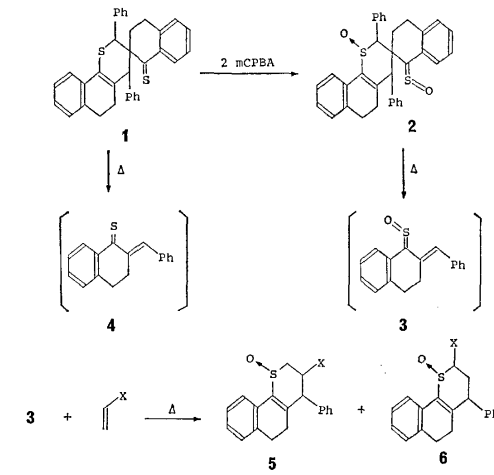
(Received June 29, 1981)

Synopsis. The cycloaddition reaction of 2-benzylidenetetralin-1-thione *S*-oxide with acrylonitrile (or styrene) gave a mixture of 2- and 3-cyano(or phenyl)-4-phenyl-3,4,5,6-tetrahydro-2*H*-naphtho[1,2-*b*]thiopyran *S*-oxide. Pummerer reaction of these *S*-oxides resulted to afford the corresponding acetates.

α,β-Unsaturated sulfines[1] have been inaccessible compounds and their chemical properties have not been investigated. Previously, we reported the generation of α,β-unsaturated sulfine [2-benzylidenetetralin-1-thione *S*-oxide (**3**)] by the thermolysis of its dimer (**2**), and the cycloaddition reaction of **3** with norbornene.[1b] α,β-Unsaturated thiones such as the compound (**4**) are known to react with various kinds of olefins giving Diels-Alder type 1,4-cycloaddition products,[2] and we are interested in the reaction of **3** with some olefinic compounds.

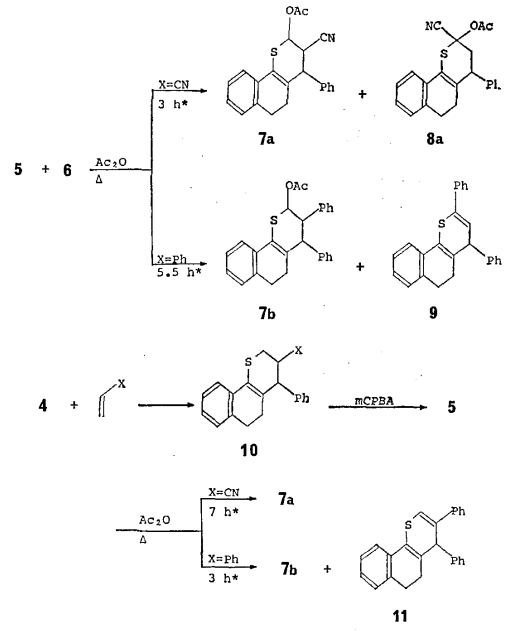
When a mixture of **2** and acrylonitrile in xylene was heated to reflux, a mixture of the adducts **5a** and **6a** were obtained. They were separated and identified by the conversion into their sulfides by Pummerer reaction. Refluxing of the mixture (**5a** and **6a**) in acetic anhydride afforded two acetates **7a** and **8a**. Both **7a** and **8a** showed absorptions at 2250 cm^{-1} for cyano group and at 1760 and 1210 cm^{-1} for $OCOCH_3$ in their IR spectra. The ^1H-NMR spectrum of **7a** showed signals at δ 3.68 (dd, J=4 and 6 Hz) 3.93 (d, J=6 Hz), and 6.34 (d, J=4 Hz). These signals were readily assigned to those of the C-3, the C-4 and the C-2 protons, respectively. The proton-noise-decoupled ^{13}C-NMR spectrum of **7a** also showed three methine carbon signals at δ 37.1, 45.4, and 69.5. The structure of **7a** was further confirmed by an independent synthesis. Namely, oxidation of **10a** with *m*-chloroperbenzoic acid (mCPBA) followed by the treatment with acetic anhydride produced the acetate, which was completely identical with that obtained from **5a**. The ^1H-NMR spectrum of **8a** showed signals at δ 3.96 (m, 1H) and 2.83 (m, 2H) and the ^{13}C-NMR spectrum showed signals at δ 41.7 for the C-3, 44.4 for the C-4, and 71.9 for the C-2 carbons.

Similarly, the reaction of **3** with styrene gave a mixture of the adducts **5b** and **6b**. The Pummerer reaction of the mixture afforded two products **7b** and **9**. The IR spectrum of **7b** showed absorptions at 1760 and 1210 cm^{-1} for $OCOCH_3$. The ^1H-NMR spectrum showed signals at δ 3.69 (dd, J=4 and 6 Hz) for the C-3, 3.90 (d, J=6 Hz) for the C-4, and 6.19 (d, J=4 Hz) for the C-2 protons. The ^{13}C-NMR spectrum showed the three methine carbon signals at δ 50.8, 51.4, and 75.7. Also, **7b** was identical with the spectrum prepared by an independent synthetic route from **10b** (Scheme 2). The IR spectrum of **9** had no band in the near region of 1720 cm^{-1} for $OCOCH_3$ and the mass spectrum showed a molecular ion peak at 352. The ^1H-NMR spectrum showed signals at δ 4.31 (d, J=6 Hz) for the C-4 and 6.01 (d, J=6 Hz) for the C-3 protons. The ^{13}C-NMR spectrum showed a signal at δ 50.1 for the C-4 carbon. These data and elementary analysis



a: X=CN, b: X=Ph

Scheme 1.



a: X=CN, b: X=Ph * Reaction time

Scheme 2.

were in agreement with the proposed structure (**9**).

The reaction of **3** with maleic anhydride gave tarry unidentified products. Butyl vinyl ether or 1-morpholinocyclohexene did not react with **3** but the thermal rearrangement of **3** to β-thioxo ketone[3] was observed in this case.

As a result, it has been found that the α,β-unsaturated sulfine **3** does not react with electron rich dienophiles and that the cycloaddition reaction of **3** is less regioselective than that of the corresponding α,β-unsaturated thione **4**.

Experimental

All the melting points are uncorrected. ^{1}H-NMR (100 MHz) and ^{13}C-NMR (25 MHz) spectra were recorded on a JEOL JNM-FX 100 spectrometer with Me_4Si as an internal standard. IR spectra were obtained on a Hitachi Model 260-10 infrared spectrometer. Mass spectral data were obtained with a Hitachi RMU-7M double-focusing mass spectrometer.

*A Typical Procedure for the Reaction of **3** with Olefins.* A suspension of **2**[2b] (0.65 g) and acrylonitrile (1.2 g) in dry xylene (6 cm^3) was refluxed for 2.5 h under a nitrogen atmosphere. The solvent was evaporated to give a mixture of **5a** and **6a** which could not be separated by crystallization or chromatography: yield 32%; colorless powder. Found: C, 75.43; H, 5.29%. Calcd for $C_{20}H_{17}NOS$: C, 75.21; H, 5.29%. A mixture of **5b** and **6b** (reaction time 1 h): yield 67%; colorless powder. Found: C, 80.84; H, 5.96%. Calcd for $C_{25}H_{22}OS$: C, 81.04; H, 5.99%.

*A Typical Procedure for the Reaction of the Sulfoxide (**5** and **6**) with Acetic Anhydride.* A suspension of a mixture of **5a** and **6a** (2.62 g) in acetic anhydride (15 cm^3) was refluxed for 3 h under a nitrogen atmosphere. The excess acetic anhydride was evaporated and the residue was chromatographed on Wakogel C-200 [eluting with benzene–hexane (1:1)]. **7a**: yield 10%; mp 190—191 °C; MS (70 eV) *m/e* 361 (43), 250 (60), 249 (100); ^{1}H-NMR ($CDCl_3$) δ 1.76 (s, 3H), 2.12—2.85 (m, 4H), 3.68 (dd, *J*=4 and 6 Hz, 1H), 3.93 (d, *J*=6 Hz, 1H), 6.34 (d, *J*=4 Hz, 1H), 7.04—7.60 (m, 9H); ^{13}C-NMR ($CDCl_3$) δ 20.4 (q), 28.0 (t), 29.9 (t), 37.1 (d), 45.4 (d). Found: C, 73.08; H, 5.21; N, 3.81; S, 8.76%. Calcd for $C_{22}H_{19}O_2NS$: C, 73.10; H, 5.30; N, 3.88; S, 8.87%.

Electrooxidative Conversion of Aldehydes into Methyl Carboxylates

Toshiro CHIBA,* Mitsuhiro OKIMOTO, Hiroshi NAGAI, and Yoshiyuki TAKATA**
Department of Applied Chemistry, Kitami Institute of Technology, Koen-cho 165, Kitami 090
***Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received January 26, 1981)

Synopsis. The electrolytic oxidation of methanolic solutions of aldehydes in the presence of sodium cyanide at a platinum anode was found to produce corresponding methyl carboxylates.

Several chemical procedures for the preparation of methyl carboxylates from aldehydes in methanolic media using peroxides,[1] ozone,[2] or manganese dioxide[3] have been reported, but only a few reports are available on the electrooxidative conversion of aldehydes into methyl carboxylates.[4]

Thus, we wish to report here the electrochemical oxidation of aldehydes[5] in methanol containing sodium cyanide, which can afford methyl benzoates in good yields.

Results and Discussion

Table 1 shows the results of the electrooxidation of several aldehydes in methanolic sodium cyanide on a macro-scale. These electrolyses were performed in a divided cell at room temperature using a platinum gauge anode under constant current conditions until almost all of the aldehyde was consumed.

Generally, aromatic aldehydes readily underwent anodic oxidation and were converted into the respective methyl benzoates. As an example of the oxidation of benzaldehyde, the ester yield at the stage where $2F$/mol of electricity passed was 62%, and by passing an excess of electricity it reached approximately 90%, according to GLC analysis. From the resulting anolyte, essentially pure methyl benzoate could be isolated by simple distillation in a yield of 80%. Chemical side reactions such as benzoin condensation rarely took place under the present conditions in spite of the reaction in the presence of sodium cyanide.

Similar results were obtained in the oxidation of substituted benzaldehydes with a methyl group or chlorine atom in an *ortho* or *para* position. The yield of their esters was hardly affected by the substituent and its position. However, *p*-methoxybenzaldehyde afforded methyl *p*-methoxybenzoate in yield less than 50% along with the nuclear cyanation product of the ester in yield *ca.* 15%.[6]

Attempted oxidation of aliphatic aldehydes by the same procedure gave only about a 40% yield of the methyl carboxylates and a considerable amount of a highly viscous liquid which may be derived from aldol condensation.

The aldehydes were more oxidizable in methanolic sodium cyanide than in a lithium perchlorate-acetonitrile electrolyte system, since benzaldehyde was oxidized at the potential of 2.3 V *vs.* SCE in lithium perchlorate-acetonitrile solution in contrast to the potential at about 1.7 V in methanolic sodium cyanide.[7] Therefore, it was assumed that the anodically oxidized species would not be the aldehyde itself, but its derivatives such as cyanohydrin.

The present reaction seems to proceed by a scheme

analogous to that of the oxidative conversion of aldehydes into esters with mangenese dioxide and sodium cyanide,[3] in which the initial step is the formation of cyanohydrin, followed by oxidation to acyl cyanide which can readily react with alcohol to form the ester.

In fact, a similar electrolysis of mandelonitrile gave methyl benzoate in a reasonable yield, but the ester was scarcely obtainable by anodic oxidation of benzaldehyde using sodium perchlorate or tetraethylammonium *p*-toluenesulfonate in place of sodium cyanide as the supporting electrolyte.

Apparently, the cyanide ion played an important role in this reaction; however, the exact catalytic behavior could not be recognized, because the consumption of the cyanide ion was confirmed. Consequently, an excess of more than an equivalent of sodium cyanide to the aldehyde should be used to obtain the ester effectively.

This electrolysis was not applicable to α,β-unsaturated aldehydes such as cinnamaldehyde or 2-methyl-2-pentanal under the present experimental conditions. In these cases, many unidentified miscellaneous products were formed.

Experimental

The macro-scale electrolyses were carried out in a 200 ml beaker separated from the cathode compartment by a glass filter. The anode was a cylindrical platinum gauge (4.5 cm in high, 11 cm in circumference, 55 mesh), and the cathode was a platinum coil (0.8 mmϕ, 20 cm). The cell was externally cooled with water, and the anolyte was stirred by a magnetic stirring bar.

The general procedure is as follows. A solution of benzaldehyde (50 mmol) in methanol (160 ml) containing sodium cyanide (76 mmol) was electrolyzed at a constant current of 0.8 A for 9.4 h. After completion of the reaction, the solvent was distilled off, and the residue was washed with water, followed by dual extraction with ether. The combined extracts were concentrated on a water bath, and the warm residue was vigorously shaken with a small quantity of saturated sodium hydrogensulfite solution. The oily layer was extracted with ether, and then distilled under reduced pressure after dehydration with anhydrous sodium sulfate.

Identification of products was made by infrared spectroscopy and comparison with authentic samples prepared by the usual manner.

ortho-Disubstituted *F*-Benzenes. IV. The Formation of 2-Acyl-*F*-phenyl Carboxylates from (*F*-Benzo)furans by the Oxidative Cleavage of the Furan-ring

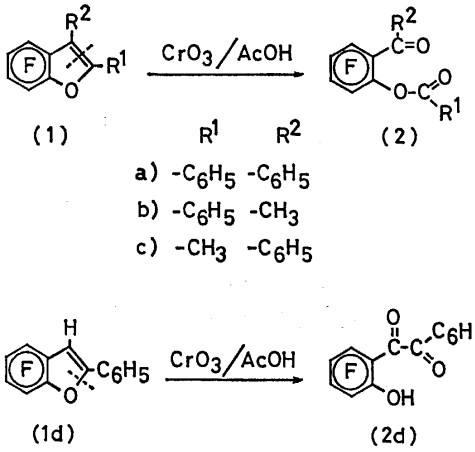
Yoshinari INUKAI,† Takaaki SONODA, and Hiroshi KOBAYASHI*

Research Institute of Industrial Science, Kyushu University 86, Kasuga 816

(Received May 6, 1981)

Synopsis. 2,3-Diphenyl-, 2-phenyl-3-methyl-, and 2-methyl-3-phenyl(*F*-benzo)furans were oxidized with chromium trioxide in acetic acid to yield 2-benzoyl-*F*-phenyl benzoate, 2-acetyl-*F*-phenyl benzoate, and 2-benzoyl-*F*-phenyl acetate respectively, while 2-phenyl(*F*-benzo)furan was least susceptible to the same reagent, affording 1-(2-hydroxy-*F*-phenyl)-2-phenylethanedione in a poor yield. The spectral data of the products were compatible with the structure of *ortho*-disubstituted *F*-benzene.

In connection with the studies of the *ortho*-disubstituted *F*-benzenes,[1,2] we have examined the oxidative cleavage of the side-ring of (*F*-benzo)furans (**1**), which were previously described.[3] In a manner similar to that of unfluorinated analogues,[4] the (*F*-benzo)furans (**1**) were oxidatively cleaved between the 2- and 3-positions of the furan ring with chromium trioxide to give *ortho*-disubstituted *F*-benzenes. 2,3-Diphenyl-, 2-phenyl-3-methyl-, and 2-methyl-3-phenyl-(*F*-benzo)furans (**1a**—**c**) yielded 2-benzoyl-*F*-phenyl benzoate (**2a**), 2-acetyl-*F*-phenyl benzoate (**2b**), and 2-benzoyl-*F*-phenyl acetate (**2c**) respectively. The *F*-phenyl ester groups remained intact; they were not hydrolyzed in acid-reaction media. 2-Phenyl(*F*-benzo)furan (**1d**), however, behaved in a different manner upon oxidation with the same reagent. The (*F*-benzo)furan (**1d**) was cleaved at the C–O bond under similar reaction conditions to give 1-(2-hydroxy-*F*-phenyl)-2-phenylethanedione (**2d**) in a poor yield. In the meantime, approximately one-third of the starting compound was recovered unchanged. Although a considerable amount of benzoic acid was isolated from the resulting mixture, no trace was found relating to the *F*-benzo moiety, which would be present in the form of *F*-salicylic acid or salicylaldehyde.



The cleavage of the furan-ring structure was proved by the disappearance of the UV band characteristic of the benzofuran moiety.[5] The ^{19}F-NMR signal of the fluorine atom at the 3-position in Compound (**2b**) was assigned by means of the long-range coupling between the fluorine and the three hydrogens on the vicinal-acetyl group. The fluorine atoms at the 3- and 6-positions in Compounds (**2a**) and (**2c**) were assigned on the basis of the fluorine chemical shifts obtained in Compound (**2b**). Those of Compound (**2d**) were tentatively assigned according to the spin-spin coupling pattern exhibited in its ^{19}F-NMR spectrum.

Experimental

General Procedure. A solution of chromium trioxide (2.9 mmol) in water (2 ml) was added to a mixture of a (*F*-benzo)furan derivative (**1a**—**c**) (1.2 mmol) and acetic acid (60 ml). The mixture was refluxed for 9 h, cooled, concentrated to a quarter of the original volume, and poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on a silica-gel column. The fraction eluted with hexane–dichloromethane gave a 2-acyl-*F*-phenyl carboxylate (**2a**—**c**). No fraction of the starting compound remained unchanged in the reaction mixture. The ^{1}H- and ^{19}F-NMR shifts were measured against TMS and *F*-benzene respectively as internal references.[6]

*2-Benzoyl-*F*-phenyl Benzoate (**2a**)*: Yield: 61%. Recrystallization from hexane gave colorless needles, mp 53—54 °C. The Reactions of the 1,2-Ethanediylbis(trithiocarbonic acid) Dianion with Several Electrophilic Reagents

Shigeo TANIMOTO,* Tatsuo OIDA, Toshio KOKUBO, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received June 17, 1981)

Synopsis. It has been found that the reaction of the 1,2-ethanediylbis(trithiocarbonic acid) dianion with haloacetic esters, chloromethyl ethers, and chloromethyl sulfides in tetrahydrofuran proceeds smoothly to afford 1,2-ethanediylbis(alkoxycarbonylmethyl trithiocarbonates), 1,2-ethanediylbis(alkoxymethyl trithiocarbonates) and bis(alkylthiomethyl) trithiocarbonates plus ethylene trithiocarbonate respectively.

We have recently reported[1] that 2,2′-[1,2-ethanediylbis(thio)]bis-1,3-dithiolane (**1**) is easily metalated with butyllithium in tetrahydrofuran to generate the 1,2-ethanediylbis(trithiocarbonic acid) dianion (**2**), with the elimination of 2 moles of ethylene; the dianion is then condensed with a variety of alkyl bromides and iodides to give 1,2-ethanediylbis(alkyl trithiocarbonates) and/or dialkyl trithiocarbonates plus ethylene trithiocarbonate (**8**). However, to the best of our knowledge, there has not been any other information concerning the synthetic utility of this anion. In this paper we would like to report the results of the reactions of **2** with several electrophilic reagents, such as haloacetic esters, chloromethyl ethers, and chloromethyl sulfides. The reaction of **2** with alkyl chlorides, studied under like conditions, did not show the formation of any products, suggesting a selectivity of **2** toward alkyl halides. Such selectivity was not observed in the reaction with haloacetic esters as the trapping agent. Bromoacetic esters undergo a condensation reaction with **2** similar to that observed with methyl iodide to afford 1,2-ethanediylbis(alkoxycarbonylmethyl trithiocarbonates) (**3**), along with a small amount of **8**. The reaction utilizing the chloro analogs, chloroacetic esters, had the same result, but the yields were somewhat lower. The results obtained by the reaction of **2** with several haloacetic esters are listed in Table 1, along with the physical data of the products.

a: X=Cl, R=CH_3, **b**: X=Cl, R=C_2H_5, **c**: X=Br, R=CH_3, **d**: X=Br, R=C_2H_5, **e**: X=Br, R=$CH_3(CH_2)_2$, **f**: X=Br, R=$CH_3(CH_2)_3$, **g**: X=Br, R=$C_6H_5CH_2$

Price and Oae[2] have pointed out that, in a certain nucleophilic substitution reaction, chloromethyl ethyl sulfide reacts about several thousand times as fast as butyl chloride; furthermore, chloromethyl ethyl ether was found to react far faster than the sulfur analog. Thus, we have investigated the reactions of **2** with chloromethyl ethers and sulfides. When some chloromethyl ethers were employed, 1,2-ethanediylbis(alkoxymethyl trithiocarbonates) (**4**) were obtained, suggesting that the ethers attack directly both of the nucleophilic ends of **2** (Eq. 2). On the other hand, when some chloromethyl sulfides were used, the products consist of an approximately equal mixture of bis(alkylthiomethyl) trithiocarbonates (**7**) and **8**, indicating that the reaction assuredly occurred acoording to Eq. 3. Thus, an obvious difference in behavior between chloromethyl ethers and sulfides was noted. In addition, it was found that the fragmentation of **2** by the intramolecular attack of its own nucleophilic end does not occur under the given conditions; that is, even if a solution of **2** in tetrahydrofuran had been stored at −5——10 °C for 5 h or more prior to the addition of haloacetic esters or chloromethyl ethers, substantially the same result was obtained. This evi-

TABLE 1. REACTION OF THE 1,2-ETHANEDIYLBIS(TRITHIOCARBONIC ACID) DIANION WITH SEVERAL HALOACETIC ESTERS

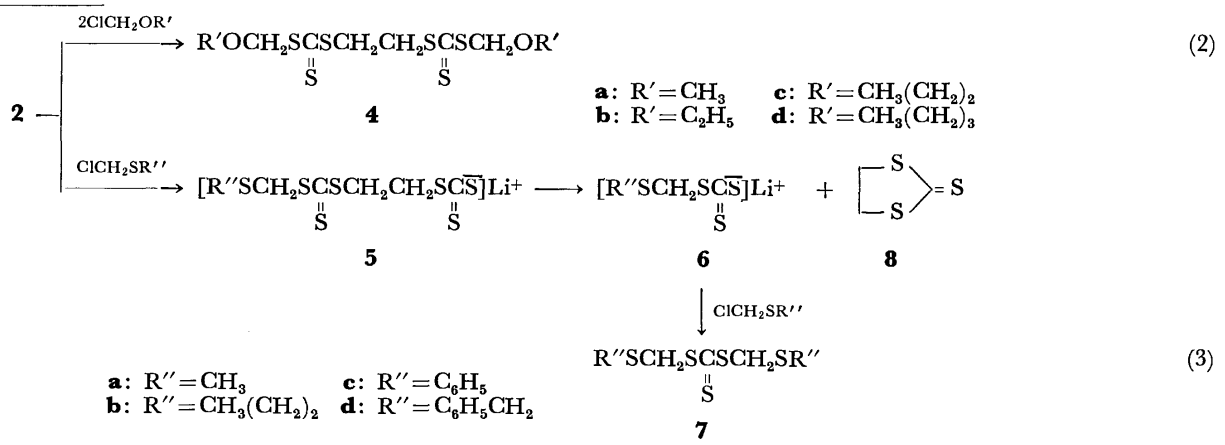
a) All **3** products gave satisfactory elemental analyses and exhibited spectral properties in accordance with the assigned structures. The ^{1}H-NMR spectra (δ values, in $CDCl_3$) are as follows: **3a**: 3.47(s, 4H), 3.52(s, 6H), 3.97(s, 4H). **3b**: 1.21(t, 6H), 3.50(s, 4H), 3.97(s, 4H), 4.00(q, 4H). **3e**: 0.89(t, 6H), 1.2—1.9(m, 4H), 3.50(s, 4H), 3.90(t, 4H), 3.97(s, 4H). **3f**: 0.82(t, 6H), 1.0—1.7(m, 8H), 3.40 (s, 4H), 3.81(t, 4H), 3.86(s, 4H). **3g**: 3.39(s, 4H), 3.91(s, 4H), 4.86(s, 4H), 6.7—7.1(m, 10H). Although a relatively small amount of **8** was observed in all runs, we were unable to find any bis(alkoxycarbonylmethyl) trithiocarbonate, which is supposed to arise simultaneously, within the limits of our detection.

dence leads us to favor the above mechanism. The products obtained by the reaction of **2** with several chloromethyl ethers and sulfides are listed in Tables 2 and 3, along with their physical data.



(2)

(3)

Among the products described in this report, **3** and **4** are difficult to synthesize by the other routes; moreover, the former may have great synthetic potential resulting from the presence of the two alkoxycarbonyl groups at both molecular ends.

Experimental

Reaction Summarized in Tables 1, 2, and 3. In each experiment, 2.0 g (6.6 mmol) of 2,2'-[1,2-ethanediylbis-(thio)]bis-1,3-dithiolane (**1**) was used; the mole ratio of electrophilic reagents to **1** and the eluents used for column chromatography are noted in the tables. All the reactions were carried out in the manner described in the preceeding report.[1]

Studies of Unusual Amino Acids and Their Peptides. XIV. The Asymmetric Hydrogenation of the Phenylhydrazone of Methyl *N*-(3,3-Dimethyl-2-oxobutanoyl)-L-valinate

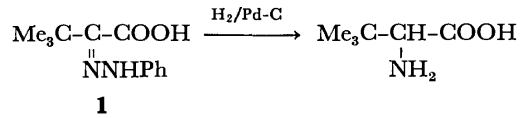
Toshifumi MIYAZAWA,* Katsumi TAKASHIMA, Takashi YAMADA, Shigeru KUWATA, and (the late) Hiroshi WATANABE

Department of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada-ku, Kobe 658

(Received July 6, 1981)

Synopsis. The asymmetric hydrogenation of the phenylhydrazone of methyl *N*-(3,3-dimethyl-2-oxobutanoyl)-L-valinate was investigated using palladium catalysts. The configuration of the newly formed *t*-leucine moiety was found to be L.

In the previous papers,[1,2] the present authors have reported on the convenient syntheses and the optical resolution of *t*-leucine (2-amino-3,3-dimethylbutanoic acid). One of our attempts at preparing racemic *t*-leucine on a large scale consisted in the reductive cleavage of the phenylhydrazone (**1**) of 3,3-dimethyl-2-oxobutanoic acid by hydrogenation (Scheme 1).



Scheme 1.

The success of this method prompted us to examine the asymmetric synthesis of this amino acid through the hydrogenation of the condensation product between the phenylhydrazone (**1**) and an amino-acid ester as the source of chirality. Methyl L-valinate was chosen in the present investigation, as in our previous study of the kinetic resolution of *t*-leucine.[3] The diastereomeric ratio of the resulting dipeptide, after conversion to the *N*-pivaloyl derivative, can easily be estimated by means of GLC analysis.[3,4]

Thus, the phenylhydrazone (**1**) was coupled with methyl L-valinate by means of the DCC[5] method. The resulting phenylhydrazone (**2**) of methyl *N*-(3,3-dimethyl-2-oxobutanoyl)-L-valinate was hydrogenated in methanol in the presence of a double molar amount of *p*-toluenesulfonic acid, using a palladium catalyst. For estimating the diastereomeric ratio of the resulting dipeptide, the crude product was pivaloylated in the usual manner.[4] The results are summarized in Table 1. The authentic samples were prepared by condensing *N*-Z-L- or *N*-Z-D-*t*-leucine with methyl L-valinate by means of the DCC method, followed by debenzyloxycarbonylation and the subsequent pivaloylation.

When palladium on carbon was used as a catalyst, the configuration of the newly formed *t*-leucine moiety was L (L-Tle–L-Val:D-Tle–L-Val=67:33). The reaction temperature, as far as we examined it, had little influence on the diastereomeric ratio. In a series of studies[6] of the asymmetric amino-acid syntheses through the hydrogenation of oximes or Schiff bases of α-keto esters or amides, Harada *et al.* postulated an intermediate substrate-catalyst complex for explaining the configurations and the optical yields of the products. According to this hypothesis, the present results could be explained by assuming the preferred conformation of the intermediate complex formed prior to hydrogenation to be as is shown in Scheme 2.[7] The choice of catalyst was found to have a significant influence on the present asymmetric hydrogenation. Thus, the use of palladium black or palladium oxide resulted in a higher optical purity of the *t*-leucine moiety than in the case of palladium on carbon.

TABLE 1. *t*-LEUCYL DIPEPTIDE PREPARED VIA THE ASYMMETRIC HYDROGENATION[a] OF THE PHENYLHYDRAZONE (**2**) OF METHYL *N*-(3,3-DIMETHYL-2-OXOBUTANOYL)-L-VALINATE

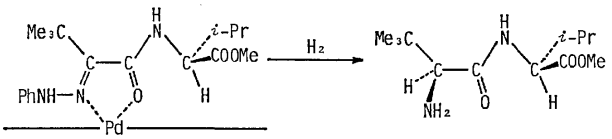

Scheme 2.

Experimental

All the melting points are uncorrected. The optical rotations were measured with a JASCO DIP-4 polarimeter. The ^{1}H NMR spectra (in $CDCl_3$) were recorded on a Hitachi R-24B spectrometer, with TMS as the internal standard. The GLC analyses were performed on a Hitachi 063 gas chromatograph equipped with a flame-ionization detector, using a column packed with 0.5% FFAP on Chromosorb G (ϕ 3 mm×2 m; column temp 150 °C; carrier gas, N_2 11 ml/min; injector temp, 250 °C). Merck Kieselgel 60 and Kieselgel GF_{254} (Type 60) were used for the column chromatography and the preparative TLC respectively.

Phenylhydrazone (2) of Methyl N-(3,3-Dimethyl-2-oxobutanoyl)-L-valinate. Into a chilled mixture of the phenylhydrazone (**1**) of 3,3-dimethyl-2-oxobutanoic acid (17.6 g), L-Val-OMe·HCl (14.1 g), and triethylamine (8.5 g) in THF (240 ml), a solution of DCC (16.5 g) in THF (40 ml) was stirred.

Stirring was continued at 0 °C for 2 h and then at room temperature overnight. After *N,N'*-dicyclohexylurea had been removed by filtration, the filtrate was evaporated under reduced pressure. The residue was dissolved in EtOAc, washed successively with water, 0.5 M HCl, water, 0.5 M $NaHCO_3$, and water, and dried over $MgSO_4$. After the removal of the solvent, the residue was chromatographed on a silica-gel column with $CHCl_3$–EtOAc (1:1). The first colored fraction gave the desired product (**2**) as pale yellow needles: yield, 20.5 g (77%); mp 110—112 °C (from MeOH aq); $[\alpha]_D^{20}$ −16.9° (*c* 1.0, MeOH). Found: C, 64.78; H, 8.35; N, 12.34%. Calcd for $C_{18}H_{27}N_3O_3$: C, 64.84; H, 8.16; N, 12.60%.

The phenylhydrazone of ethyl *N*-(3,3-dimethyl-2-oxobutanoyl)-L-valinate was prepared in the same manner as above: mp 99—100 °C (from EtOH aq); $[\alpha]_D^{20}$ −20.9° (*c* 1.0, MeOH). Found: C, 65.71; H, 8.70; N, 11.86%. Calcd for $C_{19}H_{29}N_3O_3$: C, 65.68; H, 8.41; N, 12.09%.

Hydrogenation of the Phenylhydrazone **2**. The phenylhydrazone **2** (1.00 g) and *p*-toluenesulfonic acid monohydrate (1.26 g) were dissolved in MeOH (50 ml), after which the mixture was hydrogenated overnight in the presence of a palladium catalyst (0.5 g) under the conditions shown in Table 1. The reaction mixture was freed from the catalyst and evaporated to dryness under reduced pressure. The residue was dissolved in CH_2Cl_2 (30 ml) and acylated with Piv–Cl (0.94 g) in the presence of *N,N*-diisopropylethylamine (1.86 g) in the usual manner.[4] A part of the crude product was used without purification for the GLC analysis in order to estimate the diastereomeric ratio. The *N*-pivaloyl derivative was isolated as a mixture of diastereomers by preparative TLC on silica gel using benzene–EtOAc (9:1). The results are summarized in Table 1.

Preparation of Authentic Samples. *Z-L-Tle-L-Val-OMe*: Into a chilled mixture of Z-L-Tle[1] (398 mg), L-Val-OMe·HCl (252 mg), *N*-ethylmorpholine (173 mg), and THF (3.5 ml), DCC (340 mg) was stirred. The mixture was stirred at 0 °C for 2 h and then at room temperature overnight. The usual work-up afforded white crystals; yield, 457 mg (81%). The analytical sample was obtained by recrystallization from EtOAc–Et_2O–petroleum ether: mp 71—72.5 °C; $[\alpha]_D^{25}$ −21.2° (*c* 1.0, MeOH); ^1H NMR δ=0.91 (6H, d, J=7 Hz), 1.00 (9H, s), 2.11 (1H, m), 3.67 (3H, s), 4.05 (1H, d, J=9 Hz), 4.47 (1H, dd, J=5 Hz and 8.5 Hz), 5.05 (2H, s), 5.54 (1H, bd, J=9 Hz), 6.48 (1H, bd, J=8.5 Hz), and 7.23 (5H, s). Found: C, 63.40; H, 8.16; N, 7.42%. Calcd for $C_{20}H_{30}N_2O_5$: C, 63.47; H, 7.99; N, 7.40%.

Piv-L-Tle-L-Val-OMe: A solution of Z-L-Tle-L-Val-OMe (182 mg) in MeOH (5 ml) was hydrogenated in the presence of concd HCl (53 mg), using 5% Pd-C (50 mg). The catalyst was then filtered off, and the filtrate was evaporated under reduced pressure, followed by the successive addition and the evaporation of MeOH. The residual solid (125 mg) was dissolved in CH_2Cl_2 (3 ml), and the mixture was treated with Piv–Cl (71 mg) in the presence of *N,N*-diisopropylethylamine (134 mg); yield, 125 mg (85%). The analytical sample was obtained by recrystallization from EtOAc–hexane: mp 138.5—139.5 °C; $[\alpha]_D^{25}$ −39.4° (*c* 1.0, MeOH); GLC t_R=62.3 min; ^1H NMR δ=0.90 (6H, d, J=7 Hz), 0.99 (9H, s), 1.20 (9H, s), around 2.15 (1H, m), 3.69 (3H, s), 4.23 (1H, d, J=9.5 Hz), 4.37 (1H, dd, J=5.5 Hz and 8.5 Hz), and 6.0—6.45 (2H, b). Found: C, 62.31; H, 9.83; N, 8.63%. Calcd for $C_{17}H_{32}N_2O_4$: C, 62.16; H, 9.82; N, 8.53%.

The corresponding D-L-isomer was obtained, starting from Z-D-Tle,[1] in the same manner as above.

Z-D-Tle-L-Val-OMe: mp 78—79 °C (from hexane); $[\alpha]_{25}^{D}$ −7.8°(*c* 1.0, MeOH); ^1H NMR δ=0.91 (6H, d, J=7 Hz), 1.01 (9H, s), 2.13 (1H, m), 3.65 (3H, s), 4.06 (1H, d, J=9.5 Hz), 4.49 (1H, dd, J=5 Hz and 8.5 Hz), 5.05 (2H, s), 5.65 (1H, bd, J=9.5 Hz), 6.61 (1H, bd, J=8.5 Hz), and 7.25 (5H, s). Found: C, 63.35; H, 8.04; N, 7.66%.

Piv-D-Tle-L-Val-OMe: mp 129—130 °C (from hexane); $[\alpha]_D^{25}$ +0.6° (*c* 1.0, MeOH); GLC t_R=58.3 min; ^1H NMR δ=0.94 (6H, d, J=6.5 Hz), 1.01 (9H, s), 1.21 (9H, s), 2.15 (1H, m), 3.68 (3H, s), 4.35 (1H, d, J=9 Hz), 4.45 (1H, dd, J=5 Hz and 8.5 Hz), 6.32 (1H, bd, J=9 Hz), and 6.61 (1H, bd, J=8.5 Hz). Found: C, 62.35; H, 9.75; N, 8.59%.

Selective Hydrogenation of Cyclic Diolefins to Monoolefins Catalyzed by a Nickel Complex

Mutsuji SAKAI,* Fumiya HARADA, Yasumasa SAKAKIBARA, and Norito UCHINO
Department of Fiber Chemistry, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606
(Received July 29, 1981)

Synopsis. Cyclic diolefins were hydrogenated selectively to monoolefins with a nickel catalyst prepared from bis(acetylacetonato)nickel(II), triethyldialuminium trichloride, and triphenylphosphine at 40 °C under an atmospheric hydrogen pressure.

The hydrogenation of olefins using homogeneous Ziegler catalysts has been studied.[1] We found that the nickel catalyst prepared from bis(acetylacetonato)-nickel(II), triethyldialuminium trichloride, and triphenylphosphine (mole ratio, $Ni(acac)_2:Al_2Et_3Cl_3:PPh_3=1:10:5$) catalyzed the selective hydrogenation of conjugated diolefins.[2] In the preceding paper[3] the selective hydrogenation of 2,3-dimethyl-1,3-butadiene to monoenes with the nickel catalyst was studied kinetically. This paper reports that cyclic diolefins were hydrogenated selectively to monoolefins with the nickel catalyst under mild conditions (40 °C, 1 atm H_2).

Results and Discussion

1,4-Cyclohexadiene was hydrogenated to produce cyclohexene alone in a high yield of 81%. Trace amounts of benzene (disproportionation product) were detected in the hydrogenation. Under nitrogen 1,4-cyclohexadiene neither isomerized to 1,3-diene nor disproportionated to benzene and cyclohexene with the catalyst, remaining unchanged. On the contrary, a Ziegler-type nickel catalyst, Ni(II)–$AlEt_3$, has been reported to be active for the disproportionation.[4]

Substituted cyclic 1,4-diene, such as 1-methyl- and 1,2-dimethyl-1,4-cyclohexadiene, were hydrogenated selectively to similar extents, as shown in Table 1. In the case of 1-methyl-1,4-cyclohexadiene the hydrogenation products were 1-methyl-1-cyclohexene (yield, 67%) and a mixture of 3- and 4-methyl-1-cyclohexene (yield, 7%). Under the conditions used, however, the resulting latter two methylcyclohexenes isomerized very rapidly to thermodynamically more stable 1-methyl-1-cyclohexene. The equilibrium composition consisted of 90% of 1-methyl-1-cyclohexene and 10% of a mixture of 3- and 4-methyl isomers. Thus, the alkyl substituted 1,4-dienes may be hydrogenated selectively to the corresponding thermodynamically more stable monoolefins.

In the case of 1,3-cyclohexadiene polymerization occurred exclusively. However, 1,3-cyclohexadiene was hydrogenated selectively to cyclohexene by adding the 1,3-diene dropwise to the catalyst system. The order and rate of addition played a significant role in the hydrogenation of the 1,3-diene. 1,3-Cyclooctadiene was hydrogenated selectively without requiring its slow addition, while 1,5-cyclooctadiene isomerized quantitatively to bicyclo[3.3.0]oct-2-ene. 1,5,9-Cyclododecatriene also was hydrogenated to cyclododecene. 2,5-Norbornadiene and 4-vinyl-1-cyclohexene polymerized with the catalyst.

The nickel catalyst is thus useful for the selective hydrogenation of cyclic diolefins.

Experimental

Materials. 1-Methyl-1,4-cyclohexadiene and 1,2-dimethyl-1,4-cyclohexadiene were prepared by Birch reduction.[5] The other reagents were commercially available. Solvents were distilled over sodium and diolefins were distilled freshly before use.

Hydrogenation. To a 200 ml flask fitted with a hydrogen buret, a septum inlet, and a magnetic stirrer were added

TABLE 1. HYDROGENATION OF CYCLIC DIOLEFINS BY A NICKEL COMPLEX CATALYST
Diolefin 11 mol, $Ni(acac)_2$, 0.11 mol, $Ni:Al_2:P=1:10:5$, solvent 100 ml, temp 40 °C, H_2 1 atm.

Diolefin	Solvent	Time / h	Conv. / %	Product (Select/%)
1,4-Cyclohexadiene	Toluene	6	100	Cyclohexene(81) Cyclohexane(0)
1-Methyl-1,4-cyclohexadiene	Toluene	8	100	1-Methyl-1-cyclohexene(67) 3- and 4-Methyl-1-cyclohexene(7) 1-Methylcyclohexane(2)
1,2-Dimethyl-1,4-cyclohexadiene	Ethylbenzene	22	100	1,2-Dimethylcyclohexene(73) 1,2-Dimethylcyclohexane(0)

1,5,9-Cyclododecatriene	Toluene	30[b]	70	Cyclododecene(48) Cyclododecane(0)

a) 1,3-Cyclohexadiene was added dropwise over a period of 5 h. b) 50 °C.

$Ni(acac)_2$ (0.11 mmol) and PPh_3 (0.55 mmol) in toluene. After the atmosphere had been replaced with hydrogen the diolefin (11 mmol) in toluene was added. The hydrogenation reaction was started by the addition of $Al_2Et_3Cl_3$ (1.1 mmol) in toluene. The mixture became a homogeneous solution. The solution was stirred with a magnetic stirrer and kept in a thermostated bath. An aliquot (2 ml) of the solution was taken and treated with a methanol–aqueous hydrochloric acid mixture. The organic layer was separated, washed with water, and subjected to GLC analysis.

Analysis. The gas chromatographic analyses were made by a Yanagimoto G-80 apparatus using columns of bis(2-cyanoethyl) ether, poly(ethylene glycol) 20 M, and 1,2,3-tris(2-cyanoethoxy)propane.

$SbCl_5$ Complexes of Pyridine *N*-Oxide and Trimethylamine Oxide as the Oxidizing Agent

Jiro YAMAMOTO,* Mitushige MURAKAMI, Noriaki KAMEOKA, Norio OTANI, Masahiro UMEZU, and Teruo MATSUURA†

Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Tottori 680

† *Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606*

(Received April 25, 1981)

Synopsis. A 1:1 complex of pyridine *N*-oxide or trimethylamine oxide with $SbCl_5$ acted as an oxidizing agent to benzyl alcohol, bezoin, furoin, and thiophenols more easily than *via* the oxides to give benzaldehyde, benzil, furil, and the corresponding disulfides respectively. The trimethylamine oxide–$SbCl_5$ also oxidized *p*-xylene to *p*-tolualdehyde under nitrogen and to *p*-toluic acid under air.

We reported previously that α-pyridone is formed in a high yield by a thermally occurring intramolecular oxygen-transfer reaction of the pyridine *N*-oxide–$SbCl_5$ (1:1) complex (Complex A), and that the thermolysis of the *N,N*-dimethylaniline *N*-oxide–$SbCl_5$ (1:1) complex gives *o*-dimethylaminophenol.[1-2] We now find that Complex A and the trimethylamine oxide–$SbCl_5$ (1:1) complex (Complex B) can oxidized such organic compounds *i.e.* as benzyl alcohol, benzoin, furoin, thiophenols and *p*-xylene more easily than their parent oxides.

Results and Discussion

Complex B was prepared by the same procedure as has been reported for Complex A[2] (98.4%). Complex B is a white and hygroscopic solid: mp 98—100 °C (in a sealed capillary tube). Found: C, 9.73; H, 2.77; N, 3.71%. Calcd for $C_3H_9NOSbCl_5$: C, 9.66; H, 2.43; N, 3.74%. ν_{max}^{KBr}, 1610 cm^{-1}, 1470 cm^{-1}, 1440 cm^{-1}, 1230 cm^{-1}, 980 cm^{-1}; $\lambda_{max}^{CHCl_3}$ 270 nm (ε: 2400).

The thermolysis of Complex B in benzyl alcohol resulted in the formation of benzaldehyde in high yields (for example, a 63% yield in 300:1 (benzyl alc.:Complex B) at room temperature for 47 h and a 84.5% yield in 100:1 (benzyl alc.:Complex B) at 160 °C for 2 h), whereas trimethylamine oxide did not oxidize benzyl alcohol under similar conditions.

Thiophenols were more easily oxidized to give the corresponding diaryl disulfides in high yields with Complexes A and B than in the cases of oxidation using pyridine *N*-oxide and trimethylamine oxide (see Table 1). The effects of the para substituents on the oxidation rate of thiophenols were in the following order; $CH_3>H>NO_2$. Benzoin and furoin were also oxidized with Complexes A and B to give benzil and furil respectively (see the table). *p*-Xylene was found to be oxidized with Complex B under aerial conditions to give *p*-toluic acid in a 35% yield, while *p*-tolualdehyde was obtained in a 27% yield under nitrogen.

The reaction of Complex A with thiophenols appears to proceed according to the following stoichiometry. Complex A may first oxidize a thiophenol

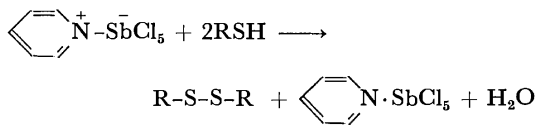

TABLE 1. THE OXIDATION OF THIOPHENOLS AND BENZOINS BY AMINE *N*-OXIDE–$SbCl_5$ (1:1) COMPLEXES

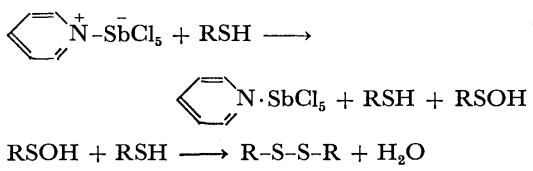
Substrates	X	Oxidants	Molar ratio (Substrates : Oxidants)	Temp/°C	Time/h	Solvents[c]	Yield/% of products[d]
	H		1 : 1	50	2	C_6H_6	No detected
		Complex A[a]	1 : 1	50	2	C_6H_6	16.7
				Room temp	20	CH_3NO_2	77.5
		$(CH_3)_3N\rightarrow O$	1 : 1	Room temp	20	CH_3NO_2	55.3
		Complex B[b]	1 : 1	Room temp	20	CH_3NO_2	84.1
	CH_3	Complex B	1 : 1	Room temp	20	CH_3NO_2	92.7
	NO_2	Complex B	1 : 1	Room temp	20	CH_3NO_2	14.2
		Complex A	1 : 2.1	40	5	CH_3NO_2	84.5
		Complex B	1 : 2.1	40	5	CH_3NO_2	66.0
		Complex A	1 : 1	40	0.5	CH_3NO_2	65.3
		Complex B	1 : 2	65	1.5	CH_3NO_2	60.5

In a typical run, a solution of thiophenol (4.3 g, 19.5 mmol) and Complex B (7.3 g, 19.5 mmol) in nitromethane (10 ml) was allowed to stand at room temperature for 20 h. The mixture was diluted with water and extracted with ether. The ethereal layer was washed with a 3% sodium hydroxide solution, water, dilute hydrochloric acid, and water successively and then dried. After the evaporation of the ether, the residue was practically distilled in a vacuum to give diphenyl disulfide (3.3 g, 77.5%). a) . b) $(CH_3)_3N$–O–$SbCl_5$. c) The dessolved oxygen in these solvents did not affect any run. d) The oxidation products were identified by a comparison of their melting points and IR spectra with those of authentic samples.

to a sulfenic acid, similar to the formation of a sulfenic acid from $R_3\overset{+}{N}OH$ and RS^- ions.[3] The sulfenic acid thus reacts with a thiophenol to give a disulfide.[4]



$$RSOH + RSH \longrightarrow R\text{-}S\text{-}S\text{-}R + H_2O$$

Benzaldehyde, *p*-tolualdehyde, and cinnamaldehyde resist oxidation with Complexes A and B, probably because of the formation of a stable adduct between an aldehyde and $SbCl_5$[5-6].

Reduction of Aromatic Compounds by Solvated Electrons Generated at Cathode

Ram A. Misra* and Ashok K. Yadav
Department of Chemistry, University of Rajasthan, Jaipur-302004, India
(Received January 17, 1981)

Synopsis. Phenol, anisole, and toluene can be reduced electrochemically to cyclohexanol, methoxycyclohexane, and methylcyclohexane respectively, in ethanol containing hexamethylphosphoric triamide (HMPA) at aluminium cathode. The reduction of these aromatics is believed to occur due to electrochemically generated solvated electrons.

The electrochemical reduction of benzene has been reported in variety of reaction conditions.[1-5] In some reports[4,5] it has been observed that direct electron transfer from cathode to aromatic nucleus does not take place, but the electron is introduced into the solution as solvated electrons, which may cause the reduction of benzene away from the electrode in the bulk of the solution.

$$e^-_{(cathode)} + \text{solvent} \rightleftharpoons e^-_{(solvent)}$$

The use of solvated electrons is of particular significance because the reported chemical methods involve high temperature and pressure. Furthermore, the yield of the reduced product in chemical hydrogenation depends upon a number of factors such as acid concentration, catalyst, hydrogen pressure, mode of addition and presence of water soluble quaternary ammonium compounds.[6-9] Fichter and Stocker[10] reported the reduction of phenol to cyclohexanol in 2 mol dm^{-3} sulfuric acid at platinized platinum electrode in poor yield. The use of solvated electrons in reduction of benzene has been reported by Sternberg and coworkers.[11,12] Recently Misra and Sharma[13] investigated the cathodic reduction of phenol and 2-naphthol to cyclohexanol and *trans*-2-dacalol respectively, at platinum foil in 2 mol dm^{-3} perchloric acid in good yield. In the present communication, we report the electrochemical reduction of phenol, anisole, and toluene in EtOH–HMPA (67:33). Lithium chloride was used as supporting electrolyte.

Experimental

Materials. Phenol, toluene, and anisole (all B.D.H.), lithium chloride (SISCO) and hexamethylphosphoric triamide(Fluka) were used without further purification.

Cell Assembly. A 400 ml beaker with provision to hold the cathode, porous diaphragm, thermometer, and magnetic bar, was used as electrolysis cell. Aluminium sheet was used as cathode and a carbon plate inside the diaphragm served as anode. A constant current was passed from a current regulated power supply (0-10 A/0-100 V).

Electrolysis, Work Up, and Analysis. Following is the detail of electrolysis: catholyte 125 ml, 3% lithium chloride solution in EtOH–HMPA (67:33), and 0.025 mol dm^{-3} of organic compound, anolyte 35 ml, 3% lithium chloride solution in EtOH–HMPA (67:33), current (0.3 A, current density 0.0326 A/C m^2), cell temperature (28±2 °C).

After the theoretical time corresponding to 6 F/mol, the catholyte was filtered and poured into 200 ml of water and acidified with dilute hydrochloric acid. The organic material was extracted with hexane (in case of phenol, the remain is also extracted with ether), and the organic layer was fractionally distilled to separate the reduced product and unreacted aromatic compound. The reduced product thus obtained was redistilled to get pure product. Their bp, yield, IR, and NMR data are given in Table 1.

Results and Discussion

The aromatics *viz.*, phenol, anisole, and toluene in EtOH–HMPA at aluminium cathode in a divided cell afforded the corresponding hexahydro derivatives. The cathodic potential which initiates the reduction of phenol, anisole, and toluene was −2.4, −2.10, and −2.00 V (*vs.* saturated calomel electrode) respectively. A blue colouration during the reaction indicates the formation of solvated electrons whose existence has been proved and detected by electron

Table 1. Physico-chemical and spectral characteristics of cyclohexanol, methoxycyclohexane, and methylcyclohexane

Product	Bp θ_b/°C Found (reported)	Yield %	IR[a] $\nu_{O-H/O-CH_3}$ cm^{-1}	IR[a] ν_{C-H} cm^{-1}	^1H NMR[b] δ
Cyclohexanol	160—161 (161)[c]	51.7	3450—3300 ν_{O-H}	2825, 2750	1.1—2.9 (m, 1OH; CH_2) 3.8 (s, 1H; CH) 5.4 (s, 1H; CH)
Methoxycyclohexane	134—136 (135—136)[d]	45.8	3060—3010 ν_{O-CH_3}	2825, 2750, 2725	1.0—2.9 (m, 1OH; CH_2) 3.45 (s, 1H; CH) 3.85 (s, 3H; CH_3)

spin resonance studies.[4,11] The solvated electrons formed by the reduction of metal ion followed by a dissolution step, interact with the monosubstituted benzene to give the dihydro derivative by the same mechanism reported previously.[14] Further reduction of dihydro product depends upon reaction conditions. For example, electrochemical reduction of benzene in methylamine[15] and tetralin in ethylenediamine[16] produces di- and tetra- hydro derivatives *viz.*, cyclohexadiene and cyclohexene in case of benzene, hexahydronaphthalene and octahydronaphthalene in case of tetralin. The non reducibility of benzene from olefin stage in amine solvent is due to the reason that the reduction of isolated double bond is much slower than the reduction of benzene to cyclohexadiene. But in our case fully reduced products of aromatics were isolated, indicating thereby that hydrogen evolution reaction 1 is suppressed, because HMPA is selec-

$$e^-_{cathode} + C_2H_5OH \longrightarrow C_2H_5\bar{O} + 0.5\,H_2 \quad (1)$$

tively adsorbed on the metal surface and hence preventing the decomposition of ethanol.

In addition to suppressing the hydrogen evolution at cathode, HMPA must also suppress the hydrogen evolution in solution. This is corroborated by the fact that when the reduction of phenol is carried out in absence of HMPA, the yield of cyclohexanol is very low ($\approx 5\%$). Hence it is reasonable to deduce that the reduction of phenol (also anisole and toluene) is possible if the electron and proton transfer reactions 2 and 3 are faster

$$\bar{e}_{C_2H_5OH} + R \longrightarrow R^{\cdot-} + C_2H_5OH \quad (2)$$

$$R^{\cdot-} + C_2H_5OH \longrightarrow RH^{\cdot} + C_2H_5\bar{O} \quad (3)$$

than the two competing hydrogen forming reactions 4 and 5.

$$\bar{e}_{C_2H_5OH} + \bar{e}_{C_2H_5OH} \longrightarrow H_2 + 2\,C_2H_5\bar{O} \quad (4)$$

$$\bar{e}_{C_2H_5OH} + C_2H_5OH \longrightarrow 0.5\,H_2 + C_2H_5\bar{O} \quad (5)$$

(Received May 23, 1981)

Synopsis. Cyclization of 2-hydrazino-4-methylbenzo[*h*]quinoline and 3-hydrazino-1-methylbenzo[*f*]quinoline with formic acid occurs on nitrogen rather than carbon to give 5-methylbenzo[*h*][1,2,4]triazolo[4,3-*a*]quinoline and 11-methylbenzo[*f*][1,2,4]triazolo[4,3-*a*]quinoline and not 7-methyl-10*H*-benzo[*h*]pyrazolo[3,4-*b*]quinoline and 11-methyl-8*H*-benzo[*f*]pyrazolo[3,4-*b*]quinoline, respectively, as it has been claimed before.

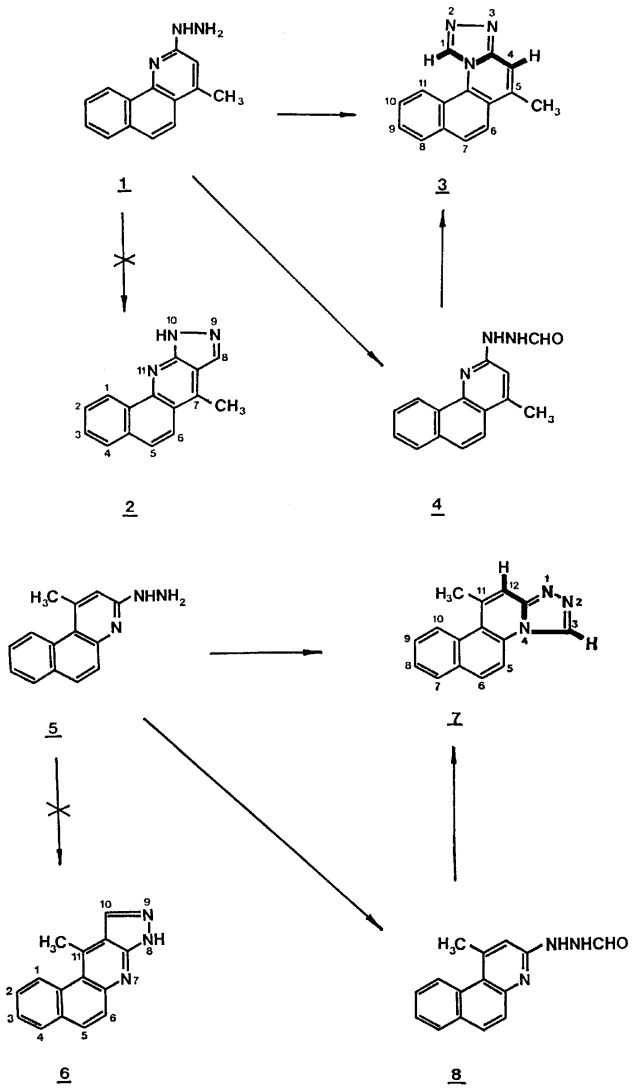
During our continuous interest in the field of polycyclic polyaza heterocyclic systems of "steroid" and "helicene" type,[1–9] a report by Tiagi and Yoshi[10] has attracted our attention. Namely, it has been claimed that the reaction of 2-hydrazino-4-methylbenzo[*h*]quinoline (**1**) and 3-hydrazino-1-methylbenzo[*f*]quinoline (**5**) with formic acid gave 7-methyl-10*H*-benzo[*h*]pyrazolo[3,4-*b*]quinoline (**2**) and 11-methyl-8*H*-benzo[*f*]pyrazolo[3,4-*b*]quinoline (**6**), respectively.

There are no other examples, known in the literature, in which cyclization of hydrazino group at α-position to ring nitrogen is taking place onto carbon atom. To the contrary, according to the common experience, cyclization of hydrazino group attached at α-position to ring nitrogen is taking place onto ring nitrogen to give *s*-triazolo[4,3-*x*]azines.[11–14] Therefore, it seems, that reinterpretation of the results reported by Tiagi and Yoshi is fully justified.

When 2-hydrazino-4-methylbenzo[*h*]quinoline (**1**) was heated with formic acid as discribed by Tiagi and Yoshi,[10] a product with mp 167—168 °C (*cf.*[10] mp 204—205 °C) was obtained. Mass spectrum (M^+=251) together with elemental analysis gave molecular formula $C_{15}H_{13}ON_3$. IR absorption (1690 cm^{-1}) characteristic for a formyl group and a singlet at δ=7.63, a doublet for CH_3 group (δ=2.45) and a quartet for H-3 with a coupling constant ($J_{3\text{-H},4\text{-CH}_3}$ =1.0 Hz) characteristic for the coupling of a methyl group with an ortho proton in aromatic and heteroaromatic compounds in NMR spectrum suggest that the product is 2-(2-formylhydrazino)-4-methylbenzo[*h*]quinoline (**2**) and not the corresponding benzopyrazoloquinoline **2**, which presumably, according to the authors,[10] crystallizes with one half mole of water, in order to explain the low analysis for nitrogen.

On the other hand, the cyclization was effected by treatment of hydrazino compound **1** with triethyl orthoformate to give 5-methylbenzo[*h*][1,2,4]triazolo[4,3-*a*]quinoline (**3**), mp 299—300 °C, and not 7-methyl-10*H*-benzo[*h*]pyrazolo[3,4-*b*]quinoline (**2**) as reported by Tiagi and Yoshi.[10] That cyclization occured onto nitrogen rather than carbon is supported by the coupling of the methyl group at position 5 with 4-H ($J_{4\text{-H},5\text{-CH}_3}$=1.0 Hz) and by a long-range coupling of 1-H and 4-H ($J_{1\text{-H},4\text{-H}}$=0.9 Hz). This latter coupling is charasteristic for all 1,2,4-triazolo- and other azoloazines with bridgehead nitrogen atom.[15–17] The same tetracyclic compound was obtained also by prolonged heating of the 2-formylhydrazino compound **4**, however in lower yield.

3-Hydrazino-1-methylbenzo[*f*]quinoline (**5**) when treated with either triethyl orthoformate or formic acid gave a compound with mp 280—282 °C. Mass spectrum (M^+=233) and elemental analysis correspond to molecular formula $C_{15}H_{11}N_3$. A doublet for a methyl group ($J_{12\text{-H},11\text{-CH}_3}$=0.6 Hz) further supported by a long-range coupling between 3-H and 12-H ($J_{3\text{-H},12\text{-H}}$=0.6 Hz) are unambiguously consistent with 11-methylbenzo[*f*][1,2,4]triazolo[4,3-*a*]quinoline (**7**). On this basis, 11-methyl-8*H*-benzo[*f*]pyrazolo[3,4-*b*]quinoline (**6**) proposed by Tiagi and Yoshi[10] can be excluded. Furthermore, the compound obtained by Tiagi and Yoshi from hydrazino



compound **5** with formic acid is most probably the corresponding 2-formylhydrazino derivative **8** since the reported analysis for nitrogen (Found: 17.28%; Calcd: N, 16.72%) fits this much better than the cyclized products **6** or **7**. However, we have not been able to isolate this intermediate under reported conditions.

An analoguous reinterpretation for the products obtained from hydrazines **1** and **5** with nitrous acid has been reported recently.[18]

Experimental

2-Hydrazino-4-methylbenzo[*h*]quinoline (**1**) and 3-hydrazino-1-methylbenzo[*f*]quinoline (**5**) were prepared according to the procedure described in the literature.[10,18] ^{1}H NMR spectra were recorded on a JEOL JNM C60-HI spectrometer, IR spectra on Perkin-Elmer 727B instrument, and mass spectra were obtained on a Hitachi-Perkin-Elmer RMU-6L instrument.

2-(Formylhydrazino)-4-methylbenzo[h]*quinoline (**4**).* 2-Hydrazino-4-methylbenzo[*h*]quinoline (**1**) (800 mg) and formic acid (98—100%, 6 ml) were heated under reflux for two hours. The mixture was evaported to dryness and methanol (20 ml) was added to dry residue, followed by addition of water (20 ml). After cooling the precipitate was collected by filtration and recrystallized from a mixture of methanol and water (4:1) to give 2-(2-formylhydrazino)-4-methylbenzo[*h*]quinoline (**4**) (620 mg, 69%), mp 167—168 °C, *m/e* 252 (M^+), NMR (d_6-DMSO, 110 °C): 9.5—9.2 (2H, br, NHNH), 8.4 (1H, m, 10-H), 7.63 (1H, s, CHO), 7.50—6.95 (5H, m, 5-H, 6-H, 7-H, 8-H, 9-H), 6.38 (1H, q, 3-H), 2.45 (3H, d, 4-CH_3); $J_{3\text{-H},4\text{-CH}_3}=1.0$ Hz). Found: C, 71.35; H, 5.52; N, 16.97%. Calcd for $C_{15}H_{13}N_3O$: C, 71.69; H, 5.21; N, 16.72%.

5-Methylbenzo[h][*1,2,4*]*triazolo*[*4,3*-a]*quinoline (**3**).*
Method A: 2-Hydrazino-4-methylbenzo[*h*]quinoline (**1**) (800 mg) and triethyl orthoformate (4 ml) were heated under reflux for 1 h. After cooling ether (16 ml) was added and precipitate collected by filtration and recrystallized from ethanol to give 5-methylbenzo[*h*][1,2,4]triazolo[4,3-*a*]quinoline (**3**), (470 mg, 56%), mp 299—300 °C, *m/e* 233 (NMR (d_6-DMSO): 9.35 (1H, d, 1-H), 8.35—8.10 (1H, m, 11-H), 7.60—7.05 (6H, m, 4-H, 6-H, 7-H, 8-H, 9-H, 10-H), 2.57 (3H, d, 5-CH_3), $J_{4\text{-H},5\text{-CH}_3}=1.0$ Hz, $J_{1\text{-H},4\text{-H}}=0.9$ Hz. Found: C, 77.26; H, 5.14; N, 18.29%. Calcd for $C_{15}H_{13}N_3$: C, 77.23; H, 4.75; N, 18.02%.

Method B: 2-Hydrazino-4-methylbenzo[*h*]quinoline (**1**) (100 mg), sodium acetate (10 mg), dioxane (1 ml) and formic acid (98-100%, 1 ml) were heated under reflux for 6 h. After evaporation to dryness methanol (1 ml) and water (1 ml) were added to the residue, and the solid collected by filtration. Recrystallization from ethanol gave **3** (48%). The compound was identical in every respect to the compound described above.

11-Methylbenzo[f][*1,2,4*]*triazolo*[*4,3*-a]*quinoline (**7**).*
Method A: 1-Methyl-3-hydrazinobenzo[*f*]quinoline (**5**) (1,0 g) and triethyl orthoformate (5 ml) were heated under reflux for 1 h. After cooling ether (20 ml) was added, precipitate collected by filtration and recrystallized from ethanol to give 11-methylbenzo[*f*][1,2,4]triazolo[4,3-*a*]quinoline (**7**), (780 mg, 79%), mp 280—282 °C, *m/e* 233 (M^+), NMR (d_6-DMSO): 9.1 (1H, d, 3-H), 8.25—8.02 (1H, m, 10-H), 7.75 (1H, d, 5-H), 7.50 (1H, d, 6-H), 7.40—6.90 (4H, m, 7-H, 8-H, 9-H, 12-H), 2.82 (3H, d, 11-CH_3), $J_{3\text{-H},12\text{-H}}=0.6$ Hz, $J_{5\text{-H},6\text{-H}}=8.0$ Hz, $J_{12\text{-H},11\text{-CH}_3}=1.0$ Hz). Found: C, 77.41; H, 4.87; N, 18.05%. Calcd for $C_{15}H_{11}N_3$: C, 77.23; H, 4.75; N, 18.02%.

Method B: 1-Methyl-3-hydrazinobenzo[*f*]quinoline (**5**) (200 mg) and formic acid (98—100%, 1.5 ml) were heated under reflux for three hours. Ethanol (5 ml) was added and the mixture evaporated to dryness. Dry residue was suspended in ether (10 ml) and the solid collected by filtration and recrystallized from ethanol to give 11-methylbenzo[*f*][1,2,4]triazolo[4,3-*a*]quinoline (**7**), (81%). The compound was identical in every respect with the compound obtained from **5** and triethyl orthoformate as described above.

Additive Effect of CF_3Cl on an Oxidation Reaction in Shock Waves. I. Study with H_2–O_2

Yoshiaki HIDAKA,* Hiroyuki KAWANO, and Masao SUGA

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received January 30, 1981)

Sample gases, H_2–O_2, H_2–O_2–CF_3Cl, and CF_3Cl, highly diluted with Ar were heated behind reflected shock waves over the temperature range 1400—2200 K and an additive effect of CF_3Cl at various concentrations (0—0.5%) was studied by monitoring ultraviolet and visible emissions. At a temperature below 2200 K, C_2* and CH* species were found to be formed in the oxidation reaction of H_2 together with CF_3Cl, but hardly formed in the thermal decomposition of CF_3Cl. The addition of small and large amounts of CF_3Cl increased and decreased, respectively, the intensity of OH* emission from the H_2–O_2 mixture heated to a constant temperature. An ignition delay time at a fixed temperature above 1400 K was found to shorten with an increase in the concentration of CF_3Cl. A brief discussion is given of the mechanism for the formation of the chemiluminescent species.

The additive effect of an organic halogen compound (*e.g.*, CH_3I, CH_3Br, CH_3F, CF_3Br, CF_3Cl, or CCl_4) on a combustion reaction has been studied by measuring flammability limit,[1] burning velocity,[2-3] flame structure,[4] induction period,[5] *etc.*, and the compound has been found to generally lower the concentration of active species such as H, OH, and O, thereby inhibiting the combustion reaction. According to a study of the burning velocity in a methane oxidation,[3] however, CF_3Cl acts as an inhibitor under some conditions but as a promoter under others. This reversible action of CF_3Cl is particularly interesting, and a detailed investigation of the action seems helpful in elucidating an effect of organic halogen compounds on an oxidation reaction.

A visible emission from reaction mixtures including halogen compounds has been studied by using discharges[6,7] counterflow diffusion flame,[8] shock waves,[9,10] *etc.*, and both C_2* ($A\,^3\Pi_g$) and CH* ($A^2\Delta$) were observed in the reaction of H with CCl_4, $CHCl_3$, or CH_3Br.[6] In addition, C_2* was observed when halomethanes $CH_{2-n}X_{2+n}$ (X=Cl, Br, or I) were introduced into a stream of H produced by passing a H_2–He mixture through a 2450 MHz microwave discharge[7] and also when a decomposition reaction of CF_4 or CCl_4 occurred in a shock tube at a temperature above 4000 K.[10] At a relatively low temperature below 2200 K, however, such a C_2* formation from organic halogen compounds has not yet been reported.

From the viewpoints described above, we have examined the additive effect of CF_3Cl on the light emission from chemiluminescent species produced in the oxidation reaction of CH_4 over the temperature range 1600—2200 K by using a shock tube, and have found that the addition of CF_3Cl increases the C_2* and CH* emission intensities.[11] This previous result is not interpreted reasonably by a mechanism proposed by Gaydon,[12] and hence suggests that another mechanism should be taken into consideration. Namely, C_2* and CH* may be formed from some species produced by the decomposition of CF_3Cl in the oxidation reaction. A mixture of H_2–O_2–CF_3Cl–Ar seems most suited to check this mechanism experimentally, because no emissions of CH* and C_2* are observed in the oxidation reaction of H_2.

Our purpose of this work is to clarify the CH* and C_2* formation in H_2–O_2–CF_3Cl–Ar, and also to investigate the additive effect of CF_3Cl on the oxidation reaction of H_2.

Experimental

The apparatus and procedures employed in this work are essentially the same as in previous work.[13,14] Therefore, only a brief description will be given here. In order to record an emission spectrum, a high sensitive film (Kodak 2475) was exposed as many as 15 times by repeating runs with a reaction mixture heated at 2100 ± 50 K, but this trial was fruitless because all of the resultant emissions were extremely weak. Therefore, the spectral distribution was measurod with a system consisting of a monochromator with the half-width 25 Å (Rico-MC-20) and of a photomultiplier (Hamamatsu R-306). Wavelength dependence of the relative detection sensitivity (β) of the system was determined according to NBS data (lamp input voltage 96 V and PM H. V. 1220 V, EMI 9635QA), and the result thus obtained is shown in Fig. 1, on the basis of which the emission intensities measured at various wavelengths were corrected. The emissions at 3055, 4330, 5150, and 2400 Å were monitored with four filters, the half-widths of which were 150, 120, 110, and 200 Å, respectively. After passing through one of the interference filters located behind a quartz window of the shock tube and through two slits with widths 0.2 and 0.4 mm, three kinds of emission among the four were simultaneously monitored at various temperatures by using three photomultipliers (Hamamatsu R-306).

The computer routine used Gear-type integration of the set of differential equations describing the chemical kinetics under constant density conditions for reflected shock waves. Thermochemical properties were computed as functions of temperature using accurate polynomial representations of

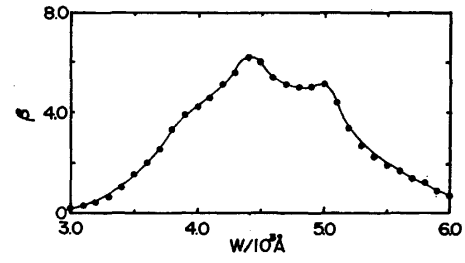

Fig. 1. The relative sensitivity (β) at different wavelengths (W) observed with the measurement system in this work.

JANAF data.[15] Reverse reactions were automatically included with rate constants calculated from the forward rate constants and equilibrium constants. All temperatures referred to in connection with data were calculated from the incident shock velocity assuming full vibrational relaxation but no chemical reaction. The computer programs used previously[16] were modified to match the Facom 230-28 system.

The gases of CF_3Cl, H_2, O_2, and Ar specified to be 99.0, 99.9, 99.9, and 99.99% pure, respectively, were obtained from commercial cylinders and were used without further purification. Table 1 summarizes the composition of the reaction gas mixtures used, each of which had the initial pressure 100±0.1 Torr (1 Torr≈133. 322 Pa).

TABLE 1. MIXTURE COMPOSITION

Mixture	H_2 (%)	O_2 (%)	CF_3Cl (%)	Ar (%)
(A)	0.50	0.25		99.25
(B)	0.50	0.25	0.05	99.20
(C)	0.50	0.25	0.10	99.15
(D)	0.50	0.25	0.17	99.08
(E)	0.50	0.25	0.25	99.00
(F)	0.50	0.25	0.35	98.90
(G)	0.50	0.25	0.50	98.75
(H)			0.50	99.50
(I)	0.50		0.50	99.00
(J)		0 25	0.50	99.25

Results and Discussion

An emission spectrum recorded with the mixture (G) at intervals of about 100 Å is illustrated in Fig. 2, which shows that strong emissions appear at 3900, 4315, 4700, 5165, and 5600 Å. According to Gaydon,[17] (1) the Swan bands of C_2* lie in the wavelength region 4365—6762 Å, (2) the outstanding heads of C_2* exist at 4737, 5165, and 5635 Å, (3) the emission bands of CH* are situated in the region 3144—4941 Å, and (4) the strong peaks of CH* appear at 3871 and 4315 Å. Therefore, the two groups (A_1 and A_2) of the strong heads at 4700, 5165, and 5600 Å and at 3900 and 4315 Å shown in Fig. 2 correspond to spectra of the electronically excited species C_2* and CH*, respectively. As may be known well, C_2* and CH* bands are characteristic of hydrocarbon-flames. To our particular interest, such bands are observed in the oxidation reaction of the H_2–O_2–CF_3Cl–Ar mixtures, too, as shown in Fig. 2, where the spectral distribution is quite similar to that in the oxidation reaction of CH_4.[11] With the mixtures of CF_3Cl–Ar (H), H_2–CF_3Cl–Ar (I), and O_2–CF_3Cl–Ar (J) heated to 1400—2200 K, on the other hand, neither CH* nor C_2* was observed. Hence, it is concluded that, even at the temperature below 2200 K, CH* and C_2* are formed in the oxidation reaction of H_2 together with CF_3Cl, but are produced in neither the thermal decomposition of CF_3Cl nor the reaction of CF_3Cl with O_2 or with H_2. This makes us infer that H, O, or OH which is the active species formed in the oxidation reaction of H_2 helps to form CH* and C_2*.

Since the intensities of emissions at 4315 Å (CH*) and 5165 Å (C_2*) are very strong and also since the emissions other than the CH* and C_2* do not exist in the vicinity of 4315 Å and 5165 Å, the emissions observed at 4330 and 5150 Å by using the interference filters are concluded to come from CH* and C_2*, respectively.

The OH* emission at 3064 Å which is generally observed in the oxidation reaction of H_2 doesn't appear in Fig. 2. This may be due to both the weak emission of OH* observed with the mixture (G) (see Fig. 3) and the low sensitivity near 3064 Å in our measurement system, as shown in Fig. 1. The emission at 3055 Å found with the filter probably comes from the electronically excited species OH* because the strong band of OH* has a main head at 3064 Å.[17] In addition, we observed the emission at 2400 Å, which may be concluded to come from the electronically excited species CF* because the CF*($A^2\Sigma^+$—$X^2\Pi$) bands extend from 2240 to 2560 Å, among which the emission at 2404 Å is particularly strong.[17]

By using one of the filters mentioned above, the emission intensities at 3055, 4330, 5150, and 2400 Å corresponding to OH*, CH*, C_2*, and CF*, respectively, were measured with the mixtures (A)—(G) in the range 1600—2200 K, and their respective maximum intensities are plotted against the concentration (C) of CF_3Cl in Figs. 3—6. In contrast to OH*, neither CH*, C_2*, nor CF* emission at any temperatures is

naturally observed at C=0 %. At C>0 %, however, any of the four emission intensities at a fixed temperature increases and reaches a maximum at C=0.1—0.3 %, above which each emission intensity decreases gradually. This pattern is quite similar among the five curves at different temperatures. Especially CH* and CF* among the four species have a quite similar pattern at each temperature.

Some of the elementary reactions that may be helpful to find a formation mechanism for the chemiluminescent species in this work are summarized in Table 2 together with respective enthalpy changes ΔH. As mentioned above, fair amounts of C_2*, CF*, and CH* are formed under our experimental condition. When the values of ΔH in Table 2 are taken into consideration, the existence of the above electronically excited species makes us infer that both C_2 and CH species must be formed in the reaction process.

Some of typical oscillograms obtained at a middle temperature (about 1850 K) are shown in Fig. 7. The emission curve of C_2* observed with each mixture was similar in shape to that of CH* or CF* emission.

The OH* emission curves thus recorded with the five mixtures heated to high temperature (2150 K) are shown in Fig. 8. The emission intensity of OH* measured with the CF_3Cl-free mixture (A) increases rather slowly up to a maximum after the ignition delay time (τ) which is the time lag between the reflected shock arrival and the onset of the rapid increase of the emission signal, and then decreases more slowly toward the base line. When a small amount of CF_3Cl is added, the emission of OH* rises rapidly to a maximum, falls quickly to some intensity, and then declines slowly

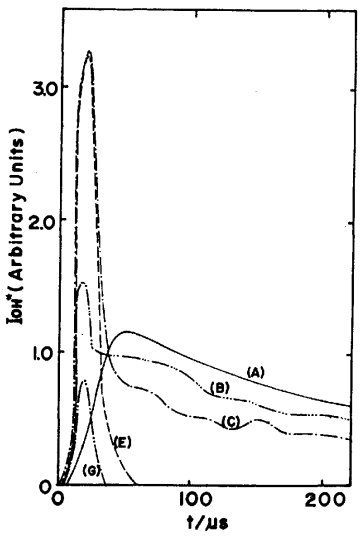

Fig. 8. Time variation of the OH* emissions at 2150± 20 K observed with the five mixtures.

toward the base line, thereby showing a spike with a shoulder, as may be seen in Figs. 7b, 7c, and 8. When CF_3Cl is added abundantly, on the other hand, OH* shows a spike with no shoulder (see Figs. 7d and 8).

OH* may be formed through the reactions (23′) and (24′) in the oxidation of hydrogen[18-21] and of hydrocarbon,[22-23] respectively.

$$O + H + M = OH^* + M \quad (23')$$

$$CH + O_2 = OH^* + CO \quad (24')$$

Compared with chemical excitation, thermal excitation below 2000 K seems to have little contribution to the OH* formation.[18] Even at a high temperature the emission intensity of OH* (I_{OH}*) observed in the hydrogen oxidation slowly decreases with time from a maximum intensity as shown in Figs. 7a and 8, and this slow decrease of OH* is considered to be a characteristic of the OH* formation through the reaction(23′). These OH* emission curves shown in Figs. 7a and 8 have a striking contrast to those previously obtained with the hydrocarbon oxidation, where I_{OH}* rapidly decreased from a maximum intensity.[11,13] This rapid decrease of OH* may be a characteristic of the OH* formation through the reaction (24′). As already described above, the addition of CF_3Cl has a strong effect upon the emission pattern and intensity of OH*. As may be seen in Figs. 7 and 8, the spike of OH* (rapid decrease of OH* emission from a maximum) appears when CF_3Cl is added. Therefore, this spike suggests that some OH* species are formed through the reaction (24′). For the OH* formation under our experimental condition, the existence of CH needs, in analogy with the C_2* formation mentioned below. Therefore, we consider the reactions for the CH formation, as mentioned below.

It is known well that the reaction $C_2H_6+M=2CH_3+M$ occurs at the temperature above 1300 K.[24] Quite similarly the dissociation reaction (1) may occur readily to produce CF_3[25] because both of the reactions are nearly identical in ΔH. In the present experiment with H_2–O_2–CF_3Cl–Ar mixture, therefore, a fairly large amount of CF_3 may be produced during the reaction process. Since the reactions (5)—(7) are exothermic, the intermediate products CF and C also may be produced quite easily. There exists a large amount of H_2 at the initial stage in the present experiment, and the ΔH values of the reactions (17), (18), and (19) are 24, 17, and 21 kcal/mol, respectively. Hence, it may be possible through the reactions, (17), (18), and (19) that CH is produced in the present experiment. By considering the reactions, as mentioned above, we have repeated computations and finally completed the mechanism and the rate-constant expressions, as shown in Table 3, which are employed in order to obtain the concentration-time relations of all the species at 1800 K. The rate constants for the OH* formation in the H_2–O_2 reaction shown in Table 3 are cited from other paper.[21] The curve calculated with it fits the experimental data best, as may be seen in Fig. 3. When the CH formation reactions (15), (17), and (19), without the reaction (18), were used for the computation, the experimental finding shown in Fig. 3 can not reasonably be explained. Therefore, CH seems to be produced through the reaction (18) in the present experiment. In the computation except the reaction (23′) or (24′) from the mechanism in Table 3, we also were capable to substantiate the characteristic time-variation for the OH* emission, as mentioned above, and found that much existence of CF_3Cl makes it difficult to form OH* through the reaction (23′). The OH* concentration variation computed at 1800 K is shown in Fig. 9. This figure interprets well the relationship, as shown in Figs. 7 and 8. Provided that CH is produced in our

Table 3. Elementary reactions and rate constant expressions[a)]

a) Rate constants in the form, $AT^n\exp(-E/RT)$, in cm, mol, cal, and K units. b) Rate constants assumed for the reaction at 1800 K.

experiment, then C_2^* is probably formed by some of the following reactions:

$$C + CH = C_2^* + H, \quad (8')$$

$$CH + CH = C_2^* + H_2, \quad (9')$$

$$CH_2 + C = C_2^* + H_2, \quad (10')$$

$$CF + CH = C_2^* + HF. \quad (11')$$

The reactions (8′)—(10′) have already been reported for the C_2^* formation in the hydrocarbon oxidation.[26-28]

The concentration of CH thus produced is less than that of CF, as shown in Fig. 10. Accordingly, assumed that the rate constants of these reactions are nearly equal, it appeared that the reaction (11′) was most important for the C_2^* formation under our experimental condition. The CH and CF concentrations calculated with mixture (G) were smaller than those calculated with mixtures (C) and (D), respectively. Hence, it may be possible to explain the relationship between maximum C_2^* intensity and CF_3Cl concentration, as shown in Fig. 5.

As already mentioned above, the endothermic reaction (18) among reactions (17)—(19) contributed to the formation of not CH* but CH in this work because none of the ΔH values (17—24 kcal/mol) is small enough to form CH*. However, the reaction (15) is strongly exothermic, and C_2 and C exist during the reaction process, as shown in Fig. 10. Consequently, it is concluded that CH* is mainly formed by

$$C_2 + OH = CH^* + CO. \quad (15')$$

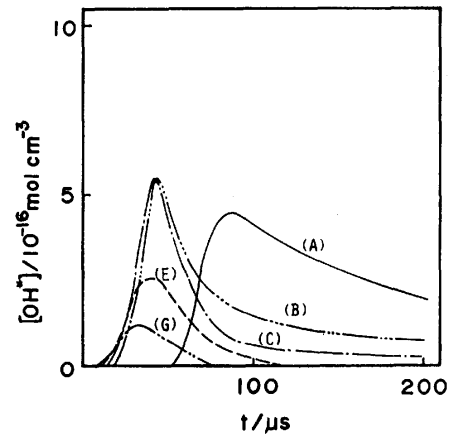

Fig. 9. OH* concentration profiles computed with mixtures (A), (B), (C), (E), and (G) using the mechanism and rate constants in Table 3.

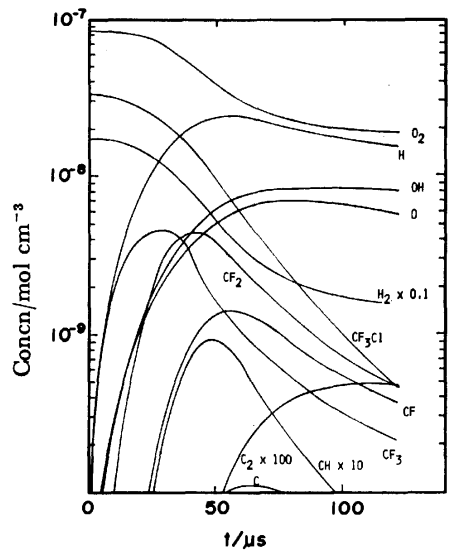

Fig. 10. Concentration profiles computed for mixture (C) at 1800 K using the mechanism and rate constants shown in Table 3.

The OH concentration calculated with mixture (G) is almost the same as that calculated with mixtures (C) and (D), but the C_2 concentration with mixture (G) is extremely smaller than that calculated with mixture (C) or (D). The relationship between maximum CH* intensity and CF_3Cl concentration, as shown in Fig. 4 may be easily interpreted. According to our computation, the increase and decrease of OH*, CH*, and C_2* concentrations owing to the addition of a small and large amounts of CF_3Cl, respectively, were also concluded to mainly come from the competition of the reactions $CF+CF_3+M=C_2F_4+M$ and $CF+H_2=CH+HF$.

Since the reaction (21) is greatly exothermic and since C and F_2 exist abundantly enough to cause the reaction (21′), the reaction (21′) is concluded to be a main process for the CF* formation.

$$C + F_2 = CF^* + F. \qquad (21')$$

Temperature dependence of the ignition delay time τ observed with OH* is shown in Fig. 11, which reveals that τ at a temperature above 1500 K decreases with

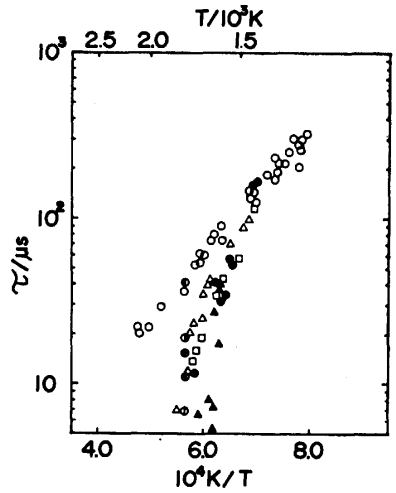

Fig. 11. Temperature dependence of the ignition delay time τ measured with the OH* emission for the mixtures (A)—(G), ○: (A), △: (B), □: (C), ●: (E), ▲: (G), and calculated at 1800 K for the mixtures (A)—(G), ◐: (A), ◑: (B), ◎: (C), ⊙: (E), ⊕: (G).

an increase in C. Fig. 11 also shows the value τ computed with mixtures (A), (B), (C), (E), and (G) at 1800 K. τ observed is in fair agreement with that simulated.

Under our experimental condition employed with the H_2–O_2–CF_3Cl–Ar mixtures, a fair amount of CF_3 and Cl may be produced through the reaction (1), as shown in Fig. 10. These intermediate products CF_3 and Cl easily generate the active species H through the reactions (2) and (3). In the oxidation reaction of the H_2–O_2–CF_3Cl–Ar mixtures, an occurrance of the reactions (1)—(3) increases the H concentration at the initial stage, thereby promoting the overall reaction rate, as shown in Fig. 11. In the H_2 oxidation over the range 1500—2200 K, therefore, CF_3Cl is concluded to act as a promoter.

The authors wish to express their thanks to Prof. Toshiaki Yokota for his kindness in measuring the relative sensitivity. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 174145 from the Ministry of Education, Science and Culture.

The Electron Exchange Rates of Anthracene/Anthracene Radical Anion Ion-paired with Various Tetraalkylammonium Cations

Kosaku SUGA* and Shigeru AOYAGUI

Department of Chemical Engineering, Faculty of Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received March 13, 1981)

The electron exchange reaction between anthracene and its radical anion formed by the sodium reduction of the parent molecule in 1,2-dimethoxyethane, tetrahydrofuran, and a tetrahydrofuran-1,4-dioxane mixture was studied by ESR spectroscopy in the preseuce of tetraalkylammonium cations of various kinds and amounts. Analytical equations were presented to evaluate the rate constants of two competitive electron exchange reactions between anthracene and its anion, which was ion-paired in part with a tetraalkylammonium cation and in part with a sodium cation. The experimental results obeyed the theoretical equations and, consequently, yielded the electron exchange rate constants for the ion pairs of the former type, which were unaffected by the coexistence of the ion pairs of the latter type. They were of the order of 10^8 M^{-1} s^{-1} (1 M = 1 mol dm^{-3}), a value which was one order of magnitude smaller than the rate constant for the solvent-separated ion pair of anthracene anion with sodium cation. They were smaller for tetraalkylammonium cations with longer carbon chains. These findings are discussed on the basis of the theory of Marcus.

It is a well-known fact that a solution of anthracene radical anion (A^-) formed by sodium reduction of anthracene (A) in tetrahydrofuran (THF) gives an ESR spectrum with hyperfine splittings due to ^{23}Na, besides those due to ^1H.[1,2] This specific splitting pattern is considered to be evidence for the tight ion-pairing between Na^+ and A^-. In a previous paper[2] we reported a finding that the ^{23}Na-splittings disappeared on addition of tetrabutylammonium perchlorate (Bu_4NClO_4) to this solution, and suggested that A^- formed a more stable ion pair with Bu_4N^+ than with Na^+. By using a solution of this composition, measurements were made on the electron exchange rate constants for a few redox systems of aromatic hydrocarbons and their radical anions ion-paired with Bu_4N^+. No kinetic information had been available concerning the electron transfer reaction of ion pairs, except those of alkali metal cations.

In that work, however, no regard was paid on other kinds of ion pairs coexisting with those between Bu_4N^+ and A^-. According to Hirota *et al.*[3] sodium dihydroanthrylide (NaA) in THF exists as the following chemical species: the free anion, A^-, the loose or solvent-separated ion pair, $Na^+:A^-$, and the tight ion pair, $Na^+\cdot A^-$. Conductometrically, A^- can be distinguished from the others and ESR-spectroscopically, $Na^+\cdot A^-$ can be distinguished. Consequently, there is an unfortunate possibility that our previous rate constant for the A/A^- electron exchange in the presence of Bu_4N^+ was an average of the rate constants for the reactions in which A^-, $Na^+:A^-$, $Bu_4N^+:A^-$, and $Bu_4N^+\cdot A^-$ participated. $Na^+\cdot A^-$ is excluded on the basis of the previous finding described above.

This paper presents an analytical procedure to obtain the rate constant for the electron exchange between an aromatic hydrocarbon and its anion ion-paired with a tetraalkylammonium cation in the presence of the ion pair with Na^+. It is applied to the redox systems of A/A^- ion-paired with various kinds of tetraalkylammonium cations (R_4N^+).

Experimental

Anthracene was recrystallized twice from benzene. The perchlorates of tetrabutylammonium, tetrapropylammonium (Pr_4N^+), tetraethylammonium (Et_4N^+), and tetramethylammonium (Me_4N^+) were prepared from perchloric acid and the respective tetraalkylammonium iodides (R_4NI). They were recrystallized from water and then from ethylacetate. Bu_4NI was synthesized by the usual methods from tributylamine and butyl iodide. Other iodides, including tetraamylammonium iodide (Am_4NI), were commercially obtained.

The purification of the solvents used, THF, 1,2-dimethoxyethane (DME), and 1,4-dioxane (DO) and the preparation of the test solution were performed in the same way as described previously.[4] Sodium metal was used as the reducing agent.

The electron-transfer rates at 25±2°C were determined by the conventional method based on the line broadening of ESR spectra. A JEOL Model JES-3BSX spectrometer was used.

Analytical Procedure

The following ion pairs may exist in a solution containing NaA and a large excess of R_4NClO_4: $Na^+:A^-$, $R_4N^+\cdot A^-$, $R_4N^+:A^-$, $Na^+\cdot ClO_4^-$, $Na^+:ClO_4^-$, $R_4N^+\cdot ClO_4^-$, and $R_4N^+:ClO_4^-$. Since we cannot distinguish between $R_4N^+\cdot A^-$ and $R_4N^+:A^-$, $R_4N^+\cdot ClO_4^-$ and $R_4N^+:ClO_4^-$, and $Na^+\cdot ClO_4^-$ and $Na^+:ClO_4^-$, these couples of ion pairs are denoted by the common formulae $R_4N^+A^-$, $R_4N^+ClO_4^-$, and $Na^+ClO_4^-$, respectively.

Among these ion pairs and the free ions the following equilibria are established:

$$Na^+ + A^- \overset{K_1}{\rightleftharpoons} Na^+:A^-, \quad (1)$$

$$R_4N^+ + A^- \overset{K_2}{\rightleftharpoons} R_4N^+A^-, \quad (2)$$

$$R_4N^+ + ClO_4^- \overset{K_3}{\rightleftharpoons} R_4N^+ClO_4^-, \quad (3)$$

$$Na^+ + ClO_4^- \overset{K_4}{\rightleftharpoons} Na^+ClO_4^-, \quad (4)$$

where the K's are the formation constants of the ion pairs.

When the concentration of A^- is much smaller than

that of $Na^+: A^-$, which is true of solutions of low dielectric constants, the anthracene molecules added to this solution undergo the following electron exchange reactions:

$$Na^+: A^- + A \underset{}{\overset{k_1}{\rightleftharpoons}} A + Na^+: A^-, \quad (5)$$

$$R_4N^+A^- + A \underset{}{\overset{k_2}{\rightleftharpoons}} A + R_4N^+A^-, \quad (6)$$

where k's are the electron-exchange rate constants. The values for the coupling constant and the line width of the ESR spectrum of a solution containing $Na^+: A^-$ and $R_4N^+A^-$ should be, respectively, the average values for the spectra of these ion pairs, if the following exchange reaction is sufficiently fast:

$$Na^+: A^- + R_4N^+A^- \rightleftharpoons R_4N^+A^- + Na^+: A^-. \quad (7)$$

This condition may be fulfilled, since the solution containing NaA and R_4NClO_4 gave only a single ESR spectrum similar to that of free A^-. Therefore, it is assumed after Stevenson *et al.*[5] that the observed increase in line width is equal to the weighted mean of the increases due to Reactions 5 and 6. Then the observed rate constant, k, can be expressed in terms of k_1 and k_2 as follows:

$$k = (k_1[Na^+: A^-] + k_2[R_4N^+A^-])/([Na^+: A^-] + [R_4N^+A^-])$$
$$= (k_1 + k_2K_2[R_4N^+]/K_1[Na^+])/(1 + K_2[R_4N^+]/K_1[Na^+]), \quad (8)$$

where the brackets mean the concentration in molarity.

When it is assumed that the K values are large enough for the existence of any free ions to be neglected, which may be true of solvents of low dielectric constant such as THF, DME, and DO, Eq. 8 can be rewritten as follows (see Appendix):

$$k = k_2 + (k_1 - k_2)/(1 + K_2K_4[R_4NClO_4]_0/K_1K_3[A^-]_0), \quad (9)$$

where the subscript 0 denotes the analytical concentration of the substance indicated. Equation 9 can be linearized with respect to $[R_4NClO_4]_0$ or its inverse in the following forms:

$$(k_1 - k)^{-1} = K^{-1}(k_1 - k_2)^{-1}[R_4NClO_4]_0^{-1} + (k_1 - k_2)^{-1}, \quad (10)$$

or

$$(k - k_2)^{-1} = K(k_1 - k_2)^{-1}[R_4NClO_4]_0 + (k_1 - k_2)^{-1}, \quad (11)$$

with

$$K = K_2K_4/K_1K_3[A^-]_0. \quad (12)$$

When the k_1 value is known, the k_2 value can be obtained from the intercept of a linear plot of $(k_1 - k)^{-1}$ *vs.* $[R_4NClO_4]_0^{-1}$ and the K value can be obtained from the intercept and the slope together. When k_1 is not known, measurements must be made by using a concentration $[R_4NClO_4]_0$ high enough for the relation $K[R_4NClO_4]_0 \gg 1$ to be satisfied. Then Eq. 9 can be adequately approximated by the following linear relation between k and $[R_4NClO_4]_0^{-1}$:

$$k = k_2 + (k_1 - k_2)/K[R_4NClO_4]_0. \quad (13)$$

The k_2 value is obtained from the intercept of the linear plot drawn after Eq. 13. The k_1 value can then be obtained from the intercept and the slope together.

Results and Discussion

ESR Spectra of NaA in Solutions with and without R_4N^+. The ESR spectrum of NaA in THF exhibited hyperfine splittings due to ^{23}Na, whereas that in DME did not. The ^{23}Na hyperfine coupling constant was as large as 0.15 mT for a 1:1 THF–DO mixed solution whose dielectric constant was lower than that of THF. According to Hirota *et al.*[3] the ion-pairing reaction of A^- with Na^+ and the conversion reaction between $Na^+ \cdot A^-$ and $Na^+: A^-$ are both very rapid and, consequently, the ^{23}Na hyperfine coupling constant of the ion pair is the mean value of the coupling constants for $Na^+ \cdot A^-$ and $Na^+: A^-$ or A^-.

No ^{23}Na hyperfine structure was observed in the spectra for 0.1 mM NaA solutions in THF and THF–DO when they contained more than 0.5 mM R_4NClO_4 (R=Me, Et, Pr, Bu, and Am). This result can be explained on the basis of the ion-pair concept of Hirota *et al.* in the following way: most anthracene anions in DME exist as A^- and $Na^+: A^-$; in THF and THF–DO containing no R_4N^+, a part of the anthracene anions exist as $Na^+ \cdot A^-$; in the presence of R_4N^+, however, $Na^+ \cdot A^-$ may be converted into $R_4N^+ \cdot A^-$ and $R_4N^+: A^-$. The analytical equations derived above are based on these premises.

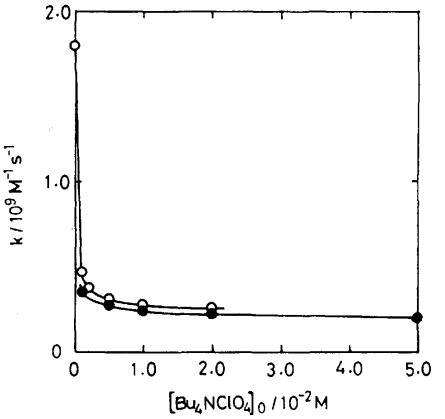

Fig. 1. Dependence of the electron-exchange rate constants for A/A^- in (○) DME and (●) THF on the concentration of added Bu_4NClO_4, $[Bu_4NClO_4]_0$.

Dependence of k on $[Bu_4NClO_4]_0$. Figure 1 shows the rate constants for the electron exchange reactions between anthracene and its radical anion in THF and DME at various Bu_4NClO_4 concentrations. The k value in DME decreases very rapidly with increasing $[Bu_4NClO_4]_0$ and then decreases gradually, approaching the value of *ca.* 2×10^8 M^{-1} s^{-1}. The k *vs.* $[Bu_4NClO_4]_0$ curve in THF also behaves in a similar way. The k value at $[Bu_4NClO_4]_0 = 0$ in DME, 1.8×10^9 M^{-1} s^{-1}, was taken from our previous paper.[4] This is regarded as the k_1 value. The same quantity in THF could not be obtained from ESR spectra, because ^{23}Na hyperfine lines due to $Na^+ \cdot A^-$ made them too complicated to be analyzed. The k *vs.* $[R_4NClO_4]_0$ curves for Pr_4NClO_4 and Et_4NClO_4 in DME are shown in Fig. 2. Because of the low solubility of these salts, the available concentration ranges were much narrower than the range for Bu_4NClO_4.

Evaluation of k_2. The $(k_1 - k)^{-1}$ *vs.* $[R_4NClO_4]_0^{-1}$ plot for Bu_4NClO_4 in DME is shown in Fig. 3. The

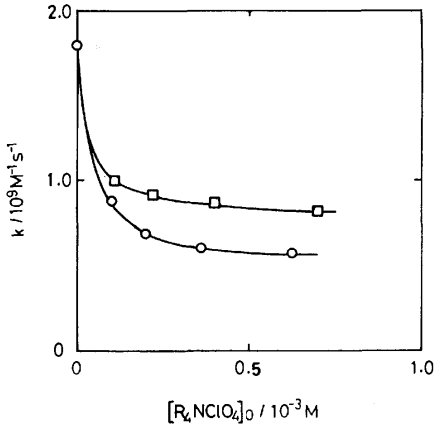

Fig. 2. Dependence of the electron-exchange rate constants for A/A^- in DME on the concentrations of (□) Et_4NClO_4 and (○) Pr_4NClO_4.

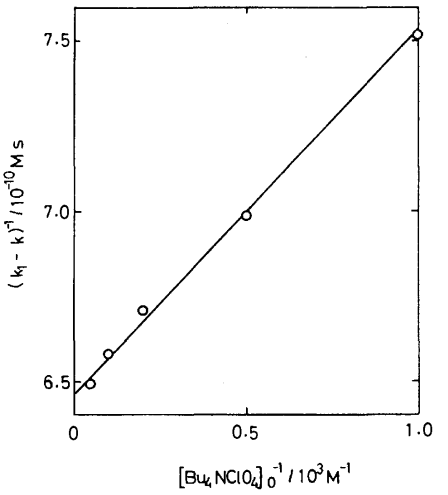

Fig. 3. $(k_1-k)^{-1}$ *vs.* $[Bu_4NClO_4]_0^{-1}$ in DME plotted after Eq. 10.

experimental points lie on a straight line in accord with the theoretical requirement of Eq. 10. The values for k_2 and K were obtained, respectively, as 2.5×10^8 M^{-1} s^{-1} and 4.8×10^3 M^{-1}.

Since the k_1 value in THF is not known, the k_2 value in this solvent was determined to be 1.8×10^8 M^{-1} s^{-1} from the intercept of the k *vs.* $[Bu_4NClO_4]_0^{-1}$ plot at $[Bu_4NClO_4]_0\rightarrow\infty$ in Fig. 4. The linearity of the experimental plot of $(k-k_2)^{-1}$ *vs.* $[Bu_4NClO_4]_0$ was excellent, as is shown in Fig. 5. On the basis of Eq. 11 the k_1 and K values were obtained, respectively, as 5×10^8 M^{-1} s^{-1} and 2.5×10^2 M^{-1}. However, it should be noted that this k_1 value was obtained at the infinite dilution of Bu_4NClO_4 at which the tight ion pair $Na^+\cdot A^-$ exists. Thus, the physical meaning of k_1 in THF is less clear than that in DME. The difference between the k_1 values in THF and DME may be caused by these circumstances, rather than the difference between the solvent properties.

The literature values for K_1 and $K_3(Bu_4N^+ClO_4^-)$ in THF at 25 °C are 2.3×10^5 M^{-1} [6] and 1.6×10^6 M^{-1}, [7] respectively. The $[A^-]_0$ value was held constant at

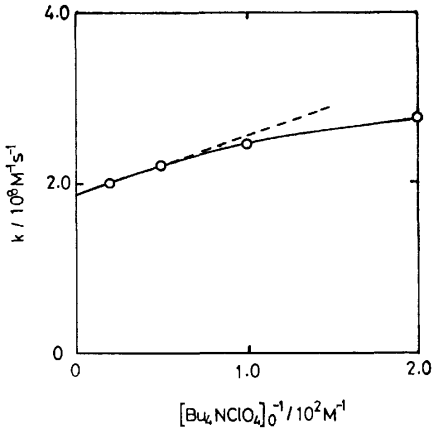

Fig. 4. *k vs.* $[Bu_4NClO_4]_0^{-1}$ in THF plotted after Eq. 13.

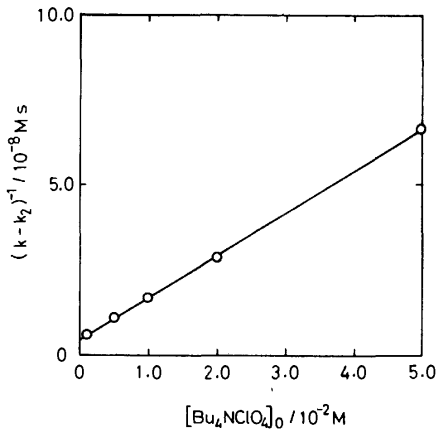

Fig. 5. $(k-k_2)^{-1}$ *vs.* $[Bu_4NClO_4]_0$ in THF plotted after Eq. 11.

about 10^{-4} M. According to Eq. 12 and the K value just obtained, the product K_2K_4 would be of the order of 10^{10} M^{-2}. Although neither K_2 nor K_4 is known, this may be a reasonable value, because most of the association constants in THF at 25 °C fall in the range of 10^4-10^6 M^{-1}. [7-9]

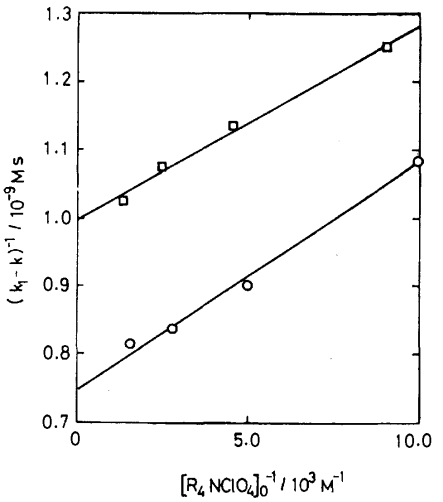

Fig. 6. $(k_1-k)^{-1}$ *vs.* (□) $[Et_4NClO_4]_0^{-1}$ and (○) $[Pr_4NClO_4]_0^{-1}$ in DME plotted after Eq. 10.

Equation 9 has been derived under the condition $[R_4NClO_4]_0 \gg [A^-]_0$. Though this condition was not fulfilled in the DME solutions of Pr_4NClO_4 and Et_4NClO_4, as seen in Fig. 2, the $(k_1-k)^{-1}$ *vs.* $[R_4NClO_4]_0$ plots in Fig. 6 exhibited the linearity required by Eq. 10 and yielded the following k_2 and K values: $k_2=4.6\times10^8$ (Pr_4NClO_4) and 8.1×10^8 (Et_4NClO_4) $M^{-1}s^{-1}$; $K=3.4\times10^4$ (Pr_4NClO_4) and 2.3×10^4 (Et_4NClO_4) M^{-1}.

These K values are compared with the value 4.8×10^3 M^{-1} for the Bu_4NClO_4 case. It may be safe to conclude that $K_2=KK_1K_3[A^-]_0/K_4$ is larger for smaller R_4N^+ ions, because K_3 may be larger for smaller ions and K_1, K_4, and $[A^-]_0$ are invariable.

Table 1. Rate constants for electron-exchange reactions between $R_4N^+A^-$ and A in different solvents

R_4NClO_4	$k_2/10^8$ $M^{-1}s^{-1}$		
	DME	THF	THF+DO (1 : 1)
Et_4NClO_4	8.1	(7.5) [b]	(6.6) [d]
Pr_4NClO_4	4.6	(4.9) [c]	(3.8) [d]
Bu_4NClO_4	2.5	1.8	(2.9) [e]
Am_4NClO_4	(1.5) [a]		

a) Obtained only with a 1 mM Am_4NI solution. b) Obtained only with a saturated solution of Et_4NClO_4 whose concentration is less than 5 mM. c) Obtained only with a 5 mM Pr_4NClO_4 solution. d) Obtained only with a saturated solution of R_4NClO_4. e) Obtained only with a 1 mM Bu_4NClO_4 solution.

The k_2 values thus obtained are summarized in Table 1. This also shows some approximate k_2 values in parentheses. Each of them was obtained at a fixed R_4NClO_4 concentration. Consequently, they should be averages of the real values for k_1 and k_2. However, the contribution of k_1 cannot be important, because k_1 and k_2 are of the same order and, furthermore, Figs. 1 and 2 suggest that anthracene anion should exist exclusively as $R_4N^+A^-$ under the given experimental conditions. In fact, the previously reported k value in THF containing 20 mM Bu_4NClO_4, 2.0×10^8 M^{-1} s^{-1},[2] is in good agreement with the k_2 value described above, 1.8×10^8 M^{-1} s^{-1}. This agreement points to the validity of the previous rate constant values obtained with no consideration of the competing reaction of Eq. 2. This may be due to the high Bu_4NClO_4 concentration which would make Na^+: A^- negligible.

Table 1 shows that $R_4N^+A^-$ undergoes a slower electron exchange than Na^+: A^-, whose k value in DME is 1.8×10^9 M^{-1} s^{-1}, and that the electron exchange rate decreases with increasing length of alkyl carbon chain. The former finding is in contrast with the finding of Campion *et al.*[10] that the rate of electron exchange between $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ in aqueous solutions is enhanced in the presence of R_4N^+ cations, whereas the latter agrees with theirs. However, it is doubtful that such a comparison makes sense. One of the reactants is uncharged in our experiments, but in theirs both reactants are highly charged and, consequently, the electrostatic repulsion between the reactants can have a serious effect on the electron exchange rate. They suggested that the ion-pairing of the reactant anions with R_4N^+ cations might reduce the effective charge on the reactants and thus might cause the enhancement in electron exchange rate. However, our experimental results show that the electrostatic effect is not the only effect of ion-pairing on the electron exchange rate.

The theories of electron transfer reaction which have been proposed so far are applicable only to reactions with the outer-sphere mechanism.[11] It is evident that the electron-transfer reaction between A and $R_4N^+A^-$ do not belong to this category of reaction. However, it may be worthwhile to extend the basic concept of nuclear rearrangement in the Marcus theory[12] to the reactions of our present concern. The intervening of R_4N^+ between A and A^- elongates their separation; the elongation may be greater for R_4N^+ with longer carbon chains. According to the theory, such a longer distance can account for the higher outer-sphere reorganization energy and, in turn, for the lower reaction rate. Furthermore, the intervening of R_4N^+ may decrease the activation entropy and, consequently, the rate constant, because the effective collision number in the electron exchange between $R_4N^+A^-$ and A may be smaller than that between A^- and A. It is probable that these effects are reflected in the observed rate constants.

Appendix

Derivation of Eq. 9. In solvents of low dielectric constants such as those used in this work, the concentrations of free ions are all negligible compared with those of the associated species. Then the following stoichiometric relations can be written among the chemical species existing in a solution containing sodium dihydroanthrylide and tetraalkylammonium perchlorate:

$$[R_4N^+A^-] + [R_4N^+ClO_4^-] = [R_4NClO_4]_0, \quad (A1)$$

$$[Na^+:A^-] + [R_4N^+A^-] = [A^-]_0, \quad (A2)$$

and

$$[Na^+ClO_4^-] = [R_4N^+A^-]. \quad (A3)$$

When $[R_4NClO_4]_0 \gg [A^-]_0$, the terms $[R_4N^+A^-]$ and $[Na^+:A^-]$ can be neglected in comparison with $[R_4N^+ClO_4^-]$ and $[R_4N^+A^-]$, respectively. Consequently the following relations are obtained:

$$[R_4NClO_4]_0 = [R_4N^+ClO_4^-] = K_3[R_4N^+][ClO_4^-], \quad (A4)$$

and

$$[A^-]_0 = [Na^+ClO_4^-] = K_4[Na^+][ClO_4^-], \quad (A5)$$

which lead to the relation

$$[R_4N^+]/[Na^+] = K_4[R_4NClO_4]_0/K_3[A^-]_0. \quad (A6)$$

Equation 9 in the text can be obtained from Eqs. 8 and A6.

Conformational Analysis of Intramolecular Excimer Formation in Dinaphthylalkanes

Shinzaburo Ito,* Masahide Yamamoto, and Yasunori Nishijima

Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 23, 1981)

Intramolecular excimer formation processes were explained by the conformational energy calculated by an empirical method. Observed rate constants of excimer formation processes are closely correlated to the fraction of *tg* conformation. This indicates that intramolecular excimers are mainly formed by the internal rotation, *trans*→*gauche*, with reference to the naphthalene unit. The fraction of the *tg* conformation, which is an adjacent conformation to the excimer conformation on the conformational energy map, serves as an effective concentration of the intramolecular reaction. The small formation rate for *rac*-2,4-di(2-naphthyl)pentane is due to the unfavorable rotational mode ($g^+ \rightleftarrows g^-$) required to take the excimer conformation.

Since intramolecular excimers have been observed in various vinyl aromatic polymers and their dimer model compounds, it has become clear that the efficiency of excimer formation is greatly governed by the micro structures of molecules. Hirayama,[1] Longworth,[2] Chandross,[3] and Klöpffer[4] studied configurational requirements for the intramolecular excimer formation, and showed that the molecular structure in which two aromatic groups are separated with three carbon atoms of the methylene chain is the most favorable configuration for the intramolecular excimer formation. Their results show that the parallel sandwich arrangement of the aromatic groups is attainable with a propane chain, and that in the other type of compounds with shorter or longer chains than the propane chain, *e.g.*, ethane, butane, and pentane, two aromatic groups cannot approach each other owing to the conformational instability. This selectivity for the excimer formation in diarylalkanes is generally accepted as the $n=3$ rule.

Since we know that the intramolecular excimers are formed by the conformational relaxation after excitation of chromophores, the formation processes should be interpreted by the equilibrium conformations of the molecules and their internal rotation processes. For example, different efficiencies of the excimer formation even for the compounds holding $n=3$ rule, were reported by Hirayama,[1] and similar results were recently obtained by other workers.[5-7] These results suggest that there are some conformational factors controlling the intramolecular excimer formation besides the $n=3$ rule. But, in order to discuss the process of the intramolecular excimer formation in greater detail, quantitative data for the rate constant of the formation process are required.

In the preceding paper,[8] we reported a large difference in the efficiency of the excimer formation for the compounds satisfying the $n=3$ rule: 1,3-di(2-naphthyl)propane (1,3-DNPr), 1,3-di(2-naphthyl)butane (1,3-DNBu), *meso*-2,4-di(2-naphthyl)pentane (2,4-DNPe (*meso*)), and *rac*-2,4-di(2-naphthyl)pentane (2,4-DNPe (*rac*)). It was also shown by time-resolving measurements that the excimer formation rate constants change markedly with the molecular structures of the samples. We have tried to elucidate the internal rotation processes which lead to the intramolecular excimer formation.

In this paper, conformational energies of the four compounds mentioned above were calculated as functions of rotations about their C–C bonds, using an empirical treatment for the repulsive energies between nonbonded atoms and intrinsic torsional energies. The pathway of the internal rotation from the most stable conformation to the excimer conformation is discussed on the basis of the conformational energies. The observed rates of excimer formation are quantitatively well explained by these conformational analyses.

Procedures of the Calculation

The conformational energies of dinaphthylalkanes were calculated by using the conventional empirical method described in the preceding paper.[9] Potential energies due to the van der Waals interaction between nonbonded atoms and due to the intrinsic torsional potential energies associated with the rotation about the bonds are considered. For calculation of the van der Waals interaction, a potential function of Lennard-Jones type is used. The potential function is truncated by considering the molecule-solvent interaction according to Flory *et al.*[10,12] The total potential energy due to the van der Waals interaction is calculated as the sum over all pairs of nonbonded atoms. The intrinsic torsional potential energy for the skeletal alkane chain, $E(\phi)$, is calculated for the rotational angle ϕ, which is regarded as having a three fold periodicity:

$$E(\phi) = (E_0/2)\ (1-\cos 3\phi),$$

where E_0 is the torsional barrier energy, and is taken to be 12 kJ/mol.[11] The torsional energy for the rotation of naphthalene units, θ_i, is neglected, since the potential barrier is too low. The total potential energy is given by the sum of the potential energies due to the van der Waals interaction and the intrinsic torsional potentials.

The structural parameters used in this calculation are shown in Fig. 1. We must consider four independent angles to generate a given conformation of the dimers: two rotational angles, ϕ_1 and ϕ_2, for the chain skeleton and two rotational angles, θ_1 and θ_2, for the naphthyl groups, which are denoted as shown in Fig. 2. Angles are taken as 0 ° in the *trans* conformation. The naphthalene substituents are adopted as a reference conformation for the notation of *trans* and *gauche* conformations, in order to represent consistently the conformations of all

Fig. 2. Dinaphthylalkanes in the *tt* conformation. 1,3-DNPr: (R_1=H, R_2=H, R_3=H, R_4=H), 1,3-DNBu: (R_1=H, R_2=H, R_3=CH_3, R_4=H), 2,4-DNPe(*meso*): (R_1=CH_3, R_2=H, R_3=CH_3, R_4=H), 2,4-DNPe(*rac*): (R_1=H, R_2=CH_3, R_3=CH_3, R_4=H). N_P=2-naphthyl.

compounds used in this study. For example, the *tt* conformation of 2,4-DNPe(*meso*), which is situated at (ϕ_1, ϕ_2)=(0°, 0°), represents the conformation in which two naphthalene units are extended at the ends of trimethylene chain as shown in Fig. 2, but this does not mean the planar zigzag conformation of the five skeletal carbon atoms.

Conformation maps should be drawn as a function of four angles: θ_1, ϕ_1, ϕ_2, and θ_2. But, in order to make the survey easier for the energy maps, they are drawn as a function of skeletal bond rotations ϕ_1 and ϕ_2. The other rotational angles, θ_1 and θ_2, are fixed on the angles to give a minimum energy at the most stable position of ϕ_1 and ϕ_2. For some specific region on the energy maps, the conformational energy is calculated as a function of all four angles, and the minimum energy was adopted. With the rotation of the skeletal angles, several stable conformations appear on the conformation maps. The fraction of i-th conformation f_i is calculated on the assumption that the distribution of conformations obeys the Boltzmann distribution including a weighting factor W_i,

$$f_i = \{W_i \exp(-E_i/RT)\}/\sum_i W_i \exp(-E_i/RT),$$

where E_i is the minimized potential energy for i-th conformation. The weighting factor is estimated by the 2-dimensional local energy maps for the rotation angles (θ_1, ϕ_1) and (θ_2, ϕ_2); here the values of one angle set are varied, holding the angles of the other set constant at the minimum position of the energy. In their local energy maps, the area surrounded by the contour which is 2.1 kJ/mol higher than the energy of each minimum is measured, and the weighting factor is calculated by $W_i=w_{1,i}\times w_{2,i}$, where $w_{1,i}$ and $w_{2,i}$ are proportional to calculated areas on the local energy maps for (θ_1, ϕ_1) and (θ_2, ϕ_2), respectively, corresponding to i-th conformation.

Conformational Energies

The calculation is carried out at first for 1-(2-naphthyl)propane (R=H in Fig. 1) and 2-(2-naphthyl)-butane (R=CH_3 in Fig. 1) which are the model compounds corresponding to the monomer units of dinaphthylalkanes. Conformational energy maps for these compounds are shown in Figs. 3 and 4, where

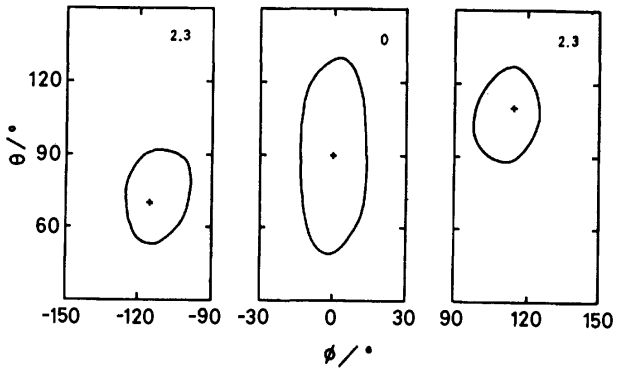

Fig. 3. Conformational energy maps of 1-(2-naphthyl)-propane. The energy minima are marked by+signs. The contour lines indicate the 2.1 kJ/mol higher energies than each minimum. Numerals in the figures show the potential energy at the minimum position in the unit of kJ/mol.

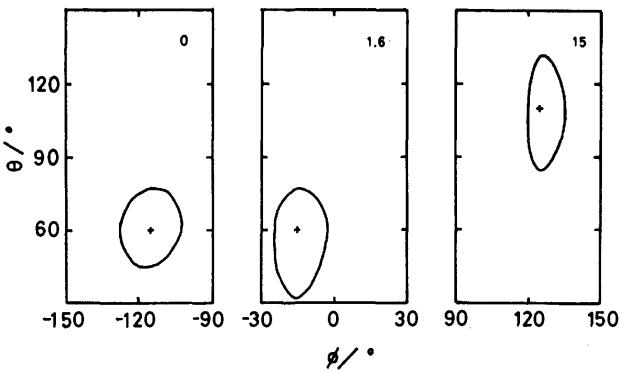

Fig. 4. Conformational energy maps of 2-(2-naphthyl)-butane.

the potential energies are calculated at intervals of 5° for each rotation angle. For 1-(2-naphthyl)propane, the potential minima are situated at (θ, ϕ)=(90°, 0°), (70°, −115°), and (110°, 115°). The potential minima for 2-(2-naphthyl)butane are found at (θ, ϕ)=(60°, −15°), (60°, −115°), and (110°, 125°). The stable conformations considerably deviate from the *trans* or *gauche* positions, owing to the repulsion between the methyl and naphthyl groups. The areas surrounded by the contour for each energy minimum differ significantly. The areas for the *trans* conformations are larger than that for *gauche* conformation; they are about 2.4 times or 1.2 times larger than the other potential

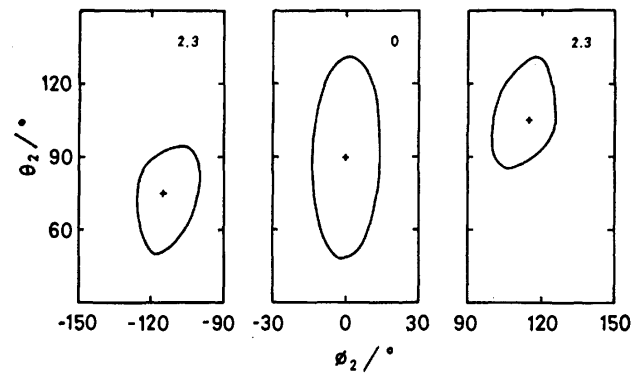

Fig. 5. Conformational energy maps of 1,3-DNPr as a function of θ_2 and ϕ_2, where θ_1 and ϕ_1 are fixed at *trans* position ($\theta_1=90°$, $\phi_1=0°$). Notations of the contour lines and numerals are the same as Fig. 3.

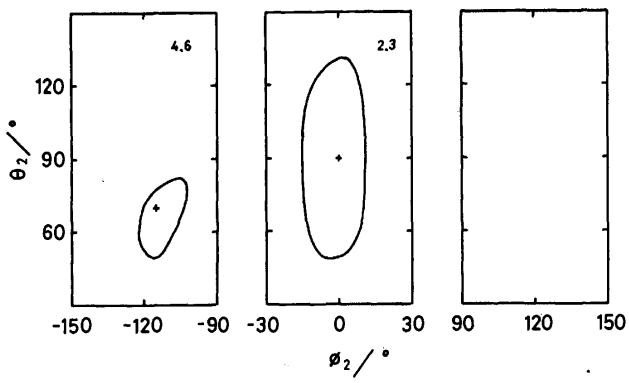

Fig. 6. Conformational energy maps of 1,3-DNPr as a function of θ_2 and ϕ_2, where θ_1 and ϕ_1 are fixed at *gauche* position ($\theta_1=70°$, $\phi_1=-115°$). Notations of the contour lines and numerals are the same as Fig. 3.

minima of 1-(2-naphthyl)propane or 2-(2-naphthyl)-butane, respectively. This must be reflected in the calculation of the fraction of each conformation. Next, the local energy maps as a function of θ_2 and ϕ_2 for the dimer compounds were calculated; in this calculations the angles θ_1 and ϕ_1 are held at the values obtained by the calculation for the monomeric model compounds. The local maps for 1,3-DNPr are shown in Figs. 5 and 6. The energy maps were calculated once more, by changing the rotational angle set to θ_1 and ϕ_1 and holding θ_2 and ϕ_2 to the minimum positions obtained on the previous maps. These procedures are repeated until the minimum position becomes consistent with that obtained on the previous map. For each stable conformation, the angles, minimized potential energy, weighting factor, and fraction of the conformation at 25 °C are listed in Tables 1, 2, and 3.

For 1,3-DNPr, the conformational energy map as a function of skeletal bond rotations, ϕ_1 and ϕ_2, is shown in Fig. 7, where the angles, θ_1 and θ_2 are fixed at $\theta_1=90°$ and $\theta_2=90°$. In this figure, a minimum position (*tt*) is marked by the symbol +, and the excimer conformations (g^+g^- and g^-g^+) are represented by the symbol ●. The most stable conformation is situated at *tt*, and is surrounded by four equivalent *tg* conformations. The potential energy of *tg* conformation is *ca.* 2.1 kJ/mol higher than that of *tt*. The minimized energy by the rotation of all angles at the important region of Fig. 7 is calculated. This result indicates that the barrier energies corresponding to the transitions of $tt \rightleftarrows tg$ and $tt \rightleftarrows g^+g^-$ ($tt \rightleftarrows g^-g^+$) are about 15 kJ/mol and 29 kJ/mol, respectively. These potential energies are caused mainly by the intrinsic torsional energies.

For 1,3-DNBu, the conformational energy map is shown in Fig. 8. The fixed angles θ_1 and θ_2 are chosen to be $\theta_1=90°$ and $\theta_2=120°$ for 1- and 3-naphthyl groups according to the result obtained from the local potential maps. The most stable conformation is found at tg^+, and metastable conformations appear at *tt*, g^-t, and g^+g^+. The barrier energy corresponding to the transition of $tt \rightleftarrows tg^+$ and $tt \rightleftarrows g^-g^+$ has the same values as that for 1,3-DNPr.

For 2,4-DNPe, conformational energy maps are shown

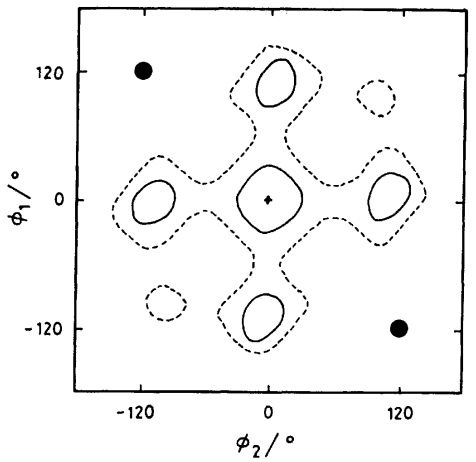

Fig. 7. Conformational energy map of 1,3-DNPr as a function of ϕ_1 and ϕ_2. The rotational angles of naphthalene units, θ_1 and θ_2 are fixed at $\theta_1=\theta_2=90°$. The most stable position and the excimer conformations are marked by the signs, + and ●, respectively. Solid lines indicate the 8.5 kJ/mol higher energy than the minimum. Broken lines show the 17 kJ/mol higher energy than the minimum.

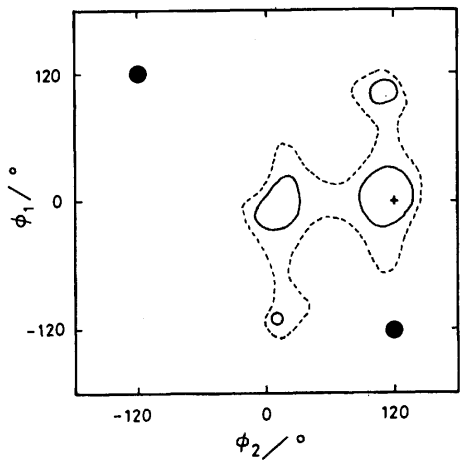

Fig. 8. Conformational energy map of 1,3-DNBu as a function of ϕ_1 and ϕ_2. The rotational angles of naphthalene units, θ_1 and θ_2 are fixed at $\theta_1=90°$, $\theta_2=120°$. Notations of the signs and lines are the same as Fig. 7.

in Fig. 9 for *meso* isomer and in Fig. 10 for *racemo* isomer. In these compounds, most of the conformations are unstable due to the steric hindrance of methyl substituents. Only two conformations are allowed: tg^+ and g^-t conformations for *meso* isomer, tt and g^+g^+ conformations for *racemo* isomer. In Fig. 9, a third potential minimum is observed besides the excimer conformation, g^-g^+, but its fraction is so small, as shown in Table 3, that it can be neglected.

Discussion

All rate constants in the photophysical kinetic scheme were reported in the previous paper. The observed excimer formation rate constant k_{21}, is shown again in Table 4. The values of k_{21} are much different for each

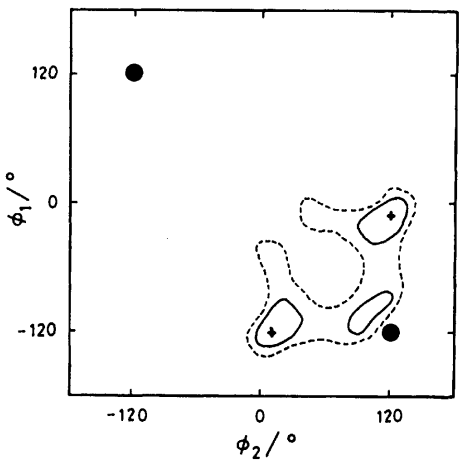

Fig. 9. Conformational energy map of 2,4-DNPe(*meso*). The rotational angles, θ_1 and θ_2 are fixed at $\theta_1=-120°$, $\theta_2=-120°$. Notations of the signs and lines are the same as Fig. 7.

compound. In order to discuss the relationship between the excimer formation rate constants and the configuration of the compounds, it is necessary to follow the pathway of conformational changes on the potential

energy map for each compound.

In the ground state, the excimer conformation marked by ● is one of the unstable conformations, because of the steric hindrance of naphthalene units. However, in the excited state, this conformation is stabilized by the electronic interactions between two naphthalene units. The enthalpy change due to excimer formation is found to be *ca.* 19 kJ/mol for the intermolecular excimer formation in THF. This electronic interaction acts mainly in the parallel alignment of two naphthalene units.

The investigations on various dinaphthylalkanes have demonstrated the strict geometrical requirements for the attractive interaction in naphthalene chromophores.[3,13] The initial distribution of the molecular conformations at the instant of photo-excitation is the same as that in the ground state, and conformational relaxation to the excimer state occurs from the initial distribution. In the low temperature region, where the molecular motion is frozen, there is no indication of specific interaction between naphthalene chromophores. Hence, the relaxation processes will be discussed hereinafter on the assumption that there is no attractive interaction between two naphthalene units except in the excimer state.

For 1,3-DNPr, the conformational energy map shows that the *tt* position (0°, 0°) is the stable conformation where the naphthalene units are furthest apart from each other. Two excimer conformations, g^+g^- (g^-g^+), are equivalent in this compound. As for the pathway to the excimer conformations, the direct conformational changes from *tt* to g^+g^- (g^-g^+), are unfavorable, since such transitions require the co-operative motion of two rotational angles, ϕ_1 and ϕ_2; the calculated barrier energy is found to be 29 kJ/mol. This barrier comes from the intrinsic torsional potential. This value is higher than the activation energy observed for the excimer formation process: *ca.* 21 kJ/mol. Therefore, in order to reach the excimer conformations, it is necessary to pass through the *tg* conformations which are neighbors with both the stable *tt* and the excimer conformations. For the fraction of the *tg* conformation, a fairly large value is obtained: 0.4. The barrier energy for the conformational change from *tt* to *tg* is found to be 15 kJ/mol, and this value is sufficiently smaller than the observed activation energy of excimer formation. Hence, the appearance of *tg* conformations under the equilibrium, $tt \rightleftarrows tg$, contributes to the intramolecular excimer formation in 1,3-DNPr. The *tg* conformation can be considered as a precursory conformation of the intramolecular excimers.

For 1,3-DNBu, the energy map indicates that the most stable conformation is tg^+, which corresponds to the planar conformation of skeletal carbon atoms. The minimized energy for the *tt* conformation is 1.3 kJ/mol higher than that of lowest conformation *tg*, and the barrier energy for the transition from the *tt* conformation to the excimer state is the same as that of 1,3-DNPr: 29 kJ/mol. The fractions of the other conformations, except for tg^+ and *tt*, are negligibly small owing to the steric hindrance of the methyl substituent. In this compound, two excimer conformations, g^+g^- and g^-g^+ are not equivalent. The g^+g^- conformation which lies in the upper left-hand corner in Fig. 8, is unable to become an excimer site, since there is no available adjacent conformation to the excimer one. The intramolecular excimers in 1,3-DNBu, therefore, are formed at the g^-g^+ conformation. The sum of fractions for tg^+ and g^-t which are neighbors with the excimer site, is found to be 0.6. This predicts a larger excimer formation rate constant for 1,3-DNBu than that for 1,3-DNPr.

For 2,4-DNPe(*meso*), the calculation shows three potential minimum: tg^+ of lowest energy, its mirror image g^-t, and g^-g^+, which corresponds to the excimer conformation. Fractions of other conformations are rather small. The distribution is found predominantly in the tg^+ and g^-t forms, which are adjacent conformations to the excimer one, g^-g^+. There is a little fraction for the excimer conformation, g^-g^+ in the ground state. This rotational isomer was also found in the calculations of *meso*-2,4-diphenylpentane and its derivatives.[14,15] The fraction of this g^-g^+ conformation has been reported to be a few percent by NMR spectroscopy.[16] In this calculation, it was estimated to be 1—2% at 25 °C. If an appreciable fraction of 2,4-DNPe(*meso*) takes this conformation, a large component of excimer emission, rising immediately after the excitation pulse, should be observed in the time-resolving measurements. However, such a fast-rise component cannot be observed at all. Efficient intramolecular excimer formation is expected for 2,4-DNPe(*meso*), since a large portion of the molecules takes the adjacent conformations to the excimer state, g^-g^+. The other excimer conformation, g^+g^- can be neglected, because it has no available conformation for the excimer formation. Moreover, there is a steric hindrance between the two methyl substituents at this excimer state, g^+g^-.

The calculation for the three compounds: 1,3-DNPr, 1,3-DNBu, and 2,4-DNPe(*meso*), indicates that the intramolecular excimers are formed by the internal

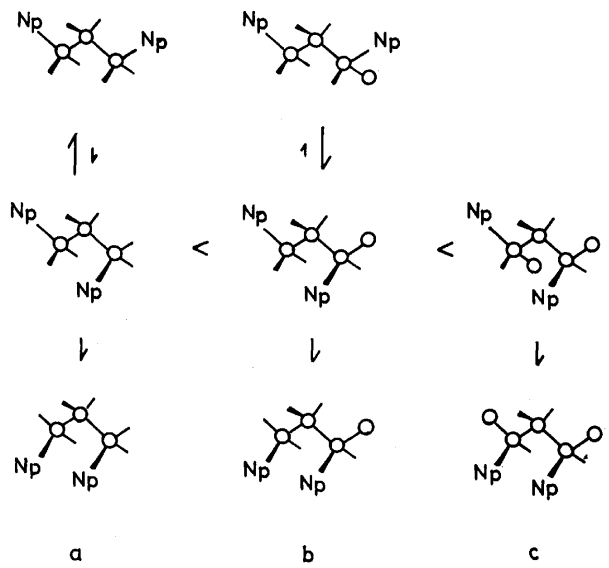

Fig. 11. Schematic illustration of excimer formation processes in dinaphthylalkanes. (a): 1,3-DNPr, (b) 1,3-DNBu, and (c) 2,4-DNPe(*meso*). N_P=2-naphthyl.

rotation, *trans*→*gauche* from the tg^+ or g^-t conformations, as shown in Fig. 11. Since the activation energies for the excimer formation processes are almost the same, the difference between the rate constants of the excimer formation is due to the frequency factors of their rate constants. These factors should be proportional to the fraction of the adjacent conformations, tg^+ and g^-t, if the intramolecular excimers are formed by the same rotational mode. Calculated fractions are 0.4 for 1,3-DNPr, 0.6 for 1,3-DNBu, and 0.98 for 2,4-DNPe(*meso*). These values are consistent with the results of excimer formation rate constants obtained experimentally: 2.1×10^8 s^{-1} for 1,3-DNPr, 2.8×10^8 s^{-1} for 1,3-DNBu, and 7.9×10^8 s^{-1} for 2,4-DNPe(*meso*). The somewhat larger value of 2,4-DNPe(*meso*) than that expected by the calculation may come from the existence of the metastable g^-g^+ conformation in the ground state, which slightly lowers the activation energy for the excimer formation process.

For 2,4-DNPe(*rac*), the situation is much different from that described above. Calculations reveal the lowest energy for the g^+g^+ form, which corresponds to the planar *trans* conformation of the skeletal five carbon atoms, and which is also a neighbor with the excimer conformation. However, the internal rotations, $g^+g^+\rightleftarrows g^+g^-$ ($g^+g^+\rightleftarrows g^-g^+$) are required for the excimer formation. This transition is a different type of rotation from that of the other three compounds. It is known that the barrier to the interconversion of *gauche* forms, $g^+\rightleftarrows g^-$ is higher than that between *t* and *g* forms; the barrier energy has been reported to be *ca.* 27 kJ/mol.[17] On the route to the excimer state, it is also possible to take the tg^+ (g^+t) conformations. But these conformations are unstable because of the steric hindrance, and the imposed energy is 13—17 kJ/mol.[16] Moreover, the *trans*→*gauche* transition to the excimer conformation ($tg^+\rightarrow g^-g^+$ or $g^+t\rightarrow g^+g^-$) becomes a $g^+\rightleftarrows g^-$ transition with reference to the methyl groups. Thus, for 2,4-DNPe(*rac*), the interconversion $g^+\rightleftarrows g^-$ is necessary in the case of either rotation in order to reach the excimer site. The small value of the formation rate constant ($8.7\times10^7\,s^{-1}$) and the somewhat higher activation energy (23 kJ/mol) obtained for this compound is not determined by the fraction of the adjacent conformation but by the different transition mode of the internal rotation.

Our calculation did not include the interaction energy in the electronically excited state. However, the rate of intramolecular excimer formation can be interpreted reasonably by this conformational analysis. The agreement between the observed rate constants and the results of calculations indicates that the formation of intramolecular excimers are determined by the internal rotation, *trans*→*gauche*, and that the fraction of the *tg* conformation, which is an adjacent conformation to the excimer one, serves as an effective concentration in the intramolecular reaction.

Synthesis, Electrical Resistivities, and Electronic Reflection Spectra of Alkaline-earth Metal Cation-TCNQ-Crown Ether Complexes

Tsuruyoshi MATSUMOTO, Takashi NOGAMI,* Hidekazu TANAKA, and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565

(Received May 6, 1981)

Two types of alkaline-earth metal cation–TCNQ–crown ether complexes were synthesized: one is the simple salt, expressed as $[M^{2+}(TCNQ^-)_2]_m$(crown ether)$_n$ and the other is the complex salt expressed as $[M^{2+}(TCNQ^-)_2]_m(TCNQ)_n$(crown ether)$_t$. The electrical resistivities of the complexes were measured for compacted samples and single crystals. The resistivities of the simple salts were greater than 10^5 Ω cm, so they are much less conductive than the original TCNQ salts, $M^{2+}(TCNQ^-)_2$. Most of the complex salts were more conductive than the original TCNQ salts, with the resistivities of 4—10^3 Ω cm.

The studies on the electrical conductivities of 7,7,8,8-tetracyanoquinodimethan (TCNQ) complexes have clarified that the mixed valent complex is more conductive than the other type complex which does not contain neutral TCNQ.[1] Many metal-cation TCNQ salts have been synthesized. However, most of them are simple salts, expressable as $M^{m+}(TCNQ^-)_m$.[2] Therefore, we can not expect high conductivity.[3] Even if we try to synthesize a complex salt, $M^{m+}(TCNQ^-)_m(TCNQ)_n$, from a solution by the reaction of a simple salt with neutral TCNQ, the simple salt only crystallizes out because of its poor solubility. We noticed that a series of macrocyclic polyethers called crown ethers have a specific property of accepting metal cations into their cavities and thereby of solubilizing many inorganic salts into organic solvents like benzene.[4] We thought that a simple salt solubilized by using crown ether would complex with neutral TCNQ in solution to produce complex salt. In fact, we could obtain several complex salts, as well as simple salts, in the case of alkali-metal cation–TCNQ–crown ether complexes.[5] Comparing the conductivities of the complexes thus obtained with those of the original TCNQ salts, we found comparable conductivities. This fact will be explained as follows. Although the introduction of the crown ether has a negative effect on the conductivity by the steric hindrance, the complex salt formation has a positive effect on the conductivity. Thus, compensation of the two effects resulted in the same order of magnitude of the conductivity in the case of the alkali-metal cation complex. We thought that the former negative effect could be overcome by using the multi-valent cation TCNQ salts. One metal-cation accompanies more than one TCNQ molecule in this case; this may result in a closer distance between TCNQ molecules as compared with the spacing in the alkali-metal cation complex. So we synthesized alkaline-earth metal cation–TCNQ–crown ether complexes, and measured the electrical resistivities of the compacted samples and two single crystals in expectation of achieving highly conductive materials. We also measured the electronic diffuse reflection spectra of the new complexes in order to know the electronic interaction between TCNQ molecules in the solid-state.

Experimental

Materials. Alkaline-earth metal–TCNQ salts were synthesized according to the reported procedures.[6] All the crown ethers were purchased from Nakarai Chemicals, Ltd.

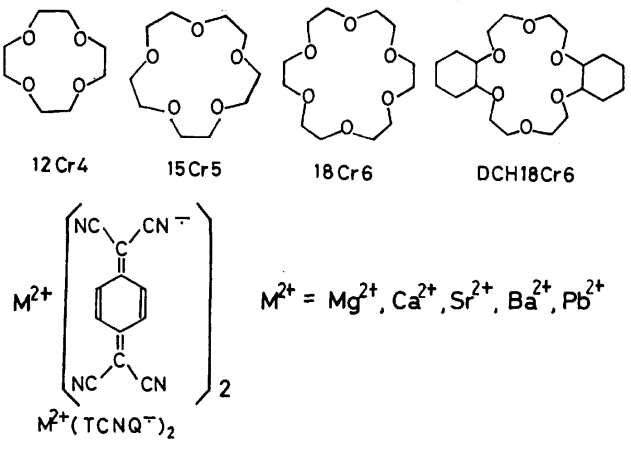
Synthesis of Cation–TCNQ–Crown Ether Complexes. Simple salts, $[M^{2+}(TCNQ^-)_2]_m$(crown ether)$_n$, were synthesized by the reaction of the original $M^{2+}(TCNQ^-)_2$ with a crown ether in methanol. Complex salts, $[M^{2+}(TCNQ^-)_2]_m(TCNQ)_n$(crown ether)$_t$, were synthesized either by the reaction of a simple salt with neutral TCNQ or by the reaction of $M^{2+}(TCNQ^-)_2$, crown ether and neutral TCNQ in organic solvent. The details of the synthesis were described before.[5]

Electrical Resistivity Measurements. Electrical resistivity in the compacted sample was measured by the same procedures as described before.[5] The electrical resistivity of the single crystal was measured by a four probe method, and the temperature was regulated by type-D Cryomini refrigerator (Osaka Sanso Co., Ltd).

Electronic Diffuse Reflection Spectra. Electronic diffuse reflection spectra of the complexes were measured by a Hitachi 340 Recording Spectrophotometer. The sample was smeared onto a filter paper. The reflected light was collected by integrating over a sphere.

Results and Discussion

Isolation of Alkaline-earth Metal Cation–TCNQ–Crown Ether Complexes. The following crown ethers and TCNQ salts were used for the preparation of the complexes: 12-crown-4,15-crown-5, 18-crown-6, perhydrobenzo[*b*,*k*][1,4,7,10,13,16]hexaoxacyclooctadecane



(usually called as "dicyclohexy-18-crown-6"), $Mg^{2+}(TCNQ^-)_2 6H_2O$, $Ca^{2+}(TCNQ^-)_2$, $Sr^{2+}(TCNQ^-)_2$, $Ba^{2+}(TCNQ^-)_2$, and $Pb^{2+}(TCNQ^-)_2\ 1.5H_2O$, the molecular structures of which are shown above. In the above figure, the abbreviations of Cr, and DCH mean crown ether, and bis(perhydrobenzo) component, respectively. Thus, DCH18Cr6 denotes "dicyclohexyl-18-crown-6." We have isolated two types of complexes: one is in the simple salts and expressed as $[M^{2+}(TCNQ^-)_2]_m$-(crown ether)$_n$ and the other is in the complex salt and expressed as $[M^{2+}(TCNQ^-)_2]_m$–$(TCNQ)_n$-(crown ether)$_i$. Table 1 summarizes the complexes isolated and their yields, melting points, analytical data, and appearences and colors. As expected, the stoichiometry of the simple salt has a tendency for the crown ether with a cavity comparable to or larger than the cation size to have a one-to-one stoichiometry, while the crown ether with a cavity smaller than the cation size has a two-to-one stoichiometry arising from the cation being sandwiched by crown ethers.[7] The stoichiometries of most of the complex salts are derived from the simple salts plus one molecule of neutral TCNQ. However, the complex salts, including DCH18Cr6, have two molecules of neutral TCNQ. In general, the solubility becomes low when a simple salt complexes with neutral TCNQ. Because the solubilities of DCH18Cr6 complexes are higher than those of the other crown ether complexes, the complex salt of DCH18Cr6 does not crystallize out from the solution until two molecules of neutral TCNQ complex with one simple salt. Some of the magnesium complexes contained water of crystallization. A variety of crystal colors (violet, green, yellow green, or purple) were found in the simple salts; these resulted from the

a) Besides these reflection peaks, all the complex-salts have the reflection bands lower than 7×10^3 cm^{-1} ascribable to the charge-transfer transition from $TCNQ^-$ to TCNQ. b) Compacted Sample. c) Single crystal.

differences of the electronic interaction between the TCNQ anion radicals in the solid state. In other words, we can modify the interaction between TCNQ anion radicals in the solid state by introducing the crown ether. The colors of most of the complex salts were black. The melting points of the complexes thus obtained were much lower than those of the original salts, $M^{2+}(TCNQ^-)_2$, which are higher than 300 °C. This fact will result from the much weaker electrostatic attraction between metal cation and $TCNQ^-$; this results in a much smaller Madelung energy than in the cases of the original salts. Unlike the poor solubilities of the original TCNQ salts in the usual organic solvent, the solubilities of the complexes isolated here were large as expected. Their high solubilities in the organic solvents may be useful for practical applications. These complexes were stable in air for several months.

Electrical Resistivities. The electrical resistivities of the simple salts and complex salts were measured for the compressed samples at room temperature. The resistivities of the conductive salts, $Mg^{2+}(TCNQ^-)_2$-$TCNQ(15Cr5)_2 2H_2O$ and $Ca^{2+}(TCNQ^-)_2$ $TCNQ(12Cr4)_2$ were measured for single crystals. Table 2 summarizes the observed results. Table 3 shows the electrical resistivities of the original TCNQ salts, for the sake of comparison. Table 2 shows that the resistivities of the simple salts are greater than 10^5 Ω cm; these salts are thus much less conductive than the original TCNQ salts (see Table 3). On the other hand, the complex salts are much more conductive than the corresponding simple salts, with the electrical resistivities of 4—10^3 Ω cm. Thus, most of the complex salts were more conductive than the original TCNQ salts, which is in line with our expectation. The lowest resistivity (4 Ω cm) was found in $Mg^{2+}(TCNQ^-)_2$ $TCNQ(15Cr5)_2$ $2H_2O$ single crystal at room temperature. The signle crystal of $Ca^{2+}(TCNQ^-)_2$ TCNQ-$(12Cr4)_2$ showed a resistivity of 10 Ω cm at room temperature. The temperature dependence of the electrical resistivity of the former single crystal is shown in Fig. 1.[8] The change of the temperature dependence of the resistivity at 154 K may be caused by a phase transition. The activation energies were 0.06 eV and 0.02 eV at the higher and lower temperature ranges, respectively. The complex, $Ca^{2+}(TCNQ^-)_2TCNQ$-$(12Cr4)_2$, is expected to incorporate another neutral TCNQ in principle, although we could not isolate such a type of complex from the solution. However, we

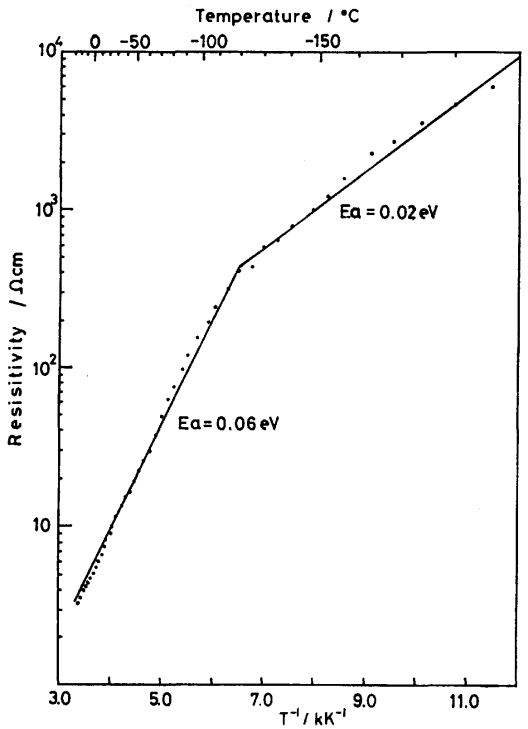

Fig. 1. Temperature dependence of the electrical resistivity of $Mg^{2+}(TCNQ^-)_2$ $TCNQ(15Cr5)_2 2H_2O$ single crystal.

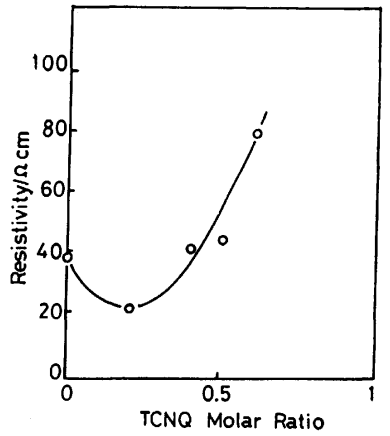

Fig. 2. The plot of the electrical resistivity against the molar fraction of neutral TCNQ added to Ca^{2+}-$(TCNQ^-)_2$ $TCNQ(12Cr4)_2$.

found that the complex salt formation occurs by simply grinding $Ca^{2+}(TCNQ^-)_2TCNQ(12Cr4)_2$ with neutral TCNQ in an agate bowl. Figure 2 shows the plot of the electrical resistivity against the molar fraction of neutral TCNQ added to Ca^{2+} $(TCNQ^-)_2$ TCNQ-$(12Cr4)_2$. This complex had a values of 38 Ω cm for the compacted sample at room temperature. As more and more neutral TCNQ was added to this complex, the resistivity of the complex first decreased down to 20 Ω cm and then increased. The increase of the conductivity in the range of less than 0.2 added TCNQ molar fraction indicates that the solid-state complex-salt formation reaction occurs simply by grinding the original salt with neutral TCNQ in an agate bowl. An analogous reaction was also found in alkali-metal cation-TCNQ–crown ether complex.[5] Thus, the solid-state reaction is characteristic of these crown ether complexes: it is not found in the original TCNQ salts. The fact that the above mentioned 12Cr4 complex is a good conductor suggests that the small crown ether may be an important factor in the high conductivity. But the order of the conductivity of the 12Cr4-complex salts does not correspond to the order of the cation size. Thus, we could not simply correlate the conductivities of the complex-salts with the cation size.[9]

Now, let us compare the electrical resistivities of the complexes isolated here with those of the alkali-metal-TCNQ–crown ether complexes. In the case of the alkali-metal cation complexes, simple salts and complex salts had resistivities of the order of 10^8—10^{14} Ω cm and 10^3—10^4 Ω cm, respectively, On the other hand, in the case of the alkaline-earth metal cation complexes, simple salts and complex salts had resistivities of the order of 10^5—10^{10} Ω cm and 10^0—10^3 Ω cm, respectively. Thus, the alkaline-earth metal cation complexes are much more conductive than the alkali-metal cation complexes both in the simple and complex salts, which is in line with our expectation.

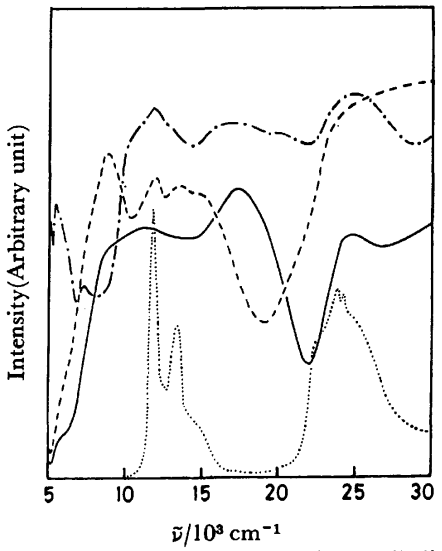

Fig. 3. Diffuse reflection spectra of the alkaline-earth metal cation–TCNQ–crown ether complexes.
——: $Ca^{2+}(TCNQ^-)_2(12Cr4)_2$, ------: $Ba^{2+}(TCNQ^-)_2$-$(15Cr5)_2$, —·—: $Ca^{2+}(TCNQ^-)_2TCNQ(12Cr4)_2$, ……: K^+TCNQ^- in acetonitrile solution.

Electronic Diffuse Reflection Spectra. Electronic diffuse reflection spectra of the complexes were measured at room temperature.[10] Figure 3 shows the spectra of $Ca^{2+}(TCNQ^-)_2(12Cr4)_2$, $Ba^{2+}(TCNQ^-)_2(15Cr5)_2$, and $Ca^{2+}(TCNQ^-)_2$ $TCNQ(12Cr4)_2$ as typical examples. This figure also shows the absorption spectra of K^+-$TCNQ^-$ in acetonitrile solution for the sake of comparison.

All the violet complexes showed two broad absorption peaks at less than 20×10^3 cm^{-1}, like $Ca^{2+}(TCNQ^-)_2$-$(12Cr4)_2$. Although the crystallographic study and polarized absorption measurements are needed for the

assignments of these absorption bands, the most probable assignment of the lowest energy band is the charge-transfer (CT) transition between TCNQ anion radicals, and that of the next band is the local excitation band within $TCNQ^-$.[11] Thus, a TCNQ dimer structure is suggested from the spectra. On the other hand, all the green complexes have the characteristic profiles at 8—15×10^3 cm^{-1} like $Ba^{2+}(TCNQ^-)_2(15Cr5)_2$. In view of the similarity of the spectrum of the green complex to that of K^+TCNQ^- in solution, one possibility is that the $TCNQ^-$ is isolated in the crystal.[12] All the complex salts gave almost the same reflection spectra as $Ca^{2+}(TCNQ^-)_2TCNQ(12Cr4)_2$. The absorption band at less than 7×10^3 cm^{-1} is ascribed to the CT transition from TCNQ anion radical to neutral TCNQ. Table 2 shows the absorption peak positions of the isolated simple and complex salts. Some relation exists between the colors of the simple salts and their resistivities: violet complexes were more conductive than the green ones in the simple salts. If $TCNQ^-$ is isolated in the green complex as discussed above, its poor conductivity can be explained by the small overlap of the π-electron could between adjacent TCNQ molecules.

We are grateful to Miss Junko Maenaka, Mr. Kazuaki Muneishi, and Miss Yuriko Sako, Faculty of Engineering, Osaka University, for the elemental analyses.

12) The reflection spectrum of the green complex may be due to the isolated $TCNQ^-$ in the crystal, shifted about 3×10^3 cm^{-1} to the lower energy side by the crystal field. Another possibility is that the band at 8.85×10^3 cm^{-1} is the CT transition between $TCNQ^-$ molecules and that the bands at 10—15×10^3 cm^{-1} correspond to the isolated $TCNQ^-$.

Dual Fluorescence of Pyrazine Cooled in a Supersonic Free Jet

Naohiko MIKAMI,* Hisao IGARASHI, Koji KAYA,† and Mitsuo ITO
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received May 7, 1981)

The fluorescence excitation spectrum of the lowest excited $^1B_{3u}(n\,\pi^*)$ state of pyrazine cooled in a pulsed supersonic free jet was observed. The fluorescence decay of the isolated molecule was also measured in the free jet. The rotationally cooled pyrazine in the collision free condition exhibits extremely large fluorescence quantum yield and dominant slow fluorescence component for low lying vibronic levels. The ratio of the pre-exponential factors of the dual fluorescence decay was examined in terms of the available theory of singlet-triplet mixed state model. It was found that the number of coupled triplet levels obtained from the observed ratio is inconsistent with the calculated excess energy dependence of vibronic density in the triplet state. Remarkable rotational level dependence of the ratio of the pre-exponential factors was observed for the electronic origin, while such a rotational dependence was not found for the lifetime of the slow fluorescence.

The fluorescence decay of low pressure diazabenzene vapor such as pyrazine and pyrimidine is known to be bi-exponential, being composed of a pressure-independent fast decay and of a pressure-sensitive slow one.[1,2] The bi-exponential decay has been explained by a mixed state model proposed by Lahmani *et al.*[3] According to this model, the number of triplet levels coupled to a singlet level plays an important role in decay constant of the slow fluorescence component as well as in the fluorescence quantum yield ratio of the slow and fast components. The experimental results of vibronic energy dependence of the lifetimes and the yield ratio have been found to be in accordance with the prediction based on the model.[1,2] Recently, Baba *et al.*[4] have reported the rotational state dependence of the fluorescence quantum yields for low pressure pyrazine and pyrimidine vapor. The rotational dependence on the nonradiative rate has also been discussed theoretically.[5,6] These studies suggest that critical test of the model should be made for an isolated molecule excited to a particular ro-vibronic state. However, the experimental study under such a critical condition is quite difficult for room temperature vapor of large molecule because of spectral congestion of many rotational levels. Recently, it was shown by many workers[7-11] that the isolated molecule at very low rotational temperature is easily prepared by a supersonic free expansion of the molecule seeded in inert carrier gas. Combining the supersonic free expansion with a narrow band tunable laser, one can study dynamical behaviour of the excited molecule confined in a few ro-vironic level.

In the present study we observed the fluorescence excitation spectrum of the first singlet state of pyrazine ($^1B_{3u}$) in a supersonic free jet seeded in He carrier gas. It was found that the fluorescence quantum yield of the isolated molecule in the jet is extremely large for low-lying vibronic levels compared with the vapor value obtained by extrapolation to zero pressure. The observed lifetimes and the ratio of the pre-exponential factors of a bi-exponential decay were examined in terms of the mixed state model. A remarkable rotational state dependence of the fluorescence decay, which has been observed very recently by ter Horst *et al.*[12] was also found in the present work.

Experimental

Pulsed supersonic free jets of pyrazine seeded in He gas as a carrier were generated by a pulsed supersonic nozzle described in a previous paper.[13] Visible dye laser pumped by a frequency doubled YAG laser (Quanta-Ray), which is synchronized with the pulsed nozzle, was converted to tunable UV light by a SHG crystal (RDP or ADA), phase matching angle of the crystal being controlled by a microcomputer. Cresyle violet+rhodamine B in ethanol solution (650—635 nm) and rhodamine 640 in ethanol solution (640—610 nm) were used. Spectral resolution of the dye laser was about 0.4 and 1.5 cm^{-1} with and without an etalon, respectively. The supersonic free jet was irradiated by the UV light at 15 mm downstream from the nozzle and the fluorescence was observed from the direction perpendicular to the light beam and to the jet stream. By use of several light baffles, scattered light was reduced to the level not to be detected even at a maximum sensitivity of our detection system. The fluorescence was collected by a lens system ($f=2$) and the image of the fluorescent region in the jet was made on a field lens. Unwanted emission from the shock boundaries in the jet was removed by an adjustable mask which was inserted in front of the field lens, and the fluorescence from isentropic core of the jet was focussed on a photomultiplier (Hamamatsu R562) by a lens.

For the measurement of the fluorescence excitation spectrum, the total fluorescence was detected by the photomultiplier combined with a preamplifier (PAR #115) and a boxcar integrator (Brookdeal 9415) with 1.5 μs gate width. The fluorescence intensity was recorded on a strip chart recorder as a function of the exciting wavelength. For lifetime measurement, a sampling oscilloscope (Tektronix 564B) was used instead of the boxcar integrator. In order to ensure the temporal response of the photomultiplier, a high breeder current (≈10 mA) and a 50 Ω load resistance were used; time resolution was not more than 18 ns. In the case of the lifetime measurement, a solid etalon was inserted in the dye laser cavity to improve the spectral resolution for the excitation. The fluorescence spectra were taken by a monochomater (Nikon P-250) and a photon counting system (Ortec #9302, #9315, and #9325) in a gated mode with 3 μs gate width.

Fluorescence quantum yield of pyrazine in the supersonic jet was estimated by comparing the intensity of fluorescence of the 0-0 band excitation with the corresponding intensity of aniline in the jet. Assuming that the fluorescence quantum

† Present address: Department of Chemistry, Faculty of Science and Engineering, Keio Univeristy, Hiyoshi-machi, Kohoku-ku, Yokohama 223.

yield of aniline in the jet is the same as that in vapor at room temperature[14] and taking into account of differences of saturated vapor pressures and integrated absorption coefficients of pyrazine and aniline, the ratio of the fluorescence intensities of two molecules in the jet can be converted into a relative quantum yield of pyrazine with respect to that of aniline.

Results and Discussion

Quantum Yield Spectrum. The fluorescence excitation spectrum of the first excited $^1B_{3u}$ state of pyrazine in a supersonic free jet of helium carrier gas at 4 atm is shown in Fig. 1, together with the room temperature absorption spectrum of pyrazine vapor. The assignments of the vibronic bands were taken from Ref. 15. The band width (FWHM) of the 0-0 band in the supersonic jet was about 4 cm^{-1}, from which the rotational temperature of the molecule was estimated to be less than 5 K.

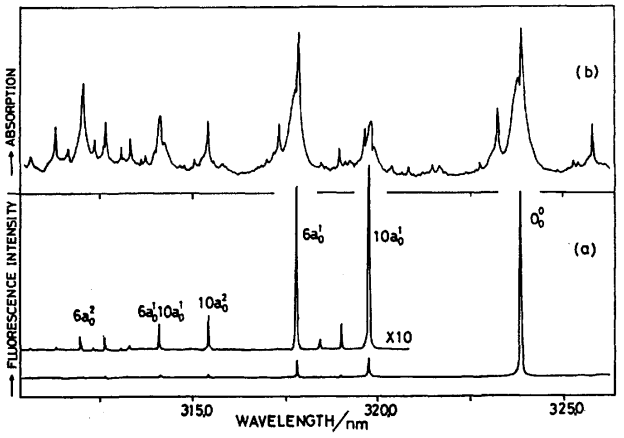

Fig. 1. (a) The excitation spectrum of pyrazine in a supersonic free jet. Saturated vapor of pyrazine at room temperature was seeded in 4 atm He carrier gas. (b) Absorption spectrum in vapor at room temperature.

As is seen from Fig. 1, the excitation spectrum in the free jet shows a rapid decrease of the band intensity with increase of the excess vibrational energy. For example, the 0-0 band is about ten times stronger than that of the $6a^1$ band, while they are comparable in the vapor spectrum. The remarkable difference between the excitation spectrum and the absorption spectrum must be ascribed to a great excitation energy dependence of the fluorescence quantum yield. Although the absorption spectrum of the supersonic jet is not available, it is reasonable to assume that integrated absorption intensities of the individual cold bands in vapor spectrum are proportional to those of the free jet. Since the main cold bands are well isolated in the vapor spectrum, the estimation of their relative integrated intensities should be made with a good accuracy. Using the fluorescence quantum yield of the zero point level obtained by the procedure described in the previous section, we have a quantum yield spectrum of the free jet, which is shown in Fig. 2. The quantum yields of the main vibronic levels are also listed in Table 1.

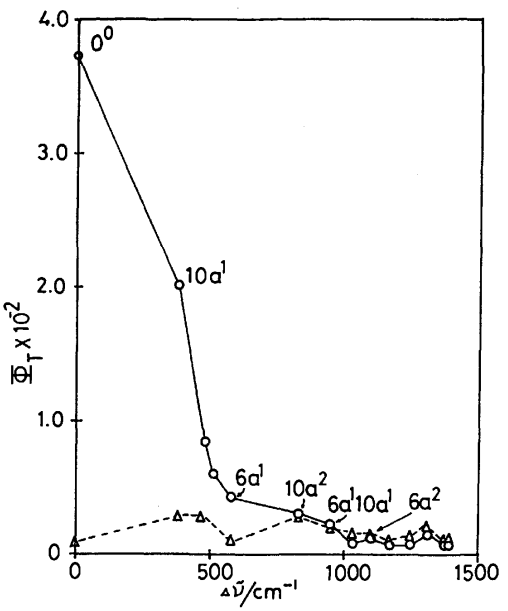

Fig. 2. Fluorescence quantum yield spectrum of pyrazine in a supersonic free jet (—○—). $\Delta\tilde{\nu}$ indicates the energy difference from the electronic origin. For comparison the quantum yield spectrum of 13.3 Pa pyrazine vapor with 2400 Pa isopentane is shown (---△---).

Table 1. Observed quantum yield and lifetime of pyrazine

Level	$\tilde{\nu}/cm^{-1}$	Φ_T[a] $\times 10^2$	τ_2[b]/ns	τ_1[c]/ps	c_1/c_2[d]
0^0	30876	3.7	455±10	130	<3
$10a^1$	31259	2 0	264±10	125	10
$6a^1$	31459	0.49	255±10	100	43
$10a^2$	31709	0.35	170±15	120	210
$6a^1 10a^1$	31821	0.29	180±15	120	240
$6a^2$	32043	0.11	200±20	95	739

a) Quantum yields of the total fluorescence in supersonic free jet. b) Lifetime of the slow fluorescence in supersonic free jet. c) Lifetime of the fast fluorescence in vapor, taken from Ref. 17. d) Ratio of the pre-exponential factors.

The quantum yield of the zero point level is 0.037, which is one order of magnitude larger than the vapor value (3×10^{-3} at 1.33 Pa in vapor phase) obtained by Frad *et al.*[1] The quantum yield of the free jet rapidly decreases with the excess vibrational energy as seen from Fig. 2 and Table 1. In Fig. 2, the quantum yield spectrum for 13.3 Pa pyrazine vapor in 2400 Pa isopentane is shown for comparison. In contrast to the case of the supersonic jet, the quantum yield is very small (1×10^{-3}) and almost constant over the excess energy region measured, although an appreciable variation is seen at the $10a^1$ level and its combinations.

Fluorescence Decay from the Vibronic Level. In our experimental condition of the supersonic free jet, translational temperature is estimated to be 0.5 K and mean collisional time will be greater than 10 μs which is the value for the hard sphere collision with helium atom. Therefore, the fluorescence which decays within

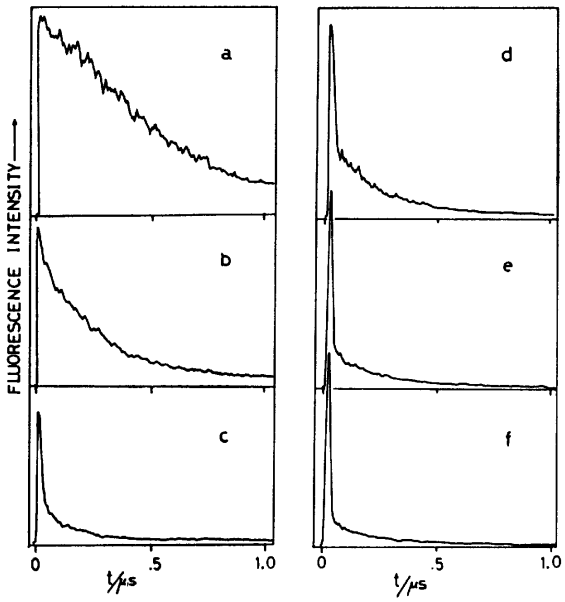

Fig. 3. Oscillogram traces of the fluorescence decay from (a) the electronic origin, (b) $6a^1$ and (c) $6a^2$ of the ultracold pyrazine seeded in 4 atm He gas. Corresponding traces of pyrazine vapor of about 6.65 Pa at room temperature are shown in (d), (e), and (f), respectively.

a time scale less than 10 μs can be regarded as being in a collision free condition.

Oscillogram traces of the fluorescence decay of the jet from several vibronic levels are shown in Fig. 3. The decay from the zero point level was approximately single exponential with lifetime of 455 ± 10 ns (see Fig. 3(a)). On going to the higher vibronic levels, the fast fluorescence component gradually shows up and increases with the excess energy from the zero point level. At a large excess energy the fast component dominates over the slow component (see Fig. 3(c)). The lifetime of the slow component decreases with increase of the excess energy and at $6a^2$ level (excess energy of 1168 cm^{-1}) it reduces to a half of the value for the zero point level (see Table 1). On the other hand, in the case of low pressure pyrazine vapor the fluorescence decay is already bi-exponential even for the zero point level as shown in Fig. 3(d). The lifetime of the slow fluorescence in vapor is about 200 ns which is shorter than the value of the jet. The different fluorescence decays between the jet and the low pressure vapor indicate that the slow fluorescence is extremely sensitive to the collisional quenching[16] which still exists in the case of vapor even at extremely low pressure regarded as collision free condition. The lifetime of the slow decay component in the free jet is summarized in Table 1.

Since our detection system is not fast enough to resolve the fast fluorescence decay, the oscillogram traces shown in Fig. 3 do not represent the real decay. Assuming a bi-exponential decay, the fluorescence intensity is given by

$$I_F(t)=I_1(t)+I_2(t)=c_1e^{-t/\tau_1}+c_2e^{-t/\tau_2}, \qquad (1)$$

where 1 and 2 refer to the fast and slow components. c_2 can be easily obtained by extrapolating the observed $I_2(t)$ into $t=0$. The difference between the oscillogram peak height at $t=0$ and the c_2 obtained is defined as A_1. Since τ_1 is known to be shorter than 10^{-9} s, the A_1 value obtained directly from the oscillogram trace is not necessarily equal to c_1. By taking a half width δ of the fast component displayed on the oscillogram trace, the integrated intensity of $I_1(t)$ will be approximately given by $A_1\delta$. On the other hand, the integrated intensity of $I_1(t)$ over a time scale greater than τ_1 can be expressed by

$$\int_0^T I_1(t)\,dt=c_1\tau_1, \qquad T\gg\tau_1. \qquad (2)$$

We have, therefore,

$$c_1=\frac{\delta}{\tau_1}\times A_1. \qquad (3)$$

δ was found to be 18 ns from a temporal resolution of our detection system. The lifetime τ_1 of the fast component reported by McDonald and Rice[17] is shown in Table 1. Since no pressure dependence of the fast decay component is observed, it is reasonable to assume that the lifetime of the fast fluorescence of the supersonic jet is the same as that of vapor. The estimated ratios†† c_1/c_2 for the individual vibronic bands are shown in the last column of Table 1.

Rotational Level Dependence of the Fluorescence Decay. The rotational level dependence of the fluorescence quantum yield has been recently reported by Baba *et al.*[4] for the zero point level of pyrazine. In order to examine the rotational level dependence, we measured the fluorescence decay from various rotational levels of the zero point vibrational level. The measurements

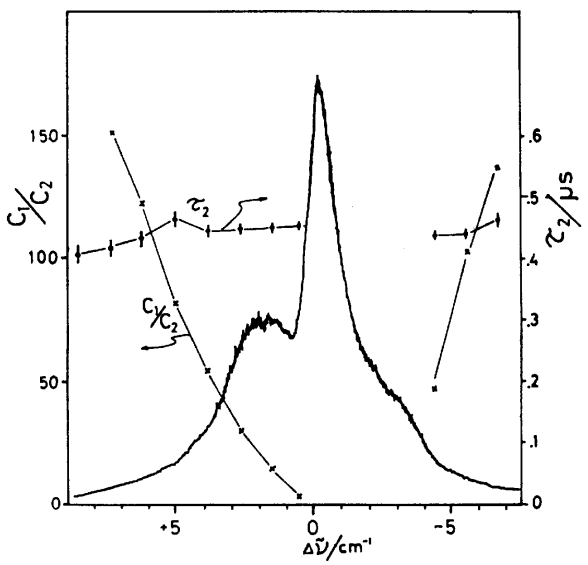

Fig. 4. Excitation spectrum of the electronic origin of pyrazine seeded in 0.05 atm He carrier gas. Lifetime τ_2 of the slow fluorescence decay (ϕ) and ratio of the pre-exponential factors c_1/c_2 ($\times$) are shown superimposedon the excitation spectrum.

†† The vapor value for $6a^1$ band at 31459 cm^{-1} (see Fig. 3(e)) was found to be about 700, which agrees with the value (10^3) obtained by Frad *et al.*[1] with the excitation at 31680 cm^{-1}.

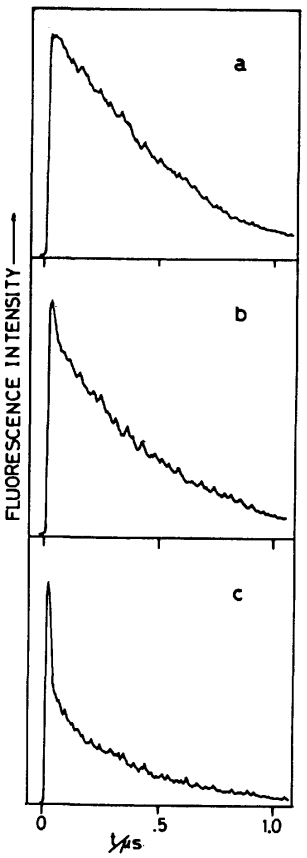

Fig. 5. Rotational dependence of the fluorescence decay from the electronic origin by the excitation of (a) $J'=\approx 1$, (b) $J'=6$—7, and (c) $J'=14$—15.

were made for the supersonic jet with a reduced stagnation pressure of helium gas. In the reduced He pressure, the rotational temperature becomes higher, so that the relatively high rotational levels can also be excited. Excitation spectrum of the 0-0 band under a stagnation pressure less than 0.05 atm of He is actually broad with a rotational envelope as shown in Fig. 4. Rotational temperature was estimated to be higher than 40 K. When the peak at 30876 cm^{-1}, which is the Q-branch head, is excited by narrow band UV light of FWHM of 0.4 cm^{-1}, a single exponential decay was obtained whose decay constant is the same as that of the jet at a high stagnation pressure (compare Fig. 5(a) and Fig. 3(a)). Tuning the pumping light to the higher energy side (R-branch) of the rotational envelope, a fast component appears prior to the slow component and the ratio of the fast to slow component increases at the far edge of the R-branch. Similar decay was observed also for the P-branch. The typical oscillogram traces are shown in Fig. 5. The results are essentially the same as those reported very recently by ter Harst *et al.*[12]

The observed lifetime of the slow fluorescence component and the ratio of the pre-exponential factors of the fast and slow components (c_1/c_2) are given in Table 2. Since the R-branch is well separated from the Q-branch, rotational quantum number J' in the excited state can be roughly assigned for the R-branch with reference to the high resolution vapor spectrum obtained by Merritt and Innes.[18] Although the onset

of the P-branch is congested by overlapping with the Q-branch, the rotational quantum number can be also estimated for the far edge of the P-branch. The estimated J' value are given in Table 2. It is seen from Fig. 4 and Table 2 that the lifetime is almost constant for different J' values, whereas the ratio c_1/c_2 greatly increases with increase of J' value.

For the other vibronic bands such as $10a_0^1$ and $6a_0^1$, the detailed lifetime measurements over their rotational structure were not successful because of their small fluorescence quantum yields. However, we could observe increase of the fast component with increase of the rotational temperature of the jet in the broad band (≈1.5 cm^{-1} FWHM) excitation at the peak positions of these vibronic bands. This result may be interpreted as follows. At the low rotational temperature the fluorescence by the broad band excitation arises mainly from a few number of rotational levels with very low J' where the c_1/c_2 is small. With increase of the rotational temperature, the fluorescence from the higher rotational levels becomes dominant, resulting in large c_1/c_2. Thus, the rotational level dependence of these vibronic bands is concluded to be essentially the same as that of the 0-0 band. According to Baba *et al.*,[4] the change of the fluorescence quantum yield over the rotational levels of the zero point level is ascribed to change of the slow fluorescence component. Their results of the high quantum yield for the low rotational levels are, therefore, consistent with our result of dominant slow component for the low rotational levels.

Fluorescence Spectrum. In order to ensure that the slow decay component is actually the fluorescence of pyrazine, we observed the spectrum of the slow decay component in the supersonic free jet. Figure 6 shows the spectrum obtained by excitation at the head of the Q-branch of the 0-0 transition. As seen from Fig. 5(a), only the slow decay component is observed in this excitation. For comparison, the ordinary SVL fluorescence spectrum in vapor at 400 Pa of pyrazine,[15]

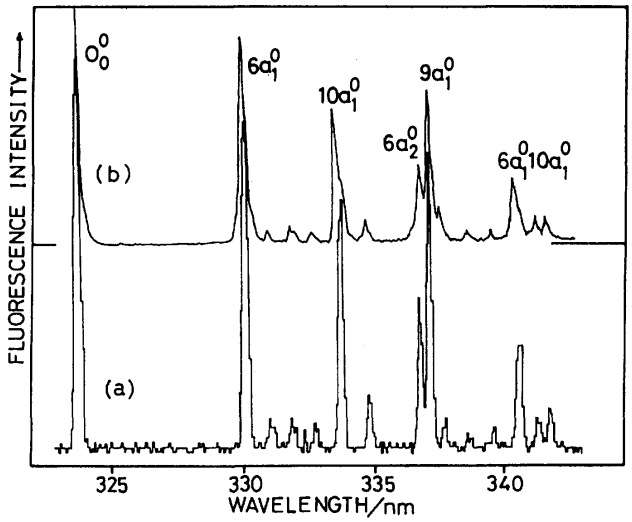

Fig. 6. (a) Fluorescence spectrum of the ultracold pyrazine in a supersonic free jet, being excited at the electronic origin. The slow fluorescence was monitored. (b) Fluorescence spectrum of 400 Pa pyrazine vapor at room temperature. The fast fluorescence was monitored.

which represents practically only the fast component, is shown in the same figure. As seen from the figure, the two spectra are idential with respect to the frequencies and relative intensities of the vibronic bands. Therefore, it is concluded that the slow decay component is really the fluorescence of the molecule.

Coupled State Density and Fluorescence Lifetime. The bi-exponential decay of the fluorescence of pyrazine has been interpreted by the model of intermediate strong coupling, where a radiative singlet state strongly interacts with non- or weakly-radiative triplet levels with a relatively large level density.[3] Consider that a single vibronic state $|S>$ in the singlet manifold interacts with N triplet levels $|T>$ through a coupling strength v_{ST}. The $|S>$ and $|T>$ levels are assumed to have total energy width γ_S and γ_T, respectively, each of which is composed of radiative and nonradiative contributions. The coupling between the zero order $|S>$ and $|T>$ levels provides $(N+1)$ quasi-stationary molecular eigen states, whose energy levels are distributed within a spectral width Δ of the exciting light. In the case of coherent excitation of these eigen states by a pulsed light, the time evolution of the wavefunction of the molecule leads to dual fluorescence with fast and slow decay as the result of coherent and incoherent superpositions of the eigen states. In the intermediate case of $|\gamma_S-\gamma_T| \ll \Delta$, the overall fluorescence decay can be approximated by a bi-exponential type given by Eq. 1. The observables in Eq. 1 can be incorporated in the following ways,[1]

$$1/\tau_1 = \frac{\gamma_S}{N} + \gamma_T + \Delta_{ST}, \tag{4}$$

$$1/\tau_2 = \frac{\gamma_S}{N} + \gamma_T, \tag{5}$$

$$c_1/c_2 = N + 1. \tag{6}$$

Since the fast fluorescence is similar to that of the large molecule case, $1/\tau_1$ is dominated by the nonradiative width Δ_{ST} which is expressed in terms of coupling v_{ST} and the density of state ρ_T in the triplet manifold as far as $v_{ST}\rho_T \gg 1$ is held. Therefore, Eq. 4 can be replaced by

$$1/\tau_1 \simeq \Delta_{ST} = 2\pi\rho_T v_{ST}^2. \tag{7}$$

Thus, the number of interacting levels N is given by

$$N = \pi\Delta_{ST}\rho_T \approx \frac{c_1}{c_2} \quad \text{for } N \gg 1, \tag{8}$$

where Eq. 6 was used. From Eqs. 7 and 8, we obtain

$$\frac{c_1}{c_2} \times \tau_1 = \pi\rho_T. \tag{9}$$

Therefore, ρ_T can be obtained for the individual vibronic levels by using c_1/c_2 and τ_1 given in Table 1. ρ_T thus obtained are plotted in Fig. 7 against the excess energy from the origin of T_1.

In order to find any correlation between the ρ_T obtained and the density of state in the triplet state, we calculated the state density of the vibrational levels ρ_T^V in T_1. The calculation of ρ_T^V was made by the method given by Haarhoff[19] by assuming the same vibrational frequencies of T_1 state as those of S_0. The result is shown by curve (b) in Fig. 7. ρ_T^V was calculated also by assuming the vibrational frequencies of S_1 for those of T_1. The calculated result is shown by curve (a) of the same figure. Since the vibrational frequency change upon the excitation from S_0 to T_1 is generally less significant than the change in the excitation to S_1,[20] the curves (a) and (b) are regarded as the maximum and minimum vibronic state densities, respectively.

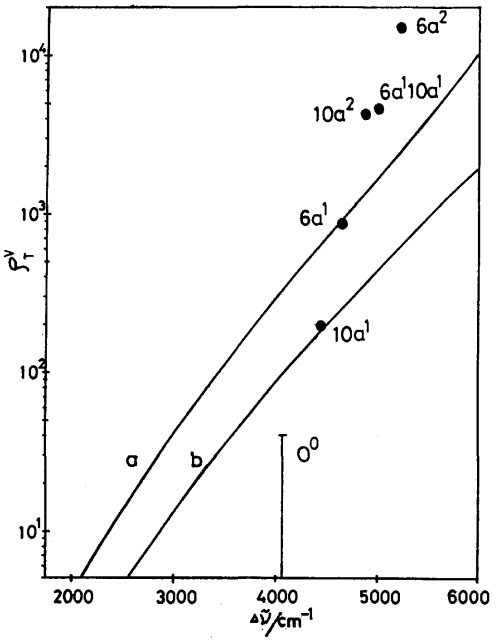

Fig. 7. The triplet state density ρ_T^V (number of levels/cm^{-1}) estimated from the N value at the vibronic levels (○) and the calculated vibronic state density ρ_T^V as a function of the excess energy $\Delta\tilde{\nu}$ from the electronic origin of the lowest triplet state. At the electronic origin 0^0 maximum value is indicated. The vibrational frequencies in the triplet state is assumed at that in the lowest excited siglet state (a) and in the ground state (b).

It is seen from Fig. 7 that the observed ρ_T value agrees with the calculated ρ_T^V for the excess energy region of around 4500 cm^{-1}. However, ρ_T is smaller than ρ_T^V for the smaller excess energy region and it is larger for the greater excess energy region. Increase of the observed ρ_T with increase of the excess energy is much rapid than expected from ρ_T^V. These facts suggest that the number of coupled triplet levles is not determined simply by the vibronic state of T_1. The disagreement between ρ_T and ρ_T^V for the larger excess energy region might be improved by taking into account of the rotational level density which is roughly two orders of magnitude larger than ρ_T^V. On the other hand, the fact that ρ_T for the lower energy region is much smaller than the calculated ρ_T^V suggests that there might be a sort of selection rule which selects the interacting levels from the vibronic or ro-vibronic levels of the triplet state.[5]

It is seen from Fig. 4 and Table 2 that the ratio c_1/c_2 exhibits a remarkable increase on going to higher J' value in the electronic origin, while the lifetime τ_2 is almost constant over the rotational quantum numberless than $J'=20$. From Eqs. 5 and 6, we have

$$\tau_2 = \frac{c_1/c_2}{\gamma_S + (c_1/c_2)\gamma_T}, \quad \text{for } N \gg 1. \tag{10}$$

A constant value of τ_2 irrespective of various values of c_1/c_2 means that τ_2 must be equal to the triplet lifetime $1/\gamma_T$. The triplet lifetime is reported to be the order of 10^{-5} s in vapor phase,[1] while $\tau_2 \simeq 450$ ns. Therefore, Eq. 10 is not supported from our experimental results. Since the change of the vibronic or ro-vibronic state density of the triplet state over a range of several wave number around the electronic origin must be very small, we expect no rotational level dependence of τ_2, as it is observed. However, the observed large rotational dependence of c_1/c_2 is hard to be explained with the mixed state model proposed by Lahmani *et al.*,[3] suggesting a need of revision of the model.

One of the author (N. M.) wishs to thank Daniel B. McDonald and Prof. S. A. Rice for providing their results. This work was suported by the Kurata Research Grant from the Kurata Foundation and by a Grant-in-Aid for Developmental Scientific Research from the Ministry of Education, Science and Culture.

(Received May 18, 1981)

The *p*-aminostyrene-*N*-vinylpyrrolidone copolymer-supported tris(2,2′-bipyridine)ruthenium(II) analogue, $[Ru(bpy)_2(pbyCOOH)]^{2+}$ (bpy=2,2′-bipyridine and pbyCOOH=polymeric bipyridine ligand), has been prepared, and the luminescence behavior of the polymer complex has been investigated in an aqueous solution. The efficiency of the quenching of the excited state of the polymer complex with $[Fe(CN)_6]^{4-}$, $[Co(phen)_3]^{2+}$, and Cu^{2+} is compared with that of $[Ru(bpy)_3]^{2+}$. The quenching of the excited state of the polymer complex by Cu^{2+} is strongly enhanced by the effect of the polymer chains. In the polymer complex/Cu^{2+} system, the quenching by Cu^{2+} in the presence of poly(*p*-styrenesulfonate) is much more effective than in the absence of the polyion. The characteristics of the polymer complex in terms of the luminescence behavior are discussed.

Recently much attention has been paid to the photochemical property of tris(2,2′-bipyridine)ruthenium(II), $[Ru(bpy)_3]^{2+}$, and the utilization of the excited state of $[Ru(bpy)_3]^{2+}$, $*[Ru(bpy)_3]^{2+}$, in solar-energy-conversion systems has been proposed by many workers.[1-6] The photochemistry of $[Ru(bpy)_3]^{2+}$ in micellar-core and polyelectrolyte solutions,[4] and those of $[Ru(bpy)_3]^{2+}$ derivatives in aqueous solutions[3,7,8] and the exterior aqueous phase of phospholipid vesicle[9] have been studied.

For the photosensitized reactions of $[Ru(bpy)_3]^{2+}$ and the related complexes, it would be desirable to immobilize them in polymer chains in order to prevent non-productive back reactions and in order to promote efficient energy capture by the reactive species.[10] The polymer-supported bis(2,2′-bipyridine)ruthenium(II) complexes, $[Ru(bpy)_2(pvp)]^{2+}$ and $[Ru(bpy)_2(pvp)Cl]^{+}$ (pvp=poly(4-vinylpyridine)), have been synthesized.[10] However, these complexes were easily decomposed by thermal and photo-substitution reactions. Polymer-supported metal complexes with bipyridine ligands were prepared by the reaction of a polystyrene-supported bipyridine ligand with a variety of transition-metal salts by Card and Neckers.[11]

In this connection, we marked a water-soluble $[Ru(bpy)_3]^{2+}$ analogue with a polymeric ligand as a polymer-bound photosensitizer.

Experimental

Materials. The $[Ru(bpy)_3]Cl_2\cdot 6H_2O$[12] and $[Ru(bpy)_2CO_3]5H_2O$[13] were prepared by the methods previously described. The *p*-aminostyrene was prepared from 1-(*p*-aminophenyl)ethanol.[14] The *p*-aminostyrene(PAS)/*N*-vinylpyrrolidone(VPo) copolymer (**1**) was prepared by the azobisisobuthyronitrile(AIBN)-initiated radical polymerization of PAS with VPo in tetrahydrofuran. Found: C, 67.30; H, 8.19; N, 12.41%. Calcd for $(C_8H_9N)_{0.14}(C_6H_9NO)_{0.86}$: C, 67.19; H, 8.02; N, 12.77%. IR spectra (in cm^{-1}): 3350 3230 (PAS, NH_2), 2930 (VPo ring, CH), 1630 1520 (PAS, ph ring), 1290 (VPo ring, CN). The intrinsic viscosity of the **1** copolymer in an aqueous solution was 0.37 at 25 °C. 2,2′-Bipyridine-4,4′-dicarboxylic acid, $bpy(COOH)_2$, was prepared by the method of Whitten *et al.*[15] The polymeric bipyridine ligand pbpCOOH, **2**, was prepared by the following method under a nitrogen atmosphere. To 50 ml of a *N*,*N*-dimethylformamide (DMF) solution containing $bpy(COOH)_2$ (2.0 g, 0.0082 mol) and triethylamine (0.83 g, 0.0082 mol), we added ethyl chloroformate (0.89 g, 0.0082 mol). The reaction mixturewas then stirred at 0—5 °C for 1 h. To the reaction mixture we then added 20 ml of a DMF solution of the **1** copolymer (0.32 g, 4.0×10^{-4} mol units of aminostyrene). The solution was stirred at 0—5 °C for 1 h and then kept overnight at room temperature. The volume of the reaction mixture was reduced to *ca.* 20 ml and the resulting precipitate was filtered. Pale yellow powder was dissolved in small amounts of ethanol. The powder of pbyCOOH was reprecipitated twice from ethanol into ether and dried in vacuo (yield, *ca.* 1.6 g). Found: C, 66.25; H, 7.08; N, 12.72%. Calcd for $(C_{20}H_{15}N_3O_3)_{0.14}(C_6H_9NO)_{0.86}$: C, 66.43; H, 6.89; N, 12.45%. IR spectra (in cm^{-1}): 2940 (VPo ring, CH), 1660 (VPo ring, CO), 1630, 1520 sh (PAS, ph ring), 1290 (VPo ring, CN), 1200 (pendant bpy ring). The results of elemental analysis and IR measurements indicate that no appreciable amounts of free amino groups remained on the polymeric ligand; the IR peak at 3350 cm^{-1} (νNH_2) of the PAS/VPo copolymer completely disappeared in the polymeric bipyridine ligand, **2**.

The polymer-supported Ru(II) complex (**3**), which is represented by $[Ru(bpy)_2(pbyCOOH)]^{2+}$, was obtained by the reaction of **2** with $[Ru(bpy)_2CO_3]$. An ethanolic solution (50 ml) of **2** (2.0 g, 0.0020 mol) and $[Ru(bpy)_2CO_3]5H_2O$ (1.13 g, 0.0020 mol) was allowed to reflux for 10 h. After the addition of several drops of 1 M HCl (1 M=1 mol dm^{-3}), the reaction mixture was dialized in cold water for 40 h under dark. The chloride salt of the polymer complex was obtained by the evaporation of the dialyzed solution under reduced pressure and dried in vacuo. The molar fraction of the Ru (II) complex unit (x) of **3** was determined to be 0.096 ± 0.005 by means of the atomic-absorption spectrum, using $[Ru(bpy)_3]Cl_2\cdot 6H_2O$ as the standard material. The dialized solution of the polymer complex was usually kept frozen.

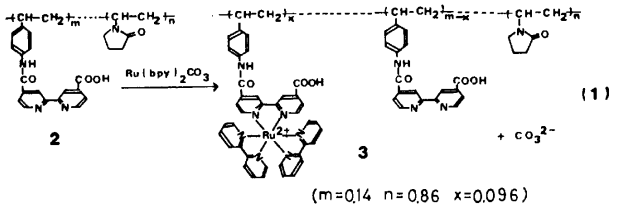
Luminescence and Quenching Experiments. Deoxygenated samples were used for the experiments. The pH values of the solution were adjusted by the addition of dil HCl or dil NaOH solutions. The ionic strength of the solutions was not adjusted to be constant by the addition of simple salt, since, if a large amount of the salt is added, the potential fields of the polymer domains are shielded with the counter ions. This causes a

shrinking of the polymer chains and, thus, a reduction of the polymer effect. The excitation wavelength was 465 nm. Comparison measurements were taken on the same day.

Instruments. The absorption spectra were recorded with a Hitachi 320 spectrophotometer. The infrared spectra (KBr disks) were measured using a Hitachi Model 200-10 infrared spectrophotometer. A Hitachi Model 170-40 atomic absorption spectrometer was used for the determination of ruthenium. The emission spectra were made in 1 cm × 1 cm quartz cell on a Shimadzu RF-500 spectrofluorometer at 25±0.1 °C by means of a thermostated cell holder. A PRA Model 3000 nanosecond fluorometer (Photochemical Research Associates, Inc.) was used for the determination of the excited lifetimes of the polymer complex.

Results and Discussion

The reaction of pbyCOOH with $[Ru(bpy)]_2CO_3$ (Eq. 1) was completed in about 10 h at 50 °C: the initial



(1)

absorption maximum at *ca.* 500 nm due to $[Ru(bpy)_2CO_3]$ shifted at *ca.* 460 nm due to the ligand-substitution reaction. The absorption and emission spectra of an aqueous solution of **3** and $[Ru(bpy)_3]^{2+}$ are shown in Fig. 1. In an aqueous solution, the molar extinction coefficients of the polymer complex and $[Ru(bpy)_3]^{2+}$ at their absorption maxima are 1.48±0.05 M^{-1} (459 nm) and 1.40±0.02 M^{-1} (455 nm) respectively. No appreciable change in the absorption spectrum of the polymer complex was observed for at least 3 d at room temperature.

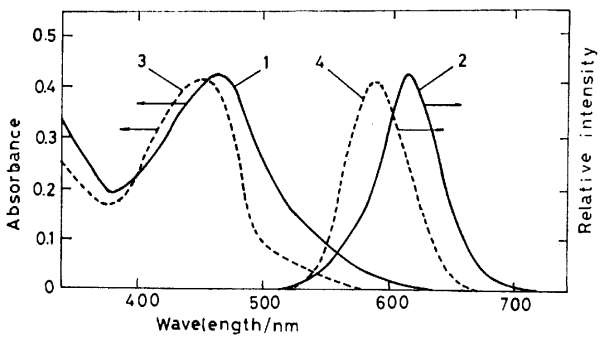


Fig. 1. Absorption and luminescence spectra of $[Ru(bpy)_2(pbyCOOH)]^{2+}$ (1 and 2) and $[Ru(bpy)_3]^{2+}$ (3 and 4) in aqueous solution at 25 °C. [Ru(II)]= 3.0×10^{-5} M.

The absorption maximum of the CTTL band of the polymer complex was dependent on the pH of the solution, whereas the molar extinction coefficient of the absorption maximum was relatively insensitive to the pH. The relative emission intensity was, however, greatly dependent on the pH, and the luminesecence

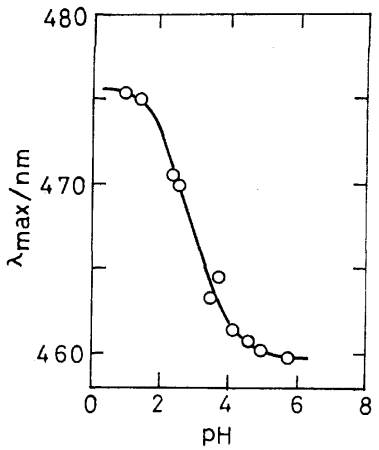

Fig. 2. Dependence of λ_{max} of $[Ru(bpy)_2(pbyCOOH)^{2+}]$ on pH at 25 °C.

maximum was not so sensitive to the pH. The pH dependence of the absorption maximum (Fig. 2) can be attributed to the acid dissociation of the -COOH on the bipyridine ring. The acid-dissociation constant of the ground state of the polymer complex, pK_a^0, was estimated to be 2.80±0.05 from the titration curve (Fig. 2).

The direct measurement of the excited-state equilibrium for $[Ru(bpy)_2(pby(COOH)_2)]^{2+}$, where bpy-$(COOH)_2$ is 2,2'-bipyridine-4,4'-dicarboxylic acid, had been accomplished by Giordano *et al.*[16] by means of luminescence titration. They demonstrated that the two acid groups of the complex behave identically and that the acid-dissociation constant of the ground state and that of the excited state were 5.50±0.05 and 8.50±0.05 respectively at 25 °C. In the present system, the pK_a^* of the polymer complex was also calculated from Eq. 2.[16]

$$pH = pK_a^* - \log\frac{\tau_p^*}{\tau_d^*}, \quad (2)$$

where the pH was taken at the inflection point in the relative intensity *vs.* the pH curve (Fig. 4) and where τ_p^* and τ_d^* are the lifetimes of the excited state of the protonated and deprotonated species of the polymer complex respectively. The effect of the pH on the luminescence spectrum and the luminescence titration curve of the polymer complex are shown in Fig. 3 and 4 respectively. For the polymer complex, the values of τ_p^* and τ_d^* were estimated to be 287 ± 0.01 ns (pH 1.4) and 359 ± 0.02 ns (pH 6.0) at 25 °C. From Eq. 4, we obtained $pK_a^*=4.30\pm0.05$. The results show that the protonated complex species is a weaker acid in the lowest excited state than in the ground state. This seems to indicate that the charge transfer from the central Ru(II) ion to the polymer ligand (Process a) is predominant.

a) The excited-state lifetimes used for the calculations of the k_q values were 290 ns for $[Ru(pby)_2(pbyCOOH)]^{2+}$, 360 ns for $[Ru(bpy)_2(pbyCOO)]^+$, and 600 ns for $[Ru(bpy)_3]^{2+}$[b] at 25 °C. b) Ref. 18. c) The errors of the Stern-Volmer constants and k_q are within $\pm5\%$. d) pH 1.4. e) pH 6.2. f) 2.8×10^{-5} M Ru(II) and 1.0×10^{-3} M PSS.

Ru(II) complex moieties on the polymer chains because the polymer domians have a large positive-charge density.

It is noteworthy that the k_q for the reaction of the deprotonated from of the polymer complex with Cu^{2+} is considerably greater than those of $[Ru(bpy)_2(pbyCOOH)]^{2+}$ and $[Ru(bpy)_3]^{2+}$ (Fig. 6 and Table 1). The higher reactivity of $[Ru(bpy)_2(pbyCOO)]^+$ with Cu^{2+} can be partly explained in terms of the "effect of the uncoordinated ligand" on the polymer chains. In the case of the polymer complex, uncoordinated bipyridine rings exist with the mole fraction of 0.044 and a part of Cu^{2+} ions probably coordinate to the uncoordinated ligands. Therefore, a hydrid metal complex with Ru(II) and Cu^{2+} is probably formed. The excited state of the Ru(II) complex on the polymer chains probably reacts rapidly with the coordinated Cu^{2+}, which can be represented by $[Cu(pbyCOO)]^+$. In the lower pH region. the uncoordinated bipyridine would be protonated; for example, the pK of HL^+ of 4,4'-bipyridine is 4.44 at 25 °C.[19] Thus, the hybrid-metal complex should not be formed in the lower pH region. This mainly accounts for the greater k_q value in $[Ru(bpy)_2(pbyCOO])^+/Cu^{2+}$ than in $[Ru(bpy)_2(pbyCOOH)]^{2+}/Cu^{2+}$. In the higher-pH region, the interactions between carboxylate ions and amide groups on the polymer ligand and Cu^{2+} ions should also be considered. However, the details of these interactions have not yet been made clear.

On the addition of sodium poly(*p*-styrenesulfonate), PSS, to $[Ru(bpy)_2(pbyCOO)]^+/Cu^{2+}$, a further enhancement of the quenching rate was observed; the value of k_q in the presence of 1.0×10^{-3} M PSS is about ten times greater than that in the absence of PSS and about 150 times greater than k_q for the reaction of $*[Ru(bpy)_3]^{2+}$ with Cu^{2+}. The acceleration of the quenching rate in this system can be attributed to the formation of the polyion-polyion complex between PSS and $[Ru(bpy)_2(pbyCOOH)]^+$. When a large excess of PSS is present, the domains of the polyion-polyion complex should have a large negative charge density. Thus, the Cu^{2+} ions would be accumulated in the negatively charged domains. In such polyion domains, the collision frequencies between the excited state of the Ru(II)-complex moieties and the coordinated Cu^{2+} and uncoordinated Cu^{2+} should be enhanced.

We would like to thank Professor Kunihiko Mizumachi for many helpful suggestions. We are also indebted to Mr. Hiroshi Yokota and Mr. Kiyomi Takato for their assistance with some of the quenching studies and Mr. Yoshihiro Yamaguchi for the measurements of the lifetimes at the Daini Seikoshya Co.

Infrared Intensities of Bending Fundamentals in Gaseous HCCCN and DCCCN

Masakatsu UYEMURA,* Shuji DEGUCHI,† Yoshikazu NAKADA,† and Takashi ONAKA†

Department of Industrial Chemistry, Faculty of Engineering, Tokyo Institute of Polytechnics, Atsugi, Kanagawa 243-02

†*Department of Astronomy, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received May 21, 1981)

The infrared spectra of three bending fundamentals (ν_5, ν_6, and ν_7) of gaseous cyanoacetylene and cyanoacetylene-*d* have been measured and their integrated absorption coefficients $A(\nu_i)$ have been determined. The spectral pattern of ν_5 fundamental region in HCCCN has been interpreted by assuming the Fermi resonance between $v_5=1$ and $v_7=3$ states. On the basis of the experimental intensity data and the normal coordinate treatment, the dipole-moment derivatives with respect to the internal bending coordinates have been calculated.

Many spectral data of cyanoacetylene have been obtained from several astronomical sources, and many microwave studies have been reported.[1] Lafferty and Lovas reviewed them to obtain information applicable to radio astronomy.[2] Several infrared studies have been reported since Turrell *et al.*'s first work of HCCCN in gaseous, liquid, and crystalline states. Job and King studied the infrared spectra of gaseous HCCCN and DCCCN; they also studied the Raman spectra of liquids. The infrared, far-infrared, and Raman spectra of crystalline HCCCN and DCCCN were reported by Nolin *et al.*[3] One of the present authors studied the infrared intensities of the stretching fundamentals in gaseous and crystalline states with special interest in the intensity changes caused by the hydrogen-bond formation.[4] Recently, Mallinson and Fayt measured the high-resolution spectra of HCCCN and DCCCN in the region of 1800—6500 cm^{-1}, in order to determine the accurate band centers for all seven fundamentals and the rotational constants for three stretching fundamentals, which had not been available from microwave studies.[5] Their spectrometer, however, was uanable to cover the lower frequency region where the three bending fundamentals lie. The present study was undertaken to measure the infrared intensities of the three bending fundamentals of gaseous HCCCN and DCCCN, and thereby to obtain the information concerning the dipole-moment changes due to molecular bending motions.

Experimental

HCCCN was kindly supplied from Takeda Chemical Industries. The methods of purification and deuteration were described previously.[4]

The deuterium content in DCCCN determined from the band intensity of resudual HCCCN, was found to be 98%. Spectra of ν_5 and ν_6 fundamentals were obtained using a Perkin-Elmer model 125 spectrometer with a 5 cm path-length cell, and those of ν_7 were obtained using a Hitachi model FIS-21 single beam far-infrared spectrometer with a 10 cm path-length cell equipped with polyethylene windows. The spectral resolution of the spectrometers were from 1.1 cm^{-1} to 1.6 cm^{-1} in the ν_5 and ν_6 band regions and about 0.6 cm^{-1} in the ν_7 band region. In the measurements of ν_5 and ν_6 bands, the sample gas was first admitted to the cell, then Helium gas was added to fill it; the total pressure was about 7×10^4 Pa. The integrated absorption coefficients:

$$B(\nu_i) = \int_{\text{band}} \ln(T_0/T)\mathrm{d}\tilde{\nu} \qquad (1)$$

were obtained and plotted against to the sample pressure p at 273 K. In the case of ν_7, the spectra were recorded first with an empty cell, and then with a cell containing the sample gas; the transmittances were calculated point by point. In these measurements, the changes of recording conditions would appreciably affect the apparent spectra, so that relatively large errors would be expected to accumulate in $B(\nu_7)$ if the integration were carried out over the entire band region. Therefore, the integratation was carried out over the Q-branch region and then this value was used to obtain the integrated molar absorption coefficient $A(\nu_7)$, as described later.

Results and Discussions

Observed frequencies of the bending fundamentals, their combinations and overtones are given in Table 1, together with those reported previously.[3,5] In the ν_5 and ν_6 band regions of HCCCN and DCCCN, two sharp and strong bands were observed, accompanied by some sub-bands. The former were assigned to the Q-branch of $v_5=1\leftarrow0$ and $v_6=1\leftarrow0$ transitions. Most of the latter may be assigned to hot bands, on the basis of their intensities relative to the fundamentals and their small frequency shifts from the $v_i=1\leftarrow0$ transitions, because the bending fundamental frequencies are relatively low in these molecules. In the ν_5 band region of HCCCN, the band at 663.7 cm^{-1} was assigned to the $v_5=1\leftarrow0$ transitions, as shown above. The situation here is, however, somewhat different in that the sub-bands shift considerably from the $v_5=1\leftarrow0$ transition and the intensity of the band at 669.8 cm^{-1} seems to be appreciably larger than that expected from a hot band (Fig. 1). In order to determine the spectral origin of these sub-bands, the spectra were recorded at different temperatures. As the temperature was changed from 51 °C to −17 °C, the bands at 649.8 cm^{-1} and 676.9 cm^{-1} showed an appreciable intensity decrease, whereas the band at 669.8 cm^{-1} did not show such a change. This observation suggests that the bands at 649.8 cm^{-1} and 676.9 cm^{-1} may be attributed to hot bands, but the band at 669.8 cm^{-1} may not. At this point, it may be noted that the ν_7 fundamental lies at 222.4 cm^{-1}, and hence the $3\nu_7$ band is expected near the ν_5 fundamental. Incidentally, in the $2\nu_5$ band region, two bands were observed at 1313.1 cm^{-1} and 1340 cm^{-1}; the former is of the parallel type and is much stronger than the letter. These two bands can be assigned to $2\nu_5$ and $\nu_5+3\nu_7$ respectively, if a resonance

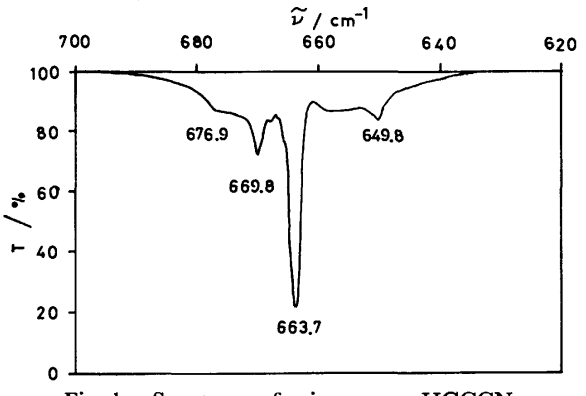

Fig. 1. Spectrum of ν_5 in gaseous HCCCN.

interaction is assumed between $v_5=2$ and $v_5=1$, $v_7=3$ states. Although the existence of the Fermi resonance between $v_5=1$ and $v_7=3$ in Π symmetry state has not been confirmed from the microwave studies,[2] and the origin of the interaction between $v_5=2$ and $v_5=1$, $v_7=3$ states is still open to discussion, the present infrared results may be best interpreted by the energy level diagram shown in Fig. 2, where the Fermi resonance between $v_5=1$ and $v_7=3$ states is taken into account. According to this energy level diagram, the large

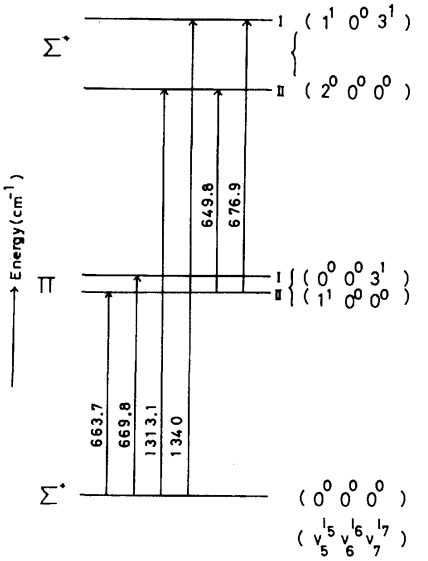

Fig. 2. Energy level diagram involving the excited states of ν_5 and ν_7 in HCCCN.

frequency shifts of the sub-bands are due to the energy splitting in the initial and final states, and the anomalous intensity of the band at 669.8 cm^{-1} is due to the intensity borrowing from ν_5 fundamental. Since the majority of the sub-bands in this region were related to the ν_5 fundamental, the integrated absorption coefficient in this region was ascribed only to the ν_5 fundamental intensity.

In the ν_6 band region of HCCCN, the band at 499.2 cm^{-1} was assigned to the Q-branch of the $v_6=1\leftarrow0$ transition; the band at 514.6 cm^{-1} was assigned to the Q-branch of the $v_6=2\leftarrow1$ transition, and the other weaker bands may be assigned to the hot bands originating from other excited states. Therefore, the observed intensities in this region were integrated to give $B(\nu_6)$.

In the case of DCCCN, ν_5 and ν_6 bands were observed to overlap and form a single band envelope. In this region, two strong bands at 522.6 cm^{-1} and 494.6 cm^{-1} were unambiguously assigned to the Q-branches of $v_5=1\leftarrow0$ and $v_6=1\leftarrow0$ transitions respectively. In addition to these bands, there appeared some bands of small frequency shifts and low intensities relative to $v_5=1\leftarrow0$ or $v_6=1\leftarrow0$ transition, and these may be assigned to a hot band. Then, the intensities in this region were integrated to give an intensity sum $B(\nu_5)+B(\nu_6)$. The method used to separate this sum into individual components will be shown in the later section. Experimental quantities, *i.e.*, $B(\nu_5)$ and $B(\nu_6)$ of HCCCN, and $B(\nu_5)+B(\nu_6)$ of DCCCN, were plotted against to sample pressure p at 273 K, as shown in Fig. 3. Then, the limiting slope at $p\rightarrow0$ was obtained to give the integrated molar absorption coefficient:

$$A(\nu_i)=\int_{\text{band}}\alpha d\tilde{\nu}. \quad (2)$$

The resultant intensity sum $A(\nu_5)+A(\nu_6)$ in DCCCN was divided by the following method. Since the Q-branch intensity of ν_5 band was close to that of ν_6, the integrated intensities were divided at the wavenumber halfway between the Q-branch maxima, and $A(\nu_5)$ and

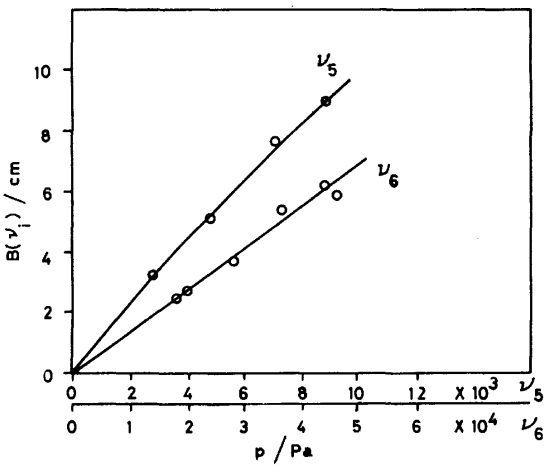

Fig. 3a. Beer's law plots for gaseous HCCCN.

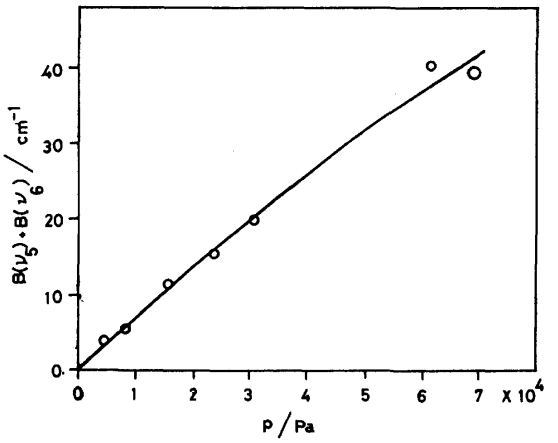

Fig. 3b. Beer's law plots for gaseous DCCCN.

$A(\nu_6)$ were assumed to be proportional to the divided areas of the higher and lower frequency sides. As for the determination of $A(\nu_7)$, the absorption coefficients were integrated over the Q-branch region of ν_6 and ν_7 bands to give $B_Q(\nu_6)$ and $B_Q(\nu_7)$. Then $A(\nu_7)$ was determined from the following expression:

$$A(\nu_7) = A(\nu_6) \times \frac{B_Q(\nu_7)}{B_Q(\nu_6)} \times \frac{p_6}{p_7} \times \frac{l_7}{l_6}, \qquad (3)$$

where l_i is the path-length of the gas cell, and p_i stands for the pressure of the sample. The integrated molar absorption coefficients obtained in this study are shown in Table 2.

TABLE 2. OBSERVED INFRARED INTENSITIES OF BENDING FUNDAMENTALS IN GASEOUS CYANOACETYLENE (km mol^{-1})

	$A(\nu_5)$	$A(\nu_6)$	$A(\nu_7)$
HCCCN	68.4	8.0	0.18
DCCCN	21.0	24.5	0.22

Now, let us consider the errors in the resultant intensities. It is well known that among the various sources of error, the relation between the spectral slit-width and the half-width of the pressure-broadened spectra is most important for the determination of $A(\nu_i)$. In the case of ν_5 and ν_6 fundamentals, the Beer's law plots are seen to be almost linear; this gives the experimental evidence that the relation between the slit-width and the half-width of the spectra was appropriate. Although the Beer's law plots was not available in the ν_7 fundamental, the relation may be regarded as close to that in ν_5 and ν_6, because the spectral slit-width and the total pressure of the gas in the measurement of ν_7 were nearly half of those in ν_5 and ν_6. It is also well known that the half-width of a spectral line is proportional to the pressure of gas when the pressure broadening is the dominant factor for the line-width. The errors in $A(\nu_i)$ may be estimated at 15% for ν_5 and ν_6, and 25% for ν_7, based on the estimation of the errors in the intensities of the stretching fundamentals in gaseous states.

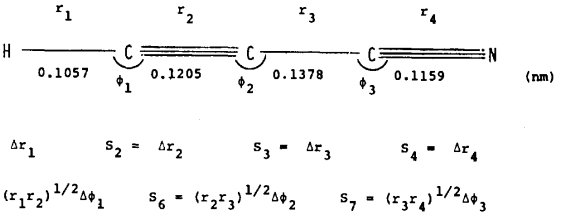

Fig. 4. Molecular structure and internal coordinates.

In order to obtain L^{-1} matrix elements which are necessary for the conversion of $(\partial\mu/\partial Q_i)$ to the dipole-moment derivatives with respect to internal coordinates $(\partial\mu/\partial S_i)$, the force constants for bending vibrations were determined by a least squares method based on the frequency data by Mallinson *et al.*[5] The force constants for stretching vibrations were determined by the same method. The molecular geometry and internal coordinates used are shown in Fig. 4. It is not practical to assume a general valence force field, because the number of the observed frequencies in HCCCN and DCCCN are limited to eight in the stretching vibration and six in the bending vibration, so that the following potential function was used;

$$\begin{aligned} 2V = {} & K_1\Delta r_1^2 + K_2\Delta r_2^2 + K_3\Delta r_3^2 + 2K(\Delta r_2\Delta r_3 + \Delta r_3\Delta r_4) \\ & + H_1 r_1 r_2 \Delta\phi_1^2 + H_2 r_2 r_3 \Delta\phi_2^2 + H_3 r_3 r_4 \Delta\phi_3^2 \\ & + 2H\sqrt{r_1 r_3}\, r_2 \Delta\phi_1\Delta\phi_2, \end{aligned} \qquad (4)$$

where K stands for the interaction between C≡C stretch and C–C stretch, and also for that between C–C stretch and C≡N stretch, whereas H stands for the interaction between HCC bend and CCC bend. When other forms of the function were assumed, the resultant force constants diverged or gave large correlation factors. The force constants, and the calculated and observed frequencies are shown in Table 3, where a fairly good agreement is obtained between them. The largest correlation factor is 0.86 for the element between K_4 and K. Then, $(\partial\mu/\partial S_j)$ were calculated by the following expression, using $(\partial\mu/\partial Q_i)$ and L^{-1} matrix elements obtained above:

$$(\partial\mu/\partial S_j) = \sum_k (\partial\mu/\partial Q_k) L_{kj}^{-1}. \qquad (5)$$

It is well known that $(\partial\mu/\partial S_j)$ derivatives obtained from Eq. 5 include some contribution due to molecular rotation, if S_j and overall rotation belong to the same symmetry species.[6,7] This is the case for the bending vibration of these molecules, so that the derivatives

a) Ref. 5. Band centers which do not include the $-l^2B_v$ term.

obtained from HCCCN and DCCCN are designated as $(\partial\mu/\partial S_j)_H$ and $(\partial\mu/\partial S_j)_D$, because the effect of the compensating rotation is different for different isotopes. In order to compare these derivatives on the same basis, a reference molecule was assumed, where the mass of hydrogen atom is supposed to be zero. Then, it can be shown that the experimental quantities $(\partial\mu/\partial S_j)_H$ and $(\partial\mu/\partial S_j)_D$ are related to $(\partial\mu/\partial S_j)_R$ in this reference molecule by the following expression:

$$(\partial\mu/\partial S_j)_R = (\partial\mu/\partial S_j)_H - (\partial\mu/\partial S_j)^{Corr}_{R.H}, \quad (6a)$$

$$(\partial\mu/\partial S_j)_R = (\partial\mu/\partial S_j)_D - (\partial\mu/\partial S_j)^{Coor}_{R.D}, \quad (6b)$$

where $(\partial\mu/\partial S_j)^{Corr}_{R.H}$ and $(\partial\mu/\partial S_j)^{Corr}_{R.D}$ stand for the rotational corrections. These correction terms can be calculated by the following expression:

$$(\partial\mu/\partial S_j)^{Corr}_{R.I} = \sum_{s=1}^{3N}(\partial\mu/\partial x_s)\sum_{n=1}^{6}(\alpha_R)_{s,n}\Big[\sum_{\substack{t=1\\ I=H.D}}^{3N}(\beta_R)_{n,t}(A_I)_{t,j}\Big], \quad (7)$$

where μ is the molecular permanent dipole-moment and A, β, and α are the matrices relating the Cartesian displacement coordinates x with the internal coordinates S and the coordinates of translation and rotation ρ:

$$x_s = \sum_{k=1}^{3N-6}(A_I)_{s,k}S_k + \sum_{n=1}^{6}(\alpha_I)_{s,n}(\rho_I)_n, \quad (8a)$$

$$S_k = \sum_{s=1}^{3N-6}B_{k,s}x_s, \quad (\rho_I)_n = \sum_{\substack{s=1\\ I=H.D}}^{3N}(\beta_I)_{n,s}x_s. \quad (8b)$$

Since the signs of $(\partial\mu/\partial Q_i)$ are not determinable experimentally, all possible sign combinations in $(\partial\mu/\partial Q_i)$ are shown in Table 4, together with the rotational correction terms. It may be seen from the table that the sign combinations $(+-+)$ and $(+--)$ with the correction term subtracted give better agreement between HCCCN and DCCCN: $(+--)$ gives the best agreement in $(\partial\mu/\partial S_5)_R$ and $(\partial\mu/\partial S_7)_R$, whereas $(+-+)$ gives the best agreement in $(\partial\mu/\partial S_6)_R$. It may be pointed out here that the observed $(\partial\mu/\partial S_6)_R$ may contain a larger error that the others, because $A(\nu_7)$ is expected to contain the largest error in the three bending fundamentals and it gives the largest contribution to $(\partial\mu/\partial S_6)_R$. Therefore, the difference of $(\partial\mu/\partial S_6)_R$ in $(+--)$ may be ascribed to the experimental error. In view of the above discussions, it seems most reasonable to take the $(+--)$ sign combination with the correction term subtracted as the most preferable one. In order to determine the direction of the rotational correction term, it is necessary to know the direction of the permanent dipole-moment μ. For this purpose, the semi-empirical SCF calculation was carried out and the dipole-moment μ was obtained to be 2.93 D, with the polarity of $\overset{+}{H}CCC\overset{-}{N}$. This polarity agrees with that expected from the generally accepted bond polarities of $\overset{+}{H}$–$\overset{-}{C}$ and $\overset{+}{C}\equiv\overset{-}{N}$. The rotational correction terms

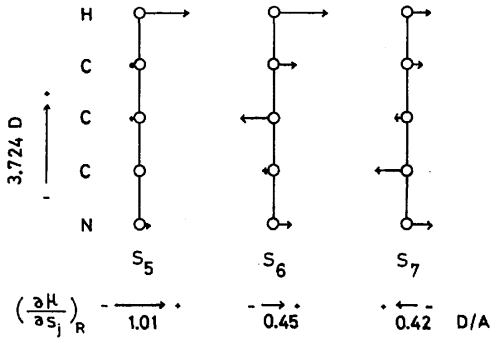

Fig. 5. Atomic displacements along internal coordinates and changes of dipole-moment.

were calculated from the dipole-moment of 3.724 D derived from the microwave studies[2] with the polarity of $\overset{+}{H}CCC\overset{-}{N}$. The experimentally determined relative signs in $(\partial\mu/\partial S_j)_R$ and $(\partial\mu/\partial S_j)^{corr}_{R,H(D)}$ then lead to the determination of the direction of each $(\partial\mu/\partial S_j)_R$. The atomic displacements along each internal coordinate and the resultant changes of the dipole-moment are shown in Fig. 5. It may be noted that $(\partial\mu/\partial S_5)_R$ of cyanoacetylene and $(\partial\mu/\partial S_2)_R$ of hydrogen cyanide have same direction and their values are close, *i.e.*, the value of $(\partial\mu/\partial S_2)_R$ in hydrogen cyanide after the rotational correction has been taken into account is 1.08 D/A. It can be seen from the B matrix elements for each internal coordinate that both dipole-moment derivatives are due to the displacement of hydrogen atoms. Therefore, the close agreement between them may be regarded as the experimental evidence of the similar nature of the H–C bond in these molecules. Though it does not seem so simple to relate the dipole-moment derivatives to each bond polarity of molecule, as in the case of $(\partial\mu/\partial S_5)_R$, the dominant part of $(\partial\mu/\partial S_7)_R$ may be due to the C≡N bond which has a high polarity of $\overset{+}{C}\equiv\overset{-}{N}$.

The authors wish to express their thanks to Professor Shiro Maeda and Professor Chiaki Hirose of Tokyo Institute of Technology for helpful discussions and encouragements. The normal coordinate calculations and the semi-empirical SCF (CNDO) calculations were carried out at the Computer Center, the University of Tokyo.

Hydrates of Organic Compounds. VI. Heats of Fusion and of Solution of Quaternary Ammonium Halide Clathrate Hydrates

Haruo NAKAYAMA

Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

(Received June 10, 1981)

The heat of solution in water of four quaternary ammonium halide clathrate hydrates, $R_4NX \cdot nH_2O$ ($R = n\text{-}C_4H_9$, X=F and Cl, $n=30$; $R = i\text{-}C_5H_{11}$, X=F and Cl, $n=39$), and the heat of dilution of their aqueous solutions were measured calorimetrically. From these results, the heat of fusion of the clathrate hydrate solid (ΔH_f) and the heat of solution of it in saturated solutions (ΔH_{sat}) were obtained. The ΔH_f was compared with a hypothetical heat of fusion of the same number of moles of ice I as the hydration number of the hydrate. The ΔH_{sat} was about 14 kJ/mol smaller than the ΔH_f in the $(n\text{-}C_4H_9)_4NX$ hydrates and about 27 kJ/mol smaller in the $(i\text{-}C_5H_{11})_4NX$ hydrates irrespective of the type of anion. Furthermore, ΔH_{sat} was calculated thermodynamically and it agreed with the calorimetrically obtained value within the experimental error.

Clathrate-like hydrates of quaternary ammonium salts, which were originally found in Kraus' laboratory in 1940[1] and were examined later in detailed structural studies by Jeffrey *et al.*,[2-4] have been known to have some unusual properties in comparison with ordinary gas hydrates. The most striking features are summarized as follows:

(1) They are easily formed by cooling their aqueous solutions at atmospheric pressure and the concentration range from which the hydrate is separated out is very wide, especially for a stable hydrate.[5] (2) Generally these hydrates are very stable, *i.e.*, they have fairly high melting points as compared to ordinary gas hydrates. Melting points at around room temperature are not unusual. (3) The formation of such a hydrate is possible for salts having a variety of anions,[2,5] but a suitable alkyl chain of the cation is almost exclusively limited to the butyl or the isopentyl group.[6]

The thermodynamic properties of aqeous tetraalkylammonium salt solutions have been extensively studied[7] and the results of these studies are often interpreted by structural modifications of water molecules around the cation from analogy with the clathrate hydrates. However little is known about the thermodynamic properties of the clathrate hydrate itself. Such thermodynamic properties as the heat of fusion and of solution of the clathrate hydrate are basic properties not only for the interpretation of the nature of the hydrogen-bonded water networks around the alkyl groups of the cation but also for an application of these hydrates as, for example, a heat reservoir utilizing the heat evolved or absorbed when their states change.

In this paper the author reports the heats of fusion and of solution in water of four clathrate hydrates, $(n\text{-}C_4H_9)_4NF \cdot 30H_2O$, $(n\text{-}C_4H_9)_4NCl \cdot 30H_2O$, $(i\text{-}C_5H_{11})_4NF \cdot 39H_2O$, and $(i\text{-}C_5H_{11})_4NCl \cdot 39H_2O$, and discusses the effect of the type of the anion and of the alkyl group of the cation on these thermal properties. In addition, the calorimetrically determined heats of solution are compared with those calculated from the data concerning both temperature dependence of the solubilities and concentration dependence of the mean molal activity coefficients.

The hydrates used in this paper are the most convenient ones for calorimetric measurement since they all have relatively high congruent melting points and each hydration number has been well determined in previous phase-diagramatic investigations.[5]

Experimental

Materials. The procedures for preparing and purifying the materials used in this experiment were the same as those in the previous work.[5,8] The concentration of the mother solution was determined by the Karl Fischer titration method for the fluoride solutions and by a standard KNCS titration method (Volhard method) for the chloride solutions.[5]

Calorimetry. A twin-type rotating-microcalorimeter manufactured by Ōyōdenki Kenkyujo (RCM-1N)[9] was used. The mixing cell was a glass cylinder of 45 mm diameter and 30 mm high. Part of it was divided into two compartments by a glass wall and a sample solution and water were loaded into each compartment from a weighed syringe fitted with a stainless steel needle.

The heats of dilution (or solution) at infinite dilution were obtained by measuring heat changes in the following two steps: sample solution (or solid)→0.07 mol kg^{-1} solution→0.005 mol kg^{-1} solution. The heat due to a further dilution from 0.005 mol kg^{-1} which was estimated to be smaller than 0.1 kJ/mol, was neglected. The heat evolved in the second stage of dilution was also small compared with that in the first stage of dilution (or solution) and was found to be 0.68 kJ/mol, 0.52 kJ/mol, 1.29 kJ/mol, and 1.14 kJ/mol for $(n\text{-}C_4H_9)_4NF$, $(n\text{-}C_4H_9)_4NCl$, $(i\text{-}C_5H_{11})_4NF$, and $(i\text{-}C_5H_{11})_4NCl$, respectively.

In this experiment the following three heats were determined for each salt. These heats and their experimental methods for measuring the heat changes in the first step of dilution (or solution) are summarized as follows:

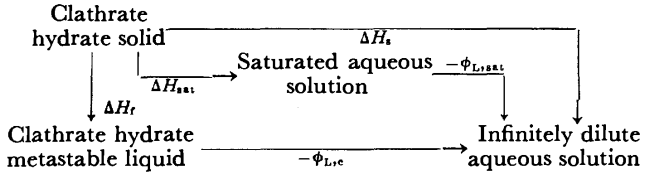
(i) The Heat of Solution of a Clathrate Hydrate Solid in Water at Infinite Dilution (ΔH_S). A given amount of a sample solution whose concentration was equal to its congruent composition (1.850 mol kg^{-1} for the tetrabutylammonium salts and 1.423 mol kg^{-1} for the tetraisopentylammonium salts) was loaded into one of the compartments of the cell at temperatures a few degrees higher than its congurent melting point (T_C). Then the cell was gradually cooled down, with occasional shaking, until the sample solution solidified after which it was kept standing for about 4 h at a temperature a few degrees lower than the T_C in order to anneal the solid. Next the cell was loaded into the calorimeter, followed by the insertion of water into the other compartment of the cell in amounts which corresponded to a final concentration of 0.07 mol kg^{-1}. After thermal equilibrium was reached, the heat change was

measured when the solid was dissolved in the water.

(ii) The Heat of Dilution in Water of a Metastable Clathrate Hydrate Liquid at Infinite Dilution ($-\phi_{L,C}$). Since the liquid sample whose concentration was equal to its congruent composition could stay in a metastable liquid state for a long time at the measuring temperature (10 °C for the (n-$C_4H_9)_4$NCl and 25°C for the other salts) if not cooled down deliberately as in (*i*), its heat of dilution could easily be measured by mixing it with water. A given amount of a sample solution whose concentration was equal to its congruent composition was loaded into one compartment of the cell at a temperature a few degrees higher than its T_C. The cell was then loaded into the calorimeter, followed by the insertion of an adequate amount of water into the other compartment of the cell. After thermal equilibrium was attained, the heat change was measured when both liquids were mixed.

(iii) The Heat of Dilution of a Salt Solution from a Saturated Solution to an Infinitely Dilute Solution ($-\phi_{L,sat}$). The heat of dilution of a given amount of salt solution whose concentration was equal to its solubility at a measuring temperature was measured in a similar way as in (*ii*).

The three heats measured and other heats discussed in later sections are mutually interconnected by the following scheme:



Solubility and Mean Molal Activity Coefficient Measurements.

The solubilities of the clathrate hydrate solid in water were measured by the following manner. In a glass cylinder, which was 30 mm diameter and 100 mm high and was immersed in a constant temperature bath, the solid hydrate was saturated in about 10 cm^3 water by vigorous stirring with a magnetic stirrer. Then a given amount of the saturated solution was withdrawn and analyzed. In the case of the fluoride solutions, concentration was determined by measuring the water content by the Karl Fischer titration method for the sample solution which had partially been concentrated by dehydration on P_2O_5 in a desiccator. The standard KNCS titration method (Volhard method[5]) was used for the chloride solutions.

The mean molal activity coefficients ($\gamma_\pm$) for the tetraisopentylammonium salt solutions were obtained from the isopiestic data by the conventional method.[10,11] The apparatus and procedure for the isopiestic measurements were the same as that in the previous work.[12]

Results and Discussion

(1) Fundamental Properties of the Clathrate Hydrates. Prior to the calorimetric experiments we must specify the fundamental properties of each clathrate hydrate such as the hydration number (n), the congruent melting point (T_C), and the solubility in water (m_{sat}). These values are summarized in Table 1. Although somewhat different hydration numbers are found in the literature,[2,5,8,13] we chose 30 for the (n-$C_4H_9)_4$NX hydrates and 39 for the (i-$C_5H_{11})_4$NX hydrates by reference to our previous phase-diagramatic results.[5] Therefore, the congruent compositions become 1.850 mol kg^{-1} for tetrabutylammonium halide systems and 1.423 mol kg^{-1} for the tetraisopentylammonium halide systems.

Table 1. Fundamental properties of the tetraalkylammonium halide (R_4NX) clathrate hydrates

R_4NX	Hydration number[5]	Mp θ_m[5] / °C	Solubility in water / mol kg^{-1}
(n-$C_4H_9)_4$NF	30	28.3	0.920±0.002[a]
(n-$C_4H_9)_4$NCl	30	15.0	0.561±0.003[b]
(i-$C_5H_{11})_4$NF	39	31.5	0.293±0.002[a]
(i-$C_5H_{11})_4$NCl	39	29.6	0.203±0.002[a]

a) At 25 °C. b) At 10 °C.

Calorimetric measurements were carried out at 10 °C for the (n-$C_4H_9)_4$NCl system and at 25 °C for the other three systems, taking into account each congruent melting point listed in Table 1.[5]

(2) Calorimetric Measurements. The observed ΔH_s's and ϕ_L's are summarized in Table 2. The physical meaning of these quantities has been explained in the experimental section. Listed values were averages of 4—5 determinations. The error limit attached to each value was estimated by taking into account the dispersion in each measurement as well as the errors inherent in sampling the solution and in determining its concentration.

Narten and Lindenbaum[13] have reported ΔH_s and $\phi_{L,c}$ for (n-$C_4H_9)_4$NF hydrate, which are also listed in Table 2. Their values are somewhat higher than the present values. The values of $\phi_{L,c}$ and $\phi_{L,sat}$ for (n-$C_4H_9)_4$NCl solutions which are calculated from the heats of dilution data at 25 °C (not at 10 °C) obtained by Lindenbaum[14] are also listed in Table 2. These

Table 2. The heats of solution of the tetraalkylammonium halide (R_4NX) clathrate hydrates and the relative apparent molal heat contents of the aqueous R_4NX solutions

R_4NX	Temperature / °C	ΔH_s / kJ mol^{-1}	$\phi_{L,c}$ / kJ mol^{-1}	$\phi_{L,sat}$ / kJ mol^{-1}
(n-$C_4H_9)_4$NF	25	158.6±3.7 (170.6[13])	25.8±0.5 (26.6[13])	12.6±0.2
(n-$C_4H_9)_4$NCl	10	136.2±4.0	19.5±0.4 (20.5[14])[a]	5.5±0.2 (5.2[14])[a]
(i-$C_5H_{11})_4$NF	25	223.1±5.0	32.8±1.2	6.2±0.3
(i-$C_5H_{11})_4$NCl	25	253.0±4.2	29.7±0.3	3.9±0.2

a) At 25 °C.

values are in fairly good agreement with the present data regardless of the slight difference in temperature.

The heat of fusion of clathrate hydrate solid (ΔH_f) and its heat of solution in a saturated aqueous solution (ΔH_{sat}) can be calculated by the following relations:

$$\Delta H_f = \Delta H_s + \phi_{L,c}, \quad (1)$$

$$\Delta H_{sat} = \Delta H_s + \phi_{L,sat}. \quad (2)$$

These heats are tabulated in Table 3 and discussed in the following sections.

Table 3. The heats of fusion of the tetraalkylammonium halide (R_4NX) clathrate hydrates and the heats of solution of them in saturated aqueous solutions

Hydrate	Temperature °C	ΔH_f kJ mol^{-1}	ΔH_{sat} kJ mol^{-1}
$(n\text{-}C_4H_9)_4NF\cdot 30H_2O$	25	184±4	171±4
$(n\text{-}C_4H_9)_4NCl\cdot 30H_2O$	10	156±4	142±4
$(i\text{-}C_5H_{11})_4NF\cdot 39H_2O$	25	256±5	229±5
$(i\text{-}C_5H_{11})_4NCl\cdot 39H_2O$	25	283±4	257±4

(3) The Heats of Fusion of Clathrate Hydrate Solids. The heat of fusion of a tetraalkylammonium halide clathrate hydrate may be considered to be made up by the following three terms:

$$\Delta H_f = \Delta H_c + \Delta H_e + \Delta H_h, \quad (3)$$

in which ΔH_c is the change in enthalpy of the hydrogen-bonded water networks (cages) when a clathrate hydrate solid melts, ΔH_e and ΔH_h is the change in electrostatic energy between ions and that in the energy due to additional hydration of ions, respectively. Although it is impossible to discuss each enthalpy change quantitatively, we can reasonably assume that the last two heats, ΔH_e and ΔH_h, are relatively small as compared with the first term, ΔH_c, from the following reasons: (1) The local structure of the melt is expected to be essentially similar to that of the solid state, as exemplified for $(n\text{-}C_4H_9)_4NF$ solution.[13] Thus, interionic distance will not change appreciably when the solid melts. (2) A large extent of additional hydration of the ions cannot be expected from the fact that all the ions are already surrounded by water molecules in the solid state and further that the total amount of water remains constant in the melting process.

Therefore, if we assume that the last two terms of Eq. 3 are negligible as compared with the first term and further that the first term may be approximately expressed as $n\cdot\Delta H_{f,ice}$, Eq. 3 becomes

$$\Delta H_f \simeq \Delta H_c \simeq n\cdot\Delta H_{f,ice}, \quad (4)$$

in which n is the hydration number of a clathrate hydrate, and $\Delta H_{f,ice}$ is a hypothetical molal heat of fusion of ice I at the measuring temperature. This heat of fusion is estimated to be 6.375 kJ/mol at 10 °C and 6.896 kJ/mol at 25 °C taking into account the heat capacity data.[15] Equation 4 has been proved to be fairly adequate for ordinary gas hydrates[16,17] or for some of the liquid hydrates.[18] However, it may not be so appropriate for the tetraalkylammonium salt hydrates since the central N atom of the cation and the fluoride anion (and probably also the chloride anion) replace water molecules within the lattice. This leads to the disappearance of some of the hydrogen bonds and a decrease in the number of stable orientations of the water molecules at sites neighboring the N^+ and F^- (and Cl^-) sites.[3,4,17]

Tentatively, the observed ΔH_f's (Table 3) were compared with the calculated $n\cdot\Delta H_{f,ice}$ in the form of the ratio of the two, $\Delta H_f/n\cdot\Delta H_{f,ice}$. This ratio was 0.89, 0.82, 0.95, and 1.05 for $(n\text{-}C_4H_9)_4NF$, $(n\text{-}C_4H_9)_4NCl$, $(i\text{-}C_5H_{11})_4NF$, and $(i\text{-}C_5H_{11})_4NCl$ hydrate, respectively. This result indicates that the apparent heats of fusion of the tetrabutylammonium halide hydrates are a little smaller (about 85%) than that of a hypothetical heat of fusion of ice I of the same number of moles as the hydration number of the hydrates, whereas those of the tetraisopentylammonium halide hydrates are approximately equal to the corresponding heats of fusion of ice I. The reason for this different behavior in the two series of hydrates can be explained, at least partly, by the following facts; (a) the proportion of the water molecules which are structurally affected by the presence of R_4N^+ cation and F^- anion (or Cl^- anion) is larger in the tetrabutylammonium halide hydrate than in the tetraisopentylammonium halide hydrate since the hydration number of the former is smaller than that of the latter; (b) the hydrogen-bonded water networks in the tetraisopentylammonium halide hydrate seem to be stabler than that in the tetrabutylammonium halide hydrate since the melting points of the tetraisopentylammonium halide hydrates are relatively high and are not so predominantly affected by the kind of anion.[2,5] Furthermore, even $(i\text{-}C_5H_{11})_4NI$ can form a clathrate-like hydrate.[5] Tetrabutylammonium iodide cannot form a clathrate hydrate, presumably because a stabilizing ability of water networks surrounding the butyl chain is not strong enough to overcome the lattice distortion caused by the presence of the bulky iodide anion.

(4) The Heats of Solution of the Clathrate Hydrate Solids in Saturated Aqueous Solutions. From Eqs. 1 and 2, the ΔH_{sat} can be expressed by the following relation:

$$\Delta H_{sat} = \Delta H_f - (\phi_{L,c} - \phi_{L,sat}). \quad (5)$$

The heat in the parenthesis of the right-hand side of the above equation is made up by two heats of dilution which are due to an additional hydration of ions including hydrophobic hydration. It should be noted that, from Table 2 (or 3), this quantity is about 14 kJ/mol for the tetrabutylammonium halide hydrates and about 27 kJ/mol for the tetraisopentylammonium halide hydrates irrespective of the type of the anion and further that these heats correspond roughly to about 10% of the ΔH_{sat} in each hydrate. Therefore, it may be concluded that the heat of solution of a clathrate hydrate has similar values to its heat of fusion and, in turn, the latter heat may approximately be estimated by Eq. 4. The phenomenon that the heat of solution of a solid is close to its heat of fusion is commonly found in the dissolution process of ordinary hydrated electrolytes like $CaCl_2\cdot 6H_2O$.[19]

On the other hand, the heat of solution of a hydrated electrolyte in saturated solution can be expressed by the following thermodynamic equation:[19]

$$\Delta H_{sat} = -\nu R(1-nm_{sat}/M)^2 \times (1 + (\partial \ln \gamma_{\pm}/\partial \ln m)_{sat}) \times (\partial \ln m'_{sat}/\partial(1/T)), \quad (6)$$

in which $\nu=\nu_+ + \nu_-$, R=the gas constant, n=the hydration number, m_{sat}=solubility expressed in molality, M=55.51, $\gamma_{\pm}$=mean molal activity coefficient, $m'_{sat}=m_{sat}/(1-nm_{sat}/M)$, and T=the absolute temperature. Though this equation has been applied to ordinary inorganic hydrated electrolytes and its validity has been verified in several systems,[19] it has not previously been applied to a clathrate hydrate system. Therefore, it is interesting to see to what extent the heat of solution which is calculated by Eq. 6 is compatible with that directly obtained by calorimetry (Table 3).

The values of $(\partial \ln \gamma_{\pm}/\partial \ln m)_{sat}$ for the two tetrabutylammonium halide solutions were calculated from existing data[20,21] and those for the tetraisopentylammonium halide solutions were newly obtained in this experiment from the isopiestic data. Because of the low solubilities of the two tetraisopentylammonium halide hydrates (Table 1), which are compatible with the concentration limit (about 0.1 mol kg^{-1} [10]) to which an accurate isopiestic measurement can be done, the values of $(\partial \ln \gamma_{\pm}/\partial \ln m)_{sat}$ for these two halide solutions have errors in the order of 4—5%. The temperature dependence of the solubilities of all the hydrates are shown in Fig. 1. The slopes of $\partial \ln m'_{sat}/\partial(1/T)$, which were obtained by graphical differentiation of Fig. 1, have also some uncertainties since $\ln m'_{sat}$ decreases nonlinearly with increasing $1/T$. The calculated ΔH_{sat} and all the values used for this calculation are summarized in Table 4. These calculated values of ΔH_{sat} agree within experimental error with those obtained by direct calorimetry (Table 3). It is interesting to note that, as is seen from Table 4, the approximate values of the ΔH_{sat} for the two chloride hydrates can be calculated only from the solubility *vs.* temperature data since the values $(\partial \ln \gamma_{\pm}/\partial \ln m)_{sat}$ are relatively small as compared with unity for these hydrates.

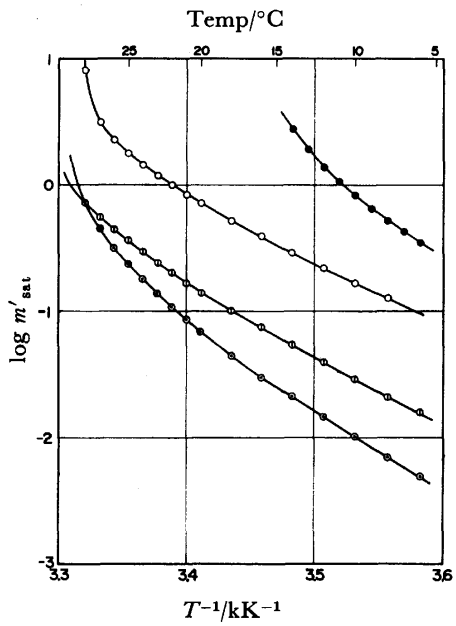


Fig. 1. Temperature dependence of the solubilities (m'_{sat}) of tetraalkylammonium halide clathrate hydrates in water:
$(n\text{-}C_4H_9)_4NF \cdot 30H_2O$ (○); $(n\text{-}C_4H_9)_4NCl \cdot 30H_2O$ (●); $(i\text{-}C_5H_{11})_4NF \cdot 39H_2O$ (◑); $(i\text{-}C_5H_{11})_4NCl \cdot 39H_2O$ (⊙).

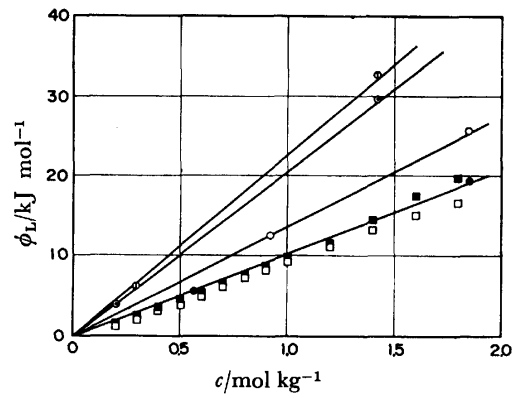

Fig. 2. Concentration dependence of the relative apparent molal heat contents (ϕ_L) of tetraalkylammonium halide solutions:
$(n\text{-}C_4H_9)_4NF$ at 25 °C (○); $(n\text{-}C_4H_9)_4NCl$ at 10 °C (●); $(i\text{-}C_5H_{11})_4NF$ at 25 °C (◑); $(i\text{-}C_5H_{11})_4NCl$ at 25 °C (⊙); $(n\text{-}C_4H_9)_4NCl$ at 25 °C taken from Ref. 14 (■); $(n\text{-}C_4H_9)_4NBr$ at 25 °C taken from Ref. 14 (□).

(5) The Relative Apparent Molal Heat Contents. In Table 2, two relative apparent molal heat contents, $\phi_{L,c}$ and $\phi_{L,sat}$, are given for each salt solution. These values are plotted against m in Fig. 2, assuming that ϕ_L is a linear function of m in the concentration range studied rather than a linear function of $\sqrt{m}$ as derived from the limiting law.[11] This assumption seems to be reasonable, at least as a first approximation, as exemplified in Fig. 2 by the data for $(n\text{-}C_4H_9)_4NCl$ and $(n\text{-}C_4H_9)_4NBr$ (at 25 °C) solutions obtained by Lindenbaum.[14] Figure 2 clearly indicates that the increase of ϕ_L with increasing m for the tetraisopentylammonium salt is more marked than that for the tetrabutylammonium salt, irrespective of the type of anion.

Table 4. The tabulation of each term in Eq. 6 and the calculation of ΔH_{sat}

Hydrate	Temp °C	$(1-nm_{sat}/M)^2$	$1+(\partial \ln \gamma_{\pm}/\partial \ln m)_{sat}$	$\partial \ln m'_{sat}/\partial(1/T)$ 10^4 K	ΔH_{sat} kJ mol^{-1}
$(n\text{-}C_4H_9)_4NF \cdot 30H_2O$	25	0.253±0.001	1.830±0.005	−2.14±0.05	165±4
$(n\text{-}C_4H_9)_4NCl \cdot 30H_2O$	10	0.486±0.003	0.931±0.005	−1.80±0.03	135±3
$(i\text{-}C_5H_{11})_4NF \cdot 39H_2O$	25	0.631±0.003	1.23 ±0.05	−1.84±0.04	237±11
$(i\text{-}C_5H_{11})_4NCl \cdot 39H_2O$	25	0.735±0.002	0.95 ±0.05	−2.27±0.05	263±15

This indicates that the structural modification of the water molecules around the isopentyl group is greater than that around the butyl group. The high stability of the tetraisopentylammonium halide hydrates has already been pointed out in section *(3)*.

Catalytic Properties of Perovskite-type Mixed Oxides, $La_{1-x}Sr_xCoO_3$

Teiji NAKAMURA, Makoto MISONO,* and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 8, 1981)

The reactivity and related properties of oxygen both in the bulk and on the surface has been investigated for perovskite-type mixed oxides ($La_{1-x}Sr_xCoO_3$), in regard to the effects of Sr^{2+}-substitution and calcination temperature. The reducibility and the readiness of oxygen desorption increased with the Sr^{2+} content, x, but the reoxidation became slower with x. These results have been explained on the basis of the change in the chemical potential of lattice oxygen. The diffusivity of oxygen in the bulk and the ability to activate the oxygen molecule also increased with x. Oxygen vacancies in the bulk and on the surface, which tended to increase with x, are likely responsible for these reactions. The release of oxygen from the bulk became more difficult as the calcination temperature increased, in conformity with the trend of the catalytic activity.

For the design of catalysts, it is very helpful to know the relationships between the solid state chemistry of catalysts and the catalytic properties, that is, the structure-property relationships. It is, therefore, desirable to study catalyst materials of which the structure is well defined and for which the surface or bulk properties can be continuously or stepwise changed without affecting the fundamental structure of the catalyst.

Perovskite-type mixed oxides (ABO_3) are typical examples suitable for this purpose, since their structures have been satisfactorily clarified and their electronic properties can be modified in various ways by the substitution of the constituting elements.[1] For example, the oxidation state of the B-site ion and the number of oxygen defects can be controlled by introducing a divalent ion in the A-site. Futhermore, perovskite-type mixed oxides are important catalysts in practical processes such as oxidation,[2,3] NO elimination[4,5] and hydrogenolysis.[6] It has already been reported that the perovskite-type mixed oxides are very active in complete oxidation reactions.[7,8]

We found previously that $La_{1-x}Sr_xCoO_3$ (x=0—0.4) showed high catalytic activity for the oxidation of C_3H_8, CH_4, and CO.[8] Among them, $La_{0.8}Sr_{0.2}CoO_3$ calcined at 850 °C was the most active, and its activity was comparable with or greater than that of Pt, Pd, and Ni catalysts. However, there have been few studies on the reaction mechanism and the reactivity of oxygen species of the perovskite-type mixed oxides, in relation to the catalytic activity for oxidation reactions.

Oxygen species responsible for the oxidation reaction have been well clarified, for example, in the case of Bi_2O_3–MoO_3[9] and γ-Fe_2O_3.[10] Both are active catalysts for allyl-type oxidation of olefins, in which lattice oxygen is responsible for catalysis. Reduction and oxidation of the whole bulk of these catalysts proceed readily under the reaction conditions, by the diffusion of lattice oxygen for Bi_2O_3–MoO_3 or metal cation for γ-Fe_2O_3. The diffusion of the cation or anion appears very important for allyl-type oxidation. As for the perovskite-type mixed oxide, it is only reported in the field of electrochemistry that the oxygen diffusion in $Nd_{1-x}Sr_xCoO_3$ is more rapid than that in ordinary metal oxides.[11] In the present work we studied the reactivity and diffusivity of oxygen in $La_{1-x}Sr_xCoO_3$, in order to clarify the relationships between these properties and the catalytic action. We studied particularly the effects of Sr^{2+}-substitution and the calcination temperature on the reactivity and related properties of oxygen, both in the bulk and on the surface.

Experimental

Catalysts. The catalysts were prepared from the mixture of metal acetates as described in the previous paper.[8] Powder X-ray diffraction patterns (XRD) were recorded with an X-ray diffractometer (Rigaku Denki, Rotaflex, RU-200) using Cu Kα radiation. All the $La_{1-x}Sr_xCoO_3$ (calcined above 850°C) used in this work showed diffration peaks only of the perovskite-type structure. Some of the samples are non-stoichiometric, $La_{1-x}Sr_xCoO_{3-\lambda}$. This non-stoichiometry and slight change in XRD observed upon reduction will be discussed in the later sections.

Apparatus. Besides conventional pulse and flow reactors, a circulation system (*ca.* 250 cm^3) was used for the reactions. These were the same as described elsewhere.[8,10]

Procedures. *Pulse Reaction*: The reduction of the catalysts by CO was conducted in the pulse reactor. Prior to the reaction, the catalysts (50 mg) were heated in O_2 stream for 1 h at 300 °C. The flow rate of carrier gas (He) was 30 cm^3 min^{-1} and the size of each CO pulse was usually 0.1 cm^3. Products were analyzed by a gas chromatograph (DMS, 5 m, 0 °C, or Porapak Q, 1.5 m, 83 °C).

Isotopic Exchange and Equilibration of O-18: ^{18}O-exchange between O_2 and perovskites and ^{18}O-equilibration of O_2 in the gas phase were conducted in the closed circulation system. Prior to reaction, the samples (300 mg) were treated with pure O_2 (10 kPa) at 300 °C (with circulation and a trap kept at liquid-nitrogen temperature) and subsequently evacuated for 1 h at 300 °C. O_2 enriched in ^{18}O (70 atom%) was purchased from Japan Radioisotope Association.^{18}O-distributions in O_2 in the gas phase was analyzed by a mass spectrometer (Hitachi Co. Ltd., RMU-S) by intermittent sampling.

Temperature Programmed Desorption (TPD) of Oxygen: TPD of oxygen was carried out with a flow system using helium as a carrier gas. Prior to each run, the samples (0.5 g or 1 g) were treated in an O_2 stream for 1 h at 300 °C and cooled to room temperature in the O_2 stream. Then an He stream was substituted for an O_2 stream at room temperature. Oxygen impurity in He was removed by a molecular sieve trap kept at the temperature of liquid nitrogen. Then the temperature of the sample was raised at the constant rate of 20 °C min^{-1} and the oxygen desorbed was detected by use of a quadrupole mass spectrometer (NEVA, NAG-531).

Results

Temperature Programmed Desorption (TPD) of Oxygen. Figure 1 shows TPD of oxygen from $La_{1-x}Sr_xCoO_3$ (x=0—0.6), where the rate of desorption calculated from the O_2 concentration in the eluent gas is plotted against temperature. It is obvious in this figure that the rate and the amount of O_2 desorption increased with the Sr^{2+} content, x. Oxygen desorbed below 600 °C amounted to 5.4 $cm^3\ g^{-1}$ (1.20 $cm^3\ m^{-2}$) for x=0.6, 2.8 $cm^3\ g^{-1}$ (0.519 $cm^3\ m^{-2}$) for x=0.4, 0.6 $cm^3\ g^{-1}$ (0.14 $cm^3\ m^{-2}$) for x=0.2, and 0.07 $cm^3\ g^{-1}$ (0.028 $cm^3\ m^{-1}$) for x=0. The amounts for x=0.4 and 0.6 corresponded to several layers of oxygen. These desorptograms of x=0—0.4 were reproducible after the heat treatment in an O_2 stream at 300 °C for 1 h. In the case of x=0.6 it was not completely reversible by this treatment, indicating that the rate of re-oxidation for x=0.6 was not rapid enough. For x=0.6, an O_2-treatment longer than 2 h at 300 °C was necessary to reproduce the initial desorptogram.

Figure 2 shows TPD of oxygen from $La_{0.8}Sr_{0.2}CoO_3$ calcined at 850, 900, and 1200 °C. The amount of oxygen desorbed decreased with the calcination temperature. The shapes of the desorptograms were rather similar: The desorption rate increased sharply at 500—600 °C after initial rises at lower temperatures. However, a significant difference was found in the temperature at which the desorption curves first increased: it was about 200 °C for $La_{0.8}Sr_{0.2}CoO_3$ calcined at 850 °C, about 250 °C for 900 °C-calcined sample, and about 350 °C for a 1200 °C-calcined sample. This result demonstrates that the release of oxygen from the bulk of $La_{1-x}Sr_xCoO_3$ becomes more difficult as the calcination temperature increased, even though the catalysts had the same composition.

It is to be noted that the increase in the readiness of oxygen desorption with increasing x was also found for 1200 °C-calcined samples.

Reversible Adsorption of Oxygen. Figure 3 shows the adsorption of oxygen for x=0 and 0.2 measured in the static system (P_{O_2}=10—20 Torr**). The samples were pre-evacuated for 0.5 h at each temperature. The adsorption isotherms exhibited saturation at about 10 Torr. The amount of adsorption increased with

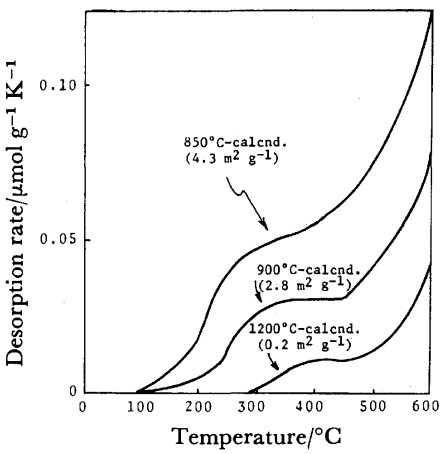

Fig. 2. TPD curves of oxygen from $La_{0.8}Sr_{0.2}CoO_3$ calcined at 850, 900, and 1200 °C. Rate of temperature increase (β)=20 °C min^{-1}.

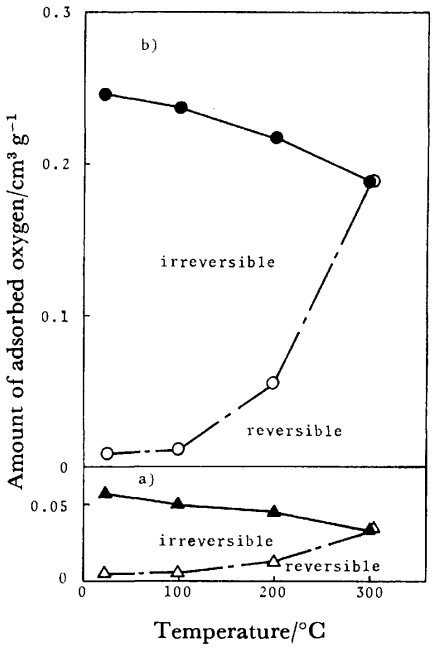

Fig. 3. Adsorption (or absorption) of oxygen by $LaCoO_3$ (a) and $La_{0.8}Sr_{0.2}CoO_3$ (b).
After the catalysts were evacuated at 300 °C for 0.5 h, O_2 was introduced at 300 °C. The solid symbols (▲, ●) at 300 °C represent the amounts of oxygen adsorbed at this stage. Then, the samples were cooled to 200, 100, and 25 °C stepwisely in the presence of O_2 (*ca.* 10 Torr). Solid symbols at each temperature express the cumulative amount of adsorbed oxygen. Open symbols (△, ○) are the amounts of oxygen which were reversibly adsorbed at each temperature. Therefore, the differences between the solid and open symbols are the irreversibly adsorbed oxygen at each temperature.

** 1 Torr≈133.3 Pa.

temperature, and the reversible adsorption of oxygen at room temperature was very small. If one assumes the value of δ to be null at room temperature, the values of δ are calculated to be 0.0049 (after 300 °C-evac.), 0.0012 (at 300 °C in O_2) for $x=0.2$, and 0.0011 (after 300 °C-evac.), 0.00046 (at 300 °C in O_2) for $x=0$.

Reducibility of Catalysts by CO (Pulse Method). Figure 4 shows results of reduction by CO pulses at 200 and 300 °C. The ordinate indicates the conversion of each CO pulse to CO_2, and the abscissa is the sum of CO_2 formed from the pulse and the preceding pulses, which expresses the extent of the reduction of the catalysts. It is noted that $La_{0.8}Sr_{0.2}CoO_3$ was reduced more easily than $LaCoO_3$ and $La_{0.8}Ce_{0.2}CoO_3$. Even after oxygen molecules corresponding to several layers of surface were removed, the reducibility maintained a high level for $La_{0.8}Sr_{0.2}CoO_3$.

This fact indicates that the rate of oxygen supply from the bulk to the surface is very rapid in the case of $La_{0.8}Sr_{0.2}CoO_3$. Rapid diffusion of bulk oxide ion to the surface is further demonstrated by the effect of CO-pulse size on the rate of reduction (Fig. 5). CO was converted completely to CO_2 at 300 °C up to the pulse size of 0.3 cm³, while the formation of CO_2 was almost saturated at 0.1—0.2 cm³ at 150 °C. Since the oxide ion on the surface (by assuming 0.96×10^{19} atom m^{-2} for one surface layer) corresponds to 0.1 cm³ of CO_2, this result demonstrates that the rate of oxygen supply is very fast at 300 °C.

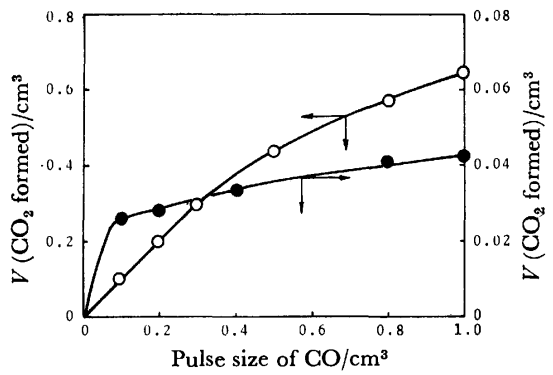

Fig. 5. Effect of pulse size on CO reduction of $La_{0.8}Sr_{0.2}CoO_3$ at 150 and 300 °C.
●: 150 °C, ○: 300 °C.

$LaCoO_3$ was much less reducible than $La_{0.8}Sr_{0.2}CoO_3$. $La_{0.8}Ce_{0.2}CoO_3$ appeared a little more reducible than $LaCoO_3$. However, the difference is small when normalized to the surface area. The conversion of the first CO pulse at 150 °C given in Table 1 demonstrates clearly the trend that the reducibility increases with the Sr^{2+} content.

0	1
0.2	25
0.4	77
0.6	100

a) Pulse size of CO: 0.1cm³.

Re-oxidation of the Reduced Catalysts. When O_2 was pulsed at 300 °C over $LaCoO_3$ and $La_{0.8}Sr_{0.2}CoO_3$ which had been reduced by CO pulses, these catalysts absorbed O_2 until its amount became equivalent to that removed in the preceding reduction, that is, the reduction and re-oxidation cycle was stoichiometric and reversible for these two catalysts. However, in the case of $La_{0.6}Sr_{0.4}CoO_3$ and $La_{0.4}Sr_{0.6}CoO_3$, the reduced catalysts were not fully re-oxidized by O_2 pulse at 300 °C. For example, $La_{0.4}Sr_{0.6}CoO_3$ (reduced by 3%) absorbed 74% of the stoichiometric amount of oxygen. This trend was enhanced at lower temperatures. At 150 °C $La_{0.6}Sr_{0.4}CoO_3$ (3% reduced) absorbed only 19% and $La_{0.4}Sr_{0.6}CoO_3$ (3% reduced) only 10%. The rate of re-oxidation tended to be faster when the catalyst was pre-reduced to a greater extent.

Structural Changes Accompanying the Reduction and Re-oxidation. Changes in XRD upon reduction and

re-oxidation are summarized in Table 2. When the catalysts were reduced by about 5% by CO pulses at 400 °C (to $La_{1-x}Sr_xCoO_{2.85}$ if the sample was $La_{1-x}Sr_xCoO_3$ in the initial state), the diffraction peaks shifted about 0.2—0.5° (2θ) to lower angles. In addition to this shifts, new weak peaks (1.94, 2.06, 2.77 Å) appeared in the case of $LaCoO_3$ and $La_{0.4}Sr_{0.6}CoO_3$. The reduction and re-oxidation of the catalysts are reversible and the structure of the catalysts did not change significantly with reduction.

△: $LaCoO_3$, ○: $La_{0.8}Sr_{0.2}CoO_3$, □: $La_{0.4}Sr_{0.6}CoO_3$.

Isotopic Equilibration and Exchange of Oxygen. Results of isotopic equilibration and exchange are shown in Fig. 6. The reaction was carried out at three different temperatures for each sample in a successive manner without replacing the gas mixture. The times required to increase the reaction temperature from 150 to 200 °C and 200 to 300 °C were 10 and 15 min, respectively. As shown in Fig. 6a, the isotopic equilibration over $La_{0.8}Sr_{0.2}CoO_3$ and $La_{0.4}Sr_{0.6}CoO_3$ proceeded rapidly at 150 °C, and the value of $[^{16}O^{18}O]^2/[^{16}O_2][^{18}O_2]$ was close to 4 at 200 and 300 °C, the value expected at equilibrium. On the other hand, the equilibration was slow over $LaCoO_3$ even at 200 °C. Figure 6b shows the results of isotopic exchange between lattice oxygen and gaseous oxygen. The rate of exchange on $LaCoO_3$ and $La_{0.8}Sr_{0.2}CoO_3$ was slow at 150 and 200 °C, but it became considerably more rapid at 300 °C. Over $La_{0.4}Sr_{0.6}CoO_3$ both reactions proceeded much more rapidly. In this case about 1.01 cm^3 of oxygen was absorbed just after the introduction of oxygen at 150 °C, indicating that desorption of oxygen was significant during the evacuation at 300 °C prior to the reaction. The ^{18}O-content in O_2 after 1 h at 300 °C was 8.4%. This value was not far from 6.5%, which is expected for complete mixing of lattice oxygen and gaseous oxygen.

Discussion

Structure and Stoichiometry of $La_{1-x}Sr_xCoO_3$ Catalysts. It was previously reported that $La_{1-x}Sr_xCoO_3$ formed perovskite structure when x did not exceed 0.8.[12] But according to a recent report,[13] this system forms a complete solid solution in the whole range of x. A slight distortion to rhombohedral exists in $LaCoO_3$, but it decreases gradually as the Sr^{2+} content, x, increases, and above $x=0.6$ the structure becomes cubic.[12] In spite of this distortion the crystal structures are essentially identical and there is only a small variation in the lattice constant of the pseudo cubic cell from 3.82 Å for $LaCoO_3$ to 3.84 Å for $SrCoO_3$.[14] In accordance with these results, the $La_{1-x}Sr_xCoO_3$ used in the present work all showed the perovskite structure.

When Sr^{2+} is partly substituted for La^{3+}(A-site) of $LaCoO_3$, the oxidation state of Co changes from Co^{3+} to Co^{4+}.[14] Although Co^{4+} was confirmed in $BaCoO_3$[15] $SrCoO_{3-\delta}$[16] and $La_{1-x}Sr_xCoO_{3-\delta}$,[14] it is not stable and tends to be reduced by releasing oxygen. For example, it was reported that the value of δ in $SrCoO_{3-\delta}$ is 0.26 when annealed under 50 bar*** of oxygen at 350 °C and 0.05 under 2000 bar at 300 °C.[16] Therefore, it is probable at a high x value that the charge compensation is accomplished by the formation of oxygen vacancies in addition to the Co^{4+} formation. Actually, according to Jonker *et al.*,[14] Co^{4+} is formed without the formation of oxygen vacancy for $x \leqq 0.4$, but oxygen vacancies are formed besides the Co^{4+} formation when x exceeds 0.4. It was recently confirmed with single crystals that stoichiometric $La_{1-x}Sr_xCoO_3$'s were obtained for $x \leqq 0.2$ by annealing in air.[17] Although the samples used in the present investigation were polycrystalline powders and were mostly calcined at a relatively low temperature, the content of Co^{4+} determined by chemical analysis[15,18] was 20 ± 1% for the sample with $x=0.2$, *i.e.*, $La_{0.8}Sr_{0.2}CoO_{3\pm0.005}$. The sample had been calcined at 850 °C, cooled slowly to 25 °C and then treated in oxygen at 300 °C. Final treatment is the same as the pre-treatment for the catalytic reactions. This result was in agreement with the results reported previously.[14,17] The composition was not determined for $x=0.6$, but it is probably close to $La_{0.4}Sr_{0.6}CoO_{2.925}$ (Co^{4+}: 45%), which was observed by Jonker *et al.*[14] For the single crystals of $x=0.5$, δ was estimated to be 0.077.[17] Consequently, δ of $La_{1-x}Sr_xCoO_{3-\delta}$ catalysts, which were calcined at 850 °C and treated in oxygen at 300 °C, may be close to zero for $x=0$ and 0.2, and 0.075 or slightly smaller for $x=0.6$. This trend in δ with the Sr^{2+} content is thus explained by the instability of Co^{4+}, in other words, the chemical potential of lattice oxygen at a given δ increases with the Sr^{2+} content. As discussed below, the changes with x in the readiness of desorption and reducibility of lattice oxygen are explained by this change in the chemical potential of the lattice oxygen.

*** 1 bar = 10^5 Pa.

Structural Changes during the Redox Cycle. When $La_{1-x}Sr_xCoO_{3-\delta}$ (x=0, 0.2, and 0.6) were reduced by 5% (from δ=0 to 0.15 for x=0 and 0.2, and from *ca.* 0.07 to *ca.* 0.22 for x=0.6) by CO at 400 °C, the diffraction peaks shifted to lower angles and the separation of the lattice planes, d, increased by 0.01—0.05 Å (Table 2). The ionic radius of Co^{3+} is 0.61 Å for high spin state and 0.525 Å for low spin state, while the ionic radius of Co^{4+} is 0.518 Å for $SrCoO_3$[16] and 0.476 Å for 2H-$BaCoO_3$.[19] Therefore, the increase of d on reduction may be due to the difference in the ionic radius between Co^{3+} and Co^{4+}; that is, Co^{4+} changed to Co^{3+} by the reduction. Similar increase in d with δ was reported for $SrCoO_{3-\delta}$ (δ=0.05—0.26).[16] New weak peaks were observed for x=0.6 after reduction besides the shifts of the original diffraction peaks. However, no new peaks were observed for x=0.2, although oxygen vacancies are probably less stable for x=0.2. Therefore, a possible explanation of the new peaks for x=0.6 may be as follows. A Sr-rich phase was present in the sample before reduction and a phase similar to $SrCoO_{2.5}$ was formed by reduction from this Sr-rich phase. $SrCoO_{2.5}$ has the brownmillerite structure, which is closely related to the perovskite structure and there is essentially little difference between these two structures, as discussed above.

For x=0, new weak peaks also appeared by reduction. It was reported that $La_4Co_3O_{10}$ and CoO were formed partially by reduction,[20] but the new peaks for x=0 do not agree with those expected for $La_4Co_3O_{10}$ and the diffraction peaks of CoO were not observed. Although the origin of the new peaks for x=0 is not evident, it is probable that oxygen vacancies are formed by reduction, causing crystal distortion, but it did not lead to decomposition or significant change in the structure. XRD peaks of $La_4Co_3O_{10}$+CoO were not observed for $LaCoO_3$, probably because the degree of reduction in this study (δ=0.15) was smaller than that in the literature (δ=0.26: 1.68 wt%).[20]

The starting perovskite structures were reversibly restored by re-oxidation for all reduced samples. Therefore, the fundamental structure of perovskite was presumably preserved during the redox cycle when the extent of reduction was small as in this study.

Adsorbed Oxygen and Lattice Oxygen. First, the amounts of oxygen desorbed from $La_{1-x}Sr_xCoO_3$ by TPD are compared with those from other metal oxides. CuO and Co_3O_4 are among the oxides showing large values; 1.42×10^{-1} cm^3 m^{-2} for CuO (0.17 m^2 g^{-1}) and 3.30×10^{-2} cm^3 m^{-2} for Co_3O_4 (5.7 m^2 g^{-1}) in the temperature range from 25 °C to 560 °C.[21] The amounts for $La_{1-x}Sr_xCoO_3$ were comparable with (for x=0.2) or much larger (for $x\geqq0.4$) than CuO. The amounts of desorbed oxygen correspond to the increase in δ by 0.012 for x=0.2, 0.051 for x=0.4, and 0.097 for x=0.6. If one assumes the surface oxide density to be 0.96×10^{19} atom m^{-2}, those amounts are about 0.7 surface layers for x=0.2 and several layers for x=0.6. Thus, it is obvious that most of the oxygen desorbed was not the adsorbed oxygen but came from the lattice oxygen.

Oxygen adsorbed after evacuation at a certain temperature was greater than oxygen desorbed in TPD up to the same temperature, indicating that the amount of oxygen desorbed in TPD at each temperature had not reached equilibrium. However, the amount was not very far from the equilibrium value. Therefore, although TPD is governed by the rate, it reflects closely the equilibrium properties. This is in accord with the result in Fig. 7, where the second TPD after the interruption mostly reproduced the rest of TPD conducted without the interruption.

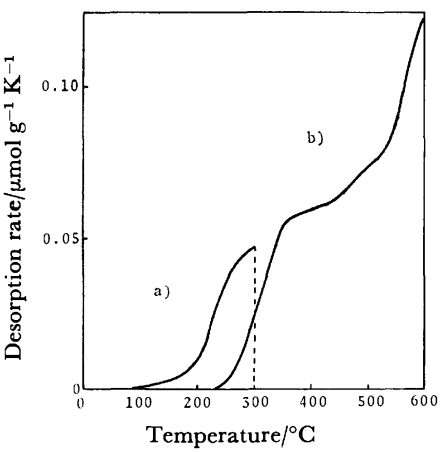

Fig. 7. TPD curues of oxygen from $La_{0.8}Sr_{0.2}CoO_3$.
a): First TPD up to 300 °C, b): second TPD after a) and cooled to room temperature.

The adsorption (and/or absorption) of oxygen at 300 °C was reversible and was saturated at about 10 Torr. When this sample (x=0.2) was cooled to room temperature in oxygen, 0.06 cm^3 g^{-1} of oxygen was adsorbed (absorbed) during the cooling process. The amount of reversible O_2 uptake at room temperature was 2.5×10^{-3} cm^3 g^{-1}, corresponding to a change in δ of 5×10^{-5}, much smaller than the oxygen desorbed in TPD. When the values of δ at 200—300 °C after evacuation (*ca.* 10^{-4} Torr) and under oxygen pressure (*ca.* 10 Torr) (both values increased with x) were plotted against P_{O_2}, difference of several orders of magnitude in the equilibrium pressure of oxygen was found at the same δ value among the samples with different x. Samples having greater x had higher equilibrium pressures of oxygen. That is to say, the chemical potential of lattice oxygen increases enormously with x. This fact confirms again that the results of TPD reflect the chemical potential of lattice oxygen.

As shown in Fig. 2, the release of oxygen from the bulk becomes more difficult for samples calcined at higher temperatures. The result reported previously that the catalytic activities of C_3H_8 oxidation over $La_{0.8}Sr_{0.2}CoO_3$ changed with the calcination temperature and showed a maximum at 850 °C[8] may be explained by the trend seen in TPD of Fig. 2.

In the reduction by CO pulse, the amount of oxygen consumed in one pulse was so large that the CO-pulse experiments reflect mainly the reactivity of lattice oxygen. The conversion of CO increased enormously with x (Table 1) similarly to the trend found with TPD. This similarity between the results of two experiments demonstrates that the reactivity of adsorbed oxygen runs parallel with that of lattice oxygen even if adsorbed

oxygen should exist. It is noted in TPD that the change from oxygen desorbed at low temperature (adsorbed oxygen or weakly bonded lattice oxygen) to oxygen desorbed at higher temperature (lattice oxygen) was continuous and a parallelism was found between the two oxygen species. Probably, it is reasonable not to distinguish between adsorbed and lattice oxygen in the present system.

There was a tendency that re-oxidation became slower on increasing Sr^{2+} substitution, contrary to the case of reduction. The easier reduction and slower re-oxidation with samples having high x mean the equilibrium pressure of oxygen is very much greater for these samples. Actually the equilibrium pressure estimated as above increased tremendously with x. This result will be discussed in more detail in the following paper.

Diffusion of Oxygen in the Bulk and Activation of Oxygen on the Surface. It is known that the diffusion of oxygen in the bulk is rapid in the perovskite-type mixed oxides.[11] We also reported that the diffusion was very rapid during the redox cycle of $La_{0.8}Sr_{0.2}CoO_3$.[22] As shown in Fig. 6b, exchange reaction between gaseous and lattice oxygen occurred under oxygen atmosphere in $La_{1-x}Sr_xCoO_3$, and ^{18}O diffused into the bulk at a considerable rate. The rates of exchange reaction at 150 °C were not so different between $x=0$ and 0.2, 0.0015 $cm^3\ g^{-1}\ min^{-1}$, but the rates at 300 °C were 0.014 $cm^3\ g^{-1}\ min^{-1}$ for $x=0$ and 0.127 $cm^3\ g^{-1}\ min^{-1}$ for $x=0.2$. Sample with $x=0.6$ exhibited a much greater value of 0.045 $cm^3\ g^{-1}\ min^{-1}$, even at 150 °C. Since equilibration was much more rapid and the equilibration usually proceeds *via* dissociation of oxygen in this temperature range, the dissociation of oxygen molecules at the surface is much more rapid than the exchange reaction. Therefore, the rate-determining step of the exchange reaction is probably not the surface reaction but the diffusion in the bulk. The acceleration of the exchange reaction by the Sr^{2+} substitution may be due to the increase in the diffusion rate of oxygen. This is reasonable, if one considers that the diffusion occurs through oxygen vacancies and the amount of the vacancy increases with the Sr^{2+} content. This rapid diffusion of oxygen was revealed also by the results of CO pulse reaction described above.

Finally, the activation of oxygen at the surface will be discussed. The rates of equilibration at 150 °C were 0.037 $cm^3\ g^{-1}\ min^{-1}$ for $x=0$ and 0.35 $cm^3\ g^{-1}\ min^{-1}$ for $x=0.2$. For $x=0.6$ it was not possible to determine the rate of equilibration because of the rapid exchange between gaseous and lattice oxygen even at 150 °C, but the rate appears greater than that for $x=0.2$. Thus, the ability to activate oxygen also increases with x. In $La_{1-x}Sr_xCoO_3$, considerable amount of oxygen vacancies are formed even under oxygen atmosphere as shown in the results of oxygen adsorption, and its amount increased with x. It can therefore be presumed that the equilibration occurs at this surface oxygen defect and the rate becomes faster when the oxygen defects at the surface increases.

Conclusion. In the perovskite-type mixed oxides, $La_{1-x}Sr_xCoO_3$, the reactivity of lattice oxygen, the desorption of oxygen and the reduction tends to become easier as the Sr^{2+} content, x, increases. This is due to the formation of unstable Co^{4+} and the high chemical potential of lattice oxygen. Unstable Co^{4+} changes to Co^{3+}, when oxygen is desorbed and oxygen vacancy is formed. As the vacancy increases, the diffusion of lattice oxygen from bulk to surface becomes easier. In this system, even in an oxygen atmosphere, oxygen vacancies are present and their amount increases with x. This is the reason why the rate of isotopic equilibration of oxygen and exchange between gaseous and lattice oxygen increased with x. Thus, easy formation of oxygen vacancies, keeping its structure unchanged, is the remarkable characteristics of the present mixed oxide system. Relationships between the present results and catalytic activity will be discussed in the following paper.

Catalysis by Heteropoly Compounds. III.† The Structure and Properties of 12-Heteropolyacids of Molybdenum and Tungsten ($H_3PMo_{12-x}W_xO_{40}$) and Their Salts Pertinent to Heterogeneous Catalysis

Makoto Misono,* Noritaka Mizuno, Koichi Katamura, Atsushi Kasai, Yasuo Konishi, Kanji Sakata, Toshio Okuhara, and Yukio Yoneda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 19, 1981)

The fundamental properties of 12-heteropolyacids of Mo and W, such as the structure, the surface area, the acidity, and the reduction-oxidation mechanism, have been studied in their solid state in relation to heterogeneous catalysis. The primary structure (heteropolyanion) was rather stable, but the secondary structure was very variable according to the interaction with various molecules, like water, alcohols, ketones, and pyridine. This structural characteristic is important for the understanding of the catalysis of these compounds; it may be called the "pseudo-liquid phase." The heteropolyacids were all strong protonic acids, as revealed by the interaction with pyridine. The redox cycle was reversible within a limited extent of reduction. The redox mechanism is also discussed in this paper.

Heteropoly compounds have recently attracted much attention as catalysts for various industrial processes, such as oxidation, hydration, esterification, and etheration.[1] Considerable efforts have also been devoted to them in basic studies. It is hoped that the structure of the catalyst can be defined on a molecular scale of the heteropolyanion.[2,3]

We have studied the acidic and redox properties of several heteropoly compounds in their solid state and have attempted to correlate these properties with the catalytic actions.[2] In our opinion, the "pseudo-liquid phase" hypothesis we have proposed represents one of the very important aspects of heteropolyacid catalysis.[4] These studies are, in a sense, an extension of our early efforts at the design of catalysts based on the relationships between the acidity or the oxidizing power and the catalytic activity or selectivity.[5] Possible way of catalyst design based on heteropoly acids has also been discussed before.[6]

In the present paper, we wish to report some of the fundamental properties pertinent to the heterogeneous catalysis of heteropolyacids, such as the structure, the water content, the surface area, the pore-size distribution, and the acidic and redox properties. The heteropolyacids studied are 12-heteropolyacids of Mo and W containing P as the heteroatom.

Experimental

X-Ray Diffraction Powder Pattern. The powder pattern of X-ray diffraction was recorded on an X-ray diffractometer (Rigaku Denki, Rotaflex). When heteropoly acids or their salts were very water-soluble, samples were usually pretreated in nitrogen or helium saturated with water vapor. In the case of heat-treated samples, they were quickly set on a sample holder and covered with a Mylar film.

Infrared Spectra. About a 5-mg portion of the sample was deposited on a silicon plate or pressed into a KBr disk, and the spectra were recorded in an in situ IR cell by means of an FT-IR spectrometer (JEOL JIR-10), as has been described previously.[7,8]

Other Properties. The water content and the amount of pyridine absorption were measured by the use of a quartz spring balance. The surface area and pore-size distribution were measured by means of the absorption of nitrogen. The latter was kindly measured at the Daicel Chem. Ind. Co., Ltd., by the use of a Sorptomatic 1800 apparatus (Carlo Erba), based on the BJH equation.[24]

Materials. $H_3PW_{12}O_{40}\cdot nH_2O$ (A) was prepared according to the literature.[9] $Na_2WO_4\cdot 2H_2O$ (100 g) and $Na_2HPO_4\cdot 12H_2O$ (50 g) were added to 160 ml of decationized water, and the mixture was refluxed at 80 °C with stirring. Then, 24% HCl (150 ml) was added to the solution at 80 °C. After the solution had been concentrated to a volume of 100 ml by evaporation at 50 °C, it was cooled to room temperature. $H_3PW_{12}O_{40}$ was extracted with an equal amount of diethyl ether (with slow agitation after the addition of several drops of 35% HCl). The ether was removed by keeping the etherate at 50 °C. Then it was dissolved in water and concentrated at 50 °C. Recrystallization from an aqueous solution and drying in a KOH-desiccator for 2 d formed $H_3PW_{12}O_{40}\cdot 21—22H_2O$. $H_3PW_{12}O_{40}\cdot nH_2O$ (B) was prepared by extraction with ether from a 50% aqueous solution of $H_3PW_{12}O_{40}$ obtained from the Nippon Inorganic Colour and Chemical Co., Ltd. After evacuation at room temperature, the n value was 6 for both samples.

$H_3PMo_{12}O_{40}\cdot nH_2O$(A) was prepared by extraction with ether from a 50% aqueous solution of $H_3PMo_{12}O_{40}$ obtained from the Nippon Inorganic Colour and Chemical Co., Ltd. The $H_3PMo_{12}O_{40}\cdot nH_2O$(B) was kindly donated by the Climax Molybdenum Co. (Japan), Ltd. Two samples different in source, (A) and (B), behaved very similarly, so that, unless otherwise stated, no distinction of the two samples will be made in the following description.

$H_3PW_6Mo_6O_{40}\cdot nH_2O$ was prepared as follows. $Na_2WO_4\cdot 2H_2O$ (45.1 g), $Na_2MoO_4\cdot 2H_2O$ (33.0 g) and $Na_2HPO_4\cdot 2H_2O$ (8.15 g) were dissolved in 200 ml of decationized water. The solution was kept at 80 °C for 3 h with agitation and then concentrated to 80 ml by the use of an evaporator. Then, 100 ml of 24% HCl was added (the solution was yellow). After extraction with ether at room temperature, the crystal

† Part I: *Proc. 7th Intern. Congr. Catal., Tokyo 1980*, Kodansha, Tokyo, and Elsevier, Amsterdam (1981), p. 1047; Part II: *Nippon Kagaku Kaishi*, accepted for publication.

was obtained in the same way as $H_3PMo_{12}O_{40}\cdot nH_2O$. The other $H_3PW_{12-x}Mo_xO_{40}$'s were similarly prepared.

The alkali salts were prepared by slowly adding equivalent amounts of alkali carbonates (aqueous solution) to the aqueous solutions of heteropolyacids following the methods in the literature.[10] The Na salt was obtained by removing water at 50—60 °C. The K and Cs salts were precipitated from a solution and evaporated to dryness.

Results

XRD and IR. Figure 1 shows the IR spectra and XRD of $H_3PMo_{12}O_{40}$ and some of its salts. These results were briefly reported before.[2] Figure 1 demonstrates that the pattern changed markedly depending on the kind of metal species. The XRD pattern of $H_3PMo_{12}O_{40}$ varied significantly also upon dehydration and rehydration. On the other hand, the IR spectra in the range of 600—1100 cm^{-1} characteristic of the heteropolyanion were quite similar with one another, indicating that the Keggin structure of the heteropolyanion (primary structure) remained unchanged. The changes in the secondary structures upon the dehydration of $H_3PMo_{12}O_{40}$ and its salts have recently been reported by Eguchi *et al.*[11] Their results and conclusion are in general agreement with ours. The IR band at *ca.* 1610 cm^{-1}, which is the bending mode of the water of crystallization, was observed for all salts, the intensity being smaller for K and Cs salts. The band at *ca.* 1720 cm^{-1}, which was presumably to be assigned to $H^+(H_2O)_n$, disappeared upon the salt formation.[8]

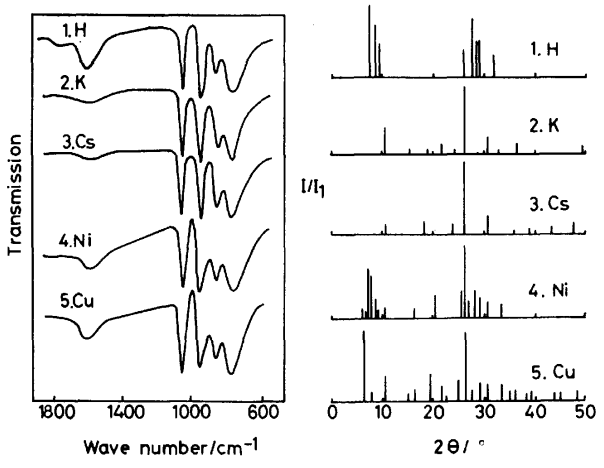

Fig. 1. IR spectra (KBr disk) and X-ray diffraction patterns of $H_3PMo_{12}O_{40}$ and its salts.

The IR spectra characteristic of the Keggin structure changed in a continuous way upon the substitution of Mo with W. The shifts in wave numbers are summarized in Table 1. In Fig. 2, the IR of $K_3PMo_6W_6O_{40}$ is compared with those of $K_3PMo_{12}O_{40}$ and $K_3PW_{12}O_{40}$ (identical XRD patterns were obtained for all of these samples). It may be seen in Fig. 2 that $PMo_6W_6O_{40}$ was not a mixture of $PMo_{12}O_{40}$ and $PW_{12}O_{40}$. Similar changes with the Mo/W ratio were also found for acid forms. However, since the bands were broader for

acid forms, the distinction of $PMo_6W_6O_{40}$ from the mixture of $PMo_{12}O_{40}$ and $PW_{12}O_{40}$ was not possible by IR.

Water Content, Surface Area, and Pore-size Distribution. The changes in the water content and the surface area are shown in Table 2 for $H_3PMo_{12}O_{40}$ and $H_3PW_{12}O_{40}$. The surface area and water content were measured after the samples had been heated in a dry helium stream and after evacuation, respectively, at given temperatures. As we have reported before,[7] the dehydration of $H_3PMo_{12}O_{40}$ proceeded at low temperatures, and the surface area, showing a maximum value when treated at about 100 °C, decreased upon treatment at higher temperatures. The pore-size distribution of $H_3PMo_{12}O_{40}$ (B) is given in Fig. 3a. The surface area as estimated from the pore-size distribution was close to that obtained by the BET method. In the case of $H_3PW_{12}O_{40}$, dehydration proceeded at somewhat higher temperatures, and the change in the surface area was smaller. Two samples different in source gave similar results.

The IR bands of ν_{OH} (≈3600 cm^{-1}) and δ_{H_2O} (≈1610 cm^{-1} for Mo; ≈1700 cm^{-1} for W) due to the water of crystallization disappeared upon evacuation at 25 °C for $H_3PMo_{12}O_{40}$ and at 100 °C for $H_3PW_{12}O_{40}$. The

a) It is assumed that heat treatment at 450°C causes $H_3PM_{12}O_{40} \rightarrow 1/2P_2O_5 + 12MoO_3 + 3/2H_2O$

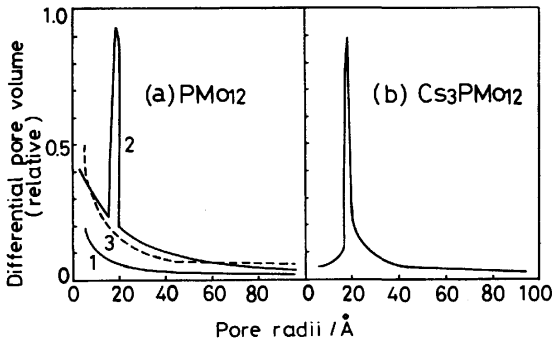

Fig. 3. Pore-size distibution.
(a) $H_3PMo_{12}O_{40}$, 1: treated at 25 °C, 2: at 110 °C, 3: at 300 °C. (b) $Cs_3PMo_{12}O_{40}$, treated at 110 °C.

bands at ≈3200 cm^{-1} of $H_3PMo_{12}O_{40}$, presumably attributable to $H^+(H_2O)_n$, remained below 200 °C, but the 1720 cm^{-1}-band became very small upon 25 °C-evacuation. The ν_{OH} band of $H_3PW_{12}O_{40}$ (3200 cm^{-1}) also decreased, but remained after the evacuation at 200—250 °C, while the bending modes of H_2O and $H^+(H_2O)_n$, which were not clearly separated into two peaks, almost disappeared upon 100 °C-evacuation. The Cs salt exhibited a very high surface area, which decreased upon heat treatment above about 300 °C. An example of the pore-size distribution is given in Fig. 3b.

The observation, by means of a microscope (×100) and a scanning-electron microscope (SEM) (×1000—5000), of the change in the appearance of $H_3PMo_{12}O_{40}$ upon heat treatment is summarized as follows. A sample was, before treatment, constituted of large lustrous particles whose surfaces were covered by fine particles *ca.* 10 μm in diameter. According to SEM, the surface of the particles was irregular (roughness in the order of 1—5 μm: probably primary particles) and had crevices of *ca.* 1 μm. After 100 °C-treatment, SEM indicated that the particles had grown (*ca.* 5 μm), possibly by experiencing partial melting. The surface had become less irregular, but the number and length of crevices (≈1 μm) had increased. After 450 °C-treatment, only aggregated fine particles (≈1 μm) were observed by SEM.

Acidic Properties. We reported previously that a considerable amount of pyridine was absorbed in the bulk of $H_3PMo_{12}O_{40}$.[8] According to the weight measurement,[2,12] $H_3PMo_{12}O_{40}$ and $H_3PW_{12}O_{40}$ absorbed several molecules of pyridine per heteropoly-anion when they were brought in contact with pyridine vapor, and after evacuation at 100—150 °C, three molecules per anion, equivalent to the number of protons, remained in the bulk. The IR spectra showed that pyridine was present exclusively in the form of the pyridinium ion, indicating the formation of pyridinium salts. Broad bands which could be assigned to the ν_{N-H} of the pyridinium ion appeared in some cases at 2500—3000 cm^{-1}, but so far we have not been able to obtain sufficient reproducibility to confirm this band, although it would be good evidence to demonstrate the uniformity of the acid strength.

The acidity was measured by means of the thermal desorption of pyridine from the pyridinium salts. The results are given in Fig. 4. Only a small amount of pyridine was desorbed by the evacuation below about 300 °C in the case of $H_3PW_{12}O_{40}$. An increase in the evacuation period from 1 h to 4 h at 300 °C changed the results little. At 350 °C, the pyridine was removed gradually. In the case of $H_3PMo_{12}O_{40}$, the removal was not significant at 250 °C, but a considerable amount was desorbed above 300 °C. Examination by means of IR revealed that this removal was accompanied by

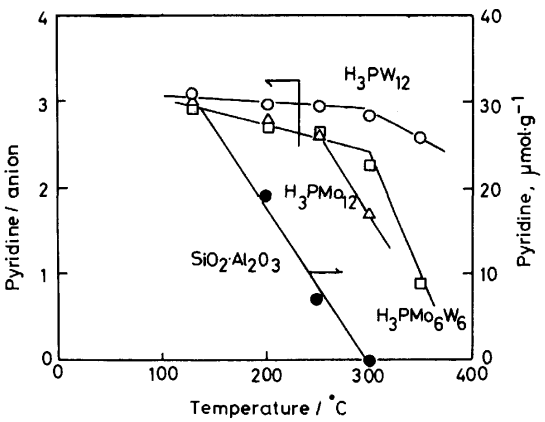

Fig. 4. Thermal desorption of pyridine.
Evacuated for 1 h at each temperature by increasing the temperature stepwise.

a partial degradation of the Keggin structure. The result for $H_3PMo_6W_6O_{40}$ was intermediate.

Redox Properties. The stoichiometry of the reduction by H_2 and re-oxidation by O_2 of $H_3PMo_{12}O_{40}$ has previously been reported.[2,4c] At 200—300 °C, reduction-oxidation by 2 electrons per polyanion proceeded reversibly in a stoichiometric manner. By this redox cycle, the intensity of the IR bands assigned to P–O (1060 cm^{-1}) and Mo–O–Mo (880 and 790 cm^{-1}) changed reversibly. However, when $H_3PMo_{12}O_{40}$ was reduced by 4 electrons per anion, the O_2-uptake was only 36% of the preceding H_2-uptake (72% of the amount required to re-oxidize to the original oxidation state). In this case, the IR spectrum after re-oxidation resembles that before reduction, but it was not identical. The sample pre-reduced by 8 electrons was re-oxidized only to 56%, and the IR spectrum after re-oxidation was significantly different. Reduction at 350 °C by 30 electrons per anion resulted in the formation of a mixture of MoO_3 and MoO_2, as revealed by XRD. Reduction by 3 electrons in the presence of water vapor was nearly reversible.

In the case of the reversible redox cycle, water (collected for 1—2 h by a trap kept at the temperature of liquid N_2) was evolved in both the reduction and re-oxidation steps. In the reduction step at 300 °C, only a half of the H_2 absorbed was collected as water. The rest was collected in the subsequent re-oxidation step, satisfying the stoichiometry, $H_2+1/2O_2\rightarrow H_2O$. As the temperature increased, the water evolved in the first step increased. The fact that only a part of the H_2 observed was collected as water in the reduction step is not likely to be the result of the incomplete desorption of water which had already been formed in this step, because only a negligible amount of water was collected by pumping after the reduction. Therefore, the water collected in the re-oxidation step was probably formed by the reaction with O_2. This idea was confirmed further by the temperature-programmed desorption (TPD) and reduction (TPR).[13] According to TPR, $H_3PW_{12}O_{40}$ was much less reducible than $H_3PMo_{12}O_{40}$.

The reduction processes of other heteropolyacids and the correlation with the catalytic activity were previously reported briefly.[2,14] The details will be reported in forthcoming papers.

Interaction of Heteropolyacids with Inorganic and Organic Molecules. Water: A large amount of water was absorbed or desorbed rapidly in the case of acid forms. When D_2O was brought into contact with $H_3PW_{12}O_{40}$ at 25 °C after evacuation, the IR bands due to the water of crystallization (δ_{H_2O}) exhibited a very rapid shift (in 1 min) from the 1700 cm^{-1}-region to 1272 cm^{-1}.[12] A similar rapid exchange was also found in the case of $H_3PMo_{12}O_{40}$. According to the absorption isotherm of water, about one molecule of water was absorbed per anion at 300 °C for $H_3PMo_{12}O_{40}$ at 10—30 Torr**.

The oxygen exchange between water vapor and the heteropoly anion was also very rapid.[15] The oxygen of the heteropoly anion in the whole bulk (except for PO_4) of $H_3PMo_{12}O_{40}$ and $Cu_{3/2}PMo_{12}O_{40}$ exchanged at 150—250 °C, as was revealed by the IR isotope shifts (10—15 cm^{-1}).

CO_2 and O_2: The ^{18}O-exchange of $H_3PMo_{12}O_{40}$ with CO_2 was much slower than with H_2O. The rate was represented by a first-order rate equation where the whole bulk oxygen atoms participate equally. The exchange with O_2 was still slower, the rate being $H_2O \gg CO_2 \gg O_2$.

Other Molecules: The rate and amount of absorption varied from molecule to molecule. The pretreatment temperature also had an influence on the rate of absorption. For example, the absorption process of acetone was as follows (as monitored by IR bands). Over $H_3PMo_{12}O_{40}$ having about 5 molecules of crystal water (pre-evacuated at 25 °C), the amount of acetone which was absorbed within 30 min at 25 °C increased linearly with the pressure of acetone. However, in the case of $H_3PMo_{12}O_{40}\cdot H_2O$, there was a critical pressure for absorption. Acetone suddenly started to be absorbed when its partial pressure reached 60 Torr. The critical pressure was also observed for acrolein.

Table 3. Absorption (and adsorption) of various molecules by $H_3PW_{12}O_{40}$ at room temperature (molecule/heteropoly anion)

Molecule	Irreversible	Total
Pyridine	6.0	>9
NH_3	3.2	4.3
2-Propanol	6.3	∞
Ethanol	6.2	∞
Methanol	2.2	∞
Benzene	0.1 (0.8)[a]	0.5
Toluene	0.04 (0.4)	0.4
1-Butene	0.2 (1.1)	0.25
Ethylene	0.03 (0.05)	0.04

a) Figures in parentheses are surface coverage.

The amounts of reversible and irreversible adsorption (or absorption) by $H_3PW_{12}O_{40}$ at 25 °C are given in Table 3. The uptake of hydrocarbons was very small. Probably adsorption took place only on the surface. In support of this idea, no change in the IR spectrum was found by contact with butene at 25 °C. On the other hand, polar molecules containing oxygen or nitrogen (O-base and N-base) were adsorbed rapidly, and 2—6 molecules per anion were retained in $H_3PW_{12}O_{40}$ after evacuation. Most of the O-bases were desorbed when evacuated at a slightly higher temperature. For example, changes upon heat treatment in the IR spectra of $H_3PMo_{12}O_{40}$ and $H_3PW_{12}O_{40}$ which had absorbed acetone are shown in Fig. 5. A large portion of the acetone observed for $H_3PMo_{12}O_{40}$ (1100—600 cm^{-1}) were changed to the reduced state after evacuation at 130 °C. When $H_3PMo_{12}O_{40}$ was evacuated at 130 °C in the absence of acetone, such a great change was not observed. In the case of $H_3PW_{12}O_{40}$ pre-evacuated at 25 °C, acetone was more easily absorbed into the bulk at a low pressure. This absorbed acetone was held in the bulk more tightly than in $H_3PMo_{12}O_{40}$. New peaks (1461, 1538, and

** 1 Torr≈133.322 Pa.

1592 cm^{-1}) began to appear at 80 °C, accompanied by a decrease in the bands corresponding to acetone. Then, these new peaks increased with the increase in the evacuation temperature up to 130 °C. Their intensities were reduced at 160 °C.

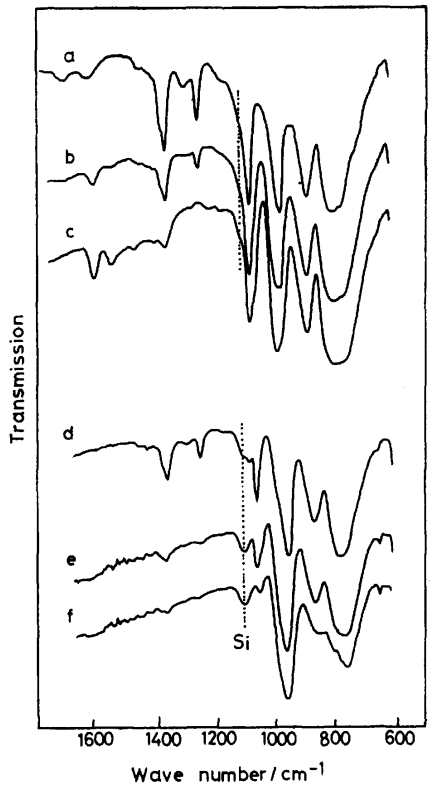

Fig. 5. Thermal desorption of acetone from $H_3PW_{12}O_{40}$ and $H_3PMo_{12}O_{40}$.
$H_3PW_{12}O_{40}$; a: Acetone (60 Torr) and evacuated at 25 °C, b: evacuated at 80 °C, c: evacuated at 130 °C. $H_3PMo_{12}O_{40}$; d: Acetone (120 Torr) and evacuated at 25 °C, e: evacuated at 80 °C, f: evacuated at 130 °C. Samples were pre-evacuated at 25 °C.

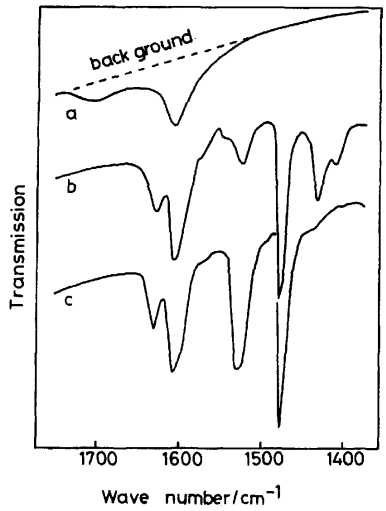

Fig. 6. IR spectral change by the interaction of $H_3PMo_{12}O_{40}$ with pyridine.
a: Evacuated for 30 s at 25° C, b: 1 h after the introduction of pyridine vapor (4 Torr), c: evaculated for 1 h at 130 °C after b.

The absorption of pyridine was followed by means of the IR, as is shown in Fig. 6. As the 1720 cm^{-1}-band and probably also the 1620 cm^{-1}-band disappeared, the 1540 cm^{-1}-band, characteristic of the pyridinium ion, appeared, together with the other bands of absorbed pyridine. Upon evacuation at 130 °C, the bands at 1400—1700 cm^{-1} became identical with that of the authentic pyridinium ion (Fig. 6c).[16] The re-addition of pyridine at 25 °C and evacuation at 130 °C reversibly changed the spectrum between b and c.

Discussion

Primary and Secondary Structure. As is shown by the IR spectra in Fig. 1, the Keggin structure is retained upon salt formation and dehydration (or rehydration). However, the XRD patterns which reflect a three-dimensional regularity vary tremendously. These facts led us to conclude that the "primary structure" (the Keggin unit) of heteropoly acids ($PMo_{12}O_{40}^{3-}$, in this case) is stable, but that the "secondary structure" (the three-dimensional arrangement of the heteropolyanion, water, and the counter cation) is subject to easy rearrangement.[2,4] We consider that a clear distinction between the primary and secondary structures is important for understanding the catalytic action of heteropoly acids. These characteristics make heteropoly acids behave like a solution, and in some cases the catalytic reactions proceed in the interstitial space of the bulk. This is the hypothesis of the "pseudo-liquid phase."[2,4] In this respect, water in the bulk and in the gas phase often plays an important role. Evidence to support the reactions in the bulk has previously been reported.[17,18]

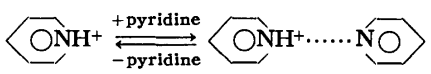
Since the lattice constant of $H_3PW_{12}O_{40}\cdot 29H_2O$ is 23.3 Å,[19a] and since the $H_3PW_{12}O_{40}\cdot 6H_2O$ which is formed by dehydration has the lattice constant of 12.5 Å,[19b] dehydration obviously causes a shrinkage of the unit cell. Adjacent heteropolyanions come much closer when water molecules between the anions are removed. Therefore, the water of crystallization is not zeolitic in this case. The pore-size distribution also supports this idea as has been discussed before.[7] Since the size of the Keggin unit is about 10 Å or a little greater in diameter, the pore size which would be expected from the zeolitic desorption of water should be 5—7 Å in radius for 29-hydrate and 1—2 Å for 6-hydrate. This does not agree with the pore-size distribution observed. Therefore, the pore actually measured must have been formed between fine primary particles which had been shrunk by dehydration. The apparent expansion of the volume by the absorption of water, pyridine, *etc.* also supports the idea that water is not zeolitic. These molecules penetrate into the bulk by expanding the interstitial space. A similar explanation may be applied to water-soluble metal salts. The dehydration-rehydration of 0—2 hydrates probably proceeds in essentially the same way, although no direct evidence has been obtained.

In the case of water-insoluble salts, like K, Cs, and NH_4 salts, almost the same XRD patterns, which were close to the ASTM card of K or NH_4 salt (9-408, 412), were reproducibly obtained, indicating that the secondary structures of these salts are rather stable. Recently, Eguchi, Yamazoe, and Seiyama reported that water is zeolitic for these salts.[11]

Acidic and Redox Properties. The acidic properties (amount, strength, and type (Brønsted or Lewis)) of ordinary solid acids can be determined most reliably when the thermal desorption of pyridine is measured by IR spectroscopy. Therefore, the thermal desorption of pyridine (or the thermal decomposition of pyridinium salt) given in Fig. 4 reasonably reflects the acidic properties of these compounds. The amount of pyridine which remained after evacuation represents the amount of acidic protons, and the change in this amount by the evacuation temperature is related to the acid-strength distribution. Although the number of pyridine did not change by a prolonged period of evacuation, we are still uncertain whether or not these data reflect the true equilibrium. Therefore, we will discuss here only the number of acidic protons and the qualitative trend of the acid strength.

The quantity of pyridine which was not removed by 100—250 °C-evacuation agreed with the total number of protons for three heteropoly acids. Thus, uniform pyridinium salts were formed after this procedure. This uniformity enables us to estimate the number of acidic protons on or near the surface. If one assumes the surface area to be 10 $m^2\ g^{-1}$, and the number of Keggin units on the surface to be 1/100 $Å^2$, the number of the surface acidic proton becomes 50 $\mu eq\ g^{-1}$, which is comparable with the value of 30—50 $\mu eq\ g^{-1}$ of Brønsted sites for SiO_2–Al_2O_3.[21] As for the acid strength, we may conclude qualitatively that heteropolyacids are stronger than SiO_2–Al_2O_3, since the pyridinium ion on SiO_2–Al_2O_3 almost disappears upon evacuation above 300 °C, as is shown in Fig. 4. Pyridine started to be removed at about 250 °C in the case of heteropolyacids containing Mo. However, a partial degradation was indicated by the IR in this case, so that the desorption at lower temperatures does not necessarily mean that their acid strength is weaker than $H_3PW_{12}O_{40}$.

The IR spectra of pyridine absorbed changed by evacuation at 130 °C and the readdition of pyridine at 25 °C, as is shown in Fig. 5. This process was reversible, and the spectrum after evacution (Spectrum d) was identical with the authentic pyridinium salt given in the literature.[16] It was suggested that the 1540-cm^{-1}-band characteristic of the pyridinium ion becomes weak when a dimer ion is formed.[20] Therefore, the change taking place between Spectra b and c in Fig. 5 may be as follows, if one takes into account the fact that the pyridine/proton ratio was about two after evacuation at 25 °C:



The general redox properties have already been discussed by several investigators.[2,4,13,22,23] We will discuss here only the spectral changes in the IR spectra given in Fig. 5. The spectral change in $H_3PMo_{12}O_{40}$ in the 600—1100 cm^{-1} region may be due to the reduction of $H_3PMo_{12}O_{40}$ by acetone, since it is much more reducible than $H_3PW_{12}O_{40}$ and the spectral change resembles that found upon reduction by H_2.[2,13] The new peaks which appeared at 1400—1600 cm^{-1} for $H_3PW_{12}O_{40}$ may be attributed to the mesityl oxide formed from acetone, since mesityl oxide absorbed by $H_3PW_{12}O_{40}$ gave IR bands at 1619, 1442, and 1376 cm^{-1}.

This work was supported in part by Grant-in-Aid for Special Project Research No. 520804 from the Ministry of Education, Science and Culture.

(Received June 26, 1981)

The crystal structure of hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin–*p*-iodoaniline complex, $C_{54}H_{96}O_{30}\cdot C_6H_6NI\cdot H_2O$, was determined by the X-ray method. The crystal is monoclinic with the space group $P2_1$, $Z=2$, $a=11.440(4)$, $b=23.674(6)$, $c=13.531(3)$ Å, and $\beta=91.90(2)°$. The structure was solved by the heavy atom method combined with the rigid-body least-squares technique and refined by the block-diagonal least-squares method to the final *R*-value of 0.11 for 2186 reflections ($\sin\theta/\lambda<0.49$). Hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin is in the shape of a truncated elliptical cone; these cones are stacked along the a axis to form a channel-type structure. The guest *p*-iodoaniline and water molecules are located in the channel. The iodophenyl group is inserted rather loosely from the base side of the truncated cone. The iodine atom is located at the center of the cavity, while the amino group outside the host cavity forms a hydrogen bond with the water molecule. The water molecule is also hydrogen bonded to the adjacent host molecule along the channel. The crystal is built up of columns of the host molecules, which are closely packed in the van der Waals contact.

The chemical modification of cyclodextrins has been investigated to improve complexing and catalytic abilities by introducing various groups into the macrocyclic ring.[1] Permethylation of cyclodextrins gives compounds which are quite interesting in their macrocyclic structure and complex formation, since permethylated cyclodextrins have no hydroxyl groups. Syntheses and some chemical and spectroscopic data have been recently reported,[2-5] but their structural features have not yet published. The crystal structure of hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin(methyl-α-CDx)complex with *p*-iodoaniline has been investigated by the X-ray method. In this paper, the structure of the complex will be discussed mainly by comparison with the structure of α-cyclodextrin–*p*-indoaniline complex.[6]

Experimental

Methyl-α-CDx was added to a *p*-iodoaniline-saturated aqueous solution at 40 °C to prepare a 5% solution. The solution was cooled to 0 °C to dissolve methyl-α-CDx, then allowed to stand at 50 °C. Colorless rod-like crystals were obtained. Lattice parameters and intensities were measured on a Nicolet P3/F diffractometer with graphite-monochromated Cu *Kα* radiation. 2168 independent reflections with $|F_o|\geq 3\sigma(F)$ were obtained up to 90° in 2θ. No corrections were made for absorption and extinction.

Crystal Data. $C_{54}H_{96}O_{30}\cdot C_6H_6NI\cdot H_2O$, *F.W.*=1462.4, monoclinic, space group $P2_1$, $Z=2$, $a=11.440(4)$, $b=23.674(6)$, $c=13.531(3)$ Å, $\beta=91.90(2)°$, $V=3662.6$ Å^3, $D_x=1.326$, $D_m=1.31$ g cm^{-3}.

Determination and Refinement of the Structure

The structure was solved by the heavy atom method. The electron-density map calculated with iodine phases revealed that the methyl-α-CDx ring is located nearly perpendicular to the a axis. But the center of symmetry which appeared in the map made it quite difficult to estimate the position of light atoms. Therefore, the rigid-body least-squares technique was adopted to determine the orientation and disposition of each 2,3,6-tri-*O*-methylglucose residue. Non-iodine atoms in *p*-iodoaniline and water molecules were found on Fourier and difference-Fourier maps. The structure was refined

by the block-diagonal least-squares method. Anisotropic temperature factors were used for *p*-iodoaniline and water, isotropic ones for methyl-α-CDx. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1.0$ for all the reflections. The final *R*-value was 0.11. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[7] The atomic parameters are given in Tables 1 and 2. Tables of observed and calculated structure factors, anisotropic temperature factors of *p*-iodoaniline and water, bond-distances, angles, and conformation angles of methyl-α-CDx are kept at The Chemical Society of Japan (Document No. 8211).

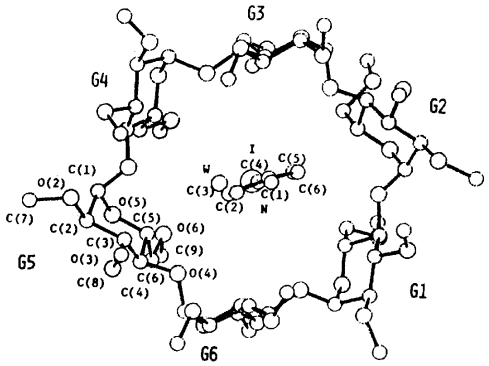

Fig. 1. Structure and numbering scheme of hexakis (2,3,-6-tri-*O*-methyl)-α-cyclodextrin–*p*-iodoaniline monohydrate. The water molecule is denoted by W.

Description and Discussion of the Structure

Outline of the Structure. The structure and numbering scheme of the methyl-α-CDx–*p*-iodoaniline complex are shown in Figs. 1 and 2. Methyl-α-CDx is in the shape of a truncated elliptical cone, and is stacked along the a axis with a head-to-tail fashion to form a channel-type structure, as shown in Fig. 3. About two-thirds of the guest *p*-indoaniline molecules are inserted from the O(2), O(3) side of methyl-α-CDx. The amino group forms a hydrogen bond with the water molecule.

Conformation of Methyl-α-CDx. Average bond distances and angles over six 2,3,6-tri-*O*-methylglucose residues are shown in Fig. 4. Geometrical data for the methyl-α-CDx ring are given in Tables 3—5. The C(6)–O(6) bonds of G1 and G2 residues are in the *gauche-gauche* conformation, the other four C(6)–O(6) bonds

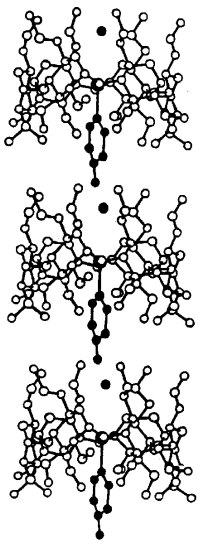

Fig. 3. A stacking feature of the complex. *p*-Iodoaniline and water are shown by black dots.

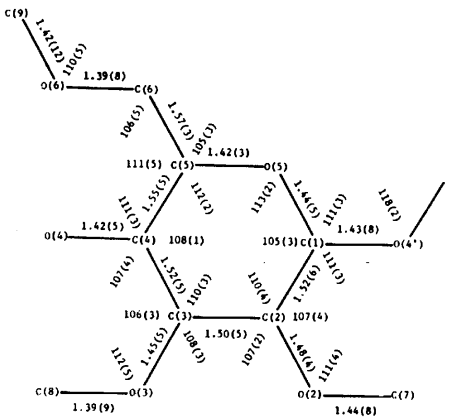

Fig. 4. Average bond distances (l/Å) and angles (ϕ/°) of hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin over six 2,3,-6-tri-*O*-methylglucose residues. Standard deviations in parentheses were estimated according to the equation, $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x}^2)/5]^{1/2}$, where x_i referes to the bond distance or angle in the *i*-th residue and $\bar{x}$ is the average value.

being in the *gauche-trans* conformation. All O(6)–C(9) bonds are *trans* to the C(5)–C(6) bond. The orientations of O(2)–C(7) and O(3)–C(8) bonds are different. All O(2)–C(7) bonds are oriented outside the methyl-α-CDx

Table 4. Least-squares plane through six O(4) atoms and deviations from the plane

The plane equation is of the $AX+BY+CZ=D$ form, where X, Y, and Z are the coordinates in Å units along the a, b, and c* axes, respectively.

$0.9979X+0.0418Y+0.0497Z=1.9499$

Deviations of atoms from the plane (*l*/Å)

O(4,G1)	0.16	O(4,G4)	0.15
O(4,G2)	−0.24	O(4,G5)	−0.24
O(4,G3)	0.08	O(4,G6)	0.08

Table 5. Torsion-angle indices and tilt-angles

Residue	φ/°	Residue	φ/°
I. Torsion-angle index[a]			
G1	160	G4	491
G2	145	G5	142
G3	151	G6	134
II. Tilt-angle[b]			
G1	24.5	G4	23.6
G2	22.6	G5	22.1
G3	3.0	G6	3.0

a) The torsion-angle index is defined as follows: $|\phi(C(1)-C(2))|+|\phi(C(2)-C(3))|+|\phi(C(5)-O(5))|+|\phi(O(5)-C(1))|-|\phi(C(3)-C(4))|-|\phi(C(4)-C(5))|$.

b) The tilt-angle is defined as the angle made by the plane through six O(4) atoms and the plane through O(4′), C(1), C(4), and O(4) of each glucose residue.

ring; the average conformation angles of C(1)–C(2)–O(2)–C(7) and C(3)–C(2)–O(2)–C(7) are 106° and −137°, respectively. On the other hand, the O(3)–C(8) bonds turn inside the methyl-α-CDx ring, giving the average C(2)–C(3)–O(3)–C(8) and C(4)–C(3)–O(3)–C(8) angles of −120° and 123°, respectively.

Methyl-α-CDx is in the shape of an elliptically distorted and truncated cone (Fig. 2). The diagonal O(4)···O(4) distances of 8.27, 8.37, and 8.82 Å are similar to those of the α-cyclodextrin-*p*-iodoaniline complex (8.16, 8.44, and 8.88 Å). The longest diagonal is found along the plane of the included *p*-iodoaniline. The O(4)···O(4) distances between adjacent 2,3,6-tri-*O*-methylglucose residues (4.11—4.36 Å) also resemble those of the α-cyclodextrin–*p*-iodoaniline complex (4.07—4.40 Å). But the torsion angle indices (134—160°) are significantly larger than those of the α-cyclodextrin complex (115—134°), suggesting that the pyranose-ring conformation is slightly different in methyl-α-CDx and α-cyclodextrin.

The deviations of O(4) atoms from their least-squares plane (Table 4) shows that these atoms are arranged in a boat form. The boat form is also observed in the α-cyclodextrin–*p*-iodoaniline complex, although the atomic deviation in the α-cyclodextrin complex is smaller than that in the methyl-α-CDx complex. Significant conformational differences between α-cyclodextrin and methyl-α-CDx are observed in O(2)···O(3) distances between the adjacent residues and tilt-angles. The O(2)···O(3) distances in methyl-α-CDx range from 3.23 to 3.37 Å. On the other hand, the corresponding distances in α-cyclodextrin are in the range 2.68—3.00 Å, indicating hydrogen-bond formation. The relatively large O(2)···O(3) distances in methyl-α-CDx are mainly ascribed to the steric hindrance between O(2) and C(8) methyl group of adjacent residue. As seen from Table 3, relatively short distances are found between O(2) and C(8) (3.04—3.39 Å). The steric hindrance also affects the tilt-angle of the 2,3,6-tri-*O*-methylglucose residues (Table 5). The G3 and G6

Table 6. Intermolecular distances less than 3.5 Å

Distance(*l*/Å)		Distance(*l*/Å)	
O(6,G4)–O(W)	2.77	C(2,G2)–O(5,G4)	3.43(c)

N(IA)–O(W)	2.49(a)	O(6,G2)–C)2,G4)	3.38(c)
C(1,IA)–O(W)	3.43(a)	O(6,G2)–O(3,G4)	3.39(c)
C(2,IA)–O(W)	3.39(a)	C(9,G1)–O(3,G5)	2.95(d)
C(7,G3)–O(3,G6)	3.47(b)	O(6,G1)–O(3,G5)	3.46(d)
O(3,G3)–C(7,G6)	3.38(b)		

Code	Symmetry operator		
None	x,	y,	z
a	$1+x$,	y,	z
b	x,	y,	$-1+z$
c	$-x$,	$1/2+y$,	$-z$
d	$-x$,	$1/2+y$,	$1-z$

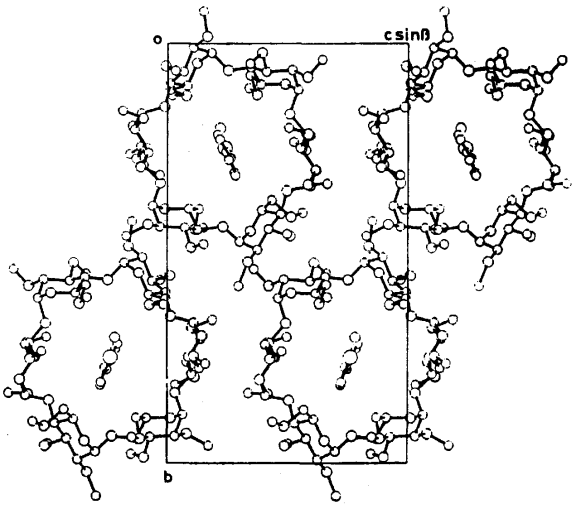

Fig. 5. Crystal structure viewed down the a axis.

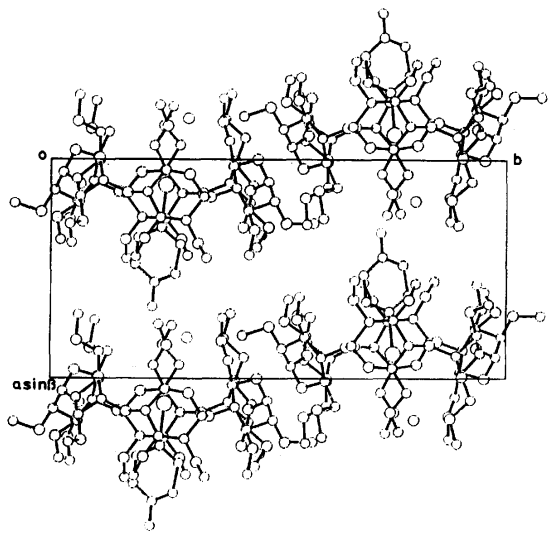

Fig. 6. Crystal structure viewed down the c axis.

residues are almost perpendicular to the O(4) plane, but the other four residues are tilted by the angles of 22.1—24.5°. In the α-cyclodextrin–*p*-iodoaniline complex, the tilt-angles are in the range from 2.1 to 15.6°, and the average value (10.8°) is smaller than that of methyl-α-CDx (16.7°). The conformation of α-cyclodextrin is held by the O(2)···O(3) hydrogen bonds. Since methyl-α-CDx forms no intramolecular hydrogen bonds, the macrocyclic conformation may be more responsible for the steric hindrance between 2,3,6-tri-*O*-methylglucose residues, host-guest interaction, and molecular packing in the crystal.

Methyl-α-CDx–Guest Interaction. *p*-Iodoaniline molecule is inserted into the methyl-α-CDx ring from the O(2), O(3) side, and about two-thirds of the molecule is included. The shortest methyl-α-CDx···guest distance is 3.87 Å, which is found between O(4,G1) and C(5,1A). Therefore, *p*-iodaniline is rather loosely bound in the methyl-α-CDx cavity. The benzene ring is nearly parallel to the C(2,G2)···C(2,G5) diagonal, along which the methyl-α-CDx is elliptically distorted. The iodine atom is located at the center of the cavity. This inclusion geometry is different from that of the α-cyclodextrin complex, in which the whole iodophenyl group is tightly included, although *p*-iodoaniline is also inserted from the O(2), O(3) side. In the methyl-α-CDx complex, the deep penetration of *p*-iodoaniline may be interrupted by the large tilt of G1, G2, G4, and G5 residues, making the O(6) side narrower. The amino group is hydrogen-bonded to a water molecule located at the O(6) side of the adjacent methyl-α-CDx. The water molecule is also hydrogen-bonded to the O(6) atoms of G4 and G5 residues, thus forming $-NH_2\cdots$ water···O(6) hydrogen-bond bridges.

Molecular Packing. Methyl-α-CDx molecules are stacked along the a axis to form a typical channel-type structure. This packing feature resembles those of the α-cyclodextrin complexes with *m*-nitroaniline[8] and benzaldehyde.[9] But, owing to the methylation of all hydroxyl groups, no hydrogen bonds can be formed between methyl-α-CDx molecules along the channel. The O(4) plane is nearly perpendicular to the channel axis (86.3°). *p*-Iodoaniline and water molecules are alternately arranged in the channel. The α-cyclodextrin–*p*-iodoaniline complex does not form a channel-type structure because the dimension of *p*-iodoaniline is large compared with the repetition unit of the channel. In contrast, the repetition unit in the methyl-α-CDx complex is larger than the size of the guest *p*-iodoaniline; thus, a water molecule is also located in the channel to fill the vacant space.

Projections of the crystal structure are shown in Figs. 5 and 6. Since the two-fold screw axis is perpendicular to the channel axis, methyl-α-CDx in the symmetry-related column are arranged upside down. The methyl-α-CDx columns are closely packed in the crystal (Fig. 5). A somewhat short contact (2.95 Å) is found between C(9,G1) and O(3,G5), but other intermolecular distances (Table 6) indicate that the methyl-α-CDx columns are in the van der Waals contact.

(Received June 30, 1981)

The algorithm for data processing in correlation NMR spectroscopy has been closely checked. Procedures have been proposed by which one can obtain the spectrum free from artifacts and can carry out phase correction of the spectrum easily.

In correlation NMR spectroscopy developed by Dadok and Sprecher,[1] the steady-state spectrum is derived from the response to a linear rapid frequency scan. In previous papers,[2-8] we have described a system where a variety of capabilities were incorporated to allow additional freedom in the correlation technique. So far we have written several programs which are based on different algorithms for dealing with the rapid scan response. It has been noticed that in some cases, even when the baseline of the rapid scan response is sufficiently flat, the finally obtained spectrum is accompanied by an oscillation which is spread over the entire range of frequency. In view of this, the algorithm for data processing in correlation NMR has been closely checked. It will be shown how improper ways of data processing result in artifacts in the final steady-state spectrum. Procedures will be described by which one can obtain the spectrum free from artifacts and can make phase correction of the spectrum easily.

Data Processing of Correlation NMR Spectroscopy

It has been shown[9] that the steady-state NMR spectrum $H(f)$ can be obtained by Fourier transforming the free induction decay $h(t)$ which is given by

$$h(t) = g(t)\exp(-ibt^2/2), \tag{1}$$

where $b/2\pi$ is the sweep rate of the linear rapid frequency scan in Hz/s, and $g(t)$ is the inverse Fourier transform of the rapid scan response $G(f)$ which is observed after the phase sensitive detection of the radio frequency. It will hereafter be assumed that the rapid scan response $G(f)$ is sampled using N data points at a time interval of Δt s or at every $\Delta f = b\Delta t/2\pi$ Hz of the spectrum. The values of $G(f)$ at $s\Delta t$ s and at frequency positions of $s\Delta f$ Hz where $s=0,1,\cdots,N-1$ will be denoted by $G[s]$.

Quadrature Phase Detection. The quadrature phase detection of the rapid scan response would provide $G[s]$ expressed in complex numbers as

$$G[s] = X[s] + iY[s], \quad s=0, 1,\cdots, N-1, \tag{2}$$

where $X[s]$ and $Y[s]$ are the response in quadrature. Inverse Fourier transformation of $G[s]$ gives $g[k]$,

$$g[k] \equiv A[k] - iB[k] = (1/N)\sum_{s=0}^{N-1}(X[s] + iY[s])\exp(2\pi iks/N), \quad k=0, 1,\cdots, N-1, \tag{3}$$

where

$$A[k] = 0, \quad k = N/2 + 1, N/2 + 2,\cdots, N-1, \tag{4a}$$

$$B[0] = 0, \tag{4b}$$

$$B[k] = 0, \quad k = N/2, N/2 + 1,\cdots, N-1. \tag{4c}$$

The $N/2+1$ values of $A[k]$ and $B[k]$ ($k=0,1,\cdots, N/2$) are used to calculate the discrete values $h[k]$ ($k=0,1,\cdots, N/2$) of the free induction decay $h(t)$ at $k\delta t$ s where

$$\delta t = 1/N\Delta f = 2\pi/Nb\Delta t, \tag{5a}$$

which is given by

$$h[k] \equiv D[k] - iE[k] = (A[k] - iB[k])(\cos(b(k\delta t)^2/2) - i\sin(b(k\delta t)^2/2)), \quad k=0, 1,\cdots, N/2, \tag{6a}$$

with

$$E[0] = 0. \tag{6b}$$

The N values $H[s]$ ($s=0,1,\cdots,N-1$) which represent the steady-state spectrum $H(f)$ at $s\delta f$ Hz where

$$\delta f = 1/N\delta t = b\Delta t/2\pi = \Delta f \tag{5b}$$

can be derived by putting

$$D[k] - iE[k] = 0, \quad k = N/2 + 1, N/2 + 2,\cdots, N - 1, \tag{7}$$

and Fourier transforming $h[k]$ ($k=0,1,\cdots,N-1$) according to the following equation:

$$H[s] \equiv U[s] + iV[s] = \sum_{k=0}^{N-1}(D[k] - iE[k])\exp(-2\pi isk/N), \quad s = 0, 1,\cdots, N - 1. \tag{8}$$

The phase correction of the spectrum is performed by mixing $U[s]$ and $V[s]$,

$$U[s]' = U[s]\cos\theta + V[s]\sin\theta, \quad s = 0, 1,\cdots, N - 1, \tag{9a}$$

$$V[s]' = -U[s]\sin\theta + V[s]\cos\theta, \quad s = 0, 1,\cdots, N - 1. \tag{9b}$$

Single Phase Detection. In the case of single phase detection which is generally used, inverse Fourier analysis of the rapid scan response $X[s]$ ($s=0, 1,\cdots, N-1$) in Eq. 2 gives

$$A[k]' = (1/N)\sum_{s=0}^{N-1}X[s]\cos(2\pi ks/N), \quad k = 0, 1,\cdots, N/2, \tag{10a}$$

$$B[k]' = -(1/N)\sum_{s=0}^{N-1} X[s]\sin(2\pi ks/N),$$
$$k = 1, 2, \cdots, N/2-1, \quad (10b)$$
$$B[0]' = B[N/2]' = 0. \quad (10c)$$

It should be noted that $A[k]'$ and $B[k]'$ in Eq. 10 are related to $A[k]$ and $B[k]$ obtained by Eq. 3 as in the following:

$$A[0] = A[0]', \quad (11a)$$
$$A[k] = 2A[k]', \quad k = 1, 2, \cdots, N/2-1, \quad (11b)$$
$$A[N/2] = A[N/2]', \quad (11c)$$
$$B[0] = B[0]' = 0, \quad (11d)$$
$$B[k] = 2B[k]', \quad k = 1, 2, \cdots, N/2-1, \quad (11e)$$
$$B[N/2] = B[N/2]' = 0. \quad (11f)$$

In order to calculate the steady-state spectrum with a phase correction angle of θ, the free induction decay $h[k]$ ($k=0,1,\cdots,N/2$) is obtained by Eq. 6 after Eq. 11 is applied to $A[k]'$ and $B[k]'$ ($k=0,1,\cdots,N/2$), which is modified to $D[k]'$ ($k=0,1,\cdots,N/2$) and $E[k]'$ ($k=1,2,\cdots,N/2-1$) by the following relation:

$$D[0]' = D[0]\cos\theta, \quad (12a)$$
$$D[k]' = (1/2)(D[k]\cos\theta + E[k]\sin\theta),$$
$$k = 1, 2, \cdots, N/2-1, \quad (12b)$$
$$D[N/2]' = D[N/2]\cos\theta, \quad (12c)$$
$$E[k]' = -(1/2)(D[k]\sin\theta - E[k]\cos\theta),$$
$$k = 1, 2, \cdots, N/2-1. \quad (12d)$$

Inverse Fourier synthesis of $D[k]'$ and $E[k]'$ is then performed to give N values of the phase-corrected steady-state spectrum $U[s]'$,

$$U[s]' = D[0]' + 2\sum_{k=1}^{N/2-1}(D[k]'\cos(2\pi sk/N) - E[k]'\sin(2\pi sk/N)) + D[N/2]'\cos(\pi s),$$
$$s = 0, 1, \cdots, N-1. \quad (13)$$

Discussion

For the convenience of the following discussion, a schematic diagram of the algorithms of correlation NMR is illustrated in Fig. 1, where Procudure A and Procedure B correspond to the cases of quadrature phase and single phase detections described in the previous section, respectively.

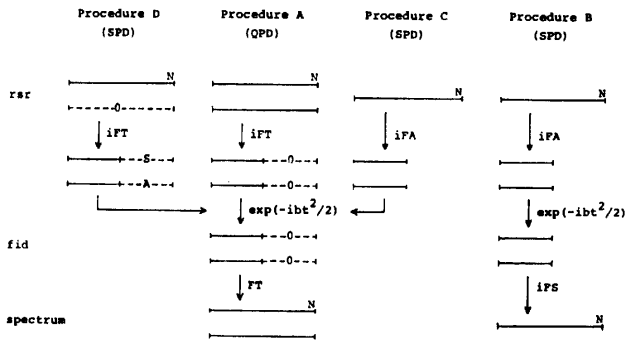

Fig. 1. Schematic diagram of the algorithms of correlation NMR spectroscopy. The symbols iFT, FT, iFA, and iFS stand for inverse Fourier transformation, Fourier transformation, inverse Fourier analysis, and inverse Fourier synthesis, respectively.

It is necessary for correct data processing in the correlation technique that the in-phase component $U[s]'$ of the spectrum becomes identical to the rapid scan response $X[s]$ when the phase correction angle θ is zero and the sweep rate b is extrapolated to zero. Procedures A and B satisfy this condition. What is important in obtaining the correct result is that $N/2+1$ points rather than $N/2$ points of the free induction decay have to be calculated by Eq. 6 before Eq. 8 or Eq. 13 is used to obtain the spectrum. Unless the $N/2+1$st point of the free induction decay is used in the calculation, an oscillation appears which is equally spread over the entire range of the spectrum. This point will also be discussed later.

In the case of single phase detection which is generally used, a most natural way in mathematical sense to obtain the spectrum is to use a combination of inverse Fourier analysis (Eq. 10) and inverse Fourier synthesis (Eq. 13) as shown in Procedure B. This procedure is equivalent to what has been given by Patt.[10] A disadvantage of Procedure B to Procedure A is that whenever one wants to change the phase of the spectrum, one has to go back to the free induction decay $D[k]'$ and $E[k]'$ by performing inverse Fourier analysis of the phase-corrected spectrum $U[s]'$, and inverse Fourier synthesize it again using the appropriate value of θ (Eqs. 12—13). When one wants to change the phase of the spectrum by mixing its in-phase and out-of-phase components (Eq. 9), Procedure A should be followed starting with the rapid scan response observed by quadrature phase detection. In this case, a combination of inverse Fourier transform (Eq. 3) and Fourier transform (Eq. 8) of complex numbers is employed to obtain the spectrum.

It should be noticed that, even when single phase detection is employed, the in-phase and out-of-phase components of the spectrum can be calculated and the phase correction of the spectrum can easily be made by mixing these components if one uses a combination of Eqs. 10—11 and Eqs. 6—9 as shown in Procedure C of Fig. 1. In this case, the free induction decay is calculated by Eq. 6 after $A[k]'$ and $B[k]'$ are modified to $A[k]$ and $B[k]$ using Eq. 11; Eps. 7—9 involving Fourier transformation of complex numbers are then used to obtain the phase-corrected spectrum.

Another way of dealing with the single phase detected rapid scan response $X[s]$ ($s=0,1,\cdots,N-1$) is to inverse Fourier transform it assuming that its imaginary part $Y[s]$ ($s=0,1,\cdots,N-1$) is all zero as shown in Procedure D of Fig. 1. This procedure is similar to the one outlined by Gupta, Ferretti, and Becker[9] without detailed discussion on the algorithm and the values of the calculated data. It can be shown that the values $A[k]'$ and $B[k]'$ obtained by the inverse Fourier transformation of $X[s]$,

$$g[k]' \equiv A[k]' - iB[k]'$$
$$= (1/N)\sum_{s=0}^{N-1} X[s]\exp(2\pi iks/N),$$
$$k = 0, 1, \cdots, N-1, \quad (14)$$

are identical to those given by Eq. 10 for $k=0,1,\cdots,N/2$

and that

$$A[k]' = A[N-k]', \quad k = N/2+1, N/2+2, \cdots, N-1, \tag{15a}$$

$$B[k]' = -B[N-k]', \quad k = N/2+1, N/2+2, \cdots, N-1. \tag{15b}$$

Therefore, after $A[k]$ and $B[k]$ ($k=0,1,\cdots,N/2$) are obtained using Eq. 11, the phase-corrected spectrum can be calculated by Eqs. 6—9 just as in the case of quadrature phase detection.

In Procedures B, C, and D, it must always be remembered that $A[k]'$ and $B[k]'$ where $k=1,2,\cdots,N/2-1$ are to be multiplied by a factor of two to obtain $A[k]$ and $B[k]$ ($k=0,1,\cdots,N/2$) according to the relation in Eq. 11 before Eq. 6 is used to calculate the free induction decay. This is closely related to the fact that the first and $N/2+1$st points of $A[k]'$ are different from others in a sense that these two points are equal in magnitude to $A[0]$ and $A[N/2]$ which would be observed when quadrature detection is employed with two detectors each of which has kept its gain exactly the same as in the case of single phase detection; as far as other points ($k=1,2,\cdots,N/2-1$) are concerned, the coefficients $A[k]$ and $B[k]$ are twice as large as $A[k]'$ and $B[k]'$. If $A[k]'$ and $B[k]'$ where $k=0,1,\cdots,N/2$ are substituted into Eq. 6 to obtain the free induction decay, an oscillation appears in the final spectrum in addition to that the magnitude of the spectrum is half as large as it should be. This oscillation is exactly the same in origin as the one observed when the $N/2+1$st point of the free induction decay is eliminated in Eq. 8 or Eq. 13. What actually happens is that the baseline level for the even-numbered points of the obtained spectrum is different from that for the odd-numbered points. Another kind of artifact which is observed when one fails to modify $A[k]'$ and $B[k]'$ is that the average value of the spectrum depends on the value of first point of the free induction decay which is calculated from the rapid scan response and on the number of sampling points. In this case, it would become impossible to compare the intensities of signals from two or more spectra simply by reading their values.

A different type of oscillation which is inherent in correlation NMR appears when the baseline of the rapid scan response is tilted. This can effectively be removed by *wing processing* which has been previously described.[6,8]

One can obtain a smoothed spectrum $U[s]'$ at $s\delta f/m = sb\Delta t/2m\pi$ Hz where $s=0,1,\cdots,mN-1$ when *zero supplement*[6,11] of the free induction decay is carried out to make it m times in length; equation 7 is replaced by

$$D[k] - iE[k] = 0, \quad k = N/2+1, N/2+2, \cdots, mN-1, \tag{16}$$

to get $h[k]$ ($k=0,1,\cdots,mN-1$), or Eq. 12c is replaced by

$$D[N/2]' = (1/2)D[N/2]\cos\theta \tag{17a}$$

and Eqs. 12a—b, 17a, and 12d are supplemented by

$$D[k]' = 0, \quad k = N/2+1, N/2+2, \cdots, mN/2, \tag{17b}$$

$$E[N/2]' = -(1/2)D[N/2]\sin\theta, \tag{17c}$$

$$E[k]' = 0, \quad k = N/2+1, N/2+2, \cdots, mN/2-1, \tag{17d}$$

to get $D[k]'$ ($k=0,1,\cdots,mN/2$) and $E[k]'$ ($k=1,2,\cdots,mN/2-1$) before Fourier transformation or inverse Fourier synthesis to obtain mN data points is made, respectively. Although the values $U[s]'$, $s=0,m,2m,\cdots,(N-1)m$, obtained by these procedures are equal to $U[s]'$, $s=0,1,2,\cdots,N-1$, which are obtained without *zero supplement*, the values of the interpolated points $U[s]'$, $s\neq 0,m,2m,\cdots,(N-1)m$, which lie near either end of the spectrum become different from what they should be even when the sweep rate b is extrapolated to zero. In this case, the method of *wing processing*[6] has also been proved useful in order to decrease the error of the interpolated values.

In the case of conventional pulse Fourier transform NMR, Fourier analysis of the free induction decay is performed to obtain the spectrum; N' points of the free induction decay is Fourier analyzed to give the in-phase and out-of-phase spectra each of which is made of $N'/2+1$ data points. On the other hand, in the case of quadrature phase detection pulse Fourier transform NMR, a set of $N'/2$ points of the free induction decay observed in quadrature is used to obtain $N'/2$ points of the in-phase and $N'/2$ points of the out-of-phase components of the spectrum. A similar procedure can be used in the case of correlation NMR. The free induction decay in Eq. 6 is modified to

$$h[k]'' \equiv D[k]'' - iE[k]'', \quad k = 0, 1, \cdots, N/2-1, \tag{18}$$

using the relation

$$D[0]'' - iE[0]'' = (D[0] + D[N/2]) - i(E[0] + E[N/2]), \tag{19a}$$

$$D[k]'' - iE[k]'' = D[k] - iE[k], \quad k = 1, 2, \cdots, N/2-1, \tag{19b}$$

and the spectrum $H[s]''$ which consists of $N/2$ data points is obtained by Fourier transforming $N/2$ data points of $h[k]''$. The values $H[s]''$, $s=0,1,2,\cdots,N/2-1$, obtained by this procedure are equal to $H[s]$, $s=0,2,4,\cdots,N-2$, obtained by Eq. 8. The phase correction of the spectrum can then be done by mixing the in-phase and out-of-phase components of $H[s]''$.

It should be noted that in quadrature phase detection pulse Fourier transform NMR, N' points of the in-phase and N' points of the out-of-phase components of the spectrum can be calculated from a set of $N'/2+1$ points of the free induction decay if one follows the procedure in Eqs. 7—9. In this case, one has to have a size of computer memory which is twice as large as what is needed to store the free induction decay. If one follows the procedure in Eqs. 12—13 involving inverse Fourier synthesis, one obtains N' points of the phase-corrected spectrum without having an additional size of memory at a sacrifice of convenience of the phase correction.

The authors wish to express their hearty gratitude to Prof. Shizuo Fujiwara for his continuous encouragement throughout the present work.

Solvent Effects on the Intensities of Forbidden Bands of Molecules. Absorption Spectra of Acetone and Cyclopentanone[1]

Kenichi NAKASHIMA,† Kuniko UCHIDA-KAI, Motohiko KOYANAGI,* and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 13, 1981)

The near ultraviolet absorption spectra of acetone and cyclopentanone have been studied in various fluid solutions at room temperature. The intensity enhancements observed are ascribed to perturbation of dispersion forces between solute and solvent molecules. The results are parallel to those of the Ham effect in benzene. No correlation was found between the intensity increments and solvent polarities. This is at variance with the correlation that has been reported in the $S_1(L_b)$—S_0 transition spectra of pyrene and coronene.

Many investigations have been reported on solvent effects for electronically forbidden transitions of molecules[2–14] since the first finding of the "Ham bands" in the 260 nm absorption spectrum of benzene in a solid solution containing 7% CCl_4.[12] From a systematic study on the $S_1(L_b)$←S_0 absorption spectra of benzene, naphthalene, and phenanthrene in solid glasses at 83 K, Durocher and Sandorfy have suggested that the environmental perturbation causing the Ham effect of benzene is essentially the same for the others.[6] One of the authors (M. K.) has derived the formulas by which the absorption enhancements of benzene and naphthalene are closely correlated with solvent polarizabilities and solute-solvent intermolecular distances.[9]

An interesting example of solvent perturbations was demonstrated in the absorption and fluorescence spectra of pyrene and coronene in polar solvents by Nakajima.[11,15] The intensity enhancements of the origin bands in the S_1—S_0 spectra of pyrene and coronene were found closely correlative with solvent polarities rather than with solvent refractive indexes. This correlation is at variance with the Ham effect in benzene and similar effects in the other aromatic compounds.[7,10] Very recently, Nakajima also proposed that quadrupole-dipole interactions should be taken into account[15] besides dipole-dipole interactions which have been employed for the explanation of the Ham effect by Koyanagi.[9] On the other hand, Lianos and Georghiou have suggested on the basis of the IR studies that a weak complex is formed between pyrene and a certain polar solvent.[16] By studying the $S_2(L_a)$←S_0 absorption spectra in several polar solvents, we have also confirmed the validity of their suggestions.[17]

In the present work we studied the $S_1(n\pi^*)$←S_0 absorption spectra of acetone and cyclopentanone in various solvents and found that the correlation of the absorption increments with solvent properties is very similar to those in benzene and naphthalene.

Experimental

Materials and Apparatus. The solutes, acetone (Dotite Spectrosol) and cyclopentanone (a reagent from Wako Pure Chemical Industries, Ltd.), were distilled *in vacuo* after drying over anhydrous potassium carbonate and anhydrous sodium sulfate, respectively. The solvents employed were of spectroscopically pure grade (Dotite Spectrosol) except benzonitrile and perfluorohexane (GR grade reagents from Wako Chemical Industries, Ltd. and Tokyo Kasei Co. Ltd., respectively). Almost all of the solvents were thus used without further purification. The exceptions are for benzene, toluene, and benzonitrile. Since these aromatics in the atmosphere have well been known to give poor transparency below 350 nm due to formation of transient complexes with oxygen, *i.e.*, the so-called contact charge transfer complexes,[18,19] nitrogen gas was bubbled into the solvents prior to use.

Absorption spectra were observed at room temperature using a Shimadzu Multipurpose Spectrometer type MPS-50 and/or a Hitachi Perkin-Elmer 139 UV-VIS Spectrometer. Cells employed were of 1.0 cm in optical path. The other experimental conditions are similar to those given previously.[5]

Intensity Measurements. The *f*-values of the absorption spectra of two ketones were determined by means of the usual expression of the integrated absorption intensity:[20]

$$f = 4.317 \times 10^{-9} \int_{pq} \varepsilon(\tilde{\nu}) d\tilde{\nu},$$

where the integral denotes the area under a plot of molecular extinction coefficients ε in $dm^3\ mol^{-1}\ cm^{-1}$ units *versus* $\tilde{\nu}$ in cm^{-1} units. The alphabetical indexes p and q limit the wavenumber range within which the $S_1(n\pi^*)$←S_0 absorption of light in effect takes place. The substantial absorptions of acetone and cyclopentanone extend, in many cases, from 29800 to 45400 cm^{-1} and 28000 to 43500 cm^{-1}, respectively (for example, see Figs. 1—4). Unfortunately, however, several solvents showed poor transparency in the short wavelength region of the absorption spectra in question and only a part of each absorption system was measurable in these solutions. The *f*-value of each ketone in such a case was then obtained by comparing the partial absorption area in the solution with the corresponding area in cyclohexane used as a standard solvent: On an assumption that a change in the frequencies of the prominent vibrations in the spectra of the ketones is little with a change in solvents, the wavelength truncation in these solutions was carried out at an equal wavenumber position from the absorption maximum in the case of acetone and also at an equal wavenumber position from one of the prominent vibronic peaks in the case of cyclopentanone. The solvents treated in this way are $CHCl_3$, CCl_4, benzene, toluene, and benzonitrile.

Molecular Radii and Other Molecular Properties. The molecular radii employed were calculated using molecular weights and densities available for the liquid states, on an assumption that all the molecules are spherical. No correction factor was taken for the assumption of the spherical volume. The polarizability data[21] is summarized in Table 1 together with other properties of solvents.[22,23]

Results and Discussion

In their electronic ground states, both acetone and cyclopentanone can be treated as a nonrigid species belonging to a point group isomorphous with C_{2v}. No matter what it may be, however, the $S_1(n\pi^*)\leftarrow S_0$ absorption transition of each molecule is considered to be essentially electric dipole forbidden.[24-26)] The very small oscillator strengths observed confirm that this is the case.

The absorption spectra of acetone and cyclopentanone were studied in various solvents at room temperature. Some representative spectra are shown in Figs. 1 and 2, respectively. The spectra of acetone do not show any prominent vibronic band, but only a broad band maximum around 36000 cm^{-1}. This broadness in the spectra is assumed to come from (i) a low energy barrier to rotation of the methyl group about the bond to the C=O chromophore (*e.g.*, ≈3.15 kJ mol^{-1} in the vapor[27)]) and (ii) active participation of several low frequency modes as has been demonstrated in the $n\pi^*$ spectra of acetones.[28)] The greater enhancement of the absorption intensity is found in solvents with the greater molecular polarizability. For example, the relative ratios of the band areas in Fig. 1 are 1.00 : 1.21 : 1.25 : 1.32 : 1.41 : 1.57 in C_6F_{14}, CH_3CN, C_6H_{12}, CH_2Cl_2, $CHCl_3$, and CCl_4, respectively. As for C_6F_{14}, it is well known that spectra in perfluoro-hydrocarbons generally give *quasi*-vapor spectra.[7,13)]

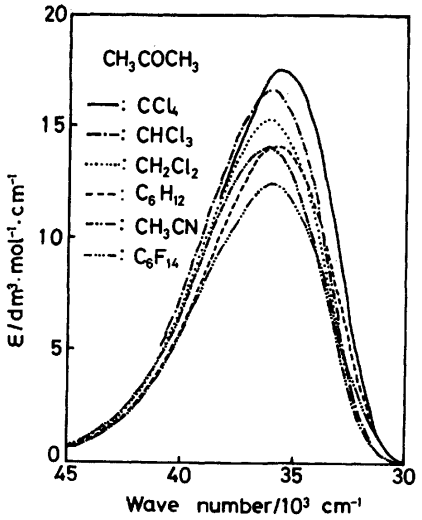

Fig. 1. The $S_1(n\pi^*)\leftarrow S_0$ absorption spectra of acetone in several solvents at 20 °C.

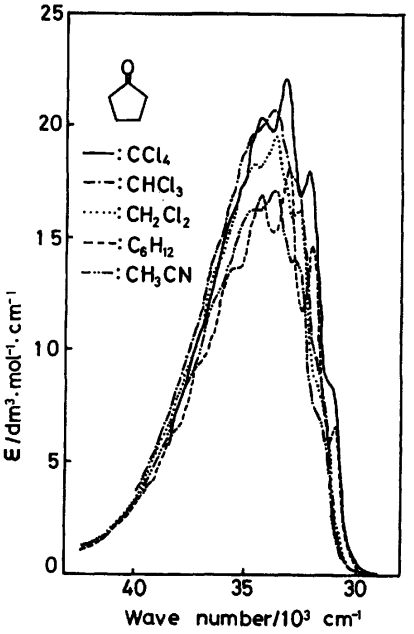

Fig. 2. The $S_1(n\pi^*)\leftarrow S_0$ absorption spectra of cyclopentanone in several solvents at 20 °C.

Another spectral aspect is found in Fig. 3 which displays the spectral behavior in a binary solvent system of CCl_4 and hexane. The intensity enhancement of the overall band system seems to almost satisfy an additivity rule between the respective solvents. This fact never supports an idea that the intensity enhancement might closely be related with some complex formation between the solute and solvent molecules.[5,17)] Similar additive properties in the spectral behaviors are also found in many other binary solvent systems employed.

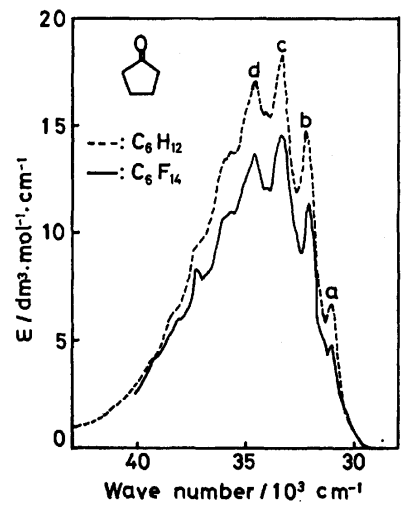

Fig. 4. The absorption spectra of cyclopentanone in cyclohexane and perfluorohexane at 20 °C.

In contrast with the acetone case mentioned above, the absorption spectra of cyclopentanone show several prominent vibrational structures in the vapor and in most fluid solutions (Fig. 2). For a further advance in discussion, the absorption spectra in cyclohexane and perfluorohexane solutions are chosen and demonstrated in Fig. 4. Here four characteristic bands are designated as *a*, *b*, *c*, and *d*. The detailed vibrational assignment of the absorption bands in the vapor and some comments on the spectra in solutions have been given by Howard-Lock and King.[29] Since one-to-one band correspondence between the spectra in fluid solutions and in the vapor is quite inferior to those in the cases of benzene and naphthalene because of great inhomogeneous broadening and participation of several intense sequence bands in the case of cyclopentanone, it is very difficult to definitely identify the origin band in the spectra of cyclopentanone in such fluid solutions. However, comparison of a very low resolution spectrum in the vapor with the spectra in solutions enables us to predict a probable location of the origin band in the solutions around the band *a* (Fig. 4).

In the vapor a cold *pseudo*-origin band of 25_0^1 due to the inversion doubling splitting along to the b_1 out-of-plane vibrational coordinate has been observed close to the undetected 0-0 band (see Ref. 30 for the vibrational notation and assignment of cyclopentanone in the ground state): The splitting has been established to be extremely small, say, less than 0.2 cm^{-1}.[29] Furthermore, there appear several sequence bands with considerable intensity in the neighborhood of the origin band. For these reasons, it is also very difficult to fully estimate the intensity contribution of the origin band in these solutions.

Despite the obscured assignment of the origin band, it is favorable to see that intensities of almost all of the "bands," *e.g.*, those of bands *a*—*d* shown in Fig. 4, are enhanced in a proportional ratio when solvents are changed from perfluorohexane to cyclohexane (see Fig. 4). This proportionality in the intensity enhancement is possibly of an apparent feature, originating mainly in the inhomogeneous broadening of these solution spectra superimposed on the vibrationally tangled band system in the spectrum of cyclopentanone. Similar intensity increments are also found to take place in the other solvent systems (see Fig. 2).

The total intensity of each solute is thus taken as a measure of the environmental effects about which some discussion will be given below. First let us apply the treatments of environmental effects given by Nakajima[11] to our ketone cases. For the explanation of the anomalous $S_1(L_b)$—S_0 spectra of pyrene in polar solvents, he has introduced a new solvent parameter f'. The parameter is rewritten as follows:

$$f' = (D-1)/(2D+1) - x(n^2-1)/(2n^2+1),$$

where D denotes the dielectric constant, n the refractive index of the solvent, and x an adjustable dimensionless parameter. Although the physical meaning of f' is not necessarily clear, his treatments with a partial success seem to give a correlation between f' and ε_p, where ε_p means the molar extinction coefficient of the $S_1 \leftarrow S_0$ absorption origin band of pyrene. In Fig. 5 the oscillator strength of cyclopentanone, f, is plotted against the

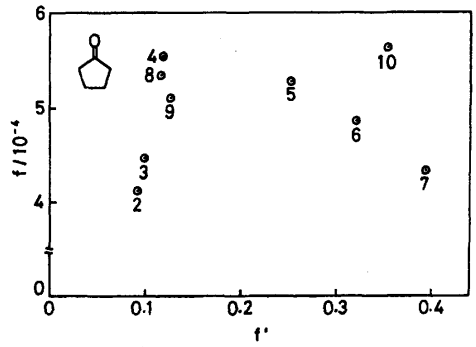

Fig. 5. Plots of the oscillator strength of cyclopentanone, f, against the solvent parameter given by Nakajima (Ref. 11), $f'=(D-1)/(2D+1)-0.5\,(n^2-1)/(2n^2+1)$. The numbering of the plots is as follows: (1) C_6F_{14}; (2) C_6H_{14}; (3) *cyclo*-C_6H_{12}; (4) CCl_4; (5) $CHCl_3$; (6) CH_2Cl_2; (7) CH_3CN; (8) C_6H_6; (9) $C_6H_5CH_3$; and (10) C_6H_5CN.

solvent parameter f' with $x=0.5$, the value which Nakajima has employed for the elucidation of the environmental effect in the S_1—S_0 spectra of pyrene. However, we could not find any straightforward correlation between f and f'. This was never improved for the other solute, acetone; no settled correlation was obtained between f and f' in the case of acetone, either. It seems thus that the Nakajima-like treatments[31] are not valid for the explanation of the environmental intensity enhancement in the $S_1(n\pi^*)\leftarrow S_0$ spectra of acetone and cyclopentanone in fluid solutions.

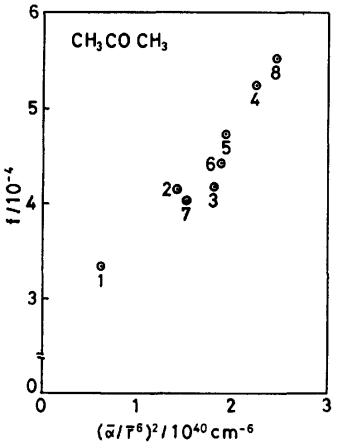

Fig. 6. A correlation diagram between the oscillator strength of acetone, f, and the squared value of the relative dispersion energy of solvents, $(\bar{\alpha}/\bar{r}^6)^2$. For the numbering of the plots, see the caption given in Fig. 5.

Next let us adopt another treatment given by one of the authors (M. K.) who has succeeded in explaining the Ham effect in terms of other solvent properties.[9] In Fig. 6 the oscillator strength of acetone, f, is plotted as a function of the squared value of a relative dispersion energy between the solute and solvent molecules, $(\bar{\alpha}/\bar{r}^6)^2$. Here $\bar{\alpha}$ denotes the mean molecular polarizability of the solvent and $\bar{r}$ the mean molecular distance between the solute and solvent molecules. Despite

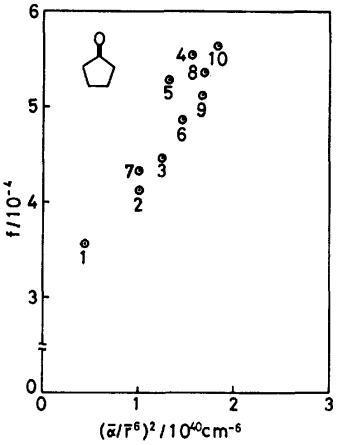

Fig. 7. A correlation diagram between the oscillator strength of cyclopentanone, f, and the squared value of the relative dispersion energy of solvents, $(\bar{\alpha}/\bar{r}^6)^2$. For the numbering of the plots, see the caption given in Fig. 5.

roughness in the approximation for $\bar{r}$, the observed oscillator strengths of acetone show an approximately linear increase with an increase in $(\bar{\alpha}/\bar{r}^6)^2$. A similar correlation is also found to hold for cyclopentanone (see Fig. 7).

With the help of the perturbation theory, we shall here give a qualitative explanation and a comment on the environmental intensification observed. Now let us take a model that one solute molecule is surrounded by n solvent molecules. The total Hamiltonian H is then given by

$$H = H_0 + H', \tag{1}$$

where H_0 is the zeroth order Hamiltonian, that is, the intramolecular terms of the free molecules, and H' is the total perturbation sum between the solute and n solvent molecules.

$$H' = \sum_a^n \sum_i \sum_j h_a(\xi_i, \eta_{aj}), \tag{2}$$

where ξ_i denotes i-th charge(electron) coordinates of the solute, η_{aj} j-th electron coordinates of a-th solvent molecule, and $\sum_i \sum_j h_a(\xi_i, \eta_{aj}) \equiv \phi_a$ represents interactions between the solute and the a-th solvent molecule. For the intermolecular interactions of neutral molecules the terms ϕ_a are generally described by a two-center expansion of reciprocal intermolecular distance r^{-1} in terms of spherical harmonics:[33]

$$\phi_a = \sum_{k=1}^{\infty} (b_{k+2}/r^{k+2}). \tag{3}$$

Here the first term in Eq. 3 represents the so-called dipole-dipole interactions. A further detailed description for them is found in Ref. 33.

If Ψ_0°, Ψ_1°, $\cdots$, Ψ_S° are the electronic wavefunctions for the free solute molecule, the k-th wavefunction of the solute in a fluid solution can be described as follows:

$$\Psi_k = \sum_j^s C_{jk}\Psi_j^\circ, \tag{4}$$

where the absolute values of coefficients, $|C_{jk}|_{j\neq k}$, are much smaller than unity and their magnitudes are evaluated by off-diagonal matrix elements, $\langle \Psi_j^\circ | H' | \Psi_k^\circ \rangle$, and energy differences between the respective states, ΔE_{jk}.

In general, environmental interactions may mix Ψ_j° with Ψ_k°. The coefficients C_{jk} will then be related to solvent properties as follows:

$$C_{jk} = \sum_{q,q'}^{X,Y,Z} \sum_{\hat{q},\hat{q}}^{x,y,z} \{A_q(\mu_{\hat{q}}/r^3) + B_{qq'} + (\mu_{\hat{q}}/r^4) + B'_{q'} \times (Q_{\hat{q}\hat{q}'}/r^4) + C_{qq'}(Q_{\hat{q}\hat{q}'}/r^5) + D_{qq'}(\alpha_{\hat{q}\hat{q}}/r^6) + \cdots\}. \tag{5}$$

Here A, B, B', C, $\cdots$ denote intramolecular integrals of the solute multiplied by appropriate proportional constants; each of the subscripts q and q' represents one component of the Cartesian coordinates (X,Y,Z) of the solute and each of $\hat{q}$ and $\hat{q}'$ one component of the Cartesian coordinates (x,y,z) of the solvent; and μ, Q, α are the dipole moment, quadrupole moment, molecular polarizability of the solvent molecule, respectively.

Here it should be noted that only a small number of the terms are effective for the intensity borrowing mechanism: This contrasts with the solvent shift

mechanism for which many terms with large matrix elements in Eq. 5 generally play an important role. In the case of a high symmetry molecule such as benzene, for example, the transition-dipole selection rule severely restricts the number of effective perturbation terms in Eq. 5. The terms D_{xx} and D_{yy} have thus been shown to be most important and predominant in the benzene 260 nm absorption case.[9] At present *a priori* we can offer no quantitative explanation for the observed intensity enhancement of acetone and cyclopentanone, because the treatments employed in an explanation of the Ham effect of benzene can not be applied to lower symmetric guest and host molecules without further revision and extention. However, *a posteriori* we may postulate, in the present cases,

$$C_{j1} \propto (\bar{\alpha}/\bar{r}^6), \tag{6}$$

where j may possibly be taken as $^1\pi\pi^*$. Supposing that the electronic transition $1 \leftrightarrow 0$ is forbidden in the free molecule, we may then relate the borrowed intensity of the transition in the fluid solutions to the squared value of C_{j1}. Thus we obtain for the intensity of the origin band:

$$I_{0-0} \propto (\bar{\alpha}/\bar{r}^6)^2. \tag{7}$$

In conclusion the intensity enhancement of the $S_1(n\pi^*) \leftarrow S_0$ absorption spectra of acetone and cyclopentanone in fluid solutions is qualitatively interpreted in terms of dispersion force interactions unless solvents have no strong chemical interactions such as hydrogen bondings and charge transfer interactions with the solute molecules.[34,35] Although we strongly believe the dispersion force interactions play a main role also in the intensifications of many other aliphatic carbonyls,[36,37] careful check must be required for further generalization.

One of the authors (K. N.) wishes to express thanks to Professor Y. Gondo for his warm hospitality and encouragements in Kyushu University. This work has in part been supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

36) Some interesting data of several aliphatic ketones have been reported by Bayliss and Wills-Johnson (Ref. 34). However, the data for benzene solutions are likely to contain great errors coming mainly from less transparency of the solvent below 280 nm. It is well known that the use of wide slits for such less transparency solutions leads sometimes to counterfeit bands (see also Ref. 38). Using degassed (oxygen-free) benzene and two different types of spectrometers, we carefully reexamined the absorption spectra of acetone and cyclopentanone in benzene. We thus determined the band maximum of acetone at 36.0×10^3 cm^{-1} with $\varepsilon_{max} = 19.8$ dm^3 mol^{-1} cm^{-1}, whereas Bayliss and Wills-Johnson reported $\nu_{max} = 35.45 \times 10^3$ cm^{-1} and $\varepsilon_{max} = 16.4$ dm^3 mol^{-1} cm^{-1}.

Cation Interdiffusion in Polycrystalline Fluorite-cubic MgO-ZrO_2 Solid Solution

Yoshio SAKKA, Yasumichi OISHI,* and Ken ANDO
Department of Nuclear Engineering, Kyushu University, Higashi-ku Fukuoka 812
(Received July 24, 1981)

Lattice and grain-boundary interdiffusion coefficients were calculated from the concentration distributions as determined for cation interdiffusion in polycrystalline MgO-stabilized zirconias by applying a grain-boundary enhanced diffusion model. Lattice interdiffusion coefficients in the temperature range of 1650—1990 °C were represented by $\tilde{D}=5.9\times10^{-4}\exp[-293(\mathrm{kJ/mol})/RT]\ \mathrm{cm^2/s}$. Magnesium self-diffusion coefficients were calculated from the obtained interdiffusion coefficients and the reported Zr self-diffusion coefficients. The results confirmed that interdiffusion in the fluorite-cubic solid solution is primarily controlled by the diffusivity of the faster cation.

MgO-stabilized ZrO_2 (MSZ) is a fluorite-type cubic solid solution[1] similar to CaO-stabilized ZrO_2 (CSZ). One difference is that the radius of the Mg ion is smaller than that of the Zr ion in MSZ, while that of the Ca ion is larger than that of the Zr ion in CSZ. Since MSZ exhibits high oxygen diffusivities similar to those of CSZ at high temperatures,[2] the defects in MSZ are assumed to be of the oxygen-vacancy type, as in CSZ.

During interdiffusion in oxygen-vacancy type fluorite structures, differing diffusivities of the two cations cause mass flow and electrical field effects on the cation interdiffusion, while the interchange of oxygen ions and oxygen vacancies on the simple cubic sublattice contributes only to the electrical field effect but does not necessarily contribute to the mass flow effect (since the concentration of the oxygen vacancy is equal to that of the dopant cation and therefore temperature-independent). For such conditions, an interdiffusion coefficient has been theoretically derived in terms of the self-diffusion coefficients of the constituent ions. The derived interdiffusion coefficient described satisfactorily interdiffusion in a CSZ system.[3] In the present work, a similar analysis was carried out for interdiffusion in the MSZ system to clarify the interdiffusion mechanism.

The self-diffusion coefficient of the oxygen ion in MSZ has been determined,[2] but that of the Mg ion has not. The tracer diffusion coefficient of the Zr ion in MSZ has not so far been determined but has been estimated from the Zr-Hf interdiffusion in the MgO–$(Zr+Hf)O_2$ system.[4] Since cation diffusion is enhanced by grain boundaries in polycrystalline CSZ,[5] a similar grain-boundary enhancement is assumed for the cations in polycrystalline MSZ.

In the present study, cation concentration distributions are determined after interdiffusion of polycrystalline diffusion couples, and lattice and grain-boundary interdiffusion coefficients are separately calculated. The results are compared with those of the CSZ system.[6]

Experimental

Diffusion Couples and Diffusion Annealing. Appropriate mixtures of MgO (99.7% purity) and ZrO_2 (99.69% purity) to give the compositions of $12MgO\cdot88ZrO_2$, $16MgO\cdot84ZrO_2$, and $18MgO\cdot82ZrO_2$ were isostatically pressed into a pellet of 10 mm dia. and 10 mm height with the aid of dextrin under a pressure of $6—7\times10^3\ \mathrm{kg/cm^2}$. Pressed pellets were sintered in two ways: at 1750 °C for over 12 h in air, and at 2200°C for 3 h in an Ar atmosphere. The densities of the sintered pellets ranged from 93—99% of the theoretical. The grain radii of the pellets, necessary to the present analysis, were determined using Fullman's relation.[7]

Diffusion couples were prepared by joining pellets of different compositions at 1650 °C for 10 min in a molybdenum susceptor high-frequency induction furnace. Diffusion anneals were carried out at temperatures between 1650 and 1990 °C, where a single fluorite-cubic phase is stable according to the MgO–ZrO_2 phase diagram proposed by Grain.[1] Diffusion anneals below 1730 °C were conducted in air using an SiC furnace, and those above 1823 °C using a tungsten-mesh heater furnace in an Ar atmosphere at 100 Torr. (1 Torr≈133.322 Pa).

Electron Probe Microanalysis. After diffusion annealing, each diffusion couple was sawed into halves parallel to the diffusion direction. One half was used for measuring the grain size to confirm that no grain growth occurred during diffusion annealing. The other half was employed for determining the concentration distribution by electron probe microanalysis. Mg and Zr distributions were determined at 20 μm intervals from the interface along the diffusion direction. Chemical compositions were determined from the relative intensities of the Mg $K\alpha$ and Zr $L\alpha_1$ lines by using a calibration curve previously determined from standard samples.

Because of preferential diffusion of Mg and Zr ions along grain-boundaries, the Mg and Zr distributions perpendicular to the diffusion direction were not homogeneous in the present polycrystalline samples. Thus the composition at a given diffusion distance represents an average composition obtained by scanning perpendicular to the diffusion direction.[4]

Results

The concentration distribution for grain-boundary enhanced diffusion has been described by Oishi and Ichimura as a function of the lattice and grain-boundary interdiffusion coefficients by,[6]

$$\frac{2(C-C_1)}{C_2-C_1}=\frac{M_t}{M_\infty}\exp(-my), \tag{1}$$

where

$$\frac{M_t}{M_\infty}=1-\frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-\frac{\tilde{D}n^2\pi^2t}{r^2}\right), \tag{2}$$

$$m=\left[\frac{4\tilde{D}}{r\delta\tilde{D}'}\sum_{n=1}^{\infty}\exp\left(-\frac{\tilde{D}n^2\pi^2t}{r^2}\right)\right]^{1/2}, \tag{3}$$

y is the diffusion distance from the interface, C the

avarage concentration at y, C_1 and C_2 the initial concentrations of the diffusion couple, M_t and M_∞ the diffusion amounts at times t and infinity, respectively, $\tilde{D}$ and $\tilde{D}'$ the lattice and grain-boundary interdiffusion coefficients, respectively, r the grain radius, and δ the grain-boundary thickness.

Equation 1 can be rewritten as Eq. 4 in a logarithmic form,

$$\ln\frac{2(C-C_1)}{C_2-C_1} = \ln\frac{M_t}{M_\infty} - my, \qquad (4)$$

showing that $\ln[2(C-C_1)/(C_2-C_1)]$ is proportional to the diffusion distance y.

An example of the MgO concentration distribution is shown in Fig. 1 for the diffusion couple of $12MgO\cdot88ZrO_2$ with 45 μm grain radius and $16MgO\cdot84ZrO_2$ with 57 μm grain radius after annealing at 1650 °C for 48 h. Also shown is the MgO concentration for the diffusion couple of $12MgO\cdot88ZrO_2$ with 49 μm grain radius and $16MgO\cdot84ZrO_2$ with 55 μm grain radius after annealing at 1823 °C for 12 h. The corresponding $\ln[2(C-C_1)/(C_2-C_1)]$ values are plotted in Fig. 2 as a function of y, where the satisfactorily linear relationships indicate that the diffusion model represented by Eq. 1 is applicable to the present interdiffusion. The solid lines in Figs. 1 and 2 represent theoretical values calculated by Eq. 1 so as to provide the best fit to the experimental results. From the slopes and intercepts of the straight lines in Fig. 2, $\tilde{D}$ and $\delta\tilde{D}'$ are separately calculated from Eqs. 2 and 3. A correction to diffusion time was made in all calculations for the period of joining the diffusion couple as well as for increasing and decreasing the temperature before and after an isothermal diffusion annealing.[6]

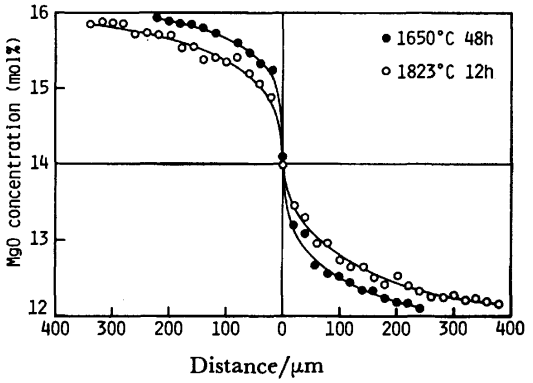

Fig. 1. Concentration distributions for the diffusion couples of $12MgO\cdot88ZrO_2$ and $16MgO\cdot84ZrO_2$.

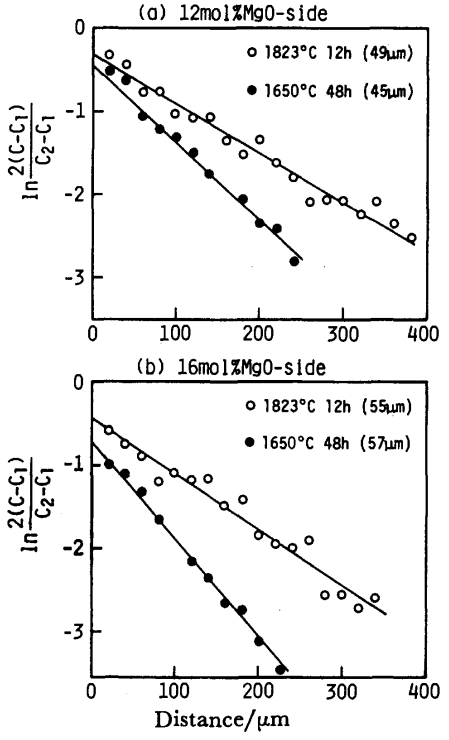

Fig. 2. Logarithmic concentration distributions for the diffusion couples of $12MgO\cdot88ZrO_2$ and $16MgO\cdot84ZrO_2$.
(a) 12 mol% MgO-side. (b) 16 mol% MgO-side.

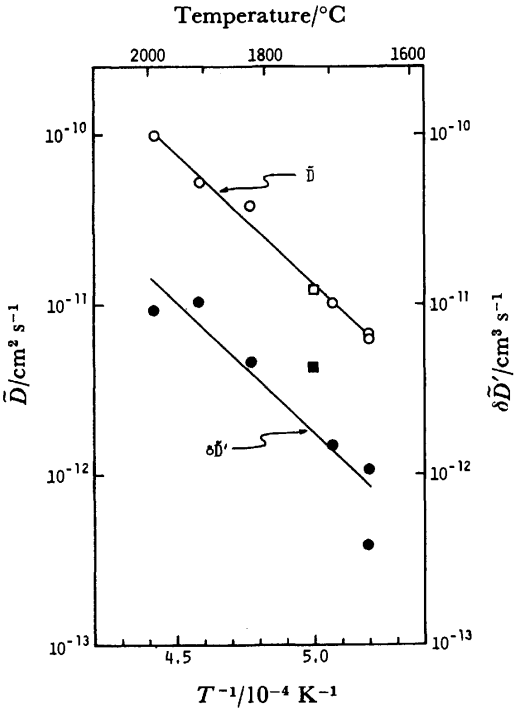

Fig. 3. Lattice interdiffusion coefficients and grain-boundary diffusion parameters for MSZ as a function of temperature. Circles denote the couple of $12MgO\cdot88ZrO_2$–$16MgO\cdot84ZrO_2$ and squares the couple of $12MgO\cdot88ZrO_2$–$18MgO\cdot82ZrO_2$.

The $\tilde{D}$ and $\delta\tilde{D}'$ thus calculated are shown in Fig. 3, where the averages of values obtained on both sides of the diffusion couples are plotted. Circles denote the couple of $12MgO\cdot88ZrO_2$–$16MgO\cdot84ZrO_2$ and squares the couple of $12MgO\cdot88ZrO_2$–$18MgO\cdot82ZrO_2$. Comparison of $\tilde{D}$ for the two diffusion couples with different combinations of MgO contents indicates no significant composition dependence. Comparison of results from diffusion anneals conducted in air (below 1730 °C) and in an Ar atmosphere (above 1823 °C) indicates no noticeable effect of the atmosphere on the results.

Values of $\tilde{D}$ and $\delta\tilde{D}'$ for the temperature range of

1650—1990 °C are described by Eqs. 5 and 6, respectively.

$$\tilde{D} = \left(5.9^{+5.8}_{-2.9}\right) \times 10^{-4} \exp[-293 \pm 11(\mathrm{kJ/mol})/RT]\ \mathrm{cm^2/s}, \quad (5)$$

$$\delta\tilde{D}' = \left(1.0^{+5.1}_{-0.8}\right) \times 10^{-4} \exp[-279 \pm 30(\mathrm{kJ/mol})/RT]\ \mathrm{cm^3/s}. \quad (6)$$

The activation energy for the grain-boundary diffusion parameter $\delta\tilde{D}'$ is close to that for lattice interdiffusion. Similar results have been also demonstrated for the CSZ system.[6]

Discussion

The calculated $\tilde{D}$ values are much smaller than the self-diffusion coefficients of the oxygen ion.[2]

The relation between the interdiffusion coefficient and the self-diffusion coefficients of the constituent ions for the fluorite-cubic solid solution has been given by Eq. 7 as,[3]

$$D = \frac{(Z_A^2C_AC_B - Z_AZ_BC_AC_B + Z_0^2C_BC_0)D_AD_0 + (Z_B^2C_AC_B - Z_AZ_BC_AC_B + Z_0^2C_AC_0)D_BD_0}{(Z_A^2C_AC_B - Z_AZ_BC_AC_B)D_A + (Z_B^2C_AC_B - Z_AZ_BC_AC_B)D_B + (Z_0^2C_AC_0 + Z_0^2C_BC_0)D_0}, \quad (7)$$

where Z is the valence, C the mole concentration, D the self-diffusion coefficient, and subscripts refer to the constituent ions. Since D_0 is much greater than D_{Zr} and D_{Mg} in the MSZ system, Eq. 7 reduces to Eq. 8.

$$D = [(Z_{Zr}^2C_{Zr}C_{Mg} - Z_{Zr}Z_{Mg}C_{Zr}C_{Mg} + Z_0^2C_{Mg}C_0)D_{Zr} + (Z_{Mg}^2C_{Zr}C_{Mg} - Z_{Zr}Z_{Mg}C_{Zr}C_{Mg} + Z_0^2C_{Zr}C_0)D_{Mg}] \times (Z_0^2C_{Zr}C_0 + Z_0^2C_{Mg}C_0)^{-1} \quad (8)$$

The Mg self-diffusion coefficients can be calculated by using Eq. 8 from known values of D and D_{Zr}. The Zr self-diffusion coefficients estimated for MSZ in the temperature range of 1680—2083 °C[4] have been represented by Eq. 9.

$$D_{Zr} = 0.033 \exp[-381(\mathrm{kJ/mol})/RT]\ \mathrm{cm^2/s}. \quad (9)$$

The D_{Mg} values calculated by Eq. 8 from D_{Zr} (Eq. 9) and $\tilde{D}$ (Eq. 5) for the average composition of the diffusion couple are represented by Eq. 10.

$$D_{Mg} = 3.7 \times 10^{-4} \exp[-285(\mathrm{kJ/mol})/RT]\mathrm{cm^2/s}. \quad (10)$$

As shown in Fig. 4, the interdiffusion coefficient is higher in magnitude and lower in activation energy than D_{Zr}, and close to the calculated value of D_{Mg} both in magnitude and in activation energy. (The D_{Zr} in MSZ is similar to the D_{Zr} in CSZ in both magnitude and activation energy.[4])

The activation energy of D_{Mg} in MSZ (285 kJ/mol) is smaller than that of D_{Ca} in CSZ (419.2 kJ/mol).[5] This difference is interpreted as due to the ionic radii of the dopant cations relative to that of the Zr ion; that is, the Mg ion in MSZ is smaller than the Ca ion in CSZ.

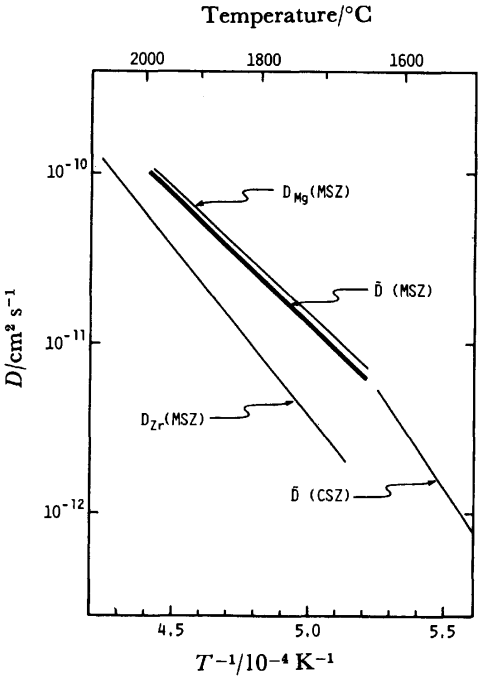

Fig. 4. Lattice interdiffusion coefficient and self-diffusion coefficients of Mg and Zr[4] ions in MSZ; lattice interdiffusion coefficient in CSZ.[6]

Since D_R (R=Mg or Ca) is greater than D_{Zr} in both MSZ and CSZ, $\tilde{D}$ tends to be close to D_R in the respective systems in accordance with Eq. 7. Consequently, the small activation energy of interdiffusion in MSZ relative to that in CSZ, as shown in Fig. 4, is attributed to the activation energy of D_{Mg} in MSZ being smaller than that of D_{Ca} in CSZ.

In summary, cation interdiffusion in MgO-stabilized zirconia is controlled primarily by the diffusivity of the faster cation (Mg), and the contribution of the high diffusivity of the oxygen ion is small.

The authors acknowledge H. S. Spacil's comments to the manuscript.

Chemical Systems Exhibiting Complicated Temporal Oscillations

Kazutoshi IWAMOTO, Susumu KAWAUCHI, Kiyoshi SAWADA, and Manabu SENŌ*
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received July 27, 1981)

Two model systems exhibiting complicated oscillations were proposed and analyzed. One of them is a double oscillation system, which shows alternating oscillations of large and small amplitudes and the mechanism for appearance of the double oscillations is clarified. In the other system, either large or small amplitude oscillation appears depending on the parameter values, and the transition between the large and the small amplitude oscillation is very abrupt and sensitive to the change in external constraints.

Until now, many papers concerning various kinds of behaviors of chemical systems far from equilibrium states have been reported.[1-27] These systems show occasionally some characteristic behaviors like chemical oscillations,[1,2] excitation,[3-5] wave propagation,[6-9] and so on. The well-known chemical oscillatory system is the Belousov-Zhabotinskii reaction,[14,15] in which malonic acid is oxidized by bromate ion catalyzed by some metallic ions in sulfuric acid solutions, and its reaction mechanism has been studied in detail.[16] As a model system for this reaction the Oregonator was proposed and analyzed with a computer simulation method by Field *et al.* of the University of Oregon.[5,17] Similar chemical oscillation models were proposed and analyzed by some investigators.[1-4,18,19] We also proposed a simple model which explains chemical oscillation and excitation,[4] and applied it for interpretation of some problems.[20-23] The characteristic point of the Oregonator and our model is that both of them include a subsystem having multiple steady states, some of which are stable and other are unstable.[4]

In this article, we investigate two chemical systems exhibiting temporal oscillations, one of which shows double oscillation and the other exhibits abrupt changes in the amplitude of oscillation depending on the parameter values.

The former system is obtained by some modifications of our original system[4] and it is useful to investigate the appearance of alternating large and small amplitude oscillations, which are observed in the Belousov-Zhabotinskii reaction in a well-stirred continuous flow reactor.[24,25] A chaotic behavior was also reported in this system.[24] Showalter *et al.* studied a modified Oregonator which exhibits complicated behaviors in a flow system.[26] Although their system, in which two intermediates are newly introduced to the original Oregonator, is fairly complicated, it can well explain the behaviors of the Belousov-Zhabotinskii reaction in the well-stirred continuous flow reactor. A similar model system was studied by Janz *et al.*[27] On the other hand, our system proposed in the present paper contains three intermediates and well explains the appearance of alternating large and small amplitude oscillation.

In the latter system, either large or small amplitude oscillation emerges depending on the parameter values, and the transition between the large and the small amplitude oscillation at critical values of parameters is so abrupt that the system is very sensitive to changes in the external constraints. In this case the behavior of the system at the critical point is largely affected by fluctuations in a similar way as reported already.[3,4,20-22]

Chemical System Exhibiting Double Oscillation

In a preceding paper,[4] we proposed a simple chemical system exhibiting temporal oscillations. Here, the system is modified a little as follows:

$$P + Z \xrightarrow{k_1} E + Z, \qquad \text{(R-1)}$$

$$E + X \xrightarrow{k_2} R + X, \qquad \text{(R-2)}$$

$$A + 2X + E \underset{k_4}{\overset{k_3}{\rightleftharpoons}} 3X + E, \qquad \text{(R-3)}$$

$$B + X \underset{k_6}{\overset{k_5}{\rightleftharpoons}} C, \qquad \text{(R-4)}$$

where the concentrations of A, B, C, P, and R are kept constant to maintain the total system far from an equilibrium state, E and X are intermediates, and Z is a newly introduced chemical species acting as a catalyst in the process (R-1). The chemical species Z is introduced to control the rate of the process (R-1) and for a while its concentration is assumed to be constant.

The rate equations of E and X are written as follows:

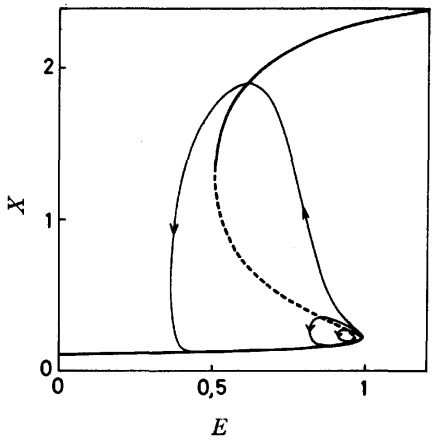

Fig. 1. Phase plane diagrams for Eqs. 3 and 4. Steady states S and S′ are stable and unstable, respectively. The closed cycle shows the trajectory of the temporal oscillation determined by Eqs. 1 and 2 for $Z=1.0$. Parameter values used are: $k_1=1.0$, $k_2=4.76$, $k_3=100.0$, $k_4=48.64$, $k_5=10.0$, $k_6=1.0$, $A=1.332$, $B=5.02$, $C=5.32$, and $P=1.13$.

$$\frac{dE}{dt} = k_1PZ - k_2EX, \quad (1)$$

$$\frac{dX}{dt} = k_3AEX^2 - k_4EX^3 - k_5BX + k_6C. \quad (2)$$

Putting the steady state conditions, $dE/dt=0$ and $dX/dt=0$, into Eqs. 1 and 2 gives

$$k_1PZ - k_2EX = 0, \quad (3)$$

$$k_3AEX^2 - k_4EX^3 - k_5BX + k_6C = 0. \quad (4)$$

By plotting Eqs. 3 and 4 on an E-X phase plane, we get Fig. 1, where two curves from Eq. 3 are shown for $Z=1.0$ and 0.8, respectively. All the parameter values used are as follows:

$k_1 = 1.0$, $k_2 = 4.76$, $k_3 = 100.0$, $k_4 = 48.64$, $k_5 = 10.0$,

$k_6 = 1.0$, $A = 1.332$, $B = 5.02$, $C = 5.32$, and $P = 1.13$.

The crossing point of the curve of Eq. 3 and that of Eq. 4 represents the steady state of the total chemical system. The steady state indicated with S′, where the value of Z is 1.0, is unstable,[4] and then an oscillatory behavior appears. Its trajectory is shown by a closed cycle in Fig. 1. When the value of Z is 0.8, the crossing point S is a stable steady state, into which the chemical system falls with time independently of the initial states.

Now, let us introduce the following processes.

$$Q \xrightarrow{k_7} Z, \quad (R\text{-}5)$$

$$Z + X \xrightarrow{k_8} D + X, \quad (R\text{-}6)$$

where the concentrations of Q and D are kept constant. Then, the concentration of Z changes according to the following equation.

$$\frac{dZ}{dt} = k_7Q - k_8XZ. \quad (5)$$

In this equation, the consuming rate of Z, k_8XZ, increases with an increasing concentration of X. When $dZ/dt>0$, that is, the production rate of Z, k_7Q, is larger than the consuming rate of Z, for the system at the state S in Fig. 1, the concentration of Z increases and in time the chemical system will transit towards an oscillatory state. On the other hand, the system in the oscillatory region takes sometimes so large X values during the oscillatory path that the consumption rate of Z increases largely beyond the production rate of Z. Then, the concentration of Z decreases again and the system approaches to the stable steady state showing a damped oscillation.

Repetition of these processes causes alternating large and small amplitude oscillations. Figure 2 shows the typical examples of temporal changes of X of the system determined by solving Eqs. 1, 2, and 5 for three values of P. The oscillating behavior changes according to the P value. These results resemble those reported by Hudson *et al.*,[25] although the flow terms are not taken into consideration in the present treatment.

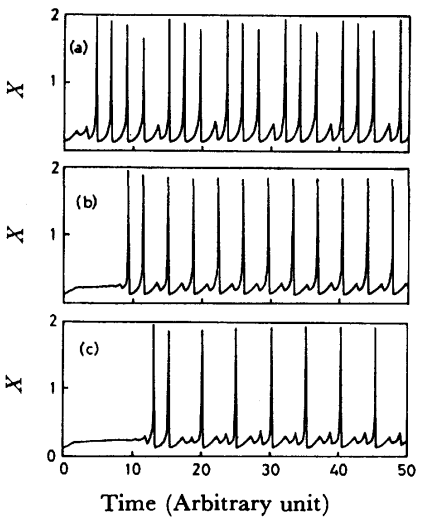

Fig. 2. Some typical behaviors of the double oscillation defined by Eqs. 1, 2, and 5. (a) $P=1.2$, (b) $P=1.13$, (c) $P=1.1$, and $Q=1.0$, $k_7=0.1$, $k_8=0.4$, and other parameter values are the same as those of Fig. 1.

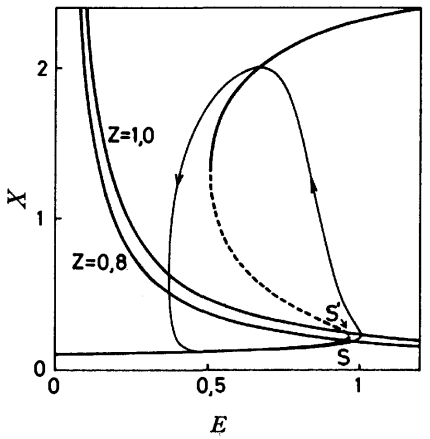

Fig. 3. Projection onto E-X phase plane of the double oscillation trajectory for $P=1.1$. The system evolves from a smallest cycle to a larger and a largest cycles, returning the original smallest amplitude oscillatory state. The parameter values are the same as those of Figs. 1 and 2.

In Fig. 3, the trajectory of oscillation in the case of $P=1.1$ is shown on the E-X phase plane. The thin line representing the trajectory shows that a phase point starts from a certain point on the smallest cycle and transits the phase space into larger cycles, returning to the original small cycle.

Chemical System Showing Abrupt Change in Amplitude

Behaviors of Chemical Reaction Model. Let us consider a system consisting of the following chemical reactions:

$$P' \xrightarrow{pk_9} E', \quad (R\text{-}7)$$

$$E' + X' \xrightarrow{pk_{10}} X' + R', \quad (R\text{-}8)$$

$$A' + 4X' + E' \underset{k_{12}}{\overset{k_{11}}{\rightleftharpoons}} 5X' + E', \quad (R\text{-}9)$$

$$B' + 2X' \underset{k_{14}}{\overset{k_{13}}{\rightleftharpoons}} 3X' + C', \quad (R\text{-}10)$$

$$D' + X' \underset{k_{16}}{\overset{k_{15}}{\rightleftharpoons}} G', \qquad \text{(R-11)}$$

where E' and X' are intermediate species. All the chemical species are represented by superscript dashes to discriminate this chemical system from the double oscillation system described in the preceding section. The concentrations of A', B', C', D', G', P', and R' are kept constant to sustain the system far from an equilibrium state.

The temporal changes of E' and X' are given by

$$\frac{dE'}{dt} = \rho k_9 P' - \rho k_{10} E' X', \qquad (6)$$

$$\frac{dX'}{dt} = k_{11} A' E' X'^4 - k_{12} E' X'^5 + k_{13} B' X'^2 - k_{14} C' X'^3 - k_{15} D' X' + k_{16} G'. \qquad (7)$$

At the steady state, where dE'/dt and dX'/dt are zero,

$$k_9 P' - k_{10} E' X' = 0, \qquad (8)$$

$$k_{11} A' E' X'^4 - k_{12} E' X'^5 + k_{13} B' X'^2 - k_{14} C' X'^3 - k_{15} D' X' + k_{16} G' = 0. \qquad (9)$$

In Fig. 4, Eqs. 8 and 9 are shown on the E-X phase plane for two different values of P'. The parameter values used are:

$A' = B' = C' = D' = G' = 1.0$, $k_9 = 1.0$, $k_{10} = 1.40 \times 10^2$, $k_{11} = 2.5 \times 10^5$, $k_{12} = 5.67 \times 10^5$, $k_{13} = 8.91 \times 10^2$, $k_{14} = 2.50 \times 10^4$, $k_{15} = 12.0$, and $k_{16} = 5.37 \times 10^{-2}$.

The crossing point of the two curves represents the steady state of this chemical system. It was clarified according to the linearized stability analysis[1] that the steady state of the chemical system for adequately small ρ values, *e.g.*, smaller than unity, is unstable when the two curves intersect in the dotted parts of the curve drawn by Eq. 9, and in this case we can expect evolution of the system into an oscillatory state.[4] The trajectories are dependent on the value of parameter ρ. The closed cycle in Fig. 4 shows approximate path of the temporal oscillation for $P' = 7.90$, where the value of ρ is selected to be 0.01. Dependence of the oscillation behaviors on the position of crossing point is shown in Fig. 5.

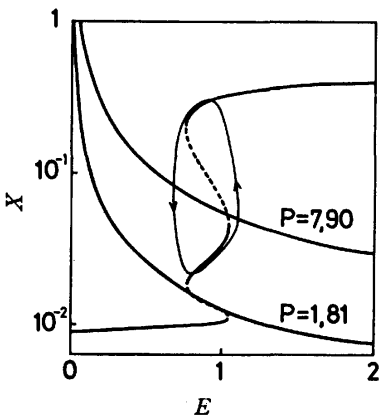

Fig. 4. Phase plane diagrams for Eqs. 8 and 9. The closed cycle is the trajectory of the temporal oscillation determined from Eqs. 6 and 7 in the case of $P' = 7.90$. Parameter values used for calculations are: $A' = B' = C' = D' = G' = 1.0$, $k_9 = 1.0$, $k_{10} = 1.40 \times 10^2$, $k_{11} = 2.5 \times 10^5$, $k_{12} = 5.67 \times 10^5$, $k_{13} = 8.91 \times 10^2$, $k_{14} = 2.50 \times 10^4$, $k_{15} = 12.0$, $k_{16} = 5.37 \times 10^{-2}$, and $\rho = 0.01$.

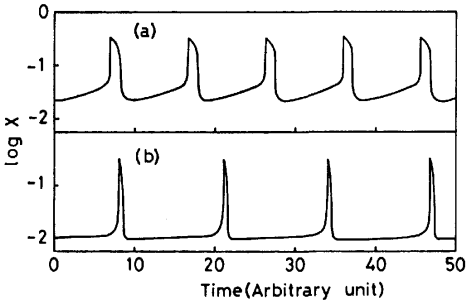

Fig. 5. Oscillatory behaviors of the chemical system. (a) $P' = 7.90$ and (b) $P' = 1.81$. Parameter values used for calculations are the same as those of Fig. 4.

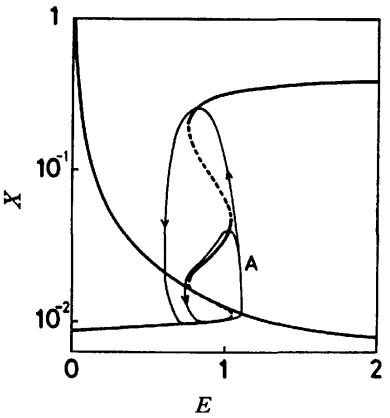

Fig. 6. Trajectories of the oscillations in the case of $P' = 1.81$. Two closed cycles show schematic courses of oscillations for two values, 0.01 and 0.02, of ρ. Point A is a junction at the two cycles. When $\rho = 0.02$, the decreasing rate of E at A is larger than that in the case of $\rho = 0.01$ and the chemical system chooses the course to the small amplitude oscillation.

Next, while the value of P' is fixed to be 1.81, changes in oscillatory behaviors according to the value of ρ is examined. It was revealed that, when ρ is 0.02, the chemical system shows an oscillation of a small amplitude and when ρ is 0.01, an oscillation of a large amplitude appears. Figure 6 shows the approximate trajectories of the chemical system for the two cases of $\rho = 0.01$ and 0.02, respectively. In the case of $\rho = 0.02$, the decreasing rate of E at the junction A at the two passes is faster than that in the case of $\rho = 0.01$ and, therefore, the chemical system chooses the course of the small cycle. Both the oscillatory behaviors are shown in Fig. 7. The larger amplitude oscillation has longer period than that of the smaller amplitude oscillation. The abrupt change in amplitude is observed between 0.019 and 0.018 of ρ value, and for ρ values larger than 0.019, the smaller amplitude oscillation appears.

The characteristic point of the present chemical system is that the amplitude of oscillations changes largely at a certain value of ρ, and we can say that this system is very sensitive to change of parameter values.

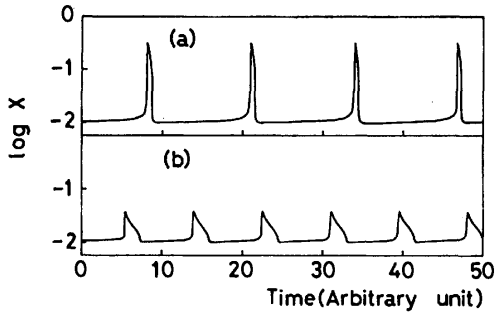

Fig. 7. Oscillatory behaviors of the chemical system for $P'=1.81$. (a) $\rho=0.01$ and (b) $\rho=0.02$. Other parameter values are the same as those of Fig. 5. The critical value of ρ, at which the amplitude changes abruptly, is between 0.018 and 0.019.

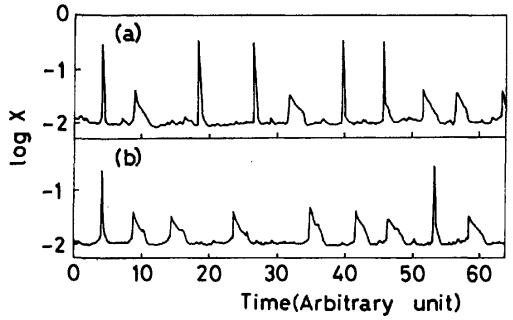

Fig. 8. Appearance of random oscillations in amplitude under the influence of fluctuation. $P'=1.81$. (a) $\rho=0.018$ and (b) $\rho=0.019$. The strengths of fluctuations are selected to be $\alpha=0$ and $\beta=0.1$ for calculations. Other parameter values are the same as those of Fig. 5.

Effects of Fluctuations on the Behaviors of the Chemical System. Since the chemical system described in this section is very sensitive to a small variation in the parameter values, it would be expected that the amplitude of oscillations of this chemical system changes randomly under the influence of fluctuation. To confirm this expectation, the following Langevin type equations representing the behaviors of the chemical system subjected to fluctuation should be examined; that is,

$$\frac{dE'}{dt} = \rho k_9 P' - \rho k_{10} E'X' + \alpha F(t), \tag{10}$$

$$\frac{dX'}{dt} = k_{11}A'E'X'^4 - k_{12}E'X'^5 + k_{13}B'X'^2 - k_{14}C'X'^3 - k_{15}D'X' + k_{16}G' + \beta H(t), \tag{11}$$

where $F(t)$ and $H(t)$ are the fluctuation terms of Gaussian type. The average values $\langle F(t)\rangle$ and $\langle H(t)\rangle$ are zero and the standard deviations are set to be 0.1. The coefficients α and β represent the strengths of fluctuations. Figure 8 illustrates typical behaviors of the chemical system under the influence of fluctuations, which were obtained by solving these equations in some cases. Certainly, random appearance of large and small amplitude oscillations is observed.
